where E_i, $i = e, \bar\nu_e, \nu_\mu$ are the energies of the final state particles in the muon rest frame. In the following we shall neglect both the electron mass and the momentum in the W-propagator compared to the W-boson mass, so $D_W^2 \to m_W^4$. We can now use the following identity to integrate over the neutrino momenta [168]

$$\int \frac{d^3\vec{\boldsymbol{k}}_{\bar\nu_e}}{(2\pi)^3 2E_{\bar\nu_e}}\frac{d^3\vec{\boldsymbol{k}}_{\nu_\mu}}{(2\pi)^3 2E_{\nu_\mu}}(2\pi)^4\delta^4(q - k_{\bar\nu_e} - k_{\nu_\mu})k^\rho_{\bar\nu_e}k^\tau_{\nu_\mu} = \frac{1}{96\pi}(q^2 g^{\rho\tau} + 2q^\rho q^\tau)\,, \tag{29.6.5}$$

where $q = p - k_e$. It follows that

$$d\Gamma = \frac{g^4}{1536\pi^4 m_\mu m_W^4}\left[q^2\,k_e\cdot(p - m_\mu S) \;+\; 2q\cdot k_e\,q\cdot(p - m_\mu S)\right]\frac{d^3\vec{\boldsymbol{k}}_e}{E_e}\,. \tag{29.6.6}$$

In the muon rest frame, $k_e = E_e(1; \cos\phi\sin\theta, \sin\phi\sin\theta, \cos\theta)$ and $S = (0; 0, 0, 1)$, so that $q^2 = m_\mu^2 - 2E_e m_\mu$ and $k_e\cdot(p - m_\mu S) = m_\mu E_e(1 + \cos\theta)$ and $q\cdot k_e = m_\mu E_e$ and $q\cdot(p - m_\mu S) = m_\mu(m_\mu -$

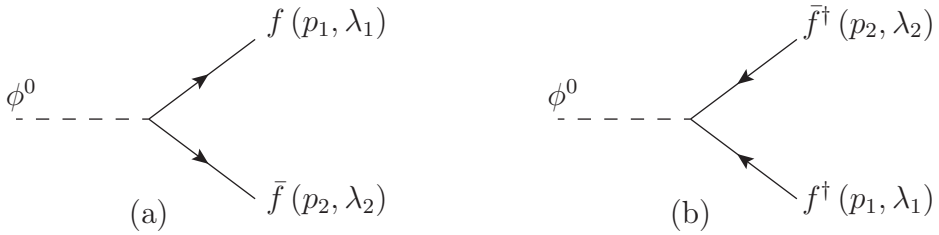

Figure 29.6.1: The Feynman diagrams for the decays $\phi^0 \to f\bar{f}$, where $\phi^0 = h^0, H^0, A^0$ are the neutral Higgs scalar bosons of the MSSM, and f is a Standard Model quark or lepton, and $\bar{f}$ is the corresponding antiparticle. We have labeled the external fermions according to the two-component field names.

$E_e - E_e\cos\theta$). Noting that the maximum energy of the electron is $m_\mu/2$ (when the neutrino and antineutrino both recoil in the opposite direction), we obtain

$$\frac{d\Gamma}{d(\cos\theta)} = \frac{g^4 m_\mu^2}{768\pi^3 m_W^4}\int_0^{m_\mu/2} dE_e E_e^2\left[3 - \frac{4E_e}{m_\mu} + \left(1 - \frac{4E_e}{m_\mu}\right)\cos\theta\right]$$
$$= \frac{g^4 m_\mu^5}{3\cdot 2^{12}\pi^3 m_W^4}\left(1 - \tfrac{1}{3}\cos\theta\right)\,, \tag{29.6.7}$$

in agreement with ref. [168]. Introducing the Fermi constant, $G_F \equiv \sqrt{2}g^2/(8m_W^2)$, we can rewrite eq. (29.6.7) as:

$$\frac{d\Gamma}{d(\cos\theta)} = \frac{G_F^2 m_\mu^5}{384\pi^3}\left(1 - \tfrac{1}{3}\cos\theta\right)\,. \tag{29.6.8}$$

Integrating over $\cos\theta$ reproduces the well-known total muon decay width,

$$\Gamma = \frac{G_F^2 m_\mu^5}{192\pi^3}\,. \tag{29.6.9}$$

29.6.5 Neutral MSSM Higgs boson decays: $\phi^0 \to f\bar{f}$ for $\phi^0 = h^0, H^0, A^0$

In this subsection, we consider the decays of the neutral Higgs scalar bosons $\phi^0 = h^0$, H^0, and A^0 of the MSSM into Standard Model fermion-antifermion pairs. The relevant tree-level Feynman diagrams are shown in Fig. 29.6.1. The final state fermion is assigned four-momentum p_1 and polarization λ_1, and the antifermion is assigned four-momentum p_2 and polarization λ_2. We will first work out the case that f is a charge $-1/3$ quark or a charged lepton, and later note the simple change needed for charge $+2/3$ quarks. The Feynman rules of Fig. K.1.1 of Appendix K tell us that the amplitudes are:

$$i\mathcal{M}_a = -\frac{i}{\sqrt{2}}\,Y_f\,k^*_{d\phi^0}\,x_1^\dagger x_2^\dagger\,, \tag{29.6.1}$$

$$i\mathcal{M}_b = -\frac{i}{\sqrt{2}}\,Y_f\,k_{d\phi^0}\,y_1 y_2\,. \tag{29.6.2}$$

Here Y_f is the Yukawa coupling of the fermion, $k_{d\phi^0}$ is the Higgs mixing parameter from eq. (K.1.8), and the external wave functions are denoted $x_1 \equiv x(\vec{\boldsymbol{p}}_1, \lambda_1)$, $y_1 \equiv y(\vec{\boldsymbol{p}}_1, \lambda_1)$ for the fermion and

$x_2 \equiv x(\vec{\boldsymbol{p}}_2, \lambda_2)$, $y_2 \equiv y(\vec{\boldsymbol{p}}_2, \lambda_2)$ for the antifermion. Squaring the total amplitude $i\mathcal{M} = i\mathcal{M}_a + i\mathcal{M}_b$ using eq. (29.44) results in:

$$|\mathcal{M}|^2 = \frac{1}{2}|Y_f|^2 \left[|k_{d\phi^0}|^2 (y_1 y_2\, y_2^\dagger y_1^\dagger + x_1^\dagger x_2^\dagger\, x_2 x_1) + (k^*_{d\phi^0})^2 x_1^\dagger x_2^\dagger\, y_2^\dagger y_1^\dagger + (k_{d\phi^0})^2 y_1 y_2\, x_2 x_1 \right]. \tag{29.6.3}$$

Summing over the final state antifermion spin using eqs. (29.3.57)–(29.3.60) gives:

$$\sum_{\lambda_2} |\mathcal{M}|^2 = \frac{1}{2}|Y_f|^2 \left[|k_{d\phi^0}|^2 (y_1 p_2\cdot\sigma y_1^\dagger + x_1^\dagger p_2\cdot\overline{\sigma} x_1) - (k^*_{d\phi^0})^2 m_f x_1^\dagger y_1^\dagger - (k_{d\phi^0})^2 m_f y_1 x_1 \right]. \tag{29.6.4}$$

Summing over the fermion spins in the same way yields:

$$\begin{aligned} \sum_{\lambda_1,\lambda_2} |\mathcal{M}|^2 &= \frac{1}{2}|Y_f|^2 \left\{ |k_{d\phi^0}|^2 (\mathrm{Tr}[p_2\cdot\sigma p_1\cdot\overline{\sigma}] + \mathrm{Tr}[p_2\cdot\overline{\sigma} p_1\cdot\sigma]) - 2(k^*_{d\phi^0})^2 m_f^2 - 2(k_{d\phi^0})^2 m_f^2 \right\} \\ &= |Y_f|^2 \left\{ 2|k_{d\phi^0}|^2 p_1\cdot p_2 - 2\mathrm{Re}[(k_{d\phi^0})^2] m_f^2 \right\} \\ &= |Y_f|^2 \left\{ |k_{d\phi^0}|^2 (m_{\phi^0}^2 - 2m_f^2) - 2\mathrm{Re}[(k_{d\phi^0})^2] m_f^2 \right\}, \end{aligned} \tag{29.6.5}$$

where we have used the trace identity eq. (29.56) to obtain the second equality. The corresponding expression for charge +2/3 quarks can be obtained by simply replacing $k_{d\phi^0}$ with $k_{u\phi^0}$. The total decay rates now follow from integration over phase space [169]

$$\Gamma(\phi^0 \to f\bar{f}) = \frac{N_c^f}{16\pi m_{\phi^0}} \left(1 - 4m_f^2/m_{\phi^0}^2\right)^{1/2} \sum_{\lambda_1,\lambda_2} |\mathcal{M}|^2. \tag{29.6.6}$$

The factor of $N_c^f = 3$ for quarks and 1 for leptons comes from the sum over colors.

Results for special cases are obtained by putting in the relevant values for the couplings and the mixing parameters from eqs. (K.1.7) and (K.1.8). In particular, for the CP-even Higgs bosons h^0 and H^0, $k_{d\phi^0}$ and $k_{u\phi^0}$ are real, so one obtains:

$$\Gamma(h^0 \to b\bar{b}) = \frac{3}{16\pi} Y_b^2 \sin^2\!\alpha\, m_{h^0} \left(1 - 4m_b^2/m_{h^0}^2\right)^{3/2}, \tag{29.6.7}$$

$$\Gamma(h^0 \to c\bar{c}) = \frac{3}{16\pi} Y_c^2 \cos^2\!\alpha\, m_{h^0} \left(1 - 4m_c^2/m_{h^0}^2\right)^{3/2}, \tag{29.6.8}$$

$$\Gamma(h^0 \to \tau^+\tau^-) = \frac{1}{16\pi} Y_\tau^2 \sin^2\!\alpha\, m_{h^0} \left(1 - 4m_\tau^2/m_{h^0}^2\right)^{3/2}, \tag{29.6.9}$$

$$\Gamma(H^0 \to t\bar{t}) = \frac{3}{16\pi} Y_t^2 \sin^2\!\alpha\, m_{H^0} \left(1 - 4m_t^2/m_{H^0}^2\right)^{3/2}, \tag{29.6.10}$$

$$\Gamma(H^0 \to b\bar{b}) = \frac{3}{16\pi} Y_b^2 \cos^2\alpha\, m_{H^0} \left(1 - 4m_b^2/m_{H^0}^2\right)^{3/2}, \tag{29.6.11}$$

etc., which check with the expressions in Appendix C of ref. [170]. For the CP-odd Higgs boson A^0, the mixing parameters $k_{uA^0} = i\cos\beta_0$ and $k_{dA^0} = i\sin\beta_0$ are purely imaginary, so

$$\Gamma(A^0 \to t\bar{t}) = \frac{3}{16\pi} Y_t^2 \cos^2\!\beta_0\, m_{A^0} \left(1 - 4m_t^2/m_{A^0}^2\right)^{1/2}, \tag{29.6.12}$$

$$\Gamma(A^0 \to b\bar{b}) = \frac{3}{16\pi} Y_b^2 \sin^2\!\beta_0\, m_{A^0} \left(1 - 4m_b^2/m_{A^0}^2\right)^{1/2}, \tag{29.6.13}$$

$$\Gamma(A^0 \to \tau^+\tau^-) = \frac{1}{16\pi} Y_\tau^2 \sin^2\!\beta_0\, m_{A^0} \left(1 - 4m_\tau^2/m_{A^0}^2\right)^{1/2}. \tag{29.6.14}$$

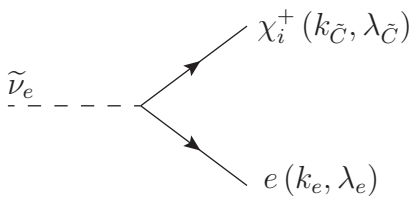

Figure 29.6.1: The Feynman diagram for $\widetilde{\nu}_e \to \widetilde{C}_i^+ e^-$ in the MSSM.

Note that the differing kinematic factors for the CP-odd Higgs decays came about because of the different relative sign between the two Feynman diagrams. For example, in the case of $h^0 \to b\bar{b}$, the matrix element is

$$i\mathcal{M} = \frac{i}{\sqrt{2}} Y_b \sin\alpha\, (y_1 y_2 + x_1^\dagger x_2^\dagger), \tag{29.6.15}$$

while for $A^0 \to b\bar{b}$, it is

$$i\mathcal{M} = \frac{1}{\sqrt{2}} Y_b \sin\beta_0\, (y_1 y_2 - x_1^\dagger x_2^\dagger). \tag{29.6.16}$$

The differing relative sign between $y_1 y_2$ and $x_1^\dagger x_2^\dagger$ follows from the imaginary pseudoscalar Lagrangian coupling, which is complex conjugated in the second diagram.

29.6.6 Sneutrino decay: $\widetilde{\nu}_e \to \widetilde{C}_i^+ e^-$

Next we consider the process of sneutrino decay $\widetilde{\nu}_e \to \widetilde{C}_i^+ e^-$ in the MSSM. Because only the left-handed electron can couple to the chargino and sneutrino (with the excellent approximation that the electron Yukawa coupling vanishes), there is just one Feynman diagram, shown in Fig. 29.6.1. The external wave functions of the electron and chargino are denoted as $x_e \equiv x(\vec{\boldsymbol{k}}_e, \lambda_e)$, and $x_{\tilde{C}} \equiv x(\vec{\boldsymbol{k}}_{\tilde{C}}, \lambda_{\tilde{C}})$, respectively. From the corresponding Feynman rule given in Fig. K.4.1 of Appendix K , the amplitude is:

$$i\mathcal{M} = -igV_{i1}\, x_{\tilde{C}}^\dagger x_e^\dagger, \tag{29.6.1}$$

where V_{ij} is one of the two matrices used to diagonalize the chargino masses [cf. eq. (K.2.6)]. Squaring this using eq. (29.44) yields:

$$|\mathcal{M}|^2 = g^2 |V_{i1}|^2\, (x_{\tilde{C}}^\dagger x_e^\dagger)(x_e x_{\tilde{C}})\,. \tag{29.6.2}$$

Summing over the electron and chargino spin polarizations using eq. (29.3.57) yields

$$\sum_{\lambda_e, \lambda_{\tilde{C}}} |\mathcal{M}|^2 = g^2 |V_{i1}|^2 \mathrm{Tr}[k_e \cdot \overline{\sigma}\, k_{\tilde{C}} \cdot \sigma] = 2g^2 |V_{i1}|^2\, k_e \cdot k_{\tilde{C}} = g^2 |V_{i1}|^2 (m_{\widetilde{\nu}_e}^2 - m_{\widetilde{C}_i}^2)\,, \tag{29.6.3}$$

where we have used $2k_e \cdot k_{\tilde{C}} = m_{\widetilde{\nu}_e}^2 - m_{\widetilde{C}_i}^2$, neglecting the electron mass. Therefore, after integrating over phase space in the standard way, the decay width is:

$$\Gamma(\widetilde{\nu}_e \to \widetilde{C}_i^+ e^-) = \frac{1}{16\pi m_{\widetilde{\nu}_e}} \left(1 - \frac{m_{\widetilde{C}_i}^2}{m_{\widetilde{\nu}_e}^2}\right) \left[\sum_{\lambda_e, \lambda_{\tilde{C}}} |\mathcal{M}|^2\right] = \frac{g^2}{16\pi} |V_{i1}|^2 m_{\widetilde{\nu}_e} \left(1 - \frac{m_{\widetilde{C}_i}^2}{m_{\widetilde{\nu}_e}^2}\right)^2, \tag{29.6.4}$$

which agrees with ref. [171] and eq. (3.8) in ref. [7].

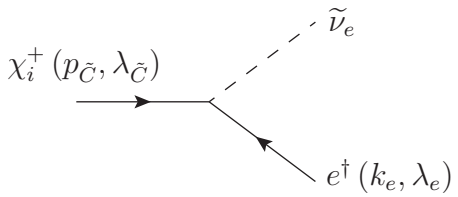

Figure 29.6.1: The Feynman diagram for $\widetilde{C}_i^+ \to \widetilde{\nu}_e e^+$ in the MSSM.

29.6.7 Chargino decay: $\widetilde{C}_i^+ \to \widetilde{\nu}_e e^+$

Here again, there is just one Feynman diagram (neglecting the electron mass in the Yukawa coupling) shown in Fig. 29.6.1. The external wave functions for the chargino and the positron are denoted by $x_{\tilde{C}} \equiv x(\vec{\boldsymbol{p}}_{\tilde{C}}, \lambda_{\tilde{C}})$ and $y_e \equiv y(\vec{\boldsymbol{k}}_e, \lambda_e)$, respectively. The fermion momenta and helicities are denoted as in Fig. 29.6.1. As in the previous example, the amplitude can be directly determined using the Feynman rule given in Fig. K.4.1 in Appendix K :

$$\mathcal{M} = -igV_{i1}^* \, x_{\tilde{C}} \, y_e \, . \tag{29.6.1}$$

Squaring this using eq. (29.44) yields:

$$|\mathcal{M}|^2 = g^2 |V_{i1}|^2 \, (x_{\tilde{C}} y_e) \, (y_e^\dagger x_{\tilde{C}}^\dagger) \, . \tag{29.6.2}$$

Summing over the electron helicity and averaging over the chargino helicity using eqs. (29.3.57) and (29.3.58) we obtain:

$$\tfrac{1}{2} \sum_{\lambda_e, \lambda_{\tilde{C}}} |\mathcal{M}|^2 = \tfrac{1}{2} g^2 |V_{i1}|^2 \mathrm{Tr}[k_e \cdot \sigma \, p_{\tilde{C}} \cdot \overline{\sigma}] = g^2 |V_{i1}|^2 k_e \cdot p_{\tilde{C}} = \frac{g^2}{2} |V_{i1}|^2 (m_{\tilde{C}_i}^2 - m_{\tilde{\nu}_e}^2) \, . \tag{29.6.3}$$

So the decay width is, neglecting the electron mass:

$$\Gamma(\widetilde{C}_i^+ \to \widetilde{\nu} e^+) = \frac{1}{16\pi m_{\tilde{C}_i}} \left(1 - \frac{m_{\tilde{\nu}_e}^2}{m_{\tilde{C}_i}^2}\right) \left(\frac{1}{2} \sum_{\lambda_e, \lambda_{\tilde{C}}} |\mathcal{M}|^2\right) = \frac{g^2}{32\pi} |V_{i1}|^2 m_{\tilde{C}_i} \left(1 - \frac{m_{\tilde{\nu}_e}^2}{m_{\tilde{C}_i}^2}\right)^2 , \tag{29.6.4}$$

which agrees with ref. [171].

29.6.8 Neutralino decays: $\widetilde{N}_i \to \phi^0 \widetilde{N}_j$ for $\phi^0 = h^0, H^0, A^0$

Next we consider the decay of a neutralino to a lighter neutralino and neutral Higgs boson $\phi^0 = h^0$, H^0, or A^0. The two tree-level Feynman graphs are shown in Fig. 29.6.1, where we have also labeled the momenta and helicities. We denote the masses for the neutralinos and the Higgs boson as $m_{\widetilde{N}_i}$, $m_{\widetilde{N}_j}$, and m_{ϕ^0}. Using the Feynman rules of Fig. K.3.1, the amplitudes are respectively given by

$$i\mathcal{M}_1 = -iY \, x_i y_j \, , \tag{29.6.1}$$

$$i\mathcal{M}_2 = -iY^* \, y_i^\dagger x_j^\dagger \, , \tag{29.6.2}$$

where the coupling $Y \equiv Y^{\phi^0 \chi_i^0 \chi_j^0}$ is defined in eq. (K.3.1), and the external wave functions are $x_i \equiv x(\vec{\boldsymbol{p}}_i, \lambda_i)$, $y_i^\dagger \equiv y^\dagger(\vec{\boldsymbol{p}}_i, \lambda_i)$, $y_j \equiv y(\vec{\boldsymbol{k}}_j, \lambda_j)$, and $x_j^\dagger \equiv x^\dagger(\vec{\boldsymbol{k}}_j, \lambda_j)$.

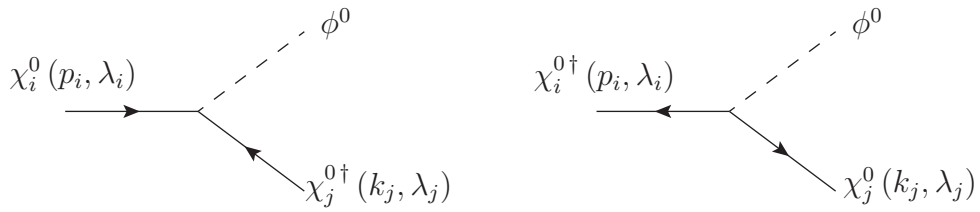

Figure 29.6.1: The Feynman diagrams for $\widetilde{N}_i \to \widetilde{N}_j \phi^0$ in the MSSM.

Taking the square of the total matrix element using eq. (29.44) gives:

$$|\mathcal{M}|^2 = |Y|^2(x_i y_j y_j^\dagger x_i^\dagger + y_i^\dagger x_j^\dagger x_j y_i) + Y^2 x_i y_j x_j y_i + Y^{*2} y_i^\dagger x_j^\dagger y_j^\dagger x_i^\dagger. \tag{29.6.3}$$

Summing over the final state neutralino spins using eqs. (29.3.57)–(29.3.60) yields

$$\sum_{\lambda_j} |\mathcal{M}|^2 = |Y|^2(x_i k_j\cdot\sigma x_i^\dagger + y_i^\dagger k_j\cdot\overline{\sigma} y_i) - Y^2 m_{\widetilde{N}_j} x_i y_i - Y^{*2} m_{\widetilde{N}_j} y_i^\dagger x_i^\dagger. \tag{29.6.4}$$

Averaging over the initial state neutralino spins in the same way gives

$$\begin{aligned}\frac{1}{2}\sum_{\lambda_i,\lambda_j} |\mathcal{M}|^2 &= \frac{1}{2}|Y|^2(\mathrm{Tr}[k_j\cdot\sigma p_i\cdot\overline{\sigma}] + \mathrm{Tr}[k_j\cdot\overline{\sigma} p_i\cdot\sigma]) + \mathrm{Re}[Y^2] m_{\widetilde{N}_i} m_{\widetilde{N}_j} \mathrm{Tr}[\mathbb{1}_{2\times 2}] \\ &= 2|Y|^2 p_i\cdot k_j + 2\mathrm{Re}[Y^2] m_{\widetilde{N}_i} m_{\widetilde{N}_j} \\ &= |Y|^2(m_{\widetilde{N}_i}^2 + m_{\widetilde{N}_j}^2 - m_{\phi^0}^2) + 2\mathrm{Re}[Y^2] m_{\widetilde{N}_i} m_{\widetilde{N}_j},\end{aligned} \tag{29.6.5}$$

where we have used eq. (29.56) to obtain the second equality. The total decay rate is therefore

$$\begin{aligned}\Gamma(\widetilde{N}_i \to \phi^0 \widetilde{N}_j) &= \frac{1}{16\pi m_{\widetilde{N}_i}^3} \lambda^{1/2}(m_{\widetilde{N}_i}^2, m_{\phi^0}^2, m_{\widetilde{N}_j}^2) \left(\frac{1}{2}\sum_{\lambda_i,\lambda_j} |\mathcal{M}|^2\right) \\ &= \frac{m_{\widetilde{N}_i}}{16\pi} \lambda^{1/2}(1, r_\phi, r_j) \left[|Y^{\phi^0 \chi_i^0 \chi_j^0}|^2 (1 + r_j - r_\phi) + 2\mathrm{Re}\left[\left(Y^{\phi^0 \chi_i^0 \chi_j^0}\right)^2\right]\sqrt{r_j}\right],\end{aligned} \tag{29.6.6}$$

where the triangle function $\lambda^{1/2}$ is defined in eq. (29.6.11), $r_j \equiv m_{\widetilde{N}_j}^2/m_{\widetilde{N}_i}^2$ and $r_\phi \equiv m_{\phi^0}^2/m_{\widetilde{N}_i}^2$. The results for $\phi^0 = h^0, H^0, A^0$ can now be obtained by using eqs. (K.1.7) and (K.1.8) in eq. (K.3.1). In comparing eq. (29.6.6) with the original calculation in [172], it is helpful to employ eqs. (4.51) and (4.53) of [173]. The results agree.

29.6.9 $\widetilde{N}_i \to Z^0 \widetilde{N}_j$

For this two-body decay there are two tree-level Feynman diagrams, shown in Fig. 29.6.1 with the definitions of the helicities and the momenta. Using the Feynman rules of Fig. K.2.1, the two amplitudes are given by[66]

$$i\mathcal{M}_1 = -i\frac{g}{c_W} \mathcal{O}''^L_{ji} x_i \sigma^\mu x_j^\dagger \varepsilon_\mu^*\,, \tag{29.6.1}$$

$$i\mathcal{M}_2 = i\frac{g}{c_W} \mathcal{O}''^L_{ij} y_i^\dagger \overline{\sigma}^\mu y_j \varepsilon_\mu^*\,, \tag{29.6.2}$$

[66] When comparing with the four-component Feynman rule in ref. [7] note that $\mathcal{O}''^L_{ij} = -\mathcal{O}''^{R*}_{ij}$ [cf. eq. (K.2.5)].

where the external wave functions are $x_i = x(\vec{\boldsymbol{p}}_i, \lambda_i)$, $y_i^\dagger = y^\dagger(\vec{\boldsymbol{p}}_i, \lambda_i)$, $x_j^\dagger = x^\dagger(\vec{\boldsymbol{k}}_j, \lambda_j)$, $y_j = y(\vec{\boldsymbol{k}}_j, \lambda_j)$, and $\varepsilon_\mu^* = \varepsilon_\mu(\vec{\boldsymbol{k}}_Z, \lambda_Z)^*$. Noting that $\mathcal{O}''^L_{ji} = \mathcal{O}''^{L*}_{ij}$ [see eq. (K.2.5)], and applying eqs. (29.45) and (29.46), we find that the squared matrix element is:

$$|\mathcal{M}|^2 = \frac{g^2}{c_W^2}\varepsilon_\mu^*\varepsilon_\nu\Big[|\mathcal{O}''^L_{ij}|^2(x_i\sigma^\mu x_j^\dagger x_j\sigma^\nu x_i^\dagger + y_i^\dagger\overline{\sigma}^\mu y_j y_j^\dagger\overline{\sigma}^\nu y_i) - \left(\mathcal{O}''^L_{ij}\right)^2 y_i^\dagger\overline{\sigma}^\mu y_j x_j\sigma^\nu x_i^\dagger - \left(\mathcal{O}''^{L*}_{ij}\right)^2 x_i\sigma^\mu x_j^\dagger y_j^\dagger\overline{\sigma}^\nu y_i\Big]. \tag{29.6.3}$$

Summing over the final state neutralino spin using eqs. (29.3.57)–(29.3.60) yields:

$$\sum_{\lambda_j}|\mathcal{M}|^2 = \frac{g^2}{c_W^2}\varepsilon_\mu^*\varepsilon_\nu\Big[|\mathcal{O}''^L_{ij}|^2(x_i\sigma^\mu k_j\cdot\overline{\sigma}\sigma^\nu x_i^\dagger + y_i^\dagger\overline{\sigma}^\mu k_j\cdot\sigma\overline{\sigma}^\nu y_i) + \left(\mathcal{O}''^L_{ij}\right)^2 m_{\widetilde{N}_j} y_i^\dagger\overline{\sigma}^\mu\sigma^\nu x_i^\dagger + \left(\mathcal{O}''^{L*}_{ij}\right)^2 m_{\widetilde{N}_j} x_i\sigma^\mu\overline{\sigma}^\nu y_i\Big]. \tag{29.6.4}$$

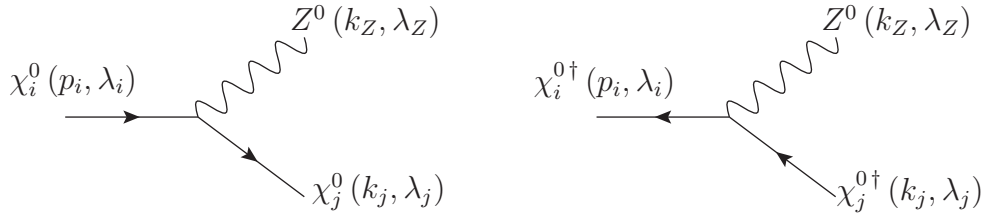

Figure 29.6.1: The Feynman diagrams for $\widetilde{N}_i \to \widetilde{N}_j Z^0$ in the MSSM.

Averaging over the initial state neutralino spins in the same way gives

$$\begin{aligned}\frac{1}{2}\sum_{\lambda_i,\lambda_j}|\mathcal{M}|^2 &= \frac{g^2}{2c_W^2}\varepsilon_\mu^*\varepsilon_\nu\Big[|\mathcal{O}''^L_{ij}|^2\Big(\mathrm{Tr}[\sigma^\mu k_j\cdot\overline{\sigma}\sigma^\nu p_i\cdot\overline{\sigma}] + \mathrm{Tr}[\overline{\sigma}^\mu k_j\cdot\sigma\overline{\sigma}^\nu p_i\cdot\sigma]\Big) \\ &\quad - \left(\mathcal{O}''^L_{ij}\right)^2 m_{\widetilde{N}_i}m_{\widetilde{N}_j}\mathrm{Tr}[\overline{\sigma}^\mu\sigma^\nu] - \left(\mathcal{O}''^{L*}_{ij}\right)^2 m_{\widetilde{N}_i}m_{\widetilde{N}_j}\mathrm{Tr}[\sigma^\mu\overline{\sigma}^\nu]\Big] \\ &= \frac{2g^2}{c_W^2}\varepsilon_\mu^*\varepsilon_\nu\Big\{|\mathcal{O}''^L_{ij}|^2\left(k_j^\mu p_i^\nu + p_i^\mu k_j^\nu - p_i\cdot k_j g^{\mu\nu}\right) - \mathrm{Re}\Big[\left(\mathcal{O}''^L_{ij}\right)^2\Big]m_{\widetilde{N}_i}m_{\widetilde{N}_j}g^{\mu\nu}\Big\},\end{aligned} \tag{29.6.5}$$

where in the last equality we have applied eqs. (29.56)–(29.58). Using

$$\sum_{\lambda_Z}\varepsilon^{\mu*}\varepsilon^\nu = -g^{\mu\nu} + k_Z^\mu k_Z^\nu/m_Z^2\,, \tag{29.6.6}$$

we obtain

$$\frac{1}{2}\sum_{\lambda_i,\lambda_j,\lambda_Z}|\mathcal{M}|^2 = \frac{2g^2}{c_W^2}\Big\{|\mathcal{O}''^L_{ij}|^2\left(p_i\cdot k_j + 2p_i\cdot k_Z k_j\cdot k_Z/m_Z^2\right) + 3m_{\widetilde{N}_i}m_{\widetilde{N}_j}\mathrm{Re}\big[\left(\mathcal{O}''^L_{ij}\right)^2\big]\Big\}. \tag{29.6.7}$$

Using $2k_j\cdot k_Z = m^2_{\widetilde{N}_i} - m^2_{\widetilde{N}_j} - m^2_Z$, $2p_i\cdot k_j = m^2_{\widetilde{N}_i} + m^2_{\widetilde{N}_j} - m^2_Z$, and $2p_i\cdot k_Z = m^2_{\widetilde{N}_i} - m^2_{\widetilde{N}_j} + m^2_Z$, we obtain the total decay width:

$$\begin{aligned}\Gamma(\widetilde{N}_i \to Z^0 \widetilde{N}_j) &= \frac{1}{16\pi m^3_{\widetilde{N}_i}} \lambda^{1/2}\big(m^2_{\widetilde{N}_i}, m^2_Z, m^2_{\widetilde{N}_j}\big) \left(\frac{1}{2}\sum_{\lambda_i,\lambda_j,\lambda_Z} |\mathcal{M}|^2\right) \\ &= \frac{g^2 m_{\widetilde{N}_i}}{16\pi c^2_W} \lambda^{1/2}(1, r_Z, r_j)\left[|\mathcal{O}''^L_{ij}|^2\left(1 + r_j - 2r_Z + (1-r_j)^2/r_Z\right) + 6\mathrm{Re}\big[\big(\mathcal{O}''^L_{ij}\big)^2\big]\sqrt{r_j}\right], \quad (29.6.8)\end{aligned}$$

where

$$r_j \equiv m^2_{\widetilde{N}_j}/m^2_{\widetilde{N}_i}\,, \qquad r_Z \equiv m^2_Z/m^2_{\widetilde{N}_i}\,, \quad (29.6.9)$$

and the triangle function $\lambda^{1/2}$ is defined in eq. (29.6.11). The result obtained in eq. (29.6.8) agrees with the original calculation in [172].

29.6.10 Selectron pair production in electron-electron collisions

$e^-e^- \to \widetilde{e}^-_L \widetilde{e}^-_R$

Here there are two Feynman graphs (neglecting the electron mass and Yukawa couplings), shown in Fig. 29.6.1. Note that these two graphs are related by interchange of the identical initial state electrons. Let the electrons have momenta p_1 and p_2 and the selectrons have momenta $k_{\widetilde{e}_L}$ and $k_{\widetilde{e}_R}$, so that $p_1^2 = p_2^2 = 0$; $k_1^2 = m^2_{\widetilde{e}_L}$; $k_2^2 = m^2_{\widetilde{e}_R}$; $s = (p_1+p_2)^2 = (k_1+k_2)^2$; $t = (k_1-p_1)^2 = (k_2-p_2)^2$; $u = (k_1-p_2)^2 = (k_2-p_1)^2$.

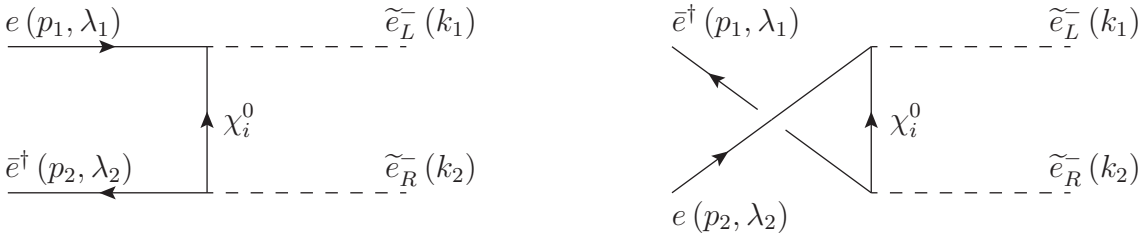

Figure 29.6.1: Feynman diagrams for $e^-e^- \to \widetilde{e}^-_L\widetilde{e}^-_R$.

Using the Feynman rules of Fig. K.4.2, the matrix element for the first graph, for each neutralino $\widetilde{N}_i$ exchanged in the t channel, is:

$$i\mathcal{M}_t = \left[i\frac{g}{\sqrt{2}}\left(N^*_{i2} + \frac{s_W}{c_W}N^*_{i1}\right)\right]\left[-i\sqrt{2}g\frac{s_W}{c_W}N_{i1}\right]\, x_1\left[\frac{i(k_1-p_1)\cdot\sigma}{(k_1-p_1)^2 - m^2_{\widetilde{N}_i}}\right] y_2^\dagger\,. \quad (29.6.1)$$

We employ the notation for the external wave functions $x_i = (\vec{\boldsymbol{p}}_i, \lambda_i)$, $i = 1, 2$ and analogously for $y_i, x_i^\dagger, y_i^\dagger$. The matrix element for the second (u-channel) graph is the same with the two incoming electrons exchanged, $e_1 \leftrightarrow e_2$:

$$i\mathcal{M}_u = (-1)\left[i\frac{g}{\sqrt{2}}\left(N^*_{i2} + \frac{s_W}{c_W}N^*_{i1}\right)\right]\left[-i\sqrt{2}g\frac{s_W}{c_W}N_{i1}\right]\, x_2\left[\frac{i(k_1-p_2)\cdot\sigma}{(k_1-p_2)^2 - m^2_{\widetilde{N}_i}}\right] y_1^\dagger\,. \quad (29.6.2)$$

Note that since we have written the fermion wave function spinors in the opposite order in $\mathcal{M}_2$ compared to $\mathcal{M}_1$, there is a factor (-1) for Fermi-Dirac statistics. Alternatively, starting at the electron with momentum p_1 and using the Feynman rules as above, we can directly write:

$$i\mathcal{M}_u = \left[i\frac{g}{\sqrt{2}}\left(N_{i2}^* + \frac{s_W}{c_W}N_{i1}^*\right)\right]\left[-i\sqrt{2}g\frac{s_W}{c_W}N_{i1}\right]\, y_1^\dagger\left[\frac{-i(k_1-p_2)\cdot\overline{\sigma}}{(k_1-p_2)^2 - m_{\tilde{N}_i}^2}\right] x_2\,. \tag{29.6.3}$$

This has no Fermi-Dirac factor (-1) because the wave function spinors are written in the same order as in $\mathcal{M}_t$. However, now the Feynman rule for the propagator has an extra minus sign, as can be seen in Fig. 29.4.2. We can also obtain eq. (29.6.3) from eq. (29.6.2) by using eq. (29.62). So we can write for the total amplitude:

$$\mathcal{M} = \mathcal{M}_t + \mathcal{M}_u = x_1 a\cdot\sigma y_2^\dagger + y_1^\dagger b\cdot\overline{\sigma} x_2\,, \tag{29.6.4}$$

where

$$a^\mu \equiv \frac{g^2 s_W}{c_W}(k_1^\mu - p_1^\mu)\sum_{i=1}^4 N_{i1}(N_{i2}^* + \frac{s_W}{c_W}N_{i1}^*)\frac{1}{t - m_{\tilde{N}_i}^2}\,, \tag{29.6.5}$$

$$b^\mu \equiv -\frac{g^2 s_W}{c_W}(k_1^\mu - p_2^\mu)\sum_{i=1}^4 N_{i1}(N_{i2}^* + \frac{s_W}{c_W}N_{i1}^*)\frac{1}{u - m_{\tilde{N}_i}^2}\,. \tag{29.6.6}$$

Hence, using eqs. (29.45) and (29.46):

$$\begin{aligned}|\mathcal{M}|^2 = &\left(x_1 a\cdot\sigma y_2^\dagger\right)\left(y_2 a^*\cdot\sigma x_1^\dagger\right) + \left(y_1^\dagger b\cdot\overline{\sigma} x_2\right)\left(x_2^\dagger b^*\cdot\overline{\sigma} y_1\right)\\ &+ \left(x_1 a\cdot\sigma y_2^\dagger\right)\left(x_2^\dagger b^*\cdot\overline{\sigma} y_1\right) + \left(y_1^\dagger b\cdot\overline{\sigma} x_2\right)\left(y_2 a^*\cdot\sigma x_1^\dagger\right)\,.\end{aligned} \tag{29.6.7}$$

Averaging over the initial state electron spins using eqs. (29.3.57)–(29.3.60), the a, b^* and a^*, b cross terms are proportional to m_e and can thus be neglected in our approximation. We get:

$$\frac{1}{4}\sum_{\lambda_1,\lambda_2}|\mathcal{M}|^2 = \frac{1}{4}\mathrm{Tr}[a\cdot\sigma\; p_2\cdot\overline{\sigma}\; a^*\cdot\sigma\; p_1\cdot\overline{\sigma}] + \frac{1}{4}\mathrm{Tr}[b\cdot\overline{\sigma}\; p_2\cdot\sigma\; b^*\cdot\overline{\sigma}\; p_1\cdot\sigma]\,. \tag{29.6.8}$$

These terms can be simplified using the identities:

$$\begin{aligned}\mathrm{Tr}[(k_1-p_1)\cdot\sigma\; p_2\cdot\overline{\sigma}\; (k_1-p_1)\cdot\sigma\; p_1\cdot\overline{\sigma}] &= \mathrm{Tr}[(k_1-p_2)\cdot\overline{\sigma}\; p_2\cdot\sigma\; (k_1-p_2)\cdot\overline{\sigma}\; p_1\cdot\sigma]\\ &= tu - m_{\tilde{e}_L}^2 m_{\tilde{e}_R}^2,\end{aligned} \tag{29.6.9}$$

which follow from eq. (29.57) and (29.58), resulting in:

$$\begin{aligned}\frac{1}{4}\sum_{\lambda_1,\lambda_2}|\mathcal{M}|^2 = \frac{g^4 s_W^2}{4c_W^2}(tu - m_{\tilde{e}_L}^2 m_{\tilde{e}_R}^2)\sum_{i,j=1}^4 N_{j1}N_{i1}^*(N_{j2}^* + \frac{s_W}{c_W}N_{j1}^*)(N_{i2} + \frac{s_W}{c_W}N_{i1})\\ \left[\frac{1}{(t - m_{\tilde{N}_i}^2)(t - m_{\tilde{N}_j}^2)} + \frac{1}{(u - m_{\tilde{N}_i}^2)(u - m_{\tilde{N}_j}^2)}\right]\,.\end{aligned} \tag{29.6.10}$$

To get the differential cross-section $d\sigma/dt$, multiply this by $1/(16\pi s^2)$:

$$\frac{d\sigma}{dt} = \frac{\pi\alpha^2}{4s_W^2 c_W^2}\left(\frac{tu - m_{\tilde{e}_L}^2 m_{\tilde{e}_R}^2}{s^2}\right)\sum_{i,j=1}^4 N_{j1}N_{i1}^*(N_{j2}^* + \frac{s_W}{c_W}N_{j1}^*)(N_{i2} + \frac{s_W}{c_W}N_{i1})$$

$$\left[\frac{1}{(t-m^2_{\widetilde{N}_i})(t-m^2_{\widetilde{N}_j})}+\frac{1}{(u-m^2_{\widetilde{N}_i})(u-m^2_{\widetilde{N}_j})}\right]. \qquad (29.6.11)$$

To compare with the original calculation in [174] and with eq. E26, p. 244 in ref. [7], note that for a pure photino exchange, $N_{i1}\to c_W\delta_{i1}$ and $N_{i2}\to s_W\delta_{i1}$, so that

$$\frac{1}{4s_W^2c_W^2}|N_{i1}|^2|N_{i2}+\frac{s_W}{c_W}N_{i1}|^2 \;\to\; 1\,. \qquad (29.6.12)$$

Also note that in [174] polarized electron beams are assumed. The result checks.

$e^-e^-\to\widetilde{e}^-_R\widetilde{e}^-_R$

For this process, there are again two Feynman graphs, which are related by the exchange of identical electrons in the initial state or equivalently by exchange of the identical selectrons in the final state, as shown in Fig. 29.6.2. (We again neglect the electron mass and thus the higgsino coupling to the electron.) Let the electrons have momenta p_1 and p_2 and the selectrons have momenta k_1 and k_2, so that $p_1^2=p_2^2=0$; $k_1^2=k_2^2=m^2_{\widetilde{e}_R}$; $s=(p_1+p_2)^2$; $t=(k_1-p_1)^2$; $u=(k_1-p_2)^2$.

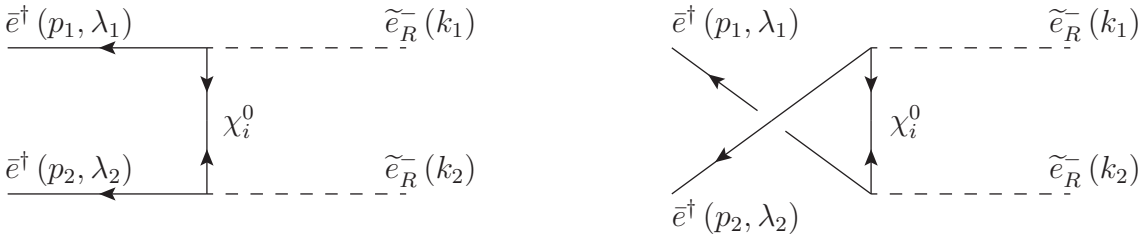

Figure 29.6.2: The two Feynman diagrams for $e^-e^-\to\widetilde{e}^-_R\widetilde{e}^-_R$ in the limit where $m_e\to 0$.

Using the Feynman rules of Fig. K.4.2, the amplitude for the first graph is:

$$i\mathcal{M}_t=\left(-i\sqrt{2}g\frac{s_W}{c_W}N_{i1}\right)^2\left[\frac{i\,m_{\widetilde{N}_i}}{(k_1-p_1)^2-m^2_{\widetilde{N}_i}}\right]y_1^\dagger y_2^\dagger\,, \qquad (29.6.13)$$

for each exchanged neutralino. The amplitude for the second graph is the same, but with the electrons interchanged:

$$i\mathcal{M}_u=\left(-i\sqrt{2}g\frac{s_W}{c_W}N_{i1}\right)^2\left[\frac{i\,m_{\widetilde{N}_i}}{(k_1-p_2)^2-m^2_{\widetilde{N}_i}}\right]y_1^\dagger y_2^\dagger\,. \qquad (29.6.14)$$

Since we have chosen to write the external state wave function spinors in the same order in $\mathcal{M}_t$ and $\mathcal{M}_u$, there is no factor of (-1) for Fermi-Dirac statistics. So, applying eq. (29.44), the total amplitude squared is:

$$|\mathcal{M}|^2=\frac{4g^4s_W^4}{c_W^4}(y_1^\dagger y_2^\dagger)(y_2y_1)\left|\sum_{i=1}^4(N_{i1})^2m_{\widetilde{N}_i}\left(\frac{1}{t-m^2_{\widetilde{N}_i}}+\frac{1}{u-m^2_{\widetilde{N}_i}}\right)\right|^2. \qquad (29.6.15)$$

The sum over the electron spins is obtained from

$$\sum_{\lambda_1,\lambda_2}(y_1^\dagger y_2^\dagger)(y_2y_1)=\mathrm{Tr}[p_2{\cdot}\overline{\sigma}p_1{\cdot}\sigma]=2p_2{\cdot}p_1=s\,. \qquad (29.6.16)$$

So, using eq. (29.3.58), the spin-averaged differential cross-section is:

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}\left(\frac{1}{4}\sum_{\lambda_1,\lambda_2}|\mathcal{M}|^2\right) = \frac{\pi\alpha^2}{2c_W^4 s}\left|\sum_{i=1}^{4}(N_{i1})^2 m_{\widetilde{N}_i}\left(\frac{1}{t-m^2_{\widetilde{N}_i}}+\frac{1}{u-m^2_{\widetilde{N}_i}}\right)\right|^2 . \tag{29.6.17}$$

After integrating over t to obtain the total cross-section, the resulting expression must be multiplied by a factor of $1/2$ to account for the identical sleptons in the final state (to avoid the double counting of indistinguishable particles).

To compare with [174] and also with eq. E27 of ref. [7], note that for a pure photino exchange, $N_{i1} \to c_W \delta_{i1}$, so it checks.

$e^-e^- \to \widetilde{e}_L^-\widetilde{e}_L^-$

Again, in the limit of vanishing electron mass, there are two Feynman graphs, which are related by the exchange of identical electrons in the initial state or equivalently by exchange of the identical selectrons in the final state. As shown in Fig. 29.6.3, they are exactly like the previous example, but with all arrows reversed.

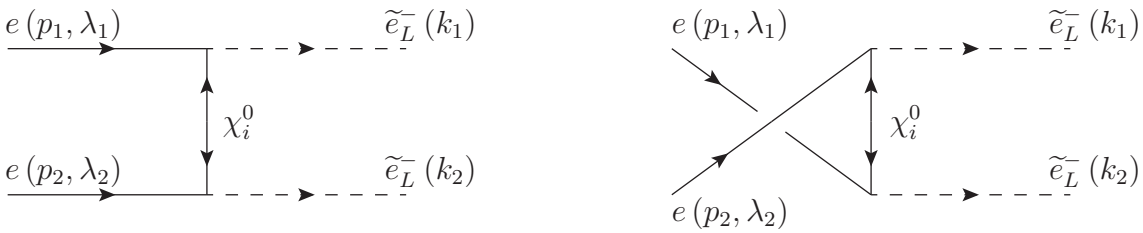

Figure 29.6.3: The two Feynman diagrams for $e^-e^- \to \widetilde{e}_L^-\widetilde{e}_L^-$ in the limit of vanishing electron mass.

Using the Feynman rules of Fig. K.4.2, the amplitude for the first graph is:

$$\mathcal{M}_t = \left(i\frac{g}{\sqrt{2}}[N^*_{i2}+\frac{s_W}{c_W}N^*_{i1}]\right)^2\left[\frac{i\,m_{\widetilde{N}_i}}{(p_1-k_1)^2-m^2_{\widetilde{N}_i}}\right]x_1x_2\,, \tag{29.6.18}$$

for each exchanged neutralino. The amplitude for the second graph is the same, but with $p_1 \leftrightarrow p_2$:

$$\mathcal{M}_u = \left(i\frac{g}{\sqrt{2}}[N^*_{i2}+\frac{s_W}{c_W}N^*_{i1}]\right)^2\left[\frac{i\,m_{\widetilde{N}_i}}{(p_2-k_1)^2-m^2_{\widetilde{N}_i}}\right]x_1x_2\,. \tag{29.6.19}$$

Since we have chosen to write the external state wave function spinors in the same order in $\mathcal{M}_1$ and $\mathcal{M}_2$, there is no factor of (-1) for Fermi-Dirac statistics. The total amplitude squared is:

$$|\mathcal{M}|^2 = \frac{g^4}{4}(x_1x_2)(x_2^\dagger x_1^\dagger)\left|\sum_{i=1}^{4}(N^*_{i2}+\frac{s_W}{c_W}N^*_{i1})^2 m_{\widetilde{N}_i}\left(\frac{1}{t-m^2_{\widetilde{N}_i}}+\frac{1}{u-m^2_{\widetilde{N}_i}}\right)\right|^2 . \tag{29.6.20}$$

The average over the electron spins follows from eq. (29.3.57):

$$\sum_{\lambda_1,\lambda_2}(x_1x_2)(x_2^\dagger x_1^\dagger) = \mathrm{Tr}[p_2{\cdot}\sigma p_1{\cdot}\overline{\sigma}] = 2p_2{\cdot}p_1 = s\,. \tag{29.6.21}$$

So the spin-averaged differential cross-section is:

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}\left(\frac{1}{4}\sum_{\lambda_1,\lambda_2}|\mathcal{M}|^2\right) = \frac{\pi\alpha^2}{16 s_W^4 s}\left|\sum_{i=1}^{4}(N_{i2}^* + \frac{s_W}{c_W}N_{i1}^*)^2 m_{\widetilde{N}_i}\left(\frac{1}{t-m_{\widetilde{N}_i}^2}+\frac{1}{u-m_{\widetilde{N}_i}^2}\right)\right|^2 . \tag{29.6.22}$$

After integrating over t to obtain the total cross-section, one must multiply the resulting expression by a factor of 1/2 to account for the identical sleptons in the final state [as noted below eq. (29.6.17)]. To compare with [174] and also with eq. (E27) of ref. [7], note that for a pure photino exchange, $N_{i1} \to c_W\delta_{i1}$ and $N_{i2} \to s_W\delta_{i1}$, so it checks.

29.6.11 $e^-e^+ \to \widetilde{\nu}\widetilde{\nu}^*$

Consider now the pair production of sneutrinos in electron-positron collisions. There are two graphs featuring the s-channel exchange of the Z^0. We will neglect the electron mass and Yukawa coupling, so there is only one graph involving the t-channel exchange of the charginos. These three Feynman diagrams are shown in Fig. 29.6.1, where we have also defined the helicities and momenta of the particles. The Mandelstam variables can be expressed in terms of the external momenta and the sneutrino mass:

$$2p_1\cdot p_2 = s\,, \qquad 2k_1\cdot k_2 = s - 2m_{\widetilde{\nu}}^2\,, \tag{29.6.1}$$

$$2p_1\cdot k_1 = 2p_2\cdot k_2 = m_{\widetilde{\nu}}^2 - t\,, \qquad 2p_1\cdot k_2 = 2p_2\cdot k_1 = m_{\widetilde{\nu}}^2 - u\,. \tag{29.6.2}$$

Using the Feynman rules of Fig. J.1.2, the amplitudes for the two s-channel Z boson exchange diagrams are:[67]

$$i\mathcal{M}_1 = \left[-i\frac{g}{2c_W}(k_1-k_2)_\mu\right]\left[\frac{-ig^{\mu\nu}}{D_Z}\right]\left[i\frac{g}{c_W}(s_W^2-\tfrac{1}{2})\right]x_1\sigma_\nu y_2^\dagger\,, \tag{29.6.3}$$

$$i\mathcal{M}_2 = \left[-i\frac{g}{2c_W}(k_1-k_2)_\mu\right]\left[\frac{-ig^{\mu\nu}}{D_Z}\right]\left[i\frac{g s_W^2}{c_W}\right]y_1^\dagger\overline{\sigma}_\nu x_2\,, \tag{29.6.4}$$

where the first factor in each case is the Feynman rule from the Z boson coupling to the sneutrinos (see Fig. 72c, ref. [7]), and $D_Z \equiv s - m_Z^2 + i\Gamma_Z m_Z$ is the denominator of the Z boson propagator.[68] The t-channel diagram due to each chargino gives a contribution

$$i\mathcal{M}_3 = (-igV_{i1}^*)\,(-igV_{i1})\,x_1\left[\frac{i(k_1-p_1)\cdot\sigma}{(k_1-p_1)^2 - m_{\widetilde{C}_i}^2}\right]y_2^\dagger, \tag{29.6.5}$$

using the rules of Fig. K.4.1. Therefore, the total amplitude can be rewritten as:

$$\mathcal{M} = c_1 x_1(k_1-k_2)\cdot\sigma y_2^\dagger + c_2 y_1^\dagger(k_1-k_2)\cdot\overline{\sigma}x_2 + c_3 x_1(k_1-p_1)\cdot\sigma y_2^\dagger\,, \tag{29.6.6}$$

where

$$c_1 \equiv \frac{g^2(1-2s_W^2)}{4c_W^2 D_Z}, \qquad c_2 \equiv -\frac{g^2 s_W^2}{2c_W^2 D_Z}, \qquad c_3 \equiv g^2\sum_{i=1}^{2}\frac{|V_{i1}|^2}{m_{\widetilde{C}_j}^2 - t}\,. \tag{29.6.7}$$

[67] Because we neglect the electron mass, we may drop the $Q^\mu Q^\nu$ term of the Z propagator, where $Q \equiv p_1 + p_2$ is the propagating four-momentum in the s-channel [cf. Fig. 29.4.5].

[68] The explicit inclusion of the finite decay width in the propagator of an unstable particle involves subtle issues of gauge invariance and unitarity, particularly in higher loop computations. The authors of [175] recommend the complex-mass scheme for perturbative calculations with unstable particles, first introduced in [176].

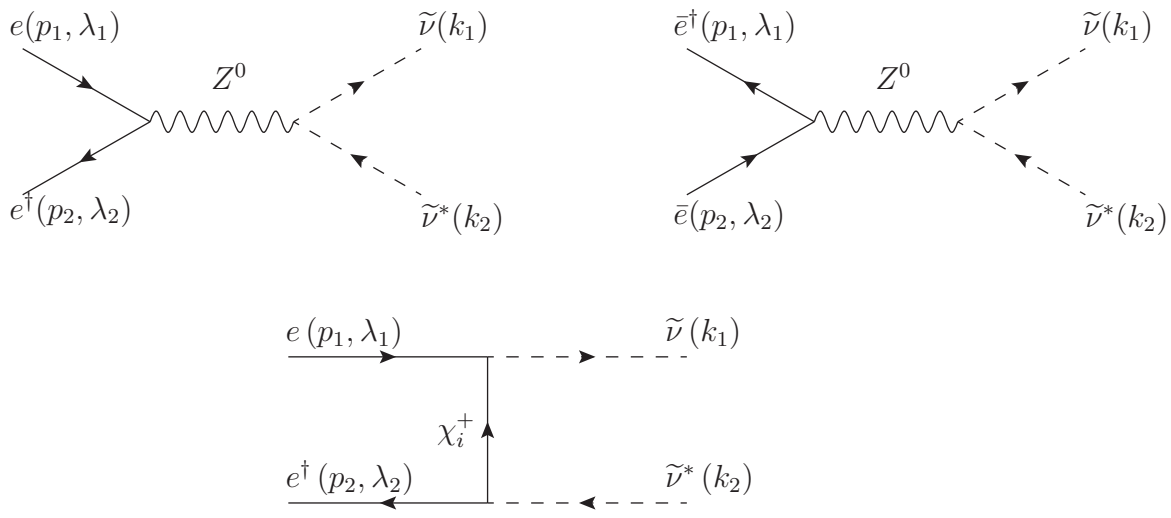

Figure 29.6.1: The Feynman diagrams for $e^-e^+ \to \widetilde{\nu}\widetilde{\nu}^*$.

Squaring the amplitude and summing over the electron and positron spins, the interference terms involving c_2 will vanish in the massless electron limit due to eqs. (29.3.59) and (29.3.60). Therefore, we obtain

$$\begin{aligned}\sum_{\lambda_1,\lambda_2}|\mathcal{M}|^2 &= \sum_{\lambda_1,\lambda_2}\Big\{|c_1|^2\,x_1(k_1-k_2)\cdot\sigma y_2^\dagger\,y_2(k_1-k_2)\cdot\sigma x_1^\dagger + |c_2|^2\,y_1^\dagger(k_1-k_2)\cdot\overline{\sigma}x_2\,x_2^\dagger(k_1-k_2)\cdot\overline{\sigma}y_1 \\ &\qquad + c_3^2\,x_1(k_1-p_1)\cdot\sigma y_2^\dagger\,y_2(k_1-p_1)\cdot\sigma x_1^\dagger + 2\mathrm{Re}[c_1c_3\,x_1(k_1-k_2)\cdot\sigma y_2^\dagger\,y_2(k_1-p_1)\cdot\sigma x_1^\dagger]\Big\} \\ &= |c_1|^2\,\mathrm{Tr}[(k_1-k_2)\cdot\sigma p_2\cdot\overline{\sigma}(k_1-k_2)\cdot\sigma p_1\cdot\overline{\sigma}] + |c_2|^2\,\mathrm{Tr}[(k_1-k_2)\cdot\overline{\sigma}p_2\cdot\sigma(k_1-k_2)\cdot\overline{\sigma}p_1\cdot\sigma] \\ &\quad + c_3^2\,\mathrm{Tr}[(k_1-p_1)\cdot\sigma p_2\cdot\overline{\sigma}(k_1-p_1)\cdot\sigma p_1\cdot\overline{\sigma}] + 2\mathrm{Re}[c_1]c_3\,\mathrm{Tr}[(k_1-k_2)\cdot\sigma p_2\cdot\overline{\sigma}(k_1-p_1)\cdot\sigma p_1\cdot\overline{\sigma}],\end{aligned} \tag{29.6.8}$$

where we have used eqs. (29.3.57) and (29.3.58) to perform the spin sums. Applying the trace identities eqs. (29.57) and (29.58) and simplifying the results using eqs. (29.6.1)–(29.6.2) and $u = 2m_{\tilde{\nu}}^2 - s - t$, we get

$$\sum_{\lambda_1,\lambda_2}|\mathcal{M}|^2 = -[st + (t-m_{\tilde{\nu}}^2)^2]\left(4|c_1|^2 + 4|c_2|^2 + c_3^2 + 4\mathrm{Re}[c_1]c_3\right). \tag{29.6.9}$$

When $m_{\tilde{C}_1} = m_{\tilde{C}_2}$, this agrees with eqs. (E46)–(E48) of [7] [69] and with [177]. The differential cross-section follows in the standard way by averaging over the initial state spins:

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}\left(\frac{1}{4}\sum_{\lambda_1,\lambda_2}|\mathcal{M}|^2\right). \tag{29.6.10}$$

Note that

$$t = m_{\tilde{\nu}}^2 - \tfrac{1}{2}(1-\beta\cos\theta)s\,, \qquad \beta \equiv \left(1 - \frac{4m_{\tilde{\nu}}^2}{s}\right)^{1/2}, \tag{29.6.11}$$

[69] There is a typographical error in eq. (E48) of [7]; the right-hand side should be multiplied by $1/\cos^2\theta_W$.

where θ is the angle between the initial state electron and the final state sneutrino in the center-of-momentum frame. The upper and lower limits t_+ and t_- are obtained by inserting $\cos\theta = \pm 1$ above, respectively.

Performing the integration over t to obtain the total cross-section, one obtains

$$\sigma = \int_{t_-}^{t_+} \frac{d\sigma}{dt} dt = \frac{g^4}{64\pi s}\left(S_Z + \sum_{i,j=1}^{2} S_{ij} + \sum_{i=1}^{2} S_{Zi}\right), \tag{29.6.12}$$

where

$$S_Z = \frac{\beta^3}{24 c_W^4}(8s_W^4 - 4s_W^2 + 1)\frac{s^2}{|D_Z|^2}, \tag{29.6.13}$$

$$S_{ii} = |V_{i1}|^4 \left[(1-2\gamma_i)L_i - 2\beta\right], \tag{29.6.14}$$

$$S_{12} = S_{21} = |V_{11}V_{12}|^2 \left\{ \frac{(m^2_{\tilde{C}_2} + s\gamma_2^2)L_2 - (m^2_{\tilde{C}_1} + s\gamma_1^2)L_1}{m^2_{\tilde{C}_2} - m^2_{\tilde{C}_1}} - \beta \right\}, \tag{29.6.15}$$

$$S_{Zi} = \frac{(2s_W^2 - 1)}{c_W^2}|V_{i1}|^2 \left[(m^2_{\tilde{C}_i} + s\gamma_i^2)L_i + s\beta(\gamma_i - 1/2)\right] \frac{(s - m_Z^2)}{|D_Z|^2}, \tag{29.6.16}$$

with

$$\gamma_i \equiv \frac{m^2_{\tilde{\nu}} - m^2_{\tilde{C}_i}}{s}, \qquad\qquad L_i \equiv \ln\left(\frac{m^2_{\tilde{C}_i} - t_-}{m^2_{\tilde{C}_i} - t_+}\right). \tag{29.6.17}$$

This agrees with eqs. (E49)-(E52) of ref. [7] in the limit of degenerate charginos, or of a single wino chargino with $|V_{11}| = 1$ and $V_{12} = 0$. It also agrees with [177].

29.6.12 $e^-e^+ \to \widetilde{N}_i\widetilde{N}_j$

Next we consider the pair production of neutralinos via e^-e^+ annihilation. There are four Feynman graphs for s-channel Z^0 exchange, shown in Fig. 29.6.1, and four for t/u-channel selectron exchange, shown in Fig. 29.6.2. The momenta and polarizations are as labeled in the graphs. We denote the neutralino masses as $m_{\tilde{N}_i}, m_{\tilde{N}_j}$ and the selectron masses as $m_{\tilde{e}_L}$ and $m_{\tilde{e}_R}$. The electron mass will again be neglected. The kinematic variables are then given by

$$s = 2p_1\cdot p_2 = m^2_{\tilde{N}_i} + m^2_{\tilde{N}_j} + 2k_i\cdot k_j, \tag{29.6.1}$$

$$t = m^2_{\tilde{N}_i} - 2p_1\cdot k_i = m^2_{\tilde{N}_j} - 2p_2\cdot k_j, \tag{29.6.2}$$

$$u = m^2_{\tilde{N}_i} - 2p_2\cdot k_i = m^2_{\tilde{N}_j} - 2p_1\cdot k_j. \tag{29.6.3}$$

By applying the Feynman rules of Figs. J.1.2 and K.2.1, we obtain for the sum of the s-channel diagrams in Fig. 29.6.1 [cf. footnote 67],

$$i\mathcal{M}_Z = \frac{-ig^{\mu\nu}}{D_Z}\left[\frac{ig(s_W^2 - \frac{1}{2})}{c_W} x_1\sigma_\mu y_2^\dagger + \frac{igs_W^2}{c_W} y_1^\dagger\overline{\sigma}_\mu x_2\right]\left[\frac{ig}{c_W}O''^L_{ij} x_i^\dagger\overline{\sigma}_\nu y_j - \frac{ig}{c_W}O''^L_{ji} y_i\sigma_\nu x_j^\dagger\right], \tag{29.6.4}$$

where O''_{ij} is given in eq. (K.2.5), and $D_Z \equiv s - m_Z^2 + i\Gamma_Z m_Z$. The fermion spinors are denoted by $x_1 \equiv x(\vec{\boldsymbol{p}}_1, \lambda_1)$, $y_2^\dagger \equiv y^\dagger(\vec{\boldsymbol{p}}_2, \lambda_2)$, $x_i^\dagger \equiv x^\dagger(\vec{\boldsymbol{k}}_i, \lambda_i)$, $y_j \equiv y(\vec{\boldsymbol{k}}_j, \lambda_j)$, etc. Note that we have combined the

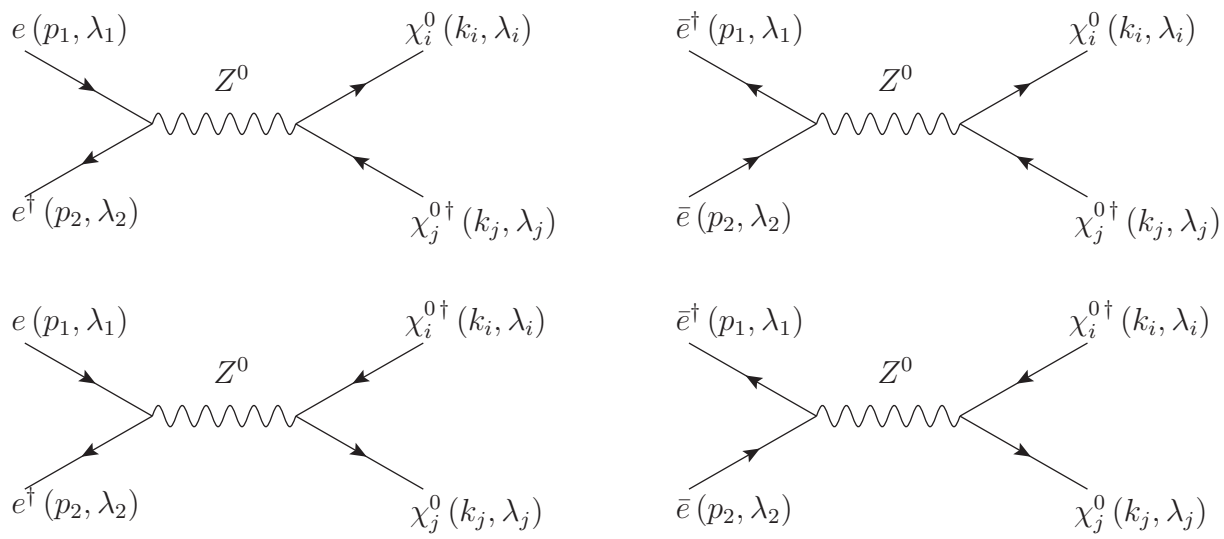

Figure 29.6.1: The four Feynman diagrams for $e^-e^+ \to \widetilde{N}_i\widetilde{N}_j$ via s-channel Z^0 exchange.

matrix elements of the four diagrams by factorizing with respect to the common boson propagator. For the four t/u-channel diagrams, we obtain, by applying the rules of Fig. K.4.2:

$$i\mathcal{M}^{(t)}_{\tilde{e}_L} = (-1)\left[\frac{i}{t-m^2_{\tilde{e}_L}}\right]\left[\frac{ig}{\sqrt{2}}\Big(N^*_{i2}+\frac{s_W}{c_W}N^*_{i1}\Big)\right]\left[\frac{ig}{\sqrt{2}}\Big(N_{j2}+\frac{s_W}{c_W}N_{j1}\Big)\right]x_1y_iy_2^\dagger x_j^\dagger, \tag{29.6.5}$$

$$i\mathcal{M}^{(u)}_{\tilde{e}_L} = \left[\frac{i}{u-m^2_{\tilde{e}_L}}\right]\left[\frac{ig}{\sqrt{2}}\Big(N^*_{j2}+\frac{s_W}{c_W}N^*_{j1}\Big)\right]\left[\frac{ig}{\sqrt{2}}\Big(N_{i2}+\frac{s_W}{c_W}N_{i1}\Big)\right]x_1y_jy_2^\dagger x_i^\dagger, \tag{29.6.6}$$

$$i\mathcal{M}^{(t)}_{\tilde{e}_R} = (-1)\left[\frac{i}{t-m^2_{\tilde{e}_R}}\right]\Big(-i\sqrt{2}g\frac{s_W}{c_W}N_{i1}\Big)\Big(-i\sqrt{2}g\frac{s_W}{c_W}N^*_{j1}\Big)y_1^\dagger x_i^\dagger x_2y_j, \tag{29.6.7}$$

$$i\mathcal{M}^{(u)}_{\tilde{e}_R} = \left[\frac{i}{u-m^2_{\tilde{e}_R}}\right]\Big(-i\sqrt{2}g\frac{s_W}{c_W}N_{j1}\Big)\Big(-i\sqrt{2}g\frac{s_W}{c_W}N^*_{i1}\Big)y_1^\dagger x_j^\dagger x_2y_i. \tag{29.6.8}$$

The first factors of (-1) in each of eqs. (29.6.5) and (29.6.7) are present because the order of the spinors in each case is an odd permutation of the ordering $(1,2,i,j)$ established by the s-channel contribution. The other contributions have spinors in an even permutation of that ordering.

The s-channel diagram contribution of eq. (29.6.4) can be profitably rearranged using the Fierz identities of eqs. (29.68) and (29.69). Then, combining the result with the t/u-channel and s-channel contributions, we have for the total:

$$\mathcal{M} = c_1x_1y_jy_2^\dagger x_i^\dagger + c_2x_1y_iy_2^\dagger x_j^\dagger + c_3y_1^\dagger x_i^\dagger x_2y_j + c_4y_1^\dagger x_j^\dagger x_2y_i, \tag{29.6.9}$$

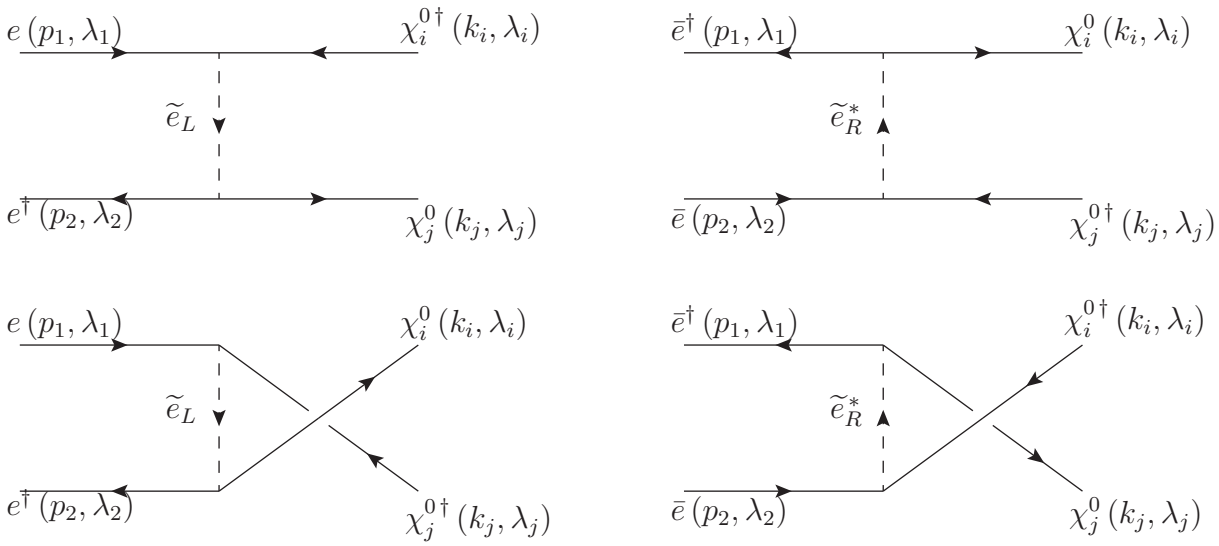

Figure 29.6.2: The four Feynman diagrams for $e^-e^+ \to \widetilde{N}_i\widetilde{N}_j$ via t/u-channel selectron exchange.

where

$$c_1 = \frac{g^2}{c_W^2}\left[(1-2s_W^2)O''^L_{ij}/D_Z - \tfrac{1}{2}(c_W N_{i2} + s_W N_{i1})(c_W N^*_{j2} + s_W N^*_{j1})/(u - m^2_{\tilde{e}_L})\right], \tag{29.6.10}$$

$$c_2 = \frac{g^2}{c_W^2}\left[(2s_W^2-1)O''^L_{ji}/D_Z + \tfrac{1}{2}(c_W N^*_{i2} + s_W N^*_{i1})(c_W N_{j2} + s_W N_{j1})/(t - m^2_{\tilde{e}_L})\right], \tag{29.6.11}$$

$$c_3 = \frac{2g^2 s_W^2}{c_W^2}\left[-O''^L_{ij}/D_Z + N_{i1}N^*_{j1}/(t - m^2_{\tilde{e}_R})\right], \tag{29.6.12}$$

$$c_4 = \frac{2g^2 s_W^2}{c_W^2}\left[O''^L_{ji}/D_Z - N^*_{i1}N_{j1}/(u - m^2_{\tilde{e}_R})\right]. \tag{29.6.13}$$

Squaring the amplitude and averaging over electron and positron spins, only terms involving $x_1x_1^\dagger$ or $y_1y_1^\dagger$, and $x_2x_2^\dagger$ or $y_2y_2^\dagger$ survive in the massless electron limit. Thus,

$$\begin{aligned}\sum_{\lambda_1,\lambda_2}|\mathcal{M}|^2 = \sum_{\lambda_1,\lambda_2}\Big(&|c_1|^2 y_j^\dagger x_1^\dagger x_1 y_j x_i y_2 y_2^\dagger x_i^\dagger + |c_2|^2 y_i^\dagger x_1^\dagger x_1 y_i x_j y_2 y_2^\dagger x_j^\dagger \\ &+|c_3|^2 x_i y_1 y_1^\dagger x_i^\dagger y_j^\dagger x_2^\dagger x_2 y_j + |c_4|^2 x_j y_1 y_1^\dagger x_j^\dagger y_i^\dagger x_2^\dagger x_2 y_i \\ &+2\mathrm{Re}\big[c_1 c_2^* y_i^\dagger x_1^\dagger x_1 y_j x_j y_2 y_2^\dagger x_i^\dagger\big] + 2\mathrm{Re}\big[c_3 c_4^* x_j y_1 y_1^\dagger x_i^\dagger y_i^\dagger x_2^\dagger x_2 y_j\big]\Big) \\ = |c_1|^2 y_j^\dagger p_1\cdot\overline{\sigma} y_j\, x_i p_2\cdot\sigma x_i^\dagger &+ |c_2|^2 y_i^\dagger p_1\cdot\overline{\sigma} y_i\, x_j p_2\cdot\sigma x_j^\dagger \\ &+|c_3|^2 x_i p_1\cdot\sigma x_i^\dagger\, y_j^\dagger p_2\cdot\overline{\sigma} y_j + |c_4|^2 x_j p_1\cdot\sigma x_j^\dagger\, y_i^\dagger p_2\cdot\overline{\sigma} y_i \\ &+2\mathrm{Re}\big[c_1 c_2^* y_i^\dagger p_1\cdot\overline{\sigma} y_j\, x_j p_2\cdot\sigma x_i^\dagger\big] + 2\mathrm{Re}\big[c_3 c_4^* x_j p_1\cdot\sigma x_i^\dagger\, y_i^\dagger p_2\cdot\overline{\sigma} y_j\big],\end{aligned} \tag{29.6.14}$$

after employing the results of eqs. (29.3.57)–(29.3.60).

We now perform the remaining spin sums using eqs. (29.3.57)–(29.3.60) again, obtaining:

$$\begin{aligned}\sum_{\lambda_1,\lambda_2,\lambda_i,\lambda_j} |\mathcal{M}|^2 = {}& |c_1|^2 \mathrm{Tr}[p_1\cdot\overline{\sigma}k_j\cdot\sigma]\mathrm{Tr}[p_2\cdot\sigma k_i\cdot\overline{\sigma}] + |c_2|^2\mathrm{Tr}[p_1\cdot\overline{\sigma}k_i\cdot\sigma]\mathrm{Tr}[p_2\cdot\sigma k_j\cdot\overline{\sigma}] \\ & + |c_3|^2\mathrm{Tr}[p_1\cdot\sigma k_i\cdot\overline{\sigma}]\mathrm{Tr}[p_2\cdot\overline{\sigma}k_j\cdot\sigma] + |c_4|^2\mathrm{Tr}[p_1\cdot\sigma k_j\cdot\overline{\sigma}]\mathrm{Tr}[p_2\cdot\overline{\sigma}k_i\cdot\sigma] \\ & + 2\mathrm{Re}[c_1c_2^*]m_{\widetilde{N}_i}m_{\widetilde{N}_j}\mathrm{Tr}[p_2\cdot\sigma p_1\cdot\overline{\sigma}] + 2\mathrm{Re}[c_3c_4^*]m_{\widetilde{N}_i}m_{\widetilde{N}_j}\mathrm{Tr}[p_1\cdot\sigma p_2\cdot\overline{\sigma}]. \end{aligned} \quad (29.6.15)$$

Applying the trace identity of eq. (29.56) to this yields

$$\begin{aligned}\sum_{\text{spins}} |\mathcal{M}|^2 = {}& (|c_1|^2 + |c_4|^2)4p_1\cdot k_j\, p_2\cdot k_i + (|c_2|^2 + |c_3|^2)4p_1\cdot k_i\, p_2\cdot k_j \\ & + 4\mathrm{Re}[c_1c_2^* + c_3c_4^*]m_{\widetilde{N}_i}m_{\widetilde{N}_j}p_1\cdot p_2 \\ = {}& (|c_1|^2 + |c_4|^2)(u - m^2_{\widetilde{N}_i})(u - m^2_{\widetilde{N}_j}) + (|c_2|^2 + |c_3|^2)(t - m^2_{\widetilde{N}_i})(t - m^2_{\widetilde{N}_j}) \\ & + 2\mathrm{Re}[c_1c_2^* + c_3c_4^*]m_{\widetilde{N}_i}m_{\widetilde{N}_j}s. \end{aligned} \quad (29.6.16)$$

The differential cross-section then follows:

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}\left(\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2\right). \quad (29.6.17)$$

This agrees with the first complete calculation presented in [178]. For the case of pure photino pair production, i.e. $N_{i1} \to c_W\delta_{i1}$ and $N_{i2} \to s_W\delta_{i1}$ and for degenerate selectron masses this also agrees with eq. (E9) of the erratum of [7]. Other earlier calculations with some simplifications are given in refs. [179, 180].

Defining $\cos\theta = \hat{\boldsymbol{p}}_{\boldsymbol{1}}\cdot\hat{\boldsymbol{k}}_{\boldsymbol{i}}$ (the cosine of the angle between the initial state electron and one of the neutralinos in the center-of-momentum frame), the Mandelstam variables t, u are given by

$$t = \frac{1}{2}\left[m^2_{\widetilde{N}_i} + m^2_{\widetilde{N}_j} - s + \lambda^{1/2}(s, m^2_{\widetilde{N}_i}, m^2_{\widetilde{N}_j})\cos\theta\right], \quad (29.6.18)$$

$$u = \frac{1}{2}\left[m^2_{\widetilde{N}_i} + m^2_{\widetilde{N}_j} - s - \lambda^{1/2}(s, m^2_{\widetilde{N}_i}, m^2_{\widetilde{N}_j})\cos\theta\right], \quad (29.6.19)$$

where the triangle function $\lambda^{1/2}$ is defined in eq. (29.6.11). Taking into account the identical fermions in the final state when $i = j$, the total cross-section is

$$\sigma = \frac{1}{1+\delta_{ij}}\int_{t_-}^{t_+}\frac{d\sigma}{dt}dt\,, \quad (29.6.20)$$

where t_- and t_+ are obtained by inserting $\cos\theta = \mp 1$ in eq. (29.6.18), respectively.

29.6.13 $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$

In this section, we compute the annihilation rate for $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$, where f is any kinematically allowed quark, charged lepton or neutrino. The case of $f = e^-$ is the reversed reaction of the process examined in Section 29.6.12 (with $i = j = 1$). In R-parity-conserving supersymmetric models in which $\widetilde{N}_1$ is the lightest supersymmetric particle (and hence is stable), the $\widetilde{N}_1\widetilde{N}_1$ annihilation process is relevant for the computation of the neutralino relic density [181]. In particular, $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$ can be an important contribution to cold dark matter annihilation [181, 182, 183, 184]. Neutralino dark matter is typically heavier than about 6 GeV [185]; for lighter neutralinos see [186].

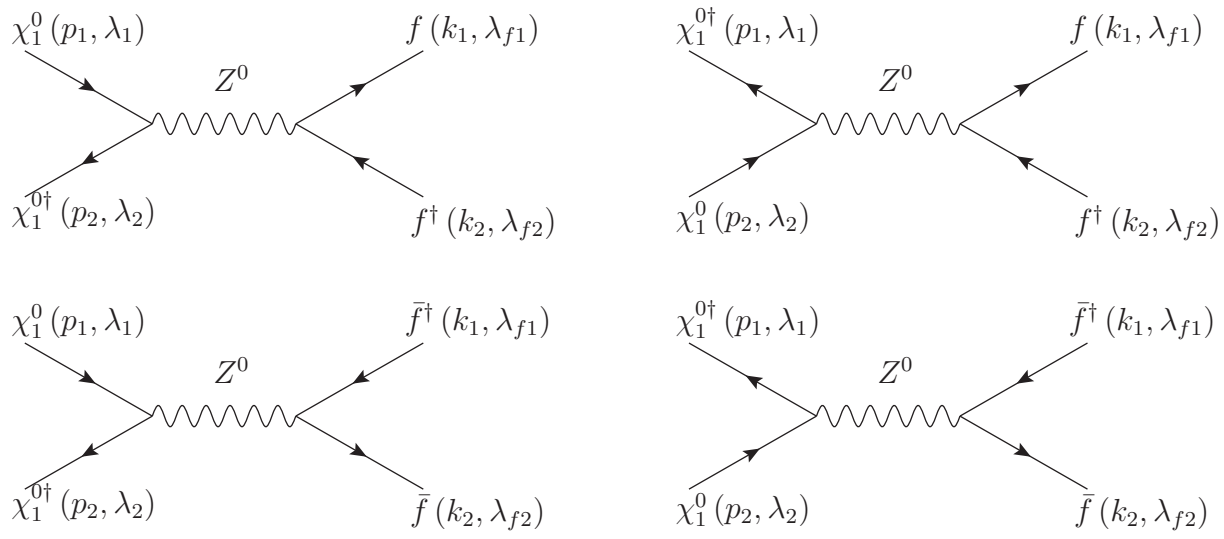

Figure 29.6.1: The four Feynman diagrams for $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$ via s–channel Z^0 exchange, where f is a quark or lepton.

In the computation of the relic density, one computes $v_{\rm rel}\sigma_{\rm ann}$, where $\sigma_{\rm ann}$ is the $\widetilde{N}_1\widetilde{N}_1$ annihilation cross-section and $v_{\rm rel}$ is the relative velocity of the two neutralinos in the center-of-momentum frame. The square of the relative velocity is taken to be its thermal average, $v_{\rm rel}^2 \simeq 6k_BT/m_{\widetilde{N}_1}$ [181], which is typically non-relativistic when the temperature is of order the freeze-out temperature [183] (where the neutralino falls out of thermal equilibrium). Hence, it is sufficient to compute the annihilation cross-section for $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$ in the non-relativistic limit.

As in Section 29.6.12, there are four Feynman graphs for s-channel Z^0 exchange, shown in Fig. 29.6.1. In addition, there are s-channel neutral Higgs exchange graphs, shown in Fig. 29.6.2, that yield contributions to the annihilation amplitude proportional to the fermion mass, m_f.[70] Likewise, as in Section 29.6.12, there are four Feynman graphs for t/u-channel $\widetilde{f}_L$ and $\widetilde{f}_R$ exchange, shown in Fig. 29.6.3. However, because we do not set m_f to zero, four additional t/u-channel graphs contribute, shown in Fig. 29.6.4, that are sensitive to the higgsino components of the neutralino.

The neutralino and the final state fermion four-momenta and polarizations are as labeled in the Feynman graphs. In the center-of-momentum (CM) frame, the four-momenta are

$$p_1^\mu = (E\,;\,\vec{\boldsymbol{p}})\,, \qquad p_2^\mu = (E\,;\,-\vec{\boldsymbol{p}})\,, \qquad k_1^\mu = E(1\,;\,\beta\hat{\boldsymbol{k}})\,, \qquad k_2^\mu = E(1\,;\,-\beta\hat{\boldsymbol{k}})\,, \tag{29.6.1}$$

where

$$\beta \equiv \sqrt{1 - \frac{m_f^2}{E^2}}\,. \tag{29.6.2}$$

In the non-relativistic limit where $|\vec{\boldsymbol{p}}| \ll m_{\widetilde{N}_1}$,

$$E \simeq m_{\widetilde{N}_1} + \frac{|\vec{\boldsymbol{p}}|^2}{2m_{\widetilde{N}_1}}\,, \tag{29.6.3}$$

[70] In regions of parameter space where $m_{\widetilde{N}_1} \simeq \frac{1}{2}m_Z$ or $m_{\widetilde{N}_1} \simeq \frac{1}{2}m_{\phi^0}$ (where $\phi^0 = h^0$, H^0 or A^0), the resonant $2 \to 1$ annihilation $\widetilde{N}_1\widetilde{N}_1 \to Z^0$ or $\widetilde{N}_1\widetilde{N}_1 \to \phi^0$ dominates the $2 \to 2$ annihilation processes considered here.

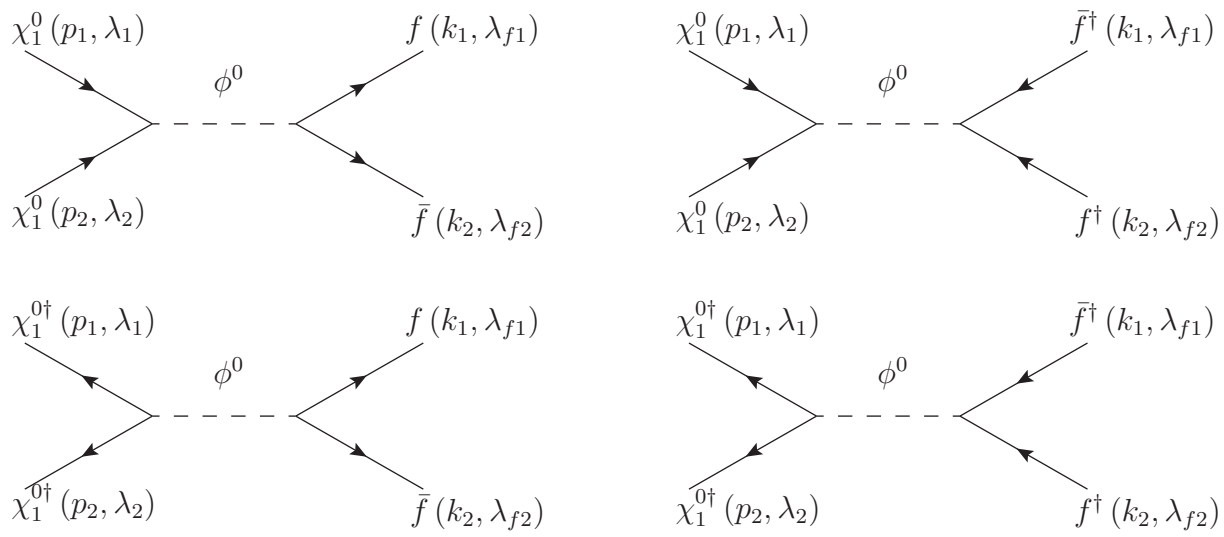

Figure 29.6.2: Feynman diagrams for $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$ via s–channel Higgs exchange. There are four diagrams for each possible neutral Higgs state $\phi^0 = h^0$, H^0 and A^0.

and the kinematic invariants are given by

$$s = (p_1+p_2)^2 = 4E^2 = 4m_{\widetilde{N}_1}^2 + 4|\vec{\boldsymbol{p}}|^2\,, \tag{29.6.4}$$

$$t = (p_1-k_1)^2 = m_{\widetilde{N}_1}^2 + m_f^2 - 2p_1\cdot k_1 \simeq -m_{\widetilde{N}_1}^2 + m_f^2 + 2\beta m_{\widetilde{N}_1}|\vec{\boldsymbol{p}}|\cos\theta - 2|\vec{\boldsymbol{p}}|^2\,, \tag{29.6.5}$$

$$u = (p_1-k_2)^2 = m_{\widetilde{N}_1}^2 + m_f^2 - 2p_1\cdot k_2 \simeq -m_{\widetilde{N}_1}^2 + m_f^2 - 2\beta m_{\widetilde{N}_1}|\vec{\boldsymbol{p}}|\cos\theta - 2|\vec{\boldsymbol{p}}|^2\,, \tag{29.6.6}$$

where θ is the CM scattering angle. Subsequently, we shall neglect the subdominant $\mathcal{O}(|\vec{\boldsymbol{p}}|)$ terms in the t and u-channel propagator denominators by setting $t \simeq u \simeq -m_{\widetilde{N}_1}^2 + m_f^2$.

By applying the Feynman rules of Figs. J.1.2 and K.2.1, and using the unitary gauge for the Z-boson propagator, we obtain for the sum of the s-channel Z-exchange diagrams of Fig. 29.6.1,

$$i\mathcal{M}_Z = \frac{i\,(-g^{\mu\nu} + Q^\mu Q^\nu/m_Z^2)}{D_Z}\left(\frac{-ig}{c_W}\right)^2 O_{11}''^L\Big[x_1\sigma_\mu y_2^\dagger - y_1^\dagger\overline{\sigma}_\mu x_2\Big]\Big[(T_3^f - s_W^2 Q_f)x_{f1}^\dagger\overline{\sigma}_\nu y_{f2} - s_W^2 Q_f y_{f1}\sigma_\nu x_{f2}^\dagger\Big]\,, \tag{29.6.7}$$

where $O_{11}''^L$ is given in eq. (K.2.5), $D_Z \equiv s - m_Z^2 + i\Gamma_Z m_Z$, and $Q \equiv p_1 + p_2 = k_1 + k_2$. The spinor wave functions are denoted by $x_1 \equiv x(\vec{\boldsymbol{p}}_1,\lambda_1)$, $y_2^\dagger \equiv y^\dagger(\vec{\boldsymbol{p}}_2,\lambda_2)$, $x_{f1}^\dagger \equiv x^\dagger(\vec{\boldsymbol{k}}_1,\lambda_{f1})$, $y_{f2} \equiv y(\vec{\boldsymbol{k}}_2,\lambda_{f2})$, etc. In obtaining eq. (29.6.7), we have combined the matrix elements of the four diagrams by factorizing with respect to the common Z-boson propagator. Note that all four terms in eq. (29.6.7) have the same order of spinor wave functions (1,2,f1,f2). Thus, no additional relative signs arise (beyond the sign associated with the choice of the σ or $\overline{\sigma}$ version of the vertex Feynman rules). One can simplify the terms that originate from the $Q^\mu Q^\nu$ part of the Z-boson propagator by writing $Q^\mu = (p_1+p_2)^\mu$ and $Q^\nu = (k_1+k_2)^\nu$. Contracting the μ and ν indices with the help of eqs. (29.3.9)–(29.3.12) yields:

$$(p_1+p_2)^\mu\Big[x_1\sigma_\mu y_2^\dagger - y_1^\dagger\overline{\sigma}_\mu x_2\Big] = 2m_{\widetilde{N}_1}\Big(x_1x_2 - y_1^\dagger y_2^\dagger\Big)\,, \tag{29.6.8}$$

$$(k_1+k_2)^\nu\Big[(T_3^f - s_W^2Q_f)x_{f1}^\dagger\overline{\sigma}_\nu y_{f2} - s_W^2Q_f y_{f1}\sigma_\nu x_{f2}^\dagger\Big] = T_3^f m_f\Big(y_{f1}y_{f2} - x_{f1}^\dagger x_{f2}^\dagger\Big)\,. \tag{29.6.9}$$

Hence, we shall write

$$\mathcal{M}_Z \equiv \mathcal{M}_Z^{(1)} + \mathcal{M}_Z^{(2)}\,, \tag{29.6.10}$$

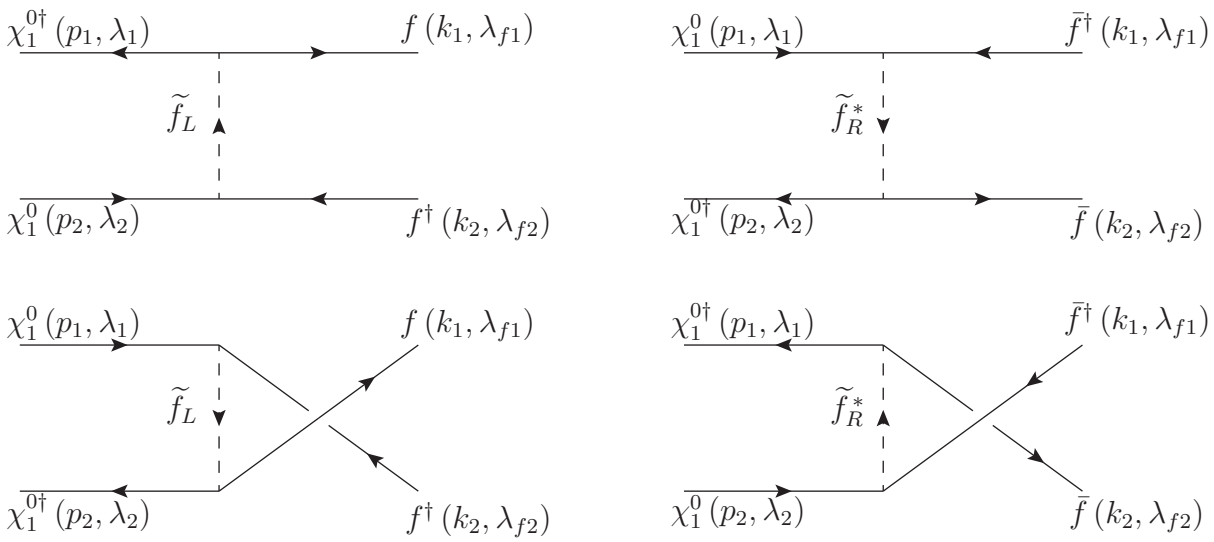

Figure 29.6.3: The four Feynman diagrams for $\widetilde{N}_i\widetilde{N}_j \to f\bar{f}$ via t/u–channel $\widetilde{f}_L$ and $\widetilde{f}_R$ exchange, where $\widetilde{f}_L$ and $\widetilde{f}_R$ couple to the gaugino components of the neutralino.

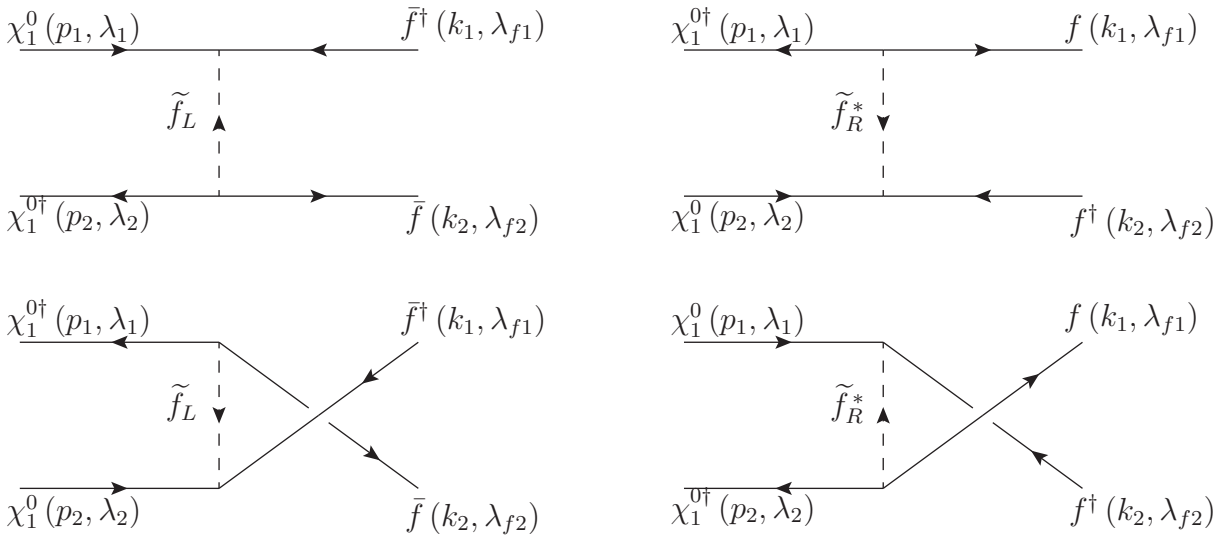

Figure 29.6.4: The four Feynman diagrams for $\widetilde{N}_i\widetilde{N}_j \to f\bar{f}$ via t/u–channel $\widetilde{f}_L$ and $\widetilde{f}_R$ exchange, where $\widetilde{f}_L$ and $\widetilde{f}_R$ couple to the higgsino components of the neutralino.

where

$$i\mathcal{M}_Z^{(1)} = \frac{-ig^{\mu\nu}}{D_Z}\left(\frac{-ig}{c_W}\right)^2 O''^L_{11}\Big[x_1\sigma_\mu y_2^\dagger - y_1^\dagger\overline{\sigma}_\mu x_2\Big]\Big[(T_3^f - s_W^2 Q_f)x_{f1}^\dagger\overline{\sigma}_\nu y_{f2} - s_W^2 Q_f y_{f1}\sigma_\nu x_{f2}^\dagger\Big], \tag{29.6.11}$$

$$i\mathcal{M}_Z^{(2)} = \frac{im_f m_{\widetilde{N}_1}}{m_Z^2 D_Z}\left(\frac{-ig}{c_W}\right)^2 O''^L_{11}(2T_3^f)\left(x_1x_2 - y_1^\dagger y_2^\dagger\right)\left(y_{f1}y_{f2} - x_{f1}^\dagger x_{f2}^\dagger\right). \tag{29.6.12}$$

Next, we apply the Feynman rules of Figs. K.1.1 and K.3.1 to obtain the sum of the four s-channel Higgs exchange diagrams (for $\phi^0 = h^0$, H^0 and A^0) of Fig. 29.6.2,

$$i\mathcal{M}_H = \sum_{\phi^0=h^0,H^0,A^0} \frac{i}{D_{\phi^0}} \left(\frac{-m_f}{\sqrt{2}\,v_f}\right) \left[(Y^{\phi^0\chi_1^0\chi_1^0})x_1x_2 + (Y^{\phi^0\chi_1^0\chi_1^0})^* y_1^\dagger y_2^\dagger\right] \left[k_{f\phi^0}y_{f1}y_{f2} + k^*_{f\phi^0}x^\dagger_{f1}x^\dagger_{f2}\right], \tag{29.6.13}$$

where $Y^{\phi^0\chi_1^0\chi_1^0}$ is given by eq. (K.3.1), and $D_{\phi^0} \equiv s - m^2_{\phi^0} + i\Gamma_{\phi^0}m_{\phi^0}$. In addition, we have introduced the following notation

$$k_{f\phi^0} \equiv \begin{cases} k_{d\phi^0}\,, & \text{for } f = d\,, e^-\,, \\ k_{u\phi^0}\,, & \text{for } f = u\,, \\ 0\,, & \text{for } f = \nu\,, \end{cases} \qquad v_f \equiv \begin{cases} v_d\,, & \text{for } f = d\,, e^-\,, \\ v_u\,, & \text{for } f = u\,, \nu\,, \end{cases} \tag{29.6.14}$$

where v_u, v_d are the neutral Higgs vacuum expectation values [cf. eq. (K.1.9)] and $k_{u\phi^0}$ and $k_{d\phi^0}$ are defined in eqs. (K.1.7) and (K.1.8). As the order of the spinor wave functions is $(1, 2, f1, f2)$ for all four terms of $\mathcal{M}_H$, no extra minus signs appear.

A good check of the above calculations is to repeat the analysis in the 't Hooft–Feynman gauge (where the gauge parameter $\xi = 1$). In this gauge, $\mathcal{M}_Z = \mathcal{M}_Z^{(1)}$, since the term proportional to $Q^\mu Q^\nu$ is absent from the gauge boson propagator. However, we must now include the diagrams of Fig. 29.6.2 with $\phi^0 = G^0$. In the 't Hooft–Feynman gauge, $m_{G^0} = m_Z$ and $D_{G^0} = D_Z$. Moreover, using eqs. (K.1.7) and (K.1.8),

$$\frac{k_{fG^0}}{v_f} = \frac{2iT_f}{v}\,. \tag{29.6.15}$$

Hence, using eq. (29.6.13) with $\phi^0 = G^0$,

$$i\mathcal{M}_G = \frac{m_f}{\sqrt{2}\,vD_Z}(2T_f)\,Y^{G^0\chi_1^0\chi_1^0}\left(x_1x_2 - y_1^\dagger y_2^\dagger\right)\left(y_{f1}y_{f2} - x^\dagger_{f1}x^\dagger_{f2}\right), \tag{29.6.16}$$

where we have noted that $iY^{G^0\chi_1^0\chi_1^0}$ is real. In particular, using eq. (K.3.14) and recalling that $m_W^2 = m_Z^2c_W^2 = \frac{1}{2}g^2v^2$, we confirm that $\mathcal{M}_G = \mathcal{M}_Z^{(2)}$ as expected from gauge invariance.

We next evaluate the t/u-channel exchange diagrams shown in Figs. 29.6.3 and 29.6.4. We neglect $\widetilde{f}_L$–$\widetilde{f}_R$ mixing. Eight Feynman graphs contribute, and we denote the total invariant amplitude by:

$$\mathcal{M}_{\tilde{f}} = \sum_{j=1}^{2}(\mathcal{M}^{(tj)}_{\tilde{f}_L} + \mathcal{M}^{(uj)}_{\tilde{f}_L} + \mathcal{M}^{(tj)}_{\tilde{f}_R} + \mathcal{M}^{(uj)}_{\tilde{f}_R})\,, \tag{29.6.17}$$

where $j = 1, 2$ labels the contributions of Figs. 29.6.3 and 29.6.4, respectively, and the other superscripts (t or u) and subscripts ($\widetilde{f}_L$ or $\widetilde{f}_R$) indicate the exchange channel and the exchanged particle, respectively. These matrix elements are evaluated by applying the rules of Fig. K.4.2.

The graphs of Fig. 29.6.3 are sensitive to the gaugino components of $\widetilde{N}_1$, and yield

$$i\mathcal{M}^{(t1)}_{\tilde{f}_L} = (-1)\left(-ig\sqrt{2}\right)^2\left(\frac{i}{t - m^2_{\tilde{f}_L}}\right)\left|T_3^f N_{12} + \frac{s_W}{c_W}(Q_f - T_3^f)N_{11}\right|^2 (y_1^\dagger x^\dagger_{f1})(x_2y_{f2})\,, \tag{29.6.18}$$

$$i\mathcal{M}^{(u1)}_{\tilde{f}_L} = \left(-ig\sqrt{2}\right)^2\left|T_3^f N_{12} + \frac{s_W}{c_W}(Q_f - T_3^f)N_{11}\right|^2\left(\frac{i}{u - m^2_{\tilde{f}_L}}\right)(x_1y_{f2})(y_2^\dagger x^\dagger_{f1})\,, \tag{29.6.19}$$

$$i\mathcal{M}^{(t1)}_{\tilde{f}_R} = (-1)\left(i\sqrt{2}g\frac{s_W}{c_W}Q_f\right)^2\left(\frac{i}{t - m^2_{\tilde{f}_R}}\right)|N_{11}|^2\,(x_1y_{f1})(y_2^\dagger x^\dagger_{f2})\,, \tag{29.6.20}$$

$$i\mathcal{M}^{(u1)}_{\tilde{f}_R} = \left(i\sqrt{2}g\frac{s_W}{c_W}Q_f\right)^2\left(\frac{i}{u - m^2_{\tilde{f}_R}}\right)|N_{11}|^2\,(y_1^\dagger x^\dagger_{f2})(x_2y_{f1})\,. \tag{29.6.21}$$

The explicit factors of (-1) in eqs. (29.6.18) and (29.6.20) are present because the order of the spinor wave functions in these cases is an odd permutation of the ordering $(1, 2, f1, f2)$ established in the computation of the s-channel amplitudes.

The graphs of Fig. 29.6.4 are sensitive to the higgsino components of $\widetilde{N}_1$, and yield

$$i\mathcal{M}^{(t2)}_{\tilde{f}_L} = (-1)\left(\frac{-im_f}{v_f}\right)^2\left(\frac{i}{t-m^2_{\tilde{f}_L}}\right)|N_{1f}|^2\,(x_1y_{f1})(y_2^\dagger x_{f2}^\dagger)\,, \tag{29.6.22}$$

$$i\mathcal{M}^{(u2)}_{\tilde{f}_L} = \left(\frac{-im_f}{v_f}\right)^2\left(\frac{i}{u-m^2_{\tilde{f}_L}}\right)|N_{1f}|^2\,(y_1^\dagger x_{f2}^\dagger)(x_2y_{f1})\,, \tag{29.6.23}$$

$$i\mathcal{M}^{(t2)}_{\tilde{f}_R} = (-1)\left(\frac{-im_f}{v_f}\right)^2\left(\frac{i}{t-m^2_{\tilde{f}_R}}\right)|N_{1f}|^2\,(y_1^\dagger x_{f1}^\dagger)(x_2y_{f2})\,, \tag{29.6.24}$$

$$i\mathcal{M}^{(u2)}_{\tilde{f}_R} = \left(\frac{-im_f}{v_f}\right)^2\left(\frac{i}{u-m^2_{\tilde{f}_R}}\right)|N_{1f}|^2\,(x_1y_{f2})(y_2^\dagger x_{f1}^\dagger)\,, \tag{29.6.25}$$

where v_f is defined in eq. (29.6.14), and

$$N_{1f} \equiv \begin{cases} N_{13}\,, & \text{for } f = d\,,\, e^-\,, \\ N_{14}\,, & \text{for } f = u\,, \\ 0\,, & \text{for } f = \nu\,. \end{cases} \tag{29.6.26}$$

As before, the explicit factors of (-1) are due to the ordering of the spinor wave functions.

It is convenient to write the total matrix element for $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$ as the sum of products of separate neutralino and final state fermionic currents. The contributions of the s-channel diagrams are already in this form. The contributions of the t– and u–channel diagrams given in eqs. (29.6.18)–(29.6.25) can be rearranged using the Fierz identities of eqs. (29.68)–(29.70),

$$y_1^\dagger x_{f1}^\dagger x_2 y_{f2} = -\tfrac{1}{2}(y_1^\dagger\overline{\sigma}^\mu x_2)(x_{f1}^\dagger\overline{\sigma}_\mu y_{f2})\,, \tag{29.6.27}$$

$$x_1 y_{f2} y_2^\dagger x_{f1}^\dagger = -\tfrac{1}{2}(x_1\sigma^\mu y_2^\dagger)(x_{f1}^\dagger\overline{\sigma}_\mu y_{f2})\,, \tag{29.6.28}$$

$$x_1 y_{f1} y_2^\dagger x_{f2}^\dagger = -\tfrac{1}{2}(x_1\sigma^\mu y_2^\dagger)(y_{f1}\sigma_\mu x_{f2}^\dagger)\,, \tag{29.6.29}$$

$$y_1^\dagger x_{f2}^\dagger x_2 y_{f1} = -\tfrac{1}{2}(y_1^\dagger\overline{\sigma}^\mu x_2)(y_{f1}\sigma_\mu x_{f2}^\dagger)\,. \tag{29.6.30}$$

Combining the result of the s, t, and u–channel contributions, we have for the total amplitude:

$$\begin{aligned}\mathcal{M} = {}& \frac{m_f m_{\widetilde{N}_1}}{m_Z^2}c_0\left(x_1x_2 - y_1^\dagger y_2^\dagger\right)\left(y_{f1}y_{f2} - x_{f1}^\dagger x_{f2}^\dagger\right) \\ & + c_1(y_1^\dagger\overline{\sigma}^\mu x_2)(x_{f1}^\dagger\overline{\sigma}_\mu y_{f2}) + c_2(x_1\sigma^\mu y_2^\dagger)(x_{f1}^\dagger\overline{\sigma}_\mu y_{f2}) + c_3(x_1\sigma^\mu y_2^\dagger)(y_{f1}\sigma_\mu x_{f2}^\dagger) + c_4(y_1^\dagger\overline{\sigma}^\mu x_2)(y_{f1}\sigma_\mu x_{f2}^\dagger) \\ & + m_f\left[c_5(x_1x_2)(y_{f1}y_{f2}) + c_6(x_1x_2)(x_{f1}^\dagger x_{f2}^\dagger) + c_7(y_1^\dagger y_2^\dagger)(y_{f1}y_{f2}) + c_8(y_1^\dagger y_2^\dagger)(x_{f1}^\dagger x_{f2}^\dagger)\right]\,,\end{aligned} \tag{29.6.31}$$

where the coefficients c_0 , c_1 , ... , c_4 are given by

$$c_0 = -g^2 \frac{2T_3^f O''^L_{11}}{c_W^2 D_Z} \,, \tag{29.6.32}$$

$$c_1 = -g^2 \left[\frac{(T_3^f - s_W^2 Q_f) O''^L_{11}}{c_W^2 D_Z} + \frac{|T_3^f N_{12} + \frac{s_W}{c_W}(Q_f - T_3^f) N_{11}|^2}{t - m^2_{\tilde{f}_L}} \right] - \frac{m_f^2}{2v_f^2} \left(\frac{|N_{1f}|^2}{t - m^2_{\tilde{f}_R}} \right) \,, \tag{29.6.33}$$

$$c_2 = g^2 \left[\frac{(T_3^f - s_W^2 Q_f) O''^L_{11}}{c_W^2 D_Z} + \frac{|T_3^f N_{12} + \frac{s_W}{c_W}(Q_f - T_3^f) N_{11}|^2}{u - m^2_{\tilde{f}_L}} \right] + \frac{m_f^2}{2v_f^2} \left(\frac{|N_{1f}|^2}{u - m^2_{\tilde{f}_R}} \right) \,, \tag{29.6.34}$$

$$c_3 = -g^2 \frac{s_W^2}{c_W^2} Q_f \left[\frac{O''^L_{11}}{D_Z} + \frac{Q_f |N_{11}|^2}{t - m^2_{\tilde{f}_R}} \right] - \frac{m_f^2}{2v_f^2} \left(\frac{|N_{1f}|^2}{t - m^2_{\tilde{f}_L}} \right) \,, \tag{29.6.35}$$

$$c_4 = g^2 \frac{s_W^2}{c_W^2} Q_f \left[\frac{O''^L_{11}}{D_Z} + \frac{Q_f |N_{11}|^2}{u - m^2_{\tilde{f}_R}} \right] + \frac{m_f^2}{2v_f^2} \left(\frac{|N_{1f}|^2}{u - m^2_{\tilde{f}_L}} \right) \,. \tag{29.6.36}$$

The coefficients c_5, ..., c_8 are obtained from eq. (29.6.13) and represent the s-channel Higgs exchange contributions to the annihilation matrix element.

In the non–relativistic limit, $|\vec{\boldsymbol{p}}| \ll m_{\widetilde{N}_1}$. Then $t \simeq u \simeq -m^2_{\widetilde{N}_1} + m_f^2$, and we can approximate[71] $c_1 = -c_2$ and $c_3 = -c_4$. Hence, the total amplitude, eq. (29.6.31), can be written as

$$\begin{aligned} \mathcal{M} = {} & \frac{m_f m_{\widetilde{N}_1}}{m_Z^2} c_0 \left(x_1 x_2 - y_1^\dagger y_2^\dagger \right) \left(y_{f1} y_{f2} - x_{f1}^\dagger x_{f2}^\dagger \right) \\ & + \left[y_1^\dagger \overline{\sigma}^\mu x_2 - x_1 \sigma^\mu y_2^\dagger \right] \left[c_1 (x_{f1}^\dagger \overline{\sigma}_\mu y_{f2}) - c_3 (y_{f1} \sigma_\mu x_{f2}^\dagger) \right] + \mathcal{M}_H \,, \end{aligned} \tag{29.6.37}$$

where the s-channel Higgs exchange contributions, $\mathcal{M}_H$, will be neglected for simplicity in the subsequent analysis. The spin-averaged squared matrix element for $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$ then takes the following form:

$$\begin{aligned} \tfrac{1}{4} \sum_{s_1,s_2,s_{f1},s_{f2}} |\mathcal{M}_Z + \mathcal{M}_{\tilde{f}}|^2 = {} & N_{\mu\nu} \left[|c_1|^2 F_1^{\mu\nu} + |c_3|^2 F_2^{\mu\nu} - 2\mathrm{Re}(c_1 c_3^*) F_{12}^{\mu\nu} \right] + \frac{m_f^2 m^2_{\widetilde{N}_1}}{m_Z^4} |c_0|^2 N F \\ & + \frac{2 m_f m_{\widetilde{N}_1}}{m_Z^2} \mathrm{Re}[c_0^* (c_1 + c_3)] N_\mu F^\mu \,, \end{aligned} \tag{29.6.38}$$

where $N_{\mu\nu}$, N_μ and N are spin-averaged tensor, vector and scalar quantities that depend on the initial state neutralino kinematics and $F^{\mu\nu}_{1,2,12}$, F^μ and F are spin-summed tensor, vector and scalar quantities that depend on the final state fermion kinematics. These quantities are easily computed using the projection operators of eqs. (29.3.57)–(29.3.60) and the standard trace techniques to perform the spin averages and sums. Explicitly, the spin-averaged neutralino quantities are

$$N \equiv \tfrac{1}{4} \sum_{s_1,s_2} (x_1 x_2 - y_1^\dagger y_2^\dagger)(x_2^\dagger x_1^\dagger - y_2 y_1) = p_1 \cdot p_2 + m^2_{\widetilde{N}_1} = 2E^2 \,, \tag{29.6.39}$$

$$N^\mu \equiv \tfrac{1}{4} \sum_{s_1,s_2} (y_1^\dagger \overline{\sigma}^\mu x_2 - x_1 \sigma^\mu y_2^\dagger)(x_2^\dagger x_1^\dagger - y_2 y_1) = -m_{\widetilde{N}_1} (p_1 + p_2)^\mu = \begin{cases} -2 m_{\widetilde{N}_1} E \,, & \mu = 0 \,, \\ 0 \,, & \mu = i \,, \end{cases} \tag{29.6.40}$$

[71] In particular, we assume that $\widetilde{f}_L$ and $\widetilde{f}_R$ are significantly heavier than all other particles in the annihilation process. Consequently, we can ignore all $\mathcal{O}(|\vec{\boldsymbol{p}}|/m_{\tilde{f}_{L,R}})$ terms in $c_1 + c_2$ and $c_3 + c_4$.

and a symmetric second-rank tensor,

$$N^{\mu\nu} \equiv \tfrac{1}{4}\sum_{s_1,s_2}(y_1^\dagger\overline{\sigma}^\mu x_2 - x_1\sigma^\mu y_2^\dagger)(x_2^\dagger\overline{\sigma}^\nu y_1 - y_2\sigma^\nu x_1^\dagger) = p_1^\mu p_2^\nu + p_2^\mu p_1^\nu - g^{\mu\nu}(p_1\cdot p_2 - m_{\widetilde{N}_1}^2)$$

$$= \begin{cases} 2m_{\widetilde{N}_1}^2\,, & \mu=\nu=0\,, \\ 0\,, & \mu=0\,,\ \nu=j \ \text{ or } \ \mu=i\,,\ \nu=0\,, \\ 2\left[|\vec{\boldsymbol{p}}|^2\,\delta^{ij} - p^i p^j\right]\,, & \mu=i,\ \nu=j\,, \end{cases} \tag{29.6.41}$$

where the final results given in eqs. (29.6.39)–(29.6.41) have been evaluated in the CM frame. Similarly, the spin-summed final state fermion quantities are

$$F \equiv \sum_{s_{f1},s_{f2}}(y_{f1}y_{f2} - x_{f1}^\dagger x_{f2}^\dagger)(y_{f2}^\dagger y_{f1}^\dagger - x_{f2}x_{f1}) = 4(k_1\cdot k_2 + m_f^2) = 8E^2\,, \tag{29.6.42}$$

$$F^\mu \equiv \sum_{s_{f1},s_{f2}}(x_{f1}^\dagger\overline{\sigma}^\mu y_{f2})(y_{f2}^\dagger y_{f1}^\dagger - x_{f2}x_{f1}) = -\sum_{s_{f1},s_{f2}}(y_{f1}\sigma^\mu x_{f2}^\dagger)(y_{f2}^\dagger y_{f1}^\dagger - x_{f2}x_{f1})$$

$$= 2m_f(k_1+k_2)^\mu = \begin{cases} 4m_f E\,, & \mu=0\,, \\ 0\,, & \mu=i\,, \end{cases} \tag{29.6.43}$$

after evaluating the above quantities in the CM frame, and

$$F_1^{\mu\nu} \equiv \sum_{s_{f1},s_{f2}}(x_{f1}^\dagger\overline{\sigma}^\mu y_{f2})(y_{f2}^\dagger\overline{\sigma}^\nu x_{f1}) = k_{1\rho}k_{2\lambda}\,\mathrm{Tr}(\sigma^\rho\overline{\sigma}^\mu\sigma^\lambda\overline{\sigma}^\nu)\,, \tag{29.6.44}$$

$$F_2^{\mu\nu} \equiv \sum_{s_{f1},s_{f2}}(y_{f1}\sigma^\mu x_{f2}^\dagger)(x_{f2}\sigma^\nu y_{f1}^\dagger) = k_{1\rho}k_{2\lambda}\,\mathrm{Tr}(\overline{\sigma}^\rho\sigma^\mu\overline{\sigma}^\lambda\sigma^\nu)\,, \tag{29.6.45}$$

$$F_{12}^{\mu\nu} \equiv \sum_{s_{f1},s_{f2}}(y_{f1}\sigma^\mu x_{f2}^\dagger)(y_{f2}^\dagger\overline{\sigma}^\nu x_{f1}) = \sum_{s_{f1},s_{f2}}(x_{f1}^\dagger\overline{\sigma}^\mu y_{f2})(x_{f2}\sigma^\nu y_{f1}^\dagger) = -m_f^2\,\mathrm{Tr}(\sigma^\mu\overline{\sigma}^\nu). \tag{29.6.46}$$

Since $N^{\mu\nu}$ is symmetric, the antisymmetric parts of $F_1^{\mu\nu}$ and $F_2^{\mu\nu}$ do not contribute in eq. (29.6.38). The symmetric parts of $F_1^{\mu\nu}$ and $F_2^{\mu\nu}$ are equal and given by:

$$[F_1^{\mu\nu}]_{\rm symm} = [F_2^{\mu\nu}]_{\rm symm} = 2(k_1^\mu k_2^\nu + k_1^\nu k_2^\mu - k_1\cdot k_2 g^{\mu\nu})$$

$$= \begin{cases} 2m_f^2\,, & \mu=\nu=0\,, \\ 0\,, & \mu=0\,,\ \nu=j \ \text{ or } \ \mu=i\,,\ \nu=0\,, \\ 2m_f^2(2\hat{\boldsymbol{k}}^i\hat{\boldsymbol{k}}^j - \delta^{ij}) - 4E^2(\hat{\boldsymbol{k}}^i\hat{\boldsymbol{k}}^j - \delta^{ij})\,, & \mu=i,\ \nu=j\,, \end{cases} \tag{29.6.47}$$

and $F_{12}^{\mu\nu} = -2m_f^2 g^{\mu\nu}$. The spin-averaged squared matrix element for $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$ given by eq. (29.6.38) can now be fully evaluated, resulting in

$$\tfrac{1}{4}\sum_{s_1,s_2,s_{f1},s_{f2}}|\mathcal{M}_Z + \mathcal{M}_{\tilde{f}}|^2 = 4(|c_1|^2+|c_3|^2)\left[m_{\widetilde{N}_1}^2 m_f^2 + 2|\vec{\boldsymbol{p}}|^2(E^2(1+\cos^2\theta) - m_f^2\cos^2\theta)\right]$$

$$+8m_f^2\,\mathrm{Re}(c_1c_3^*)\left[m_{\widetilde{N}_1}^2 - 2|\vec{\boldsymbol{p}}|^2\right]$$

$$+\frac{16m_f^2 m_{\widetilde{N}_1}^2}{m_Z^4}\,E^2\left[E^2|c_0|^2 - m_Z^2\mathrm{Re}[c_0^*(c_1+c_3)]\right], \tag{29.6.48}$$

where $\cos\theta = \vec{\boldsymbol{p}}\cdot\hat{\boldsymbol{k}}/|\vec{\boldsymbol{p}}|$. In the non-relativistic limit, we use eq. (29.6.3) and drop terms of $\mathcal{O}(|\vec{\boldsymbol{p}}|^4)$.

To compute $v_{\rm rel}\sigma_{\rm ann}$, we make use of the following result for the differential annihilation cross-section in the CM frame:

$$v_{\rm rel}\left(\frac{d\sigma}{d\Omega}\right)_{\rm CM} = \frac{1}{32\pi^2 s}\left(1-\frac{4m_f^2}{s}\right)^{1/2}|\mathcal{M}|^2_{\rm ave}\,, \tag{29.6.49}$$

where $|\mathcal{M}|^2_{\rm ave}$ is the squared matrix element for the annihilation process, averaged over initial spins and summed over final spins, and the relative velocity of the initial state neutralinos in the CM frame is given by $v_{\rm rel} = 4|\vec{\boldsymbol{p}}|/\sqrt{s} \simeq 2|\vec{\boldsymbol{p}}|/m_{\widetilde{N}_1}$, after noting that $\sqrt{s} \simeq 2m_{\widetilde{N}_1}$ in the non-relativistic limit. Inserting the squared matrix element obtained above into eq. (29.6.49) and integrating over solid angles, we end up with:

$$\begin{aligned} v_{\rm rel}\sigma_{\rm ann} = \frac{1}{8\pi E^2}\left(1-\frac{m_f^2}{E^2}\right)^{1/2}\Bigg\{&(|c_1|^2+|c_3|^2)\left[m_{\widetilde{N}_1}^2 m_f^2 + \frac{2|\vec{\boldsymbol{p}}|^2}{3}\left(4m_{\widetilde{N}_1}^2 - m_f^2\right)\right] \\ &+\frac{4m_f^2 m_{\widetilde{N}_1}^2}{m_Z^4}\left[m_{\widetilde{N}_1}^2(m_{\widetilde{N}_1}^2+2|\vec{\boldsymbol{p}}|^2)|c_0|^2 - m_Z^2(m_{\widetilde{N}_1}^2+|\vec{\boldsymbol{p}}|^2)\,{\rm Re}[c_0^*(c_1+c_3)]\right] \\ &+2m_f^2\,{\rm Re}(c_1c_3^*)\left[m_{\widetilde{N}_1}^2 - 2|\vec{\boldsymbol{p}}|^2\right] + \mathcal{O}(|\vec{\boldsymbol{p}}|^4)\Bigg\}\,, \end{aligned} \tag{29.6.50}$$

where the effects of the s-channel Higgs boson exchanges have been omitted.

The momentum dependence of eq. (29.6.50) reflects the famous p-wave suppression of the annihilation cross-section in the $m_f = 0$ limit noted in [181].[72] In general, the annihilation cross-section in the non-relativistic limit behaves as $v_{\rm rel}\,\sigma_{\rm ann} \propto |\vec{\boldsymbol{p}}|^{2\ell}$. Applying this result to eq. (29.6.50) in the $m_f = 0$ limit implies that $\ell = 1$. This is a consequence of the Majorana nature of the neutralino. In particular, in the limit of $m_f = 0$, the $f\bar{f}$ pair is in a $J = 1$ angular momentum state. However, Fermi statistics dictates that at threshold, a pair of identical Majorana fermions in a $J = 1$ state must have relative orbital angular momentum $\ell = 1$ (corresponding to p-wave annihilation). The s-wave annihilation (corresponding to the Majorana fermion pair in a $J = 0$ state) is suppressed by a factor of m_f^2, as is evident from eq. (29.6.50).

We have checked that eq. (29.6.50) corresponds to a result first obtained in [182] (although the latter reference omits the terms in eq. (29.6.50) proportional to c_0). However, we emphasize that this formula neglects the effects of s-channel Higgs boson exchanges. We invite the reader to complete the computation of the annihilation cross-section by including these terms (along with the effects of interference between the neglected contributions and the ones computed above).

The annihilation of $\widetilde{N}_1\widetilde{N}_1$ into heavy quarks (c, b and t), followed by the decay of the heavy quarks, can yield observable signatures suitable for indirect dark matter detection. For example, the annihilation of neutralinos in the galaxy provides a possible source of indirect dark matter detection via the observation of positrons in cosmic rays [187]. Neutralino dark matter can also be captured in the sun [188]. The neutrinos that arise (either directly or indirectly) from the neutralino annihilation in the sun can be detected on Earth (see, e.g., [189]).

29.6.14 $e^-e^+ \to \widetilde{C}_i^-\widetilde{C}_j^+$

Next we consider the pair production of charginos in electron-positron collisions. The s-channel Feynman diagrams are shown in Fig. 29.6.1, where we have also introduced the notation for the

[72] In [181], the annihilation rate for photinos is computed, corresponding to $N_{11} = c_W$, $N_{12} = s_W$ and $N_{13} = N_{14} = 0$. In this case, the Z boson and Higgs boson s-channel exchange diagrams are absent. The result presented in [181] should be multiplied by a factor of two (H. Goldberg, private communication)—the corrected expression then agrees with eq. (29.6.50).

fermion momenta and polarizations. The Mandelstam variables are given by

$$s = 2p_1{\cdot}p_2 = m^2_{\widetilde{C}_i} + m^2_{\widetilde{C}_j} + 2k_i{\cdot}k_j, \tag{29.6.1}$$

$$t = m^2_{\widetilde{C}_i} - 2p_1{\cdot}k_i = m^2_{\widetilde{C}_j} - 2p_2{\cdot}k_j, \tag{29.6.2}$$

$$u = m^2_{\widetilde{C}_i} - 2p_2{\cdot}k_i = m^2_{\widetilde{C}_j} - 2p_1{\cdot}k_j. \tag{29.6.3}$$

Note that the negatively charged chargino carries momentum and polarization (k_i, λ_i), while the positively charged one carries (k_j, λ_j).

Using the Feynman rules of Figs. J.1.2 and K.2.1, the sum of the photon-exchange diagrams is given by:

$$i\mathcal{M}_\gamma = \frac{-ig^{\mu\nu}}{s}\left(-ie\, x_1\sigma_\mu y_2^\dagger - ie\, y_1^\dagger\overline{\sigma}_\mu x_2\right)\left(ie\,\delta_{ij}y_i\sigma_\nu x_j^\dagger + ie\,\delta_{ij}x_i^\dagger\overline{\sigma}_\nu y_j\right). \tag{29.6.4}$$

The Z-exchange diagrams yields [cf. footnote 67]:

$$i\mathcal{M}_Z = \frac{-ig^{\mu\nu}}{D_Z}\left[\frac{ig}{c_W}(s_W^2 - \tfrac{1}{2})\, x_1\sigma_\mu y_2^\dagger + \frac{igs_W^2}{c_W}\, y_1^\dagger\overline{\sigma}_\mu x_2\right]\left[-\frac{ig}{c_W}O'^L_{ji}\, y_i\sigma_\nu x_j^\dagger - \frac{ig}{c_W}O'^R_{ji}\, x_i^\dagger\overline{\sigma}_\nu y_j\right], \tag{29.6.5}$$

where $D_Z \equiv s - m_Z^2 + i\Gamma_Z m_Z$. The t-channel Feynman diagram via sneutrino exchange is shown in Fig. 29.6.2. Applying the rules of Fig. K.4.1, we find:

$$i\mathcal{M}_{\tilde{\nu}_e} = (-1)\frac{i}{t - m^2_{\tilde{\nu}_e}}\left(-igV_{i1}^* x_1 y_i\right)\left(-igV_{j1}y_2^\dagger x_j^\dagger\right). \tag{29.6.6}$$

The Fermi-Dirac factor (-1) in this equation arises because the spinors appear an order which is an odd permutation of the order used in all of the s-channel diagram results.

One can now apply the Fierz transformation identities eqs. (29.68)–(29.70) to eqs. (29.6.4) and (29.6.5) to remove the σ and $\overline{\sigma}$ matrices. The result can be combined with the t-channel

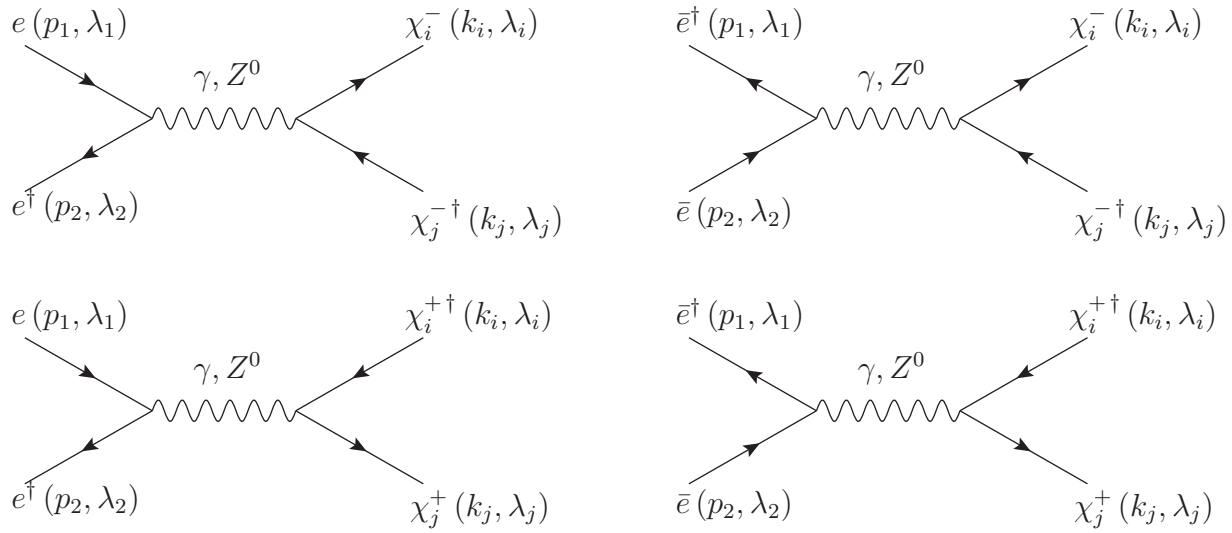

Figure 29.6.1: Feynman diagrams for $e^-e^+ \to \widetilde{C}_i^-\widetilde{C}_j^+$ via s-channel γ and Z^0 exchange.

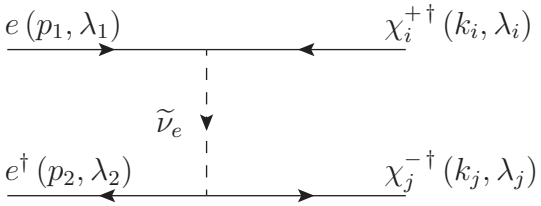

Figure 29.6.2: The Feynman diagram for $e^-e^+ \to \widetilde{C}_i^- \widetilde{C}_j^+$ via the t-channel exchange of a sneutrino.

contribution to obtain a total matrix element $\mathcal{M}$ with exactly the same form as eq. (29.6.9), but now with:

$$c_1 = 2\frac{e^2\delta_{ij}}{s} - \frac{g^2}{c_W^2 D_Z}(1-2s_W^2)O'^R_{ji}, \tag{29.6.7}$$

$$c_2 = \frac{2e^2\delta_{ij}}{s} - \frac{g^2}{c_W^2 D_Z}(1-2s_W^2)O'^L_{ji} + \frac{g^2 V^*_{i1}V_{j1}}{t-m^2_{\widetilde{\nu}_e}}, \tag{29.6.8}$$

$$c_3 = \frac{2e^2\delta_{ij}}{s} + \frac{2g^2 s_W^2}{c_W^2 D_Z}O'^R_{ji}\,, \tag{29.6.9}$$

$$c_4 = \frac{2e^2\delta_{ij}}{s} + \frac{2g^2 s_W^2}{c_W^2 D_Z}O'^L_{ji}. \tag{29.6.10}$$

The rest of this calculation is identical in form to eqs. (29.6.9)–(29.6.16), so that the result is:

$$\sum_{\text{spins}} |\mathcal{M}|^2 = (|c_1|^2+|c_4|^2)(u-m^2_{\widetilde{C}_i})(u-m^2_{\widetilde{C}_j}) + (|c_2|^2+|c_3|^2)(t-m^2_{\widetilde{C}_i})(t-m^2_{\widetilde{C}_j})$$
$$+2\text{Re}[c_1c_2^* + c_3c_4^*]m_{\widetilde{C}_i}m_{\widetilde{C}_j}s\,. \tag{29.6.11}$$

The differential cross-section then follows:

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}\left(\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2\right). \tag{29.6.12}$$

As in the previous subsection, we define $\cos\theta = \hat{\boldsymbol{p}}_{\boldsymbol{1}}\cdot\hat{\boldsymbol{k}}_{\boldsymbol{i}}$ (where θ is the angle between the initial state electron and $\widetilde{C}_i^-$ in the center-of-momentum frame). The Mandelstam variables t, u are given by

$$t = \frac{1}{2}\left[m^2_{\widetilde{C}_i} + m^2_{\widetilde{C}_j} - s + \lambda^{1/2}(s, m^2_{\widetilde{C}_i}, m^2_{\widetilde{C}_j})\cos\theta\right], \tag{29.6.13}$$

$$u = \frac{1}{2}\left[m^2_{\widetilde{C}_i} + m^2_{\widetilde{C}_j} - s - \lambda^{1/2}(s, m^2_{\widetilde{C}_i}, m^2_{\widetilde{C}_j})\cos\theta\right]. \tag{29.6.14}$$

The total cross-section can now be computed as

$$\sigma = \int_{t_-}^{t_+}\frac{d\sigma}{dt}dt\,, \tag{29.6.15}$$

where t_- and t_+ are obtained with $\cos\theta = -1$ and $+1$ in eq. (29.6.13), respectively. Our results agree with the original first complete calculation in [190]. Earlier work with simplifying assumptions is given in [191]. An extended calculation for the production of polarized charginos is given in [192].

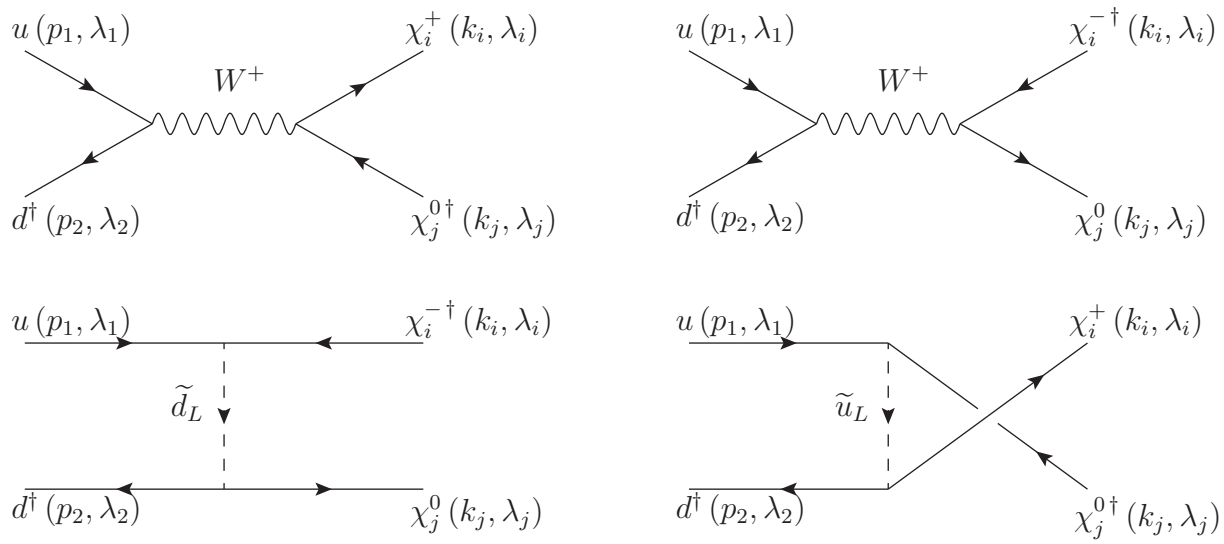

Figure 29.6.1: The four tree-level Feynman diagrams for $u\bar{d} \to \widetilde{C}_i^+ \widetilde{N}_j$.

29.6.15 $u\bar{d} \to \widetilde{C}_i^+ \widetilde{N}_j$

Next we consider the associated production of a chargino and a neutralino in quark, antiquark collisions. The leading order Feynman diagrams are shown in Fig. 29.6.1, where we have also defined the momenta and the helicities. The corresponding Mandelstam variables are

$$s = 2p_1{\cdot}p_2 = m^2_{\widetilde{C}_i} + m^2_{\widetilde{N}_j} + 2k_i{\cdot}k_j, \tag{29.6.1}$$

$$t = m^2_{\widetilde{C}_i} - 2p_1{\cdot}k_i = m^2_{\widetilde{N}_j} - 2p_2{\cdot}k_j, \tag{29.6.2}$$

$$u = m^2_{\widetilde{C}_i} - 2p_2{\cdot}k_i = m^2_{\widetilde{N}_j} - 2p_1{\cdot}k_j. \tag{29.6.3}$$

The matrix elements for the s-channel diagrams are obtained by applying the Feynman rules of Figs. J.1.2 and K.2.2:

$$i\mathcal{M}_s = \frac{-ig^{\mu\nu}}{s - m_W^2}\left(\frac{ig}{\sqrt{2}}x_1\sigma_\mu y_2^\dagger\right)\left(igO_{ji}^{L*}x_i^\dagger\overline{\sigma}_\nu y_j + igO_{ji}^{R*}y_i\sigma_\nu x_j^\dagger\right). \tag{29.6.4}$$

The external spinors are denoted by $x_1 \equiv x(\vec{\boldsymbol{p}}_1,\lambda_1)$, $y_2^\dagger \equiv y^\dagger(\vec{\boldsymbol{p}}_2,\lambda_2)$, $x_i^\dagger \equiv x^\dagger(\vec{\boldsymbol{k}}_i,\lambda_i)$, $y_j \equiv y(\vec{\boldsymbol{k}}_j,\lambda_j)$, etc. The matrix elements for the t and u channel graphs follow from the rules of Figs. K.4.1 and K.4.2:

$$i\mathcal{M}_t = (-1)\frac{i}{t - m^2_{\tilde{d}_L}}(-igU_{i1}^*)\left(\frac{ig}{\sqrt{2}}\Big[N_{j2} - \frac{s_W}{3c_W}N_{j1}\Big]\right)x_1y_iy_2^\dagger x_j^\dagger\,, \tag{29.6.5}$$

$$i\mathcal{M}_u = \frac{i}{u - m^2_{\tilde{u}_L}}(-igV_{i1})\left(\frac{ig}{\sqrt{2}}\Big[-N_{j2}^* - \frac{s_W}{3c_W}N_{j1}^*\Big]\right)x_1y_jy_2^\dagger x_i^\dagger\,. \tag{29.6.6}$$

The first factor of (-1) in eq. (29.6.5) is required because the order of the spinors $(1,i,2,j)$ is in an odd permutation of the order $(1,2,i,j)$ used in the s-channel and u-channel results.

Now we can use the Fierz relations eqs. (29.68) and (29.70) to rewrite the s-channel amplitude in a form without σ or $\overline{\sigma}$ matrices. Combining the result with the t-channel and u-channel

contributions yields a total $\mathcal{M}$ with exactly the same form as eq. (29.6.9), but now with

$$c_1 = -\sqrt{2} g^2 \left[\frac{O^{L*}_{ji}}{s - m_W^2} + \left(\frac{1}{2} N^*_{j2} + \frac{s_W}{6 c_W} N^*_{j1} \right) \frac{V_{i1}}{u - m_{\tilde{u}_L}} \right], \tag{29.6.7}$$

$$c_2 = -\sqrt{2} g^2 \left[\frac{O^{R*}_{ji}}{s - m_W^2} + \left(\frac{1}{2} N^*_{j2} - \frac{s_W}{6 c_W} N^*_{j1} \right) \frac{U^*_{i1}}{t - m_{\tilde{d}_L}} \right], \tag{29.6.8}$$

$$c_3 = c_4 = 0. \tag{29.6.9}$$

The rest of this calculation is identical in form to that of eqs. (29.6.9)–(29.6.16), leading to:

$$\sum_{\text{spins}} |\mathcal{M}|^2 = |c_1|^2 (u - m^2_{\widetilde{C}_i})(u - m^2_{\widetilde{N}_j}) + |c_2|^2 (t - m^2_{\widetilde{C}_i})(t - m^2_{\widetilde{N}_j}) + 2\text{Re}[c_1 c_2^*] m_{\widetilde{C}_i} m_{\widetilde{N}_j} s. \tag{29.6.10}$$

From this, one can obtain:

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2} \left(\frac{1}{3 \cdot 4} \sum_{\text{spins}} |\mathcal{M}|^2 \right), \tag{29.6.11}$$

where we have included a factor of 1/3 from the color average for the incoming quarks. As in the previous two subsections, eq. (29.6.11) can be expressed in terms of the angle between the u quark and the chargino in the center-of-momentum frame, using

$$t = \frac{1}{2} \left[m^2_{\widetilde{C}_i} + m^2_{\widetilde{N}_j} - s + \lambda^{1/2}(s, m^2_{\widetilde{C}_i}, m^2_{\widetilde{N}_j}) \cos\theta \right], \tag{29.6.12}$$

$$u = \frac{1}{2} \left[m^2_{\widetilde{C}_i} + m^2_{\widetilde{N}_j} - s - \lambda^{1/2}(s, m^2_{\widetilde{C}_i}, m^2_{\widetilde{N}_j}) \cos\theta \right]. \tag{29.6.13}$$

This process occurs in proton-antiproton and proton-proton collisions, where $\sqrt{s}$ is not fixed, and the angle θ is different than the lab frame angle. The observable cross-section depends crucially on experimental cuts. Our result in eq. (29.6.11) agrees with the complete computation in [193]. Earlier calculations in special supersymmetric scenarios, e.g. with photino mass eigenstates, are given in refs. [180, 194].

29.6.16 $\widetilde{N}_i \to \widetilde{N}_j \widetilde{N}_k \widetilde{N}_\ell$

Next we consider the decay of a neutralino $\widetilde{N}_i$ to three lighter neutralinos: $\widetilde{N}_j, \widetilde{N}_k, \widetilde{N}_\ell$. To the best of our knowledge, this process has not been computed in the literature. This decay is not likely to be phenomenologically relevant, because a variety of two-body decay modes will always be available. Furthermore, the calculation itself is quite complicated because of the large number of Feynman diagrams involved. Therefore, we consider this only as a matter-of-principle example of a process with four external state Majorana fermions, and will restrict ourselves to writing down the contributing matrix element amplitudes.

At tree level, the decay can proceed via a virtual Z^0 boson; the Feynman graphs are shown in Fig. 29.6.1. In addition, it can proceed via the exchange of any of the neutral scalar Higgs bosons of the MSSM, $\phi^0 = h^0, H^0, A^0$, as shown in Fig. 29.6.2. Since any of the final state neutralinos can directly couple to the initial state neutralino there are two more diagrams for each one shown in Figs. 29.6.1 and 29.6.2, for a total of 48 tree-level diagrams (counting each intermediate Higgs boson state as distinct). In all cases, the four-momenta of the neutralinos $\widetilde{N}_i$, $\widetilde{N}_j$, $\widetilde{N}_k$, $\widetilde{N}_\ell$ are denoted p_i, k_j, k_k, k_ℓ respectively.

We obtain the sum of the four diagrams in Fig. 29.6.1 by implementing the rules of Fig. K.2.1, and using the 't Hooft-Feynman gauge:

$$i\mathcal{M}_Z^{(1)} = \frac{-ig^2/c_W^2}{(p_i - k_j)^2 - m_Z^2}\Big(O''^L_{ji} x_i \sigma_\mu x_j^\dagger - O''^L_{ij} y_i^\dagger \overline{\sigma}_\mu y_j\Big)\Big(O''^L_{k\ell} x_k^\dagger \overline{\sigma}^\mu y_\ell - O''^L_{\ell k} y_k \sigma^\mu x_\ell^\dagger\Big)\,. \tag{29.6.1}$$

The external wave functions are $x_i \equiv x(\vec{\boldsymbol{p}}_i, \lambda_i)$, $x_{j,k,\ell} \equiv x(\vec{\boldsymbol{k}}_{j,k,\ell}, \lambda_{j,k,\ell})$, and analogously for $x^\dagger_{i,j,k,\ell}$, and $y_{i,j,k,\ell}$ and $y^\dagger_{i,j,k,\ell}$. Note that we have factorized the sum of the four diagrams, taking advantage of the common virtual boson line propagator. By a judicious use of the σ or $\overline{\sigma}$ version of the vertex rule, we have ensured that the order of the four spinor wave functions is the same for each of the four diagrams. Hence, no additional relative minus signs are required.

The contributions from the diagrams related to these by permutations can now be obtained from the appropriate substitutions $(j \leftrightarrow k)$ and $(j \leftrightarrow \ell)$:

$$i\mathcal{M}_Z^{(2)} = (-1)\frac{-ig^2/c_W^2}{(p_i - k_k)^2 - m_Z^2}\Big(O''^L_{ki} x_i \sigma_\mu x_k^\dagger - O''^L_{ik} y_i^\dagger \overline{\sigma}_\mu y_k\Big)\Big(O''^L_{j\ell} x_j^\dagger \overline{\sigma}^\mu y_\ell - O''^L_{\ell j} y_j \sigma^\mu x_\ell^\dagger\Big), \tag{29.6.2}$$

$$i\mathcal{M}_Z^{(3)} = (-1)\frac{-ig^2/c_W^2}{(p_i - k_\ell)^2 - m_Z^2}\Big(O''^L_{\ell i} x_i \sigma_\mu x_\ell^\dagger - O''^L_{i\ell} y_i^\dagger \overline{\sigma}_\mu y_\ell\Big)\Big(O''^L_{kj} x_k^\dagger \overline{\sigma}^\mu y_j - O''^L_{jk} y_k \sigma^\mu x_j^\dagger\Big). \tag{29.6.3}$$

The first factors of (-1) in $i\mathcal{M}_Z^{(2)}$ and $i\mathcal{M}_Z^{(3)}$ are present because the order of the spinors in each case appear in an odd permutation of the canonical order set by $i\mathcal{M}_Z^{(1)}$. Note that if we were to proceed to a computation of the decay rate, the very first step would be to apply the Fierz relations of eqs. (29.68)–(29.70) to eliminate all of the σ and $\overline{\sigma}$ matrices in the above amplitudes.

The diagrams in Fig. 29.6.2 combine to give a contribution:

$$i\mathcal{M}_{\phi^0}^{(1)} = \frac{-i}{(p_i - k_j)^2 - m_{\phi^0}^2}(Y^{ij} x_i y_j + Y_{ij} y_i^\dagger x_j^\dagger)(Y^{k\ell} y_k y_\ell + Y_{k\ell} x_k^\dagger x_\ell^\dagger)\,, \tag{29.6.4}$$

where we have used the Feynman rules of Fig. K.3.1, and adopted the shorthand notation $Y^{ij} = (Y_{ij})^* = Y^{\phi^0 \chi_i^0 \chi_j^0}$. Again we have factored the amplitude using the common virtual boson propagator. As in the Z-exchange diagrams, the other contributions can be obtained by the appropriate

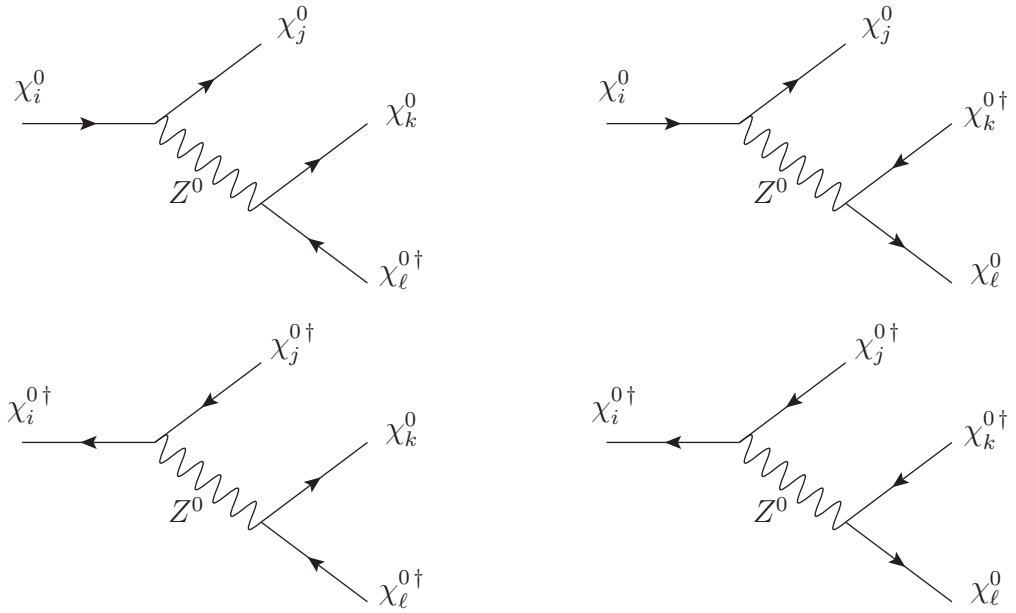

Figure 29.6.1: Four Feynman diagrams for $\widetilde{N}_i \to \widetilde{N}_j \widetilde{N}_k \widetilde{N}_\ell$ in the MSSM via Z^0 exchange. There are four more where $\widetilde{N}_j \leftrightarrow \widetilde{N}_k$ and another four where $\widetilde{N}_j \leftrightarrow \widetilde{N}_\ell$.

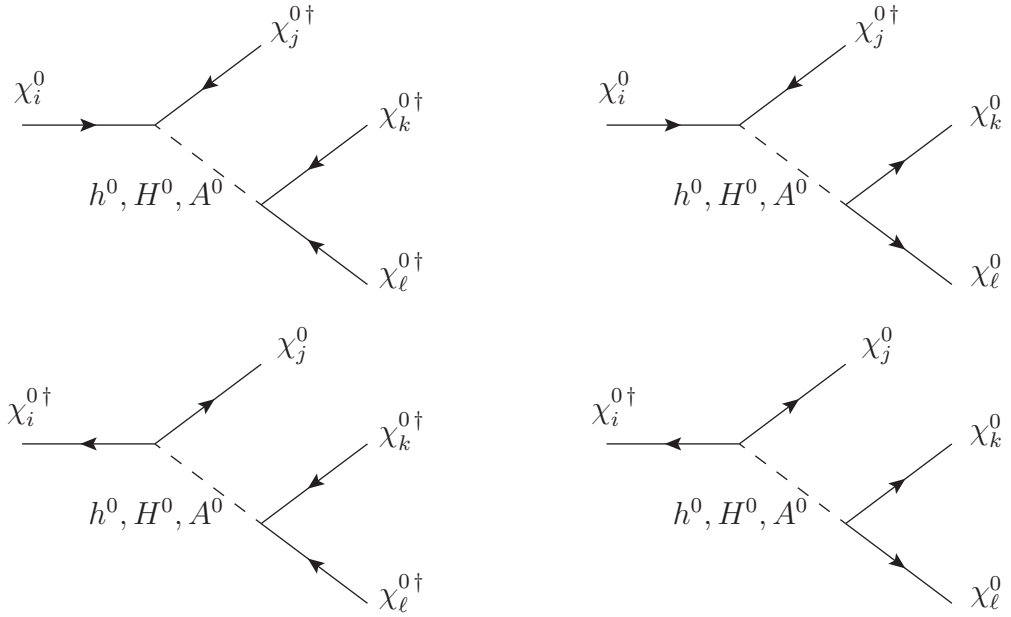

Figure 29.6.2: Four Feynman diagrams for $\widetilde{N}_i \to \widetilde{N}_j \widetilde{N}_k \widetilde{N}_\ell$ in the MSSM via $\phi^0 = h^0$, H^0, A^0 exchange. There are four more where $\widetilde{N}_j \leftrightarrow \widetilde{N}_k$ and another four where $\widetilde{N}_j \leftrightarrow \widetilde{N}_\ell$.

substitutions:

$$i\mathcal{M}^{(2)}_{\phi^0} = (-1)\frac{-i}{(p_i - k_k)^2 - m^2_{\phi^0}}(Y^{ik}x_i y_k + Y_{ik}y_i^\dagger x_k^\dagger)(Y^{j\ell}y_j y_\ell + Y_{j\ell}x_j^\dagger x_\ell^\dagger)\,, \tag{29.6.5}$$

$$i\mathcal{M}^{(3)}_{\phi^0} = (-1)\frac{-i}{(p_i - k_\ell)^2 - m^2_{\phi^0}}(Y^{i\ell}x_i y_\ell + Y_{i\ell}y_i^\dagger x_\ell^\dagger)(Y^{kj}y_k y_j + Y_{kj}x_k^\dagger x_j^\dagger)\,. \tag{29.6.6}$$

The first factors of (-1) in $i\mathcal{M}^{(2)}_{\phi^0}$ and $i\mathcal{M}^{(3)}_{\phi^0}$ are needed because the spinors in each case are in an odd permutation of the canonical order established earlier.

The total matrix element is obtained by adding all the contributing diagrams:

$$\mathcal{M} = \sum_{n=1}^{3}\mathcal{M}^{(n)}_Z + \sum_{\phi^0}\sum_{n=1}^{3}\mathcal{M}^{(n)}_{\phi^0}\,. \tag{29.6.7}$$

Squaring the matrix element, dividing by $2M_{\widetilde{N}_i}$, and integrating over phase space yields the total decay rate. Note that final states differing by the interchange of identical particles must be considered as a single state, counted once [39]. Given an N-body final state made up of ν_r particles of type r (where $r \le N$), we define a statistical factor S,

$$S = \prod_r \nu_r!\,, \qquad \text{where} \qquad \sum_r \nu_r = N\,. \tag{29.6.8}$$

Then, in computing the total decay rate, the integration over the total phase space must be divided by S to avoid over-counting. In the present example, $N = 3$ with $S = 2$ [or $S = 6$] in the case of two [or three] identical neutralinos in the final state, respectively

29.6.17 Three-body slepton decays: $\widetilde{\ell}_R^- \to \ell^- \tau^\pm \widetilde{\tau}_1^\mp$ for $\ell = e, \mu$

We next consider the three-body decays of sleptons through a virtual neutralino. The usual assumption in supersymmetric phenomenology is that these decays will have a very small branching

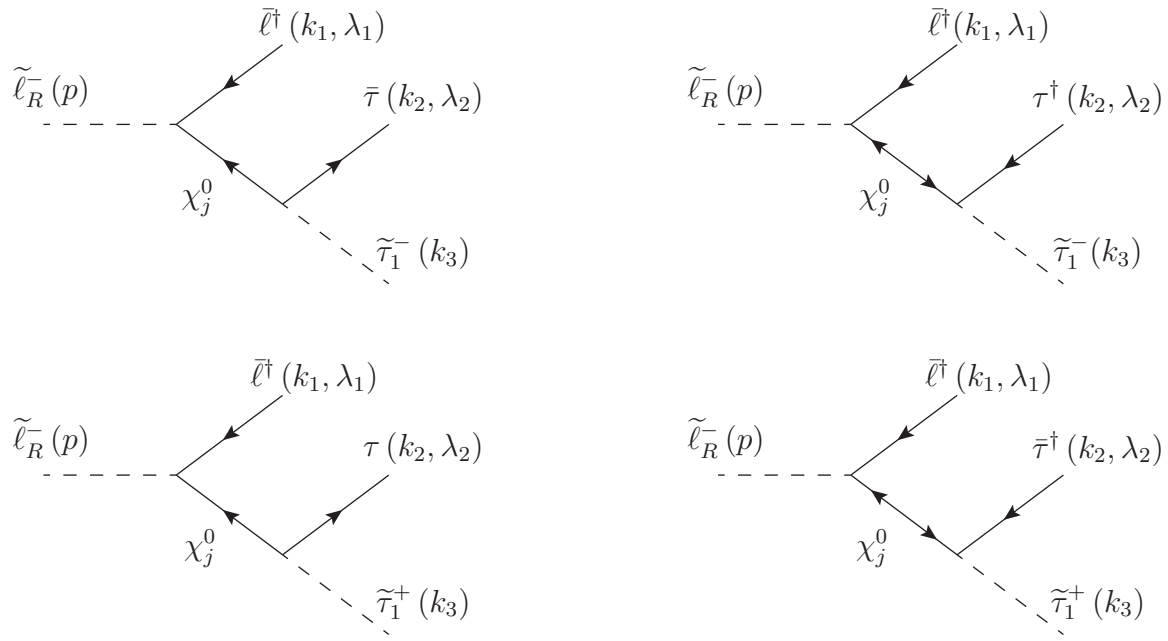

Figure 29.6.1: Feynman diagrams for the three-body slepton decays $\widetilde{\ell}_R^- \to \ell^- \tau^+ \widetilde{\tau}_1^-$ (top row) and $\widetilde{\ell}_R^- \to \ell^- \tau^- \widetilde{\tau}_1^+$ (bottom row) in the MSSM.

fraction, because a two-body decay to a lighter neutralino and lepton is always open. However, in Gauge Mediated Supersymmetry Breaking models with a non-minimal messenger sector, the sleptons can be lighter than the lightest neutralino [195, 196]. In that case, the mostly R-type smuon and selectron, $\widetilde{\mu}_R$ and $\tilde{e}_R$, will decay by $\widetilde{\ell}_R^- \to \ell^- \tau^\pm \widetilde{\tau}_1^\mp$. The lightest stau mass eigenstate, $\widetilde{\tau}_1^\pm$, is a mixture of the weak eigenstates $\widetilde{\tau}_L^\pm$ and $\widetilde{\tau}_R^\pm$, as described in Appendix K.4 :

$$\widetilde{\tau}_1^- = R^*_{\tilde{\tau}_1} \widetilde{\tau}_R^- + L^*_{\tilde{\tau}_1} \widetilde{\tau}_L^-, \tag{29.6.1}$$

and $\widetilde{\tau}_1^+ = (\widetilde{\tau}_1^-)^*$, while the $\widetilde{\mu}_R$ and $\tilde{e}_R$ are taken to be unmixed.

First consider the decay $\widetilde{\ell}_R^- \to \ell^- \tau^+ \widetilde{\tau}_1^-$, which proceed by the diagrams in the top row of Fig. 29.6.1. The momenta and polarizations of the particles are also indicated on the diagram. Using the Feynman rules of Fig. K.4.4, we find that the amplitudes of these two diagrams, for each neutralino $\tilde{N}_j$ exchanged, are:

$$i\mathcal{M}_1 = (-ia_j^{\tilde{\ell}*})(-ia_j^{\tilde{\tau}})\, y_1 \left[\frac{-i(p-k_1)\cdot\sigma}{(p-k_1)^2 - m^2_{\tilde{N}_j}}\right] x_2^\dagger, \tag{29.6.2}$$

$$i\mathcal{M}_2 = (-ia_j^{\tilde{\ell}*})(-ib_j^{\tilde{\tau}})\, y_1 \left[\frac{i m_{\tilde{N}_j}}{(p-k_1)^2 - m^2_{\tilde{N}_j}}\right] y_2. \tag{29.6.3}$$

where

$$a_j^{\tilde{\ell}} = \sqrt{2} g' N_{j1}, \tag{29.6.4}$$

$$a_j^{\tilde{\tau}} = Y_\tau N_{j3} L^*_{\tilde{\tau}_1} + \sqrt{2} g' N_{j1} R^*_{\tilde{\tau}_1}, \tag{29.6.5}$$

$$b_j^{\tilde{\tau}} = Y_\tau N^*_{j3} R^*_{\tilde{\tau}_1} - \frac{1}{\sqrt{2}} (g N^*_{j2} + g' N^*_{j1}) L^*_{\tilde{\tau}_1}. \tag{29.6.6}$$

The spinor wave function factors are $y_1 = y(\vec{\boldsymbol{k}}_1, \lambda_1)$, $y_2 = y(\vec{\boldsymbol{k}}_2, \lambda_2)$, and $x_2^\dagger = x^\dagger(\vec{\boldsymbol{k}}_2, \lambda_2)$.

In the following, we will use the kinematic variables

$$z_\ell \equiv 2p\cdot k_1/m^2_{\tilde{\ell}_R} = 2E_\ell/m_{\tilde{\ell}_R}, \qquad z_\tau \equiv 2p\cdot k_2/m^2_{\tilde{\ell}_R} = 2E_\tau/m_{\tilde{\ell}_R}, \tag{29.6.7}$$

$$r_{\tilde{N}_j} \equiv m_{\tilde{N}_j}/m_{\tilde{\ell}_R}, \qquad r_{\tilde{\tau}} \equiv m_{\tilde{\tau}_1}/m_{\tilde{\ell}_R}, \tag{29.6.8}$$

$$r_\tau \equiv m_\tau/m_{\tilde{\ell}_R}, \qquad r_\ell \equiv m_\ell/m_{\tilde{\ell}_R}. \tag{29.6.9}$$

The total amplitude then can be written as

$$\mathcal{M} = \sum_{j=1}^{4} \left[c_j y_1 (p-k_1)\cdot\sigma x_2^\dagger + d_j y_1 y_2 \right] , \tag{29.6.10}$$

where

$$c_j = -a_j^{\tilde{\ell}*} a_j^{\tilde{\tau}}/[m^2_{\ell_R}(r^2_{\tilde{N}_j} - 1 + z_\ell)], \tag{29.6.11}$$

$$d_j = a_j^{\tilde{\ell}*} b_j^{\tilde{\tau}} m_{\tilde{N}_j}/[m^2_{\ell_R}(r^2_{\tilde{N}_j} - 1 + z_\ell)]. \tag{29.6.12}$$

We consistently neglect the electron and muon masses and Yukawa couplings (so $r_\ell = 0$) in the matrix elements, but not below in the kinematic integration over phase space, where the muon mass can be important.

Using eqs. (29.44) and (29.45), we find

$$\begin{aligned} |\mathcal{M}|^2 = \sum_{j,k} \Big[& c_j c_k^*\, y_1 (p-k_1)\cdot\sigma x_2^\dagger\, x_2 (p-k_1)\cdot\sigma y_1^\dagger + d_j d_k^* y_1 y_2\, y_2^\dagger y_1^\dagger \\ & + c_j d_k^* y_1 (p-k_1)\cdot\sigma x_2^\dagger\, y_2^\dagger y_1^\dagger + c_j^* d_k x_2 (p-k_1)\cdot\sigma y_1^\dagger\, y_1 y_2 \Big]. \end{aligned} \tag{29.6.13}$$

Summing over the lepton spins using eqs. (29.3.57)–(29.3.60) gives

$$\begin{aligned} \sum_{\lambda_1,\lambda_2} |\mathcal{M}|^2 = \sum_{j,k} \Big[& c_j c_k^* \mathrm{Tr}[(p-k_1)\cdot\sigma k_2\cdot\overline{\sigma}(p-k_1)\cdot\sigma k_1\cdot\overline{\sigma}] + d_j d_k^* \mathrm{Tr}[k_2\cdot\sigma k_1\cdot\overline{\sigma}] \\ & - c_j d_k^* m_\tau \mathrm{Tr}[(p-k_1)\cdot\sigma k_1\cdot\overline{\sigma}] - c_j^* d_k m_\tau \mathrm{Tr}[(p-k_1)\cdot\sigma k_1\cdot\overline{\sigma}] \Big]. \end{aligned} \tag{29.6.14}$$

Taking the traces using eqs. (29.56) and (29.57) yields

$$\begin{aligned} \sum_{\text{spins}} |\mathcal{M}|^2 &= \sum_{j,k} \Big\{ c_j c_k^* [4k_1\cdot(p-k_1) k_2\cdot(p-k_1) - 2k_1\cdot k_2 (p-k_1)^2] + 2 d_j d_k^* k_1\cdot k_2 \\ &\qquad - 4\mathrm{Re}[c_j d_k^*] m_\tau k_1\cdot(p-k_1) \Big\} \\ &= \sum_{j,k} \Big\{ c_j c_k^* m^4_{\tilde{\ell}_R} [(1-z_\ell)(1-z_\tau) - r_{\tilde{\tau}}^2 + r_\tau^2] \\ &\qquad + d_j d_k^* m^2_{\tilde{\ell}_R} (z_\ell + z_\tau - 1 + r_{\tilde{\tau}}^2 - r_\tau^2) - 2\mathrm{Re}[c_j d_k^*] m_\tau m^2_{\tilde{\ell}_R} z_\ell \Big\}. \end{aligned} \tag{29.6.15}$$

The differential decay rate for $\widetilde{\ell}_R^- \to \ell^- \tau^+ \widetilde{\tau}_1^-$ then follows:

$$\frac{d^2\Gamma}{dz_\ell dz_\tau} = \frac{m_{\tilde{\ell}_R}}{256\pi^3} \left(\sum_{\text{spins}} |\mathcal{M}|^2 \right). \tag{29.6.16}$$

The total decay rate in that channel can be found by integrating over z_ℓ, z_τ, with the limits (see for example ref. [166]):

$$2r_\ell < z_\ell < 1 + r_\ell^2 - (r_\tau + r_{\tilde{\tau}})^2, \tag{29.6.17}$$

$$(z_\tau)_{\rm min} < z_\tau < (z_\tau)_{\rm max}\,, \tag{29.6.18}$$

where

$$(z_\tau)_{\rm min\,,max} = \frac{1}{2(1 - z_\ell + r_\ell^2)}\Big[(2 - z_\ell)(1 + r_\ell^2 + r_\tau^2 - r_{\tilde{\tau}}^2 - z_\ell) \mp (z_\ell^2 - 4r_\ell^2)^{1/2}\lambda^{1/2}(1 + r_\ell^2 - z_\ell, r_\tau^2, r_{\tilde{\tau}}^2)\Big]\,, \tag{29.6.19}$$

and the triangle function $\lambda^{1/2}$ is defined in eq. (29.6.11).

Now we turn to the competing decay $\widetilde{\ell}_R^- \to \ell^-\tau^-\widetilde{\tau}_1^+$, with diagrams appearing in the bottom row of Fig. 29.6.1. By appealing again to the Feynman rules of Fig. K.4.3, we find that the amplitude has exactly the same form as in eqs. (29.6.2) and (29.6.3), except now with $a_j^{\tilde{\tau}} \leftrightarrow b_j^{\tilde{\tau}*}$. Therefore, the entire previous calculation goes through precisely as before, but now with

$$c_j = \frac{-a_j^{\tilde{\ell}*} b_j^{\tilde{\tau}*}}{m_{\tilde{\ell}_R}^2 (r_{\tilde{N}_j}^2 - 1 + z_\ell)}, \tag{29.6.20}$$

$$d_j = \frac{a_j^{\tilde{\ell}*} a_j^{\tilde{\tau}*} m_{\tilde{N}_j}}{m_{\tilde{\ell}_R}^2 (r_{\tilde{N}_j}^2 - 1 + z_\ell)}. \tag{29.6.21}$$

The differential decay widths found above can be integrated to find the total decay widths. The results agree with ref. [197], except that the signs of the coefficient $c_{ij}^{(3)}$ and $c_{ij}^{(4)}$ in the published version of that paper are incorrect; the arXiv eprint version has been corrected. (Also, the notations for the sfermion mixing angle are different in that paper.) If $m_{\tilde{\ell}_R} - m_{\tilde{\tau}_1} - m_\tau$ is not too large, the resulting decays can have a macroscopic length in a detector, and the ratio of the two decay modes can provide an interesting probe of the supersymmetric Lagrangian.

29.6.18 Neutralino decay to photon and Goldstino: $\widetilde{N}_i \to \gamma\widetilde{G}$

The Goldstino $\widetilde{G}$ is a massless Weyl fermion that couples to the neutralino and photon fields according to the non-renormalizable Lagrangian term [198]:

$$\mathscr{L} = -\frac{a_i}{2}(\chi_i^0 \sigma^\mu \overline{\sigma}^\rho \sigma^\nu \partial_\mu \widetilde{G}^\dagger)\,(\partial_\nu A_\rho - \partial_\rho A_\nu) + \text{h.c.} \tag{29.6.1}$$

Here χ_i^0 is the left-handed two-component fermion field that corresponds to the neutralino $\widetilde{N}_i$ particle, $\widetilde{G}$ is the two-component fermion field corresponding to the (nearly) massless Goldstino, and the effective coupling is

$$a_i \equiv \frac{1}{\sqrt{2}\langle F\rangle}(N_{i1}^* \cos\theta_W + N_{i2}^* \sin\theta_W), \tag{29.6.2}$$

where N_{ij} the mixing matrix for the neutralinos [see eq. (K.2.8)], and $\langle F\rangle$ is the F-term expectation value associated with supersymmetry breaking. Therefore $\widetilde{N}_i$ can decay to γ plus $\widetilde{G}$ through the diagrams shown in Fig. 29.6.1, with amplitudes:

$$i\mathcal{M}_1 = i\frac{a_i}{2}\, x_{\tilde{N}} k_{\tilde{G}}\cdot\sigma\,(\varepsilon^*\cdot\overline{\sigma}\, k_\gamma\cdot\sigma - k_\gamma\cdot\overline{\sigma}\,\varepsilon^*\cdot\sigma)\, x_{\tilde{G}}^\dagger\,, \tag{29.6.3}$$

$$i\mathcal{M}_2 = -i\frac{a_i^*}{2}\, y_{\tilde{N}}^\dagger k_{\tilde{G}}\cdot\overline{\sigma}\,(\varepsilon^*\cdot\sigma\, k_\gamma\cdot\overline{\sigma} - k_\gamma\cdot\sigma\,\varepsilon^*\cdot\overline{\sigma})\, y_{\tilde{G}}\,. \tag{29.6.4}$$

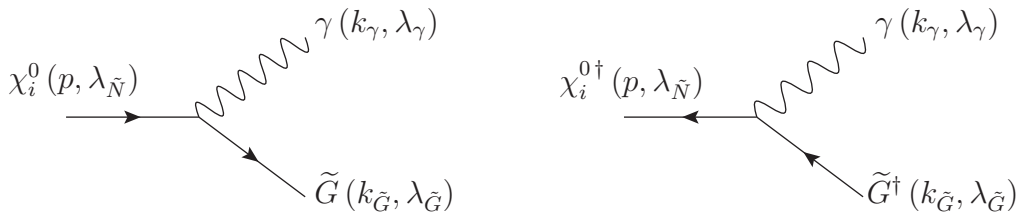

Figure 29.6.1: The two Feynman diagrams for $\widetilde{N}_i \to \gamma\widetilde{G}$ in supersymmetric models with a light Goldstino.

Here $x_{\tilde{N}} \equiv x(\vec{\boldsymbol{p}}, \lambda_{\tilde{N}})$, $y^\dagger_{\tilde{N}} \equiv y^\dagger(\vec{\boldsymbol{p}}, \lambda_{\tilde{N}})$, and $x^\dagger_{\tilde{G}} \equiv x^\dagger(\vec{\boldsymbol{k}}_{\tilde{G}}, \lambda_{\tilde{G}})$, $y_{\tilde{G}} \equiv y(\vec{\boldsymbol{k}}_{\tilde{G}}, \lambda_{\tilde{G}})$, and $\varepsilon^* = \varepsilon^*(\vec{\boldsymbol{k}}_\gamma, \lambda_\gamma)$ are the external wave function factors for the neutralino, Goldstino, and photon, respectively. Using the on-shell condition $k_\gamma\cdot\varepsilon^* = 0$, we have $k_\gamma\cdot\sigma\varepsilon^*\cdot\overline{\sigma} = -\varepsilon^*\cdot\sigma k_\gamma\cdot\overline{\sigma}$ and $k_\gamma\cdot\overline{\sigma}\varepsilon^*\cdot\sigma = -\varepsilon^*\cdot\overline{\sigma}k_\gamma\cdot\sigma$ from eqs. (29.52) and (29.53). So we can rewrite the total amplitude as

$$\mathcal{M} = \mathcal{M}_1 + \mathcal{M}_2 = x_{\tilde{N}} A x^\dagger_{\tilde{G}} + y^\dagger_{\tilde{N}} B y_{\tilde{G}}\,, \tag{29.6.5}$$

where

$$A = a_i\, k_{\tilde{G}}\cdot\sigma\, \varepsilon^*\cdot\overline{\sigma}\, k_\gamma\cdot\sigma, \tag{29.6.6}$$
$$B = -a_i^*\, k_{\tilde{G}}\cdot\overline{\sigma}\, \varepsilon^*\cdot\sigma\, k_\gamma\cdot\overline{\sigma}. \tag{29.6.7}$$

The complex square of the matrix element is therefore

$$|\mathcal{M}|^2 = x_{\tilde{N}} A x^\dagger_{\tilde{G}} x_{\tilde{G}} \hat{A} x^\dagger_{\tilde{N}} + y^\dagger_{\tilde{N}} B y_{\tilde{G}} y^\dagger_{\tilde{G}} \hat{B} y_{\tilde{N}} + x_{\tilde{N}} A x^\dagger_{\tilde{G}} y^\dagger_{\tilde{G}} \hat{B} y_{\tilde{N}} + y^\dagger_{\tilde{N}} B y_{\tilde{G}} x_{\tilde{G}} \hat{A} x^\dagger_{\tilde{N}}, \tag{29.6.8}$$

where $\hat{A}$ and $\hat{B}$ are obtained from A and B by reversing the order of the σ and $\overline{\sigma}$ matrices and taking the complex conjugates of a_i and ε [cf. eq. (29.4.4) and the associated text].

Summing over the Goldstino spins using eqs. (29.3.57)–(29.3.60) now yields:

$$\sum_{\lambda_{\tilde{G}}} |\mathcal{M}|^2 = x_{\tilde{N}} A k_{\tilde{G}}\cdot\overline{\sigma}\hat{A} x^\dagger_{\tilde{N}} + y^\dagger_{\tilde{N}} B k_{\tilde{G}}\cdot\sigma\hat{B} y_{\tilde{N}}. \tag{29.6.9}$$

(The $A, \hat{B}$ and $\hat{A}, B$ cross terms vanish because of $m_{\tilde{G}} = 0$.) Averaging over the neutralino spins using eqs. (29.3.57) and (29.3.58), we find

$$\begin{aligned}\frac{1}{2}\sum_{\lambda_{\tilde{N}},\lambda_{\tilde{G}}} |\mathcal{M}|^2 &= \frac{1}{2}\mathrm{Tr}[A k_{\tilde{G}}\cdot\overline{\sigma}\hat{A} p\cdot\overline{\sigma}] + \frac{1}{2}\mathrm{Tr}[B k_{\tilde{G}}\cdot\sigma\hat{B} p\cdot\sigma] \\ &= \frac{1}{2}|a_i|^2\mathrm{Tr}[\varepsilon^*\cdot\overline{\sigma}\, k_\gamma\cdot\sigma\, k_{\tilde{G}}\cdot\overline{\sigma}\, k_\gamma\cdot\sigma\, \varepsilon\cdot\overline{\sigma}\, k_{\tilde{G}}\cdot\sigma\, p\cdot\overline{\sigma}\, k_{\tilde{G}}\cdot\sigma] + (\sigma \leftrightarrow \overline{\sigma}).\end{aligned} \tag{29.6.10}$$

We now use

$$k_\gamma\cdot\sigma\, k_{\tilde{G}}\cdot\overline{\sigma}\, k_\gamma\cdot\sigma = 2k_{\tilde{G}}\cdot k_\gamma\, k_\gamma\cdot\sigma, \tag{29.6.11}$$
$$k_{\tilde{G}}\cdot\sigma\, p\cdot\overline{\sigma}\, k_{\tilde{G}}\cdot\sigma = 2k_{\tilde{G}}\cdot p\, k_{\tilde{G}}\cdot\sigma, \tag{29.6.12}$$

which follow from eq. (29.54), and the corresponding identities with $\sigma \leftrightarrow \overline{\sigma}$, to obtain:

$$\frac{1}{2}\sum_{\lambda_{\tilde{N}},\lambda_{\tilde{G}}} |\mathcal{M}|^2 = 2|a_i|^2(k_{\tilde{G}}\cdot k_\gamma)(k_{\tilde{G}}\cdot p)\mathrm{Tr}[\varepsilon^*\cdot\overline{\sigma}\, k_\gamma\cdot\sigma\, \varepsilon\cdot\overline{\sigma}\, k_{\tilde{G}}\cdot\sigma] + (\sigma \leftrightarrow \overline{\sigma}). \tag{29.6.13}$$

Applying the photon spin-sum identity

$$\sum_{\lambda_\gamma} \varepsilon^\mu \varepsilon^{\nu *} = -g^{\mu\nu}\,, \tag{29.6.14}$$

and the trace identities eq. (29.57) and (29.58), we get

$$\frac{1}{2}\sum_{\lambda_\gamma,\lambda_{\tilde{N}},\lambda_{\tilde{G}}} |\mathcal{M}|^2 = 16|a_i|^2 (k_{\tilde{G}}\cdot k_\gamma)^2 (k_{\tilde{G}}\cdot p) = 2|a_i|^2 m_{\widetilde{N}_i}^6\,. \tag{29.6.15}$$

So, the decay rate is [199, 195]:

$$\Gamma(\widetilde{N}_i \to \gamma\widetilde{G}) = \frac{1}{16\pi m_{\widetilde{N}_i}}\left(\frac{1}{2}\sum_{\lambda_\gamma,\lambda_{\tilde{N}},\lambda_{\tilde{G}}} |\mathcal{M}|^2\right) = |N_{i1}\cos\theta_W + N_{i2}\sin\theta_W|^2 \frac{m_{\widetilde{N}_i}^5}{16\pi|\langle F\rangle|^2}. \tag{29.6.16}$$

29.6.19 Gluino pair production from gluon fusion: $gg \to \widetilde{g}\widetilde{g}$

In this subsection we will compute the cross-section for the process $gg \to \widetilde{g}\widetilde{g}$. The relevant Feynman diagrams are shown in Fig. 29.6.1. The initial state gluons have $SU(3)_c$ adjoint representation indices a and b, with momenta p_1 and p_2 and polarization vectors $\varepsilon_1^\mu = \varepsilon^\mu(\vec{\boldsymbol{p}}_1, \lambda_1)$ and $\varepsilon_2^\mu = \varepsilon^\mu(\vec{\boldsymbol{p}}_2, \lambda_2)$, respectively. The final state gluinos carry adjoint representation indices c and d, with momenta k_1 and k_2 and wave function spinors $x_1^\dagger = x^\dagger(\vec{\boldsymbol{k}}_1, \lambda_1')$ or $y_1 = y(\vec{\boldsymbol{k}}_1, \lambda_1')$ and $x_2^\dagger = x^\dagger(\vec{\boldsymbol{k}}_2, \lambda_2')$ or $y_2 = y(\vec{\boldsymbol{k}}_2, \lambda_2')$, respectively.

The Feynman rules for the gluino couplings in the supersymmetric extension of QCD are given in Fig. K.5.1. For the two s-channel amplitudes, we obtain:

$$\begin{aligned} i\mathcal{M}_s = {} & \big(-g_s f^{abe}[g_{\mu\nu}(p_1-p_2)_\rho + g_{\nu\rho}(p_1+2p_2)_\mu - g_{\mu\rho}(2p_1+p_2)_\nu]\big)\left(\frac{-ig^{\rho\kappa}}{s}\right)\varepsilon_1^\mu\varepsilon_2^\nu \\ & \times \Big[\big(-g_s f^{cde}\big)\, x_1^\dagger \overline{\sigma}_\kappa y_2 \;+\; \big(g_s f^{dce}\big)\, y_1 \sigma_\kappa x_2^\dagger\Big]\,. \end{aligned} \tag{29.6.1}$$

The first factor is the Feynman rule for the three-gluon interaction of standard QCD, and the second factor is the gluon propagator. The next four (t-channel) diagrams have a total amplitude:

$$\begin{aligned} i\mathcal{M}_t = {} & \big(-g_s f^{cea}\varepsilon_1^\mu\big)\big(-g_s f^{edb}\varepsilon_2^\nu\big)\, x_1^\dagger \overline{\sigma}_\mu \left[\frac{i(k_1-p_1)\cdot\sigma}{(k_1-p_1)^2 - m_{\tilde{g}}^2}\right]\overline{\sigma}_\nu y_2 \\ & + \big(g_s f^{eca}\varepsilon_1^\mu\big)\big(g_s f^{deb}\varepsilon_2^\nu\big)\, y_1 \sigma_\mu \left[\frac{i(k_1-p_1)\cdot\overline{\sigma}}{(k_1-p_1)^2 - m_{\tilde{g}}^2}\right]\sigma_\nu x_2^\dagger \\ & + \big(-g_s f^{cea}\varepsilon_1^\mu\big)\big(g_s f^{deb}\varepsilon_2^\nu\big)\, x_1^\dagger \overline{\sigma}_\mu \left[\frac{im_{\tilde{g}}}{(k_1-p_1)^2 - m_{\tilde{g}}^2}\right]\sigma_\nu x_2^\dagger \\ & + \big(g_s f^{eca}\varepsilon_1^\mu\big)\big(-g_s f^{edb}\varepsilon_2^\nu\big)\, y_1 \sigma_\mu \left[\frac{im_{\tilde{g}}}{(k_1-p_1)^2 - m_{\tilde{g}}^2}\right]\overline{\sigma}_\nu y_2. \end{aligned} \tag{29.6.2}$$

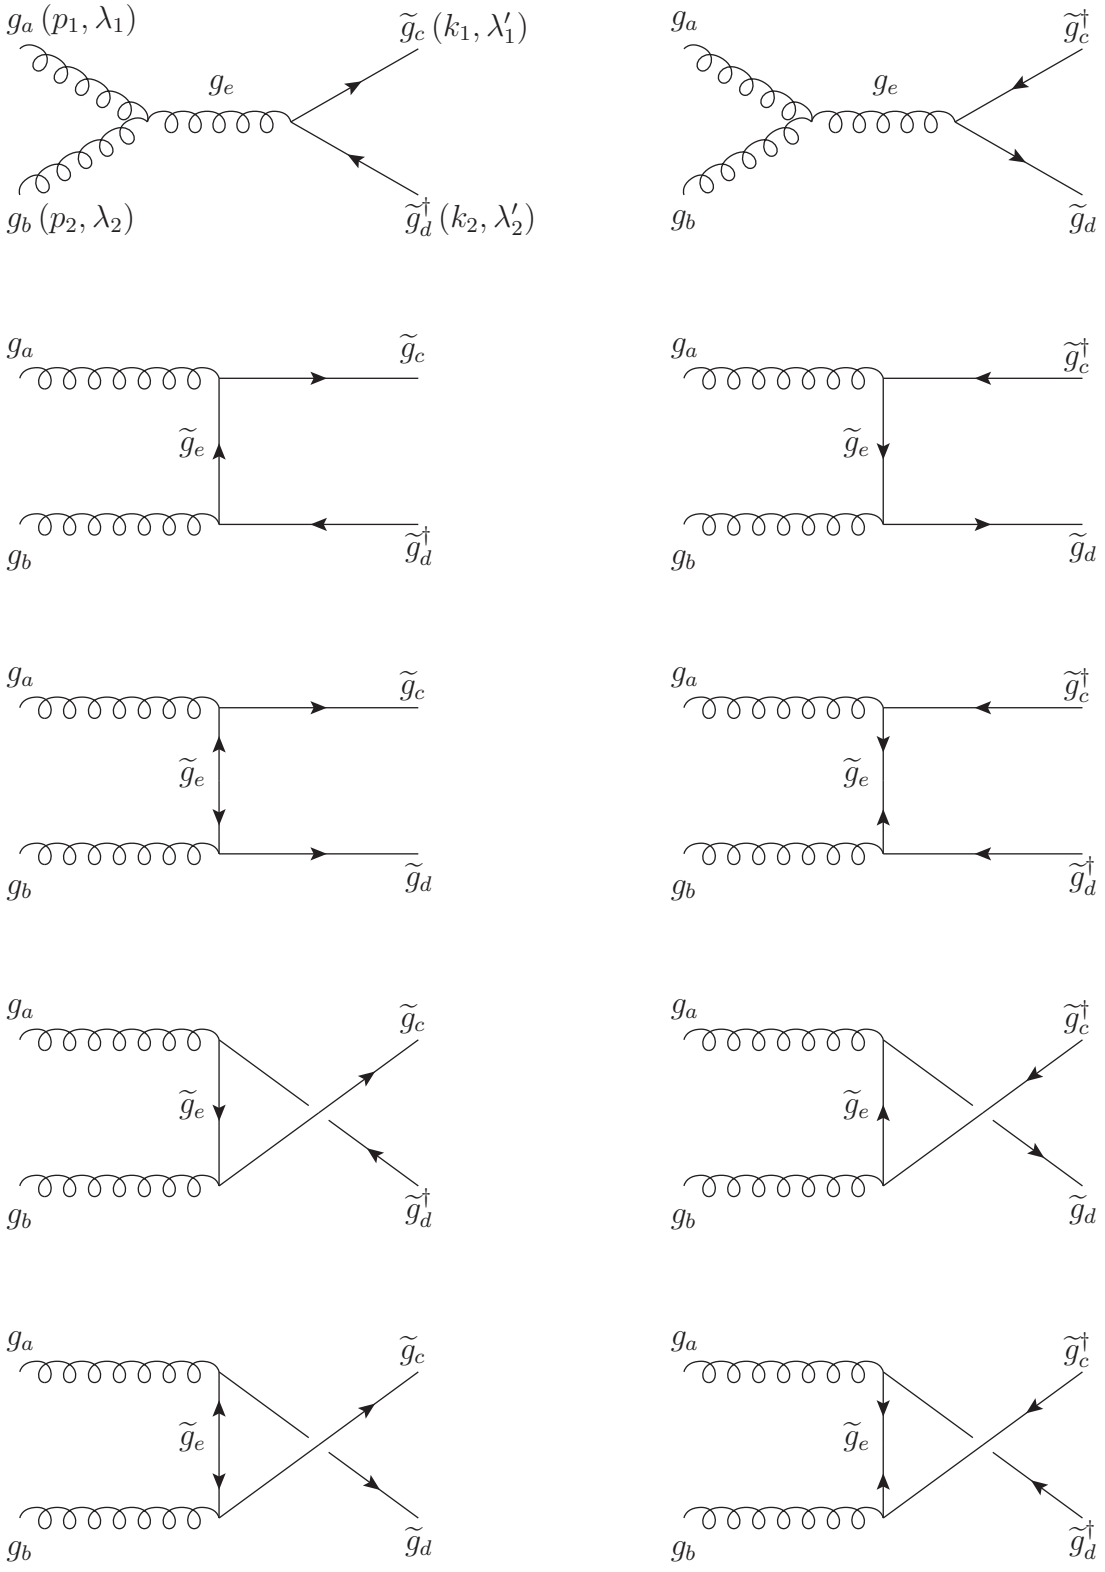

Figure 29.6.1: The ten Feynman diagrams for $gg \to \widetilde{g}\widetilde{g}$. The momentum and spin polarization assignments are indicated on the first diagram.

Finally, the u-channel Feynman diagrams result in:

$$\begin{aligned} i\mathcal{M}_u = {} & \big(-g_s f^{eda}\varepsilon_1^\mu\big)\big(-g_s f^{ceb}\varepsilon_2^\nu\big)\, x_1^\dagger \overline{\sigma}_\nu \left[\frac{i(k_1-p_2)\cdot\sigma}{(k_1-p_2)^2-m_{\tilde{g}}^2}\right]\overline{\sigma}_\mu y_2 \\ & + \big(g_s f^{dea}\varepsilon_1^\mu\big)\big(g_s f^{ecb}\varepsilon_2^\nu\big)\, y_1 \sigma_\nu \left[\frac{i(k_1-p_2)\cdot\overline{\sigma}}{(k_1-p_2)^2-m_{\tilde{g}}^2}\right]\sigma_\mu x_2^\dagger \\ & + \big(g_s f^{dea}\varepsilon_1^\mu\big)\big(-g_s f^{ceb}\varepsilon_2^\nu\big)\, x_1^\dagger \overline{\sigma}_\nu \left[\frac{im_{\tilde{g}}}{(k_1-p_2)^2-m_{\tilde{g}}^2}\right]\sigma_\mu x_2^\dagger \\ & + \big(-g_s f^{eda}\varepsilon_1^\mu\big)\big(g_s f^{ecb}\varepsilon_2^\nu\big)\, y_1 \sigma_\nu \left[\frac{im_{\tilde{g}}}{(k_1-p_2)^2-m_{\tilde{g}}^2}\right]\overline{\sigma}_\mu y_2. \end{aligned} \tag{29.6.3}$$

We choose to work with *real* transverse polarization vectors ε_1, ε_2. These vectors must both be orthogonal to the initial state collision axis in the center-of-momentum frame. Hence,

$$\varepsilon_1\cdot\varepsilon_1 = \varepsilon_2\cdot\varepsilon_2 = -1\,, \tag{29.6.4}$$
$$\varepsilon_1\cdot p_1 = \varepsilon_2\cdot p_1 = \varepsilon_1\cdot p_2 = \varepsilon_2\cdot p_2 = 0, \tag{29.6.5}$$
$$\varepsilon_1\cdot k_2 = -\varepsilon_1\cdot k_1, \tag{29.6.6}$$
$$\varepsilon_2\cdot k_2 = -\varepsilon_2\cdot k_1, \tag{29.6.7}$$

for each choice of λ_1, λ_2. The sums over gluon polarizations will be performed using [cf. eq. (I.2.61)]:

$$\sum_{\lambda_1}\varepsilon_1^\mu\varepsilon_1^\nu = \sum_{\lambda_2}\varepsilon_2^\mu\varepsilon_2^\nu = -g^{\mu\nu} + \frac{2\,(p_1^\mu p_2^\nu + p_2^\mu p_1^\nu)}{s}. \tag{29.6.8}$$

Note that in QCD processes with two or more external gluons, the term $2\,(p_1^\mu p_2^\nu + p_2^\mu p_1^\nu)\,/s$ in eq. (29.6.8) cannot in general be dropped [200]. This is to be contrasted to the photon polarization sum [cf. eq. (29.6.14)], where this latter term can always be neglected (due to a Ward identity of quantum electrodynamics).

Before taking the complex square of the amplitude, it is convenient to rewrite the last two terms in each of eqs. (29.6.2) and (29.6.3) by using the identities [see eq. (29.3.12)]:

$$m_{\tilde{g}} x_1^\dagger = y_1(k_1\cdot\sigma)\,, \qquad\qquad m_{\tilde{g}} y_1 = x_1^\dagger(k_1\cdot\overline{\sigma})\,. \tag{29.6.9}$$

Using eqs. (29.54) and (29.55), the resulting total matrix element is then reduced to a sum of terms that each contain exactly one σ or $\overline{\sigma}$ matrix. We define convenient factors:

$$G_s \equiv g_s^2 f^{abe} f^{cde}/s, \tag{29.6.10}$$
$$G_t \equiv g_s^2 f^{ace} f^{bde}/(t-m_{\tilde{g}}^2), \tag{29.6.11}$$
$$G_u \equiv g_s^2 f^{ade} f^{bce}/(u-m_{\tilde{g}}^2). \tag{29.6.12}$$

where the usual Mandelstam variables are:

$$s = (p_1+p_2)^2 = (k_1+k_2)^2, \tag{29.6.13}$$
$$t = (k_1-p_1)^2 = (k_2-p_2)^2, \tag{29.6.14}$$
$$u = (k_1-p_2)^2 = (k_2-p_1)^2. \tag{29.6.15}$$

Then the total amplitude is (noting that the gluon polarizations $\varepsilon_1, \varepsilon_2$ were chosen real):

$$\mathcal{M} = \mathcal{M}_s + \mathcal{M}_t + \mathcal{M}_u = x_1^\dagger a\cdot\overline{\sigma} y_2 + y_1 a^*\cdot\sigma x_2^\dagger, \tag{29.6.16}$$

where

$$a^\mu \equiv -(G_t+G_s)\varepsilon_1\cdot\varepsilon_2\, p_1^\mu - (G_u-G_s)\varepsilon_1\cdot\varepsilon_2\, p_2^\mu - 2G_t k_1\cdot\varepsilon_1\,\varepsilon_2^\mu - 2G_u k_1\cdot\varepsilon_2\,\varepsilon_1^\mu \\ -i\epsilon^{\mu\nu\rho\kappa}\varepsilon_{1\nu}\varepsilon_{2\rho}(G_t p_1 - G_u p_2)_\kappa. \tag{29.6.17}$$

Squaring the amplitude using eqs. (29.45) and (29.46), we get:

$$|\mathcal{M}|^2 = x_1^\dagger a\cdot\overline{\sigma} y_2 y_2^\dagger a^*\cdot\overline{\sigma} x_1 + y_1 a^*\cdot\sigma x_2^\dagger x_2 a\cdot\sigma y_1^\dagger + x_1^\dagger a\cdot\overline{\sigma} y_2 x_2 a\cdot\sigma y_1^\dagger + y_1 a^*\cdot\sigma x_2^\dagger y_2^\dagger a^*\cdot\overline{\sigma} x_1. \tag{29.6.18}$$

Summing over the gluino spins using eqs. (29.3.57)–(29.3.60), we find:

$$\sum_{\lambda_1',\lambda_2'} |\mathcal{M}|^2 = \mathrm{Tr}[a\cdot\overline{\sigma} k_2\cdot\sigma a^*\cdot\overline{\sigma} k_1\cdot\sigma] + \mathrm{Tr}[a^*\cdot\sigma k_2\cdot\overline{\sigma} a\cdot\sigma k_1\cdot\overline{\sigma}] \\ -m_{\tilde{g}}^2\mathrm{Tr}[a\cdot\overline{\sigma} a\cdot\sigma] - m_{\tilde{g}}^2\mathrm{Tr}[a^*\cdot\sigma a^*\cdot\overline{\sigma}]. \tag{29.6.19}$$

Performing the traces with eqs. (29.56)–(29.58) then yields:

$$\sum_{\lambda_1',\lambda_2'} |\mathcal{M}|^2 = 8\,\mathrm{Re}[a\cdot k_1 a^*\cdot k_2] - 4a\cdot a^*\, k_1\cdot k_2 - 4i\epsilon^{\mu\nu\rho\kappa} k_{1\mu} k_{2\nu} a_\rho a_\kappa^* - 4m_{\tilde{g}}^2\mathrm{Re}[a^2]. \tag{29.6.20}$$

Inserting the explicit form for a^μ [eq. (29.6.17)] into the above result, we obtain:

$$\sum_{\lambda_1',\lambda_2'} |\mathcal{M}|^2 = 2(t-m_{\tilde{g}}^2)(u-m_{\tilde{g}}^2)[(G_t+G_u)^2 + 4(G_s+G_t)(G_s-G_u)(\varepsilon_1\cdot\varepsilon_2)^2] \\ +16(G_t+G_u)[G_s(t-u)+G_t(t-m_{\tilde{g}}^2)+G_u(u-m_{\tilde{g}}^2)](\varepsilon_1\cdot\varepsilon_2)(k_1\cdot\varepsilon_1)(k_1\cdot\varepsilon_2) \\ -32(G_t+G_u)^2(k_1\cdot\varepsilon_1)^2(k_1\cdot\varepsilon_2)^2. \tag{29.6.21}$$

The sums over gluon polarizations can be done using eq. (29.6.8), which implies:

$$\sum_{\lambda_1,\lambda_2} 1 = 4, \qquad \sum_{\lambda_1,\lambda_2} (\varepsilon_1\cdot\varepsilon_2)^2 = 2, \tag{29.6.22}$$

$$\sum_{\lambda_1,\lambda_2} (\varepsilon_1\cdot\varepsilon_2)(k_1\cdot\varepsilon_1)(k_1\cdot\varepsilon_2) = m_{\tilde{g}}^2 - (t-m_{\tilde{g}}^2)(u-m_{\tilde{g}}^2)/s, \tag{29.6.23}$$

$$\sum_{\lambda_1,\lambda_2} (k_1\cdot\varepsilon_1)^2(k_1\cdot\varepsilon_2)^2 = \left(m_{\tilde{g}}^2 - (t-m_{\tilde{g}}^2)(u-m_{\tilde{g}}^2)/s\right)^2. \tag{29.6.24}$$

Summing over colors using $f^{abe}f^{cde}f^{abe'}f^{cde'} = 2f^{abe}f^{cde}f^{ace'}f^{bde'} = N_c^2(N_c^2-1) = 72$,

$$\sum_{\text{colors}} G_s^2 = \frac{72g_s^4}{s^2}, \qquad \sum_{\text{colors}} G_t^2 = \frac{72g_s^4}{(t-m_{\tilde{g}}^2)^2}, \tag{29.6.25}$$

$$\sum_{\text{colors}} G_u^2 = \frac{72g_s^4}{(u-m_{\tilde{g}}^2)^2}, \qquad \sum_{\text{colors}} G_sG_t = \frac{36g_s^4}{s(t-m_{\tilde{g}}^2)}, \tag{29.6.26}$$

$$\sum_{\text{colors}} G_sG_u = -\frac{36g_s^4}{s(u-m_{\tilde{g}}^2)}, \qquad \sum_{\text{colors}} G_tG_u = \frac{36g_s^4}{(t-m_{\tilde{g}}^2)(u-m_{\tilde{g}}^2)}. \tag{29.6.27}$$

Putting all the factors together, and averaging over the initial state colors and spins, we have:

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}\left(\frac{1}{64}\sum_{\text{colors}}\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2\right) \\ = \frac{9\pi\alpha_s^2}{4s^4}\left[2(t-m_{\tilde{g}}^2)(u-m_{\tilde{g}}^2) - 3s^2 - 4m_{\tilde{g}}^2 s + \frac{s^2(s+2m_{\tilde{g}}^2)^2}{(t-m_{\tilde{g}}^2)(u-m_{\tilde{g}}^2)} - \frac{4m_{\tilde{g}}^4 s^4}{(t-m_{\tilde{g}}^2)^2(u-m_{\tilde{g}}^2)^2}\right], \tag{29.6.28}$$

which agrees with the result of [201, 180] (after some rearrangement). Note that in the center-of-momentum frame, the Mandelstam variable t is related to the scattering angle θ between an initial state gluon and a final state gluino by:

$$t = m_{\tilde{g}}^2 + \frac{s}{2}\left(\cos\theta\sqrt{1-4m_{\tilde{g}}^2/s} - 1\right). \tag{29.6.29}$$

Since the final state has identical particles, the total cross-section can now be obtained by:

$$\sigma = \frac{1}{2}\int_{t_-}^{t_+} \frac{d\sigma}{dt} dt\,, \tag{29.6.30}$$

where $t_\pm$ are obtained by inserting $\cos\theta = \pm 1$ into eq. (29.6.29).

29.6.20 R-parity violating stau decay: $\widetilde{\tau}_R^+ \to e^+\bar{\nu}_\mu$

In an R-parity-violating extension of the MSSM (denoted henceforth by RPV-MSSM), new Yukawa couplings can arise [see eqs. (L.1)–(L.3)] that violate either a global U(1) lepton number L or baryon number B. The corresponding Feynman rules are derived in Appendix L . Consider the decay of a right-handed scalar tau via an L-violating $LL\bar{e}$ coupling governed by eq. (L.1). This is particularly relevant when the scalar tau is the lightest supersymmetric particle (LSP) [202, 203] and in the case of resonant slepton production [204, 205]. Note that in R-parity violation the LSP need not be the lightest neutralino and in a minimal supergravity embedding often it is not [206, 207]. The Feynman diagram is shown in Fig. **??**, where we have also defined the momenta and the helicities of the fermions.

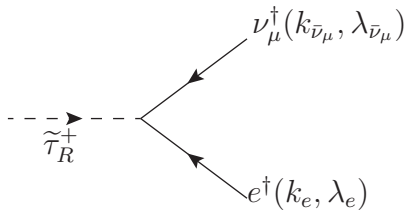

Figure 29.6.1: Feynman diagram for the R-parity-violating decay $\widetilde{\tau}_R^+ \to e^+\bar{\nu}_\mu$

The amplitude for the R-parity-violating $\tilde{\tau}_R^+$ decay is given by:

$$i\mathcal{M} = -i\lambda y_e y_{\bar{\nu}_\mu}\,. \tag{29.6.1}$$

Here we have defined $\lambda \equiv \lambda_{123}$, and the external wave functions are denoted by $y_e \equiv y(\vec{\boldsymbol{k}}_e, \lambda_e)$, and $y_{\bar{\nu}_\mu} \equiv y(\vec{\boldsymbol{k}}_{\bar{\nu}_\mu}, \lambda_{\bar{\nu}_\mu})$, respectively. Using eq. (29.44), the amplitude squared is

$$|\mathcal{M}|^2 = |\lambda|^2 y_e y_{\bar{\nu}_\mu} y_{\bar{\nu}_\mu}^\dagger y_e^\dagger. \tag{29.6.2}$$

Summing over the fermion spins using eq. (29.3.58) gives:

$$\sum_{\lambda_e, \lambda_{\bar{\nu}_\mu}} |\mathcal{M}|^2 = |\lambda|^2 \mathrm{Tr}[k_e\cdot\sigma\, k_{\bar{\nu}_\mu}\cdot\overline{\sigma}] = |\lambda|^2 m_{\tilde{\tau}_R}^2\,, \tag{29.6.3}$$

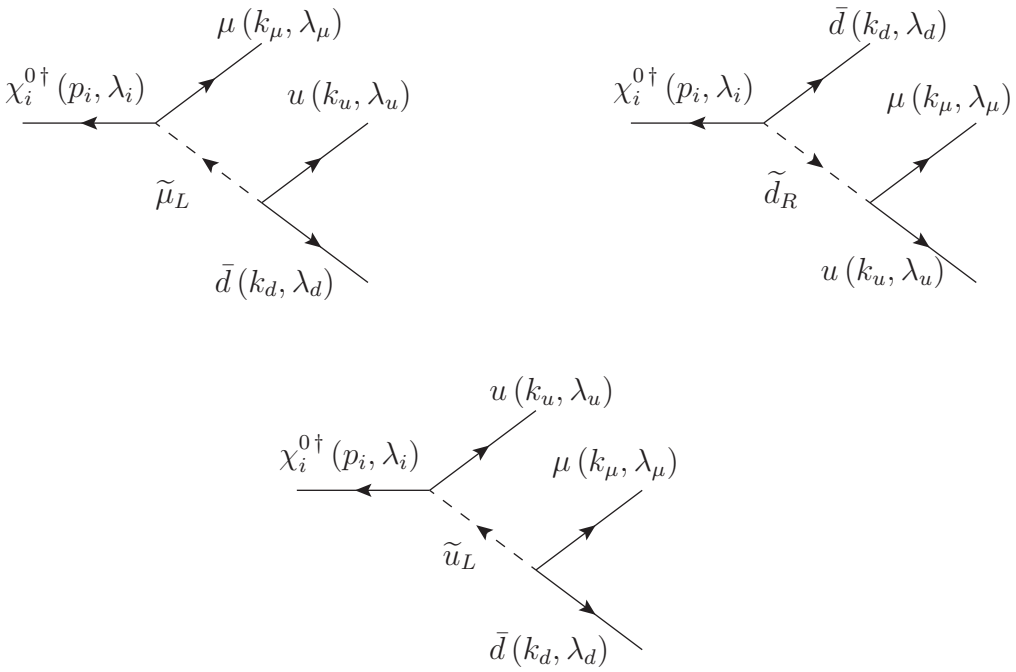

Figure 29.6.1: Feynman diagrams for the R-parity violating decay $\widetilde{N}_i \to \mu^- u \bar{d}$.

where in the last step we have used the trace formula eq. (29.56), and neglected the mass of the electron and the neutrino. The total decay rate is then given by

$$\Gamma = \frac{1}{16\pi m_{\tilde{\tau}_R}} \left(\sum_{\lambda_e, \lambda_{\bar{\nu}_\mu}} |\mathcal{M}|^2 \right) = \frac{|\lambda|^2}{16\pi} m_{\tilde{\tau}_R} \,, \tag{29.6.4}$$

which agrees with the computation in refs. [208, 209, 210]. Completely analogously we can obtain the total rate for the decays $\widetilde{\nu}_\mu \to \tau^- e^+$ and $\widetilde{e}_L^- \to \tau^- \bar{\nu}_\mu$, which proceed via the same operator, by replacing $m_{\tilde{\tau}_R} \to (m_{\tilde{e}_L}, m_{\tilde{\nu}_\mu})$, respectively.

In general the two-body decay rate of a sfermion $\widetilde{f}$ via the L-violating $LQ\bar{d}$ coupling governed by eq. (L.2) or the B-violating $\bar{u}\bar{d}\bar{d}$ coupling governed by eq. (L.3) is given by:

$$\Gamma(\tilde{f} \to f_1 f_2) = \frac{C|\lambda|^2}{16\pi} m_{\tilde{f}} \,, \tag{29.6.5}$$

where we have neglected the masses $m_{1,2}$ of the final state fermions. The factor C denotes the color factor. For the slepton decays via the $LQ\bar{d}$ coupling which are summed over the final state quark colors, $C = \delta^{ij}\delta_{ij} = 3$, where $i, j = 1, 2, 3$ and δ_{ij} is the symmetric invariant tensor of color SU(3). For the squark decays via the $LQ\bar{d}$ where the initial state color is averaged over and the final state color is summed, $C = 1$. For the squark decays via the $\bar{u}\bar{d}\bar{d}$ coupling, $C = \frac{1}{3}\epsilon^{ijk}\epsilon_{ijk} = 2$, where the Levi-Civita tensor, $\epsilon^{ijk} = \epsilon_{ijk}$, is the antisymmetric invariant tensor of color SU(3). In realistic cases, one must also include the effects of mixing for the third-family sfermions, which we have omitted here for simplicity.

29.6.21 R-parity-violating neutralino decay: $\widetilde{N}_i \to \mu^- u \bar{d}$

Next we consider the R-parity-violating three-body decay of a neutralino $\widetilde{N}_i \to \mu^- u \bar{d}$, which arises due to the L-violating $LQ\bar{d}$ coupling governed by eq. (L.2). This is of particular interest

when the neutralino is the LSP, since it determines the final state signatures [211, 212, 213]. The three Feynman diagrams are shown in Fig. 29.6.1, including the definitions of the momenta and helicities. We have neglected sfermion mixing, i.e. we assume $\widetilde{\mu}_L$, $\widetilde{u}_L$, and $\widetilde{d}_R$ are mass eigenstates. Using the Feynman rules given in Figs. L.2 and K.4.2 (or K.4.4), we obtain the corresponding contributions to the decay amplitude,

$$i\mathcal{M}_1 = (i\lambda'^*)\left[\frac{i}{\sqrt{2}}(gN_{i2} + g'N_{i1})\right]\left[\frac{i}{(p_i - k_\mu)^2 - m^2_{\tilde{\mu}_L}}\right] y_i^\dagger x_\mu^\dagger x_u^\dagger x_d^\dagger\,, \tag{29.6.1}$$

$$i\mathcal{M}_2 = (i\lambda'^*)\left[-\frac{i\sqrt{2}}{3}g'N_{i1}\right]\left[\frac{i}{(p_i - k_d)^2 - m^2_{\tilde{d}_R}}\right] y_i^\dagger x_d^\dagger x_\mu^\dagger x_u^\dagger\,, \tag{29.6.2}$$

$$i\mathcal{M}_3 = (i\lambda'^*)\left[-\frac{i}{\sqrt{2}}(gN_{i2} + g'N_{i1}/3)\right]\left[\frac{i}{(p_i - k_u)^2 - m^2_{\tilde{u}_L}}\right] y_i^\dagger x_u^\dagger x_d^\dagger x_\mu^\dagger\,. \tag{29.6.3}$$

Here we have defined $\lambda' \equiv \lambda'_{211}$, and the external wave functions are denoted by $y_i^\dagger \equiv y^\dagger(\vec{\boldsymbol{p}}_i, \lambda_i)$, $x_\mu^\dagger \equiv x^\dagger(\vec{\boldsymbol{k}}_\mu, \lambda_\mu)$, $x_u^\dagger \equiv x^\dagger(\vec{\boldsymbol{k}}_u, \lambda_u)$, and $x_d^\dagger \equiv x^\dagger(\vec{\boldsymbol{k}}_d, \lambda_d)$, respectively. In the following, we will neglect all of the final state fermion masses. The results will be expressed in terms of the kinematic variables

$$z_\mu \equiv 2p_i{\cdot}k_\mu/m^2_{\tilde{N}_i} = 2E_\mu/m_{\tilde{N}_i}, \tag{29.6.4}$$

$$z_d \equiv 2p_i{\cdot}k_d/m^2_{\tilde{N}_i} = 2E_d/m_{\tilde{N}_i}, \tag{29.6.5}$$

$$z_u \equiv 2p_i{\cdot}k_u/m^2_{\tilde{N}_i} = 2E_u/m_{\tilde{N}_i}, \tag{29.6.6}$$

which satisfy $z_\mu + z_d + z_u = 2$. Then we can rewrite the total matrix element as:

$$\mathcal{M} = c_1 y_i^\dagger x_\mu^\dagger x_u^\dagger x_d^\dagger + c_2 y_i^\dagger x_d^\dagger x_\mu^\dagger x_u^\dagger + c_3 y_i^\dagger x_u^\dagger x_d^\dagger x_\mu^\dagger\,, \tag{29.6.7}$$

where

$$c_1 \equiv \frac{1}{\sqrt{2}}\lambda'^*(gN_{i2} + g'N_{i1})/[m^2_{\tilde{\mu}_L} - m^2_{\tilde{N}_i}(1 - z_\mu)], \tag{29.6.8}$$

$$c_2 \equiv -\frac{\sqrt{2}}{3}\lambda'^* g'N_{i1}/[m^2_{\tilde{d}_R} - m^2_{\tilde{N}_i}(1 - z_d)], \tag{29.6.9}$$

$$c_3 \equiv -\frac{1}{\sqrt{2}}\lambda'^*(gN_{i2} + g'N_{i1}/3)/[m^2_{\tilde{u}_L} - m^2_{\tilde{N}_i}(1 - z_u)]. \tag{29.6.10}$$

Before squaring the amplitude, it is convenient to use the Fierz identity [eq. (29.67)] to reduce the number of terms:

$$\mathcal{M} = (c_1 - c_3) y_i^\dagger x_\mu^\dagger x_u^\dagger x_d^\dagger + (c_2 - c_3) y_i^\dagger x_d^\dagger x_\mu^\dagger x_u^\dagger. \tag{29.6.11}$$

Using eq. (29.44), we obtain

$$\begin{aligned}|\mathcal{M}|^2 = {}& |c_1 - c_3|^2 y_i^\dagger x_\mu^\dagger x_\mu y_i x_u^\dagger x_d^\dagger x_d x_u + |c_2 - c_3|^2 y_i^\dagger x_d^\dagger x_d y_i x_\mu^\dagger x_u^\dagger x_u x_\mu \\ & -2\mathrm{Re}[(c_1 - c_3)(c_2^* - c_3^*) y_i^\dagger x_\mu^\dagger x_\mu x_u x_u^\dagger x_d^\dagger x_d y_i]\,,\end{aligned} \tag{29.6.12}$$

where eq. (29.60) was used on the last term. Summing over the fermion spins using eqs. (29.3.57)–(29.3.60), we obtain:

$$\begin{aligned}\sum_{\text{spins}} |\mathcal{M}|^2 = {}& |c_1 - c_3|^2 \mathrm{Tr}[k_\mu{\cdot}\overline{\sigma} p_i{\cdot}\sigma]\mathrm{Tr}[k_d{\cdot}\overline{\sigma} k_u{\cdot}\sigma] + |c_2 - c_3|^2 \mathrm{Tr}[k_d{\cdot}\overline{\sigma} p_i{\cdot}\sigma]\mathrm{Tr}[k_u{\cdot}\overline{\sigma} k_\mu{\cdot}\sigma] \\ & -2\mathrm{Re}\big[(c_1 - c_3)(c_2^* - c_3^*)\mathrm{Tr}[k_\mu{\cdot}\overline{\sigma} k_u{\cdot}\sigma k_d{\cdot}\overline{\sigma} p_i{\cdot}\sigma]\big]\,.\end{aligned} \tag{29.6.13}$$

Applying the trace formulae, eqs. (29.56) and (29.58), we obtain

$$\begin{aligned}\sum_{\text{spins}}|\mathcal{M}|^2 &= 4|c_1-c_3|^2 p_i{\cdot}k_\mu\, k_d{\cdot}k_u + 4|c_2-c_3|^2 p_i{\cdot}k_d\, k_\mu{\cdot}k_u \\ &\quad -4\text{Re}\big[(c_1-c_3)(c_2^*-c_3^*)\big](k_\mu{\cdot}k_u\, p_i{\cdot}k_d + p_i{\cdot}k_\mu\, k_d{\cdot}k_u - k_\mu{\cdot}k_d\, p_i{\cdot}k_u) \\ &= m_{\tilde{N}_i}^4\Big[|c_1|^2 z_\mu(1-z_\mu) + |c_2|^2 z_d(1-z_d) + |c_3|^2 z_u(1-z_u) \\ &\quad -2\text{Re}[c_1c_2^*](1-z_\mu)(1-z_d) - 2\text{Re}[c_1c_3^*](1-z_\mu)(1-z_u) \\ &\quad -2\text{Re}[c_2c_3^*](1-z_d)(1-z_u)\Big]\,, \end{aligned} \tag{29.6.14}$$

where in the last equality we have used eqs. (29.6.4)–(29.6.6) and

$$2k_\mu{\cdot}k_d = (1-z_u)m_{\tilde{N}_i}^2, \qquad 2k_\mu{\cdot}k_u = (1-z_d)m_{\tilde{N}_i}^2, \qquad 2k_d{\cdot}k_u = (1-z_\mu)m_{\tilde{N}_i}^2. \tag{29.6.15}$$

The differential decay rate follows:

$$\frac{d^2\Gamma}{dz_\mu dz_d} = \frac{N_c m_{\tilde{N}_i}}{2^8\pi^3}\left(\frac{1}{2}\sum_{\text{spins}}|\mathcal{M}|^2\right), \tag{29.6.16}$$

where a factor of $N_c = 3$ has been included for the sum over colors, a factor of $1/2$ to average over the neutralino spin, and the kinematic limits are

$$0 < z_\mu < 1, \tag{29.6.17}$$
$$1 - z_\mu < z_d < 1. \tag{29.6.18}$$

In the limit of heavy sfermions, the integrations over z_d and then z_μ are simple, with the result for the total decay width:

$$\Gamma = \frac{N_c m_{\tilde{N}_i}^5}{2^{11}\cdot 3\pi^3}\left(|c_1'|^2 + |c_2'|^2 + |c_3'|^2 - \text{Re}[c_1'c_2'^* + c_1'c_3'^* + c_2'c_3'^*]\right), \tag{29.6.19}$$

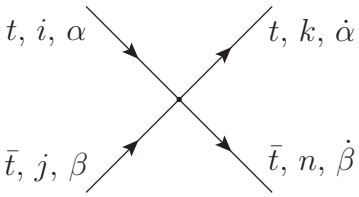
where the c_i' are obtained from c_i of eqs. (29.6.8)–(29.6.10) by neglecting $m_{\tilde{N}_i}^2$ in the denominators. Our results agree with the complete computation (which includes mixing) given in refs. [214, 209, 210]. Earlier calculations with some simplifications are given in refs. [212, 215].

29.6.22 Top-quark condensation from a Nambu-Jona-Lasinio model gap equation

The previous examples have involved renormalizable field theories. However, there are cases in which it is preferable to use effective four-fermion interactions. The obvious historical example is the four-fermion Fermi theory of weak decays. This has been superseded by a more complete and accurate theory of the weak interactions but is still useful for leading order calculations of low-energy processes. Another case of some interest is the use of strong coupling four-fermion interactions to drive symmetry breaking via a Nambu-Jona-Lasinio model [216], as in the top quark condensate approach [217, 218, 219, 220, 221] to electroweak symmetry breaking.

Consider an effective four-fermion Lagrangian involving the top quark [219], written in two-component fermion form as:

$$\mathscr{L} = it^\dagger\overline{\sigma}^\mu\partial_\mu t + i\bar{t}^\dagger\overline{\sigma}^\mu\partial_\mu\bar{t} + \frac{G}{\Lambda^2}(t\bar{t})(t^\dagger\bar{t}^\dagger). \tag{29.6.1}$$



$$i\frac{G}{\Lambda^2}\delta_i^j\delta_n^k\delta_\alpha^\beta\delta_{\dot\alpha}^{\dot\beta}$$

Figure 29.6.1: Feynman rule for the four-fermion interaction in the top quark condensate model. The indices $i, j, k, n = 1, 2, 3$ are for color in the fundamental representation of $SU(3)$, and the indices $\alpha, \beta, \dot\alpha, \dot\beta$ are two-component spinor indices.

Here the Standard Model gauge interactions have been suppressed; the quantities within parentheses are color singlets. Note also that there is no top quark Yukawa coupling to a Higgs scalar boson, nor a top quark mass term, which would normally appear in the form $-m_t(t\bar t + t^\dagger \bar t^\dagger)$. Instead, the effective top quark mass is supposed to be driven by a non-perturbatively large and positive dimensionless coupling G, with Λ the cutoff scale at which G arises from some more fundamental physics such as topcolor [221].

The Feynman rule for the four-fermion interaction can be derived from the mode expansion results of Section 29.3, and is given in Fig. 29.6.1. The resulting gap equation for the dynamically generated top quark mass is shown in Fig. 29.6.2.

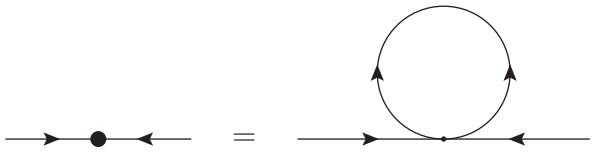


Figure 29.6.2: The Nambu-Jona-Lasinio gap equation for a possible dynamically generated top quark mass m_t.

Evaluating this using the Feynman rules of Figs. 29.4.3 and 29.4.4, one finds:

$$-im_t\delta_i^j\delta_\alpha^\beta = (-1)\int^\Lambda \frac{d^4k}{(2\pi)^4}\left(i\frac{G}{\Lambda^2}\delta_i^j\delta_n^k\delta_\alpha^\beta\delta_{\dot\alpha}^{\dot\beta}\right)\left(\delta_k^n\delta_{\dot\beta}^{\dot\alpha}\frac{im_t}{k^2-m_t^2+i\epsilon}\right). \tag{29.6.2}$$

Here i, j, k, n are color indices of the fundamental representation of $SU(3)$, and $\alpha, \beta, \dot\alpha, \dot\beta$ are two-component spinor indices. The factor of (-1) on the right-hand side is due to the presence of a fermion loop.

Euclideanizing the loop integration over k^μ by $k^2 \to -k_E^2$ and $\int d^4k \to i\int d^4k_E$, and then rewriting the integration in terms of $x = k_E^2$, this amounts to [219]:

$$m_t = \frac{2N_cGm_t}{16\pi^2\Lambda^2}\int_0^{\Lambda^2} dx/(1+m_t^2/x) = \frac{3Gm_t}{8\pi^2}[1-(m_t^2/\Lambda^2)\ln(\Lambda^2/m_t^2)+\ldots], \tag{29.6.3}$$

where $N_c = 3$ is the number of colors, and a factor of two arises from the sum over dotted spinor indices of $\delta_{\dot\alpha}^{\dot\beta}\delta_{\dot\beta}^{\dot\alpha}$.

For small or negative G, only the trivial solution $m_t = 0$ is possible. However, for $G \geq G_{\rm critical} = 8\pi^2/3 \approx 26$, there is a positive solution for m_t^2/Λ^2 [219]. It is now known that this minimal version of the model cannot explain the top quark mass and the observed features of electroweak symmetry breaking, but extensions of it may be viable [222].

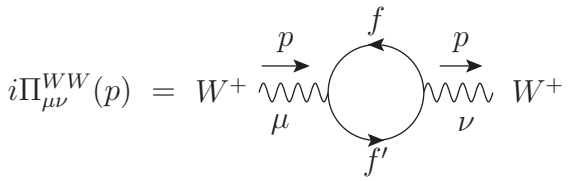

Figure 29.6.1: Contributions to the self-energy function for the W boson in the Standard Model, from loops involving the left-handed quark and lepton pairs $(f, f') = (e, \nu_e)$, (μ, ν_μ), (τ, ν_τ), (d, u), (s, c), and (b, t). The momentum of the positively charged W^+ flows from left to right.

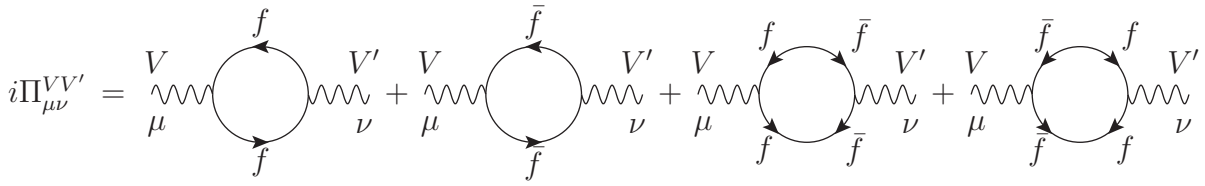

Figure 29.6.2: Contributions to the diagonal and off-diagonal self-energy functions for the neutral vector bosons $V, V' = \gamma, Z$ in the Standard Model, from loops involving the three generations of leptons and quarks: $f = e, \nu_e, \mu, \nu_\mu, \tau, \nu_\tau, d, u, s, c, b, t$.

29.6.23 Electroweak vector boson self-energies from fermion loops

In this subsection, we consider the contributions to the self-energy functions of the Standard Model electroweak vector bosons coming from quark and lepton loops. (For a derivation of equivalent results in the four-component fermion formalism, see for example Section 21.3 of [115].) The independent self-energies are given by $\Pi^{WW}_{\mu\nu}$, $\Pi^{ZZ}_{\mu\nu}$, $\Pi^{\gamma Z}_{\mu\nu} = \Pi^{Z\gamma}_{\mu\nu}$, and $\Pi^{\gamma\gamma}_{\mu\nu}$, as shown in Figs. 29.6.1 and 29.6.2. In each case, $i\Pi_{\mu\nu}$ is equal to the sum of Feynman diagrams for two-point functions with amputated external legs, and is implicitly a function of the external momentum p^μ.

First consider the self-energy function for the W boson, shown in Fig. 29.6.1. The W boson only couples to left-handed fermions, so there is only one Feynman diagram for each Standard model weak isodoublet. Taking the external momentum flowing from left to right to be p, and the loop momentum flowing counterclockwise in the upper fermion line (f) to be k, we have from the Feynman rules of Fig. J.1.2:

$$i\Pi^{WW}_{\mu\nu} = (-1)\,\mu^{2\epsilon} \int \frac{d^d k}{(2\pi)^d} \sum_{(f,f')} N_c^f \mathrm{Tr}\left[\left(-i\frac{g}{\sqrt{2}}\overline{\sigma}_\mu\right)\left(\frac{ik\cdot\sigma}{k^2 - m_f^2}\right)\left(-i\frac{g}{\sqrt{2}}\overline{\sigma}_\nu\right)\left(\frac{i(k+p)\cdot\sigma}{(k+p)^2 - m_{f'}^2}\right)\right]. \tag{29.6.1}$$

Here μ is a regularization scale for dimensional regularization in $d \equiv 4 - 2\epsilon$ dimensions. The sum in eq. (29.6.1) is over the six isodoublet pairs $(f, f') = (e, \nu_e)$, (μ, ν_μ), (τ, ν_τ), (d, u), (s, c), and (b, t) with CKM mixing neglected, and

$$N_c^f = \begin{cases} 3\,, & f = \text{quarks}\,, \\ 1\,, & f = \text{leptons}\,. \end{cases} \tag{29.6.2}$$

The first factor of (-1) in eq. (29.6.1) is due to the presence of a closed fermion loop. The trace is taken over the two-component dotted spinor indices. Using eq. (B.2.27), it follows that

$$\Pi^{WW}_{\mu\nu} = \frac{g^2}{32\pi^2} \sum_f N_c^f I_{\mu\nu}(m_f^2, m_{f'}^2)\,, \tag{29.6.3}$$

where we have defined

$$I_{\mu\nu}(x,y) = i(16\pi^2)\,\mu^{2\epsilon}\int \frac{d^dk}{(2\pi)^d}\,\frac{4k_\mu k_\nu + 2k_\mu p_\nu + 2k_\nu p_\mu - 2k\cdot(k+p)\,g_{\mu\nu}}{(k^2-x)[(k+p)^2-y]}\,. \tag{29.6.4}$$

We do not explicitly exhibit above the term proportional to $\epsilon_{\mu\nu\alpha\beta}$, as it integrates to zero. The integral $I_{\mu\nu}$ can be evaluated by the standard dimensional regularization methods [115, 223],

$$I_{\mu\nu}(x,y) = (p^2 g_{\mu\nu} - p_\mu p_\nu) I_1(p^2;x,y) + g_{\mu\nu} I_2(p^2;x,y)\,, \tag{29.6.5}$$

where

$$I_1(s;x,y) = -\frac{2}{3\epsilon} + \frac{2}{3s^2}\Big\{(2x-2y-s)A(x) + (2y-2x-s)A(y) + \Big[2(x-y)^2 - s(x+y) - s^2\Big]B(s;x,y) - s(x+y) + s^2/3\Big\}, \tag{29.6.6}$$

$$I_2(s;x,y) = \frac{x+y}{\epsilon} - \frac{1}{s}\Big\{(x-y)\big[A(x)-A(y)\big] + \Big[(x-y)^2 - s(x+y)\Big]B(s;x,y)\Big\}\,, \tag{29.6.7}$$

after neglecting terms that vanish as $\epsilon \to 0$. The functions

$$A(x) \equiv x\ln(x/Q^2) - x, \tag{29.6.8}$$

$$B(s;x,y) \equiv -\int_0^1 dt\,\ln\left(\frac{tx + (1-t)y - t(1-t)s - i\varepsilon}{Q^2}\right), \tag{29.6.9}$$

are the finite parts of one-loop Passarino-Veltman functions [224], with the renormalization scale Q related to the regularization scale μ by the modified minimal subtraction relation

$$\mu^2 = Q^2 e^\gamma/4\pi, \tag{29.6.10}$$

where $\gamma = 0.577216\ldots$ is Euler's constant.

The photon and Z boson have mixed self-energy functions, defined in Fig. 29.6.2. Applying the pertinent Feynman rules from Fig. J.1.2, we obtain:

$$\begin{aligned} i\Pi^{VV'}_{\mu\nu} \;=\; (-1)\mu^{2\epsilon}\int \frac{d^dk}{(2\pi)^d}\sum_f N_c^f \mathrm{Tr}\Big\{ &\big(-iG_V^f\overline{\sigma}_\mu\big)\left(\frac{ik\cdot\sigma}{k^2-m_f^2}\right)\big(-iG_{V'}^f\overline{\sigma}_\nu\big)\left(\frac{i(k+p)\cdot\sigma}{(k+p)^2-m_f^2}\right) \\ &+\big(-iG_V^{\bar f}\overline{\sigma}_\mu\big)\left(\frac{ik\cdot\sigma}{k^2-m_f^2}\right)\big(-iG_{V'}^{\bar f}\overline{\sigma}_\nu\big)\left(\frac{i(k+p)\cdot\sigma}{(k+p)^2-m_f^2}\right) \\ &+\big(-iG_V^f\overline{\sigma}_\mu\big)\left(\frac{im_f}{k^2-m_f^2}\right)\big(iG_{V'}^{\bar f}\sigma_\nu\big)\left(\frac{im_f}{(k+p)^2-m_f^2}\right) \\ &+\big(-iG_V^{\bar f}\overline{\sigma}_\mu\big)\left(\frac{im_f}{k^2-m_f^2}\right)\big(iG_{V'}^{f}\sigma_\nu\big)\left(\frac{im_f}{(k+p)^2-m_f^2}\right)\Big\}, \end{aligned} \tag{29.6.11}$$

where V and V' can each be either γ or Z, and $\sum_f$ is taken over the 12 Standard Model fermions. The corresponding Vff and $V\bar f\bar f$ couplings are:[73]

$$G_\gamma^f = -G_\gamma^{\bar f} = eQ_f, \tag{29.6.12}$$

$$G_Z^f = \frac{g}{c_W}(T_3^f - s_W^2 Q_f), \qquad G_Z^{\bar f} = \frac{g}{c_W}s_W^2 Q_f. \tag{29.6.13}$$

[73] Note that there is no contribution from the left-handed two-component antineutrino fields, $\bar\nu_e$, $\bar\nu_\mu$, $\bar\nu_\tau$, which do not exist in the Standard Model.

The four terms in eq. (29.6.11) correspond to the four diagrams in Fig. 29.6.2, in the same order.

The first two terms in eq. (29.6.11) are computed exactly as for $\Pi^{WW}_{\mu\nu}$, while in the last two terms we use eq. (B.2.5) to compute the trace. It follows that the neutral electroweak vector boson self-energy function matrix, after dropping terms that vanish as $\epsilon \to 0$, is given by

$$\Pi^{VV'}_{\mu\nu} = \frac{1}{16\pi^2}\sum_f N_c^f \Big[(G_V^f G_{V'}^f + G_V^{\bar f} G_{V'}^{\bar f}) I_{\mu\nu}(m_f^2, m_f^2) + g_{\mu\nu}(G_V^f G_{V'}^{\bar f} + G_V^{\bar f} G_{V'}^f) m_f^2 I_3(m_f^2, m_f^2)\Big], \tag{29.6.14}$$

where $I_{\mu\nu}(x,y)$ was defined in eqs. (29.6.5)–(29.6.7), and we have defined the function

$$I_3(x,y) = -i(16\pi^2)\,\mu^{2\epsilon}\int \frac{d^dk}{(2\pi)^d}\,\frac{2}{(k^2-x)[(k+p)^2-y]} = \frac{2}{\epsilon} + 2B(p^2;x,y). \tag{29.6.15}$$

The photon self-energy function is a simple special case of eq. (29.6.14):

$$\Pi^{\gamma\gamma}_{\mu\nu} = \frac{1}{16\pi^2}\sum_f 2N_c^f (eQ_f)^2 \big[I_{\mu\nu}(m_f^2, m_f^2) - g_{\mu\nu} m_f^2 I_3(m_f^2, m_f^2)\big]\,. \tag{29.6.16}$$

Evaluating the integrals $I_{\mu\nu}$ and I_3 yields

$$\Pi^{\gamma\gamma}_{\mu\nu} = \frac{\alpha}{3\pi}\sum_f N_c^f Q_f^2 \left(p^2 g_{\mu\nu} - p_\mu p_\nu\right)\left\{-\frac{1}{\epsilon} + \frac{1}{3} - \frac{2}{p^2}\left[A(m_f^2) + m_f^2\right] - \left(1 + \frac{2m_f^2}{p^2}\right) B(p^2; m_f^2, m_f^2)\right\}, \tag{29.6.17}$$

in agreement with the result given in, for example, eq. (7.90) of [115]. This formula satisfies $p^\mu \Pi^{\gamma\gamma}_{\mu\nu} = p^\nu \Pi^{\gamma\gamma}_{\mu\nu} = 0$ as required by the Ward identity of QED, and is regular in the limit $p^2 \to 0$.

In each of eqs. (29.6.3), (29.6.14), and (29.6.17), there are $1/\epsilon$ poles, contained in the loop integral functions. In the $\overline{\rm MS}$ renormalization scheme, these poles are simply removed by counterterms, which have no other effect.

In eqs. (29.6.1) and (29.6.11), we chose to write a $\overline{\sigma}_\mu$ for the left vertex in the Feynman diagram in each case. This is an arbitrary choice; we could also have chosen to use instead $-\sigma_\mu$ for the left vertex in any given diagram, as mentioned in the caption for Fig. J.1.2. This would have dictated the replacements $\overline{\sigma} \leftrightarrow -\sigma$ throughout the expression for the diagram, including for the fermion propagators, as was indicated in Fig. 29.4.4. It is not hard to check that the result after computing the spinor index traces is unaffected. Note that the contribution proportional to $\epsilon_{\mu\nu\rho\kappa}$ from eq. (B.2.26) or eq. (B.2.27) vanishes; this is clear because the self-energy function is symmetric under interchange of vector indices, and there is only one independent momentum in the problem.

29.6.24 Self-energy and pole mass of the top quark

We next consider the one-loop calculation of the self-energy and the pole mass of the top quark in the Standard Model, including the effects of the gauge interactions and the top and bottom quark Yukawa couplings. As in Section 29.6.1, we treat this as a one-generation problem, neglecting CKM mixing. Consequently, the corresponding Yukawa couplings Y_t and Y_b are real and positive (by a suitable phase redefinition of the Higgs field[74]). Using the formalism of Section 29.4.6 for Dirac fermions, the independent 1PI self-energy functions are given by[75] Σ_{Lt}, Σ_{Rt} and Σ_{Dt} (defined in Fig. 29.4.5) as shown in Fig. 29.6.1.

[74] As shown in Section 29.3.2, after the fermion mass matrix diagonalization procedure, the tree-level fermion masses are real and non-negative. If CKM mixing is neglected, it follows from eq. (J.1.9) that the corresponding diagonal Yukawa couplings are real and positive if the phase of the Higgs field is chosen such that the neutral Higgs vacuum expectation value $v > 0$.

[75] Since the Yukawa couplings can be chosen real (in the one-generation model), $\overline{\Sigma}_{Lt} = \Sigma_{Lt}$. Note that after suppressing the color degrees of freedom, Σ_{Lt}, Σ_{Rt} and Σ_{Dt} are one-dimensional matrices, so we do not employ boldface letters in this case.

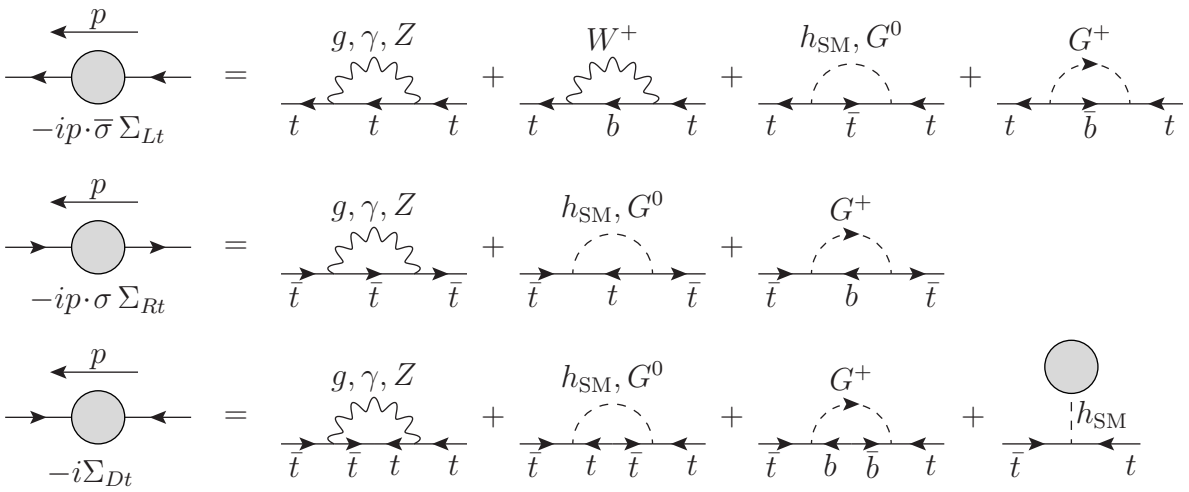

Figure 29.6.1: One-loop contributions to the 1PI self-energy functions for the top quark in the Standard Model. The external momentum of the physical top quark, p^μ, flows from the right to the left. The loop momentum k^μ in the text is taken to flow clockwise. Spinor and color indices are suppressed. The external legs are amputated. The last diagram contains one-loop tadpole contributions.

Note that in these diagrams, the physical top quark moves from right to left, carrying momentum p^μ. Then according to the general formula obtained in eq. (29.4.32), the complex pole squared mass of the top quark is given by:

$$M_t^2 - i\Gamma_t M_t = \frac{(m_t + \Sigma_{Dt})^2}{(1 - \Sigma_{Lt})(1 - \Sigma_{Rt})}\,, \tag{29.6.1}$$

where m_t is the tree-level mass. Working consistently to one-loop order, this yields[76]

$$M_t^2 - i\Gamma_t M_t = \left[m_t^2(1 + \Sigma_{Lt} + \Sigma_{Rt}) + 2m_t\Sigma_{Dt}\right]\Big|_{s=m_t^2+i\varepsilon}. \tag{29.6.2}$$

It remains to calculate the self-energy functions Σ_{Lt}, Σ_{Rt} and Σ_{Dt}. Two regularization procedures will be used simultaneously—the $\overline{\rm MS}$ scheme [225] based on dimensional regularization [125] and the $\overline{\rm DR}$ scheme based on dimensional reduction [226]. This is accomplished by integrating over the loop momentum in

$$d \equiv 4 - 2\epsilon \tag{29.6.3}$$

dimensions, but with the vector bosons possessing

$$D \equiv 4 - 2\epsilon\delta_{\overline{\rm MS}} \tag{29.6.4}$$

components, where

$$\delta_{\overline{\rm MS}} \equiv \begin{cases} 1 & \text{for } \overline{\rm MS}\,, \\ 0 & \text{for } \overline{\rm DR}\,. \end{cases} \tag{29.6.5}$$

In other words, the metric $g^{\mu\nu}$ appearing explicitly in the vector propagator is treated as four dimensional in $\overline{\rm DR}$, but as d-dimensional in $\overline{\rm MS}$. The renormalization scale Q is related to the regularization scale μ in both cases by the modified minimal subtraction relation of eq. (29.6.10).

[76] It would be just as valid to substitute in $s = M_t^2 + i\varepsilon$ here, as two-loop order effects are being neglected.

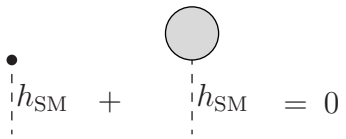

Figure 29.6.2: The tree-level Higgs tadpole cancels against the one-loop Higgs tadpole, provided that one expands around a Higgs vacuum expectation value that minimizes the one-loop effective potential (rather than the tree-level Higgs potential, which would yield no tree-level tadpole).

The calculation of the non-tadpole contributions to the self-energy functions will be performed below in a general R_ξ gauge, with a vector boson propagator as in Fig. 29.4.5. There are different ways to treat the tadpole contributions, corresponding to different choices for the Higgs vacuum expectation value around which the tree-level Lagrangian is expanded. If one chooses to expand around the minimum of the tree-level Higgs potential, then there are no tree-level tadpoles, but there will be non-zero contributions from the last diagram shown in Fig. 29.6.1. (This corresponds to the treatment given, for example, in ref. [227].) Alternatively, one can choose to expand around the Higgs vacuum expectation value v that minimizes the one-loop Landau gauge[77] effective potential. In that case, the one-loop tadpole contribution is precisely canceled by the tree-level Higgs tadpole, as shown in Fig. 29.6.2. Here, we have in mind the latter prescription; the calculation for the pole mass is therefore complete without tadpole contributions provided that the tree-level top quark mass is taken to be

$$m_t = Y_t v, \tag{29.6.6}$$

where Y_t is the $\overline{\rm MS}$ or $\overline{\rm DR}$ Yukawa coupling, and v is the Higgs vacuum expectation value at the minimum of the one-loop effective potential in Landau gauge. To be consistent with this choice, $\xi = 0$ should be taken in all formulae below that involve electroweak gauge bosons or Goldstone bosons. (The gluon contribution is naturally independent of ξ because the gauge symmetry is unbroken, providing a check of gauge-fixing invariance.) Nevertheless, for the sake of generality we will keep the dependence on ξ in the computation of the individual non-tadpole self-energy diagrams below.

Consider the one-loop calculation of the self-energy Σ_{Lt}, which is the sum of individual diagram contributions $\Sigma_{Lt} = [\Sigma_{Lt}]_g + [\Sigma_{Lt}]_\gamma + [\Sigma_{Lt}]_Z + [\Sigma_{Lt}]_W + [\Sigma_{Lt}]_{h_{\rm SM}} + [\Sigma_{Lt}]_{G^0} + [\Sigma_{Lt}]_{G^+}$. First, consider the diagrams involving exchanges of the scalars $\phi = h_{\rm SM}, G^0, G^\pm$. These contributions all have the same form

$$-ip\cdot\overline{\sigma}\,[\Sigma_{Lt}]_\phi \;=\; \mu^{2\epsilon}\int \frac{d^dk}{(2\pi)^d}\,(-iY^*)\left(\frac{i(k+p)\cdot\overline{\sigma}}{(k+p)^2-m_f^2}\right)(-iY)\left(\frac{i}{k^2-m_\phi^2}\right), \tag{29.6.7}$$

where the loop momentum k^μ flows clockwise, and the couplings and propagator masses are, using the Feynman rules of Figs. J.1.3 and J.1.4,

$$\text{for } \phi = h_{\rm SM}: \qquad Y = Y_t/\sqrt{2}; \qquad m_f = m_t; \qquad m_\phi^2 = m_{h_{\rm SM}}^2, \tag{29.6.8}$$

$$\text{for } \phi = G^0: \qquad Y = iY_t/\sqrt{2}; \qquad m_f = m_t; \qquad m_\phi^2 = \xi m_Z^2, \tag{29.6.9}$$

$$\text{for } \phi = G^\pm: \qquad Y = Y_b; \qquad m_f = m_b; \qquad m_\phi^2 = \xi m_W^2. \tag{29.6.10}$$

Multiplying both sides by $p\cdot\sigma$ and taking the trace over spinor indices using eq. (B.2.5), one finds

$$[\Sigma_{Lt}]_\phi \;=\; i|Y|^2\frac{\mu^{2\epsilon}}{p^2}\int\frac{d^dk}{(2\pi)^d}\frac{p\cdot(k+p)}{[(k+p)^2-m_f^2][k^2-m_\phi^2]}\,. \tag{29.6.11}$$

[77] This procedure is considerably more involved outside of Landau gauge, because the propagators mix the longitudinal components of the vector boson with the Nambu-Goldstone bosons for $\xi \neq 0$ if one expands around a Higgs vacuum expectation value that does not minimize the tree-level potential. This is the same reason the effective potential is traditionally calculated specifically in Landau gauge.

Performing the loop momentum integration in the standard way [115, 223], and expanding in ϵ up to constant terms, one finds that in each case

$$[\Sigma_{Lt}]_\phi = -\frac{1}{16\pi^2}|Y|^2\, I_{FS}(s; m_f^2, m_\phi^2). \tag{29.6.12}$$

Here we have introduced some notation for the loop integral:

$$I_{FS}(s;x,y) \equiv \frac{1}{2\epsilon} + \frac{(s+x-y)B(s;x,y) + A(x) - A(y)}{2s}\,, \tag{29.6.13}$$

where the Passarino-Veltman functions $A(x)$ and $B(s;x,y)$ were defined in eqs. (29.6.8) and (29.6.9). These functions depend on the renormalization scale Q, which is related to μ via eq. (29.6.10). It can be checked that $I_{FS}(s;x,y)$ has a smooth limit as $s \to 0$.

Next, let us consider the contributions to Σ_{Lt} involving the vector bosons $V = g, \gamma, Z, W$. These have the common form:

$$\begin{aligned} -ip\cdot\overline{\sigma}[\Sigma_{Lt}]_V \;=\; \mu^{2\epsilon}\int \frac{d^dk}{(2\pi)^d}\; (-iG\,\overline{\sigma}_\mu)\left(\frac{i(k+p)\cdot\sigma}{(k+p)^2-m_f^2}\right)(-iG\,\overline{\sigma}_\nu) \\ \left(\frac{-i}{k^2-m_V^2}\right)\left(g^{\mu\nu} + \frac{(\xi-1)k^\mu k^\nu}{k^2-\xi m_V^2}\right), \end{aligned} \tag{29.6.14}$$

where again the loop momentum k flows clockwise, and, using the rules of Figs. J.1.2 and K.5.1:

$$\text{for } V = g: \qquad G = g_s T^a\,, \qquad m_f = m_t, \tag{29.6.15}$$

$$\text{for } V = \gamma: \qquad G = eQ_t\,, \qquad m_f = m_t, \tag{29.6.16}$$

$$\text{for } V = Z: \qquad G = g(T_3^t - s_W^2 Q_t)/c_W\,, \qquad m_f = m_t, \tag{29.6.17}$$

$$\text{for } V = W: \qquad G = g/\sqrt{2}\,, \qquad m_f = m_b. \tag{29.6.18}$$

In the case of gluon exchange ($V = g$), the T^a are the $SU(3)_C$ generators (with color indices suppressed). The adjoint representation index a is summed over, producing a factor of the Casimir invariant $(T^aT^a)_{ij} = C_F\delta_{ij} = \frac{4}{3}\delta_{ij}$. We now use $\overline{\sigma}_\mu\,\sigma_\rho\,\overline{\sigma}_\nu\,g^{\mu\nu} = -(D-2)\,\overline{\sigma}_\rho$ [see eq. (B.2.11)]; note that this introduces a difference between the $\overline{\rm MS}$ and $\overline{\rm DR}$ schemes. Also, we use $k\cdot\overline{\sigma}(k+p)\cdot\sigma k\cdot\overline{\sigma} = (k^2+2k\cdot p)k\cdot\overline{\sigma} - k^2p\cdot\overline{\sigma}$, which follows from eq. (29.55). One therefore obtains, after multiplying by $p\cdot\sigma$ and taking the trace over spinor indices:

$$\begin{aligned} [\Sigma_{Lt}]_V = -i\,G^2\frac{\mu^{2\epsilon}}{p^2}\int\frac{d^dk}{(2\pi)^d}\,\frac{1}{[(k+p)^2-m_f^2][k^2-m_V^2]}\Big[(2-D)p\cdot(k+p) \\ + \left(k^2k\cdot p + 2(k\cdot p)^2 - k^2p^2\right)\frac{(\xi-1)}{k^2-\xi m_V^2}\Big]. \end{aligned} \tag{29.6.19}$$

Performing the loop momentum integration, one finds that

$$[\Sigma_{Lt}]_V = -\frac{1}{16\pi^2}G^2 I_{FV}(s; m_f^2, m_V^2), \tag{29.6.20}$$

where we have introduced the notation

$$\begin{aligned} I_{FV}(s;x,y) = \frac{\xi}{\epsilon} + [(s+x-y)B(s;x,y) + A(x) - A(y)]/s - \delta_{\overline{\rm MS}} + \big\{(s-x)[A(y) - A(\xi y)] \\ +[(s-x)^2 - y(s+x)]B(s;x,y) - [(s-x)^2 - \xi y(s+x)]B(s;x,\xi y)\big\}/2ys, \end{aligned} \tag{29.6.21}$$

after dropping terms that vanish as $\epsilon \to 0$. Combining the results of eqs. (29.6.12) and (29.6.20):

$$\begin{aligned}\Sigma_{Lt} = -\frac{1}{16\pi^2}\Big[&\Big(g_s^2 C_F + e^2 Q_t^2\Big) I_{FV}(m_t^2; m_t^2, 0) + [g(T_3^t - s_W^2 Q_t)/c_W]^2 I_{FV}(m_t^2; m_t^2, m_Z^2) \\ &+\frac{1}{2} g^2 I_{FV}(m_t^2; m_b^2, m_W^2) + \frac{1}{2} Y_t^2 I_{FS}(m_t^2; m_t^2, m_{h_{\rm SM}}^2) \\ &+\frac{1}{2} Y_t^2 I_{FS}(m_t^2; m_t^2, \xi m_Z^2) + Y_b^2 I_{FS}(m_t^2; m_b^2, \xi m_W^2)\Big],\end{aligned} \tag{29.6.22}$$

where we have now substituted $s = m_t^2$. It is useful to note that for massless gauge bosons,

$$I_{FV}(x; x, 0) = \xi\left[\frac{1}{\epsilon} - \ln(x/Q^2) + 2\right] + 1 - \delta_{\overline{\rm MS}}. \tag{29.6.23}$$

The contributions to $\Sigma_{Rt} = [\Sigma_{Rt}]_g + [\Sigma_{Rt}]_\gamma + [\Sigma_{Rt}]_Z + [\Sigma_{Rt}]_{h_{\rm SM}} + [\Sigma_{Rt}]_{G^0} + [\Sigma_{Rt}]_{G^\pm}$ are obtained similarly. [Note that there is no W boson contribution, since the right-handed top quark is an $SU(2)_L$ singlet.] For the scalar exchange diagrams with $\phi = h_{\rm SM}, G^0, G^\pm$, the general form is:

$$-ip\cdot\sigma[\Sigma_{Rt}]_\phi \;=\; \mu^{2\epsilon}\int \frac{d^dk}{(2\pi)^d}\,(-iY)\left(\frac{i(k+p)\cdot\sigma}{(k+p)^2 - m_f^2}\right)(-iY^*)\left(\frac{i}{k^2 - m_\phi^2}\right), \tag{29.6.24}$$

which yields

$$[\Sigma_{Rt}]_\phi = -\frac{1}{16\pi^2}|Y|^2\, I_{FS}(s; m_f^2, m_\phi^2). \tag{29.6.25}$$

Here the couplings and propagator masses for $h_{\rm SM}$ and G^0 are the same as in eqs. (29.6.8), (29.6.9), but now instead of eq. (29.6.10),

$$\text{for } \phi = G^\pm: \qquad Y = -Y_t\,, \qquad m_f = m_b\,, \qquad m_\phi^2 = \xi m_W^2\,, \tag{29.6.26}$$

from Fig. J.1.4. For the contributions due to exchanges of vectors $v = g, \gamma, Z$, the general form is given by

$$\begin{aligned}-ip\cdot\sigma[\Sigma_{Rt}]_V \;=\; \mu^{2\epsilon}\int \frac{d^dk}{(2\pi)^d}\;&(iG\,\sigma_\mu)\left(\frac{i(k+p)\cdot\overline{\sigma}}{(k+p)^2 - m_f^2}\right)(iG\,\sigma_\nu) \\ &\left(\frac{-i}{k^2 - m_V^2}\right)\left(g^{\mu\nu} + \frac{(\xi-1)k^\mu k^\nu}{k^2 - \xi m_V^2}\right),\end{aligned} \tag{29.6.27}$$

where

$$\text{for } V = g: \qquad G = -g_s \boldsymbol{T^a}\,, \tag{29.6.28}$$
$$\text{for } V = \gamma: \qquad G = -eQ_t\,, \tag{29.6.29}$$
$$\text{for } V = Z: \qquad G = g s_W^2 Q_t/c_W\,, \tag{29.6.30}$$

after using the rules of Figs. J.1.2 and K.5.1 with $m_f = m_t$ in each case. We then make use of $\sigma_\mu\,\overline{\sigma}_\rho\,\sigma_\nu\,g^{\mu\nu} = -(D-2)\,\sigma_\rho$ [cf. eq. (B.2.10)] and $k\cdot\sigma(k+p)\cdot\overline{\sigma}k\cdot\sigma = (k^2 + 2k\cdot p)k\cdot\sigma - k^2 p\cdot\sigma$ [cf. eq. (29.54)]. After multiplying by $p\cdot\overline{\sigma}$ and taking the trace over spinor indices [using eq. (B.2.5)], we obtain

$$[\Sigma_{Rt}]_V = -\frac{1}{16\pi^2} G^2 I_{FV}(s; m_t^2, m_V^2)\,, \tag{29.6.31}$$

in terms of the same function appearing in eqs. (29.6.21) and (29.6.23). Adding up these contributions and taking $s = m_t^2$ yields

$$\Sigma_{Rt} = -\frac{1}{16\pi^2}\Big[\Big(g_s^2 C_F + e^2 Q_t^2\Big) I_{FV}(m_t^2; m_t^2, 0) + (g^2 Q_t^2 s_W^4/c_W^2) I_{FV}(m_t^2; m_t^2, m_Z^2) + \frac{1}{2} Y_t^2 I_{FS}(m_t^2; m_t^2, m_{h_{\rm SM}}^2) + \frac{1}{2} Y_t^2 I_{FS}(m_t^2; m_t^2, \xi m_Z^2) + Y_t^2 I_{FS}(m_t^2; m_b^2, \xi m_W^2)\Big]. \quad (29.6.32)$$

Next, consider the contributions to $\Sigma_{Dt} = [\Sigma_{Dt}]_g + [\Sigma_{Dt}]_\gamma + [\Sigma_{Dt}]_Z + [\Sigma_{Dt}]_{h_{\rm SM}} + [\Sigma_{Dt}]_{G^0} + [\Sigma_{Dt}]_{G^\pm}$, ignoring the tadpole contribution for now. The diagrams involving the exchange of scalars $\phi = h_{\rm SM}, G^0, G^\pm$ have the form:

$$-i[\Sigma_{Dt}]_\phi \;=\; \mu^{2\epsilon} \int \frac{d^d k}{(2\pi)^d}\; (-iY_1) \left(\frac{i m_f}{(k+p)^2 - m_f^2}\right) (-iY_2) \left(\frac{i}{k^2 - m_\phi^2}\right), \quad (29.6.33)$$

so that

$$[\Sigma_{Dt}]_\phi = i m_f Y_1 Y_2 \mu^{2\epsilon} \int \frac{d^d k}{(2\pi)^d} \frac{1}{[(k+p)^2 - m_f^2][k^2 - m_\phi^2]} = \frac{1}{16\pi^2} m_f Y_1 Y_2 I_{\overline{F}S}(s; m_f^2, m_\phi^2)\,, \quad (29.6.34)$$

where we have introduced the notation:

$$I_{\overline{F}S}(s; x, y) \equiv -\frac{1}{\epsilon} - B(s; x, y), \quad (29.6.35)$$

after dropping terms that vanish as $\epsilon \to 0$. The relevant couplings and masses are, from Figs. J.1.3 and J.1.4:

$$\text{for } \phi = h_{\rm SM}: \quad Y_1 = Y_2 = Y_t/\sqrt{2}\,, \quad m_f = m_t\,, \quad m_\phi^2 = m_{h_{\rm SM}}^2, \quad (29.6.36)$$

$$\text{for } \phi = G^0: \quad Y_1 = Y_2 = iY_t/\sqrt{2}, \quad m_f = m_t\,, \quad m_\phi^2 = \xi m_Z^2, \quad (29.6.37)$$

$$\text{for } \phi = G^\pm: \quad Y_1 = Y_b, \quad Y_2 = -Y_t, \quad m_f = m_b\,, \quad m_\phi^2 = \xi m_W^2. \quad (29.6.38)$$

The contributions from vector boson exchanges are of the form

$$-i[\Sigma_{Dt}]_V \;=\; \mu^{2\epsilon} \int \frac{d^d k}{(2\pi)^d}\; (iG_1\sigma_\mu) \left(\frac{i m_f}{(k+p)^2 - m_f^2}\right) (-iG_2\overline{\sigma}_\nu) \left(\frac{-i}{k^2 - m_V^2}\right) \left(g^{\mu\nu} + \frac{(\xi-1)k^\mu k^\nu}{k^2 - \xi m_V^2}\right), \quad (29.6.39)$$

Using $\sigma_\mu \overline{\sigma}_\nu g^{\mu\nu} = D$ [see eq. (B.2.8)] and $k\cdot\sigma k\cdot\overline{\sigma} = k^2$ [from eq. (29.52)] yields

$$[\Sigma_{Dt}]_V = i m_f G_1 G_2 \mu^{2\epsilon} \int \frac{d^d k}{(2\pi)^d} \frac{1}{[(k+p)^2 - m_f^2][k^2 - m_V^2]} \left[D + \frac{(\xi-1)k^2}{k^2 - \xi m_V^2}\right] = \frac{1}{16\pi^2} m_f G_1 G_2 I_{\overline{F}V}(s; m_f^2, m_V^2)\,, \quad (29.6.40)$$

where

$$I_{\overline{F}V}(s; x, y) \equiv -\frac{3+\xi}{\epsilon} - 3B(s; x, y) - \xi B(s; x, \xi y) + 2\delta_{\overline{\rm MS}}, \quad (29.6.41)$$

after dropping terms that vanish as $\epsilon \to 0$. It is useful to note that for massless gauge bosons

$$I_{\overline{F}V}(x;x,0) \equiv -\frac{3+\xi}{\epsilon} + (3+\xi)[\ln(x/Q^2) - 2] + 2\delta_{\overline{\rm MS}}. \tag{29.6.42}$$

The relevant couplings are obtained from the rules of Figs. J.1.2 and K.5.1:

$$\text{for } V = g: \qquad G_1 = -G_2 = g_s T^a, \tag{29.6.43}$$
$$\text{for } V = \gamma: \qquad G_1 = -G_2 = eQ_t, \tag{29.6.44}$$
$$\text{for } V = Z: \qquad G_1 = g(T_3^t - s_W^2 Q_t)/c_W, \qquad G_2 = g s_W^2 Q_t/c_W, \tag{29.6.45}$$

and $m_f = m_t$ in each case. Adding up these contributions and taking $s = m_t^2$, we have:

$$\Sigma_{Dt} = \frac{m_t}{16\pi^2}\Big\{ g^2\left[(T_3^t - s_W^2 Q_t)s_W^2 Q_t/c_W^2\right] I_{\overline{F}V}(m_t^2; m_t^2, m_Z^2) - (g_s^2 C_F + e^2 Q_t^2) I_{\overline{F}V}(m_t^2; m_t^2, 0)$$
$$+\tfrac{1}{2}Y_t^2 I_{\overline{F}S}(m_t^2; m_t^2, m_{h_{\rm SM}}^2) - \tfrac{1}{2}Y_t^2 I_{\overline{F}S}(m_t^2; m_t^2, \xi m_Z^2) - Y_b^2 I_{\overline{F}S}(m_t^2; m_b^2, \xi m_W^2)\Big\}, \tag{29.6.46}$$

where $Y_t = m_t Y_b/m_b$ was used on the last term.

In each of the self-energy functions above, there are poles in $1/\epsilon$, contained within the functions I_{FV}, I_{FS}, $I_{\overline{F}V}$ and $I_{\overline{F}S}$. In the $\overline{\rm MS}$ or $\overline{\rm DR}$ schemes, these poles are simply canceled by counterterms, which have no other effect at one-loop order. The one-loop top quark pole mass can now be obtained by plugging eqs. (29.6.22), (29.6.32), and (29.6.46) into eq. (29.6.2) with $\xi = 0$, as discussed earlier. It is not hard to check that the terms from massless Nambu-Goldstone boson exchange just cancel against the terms from the vector exchange diagrams that came from ξm_W^2 and ξm_Z^2.

As a simple example, consider the one-loop pole mass with only QCD effects included. Then the result of eq. (29.6.2) has no imaginary part. Taking the square root (and dropping a two-loop order part) yields the well-known result [228]:

$$\begin{aligned} M_{t,\rm pole} &= m_t(1 + \tfrac{1}{2}\Sigma_{Lt} + \tfrac{1}{2}\Sigma_{Rt}) + \Sigma_{Dt} \\ &= m_t\Big(1 - \frac{C_F g_s^2}{16\pi^2}\Big[I_{FV}(m_t^2; m_t^2, 0) + I_{\overline{F}V}(m_t^2; m_t^2, 0)\Big]\Big) \\ &= m_t\Big(1 + \frac{\alpha_s}{4\pi} C_F\Big[5 - \delta_{\overline{\rm MS}} - 3\ln(m_t^2/Q^2)\Big]\Big). \end{aligned} \tag{29.6.47}$$

As another check, consider the imaginary part of the pole squared mass of the top quark. At leading order, eq. (29.6.2) implies:

$$\begin{aligned} \Gamma_t &= -{\rm Im}[m_t(\Sigma_{Lt} + \Sigma_{Rt}) + 2\Sigma_{Dt}] \\ &= \frac{m_t}{16\pi^2}{\rm Im}\Big[\frac{g^2}{2} I_{FV}(m_t^2; m_b^2, m_W^2) + (Y_t^2 + Y_b^2) I_{FS}(m_t^2; m_b^2, \xi m_W^2) + 2Y_b^2 I_{\overline{F}S}(m_t^2; m_b^2, \xi m_W^2)\Big] \\ &= \frac{1}{32\pi^2 m_t}\left\{(g^2 + Y_t^2 + Y_b^2)(m_t^2 + m_b^2 - m_W^2) - 4Y_b^2 m_t^2\right\} {\rm Im}[B(m_t^2; m_b^2, m_W^2)]. \end{aligned} \tag{29.6.48}$$

The fact that the ξ dependence canceled here is a successful check of gauge-fixing invariance, since the tadpole diagram in Fig. 29.6.1 does not contribute to the absorptive part of the self-energy. One can express ${\rm Im}[B(s;x,y)]$ in terms of the triangle function [cf. eq. (29.6.11)],

$${\rm Im}[B(s;x,y)] = \begin{cases} 0 & \text{for} \quad s \le (\sqrt{x} + \sqrt{y})^2, \\ \pi\lambda^{1/2}(s,x,y)/s & \text{for} \quad s > (\sqrt{x} + \sqrt{y})^2. \end{cases} \tag{29.6.49}$$

Eq. (29.6.48) then reproduces the result of eq. (29.6.10) for the top quark width at leading order.

29.6.25 Self-energy and pole mass of the gluino

The Feynman diagrams for the gluino self-energy are shown in Fig. 29.6.1. Since the gluino is a Majorana fermion, we can use the general formalism of Section 29.4.6. We will compute the self-energy functions $\Xi_{\tilde{g}} \equiv \Xi_{\tilde{g}}^{\tilde{g}}$ and $\Omega_{\tilde{g}} \equiv \Omega^{\tilde{g}\tilde{g}}$ defined in Fig. 29.4.3, and infer $\overline{\Omega}_{\tilde{g}} \equiv \overline{\Omega}_{\tilde{g}\tilde{g}}$ from the latter by replacing all Lagrangian parameters by their complex conjugates.[78] At one-loop order, it follows from the general result of eq. (29.4.24) that the complex pole squared mass of the gluino is related to the tree-level mass $m_{\tilde{g}}$ by

$$M_{\tilde{g}}^2 - iM_{\tilde{g}}\Gamma_{\tilde{g}} = \left[m_{\tilde{g}}^2(1+2\Xi_{\tilde{g}}) + m_{\tilde{g}}(\Omega_{\tilde{g}} + \overline{\Omega}_{\tilde{g}})\right]\Big|_{s=m_{\tilde{g}}^2+i\varepsilon}. \tag{29.6.1}$$

It is convenient to split the self-energy functions into gluon/gluino loop and squark/quark loop contributions, as

$$\Xi_{\tilde{g}} = [\Xi_{\tilde{g}}]_g + \sum_q \sum_{x=1,2} [\Xi_{\tilde{g}}]_{\tilde{q}_x}, \qquad \text{and} \qquad \Omega_{\tilde{g}} = [\Omega_{\tilde{g}}]_g + \sum_q \sum_{x=1,2} [\Omega_{\tilde{g}}]_{\tilde{q}_x}, \tag{29.6.2}$$

where the sum over q runs over the six squark flavors u, d, s, c, b, t, and $x = 1, 2$ corresponds to the two squark mass eigenstates [i.e., the two appropriate linear combinations (for fixed squark flavor) of $\widetilde{q}_L$ and $\widetilde{q}_R$]. The gluon exchange contributions, following from the Feynman rules of Fig. K.5.1, are:

$$\begin{aligned} -ip\cdot\overline{\sigma}\,[\Xi_{\tilde{g}}]_g\,\delta^{ab} = \mu^{2\epsilon}\int \frac{d^dk}{(2\pi)^d}\,(-g_s f^{aec}\overline{\sigma}_\mu)\left(\frac{i(k+p)\cdot\sigma}{(k+p)^2 - m_{\tilde{g}}^2}\right)(-g_s f^{ebc}\overline{\sigma}_\nu) \\ \left(\frac{-i}{k^2}\right)\left(g^{\mu\nu} + (\xi-1)\frac{k^\mu k^\nu}{k^2}\right), \end{aligned} \tag{29.6.3}$$

$$\begin{aligned} -i\,[\Omega_{\tilde{g}}]_g\,\delta^{ab} = \mu^{2\epsilon}\int \frac{d^dk}{(2\pi)^d}\,(g_s f^{eac}\sigma_\mu)\left(\frac{im_{\tilde{g}}}{(k+p)^2 - m_{\tilde{g}}^2}\right)(-g_s f^{ebc}\overline{\sigma}_\nu) \\ \left(\frac{-i}{k^2}\right)\left(g^{\mu\nu} + (\xi-1)\frac{k^\mu k^\nu}{k^2}\right). \end{aligned} \tag{29.6.4}$$

The internal gluon and gluino lines carry $SU(3)_c$ adjoint representation indices c and e respectively, while the external gluinos on the left and right carry indices a and b respectively. The gluino external momentum p^μ flows from right to left, and the loop momentum k^μ flows clockwise. Comparing with the derivations of eqs. (29.6.20) and (29.6.40) in the previous subsection, and using $-f^{aec}f^{ebc} = f^{eac}f^{ebc} = \delta^{ab}C_A$ [with $C_A = 3$ for $SU(3)_c$], we can immediately conclude that

$$[\Xi_{\tilde{g}}]_g = -\frac{\alpha_s}{4\pi}C_A I_{FV}(s; m_{\tilde{g}}^2, 0), \tag{29.6.5}$$

$$[\Omega_{\tilde{g}}]_g = -\frac{\alpha_s}{4\pi}C_A m_{\tilde{g}} I_{\overline{F}V}(s; m_{\tilde{g}}^2, 0), \tag{29.6.6}$$

where the loop integral functions I_{FV} and $I_{\overline{F}V}$ were defined in eqs. (29.6.21) and (29.6.41).

[78] Suppressing the color degrees of freedom, Ξ, Ω and $\overline{\Omega}$ are one-dimensional matrices, so we do not employ boldface letters in this case.

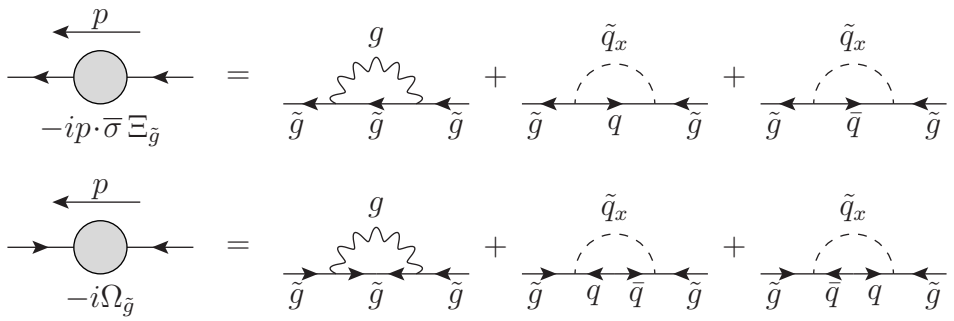

Figure 29.6.1: Self-energy functions for the gluino in supersymmetry. The external momentum p^μ flows from the right to the left. The loop momentum k^μ in the text is taken to flow clockwise. Spinor and color indices are suppressed. The index $x = 1, 2$ labels the two squark mass eigenstates of a given flavor $q = u, d, s, c, b, t$. Both x and q must be summed over. The external legs are amputated.

Next consider the virtual squark exchange diagrams contributing to $\Xi_{\tilde{g}}$. Labeling the quark and squark with color indices j, k respectively, we have for each squark mass eigenstate:

$$-ip\cdot\overline{\sigma}\,[\Xi_{\tilde{g}}]_{\tilde{q}_x}\,\delta^{ab} = \mu^{2\epsilon}\int\frac{d^dk}{(2\pi)^d}(-i\sqrt{2}g_sT_j^{ak}L_{\tilde{q}_x})\left(\frac{i(k+p)\cdot\overline{\sigma}}{(k+p)^2-m_q^2}\right)(-i\sqrt{2}g_sT_k^{bj}L_{\tilde{q}_x}^*)\left(\frac{i}{k^2-m_{\tilde{q}_x}^2}\right)$$
$$+\mu^{2\epsilon}\int\frac{d^dk}{(2\pi)^d}\left(i\sqrt{2}g_sT_k^{aj}R_{\tilde{q}_x}^*\right)\left(\frac{i(k+p)\cdot\overline{\sigma}}{(k+p)^2-m_q^2}\right)\left(i\sqrt{2}g_sT_j^{bk}R_{\tilde{q}_x}\right)\left(\frac{i}{k^2-m_{\tilde{q}_x}^2}\right). \quad (29.6.7)$$

This uses the Feynman rules shown in Fig. K.5.3, given in terms of the squark mixing parameters $L_{\tilde{q}_x}$ and $R_{\tilde{q}_x}$ defined in eq. (K.4.1). Using $\mathrm{Tr}[T^aT^b] = \frac{1}{2}\delta^{ab}$ and $|L_{\tilde{q}_x}|^2 + |R_{\tilde{q}_x}|^2 = 1$, and comparing to the derivation of eq. (29.6.12) of the previous subsection, we obtain:

$$[\Xi_{\tilde{g}}]_{\tilde{q}_x} = -\frac{\alpha_s}{4\pi}I_{FS}(s; m_q^2, m_{\tilde{q}_x}^2). \quad (29.6.8)$$

Similarly, for the last two diagrams of Fig. 29.6.1, we obtain:

$$-i[\Omega_{\tilde{g}}]_{\tilde{q}_x}\,\delta^{ab} = \mu^{2\epsilon}\int\frac{d^dk}{(2\pi)^d}\left(-i\sqrt{2}g_sT_k^{aj}L_{\tilde{q}_x}^*\right)\left(\frac{im_q}{(k+p)^2-m_q^2}\right)\left(i\sqrt{2}g_sT_j^{bk}R_{\tilde{q}_x}\right)\left(\frac{i}{k^2-m_{\tilde{q}_x}^2}\right)$$
$$+\mu^{2\epsilon}\int\frac{d^dk}{(2\pi)^d}\left(i\sqrt{2}g_sT_j^{ak}R_{\tilde{q}_x}\right)\left(\frac{im_q}{(k+p)^2-m_q^2}\right)\left(-i\sqrt{2}g_sT_k^{bj}L_{\tilde{q}_x}^*\right)\left(\frac{i}{k^2-m_{\tilde{q}_x}^2}\right), \quad (29.6.9)$$

again using the Feynman rules shown in Fig. K.5.3. As before, j and k are the color indices for the quark and the squark, respectively. Comparing to the derivation of eq. (29.6.34) of the previous subsection, we obtain:

$$[\Omega_{\tilde{g}}]_{\tilde{q}_x} = -\frac{\alpha_s}{2\pi}L_{\tilde{q}_x}^*R_{\tilde{q}_x}m_qI_{\overline{F}S}(s; m_q^2, m_{\tilde{q}_x}^2)\,. \quad (29.6.10)$$

Summing up the results obtained above, and taking $s = m_{\tilde{g}}^2$, we have:

$$\Xi_{\tilde{g}} = -\frac{\alpha_s}{4\pi}\left[C_AI_{FV}(m_{\tilde{g}}^2; m_{\tilde{g}}^2, 0) + \sum_q\sum_{x=1,2}I_{FS}(m_{\tilde{g}}^2; m_q^2, m_{\tilde{q}_x}^2)\right], \quad (29.6.11)$$

$$\Omega_{\tilde{g}} = -\frac{\alpha_s}{4\pi}\left[C_Am_{\tilde{g}}I_{\overline{F}V}(m_{\tilde{g}}^2; m_{\tilde{g}}^2, 0) + 2\sum_q\sum_{x=1,2}L_{\tilde{q}_x}^*R_{\tilde{q}_x}m_qI_{\overline{F}S}(m_{\tilde{g}}^2; m_q^2, m_{\tilde{q}_x}^2)\right]. \quad (29.6.12)$$

As previously noted, we can now write down $\overline{\Omega}_{\tilde{g}}$ by replacing the Lagrangian parameters of eq. (29.6.12) by their complex conjugates:

$$\overline{\Omega}_{\tilde{g}} = -\frac{\alpha_s}{4\pi}\left[C_A m_{\tilde{g}} I_{\overline{F}V}(m_{\tilde{g}}^2; m_{\tilde{g}}^2, 0) + 2\sum_q \sum_{x=1,2} L_{\tilde{q}_x} R_{\tilde{q}_x}^* m_q I_{\overline{F}S}(m_{\tilde{g}}^2; m_q^2, m_{\tilde{q}_x}^2)\right]. \tag{29.6.13}$$

Inserting the results of eqs. (29.6.11)–(29.6.13) into eq. (29.6.1), one obtains the result [229, 230]:

$$M_{\tilde{g}}^2 - iM_{\tilde{g}}\Gamma_{\tilde{g}} = m_{\tilde{g}}^2\Bigg[1 + \frac{\alpha_s}{2\pi}\Big\{C_A\left[5 - \delta_{\overline{\rm MS}} - 3\ln\big(m_{\tilde{g}}^2/Q^2\big)\right] - \sum_q \sum_{x=1,2}\left[I_{FS}(m_{\tilde{g}}^2; m_q^2, m_{\tilde{q}_x}^2) + 2{\rm Re}[L_{\tilde{q}_x}^* R_{\tilde{q}_x}]\frac{m_q}{m_{\tilde{g}}} I_{\overline{F}S}(m_{\tilde{g}}^2; m_q^2, m_{\tilde{q}_x}^2)\right]\Big\}\Bigg], \tag{29.6.14}$$

with $\delta_{\overline{\rm MS}}$ defined in eq. (29.6.5).

29.6.26 Triangle anomaly from chiral fermion loops

As our final example, we consider the anomaly in chiral symmetries for fermions, arising from the triangle diagram involving three currents carrying vector indices.[79] Since the anomaly is independent of the fermion masses, we simplify the computation by setting all fermion masses to zero. In four-component notation,[80] the treatment of the anomaly requires care because of the difficulty in defining a consistent and unambiguous γ_5 and the epsilon tensor in dimensional regularization [233, 234]. The same subtleties arise in two-component language, of course, but in a slightly different form since γ_5 does not appear explicitly.

We shall assemble all the $(\frac{1}{2}, 0)$ [left-handed] two-component fermion fields of the theory into a multiplet ψ_j. For example, the fermions of the Standard Model are: $\psi_j = (\ell_k\,,\ \bar{\ell}_k\,,\ \nu_k\,,\ q_{i\ell}\,,\ \bar{q}_{i\ell})$, where $k = 1, 2, 3$ and $i = 1, 2, ..., 6$ are flavor labels and $\ell = 1, 2, 3$ are color labels [see Table 29.1]. The two-component spinor indices are suppressed here. Let the symmetry generators be given by hermitian matrices $\boldsymbol{T^a}$, so that the ψ_j transform as:

$$\delta\psi_j = -i\theta^a(\boldsymbol{T^a})_j{}^k\psi_k, \tag{29.6.1}$$

for infinitesimal parameters θ^a. The matrices $\boldsymbol{T^a}$ form a representation R of the generators of the Lie algebra of the symmetry group. In general R will be reducible, in which case the $\boldsymbol{T^a}$ have a block diagonal structure, where each block separately transforms (irreducibly) the corresponding field of ψ_j according to its symmetry transformation properties. Some or all of these symmetries may be gauged. The Feynman rule for the corresponding currents is the same as for external gauge bosons, as in Fig. 29.4.2 (but without the gauge couplings), and is shown in Fig. 29.6.1.

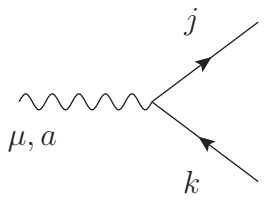
Fig. 29.6.2 exhibits the two Feynman diagrams that contribute at one-loop to the three-point function of the symmetry currents. Applying the $\overline{\sigma}$-version of the Feynman rule for the currents given in Fig. 29.6.1, and employing the Feynman rules of Fig. 29.4.1 (with $m = 0$) for the propagators [traversing the loop in the direction dictated by eq. (29.4.2)], the sum of the two triangle diagrams shown in Fig. 29.6.2 can be evaluated.

The resulting sum of loop integrals is

$$i\Gamma^{abc}_{\mu\nu\rho} = (-1)\int \frac{d^4k}{(2\pi)^4}{\rm Tr}\Bigg\{(-i\overline{\sigma}_\mu \boldsymbol{T}^a)\frac{i(k-p+A)\cdot\sigma}{(k-p+A)^2}(-i\overline{\sigma}_\nu \boldsymbol{T}^b)\frac{i(k+A)\cdot\sigma}{(k+A)^2}(-i\overline{\sigma}_\rho \boldsymbol{T}^c)\frac{i(k+q+A)\cdot\sigma}{(k+q+A)^2}$$
$$+(-i\overline{\sigma}_\mu \boldsymbol{T}^a)\frac{i(k-q+B)\cdot\sigma}{(k-q+B)^2}(-i\overline{\sigma}_\rho \boldsymbol{T}^c)\frac{i(k+B)\cdot\sigma}{(k+B)^2}(-i\overline{\sigma}_\nu \boldsymbol{T}^b)\frac{i(k+p+B)\cdot\sigma}{(k+p+B)^2}\Bigg\}, \tag{29.6.2}$$

[79] The discussion here parallels that given in ref. [231], Section 22.3.

[80] For an excellent review of the computation of the chiral anomaly via four-component massless and massive spinor triangle loops, see [232].



$$-i(\boldsymbol{T^a})_j{}^k\,\overline{\sigma}_\mu \quad \text{or} \quad i(\boldsymbol{T^a})_j{}^k\,\sigma_\mu$$

Figure 29.6.1: Feynman rule for the coupling of a current carrying vector index μ and corresponding to the symmetry generator $\boldsymbol{T^a}$ acting on $(\frac{1}{2},0)$ [left-handed] fermions. Spinor indices are suppressed.

where the overall factor of (-1) is due to the presence of a closed fermion loop. The trace is taken over fermion flavor/group and spinor indices, both of which are suppressed. Because the individual integrals are linearly divergent, we must allow for arbitrary constant four-vectors A^μ and B^μ as offsets for the loop momentum when defining the loop integrations for the two diagrams [235, 236].

The persistence of the symmetry in the quantum theory for the currents labeled by μ, a and ν, b and ρ, c implies the naive Ward identities:[81]

$$(p+q)^\mu\, i\Gamma^{abc}_{\mu\nu\rho}(-p-q,p,q) = f^{abd}\Pi^{dc}_{\nu\rho}(q) + f^{acd}\Pi^{bd}_{\nu\rho}(p)\,, \tag{29.6.3}$$

$$-p^\nu\, i\Gamma^{abc}_{\mu\nu\rho}(-p-q,p,q) = f^{bcd}\Pi^{da}_{\rho\mu}(p+q) + f^{bad}\Pi^{cd}_{\rho\mu}(q)\,, \tag{29.6.4}$$

$$-q^\rho\, i\Gamma^{abc}_{\mu\nu\rho}(-p-q,p,q) = f^{cad}\Pi^{db}_{\mu\nu}(p) + f^{cbd}\Pi^{ad}_{\mu\nu}(p+q)\,, \tag{29.6.5}$$

where $i\Pi^{ab}_{\mu\nu}(p)$ is the one-loop current-current two-point function shown in Fig. 29.6.3.

By Lorentz covariance, $\Pi^{ab}_{\mu\nu}(p)$ is a rank-two symmetric tensor that is an even function of the four-momentum p [cf. eq. (29.6.41)]. In eqs. (29.6.3)–(29.6.5), we have employed a convention in which the arguments of $i\Gamma$ correspond to the *outgoing* momentum of the external legs of the corresponding one-loop Feynman diagrams, and the order of the momentum arguments matches the order of the indices.

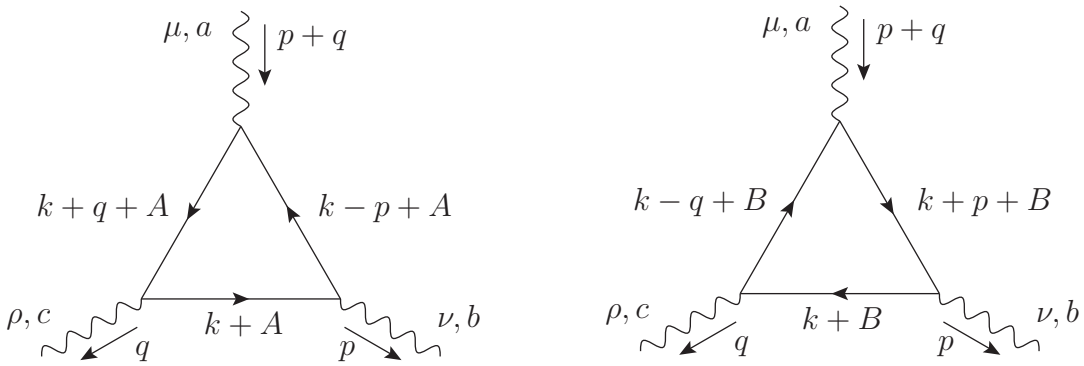


Figure 29.6.2: Triangle Feynman diagrams leading to the chiral fermion anomaly. Fermion spinor and flavor indices are suppressed. The fermion momenta, as labeled, flow in the arrow directions.

[81] The derivation of the Ward identities is most easily achieved by writing the three-point function in position space as a vacuum expectation value of the time-ordered product of three currents. After taking the divergence (with respect to the position of any one of the three currents) of the time-ordered product and using the fact that the currents are conserved ($\partial_\mu j^{a\mu} = 0$), the surviving terms can be evaluated using the equal-time commutation relations, $\delta(x^0-y^0)[j^{a0}(x), j^{b\nu}(y)] = if^{abc}j^{c\nu}(x)\delta^4(x-y)$. Fourier-transforming the result yields the terms on the right-hand side of eqs. (29.6.3)–(29.6.5). See refs. [237, 238] for further details.

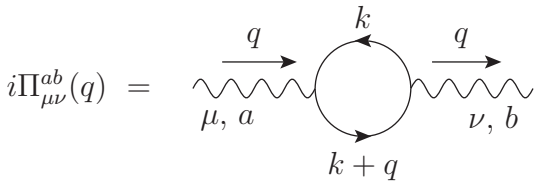

Figure 29.6.3: The one-loop contribution to the current-current two-point function. The fermion momenta, as labeled, flow along the corresponding arrow directions.

It is convenient to define the *symmetrized* three-point function by symmetrizing over the indices a, b and c:

$$\mathcal{A}^{abc}_{\mu\nu\rho} = \tfrac{1}{6} i\Gamma^{abc}_{\mu\nu\rho} + [\text{five permutations of } a, b, c]. \tag{29.6.6}$$

In terms of the symmetrized three-point function, the naive Ward identities imply

$$(p+q)^\mu \mathcal{A}^{abc}_{\mu\nu\rho} = 0\,, \qquad -p^\nu \mathcal{A}^{abc}_{\mu\nu\rho} = 0\,, \quad \text{and} \quad -q^\rho \mathcal{A}^{abc}_{\mu\nu\rho} = 0\,. \tag{29.6.7}$$

We now perform the explicit diagrammatic computation to show that the naive Ward identities exhibited in eq. (29.6.7) are violated due to a quantum anomaly. Although the symmetrized three-point function is ultraviolet finite, the individual loop momentum integrals are divergent, and must be defined with care. We do not regularize them by the usual procedure of continuing to $d = 4 - 2\epsilon$ dimensions, because the trace over sigma matrices crucially involves the antisymmetric tensor with four indices, brought in by eqs. (B.2.26) and (B.2.27), for which there is no consistent and unambiguous generalization outside of four dimensions. (This is related to the difficulty of defining γ_5 in the four-component spinor formalism.) The existence of the vectors A and B corresponds to an ambiguity in the regulation procedure, which can be fixed to preserve some of the symmetries, as we will see below.

Starting from eq. (29.6.2), it follows from eq. (E.2.7) that the symmetrized three-point function is proportional to the group theory factor (often called the anomaly coefficient),

$$D^{abc} = \tfrac{1}{2}\mathrm{Tr}[\{\boldsymbol{T^a}, \boldsymbol{T^b}\}\boldsymbol{T^c}]\,, \tag{29.6.8}$$

where the numerical values of the D^{abc} depend on the representation R. As discussed in Appendix E , D^{abc} vanishes for all simple Lie groups, with the exception of SU(N) for $N \geq 3$. The D^{abc} are also non-vanishing in general for any non-semisimple compact Lie group, which contains at least one U(1) factor.

First, consider the result for $(p+q)^\mu \mathcal{A}^{abc}_{\mu\nu\rho}$. This can be simplified by rewriting

$$(p+q)^\mu = (k+q+A)^\mu - (k-p+A)^\mu\,, \tag{29.6.9}$$
$$(p+q)^\mu = (k+p+B)^\mu - (k-q+B)^\mu\,, \tag{29.6.10}$$

in the first and second diagram terms, respectively, and then applying the formulae

$$v{\cdot}\sigma\, v{\cdot}\overline{\sigma} \;=\; v^2\,, \qquad v{\cdot}\overline{\sigma}\, v{\cdot}\sigma \;=\; v^2\,, \tag{29.6.11}$$

which follow from eqs. (B.2.1) and (B.2.2). After rearranging the terms using the cyclic property of the trace, we obtain:

$$\begin{aligned}(p+q)^\mu \mathcal{A}^{abc}_{\mu\nu\rho} \;&=\; -D^{abc}\,\mathrm{Tr}[\sigma_\kappa \overline{\sigma}_\nu \sigma_\lambda \overline{\sigma}_\rho]\, X^{\kappa\lambda}, \\ &= -2D^{abc}\left[X_{\nu\rho} + X_{\rho\nu} - g_{\nu\rho} X_\lambda{}^\lambda + i\epsilon_{\kappa\nu\lambda\rho} X^{\kappa\lambda}\right]\,,\end{aligned} \tag{29.6.12}$$

after applying eq. (B.2.26). (In our conventions, $\epsilon_{0123} = -1$.) The integral $X^{\kappa\lambda}$ is given by:

$$X^{\kappa\lambda} = \int \frac{d^4k}{(2\pi)^4} \left[\frac{(k-p+A)^\kappa}{(k-p+A)^2} \frac{(k+A)^\lambda}{(k+A)^2} - \frac{(k+q+A)^\kappa}{(k+q+A)^2} \frac{(k+A)^\lambda}{(k+A)^2} \right.$$
$$\left. + \frac{(k+B)^\kappa}{(k+B)^2} \frac{(k-q+B)^\lambda}{(k-q+B)^2} - \frac{(k+B)^\kappa}{(k+B)^2} \frac{(k+p+B)^\lambda}{(k+p+B)^2} \right]. \tag{29.6.13}$$

Naively, this integral appears to vanish, because the first term is equal to the negative of the fourth term after a momentum shift $k \to k-p+A-B$, and the second term is equal to the negative of the third term after $k \to k+q+A-B$. However, these momentum shifts are not valid for the individually divergent integrals. Instead, $X^{\kappa\lambda}$ can be evaluated by a Wick rotation to Euclidean space, followed by isolating the terms that contribute for large k^2 and are responsible for the integral not vanishing, and then employing the divergence (Gauss') theorem in four dimensions to rewrite $X^{\kappa\lambda}$ as an angular integral over a three-sphere with radius tending to infinity. This integral is initially evaluated at large but finite Euclidean k, with the limit $k \to \infty$ taken at the end of the computation. For example, consider a smooth function $f(k)$ of the four-momentum k with the property that the integral

$$\int d^4k f(k) \tag{29.6.14}$$

is at worst quadratically divergent. We define the even and odd parts of $f(k)$, respectively, by:

$$f_e(k) \equiv \tfrac{1}{2}\left[f(k) + f(-k)\right], \qquad f_o(k) \equiv \tfrac{1}{2}\left[f(k) - f(-k)\right]. \tag{29.6.15}$$

It then follows that [237, 239, 240]

$$\int \frac{d^4k}{(2\pi)^4} \left[f(k+a) - f(k)\right] = \frac{i}{(2\pi)^4} \left[2\pi^2 a_\mu \lim_{k\to\infty} k^\mu k^2 f_o(k) + \pi^2 a_\mu a_\nu \lim_{k\to\infty} k^\mu k^2 \frac{\partial}{\partial k_\nu} f_e(k) \right] \tag{29.6.16}$$

has a finite limit.[82] In deriving this result, we have expanded $f(k+a)$ in a Taylor expansion and follow the procedure outlined above eq. (29.6.14). Note that the angular integration removes the even parts of $f(k)$ and $\partial f/\partial k^\nu \equiv 2k_\nu\, \partial f/\partial k^2$ from the right-hand side of eq. (29.6.16). The "limits" in eq. (29.6.16) actually correspond to an average over the three-sphere at large Euclidean k, and thus should be interpreted by the use of:

$$\lim_{k\to\infty} \frac{k^\mu k^\nu}{k^2} = \tfrac{1}{4} g^{\mu\nu}, \tag{29.6.17}$$

$$\lim_{k\to\infty} \frac{k^\mu k^\nu k^\rho k^\lambda}{(k^2)^2} = \frac{1}{24}\left(g^{\mu\nu}g^{\rho\lambda} + g^{\mu\rho}g^{\nu\lambda} + g^{\mu\lambda}g^{\nu\rho}\right). \tag{29.6.18}$$

For example, if

$$f(k) = \frac{(k-p+A)^\kappa (k+A)^\lambda}{(k-p+A)^2 (k+A)^2}, \tag{29.6.19}$$

then in evaluating eq. (29.6.16), it is sufficient to write:

$$f_o(k) \simeq \tfrac{1}{2}(k-p+A)^\kappa (k+A)^\lambda \left[\frac{1}{(k^2)^2} + \frac{2k\cdot(p-2A)}{(k^2)^3} \right] - (k \to -k)$$
$$\simeq \frac{k^\kappa A^\lambda - k^\lambda (p-A)^\kappa}{(k^2)^2} + \frac{2k^\kappa k^\lambda\, k\cdot(p-2A)}{(k^2)^3}, \tag{29.6.20}$$

[82] If eq. (29.6.14) is linearly divergent, then the second term on the right-hand side of eq. (29.6.16) is zero. If eq. (29.6.14) is logarithmically divergent or finite, then the right-hand side of eq. (29.6.16) vanishes.

where we have dropped terms that do not contribute to eq. (29.6.16) in the limit of $k \to \infty$. Similarly,

$$\frac{\partial f_e}{\partial k_\nu} \simeq \frac{g^{\kappa\nu}k^\lambda + g^{\lambda\nu}k^\kappa}{(k^2)^2} - \frac{4k^\kappa k^\lambda k^\nu}{(k^2)^3}\,. \tag{29.6.21}$$

The evaluation of $X^{\kappa\lambda}$ is now straightforward [after using eqs. (29.6.17) and (29.6.18)]:

$$X^{\kappa\lambda} = \frac{i}{96\pi^2}\Big[g^{\kappa\lambda}(p+q)\cdot(A+B) + (A-2B)^\kappa(p+q)^\lambda + (p+q)^\kappa(B-2A)^\lambda\Big]. \tag{29.6.22}$$

Hence, eq. (29.6.12) yields the result for the anomaly in the current labeled by μ, a:

$$(p+q)^\mu \mathcal{A}^{abc}_{\mu\nu\rho} = \frac{i}{48\pi^2}D^{abc}\Big[(p+q)_\nu(A+B)_\rho + (A+B)_\nu(p+q)_\rho + g_{\nu\rho}(p+q)\cdot(A+B) \\ -3i\epsilon_{\nu\rho\kappa\lambda}(p+q)^\kappa(A-B)^\lambda\Big]. \tag{29.6.23}$$

Repeating all of the steps starting with eq. (29.6.9), we similarly obtain:[83]

$$-p^\nu \mathcal{A}^{abc}_{\mu\nu\rho} = -\frac{i}{48\pi^2}D^{abc}\Big[p_\rho(A+B)_\mu + p_\mu(A+B)_\rho + g_{\mu\rho}p\cdot(A+B) - 3i\epsilon_{\rho\mu\kappa\lambda}p^\kappa(A-B+2q)^\lambda\Big], \tag{29.6.24}$$

$$-q^\rho \mathcal{A}^{abc}_{\mu\nu\rho} = -\frac{i}{48\pi^2}D^{abc}\Big[q_\mu(A+B)_\nu + q_\nu(A+B)_\mu + g_{\mu\nu}q\cdot(A+B) - 3i\epsilon_{\mu\nu\kappa\lambda}q^\kappa(A-B-2p)^\lambda\Big]. \tag{29.6.25}$$

Non-chiral anomalies will arise for all three of the currents (assuming D^{abc} is non-vanishing), unless we choose the arbitrary constant vectors A and B such that

$$A + B = 0\,, \tag{29.6.26}$$

with the result:

$$(p+q)^\mu \mathcal{A}^{abc}_{\mu\nu\rho} = \frac{1}{8\pi^2}D^{abc}\epsilon_{\nu\rho\kappa\lambda}(p+q)^\kappa A^\lambda, \tag{29.6.27}$$

$$-p^\nu \mathcal{A}^{abc}_{\mu\nu\rho} = -\frac{1}{8\pi^2}D^{abc}\epsilon_{\rho\mu\kappa\lambda}p^\kappa(A+q)^\lambda, \tag{29.6.28}$$

$$-q^\rho \mathcal{A}^{abc}_{\mu\nu\rho} = -\frac{1}{8\pi^2}D^{abc}\epsilon_{\mu\nu\kappa\lambda}q^\kappa(A-p)^\lambda. \tag{29.6.29}$$

If D^{abc} is non-vanishing, it is not possible to avoid an anomaly simultaneously in all three symmetries, but one can still arrange for two of the symmetries to be non-anomalous. If one wants an anomaly to arise only in the current labeled by μ, a (for example, if the symmetries labeled by b, c are gauged), one must now choose $A = p - q$. The standard result follows:

$$(p+q)^\mu \mathcal{A}^{abc}_{\mu\nu\rho} = -\frac{1}{4\pi^2}D^{abc}\epsilon_{\nu\rho\kappa\lambda}p^\kappa q^\lambda, \tag{29.6.30}$$

$$-p^\nu \mathcal{A}^{abc}_{\mu\nu\rho} = 0, \tag{29.6.31}$$

$$-q^\rho \mathcal{A}^{abc}_{\mu\nu\rho} = 0. \tag{29.6.32}$$

[83] Alternatively, one can simply note that eq. (29.6.24) follows from eq. (29.6.23) by making the replacements $\mu \to \nu$, $\nu \to \rho$, $\rho \to \mu$, $A \to A+q$, $B \to B-q$, $p \to q$, and $q \to -p-q$, while eq. (29.6.25) follows from eq. (29.6.23) by making the replacements $\mu \to \rho$, $\nu \to \mu$, $\rho \to \nu$, $A \to A-p$, $B \to B+p$, $p \to -p-q$, and $q \to p$.

In particular, one cannot gauge all three symmetries labeled by a, b, c unless $D^{abc} = 0$.

If all three currents are identical, then by Bose symmetry the anomalies of the three currents must coincide. This can be achieved by choosing $A = \frac{1}{3}(p - q)$, in which case,

$$(p+q)^\mu \mathcal{A}^{abc}_{\mu\nu\rho} = -\frac{1}{12\pi^2} D^{abc} \epsilon_{\nu\rho\kappa\lambda} p^\kappa q^\lambda, \tag{29.6.33}$$

$$-p^\nu \mathcal{A}^{abc}_{\mu\nu\rho} = -\frac{1}{12\pi^2} D^{abc} \epsilon_{\rho\mu\kappa\lambda} p^\kappa q^\lambda, \tag{29.6.34}$$

$$-q^\rho \mathcal{A}^{abc}_{\mu\nu\rho} = -\frac{1}{12\pi^2} D^{abc} \epsilon_{\mu\nu\kappa\lambda} p^\kappa q^\lambda. \tag{29.6.35}$$

Returning briefly to the original naive Ward identities given in eqs. (29.6.3)–(29.6.5), the analysis above shows that these identities must be modified by an additional additive contribution given by the right-hand side of eqs. (29.6.27)–(29.6.29). In particular, there is no anomalous contribution proportional to f^{abc}. This can be checked explicitly by a diagrammatic computation of the two-point and three-point functions that appear in eqs. (29.6.3) and (29.6.5). We use eqs. (E.2.11) and (E.2.14) to write

$$\mathrm{Tr}(\boldsymbol{T^a T^b T^c}) = D^{abc}(R) + \frac{i}{2} I_2(R) f^{abc}\,, \tag{29.6.36}$$

where $I_2(R)$ is the index defined in eq. (E.2.1) and R is the representation of the generators $\boldsymbol{T^a}$. For example, inserting this result in eq. (29.6.2), it follows that:

$$(p+q)^\mu \, i\Gamma^{abc}_{\mu\nu\rho} = -\left[D^{abc}\, X^{\kappa\lambda} + \frac{i}{2} I_2(R) f^{abc}\, Y^{\kappa\lambda} \right] \mathrm{Tr}[\sigma_\kappa \overline{\sigma}_\nu \sigma_\lambda \overline{\sigma}_\rho]\,, \tag{29.6.37}$$

where the integral $Y^{\kappa\lambda}$ is given by:[84]

$$Y^{\kappa\lambda} = \int \frac{d^4k}{(2\pi)^4} \left[\frac{(k-p)^\kappa}{(k-p)^2} \frac{k^\lambda}{k^2} - \frac{(k+q)^\kappa}{(k+q)^2} \frac{k^\lambda}{k^2} - \frac{k^\kappa}{k^2} \frac{(k-q)^\lambda}{(k-q)^2} + \frac{k^\kappa}{k^2} \frac{(k+p)^\lambda}{(k+p)^2} \right]. \tag{29.6.38}$$

By letting $k \to -k$ in the third and fourth term in the integrand of eq. (29.6.38), we see that $Y^{\kappa\lambda} = Y^{\lambda\kappa}$, and hence by eq. (B.2.26),

$$-\frac{i}{2} I_2(R) f^{abc}\, Y^{\kappa\lambda} \mathrm{Tr}[\sigma_\kappa \overline{\sigma}_\nu \sigma_\lambda \overline{\sigma}_\rho] = -i I_2(R) f^{abc} \left[2Y_{\nu\rho} - g_{\nu\rho} Y_\lambda{}^\lambda \right]\,. \tag{29.6.39}$$

Since no ϵ-tensor appears, we can evaluate this integral in $d \neq 4$ dimensions using the standard techniques of dimensional regularization.

One can check that this result matches the diagrammatic calculation of the right-hand side of eq. (29.6.27). In particular, Fig. 29.6.3 yields

$$\begin{aligned} i\Pi^{ab}_{\mu\nu}(q) &= (-1) \int \frac{d^4k}{(2\pi)^4} \,\mathrm{Tr}\left[(-i\overline{\sigma}_\mu \boldsymbol{T^a}) \frac{ik\cdot\sigma}{k^2} (-i\overline{\sigma}_\nu \boldsymbol{T^b}) \frac{i(k+q)\cdot\sigma}{(k+q)^2} \right] \\ &= -I_2(R) \delta^{ab}\, \mathrm{Tr}(\overline{\sigma}_\mu \sigma_\rho \overline{\sigma}_\nu \sigma_\lambda) \int \frac{d^4k}{(2\pi)^4} \frac{k^\rho (k+q)^\lambda}{k^2 (k+q)^2}\,, \end{aligned} \tag{29.6.40}$$

where we have used eq. (E.2.1). Lorentz covariance implies that

$$i\Pi^{ab}_{\mu\nu}(q) = \delta^{ab} \left[C_1(q^2) g_{\mu\nu} + C_2(q^2) q_\mu q_\nu \right]\,, \tag{29.6.41}$$

[84] Here $Y^{\kappa\lambda}$ is obtained from $X^{\kappa\lambda}$ by setting $A = B = 0$, since we can use dimensional regularization for this part of the computation as explained below eq. (29.6.38).

for some scalar functions C_1 and C_2. It follows that $\Pi^{ab}_{\mu\nu}(q) = \Pi^{ab}_{\mu\nu}(-q)$ and $\Pi^{ab}_{\mu\nu}(q) = \Pi^{ab}_{\nu\mu}(q)$. Consequently, we can write:

$$\Pi^{ab}_{\mu\nu}(q) = \frac{i}{2} I_2(R)\delta^{ab}\,\mathrm{Tr}(\overline{\sigma}_\mu\sigma_\rho\overline{\sigma}_\nu\sigma_\lambda + \overline{\sigma}_\nu\sigma_\rho\overline{\sigma}_\mu\sigma_\lambda)\int \frac{d^4k}{(2\pi)^4}\frac{k^\rho(k+q)^\lambda}{k^2(k+q)^2}\,, \tag{29.6.42}$$

and so no ϵ-tensor appears in the evaluation of the trace. As above, we are now free to evaluate the integral in $d \neq 4$ dimensions. Comparing eqs. (29.6.37) and (29.6.38) to eq. (29.6.42), and using eq. (29.6.27), the end result is

$$(p+q)^\mu\, i\Gamma^{abc}_{\mu\nu\rho}(-p-q,p,q) = I_2(R) f^{abc}\,[\Pi_{\nu\rho}(q) - \Pi_{\nu\rho}(p)] + \frac{1}{8\pi^2} D^{abc}(R)\epsilon_{\nu\rho\kappa\lambda}(p+q)^\kappa A^\lambda\,, \tag{29.6.43}$$

where we have written $\Pi^{ab}_{\nu\rho} \equiv I_2(R)\delta^{ab}\Pi_{\nu\rho}$. Indeed the terms on the right-hand side proportional to f^{abc} match those of the naive Ward identity given in eq. (29.6.3). As previously asserted, the anomaly only resides in the contributions to the Ward identity proportional to D^{abc}.

In writing down eq. (29.6.2), we chose to use the rules with $\overline{\sigma}$ matrices for the current vertices and σ matrices for the massless fermion propagators. If we had chosen the opposite prescription (i.e., σ matrices for the current vertices and $\overline{\sigma}$ matrices for the massless fermion propagators), then the order of the factors inside the trace of eq. (29.6.2) would have been reversed.[85] Instead of eq. (29.6.12), we would have obtained

$$(p+q)^\mu \mathcal{A}^{abc}_{\mu\nu\rho} \;=\; -D^{abc}\,\mathrm{Tr}[\overline{\sigma}_\kappa\sigma_\nu\overline{\sigma}_\lambda\sigma_\rho]\,\bar{X}^{\kappa\lambda} = -2D^{abc}\left[\bar{X}_{\nu\rho} + \bar{X}_{\rho\nu} - g_{\nu\rho}\bar{X}_\lambda{}^\lambda - i\epsilon_{\kappa\nu\lambda\rho}\bar{X}^{\kappa\lambda}\right], \tag{29.6.44}$$

after applying eq. (B.2.27). The integral $\bar{X}^{\kappa\lambda}$ is simply related to $X^{\kappa\lambda}$ by:

$$\bar{X}^{\kappa\lambda} = X^{\lambda\kappa}\,. \tag{29.6.45}$$

Inserting eq. (29.6.45) into eq. (29.6.44), we immediately reproduce the result of eq. (29.6.12), as expected.

It is instructive to examine the case of massless QED. The terms of the Lagrangian involving the electron fields is given by

$$\mathscr{L} = i\chi^\dagger\overline{\sigma}^\mu D_\mu\chi + i\eta^\dagger\overline{\sigma}^\mu D_\mu\eta\,, \tag{29.6.46}$$

where $D_\mu \equiv \partial_\mu + iQA_\mu$ is the covariant derivative, and Q is the charge operator. Here, we identify χ as the two-component (left-handed) electron field and η as the two-component (left-handed) positron field. The corresponding eigenvalues of the charge operator are: $Q\chi = -e\chi$ and $Q\eta = +e\eta$ (where $e > 0$ is the electromagnetic gauge coupling constant, or equivalently the electric charge of the positron).

At the classical level, the massless QED Lagrangian [eq. (29.6.46)] is invariant under a $\mathrm{U}(1)_V\times\mathrm{U}(1)_A$ global symmetry. Under a $\mathrm{U}(1)_V\times\mathrm{U}(1)_A$ transformation specified by the infinitesimal parameters θ_V and θ_A,

$$\mathrm{U}(1)_V: \qquad \delta\chi = ie\theta_V\chi\,, \qquad\qquad \delta\eta = -ie\theta_V\eta\,, \tag{29.6.47}$$

$$\mathrm{U}(1)_A: \qquad \delta\chi = i\theta_A\chi\,, \qquad\qquad \delta\eta = i\theta_A\eta\,. \tag{29.6.48}$$

We can combine these equations into a two-dimensional matrix equation,

$$\delta\psi_j = -i\theta_a(\boldsymbol{T_a})_j{}^k\psi_k\,, \qquad \text{where} \qquad \psi = \begin{pmatrix}\chi\\ \eta\end{pmatrix}\,, \tag{29.6.49}$$

[85] The arrowed fermion lines in the loop must be traversed in the direction parallel [antiparallel] to the arrow directions when the $\overline{\sigma}$ [σ] versions of the propagator rule are employed, as indicated in eq. (29.4.2) [and in the discussion that follows]. This rule determines the order of the factors inside the spinor trace.

and the index a takes on two values, $a = V$, A. It follows that the $\mathrm{U}(1)_V \times \mathrm{U}(1)_A$ generators are given by

$$T_V = e \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} , \qquad \text{for} \quad \mathrm{U}(1)_V \,, \tag{29.6.50}$$

$$T_A = \begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix} , \qquad \text{for} \quad \mathrm{U}(1)_A \,. \tag{29.6.51}$$

The classically conserved Noether currents corresponding to the $\mathrm{U}(1)_V \times \mathrm{U}(1)_A$ global symmetry are the vector and axial currents:[86]

$$J_V^\mu = -e(\chi^\dagger \overline{\sigma}^\mu \chi - \eta^\dagger \overline{\sigma}^\mu \eta) \,, \tag{29.6.52}$$

$$J_A^\mu = -\chi^\dagger \overline{\sigma}^\mu \chi - \eta^\dagger \overline{\sigma}^\mu \eta \,. \tag{29.6.53}$$

Since the $\mathrm{U}(1)_V$ symmetry is gauged, we demand that this symmetry should be anomaly free. Thus, we make use of eqs. (29.6.30)–(29.6.32), where we identify the index pair μ, a with the axial vector current and the index pairs ν, b and ρ, c with the vector current. Thus, we compute:

$$D^{AVV} = \mathrm{Tr}\,(T_A T_V T_V) = -2e^2 \,. \tag{29.6.54}$$

Moreover, for an abelian symmetry group, $f^{abc} = 0$. Hence, using eq. (29.6.30) [which also applies in this case to the unsymmetrized three-point function], the U(1) axial vector anomaly equation reads:

$$(p+q)^\mu \, i\Gamma^{AVV}_{\mu\nu\rho} \;=\; \frac{e^2}{2\pi^2} \epsilon_{\nu\rho\kappa\lambda} p^\kappa q^\lambda \,, \tag{29.6.55}$$

in agreement with the well-known result.[87]

We now convert eq. (29.6.55) into an operator equation. Consider the process of two photon production by an axial vector current source [242]. First, we note that $\partial_\mu J_A^\mu(x) = i[P^\mu, J_{A\mu}(x)]$, where P^μ is the momentum operator. It follows that:

$$\langle p\,,\, q\,|\,\partial_\mu J_A^\mu(0)\,|\,0\rangle = i\,\langle p\,,\, q\,|\,[P^\mu\,,\, J_{A\mu}(0)]\,|\,0\rangle = i(p+q)^\mu\,\langle p\,,\, q\,|\,J_{A\mu}(0)|\,0\rangle \;. \tag{29.6.56}$$

We identify the S-matrix amplitude for the two photon production as:

$$i\Gamma^{AVV}_{\mu\nu\rho}\;\varepsilon^{\nu\,*}(p)\varepsilon^{\rho\,*}(q) = \langle p\,,\, q\,|\,-iJ_{A\mu}(0)|\,0\rangle \;, \tag{29.6.57}$$

where $\varepsilon(p)$ and $\varepsilon(q)$ are the polarization vectors for the final state photons. Note that the factor of $-i$ on the right-hand side of eq. (29.6.57) has been inserted to be consistent with the Feynman rule for the axial vector current insertion given in Fig. 29.6.1. Thus, using eqs. (29.6.55)–(29.6.57), we end up with [115]:

$$\begin{aligned} \langle p\,,\, q\,|\,\partial_\mu J_A^\mu(0)\,|\,0\rangle &= -\,\frac{e^2}{2\pi^2}\epsilon_{\nu\rho\kappa\lambda}\varepsilon^{\nu\,*}(p)\varepsilon^{\rho\,*}(q)p^\kappa q^\lambda \\ &= -\,\frac{e^2}{16\pi^2}\langle p\,,\, q\,|\,\epsilon_{\kappa\nu\lambda\rho}F^{\kappa\nu}F^{\lambda\rho}(0)\,|0\rangle \,, \end{aligned} \tag{29.6.58}$$

[86] Note that the interaction Lagrangian for massless QED is $\mathscr{L}_{\rm int} = -J_V^\mu A_\mu$, as expected. This accounts for the factor of e in the definition of the vector current. The axial vector current does not couple to the photon field; hence no coupling constant is included in its definition.

[87] This result was first obtained by Adler [241]. In comparing eq. (29.6.55) with Adler's result, note that the normalization of the triangle amplitude in [241] differs by a factor of $(2\pi)^4$ and the opposite sign convention for ϵ_{0123} is employed.

where $\epsilon_{\kappa\nu\lambda\rho}F^{\kappa\nu}F^{\lambda\rho} = 4\epsilon_{\kappa\nu\lambda\rho}(\partial^\kappa A^\nu)(\partial^\lambda A^\rho)$ has been used to eliminate the photon fields in favor of a product of electromagnetic field strength tensors. In deriving eq. (29.6.58), an additional factor of two arises due to two possible contractions of the photon fields with the external states. We thus obtain the operator form for the axial vector anomaly:[88]

$$\partial_\mu J^\mu_A = -\frac{e^2}{8\pi^2}F^{\lambda\rho}\widetilde{F}_{\lambda\rho}\,, \tag{29.6.59}$$

where the dual electromagnetic field strength tensor is defined by $\widetilde{F}_{\lambda\rho} \equiv \frac{1}{2}\epsilon_{\kappa\nu\lambda\rho}F^{\kappa\nu}$.

As a final example, we examine the anomalous baryon number and lepton number currents in the theory of electroweak interactions [243, 244, 245]. For simplicity of notation, we consider a one-generation model. The baryon number current is a vector current given by:

$$J^\mu_B = \tfrac{1}{3}\left[u^\dagger\overline{\sigma}^\mu u + d^\dagger\overline{\sigma}^\mu d - \bar{u}^\dagger\overline{\sigma}^\mu\bar{u} - \bar{d}^\dagger\overline{\sigma}^\mu\bar{d}\right]\,, \tag{29.6.60}$$

following the particle naming conventions of Table 29.1. Consider the process of gauge boson pair production by a baryon number current source. It is convenient to work in the interaction basis of gauge fields, $\{W^{\mu\,a}\,,\,B^\mu\}$, where $W^{\mu\,a}$ is an SU(2)-triplet of gauge fields and B^μ is a $\mathrm{U(1)_Y}$ hypercharge gauge field. We consider triangle diagrams where one generation of quarks runs in the loop. The external vertices consist of the baryon number current source and the two gauge bosons.

The generators corresponding to the SU(2) gauge boson vertices are given in block diagonal form by:

$$\boldsymbol{T^b} = g\,\mathrm{diag}\left(\frac{\tau^b}{2}\otimes\mathbb{1}_{3\times3}\,,\;0\,,\;0\right)\,, \tag{29.6.61}$$

where the τ^b are the Pauli matrices, $\mathbb{1}_{3\times3}$ is the identity matrix in color space, and $\otimes$ is the Kronecker product.[89] We have included a factor of the weak SU(2) coupling g in the definition of $\boldsymbol{T^b}$, since the Feynman rule given by Fig. 29.6.1 does not explicitly include the gauge coupling. Likewise, the generators corresponding to the $\mathrm{U(1)_Y}$ gauge boson vertices are given in block diagonal form by (cf. Table J.1):

$$\boldsymbol{Y} = g'\,\mathrm{diag}\left(\tfrac{1}{6}\mathbb{1}_{2\times2}\otimes\mathbb{1}_{3\times3}\,,\;-\tfrac{2}{3}\mathbb{1}_{3\times3}\,,\;\tfrac{1}{3}\mathbb{1}_{3\times3}\right)\,, \tag{29.6.62}$$

where $\mathbb{1}_{2\times2}$ is the identity matrix in weak isospin space, and g' is the $\mathrm{U(1)_Y}$ hypercharge gauge coupling. Finally, the generator corresponding to the baryon number current source is given in block diagonal form by:

$$\boldsymbol{B} = \tfrac{1}{3}\mathrm{diag}\left(\mathbb{1}_{2\times2}\otimes\mathbb{1}_{3\times3}\,,\;-\mathbb{1}_{3\times3}\,,\;-\mathbb{1}_{3\times3}\right)\,. \tag{29.6.63}$$

Consider first the production of two SU(2)-triplet gauge fields. We put $\boldsymbol{T^a} = \boldsymbol{B}$ and associate the indices b and c with the SU(2)-triplet gauge bosons. A simple calculation yields

$$D^{Bbc} = g^2\,\mathrm{Tr}(\boldsymbol{B}\boldsymbol{T^b}\boldsymbol{T^c}) = \tfrac{1}{2}g^2\delta^{bc}\,, \tag{29.6.64}$$

where the superscript index B refers to the baryon number current. Since the gauged weak SU(2) and hypercharge $\mathrm{U(1)_Y}$ currents must be anomaly free for the mathematical consistency of

[88] In the literature, eq. (29.6.59) often occurs with the opposite sign due to a sign convention for the Levi-Civita ϵ-tensor that is opposite to the one employed in this review. Here, we have reproduced the form given in [115].

[89] The Kronecker product of an $n\times n$ matrix and an $m\times m$ matrix is an $nm\times nm$ matrix. In addition, the following two properties of the Kronecker product are noteworthy [161, 246]: (i) $(A\otimes B)(C\otimes D) = AC\otimes BD$, and (ii) $\mathrm{Tr}(A\otimes B) = \mathrm{Tr}\,A\;\mathrm{Tr}\,B$.

the electroweak theory, it follows that eqs. (29.6.30)–(29.6.32) apply. That is, the symmetrized amplitude for the production of SU(2) gauge boson pairs by a baryon number source is anomalous:

$$(p+q)^\mu \mathcal{A}^{Bbc}_{\mu\nu\rho} = -\frac{g^2}{8\pi^2}\delta^{bc}\epsilon_{\nu\rho\kappa\lambda}p^\kappa q^\lambda\,. \tag{29.6.65}$$

Next, consider the production of two $\mathrm{U}(1)_\mathrm{Y}$ hypercharge gauge fields. A simple calculation yields

$$D^{BYY} = g'^2\,\mathrm{Tr}(\boldsymbol{BY^2}) = -\tfrac{1}{2}g'^2\,. \tag{29.6.66}$$

That is, the symmetrized amplitude for the production of $\mathrm{U}(1)_\mathrm{Y}$ gauge boson pairs by a baryon number source is anomalous:

$$(p+q)^\mu \mathcal{A}^{BYY}_{\mu\nu\rho} = \frac{g'^2}{8\pi^2}\epsilon_{\nu\rho\kappa\lambda}p^\kappa q^\lambda\,. \tag{29.6.67}$$

Finally, the symmetrized amplitude for the associated production of an SU(2)-triplet and $\mathrm{U}(1)_\mathrm{Y}$ hypercharge gauge field exhibits no anomaly as the corresponding $D^{BYc} = gg'\,\mathrm{Tr}(\boldsymbol{BYT^c}) = 0$.

The symmetrized amplitudes of the triangle diagrams involving a baryon number current source and a pair of SU(2) or $\mathrm{U}(1)_\mathrm{Y}$ gauge bosons are anomalous. Since the baryon number current is a vector current, we conclude that the source of the anomaly is a VVA triangle diagram in which one of the gauge boson currents is vector (V) and the other gauge boson current is axial vector (A). Nevertheless, the gauge boson axial vector current must be conserved, as noted above. Hence, the baryon number vector current must be anomalous [243]. In eqs. (29.6.55)–(29.6.58), we showed how to derive the operator form of the anomaly equation from the anomalous non-conservation of the symmetrized triangle amplitude. Following the same set of steps starting with eqs. (29.6.65) and (29.6.67), one obtains the anomalous non-conservation of the baryon number vector current, in a model with N_g quark generations [244, 56, 245]:

$$\partial_\mu J^\mu_B = \frac{g^2 N_g}{32\pi^2}W^{\lambda\rho b}\widetilde{W}^b_{\lambda\rho} - \frac{g'^2 N_g}{32\pi^2}B^{\lambda\rho}\widetilde{B}_{\lambda\rho}\,, \tag{29.6.68}$$

where $B_{\lambda\rho}$ and

$$W^b_{\lambda\rho} = \partial_\lambda W^b_\rho - \partial_\rho W^b_\lambda - g\epsilon^{bca}W^c_\lambda W^a_\rho\,, \tag{29.6.69}$$

are the field strength tensors for the hypercharge $\mathrm{U}(1)_\mathrm{Y}$ gauge boson and SU(2) gauge boson fields, respectively.[90] Note that for the non-abelian SU(2) gauge fields W^a_μ,

$$\begin{aligned} W^{\lambda\rho b}\,\widetilde{W}^b_{\lambda\rho} &= 2\epsilon^{\kappa\nu\lambda\rho}\left[(\partial_\kappa W^b_\nu)(\partial_\lambda W^b_\rho) - g\epsilon^{abc}(\partial_\kappa W^a_\nu)W^b_\lambda W^c_\rho\right] \\ &= 2\epsilon^{\kappa\nu\lambda\rho}\partial_\kappa\left[W^b_\nu(\partial_\lambda W^b_\rho) - \tfrac{1}{3}g\epsilon^{abc}W^a_\nu W^b_\lambda W^c_\rho\right]\,. \end{aligned} \tag{29.6.70}$$

Strictly speaking, the triangle graphs yield only the terms on the right-hand side of eq. (32.5) that are quadratic in the gauge fields. To obtain the corresponding terms that are cubic in the gauge terms, one must compute the anomalies that arise from VVVA and VAAA box diagrams [247, 237].

For completeness, we re-express the anomalous non-conservation of the baryon number current in terms of the mass eigenstate $\mathrm{SU}(2)\times\mathrm{U}(1)_\mathrm{Y}$ gauge fields:

$$\partial_\mu J^\mu_B = \frac{g^2 N_g}{16\pi^2}W^{\lambda\rho+}\widetilde{W}^-_{\lambda\rho} - \frac{g^2 N_g}{32\pi^2 c_W^2}Z^{\lambda\rho}\widetilde{Z}_{\lambda\rho} - \frac{egN_g}{32\pi^2 c_W}\left[Z^{\lambda\rho}\widetilde{F}_{\lambda\rho} + F^{\lambda\rho}\widetilde{Z}_{\lambda\rho}\right]\,, \tag{29.6.71}$$

[90] We again caution the reader that a different overall sign in eq. (32.5) often appears in the literature due to a sign convention for the Levi-Civita ϵ-tensor that is opposite to the one employed in this review. Here, we have chosen $\epsilon^{0123} = +1$.

where $c_W \equiv \cos\theta_W$, and $W^\pm_{\lambda\rho}$, $Z_{\lambda\rho}$ and $F_{\lambda\rho}$ are the $W^\pm$, Z and the electromagnetic field strength tensors, respectively.

By a similar analysis, one can also compute the anomalous non-conservation of the lepton number current,

$$J^\mu_L = \ell^\dagger\overline{\sigma}^\mu\ell + \nu^\dagger\overline{\sigma}^\mu\nu - \bar{\ell}^\dagger\overline{\sigma}^\mu\bar{\ell}\,, \tag{29.6.72}$$

due to triangle diagrams with N_g generations of leptons running in the loop. In the one-generation calculation, the relevant generators are:

$$\boldsymbol{T^b} = g\,\mathrm{diag}\left(\frac{\tau^b}{2}\,,\ 0\right)\,, \qquad \boldsymbol{Y} = g'\,\mathrm{diag}\left(-\tfrac{1}{2}\mathbb{1}_{2\times2}\,,\ 1\right)\,, \qquad \boldsymbol{L} = \mathrm{diag}\left(\mathbb{1}_{2\times2}\,,\ -1\right)\,. \tag{29.6.73}$$

Thus, we end up with:

$$D^{Lbc} = \tfrac{1}{2}g^2\delta^{bc}\,, \qquad D^{LYY} = -\tfrac{1}{2}g'^2\,, \qquad D^{LYc} = 0\,. \tag{29.6.74}$$

Thus, in the Standard Model with N_g generations of quarks and leptons,

$$\partial_\mu J^\mu_L = \partial_\mu J^\mu_B\,. \tag{29.6.75}$$

Hence, the $B-L$ current is conserved. However, $B-L$ is *not* anomaly free, due to the fact that the lepton number current exhibited in eq. (29.6.72) has both vector and axial vector pieces. In particular, the symmetrized amplitude of the triangle diagrams with three lepton number current sources is anomalous. To avoid this anomaly, one can add a right-handed neutrino to the Standard Model, in which case the leptonic current, $J^\mu_L = \ell^\dagger\overline{\sigma}^\mu\ell + \nu^\dagger\overline{\sigma}^\mu\nu - \bar{\ell}^\dagger\overline{\sigma}^\mu\bar{\ell} - \bar{\nu}^\dagger\overline{\sigma}^\mu\bar{\nu}$, is a vector current. In this case, eq. (29.6.75) still holds, and the $B-L$ current is conserved and anomaly free.

29.7 Appendixes

29.7.1 Metric and sigma matrix conventions

In this review, the metric tensor of four-dimensional Minkowski space is taken to be:[91]

$$g_{\mu\nu} = g^{\mu\nu} = \mathrm{diag}(+1,-1,-1,-1)\,, \tag{A.1}$$

where $\mu,\nu = 0,1,2,3$ are spacetime vector indices. Contravariant four-vectors (e.g. positions, momenta, gauge fields and currents) are defined with raised indices, and covariant four-vectors (e.g. derivatives) with lowered indices:

$$x^\mu = (t\,;\,\vec{\boldsymbol{x}})\,, \tag{A.2}$$
$$p^\mu = (E\,;\,\vec{\boldsymbol{p}})\,, \tag{A.3}$$
$$A^\mu(x) = (\Phi(\vec{\boldsymbol{x}},t)\,;\,\vec{\boldsymbol{A}}(\vec{\boldsymbol{x}},t))\,, \tag{A.4}$$
$$J^\mu(x) = (\rho(\vec{\boldsymbol{x}},t)\,;\,\vec{\boldsymbol{J}}(\vec{\boldsymbol{x}},t))\,, \tag{A.5}$$
$$\partial_\mu \equiv \frac{\partial}{\partial x^\mu} = (\partial/\partial t\,;\,\vec{\boldsymbol{\nabla}})\,, \tag{A.6}$$

in units with $c=1$. The totally antisymmetric pseudo-tensor $\epsilon^{\mu\nu\rho\sigma}$ is defined such that

$$\epsilon^{0123} = -\epsilon_{0123} = +1\,. \tag{A.7}$$

Eqs. (A.2)–(A.7) are taken to be independent of the metric signature convention.

[91] An otherwise identical version of this paper with the opposite metric signature is also available; see footnote 8.

The sigma matrices are defined with a raised (contravariant) index to be independent of the metric signature convention,

$$\sigma^\mu = (\mathbb{1}_{2\times2}\,;\,\vec{\boldsymbol{\sigma}})\,, \qquad\qquad \overline{\sigma}^\mu = (\mathbb{1}_{2\times2}\,;\,-\vec{\boldsymbol{\sigma}})\,, \tag{A.8}$$

where the three-vector of Pauli matrices is given by $\vec{\boldsymbol{\sigma}} \equiv (\sigma^1\,,\,\sigma^2\,,\,\sigma^3)$ [cf. eq. (29.29)] and $\mathbb{1}_{2\times2}$ is the 2×2 identity matrix. The corresponding quantities with lower (covariant) index are:

$$\sigma_\mu = g_{\mu\nu}\sigma^\nu = (\mathbb{1}_{2\times2}\,;\,-\vec{\boldsymbol{\sigma}})\,, \qquad\qquad \overline{\sigma}_\mu = g_{\mu\nu}\overline{\sigma}^\nu = (\mathbb{1}_{2\times2}\,;\,\vec{\boldsymbol{\sigma}})\,. \tag{A.9}$$

Various identities involving products of sigma matrices are given in Appendix B . The generators of the $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ representations of the Lorentz group are, respectively, given by:

$$\sigma^{\mu\nu} \equiv \frac{i}{4}(\sigma^\mu\overline{\sigma}^\nu - \sigma^\nu\overline{\sigma}^\mu)\,, \qquad\qquad \overline{\sigma}^{\mu\nu} \equiv \frac{i}{4}(\overline{\sigma}^\mu\sigma^\nu - \overline{\sigma}^\nu\sigma^\mu)\,. \tag{A.10}$$

In adopting the above definition of the sigma matrices, we differ from the corresponding conventions of Wess and Bagger [69] and Bilal [83]. The Wess/Bagger and Bilal (WBB) definition of the sigma matrices can be written (with lowered index μ) as:[92]

$$(\sigma^{\rm WBB})_{\mu\,\alpha\dot\beta} = \sigma_{0\alpha\dot\gamma}\overline{\sigma}_\mu^{\dot\gamma\delta}\sigma_{0\delta\dot\beta} = (\mathbb{1}_{2\times2}\,;\,\vec{\boldsymbol{\sigma}})\,, \tag{A.11}$$

$$(\overline{\sigma}^{\rm WBB})_\mu^{\dot\alpha\beta} = \overline{\sigma}_0^{\dot\alpha\gamma}\sigma_{\mu\gamma\dot\delta}\overline{\sigma}_0^{\dot\delta\beta} = (\mathbb{1}_{2\times2}\,;\,-\vec{\boldsymbol{\sigma}})\,. \tag{A.12}$$

One consequence of the WBB definition of σ and $\overline{\sigma}$ is that $\gamma_5 = \mathrm{diag}(\mathbb{1}_{2\times2}\,,\,-\mathbb{1}_{2\times2})$ in the chiral representation [cf. eq. (G.1.2)]. This associates a lowered undotted [raised dotted] two-component spinor with a right-handed [left-handed] four-component spinor [cf. eqs. (G.1.7) and (G.1.9)]. Indeed, this was the common convention in the older literature (e.g., see refs. [36, 37, 39, 40, 42, 59]).[93] However, in the modern formulation of electroweak theory in terms of left-handed fermions, it is now more common to associate a lower undotted [raised dotted] two-component spinor with a left-handed [right-handed] four-component spinor. This is the motivation for our conventions for the sigma matrices given in eqs. (A.8) and (A.9).

In order to facilitate the comparison with the metric signature with $g_{00} = -1$, we provide the key ingredients needed for translating between Minkowski metrics of opposite signature. In our conventions [cf. eqs. (A.2)–(A.9)], each of the following objects (with the Lorentz index heights as shown) is defined *independently* of the metric signature:

$$x^\mu\,,\,p^\mu\,,\,J^{\mu\nu}\,,\,J_{\mu\nu}\,,\,\partial_\mu\,,\,\sigma^\mu\,,\,\overline{\sigma}^\mu\,,\,S^\mu\,,\,J^\mu\,,\,A^\mu\,,\,D_\mu\,,\,G^\mu{}_\nu\,,\,\gamma^\mu\,,\,\gamma_5\,,\,\delta^\mu_\nu\,,\,\epsilon^{\mu\nu\rho\sigma}\,,\,\epsilon_{\mu\nu\rho\sigma}\,,\,\theta^\mu{}_\nu \qquad \text{[no sign change]}, \tag{A.13}$$

whereas the following objects change sign when the Minkowski metric signature is reversed:

$$g_{\mu\nu}\,,\,g^{\mu\nu}\,,\,x_\mu\,,\,p_\mu\,,\,\partial^\mu\,,\,\sigma_\mu\,,\,\overline{\sigma}_\mu\,,\,S_\mu\,,\,J_\mu\,,\,A_\mu\,,\,D^\mu\,,\,G^{\mu\nu}\,,\,G_{\mu\nu}\,,\,\gamma_\mu\,,\,\theta^{\mu\nu}\,,\,\theta_{\mu\nu} \qquad \text{[sign change]}. \tag{A.14}$$

Here, $J^{\mu\nu}$ is the angular momentum tensor, the spin four-vector S^μ is defined in eq. (29.3.15), J^μ is any conserved current, A^μ is any gauge vector potential, and D_μ and $G_{\mu\nu}$ are the corresponding covariant derivative and antisymmetric tensor field strength, respectively. The Dirac gamma matrices are defined in eq. (G.1.2), and the tensor $\theta^{\mu\nu}$ parameterizes Lorentz transformations [cf. eqs. (29.8), (29.15), and (29.100)–(29.102)]. The list of eq. (A.14) can be deduced from eq. (A.13) by using the metric tensor and its inverse to lower and raise Lorentz indices, simply

[92] Although Wess/Bagger and Bilal employ opposite metric signatures of $g_{00} = -1$ and $g_{00} = +1$, respectively, their definitions of σ_μ and $\overline{\sigma}_\mu$ (with covariant index μ) coincide. Note that the spinor structure of the σ and $\overline{\sigma}$ matrices and the definitions of the various (two-index and four-index) epsilon tensors [cf. eqs. (29.21) and (A.7)] are identical in both the WBB conventions and in our conventions.

[93] This convention persists in the literature of the spinor helicity method (cf. footnote 163 in Appendix I.2).

because each metric or inverse metric changes sign when the metric signature is reversed. Given any other object not included in eqs. (A.13) and (A.14), it is straightforward to make the appropriate assignment by considering how the object is defined. For example, we must assign $\sigma_{\mu\nu}$, $\overline{\sigma}_{\mu\nu}$, $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$ to the list of eq. (A.13), based on the definitions given in eqs. (29.71) and (29.72). In general, objects that do not carry Lorentz vector indices (including all fermion spinor fields and spinor wave functions) are defined to be the same in the two metric signatures, with the obvious exception of scalar quantities formed from an odd number of objects from the list of eq. (A.14). For example, the dot product of two four-vectors may or may not change sign when the Minkowski metric signature is reversed. By writing out the dot product explicitly using the metric tensor to contract the indices, one can use eqs. (A.13) and (A.14) to determine the behavior of a dot product under the reversal of the metric signature. In particular, $p\cdot A$ changes sign whereas $\sigma\cdot\partial$ and $\overline{\sigma}\cdot\partial$ do not change sign, when the Minkowski metric signature is reversed.

The translation between Minkowski metrics of opposite signatures is now straightforward. Given any relativistic covariant quantity or equation in the convention where $g_{00} = +1$, one need only employ eqs. (A.13) and (A.14) to obtain the same quantity or equation in the convention where $g_{00} = -1$, and vice versa.[94]

As an example, let us verify that under the reversal of the Minkowski metric signature the gauge covariant derivative D_μ does not change sign and the gauge field strength tensor $G^{\mu\nu}$ changes sign. In the metric signature with $g_{00} = +1$, we define

$$D_\mu \equiv \boldsymbol{I}_{d_R}\partial_\mu + igA_\mu\,, \qquad\qquad (g_{00} = +1)\,, \tag{A.15}$$

where $A_\mu \equiv A^a_\mu \boldsymbol{T^a}$ is the matrix gauge field for a representation R of dimension d_R, and $\boldsymbol{I}_{d_R}$ is the $d_R \times d_R$ identity matrix. Since under the reversal of the metric signature, ∂_μ does not change sign [according to eq. (A.13)] whereas A_μ changes sign [according to eq. (A.14)], it follows that the quantity defined in the metric signature where $g_{00} = -1$,

$$D_\mu \equiv \boldsymbol{I}_{d_R}\partial_\mu - igA_\mu\,, \qquad\qquad (g_{00} = -1) \tag{A.16}$$

has the same overall sign as eq. (A.15). It follows that when the metric signature is reversed, D_μ does not change sign whereas $D^\mu \equiv g^{\mu\nu}D_\nu$ does change sign, as indicated in eqs. (A.13) and (A.14). Next, consider the matrix gauge field strength tensor $G_{\mu\nu} \equiv G^a_{\mu\nu}\boldsymbol{T^a}$, defined by

$$G^{\mu\nu} \equiv \frac{-i}{g}\,[D^\mu\,,\,D^\nu] = \partial^\mu A^\nu - \partial^\nu A^\mu + ig[A^\mu\,,\,A^\nu]\,, \qquad (g_{00} = +1)\,, \tag{A.17}$$

where the commutator $[D^\mu\,,\,D^\nu]$ is an operator that acts on fields that transform with respect to an arbitrary representation R. In the metric signature with $g_{00} = -1$, we define the gauge field strength tensor as a commutator of covariant derivatives with the *opposite* overall sign:

$$G^{\mu\nu} \equiv \frac{i}{g}\,[D^\mu\,,\,D^\nu] = \partial^\mu A^\nu - \partial^\nu A^\mu - ig[A^\mu\,,\,A^\nu]\,, \qquad (g_{00} = -1)\,, \tag{A.18}$$

where D^μ is now defined as in eq. (A.16). Since under a reversal of the metric signature, A^μ does not change sign [according to eq. (A.13)] whereas ∂^μ changes sign [according to eq. (A.14)], it follows that $G^{\mu\nu}$ and $G_{\mu\nu} \equiv g_{\mu\rho}g_{\nu\sigma}G^{\rho\sigma}$ do indeed change sign when the metric signature is reversed, as stated in eq. (A.14).

As another simple illustration, consider the σ-matrix identity,

$$\overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho = g^{\mu\nu}\overline{\sigma}^\rho - g^{\mu\rho}\overline{\sigma}^\nu + g^{\nu\rho}\overline{\sigma}^\mu - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa\,, \qquad (g_{00} = +1)\,, \tag{A.19}$$

[94] Note that for any relativistic covariant term appearing additively in a valid equation, the *relative* sign that results from changing between Minkowski metrics of opposite signature is simply given by $\mathcal{S} = (-1)^{\mathcal{N}}$, where $\mathcal{N} \equiv N_m + N_d + N_G + ...$ Here N_m is the number of metric tensors appearing either explicitly or implicitly through contracted upper and lower indices, N_d is the number of spacetime and/or covariant derivatives, N_G is the number of gauge field strength tensors, and the ellipsis (...) accounts for any additional quantities whose contravariant forms (with all Lorentz indices raised) appear in the list of eq. (A.14).

In the opposite metric signature with $g_{00} = -1$, we apply the results of eqs. (A.13) and (A.14) and then multiply both sides of the equation by -1 to obtain:

$$\overline{\sigma}^\mu \sigma^\nu \overline{\sigma}^\rho = -g^{\mu\nu}\overline{\sigma}^\rho + g^{\mu\rho}\overline{\sigma}^\nu - g^{\nu\rho}\overline{\sigma}^\mu + i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa\,, \qquad (g_{00} = -1)\,. \tag{A.20}$$

Finally, in the sigma matrix conventions of Wess/Bagger [69] and Bilal [83], both eqs. (A.19) and (A.20) are modified by changing the overall sign of $i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa$. In general, to convert the identities of Appendix B to the conventions of WBB, one must first convert (if necessary) to the appropriate metric signature, and then interchange $\sigma \leftrightarrow \overline{\sigma}$ [cf. eqs. (A.11) and (A.12)].

We end this Appendix with a brief summary of our conventions for four-dimensional Euclidean space. The Euclidean components of the coordinates [represented in Minkowski space by the contravariant four-vector, $x^\mu = (x^0\,;\,\vec{\boldsymbol{x}})$, for $\mu = 0, 1, 2, 3$], are defined as

$$x^\mu_E = x_{E\,\mu} = (\vec{\boldsymbol{x}}\,,\, x^4_E)\,, \qquad x^4_E = x_{E4} \equiv ix^0\,, \qquad (\mu = 1, 2, 3, 4)\,. \tag{A.21}$$

The four-momentum operator in Minkowski space is $p^\mu = i\partial^\mu = i(\partial/\partial t\,,\, -\vec{\boldsymbol{\nabla}})$. Following the conventions of [248], the Euclidean counterpart of the momentum operator is

$$p^\mu_E = p_{E\mu} = (\vec{\boldsymbol{p}}\,,\, p^4_E) = -i\partial^\mu_E = -i(\vec{\boldsymbol{\nabla}}\,,\, \partial/\partial x^4_E)\,, \qquad p^4_E = p_{E4} = ip^0\,, \tag{A.22}$$

The Minkowski space Green functions are obtained from Euclidean space Green functions by means of a Wick rotation [124, 249, 248] of $x^4_E \equiv ix^0$ in a counterclockwise sense.[95] Scalar products of Euclidean four-vectors are carried out by employing the Euclidean metric tensor $\delta_{\mu\nu} = \delta^{\mu\nu} = \mathrm{diag}(1\,,\,1\,,\,1\,,\,1)$. For example, the Euclidean counterpart of $-p\cdot x = -p^0x^0 + \vec{\boldsymbol{p}}\cdot\vec{\boldsymbol{x}}$ is $p^\mu_E x^\mu_E = \vec{\boldsymbol{p}}\cdot\vec{\boldsymbol{x}} + p^4_E x^4_E$, etc. Given any tensorial equation in Euclidean space, the heights of the indices is irrelevant. Consequently, one can simply place all indices at the same height (either all raised or all lowered), with an implied sum over a pair of repeated indices.

One can also introduce Euclidean sigma matrices [250]:

$$\sigma^\mu_E \equiv (-i\vec{\boldsymbol{\sigma}}\,,\, \sigma^4_E)\,, \qquad \overline{\sigma}^\mu_E \equiv (i\vec{\boldsymbol{\sigma}}\,,\, \overline{\sigma}^4_E)\,, \qquad \text{where } \sigma^4_E = \overline{\sigma}^4_E \equiv \mathbb{1}_{2\times2}\,, \tag{A.23}$$

which satisfy:[96]

$$\sigma^\mu_E\overline{\sigma}^\nu_E + \sigma^\nu_E\overline{\sigma}^\mu_E = 2\delta^{\mu\nu}\,, \qquad \overline{\sigma}^\mu_E\sigma^\nu_E + \overline{\sigma}^\nu_E\sigma^\mu_E = 2\delta^{\mu\nu}\,. \tag{A.24}$$

The four-dimensional rotation group in Euclidean space is SO(4), which is locally equivalent to SU(2)×SU(2). It possesses two independent pseudo-real two-dimensional spinor representations $(\frac{1}{2}, 0)$ and $(0, \frac{1}{2})$ [not related by hermitian conjugation in contrast to the Lorentz group], with corresponding hermitian generators $\sigma^{\mu\nu}_E$ and $\overline{\sigma}^{\mu\nu}_E$, respectively:

$$\sigma^{\mu\nu}_E = \frac{i}{4}\,(\sigma^\mu_E\overline{\sigma}^\nu_E - \sigma^\nu_E\overline{\sigma}^\mu_E)\,, \qquad \overline{\sigma}^{\mu\nu}_E = \frac{i}{4}\,(\overline{\sigma}^\mu_E\sigma^\nu_E - \overline{\sigma}^\nu_E\sigma^\mu_E)\,. \tag{A.25}$$

These tensors are anti-self-dual and self-dual, respectively [121],

$$\sigma^{\mu\nu}_E = -\tfrac{1}{2}\epsilon^{\mu\nu\rho\tau}\sigma^{\rho\tau}_E\,, \qquad \overline{\sigma}^{\mu\nu}_E = \tfrac{1}{2}\epsilon^{\mu\nu\rho\tau}\overline{\sigma}^{\rho\tau}_E\,, \tag{A.26}$$

where the totally antisymmetric Levi-Civita tensor is defined in Euclidean space such that $\epsilon^{1234} = \epsilon_{1234} = +1$. One can express $\sigma^{\mu\nu}_E$ and $\overline{\sigma}^{\mu\nu}_E$ in terms of the 't Hooft eta symbols [251],

$$\sigma^{\mu\nu}_E = -\tfrac{1}{2}\overline{\eta}^{k\mu\nu}\sigma^k\,, \qquad \overline{\sigma}^{\mu\nu}_E = -\tfrac{1}{2}\eta^{k\mu\nu}\sigma^k\,, \tag{A.27}$$

[95] Expressing the corresponding Green functions as Fourier transforms of momentum-space Green functions, one must simultaneously Wick-rotate $p^4_E \equiv ip^0$ in a clockwise sense to avoid singularities in the complex p^0-plane.

[96] It is seemingly more natural to define $\sigma^\mu_E \equiv (\vec{\boldsymbol{\sigma}}\,,\, \sigma^4_E)$ and $\overline{\sigma}^\mu_E \equiv (-\vec{\boldsymbol{\sigma}}\,,\, \overline{\sigma}^4_E)$ where $\sigma^4_E = \overline{\sigma}^4_E \equiv i\mathbb{1}_{2\times2}$, in which case one must replace $\delta^{\mu\nu}$ with $-\delta^{\mu\nu}$ in eq. (A.24). Nevertheless we prefer eq. (A.23), which avoids an overall minus sign in the respective anticommutation relations of the Euclidean sigma and gamma matrices [cf. footnote 140].

where $\mu,\nu = 1,2,3,4$ and there is an implicit sum over $k = 1,2,3$. Equivalently,

$$\sigma^\mu_E \overline{\sigma}^\nu_E = \delta^{\mu\nu} + i\overline{\eta}^{k\mu\nu}\sigma^k\,, \qquad\qquad \overline{\sigma}^\mu_E \sigma^\nu_E = \delta^{\mu\nu} + i\eta^{k\mu\nu}\sigma^k\,. \tag{A.28}$$

The 't Hooft symbols η and $\overline{\eta}$ satisfy self-duality and anti-self-duality properties, respectively:

$$\eta^{k\mu\nu} = \tfrac{1}{2}\epsilon^{\mu\nu\rho\lambda}\eta^{k\rho\lambda}\,, \qquad\qquad \overline{\eta}^{k\mu\nu} = -\tfrac{1}{2}\epsilon^{\mu\nu\rho\lambda}\overline{\eta}^{k\rho\lambda}\,, \tag{A.29}$$

and are explicitly given by:

$$\eta^{kij} = \overline{\eta}^{kij} = \epsilon^{ijk}\,, \qquad \eta^{kj4} = -\eta^{k4j} = \overline{\eta}^{k4j} = -\overline{\eta}^{kj4} = \delta^{kj}\,, \qquad \eta^{k44} = \overline{\eta}^{k44} = 0\,. \tag{A.30}$$

For a more comprehensive treatment of two-component spinors in Euclidean space, see [130].

29.7.2 Sigma matrix identities and Fierz identities

In Section 29.2, we derived a number of identities involving σ^μ, $\overline{\sigma}^\mu$, $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$. When considering a theory regularized by dimensional continuation [125], one must give meaning to the sigma matrices and their respective identities in $d \neq 4$ dimensions. In many cases, it is possible to reinterpret the sigma matrix identities for $d \neq 4$. However, the Fierz identities, which depend on the completeness of $\{\mathbb{1}_{2\times 2}\,,\,\sigma^i\}$ in the vector space of 2×2 matrices, do not have a consistent, unambiguous meaning outside of four dimensions (e.g., see refs. [252, 253, 254, 255] and references therein). In Appendix B.1 , we exhibit a comprehensive list of identities from which many generalized Fierz identities can be derived. In Appendix B.2 , we examine the class of sigma matrix identities that can unambiguously be extended to $d \neq 4$ dimension and thus can be employed in the context of dimensional regularization.

Two-component spinor Fierz identities

We begin with the basic identity for 2×2 matrices [78],

$$\delta_{ab}\delta_{cd} = \tfrac{1}{2}\left[\delta_{ad}\delta_{cb} + \sigma^i_{ad}\sigma^i_{cb}\right]\,, \tag{B.1.1}$$

where there is an implicit sum over the repeated superscript $i = 1,2,3$. Eq. (B.1.1) is a consequence of the completeness of $\{\mathbb{1}_{2\times 2}\,,\,\sigma^i\}$ in the four-dimensional vector space of 2×2 matrices. Applying these considerations to matrices that possess two indices, either undotted and/or dotted, one can establish four isomorphic four-dimensional vector spaces, each of which is spanned by four linearly independent hermitian matrices,

$$\mathcal{V} = \{\delta_\alpha{}^\beta\,,\, i(\sigma^{0i})_\alpha{}^\beta\}\,, \qquad \overline{\mathcal{V}} = \{\delta^{\dot\alpha}{}_{\dot\beta}\,,\, i(\overline{\sigma}^{0i})^{\dot\alpha}{}_{\dot\beta}\}\,, \qquad \mathcal{V}' = \{\sigma^\mu_{\alpha\dot\beta}\}\,, \qquad \overline{\mathcal{V}}' = \{\overline{\sigma}^{\mu\,\dot\alpha\beta}\}\,. \tag{B.1.2}$$

Note that the σ^{jk} and $\overline{\sigma}^{jk}$ are completely determined by the six matrices σ^{0i} and $\overline{\sigma}^{0i}$ (where $i,j,k = 1,2,3$) due to the self-duality relations given by eq. (29.76).

It is therefore convenient to consider the set of matrices,

$$\Gamma \equiv \left\{\delta_\alpha{}^\beta\,,\,\sigma^\mu_{\alpha\dot\beta}\,,\,\sigma^{\mu\nu}{}_\alpha{}^\beta\,,\,\delta^{\dot\alpha}{}_{\dot\beta}\,,\,\sigma^{\mu\,\dot\alpha\beta}\,,\,\overline{\sigma}^{\mu\nu\,\dot\alpha}{}_{\dot\beta}\right\}\,. \tag{B.1.3}$$

Elements of Γ will be denoted by $\Gamma^{(n)}$ $(n = 1,2,...,6)$. Starting from eq. (B.1.1), one can establish a set of 21 identities of the following form:

$$(\Gamma^{(k)})^I_{AB}(\Gamma^{(n)})^J_{CD} = \sum_{p,q,K,L} (C^{kn}_{pq})^{IJ}_{KL}\,(\Gamma^{(p)})^K_{AD}(\Gamma^{(q)})^L_{CB}\,, \tag{B.1.4}$$

where each label I, J, K and L can represent zero, one or two Lorentz spacetime indices, and A, B, C and D represent two-component spinor indices, each of which may be undotted or dotted and in the lowered or raised position as appropriate. The sum in eq. (B.1.4) is taken over the matrices specified in eq. (B.1.3), and the C_{pq}^{kn} are numerical coefficients [cf. eqs. (B.1.6)–(B.1.26)].

Let us multiply eq. (B.1.4) by four (commuting or anticommuting) two-component spinors $Z_{1A}Z_{2B}Z_{3C}Z_{4D}$, where Z_i stands for either the undaggered or daggered spinor z_i or $z_i^\dagger$, depending on whether the corresponding spinor index is undotted or dotted. This procedure yields generalized Fierz identities of the form [78, 89, 75, 86]:

$$(Z_1\Gamma^{(k)I}Z_2)(Z_3\Gamma^{(n)J}Z_4) = (-1)^A \sum_{p,q,K,L} (C_{pq}^{kn})_{KL}^{IJ}(Z_1\Gamma^{(p)K}Z_4)(Z_3\Gamma^{(q)L}Z_2)\,, \tag{B.1.5}$$

where $(-1)^A = +1$ [-1] for commuting [anticommuting] spinors.[97]

[97] It is often convenient to reverse the order of the spinors Z_2 and Z_3 on the right-hand side of eq. (B.1.5) by using eqs. (29.60)–(29.62) and (29.95)–(29.96) to eliminate the factor of $(-1)^A$ [cf. eq. (29.68)].

The explicit expressions for the 21 identities represented by eq. (B.1.4) are as follows.

$$\delta_\alpha{}^\beta \delta^{\dot\beta}{}_{\dot\alpha} = \tfrac{1}{2}\sigma^\mu_{\alpha\dot\alpha}\overline{\sigma}_\mu^{\dot\beta\beta}\,, \tag{B.1.6}$$

$$\delta_\alpha{}^\beta \delta_\gamma{}^\tau = \tfrac{1}{2}\left[\delta_\alpha{}^\tau \delta_\gamma{}^\beta + (\sigma^{\mu\nu})_\alpha{}^\tau (\sigma_{\mu\nu})_\gamma{}^\beta\right]\,, \tag{B.1.7}$$

$$\delta^{\dot\alpha}{}_{\dot\beta}\delta^{\dot\gamma}{}_{\dot\tau} = \tfrac{1}{2}\left[\delta^{\dot\alpha}{}_{\dot\tau}\delta^{\dot\gamma}{}_{\dot\beta} + (\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\tau}(\overline{\sigma}_{\mu\nu})^{\dot\gamma}{}_{\dot\beta}\right]\,, \tag{B.1.8}$$

$$\delta_\alpha{}^\beta \sigma^\mu_{\gamma\dot\alpha} = \tfrac{1}{2}\sigma^\mu_{\alpha\dot\alpha}\delta_\gamma{}^\beta - i\sigma_{\nu\,\alpha\dot\alpha}(\sigma^{\mu\nu})_\gamma{}^\beta\,, \tag{B.1.9}$$

$$\delta_\alpha{}^\beta \overline{\sigma}^{\mu\,\dot\beta\gamma} = \tfrac{1}{2}\delta_\alpha{}^\gamma \overline{\sigma}^{\mu\,\dot\beta\beta} + i(\sigma^{\mu\nu})_\alpha{}^\gamma \overline{\sigma}_\nu^{\dot\beta\beta}\,, \tag{B.1.10}$$

$$\delta^{\dot\alpha}{}_{\dot\beta}\sigma^\mu_{\beta\dot\gamma} = \tfrac{1}{2}\delta^{\dot\alpha}{}_{\dot\gamma}\sigma^\mu_{\beta\dot\beta} + i(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\gamma}\sigma_{\nu\,\beta\dot\beta}\,, \tag{B.1.11}$$

$$\delta^{\dot\alpha}{}_{\dot\beta}\overline{\sigma}^{\mu\,\dot\gamma\alpha} = \tfrac{1}{2}\overline{\sigma}^{\mu\,\dot\alpha\alpha}\delta^{\dot\gamma}{}_{\dot\beta} - i\overline{\sigma}_\nu^{\dot\alpha\alpha}(\overline{\sigma}^{\mu\nu})^{\dot\gamma}{}_{\dot\beta}\,, \tag{B.1.12}$$

$$\delta_\alpha{}^\beta (\sigma^{\mu\nu})_\gamma{}^\tau = \tfrac{1}{2}\Big\{(\sigma^{\mu\nu})_\alpha{}^\tau \delta_\gamma{}^\beta + \delta_\alpha{}^\tau (\sigma^{\mu\nu})_\gamma{}^\beta - ig_{\rho\kappa}\left[(\sigma^{\mu\kappa})_\alpha{}^\tau (\sigma^{\nu\rho})_\gamma{}^\beta - (\sigma^{\nu\kappa})_\alpha{}^\tau (\sigma^{\mu\rho})_\gamma{}^\beta\right]\Big\}, \tag{B.1.13}$$

$$\delta_\alpha{}^\beta (\overline{\sigma}^{\mu\nu})^{\dot\beta}{}_{\dot\alpha} = -\tfrac{1}{4}i\left[\sigma^\mu_{\alpha\dot\alpha}\overline{\sigma}^{\nu\,\dot\beta\beta} - \sigma^\nu_{\alpha\dot\alpha}\overline{\sigma}^{\mu\,\dot\beta\beta} + i\epsilon^{\mu\nu\rho\kappa}\sigma_{\rho\,\alpha\dot\alpha}\overline{\sigma}_\kappa^{\dot\beta\beta}\right]\,, \tag{B.1.14}$$

$$\delta^{\dot\alpha}{}_{\dot\beta}(\sigma^{\mu\nu})_\beta{}^\alpha = -\tfrac{1}{4}i\left[\overline{\sigma}^{\mu\,\dot\alpha\alpha}\sigma^\nu_{\beta\dot\beta} - \overline{\sigma}^{\nu\,\dot\alpha\alpha}\sigma^\mu_{\beta\dot\beta} - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\rho^{\dot\alpha\alpha}\sigma_{\kappa\,\beta\dot\beta}\right]\,, \tag{B.1.15}$$

$$\delta^{\dot\alpha}{}_{\dot\beta}(\overline{\sigma}^{\mu\nu})^{\dot\gamma}{}_{\dot\tau} = \tfrac{1}{2}\Big\{(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\tau}\delta^{\dot\gamma}{}_{\dot\beta} + \delta^{\dot\alpha}{}_{\dot\tau}(\overline{\sigma}^{\mu\nu})^{\dot\gamma}{}_{\dot\beta} - ig_{\rho\kappa}\left[(\overline{\sigma}^{\mu\kappa})^{\dot\alpha}{}_{\dot\tau}(\overline{\sigma}^{\nu\rho})^{\dot\gamma}{}_{\dot\beta} - (\overline{\sigma}^{\nu\kappa})^{\dot\alpha}{}_{\dot\tau}(\overline{\sigma}^{\mu\rho})^{\dot\gamma}{}_{\dot\beta}\right]\Big\}, \tag{B.1.16}$$

$$\sigma^\mu_{\alpha\dot\alpha}\sigma^\nu_{\beta\dot\beta} = \tfrac{1}{2}\left[\sigma^\mu_{\alpha\dot\beta}\sigma^\nu_{\beta\dot\alpha} + \sigma^\nu_{\alpha\dot\beta}\sigma^\mu_{\beta\dot\alpha} - g^{\mu\nu}\sigma^\lambda_{\alpha\dot\beta}\sigma_{\lambda\,\beta\dot\alpha} + i\epsilon^{\mu\nu\rho\kappa}\sigma_{\rho\,\alpha\dot\beta}\,\sigma_{\kappa\,\beta\dot\alpha}\right]\,, \tag{B.1.17}$$

$$\overline{\sigma}^{\mu\dot\alpha\alpha}\overline{\sigma}^{\nu\dot\beta\beta} = \tfrac{1}{2}\left[\overline{\sigma}^{\mu\dot\alpha\beta}\overline{\sigma}^{\nu\dot\beta\alpha} + \overline{\sigma}^{\nu\dot\alpha\beta}\overline{\sigma}^{\mu\dot\beta\alpha} - g^{\mu\nu}\overline{\sigma}^{\lambda\,\dot\alpha\beta}\overline{\sigma}_\lambda^{\dot\beta\alpha} - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\rho^{\dot\alpha\beta}\,\overline{\sigma}_\kappa^{\dot\beta\alpha}\right]\,, \tag{B.1.18}$$

$$\sigma^\mu_{\alpha\dot\alpha}\overline{\sigma}^{\nu\dot\beta\beta} = \tfrac{1}{2}\left[g^{\mu\nu}\delta_\alpha{}^\beta\delta^{\dot\beta}{}_{\dot\alpha} - 2i(\sigma^{\mu\nu})_\alpha{}^\beta\delta^{\dot\beta}{}_{\dot\alpha} + 2i\delta_\alpha{}^\beta(\overline{\sigma}^{\mu\nu})^{\dot\beta}{}_{\dot\alpha} - 4g_{\rho\kappa}(\sigma^{\mu\kappa})_\alpha{}^\beta(\overline{\sigma}^{\nu\rho})^{\dot\beta}{}_{\dot\alpha}\right]\,, \tag{B.1.19}$$

$$\begin{aligned}(\sigma^{\mu\nu})_\alpha{}^\beta\sigma^\rho_{\gamma\dot\alpha} = \tfrac{1}{2}\big[&\sigma^\nu_{\alpha\dot\alpha}(\sigma^{\mu\rho})_\gamma{}^\beta - \sigma^\mu_{\alpha\dot\alpha}(\sigma^{\nu\rho})_\gamma{}^\beta + i\epsilon^{\mu\nu\kappa}{}_\lambda\sigma_{\kappa\,\alpha\dot\alpha}(\sigma^{\lambda\rho})_\gamma{}^\beta\\ &-\tfrac{1}{2}i\,\left(g^{\mu\rho}\sigma^\nu_{\alpha\dot\alpha} - g^{\nu\rho}\sigma^\mu_{\alpha\dot\alpha} - i\epsilon^{\mu\nu\rho\kappa}\sigma_{\kappa\,\alpha\dot\alpha}\right)\delta_\gamma{}^\beta\big]\,,\end{aligned} \tag{B.1.20}$$

$$\begin{aligned}\overline{\sigma}^{\rho\,\dot\alpha\beta}(\sigma^{\mu\nu})_\gamma{}^\alpha = \tfrac{1}{2}\big[&\overline{\sigma}^{\nu\,\dot\alpha\alpha}(\sigma^{\mu\rho})_\gamma{}^\beta - \overline{\sigma}^{\mu\,\dot\alpha\alpha}(\sigma^{\nu\rho})_\gamma{}^\beta + i\epsilon^{\mu\nu\kappa}{}_\lambda\overline{\sigma}_\kappa^{\dot\alpha\alpha}(\sigma^{\lambda\rho})_\gamma{}^\beta\\ &+\tfrac{1}{2}i\,\left(g^{\mu\rho}\overline{\sigma}^{\nu\,\dot\alpha\alpha} - g^{\nu\rho}\overline{\sigma}^{\mu\,\dot\alpha\alpha} - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa^{\dot\alpha\alpha}\right)\delta_\gamma{}^\beta\big]\,,\end{aligned} \tag{B.1.21}$$

$$\begin{aligned}\sigma^\rho_{\alpha\dot\beta}(\overline{\sigma}^{\mu\nu})^{\dot\gamma}{}_{\dot\alpha} = \tfrac{1}{2}\big[&\sigma^\nu_{\alpha\dot\alpha}(\overline{\sigma}^{\mu\rho})^{\dot\gamma}{}_{\dot\beta} - \sigma^\mu_{\alpha\dot\alpha}(\overline{\sigma}^{\nu\rho})^{\dot\gamma}{}_{\dot\beta} - i\epsilon^{\mu\nu\kappa}{}_\lambda\sigma_{\kappa\,\alpha\dot\alpha}(\overline{\sigma}^{\lambda\rho})^{\dot\gamma}{}_{\dot\beta}\\ &+\tfrac{1}{2}i\,\left(g^{\mu\rho}\sigma^\nu_{\alpha\dot\alpha} - g^{\nu\rho}\sigma^\mu_{\alpha\dot\alpha} + i\epsilon^{\mu\nu\rho\kappa}\sigma_{\kappa\,\alpha\dot\alpha}\right)\delta^{\dot\gamma}{}_{\dot\beta}\big]\,,\end{aligned} \tag{B.1.22}$$

\end{aligned}
$$

From eqs. (B.1.6)–(B.1.26), one immediately obtains the corresponding 21 Fierz identities represented by eq. (B.1.5). Eleven of these identities also appear in Appendix A of [78].[98]

The derivation of the 21 identities listed above is straightforward. Eqs. (B.1.6)–(B.1.8) are equivalent to the completeness relation of eq. (B.1.1). The next eight identities [eqs. (B.1.9)–(B.1.16)] are easily derived starting from eqs. (B.1.6)–(B.1.8). As a simple example, using the results of eqs. (B.1.7) and (B.2.20), it follows that

$$
\begin{aligned}
\delta_\alpha{}^\beta\sigma^\mu_{\gamma\dot\alpha} = \delta_\alpha{}^\beta\delta_\gamma{}^\tau\sigma^\mu_{\tau\dot\alpha} &= \tfrac{1}{2}\left[\delta_\alpha{}^\tau\delta_\gamma{}^\beta + (\sigma^{\rho\kappa})_\alpha{}^\tau(\sigma_{\rho\kappa})_\gamma{}^\beta\right]\sigma^\mu_{\tau\dot\alpha} \\
&= \tfrac{1}{2}\left[\sigma^\mu_{\alpha\dot\alpha}\delta_\gamma{}^\beta + (\sigma^{\rho\kappa}\sigma^\mu)_{\alpha\dot\alpha}(\sigma_{\rho\kappa})_\gamma{}^\beta\right] \\
&= \tfrac{1}{2}\left[\sigma^\mu_{\alpha\dot\alpha}\delta_\gamma{}^\beta + \tfrac{1}{2}i(g^{\kappa\mu}\sigma^\rho - g^{\rho\mu}\sigma^\kappa + i\epsilon^{\rho\kappa\mu\nu}\sigma_\nu)_{\alpha\dot\alpha}(\sigma_{\rho\kappa})_\gamma{}^\beta\right] \\
&= \tfrac{1}{2}\delta_\alpha{}^\gamma\overline{\sigma}^{\mu\,\dot\beta\beta} + i(\sigma^{\mu\nu})_\alpha{}^\gamma\overline{\sigma}_\nu^{\dot\beta\beta}\,, \qquad \text{(B.1.27)}
\end{aligned}
$$

where eq. (29.76) was employed in the final step. We can now use eqs. (B.1.9)–(B.1.12) to derive eqs. (B.1.17)–(B.1.23) by a similar technique. Finally, starting from eqs. (B.1.13)–(B.1.16) we may employ the same technique once more to derive eqs. (B.1.24)–(B.1.26).[99] A useful check of the last three identities can be carried out by multiplying these results by $g_{\mu\rho}g_{\nu\kappa}$ and summing over the

[98] Note that in [78], $\epsilon^{\mu\nu\rho\kappa}$ has the opposite sign with respect to our conventions, and $\sigma^{\mu\nu}$ is defined without an overall factor of i. Taking these differences into account, we have confirmed that the results of Appendix A of [78] match the corresponding results obtained here.

[99] In particular, the identities given in eqs. (B.2.18) and (B.2.19) are especially useful in the evaluation of eqs. (B.1.20)–(B.1.25).

two repeated Lorentz index pairs. We then find:

$$(\sigma^{\mu\nu})_\alpha{}^\beta(\sigma_{\mu\nu})_\gamma{}^\tau = -\tfrac{1}{2}(\sigma^{\mu\nu})_\alpha{}^\tau(\sigma_{\mu\nu})_\gamma{}^\beta + \tfrac{3}{2}\delta_\alpha{}^\tau\delta_\gamma{}^\beta\,, \tag{B.1.28}$$

$$(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\beta}(\overline{\sigma}_{\mu\nu})^{\dot\gamma}{}_{\dot\tau} = -\tfrac{1}{2}(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\tau}(\overline{\sigma}_{\mu\nu})^{\dot\gamma}{}_{\dot\beta} + \tfrac{3}{2}\delta^{\dot\alpha}{}_{\dot\tau}\delta^{\dot\gamma}{}_{\dot\beta}\,, \tag{B.1.29}$$

$$(\sigma^{\mu\nu})_\alpha{}^\beta(\overline{\sigma}_{\mu\nu})^{\dot\gamma}{}_{\dot\tau} = 0\,. \tag{B.1.30}$$

Eq. (B.1.30) has already been recorded in eq. (29.84). To verify eqs. (B.1.28) and (B.1.29), we first rewrite these equations with the interchange of $\beta \leftrightarrow \tau$ and $\dot\beta \leftrightarrow \dot\tau$. Inserting the resulting equations back into eqs. (B.1.28) and (B.1.29) then yields the previously obtained eqs. (29.82) and (29.83) [or equivalently, eqs. (B.1.7) and (B.1.8)].

A similar check can be performed on eqs. (B.1.17)–(B.1.19) by multiplying these results by $g_{\mu\nu}$ and summing over the repeated Lorentz index pair [with assistance from eq. (B.1.30)]:

$$\sigma^\mu_{\alpha\dot\alpha}\sigma_{\mu\,\beta\dot\beta} = -\sigma^\mu_{\alpha\dot\beta}\sigma_{\mu\,\beta\dot\alpha}\,, \tag{B.1.31}$$

$$\overline{\sigma}^{\mu\,\dot\alpha\alpha}\overline{\sigma}^{\dot\beta\beta}_\mu = -\overline{\sigma}^{\mu\,\dot\alpha\beta}\overline{\sigma}^{\dot\beta\alpha}_\mu\,, \tag{B.1.32}$$

$$\sigma^\mu_{\alpha\dot\alpha}\overline{\sigma}^{\dot\beta\beta}_\mu = 2\,\delta_\alpha{}^\beta\delta^{\dot\beta}{}_{\dot\alpha}\,. \tag{B.1.33}$$

It follows that:

$$\sigma^\mu_{\alpha\dot\alpha}\sigma_{\mu\,\beta\dot\beta} = 2\,\epsilon_{\alpha\beta}\epsilon_{\dot\alpha\dot\beta}\,, \tag{B.1.34}$$

$$\overline{\sigma}^{\mu\,\dot\alpha\alpha}\overline{\sigma}^{\dot\beta\beta}_\mu = 2\,\epsilon^{\alpha\beta}\epsilon^{\dot\alpha\dot\beta}\,, \tag{B.1.35}$$

since eqs. (B.1.31) and (B.1.32) are antisymmetric under the separate interchanges of $\alpha \leftrightarrow \beta$ and $\dot\alpha \leftrightarrow \dot\beta$. The coefficients in eqs. (B.1.34) and (B.1.35) are determined by substituting $\alpha = \dot\alpha = 1$ and $\beta = \dot\beta = 2$. Thus, we have confirmed the results previously obtained in eqs. (29.49)–(29.51).

Eqs. (B.1.6)–(B.1.8) can also be used to derive four additional identities, which yield Fierz identities of a different form. Simply multiply each of these equations by two ϵ symbols (with appropriately chosen undotted and/or dotted spinor indices), and use eqs. (29.32) and (29.79). Two of the resulting identities coincide with eqs. (B.1.34) and (B.1.35), while the other two are:

$$\epsilon_{\alpha\beta}\epsilon^{\gamma\tau} = -\tfrac{1}{2}\left[\delta_\alpha{}^\gamma\delta_\beta{}^\tau - (\sigma^{\mu\nu})_\alpha{}^\gamma(\sigma_{\mu\nu})_\beta{}^\tau\right], \tag{B.1.36}$$

$$\epsilon^{\dot\alpha\dot\beta}\epsilon_{\dot\gamma\dot\tau} = -\tfrac{1}{2}\left[\delta^{\dot\alpha}{}_{\dot\gamma}\delta^{\dot\beta}{}_{\dot\tau} - (\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\gamma}(\overline{\sigma}_{\mu\nu})^{\dot\beta}{}_{\dot\tau}\right]. \tag{B.1.37}$$

One can check that eqs. (B.1.36) and (B.1.37) are equivalent to the previously obtained eqs. (29.82) and (29.83). Multiplying eqs. (B.1.34)–(B.1.37) by four (commuting or anticommuting) two-component spinors $Z_{1A}Z_{2B}Z_{3C}Z_{4D}$ yields the corresponding Fierz identities of the form:

$$(Z_1\Gamma^{(k)I}Z_2)(Z_3\Gamma^{(n)J}Z_4) = (-1)^A\sum_{p,q,K,L}(C^{kn}_{pq})^{IJ}_{KL}(Z_1\Gamma^{(p)K}Z_3)(Z_2\Gamma^{(q)L}Z_4)\,, \tag{B.1.38}$$

which differs from eq. (B.1.5) in the ordering of the spinors on the right-hand side.

Finally, we note that the Schouten identities,

$$\epsilon_{\alpha\beta}\epsilon_{\gamma\delta} + \epsilon_{\alpha\gamma}\epsilon_{\delta\beta} + \epsilon_{\alpha\delta}\epsilon_{\beta\gamma} = 0\,, \qquad \epsilon_{\dot\alpha\dot\beta}\epsilon_{\dot\gamma\dot\delta} + \epsilon_{\dot\alpha\dot\gamma}\epsilon_{\dot\delta\dot\beta} + \epsilon_{\dot\alpha\dot\delta}\epsilon_{\dot\beta\dot\gamma} = 0\,, \tag{B.1.39}$$

are the basis for Fierz identities given by eqs. (29.66) and (29.67), which do not assume the simple forms of either eqs. (B.1.5) or (B.1.38).

Sigma matrix identities in $d \neq 4$ dimensions

When considering a theory regularized by dimensional continuation [125], one must be careful in treating cases with contracted spacetime vector indices $\mu, \nu, \kappa, \rho, \ldots$. Instead of taking on four possible values, these vector indices formally run over d values, where d is infinitesimally different from 4. This means that some identities that would hold in unregularized four-dimensional theories are inconsistent and must not be used; other identities remain valid if d replaces 4 in the appropriate spots; and still other identities hold without modification.

Two important identities that do hold in $d \neq 4$ dimensions are:

$$[\sigma^\mu\overline{\sigma}^\nu + \sigma^\nu\overline{\sigma}^\mu]_\alpha{}^\beta = 2g^{\mu\nu}\delta_\alpha{}^\beta\,, \tag{B.2.1}$$
$$[\overline{\sigma}^\mu\sigma^\nu + \overline{\sigma}^\nu\sigma^\mu]^{\dot\alpha}{}_{\dot\beta} = 2g^{\mu\nu}\delta^{\dot\alpha}{}_{\dot\beta}\,. \tag{B.2.2}$$

Equivalently,

$$(\sigma^\mu\overline{\sigma}^\nu)_\alpha{}^\beta = g^{\mu\nu}\delta_\alpha{}^\beta - 2i(\sigma^{\mu\nu})_\alpha{}^\beta\,, \tag{B.2.3}$$
$$(\overline{\sigma}^\mu\sigma^\nu)^{\dot\alpha}{}_{\dot\beta} = g^{\mu\nu}\delta^{\dot\alpha}{}_{\dot\beta} - 2i(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\beta}\,, \tag{B.2.4}$$

where $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$ are defined in eq. (A.10). The trace identities,

$$\mathrm{Tr}[\sigma^\mu\overline{\sigma}^\nu] = \mathrm{Tr}[\overline{\sigma}^\mu\sigma^\nu] = 2g^{\mu\nu}\,, \tag{B.2.5}$$
$$\mathrm{Tr}\,\sigma^{\mu\nu} = \mathrm{Tr}\,\overline{\sigma}^{\mu\nu} = 0\,, \tag{B.2.6}$$

then follow. We also note that the spinor index trace identity,

$$\mathrm{Tr}[\mathbb{1}] = \delta^\alpha_\alpha = \delta^{\dot\alpha}_{\dot\alpha} = 2\,, \tag{B.2.7}$$

continues to hold in dimensional continuation regularization methods. In contrast, the Fierz identities of Appendix B.1 do not have a consistent, unambiguous meaning outside of four dimensions [252, 253, 254, 255]. However, the following identities that are implied by eq. (B.1.6) do consistently generalize to $d \neq 4$ spacetime dimensions:

$$[\sigma^\mu\overline{\sigma}_\mu]_\alpha{}^\beta = d\delta^\beta_\alpha\,, \tag{B.2.8}$$
$$[\overline{\sigma}^\mu\sigma_\mu]^{\dot\alpha}{}_{\dot\beta} = d\delta^{\dot\alpha}_{\dot\beta}\,. \tag{B.2.9}$$

Using eqs. (B.2.8) and (B.2.9) along with the repeated use of eqs. (B.2.1) and (B.2.2) then yields:

$$[\sigma^\mu\overline{\sigma}^\nu\sigma_\mu]_{\alpha\dot\beta} = -(d-2)\sigma^\nu_{\alpha\dot\beta}\,, \tag{B.2.10}$$
$$[\overline{\sigma}^\mu\sigma_\nu\overline{\sigma}_\mu]^{\dot\alpha\beta} = -(d-2)\overline{\sigma}_\nu^{\dot\alpha\beta}\,, \tag{B.2.11}$$
$$[\sigma^\mu\overline{\sigma}^\nu\sigma^\rho\overline{\sigma}_\mu]_\alpha{}^\beta = 4g^{\nu\rho}\delta^\beta_\alpha - (4-d)[\sigma^\nu\overline{\sigma}^\rho]_\alpha{}^\beta\,, \tag{B.2.12}$$
$$[\overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho\sigma_\mu]^{\dot\alpha}{}_{\dot\beta} = 4g^{\nu\rho}\delta^{\dot\alpha}_{\dot\beta} - (4-d)[\overline{\sigma}^\nu\sigma^\rho]^{\dot\alpha}{}_{\dot\beta}\,, \tag{B.2.13}$$
$$[\sigma^\mu\overline{\sigma}^\nu\sigma^\rho\overline{\sigma}^\kappa\sigma_\mu]_{\alpha\dot\beta} = -2[\sigma^\kappa\overline{\sigma}^\rho\sigma^\nu]_{\alpha\dot\beta} + (4-d)[\sigma^\nu\overline{\sigma}^\rho\sigma^\kappa]_{\alpha\dot\beta}\,, \tag{B.2.14}$$
$$[\overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho\sigma^\kappa\overline{\sigma}_\mu]^{\dot\alpha\beta} = -2[\overline{\sigma}^\kappa\sigma^\rho\overline{\sigma}^\nu]^{\dot\alpha\beta} + (4-d)[\overline{\sigma}^\nu\sigma^\rho\overline{\sigma}^\kappa]^{\dot\alpha\beta}\,. \tag{B.2.15}$$

Identities that involve the (explicitly and inextricably four-dimensional) $\epsilon^{\mu\nu\rho\kappa}$ symbol

$$\overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho = g^{\mu\nu}\overline{\sigma}^\rho - g^{\mu\rho}\overline{\sigma}^\nu + g^{\nu\rho}\overline{\sigma}^\mu - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa\,, \tag{B.2.16}$$
$$\sigma^\mu\overline{\sigma}^\nu\sigma^\rho = g^{\mu\nu}\sigma^\rho - g^{\mu\rho}\sigma^\nu + g^{\nu\rho}\sigma^\mu + i\epsilon^{\mu\nu\rho\kappa}\sigma_\kappa\,, \tag{B.2.17}$$
$$\epsilon^{\mu\nu\kappa}{}_\lambda\sigma^{\lambda\rho} = -i\left(g^{\kappa\rho}\sigma^{\mu\nu} - g^{\nu\rho}\sigma^{\mu\kappa} + g^{\mu\rho}\sigma^{\nu\kappa}\right)\,, \tag{B.2.18}$$
$$\epsilon^{\mu\nu\kappa}{}_\lambda\overline{\sigma}^{\lambda\rho} = i\left(g^{\kappa\rho}\overline{\sigma}^{\mu\nu} - g^{\nu\rho}\overline{\sigma}^{\mu\kappa} + g^{\mu\rho}\overline{\sigma}^{\nu\kappa}\right)\,, \tag{B.2.19}$$
$$\sigma^{\mu\nu}\sigma^\rho = \tfrac{1}{2}i\left(g^{\nu\rho}\sigma^\mu - g^{\mu\rho}\sigma^\nu + i\epsilon^{\mu\nu\rho\kappa}\sigma_\kappa\right)\,, \tag{B.2.20}$$
$$\overline{\sigma}^{\mu\nu}\overline{\sigma}^\rho = \tfrac{1}{2}i\left(g^{\nu\rho}\overline{\sigma}^\mu - g^{\mu\rho}\overline{\sigma}^\nu - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa\right)\,, \tag{B.2.21}$$
$$\overline{\sigma}^\mu\sigma^{\nu\rho} = \tfrac{1}{2}i\left(g^{\mu\nu}\overline{\sigma}^\rho - g^{\mu\rho}\overline{\sigma}^\nu - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa\right)\,, \tag{B.2.22}$$
$$\sigma^\mu\overline{\sigma}^{\nu\rho} = \tfrac{1}{2}i\left(g^{\mu\nu}\sigma^\rho - g^{\mu\rho}\sigma^\nu + i\epsilon^{\mu\nu\rho\kappa}\sigma_\kappa\right)\,, \tag{B.2.23}$$
$$\sigma^{\mu\nu}\sigma^{\rho\kappa} = -\tfrac{1}{4}(g^{\nu\rho}g^{\mu\kappa} - g^{\mu\rho}g^{\nu\kappa} + i\epsilon^{\mu\nu\rho\kappa}) + \tfrac{1}{2}i(g^{\nu\rho}\sigma^{\mu\kappa} + g^{\mu\kappa}\sigma^{\nu\rho} - g^{\mu\rho}\sigma^{\nu\kappa} - g^{\nu\kappa}\sigma^{\mu\rho})\,, \tag{B.2.24}$$
$$\overline{\sigma}^{\mu\nu}\overline{\sigma}^{\rho\kappa} = -\tfrac{1}{4}(g^{\nu\rho}g^{\mu\kappa} - g^{\mu\rho}g^{\nu\kappa} - i\epsilon^{\mu\nu\rho\kappa}) + \tfrac{1}{2}i(g^{\nu\rho}\overline{\sigma}^{\mu\kappa} + g^{\mu\kappa}\overline{\sigma}^{\nu\rho} - g^{\mu\rho}\overline{\sigma}^{\nu\kappa} - g^{\nu\kappa}\overline{\sigma}^{\mu\rho})\,, \tag{B.2.25}$$

are also only meaningful in exactly four dimensions. This applies as well to the trace identities which follow from them.[100] For example,

$$\mathrm{Tr}[\sigma^\mu\overline{\sigma}^\nu\sigma^\rho\overline{\sigma}^\kappa] = 2\left(g^{\mu\nu}g^{\rho\kappa} - g^{\mu\rho}g^{\nu\kappa} + g^{\mu\kappa}g^{\nu\rho} + i\epsilon^{\mu\nu\rho\kappa}\right)\,, \tag{B.2.26}$$
$$\mathrm{Tr}[\overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho\sigma^\kappa] = 2\left(g^{\mu\nu}g^{\rho\kappa} - g^{\mu\rho}g^{\nu\kappa} + g^{\mu\kappa}g^{\nu\rho} - i\epsilon^{\mu\nu\rho\kappa}\right)\,. \tag{B.2.27}$$

This could lead to ambiguities in loop computations where it is necessary to perform the computation in $d \neq 4$ dimensions (until the end of the calculation where the limit $d \to 4$ is taken). However, in practice one typically finds that the above expressions appear multiplied by the metric and/or other external tensors (such as four-momenta appropriate to the problem at hand). In almost all such cases, two of the indices appearing in eqs. (B.2.26) and (B.2.27) are symmetrized which eliminates the $\epsilon^{\mu\nu\rho\kappa}$ term, rendering the resulting expressions unambiguous. Similarly, the sum of the above trace identities can be assigned an unambiguous meaning in $d \neq 4$ dimensions:

$$\mathrm{Tr}[\sigma^\mu\overline{\sigma}^\nu\sigma^\rho\overline{\sigma}^\kappa] + \mathrm{Tr}[\overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho\sigma^\kappa] = 4\left(g^{\mu\nu}g^{\rho\kappa} - g^{\mu\rho}g^{\nu\kappa} + g^{\mu\kappa}g^{\nu\rho}\right)\,. \tag{B.2.28}$$

One can recursively derive trace formulae for products of six or more $\sigma/\overline{\sigma}$ matrices by using the results of eqs. (B.2.16) and (B.2.17) to reduce the number of $\sigma/\overline{\sigma}$ matrices by two. For example,

$$\begin{aligned}\mathrm{Tr}[\sigma^\mu\overline{\sigma}^\nu\sigma^\rho\overline{\sigma}^\kappa\sigma^\lambda\overline{\sigma}^\delta] = {}& g^{\mu\nu}\mathrm{Tr}[\sigma^\rho\overline{\sigma}^\kappa\sigma^\lambda\overline{\sigma}^\delta] - g^{\mu\rho}\mathrm{Tr}[\sigma^\nu\overline{\sigma}^\kappa\sigma^\lambda\overline{\sigma}^\delta] + g^{\nu\rho}\mathrm{Tr}[\sigma^\mu\overline{\sigma}^\kappa\sigma^\lambda\overline{\sigma}^\delta] \\ & + i\epsilon^{\mu\nu\rho\epsilon}\mathrm{Tr}[\sigma_\epsilon\overline{\sigma}^\kappa\sigma^\lambda\overline{\sigma}^\delta]\,,\end{aligned} \tag{B.2.29}$$

$$\begin{aligned}\mathrm{Tr}[\overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho\sigma^\kappa\overline{\sigma}^\lambda\sigma^\delta] = {}& g^{\mu\nu}\mathrm{Tr}[\overline{\sigma}^\rho\sigma^\kappa\overline{\sigma}^\lambda\sigma^\delta] - g^{\mu\rho}\mathrm{Tr}[\overline{\sigma}^\nu\sigma^\kappa\overline{\sigma}^\lambda\sigma^\delta] + g^{\nu\rho}\mathrm{Tr}[\overline{\sigma}^\mu\sigma^\kappa\overline{\sigma}^\lambda\sigma^\delta] \\ & - i\epsilon^{\mu\nu\rho\epsilon}\mathrm{Tr}[\overline{\sigma}_\epsilon\sigma^\kappa\overline{\sigma}^\lambda\sigma^\delta]\,.\end{aligned} \tag{B.2.30}$$

We then use eqs. (B.2.26) and (B.2.27) to evaluate the remaining traces over four $\sigma/\overline{\sigma}$ matrices.

29.7.3 Explicit forms for the two-component spinor wave functions

In this Appendix, we construct the explicit forms for the eigenstates of the spin operator $\frac{1}{2}\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}}$, and examine their properties. For massive fermions, it is possible to transform to the rest frame,

[100] This is analogous to the statement that Tr $(\gamma_5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\kappa) = -4i\epsilon^{\mu\nu\rho\kappa}$ [in our convention where $\epsilon^{0123} = +1$, and γ_5 is defined by eq. (G.1.2)] is only meaningful in $d = 4$ dimensions. In two-component notation, the equivalent result is $\mathrm{Tr}[\sigma^\mu\overline{\sigma}^\nu\sigma^\rho\overline{\sigma}^\kappa - \overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho\sigma^\kappa] = 4i\epsilon^{\mu\nu\rho\kappa}$. In the literature various schemes have been proposed for defining the properties of γ_5 in $d \neq 4$ dimensions [234, 255]. In two-component notation, this would translate into a procedure for dealing with general traces involving four or more $\sigma/\overline{\sigma}$ matrices.

and quantize the spin along a fixed axis in space. The corresponding spinor wave functions will be called fixed-axis spinors. For either massive or massive fermions, one can quantize the spin along the direction of momentum. The corresponding spinor wave functions are helicity spinors. Helicity spinor wave functions are most conveniently applied to massless fermions or fermions in the relativistic limit of high energy $E \gg m$. Fixed-axis spinors are most conveniently applied to massive fermions in the non-relativistic limit.

Fixed-axis spinor wave functions

Consider a spin-1/2 fermion in its rest frame and quantize the spin along a fixed axis specified by the unit vector

$$\hat{\boldsymbol{s}} \equiv (\sin\theta\cos\phi\,,\ \sin\theta\sin\phi\,,\ \cos\theta)\,, \tag{C.1.1}$$

with polar angle θ and azimuthal angle ϕ with respect to a fixed z-axis. The corresponding spin states will be called fixed-axis spin states. The relevant basis of two-component fixed-axis spinors χ_s are eigenstates of $\frac{1}{2}\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}$, i.e.,

$$\tfrac{1}{2}\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}\,\chi_s = s\chi_s\,, \qquad s = \pm\tfrac{1}{2}\,. \tag{C.1.2}$$

In order to construct the eigenstates of $\frac{1}{2}\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}$, we first consider the case where $\hat{\boldsymbol{s}} = \hat{\boldsymbol{z}}$. In this case, we define the eigenstates of $\frac{1}{2}\sigma^3$ to be:

$$\chi_{1/2}(\hat{\boldsymbol{z}}) = \begin{pmatrix}1\\0\end{pmatrix}, \qquad \chi_{-1/2}(\hat{\boldsymbol{z}}) = \begin{pmatrix}0\\1\end{pmatrix}. \tag{C.1.3}$$

By convention, we have set an arbitrary overall multiplicative phase factor for each spinor of eq. (C.1.3) to unity. We then determine $\chi_s(\hat{\boldsymbol{s}})$ from $\chi_s(\hat{\boldsymbol{z}})$ by employing the spin-1/2 rotation operator that corresponds to a rotation from $\hat{\boldsymbol{z}}$ to $\hat{\boldsymbol{s}}$. This rotation is represented by a 3×3 matrix $\mathcal{R}$ such that $\hat{\boldsymbol{s}} = \mathcal{R}\hat{\boldsymbol{z}}$. However, this rotation operator is not unique. In its most general form, the rotation operator can be parameterized in terms of three Euler angles (e.g., see refs. [45, 46]):

$$\mathcal{R}(\phi\,,\,\theta\,,\,\gamma) \equiv R(\hat{\boldsymbol{z}}\,,\,\phi)\,R(\hat{\boldsymbol{y}}\,,\,\theta)\,R(\hat{\boldsymbol{z}}\,,\,\gamma)\,, \tag{C.1.4}$$

The Euler angles can be chosen to lie in the range $0 \leq \theta \leq \pi$ and $0 \leq \phi\,,\,\gamma < 2\pi$. In general, $R(\hat{\boldsymbol{n}}\,,\,\theta)$ is a 3×3 orthogonal matrix of unit determinant that represents a rotation by an angle θ about a fixed axis $\hat{\boldsymbol{n}}$,

$$R^{ij}(\hat{\boldsymbol{n}}\,,\,\theta) = \exp(-i\theta\hat{\boldsymbol{n}}\boldsymbol{\cdot}\vec{\boldsymbol{\mathcal{S}}}) = n^i n^j + (\delta^{ij} - n^i n^j)\cos\theta - \epsilon^{ijk}n^k\sin\theta\,, \tag{C.1.5}$$

where the $\vec{\boldsymbol{\mathcal{S}}} = (\mathcal{S}^1\,,\,\mathcal{S}^2\,,\,\mathcal{S}^3)$ are three 3×3 matrices whose matrix elements are given by $(\mathcal{S}^i)^{jk} = -i\epsilon^{ijk}$ [cf. eq. (29.9)].

However, the angle γ is arbitrary, since $R(\hat{\boldsymbol{z}}\,,\,\gamma)\hat{\boldsymbol{z}} = \hat{\boldsymbol{z}}$. Thus,

$$\hat{\boldsymbol{s}} = \mathcal{R}\hat{\boldsymbol{z}} = (\sin\theta\cos\phi\,,\ \sin\theta\sin\phi\,,\ \cos\theta)\,, \tag{C.1.6}$$

independently of the choice of γ. For $\theta = 0$ or $\theta = \pi$, where $\hat{\boldsymbol{s}}$ is parallel to the z-axis, the azimuthal angle ϕ is undefined. Since $\hat{\boldsymbol{s}} \to -\hat{\boldsymbol{s}}$ corresponds in general to $\theta \to \pi - \theta$ and $\phi \to \phi + \pi \pmod{2\pi}$, we shall adopt a convention whereby:

$$\phi = \begin{cases} 0\,, & \text{for } \hat{\boldsymbol{s}} = \hat{\boldsymbol{z}}\,, \quad (\theta = 0)\,, \\ \pi\,, & \text{for } \hat{\boldsymbol{s}} = -\hat{\boldsymbol{z}}\,, \quad (\theta = \pi)\,. \end{cases} \tag{C.1.7}$$

Using the spin-1/2 rotation operator corresponding to $\mathcal{R}(\phi\,,\,\theta\,,\,\gamma)$, one can compute $\chi_s(\hat{\boldsymbol{s}})$,

$$\chi_s(\hat{\boldsymbol{s}}) = \mathcal{D}(\phi\,,\,\theta\,,\,\gamma)\,\chi_s(\hat{\boldsymbol{z}})\,, \tag{C.1.8}$$

where $\mathcal{D}$ is the spin-1/2 unitary representation matrix [256]

$$\mathcal{D}(\phi\,,\,\theta\,,\,\gamma) \equiv D(\hat{\boldsymbol{z}},\phi)\,D(\hat{\boldsymbol{y}},\theta)\,D(\hat{\boldsymbol{z}},\gamma)\,, \tag{C.1.9}$$

and D is the 2×2 unitary matrix

$$D(\hat{\boldsymbol{n}},\theta) \equiv \exp\left(-i\theta\hat{\boldsymbol{n}}\cdot\vec{\boldsymbol{\sigma}}/2\right) = \cos\frac{\theta}{2} - i\hat{\boldsymbol{n}}\cdot\vec{\boldsymbol{\sigma}}\sin\frac{\theta}{2}\,. \tag{C.1.10}$$

Eq. (C.1.8) yields explicit forms for the eigenstates of $\frac{1}{2}\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}}$:

$$\chi_{1/2}(\hat{\boldsymbol{s}}) = \begin{pmatrix} e^{-i(\phi+\gamma)/2}\cos\dfrac{\theta}{2} \\[2ex] e^{i(\phi-\gamma)/2}\sin\dfrac{\theta}{2} \end{pmatrix}, \qquad \chi_{-1/2}(\hat{\boldsymbol{s}}) = \begin{pmatrix} -e^{-i(\phi-\gamma)/2}\sin\dfrac{\theta}{2} \\[2ex] e^{i(\phi+\gamma)/2}\cos\dfrac{\theta}{2} \end{pmatrix}. \tag{C.1.11}$$

The well-known two-to-one mapping between SU(2) and SO(3) implies that for a given rotation matrix $\mathcal{R}$ there are two corresponding spin-1/2 rotation matrices $\mathcal{D}$. In particular,

$$\mathcal{D}(\phi+2\pi\,,\,\theta\,,\,\gamma) = -\mathcal{D}(\phi\,,\,\theta\,,\,\gamma)\,, \tag{C.1.12}$$

which implies that a rotation of a spinor by 2π yields an overall change of sign in the spinor wave function (an effect that can be observed in quantum interference experiments!). Strictly speaking, we should take the range of the Euler angles to be $0\leq\phi<4\pi$, $0\leq\theta\leq\pi$ and $0\leq\gamma<2\pi$. However, when constructing the spinor wave function of a spin-1/2 particle whose spin quantization axis is given by eq. (C.1.6), we will fix the overall sign of the spinor wave function by convention.

More generally, the overall phase of the spinor wave function is unphysical. Noting that $D(\hat{\boldsymbol{z}},\gamma)\,\chi_s(\hat{\boldsymbol{z}}) = e^{-is\gamma}\chi_s(\hat{\boldsymbol{z}})$, the choice of γ is also a matter of convention. First, we will require that when $\hat{\boldsymbol{s}}=\hat{\boldsymbol{z}}$, eq. (C.1.8) should reproduce the spinor wave functions given in eq. (C.1.3). This implies that:

$$\gamma = 0\,, \qquad \text{for } \hat{\boldsymbol{s}}=\hat{\boldsymbol{z}}\,, \quad (\theta=\phi=0)\,. \tag{C.1.13}$$

For $\hat{\boldsymbol{s}}=-\hat{\boldsymbol{z}}$, we use eq. (C.1.7) to obtain:

$$\chi_s(-\hat{\boldsymbol{z}}) = ie^{-is\gamma(-\hat{\boldsymbol{z}})}\,\chi_{-s}(\hat{\boldsymbol{z}})\,, \qquad\qquad s=\pm\tfrac{1}{2}\,, \tag{C.1.14}$$

where the notation $\gamma(-\hat{\boldsymbol{z}})$ has been employed to allow the possibility that the convention for γ depends on the direction indicated by its argument.

Two different conventions are commonly employed in the literature. In the first convention, one chooses $\gamma=-\phi$. This choice has the good feature that $\mathcal{R}(\phi\,,\,0\,,\,-\phi)=\mathbb{1}_{3\times3}$, independently of the angle ϕ, which is undefined when $\theta=0$.[101] Moreover, the rotation matrix $\mathcal{R}(\phi\,,\,\theta\,,\,-\phi)$ and the corresponding spin-1/2 rotation matrix $\mathcal{D}(\phi\,,\,\theta\,,\,-\phi)$ can be expressed simply as a single rotation by an angle θ about a fixed axis that points along a unit vector in the azimuthal direction:

$$\hat{\boldsymbol{\varphi}} \equiv (-\sin\phi\,,\,\cos\phi\,,\,0)\,, \tag{C.1.15}$$

In particular,

$$R(\hat{\boldsymbol{\varphi}}\,,\,\theta) = R(\hat{\boldsymbol{z}}\,,\,\phi)\,R(\hat{\boldsymbol{y}}\,,\,\theta)\,R(\hat{\boldsymbol{z}}\,,\,-\phi)\,, \tag{C.1.16}$$

$$D(\hat{\boldsymbol{\varphi}}\,,\,\theta) = \mathcal{D}(\phi\,,\,\theta\,,\,-\phi)\,. \tag{C.1.17}$$

Hence, in this convention $\chi_s(\hat{\boldsymbol{s}}) = D(\hat{\boldsymbol{\varphi}}\,,\,\theta)\chi_s(\hat{\boldsymbol{z}})$, which is the most common choice for the spinor wave function [37, 257, 258].

[101] However, $\mathcal{R}(\phi\,,\,\pi\,,\,-\phi)\neq\mathbb{1}_{3\times3}$ even though ϕ is also undefined when $\theta=\pi$.

In the second convention, one chooses $\gamma = 0$. One motivation for this choice is that the corresponding rotation matrix is somewhat simpler:

$$\mathcal{R}(\phi\,,\,\theta\,,\,0) = R(\hat{\boldsymbol{z}}\,,\,\phi)\,R(\hat{\boldsymbol{y}}\,,\,\theta) = \begin{pmatrix} \cos\theta\cos\phi & -\sin\phi & \sin\theta\cos\phi \\ \cos\theta\sin\phi & \cos\phi & \sin\theta\sin\phi \\ -\sin\theta & 0 & \cos\theta \end{pmatrix}. \tag{C.1.18}$$

Employing the corresponding spin-1/2 rotation operator $\mathcal{D}(\phi\,,\,\theta\,,\,0)$ in eq. (C.1.8) yields a slightly more symmetrical form for the spinor wave function [259].

Explicit forms for the spinor wave functions in the two conventions are obtained from eq. (C.1.11) by taking $\gamma(\hat{\boldsymbol{s}}) = -\phi$ and $\gamma(\hat{\boldsymbol{s}}) = 0$, respectively. For example, eq. (C.1.14) reduces to:

$$\chi_s(-\hat{\boldsymbol{z}}) = \begin{cases} -2s\chi_{-s}(\hat{\boldsymbol{z}}) & \text{for } \gamma(-\hat{\boldsymbol{z}}) = -\phi = -\pi\,, \\ i\chi_{-s}(\hat{\boldsymbol{z}}) & \text{for } \gamma(-\hat{\boldsymbol{z}}) = 0\,, \end{cases} \qquad s = \pm\tfrac{1}{2}\,, \tag{C.1.19}$$

in the convention specified by eq. (C.1.7).

Many of the properties of the spinor wave functions are independent of the choice of the Euler angle γ. The spinor wave functions χ_s defined by eq. (C.1.8) are normalized such that

$$\chi_s^\dagger(\hat{\boldsymbol{s}})\chi_{s'}(\hat{\boldsymbol{s}}) = \delta_{ss'}\,, \tag{C.1.20}$$

and satisfy the following completeness relation:

$$\sum_s \chi_s(\hat{\boldsymbol{s}})\chi_s^\dagger(\hat{\boldsymbol{s}}) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}. \tag{C.1.21}$$

The spinor wave functions $\chi_s(\hat{\boldsymbol{s}})$ and $\chi_{-s}(\hat{\boldsymbol{s}})$ are connected by the following relation:

$$\chi_{-s}(\hat{\boldsymbol{s}}) = -2si\sigma^2\,\chi_s^*(\hat{\boldsymbol{s}})\,. \tag{C.1.22}$$

Consider a spin-1/2 fermion with four-momentum $p^\mu = (E\,,\,\vec{\boldsymbol{p}})$, with $E = (|\vec{\boldsymbol{p}}|^2 + m^2)^{1/2}$, and the direction of $\vec{\boldsymbol{p}}$ given by

$$\hat{\boldsymbol{p}} = (\sin\theta_p\cos\phi_p\,,\,\sin\theta_p\sin\phi_p\,,\,\cos\theta_p)\,. \tag{C.1.23}$$

Using eqs. (29.108) and (29.109), one can employ eqs. (29.3.18)–(29.3.21) to obtain explicit expressions for the two-component spinor wave functions $x(\vec{\boldsymbol{p}}, s)$, $y(\vec{\boldsymbol{p}}, s)$, $x^\dagger(\vec{\boldsymbol{p}}, s)$ and $y^\dagger(\vec{\boldsymbol{p}}, s)$.

Additional properties of the χ_s can be derived by introducing an orthonormal set of unit three-vectors $\hat{\boldsymbol{s}}^a$ that provide a basis for a right-handed coordinate system. Explicitly,

$$\hat{\boldsymbol{s}}^{\boldsymbol{a}}\cdot\hat{\boldsymbol{s}}^{\boldsymbol{b}} = \delta^{ab}\,, \tag{C.1.24}$$

$$\hat{\boldsymbol{s}}^{\boldsymbol{a}}\times\hat{\boldsymbol{s}}^{\boldsymbol{b}} = \epsilon^{abc}\hat{\boldsymbol{s}}^{\boldsymbol{c}}\,. \tag{C.1.25}$$

We shall identify

$$\hat{\boldsymbol{s}}^{\boldsymbol{3}} \equiv \hat{\boldsymbol{s}} \tag{C.1.26}$$

as the quantization axis used in defining the third component of the spin of the fermion in its rest frame. The unit vectors $\hat{\boldsymbol{s}}^{\boldsymbol{1}}$ and $\hat{\boldsymbol{s}}^{\boldsymbol{2}}$ are then chosen such that eqs. (C.1.24) and (C.1.25) are satisfied. To explicitly construct the $\hat{\boldsymbol{s}}^{\boldsymbol{a}}$, we begin with the orthonormal set $\{\hat{\boldsymbol{x}}\,,\,\hat{\boldsymbol{y}}\,,\,\hat{\boldsymbol{z}}\}$, and employ the *same* rotation operator $\mathcal{R}$ used to define $\chi_s(\hat{\boldsymbol{s}})$. That is,

$$(\hat{\boldsymbol{s}}^{\boldsymbol{1}}\,,\,\hat{\boldsymbol{s}}^{\boldsymbol{2}}\,,\,\hat{\boldsymbol{s}}^{\boldsymbol{3}}) = (\mathcal{R}\hat{\boldsymbol{x}}\,,\,\mathcal{R}\hat{\boldsymbol{y}}\,,\,\mathcal{R}\hat{\boldsymbol{z}})\,, \qquad \text{where} \quad \mathcal{R} \equiv \mathcal{R}(\phi\,,\,\theta\,,\,\gamma)\,, \tag{C.1.27}$$

and ϕ, θ and γ are the Euler angles used to define the spinor wave function in eq. (C.1.8). From eq. (C.1.27), one can immediately derive the completeness relation (as a consequence of $\mathcal{R}\mathcal{R}^{\mathsf{T}} = \mathbb{1}$),

$$\hat{\boldsymbol{s}}^{\boldsymbol{a}i}\hat{\boldsymbol{s}}^{\boldsymbol{a}j} = \delta^{ij}\,, \tag{C.1.28}$$

where i and j label the space components of the three-vector $\hat{\boldsymbol{s}}^{\boldsymbol{a}}$.

We can use the $\hat{\boldsymbol{s}}^{\boldsymbol{a}}$ to extend the defining equation of χ_s [eq. (C.1.2)]:

$$\tfrac{1}{2}\,\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\chi_{s'}(\hat{\boldsymbol{s}}) = \tfrac{1}{2}\tau^a_{ss'}\chi_s(\hat{\boldsymbol{s}})\,, \tag{C.1.29}$$

where the $\tau^a_{ss'}$ are the matrix elements of the Pauli matrices.[102] That is, $\frac{1}{2}\vec{\boldsymbol{\sigma}}\cdot(\boldsymbol{s^1} \pm i\boldsymbol{s^2})$ serve as ladder operators that connect the spinor wave functions $\chi_{1/2}$ and $\chi_{-1/2}$. Using eq. (C.1.20), it follows that eq. (C.1.29) is equivalent to:

$$\chi^\dagger_s(\hat{\boldsymbol{s}})\,\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\chi_{s'}(\hat{\boldsymbol{s}}) = \tau^a_{ss'}\,. \tag{C.1.30}$$

It is instructive to prove eq. (C.1.30) directly. Employing eq. (C.1.8) and using the fact that $\mathcal{D}$ is a unitary matrix,

$$\chi^\dagger_s(\hat{\boldsymbol{s}})\,\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\chi_{s'}(\hat{\boldsymbol{s}}) = \chi^\dagger_s(\hat{\boldsymbol{z}})\,[\mathcal{D}(\phi\,,\theta\,,\gamma)]^{-1}\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\,\mathcal{D}(\phi\,,\theta\,,\gamma)\chi_{s'}(\hat{\boldsymbol{z}})\,. \tag{C.1.31}$$

The above result can be simplified by a repeated use of the following identity,

$$e^{i\theta\hat{\boldsymbol{n}}\boldsymbol{\cdot}\vec{\boldsymbol{\sigma}}/2}\,\sigma^j\,e^{-i\theta\hat{\boldsymbol{n}}\boldsymbol{\cdot}\vec{\boldsymbol{\sigma}}/2} = R^{jk}(\hat{\boldsymbol{n}}\,,\theta)\sigma^k\,, \tag{C.1.32}$$

which is valid for any fixed axis $\hat{\boldsymbol{n}}$, where $R(\hat{\boldsymbol{n}}\,,\theta)$ is the rotation matrix defined in eq. (C.1.5). It follows that

$$[\mathcal{D}(\phi\,,\theta\,,\gamma)]^{-1}\,\sigma^j\,\mathcal{D}(\phi\,,\theta\,,\gamma) = \mathcal{R}^{jk}(\phi\,,\theta\,,\gamma)\,\sigma^k\,, \tag{C.1.33}$$

where $\mathcal{R}(\phi\,,\theta\,,\gamma)$ is defined in eq. (C.1.4). Since $\mathcal{R}^{\mathsf{T}} = \mathcal{R}^{-1}$,

$$\chi^\dagger_s(\hat{\boldsymbol{s}})\,\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\chi_{s'}(\hat{\boldsymbol{s}}) = \chi^\dagger_s(\hat{\boldsymbol{z}})\,\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\left[\mathcal{R}^{-1}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\right]\,\chi_{s'}(\hat{\boldsymbol{z}})\,. \tag{C.1.34}$$

Eq. (C.1.27) implies that $(\mathcal{R}^{-1}\hat{\boldsymbol{s}}^{\boldsymbol{1}}\,,\,\mathcal{R}^{-1}\hat{\boldsymbol{s}}^{\boldsymbol{2}}\,,\,\mathcal{R}^{-1}\hat{\boldsymbol{s}}^{\boldsymbol{3}}) = (\hat{\boldsymbol{x}}\,,\,\hat{\boldsymbol{y}}\,,\,\hat{\boldsymbol{z}})$, and it follows that

$$\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\left[\mathcal{R}^{-1}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\right] = \sigma^a\,. \tag{C.1.35}$$

Consequently, we end up with

$$\chi^\dagger_s(\hat{\boldsymbol{s}})\,\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\chi_{s'}(\hat{\boldsymbol{s}}) = \chi^\dagger_s(\hat{\boldsymbol{z}})\sigma^a\chi_{s'}(\hat{\boldsymbol{z}}) \equiv \tau^a_{ss'}\,, \tag{C.1.36}$$

which defines the matrix elements of the Pauli matrices, and our proof of eq. (C.1.30) is complete.

Using the completeness relation given by eq. (C.1.28), we can rewrite eq. (C.1.30) as

$$\chi^\dagger_s(\hat{\boldsymbol{s}})\,\sigma^i\chi_{s'}(\hat{\boldsymbol{s}}) = \tau^a_{ss'}\hat{\boldsymbol{s}}^{\boldsymbol{a}i}\,. \tag{C.1.37}$$

Taking the hermitian conjugate of eq. (C.1.37) is equivalent to interchanging $s \leftrightarrow s'$, since the σ^i are hermitian matrices and $(\tau^a_{ss'})^* = \tau^a_{s's}$. To evaluate expressions similar to eq. (C.1.37) that contain products of σ-matrices, it is sufficient to use the relation $\sigma^i\sigma^j = \delta^{ij}\mathbb{1} + i\epsilon^{ijk}\sigma^k$ as many

[102] We use the symbol τ rather than σ to emphasize that the indices of the Pauli matrices τ^a are spin labels s, s' and *not* spinor indices α, $\dot{\alpha}$. The first (second) row and column of the τ-matrices correspond to $s = 1/2$ $(-1/2)$. For example, $\tau^3_{ss'} = 2s\delta_{ss'}$ (no sum over s).

times as needed to reduce the final expression to terms containing at most one σ-matrix. For example, using eqs. (C.1.20) and (C.1.37), it follows that

$$\chi_s^\dagger(\hat{\boldsymbol{s}})\,\sigma^i\sigma^j\chi_{s'}(\hat{\boldsymbol{s}}) = \delta_{ss'}\delta^{ij} + i\epsilon^{ijk}\tau^a_{ss'}\hat{\boldsymbol{s}}^{\boldsymbol{a}k}\,. \tag{C.1.38}$$

It is sometimes useful to have a more explicit representation of the $\hat{\boldsymbol{s}}^{\boldsymbol{a}}$. In the convention where $\gamma = -\phi$, eq. (C.1.27) yields:

$$\begin{aligned}
\hat{\boldsymbol{s}}^{\boldsymbol{1}} &= (1 - 2\cos^2\phi\,\sin^2\frac{\theta}{2}\,,\, -\sin 2\phi\,\sin^2\frac{\theta}{2}\,,\, -\sin\theta\cos\phi)\,,\\
\hat{\boldsymbol{s}}^{\boldsymbol{2}} &= (-\sin 2\phi\,\sin^2\frac{\theta}{2}\,,\, 1 - 2\sin^2\phi\,\sin^2\frac{\theta}{2}\,,\, -\sin\theta\sin\phi)\,,\\
\hat{\boldsymbol{s}}^{\boldsymbol{3}} &= (\sin\theta\cos\phi\,,\,\sin\theta\sin\phi\,,\,\cos\theta)\,.
\end{aligned} \tag{C.1.39}$$

The explicit forms for the $\hat{\boldsymbol{s}}^{\boldsymbol{a}}$ are somewhat simpler in the convention where $\gamma = 0$. In this case, eqs. (C.1.18) and (C.1.27) yield:

$$\begin{aligned}
\hat{\boldsymbol{s}}^{\boldsymbol{1}} &= (\cos\theta\cos\phi,\,\cos\theta\sin\phi,\,-\sin\theta)\,,\\
\hat{\boldsymbol{s}}^{\boldsymbol{2}} &= (-\sin\phi,\,\cos\phi,\,0)\,,\\
\hat{\boldsymbol{s}}^{\boldsymbol{3}} &= (\sin\theta\cos\phi,\,\sin\theta\sin\phi,\,\cos\theta)\,.
\end{aligned} \tag{C.1.40}$$

Fixed-axis spinors in the non-relativistic limit

Consider an on-shell massive fermion of three-momentum $\vec{\boldsymbol{p}}$, mass m and spin quantum number s, where $s = \pm\frac{1}{2}$ are the possible projections of the spin vector (in units of $\hbar$) along the fixed $\hat{\boldsymbol{s}}$ direction [cf. eq. (C.1.2)]. The spinor wave functions, x, y, and their hermitian conjugates are given by eqs. (29.3.18)–(29.3.21). In the non-relativistic limit,

$$\sqrt{p\cdot\sigma} \simeq \sqrt{m}\left(\mathbb{1} - \frac{\vec{\boldsymbol{\sigma}}\cdot\vec{\boldsymbol{p}}}{2m}\right)\,, \tag{C.2.1}$$

$$\sqrt{p\cdot\overline{\sigma}} \simeq \sqrt{m}\left(\mathbb{1} + \frac{\vec{\boldsymbol{\sigma}}\cdot\vec{\boldsymbol{p}}}{2m}\right)\,, \tag{C.2.2}$$

where we keep terms only up to $\mathcal{O}(|\vec{\boldsymbol{p}}|/m)$. Inserting the above results into eqs. (29.3.18)–(29.3.21) yields:

$$x_\alpha(\vec{p},s) \simeq \sqrt{m}\left(\mathbb{1} - \frac{\vec{\boldsymbol{\sigma}}\cdot\vec{\boldsymbol{p}}}{2m}\right)\chi_s(\hat{\boldsymbol{s}})\,, \tag{C.2.3}$$

$$x^\alpha(\vec{p},s) \simeq -2s\sqrt{m}\,\chi^\dagger_{-s}(\hat{\boldsymbol{s}})\left(\mathbb{1} + \frac{\vec{\boldsymbol{\sigma}}\cdot\vec{\boldsymbol{p}}}{2m}\right)\,, \tag{C.2.4}$$

$$y_\alpha(\vec{p},s) \simeq 2s\sqrt{m}\left(\mathbb{1} - \frac{\vec{\boldsymbol{\sigma}}\cdot\vec{\boldsymbol{p}}}{2m}\right)\chi_{-s}(\hat{\boldsymbol{s}})\,, \tag{C.2.5}$$

$$y^\alpha(\vec{p},s) \simeq \sqrt{m}\,\chi^\dagger_s(\hat{\boldsymbol{s}})\left(\mathbb{1} + \frac{\vec{\boldsymbol{\sigma}}\cdot\vec{\boldsymbol{p}}}{2m}\right)\,, \tag{C.2.6}$$

for the undotted spinor wave functions and

$$x^{\dagger\dot\alpha}(\vec p,s)\simeq -2s\sqrt{m}\,\left(\mathbb{1}+\frac{\vec{\boldsymbol\sigma}\cdot\vec{\boldsymbol p}}{2m}\right)\chi_{-s}(\hat{\boldsymbol s})\,, \tag{C.2.7}$$

$$x^{\dagger}_{\dot\alpha}(\vec p,s)\simeq \sqrt{m}\,\chi^{\dagger}_{s}(\hat{\boldsymbol s})\left(\mathbb{1}-\frac{\vec{\boldsymbol\sigma}\cdot\vec{\boldsymbol p}}{2m}\right)\,, \tag{C.2.8}$$

$$y^{\dagger\dot\alpha}(\vec p,s)\simeq \sqrt{m}\,\left(\mathbb{1}+\frac{\vec{\boldsymbol\sigma}\cdot\vec{\boldsymbol p}}{2m}\right)\chi_{s}(\hat{\boldsymbol s})\,, \tag{C.2.9}$$

$$y^{\dagger}_{\dot\alpha}(\vec p,s)\simeq 2s\sqrt{m}\,\chi^{\dagger}_{-s}(\hat{\boldsymbol s})\left(\mathbb{1}-\frac{\vec{\boldsymbol\sigma}\cdot\vec{\boldsymbol p}}{2m}\right)\,, \tag{C.2.10}$$

for the dotted spinor wave functions.

In the computation of the S-matrix amplitudes for scattering and decay processes, one typically must evaluate a bilinear product of spinors, i.e. quantities of the form

$$z_1(\vec{\boldsymbol p}_1,s_1)\,\Gamma\,z_2(\vec{\boldsymbol p}_2,s_2)\,, \tag{C.2.11}$$

where z_1 and z_2 represent one of the two-component spinor wave functions x, y, $x^\dagger$ or $y^\dagger$, and Γ is a 2×2 matrix (in spinor space) that is either the identity matrix, or is made up of alternating products of σ and $\overline{\sigma}$. In the non-relativistic limit, these bilinears take on rather simple forms. In what follows, we work to first order in $|\vec{\boldsymbol p}_i|/m_i$. For example,

$$\begin{aligned} y^{\alpha}(\vec{\boldsymbol p}_1,s_1)x_\alpha(\vec{\boldsymbol p}_2,s_2)&\simeq\sqrt{m_1m_2}\,\chi^{\dagger}_{s_1}(\hat{\boldsymbol s})\left(\mathbb{1}+\frac{\vec{\boldsymbol\sigma}\cdot\vec{\boldsymbol p}}{2m_1}-\frac{\vec{\boldsymbol\sigma}\cdot\vec{\boldsymbol p}}{2m_2}\right)\chi_{s_2}(\hat{\boldsymbol s})\\ &\simeq\sqrt{m_1m_2}\left[\delta_{s_1,s_2}+\left(\frac{\vec{\boldsymbol p}_1}{2m_1}-\frac{\vec{\boldsymbol p}_2}{2m_2}\right)\cdot\hat{\boldsymbol s}^{\boldsymbol a}\tau^a_{s_1,s_2}\right]\,, \end{aligned} \tag{C.2.12}$$

where we have used the results of eqs. (C.1.20) and (C.1.37). Similarly,

$$\begin{aligned} y^{\alpha}(\boldsymbol p_{\boldsymbol 1},s_1)\sigma^\mu_{\alpha\dot\beta}y^{\dagger\dot\beta}(\boldsymbol p_{\boldsymbol 2},s_2)&\simeq\sqrt{m_1m_2}\,\chi^{\dagger}_{s_1}(\hat{\boldsymbol s})\left[\sigma^\mu+\frac{\vec{\boldsymbol\sigma}\cdot\vec{\boldsymbol p}_{\boldsymbol 1}}{2m_1}\sigma^\mu+\sigma^\mu\frac{\vec{\boldsymbol\sigma}\cdot\vec{\boldsymbol p}_{\boldsymbol 2}}{2m_2}\right]\chi_{s_2}(\hat{\boldsymbol s})\\ &\simeq\sqrt{m_1m_2}\,Z^\mu_{s_1,s_2}(\vec{\boldsymbol p}_{\boldsymbol 1},\vec{\boldsymbol p}_{\boldsymbol 2})\,, \end{aligned} \tag{C.2.13}$$

where[103]

$$Z^\mu_{ss'}(\vec{\boldsymbol p}_{\boldsymbol 1},\vec{\boldsymbol p}_{\boldsymbol 2})\equiv\begin{cases}\delta_{ss'}+\left(\dfrac{\vec{\boldsymbol p}_1}{2m_1}+\dfrac{\vec{\boldsymbol p}_2}{2m_2}\right)\cdot\hat{\boldsymbol s}^{\boldsymbol a}\tau^a_{ss'}\,, & \text{for }\mu=0\,,\\ \hat{\boldsymbol s}^{\boldsymbol a i}\tau^a_{ss'}+\left(\dfrac{p_1^i}{2m_1}+\dfrac{p_2^i}{2m_2}\right)\delta_{ss'}+\left(\dfrac{p_2^j}{2m_2}-\dfrac{p_1^j}{2m_1}\right)i\epsilon^{ijk}\hat{\boldsymbol s}^{\boldsymbol a k}\tau^a_{ss'}\,, & \text{for }\mu=i=1,2,3\,,\end{cases} \tag{C.2.14}$$

is obtained after using the results of eqs. (C.1.37) and (C.1.38).

In summary, we list the non-relativistic forms of the spinor bilinears. Referring to eq. (C.2.11),

[103] We also define $Z^\mu_{s's}(\vec{\boldsymbol p}_{\boldsymbol 2},\vec{\boldsymbol p}_{\boldsymbol 1})$ as the expression given by eq. (C.2.14) with the interchange of $\{s\,,\,\vec{\boldsymbol p}_{\boldsymbol 1}\,,\,m_1\}$ and $\{s'\,,\,\vec{\boldsymbol p}_{\boldsymbol 2}\,,\,m_2\}$.

if $\Gamma = \mathbb{1}$, then

$$x^\alpha(\vec{\boldsymbol{p}}_1, s_1)x_\alpha(\vec{\boldsymbol{p}}_2, s_2) \simeq 2s_2\sqrt{m_1m_2}\left[\delta_{-s_2,s_1} + \left(\frac{\vec{\boldsymbol{p}}_1}{2m_1} - \frac{\vec{\boldsymbol{p}}_2}{2m_2}\right)\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}\tau^a_{-s_2,s_1}\right], \tag{C.2.15}$$

$$y^\alpha(\vec{\boldsymbol{p}}_1, s_1)y_\alpha(\vec{\boldsymbol{p}}_2, s_2) \simeq 2s_2\sqrt{m_1m_2}\left[\delta_{s_1,-s_2} + \left(\frac{\vec{\boldsymbol{p}}_1}{2m_1} - \frac{\vec{\boldsymbol{p}}_2}{2m_2}\right)\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}\tau^a_{s_1,-s_2}\right], \tag{C.2.16}$$

$$x^\alpha(\vec{\boldsymbol{p}}_1, s_1)y_\alpha(\vec{\boldsymbol{p}}_2, s_2) \simeq \sqrt{m_1m_2}\left[-\delta_{s_2,s_1} + \left(\frac{\vec{\boldsymbol{p}}_1}{2m_1} - \frac{\vec{\boldsymbol{p}}_2}{2m_2}\right)\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}\tau^a_{s_2,s_1}\right], \tag{C.2.17}$$

$$y^\alpha(\vec{\boldsymbol{p}}_1, s_1)x_\alpha(\vec{\boldsymbol{p}}_2, s_2) \simeq \sqrt{m_1m_2}\left[\delta_{s_1,s_2} + \left(\frac{\vec{\boldsymbol{p}}_1}{2m_1} - \frac{\vec{\boldsymbol{p}}_2}{2m_2}\right)\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}\tau^a_{s_1,s_2}\right], \tag{C.2.18}$$

where we have used

$$\tau^a_{s's} = -4ss'\tau^a_{-s,-s'}\,, \qquad\qquad s, s' = \pm\tfrac{1}{2}\,, \tag{C.2.19}$$

to arrive at the final forms given in eqs. (C.2.15) and (C.2.17). However, in using the above results, one must now pay close attention to the ordering of the subscript indices of the τ^a. The corresponding formulae for dotted spinor wave function bilinears are obtained by taking the hermitian conjugates of eqs. (C.2.15)–(C.2.18), which complex-conjugates the τ^a that appear on the right-hand side of these equations. Since $(\tau^a_{ss'})^* = \tau^a_{s's}$, we obtain

$$x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}_1, s_1)x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}}_2, s_2) \simeq 2s_1\sqrt{m_1m_2}\left[\delta_{s_2,-s_1} - \left(\frac{\vec{\boldsymbol{p}}_1}{2m_1} - \frac{\vec{\boldsymbol{p}}_2}{2m_2}\right)\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}\tau^a_{s_2,-s_1}\right], \tag{C.2.20}$$

$$y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}_1, s_1)y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}}_2, s_2) \simeq 2s_1\sqrt{m_1m_2}\left[\delta_{-s_1,s_2} - \left(\frac{\vec{\boldsymbol{p}}_1}{2m_1} - \frac{\vec{\boldsymbol{p}}_2}{2m_2}\right)\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}\tau^a_{-s_1,s_2}\right], \tag{C.2.21}$$

$$y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}_1, s_1)x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}}_2, s_2) \simeq -\sqrt{m_1m_2}\left[\delta_{s_2,s_1} + \left(\frac{\vec{\boldsymbol{p}}_1}{2m_1} - \frac{\vec{\boldsymbol{p}}_2}{2m_2}\right)\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}\tau^a_{s_2,s_1}\right], \tag{C.2.22}$$

$$x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}_1, s_1)y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}}_2, s_2) \simeq \sqrt{m_1m_2}\left[\delta_{s_1,s_2} - \left(\frac{\vec{\boldsymbol{p}}_1}{2m_1} - \frac{\vec{\boldsymbol{p}}_2}{2m_2}\right)\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}\tau^a_{s_1,s_2}\right]. \tag{C.2.23}$$

Likewise, if $\Gamma = \sigma^\mu$, then

$$x^\alpha(\boldsymbol{p_1}, s_1)\sigma^\mu_{\alpha\dot\beta}x^{\dagger\dot\beta}(\boldsymbol{p_2}, s_2) \simeq 4s_1s_2\sqrt{m_1m_2}\,Z^\mu_{-s_1,-s_2}(\vec{\boldsymbol{p}}_{\boldsymbol{1}}, \vec{\boldsymbol{p}}_{\boldsymbol{2}})\,, \tag{C.2.24}$$

$$y^\alpha(\boldsymbol{p_1}, s_1)\sigma^\mu_{\alpha\dot\beta}y^{\dagger\dot\beta}(\boldsymbol{p_2}, s_2) \simeq \sqrt{m_1m_2}\,Z^\mu_{s_1,s_2}(\vec{\boldsymbol{p}}_{\boldsymbol{1}}, \vec{\boldsymbol{p}}_{\boldsymbol{2}})\,, \tag{C.2.25}$$

$$x^\alpha(\boldsymbol{p_1}, s_1)\sigma^\mu_{\alpha\dot\beta}y^{\dagger\dot\beta}(\boldsymbol{p_2}, s_2) \simeq -2s_1\sqrt{m_1m_2}\,Z^\mu_{-s_1,s_2}(\vec{\boldsymbol{p}}_{\boldsymbol{1}}, \vec{\boldsymbol{p}}_{\boldsymbol{2}})\,, \tag{C.2.26}$$

$$y^\alpha(\boldsymbol{p_1}, s_1)\sigma^\mu_{\alpha\dot\beta}x^{\dagger\dot\beta}(\boldsymbol{p_2}, s_2) \simeq -2s_2\sqrt{m_1m_2}\,Z^\mu_{s_1,-s_2}(\vec{\boldsymbol{p}}_{\boldsymbol{1}}, \vec{\boldsymbol{p}}_{\boldsymbol{2}})\,, \tag{C.2.27}$$

where $Z^\mu_{ss'}(\vec{\boldsymbol{p}}_{\boldsymbol{1}}, \vec{\boldsymbol{p}}_{\boldsymbol{2}})$ is defined in eq. (C.2.14). If $\Gamma = \overline{\sigma}^\mu$, one can use $z_1\sigma^\mu z_2^\dagger = z_2^\dagger\overline{\sigma}^\mu z_1$ [i.e. eq. (29.62) for commuting spinors] to obtain the corresponding formulae for the spinor wave function bilinears (cf. footnote 103):

$$x^\dagger_{\dot\alpha}(\boldsymbol{p_1}, s_1)\overline{\sigma}^{\mu\dot\alpha\beta}x_\beta(\boldsymbol{p_2}, s_2) \simeq 4s_1s_2\sqrt{m_1m_2}\,Z^\mu_{-s_2,-s_1}(\vec{\boldsymbol{p}}_{\boldsymbol{2}}, \vec{\boldsymbol{p}}_{\boldsymbol{1}})\,, \tag{C.2.28}$$

$$y^\dagger_{\dot\alpha}(\boldsymbol{p_1}, s_1)\overline{\sigma}^{\mu\dot\alpha\beta}y_\beta(\boldsymbol{p_2}, s_2) \simeq \sqrt{m_1m_2}\,Z^\mu_{s_2,s_1}(\vec{\boldsymbol{p}}_{\boldsymbol{2}}, \vec{\boldsymbol{p}}_{\boldsymbol{1}})\,, \tag{C.2.29}$$

$$y^\dagger_{\dot\alpha}(\boldsymbol{p_1}, s_1)\overline{\sigma}^{\mu\dot\alpha\beta}x_\beta(\boldsymbol{p_2}, s_2) \simeq -2s_2\sqrt{m_1m_2}\,Z^\mu_{-s_2,s_1}(\vec{\boldsymbol{p}}_{\boldsymbol{2}}, \vec{\boldsymbol{p}}_{\boldsymbol{1}})\,, \tag{C.2.30}$$

$$x^\dagger_{\dot\alpha}(\boldsymbol{p_1}, s_1)\overline{\sigma}^{\mu\dot\alpha\beta}y_\beta(\boldsymbol{p_2}, s_2) \simeq -2s_1\sqrt{m_1m_2}\,Z^\mu_{s_2,-s_1}(\vec{\boldsymbol{p}}_{\boldsymbol{2}}, \vec{\boldsymbol{p}}_{\boldsymbol{1}})\,. \tag{C.2.31}$$

These results can also be derived directly from eqs. (C.2.3)–(C.2.10), after employing eq. (C.2.19).

It is straightforward to evaluate the spinor wave function bilinears when Γ is a product of two or more $\sigma/\overline{\sigma}$ matrices. As the corresponding expressions are considerably more complicated, we shall not write them out explicitly here.

Helicity spinor wave functions

All the results of Appendix C.1 apply to the helicity spinors χ_λ, which are defined to be eigenstates of $\frac{1}{2}\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{p}}$, i.e.,

$$\tfrac{1}{2}\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{p}}\,\chi_\lambda(\hat{\boldsymbol{p}}) = \lambda\chi_\lambda(\hat{\boldsymbol{p}})\,, \qquad \lambda = \pm\tfrac{1}{2}\,, \tag{C.3.1}$$

where $\hat{\boldsymbol{p}} = (\sin\theta_p\cos\phi_p\,,\,\sin\theta_p\sin\phi_p\,,\,\cos\theta_p)$. It follows that:

$$\sqrt{p\cdot\sigma}\,\chi_\lambda(\hat{\boldsymbol{p}}) = \omega_{-\lambda}(\vec{\boldsymbol{p}})\,\chi_\lambda(\hat{\boldsymbol{p}})\,, \qquad \sqrt{p\cdot\overline{\sigma}}\,\chi_\lambda(\hat{\boldsymbol{p}}) = \omega_\lambda(\vec{\boldsymbol{p}})\,\chi_\lambda(\hat{\boldsymbol{p}})\,, \tag{C.3.2}$$

where $\omega_\lambda(\vec{\boldsymbol{p}}) \equiv (E + 2\lambda|\vec{\boldsymbol{p}}|\,)^{1/2}$ and $E = \sqrt{|\vec{\boldsymbol{p}}|^2 + m^2}$. As a result, the explicit forms for the two-component helicity spinor wave functions [cf. eqs. (29.3.18)–(29.3.21)] simplify:

$$x_\alpha(\vec{\boldsymbol{p}},\lambda) = \omega_{-\lambda}\,\chi_\lambda(\hat{\boldsymbol{p}})\,, \qquad x^\alpha(\vec{\boldsymbol{p}},\lambda) = -2\lambda\,\omega_{-\lambda}\,\chi^\dagger_{-\lambda}(\hat{\boldsymbol{p}})\,, \tag{C.3.3}$$

$$y_\alpha(\vec{\boldsymbol{p}},\lambda) = 2\lambda\,\omega_\lambda\,\chi_{-\lambda}(\hat{\boldsymbol{p}})\,, \qquad y^\alpha(\vec{\boldsymbol{p}},\lambda) = \omega_\lambda\,\chi^\dagger_\lambda(\hat{\boldsymbol{p}})\,, \tag{C.3.4}$$

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda) = -2\lambda\,\omega_{-\lambda}\,\chi_{-\lambda}(\hat{\boldsymbol{p}})\,, \qquad x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda) = \omega_{-\lambda}\,\chi^\dagger_\lambda(\hat{\boldsymbol{p}})\,, \tag{C.3.5}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda) = \omega_\lambda\,\chi_\lambda(\hat{\boldsymbol{p}})\,, \qquad y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda) = 2\lambda\,\omega_\lambda\,\chi^\dagger_{-\lambda}(\hat{\boldsymbol{p}})\,, \tag{C.3.6}$$

where $\omega_{\pm\lambda} = \omega_{\pm\lambda}(\vec{\boldsymbol{p}})$.

In analogy with the $\hat{\boldsymbol{s}}^{\boldsymbol{a}}$, it is convenient to introduce an orthonormal set of unit three-vectors $\hat{\boldsymbol{p}}^{\boldsymbol{a}}$ such that $\hat{\boldsymbol{p}}^{\boldsymbol{3}} = \hat{\boldsymbol{p}}$. Then, eqs. (C.1.24)–(C.1.30) apply as well to the two-component helicity spinors after taking $\hat{\boldsymbol{s}}^{\boldsymbol{a}} = \hat{\boldsymbol{p}}^{\boldsymbol{a}}$.

In scattering processes, it is often convenient to work in the rest frame of the incoming particles, in which the corresponding incoming fermion three-momenta are denoted by $\vec{\boldsymbol{p}}$ and $-\vec{\boldsymbol{p}}$, respectively. The helicity spinor wave function of the second fermion depends on the definition of $\chi_\lambda(-\hat{\boldsymbol{p}})$. In this review, we follow a convention[104] in which $\chi_\lambda(-\hat{\boldsymbol{p}})$ is defined to be the spinor wave function obtained from $\chi_\lambda(\hat{\boldsymbol{z}})$ via a rotation by a polar angle $\pi - \theta_p$ and an azimuthal angle $\phi_p + \pi$ with respect to the $\hat{\boldsymbol{z}}$-direction. Then,

$$\chi_\lambda(-\hat{\boldsymbol{p}}) = \mathcal{D}(\phi_p + \pi\,,\,\pi - \theta_p\,,\,\gamma(-\hat{\boldsymbol{p}}))\,\chi_\lambda(\hat{\boldsymbol{z}})\,, \tag{C.3.7}$$

where we have exhibited the possible dependence of γ on the direction $-\hat{\boldsymbol{p}}$. Using the properties of the spin-1/2 rotation matrices, one can derive

$$\mathcal{D}(\phi_p + \pi\,,\,\pi - \theta_p\,,\,\gamma(-\hat{\boldsymbol{p}})) = -\mathcal{D}(\phi_p\,,\,\theta_p\,,\,\gamma(\hat{\boldsymbol{p}}))\,D(\hat{\boldsymbol{z}}, -\gamma(\hat{\boldsymbol{p}}) - \gamma(-\hat{\boldsymbol{p}}))\,D(\hat{\boldsymbol{x}},\pi)\,. \tag{C.3.8}$$

Inserting this result in eq. (C.3.7) and using the relation

$$D(\hat{\boldsymbol{x}},\pi)\chi_\lambda(\hat{\boldsymbol{z}}) = -i\sigma^1\chi_\lambda(\hat{\boldsymbol{z}}) = -i\chi_{-\lambda}(\hat{\boldsymbol{z}})\,, \tag{C.3.9}$$

we obtain

$$\chi_\lambda(-\hat{\boldsymbol{p}}) = \xi_{-\lambda}(\hat{\boldsymbol{p}})\chi_{-\lambda}(\hat{\boldsymbol{p}})\,, \tag{C.3.10}$$

[104] An alternative convention (called the *second-particle convention*) advocated by Jacob and Wick [260] is to define $\chi_\lambda(-\hat{\boldsymbol{p}})$ by starting with $\chi_{-\lambda}(\hat{\boldsymbol{z}})$ and then rotating the spinor by polar and azimuthal angles θ_p and ϕ_p. In this case, $\chi_\lambda(-\hat{\boldsymbol{p}}) = \chi_{-\lambda}(\hat{\boldsymbol{p}})$, and the extra phase factors of eq. (C.3.10) is absent, i.e. $\xi_\lambda(\hat{\boldsymbol{p}}) = 1$ in eq. (C.3.10). However, this convention is less suited to scattering processes involving final states with more than two fermions. Hence, we do not adopt the second-particle convention in this review.

where the phase factor $\xi_\lambda(\hat{\boldsymbol{p}})$ is given by

$$\xi_\lambda(\hat{\boldsymbol{p}}) = ie^{i\lambda[\gamma(\hat{\boldsymbol{p}})+\gamma(-\hat{\boldsymbol{p}})]}\,, \qquad \lambda = \pm\tfrac{1}{2}\,. \tag{C.3.11}$$

Since γ is a real angle, it follows that:

$$\xi^*_\lambda(\hat{\boldsymbol{p}}) = \frac{1}{\xi_\lambda(\hat{\boldsymbol{p}})} = -\xi_{-\lambda}(\hat{\boldsymbol{p}})\,. \tag{C.3.12}$$

Using eq. (C.3.11), we note that $\chi_\lambda(\hat{\boldsymbol{p}})$ possesses the peculiar property that:

$$\chi_\lambda(-(-\hat{\boldsymbol{p}})) = -\chi_\lambda(\hat{\boldsymbol{p}})\,. \tag{C.3.13}$$

This is a consequence of the fact that the result of two successive inversions is equivalent to $\phi_p \to \phi_p + 2\pi$, which yields an overall change of sign of a spinor wave function [cf. eq. (C.1.12)].[105]

For example, corresponding to the two conventional choices for γ,

$$\xi_\lambda(\hat{\boldsymbol{p}}) = \begin{cases} (-1)^{\frac{1}{2}-\lambda}\, e^{-2i\lambda\phi_p} & \text{for } \ \gamma(\hat{\boldsymbol{p}}) = -\phi_p\,, \quad \gamma(-\hat{\boldsymbol{p}}) = -\phi_p - \pi\,, \\ i & \text{for } \ \gamma(\hat{\boldsymbol{p}}) = \gamma(-\hat{\boldsymbol{p}}) = 0\,, \end{cases} \tag{C.3.14}$$

with the proviso that for $\hat{\boldsymbol{p}} = \pm\hat{\boldsymbol{z}}$, we define ϕ_p according to eq. (C.1.7).

Suppose that the two fermions considered above have equal mass. In the center-of-mass frame, if the four-momentum of one of the fermions is $p^\mu = (E\,;\,\vec{\boldsymbol{p}})$, then the four-momentum of the other fermion is $\widetilde{p}^\mu \equiv (E\,;\,-\vec{\boldsymbol{p}})$. The following *numerical* identities are then satisfied: $\sigma\cdot\widetilde{p} = \overline{\sigma}\cdot p$ and $\overline{\sigma}\cdot\widetilde{p} = \sigma\cdot p$. However, in order to maintain covariance with respect to the undotted and dotted spinor indices, we shall write these identities as:

$$\widetilde{p}\cdot\sigma_{\alpha\dot\beta} = \sigma^0_{\alpha\dot\alpha}(p\cdot\overline{\sigma}^{\dot\alpha\beta})\,\sigma^0_{\beta\dot\beta}\,, \qquad \widetilde{p}\cdot\overline{\sigma}^{\dot\alpha\beta} = \overline{\sigma}^{0\dot\alpha\alpha}(p\cdot\sigma_{\alpha\dot\beta})\,\overline{\sigma}^{0\dot\beta\beta}\,. \tag{C.3.15}$$

Taking the matrix square root of both sides of the equations above removes one of the factors of σ^0 and $\overline{\sigma}^0$, respectively [cf. eqs. (29.110)–(29.116)]. Thus, using eqs. (29.3.18) and (C.3.10),

$$x_\alpha(-\vec{\boldsymbol{p}},-\lambda) = \sqrt{\widetilde{p}\cdot\sigma}\chi_{-\lambda}(-\hat{\boldsymbol{p}}) = \sigma^0\sqrt{p\cdot\overline{\sigma}}\,\xi_\lambda(\hat{\boldsymbol{p}})\,\chi_\lambda(\vec{\boldsymbol{p}}) = \sigma^0_{\alpha\dot\beta}\,\xi_\lambda(\hat{\boldsymbol{p}})\,y^{\dagger\dot\beta}(\vec{\boldsymbol{p}},\lambda)\,. \tag{C.3.16}$$

In this way, we can derive all relations of this kind for the helicity spinor wave functions:

$$x_\alpha(-\vec{\boldsymbol{p}},-\lambda) = \xi_\lambda\sigma^0_{\alpha\dot\beta}\,y^{\dagger\dot\beta}(\vec{\boldsymbol{p}},\lambda) = \omega_\lambda\xi_\lambda\,\chi_\lambda(\hat{\boldsymbol{p}})\,, \tag{C.3.17}$$

$$y_\alpha(-\vec{\boldsymbol{p}},-\lambda) = \xi_{-\lambda}\sigma^0_{\alpha\dot\beta}\,x^{\dagger\dot\beta}(\vec{\boldsymbol{p}},\lambda) = -2\lambda\,\omega_{-\lambda}\xi_{-\lambda}\,\chi_{-\lambda}(\hat{\boldsymbol{p}})\,, \tag{C.3.18}$$

$$x^{\dagger\dot\alpha}(-\vec{\boldsymbol{p}},-\lambda) = \xi_{-\lambda}\overline{\sigma}^{0\dot\alpha\beta}\,y_\beta(\vec{\boldsymbol{p}},\lambda) = 2\lambda\,\omega_\lambda\xi_{-\lambda}\,\chi_{-\lambda}(\hat{\boldsymbol{p}})\,, \tag{C.3.19}$$

$$y^{\dagger\dot\alpha}(-\vec{\boldsymbol{p}},-\lambda) = \xi_\lambda\overline{\sigma}^{0\dot\alpha\beta}\,x_\beta(\vec{\boldsymbol{p}},\lambda) = \omega_{-\lambda}\xi_\lambda\,\chi_\lambda(\hat{\boldsymbol{p}})\,, \tag{C.3.20}$$

where $\omega_{\pm\lambda} \equiv \omega_{\pm\lambda}(\vec{\boldsymbol{p}})$ and $\xi_\lambda \equiv \xi_\lambda(\hat{\boldsymbol{p}})$. Raising [lowering] the undotted [dotted] index yields:

$$x^\alpha(-\vec{\boldsymbol{p}},-\lambda) = -y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},\lambda)\,\xi_\lambda\overline{\sigma}^{0\dot\beta\alpha} = -2\lambda\,\omega_\lambda\xi_\lambda\chi^\dagger_{-\lambda}(\hat{\boldsymbol{p}})\,, \tag{C.3.21}$$

$$y^\alpha(-\vec{\boldsymbol{p}},-\lambda) = -x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},\lambda)\,\xi_{-\lambda}\overline{\sigma}^{0\dot\beta\alpha} = -\omega_{-\lambda}\xi_{-\lambda}\,\chi^\dagger_\lambda(\hat{\boldsymbol{p}})\,, \tag{C.3.22}$$

$$x^\dagger_{\dot\alpha}(-\vec{\boldsymbol{p}},-\lambda) = -y^\beta(\vec{\boldsymbol{p}},\lambda)\,\xi_{-\lambda}\sigma^0_{\beta\dot\alpha} = -\omega_\lambda\xi_{-\lambda}\,\chi^\dagger_\lambda(\hat{\boldsymbol{p}})\,, \tag{C.3.23}$$

$$y^\dagger_{\dot\alpha}(-\vec{\boldsymbol{p}},-\lambda) = -x^\beta(\vec{\boldsymbol{p}},\lambda)\,\xi_\lambda\sigma^0_{\beta\dot\alpha} = 2\lambda\,\omega_{-\lambda}\xi_\lambda\,\chi^\dagger_{-\lambda}(\hat{\boldsymbol{p}})\,. \tag{C.3.24}$$

Eqs. (C.3.17)–(C.3.24) can also be obtained directly from eqs. (C.3.3)–(C.3.6).

[105] A slightly modified procedure (not adopted in this review) is to take the azimuthal angle of $-\hat{\boldsymbol{p}}$ to be $\phi_p \pm \pi$, where the $\pm$ sign is chosen according to which of the two conditions $0 \leq \phi_p \pm \pi < 2\pi$ is true. This procedure would yield an extra minus sign in the definition of $\xi_\lambda(\hat{\boldsymbol{p}})$ when $\pi \leq \phi_p < 2\pi$. In this convention, two successive inversions are equivalent to the identity rotation so that $\chi_\lambda(-(-\hat{\boldsymbol{p}})) = \chi_\lambda(\hat{\boldsymbol{p}})$.

29.7.4 Matrix decompositions for mass matrix diagonalization

In scalar field theory, the diagonalization of the scalar squared-mass matrix M^2 is straightforward. For a theory of n complex scalar fields, M^2 is an hermitian $n \times n$ matrix, which can be diagonalized by a unitary matrix W:

$$W^\dagger M^2 W = m^2 = \text{diag}(m_1^2, m_2^2, ..., m_n^2)\,. \tag{D.1}$$

For a theory of n real scalar fields, M^2 is a real symmetric $n \times n$ matrix, which can be diagonalized by an orthogonal matrix Q:

$$Q^\mathsf{T} M^2 Q = m^2 = \text{diag}(m_1^2, m_2^2, ..., m_n^2)\,. \tag{D.2}$$

In both cases, the eigenvalues m_k^2 of M^2 are real. These are the standard matrix diagonalization problems that are treated in all elementary linear algebra textbooks.

In spin-1/2 fermion field theory, the most general fermion mass matrix, obtained from the Lagrangian, written in terms of two-component spinors, is complex and symmetric [cf. Section 29.3.2]. If the Lagrangian exhibits a U(1) symmetry, then a basis can be found such that fields that are charged under the U(1) pair up into Dirac fermions. The fermion mass matrix then decomposes into the direct sum of a complex Dirac fermion mass matrix and a complex symmetric neutral fermion mass matrix. In this Appendix, we review the linear algebra theory relevant for the matrix decompositions associated with the general charged and neutral spin-1/2 fermion mass matrix diagonalizations. The diagonalization of the Dirac fermion mass matrix is governed by the singular value decomposition of a complex matrix, as shown in Appendix D.1 . In contrast, the diagonalization of a neutral fermion mass matrix is governed by the Takagi diagonalization of a complex symmetric matrix, which is treated in Appendix D.2 .[106] These two techniques are compared and contrasted in Appendix D.3 . Dirac fermions can also arise in the case of a pseudo-real representation of fermion fields. As shown in Section 29.3.2, this latter case requires the reduction of a complex antisymmetric fermion mass matrix to real normal form. The relevant theorem and its proof are given in Appendix D.4 .

Singular value decomposition

The diagonalization of the charged (Dirac) fermion mass matrix requires the singular value decomposition of an arbitrary complex matrix M.

Theorem: For any complex [or real] $n \times n$ matrix M, unitary [or real orthogonal] matrices L and R exist such that

$$L^\mathsf{T} M R = M_D = \text{diag}(m_1, m_2, ..., m_n), \tag{D.1.1}$$

where the m_k are real and non-negative. This is called the singular value decomposition of the matrix M (e.g., see refs. [149, 261]).

In general, the m_k are *not* the eigenvalues of M. Rather, the m_k are the *singular values* of the general complex matrix M, which are defined to be the non-negative square roots of the eigenvalues of $M^\dagger M$ (or equivalently of $MM^\dagger$). An equivalent definition of the singular values can be established as follows. Since $M^\dagger M$ is an hermitian non-negative matrix, its eigenvalues are real and non-negative and its eigenvectors, v_k, defined by $M^\dagger M v_k = m_k^2 v_k$, can be chosen to be orthonormal.[107] Consider first the eigenvectors corresponding to the non-zero eigenvalues of $M^\dagger M$. Then, we define the vectors w_k such that

$$M v_k = m_k w_k^*\,. \tag{D.1.2}$$

[106] One may choose not to work in a basis where the fermion fields are eigenstates of the U(1) charge operator. In this case, all fermions are governed by a complex symmetric mass matrix, which can be Takagi-diagonalized according to the procedure described in Appendix D.2 .

[107] We define the inner product of two vectors to be $\langle v|w\rangle \equiv v^\dagger w$. Then, v and w are orthonormal if $\langle v|w\rangle = 0$. The norm of a vector is defined by $\|v\| = \langle v|v\rangle^{1/2}$.

It follows that $m_k^2 v_k = M^\dagger M v_k = m_k M^\dagger w_k^*$, which yields: $M^\dagger w_k^* = m_k v_k$. Note that these equations also imply that $MM^\dagger w_k^* = m_k^2 w_k^*$. The orthonormality of the v_k implies the orthonormality of the w_k, and vice versa. For example,

$$\delta_{jk} = \langle v_j | v_k \rangle = \frac{1}{m_j m_k} \langle M^\dagger w_j^* | M^\dagger w_k^* \rangle = \frac{1}{m_j m_k} \langle w_j | M M^\dagger w_k^* \rangle = \frac{m_k}{m_j} \langle w_j^* | w_k^* \rangle \,, \tag{D.1.3}$$

which yields $\langle w_k | w_j \rangle = \delta_{jk}$. If M is a real matrix, then the eigenvectors v_k can be chosen to be real, in which case the corresponding w_k are also real.

If v_i is an eigenvector of $M^\dagger M$ with zero eigenvalue, then $0 = v_i^\dagger M^\dagger M v_i = \langle M v_i | M v_i \rangle$, which implies that $M v_i = 0$. Likewise, if w_i^* is an eigenvector of $MM^\dagger$ with zero eigenvalue, then $0 = w_i^{\mathsf{T}} M M^\dagger w_i^* = \langle M^{\mathsf{T}} w_i | M^{\mathsf{T}} w_i \rangle^*$, which implies that $M^{\mathsf{T}} w_i = 0$. Because the eigenvectors of $M^\dagger M$ [$MM^\dagger$] can be chosen orthonormal, the eigenvectors corresponding to the zero eigenvalues of M [$M^\dagger$] can be taken to be orthonormal.[108] Finally, these eigenvectors are also orthogonal to the eigenvectors corresponding to the non-zero eigenvalues of $M^\dagger M$ [$MM^\dagger$]. That is, if the indices i and j run over the eigenvectors corresponding to the zero and non-zero eigenvalues of $M^\dagger M$ [$MM^\dagger$], respectively, then

$$\langle v_j | v_i \rangle = \frac{1}{m_j} \langle M^\dagger w_j^* | v_i \rangle = \frac{1}{m_j} \langle w_j^* | M v_i \rangle = 0 \,, \tag{D.1.4}$$

and similarly $\langle w_j | w_i \rangle = 0$.

Thus, we can define the singular values of a general complex $n \times n$ matrix M to be the simultaneous solutions (with real non-negative m_k) of:[109]

$$M v_k = m_k w_k^* \,, \qquad\qquad w_k^{\mathsf{T}} M = m_k v_k^\dagger \,. \tag{D.1.5}$$

The corresponding v_k (w_k), normalized to have unit norm, are called the right (left) singular vectors of M. In particular, the number of linearly independent v_k coincides with the number of linearly independent w_k and is equal to n.

Proof of the singular value decomposition theorem: Eqs. (D.1.3) and (D.1.4) imply that the right [left] singular vectors can be chosen to be orthonormal. Consequently, the unitary matrix R [L] can be constructed such that its kth column is given by the right [left] singular vector v_k [w_k]. It then follows from eq. (D.1.5) that:

$$w_k^{\mathsf{T}} M v_\ell = m_k \delta_{k\ell} \,, \qquad\qquad \text{(no sum over } k\text{)}. \tag{D.1.6}$$

In matrix form, eq. (D.1.6) coincides with eq. (D.1.1), and the singular value decomposition is established. If M is real, then the right and left singular vectors, v_k and w_k, can be chosen to be real, in which case eq. (D.1.1) holds for real orthogonal matrices L and R.

The singular values of a complex matrix M are unique (up to ordering), as they correspond to the eigenvalues of $M^\dagger M$ (or equivalently the eigenvalues of $MM^\dagger$). The unitary matrices L and R are not unique. The matrix R must satisfy

$$R^\dagger M^\dagger M R = M_D^2 \,, \tag{D.1.7}$$

which follows directly from eq. (D.1.1) by computing $M_D^\dagger M_D = M_D^2$. That is, R is a unitary matrix that diagonalizes the non-negative definite matrix $M^\dagger M$. Since the eigenvectors of $M^\dagger M$ are orthonormal, each v_k corresponding to a non-degenerate eigenvalue of $M^\dagger M$ can be multiplied by

[108] This analysis shows that the number of linearly independent eigenvectors of $M^\dagger M$ [$MM^\dagger$] with zero eigenvalue coincides with the number of linearly independent eigenvectors of M [$M^\dagger$] with zero eigenvalue.

[109] One can always find a solution to eq. (D.1.5) such that the m_k are real and non-negative. Given a solution where m_k is complex, we simply write $m_k = |m_k| e^{i\theta}$ and redefine $w_k \to w_k e^{i\theta}$ to remove the phase θ.

an arbitrary phase $e^{i\theta_k}$. For the case of degenerate eigenvalues, any orthonormal linear combination of the corresponding eigenvectors is also an eigenvector of $M^\dagger M$. It follows that within the subspace spanned by the eigenvectors corresponding to non-degenerate eigenvalues, R is uniquely determined up to multiplication on the right by an arbitrary diagonal unitary matrix. Within the subspace spanned by the eigenvectors of $M^\dagger M$ corresponding to a degenerate eigenvalue, R is determined up to multiplication on the right by an arbitrary unitary matrix.

Once R is fixed, L is obtained from eq. (D.1.1):

$$L = (M^{\mathsf{T}})^{-1} R^* M_D \,. \tag{D.1.8}$$

However, if some of the diagonal elements of M_D are zero, then L is not uniquely defined. Writing M_D in 2×2 block form such that the upper left block is a diagonal matrix with positive diagonal elements and the other three blocks are equal to the zero matrix of the appropriate dimensions, it follows that, $M_D = M_D W$, where

$$W = \begin{pmatrix} \mathbb{1} & \mathbb{0} \\ \mathbb{0} & W_0 \end{pmatrix} , \tag{D.1.9}$$

W_0 is an arbitrary unitary matrix whose dimension is equal to the number of zeros that appear in the diagonal elements of M_D, and $\mathbb{1}$ and $\mathbb{0}$ are respectively the identity matrix and zero matrix of the appropriate size. Hence, we can multiply both sides of eq. (D.1.8) on the right by W, which means that L is only determined up to multiplication on the right by an arbitrary unitary matrix whose form is given by eq. (D.1.9).[110]

If M is a real matrix, then the singular value decomposition of M is given by Eq. (D.1.1), where L and R are real orthogonal matrices. This result is easily established by replacing "phase" with "sign" and replacing "unitary" by "real orthogonal" in the above proof.

Takagi diagonalization

The mass matrix of neutral fermions (or a system of two-component fermions in a generic basis) is complex and symmetric. This mass matrix must be diagonalized in order to identify the physical fermion mass eigenstates and to compute their masses. However, the fermion mass matrix is *not* diagonalized by the standard unitary similarity transformation. Instead a different diagonalization equation is employed that was discovered by Takagi [112], and rediscovered many times since [149].[111]

Theorem: For any complex symmetric $n \times n$ matrix M, there exists a unitary matrix Ω such that:

$$\Omega^{\mathsf{T}} M \, \Omega = M_D = \mathrm{diag}(m_1, m_2, ..., m_n) \,, \tag{D.2.1}$$

where the m_k are real and non–negative. This is the Takagi diagonalization[112] of the complex symmetric matrix M.

[110] Of course, one can reverse the above procedure by first determining the unitary matrix L. Eq. (D.1.1) implies that $L^{\mathsf{T}} M M^\dagger L^* = M_D^2$, in which case L is determined up to multiplication on the right by an arbitrary [diagonal] unitary matrix within the subspace spanned by the eigenvectors corresponding to the degenerate [non-degenerate] eigenvalues of $MM^\dagger$. Having fixed L, one can obtain $R = M^{-1} L^* M_D$ from eq. (D.1.1). As above, R is only determined up to multiplication on the right by a unitary matrix whose form is given by eq. (D.1.9).

[111] Subsequently, it was recognized in Ref. [261] that the Takagi diagonalization was first established for nonsingular complex symmetric matrices by Autonne [262]. In the physics literature, the first proof of eq. (D.2.1) was given in [151]. Applications of Takagi diagonalization to the study of neutrino mass matrices can be found in refs. [5, 263].

[112] In Ref. [149], eq. (D.2.1) is called the Takagi factorization of a complex symmetric matrix. We choose to refer to this as Takagi *diagonalization* to emphasize and contrast this with the more standard diagonalization of normal matrices by a unitary similarity transformation. In particular, not all *complex* symmetric matrices are diagonalizable by a similarity transformation, whereas complex symmetric matrices are *always* Takagi-diagonalizable.

In general, the m_k are *not* the eigenvalues of M. Rather, the m_k are the singular values of the symmetric matrix M. From eq. (D.2.1) it follows that:

$$\Omega^\dagger M^\dagger M \Omega = M_D^2 = \mathrm{diag}(m_1^2, m_2^2, ..., m_n^2)\,. \tag{D.2.2}$$

If all of the singular values m_k are non-degenerate, then one can find a solution to eq. (D.2.1) for Ω from eq. (D.2.2). This is no longer true if some of the singular values are degenerate. For example, if $M = \left(\begin{smallmatrix} 0 & m \\ m & 0 \end{smallmatrix}\right)$, then the singular value $|m|$ is doubly–degenerate, but eq. (D.2.2) yields $\Omega^\dagger\Omega = \mathbb{1}_{2\times 2}$, which does not specify Ω. That is, in the degenerate case, the physical fermion states *cannot* be determined by the diagonalization of $M^\dagger M$. Instead, one must make direct use of eq. (D.2.1). Below, we shall present a constructive method for determining Ω that is applicable in both the non-degenerate and the degenerate cases.

Eq. (D.2.1) can be rewritten as $M\Omega = \Omega^* M_D$, where the columns of Ω are orthonormal. If we denote the kth column of Ω by v_k, then,

$$Mv_k = m_k v_k^*\,, \tag{D.2.3}$$

where the m_k are the singular values and the vectors v_k are normalized to have unit norm. Following Ref. [264], the v_k are called the *Takagi vectors* of the complex symmetric $n \times n$ matrix M. The Takagi vectors corresponding to non–degenerate non–zero [zero] singular values are unique up to an overall sign [phase]. Any orthogonal [unitary] linear combination of Takagi vectors corresponding to a set of degenerate non–zero [zero] singular values is also a Takagi vector corresponding to the same singular value. Using these results, one can determine the degree of non–uniqueness of the matrix Ω. For definiteness, we fix an ordering of the diagonal elements of M_D.[113] If the singular values of M are distinct, then the matrix Ω is uniquely determined up to multiplication by a diagonal matrix whose entries are either ± 1 (i.e., a diagonal orthogonal matrix). If there are degeneracies corresponding to non–zero singular values, then within the degenerate subspace, Ω is unique up to multiplication on the right by an arbitrary orthogonal matrix. Finally, in the subspace corresponding to zero singular values, Ω is unique up to multiplication on the right by an arbitrary unitary matrix.

For a real symmetric matrix M, the Takagi diagonalization [eq. (D.2.1)] still holds for a unitary matrix Ω, which is easily determined as follows. Any real symmetric matrix M can be diagonalized by a real orthogonal matrix Z,

$$Z^{\mathsf{T}} M Z = \mathrm{diag}(\varepsilon_1 m_1\,,\, \varepsilon_2 m_2\,,\, \ldots\,,\, \varepsilon_n m_n)\,, \tag{D.2.4}$$

where the m_k are real and non-negative and the $\varepsilon_k m_k$ are the real eigenvalues of M with corresponding signs $\varepsilon_k = \pm 1$.[114] Then, the Takagi diagonalization of M is achieved by taking:

$$\Omega_{ij} = \varepsilon_j^{1/2} Z_{ij}\,, \qquad \text{no sum over } j\,. \tag{D.2.5}$$

Proof of the Takagi diagonalization. To prove the existence of the Takagi diagonalization of a complex symmetric matrix, it is sufficient to provide an algorithm for constructing the orthonormal Takagi vectors v_k that make up the columns of Ω. This is achieved by rewriting the $n\times n$ complex matrix equation $Mv = mv^*$ [with m real and non–negative] as a $2n\times 2n$ real matrix equation [265, 266]:

$$M_R \begin{pmatrix} \mathrm{Re}\, v \\ \mathrm{Im}\, v \end{pmatrix} \equiv \begin{pmatrix} \mathrm{Re}\, M & -\mathrm{Im}\, M \\ -\mathrm{Im}\, M & -\mathrm{Re}\, M \end{pmatrix} \begin{pmatrix} \mathrm{Re}\, v \\ \mathrm{Im}\, v \end{pmatrix} = m \begin{pmatrix} \mathrm{Re}\, v \\ \mathrm{Im}\, v \end{pmatrix}\,, \quad \text{where } m \geq 0\,. \tag{D.2.6}$$

Since $M = M^{\mathsf{T}}$, the $2n \times 2n$ matrix $M_R \equiv \left(\begin{smallmatrix} \mathrm{Re}\, M & -\mathrm{Im}\, M \\ -\mathrm{Im}\, M & -\mathrm{Re}\, M \end{smallmatrix}\right)$ is a real symmetric matrix.[115] In particular, M_R is diagonalizable by a real orthogonal similarity transformation, and its eigenvalues

[113] Permuting the order of the singular values is equivalent to permuting the order of the columns of Ω.

[114] In the case of $m_k = 0$, we conventionally choose the corresponding $\varepsilon_k = +1$.

[115] The $2n \times 2n$ matrix M_R is a real representation of the $n \times n$ complex matrix M.

are real. Moreover, if m is an eigenvalue of M_R with eigenvector $(\,\mathrm{Re}\,v\,,\ \mathrm{Im}\,v)$, then $-m$ is an eigenvalue of M_R with (orthogonal) eigenvector $(-\,\mathrm{Im}\,v\,,\ \mathrm{Re}\,v)$. This observation implies that M_R has an equal number of positive and negative eigenvalues and an even number of zero eigenvalues.[116] Thus, eq. (D.2.3) has been converted into an ordinary eigenvalue problem for a real symmetric matrix. Since $m \geq 0$, we solve the eigenvalue problem $M_R u = mu$ for the real eigenvectors $u \equiv (\,\mathrm{Re}\,v\,,\ \mathrm{Im}\,v)$ corresponding to the non–negative eigenvalues of M_R,[117] which then immediately yields the complex Takagi vectors, v. It is straightforward to prove that the total number of linearly independent Takagi vectors is equal to n. Simply note that the orthogonality of $(\,\mathrm{Re}\,v_1\,,\ \mathrm{Im}\,v_1)$ and $(-\,\mathrm{Im}\,v_1\,,\ \mathrm{Re}\,v_1)$ with $(\,\mathrm{Re}\,v_2\,,\ \mathrm{Im}\,v_2)$ implies that $v_1^\dagger v_2 = 0$.

Thus, we have derived a constructive method for obtaining the Takagi vectors v_k. If there are degeneracies, one can always choose the v_k in the degenerate subspace to be orthonormal. The Takagi vectors then make up the columns of the matrix Ω in eq. (D.2.1). A numerical package for performing the Takagi diagonalization of a complex symmetric matrix has recently been presented in [267] (see also refs. [264, 268] for previous numerical approaches to Takagi diagonalization).

Relation between Takagi diagonalization and singular value decomposition

The Takagi diagonalization is a special case of the singular value decomposition. If the complex matrix M in eq. (D.1.1) is symmetric, $M = M^{\mathsf{T}}$, then the Takagi diagonalization corresponds to $\Omega = L = R$. In this case, the right and left singular vectors coincide ($v_k = w_k$) and are identified with the Takagi vectors defined in eq. (D.2.3). However as previously noted, the matrix Ω cannot be determined from eq. (D.2.2) in cases where there is a degeneracy among the singular values.[118] For example, one possible singular value decomposition of the matrix $M = \left(\begin{smallmatrix} 0 & m \\ m & 0 \end{smallmatrix}\right)$ [with m assumed real and positive] can be obtained by choosing $R = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right)$ and $L = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, in which case $L^{\mathsf{T}} M R = \left(\begin{smallmatrix} m & 0 \\ 0 & m \end{smallmatrix}\right) = M_D$. Of course, this is not a Takagi diagonalization because $L \neq R$. Since R is only defined modulo the multiplication on the right by an arbitrary 2×2 unitary matrix $\mathcal{O}$, then at least one singular value decomposition exists that is also a Takagi diagonalization. For the example under consideration, it is not difficult to deduce the Takagi diagonalization: $\Omega^{\mathsf{T}} M \Omega = M_D$, where

$$\Omega = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & i \\ 1 & -i \end{pmatrix} \mathcal{O}\,, \tag{D.3.1}$$

and $\mathcal{O}$ is any 2×2 orthogonal matrix.

Since the Takagi diagonalization is a special case of the singular value decomposition, it seems plausible that one can prove the former from the latter. This turns out to be correct; for completeness, we provide the proof below. Our second proof depends on the following lemma:

Lemma: For any symmetric unitary matrix V, there exists a unitary matrix U such that $V = U^{\mathsf{T}} U$.

Proof of the Lemma: For any $n \times n$ unitary matrix V, there exists an hermitian matrix H such that $V = \exp(iH)$ (this is the polar decomposition of V). If $V = V^{\mathsf{T}}$ then $H = H^{\mathsf{T}} = H^*$ (since H is hermitian); therefore H is real symmetric. But, any real symmetric matrix can be diagonalized by an orthogonal transformation. It follows that V can also be diagonalized by an orthogonal transformation. Since the eigenvalues of any unitary matrix are pure phases, there exists a real orthogonal matrix Q such that $Q^{\mathsf{T}} V Q = \mathrm{diag}\,(\mathrm{e}^{\mathrm{i}\theta_1}\,,\ \mathrm{e}^{\mathrm{i}\theta_2}\,,\ \ldots\,,\ \mathrm{e}^{\mathrm{i}\theta_n})$. Thus, the unitary

[116] Note that $(-\,\mathrm{Im}\,v\,,\ \mathrm{Re}\,v)$ corresponds to replacing v_k in eq. (D.2.3) by iv_k. However, for $m < 0$ these solutions are not relevant for Takagi diagonalization (where the m_k are by definition non–negative). The case of $m = 0$ is considered in footnote 117.

[117] For $m = 0$, the corresponding vectors $(\,\mathrm{Re}\,v\,,\ \mathrm{Im}\,v)$ and $(-\,\mathrm{Im}\,v\,,\ \mathrm{Re}\,v)$ are two linearly independent eigenvectors of M_R; but these yield only one independent Takagi vector v (since v and iv are linearly dependent).

[118] This is in contrast to the singular value decomposition, where R can be determined from eq. (D.1.7) modulo right multiplication by a [diagonal] unitary matrix in the [non-]degenerate subspace and L is then determined by eq. (D.1.8) modulo multiplication on the right by eq. (D.1.9).

matrix,

$$U = \text{diag}\,(e^{i\theta_1/2}\,,\, e^{i\theta_2/2}\,,\, \ldots\,,\, e^{i\theta_n/2})\,Q^{\mathsf{T}}\,, \tag{D.3.2}$$

satisfies $V = U^{\mathsf{T}}U$ and the lemma is proved. Note that U is unique modulo multiplication on the left by an arbitrary real orthogonal matrix.

Second Proof of the Takagi diagonalization. Starting from the singular value decomposition of M, there exist unitary matrices L and R such that $M = L^*M_DR^\dagger$, where M_D is the diagonal matrix of singular values. Since $M = M^{\mathsf{T}} = R^*M_DL^\dagger$, we have two different singular value decompositions for M. However, as noted below eq. (D.1.7), R is unique modulo multiplication on the right by an arbitrary [diagonal] unitary matrix, V, within the [non-]degenerate subspace. Thus, it follows that a [diagonal] unitary matrix V exists such that $L = RV$. Moreover, $V = V^{\mathsf{T}}$. This is manifestly true within the non-degenerate subspace where V is diagonal. Within the degenerate subspace, M_D is proportional to the identity matrix so that $L^*R^\dagger = R^*L^\dagger$. Inserting $L = RV$ then yields $V^{\mathsf{T}} = V$. Using the Lemma proved above, there exists a unitary matrix U such that $V = U^{\mathsf{T}}U$. That is,

$$L = RU^{\mathsf{T}}U\,, \tag{D.3.3}$$

for some unitary matrix U. Moreover, it is now straightforward to show that

$$M_DU^* = U^*M_D\,. \tag{D.3.4}$$

To see this, note that within the degenerate subspace, eq. (D.3.4) is trivially true since M_D is proportional to the identity matrix. Within the non-degenerate subspace V is diagonal; hence we may choose $U = U^{\mathsf{T}} = V^{1/2}$, so that eq. (D.3.4) is true since diagonal matrices commute. Using eqs. (D.3.3) and (D.3.4), we can write the singular value decomposition of M as follows

$$M = L^*M_DR^\dagger = R^*U^\dagger U^*M_DR^\dagger = (RU^{\mathsf{T}})^*M_DU^*R^\dagger = \Omega^*M_D\Omega^\dagger\,, \tag{D.3.5}$$

where $\Omega \equiv RU^{\mathsf{T}}$ is a unitary matrix. Thus the existence of the Takagi diagonalization of an arbitrary complex symmetric matrix [eq. (D.2.1)] is once again proved.

In the diagonalization of the two-component fermion mass matrix, M, the eigenvalues of $M^\dagger M$ typically fall into two classes—non-degenerate eigenvalues corresponding to neutral fermion mass eigenstates and degenerate pairs corresponding to charged (Dirac) mass eigenstates. In this case, the sector of the neutral fermions corresponds to a non-degenerate subspace of the space of fermion fields. Hence, in order to identify the neutral fermion mass eigenstates, it is sufficient to diagonalize $M^\dagger M$ with a unitary matrix R [as in eq. (D.1.7)], and then adjust the overall phase of each column of R so that the resulting matrix Ω satisfies $\Omega^{\mathsf{T}}M\Omega = M_D$, where M_D is a diagonal matrix of the non-negative fermion masses. This last result is a consequence of eqs. (D.3.3)–(D.3.5), where $\Omega = RV^{1/2}$ and V is a diagonal matrix of phases.

Reduction of a complex antisymmetric matrix to real normal form

In the case of two-component fermions that transform under a pseudo-real representation of a compact Lie group [cf. eq. (29.3.35)], the corresponding mass matrix is in general complex and antisymmetric. In this case, one needs the antisymmetric analogue of the Takagi diagonalization of a complex symmetric matrix [149].

Theorem: For any complex [or real] antisymmetric $n \times n$ matrix M, there exists a unitary [or real orthogonal] matrix U such that:

$$U^{\mathsf{T}}MU = N \equiv \text{diag}\left\{\begin{pmatrix} 0 & m_1 \\ -m_1 & 0 \end{pmatrix}\,,\, \begin{pmatrix} 0 & m_2 \\ -m_2 & 0 \end{pmatrix}\,,\, \cdots\,,\, \begin{pmatrix} 0 & m_p \\ -m_p & 0 \end{pmatrix}\,,\, \mathbb{O}_{n-2p}\right\}\,, \tag{D.4.1}$$

where N is written in block diagonal form with 2×2 matrices appearing along the diagonal, followed by an $(n-2p) \times (n-2p)$ block of zeros (denoted by $\mathbb{O}_{n-2p}$), and the m_j are real and positive. N is called the *real normal form* of an antisymmetric matrix [151, 269, 270].

Proof: A number of proofs can be found in the literature [151, 269, 150, 270, 271]. Here we provide a proof inspired by [269]. Following Appendix D.1 , we first consider the eigenvalue equation for $M^\dagger M$:

$$M^\dagger M v_k = m_k^2 v_k\,, \qquad m_k > 0\,, \qquad \text{and} \qquad M^\dagger M u_k = 0\,, \tag{D.4.2}$$

where we have distinguished the eigenvectors corresponding to positive eigenvalues and zero eigenvalues, respectively. The quantities m_k are the positive singular values of M. Noting that $u_k^\dagger M^\dagger M u_k = \langle M u_k \,|\, M u_k\rangle = 0$, it follows that

$$M u_k = 0\,, \tag{D.4.3}$$

so that the u_k are the eigenvectors corresponding to the zero eigenvalues of M. For each eigenvector of $M^\dagger M$ with $m_k \neq 0$, we define a new vector

$$w_k \equiv \frac{1}{m_k} M^* v_k^*\,. \tag{D.4.4}$$

It follows that $m_k^2 v_k = M^\dagger M v_k = m_k M^\dagger w_k^*$, which yields $M^\dagger w_k^* = m_k v_k$. Comparing with eq. (D.1.5), we identify v_k and w_k as the right and left singular vectors, respectively, corresponding to the non-zero singular values of M. For any antisymmetric matrix, $M^\dagger = -M^*$. Hence,

$$M v_k = m_k w_k^*\,, \qquad\qquad M w_k = -m_k v_k^*\,, \tag{D.4.5}$$

and

$$M^\dagger M w_k = -m_k M^\dagger v_k^* = m_k M^* v_k^* = m_k^2 w_k\,, \qquad m_k > 0\,. \tag{D.4.6}$$

That is, the w_k are also eigenvectors of $M^\dagger M$.

The key observation is that for fixed k the vectors v_k and w_k are orthogonal, since eq. (D.4.5) implies that:

$$\langle w_k | v_k\rangle = \langle v_k | w_k\rangle^* = -\frac{1}{m_k^2}\langle M w_k | M v_k\rangle = -\frac{1}{m_k^2}\langle w_k | M^\dagger M v_k\rangle = -\langle w_k | v_k\rangle\,, \tag{D.4.7}$$

which yields $\langle w_k | v_k\rangle = 0$. Thus, if all the m_k are distinct, it follows that m_k^2 is a doubly degenerate eigenvalue of $M^\dagger M$, with corresponding linearly independent eigenvectors v_k and w_k, where $k = 1, 2, ..., p$ (and $p \leq \frac{1}{2}n$). The remaining zero eigenvalues are $(n-2p)$-fold degenerate, with corresponding eigenvectors u_k (for $k = 1, 2, ..., n-2p$). If some of the m_k are degenerate, these conclusions still apply. For example, suppose that $m_j = m_k$ for $j \neq k$, which means that m_k^2 is at least a three-fold degenerate eigenvalue of $M^\dagger M$. Then, there must exist an eigenvector v_j that is orthogonal to v_k and w_k such that $M^\dagger M v_j = m_k^2 v_j$. We now construct $w_j \equiv M^* v_j^*/m_k$ according to eq. (D.4.4). According to eq. (D.4.7), w_j is orthogonal to v_j. However, we still must show that w_j is also orthogonal to v_k and w_k. But this is straightforward:

$$\langle w_j | w_k\rangle = \langle w_k | w_j\rangle^* = \frac{1}{m_k^2}\langle M v_k | M v_j\rangle = \frac{1}{m_k^2}\langle v_k | M^\dagger M v_j\rangle = \langle v_k | v_j\rangle = 0\,, \tag{D.4.8}$$

$$\langle w_j | v_k\rangle = \langle v_k | w_j\rangle^* = -\frac{1}{m_k^2}\langle M w_k | M v_j\rangle = -\frac{1}{m_k^2}\langle w_k | M^\dagger M v_j\rangle = -\langle w_k | v_j\rangle = 0\,, \tag{D.4.9}$$

where we have used the assumed orthogonality of v_j with v_k and w_k, respectively. It follows that v_j, w_j, v_k and w_k are linearly independent eigenvectors corresponding to a four-fold degenerate eigenvalue m_k^2 of $M^\dagger M$. Additional degeneracies are treated in the same way.

Thus, the number of non-zero eigenvalues of $M^\dagger M$ must be an even number, denoted by $2p$ above. Moreover, one can always choose the complete set of eigenvectors $\{u_k\,,\, v_k\,,\, w_k\}$ of $M^\dagger M$

to be orthonormal. These orthonormal vectors can be used to construct a unitary matrix U with matrix elements:

$$\begin{aligned} &U_{\ell\,,2k-1} = (w_k)_\ell\,, \qquad U_{\ell\,,2k} = (v_k)_\ell\,, \qquad\qquad k = 1\,,2\,,\ldots\,,p\,,\\ &U_{\ell\,,k+2p} = (u_k)_\ell\,, \qquad\qquad\qquad\qquad\quad k = 1\,,2\,,\ldots\,,n-2p\,, \end{aligned} \tag{D.4.10}$$

for $\ell = 1\,,2\,,\ldots\,,n$, where e.g., $(v_k)_\ell$ is the ℓth component of the vector v_k with respect to the standard orthonormal basis. The orthonormality of $\{u_k\,,\,v_k\,,\,w_k\}$ implies that $(U^\dagger U)_{\ell k} = \delta_{\ell k}$ as required. Eqs. (D.4.3) and (D.4.5) are thus equivalent to the matrix equation $MU = U^* N$, which immediately yields eq. (D.4.1), and the theorem is proven. If M is a real antisymmetric matrix, then all the eigenvectors of $M^\dagger M$ can be chosen to be real, in which case U is a real orthogonal matrix.

Finally, we address the non-uniqueness of the matrix U. For definiteness, we fix an ordering of the 2×2 blocks containing the m_k in the matrix N. In the subspace corresponding to a non-zero singular value of degeneracy d, U is unique up to multiplication on the right by a $2d\times 2d$ unitary matrix S that satisfies:

$$S^{\mathsf{T}} J S = J\,, \tag{D.4.11}$$

where the $2d\times 2d$ matrix J, defined by

$$J = \mathrm{diag}\left\{ \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \cdots, \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \right\}, \tag{D.4.12}$$

is a block diagonal matrix with d blocks of 2×2 matrices. A unitary matrix S that satisfies eq. (D.4.11) is an element of the unitary symplectic group, $\mathrm{Sp}(d)$. If there are no degeneracies among the m_k, then $d = 1$. Identifying $\mathrm{Sp}(1)\cong \mathrm{SU}(2)$, it follows that within the subspace corresponding to a non-degenerate singular value, U is unique up to multiplication on the right by an arbitrary SU(2) matrix. Finally, in the subspace corresponding to the zero eigenvalues of M, U is unique up to multiplication on the right by an arbitrary unitary matrix.

29.7.5 Lie group theoretical techniques for gauge theories

Basic facts about Lie groups, Lie algebras and their representations

Consider a compact connected Lie Group G [272]. The most general form for G is a direct product of compact simple groups and U(1) groups. If no U(1) factors are present, then G is semisimple. For any $U\in G$,

$$U = \exp(-i\theta^a \boldsymbol{T^a})\,, \tag{E.1.1}$$

where the $\boldsymbol{T^a}$ are called the generators of G, and the θ^a are real numbers that parameterize the elements of G. The corresponding real Lie algebra $\mathfrak{g}$ consists of arbitrary real linear combinations of the generators, $\theta^a \boldsymbol{T^a}$. The Lie group generators $\boldsymbol{T^a}$ satisfy the commutation relations:

$$[\boldsymbol{T^a}, \boldsymbol{T^b}] = i f_c^{ab} \boldsymbol{T^c}\,, \tag{E.1.2}$$

where the real structure constants f_c^{ab} define the compact Lie algebra. The generator indices run over a, b, $c = 1, 2, ..., d_G$, where d_G is the dimension of the Lie algebra. For compact Lie algebras, the Killing form $g^{ab} = \mathrm{Tr}(\boldsymbol{T^a T^b})$ is positive definite, so one can always choose a basis for the Lie algebra in which $g^{ab} \propto \delta^{ab}$ (where the proportionality constant is a positive real number). With respect to this new basis, the structure constants $f^{abc} \equiv g^{ad} f_d^{bc}$ are totally antisymmetric with respect to the interchange of the indices a, b and c. Henceforth, we shall always assume that such a *preferred* basis of generators has been chosen.

The elements of the compact Lie group G act on a multiplet of fields that transform under some d_R-dimensional representation R of G. The group elements $U\in G$ are represented by $d_R\times d_R$

unitary matrices, $D_R(U) = \exp(-i\theta^a \boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}})$, where the $\boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}}$ are $d_R \times d_R$ hermitian matrices that satisfy eq. (E.1.2) and thus provide a representation of the Lie group generators. For any representation R of a semisimple group, $\mathrm{Tr}\, \boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}} = 0$ for all a. A representation R' is unitarily equivalent to R if there exists a fixed unitary matrix S such that $D_{R'}(U) = S^{-1} D_R(U) S$ for all $U \in G$. Similarly, the corresponding generators satisfy $\boldsymbol{T}_{\boldsymbol{R'}}^{\boldsymbol{a}} = S^{-1} \boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}} S$ for all $a = 1, 2, \ldots, d_G$.

For compact semisimple Lie groups, two representations are noteworthy. If G is one of the classical groups, SU(N) [for $N \geq 2$], SO(N) [for $N \geq 3$] or Sp($N/2$) [the latter is defined by eqs. (D.4.11) and (D.4.12) for even $N \geq 2$], then the $N \times N$ matrices that define these groups comprise the *fundamental (or defining) representation* F, with $d_F = N$. For example, the fundamental representation of SU(N) consists of $N \times N$ unitary matrices with determinant equal to one, and the corresponding generators comprise a suitably chosen basis for the $N \times N$ traceless hermitian matrices. Every Lie group G also possesses an *adjoint representation* A, with $d_A = d_G$. The matrix elements of the generators in the adjoint representation are given by[119]

$$(\boldsymbol{T}_{\boldsymbol{A}}^{\boldsymbol{a}})^{bc} = -i f^{abc}\,. \tag{E.1.3}$$

Given the unitary representation matrices $D_R(U)$ of the representation R of G, the matrices $[D_R(U)]^*$ constitute the *conjugate* representation R^*. Equivalently, if the $\boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}}$ comprise a representation of the Lie algebra $\mathfrak{g}$, then the $-(\boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}})^* = -(\boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}})^{\mathsf{T}}$ comprise a representation R^* of $\mathfrak{g}$ of the same dimension d_R. If R and R^* are unitarily equivalent representations, then we say that the representation R is *self-conjugate*. Otherwise, we say that the representation R is *complex*, or "strictly complex" in the language of [273]. However, the representation matrices $D_R(U)$ of a self-conjugate representation can also be complex. We can then define two classes of self-conjugate representations. If R and R^* are unitarily equivalent to a representation R' that satisfies the reality property $[D_{R'}(U)]^* = [D_{R'}(U)]$ for all $U \in G$ (equivalently, the matrices $i\boldsymbol{T}_{\boldsymbol{R'}}^{\boldsymbol{a}}$ are real for all a), then R is said to be *real*, or "strictly real" in the language of [273]. If R and R^* are unitarily equivalent representations, but neither is unitarily equivalent to a representation that satisfies the reality property above, then R is said to be *pseudo-real*.

Henceforth, we drop the adjective "strictly" and simply refer to real, pseudo-real and complex representations. Self-conjugate representations are either real or pseudo-real. An important theorem states that for self-conjugate representations, there exists a constant unitary matrix W such that [273]

$$[D_R(U)]^* = W D_R(U) W^{-1}\,, \quad \text{or equivalently,} \quad (i\boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}})^* = W (i\boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}}) W^{-1}\,, \tag{E.1.4}$$

where

$$WW^* = \mathbb{1}\,, \qquad W^{\mathsf{T}} = W\,, \qquad \text{for real representations}\,, \tag{E.1.5}$$

$$WW^* = -\mathbb{1}\,, \qquad W^{\mathsf{T}} = -W\,, \qquad \text{for pseudo-real representations}\,, \tag{E.1.6}$$

and $\mathbb{1}$ is the $d_R \times d_R$ identity matrix. Taking the determinant of eq. (E.1.6), and using the fact that W is unitary (and hence invertible), it follows that $1 = (-1)^{d_R}$. Therefore, a pseudo-real representation must be even-dimensional.

If we redefine the basis for the Lie group generators by $\boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}} \to V^{-1} \boldsymbol{T}_{\boldsymbol{R}}^{\boldsymbol{a}} V$, where V is unitary, then $W \to V^{\mathsf{T}} W V$. We can make use of this change of basis to transform W to a canonical form. Since W is unitary, its singular values (i.e. the positive square roots of the eigenvalues of $W^\dagger W$) are all equal to 1. Hence, in the two cases corresponding to $W^{\mathsf{T}} = \pm W$, respectively, eqs. (D.2.1) and (D.4.1) yield the following canonical forms (for an appropriately chosen V),

$$W = \mathbb{1}\,, \qquad \text{for a real representation } R\,, \tag{E.1.7}$$

$$W = J\,, \qquad \text{for a pseudo-real representation } R\,, \tag{E.1.8}$$

[119] Since the f^{abc} are real, the $i\boldsymbol{T}_{\boldsymbol{A}}^{\boldsymbol{a}}$ are real antisymmetric matrices. The heights of the adjoint labels a, b and c are not significant, as they can be lowered by the inverse Killing form given by $g_{ab} \propto \delta_{ab}$ in the preferred basis.

where $J \equiv \mathrm{diag}\left\{\left(\begin{smallmatrix}0 & 1\\ -1 & 0\end{smallmatrix}\right), \left(\begin{smallmatrix}0 & 1\\ -1 & 0\end{smallmatrix}\right), \cdots, \left(\begin{smallmatrix}0 & 1\\ -1 & 0\end{smallmatrix}\right)\right\}$ is a $d_R \times d_R$ matrix (and d_R is even).

There are many examples of complex, real and pseudo-real representations in mathematical physics. For example, the fundamental representation of SU(N) is complex for $N \geq 3$. The adjoint representation of any compact Lie group is real [cf. footnote 119]. The simplest example of a pseudo-real representation is the two-dimensional representation of SU(2),[120] where $\boldsymbol{T^a} = \frac{1}{2}\tau^a$ (and the τ^a are the usual Pauli matrices). More generally, the generators of a pseudo-real representation must satisfy

$$(i\boldsymbol{T_R^a})^* = C^{-1}(i\boldsymbol{T_R^a})C\,, \tag{E.1.9}$$

for some fixed unitary antisymmetric matrix C [previously denoted by W^{-1} in eqs. (E.1.4) and (E.1.6)]. For the doublet representation of SU(2) just given, $C^{ab} = (i\tau^2)^{ab} \equiv \epsilon^{ab}$ is the familiar SU(2)-invariant tensor.

Finally, we note that for U(1), all irreducible representations are one-dimensional. The structure constants vanish and any d-dimensional representation of the U(1)-generator is given by the $d \times d$ identity matrix multiplied by the corresponding U(1)-charge. For a Lie group that is a direct product of a semisimple group and U(1) groups, $\mathrm{Tr}\,\boldsymbol{T_R^a}$ is non-zero when a corresponds to one of the U(1)-generators, unless the sum of the corresponding U(1)-charges of the states of the representation R vanishes.

The quadratic and cubic index and Casimir operator

In this section, we define the index and Casimir operator of a representation of a compact semisimple Lie algebra $\mathfrak{g}$. The *index* $I_2(R)$ of the representation R is defined by [272, 274, 275, 276]

$$\mathrm{Tr}(\boldsymbol{T_R^a T_R^b}) = I_2(R)\delta^{ab}\,, \tag{E.2.1}$$

where $I_2(R)$ is a positive real number that depends on R. Once $I_2(R)$ is defined for one representation, its value is uniquely fixed for any other representation. In the case of a simple compact Lie algebra $\mathfrak{g}$, it is traditional to normalize the generators of the fundamental (or defining) representation F according to[121]

$$\mathrm{Tr}(\boldsymbol{T_F^a T_F^b}) = \tfrac{1}{2}\delta^{ab}\,. \tag{E.2.2}$$

If the representation R is reducible, it can be decomposed into the direct sum of irreducible representations, $R = \sum\limits_k R_k$. In this case, the index of R is given by

$$I_2(R) = \sum_k I_2(R_k)\,. \tag{E.2.3}$$

The index of a tensor product of two representations R_1 and R_2 is given by [274]

$$I_2(R_1 \otimes R_2) = d_{R_1} I_2(R_2) + d_{R_2} I_2(R_1)\,. \tag{E.2.4}$$

Finally, we note that if R^* is the complex conjugate of the representation R, then $I_2(R^*) = I_2(R)$.

A Casimir operator of a Lie algebra $\mathfrak{g}$ is an operator that commutes with all the generators $\boldsymbol{T^a}$. If the representation of the $\boldsymbol{T^a}$ is *irreducible*, then Schur's lemma implies that the Casimir operator is a multiple of the identity. The proportionality constant depends on the representation R. The quadratic Casimir operator of an *irreducible* representation R is given by

$$(\boldsymbol{T_R^2})_i{}^j \equiv (\boldsymbol{T_R^a})_i{}^k (\boldsymbol{T_R^a})_k{}^j = C_R \delta_i{}^j\,, \tag{E.2.5}$$

[120] No unitary matrix W exists such that the $Wi\tau^a W^{-1}$ are real for all $a = 1, 2, 3$. Thus, the two-dimensional representation of SU(2) is not real. However, $(i\tau^a)^* = (i\tau^2)(i\tau^a)(i\tau^2)^{-1}$ for $a = 1, 2, 3$, which proves that the two-dimensional representation of SU(2) is pseudo-real.

[121] In the literature, the index is often defined as the ratio $I_2(R)/I_2(F)$, where $I_2(F)$ is fixed by some convention. This has the advantage that the index of R is independent of the normalization convention of the generators. In this Appendix, we will simply refer to $I_2(R)$ as the index.

where the sum over the repeated indices are implicit and i, j, $k = 1, 2...d_R$. A simple computation then yields the eigenvalue of the quadratic Casimir operator, C_R,

$$C_R = \frac{I_2(R) d_G}{d_R} \,. \tag{E.2.6}$$

For a simple Lie algebra (where the adjoint representation is irreducible), it immediately follows that $C_A = I_2(A)$. For a reducible representation, $\boldsymbol{T^2}$ is a block diagonal matrix consisting of $d_{R_k} \times d_{R_k}$ blocks given by $C_{R_k} \mathbb{1}$ for each irreducible component R_k of R.

The example of the simple Lie algebra $\mathfrak{su}(N)$ is well known. The dimension of this Lie algebra (equal to the number of generators) is given by N^2-1. As previously noted, $d_F = N$ and $I_2(F) = \frac{1}{2}$. It then follows that $C_F = (N^2-1)/(2N)$. One can also check that $C_A = I_2(A) = N$.

The Lie algebras $\mathfrak{su}(N)$ [$N \geq 3$] are the only simple Lie algebra that possesses a cubic Casimir operator. First, we define the symmetrized trace of three generators [276, 277]:

$$D^{abc} \equiv \mathrm{Str}\ (\boldsymbol{T^a T^b T^c}) = \tfrac{1}{6}\,\mathrm{Tr}(\boldsymbol{T^a T^b T^c} + \mathrm{perm.})\,, \tag{E.2.7}$$

where "perm." indicates five other terms obtained by permuting the indices a, b and c in all possible ways. Due to the properties of the trace, it follows that for a given representation R,

$$D^{abc}(R) = \tfrac{1}{2}\,\mathrm{Tr}\left[\{\boldsymbol{T^a_R}, \boldsymbol{T^b_R}\}\boldsymbol{T^c_R}\right] \,. \tag{E.2.8}$$

For the N-dimensional defining representation of $\mathfrak{su}(N)$, it is conventional to define

$$d^{abc} \equiv 2\,\mathrm{Tr}\left[\{\boldsymbol{T^a_F}, \boldsymbol{T^b_F}\}\boldsymbol{T^c_F}\right] \,. \tag{E.2.9}$$

One important property of the d^{abc} is [278, 279]:

$$d^{abc} d^{abc} = \frac{(N^2-1)(N^2-4)}{N} \,. \tag{E.2.10}$$

In general, $D^{abc}(R)$ is proportional to d^{abc}. In particular, the *cubic index* $I_3(R)$ of a representation R is defined such that [280, 278, 276],

$$D^{abc}(R) = I_3(R) d^{abc} \,. \tag{E.2.11}$$

Having fixed $I_3(F) = \frac{1}{4}$, the cubic index is uniquely determined for all representations of $\mathfrak{su}(N)$ [280, 278, 281, 282]. As in the case of the quadratic index $I_2(R)$, we have:

$$I_3(R) = \sum_k I_3(R_k)\,, \tag{E.2.12}$$

for a reducible representation $R = \sum\limits_k R_k$. The cubic index of a tensor product of two representations R_1 and R_2 is given by [280]

$$I_3(R_1 \otimes R_2) = d_{R_1} I_3(R_2) + d_{R_2} I_3(R_1)\,. \tag{E.2.13}$$

If the generators of the representation R are $\boldsymbol{T^a_R}$, then the generators of the complex conjugate representation R^* are $-\boldsymbol{T^{a\,T}_R}$. It then follows that $I_3(R^*) = -I_3(R)$. In particular, the cubic index of a self-conjugate representation vanishes. Note that the converse is not true. That is, it is possible for the cubic index of a complex representation of $\mathfrak{su}(N)$ to vanish in special circumstances [282].

One can show that among the simple Lie groups, $D^{abc} = 0$ except for the case of SU(N), when $N \geq 3$ [278]. For any non-semisimple Lie group (i.e., a Lie group that is a direct product of simple

Lie groups and at least one U(1) factor), D^{abc} is generally non-vanishing. For example, suppose that the $\boldsymbol{T_R^a}$ constitute an irreducible representation of the generators of $G\times$U(1), where G is a semisimple Lie group. Then the U(1) generator (which we denote by setting $\boldsymbol{a} = \boldsymbol{Q}$) is $\boldsymbol{T_R^Q} \equiv q\mathbb{1}$, where q is the corresponding U(1)-charge. It then follows that $D^{Qab} = qI_2(R)\delta^{ab}$. More generally, for a compact non-semisimple Lie group, D^{abc} can be non-zero when either one or three of its indices corresponds to a U(1) generator.

In the computation of the anomaly [cf. Section 29.6.26], the quantity $\mathrm{Tr}(\boldsymbol{T_R^a T_R^b T_R^c})$ appears. We can evaluate this trace using eqs. (E.1.2) and (E.2.11):

$$\mathrm{Tr}(\boldsymbol{T_R^a T_R^b T_R^c}) = I_3(R)d^{abc} + \frac{i}{2}I_2(R)f^{abc}\,. \tag{E.2.14}$$

The cubic Casimir operator of an *irreducible* representation R is given by

$$(\boldsymbol{T_R^3})_i{}^j \equiv d^{abc}(\boldsymbol{T_R^a T_R^b T_R^c})_i{}^j = C_{3R}\delta_i{}^j\,. \tag{E.2.15}$$

Using eqs. (E.2.10) and (E.2.11), we obtain a relation between the eigenvalue of the cubic Casimir operator, C_{3R} and the cubic index [278]:

$$C_{3R} = \frac{(N^2-1)(N^2-4)I_3(R)}{Nd_R}\,. \tag{E.2.16}$$

Again, we provide two examples. For the fundamental representation of $\mathfrak{su}(N)$, $I_3(F) = \frac{1}{4}$ and $C_{3F} = (N^2-1)(N^2-4)/(4N^2)$. For the adjoint representation, $I_3(A) = C_{3A} = 0$, since the adjoint representation is self-conjugate. A general formula for the eigenvalue of the cubic Casimir operator in an arbitrary $\mathfrak{su}(N)$ representation [or equivalently the cubic index $I_3(R)$, which is related to C_{3R} by eq. (E.2.16)] can be found in refs. [280, 278, 281, 282].

29.7.6 Path integral treatment of two-component fermion propagators

In Section 29.4.2 we derived the two-component fermion propagators in momentum space, which are the Fourier transforms of the free-field expectation values of time-ordered products of two two-component fermion fields, for example,

$$\langle 0|\,T\xi_\alpha(x)\xi^\dagger_{\dot\beta}(y)\,|0\rangle_{\rm FT} \equiv \int d^4w\,\langle 0|\,T\xi_\alpha(x)\xi^\dagger_{\dot\beta}(y)\,|0\rangle\,e^{ip\cdot w}\,, \qquad w\equiv x-y\,, \tag{F.1}$$

where the (translationally invariant) expectation values such as $\langle 0|\,T\xi_\alpha(x)\xi^\dagger_{\dot\beta}(y)\,|0\rangle$ are functions of the coordinate difference $w \equiv x-y$. In Section 29.4.2, the Fourier transforms of these quantities were computed by using the free-field expansion obtained from the canonical quantization procedure, and then evaluating the resulting spin sums. In this Appendix, we provide a derivation of the same result by employing path integral techniques. We follow the analysis given in Appendix C of ref. [283] (with a few minor changes in notation). For a similar textbook treatment of two-component fermion propagators see for example [223]. For the analogous treatment of the four-component fermion propagator, see for example [115].

We first consider the action for a single massive neutral two-component fermion $\xi_\alpha(x)$, coupled to an anticommuting two-component fermionic source term $J_\alpha(x)$ [cf. eq. (29.3.1)]:

$$S = \int d^4x\,(\mathscr{L}+J\xi+\xi^\dagger J^\dagger) = \int d^4x\,\Big\{\tfrac{1}{2}\left[i\xi^\dagger\overline{\sigma}^\mu\partial_\mu\xi + i\xi\sigma^\mu\partial_\mu\xi^\dagger - m(\xi\xi+\xi^\dagger\xi^\dagger)\right]+J\xi+\xi^\dagger J^\dagger\Big\}\,, \tag{F.2}$$

where we have split the kinetic energy term symmetrically into two terms. The generating functional is given by

$$W[J,\,J^\dagger\,] = N\int \mathcal{D}\xi\,\mathcal{D}\xi^\dagger\,e^{iS[\xi,\,\xi^\dagger,\,J,\,J^\dagger]}\,, \tag{F.3}$$

where N is a normalization factor chosen such that $W[0,0] = 1$ and $\mathcal{D}\xi\,\mathcal{D}\xi^\dagger$ is the integration measure. It is convenient to Fourier transform the fields $\xi(x)$, $\xi^\dagger(x)$ and sources $J(x)$, $J^\dagger(x)$ in eq. (F.3), and rewrite the action in terms of the corresponding Fourier coefficients $\widehat{\xi}(p)$, $\widehat{\xi}^\dagger(p)$, $\widehat{J}(p)$ and $\widehat{J}^\dagger(p)$:

$$\xi_\alpha(x) = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot x}\widehat{\xi}_\alpha(p)\,, \qquad \xi^\dagger_{\dot\alpha}(x) = \int \frac{d^4p}{(2\pi)^4} e^{ip\cdot x}\widehat{\xi}^\dagger_{\dot\alpha}(p)\,, \tag{F.4}$$

$$J_\alpha(x) = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot x}\widehat{J}_\alpha(p)\,, \qquad J^\dagger_{\dot\alpha}(x) = \int \frac{d^4p}{(2\pi)^4} e^{ip\cdot x}\widehat{J}^\dagger_{\dot\alpha}(p)\,. \tag{F.5}$$

Furthermore, we introduce the integral representation of the delta function:

$$\delta^{(4)}(x-x') = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot(x-x')}\,. \tag{F.6}$$

In order to rewrite eq. (F.3) in a more convenient matrix form, we introduce the following definitions:

$$\Omega(p) \equiv \begin{pmatrix} \widehat{\xi}^{\dagger\dot\alpha}(-p) \\ \widehat{\xi}_\alpha(p) \end{pmatrix}, \qquad X(p) \equiv \begin{pmatrix} \widehat{J}_\alpha(p) \\ \widehat{J}^{\dagger\dot\alpha}(-p) \end{pmatrix}, \qquad \mathcal{M}(p) \equiv \begin{pmatrix} p\cdot\sigma_{\alpha\dot\beta} & -m\,\delta_\alpha{}^\beta \\ -m\,\delta^{\dot\alpha}{}_{\dot\beta} & p\cdot\overline{\sigma}^{\dot\alpha\beta} \end{pmatrix}. \tag{F.7}$$

Note that $\mathcal{M}$ is an hermitian matrix. We can then rewrite the action [eq. (F.2)] in the following matrix form [after using eqs. (29.60) and (29.61) to write the product of the spinor field and the source in a symmetrical fashion]:

$$S = \frac{1}{2}\int \frac{d^4p}{(2\pi)^4}\,\left(\Omega^\dagger\mathcal{M}\Omega + \Omega^\dagger X + X^\dagger\Omega\right)\,. \tag{F.8}$$

The linear term in the field Ω can be removed by a field redefinition

$$\Omega' = \Omega + \mathcal{M}^{-1}X\,. \tag{F.9}$$

In terms of Ω', the action now takes the convenient form:

$$S = \frac{1}{2}\int \frac{d^4p}{(2\pi)^4}\,\left(\Omega'^\dagger\mathcal{M}\Omega' - X^\dagger\mathcal{M}^{-1}X\right)\,, \tag{F.10}$$

where the inverse of the matrix $\mathcal{M}$ is given by

$$\mathcal{M}^{-1} = \frac{1}{p^2-m^2}\begin{pmatrix} p\cdot\overline{\sigma}^{\dot\alpha\beta} & m\,\delta^{\dot\alpha}{}_{\dot\beta} \\ m\,\delta_\alpha{}^\beta & p\cdot\sigma_{\alpha\dot\beta} \end{pmatrix}. \tag{F.11}$$

The Jacobian of the field transformation given in eq. (F.9) is unity. Hence, one can insert the new action, eq. (F.10), in the generating functional, eq. (F.3) to obtain (after dropping the primes on the two-component fermion fields):

$$\begin{aligned} W[\widehat{J},\,\widehat{J}^\dagger\,] &= N\int \mathcal{D}\xi\,\mathcal{D}\xi^\dagger \exp\left\{\frac{i}{2}\int\frac{d^4p}{(2\pi)^4}\,\left(\Omega^\dagger\mathcal{M}\Omega - X^\dagger\mathcal{M}^{-1}X\right)\right\} \\ &= N\left[\int \mathcal{D}\xi\,\mathcal{D}\xi^\dagger\,\exp\left\{\frac{i}{2}\Omega^\dagger\mathcal{M}\Omega\right\}\right]\,\exp\left\{-\frac{i}{2}\int\frac{d^4p}{(2\pi)^4}\,X^\dagger\mathcal{M}^{-1}X\right\} \\ &= \exp\left\{-\frac{i}{2}\int\frac{d^4p}{(2\pi)^4}\,X^\dagger\mathcal{M}^{-1}X\right\}\,, \end{aligned} \tag{F.12}$$

where we have defined the normalization constant N such that $W[0,0]=1$. Inserting the explicit forms for X and $\mathcal{M}$ into eq. (F.12), we obtain

$$W[\widehat{J},\,\widehat{J}^\dagger\,]=\exp\biggl\{-\frac{1}{2}\int\frac{d^4p}{(2\pi)^4}\biggl(\widehat{J}^\alpha(-p)\frac{ip\cdot\sigma_{\alpha\dot\beta}}{p^2-m^2}\widehat{J}^{\dagger\dot\beta}(-p)+\widehat{J}^\dagger_{\dot\alpha}(p)\frac{ip\cdot\overline{\sigma}^{\dot\alpha\beta}}{p^2-m^2}\widehat{J}_\beta(p)$$
$$+\widehat{J}^\alpha(-p)\frac{im\delta_\alpha{}^\beta}{p^2-m^2}\widehat{J}_\beta(p)+\widehat{J}^\dagger_{\dot\alpha}(p)\frac{im\delta^{\dot\alpha}{}_{\dot\beta}}{p^2-m^2}\widehat{J}^{\dagger\dot\beta}(-p)\biggr)\biggr\}\,. \tag{F.13}$$

Using eq. (29.62), it is convenient to rewrite the first two terms of the integrand on the right-hand side of eq. (F.13) in two different ways:

$$\frac{1}{2}\int\frac{d^4p}{(2\pi)^4}\left[\widehat{J}^\alpha(-p)\frac{ip\cdot\sigma_{\alpha\dot\beta}}{p^2-m^2}\widehat{J}^{\dagger\dot\beta}(-p)+\widehat{J}^\dagger_{\dot\alpha}(p)\frac{ip\cdot\overline{\sigma}^{\dot\alpha\beta}}{p^2-m^2}\widehat{J}_\beta(p)\right]$$
$$=\int\frac{d^4p}{(2\pi)^4}\,\widehat{J}^\alpha(-p)\frac{ip\cdot\sigma_{\alpha\dot\beta}}{p^2-m^2}\widehat{J}^{\dagger\dot\beta}(-p)=\int\frac{d^4p}{(2\pi)^4}\,\widehat{J}^\dagger_{\dot\alpha}(p)\frac{ip\cdot\overline{\sigma}^{\dot\alpha\beta}}{p^2-m^2}\widehat{J}_\beta(p)\,, \tag{F.14}$$

where we have changed integration variables from $p\to-p$ in relating the two terms above. The vacuum expectation value of the time-ordered product of two spinor fields in configuration space is obtained by taking two functional derivatives of the generating functional with respect to the sources J and $J^\dagger$ and then setting $J=J^\dagger=0$ at the end of the computation (e.g., see [115]). For example,

$$\left(-i\frac{\overrightarrow{\delta}}{\delta J^\alpha(x_1)}\right)W[J,J^\dagger]\left(-i\frac{\overleftarrow{\delta}}{\delta J^{\dagger\dot\beta}(x_2)}\right)\biggr|_{J=J^\dagger=0}=N\int\mathcal{D}\xi\,\mathcal{D}\xi^\dagger\;\xi_\alpha(x_1)\xi^\dagger_{\dot\beta}(x_2)\exp\left(i\int d^4x\,\mathscr{L}\right)$$
$$=\langle0|T\xi_\alpha(x_1)\xi^\dagger_{\dot\beta}(x_2)|0\rangle\,, \tag{F.15}$$

where the functional derivatives act in the indicated direction (which ensures that no extra minus signs are generated due to the anticommutativity properties of the sources and their functional derivatives). To obtain the two-point functions involving the product of two spinor fields with different combinations of dotted and undotted spinors, it may be more convenient to write $J\xi=\xi J$ and/or $\xi^\dagger J^\dagger=J^\dagger\xi^\dagger$ in eq. (F.3). One can then easily verify the following expressions for the four possible two-point functions:

$$\langle0|T\xi_\alpha(x_1)\xi^\dagger_{\dot\beta}(x_2)|0\rangle=\left(-i\frac{\overrightarrow{\delta}}{\delta J^\alpha(x_1)}\right)W[J,J^\dagger]\left(-i\frac{\overleftarrow{\delta}}{\delta J^{\dagger\dot\beta}(x_2)}\right)\biggr|_{J=J^\dagger=0}\,, \tag{F.16}$$

$$\langle0|T\xi^{\dagger\dot\alpha}(x_1)\xi^\beta(x_2)|0\rangle=\left(-i\frac{\overrightarrow{\delta}}{\delta J^\dagger_{\dot\alpha}(x_1)}\right)W[J,J^\dagger]\left(-i\frac{\overleftarrow{\delta}}{\delta J_\beta(x_2)}\right)\biggr|_{J=J^\dagger=0}\,, \tag{F.17}$$

$$\langle0|T\xi^{\dagger\dot\alpha}(x_1)\xi^\dagger_{\dot\beta}(x_2)|0\rangle=\left(-i\frac{\overrightarrow{\delta}}{\delta J^\dagger_{\dot\alpha}(x_1)}\right)W[J,J^\dagger]\left(-i\frac{\overleftarrow{\delta}}{\delta J^{\dagger\dot\beta}(x_2)}\right)\biggr|_{J=J^\dagger=0}\,, \tag{F.18}$$

$$\langle0|T\xi_\alpha(x_1)\xi^\beta(x_2)|0\rangle=\left(-i\frac{\overrightarrow{\delta}}{\delta J^\alpha(x_1)}\right)W[J,J^\dagger]\left(-i\frac{\overleftarrow{\delta}}{\delta J_\beta(x_2)}\right)\biggr|_{J=J^\dagger=0}\,. \tag{F.19}$$

As an example, we provide details for the evaluation of eq. (F.16). Using eqs. (F.13) and (F.14), we obtain:

$$\langle0|T\xi_\alpha(x_1)\xi^\dagger_{\dot\beta}(x_2)|0\rangle=\frac{\overrightarrow{\delta}}{\delta J^\alpha(x_1)}\left(\int\frac{d^4p}{(2\pi)^4}\,\widehat{J}^\alpha(-p)\frac{ip\cdot\sigma_{\alpha\dot\beta}}{p^2-m^2}\widehat{J}^{\dagger\dot\beta}(-p)\right)\frac{\overleftarrow{\delta}}{\delta J^{\dagger\dot\beta}(x_2)}\,. \tag{F.20}$$

The chain rule for functional differentiation and the inverse Fourier transforms of eq. (F.5) yield:

$$\frac{\delta}{\delta J^\alpha(x_1)} = \int d^4p_1 \, \frac{\delta \widehat{J}^\beta(-p_1)}{\delta J^\alpha(x_1)} \frac{\delta}{\delta \widehat{J}^\beta(-p_1)} = \int d^4p_1 \, e^{-ip_1\cdot x_1} \frac{\delta}{\delta \widehat{J}^\alpha(-p_1)} \,, \tag{F.21}$$

$$\frac{\delta}{\delta J^{\dagger\dot\beta}(x_2)} = \int d^4p_2 \, \frac{\delta \widehat{J}^{\dagger\dot\alpha}(-p_2)}{\delta J^{\dagger\dot\beta}(x_2)} \frac{\delta}{\delta \widehat{J}^{\dagger\dot\alpha}(-p_2)} = \int d^4p_2 \, e^{ip_2\cdot x_2} \frac{\delta}{\delta \widehat{J}^{\dagger\dot\beta}(-p_2)} \,. \tag{F.22}$$

Applying eqs. (F.21) and (F.22) to eq. (F.20), we obtain:

$$\langle 0|T\xi_\alpha(x_1)\xi^\dagger_{\dot\beta}(x_2)|0\rangle = \int \frac{d^4p}{(2\pi)^4} \, e^{-ip\cdot(x_1-x_2)} \frac{ip\cdot\sigma_{\alpha\dot\beta}}{p^2-m^2} \,, \tag{F.23}$$

which is equivalent to eq. (29.4.1) of Section 29.4.2. With the same methods applied to eqs. (F.17)–(F.19), one can easily reproduce the results of eqs. (29.4.2)–(29.4.4).

We next consider the action for a single massive Dirac two-component fermion. We shall work in a basis of fields where the action, including external anticommuting sources, is given by

$$\begin{aligned} S[\chi,\chi^\dagger,\eta,\eta^\dagger,J_\chi,J_\chi^\dagger,J_\eta,J_\eta^\dagger] = \int d^4x \Big[& i\chi^\dagger\overline\sigma^\mu\partial_\mu\chi + i\eta^\dagger\overline\sigma^\mu\partial_\mu\eta - m(\chi\eta+\chi^\dagger\eta^\dagger) \\ & + J_\chi\chi + \chi^\dagger J_\chi^\dagger + J_\eta\eta + \eta^\dagger J_\eta^\dagger \Big]. \end{aligned} \tag{F.24}$$

Following the techniques employed above, we introduce Fourier coefficients for all the fields and sources and define

$$\Omega_c(p) \equiv \begin{pmatrix} \widehat\eta^{\dagger\dot\alpha}(-p) \\ \widehat\chi_\alpha(p) \end{pmatrix} , \qquad X_c(p) \equiv \begin{pmatrix} \widehat J_{\eta\alpha}(p) \\ \widehat J_\chi^{\dagger\dot\alpha}(-p) \end{pmatrix} . \tag{F.25}$$

The action functional, eq. (F.24), can then rewritten in matrix form as before (but with no overall factor of 1/2):

$$S = \int \frac{d^4p}{(2\pi)^4} \, \left(\Omega_c^\dagger \mathcal{M} \Omega_c + \Omega_c^\dagger X_c + X_c^\dagger \Omega_c \right) \,, \tag{F.26}$$

where $\mathcal{M}$ is again given by eq. (F.7). The remaining calculation proceeds as before with few modifications, and yields the Dirac two-component fermion free-field propagators given in eqs. (29.4.7)–(29.4.10).

29.7.7 Correspondence to four-component spinor notation 1

Dirac gamma matrices and four-component spinors

In four-dimensional Minkowski space, four-component spinor notation employs four-component Dirac spinor fields and the 4×4 Dirac gamma matrices, whose defining property is:

$$\{\gamma^\mu,\gamma^\nu\} = 2g^{\mu\nu}\mathbb{1} \,, \tag{G.1.1}$$

where $\mathbb{1}$ is the 4×4 identity matrix.

The correspondence between the two-component spinor notation and the four-component Dirac spinor notation is most easily exhibited in the basis in which γ_5 is diagonal (this is called the *chiral*

representation[122]). In 2×2 blocks, the gamma matrices are given by:[123]

$$\gamma^\mu \equiv \begin{pmatrix} 0 & \sigma^\mu{}_{\alpha\dot\beta} \\ \overline{\sigma}^{\mu\,\dot\alpha\beta} & 0 \end{pmatrix}, \qquad \gamma_5 \equiv i\gamma^0\gamma^1\gamma^2\gamma^3 = \begin{pmatrix} -\delta_\alpha{}^\beta & 0 \\ 0 & \delta^{\dot\alpha}{}_{\dot\beta} \end{pmatrix}, \tag{G.1.2}$$

and the 4×4 identity matrix that appears in eq. (G.1.1) can be written as:

$$\mathbb{1} = \begin{pmatrix} \delta_\alpha{}^\beta & 0 \\ 0 & \delta^{\dot\alpha}{}_{\dot\beta} \end{pmatrix}. \tag{G.1.3}$$

In addition, we identify the generators of the Lorentz group in the $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$ representation:[124]

$$\tfrac{1}{2}\Sigma^{\mu\nu} \equiv \frac{i}{4}[\gamma^\mu,\gamma^\nu] = \begin{pmatrix} \sigma^{\mu\nu}{}_\alpha{}^\beta & 0 \\ 0 & \overline{\sigma}^{\mu\nu\dot\alpha}{}_{\dot\beta} \end{pmatrix}, \tag{G.1.4}$$

where $\Sigma^{\mu\nu}$ satisfies the duality relation,

$$\gamma_5\Sigma^{\mu\nu} = \tfrac{1}{2}i\epsilon^{\mu\nu\rho\tau}\Sigma_{\rho\tau}\,. \tag{G.1.5}$$

Eq. (G.1.4) yields the spin-$\frac{1}{2}$ angular momentum matrix representation $\{\frac{1}{2}\Sigma^i\}$, $i=1,2,3$, where

$$\Sigma^i \equiv \tfrac{1}{2}\epsilon^{ijk}\Sigma_{jk} = \gamma^0\gamma^i\gamma_5 = \begin{pmatrix} -(\sigma^0\overline{\sigma}^i)_\alpha{}^\beta & 0 \\ 0 & (\overline{\sigma}^0\sigma^i)^{\dot\alpha}{}_{\dot\beta} \end{pmatrix}. \tag{G.1.6}$$

A four-component *Dirac spinor* field, $\Psi(x)$, is made up of two mass-degenerate two-component spinor fields, $\chi_\alpha(x)$ and $\eta_\alpha(x)$, of opposite U(1)-charge as follows:

$$\Psi(x) \equiv \begin{pmatrix} \chi_\alpha(x) \\ \eta^{\dagger\dot\alpha}(x) \end{pmatrix}. \tag{G.1.7}$$

We next introduce the chiral projections operators,[125]

$$P_L \equiv \tfrac{1}{2}(\mathbb{1}-\gamma_5) = \begin{pmatrix} \delta_\alpha{}^\beta & 0 \\ 0 & 0 \end{pmatrix}, \qquad \text{and} \qquad P_R \equiv \tfrac{1}{2}(\mathbb{1}+\gamma_5) = \begin{pmatrix} 0 & 0 \\ 0 & \delta^{\dot\alpha}{}_{\dot\beta} \end{pmatrix}, \tag{G.1.8}$$

[122] For a review of other representations of the Dirac gamma matrices and their properties, see e.g. refs. [284, 285].

[123] Employing the conventions for the sigma matrices described in Appendix A , it follows that the definition of γ^μ is independent of the choice of metric signature, whereas $\gamma_\mu \equiv g_{\mu\nu}\gamma^\nu$ changes sign under a reversal of the metric signature. In the metric signature convention with $g_{00}=+1$, our gamma matrix conventions follow those of [115], whereas in the convention with $g_{00}=-1$, our gamma matrix conventions follow those of [66].

[124] In most textbooks, $\Sigma^{\mu\nu}$ is called $\sigma^{\mu\nu}$. Here, we use the former symbol so that there is no confusion with $\sigma^{\mu\nu}{}_\alpha{}^\beta$ given in eq. (29.71).

[125] In the earlier literature, a different set of conventions for the sigma matrices in which the roles of σ and $\overline{\sigma}$ were reversed [e.g, as in eqs. (A.11) and (A.12)] resulted in $\gamma_5 = \mathrm{diag}(\mathbb{1}_{2\times2}\,,\,-\mathbb{1}_{2\times2})$ in the chiral representation, which differs from our convention by an overall sign [cf. eq. (G.1.2)]. As a result, in this latter convention, P_L [P_R] projects out the raised dotted [lowered undotted] two-component spinor field. This latter convention is still prevalent in the literature of the spinor helicity method (see footnote 163 in Appendix I.2).

and the (left and right-handed) *Weyl spinor* fields, $\Psi_L(x)$ and $\Psi_R(x)$, which are defined by:

$$\Psi_L(x) \equiv P_L\Psi(x) = \begin{pmatrix} \chi_\alpha(x) \\ 0 \end{pmatrix}, \qquad \Psi_R(x) \equiv P_R\Psi(x) = \begin{pmatrix} 0 \\ \eta^{\dagger\dot\alpha}(x) \end{pmatrix}. \tag{G.1.9}$$

Equivalently, one can define the Weyl spinors Ψ_L and Ψ_R as the four-component spinor eigenstates of γ_5 with corresponding eigenvalues -1 and $+1$, respectively (i.e., $\gamma_5\Psi_{L,R} = \mp\Psi_{L,R}$).

The Dirac conjugate field $\overline{\Psi}(x)$ and the charge conjugate field $\Psi^C(x)$ are defined by:

$$\overline{\Psi}(x) \equiv \Psi^\dagger A = \left(\eta^\alpha(x),\, \chi^\dagger_{\dot\alpha}(x)\right), \tag{G.1.10}$$

$$\Psi^C(x) \equiv C\overline{\Psi}^{\mathsf{T}}(x) = \begin{pmatrix} \eta_\alpha(x) \\ \chi^{\dagger\dot\alpha}(x) \end{pmatrix}, \tag{G.1.11}$$

where the Dirac conjugation matrix A and the charge conjugation matrix C satisfy [286, 287, 288]:

$$A\gamma_\mu A^{-1} = \gamma_\mu^\dagger, \qquad C^{-1}\gamma_\mu C = -\gamma_\mu^{\mathsf{T}}. \tag{G.1.12}$$

It is convenient to introduce a notation for left and right-handed charge-conjugated fields (which are also Weyl spinor fields) following the conventions of refs. [68, 289],[126]

$$\Psi^C_L(x) \equiv P_L\Psi^C(x) = C\overline{\Psi}^{\mathsf{T}}_R(x) = [\Psi_R(x)]^C, \tag{G.1.13}$$

$$\Psi^C_R(x) \equiv P_R\Psi^C(x) = C\overline{\Psi}^{\mathsf{T}}_L(x) = [\Psi_L(x)]^C. \tag{G.1.14}$$

To fix the properties of A and C, it is conventional to impose two additional conditions:

$$\Psi = A^{-1}\overline{\Psi}^\dagger, \qquad (\Psi^C)^C = \Psi. \tag{G.1.15}$$

The first of these conditions together with eq. (G.1.10) is equivalent to the statement that $\overline{\Psi}\Psi$ is hermitian. The second condition corresponds to the statement that the (discrete) charge conjugation transformation applied twice is equal to the identity operator. Using eqs. (G.1.12) and (G.1.15) and the defining property of the gamma matrices [eq. (G.1.1)], one can show (independently of the gamma matrix representation) that the matrices A and C must satisfy:

$$A^\dagger = A, \qquad C^{\mathsf{T}} = -C, \qquad (AC)^{-1} = (AC)^*. \tag{G.1.16}$$

Following [137], it is convenient to introduce a matrix D such that

$$D \equiv CA^{\mathsf{T}}, \qquad D^{-1}\gamma_\mu D = -\gamma_\mu^*, \tag{G.1.17}$$

and $D^*D = DD^* = \mathbb{1}$. The charge-conjugated four-component spinor is then given by:

$$\Psi^C(x) \equiv D\Psi^*(x). \tag{G.1.18}$$

A four-component *Majorana spinor* field, $\Psi_M(x)$, is defined by imposing the constraint $\Psi^C(x) = \Psi(x)$ on a four-component Dirac spinor, which sets $\eta = \chi$. That is, the *Majorana condition* is

$$\Psi_M(x) = D\Psi^*_M(x) = \begin{pmatrix} \chi_\alpha(x) \\ \chi^{\dagger\dot\alpha}(x) \end{pmatrix}. \tag{G.1.19}$$

[126] The reader is warned that the opposite convention is often employed in the literature (e.g., see [290]) in which Ψ^C_L is a right-handed field and Ψ^C_R is a left-handed field.

For a review of the Majorana field and its properties, see e.g. refs. [145, 146].

For completeness, we also introduce a matrix B that satisfies [291, 286, 287, 288]:

$$B \equiv -C^{-1}\gamma_5\,, \qquad B\gamma_\mu B^{-1} = \gamma_\mu^{\mathsf{T}}\,. \tag{G.1.20}$$

The matrix B arises in the study of time reversal invariance of the Dirac equation. In the chiral representation, A, B, C and D are explicitly given by

$$A = \begin{pmatrix} 0 & \delta^{\dot\alpha}{}_{\dot\beta} \\ \delta_\alpha{}^\beta & 0 \end{pmatrix}, \qquad C = \begin{pmatrix} \epsilon_{\alpha\beta} & 0 \\ 0 & \epsilon^{\dot\alpha\dot\beta} \end{pmatrix}, \tag{G.1.21}$$

$$B = \begin{pmatrix} \epsilon^{\alpha\beta} & 0 \\ 0 & -\epsilon_{\dot\alpha\dot\beta} \end{pmatrix}, \qquad D = \begin{pmatrix} 0 & \epsilon_{\alpha\beta} \\ \epsilon^{\dot\alpha\dot\beta} & 0 \end{pmatrix}. \tag{G.1.22}$$

Note the *numerical* equalities, $A = \gamma^0$, $B = \gamma^1\gamma^3$, $C = i\gamma^0\gamma^2$ and $D = -i\gamma^2$. However these identifications do not respect either the structure of the undotted and dotted spinor indices specified in eqs. (G.1.21) and (G.1.22), or the four-component spinor index structure introduced below [cf. eqs. (G.1.47) and (G.1.48)].[127] In translating between two-component and four-component spinor notation, eqs. (G.1.21) and (G.1.22) should always be used. In practical four-component spinor calculations, there is often no harm in employing the numerical values for A, B, C and D.

Using eqs. (G.1.12)–(G.1.20), the following results are easily derived:

$$A\Gamma A^{-1} = \eta^A_\Gamma \Gamma^\dagger\,, \qquad \eta^A_\Gamma = \begin{cases} +1\,, & \text{for } \Gamma = \mathbb{1}\,,\ \gamma^\mu\,,\ \gamma^\mu\gamma_5\,,\ \Sigma^{\mu\nu}\,, \\ -1\,, & \text{for } \Gamma = \gamma_5\,,\ \Sigma^{\mu\nu}\gamma_5\,, \end{cases} \tag{G.1.23}$$

$$B\Gamma B^{-1} = \eta^B_\Gamma \Gamma^{\mathsf{T}}\,, \qquad \eta^B_\Gamma = \begin{cases} +1\,, & \text{for } \Gamma = \mathbb{1}\,,\ \gamma_5\,,\ \gamma^\mu\,, \\ -1\,, & \text{for } \Gamma = \gamma^\mu\gamma_5\,,\ \Sigma^{\mu\nu}\,,\ \Sigma^{\mu\nu}\gamma_5\,, \end{cases} \tag{G.1.24}$$

$$C^{-1}\Gamma C = \eta^C_\Gamma \Gamma^{\mathsf{T}}\,, \qquad \eta^C_\Gamma = \begin{cases} +1\,, & \text{for } \Gamma = \mathbb{1}\,,\ \gamma_5\,,\ \gamma^\mu\gamma_5\,, \\ -1\,, & \text{for } \Gamma = \gamma^\mu\,,\ \Sigma^{\mu\nu}\,,\ \Sigma^{\mu\nu}\gamma_5\,, \end{cases} \tag{G.1.25}$$

$$D^{-1}\Gamma D = \eta^D_\Gamma \Gamma^*\,, \qquad \eta^D_\Gamma = \begin{cases} +1\,, & \text{for } \Gamma = \mathbb{1}\,,\ \gamma^\mu\gamma_5\,,\ \Sigma^{\mu\nu}\gamma_5\,, \\ -1\,, & \text{for } \Gamma = \gamma^\mu\,,\ \gamma_5\,,\ \Sigma^{\mu\nu}\,. \end{cases} \tag{G.1.26}$$

The Lorentz transformation properties of the four-component spinor field can be determined from those of the two-component spinor fields given in Section 29.2. The 4×4 representation matrices of the Lorentz group in the $(\frac{1}{2},0)\oplus(0,\frac{1}{2})$ representation are given by

$$\mathbb{M} = \begin{pmatrix} M & 0 \\ 0 & (M^{-1})^\dagger \end{pmatrix} = \exp\left(-\frac{i}{4}\theta_{\mu\nu}\Sigma^{\mu\nu}\right) \simeq \mathbb{1}_{4\times4} - \tfrac{1}{4}i\theta_{\mu\nu}\Sigma^{\mu\nu}\,, \tag{G.1.27}$$

where the infinitesimal forms of M and $(M^{-1})^\dagger$ are given in eqs. (29.101) and (29.102). Two useful identities that follow from eqs. (G.1.23), (G.1.25) and (G.1.27) are:[128]

$$A\,\mathbb{M}A^{-1} = (\mathbb{M}^{-1})^\dagger\,, \tag{G.1.28}$$

$$C^{-1}\mathbb{M}C = (\mathbb{M}^{-1})^{\mathsf{T}}\,. \tag{G.1.29}$$

[127] When treated as ordinary 4×4 matrices A, B, C and D are unitary. But when written in 2×2 block form [noting that $\delta^{\dot\alpha}{}_{\dot\beta} = (\delta^\alpha{}_\beta)^*$ and $\epsilon^{\dot\alpha\dot\beta} \equiv (\epsilon^{\alpha\beta})^*$, as indicated below eqs. (29.21) and (29.25)], the products $AA^\dagger$, $BB^\dagger$, $CC^\dagger$ and $DD^\dagger$ are not covariant with respect to the dotted and undotted two-component spinor indices. Similarly, these matrix products are not covariant with respect to the four-component spinor indices. In practice, only covariant combinations of A, B, C, D and the four-component spinor fields arise in typical calculations.

[128] Note that eq. (G.1.29) is a direct consequence of the identities in two-component spinor notation given in eqs. (29.103) and (29.104).

The four-component Dirac or Majorana spinor, Ψ_a, is assigned a lowered spinor index a, and is defined in terms of two-component spinors by eqs. (G.1.7) or (G.1.19), respectively. Four-component spinor indices, which will be chosen in general from the beginning of the lower case Roman alphabet, $a, b, c, ...$, can assume integer values $1, 2, 3, 4$. Under a Lorentz transformation, Ψ_a transforms as

$$\Psi_a \to \mathbb{M}_a{}^b \, \Psi_b \,. \tag{G.1.30}$$

In analogy with the conventions for two-component spinor indices, we sum implicitly over a pair of repeated indices consisting of a raised and a lowered spinor index. The transformation law for the Dirac conjugate spinor (often called the Dirac adjoint spinor), $\overline{\Psi} = \Psi^\dagger A$, is obtained from eq. (G.1.30) after employing $A^\dagger = A$ and eq. (G.1.28),

$$\overline{\Psi}^a \to \overline{\Psi}^b \, (\mathbb{M}^{-1})_b{}^a \,. \tag{G.1.31}$$

In particular, $\overline{\Psi}\Psi \equiv \overline{\Psi}^a \Psi_a$ is a Lorentz scalar, which justifies the assignment of a raised spinor index for the Dirac conjugate spinor $\overline{\Psi}^a$.

It is convenient to introduce *barred* four-component spinor indices [292] in the transformation laws of the hermitian-conjugated four-component spinors,[129]

$$\Psi^\dagger_{\bar{a}} \to \Psi^\dagger_{\bar{b}} \, (\mathbb{M}^\dagger)^{\bar{b}}{}_{\bar{a}} \,, \tag{G.1.32}$$

$$\overline{\Psi}^{\dagger\,\bar{a}} \to [(\mathbb{M}^{-1})^\dagger]^{\bar{a}}{}_{\bar{b}} \, \overline{\Psi}^{\dagger\,\bar{b}} \,, \tag{G.1.33}$$

where there is an implicit sum over the repeated lowered and raised barred spinor indices, and

$$\Psi^\dagger_{\bar{a}} \equiv (\Psi_a)^\dagger \,, \qquad\qquad \overline{\Psi}^{\dagger\,\bar{a}} \equiv (\overline{\Psi}^a)^\dagger \,. \tag{G.1.34}$$

The spinor index structure of the Dirac conjugation matrix A is then fixed by noting that the Dirac conjugate spinor, $\overline{\Psi}^b \equiv \Psi^\dagger_{\bar{a}} A^{\bar{a}b}$, has a raised unbarred spinor index, whereas the hermitian-conjugated spinor has a lowered barred spinor index.

The charge conjugation matrix can be used to raise and lower four-component spinor indices [292], which we shall employ in defining the spinors Ψ^a, $\Psi^{\dagger\,\bar{a}}$, $\overline{\Psi}_a$ and $\overline{\Psi}^\dagger_{\bar{a}}$,[130]

$$\Psi_a = C_{ab} \Psi^b \,, \qquad\qquad \Psi^a = (C^{-1})^{ab} \Psi_b \,, \tag{G.1.35}$$

$$\Psi^\dagger_{\bar{a}} = C_{\bar{a}\bar{b}} \Psi^{\dagger\,\bar{b}} \,, \qquad\qquad \Psi^{\dagger\,\bar{a}} = (C^{-1})^{\bar{a}\bar{b}} \Psi^\dagger_{\bar{b}} \,, \tag{G.1.36}$$

where

$$C_{\bar{a}\bar{b}} \equiv (C_{ab})^* \,, \qquad\qquad (C^{-1})^{\bar{a}\bar{b}} \equiv [(C^{-1})^{ab}]^* \,. \tag{G.1.37}$$

Eqs. (G.1.35) and (G.1.36) also apply to $\overline{\Psi}^a$, $\overline{\Psi}_a$ and their hermitian conjugates. In particular, one can identify the Dirac conjugate spinor with a lowered spinor index ($\overline{\Psi}_a$) as the charge-conjugated spinor, $\Psi^C \equiv C \overline{\Psi}^{\mathsf{T}}$, and the Dirac spinor with a raised spinor index (Ψ^a) as the Dirac conjugate of the charge-conjugated spinor, $\overline{\Psi^C} = -\Psi^{\mathsf{T}} C^{-1}$. That is,[131]

$$\Psi^C_a \equiv \overline{\Psi}_a = C_{ab} \overline{\Psi}^b \,, \qquad\qquad \overline{\Psi^C}^{\,a} = \Psi^a = (C^{-1})^{ab} \Psi_b \,. \tag{G.1.38}$$

The rules for raising and lowering spinor indices are consistent with the Lorentz transformation properties of eqs. (G.1.30)–(G.1.33), as a consequence of eq. (G.1.29). In particular, the condition for a self-conjugate four-component (Majorana) spinor, $\overline{\Psi}_a \equiv \Psi^C_a = \Psi_a$, is Lorentz covariant.

[129] Of course, eqs. (G.1.30)–(G.1.33) can also be derived directly from the corresponding two-component spinor transformation laws of Section 29.2.

[130] In contrast to the epsilon symbols of the two-component spinor formalism, here we prefer to explicitly exhibit the inverse symbols in $(C^{-1})^{ab}$ and $(C^{-1})^{\bar{a}\bar{b}}$ [cf. footnote 14].

[131] For a Dirac spinor field defined in eq. (G.1.7), $\overline{\Psi}_a(x) = \Psi^C_a(x)$ is given in terms of two-component spinors by eq. (G.1.11), and $\Psi^a(x) = \overline{\Psi^C}^{\,a}(x) = \Big(\chi^\alpha(x)\,,\, \eta^\dagger_{\dot{\alpha}}(x)\Big)$.

Using eqs. (G.1.16), (G.1.35), (G.1.36), and the definition of the Dirac conjugate spinor, it then follows that:

$$\overline{\Psi}_a = (A^{-1})_{a\bar{b}}\Psi^{\dagger\,\bar{b}}\,, \qquad \overline{\Psi}^{\,a} = \Psi^{\dagger}_{\bar{b}}\,A^{\bar{b}a}\,, \tag{G.1.39}$$

$$\Psi^{\dagger}_{\bar{a}} = \overline{\Psi}^{\,b}(A^{-1})_{b\bar{a}}\,, \qquad \Psi^{\dagger\,\bar{a}} = A^{\bar{a}b}\,\overline{\Psi}_b\,. \tag{G.1.40}$$

One can check that eqs. (G.1.39) and (G.1.40) are consistent with the Lorentz transformation properties of eqs. (G.1.30)–(G.1.33), as a consequence of eq. (G.1.28).

In addition to the Lorentz scalar $\overline{\Psi}\Psi \equiv \overline{\Psi}^{\,a}\Psi_a$, one can construct two additional independent Lorentz scalar quantities,[132]

$$-\Psi^{\mathsf{T}}C^{-1}\,\Psi \equiv -\Psi_a(C^{-1})^{ab}\Psi_b = \Psi^a\Psi_a\,, \tag{G.1.41}$$

and its hermitian conjugate,

$$\overline{\Psi}\,C\,\overline{\Psi}^{\mathsf{T}} \equiv \overline{\Psi}^{\,a}C_{ab}\overline{\Psi}^{\,b} = \overline{\Psi}^{\,a}\overline{\Psi}_a = \Psi^{\dagger}_{\bar{a}}\Psi^{\dagger\,\bar{a}} = (\Psi^a\Psi_a)^{\dagger}\,, \tag{G.1.42}$$

after using C^{-1} and C to raise and lower the appropriate spinor indices, respectively. The penultimate equality in eq. (G.1.42) is a consequence of eq. (G.1.40). The Lorentz invariance of $\overline{\Psi}^{\,a}\Psi_a$, $\Psi^a\Psi_a$ and $\Psi^{\dagger}_{\bar{a}}\Psi^{\dagger\,\bar{a}} = \overline{\Psi}^{\,a}\overline{\Psi}_a$ is manifest and demonstrates the power of the four-component spinor index notation developed above. After invoking eq. (G.1.38), we note that [analogous to eq. (29.37)] *descending* contracted unbarred spinor indices and *ascending* contracted barred spinor indices can be suppressed in spinor-index-contracted products. For example,

$$\overline{\Psi}^{\,a}\Psi_a \equiv \overline{\Psi}\Psi \qquad \Psi^a\Psi_a = \overline{\Psi^C}^{\,a}\Psi_a \equiv \overline{\Psi^C}\Psi \qquad \overline{\Psi}^{\,a}\overline{\Psi}_a = \overline{\Psi}^{\,a}\Psi^C_a \equiv \overline{\Psi}\Psi^C\,, \tag{G.1.43}$$

where the suppression of barred spinor indices is implicit in the definition of $\overline{\Psi}^{\,b} \equiv \Psi^{\dagger}_{\bar{a}}A^{\bar{a}b}$.

The charge-conjugated spinor can also be written as $\Psi^C_a \equiv D_a{}^{\bar{c}}\Psi^{\dagger}_{\bar{c}}$ [cf. eq. (G.1.18)]. The spinor index structure of D (and its inverse) derives from:

$$D_a{}^{\bar{c}} \equiv C_{ab}(A^{\mathsf{T}})^{b\bar{c}} = C_{ab}A^{\bar{c}b}\,, \qquad (D^{-1})_{\bar{a}}{}^{c} \equiv (C^*A)_{\bar{a}}{}^{c} = C_{\bar{a}\bar{b}}A^{\bar{b}c}\,, \tag{G.1.44}$$

where we have used $D^{-1} = D^*$. Combining the results of eqs. (G.1.35), (G.1.36), (G.1.39) and (G.1.40) then yields:

$$\overline{\Psi}_a = D_a{}^{\bar{c}}\,\Psi^{\dagger}_{\bar{c}}\,, \qquad \Psi^{\dagger}_{\bar{a}} = (D^{-1})_{\bar{a}}{}^{c}\,\overline{\Psi}_c\,, \tag{G.1.45}$$

$$\overline{\Psi}^{\,a} = -\Psi^{\dagger\,\bar{c}}(D^{-1})_{\bar{c}}{}^{a}\,, \qquad \Psi^{\dagger\,\bar{a}} = -\overline{\Psi}^{\,c}\,D_c{}^{\bar{a}}\,. \tag{G.1.46}$$

In summary, a four-component spinor Ψ_a and its charge-conjugated spinor Ψ^C_a possess a lowered unbarred spinor index, whereas the corresponding Dirac conjugates, $\overline{\Psi}^{\,a}$ and $\overline{\Psi^C}^{\,a}$, possess a raised unbarred spinor index. The corresponding hermitian-conjugated spinors exhibit barred spinor indices (with the height of each spinor index unchanged). Following eqs. (G.1.35) and (G.1.36), one can also lower or raise a four-component unbarred or barred spinor index by multiplying by the appropriate matrix C, C^{-1}, C^* or $(C^{-1})^*$, respectively.

The identity matrix, the gamma matrices and their products are denoted collectively by Γ. The spinor index structure of these matrices and their inverses is given by:

$$\delta^b_a\,,\ \Gamma_a{}^b\,,\ (\Gamma^{-1})_a{}^b\,, \tag{G.1.47}$$

where the δ^b_a are the matrix elements of the identity matrix $\mathbb{1}$. In this case, the rows are labeled by the lowered index and the columns are labeled by the raised index. Note that the quantities

[132] A fourth possible Lorentz scalar, $\Psi^a\overline{\Psi}_a = (C^{-1})^{ab}C_{ac}\Psi_b\overline{\Psi}^{\,c} = -\Psi_c\overline{\Psi}^{\,c} = \overline{\Psi}^{\,c}\Psi_c$, is not independent. Here, we have used $C^{\mathsf{T}} = -C$ and the anticommutativity of the spinors. Equivalently, $\overline{\Psi^C}\Psi^C = \overline{\Psi}\Psi$.

$\overline{\Psi}^a\,\Gamma_a{}^b\,\Psi_b$, $\Psi^a\,\Gamma_a{}^b\,\Psi_b$, and $\overline{\Psi}^a\,\Gamma_a{}^b\,\overline{\Psi}^b$ transform as Lorentz tensors, whose rank is equal to the number of (suppressed) spacetime indices of Γ.

For the matrices A, B, C, D and their inverses, the spinor index structure is given by:

$$A^{\bar{a}b}\,,\ (A^{-1})_{a\bar{b}}\,,\ B^{ab}\,,\ (B^{-1})_{ab}\,,C_{ab}\,,\ (C^{-1})^{ab}\,,D_a{}^{\bar{b}}\,,\ (D^{-1})_{\bar{a}}{}^b\,. \tag{G.1.48}$$

The corresponding complex-conjugated matrices exhibit the analogous spinor index structure with unbarred spinor indices changed to barred spinor indices and vice versa. Matrix transposition interchanges rows and columns. For example,

$$(\Gamma^{\mathsf{T}})^a{}_b \equiv \Gamma_b{}^a\,,\qquad (A^{\mathsf{T}})^{a\bar{b}} \equiv A^{\bar{b}a}\,,\qquad (C^{\mathsf{T}})_{ab} = C_{ba}\,,\qquad (D^{\mathsf{T}})^{\bar{a}}{}_b \equiv D_b{}^{\bar{a}}\,. \tag{G.1.49}$$

Hermitian conjugation is complex conjugation followed by matrix transposition. For example,

$$(\Gamma^\dagger)^{\bar{a}}{}_{\bar{b}} \equiv (\Gamma_b{}^a)^*\,,\qquad (A^\dagger)^{\bar{a}b} \equiv (A^{\bar{b}a})^*\,,\qquad (C^\dagger)_{\bar{a}\bar{b}} = (C_{ba})^*\,,\qquad (D^\dagger)^a{}_{\bar{b}} \equiv (D_b{}^{\bar{a}})^*\,. \tag{G.1.50}$$

Using the above results, it is straightforward to identify the four-component spinor index structure of eqs. (G.1.1)–(G.1.29). For example, specifying the four-component spinor indices of eq. (G.1.29) yields:

$$(C^{-1})^{ab}\mathbb{M}_b{}^cC_{cd} = [(\mathbb{M}^{-1})^{\mathsf{T}}]^a{}_d \equiv (\mathbb{M}^{-1})_d{}^a\,. \tag{G.1.51}$$

To complete the spinor index formalism, we introduce hybrid quantities L, $\overline{L}$, R and $\overline{R}$ that contain an unbarred four-component spinor index and a two-component undotted or dotted spinor index [293]:

$$L_\beta{}^b = (\mathbb{1}_{2\times2}\quad \mathbb{O}_{2\times2})\,,\qquad R^{\dot\beta\,b} = (\mathbb{O}_{2\times2}\quad \mathbb{1}_{2\times2})\,, \tag{G.1.52}$$

$$\overline{L}_b{}^\beta = \begin{pmatrix}\mathbb{1}_{2\times2}\\ \mathbb{O}_{2\times2}\end{pmatrix}\,,\qquad \overline{R}_{b\dot\beta} = \begin{pmatrix}\mathbb{O}_{2\times2}\\ \mathbb{1}_{2\times2}\end{pmatrix}\,. \tag{G.1.53}$$

These quantities satisfy:

$$\overline{L}_a{}^\alpha L_\alpha{}^b = (P_L)_a{}^b\,,\qquad L_\alpha{}^a\overline{L}_a{}^\beta = \delta_\alpha{}^\beta\,, \tag{G.1.54}$$

$$\overline{R}_{a\dot\alpha}R^{\dot\alpha\,b} = (P_R)_a{}^b\,,\qquad R^{\dot\alpha\,a}\overline{R}_{a\dot\beta} = \delta^{\dot\alpha}{}_{\dot\beta}\,, \tag{G.1.55}$$

where P_L and P_R are the chiral projection operators defined in eq. (G.1.8). It then follows that:

$$L_\alpha{}^a(P_L)_a{}^b = L_\alpha{}^b\,,\qquad (P_L)_a{}^b\overline{L}_b{}^\beta = \overline{L}_a{}^\beta\,, \tag{G.1.56}$$

$$R^{\dot\alpha\,a}(P_R)_a{}^b = R^{\dot\alpha\,b}\,,\qquad (P_R)_a{}^b\overline{R}_{b\dot\beta} = \overline{R}_{a\dot\beta}\,. \tag{G.1.57}$$

The hybrid quantities L, $\overline{L}$, R and $\overline{R}$ connect objects with four-component and two-component spinor indices. For the Dirac spinor defined in eq. (G.1.7), it follows that:

$$\chi_\alpha = L_\alpha{}^b\Psi_b\,,\qquad \eta^\alpha = \overline{\Psi}^b\,\overline{L}_b{}^\alpha\,, \tag{G.1.58}$$

$$\eta^{\dagger\dot\alpha} = R^{\dot\alpha\,b}\Psi_b\,,\qquad \chi^\dagger_{\dot\alpha} = \overline{\Psi}^b\,\overline{R}_{b\dot\alpha}\,. \tag{G.1.59}$$

The corresponding inverse relations are:

$$(P_L)_a{}^b\,\Psi_b = \overline{L}_a{}^\beta\chi_\beta\,,\qquad \overline{\Psi}^a(P_L)_a{}^b = \eta^\beta L_\beta{}^b\,, \tag{G.1.60}$$

$$(P_R)_a{}^b\,\Psi_b = \overline{R}_{a\dot\beta}\eta^{\dagger\dot\beta}\,,\qquad \overline{\Psi}^a(P_R)_a{}^b = \chi^\dagger_{\dot\beta}R^{\dot\beta\,b}\,. \tag{G.1.61}$$

One can use eqs. (G.1.2), (G.1.4) and (G.1.21) to identify:

$$\sigma^{\mu}_{\alpha\dot\beta} = L_\alpha{}^a(\gamma^\mu)_a{}^b\overline{R}_{b\dot\beta}\,, \qquad \overline{\sigma}^{\mu\dot\alpha\beta} = R^{\dot\alpha\, a}(\gamma^\mu)_a{}^b\overline{L}_b{}^\beta\,, \tag{G.1.62}$$

$$\sigma^{\mu\nu}{}_\alpha{}^\beta = L_\alpha{}^a(\tfrac{1}{2}\Sigma^{\mu\nu})_a{}^b\overline{L}_b{}^\beta\,, \qquad \overline{\sigma}^{\mu\nu\dot\alpha}{}_{\dot\beta} = R^{\dot\alpha\, a}(\tfrac{1}{2}\Sigma^{\mu\nu})_a{}^b\overline{R}_{b\dot\beta}\,, \tag{G.1.63}$$

$$\delta_\alpha{}^\beta = -L_\alpha{}^a(\gamma_5)_a{}^b\overline{L}_b{}^\beta\,, \qquad \delta^{\dot\alpha}{}_{\dot\beta} = R^{\dot\alpha\, a}(\gamma_5)_a{}^b\overline{R}_{b\dot\beta}\,, \tag{G.1.64}$$

$$\epsilon_{\alpha\beta} = L_\alpha{}^a C_{ab} L_\beta{}^b\,, \qquad \epsilon^{\dot\alpha\dot\beta} = R^{\dot\alpha\, a} C_{ab} R^{\dot\beta\, b}\,, \tag{G.1.65}$$

$$\epsilon^{\alpha\beta} = \overline{L}_a{}^\alpha (C^{-1})^{ab}\overline{L}_b{}^\beta\,, \qquad \epsilon_{\dot\alpha\dot\beta} = \overline{R}_{a\dot\alpha}(C^{-1})^{ab}\overline{R}_{b\dot\beta}\,. \tag{G.1.66}$$

Inverting these results yields:

$$(\gamma^\mu P_L)_c{}^d = \overline{R}_{c\dot\alpha}\overline{\sigma}^{\mu\dot\alpha\beta}L_\beta{}^d\,, \qquad (\gamma^\mu P_R)_c{}^d = \overline{L}_c{}^\alpha\sigma^\mu_{\alpha\dot\beta}R^{\dot\beta d}\,, \tag{G.1.67}$$

$$\tfrac{1}{2}(\Sigma^{\mu\nu}P_L)_c{}^d = \overline{L}_c{}^\alpha\sigma^{\mu\nu}{}_\alpha{}^\beta L_\beta{}^d \qquad \tfrac{1}{2}(\Sigma^{\mu\nu}P_R)_c{}^d = \overline{R}_{c\dot\alpha}\overline{\sigma}^{\mu\nu\dot\alpha}{}_{\dot\beta}R^{\dot\beta d}\,, \tag{G.1.68}$$

$$(AP_L)_c{}^d = \overline{R}_c{}^\beta L_\beta{}^d\,, \qquad (AP_R)_c{}^d = \overline{L}_{c\dot\beta}R^{\dot\beta d}\,, \tag{G.1.69}$$

$$(P_LC)_{cd} = \epsilon_{\alpha\beta}\overline{L}_c{}^\alpha\overline{L}_d{}^\beta\,, \qquad (P_RC)_{cd} = \epsilon^{\dot\alpha\dot\beta}\overline{R}_{c\dot\alpha}\overline{R}_{d\dot\beta}\,, \tag{G.1.70}$$

$$(C^{-1}P_L)^{cd} = \epsilon^{\alpha\beta}L_\alpha{}^c L_\beta{}^d\,, \qquad (C^{-1}P_R)^{cd} = \epsilon_{\dot\alpha\dot\beta}R^{\dot\alpha c}R^{\dot\beta d}\,. \tag{G.1.71}$$

Likewise, one can introduce $L^\dagger$, $\overline{L}^\dagger$, $R^\dagger$ and $\overline{R}^\dagger$, which are hybrid quantities that contain a barred four-component spinor index and a two-component undotted or dotted spinor index:

$$(L^\dagger)^{\bar a}{}_{\dot\beta} \equiv (L_\beta{}^a)^*\,, \qquad (R^\dagger)^{\bar a\beta} \equiv (R^{\dot\beta a})^*\,, \tag{G.1.72}$$

$$(\overline{L}^\dagger)^{\dot\beta}{}_{\bar a} \equiv (\overline{L}_a{}^\beta)^*\,, \qquad (\overline{R}^\dagger)_{\beta\bar a} \equiv (\overline{R}_{a\dot\beta})^*\,. \tag{G.1.73}$$

In particular, using eqs. (G.1.60) and (G.1.61), one can relate the quantities L, $\overline{L}$, R and $\overline{R}$ and their hermitian conjugates:

$$(L^\dagger)^{\bar a}{}_{\dot\beta} = A^{\bar a b}\overline{R}_{b\dot\beta}\,, \qquad (R^\dagger)^{\bar a\beta} = A^{\bar a b}\overline{L}_b{}^\beta\,, \tag{G.1.74}$$

$$(\overline{L}^\dagger)^{\dot\beta}{}_{\bar a} = R^{\dot\beta b}(A^{-1})_{b\bar a}\,, \qquad (\overline{R}^\dagger)_{\beta\bar a} = L_\beta{}^b(A^{-1})_{b\bar a}\,, \tag{G.1.75}$$

after employing $AP_L = P_R^\dagger A$ [cf. eq. (G.1.23)] and $A^\dagger = A$. The set of equations analogous to eqs. (G.1.54)–(G.1.71) involving the corresponding hermitian-conjugated quantities can also be obtained. However, such formulae will rarely be needed in practice.

Eqs. (G.1.54)–(G.1.71) [and their hermitian conjugates] can be employed to translate any expression involving two-component spinors into the corresponding expression involving four-component spinors, and vice versa. With a little practice, both two-component and four-component spinor indices can be suppressed, which greatly simplifies the manipulation of the spinor quantities. In particular, by treating the four-component spinors Ψ_a and Ψ^C_a as column vectors and their hermitian (Dirac) conjugates $\Psi^\dagger_{\bar a}$ and $\Psi^{C\,\dagger}_{\bar a}$ ($\overline{\Psi}^a$ and $\overline{\Psi^C}^a$) as row vectors, all equations in the four-component spinor formalism have a natural interpretation as products of matrices and vectors. Henceforth, we shall suppress all four-component spinor indices.

Multiple species of fermions are indicated with a flavor index such as i and j. Dirac fermions are constructed from two-component fields of opposite charge, χ_i and η^i (hence the opposite flavor index heights). Thus, we establish the following conventions for the flavor indices of four-component Dirac fermions:

$$\Psi_i(x) \equiv \begin{pmatrix}\chi_{\alpha i}(x)\\ \eta_i^{\dagger\dot\alpha}(x)\end{pmatrix}\,, \qquad \overline{\Psi}^i(x) = \begin{pmatrix}\eta^{\alpha i}(x)\,,\ \chi^{\dagger\, i}_{\dot\alpha}(x)\end{pmatrix}\,, \qquad \Psi^{C\,i}(x) \equiv \begin{pmatrix}\eta^i_\alpha(x)\\ \chi^{\dagger\dot\alpha i}(x)\end{pmatrix}\,. \tag{G.1.76}$$

Note that $\chi^{\dagger\,i} = (\chi_i)^\dagger$ and $\eta_i^\dagger \equiv (\eta^i)^\dagger$ following the conventions established in Section 29.3.2. Raised flavor indices can only be contracted with lowered flavor indices and vice versa. In contrast, Majorana fermions are neutral so that there is no a priori distinction between raised and lowered flavor indices. That is,

$$\Psi_{Mi}(x) = \Psi_M^i(x) = \Psi_{Mi}^C(x) = \Psi_M^{C\,i}(x) \equiv \begin{pmatrix} \xi_{\alpha i}(x) \\ \xi^{\dagger\dot\alpha i}(x) \end{pmatrix}, \qquad \overline{\Psi}_{Mi}(x) = \overline{\Psi}_M^i(x) \equiv \Big(\xi_i^\alpha(x)\,,\ \xi_{\dot\alpha}^{\dagger\,i}(x)\Big)\,. \tag{G.1.77}$$

In this case, the contraction of two repeated flavor indices is allowed in all cases, irrespective of the heights of the two indices. In the convention adopted in Section 29.3.2, in which all neutral left-handed $(\frac{1}{2},0)$ [right-handed $(0,\frac{1}{2})$] fermions have lowered [raised] flavor indices, the height of the flavor index of a four-component Majorana fermion field is meaningful when multiplied by a left-handed or right-handed projection operator. Thus, the height of the flavor index for Majorana fermions can be consistently chosen according to one of the following four cases:

$$P_L\Psi_{Mi}\,, \qquad \overline{\Psi}_{Mi}P_L\,, \qquad P_R\Psi_M^i\,, \qquad \overline{\Psi}_M^i P_R\,. \tag{G.1.78}$$

Bilinear covariants are quantities that are quadratic in the spinor fields and transform irreducibly as Lorentz tensors. We first construct a translation table between the two-component form and the four-component form for the bilinear covariants made up of a pair of Dirac fields. Using eqs. (G.1.60) and (G.1.61) to convert the four-component spinor fields into the corresponding two-component spinor fields, and employing the appropriate identities involving products of the hybrid quantities L, $\overline{L}$, R and $\overline{R}$, the following results are then obtained:

$$\overline{\Psi}^i P_L\Psi_j = \eta^{\,i}\chi_j\,, \tag{G.1.79}$$

$$\overline{\Psi}^i P_R\Psi_j = \chi^{\dagger\,i}\eta_j^\dagger\,, \tag{G.1.80}$$

$$\overline{\Psi}^i\gamma^\mu P_L\Psi_j = \chi^{\dagger\,i}\overline{\sigma}^\mu\chi_j\,, \tag{G.1.81}$$

$$\overline{\Psi}^i\gamma^\mu P_R\Psi_j = \eta^{\,i}\sigma^\mu\eta_j^\dagger\,, \tag{G.1.82}$$

$$\overline{\Psi}^i\Sigma^{\mu\nu} P_L\Psi_j = 2\,\eta^{\,i}\sigma^{\mu\nu}\chi_j\,, \tag{G.1.83}$$

$$\overline{\Psi}^i\Sigma^{\mu\nu} P_R\Psi_j = 2\,\chi^{\dagger\,i}\overline{\sigma}^{\mu\nu}\eta_j^\dagger\,. \tag{G.1.84}$$

The first two results above follow immediately after using eqs. (G.1.54) and (G.1.55), respectively, and the last four results are a consequence of eqs. (G.1.62) and (G.1.63).

Eqs. (G.1.79)–(G.1.84) apply to both commuting and anticommuting fermion fields.[133] These results can then be used to express the standard four-component spinor bilinear covariants in terms of two-component spinor bilinears:

$$\overline{\Psi}^i\Psi_j = \eta^{\,i}\chi_j + \chi^{\dagger\,i}\eta_j^\dagger \tag{G.1.85}$$

$$\overline{\Psi}^i\gamma_5\Psi_j = -\eta^{\,i}\chi_j + \chi^{\dagger\,i}\eta_j^\dagger \tag{G.1.86}$$

$$\overline{\Psi}^i\gamma^\mu\Psi_j = \chi^{\dagger\,i}\overline{\sigma}^\mu\chi_j + \eta^{\,i}\sigma^\mu\eta_j^\dagger \tag{G.1.87}$$

$$\overline{\Psi}^i\gamma^\mu\gamma_5\Psi_j = -\chi^{\dagger\,i}\overline{\sigma}^\mu\chi_j + \eta^{\,i}\sigma^\mu\eta_j^\dagger \tag{G.1.88}$$

$$\overline{\Psi}^i\Sigma^{\mu\nu}\Psi_j = 2(\eta^{\,i}\sigma^{\mu\nu}\chi_j + \chi^{\dagger\,i}\overline{\sigma}^{\mu\nu}\eta_j^\dagger) \tag{G.1.89}$$

$$\overline{\Psi}^i\Sigma^{\mu\nu}\gamma_5\Psi_j = 2(-\eta^{\,i}\sigma^{\mu\nu}\chi_j + \chi^{\dagger\,i}\overline{\sigma}^{\mu\nu}\eta_j^\dagger)\,. \tag{G.1.90}$$

[133] In the case of anticommuting spinors, it is often useful to apply eq. (29.62) to eqs. (G.1.82), (G.1.87) and (G.1.88) and rewrite $\eta^{\,i}\sigma^\mu\eta_j^\dagger = -\eta_j^\dagger\overline{\sigma}^\mu\eta^{\,i}$.

Additional identities can be derived that involve the charge-conjugated four-component Dirac fermion fields. As an example, we may use $C^{\mathsf{T}} = -C$ and $\overline{\Psi^C} = -\Psi^{\mathsf{T}} C^{-1}$ to prove that

$$\overline{\Psi^C_i}\,\Gamma\,\Psi^{C\,j} = -(-1)^A \overline{\Psi}^{\,j} C\,\Gamma^{\mathsf{T}}\,C^{-1}\Psi_i = -(-1)^A \eta^C_\Gamma\,\overline{\Psi}^{\,j}\,\Gamma\,\Psi_i\,, \tag{G.1.91}$$

where the sign η^C_Γ is given in eq. (G.1.25). The factor of $(-1)^A = \pm 1$ [for commuting/anticommuting fermion fields, respectively] arises at the second step above after reversing the order of the terms by matrix transposition. Identities involving just one charge-conjugated four-component field can also be easily obtained. For example, using eqs. (G.1.58) and (G.1.71),

$$\overline{\Psi^C_i} P_L \Psi_j = -\Psi_i^{\mathsf{T}} C^{-1} P_L \Psi_j = -\Psi_{ai}\epsilon^{\alpha\beta} L_\alpha{}^a L_\beta{}^b \Psi_{bj} = -\epsilon^{\alpha\beta}\chi_{\alpha i}\chi_{\beta j} = \chi_i\chi_j\,. \tag{G.1.92}$$

In general, if one replaces Ψ_k with $\Psi^{C\,k}$ in eqs. (G.1.79)–(G.1.90), then in the corresponding two-component expression one simply interchanges $\chi_k \leftrightarrow \eta^k$ and $\chi^{\dagger\,k} \leftrightarrow \eta^\dagger_k$.

Eqs. (G.1.79)–(G.1.90) also apply to four-component Majorana spinors, Ψ_{Mi}, by setting $\chi_i = \eta^i \equiv \xi_i$, and $\chi^{\dagger\,i} = \eta^\dagger_i \equiv \xi^{\dagger\,i}$. This implements the Majorana condition, $\Psi_{Mi} = D\Psi^*_{Mi}$, and imposes additional restrictions on the Majorana bilinear covariants. For example, eqs. (G.1.25) and (G.1.91) imply that *anticommuting* Majorana four-component fermions satisfy:[134]

$$\overline{\Psi}_{Mi}\Psi_{Mj} = \overline{\Psi}_{Mj}\Psi_{Mi}\,, \tag{G.1.93}$$
$$\overline{\Psi}_{Mi}\gamma_5\Psi_{Mj} = \overline{\Psi}_{Mj}\gamma_5\Psi_{Mi}\,, \tag{G.1.94}$$
$$\overline{\Psi}_{Mi}\gamma^\mu\Psi_{Mj} = -\overline{\Psi}_{Mj}\gamma^\mu\Psi_{Mi}\,, \tag{G.1.95}$$
$$\overline{\Psi}_{Mi}\gamma^\mu\gamma_5\Psi_{Mj} = \overline{\Psi}_{Mj}\gamma^\mu\gamma_5\Psi_{Mi}\,, \tag{G.1.96}$$
$$\overline{\Psi}_{Mi}\Sigma^{\mu\nu}\Psi_{Mj} = -\overline{\Psi}_{Mj}\Sigma^{\mu\nu}\Psi_{Mi}\,, \tag{G.1.97}$$
$$\overline{\Psi}_{Mi}\Sigma^{\mu\nu}\gamma_5\Psi_{Mj} = -\overline{\Psi}_{Mj}\Sigma^{\mu\nu}\gamma_5\Psi_{Mi}\,. \tag{G.1.98}$$

By setting $i = j$, it follows that $\overline{\Psi}_M\gamma^\mu\Psi_M = \overline{\Psi}_M\Sigma^{\mu\nu}\Psi_M = \overline{\Psi}_M\Sigma^{\mu\nu}\gamma_5\Psi_M = 0$. One additional useful result is:

$$\overline{\Psi}^i_M\gamma^\mu P_L\Psi_{Mj} = -\overline{\Psi}_{Mj}\gamma^\mu P_R\Psi^i_M\,, \tag{G.1.99}$$

which follows immediately from eqs. (G.1.95) and (G.1.96). Note that in eq. (G.1.99), the heights of the flavor indices follow the convention established in eq. (G.1.78).

In the four-component spinor formalism, Fierz identities (first introduced in [294]) consist of relations among products of two bilinear covariants, in which the fermion fields appear in two different orders. The corresponding two-component spinor Fierz identities are treated in detail in Appendix B.1 . In principle, the latter can be converted into four-component spinor Fierz identities using the techniques developed in this Appendix. However, it is easier to derive the four-component spinor Fierz identities directly using the properties of the gamma matrix algebra [291, 284].

Instead of eqs. (B.1.6)–(B.1.8), the equivalent identity relevant for four-component spinors is:

$$\delta^b_a\delta^d_c = \tfrac{1}{4}\left[\delta^d_a\delta^b_c + (\gamma_5)_a{}^d(\gamma_5)_c{}^b + (\gamma^\mu)_a{}^d(\gamma_\mu)_c{}^b - (\gamma^\mu\gamma_5)_a{}^d(\gamma_\mu\gamma_5)_c{}^b + \tfrac{1}{2}(\Sigma^{\mu\nu})_a{}^d(\Sigma_{\mu\nu})_c{}^b\right]. \tag{G.1.100}$$

This is the fundamental identity from which many other such identities can be derived (cf. the Appendix of [288]). One of many possible Fierz identities can be obtained by multiplying eq. (G.1.100) by $\overline{\Psi}^a_1\Psi_{2b}\overline{\Psi}^c_3\Psi_{4d} = (-1)^A\,\overline{\Psi}^a_1\Psi_{4d}\overline{\Psi}^c_3\Psi_{2b}$, where $(-1)^A = +1$ [-1] for commuting [anticommuting] Dirac, Majorana or Weyl spinors. More generally [284, 295, 296],

$$(\overline{\Psi}_1\Gamma^{(k)I}\Psi_2)(\overline{\Psi}_3\Gamma^{(k)}_I\Psi_4) = (-1)^A\sum_{n=1}^{5} F^k{}_n\,(\overline{\Psi}_1\Gamma^{(n)J}\Psi_4)(\overline{\Psi}_3\Gamma^{(n)}_J\Psi_2)\,, \tag{G.1.101}$$

[134] Here, one is free to choose all flavor indices to be in the lowered position [cf. eq. (G.1.77)].

where the sum is taken over the 4×4 matrices, $\Gamma^{(n)}\in\Gamma$, which have been ordered as follows,[135]

$$\Gamma = \{\mathbb{1}\,,\ \gamma^\mu\,,\ \Sigma^{\mu\nu}\,(\mu<\nu)\,,\ \gamma^\mu\gamma_5\,,\ \gamma_5\}\,, \tag{G.1.102}$$

I, J represent zero, one or two spacetime indices (sums over repeated I and J are implied), and

$$F = \frac{1}{4}\begin{pmatrix} 1 & 1 & \frac{1}{2} & -1 & 1\\ 4 & -2 & 0 & -2 & -4\\ 12 & 0 & -2 & 0 & 12\\ -4 & -2 & 0 & -2 & 4\\ 1 & -1 & \frac{1}{2} & 1 & 1\end{pmatrix}. \tag{G.1.103}$$

For example, taking $k=1$ in eq. (G.1.101) yields a result equivalent to eq. (G.1.100):

$$\begin{aligned}(\overline{\Psi}_1\Psi_2)(\overline{\Psi}_3\Psi_4) = \tfrac{1}{4}(-1)^A\big[&(\overline{\Psi}_1\Psi_4)(\overline{\Psi}_3\Psi_2)+(\overline{\Psi}_1\gamma_5\Psi_4)(\overline{\Psi}_3\gamma_5\Psi_2)+(\overline{\Psi}_1\gamma^\mu\Psi_4)(\overline{\Psi}_3\gamma_\mu\Psi_2)\\ &-(\overline{\Psi}_1\gamma^\mu\gamma_5\Psi_4)(\overline{\Psi}_3\gamma_\mu\gamma_5\Psi_2)+\tfrac{1}{2}(\overline{\Psi}_1\Sigma^{\mu\nu}\Psi_4)(\overline{\Psi}_3\Sigma_{\mu\nu}\Psi_2)\big]\,.\end{aligned} \tag{G.1.104}$$

For a comprehensive treatment of all possible four-component spinor Fierz identities, see [297]. Simple derivations of generalized Fierz identities have also been given in refs. [296, 298]. A Mathematica package for performing Fierz transformations is available in [299].

Free-field four-component fermion Lagrangians

The free-field Lagrangian density in four-component spinor notation can be obtained from the corresponding two-component fermion Lagrangian by employing the relevant identities for the bilinear covariants given in eqs. (G.1.79)–(G.1.90). First, consider a collection of free anticommuting four-component Majorana fields, $\Psi_{Mi}=\Psi_{Mi}^C$. The free-field Lagrangian (in terms of mass eigenstate fields) may be obtained from eq. (29.3.10) by converting to four-component spinor notation using eqs. (G.1.85) and (G.1.87) with $\chi=\eta\equiv\xi$, which yields [3]:

$$\mathscr{L} = \tfrac{1}{2}i\overline{\Psi}_{Mi}\gamma^\mu\partial_\mu\Psi_{Mi} - \tfrac{1}{2}m_i\overline{\Psi}_{Mi}\Psi_{Mi}\,, \tag{G.2.1}$$

where the sum over i is implicit. The corresponding free-field equation for Ψ_{Mi} is the Dirac equation:

$$(i\gamma^\mu\partial_\mu - m)\Psi_{Mi} = 0\,. \tag{G.2.2}$$

For simplicity, we focus on a theory of a single four-component Majorana fermion field, $\Psi_M(x)=\Psi_M^C(x)$. One can rewrite the free-field Majorana fermion Lagrangian in terms of a single Weyl fermion, $\Psi_L(x)\equiv P_L\Psi(x)$, where $\Psi(x)$ is a four-component fermion field whose lower two components (in the chiral representation) are irrelevant for the present discussion. The Majorana and Weyl fields are related by:

$$\Psi_{\!M}(x) = \Psi_{\!L}(x) + \Psi_{\!R}^C(x)\,, \tag{G.2.3}$$

where $\Psi_{\!R}^C(x)$ is defined in eq. (G.1.14). The corresponding Dirac conjugate field is given by $\overline{\Psi}_{\!M}(x)=\overline{\Psi}_{\!L}(x)+\overline{\Psi_{\!R}^C}(x)$, where

$$\overline{\Psi}_{\!L}(x) \equiv [P_L\Psi(x)]^\dagger A = \overline{\Psi}(x)P_R\,, \tag{G.2.4}$$

$$\overline{\Psi_{\!R}^C}(x) \equiv \overline{\Psi^C}(x)P_L = -\Psi^{\mathsf{T}}(x)C^{-1}P_L = -\Psi_L^{\mathsf{T}}(x)C^{-1}\,. \tag{G.2.5}$$

Using the identity:[136]

$$\overline{\Psi_{\!R}^C}\gamma^\mu\partial_\mu\Psi_{\!R}^C = -\Psi^{\mathsf{T}}C^{-1}P_L\gamma^\mu\partial_\mu P_RC\overline{\Psi}^{\mathsf{T}} = \overline{\Psi}_{\!L}\gamma^\mu\partial_\mu\Psi_{\!L} + \text{total divergence}\,, \tag{G.2.6}$$

[135] The 16 matrices of Γ constitute a complete set that spans the sixteen-dimensional vector space of 4×4 matrices.

[136] In deriving eq. (G.2.6), we have used eq. (G.1.25) and the anticommutativity of the spinor fields. The total divergence can be dropped from the Lagrangian, as it does not contribute to the field equations.

the Lagrangian for a single Majorana field can be written in terms of a single Weyl field:[137]

$$\mathscr{L} = i\overline{\Psi}_L\gamma^\mu\partial_\mu\Psi_L + \tfrac{1}{2}m\left(\Psi_L^{\mathsf{T}}C^{-1}\Psi_L - \overline{\Psi}_L C\overline{\Psi}_L^{\mathsf{T}}\right) . \tag{G.2.7}$$

The corresponding free-field equation is

$$i\gamma^\mu\partial_\mu\Psi_L = mC\overline{\Psi}_L^{\mathsf{T}} , \tag{G.2.8}$$

where we have used $(\overline{\Psi}_L C)^{\mathsf{T}} = -C\overline{\Psi}_L^{\mathsf{T}}$ and the anticommutativity of Ψ_L, $\overline{\Psi}_L$. The generalization of eqs. (G.2.3)–(G.2.7) to the case of a multiplet of four-component Majorana fields is straightforward and is left as an exercise for the reader.

Of course, one could have chosen instead to rewrite the four-component Majorana fermion Lagrangian in terms of a single Weyl fermion, $\Psi_R(x) \equiv P_R\Psi(x)$, in which case the upper two components (in the chiral representation) of $\Psi(x)$ are not relevant. In this case, the Majorana and Weyl fields are related by:[138]

$$\Psi_M(x) = \Psi_R(x) + \Psi_L^C(x) , \tag{G.2.9}$$

where $\Psi_L^C(x)$ is defined in eq. (G.1.13). The corresponding Dirac conjugate field is given by $\overline{\Psi}_M(x) = \overline{\Psi}_R(x) + \overline{\Psi_L^C}(x)$, where

$$\overline{\Psi}_R(x) \equiv [P_R\Psi(x)]^\dagger A = \overline{\Psi}(x)P_L , \tag{G.2.10}$$

$$\overline{\Psi_L^C}(x) \equiv \overline{\Psi^C}(x)P_R = -\Psi^{\mathsf{T}}(x)C^{-1}P_R = -\Psi_R^{\mathsf{T}}(x)C^{-1} . \tag{G.2.11}$$

The corresponding Weyl fermion Lagrangian is given by eq. (G.2.7) with L replaced by R.

Thus, a Majorana fermion can be represented either by a four-component self-conjugate field $\Psi_M(x)$ or by a single Weyl field [either $\Psi_L(x)$ or $\Psi_R(x)$]. Both descriptions are unitarily equivalent [290, 300]; i.e., one can construct a unitary similarity transformation that connects a Majorana field operator and a Weyl field operator (and vice versa). Of course, this is hardly a surprise in the two-component spinor formalism, where both the Majorana and Weyl forms of the Lagrangian correspond to the same field theory of a single two-component spinor field $\xi_\alpha(x)$.

For $m \neq 0$, the Weyl Lagrangian given by eq. (G.2.7) possesses no global symmetry, and hence no conserved charge. In contrast, for $m = 0$ the Weyl Lagrangian exhibits a U(1) chiral symmetry. In a theory of massless neutrinos, the U(1) chiral charge of the neutrino is correlated with its lepton number L, and one is free to use either a Majorana or Weyl description. In the former, the neutrino is a neutral self-conjugate fermion, which is not an eigenstate of L. In the latter, $\Psi_L(x)$ corresponds to the left-handed neutrino and $\Psi_R^C(x)$ corresponds to the right-handed antineutrino, which are eigenstates of L with opposite sign lepton numbers. No experimental observable can distinguish between these two descriptions.

We now consider a collection of free anticommuting four-component Dirac fields, Ψ_i. The free-field Lagrangian (in terms of mass eigenstate fields) may be obtained from eq. (29.3.34) by converting to four-component spinor notation. We then obtain the standard textbook result:

$$\mathscr{L} = i\overline{\Psi}^i\gamma^\mu\partial_\mu\Psi_i - m_i\overline{\Psi}^i\Psi_i . \tag{G.2.12}$$

By writing $\Psi = \Psi_L + \Psi_R$, we see that the Lagrangian for a single Dirac field can be written in terms of two Weyl fields:

$$\mathscr{L} = i\overline{\Psi}_L\gamma^\mu\partial_\mu\Psi_L + i\overline{\Psi}_R\gamma^\mu\partial_\mu\Psi_R - m\left(\overline{\Psi}_L\Psi_R + \overline{\Psi}_R\Psi_L\right) . \tag{G.2.13}$$

[137] Using eq. (G.1.16), it follows that $(\Psi^{\mathsf{T}}C^{-1}\Psi)^\dagger = -\overline{\Psi}A^{-1}C^{-1\,*}A^{-1\,*}\overline{\Psi}^{\mathsf{T}} = -\overline{\Psi}\,C\,\overline{\Psi}^{\mathsf{T}}$.

[138] If Ψ is an unconstrained four-component spinor, then Ψ_L and Ψ_R are independent Weyl fields, in which case $\Psi_L + \Psi_R^C$ and $\Psi_R + \Psi_L^C$ are independent self-conjugate fields.

The corresponding free-field equations are:

$$i\gamma^\mu\partial_\mu\Psi_L = m\Psi_R\,, \qquad\qquad i\gamma^\mu\partial_\mu\Psi_R = m\Psi_L\,. \tag{G.2.14}$$

Summing these two equations yields the Dirac equation, $(i\gamma^\mu\partial_\mu - m)\Psi = 0$.

As a pedagogical example in which both Dirac and Majorana mass terms are present, we perform the diagonalization of the neutrino mass matrix in a one-generation seesaw model[139] using the four-component spinor formalism. Following Appendix A of [301], we first introduce a four-component anticommuting neutrino field ν_D, and the corresponding Weyl fields,

$$\nu_L \equiv P_L\nu_D\,, \qquad \nu_L^C \equiv P_L\nu_D^C\,, \qquad \nu_R \equiv P_R\nu_D\,, \quad \text{and} \quad \nu_R^C \equiv P_R\nu_D^C\,. \tag{G.2.15}$$

Note that eqs. (G.1.13) and (G.2.5) imply that the anticommuting Weyl fermion fields satisfy:

$$\overline{\nu_R^C}\nu_L^C = \overline{\nu_R}\nu_L\,, \qquad\qquad \overline{\nu_L^C}\nu_R^C = \overline{\nu_L}\nu_R\,. \tag{G.2.16}$$

A Dirac mass term for the neutrinos in the one-generation seesaw model couples ν_L and ν_L^C (and by hermiticity of the Lagrangian, ν_R^C and ν_R), and can be written equivalently as:

$$m_D(\nu_L^{\mathsf{T}}C^{-1}\nu_L^C + \nu_R^{\mathsf{T}}C^{-1}\nu_R^C) = -m_D(\overline{\nu_R^C}\nu_L^C + \overline{\nu_L^C}\nu_R^C) = -m_D(\overline{\nu_R}\nu_L + \overline{\nu_L}\nu_R) = -m_D\overline{\nu}_D\nu_D\,, \tag{G.2.17}$$

after making use of eq. (G.2.16). The Majorana mass term for the neutrinos in the one-generation seesaw model couples ν_L^C to itself (and by hermiticity of the Lagrangian, ν_R to itself), and can be written equivalently as:

$$\tfrac{1}{2}M(\nu_L^{C\,\mathsf{T}}C^{-1}\nu_L^C + \nu_R^{\mathsf{T}}C^{-1}\nu_R) = -\tfrac{1}{2}M(\overline{\nu_R}\nu_L^C + \overline{\nu_L^C}\nu_R)\,. \tag{G.2.18}$$

We shall define the phases of the neutrino fields such that the parameters m_D and M are real and non-negative.

Thus, the mass terms of the one-generation neutrino seesaw Lagrangian, given in eq. (J.2.18) in terms of two-component fermion fields, translates in four-component spinor notation to

$$\begin{aligned}
\mathscr{L}_{\text{mass}} &= -\tfrac{1}{2}m_D(\overline{\nu_L}\nu_R + \overline{\nu_R}\nu_L + \overline{\nu_L^C}\nu_R^C + \overline{\nu_R^C}\nu_L^C) - \tfrac{1}{2}M(\overline{\nu_R}\nu_L^C + \overline{\nu_L^C}\nu_R) \\
&= -\tfrac{1}{2}\begin{pmatrix}\overline{\nu_R^C} & \overline{\nu_R}\end{pmatrix}\begin{pmatrix}0 & m_D\\ m_D & M\end{pmatrix}\begin{pmatrix}\nu_L\\ \nu_L^C\end{pmatrix} - \tfrac{1}{2}\begin{pmatrix}\overline{\nu_L} & \overline{\nu_L^C}\end{pmatrix}\begin{pmatrix}0 & m_D\\ m_D & M\end{pmatrix}\begin{pmatrix}\nu_R^C\\ \nu_R\end{pmatrix} \\
&= \tfrac{1}{2}\begin{pmatrix}\nu_L^{\mathsf{T}} & \nu_L^{C\,\mathsf{T}}\end{pmatrix}C^{-1}\begin{pmatrix}0 & m_D\\ m_D & M\end{pmatrix}\begin{pmatrix}\nu_L\\ \nu_L^C\end{pmatrix} + \text{h.c.}\,,
\end{aligned} \tag{G.2.19}$$

where we have used eq. (G.2.16) to write the first line of eq. (G.2.19) in a symmetrical fashion and eqs. (G.1.13) and (G.2.5) to obtain the final form above. Note that if $M = 0$, then one can write $\mathscr{L}_{\text{mass}} = -m_D\overline{\nu}_D\nu_D$ and identify ν_D as a four-component massive Dirac neutrino.

The Takagi diagonalization of the neutrino mass matrix yields two mass eigenstates, which we designate by ν_ℓ and ν_h, where ℓ and h stand for *light* and *heavy*, respectively. The mass eigenstate Weyl neutrino fields are related to the interaction eigenstate Weyl neutrino fields via

$$\begin{pmatrix}\nu_L\\ \nu_L^C\end{pmatrix} = \mathcal{U}\begin{pmatrix}P_L\nu_\ell\\ P_L\nu_h^C\end{pmatrix}\,, \tag{G.2.20}$$

[139] In Appendix J.2 , the seesaw model of neutrino masses is introduced using the two-component spinor formalism.

where $\mathcal{U}$ is a 2×2 unitary matrix that is chosen such that

$$\mathcal{U}^{\mathsf{T}}\begin{pmatrix} 0 & m_D \\ m_D & M \end{pmatrix}\mathcal{U} = \begin{pmatrix} m_{\nu_\ell} & 0 \\ 0 & m_{\nu_h} \end{pmatrix}. \tag{G.2.21}$$

For $M \neq 0$, the neutrino mass eigenstates are *not* Dirac fermions. In the seesaw limit of $M \gg m_D$, the corresponding neutrino masses are $m_{\nu_\ell} \simeq m_D^2/M$ and $m_{\nu_h} \simeq M + m_D^2/M$, with $m_{\nu_\ell} \ll m_{\nu_h}$. In terms of the mass eigenstates, the neutrino mass Lagrangian is:

$$\mathscr{L}_{\rm mass} = \tfrac{1}{2}\left[m_{\nu_\ell}\nu_\ell^{\mathsf{T}}C^{-1}P_L\nu_\ell + m_{\nu_h}\nu_h^{C\,\mathsf{T}}C^{-1}P_L\nu_h^C\right] + \text{h.c.}\,, \tag{G.2.22}$$

after using eq. (G.1.25). We now define four-component self-conjugate Majorana neutrino fields, denoted by Ψ_ℓ and Ψ_h respectively, according to eqs. (G.2.3) and (G.2.9),

$$\Psi_\ell \equiv P_L\nu_\ell + P_R\,C\overline{\nu}_\ell^{\mathsf{T}}\,, \qquad \overline{\Psi}_\ell \equiv \overline{\nu}_\ell P_R - \nu_\ell^{\mathsf{T}}C^{-1}P_L\,, \tag{G.2.23}$$

$$\Psi_h \equiv P_R\nu_h + P_L C\overline{\nu}_h^{\mathsf{T}}\,, \qquad \overline{\Psi}_h \equiv \overline{\nu}_h P_L - \nu_h^{\mathsf{T}}C^{-1}P_R\,. \tag{G.2.24}$$

Then, eq. (G.2.22) reduces to the expected form:

$$\mathscr{L}_{\rm mass} = -\tfrac{1}{2}\left[m_{\nu_\ell}\overline{\Psi}_\ell\Psi_\ell + m_{\nu_h}\overline{\Psi}_h\Psi_h\right]. \tag{G.2.25}$$

A comparison with the analysis of the neutrino mass matrix given in Appendix J.2 exhibits the power and the simplicity of the two-component spinor formalism, as compared to the rather awkward four-component spinor analysis presented above.

29.7.8 Correspondence to four-component spinor notation 2

Gamma matrices and spinors in spacetimes of diverse dimensions and signatures

The translation from two-component to four-component spinor notation given in Appendix G.1 is specific to $3+1$ spacetime dimensions. In $d=4$ Euclidean space dimensions (independently of the choice of convention for the Minkowski metric), the Dirac gamma matrix algebra is defined by $\{\gamma_E^\mu\,,\,\gamma_E^\nu\} = 2\delta^{\mu\nu}\mathbb{1}$, where $\delta^{\mu\nu} \equiv \text{diag}(1\,,\,1\,,\,1\,,\,1)$. Using eqs. (A.23) and (G.1.2), the Euclidean gamma matrices (defined for $\mu,\,\nu = 1\,,\,\ldots\,,\,4$) are hermitian and given by $\gamma_E^k \equiv -i\gamma^k$ $(k=1,2,3)$, $\gamma_E^4 \equiv \gamma^0$ and $\gamma_{5E} \equiv -\gamma_E^1\gamma_E^2\gamma_E^3\gamma_E^4 = \gamma_5$ (e.g, see Appendix A.1.2 of [302]).[140] The four-dimensional reducible (Dirac) spinor representation corresponds to the $(\frac{1}{2},0)\otimes(0,\frac{1}{2})$ representation of SO(4), although the $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ representations are independent pseudo-real representations of SO(4) not related by hermitian conjugation, as noted at the end of Section 29.2. A complete treatment of Euclidean two-component spinors can be found in [130].

The Euclidean space formalism for fermions is necessary for a rigorous definition of the path integral in quantum field theory [122, 123]. Using the Euclidean Dirac gamma matrices introduced above, one can express the four-component Dirac Lagrangian directly in Euclidean space [223]. Carrying out the same procedure for the four-component Majorana Lagrangian is problematical. Because the $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ representations of SO(4) are not hermitian conjugates of each other, a self-conjugate Euclidean Majorana fermion does not exist. Nevertheless, it is possible to devise a continuous Wick rotation from Minkowski spacetime to Euclidean space for Dirac, Majorana

[140] One can also choose to define the Euclidean Dirac algebra by $\{\gamma_E^\mu\,,\,\gamma_E^\nu\} = -2\delta^{\mu\nu}\mathbb{1}$ (simply by multiplying all gamma matrices by a factor of i), in which case the Euclidean gamma matrices, $\gamma_E^k \equiv \gamma^k$ and $\gamma_E^4 \equiv i\gamma^0$ are anti-hermitian, and $\gamma_{5E} \equiv -\gamma_E^1\gamma_E^2\gamma_E^3\gamma_E^4 = \gamma_5$ is hermitian (e.g., see [303]). These conventions arise more naturally in the general treatment of gamma matrices in d spacetime dimensions as defined in eq. (G.3.1). The corresponding Euclidean sigma matrices would then be defined as in footnote 96.

and Weyl spinor fields and the gamma matrices. In particular, one can construct a non-hermitian Euclidean action for a single Majorana or Weyl field whose Green functions are related to the usual Minkowski space Green functions by analytic continuation and a Wick rotation of the spinor fields. Further details can be found in refs. [127, 128, 129].[141]

The two-component spinor technology of this review is specifically designed to treat spinors in three space and one time dimension. In theories of d spacetime dimensions (where d is any positive integer), more general techniques are required. By considering spinors in this more general setting, one gains insight into the concepts of Majorana, Weyl and Dirac spinors and their distinguishing features.

The mathematics of spinors [132] in spacetimes of dimension $d = t + s$ (where t is the number of time dimensions and s is the number of space dimensions) is most easily treated by introducing higher-dimensional analogues of the gamma matrices, Γ^μ, which satisfy the Clifford algebra [91, 92, 129, 133, 134, 135, 136, 137, 138, 142, 143, 144, 292, 304],[142]

$$\{\Gamma^\mu\,,\,\Gamma^\nu\} = 2\eta^{\mu\nu}\mathbb{1}\,, \qquad \eta^{\mu\nu} = \mathrm{diag}(\underbrace{+\,+\cdots+}_{t}\,,\underbrace{-\,-\cdots-}_{s})\,, \tag{G.3.1}$$

where the identity matrix $\mathbb{1}$ and the Γ^μ are $2^{[d/2]}\times 2^{[d/2]}$ matrices, and $[d/2]$ is the integer part of $d/2$,

$$[d/2] \equiv \begin{cases} d/2\,, & \text{for } d \text{ even},\\ (d-1)/2\,, & \text{for } d \text{ odd}. \end{cases} \tag{G.3.2}$$

The choice of (s,t) denotes the signature of the spacetime. One can choose $\Gamma^{\mu\,\dagger} = \Gamma^\mu$ for $\mu = 1,2,...,t$ and $\Gamma^{\mu\,\dagger} = -\Gamma^\mu$ for $\mu = t{+}1\,,\ t{+}2\,,\ ...\,,\ d$. We identify $\frac{1}{2}\Sigma^{\mu\nu} \equiv \frac{1}{4}\,i\,[\Gamma^\mu\,,\,\Gamma^\nu]$ as the generators of $\mathrm{SO}(s,t)$ in the spinor representation. Next, we introduce the $[d/2]$-component (complex) Dirac spinor Ψ and its Dirac conjugate $\overline{\Psi} \equiv \Psi^\dagger A$, where $A = \Gamma^1\Gamma^2\cdots\Gamma^t$ is a unitary matrix that satisfies:[143]

$$A\Gamma^\mu A^{-1} = (-1)^{t+1}\Gamma^{\mu\,\dagger}\,, \qquad A^\dagger = (-1)^{t(t-1)/2}A\,. \tag{G.3.3}$$

One can now build $\mathrm{SO}(s,t)$-covariant bilinears, $\overline{\Psi}\Gamma\Psi$, where Γ is a product of gamma matrices. Biquadratic spinor Fierz identities involving quantities such as $(\overline{\Psi}_1\Gamma^I\Psi_2)(\overline{\Psi}_3\Gamma_I\Psi_4)$ can also be derived [305], where the $\Gamma^I = \big\{\mathbb{1}\,,\,\Gamma^\mu, \Gamma^{\mu\nu}\ (\mu<\nu)\,,\,\Gamma^\mu\Gamma^\nu\Gamma^\lambda\ (\mu<\nu<\lambda)\,,\,...,\Gamma^1\Gamma^2\cdots\Gamma^{2[d/2]}\big\}$ are a complete set of $2^{2[d/2]}$ linearly independent matrices [which generalizes eq. (G.1.102)].

If d is even, one can also introduce the d-dimensional analogue of γ_5 by defining[144]

$$\Gamma_{d+1} \equiv i^{(s-t)/2}\,\Gamma^1\Gamma^2\cdots\Gamma^d\,, \tag{G.3.4}$$

which is hermitian and satisfies $(\Gamma_{d+1})^2 = \mathbb{1}$ and $\{\Gamma^\mu\,,\,\Gamma_{d+1}\} = 0$. In the case of even-dimensional spacetimes, there are two possible choices for the charge-conjugated spinor Ψ^C,[145]

$$\Psi^C = B_\eta^{-1}\Psi^*\,, \qquad \text{where} \quad \eta = \pm 1\,, \tag{G.3.5}$$

and the B_η are unitary matrices that satisfy:

$$B_\eta\Gamma^\mu B_\eta^{-1} = \eta\Gamma^{\mu\,*}\,, \qquad \eta = \pm 1\,. \tag{G.3.6}$$

[141] Previous attempts in the literature to define Euclidean Majorana field theories can be found in [126].

[142] This includes the Euclidean case [141] corresponding to $t = 0$ and $s = d$ [cf. footnote 140], and the Minkowski case corresponding to $t = 1$ and $s = d - 1$.

[143] In d-dimensional Euclidean space (where $t = 0$), $\Gamma^{\mu\,\dagger} = -\Gamma^\mu$ for all $\mu = 1,2,...,d$. As a result, we may choose $A = \mathbb{1}$, in which case $\overline{\Psi} = \Psi^\dagger$.

[144] For $t = 1$ and d even, one traditionally takes $\mu = 0,1,2,...,d-1$ (where 0 is the time index), in which case, $\Gamma_{d+1} \equiv i^{(d-2)/2}\,\Gamma^0\Gamma^1\cdots\Gamma^{d-1}$.

[145] In four-dimensional Minkowski spacetime, we identify $D = B_-^{-1}$ [cf. eq. (G.1.18)] and $\gamma_5 D = B_+^{-1}$.

For even d, a convenient choice is $B_+ = B_-\Gamma_{d+1}$ [137].

If d is odd with signature (s,t), then the $2^{(d-1)/2}\times 2^{(d-1)/2}$ gamma matrices Γ^μ $(\mu = 1,2,...,d)$ consist of $\{\Gamma^1,\Gamma^2,...,\Gamma^{d-1},\pm i\Gamma_{d+1}\}$ of the $(d-1)$-dimensional theory of signature $(s-1,t)$. By assumption, $\mu = d$ is a space index, so that $\Gamma^d \equiv \pm i\Gamma_{d+1}$ is anti-hermitian. In the case of odd d, only one sign choice for η, namely $\eta = (-1)^{(s-t+1)/2}$, is consistent with eq. (G.3.6) as applied to Γ^d.[146] Consequently, only one definition of the charge-conjugated spinor is viable, namely $\Psi^C = B_-^{-1}\Psi^*$ for $s-t = 1,\,5 \pmod 8$ and $\Psi^C = B_+^{-1}\Psi^*$ for $s-t = 3,\,7 \pmod 8$.

One important property of the B_η is [129, 133, 136, 142, 143]:

$$B_\eta^* B_\eta = \varepsilon_\eta\,, \qquad \varepsilon_\eta = \pm 1\,, \tag{G.3.7}$$

for $\eta = \pm 1$ in even-dimensional spacetimes and $\eta = (-1)^{(s-t+1)/2}$ in odd-dimensional spacetimes. In particular [136],[147]

$$\varepsilon_- = \begin{cases} +1\,, & \text{for } s-t = 0,1,2 \pmod 8\,,\\ -1\,, & \text{for } s-t = 4,5,6 \pmod 8\,,\end{cases} \qquad \varepsilon_+ = \begin{cases} +1\,, & \text{for } s-t = 0,6,7 \pmod 8\,,\\ -1\,, & \text{for } s-t = 2,3,4 \pmod 8\,.\end{cases} \tag{G.3.8}$$

Using the charge-conjugated spinor defined in eq. (G.3.5), one can define a self-conjugate spinor, $\Psi^C = \Psi$. Two cases arise depending on the sign of η [136, 142, 143, 144],

$$\text{Majorana spinor:} \qquad \Psi = B_-^{-1}\Psi^*\,, \tag{G.3.9}$$

$$\text{pseudo-Majorana spinor:} \qquad \Psi = B_+^{-1}\Psi^*\,. \tag{G.3.10}$$

Due to the reality conditions [eqs. (G.3.9) and (G.3.10)], the (pseudo-)Majorana spinor possesses $2^{[d/2]}$ real degrees of freedom. Using eq. (G.3.7), one immediately sees that eqs. (G.3.9) and (G.3.10) are respectively consistent if and only if $\varepsilon_\eta = +1$.[148] The possible existence of Majorana [pseudo-Majorana] spinors in d-dimensional spacetime depends on the choice of $s-t$ such that $\varepsilon_- = +1$ [$\varepsilon_+ = +1$]. Using eq. (G.3.8), it follows that Majorana spinors can only exist in spacetimes where $s-t = 0,\,1,\,2 \pmod 8$, and pseudo-Majorana can only exist in spacetimes where $s-t = 0,\,6,\,7 \pmod 8$.[149] In particular, a Majorana spinor cannot exist in four-dimensional Euclidean space.

Given a choice of sign for $\eta = \pm 1$, one can define a corresponding charge conjugation matrix C_η, which is unitary and is defined by[150]

$$C_\eta \equiv B_\eta^{\mathsf T} A\,, \qquad \text{where} \quad C_\eta \Gamma^\mu C_\eta^{-1} = \eta(-1)^{t+1}\Gamma^{\mu\,\mathsf T}\,. \tag{G.3.11}$$

Eq. (G.3.5) then yields $\Psi^C = C_\eta^*\,\overline{\Psi}^{\mathsf T}$. The unitary matrices A, B_η and C_η satisfy the following useful identities[136, 142]:

$$B_\eta^{\mathsf T} = \varepsilon_\eta B_\eta\,, \qquad C_\eta^{\mathsf T} = \varepsilon_\eta \eta^t (-1)^{t(t-1)/2} C_\eta\,, \qquad A^* B_\eta = \eta^t B_\eta A\,, \qquad A^{\mathsf T} C_\eta = \eta^t C_\eta A^{-1}\,. \tag{G.3.12}$$

[146] The two sign choices for Γ^d correspond to two inequivalent representations of the Clifford algebra [eq. (G.3.1)] for d odd. Nevertheless, the corresponding $\Sigma^{\mu\nu}$ yield equivalent spinor representations of $\mathrm{SO}(s,t)$.

[147] For d even, one can use $B_+ = B_-\Gamma_{d+1}$ and $B_\eta\Gamma_{d+1}B_\eta^{-1} = (-1)^{(s-t)/2}\Gamma_{d+1}^*$ to derive $\varepsilon_+ = (-1)^{(s-t)/2}\,\varepsilon_-$.

[148] If $\varepsilon_\eta = -1$ then one can introduce a generalized reality condition [cf. eq. (G.3.16)], which constrains the structure of a multiplet of Dirac fermions that transforms under a pseudo-real representation of the flavor group. In this case, the corresponding (generalized) self-conjugate spinors are called symplectic (pseudo-)Majorana spinors, as discussed below eq. (G.3.20).

[149] As shown in [136, 142], no $\mathrm{SO}(s,t)$-invariant mass term is allowed for a pseudo-Majorana spinor.

[150] In four-dimensional Minkowski spacetime, we identify $C = (C_-^{\mathsf T})^{-1} = C_-^*$ [cf. eq. (G.1.11)] and $B = C_+$ [cf. eq. (G.1.20)]. In this case, one cannot use C_+ to consistently define a self-conjugate spinor, as the corresponding $\varepsilon_+ = -1$.

In the case of even d, one can define left and right-handed chiral projection operators:

$$P_L \equiv \tfrac{1}{2}(1-\Gamma_{d+1})\,, \qquad P_R \equiv \tfrac{1}{2}(1+\Gamma_{d+1})\,, \tag{G.3.13}$$

and introduce Weyl fermions, Ψ_L and Ψ_R, which satisfy $\Gamma_{d+1}\Psi_{R,L} = \pm\Psi_{R,L}$. Equivalently,

$$\Psi_L \equiv P_L\Psi\,, \qquad \Psi_R \equiv P_R\Psi\,, \tag{G.3.14}$$

so that Ψ_L (and likewise Ψ_R) possesses $2^{(d-2)/2}$ complex degrees of freedom. It is possible for a spinor to be simultaneously a (pseudo) Majorana and a Weyl spinor if the spinor and its charge conjugate have the same chirality, in which case $B_\eta\Gamma_{d+1}B_\eta^{-1} = \Gamma_{d+1}^*$ (for even d). The latter condition holds when $i^{s-t} = 1$ or equivalently $s-t = 0$ (mod 4). Combining this requirement with the condition for the existence of a (pseudo) Majorana spinor, it follows that a (pseudo) Majorana-Weyl spinor, which possesses $2^{(d-2)/2}$ real degrees of freedom, can only exist in spacetimes where $s-t = 0$ (mod 8). For further details, see refs. [92, 133, 134, 135, 136, 142, 143, 144, 292].

As in Section 29.3.2, one can also consider a multiplet of fermions Ψ_i that transforms under a complex, real or pseudo-real representation R of the flavor group G as

$$\Psi_i \to (D_R)_i{}^j\Psi_j\,, \qquad D_R = \exp(-i\theta^a\boldsymbol{T_R^a})\,, \qquad i,j = 1,2,...,d_R\,, \tag{G.3.15}$$

where D_R is unitary and the corresponding generators $\boldsymbol{T_R^a}$ are hermitian. The dimension of R is denoted by d_R, which must be even in the pseudo-real case. In both the real and pseudo-real cases, one can also impose a reality condition that generalizes the Majorana conditions of eqs. (G.3.9) and (G.3.10),

$$(\Psi_i)^* \equiv \Psi^{*\,i} = W^{ij}B_\eta\Psi_j\,, \tag{G.3.16}$$

where W is a unitary matrix and B_η acts on the (suppressed) spinor indices of Ψ_j. Additional constraints on the form of W are obtained as follows. First, taking the complex conjugate of eq. (G.3.16) and inserting the result back into the same equation, it follows that

$$W^*W = \varepsilon_\eta\mathbb{1}\,, \tag{G.3.17}$$

after making use of eq. (G.3.7). Second, eq. (G.3.16) must hold true if Ψ is replaced by $D_R\Psi$ on both sides of the equation, in order to be compatible with the flavor symmetry group transformation law [eq. (G.3.15)]. This latter requirement combined with eq. (G.3.17) yields:

$$D_R = \varepsilon_\eta W^* D_R^* W = W^{-1}D_R^* W\,. \tag{G.3.18}$$

Eq. (G.3.18) can be expressed in terms of the flavor group generators,

$$i\boldsymbol{T_R^a} = W^{-1}(i\boldsymbol{T_R^a})^*\,W\,. \tag{G.3.19}$$

Comparing with eqs. (E.1.4)–(E.1.6), we conclude that the unitary matrix W satisfies:

$$W = \varepsilon_\eta W^{\mathsf{T}}\,, \qquad \varepsilon_\eta = \begin{cases} +1\,, & R \text{ is a real representation}\,, \\ -1\,, & R \text{ is a pseudo-real representation}\,. \end{cases} \tag{G.3.20}$$

When R is a real representation, $W = W^{\mathsf{T}}$, and a basis for the flavor group generators can be chosen such that $W = \mathbb{1}$ [cf. eq. (E.1.7)], in which case D_R is a real orthogonal matrix. Since $\varepsilon_\eta = +1$, eq. (G.3.16) yields (pseudo-)Majorana spinors (depending on the sign of η) as defined previously in eqs. (G.3.9) and (G.3.10).

When R is a pseudo-real representation, $W = -W^{\mathsf{T}}$, and a basis for the flavor group generators can be chosen such that $W = J \equiv \mathrm{diag}\left\{\left(\begin{smallmatrix}0&1\\-1&0\end{smallmatrix}\right), \left(\begin{smallmatrix}0&1\\-1&0\end{smallmatrix}\right), \cdots, \left(\begin{smallmatrix}0&1\\-1&0\end{smallmatrix}\right)\right\}$ is a $d_R \times d_R$ matrix, where d_R is even [cf. eq. (E.1.8)]. In this case, $D_R^{\mathsf{T}}JD_R = J$, which implies that D_R is a unitary

symplectic matrix [138]. Moreover, $\varepsilon_\eta = -1$, which was incompatible with the reality conditions of eqs. (G.3.9) and (G.3.10), but is compatible with the generalized reality condition of eq. (G.3.16).

Therefore, we define *symplectic* (pseudo-)Majorana spinors [139, 136, 138, 144, 292] to be spinors that transform as a pseudo-real representation under some flavor group and satisfy the generalized reality condition of eq. (G.3.16), where W is a unitary antisymmetric matrix, depending on the choice of $\eta = \pm 1$ (with $\eta = -1$ yielding the "pseudo" designation). As suggested by eqs. (29.3.35)–(29.3.40), $2d_R$ symplectic (pseudo-)Majorana spinors are equivalent to d_R Dirac fermions. The possible existence of symplectic (pseudo-)Majorana spinors in a d-dimensional spacetime is governed by eq. (G.3.8). Requiring that $\varepsilon_\eta = -1$ implies that symplectic Majorana spinors exist in spacetimes where $s-t = 4, 5, 6 \pmod 8$, and symplectic pseudo-Majorana spinors exist in spacetimes where $s-t = 2, 3, 4 \pmod 8$. Using this nomenclature, the fermions described by the four-dimensional Minkowski space Lagrangian given in eq. (29.3.35) are symplectic pseudo-Majorana spinors.

Four-component spinor wave functions

In four-dimensional Minkowski space, the free four-component Majorana field can be expanded in a Fourier series; each positive [negative] frequency mode is multiplied by a *commuting* spinor wave function $u(\vec{\boldsymbol{p}}, s)$ [$v(\vec{\boldsymbol{p}}, s)$] as in eq. (29.3.11),[151]

$$\Psi_{Mi}(x) = \sum_s \int \frac{d^3\vec{\boldsymbol{p}}}{(2\pi)^{3/2}(2E_{\boldsymbol{p}i})^{1/2}} \left[u(\vec{\boldsymbol{p}}, s)a_i(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x} + v(\vec{\boldsymbol{p}}, s)a_i^\dagger(\vec{\boldsymbol{p}}, s)e^{ip\cdot x}\right] , \tag{G.4.1}$$

where $E_{\boldsymbol{p}i} \equiv (|\vec{\boldsymbol{p}}|^2 + m_i^2)^{1/2}$, and the creation operators $a_i^\dagger$ and the annihilation operators a_i satisfy anticommutation relations:

$$\{a_i(\vec{\boldsymbol{p}}, s), a_j^\dagger(\vec{\boldsymbol{p}}\,', s')\} = \delta^3(\vec{\boldsymbol{p}} - \vec{\boldsymbol{p}}')\delta_{ss'}\delta_{ij} , \tag{G.4.2}$$

with all other anticommutation relations vanishing. We employ covariant normalization of the one-particle states given by eq. (29.3.13). It then follows that

$$\langle 0|\, \Psi_M(x)\, |\vec{\boldsymbol{p}}, s\rangle = u(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x} , \qquad \langle 0|\, \overline{\Psi}_M(x)\, |\vec{\boldsymbol{p}}, s\rangle = \bar{v}(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x} , \tag{G.4.3}$$

$$\langle \vec{\boldsymbol{p}}, s|\, \overline{\Psi}_M(x)\, |0\rangle = \bar{u}(\vec{\boldsymbol{p}}, s)e^{ip\cdot x} , \qquad \langle \vec{\boldsymbol{p}}, s|\, \Psi_M(x)\, |0\rangle = v(\vec{\boldsymbol{p}}, s)e^{ip\cdot x} . \tag{G.4.4}$$

These results are the four-component spinor versions of eqs. (29.3.7) and (29.3.8).

Likewise, the free Dirac field can be expanded in a Fourier series,

$$\Psi_i(x) = \sum_s \int \frac{d^3\vec{\boldsymbol{p}}}{(2\pi)^{3/2}(2E_{\boldsymbol{p}i})^{1/2}} \left[u(\vec{\boldsymbol{p}}, s)a_i(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x} + v(\vec{\boldsymbol{p}}, s)b_i^\dagger(\vec{\boldsymbol{p}}, s)e^{ip\cdot x}\right] , \tag{G.4.5}$$

where the creation operators $a_i^\dagger$ and $b_i^\dagger$ and the annihilation operators a_i and b_i satisfy anticommutation relations:

$$\{a_i(\vec{\boldsymbol{p}}, s), a_j^\dagger(\vec{\boldsymbol{p}}\,', s')\} = \delta^3(\vec{\boldsymbol{p}} - \vec{\boldsymbol{p}}')\delta_{ss'}\delta_{ij} , \tag{G.4.6}$$

$$\{b_i(\vec{\boldsymbol{p}}, s), b_j^\dagger(\vec{\boldsymbol{p}}\,', s')\} = \delta^3(\vec{\boldsymbol{p}} - \vec{\boldsymbol{p}}')\delta_{ss'}\delta_{ij} , \tag{G.4.7}$$

with all other anticommutation relations vanishing. We employ covariant normalization of the fermion (F) and antifermion ($\overline{F}$) one-particle states given by eq. (29.3.22). It then follows that

$$\langle 0|\, \Psi(x)\, |\vec{\boldsymbol{p}}, s; F\rangle = u(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x} , \qquad \langle 0|\, \overline{\Psi}(x)\, \big|\vec{\boldsymbol{p}}, s; \overline{F}\big\rangle = \bar{v}(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x} , \tag{G.4.8}$$

$$\langle \vec{\boldsymbol{p}}, s; F|\, \overline{\Psi}(x)\, |0\rangle = \bar{u}(\vec{\boldsymbol{p}}, s)e^{ip\cdot x} , \qquad \big\langle \vec{\boldsymbol{p}}, s; \overline{F}\big|\, \Psi(x)\, |0\rangle = v(\vec{\boldsymbol{p}}, s)e^{ip\cdot x} , \tag{G.4.9}$$

[151] Some subtleties arise in the choice of relative phases of the creation and annihilation operators, which are related to the C, CP and CPT transformation properties of the Majorana field. For further details, see [306].

and the four other single-particle matrix elements vanish. These results are the four-component spinor versions of eqs. (29.3.23)–(29.3.26). The Fourier expansion of the charge-conjugated free Dirac field $\Psi_i^C(x) = C\overline{\Psi}_i^{\mathsf{T}}(x)$ is given by:

$$\Psi_i^C(x) = \sum_s \int \frac{d^3\vec{\boldsymbol{p}}}{(2\pi)^{3/2}(2E_{\boldsymbol{p}i})^{1/2}} \left[u(\vec{\boldsymbol{p}},s)b_i(\vec{\boldsymbol{p}},s)e^{-ip\cdot x} + v(\vec{\boldsymbol{p}},s)a_i^\dagger(\vec{\boldsymbol{p}},s)e^{ip\cdot x}\right], \tag{G.4.10}$$

where we have used eq. (G.4.13). That is, the charge conjugation transformation interchanges the annihilation and creation operators, $a_i \leftrightarrow b_i$ and $a_i^\dagger \leftrightarrow b_i^\dagger$. Thus, if $\Psi^C(x) = \Psi(x)$, then we must identify $a = b$ and $a^\dagger = b^\dagger$, corresponding to the free Majorana field given in eq. (G.4.1).

The two-component spinor momentum space wave functions are related to the traditional four-component spinor wave functions according to:

$$u(\vec{\boldsymbol{p}},s) = \begin{pmatrix} x_\alpha(\vec{\boldsymbol{p}},s) \\ y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)\end{pmatrix}, \qquad \bar u(\vec{\boldsymbol{p}},s) = (y^\alpha(\vec{\boldsymbol{p}},s),\ x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)), \tag{G.4.11}$$

$$v(\vec{\boldsymbol{p}},s) = \begin{pmatrix} y_\alpha(\vec{\boldsymbol{p}},s) \\ x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)\end{pmatrix}, \qquad \bar v(\vec{\boldsymbol{p}},s) = (x^\alpha(\vec{\boldsymbol{p}},s),\ y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)), \tag{G.4.12}$$

where the u and v-spinors are related by

$$v(\vec{\boldsymbol{p}},s) = C\bar u(\vec{\boldsymbol{p}},s)^{\mathsf{T}}, \qquad u(\vec{\boldsymbol{p}},s) = C\bar v(\vec{\boldsymbol{p}},s)^{\mathsf{T}}, \tag{G.4.13}$$

$$\bar v(\vec{\boldsymbol{p}},s) = -u(\vec{\boldsymbol{p}},s)^{\mathsf{T}}C^{-1}, \qquad \bar u(\vec{\boldsymbol{p}},s) = -v(\vec{\boldsymbol{p}},s)^{\mathsf{T}}C^{-1}. \tag{G.4.14}$$

The spin quantum number takes on values $s = \pm\frac{1}{2}$, and refers either to the component of the spin as measured in the rest frame with respect to a fixed axis or to the helicity (as discussed in Section 29.3.1 and Appendix C). Note that the u and v-spinors also satisfy:

$$v(\vec{\boldsymbol{p}},s) = -2s\gamma_5 u(\vec{\boldsymbol{p}},-s), \qquad u(\vec{\boldsymbol{p}},s) = 2s\gamma_5 v(\vec{\boldsymbol{p}},-s), \tag{G.4.15}$$

which follows from eq. (29.3.22). Explicit forms for the four-component spinor wave functions in the chiral representation can be obtained using eqs. (29.3.18)–(29.3.21), where $\chi_s(\hat{\boldsymbol{s}})$ is given in eq. (C.1.11). For helicity spinors, further simplifications result by employing eqs. (C.3.3)–(C.3.6).

One can check that u and v satisfy the Dirac equations

$$(\not p - m)\,u(\vec{\boldsymbol{p}},s) = (\not p + m)\,v(\vec{\boldsymbol{p}},s) = 0, \tag{G.4.16}$$

$$\bar u(\vec{\boldsymbol{p}},s)\,(\not p - m) = \bar v(\vec{\boldsymbol{p}},s)\,(\not p + m) = 0, \tag{G.4.17}$$

corresponding to eqs. (29.3.9)–(29.3.12), and

$$(2s\gamma_5 \not S - 1)\,u(\vec{\boldsymbol{p}},s) = (2s\gamma_5 \not S - 1)\,v(\vec{\boldsymbol{p}},s) = 0, \tag{G.4.18}$$

$$\bar u(\vec{\boldsymbol{p}},s)\,(2s\gamma_5 \not S - 1) = \bar v(\vec{\boldsymbol{p}},s)\,(2s\gamma_5 \not S - 1) = 0, \tag{G.4.19}$$

corresponding to eqs. (29.3.23)–(29.3.26), where the spin vector S^μ is defined in eq. (29.3.15).[152] For massive fermions, eqs. (29.3.45)–(29.3.48) correspond to

$$u(\vec{\boldsymbol{p}},s)\bar u(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(1 + 2s\gamma_5 \not S)\,(\not p + m), \tag{G.4.20}$$

$$v(\vec{\boldsymbol{p}},s)\bar v(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(1 + 2s\gamma_5 \not S)\,(\not p - m). \tag{G.4.21}$$

[152] We use the standard Feynman slash notation: $\not p \equiv \gamma_\mu p^\mu$ and $\not S \equiv \gamma_\mu S^\mu$.

To apply the above formulae to the massless case we must employ helicity states, where s is replaced by the helicity quantum number λ, and S^μ is defined by eq. (29.3.16). In particular, in the $m \to 0$ limit, $S^\mu = p^\mu/m + \mathcal{O}(m/E)$. Inserting this result in eqs. (G.4.18) and (G.4.19) and using the Dirac equations, it follows that the massless helicity spinors are eigenstates of γ_5,

$$\gamma_5 u(\vec{\boldsymbol{p}},\lambda) = 2\lambda u(\vec{\boldsymbol{p}},\lambda)\,, \qquad\qquad \gamma_5 v(\vec{\boldsymbol{p}},\lambda) = -2\lambda v(\vec{\boldsymbol{p}},\lambda)\,. \tag{G.4.22}$$

Combining these results with eq. (G.4.15) [with s replaced by λ] yields:

$$v(p,\lambda) = -2\lambda\gamma_5 u(p,-\lambda) = u(p,-\lambda)\,, \qquad\qquad \lambda = \pm\tfrac{1}{2}\,, \tag{G.4.23}$$

and we see that the massless u and v spinors of opposite helicity are the same.

Applying the above $m \to 0$ limiting procedure to eqs. (G.4.20) and (G.4.21) and using the mass-shell condition ($\not{p}\not{p} = p^2 = m^2$), one obtains the massless helicity projection operators corresponding to eqs. (29.3.53)–(29.3.56):

$$u(\vec{\boldsymbol{p}},\lambda)\bar{u}(\vec{\boldsymbol{p}},\lambda) = \tfrac{1}{2}(1+2\lambda\gamma_5)\,\not{p}\,, \tag{G.4.24}$$

$$v(\vec{\boldsymbol{p}},\lambda)\bar{v}(\vec{\boldsymbol{p}},\lambda) = \tfrac{1}{2}(1-2\lambda\gamma_5)\,\not{p}\,. \tag{G.4.25}$$

Summing over the spin degree of freedom, we obtain the spin-sum identities corresponding to eqs. (29.3.57)–(29.3.60),

$$\sum_s u(\vec{\boldsymbol{p}},s)\bar{u}(\vec{\boldsymbol{p}},s) = \not{p} + m\,, \tag{G.4.26}$$

$$\sum_s v(\vec{\boldsymbol{p}},s)\bar{v}(\vec{\boldsymbol{p}},s) = \not{p} - m\,, \tag{G.4.27}$$

$$\sum_s u(\vec{\boldsymbol{p}},s)v^{\mathsf{T}}(\vec{\boldsymbol{p}},s) = (\not{p}+m)C^{\mathsf{T}}\,, \tag{G.4.28}$$

$$\sum_s \bar{u}^{\mathsf{T}}(\vec{\boldsymbol{p}},s)\bar{v}(\vec{\boldsymbol{p}},s) = C^{-1}(\not{p}-m)\,, \tag{G.4.29}$$

$$\sum_s \bar{v}^{\mathsf{T}}(\vec{\boldsymbol{p}},s)\bar{u}(\vec{\boldsymbol{p}},s) = C^{-1}(\not{p}+m)\,, \tag{G.4.30}$$

$$\sum_s v(\vec{\boldsymbol{p}},s)u^{\mathsf{T}}(\vec{\boldsymbol{p}},s) = (\not{p}-m)C^{\mathsf{T}}\,, \tag{G.4.31}$$

which are valid for both the massive case and the massless $m \to 0$ limit.

As previously noted, the results for the bilinear covariants obtained in eqs. (G.1.79)–(G.1.90) can also be applied to expressions involving the commuting spinor wave functions. Various relations among the possible bilinear covariants can be established by using eqs. (G.4.13) and (G.4.14). As an example, for $\Gamma = \mathbb{1}\,,\ \gamma_5\,,\ \gamma^\mu\,,\ \gamma^\mu\gamma_5\,,\ \Sigma^{\mu\nu}\,,\ \Sigma^{\mu\nu}\gamma_5$,

$$\bar{u}(\vec{\boldsymbol{p}}_1,s_1)\Gamma v(\vec{\boldsymbol{p}}_2,s_2) = -v(\vec{\boldsymbol{p}}_1,s_1)^{\mathsf{T}}C^{-1}\Gamma C\bar{u}(\vec{\boldsymbol{p}}_2,s_2)^{\mathsf{T}} = -\eta_\Gamma^C\,\bar{u}(\vec{\boldsymbol{p}}_2,s_2)\Gamma v(\vec{\boldsymbol{p}}_1,s_1)\,, \tag{G.4.32}$$

$$\bar{u}(\vec{\boldsymbol{p}}_1,s_1)\Gamma u(\vec{\boldsymbol{p}}_2,s_2) = -v(\vec{\boldsymbol{p}}_1,s_1)^{\mathsf{T}}C^{-1}\Gamma C\bar{v}(\vec{\boldsymbol{p}}_2,s_2)^{\mathsf{T}} = -\eta_\Gamma^C\,\bar{v}(\vec{\boldsymbol{p}}_2,s_2)\Gamma v(\vec{\boldsymbol{p}}_1,s_1)\,, \tag{G.4.33}$$

where the sign η_Γ^C [defined in eq. (G.1.25)] arises after taking the transpose and applying eq. (G.1.25). In particular, the (commuting) u and v spinors satisfy the following relations:

$$\bar{u}(\vec{\boldsymbol{p}}_1,s_1)P_L v(\vec{\boldsymbol{p}}_2,s_2) = -\bar{u}(\vec{\boldsymbol{p}}_2,s_2)P_L v(\vec{\boldsymbol{p}}_1,s_1)\,, \tag{G.4.34}$$

$$\bar{u}(\vec{\boldsymbol{p}}_1,s_1)P_R v(\vec{\boldsymbol{p}}_2,s_2) = -\bar{u}(\vec{\boldsymbol{p}}_2,s_2)P_R v(\vec{\boldsymbol{p}}_1,s_1)\,, \tag{G.4.35}$$

$$\bar{u}(\vec{\boldsymbol{p}}_1,s_1)\gamma^\mu P_L v(\vec{\boldsymbol{p}}_2,s_2) = \bar{u}(\vec{\boldsymbol{p}}_2,s_2)\gamma^\mu P_R v(\vec{\boldsymbol{p}}_1,s_1)\,, \tag{G.4.36}$$

$$\bar{u}(\vec{\boldsymbol{p}}_1,s_1)\gamma^\mu P_R v(\vec{\boldsymbol{p}}_2,s_2) = \bar{u}(\vec{\boldsymbol{p}}_2,s_2)\gamma^\mu P_L v(\vec{\boldsymbol{p}}_1,s_1)\,, \tag{G.4.37}$$

and four similar relations obtained by interchanging $v(\vec{\boldsymbol{p}}_2,s_2) \leftrightarrow u(\vec{\boldsymbol{p}}_2,s_2)$.

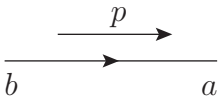
Feynman rules for four-component fermions

We now illustrate some basic applications of the above formalism. In particular, we shall establish a set of Feynman rules for four-component fermions that treat both Dirac and Majorana fermions on the same footing. These rules generalize the standard Feynman rules for four-component Dirac fermions found in most quantum field theory textbooks. Two advantages of the rules presented here are: (i) no factors of the charge conjugation matrix C are required for fermion interaction vertices and propagators, and (ii) the *relative* sign between different diagrams corresponding to the same physical process is simply determined. Our rules have been obtained by translating our two-component fermion Feynman rules into the four-component spinor language. The resulting Feynman rules for four-component Majorana fermions are equivalent to the set of rules independently obtained in [307] (see also refs. [308, 309]).

Consider first the Feynman rule for the four-component fermion propagator. Virtual Dirac fermion lines can either correspond to Ψ or Ψ^C. Here, there is no ambiguity in the propagator Feynman rule, since for free Dirac fermion fields,[153]

$$\langle 0|\, T[\Psi_a(x)\overline{\Psi}^b(y)]\,|0\rangle = \langle 0|\, T[\Psi^C_a(x)\overline{\Psi^C}^{\,b}(y)]\,|0\rangle \ , \tag{G.5.1}$$

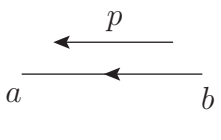
so that the Feynman rules for the propagator of a Ψ and Ψ^C line, exhibited in Fig. G.5.1, are identical. The same rule also applies to a four-component Majorana fermion.



$$\frac{i(\not{p}+m)_a{}^b}{p^2-m^2+i\epsilon}$$

Figure G.5.1: Feynman rule for the propagator of a four-component fermion with mass m. The same rule applies to a Majorana, Dirac and charge-conjugated Dirac fermion. The four-component spinor labels a and b are specified.

Using eq. (G.1.2), the four-component fermion propagator Feynman rule can be expressed as a partitioned matrix of 2×2 blocks,



$$= \left(\begin{array}{cc} \leftarrow\!\!\rightarrow & \leftarrow \\ \rightarrow & \rightarrow\!\!\leftarrow \end{array}\right) = \frac{i}{p^2-m^2+i\epsilon}\begin{pmatrix} m\,\delta_\alpha{}^\beta & p\cdot\sigma_{\alpha\dot\beta} \\ p\cdot\overline{\sigma}^{\dot\alpha\beta} & m\,\delta^{\dot\alpha}{}_{\dot\beta} \end{pmatrix} , \tag{G.5.2}$$

where a and b are four-component spinor indices. That is, eq. (G.5.2) is a partitioned matrix whose blocks consist of two-component fermion propagators defined in Fig. 29.4.1, with the undotted and dotted α [β] indices on the left [right] and with the momentum flowing from right to left.

The derivation of the four-component Dirac fermion propagator is treated in most modern textbooks of quantum field theory (see, e.g., [115]). Here, we briefly sketch the path integral derivation of the four-component fermion propagator by exploiting the path integral treatment of the two-component fermion propagators outlined in Appendix F . Consider a single massive Dirac fermion $\Psi(x)$ coupled to an anticommuting four-component Dirac fermionic source term

$$J_\psi(x) \equiv \begin{pmatrix} J_{\eta\alpha}(x) \\ J^{\dagger\dot\alpha}_\chi(x) \end{pmatrix} . \tag{G.5.3}$$

[153] In deriving eq. (G.5.1), we have used $\mathcal{C}\,\Psi_a\,\mathcal{C}^{-1} = \eta_c\Psi^C_a$ and $\mathcal{C}\,\overline{\Psi}^{\,a}\,\mathcal{C}^{-1} = \eta_c^*\,\overline{\Psi^C}^{\,a}$, where $\mathcal{C}$ is the charge conjugation *operator* that acts on the quantum Hilbert space and η_c is a convention-dependent phase factor [37, 39]. Note that $\mathcal{C}$ is a unitary operator and $\mathcal{C}\,|0\rangle = |0\rangle$ in the free-field vacuum.

The corresponding action [eq. (F.2)] in four-component notation is given by

$$S = \int d^4x\,(\mathscr{L} + \overline{J}_\psi\Psi + \overline{\Psi}\,J_\psi) = \int d^4x\,\left[\overline{\Psi}(i\partial\!\!\!/ - m)\Psi + \overline{J}_\psi\Psi + \overline{\Psi}\,J_\psi\right]\,. \tag{G.5.4}$$

Introducing the momentum space Fourier coefficients:

$$\Psi(x) = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot x}\widehat{\Psi}(p)\,, \qquad J_\psi(x) = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot x}\widehat{J}_\psi(p)\,, \tag{G.5.5}$$

we can identify the following four-component quantities with matrices of two-component quantities given in eqs. (F.7) and (F.25):

$$\widehat{\Psi}(p) = A^{-1}\Omega_c(p)\,, \qquad \widehat{J}_\psi(p) = X_c(p)\,, \qquad p\!\!\!/ - m = \mathcal{M}(p)A\,, \tag{G.5.6}$$

where A is the Dirac conjugation matrix defined in eqs. (G.1.10) and (G.1.12). Using the results of Appendix F , one easily derives:

$$\langle 0|T(\Psi(x_1)\overline{\Psi}(x_2))|0\rangle = \left(-i\frac{\overrightarrow{\delta}}{\delta\overline{J}_\psi(x_1)}\right) W[J,\overline{J}] \left(-i\frac{\overleftarrow{\delta}}{\delta J_\psi(x_2)}\right)\Bigg|_{J_\psi=\overline{J}_\psi=0}\,, \tag{G.5.7}$$

where

$$W[J_\psi\,,\,\overline{J}_\psi] = \exp\left\{-i\int \frac{d^4p}{(2\pi)^4}\widehat{\overline{J}}_\psi(p)\frac{p\!\!\!/ + m}{p^2 - m^2}\widehat{J}_\psi(p)\right\}\,. \tag{G.5.8}$$

Using the analogues of eqs. (F.21) and (F.22), we end up with the expected result

$$\langle 0|T(\Psi(x_1)\overline{\Psi}(x_2))|0\rangle = \int \frac{d^4p}{(2\pi)^4}\, e^{-ip\cdot(x_1-x_2)}\,\frac{i(p\!\!\!/ + m)}{p^2 - m^2}\,. \tag{G.5.9}$$

In principle, the analogous computation can be carried out for a single four-component Majorana fermion field $\Psi_M(x)$ coupled to a Majorana fermionic source, $J_\xi(x)$. The corresponding action is similar to that of eq. (G.5.4), with an extra overall factor of 1/2. However, in evaluating the functional derivative in eq. (G.5.8), one must take into account that the Majorana fermionic source $J_\xi(x)$ satisfies $J_\xi^C \equiv C\overline{J}_\xi^{\mathsf{T}} = J_\xi$. Consequently, the functional derivative with respect to $\overline{J}_\xi$ is related to the corresponding functional derivative with respect to J_ξ. Hence, the calculation of eq. (G.5.8) will yield two equal terms that will cancel the overall factor of 1/2, resulting again in eq. (G.5.9). Nevertheless, this computation is somewhat awkward using four-component spinor notation, in contrast to the straightforward calculation of Appendix F .

We next examine the various interactions involving four-component fermions. First, we consider the interactions of a neutral scalar ϕ or a gauge boson A^a_μ with a pair of Majorana fermions To obtain the interactions of the four-component fermion fields, we first identify the neutral two-component fermion mass eigenstate neutral fields ξ_i. Using eqs. (29.4.9) and (29.4.15), the interaction Lagrangian in two-component form is given by:

$$\mathscr{L}_{\rm int} = -\tfrac{1}{2}(\lambda^{ij}\xi_i\xi_j + \lambda_{ij}\xi^{\dagger i}\xi^{\dagger j})\phi - (G^a)_i{}^j\,\xi^{\dagger i}\overline{\sigma}^\mu\xi_j A^a_\mu\,, \tag{G.5.10}$$

where λ is a complex symmetric matrix with $\lambda^{ij} \equiv \lambda^*_{ij}$ [cf. eq. (29.3.2)], the A^a_μ are the mass eigenstate gauge fields, and the corresponding hermitian matrices G^a are defined in eq. (29.4.16). It is now simple to convert this result into four-component notation:

$$\mathscr{L}_{\rm int} = -\tfrac{1}{2}(\lambda^{ij}\overline{\Psi}_{Mi}P_L\Psi_{Mj} + \lambda_{ij}\overline{\Psi}^i_M P_R\Psi^j_M)\phi - (G^a)_i{}^j\overline{\Psi}^i_M\gamma^\mu P_L\Psi_{Mj}A^a_\mu\,, \tag{G.5.11}$$

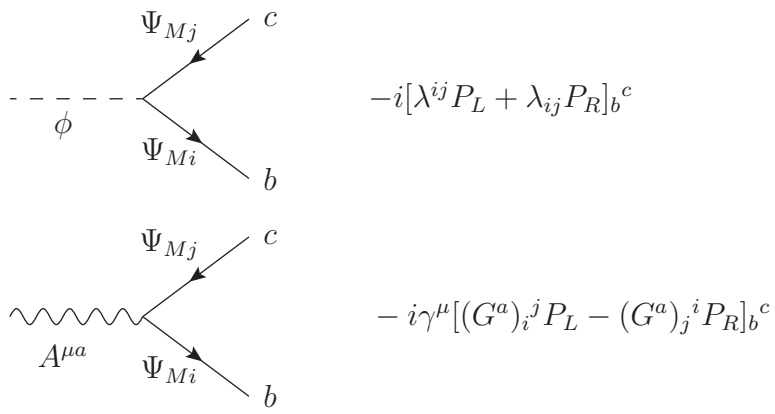


Figure G.5.2: Feynman rules for neutral scalar and gauge boson interactions with a pair of four-component Majorana fermions (labeled by four-component spinor indices b and c). The G^a are defined in eq. (29.4.16). The index a runs over the neutral (mass eigenstate) gauge bosons.

where the Ψ_{Mj} are a set of (neutral) Majorana four-component fermions. It is convenient to use eq. (G.1.99) to rewrite the term proportional to $(G^a)_i{}^j$ in eq. (G.5.11) as follows

$$\begin{aligned}(G^a)_i{}^j\overline{\Psi}{}^i_M\gamma^\mu P_L\Psi_{Mj} &= \tfrac{1}{2}(G^a)_i{}^j\left[\overline{\Psi}{}^i_M\gamma^\mu P_L\Psi_{Mj} - \overline{\Psi}_{Mj}\gamma^\mu P_R\Psi^i_M\right]\\ &= \tfrac{1}{2}\overline{\Psi}_{Mi}\gamma^\mu\left[(G^a)_i{}^j P_L - (G^a)_j{}^i P_R\right]\Psi_{Mj}\,.\end{aligned}\tag{G.5.12}$$

In the last step above, we have lowered the flavor indices of the four-component Majorana fermion fields, as the heights of these indices can be arbitrarily chosen [cf. eq. (G.1.77)].

Using standard four-component spinor methods, the corresponding four-component spinor Feynman rules are displayed in Fig. G.5.2. A Majorana fermion is neutral under all conserved charges (and thus equal to its own antiparticle). Hence, an arrow on a Majorana fermion line simply reflects the structure of the interaction Lagrangian; i.e., $\overline{\Psi}_M$ [Ψ_M] is represented by an arrow pointing out of [into] the vertex. These arrows are then used for determining the placement of the u and v spinors in an invariant amplitude, according to the rules of Appendix G.6 . In particular, the four-component spinor labels of Fig. G.5.2 indicate that one should traverse any continuous fermion line by moving antiparallel to the direction of the fermion arrows.

Next, we consider the interactions of a (possibly complex) scalar Φ or a gauge boson A^a_μ with a pair of Dirac fermions. The Dirac fermions are charged with respect to some global or local U(1) symmetry, which is assumed to be a symmetry of the Lagrangian. To obtain the interactions of the four-component fermion fields, we first identify the mass-degenerate oppositely charged pairs χ_j and η_j (with U(1)-charges q_j and $-q_j$, respectively) that combine to form the mass eigenstate Dirac fermions. The scalar field Φ carries a U(1)-charge q_Φ. We also identify the gauge boson mass eigenstates of definite U(1)-charge by A^a_μ as described in Section 29.4.3 (cf. footnote 47). Using eqs. (29.4.9) and (29.4.18), the interaction Lagrangian in two-component form is given by:

$$\mathscr{L}_{\rm int} = -\kappa^i{}_j\chi_i\eta^j\Phi - \kappa_i{}^j\chi^{\dagger i}\eta^\dagger_j\Phi^\dagger - \left[(G^a_L)_i{}^j\chi^{\dagger i}\overline{\sigma}^\mu\chi_j - (G^a_R)_j{}^i\eta^\dagger_i\overline{\sigma}^\mu\eta^j\right]A^a_\mu\,,\tag{G.5.13}$$

where $\kappa_i{}^j \equiv (\kappa^i{}_j)^*$ [cf. eq. (29.3.28)] and κ is an arbitrary complex matrix coupling, subject to the conditions that $\kappa^i{}_j = 0$ unless $q_\Phi = q_j - q_i$. For the gauge boson couplings, we follow the notation of eqs. (29.4.19) and (29.4.20). In particular, $A^a_\mu G^a_L$ and $A^a_\mu G^a_R$ are hermitian matrix-valued gauge fields, which when summed over a can contain both neutral and charged [with respect to U(1)] mass eigenstate gauge boson fields. Converting to four-component notation yields:

$$\mathscr{L}_{\rm int} = -\kappa^i{}_j\overline{\Psi}{}^j P_L\Psi_i\Phi - \kappa_i{}^j\overline{\Psi}{}^i P_R\Psi_j\Phi^\dagger - \left[(G^a_L)_i{}^j\overline{\Psi}{}^i\gamma^\mu P_L\Psi_j + (G^a_R)_i{}^j\overline{\Psi}{}^i\gamma^\mu P_R\Psi_j\right]A^a_\mu\,,\tag{G.5.14}$$

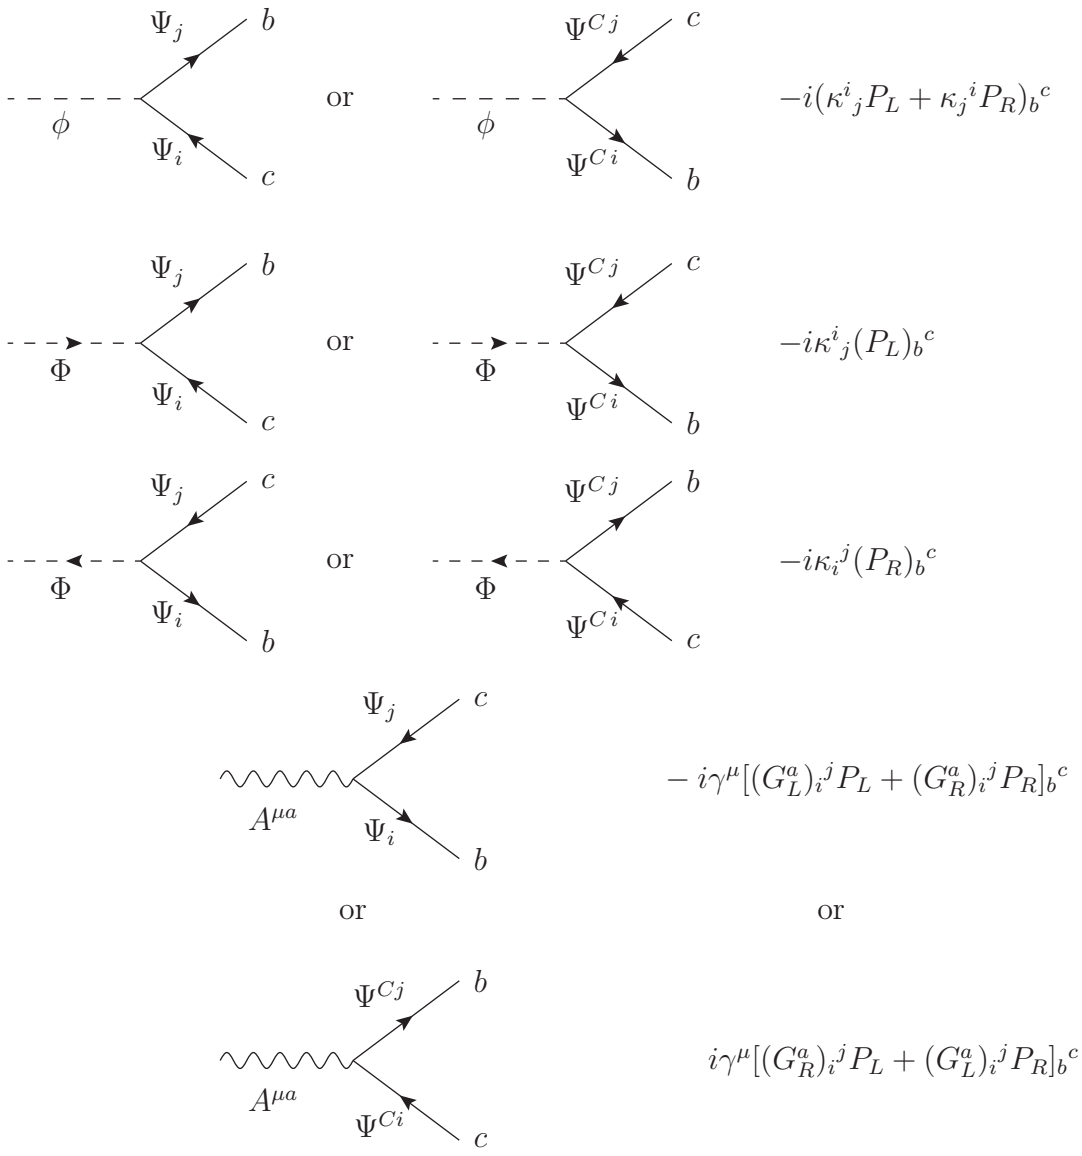

Figure G.5.3: Feynman rules for neutral scalar (ϕ), charged scalar (Φ) and gauge boson ($A^{\mu a}$) interactions with a pair of four-component Dirac fermions (labeled by four-component spinor indices b and c). In each case, one has two choices for the corresponding Feynman rule: one involving Ψ and one involving the oppositely charged Ψ^C (with the arrows of the corresponding Ψ and Ψ^C lines pointing in opposite directions). The arrows indicate the direction of flow of the U(1)-charges of the Dirac fermion and charged scalar fields. The index a runs over both neutral and charged (mass eigenstate) gauge bosons, consistent with charge conservation at the vertex.

where the Ψ_j are a set of Dirac four-component fermions. If Φ is a real (neutral) scalar field, then we shall write $\phi \equiv \Phi = \Phi^\dagger$. The corresponding four-component spinor Feynman rules are exhibited in Fig. G.5.3. The rules involving the charge-conjugated Dirac fields have been obtained by using eq. (G.1.91). Note that the arrows on the charged scalar and Dirac fermion lines depict the flow of the conserved U(1)-charge.

Finally, we treat the interaction of a charged scalar boson Φ (with U(1)-charge q_Φ) or a charged vector boson W (with U(1)-charge q_W) with a fermion pair consisting of one Majorana and one

Dirac fermion. We denote the neutral fermion mass eigenstate fields by ξ_i and pairs of oppositely charged fermion mass eigenstate fields by χ_j and η^j (with U(1)-charges q_j and $-q_j$, respectively). Using eqs. (29.4.9) and (29.4.21), the interaction Lagrangian is given by:

$$\begin{aligned}\mathscr{L}_{\rm int} = &-(\kappa_1)^i{}_j\xi_i\eta^j + (\kappa_2)_{ij}\xi^{\dagger i}\chi^{\dagger j}]\Phi - [(\kappa_2)^{ij}\xi_i\chi_j + (\kappa_1)_i{}^j\xi_i^{\dagger i}\eta_j^\dagger]\Phi^\dagger \\ &-[(G_1)_j{}^i\chi^{\dagger j}\overline{\sigma}^\mu\xi_i - (G_2)_{ij}\xi^{\dagger i}\overline{\sigma}^\mu\eta^j]W_\mu - [(G_1)^j{}_i\xi^{\dagger i}\overline{\sigma}^\mu\chi_j - (G_2)^{ij}\eta_j^\dagger\overline{\sigma}^\mu\xi_i]W_\mu^\dagger\,, \qquad \text{(G.5.15)}\end{aligned}$$

where κ_1, κ_2, G_1, and G_2 are arbitrary complex coupling matrices, subject to the conditions that $(\kappa_1)^i{}_j = (\kappa_2)_{ij} = 0$ unless $q_\Phi = q_j$, and $(G_1)_j{}^i = (G_2)_{ij} = 0$ unless $q_W = q_j$. Converting to four-component spinor notation yields:

$$\begin{aligned}\mathscr{L}_{\rm int} = &-\left[(\kappa_1)^i{}_j\overline{\Psi}^j P_L\Psi_{Mi} + (\kappa_2)_{ij}\overline{\Psi}^j P_R\Psi_M^i\right]\Phi \\ &-\left[(G_1)_j{}^i\overline{\Psi}^j\gamma^\mu P_L\Psi_{Mi} + (G_2)_{ij}\overline{\Psi}^j\gamma^\mu P_R\Psi_M^i\right]W_\mu + \text{h.c.} \qquad \text{(G.5.16)}\end{aligned}$$

The corresponding four-component spinor Feynman rules are exhibited in Fig. G.5.4.

There is an equivalent form for the interactions given by eqs. (G.5.13) and (G.5.16) where $\mathscr{L}_{\rm int}$ is written in terms of charge-conjugated Dirac fields [after using eq. (G.1.91)]. The Feynman rules involving Dirac fermions can take two possible forms, as shown in Figs. G.5.3 and G.5.4. As previously noted, the direction of an arrow on a Dirac fermion line indicates the direction of the fermion charge flow (whereas the arrow on the Majorana fermion line is unconnected to charge flow). However, we are free to choose either a Ψ or Ψ^C line to represent a Dirac fermion at any place in a given Feynman graph.[154] For any decay or scattering process, a suitable choice of either the Ψ-rule or the Ψ^C-rule at each vertex (the choice can be different at different vertices), will guarantee that the arrow directions on fermion lines flow continuously through the Feynman diagram. Then, to evaluate an invariant amplitude, one should traverse *any* continuous fermion line (either Ψ or Ψ^C) by moving antiparallel to the direction of the fermion arrows, as indicated by the order of the four-component spinor labels in the Feynman rules of Figs. G.5.3 and G.5.4. Examples will be provided in Appendix G.6 .

29.7.9 Correspondence to four-component spinor notation 3

Applications of four-component spinor Feynman rules

For a given process, there may be a number of distinct choices for the arrow directions on the Majorana fermion lines, which may depend on whether one represents a given Dirac fermion by Ψ or Ψ^C. However, different choices do *not* lead to independent Feynman diagrams.[155] When computing an invariant amplitude, one first writes down the relevant Feynman diagrams with no arrows on any Majorana fermion line. The number of distinct graphs contributing to the process is then determined. Finally, one makes some choice for how to distribute the arrows on the Majorana fermion lines and how to label Dirac fermion lines (either as the field Ψ or its charge conjugate Ψ^C) in a manner consistent with the rules of Figs. G.5.2 and G.5.4. The end result for the invariant amplitude (apart from an overall unobservable phase) does not depend on the choices made for the direction of the fermion arrows.

Using the above procedure, the Feynman rules for the external fermion wave functions are the same for Dirac and Majorana fermions:

- $u(\vec{\boldsymbol{p}}, s)$: incoming Ψ [or Ψ^C] with momentum $\vec{\boldsymbol{p}}$ parallel to the arrow direction,

[154] Since the charge of Ψ^C is opposite in sign to the charge of Ψ, the corresponding arrow directions of the Ψ and Ψ^C lines must point in opposite directions.

[155] In contrast, the two-component Feynman rules developed in Section 29.4 require that two vertices differing by the direction of the arrows on the two-component fermion lines must both be included in the calculation of the matrix element.

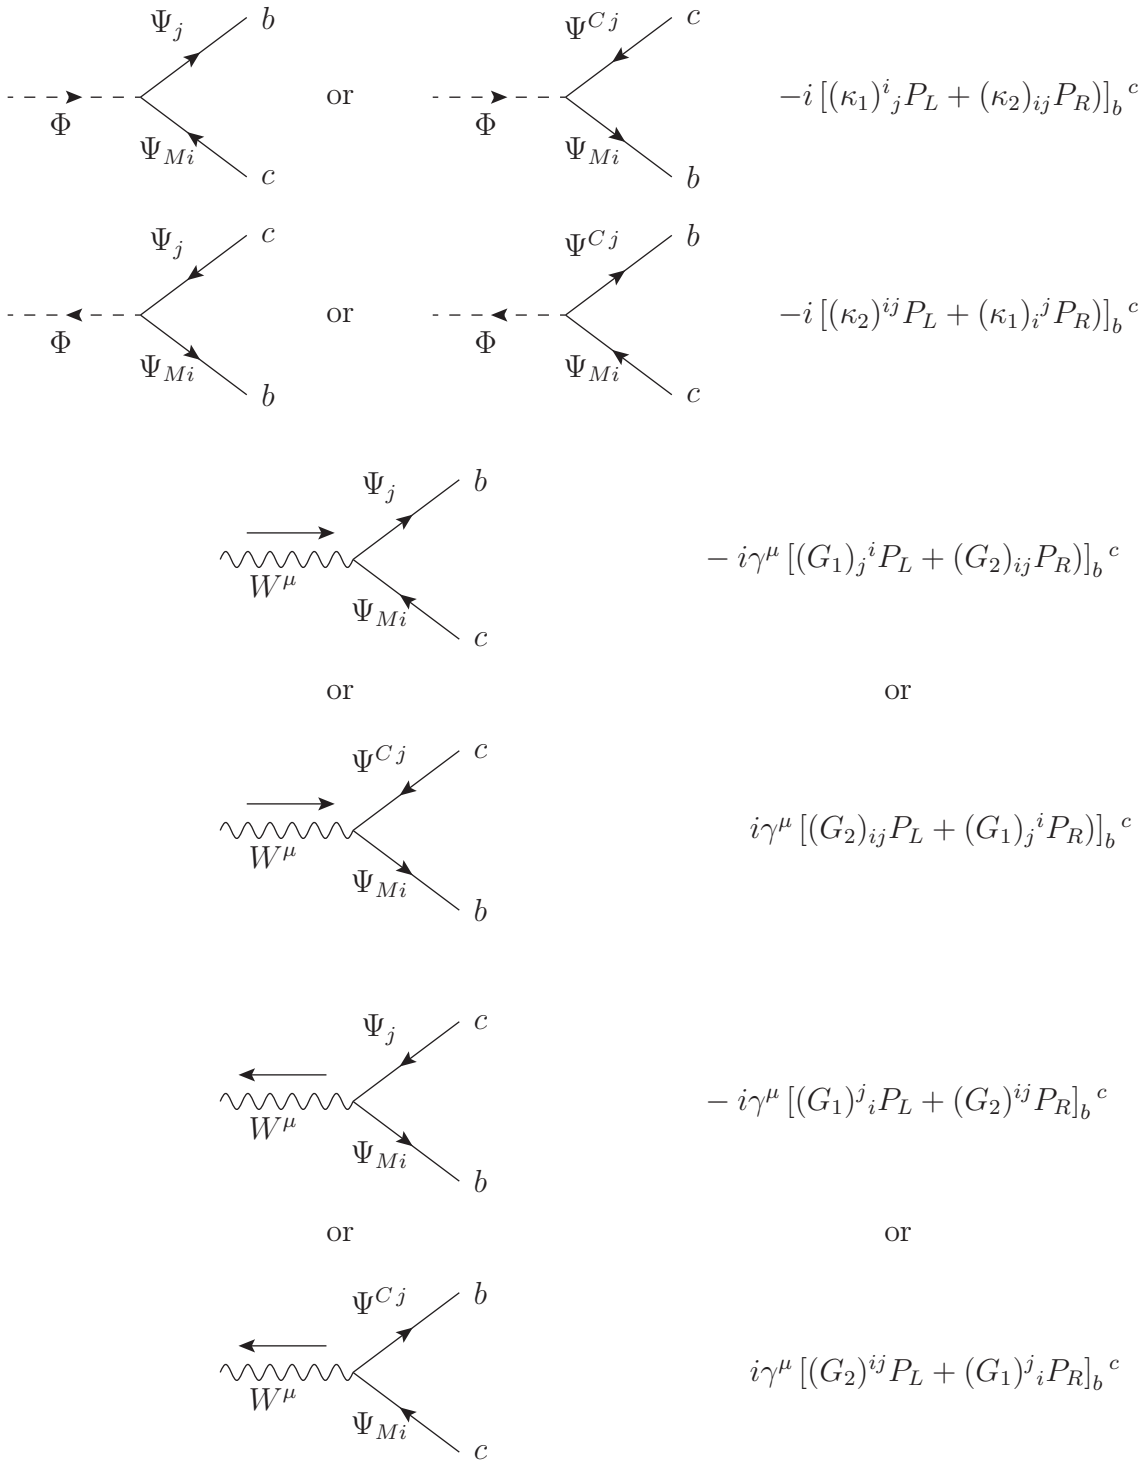

Figure G.5.4: Feynman rules for charged scalar and vector boson interactions with a fermion pair consisting of one Majorana and one Dirac four-component fermion (labeled by four-component spinor indices b and c). In each case, one has two choices for the corresponding Feynman rule: one involving Ψ and one involving the oppositely charged Ψ^C (with the arrows of the Ψ and Ψ^C lines pointing in opposite directions). The arrows of the Dirac fermion and charged bosons indicate the direction of flow of the corresponding U(1)-charges. That is, the charge of the boson (either Φ or W above) must coincide with the charge of Ψ_j. The arrows of the Majorana fermions satisfy the requirement that the fermion line arrow directions flow continuously through the vertex.

- $\bar{u}(\vec{\boldsymbol{p}}, s)$: outgoing Ψ [or Ψ^C] with momentum $\vec{\boldsymbol{p}}$ parallel to the arrow direction,
- $v(\vec{\boldsymbol{p}}, s)$: outgoing Ψ [or Ψ^C] with momentum $\vec{\boldsymbol{p}}$ antiparallel to the arrow direction,
- $\bar{v}(\vec{\boldsymbol{p}}, s)$: incoming Ψ [or Ψ^C] with momentum $\vec{\boldsymbol{p}}$ antiparallel to the arrow direction.

The proof that the above rules for external wave functions apply unambiguously to Majorana fermions is straightforward. Simply insert the plane wave expansion of the Majorana field given by eq. (G.4.1) into eq. (G.5.11), and evaluate matrix elements for, e.g., the decay of a scalar or vector particle into a pair of Majorana fermions.

We now reconsider the matrix elements for scalar and vector particle decays into fermion pairs and $2 \to 2$ elastic scattering of a fermion off a scalar and vector boson, respectively. We shall compute the matrix elements using the Feynman rules of Fig. G.5.2, and check that the results agree with the ones obtained by two-component methods in Section 29.4.5.

Consider first the decay of a neutral scalar boson ϕ into a pair of Majorana fermions, $\phi \to \Psi_{Mi}(\vec{\boldsymbol{p}}_1, s_1)\Psi_{Mj}(\vec{\boldsymbol{p}}_2, s_2)$, of flavor i and j, respectively. Here, $\Psi_{Mi}(\vec{\boldsymbol{p}}, s)$ denotes the one-particle state given by eq. (29.3.13). The matrix element for the decay is given by

$$i\mathcal{M} = -i\bar{u}(\vec{\boldsymbol{p}}_1, s_1)(\lambda^{ij} P_L + \lambda_{ij} P_R) v(\vec{\boldsymbol{p}}_2, s_2)\,. \tag{G.6.1}$$

One can easily check that this result matches with eq. (29.4.2), which was derived using two-component spinor techniques. Note that if one had chosen to switch the two final states (equivalent to switching the directions of the Majorana fermion arrows), then the resulting matrix element would simply exhibit an overall sign change [due to the results of eqs. (G.4.34) and (G.4.35)]. This overall sign change is a consequence of the Fermi-Dirac statistics, and corresponds to changing which order one uses to construct the two-particle final state.

Consider next the decay of a (neutral or charged) scalar boson Φ into a pair of Dirac fermions, $\Phi \to F_i(\vec{\boldsymbol{p}}_1, s_1)\overline{F}^j(\vec{\boldsymbol{p}}_2, s_2)$, where by $F(\vec{\boldsymbol{p}}, s)$ and $\overline{F}(\vec{\boldsymbol{p}}, s)$ we mean the one-particle states given by eq. (29.3.22). The matrix element for the decay is given by

$$i\mathcal{M} = -i\bar{u}(\vec{\boldsymbol{p}}_1, s_1)(\kappa^j{}_i P_L + \kappa_i{}^j P_R) v(\vec{\boldsymbol{p}}_2, s_2)\,, \tag{G.6.2}$$

which is equivalent to eq. (29.4.5), which was derived using two-component spinor techniques.

For the decay of a neutral vector boson (denoted by A_μ) into a pair of Majorana fermions, $A_\mu \to \Psi_{Mi}(\vec{\boldsymbol{p}}_1, s_1)\Psi_{Mj}(\vec{\boldsymbol{p}}_2, s_2)$, we use the Feynman rules of Fig. G.5.2 to obtain:

$$i\mathcal{M} = -i\bar{u}(\vec{\boldsymbol{p}}_1, s_1)\gamma^\mu \left[G_i{}^j P_L - G_j{}^i P_R\right] v(\vec{\boldsymbol{p}}_2, s_2)\varepsilon_\mu\,, \tag{G.6.3}$$

The above result is equivalent to eq. (29.4.8), which was derived using two-component spinor techniques. Again, we note that if one had chosen to switch the two final states (equivalent to switching the directions of the Majorana fermion arrows), then the resulting matrix element would simply exhibit an overall sign change [due to the results of eqs. (G.4.36) and (G.4.37)].

For $i = j$, eq. (G.6.3) simplifies to

$$i\mathcal{M} = iG\bar{u}(\vec{\boldsymbol{p}}_1, s_1)\gamma^\mu\gamma_5 v(\vec{\boldsymbol{p}}_2, s_2)\varepsilon_\mu\,, \tag{G.6.4}$$

where $G \equiv G_i{}^i$. The absence of a vector coupling of the vector boson to a pair of identical Majorana fermions is a consequence of the identity $\overline{\Psi}_M\gamma^\mu\Psi_M = 0$ noted below eq. (G.1.98).

For the decay of a (neutral or charged) vector particle A_μ into a fermion pair consisting of a Dirac fermion and antifermion, $A_\mu \to F_i(\vec{\boldsymbol{p}}_1, s_1)\overline{F}^j(\vec{\boldsymbol{p}}_2, s_2)$, the matrix element is given by:

$$i\mathcal{M} = -i\bar{u}(\vec{\boldsymbol{p}}_1, s_1)\gamma^\mu \left[(G_L)_i{}^j P_L + (G_R)_i{}^j P_R\right] v(\vec{\boldsymbol{p}}_2, s_2)\varepsilon_\mu\,, \tag{G.6.5}$$

which matches the result of eq. (29.4.12).

Finally, we consider the decay of a charged boson to a fermion pair consisting of one Dirac fermion and one Majorana fermion. Using the Feynman rules of Fig. G.5.4, we see that we have a choice of two rules for each decay process. As an example, consider the decay $W \to \Psi_{Mi}(\vec{\boldsymbol{p}}_1, s_1)F_j(\vec{\boldsymbol{p}}_2, s_2)$. If we apply the $W\Psi_M\Psi$ Feynman rule of Fig. G.5.4, we obtain:

$$i\mathcal{M} = -i\bar{u}(\vec{\boldsymbol{p}}_2, s_2)\left[(G_1)_j{}^i P_L + (G_2)_{ij}P_R\right] v(\vec{\boldsymbol{p}}_1, s_1)\,. \tag{G.6.6}$$

If we apply the corresponding $W\Psi_M\Psi^C$ Feynman rule, we obtain the negative of eq. (G.6.6) with $P_L \leftrightarrow P_R$ and $(\vec{\boldsymbol{p}}_1, s_1) \leftrightarrow (\vec{\boldsymbol{p}}_2, s_2)$. Using eqs. (G.4.36) and (G.4.37), the resulting amplitude is the negative of eq. (G.6.6), as expected since the order of the spinor wave functions in the two computations is reversed. A similar conclusion is obtained for the decay $\Phi \to \Psi_{Mi}F_j$.

Turning to the elastic scattering of a Majorana fermion and a neutral scalar, we shall examine two equivalent ways for computing the amplitude. Following the rules previously stated, there are two possible choices for the direction of arrows on the Majorana fermion lines. Thus, we may evaluate either one of the following two diagrams:

plus a second set of diagrams (not shown) where the initial and final state scalars are crossed.

Evaluating the first diagram above, the matrix element for $\phi\Psi_M \to \phi\Psi_M$ is given by:

$$\begin{aligned} i\mathcal{M} &= \frac{-i}{s-m^2}\,\bar{u}(\vec{\boldsymbol{p}}_2, s_2)(\lambda P_L + \lambda^* P_R)(\not{p}+m)(\lambda P_L + \lambda^* P_R)u(\vec{\boldsymbol{p}}_1, s_1) + (\text{crossed}) \\ &= \frac{-i}{s-m^2}\,\bar{u}(\vec{\boldsymbol{p}}_2, s_2)\left[|\lambda|^2\not{p} + \left(\lambda^2 P_L + (\lambda^*)^2 P_R\right)m\right]u(\vec{\boldsymbol{p}}_1, s_1) + (\text{crossed})\,, \end{aligned} \tag{G.6.7}$$

where m is the Majorana fermion mass and $\sqrt{s}$ is the center-of-mass energy. Using eqs. (G.1.2) and (G.4.11), one recovers the results of eq. (29.4.13). Had we chosen to evaluate the second diagram instead, the resulting amplitude would have been given by:

$$i\mathcal{M} = \frac{-i}{s-m^2}\,\bar{v}(\vec{\boldsymbol{p}}_1, s_1)\left[-|\lambda|^2\not{p} + \left(\lambda^2 P_L + (\lambda^*)^2 P_R\right)m\right]v(\vec{\boldsymbol{p}}_2, s_2) + (\text{crossed})\,. \tag{G.6.8}$$

Using eq. (G.4.33), it follows that:

$$\bar{v}(\vec{\boldsymbol{p}}_1, s_1)v(\vec{\boldsymbol{p}}_2, s_2) = -\bar{u}(\vec{\boldsymbol{p}}_2, s_2)u(\vec{\boldsymbol{p}}_1, s_1)\,, \tag{G.6.9}$$

$$\bar{v}(\vec{\boldsymbol{p}}_1, s_1)\gamma^\mu v(\vec{\boldsymbol{p}}_2, s_2) = \bar{u}(\vec{\boldsymbol{p}}_2, s_2)\gamma^\mu u(\vec{\boldsymbol{p}}_1, s_1)\,. \tag{G.6.10}$$

Consequently, the amplitude computed in eq. (G.6.8) is just the negative of eq. (G.6.7). This is expected, since the order of spinor wave functions in eq. (G.6.8) is an odd permutation of the order of spinor wave functions in eq. (G.6.7) [(12) and (21), respectively]. As in the two-component Feynman rules, the overall sign of the amplitude is arbitrary, but the relative signs of any pair of diagrams is unambiguous. This relative sign is positive [negative] if the permutation of the order of spinor wave functions of one diagram relative to the other diagram is even [odd].

Next, we consider the elastic scattering of a charged fermion and a neutral scalar. Again, we examine two equivalent ways for computing the amplitude. Following our rules, there are two possible choices for the directions of the fermion line arrows, depending on whether we represent the fermion by Ψ or Ψ^C. Thus, we may evaluate either one of the following two diagrams:

plus a second set of diagrams (not shown) where the initial and final state scalars are crossed. Evaluating the first diagram above, the matrix element for $\phi F \to \phi F$ is given by eq. (G.6.7), with λ replaced by κ. Had we chosen to evaluate the second diagram instead, the resulting amplitude would have been given by eq. (G.6.8), with λ replaced by κ. Thus, the discussion above in the case of neutral fermion scattering processes also applies to charged fermion scattering processes.

In processes that only involve vertices with two Dirac fields, it is never necessary to use charge-conjugated Dirac fermion lines. In contrast, consider the following process that involves a vertex with one Dirac and one Majorana fermion. Specifically, we examine the scattering of a Dirac fermion and a charged scalar into its charge-conjugated final state, via the exchange of a Majorana fermion: $\Phi^\dagger F \to \Phi \overline{F}$. If one attempts to draw the relevant Feynman diagram employing Dirac fermion lines but with no charge-conjugated Dirac fermion lines, one finds that there is no possible choice of arrow direction for the Majorana fermion that is consistent with the vertex rules of Fig. G.5.4. The resolution is simple: one can choose the incoming line to be Ψ and the outgoing line to be Ψ^C or vice versa. Thus, the two possible choices are given by:

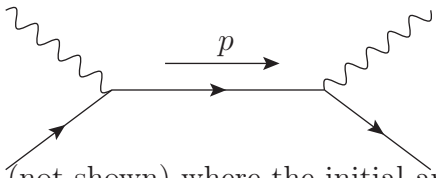
plus a second diagram in each case (not shown) in which the initial and final scalars are crossed. If we evaluate the first diagram, the resulting amplitude is given by:

$$\begin{aligned} i\mathcal{M} &= \frac{-i}{s-m^2}\,\bar{u}(\vec{\boldsymbol{p}}_2,s_2)(\kappa_2 P_L+\kappa_1^* P_R)(\not{p}+m)(\kappa_2 P_L+\kappa_1^* P_R)u(\vec{\boldsymbol{p}}_1,s_1)+(\text{crossed}) \\ &= \frac{-i}{s-m^2}\,\bar{u}(\vec{\boldsymbol{p}}_2,s_2)\left[\kappa_1^*\kappa_2\not{p}+\left(\kappa_2^2 P_L+(\kappa_1^*)^2 P_R\right)m\right]u(\vec{\boldsymbol{p}}_1,s_1)+(\text{crossed})\,, \end{aligned} \tag{G.6.11}$$

where m is the Majorana fermion mass. This result is equivalent to eq. (29.4.17) obtained via the two-component spinor methods. Had we chosen to evaluate the second diagram instead, the resulting amplitude [after using eqs. (G.6.9) and (G.6.10)] would have been found to be the negative of eq. (G.6.11), as expected. As before, the relative sign between diagrams for the same process is unambiguous.

In the literature, there are a number of alternative methods for dealing with scattering processes involving Majorana particles. For example, one can define a fermion number violating propagator for four-component fermions (see, *e.g.*, [7]). Using the methods of [7], factors of the charge conjugation matrix C appear both in fermion-number-violating propagators and vertices. However, all such factors of C eventually cancel out by the end of the computation of any S-matrix amplitude. Moreover, such methods often involve subtle choices of signs that require first-principles computations to verify. As previously noted, our four-component fermion diagrammatic techniques do not suffer from either of these complications.

In the case of elastic scattering of a Majorana fermion and a neutral vector boson, the two contributing diagrams include the following diagram:



plus a second diagram (not shown) where the initial and final state vector bosons are crossed. Consider first the scattering of a neutral Majorana fermion of mass m. Using the Feynman rules of Fig. G.5.2, the Feynman rule for the $A_\mu \overline{\Psi}_M \Psi_M$ vertex is given by $iG\gamma^\mu\gamma_5$. Hence, the corresponding matrix element is given by

$$i\mathcal{M} = \frac{-iG^2}{s-m^2}\bar{u}(\vec{\boldsymbol{p}}_2, s_2)\,\gamma\cdot\varepsilon_2^*\,(\not{p}-m)\,\gamma\cdot\varepsilon_1 u(\vec{\boldsymbol{p}}_1, s_1) + (\text{crossed})\,, \tag{G.6.12}$$

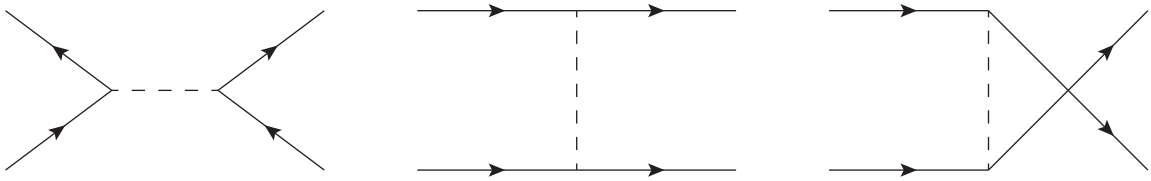
where we have used $\gamma^\nu\gamma_5(\not{p}+m)\gamma^\mu\gamma_5 = \gamma^\nu(\not{p}-m)\gamma^\mu$. Using eqs. (G.1.2) and (G.4.11), one easily recovers the results of eq. (29.4.14).

The scattering of a Dirac fermion of mass m and a neutral vector boson can be similarly treated. The relevant Feynman graphs are the same as in the previous case, and the matrix element is given by

$$\begin{aligned} i\mathcal{M} &= \frac{-i}{s-m^2}\bar{u}(\vec{\boldsymbol{p}}_2, s_2)\,\gamma\cdot\varepsilon_2^*\,(G_L P_L + G_R P_R)(\not{p}+m)\,\gamma\cdot\varepsilon_1\,(G_L P_L + G_R P_R)u(\vec{\boldsymbol{p}}_1, s_1) + (\text{crossed}) \\ &= \frac{-i}{s-m^2}\bar{u}(\vec{\boldsymbol{p}}_2, s_2)\,\gamma\cdot\varepsilon_2^*\left[(G_L^2 P_L + G_R^2 P_R)\not{p} + G_L G_R m\right]\,\gamma\cdot\varepsilon_1 u(\vec{\boldsymbol{p}}_1, s_1) + (\text{crossed})\,. \end{aligned} \tag{G.6.13}$$

One can easily check that this result coincides with that of eq. (29.4.18).

Finally, we examine the elastic scattering of two identical Majorana fermions via scalar exchange. The three contributing diagrams are:



and the corresponding matrix element is given by

$$\begin{aligned} i\mathcal{M} = {} & \frac{-i}{s-m_\phi^2}\left[\bar{v}_1(\lambda P_L + \lambda^* P_R)u_2\,\bar{u}_3(\lambda P_L + \lambda^* P_R)v_4\right] \\ & + (-1)\frac{-i}{t-m_\phi^2}\left[\bar{u}_3(\lambda P_L + \lambda^* P_R)u_1\,\bar{u}_4(\lambda P_L + \lambda^* P_R)u_2\right] \\ & + \frac{-i}{u-m_\phi^2}\left[\bar{u}_4(\lambda P_L + \lambda^* P_R)u_1\,\bar{u}_3(\lambda P_L + \lambda^* P_R)u_2\right]\,, \end{aligned} \tag{G.6.14}$$

where $u_i \equiv u(\vec{\boldsymbol{p}}_i, s_i)$, $v_j \equiv v(\vec{\boldsymbol{p}}_j, s_j)$ and m_ϕ is the exchanged scalar mass. The relative minus sign of the t-channel graph relative to the s and u-channel graphs is obtained by noting that 3142 [4132] is an odd [even] permutation of 1234. Using eqs. (G.1.8), (G.4.11) and (G.4.12), one easily recovers the results of eq. (29.4.19).

Self-energy functions and pole masses for four-component fermions

In this section, we examine the self-energy functions and the pole masses for a set of four-component fermions. We first consider four-component Dirac fermion fields Ψ_{ai}, where a is the

four-component spinor index and i is the flavor index. The full, loop-corrected Feynman propagators with four-momentum p^μ are defined by the Fourier transforms [cf. footnote 41] of vacuum expectation values of time-ordered products of bilinears of the fully interacting four-component fermion fields:

$$\langle 0|\, T\Psi_{ai}(x)\overline{\Psi}^{bj}(y)\,|0\rangle_{\rm FT} = i(\boldsymbol{S}_a{}^b)_i{}^j(p)\,, \tag{G.7.1}$$

with [310, 311, 312, 313, 314, 315, 316, 317]

$$\boldsymbol{S}(p) \equiv \not{p}\left[P_L\boldsymbol{S}_{\boldsymbol{L}}^{\mathsf{T}}(p^2) + P_R\boldsymbol{S}_{\boldsymbol{R}}(p^2)\right] + P_L\overline{\boldsymbol{S}}_{\boldsymbol{D}}^{\mathsf{T}}(p^2) + P_R\boldsymbol{S}_{\boldsymbol{D}}(p^2)\,, \tag{G.7.2}$$

where the four-component spinor indices a and b and the flavor indices i and j have been suppressed. As in Section 29.4.6, we shall organize the computation of the full propagator in terms of the 1PI self-energy function[313]:[156]

$$\boldsymbol{\Sigma}(p) \equiv \not{p}\left[P_L\boldsymbol{\Sigma}_{\boldsymbol{L}}(p^2) + P_R\boldsymbol{\Sigma}_{\boldsymbol{R}}^{\mathsf{T}}(p^2)\right] + P_L\boldsymbol{\Sigma}_{\boldsymbol{D}}(p^2) + P_R\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}^{\mathsf{T}}(p^2)\,. \tag{G.7.3}$$

Diagrammatically, $i\boldsymbol{S}$ and $-i\boldsymbol{\Sigma}$ are shown in Fig. G.7.1.

Figure G.7.1: The full, loop-corrected propagator for four-component Dirac fermions, $i(\boldsymbol{S}_a{}^b)_i{}^j(p)$, is denoted by the shaded box, which represents the sum of all connected Feynman diagrams, with external legs included. The self-energy function for four-component Dirac fermions, $-i(\boldsymbol{\Sigma}_a{}^b)_i{}^j(p)$, is denoted by the shaded circle, which represents the sum of all one-particle irreducible, connected Feynman diagrams with the external legs amputated. In both cases, The four-momentum p flows from right to left.

The hermiticity of the effective action implies that $\boldsymbol{S}$ and $\boldsymbol{\Sigma}$ satisfy hermiticity conditions [318, 302]

$$[\boldsymbol{S}^{\mathsf{T}}]^\star = A\boldsymbol{S}A^{-1}\,, \qquad [\boldsymbol{\Sigma}^{\mathsf{T}}]^\star = A\boldsymbol{\Sigma}A^{-1}\,, \tag{G.7.4}$$

where A is the Dirac conjugation matrix [$A = \gamma^0$ in the standard representations; see eq. (G.1.21) and the text that follows] and the star symbol was defined in the paragraph below eq. (29.4.6). Applying eq. (G.7.4) to eqs. (G.7.2) and (G.7.3) then yields the following conditions for the complex matrix functions:

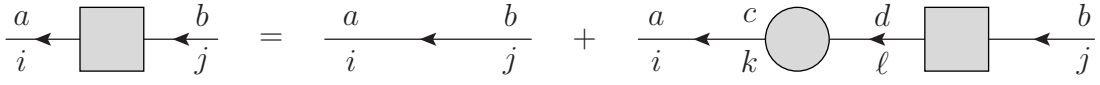
$$[\boldsymbol{S}_{\boldsymbol{L}}^{\mathsf{T}}]^\star = \boldsymbol{S}_{\boldsymbol{L}}\,, \qquad [\boldsymbol{S}_{\boldsymbol{R}}^{\mathsf{T}}]^\star = \boldsymbol{S}_{\boldsymbol{R}}\,, \qquad \overline{\boldsymbol{S}}_{\boldsymbol{D}} = \boldsymbol{S}_{\boldsymbol{D}}^\star\,, \tag{G.7.5}$$

$$[\boldsymbol{\Sigma}_{\boldsymbol{L}}^{\mathsf{T}}]^\star = \boldsymbol{\Sigma}_{\boldsymbol{L}}\,, \qquad [\boldsymbol{\Sigma}_{\boldsymbol{R}}^{\mathsf{T}}]^\star = \boldsymbol{\Sigma}_{\boldsymbol{R}}\,, \qquad \overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}} = \boldsymbol{\Sigma}_{\boldsymbol{D}}^\star\,. \tag{G.7.6}$$

Starting at tree level and comparing with Fig. G.5.1, the full propagator function is given by:

$$\boldsymbol{S}_i{}^j(p) = (\not{p} + m)\delta_i^j/(p^2 - m_i^2) + \ldots\,, \tag{G.7.7}$$

with no sum over i implied. The full loop-corrected propagator can be expressed diagrammatically in terms of the 1PI self-energy function:



(G.7.8)

[156] Our notation in eq. (G.7.3) differs from that of [313], as we employ $\boldsymbol{\Sigma}_{\boldsymbol{R}}^{\mathsf{T}}$ instead of $\boldsymbol{\Sigma}_{\boldsymbol{R}}$. Our motivation for this choice is that in the case of Majorana fermions [cf. eq. (G.7.15)], we simply have $\boldsymbol{\Sigma}_{\boldsymbol{L}} = \boldsymbol{\Sigma}_{\boldsymbol{R}}$, without an extra transpose (or conjugation). We have also chosen to employ $\boldsymbol{S}_{\boldsymbol{L}}^{\mathsf{T}}$ in eq. (G.7.2) for similar reasons.

As in Section 29.4.6, the algebraic representation of eq. (G.7.8) can be written as [cf. footnote 59]:

$$\boldsymbol{S} = \boldsymbol{T} + \boldsymbol{T}\boldsymbol{\Sigma}\boldsymbol{S} = (\boldsymbol{T}^{-1} - \boldsymbol{\Sigma})^{-1}\,, \tag{G.7.9}$$

where $\boldsymbol{T}_i{}^j \equiv (\not{p} + m)\delta_i^j/(p^2 - m_i^2)$ is the tree-level contribution to $\boldsymbol{S}$ given in eq. (G.7.7). By writing the expressions for $\boldsymbol{S}$ and $\boldsymbol{\Sigma}$ given in eqs. (G.7.2) and (G.7.3) and $\boldsymbol{T}$ in block matrix form using eq. (G.1.2), one can verify that eq. (G.7.9) is equivalent to eq. (29.4.27). Consequently, the complex pole masses of the corresponding Dirac fermions are again determined from eq. (29.4.32).

In the special case of a parity-conserving vectorlike theory of Dirac fermions (such as QED or QCD), the pseudoscalar and pseudovector parts of $\boldsymbol{S}(p)$ and $\boldsymbol{\Sigma}(p)$ must be absent. Thus, the following relations must hold among the loop-corrected propagator functions and self-energy functions, respectively:

$$\boldsymbol{S_R} = \boldsymbol{S_L^{\mathsf{T}}}\,, \qquad \boldsymbol{S_D} = [\boldsymbol{S_D^{\mathsf{T}}}]^\star\,, \tag{G.7.10}$$

$$\boldsymbol{\Sigma_L} = \boldsymbol{\Sigma_R^{\mathsf{T}}}\,, \qquad \boldsymbol{\Sigma_D} = [\boldsymbol{\Sigma_D^{\mathsf{T}}}]^\star\,, \tag{G.7.11}$$

in agreement with eqs. (29.4.33) and (29.4.34).

In the case of a set of four-component Majorana fermion fields, we can still use the results of eqs. (G.7.2)–(G.7.9). However, one obtains additional constraints on the full propagator and self-energy matrix functions due to the Majorana condition $\Psi_{Mi} = C\overline{\Psi}_{Mi}^{\mathsf{T}}$. Inserting this result into eq. (G.7.1), and making use of the anticommutativity of the fermion fields, one easily derives:

$$\langle 0|\, T\Psi_{Mai}(x)\overline{\Psi}_{Mj}^{\,b}(y)\,|0\rangle_{\rm FT} = C_{ae}\,\langle 0|\, T\Psi_{Mdi}(x)\overline{\Psi}_{Mj}^{\,e}(y)\,|0\rangle_{\rm FT}\,(C^{-1})^{db}\,. \tag{G.7.12}$$

Consequently,

$$C\boldsymbol{S}^{\mathsf{T}}C^{-1} = \boldsymbol{S}\,, \qquad C\boldsymbol{\Sigma}^{\mathsf{T}}C^{-1} = \boldsymbol{\Sigma}\,. \tag{G.7.13}$$

Inserting the expressions for $\boldsymbol{S}$ and $\boldsymbol{\Sigma}$ [eqs. (G.7.2) and (G.7.3)] and using the result of eq. (G.1.91), it follows that:

$$\boldsymbol{S_L} = \boldsymbol{S_R}\,, \qquad \boldsymbol{S_D} = \boldsymbol{S_D^{\mathsf{T}}}\,, \qquad \overline{\boldsymbol{S}}_{\boldsymbol{D}} = \overline{\boldsymbol{S}}_{\boldsymbol{D}}^{\mathsf{T}}\,, \tag{G.7.14}$$

$$\boldsymbol{\Sigma_L} = \boldsymbol{\Sigma_R}\,, \qquad \boldsymbol{\Sigma_D} = \boldsymbol{\Sigma_D^{\mathsf{T}}}\,, \qquad \overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}} = \overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}^{\mathsf{T}}\,. \tag{G.7.15}$$

As expected, with these constraints the form of eq. (29.4.27) matches precisely with the form of eq. (29.4.17), corresponding to the equation for the full propagator functions for a theory of generic two-component fermion fields. In the notation of Section 29.4.6, we can therefore identify: $\boldsymbol{C} \equiv \boldsymbol{S_L} = \boldsymbol{S_R}$, $\boldsymbol{D} \equiv \boldsymbol{S_D}$, $\boldsymbol{\Xi} \equiv \boldsymbol{\Sigma_L} = \boldsymbol{\Sigma_R}$, and $\boldsymbol{\Omega} \equiv \boldsymbol{\Sigma_D}$.

29.7.10 Covariant spin operators and the Bouchiat-Michel formulae

Bouchiat and Michel derived a useful set of formulae [113] that generalize the spin projection operators used in four-component spinor computations. In this Appendix, we establish the two-component analogues of the Bouchiat-Michel formulae, and demonstrate their equivalence to the corresponding four-component spinor formulae.

The covariant spin operators for a spin-1/2 fermion

Consider a massive spin-1/2 fermion of mass m and four-momentum p. We define a set of three four-vectors $S^{a\mu}$ $(a = 1, 2, 3)$ such that the $S^{a\mu}$ and p^μ/m form an orthonormal set of four-vectors. In the rest frame of the fermion, where $p^\mu = (m\,;\,\vec{\boldsymbol{0}})$, we can define

$$S^{a\mu} \equiv (0\,;\,\hat{\boldsymbol{s}}^{\boldsymbol{a}})\,, \qquad a = 1, 2, 3\,, \tag{H.1.1}$$

where the unit vectors $\hat{\boldsymbol{s}}^{\boldsymbol{a}}$ are a mutually orthonormal set of unit three-vectors that form a basis for a right-handed coordinate system. Explicit forms for the $\hat{\boldsymbol{s}}^{\boldsymbol{a}}$ depend on the Euler angle γ used to define the spinor wave function $\chi_s(\hat{\boldsymbol{s}})$. Two common choices corresponding to $\gamma = -\phi$ and $\gamma = 0$ are given in eqs. (C.1.39) and (C.1.40), respectively. Using eq. (29.117), the three four-vectors $S^{a\mu}$, in a reference frame in which the four-momentum of the fermion is $p^\mu = (E\,;\,\vec{\boldsymbol{p}})$, are given by:

$$S^{a\mu} = \left(\frac{\vec{\boldsymbol{p}}\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}}{m}\,;\,\hat{\boldsymbol{s}}^{\boldsymbol{a}} + \frac{(\vec{\boldsymbol{p}}\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}})\,\vec{\boldsymbol{p}}}{m(E+m)}\right), \qquad a = 1,2,3\,. \tag{H.1.2}$$

As discussed in Appendix C , we identify $\hat{\boldsymbol{s}} = \hat{\boldsymbol{s}}^{\boldsymbol{3}}$ as the quantization axis used in defining the third component of the spin of the fermion in its rest frame. It then follows that the spin four-vector, previously introduced in eq. (29.3.15) is given by $S^\mu = S^{3\mu}$.

The orthonormal set of four four-vectors p^μ/m and the $S^{a\mu}$ satisfy the following Lorentz-covariant relations:

$$p\cdot S^a = 0\,, \tag{H.1.3}$$

$$S^a\cdot S^b = -\delta^{ab}\,, \tag{H.1.4}$$

$$\epsilon^{\mu\nu\lambda\sigma}p_\mu S^1_\nu S^2_\lambda S^3_\sigma = -m\,, \tag{H.1.5}$$

$$S^a_\mu S^b_\nu - S^a_\nu S^b_\mu = \epsilon^{abc}\epsilon_{\mu\nu\rho\sigma}S^{c\rho}\,\frac{p^\sigma}{m}\,, \tag{H.1.6}$$

$$S^a_\mu\, S^a_\nu = -g_{\mu\nu} + \frac{p_\mu p_\nu}{m^2}\,, \tag{H.1.7}$$

where the sum over the repeated indices is implicit. It is convenient to define a matrix-valued spin four-vector $\mathscr{S}^\mu$, whose matrix elements are given by:

$$\mathscr{S}^\mu_{ss'} \equiv S^{a\mu}\tau^a_{ss'}\,, \qquad s, s' = \pm\tfrac{1}{2}\,, \tag{H.1.8}$$

where $\tau^a_{ss'}$ are the matrix elements of the Pauli matrices (see footnote 102). Then, we can rewrite eqs. (H.1.4) and (H.1.6) as:

$$\tfrac{1}{3}\,g_{\mu\nu}\mathscr{S}^\mu\mathscr{S}^\nu = -\mathbb{1}_{2\times2}\,, \tag{H.1.9}$$

$$\mathscr{S}^\mu\mathscr{S}^\nu - \mathscr{S}^\nu\mathscr{S}^\mu = \frac{2i}{m}\epsilon^{\mu\nu\rho\sigma}\mathscr{S}_\rho p_\sigma\,, \tag{H.1.10}$$

where the product $\mathscr{S}^\mu\mathscr{S}^\nu$ corresponds to ordinary 2×2 matrix multiplication. The $\mathscr{S}^\mu$ serve as covariant spin operators for a spin-1/2 fermion. In particular, in the rest frame, the $\frac{1}{2}\mathscr{S}^i$ satisfy the usual SU(2) commutation relations, with $(\frac{1}{2}\vec{\boldsymbol{\mathscr{S}}})^2 = \frac{3}{4}$ as expected for a spin-1/2 particle.

It is often desirable to work with helicity states. In this case, we choose:

$$\hat{\boldsymbol{s}}^{\boldsymbol{a}} = \hat{\boldsymbol{p}}^{\boldsymbol{a}}\,, \tag{H.1.11}$$

where the $\hat{\boldsymbol{p}}^{\boldsymbol{a}}$ are an orthonormal triad of unit three-vectors with $\hat{\boldsymbol{p}}^{\boldsymbol{3}} \equiv \hat{\boldsymbol{p}}$. Moreover, since $\hat{\boldsymbol{p}}^{\boldsymbol{a}}\cdot\hat{\boldsymbol{p}} = 0$ for $a \neq 3$, it follows that $S^{a\mu} = (0\,;\,\hat{\boldsymbol{p}}^{\boldsymbol{a}})$ for $a = 1,2$ in all reference frames obtained from the rest frame by a boost in the $\hat{\boldsymbol{p}}$ direction. Hence, in a reference frame where $p^\mu = (E\,;\,\vec{\boldsymbol{p}})$, eq. (H.1.2) yields,

$$S^{1\mu} = (0\,;\,\hat{\boldsymbol{p}}^{\boldsymbol{1}})\,, \tag{H.1.12}$$

$$S^{2\mu} = (0\,;\,\hat{\boldsymbol{p}}^{\boldsymbol{2}})\,, \tag{H.1.13}$$

$$S^{3\mu} = \left(\frac{|\vec{\boldsymbol{p}}|}{m}\,;\,\frac{E}{m}\,\hat{\boldsymbol{p}}\right), \tag{H.1.14}$$

in a coordinate system where $\hat{\boldsymbol{p}} = (\sin\theta\cos\phi,\, \sin\theta\sin\phi,\, \cos\theta)$. One can check that eqs. (H.1.1)–(H.1.7) are also satisfied by the $S^{a\mu}$ defined in eqs. (H.1.12)–(H.1.14).

As expected, $S^{3\mu}$ is the spin four-vector for helicity states obtained in eq. (29.3.16). In the high energy limit ($E \gg m$),

$$mS^{a\mu} = p^\mu\,\delta^{a3} + \mathcal{O}(m)\,. \tag{H.1.15}$$

Explicit forms for $\hat{\boldsymbol{p}}^{\boldsymbol{1}}$ and $\hat{\boldsymbol{p}}^{\boldsymbol{2}}$ are convention dependent and depend on the conventional choice of the Euler angle γ. For example, consider the quantities:

$$S^\mu_- \equiv \tfrac{1}{2}S^{a\mu}\tau^a_{\frac{1}{2},-\frac{1}{2}} = \tfrac{1}{2}(S^{1\mu} - iS^{2\mu})\,, \qquad S^\mu_+ \equiv \tfrac{1}{2}S^{a\mu}\tau^a_{-\frac{1}{2},\frac{1}{2}} = \tfrac{1}{2}(S^{1\mu} + iS^{2\mu})\,. \tag{H.1.16}$$

Using eqs. (H.1.11)–(H.1.14) and employing eq. (C.1.27) with $\mathcal{R}$ given by eq. (C.1.4),

$$\sigma\cdot S_- = e^{i\gamma}\begin{pmatrix} \frac{1}{2}\sin\theta & e^{-i\phi}\sin^2\frac{\theta}{2} \\ -e^{i\phi}\cos^2\frac{\theta}{2} & -\frac{1}{2}\sin\theta \end{pmatrix}, \qquad \overline{\sigma}\cdot S_+ = e^{-i\gamma}\begin{pmatrix} \frac{1}{2}\sin\theta & -e^{-i\phi}\cos^2\frac{\theta}{2} \\ e^{i\phi}\sin^2\frac{\theta}{2} & -\frac{1}{2}\sin\theta \end{pmatrix}. \tag{H.1.17}$$

In the convention of eq. (C.1.39) [eq. (C.1.40)], we take $\gamma = -\phi$ [$\gamma = 0$], respectively.

Two-component spinor wave function relations

In Section 29.3.1, we wrote down explicit forms for the undotted spinor wave functions

$$x_\alpha(\vec{\boldsymbol{p}}, s) = \sqrt{p\cdot\sigma}\,\chi_s\,, \qquad x^\alpha(\vec{\boldsymbol{p}}, s) = -2s\chi^\dagger_{-s}\sqrt{p\cdot\overline{\sigma}}\,, \tag{H.2.1}$$

$$y_\alpha(\vec{\boldsymbol{p}}, s) = 2s\sqrt{p\cdot\sigma}\,\chi_{-s}\,, \qquad y^\alpha(\vec{\boldsymbol{p}}, s) = \chi^\dagger_s\sqrt{p\cdot\overline{\sigma}}\,, \tag{H.2.2}$$

and the dotted spinor wave functions

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}}, s) = -2s\sqrt{p\cdot\overline{\sigma}}\,\chi_{-s}\,, \qquad x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, s) = \chi^\dagger_s\sqrt{p\cdot\sigma}\,, \tag{H.2.3}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}}, s) = \sqrt{p\cdot\overline{\sigma}}\,\chi_s\,, \qquad y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, s) = 2s\chi^\dagger_{-s}\sqrt{p\cdot\sigma}\,, \tag{H.2.4}$$

where $\sqrt{p\cdot\sigma}$ and $\sqrt{p\cdot\overline{\sigma}}$ are defined by eqs. (29.108) and (29.109), respectively.

As shown in Appendix C , the two-component spinors χ_s satisfy:

$$\tfrac{1}{2}\,\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\chi_{s'} = \tfrac{1}{2}\tau^a_{ss'}\chi_s\,, \qquad \chi^\dagger_s(\hat{\boldsymbol{s}})\chi_{s'}(\hat{\boldsymbol{s}}) = \delta_{ss'}\,, \qquad s\,, s' = \pm\tfrac{1}{2}\,. \tag{H.2.5}$$

Next, we use eq. (29.118) to obtain:

$$\sqrt{p\cdot\sigma}\,S^a\cdot\overline{\sigma}\,\sqrt{p\cdot\sigma} = m\,\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\,, \tag{H.2.6}$$

$$\sqrt{p\cdot\overline{\sigma}}\,S^a\cdot\sigma\,\sqrt{p\cdot\overline{\sigma}} = -m\,\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\,, \tag{H.2.7}$$

which extends the results of eq. (29.3.17). As a result, we obtain a generalization of eqs. (29.3.23)–(29.3.26):

$$(S^a\cdot\overline{\sigma})^{\dot\alpha\beta}x_\beta(\vec{\boldsymbol{p}}, s') = \tau^a_{ss'}y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}}, s)\,, \qquad (S^a\cdot\sigma)_{\alpha\dot\beta}y^{\dagger\dot\beta}(\vec{\boldsymbol{p}}, s') = -\tau^a_{ss'}x_\alpha(\vec{\boldsymbol{p}}, s)\,, \tag{H.2.8}$$

$$(S^a\cdot\sigma)_{\alpha\dot\beta}x^{\dagger\dot\beta}(\vec{\boldsymbol{p}}, s') = -\tau^a_{s's}y_\alpha(\vec{\boldsymbol{p}}, s)\,, \qquad (S^a\cdot\overline{\sigma})^{\dot\alpha\beta}y_\beta(\vec{\boldsymbol{p}}, s') = \tau^a_{s's}x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}}, s)\,, \tag{H.2.9}$$

$$x^\alpha(\vec{\boldsymbol{p}}, s')(S^a\cdot\sigma)_{\alpha\dot\beta} = -\tau^a_{s's}y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}}, s)\,, \qquad y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, s')(S^a\cdot\overline{\sigma})^{\dot\alpha\beta} = \tau^a_{s's}x^\beta(\vec{\boldsymbol{p}}, s)\,, \tag{H.2.10}$$

$$x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, s')(S^a\cdot\overline{\sigma})^{\dot\alpha\beta} = \tau^a_{ss'}y^\beta(\vec{\boldsymbol{p}}, s)\,, \qquad y^\alpha(\vec{\boldsymbol{p}}, s')(S^a\cdot\sigma)_{\alpha\dot\beta} = -\tau^a_{ss'}x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}}, s)\,, \tag{H.2.11}$$

where there are implicit sums over the repeated labels $s = \pm\frac{1}{2}$. As expected, the case of $a = 3$ simply reproduces the results of eqs. (29.3.23)–(29.3.26) obtained previously. The above equations also apply to helicity wave functions $x(\vec{\boldsymbol{p}}, \lambda)$ and $y(\vec{\boldsymbol{p}}, \lambda)$ by replacing s, s' with λ, λ' and defining the $S^{a\mu}$ by eqs. (H.1.12)–(H.1.14).

The derivation of eqs. (H.2.8)–(H.2.11) for arbitrary a closely follows the corresponding derivation for $a = 3$ previously given. For example, using eqs. (H.2.6) and (H.2.7) and the definitions for $x_\alpha(\vec{\boldsymbol{p}}, s)$ and $y^{\dagger\dot{\alpha}}(\vec{\boldsymbol{p}}, s)$, we find (suppressing spinor indices),

$$\sqrt{p\cdot\sigma}\, S^a\cdot\overline{\sigma}\, x(\vec{\boldsymbol{p}}, s') = \sqrt{p\cdot\sigma}\, S^a\cdot\overline{\sigma}\, \sqrt{p\cdot\sigma}\, \chi_{s'} = m\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^{\boldsymbol{a}}\, \chi_{s'} = m\tau^a_{ss'}\, \chi_s\,, \tag{H.2.12}$$

after using eq. (H.2.5). Multiplying both sides of eq. (H.2.12) by $\sqrt{p\cdot\overline{\sigma}}$, we end up with

$$S^a\cdot\overline{\sigma}\, x(\vec{\boldsymbol{p}}, s') = \tau^a_{ss'}\sqrt{p\cdot\overline{\sigma}}\, \chi_s = \tau^a_{ss'}\, y^\dagger(\vec{\boldsymbol{p}}, s)\,. \tag{H.2.13}$$

Similarly,

$$S^a\cdot\sigma x^\dagger(\vec{\boldsymbol{p}}, s') = 2s'\tau^a_{-s,-s'}\sqrt{p\cdot\sigma}\, \chi_{-s} = -\tau^a_{s's}\, y(\vec{\boldsymbol{p}}, s)\,, \tag{H.2.14}$$

where we have used:

$$4ss'\tau^a_{-s,-s'} = -\tau^a_{s's}\,, \qquad \text{for} \quad s, s' = \pm 1/2\,. \tag{H.2.15}$$

All the results of eqs. (H.2.8)–(H.2.11) can be derived in this manner.

Two-component Bouchiat-Michel formulae

To establish the Bouchiat-Michel formulae, we begin with the following identity:

$$\tfrac{1}{2}(\delta_{ss'} + \vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^a\, \tau^a_{ss'}) \sum_{t=\pm 1/2} \chi_t\chi_t^\dagger = \chi_{s'}\chi_s^\dagger\,. \tag{H.3.1}$$

To verify eq. (H.3.1), we first make use of eq. (H.2.5) to write $\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}^a\chi_t = \tau^a_{t't}\chi_{t'}$ and evaluate the product of two Pauli matrices:

$$\tau^a_{ss'}\tau^a_{t't} = 2\,\delta_{st}\delta_{s't'} - \delta_{ss'}\delta_{tt'}\,. \tag{H.3.2}$$

We then use eq. (H.2.6) and the completeness relation given in eq. (C.1.21) to rewrite eq. (H.3.1) in terms of $\mathscr{S}^\mu_{ss'}$ defined in eq. (H.1.8),

$$\chi_{s'}\chi_s^\dagger = \tfrac{1}{2}\left(\delta_{ss'} + \frac{1}{m}\sqrt{p\cdot\sigma}\,\mathscr{S}_{ss'}\cdot\overline{\sigma}\,\sqrt{p\cdot\sigma}\right)\,. \tag{H.3.3}$$

Hence, with both spinor indices in the lowered position,

$$\begin{aligned} x(\vec{\boldsymbol{p}}, s')x^\dagger(\vec{\boldsymbol{p}}, s) &= \sqrt{p\cdot\sigma}\,\chi_{s'}\chi_s^\dagger\,\sqrt{p\cdot\sigma} \\ &= \tfrac{1}{2}\sqrt{p\cdot\sigma}\left[\delta_{ss'} + \frac{1}{m}\sqrt{p\cdot\sigma}\,\mathscr{S}_{ss'}\cdot\overline{\sigma}\,\sqrt{p\cdot\sigma}\right]\sqrt{p\cdot\sigma} \\ &= \tfrac{1}{2}\left[p\cdot\sigma\delta_{ss'} + \frac{1}{m}\,p\cdot\sigma\,\mathscr{S}_{ss'}\cdot\overline{\sigma}\,p\cdot\sigma\right] \\ &= \tfrac{1}{2}\left(p\cdot\sigma\delta_{ss'} - m\mathscr{S}_{ss'}\cdot\sigma\right)\,. \end{aligned} \tag{H.3.4}$$

In the final step of eq. (H.3.4), we simplified the product of three dot products by noting that $p\cdot S^a = 0$ implies that $\mathscr{S}_{ss'}\cdot\overline{\sigma}\; p\cdot\sigma = -p\cdot\overline{\sigma}\;\mathscr{S}_{ss'}\cdot\sigma$. Eq. (H.3.4) is the two-component version of one

of the Bouchiat-Michel formulae. We list below a complete set of Bouchiat-Michel formulae, which can be derived by similar techniques:

$$x_\alpha(\vec{\boldsymbol{p}},s')x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(p\,\delta_{ss'} - m\mathscr{S}_{ss'})\cdot\sigma_{\alpha\dot\beta}\,, \tag{H.3.5}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s')y^\beta(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(p\,\delta_{ss'} + m\mathscr{S}_{ss'})\cdot\overline{\sigma}^{\dot\alpha\beta}\,, \tag{H.3.6}$$

$$x_\alpha(\vec{\boldsymbol{p}},s')y^\beta(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}\left[m\delta_{ss'}\delta_\alpha{}^\beta - [(\sigma\cdot\mathscr{S}_{ss'})\,(\overline{\sigma}\cdot p)]_\alpha{}^\beta\right]\,, \tag{H.3.7}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s')x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}\left[m\delta_{ss'}\delta^{\dot\alpha}{}_{\dot\beta} + [(\overline{\sigma}\cdot\mathscr{S}_{ss'})\,(\sigma\cdot p)]^{\dot\alpha}{}_{\dot\beta}\right]\,. \tag{H.3.8}$$

If we set $s = s'$, we recover eqs. (29.3.45)–(29.3.48) as expected. The Bouchiat-Michel formulae can also be verified directly by using the explicit forms for the two-component spinor wave functions [eq. (C.1.11)] and the $\mathscr{S}^\mu_{ss'}$ [defined in eq. (H.1.8)]. The latter depends on the explicit form of the $\hat{\boldsymbol{s}}^{\boldsymbol{a}}$ via eq. (H.1.2).

An equivalent set of Bouchiat-Michel formulae can be obtained by raising and/or lowering the appropriate free spinor indices using eqs. (29.32) and (29.79):

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s')x^\beta(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(p\,\delta_{s's} - m\mathscr{S}_{s's})\cdot\overline{\sigma}^{\dot\alpha\beta}\,, \tag{H.3.9}$$

$$y_\alpha(\vec{\boldsymbol{p}},s')y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(p\,\delta_{s's} + m\mathscr{S}_{s's})\cdot\sigma_{\alpha\dot\beta}\,, \tag{H.3.10}$$

$$y_\alpha(\vec{\boldsymbol{p}},s')x^\beta(\vec{\boldsymbol{p}},s) = -\tfrac{1}{2}\left[m\delta_{s's}\delta_\alpha{}^\beta + [(\sigma\cdot\mathscr{S}_{s's})\,(\overline{\sigma}\cdot p)]_\alpha{}^\beta\right]\,, \tag{H.3.11}$$

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s')y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = -\tfrac{1}{2}\left[m\delta_{s's}\delta^{\dot\alpha}{}_{\dot\beta} - [(\overline{\sigma}\cdot\mathscr{S}_{s's})\,(\sigma\cdot p)]^{\dot\alpha}{}_{\dot\beta}\right]\,. \tag{H.3.12}$$

In this derivation, the spin labels in eqs. (H.3.9)–(H.3.12) are reversed relative to those in eqs. (H.3.5)–(H.3.8) due to eq. (H.2.15). Eight additional relations of the Bouchiat-Michel type can be obtained by replacing one x-spinor with a y-spinor (or vice versa). Recalling that the x and y spinors are related by [cf. eq. (29.3.22)],

$$y(\vec{\boldsymbol{p}},s) = 2sx(\vec{\boldsymbol{p}},-s)\,, \qquad\qquad y^\dagger(\vec{\boldsymbol{p}},s) = 2sx^\dagger(\vec{\boldsymbol{p}},-s)\,, \tag{H.3.13}$$

all possible spinor bilinears can be obtained from eqs. (H.3.5)–(H.3.12).

Note that eqs. (H.3.5)–(H.3.12) also apply to helicity spinor wave functions $x(\vec{\boldsymbol{p}},\lambda)$ and $y(\vec{\boldsymbol{p}},\lambda)$ after replacing s, s' with λ, λ' and using the $S^{a\mu}$ as defined in eqs. (H.1.12)–(H.1.14). Strictly speaking, all results involving the spinor wave functions obtained up to this point apply in the case of a massive spin-1/2 fermion. If we take the massless limit, then the four-vector $S^{3\mu}$ does not exist, as its definition depends on the existence of a rest frame. (In contrast, the four-vectors $S^{1\mu}$ and $S^{2\mu}$ do exist in the massless limit.) Nevertheless, massless helicity spinor wave functions are well defined; explicit forms can be found in eqs. (29.3.36)–(29.3.39). Using these forms, one can derive the Bouchiat-Michel formulae for a massless spin-1/2 fermion:

$$x_\alpha(\vec{\boldsymbol{p}},\lambda')x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}-\lambda)\,\delta_{\lambda\lambda'}\,p\cdot\sigma_{\alpha\dot\beta}\,, \tag{H.3.14}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda')y^\beta(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}+\lambda)\,\delta_{\lambda\lambda'}\,p\cdot\overline{\sigma}^{\dot\alpha\beta}\,, \tag{H.3.15}$$

$$x_\alpha(\vec{\boldsymbol{p}},\lambda')y^\beta(\vec{\boldsymbol{p}},\lambda) = -(\tfrac{1}{2}-\lambda')(\tfrac{1}{2}+\lambda)\,[(\sigma\cdot S_-)(\overline{\sigma}\cdot p)]_\alpha{}^\beta\,, \tag{H.3.16}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda')x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}+\lambda')(\tfrac{1}{2}-\lambda)\,[(\overline{\sigma}\cdot S_+)(\sigma\cdot p)]^{\dot\alpha}{}_{\dot\beta}\,, \tag{H.3.17}$$

where S^μ_- and S^μ_+ are defined in eq. (H.1.16). The equivalent set of Bouchiat-Michel formulae, obtained by raising and/or lowering the appropriate free spinor indices, is given by:

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda')x^{\beta}(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}-\lambda)\,\delta_{\lambda\lambda'}\,p{\cdot}\overline{\sigma}^{\dot\alpha\beta}\,, \tag{H.3.18}$$

$$y_{\alpha}(\vec{\boldsymbol{p}},\lambda')y^{\dagger}_{\dot\beta}(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}+\lambda)\,\delta_{\lambda\lambda'}\,p{\cdot}\sigma_{\alpha\dot\beta}\,, \tag{H.3.19}$$

$$y_{\alpha}(\vec{\boldsymbol{p}},\lambda')x^{\beta}(\vec{\boldsymbol{p}},\lambda) = -(\tfrac{1}{2}+\lambda')(\tfrac{1}{2}-\lambda)\,[(\sigma{\cdot}S_-)(\overline{\sigma}{\cdot}p)]_{\alpha}{}^{\beta}\,, \tag{H.3.20}$$

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda')y^{\dagger}_{\dot\beta}(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}-\lambda')(\tfrac{1}{2}+\lambda)\,[(\overline{\sigma}{\cdot}S_+)(\sigma{\cdot}p)]^{\dot\alpha}{}_{\dot\beta}\,. \tag{H.3.21}$$

Eight additional relations of the Bouchiat-Michel type can be obtained by replacing one x-spinor with a y-spinor (or vice versa), using the results of eq. (H.3.13). As a check, one can verify that the above results follow from eqs. (H.3.5)–(H.3.12) by replacing s with λ, setting $mS^{a\mu} = p^{\mu}\,\delta^{a3}$, applying the mass-shell condition ($p^2 = m^2$), and taking the $m \to 0$ limit at the end of the computation.

We now demonstrate how to use the Bouchiat-Michel formulae to evaluate helicity amplitudes involving two equal mass spin-1/2 fermions. A typical amplitude involving a fermion-antifermion pair, evaluated in the center-of-mass frame of the pair has the generic structure:

$$z(\vec{\boldsymbol{p}},\lambda)\,\Gamma\,z'(-\vec{\boldsymbol{p}},\lambda')\,, \tag{H.3.22}$$

where z is one of the two-component spinor wave functions x, $x^\dagger$, y, or $y^\dagger$, and Γ is a 2×2 matrix (in spinor space) that is either the identity matrix, or is made up of alternating products of σ and $\overline{\sigma}$. As an illustration, we evaluate:

$$x^{\dagger}_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha\beta}\,y_{\beta}(-\vec{\boldsymbol{p}},\lambda') = 2\lambda'\,\Gamma^{\dot\alpha\beta}\,x_{\beta}(-\vec{\boldsymbol{p}},-\lambda')x^{\dagger}_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda) = 2\lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\;\Gamma^{\dot\alpha\beta}\sigma^{0}_{\beta\dot\beta}\,y^{\dagger\dot\beta}(\vec{\boldsymbol{p}},\lambda')x^{\dagger}_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,, \tag{H.3.23}$$

where $\xi_{\lambda'}(\hat{\boldsymbol{p}})$ is defined in eq. (C.3.14), and we have used eqs. (C.3.17) and (29.3.22). We can now employ the Bouchiat-Michel formula to convert the above result into a trace. By a similar computation, all expressions of the form of eq. (H.3.22) can be expressed as a trace:

$$x^{\dagger}_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha\beta}\,y_{\beta}(-\vec{\boldsymbol{p}},\lambda') = \lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\;\mathrm{Tr}\left[\Gamma\,\sigma^{0}(m\delta_{\lambda\lambda'}+\overline{\sigma}{\cdot}\mathscr{S}_{\lambda\lambda'}\,\sigma{\cdot}p)\right]\,, \tag{H.3.24}$$

$$y^{\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma_{\alpha\dot\beta}\,x^{\dagger\dot\beta}(-\vec{\boldsymbol{p}},\lambda') = -\lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\;\mathrm{Tr}\left[\Gamma\,\overline{\sigma}^{0}(m\delta_{\lambda\lambda'}-\sigma{\cdot}\mathscr{S}_{\lambda\lambda'}\,\overline{\sigma}{\cdot}p)\right]\,, \tag{H.3.25}$$

$$y^{\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma_{\alpha}{}^{\beta}\,y_{\beta}(-\vec{\boldsymbol{p}},\lambda') = \lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\;\mathrm{Tr}\left[\Gamma\,\sigma^{0}(\overline{\sigma}{\cdot}p\,\delta_{\lambda\lambda'}+m\overline{\sigma}{\cdot}\mathscr{S}_{\lambda\lambda'})\right]\,, \tag{H.3.26}$$

$$x^{\dagger}_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha}{}_{\dot\beta}\,x^{\dagger\dot\beta}(-\vec{\boldsymbol{p}},\lambda') = -\lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\;\mathrm{Tr}\left[\Gamma\,\overline{\sigma}^{0}(\sigma{\cdot}p\,\delta_{\lambda\lambda'}-m\sigma{\cdot}\mathscr{S}_{\lambda\lambda'})\right]\,, \tag{H.3.27}$$

after making use of eqs. (H.3.5) and (H.3.8). Similarly, there are four additional results that make use of eqs. (H.3.9) and (H.3.12):

$$y^{\dagger}_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha\beta}\,x_{\beta}(-\vec{\boldsymbol{p}},\lambda') = \lambda'\,\xi_{-\lambda'}(\hat{\boldsymbol{p}})\;\mathrm{Tr}\left[\Gamma\,\sigma^{0}(m\delta_{\lambda'\lambda}-\overline{\sigma}{\cdot}\mathscr{S}_{\lambda'\lambda}\,\sigma{\cdot}p)\right]\,, \tag{H.3.28}$$

$$x^{\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma_{\alpha\dot\beta}\,y^{\dagger\dot\beta}(-\vec{\boldsymbol{p}},\lambda') = -\lambda'\,\xi_{-\lambda'}(\hat{\boldsymbol{p}})\;\mathrm{Tr}\left[\Gamma\,\overline{\sigma}^{0}(m\delta_{\lambda'\lambda}+\sigma{\cdot}\mathscr{S}_{\lambda'\lambda}\,\overline{\sigma}{\cdot}p)\right]\,, \tag{H.3.29}$$

$$x^{\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma_{\alpha}{}^{\beta}\,x_{\beta}(-\vec{\boldsymbol{p}},\lambda') = -\lambda'\,\xi_{-\lambda'}(\hat{\boldsymbol{p}})\;\mathrm{Tr}\left[\Gamma\,\sigma^{0}(\overline{\sigma}{\cdot}p\,\delta_{\lambda'\lambda}-m\overline{\sigma}{\cdot}\mathscr{S}_{\lambda'\lambda})\right]\,, \tag{H.3.30}$$

$$y^{\dagger}_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha}{}_{\dot\beta}\,y^{\dagger\dot\beta}(-\vec{\boldsymbol{p}},\lambda') = \lambda'\,\xi_{-\lambda'}(\hat{\boldsymbol{p}})\;\mathrm{Tr}\left[\Gamma\,\overline{\sigma}^{0}(\sigma{\cdot}p\,\delta_{\lambda'\lambda}+m\sigma{\cdot}\mathscr{S}_{\lambda'\lambda})\right]\,. \tag{H.3.31}$$

For amplitudes involving equal mass fermions (or equal mass antifermions), other combinations of spinor bilinears appear in which one x-spinor above is replaced by a y-spinor or vice versa. These amplitudes can be reduced to one of the eight listed above by using eq. (29.3.22).

In the massless limit, one can again put $mS^{a\mu} = p^{\mu}\delta^{a3}$, set $p^2 = m^2$ and take $m \to 0$ at the end of the computation. Alternatively, one can repeat the derivation of eqs. (H.3.24)–(H.3.31) using

the results of eqs. (H.3.14) and (H.3.21). For completeness, we record the end result here.

$$x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha\beta}\,y_\beta(-\vec{\boldsymbol{p}},\lambda') = (\tfrac{1}{2}+\lambda')(\tfrac{1}{2}-\lambda)\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\ \mathrm{Tr}(\Gamma\,\sigma^0\overline{\sigma}\cdot S_-\,\sigma\cdot p)\,, \tag{H.3.32}$$

$$y^\alpha(\vec{\boldsymbol{p}},\lambda)\,\Gamma_{\alpha\dot\beta}\,x^{\dagger\dot\beta}(-\vec{\boldsymbol{p}},\lambda') = -(\tfrac{1}{2}-\lambda')(\tfrac{1}{2}+\lambda)\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\ \mathrm{Tr}(\Gamma\,\overline{\sigma}^0\sigma\cdot S_-\,\overline{\sigma}\cdot p)\,, \tag{H.3.33}$$

$$y^\alpha(\vec{\boldsymbol{p}},\lambda)\,\Gamma_\alpha{}^\beta\,y_\beta(-\vec{\boldsymbol{p}},\lambda') = (\tfrac{1}{2}+\lambda)\,\delta_{\lambda\lambda'}\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\ \mathrm{Tr}(\Gamma\,\sigma^0\,\overline{\sigma}\cdot p)\,, \tag{H.3.34}$$

$$x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha}{}_{\dot\beta}\,x^{\dagger\dot\beta}(-\vec{\boldsymbol{p}},\lambda') = (\tfrac{1}{2}-\lambda)\,\delta_{\lambda\lambda'}\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\ \mathrm{Tr}(\Gamma\,\overline{\sigma}^0\,\sigma\cdot p)\,. \tag{H.3.35}$$

The equivalent set of formulae, obtained by raising and/or lowering the appropriate free spinor indices as before, is given by:

$$y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha\beta}\,x_\beta(-\vec{\boldsymbol{p}},\lambda') = (\tfrac{1}{2}-\lambda')(\tfrac{1}{2}+\lambda)\,\xi_{-\lambda'}(\hat{\boldsymbol{p}})\ \mathrm{Tr}(\Gamma\,\sigma^0\overline{\sigma}\cdot S_+\,\sigma\cdot p)\,, \tag{H.3.36}$$

$$x^\alpha(\vec{\boldsymbol{p}},\lambda)\,\Gamma_{\alpha\dot\beta}\,y^{\dagger\dot\beta}(-\vec{\boldsymbol{p}},\lambda') = -(\tfrac{1}{2}+\lambda')(\tfrac{1}{2}-\lambda)\,\xi_{-\lambda'}(\hat{\boldsymbol{p}})\ \mathrm{Tr}(\Gamma\,\overline{\sigma}^0\sigma\cdot S_+\,\overline{\sigma}\cdot p)\,, \tag{H.3.37}$$

$$x^\alpha(\vec{\boldsymbol{p}},\lambda)\,\Gamma_\alpha{}^\beta\,x_\beta(-\vec{\boldsymbol{p}},\lambda') = (\tfrac{1}{2}-\lambda)\,\delta_{\lambda\lambda'}\,\xi_{-\lambda'}(\hat{\boldsymbol{p}})\ \mathrm{Tr}(\Gamma\,\sigma^0\,\overline{\sigma}\cdot p)\,, \tag{H.3.38}$$

$$y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha}{}_{\dot\beta}\,y^{\dagger\dot\beta}(-\vec{\boldsymbol{p}},\lambda') = (\tfrac{1}{2}+\lambda)\,\delta_{\lambda\lambda'}\,\xi_{-\lambda'}(\hat{\boldsymbol{p}})\ \mathrm{Tr}(\Gamma\,\overline{\sigma}^0\,\sigma\cdot p)\,. \tag{H.3.39}$$

The traces are easily evaluated using the results of Appendix B . Here, we apply the above results to the amplitude for the decay $Z^0 \to f\bar f$ [see Section 29.6.2]. The corresponding center-of-mass frame helicity amplitude is a linear combination of eqs. (H.3.24) and (H.3.25) with $\Gamma = \overline{\sigma}$ and $\Gamma = \sigma$, respectively. Evaluating the corresponding terms, we find for $\Gamma = \overline{\sigma}$,

$$x^\dagger(\vec{\boldsymbol{p}},\lambda)\overline{\sigma}^\mu y(-\vec{\boldsymbol{p}},\lambda') = 2\lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\,\left[mg^{\mu 0}\delta_{\lambda\lambda'} + p^\mu \mathscr{S}^0_{\lambda\lambda'} - p^0\mathscr{S}^\mu_{\lambda\lambda'} - 2m(\mathscr{S}^\mu\mathscr{S}^0 - \mathscr{S}^0\mathscr{S}^\mu)_{\lambda\lambda'}\right]\,, \tag{H.3.40}$$

where we have used eq. (H.1.10) to replace the term with the Levi-Civita tensor. Similarly, we calculate for $\Gamma = \sigma$,

$$y(\vec{\boldsymbol{p}},\lambda)\sigma^\mu x^\dagger(-\vec{\boldsymbol{p}},\lambda') = 2\lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\,\left[-mg^{\mu 0}\delta_{\lambda\lambda'} + p^\mu \mathscr{S}^0_{\lambda\lambda'} - p^0\mathscr{S}^\mu_{\lambda\lambda'} + 2m(\mathscr{S}^\mu\mathscr{S}^0 - \mathscr{S}^0\mathscr{S}^\mu)_{\lambda\lambda'}\right]\,. \tag{H.3.41}$$

Eqs. (H.3.40) and (H.3.41) provide explicit forms for the $Z^0 \to f\bar f$ decay helicity amplitudes defined in eqs. (29.6.3) and (29.6.4).

The above method is not applicable if the two fermions have unequal mass. In order to compute the helicity amplitudes of the form given by eq. (H.3.22) for unequal masses, a generalization of the above techniques is required. Some methods for four-component spinor wave functions have been proposed in [319]. We leave it as an exercise for the reader to translate these techniques so that they are applicable to helicity amplitudes expressed in terms of two-component spinor wave functions. An alternative approach, which is applicable to the computation of helicity amplitudes for processes involving multi-fermion final states of arbitrary mass, is reviewed in Appendix I.1 .

Four-component Bouchiat-Michel formulae

Using the results of Appendix G , the translation of the results of Appendix H.3 into four-component spinor notation is straightforward. First, we consider a massive spin-1/2 fermion. Eqs. (H.2.8)–(H.2.11) yield [288]:

$$\gamma_5 \not{S}^a\, u(\vec{\boldsymbol{p}},s') = \tau^a_{ss'}\,u(\vec{\boldsymbol{p}},s)\,, \qquad \gamma_5\not{S}^a\, v(\vec{\boldsymbol{p}},s') = \tau^a_{s's}\,v(\vec{\boldsymbol{p}},s)\,, \tag{H.4.1}$$

$$\bar u(\vec{\boldsymbol{p}},s')\,\gamma_5\not{S}^a = \tau^a_{ss'}\,\bar u(\vec{\boldsymbol{p}},s)\,, \qquad \bar v(\vec{\boldsymbol{p}},s')\,\gamma_5\not{S}^a = \tau^a_{s's}\,\bar v(\vec{\boldsymbol{p}},s)\,. \tag{H.4.2}$$

In the case of $a = 3$, eqs. (H.4.1) and (H.4.2) reduce to those of eqs. (G.4.18) and (G.4.19).

The four-component Bouchiat-Michel formulae [113, 320, 319] can be obtained from eqs. (H.3.5)–(H.3.12):

$$u(\vec{\boldsymbol{p}},s')\bar u(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}\left[\delta_{ss'} + \gamma_5\gamma_\mu\mathscr{S}^\mu_{ss'}\right](\not p + m)\,, \tag{H.4.3}$$

$$v(\vec{\boldsymbol{p}},s')\bar v(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}\left[\delta_{s's} + \gamma_5\gamma_\mu\mathscr{S}^\mu_{s's}\right](\not p - m)\,, \tag{H.4.4}$$

where $\mathscr{S}^{\mu}_{ss'} \equiv S^{a\mu}\tau^{a}_{ss'}$. As expected, the above results for $s = s'$ correspond to the spin projection operators given in eqs. (G.4.20) and (G.4.21). Related formulae involving products of u and v-spinors can be obtained by using [cf. eq. (G.4.15)]:

$$v(\vec{\boldsymbol{p}}, s) = -2s\gamma_5 u(\vec{\boldsymbol{p}}, -s)\,, \qquad\qquad u(\vec{\boldsymbol{p}}, s) = 2s\gamma_5 v(\vec{\boldsymbol{p}}, -s)\,. \tag{H.4.5}$$

Eqs. (H.4.1)–(H.4.4) also apply to helicity u and v-spinors, after replacing s, s' with λ, λ' and using the S^a as defined in eq. (H.1.14). The four-component versions of eqs. (C.3.17)–(C.3.20) yield:

$$u(-\boldsymbol{p}\,,\,-\lambda) = \xi_{\lambda}(\hat{\boldsymbol{p}})\,\gamma^0\,u(\boldsymbol{p}\,,\,\lambda)\,, \qquad\qquad v(-\boldsymbol{p}\,,\,-\lambda) = \xi_{-\lambda}(\hat{\boldsymbol{p}})\,\gamma^0\,v(\boldsymbol{p}\,,\,\lambda)\,, \tag{H.4.6}$$

$$\bar{u}(-\boldsymbol{p}\,,\,-\lambda) = -\bar{u}(\boldsymbol{p}\,,\,\lambda)\,\gamma^0\,\xi_{-\lambda}(\hat{\boldsymbol{p}})\,, \qquad\qquad \bar{v}(-\boldsymbol{p}\,,\,-\lambda) = -\bar{v}(\boldsymbol{p}\,,\,\lambda)\,\gamma^0\,\xi_{\lambda}(\hat{\boldsymbol{p}})\,, \tag{H.4.7}$$

where the phase $\xi_\lambda(\hat{\boldsymbol{p}})$ was defined in eq. (C.3.11). In order to consider the massless limit, one must employ helicity spinors, as discussed in Appendix H.3 . For $a = 1, 2$, eqs. (H.4.1) and (H.4.2) apply in the $m \to 0$ limit as written. The corresponding massless limit for the case of $a = 3$ is smooth and results in eq. (G.4.22). Similarly, the massless limit of the Bouchiat-Michel formulae for helicity spinors can be obtained by setting $mS^{a\mu} = p^\mu\,\delta^{a3}$, applying the mass-shell condition ($p^2 = m^2$), and taking the $m \to 0$ limit at the end of the computation. The end result is given by

$$u(p,\lambda')\bar{u}(p,\lambda) = \tfrac{1}{2}(1 + 2\lambda\gamma_5)\,\not{p}\,\delta_{\lambda\lambda'} + \tfrac{1}{2}\gamma_5[\not{S}^1\tau^1_{\lambda\lambda'} + \not{S}^2\tau^2_{\lambda\lambda'}]\,\not{p}\,, \tag{H.4.8}$$

$$v(p,\lambda')\bar{v}(p,\lambda) = \tfrac{1}{2}(1 - 2\lambda\gamma_5)\,\not{p}\,\delta_{\lambda'\lambda} + \tfrac{1}{2}\gamma_5[\not{S}^1\tau^1_{\lambda'\lambda} + \not{S}^2\tau^2_{\lambda'\lambda}]\,\not{p}\,. \tag{H.4.9}$$

As expected, when $\lambda = \lambda'$, we recover the helicity projection operators for massless spin-1/2 particles given in eqs. (G.4.24) and (G.4.25).

As before, we can use the Bouchiat-Michel formulae to evaluate helicity amplitudes involving two equal mass spin-1/2 fermions. A typical amplitude involving a fermion-antifermion pair, evaluated in the center-of-mass frame of the pair, has the generic structure:

$$\overline{w}(\vec{\boldsymbol{p}}, \lambda)\,\Gamma\,w'(-\vec{\boldsymbol{p}}, \lambda')\,, \tag{H.4.10}$$

where w is either a u or v spinor, w' is respectively either a v or u spinor, and Γ is a product of Dirac gamma matrices. For example,

$$\bar{u}(\vec{\boldsymbol{p}}, \lambda)\,\Gamma\,v(-\vec{\boldsymbol{p}}, \lambda') = -2\lambda'\bar{u}(\vec{\boldsymbol{p}}, \lambda)\,\Gamma\,\gamma_5\,u(-\vec{\boldsymbol{p}}, -\lambda') = -2\lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\,\bar{u}(\vec{\boldsymbol{p}}, \lambda)\,\Gamma\,\gamma_5\,\gamma^0\,u(\vec{\boldsymbol{p}}, \lambda')\,, \tag{H.4.11}$$

where we have used the results of eqs. (H.4.5) and (H.4.6). We can now employ the Bouchiat-Michel formula to convert the above result into a trace. By a similar computation, all expressions of the form of eq. (H.4.10) can be expressed as a trace:

$$\bar{u}(\vec{\boldsymbol{p}}, \lambda)\,\Gamma\,v(-\vec{\boldsymbol{p}}, \lambda') = -\lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\,\mathrm{Tr}\left[\Gamma\gamma_5\gamma^0(\delta_{\lambda\lambda'} + \gamma_5\gamma_\mu\mathscr{S}^{\mu}_{\lambda\lambda'})(\not{p} + m)\right], \tag{H.4.12}$$

$$\bar{v}(\vec{\boldsymbol{p}}, \lambda)\,\Gamma\,u(-\vec{\boldsymbol{p}}, \lambda') = \lambda'\,\xi_{-\lambda'}(\hat{\boldsymbol{p}})\,\mathrm{Tr}\left[\Gamma\gamma_5\gamma^0(\delta_{\lambda'\lambda} + \gamma_5\gamma_\mu\mathscr{S}^{\mu}_{\lambda'\lambda})(\not{p} - m)\right]. \tag{H.4.13}$$

These results are the four-component analogues of eqs. (H.3.24)–(H.3.27) and eqs. (H.3.28)–(H.3.31), respectively. For amplitudes that involve a pair of equal mass fermions [or equal mass antifermions], w and w' in eq. (H.4.10) are both u-spinors [or v-spinors]. Using eq. (G.4.15), these amplitudes can then be evaluated using the results of eqs. (H.4.12) and (H.4.13) above.

In the massless limit, one can again put $mS^{a\mu} = p^\mu\delta^{a3}$, set $p^2 = m^2$ and take $m \to 0$ at the end of the computation. Alternatively, one can repeat the derivation of eqs. (H.4.12)–(H.4.13) using the results of eqs. (H.4.8) and (H.4.9). For completeness, we record the end result here.

$$\bar{u}(\vec{\boldsymbol{p}}, \lambda)\,\Gamma\,v(-\vec{\boldsymbol{p}}, \lambda') = \xi_{\lambda'}(\hat{\boldsymbol{p}})\Big\{\tfrac{1}{2}\delta_{\lambda\lambda'}\ \mathrm{Tr}[\Gamma\gamma^0(1 + 2\lambda\gamma_5)\not{p}] + \lambda'\ \mathrm{Tr}[\Gamma\gamma^0(\not{S}^1\tau^1_{\lambda\lambda'} + \not{S}^2\tau^2_{\lambda\lambda'})\,\not{p}]\Big\}, \tag{H.4.14}$$

$$\bar{v}(\vec{\boldsymbol{p}}, \lambda)\,\Gamma\,u(-\vec{\boldsymbol{p}}, \lambda') = \xi_{-\lambda'}(\hat{\boldsymbol{p}})\Big\{\tfrac{1}{2}\delta_{\lambda'\lambda}\ \mathrm{Tr}[\Gamma\gamma^0(1 - 2\lambda\gamma_5)\not{p}] - \lambda'\ \mathrm{Tr}[\Gamma\gamma^0(\not{S}^1\tau^1_{\lambda'\lambda} + \not{S}^2\tau^2_{\lambda'\lambda})\,\not{p}]\Big\}. \tag{H.4.15}$$

As an example, we consider once again the decay $Z^0 \to f\bar{f}$. The decay amplitude is equal to eq. (H.4.12), where Γ is a linear combination of $\frac{1}{2}\gamma^\mu(1-\gamma_5)$ and $\frac{1}{2}\gamma^\mu(1+\gamma_5)$. Evaluating the corresponding traces yields:

$$\bar{u}(\vec{\boldsymbol{p}},\lambda)\,\tfrac{1}{2}\gamma^\mu(1-\gamma_5)\,v(-\vec{\boldsymbol{p}},\lambda') = 2\lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\,\left[mg^{\mu 0}\delta_{\lambda\lambda'} + p^\mu \mathscr{S}^0_{\lambda\lambda'} - p^0\mathscr{S}^\mu_{\lambda\lambda'} + i\epsilon^{0\mu\nu\rho}(\mathscr{S}_{\lambda\lambda'})_\nu p_\rho\right]\,, \tag{H.4.16}$$

$$\bar{u}(\vec{\boldsymbol{p}},\lambda)\,\tfrac{1}{2}\gamma^\mu(1+\gamma_5)\,v(-\vec{\boldsymbol{p}},\lambda') = 2\lambda'\,\xi_{\lambda'}(\hat{\boldsymbol{p}})\,\left[-mg^{\mu 0}\delta_{\lambda\lambda'} + p^\mu \mathscr{S}^0_{\lambda\lambda'} - p^0\mathscr{S}^\mu_{\lambda\lambda'} - i\epsilon^{0\mu\nu\rho}(\mathscr{S}_{\lambda\lambda'})_\nu p_\rho\right]\,. \tag{H.4.17}$$

Using eq. (H.1.10), we see that eqs. (H.4.16) and (H.4.17) reproduce exactly the results of eqs. (H.3.40) and (H.3.41), respectively.

Finally, we note that if the two fermions do not have the same mass, then the method presented above is not applicable. However, generalizations of the above method exist in the literature that can be employed to evaluate helicity amplitudes of the form of eq. (H.4.10) for unequal mass fermions; see, e.g., [319]. An alternative approach due to Hagiwara and Zeppenfeld [106] is reviewed in Appendix I.1 .

29.7.11 Helicity amplitudes and the spinor helicity method

In Appendix H , we showed how to use the Bouchiat-Michel formulae (with versions applicable to both two-component and four-component spinor wave functions) to construct helicity amplitudes for processes with two initial state and two final state equal mass fermions (or a fermion-antifermion pair) in the center-of-mass frame of the two fermions. For practical applications, it is important to extend these techniques to allow for final states with an arbitrary number of particles. The techniques should be powerful enough to allow for pairs of fermions of unequal mass, and both massless and massive spin-1 particles. Ideally, these techniques should produce simple analytic results (when possible) and yield efficient numerical algorithms for the evaluation of the helicity amplitudes.

The helicity amplitude technique of Hagiwara and Zeppenfeld

One method for computing helicity amplitudes for multi-particle final states that is easily amenable to numerical analysis was developed by Hagiwara and Zeppenfeld (HZ) [106]. The HZ formalism was subsequently employed in refs. [321, 322] in developing a fast numerical algorithm for the computation of multi-parton processes. In this section, we demonstrate how our two-component formalism (denoted by DHM) can be connected to theirs. In particular, we present a translation between the two formalisms in Table I.1.1.

After removing the propagator factors, an arbitrary tree amplitude with external fermions can be expressed in terms of a four-component fermion string

$$\overline{\Psi}_i P_\tau \not{\phi}_1 \not{\phi}_2 \ldots \not{\phi}_n \Psi_j\,, \qquad\qquad \tau = \pm 1\,, \tag{I.1.1}$$

where Ψ_j is a four-component spinor wave function $u(p_j,\lambda_j)$ or $v(p_j,-\lambda_j)$,[157] and $P_\pm = \frac{1}{2}(1\pm\gamma_5)$ are the chiral projection operators. Furthermore, $\not{a}_k \equiv \gamma_\mu a_k^\mu$ where a_k represents an arbitrary Lorentz four-vector, which can be a four-momentum p_k^μ, a vector boson wave function $\epsilon^\mu(p_k,\lambda_k)$, an axial vector (e.g., $\epsilon^{\mu\nu\rho\sigma}p_{k\nu}p_{m\rho}p_{n\sigma}$) or another fermion string with uncontracted Lorentz indices (e.g., $\overline{\Psi}_m\gamma^\mu\Psi_n$).

[157] HZ defines $v(p,\lambda) = C\bar{u}^{\mathsf{T}}(p,\lambda)$, where $C = i\gamma^2\gamma^0$, which differs by an overall minus sign from the conventions employed in this review [cf. eq. (G.1.21)]. In this section, we will modify the HZ results in order to be consistent with our sign convention.

DHM Formalism	HZ Formalism
$x_\alpha(p,\lambda)$	$u(p,\lambda)_-$
$x^\alpha(p,\lambda)$	$v^\dagger(p,\lambda)_+$
$x^{\dagger\dot\alpha}(p,\lambda)$	$v(p,\lambda)_+$
$x^\dagger_{\dot\alpha}(p,\lambda)$	$u^\dagger(p,\lambda)_-$
$y_\alpha(p,\lambda)$	$v(p,\lambda)_-$
$y^\alpha(p,\lambda)$	$u^\dagger(p,\lambda)_+$
$y^{\dagger\dot\alpha}(p,\lambda)$	$u(p,\lambda)_+$
$y^\dagger_{\dot\alpha}(p,\lambda)$	$v^\dagger(p,\lambda)_-$
$p\cdot\sigma$	$(\not p)_+$
$p\cdot\overline{\sigma}$	$(\not p)_-$
σ^μ	σ^μ_+
$\overline{\sigma}^\mu$	σ^μ_-
P_R	P_+
P_L	P_-
$\lambda=\pm\frac{1}{2}$	$\lambda=\pm1$
$\chi_\lambda(-\hat{\boldsymbol{z}})$	$-\chi_\lambda(-\hat{\boldsymbol{z}})$

Table I.1.1: Translation between our notation (denoted by DHM) and the notation of Hagiwara and Zeppenfeld (HZ) [106]. The sign convention governing the definition of $v(p,\lambda)_\pm$ is opposite to that of HZ (cf. footnote 157).

In order to rewrite the fermion string, eq. (I.1.1), in terms of two-component spinors, HZ decomposes the four-component spinors as follows:

$$\Psi_j \equiv \begin{pmatrix} (\psi_j)_- \\ (\psi_j)_+ \end{pmatrix}, \qquad u(p_j,\lambda_j) \equiv \begin{pmatrix} u(p_j,\lambda_j)_- \\ u(p_j,\lambda_j)_+ \end{pmatrix}, \qquad v(p_j,\lambda_j) \equiv \begin{pmatrix} v(p_j,\lambda_j)_- \\ v(p_j,\lambda_j)_+ \end{pmatrix}. \tag{I.1.2}$$

Comparing with eqs. (G.4.11) and (G.4.12), the corresponding expressions in our notation are given in Table I.1.1. Note that $\lambda=\pm1$ in the notation of HZ, whereas in our notation (which we follow below) $\lambda=\pm\frac{1}{2}$.

The four-component fermion string is then replaced by the two-component fermion string:

$$\overline{\Psi}_i P_\tau \not a_1 \not a_2 \ldots \not a_n \Psi_j = (\psi_i)^\dagger_\tau (\not a_1)_\tau (\not a_2)_{-\tau} \ldots (\not a_n)_{-\delta_n\tau} (\psi_j)_{-\delta_n\tau}\,, \qquad \tau=\pm1\,, \quad \text{where } \delta_n \equiv (-1)^n\,. \tag{I.1.3}$$

In the notation of HZ,

$$(\not a)_\pm = a_\mu \sigma^\mu_\pm\,, \tag{I.1.4}$$

where $\sigma_+^\mu \equiv \sigma^\mu$ and $\sigma_-^\mu \equiv \overline{\sigma}^\mu$. In eq. (I.1.3), the helicity labels are suppressed; more explicitly,

$$(\psi_k)_\tau \equiv \psi_k(p_k\,,\,\lambda_k)_\tau = u(p_k\,,\,\lambda_k)_\tau \quad \text{or} \quad v(p_k\,,\,-\lambda_k)_\tau\,. \tag{I.1.5}$$

This convention of HZ (note the $-\lambda_k$ argument of v) allows one to write simple generic formulae in terms of $(\psi)_\pm$ that are applicable to both $u_\pm$ and $v_\pm$.

Using the results of Table I.1.1, one can verify that eq. (I.1.3) is covariant with respect to dotted and undotted indices. That is, the sign τ of $\psi_i^\dagger$ must match the sign of the first σ-matrix in the string $(\not{\phi}_1)_\tau(\not{\phi}_2)_{-\tau}...(\not{\phi}_n)_{-\delta_n\tau}$. The signs of the sigma matrices within this string alternate (either $+-+-...$ or $-+-+...$ in the case of $\tau = +1$ or -1, respectively). Finally, the sign of the last σ-matrix in the string [which must be equal to $-\delta_n\tau$ in light of the previous statement] must match the sign of ψ_j as indicated.

As noted above, it is possible that one of the $(\not{\phi}_i)_\tau$ could be of the form σ_τ^μ multiplied by another fermion string with a free μ-index. One can uncouple the two fermion strings by employing the Fierz identities given by eqs. (29.68)–(29.70). For example,

$$\begin{aligned}&[(u_1)_-^\dagger(\not{\phi}_1)_-\sigma_+^\mu(\not{\phi}_2)_-(u_2)_-][(u_3)_-^\dagger(\not{\phi}_3)_-\sigma_{+\mu}(\not{\phi}_4)_-(u_4)_-]\\ &\qquad = [(u_1)_-^\dagger(\not{\phi}_1)_-(\not{\phi}_3)_+(v_3)_+][(v_4)_+^\dagger(\not{\phi}_4)_+(\not{\phi}_2)_-(u_2)_-]\,,\end{aligned} \tag{I.1.6}$$

which is easily derived after translating to the DHM notation.[158] As a result, the helicity tree amplitude for any process can be expressed as the product of *uncoupled* strings of two-component fermion spinors

$$\mathrm{FS} = (\psi_i)_\tau^\dagger(\not{\phi}_1)_\tau(\not{\phi}_2)_{-\tau}...(\not{\phi}_n)_{-\delta_n\tau}(\psi_j)_{-\delta_n\tau}\,. \tag{I.1.7}$$

To evaluate the fermion string FS, we employ the explicit forms for the two-component helicity spinor wave functions given in eqs. (C.3.3)–(C.3.6), which can be rewritten as

$$\psi(p_k,\lambda_k)_\tau = C_k\,\omega_{\tau\lambda_k}(\vec{\boldsymbol{p}})\,\chi_{\lambda_k}(\hat{\boldsymbol{p}}_{\boldsymbol{k}})\,, \tag{I.1.8}$$

where, following the convention of eq. (I.1.5),

$$C_k = \begin{cases} 1 & \text{for} \quad (\psi_k)_\tau = u(p_k,\lambda_k)_\tau\,,\\ 2\lambda_k\tau & \text{for} \quad (\psi_k)_\tau = v(p_k,-\lambda_k)_\tau\,,\end{cases} \qquad \tau = \pm 1, \qquad \lambda_k = \pm 1/2\,, \tag{I.1.9}$$

and $\omega_\lambda(\vec{\boldsymbol{p}}) \equiv (E + 2\lambda|\vec{\boldsymbol{p}}|)^{1/2}$ for $\lambda = \pm 1/2$. Hence, the fermion string [eq. (I.1.7)] is given by[106]

$$\mathrm{FS} = C_i\,C_j\,\omega_{\tau\lambda_i}(\vec{\boldsymbol{p}}_{\boldsymbol{i}})\,\omega_{-\delta_n\tau\lambda_j}(\vec{\boldsymbol{p}}_{\boldsymbol{j}})\,S(p_i,a_1,a_2,...,a_n,p_j)^\tau_{\lambda_i\lambda_j}\,, \tag{I.1.10}$$

where the function S is defined as

$$S(p_i,a_1,a_2,...,a_n,p_j)^\tau_{\lambda_i\lambda_j} \equiv \chi^\dagger_{\lambda_i}(\hat{\boldsymbol{p}}_{\boldsymbol{i}})\left[\prod_{k=1}^n(\not{\phi}_k)_{-\delta_k\tau}\right]\chi_{\lambda_j}(\hat{\boldsymbol{p}}_{\boldsymbol{j}})\,, \tag{I.1.11}$$

where $\delta_k \equiv (-1)^k$. In the absence of the $\not{\phi}_{\pm\tau}$ factors, we define

$$S(p_i\,,\,p_j)_{\lambda_i\lambda_j} \equiv T(\hat{\boldsymbol{p}}_{\boldsymbol{i}}\,,\,\hat{\boldsymbol{p}}_{\boldsymbol{j}})_{2\lambda_i,2\lambda_j} = \chi^\dagger_{\lambda_i}(\hat{\boldsymbol{p}}_{\boldsymbol{i}})\chi_{\lambda_j}(\hat{\boldsymbol{p}}_{\boldsymbol{j}})\,, \tag{I.1.12}$$

where the $T(\hat{\boldsymbol{p}}_{\boldsymbol{i}}\,,\,\hat{\boldsymbol{p}}_{\boldsymbol{j}})_{2\lambda_i,2\lambda_j}$ are proportional to the (massless) spinorial products introduced by Kleiss [99] [cf. eqs. (I.2.22) and (I.2.23)].

[158] Here, we differ from HZ, who employ a Fierz identity that is not covariant with respect to the dotted and undotted indices [note the comment below eq. (29.55)]. Thus, eq. (I.1.6) differs from the result obtained in eq. (3.17b) of HZ.

To evaluate S, we assume that the four-vectors a_k^μ are real.[159] Then, we may employ the following identity:[160]

$$(\not{a})_\tau = \sum_{\tau'=\pm} \left[a^0 - \tau'\tau|\vec{\boldsymbol{a}}|\right] \chi_{\tau'/2}(\hat{\boldsymbol{a}})\chi^\dagger_{\tau'/2}(\hat{\boldsymbol{a}})\,, \tag{I.1.13}$$

where $\chi_{\tau'/2}(\hat{\boldsymbol{a}})$ is a two-component helicity spinor with three-momentum $\vec{\boldsymbol{a}}$. Using eq. (I.1.13) in eq. (I.1.11), we end up with the desired expression:

$$\begin{aligned} S(p_i, a_1, a_2, ..., a_n, p_j)^\tau_{\lambda_i\lambda_j} \;=\; & \left[\prod_{k=1}^{n}\sum_{\tau_k=\pm}\left[a_k^0 + \tau_k\delta_k\tau|\vec{\boldsymbol{a}}_{\boldsymbol{k}}|\right]\right] T(\hat{\boldsymbol{p}}_i, \hat{\boldsymbol{a}}_1)_{2\lambda_i,\tau_1} T(\hat{\boldsymbol{a}}_1, \hat{\boldsymbol{a}}_2)_{\tau_1\tau_2} \\ & \times \cdots T(\hat{\boldsymbol{a}}_{n-1}, \hat{\boldsymbol{a}}_n)_{\tau_{n-1}\tau_n} T(\hat{\boldsymbol{a}}_n, \hat{\boldsymbol{p}}_j)_{\tau_n,2\lambda_j}\,. \end{aligned} \tag{I.1.14}$$

All that remains is to evaluate the spinorial product $T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})_{\tau_a\,\tau_b}$ (τ_a, $\tau_b = \pm 1$) for arbitrary unit three-vectors $\hat{\boldsymbol{a}}$ and $\hat{\boldsymbol{b}}$. Two properties of the spinorial product $T(\hat{\boldsymbol{a}}\,, \hat{\boldsymbol{b}})_{\tau_a,\tau_b}$ are noteworthy. First, as this product is a scalar, it follows that $T(\hat{\boldsymbol{a}}\,, \hat{\boldsymbol{b}})^*_{\tau_a,\tau_b} = T(\hat{\boldsymbol{a}}\,, \hat{\boldsymbol{b}})^\dagger_{\tau_a,\tau_b}$. Hence, eq. (I.1.12) implies that

$$T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})_{\tau_a\,\tau_b} = T(\hat{\boldsymbol{b}}, \hat{\boldsymbol{a}})^*_{\tau_b\,\tau_a}\,. \tag{I.1.15}$$

Second, we use eq. (C.1.8) to write:

$$\begin{aligned} T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})_{\tau_a\,\tau_b} = {} & \chi^\dagger_{\tau_a/2}(\hat{\boldsymbol{z}})\, \exp(i\gamma_a\sigma^3/2)\, \exp(i\theta_a\sigma^2/2)\, \exp(i\phi_a\sigma^3/2) \\ & \times \exp(-i\phi_b\sigma^3/2)\, \exp(-i\theta_b\sigma^2/2)\, \exp(-i\gamma_b\sigma^3/2)\, \chi_{\tau_b/2}(\hat{\boldsymbol{z}})\,. \end{aligned} \tag{I.1.16}$$

Complex conjugating this result, and using the fact that $\chi(\hat{\boldsymbol{z}})$, σ^1 and σ^3 are real and σ^2 is pure imaginary,

$$\begin{aligned} T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})^*_{\tau_a\,\tau_b} = {} & \tau_a\tau_b\, \chi^\dagger_{-\tau_a/2}(\hat{\boldsymbol{z}})\, \sigma^2\, \exp(-i\gamma_a\sigma^3/2)\, \exp(i\theta_a\sigma^2/2)\, \exp(-i\phi_a\sigma^3/2) \\ & \times \exp(i\phi_b\sigma^3/2)\, \exp(-i\theta_b\sigma^2/2)\, \exp(i\gamma_b\sigma^3/2)\, \sigma^2\, \chi_{-\tau_b/2}(\hat{\boldsymbol{z}})\,, \end{aligned} \tag{I.1.17}$$

after using eq. (C.1.22). Since σ^2 anticommutes with σ^3, we end up with:

$$\begin{aligned} T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})^*_{\tau_a\,\tau_b} &= \tau_a\tau_b\, \chi^\dagger_{-\tau_a/2}(\hat{\boldsymbol{z}})\, \exp(i\gamma_a\sigma^3/2)\, \exp(i\theta_a\sigma^2/2)\, \exp(i\phi_a\sigma^3/2) \\ &\quad \times \exp(-i\phi_b\sigma^3/2)\, \exp(-i\theta_b\sigma^2/2)\, \exp(-i\gamma_b\sigma^3/2)\, \chi_{-\tau_b/2}(\hat{\boldsymbol{z}}) \\ &= \tau_a\tau_b\, T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})_{-\tau_a\,,\,-\tau_b}\,. \end{aligned} \tag{I.1.18}$$

Since τ_a, $\tau_b = \pm 1$, it follows that

$$T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})_{-\tau_a,-\tau_b} = \tau_a\, \tau_b\, T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})^*_{\tau_a\,\tau_b}\,. \tag{I.1.19}$$

Using eqs. (I.1.15) and (I.1.19), it is sufficient to give explicit forms for only two of the spinorial products [100, 106]. Eq. (I.1.16) yields:

$$T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})_{++} = e^{i(\phi_a-\phi_b+\gamma_a-\gamma_b)/2}\, \cos\frac{\theta_a}{2}\cos\frac{\theta_b}{2} + e^{-i(\phi_a-\phi_b-\gamma_a+\gamma_b)/2}\, \sin\frac{\theta_a}{2}\sin\frac{\theta_b}{2}\,, \tag{I.1.20}$$

$$T(\hat{\boldsymbol{a}}, \hat{\boldsymbol{b}})_{-+} = e^{-i(\phi_a-\phi_b+\gamma_a+\gamma_b)/2}\, \cos\frac{\theta_a}{2}\sin\frac{\theta_b}{2} - e^{i(\phi_a-\phi_b-\gamma_a-\gamma_b)/2}\, \sin\frac{\theta_a}{2}\cos\frac{\theta_b}{2}\,, \tag{I.1.21}$$

[159] In the case of complex a^μ, one should decompose a^μ into its real and imaginary parts and evaluate separately the real and imaginary parts of S.

[160] To obtain eq. (I.1.13), we make use of eq. (29.3.42) applied to helicity spinors: $\chi_\lambda\chi^\dagger_\lambda = \frac{1}{2}(1 + 2\lambda\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{p}})$.

where (θ_p, ϕ_p) are the polar and azimuthal angles of $\hat{\boldsymbol{p}}$ (for $\hat{\boldsymbol{p}} = \hat{\boldsymbol{a}}$ and $\hat{\boldsymbol{b}}$, respectively). In the case where $\hat{\boldsymbol{a}}$ and/or $\hat{\boldsymbol{b}}$ are parallel to the negative z-axis, we employ the convention of eq. (C.1.7) and choose the corresponding azimuthal angle equal to π.[161] Note that HZ employ a convention for their spinor wave functions [cf. eq. (C.1.8)] in which $\gamma = -\phi$, although the convention in which $\gamma = 0$ yields a slightly more symmetrical form for the spinorial products.

Eqs. (I.1.7), (I.1.10) and (I.1.11) can be written in a form that is reminiscent of the results obtained in Appendix H.3 . For example, using eqs. (C.3.3)–(C.3.6),

$$x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha\beta}\,y_\beta(\vec{\boldsymbol{p}}',-\lambda') = -2\lambda'\omega_{-\lambda}(\vec{\boldsymbol{p}})\omega_{-\lambda'}(\vec{\boldsymbol{p}}')\chi^\dagger_\lambda(\hat{\boldsymbol{p}})\Gamma\chi_{\lambda'}(\hat{\boldsymbol{p}}')\,, \tag{I.1.22}$$

$$y^\alpha(\vec{\boldsymbol{p}},\lambda)\,\Gamma_{\alpha\dot\beta}\,x^{\dagger\dot\beta}(\vec{\boldsymbol{p}}',-\lambda') = 2\lambda'\omega_{\lambda}(\vec{\boldsymbol{p}})\omega_{\lambda'}(\vec{\boldsymbol{p}}')\chi^\dagger_\lambda(\hat{\boldsymbol{p}})\Gamma\chi_{\lambda'}(\hat{\boldsymbol{p}}')\,, \tag{I.1.23}$$

$$y^\alpha(\vec{\boldsymbol{p}},\lambda)\,\Gamma_\alpha{}^\beta\,y_\beta(\vec{\boldsymbol{p}}',-\lambda') = -2\lambda'\omega_{\lambda}(\vec{\boldsymbol{p}})\omega_{-\lambda'}(\vec{\boldsymbol{p}}')\chi^\dagger_\lambda(\hat{\boldsymbol{p}})\Gamma\chi_{\lambda'}(\hat{\boldsymbol{p}}')\,, \tag{I.1.24}$$

$$x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda)\,\Gamma^{\dot\alpha}{}_{\dot\beta}\,x^{\dagger\dot\beta}(\vec{\boldsymbol{p}}',-\lambda') = 2\lambda'\omega_{-\lambda}(\vec{\boldsymbol{p}})\omega_{\lambda'}(\vec{\boldsymbol{p}}')\chi^\dagger_\lambda(\hat{\boldsymbol{p}})\Gamma\chi_{\lambda'}(\hat{\boldsymbol{p}}')\,, \tag{I.1.25}$$

where Γ is a product of alternating σ and $\overline{\sigma}$ matrices. The spinor index structure determines the identity of the first and last matrix (e.g., $\Gamma^{\dot\alpha}{}_{\dot\beta}$ indicates a string of matrices that begins with a $\overline{\sigma}$ and ends with a σ, etc.). By suitable interchanges of x and y, twelve additional equations of similar type may be written. Note that $\chi^\dagger_\lambda\Gamma\chi_{\lambda'}$ [appearing on the right-hand side of eqs. (I.1.22)–(I.1.25)] corresponds precisely to the $S(p,a_1,a_2,...,a_n,p')^\tau_{\lambda\lambda'}$ of eq. (I.1.11), where the four possible $(\tau\,,\,\delta_n)$ combinations are in one-to-one correspondence with the four possible spinor index structures of Γ. If $\vec{\boldsymbol{p}}' = -\vec{\boldsymbol{p}}$, then one should recover eqs. (H.3.24)–(H.3.27). Thus, the HZ method provides a powerful generalization of the helicity amplitude methods derived in Appendix H.3 .

The spinor helicity method

In many practical calculations, the masses of the fermions can be neglected. In this case the computation of multi-particle helicity amplitudes simplifies considerably. In this section, we give a brief introduction to the spinor helicity method; for a review, see refs. [323, 324]. The spinor helicity method is a powerful technique for computing helicity amplitudes for multi-particle processes involving massless spin-1/2 and spin-1 particles. Although initially applied to tree-level processes, more general techniques have also been developed that are applicable to one-loop (and multiloop) diagrams [325]. Rules for computing dimensionally regularized amplitudes within the framework of the spinor helicity method have been given by [326]. The spinor helicity techniques are ideal for QCD where light quark masses can almost always be neglected. Generalizations of these methods that incorporate massive spin-1/2 and spin-1 particles exist, although they tend to be quite cumbersome [327, 328]. A Mathematica implementation of the spinor helicity formalism can be found in [329]. In this section, we restrict the discussion to the massless case.

The spinor helicity technique described below is based on a formalism developed by Xu, Zhang and Chang [102] (denoted henceforth by XZC), which is a modification of techniques established by the CALKUL collaboration [330]. The XZC formalism (which was also independently developed in refs. [100, 331]) is based on the four-component spinor formalism. Using eq. (G.4.23), XZC introduce a very useful notation for massless spinors

$$|p\pm\rangle \equiv u(p,\pm\tfrac{1}{2}) = v(p,\mp\tfrac{1}{2})\,, \tag{I.2.1}$$

$$\langle p\pm| \equiv \bar u(p,\pm\tfrac{1}{2}) = \bar v(p,\mp\tfrac{1}{2})\,. \tag{I.2.2}$$

Using these spinor wave functions, they define two non-trivial (massless) spinor products (which are equivalent to the spinorial products introduced by Kleiss [99]):[162]

$$\langle p\,q\rangle \equiv \langle p-|q+\rangle = \bar u(p,-\tfrac{1}{2})\,u(q,+\tfrac{1}{2})\,, \tag{I.2.3}$$

$$[p\,q] \equiv \langle p+|q-\rangle = \bar u(p,+\tfrac{1}{2})\,u(q,-\tfrac{1}{2})\,. \tag{I.2.4}$$

[161] This convention yields a value of $\chi_\lambda(-\hat{\boldsymbol{z}})$ that is opposite in sign to the convention adopted by HZ.

[162] Note that $\langle p-|q-\rangle = \langle p+|q+\rangle = 0$ due to $P_LP_R = P_RP_L = 0$.

The $\pm$ notation specified by the bra and ket indicates the chirality (i.e. the eigenvalue of γ_5) of the corresponding four-component spinor [cf. eq. (G.4.22)].

However, the two-component spinor formalism is especially economical in the case of massless spin-1/2 fermions. Hence, we shall reformulate the XZC approach using two-component spinor notation. First, we consider the explicit forms for the two-component helicity spinor wave functions [given by eqs. (29.3.36)–(29.3.39)] in the massless limit:

$$x_\alpha(\vec{\boldsymbol{p}},-\tfrac{1}{2}) = y_\alpha(\vec{\boldsymbol{p}},\tfrac{1}{2}) = (2E)^{1/2}\,\chi_{-1/2}(\hat{\boldsymbol{p}})\,, \qquad x^\alpha(\vec{\boldsymbol{p}},-\tfrac{1}{2}) = y^\alpha(\vec{\boldsymbol{p}},\tfrac{1}{2}) = (2E)^{1/2}\,\chi^\dagger_{1/2}(\hat{\boldsymbol{p}})\,, \tag{I.2.5}$$

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},-\tfrac{1}{2}) = y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\tfrac{1}{2}) = (2E)^{1/2}\,\chi_{1/2}(\hat{\boldsymbol{p}})\,, \qquad x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},-\tfrac{1}{2}) = y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\tfrac{1}{2}) = (2E)^{1/2}\,\chi^\dagger_{-1/2}(\hat{\boldsymbol{p}})\,, \tag{I.2.6}$$

where $E = |\vec{\boldsymbol{p}}|$. For all other choices of helicities, the corresponding helicity spinor wave functions vanish. Hence, we define:[163]

$$|p+\rangle = y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\tfrac{1}{2}) = x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},-\tfrac{1}{2})\,, \qquad \langle p+| = y^\alpha(\vec{\boldsymbol{p}},\tfrac{1}{2}) = x^\alpha(\vec{\boldsymbol{p}},-\tfrac{1}{2})\,, \tag{I.2.7}$$

$$|p-\rangle = x_\alpha(\vec{\boldsymbol{p}},-\tfrac{1}{2}) = y_\alpha(\vec{\boldsymbol{p}},\tfrac{1}{2})\,, \qquad \langle p-| = x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},-\tfrac{1}{2}) = y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\tfrac{1}{2})\,. \tag{I.2.8}$$

The $|p\pm\rangle$ and $\langle p\pm|$ satisfy the massless Dirac equation [cf. eqs. (29.3.9)–(29.3.12)]:

$$p\cdot\sigma_\pm\,|p\pm\rangle = 0, \qquad \langle p\pm|\,p\cdot\sigma_\pm = 0\,, \tag{I.2.9}$$

where $\sigma_+ \equiv \sigma$ and $\sigma_- \equiv \overline{\sigma}$ as indicated in Table I.1.1. The above and the following equations should each be read as two separate equations corresponding to the upper and lower set of signs, respectively. The following properties are also noteworthy:

$$|p\pm\rangle\,\langle p\pm| = p\cdot\sigma_\mp\,, \tag{I.2.10}$$

$$\langle p\pm|\,\sigma^\mu_\pm\,|p\pm\rangle = 2p^\mu\,, \tag{I.2.11}$$

$$\langle p\pm|q\mp\rangle = -\,\langle q\pm|p\mp\rangle\ , \tag{I.2.12}$$

$$\langle p+|\,\sigma^\mu_+\,|q+\rangle = \langle q-|\,\sigma^\mu_-\,|p-\rangle\ , \tag{I.2.13}$$

$$\langle p\pm|\,\sigma^\mu_\pm\sigma^\nu_\mp\,|q\mp\rangle = -\,\langle q\pm|\,\sigma^\nu_\pm\sigma^\mu_\mp\,|p\mp\rangle\ . \tag{I.2.14}$$

Note that eqs. (I.2.9)–(I.2.14) are covariant with respect to the undotted and dotted spinor indices. Eqs. (I.2.10) and (I.2.11) follow from eqs. (29.3.53) and (29.3.54). For example,

$$\langle p+|\,\sigma^\mu_+\,|p+\rangle = y^\alpha(\vec{\boldsymbol{p}},\tfrac{1}{2})\sigma^\mu_{\alpha\dot\beta}\,y^{\dagger\dot\beta}(\vec{\boldsymbol{p}},\tfrac{1}{2}) = \sigma^\mu_{\alpha\dot\beta}\,y^{\dagger\dot\beta}(\vec{\boldsymbol{p}},\tfrac{1}{2})y^\alpha(\vec{\boldsymbol{p}},\tfrac{1}{2}) = \,\mathrm{Tr}\,(\sigma^\mu p\cdot\overline{\sigma}) = 2p^\mu\,, \tag{I.2.15}$$

and similarly for $\langle p-|\,\sigma^\mu_-\,|p-\rangle$. Eqs. (I.2.12)–(I.2.14) follow immediately from eqs. (29.60)–(29.64). Eqs. (I.2.13) and (I.2.14) generalize easily to the case of a product of an even and odd number of $\sigma/\overline{\sigma}$ matrices. For any positive integer n,

$$\langle p+|\,\sigma^{\mu_1}_+\sigma^{\mu_2}_-\cdots\sigma^{\mu_{2n-1}}_+\,|q+\rangle = \langle q-|\,\sigma^{\mu_{2n-1}}_-\cdots\sigma^{\mu_2}_+\sigma^{\mu_1}_-\,|p-\rangle\ , \tag{I.2.16}$$

$$\langle p\pm|\,\sigma^{\mu_1}_\pm\sigma^{\mu_2}_\mp\cdots\sigma^{\mu_{2n}}_\mp\,|q\mp\rangle = -\,\langle q\pm|\,\sigma^{\mu_{2n}}_\pm\cdots\sigma^{\mu_2}_\pm\sigma^{\mu_1}_\mp\,|p\mp\rangle\ . \tag{I.2.17}$$

[163] The association of undotted and dotted indices in eqs. (I.2.7) and (I.2.8) is a consequence of our convention for the Dirac gamma matrices given in Appendix G [cf. eq. (G.1.2)]. Note that in this convention, the left-handed [right-handed] projection operator P_L [P_R] projects out the lowered undotted [raised dotted] index components of the four-component spinor [cf. eq. (G.1.7)]. However, the reader is warned that in the literature on the spinor helicity method, one often finds $|p+\rangle$ associated with a lowered undotted index and $|p-\rangle$ associated with an upper dotted index. This is due to a different convention for the sigma matrices, such as the Wess and Bagger definition given in eqs. (A.11) and (A.12). Numerically, this is equivalent to a convention for the Dirac gamma matrices in which σ^μ and $\overline{\sigma}^\mu$ are interchanged in eq. (G.1.2), resulting in an overall change of sign in the matrix representation of γ_5. As a result, in this latter convention the lowered undotted [raised dotted] index components are associated with positive [negative] chirality. For an historical perspective, see the discussion following eq. (A.12).

Spinor products can be formed from the bras and kets in the usual way and satisfy:

$$\langle p \pm |q\mp\rangle^* = \langle q \mp |p\pm\rangle \,, \tag{I.2.18}$$
$$\langle p \pm |\sigma^\mu_\pm| q\pm\rangle^* = \langle q \pm |\sigma^\mu_\pm| p\pm\rangle \,, \tag{I.2.19}$$

where we have used the fact that the $\sigma^\mu_\pm$ are hermitian. Covariance with respect to the undotted and dotted spinors allows only two possible spinor products:[164]

$$\langle p\, q\rangle \equiv \langle p - |q+\rangle = x^\dagger(\vec{\boldsymbol{p}}, -\tfrac{1}{2})\, y^\dagger(\vec{\boldsymbol{q}}, \tfrac{1}{2})\,, \tag{I.2.20}$$
$$[p\, q] \equiv \langle p + |q-\rangle = y(\vec{\boldsymbol{p}}, \tfrac{1}{2})\, x(\vec{\boldsymbol{q}}, -\tfrac{1}{2})\,. \tag{I.2.21}$$

In particular, the products $\langle p+|q+\rangle$ and $\langle p-|q-\rangle$ never arise in a computation using two-component spinor notation. In terms of the spinorial products defined in eq. (I.1.12),

$$\langle p\, q\rangle \equiv \langle p - |q+\rangle = (2E_p)^{1/2}(2E_q)^{1/2} T(\hat{\boldsymbol{p}}\,,\, \hat{\boldsymbol{q}})_{-+}\,, \tag{I.2.22}$$
$$[p\, q] \equiv \langle p + |q-\rangle = (2E_p)^{1/2}(2E_q)^{1/2} T(\hat{\boldsymbol{p}}\,,\, \hat{\boldsymbol{q}})_{+-}\,, \tag{I.2.23}$$

where $E_p = |\vec{\boldsymbol{p}}|$ and $E_q = |\vec{\boldsymbol{q}}|$. Explicit forms for $T(\hat{\boldsymbol{p}}\,,\, \hat{\boldsymbol{q}})_{-+}$ and $T(\hat{\boldsymbol{p}}\,,\, \hat{\boldsymbol{q}})_{+-} = -T(\hat{\boldsymbol{p}}\,,\, \hat{\boldsymbol{q}})^*_{-+}$ can be obtained from eq. (I.1.21). Using eqs. (I.1.15) and (I.1.19) [or equivalently, using eqs. (I.2.12) and (I.2.18)], the spinor products satisfy the following relations:

$$\langle p\, q\rangle = -\langle q\, p\rangle \,, \tag{I.2.24}$$
$$[p\, q] = -[q\, p]\,, \tag{I.2.25}$$
$$\langle p\, q\rangle^* = -[p\, q]\,. \tag{I.2.26}$$

One immediate consequence of the above results is:

$$\langle p\, p\rangle = \langle p - |p+\rangle = 0\,, \tag{I.2.27}$$
$$[p\, p] = \langle p + |p-\rangle = 0\,. \tag{I.2.28}$$

We next compute the absolute square of the spinor product:

$$\begin{aligned} |\,\langle p\, q\rangle\,|^2 &= x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, -\tfrac{1}{2})\; y^{\dagger\dot\alpha}(\vec{\boldsymbol{q}}, \tfrac{1}{2})\, x_\alpha(\vec{\boldsymbol{p}}, -\tfrac{1}{2})\, y^\alpha(\vec{\boldsymbol{q}}, \tfrac{1}{2}) = x_\alpha(\vec{\boldsymbol{p}}, -\tfrac{1}{2})\, x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, -\tfrac{1}{2})\, y^{\dagger\dot\alpha}(\vec{\boldsymbol{q}}, \tfrac{1}{2})\, y^\alpha(\vec{\boldsymbol{q}}, \tfrac{1}{2}) \\ &= p{\cdot}\sigma_{\alpha\dot\alpha}\, q{\cdot}\overline{\sigma}^{\dot\alpha\alpha} = p_\mu q_\nu\; \mathrm{Tr}(\sigma^\mu\overline{\sigma}^\nu) = 2p{\cdot}q\,. \end{aligned} \tag{I.2.29}$$

Using this result and eq. (I.2.26) yields

$$|\,\langle p\, q\rangle\,|^2 = |[p\, q]|^2 = 2p{\cdot}q\,, \tag{I.2.30}$$

which indicates that the spinor products are roughly the square roots of the corresponding dot products. One other noteworthy relation is:

$$\begin{aligned} \langle p_1\, p_2\rangle\, [p_2\, p_3]\, \langle p_3\, p_4\rangle\, [p_4\, p_1] &= \mathrm{Tr}\,(\sigma{\cdot}p_1\, \overline{\sigma}{\cdot}p_2\, \sigma{\cdot}p_3\, \overline{\sigma}{\cdot}p_4) \\ &= 2(g_{\mu\nu}g_{\rho\kappa} - g_{\mu\rho}g_{\nu\kappa} + g_{\mu\kappa}g_{\nu\rho} + i\epsilon_{\mu\nu\rho\kappa})p_1^\mu p_2^\nu p_3^\rho p_4^\kappa\,, \end{aligned} \tag{I.2.31}$$

where the trace has been evaluated using eq. (B.2.26). Note that the first line of eq. (I.2.31) immediately follows from eqs. (29.3.53) and (29.3.54) after plugging in the definition of the spinor products.

[164] Since we wish to preserve the definition of the spinor products given in eq. (I.2.3), $\langle p\, q\rangle$ is a sum over dotted indices and $[p\, q]$ is a sum over undotted indices in our two-component spinor conventions. This is to be contrasted with most of the literature on the spinor helicity method, in which $\langle p\, q\rangle$ is written as a sum over undotted indices and $[p\, q]$ as a sum over dotted indices. The origin of this difference is explained in footnote 163.

In Appendix I.1 , we showed that a fermion string can be expressed in terms of products of the spinorial products T [cf. eq. (I.1.14)]. When applied to massless spinors, eq. (I.2.30) indicates that the square of the helicity amplitude of a multi-fermion scattering process can be expressed in terms of products of dot products of pairs of fermion momenta. If more than one diagram contributes to a helicity amplitude, then it is often possible to combine the contributions after a rearrangement of momenta via the Fierz identities. Using eqs. (29.66)–(29.70), it follows that:

$$\langle p_1\, p_2\rangle\, \langle p_3\, p_4\rangle = \langle p_1\, p_3\rangle\, \langle p_2\, p_4\rangle + \langle p_1\, p_4\rangle\, \langle p_3\, p_2\rangle\ , \tag{I.2.32}$$

$$[p_1\, p_2]\, [p_3\, p_4] \ = \ [p_1\, p_3]\, [p_2\, p_4] \ + \ [p_1\, p_4]\, [p_3\, p_2]\,, \tag{I.2.33}$$

$$\langle p_1 + |\sigma_+^\mu| p_2 +\rangle\, \langle p_3 + |\sigma_{+\mu}| p_4 +\rangle = 2\, [p_1\, p_3]\ \langle p_4\, p_2\rangle\ , \tag{I.2.34}$$

$$\langle p_1 - |\sigma_-^\mu|\, p_2 -\rangle\, \langle p_3 - |\sigma_{-\mu}| p_4 -\rangle = 2\, \langle p_1\, p_3\rangle\ [p_4\, p_2]\,, \tag{I.2.35}$$

$$\langle p_1 + |\sigma_+^\mu| p_2 +\rangle\, \langle p_3 - |\sigma_{-\mu}| p_4 -\rangle = 2\, [p_1\, p_4]\ \langle p_3\, p_2\rangle\ . \tag{I.2.36}$$

Eqs. (I.2.32) and (I.2.33) are often called the Schouten identities, as they follow from eq. (29.28).

It is desirable to extend the spinor helicity formalism to multi-particle processes involving massless fermions and massless spin-1 bosons. In particular, XZC developed a simple technique for expressing the squares of the corresponding helicity amplitudes in terms of ratios of products of dot products. Their trick was to introduce a convenient expression for the massless spin-1 polarization vector in terms of products of massless spin-1/2 spinor wave functions. Before exhibiting their result, we provide a brief review of spin-1 polarization vectors in the helicity basis.

We first consider a massless spin-1 particle moving in the z-direction with four-momentum $k^\mu = E(1\,;\,0\,,\,0\,,\,1)$. The textbook expression for the helicity ±1 polarization vectors of a massless spin-1 boson is given by [257, 258, 259, 332]:

$$\varepsilon^\mu(\hat{\boldsymbol{z}}, \pm1) = \frac{1}{\sqrt{2}}\,(0\,;\,\mp1\,,\,-i\,,\,0)\ . \tag{I.2.37}$$

Note that the $\varepsilon^\mu(\hat{\boldsymbol{z}}, \lambda)$ are normalized eigenvectors of the spin-1 operator $\vec{\boldsymbol{\mathcal{S}}}\cdot\hat{\boldsymbol{z}}$,

$$(\vec{\boldsymbol{\mathcal{S}}}\cdot\hat{\boldsymbol{z}})^\mu{}_\nu\, \varepsilon^\nu(\hat{\boldsymbol{z}}, \lambda) = \lambda\, \varepsilon^\mu(\hat{\boldsymbol{z}}, \lambda)\,, \tag{I.2.38}$$

where $\mathcal{S}^i \equiv \frac{1}{2}\epsilon^{ijk}\mathcal{S}_{jk}$, and the matrix elements of the 4×4 matrices $\mathcal{S}_{jk}$ are given by eq. (29.9).

If we transform $\varepsilon^\mu(\hat{\boldsymbol{z}}, \lambda)$ by employing a three-dimensional rotation $\mathcal{R}$ such that $\hat{\boldsymbol{k}} = \mathcal{R}\,\hat{\boldsymbol{z}}$, then we can obtain the polarization vector for a massless spin-1 boson of energy E moving in the direction $\hat{\boldsymbol{k}} = (\sin\theta\cos\phi\,,\ \sin\theta\sin\phi\,,\ \cos\theta)$. That is,

$$\varepsilon^\mu(\hat{\boldsymbol{k}}, \lambda) = \Lambda^\mu{}_\nu(\phi\,,\theta\,,\,\gamma)\, \varepsilon^\nu(\hat{\boldsymbol{z}}, \lambda)\,, \tag{I.2.39}$$

where

$$\Lambda^0{}_0 = 1\,, \qquad \Lambda^i{}_0 = \Lambda^0{}_i = 0\,, \quad \text{and} \quad \Lambda^i{}_j = \mathcal{R}^{ij}(\phi\,,\theta\,,\,\gamma)\,, \tag{I.2.40}$$

and $\mathcal{R}(\phi\,,\theta\,,\,\gamma)$ is the rotation matrix introduced in eq. (C.1.4). A simple computation yields:

$$\varepsilon^\mu(\hat{\boldsymbol{k}}, \pm1) = \frac{1}{\sqrt{2}}\, e^{\mp i\gamma}\,(0\,;\,\mp\cos\theta\cos\phi + i\sin\phi\,,\,\mp\cos\theta\sin\phi - i\cos\phi\,,\,\pm\sin\theta)\ . \tag{I.2.41}$$

Note that $\varepsilon^\mu(\hat{\boldsymbol{k}}, \pm1)$ depends only on the direction of $\vec{\boldsymbol{k}}$ and not on its magnitude $E = |\vec{\boldsymbol{k}}|$. One can easily check that the $\varepsilon^\mu(\hat{\boldsymbol{k}}, \pm1)$ are normalized eigenstates of $\vec{\boldsymbol{\mathcal{S}}}\cdot\hat{\boldsymbol{k}}$ with corresponding eigenvalues ±1.

Similar to the corresponding discussion in Appendix C for the spin-1/2 spinor wave functions, the Euler angle γ is arbitrary. In the literature, one typically finds conventions where $\gamma = -\phi$ [37, 257, 258] or $\gamma = 0$ [259], and we will consider both possibilities below.

Although we will not need it here, the expressions given by eqs. (I.2.37) and (I.2.41) also apply in the case of a massive spin-1 particle. In addition, there is a helicity $\lambda = 0$ polarization vector which depends on the magnitude of the momentum as well as its direction:

$$\varepsilon^\mu(|\vec{\boldsymbol{k}}|\hat{\boldsymbol{z}}\,,\,0) = (|\vec{\boldsymbol{k}}|/m\,;\,0\,,\,0\,,\,E/m)\,, \tag{I.2.42}$$

where $E = (|\vec{\boldsymbol{k}}|^2 + m^2)^{1/2}$. One can use eq. (I.2.39) to obtain the helicity zero polarization vector for a massive spin-1 particle moving in an arbitrary direction

$$\varepsilon^\mu(\vec{\boldsymbol{k}}\,,\,0) = \frac{1}{m}\left(|\vec{\boldsymbol{k}}|\,;\,E\sin\theta\cos\phi\,,\,E\sin\theta\sin\phi\,,\,E\cos\theta\right)\,. \tag{I.2.43}$$

Note that both the massless and massive spin-1 polarization vectors satisfy:[165]

$$\varepsilon^\mu(\vec{\boldsymbol{k}}\,,\,\lambda)^* = (-1)^\lambda\varepsilon^\mu(\vec{\boldsymbol{k}}\,,\,-\lambda)\,. \tag{I.2.44}$$

One can check that the $\varepsilon^\mu(\vec{\boldsymbol{k}},\lambda)$ also satisfies the standard conditions for a valid polarization four-vector:

$$k\cdot\varepsilon(\vec{\boldsymbol{k}}\,,\,\lambda) = 0\,, \qquad\qquad \varepsilon(\vec{\boldsymbol{k}}\,,\,\lambda)\cdot\varepsilon(\vec{\boldsymbol{k}}\,,\,\lambda')^* = -\delta_{\lambda\lambda'}\,. \tag{I.2.45}$$

If the spin-1 boson three-momentum is $-\vec{\boldsymbol{k}}$, then its polarization vector can be obtained from eqs. (I.2.41) and (I.2.43) by taking $\theta \to \pi - \theta$ and $\phi \to \phi + \pi$. It can also be derived from eqs. (I.2.39) and (I.2.40) by making use of the spin-1 analogue of eq. (C.3.8),

$$\mathcal{R}(\phi+\pi\,,\,\pi-\theta\,,\,\gamma(-\hat{\boldsymbol{k}})) = \mathcal{R}(\phi\,,\,\theta\,,\,\gamma(\hat{\boldsymbol{k}}))\,R(\hat{\boldsymbol{z}},-\gamma(\hat{\boldsymbol{k}})-\gamma(-\hat{\boldsymbol{k}}))\,R(\hat{\boldsymbol{x}},\pi)\,, \tag{I.2.46}$$

where we have exhibited the possible dependence of γ on the direction of $\hat{\boldsymbol{k}}$, and R is the rotation matrix given by eq. (C.1.5). Introducing the notation $\varepsilon^\mu \equiv (\varepsilon^0\,;\,\hat{\boldsymbol{\varepsilon}})$, and noting the relations:

$$R(\hat{\boldsymbol{x}},\pi)\hat{\boldsymbol{\varepsilon}}(\hat{\boldsymbol{z}},\lambda) = -\hat{\boldsymbol{\varepsilon}}(\hat{\boldsymbol{z}},-\lambda)\,, \tag{I.2.47}$$

$$R(\hat{\boldsymbol{z}},\beta)\hat{\boldsymbol{\varepsilon}}(\hat{\boldsymbol{z}},\lambda) = e^{-i\lambda\beta}\,\hat{\boldsymbol{\varepsilon}}(\hat{\boldsymbol{z}},\lambda)\,, \tag{I.2.48}$$

it follows that:

$$\varepsilon^\mu(-\vec{\boldsymbol{k}}\,,\,\lambda) = -g_{\mu\mu}\,\xi_{-\lambda}(\hat{\boldsymbol{k}})\,\varepsilon^\mu(\vec{\boldsymbol{k}}\,,\,-\lambda)\,, \qquad \lambda = 0\,,\pm1\,, \tag{I.2.49}$$

where there is no sum over the repeated index μ, and

$$\xi_\lambda(\hat{\boldsymbol{k}}) = -e^{i\lambda[\gamma(\hat{\boldsymbol{k}})+\gamma(-\hat{\boldsymbol{k}})]}\,, \qquad \lambda = 0,\pm1\,. \tag{I.2.50}$$

Note that for $\lambda = \pm1$, the phase factor $\xi_\lambda(\hat{\boldsymbol{k}})$ depends on the convention for the definition of the Euler angle γ used to define the spin-1 polarization vector. As an example, corresponding to the two conventional choices for γ,

$$\xi_\lambda(\hat{\boldsymbol{k}}) = \begin{cases} (-1)^{1-\lambda}e^{-2i\lambda\phi} & \text{for}\;\; \gamma(\hat{\boldsymbol{k}}) = -\phi\,, \quad \gamma(-\hat{\boldsymbol{k}}) = -\phi-\pi\,, \\ -1 & \text{for}\;\; \gamma(\hat{\boldsymbol{k}}) = \gamma(-\hat{\boldsymbol{k}}) = 0\,. \end{cases} \tag{I.2.51}$$

To motivate the XZC form for the massless spin-1 polarization vectors, we first introduce a four-vector

$$\widetilde{k}^\mu \equiv E(1\,;\,-\hat{\boldsymbol{k}})\,, \tag{I.2.52}$$

[165] Some authors introduce polarization vectors where the sign factor $(-1)^\lambda$ in eq. (I.2.44) is omitted. One motivation for eq. (I.2.44) is to maintain consistency with the Condon-Shortley phase conventions [333] for the eigenfunctions of the spin angular momentum operators $\vec{\boldsymbol{S}}^{\boldsymbol{2}}$ and S_z (for spin-1 particles). In particular, note the relation $\hat{\boldsymbol{r}}\cdot\hat{\boldsymbol{\varepsilon}}^\mu(\hat{\boldsymbol{z}},\pm1) = (4\pi/3)^{1/2}Y_{1,\pm1}(\theta,\phi)$ between the polarization three-vector and the $\ell = 1$ spherical harmonics without any additional sign factors.

corresponding to the four-momentum $k^\mu = E(1\,;\,\hat{\boldsymbol{k}})$ of the massless spin-1 boson. A straightforward calculation then shows that

$$\varepsilon^\mu(k\,,\pm 1) = \frac{1}{\sqrt{2}}\,\frac{\langle k\mp|\sigma^\mu_\mp|\,\widetilde{k}\mp\rangle}{\langle k\pm|\widetilde{k}\mp\rangle} \tag{I.2.53}$$

precisely reproduces the result of eq. (I.2.41), where the massless spinor wave functions are defined according to eq. (C.1.8). Eq. (I.2.53) is somewhat inconvenient because the four-vector $\widetilde{k}$ cannot be covariantly defined in terms of k. XZC finessed this problem by introducing a "reference" four-vector p (in practical computations, p is taken to be another four-momentum vector in the scattering process of interest), with the properties that $p^2 = 0$ and $p\cdot k \neq 0$. The XZC spin-1 polarization vectors are given by [cf. eq. (29.34)] [166]

$$\varepsilon^\mu(k\,,\pm 1) = \frac{1}{\sqrt{2}}\,\frac{\langle k\mp|\,\sigma^\mu_\mp\,|p\mp\rangle}{\langle k\pm|p\mp\rangle}\,. \tag{I.2.54}$$

One can immediately check that $\varepsilon^\mu(k,\lambda)$ so defined satisfy the standard conditions for a valid polarization four-vector given in eq. (I.2.45) and the phase convention of eq. (I.2.44). The representation of the massless spin-1 polarization vector in terms of spinor products [eqs. (I.2.53) and (I.2.54)] is an application of the spinor calculus that was first developed by van der Waerden [1].

The significance of the reference four-vector p can be discerned from the property that if a different reference momentum is chosen then ε^μ is shifted by a factor proportional to k^μ. Explicitly, if $\varepsilon^\mu(k\,,\,p\,,\,\lambda)$ is a polarization vector with reference momentum p, then[167]

$$\varepsilon^\mu(k\,,\,q\,,\,\pm 1) = \varepsilon^\mu(k\,,\,p\,,\,\pm 1) + \frac{\sqrt{2}\,\langle q\pm|p\mp\rangle}{\langle k\pm|q\mp\rangle\,\langle k\pm|p\mp\rangle}\,k^\mu\,. \tag{I.2.55}$$

In particular, if we choose $q = \widetilde{k}$, we see that the difference of the XZC spin-1 polarization vector and the polarization vector given by eq. (I.2.41) is proportional to k^μ. This shift of the reference momentum from p to q in the XZC definition of the polarization vector does not affect eq. (I.2.45) since $k^2 = 0$ for massless spin-1 particles. Moreover, this shift does not affect the final result for any observable (in particular the sum of amplitudes of any gauge invariant set of Feynman diagrams remains unchanged). Thus, the presence of the arbitrary four-vector p just reflects the gauge invariance of the theory of massless spin-1 particles.

We can also verify that $\varepsilon^\mu(k\,,\,p\,,\,\lambda)$ defined in eq. (I.2.54) behaves as expected under rotations. Using eq. (C.1.8), massless spinors transform as:

$$|k\pm\rangle \longrightarrow \mathcal{D}(\phi,\theta,\gamma)\,|k\pm\rangle\,, \qquad \langle k\pm| \longrightarrow \langle k\pm|\,[\mathcal{D}(\phi,\theta,\gamma)]^{-1}\,, \tag{I.2.56}$$

under a rotation specified by the Euler angles ϕ, θ and γ. We shall rotate the spin-1 polarization vectors by rotating both $\vec{\boldsymbol{k}}$ and the reference momentum $\vec{\boldsymbol{p}}$ simultaneously (since one is always free to shift the reference vector with no physical consequence). Using eq. (C.1.33), it follows that:

$$[\mathcal{D}(\phi,\theta,\gamma)]^{-1}\,\sigma^\mu_\pm\,\mathcal{D}(\phi,\theta,\gamma) = \Lambda^\mu{}_\nu\sigma^\nu_\pm\,, \tag{I.2.57}$$

[166] In the literature on the spinor helicity method, the spin-1 polarization vector ε is employed in Feynman diagram computations for an *outgoing* final state boson, in contrast to the standard conventions of most quantum field theory textbooks. In this review, we subscribe to the latter [as indicated at the end of Section 29.4.1]. Hence, to be consistent with our conventions above for the spin-1 polarization vector, we have taken the complex conjugate of the original definition of the XZC spin-1 polarization vectors. In addition, we have removed an overall $\pm$ sign in order to conform to eq. (I.2.44) [cf. footnote 165].

[167] To derive eq. (I.2.55), evaluate $\varepsilon^\mu(k\,,\,q\,,\,\lambda) - \varepsilon^\mu(k\,,\,p\,,\,\lambda)$, and simplify the resulting expression using eqs. (I.2.10), (I.2.13) and (I.2.14).

where $\Lambda^\mu{}_\nu$ is specified by eq. (I.2.40). Indeed, if we simultaneously rotate both k and p via $k^\mu \to \Lambda^\mu{}_\nu k^\nu$ and $p^\mu \to \Lambda^\mu{}_\nu p^\nu$, then

$$\varepsilon^\mu(k\,,\,p\,,\,\lambda) \longrightarrow \Lambda^\mu{}_\nu\,\varepsilon^\nu(k\,,\,p\,,\,\lambda)\,, \tag{I.2.58}$$

as expected. By a similar computation, one can check that under $\vec{\boldsymbol{k}} \to -\vec{\boldsymbol{k}}$ and $\vec{\boldsymbol{p}} \to -\vec{\boldsymbol{p}}$, eq. (I.2.49) is satisfied.[168] In terms of the $\xi_{\pm 1/2}$ defined in eq. (C.3.11), we find

$$\xi_\lambda(\vec{\boldsymbol{k}}) = -\left(\frac{\xi_{-\lambda/2}(\vec{\boldsymbol{k}})}{\xi_{\lambda/2}(\vec{\boldsymbol{k}})}\right)^* = \Big[\xi_{\lambda/2}(\vec{\boldsymbol{k}})\Big]^2\,, \qquad \lambda = \pm 1\,, \tag{I.2.59}$$

which agrees with eq. (I.2.50).

The following additional properties of $\varepsilon^\mu(k\,,\,p\,,\,\lambda)$ defined in eq. (I.2.54) are noteworthy:

$$p{\cdot}\varepsilon(k\,,\,p\,,\,\lambda) = 0\,, \tag{I.2.60}$$

$$\sum_{\lambda=\pm 1} \varepsilon_\mu(k\,,\,p\,,\,\lambda)\varepsilon_\nu(k\,,\,p\,,\,\lambda)^* = -g_{\mu\nu} + \frac{p_\mu k_\nu + p_\nu k_\mu}{p{\cdot}k}\,. \tag{I.2.61}$$

For example, to prove eq. (I.2.61), we use eqs. (I.2.18) and (I.2.19), and simplify the resulting expression with the help of eqs. (I.2.10) and (I.2.16), which yields:

$$\sum_{\lambda=\pm 1} \varepsilon_\mu(k\,,\,p\,,\,\lambda)\varepsilon_\nu(k\,,\,p\,,\,\lambda)^* = \frac{\langle k+|\,(\sigma_\mu p{\cdot}\overline{\sigma}\sigma_\nu + \sigma_\nu p{\cdot}\overline{\sigma}\sigma_\mu)\,|k+\rangle}{2\,\langle k+|\,p{\cdot}\sigma\,|k+\rangle}\,. \tag{I.2.62}$$

Using eq. (B.2.17) to simplify the product of three $\sigma/\overline{\sigma}$ matrices, and employing eq. (I.2.11) then yields eq. (I.2.61).

Finally, using the Fierz identities given in eqs. (B.1.6)–(B.1.8), one derives from eq. (I.2.54) that

$$\sigma_\pm{\cdot}\varepsilon(k\,,\,\pm 1) = \frac{\sqrt{2}\,|p\mp\rangle\,\langle k\,\mp|}{\langle k\,\pm\,|p\mp\rangle}\,, \qquad \sigma_\pm{\cdot}\varepsilon(k\,,\,\pm 1)^* = \frac{\sqrt{2}\,|k\mp\rangle\,\langle p\mp|}{\langle p\,\mp\,|k\pm\rangle}\,, \tag{I.2.63}$$

$$\sigma_\mp{\cdot}\varepsilon(k\,,\,\pm 1) = \frac{\sqrt{2}\,|k\pm\rangle\,\langle p\pm|}{\langle k\,\pm\,|p\mp\rangle}\,, \qquad \sigma_\mp{\cdot}\varepsilon(k\,,\,\pm 1)^* = \frac{\sqrt{2}\,|p\pm\rangle\,\langle k\pm|}{\langle p\,\mp\,|k\pm\rangle}\,. \tag{I.2.64}$$

Note that each equation in eqs. (I.2.63) and (I.2.64) represents two separate equations, corresponding to the upper and lower signs in each equation, respectively.

It should now be clear how to convert the square of a helicity amplitude for a multi-particle process involving massless spin-1/2 and massless spin-1 particles into a ratio of products of dot products of momenta. By writing all massless spin-1 polarization vectors in the form of eq. (I.2.54) and using the properties given above, the helicity amplitudes can easily be expressed as a ratio of two quantities, each of which is a product of spinor products. Squaring the corresponding amplitude then yields a ratio of products of dot products of four-momenta. A following simple example will demonstrate the technique.

Consider Compton scattering in QED, $e^-(\vec{\boldsymbol{p}}_1,\lambda_1)\gamma(\vec{\boldsymbol{k}}_1,\lambda_1') \to e^-(\vec{\boldsymbol{p}}_2,\lambda_2)\gamma(\vec{\boldsymbol{k}}_2,\lambda_2')$, in the limit of massless electrons. The amplitude for this process is given by eq. (29.4.18) with $m = 0$ and $G_L = G_R = -e$. Writing out the "crossed" term explicitly, and noting that for massless particles, $s \equiv (p_1+k_1)^2 = 2p_1{\cdot}k_1$ and $u \equiv (p_1-k_2)^2 = -2p_1{\cdot}k_2$,

$$\begin{aligned} i\mathcal{M} = {}& \frac{-ie^2}{2p_1{\cdot}k_1}\Big\{x^\dagger(\vec{\boldsymbol{p}}_2,\lambda_2)\,\overline{\sigma}{\cdot}\varepsilon_2^*\,\sigma{\cdot}(p_1+k_1)\,\overline{\sigma}{\cdot}\varepsilon_1\,x(\vec{\boldsymbol{p}}_1,\lambda_1) + y(\vec{\boldsymbol{p}}_2,\lambda_2)\,\sigma{\cdot}\varepsilon_2^*\,\overline{\sigma}{\cdot}(p_1+k_1)\,\sigma{\cdot}\varepsilon_1 y^\dagger(\vec{\boldsymbol{p}}_1,\lambda_1)\Big\} \\ & + \frac{ie^2}{2p_1{\cdot}k_2}\Big\{x^\dagger(\vec{\boldsymbol{p}}_2,\lambda_2)\,\overline{\sigma}{\cdot}\varepsilon_1\,\sigma{\cdot}(p_1-k_2)\,\overline{\sigma}{\cdot}\varepsilon_2^*\,x(\vec{\boldsymbol{p}}_1,\lambda_1) + y(\vec{\boldsymbol{p}}_2,\lambda_2)\,\sigma{\cdot}\varepsilon_1\,\overline{\sigma}{\cdot}(p_1-k_2)\,\sigma{\cdot}\varepsilon_2^* y^\dagger(\vec{\boldsymbol{p}}_1,\lambda_1)\Big\}\,. \end{aligned} \tag{I.2.65}$$

[168] Here, we have used eqs. (B.2.16) and (B.2.17) to write $\sigma_\pm^0\sigma_\mp^\mu\sigma_\pm^0 = -\sigma_\pm^\mu + 2g^{\mu 0}\sigma_\pm^0 = g^{\mu\mu}\sigma_\pm^\mu$ (no sum over μ).

The results of eqs. (29.3.36)–(29.3.39) imply that the helicity amplitudes with $\lambda_1 \neq \lambda_2$ vanish. Using eqs. (I.2.7) and (I.2.8), we identify:

$$i\mathcal{M}(\lambda_1=\lambda_2=\tfrac{1}{2}) = \frac{-ie^2}{2p_1\cdot k_1}\,\langle p_2+|\sigma_+\cdot\varepsilon_2^*\,\sigma_-\cdot(p_1+k_1)\,\sigma_+\cdot\varepsilon_1|p_1+\rangle \\ +\frac{ie^2}{2p_1\cdot k_2}\,\langle p_2+|\sigma_+\cdot\varepsilon_1\,\sigma_-\cdot(p_1-k_2)\,\sigma_+\cdot\varepsilon_2^*|p_1+\rangle\ , \tag{I.2.66}$$

$$i\mathcal{M}(\lambda_1=\lambda_2=-\tfrac{1}{2}) = \frac{-ie^2}{2p_1\cdot k_1}\,\langle p_2-|\sigma_-\cdot\varepsilon_2^*\,\sigma_+\cdot(p_1+k_1)\,\sigma_-\cdot\varepsilon_1|p_1-\rangle \\ +\frac{ie^2}{2p_1\cdot k_2}\,\langle p_2-|\sigma_-\cdot\varepsilon_1\,\sigma_+\cdot(p_1-k_2)\,\sigma_-\cdot\varepsilon_2^*|p_1-\rangle\ . \tag{I.2.67}$$

Further simplification ensues when we apply the results of eqs. (I.2.63) and (I.2.64). To use these results, we must select a reference momentum p, which can be any lightlike four-vector that is not parallel to the corresponding photon polarization vector. One is free to choose a different reference momentum for each photon polarization vector. Moreover, when computing two different helicity amplitudes (each of which are gauge invariant quantities), one may select a different reference momentum for the *same* photon polarization vector in the two computations. The decision on which reference momenta to choose is somewhat of an art; experience will teach you which choices lead to the most simplification in a given calculation.

We shall consider two possible choices for the reference momenta for ε_1 and ε_2, which we denote as $p^{(1)}$ and $p^{(2)}$, respectively:

1. $p^{(1)}=p_1$ and $p^{(2)}=p_2$,
2. $p^{(1)}=p_2$ and $p^{(2)}=p_1$.

With either choice, it is straightforward to show that $\mathcal{M}(\lambda_1=\lambda_2=\pm\frac{1}{2})$ vanish unless the photon helicities are equal, i.e. $\lambda_1'=\lambda_2'$. This leaves only four possible non-vanishing helicity amplitudes.

For the case of $\lambda_1=\lambda_2=\pm\frac{1}{2}$ and $\lambda_1'=\lambda_2'=\pm1$ (i.e., $\lambda_1\lambda_1'>0$), we choose reference momenta $p^{(1)}=p_2$ and $p^{(2)}=p_1$. Then, the second term vanishes on the right-hand side of eqs. (I.2.66) and (I.2.67), respectively. Making use of eqs. (I.2.10), (I.2.63) and (I.2.64), we find

$$i\mathcal{M}(\lambda_1=\lambda_2=\tfrac{1}{2}\,,\,\lambda_1'=\lambda_2'=1) = \frac{-ie^2}{p_1\cdot k_1}\,\frac{\langle p_2+|k_2-\rangle\,\langle p_1-|k_1+\rangle\,\langle k_1+|p_2-\rangle\,\langle k_1-|p_1+\rangle}{\langle p_1-|k_2+\rangle\,\langle k_1+|p_2-\rangle} \\ = \frac{-ie^2}{p_1\cdot k_1}\,\frac{\langle p_1\,k_1\rangle\,\langle k_1\,p_1\rangle\,[p_2\,k_2]}{\langle p_1\,k_2\rangle}\,. \tag{I.2.68}$$

Using eqs. (I.2.24) and (I.2.30) to write the dot product in terms of spinor products, we obtain:

$$i\mathcal{M}(\lambda_1=\lambda_2=\tfrac{1}{2}\,,\,\lambda_1'=\lambda_2'=1) = 2ie^2\,\frac{\langle p_1\,k_1\rangle}{\langle p_1\,k_1\rangle^*}\,\frac{[p_2\,k_2]}{\langle p_1\,k_2\rangle}\,. \tag{I.2.69}$$

A similar computation yields

$$i\mathcal{M}(\lambda_1=\lambda_2=-\tfrac{1}{2}\,,\,\lambda_1'=\lambda_2'=-1) = 2ie^2\,\frac{[p_1\,k_1]}{[p_1\,k_1]^*}\,\frac{\langle p_2\,k_2\rangle}{[p_1\,k_2]}\,. \tag{I.2.70}$$

For the case of $\lambda_1=\lambda_2=\pm\frac{1}{2}$ and $\lambda_1'=\lambda_2'=\mp1$ (i.e., $\lambda_1\lambda_1'<0$), we choose reference momenta $p^{(1)}=p_1$ and $p^{(2)}=p_2$. Then, the first term vanishes on the right-hand side of eqs. (I.2.66) and

(I.2.67), respectively. A similar calculation to the one given above yields:

$$i\mathcal{M}(\lambda_1=\lambda_2=-\tfrac{1}{2}\,,\ \lambda_1'=\lambda_2'=1)=2ie^2\,\frac{[p_1\,k_2]}{[p_1\,k_2]^*}\,\frac{\langle p_2\,k_1\rangle}{[p_1\,k_1]}\,, \tag{I.2.71}$$

$$i\mathcal{M}(\lambda_1=\lambda_2=\tfrac{1}{2}\,,\ \lambda_1'=\lambda_2'=-1)=2ie^2\,\frac{\langle p_1\,k_2\rangle}{\langle p_1\,k_2\rangle^*}\,\frac{[p_2\,k_1]}{\langle p_1\,k_1\rangle}\,. \tag{I.2.72}$$

Note that each pair of helicity amplitudes above is simply related:

$$\mathcal{M}_{\lambda_1\,,\,\lambda_1';\lambda_2\,,\,\lambda_2'}(s,\theta,\phi)^*=\mathcal{M}_{-\lambda_1\,,\,-\lambda_1';-\lambda_2\,,\,-\lambda_2'}(s,\theta,\phi)\,, \tag{I.2.73}$$

which is a consequence of rotational and parity invariance (as shown below). Thus in this example, we only need to evaluate two non-zero helicity amplitudes. It is clear that we have simplified the computation enormously by our choice of reference momenta. With a less judicious choice, the calculation is significantly more tedious, although gauge invariance guarantees that one must arrive at the same result for the helicity amplitudes quoted above.

One can easily evaluate the spinor products above in the center-of-mass system. Writing $p_1^\mu=E(1\,;\,\hat{\boldsymbol{z}})$, $k_1^\mu=E(1\,;\,-\hat{\boldsymbol{z}})$, $p_2^\mu=E(1\,;\,\hat{\boldsymbol{p}}_{\rm CM})$ and $k_2^\mu=E(1\,;\,-\hat{\boldsymbol{p}}_{\rm CM})$, and using the results of eqs. (I.1.21) and (I.2.22), we obtain:

$$\langle p_1\,k_1\rangle=2E\xi_{-1/2}(\hat{\boldsymbol{z}})\,,\qquad \langle p_1\,k_2\rangle=2Ee^{i[\phi+\gamma(\hat{\boldsymbol{p}}_{\rm CM})]/2}\xi_{-1/2}(\hat{\boldsymbol{p}}_{\rm CM})\cos(\theta/2)\,, \tag{I.2.74}$$

$$\langle p_2\,k_2\rangle=2E\xi_{-1/2}(\hat{\boldsymbol{p}}_{\rm CM})\,,\qquad \langle p_2\,k_1\rangle=2Ee^{-i[\phi+\gamma(\hat{\boldsymbol{p}}_{\rm CM})]/2}\xi_{-1/2}(\hat{\boldsymbol{z}})\cos(\theta/2)\,, \tag{I.2.75}$$

where θ and ϕ are the polar and azimuthal angles of $\hat{\boldsymbol{p}}_{\rm CM}$. Phase factors involving $\xi_{-1/2}$ arise from the use of eqs. (C.3.10) and (C.3.11). For example, corresponding to the two conventional choices for γ, we use eq. (C.3.14) to obtain

$$\xi_{-1/2}(\hat{\boldsymbol{z}})=\begin{cases}-1 & \text{for } \gamma(\hat{\boldsymbol{z}})=0\,,\quad \gamma(-\hat{\boldsymbol{z}})=-\pi\,,\\ i & \text{for } \gamma(\hat{\boldsymbol{z}})=\gamma(-\hat{\boldsymbol{z}})=0\,,\end{cases} \tag{I.2.76}$$

$$\xi_{-1/2}(\hat{\boldsymbol{p}}_{\rm CM})=\begin{cases}-e^{i\phi} & \text{for } \gamma(\hat{\boldsymbol{p}}_{\rm CM})=-\phi\,,\quad \gamma(-\hat{\boldsymbol{p}}_{\rm CM})=-\phi-\pi\\ i & \text{for } \gamma(\hat{\boldsymbol{p}}_{\rm CM})=\gamma(-\hat{\boldsymbol{p}}_{\rm CM})=0\,.\end{cases} \tag{I.2.77}$$

All other relevant spinor products can be found using eqs. (I.2.24)–(I.2.26).

It is always possible to define the plane of the scattering process to be the x–z plane, in which case $\phi=0$ and all the spinor products in eqs. (I.2.74) and (I.2.75) are manifestly real. Nevertheless, by keeping the explicit ϕ-dependence, one maintains a useful check of the calculation. Inserting the explicit forms for the spinor products into eqs. (I.2.69)–(I.2.72), we confirm that the ϕ-dependence of the helicity amplitudes is given by [334, 259]:

$$\mathcal{M}_{\lambda_1\,,\,\lambda_1';\lambda_2\,,\,\lambda_2'}(s,\theta,\phi)=\begin{cases}e^{i(\lambda_1-\lambda_1'-\lambda_2-\lambda_2')\phi}\mathcal{M}_{\lambda_1\,,\,\lambda_1';\lambda_2\,,\,\lambda_2'}(s,\theta)\,, & \text{for } \gamma(\hat{\boldsymbol{p}}_{\rm CM})=-\phi\,,\text{ and}\\ & \quad\gamma(-\hat{\boldsymbol{p}}_{\rm CM})=-\phi-\pi\,,\\ e^{i(\lambda_1-\lambda_1')\phi}\mathcal{M}_{\lambda_1\,,\,\lambda_1';\lambda_2\,,\,\lambda_2'}(s,\theta)\,, & \text{for } \gamma(\hat{\boldsymbol{p}}_{\rm CM})=\gamma(-\hat{\boldsymbol{p}}_{\rm CM})=0\,,\end{cases} \tag{I.2.78}$$

as a consequence of rotational invariance [260].[169] The remaining θ-dependent amplitudes are easily evaluated and are in agreement with the results of refs. [259, 335]. Note that parity invariance implies that eqs. (I.2.69)–(I.2.72) must satisfy [260, 259, 335]

$$\mathcal{M}_{\lambda_1\,,\,\lambda_1';\lambda_2\,,\,\lambda_2'}(s,\theta)=\mathcal{M}_{-\lambda_1\,,\,-\lambda_1';-\lambda_2\,,\,-\lambda_2'}(s,\theta)\,. \tag{I.2.79}$$

[169] In the first case, where $\gamma(\hat{\boldsymbol{p}}_{\rm CM})=-\phi$ and $\gamma(-\hat{\boldsymbol{p}}_{\rm CM})=-\phi-\pi$, the sign of λ_2' in the ϕ-dependent phase factor of eq. (I.2.78) is opposite to the one given in [260], due to the Jacob-Wick second-particle convention, which we do not employ here. Since $\lambda_1=\lambda_2$ and $\lambda_1'=\lambda_2'$, the latter would imply that the ϕ-dependent phase cancels exactly if the Jacob-Wick second-particle convention is used. This is easily checked by putting $\gamma(\hat{\boldsymbol{p}}_{\rm CM})=-\phi$ and $\xi_\lambda=1$ in eqs. (I.2.74) and (I.2.75), in which case all the spinor products are real.

Indeed, in our computation above, eq. (I.2.73) is satisfied, which is consistent with eq. (I.2.79) in light of eq. (I.2.78).

To compute the unpolarized cross-section for Compton scattering, one must sum the absolute squares of the helicity amplitudes and divide by 4 to average over the initial helicities. Since quantities such as $\langle p_1\, k_1\rangle \,/\, \langle p_1\, k_1\rangle^*$ are pure phases, one immediately obtains:

$$|\mathcal{M}(\lambda_1 = \lambda_2 = \tfrac{1}{2}\,,\, \lambda_1' = \lambda_2' = 1)|^2 = |\mathcal{M}(\lambda_1 = \lambda_2 = -\tfrac{1}{2}\,,\, \lambda_1' = \lambda_2' = -1)|^2 = 4e^4 \frac{p_1\cdot k_1}{p_1\cdot k_2}\,, \quad \text{(I.2.80)}$$

$$|\mathcal{M}(\lambda_1 = \lambda_2 = -\tfrac{1}{2}\,,\, \lambda_1' = \lambda_2' = 1)|^2 = |\mathcal{M}(\lambda_1 = \lambda_2 = \tfrac{1}{2}\,,\, \lambda_1' = \lambda_2' = -1)|^2 = 4e^4 \frac{p_1\cdot k_2}{p_1\cdot k_1}\,, \quad \text{(I.2.81)}$$

after employing eq. (I.2.30) and noting that $p_1\cdot k_1 = p_2\cdot k_2$ and $p_1\cdot k_2 = p_2\cdot k_1$ (which follow from four-momentum conservation, $p_1 + k_1 = p_2 + k_2$, for the scattering of massless particles). Thus,

$$\tfrac{1}{4}\sum_{\text{spins}} |\mathcal{M}|^2 = 2e^4 \left(\frac{p_1\cdot k_1}{p_1\cdot k_2} + \frac{p_1\cdot k_2}{p_1\cdot k_1}\right)\,, \quad \text{(I.2.82)}$$

which coincides with the well-known result quoted in [115].

29.7.12 The Standard Model and its seesaw extension 1

In the Standard Model, three generations of quarks and leptons are described by the two-component fermion fields listed in Table J.1, where Y is the weak hypercharge, T_3 is the third component of the weak isospin, and $Q = T_3 + Y$ is the electric charge. After $\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$ breaking, the quark and lepton fields gain mass in such a way that the above two-component fields combine to make up four-component Dirac fermions:

$$U_i = \begin{pmatrix} u_i \\ \bar{u}^{\dagger i} \end{pmatrix}\,, \qquad D_i = \begin{pmatrix} d_i \\ \bar{d}^{\dagger i} \end{pmatrix}\,, \qquad L_i = \begin{pmatrix} \ell_i \\ \bar{\ell}^{\dagger i} \end{pmatrix}\,, \quad \text{(J.1)}$$

while the neutrinos ν_i remain massless. The extension of the Standard Model to include neutrino masses will be treated in Appendix J.2 .

Here, we follow the convention for particle symbols established in Table 29.1. Note that u, $\bar{u}$, d, $\bar{d}$, ℓ and $\bar{\ell}$ are two-component fields, whereas the usual four-component quark and charged lepton fields are denoted by capital letters U, D and E. Consider a generic four-component field expressed in terms of the corresponding two-component fields:

$$F = \begin{pmatrix} f \\ \bar{f}^{\dagger} \end{pmatrix}\,. \quad \text{(J.2)}$$

The electroweak quantum numbers of f are denoted by T_3^f, Y_f and Q_f, whereas the corresponding quantum numbers for $\bar{f}$ are $T_3^{\bar{f}} = 0$ and $Q_{\bar{f}} = Y_{\bar{f}} = -Q_f$. Thus we have the correspondence to our general notation [eq. (G.1.7)]

$$f \longleftrightarrow \chi, \qquad \bar{f} \longleftrightarrow \eta\,. \quad \text{(J.3)}$$

We can then immediately translate the couplings given in the general case in Fig. 29.4.3 to the Standard Model.

Two-component fermion fields	SU(3)	$SU(2)_L$	Y	T_3	$Q = T_3 + Y$
$\boldsymbol{Q}_i \equiv \begin{pmatrix} u_i \\ d_i \end{pmatrix}$	triplet	doublet	$\frac{1}{6}$	$\frac{1}{2}$	$\frac{2}{3}$
	triplet		$\frac{1}{6}$	$-\frac{1}{2}$	$-\frac{1}{3}$

Table J.1: Fermions of the Standard Model (following the naming conventions of Table 29.1) and their $SU(3)\times SU(2)_L\times U(1)_Y$ quantum numbers. The generation indices run over $i = 1, 2, 3$. Color indices for the quarks are suppressed. The bars on the two-component antifermion fields are part of their names, and do not denote some form of complex conjugation.

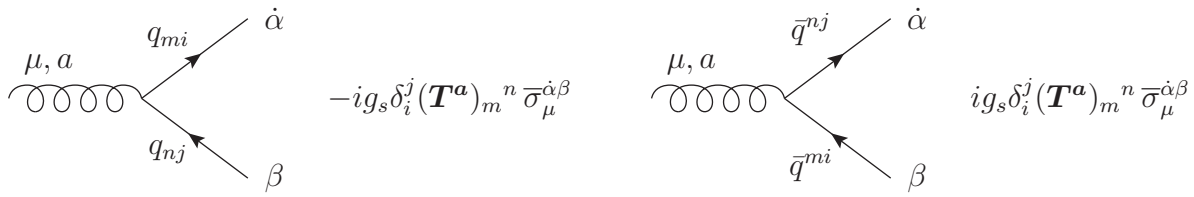

Figure J.1.1: Fermionic Feynman rules for QCD that involve the gluon, with $q = u, d, c, s, t, b$. Lowered (raised) indices m, n correspond to the fundamental (anti-fundamental) representation of $SU(3)_c$. The gluon interactions are flavor-diagonal (where i, j are flavor indices). For each rule, a corresponding one with lowered spinor indices is obtained by $\overline{\sigma}_\mu^{\dot{\alpha}\beta} \to -\sigma_{\mu\beta\dot{\alpha}}$.

Standard Model fermion interaction vertices

The QCD color interactions of the quarks are governed by the following interaction Lagrangian:

$$\mathscr{L}_{\rm int} = -g_s A_a^\mu q^{\dagger mi}\,\overline{\sigma}_\mu(\boldsymbol{T}^a)_m{}^n q_{ni} + g_s A_a^\mu \bar{q}_{ni}^\dagger\,\overline{\sigma}_\mu(\boldsymbol{T}^a)_m{}^n \bar{q}^{mi}\,, \tag{J.1.1}$$

summed over the generations i, where q is a (mass eigenstate) quark field, m and n are SU(3) color triplet indices, A_a^μ is the gluon field (with the corresponding gluons denoted by g_a), and $\boldsymbol{T}^a$ are the color generators in the triplet representation of SU(3). The corresponding Feynman rules are given in Fig. J.1.1.

Next, we write out the Feynman rules for the electroweak interactions of quarks and leptons.

Using eqs. (29.4.11) and (29.4.12), the interactions of the gauge bosons and quarks are given by:

$$\begin{aligned}\mathscr{L}_{\rm int} = &-\frac{g}{\sqrt{2}}\left[(\hat{u}^{\dagger i}\overline{\sigma}^\mu \hat{d}_i + \hat{\nu}^{\dagger i}\overline{\sigma}^\mu \hat{\ell}_i)W^+_\mu + (\hat{d}^{\dagger i}\overline{\sigma}^\mu \hat{u}_i + \hat{\ell}^{\dagger i}\overline{\sigma}^\mu \hat{\nu}_i)W^-_\mu\right] \\ &-\frac{g}{c_W}\sum_{f=u,d,\nu,\ell}\left\{(T_3^f - s_W^2 Q_f)\hat{f}^{\dagger i}\overline{\sigma}^\mu \hat{f}_i + s_W^2 Q_f \hat{\hat{f}}^{\dagger i}\overline{\sigma}^\mu \hat{\hat{f}}_i\right\} Z_\mu \\ &-e\sum_{f=u,d,\ell} Q^f(\hat{f}^{\dagger i}\overline{\sigma}^\mu \hat{f}_i - \hat{\hat{f}}^{\dagger i}\overline{\sigma}^\mu \hat{\hat{f}}_i)A_\mu\,, \end{aligned} \tag{J.1.2}$$

where $s_W \equiv \sin\theta_W$, $c_W \equiv \cos\theta_W$, the hatted symbols indicate fermion interaction eigenstates and i labels the generations. Following the discussion of Section 29.3.2, we must convert from fermion interaction eigenstates to mass eigenstates. In order to accomplish this step, we must first identify the quark and lepton mass matrices. In the electroweak theory, the fermion mass matrices originate from the fermion-Higgs Yukawa interactions.

The Higgs field of the Standard Model is a complex $\mathrm{SU}(2)_L$ doublet of hypercharge $Y = \frac{1}{2}$,

$$\boldsymbol{\Phi}_a \equiv \begin{pmatrix}\Phi^+ \\ \Phi^0\end{pmatrix}\,, \tag{J.1.3}$$

where the $\mathrm{SU}(2)_L$ index $a = 1, 2$ is defined such that $\boldsymbol{\Phi}_1 \equiv \Phi^+$ and $\boldsymbol{\Phi}_2 \equiv \Phi^0$. Here, the superscripts $+$ and 0 refer to the electric charge of the Higgs field, $Q = T_3 + Y$, with $Y = \frac{1}{2}$ and $T_3 = \pm\frac{1}{2}$. Since $\boldsymbol{\Phi_a}$ is complex, we can also introduce the complex conjugate Higgs doublet field with hypercharge $Y = -\frac{1}{2}$,

$$\boldsymbol{\Phi}^{\dagger\, a} \equiv \left(\Phi^-\,,\ \ (\Phi^0)^\dagger\right)\,, \tag{J.1.4}$$

where $\Phi^- \equiv (\Phi^+)^\dagger$. The $\mathrm{SU}(2)_L\times\mathrm{U}(1)_Y$ gauge invariant Yukawa interactions of the quarks and leptons with the Higgs field are then given by:

$$\mathscr{L}_{\rm Y} = \epsilon^{ab}(\boldsymbol{Y}_u)^i{}_j \boldsymbol{\Phi}_a \hat{\boldsymbol{Q}}_{bi}\bar{u}^j - (\boldsymbol{Y}_d)^i{}_j \boldsymbol{\Phi}^{\dagger\, a}\hat{\boldsymbol{Q}}_{ai}\hat{\bar{d}}^j - (\boldsymbol{Y}_\ell)^i{}_j \boldsymbol{\Phi}^{\dagger\, a}\hat{\boldsymbol{L}}_{ai}\hat{\bar{\ell}}^j + \text{h.c.} \tag{J.1.5}$$

where ϵ^{ab} is the antisymmetric invariant tensor of $\mathrm{SU}(2)_L$, defined such that $\epsilon^{12} = -\epsilon^{21} = +1$. Using the definitions of the $\mathrm{SU}(2)_L$ doublet quark and lepton fields given in Table J.1, one can rewrite eq. (J.1.5) more explicitly as:

$$-\mathscr{L}_{\rm Y} = (\boldsymbol{Y}_u)^i{}_j\left[\Phi^0\hat{u}_i\hat{\bar{u}}^j - \Phi^+\hat{d}_i\hat{\bar{u}}^j\right] + (\boldsymbol{Y}_d)^i{}_j\left[\Phi^-\hat{u}_i\hat{\bar{d}}^j + \Phi^{0*}\hat{d}_i\hat{\bar{d}}^j\right] + (\boldsymbol{Y}_\ell)^i{}_j\left[\Phi^-\hat{\nu}_i\hat{\bar{\ell}}^j + \Phi^{0*}\hat{\ell}_i\hat{\bar{\ell}}^j\right] + \text{h.c.} \tag{J.1.6}$$

The Higgs fields can be written in terms of the physical Higgs scalar $h_{\rm SM}$ and Nambu-Goldstone bosons $G^0, G^\pm$ as

$$\Phi^0 = v + \frac{1}{\sqrt{2}}(h_{\rm SM} + iG^0)\,, \tag{J.1.7}$$

$$\Phi^+ = G^+ = (\Phi^-)^\dagger = (G^-)^\dagger. \tag{J.1.8}$$

where $v = \sqrt{2}m_W/g \simeq 174$ GeV. In the unitary gauge appropriate for tree-level calculations, the Nambu-Goldstone bosons become infinitely heavy and decouple. We identify the quark and lepton mass matrices by setting $\Phi^0 = v$ and $\Phi^+ = \Phi^- = 0$ in eq. (J.1.6):

$$(\boldsymbol{M}_u)^i{}_j = v(\boldsymbol{Y}_u)^i{}_j\,, \qquad (\boldsymbol{M}_d)^i{}_j = v(\boldsymbol{Y}_d)^i{}_j\,, \qquad (\boldsymbol{M}_\ell)^i{}_j = v(\boldsymbol{Y}_\ell)^i{}_j\,. \tag{J.1.9}$$

The neutrinos remain massless. An extension of the Standard Model that incorporates massive neutrinos is treated in Appendix J.2 .

To diagonalize the quark and lepton mass matrices, we introduce four unitary matrices for the quark mass diagonalization, L_u, L_d, R_u and R_d, and two unitary matrices for the lepton mass diagonalization, L_ℓ and R_ℓ [cf. eq. (29.3.31)] such that

$$\hat{u}_i = (L_u)_i{}^j u_j\,, \qquad \hat{d}_i = (L_d)_i{}^j d_j\,, \qquad \hat{\bar{u}}^i = (R_u)^i{}_j \bar{u}^j\,, \qquad \hat{\bar{d}}^i = (R_d)^i{}_j \bar{d}^j\,, \tag{J.1.10}$$

$$\hat{\ell}_i = (L_\ell)_i{}^j \ell_j\,, \qquad \hat{\bar{\ell}}^i = (R_\ell)^i{}_j \bar{\ell}^j\,, \tag{J.1.11}$$

where the unhatted fields u, d, $\bar{u}$ and $\bar{d}$ are the corresponding quark mass eigenstates and ν, ℓ and $\bar{\ell}$ are the corresponding lepton mass eigenstates. The fermion mass diagonalization procedure consists of the singular value decomposition of the quark and lepton mass matrices:

$$L_u^\mathsf{T} \boldsymbol{M}_u R_u = \mathrm{diag}(m_u\,,\, m_c\,,\, m_t)\,, \tag{J.1.12}$$

$$L_d^\mathsf{T} \boldsymbol{M}_d R_d = \mathrm{diag}(m_d\,,\, m_s\,,\, m_b)\,, \tag{J.1.13}$$

$$L_\ell^\mathsf{T} \boldsymbol{M}_\ell R_\ell = \mathrm{diag}(m_e\,,\, m_\mu\,,\, m_\tau)\,, \tag{J.1.14}$$

where the diagonalized masses are real and non-negative (cf. Appendix D.1). Since the neutrinos are massless, we are free to define the physical neutrino fields, ν_i, as the weak SU(2) partners of the corresponding charged lepton mass eigenstate fields. That is,

$$\hat{\nu}_i = (L_\ell)_i{}^j \nu_j\,. \tag{J.1.15}$$

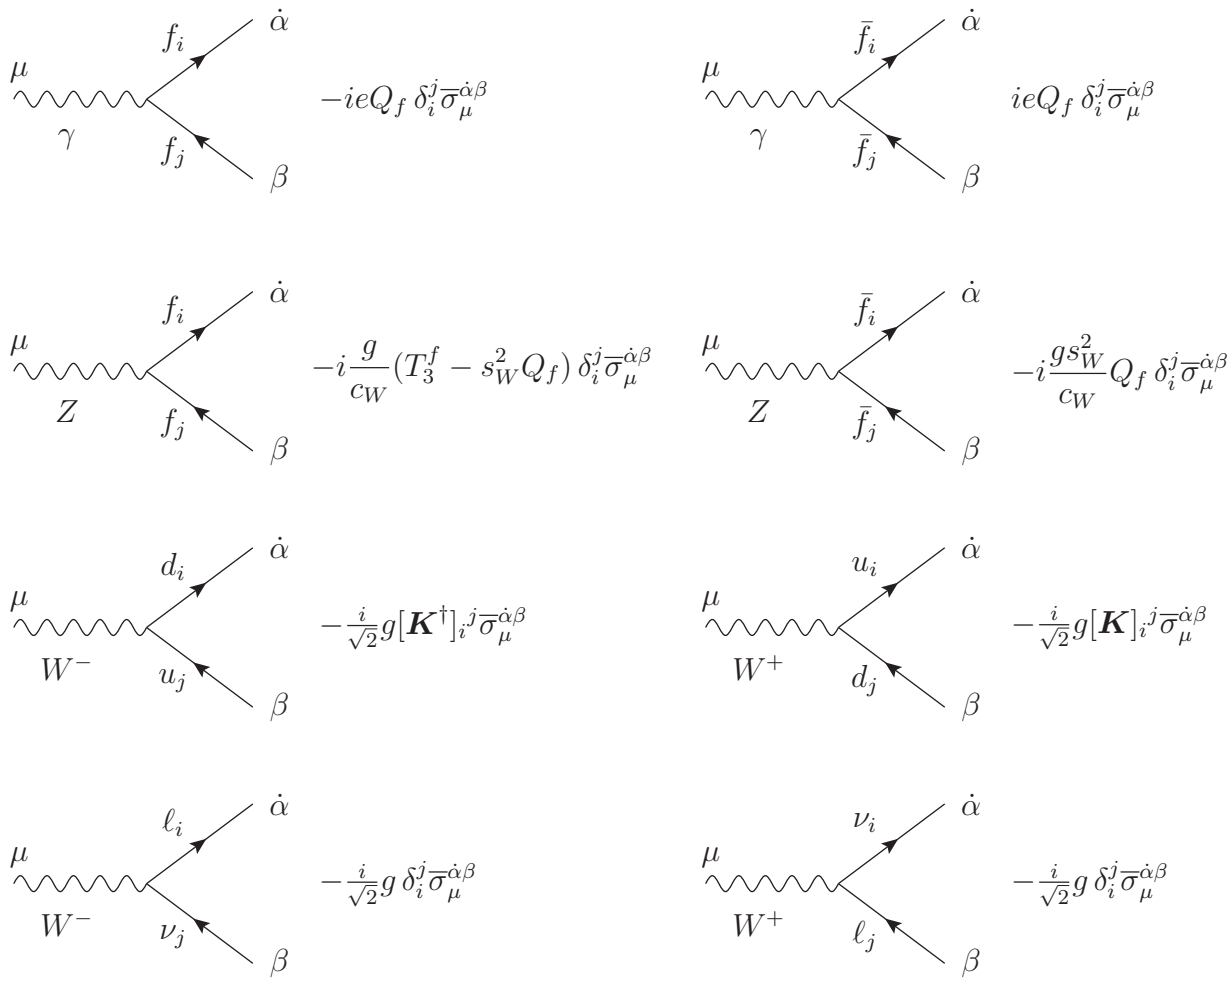

Figure J.1.2: Feynman rules for the two-component fermion interactions with electroweak gauge bosons in the Standard Model. The couplings of the fermions to γ and Z are flavor-diagonal. In all couplings, i and j label the fermion generations; an upper [lowered] flavor index in the corresponding Feynman rule is associated with a fermion line that points into [out from] the vertex. For the $W^\pm$ bosons, the charge indicated is flowing into the vertex. The electric charge is denoted by Q_f (in units of $e>0$), with $Q_e=-1$ for the electron. $T_3^f=1/2$ for $f=u$, ν, and $T_3^f=-1/2$ for $f=d$, ℓ. The CKM mixing matrix is denoted by $\boldsymbol{K}$, and $s_W\equiv\sin\theta_W$, $c_W\equiv\cos\theta_W$ and $e\equiv g\sin\theta_W$. For each rule, a corresponding one with lowered spinor indices is obtained by $\overline\sigma_\mu^{\dot\alpha\beta}\to-\sigma_{\mu\beta\dot\alpha}$.

We can now write out the couplings of the mass eigenstate quarks and leptons to the gauge bosons and Higgs bosons. Consider first the charged current interactions of the quarks and leptons. Using eq. (J.1.10), it follows that $\hat u^{\dagger i}\overline\sigma^\mu\hat d_i=\boldsymbol{K}_i{}^j u^{\dagger i}\overline\sigma^\mu d_j$, where

$$\boldsymbol{K}=L_u^\dagger L_d \tag{J.1.16}$$

is the unitary Cabibbo-Kobayashi-Maskawa (CKM) matrix [336].[170] Due to eq. (J.1.15), the corresponding leptonic CKM matrix is the unit matrix. Hence, the charged current interactions take the form

$$\mathscr{L}_{\rm int}=-\frac{g}{\sqrt2}\left[\boldsymbol{K}_i{}^j u^{\dagger i}\overline\sigma^\mu d_j W_\mu^+ + (\boldsymbol{K}^\dagger)_i{}^j d^{\dagger i}\overline\sigma^\mu u_j W_\mu^- + \nu^{\dagger i}\overline\sigma^\mu\ell_i W_\mu^+ + \ell^{\dagger i}\overline\sigma^\mu\nu_i W_\mu^-\right], \tag{J.1.17}$$

[170] The CKM matrix elements V_{ij} as defined in ref. [337] are related by, for example, $V_{tb}=\boldsymbol{K}_3{}^3$ and $V_{us}=\boldsymbol{K}_1{}^2$.

where $[\boldsymbol{K}^\dagger]_i{}^j \equiv [\boldsymbol{K}_j{}^i]^*$. Note that in the Standard Model, $\bar{u}$, $\bar{d}$ and $\bar{\ell}$ do not couple to the $W^\pm$.

To obtain the neutral current interactions, we insert eqs. (J.1.10)–(J.1.15) into eq. (J.1.2). All factors of the *unitary* matrices L_f and R_f ($f = u, d, \ell$) cancel out, and the resulting interactions are flavor-diagonal. That is, we may simply remove the hats from the quark and lepton fields that couple to the Z and photon fields in eq. (J.1.2). This is the well-known Glashow-Iliopoulos-Maiani (GIM) mechanism for the flavor-conserving neutral currents [338].[171]

The Feynman rules for the interactions of the quarks and leptons with the charged and neutral gauge bosons are exhibited in Fig. J.1.2. For each of the rules of Fig. J.1.2, we have chosen to employ $\overline{\sigma}_\mu^{\dot\alpha\beta}$. If the indices are lowered one should take $\overline{\sigma}_\mu^{\dot\alpha\beta} \to -\sigma_{\mu\beta\dot\alpha}$.

Finally, we exhibit the interactions of the quark and lepton mass eigenstates with the Higgs fields. The diagonalization of the fermion mass matrices is equivalent to the diagonalization of the Yukawa couplings [cf. eqs. (J.1.9) and (J.1.12)–(J.1.14)]. Thus, we define[172]

$$Y_{fi} = m_{fi}/v\,, \qquad f = u, d, \ell\,, \tag{J.1.18}$$

where i labels the fermion generation. It is convenient to rewrite eqs. (J.1.12)–(J.1.14) as follows:

$$(L_f)_k{}^j(\boldsymbol{Y}_f)^k{}_m(R_f)^m{}_i = Y_{fi}\delta_i^j\,, \qquad f = u, d, \ell\,, \tag{J.1.19}$$

with no sum over the repeated index i. Using the unitarity of L_f ($f = u$, d), eq. (J.1.19) is equivalent to the following convenient form:

$$(\boldsymbol{Y}_f R_f)^k{}_i = Y_{fi}(L_f^\dagger)_i{}^k\,. \tag{J.1.20}$$

Inserting eqs. (J.1.10), (J.1.15) and (J.1.19) into eq. (J.1.6), the resulting Higgs-fermion Lagrangian is flavor-diagonal:

$$\mathscr{L}_{\rm int} = -\frac{1}{\sqrt{2}} h_{\rm SM}\left[Y_{ui}u_i\bar{u}^i + Y_{di}d_i\bar{d}^i + Y_{\ell i}\ell_i\bar{\ell}^i\right] + \text{h.c.} \tag{J.1.21}$$

The corresponding Feynman rules for the Higgs-fermion interaction are shown in Fig. J.1.3.

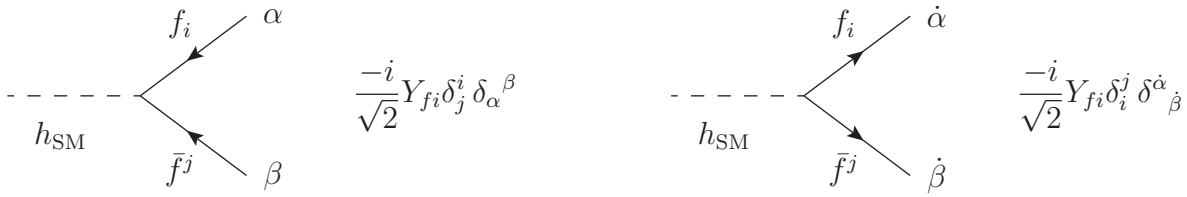

Figure J.1.3: Feynman rules for the Standard Model Higgs boson interactions with fermions, where $Y_{fi} \equiv m_{fi}/v$, and i, j label the generations.

In the case of more general covariant gauge-fixing (e.g., the 't Hooft-Feynman gauge or Landau gauge), the Goldstone bosons appear explicitly in internal lines of Feynman diagrams. The Feynman rules for G^0-fermion interactions are flavor-diagonal, whereas the corresponding rules for $G^\pm$ exhibit flavor-changing interactions that depend on the CKM matrix elements, as shown in Fig. J.1.4. In the derivation of the couplings of the Nambu-Goldstone bosons to the fermion mass eigenstates [cf. eqs. (J.1.6)–(J.1.8)], the following quantities appear:

$$(L_d)_k{}^j(\boldsymbol{Y}_u)^k{}_m(R_u)^m{}_i = Y_{ui}(L_d)_k{}^j(L_u^\dagger)_i{}^k = Y_{ui}(L_u^\dagger L_d)_i{}^j = [\boldsymbol{K}]_i{}^j Y_{ui}\,, \tag{J.1.22}$$

$$(L_u)_k{}^j(\boldsymbol{Y}_d)^k{}_m(R_d)^m{}_i = Y_{di}(L_u)_k{}^j(L_d^\dagger)_i{}^k = Y_{di}(L_d^\dagger L_u)_i{}^j = [\boldsymbol{K}^\dagger]_i{}^j Y_{di}\,, \tag{J.1.23}$$

[171] This also provides the justification for employing mass eigenstate quark fields in the QCD interaction Lagrangian in eq. (J.1.1).

[172] Boldfaced symbols are used for the non-diagonal Yukawa matrices, while non-boldfaced symbols are used for the diagonalized Yukawa couplings.

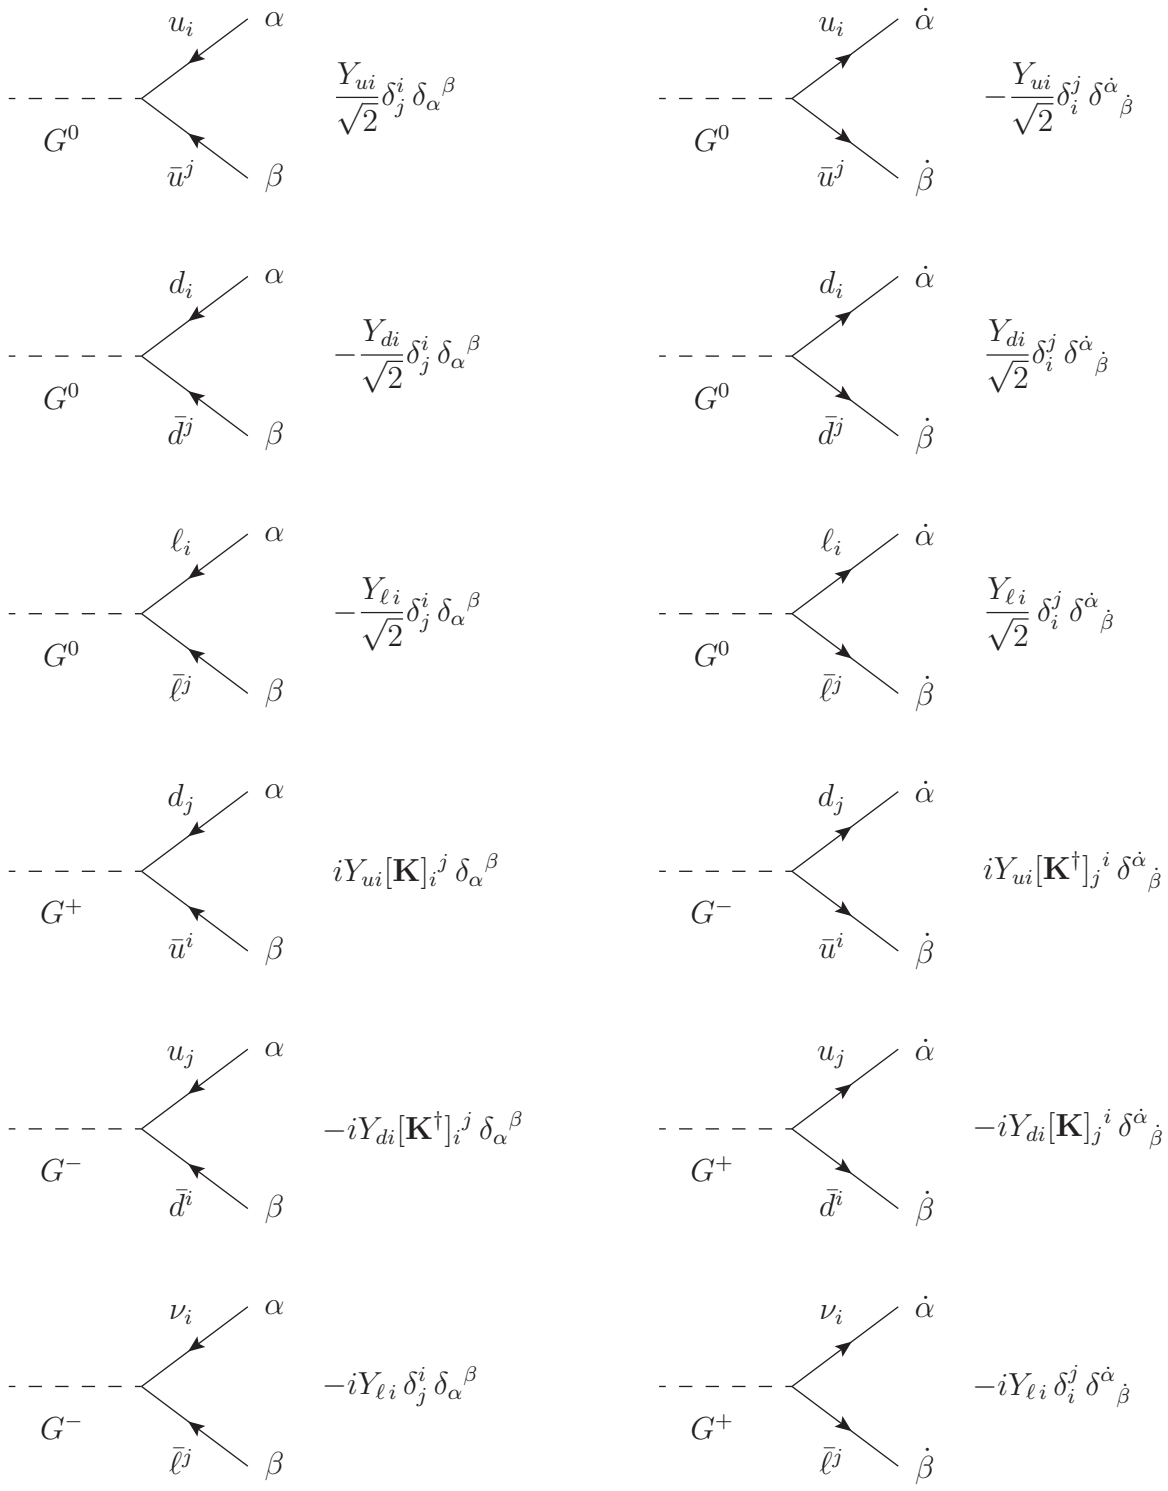

Figure J.1.4: Feynman rules for the Standard Model Nambu-Goldstone boson interactions with quarks and leptons, where $Y_{fi} \equiv m_{fi}/v$, and i, j label the generations.

with no sum over the repeated index i. The CKM matrix, $\boldsymbol{K}$, appears by virtue of eqs. (J.1.16) and (J.1.20). Hence, the interaction Lagrangian for the coupling of the Nambu-Goldstone bosons

to the fermion mass eigenstates is given by:

$$\mathscr{L}_{\rm int} = Y_{ui}[\boldsymbol{K}]_i{}^j d_j \bar{u}^i G^+ - Y_{di}[\boldsymbol{K}^\dagger]_i{}^j u_j \bar{d}^i G^- - Y_{\ell i}\nu_i \bar{\ell}^i G^- + \frac{i}{\sqrt{2}}\left[Y_{di} d_i \bar{d}^i - Y_{ui} u_i \bar{u}^i + Y_{\ell\, i}\ell_i \bar{\ell}^i\right] G^0 + \text{h.c.}, \tag{J.1.24}$$

which yields the diagrammatic Feynman rules shown in Fig. J.1.4.

29.7.13 The Standard Model and its seesaw extension 2

Incorporating massive neutrinos into the Standard Model

To accommodate massive neutrinos, we must slightly extend the Standard Model [339]. The simplest approach is to introduce an SU(2)×U(1) gauge invariant dimension-five operator [340],

$$\begin{aligned}\mathscr{L}_5 &= -\frac{\hat{\boldsymbol{F}}^{ij}}{2\Lambda}(\epsilon^{ab}\boldsymbol{\Phi}_a \hat{\boldsymbol{L}}_{bi})(\epsilon^{cd}\boldsymbol{\Phi}_c \hat{\boldsymbol{L}}_{dj}) + \text{h.c.} \\ &= -\frac{\hat{\boldsymbol{F}}^{ij}}{2\Lambda}(\Phi^0\hat{\nu}_i - \Phi^+\hat{\ell}_i)(\Phi^0\hat{\nu}_j - \Phi^+\hat{\ell}_j) + \text{h.c.}\,,\end{aligned} \tag{J.2.1}$$

where $\hat{\boldsymbol{F}}^{ij}$ are generalized Yukawa couplings, the hatted fields indicate two-component fermion interaction eigenstates (with spinor indices suppressed), and i, j label the three generations. After electroweak symmetry breaking, the neutral component of the doublet Higgs field acquires a vacuum expectation value, and a Majorana mass matrix for the neutrinos is generated.

The diagonalization of the charged lepton mass matrix is unmodified from the treatment given in Appendix J.1 , where the unhatted mass eigenstate charged lepton fields are given by eq. (J.1.11), and L_ℓ and R_ℓ satisfy eq. (J.1.14). However, the unhatted neutrino field introduced in eq. (J.1.15) is *not* a neutrino mass eigenstate field when the effect of the dimension-five Lagrangian, eq. (J.2.1), is taken into account. To avoid confusion, we replace the unhatted neutrino fields of eq. (J.1.15) with new neutrino fields $\breve{\nu}_j$. That is, we define

$$\hat{\nu}_i = (L_\ell)_i{}^j \breve{\nu}_j\,. \tag{J.2.2}$$

We then rewrite eq. (J.2.1) in terms of the charged lepton mass eigenstate field and the new neutrino field defined by eq. (J.2.2):

$$\mathscr{L}_5 = -\frac{\boldsymbol{F}^{ij}}{2\Lambda}(\Phi^0\breve{\nu}_i - \Phi^+\ell_i)(\Phi^0\breve{\nu}_j - \Phi^+\ell_j) + \text{h.c.}\,, \tag{J.2.3}$$

where $\boldsymbol{F} \equiv L_\ell^{\mathsf{T}}\hat{\boldsymbol{F}}L_\ell$. Setting $\Phi^0 = v$ and $\Phi^+ = \Phi^- = 0$, we identify the 3×3 complex symmetric effective light neutrino mass matrix, $\boldsymbol{M}_{\boldsymbol{\nu\ell}}$, by

$$-\mathscr{L}_{m_\nu} = \tfrac{1}{2}(\boldsymbol{M}_{\boldsymbol{\nu\ell}})^{ij}\breve{\nu}_i\breve{\nu}_j + \text{h.c.}\,, \tag{J.2.4}$$

where

$$\boldsymbol{M}_{\boldsymbol{\nu\ell}} = \frac{v^2}{\Lambda}\boldsymbol{F}\,. \tag{J.2.5}$$

Current bounds on light neutrino masses suggest that $v^2/\Lambda \lesssim 1$ eV, or $\Lambda \gtrsim 10^{13}$ GeV [337, 341].

The physical neutrino mass eigenstate fields can be identified by introducing the unitary Maki-Nakagawa-Sakata (MNS) matrix, $\boldsymbol{U}_{\rm MNS}$, such that [342],[173]

$$(\breve{\nu}_\ell)_i = (\boldsymbol{U}_{\rm MNS})_i{}^j(\nu_\ell)_j\,, \tag{J.2.6}$$

[173] In the literature, the MNS matrix is often defined such that $\boldsymbol{U}^*_{\rm MNS}$ (and *not* $\boldsymbol{U}_{\rm MNS}$) appears in eq. (J.2.6).

where the unhatted $(\nu_\ell)_j$ fields [$j = 1, 2, 3$] denote the physical (mass eigenstate) Majorana neutrino fields. $\boldsymbol{U}_{\rm MNS}$ is determined by the Takagi diagonalization of $\boldsymbol{M}_{\boldsymbol{\nu\ell}}$ [cf. Appendix D.2]:

$$\boldsymbol{U}_{\rm MNS}^{\mathsf{T}}\boldsymbol{M}_{\boldsymbol{\nu\ell}}\boldsymbol{U}_{\rm MNS} = {\rm diag}(m_{\nu_\ell 1}\,,\, m_{\nu_\ell 2}\,,\, m_{\nu_\ell 3})\,, \tag{J.2.7}$$

where the $m_{\nu_\ell j}$ are the (real non-negative) masses of the physical neutrinos.

The interaction Lagrangian of the neutrino mass eigenstates can now be determined. The charged current neutrino interactions are given by [cf. eq. (J.1.17)]:

$$\begin{aligned}\mathscr{L}_{\rm int} &= -\frac{g}{\sqrt{2}}\left[\breve{\nu}^{\dagger i}\overline{\sigma}^\mu\ell_i W_\mu^+ + \ell^{\dagger i}\overline{\sigma}^\mu\breve{\nu}_i W_\mu^-\right] \\ &= -\frac{g}{\sqrt{2}}\left[(\boldsymbol{U}_{\rm MNS}^\dagger)_j{}^i\nu_\ell^{\dagger j}\overline{\sigma}^\mu\ell_i W_\mu^+ + (\boldsymbol{U}_{\rm MNS})_i{}^j\ell^{\dagger i}\overline{\sigma}^\mu\nu_{\ell j}W_\mu^-\right]\,,\end{aligned} \tag{J.2.8}$$

where we have used eq. (J.2.6) to express the interaction Lagrangian in terms of the neutrino mass eigenstate fields. The neutral current neutrino interactions are flavor-diagonal (which follows from the unitarity of $U_{\rm MNS}$), and are thus equivalent to those of the Standard Model. Finally, the couplings of the neutrinos to the Higgs and Nambu-Goldstone fields arise from eq. (J.2.3) and from the term in eq. (J.1.6) proportional to $\boldsymbol{Y}_\ell$. Neglecting terms of $\mathcal{O}(m_\nu^2/v^2)$, one obtains:

$$\begin{aligned}\mathscr{L}_{\rm int} = \frac{1}{v}\sum_{i,j}\Big[&(m_{\nu_\ell})_j(\boldsymbol{U}_{\rm MNS}^\dagger)_j{}^i(\nu_\ell)_j\,\ell_i\,G^+ - (m_\ell)_i(\boldsymbol{U}_{\rm MNS})_i{}^j(\nu_\ell)_j\,\bar{\ell}^i\,G^- + {\rm h.c.}\Big] \\ -\frac{1}{\sqrt{2}v}\sum_j&(m_{\nu_\ell})_j\left[(\nu_\ell)_j(\nu_\ell)_j(h_{\rm SM}+iG^0) + {\rm h.c.}\right]\,.\end{aligned} \tag{J.2.9}$$

The Feynman rules for the interactions of the neutrino with the electroweak gauge bosons, the Higgs boson and the Nambu-Goldstone bosons are exhibited in Fig. J.2.1.

The dimension-five Lagrangian, eq. (J.2.1), is generated by new physics beyond the Standard Model at the scale Λ. A possible realization of eq. (J.2.1) is the seesaw mechanism, which was independently discovered on a number of occasions [4]. In the seesaw extension of the Standard Model [5], one introduces the SU(3)×SU(2)×U(1) gauge singlet two-component neutrino fields $\bar{\nu}^I$ ($I = 1, 2, ..., n$) and writes down the most general renormalizable couplings of the $\bar{\nu}^I$ to the Standard Model fields:

$$\mathscr{L}_{\rm seesaw} = \epsilon^{ab}(\hat{\boldsymbol{Y}}_\nu)^i{}_J\boldsymbol{\Phi}_a\hat{\boldsymbol{L}}_{bi}\hat{\bar{\nu}}^J - \tfrac{1}{2}\hat{\boldsymbol{M}}_{IJ}\hat{\bar{\nu}}^I\hat{\bar{\nu}}^J + {\rm h.c.}\,, \tag{J.2.10}$$

where the Yukawa coupling proportional to $\hat{\boldsymbol{Y}}_\nu$ is the leptonic analogue of the Higgs-quark Yukawa coupling proportional to $\hat{\boldsymbol{Y}}_u$ [cf. eq. (J.1.5)]. In eq. (J.2.10), we have distinguished the flavor labels of three generations of Standard Model neutrino and charged lepton fields (denoted by lower case Roman letters i, j, ...) and the flavor labels of singlet neutrino fields (denoted by upper case Roman letters I, J, ...). Note that $\hat{\boldsymbol{Y}}_\nu$ is a $3\times n$ matrix and $\hat{\boldsymbol{M}}$ is an $n\times n$ matrix, where n is the number of singlet neutrino flavors. In general, we shall not specify the value of n, which may differ from the number of Standard Model lepton generations.

If $\Lambda \equiv \|\hat{\boldsymbol{M}}\| \gg v$,[174] then a dimension-five operator of the form given by eq. (J.2.1) is generated in the effective theory at energy scales below Λ. In this limit, we may neglect the kinetic energy term of the gauge singlet neutrino fields. Using the Lagrange field equations, we may solve for $\hat{\bar{\nu}}^I$. Inserting the solution back into eq. (J.2.10) then yields eq. (J.2.1), with $\hat{\boldsymbol{F}}/\Lambda$ given by

$$\hat{\boldsymbol{F}}^{ij}/\Lambda = -(\hat{\boldsymbol{Y}}_\nu)^i{}_K(\hat{\boldsymbol{Y}}_\nu)^j{}_N(\hat{\boldsymbol{M}}^{-1})^{KN}\,. \tag{J.2.11}$$

[174]The Euclidean matrix norm is defined by $\|A\| \equiv \left[{\rm Tr}(A^\dagger A)\right]^{1/2} = \left[\sum_{i,j}|a_{ij}|^2\right]^{1/2}$, for a matrix A whose matrix elements are given by a_{ij}.

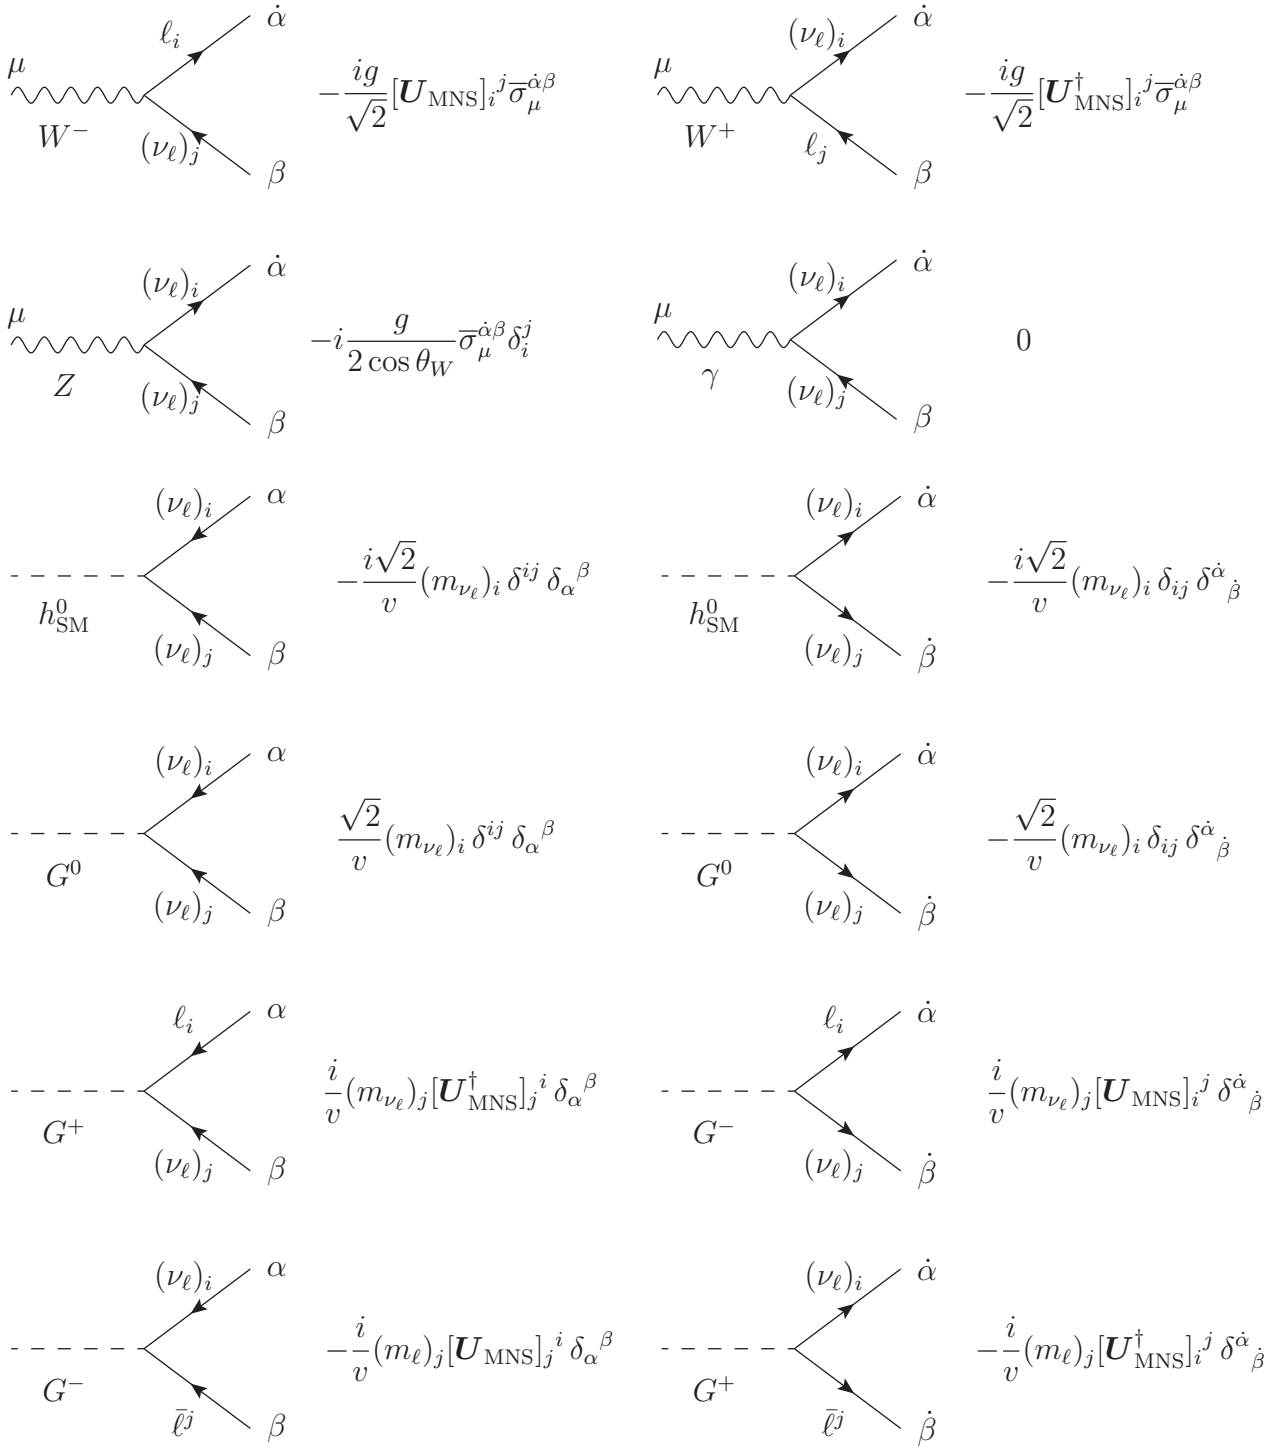

Figure J.2.1: Feynman rules for the interactions of the two-component light neutrino (ν_ℓ) with electroweak gauge bosons, the Standard Model Higgs boson and the Nambu-Goldstone bosons, where i, j label the generation. For the $W^\pm$ bosons and $G^\pm$ scalars, the charge indicated is flowing into the vertex. The MNS mixing matrix is denoted by $\boldsymbol{U}_{\rm MNS}$. For the rules involving $W^\pm$ and Z bosons, a corresponding one with lowered spinor indices is obtained by $\overline{\sigma}_\mu^{\dot\alpha\beta} \to -\sigma_{\mu\beta\dot\alpha}$. In the $h^0_{\rm SM}$ and G^0 interactions, a factor of 2 is included to account for the identical neutrinos.

Using the definition of the $\mathrm{SU}(2)_L$ doublet lepton field given in Table J.1, one can rewrite

eq. (J.2.10) more explicitly as:

$$\mathscr{L}_{\text{seesaw}} = -(\hat{\boldsymbol{Y}}_\nu)^i{}_J \left[\Phi^0 \hat{\nu}_i \hat{\bar{\nu}}^J - \Phi^+ \hat{\ell}_i \hat{\bar{\nu}}^J\right] - \tfrac{1}{2}\hat{\boldsymbol{M}}_{IJ}\hat{\bar{\nu}}^I \hat{\bar{\nu}}^J + \text{h.c.} \tag{J.2.12}$$

To analyze the physical consequences of the seesaw Lagrangian, we first express eq. (J.2.12) in terms of the unhatted mass eigenstate charged lepton fields [cf. eq. (J.1.11)], and the light neutrino fields $\breve{\nu}_i$ introduced in eq. (J.2.2). It is also convenient to introduce new gauge singlet neutrino fields $\breve{\bar{\nu}}^J$ by defining

$$\hat{\bar{\nu}}^I = N^I{}_J \breve{\bar{\nu}}^J\,, \tag{J.2.13}$$

where N is the unitary matrix that Takagi-diagonalizes the complex symmetric matrix $\hat{\boldsymbol{M}}$. That is,

$$\boldsymbol{M} \equiv N^{\mathsf{T}} \hat{\boldsymbol{M}} N = \text{diag}(M_1\,,\, M_2\,, \ldots\,, M_n)\,, \tag{J.2.14}$$

where the M_I are the singular values of $\hat{\boldsymbol{M}}$ (i.e., the non-negative square roots of the eigenvalues of $\hat{\boldsymbol{M}}^\dagger \hat{\boldsymbol{M}}$). In terms of the mass eigenstate charged lepton fields ℓ_i and the neutrino fields $\breve{\nu}_i$ and $\breve{\bar{\nu}}^I$, the seesaw Lagrangian [eq. (J.2.12)] is then given by:

$$\mathscr{L}_{\text{seesaw}} = -(\boldsymbol{Y}_\nu)^i{}_J \left[\Phi^0 \breve{\nu}_i \breve{\bar{\nu}}^J - \Phi^+ \ell_i \breve{\bar{\nu}}^J\right] - \tfrac{1}{2}\boldsymbol{M}_{IJ}\breve{\bar{\nu}}^I \breve{\bar{\nu}}^J + \text{h.c.}\,, \tag{J.2.15}$$

where

$$\boldsymbol{Y}_\nu \equiv L_\ell^{\mathsf{T}} \hat{\boldsymbol{Y}}_\nu N\,. \tag{J.2.16}$$

As above, in the limit of $\Lambda \equiv \|\hat{\boldsymbol{M}}\| = \|\boldsymbol{M}\| \gg v$, it is also possible to directly generate the effective dimension-five operator [eq. (J.2.3)] in terms of the mass eigenstate charged lepton fields and the new neutrino fields $\breve{\nu}_j$. We then identify the corresponding coefficient, $\boldsymbol{F}/\Lambda$, as

$$\boldsymbol{F}^{ij}/\Lambda = -(\boldsymbol{Y}_\nu)^i{}_K (\boldsymbol{Y}_\nu)^j{}_N (\boldsymbol{M}^{-1})^{KN}\,. \tag{J.2.17}$$

Recalling that $\boldsymbol{F} = L_\ell^{\mathsf{T}} \hat{\boldsymbol{F}} L_\ell$, one can check that eq. (J.2.17) indeed follows from eqs. (J.2.11), (J.2.14) and (J.2.16).

To identify the neutrino mass matrix, we set $\Phi^0 = v$ and $\Phi^+ = \Phi^- = 0$ in eq. (J.2.15):

$$-\mathscr{L}_{m_\nu} = \tfrac{1}{2}\begin{pmatrix}\breve{\nu}_i & \breve{\bar{\nu}}^J\end{pmatrix} \mathcal{M}_\nu \begin{pmatrix}\breve{\nu}_k \\ \breve{\bar{\nu}}^M\end{pmatrix} + \text{h.c.} \tag{J.2.18}$$

The neutrino mass matrix $\mathcal{M}_\nu$ is a $(3+n)\times(3+n)$ complex symmetric matrix given in block form by:

$$\mathcal{M}_\nu \equiv \begin{pmatrix} \mathbb{O} & \boldsymbol{M_D} \\ \boldsymbol{M_D}^{\mathsf{T}} & \boldsymbol{M}\end{pmatrix}\,, \tag{J.2.19}$$

where $\mathbb{O}$ is the 3×3 zero matrix, $\boldsymbol{M}$ is the diagonal matrix defined in eq. (J.2.14) and $\boldsymbol{M_D}$ is a $3\times n$ complex matrix (called the Dirac neutrino mass matrix),

$$(\boldsymbol{M_D})^i{}_J \equiv v(\boldsymbol{Y}_\nu)^i{}_J\,. \tag{J.2.20}$$

Note that if $n=3$ and $\boldsymbol{M}=\mathbb{O}$, then $\boldsymbol{M_D}$ is a 3×3 matrix that is simply the leptonic analogue of the up-type quark mass matrix $\boldsymbol{M}_u$. In this case, we would perform a singular value decomposition of $\boldsymbol{M_D}$ and identify the unhatted neutrino mass eigenstate fields, which can be assembled into three generations of four-component Dirac neutrinos,

$$N_i = \begin{pmatrix}\nu_i \\ \bar{\nu}^{\dagger i}\end{pmatrix}\,, \qquad i=1,2,3\,. \tag{J.2.21}$$

In the seesaw model (with n not specified), we assume that $\|\boldsymbol{M}\| \gg \|\boldsymbol{M_D}\|$. In this case, the neutrino mass matrix can be perturbatively Takagi-block-diagonalized as follows [283, 343, 301]. Introduce the $(3+n)\times(3+n)$ (approximate) unitary matrix:

$$\mathcal{U} = \begin{pmatrix} \mathbb{1}_{3\times 3} - \frac{1}{2}\boldsymbol{M_D^*}\boldsymbol{M}^{-2}\boldsymbol{M_D^{\mathsf{T}}} & \boldsymbol{M_D^*}\boldsymbol{M}^{-1} \\ -\boldsymbol{M}^{-1}\boldsymbol{M_D^{\mathsf{T}}} & \mathbb{1}_{n\times n} - \frac{1}{2}\boldsymbol{M}^{-1}\boldsymbol{M_D^{\mathsf{T}}}\boldsymbol{M_D^*}\boldsymbol{M}^{-1} \end{pmatrix}, \tag{J.2.22}$$

where $\mathbb{1}$ is the identity matrix (whose dimension is explicitly specified above). We define transformed [light (ℓ) and heavy (h)] neutrino states $(\breve{\nu}_\ell)_i$ and $(\breve{\breve{\nu}}_h)^j$ by:

$$\begin{pmatrix} \breve{\nu}_i \\ \breve{\breve{\nu}}^J \end{pmatrix} = \mathcal{U}\begin{pmatrix} (\breve{\nu}_\ell)_k \\ (\breve{\breve{\nu}}_h)^M \end{pmatrix}. \tag{J.2.23}$$

By straightforward matrix multiplication, one can verify that to second order accuracy in perturbation theory,

$$\mathcal{U}^{\mathsf{T}}\mathcal{M}_\nu\mathcal{U} \simeq \begin{pmatrix} -\boldsymbol{M_D}\boldsymbol{M}^{-1}\boldsymbol{M_D^{\mathsf{T}}} & \mathbb{O} \\ \mathbb{O}^{\mathsf{T}} & \boldsymbol{M} + \frac{1}{2}(\boldsymbol{M}^{-1}\boldsymbol{M_D^\dagger}\boldsymbol{M_D} + \boldsymbol{M_D^{\mathsf{T}}}\boldsymbol{M_D^*}\boldsymbol{M}^{-1}) \end{pmatrix}, \tag{J.2.24}$$

where $\mathbb{O}$ is the $3\times n$ zero matrix.

We now can identify an effective 3×3 complex symmetric mass matrix $\boldsymbol{M_{\nu_\ell}}$ for the three light neutrinos as the upper left-hand block of eq. (J.2.24),

$$\boldsymbol{M_{\nu_\ell}} \simeq -\boldsymbol{M_D}\boldsymbol{M}^{-1}\boldsymbol{M_D^{\mathsf{T}}}, \tag{J.2.25}$$

where corrections of $\mathcal{O}(v^4/\Lambda^3)$ have been neglected. Using eqs. (J.2.17) and (J.2.20), we see that the light neutrino mass matrix obtained in eq. (J.2.5) has been correctly reproduced to leading order in v^2/Λ^2.

The physical light neutrino mass eigenstate fields and their masses are identified by eqs. (J.2.6) and (J.2.7). At energy scales below the heavy neutrino mass scale, $\Lambda \equiv \|\boldsymbol{M}\|$, and we can set $\breve{\breve{\nu}}_h = 0$. Neglecting corrections of $\mathcal{O}(v^2/\Lambda^2)$, eqs. (J.2.20)–(J.2.25) imply that[175]

$$\breve{\nu}_i \simeq (\boldsymbol{U}_{\rm MNS})_i{}^j(\nu_\ell)_j\,, \tag{J.2.26}$$

$$(\boldsymbol{Y}_\nu)^i{}_J\breve{\breve{\nu}}^J \simeq \frac{1}{v}(\boldsymbol{M_{\nu_\ell}}\boldsymbol{U}_{\rm MNS})^{ik}(\nu_\ell)_k = \frac{1}{v}\sum_k (\boldsymbol{U}^\dagger_{\rm MNS})_k{}^i\,(m_{\nu_\ell})_k(\nu_\ell)_k\,, \tag{J.2.27}$$

where in the last step above we have used eq. (J.2.7) and $(\boldsymbol{U}^\dagger_{\rm MNS})_j{}^i \equiv [(\boldsymbol{U}_{\rm MNS})_i{}^j]^*$. Using eqs. (J.2.26) and (J.2.27) to express the seesaw Lagrangian in terms of the light neutrino mass eigenstate fields, one can verify that the resulting interactions of the light neutrinos (and charged leptons) to gauge bosons, the Higgs boson and the Nambu-Goldstone bosons reproduce the results of eqs. (J.2.8) and (J.2.9) at leading order in v^2/Λ^2.

For completeness, we examine the effective $n\times n$ complex symmetric mass matrix of the heavy neutrino states, $\boldsymbol{M_{\nu_h}}$, which is identified as the lower right-hand block in eq. (J.2.24),

$$\boldsymbol{M_{\nu_h}} \simeq \boldsymbol{M} + \frac{1}{2}(\boldsymbol{M}^{-1}\boldsymbol{M_D^\dagger}\boldsymbol{M_D} + \boldsymbol{M_D^{\mathsf{T}}}\boldsymbol{M_D^*}\boldsymbol{M}^{-1})\,. \tag{J.2.28}$$

[175] Strictly speaking, eq. (J.2.27) should be written as:

$$(\boldsymbol{Y}_\nu)^i{}_J\breve{\breve{\nu}}^J \simeq \frac{1}{v}\sum_{k,n}(\boldsymbol{U}^\dagger_{\rm MNS})_n{}^i\,\delta^{nk}(m_{\nu_\ell})_k(\nu_\ell)_k\,,$$

to maintain covariance in the flavor indices.

Although $\boldsymbol{M}$ is diagonal by definition [cf. eq. (J.2.14)], the right-hand side of eq. (J.2.28) is no longer diagonal due to the second order perturbative correction. However, we do not have to perform another Takagi diagonalization, since the off-diagonal elements of the lower right-hand block only affect the physical (diagonal) masses at higher order in perturbation theory. Thus, we identify the physical heavy neutrino mass eigenstates to leading order by the unhatted fields,

$$\bar{\nu}_h^J \simeq \breve{\bar{\nu}}_h^J \,, \tag{J.2.29}$$

with masses

$$m_{\nu_{hJ}} \simeq M_J \left(1 + \frac{1}{M_J^2} \sum_i |(\boldsymbol{M_D})^i{}_J|^2 \right) , \tag{J.2.30}$$

where the M_J are the diagonal elements of $\boldsymbol{M}$ (and no sum over the repeated index J is implied). That is, the masses of the heavy neutrinos are simply given by $m_{\nu_{hJ}} \simeq M_J$, up to corrections that are of the same order as the light neutrino masses.

The interactions of the heavy neutrinos can be likewise obtained. The only unsuppressed interactions are heavy neutrino couplings to the Higgs boson and Nambu-Goldstone bosons that are proportional to the Dirac neutrino mass matrix,

$$\mathscr{L}_{\rm int} = -\frac{1}{\sqrt{2}v}(\boldsymbol{U}_{\rm MNS}^{\mathsf{T}}\boldsymbol{M_D})^k{}_J\bar{\nu}_h^J(\nu_\ell)_k(h^0_{\rm SM} + iG^0) + \frac{1}{v}(\boldsymbol{M_D})^i{}_J\ell_i\bar{\nu}_h^J G^+ + \text{h.c.} \tag{J.2.31}$$

All other couplings of the heavy neutrinos to the $W^\pm$ and Z bosons (and additional contributions to the couplings of the heavy neutrinos to the Higgs boson and Nambu-Goldstone bosons) are suppressed by (at least) a factor of $\mathcal{O}(v/\Lambda)$.

29.7.14 MSSM fermion interaction vertices

In this section, we provide the Feynman rules for the MSSM interaction vertices. To complete the tabulation of all MSSM Feynman rules, one requires the rules for the purely bosonic interactions of the MSSM. These can be found in refs. [344, 345].

Higgs-fermion interaction vertices in the MSSM

The MSSM Higgs sector is a two Higgs doublet model containing eight real scalar degrees of freedom: one complex $Y = -\frac{1}{2}$ doublet, $\boldsymbol{H_d} = (H_d^0\,,\, H_d^-)$ and one complex $Y = +\frac{1}{2}$ doublet, $\boldsymbol{H_u} = (H_u^+\,,\, H_u^0)$. The notation reflects the form of the MSSM Higgs sector coupling to fermions:

$$\mathscr{L}_{\rm Y} = \epsilon^{ab}\left[(\boldsymbol{Y}_u)^i{}_j(\boldsymbol{H_u})_a\hat{\boldsymbol{Q}}_{bi}\hat{\bar{u}}^j - (\boldsymbol{Y}_d)^i{}_j(\boldsymbol{H_d})_a\hat{\boldsymbol{Q}}_{bi}\hat{\bar{d}}^j - (\boldsymbol{Y}_\ell)^i{}_j(\boldsymbol{H_d})_a\hat{\boldsymbol{L}}_{bi}\hat{\bar{\ell}}^j\right] + \text{h.c.}\,, \tag{K.1.1}$$

where the hatted fields are interaction eigenstate quark and lepton fields (with generation labels i and j), a and b are $\mathrm{SU}(2)_L$ indices and the invariant $\mathrm{SU}(2)_L$ tensor ϵ^{ab} is defined below eq. (J.1.5). That is, the neutral Higgs fields H_d^0 [H_u^0] couple exclusively to down-type [up-type] fermion pairs, respectively. In the supersymmetric model, both hypercharge $Y = -\frac{1}{2}$ and $Y = +\frac{1}{2}$ complex Higgs doublets are required in order that the theory (which now contains the corresponding higgsino superpartners) remain anomaly free. The supersymmetric structure of the theory forbids the coupling of $\boldsymbol{H_u^\dagger}$ to $\hat{\bar{d}}^j$ and $\hat{\bar{\ell}}^j$ or the coupling of $\boldsymbol{H_d^\dagger}$ to $\hat{\bar{u}}^j$, as such couplings would not be holomorphic. Consequently, (at least) two Higgs doublets are required in the MSSM to generate mass for both "up"-type and "down"-type quarks and charged leptons [346, 347, 173].

To find the couplings of the Higgs fields, we expand them around the neutral Higgs field vacuum expectation values $v_d \equiv \langle H_d^0\rangle$ and $v_u \equiv \langle H_u^0\rangle$. Depending on the application, these may be chosen to be the minimum of the tree-level scalar potential, or of the full loop-corrected effective potential,

or just left arbitrary. It is always possible to choose the phases of the Higgs fields such that v_u and v_d are real and positive. We then define

$$\beta \equiv \tan^{-1}\left(\frac{v_u}{v_d}\right), \qquad 0 \leq \beta \leq \frac{\pi}{2}. \tag{K.1.2}$$

The one potentially complex squared-mass parameter that appears in the tree-level MSSM Higgs scalar potential is necessarily real in the convention where the vacuum expectation values of the neutral Higgs fields are real and positive.[176] Consequently, the tree-level MSSM Higgs sector conserves CP, which implies that the neutral Higgs mass eigenstates possess definite CP quantum numbers.[177] Spontaneous electroweak symmetry breaking results in three Goldstone bosons $G^\pm$, G^0 (the neutral Goldstone boson is a CP-odd scalar field), which are absorbed and become the longitudinal components of the $W^\pm$ and Z. The remaining five physical Higgs particles consist of a charged Higgs pair $H^\pm$, one CP-odd scalar A^0, and two CP-even scalars h^0 and H^0.

It is convenient to define $H_u^- \equiv (H_u^+)^\dagger$ and $H_d^+ \equiv (H_d^-)^\dagger$. One can then parameterize the mixing angles between Higgs gauge eigenstates and mass eigenstates by writing:

$$H_u^0 = v_u + \frac{1}{\sqrt{2}}\sum_{\phi^0} k_{u\phi^0}\phi^0, \qquad H_u^\pm = \sum_{\phi^\pm} k_{u\phi^\pm}\phi^\pm, \tag{K.1.3}$$

$$H_d^0 = v_d + \frac{1}{\sqrt{2}}\sum_{\phi^0} k_{d\phi^0}\phi^0, \qquad H_d^\pm = \sum_{\phi^\pm} k_{d\phi^\pm}\phi^\pm. \tag{K.1.4}$$

For $\phi^\pm = (H^\pm,\, G^\pm)$,[178]

$$k_{u\phi^\pm} = (\cos\beta_\pm,\ \sin\beta_\pm), \tag{K.1.5}$$

$$k_{d\phi^\pm} = (\sin\beta_\pm,\ -\cos\beta_\pm), \tag{K.1.6}$$

and for $\phi^0 = (h^0,\, H^0,\, A^0,\, G^0)$,

$$k_{u\phi^0} = (\cos\alpha,\ \sin\alpha,\ i\cos\beta_0,\ i\sin\beta_0), \tag{K.1.7}$$

$$k_{d\phi^0} = (-\sin\alpha,\ \cos\alpha,\ i\sin\beta_0,\ -i\cos\beta_0), \tag{K.1.8}$$

where the mixing angle α parameterizes the orthogonal matrix that diagonalizes the 2×2 CP-even Higgs squared-mass matrix $\mathcal{M}_0^2$ [defined in eq. (K.1.11) below].

In eqs. (K.1.3) and (K.1.4), the normalization of the vacuum expectation values is

$$v_d^2 + v_u^2 = 2m_W^2/g^2 \simeq (174\ \text{GeV})^2, \tag{K.1.9}$$

if one chooses v_u, v_d to be near the true minimum of the Higgs effective potential. Note that in the special case that v_u and v_d are at the minimum of the *tree-level* potential, the mixing angles $\beta_\pm$ in the charged Higgs sector and β_0 in the CP-odd neutral Higgs sectors coincide such that $\beta_\pm = \beta_0 = \beta$, where β is defined in eq. (K.1.2). However, if one expands around a more general choice of v_u, v_d, including for example the minimum of the full effective potential, then the tree-level mixing angles β_0 and $\beta_\pm$ are distinct from each other and from β. (Depending on the choice of renormalization scale for a particular calculation, the tree-level potential in the MSSM may have a very different minimum from the true minimum of the full effective potential, or may not have

[176] The coefficients of the quartic terms of the tree-level MSSM Higgs potential are related to the electroweak gauge couplings and are manifestly real, independently of the convention for the phases of the Higgs fields.

[177] When one-loop corrections are taken into account, new MSSM phases can enter in the loops that cannot be removed. In this case, the physical neutral Higgs states can be mixtures of CP-even and CP-odd scalar states [348].

[178] Note that $\phi^- \equiv (\phi^+)^\dagger$. Since the $k_{f\phi^\pm}$ (for $f = u, d$) are real quantities, we adopt the notation in which $k_{f\phi^+} = k_{f\phi^-} \equiv k_{\phi^\pm}$ and $\beta_+ = \beta_- \equiv \beta_\pm$.

a proper minimum at all.) Therefore, we do not assume anything specific about v_u and v_d except that they are real and positive by convention.

All MSSM Higgs boson masses and the mixing angle α are determined at tree level by two Higgs sector parameters, usually taken to be the ratio of the tree-level vacuum expectation values, $\tan\beta = v_u/v_d$, and the mass of the CP-odd Higgs scalar, m_A [347, 173]. The tree-level value of the squared mass of the charged Higgs boson is given by

$$m^2_{H^\pm} = m^2_A + m^2_W \,. \tag{K.1.10}$$

The CP-even Higgs bosons h^0 and H^0 are eigenstates of the tree-level squared-mass matrix,

$$\mathcal{M}^2_0 = \begin{pmatrix} m^2_A \sin^2\beta + m^2_Z \cos^2\beta & -(m^2_A + m^2_Z)\sin\beta\cos\beta \\ -(m^2_A + m^2_Z)\sin\beta\cos\beta & m^2_A\cos^2\beta + m^2_Z\sin^2\beta \end{pmatrix} . \tag{K.1.11}$$

The eigenvalues of $\mathcal{M}^2_0$ are the tree-level squared masses of the two CP-even Higgs scalars,

$$m^2_{H,h} = \tfrac{1}{2}\left(m^2_A + m^2_Z \pm \sqrt{(m^2_A + m^2_Z)^2 - 4m^2_Z m^2_A \cos^2 2\beta}\,\right) , \tag{K.1.12}$$

with $m_h \leq m_H$. The angle α of the orthogonal matrix that diagonalizes $\mathcal{M}^2_0$ is given by [349]:

$$\sin 2\alpha = -\sin 2\beta \left(\frac{m^2_A + m^2_Z}{m^2_H - m^2_h}\right) , \qquad \cos 2\alpha = -\cos 2\beta \left(\frac{m^2_A - m^2_Z}{m^2_H - m^2_h}\right) . \tag{K.1.13}$$

Since $\sin 2\alpha \leq 0$, the tree-level value of α is restricted to lie in the range $-\pi/2 \leq \alpha \leq 0$.

Radiative corrections can have a significant impact on the tree-level Higgs masses and mixing angle α [348, 350]. For example, the tree-level bound $m_h \leq m_Z|\cos 2\beta| \leq m_Z$ [which follows from eq. (K.1.12)] is significantly modified by an incomplete cancellation of top quark and top squark loop corrections. Including the latter implies that $m_h \lesssim 135$ GeV [351], which (in contrast to the tree-level prediction) is not experimentally excluded.

The Higgs-fermion Yukawa couplings in the gauge-interaction basis are given by eq. (K.1.1). Explicitly,

$$\begin{aligned} -\mathscr{L}_{\rm Y} = (\boldsymbol{Y}_u)^i{}_j \left[\hat{u}_i \hat{\bar{u}}^j H^0_u - \hat{d}_i \hat{\bar{u}}^j H^+_u\right] + (\boldsymbol{Y}_d)^i{}_j \left[\hat{d}_i \hat{\bar{d}}^j H^0_d - \hat{u}_i \hat{\bar{d}}^j H^-_d\right] \\ + (\boldsymbol{Y}_\ell)^i{}_j \left[\hat{\ell}_i \hat{\bar{\ell}}^j H^0_d - \hat{\nu}_i \hat{\bar{\ell}}^j H^-_d\right] + \text{h.c.} \end{aligned} \tag{K.1.14}$$

We use eqs. (K.1.3) and (K.1.4) to express the interaction-eigenstate Higgs fields in terms of the physical Higgs fields and Goldstone fields. We can identify the quark and lepton mass matrices simply by setting $H^0_u = v_u$, $H^0_d = v_d$ and $H^+_u = H^-_d = 0$ in eq. (K.1.14) ,

$$(\boldsymbol{M}_u)^i{}_j = v_u(\boldsymbol{Y}_u)^i{}_j \,, \qquad (\boldsymbol{M}_d)^i{}_j = v_d(\boldsymbol{Y}_d)^i{}_j \,, \qquad (\boldsymbol{M}_\ell)^i{}_j = v_d(\boldsymbol{Y}_\ell)^i{}_j \,. \tag{K.1.15}$$

We then use eqs. (J.1.10) and (J.1.11) to express the interaction-eigenstate quark and lepton fields in terms of the corresponding mass eigenstate fields. Eqs. (J.1.12) and (J.1.14) ensure that the fermion mass matrices are diagonal (with real non-negative elements) in the fermion mass eigenstate basis. In this basis, the resulting neutral Higgs-fermion interactions are diagonal. Here, the diagonalized Higgs-fermion Yukawa coupling matrices appear:

$$\text{diag}(Y_{u1}, Y_{u2}, Y_{u3}) \equiv \text{diag}(Y_u, Y_c, Y_t) = L^{\mathsf{T}}_u \boldsymbol{Y}_u R_u \,, \tag{K.1.16}$$

$$\text{diag}(Y_{d1}, Y_{d2}, Y_{d3}) \equiv \text{diag}(Y_d, Y_s, Y_b) = L^{\mathsf{T}}_d \boldsymbol{Y}_d R_d \,, \tag{K.1.17}$$

$$\text{diag}(Y_{\ell 1}, Y_{\ell 2}, Y_{\ell 3}) \equiv \text{diag}(Y_e, Y_\mu, Y_\tau) = L^{\mathsf{T}}_\ell \boldsymbol{Y}_\ell R_\ell \,. \tag{K.1.18}$$

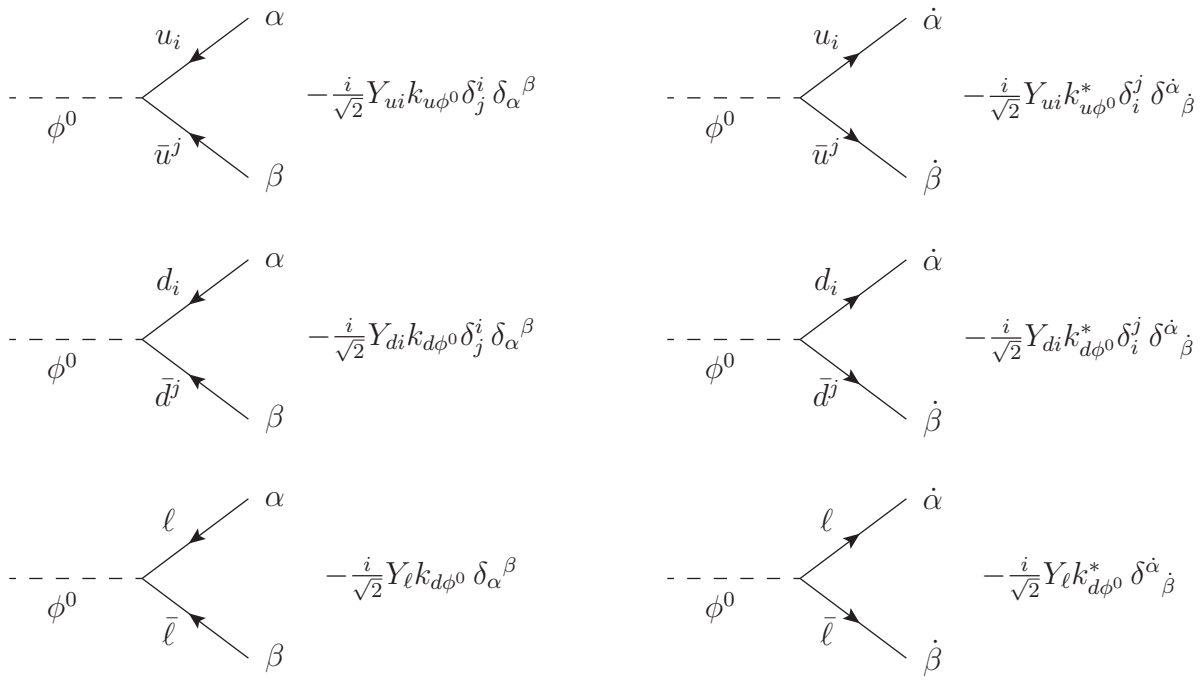

Figure K.1.1: Feynman rules for the interactions of neutral Higgs bosons $\phi^0 = (h^0, H^0, A^0, G^0)$ with fermion-antifermion pairs in the MSSM. The repeated index i is not summed.

The diagonalized Yukawa couplings are related to the corresponding fermion masses by

$$Y_{ui} = m_{u_i}/v_u\,, \qquad Y_{di} = m_{d_i}/v_d\,, \qquad Y_{\ell i} = m_{\ell_i}/v_d\,. \tag{K.1.19}$$

We have used the same symbol for the Yukawa couplings in the MSSM as we did for the Standard Model Yukawa couplings in Appendix J.1 . However, it is important to note that the MSSM Yukawa couplings are normalized differently because of the presence of two neutral Higgs field vacuum expectation values. Using a superscript SM to denote the Standard Model Yukawa couplings of Appendix J.1 , the MSSM Yukawa couplings defined here are related by:

$$Y_{ui} = Y^{\rm SM}_{ui}/\sin\beta\,, \qquad Y_{di} = Y^{\rm SM}_{di}/\cos\beta\,, \qquad Y_{\ell i} = Y^{\rm SM}_{\ell i}/\cos\beta\,. \tag{K.1.20}$$

The interactions of the neutral Higgs and Goldstone scalars $\phi^0 = (h^0, H^0, A^0, G^0)$ with Standard Model fermions are given in Fig. K.1.1. Note that the rules involving undotted spinor indices are proportional to either couplings $k_{d\phi^0}$ and $k_{u\phi^0}$, whereas the rules involving dotted spinor indices are proportional to the corresponding complex conjugated couplings. For the CP-even scalars, h^0 and H^0, the corresponding couplings are real. Hence, starting with the rule for the coupling of the CP-even neutral scalars to fermions with undotted indices, one obtains the corresponding rule for the coupling to fermions with dotted indices (with the direction of the arrows reversed) by taking $\delta_\alpha{}^\beta \to \delta^{\dot\alpha}{}_{\dot\beta}$. In contrast, for the CP-odd scalars, A^0 and G^0, the corresponding couplings $k_{d\phi^0}$ and $k_{u\phi^0}$ are purely imaginary. Therefore, starting with the rule for the coupling of the CP-odd neutral scalars to fermions with undotted indices, one obtains the corresponding rule for the coupling to fermions with dotted indices (with the direction of the arrows reversed) by taking $\delta_\alpha{}^\beta \to -\delta^{\dot\alpha}{}_{\dot\beta}$. The latter minus sign is a signal that A^0 and G^0 are CP-odd scalars. In particular, due to the fact that the Feynman rules for A^0 and G^0 arise from a term in $\mathscr{L}_{\rm int}$ proportional to i Im H^0, the latter i flips sign when the rule is conjugated resulting in the extra minus sign noted above. As an additional consequence, since the Feynman rules are obtained from $i\mathscr{L}_{\rm int}$, the overall A^0 and G^0 rules are real.

The couplings of the charged Higgs and Goldstone bosons to quark-antiquark pairs are not flavor-diagonal and involve the CKM matrix $\boldsymbol{K}$. Starting with eq. (K.1.14), and changing to the

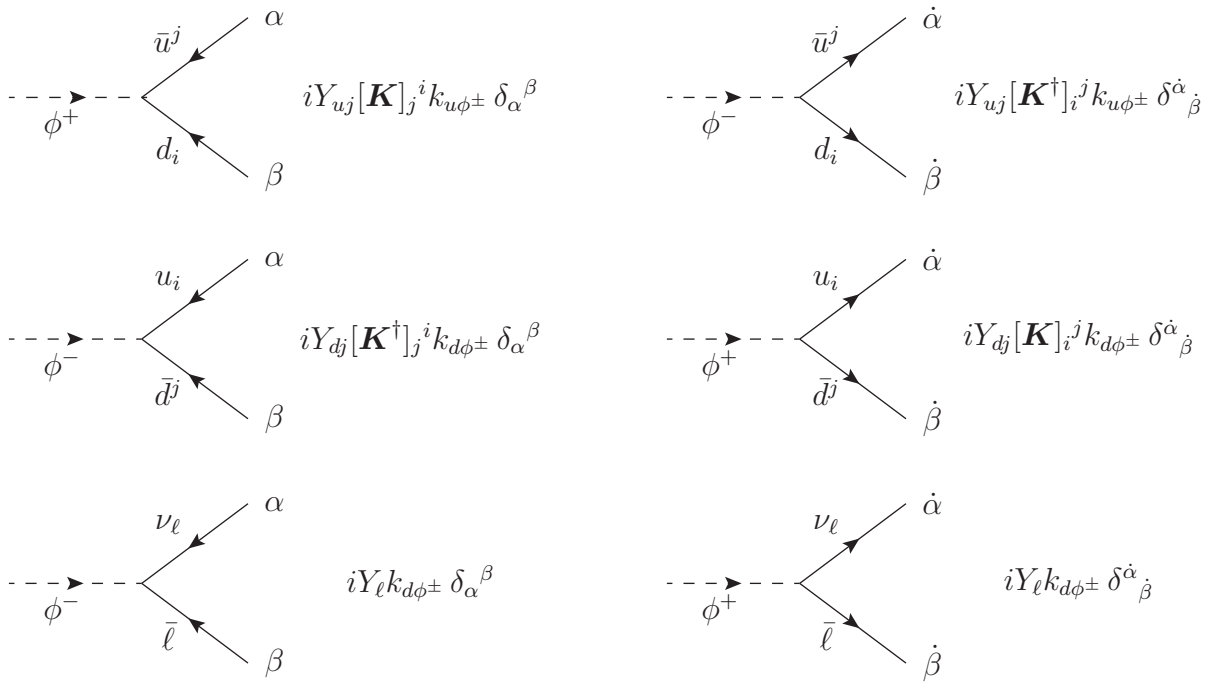

Figure K.1.2: Feynman rules for the interactions of charged Higgs bosons $\phi^\pm = (H^\pm, G^\pm)$ with fermion-antifermion pairs in the MSSM. The repeated index j is not summed.

mass eigenstate basis as before, we make use of eqs. (J.1.22) and (J.1.23) to obtain

$$\begin{aligned}\mathscr{L}_{\rm int} = {} & Y_{ui}[\boldsymbol{K}]_i{}^j d_j \bar{u}^i H^+ \cos\beta_\pm + Y_{di}[\boldsymbol{K}^\dagger]_i{}^j u_j \bar{d}^i H^- \sin\beta_\pm + Y_{\ell i}\nu_i \bar{\ell}^i H^- \sin\beta_\pm \\ & + Y_{ui}[\boldsymbol{K}]_i{}^j d_j \bar{u}^i G^+ \sin\beta_\pm - Y_{di}[\boldsymbol{K}^\dagger]_i{}^j u_j \bar{d}^i G^- \cos\beta_\pm - Y_{\ell i}\nu_i \bar{\ell}^i G^- \cos\beta_\pm + \text{h.c.}\end{aligned} \tag{K.1.21}$$

The resulting charged scalar Feynman rules of the MSSM are given in Fig. K.1.2. Note that when eq. (K.1.20) is taken into account, the fermion couplings to the neutral and charged Goldstone bosons are equivalent to those of the Standard Model [cf. eq. (J.1.24)] if we choose $\beta_0 = \beta_\pm = \beta$.

Gauge interaction vertices for neutralinos and charginos

Following eqs. (C83) and (C88) of [7], we define:

$$O^L_{ij} = -\tfrac{1}{\sqrt{2}} N_{i4} V^*_{j2} + N_{i2} V^*_{j1}\,, \tag{K.2.1}$$

$$O^R_{ij} = \tfrac{1}{\sqrt{2}} N^*_{i3} U_{j2} + N^*_{i2} U_{j1}\,, \tag{K.2.2}$$

$$O'^L_{ij} = -V_{i1} V^*_{j1} - \tfrac{1}{2} V_{i2} V^*_{j2} + \delta_{ij} s^2_W\,, \tag{K.2.3}$$

$$O'^R_{ij} = -U^*_{i1} U_{j1} - \tfrac{1}{2} U^*_{i2} U_{j2} + \delta_{ij} s^2_W\,, \tag{K.2.4}$$

$$O''^L_{ij} = -O''^R_{ji} = \tfrac{1}{2}(N_{i4} N^*_{j4} - N_{i3} N^*_{j3})\,, \tag{K.2.5}$$

where $s_W \equiv \sin\theta_W$. Here U and V are the unitary matrices that diagonalize the chargino mass matrix via the singular value decomposition:

$$U^* M_{\psi^\pm} V^{-1} = \text{diag}(m_{\widetilde{C}_1}, m_{\widetilde{C}_2})\,, \tag{K.2.6}$$

with

$$M_{\psi^\pm} = \begin{pmatrix} M_2 & g v_u \\ g v_d & \mu \end{pmatrix}\,. \tag{K.2.7}$$

Similarly, N is a unitary matrix that Takagi-diagonalizes the neutralino mass matrix,

$$N^* M_{\psi^0} N^{-1} = \mathrm{diag}(m_{\widetilde{N}_1}, m_{\widetilde{N}_2}, m_{\widetilde{N}_3}, m_{\widetilde{N}_4})\,, \tag{K.2.8}$$

with

$$M_{\psi^0} = \begin{pmatrix} M_1 & 0 & -g'v_d/\sqrt{2} & g'v_u/\sqrt{2} \\ 0 & M_2 & gv_d/\sqrt{2} & -gv_u/\sqrt{2} \\ -g'v_d/\sqrt{2} & gv_d/\sqrt{2} & 0 & -\mu \\ g'v_u/\sqrt{2} & -gv_u/\sqrt{2} & -\mu & 0 \end{pmatrix}. \tag{K.2.9}$$

As noted above eq. (K.1.2), we work in a convention in which v_u and v_d are real and positive. The gaugino mass parameters M_1, M_2 and the higgsino mass parameter μ are potentially complex.

We now list the gauge boson interactions with the neutralinos and charginos in the form of Feynman rules. Here, we make use of the results presented in Figs. 29.4.2–29.4.4. The Feynman rules for Z and γ interactions with charginos and neutralinos are given in Fig. K.2.1 and the corresponding rules for $W^\pm$ interactions are given in Fig. K.2.2. For each of these rules, one has a version with lowered spinor indices by replacing $\overline{\sigma}_\mu^{\dot\alpha\beta} \to -\sigma_{\mu\beta\dot\alpha}$. We label fermion lines with the symbols of the two-component fermion fields as given in Table 29.1. The $Z\widetilde{N}_i\widetilde{N}_j$ interaction vertex also subsumes the O''^R_{ij} interaction found in four-component Majorana Feynman rules as in ref. [7], due to the result of eq. (G.1.99) and the relation $O''^R_{ij} = -O''^L_{ji}$ of eq. (K.2.5).

The chargino sector is CP-conserving if $\mathrm{Im}\,(M_2\mu^*) = 0$. In this case, the chargino fields can be rephased such that M_2 and μ are real, and the chargino mixing matrices U and V can be chosen to be real orthogonal. In particular, the couplings O'^L and O'^R are manifestly real. Likewise, the

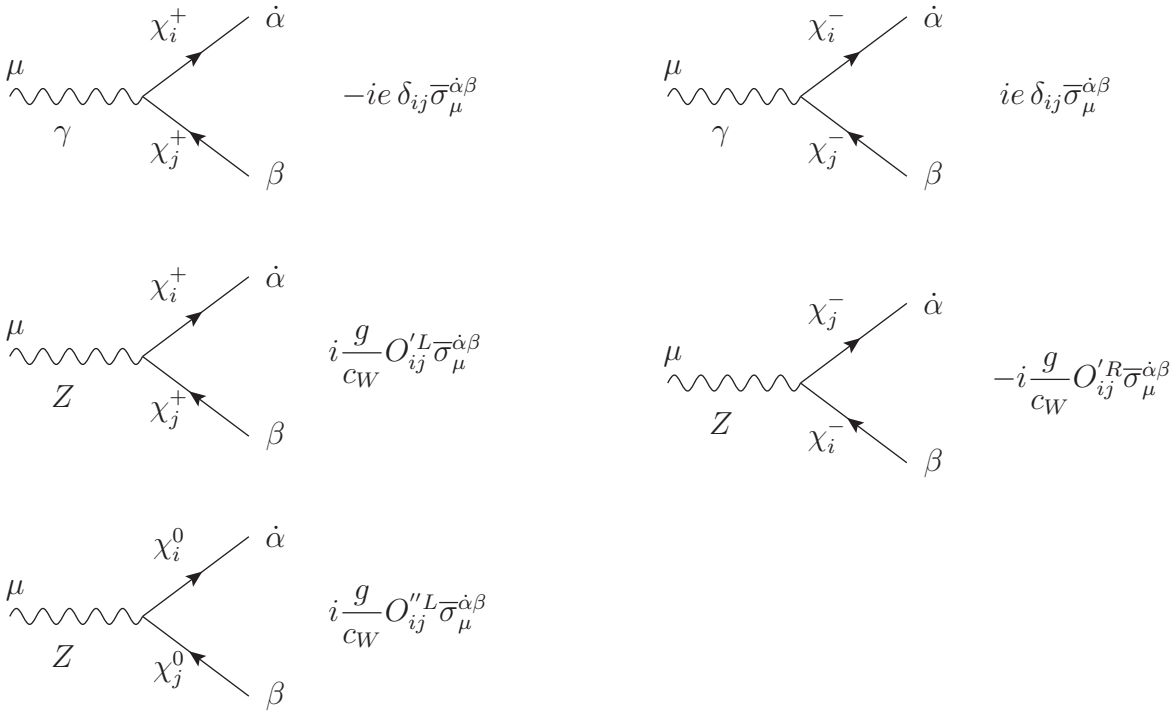

Figure K.2.1: Feynman rules for the chargino and neutralino interactions with neutral gauge bosons. The coupling matrices are defined in eqs. (K.2.3)–(K.2.5) and $c_W \equiv \cos\theta_W$. For each rule, a corresponding one with lowered spinor indices is obtained by $\overline{\sigma}_\mu^{\dot\alpha\beta} \to -\sigma_{\mu\beta\dot\alpha}$.

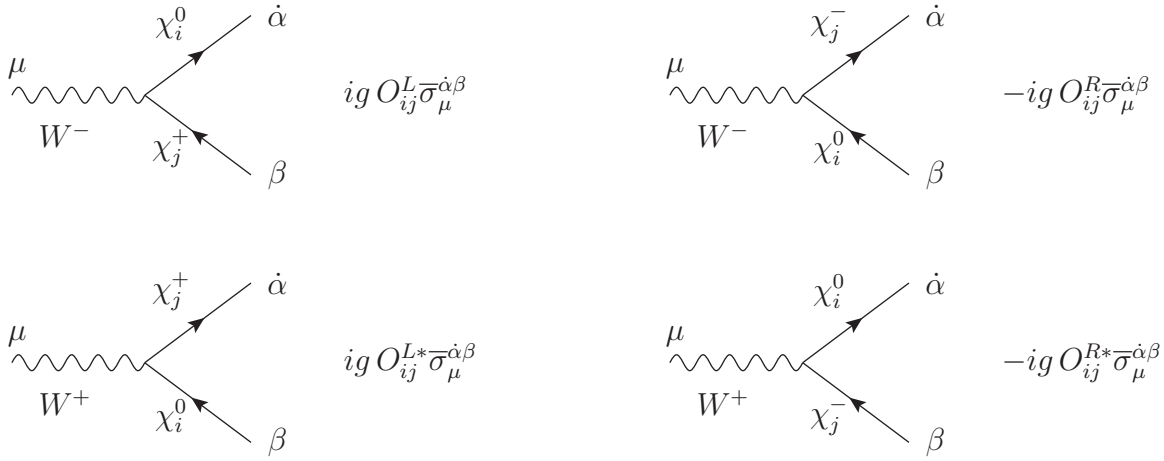

Figure K.2.2: Feynman rules for the chargino and neutralino interactions with $W^\pm$ gauge bosons. The charge indicated on the W boson is flowing into the vertex in each case. The coupling matrices are defined in eqs. (K.2.1) and (K.2.2). For each rule, a corresponding one with lowered spinor indices is obtained by $\overline\sigma_\mu^{\dot\alpha\beta} \to -\sigma_{\mu\beta\dot\alpha}$.

neutralino sector is CP-conserving if $\mathrm{Im}\,(M_1\mu^*) = \mathrm{Im}\,(M_2\mu^*) = \mathrm{Im}\,(M_1 M_2^*) = 0$.[179] In this case, the neutralino fields can be rephased such that M_1, M_2 and μ are all real, and the neutralino mixing matrix can be chosen [cf. eqs. (D.2.4) and (D.2.5)] such that [173]:

$$N_{ij} = \varepsilon_i^{1/2} Z_{ij}\,, \qquad \text{no sum over } i\,, \tag{K.2.10}$$

where Z is a real orthogonal matrix, and ε_i is the sign (either ± 1) of the ith eigenvalue of the real symmetric neutralino mass matrix, M_{ψ^0}. That is, the ith row of N is purely real [imaginary] if $\varepsilon_i = +1$ [-1]. In particular, the matrix element O''^L_{ij} is purely real [imaginary] if $\varepsilon_i\varepsilon_j = +1$ [-1]. More generally, the neutralino and chargino interactions with the electroweak gauge bosons are CP-conserving if the corresponding Feynman rules for the interaction vertices are either purely real or purely imaginary.

In the CP-violating case, the matrices U and V cannot be chosen to be real orthogonal, and N cannot be written in the form of eq. (K.2.10).[180] Nevertheless, the diagonal couplings O'^L_{ii}, O'^R_{ii} and O''^L_{ii} are manifestly real. This indicates that the diagonal $Z^0\widetilde C_i^+\widetilde C_i^-$ and $Z^0\widetilde N_i\widetilde N_i$ couplings are CP-conserving at tree level, even in the presence of a CP-violating chargino and neutralino sector. Similarly, the diagonal $\gamma\widetilde C_i^+\widetilde C_i^-$ couplings are CP-conserving, whereas the off-diagonal $\gamma\widetilde C_i^\pm\widetilde C_j^\mp$ couplings ($i \neq j$) vanish at tree level, as expected from gauge invariance.

Higgs interactions with charginos and neutralinos

The couplings of chargino and neutralino mass eigenstates to the Higgs mass eigenstates can be written, in terms of the Higgs mixing parameters of eqs. (K.1.7) and (K.1.8) and the neutralino

[179] If all three of the potentially complex parameters M_1, M_2 and μ are non-zero, then only two of the three conditions for a CP-conserving neutralino sector are independent, since the third condition follows automatically from the first two conditions.

[180] Since M_{ψ^0} is in general a *complex* symmetric matrix, its eigenvalues are not necessarily all real. In particular, if the ith eigenvalue is not real, then there is no longer any meaning to the sign ε_i.

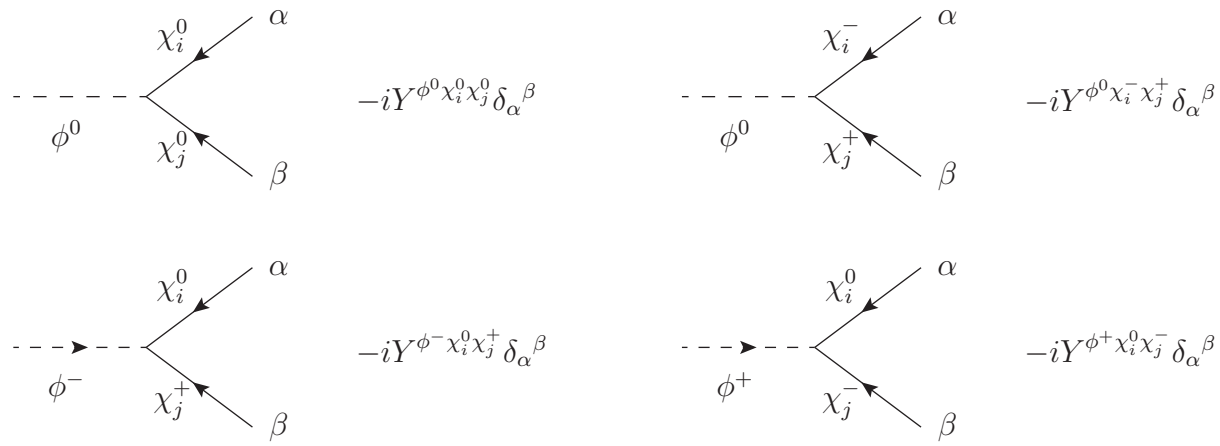

Figure K.3.1: Feynman rules for the interactions of neutral Higgs bosons $\phi^0 = (h^0, H^0, A^0, G^0)$ with neutralino pairs and chargino pairs, respectively, and the interaction of charged Higgs bosons $\phi^\pm = (H^\pm, G^\pm)$ with chargino-neutralino pairs. For each rule, there is a corresponding one with all arrows reversed, undotted indices changed to dotted indices with the opposite height, and the Y coupling (without the explicit $-i$) replaced by its complex conjugate.

and chargino mixing matrices of Appendix K.2 , as [173]:

$$Y^{\phi^0\chi_i^0\chi_j^0} = \frac{1}{2}(k^*_{d\phi^0}N^*_{i3} - k^*_{u\phi^0}N^*_{i4})(gN^*_{j2} - g'N^*_{j1}) + (i \leftrightarrow j)\,, \tag{K.3.1}$$

$$Y^{\phi^0\chi_i^-\chi_j^+} = \frac{g}{\sqrt{2}}(k^*_{u\phi^0}U^*_{i1}V^*_{j2} + k^*_{d\phi^0}U^*_{i2}V^*_{j1})\,, \tag{K.3.2}$$

$$Y^{\phi^+\chi_i^0\chi_j^-} = k_{d\phi^\pm}\big[g(N^*_{i3}U^*_{j1} - \frac{1}{\sqrt{2}}N^*_{i2}U^*_{j2}) - \frac{g'}{\sqrt{2}}N^*_{i1}U^*_{j2}\big]\,, \tag{K.3.3}$$

$$Y^{\phi^-\chi_i^0\chi_j^+} = k_{u\phi^\pm}\big[g(N^*_{i4}V^*_{j1} + \frac{1}{\sqrt{2}}N^*_{i2}V^*_{j2}) + \frac{g'}{\sqrt{2}}N^*_{i1}V^*_{j2}\big]\,, \tag{K.3.4}$$

for $\phi^0 = h^0, H^0, A^0, G^0$ and $\phi^\pm = H^\pm, G^\pm$. We exhibit the Higgs boson and Goldstone boson interactions with the neutralinos and charginos in Fig. K.3.1. For each of the Feynman rules in Fig. K.3.1, one can reverse all arrows by taking $\delta_\alpha{}^\beta \to \delta^{\dot\alpha}{}_{\dot\beta}$ and complex conjugating the corresponding coupling (but not the overall factor of $-i$).

Goldstone bosons may appear as internal lines in of Feynman graphs that are evaluated in the 't Hooft-Feynman gauge. The propagation of a Goldstone boson yields a result that is identical to the propagation of the corresponding longitudinal gauge boson in the unitary gauge. It is thus convenient to express the Goldstone boson couplings to the neutralinos and charginos in terms of the corresponding gauge boson couplings. To accomplish this, we first record a number of identities among the neutralino and chargino mixing matrices. First, we use eqs. (K.2.6) and (K.2.7) to derive:

$$M_2U^*_{i1} + gv_dU^*_{i2} = m_{\widetilde{C}_i}V_{i1}\,, \qquad gv_uU^*_{i1} + \mu U^*_{i2} = m_{\widetilde{C}_i}V_{i2}\,, \tag{K.3.5}$$

$$M_2V^*_{i1} + gv_uV^*_{i2} = m_{\widetilde{C}_i}U_{i1}\,, \qquad gv_dV^*_{i1} + \mu V^*_{i2} = m_{\widetilde{C}_i}U_{i2}\,. \tag{K.3.6}$$

Next, we use eqs. (K.2.8) and (K.2.9) to derive:

$$m_{\widetilde{N}_i} N_{i4} = \sum_{j=1}^{4} N_{ij}^* (M_{\psi^0})_{j4} = \frac{v_u}{\sqrt{2}} \left(g' N_{i1}^* - g N_{i2}^* \right) - \mu N_{i3}^* \,, \tag{K.3.7}$$

$$m_{\widetilde{N}_i} N_{i3} = \sum_{j=1}^{4} N_{ij}^* (M_{\psi^0})_{j3} = -\frac{v_d}{\sqrt{2}} \left(g' N_{i1}^* - g N_{i2}^* \right) - \mu N_{i4}^* \,, \tag{K.3.8}$$

$$m_{\widetilde{N}_i} N_{i2} = \sum_{j=1}^{4} N_{ij}^* (M_{\psi^0})_{j2} = N_{i2}^* M_2 + \frac{g}{\sqrt{2}} \left(v_d N_{i3}^* - v_u N_{i4}^* \right) \,. \tag{K.3.9}$$

By a judicious combination of the above identities, μ and M_2 can be eliminated. One can then rewrite the Goldstone boson couplings of eqs. (K.3.1)–(K.3.4) in terms of the gauge boson couplings $O^{L,R}$, $O'^{L,R}$ and $O''^{L,R}$ defined in eqs. (K.2.1)–(K.2.5). It then follows that:

$$iY^{G^0\chi_i^0\chi_j^0} = \frac{\sqrt{2}}{v} \left(m_{\widetilde{N}_i} O''^{L}_{ij} - m_{\widetilde{N}_j} O''^{R}_{ij} \right) \,, \tag{K.3.10}$$

$$iY^{G^0\chi_i^-\chi_j^+} = \frac{\sqrt{2}}{v} \left(m_{\widetilde{C}_i} O'^{L}_{ij} - m_{\widetilde{C}_j} O'^{R}_{ij} \right) \,, \tag{K.3.11}$$

$$Y^{G^+\chi_i^0\chi_j^-} = \frac{\sqrt{2}}{v} \left(m_{\widetilde{C}_j} O^{L\,*}_{ij} - m_{\widetilde{N}_i} O^{R\,*}_{ij} \right) \,, \tag{K.3.12}$$

$$Y^{G^-\chi_i^0\chi_j^+} = -\frac{\sqrt{2}}{v} \left(m_{\widetilde{N}_i} O^{L}_{ij} - m_{\widetilde{C}_j} O^{R}_{ij} \right) \,. \tag{K.3.13}$$

Note that by using $O''^{R}_{ij} = -O''^{L}_{ji}$, it follows from eq. (K.3.10) that $iY^{G^0\chi_i^0\chi_j^0}$ is symmetric under the interchange of i and j, as expected.

In general, for a CP-violating chargino and neutralino sector, the couplings $Y^{\phi^0\chi_i^0\chi_i^0}$ and $Y^{\phi^0\chi_i^+\chi_i^-}$ for $\phi^0 = h^0, H^0, A^0$ are neither purely real nor purely imaginary. That is, the diagonal neutralino and chargino couplings to the physical neutral Higgs bosons are generically CP-violating. However for $\phi^0 = G^0$, the diagonal neutralino and chargino couplings to the neutral Goldstone boson (when multiplied by i) are manifestly real. In particular, eqs. (K.3.10) and (K.3.11) yield:

$$iY^{G^0\chi_i^0\chi_i^0} = \frac{2\sqrt{2} m_{\widetilde{N}_i}}{v} O''^{L}_{ii} = \frac{\sqrt{2}\, m_{\widetilde{N}_i}}{v} \left[|N_{i4}|^2 - |N_{i3}|^2 \right] \,, \tag{K.3.14}$$

$$iY^{G^0\chi_i^-\chi_i^+} = \frac{\sqrt{2}\, m_{\widetilde{C}_i}}{v} (O'^{L}_{ii} - O'^{R}_{ii}) = \frac{m_{\widetilde{C}_i}}{\sqrt{2}\, v} \left[|V_{i2}|^2 - |U_{i2}|^2 \right] \,, \tag{K.3.15}$$

where the unitarity of U and V has been used to obtain the final expression in eq. (K.3.15). It follows that the diagonal neutralino and chargino couplings to the neutral Goldstone boson are CP-conserving. This result is not surprising, as the corresponding diagonal tree-level couplings of the (longitudinal) Z^0 boson are always CP-conserving as noted at the end of Appendix K.2 .

Chargino and neutralino interactions with fermions and sfermions

In the MSSM, the scalar partners of the two-component fields q and $\bar{q}^\dagger$ are the squarks, denoted by $\widetilde{q}_L$ and $\widetilde{q}_R$, respectively. In our notation, $\widetilde{q}_L^*$ and $\widetilde{q}_R^*$ denote both the complex conjugate fields and the names of the corresponding anti-squarks. Thus u, $\widetilde{u}_L$ and $\widetilde{u}_R$ all have electric charges $+2/3$, whereas $\bar{u}$, $\widetilde{u}_L^*$ and $\widetilde{u}_R^*$ all have electric charges $-2/3$. Likewise, the scalar partners of the two-component fields ℓ and $\bar{\ell}^\dagger$ are the charged sleptons, denoted by $\widetilde{\ell}_L$ and $\widetilde{\ell}_R$, respectively, with

$\ell = e, \mu, \tau$. The sneutrino, $\widetilde{\nu}$ is the superpartner of the neutrino. There is no $\widetilde{\nu}_R$, since there is no $\bar{\nu}$ in the theory.[181]

The Feynman rules for the chargino-quark-squark interactions are given in Fig. K.4.1, and the rules for the neutralino-quark-squark interactions are given in Fig. K.4.2. Here we have taken the quark and lepton two-component fields to be in a mass eigenstate basis, and the squark and slepton field basis consists of the superpartners of these fields, as described above. Therefore, in practical applications, one must include unitary rotation matrix elements relating the squarks and sleptons as given to the mass eigenstates, which can be different.

In principle, all sfermions with a given electric charge can mix with each other. However, there is a popular, and perhaps phenomenologically and theoretically favored, approximation in which only the sfermions of the third family have significant mixing. For $f = t, b, \tau$, one can then write the relationship between the gauge eigenstates $\tilde{f}_L$, $\tilde{f}_R$ and the mass eigenstates $\tilde{f}_1$, $\tilde{f}_2$ as [352]

$$\begin{pmatrix} \tilde{f}_R \\ \tilde{f}_L \end{pmatrix} = X_{\tilde{f}} \begin{pmatrix} \tilde{f}_1 \\ \tilde{f}_2 \end{pmatrix}, \qquad X_{\tilde{f}} \equiv \begin{pmatrix} R_{\tilde{f}_1} & R_{\tilde{f}_2} \\ L_{\tilde{f}_1} & L_{\tilde{f}_2} \end{pmatrix}, \tag{K.4.1}$$

where X is a 2×2 unitary matrix. Then one can choose $R_{\tilde{f}_1} = L^*_{\tilde{f}_2} = c_{\tilde{f}}$, and $L_{\tilde{f}_1} = -R^*_{\tilde{f}_2} = s_{\tilde{f}}$ with

$$|c_{\tilde{f}}|^2 + |s_{\tilde{f}}|^2 = 1. \tag{K.4.2}$$

If there is no CP violation, then $c_{\tilde{f}}$ and $s_{\tilde{f}}$ can be taken real, and they are the cosine and sine of a sfermion mixing angle.[182] For the other charged sfermions ($\widetilde{f} = \widetilde{u}, \widetilde{d}, \widetilde{c}, \widetilde{s}, \widetilde{e}, \widetilde{\mu}$), one can use the same notation, and approximate $L_{\tilde{f}_2} = R_{\tilde{f}_1} = 1$ and $L_{\tilde{f}_1} = R_{\tilde{f}_2} = 0$. The resulting Feynman rules for squarks and sleptons that mix within each generation are shown in Figs. K.4.3 and K.4.4.

For each Feynman rule in Figs. K.4.1–K.4.4, one can reverse all arrows by taking $\delta_\alpha{}^\beta \to \delta^{\dot{\alpha}}{}_{\dot{\beta}}$ and complex conjugating the corresponding rule (but leaving the explicit factor of i intact).

SUSY-QCD Feynman rules

In supersymmetric (SUSY) QCD, the Lagrangian governing the gluon interactions with colored fermions (gluinos and quarks) in two-component spinor notation, which derives from the covariant derivatives in the kinetic terms, is given by

$$\mathscr{L}_{\rm int} \;=\; i g_s f^{abd} (\tilde{g}^\dagger_a \overline{\sigma}_\mu \tilde{g}_b) A^\mu_d - g_s T^{ak}_j \sum_q \left[q^{\dagger j} \overline{\sigma}_\mu q_k - \bar{q}^\dagger_k \overline{\sigma}_\mu \bar{q}^j \right] A^\mu_a \,. \tag{K.5.1}$$

Here g_s is the strong coupling constant, $a, b, d = 1, 2, ..., 8$ are $SU(3)_c$ adjoint representation indices, and f^{abd} are the $SU(3)$ structure constants. Raised (lowered) indices $j, k = 1, 2, 3$ are color indices in the fundamental (anti-fundamental) representation. We have denoted the two-component gluino field by $\widetilde{g}_a$ as in Table 29.1 and the gluon field by A^μ_a. The sum $\sum_q$ is over the six flavors $q = u, d, s, c, b, t$ (in either the mass eigenstate or electroweak gauge-eigenstate basis). The corresponding Feynman rules are shown in Fig. K.5.1. The gluino-squark-quark Lagrangian is given by:

$$\mathscr{L}_{\rm int} = -\sqrt{2} g_s T^{ak}_j \sum_q \left[\tilde{g}_a q_k \, \tilde{q}^{*j}_L + \tilde{g}^\dagger_a q^{\dagger j} \, \tilde{q}_{Lk} - \tilde{g}_a \bar{q}^j \, \tilde{q}_{Rk} - \tilde{g}^\dagger_a \bar{q}^\dagger_k \, \tilde{q}^{*j}_R \right], \tag{K.5.2}$$

[181] It is possible to construct a seesaw-extended MSSM that would be the minimal supersymmetric extension of the seesaw-extended Standard Model described in Appendix J.2 . In the seesaw-extended MSSM, both $\bar{\nu}$ and its supersymmetric partner $\widetilde{\nu}_R$ exist. For further details on the sneutrino sector of the seesaw-extended MSSM, see [301].

[182] Our convention for $c_{\tilde{f}}, s_{\tilde{f}}$ has the property that for zero mixing angle, $\widetilde{f}_1 = \widetilde{f}_R$ and $\widetilde{f}_2 = \widetilde{f}_L$. The conventions most commonly found in the literature unfortunately do not have this nice property.

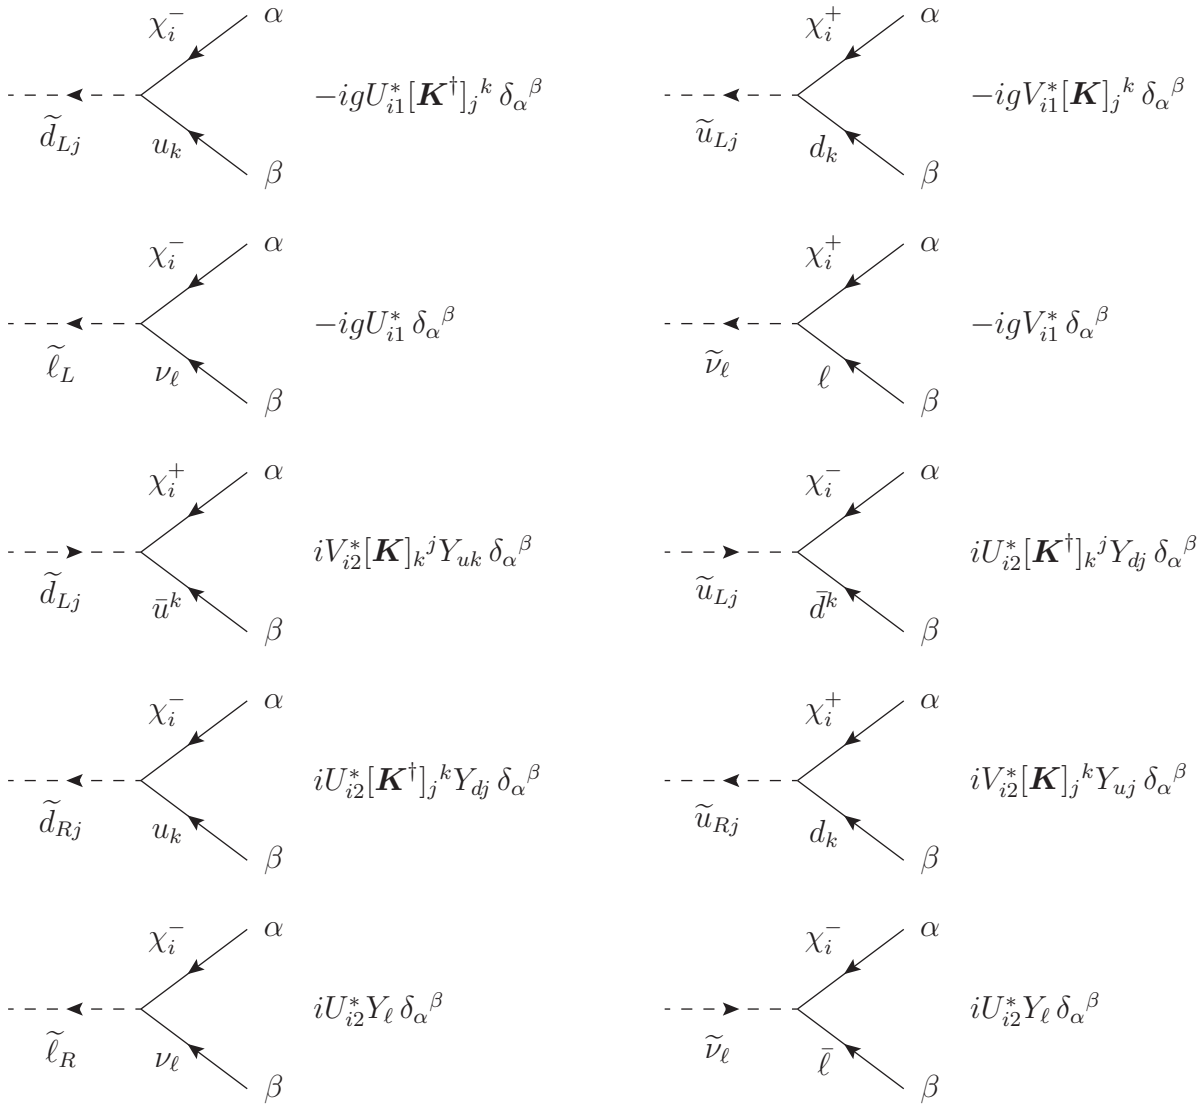

Figure K.4.1: Feynman rules for the interactions of charginos with fermion/sfermion pairs in the MSSM. The fermions are taken to be in a mass eigenstate basis, and the sfermions are in a basis whose elements are the supersymmetric partners of them. For each rule, there is a corresponding one with all arrows reversed, undotted indices changed to dotted indices with the opposite height, and the coupling (without the explicit i) replaced by its complex conjugate. Note that chargino interaction vertices involving $\bar{u}\widetilde{d}_R$ and $\bar{d}\widetilde{u}_R$ do not occur in the MSSM. An alternative version of these rules, for the case that mixing is allowed only among third-family sfermions, is given in Fig. K.4.3.

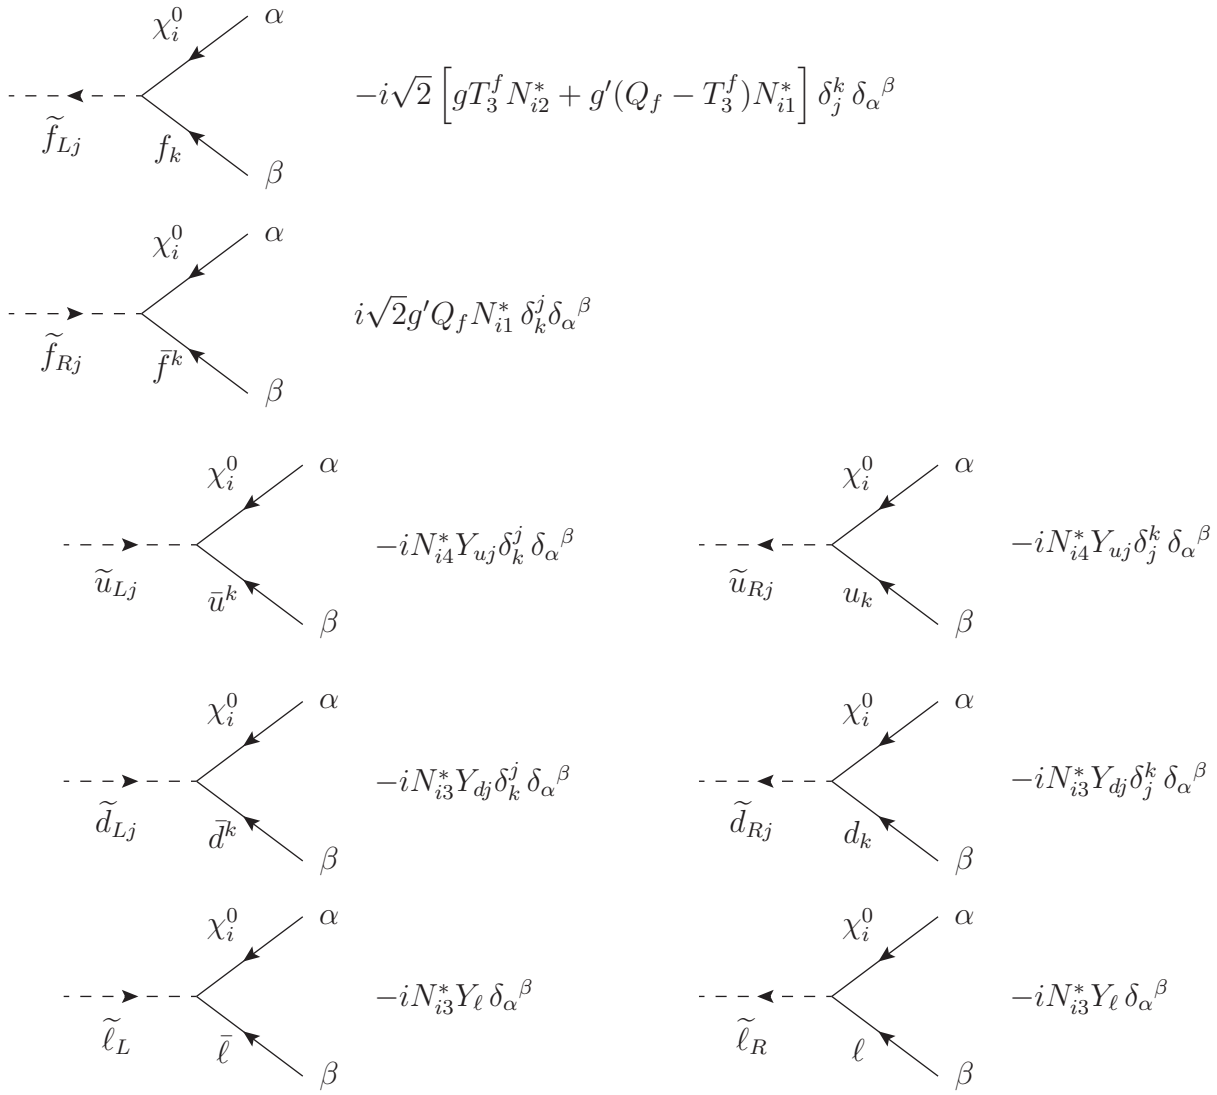

Figure K.4.2: Feynman rules for the interactions of neutralinos with fermion/sfermion pairs in the MSSM. The fermions are taken to be in a mass eigenstate basis, and the sfermions are in a basis whose elements are the supersymmetric partners of them. For each rule, there is a corresponding one with all arrows reversed, undotted indices changed to dotted indices with the opposite height, and the coupling (without the explicit i) replaced by its complex conjugate. An alternative version of these rules, for the case that mixing is allowed only among third-family sfermions, is given in Fig. K.4.4.

where the squark fields are taken to be in the same basis as the quarks. The Feynman rules resulting from these Lagrangian terms are shown in Fig. K.5.2.

For practical applications, one typically takes the quark fields as the familiar mass eigenstates, and then performs a unitary rotation on the squarks in the corresponding basis to obtain their mass eigenstate basis. In the approximation described at the end of Appendix K.4 [cf eqs. (K.4.1) and (K.4.2) and the accompanying text], one obtains the Feynman rules of Fig. K.5.3, as an alternative to those of Fig. K.5.2.

29.7.15 Trilinear R-parity-violating Yukawa interactions

In the MSSM, a multiplicative R-parity invariance is imposed, where $R = (-1)^{3(B-L)+2S}$ for a particle of baryon number B, lepton number L and spin S[353]. Equivalently, R-parity can be

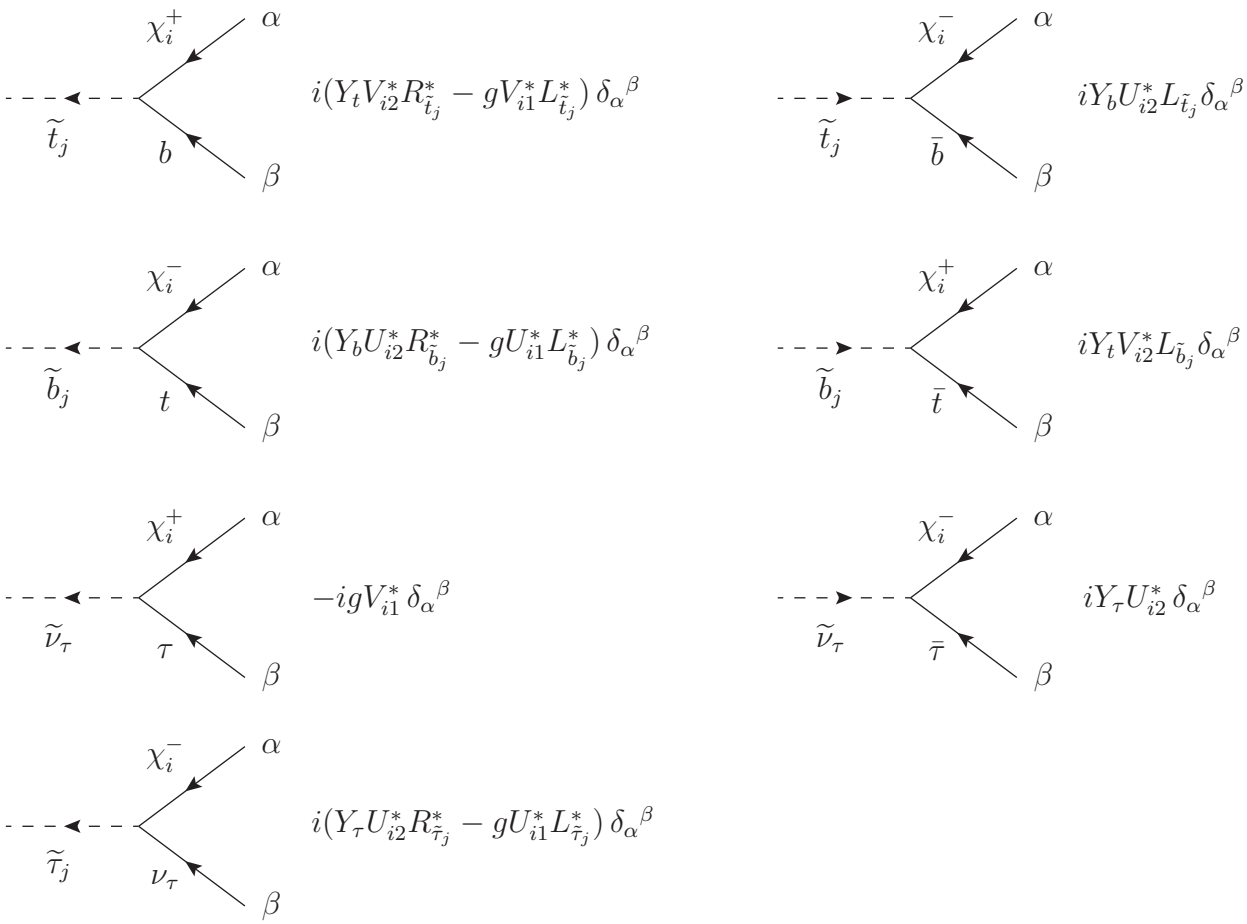

Figure K.4.3: Feynman rules for the interactions of charginos with third-family fermion/sfermion pairs in the MSSM. The fermions are taken to be in a mass eigenstate basis. CKM mixing is neglected, and the sfermions are assumed to only mix within the third family. The corresponding rules for the first and second families with the approximation of no mixing and vanishing fermion masses can be obtained from these by setting $Y_f = 0$ and $L_{\tilde{f}_2} = R_{\tilde{f}_1} = 1$ and $L_{\tilde{f}_1} = R_{\tilde{f}_2} = 0$ (so that $\widetilde{f}_1 = \widetilde{f}_R$ and $\widetilde{f}_2 = \widetilde{f}_L$). For each rule, there is a corresponding one with all arrows reversed, undotted indices changed to dotted indices with the opposite height, and the coupling (without the explicit i) replaced by its complex conjugate.

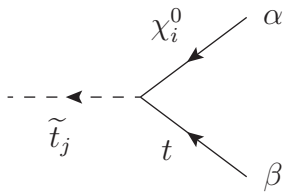
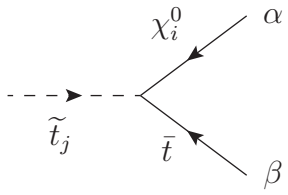
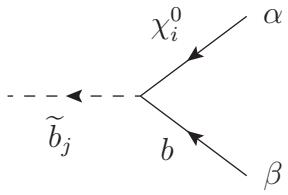


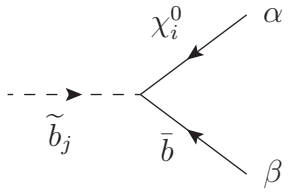
$$-i\left[Y_t N^*_{i4} R^*_{\tilde{t}_j} + \tfrac{1}{\sqrt{2}}(gN^*_{i2} + \tfrac{1}{3}g'N^*_{i1})L^*_{\tilde{t}_j}\right]\delta_\alpha{}^\beta$$



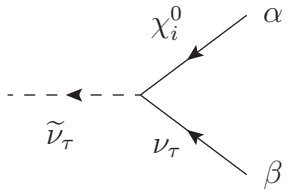
$$-i\left[Y_t N^*_{i4} L_{\tilde{t}_j} - \tfrac{2\sqrt{2}}{3}g'N^*_{i1}R_{\tilde{t}_j}\right]\delta_\alpha{}^\beta$$



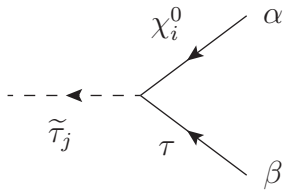
$$-i\left[Y_b N^*_{i3} R^*_{\tilde{b}_j} + \tfrac{1}{\sqrt{2}}(-gN^*_{i2} + \tfrac{1}{3}g'N^*_{i1})L^*_{\tilde{b}_j}\right]\delta_\alpha{}^\beta$$



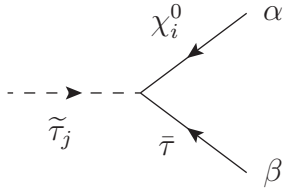
$$-i\left[Y_b N^*_{i3} L_{\tilde{b}_j} + \tfrac{\sqrt{2}}{3}g'N^*_{i1}R_{\tilde{b}_j}\right]\delta_\alpha{}^\beta$$



$$-\tfrac{i}{\sqrt{2}}(gN^*_{i2} - g'N^*_{i1})\,\delta_\alpha{}^\beta$$



$$-i\left[Y_\tau N^*_{i3} R^*_{\tilde{\tau}_j} - \tfrac{1}{\sqrt{2}}(gN^*_{i2} + g'N^*_{i1})L^*_{\tilde{\tau}_j}\right]\delta_\alpha{}^\beta$$



$$-i\left[Y_\tau N^*_{i3} L_{\tilde{\tau}_j} + \sqrt{2}g'N^*_{i1}R_{\tilde{\tau}_j}\right]\delta_\alpha{}^\beta$$

Figure K.4.4: Feynman rules for the interactions of neutralinos with third-family fermion/s-fermion pairs in the MSSM. The comments of the caption of Fig. K.4.3 also apply here.

defined to be an additive quantum number modulo 2, where $R = +1$ corresponds to an even R-parity and $R = -1$ corresponds to an odd R-parity. In particular, all the ordinary Standard Model particles are R parity even, whereas the corresponding supersymmetric partners are R parity odd. In the R-parity-violating extension of the MSSM (denoted below as RPV-MSSM), new interactions are allowed that violate R-parity. Such interactions necessarily violate the $B - L$ global symmetry. R-parity-violating interactions can significantly alter the phenomenology at colliders (see for example [208, 211]), especially as the lightest supersymmetric particle (LSP) is no longer stable [354, 212]. Moreover, the LSP need not be restricted to the lightest neutralino (or perhaps the sneutrino) as in the MSSM, but can be any supersymmetric particle [207].

In this appendix, we focus on new trilinear supersymmetric Yukawa interactions that can appear in an RPV-MSSM [355, 354, 356, 357]:

$$\mathscr{L}_{LL\bar{e}} = -\tfrac{1}{2}\lambda_{ijk}\left(\widetilde{\ell}^*_{Rk}\nu_i\ell_j + \widetilde{\nu}_i\ell_j\bar{\ell}_k + \widetilde{\ell}_{Lj}\bar{\ell}_k\nu_i - \widetilde{\ell}^*_{Rk}\ell_i\nu_j - \widetilde{\nu}_j\bar{\ell}_k\ell_i - \widetilde{\ell}_{Li}\nu_j\bar{\ell}_k\right) + \text{h.c.}\,, \tag{L.1}$$

$$\mathscr{L}_{LQ\bar{d}} = -\lambda'_{ijk}\left(\widetilde{d}^*_{Rk}\nu_i d_j + \widetilde{\nu}_i d_j\bar{d}_k + \widetilde{d}_{Lj}\bar{d}_k\nu_i - \widetilde{d}^*_{Rk}\ell_i u_j - \widetilde{u}_{Lj}\bar{d}_k\ell_i - \widetilde{\ell}_{Li}u_j\bar{d}_k\right) + \text{h.c.}\,, \tag{L.2}$$

$$\mathscr{L}_{\bar{u}\bar{d}\bar{d}} = -\tfrac{1}{2}\lambda''_{ijk}\epsilon_{pqr}\left[\widetilde{u}^{p*}_{Ri}\bar{d}^q_j\bar{d}^r_k + \widetilde{d}^{q*}_{Rj}\bar{u}^p_i\bar{d}^r_k + \widetilde{d}^{r*}_{Rk}\bar{u}^p_i\bar{d}^q_j\right] + \text{h.c.}\,, \tag{L.3}$$

where repeated indices are summed over.[183] In eqs. (L.1)–(L.3), λ_{ijk}, λ'_{ijk}, λ''_{ijk} are dimensionless coupling constants, i, j, k are generation indices, and $p, q, r = 1, 2, 3$ are color $SU(3)$ indices, respectively. The couplings proportional to λ and λ' violate L and conserve B, whereas the couplings proportional to λ'' violate B and conserve L. Various phenomenological constraints on these couplings are summarized in refs. [357].

In addition to λ_{ijk}, λ'_{ijk}, λ''_{ijk}, the Lagrangian of the RPV-MSSM contains one additional supersymmetric L-violating mass parameter, κ_i, which leads to slepton–Higgs mixing and lepton–higgsino mixing. Finally, supersymmetry-breaking R-parity-violating parameters would also contribute to slepton–Higgs mixing and yields new trilinear scalar interactions. These effects modify the Feynman rules of Appendix K through additional mixing matrices, which we do not include here (for further details, see e.g. ref. [202]).

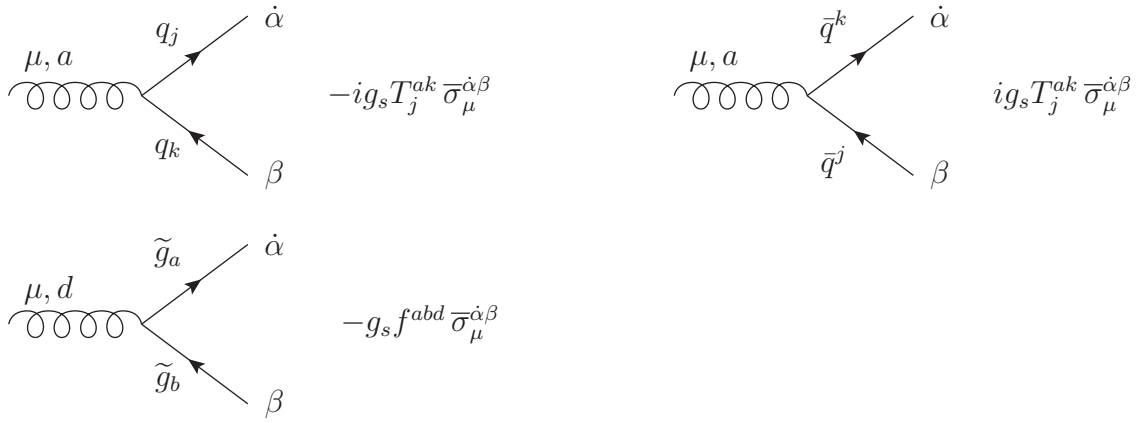


Figure K.5.1: Fermionic Feynman rules for SUSY-QCD that involve the gluon, with $q = u, d, c, s, t, b$. Lowered (raised) indices j, k correspond to the fundamental (anti-fundamental) representation of $SU(3)_c$. For each rule, a corresponding one with lowered spinor indices is obtained by $\overline{\sigma}^{\dot{\alpha}\beta}_\mu \to -\sigma_{\mu\beta\dot{\alpha}}$.

[183] The extra factors of $\frac{1}{2}$ in eqs. (L.1) and (L.3) have been chosen for convenience, due to the antisymmetry properties of the corresponding couplings: $\lambda_{ijk} = -\lambda_{jik}$, $\lambda''_{ijk} = -\lambda''_{ikj}$.

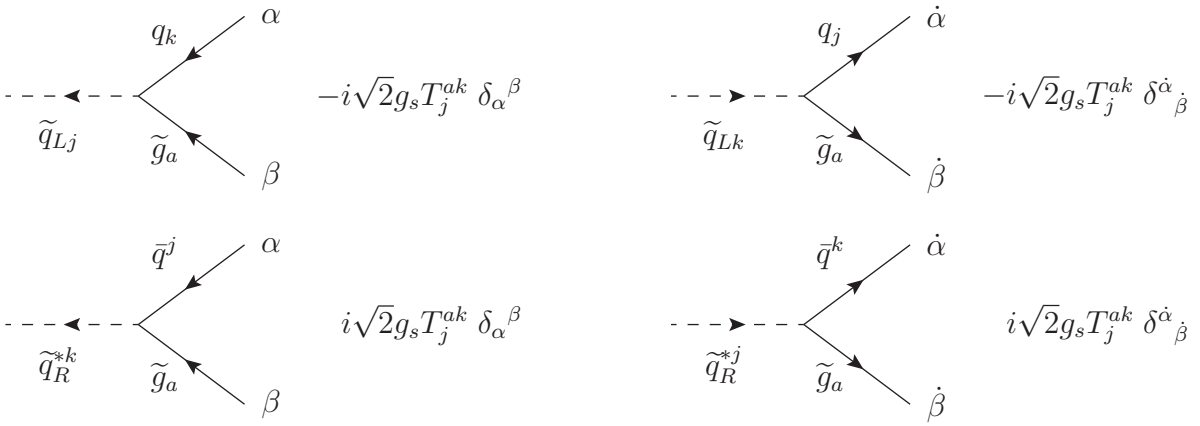

Figure K.5.2: Fermionic Feynman rules for SUSY-QCD that involve the squarks, in a basis corresponding to the quark mass eigenstates $q = u, d, c, s, t, b$. Lowered (raised) indices j, k correspond to the fundamental (anti-fundamental) representation of $SU(3)_c$, and the index a labels the adjoint representation carried by the gluino. The spinor index heights can be exchanged in each case, by replacing $\delta_\alpha{}^\beta \to \delta_\beta{}^\alpha$ or $\delta^{\dot\alpha}{}_{\dot\beta} \to \delta^{\dot\beta}{}_{\dot\alpha}$. For an alternative set of rules, incorporating $\widetilde{q}_L$–$\widetilde{q}_R$ mixing, see Fig. K.5.3.

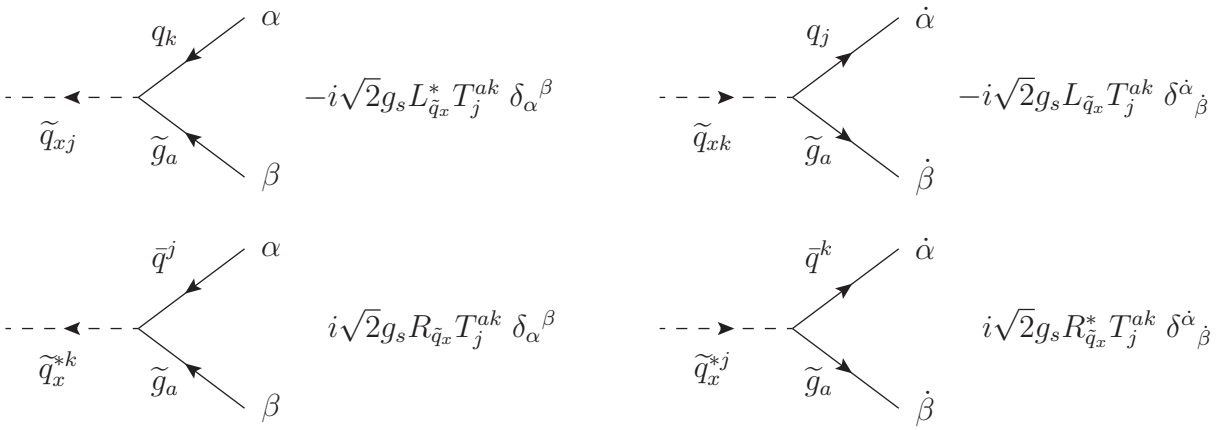

Figure K.5.3: Fermionic Feynman rules for SUSY-QCD that involve the squarks in the mass eigenstate basis labeled by $x = 1, 2$ and $q = u, d, c, s, t, b$, in the approximation where mixing is allowed only within a given flavor (typically, for the third family only), as in eq. (K.4.1). Lowered (raised) indices j, k correspond to the fundamental (anti-fundamental) representation of $SU(3)_c$, and the index a labels the adjoint representation carried by the gluino. The spinor index heights can be exchanged in each case, by replacing $\delta_\alpha{}^\beta \to \delta_\beta{}^\alpha$ or $\delta^{\dot\alpha}{}_{\dot\beta} \to \delta^{\dot\beta}{}_{\dot\alpha}$.

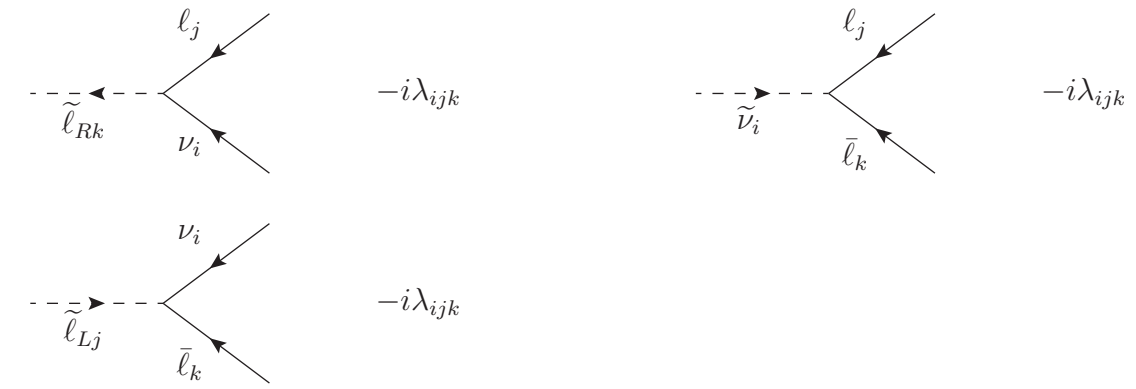

Figure L.1: Feynman rules for the Yukawa couplings of two-component fermions due to the supersymmetric, R-parity-violating Yukawa Lagrangian $\mathscr{L}_{LL\bar{e}}$ [cf. eq. (L.1)]. For each diagram, there is another with all arrows reversed and $\lambda_{ijk} \to \lambda^*_{ijk}$.

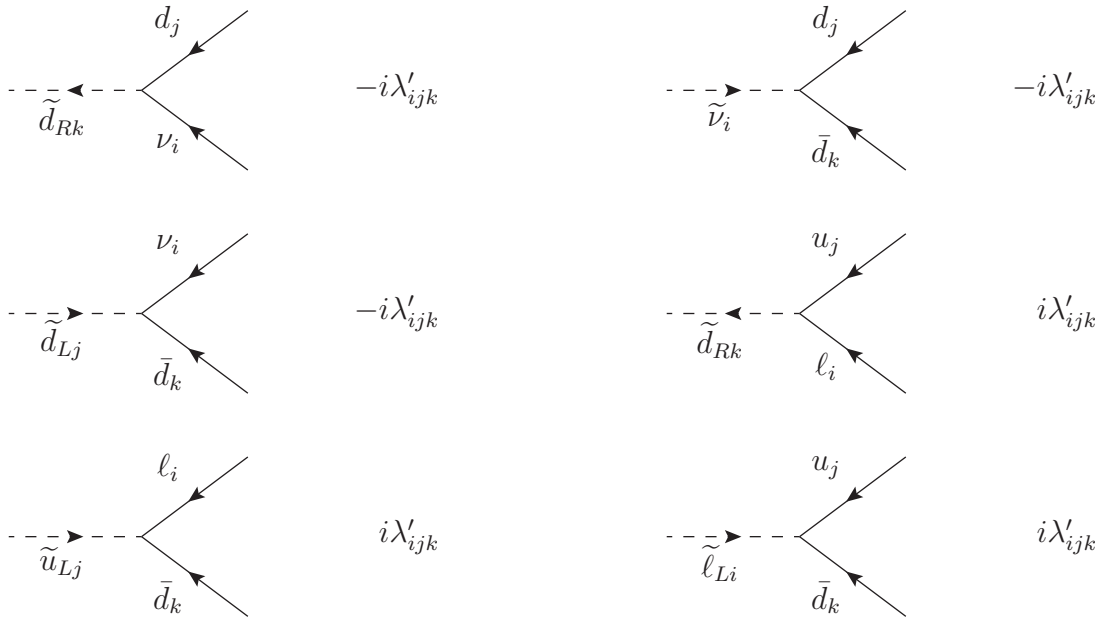

Figure L.2: Feynman rules for the Yukawa couplings of two-component fermions for the supersymmetric, R-parity-violating Yukawa Lagrangian $\mathscr{L}_{LQ\bar{d}}$ [cf. eq. (L.2)]. For each diagram, there is another with all arrows reversed and $\lambda'_{ijk} \to \lambda'^*_{ijk}$.

Recently, the two-component fermion Feynman rules for the neutral fermions have been given in refs. [358, 283]. Using eq. (29.4.2) and Fig. 29.4.1 we can now directly determine the corresponding Feynman rules. These are given in Figs. L.1, L.2, and L.3. The same Lagrangian for the Yukawa interactions is given in terms of four-component fermions in refs. [209, 210]. Two sample computations that make use of these rules are presented in Sections 29.6.20 and 29.6.21.

Figure L.3: Feynman rules for the Yukawa couplings of two-component fermions due to the supersymmetric, R-parity-violating Yukawa Lagrangian $\mathscr{L}_{\bar{u}\bar{d}\bar{d}}$ [cf. eq. (L.3)]. For each diagram, there is another with all arrows reversed and $\lambda''_{ijk} \to \lambda''^*_{ijk}$.

30.1 Zi.IV Symmetry and Symmetry Breaking

30.1.1 Zi.IV.1 Symmetry Breaking

Как скучен был бы симметричный мир

Нам бы хотелось, чтобы фундаментальные законы природы были симметричными, хотя сами не представляем, насколько скучным был бы симметричный мир. На самом деле реальный мир не совсем симметричен. Точнее, хорошо было бы, если бы симметричным был лагранжиан, а не мир, описываемый лагранжианом. Главной целью современной физики действительно является изучение того, как могут нарушиться свойства симметрии лагранжиана. В следующих главах мы увидим, что наши знания фундаментальных законов физики основаны на понимании процессов нарушения симметрии.

Рассмотрим лагранжиан, который мы изучали в главе I.9:

$$\mathcal{L} = \frac{1}{2}\left[(\partial\vec{\varphi})^2 - \mu^2\vec{\varphi}^2\right] - \frac{\lambda}{4}\left(\vec{\varphi}^2\right)^2,$$

где $\vec{\varphi} = (\varphi_1, \varphi_2, ..., \varphi_N)$. Этот лагранжиан обладает $O(N)$-симметрией, при которой $\vec{\varphi}$ преобразуется как N-компонентный вектор.

Мы можем легко добавить в лагранжиан члены, не обладающие свойством симметрии. Например, добавим члены φ_1^2, φ_1^4 и $\varphi_1^2\vec{\varphi}^2$ и нарушим $O(N)$-симметрию до $O(N-1)$, при которой $\varphi_2, ..., \varphi_N$ преобразуются как $N-1$-компонентный вектор. Такой способ нарушения симметрии («руками») называется явным нарушением.

Можно нарушать симметрию поэтапно. Очевидно, что по желанию мы можем нарушить ее до $O(N-M)$ для любого $M < N$.

Обратите внимание, что в этом примере добавление новых членов не нарушает симметрию относительно отражений $\varphi_a \to -\varphi_a$ (при любом a). Этот вид симметрии также легко нарушить, если добавить, например, член φ_a^3.

Явное нарушение симметрии не представляет никакого интереса. С тем же успехом мы могли бы начать наши рассуждения со случая несимметричного лагранжиана.

Спонтанное нарушение симметрии

Гораздо интереснее позволить системе «самой нарушить симметрию», т. е. дождаться так называемого спонтанного нарушения симметрии. Поясню на примере. Изменим знак члена $\vec{\varphi}^2$ в лагранжиане (1) на противоположный и запишем:

$$\mathcal{L} = \frac{1}{2}\left[(\partial\vec{\varphi})^2 + \mu^2\vec{\varphi}^2\right] - \frac{\lambda}{4}\left(\vec{\varphi}^2\right)^2$$

Наивно для малых λ поле φ создает частицу массой $\sqrt{-\mu^2} = i\mu$. Что-то, очевидно, не так.

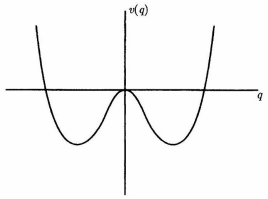

Рис. IV.1.1

Физический смысл этого наблюдения аналогичен тому, что произошло бы, если бы мы записали коэффициент пружины для ангармонического осциллятора с неверным знаком, т. е. $L = \frac{1}{2}\left(\dot{q}^2 + kq^2\right) - (\lambda/4)q^4$. Все знают, что делать в этом случае в классической механике. Потенциальная энергия $V(q) = -\frac{1}{2}kq^2 + (\lambda/4)q^4$ [известная как двухъямный потенциал (рис. IV.1.1)] имеет два минимума при $q = \pm v$, где $v \equiv (k/\lambda)^{\frac{1}{2}}$. При низких энергиях мы выбираем любой из двух минимумов и анализируем малые колебания относительно этого минимума. Привязка к одному или другому минимуму нарушает симметрию относительно отражений $q \to -q$ системы.

В квантовой механике, однако, частица может проникать сквозь потенциальный барьер между двумя минимумами; высота барьера равна $V(0)$ - $-V(\pm v)$. Вероятность нахождения в каждом из двух минимумов должна быть равной, т. е. симметрия гамильтониана $q \to -q$ гамильтониана сохраняется. В частности, волновая функция основного состояния $\psi(q) = \psi(-q)$ является четной.

Попробуем применить подобные рассуждения для квантовой теории поля. Найдем для лагранжиана собственного скалярного поля $\mathcal{L} = \frac{1}{2}\left(\partial_0\varphi\right)^2 - \frac{1}{2}\left(\partial_i\varphi\right)^2 - V(\varphi)$ минимальное значение потенциальной энергии $\int d^D x \left[\frac{1}{2}\left(\partial_i\varphi\right)^2 + V(\varphi)\right]$, где D - размерность пространства. Ясно, что любое пространственное изменение φ лишь увеличит энергию, поэтому считаем $\varphi(x)$ независимой от пространства-времени величиной φ и ищем минимум $V(\varphi)$. В частности, для лагранжиана (2) имеем:

$$V(\varphi) = -\frac{1}{2}\mu^2\vec{\varphi}^2 + \frac{\lambda}{4}\left(\vec{\varphi}^2\right)^2$$

Далее мы увидим, что случаи $N = 1$ и $N \geqslant 2$ существенно отличаются друг от друга.

Отличия между квантовой механикой и квантовой теорией поля

Рассмотрим сначала случай $N = 1$. Потенциал $V(\varphi)$ аналогичен потенциалу на рис. IV.1.1, за исключением того, что горизонтальная ось теперь обозначена параметром φ. Существуют два минимума при $\varphi = \pm v = \pm\left(\mu^2/\lambda\right)^{\frac{1}{2}}$

Некоторые моменты, однако, существенно отличаются между собой для квантовой теории поля и квантовой механики. Туннельный барьер теперь равен $[V(0) - V(\pm v)] \int d^D x$($D$ - размерность пространства) и, следовательно, бесконечен (или, точнее говоря, пропорционален размеру системы)! Туннельный эффект отсутствует, волновая функция основного состояния локализуется в окрестности $+v$ или $-v$. Необходимо выбрать одну из двух возможностей для основного состояния и построить теорию возмущений относительно него. Не важно, какой вариант мы выберем: будет одна и та же физика. Однако, осуществляя выбор, мы нарушаем симметрию $\varphi \to -\varphi$ лагранжиана.

Симметрия относительно отражений нарушается спонтанно! Мы не вводили в лагранжиан нарушающие симметрию члены, а она все равно нарушилась 1.

[1] Сделаю не очень важное техническое замечание для придирчивых читателей: строго говоря. в теории поля волновая функция основного состояния должна по идее именоваться волновым функционалом, поскольку $\Psi[\varphi(\vec{x})]$ есть функционал функции $\varphi(\vec{x})$. Выберем основное состояние в $+v$ и запишем $\varphi = v + \varphi'$. Разлагая в ряд по φ', получаем, что:

$$\mathcal{L} = \frac{\mu^4}{4\lambda} + \frac{1}{2}\left(\partial\varphi'\right)^2 - \mu^2\varphi^2 - O\left(\varphi^3\right)$$

Физическая частица, отвечающая сдвинутому полю φ', имеет массу $\sqrt{2}\mu$. Квадрат физической массы должен быть положительным, поскольку это, как легко сообразить, всего-навсего $V''(\varphi)|_{\varphi=v}$.

Аналогично вы увидите, что первый член лагранжиана (4) есть $-V(\varphi)|_{\varphi=v}$. Если нас интересует лишь рассеяние мезонов, связанное с φ', этот член не должен входить в лагранжиан. Действительно, мы всегда можем добавить в $\mathcal{L}$ произвольную константу. Мы довольно произвольно выбирали $V(\varphi = 0)$ равным нулю. Такая же ситуация возникает в квантовой механике: у гармонического осциллятора, энергия нулевых колебаний $\frac{1}{2}\hbar\omega$ ненаблюдаема; физическими являются лишь переходы между энергетическими уровнями энергии. Мы вернемся к этому вопросу в главе VIII.2.

Еще одна точка зрения на (2) состоит в том, что в квантовой теории поля вычисляют евклидов функциональный интеграл

$$Z = \int D\varphi e^{-\int d^dx\left\{\frac{1}{2}\left[(\partial\varphi)^2-\mu^2\varphi^2\right]+\frac{\lambda}{4}\left(\varphi^2\right)^2\right\}}$$

а теория возмущений сводится к изучению малых колебаний относительно минимума евклидова действия. Обычно мы раскладываем лагранжиан относительно минимума $\varphi = 0$, если перед φ^2 стоит знак минус. Если φ^2 входит с положительным знаком, $\varphi = 0$ является не минимумом, а локальным максимумом.

В квантовой теории поля основное состояние называют вакуумом, так как это буквально такое состояние, в котором поле «покоится» и нет ни одной частицы. В нашем случае мы имеем два физически эквивалентных вакуума, из которых мы должны выбрать один. Значение φ в основном состоянии (либо v или $-v$ в рассматриваемом примере) называют вакуумным средним для φ. Говорят, что поле φ получило вакуумное среднее.

Непрерывная симметрия

Вернемся к формуле (2) для случая $N \geqslant 2$. На рис. IV.1.2 изображен потенциал (3) при $N = 2$. Форму потенциала сравнивают с дном бутылки или сомбреро. Потенциал имеет минимум при $\vec{\varphi}^2 = \mu^2/\lambda$. Интересно, что у нас есть бесконечное число вакуумов, характеризуемых направлением $\vec{\varphi}$ в данном вакууме. Благодаря $O(2)$-симметрии лагранжиана все они физически эквивалентны. Желательно, чтобы результат не зависел от нашего выбора. Пусть $\vec{\varphi}$ направлен вдоль первой координаты, т. е. $\varphi_1 = v \equiv +\sqrt{\mu^2/\lambda}$ и $\varphi_2 = 0$.

Теперь рассмотрим флуктуации относительно этой конфигурации поля, другими словами, запишем $\varphi_1 = v+\varphi_1'$ и $\varphi_2 = \varphi_2'$. Подставим эти выражения в (2) для случая $N = 2$ и разложим $\mathcal{L}$ в ряд. Предлагаю вам самим проделать простые выкладки. У вас должно получиться (опустив штрихи у полей, чтобы не перегружать обозначения):

$$\mathcal{L} = \frac{\mu^4}{4\lambda} + \frac{1}{2}\left[(\partial\varphi_1)^2 + (\partial\varphi_2)^2\right] - \mu^2\varphi_1^2 + O\left(\varphi^3\right)$$

Постоянный член в точности как и в (4), как и поле φ' в (4), поле φ_1 имеет массу $\sqrt{2}\mu$. Теперь обратите внимание на отличительное свойство лагранжиана (5): отсутствует член φ_2^2. Поле φ_2 безмассово!

Появление безмассового бозона

Тот факт, что поле φ_2 оказалось безмассовым, не случаен. Я сейчас объясню, что безмассовость - это общее и точное явление.

Из рис. IV.1.2 мы можем легко выяснить спектр частиц. Возбуждения поля φ_1 соответствуют флуктуациям в радиальном направлении (так сказать, «забираемся на стену»), а возбуждения поля φ_2 соответствуют флуктуациям в угловом направлении (так сказать, «вращаемся вдоль желоба»). Чтобы шарик катился вдоль минимумов потенциальной энергии, переходя от одного минимума к другому, не требуется затрат энергии. Чтобы пояснить данное утверждение, изобразим длинноволновое возбуждение вида $\varphi_2 = a\sin(\omega t - \vec{k}\vec{x})$, где a мало. В области, где масштаб длины меньше $|\vec{k}|^{-1}$, поле φ_2 постоянно и, следовательно, поле $\vec{\varphi}$ просто слегка отклоняется от направления 1, эквивалентного вакууму вследствие $O(2)$-симметрии. Только в тех областях, где масштаб длины больше $|\vec{k}|^{-1}$, для возбуждения требуются затраты энергии. Таким образом, при $|\vec{k}| \to 0$ можно ожидать, что энергия возбуждения обратится в нуль.

Теперь мы понимаем ключевое различие между случаями $N = 1$ и $N = 2$: для первого из них характерна дискретная симметрия относительно отражений, а для второго - непрерывная $O(2)$-симметрия.

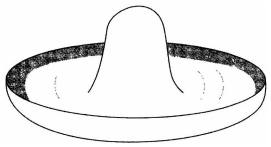

Рис. IV.1.2

После того как мы детально проанализировали случай $N = 2$, вы сможете обобщить наши рассуждения до произвольного $N \geqslant 2$ (см. упражнение (IV.1.1)).

Между тем взглянем на случай $N = 2$ с другой стороны. Многие теории поля могут быть записаны более чем одним способом, и важно узнавать их под разными видами. Зададим комплексное поле $\varphi = (1/\sqrt{2})\,(\varphi_1 + i\varphi_2)$; имеем $\varphi^\dagger\varphi = \frac{1}{2}\,(\varphi_1^2 + \varphi_2^2)$, поэтому перепишем (2) в виде:

$$\mathcal{L} = \partial\varphi^\dagger\partial\varphi + \mu^2\varphi^\dagger\varphi - \lambda\left(\varphi^\dagger\varphi\right)^2$$

явно инвариантном относительно $U(1)$-преобразования $\varphi \to e^{i\alpha}\varphi$ (вспомните главу I.9). Это соответствует условию локальной изоморфности групп $O(2)$ и $U(1)$. Вектор можно записать не только в декартовых или полярных координатах, но и параметризовать поле $\varphi(x) = \rho(x)e^{i\theta(x)}$ (как в главе III.5), чтобы получить $\partial_\mu\varphi = (\partial_\mu\rho + i\rho\partial_\mu\theta)\,e^{i\theta}$. Приходим к лагранжиану $\mathcal{L} = \rho^2(\partial\theta)^2 + (\partial\rho)^2 + \mu^2\rho^2 - \lambda\rho^4$. Спонтанное нарушение симметрии предполагает задание $\rho = v + \chi$, где $v = +\sqrt{\mu^2/2\lambda}$. Тогда [2]

$$\mathcal{L} = v^2(\partial\theta)^2 + \left[(\partial\chi)^2 - 2\mu^2\chi^2 - 4\sqrt{\frac{\mu^2\lambda}{2}}\chi^3 - \lambda\chi^4\right] + \left(\sqrt{\frac{2\mu^2}{\lambda}}\chi + \chi^2\right)(\partial\theta)^2.$$

Видим, что фаза $\theta(x)$ есть безмассовое поле. Мы объединили члены лагранжиана в три группы: кинетическая энергия безмассового поля θ, кинетическая и потенциальная энергия массивного поля χ и члены взаимодействия θ и χ.

[2] Автор опустил постоянный член в лагранжиане. - Прим. ред.

Теорема Голдстоуна

Теперь докажем теорему Голдстоуна, согласно которой при спонтанном нарушении непрерывной симметрии появляются безмассовые поля, известные как намбу-голдстоуновские бозоны.

Вспомним, что с любой непрерывной симметрией связан сохраняющийся заряд Q. Тот факт, что Q генерирует симметрию, выражается условием:

$$[H, Q] = 0.$$

Пусть вакуум (или основное состояние в квантовой механике) обозначается как $|0\rangle$. Добавив в гамильтониан соответствующую константу $H \to H+ +c$, мы всегда можем записать $H|0\rangle = 0$. Обычно вакуум инвариантен относительно преобразования симметрии $e^{i\theta Q}|0\rangle = |0\rangle$, другими словами, $Q|0\rangle = 0$.

Однако предположим, что симметрия спонтанно нарушается и вакуум перестает быть инвариантным относительно преобразования симметрии, т. е. $Q|0\rangle \neq 0$. Рассмотрим состояние $Q|0\rangle$. Какова его энергия? Итак,

$$HQ|0\rangle = [H, Q]|0\rangle = 0.$$

Первое равенство следует из условия $H|0\rangle = 0$, а второе - из условия (8). Следовательно, мы нашли другое состояние $Q|0\rangle$ с той же энергией, как и $|0\rangle$.

Обратите внимание, что доказательство не опиралось на релятивистскую инвариантность или поля. Видим также, что оно просто формализует картину с вращением шарика вдоль желоба.

В квантовой теории поля есть локальные токи, поэтому

$$Q = \int d^D x J^0(\vec{x}, t)$$

где D - размерность пространства. Сохранение заряда Q означает, что вычисление интеграла может проводиться в произвольный момент времени. Рассмотрим состояние

$$|s\rangle = \int d^D x e^{i\vec{k}\vec{x}} J^0(\vec{x}, t)|0\rangle$$

с пространственным импульсом $\vec{k}$[3]. Если $\vec{k}$ стремится к нулю, состояние

[3] Действуя на него с помощью P^i (упражнение I.10.3) и учитывая условие $P^i|0\rangle = 0$, после интегрирования по частям получаем

$$P^i|s\rangle = \int d^D x e^{i\vec{k}\vec{x}} \left[P^i, J^0(\vec{x}, t)\right] |0\rangle = k^i|s\rangle$$

переходит в состояние $Q|0\rangle$ с нулевой энергией (что следует из (9)). Значит, если импульс состояния $|s\rangle$ стремится к нулю, его энергия также стремится к нулю. В релятивистской теории это в точности означает, что состояние $|s\rangle$ описывает безмассовую частицу.

Из доказательства следует, что теорема практически универсальна: она справедлива для любой спонтанно нарушенной непрерывной симметрии.

Подсчет намбу-голдстоуновских бозонов

Из нашего доказательства следует, что число намбу-голдстоуновских бозонов, очевидно, равно числу сохраняющихся зарядов, которые не оставляют вакуум инвариантным, т. е. не уничтожают $|0\rangle$. Для каждого такого заряда Q^α можно построить состояние с нулевой энергией $Q^\alpha|0\rangle$.

В нашем примере присутствует лишь один ток $J_\mu = i(\varphi_1\partial_\mu\varphi_2 - -\varphi_2\partial_\mu\varphi_1)$ и, следовательно, единственный намбу-голдстоуновский бозон. В общем случае, если лагранжиан остается инвариантен относительно группы симметрии G с $n(G)$-генераторами, а вакуум остается инвариантен относительно подгруппы H группы G с $n(H)$ генераторами, то число намбу-голдстоуновских бозонов равно $n(G) - n(H)$. Если вы хотите продемонстрировать свое владение математической лексикой, то можете сказать, что: намбу-голдстоуновские бозоны живут в фактор-пространстве G/H.

Ферромагнетики и спиновая волна

Из общности доказательства следует, что теорема Голдстоуна применима не только к физике элементарных частиц. В действительности она берет начало из физики конденсированных сред, классическим примером является ферромагнетик. Гамильтониан, в который входит только взаимодействие нерелятивистских электронов с ионами в твердом теле, является инвариантным относительно группы вращения $SO(3)$, но вектор намагничивания $\vec{M}$ выбирает одно направление, так что ферромагнетик остается инвариантным только относительно подгруппы $SO(2)$, которую составляют вращения вокруг оси $\vec{M}$. Теорему Намбу-Голдстоуна легко визуализировать с физической точки зрения. Рассмотрим «спиновую волну», в которой локальные намагниченности $\vec{M}(\vec{x})$ медленно меняются от точки к точке. Физик, живущий в мире, малом по сравнению с длиной волны, даже не представляет себе, что он больше не находится в «вакууме». Следовательно, частота волны должна стремиться к нулю по мере того, как длина волны стремится к бесконечности. Это, конечно, такой же эвристический аргумент, к которым мы прибегали ранее. Обратите внимание, что квантовая механика нужна только для того, чтобы сопоставить волновому вектору $\vec{k}$ импульс, а частоте ω - энергию. К вопросу о магнетиках и спиновых волнах вернемся в главах V.3 и VI.5.

Квантовые флуктуации и размерность пространства-времени

Наше обсуждение спонтанного нарушения симметрии является, по существу, классическим. Что происходит при учете квантовых флуктуаций? Более детально рассмотрим этот вопрос в главе IV.3, а пока обратимся снова к лагранжиану (5). В основном состоянии $\varphi_1 = v$ и $\varphi_2 = 0$. Вспомним, что в матрацной модели теории скалярного поля масса обусловлена действием пружин, приводящим матрац в равновесное положение. Член $-\mu^2\varphi_1'^2$ (обратите внимание на штрих) в выражении (5) означает, что для ухода поля φ_1' из основного состояния, в котором $\varphi_1' = 0$, необходимо затратить действие. Но теперь нас беспокоит следующее: поле φ_2 безмассово. Сможет ли оно уйти из своего основного состояния? Чтобы ответить на этот вопрос, вычислим среднеквадратичную флуктуацию

$$\begin{aligned}\left\langle(\varphi_2(0))^2\right\rangle &= \frac{1}{Z}\int D\varphi e^{iS(\varphi)}\left[\varphi_2(0)\right]^2 = \\ &= \lim_{x\to 0}\frac{1}{Z}\int D\varphi e^{iS(\varphi)}\varphi_2(x)\varphi_2(0) = \\ &= \lim_{x\to 0}\int\frac{d^dk}{(2\pi)^d}\frac{e^{ikx}}{k^2}.\end{aligned}$$

(Мы узнаем функциональный интеграл, определяющий пропагатор; см. главу I.7.) Верхний предел интеграла в выражении (10) обрезается на некотором значении Λ (соответствующем обратному значению шага решетки, если говорить о ферромагнетике). Как говорилось в главе III.1 (и будет говориться в главе VIII.3), нас не должна волновать ультрафиолетовая расходимость для больших значений k. Мы должны беспокоиться по поводу возможной инфракрасной расходимости для малых значений k. (Замечу, что в случае массивного поля член $1/k^2$ в выражении (10) следовало бы заменить членом $1/\left(k^2+\mu^2\right)$ и тогда бы не стало инфракрасной расходимости.) Видим, что при $d > 2$ инфракрасной расходимости нет. Рассмотренная нами схема спонтанного нарушения непрерывной симметрии справедлива в нашем (3+1)-мерном мире. Однако при $d \leqslant 2$ среднеквадратичная флуктуация поля φ_2 оказывается бесконечной, так что наша схема уже не действует. Приходим к теореме Коулмена-Мермина-Вагнера (независимо доказанной теоретиком в области физики элементарных частиц и двумя теоретиками в области физики конденсированных сред), которая гласит, что для $d = 2$ спонтанное нарушение непрерывной симметрии невозможно. Обратите внимание, что данная теорема справедлива не только

для рассмотренной нами $O(2)$-симметрии, но и для любой непрерывной симметрии, поскольку она зависит исключительно от присутствия намбу-голдстоуновских полей.

В наших примерах спонтанного нарушения симметрии спонтанно нарушалась скалярным полем φ, но ничего не говорится о том, что поле φ должно быть элементарным. Во многих конденсированных средах, например в сверхпроводниках, симметрии нарушаются спонтанно, хотя система состоит из электронов и атомных ядер. Поле φ генерируется динамически, например, как связанное состояние двух электронов в сверхпроводниках. Подробнее об этом в главе V.4. Спонтанное нарушение симметрии динамически генерируемым полем иногда называют динамическим нарушением симметрии [4].

Упражнения

IV.1.1. Явно покажите существование $N-1$ намбу-голдстоуновских бозонов в $G=O(N)$ в примере (2).

IV.1.2. Постройте аналог выражения (2) с N комплексными скалярными полями инвариантный относительно $SU(N)$. Найдите число намбу-голдстоуновских бозонов для случая, когда одно из скалярных полей получает вакуумное среднее.

[4] Эта глава посвящена памяти покойного Йорге Свиека.

30.1.2 Zi.IV.2 Pion as a Nambu–Goldstone Boson

Кризис теории поля

В 1950-1960-х гг. после нескольких впечатляющих успехов квантовой теории поля в случае электромагнитного взаимодействия ученые, естественно, были решительно настроены на то, чтобы применить ее к случаям сильного и слабого взаимодействий. Как мы уже знаем, теория поля оказывается неперенормируемой в случае слабого взаимодействия. Что касается сильных взаимодействий, то теория поля оказывается несостоятельной по другим причинам. С одной стороны, по мере того как экспериментальной оценке стало поддаваться все больше и больше адронов (т. е. сильно взаимодействующих частиц), ученые пришли к выводу, что, если каждому адрону поставить в соответствие поле, результирующая теория поля окажется запутанной, с огромным количеством произвольных констант связи. Даже если мы ограничимся рассмотрением нуклонов и пионов, известная константа связи во взаимодействии между пионами и нуклонами будет большой. (Отсюда термин «сильное взаимодействие».) Пертурбативный подход, так впечатляюще эффективный в квантовой электродинамике, обречен на неудачу.

Многие выдающиеся физики того времени выступали за отказ от квантовой теории поля, а в некоторых высших учебных заведениях квантовую теорию поля даже исключили из учебной программы. И лишь в начале 1970-х гг. произошло триумфальное возвращение квантовой теории поля. Была сформулирована теория поля для сильных взаимодействий в терминах кварков и глюонов, а не адронов. Мы рассмотрим ее в главе VII.3.

Слабый распад пионов

Чтобы понять кризис, который наступил для теории поля, вернемся назад во времени и представим себе, что мог бы делать физик-теоретик в конце 1950-х гг. Поскольку эта книга вовсе не посвящена физике элементарных частиц, изложу лишь основные факты. Подробности найдете в соответствующих монография [1]. К тому времени были измерены многие полулептонные распады, такие как $n\to p+e^-+\bar\nu, \pi^-\to e^-+\bar\nu$ и $\pi^-\to\pi^0+e^-+\bar\nu$.$\beta$-распад нейтрона $n\to p+e^-+\bar\nu$; тот самый процесс, для которого Ферми предложил свою теорию, в то время описывался лагранжианом вида $\mathcal{L}=G\left[\bar e\gamma^\mu\left(1-\gamma_5\right)\nu\right]\left[\bar p\gamma_\mu\left(1-\gamma_5\right)n\right]$, где n - поле нейтрона, поглощающее нейтрон, p - поле протона, поглощающее протон, ν - поле нейтрино, поглощающее нейтрино (или рождающее антинейтрино, как в β-распаде), а e - поле электрона, поглощающее электрон.

Становится понятно, почему теоретики не могли написать поле для каждого адрона и лагранжиан для каждого процесса распада, хотя фактически занимались этим все время. Вместо этого следует записать

$$\mathcal{L} = G\left[\bar{e}\gamma^{\mu}\left(1-\gamma_5\right)\nu\right]\left(J_{\mu}-J_{5\mu}\right)$$

где J_{μ} и $J_{5\mu}$ - два тока, преобразующихся как лоренцовский и аксиальный векторы соответственно. В канонической формулировке теории поля токи J_{μ} и $J_{5\mu}$ рассматриваются как квантовые операторы. Наша задача тогда сводилась бы к вычислению матричных элементов между адронными состояниями, $\langle p\left|\left(J_{\mu}-J_{5\mu}\right)\right|n\rangle, \langle 0\left|\left(J_{\mu}-J_{5\mu}\right)\right|\pi^{-}\rangle, \langle\pi^{0}\left|\left(J_{\mu}-J_{5\mu}\right)\right|\pi^{-}\rangle$ и т. д., которые соответствуют трем распадам, упоминаемым выше. (Следует пояснить, что, хотя речь идет о слабых распадах, вычисление этих матричных элементов является задачей о сильном взаимодействии. Другими словами, чтобы понять природу распада, сильное взаимодействие необходимо учитывать во всех порядках константы сильного взаимодействия, а слабое взаимодействие достаточно учесть в низшем порядке по константе слабого взаимодействия G.) На самом деле существует прецедент, из-за которого мы придерживаемся этой точки зрения. Чтобы вычислить ядерный β-распад $(Z,A)\rightarrow(Z+1,A)+e^{-}+\bar{\nu}$, Ферми вовсе не записывал отдельный лагранжиан для каждого ядра. Вычислением матричного элемента $\langle Z+1,A\left|\left[\bar{p}\gamma_{\mu}\left(1-\gamma_5\right)n\right]\right|Z,A\rangle$ должен был заниматься скорее теоретикспециалист по атомному ядру. Аналогично, вычисление матричных элементов $\langle p\left|\left(J_{\mu}-J_{5\mu}\right)\right|n\rangle$ есть задача теоретика-специалиста по сильным взаимодействиям.

Для нашего сюжета я сосредоточусь на вычислении матричного элемента аксиального тока J_5^{μ} между нейтроном и протоном. Слегка изменим обозначения: отныне мы не будем говорить, что нейтрон находится в начальном состоянии, а протон - в конечном состоянии, вместо этого будем указывать на то, что импульс нейтрона равен p, а импульс протона - p'.

[1] См., например. E. Commins and P. H. Bucksbaum, Weak Interactions of Leptons and Quarks (Комминс Ю., Буксбаум Б. Слабые взаимодействия лептонов и кварков. - М.: Энергоатомиздат, 1987.). Не забывайте, к тому же, что все поля и токи в выражении (1) являются функциями от координаты пространства-времени x. Следовательно, необходимо вычислить $\langle p'\left|J_5^{\mu}(x)\right|p\rangle$, что, однако, вследствие трансляционной инвариантности равно $\langle p'\left|J_5^{\mu}(0)\right|p\rangle e^{+i(p'-p)\cdot x}$. Поэтому просто вычисляем $\langle p'\left|J_5^{\mu}(0)\right|p\rangle$ и опускаем 0. Заметим, что спиновые значки уже опущены.

Лоренцевская инвариантность и четность позволяют нам несколько продвинуться. Из них следует, что [2]:

$$\langle p'\left|J_5^{\mu}\right|p\rangle = \bar{u}\left(p'\right)\left[\gamma^{\mu}\gamma^{5}F\left(q^2\right)+q^{\mu}\gamma^{5}G\left(q^2\right)\right]u(p)$$

где $q\equiv p'-p$ [сравните с выражением (III.6.7)]. Но лоренцевская инвариантность и четность больше ничего не могут для нас сделать, поскольку мы ничего не знаем о «форм-факторах» $F\left(q^2\right)$ и $G\left(q^2\right)$.

Аналогично для матричного элемента $\langle 0\left|J_5^{\mu}\right|\pi^{-}\rangle$лоренцевская инвариантность означает следующее:

$$\langle 0\left|J_5^{\mu}\right|k\rangle = fk^{\mu}$$

Начальное состояние я обозначил импульсом k для пиона. Правая часть уравнения (3) должна быть вектором и, так как k - единственный имеющийся вектор, пропорциональной k. Подобно параметрам $F\left(q^2\right)$ и $G\left(q^2\right)$, константа f - это величина, определяемая сильным взаимодействием, вычислять которую мы не умеем. С другой стороны, значения $F\left(q^2\right), G\left(q^2\right)$ и f можно установить экспериментальным путем. Например, ясно, что скорость распада $\pi^{-}\rightarrow e^{-}+\bar{\nu}$ зависит от f^2.

Слишком много диаграмм

Давайте заглянем чрез плечо теоретика конца 1950-х гг., пытающегося вычислить $\langle p'\left|J_6^{\mu}\right|p\rangle$ и $\langle 0\left|J_5^{\mu}\right|k\rangle$ в выражении (2). Он бы начал строить фейнмановские диаграммы,

подобные изображенным на рис. IV.2.1 и IV.2.2, и вскоре бы осознал всю безнадежность своей попытки. Из-за сильной связи ему пришлось бы вычислить бесконечное число диаграмм, даже если бы сильное взаимодействие описывалось теорией поля, понятием уже отвергнутым многими светилами того времени.

Я не собираюсь вдаваться во все подробности, связанные с захватывающей историей развития данной области, полной недоразумений и тупиковых моментов. Вместо этого я, с оглядкой на прошлое, выбираю педагогически наилучший подход для изложения сюжета.

[2] Другой возможный член вида $(p' + p)^\mu \gamma^5$ зануляется вследствие симметрии относительно зарядового сопряжения и изоспиновой симметрии.

(b)

Рис. IV.2.1

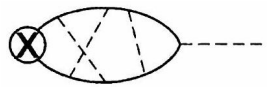

Рис. IV.2.2

Пион очень легкий

Переломным моментом послужило наблюдение, которое показало, что масса π^-, равная 139 МэВ, значительно меньше массы протона, равной 938 МэВ. Долгое время это воспринимали просто как факт и не пытались никак объяснять. В конце концов некоторые теоретики задумались, почему это один адрон должен быть гораздо легче другого.

Наконец они предприняли смелый шаг, вообразив «идеальный мир», в котором π^-безмассов. Идея была в том, что этот идеальный мир является хорошим приближением реального мира с точностью около 15% ($\sim 139/938$).

Помните ли вы одно обстоятельство, при котором происходит естественное появление безмассовой и бесспиновой частицы? Конечно, это спонтанное нарушение симметрии! В одном из тех ярких озарений, которые определяли историю физики элеметарных частиц, теоретики предположили, что π-мезоны есть намбу-голдстоуновские бозоны некоторой спонтанно нарушенной симметрии. Действительно, умножим (3) на k_μ:

$$k_\mu \langle 0 | J_5^\mu | k \rangle = f k^2 = f m_\pi^2,$$

что равно нулю в идеальном мире. Из обсуждения трансляционной инвариантности вспомним, что

$$\langle 0 | J_5^\mu(x) | k \rangle = \langle 0 | J_5^\mu(0) | k \rangle e^{-ik\cdot x}$$

и, следовательно,

$$\langle 0 | \partial_\mu J_5^\mu(x) | k \rangle = -ik_\mu \langle 0 | J_5^\mu(0) | k \rangle e^{-ik\cdot x}.$$

Таким образом, если в идеальном мире сохраняется аксиальный ток, $\partial_\mu J_5^\mu(x) = 0$, из условия $k_\mu \langle 0 | J_5^\mu | k \rangle = 0$ и уравнения (5) следует $m_\pi^2 = 0$.

Для рассматриваемого нами идеального мира характерна симметрия, известная под названием киральной симметрии сильного взаимодействия. В основном состоянии, в котором мы живем, симметрия нарушается спонтанно и образуется π-мезон как намбу-голдстоуновский бозон. Связанный с этой симметрией нетеровский ток есть сохраняющийся ток J_5^μ.

Вы, наверное, уже догадались, что совершенные нами выкладки тесно связаны с доказательством теоремы Намбу-Голдстоуна, приведенным в главе (IV.1).

Соотношение Голдбергера-Треймана

Подходим к кульминации. Умножим (2) на $(p'-p)_\mu$. Согласно той же трансляционной инвариантности имеем

$$(p'-p)_\mu \langle p' | J_5^\mu(0) | p \rangle = -i \langle p' | \partial_\mu J_5^\mu(x) | p \rangle e^{i(p'-p)\cdot x}.$$

Если $\partial_\mu J_5^\mu = 0$, полученное выражение зануляется. С другой стороны, умножая правую часть уравнения (2) на $(p'-p)_\mu$, получим $\bar{u}(p')\left[(\not{p}' - \not{p})\gamma^5 F(q^2) + q^2\gamma^5 G(q^2)\right] u(p)$. С учетом уравнения Дирака приходим к выводу, что

$$0 = 2m_N F\left(q^2\right) + q^2 G\left(q^2\right)$$

где m_N - масса нуклона.

Каждый из форм-факторов $F(q^2)$ и $G(q^2)$ определяется бесконечным числом фейнмановских диаграмм. Мы не можем их вычислить, но все же нам удалось связать их соотношением! Такая распространенная стратегия используется во многих областях физики: если сталкиваешься с различными величинами, которые не знаешь как вычислить, можно попытаться связать их.

Мы можем еще продвинуться, положив (5) $q \to 0$. Возвращаясь к (2), видим, что $F(0)$ измеряется экспериментально в распаде $n \to p + e^- + +\bar{\nu}$ (в масштабе сильных взаимодействий передача импульса пренебрежимо мала). Однако сталкиваемся с другой проблемой: масса нуклона m_N получается равной нулю!

Решить проблему помогает IV.2.1b: существует бесконечное количество диаграмм, полюс которых обусловлен не чем иным, как безмассовым π-мезоном, который дает

$$f q^\mu \frac{1}{q^2} g_{\pi NN} \bar{u}(p')\gamma^5 u(p).$$

Когда π-пропагатор соединяется с нуклонной линией, сумма бесконечного количества диаграмм дает экспериментально наблюдаемую константу связи $g_{\pi NN}$ пион-нуклонного

взаимодействия. Следовательно, возвращаясь к уравнению (2), видим, что при $q \sim 0$ форм-фактор равен $G(q^2) \sim f(1/q^2)\, g_{\pi NN}$. Подставляя это выражение в (5), приходим к известному соотношению Голдбергера-Треймана:

$$2m_N F(0) + f g_{\pi NN} = 0,$$

которое связывает четыре экспериментально измеримые величины. Как и ожидалось, его точность составляет 15%; погрешность обусловлена тем, что на самом деле мы не живем в мире с безмассовым π-мезоном.

К теории сильных взаимодействий

Искусство установления связи между бесконечными наборами фейнмановских диаграмм без их вычисления, и это вид искусства, требующий большого мастерства, было развито в теории дисперсионных соотношений и теории S-матрицы. Эти теории лежат в основе нашего современного понимания сильных взаимодействий. Стоит заметить, что важной составляющей дисперсионных соотношений являлось изучение аналитических свойств фейнмановских диаграмм. Например, в главе III.7 мы показали, что диаграмма поляризации вакуума имеет разрез. Суть аргументов Голдбергера-Треймана состоит в разделении бесконечного количества диаграмм на диаграммы с полюсом в комплексной q^2-плоскости и диаграммы без полюса (но с разрезом). Открытие того факта, что у сильного взаимодействия есть спонтанно нарушенная симметрия, явилось ключом к построению теории, лежащей в основе сильных взаимодействий, и неизбежно привело к появлению понятий кварков и глюонов.

Замечание для историка науки: отношение физиков-теоретиков к некоторой величине как к большой или как к малой зависит (очевидно) от культурной и интеллектуальной среды, в которой они выросли. Как-то Трейман сказал мне, что для поколения, выросшего вместе с атомной бомбой (сам Трейман был в составе вооруженных сил в Тихом океане), казалось верхом абсурдности считать 138 МэВ равными нулю, когда энергия, выделяемая при распаде одного ядра, оказывается порядка 10МВ. А сегодня новое поколение молодых теоретиков, работающих в области теории струн, совершенно спокойно считает равным нулю все, что меньше энергии Планка в 10^{19} ГэВ.

30.1.3 Zi.IV.3 Effective Potential

Квантовые флуктуации и нарушение симметрии

Такое важное явление, как спонтанное нарушение симметрии, основывается на нахождении минимумов классической потенциальной энергии $V(\varphi)$ квантовой теории поля. Естественно задаться вопросом, как на описанную картину повлияют квантовые флуктуации?

Рассмотрим еще раз лагранжиан (III.3.4)

$$\mathcal{L} = \frac{1}{2}(\partial\varphi)^2 - \frac{1}{2}\mu^2\varphi^2 - \frac{1}{4!}\lambda\varphi^4 + A(\partial\varphi)^2 + B\varphi^2 + C\varphi^4.$$

(Когда речь идет о квантовых флуктуациях, необходимо включать контрчлены, что мы и сделали.) Что вы знаете об этой теории? Для $\mu^2 > 0$ экстремум действия находится при $\varphi = 0$, и, квантуя малые флуктуации относительно $\varphi = 0$, получаем скалярные частицы, рассеивающиеся друг на друге. Для $\mu^2 < 0$ экстремум действия находится при некотором значении $\varphi_{\min}$, а дискретная симметрия $\varphi \to -\varphi$ спонтанно нарушается (см. главу IV.1). Что происходит при $\mu = 0$? Нарушать или не нарушать - вот в чем вопрос.

Первое предположение таково, что квантовые флуктуации нарушат симметрию. Теория $\mu = 0$ находится на грани нарушения симметрии и квантовые флуктуации должны бы вытолкнуть ее за эту грань. Представьте себе карандаш, балансирующий на своем острие, а затем «включите» квантовую механику.

Житейская мудрость

Следуя Швингеру и Йона-Лозиньо, построим формализм, который позволит ответить на поставленный вопрос. Рассмотрим теорию скалярного поля, задаваемую как

$$Z = e^{iW(J)} = \int D\varphi e^{i[S(\varphi)+J\varphi]}$$

[с удобным сокращением $J\varphi = \int d^4x J(x)\varphi(x)$]. Если вычислить функциональный интеграл, получим производящий функционал $W(J)$. Как говорилось в главе I.7, путем повторного дифференцирования W по источнику $J(x)$ можно получить любую функцию Грина и, следовательно, любую желаемую амплитуду рассеяния. В частности,

$$\varphi_c(x) \equiv \frac{\delta W}{\delta J(x)} = \frac{1}{Z}\int D\varphi e^{i[S(\varphi)+J\varphi]}\varphi(x).$$

Подстрочный индекс c традиционно используется для того, чтобы напомнить (см. приложение к главе I.8), что в каноническом формализме $\varphi_c(x)$ обозначает среднее $\langle 0|\hat{\varphi}|0\rangle$ квантового оператора $\hat{\varphi}$. Не путайте с переменной интегрирования φ из уравнения (3). Чтобы не загромождать запись, далее будем опускать индекс c без какого бы то ни было риска создать путаницу.

Если задан функционал W для J, можно осуществить преобразование Лежандра и получить функционал Γ для φ (т.е. φ_c). Под преобразованием Лежандра понимают простое соотношение

$$\Gamma(\varphi) = W(J) - \int d^4x J(x)\varphi(x).$$

Хоть соотношение и простое, будьте осторожны, когда раскрываете его смысл: оно определяет функционал для $\varphi(x)$ через неявную зависимость J от φ. В правой части выражения (4) необходимо выразить J через φ путем решения уравнения (3). Раскладываем функционал $\Gamma(\varphi)$ следующим образом:

$$\Gamma(\varphi) = \int d^4x \left[-V_{3\phi.}.(\varphi) + Z(\varphi)(\partial\varphi)^2 + ...\right]$$

где (..) обозначает члены с более высоким порядком ∂. Вскоре мы убедимся в справедливости обозначения $V_{.}(\varphi)$.

У преобразования Лежандра простая и удобная форма функциональной производной от Γ:

$$\frac{\delta\Gamma(\varphi)}{\delta\varphi(y)} = \int d^4x \frac{\delta J(x)}{\delta\varphi(y)}\frac{\delta W(J)}{\delta J(x)} - \int d^4x \frac{\delta J(x)}{\delta\varphi(y)}\varphi(x) - J(y) = -J(y).$$

Это соотношение можно считать «дуальным» соотношению $\delta W(J)/\delta J(x) = \varphi(x)$.

Если вам начинает казаться, что подобные преобразования вам уже встречались раньше в вашем физическом образовании, то вы правы! В курсе термодинамики вы прибегали к преобразованию Лежандра, связавшему свободную энергию с энергией $F = E - TS$, где F - функция от температуры T, а E - функция от энтропии S. Следовательно, J и φ образуют «сопряженные» пары, подобные паре T и S (или, что еще более очевидно, паре напряженность магнитного поля H и намагниченность M). Можете удостовериться, что это не просто совпадение.

Для J и φ, независимых от x, из уравнения (5) следует, что условие (6) сводится к виду:

$$V'_{\text{эфф.}}(\varphi) = J.$$

Это соотношение проясняет, для чего служит эффективный потенциал $V_{\text{эфф.}}(\varphi)$. Посмотрим, что произойдет в отсутствие внешнего источника J. Ответ очевиден: из соотношения (7) следует, что

$$V'(\varphi) = 0.$$

Другими словами, вакуумное среднее значение φ в отсутствие внешнего источника определяется минимумами $V(\varphi)$.

Первый порядок по квантовым флуктуациям

Все эти формальные манипуляции ничего не стоят, если мы не можем вычислить $W(J)$. В большинстве случаев мы можем найти $e^{iW(J)} = \int D\varphi e^{i[S(\varphi)+J\varphi]}$ лишь в приближении наискорейшего спуска (см. главу I.2). Найдем «точку» наискорейшего спуска $\varphi_s(x)$, т. е. решение уравнения

$$\left.\frac{\delta\left[S(\varphi) + \int d^4y J(y)\varphi(y)\right]}{\delta\varphi(x)}\right|_{\varphi_s} = 0$$

или, в более явной форме,

$$\partial^2\varphi_s(x) + V'\left[\varphi_s(x)\right] = J(x).$$

Запишем переменную интегрирования в (2) как $\varphi = \varphi_s + \widetilde{\varphi}$ и разложим до членов второго порядка $\widetilde{\varphi}$:

$$\begin{aligned} Z = e^{(i/\hbar)W(J)} &= \int D\varphi e^{(i/\hbar)[S(\varphi)+J\varphi]} \simeq \\ &\simeq e^{(i/\hbar)[S(\varphi)+J\varphi]} \int D\widetilde{\varphi} e^{(i/\hbar)\int d^4x \frac{1}{2}\left[(\partial\widetilde{\varphi})^2 - V''(\varphi_*)\widetilde{\varphi}^2\right]} = \\ &= e^{(i/\hbar)[S(\varphi)+J\varphi] - \frac{1}{2}\operatorname{tr}\log\left[\partial^2 + V''(\varphi_s)\right]}. \end{aligned}$$

Для представления детерминанта, возникшего в результате интегрирования по $\widetilde{\varphi}$, мы воспользовались тождеством (II.5.2). Обратите внимание, что я вернул постоянную Планка $\hbar$. Здесь φ_s, решение (10), следует рассматривать как функцию от J.

Теперь, когда мы определили

$$W(J) = \left[S\left(\varphi_s\right) + J\varphi_s\right] + \frac{i\hbar}{2}\operatorname{tr}\log\left[\partial^2 + V''\left(\varphi_s\right)\right] + O\left(\hbar^2\right),$$

переходим к преобразованию Лежандра. Опишу следующие действия более подробно:

$$\varphi = \frac{\delta W}{\delta J} = \frac{\delta\left[S\left(\varphi_s\right) + J\varphi_s\right]}{\delta\varphi_s}\frac{\delta\varphi_s}{\delta J} + \varphi_s + O(\hbar) = \varphi_s + O(\hbar).$$

В главном порядке $\hbar$ значение φ (известное раньше как φ_c) равно φ_s. Таким образом, из соотношения (4) получаем:

$$\Gamma(\varphi) = S(\varphi) + \frac{i\hbar}{2}\operatorname{tr}\log\left[\partial^2 + V''(\varphi)\right] + O\left(\hbar^2\right).$$

Несмотря на то что эта формула выглядит достаточно простой, на практике оказывается невозможным вычислить след для произвольного $\varphi(x)$: необходимо найти все собственные значения оператора $\partial^2 + V''(\varphi)$, найти их логарифм и просуммировать. Задача существенно упрощается, если мы анализируем функционал $\Gamma(\varphi)$ для φ, который не зависит от x, потому что в этом случае значение $V''(\varphi)$ постоянно, а оператор $\partial^2 + V''(\varphi)$ трансляционно-инвариантен и легко вычисляется в импульсном пространстве:

$$\begin{aligned}\operatorname{tr}\log\left[\partial^2+V''(\varphi)\right] &= \int d^4x\,\langle x\,|\log\left[\partial^2+V''(\varphi)\right]|\,x\rangle = \\ &= \int d^4x\int\frac{d^4k}{(2\pi)^4}\langle x|k\rangle\,\langle k\,|\log\left[\partial^2+V''(\varphi)\right]|\,k\rangle\,\langle k|x\rangle = \\ &= \int d^4x\int\frac{d^4k}{(2\pi)^4}\log\left[-k^2+V''(\varphi)\right].\end{aligned}$$

С учетом (5) получаем:

$$V_{3\phi\phi.}(\varphi)=V(\varphi)-\frac{i\hbar}{2}\int\frac{d^4k}{(2\pi)^4}\log\left[\frac{k^2-V''(\varphi)}{k^2}\right]+O\left(\hbar^2\right),$$

известный как эффективный потенциал Коулмена-Вайнберга. Итак, мы вычислили поправку к классическому потенциалу $V(\varphi)$ до порядка $\hbar$. Напоминаю, что мы добавили независимую от φ константу, чтобы сделать аргумент логарифма безразмерным.

Можно дать красивую физическую интерпретацию формулы (14). Определим так называемое фоновое поле, заполнив Вселенную скалярным полем $\varphi(x)$, принимающим значение φ. Для $V(\varphi)=\frac{1}{2}\mu^2\varphi^2+(1/4!)\lambda\varphi^4$ имеем $V''(\varphi)=\mu^2+\frac{1}{2}\lambda\varphi^2\equiv\mu(\varphi)^2$, что соответствует квадрату зависящей от φ эффективной массы скалярной частицы, распространяющейся в фоновом поле φ. Квадрат массы μ^2 в лагранжиане получает поправку $\frac{1}{2}\lambda\varphi^2$, обусловленным взаимодействием частицы с фоновым полем φ. Теперь становится очевидным смысл выражения (14): первый член $V(\varphi)$ представляет собой плотность классической энергии, содержащейся в фоновом поле φ, а второй член есть плотность энергии вакуума для скалярного поля, квадрат массы которого равен $V''(\varphi)$ (см. выражение (II.5.3) и упражнение IV.3.4).

Ваша теория перенормировок в деле

Интеграл в (14) квадратично расходится, а если точнее, квадратично зависит от обрезания. Ничего страшного, мы ввели три контрчлена, лишь два из которых нам потребуются, поскольку φ не зависит от x. Поэтому на самом деле получаем:

$$\begin{aligned}V_{\text{эф.}}(\varphi)=V(\varphi)+\frac{\hbar}{2}\int\frac{d^4k_E}{(2\pi)^4}\log\left[\frac{k_E^2+V''(\varphi)}{k_E^2}\right]+ \\ +B\varphi^2+C\varphi^4+O\left(\hbar^2\right),\end{aligned}$$

где сделали виковский поворот к евклидову интегралу (см. приложение D). Используя соотношение (D.9) и интегрируя до $k_E^2=\Lambda^2$, получаем (опуская $\hbar$)

$$V_{.}(\varphi)=V(\varphi)+\frac{\Lambda^2}{32\pi^2}V''(\varphi)-\frac{\left[V''(\varphi)\right]^2}{64\pi^2}\log\frac{e^{\frac{1}{2}}\Lambda^2}{V''(\varphi)}+B\varphi^2+C\varphi^4$$

Как и ожидалось, интеграл квадратично и логарифмически зависит от обрезания Λ^2, поскольку подынтегральное выражение в (15) для больших k_E^2 имеет вид $1/k_E^2$.

Такова теория перенормировки в действии! Так как V есть многочлен четвертой степени от $\varphi, V''(\varphi)$ - это квадратичный многочлен, а $\left[V''(\varphi)\right]^2$ - многочлен четвертой степени. Следовательно, для устранения зависимости от обрезания достаточно ввести два контрчлена $B\varphi^2+C\varphi^4$. Рассмотренный пример, в частности, ясно демонстрирует, как работает метод добавления контрчленов.

Чтобы понять, что плохого может произойти в неперенормируемой теории, представим себе, что V есть многочлен шестой степени от φ. Мы могли мы добавить три контрчлена $B\varphi^2+C\varphi^4+D\varphi^6$, но этого будет недостаточно, поскольку $\left[V''(\varphi)\right]^2$ будет являться многочленом восьмой степени. Это значит, что нам следовало начать с V как многочлена

восьмой степени, но тогда выражение $[V''(\varphi)]^2$ было бы многочленом двенадцатой степени. Очевидно, что в итоге придем к многочлену бесконечной степени. В этом состоит отличительное свойство неперенормируемой теории: в ее неутолимой потребности в контрчленах.

Наложение условий перенормируемости

Вернемся из кошмара бесконечного количества окружающих нас контрчленов и обратимся к простой перенормируемой теории φ^4. В главе III.3 мы фиксировали контрчлены заданием условий для различных амплитуд рассеяния. Теперь нам надо зафиксировать коэффициенты B и C заданием двух условий для $V.(\varphi)$ при определенных значениях φ. Мы, так сказать, работаем с пространством полей, а не пространством импульсов, но с прежней концептуальной основой.

Можно было бы начать с общего многочлена четвертой степени $V(\varphi)$, но лучше сначала ответим на главный вопрос, поставленный в главе: что произойдет при $\mu = 0$, т. е. когда $V(\varphi) = (1/4!)\lambda\varphi^4$? Выкладки тоже упрощаются.

Вычисляя (16), получаем:

$$V_{\phi..}(\varphi) = \left(\frac{\Lambda^2}{64\pi^2}\lambda + B\right)\varphi^2 + \left(\frac{1}{4!}\lambda + \frac{\lambda^2}{(16\pi)^2}\log\frac{\varphi^2}{\Lambda^2} + C\right)\varphi^4 + O\left(\lambda^3\right)$$

(после включения нескольких независимых от φ коэффициентов в C). Видим, что зависимость от Λ можно включить в B и C.

Мы начали с многочлена четвертой степени $V(\varphi)$. Квантовые флуктуации породили квадратично расходящийся член φ^2, который можно сократить с контрчленом B. Что означает условие $\mu = 0$? Оно означает, что член $(d^2V/d\varphi^2)|_{\varphi=0}$ исчезает. Теория $\mu = 0$ предполагает обязательное сокращение квадрата ренормированной массы, обозначаемой в нашем случае коэффициентом при φ^2. Таким образом, приходим к первому условию:

$$\left.\frac{d^2V_{\text{Эфф.}}}{d\varphi^2}\right|_{\varphi=0} = 0$$

Иначе говоря, мы хотим, чтобы $B = -\left(\Lambda^2/64\pi^2\right)\lambda$ в данном порядке.

Аналогично можно было бы сформулировать второе условие как требование равенства $(d^4V_{\text{эфф.}}/d\varphi^4)|_{\varphi=0}$ некоторой константе связи. Однако,

дифференцируя член $\varphi^4\log\varphi$ в выражении для $V_{\text{эфф.}}$ четыре раза, получим

член $\log\varphi$, значение которого не определено при $\varphi = 0$. Мы должны наложить условие на $d^4V_{\text{эфф.}}/d\varphi^4$ не для $\varphi = 0$, а для φ, равного некоторой произвольно выбранной массе M. (Вспомним, что размерность φ совпадает с размерностью массы.) Следовательно, второе условие будет иметь вид:

$$\left.\frac{d^4V_{\text{эфф.}}}{d\varphi^4}\right|_{\varphi=M} = \lambda(M)$$

где $\lambda(M)$ - явно зависимая от M константа связи. Подставляя в (18) выражение

$$V_{\text{эфф.}}(\varphi) = \left(\frac{1}{4!}\lambda + \frac{\lambda^2}{(16\pi)^2}\log\frac{\varphi^2}{\Lambda^2} + C\right)\varphi^4 + O\left(\lambda^3\right)$$

видим, что $\lambda(M)$ равно λ плюс поправки $O\left(\lambda^2\right)$, среди которых фигурирует член $\lambda^2\log M$. Дифференцируя $\lambda(M)$, получаем явное соотношение:

$$\begin{aligned} M\frac{d\lambda(M)}{dM} &= \frac{3}{16\pi^2}\lambda^2 + O\left(\lambda^3\right) = \\ &= \frac{3}{16\pi^2}\lambda(M)^2 + O\left[\lambda(M)^3\right] \end{aligned}$$

где второе равенство справедливо в данном порядке. Анализ соотношения показывает, как константа связи $\lambda(M)$ зависит от масштаба массы M, при котором она задается. Вспомните упражнение III.1.3. К данному соотношению мы вернемся в главе VI.7, когда речь пойдет о ренорм-группе.

А пока продолжим. Выразим из условия (18) константу C и, подставив

ее в выражение для $V_{\text{эфф.}}$, получим:

$$V_{\text{эфф.}}\,(\varphi) = \frac{1}{4!}\lambda(M)\varphi^4 + \frac{\lambda(M)^2}{(16\pi)^2}\varphi^4\left(\log\frac{\varphi^2}{M^2} - \frac{25}{6}\right) + O\left[\lambda(M)^3\right].$$

Надеюсь, вас не удивляет, почему больше нет константы C и обрезания Λ. Вот вам и перенормируемая теория!

Тот факт, что $V_{\text{эфф.}}$ не зависит от произвольно выбранной массы M, т. е.

$M\,(dV_{\text{эфф.}}\,/dM) = 0$, в указанном порядке выражается соотношением (19).

Нарушение симметрии квантовыми флуктуациями

Теперь ответим на главный вопрос: нарушать или не нарушать?

Квантовые флуктуации генерируют поправку к потенциалу вида $+\varphi^4\log\varphi^2$, но значение $\log\varphi^2$ чрезвычайно велико и отрицательно для малых φ. Поправка $O(\hbar)$ превосходит классический $O\,(\hbar^0)$-потенциал $+\varphi^4$ вблизи $\varphi = 0$. Квантовые флуктуации нарушают дискретную симметрию $\varphi \to -\varphi$.

Достаточно легко определить минимумы $\pm\varphi_{\min}$ эффективного потенциала $F_{3\phi\phi}(\varphi)$ (чтобы иметь представлсние, нарисуйте потенциал от φ). Более детальный анализ показывает, что нельзя всерьез рассматривать точ-

ное значение $\varphi_{\min}$; $V_{\text{эфф.}}$ имеет вид $\lambda\varphi^4(1+\lambda\log\varphi+\ldots)$, т. е. параметром

разложения в действительности будет $\lambda\log\varphi$. [Постарайтесь убедиться, что

$(\ldots)$ начинаются с $[\lambda\log\varphi]^2$.] Минимум $\varphi_{\min}$ функции $V_{\text{эфф.}}$ лежит там, где

параметр разложения порядка единицы. В упражнении к главе IV.6 вы познакомитесь с остроумным способом обойти эту проблему.

Фермионы

В выражении (11) φ_s выступает в качестве внешнего поля, а $\widetilde{\varphi}$ соответствует квантовому полю, по которому проводится интегрирование. Роль $\widetilde{\varphi}$ может играть поле фермиона ψ. Добавим в лагранжиан член $\bar{\psi}(i\not{\partial} - m - -f\varphi)\psi$. В интеграле по траекториям

$$Z = \int D\varphi D\bar{\psi} D\psi e^{i\int d^4x\left[\frac{1}{2}(\partial\varphi)^2 - V(\varphi) + \bar{\psi}(i\not{\partial} - m - f\varphi)\psi\right]}$$

можно сначала проинтегрировать по ψ и получить

$$Z = \int D\varphi e^{i\int d^4x\left[\frac{1}{2}(\partial\varphi)^2 - V(\varphi)\right] + \operatorname{tr}\log(i\not{\partial} - m - f\varphi)}.$$

Совершая те же шаги, что и в (13), приходим к выводу, что вклад фермионного поля в $V_{\text{эфф.}}\,(\varphi)$ равен:

$$V_F(\varphi) = +i\int\frac{d^4p}{(2\pi)^4}\operatorname{tr}\log\frac{\not{p} - m - f\varphi}{\not{p}}.$$

(След в (23) берется по гамма-матрицам.) Из главы II.5 следует, что физически параметр $V_F(\varphi)$ дает вакуумную энергию фермиона с эффективной массой $m(\varphi) \equiv m + f\varphi$.

Получить след логарифма можно с помощью $\operatorname{tr}\log M = \log\det M$ (II.5.2), циклически переставляя множители в детерминанте:

$$\begin{aligned}\operatorname{tr}\log(\not p - a) &= \operatorname{th}\log\gamma^5(\not p - a)\gamma^5 = \operatorname{tr}\log(-\not p - a) = \\ &= \frac{1}{2}\operatorname{tr}(\log(\not p - a) + \log(\not p + a)) + \frac{1}{2}\operatorname{tr}\log(-1) = \\ &= \frac{1}{2}\operatorname{tr}\log(-1)\left(p^2 - a^2\right).\end{aligned}$$

Следовательно,

$$\operatorname{tr}\log\frac{(\not p - a)}{\not p} = \frac{1}{2}\operatorname{tr}\log\frac{p^2 - a^2}{p^2} = 2\log\frac{p^2 - a^2}{p^2}$$

и поэтому

$$V_F(\varphi) = 2i\int\frac{d^4p}{(2\pi)^4}\log\frac{p^2 - m(\varphi)^2}{p^2}.$$

Обратите внимание на то, что общий знак противоположен знаку в (14): противоположность знаков между фермионной и бозонной петлями объяснялась в главе II.5.

Итак, эффективный потенциал, порождаемый квантовыми флуктуациями, интерпретируется следующим образом: он соответствует плотности энергии, обусловленной флуктуирующей энергией, которая полностью аналогична энергии нулевых колебаний гармонического осциллятора, для квантовых полей в фоновом поле φ (см. упражнение IV.3.5).

Упражнения

IV.3.1. Рассмотрите эффективный потенциал в (0+1)-мерном пространстве-времени:

$$V_{\text{s}\phi\phi.}(\varphi) = V(\varphi) + \frac{\hbar}{2}\int\frac{dk_E}{(2\pi)}\log\frac{k_E^2 + V''(\varphi)}{k_E^2} + O\left(\hbar^2\right).$$

Поскольку интеграл сходится, нет необходимости добавлять контрчлены. Однако $(0+1)$-мерная теория поля - это всего лишь квантовая механика. Вычислите интеграл и покажите, что $V_{\text{жф.}}$ не противоречит вашим знаниям о квантовой механике.

IV.3.2. Изучите $V_{\text{эфф. в}}$ $(1+1)$-мерном пространстве-времени.

IV.3.3. Рассмотрите безмассовое фермионное поле ψ, взаимодействующее со скалярным полем φ посредством $f\varphi\bar\psi\psi$ в (1+1)-мерном пространстве-времени. Покажите, что

$$V_F = \frac{1}{2\pi}(f\varphi)^2\log\frac{\varphi^2}{M^2}$$

после добавления подходящего контрчлена. В главе V.5, посвященной нестабильности Пайерлса, мы увидим, что полученный результат имеет большое значение для физики конденсированных сред.

IV.3.4. Попробуйте понять смысл выражения (14) с помощью фейнмановских диаграмм. Покажите, что $V_{\text{эф}}$ порождается бесконечным количеством диаграмм. [Указание: разложите логарифм в (14) в ряд по $V''(\varphi)/k^2$ и постарайтесь сопоставить для каждого члена ряда фейнмановскую диаграмму.]

IV.3.5. Рассмотрите электродинамику комплексного скалярного поля

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \left[\left(\partial^\mu + ieA^\mu\right)\varphi^\dagger\right]\left[\left(\partial_\mu - ieA_\mu\right)\varphi\right] + \mu^2\varphi^\dagger\varphi - \lambda\left(\varphi^\dagger\varphi\right)^2.$$

Во Вселенной, заполненной скалярным полем $\varphi(x)$, принимающим независимое от x значение φ, лагранжиан будет содержать член $\left(e^2\varphi^\dagger\varphi\right)A_\mu A^\mu$, так что квадрат эффективной массы фотонного поля становится равным $M(\varphi)^2 \equiv e^2\varphi^\dagger\varphi$. Покажите, что его вклад в $V_.(\varphi)$ равен:

$$\int \frac{d^4k}{(2\pi)^4}\log\frac{k^2 - M(\varphi)^2}{k^2}$$

Сравните с выражениями (14) и (26). [Указание: для упрощения вычислений воспользуйтесь калибровкой Ландау.] Если вам нужна помощь, настоятельно рекомендую прочесть работу Коулмена и Вайнберга (S. Coleman and E. Weinberg, Phys. Rev. D7: 1888, 1973), которая очень понятно и четко написана.

30.1.4 Zi.IV.4 Magnetic Monopole

Квантовая механика и магнитные монополи

Довольно любопытно, хотя электрические заряды стали вполне привычным делом, никто никогда не видел магнитный заряд или монополь. В классической физике мы можем совершенно спокойно модифицировать одно из уравнений Максвелла, записав его в виде $\vec{\nabla}\cdot\vec{B} = \rho_M$, где ρ_M обозначает плотность магнитных монополей. При этом мы больше не можем представлять поле $\vec{B}$ как $\vec{B} = \vec{\nabla}\times\vec{A}$, поскольку иначе $\vec{\nabla}\cdot\vec{B} = \vec{\nabla}\cdot\vec{\nabla}\times\vec{A} = \varepsilon_{ijk}\partial_i\partial_j A_k = 0$. Ньютон и Лейбниц сообщили нам, что производные коммутируют друг с другом.

И что из этого? Действительно, кого волнует, что $\vec{B}$ больше нельзя записать в виде $\vec{\nabla}\times\vec{A}$? Векторный потенциал $\vec{A}$ ввели в физику исключительно из математических соображений, причем до сих пор студентам так и говорят в курсе классического электромагнетизма. Как сказал выдающийся физик девятнадцатого века Хэвисайд: «Физику надо очистить от такой чепухи, как скалярные и векторные потенциалы; физический смысл имеют лишь поля $\vec{E}$ и $\vec{B}$ ».

С приходом квантовой механики, однако, оказалось, что Хэвисайд был не прав. Вспомните, например, нерелятивистское уравнение Шредингера для заряженной частицы в электромагнитном поле:

$$\left[-\frac{1}{2m}(\vec{\nabla} - ie\vec{A})^2 + e\phi\right]\psi = E\psi$$

Заряженные частицы непосредственно взаимодействуют с векторным и скалярным потенциалами $\vec{A}$ и ϕ, которые теперь рассматриваются иногда как более фундаментальные понятия, чем электромагнитные поля $\vec{E}$ и $\vec{B}$ (см. главу III.4). Для квантовой физики просто необходим векторный потенциал. Дирак гениально заметил, что эти утверждения ведут к внутреннему конфликту между квантовой механикой и понятием магнитных монополей. При более тщательном анализе он пришел к выводу, что квантовая механика вовсе не запрещает существование магнитных монополей. Просто она разрешает существование только таких монополей, которые несут определенное количество магнитного заряда.

Дифференциальные формы

Для дальнейшего обсуждения вопроса магнитных монополей и теории Янга-Миллса в следующей главе очень удобно пользоваться языком дифференциальных форм. Не бойтесь, нам понадобится лишь несколько элементарных понятий. Пусть x^μ обозначает D действительных переменных (т. е. индекс μ может принимать D разных значений), а A_μ (не обязательно электромагнитный калибровочный потенциал в нашем чисто математическом разделе) обозначает D функций от x. В наших приложениях x^μ - это координаты и, как мы увидим, дифференциальные формы имеют естественную геометрическую интерпретацию.

Назовем объект $A \equiv A_\mu dx^\mu$ 1-формой. Дифференциалы dx^μ рассматриваются следуя Ньютону и Лейбницу. При замене координат $x \to x'$, как обычно, $dx^\mu = (\partial x^\mu/\partial x'^\nu)\, dx'^\nu$, так что $A \equiv A_\mu dx^\mu = A_\mu (\partial x^\mu/\partial x'^\nu)\, dx'^\nu \equiv A'_\nu dx'^\nu$. Мы записали стандартный закон преобразования векторов при координатном преобразовании $A'_\nu = A_\mu (\partial x^\mu/\partial x'^\nu)$. В качестве примера рассмотрим $A = \cos\theta d\varphi$. Считая θ и φ угловыми координатами на 2-сфере (т. е. поверхности 3-шара), получаем $A_\theta = 0$ и $A_\varphi = \cos\theta$. Аналогично определяем p-форму как $H = (1/p!) H_{\mu_1\mu_2\ldots\mu_p} dx^{\mu_1} dx^{\mu_2} \ldots dx^{\mu_p}$. (Повторяющиеся индексы, как обычно, суммируются.) «Вырожденным» примером является 0-форма, назовем ее Λ, которая представляет собой скалярную функцию от координат x^μ. Примером 2-формы служит $F = (1/2!) F_{\mu\nu} dx^\mu dx^\nu$.

Приходим к вопросу, как рассматривать произведения дифференциалов. Из элементарного курса дифференциального исчисления мы знаем, 'то $dxdy$ представляет собой область бесконечно малого прямоугольника с длиной dx и шириной dy. Тогда мы чисто автоматически считали, что $dydx$ равняется $dxdy$. Порядок написания дифференциалов не был важен. ()днако если осуществить координатное преобразование, то $x = x(x', y')$ $y = y(x', y')$ будут функциями от новых координат x' и y'. Теперь посмотрим на

$$dxdy = \left(\frac{\partial x}{\partial x'}dx' + \frac{\partial x}{\partial y'}dy'\right)\left(\frac{\partial y}{\partial x'}dx' + \frac{\partial y}{\partial y'}dy'\right).$$

() братите внимание, что коэффициент при $dx'dy'$ равен $(\partial x/\partial x')(\partial y/\partial y')$, а коэффициент при $dy'dx'$ равен $(\partial x/\partial y')(\partial y/\partial x')$. Видим, что дифференциалы dx^μ лучше рассматривать как антикоммутирующие объекты [кото- рые математики называют грассмановыми переменными (вспомните главу II.5)], поэтому $dy'dx' = -dx'dy'$ и $dx'dx' = 0 = dy'dy'$. Тогда (2) сводится к виду:

$$dxdy = \left(\frac{\partial x}{\partial x'}\frac{\partial y}{\partial y'} - \frac{\partial x}{\partial y'}\frac{\partial y}{\partial x'}\right) dx'dy' \equiv J(x, y; x', y')\, dx'dy'.$$

Мы получили правильный якобиан $J(x, y; x', y')$, преобразующий элемент площади $dxdy$ в элемент площади $dx'dy'$.

Во многих текстах $dxdy$ записывают как $dx^\wedge dy$. Мы будем опускать знак $\wedge$, чтобы не загромождать записи.

Это небольшое упражнение показывает, что нам следует определить $dx^\mu dx^\nu = -dx^\nu dx^\mu$ и считать элемент площади $dx^\mu dx^\nu$ направленным. Элементы площади $dx^\mu dx^\nu$ и $dx^\nu dx^\mu$ одинаковы по величине и противоположны по направлению.

Теперь зададим дифференциальный оператор d, действующий на любую форму. Действуя им на p-форму H, получаем, по определению,

$$dH = \frac{1}{p!}\partial_\nu H_{\mu_1\mu_2\ldots\mu_p} dx^\nu dx^{\mu_1} dx^{\mu_2} \ldots dx^{\mu_p}.$$

Следовательно, $d\Lambda = \partial_\nu \Lambda dx^\nu$ и

$$dA = \partial_\nu A_\mu dx^\nu dx^\mu = \frac{1}{2}(\partial_\nu A_\mu - \partial_\mu A_\nu)\, dx^\nu dx^\mu.$$

Видим, что этот математический формализм сделан почти как по заказу для описания электромагнетизма. Если назвать 1-форму $A \equiv A_\mu dx^\mu$ потенциалом, а A_μ считать электромагнитным потенциалом, тогда $F = dA$ конечно будет 2-формой поля. Если

записать F через его компоненты $F = (1/2!)F_{\mu\nu}dx^\mu dx^\nu$, то $F_{\mu\nu}$ действительно будет электромагнитным полем.

Замечу, что x^μ не является формой, а dx^μ не обозначает действие d на форму.

Если хотите, можете считать дифференциальные формы всего лишь элегантным и компактным обозначением. Главное - рассматривать объекты A и F как нечто целое, не привязанное к определенной координатной системе. Такой подход удобен в том случае, когда приходится иметь дело с объектами, более сложными, чем A и F, например, в теории струн. Дифференциальные формы освобождают нас от использования целого моря индексов. Важным тождеством является следующее:

$$dd = 0$$

Оно означает, что двукратное действие d на любую форму дает нуль. В качестве упражнения можете проверить это утверждение. В частности, $dF = ddA = 0$. Если записать его в компонентах, придем к стандартному тождеству электромагнетизма - «тождеству Бьянки».

Замкнутая форма не обязательно точна глобально

Удобно сейчас ввести несколько новых терминов. Говорят, что p-форма α замкнута, если $d\alpha = 0$. Говорят, что она точна, если существует такая $(p-1)$-форма β, что $\alpha = d\beta$.

В этих терминах (4) означает, что точные формы замкнуты.

Верно ли обратное? В некотором смысле. Согласно лемме Пуанкаре, замкнутая форма локально точна. Другими словами, если $dH = 0$, где H - некоторая p-форма, то локально справедливо

$$H = dK$$

для некоторой $(p-1)$-формы K. Однако не обязательно, что $H = dK$ истинно в глобальном смысле, т. е. везде. На самом деле мы уже сталкивались с леммой Пуанкаре. Например, я уверен, вы знаете, что, если равен нулю ротор векторного поля, векторное поле локально становится градиентом некоторого скалярного поля.

Для интегрирования форм не нужна никакая дополнительная информация. Например, задана 2-форма $F = (1/2!)F_{\mu\nu}dx^\mu dx^\nu$. Для любого 2-многообразия M можно записать $\int\limits_M F$. Обратите внимание, что в интеграл уже включена мера, так что нет необходимости делать координатный выбор. Помните вы это или нет, но вас уже знакомили с одной важной теоремой:

$$\int\limits_M dH = \int\limits_{\partial M} H$$

где H – p-форма, а ∂M - граница $(p+1)$-мерного многообразия M.

Дираковское квантование магнитного заряда

После такого экскурса в математику мы готовы заняться физикой. Рассмотрим сферу, окружающую магнитный монополь с магнитным зарядом g. Тогда 2-форма электромагнитного поля задается как $F = (g/4\pi)d\cos\theta d\varphi$, что практически совпадает с определением магнитного монополя (см. упражнение IV.4.3). В частности, вычислим магнитный поток путем интегрирования F по сфере S^2:

$$\int\limits_{S^2} F = g$$

Я уже говорил, что элемент площади включается автоматически. Вы, должно быть, уже узнали в $d\cos\theta d\varphi = -\sin\theta d\theta d\varphi$ элемент площади на единичной сфере. Замечу, что

при «обычном обозначении» в выражении (7) будет использоваться магнитное поле $\vec{B} = (g/4\pi r^2)\,\widehat{r}$, где $\widehat{r}$ - единичный вектор в радиальном направлении.

Теперь приведу довольно математический, но строгий вывод дираковского квантования магнитного заряда g, впервые полученный Ву и Янгом.

Сначала вспомним, как работает калибровочная инвариантность на примере (II.7.3). При преобразовании поля электрона $\psi(x) \to e^{i\Lambda(x)}\psi(x)$ электромагнитное калибровочное поле изменяется на

$$A_\mu(x) \to A_\mu(x) + \frac{1}{ie} e^{-i\Lambda(x)} \partial_\mu e^{i\Lambda(x)}$$

или, в терминах дифференциальных форм,

$$A \to A + \frac{1}{ie} e^{-i\Lambda} d e^{i\Lambda}.$$

Дифференцируя, получаем:

$$A_\mu(x) \to A_\mu(x) + \frac{1}{e}\partial_\mu \Lambda(x).$$

Использованная здесь форма напоминает нам, что калибровочное преобразование определяется умножением на фазовый множитель $e^{i\Lambda(x)}$, так что $\Lambda(x)$ и $\Lambda(x) + 2\pi$ описывают одно и то же преобразование.

В квантовой механике A физическое (при всем нашем уважении к Хэвисайду), поэтому нам лучше задаться вопросом, какое значение A привело бы к $F = (g/4\pi) d\cos\theta d\varphi$. Ответ кажется очевидным: $A = (g/4\pi)\cos\theta d\varphi$. (Если решите проверить это, вычислив dA, не забывайте, что $dd = 0$.)

Однако не все так быстро; ваш друг-математик утверждает, что $d\varphi$ не определено у Северного и Южного полюсов. На бытовом языке это бы соответствовало ситуации, при которой вы стоите на Северном полюсе и пытаетесь определить свою долготу. То есть, строго говоря, нельзя писать $A = (g/4\pi)\cos\theta d\varphi$. Но вы ведь достаточно умны, чтобы возразить: как насчет $A_N = (g/4\pi)(\cos\theta - 1)d\varphi$? Если подействовать на A_N оператором d, получим желаемую F; дополнительный член $(g/4\pi)(-1)d\varphi$ зануляется d вследствие тождества (4).

Хорошо, но ваш друг-математик указывает на то, что наше A_N не определено на Южном полюсе.

- Все верно, - отвечаете вы, - я это учел, добавив индекс N[1]. Теперь зададим $A_S = (g/4\pi)(\cos\theta + 1)d\varphi$. Обратите внимание, что, действуя на A_S оператором d, мы снова получаем желаемое F. Однако теперь A_S определено везде, за исключением Северного полюса.

На математическом языке мы скажем, что калибровочное поле A определено локально, но не глобально. Калибровочное поле A_N определен на карте, которая покрывает северную полусферу и простирается на юг так далеко, как мы того захотим, но не включая Северный полюс. Аналогично, A_S определено на карте, которая покрывает южную полусферу и простирается так далеко на север, как мы того захотим, за исключением Северного полюса.

Что произойдет при наложении друг на друга двух участков координатной сетки, к примеру, вдоль экватора? Калибровочные потенциалы A_N и A_S не одинаковы:

$$A_S - A_N = 2\frac{g}{4\pi} d\varphi$$

Что теперь? Ах да, это калибровочная теория! Если A_S и A_N связаны калибровочным преобразованием, то все хорошо. Итак, с учетом (8) задаем условие $2(g/4\pi)d\varphi = (1/ie)e^{-i\Lambda}de^{i\Lambda}$ для некоторой фазовой функции $e^{i\Lambda}$. Из прямой проверки следует, что $e^{i\Lambda} = e^{i2(eg/4\pi)\varphi}$.

Однако значения $\varphi = 0$ и $\varphi = 2\pi$ описывают в точности одну и ту же точку. Чтобы $e^{i\Lambda}$ имело смысл, необходимо выполнение условия $e^{i2(eg/4\pi)(2\pi)} = e^{i2(eg/4\pi)(0)=1}$; иначе говоря, $e^{ieg} = 1$ или

$$g = \frac{2\pi}{e}n$$

где n - целое число. В этом состоит знаменитое открытие Дирака: магнитный заряд на магнитном монополе квантуется в единицах $2\pi/e$. Другими словами, если существует монополь, то электрический заряд квантуется в единицах $2\pi/g$.

Не забывайте, что форма F является точной локально, а не глобально; в противном случае, согласно (6), магнитный заряд $g = \int\limits_{S^2} F$ был бы равен нулю.

[1] От англ. «north» - «север». - Прим. пер. Я привел здесь строгий математический вывод частично для того, чтобы, во-первых, избавить вас от путаницы, с которой связывают данный вывод в более простых текстах. Во-вторых, подобного рода доказательства встречаются в более передовых областях физики, например, теории струн.

Электромагнитная дуальность

Тот факт, что между электрическим и магнитным полями может существовать дуальность, приводило физиков-теоретиков в затруднительное положение на протяжении полутора веков. Кстати, если вы почитаете Максвелла, то обнаружите, что он часто говорил о магнитных зарядах. Можете проверить, что уравнения Максвелла инвариантны относительно следующего изящного преобразования: $(\vec{E} + i\vec{B}) \to e^{i\theta}(\vec{E} + i\vec{B})$ в случае существования магнитных зарядов.

Одним из интригующих свойств уравнения (10) является следующее: если e мало, то g велико, и наоборот. Как бы выглядели магнитные заряды, если бы существовали? Они ничем бы не отличались от электрических зарядов: они тоже взаимодействуют с помощью потенциала $1/r$, отталкиваясь при одноименных и притягиваясь при разноименных зарядах. В принципе мы могли бы эффективно сформулировать теорию электромагнетизма в терминах магнитных зарядов, которые выступали бы в качестве электрических зарядов. В этом случае теория была бы сильно взаимодействующей, но роль константы связи играл бы параметр g, а не e.

Физиков-теоретиков интересует дуальность по той причине, что она позволяет получить представление о теориях поля в режиме сильной связи. При преобразовании дуальности теория поля в режиме слабой связи отображается в сильно взаимодействущую теорию поля. Именно поэтому, когда несколько лет назад ученые узнали о дуальности теорий струн другим теориям, это произвело огромное впечатление на специалистов в области теории струн: теперь мы знаем, как ведут себя теории струн в режиме сильной связи. Более подробно о дуальности читайте в главе VI.3.

Формы и геометрия

Проясним геометрический характер дифференциальных форм путем анализа электромагнитного тока заряженной частицы, движущейся вдоль мировой линии $X^\mu(\tau)$ в D-мерном пространстве-времени (см. рис. IV.4.1a):

$$J^\mu(x) = \int d\tau \frac{dX^\mu}{d\tau}\delta^{(D)}[x - X(\tau)]$$

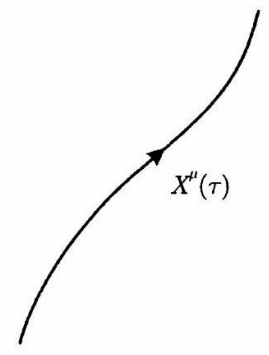
Физический смысл этой простой формулы из электродинамики очевиден: $dX^\mu/d\tau$ есть 4-скорость для заданного значения параметра τ («собственное время»), а дельта-функция гарантирует, что у x ток исчезает, если частица не проходит через x. Обратите внимание, что $J^\mu(x)$ инвариантно относительно репараметризации $\tau \to \tau'(\tau)$.

Более или менее очевидно обобщение на протяженный объект. Рассмотрим струну. Она движется вдоль мирового листа $X^\mu(\tau, \sigma)$ в пространстве-времени (см. рис. 1b), где σ - это

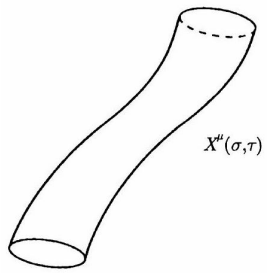
параметр, характеризующий положение вдоль струны. [Например, для замкнутой струны значение σ традиционно считается изменяющимся в диапазоне от 0 до 2π с $X^\mu(\tau,0) = X^\mu(\tau,2\pi)$.] Соответствующий струне ток равен

$$J^{\mu\nu}(x) = \int d\tau d\sigma \det \begin{pmatrix} \partial_\tau X^\mu & \partial_\tau X^\nu \\ \partial_\sigma X^\mu & \partial_\sigma X^\nu \end{pmatrix} \delta^{(D)}[x - X(\tau,\sigma)]$$

где $\partial_\tau \equiv \partial/\partial\tau$ и т. д.



(a)



(b)

Рис. IV.4.1

Детерминант обусловлен условием инвариантности относительно репараметризации $\tau \to \tau'(\tau,\sigma), \sigma \to \sigma'(\tau,\sigma)$. Отсюда следует, что $J^{\mu\nu}$ - это антисимметричный тензор. Значит, аналогом электромагнитного потенциала A_μ, взаимодействующего с током J^μ, является поле антисимметричного тензора $B_{\mu\nu}$, взаимодействующего с током $J^{\mu\nu}$. Таким образом, теория струн содержит 2-форму потенциала $B = \frac{1}{2}B_{\mu\nu}dx^\mu dx^\nu$ и соответствующую 3-форму поля $H = dB$. На самом деле в теории струн есть много p-форм.

Эффект Ааронова-Бома

Реальность калибровочного потенциала A продемонстрировали в 1959 году Ааронов и Бом. Рассмотрим магнитное поле B, ограниченное областью Ω, как изображено на рис. IV.4.2. Квантовая физика электрона описывается решением уравнения Шредингера (1). В формализме фейнмановского интеграла по траекториям амплитуда, соответствующая пути P, модифицируется за счет множитля $e^{ie\int_1 \vec{A}\cdot d\vec{x}}$, в котором одномсрный интсграл вычисляется вдоль траектории P. Таким образом, при вычислении интеграла по траекториям, определяющим вероятность перехода электрона из точки a в точку b (рис. IV.4.2), будет существовать интерференция между вкладами от траекторий 1 и 2 вида

$$\left(e^{ie\int_{P_1}\vec{A}\cdot d\vec{x}}\right)\left(e^{ie\int_{P_2}\vec{A}\cdot d\vec{x}}\right)^* = \left(e^{ie\oint \vec{A}\cdot d\vec{x}}\right)$$

Однако $\oint \vec{A} \cdot d\vec{x} = \int \vec{B} \cdot d\vec{S}$ соответствует потоку, ограниченному замкнутой кривой $(P_1 - P_2)$. Удивительно, но электрон чувствует влияние магнитного поля даже в том случае, когда он не попадает в область присутствия магнитного поля.

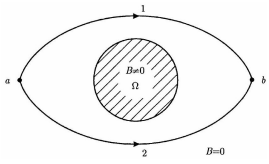


Рис. IV.4.2

Первая публикация результатов работы Аронова-Бома привела в смущение самого Нильса Бора. Впоследствии их выводы подтвердились опытами Тономуры и его сотрудников.

Однажды Коулмен рассказал о мысленном розыгрыше, позволяющем связать эффект Аронова-Бома с дираковским квантованием магнитного за- ряда. Допустим, мы помещаем очень тонкий невидимый соленоид в лабораторию ничего не подозревающего экспериментатора, например, нашего друга из главы III.1. Включаем ток и генерируем магнитное поле в соленоиде. Когда экспериментатор вдруг видит, как из ниоткуда начинает течь магнитный поток, то приходит в такой неописуемый восторг, что начинает планировать свою поездку в Стокгольм (за Нобелевской премией).

При каком условии экспериментатор не сможет обнаружить розыгрыш? Дотошный экспериментатор может начать рассеивать электроны, чтобы попытаться найти соленоид. Условием, гарантирующим, что он не увидит эффект Аронова-Бома и, следовательно, не обнаружит розыгрыш, служит тот факт, что поток, текущий через соленоид, должен быть кратен $2\pi/e$. То есть заряд магнитного монополя точно соответствует магнитному заряду, предсказанному Дираком!

Упражнения

IV.4.1. Докажите, что $dd = 0$.

IV.4.2. Запишите в компонентах уравнение $dF = 0$ и убедитесь, что раньше вы уже встречались с ним, но не узнали в краткой записи.

IV.4.3. Рассмотрим $F = (g/4\pi)d\cos\theta d\varphi$. Перейдя в декартовы координаты, покажите, что оно описывает магнитное поле, направленное наружу, вдоль радиуса.

IV.4.4. Восстановите коэффициенты $\hbar$ и c в условии дираковского квантования.

IV.4.5. Запишите инвариантный относительно репараметризации ток $J^{\mu\nu\lambda}$ в мембране.

IV.4.6. Пусть $g(x)$ - это элемент группы G. 1-форма $v = gdg^\dagger$ известна как форма Маурера-Картана. Тогда след $\operatorname{tr} v^N$ замкнут на N-мерном многообразии, поскольку сам является N-формой. Рассмотрите $Q = \int\limits_{S^N} \operatorname{tr} v^N$, где S^N N-мерная сфера. Выясните и топологический смысл Q. Это окажется полезным для дальнейшего обсуждения топологии в теории поля в главе V.7. [Указание: проанализируйте случай $N = 3$ и $G = SU(2)$.]

30.1.5 Zi.IV.5 Non-Abelian Gauge Theory

От большинства подобных идей в конечном итоге отказываются или откладывают на неопределенное время. Но некоторые продолжают существовать и могут стать наваждением. Изредка наваждение в конце концов может обернуться чем-то хорошим.

Ч. Н. Янг об идее, которая впервые пришла к нему в голову в студенческие времена и к которой он возвращался год от года [1].

Локальное преобразование

Речь идет о довольно простой идее.

Чтобы объяснить, о какой идее говорит Янг, напомним наше обсуждение симметрии в главе I.9. Для определенности зададим N-компонентное комплексное скалярное поле $\varphi(x) = \{\varphi_1(x), \varphi_2(x), ..., \varphi_N(x)\}$, преобразующееся как $\varphi(x) \to U\varphi(x)$, где U - элемент группы $SU(N)$. Так как $\varphi^\dagger \to \varphi^\dagger U^\dagger$ и $U^\dagger U = 1$, имеем $\varphi^\dagger\varphi \to \varphi^\dagger\varphi$ и $\partial\varphi^\dagger\partial\varphi \to \partial\varphi^\dagger\partial\varphi$. Для любого многочлена V очевидна инвариантность лагранжиана $\mathcal{L} = \partial\varphi^\dagger\partial\varphi - V\left(\varphi^\dagger\varphi\right)$ относительно группы преобразований $SU(N)$.

Среди физиков-теоретиков больше тех, кто умеет отвечать на хорошо поставленные вопросы, чем тех, кто умеет задавать действительно важные вопросы. Физики второго типа, к тому же, умеют многое из того, что делают физики первого типа, тогда как обратное утверждение заведомо невсрно.

В 1954 году Ч.Н. Янг и Р. Миллс задались вопросом, что произойдет, если преобразование будет меняться от точки к точке в пространстве-времени, другими словами, если $U = U(x)$ будет зависеть от x.

'C. N. Yang, Selected Papers 1945-1980 with Commentary, p. 19. Ясно, что $\varphi^\dagger\varphi$ остается инвариантным. Но $\partial\varphi^\dagger\partial\varphi$, наоборот, больше не будет инвариантным. Действительно,

$$\partial_\mu\varphi \to \partial_\mu(U\varphi) = U\partial_\mu\varphi + (\partial_\mu U)\,\varphi = U\left[\partial_\mu\varphi + \left(U^\dagger\partial_\mu U\right)\varphi\right].$$

Чтобы сократить нежелательный для нас член $\left(U^\dagger\partial_\mu U\right)\varphi$, мы обобщаем обычную производную ∂_μ до ковариантной производной D_μ, которая при действии на φ дает

$$D_\mu\varphi(x) = \partial_\mu\varphi(x) - iA_\mu(x)\varphi(x).$$

Поле A_μ называется калибровочным потенциалом по аналогии с электромагнетизмом.

Как необходимо преобразовать A_μ, чтобы оказалось справедливым $D_\mu\varphi(x) \to U(x)D_\mu\varphi(x)$? Иначе говоря, нам необходимо преобразовать $D_\mu\varphi(x)$ так же, как преобразовано $\partial_\mu\varphi(x)$, при условии, что U не зависит от x. Если так, то выражение $[D_\mu\varphi(x)]^\dagger D_\mu\varphi(x) \to [D_\mu\varphi(x)]^\dagger D_\mu\varphi(x)$ можно использовать в качестве инвариантного кинетического члена для поля φ.

Двигаясь в обратном направлении, видим, что преобразование $D_\mu\varphi(x) \to U(x)D_\mu\varphi(x)$ оказывается справедливым (не стоит и напоминать, но вам лучше это проверить) в случае, когда

$$A_\mu \to UA_\mu U^\dagger - i\,(\partial_\mu U)\,U^\dagger = UA_\mu U^\dagger + iU\partial_\mu U^\dagger.$$

(Равенство следует из условия $UU^\dagger = 1$.) A_μ мы называем неабелевым калибровочным потенциалом, а выражение (2) неабелевым калибровочным преобразованием.

Сделаем ряд простых наблюдений.

1. Очевидно, что A_μ должны быть матрицами $N \times N$. Из (2) получите закон преобразования для $A_\mu^\dagger$ и покажите, что условие $A_\mu - A_\mu^\dagger = 0$ сохраняется при калибровочном преобразовании. Поэтому можно считать A_μ эрмитовым. В частности, установите смысл сказанного для группы $SU(2)$, такой что $U = e^{i\theta\cdot\tau/2}$, где $\theta\cdot\tau = \theta^a\tau^a$ и τ^a - известные вам матрицы Паули.

2. Записав $U = e^{i\theta\cdot T}$, где T^a - генераторы группы $SU(N)$, получим

$$A_\mu \to A_\mu + i\theta^a\,[T^a, A_\mu] + \partial_\mu\theta^a T^a$$

относительно инфинитезимального преобразования $U \simeq 1 + i\theta\cdot T$. Как правило, инфинитезимальной формы (3) бываст достаточно. 3. Вычислив след (3), видим, что след A_μ не преобразуется, поэтому можно считать, мы можем выбрать A_μ эрмитовым и

бесследовым. Это означает, что мы можем всегда написать $A_\mu = A^a_\mu T^a$ и таким образом разложить матричное поле A_μ по компонентам A^a_μ. Существует столько компонент A^a_μ, сколько генераторов у группы [3 для $SU(2), 8$ для $SU(3)$ и т. д.].

4. В приложении B мы напомним, что алгебра Ли для группы задается выражением $\left[T^a, T^b\right] = if^{abc}T^c$, где числа f^{abc} называются структурными константами. Например, для $SU(2)$ имеем $f^{abc} = \varepsilon^{abc}$. Значит, выражение (3) можно переписать в виде:

$$A^a_\mu \to A^a_\mu - f^{abc}\theta^b A^c_\mu + \partial_\mu \theta^a$$

Если θ не зависит от x, компоненты поля A^a_μ преобразуются в присоединенном представлении группы.

5. Если $U(x) = e^{i\theta(x)}$ - всего лишь элемент абелевой группы $U(1)$, то все эти выражения упрощаются, A_μ есть просто абелев калибровочный потенциал, известный из электродинамики, а выражение (2) описывает обычное абелево калибровочное преобразование. Поэтому A_μ известен как неабелев калибровочный потенциал.

Преобразование U, зависящее от пространственно-временных координат x называют калибровочным преобразованием или локальным преобразованием. Говорят, что инвариантный относительно калибровочного преобразования лагранжиан $\mathcal{L}$ является калибровочно инвариантным.

Построение напряженности поля

Теперь мы можем записать калибровочно-инвариантный лагранжиан

$$\mathcal{L} = \left(D_\mu \varphi\right)^\dagger \left(D_\mu \varphi\right) - V\left(\varphi^\dagger \varphi\right)$$

но калибровочный потенциал A_μ не будет иметь собственной динамики. В знакомом примере $U(1)$ калибровочной инвариантности мы уже записали взаимодействие электромагнитного потенциала A_μ с полем материи φ, но еще мы должны были записать в лагранжиане максвеллов член $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$. Наша первая задача - построить напряженность поля $F_{\mu\nu}$ из A_μ. Как это сделать? По-видимому, Янг и Миллс воспользовались методом проб и ошибок. В качестве упражнения попробуйте сделать это до прочтения текста. Для этого будет полезен язык дифференциальных форм, с которым мы познакомились в главе IV.4. Удобно избавиться от множителя $-i$, переопределив $A^M_\mu \equiv -iA^P_\mu$, где A^P_μ обозначает знакомый нам калибровочный потенциал. Впредь, до особого указания, под обозначением A_μ будем понимать A^M_μ. Из (1) видим, что ковариантная производная равна $D_\mu = \partial_\mu + A_\mu$. (Кстати, индексы M и P означают потенциал, появляющийся в математической и физической литературе соответственно.) Как и раньше, введем матричную 1-форму $A = A_\mu dx^\mu$, т. е. форму, являющуюся, к тому же, матрицей в фундаментальном представлении алгебры Ли [например, для $SU(N)$ эрмитовой матрицей $N \times N$ с нулевым следом]. Обратите внимание, что

$$A^2 = A_\mu A_\nu dx^\mu dx^\nu = \frac{1}{2}\left[A_\mu, A_\nu\right] dx^\mu dx^\nu$$

не равно нулю для неабелева калибровочного потенциала. (Очевидно, что в электродинамике такого объекта нет.)

Наша задача - получить 2-форму $F = \frac{1}{2}F_{\mu\nu}dx^\mu dx^\nu$ из 1-формы A. Воспользуемся прямым методом. Из A можно получить лишь две возможные 2-формы: dA и A^2. Таким образом, F должна быть линейной комбинацией этих двух форм.

В наших обозначениях закон преобразования (2) сводится к виду:

$$A \to UAU^\dagger + UdU^\dagger$$

где U – 0-форма (и, следовательно, $dU^\dagger = \partial_\mu U^\dagger dx^\mu$). Действуя на (6) оператором d, получаем:

$$dA \to UdAU^\dagger + dUAU^\dagger - UAdU^\dagger + dUdU^\dagger$$

Обратите внимание на знак минус перед третьим членом. С другой стороны, возводя (6) в квадрат, получаем:

$$A^2 \to UA^2U^\dagger + UAdU^\dagger + UdU^\dagger UAU^\dagger + UdU^\dagger UdU^\dagger$$

Действуя на $UU^\dagger = 1$ оператором d, получаем $UdU^\dagger = -dUU^\dagger$. Поэтому можно переписать (8) в виде:

$$A^2 \to UA^2U^\dagger + UAdU^\dagger - dUAU^\dagger - dUdU^\dagger$$

Внимание! Если сложить (7) и (9), шесть членов взаимно сократятся, и у нас останется нечто очень простое:

$$dA + A^2 \to U\left(dA + A^2\right)U^\dagger$$

Математическая структура, таким образом, привела Янга и Миллса к следующему определению напряженности поля:

$$F = dA + A^2$$

В отличие от A, 2-форма напряженности поля F преобразуется однородно:

$$F \to UFU^\dagger$$

В абелевом случае A^2 исчезает, и выражение для F сводится к обычному электромагнитному виду. В неабелевом случае F не калибровочно инвариантна, но калибровочно ковариантна. Конечно, вы можете построить $F^a_{\mu\nu}$, без использования дифференциальных форм. В качестве упражнения проделайте это, начав с выражения (4). После этого вы оцените по достоинству дифференциальные формы! Мы должны ценить дифференциальные формы, по крайней мере как изящное компактное обозначение, позволяющее опустить индексы a и μ в выражении (4). В то же время тот факт, что (11) возникает так естественно, очевидно означает, что в основе лежит глубокая математическая структура. Действительно, существует взаимно-однозначное соответствие между языком физика, рассуждающего в терминах калибровочной теории, и языком математика, рассуждающего в терминах расслоений.

К формуле (11) можно прийти другим путем. По аналогии с оператором d определим оператор $D = d + A$, действующий на форму слева. Вычислим

$$D^2 = (d + A)(d + A) = d^2 + dA + Ad + A^2.$$

Первый член равен нулю, второй можно записать в виде $dA = (dA) - Ad$; круглые скобки обозначают, что d действует только на A. Таким образом,

$$D^2 = (dA) + A^2 = F$$

Ловко, не правда ли? Я оставляю вам в качестве упражнения показать, что D^2 преобразуется однородно и, следовательно, также преобразуется F.

Несмотря на то что дифференциальные формы очень изящны, в физике часто бывает желательно использовать более явные формулы. Выражение (11) можно переписать в виде:

$$F = \left(\partial_\mu A_\nu + A_\mu A_\nu\right) dx^\mu dx^\nu = \frac{1}{2}\left(\partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu]\right) dx^\mu dx^\nu.$$

Если определить $F \equiv \frac{1}{2} F_{\mu\nu} dx^\mu dx^\nu$, получим:

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + [A_\mu, A_\nu]$$

Здесь можно вернуться к физической системе обозначений. Вспомним, что A_μ в выражении (15) фактически представляет собой $A_\mu^M \equiv -iA_\mu^P$, поэтому по аналогии определим $F_{\mu\nu} = -iF_{\mu\nu}^P$. Получим:

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu - i\,[A_\mu, A_\nu]$$

где A_μ теперь и впредь обозначает A_μ^P. (В выражении (16) необходимо использование i по той причине, что физики любят выражать A_μ эрмитовой матрицей, а коммутатор двух эрмитовых матриц является антиэрмитовым.)

Мы можем сделать формулы еще более явными, выписав групповые и лоренцевы индексы. По аналогии с $A_\mu = A_\mu^a T^a$ запишем $F_{\mu\nu} = F_{\mu\nu}^a T^a$. Тогда (16) сводится к виду:

$$F_{\mu\nu}^a = \partial_\mu A_\nu^a - \partial_\nu A_\mu^a + f^{abc} A_\mu^b A_\nu^c.$$

Я уже говорил, что для $SU(2) A$ и F преобразуются как векторы, а структурная константа f^{abc} равна ε^{abc}, поэтому в этом случае часто используется векторное обозначение $\vec{F}_{\mu\nu} = \partial_\mu \vec{A}_\nu - \partial_\nu \vec{A}_\mu + \vec{A}_\mu \times \vec{A}_\nu$.

Лагранжиан Янга-Миллса

С учетом того что F преобразуется однородно (12), мы можем сразу записать аналог лагранжиана Максвелла, называемый лагранжианом ЯнгаМиллса

$$\mathcal{L} = -\frac{1}{2g^2} \operatorname{tr} F_{\mu\nu} F^{\mu\nu}$$

Мы нормируем $T^a \operatorname{tr} T^a T^b = \frac{1}{2}\delta^{ab}$, так что $\mathcal{L} = -(1/4g^2)\, F_{\mu\nu}^a F^{a\mu\nu}$. Теория, описываемая этим лагранжианом известна, как чистая теория ЯнгаМиллса, или неабелева калибровочная теория.

Помимо квадратичного члена $\left(\partial_\mu A_\nu^a - \partial_\nu A_\mu^a\right)^2$, лагранжиан $\mathcal{L} = -(1/4g^2)\, F_{\mu\nu}^a F^{a\mu\nu}$ также содержит кубический член $f^{abc} A^{b\mu} A^{c\nu} \left(\partial_\mu A_\nu^a - \partial_\nu A_\mu^a\right)$ и член четвертой степени $\left(f^{abc} A_\mu^a A_\nu^c\right)$. Как в электродинамке квадратичный член описывает распространение безмассового векторного бозона, несущего внутренний индекс a и называемого неабелевым калибровочным бозоном, или бозоном Янга-Миллса. Члены третьей и четвертой степеней, отсутствующие в электродинамике, описывают самодействие неабелева калибровочного бозона. На рис. IV.5.1a,b,c приведены соответствующие диаграммы Фейнмана.

Несложно понять физику, стоящую за этим самодействием бозонов Янта-Миллса. Фотон взаимодействует с заряженными полями, хотя сам не является заряженным. Подобно тому, как по заряду поля можно говорить о характере преобразования поля относительно калибровочной группы $U(1)$, аналогом заряда поля в неабелевой калибровочной теории является то, к какому представлению поле принадлежит. Бозоны Янга-Миллса взаимодействуют со всеми полями, нетривиально преобразующимися относительно калибровочной группы. Однако бозоны Янга-Миллса сами по себе преобразуются нетривиально: мы уже говорили, что они преобразуются по присоединенному представлению. Получается, что они должны взаимодействовать сами с собой.

Чистая теория Максвелла является свободной и, по существу, элементарной. Она описывает невзаимодействующий фотон. Теория ЯнгаМиллса, напротив, содержит самодействие, поэтому ее никак нельзя назвать элементарной. Обратите внимание, что структурные коэффициенты f^{abc} полностью фиксируются теорией групп, поэтому, в отличие от теории скалярного поля, самодействия калибровочных бозонов третьей и четвертой степени, включая их относительные величины, полностью фиксируются

симметрией. Если можно точно решить какую-нибудь 4-мерную теорию поля, она может оказаться чистой теорией Янга-Миллса. Но, несмотря на все колоссальные усилия теоретиков, она остается нерешенной (см. главы VII.3 и VII.4).

Рис. IV.5.1

Формализм двойных линий 't Хоофта

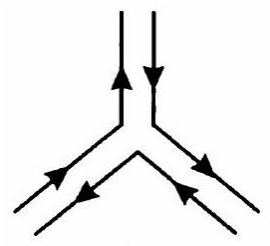
Хотя для многих целей удобно пользоваться компонентными полями A^a_μ, матричное поле $A_\mu = A^a_\mu T^a$ более изящным образом реализует математическую структуру неабелевой калибровочной теории. Пропагато- ры компонент матричного поля в калибровочной теории $U(N)$ имеют вид:

$$\begin{aligned}&\left\langle 0\left|TA_\mu(x)^i_j A_\nu(0)^k_l\right|0\right\rangle = \\ &= \left\langle 0\left|TA^a_\mu(x)A^b_\nu(0)\right|0\right\rangle (T^a)^i_j \left(T^b\right)^k_l \propto \\ &\propto \delta^{ab}\,(T^a)^i_j \left(T^b\right)^k_l \propto \delta^i_l \delta^k_j.\end{aligned}$$

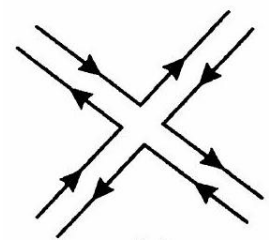
Матричная структура $A^i_{\mu j}$ естественным образом побуждает нас, вслед за 't Хоофтом, ввести формализм двойных линий, в котором калибровочный потенциал описывается двумя линиями, каждая из которых соответствует одному из двух индексов i или j. Пусть верхний индекс входит в диаграмму, а нижний индекс - выходит из диаграммы. На рис. IV.5.2a изображен пропагатор из (19). Формализм двойных линий позволяет нам естественным образом представить структуру индексов $\delta^i_l \delta^k_j$. На рис. IV.5.2b,c изображены взаимодействия третьей и четвертой степеней.

Константа g, введенная в (18), известна как константа связи ЯнгаМиллса. Мы всегда можем написать квадратичный член в (18) в нормировке, обычно используемой в электродинамике, тривиально переопределяя $A \to gA$. После этого взаимодействия третьей и четвертой степеней для бозона Янга-Миллса будут пропорциональны g и g^2 соответственно. Ковариантная производная в (1) принимает вид $D_\mu\varphi = \partial_\mu\varphi - igA_\mu\varphi$, из которого видно, что g характеризует также взаимодействие бозона ЯнгаМиллса с полем материи.

(a)



(b)



(c)
Рис. IV.5.2

Однако используемая нами нормировка, болсс явно раскрывает математическую структуру неабелевой калибровочной тсории. (18), g^2 характеризует легкость, с которой распространяется бозон Янга-Миллса. Из главы III.7 вспомним, что в электродинамике определение константы связи, как меры распространения, также считалось удобным. В главе VIII.1 мы увидим, что ньютоновская константа появляется таким же образом в действии Эйнштейна-Гильберта для гравитации.

θ-член

Помимо $\operatorname{tr} F_{\mu\nu}F^{\mu\nu}$, можно написать член, имеющий размерность 4 $\varepsilon^{\mu\nu\lambda\rho}\operatorname{tr} F_{\mu\nu}F_{\lambda\rho}$. Очевидно, что он нарушает инвариантность относительно обращения времени T и четности P, поскольку содержит единственный индекс для времени и три пространственных индекса. Позже мы увидим, что сильное взаимодействие описывается неабелевой калибровочной теорией, лагранжиан в которой содержит так называемый θ-член $(\theta/32\pi^2)\,\varepsilon^{\mu\nu\lambda\rho}\operatorname{tr} F_{\mu\nu}F_{\lambda\rho}$. В упражнении IV.5.3 вам предстоит показать, что этот член является полной производной и не влияет на уравнения движения. Тем не менее он индуцирует электрический дипольный момент для нейтрона. Максимальное экспериментальное ограничение сверху для электрического дипольного момента для нейтрона приводит к ограничению сверху на θ, которое порядка 10^{-9}. Не буду вдаваться в подробности, как специалисты в области физики элементарных частиц разрешают проблему малости значения θ или его полного зануления.

Взаимодействие с полями материи

Возьмем скалярное поле φ в фундаментальном представлении группы. В общем случае φ может преобразовываться в произвольном представлении $\mathcal{R}$ калибровочной группы G. Запишем ковариантную производную в виде:

$$D_\mu\varphi = \left(\partial_\mu - iA^a_\mu T^a_{(\mathcal{R})}\right)\varphi$$

где $T^a_{(\mathcal{R})}$ представляет собой a-ый генератор в представлении $\mathcal{R}$ (см. упражнение IV.5.1).

Очевидно, что для перевода глобально симметричной теории в локально симметричную теорию необходимо заменить обычную производную ∂_μ, действующую на любое поле (бозон или фермион), которое принадлежит представлению $\mathcal{R}$, ковариантной производной $D_\mu = \left(\partial_\mu - iA^a_\mu T^a_{(\mathcal{R})}\right)$. Таким образом, взаимодействие неабелева калибровочного потенциала с фермионным полем описывается лагранжианом

$$\mathcal{L} = \bar{\psi}\left(i\gamma^\mu D_\mu - m\right)\psi = \bar{\psi}\left(i\gamma^\mu\partial_\mu + \gamma^\mu A^a_\mu T^a_{(\mathcal{R})} - m\right)\psi$$

Поля, принадлежащие представлению $\mathcal{R}$, «слышат» калибровочные бозоны Янга-Миллса, а поля, принадлежащие тривиальному единичному представлению, не слышат зов калибровочных бозонов. В специальном случае калибровочной теории $U(1)$, известном как теория электромагнетизма, $\mathcal{R}$ соответствует электрическому заряду поля. Поля, преобразующиеся относительно $U(1)$ тривиально, являются электрически нейтральными.

Приложение

Рассмотрим появление структуры Янга-Миллса [2] в другом контексте, несколько необычном на первый взгляд. Рассмотрим уравнение Шредингера

$$i\frac{\partial}{\partial t}\Psi(t) = H(t)\Psi(t)$$

с зависящим от времени гамильтонианом $H(t)$. Будем придерживаться общего подхода: можно, например, говорить о спиновых состояниях в магнитном поле или об одночастичном нерелятивистском гамильтониане с волновой функцией $\Psi(\vec{x},t)$. Будем опускать в обозначении зависимость H и Ψ от всех переменных, кроме времени t.

Сначала решим задачу на собственные значения $H(t)$. Предположим, что вследствие симметрии или какой-либо другой причины, спектр $H(t)$ содержит n-кратное вырождение, другими словами, существует n различных решений уравнения $H(t)\psi_a(t) = E(t)\psi_a(t)$, где $a = 1, ..., n$. Обратите внимание, что $E(t)$ может изменяться с течением времени, но мы предполагаем, что вырождение сохраняется с течением времени, т. е. вырождение не может возникнуть «случайным образом» в какой-то момент времени. Всегда можно заменить $H(t)$ на $H(t) - E(t)$, поэтому с этого момента $H(t) = 0$. К тому же, состояния могут быть выбраны ортогональными, так что $\langle\psi_b(t)|\psi_a(t)\rangle = \delta_{ba}$. (Для ясности обозначений удобно переключаться между шредингеровскими и дираковскими обозначениями. Чтобы внести окончательную ясность, запишем

$$\langle\psi_b(t)|\psi_a(t)\rangle = \int d\vec{x}\psi^*_b(\vec{x},t)\psi_a(\vec{x},t)$$

для случая одночастичной квантовой механики.)

Теперь изучим уравнение (22) в адиабатическом пределе, т. е. примем, что временной масштаб, в котором меняется $H(t)$, гораздо больше, чем $1/\Delta E$, где ΔE - энергетическая щель между состояниями $\psi_a(t)$ и соселними с ними состояниями. Если в этом случае функция $\Psi(t)$ начинает эволюционировать в подпространстве, образованном состояниями $\{\psi_a(t)\}$, то она останстся в нем, поэтому можно записать $\Psi(t) = \sum_a c_a(t)\psi_a(t)$. Подставив это выраженис в уравнение (22), получим

"Wilczek and A. Zee. "Appearance of Gauge Structure in Simple Dynamical Systems." Phys. Rev. Lett. 52:2111. 1984. $\sum_a \left[\left(dc_a/dt\right)\psi_a(t) + c_a(t)\left(\partial\psi_a/\partial t\right)\right] = 0$. Если скалярно умножить на $\psi_b(t)$, придем к уравнению:

$$\frac{dc_b}{dt} = -\sum_a A_{ba}c_a$$

с матрицей $n \times n$

$$A_{ba}(t) \equiv \langle \psi_b(t)| \, \frac{\partial \psi_a}{\partial t}$$

Допустим, кто-то еще решает использовать другой базис, $\psi'_a(t) = U^*_{ac}(t) \, (\psi_c(t)$, связанный с нашим унитарным преобразованием. (Матрица, комплексно-сопряженная унитарной матрице U, нужна нам для того, чтобы наше окончательное уравнение совпадало по виду с уравнением, полученным ранее; см. далее.) Также я просуммировал члены с повторяющимися индексами. Дифференцируя, получаем $(\partial \psi'_a/\partial t) = U^*_{ac}(t) \, (\partial \psi_c/\partial t) + (dU^*_{ac}/dt) \, \psi_c(t)$. Сворачивая с $\psi'_b(t) = U_{bd}(t)\psi^*_d(t)$ и умножая иа i. ириходим к:

$$A' = UAU^\dagger + iU\frac{\partial U^\dagger}{\partial t}$$

Пусть гамильтониан $H(t)$ зависит от d параметров $\lambda^1, ..., \lambda^d$. Изменяем значения параметров, отмечая путь, задаваемый как $\{\lambda^\mu(t), \mu = 1, ..., d\}$, в d-мерном пространстве параметров. Например, для спинового гамильтониана λ^μ может соответствовать внешнему магнитному полю. Итак, выражение (23) сводится к виду:

$$\frac{dc_b}{dt} = -\sum_a (A_\mu)_{ba} \, c_a \frac{d\lambda^\mu}{dt}$$

если задать $(A_\mu)_{ba} \equiv i \, \langle \psi_b | \partial_\mu \psi_a \rangle$, где $\partial_\mu \equiv \partial/\partial\lambda^\mu$. В общем виде уравнение (25) будет следующим:

$$A'_\mu = UA_\mu U^\dagger + iU\partial_\mu U^\dagger$$

Оно совпадает с (IV.5.2). Вот так, на наших собственных глазах появляется калибровочный потенциал Янга-Миллса A_μ !

Уравнение «переноса» (26) можно формально решить, если записать $c(\lambda) = Pe^{-\int A_\mu d\lambda''}$, где одномерный интеграл берется по траектории, соединяющей начальную точку в пространстве параметров с некоторой конечной точкой λ, а P обозначает упорядочение вдоль пути. Разбиваем траекторию на бесконечно малые сегменты и перемножаем между собой некоммутирующие составляющие $e^{-A_{1\nu}\Delta\lambda^\mu}$ из каждого сегмента, упорядоченные вдоль траектории. В частности, если траектория явзяется замкнутой кривой, через некоторое время мы вернемся к начальным значениям параметров; волновая функция будет содержать матричный фазовый множитель, называемый неабелевой фазой Берри. Обратите внимание на тесную связь с фазой Ааронова-Бома из предыдущей главы.

Чтобы увидеть неабелеву фазу, все, что мы должны сделать, - это взять некоторую квантовую систему с вырожденностью в спектре и изменить какой-нибудь внешний параметр, например, магнитное поле [3]. В своей работе Янг и Миллс говорят о вырожденности протона и нейтрона с изоспином в идеализированном мире и рассматривают процесс переноса протона из одной точки Вселенной в другую. Чтобы была возможность интерпретировать протон в одной точке как нейтрон в другой, необходимо введение неабелева калибровочного потенциала. Разве не удивительно, что сейчас аналогичным образом можно в лабораторных условиях реализовать такой воображаемый перенос?

Теперь проведем параллель между текущими пояснениями и вышеизложенным в тексте материалом, когда было получено уравнение (IV.5.2). Зависящее от пространства-времени преобразование симметрии соответствует зависящему от параметра изменению базиса. Когда в главе VIII.1 речь пойдет о гравитации, вы увидите, что движение базиса $\{\psi_a\}$ в пространстве параметров аналогично параллельному переносу локальной системы координат в дифференциальной геометрии и общей теории относительности. В главе VII.1 мы снова столкнемся с величиной $Pe^{-\int A_\mu d\lambda'}$, под названием петли Вильсона.

Упражнения

IV.5.1. Запишите лагранжиан для $SU(2)$ калибровочной теории со скалярным полем в представлении $I = 2$.

IV.5.2. Докажите тождество Бьянки $DF \equiv dF + [A, F] = 0$. Запишите его в явном виде с использованием индексов и докажите, что в абелевом случае оно сводится к половине уравнений Максвелла.

IV.5.3. В четырех измерениях $\varepsilon^{\mu\nu\lambda\rho} \operatorname{tr} F_{\mu\nu} F_{\lambda\rho}$ можно записать как $\operatorname{tr} F^2$. Покажите, что в любом числе измерений $d \operatorname{tr} F^2 = 0$.

IV.5.4. Используя лемму Пуанкаре (IV.4.5) и результат упражнения IV.5.3, покажите, что $F^2 = d \operatorname{tr}\left(AdA + \frac{2}{3}A^3\right)$. Запишите его в явном виде с индексами. Определите эти величины в случае электродинамики.

IV.5.5. Попытаетесь показать, что все $\operatorname{tr} F^n$, которые появляются в теориях более высокой размерности (например, теории струн), являются полными производными. Другими словами, существует $(2\pi - 1)$-форма $\omega_{2n-1}(A)$, такая что $\operatorname{tr} F^n = d\omega_{2n-1}(A)$. [Указание: существует краткая запись формы $\omega_{2n-1}(A) = \int\limits_0^1 dt f_{2n-1}(t, A)$.] Запишите в явном виде выражение для $\omega_5(A)$ и попробуйте обобщить его, зная ω_3 и ω_5. Найдите $(2n-1)$-форму $f_{2n-1}(t, A)$. За помощью обращайтесь к работе B. Zumino et al., Nucl. Phys. B239:477, 1984.

IV.5.6. Запишите лагранжиан для калибровочной теории $SU(3)$ с фермионным полем в фундаментальном триплетном представлении.

[3] A. Zee. "On the Non-Abelian Gauge Structure in Nuclear Quadrupole Resonanse." Phvs. Rev. A38:1, 1988. Позже предложенный эксперимент провел Л. Пайнс.

30.1.6 Zi.IV.6 Anderson-Higgs Mechanism

Калибровочный потенциал поглощает намбу-голдстоуновский бозон

Как я уже говорил, в физике принципиально важной является способность задавать хорошие вопросы. Вот отличный вопрос: как проявляется спонтанное нарушение симметрии в калибровочных теориях?

Возвращаясь к главе IV.1, прокалибруем теорию $U(1)$ в (IV.1.6), заменяя $\partial_\mu\varphi$ на $D_\mu\varphi = (\partial_\mu - ieA_\mu)\,\varphi$, так что

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + (D\varphi)^\dagger D\varphi + \mu^2\varphi^\dagger\varphi - \lambda\left(\varphi^\dagger\varphi\right)^2$$

При переходе к полярным координатам $\varphi = \rho e^{i\theta}$ получим $D_\mu\varphi = [\partial_\mu\rho + \ + i\rho\,(\partial_\mu\theta - eA_\mu)]\,e^{i\theta}$ и, таким образом

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \rho^2\,(\partial_\mu\theta - eA_\mu)^2 + (\partial\rho)^2 + \mu^2\rho^2 - \lambda\rho^4.$$

(Сравните с лагранжианом $\mathcal{L} = \rho^2\,(\partial_\mu\theta)^2 + (\partial\rho)^2 + \mu^2\rho^2 - \lambda\rho^4$ для случая, когда отсутствует калибровочное поле.) При калибровочном преобразовании $\varphi \to e^{i\alpha}\varphi$ (так что $\theta \to \theta + \alpha$) и $eA_\mu \to eA_\mu + \partial_\mu\alpha$, поэтому комбинация $B_\mu \equiv A_\mu - (1/e)\partial_\mu\theta$ является калибровочно-инвариантной. Значит, первые два члена в $\mathcal{L}$ сводятся к виду $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + e^2\rho^2B_\mu^2$. Обратите внимание, что в терминах поля B_μ выражение для $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu = \partial_\mu B_\nu - \partial_\nu B_\mu$ имеет аналогичную форму.

При спонтанном нарушении симметрии запишем $\rho = (1/\sqrt{2})(v + \chi)$, где $v = \sqrt{\mu^2/\lambda}$. Следовательно,

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}M^2B_\mu^2 + e^2v\chi B_\mu^2 + \frac{1}{2}e^2\chi^2B_\mu^2 + \\ + \frac{1}{2}(\partial\chi)^2 - \mu^2\chi^2 - \sqrt{\lambda}\mu\chi^3 - \frac{\lambda}{4}\chi^4 + \frac{\mu^4}{4\lambda}.$$

Теперь теория состоит из векторного поля B_μ массой

$$M = ev$$

взаимодействующего со скалярным полем χ массой $\sqrt{2}\mu$. Фаза θ, которая стала бы намбу-голдстоуновским бозоном в некалиброванной теории, исчезла. Мы говорим, что калибровочное поле A_μ поглотило намбуголдстоуновский бозон; оно приобрело массу и изменило обозначение на B_μ.

Вспомним, что безмассовое калибровочное поле имеет всего 2 степени свободы, тогда как массивное калибровочное поле - 3 степени свободы. Безмассовое калибровочное поле должно поглотить намбуголдстоуновский бозон, чтобы приобрести необходимое количество степеней свободы. Намбу-голдстоуновский бозон становится продольной степенью свободы массивного калибровочного поля. Мы не теряем ни одну степень свободы, что радует.

Явление превращения безмассового калибровочного поля в массивное за счет поглощения намбу-голдстоуновского бозона носит название механизма Хиггса. Его открыли специалисты в области физики элементарных частиц'. Поле Хиггса обозначают как φ или реже χ. Аналогичное явление было открыто в физике конденсированных сред Ландау, Гинзбургом и Андерсоном - и стало известно как механизм Андерсона.

Приведем более сложный пример. Рассмотрим калибровочную теорию $O(3)$ с полем Хигтса $\varphi^a (a = 1, 2, 3)$, преобразующимся в векторном представлении. Лагранжиан содержит член кинетической энергии $\frac{1}{2}\left(D_\mu\varphi^a\right)^2$, где $D_\mu\varphi^a = \partial_\mu\varphi^a + g\varepsilon^{abc}A_\mu^b\varphi^c$ согласно (IV.5.20). При спонтанном нарушении симметрии $\vec{\varphi}$ получает среднее вакуумное значение, которое мы можем выбрать совпадающим с третьим направлением, так что $\langle\varphi^a\rangle = v\delta^{a3}$. Задаем $\varphi^3 = v$ и видим, что

$$\frac{1}{2}\left(D_\mu\varphi^a\right)^2 \to \frac{1}{2}(gv)^2\left(A_\mu^1A^{\mu 1} + A_\mu^2A^{\mu 2}\right)$$

Калибровочные поля A_μ^1 и A_μ^2 приобретают массу gv [сравните с (4)], тогда как поле A_μ^3 остается безмассовым.

Еще более сложный пример - калибровочная теория $SU(5)$ с полем φ, в 24-мерном присоединенном представлении. (См. в приложении В необходимые сведения из теории групп.) Поле φ представляет собой эрмитову

' Включая Хиггса. Энглерта. Броута, Гуралника. Хагена и Киббла. бесследовую матрицу 5×5. Поскольку присоединенное представление преобразуется как $\varphi \to \varphi + i\theta^a\left[T^a, \varphi\right]$, получаем $D_\mu\varphi = \partial_\mu\varphi - igA_\mu^a\left[T^a, \varphi\right] (a = 1, ..., 24$ пробегает по 24 генераторам группы $SU(5))$. Вследствие преобразования симметрии, вакуумное значение φ можно выбрать диагональным $\left\langle\varphi_j^i\right\rangle = v_j\delta_j^i (i, j = 1, ..., 5)$, где $\sum\limits_j v_j = 0$. (Это аналогично нашему выбору $\langle\vec{\varphi}\rangle$ вдоль третьей оси в предыдущем примере.) В лагранжиане имеем

$$\operatorname{tr}\left(D_\mu\varphi\right)\left(D^\mu\varphi\right) \to g^2\operatorname{tr}\left[T^a, \langle\varphi\rangle\right]\left[\langle\varphi\rangle, T^b\right]A_\mu^aA^{\mu b}.$$

Квадраты массы калибровочных бозонов совпадают с собственными значениями 24×24-матрицы, $g^2\operatorname{tr}\left[T^a, \langle\varphi\rangle\right]\left[\langle\varphi\rangle, T^b\right]$, которые можно, потрудившись, вычислить для любого заданного $\langle\varphi\rangle$.

Легко увидеть, однако, какие калибровочные бозоны остаются безмассовыми. В качестве характерного примера (который будет представлять для нас интерес в главе VII.6) рассмотрим поле

$$\langle\varphi\rangle = v\begin{pmatrix} 2 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 0 & 0 & -3 \end{pmatrix}.$$

Какие из генераторов T^a коммутируют с $\langle\varphi\rangle$? Ясно, что это делают генераторы вида $\begin{pmatrix} A & 0 \\ 0 & 0 \end{pmatrix}$ и $\begin{pmatrix} 0 & 0 \\ 0 & B \end{pmatrix}$. Здесь A обозначает эрмитовы матрицы 3×3 с нулевым следом (из которых $3^2-1=8$ так называемых матриц Гелл-Манна), а B обозначает эрмитовы матрицы 2×2 с нулевым следом (из которых $2^2-1=3$ так называемых матриц Паули). Более того, генератор

$$\begin{pmatrix} 2 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 0 & 0 & -3 \end{pmatrix}$$

пропорционален $\langle\varphi\rangle$ и, следовательно, коммутирует с $\langle\varphi\rangle$. Очевидно, что эти генераторы образуют группы $SU(3), SU(2)$ и $U(1)$ соответственно. Таким образом, в матрице 24×24 из квадратов массы $g^2\,\mathrm{tr}\,[T^a,\langle\varphi\rangle]\left[\langle\varphi\rangle,T^b\right]$ выделяются зануляющиеся блоки, а именно блок 8×8, блок 3×3 и блок 1×1. Получаем $8+3+1=12$ безмассовых калибровочных бозонов. Оставшиеся $24-12=12$ калибровочных бозонов получают массу.

Подсчет безмассовых калибровочных бозонов

Рассмотрим теорию с глобальной группой симметрии G, спонтанно нарушенной в подгруппу H. Из главы IV.1 мы знаем, что появляются $n(G)-n(H)$ намбу-голдстоуновских бозонов. Теперь допустим, что группа симметрии G калибруется. Начнем с $n(G)$ безмассовых калибровочных бозонов, по одному на каждый генератор. При спонтанном нарушении симметрии $n(G)-n(H)$ намбу-голдстоуновских бозонов поглощается $n(G)$ - $-n(H)$ калибровочными бозонами, в результате чего $n(H)$ калибровочных бозонов остаются безмассовыми. Похоже, полученное число является верным, поскольку связанные с выжившей калибровочной группой H калибровочные бозоны должны остаться безмассовыми.

В первом нашем примере $G=U(1), H=$ отсутствует: $n(G)=1$ и $n(H)=0$. Во втором примере $G=O(3), H=O(2)\simeq U(1): n(G)=3$ и $n(H)=1$, так что остается один безмассовый калибровочный бозон. В третьем примере $G=SU(5), H=SU(3)\otimes SU(2)\otimes U(1)$, так что $n(G)=24$ и $n(H)=12$. Другие примеры и обобщения предложены в качестве упражнений.

Спектр масс калибровочного бозона

Довольно легко проанализировать в явном виде спектр масс. Ковариантная производная поля Хиггса равна $D_\mu\varphi=\partial_\mu\varphi+gA^a_\mu T^a\varphi$, где g - калибровочная константа связи, T^a - генераторы группы G при действии на φ, а A^a_μ - калибровочный потенциал, соответствующий a-ому генератору. При спонтанном нарушении симметрии мы заменяем φ его вакуумным средним значением $\langle\varphi\rangle=v$. В результате член $D_\mu\varphi$ заменяется выражением $gA^a_\mu T^a v$. Кинетический член $\frac{1}{2}\left(D^\mu\varphi\cdot D_\mu\varphi\right)$ [здесь $(\cdot)$ обозначает скалярное произведение в группе G] в лагранжиане сводится к виду:

$$\frac{1}{2}g^2\left(T^a v\cdot T^b v\right)A^{\mu a}A^b_\mu\equiv\frac{1}{2}A^{\mu a}\left(\mu^2\right)^{ab}A^b_\mu,$$

где мы ввели матрицу квадратов массы

$$\left(\mu^2\right)^{ab} = g^2 \left(T^a v \cdot T^b v\right)$$

для калибровочных бозонов. [Выражение (9) является обобщением (4); сравните также (5) и (6).] Чтобы найти массы калибровочных бозонов, необходимо диагонализовать $\left(\mu^2\right)^{ab}$. По собственным векторам можно сказать, какие линейные комбинации A^a_μ соответствуют массивным собственным состояниям. Обратите внимание, что μ^2 является матрицей $n(G) \times n(G)$ с $n(H)$ нулевыми собственными значениями, существование которых можно установить явным образом. Пусть T^c - генератор H. Утверждение, согласно которому H не нарушается вакуумным средним значением v, соответствует случаю, при котором v остается инвариантным относительно преобразования симметрии, с генератором T^c. Другими словами, $T^c v = 0$ и, следовательно, калибровочный бозон, связанный с T^c, остается безмассовым. Все эти выводы очевидны в рассмотренном нами $SU(5)$ примере.

Правила Фейнмана в спонтанно нарушенных калибровочных теориях

Несложно сформулировать правила Фейнмана для спонтанно нарушснных калибровочных теорий. Возьмем, например, лагранжиан (3). Как обычно, найдем в нем члены второго порядка, преобразуем их по Фурье и обратим. Видим, что пропагатор калибровочного бозона задается выражением

$$\frac{-i}{k^2 - M^2 + i\varepsilon}\left(g_{\mu\nu} - \frac{k_\mu k_\nu}{M^2}\right)$$

а пропагатор χ - выражением

$$\frac{i}{k^2 - 2\mu^2 + i\varepsilon}$$

Попробуйте самостоятельно вывести правила для вершин взаимодействия. Как я уже говорил по другому поводу, теории поля часто существуют в нескольких эквивалентных формах. Возьмем теорию $U(1)$ в (1) и вместо полярных координат перейдем к декартовым $\varphi = (1/\sqrt{2})\,(\varphi_1 + i\varphi_2)$. Получим:

$$D_\mu\varphi = \partial_\mu\varphi - ieA_\mu\varphi = \frac{1}{\sqrt{2}}\left[\left(\partial_\mu\varphi_1 + eA_\mu\varphi_2\right) + i\left(\partial_\mu\varphi_2 - eA_\mu\varphi_1\right)\right]$$

Тогда (1) сводится к виду:

$$\begin{aligned}\mathcal{L} = &-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}\left[\left(\partial_\mu\varphi_1 + eA_\mu\varphi_2\right)^2 + \left(\partial_\mu\varphi_2 - eA_\mu\varphi_1\right)^2\right] + \\ &+ \frac{1}{2}\mu^2\left(\varphi_1^2 + \varphi_2^2\right) - \frac{1}{4}\lambda\left(\varphi_1^2 + \varphi_2^2\right).\end{aligned}$$

Спонтанное нарушение симметрии означает, что $\varphi_1 \to v + \varphi_1'$, где $v = \sqrt{\mu^2/\lambda}$

Физический смысл (12) и (3) должен быть одинаковым. Действительно, разложим лагранжиан (12) до второго порядка по полям:

$$\begin{aligned}\mathcal{L} = \frac{\mu^4}{4\lambda} - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}M^2A_\mu^2 - MA_\mu\partial^\mu\varphi_2 + \frac{1}{2}\left[\left(\partial_\mu\varphi_1'\right)^2 - 2\mu^2\varphi_1'\right] + \\ + \frac{1}{2}\left(\partial_\mu\varphi_2\right)^2 + \ldots\end{aligned}$$

Спектр - калибровочный бозон A массой $M = ev$ и скалярный бозон φ_1' массой $\sqrt{2}\mu$ совпадает со спектром в (3). (Там частицы обозначались как B и χ.

Однако вы могли заметить нечто очень странное: появление члена $-MA_\mu\partial^\mu\varphi_2$, который смешивает поля A_μ и φ_2. К тому же, возникает вопрос, почему вообще продолжает существовать поле φ_2? Разве его не должны были поглотить? Что делать?

Конечно, можно прибегнуть к диагонализации, но гораздо удобнее совсем избавиться от смешанного члена. Применяя квантование калибровочных теорий Фаддеева-Попова, рассмотренное нами в главе III.4, приходим к выводу, что член, фиксирующий калибровку, обуславливает введение в лагранжиан $\mathcal{L}$ дополнительного члена. Если калибровочную функцию принять равной $f(A) = \partial A + \xi ev\varphi_2 - \sigma$, то нежелательный для нас смешанный член сократится. В конечном итоге получим лагранжиан $\mathcal{L}_{\text{эфф.}} = \mathcal{L} - (1/2\xi)\left(\partial A + \xi M\varphi_2\right)^2$ [сравните с (III.4.7)]. Теперь нежелательный член $-MA_\mu\partial^\mu\varphi_2$ в лагранжиане $\mathcal{L}$ сокращается после интегрирования по частям. В $\mathcal{L}_{\text{эфф.}}$ члены второго порядка по A принимают вид $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}M^2A_\mu^2 - (1/2\xi)(\partial A)^2$, тогда как члены второго порядка по φ_2 равны $\frac{1}{2}\left[\left(\partial_\mu\varphi_2\right)^2 - \xi M^2\varphi_2^2\right]$. С учетом этого пропагатор калибровочного бозона будет иметь вид:

$$\frac{-i}{k^2 - M^2 + i\varepsilon}\left[g_{\mu\nu} - (1-\xi)\frac{k_\mu k_\nu}{k^2 - \xi M^2 + i\varepsilon}\right]$$

а пропагатор φ_2 - вид:

$$\frac{i}{k^2 - \xi M^2 + i\varepsilon}$$

Это однопараметрическое семейство калибровок называют R_ξ-калибровкой. Обратите внимание, что хотя голдстоуновское поле φ_2 остается в лагранжиане, но сам факт, что его масса зависит от параметра калибровки ξ, делает его нефизическим. В любом физическом процессе зависимость пропагаторов φ_2 и A от параметра ξ должна сокращаться, чтобы физическая амплитуда оставалась независимой от ξ. В упражнении IV.6.9 на простом примере мы проверим, что это действительно так.

Разные преимущества у разных калибровок

Вы, должно быть, удивляетесь, зачем прибегать к R_ξ-калибровке, когда можно воспользоваться эквивалентной формулировкой теории (3), известной под названием унитарной калибровки? В унитарной калибровке пропагатор калибровочного бозона (10) имеет гораздо более простой вид, по сравнению с выражением (14), и мы не встречаемся с нефизическим полсм φ_2. Причина в том, что R_ξ-калибровка и унитарная калибровка дополняют друг друга. В R_ξ-калбировке пропагатор калибровочного бозона (14) при больших значениях k ведет себя как $1/k^2$, так что легко доказать перенормируемость теории. С другой стороны, для унитарной калибровки все поля являются физическими (потому ее и называют «унитарной»), но пропагатор калибровочного бозона (10) при больших значениях k пропорционален $k_\mu k_\nu/k^2$; для доказательства перенормируемости мы должны показать, что $k_\mu k_\nu$ в пропагаторе не вносит вклада. Используя обе калибровки, легко доказать как перенормируемость, так и унитарность теории. Кстати, в пределе $\xi \to \infty$ выражение (14) стремится к (10), а поле φ_2 исчезает, по крайней мере формально.

В практических вычислениях приходится иметь дело с большим количеством диаграмм. В R_ξ-калибровке параметр ξ должен изчезнуть в выражении для физической амплитуды на массовой поверхности. R_ξ-калибровка столь популярна именно потому, что это требование обеспечивает мощную проверку практических вычислений.

Ранее отмечалось, что, строго говоря, калибровочная инвариантность не является симметрией, а отражает избыточность используемых степеней свободы. (У фотона всего две степени свободы, но мы используем поле A_μ с четырьмя компонентами.) В том же духе можно утверждать, что не существует такой вещи, как спонтанное нарушение калибровочной симметрии. Напомню, что спонтанное нарушение симметрии означает, что $\rho \equiv |\varphi|$ равно v, а $\theta - 0$ в уравнении (2). Условие $|\varphi| = v$ является инвариантным относительно $U(1)$, поскольку определяет окружность в пространстве φ. Выбирая на окружности точку $\theta = 0$ в теории с глобальной симметрией, мы нарушаем эту симметрию.

В калибровочной теории, напротив, мы можем использовать калибровочную свободу, чтобы фиксировать $\theta = 0$ в любой точке пространства-времени. Отсюда и невозможность спонтанного нарушения калибровочной симметрии. Я не буду столь педантичен в этой книге и продолжу использовать удобный язык нарушения симметрии даже в калибровочной теории.

Упражнения

IV.6.1. Рассмотрим $SU(5)$ калибровочную теориюо с полем Хиггса φ, преобразующимся по 5-мерному представлению: $\varphi^i, i = 1, 2, ..., 5$. Покажите, что вакуумное среднее φ нарушает $SU(5)$ до $SU(4)$. Затем введите дополнительное поле Хиггса φ', также преобразующееся как 5-мерное представление. Покажите, что $SU(4)$ симметрия либо сохраняется, либо нарушается до $SU(3)$.

IV.6.2. В общем случае может существовать несколько полей Хиггса, принадлежащих разным представлениям α. Покажите, что матрица квадратов массы для калибровочного бозона в общем виде равна $(\mu^2)^{ab} = \sum_\alpha g^2 \left(T^a_\alpha v_\alpha \cdot T^b_\alpha v_\alpha\right)$, где v_α - вакуумное среднее поля φ_α, а $T^a_\alpha - a$-ый генератор, в представлении φ_α. Объедините случаи из упражнений IV.6.1 и IV.6.2 и получите спектр масс калибровочных бозонов.

IV.6.3. Калибровочная группа G не обязана быть простой; она может иметь вид $G_1 \otimes G_2 \otimes ... \otimes G_k$ с константами связи $g_1, g_2, ..., g_k$. Рассмотрите случай $G = SU(2) \otimes U(1)$, когда поле Хиггса φ преобразуется как дублет относительно $SU(2)$ и как поле с зарядом $\frac{1}{2}$ относительно $U(1)$, так что $D_\mu\varphi = \partial_\mu\varphi - i\left[gA^a_\mu(\tau^a/2) + g'B_\mu\frac{1}{2}\right]\varphi$. Пусть $\langle\varphi\rangle = \begin{pmatrix} o \\ v \end{pmatrix}$. Найдите линейные комбинации калибровочных бозонов A^a_μ и B_μ, которые приобретают массу.

IV.6.4. В главе IV.5 вы работали с калибровочной теорией $SU(2)$, со скалярным полем φ в представлении $I = 2$. Запишите наиболее общее выражение для потенциала $V(\varphi)$ четвертой степени и проанализируйте возможную схему нарушения симметрии.

IV.6.5. Завершите вывод правил Фейнмана для теории (3) и вычислите амплитуду для физического процесса $\chi + \chi \to B + B$.

IV.6.6. Выведите (14). [Указание: процедура аналогична выводу уравнения (III.4.9).] Запишите $\mathcal{L} = \frac{1}{2}A_\mu Q^{\mu\nu}A_\nu$, где $Q^{\mu\nu} = (\partial^2 + M^2)\,g^{\mu\nu} - [1 - (1/\xi)]\partial^\mu\partial^\nu$ или, в импульсном пространстве, $Q^{\mu\nu} = -\left(k^2 - M^2\right)g^{\mu\nu} + [1 - (1/\xi)]k^\mu k^\nu$. Пропагатор есть обратный к $Q^{\mu\nu}$.

IV.6.7. Получите (...) в (13) и правила Фейнмана для разных вершин взаимодействия.

IV.6.8. Используя правила Фейнмана из упражнения IV.6.8, вычислите амплитуду для физического процесса $\varphi'_1 + \varphi'_1 \to A + A$ и покажите, что зависимость от ξ сокращается. Сравните с результатом упражнения IV.6.6. [Указание: есть две диаграммы, одна с обменом A, а другая с обменом φ_2.] IV.6.9. Рассмотрите теорию, задаваемую в (12), при $\mu = 0$. Основываясь на результатах упражнения IV.3.5, покажите, что

$$V_{3\phi.}(\varphi) = \frac{1}{4}\lambda\varphi^4 + \frac{1}{64\pi^2}\left(10\lambda^2 + 3e^4\right)\varphi^4\left(\log\frac{\varphi^2}{M^2} - \frac{25}{6}\right) + ...$$

где $\varphi^2 = \varphi_1^2 + \varphi_2^2$. Минимальное значение данного потенциала находится вне точки $\varphi = 0$, поэтому калибровочная симметрия спонтанно нарушается квантовыми флуктуациями. В главе IV.3, где у нас не было члена e^4, мы показали, что полученному значению минимума нельзя доверять. Теперь мы можем компенсировать $\lambda\varphi^4$ членом $e^4\varphi^4\log(\varphi^2/M^2)$ для λ того же порядка, что и e^4. Найденному минимуму можно доверять. Покажите, что спектр этой теории содержит массивный скалярный бозон и массивный векторный бозон, такие что

$$\frac{m^2\ (\text{скалярн.})}{m^2\ (\text{векторн.})} = \frac{3}{2\pi}\frac{e^2}{4\pi}.$$

30.1.7 Zi.IV.7 Chiral Anomaly (????)

Классическая симметрия против квантовой симметрии

Я уже подчеркивал, насколько важно задавать хорошие вопросы. Вот очередной: всегда ли симметрия в классической физике является симметрией в квантовой физике?

О симметрии в классической физике мы говорим тогда, когда действие $S(\varphi)$ остается инвариантным относительно преобразования $\varphi \to \varphi + +\delta\varphi$. О симметрии в квантовой физике мы говорим тогда, когда преобразование оставляет интеграл по траекториям $\int D\varphi e^{iS(\varphi)}$ инвариантным.

Если сформулировать наш вопрос в терминах интеграла по траекториям, то ответ кажется очевидным: не обязательно. Действительно, мера $D\varphi$ может быть, а может и не быть инвариантной.

Исторически теоретики-полевики считали почти самоочевидным, что любая симметрия в классической физике с необходимостью является симметрией в квантовой физике. Почти все симметрии, о которых было известно физикам на раннем этапе развития теории поля, оставались симметриями как классической, так и квантовой физики. Например, квантовую механику мы, естественно, считаем инвариантной относительно вращения. Было бы очень странно, если бы квантовые флуктуации выбирали себе определенное направление.

Теперь представьте себе, каким шоком в конце 1960-х гг. послужило для теоретиков-полевиков открытие, согласно которому квантовые флуктуации на самом деле могут нарушать классические симметрии. Они были настолько шокированы, что ошибочно назвали данное явление «аномалией». Оглядываясь назад, мы понимаем, что аномалия не представляет собой никакого концептуального вреда и что, изменяя в интеграле переменные интегрирования, мы просто не должны забывать о якобиане.

Со временем теоретики развили много разных подходов к описанию аномалии, несколько способов борьбы с аномалией. Все они полезны, поскольку по-разному раскрывают природу появления аномалии. В этой книге я решил для примера продемонстрировать существование аномалии явным вычислением фейнмановских диаграмм. Диаграммный метод более трудоемок, в сравнении с другими методами, но у него есть одно преимущество вы своими собственными глазами увидите, как исчезает классическая симметрия! Без всяких формальных аргументов.

Меньшее из двух зол

Рассмотрим теорию с одним безмассовым фермионом $\mathcal{L} = \bar{\psi} i\gamma^\mu \partial_\mu \psi$. Более простой теории и придумать сложно! Из главы II.1 известно, что лагранжиан $\mathcal{L}$ инвариантен относительно преобразований $\psi \to e^{i\theta}\psi$ и $\psi \to e^{i\theta\gamma^5}\psi$, соответствующих сохраняющемуся векторному току $J^\mu = \bar{\psi}\gamma^\mu\psi$ и сохраняющемуся аксиальному току $J_5^\mu = \bar{\psi}\gamma^\mu\gamma^5\psi$ соответственно. Вы можетс проверить, что $\partial_\mu J^\mu = 0$ и $\partial_\mu J_5^\mu = 0$ сразу следуют из классических уравнений движения $i\gamma^\mu\partial_\mu\psi = 0$.

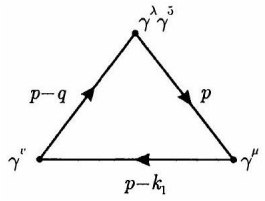
Вычислим амплитуду пространственно-временного процесса, в котором в x_1 рождается пара фермион-антифермион, а в x_2 векторным током создается другая такая пара. Фермион из одной пары аннигилирует с антифермионом из другой пары, а оставшаяся пара фермион-антифермион уничтожается аксиальным током. Для описания этой амплитуды $\left\langle 0 \left| T J_5^\lambda(0) J^\mu(x_1) J^\nu(x_2) \right| 0 \right\rangle$ требуется так много слов, но я хочу быть уверенным, что вы понимаете, о чем я говорю. Согласно Фейнману, фурье-преобразование амплитуды определяется двумя «треугольными» диаграммами на рис. IV.7.1a и b.

$$\Delta^{\lambda\mu\nu}(k_1,k_2) = (-1)i^3 \int \frac{d^4p}{(2\pi)^4} \times$$
$$\times \operatorname{tr}\left(\gamma^\lambda\gamma^5 \frac{1}{\not p - \not q}\gamma^\nu \frac{1}{\not p - \not k_1}\gamma^\mu \frac{1}{\not p} + \gamma^\lambda\gamma^5 \frac{1}{\not p - \not q}\gamma^\mu \frac{1}{\not p - \not k_2}\gamma^\nu \frac{1}{\not p} \right)$$

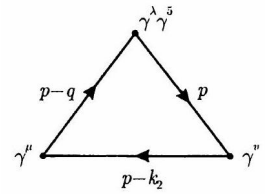
где $q = k_1 + k_2$. Обратите внимание, что появление двух членов обусловлено статистикой Бозе. Общий множитель (-1) обусловлен замкнутой фермионной петлей.

В классическом случае у нас есть две симметрии $\partial_\mu J^\mu = 0$ и $\partial_\mu J_5^\mu = 0$. В квантовой теории, если условие $\partial_\mu J^\mu = 0$ продолжает выполняться, $k_{1\mu}\Delta^{\lambda\mu\nu} = 0$ и $k_{2\nu}\Delta^{\lambda\mu\nu} = 0$, а выполнение $\partial_\mu J_5^\mu = 0$ означает, что $q_\lambda \Delta^{\lambda\mu\nu} = 0$. Теперь можно приступать к вычислению $\Delta^{\lambda\mu\nu}$, результаты которого нам покажут, сохраняют ли квантовые флуктуации эти две симметрии. Ничего сложного. Прежде чем погрузиться в вычисления, зададимся вопросом, огорчит ли нас тот факт, что один из двух токов J^μ и J_5^μ окажется несохраняющимся? Мы сильно огорчимся, если векторный ток не будет сохраняться. Соответствующий заряд $Q = \int d^3x J^0$ считает число фермионов. Мы бы не хотели, чтобы наши фермионы бесследно исчезали и появлялись из ничего. Более того, было бы хорошо, если бы фотон взаимодействовал с фермионным полем ψ. В этом случае нам понадобится условие $\partial_\mu J^\mu = 0$ для сохранения калибровочной инвариантности (см. главу II.6) и, как следствие, всего две поляризации для фотона. Более явно, представьте себе фотонную линию, входящую в вершину μ на рис. IV.7.1a и b, имеющую пропагатор $(i/k_1^2)\left[(1-\xi)\left(k_{1\mu}k_{1\rho}/k_1^2\right) - g_{\mu\rho}\right]$. Зависящий от калибровки член $\xi\left(k_{1\mu}k_{1\rho}/k_1^2\right)$ никуда не исчезнет, если векторный ток будет несохраняющимся, т. е. если не занулится член $k_{1\mu}\Delta^{\lambda\mu\nu}$.

С другой стороны, если говорить откровенно, только между нами, друзья, мы не слишком-то и огорчимся, если вследствие квантовых флуктуаций не будет сохраняться аксиальный ток. Кого волнует, что аксиальный заряд $Q^5 = \int d^3x J_5^0$ не будет постоянным во времени?



(a)



(b)
Рис. IV.7.1.

Сдвиг переменной интегрирования

Итак, зануляются ли члены $k_{1\mu}\Delta^{\lambda\mu\nu}$ и $k_{2\nu}\Delta^{\lambda\mu\nu}$? Посмотрим за плечо профессора Конфузио, когда он вычисляет $k_{1\mu}\Delta^{\lambda\mu\nu}$. (Мы в 1960-х годах, спустя много времени после появления теории перенормируемости, описанной в главе III.1; и Конфузио получил пятилетнюю позицию ассистента [1].) Он сворачивает $\Delta^{\lambda\mu\nu}$ в (7) с $k_{1\mu}$ и, основываясь на знаниях из главы II.7, записывает k_1 в первом члене как $\not{p} - (\not{p} - \not{k}_1)$, а во втором

[1] tenure track assistant professorship. - Прим. ped.

члене как $(\not{p} - \not{k}_2) - (\not{p} - \not{q})$. В итоге получает выражение:

$$k_{1\mu}\Delta^{\lambda\mu\nu}(k_1,k_2) = \\ = i\int \frac{d^4p}{(2\pi)^4}\,\mathrm{tr}\left(\gamma^\lambda\gamma^5\frac{1}{\not{p}-\not{q}}\gamma^\nu\frac{1}{\not{p}-k_1} - \gamma^\lambda\gamma^5\frac{1}{\not{p}-\not{k}_2}\gamma^\nu\frac{1}{\not{p}}\right).$$

Как и в главе II.7, профессор Конфузио узнает в первом члене подынтегрального выражения второй член, но со сдвинутой переменной интегрирования $p \to p - k_1$. Два члена сокращаются друг с другом, и профессор Конфузио публикует статью, утверждая, что $k_{1\mu}\Delta^{\lambda\mu\nu} = 0$, как мы все и ожидали.

В главе II. 7 я говорил, что позже нам предстоит озаботиться тем, имеем ли право сдвигать переменные интегрирования. Вот и настало это время!

Вполне возможно, что вы уже задавали такой вопрос своим преподавателям математического анализа. В каких случаях $\int\limits_{-\infty}^{+\infty} dpf(p+a)$ равняется $\int\limits_{-\infty}^{+\infty} dpf(p)$? Разница двух интегралов равна

$$\int\limits_{-\infty}^{+\infty} dp\left(a\frac{d}{dp}f(p)+...\right) = a(f(+\infty)-f(-\infty))+...$$

Видим, что сдвиг недопустим, когда $(+\infty)$ и $f(-\infty)$ есть две разные константы. Но если интеграл $\int\limits_{-\infty}^{+\infty} dpf(p)$ сходится или даже логарифмически расходится, то сдвиг возможен. В главе II.6 он был допустим, но сейчас, в выражении (2), определенно нет.

Как обычно, повернем фейнмановскую подынтегральную функцию в евклидово пространство. Обобщая наши наблюдения до d-мерного евклидова пространства, получаем

$$\int d_E^d p[f(p+a)-f(p)] = \int d_E^d p\left[a^\mu \partial_\mu f(p)+...\right]$$

которое по теореме Гаусса равно

$$\lim_{P\to\infty} a^\mu \left(\frac{P_\mu}{P}\right) f(P) S_{d-1}(P)$$

где $S_{d-1}(P)$ - площадь $(d-1)$-мерной сферы (см. приложение D), в которой находится среднее по поверхности сферы значение. (Из расчета фейнмановских диаграмм мы знаем, что среднее для $P^\mu P^\nu/P^2$ значение равно $\frac{1}{4}\eta^{\mu\nu}$ вследствие симметрии; нормировка $\frac{1}{4}$ фиксируется сворачиванием с $\eta_{\mu\nu}$). Вращая обратно, получаем 4-мерный интеграл Минковского

$$\int d^d p[f(p+a)-f(p)] = \lim_{P\to\infty} ia^\mu \left(\frac{P_\mu}{P}\right) f(P)\left(2\pi^2 P^3\right).$$

Обратите внимание, что множитель i обусловлен виковским обратным поворотом.

Объединяя (3) с

$$f(p) = \mathrm{tr}\left(\gamma^\lambda\gamma^5 \frac{1}{\not p - \not k_2}\gamma^\nu \frac{1}{\not p}\right) = \frac{\mathrm{tr}\left[\gamma^5(\not p - \not k_2)\gamma^\nu \not p \gamma^\lambda\right]}{(p-k_2)^2 p^2} = \frac{4i\varepsilon^{\tau\nu\sigma\lambda}k_{2\tau}p_\sigma}{(p-k_2)^2 p^2}$$

получаем

$$k_{1\mu}\Delta^{\lambda\mu\nu} = \frac{i}{(2\pi)^4}\lim_{P\to\infty} i(-k_1)^\mu \frac{P_\mu}{P}\frac{4i\varepsilon^{\tau\nu\sigma\lambda}k_{2\tau}P_\sigma}{P^4}2\pi^2 P^3 = \frac{i}{8\pi^2}\varepsilon^{\lambda\nu\tau\sigma}k_{1\tau}k_{2\sigma}.$$

Вопреки словам профессора Конфузио, $k_{1\mu}\Delta^{\lambda\mu\nu} \neq 0$.

Как я уже говорил, это для нас катастрофа. Количество фермионов не сохраняется, и материя вокруг нас разрушается! Как выйти из данного положения?

В действительности мы лишь слегка сообразительнее профессора Конфузио. Мы не заметили того, что интеграл, определяющий $\Delta^{\lambda\mu\nu}$ в (1), линейно расходится и потому не является хорошо определенным.

Гм, прежде чем волноваться по поводу вычисления $k_{1\mu}\Delta^{\lambda\mu\nu}$ и $k_{2\mu}\Delta^{\lambda\mu\nu}$, нам следовало бы задаться вопросом, зависит ли $\Delta^{\lambda\mu\nu}$ от физика, производящего вычисление? Предположим, что другой физик решает [2] сдвинуть переменную интегрирования p в линейно расходящемся интеграле в (1) на произвольный 4-вектор a, определяя как

$$\begin{aligned}&\Delta^{\lambda\mu\nu}(a,k_1,k_2)=\\&=(-1)i^3\int\frac{d^4p}{(2\pi)^4}\operatorname{tr}\left(\gamma^\lambda\gamma^5\frac{1}{\not p+\not a-\not q}\gamma^\nu\frac{1}{\not p+\not a-\not k_1}\gamma^\mu\frac{1}{\not p+\not a}\right)+\\&+\{\mu,k_1\leftrightarrow\nu,k_2\}.\end{aligned}$$

Сколько на свете физиков, столько и разных ответов можно получить для фейнмановских диаграмм на рис. IV.7.1a и b, что, конечно, было бы концом физики или по крайней мере квантовой теории поля.

2 Это свобода выбора обозначения внутреннего импульса. о котором упоминалось в глаВе I.7. Чей результат мы должны объявить правильным?

Единственным разумным ответом на данный вопрос является следующий: надо доверять человеку, который выбирает такое a, что сокращаются $k_{1\mu}\Delta^{\lambda\mu\nu}(a,k_1,k_2)$ и $k_{2\mu}\Delta^{\lambda\mu\nu}(a,k_1,k_2)$, а фотон имеет должное количество степеней свободы.

Вычислим разность $\Delta^{\lambda\mu\nu}(a,k_1,k_2)-\Delta^{\lambda\mu\nu}(k_1,k_2)$, объединяя (3) и $f(p)=\operatorname{tr}\left(\gamma^\lambda\gamma^5\frac{1}{\not p-\not q}\gamma^\nu\frac{1}{\not p-\not k}\gamma^\mu\frac{1}{\not p}\right)$. С учетом того что

$$\begin{aligned}f(P)&=\lim_{P\to\infty}\frac{\operatorname{tr}\left(\gamma^\lambda\gamma^5\not\gamma^\nu\not\gamma^\mu\not P\right)}{P^6}=\\&=\frac{2P^\mu\operatorname{tr}\left(\gamma^\lambda\gamma^5\not\gamma^\nu\not P\right)-P^2\operatorname{tr}\left(\gamma^\lambda\gamma^5\not P\not\gamma^\nu\gamma^\mu\right)}{P^6}=\frac{-4iP^2P_\sigma\varepsilon^{\sigma\nu\mu\lambda}}{P^6}\end{aligned}$$

приходим к выражению:

$$\begin{aligned}\Delta^{\lambda\mu\nu}(a,k_1,k_2)-\Delta^{\lambda\mu\nu}(k_1,k_2)&=\frac{-4i}{8\pi^2}\lim_{P\to\infty}a^\omega\frac{P_\omega P_\sigma}{P^2}\varepsilon^{\sigma\nu\mu\lambda}+\{\mu,k_1\leftrightarrow\nu,k_2\}=\\&=\frac{-i}{8\pi^2}\varepsilon^{\sigma\nu\mu\lambda}a_\sigma+\{\mu,k_1\leftrightarrow\nu,k_2\}\end{aligned}$$

В задаче есть два независимых импульса k_1 и k_2, поэтому можно выбрать $a=\alpha(k_1+k_2)+\beta(k_1-k_2)$. Подставляя это выражение в (5), получаем:

$$\Delta^{\lambda\mu\nu}(a,k_1,k_2)=\Delta^{\lambda\mu\nu}(k_1,k_2)-\frac{i\beta}{4\pi^2}\varepsilon^{\lambda\mu\nu\sigma}(k_1-k_2)_\sigma$$

Обратите внимание, что параметр α выпадает.

Как и ожидалось, $\Delta^{\lambda\mu\nu}(a,k_1,k_2)$ зависит от β и, следовательно, от a. Наше непоколебимое желание иметь сохраняющийся векторный ток, при котором $k_{1\mu}\Delta^{\lambda\mu\nu}(a,k_1,k_2)=0$, фиксирует параметр β выполнением условия

$$k_{1\mu}\Delta^{\lambda\mu\nu}(k_1,k_2)=\frac{i}{8\pi^2}\varepsilon^{\lambda\nu\tau\sigma}k_{1\tau}k_{2\sigma}$$

Таким образом, наш выбор должен падать на $\Delta^{\lambda\mu\nu}(a,k_1,k_2)$ с $\beta=-\frac{1}{2}$. Рассмотрим все вышесказанное с точки зрения правил Фейнмана. При формулировании правил Фейнмана недостаточно определить $\left\langle 0\left|TJ_5^\lambda(0)J^\mu(x_1)J^\nu(x_2)\right|0\right\rangle$. Их необходимо дополнить условием сохранения векторного тока. Амплитуда $\left\langle 0\left|TJ_5^\lambda(0)J^\mu(x_1)J^\nu(x_2)\right|0\right\rangle$ определяется с помощью $\Delta^{\lambda\mu\nu}(a,k_1,k_2)$ при $\beta=-\frac{1}{2}$.

Квантовые флуктуации нарушают сохранение аксиального тока

Подходим к кульминации истории. Мы потребовали сохранение векторного тока. Сохраняется ли аксиальный ток?

Чтобы ответить на этот вопрос, нам нужно просто вычислить:

$$q_\lambda \Delta^{\lambda\mu\nu}(a,k_1,k_2) = q_\lambda \Delta^{\lambda\mu\nu}(k_1,k_2) + \frac{i}{4\pi^2}\varepsilon^{\mu\nu\lambda\sigma}k_{1\lambda}k_{2\sigma}$$

Вы уже знаете, как это сделать:

$$\begin{aligned} q_\lambda \Delta^{\lambda\mu\nu}(k_1,k_2) = i\int \frac{d^4p}{(2\pi)^4}\,\mathrm{tr}\left(\gamma^5 \frac{1}{\not p - \not q}\gamma^\nu \frac{1}{\not p - \not k_1}\gamma^\mu - \right. \\ \left. -\gamma^5 \frac{1}{\not p - \not k_2}\gamma^\nu \frac{1}{p\gamma^\mu}\right) + \{\mu, k_1 \leftrightarrow \nu\cdot k_2\} = \\ = \frac{i}{4\pi^2}\varepsilon^{\mu\nu\lambda\sigma}k_{1\lambda}k_{2\sigma} \end{aligned}$$

В самом деле, это интегрирование было выполнено (2). В конечном итоге получаем:

$$q_\lambda \Delta^{\lambda\mu\nu}(a,k_1,k_2) = \frac{i}{2\pi^2}\varepsilon^{\mu\nu\lambda\sigma}k_{1\lambda}k_{2\sigma}$$

Аксиальный ток не сохраняется!

Итак, для простой теории $\mathcal{L} = \bar\psi i\gamma^\mu\partial_\mu\psi$ в классическом случае сохраняются и векторный, и аксиальный токи, а в квантовом случае - только векторный. Это явление называют аномалией, аксиальной аномалией или киральной аномалией.

Следетвия аномалии

Как я уже говорил, аномалия представляет собой чрезвычайно богатое явление. Сделаю ряд замечаний, детали которых вы можете проработать в качестве упражнений.

1. Допустим, мы калибруем нашу простую теорию $\mathcal{L} = \bar\psi i\gamma^\mu(\partial_\mu - ieA_\mu)\psi$ и рассматриваем A_μ в качестве фотонного поля. Тогда рис. IV.7.1 будет соответствовать случаю, когда две фотонные линии выходят из вершин μ и ν. Полученный ранее рсзультат (9) можно переписать теперь в виде двух операторных уравнений:

КЛАССИЧЕСКАЯ ФИЗИКА: $\partial_\mu J_5^\mu = 0$,
КВАНТОВАЯ ФИЗИКА:

$$\partial_\mu J_5^\mu = \frac{e^2}{(4\pi)^2}\varepsilon^{\mu\nu\lambda\sigma}F_{\mu\nu}F_{\lambda\sigma}$$

Производная аксиального тока $\partial_\mu J_5^\mu$ равна не нулю, а оператору, способному создать два фотона.

2. Следуя логике главы IV.2, можно вычислить скорость распада $\pi^0 \to \gamma + \gamma$. Раньше физики, основываясь на ошибочном результате (10), полагали, что этот распад, наблюдаемый экспериментальным путем, невозможен! См. упражнение IV.7.2. Разрешение этого несомненного парадокса привело к верному результату (11).

3. Записав лагранжиан в терминах левого ψ_L и правого ψ_R полей и вводя левый и правый токи $J_R^\mu \equiv \bar\psi_R\gamma^\mu\psi_R$ и $J_L^\mu \equiv \bar\psi_L\gamma^\mu\psi_L$, можно сформулировать аномалию в виде:

$$\partial_\mu J^\mu_R = \frac{1}{2}\frac{e^2}{(4\pi)^2}\varepsilon^{\mu\nu\lambda\sigma}F_{\mu\nu}F_{\lambda\sigma}$$

И

$$\partial_\mu J^\mu_L = -\frac{1}{2}\frac{e^2}{(4\pi)^2}\varepsilon^{\mu\nu\lambda\sigma}F_{\mu\nu}F_{\lambda\sigma}$$

(Отсюда название «киральная»!) Мы можем считать, что левый и правый фермионы бегут по петле на рис. IV.7.1, внося противоположный вклад в аномалию.

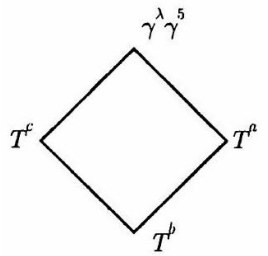
4. Рассмотрим теорию $\mathcal{L} = \bar\psi\left(i\gamma^\mu\partial_\mu - m\right)\psi$. Инвариантность относительно преобразования $\psi \to e^{i\theta\gamma^5}\psi$ нарушается массовым членом. В классическом случае имеем $\partial_\mu J^\mu_5 = 2m\bar\psi i\gamma^5\psi$, т. е. аксиальный ток явно не сохраняется. Аномалия выражается в том, что квантовые флуктуации теперь обуславливают появление дополнительного члена. В теории $\mathcal{L} = \bar\psi\left(i\gamma^\mu\left(\partial_\mu - ieA_\mu\right) - m\right)\psi$ имеем:

$$\partial_\mu J^\mu_5 = 2m\bar\psi i\gamma^5\psi + \frac{e^2}{(4\pi)^2}\varepsilon^{\mu\nu\lambda\sigma}F_{\mu\nu}F_{\lambda\sigma}$$

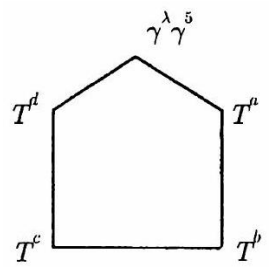
5. Вспомним, что в главе III.7, при вычислении поляризации вакуума, мы вводили регуляторы Паули-Вилларса. Мы вычитали из подынтегрального выражения такое подынтегральное выражение, в котором масса электрона заменяется некоторой массой регулятора. Масса электрона в (1) равна нулю, поэтому вычтем из подынтегрального выражения такое подынтегральное выражение, в котором 0 заменяется на массу регулятора M. Запишем:

$$\begin{aligned}\Delta^{\lambda\mu\nu}(k_1,k_2) =& (-1)i^3\int\frac{d^4p}{(2\pi)^4}\,\mathrm{tr}\left(\gamma^\lambda\gamma^5\frac{1}{\not p - \not q}\gamma^\nu\frac{1}{\not p - \not k_1}\gamma^\mu\frac{1}{\not p} - \right.\\ &\left. -\gamma^\lambda\gamma^5\frac{1}{\not p - \not q - M}\gamma^\nu\frac{1}{\not p - \not k_1 - M}\gamma^\mu\frac{1}{\not p - M}\right) + \\ &+ \left\{\mu, k_1 \leftrightarrow \nu, k_2\right\}.\end{aligned}$$

Заметим, что при $p \to \infty$ подынтегральное выражение стремится к нулю быстрее, чем $1/p^3$, что находится в согласии с философией регуляризации, описанной в общих чертах в главах III.1 и III.7: для $p \ll M$, границы неведения, подынтегральное выражение остается неизменным, а для $p \gg M$ подынтегральное выражение обрезается. В нашем случае интеграл в (14) имеет кажущуюся логарифмическую расходимость, поэтому по своему усмотрению можно сдвинуть переменную интегрирования p.



(a)



(b)
Рис. IV.7.2

Как возникает киральная аномалия? Включив массу регулятора M, мы явным образом нарушили условие сохранения аксиального тока. Аномалия заключается в том, что данное нарушение имеет место даже в случае $M \to \infty$. Будет чрезвычайно полезно, если вы проверите это утверждение (упражнение IV.7.4). 6. Рассмотрим неабелеву теорию $\mathcal{L} = \bar{\psi} i\gamma^\mu \left(\partial_\mu - igA_\mu^a T^a\right)\psi$. Достаточно ввести в выражение для фейнмановской амплитуды множитель T^a для вершины μ и множитель T^b для вершины ν. Повторяем все изложенные выше шаги за исключением того, что при суммировании по всем различным фермионам, бегущим по петле, получаем множитель $\operatorname{tr} T^a T^b$. Следовательно, в неабелевой калибровочной теории имеем:

$$\partial_\mu J_5^\mu = \frac{g^2}{(4\pi)^2}\varepsilon^{\mu\nu\lambda\sigma} \operatorname{tr} F_{\mu\nu} F_{\lambda\sigma}$$

где $F_{\mu\nu} = F_{\mu\nu}^a T^a$ - напряженность матричного поля, определенная в главе IV.5. Неабелева симметрия обладает одним замечательным свойством: объект $\varepsilon^{\mu\nu\lambda\sigma} \operatorname{tr} F_{\mu\nu} F_{\lambda\sigma}$ содержит не только член второго порядка по A, но и члены третьей и четвертой степени по A, поэтому наблюдается киральная аномалия с тремя и четырьмя входящими калибровочными бозонами, как на рис. IV.7.2a и b. Некоторые называют аномалии на рис. IV.7.1 и IV.7.2 треугольной, квадратичной и пятиугольной аномалией. Когда была обнаружена треугольная аномалия, шли споры по поводу того, существуют ли вообще квадратичная и пятиугольная аномалии. Видим, что неабелева симметрия разрешает спор очевидным образом, однако в те времена люди вычисляли фейнмановские диаграммы явно и любой неосторожный шаг мог привести к ошибке.

7. В главе V.7 мы увидим, что аномалия тесно связана с топологией.

8. Мы вычислили киральную аномалию в свободной теории $\mathcal{L} = \bar{\psi}\left(i\gamma^\mu \partial_\mu - m\right)\psi$. Предположим, что фермион взаимодействует со скалярным полем посредством добавления члена $f\varphi\bar{\psi}\psi$ или с электромагнитным полем. Необходимо вычислить диаграммы более высокого порядка, например, трехпетлевую диаграмму на рис. IV.7.3. Можно предположить, что правую часть уравнения (9) следует умножить на $1 + h(f, e, ...)$, где h - некоторая неизвестная функция от всех констант связи, фигурирующих в теории.

А теперь сюрприз! Адлер и Бардин доказали, что $h = 0$. Этот удивительный факт, называемый неперенормируемостью аномалии, можно объяснить эвристически. Перед интегрированием по импульсам скалярных пропагаторов на рис. IV.7.3 (обозначенных как W_1 и W_2) фейнмановское подынтегральное выражение содержит семь фермионных пропагаторов и, следовательно, хорошо сходится. Значит, можно безболезненно сдвинуть переменные интегрирования. Итак, перед интегрированием по W_1 и W_2 выполняются все соответствующие тождества

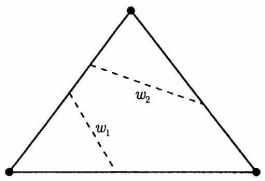


Рис. IV.7.3

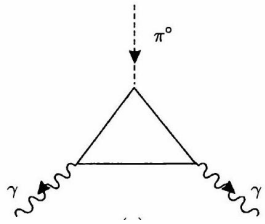
Уорда, например, $q_\lambda \Delta_3^{\lambda\mu\nu}(k_1, k_2; W_1, W_2) = 0$. Попробуйте продолжить доказательство самостоятельно. В упражнении VI.7.13 вы должны будете дать доказательство, основанное на топологии [3].

9. Полученный выше результат имел большое значение для физики элементарных частиц, поскольку непосредственно связан с представлениями о цвете, и речь об этом пойдет в главе VII.3. Условие неперенормируемости аномалии позволило точно вычислить амплитуду распада $\pi^0 \to \gamma + \gamma$ в конце 1960−-х гг. Хотя в кварковой модели того времени амплитуда задается бесконечным числом фейнмановских диаграмм (рис. IV.7.4), условие неперенормируемости аномалии говорит о том, что только диаграмма на рис. IV.7.4a дает вклад. Иначе говоря, амплитуда не зависит от деталей сильного взаимодействия. Тот факт, что амплитуда оказывается втрое меньше требуемой, свидетельствует о существовании трех экземпляров кварков (глава VII.3).

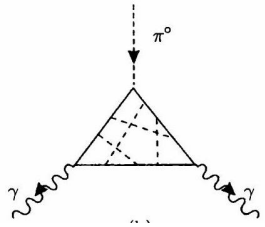
10. Естественно задаться вопросом, являются ли кварки и лептоны составными объектами из более элементарных фермионов, называемых преонами? Условие неперенормируемости киральной аномалии предоставляет нам мощное средство для решения данного вопроса. Не важно, насколько сложными могут быть взаимодействия, но, до тех пор пока они описываются теорией поля, аномалия, вычисленная на преонном уровне, должна совпадать с аномалией, вычисленной на кварк-лептонном уровне. Получаем так называемое условие соответствия аномалии [4], которое существенно ограничивает возможные преонные теории.

11. Исторически теоретики-полевики с большим недоверием относились к интегралу по траекториям, отдавая предпочтение каноническому

[3] Простое доказательство, без привлечения топологии, смотрите в книге Коллинза (. Col-



(a)



(b)
Рис. IV.7.4

подходу. Когда была открыта киральная аномалия, некоторые физики продолжали утверждать, что существование киральной аномалии доказывает некорректность интеграла по траекториям. Они говорили, что интеграл по траекториям

$$\int D\bar{\psi}D\psi e^{i\int d^4x\bar{\psi}i\gamma^\mu(\partial_\mu - iA_\mu)\psi}$$

кажется настолько глупым, что никак не может служить доказательством своей неинвариантности относительно кирального преобразования $\psi \to e^{i\theta\gamma^5}\psi$. Фудзикава [5] разрешил спор, когда доказал, что в интеграле по траекториям учитывается аномалия: при киральном преобразовании мера $D\bar{\psi}D\psi$ изменяется на якобиан. Именно этими словами я начинал главу: действие может быть инвариантно, тогда как интеграл по траекториям - нет.

Зи-у

IV.7.1. Из (9) получите (11). Импульсы $k_{1\lambda}$ и $k_{2\sigma}$, фигурирующие в (9), становятся в (11) двумя производными в $F_{\mu\nu}F_{\lambda\sigma}$.

Зи-у

IV.7.2. Опираясь на рассуждения в главе IV.2 и применяя ошибочное уравнение (10), покажите, что амплитуда распада $\pi^0 \to \gamma + \gamma$ зануляется в идеальном мире, в котором поле π^0 безмассово. Поскольку π^0 действительно распадается, а наш мир приближен к идеальному, получаем первое доказательство некорректности уравнения (10).

Зи-у

IV.7.3. Повторите все вычисления в тексте для теории $\mathcal{L} = \bar{\psi}\left(i\gamma^\mu\partial_\mu - m\right)\psi$.

Зи-у

IV.7.4. Возьмите регуляризованную методом Паули-Вилларса амплитуду $\Delta^{\lambda\mu\nu}(k_1, k_2)$ и сверните ее с q_λ. Аналогичным образом в главе II.7 член $\not{q}\gamma^5$ записывался в виде $[2M + (\not{p} - M) - (\not{p} - \not{q} + M)]\gamma^5$. Теперь можно свободно сдвинуть переменные интегрирования. Покажите, что

$$q_\lambda\Delta^{\lambda\mu\nu}(k_1, k_2) = -2M\Delta^{\mu\nu}(k_1, k_2)$$

где

$$\Delta^{\mu\nu}(k_1, k_2) \equiv (-1)i^3\int\frac{d^4p}{(2\pi)^4}$$
$$\mathrm{tr}\left(\gamma^5\frac{1}{\not{p} - \not{q} - M}\gamma^\nu\frac{1}{\not{p} - \not{K}_1 - M}\gamma^\mu\frac{1}{\not{p} - M}\right) + \{\mu, k_1 \leftrightarrow \nu, k_2\}.$$

Вычислите $\Delta^{\mu\nu}$ и покажите, что в пределе $M \to \infty\Delta_{\mu\nu}$ ведет себя как $1/M$, а правая часть уравнения (17) стремится к конечному пределу. Аномалия заключается в том, что после своего исчезновения из низкоэнергетического спектра регулятор оставляет некий след, подобно улыбке чеширского кота. [Даже не приступая к вычислениям, мы фактически можем утверждать, что $\Delta^{\mu\nu}$ будет равна $1/M$. Вследствие лоренцевской инвариантности и наличия γ^5, значение $\Delta^{\mu\nu}$ должно быть пропорционально $\varepsilon^{\mu\nu\lambda\rho}k_{1\lambda}k_{2\rho}$, но анализ размерностей показывает, что $\Delta^{\mu\nu}$ равняется $\varepsilon^{\mu\nu\lambda\rho}k_{1\lambda}k_{2\rho}/M$, умноженному на некоторую константу. Вы,

должно быть, удивляетесь, почему нельзя вместо $1/M$ использовать $1/\left(k_1^2\right)^{\frac{1}{2}}$, чтобы в итоге размерность оказалась верной. Все дело в том, что опыт расчетов фейнмановских диаграмм в (3+1)-мерном пространстве-времени говорит о невозможности получения фактора вида $1/\left(k_1^2\right)^{\frac{1}{2}}$.]

Зи-у

IV.7.5. Существует буквально N способов вывода уравнения аномалии. Вот еще один. Вычислите

$$\Delta^{\lambda\mu\nu}\left(k_1,2\right)=(-1)i^3\int\frac{d^4p}{(2\pi)^4}\,\mathrm{tr}\left(\gamma^\lambda\gamma^5\frac{1}{\not p-\not q-m}\gamma^\nu\frac{1}{\not p-\not K_1-m}\gamma^\mu\frac{1}{\not p-m}\right)+\{\mu,k_1\leftrightarrow\nu,k_2\}$$

для случая массивного фермиона, но не прямым вычислением, а используя сначала лоренцевскую инвариантность, чтобы записать

$$\Delta^{\lambda\mu\nu}\left(k_1,k_2\right)=\varepsilon^{\lambda\mu\nu\sigma}k_{1\sigma}A_1+...+\varepsilon^{\mu\nu\sigma\tau}k_{1\sigma}k_{2\tau}k_2^\lambda A_8$$

где $A_i\equiv A_i\left(k_1^2,k_2^2,q^2\right)$ - восемь функций от трех лоренцевских скаляров. Подсчетом степеней в духе глав III.3 и III.7, покажите, что в двух из восьми функциях появляются интегралы с кажущейся логарифмической расходимостью, тогда как в остальных шести - сходящиеся интегралы. Затем, применяя статистику Бозе и условие сохранения векторного тока $k_{1\mu}\Delta^{\lambda\mu\nu}=0=k_{2\nu}\Delta^{\lambda\mu\nu}$, покажите, что мы можем избежать вычисление интегралов с кажущейся логарифмической расходимостью. Вычислите сходящиеся интегралы и найдите $q_\lambda\Delta^{\lambda\mu\nu}\left(k_1,k_2\right)$.

Зи-у

IV.7.6. Рассмотрите аномалию с точки зрения анализа амплитуды

$$\left\langle 0\left|TJ_5^\lambda(0)J_5^\mu\left(x_1\right)J_5^\mu\left(x_2\right)\right|0\right\rangle$$

в низшем порядке заданной треугольными диаграммами с аксиальными токами в каждой вершине. [Указание: используйте амплитуду в импульсном пространстве $\Delta_5^{\lambda\mu\nu}\left(k_1,k_2\right)$.] Для условия $\left(\gamma^5\right)^2=1$ и симметрии Бозе докажите, что

$$\Delta_5^{\lambda\mu\nu}\left(k_1,k_2\right)=\frac{1}{3}\left[\Delta^{\lambda\mu\nu}\left(a,k_1,k_2\right)+\Delta^{\mu\nu\lambda}\left(a,k_2,-q\right)+\Delta^{\nu\lambda\mu}\left(a,-q,k_1\right)\right].$$

Теперь используйте (9), чтобы вычислить $q_\lambda\Delta_5^{\lambda\mu\nu}\left(k_1,k_2\right)$.

Зи-у

IV.7.7. Аккуратно определите фермионную меру $D\psi$ в (16), перейдя в евклидово пространство. Вычислите якобиан при киральном преобразовании и выведите аномалию.
[Указание: (K. Fujikawa, Phys. Rev. Lett. 42:1195, 1979).]

Зи-у

IV.7.8. Вычислите пятиугольную аномалию с помощью фейнмановских диаграмм для проверки замечания 6 в тексте. Иначе говоря, найдите коэффициент c в уравнении $\partial_\mu J_5^\mu=...+c\varepsilon^{\mu\nu\lambda\sigma}\,\mathrm{tr}\,A_\mu A_\nu A_\lambda A_\sigma$.

30.2 Zi.V Field Theory and Collective Phenomena

Во введении я упоминал, что одним из наиболее интеллектуально ярких достижений за последние 2-3 десятилетия является то, что методы квантовой теории поля играют все более важную роль в физике конденсированных сред. Они составляют богатый и многоплановый предмет исследований; в этой и последующей главах я едва коснусь вершины айсберга и рассмотрю лишь отдельные вопросы.

Исторически теория поля появилась в физике конденсированных сред прямым и непосредственным образом. В системе конденсированных сред нерелятивистские электроны в конденстрованной среде можно описать полем ψ в духе главы III.5. В этом случае появляется возможность написать лагранжианы, построить фейнмановские диаграммы и сформулировать соответствующие правила. Результаты можно найти в некоторых специализированных текстах. Здесь я хочу изложить в значительной степени более современный подход к описанию конденсированных систем, в терминах эффективной теории поля. Система конденсированных сред обладает одним замечательным свойством: вследствие глубоко нетривиальных многочастичных эффектов низкоэнергетические степени свободы могут полностью отличаться от электронов, с которых мы начинали. Особенно ярким примером такой системы (о ней мы поговорим в главе VI.2) является квантовая система Холла, в которой низкоэнергетическая эффективная степень свободы несет дробный заряд и подчиняется дробной статистике.

Есть и другая причина, по которой я существенную часть книги посвятил физике конденсированных сред, - с исторической и педагогической точек зрения, ренормализационную группу гораздо легче понять в рамках физики конденсированных сред, а не физики элементарных частиц.

Я нарочито не буду проводить строгую грань между физикой конденсированных сред и физикой элементарных частиц. Некоторые вопросы, обсуждаемые в пятой и шестой частях, по существу, относятся к физике элементарных частиц. И конечно, я не могу брать на себя большую ответственность за объяснение физики конденсированных сред, чем за свои объяснения физики элементарных частиц в главе IV.2.

30.2.1 Zi.V.1 Superfluid Liquids

Отталкивающиеся бозоны

Рассмотрим конечную плотность $\bar{\rho}$ нерелятивистских бозонов, с короткодействующим отталкиванием. Вернемся к лагранжиану (III.5.11):

$$\mathcal{L} = i\varphi^\dagger \partial_0 \varphi - \frac{1}{2m}\partial_i\varphi^\dagger\partial_i\varphi - g^2\left(\varphi^\dagger\varphi - \bar{\rho}\right)^2$$

Последний член есть в точности потенциал типа сомбреро из главы IV.1. Он вынуждает величину φ быть близкой к $\sqrt{\bar{\rho}}$ и тем самым предлагает нам использовать полярные переменные $\varphi \equiv \sqrt{\rho}e^{i\theta}$, как в уравнении (III.5.7). Делая подстановку и опуская полную производную $(i/2)\partial_0\rho$, получаем лагранжиан в виде

$$\mathcal{L} = -\rho\partial_0\theta - \frac{1}{2m}\left[\frac{1}{4\rho}\left(\partial_i\rho\right)^2 + \rho\left(\partial_i\theta\right)^2\right] - g^2(\rho-\bar{\rho})^2$$

Спонтанное нарушение симметрии

Запишем так, как в главе IV.1, $\sqrt{\rho} = \sqrt{\bar{\rho}} + h$ (вакуумным средним φ является $\sqrt{\bar{\rho}}$). Предположим, что $h \ll \sqrt{\bar{\rho}}$, и разложим [1]:

$$\mathcal{L} = -2\sqrt{\bar{\rho}}h\partial_0\theta - \frac{\bar{\rho}}{2m}\left(\partial_i\theta\right)^2 - \frac{1}{2m}\left(\partial_i h\right)^2 - 4g^2\bar{\rho}h^2 + ...$$

Выбрав в (3) члены второго порядка по h, используем «центральное тождество квантовой теории поля» (см. приложение А), чтобы отынтегриро-

[1] Заметим. что мы отбросили (потенциально интересный) член $-\bar{\rho}\partial_0\theta$, потому что он является полной производной. вать h. В результате имеем

$$\mathcal{L} = \bar{\rho}\partial_0\theta \frac{1}{4g^2\bar{\rho} - (1/2m)\partial_i^2}\partial_0\theta - \frac{\bar{\rho}}{2m}\left(\partial_i\theta\right)^2 + ... =$$
$$= \frac{1}{4g^2}\left(\partial_0\theta\right)^2 - \frac{\bar{\rho}}{2m}\left(\partial_i\theta\right)^2 + ...$$

Допустим, что во втором равенстве нас интересуют процессы с волновым числом k, малым по сравнению с $\sqrt{8g^2\bar{\rho}m}$, так что $(1/2m)\partial_i^2$ пренебрежимо мал, по сравнению с $4g^2\bar{\rho}$. Таким образом, легко видеть, что в этой бозе-жидкости существует бесщелевая мода (часто называемая фононом) с дисперсией

$$\omega^2 = \frac{2g^2\bar{\rho}}{m}\vec{k}^2$$

Самые продвинутые из вас осознают, что мы получили классический результат Боголюбова, даже не выполняя преобразование Боголюбова (см. приложение к этой главе).

Кратко напомню идеализированные рассуждения Ландау [2], согласно которым мода с линейной дисперсией (когда ω линейна относительно k) означает сверхтекучесть. Рассмотрим массу M жидкости, текущей по трубе со скоростью v. Эта жидкость может терять импульс и замедляться до скорости v', создавая возбуждение импульса k : $Mv = Mv' + \hbar k$. Такая ситуация возможна лишь при условии достаточного запаса энергии: $\frac{1}{2}Mv^2 \geqslant \frac{1}{2}Mv'^2 + \hbar\omega(k)$. Исключая v', получаем для M макроскопическую скорость $v \geqslant \omega/k$. Для моды с линейной дисперсией она соответствует критической скорости $v_c \equiv \omega/k$, ниже которой жидкость не может терять импульс и поэтому является сверхтекучей. [Таким образом, из (5) следует, что идеализированная скорость имеет вид $v_c = g\sqrt{2\bar{\rho}/m}$.]

Масштабируя надлежащим образом координату, можно свести низкоэнергетическую физику сверхтекучести к компактному лагранжиану

$$\mathcal{L} = \frac{1}{4g^2}\left(\partial_\mu\theta\right)^2$$

который, как легко видеть, является безмассовым вариантом теории скалярного поля (которая рассматривалась в первой части книги), но при важном условии, что поле θ является фазой, то есть $\theta(x)$ и $\theta(x) + 2\pi$ действи-

2 Л. Д. Ландау. Е. М. Лифшиц. Статическая физика. Часть 2. С. 117. тельно одинаковы. Эта бесщелевая мода, очевидно, является намбу-голдстоуновским бозоном, связанным со спонтанным нарушением глобальной $U(1)$-симметрии $\varphi \to e^{i\alpha}\varphi$.

Бесщелевая мода с линейной дисперсией

Физика становится особенно ясной, если рассуждать в терминах газа свободных бозонов. Передать импульс $\hbar\vec{k}$ любому данному бозону можно за счет проигрыша в энергии $(\hbar\vec{k})^2/2m$. В системе свободных бозонов существует много низкоэнергетических возбуждений. Но как только между бозонами возникает короткодействующее отталкивание, бозон, движущийся с импульсом $\vec{k}$, будет влиять на все другие бозоны. В результате, как было показано в (5), образуется волна плотности с энергией, пропорциональной k. Бесщелевая мода превращается из моды с квадратичной дисперсией в моду с линейной дисперсией. Число низкоэнергетических возбуждений становится гораздо меньше. Вспомним, в частности, что плотность состояний определяется как $N(E) \propto k^{D-1}(dk/dE)$. Например, для $D = 2$ плотность состояний переходит при малых

энергиях от $N(E) \propto \text{const}$ (в случае мод с квадратичной дисперсией) к $N(E) \propto E$ (в случае мод с линейной дисперсией).

Как, наряду с другими, отмечал Фейнман [3], физика сверхтекучести заключается не в присутствии бесщелевых возбуждений, а в их малом числе. (В конце концов, ферми-жидкость имеет непрерывный спектр бесщелевых мод.) Число мод, на которых сверхтекучая жидкость может терять энергию и импульс, слишком мало.

Сравнение нарушения симметрии в релятивистской и нерелятивистской теории

Рассмотрим релятивистскую теорию, $\mathcal{L} = \left(\partial\Phi^\dagger\right)(\partial\Phi) - \lambda\left(\Phi^\dagger\Phi - v^2\right)^2$. Часто удобнее оказывается взять предел $\lambda \to \infty$ при фиксированном v. На языке, использованном в главе IV.1, это будет звучать так: чтобы «подняться по стене», необходимо неограниченно больше энергии, чем для того, чтобы «катиться по желобу». Полученная в результате теория определяется лагранжианом

$$\mathcal{L} = \left(\partial\Phi^\dagger\right)(\partial\Phi)$$

со связью $\Phi^\dagger\Phi = v^2$. Это так называемая нелинейная сигма-модель, (!?!??!?) которая подробно рассматривается в главе VI.4.

Существование намбу-голдстоуновского бозона особенно легко видеть в нелинейной сигма-модели. Связь разрешается с помощью соотношения $\Phi = ve^{i\theta}$, которое при подстановке в $\mathcal{L}$ дает $\mathcal{L} = v^2(\partial\theta)^2$. Это и есть намбу-голдстоуновский бозон θ.

Повторим то же самое для нерелятивистского случая. Возьмем предел $g^2 \to \infty$ при фиксированном $\bar{\rho}$, чтобы лагранжиан (1) имел вид

$$\mathcal{L} = i\varphi^\dagger\partial_0\varphi - \frac{1}{2m}\partial_i\varphi^\dagger\partial_i\varphi$$

со связью $\varphi^\dagger\varphi = \bar{\rho}$. Но теперь, если подставить в $\mathcal{L}$ решение связи $\varphi = \sqrt{\bar{\rho}}e^{i\theta}$ (и опустить полную производную $-\bar{\rho}\partial_0\theta$)), получим $\mathcal{L} = (\bar{\rho}/2m)\left(\partial_i\theta\right)^2$ с уравнением движения $\partial_i^2\theta = 0$. Что же это такое? Это даже не распространяющаяся степень свободы. Где же намбу-голдстоуновский бозон?

Исходя из того, что я уже рассказывал, этот явный парадокс [4] не должен сильно вас смущать. Но поверьте, я ставил с его помощью в тупик немало блестящих умов, занимающихся релятивистской теорией. Намбу-голдстоуновский бозон все еще присутствует, но, как видно из (5), скорость его распространения ω/k стремится к бесконечности как g, и поэтому он исчезает из спектра для любого неравного нулю $\vec{k}$.

Почему же нам позволено переходить к «нелинейному» пределу в релятивистском случае? Потому что есть лоренц-инвариантность! Скорость моды с линейной дисперсией, если такая мода существует, гарантированно равна 1.

Простое обоснование бесщелевой моды (???????)

(на минут 20 подумать место!!!)

Применим вторично квантованный формализм с гамильтонианом

$$H = \sum_k \frac{k^2}{2m}a_k^\dagger a_k + \sum_{k,p,q} G\left(a_k^\dagger a_p^\dagger a_q a_{k+p-q}\right),$$

где $a_k^\dagger$ и a_k обозначают оператор рождения и уничтожения для бозона с 3-импульсом $\vec{k}$ (стрелка в подстрочных индексах опущена для простоты обозначений). Понимая, что макроскопическая плотность бозонов образует конденсат бозонов в основном состоянии с импульсом $\vec{k} = 0$, Боголюбов заменяет a_0 и $a_0^\dagger$ на c-числа $\langle a_0\rangle = \left\langle a_0^\dagger\right\rangle = u$, что приводит к квадратичному гамильтониану

$$H \sim \sum_k \frac{k^2}{2m} a_k^\dagger a_k + \sum_{k\neq 0} G\left(u^2 + \sum_{k\neq 0} a_k^\dagger a_k\right)\left(a_k^\dagger a_k + a_{-k}^\dagger a_{-k} + a_k^\dagger a_{-k}^\dagger + a_{-k} a_k\right).$$

Ясно, что мы получаем бесщелевую моду, поскольку с точностью до аддитивной постоянной второй член можно записать как $\sum_{k\neq 0} Gu^2\left(a_k^\dagger + a_{-k}\right)\left(a_k + a_{-k}^\dagger\right)$, и поэтому ортогональная комбинация $\left(a_k^\dagger - a_{-k}\right)$ создает бесщелевое возбуждение импульса $\vec{k}$. Решающим является то, что $\langle a_0\rangle = \left\langle a_0^\dagger\right\rangle \neq 0$, а не просто $\left\langle a_0^\dagger a_0\right\rangle \neq 0$. В последнем случае мы бы получили только щелевую моду с энергией $(2Gu^2 + k^2/2m)$. Это доказывает, что нарушение $U(1)$-симметрии бозонного числа является ключевым.

Зи-у.V.1.1. О преобразовании в сверхтекучести (????)

Проверьте, что приближение, использованное для получения лагранжиана (3), непротиворечиво.

Зи-у.V.1.2. Об уравнении Гросса-Питаевского (!!!)

Чтобы удержать сверхтекучую жидкость во внешнем потенциале $W(\vec{x})$, добавим в (1) член $-W(\vec{x})\varphi^\dagger(\vec{x},t)\varphi(\vec{\varphi},t)$. Выведите соответствующее уравнение движения для φ. Это уравнение, известное как уравнение Гросса-Питаевского, последние годы много изучалось в связи с конденсатом Бозе-Эйнштейна.

30.2.2 Zi.V.2 Euclid, Boltzmann, Hawking, and Field Theory at Finite Temperature

Статистическая механика и евклидова теория поля

В главе I.2 упоминалось, что для более строгого определения интеграла по траекториям нужно выполнить виковский поворот $t = -it_E$. Тогда теория скалярного поля вместо того, чтобы определяться интегралом по траекториям Минковского

$$\mathcal{Z} = \int D\varphi e^{(i/\hbar)\int d^d x\left[\frac{1}{2}(\partial\varphi)^2 - V(\varphi)\right]}$$

будет определяться евклидовым функциональным интегралом

$$\mathcal{Z} = \int D\varphi e^{-(1/\hbar)\int d_F^d x\left[\frac{1}{2}(\partial\varphi)^2 + V(\varphi)\right]} = \int D\varphi e^{-(1/\hbar)\mathcal{E}(\varphi)},$$

где $d^d x = -id_E^d x$, а $d_E^d x \equiv dt_E d^{(d-1)}x$. В интеграле (1) $(\partial\varphi)^2 = (\partial\varphi/\partial t)^2$ - $-(\vec{\nabla}\varphi)^2$, тогда как в интеграле (2) $(\partial\varphi)^2 = (\partial\varphi/\partial t_E)^2 + (\vec{\nabla}\varphi)^2$. Эта запись несколько сбивает с толку, но я стараюсь не вводить слишком много посторонних символов. Вам может показаться полезным представить $(\vec{\nabla}\varphi)^2 + V(\varphi)$ как одно целое, нетронутое вращением Вика. Я ввел $\mathcal{E}(\varphi) \equiv \int d_E^d x\left[\frac{1}{2}(\partial\varphi)^2 + V(\varphi)\right]$, что может естественно рассматриваться как функционал статистической энергии поля $\varphi(x)$. Таким образом, когда в d-мерном пространстве задана конфигурация $\varphi(x)$, то чем больше она меняется, тем менее вероятно, что она вносит вклад в евклидов функциональный интеграл $\mathcal{Z}$.

Не напоминает ли вам евклидов функциональный интеграл (2) что-нибудь из статистической механики. Действитсльно, герр Больцман учил нас, что в тепловом равновесии при температуре $T = 1/\beta$ вероятность возникновения конфигурации в

классической системе или вероятность возникновения состояния в квантовой системе является нормированным фактором Больцмана $e^{-\beta E}$, где E следует рассматривать как энергию конфигурации в классической системе или как собственное значение энергии состояния в квантовой системе. В частности, вспомним классическую статистическую механику системы из N частиц, для которой

$$E(p,q) = \sum_i \frac{1}{2m} p_i^2 + V\left(q_1, q_2, ..., q_N\right)$$

Статистическая сумма определяется (с точностью до некоторого общего множителя) как

$$Z = \prod_i \int dp_i dq_i e^{-\beta E(p,q)}$$

После интегрирования по p получаем (приведенную) статистическую сумму

$$Z = \prod_i \int dq_i e^{-\beta V(q_1, q_2, ..., q_N)}$$

Преобразуя ее к теории поля так, как в главе 1.3, и допуская, как и раньше, что $i \to x$ и $q_i \to \varphi(x)$, легко видеть, что статистическая сумма классической теории поля с функционалом статической энергии $\mathcal{E}(\varphi)$ имеет такой же вид, как в (2), если отождествить символ h с температурой $T = 1/\beta$. Итак,

евклидова квантовая теория поля в d-мерном пространстве-времени классическая статистическая механика в d-мерном пространстве

Представление квантовой статистической суммы в виде функционального интеграла

Еще более интересная ситуация возникает, когда мы переходим к квантовой статистической механике. Интегрирование по фазовому пространству $\{p, q\}$ заменяется на след, то есть на сумму по состояниям. Таким образом, статистическая сумма квантово-механической системы (для определенности, скажем, одной частицы) с гамильтонианом H определяется как

$$Z = \operatorname{tr} e^{-\beta H} = \sum_n \left\langle n \left| e^{-\beta H} \right| n \right\rangle$$

В главе 1.2 получено интегральное представление $\left\langle F \left| e^{-iHT} \right| I \right\rangle$. (Не следует, конечно, путать время T с температурой T.) Предположим, мы хотим получить интегральное представление статистической суммы. Для этого больше ничего не надо делать! Просто заменяем время T на $-i\beta$, задаем $|I\rangle = |F\rangle = |n\rangle$ и суммируем по $|n\rangle$, в результате получаем

$$Z = \operatorname{tr} e^{-\beta H} = \int\limits_{\text{ПГ}} Dq e^{-\int\limits_0^\beta d\tau L(q)}.$$

Прослеживая шаги от (I.2.3) до (I.2.5), можно убедиться в том, что здесь $L(q) = \frac{1}{2}(dq/d\tau)^2 + V(q)$ в точности является лагранжианом, соответствующим гамильтониану H с евклидовым временем τ. Интеграл по τ берется от 0 до β. Операция взятия следа задает равными начальное и конечное состояния, и поэтому функциональный интеграл необходимо брать по всем траекториям $q(\tau)$ с граничным условием $q(0) = q(\beta)$. Подстрочный индекс ПГУ напоминает нам об этом важном периодическом граничном условии.

Обобщение до теории поля следует немедленно. Если H является гамильтонианом квантовой теории поля в D-мерном пространстве [и, следовательно, в $d = (D+1)$-мерном пространстве-времени], то статистическая сумма (4) имеет вид

$$Z = \operatorname{tr} e^{-\beta H} = \int\limits_{\text{пГу}} D\varphi e^{-\int\limits_0^\beta d\tau \int d^D x \mathcal{L}(\varphi)}$$

с интегралом, вычисленным по всем траекториям $\varphi(\vec{x}, \tau)$, так что

$$\varphi(\vec{x}, 0) = \varphi(\vec{x}, \beta)$$

(Здесь φ представляет собой все бозе-поля в теории.)

Действительно, замечательный результат! Чтобы изучить теорию поля при конечной температуре, все, что надо сделать, - это повернуть ее в евклидово пространство и наложить граничное условие (6). Таким образом,

евклидова квантовая теория поля в $(D+1)$-мерном пространстве-времени, $0 \leqslant \tau < \beta \sim$ квантовая статистическая механика в D-мерном пространстве

В пределе нулевой температуры $\beta \to \infty$ из (5) получаем стандартную квантовую теорию поля с виковским поворотом в бесконечном пространстве-времени, как и должно быть.

Вы, несомненно, имели бы успех у мистиков, если бы сказали им, что температура является эквивалентом циклического мнимого времени. На уровне арифметики такая ассоциация следует из того факта, что основные объекты квантовой физики e^{-iHT} и статфизики $e^{-\beta H}$ формально связаны аналитическим продолжением. Некоторые физики, включая меня самого, чувствуют, что в этом может скрываться нечто очень глубокое, что мы еще не вполне понимаем.

Фейнмановские диаграммы при конечных температурах

При желании из (5) можно развить теорию возмущений при конечных температурах, формулируя правила Фейнмана и т. д. Это делается так же, как и раньше, за исключением одного существенного отличия, связанного с условием (6) $\varphi(\vec{x}, \tau = 0) = \varphi(\vec{x}, \tau = \beta)$. Ясно, что при преобразовании Фурье с множителем $e^{i\omega\tau}$, евклидова частота ω может принимать только дискретные значения $\omega_n \equiv (2\pi/\beta)n$, где n - целое число. Пропагатор скалярного поля приобретает вид $1/\left(k_4^2 + \vec{k}^2\right) \to 1/\left(\omega_n^2 + \vec{k}^2\right)$. Таким образом, чтобы вычислить статистическую сумму, просто запишем соответствующие евклидовы фейнмановские диаграммы и вместо интегрирования по частоте просуммируем по дискретному набору частот $\omega_n (2\pi T) n, n = -\infty, ..., +\infty$. Другими словами, после приведения интеграла Фейнмана к виду $\int d_E^d k F\left(k_E^2\right)$ достаточно заменить его на $2\pi T \sum\limits_n \int d^D k F\left[(2\pi T)^2 n^2 + \vec{k}^2\right]$.

Полезно посмотреть, что происходит в пределе высоких температур $T \to \infty$. При суммировании по ω_n доминирует член $n = 0$, поскольку в знаменателе появляется комбинация $(2\pi T)^2 n^2 + \vec{k}^2$. В результате эти диаграммы эффективно вычисляются в D-мерном пространстве. Мы потеряли размерность! Таким образом,

> евклидова квантовая теория поля в D-мерном пространстве-времени $\sim$ высокотемпературная квантовая статистическая механика в D-мерном пространстве

То, что при высокой температуре квантовая статистическая механика становится классической, - всего лишь утверждение [сравните с (3)].

Важным применением квантовой теории поля при конечной температуре является космология: раннюю Вселенную можно описать как варево из элементарных частиц при некоторой высокой температуре.

Излучение Хокинга

За последние несколько десятилетий хокинговское излучение черными дырами, несомненно, является самым поразительным предсказанием гравитационной физики. Понятие черных дыр существует еще со времен Лапласа, который заметил, что скорость убегания от достаточно массивного объекта может превышать скорость света. С классической точки зрения объекты падают в черные дыры и дело с концом. Но с точки зрения квантовой физики черная дыра на самом деле может излучать как абсолютно черное тело при температуре T.

С учетом того малого, что мы узнали из этой главы и главы I.10, можно фактичсски определить температуру черной дыры. Спешу добавить, что систематический вывод был бы довольно сложным и включал бы в себя много тонкостей; и действительно этому предмету посвящены целые книги. Однако, более или менее ясно, что нужно сделать. Начав с главы I.10, необходимо развить квантовую теорию поля (например, для скалярного поля φ) в искривленном пространстве-времени, в частности, в присутствии черной дыры, и рассмотреть, какое вакуумное состояние (то есть состояние, лишенное квантов φ) в далеком прошлом эволюционирует в далекое будущее. Мы бы нашли состояние, заполненное тепловым распределением квантов φ. Здесь мы это делать не будем.

В прошлом были предложены многочисленные эвристические обоснования излучения Хокинга. Приведу одно из них. Рассмотрим решснис Шварцшильда (см. главу I.10)

$$ds^2 = \left(1 - \frac{2GM}{r}\right) dt^2 - \left(1 - \frac{2GM}{r}\right)^{-1} dr^2 - r^2 d\theta^2 - r^2 \sin^2\theta d\phi^2.$$

На горизонте $r = 2GM$ коэффициенты при dt^2 и dr^2 меняют знак, указывая на то, что время и пространство, а следовательно, энергия и импульс, взаимозаменяемы. Ясно, что должно произойти нечто странное. При квантовых флуктуациях в вакууме всегда появляются и исчезают пары частица-античастица, но обычно, как мы обсуждали ранее, принцип неопределенности ограничивает время существования таких пар Δt до $\sim 1/\Delta E$. Вблизи горизонта черной дыры ситуация совершенно иная. Пара может рождаться из вакуума непосредственно у горизонта, при этом частица находится сразу за пределами горизонта, а античастица - тут же перед горизонтом. Эвристически ограничение Гейзенберга, накладываемое на Δt, можно избежать, поскольку то, что подразумевается под энергией, изменяется, как только мы пересекаем горизонт. Античастица падает в черную дыру, а частица вылетает в пространственную бесконечность. Конечно, такого рода объяснение «на пальцах» должно быть обосновано детальными расчетами.

Если черные дыры действительно излучают при определенной температуре T, а это априори вовсе не очевидно, можно легко определить T из анализа размерностей. Мы видим из (9), что можно получить только комбинацию GM, которая явно имеет размерность длины. Поскольку T имеет размерность массы, то есть обратную длине, то единственной возможностью является $T \propto 1/GM$.

Чтобы точно определить T, используем некоторую хитрость. Предупреждаю сразу, что ее следует воспринимать критически. Она необходима для того, чтобы пробудить у вас желание к более точному рассмотрению.

Представим себе процесс квантования теории скалярного поля в метрике Шварцшильда аналогично тому, как это делалось в главе I.10. Если при виковском повороте это поле «чувствует», что время периодично с периодом β, то в соответствии с тем, что известно из этой главы, кванты скалярного поля будут считать, что живут в тепловой бане при температуре $T = 1/\beta$.

Задавая $t \to -i\tau$, поворачиваем метрику и получаем

$$ds^2 = -\left[\left(1 - \frac{2GM}{r}\right) d\tau^2 + \right.$$
$$\left. + \left(1 - \frac{2GM}{r}\right)^{-1} dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta d\phi^2\right].$$

В области сразу же за горизонтом, где $r \gtrsim 2GM$, выполняем общее преобразование координат $(\tau, r) \to (\alpha, R)$, определяемое равенствами $Rd\alpha = (1-2GM/r)^{1/2}d\tau$ и $dR = (1-2GM/r)^{-1/2}dr$, такое что первые два члена в ds^2 будут равны $R^2d\alpha^2 + dR^2$, то есть возведенному в квадрат элементу длины плоского двухмерного евклидова пространства в полярных координатах. Таким образом, евклидово время τ пропорционально полярному углу α. Обозначим период времени τ как β. Поскольку нас интересует, что происходит непосредственно за горизонтом, необходимо определить (α, R) только до главного порядка в $(r-2GM)$. Интегрируя два дифференциальных уравнения, получаем

$$R(2\pi) = \left(1 - \frac{2GM}{r}\right)^{\frac{1}{2}} \beta \simeq (2GM)^{-\frac{1}{2}}(r-2GM)^{\frac{1}{2}}\beta$$

и

$$R = \int\limits_{2GM}^{r} \left(1 - \frac{2GM}{r'}\right)^{-\frac{1}{2}} dr' \simeq (2GM)^{\frac{1}{2}} \int\limits_{2GM}^{r} (r'-2GM)^{-\frac{1}{2}}\, dr' = \\ = (2GM)^{\frac{1}{2}} 2(r-2GM)^{\frac{1}{2}}.$$

Разделив, находим $\beta = (2\pi)^2 2(2GM) = 8\pi GM$ и соответственно температуру Хокинга

$$T = \frac{1}{8\pi GM} = \frac{\hbar c^3}{8\pi GM}$$

Восстанавливая $\hbar$, легко видеть, что излучение Хокинга действительно является квантовым эффектом.

Упражнения

V.2.1. Изучите теорию свободного поля $\mathcal{L} = \frac{1}{2}(\partial\varphi)^2 - \frac{1}{2}m^2\varphi^2$ при конечной температуре и выведите распределение Бозе-Эйнштейна.

V.2.2. Вас, вероятно, не удивит, что для фермионных полей периодическое граничное условие (6) заменяется антипериодическим граничным условием $\psi(\vec{x}, 0) = -\psi(\vec{x}, \beta)$ с той целью, чтобы можно было воспроизвести результаты, полученные в главе II.5. Докажите это, рассматривая простейший фермионный функциональный интеграл. [Указание: наиболее ясное проявление этого убедительного факта можно найти в приложении A к статье R. Dashen, B. Hasslacher and A. Neveu, Phys. Rev. D12: 2443, 1975.]

V.2.3. Интересно рассмотреть квантовую теорию поля для конечной плотности, которая может иметь место в плотных астрофизических объектах или при столкновениях тяжелых ионов. (В предыдущей главе мы изучили систему бозонов при конечной плотности и нулевой температуре.) Изучая статистическую механику, мы научились переходить от статистической суммы к большой статистической сумме $Z = \operatorname{tr} e^{-\beta(H-\mu N)}$, где химический потенциал μ вводится для числа N каждой сохраняющейся частицы. Например, для невзаимодействующих релятивистских фермионов лагранжиан преобразуется к виду $\mathcal{L} = \bar{\psi}(i\partial\!\!\!/ - m)\psi + \mu\bar{\psi}\gamma^0\psi$. Заметим, что конечная плотность, как и конечная температура, нарушает лоренц-инвариантность. Разработайте квантовую теорию поля при конечной плотности в такой степени, какой сможете.

30.2.3 Zi.V.3 Ginzburg–Landau Theory of Critical Phenomena

Появление неаналитичности

Исторически понятие спонтанного нарушения симметрии пришло в физику элементарных частиц из физики конденсированных сред и было впервые использовано в работе Гинзбурга и Ландау о фазовых переходах второго рода.

Рассмотрим ферромагнетик в тепловом равновесии при температуре T. Намагничивание $M(\vec{x})$ определяется как среднее атомных магнитных моментов, взятое по области намного большего размера, чем масштаб длин, характерный для рассматриваемой микроскопической физики. (В этой главе мы обсуждаем нерелятивистскую теорию и x обозначает только пространственные координаты.) Известно, что при низких температурах вращательная инвариантность спонтанно нарушается и вещество проявляет объемную намагниченность, ориентированную в некотором направлении. Когда температура растет выше некоторой критической T_c, объемная намагниченность внезапно исчезает. Понятно, что при более активном тепловом перемешивании атомные магнитные моменты в большей мере ориентированы в случайных направлениях, взаимно уничтожая друг друга. Если точнее, то экспериментально было обнаружено, что при температуре непосредственно ниже T_c намагничивание $|\vec{M}|$ исчезает как $\sim (T_c - T)^{\beta}$, где так называемая критическая экспонента равна $\beta \approx 0,37$.

Это внезапное изменение известно как фазовый переход второго рода и является примером критического явления. Исторически изучение критических явлений представляло собой трудную задачу для физиков-теоретиков. В принципе необходимо вычислить статистическую сумму $Z = \operatorname{tr} e^{-\mathcal{H}/T}$ с микроскопическим гамильтонианом $\mathcal{H}$, но Z очевидно является гладкой от T, за исключением, возможно, случая $T = 0$. Некоторые физики зашли настолько далеко, что стали утверждать невозможность такого неаналитического поведения, как $(T_c - T)^{\beta}$, и что в пределах ошибки эксперимента $|\vec{M}|$ фактически исчезает как гладкая функция от T. Тот факт, что Онсагер нашел в 1944 году всем известное точное решение двухмерной модели Изинга, имеет немаловажное значение, в том числе и в том, что оно определенно ответило на поставленный вопрос. Секрет в том, что бесконечная сумма членов, каждый из которых может быть аналитическим по некоторой переменной, не обязана быть аналитической по этой переменной. След в $\operatorname{tr} e^{-\mathcal{H}/T}$ берется по бесконечному числу членов.

Симметрийные аргументы

В большинстве случаев, как правило, невозможно вычислить Z, если начать с микроскопического гамильтониана. Ландау и Гинзбург проявили блестящую проницательность, полагая, что вид свободной энергии G как функцию $\vec{M}$ для системы с объемом V можно рассматривать исходя из общих принципов. Во-первых, для $\vec{M}$, постоянной по x, получаем в силу вращательной инвариантности выражение

$$G = V\left[a\vec{M}^2 + b\left(\vec{M}^2\right)^2 + \ldots\right]$$

где $a, b, \ldots$ являются неизвестными (но ожидаются гладкими) функциями от T. Ландау и Гинзбург предположили, что при некоторой температуре T_c функция a обращается в нуль. Если нет какой-то особой причины, можно ожидать, что $a = a_1(T - T_c) + \ldots$ [а не, скажем, $a = a_2(T - T_c)^2 + \ldots$]. Но из главы IV.1 уже известно, что произойдет. Для $T > T_c$ свободная энергия G имеет минимум при $\vec{M} = 0$, но, когда температура T падает ниже T_c, внезапно образуется новый минимум при $|\vec{M}| = \sqrt{(-a/2b)} \sim (T_c - T)^{1/2}$. Вращательная симметрия спонтанно нарушается, и таинственное неаналитическое поведение внезапно исчезает.

Чтобы учесть в модели возможность $\vec{M}$ меняться в пространстве, Ландау и Гинзбург предложили использовать G в следующем виде:

$$G = \int d^3x \left\{\partial_i\vec{M}\partial_i\vec{M} + a\vec{M}^2 + b\left(\vec{M}^2\right)^2 + \ldots\right\}$$

где коэффициент члена $\left(\partial_i\vec{M}\right)^2$ положен равным 1 за счет изменения масштаба $\vec{M}$. Легко понять, что выражение (2) является евклидовым вариантом теории скалярного поля, которую мы уже изучали. Из размерного анализа следует, что $1/\sqrt{a}$ определяет масштаб длин.

Скажем точнее: включим для $T > T_c$ возмущающее внешнее магнитное поле $\vec{H}(x)$, добавляя член $-\vec{H} \cdot \vec{M}$. Предполагая, что $\vec{M}$ мало, и минимизируя G, получаем $(-\partial^2 + a)\vec{M} \simeq \vec{H}$ и решение

$$\vec{M}(x) = \int d^3y \int \frac{d^3k}{(2\pi)^3} \frac{e^{i\vec{k}\cdot(\vec{x}-\vec{y})}}{\vec{k}^2 + a} \vec{H}(y) = \int d^3y \frac{1}{4\pi|\vec{x}-\vec{y}|} e^{-\sqrt{a}|\vec{x}-\vec{y}|} \vec{H}(y)$$

[Вспомним, что мы уже вычисляли интеграл (I.4.7), и восхитимся единством физики!]

Чтобы определить корреляционную функцию $\langle \vec{M}(x)\vec{M}(0)\rangle$, обычно задаются вопросом, каким будет намагничивание $\vec{M}(x)$, если использовать магнитное поле, сильно локализованное в начале координат, для создания там намагничивания $\vec{M}(0)$. Ожидается, что корреляционная функция спадает как $e^{-|\vec{x}|/\xi}$ на некоторой корреляционной длине ξ, которая стремится к бесконечности, когда T приближается к T_c сверху. Критическая экспонента ν обычно определяется выражением $\xi \sim 1/(T - T_c)^{\nu}$.

В теории Гинзбурга - Ландау, которую также называют теорией среднего поля, получаем $\xi = 1/\sqrt{a}$ и, следовательно, $\nu = 1/2$.

Важным фактором является не то, насколько хорошо согласуются с экспериментом предсказанные критические экспоненты, такие как β и ν, а то, насколько легко они возникают из теории Гинзбурга-Ландау. Эта теория является отправной для полной теории критических явлений, которая в итоге была разработана с использованием ренорм-группы Кадановым, Фишером, Вильсоном и другими (она будет рассмотрена в главе VI.8).

Говорят, что Ландау оценивал физиков-теоретиков по логарифмической шкале, в которой первое место занимал Эйнштейн; и что после создания теории Гинзбурга-Ландау он переместил себя на полкласса выше [1].

Упражнения

V.3.1. Другая важная критическая экспонента γ определяется тем, что восприимчивость $\chi \equiv (\partial M/\partial H)|_{H=0}$ расходится $\sim 1/|T - T_c|^{\gamma}$, когда T приближается к T_c. Определите γ в теории Гинзбурга-Ландау. [Указание: чтобы это сделать, есть два пути. (a) Добавьте $-\vec{H} \cdot \vec{M}$ в выражение (1) для постоянных в пространстве $\vec{M}$ и $\vec{H}$ и найдите $\vec{M}(\vec{H})$. (b) Вычислите функцию восприимчивости $\chi_{ij}(x-y) \equiv [\partial M_i(x)/\partial H_j(y)]|_{H=0}$ и проинтегрируйте по пространству.]

[1] Из второго класса. - Прим. ped.

30.2.4 Zi.V.4 Superconductivity

(see my special note about it)

Спаривание и конденсация

Когда некоторые материалы охлаждаются до температуры ниже критической T_c, они внезапно становятся сверхпроводящими. Исторически физики давно предполагали, что переход в сверхпроводящее состояние, как и переход в сверхтекучее состояние, как-то связан с конденсацией БозеЭйнштейна. Но электроны являются фермионами, а не бозонами, и поэтому они вначале должны спариться с образованием бозонов, которые затем конденсируются. Теперь мы знаем, что подобное общее представление является, по существу, правильным. Электроны образуют куперовские пары, конденсация которых отвечает за сверхпроводимость.

С блестящей проницательностью Ландау и Гинзбург поняли, что, изучая поле $\varphi(x)$, связанное с конденсирующимися бозонами, явление сверхпроводимости можно достаточно хорошо понять и без знания детального механизма, определяющего спаривание электронов с образованием бозонов. По аналогии с ферромагнитным переходом, при котором

намагничивание $\vec{M}(x)$ в ферромагнетике внезапно меняется от нуля до ненулевого значения при падении температуры ниже некоторого критического значения, они предположили, что поле $\varphi(x)$ становится отличным от нуля при температурах ниже T_c. (В этой главе x обозначает только пространственные координаты.) В статистической физике такие величины, как $\vec{M}(x)$ и $\varphi(x)$, которые изменяются при фазовом переходе, называют параметрами порядка.

Поле $\varphi(x)$ имеет две единицы электрического заряда и поэтому является комплексным. Теперь рассмотрение будет во многом таким же, как в главе V.3, за исключением того, что $\partial_i\varphi$ надо заменить на $D_i\varphi = (\partial_i - \ -i2eA_i)\,\varphi$, поскольку поле φ заряжено. Следуя Ландау и Гинзбургу, а также включая энергию внешнего магнитного поля, запишем свободную энергию в виде уравнения

$$\mathcal{F} = \frac{1}{4}F_{ij}^2 + |D_i\varphi|^2 + a|\varphi|^2 + \frac{b}{2}|\varphi|^4 + ...$$

которое явно инвариантно относительно $U(1)$-калибровочного преобразования $\varphi \to e^{i2e\Lambda}\varphi$ и $A_i \to A_i + \partial_i\Lambda$. Как и прежде, требование равенства коэффициента при $|D_i\varphi|^2$ единице эквивалентно выбору нормировки для φ. Сходство между (1) и (IV.6.1) очевидно.

Эффект Мейсснера

Отличительной чертой сверхпроводимости является эффект Мейсснера, когда проникающее сквозь вещество внешнее магнитное поле $\vec{B}$ вытесняется из него при падении температуры ниже T_c. Это означает, что постоянное магнитное поле внутри вещества энергетически невыгодно. Действующие законы электромагнетизма в таком веществе при T_c должны некоторым образом модифицироваться. Как правило, постоянное магнитное поле требует затрат энергии порядка $\sim \vec{B}^2V$, где V - объем вещества. Прсдположим, что плотность энергии меняется от стандартной $\vec{B}^2$ до $\vec{A}^2$ (где $\vec{\nabla}\times\vec{A} = \vec{B}$). Значение $\vec{A}$ увеличивается с расстоянием в постоянном магнитном поле $\vec{B}$, и поэтому полная энергия растет быстрее, чем V. Когда вещество становится сверхпроводящим, для поддержания постоянного магнитного поля необходимо так много дополнительной энергии, что магнитное поле выгоднее вытеснить.

Заметим, что такой член, как $\vec{A}^2$ в эффективной плотности энергии, сохраняет вращательную и трансляционную инвариантность, но нарушает электромагнитную калибровочную инвариантность. Однако из главы IV.6 мы знаем, как нарушить калибровочную инвариантность. Действительно, описанная там калибровочная теория U(1) и описанная здесь теория сверхпроводимости, по существу, одинаковы и связаны виковским поворотом.

Как и в главе V.3, предположим, что $a \simeq a_1\,(T - T_c)$, а b остается положительным при температуре $T \simeq T_c$. Свободная энергия $\mathcal{F}$ минимизируется выше T_c за счет $\varphi = 0$, а ниже T_c за счет $|\varphi| = \sqrt{-a/b} \equiv v$. Все вышесказанное хорошо знакомо тем, кто знает, что калибровочное поле приобретает массу при нарушении симметрии в калибровочной теории. Из выражения (1) просто получаем

$$\mathcal{F} = \frac{1}{4}F_{ij}^2 + (2ev)^2A_i^2 + ...$$

т. е. именно то, что необходимо для объяснения эффекта Мейсснера.

Лондоновская длина проникновения и длина когерентности

Физически магнитное поле не резко уменьшается от некоторого ненулевого значения вне сверхпроводника до нуля внутри него, а в пределах некоторого характеристического масштаба длин, называемого лондоновской длиной проникновения. Магнитное поле проникает в сверхпроводник на глубину, немного большую масштаба длины l, что

определяется конкуренцией между энергией в магнитном поле $F_{ij}^2 \sim (\partial A)^2 A^2/l^2$ и мейсснеровским членом $(2ev)^2A^2$ в (2). Так, Ландау и Гинзбург получили лондоновскую длину проникновения $l_L \sim (1/ev) = (1/e)\sqrt{b/-a}$.

Аналогично характеристический масштаб длин, в пределе которого изменяется параметр порядка φ, известен как длина когерентности l_φ. Ее можно оценить приравнивая второй и третий члены в (1), например так: $(\partial\varphi)^2 \sim \varphi^2/l_\varphi^2$ и $a\varphi^2$, что дает длину когерентности порядка $l_\varphi \sim 1/\sqrt{-a}$.

Объединяя все вместе, получаем

$$\frac{l_L}{l_\varphi} \sim \frac{\sqrt{b}}{e}$$

Заметим, что согласно главе IV.6 это есть просто отношение массы скалярного поля к массе векторного поля.

Как говорилось выше, концепция спонтанного нарушения симметрии пришла в физику элементарных частиц из физики конденсированных сред. Намбу сыграл важную роль тем, что привнес понятие спонтанного нарушения симметрии в сообщество специалистов по физике элементарных частиц после того, как услышал в университете Чикаго доклад молодого Шриффера по теории сверхпроводимости Бардина-Купера-Шриффера.

Упражнения

V.4.1. Проварьируйте (1) чтобы получить уравнение для A, и более аккуратно получите лондоновскую глубину проникновения.

V.4.2. Выведите более аккуратно выражение для длины когерентности.

30.2.5 Zi.V.5 Peierls Instability

Невзаимодействующие прыгающие электроны

Появление уравнения Дирака и релятивистской теории поля для твердого тела кажется поистине удивительным, но это на самом деле это возможно.

Рассмотрим гамильтониан

$$H = -t\sum_j \left(c_{j+1}^\dagger c_j + c_j^\dagger c_{j+1}\right)$$

описывающий невзаимодействующие прыгающие электроны на 1-мерной решетке (рис. V.5.1). Здесь c_j уничтожает электрон в узле j. Таким образом, первый член описывает электрон, скачущий из узла j в узел $j+1$ с амплитудой t. Спиновые значки мы опустили. Это лишь простейшая модель твердого тела; она хорошо изложена в фейнмановских лекциях по физике.

Выполняя Фурье-преобразование $c_j = \sum\limits_k e^{ikaj}c(k)$ (где a - расстояние между узлами), сразу же находим энергетический спектр $\varepsilon(k) = -2t\cos ka$ (рис. V.5.2). Налагая периодическое граничное условие на решетку с числом узлов N, получаем $k = (2\pi/Na)n$, где n - целое число от $-1/2N$ до $1/2N$. При $N \to \infty k$ становится непрерывной, а не дискретной переменной. Как обычно, зона Бриллюэна определяется как $-\pi/a < k \leqslant \pi/a$.

Во всем вышеизложенном нет ничего релятивистского. В самом деле, в нижней части спектра энергия (с точностью до несущественной аддитивной постоянной) определяется как $\varepsilon(k) \simeq 2t\frac{1}{2}(ka)^2 \equiv k^2/2m_{\text{eff.}}$ Электрон распространяется нерелятивистски с эффективной массой $m_{\text{eff.}}$.

Теперь заполним систему электронами до некоторого ферми-уровня ε_F (см. рис. V.5.2). Сосредоточим внимание на электроне вблизи ферми-поверхности и измерим его энергию от

ε_F и импульс от $+k_F$. Предположим, что нас интересуют электроны, энергия которых мала по сравнению с энергией ε_F, то есть $E \equiv \varepsilon - \varepsilon_F \ll \varepsilon_F$, а импульс которых мал по сравнению

Рис. V.5.1

с k_F, то есть $p \equiv k - k_F \ll k_F$. Эти электроны подчиняются линейному закону дисперсии энергии $E = v_F p$ с ферми-скоростью $v_F = (\partial\varepsilon/\partial k)|_{k=k_F}$. Обозначим поле, связанное с этими электронами, как ψ_R, где нижний индекс означает, что электроны «движутся направо», что удовлетворяет уравнению движения $(\partial/\partial t + v_F \partial/\partial x)\,\psi_R = 0$.

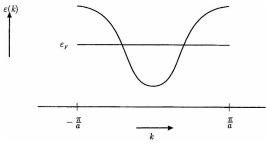


Рис. V.5.2

Аналогично электроны с импульсом порядка $-k_F$ подчиняются закону дисперсии $E = -v_F p$. Обозначим поле, связанное с этими электронами, как ψ_L, где L означает «движение налево», что удовлетворяет уравнению движения $(\partial/\partial t - v_F \partial/\partial x)\,\psi_L = 0$.

Появление уравнения Дирака

Лагранжиан, объединяющий все это, имеет вид

$$\mathcal{L} = i\psi_R^\dagger \left(\frac{\partial}{\partial t} + v_F \frac{\partial}{\partial x}\right)\psi_R + i\psi_L^\dagger \left(\frac{\partial}{\partial t} - v_F \frac{\partial}{\partial x}\right)\psi_L$$

Вводя двухкомпонентное поле $\psi = \begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix}, \bar{\psi} \equiv \psi^\dagger\gamma^0 \equiv \psi^\dagger\sigma_2$ и выбирая единицы так, чтобы $v_F = 1$, лагранжиан $\mathcal{L}$ можно записать в более ком- пактном виде

$$\mathcal{L} = i\psi^\dagger \left(\frac{\partial}{\partial t} - \sigma_3 \frac{\partial}{\partial x}\right)\psi = \bar{\psi} i\gamma^\mu \partial_\mu \psi$$

где $\gamma^0 = \sigma_2$ и $\gamma^1 = i\sigma_1$ удовлетворяют алгебре Клиффорда $\{\gamma^\mu, \gamma^\nu\} = 2g^{\mu\nu}$.

Удивительно, что (1 + 1)-мерный лагранжиан Дирака появляется в совершенно нерелятивистской ситуации!

Рис. V.5.3

Неустойчивость

Теперь перейдем к рассмотрению важного явления, известного как пайерлсовская неустойчивость. Я буду вынужден использовать несколько схематичный подход. Нет необходимости повторять, что это не учебник по физике твердого тела, но в любом случае вам нетрудно будет восполнить пробелы.

Пайерлс рассмотрел искажение решетки для случая, когда ион в узле j смещен относительно своего равновесного положения на $\cos[q(ja)]$. (Напоминает наш матрац из главы I.1!) Искажение решетки с волновым вектором $q = 2k_F$ соединяет электроны, имеющие импульс k_F, с электронами, имеющими импульс $-k_F$. Другими словами, это искажение соединяет электроны, движущиеся направо, с электронами, движущимися налево, или ψ_R с ψ_L в соответствии с используемой здесь терминологией теории поля. Поскольку электроны, движущиеся направо и налево, имеют одинаковую энергию на

ферми поверхности (а именно ε_F, что не ново), имеем интересный случай теории возмущений при наличии вырождения $\begin{pmatrix} \varepsilon_F & 0 \\ 0 & \varepsilon_F \end{pmatrix} + \begin{pmatrix} 0 & \delta \\ \delta & 0 \end{pmatrix}$ с собственными значениями $\varepsilon_F \pm \delta$. На поверхности Ферми образуется щель. Здесь δ является возмущением. Таким образом, Пайерлс пришел к выводу, что спектр изменяется радикально и система является нестабильной при возмущении с волновым вектором $2k_F$.

Особенно интересная ситуация возникает, когда система наполовину заполнена электронами (так что плотность равна одному электрону на каждый узел - напомним, что электроны имеют спин, направленный вверх или вниз). Другими словами, $k_F = \pi/2a$, и поэтому $2k_F = \pi/a$. Искажение решетки, которое показано на рис. V.5.3, имеет точно такой же волно- вой вектор. Пайерлс показал, что наполовину заполненная система будет стрсмиться исказить решетку, удваивая элементарную ячейку. Поучительно обратить внимание на то, как это физическое явление появляется в теоретико-полевой формулировке.

Обозначим смещение иона в узле j как d_j. В непрерывном пределе мы должны заменить d_j на скалярное поле. Покажем, что возмущение, связывающее ψ_R и ψ_L, взаимодействует с $\bar{\psi}\psi$ и $\bar{\psi}\gamma^5\psi$ и что линейную комбинацию $\bar{\psi}\psi$ и $\bar{\psi}\gamma^5\psi$ киральным преобразованием можно всегда повернуть к $\bar{\psi}\psi$ (см. упражнение V.5.1.). Таким образом, мы расширяем (3) до

$$\mathcal{L} = \bar{\psi} i\gamma^\mu \partial_\mu \psi + \frac{1}{2}\left[(\partial_t\varphi)^2 - v^2\,(\partial_x\varphi)^2\right] - \frac{1}{2}\mu^2\varphi^2 + g\varphi\bar{\psi}\psi + \ldots$$

Вспомним, что в упражнении (IV.3.2) вы уже вычисляли эффективный потенциал $V_{\text{eff}}(\varphi)$ такой $(1+1)$-мерной теории поля: $V_{\text{eff}}(\varphi)$ для малого φ имеет вид $\varphi^2 \log \varphi^2$, который превосходит член $\frac{1}{2}\mu^2\varphi^2$. Таким образом, симметрия $\varphi \to -\varphi$ динамически нарушается. Поле φ приобретает вакуумное среднее, и ψ становится массивным. Другими словами, в электронном спектре образуется щель.

Упражнения

V.5.1. С учетом рассуждений, приведенных в главе II.1, вы легко можете увидеть, что пространство 2×2-матриц образовано четырьмя матрицами I, γ^μ и $\gamma^5 \equiv \gamma^0\gamma^1 = \sigma_3$. (Обратите внимание на своеобразное, но стандартное обозначение γ^5.) Убедитесь в том, что $\frac{1}{2}(I \pm \gamma^5)$ проецирует правые и левые поля точно так, как в $(3+1)$-мерном пространстве-времени. Покажите, что в билинейном члене $\bar{\psi}\gamma^\mu\psi$ левые поля связаны с левыми полями, а правые с правыми и что в скаляре $\bar{\psi}\psi$ и псевдоскаляре $\bar{\psi}\gamma^5\psi$ правые поля связаны с левыми и наоборот. Наконец, обратите внимание, что при преобразовании $\psi \to e^{i\theta\gamma^5}\psi$ скаляр и псевдоскаляр обращаются друг в друга. Проверьте, что это преобразование оставляет безмассовый лагранжиан Дирака (3) инвариантным.

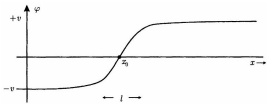
30.2.6 Zi.V.6 Solitons

Я люблю говорить студентам, которым преподаю квантовую теорию поля, что к середине 1970-х годов специалисты по теории поля начали избавляться от оков фейнмановских диаграмм. Звучит это несколько мелодраматично, но к тому времени фейнмановские диаграммы, благодаря их впечатляющему успеху в квантовой электродинамике, доминировали (возможно, даже слишком) в мышлении многих специалистов по теории поля. В студенчестве мне даже говорили, что фейнмановские диаграммы определяют квантовую теорию поля, что квантовые поля являются просто «ломтиками оленины» [1], которые использовали для выведения правил Фейнмана и от которых надо отказаться, раз уже эти правила получены. Превалировало мнение, что вряд ли имеет смысл записывать $\varphi(x)$. Открытие топологических солитонов навсегда опровергло это мнение, как мы сейчас увидим. (!?!??!?)

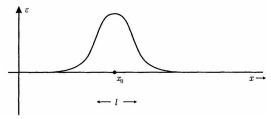
Малые колебания в сравнении со сгустками

Рассмотрим еще раз нашу любимую игрушечную модель $\mathcal{L} = \frac{1}{2}(\partial\varphi)^2 - V(\varphi)$ с пресловутым двухъямным потенциалом $V(\varphi) = (\lambda/4)\times\times\left(\varphi^2 - v^2\right)^2$ в (1+1)-мерном пространстве-времени. Из главы IV.1 известно, что из двух вакуумов $\varphi = \pm v$ нужно выбрать один и изучить относительно него малые колебания. Итак, выберем один вакуум и запишем $\varphi = v + \chi$, разложим $\mathcal{L}$ по χ и изучим динамику χ-мезона с массой $\mu = (2\lambda v^2)^{1/2}$. Тогда физика будет заключаться в квантованных соответствующим образом волнах, колеблющихся вблизи вакуума v.

' Гелл-Манн имел обыкновение говорить. что во Франции мясо фазана готовят между двумя ломтиками оленины. которые затем выбрасывают. Он убедительно рекомендовал использовать такой подход для извлечения и изучения алгебраической структуры квантовых теорий поля. а затем от них избавляться. Но это еще не все. Можно также иметь не зависящую от времени конфигурацию поля с $\varphi(x)$ (в этой и следующей главах x обозначает только пространство, если из контекста не следует что-то другое), принимающую значение $-v$, когда $x \to -\infty$, и $+v$, когда $x \to +\infty$, и изменяющуюся от $-v$ до $+v$ относительно некоторой точки x_0 на некотором масштабе длин l, как показано на рис. V.6.1a. [Заметим, что если рассматривать евклидов вариант теории поля, определять временную координату как координату y и считать $\varphi(x, y)$ намагничиванием (как в главе V.4), то такая конфигурация будет описывать «доменную стенку» в двумерной магнитной системе.]



(a)



(b)
Рис. V.6.1

Рассмотрим энергию, приходящуюся на единицу длины,

$$\varepsilon(x) = \frac{1}{2}\left(\frac{d\varphi}{dx}\right)^2 + \frac{\lambda}{4}\left(\varphi^2 - v^2\right)^2$$

для конфигурации, которая изображена на рис. V.6.1b. Вдали от x_0 мы находимся в одном из двух вакуумов, и плотность энергии отсутствует. Вблизи x_0 оба члена в $\varepsilon(x)$ вносят вклад в энергию или массу $M = \int dx\varepsilon(x)$: член «пространственной вариации» (при несколько вольном использовании терминологии часто называемый «кинетической энергией») $\int dx\frac{1}{2}(d\varphi/dx)^2 \sim l(v/l)^2 \sim v^2/l$ и член «потенциальной энергии» $\int dx\lambda\left(\varphi^2 - v^2\right)^2 \sim l\lambda v^4$. Чтобы минимизировать полную энергию, член пространственной вариации требует, чтобы масштаб l был большим, тогда как член потенциала требует, чтобы l был малым. Конкуренция $dM/dl = 0$ приводит к $v^2/l \sim l\lambda v^4$, фиксируя таким образом $l \sim (\lambda v^2)^{-1/2} \sim 1/\mu$. Масса получается равной $\sim \mu v^2 \sim \mu\left(\mu^2/\lambda\right)$.

У нас есть сгусток энергии, распределенный по области длины l, порядка комптоновской длины волны χ-мезона. Вследствие трансляционной инвариантности центр этого сгустка x_0 может находиться где угодно. Более того, поскольку эта теория является лоренц-инвариантной, всегда можно заставить сгусток двигаться с любой скоростью, какая нам нравится. По аналогии с известной репликой из анналов американской политики («Она ходит как утка, крякает как утка, так почему же, господин сенатор, вы не хотите называть ее уткой?»), в нашем случае есть частица, называемая кинком или солитоном, с массой

$\sim \mu(\mu^2/\lambda)$ и размером $\sim l$. Многие физики представляют солитон как большой тяжело двигающийся объект, возможно, из-за того, как он был открыт. Но как мы видели, размер солитона $l \sim 1/\mu$ можно сделать насколько угодно малым, увеличивая μ. Поэтому солитон может выглядеть как точечная частица. В главе VI.3 мы вернемся к этому вопросу при обсуждении дуальности.

Топологическая устойчивость

Хотя кинк и мезон имеют одинаковый размер, при малой λ кинк намного тяжелее, чем мезон. Тем не менее кинк не может распасться на мезоны, потому что, для того чтобы уничтожить кинк [например, «поднимая» $\varphi(x)$ выше потенциального барьера, чтобы изменить его от $+v$ до $-v$ для x от некоторой точки $\gtrsim x_0$ до $+\infty$], требуется неограниченно много энергии. Говорят, что кинк топологически устойчив.

Эта устойчивость формально гарантируется сохраняющимся током

$$J^\mu = \frac{1}{2\mu}\varepsilon^{\mu\nu}\partial_\nu\varphi$$

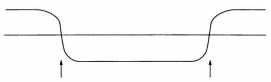
с зарядом

$$Q = \int\limits_{-\infty}^{+\infty} dx J^0(x) = \frac{1}{2v}[\varphi(+\infty) - \varphi(-\infty)]$$

Мезоны, которые представляют собой малые локализованные пакеты колебаний в поле, явно имеют $Q = 0$, тогда как кинк имеет $Q = 1$. Таким образом, кинк не может распасться на кучу мезонов. Кстати, плотность заряда $J^0 = (1/2v)(d\varphi/dx)$ локализована вокруг x_0, где, как можно ожидать, φ изменяется наиболее быстро.

Заметим, что равенство $\partial_\mu J^\mu = 0$ сразу же следует из антисимметричного символа $\varepsilon^{\mu\nu}$ и не зависит от уравнения движения. Ток J^μ известен как «топологический ток». Его существование следует не из теоремы Нётер (глава I.9), а из топологии.

Приведенные выше рассуждения также объясняют существование антикинка с $Q = -1$, который описывается конфигурацией с $\varphi(-\infty) = +v$ и $\varphi(+\infty) = -v$. Такое название оправданно, если рассмотреть конфигурацию, изображенную на рис. V.6.2, содержащую кинк и антикинк, расположенные друг от друга на большом расстоянии. Когда кинк и антикинк сближаются, они, очевидно, могут проаннигилировать с образованием мезонов, поскольку конфигурация, показанная на рис. V.6.2, и конфигурация вакуума с $\varphi(x) = +v$ повсюду разделены конечным количеством энергии.



Антикинк
Кинк
Рис. V.6.2

Непертурбативное явление

То, что масса кинка оказывается обратно пропорциональной константе связи λ, является явным признаком того, что теоретики-полевики могли бы до изнеможения проводить вычисления в теории возмущений по λ, так никогда не открыв кинк. Фейнмановские диаграммы не могли бы нам об этом сообщить.

Массу кинка можно вычислить, минимизируя функционал

$$M = \int dx \left[\frac{1}{2}\left(\frac{d\varphi}{dx}\right)^2 + \frac{\lambda}{4}\left(\varphi^2 - v^2\right)^2\right] = \left(\frac{\mu^2}{\lambda}\right)\mu \int dy \left[\frac{1}{2}\left(\frac{df}{dy}\right)^2 + \frac{1}{4}\left(f^2 - 1\right)^2\right]$$

где на последнем шаге выполнено очевидное масштабирование $\varphi(x) \to v f(y)$ и $y = \mu x$. Из масштабирования сразу же следует, что масса кинка имеет вид $M = a\,(\mu^2/\lambda)\,\mu$, где a - безразмерное число. Эвристическая оценка этой массы оказалась в высшей степени достоверной. Настоящую функцию $\varphi(x)$ и, следовательно, a можно вычислить с использованием стандартных вариационных методов.

Неравенство Богомольного

Следует обратить внимание на то, что плотность энергии (1) есть сумма двух квадратов. Используя $a^2 + b^2 \geqslant 2|ab|$, получаем

$$M \geqslant \int d \left(\frac{\lambda}{2}\right)^{1/2} \left| \left(\frac{d\varphi}{dx}\right) \left(\varphi^2 - v^2\right) \right| \geqslant \left(\frac{\lambda}{2}\right)^{1/2} \left| \left[\frac{1}{3}\varphi^3 - v^2\varphi\right]_{-\infty}^{+\infty} \right| =$$
$$= \left| \frac{4}{3\sqrt{2}} \mu \left(\frac{\mu^2}{\lambda}\right) Q \right|.$$

Приходим к изящному результату

$$M \geqslant |Q|$$

с массой M, измеряемой в единицах $(4/3\sqrt{2})\mu\,(\mu^2/\lambda)$. Это пример неравенства Богомольного, которое играет важную роль в теории струн.

Упражнения

V.6.1. Покажите, что если $\varphi(x)$ является решением уравнения движения, то решением также является $\varphi\left[(x - vt)/\sqrt{1 - v^2}\right]$.

V.6.2. Рассмотрите солитоны в так называемой теории синус-Гордона $\mathcal{L} = \frac{1}{2}(\partial\varphi)^2 - g\cos(\beta\varphi)$. Найдите топологический ток. Является ли солитон $Q = 2$ устойчивым?

V.6.3. Получите массу кинка прямым вычислением. Удовлетворяет ли она неравенству Богомольного?

30.2.7 Zi.V.7 Vortices, Monopoles, and Instantons

Кинк является лишь простейшим примером большого класса топологических объектов в квантовой теории поля.

Рассмотрим теорию комплексного скалярного поля в $(2 + 1)$-мерном пространстве-времени $\mathcal{L} = \partial\varphi^\dagger\partial\varphi - \lambda\left(\varphi^\dagger\varphi - v^2\right)^2$ с теперь уже знакомым потенциалом в форме сомбреро. С небольшими изменениями в обозначениях она соответствует теории, которая используется для описания взаимодействующих бозонов и сверхтекучих жидкостей. (Рассмотрим релятивистский, а не нерелятивистский вариант теории; как будет видно, этот выбор не связан с теми вопросами, которые здесь обсуждаются.)

Есть ли в этой теории солитоны, то есть объекты, подобные кинку?

Имея некоторую не зависящую от времени конфигурацию $\varphi(x)$, посмотрим, какую она имеет массу или энергию:

$$M = \int d^2x \left[\partial_i\varphi^\dagger\partial_i\varphi + \lambda\left(\varphi^\dagger\varphi - v^2\right)^2\right]$$

Подынтегральное выражение является суммой двух квадратов, каждый из которых должен дать конечный вклад. В частности, чтобы вклад второго члена был конечным, величина φ должна стремиться к v при пространственной бесконечности.

Однако требование конечной энергии не фиксирует фазу φ. Используя полярные координаты (r,θ), рассмотрим анзац $\varphi \overset{r\to\varphi}{\longrightarrow} ve^{i\theta}$. Записывая $\varphi=\varphi_1+i\varphi_2$, легко видеть, что на бесконечности вектор $(\varphi_1,\varphi_2)=v(\cos\theta,\sin\theta)$ направлен радиально наружу. Вспомним приведенное в главе III.5 определение тока $J_i=i\left(\partial_i\varphi^\dagger\varphi-\varphi^\dagger\partial_i\varphi\right)$ в бозонной жидкости. На пространственной бесконечности поток закручивается, и поэтому такая конфигурация называется вихрем.

Используя явное дифференцирование или анализ размерностей, получаем $\partial_i\varphi\sim v(1/r)$ при $r\to\infty$. Теперь посмотрим на первый член в M и увидим, что энергия расходится логарифмически как $v^2\int d^2x\,(1/r^2)$.

Можно ли решить эту проблему? Можно, если изменить теорию.

Вихрь в трубках потока

Предположим, что мы калибруем теорию, заменяя $\partial_i\varphi$ на $D_i\varphi=\partial_i\varphi$ - - $ieA_i\varphi$. Теперь можно получить конечную энергию, требуя, чтобы два члена в $D_i\varphi$ сокращали друг друга, так что $D_i\varphi\overset{r\to\infty}{\longrightarrow}0$ быстрее, чем $1/r$. Другими словами, $A_i\overset{r\to\infty}{\longrightarrow}-(i/e)\,(1/|\varphi|^2)\,\varphi^\dagger\partial_i\varphi$. Сразу же получаем

$$\text{Flux}\ \equiv\int d^2xF_{12}=\oint_C dx_iA_i=\frac{2\pi}{e}$$

где C является бесконечно большой окружностью на пространственной бесконечности; здесь использована теорема Стокса. Таким образом, в $U(1)$-калибровочной теории вихрь несет магнитный поток, обратно пропорциональный заряду. Говоря «магнитный», я полагаю, что A представляет собой электромагнитное калибровочное поле. Рассматриваемый здесь вихрь появляется в виде трубки потока в так называемых сверхпроводниках II рода. Следует отметить, что эта квант потока (2) в литературе по физике конденсированных сред обычно записывается в неестественных единицах, в виде

$$\Phi_0=\frac{hc}{e}$$

очень удачно объединяя три фундаментальные константы Природы.

Гомотопические группы

Поскольку пространственная бесконечность в двухмерном пространстве соответствует топологически единичной окружности S^1 и поскольку конфигурация поля с $|\varphi|=v$ также образует окружность S^1, это граничное условие может быть представлено как отображение $S^1\to S^1$. Поскольку такое отображение нельзя гладко преобразовать к тривиальному отображению, в котором S^1 отображается на точку в S^1, соответствующая конфигурация поля действительно является топологически устойчивой. (Представьте, что виток струны оборачивается вокруг кольца.)

С математической точки зрения отображения S^n в многообразие M классифицируются гомотопической группой $\Pi_n(M)$, которая подсчитывает число топологически неэквивалентных отображений. Вы можете познакомиться с гомотопическими группами для различных многообразий по таблицам'. В частности, для $n\geqslant 1\Pi_n\left(S^n\right)=Z$, где Z - математическое

[1] См. таблицы 6.V и 6.VI в энциклопедическом словаре S. Iyanaga and Y. Kawada. eds.. Enclclopedic Dictionary of Mathematics. p. 1415. обозначение множества всех целых чисел. Простейший пример $\Pi_1\left(S^1\right)=Z$ доказывается почти сразу путем представления отображений в виде $\varphi\overset{r\to\infty}{\longrightarrow}ve^{im\theta}$, где m - любое целое число (положительное или отрицательное). Для удобства можно использовать наш контекст и обозначения. Ясно, что это отображение оборачивает одну окружность вокруг другой m раЗ.

Язык гомотопических групп используется не только для того, чтобы произвести на людей впечатление, но и служит унифицированным языком при обсуждении

топологических солитонов. Действительно, оглядываясь назад, вы теперь понимаете, что кинк является физическим проявлением $\Pi_0(S^0) = Z_2$ (поскольку 0-мерная сфера $S^0 = \{+1, -1\}$ состоит только из двух точек и топологически эквивалентна пространственной бесконечности в одномерном пространстве).

Ежи и монополи

Если все предыдущее усвоено, можно перейти к $(3+1)$-мерному пространству-времени. Пространственная бесконечность теперь топологически является S^2. Вы уже представляете, что если скалярное поле существует на многообразии M, то на бесконечности получаем отображение $S^2 \to M$. Простейший вариант заключается в том, чтобы взять S^2 для M. Поэтому перейдем к скалярным полям $\varphi^a (a = 1, 2, 3)$, которые преобразуются как вектор $\vec{\varphi}$ для группы внутренней симметрии $O(3)$ и описываются лагранжианом $\mathcal{L} = \frac{1}{2}\partial\vec{\varphi}\cdot\partial\vec{\varphi} - V(\vec{\varphi}\cdot\vec{\varphi})$. (У вас не должно возникнуть путаницы при использовании стрелки для обозначения вектора в группе внутренней симметрии.)

Выберем $V = \lambda\left(\vec{\varphi}^2 - v^2\right)^2$. Ход событий разворачивается здесь во многом так же, как в случае с вихрем. Чтобы масса независимой от времени конфигурации

$$M = \int d^3x \left[\frac{1}{2}(\partial\vec{\varphi})^2 + \lambda\left(\vec{\varphi}^2 - b^2\right)^2\right]$$

была конечной, необходимо, чтобы $|\vec{\varphi}| = v$ на пространственной бесконечности, так что $\vec{\varphi}(r = \infty)$ действительно существует на S^2.

Тождественное отображение $S^2 \to S^2$ указывает на то, что нужно рассмотреть такую конфитурацию, для которой

$$\varphi^a \overset{r\to\infty}{\longrightarrow} v\frac{x^a}{r}$$

На первый взгляд это уравнение выглядит несколько странно, поскольку в нем одновременно участвует индекс группы внутренней симметрии с ин- дексом пространственных координат (но фактически мы уже сталкивались с этим явлением в вихре). На пространственной бесконечности поле $\vec{\varphi}$ направлено радиально наружу, поэтому такую конфигурацию образно называют «еж». Нарисуйте ее, если не можете представить!

Как и в случае с вихрем, условие конечности первого члена в (4) заставляет ввести $O(3)$-калибровочное поле A^b_μ, с тем чтобы можно было заменить обычную производную $\partial_i\varphi^a$ на ковариантную производную $D_i\varphi^a = \partial_i\varphi^a + e\varepsilon^{abc}A^b_i\varphi^c$. Тогда можно сделать так, чтобы $D_i\varphi^a$ обращалось в нуль на бесконечности. Используя обычную арифметику, можно показать, что для уравнения (5) калибровочный потенциал должен вести себя как

$$A^b_i \overset{r\to\infty}{\longrightarrow} \frac{1}{e}\varepsilon^{bij}\frac{x^j}{r^2}$$

Представьте себя в лаборатории на пространственной бесконечности. Поле $\vec{\varphi}$ внутри этой довольно небольшой лаборатории ориентировано в разных точках приблизительно в одном направлении. Калибровочная группа $O(3)$ нарушена до $O(2) \simeq U(1)$. В этой лаборатории экспериментаторы наблюдают за связанным с $U(1)$ безмассовым калибровочным полем, которое они вполне могут назвать электромагнитным полем («крякает как утка»). Действительно, калибровочно-инвариантное тензорное поле

$$\mathcal{F}_{\mu\nu} \equiv \frac{F^a_{\mu\nu}\varphi^a}{|\varphi|} - \frac{\varepsilon^{abc}\varphi^a\left(D_\mu\varphi\right)^b\left(D_\nu\varphi\right)^c}{e|\varphi|^3}$$

можно отождествлять с электромагнитным полем (см. упражнение V.7.5).

Электрического поля нет, поскольку такая конфигурация не зависит от времени и $A^b_0 = 0$. Можно получить только магнитное поле $\vec{B}$, которое сразу вычисляется, поскольку

известен A_i^b, но уже в силу симметрии видно, что поле $\vec{B}$ может быть ориентировано только в радиальном направлении. Это и есть легендарный магнитный монополь, впервые постулированный Дираком!

Существование магнитных монополей в спонтанно нарушенной калибровочной теории было открыто 't Хоофтом и Поляковым. Если вычислить полный магнитный поток, исходящий из монополя $\int d\vec{S} \cdot \vec{B}$ (где $d\vec{S}$, как обычно, обозначает малый элемент поверхности на бесконечности, с нормалью, ориентированной наружу), можно убедиться, что он квантован в соответствующих единицах точно так, как должно быть по утверждению Дирака (вспомним главу IV.4). Можно вновь записать неравенство Богомольного для массы монополя

$$M = \int d^3x \left[\frac{1}{4} \left(\vec{F}_{ij} \right)^2 + \frac{1}{2} \left(D_i \vec{\varphi} \right)^2 + V(\vec{\varphi}) \right]$$

$\left[\vec{F}_{ij} \right.$ преобразуется как вектор относительно $O(3)$; вспомним выражение (IV.5.17).] Обратите внимание, что

$$\frac{1}{4} \left(\vec{F}_{ij} \right)^2 + \frac{1}{2} \left(D_i \vec{\varphi} \right)^2 = \frac{1}{4} \left(\vec{F}_{ij} \pm \varepsilon_{ijk} D_k \vec{\varphi} \right)^2 \mp \frac{1}{2} \varepsilon_{ijk} \vec{F}_{ij} \cdot D_k \vec{\varphi}.$$

Таким образом

$$M \geqslant \int d^3x \left[\mp \frac{1}{2} \varepsilon_{ijk} \vec{F}_{ij} \cdot D_k \vec{\varphi} + V(\vec{\varphi}) \right]$$

Далее заметим, что выражение

$$\int d^3x \frac{1}{2} \varepsilon_{ijk} \vec{F}_{ij} \cdot D_k \vec{\varphi} = \int d^3x \frac{1}{2} \varepsilon_{ijk} \partial_k \left(\vec{F}_{ij} \cdot \vec{\varphi} \right) = v \int d\vec{S} \cdot \vec{B} = 4\pi v g$$

имеет изящную интерпретацию в терминах магнитного заряда g монополя. Кроме того, если можно отбросить $V(\vec{\varphi})$, сохраняя при этом $|\vec{\varphi}| \stackrel{r \to \infty}{\longrightarrow} v$, то неравенство $M \geqslant 4\pi v |g|$ насыщается $\vec{F}_{ij} = \pm \varepsilon_{ijk} D_k \vec{\varphi}$. Решения этого уравнения известны как состояния Богомольного-Прасада-Зоммерфельда (или БПС-состояния).

Нетрудно построить электрически заряженный магнитный монополь, называемый дионом. Для этого просто берется $A_0^b = \left(x^b / r \right) f(r)$ с некоторой подходящей функцией $f(r)$.

Замечательной особенностью топологического монополя является то, что его масса оказывается равной $\sim M_W / \alpha \sim 137 M_W$ (упражнение V.7.11), где M_W обозначает массу промежуточного векторного бозона слабого взаимодействия. В главе VII.2 мы отчасти предвидели, что калибровочный бозон, который в главе IV.6 становится массивным вследствие механизма Андерсона - Хигтса, можно отождествить с промежуточным векторным бозоном. Это естественно объясняет, почему такой монополь еще не был обнаружен.

Инстантон

Рассмотрим неабелеву калибровочную теорию и осуществим поворот в интеграле по траекториям $Z = \int DA e^{-S(A)}$ в четырехмерное евклидово пространство. Мы могли бы определить Z в приближении наискорейшего спуска, для которого необходимо найти экстремум

$$S(A) = \int d^4x \frac{1}{2g^2} \operatorname{tr} F_{\mu\nu} F_{\mu\nu}$$

с конечным действием. Это означает, что на бесконечности $|x| = \infty$ множитель $F_{\mu\nu}$ должен убывать быстрее, чем $1/|x|^2$, и поэтому калибровочное поле A_μ должно быть чистой

калибровкой: $A = gdg^\dagger$ для элемента калибровочной группы g [см. выражение (IV.5.6)]. Конфигурации, для которых это условие имеет место, называют инстантонами. Мы видим, что инстантон является еще одним звеном в «великой цепи существования»: кинк-вихрь-монополь-инстантон.

Выберем для определенности калибровочную группу $SU(2)$. В параметризации $g = x_4 + i\vec{x}\cdot\vec{\sigma}$ по определению имеем $g^\dagger g = 1$ и $\det g = l$, что означает $x_4^2 + \vec{x}^2 = 1$. Мы знаем, что групповым многообразием $SU(2)$ является S^3. Таким образом, в инстантоне калибровочный потенциал на бесконечности $A \xrightarrow{r\to\infty} gdg^\dagger + O\left(1/|x|^2\right)$ определяет отображение $S^3 \to S^3$. Не кажется ли это знакомым? Действительно, вы уже знаете, какую роль в теории поля играют $S^0 \to S^0, S^1 \to S^1, S^2 \to S^2$. ственно

Напомним, что согласно главе IV.5 $\operatorname{tr} F^2 = d\operatorname{tr}\left(AdA + \frac{2}{3}A^3\right)$. Соответ-

$$\int \operatorname{tr} F^2 = \int\limits_{S^3} \operatorname{tr}\left(AdA + \frac{2}{3}A^3\right) = \int\limits_{S^3} \operatorname{tr}\left(AF - \frac{1}{3}A^3\right) = -\frac{1}{3}\int\limits_{S^3} \operatorname{tr}\left(gdg^\dagger\right)^3,$$

где использован тот факт, что F обращается в нуль на бесконечности. Это условие явно показывает, что $\int \operatorname{tr} F^2$ зависит только от гомотопии отображения $S^3 \to S^3$, определяемого g, и, следовательно, является топологической величиной. Кстати, $\int\limits_{S^3} \operatorname{tr}\left(gdg^\dagger\right)^3$ известен математикам как индекс Понтрягина (см. упражнение V.7.13).

В главе IV.7 упоминалось, что на киральную аномалию не влияют квантовые флуктуации более высоких порядков. Теперь у вас есть возможность привести изящное топологическое доказательство этого утверждения (упражнение V.7.13).

Переход Костерлица-Таулесса

Мы немного поспешили отказаться от вихря в некалиброванной теории $\mathcal{L} = \partial\varphi^\dagger\partial\varphi - \lambda\left(\varphi^\dagger\varphi - v^2\right)^2$ в $(2+1)$-мерном пространстве-времени. Вокруг вихря поле имеет вид $\varphi \sim ve^{i\theta}$, и, как мы уже отмечали, энергия одиночного вихря расходится логарифмически. Но что происходит с вихрем в паре с антивихрем?

Изобразим вихрь и антивихрь, разделенные расстоянием R, большим по сравнению с масштабами расстояний в теории. Вокруг антивихря поле имеет вид $\varphi \sim ve^{-i\theta}$. Поле φ наматывается вокруг вихря в одном направлении, а вокруг антивихря в другом направлении. Сделав рисунок, убедитесь в том, что на пространственной бесконечности поле φ вовсе не наматывается: оно лишь стремится к фиксированному значению. Наматывание в одном направлении компенсирует наматывание в другом направлении.

Таким образом, конфигурация, состоящая из пары вихрь-антивихрь, не требует затрат бесконечной энергии. Однако она требует затрат конечного количества энергии. На самом деле в области между вихрем и антивихрем поле φ наматывается примерно в два раза быстрее (что видно по рисунку). Следовательно, приблизительная оценка энергии имеет вид $v^2\int d^2x\,(1/r^2) \sim v^2\log(R/a)$ после интегрирования по области размером R, относящейся к физической шкале в задаче. (Чтобы задача имела смысл, разделим R на размер вихря a.) Вихрь и антивихрь притягиваются друг к другу логарифмическим потенциалом. Другими словами, конфигурация не может быть статической. Вихрь и антивихрь стремятся встретиться и «в пылком объятии» уничтожить друг друга, высвободив конечное количество энергии $v^2\log(R/a)$. (Отсюда название антивихрь.)

Все это происходит при нулевой температуре, но в физике конденсированных сред нас интересует свободная энергия $F = E - TS$ (с энтропией S) при некоторой температуре T, а не энергия E. Принимая это во внимание, Костерлиц и Таулесс открыли, что при росте температуры происходит фазовый переход. Рассмотрим газ вихрей и антивихрей при некоторой ненулевой температуре. Из-за теплового перемешивания движущиеся вокруг вихри и антивихри могут или найти, или не найти друг друга. Если находят - аннигилируют. Насколько высокой должна быть температура, чтобы это произошло?

Сделаем эвристическую оценку. Рассмотрим одиночный вихрь. Согласно Больцману, энтропией является логарифм «числа» способов, которыми мы можем поместить вихрь внутрь коробки размером L (устремим его в бесконечность). Таким образом, $S \sim \log(L/a)$. Энтропия S должна бороться с энергией $E \sim v^2 \log(L/a)$. Легко видеть, что свободная энергия $F \sim (v^2 - T)\log(L/a)$ стремится к бесконечности, если $T \lesssim v^2$, которую мы определяем, по существу, как критическую температуру $\widetilde{T}_c$.

Одиночный вихрь не может существовать при температуре ниже T_c. Вихри и антивихри тесно связаны при тсмпсратуре ниже T_c, но высвобождаются при температуре выше T_c.

Черная дыра

Открытие в 1970-е годы таких топологических объектов, которые нельзя увидеть в теории возмущений, потрясло поколение физиков, воспитанных на фейнмановских диаграммах и каноническом квантовании. Их (включая вашего покорного слугу) учили, что оператор поля $\varphi(x)$ является сингулярным квантовым оператором и как таковой он не имеет физического смысла, а также тому, что квантовая теория поля определяется по теории возмущений фейнмановскими диаграммами. Даже очень известные физики в недоумении вопрошали, что бы могла означать запись типа $\varphi \stackrel{r\to\infty}{\longrightarrow} ve^{i\theta}$? Научные дискуссии, которые велись в прошлом, теперь не имеют никакого значения. Как сказано во введении к главе V.6, я люблю называть этот исторический процесс «избавлением теоретиков-полевиков от оков фейнмановских диаграмм».

Следует упомянуть один аргумент, который в то время использовали физики, чтобы убедить себя в существовании солитонов. В конце концов, черная дыра Шварцшильда, определяемая метрикой $g_{\mu\nu}(x)$ (см. главу I.10), известна с 1916 года. Что собой представляют компоненты метрики $g_{\mu\nu}(x)$? Этими компонентами являются поля, точно так же как полями являются скалярное поле $\varphi(x)$ и калибровочное поле $A_\mu(x)$. В квантовой теории гравитации $g_{\mu\nu}$ надо заменить на квантовый оператор, такой как φ и A_μ. Итак, объекты, открытые в 1970-е годы, концептуально не отличаются от черной дыры, известной в 1910-е годы. Но в начале 1970-х годов большинство теоретиков, занимающихся физикой элементарных частиц, не были особенно сведующими в квантовой гравитации.

Упражнения

V.7.1. Объясните связь между математическим утверждением $\Pi_0(S^0) = Z_2$ и физическим результатом, согласно которому кинки с $|Q| \geqslant 2$ не существуют.

V.7.2. Изучите в вихре масштабы длин, на которых меняются поля φ и A. Оцените массу вихря.

V.7.3. Рассмотрите конфигурацию вихря, в которой $\varphi \stackrel{r\to\varphi}{\longrightarrow} ve^{i\nu\theta}$, где ν - целое число. Вычислите магнитный поток. Покажите, что магнитный поток, исходящий из антивихря (для которого $\nu = -1$), направлен противоположно магнитному потоку, исходящему из вихря.

V.7.4. Поскольку с математической точки зрения $g(\theta) \equiv e^{i\nu\theta}$ можно рассматривать как элемент группы $U(1)$, мы можем говорить об отображении S^1 (окружности на пространственной бесконечности) на группу $U(1)$. Вычислите $(i/2\pi)\int\limits_{S^1} gdg^\dagger$, показывая тем самым, что степень отображения определяется этим интегралом от 1-формы. V.7.5. Покажите, что в области, где φ^a постоянно, определенный в тексте $\mathcal{F}_{\mu\nu}$ является напряженностью электромагнитного поля. Вычислите $\vec{B}$ вдали от центра магнитного монополя и покажите, что имеет место квантование Дирака.

V.7.6. Постройте явно отображение $S^2 \to S^2$, которое дважды оборачивает одну сферу вокруг другой. Проверьте, что это отображение соответствует магнитному монополю с магнитным зарядом 2.

V.7.7. Запишите вариационные уравнения, которые минимизируют (8).

V.7.8. Найдите явно решение БПС.

V.7.9. Рассмотрите дионное решение. Получите его в БПС-пределе.

V.7.10. Проверьте явно, что магнитный монополь является инвариантным относительно вращений, несмотря на внешние различия. Под этим понимается, что все физические калибровочно-инвариантные величины, такие как $\vec{B}$, при вращении ковариантны. Калибровочно-зависимые величины, такие как A_i^b, при вращении могут и действительно изменяются. Выпишите генераторы вращения.

V.7.11. Покажите, что масса магнитного монополя составляет примерно $137 M_W$.

V.7.12. Вычислите $n \equiv -(1/24\pi^2) \int\limits_{S^3} \mathrm{tr}\left(g dg^\dagger\right)^3$ для отображения $g = e^{i\vec{\theta}\cdot\vec{\sigma}}$. [Указание: по симметрии надо вычислить подынтегральное выражение лишь в малой окрестности единичного элемента группы, т. е., что эквивалентно, в окрестности северного полюса S^3. Далее рассмотреть $g = e^{i(\theta_1\sigma_1+\theta_2\sigma_2+m\theta_3\sigma_3)}$ для целого числа m и убедиться, что m соответствует числу намоток S^3 вокруг S^3.] Сравните с упражнением V.7.4 и восхититесь красотой математики.

V.7.13. Докажите, что поправки более высокого порядка не меняют киральную аномалию $\partial_\mu J_5^\mu = [1/(4\pi)^2]\,\varepsilon^{\mu\nu\lambda\sigma}\,\mathrm{tr}\,F_{\mu\nu}F_{\lambda\sigma}$ (я изменил масштаб $A \to (1/g)A$). [Указание: проинтегрируйте по пространству-времени и покажите, что левая часть определяется числом правых фермионных мод минус число левых фермионных мод, так что обе части даются целыми числами.]

30.3 Zi.VI Field Theory and Condensed Media

30.3.1 Zi.VI.1 Fractional Statistics, Chern–Simons Term, and Topological Field Theory

Дробная статистика

Существование бозонов и фермионов является одним из наиболее фундаментальных свойств квантовой физики. Если поменять местами две тождественные квантовые частицы, у волновой функции появляется множитель, равный либо +1, либо -1. Лейнаас и Мирхейм, а затем Вильчек независимо друг от друга поняли, что в (2 + 1)-мерном пространстве-времени частицы могут тоже подчиняться так называемой дробной, или анионной, статистике, отличной от бозе- или ферми-статистики. Такие частицы теперь известны как анионы.

Чтобы поменять местами две частицы, можно переместить одну из них на пол-оборота вокруг другой, а затем сдвинуть их соответствующим образом. Если один анион повернуть на пол-оборота вокруг другого аниона против часовой стрелки, то волновая функция приобретет множитель $e^{i\theta}$, где θ - характерное для частицы действительное число. Для $\theta = 0$ получаем бозоны, а для $\theta = \pi$ - фермионы. Частицы с $\theta = \pi/2$ в середине между бозонами и фермионами известны как семионы.

После выхода статьи Вильчека многие именитые физики старшего поколения были очень озадачены. Рассуждая в терминах волновой функции Шредингера, они погрузились в бесконечные споры о том, должна ли эта волновая функция быть однозначной. Действительно, анионная статистика дает поразительный пример того, насколько формализм интеграла по траекториям в некоторых случаях оказывается прозрачнее. Понятие анионной статистики можно сформулировать с помощью волновых функций, но для этого необходимо хорошо представлять конфигурационное пространство, на котором определена волновая функция.

Рассмотрим две неразличимые частицы в положениях x_1^i и x_2^i в некоторый начальный момент времени, которые через время T оказываются в положениях x_1^f и x_2^f. В представлении интеграла по траектори- ям для $\left\langle x_1^f, x_2^f \left| e^{-iHT} \right| x_1^i, x_2^i \right\rangle$ суммировать нужно по всем траекториям. В пространстве-времени мировые линии этих двух частиц переплетаются (см. рис. VI.1.1). (Мы неявно допускаем, что частицы не могут проходить друг сквозь друга, что соответствует случаю сильного отталкивания между ними.)

Очевидно, что траектории можно разделить на топологически различные классы, характеризующиеся целым числом n, равным тому, сколько раз мировые линии двух частиц оплетают друг друга. Так как эти классы не могут деформироваться друг в друга, соответствующие амплитуды не могут интерферировать квантово-механически, но нам позволено в каждом классе ставить в соответствие этим амплитудам добавочный фазовый множитель $e^{i\alpha_n}$, помимо обычного множителя, связанного с действием.

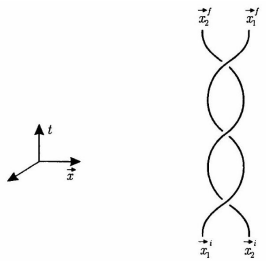


Рис. VI.1.1

Зависимость α_n от n определяется композицией квантовых амплитуд. Представим, что одна частица перемещается вокруг другой на угол $\Delta\varphi_1$; этому событию мы ставим в соответствие добавочный фазовый множитель $e^{if(\Delta\varphi_1)}$, где f - пока еще неизвестная функция. Допустим, что за этим событием следует другое, в котором та же частица перемещается вокруг другой на дополнительный угол $\Delta\varphi_2$. Фазовый множитель $e^{if(\Delta\varphi_1+\Delta\varphi_2)}$, который ставится в соответствие комбинированному событию, явно должен удовлетворять закону композиции $e^{if(\Delta\varphi_1+\Delta\varphi_2)} = e^{if(\Delta\varphi_1)}e^{if(\Delta\varphi_2)}$. Другими словами, $f(\Delta\varphi)$ должна быть линейной функцией своего аргумента.

Мы приходим к выводу, что в $(2+1)$-мерном пространстве-времени фазовый множитель $e^{i(\theta/\pi)\Delta\varphi}$, где θ - произвольный вещественный па- раметр, можно ассоциировать с квантовой амплитудой, соответствующей траекториям, по которым одна частица перемещается вокруг другой против часовой стрелки на угол $\Delta\varphi$. Заметим, что когда одна частица перемещается вокруг другой по часовой стрелке на угол $\Delta\varphi$, квантовая амплитуда приобретает фазовый множитель $e^{-i\frac{\theta}{\pi}\Delta\varphi}$.

Если менять местами два аниона, необходимо быть внимательными и следить за тем, выполнятся это перемещенис «против часовой стрслки» или «по часовой стрелке», поскольку при этом появляются множители $e^{i\theta}$ или $e^{-i\theta}$ соответственно. Такая ситуация сразу указывает на то, что нарушается четность P и инвариантность относительно обращения времени T.

Теория Черна-Саймонса

Следующий важный вопрос заключается в том, можно ли все вышесказанное включить в локальную квантовую теорию поля. Ответ был дан Вильчеком и Зи, которые показали, что дробная статистика может вытекать из эффекта взаимодействия с калибровочным полем. Важность формулировки теории поля заключается в том, насколько убедительно она демонстрирует, что понятие анионной статистики полностью совместимо с дорогими нашему сердцу принципами, которыми мы дорожим и которые являются элементами конструкции квантовой теории поля.

Имея лагранжиан $\mathcal{L}_0$ с сохраняющимся током j^μ, построим лагранжиан

$$\mathcal{L} = \mathcal{L}_0 + \gamma\varepsilon^{\mu\nu\lambda}a_\mu\partial_\nu a_\lambda + a_\mu j^\mu.$$

Здесь $\varepsilon^{\mu\nu\lambda}$ обозначает полностью антисимметричный символ в $(2+1)$-мерном пространстве-времени, а γ является произвольным вещественным параметром. При калибровочном преобразовании $a_\mu \to a_\mu + \partial_\mu\Lambda$ член $\varepsilon^{\mu\nu\lambda}a_\mu\partial_\nu a_\lambda$, известный как член Черна-Саймонса, изменяется следующим образом: $\varepsilon^{\mu\nu\lambda}a_\mu\partial_\nu a_\lambda \to \varepsilon^{\mu\nu\lambda}a_\mu\partial_\nu a_\lambda + \varepsilon^{\mu\nu\lambda}\partial_\mu\Lambda\partial_\nu a_\lambda$. Действие меняется на $\delta S = \gamma\int d^3x\varepsilon^{\mu\nu\lambda}\partial_\mu(\Lambda\partial_\nu a_\lambda)$, и поэтому, если можно отбросить

граничные члены (что мы полагаем здесь корректным), действие Черна-Саймонса калибровочно-инвариантно. Заметим в этой связи, что на языке дифференциальных форм, который известен нам из глав IV.5 и IV.6, член ЧернаСаймонса можно компактно записать как ada.

Теперь решим уравнение движения, полученное из (1):

$$2\gamma\varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda = -j^\mu$$

для частицы, находящейся в состоянии покоя (так что $j_i = 0$). Интегрируя $\mu = 0$ компоненту уравнения (2), получаем

$$\int d^2x\,(\partial_1 a_2 - \partial_2 a_1) = -\frac{1}{2\gamma}\int d^2x j^0$$

Таким образом, член Черна-Саймонса выполняет в теории роль снабжения заряженных частиц потоком. (Здесь термин «заряженные частицы» означает частицы, которые взаимодействуют с калибровочным полем a_μ. В данном контексте понятно, что, ссылаясь на заряд и поток, мы, конечно, не имеем в виду заряд и поток, связанные с обычным электромагнитным полем. Мы лишь заимствуем полезную терминологию.)

В соответствии с эффектом Аронова - Бома (глава IV.4), когда одна из таких частиц движется вокруг другой, волновая функция приобретает фазу, наделяя таким образом частицы анионной статистикой с углом $\theta = 1/4\gamma$ (см. упражнение VI.1.5).

Строго говоря, термин «дробная статистика» несколько вводит в заблуждение. Во-первых, сделаем тривиальное замечание, согласно которому параметр статистики θ не должен быть дробным. Во-вторых, статистика непосредственно не связана с подсчетом того, сколько частиц можно поместить в одно состояние. Статистику анионов, пожалуй, лучше представить как дальнодействующее фазовое взаимодействие, обусловленное калибровочным полем a.

Появление $\varepsilon^{\mu\nu\lambda}$ в (1) свидетельствует о нарушении четности P и инвариантности относительно обращения времени T, что нам уже известно.

Член Хопфа

Альтернативный подход заключается в интегрировании по a в (1). В главе III.4 мы говорили, что, как и в любой калибровочной теории, оператор, обратный дифференциальному оператору $\varepsilon\partial$, не определен. Он имеет нулевую моду, так как $\left(\varepsilon^{\mu\nu\lambda}\partial_\nu\right)(\partial_\lambda F(x)) = 0$ для любой гладкой функции $F(x)$. Выберем калибровку Лоренца $\partial_\mu a^\mu = 0$. Тогда, используя фундаментальное тождество теории поля (см. приложение А), получаем нелокальный лагранжиан

$$\mathcal{L}_{\text{Hopf}} = \frac{1}{4\gamma}\left(j_\mu \frac{\varepsilon^{\mu\nu\lambda}}{\partial^2} j_\lambda\right)$$

известный как член Хопфа.

Чтобы определить статистический параметр θ, рассмотрим событие, когда одна частица перемещается на пол-оборота вокруг другой частицы, находящейся в состоянии покоя. Тогда ток j равен сумме двух слагаемых, описывающих две частицы. Подставляя в (4), вычисляем квантовую фазу $e^{iS} = e^{i\int d^3x L_{\text{Hopf}}}$ и получаем $\theta = \frac{1}{4\gamma}$.

Топологическая теория поля

В чистой теории Черна-Саймонса есть нечто концептуально новое.

$$S = \gamma \int\limits_M d^3x\varepsilon^{\mu\nu\lambda} a_\mu \partial_\nu a_\lambda$$

Она топологическая.

Напомним, что, как описано в главе I.10, теорию поля для плоского пространства-времсни можно немедленно обобщить до теории поля в искривленном пространстве-времени путем замены метрики Минковского $\eta^{\mu\nu}$ на метрику Эйнштейна $g^{\mu\nu}$ и включения множителя $\sqrt{-g}$ в меру интегрирования по пространству-времени.

Но в теории Черна-Саймонса $\eta^{\mu\nu}$ не появляется! Лоренцевские индексы сворачиваются с полностью антисимметричным символом $\varepsilon^{\mu\nu\lambda}$. Более того, покажем, что множитель $\sqrt{-g}$ не нужен. Вспомним также, что, как говорилось в главе I.10, векторное поле преобразуется как $a_\mu(x) = \left(\partial x'^\lambda/\partial x'^\mu\right) a'_\lambda(x')$, и поэтому для трех векторных полей

$$\varepsilon^{\mu\nu\lambda} a_\mu(x) b_\nu(x) c\lambda(x) = \varepsilon^{\mu\nu\lambda} \frac{\partial x'^\sigma}{\partial x^\mu} \frac{\partial x'^\tau}{\partial x^\nu} \frac{\partial x'^\rho}{\partial x^\lambda} a'_\sigma(x') b'_\tau(x') c'_\rho(x') =$$
$$= \det\left(\frac{\partial x'}{\partial x}\right) \varepsilon^{\sigma\tau\rho} a'_\sigma(x') b'_\tau(x') c'_\rho(x')$$

С другой стороны, $d^3x' = d^3x \det(\partial x'/\partial x)$. Тогда имеет место соотношение

$$d^3x \varepsilon^{\mu\nu\lambda} a_\mu(x) b_\nu(x) c_\lambda(x) = d^3x' \varepsilon^{\sigma\tau\rho} a'_\sigma(x') b'_\tau(x') c'_\rho(x')$$

которое инвариантно без использования множителя $\sqrt{-g}$.

Итак, действие Черна-Саймонса в (5) инвариантно относительно общего координатного преобразования - оно уже написано для искривленного пространства-времени. Метрика $g^{\mu\nu}$ никуда не входит. Для построения теории Черна-Саймонса не нужны часы и линейки! Ей известна лишь топология пространства-времени, поэтому ее правильно называют топологической теорией поля. Другими словами, когда интеграл в (5) вычисляется по замкнутому многообразию M, свойство теории поля $\int Da e^{iS(a)}$ зависит только от топологии многообразия, а совсем не от метрики, которое можно оснастить это многообразие.

Вырождение основного квантового состояния

Напомним приведенное в главе I.10 основное определение энергии и импульса. Тензор энергии-импульса определяется вариацией действия относительно $g^{\mu\nu}$, но смотрите-ка, здесь действие не зависит от $g_{\mu\nu}$. Тензор энергии-импульса, а значит, и гамильтониан тождественно равны нулю! Из этого следует только один вывод: чтобы определить гамильтониан, нам нужны часы и линейки.

Что означает для квантовой системы иметь гамильтониан $H = 0$? Когда после курса квантовой механики на экзамене надо было решить задачу нахождения спектра для нулевого гамильтониана, мы легко могли это сделать! Все состояния имеют энергию $E = 0$. Мы готовы сдавать экзамен!

Однако нетривиальная задача заключается в том, чтобы найти, сколько существует состояний. Их число известно как вырождение основного состояния и зависит только от топологии многообразия M.

Массивные дираковские фермионы и член Черна- Саймонса

Рассмотрим калибровочное поле a_μ, связанное с массивным дираковским фермионом в $(2+1)$-мерном пространстве-времени: $\mathcal{L} = \bar{\psi}(i\not{\partial} + \not{a}$ - - m). Решая ранее задачу из главы II.1, вы узнали о довольно удивительном явлении, что в $(2+1)$-мерном пространстве-времени дираковский массовый член нарушает P и T. Таким образом, мы рассчитываем сгенерировать нарушающий P и T член Черна-Саймонса $\varepsilon^{\mu\nu\lambda} a_\mu \partial_\lambda a_\nu$ интегрированием по фермионам и получить в результате член $\mathrm{tr}\log(\not{\partial} + \not{K} - m)$ в эффективном действии. Аналогичным образом мы поступали в главе IV.3.

В однопетлевом порядке есть диаграмма поляризации вакуума (графически подобная диаграмме из главы III.7, но содержащая на одно измерение меньше в пространстве-времени) с интегралом Фейнмана, пропорциональным

$$\int \frac{d^3p}{(2\pi)^3}\,\mathrm{tr}\left(\gamma^\nu \frac{1}{p\!\!\!/+q\!\!\!/-m}\gamma^\mu \frac{1}{p\!\!\!/-m}\right).$$

Как мы увидим, замена $4 \to 3$ все меняет в этом мире. Я предлагаю вам самостоятельно вычислить (6) (упражнение VI.1.7), лишь отмечу явно вы- раженные здесь особенности. Так как ∂_λ в члене Черна-Саймонса соответствует q_λ в импульсном пространстве, то для определения коэффициента члена Черна-Саймонса необходимо продифференцировать (6) по q_λ и устремить $q \to 0$:

$$\int \frac{d^3p}{(2\pi)^3}\,\mathrm{tr}\left(\gamma^\nu \frac{1}{p\!\!\!/-m}\;\gamma^\lambda \frac{1}{q\!\!\!/-m}\gamma^\mu \frac{1}{p\!\!\!/-m}\right) = \\ = \int \frac{d^3p}{(2\pi)^3}\frac{\mathrm{tr}\left[\gamma^\nu(p\!\!\!/+m)\gamma^\lambda(q\!\!\!/+m)\gamma^\mu(p\!\!\!/+m)\right]}{\left(p^2-m^2\right)^3}.$$

Я сосредоточу внимание только на одной части интеграла, которая обуславливается членом в следе, пропорциональном m^3:

$$\varepsilon^{\mu\nu\lambda}m^3\int\frac{d^3p}{\left(p^2-m^2\right)^3}$$

Как отмечено в упражнении II.1.11, в $(2+1)$-мерном пространстве-времени γ^μ являются тремя матрицами Паули, и поэтому след $\gamma^\nu\gamma^\lambda\gamma^\mu$ пропорционален $\varepsilon^{\mu\nu\lambda}$. Антисимметричный символ появляется, как и ожидалось, в результате нарушения P и T.

Из размерного анализа следует, что интеграл в (8) равен $1/m^3$ с точностью до безразмерной постоянной, и поэтому m сокращается.

Но будьте внимательны! Этот интеграл зависит только от m^2 и ничего не знает о знаке m. Корректным будет сказать, что он пропорционален $1/|m|^3$, а не $1/m^3$. Таким образом, коэффициент члена Черна-Саймонса равен $m^3/|m|^3 = m/|m| =$ знаку m с точностью до безразмерной постоянной. Это поучительный пример, демонстрирующий важность знака! Полученный результат имеет смысл, поскольку при P (или T) дираковское поле с массой m преобразуется в дираковское поле с массой $-m$. В инвариантной относительно четности теории с дублетом дираковских полей, имеющих массы m и $-m$, член Черна-Саймонса не должен генерироваться.

Упражнения

VI.1.1. Можно считать, что в нерелятивистской теории есть два разных члсна Черна-Саймонса - $\varepsilon_{ij}a_i\partial_0 a_j$ и $\varepsilon_{ij}a_i\partial_i a_j$. Покажите, что калибровочная инвариантность заставляет эти два члена собираться в один член Черна-Саймонса $\varepsilon^{\mu\nu\lambda}a_\mu\partial_\nu a_\lambda$. Для члена Черна-Саймопса калибровочная инвариантность означает лоренц-инвариантность. В отличис от ттого, член Максвелла будет в общем случае нерелятивистским, состоящим из двух членов f_{0i}^2 и f_{ij}^2 с произвольным коэффициентом отношения между ними (с $f_{\mu\nu}=\partial_\mu a_\nu-\partial_\nu a_\mu$, как обычно).

VI.1.2. Исходя из соображений размерности, убедитесь, что на больших расстояниях член Черна-Саймонса доминирует над членом Максвелла. Это одна из причин, по которой специалисты в области релятивистской теории поля находят анионные жидкости столь привлекательными. Пока их интересует только физика больших расстояний, они могут не учитывать член Максвелла и заниматься релятивистской теорией (см. упражнение VI.1.1). Заметьте, что в такой ситуации $(2+1)$-мерное пространство-время выделяется как особое. В $(3+1)$-мерном пространстве-времени обобщение члена Черна-Саймонса $\varepsilon^{\mu\nu\lambda\sigma}f_{\mu\nu}f_{\lambda\sigma}$ имеет такую же размерность, как и член Максвелла f^2. В (4+1)-мерном пространстве на больших расстояниях член $\varepsilon^{\rho\mu\nu\lambda\sigma}a_\rho f_{\mu\nu}f_{\lambda\sigma}$ менее важен, чем член Максвелла f^2.

VI.1.3. Существует обобщение члена Черна-Саймонса на пространство-время с большей размерностью, которое отличается от приведенного в упражнении VI.1.2. Мы можем ввести

калибровочный потенциал p-формы (см. главу IV.4). Запишите обобщенный член Черна-Саймонса в $(2p+1)$-мерном пространстве-времени и обсудите полученную теорию.

VI.1.4. Рассмотрите лагранжиан $\mathcal{L} = \gamma\varepsilon a\partial a - (1/4g^2)\, f^2$. Вычислите пропагатор и покажите, что калибровочный бозон массивен. Некоторые физики, озадаченные дробной статистикой, приводили следующий довод: поскольку при наличии члена Максвелла калибровочный бозон является массивным и поэтому короткодействующим, он вряд ли может генерировать дробную статистику, которая явно является взаимодействием на бесконечно большом расстоянии. (Независимо от того, насколько удалены друг от друга меняющиеся местами две частицы, волновая функция все равно приобретает фазу.) Проблема разрешается исходя из того, что информация на самом деле распространяется на бесконечно большое расстояние через полюс $q = 0$, связанный с калибровочной степенью свободы. Именно этот явный парадокс оказался причиной замешательства многих физиков, когда они впервые услышали об эффекте Ааронова - Бома. Как может произвольно далекая от магнитного потока частица в области, где совсем нет магнитного поля, знать о существовании магнитного потока?

VI.1.5. Покажите, что $\theta = 1/4\gamma$. Здесь есть один хитрый множитель' 2. Поэтому не отчаивайтесь, если потеряете множитель 2. Попробуйте решить задачу еще раз.

VI.1.6. Найдите неабелеву версию члена Черна-Саймонса ada. [Указание: возможно, проще использовать дифферснциальныс формы, как в главс IV.6.]

VI.1.7. Используя канонический формализм, описанный в главе I.8, покажите, что лагранжиан Черна - Саймонса дает нулевой гамильтониан $H = 0$.

VI.1.8. Вычислите (6).

30.3.2 Zi.VI.2 Quantum Hall Liquids

Взаимное влияние двух областей физики

В последнее десятилетие появился интерес к изучению топологических квантовых жидкостей (примером которых является холловская жидкость). Квантовая система Холла состоит из электронов, движущихся в плоскости в присутствии внешнего магнитного поля B, перпендикулярного этой плоскости. Предполагается, что магнитное поле является достаточно сильным для того, чтобы все электроны имели спин, скажем, направленный вверх, и поэтому с ними можно обращаться как с бесспиновыми фермионами. Хорошо известно, что в этой, казалось бы, несущественной и простой физической ситуации содержится богатейшая физика, разъяснение которой привело к получению двух Нобелевских премий. Это необычайное богатство связано со взаимным влиянием двух основных областей физики. cTBO.

1. Хотя электрон является точечным, он занимает конечное простран-

В классическом представлении заряженная частица движется в магнитном поле по ларморовской окружности радиуса r, заданной уравнением $evB = mv^2/r$. В классическом представлении этот радиус не фиксирован, и частицы более высокой энергии движутся по большим окружностям, но если проквантовать угловой момент mvr так, чтобы $h = 2\pi$ (в единицах, где $\hbar = 1$), получим соотношение $eBr^2 \sim 2\pi$. Квантовый электрон занимает область порядка $\pi r^2 \sim 2\pi^2/eB$.

2. Электроны стремятся держаться подальше друг от друга.

Каждый электрон не только обязательно занимает конечное пространство, но должен иметь собственное пространство. Таким образом, квантовую задачу Холла можно описать как своего рода проблему заселения или как проблему предоставления площади служебных помещений в Институте тсоретической физики тем визитерам, которые не хотят делить свой офис с другими. Уже на этой стадии можно ожидать, что, когда числа электронов N_e как раз достаточно, чтобы полностью занять пространство, а именно когда область системы имеет вид $N_e\pi r^2 \sim N_e\,(2\pi^2/eB) \sim A$, происходит нечто особенное.

Уровни Ландау и целочисленный эффект Холла

Эти эвристические рассуждения, конечно же, могут быть более строгими. Задача из учебника об одном бесспиновом электроне в магнитном поле

$$-\left[(\partial_x - ieA_x)^2 + (\partial_y - ieA_y)^2\right]\psi = 2mE\psi$$

была решена Ландау десятки лет назад 1. Такие состояния электрона имеют место и являются вырожденными с энергией $E_n = \left(n+\frac{1}{2}\right)\frac{eB}{m}(n = 0,1,2,...)$, известной как n-й уровень Ландау. Каждый уровень Ландау имеет вырождение $BA/2\pi$, где A - площадь системы, отражающее тот факт, что ларморовские окружности можно поместить где угодно. Заметим, что один уровень Ландау отделен от следующего конечным количеством энергии (eB/m).

Представим, что один за другим вводятся невзаимодействующие электроны. По принципу запрета Паули каждый следующий электрон, который вводится, должен занимать другое состояние на уровне Ландау. Так как на каждом уровне Ландау может находиться $BA/2\pi$ электронов, коэффициент заполнения естественно определить как $\nu \equiv N_e/(BA/2\pi)$ (см. упражнение VI.2.1). Когда ν равно целому числу, первый уровень Ландау ν заполнен. Если вводится еще один электрон, он должен будет занять уровень Ландау $(\nu+1)$, что потребует больше энергии, чем потрачено на предшествующий электрон.

Таким образом, для ν, равного целому числу, холловская жидкость несжимаема. Любая попытка ее сжать уменьшает вырождение уровней Ландау (уменьшается эффективная область A и поэтому уменьшается вырождение $BA/2\pi$) и приводит к выталкиванию некоторых электронов на следующий уровень, что требует больших затрат энергии.

Электрическое поле E_y, наложенное на холловскую жидкость в направлении y, создает в направлении x ток $J_x = \sigma_{xy}E_y$, где $\sigma_{xy} = \nu$ (в единицах e^2/h). Это легко понять исходя из закона силы Лоренца, которому подчиняются электроны в присутствии магнитного поля. Удивительным экспериментальным открытием было то, что график зависимости

[1] В 1929 г. - Прим. ped. холловской проводимости σ_{xy} от B проходит через несколько горизонтальных участков кривой, о чем вам, возможно, известно. Чтобы понять появление таких плоских участков, нужно рассмотреть влияние примесей. Я затрону эту увлекательную тему о примесях и беспорядке в главе VI.8.

Итак, целочисленный квантовый эффект Холла понять довольно просТо.

Дробный эффект Холла

Экспериментальное открытие дробного эффекта Холла после целочисленного эффекта Холла, а именно то, что жидкость Холла также несжимаема при коэффициенте заполнения ν, равном простым дробям с нечетным знаменателем (таким, как $\frac{1}{3}$ и $\frac{1}{5}$), оказалось совершенно неожиданным для теоретиков. Для $\nu = \frac{1}{3}$ в первом уровне Ландау заполнена только одна треть состояний. Казалось бы, что добавление еще нескольких электронов не окажет столь большого воздействия на систему. Почему жидкость Холла с $\nu = \frac{1}{3}$ должна быть несжимаемой?

Оказалось, что критическим моментом является взаимодействие между электронами. Тот факт, что первый уровень Ландау на треть заполнен невзаимодействующими бесспиновыми электронами, не определяет уникальное многочастичное состояние: существует огромное вырождение, так как каждый из электронов может занять любое из доступных состояний $BA/2\pi$ только при условии соблюдения принципа запрета Паули. Но как только между электронами возникает взаимное отталкивание, на огромном пространстве вырожденных состояний, по-видимому, выбирается единственное основное состояние. Вен описал дробное состояние Холла как замысловатый танец электронов: каждый электрон не только занимает конечное пространство в танцевальном зале, но и по причине взаимного отталкивания должен заботиться о том, чтобы неожиданно не столкнуться с другим электроном. Этот танец должен быть тщательно поставлен и возможен только для специальных значений ν.

Примеси также играют существенную роль, но обсуждение примесей отложим до главы VI.6.

Чтобы понять дробный эффект Холла, учтем еще один важный момент. Напомним, что основная единица потока в главе V. 7 включает 2π, и поэтому число квантов потока, проходящих сквозь плоскость, равно $N_\phi = BA/2\pi$. Итак, загадка состоит в том, что, когда число квантов потока, приходящихся на электрон, $N_\phi/N_e = \nu^{-1}$, является нечетным цслым числом, происходит нечто особое. Я расположил главы так, чтобы то, что вы узнали из предыдущей главы, имело отношение к решению этой загадки. Предположим, что кванты потока ν^{-1} как-то связаны с каждым электроном. Когда две такие связанные системы меняются местами, появляется дополнительная фаза Ааронова-Бома, помимо фазы (-1) из статистики Ферми для электронов. Для нечетных ν^{-1} эти связанные системы эффективно подчиняются статистике Бозе и могут быть описаны комплексным скалярным полем φ. Оказывается, что конденсация поля φ отвечает за физику квантовой холловской жидкости.

Эффективная теория поля холловской жидкости

Мы хотим вывести эффективную теорию поля квантовой жидкости Холла, впервые полученную Кивелсоном, Хэнссоном и Чжаном. Для этого есть два альтернативных способа - длинный и короткий.

Если использовать длинный путь, начинают с лагранжиана, описывающего бесспиновые электроны в магнитном поле в формализме вторичного квантования

$$\mathcal{L} = \psi^+ i\left(\partial_0 - iA_0\right)\psi - \frac{1}{2m}\psi^+\left(\partial_i - iA_i\right)^2\psi - V\left(\psi^\dagger\psi\right)$$

и приводят его к необходимому виду. Из предыдущей главы известно, что путем введения калибровочного поля Черна-Саймонса можно преобразовать ψ в скалярное поле. Тогда можно воспользоваться дуальностью, о которой мы узнаем в следующей главе, чтобы представить фазовую степень свободы скалярного поля как калибровочное поле. После выполнения ряда шагов окажется, что эффективная теория холловской жидкости становится теорией Черна-Саймонса.

Вместо этого используем короткий путь. Будем рассуждать в духе: «чем еще это может быть» или, выражаясь изящнее, из общих принципов.

Начнем с перечисления того, что нам известно о системе Холла.

1. Мы живем в $(2+1)$-мерном пространстве-времени (потому что электроны ограничены плоскостью).

2. Электромагнитный ток J_μ сохраняется: $\partial_\mu J_\mu = 0$.

Очевидно, что эти два утверждения неоспоримы. Если их объединить, получим утверждение, согласно которому ток может быть записан как ротор векторного потенциала:

$$J^\mu = \frac{1}{2\pi}\epsilon^{\mu\nu\lambda}\partial_\nu a_\lambda$$

Множитель $1/(2\pi)$ определяет нормировку a_μ. Нас учили в школе, что если в трехмерном пространстве-времени производная чего-то равна нулю, то это что-то является ротором чего-то еще. Именно это и означает уравнение (2). Единственная сложность здесь заключается в том, что то, чему нас учили в школе, применимо к пространству Минковского, так же как и к евклидовому пространству - это лишь вопрос нескольких знаков.

Калибровочное поле идет нас искать

Обратите внимание, что в результате преобразования a_μ к $a_\mu \to a_\mu$ - $-\partial_\mu\Lambda$ ток остается неизменным. Другими словами, a_μ является калибровочным полем.

Мы не искали калибровочное поле; калибровочное поле само идет нас искать! Прятаться некуда. Существование калибровочного поля следует из самых общих соображений.

3. Мы хотим теоретически описать поле системы с помощью эффективного локального лагранжиана.

4. Нас интересует только физика больших расстояний и больших времен, то есть при малом волновом числе и низкой частоте.

Действительно, описание физической системы в теории поля можно рассматривать как способ систематизации различных относящихся к делу аспектов физики по степени их важности на больших расстояниях и в соответствии с принципами симметрии. Члены в лагранжиане теории поля классифицируются по степеням производных, степеням полей и т. д. Общая схема классификации членов осуществляется в соответствии с их размерностями, как объяснено в главе III.2. Калибровочное поле a_μ имеет размерность 1, как и всегда в случае любого калибровочного поля, связанного с полями материи в соответствии с калибровочным принципом; и поэтому уравнение (2) не противоречит тому факту, что ток имеет размерность 2 в $(2+1)$-мерном пространстве-времени.

5. Четность и обращение времени нарушаются внешним магнитным полем.

Последнее утверждение так же неоспоримо, как утверждения 1 и 2. Экспериментатор создает магнитное поле, пропуская ток через катушку; при этом ток течет либо по часовой стрелке, либо против часовой стрелки.

Исходя из этих пяти общих утверждений можно получить выражение для эффективного лагранжиана.

Поскольку калибровочная инвариантность запрещает в лагранжиане член размерности $2a_\mu a^\mu$, простейшим возможным членом, по существу, является член Черна-Саймонса размерности $3\epsilon^{\mu\nu\lambda}a_\mu\partial_\nu a_\lambda$. Таким образом, лагранжиан имеет вид:

$$\mathcal{L} = \frac{k}{4\pi} a\epsilon\partial a + \ldots$$

где k - безразмерный параметр, подлежащий определению.

Мы сейчас ввели и будем отныне использовать компактную запись $\epsilon a\partial b \equiv \epsilon^{\mu\nu\lambda}a_\mu\partial_\nu b_\lambda = \epsilon b\partial a$ для двух векторных полей a_μ и b_μ.

Члены, обозначенные (...) в выражении (3), включают член Максвелла размерности $4\,(1/g^2)\left(f_{0i}^2 - f_{ij}^2\right)$ и другие члены более высоких размерностей. Важно отметить, что эти члены более высоких порядков на больших расстояниях играют менее важную роль. Физика больших расстояний определяется только членом Черна-Саймонса. В общем случае коэффициент k может быть нулем, и в этом случае физика определяется членами, соответствующими малым расстояниям, которые обозначены в (3) как). .). Иначе говоря, холловскую жидкость можно определить как двухмерную систему электронов, для которой коэффициент члена ЧернаСаймонса не равен нулю и, следовательно, таков, что физика больших расстояний этой системы в значительной степени не зависит от определяющих ее мелких деталей. Действительно, двухмерные системы электронов можно классифицировать соответственно тому, равен коэффициент k нулю или нет.

Связывая систему с «внешним» или «дополнительным» электромагнитным калибровочным потенциалом A_μ и используя (2), получаем (интегрируя по частям и опуская поверхностный член)

$$\mathcal{L} = \frac{k}{4\pi}\epsilon^{\mu\nu\lambda}a_\mu\partial_\nu a_\lambda - \frac{1}{2\pi}\epsilon^{\mu\nu\lambda}A_\mu\partial_\nu a_\lambda = \frac{k}{4\pi}\epsilon^{\mu\nu\lambda}a_\mu\partial_\nu a_\lambda - \frac{1}{2\pi}\epsilon^{\mu\nu\lambda}a_\mu\partial_\nu A_\lambda.$$

Заметим, что калибровочный потенциал магнитного поля, отвечающий за эффект Холла, не должен включаться в A_μ; он уже неявно содержится в коэффициенте k.

Понятие квазичастиц или «элементарных» возбуждений составляет основу физики конденсированных сред. Эффекты взаимодействия многих тел могут быть такими, что квазичастицы в системе перестают быть электронами. Здесь мы определяем квазичастицы как объекты, которые взаимодействуют с калибровочным полем, и поэтому записываем

$$\mathcal{L} = \frac{k}{4\pi} a\epsilon\partial a + a_\mu j^\mu - \frac{1}{2\pi}\epsilon^{\mu\nu\lambda} a_\mu \partial_\nu A_\mu ...$$

Определяя $\widetilde{j}_\mu \equiv j_\mu - (1/2\pi)\varepsilon_{\mu\nu\lambda}\partial^\nu A^\lambda$ и отынтегрировав калибровочное поле, получаем [см. уравнение (VI.1.4)]

$$\mathcal{L} = \frac{\pi}{k}\widetilde{j}_\mu \left(\frac{\epsilon^{\mu\nu\lambda}\partial_\nu}{\partial^2}\right)\widetilde{j}_\lambda.$$

Дробный заряд и статистика

Теперь из (6) мы можем легко считать физику явления. Лагранжиан содержит члены трех типов: AA, Aj и jj. Член AA имеет схематический вид $A\,(\epsilon\partial\epsilon\partial\epsilon\partial/\partial^2)\,A$. Используя $\epsilon\partial\epsilon\partial \sim \partial^2$ и сокращая множители в числителе и знаменателе, получаем

$$\mathcal{L} = \frac{1}{4\pi k}\epsilon A\partial A$$

Варьируя по A, определяем электромагнитный ток

$$J^\mu_{\rm em} = \frac{1}{4\pi k} e^{\mu\nu\lambda}\partial_\nu A_\lambda$$

Компонента этого уравнения с $\mu = 0$ указывает на то, что избыточная плотность δn электронов связана с локальной флуктуацией магнитного поля отношением $\delta n = (1/2\pi k)\delta B$. Поэтому коэффициент заполнения ν можно считать равным $1/k$, а из компонент $\mu = i$, которые создают электрическое поле, определить ток в поперечном направлении с $\sigma_{xy} = (1/k) = \nu$.

Схематически член Aj имеет вид $A\,(\epsilon\partial\epsilon\partial/\partial^2)\,j$. Сокращая дифференциальные операторы, находим

$$\mathcal{L} = \frac{1}{k} A_\mu j^\mu$$

Таким образом, квазичастица несет электрический заряд $1/k$.

В итоге квазичастицы взаимодействуют друг с другом следующим образом:

$$\mathcal{L} = \frac{\pi}{k} j^\mu \frac{\epsilon_{\mu\nu\lambda}\partial^\nu}{\partial^2} j^\lambda$$

Мы просто убираем в (6) тильду. Вспоминая главу VI.1, легко видеть, что квазичастицы подчиняются дробной статистике с

$$\frac{\theta}{\pi} = \frac{1}{k}$$

Хотя до сих пор все было ясно, вас, возможно, интересует, откуда следует, что ν^{-1} должно быть нечетным целым числом?

Теперь покажем, что электрон или дырка должны появиться где-то в спектре возбуждений. В конце концов, предполагается, что теория должна описывать систему электронов, а до сих пор наш довольно общий лагранжиан не содержит никаких ссылок на электрон!

Поищем дырку (или электрон). Заметим, что в (9) связанный объект, состоящий из k квазичастиц, будет иметь заряд, равный 1. Возможно, это и есть дырка! Чтобы это было так, k должно быть целым числом. Пока все хорошо, но k все еще не должно быть нечетным.

Какая статистика у этого связанного объекта? Переместим один из таких объектов на пол-оборота вокруг другого такого же связанного объекта, таким образом эффективно меняя их

местами. Движение одной квазичастицы вокруг другой дает фазу, определяемую $\theta/\pi = 1/k$ в соответствии с (11). Но у нас есть k квазичастиц, движущихся вокруг k квазичастиц, и поэтому получаем фазу

$$\frac{\theta}{\pi} = \frac{1}{k}k^2 = k$$

Чтобы дырка была фермионом, мы должны потребовать, чтобы θ/π было нечетным. Это условие фиксирует k нечетным.

Так как $\nu = 1/k$, получаем классические лафлиновские жидкости Холла с нечетным знаменателем и с коэффициентом заполнения $\nu = \frac{1}{3}, \frac{1}{5}, \frac{1}{7}, ...$ При этом получаем известный результат, что квазичастицы несут дробные заряд и статистику [см. (9) и (11)].

Действительно, впечатляет! Электроны вращаются в плоскости в магнитном поле, соответствующим $\nu = \frac{1}{3}$, и, подумать только, каждый электрон разделяется на три части, каждая из которых имеет заряд $\frac{1}{3}$ и дробную статистику $\frac{1}{3}$!

Новый вид порядка

Задача физики конденсированных сред заключается в том, чтобы понять различные состояния вещества. Состояния вещества характеризуются присутствием (или отсутствием) порядка: ферромагнетик становится упорядоченным ниже температуры фазового перехода. Как показано в главе V.3, в теории Гинзбурга-Ландау порядок связан со спонтанным нарушением симметрии, описываемой, естественно, теорией групп. Гирвин и Мак- дональд первыми заметили, что порядок в холловских жидкостях на самом деле не встраивается в схему Ландау-Гинзбурга: мы не нарушили никакую явную симметрию. Топологическое свойство холловских жидкостей дает ключ к разгадке происходящего. Как объясняется в предыдущей главе, вырождение основного состояния холловской жидкости зависит от топологии многообразия, на котором она живет; такую зависимость теория групп объяснить не может. Вен настоятельно подчеркивал, что изучение топологического порядка, или, в более общем случае, квантового порядка, может открыть широкую перспективу возможности существования новых состояний вещества.

Комментарии и обобщение

Эту главу я завершу несколькими комментариями, которые могут побудить вас к изучению многочисленных работ, посвященных холловской жидкости.

1. Появление целых чисел означает, что нами получен разумный результат. Можно привести прекрасный довод, используя замечание из предыдущей главы, что для построения члена Черна-Саймонса не нужны часы и линейки и, как следствие, он, вероятно, не может зависеть от микрофизики, например, рассеяния электронов на примесях, которое нельзя определить без часов и линеек. В противоположность этому, физика, которая не является частью топологической теории поля и описывается как (...) в (3), будет, конечно, зависеть от микрофизики.

2. Если пойти по длинному пути вывода эффективной теории поля холловской жидкости, можно увидеть, что квазичастица на самом деле является вихрем, построенным (как описано в главе V.7) из скалярного поля, представляющего электрон. Учитывая, что холловская жидкость несжимаема, фактически единственным возбуждением, которое можно себе представить, является вихрь с когерентно вращающимися вокруг него электронами.

3. В предыдущей главе говорилось, что член Черна-Саймонса калибровочно инвариантен только при исключении граничного члена. Но в лаборатории реальные холловские жидкости находятся в образцах, у которых есть границы. Так как же теория (3) может быть правильной? Примечательно, что этот явный «дефект» теории на самом

деле является одним из ее преимуществ! Допустим, что теория (3) определена на двумерном многообразии с границей, например, на диске. Тогда, как впервые было показано Веном, на границе должны существовать физические степени свободы, представленные действием, изменение которого при калибровочном преобразовании уничтожает изменение $\int d^3x(k/4\pi)a\epsilon\partial a$. С точки зрения физики ясно, что несжимаемая жидкость имеет краевые возбуждения [2], соответствующие волнам на ее границе.

4. Что произойдет, если мы откажемся вводить калибровочный потенциал? Поскольку ток J_μ имеет размерность 2, простейший член $J_\mu J^\mu$, построенный из токов, уже имеет размерность 4; он очевидно является членом Максвелла. Локальное взаимодействие с размерностью 3 нельзя построить непосредственно из токов. Чтобы понизить размерность, необходимо ввести величину, обратную производной, и схематически записать $J(1/\epsilon\partial)J$, что, конечно, является нелокальным членом Хопфа. Таким образом, на часто задаваемый вопрос «почему именно калибровочное поле?» можно частично ответить фразой: «Введение калибровочных полей позволяет избежать рассмотрения нелокальных взаимодействий».

5. Экспериментаторы построили двухслойные квантовые системы Холла с бесконечно малой амплитудой туннелирования электронов с одного слоя на другой. Полагая, что ток $J^\mu_I (I = 1, 2)$ в каждом слое сохраняется раздельно, введем два калибровочных потенциала, записывая ток $J^\mu_I = \frac{1}{2\pi}\epsilon^{\mu\nu\lambda}\partial_\nu a_{I\lambda}$ как в (2). Можно повторить общую схему вывода и получить в результате эффективный лагранжиан

$$\mathcal{L} = \sum_{I,J} \frac{K_{IJ}}{4\pi} a_I \epsilon\partial a_J + ...$$

Целое число k превратилось в матрицу K. В качестве упражнения вы можете вывести холловскую проводимость, дробный заряд и статистику квазичастиц. Вас не удивит, что всюду, где появляется $1/k$, вместо него теперь есть обратная матрица K^{-1}. Возникает интересный вопрос: что происходит, когда K имеет нулсвое собственное значение? Например, можно получить $K = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$. Тогда низкоэнергетическая динамика калибровочного поля $a_- \equiv a_1 - a_2$ определяется не членом Черна-Саймонса, а членом Максвелла в слагаемом (...) в (13). Мы получаем моду с линейной дисперсией и, таким образом, сверхтекучесть! Это поразительное предсказание [3] проверено экспериментально.

6. Наконец, интересно отметить, что в используемом формализме туннелирование электронов соответствует несохранению тока $J^\mu_- \equiv J^\mu_1 - J^\mu_2 =$

[2] Существование краевых токов в целочисленной холловской жидкости впервые было отмечено Гальпериным.

[3] X. G. Wen and A. Zee, Phys. Rev. Lett. 69: 1811, 1992. $= (1/2\pi)\epsilon^{\mu\nu\lambda}\partial_\nu a_{-\lambda}$. Разность чисел электронов в двух слоях $N_1 - N_2$ не сохраняется. Но как может $\partial_\mu J^\mu_- \neq 0$, несмотря на то, что J^μ_- является ротором $a_{-\lambda}$ (как я явно показал)? Вспоминая главу IV.4, вы, как проницательный читатель, скажите, что все дело в магнитных монополях! Туннелирование в двухслойной системе Холла в евклидовом пространстве-времени можно описать как газ монополей и антимонополей [4]. (Подумайте, почему монополей и антимонополей?) Заметим, конечно, что это монополи не в обычном электромагнитном калибровочном поле, а в калибровочном поле $a_{-\lambda}$.

Приведенный в этом разделе вывод эффективной теории холловской жидкости на больших расстояниях кажется, конечно, не очень убедительным. Кто-то скажет, что очень неубедительным. Вернемся к приведенным выше пяти основным утверждениям или принципам. Из них четыре, безусловно, неоспоримы. На самом деле наиболее

сомнительным является третье утверждение, которое рядовому читателю кажется наиболее несущественным. В общем случае эффективный лагранжиан для системы конденсированного вещества должен быть нелокальным. Мы неявно допускаем, что такая система не содержит безмассовое поле, обмен которым привел бы к нелокальному взаимодействию 5. Также неявным в (3) является предположение, что лагранжиан можно полностью выразить через калибровочное поле a. Мы, конечно, не знаем априори, что нет других релевантных степеней свободы. Дело в том, что пока эти степени свободы не являются бесщелевыми, по ним можно интегрировать без риска.

Упражнения

VI.2.1. Чтобы точно определить коэффициент заполнения, нужно рассмотреть квантовую систему Холла на сфере, а не на плоскости. Поместим магнитный монополь с зарядом G (который по Дираку может быть только полуцелым или целым числом) в центр единичной сферы. Поток через эту сферу равен $N_\phi = 2G$. Покажите, что энергия одного электрона имеет вид $E_l = \left(\frac{1}{2}\hbar\omega_c\right)\left[l(l+1) - G^2\right]/G$ с уровнями Ландау, соответствующими $l = G, G+1, G+2, ...$, и что вырождение уровня l равно $2l+1$. Покажите, что $N_\phi = \nu^{-1}N_e - \mathcal{S}$, когда L уровней Ландау заполнено невзаимодействующими электронами ($\nu = L$), где топологическую величину $\mathcal{S}$ называют сдвигом.

[4] X. G. Wen and A. Zee. Phys. Rev. B47: 2265, 1993.

[5] Техническое примечание. Вихри (т. е. квазичастицы), локализованные на примесях в холловской жидкости. могут порождать нелокальное во времени взаимодействие. VI.2.2. Попробуйте вывести эффективную теорию поля для холловских жидкостей с коэффициентом заполнения $\nu = m/k$, где k - нечетное целое число, например, $\nu = 2/5$. [Указание: нужно ввести m калибровочных потенциалов $a_{I\lambda}$ и обобщить (2) до вида $J^\mu = (1/2\pi)\epsilon^{\mu\nu\lambda}\partial_\nu \sum_{I=1}^{m} a_{I\lambda}$. Получается, что эффективная теория имеет вид

$$\mathcal{L} = \frac{1}{4\pi}\sum_{I,J=1}^{m} a_I K_{IL}\epsilon\partial a_J + \sum_{I=1}^{m} a_{I\mu}\tilde{j}^{I\mu} + ...,$$

где целое число k заменяется на матрицу K. Сравните с лагранжианом (13).

VI.2.3. Для лагранжиана (13) выведите аналоги (8), (9) и (11).

30.3.3 Zi.VI.3 Duality

Многообешающая концепция

Дуальность является глубокой и многообещающей концепцией [1] теоретической физики, истоки которой находятся в электромагнетизме и статистической механике. Появление в последние годы дуальности в нескольких областях современной физики, начиная от квантовых холловских жидкостей до теории струн, отражает тот факт, что мы стали лучше понимать квантовую теорию поля. Здесь я приведу один конкретный пример, только чтобы передать дух этого обширного предмета.

Вначале рассмотрим релятивистскую теорию поля, а потом, когда будет понятна ее суть, перейдем к рассмотрению нерелятивистской теории. Вполне логично, что интересная физика, которую описывает нерелятивистская теория, в релятивисткой формулировке отчасти отсутствует. Более высокий уровень симметрии накладывает больше ограничений. К тому же, релятивистскую теорию, как ни удивительно, намного проще понять хотя бы из-за простоты обозначений.

Вихри

Пусть скалярное поле (2+1)-размерности взаимодействует с внешним электромагнитным калибровочным полем, где в дальнейшем для удобства электрический заряд q обозначается явно:

$$\mathcal{L} = \frac{1}{2}\left|\left(\partial_\mu - iqA_\mu\right)\varphi\right|^2 - V\left(\varphi^\dagger\varphi\right)$$

Мы уже не раз изучали эту теорию, причем совсем недавно в главе V.7 применительно к вихрям. Как обычно, запишем $\varphi = |\varphi|e^{i\theta}$. Минимизация

[1] Для первого знакомства с дуальностью настоятельно рекомендую прочитать работу J. M. Figueroa-O'Farril. Electromagnetic Duality for Children. http://www.maths.ed.ac.uk/ jmf/Teaching/Lectures/F.DC.pdf. потенциала V при $|\varphi| = v$ определяет конфигурацию поля для основного состояния. Задавая $\varphi = ve^{i\theta}$ в (1), получаем лагранжиан

$$\mathcal{L} = \frac{1}{2}v^2\left(\partial_\mu\theta - qA_\mu\right)^2$$

который при включении θ в A путем калибровочного преобразования становится лагранжианом Мейсснера. Для дальнейшего удобства введем также альтернативную форму лагранжиана

$$\mathcal{L} = -\frac{1}{2v^2}\xi_\mu^2 + \xi^\mu\left(\partial_\mu\theta - qA_\mu\right)$$

Вновь получаем (2), исключая вспомогательное поле ξ^μ (см. приложение A).

Из главы V.7 известно, что спектр возбуждения включает вихри и антивихри, расположенные там, где исчезает $|\varphi|$. Если θ изменяется на 2π вблизи нуля $|\varphi|$, получаем вихрь. Вокруг антивихря $\Delta\theta = -2\pi$. Вспомним, что вокруг неподвижного вихря электромагнитное калибровочное поле должно вести себя на пространственной бесконечности как

$$qA_i \to \partial_i\theta$$

чтобы энергия вихря была конечной, как легко видеть из (2). Магнитный поток

$$\int d^2x\varepsilon_{ij}\partial_i A_j = \oint d\vec{x}\cdot\vec{A} = \frac{\Delta\theta_{\text{вихр.}}}{q} = \frac{2\pi}{q}$$

квантован в единицах $2\pi/q$.

Остановимся на минуту, чтобы физически осмыслить происходящее. На масштабе расстояний, большом по сравнению с размером вихря, вихри и антивихри представляют собой точки. Как обсуждалось в главе V.7, энергия взаимодействия вихря и антивихря, разделенных расстоянием R, задается просто путем подстановки в (2). Игнорируя пробное поле A_μ, которое можно считать сколь угодно слабым, получаем $\sim \int\limits_a^R drr(\nabla\theta)^2 \sim \log(R/a)$, где a - обрезание на малых расстояниях. Но вспомним, что кулоновское взаимодействие в двухмерном пространстве изменяется логарифмически, поскольку из размерного анализа следует $\int d^2k\left(e^{i\vec{k}\cdot\vec{x}}/k^2\right) \sim \log(|\vec{x}|/a)$ (где a^{-1} - некоторое ультрафиолетовое обрезание). Таким образом, газ вихрей и антивихрей представляет собой газ точечных «зарядов» с кулоновским взаимодействием между ними.

Вихрь как заряд в дуальной теории

Некоторые теоретики часто понимают под дуальностью раздел высокой математики, но на самом деле она происходит из чисто физической идеи. Принимая во внимание последний

параграф, нельзя ли переписать теорию так, чтобы вихри представляли собой точечные «заряды» некоторого еще неизвестного калибровочного поля? Другими словами, необходима дуальная теория, в которой фундаментальное поле создает и уничтожает вихри, а не кванты φ. В свое время мы объясним значение слова «дуальный».

Примечательно, что переписать эту теорию можно всего лишь в несколько простых шагов. Используя физический и эвристический подходы, изобразим фазовое поле θ как плавно флуктуирующее, исключая те места, где оно закручивается на 2π. Запишем $\partial_\mu\theta = \partial_\mu\theta_{\text{плавн.}} + \partial_\mu\theta_{\text{вихр.}}$. Подставляя это в (3), получим

$$\mathcal{L} = -\frac{1}{2v^2}\xi_\mu^2 + \xi^\mu\left(\partial_\mu\theta_{\text{плавн.}} + \partial_\mu\theta_{\text{вихр.}} - qA_\mu\right)$$

Проинтегрируем по $\theta_{\text{плавн.}}$ и получим связь $\partial_\mu\xi^\mu = 0$, которую можно разрешить, записав

$$\xi^\mu = \varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda$$

Такой прием мы уже использовали в главе VI.2. Как и тогда, появляется ищущее нас калибровочное поле, так как замена $a_\lambda \to a_\lambda + \partial_\lambda\Lambda$ не меняет ξ^μ. Подставляя в (6), находим

$$\mathcal{L} = -\frac{1}{4v^2}f_{\mu\nu}^2 + \varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda\left(\partial_\mu\theta_{\text{вихр.}} - qA_\mu\right)$$

где $f_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu$.

Наши рассуждения являются эвристическими, поскольку мы игнорируем тот факт, что $|\varphi|$ исчезает на вихрях. Физически мы считаем вихри почти точечными, так что «преимущественно» везде $|\varphi| = v$. Как говорилось в главе V.6, солитоны, вихри и т. д. можно сделать сколь угодно малыми, если соответствующим образом выбрать параметры. Другими словами, мы пренебрегаем взаимодействием между $\theta_{\text{вихр. и}}$ $|\varphi|$. Строгое рассмотрение потребовало бы соответствующего обрсзания малых расстояний путем помещения этой системы на решетку [2]. Но мы нс будем учитывать подоб-

[2] Например, M. P. A. Fisher, «Mott Insulators, Spin Liquids. and Quantum Disordered Superconductivity», cond-mat/9806164, приложение A. ного рода тонкости, поскольку пытаемся понять (и, несомненно, поймем) физику явления.

Заметим для дальнейшего использования, что электромагнитный ток J^μ, будучи коэффициентом $-A_\mu$ в (8), определяется через калибровочное поле a_λ в виде

$$J^\mu = q\varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda$$

Проинтегрируем член $\varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda\partial_\mu\theta_{\text{вихр. в}}$ (8) по частям и получим $a_\lambda\varepsilon^{\lambda\mu\nu}\partial_\mu\partial_\nu\theta_{\text{вихр.}}$. Согласно Ньютону и Лейбницу ∂_μ коммутирует с ∂_ν, и потому мы явно получаем нуль. Но ∂_μ и ∂_ν коммутируют только тогда, когда действуют на глобально заданную функцию, но, ей-Богу, поле $\theta_{\text{вихр.}}$. не определено глобально, так как оно меняется на 2π, когда мы обходим вихрь. В частности, рассмотрим вихрь в состоянии покоя и посмотрим, с чем связана величина a_0 в (8), а именно в $\varepsilon^{ij}\partial_i\partial_j\theta_{\text{вихр.}} = \vec{\nabla}\times\left(\vec{\nabla}\theta_{\text{вихр.}}\right)$ в обозначениях общей физики. После интегрирования этого выражения по области, содержащей вихрь, получаем $\int d^2x\vec{\nabla}\times\left(\vec{\nabla}\theta_{\text{вихр.}}\right) = \oint d\vec{x}\cdot\vec{\nabla}\theta_{\text{вихр.}} =$

$= 2\pi$. Таким образом, легко видеть, что $(1/2\pi)\varepsilon^{ij}\partial_i\partial_j\theta_{\text{вихр.}}$ является плот-

ностью вихрей, временной компонентой некоторого вихревого тока $j^\lambda_{\text{вихр.}}$. Из лоренц-инвариантности следует, что $j^\lambda_{\text{вихр.}} = (1/2\pi)\varepsilon^{\lambda\mu\nu}\partial_\mu\partial_\nu\theta_{\text{вихр.}}$.

Теперь (8) можно записать в виде

$$\mathcal{L} = -\frac{1}{4v^2}f_{\mu\nu}^2 + (2\pi)a_\mu j^\mu_{\text{вихр.}} - A_\mu\left(q\varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda\right)$$

Вот так, мы завершили то, что намеревались сделать. Мы переписали теорию так, чтобы вихрь представлял собой «электрический заряд» для калибровочного поля a_μ. Иногда ее

называют дуальной теорией, но, строго говоря, более точным названием будет «дуальное представление исходной теории (1)».

Введем комплексное скалярное поле Φ, которое назовем вихревым полем, которое будет создавать и уничтожать вихри и антивихри. Другими словами, мы достраиваем действие (10) до

$$\mathcal{L} = -\frac{1}{4v^2} f_{\mu\nu}^2 + \frac{1}{2} \left|(\partial_\mu - i(2\pi)a_\mu)\,\Phi\right|^2 - W(\Phi) - A_\mu \left(q\varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda\right).$$

Потенциал $W(\Phi)$ содержит такие члены, как $\lambda\left(\Phi^\dagger\Phi\right)^2$, описывающие взаимодействие двух вихрей (или вихря и антивихря) на малом расстоянии. В принципе, если полностью понять всю физику малых расстояний, содержащуюся в исходной теории (1), то все эти члены будут определяться исходной теорией.

Вихрь вихря

Теперь мы подошли к наиболее увлекательной стороне дуального представления и причине, по которой вообще используется слово «дуальный». Вихревое поле Φ является таким же комплексным скалярным полем, как поле φ, с которого мы начинали. Таким образом, вполне можно сформировать вихрь из Φ, т. е. места, в окрестности которого Φ исчезает, а фаза Φ меняется на 2π. Занятно, что мы формируем, так сказать, вихрь вихря.

Так что же такое вихрь вихря?

Теорема дуальности утверждает, что вихрь вихря является не чем иным, как исходным зарядом, который описывается полем φ, с которого мы начинали! Отсюда и слово «дуальность».

Доказательство необыкновенно просто. В теории (11) вихрь несет «магнитный поток». Возвращаясь к (11), видим, что на пространственной бесконечности $2\pi a_i \to \partial_i\theta$. Используя такую же операцию, как в (5), получаем

$$2\pi \int d^2x \varepsilon_{ij}\partial_i a_j = 2\pi \oint d\vec{x}\cdot\vec{a} = 2\pi$$

Обратите внимание, что термин «магнитный поток» заключен в кавычки, поскольку очевидно, что речь идет о потоке, связанном с калибровочным полем a_μ, а не потоке, связанном с электромагнитным полем A_μ. Но вспомним, что согласно (9) электромагнитный ток имеет вид $J^\mu = q\varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda$ и, в частности, $J^0 = q\varepsilon^{ij}\partial_i a_j$. Следовательно, электрический заряд (заметьте, без кавычек) этого вихря вихря равен $\int d^2x J^0 = q$, т. е. заряду исходного комплексного скалярного поля φ. Это доказывает наше утверждение.

Здесь мы рассматривали вихри, но такого же рода дуальность применима и к монополям. Как говорилось в главе IV.4, дуальность позволяет получить представление о теориях поля в режиме сильной связи. Из главы V.7 известно, что некоторые спонтанно нарушенные неабелевы калибровочные теории в (3 + 1)-мерном пространстве-времени содержат магнитные монополи. Дуальную теорию можно записать в терминах поля монополей, из которого можно построить монополи. Монополь монополя оказывается не чем иным, как заряженными полями исходной калибровочной теории. Существование такой дуальности впервые предположили много лет назад Олив и Монтонен, и, как впоследствии было показано, дуальность реализуется в некоторых суперсимметричных калибровочных теориях ЗайбергаВиттена. Несколько лет назад изучение этой дуальности было «горячей» темой, что позволило по-новому и глубжс понять, как некоторые теории струн дуальны друг другу [3]. В противоположность этому, по мнению одного из моих коллег, выдающегося специалиста в области конденсированных сред, важное понятие дуальности все еще не получило достаточного признания сообществом физиков в области конденсированных сред.

Мейсснер порождает Максвелла и так далее

Завершим эту тему небольшим разъяснением дуальности в (2 + 1)-мерном пространстве-времени и того, какое он может иметь отношение к физике двумерных веществ. Рассмотрим лагранжиан $\mathcal{L}(a)$ второго порядка по векторному полю a_μ. Подключим внешний электромагнитный калибровочный потенциал A_μ к сохраняющемуся току $\varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda$:

$$\mathcal{L} = \mathcal{L}(a) + A_\mu \left(\varepsilon^{\mu\nu\lambda}\partial_\nu a_\lambda\right)$$

Зададимся следующим вопросом: если при разных выборах лагранжиана $\mathcal{L}(a)$ отынтегрировать a, что будет представлять собой эффективный лагранжиан $\mathcal{L}(A)$, описывающий динамику A?

Если вы добрались до этого места в книге, то с легкостью осуществите интегрирование. Снова имеем дело с основным тождеством квантовой теории поля! Имея лагранжиан

$$\mathcal{L}(a) \sim aKa$$

получаем

$$\mathcal{L}(A) \sim (\varepsilon\partial A)\frac{1}{K}(\varepsilon\partial A) \sim A\left(\varepsilon\partial\frac{1}{K}\varepsilon\partial\right)A.$$

Можно выбрать из трех лагранжианов $\mathcal{L}(a)$, которым я дал известные имена:

$\mathcal{L}(a) \sim a^2$	Мейсснер
$\mathcal{L}(a) \sim a\varepsilon\partial a$	Черн-Саймонс
$\mathcal{L}(a) \sim f^2 \sim a\partial^2 a$	Максвелл

Поскольку мы стремимся к концептуальному пониманию, я не буду отслеживать индексы и не относящиеся к данному случаю общие константы. (Вы можете их проставить в качестве упражнения.) Например, имея $\mathcal{L}(a) = f_{\mu\nu}f^{\mu\nu}$, где $f_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu$, можно записать $\mathcal{L}(a) \sim a\partial^2 a$, и поэтому $K = \partial^2$. Таким образом, эффективная динамика внешнего электромагнитного калибровочного потенциала определяется выражением (15)

[3] Например. D. I. Olive and P. C. West, eds., Duality and Supersymmetric Theories. как $\mathcal{L}(A) \sim A\left[\varepsilon\partial\left(1/\partial^2\right)\varepsilon\partial\right]A \sim A^2$, то есть мейсснеровским лагранжианом! С помощью такого «быстрого и грязного» способа заработать себе на жизнь мы задаем $\varepsilon\varepsilon \sim$ и сокращаем множители ∂ в числителе и знаменателе. Продолжая в том же духе, строим следующую таблицу:

Динамика a	K	Эффективный лагранжиан $\mathcal{L}(A) \sim A[\varepsilon\partial(1/K)\varepsilon\partial\|A$	Динамика внешнего пробного A
a^2 Мейсснера	1	$A(\varepsilon\partial\varepsilon\partial)A \sim A\partial^2 A$	F^2 Максвелла
$a\varepsilon\partial a$ Черна-Саймонса	$\varepsilon\partial$	$A\left(\varepsilon\partial\frac{1}{\varepsilon\partial}\varepsilon\partial\right)A \sim A\varepsilon\partial A$	$A\varepsilon\partial A$ Черна-Саймонса
$f^2 \sim a\partial^2 a$ Максвелла	∂^2	$A\left(\varepsilon\partial\frac{1}{0^2}\varepsilon\partial\right)A \sim AA$	A^2 Мейсснера

Мейсснер порождает Максвелла, Черн-Саймонс порождает ЧернаСаймонса и Максвелл порождает Мейсснера. Я нахожу это красивым и фундаментальным результатом, который очень убедительно представляет собой пример дуальности. Черн-Саймонс является самодуальным: он порождает сам себя.

Становясь нерелятивистским

Поучительно провести сравнение с нерелятивистским рассмотрением дуальности 4. Вернемся к лагранжиану сверхтекучей жидкости, приведенному в главе V.1:

$$\mathcal{L} = i\varphi^\dagger \partial_0 \varphi - \frac{1}{2m}\partial_i\varphi^\dagger\partial_i\varphi - g^2\left(\varphi^\dagger\varphi - \bar{\rho}\right)^2$$

Как и раньше, подставим $\varphi \equiv \sqrt{\rho}e^{i\theta}$ и получим лагранжиан

$$\mathcal{L} = -\rho\partial_0\theta - \frac{\rho}{2m}\left(\partial_i\theta\right)^2 - g^2(\rho-\bar{\rho})^2 + ...,$$

который перепишем в виде

$$\mathcal{L} = -\xi_\mu\partial^\mu\theta + \frac{m}{2\rho}\xi_i^2 - g^2(\rho-\bar{\rho})^2 + ...$$

В (19) мы отбросили член $\sim \left(\partial_i\rho^{1/2}\right)^2$. В (20) мы определили, что $\xi_0 \equiv \rho$. Интегрируя по ξ_i в (20), возвращаемся к (19).

[4] Приведенное здесь рассмотрение, по существу. вытекает из рассмотрения, данного М. П. А. Фишером и Д. Х. Ли. Делаем все, как и раньше. Записывая $\theta = \theta_{\text{глад.}} + \theta_{\text{вихр. и интегрируя}}$ по $\theta_{\text{глад., получаем связь}}$ $\partial^\mu\xi_\mu = 0$, разрешить которую можно, записав $\xi 6\mu = \epsilon^{\mu\nu\lambda}\widehat{a}_\lambda$. Шляпка над $\widehat{a}_\lambda$ понадобится нам для дальнейшего удобства. Заметим, что плотность

$$\xi_0 \equiv \rho = \epsilon_{ij}\partial_i\widehat{a}_j \equiv \widehat{f}$$

является напряженностью «магнитного» поля, тогда как

$$\xi_i = \epsilon_{ij}\left(\partial_0\widehat{a}_j - \partial_j\widehat{a}_0\right) \equiv \epsilon_{ij}\widehat{f}_{0j}$$

является напряженностью «электрического» поля.
Подставляя все это в (20), получаем

$$\mathcal{L} = \frac{m}{2\rho}\widehat{f}_{0i}^2 - g^2(\widehat{f}-\bar{\rho})^2 - 2\pi\widehat{a}_\mu j^\mu_{\text{вихр.}} + ...$$

Чтобы «вычесть» фоновое «магнитное» поле $\bar{\rho}$, очевидно, следует записать

$$\widehat{a}_\mu = \bar{a}_\mu + a_\mu$$

где фоновое калибровочное поле определяется через $\bar{a}_0 = 0, \partial_0\bar{a}_j = 0$ (фоновое «электрическое» поле отсутствует) и

$$\epsilon_{ij}\partial_i\bar{a}_j = \bar{\rho}$$

Тогда лагранжиан (23) приобретает более ясную форму

$$\mathcal{L} = \left(\frac{m}{2\bar{\rho}}f_{0i}^2 - g^2f^2\right) - 2\pi a_\mu j^\mu_{\text{вихр.}} - 2\pi\bar{a}_i j^i_{\text{вихр.}} + ...$$

Мы разложили $\rho \sim \bar{\rho}$ в первом члене. Как и в (10), первые два члена образуют максвелловский лагранжиан, а соотношение их коэффициентов определяет скорость распространения

$$c = \left(\frac{2g^2\bar{\rho}}{m}\right)^{1/2}$$

Используя единицы, в которых $c = 1$, получаем

$$\mathcal{L} = -\frac{m}{4\bar{\rho}} f_{\mu\nu} f^{\mu\nu} - 2\pi a_\mu j^\mu_{\text{вихр.}} - 2\pi \bar{a}_i j^i_{\text{вихр.}} + ...$$

Сравним этот лагранжиан с лагранжианом (10). При релятивистском рассмотрении не хватает только последнего члена в (28) по той простой причине, что мы не включили фон. Вспомним, что член типа $A_i J_i$ в обычном электромагнетизме означает, что движущаяся частица, связанная с током J_i, видит магнитное поле $\vec{\nabla} \times \vec{A}$. Таким образом, движущийся вихрь увидит «магнитное поле»

$$\epsilon_{ij} \partial_i (\bar{a} + a)_j = \bar{\rho} + \epsilon_{ij} \partial_i a_j$$

равное сумме плотности исходных бозонов $\bar{\rho}$ и флуктуирующего поля.

В кулоновской калибровке $\partial_i a_i = 0$ получаем выражение $(f_{0i})^2 = (\partial_0 a_i)^2 + (\partial_i a_0)^2$, где перекрестный член $(\partial_0 a_i)(\partial_i a_0)$ эффективно обращается в нуль при интегрировании по частям. Интегрируя по кулоновскому полю a_0, получаем

$$\mathcal{L} = -\frac{\bar{\rho}}{2m} (2\pi)^2 \iint d^2x d^2y \left[j_0(\vec{x}) \log \frac{|\vec{x} - \vec{y}|}{a} j_0(\vec{y}) \right] + \\ + \frac{m}{2\bar{\rho}} (\partial_0 a_i)^2 - g^2 f^2 + 2\pi (a_i + \bar{a}_i) j_i^{\text{вихр.}} .$$

Вихри отталкивают друг друга в результате логарифмического взаимодействия $\int d^2k \left(e^{i\vec{k}\cdot\vec{x}} / k^2 \right) \sim \log(|\vec{x}|/a)$, что нам уже давно известно.

Самодуальная теория

Интересно, что пространственная часть f^2 максвелловского лагранжиана появляется в результате отталкивания между исходными бозонами на малых расстояниях.

Если бы мы считали, что бозоны взаимодействуют через произвольный потенциал $V(x)$, то вместо последнего члена в (20) получили бы интеграл

$$\iint d^2x d^2y [\rho(x) - \bar{\rho}] V(x - y) [\rho(y) - \bar{\rho}]$$

Легко увидеть, что, по существу, все проделанные шаги аналогичны прежним, только теперь второй член лагранжиана (26) имеет вид

$$\iint d^2x d^2y f(x) V(x - y) f(y)$$

Таким образом, калибровочное поле распространяется в соответствии с дисперсионным соотношением

$$\omega^2 = (2\bar{\rho}/m) V(k) \vec{k}^2$$

где $V(k)$ является преобразованием Фурье $V(x)$. В частном случае $V(x) = g^2 \delta^{(2)}(x)$ мы восстанавливаем линейную дисперсию, приведенную в (27). Действительно, у нас есть линейная дисперсия $\omega \propto |\vec{k}|$, до тех пор пока потенциал $V(x)$ остается достаточно короткодействующим, чтобы $V(\vec{k} = 0)$ было конечным.

Интересная ситуация возникает, когда потенциал $V(x)$ является логарифмическим. Тогда $V(k)$ имеет вид $1/k^2$, и поэтому дисперсия ω постоянна. Калибровочное поле a_i становится массивным и исчезает. Низкоэнергетическая эффективная теория состоит из вихрей, с логарифмическим взаимодействием между ними. Таким образом, теория бозонов с логарифмическим отталкиванием является самодуальной в низкоэнергетическом пределе.

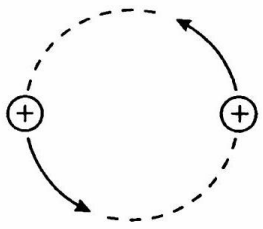
Танец вихрей и антивихрей

Завершив нерелятивистское рассмотрение дуальности, наградим себя тем, что выведем уравнение движения вихрей в жидкости. Пусть основная масса жидкости находится в состоянии покоя. В соответствии с (28) вихрь ведет себя как заряженная частица в фоновом магнитном поле $\bar{b}$, пропорциональном средней плотности жидкости $\bar{\rho}$. Таким образом, сила, действующая на вихрь, является обычной силой Лоренца $\vec{v} \times \vec{B}$, и тогда уравнение движения вихря в присутствии силы F имеет вид

$$\bar{\rho}\epsilon_{ij}\dot{x}_j = F_i$$

Хорошо известно, что при приложении силы вихрь движется в направлении, перпендикулярном этой силе.

Рассмотрим два вихря. В соответствии с (30) они отталкивают друг друга в результате логарифмического взаимодействия. Они перемещаются перпендикулярно силе и в итоге совершают круговое движение вокруг друг друга. В противоположность этому рассмотрим вихрь и антивихрь, которые притягивают друг друга. В результате притяжения они оба движутся в одном направлении, перпендикулярном соединяющей их прямой линии (см. рис. VI.3.1). Вихрь и антивихрь продолжают синхронно перемещаться, сохраняя между собой расстояние. В этом фактически состоит объяснение известного движения кольца дыма. Если разрезать кольцо дыма по центру и перпендикулярно плоскости, в которой оно находится, то для каждой части получим вихрь с антивихрем. Таким образом, все кольцо дыма движется в направлении, перпендикулярном плоскости, в которой оно находится.



(a)

(b)

Рис. VI.3.1

Все это можно понять исходя из общей физики. Важным наблюдением является тот факт, что вихри и антивихри приводят к образованию круговых потоков в жидкости, которые движутся, скажем, по часовой стрелке для вихрей и против часовой стрелки для антивихрей. Другим важным наблюдением является то, что если в жидкости есть локальный поток, то любой объект, будь то захваченный им вихрь или антивихрь, будет течь в том же направлении, что и локальный поток. Такая ситуация является следствием галилеевой инвариантности. Сделав простой рисунок, можно увидеть, что характер движения будет таким же, что рассмотренный выше.

30.3.4 Zi.VI.4 σ-Models as Effective Field Theories

Лагранжиан как мнемоника

Наша любимая квантовая теория поля прошла через два почти смертельных испытания. Первое началось где-то в середине 1930-х годов, когда оказалось, что физические величины бесконечны. Но в конце 1940-х - начале 1950-х годов она громогласно вернулась к жизни, благодаря усилиям поколения физиков, в число которых входили Фейнман, Швингер, Дайсон и другие. Второе испытание произошло в конце 1950-х годов. Как уже обсуждалось, квантовая теория поля казалась совершенно непригодной для описания сильного взаимодействия: оно было слишком сильным, чтобы от теории возмущения был какой-то толк. Многие физики, которых всех вместе называли школой S-матрицы, понимали, что теория поля не подходит для изучения сильного взаимодействия, и поддерживали программу исследований, согласно которой для получения результатов пытались использовать общие принципы без теории поля. Например, при выводе соотношения Голдбергера - Треймана можно было бы отказаться от любого упоминания теории поля и фейнмановских диаграмм.

В итоге, как реакция против такой тенденции, пришло понимание, что если какие-то результаты можно получить из общих принципов, таких как понятие спонтанного нарушения симметрии и т. д., то аналогичные результаты должен бы воспроизвести любой лагранжиан, содержащий в себе такие общие свойства. По меньшей мере, лагранжиан дает мнемонику для любого физического результата, полученного без использования квантовой теории поля. Таким образом, родилось понятие эффективной теории поля для больших расстояний или низких энергий, которая оказалась чрезвычайно полезной как в физике элементарных частиц, так и в физике конденсированных сред (как мы уже видели).

Сильное взаимодействие при низких энергиях

Одним из самых ранних примеров является σ-модель Гелл-Манна и Леви, которая описывает взаимодействие нуклонов и пионов. Теперь известно, что сильное взаимодействие должно описываться в терминах кварков и глюонов. Тем не менее на больших расстояниях степенями свободы являются два нуклона и три пиона. Протон и нейтрон преобразуются как спинор $\psi \equiv \begin{pmatrix} p \\ n \end{pmatrix}$ относительно $SU(2)$ изоспина. Рассмотрим член кинетической энергии $\bar{\psi} i\gamma\partial\psi = \bar{\psi}_L i\gamma\partial\psi_L + \bar{\psi}_R i\gamma\partial\psi_R$. Заметим, что этот член имеет более широкую симметрию $SU(2)_L \times SU(2)_R$, где левое поле ψ_L и правое поле ψ_R преобразуются как дублет относительно $SU(2)_L$ и $SU(2)_R$ соответственно. [SU(2) изоспина является диагональной подгруппой $SU(2)_L \times SU(2)_R$.] Можно записать $\psi_L \sim \left(\frac{1}{2}, 0\right)$ и $\psi_R \sim \left(0, \frac{1}{2}\right)$.

Теперь сразу видна проблема. Массовый член $m\bar{\psi}\psi = m\left(\bar{\psi}_L\psi_R + \text{э. с.}\right)$ не годится, поскольку $\bar{\psi}_L\psi_R \sim \left(\frac{1}{2}, \frac{1}{2}\right)$, 4-мерное представление $SU(2)_L \times SU(2)_R$ группы, локально изоморфной $SO(4)$.

На данном этапе уже меньше физиков могли бы сказать, в чем заключается проблема. Мы всегда знали, что сильное взаимодействие инвариантно только относительно $SU(2)$-группы изоспина, которую запишем как $SU(2)_I$. Билинейные формы, построенные из $\bar{\psi}_L$ и ψ_R, преобразуются относительно $SU(2)_I$ как $\frac{1}{2} \times \frac{1}{2} = 0 + 1$, синглет берется в виде $\bar{\psi}\psi$, а триплет в виде $\bar{\psi} i\gamma^5 \tau^a \psi$. Конечно, только лишь с $SU(2)_I$-симметрией можно включить массовый член $\bar{\psi}\psi$.

Другими словами, чтобы полностью связать все четыре билинейные формы, которые можно построить из $\bar{\psi}_L$ и ψ_R, а именно из $\bar{\psi}\psi$ и $\bar{\psi} i\gamma^5 \tau^a \psi$, нужны четыре мезонных поля, преобразующихся как векторное представление относительно $SO(4)$. Но известны только три пионных поля. Вроде ясно, что у нас есть лишь $SU(2)_I$-симметрия.

Тем не менее Гелл-Манн и Леви уверенно настаивали на более широкой симметрии $SU(2)_L \times SU(2)_R = SO(4)$ и просто постулировали присутствие дополнительного мезонного поля, которое они назвали σ, так что $(\sigma, \vec{\pi})$ образовывало четырехмерное представление.

Проверьте самостоятельно, что выражение $\bar{\psi}_L(\sigma + i\vec{\tau}\cdot\vec{\pi})\psi_R +$ э. с. $= \bar{\psi}\left(\sigma + i\vec{\tau}\cdot\vec{\pi}\gamma_5\right)\psi$ инвариантно. Следовательно, можно записать инвариантный лагранжиан

$$\mathcal{L} = \bar{\psi}\left[i\gamma\partial + g\left(\sigma + i\vec{\tau}\cdot\vec{\pi}\gamma_5\right)\right]\psi + \mathcal{L}(\sigma,\vec{\pi})$$

где часть, не включающая нуклоны, имеет вид

$$\mathcal{L}(\sigma,\vec{\pi}) = \frac{1}{2}(\partial\sigma)^2 + \frac{1}{2}(\partial\vec{\pi})^2 + \frac{\mu^2}{2}\left(\sigma^2+\vec{\pi}^2\right) - \frac{\lambda}{4}\left(\sigma^2+\vec{\pi}^2\right)^2$$

Это так называемая линейная σ-модель.

Когда σ-модель была предложена, большинству физиков она показалась довольно странной тем, что у нуклона нет массы и есть дополнительное мезонное поле. Итак, вы уже видите, что (2) соответствует лагранжиану (IV.1.2) (для $N = 4$), который мы рассматривали и который обнаруживает спонтанное нарушение симметрии. Четыре скалярных поля $(\varphi_1,\varphi_2,\varphi_3,\varphi_4)$ в лагранжиане (IV.1.2) соответствуют $(\sigma,\vec{\pi})$. Не теряя общности, можно сделать так, чтобы вакуумное среднее φ указывало первое направление, а именно вакуум, в котором $\langle 0|\sigma|0\rangle = \sqrt{\mu^2/\lambda} \equiv v$ и $\langle 0|\vec{\pi}|0\rangle = 0$. Разлагая выражение $\sigma = v + \sigma'$, сразу получаем, что нуклон имеет массу $M = gv$. Вас не должно удивлять, что пион оказывается безмассовым. У мезона, связанного с полем σ', который мы назовем σ-мезоном, нет причины быть безмассовым, и он, в самом деле, таким не является.

Может ли крайне важный параметр v иметь отношение к измеряемой величине? Несомненно, может. Вспомните из главы I.9, что аксиальный ток дается теоремой Нётер в виде $J^a_{\mu5} = \bar{\psi}\gamma_\mu\gamma_5\left(\tau^a/2\right)\psi + \pi^a\partial_\mu\sigma$ - $-\sigma\partial_\mu\pi^a$. После того как σ получает вакуумное среднее, $J^a_{\mu5}$ начинает содержать член $-v\partial_\mu\pi^a$. Этот член означает, что матричный элемент имеет вид $\left\langle 0\left|J^a_{\mu5}\right|\pi^b\right\rangle = ivk_\mu$, где k обозначает импульс пиона, и таким образом v пропорционален f, определенной в главе IV.2. В самом деле, мы видим, что соотношение для массы $M = gv$ является в точности соотношением Голдбергера-Треймана (IV.2.7), где $F(0) = 1$ (см. упражнение VI.4.4).

Нелинейная σ-модель

Со временем пришло понимание, что основное назначение существования потенциала в $\mathcal{L}(\sigma,\vec{\pi})$ заключается в том, чтобы заставлять вакуумные средние полей быть такими, какие они есть; поэтому этот потенциал можно заменить связью $\sigma^2 + \vec{\pi}^2 = v^2$. Более физическое рассмотрение можно представить так, что σ-мезон, если такой вообще существует, должен быть очень широким, поскольку при сильном взаимодействии он может распадаться на два пиона. σ-мезон также можно изгнать из низкоэнергетического спектра, сделав его массу большой. Из глав IV.1 и V.1 известно, что масса σ-мезона, а именно $\sqrt{2}\mu$, может быть устремлена к бесконечности при сохранении v фиксированным, предоставляя μ^2 и λ стремиться к бесконечности при фиксированном соотношении между ними.

Теперь сосредоточим внимание на $\mathcal{L}(\sigma,\vec{\pi})$. Вместо того чтобы рассматривать $\mathcal{L}(\sigma,\vec{\pi}) = \frac{1}{2}\left[(\partial\sigma)^2 + (\partial\vec{\pi})^2\right]$ со связью $\sigma^2+\vec{\pi}^2 = v^2$, можно решить это уравнение для связи и подставить решение $\sigma = \sqrt{v^2-\vec{\pi}^2}$ в лагранжиан, получая тем самым так называемую нелинейную σ-модель.

$$\mathcal{L} = \frac{1}{2}\left[(\partial\vec{\pi})^2 + \frac{(\vec{\pi}\cdot\partial\vec{\pi})^2}{f^2-\vec{\pi}^2}\right] = \frac{1}{2}(\partial\vec{\pi})^2 + \frac{1}{2f^2}(\vec{\pi}\cdot\partial\vec{\pi})^2 + \ldots$$

Заметим, что $\mathcal{L}$ можно записать в виде $\mathcal{L} = (\partial\pi^a)\,G^{ab}(\vec{\pi})\left(\partial\pi^b\right)$; некоторые предпочитают рассматривать G^{ab} как «метрику» в пространстве полей. [Кстати, вспомните, что ранее в главе I.3 мы ограничились простейшим членом кинетической энергии $\frac{1}{2}(\partial\varphi)^2$, отбрасывая такие варианты, как $U(\varphi)(\partial\varphi)^2$. Но вспомните также, что в главе IV. 3 говорилось, что такой член появляется при квантовых флуктуациях.]

В соответствии с рассуждениями, с которых начинается эта глава, любой лагранжиан, который обладает правильными свойствами симметрии, должен описывать одну и ту же физику низких энергий. Это значит, что кто угодно, включая вас, может ввести свою собственную параметризацию полей.

Нелинейная σ-модель на самом деле является примером широкого класса теорий поля, лагранжиан которых имеет простой вид, но появляющиеся в нем поля подчиняются некоторой нетривиальной связи. Примером является теория, определяющаяся лагранжианом

$$\mathcal{L}(U) = \frac{f^2}{4}\,\mathrm{tr}\left(\partial_\mu U^\dagger \cdot \partial^\mu U\right)$$

где $U(x)$ - матричнозначное поле и элемент $SU(2)$. Действительно, если записать $U = e^{(i/f)\vec{\pi}\cdot\vec{\tau}}$, то легко видеть, что лагранжиан $\mathcal{L}(U) = \frac{1}{2}(\partial\vec{\pi})^2 + + (1/2f^2)\,(\vec{\pi}\cdot\partial\vec{\pi})^2 + ...$, совпадает с (3) вплоть до указанных членов.

О нелинейных σ-моделях и их приложениях в физике элементарных частиц и конденсированных сред можно сказать значительно больше, но зсестороннее рассмотрение этой темы выходит за рамки настоящей книги. Поэтому некоторые свойства этих моделей я раскрою в задачах, а в слецующей главе опишу в общих чертах, как такие модели могут появляться в одном классе систем конденсированных сред.

Упражнения

VI.4.1. Покажите, что вакуумное среднее $(\sigma, \vec{\pi})$ действительно может имеет любое направление без изменения физики. На первый взгляд это утверждение кажется странным, так как за счет своего γ_5-взаимодействия с нуклоном пион является псевдоскалярным полем и не может иметь вакуумное среднее без нарушения четности. Но $(\sigma, \vec{\pi})$ всего лишь греческие буквы. Покажите, что при соответствующем преобразовании нуклонного поля четность сохраняется, как и должно быть при сильном взаимодействии.

VI.4.2. Вычислите амплитуду пион-пионного рассеяния до членов второго порядка по внешним импульсам, используя нелинейную σ-модель (3). [Указание: если нужна помощь, см. S. Weinberg, Phys. Rev. Lett. 17: 616, 1966.]

VI.4.3. Вычислите амплитуду пион-пионного рассеяния до членов второго порядка по внешним импульсам, используя линейную σ-модель (2). Не забудьте фейнмановскую диаграмму, включающую обмен σ-мезонами. Вы должны получить тот же результат, что и в упражнении VI.4.2.

VI.4.4. Покажите, что соотношение для массы $M = gv$ эквивалентно соотношению Голдбергера - Треймана.

30.3.5 Zi.VI.5 Ferromagnets and Antiferromagnets

Магнитные моменты

В главах IV.1 и V.3 обсуждалось происхождение понятия намбу-голдстоуновского бозона как спиновой волны в ферромагнитных или антиферромагнитных телах. Модельное описание таких тел представляет собой регулярную решетку, в каждом узле которой находится локальный магнитный момент, который обозначим единичным вектором $\vec{n}_j; j$ обозначает узел. В ферромагнетике магнитные моменты соседних узлов стремятся выстроиться в одном направлении, в то время как в антиферромагнетике магнитные моменты соседних узлов стремятся быть противоположно направленными. Другими словами, энергия имеет вид $\mathcal{H} = J\sum_{\langle ij\rangle}\vec{n}_i\cdot\vec{n}_j$, где i и j обозначают соседние узлы. Для антиферромагнетиков $J > 0$, а для ферромагнетиков $J < 0$.

При более микроскопическом рассмотрении следовало бы начать с гамильтониана (например, хаббардовского гамильтониана), описывающего перескоки электронов и взаимодействие между ними. В приближении среднего поля классическая переменная $\vec{n}_j$

может появиться как единичный вектор, указывающий направление $\left\langle c_j^\dagger \vec{\sigma} c_j \right\rangle$, где $c_j^\dagger$ и c_j - операторы рождения и уничтожения электронов соответственно. Но у вас в руках не учебник по физике твердого тела.

Первый или второй порядок по времени

В этом разделе мы бы хотели получить эффективное описание низкоэнергетических состояний ферромагнетика и антиферромагнетика в духе описания сигма-модели из предшествующей главы. Это описание будет существенно длиннее, чем стандартное, которое приводится в некоторых книгах по теории поля, но в нем есть небольшое преимущество - оно корректно. В том, какой член кинетической энергии надо добавить к $-\mathcal{H}$, чтобы образовать лагранжиан L, есть некоторая тонкость. Так как для единичного вектора $\vec{n}$ имеет место выражение $\vec{n} \cdot (d\vec{n}/dt) = (d(\vec{n} \cdot \vec{n})/dt) = 0$, одной производной по времени обойтись нельзя. С двумя производными можно образовать $(d\vec{n}/dt) \cdot (d\vec{n}/dt)$ и тогда

$$L_{\text{wrong}} = \frac{1}{2g^2} \sum_j \frac{\partial \vec{n}_j}{\partial t} \cdot \frac{\partial \vec{n}_j}{\partial t} - J \sum_{\langle ij \rangle} \vec{n}_i \cdot \vec{n}_j .$$

В типичном учебнике по теории поля далее записывается непрерывный предел и в результате получается плотность лагранжиана

$$\mathcal{L} = \frac{1}{2g^2} \left(\frac{\partial \vec{n}}{\partial t} \cdot \frac{\partial \vec{n}}{\partial t} - c_s^2 \sum_l \frac{\partial n}{\partial x^l} \cdot \frac{\partial \vec{n}}{\partial x^l} \right)$$

со связью $[\vec{n}(x,t)]^2 = 1$. Это еще один пример нелинейной сигма-модели. Как и в нелинейной сигма-модели, рассмотренной в главе VI.4, в этом случае лагранжиан выглядит свободным, но ограничение приводит к нетривиальной динамике. Постоянная c_s (которая определена через микроскопическую переменную J) является скоростью спиновой волны, что легко увидеть, если записать уравнение движения $(\partial^2/\partial t^2)\,\vec{n} - c_s^2 \nabla^2 \vec{n} = 0$.

Однако вам может показаться, что здесь что-то не так. Из курса квантовой механики известно, что динамика спиновой переменной $\vec{S}$ имеет первый порядок по времени. Рассмотрим наиболее типичный пример спина в постоянном магнитном поле, описываемом выражением $H = \mu \vec{S} \cdot \vec{B}$. Тогда $d\vec{S}/dt = i[H, \vec{S}] = \mu \vec{B} \times \vec{S}$. Кроме того, вы, возможно, помните из курса физики твердого тела, что в ферромагнетике дисперсионное соотношение спиновой волны имеет нерелятивистский вид $\omega \propto k^2$, а вовсе не релятивистский вид $\omega^2 \propto k^2$, что следует из выражения (2).

Разрешение этого явного парадокса основано на тождестве ПаулиХопфа. Имея единичный вектор $\vec{n}$, можно всегда записать $\vec{n} = z^\dagger \vec{\sigma} z$, где $z = \begin{pmatrix} z_1 \\ z_2 \end{pmatrix}$ состоит из двух комплексных чисел, таких что $z^\dagger z \equiv z_1^\dagger z_1 + + z_2^\dagger z_2 = 1$. Проверьте это! (Математическое отступление. Записывая z_1 и z_2 через действительные числа, находим, что это определяет так называемое отображение Хопфа $S^3 \to S^2$.) Несмотря на то что нельзя образовать член второго порядка по $\vec{n}$ и линейный по временной производной, можно записать член второго порядка по комплексному дублету z и линейный по временной производной. Не могли бы вы это проверить, прежде чем перейти к следующей строчке? Правильной версией (1) является

$$L_{\text{correct}} = i \sum_j z_j^\dagger \frac{\partial z_j}{\partial t} + \frac{1}{2g^2} \sum_j \frac{\partial \vec{n}_j}{\partial t} \cdot \frac{\partial \vec{n}_j}{\partial t} - J \sum_{\langle ij \rangle} \vec{n}_i \cdot \vec{n}_j .$$

Добавленный член известен как фаза Берри и имеет глубокий топологический смысл. Вам нужно вывести уравнение движения, используя тождество

$$\int dt\delta\left(z_j^\dagger\frac{\partial z_j}{\partial t}\right)=\frac{1}{2}i\int dt\delta\vec{n}_j\cdot\left(\vec{n}_j\times\frac{\partial\vec{n}_j}{\partial t}\right).$$

Примечательно, что, хотя член $z_j^\dagger\left(\partial z_j/\partial t\right)$ нельзя записать в терминах $\vec{n}_j$, это можно сделать для его вариации.

Низкоэнергетические моды в ферромагнетике и антиферромагнетике

В основном состоянии ферромагнетика все магнитные моменты имеют одно и то же направление, которое можно считать z-направлением. Разлагая уравнение движения по малым флуктуациям относительно этого основного состояния $\vec{n}_j=\widehat{e}_z+\delta\vec{n}_j$ (где $\widehat{e}_z$ означает соответствующий единичный вектор) и выполняя преобразование Фурье, получаем

$$\left(\begin{array}{cc}-\frac{\omega^2}{g^2}+h(k) & -\frac{1}{2}i\omega\\ \frac{1}{2}i\omega & -\frac{\omega^2}{g^2}+h(k)\end{array}\right)\left(\begin{array}{c}\delta n_x(k)\\ \delta n_y(k)\end{array}\right)=0$$

соотношение на две компоненты $\delta\vec{n}(k)$, т. е. $\delta n_x(k)$ и $\delta n_y(k)$. Условие $\vec{n}_j\cdot\vec{n}_j=1$ означает, что $\delta n_z(k)=0$. Здесь a - период решетки и $h(k)\equiv 4J[2-\cos\left(k_xa\right)-\cos\left(k_ya\right)]\simeq 2Ja^2k^2$ для малого k. (Я неявно работаю в двух пространственных измерениях, о чем свидетельствуют k_x и k_y.)

При низких частотах член Берри $i\omega$ доминирует над членом ω^2/g^2, который поэтому можно отбросить. Положив определитель матрицы равным нулю, получаем правильное квадратичное дисперсионное соотношение $\omega\propto k^2$.

Рассмотрение антиферромагнетика связано с интересной особенно-

стью. Так называемое состояние Нееля[1] для антиферромагнетика определе-

[1] Заметим, что. хотя состояние Нееля описывает конфигурацию классического антиферромагнетика с наименьшей энергией. оно не описывает основное состояние квантового антиферромагнетика. Члены $S_i^+S_j^-+S_i^-S_j^+$в гамильтониапе.J изменяют направление спинов вверх и вниз. ется выражением $\vec{n}_j=(-1)^j\widehat{e}_z$. Записывая $\vec{n}_j=(-1)^j\widehat{e}_z+\delta\vec{n}_j$, получаем выражение

$$\left(\begin{array}{cc}-\frac{\omega^2}{g^2}+f(k) & -\frac{1}{2}i\omega\\ \frac{1}{2}i\omega & -\frac{\omega^2}{g^2}+f(k)\end{array}\right)\left(\begin{array}{c}\delta n_x(k)\\ \delta n_y(k+Q)\end{array}\right)=0$$

связывающее δn_x и δn_y, зависящих от разных импульсов. Здесь $f(k)=4J\left[2+\cos\left(k_xa\right)+\cos\left(k_ya\right)\right]$ и $Q=[\pi/a,\pi/a]$. Появление Q связано с тем, что $(-1)^j=e^{iQaj}$. (Постарайтесь разобраться со слишком краткими обозначениями.) Антиферромагнитный множитель $(-1)^j$ явно нарушает трансляционную инвариантность и вставляет импульс Q, когда бы он ни появлялся. Аналогичное уравнение связывает $\delta n_y(k)$ и $\delta n_x(k+Q)$. Решая эти уравнения, находим, что существует высокочастотная ветвь, которая не представляет для нас интереса, и низкочастотная ветвь с линейной дисперсией $\omega\propto k$.

Таким образом, низкочастотную динамику антиферромагнетика можно описать нелинейной сигма-моделью (2), которую можно представить в релятивистском виде, когда скорость спиновой волны нормирована к единице:

$$\mathcal{L}=\frac{1}{2g^2}\partial_\mu\vec{n}\cdot\partial^\mu\vec{n}$$

Упражнения

VI.5.1. Получите две ветви спинового волнового спектра для случая ферромагнетика, обращая особое внимание на поляризацию.

VI.5.2. Проверьте, что в случае антиферромагнетика член фазы Берри только меняет скорость спиновой волны и не влияет качественно на спектр, как в случае ферромагнетика.

30.3.6 Zi.VI.6 Surface Growth and Field Theory

В этой главе рассматривается довольно необычная для учебника по теории поля тема, взятая из неравновесной статистической механики - одного из разделов теоретической физики, который последние несколько лет развивается наиболее активно. Я расскажу вам еще об одной области, где используются идеи теории поля.

Представим атомы, беспорядочно расположенные на некоторой поверхности. Буквально выражаясь, так выращиваются некоторые новые вещества. По мере роста высота этой поверхности $h(x,t)$ определяется уравнением Кардара-Паризи - Чжана

$$\frac{\partial h}{\partial t} = \nu\nabla^2 h + \frac{\lambda}{2}(\nabla h)^2 + \eta(\vec{x},t)$$

Это уравнение описывает обманчиво простой прототип неравновесной динамики и имеет поразительно широкую область применения.

Чтобы понять уравнение (1), рассмотрим различные слагаемые в правой его части. Смысл слагаемого $\nu\nabla^2 h$ (где $\nu > 0$) очевиден: положительное во впадинах h и отрицательное на пиках, оно стремится сгладить поверхность. При наличии единственного этого слагаемого задача была бы линейной и поэтому тривиальной. Нелинейное слагаемое $(\lambda/2)(\nabla h)^2$ делает задачу весьма нетривиальной и интересной. В качестве упражнения убедитесь в геометрическом происхождении этого слагаемого. Третье слагаемое описывает случайное появление атомов со случайной переменной $\eta(\vec{x},t)$, которая, как предполагается, подчиняется гауссовому распределению с нулевым средним значением [1] и коррелятором

$$\langle \eta(\vec{x},t)\eta(\vec{x}',t')\rangle = 2\sigma^2\delta^D(\vec{x}-\vec{x}')\,\delta(t-t').$$

Другими словами, распределение вероятности для реализации $\eta(\vec{x},t)$ определяется выражением

$$P(\eta) \propto e^{-\frac{1}{2\sigma^2}\int d''xdt\eta(\vec{x},t)^2}$$

[1] Здесь не нарушается общность. поскольку алиитивную постоянную в η можно убрать путем сдвига $h \to h + ct$. Здесь $\vec{x}$ представляет собой координаты в D-мерном пространстве. В эксперименте для описанной ситуации $D = 2$, однако теоретически можно рассматривать эту задачу для любой размерности D.

Специалистов в области физики конденсированных сред обычно интересует корреляции между высотой поверхности при двух различных положениях в пространстве и времени:

$$\left\langle [h(\vec{x},t) - h(\vec{x}',t')]^2 \right\rangle = |\vec{x}-\vec{x}'|^{2\chi} f\left(\frac{|\vec{x}-\vec{x}'|^z}{|t-t'|}\right).$$

Скобки $\langle ...\rangle$ здесь и в выражении (2) означают усреднение по разным реализациям случайной переменной $\eta(\vec{x},t)$. Правая часть (3) представляет собой выражение для динамического скейлинга, которое обычно постулируется в физике конденсированных сред, где χ и z - это так называемые экспонента шероховатости и динамическая экспонента. Итак, задача состоит в том, чтобы доказать корректность выражения для скейлинга, а также найти χ и z. Отметим, что из динамической экспоненты z (которая в общем случае не является целым числом) следует, грубо говоря, сколько степеней пространства стоят одной степени времени. (Для $\lambda = 0$ получаем простую диффузию, для которой $z = 2$.) Здесь f обозначает неизвестную функцию.

Я не буду вдаваться в прочие технические подробности. Для нас представляет интерес то, как эта задача, которая даже не включает квантовую механику, может быть преобразована в квантовую теорию поля. Начнем с выражения

$$Z \equiv \int \mathcal{D}h \int \mathcal{D}\eta e^{-\frac{1}{2\sigma^2}\int d^D x dt \eta(\vec{x},t)^2} \delta\left[\frac{\partial h}{\partial t} - \nu\nabla^2 h - \frac{\lambda}{2}(\nabla h)^2 - \eta(\vec{x},t)\right].$$

Интегрируя по η, получаем $Z = \int \mathcal{D}h e^{-S(h)}$, где действие имеет вид:

$$S(h) = \frac{1}{2\sigma^2}\int d^D\vec{x}dt\left[\frac{\partial h}{\partial t} - \nu\nabla^2 h - \frac{\lambda}{2}(\nabla h)^2\right]^2$$

Вы узнаете, что данное выражение описывает нерелятивистскую теорию скалярного поля $h(\vec{x},t)$. Тогда интересующая нас физическая величина определяется выражением

$$\left\langle \left[h(\vec{x},t) - h\left(\vec{x}',t'\right)\right]^2 \right\rangle = \frac{1}{Z}\int \mathcal{D}h e^{-S(h)}\left[h(\vec{x},t) - h\left(\vec{x}',t'\right)\right]^2.$$

Таким образом, задача определения экспоненты шероховатости и динамической экспоненты в статистической физике эквивалентна задаче определения пропагатора

$$D(\vec{x},t) \equiv \frac{1}{Z}\int \mathcal{D}h e^{-S(h)} h(\vec{x},t) h(\overrightarrow{0},0)$$

скалярного поля h.

Кстати, с учетом масштабирования $t \to t/\nu$ и $h \to \sqrt{\sigma^2/\nu}h$ действие можно записать в виде

$$S(h) = \frac{1}{2}\int d^D\vec{x}dt\left[\left(\frac{\partial}{\partial t} - \nabla^2\right)h - \frac{g}{2}(\nabla h)^2\right]^2$$

где $g^2 \equiv \lambda^2\sigma^2/\nu^3$. Раскладывая, как обычно, действие по степеням h
$S(h) = \frac{1}{2}\int d^D\vec{x}dt\left\{\left[\left(\frac{\partial}{\partial t} - \nabla^2\right)h\right]^2 - g(\nabla h)^2\left(\frac{\partial}{\partial t} - \nabla^2\right)h + \frac{g^2}{4}(\nabla h)^4\right\}$,
получаем знакомый квадратичный член, дающий довольно необычный пропагатор $1/\left(\omega^2 + k^4\right)$ для скалярного поля h, а также члены кубической и четвертой степени, описывающие взаимодействие. Как обычно, чтобы получить искомую физическую величину, вычисляем функциональный интеграл, или интеграл «по траекториям»,

$$Z = \int \mathcal{D}h e^{-S(h) + \int d^l x dt J(x,t)h(x,t)}$$

и затем функционально дифференцируем несколько раз по J.

Я хочу не столько обучить вас неравновесной статистической механике, сколько показать, как квантовая теория поля может возникать в разных физических ситуациях, в том числе тех, которые включают только классическую физику. Заметим, что «квантовые флуктуации» здесь появляются из случайного основного члена. Между хаотической динамикой и квантовой физикой явно существует тесная методологическая связь.

Упражнения

VI.6.1. Задача по элементарной геометрии: нарисуйте прямую линию под углом θ к горизонтали. Эта линия представляет сегмент поверхности в момент времени t. Теперь нарисуйте несколько окружностей диаметра d, касательных к этой линии сверху. А теперь нарисуйте другую линию под углом θ к горизонтали, которая лежит поверх окружностей, а именно касательную к ним. Эта новая линия представляет собой сегмент поверхности в более поздний момент времени (см. рис. VI.6.1). Обратите внимание, что

$\Delta h = d/\cos\theta \simeq d\left(1+\frac{1}{2}\theta^2\right)$. Покажите, что порождается нелинейный член $(\lambda/2)(\nabla h)^2$ в уравнении (1) Кардара - Паризи - Чжана. О применениях уравнения Кардара-Паризи - Чжана читайте, например, в T. Halpin-Healy and Y.-C. Zhang, Phys. Rep. 254: 215, 1995; A. L. Barabasi and H. E. Stanley, Fractal Concepts in Surface Grown.

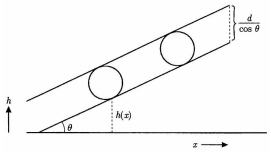


Рис. VI.6.1

VI.6.2. Покажите, что скалярное поле h имеет пропагатор $1/\left(\omega^2+k^4\right)$.

VI.6.3. Квантовая теория поля при заменах переменных может часто проявляться в довольно разных видах. Покажите, что, записав $U = e^{\frac{1}{2}gh}$, можно заменить действие (7) на

$$S = \frac{2}{g^2}\int d^D\vec{x}dt\left(U^{-1}\frac{\partial}{\partial t}U - U^{-1}\nabla^2 U\right)^2$$

то есть своего рода нелинейную σ-модель.

30.3.7 Zi.VI.7 Disorder: Replicas and Grassmann Symmetry

Примеси и случайный потенциал

Важной областью физики конденсированных сред являются неупорядоченные системы, изучению которых за последние несколько десятилетий было посвящено огромное число теоретических работ. Электроны в реальных материалах рассеиваются на неизбежно присутствующих примесях и эффективно движутся в случайном потенциале. Кратко опишу эту захватывающую тему и покажу, как подобного рода задачу можно отобразить в квантовой теории поля.

Прототипом является задача о квантовой частице, подчиняющейся уравнению Шредингера $H\psi = \left[-\nabla^2 + V(x)\right]\psi = E\psi$, где $V(x)$ - случайный потенциал (представляющий примеси), имеющий нормальное гауссово распределение $P(V) = \mathcal{N}e^{-\int d''x\left(1/2g^2\right)V(x)^2}$ с нормировочным множителем $\mathcal{N}$, который определяется выражением $\int DVP(V) = 1$. Параметр g измеряет количество примесей: чем больше g, тем сильнее разупорядочена система. Это, конечно, идеализация, в которой не учитываются взаимодействие между электронами и ряд других физических эффектов.

Как и в статистической механике, представим себе ансамбль систем, каждая из которых характеризуется конкретного вида функцией $V(x)$, взятой из распределения $P(V)$. Изучим усредненные или типичные свойства системы. В частности, нас интересует усредненная плотность состояний, определяемая выражением $\rho(E) = \langle \mathrm{tr}\,\delta(E-H)\rangle = \left\langle \sum_i \delta\left(E-E_i\right)\right\rangle$, где сумма берется по i-му собственному состоянию H с соответствующим собственным значением E_i. Обозначим среднее значение любого функционала $O(V)$ функции $V(x)$ как $\langle O(V)\rangle \equiv \int DVP(V)O(V)$. Ясно, что $E^* + \delta E \int\limits_{E^*} dE\rho(E)$ соответствует числу состояний в интервале от E^* до $E^*+ +\delta E$, которое является важным, например, в экспериментах по туннелированию.

Андерсоновская локализация

Другой важный физический вопрос заключается в том, распространяются ли волновые функции при определенной энергии E по всей системе или они локализованы в пределах

характеристического масштаба длин $\xi(E)$. Очевидно, что от этого зависит, является вещество проводником или изолятором. На первый взгляд создается впечатление, что следует изучить выражение

$$S(x,y;C) \equiv \left\langle \sum_i \delta\left(E-E_i\right)\psi_i^*(x)\psi_i(y) \right\rangle$$

из которого можно было бы узнать, как волновая функция в точке x коррелирована с волновой функцией в некоторой другой точке y. Однако выражение для S не подходит, потому что $\psi_i^*(x)\psi_i(y)$ имеет фазу, которая зависит от V. Таким образом, S должно обращаться в нуль при усреднении по беспорядку. Вместо S следует рассмотреть величину

$$K(x-y;E) \equiv \left\langle \sum_i \delta\left(E-E_i\right)\psi_i^*(x)\psi_i(y)\psi_i^*(y)\psi_i(x) \right\rangle$$

так как член $\psi_i^*(x)\psi_i(y)\psi_i^*(x)\psi_i(y)$ явно положительный. Заметим, что при усреднении по всем возможным $V(x)$ восстанавливается трансляционная инвариантность, так что K является функцией только расстояния $|x-y|$. Если $|x-y| \to \infty$, то при $K(x-y;E) \sim e^{-|x-y|/\xi(E)}$ волновые функции с энергией E локализованы на так называемой длине локализации $\xi(E)$. С другой стороны, если $K(x-y;E)$ убывает как степень от $|x-y|$, то говорят, что волновые функции не локализованы.

Андерсон с коллегами сделал поразительное открытие, заключающееся в том, что свойства локализации зависят от размерности пространства D, а не от детального вида $P(V)$ (пример понятия универсальности). Для $D = 1$ и 2 все волновые функции локализованы независимо от того, насколько слабым может быть примесный потенциал. Это утверждение в высшей степени нетривиально, поскольку априори можно прийти к заключению, что локализация или нелокализация волновых функций зависит от силы потенциала, как думали в свое время выдающиеся физики. В противоположность этому, для $D = 3$ волновые функции не локализованы для E в диапазоне $(-E_c, E_c)$. По мере того как E приближается сверху к энергии E_c (известной как предел подвижности), длина локализации $\xi(E)$ расходится как $\xi(E) \sim 1/\left(E-E_c\right)^{\mu}$ с некоторой критической экспонентой [1]μ. За эту и дру-

1Это пример квантового фазового перехода. Все обсуждение относится к нулевой температуре.

гие работы в теории конденсированных сред Андерсон получил Нобелевскую премию.

С физической точки зрения локализация обусловлена деструктивной интерференцией между квантовыми волнами, рассеивающимися на случайном потенциале.

Когда включено магнитное поле, перпендикулярное плоскости электронного газа с $D = 2$, ситуация кардинально меняется: при $E = 0$ появляется нелокализованная волновая функция. Для ненулевой E все волновые функции остаются локализованными, но с длиной локализации, расходящейся как $\xi(E) \sim 1/|E|^{\nu}$. Такая ситуация является причиной одного из наиболее поразительных особенностей квантового эффекта Холла (см. главу VI.2): холловская проводимость остается постоянной, тогда как энергия Ферми возрастает, но затем внезапно скачкообразно изменяется на дискретное значение вследствие вклада нелокализованного состояния, когда энергия Ферми переходит через $E = 0$. Количественная оценка такого поведения является сложной задачей для теоретиков в области физики конденсированных сред. Действительно, многие рассматривают аналитическое вычисление критической экспоненты ν как один из «священных Граалей» теории конденсированного вещества.

Формализм функций Грина

Слишком много информации для молниеносного знакомства с теорией локализации. Каким бы интересным ни был переход к локализации, какое отношение к этому может иметь квантовая теория поля? Все-таки это учебник по теории поля. Перед тем как продолжить, необходимо описать формализм. Рассмотрим так называемую функцию Грина

$G(z) \equiv \langle \mathrm{tr}[1/(z-H)] \rangle$ в комплексной z-плоскости. Так как $\mathrm{tr}[1/(z-H)] = \sum_i 1/(z-E_i)$, эта функция состоит из суммы полюсов при собственных значениях E_i. При усреднении полюсы сливаются в разрез. Используя стандартное тождество $\lim_{\varepsilon\to\infty} \mathrm{Im}[1/(x+i\varepsilon)] = -\pi\delta(x)$, легко видеть, что

$$\rho(E) = -\frac{1}{\pi} \lim_{\varepsilon\to 0} \mathrm{Im}\, G(E+i\varepsilon)$$

Поэтому если известна функция $G(z)$, то известна плотность состояний.

туре. В отличие от фазового перехода. рассмотренного в главе V.3, вместо температуры здесь меняются E.

Скверный знаменатель

Теперь можно объяснить, как квантовая теория поля возникает в этой задаче. Начнем с того, что возьмем логарифм тождества (A.12)

$$J^\dagger \cdot K^{-1} \cdot J = \log\left(\int D\varphi^\dagger D\varphi e^{-\varphi^\dagger \cdot K\cdot \varphi + J^\dagger\cdot\varphi + \varphi^\dagger \cdot J} \right)$$

(где, как обычно, отбрасывается несущественный член). Дифференцируя по $J^\dagger$ и J и затем задавая $J^\dagger$ и J равными 0, получаем интегральное представление для обратной эрмитовой матрицы:

$$\left(K^{-1}\right)_{ij} = \frac{\int D\varphi^\dagger D\varphi e^{-\varphi^\dagger\cdot K\cdot\varphi}\varphi_i\varphi_j^\dagger}{\int D\varphi^\dagger D\varphi e^{-\varphi^\dagger\cdot K\cdot\varphi}}$$

(Как видно, это выражение, по сути, связано с формулой (I.7.14) для пропагатора скалярного поля.) Теперь мы знаем, как представить функцию $1/(z$ - $-H)$. Надо взять ее след, что означает положить в уравнении (2) $i = j$ и просуммировать. В этой задаче $H = -\nabla^2 + V(x)$, а индекс i соответствует непрерывной переменной x, тогда как суммирование - интегрированию по пространству. Заменяя K на $i(z-H)$ (и позаботившись о соответствующей дельта-функции), получаем

$$\mathrm{tr}\,\frac{-i}{z-H} = \int d^D y \left\{ \frac{\int D\varphi^\dagger D\varphi e^{i\int d^D x\left\{\partial\varphi^\dagger\partial\varphi + [V(x)-z]\varphi^\dagger\varphi\right\}}\varphi(y)\varphi^\dagger(y)}{\int D\varphi^\dagger D\varphi e^{i\int d^I x\left\{\partial\varphi^\dagger\partial\varphi+[V(x)-z]\varphi^\dagger\varphi\right\}}} \right\}$$

Начинает походить на теорию скалярного поля в D-мерном евклидовом пространстве с действием $S = \int d^D x \left\{\partial\varphi^\dagger\partial\varphi + [V(x)-z]\varphi^\dagger\varphi\right\}$. [Заметим, что, для того чтобы уравнение (3) было хорошо определено, z должна находиться в нижней полуплоскости.]

Но теперь нужно усреднить по $V(x)$, то есть проинтегрировать по V с распределением вероятности $P(V)$. Сразу же возникает трудность, которая долгое время ставила теоретиков в тупик. Знаменатель в (3) не позволяет двигаться дальше. Если бы этого знаменателя не было, то функциональное интегрирование по $V(x)$ соответствовало бы вычислению гауссова интеграла, которым вы занимались много раз. Можно ли этот скверный знаменатель, если можно так выразиться, как-то перенести в числитель? Умные головы предложили два приема, известные соответственно как репличный и суперсимметричный. Если вы можете предложить другой прием, честь вам и хвала.

Реплики

Репличный подход основан на хорошо известном пределе $(1/x) = \lim_{n\to 0} x^{n-1}$, который позволяет записать этот столь неприятный знаменатель в виде

$$\lim_{n\to 0}\left(\int D\varphi^\dagger D\varphi e^{i\int d^l x\left\{\partial\varphi^\dagger\partial\varphi+[V(x)-z]\varphi^\dagger\varphi\right\}}\right)^{n-1}=$$
$$=\lim_{n\to 0}\int\prod_{a=2}^{n}D\varphi_a^\dagger D\varphi_a e^{i\int d^D x\sum\limits_{a=2}^{n}\left\{\partial\varphi_a^\dagger\partial\varphi_a+[V(x)-z]\varphi_a^\dagger\varphi_a\right\}}.$$

Тогда (3) приобретает вид

$$\operatorname{tr}\frac{1}{z-H}=\lim_{n\to 0}i\int d^D y\times$$
$$\times\int\left(\prod_{a=1}^{n}D\varphi_a^\dagger D\varphi_a\right)e^{i\int d^D x\sum\limits_{a=1}^{n}\left\{\partial\varphi_a^\dagger\partial\varphi_a+[V(x)-z]\varphi_a^\dagger\varphi_a\right\}}\varphi_1(y)\varphi_1^\dagger(y).$$

Заметим, что функциональный интеграл теперь берется по n комплексным скалярным полям φ_a. Реплика поля φ получена.

Усредняя по случайному потенциалу, восстанавливаем трансляционную инвариантность. Таким образом, подынтегральное выражение для $\int d^D y$ не зависит от y, а $\int d^D y$ просто дает объем системы $\mathcal{V}$. Используя (A.12), получаем

$$\left\langle\operatorname{tr}\frac{1}{z-H}\right\rangle=i\mathcal{V}\lim_{n\to 0}\int\left(\prod_{a=1}^{n}D\varphi_a^\dagger D\varphi_a\right)e^{i\int d^D x\,\mathcal{L}}\varphi_1(0)\varphi_1^\dagger(0),$$

где

$$\mathcal{L}(\varphi)\equiv\sum_{a=1}^{n}\left(\partial\varphi_a^\dagger\partial\varphi_a-z\varphi_a^\dagger\varphi_a\right)+\frac{ig^2}{2}\left(\sum_{a=1}^{n}\varphi_a^\dagger\varphi_a\right)^2$$

Мы получаем теорию поля (со специфическим множителем i) n скалярных полей со старым добрым взаимодействием φ^4, инвариантным относительно $O(n)$ (известной как репличная симметрия). Заметим целесообразность замены K на $i(z-H)$: если не включить i, то функциональный интеграл расходился бы при большом φ, что можно легко проверить. Для z в верхней полуплоскости заменим K на $-i(z-H)$. Величина, из которой можно извлечь искомую усредненную плотность состояний, определяется пропагатором скалярного поля. Кстати, в уравнении (5) $\varphi_1(0)\varphi_1^\dagger(0)$ можно заменить более симметричным выражением $(1/n)\sum\limits_{b=1}^{n}\varphi_b^\dagger\varphi_b$.

Убирая $\mathcal{V}$ и, таким образом, переходя к вычислению плотности состояний на единицу объема, находим

$$G(z)=i\lim_{n\to 0}\int\left(\prod_{a=1}^{n}D\varphi_a^\dagger D\varphi_a\right)e^{-S(\varphi)}\left(\frac{1}{n}\sum_{b=1}^{n}\varphi_b^\dagger(0)\varphi_b(0)\right).$$

Для любого целого числа n теория поля определяется однозначно, поэтому тонким моментом в репличном подходе является взятие предела $n\to 0$. Этому пределу посвящена интереснейшая литература. (Посмотрите книгу о спиновых стеклах.)

Некоторые теоретики в области физики элементарных частиц имели обыкновение пренебрежительно отзываться о физике конденсированных сред как о грязной физике. Влияние примесей и беспорядка на вещество действительно является одной из основных проблем современной физики конденсированных сред. Но, как видно из этого примера, между усреднением по беспорядочности и суммированием по квантовым флуктуациям во многих отношениях нет математического различия. В итоге получаем теорию поля φ^4, на изучение которой многие специалисты по физике элементарных частиц потратили в прошлом немало усилий. Кроме того, поразительный вывод Андерсона о том, что для

$D = 2$ любая степень беспорядка (сколь угодно малая) локализует все состояния, означает, что теорию поля, определяемую выражением (6), следует понимать в высшей степени нетривиально. Величина беспорядка проявляется как взаимодействие g^2, так что никакая теория возмущений по g^2 не может помочь нам объяснить локализацию. Андерсоновская локализация является существенно непертурбативным эффектом.

Грассманов подход

Как упоминалось выше, для борьбы со скверным знаменателем придуман не один, а два приема. Второй прием основан на интегрировании по грассмановым переменным, которое было рассмотрено в главе II.5. Пусть $\eta(x)$ и $\bar{\eta}(x)$ будут грассмановыми поля, тогда

$$\int D\eta D\bar{\eta} e^{-\int d^4x \bar{\eta} K \eta} = C \det K = \widetilde{C} \left(\int D\varphi D\varphi^\dagger e^{-\int d^4x \varphi^\dagger K \varphi} \right)^{-1},$$

где C и $\widetilde{C}$ - две несущественные константы, которые можно включить в определение $D\eta D\bar{\eta}$. С учетом этого тождества выражение (3) можно записать в виде

$$\operatorname{tr} \frac{1}{z-H} = i \int d^D y$$
$$\int D\varphi^\dagger D\varphi D\eta D\bar{\eta} e^{i\int d^D x \left\{ \left\{ \partial\varphi^\dagger \partial\varphi + \left[V(x) - z | \varphi^\dagger \varphi \right\} + \{ \partial\bar{\eta}\partial\eta + [V(x)-z]\bar{\eta}\eta \} \right\}} \varphi(y)\varphi^\dagger(y)$$

и тогда легко усреднить по беспорядку, чтобы получить

$$\left\langle \operatorname{tr} \frac{1}{z-H} \right\rangle = i \int D\varphi^\dagger D\varphi D\eta D\bar{\eta} e^{i\int d^I x \mathcal{L}\left(\bar{\eta},\eta,\varphi^\dagger,\varphi\right)} \varphi(x)\varphi^\dagger(x)$$

с лагранжианом

$$\mathcal{L}\left(\bar{\eta},\eta,\varphi^\dagger,\varphi\right) = \partial\varphi^\dagger\partial\varphi + \partial\bar{\eta}\partial\eta - z\left(\varphi^\dagger\varphi + \bar{\eta}\eta\right) + \frac{ig^2}{2}\left(\varphi^\dagger\varphi + \bar{\eta}\eta\right)^2$$

В итоге получаем теорию поля с бозонными (коммутирующими) полями $\varphi^\dagger$ и φ и фермионными (антикоммутирующими) полями η и $\bar{\eta}$, взаимодействие которых определяется беспорядком. Действие S обладает очевидной симметрией по отношению к вращению бозонных полей в фермионные поля и наоборот; и поэтому этот подход известен среди специалистов в области физики конденсированных сред как суперсимметричный. (Следует обратить внимание, что η и $\bar{\eta}$ не являются спинорными полями, что мы подчеркиваем, не записывая их в виде $\bar{\psi}$ и ψ. Суперсимметрия здесь, которую, пожалуй, лучше назвать грассмановой симметрией, крайне отличается от суперсимметрии в физике элементарных частиц, рассмотренной в глаВе VIII.4.)

У обоих подходов, как репличного, так и суперсимметричного, есть свои трудности; и я не шутил, когда говорил, что если вам удастся изобрести новый подход, в котором нет такого рода трудностей, он с восторгом будет принят специалистами по физике конденсированных сред.

Изучение локализации

Я показал, как вычислять усредненную плотность состояний $\rho(E)$. А как изучать локализацию? Попробуйте сами получить ответ на этот вопрос, решая упражнение в конце главы. Из предыдущего рассмотрения должно быть понятно, что объект, полученный из (3), нужно изучать путем замены $\varphi(y)\varphi^\dagger(y)$ на $\varphi\left(y'\right)\varphi^\dagger(y)\varphi(y)\varphi^\dagger\left(y'\right)$. Если сформулировать репличную теорию поля на языке физики элементарных частиц, т. е. как описание взаимодействия некоторого скалярного мезона, то можно увидеть, что плотность состояний будет определяться мезонным пропагатором, а локализация - мезон-мезонным рассеянием.

Упражнения

VI.7.1. Получите теорию поля, которая позволит изучать андерсоновскую локализацию. [Указание: рассмотрите объект

$$\left\langle \left(\frac{1}{z-H}\right)(x,y)\left(\frac{1}{w-H}\right)(y,x)\right\rangle$$

для двух комплексных чисел z и w. Необходимо ввести два набора репличных полей, обычно обозначаемых как φ_a^+и φ_a^-.] {Примечание: $[1/(z$ - $-H)](x,y)$ обозначает элемент xy матрицы, или оператора, $[1/(z-H)]$.

VI.7.2. В качестве другого примера рассмотрите задачу, взятую из литературы, посвященной беспорядку. Разместите случайным образом N точек в D-мерном евклидовом пространстве объемом V. Обозначьте положения этих точек как $\vec{x}_i (i = 1, ..., N)$. Пусть

$$f(\vec{x}) = (-)\int \frac{d^D k}{(2\pi)^D}\frac{e^{i\vec{k}\vec{x}}}{k^2+m^2}.$$

Рассмотрите $N \times N$-матрицу $H_{ij} = f(\vec{x}_i - \vec{x}_j)$. Вычислите плотность собственных значений $H\rho(E)$ как среднее по ансамблю матриц в пределе $N \to \infty, V \to \infty$, с фиксированной плотностью точек $\rho \equiv N/V$ (не надо путать с $\rho(E)$). [Указание: используйте репличный подход и получите действие теории поля

$$S(\varphi) = \int d^D x \left[\sum_{a=1}^{n}\left(|\nabla\varphi_a|^2 + m^2|\varphi_a|^2\right) - \rho e^{-(1/z)}\sum_{u=1}^{n}|\varphi_a|^2\right].$$

Эта задача не совсем тривиальна; если вам нужна помощь, смотрите M. Mzard et al., Nucl. Phys. B559: 689, 2000, cond-mat/9906135.

30.3.8 Zi.VI.8 RG Flow as a Natural Concept in High-Energy and Condensed Matter Physics

Таким образом, выводы, основанные на ренорм-групповом подходе... опасны и должны рассматриваться с должной осторожностью. То же относится ко всем выводам, полученным из локальных релятивистских теорий поля.
Дж. Бьеркен и С. Дрелл, 1965

Это не опасно

Ренорм-группа представляет собой наиболее важное концептуальное достижение в квантовой теории поля за последние три-четыре десятилетия. Основные идеи развивались одновременно как в сообществе специалистов в области физики высоких энергий, так и специалистов в области физики конденсированных сред, а в некоторых областях исследования ренорм-групповой поток стал частью рабочего языка.

Легко представить, насколько богат и многосторонен этот предмет; его можно рассматривать с разных точек зрения, а для полного описания потребовалась бы целая книга. К сожалению, рассмотрение этого предмета никогда не было достаточно основательным и всеобъемлющим. Рассмотрения, приведенные в некоторых ранее изданных книгах, только вводят читателей в заблуждение и являются беспорядочными, как, например, в хорошо известном учебнике, по которому я изучал квантовую теорию поля и из которого взята цитата к настоящей главе. Учитывая ограниченный объем книги, я попытаюсь изложить самую суть этого предмета, избегая, по возможности, технических подробностей. Вначале я подойду к рассмотрению с точки зрения физики высоких энергий, а затем с точки зрения физики конденсированных сред. Как и раньше, внимание будет сосредоточено на смысловом содержании, а не на вычислениях. Несмотря на порядок

изложения, вы поймете, что проще усвоить роль ренорм-группы в физике конденсированных сред, чем в физике высоких энергий.

Я заложил основу для рассмотрения ренорм-группы еще в главе III.1 я все планирую заранее! Вернемся к нашему другу-экспериментатору, с которым мы обсуждали теорию $\lambda\varphi^4$. По-прежнему будем считать, что наш мир описывается простой теорией $\lambda\varphi^4$ и приближения до порядка λ^2 достаточно.

На чем настаивают экспериментаторы

Нашего друга-экспериментатора не интересовала написанная на листе бумаги константа связи λ; для него это всего лишь греческая буква. Он настаивал на том, что признает такие величины, которые фактически можно измерить, пусть даже только в принципе экспериментально. В результате нашей с ним дискуссии понимание того, что такое константа связи, стало глубже, и мы усвоили, что надо определить физическую константу связи следующим образом [см. выражение (III.1.4)]:

$$\lambda_P(\mu) = \lambda - 3C\lambda^2 \log\left(\frac{\Lambda^2}{\mu^2}\right) + O\left(\lambda^3\right).$$

По его настоянию мы научились представлять результат для физических амплитуд через $\lambda_P(\mu)$, а не теоретически введенную λ. В частности, нужно записать амплитуду мезон-мезонного рассеяния как

$$\mathcal{M} = -i\lambda_P(\mu) + iC\lambda_P(\mu)^2\left[\log\left(\frac{\mu^2}{s}\right) + \log\left(\frac{\mu^2}{t}\right) + \log\left(\frac{\mu^2}{u}\right)\right] + \\ + O\left[\lambda_P(\mu)^3\right]$$

В чем заключается физический смысл $\lambda_P(\mu)$? Она, конечно же, измеряет силу взаимодействия между мезонами, как отражено в (2). Но почему нужно выбирать конкретное μ? Из (2) очевидно, что $\lambda_P(\mu)$ очень удобна для изучения физики в таком режиме, когда все кинематические переменные s, t и u имеют порядок μ^2. Амплитуда рассеяния имеет вид $-i\lambda_P(\mu)$ с малыми логарифмическими поправками. (Вспомним из сноски в главе III.3, что точка перенормировки $s_0 = t_0 = u_0 = \mu^2$ введена только для удобства теоретического рассмотрения и не может быть достигнута в реальных экспериментах. Для концептуального понимания здесь это не имеет отношения к делу.) Короче говоря, $\lambda_P(\mu)$ известна как константа связи, соответствующая физике на масштабе энергий μ.

В отличие от этого, если быть настолько глупыми, чтобы использовать константу связи $\lambda_P(\mu')$ при изучении физики в режиме с s, t и u, имеющими порядок μ^2, где μ очень отличается от μ', то амплитуда рассеяния имела бы вид

$$\mathcal{M} = -i\lambda_P(\mu') + iC\lambda_P(\mu')^2\left[\log\left(\frac{\mu'^2}{s}\right) + \log\left(\frac{\mu'^2}{t}\right) + \log\left(\frac{\mu'^2}{u}\right)\right] \\ + O\left[\lambda_P(\mu')^3\right]$$

где второе слагаемое [с большим $\log(\mu'^2/\mu^2)$] может быть одного порядка с первым членом или превышать его. Таким образом, для каждой энергетической шкалы μ есть «соответствующая» константа связи $\lambda_P(\mu)$.

Вычитая (2) из (3), можно легко связать $\lambda_P(\mu)$ и $\lambda_P(\mu')$ для $\mu \sim \mu'$:

$$\lambda_P(mu') = \lambda_P(\mu) + 3C\lambda_P(\mu)^2 \log\left(\frac{\mu'^2}{\mu^2}\right) + O\left[\lambda_P(\mu)^3\right]$$

Последнее выражение можно записать в виде дифференциального «уравнения потока»

$$\mu\frac{d}{d\mu}\lambda_P(\mu) = 6C\lambda_P(\mu)^2 + O\left(\lambda_P^3\right)$$

Вы уже неоднократно сталкивались с тем, что квантовая теория поля полна исторических ошибок в употреблении терминов. Описание того, как $\lambda_P(\mu)$ меняется в зависимости от μ, известно как ренорм-группа. Группа здесь появляется лишь как аддитивная [1] группа преобразования $\mu \to \mu + \delta\mu$.

Для концептуального рассмотрения материала, изложенного в главе III.1 и в этой главе, можно вовсе не знать, что собой представляет константа C. Если C окажется отрицательной, тогда константа связи $\lambda_P(\mu)$ будет убывать с увеличением масштаба энергий μ и возрастать, если C окажется положительной. (На самом деле она имеет положительный знак, так что, когда масштаб энергии увеличивается, λ_P растет относительно первоначального значения.)

[1] Группа преобразований - мультипликативна. инфинитезимальные преобразования аддитивны. - Прим. ped.

Поток электромагнитной константы связи

Рассмотренное поведение λ типично для констант связи в четырехмерных квантовых теориях поля. Например, в квантовой электродинамике константа связи e или, что эквивалентно, $\alpha = e^2/4\pi$, измеряет интенсивность электромагнитного взаимодействия. Здесь происходит то же самое, что и с теорией $\lambda\varphi^4$: нашего друга-экспериментатора не интересует латинская буква e, он хочет знать реальное взаимодействие, когда соответствующие возведенные в квадрат импульсы имеют порядок μ^2. Хорошо, что мы уже сделали вычисление: эффективную константу связи можно извлечь при таком значении импульса, который перенесен возведенным в квадрат $q^2 = \mu^2$ из уравнения (III.7.14):

$$e_P(\mu)^2 = e^2 \frac{1}{1 + e^2\Pi\left(\mu^2\right)} \simeq e^2\left[1 - e^2\Pi\left(\mu^2\right) + O\left(e^4\right)\right].$$

Возьмем значение μ, гораздо большее массы электрона m, но гораздо меньшее масштаба обрезания M. Тогда из выражения (III.7.13) получаем:

$$\mu\frac{d}{d\mu}e^P(\mu) = -\frac{1}{2}e^3\mu\frac{d}{d\mu}\Pi\left(\mu^2\right) + O\left(e^5\right) = +\frac{1}{12\pi^2}e_P^3 + O\left(e_P^5\right).$$

Видим, что электромагнитная константа связи возрастает при увеличении масштаба энергий. Электромагнетизм становится сильнее с переходом к более высоким энергиям или, что эквивалентно, к меньшим расстояниям.

В физическом смысле происхождение этого явления тесно связано с физикой диэлектриков. Рассмотрим фотон, взаимодействующий с электроном, который назовем пробным электроном, чтобы в последующем избежать путаницы. Как показано еще в главе I.1, вследствие квантовых флуктуаций пространство-время наполняется появляющимися и исчезающими электрон-позитронными парами. Вблизи пробного электрона электроны в таких виртуальных парах отталкиваются от него и поэтому стремятся от него удалиться, тогда как позитроны стремятся к нему приблизиться. Таким образом, на больших расстояниях заряд пробного электрона отчасти экранируется облаком позитронов, что приводит к более слабому взаимодействию с фотоном, в то время как на малых расстояниях взаимодействие с фотоном становится сильнее. Квантовый вакуум просто настолько же диэлектрик, как и реальный образец.

Сейчас вы уже, возможно, заметили, что само название «константа связи» является совершенно неправильным по той причине, что многое в истории физики делалось главным образом на одном масштабе энергии, а именно на «почти нулевом»! В частности, некоторые люди говорят о «постоянной» тонкой структуры $\alpha = 1/137$, и фантазеры продолжают попытки «вывести» число 137 из нумерологии или других еще более причудливых методов. На самом деле, α является просто «константой» связи электромагнитного взаимодействия при очень низких энергиях. Экспериментально установлено, что α, которую правильнее записать как $\alpha_P(\mu) \equiv e_P^2(\mu)/4\pi$, меняется вместе с рассматриваемым масштабом энергий μ. Но увы, название «константа связи», по-видимому, уже укоренилось.

Ренорм-групповой поток

В общем случае в квантовой теории поля с константой связи g имеет место уравнение ренорм-группового потока

$$\mu = \frac{dg}{d\mu} = \beta(g)$$

которое иногда записывают как $dg/dt = \beta(g)$, задавая $t \equiv \log(\mu/\mu_0)$. Теперь опустим подстрочный индекс P у физических констант связи. Если окажется, что теория имеет несколько констант связи $g_i, i = 1, ..., N$, то получаем уравнение

$$\frac{dg_i}{dt} = \beta_i(g_1, ..., g_N)$$

Можно представить $(g_1, ..., g_N)$ как координаты частицы в N-мерном пространстве, t как время и $\beta_i(g_1, ..., g_N)$ как зависящее от положения поле скоростей. Нас интересует, как движется или течет частица при увеличении μ или t. Для простоты обозначим все координаты $(g_1, ..., g_N)$ как g. Очевидно, что те связи, на которых $\beta_i(g^*)$ исчезает (для всех i), представляют особый интерес: g^* известна как фиксированная точка. Если поле скоростей вокруг фиксированной точки g^* такое, что частица движется по направлению к этой точке (и когда ее достигает, остается там, поскольку ее скорость теперь равна нулю), фиксированную точку называют притягивающей или стабильной. Таким образом, чтобы изучить асимптотическое поведение квантовой теории поля при высоких энергиях, надо «попросту» найти все ее притягивающие фиксированные точки относительно ренорм-группового потока. В данной теории мы, как правило, видим, что некоторые константы связи устремляются к большим значениям, тогда как другие стремятся к нулю.

К сожалению, это замечательное теоретическое представление сложно осуществить на практике, потому что, по сути, не существует способа вычисления функций $\beta_i(g)$. В частности, точка g^* вполне могла бы быть довольно большой, связанной с так называемой фиксированной точкой сильной связи, а теория возмущений и фейнмановские диаграммы в этом случае бесполезны при определении свойств теории. Действительно, структура фиксированной точки известна для очень немногих теорий.

К счастью, известна одна особенно простая фиксированная точка, а именно $g^* = 0$, для которой теория возмущений, безусловно, применима. Уравнение (8) всегда может быть вычислено пертурбативно: $dg_i/dt = c_i^{jk} g_j g_k + d_i^{jkl} g_j g_k g_l + ...$ (В некоторых теориях такая последовательность начинается с квадратичных членов, а в других - с кубических. Иногда присутствует также и линейный член.) Таким образом, как мы уже видели на паре примеров, асимптотическое или высокоэнергетическое поведение теории зависит от знака β_i в уравнении (8).

Давайте сейчас заглянем на съемки фильма «История физики». В конце 1960-х годов экспериментаторы, изучающие так называемое глубоко неупругое рассеяние электронов на протонах, обнаружили, что полученные результаты указывают на то, что после соударения с высокоэнергетическим электроном один из кварков внутри протона распространяется свободно, без сильного взаимодействия с другими кварками. Обычно все три кварка внутри протона связаны друг с другом сильным взаимодействием, образуя таким образом протон. В конце концов, некоторые теоретики поняли, что такая сложная ситуация объяснима, если теория сильного взаимодействия такова, что константа связи течет в сторону фиксированной точки $g^* = 0$. В этом случае сильное взаимодействие между кварками слабеет с ростом энергии.

Теперь, оглядываясь в прошлое, нам все кажется «очевидным». Но, дорогие студенты, не забывайте, что в то время теория поля считалась неприемлемой для молодых умов, а ренорм-группа рассматривалась как «вредная» даже для учебника по теории поля!

Теория сильного взаимодействия не была известна. Если бы хватило смелости принять опасные идеи ренорм-группы, то можно было даже построить теорию сильного взаимодействия путем поиска асимптотически свободных теорий, как стали нам известны теории с притягивающей фиксированной точкой при $g^* = 0$.

Асимптотически свободные теории, безусловно, удивительны. Их поведение при высоких энергиях можно изучать с использованием пертурбативных методов. Так и была открыта фундаментальная теория сильного взаимодействия, ныне известная как квантовая хромодинамика, о которой речь пойдет позже.

Рассмотрение физики на различных масштабах длин

Необходимость ренорм-групп для физики конденсированных сред очевидна. Вместо общих положений сосредоточимся на особо показательном примере, а именно поверхностном росте. Именно поэтому в главе VI.6 введено уравнение Кардара-Паризи - Жанга. Мы знаем, что для изучения поверхностного роста нужно вычислить интеграл по траекториям

$$Z(\Lambda) = \int \mathcal{D}h e^{-S(h)}$$

где, как вы помните,

$$S(h) = \frac{1}{2}\int d^D\vec{x}dt\left(\frac{\partial h}{\partial t} - \nabla^2 h - \frac{g}{2}(\nabla h)^2\right)^2.$$

Это выражение определяет теорию поля. Как в случае любой теории поля, надо ввести параметр обрезания Λ. Проинтегрируем только по тем конфигурациям полей $h(\vec{x},t)$, которые не содержат фурье-компонент с $\vec{k}$ и ω, большими, чем Λ. (В принципе, так как эта теория нерелятивистская, обрезания должны быть разными для $\vec{k}$ и ω, но в общем случае для простоты описания обозначим их одинако как Λ.) Введение параметра обрезания необходимо и совершенно обоснованно физически. По крайней мере на масштабах длин, как минимум сравнимых с размером соответствующих молекул, непрерывное описание системы в терминах поля $h(\vec{x},t)$ непримеНИМО.

С физической точки зрения можно ожидать, что в микроскопическом масштабе поверхность будет выглядеть очень неровной, как показано на рис. VI.8.1a, поскольку случайно выбранный основной член $\eta(\vec{x},t)$ соответствует белому шуму, то есть η при $\vec{x}$ и $\vec{x}'$ (а также при разных моментах времени) не коррелируют вообще. Однако предположим, что нас интересует не столько детальная микроскопическая структура, сколько поведение поверхности на больших масштабах. Другими словами, мы согласны надеть такие очки, через которые поверхность выглядит расплывчато, как на рисунке VI.8.1b. Это вполне естественный подход к изучению физической системы, который нам хорошо знаком. Нас может интересовать физика на некотором масштабе длин L, и не заботить, что происходит на масштабах длин, гораздо меньших L.

Ренорм-группа - это формализм, который позволяет нам связать физику на разных масштабах длин или, что эквивалентно, физику на разных масштабах энергии. В физике конденсированных сред есть тенденция рассматривать масштабы длин, тогда как в физике элементарных частиц -

(a)

(b)

Рис. VI.8.1

масштабы энергии. Современный подход к ренорм-группам появился в результате изучения критических явлений Кадановым, Фишером, Вильсоном и другими, как упоминалось в главе V.3. Рассмотрим, например, модель Изинга, в которой спины могут

быть направлены вверх или вниз, и с ферромагнитным взаимодействием между соседними спинами. При высоких температурах спины направлены беспорядочно вверх и вниз. Когда температура снижается до точки перехода в ферромагнитное состояние, начинают появляться острова спинов, направленных вверх (мы говорим «направленных вверх» для определенности, можно точно так же говорить о спинах, направленных вниз). Их становится все больше до тех пор, пока не будет достигнута критическая температура T_c, при которой все спины во всей системе направлены вверх. Характерный масштаб длин в физике при любой определенной температуре задается типичным размером таких островов. В физически обусловленном методе блок-спина Каданова и др. блоки направленного вверх спина рассматриваются как один эффективный направленный вверх спин, и аналогично для блоков направленных вниз спинов. Тогда понятие ренорм-группы является естественным для описания эффективных спинов эффективным гамильтонианом, соответствующим такому масштабу длин.

Более или менее ясно, как применить эту физическую идею изменения масштабов в функциональном интеграле (9). Надо проинтегрировать по тем $h(\vec{k},\omega)$, где $\vec{k}$ и ω меньше Λ. Предположим, мы делаем лишь часть того, что должны сделать. Проинтегрируем по тем $h(\vec{k},\omega)$, где $\vec{k}$ и ω больше $\Lambda-\delta\Lambda$, но меньше Λ. Именно это имеется в виду, когда мы говорим, что нас не заботят флуктуации $h(\vec{x},t)$ на масштабах длин и времени, меньших $(\Lambda$ - $-\delta\Lambda)^{-1}$.

Надеваем размывающие очки

Вернемся для простоты к нашей любимой $\lambda\varphi^4$-теории вместо того, чтобы решать задачу поверхностного роста. Вспомним из предыдущих глав важность евклидовой $\lambda\varphi^4$-теории в современной теории конденсированных сред. Итак, продолжим $\lambda\varphi^4$-теорию в евклидово пространство и проанализируем интеграл

$$Z(\Lambda)=\int\limits_{\Lambda}\mathcal{D}\varphi e^{-\int d^dx\mathcal{L}(\varphi)}$$

Обозначение $\int\limits_{\Lambda}$ указывает на то, что интегрировать необходимо только по таким конфигурациям поля $\varphi(x) = \int\left[d^dk/(2\pi)^d\right]e^{ikx}\varphi(x)$, при которых $\varphi(k) = 0$ для $|k| \equiv \left(\sum\limits_{i=1}^{d}k_i^2\right)^{1/2}$ больше, чем Λ. Как уже говорилось, подобного рода интегрирование эквивалентно надеванию размывающих очков с разрешением $L = 1/\Lambda$: мы не допускаем или не видим флуктуации с масштабами длин меньше L.

Очевидно, что $O(d)$ - инвариантность, а именно евклидовый эквивалент лоренц-инвариантности значительно облегчит нам жизнь. В противоположность этому, для задачи поверхностного роста необходимы специальные очки, которые по-разному размывают пространство и время [2].

Теперь мы готовы к тому, чтобы сделать очки еще более размытыми, позволяя $\Lambda\to\Lambda-\delta\Lambda($ с $\delta\Lambda>0)$. Запишем $\varphi=\varphi_s+\varphi_w(s$ означает «гладкий» (от англ. «smooth»), w означает «извилистый» (от англ. «wriggly»)), определенную так, что фурье-компоненты $\varphi_s(k)$ и $\varphi_w(k)$ не равны нулю только для $|k|\leqslant(\Lambda-\delta\Lambda)$ и $(\Lambda-\delta\Lambda)\leqslant|k|\leqslant\Lambda$ соответственно. (Очевидно, что обозначения «гладкий» и «извилистый» введены для удобства.) Подставляя в (11), можно записать

$$Z(\Lambda)=\int\limits_{\Lambda-\delta\Lambda}\mathcal{D}\varphi_s e^{-\int d^dx\mathcal{L}(\varphi_s)}\int\mathcal{D}\varphi_w e^{-\int d^dx\mathcal{L}_1(\varphi_s,\varphi_w)}$$

[2] В физике конденсированных сред эту разницу измеряет так называемая динамическая экспонента z. Более точно, в контексте задачи поверхностного роста коррелятор (введенный в главе VI.6) удовлетворяет типу динамическопо скейлинга, приведенному в уравнении (VI.6.3). Наивно, динамическая экспонента z должна быть равна 2. (Краткий обзор по данному

вопросу Iриведен в работе M. Kardar and A. Zee, Nucl. Phys. B464[FS]: 449. 1996, cond-mat/9507112.) где все члены в $\mathcal{L}_1(\varphi_s, \varphi_w)$ зависят от φ_w. (То, что здесь происходит, несколько напоминает то, что мы делали в главе IV.3.) Представим себе, что интеграл берется по φ_w. Вспомним результат

$$e^{-\int d^d x \delta\mathcal{L}(\varphi_s)} \equiv \int \mathcal{D}\varphi_w e^{-\int d^d x \mathcal{L}_1(\varphi_s, \varphi_w)}$$

и, таким образом, получим

$$Z(\Lambda) = \int\limits_{\Lambda - \delta\Lambda} \mathcal{D}\varphi_s e^{-\int d^d x [\mathcal{L}(\varphi_s) + \delta\mathcal{L}(\varphi_s)]}$$

Все, мы закончили! Мы переписали теорию в терминах «гладкого» поля φ_s.

Конечно, это только формальный подход, поскольку на практике интеграл по φ_w можно взять лишь пертурбативно, допуская, что соответствующие константы связи малы. Если бы интеграл по φ_w можно было взять строго, то также можно было бы вычислить интеграл по φ, и тогда эти ренорм-группы и все, что с ними связано, не были бы нужны.

В педагогических целях рассмотрим в более общем виде $\mathcal{L} = \frac{1}{2}(\partial\varphi)^2 + + \sum\limits_n \lambda_n \varphi^n + ...$ (так что λ_2 является обычным $\frac{1}{2}m^2$, а λ_4 - обычным λ). Поскольку такие члены, как $\partial\varphi_s \partial\varphi_w$, зануляются при интегрировании, получаем уравнение

$$\int d^d x \mathcal{L}_1(\varphi_s, \varphi_w) = \int d^d x \left[\frac{1}{2}(\partial\varphi_w)^2 + \frac{1}{2}m^2\varphi_w^2 + ...\right]$$

которое описывает поле φ_w, взаимодействующее как с самим собой, так и с внешним полем $\varphi_s(x)$. Из соображений симметрии следует, что $\delta\mathcal{L}(\varphi_s)$ имеет тот же вид, что и $\mathcal{L}(\varphi_s)$, но с другими коэффициентами. Таким образом, добавление $\delta\mathcal{L}(\varphi_s)$ к $\mathcal{L}(\varphi_s)$ сдвигает [3] константу связи λ_n (и коэффициент $\frac{1}{2}(\partial\varphi_s)^2$). Эти сдвиги генерируют поток в пространстве констант связи, описанный выше.

Выражение (13) вполне можно было бы рассматривать как конечный результат. Но предположим, что нужно сравнить (13) с (11). Тогда хотелось бы заменить $\int\limits_{\Lambda-\delta\Lambda}$ в (13) на $\int\limits_{\Lambda}$. Для удобства введем действительное

[3] Такие члены, как $(\partial\varphi)^4$, также можно сгенерировать, поэтому я записал выражение для $\mathcal{L}(\varphi)$ с $(...),.,$ приложений эти члены несущественны в техническом смысле, который будет определен ниже. число $b < 1$ с помощью выражения $\Lambda - \delta\Lambda = b\Lambda$. В $\int\limits_{\Lambda-\delta\Lambda}$ необходимо интегрировать по полям с$|k| \leqslant b\Lambda$. Поэтому нужно только лишь выполнить тривиальную замену переменной: пусть $k = bk'$, так что $k = bk'$. Но тогда надо соответствующим образом изменить $x = x'/b$, чтобы $e^{ikx} = e^{ik'x'}$. Делая подстановку, находим

$$\int d^d x \mathcal{L}(\varphi_s) = \int d^d x' b^{-d} \left[\frac{1}{2}b^2(\partial'\varphi_s)^2 + \sum_n \lambda\varphi_s^n + ...\right]$$

(где $\partial' = \partial/\partial x' = (1/b)\partial/\partial x$). Определим φ' через $b^{2-d}(\partial'\varphi_s)^2 = (\partial'\varphi')^2$ или, другими словами, $\varphi' = b^{\frac{1}{2}(2-d)}\varphi_s$. Тогда интеграл (14) приобретает вид

$$\int d^d x' \left[\frac{1}{2}(\partial'\varphi')^2 + \sum_n \lambda_n b^{-d+(n/2)(d-2)}\varphi'^n + ...\right]$$

Таким образом, если определить коэффициент при φ'^n как λ'_n, то получим

$$\lambda'_n = b^{(n/2)(d-2)-d}\lambda_n$$

- важный результат в теории ренорм-группы.

Релевантные, иррелевантные и маргинальные

Постараемся понять, что это значит. (На некоторое время пренебрежем $\delta\mathcal{L}(\varphi_s)$, чтобы упростить наши рассуждения.) Когда мы надеваем размывающие очки или, другими словами, когда нас интересует физика на больших расстояниях, можно снова записать $Z(\Lambda)$, как в (11), с учетом того, что константы связи λ_n надо заменить на λ'_n. Так как $b<1$, то из (15) легко видеть, что λ_n при $(n/2)(d-2)-d>0$ становятся все меньше и меньше и в конечном счете ими можно пренебречь. Немного жаргона: соответствующие операторы φ^n (по историческим причинам перейдем на миг с языка функционального интеграла на язык операторов) называют иррелевантными. Это проигравшие. В противоположность им, победители, а именно φ^n, для которых $(n/2)(d-2)-d<0$, называют релевантными. Операторы, для которых $(n/2)(d-2)-d=0$, называют маргинальными.

Например, возьмем $n=2: m'^2=b^{-2}m^2$, и массовый член всегда является релевантным в любом измерении. С другой стороны, возьмем $n=4$, и мы видим, что $\lambda'=b^{d-4}\lambda$ и оператор φ^4 является релевантным для $d<4$, иррелевантным для $d>4$ и маргинальным для $d=4$. Аналогично $\lambda'_6=b^{2d-6}\lambda$, и оператор φ^6 является маргинальным для $d=3$ и становится иррелевантным для $d>3$.

Легко видеть, что случай $d=2$ особый: все φ^n являются релевантными. Все это может показаться знакомым, если вы добросовестно решали упражнения. В упражнении III.2.1 вы должны были доказать, что константа связи λ_n имеет размерность массы $[\lambda_n]=(n/2)(2-d)+d$. Таким образом, величина $(n/2)(d-2)-d$ есть размерность длины константы связи λ_n. Например, для $d=4\lambda_6$ имеет массовую размерность -2, и поэтому, как говорилось в главе III.2, взаимодействие φ^6 является неперенормируемым и, значит, плохо себя ведет при большой энергии. Однако специалистов в области физики конденсированных сред интересует предел больших расстояний, противоположный тому, который интересует специалистов в области физики элементарных частиц. Следовательно, такие неприятные операторы, как φ^6, становятся иррелевантными в пределе больших расстояний.

Еще немного жаргона: для заданной теории скалярного поля размерность d, при которой наиболее существенное взаимодействие становится маргинальным, известна в физике конденсированных сред как критическая размерность. Например, критической размерностью для теории φ^6 является 3. Приведение уравнения (15) к дифференциальному виду - всего лишь вопрос «арифметики уровня средней школы». Запишем $\lambda'_n=\lambda_n+\delta\lambda_n$; тогда из $b=1-(\delta\Lambda/\Lambda)$ получаем $\delta\lambda_n=-\left[\frac{n}{2}(d-2)-d\right]\lambda_n(\delta\Lambda/\Lambda)$.

Теперь будем особенно осторожными со знаками. Как я уже отметил, для $(n/2)(d-2)-d>0$ константа связи λ_n (которую для определенности представим положительной) становится меньше, как следует из (15). Но поскольку Λ уменьшается до $\Lambda-\delta\Lambda$, положительный член $\delta\Lambda$ фактически соответствует разрешающей способности наших размывающих очков $L=\Lambda^{-1}$, которая возрастает до $L+L(\delta\Lambda/\Lambda)$. Таким образом, получаем

$$L\frac{d\lambda_n}{dL}=-\left[-\frac{n}{2}(d-2)-d\right]\lambda_n$$

так что для $(n/2)(d-2)-d>0$ положительная λ_n будет убывать по мере возрастания L[4].

В частности, для $n=4$ имеет место $L(d\lambda/dL)=(4-d)\lambda$. В большинстве приложений физики конденсированных сред $d\leqslant 3$, и поэтому λ

4Заметим. что в правой части выражения фигурирует линейная размерность λ_n со знаком «минус», а не линейная размерность $(n/2)(d-2)-d$, как можно было бы наивно предположить. возрастает по мере возрастания масштаба длин рассматриваемой физики. Как говорилось выше, взаимодействие φ^4 является релевантным.

Производная $\delta\mathcal{L}(\varphi_s)$, которой мы временно пренебрегли, вносит в правую часть (16) добавочный член, который назовем динамическим, в отличие от геометрического или «тривиального» члена. Таким образом, в общем случае $L(d\lambda_n/dL)=-[(n/2)(d-2)-d]\lambda_n+K(d,n,...,\lambda_j,...)$, где динамический член K зависит не только от d и n, но также от других констант связи. (Например, в (5) «тривиальный» член

обращается в нуль, так как мы находимся в четырехмерном пространстве-времени; остается только динамический вклад.)

Из нашего обсуждения следует, что более образно ренорм-группу можно назвать «трюком для вычисления интеграла почти за один прием».

Использование симметрии

Чтобы определить ренорм-групповой поток для константы связи g, можно повторить те же вычисления, что и при определении потока для констант связи λ и e в двух предыдущих примерах; а именно используя язык физики элементарных частиц, вычислить амплитуду рассеяния $h-h$ в однопетлевом приближении. Однако вместо этого мы будем следовать физической картине Каданова и др. В $Z(\Lambda)=\int \mathcal{D}h e^{-S(h)}$ интегрируем только по тем $h(\vec{k},\omega)$, где $\vec{k}$ и ω больше $\Lambda-\delta\Lambda$, но меньше Λ.

Теперь покажу, как в этом случае использовать симметрию, чтобы свести к минимуму затраты времени. Решающим здесь является не изучение динамики поверхностного роста, а метод, который пригодится вам в других ситуациях. Я выбрал особо «сложную» нерелятивистскую задачу с неявными симметриями, так что если осилить ренорм-группу для этой задачи, можно быть готовым почти к чему угодно.

Представим, что мы выполнили интегрирование по частям и получили результат $\int \mathcal{D}h e^{-\widetilde{S}(h)}$. На данном этапе следует определить симметрии, фигурирующие в задаче, так, как это показано в упражнениях. После этого можно утверждать, что $\widetilde{S}(h)$ будет иметь вид

$$\widetilde{S}(h)=\frac{1}{2}\int d^Dx dt\left[\left(\alpha\frac{\partial}{\partial t}-\beta\nabla^2\right)h-\alpha\frac{g}{2}(\nabla h)^2\right]^2+...$$

зависящий от двух параметров - α и β. Многоточием (..) обозначены члены более высокого порядка по h и его производных. Для упрощения задачи заметим, что перед $\partial h/\partial t$ и $(q/2)(\nabla h)^2$ стоит один и тот же коэффициент α. Если известны α и β, то с помощью соответствующего изменения масштаба можно свести действие $\widetilde{S}(h)$ к тому же виду, что и $S(h)$, и таким образом найти изменение g. Следовательно, достаточно посмотреть на члены $(\partial h/\partial t)^2$ и $\left(\nabla^2 h\right)^2$ в действии или, что эквивалентно, на пропагатор, который вычислить гораздо проще. Как однажды сказал Рудольф Пайерлс молодому Гансу Бете: «Erst kommt das Denken, dann das Integral» [5]. (Что примерно звучит как: «Прежде чем брать интеграл, подумайте».) Мы опустим здесь вычисления. Достаточно отметить, что g имеет знакомую со средней школы размерность: (длина) $)^{\frac{1}{2}(D-2)}$ (см. упражнение VI.8.5). Таким образом, согласно нашему обсуждению, мы должны получить

$$L\frac{dg}{dL}=\frac{1}{2}(2-D)g+C_Dg^3+...$$

Детальный расчет необходим для того, чтобы определить коэффициент c_D, который явно зависит от размерности пространства D, поскольку фейнмановские интегралы зависят от D. Уравнение показывает, как изменяется в физике поверхностного роста эффективная мера нелинейности g с изменением масштаба длин L. Для справки: $c_D=\left[S(D)/4(2\pi)^D\right](2D$ - $-3)/D$, где $S(D)$ есть D-мерный телесный угол. Интересным множителем, несомненно, является $(2D-3)$, который меняет знак [6] между $D=1$ и 2.

Локализация

Как говорилось ранее, ренорм-групповой поток буквально стал частью языка физики конденсированных сред и высоких энергий. Приведу еще один пример, демонстрирующий мощь ренорм-группы. Вернемся к андерсоновской локализации (глава VI.7), которая в свое время впечатлила сообщество физиков. Удивление вызвала сильная зависимость поведения локализации от размерности пространства D, настолько сильная, что для $D=2$ все

состояния оказываются локализованными независимо от того, насколько мала степень беспорядка. Обычная физическая интуиция подсказала бы нам, что существует критическая степень беспорядка. Сейчас мы увидим, что обе эти особенности вполне естественно объясняются на языке ренормгруппы. Уже из выражения (18) следует, что D играет определяющую роль. Теперь я приведу эвристическое, но красивое (по крайней мере для меня) доказательство, полученное Абрахамсом, Андерсоном, Личчиардел-

[5] Когда я был студентом. Джон Уилер дал мне аналогичный совет: «Никогда не приступайте к вычислениям, если не знаете ответ заранее».

[6] Кстати. эта теория точно решается для случая $D = 1$ (с использованием методов. которые в этой книге не обсуждаются). ло и Рамакришнаном, которых впоследствии стали называть в сообществе физиков конденсированных сред «бандой четырех». Прежде всего, надо понять, в чем заключается разница между удельной проводимостью σ и кондактансом G на языке физики твердого тела. Удельная проводимость [7] определяется выражением $\vec{J} = \sigma\vec{E}$, где $\vec{J}$ измеряет число электронов, проходящих через единичную область за единицу времени. Кондактанс G является обратным к сопротивлению (мнемоническое правило: эти слова рифмуются). Сопротивленис R является свойством образца и определяется в учебнике по физике для средней школы как $V = IR$, где ток I служит мерой числа электронов, проходящих за единицу времени. Чтобы связать σ и G, рассмотрим массу вещества в виде куба размером L с падением напряжения V в поперечном направлении. Тогда $I = JL^2 = \sigma EL^2 = \sigma(V/L)L^2 = \sigma LV$ и, таким образом,$G(L) = 1/R = I/V = \sigma L$. Теперь перейдем к двум измерениям. Рассмотрим тонкий лист вещества длиной и шириной L, толщиной $a \ll L$. (Мы занимаемся всего лишь школьной физикой, не обращаясь к какому-то сложному представлению двумерного пространства в теории поля!) Допустим падение напряжения V вдоль длины L: $I = J(aL) = \sigma EaL = \sigma(V/L)aL = \sigma Va$, и тогда $G(L) = 1/R = I/V = \sigma a$. Попробуйте сами перейти к одному измерению: рассмотрите провод длиной L, шириной и толщиной a. Таким образом, получаем $G(L) \propto L^{D-2}$. Кстати, специалисты по физике конденсированных сред обычно определяют безразмерную проводимость как $g(L) \equiv \hbar G(L)/e^2$.

Нам также известно поведение $g(L)$, когда $g(L)$ мало или, другими словами, когда вещество является изолятором, для которого ожидается, что $g(L) \sim ce^{-L/\xi}$, где ξ - некоторая характеристическая длина вещества, которая определяется микроскопической физикой. Таким образом, для малого $g(L)$ имеет место $L(dg/dL) = -(L/\xi)g(L) = g(L)[\log g(L) - \log c]$, где для рассматриваемых условий постоянный логарифм $\log c$ пренебрежимо мал.

[7] На протяжении нескольких лет я обращался к специалистам по теории высоких энергий с вопросом, как можно получить уравнение $\vec{J} = \sigma\vec{E}$, которое явно нарушает инвариантность относительно обращения времени, если микроскопическая физика электронного рассеяния на примесном атоме полностью подчиняется инвариантности относительно обращения времени. Очень немногие знали ответ. Разрешение этого явного парадокса заключается в порядке пределов! Специалисты по теории конденсированных сред вычисляют удельную проводимость $\sigma(\omega, \vec{k})$. зависящую от частоты и волнового вектора. и затем берут предел $\omega, \vec{k} \to 0$ и $\vec{k}^2/\omega \to 0$. До того. как предел взят. инвариантность относительно обращения времени сохраняется. Время. которое требуется частице. чтобы оказаться в ящике размером порядка $1/k$, имеет порядок $1/(Dk^2)$ (где D - коэффициент диффузии). Физическая суть заключается в том. что это время должно быть значительно больше. чем время наблюдения $\sim 1/\omega$.

[8] Сэм Трейман сказал мне, что, когда он служил в армии США радистом, его учили, что есть три вида закона Ома: $V = IR.I = V/R$ и $R = V/I$. Во втором равенстве здесь используется четвертая форма. Объединяя все вместе, получаем

$$\beta(g) \equiv \frac{L}{g}\frac{dg}{dL} = \begin{cases} (D-2) + \ldots & \text{для больших } g \\ \log g + \ldots & \text{для малых } g. \end{cases}$$

Прежде всего, тривиальное замечание: в разных дисциплинах $\beta(g)$ определяется поразному (что, конечно, не влияет на физику). Как мы говорили, в теории локализации $\beta(g)$ традиционно определяется как $d\log g/d\log L$. Из графика для $\beta(g)$ на рис. VI.8.2 видно,

что для $D = 2$ (и $D = 1$) кондактанс $g(L)$ всегда стремится к нулю при переходе к большим расстояниям (макроскопические измерения макроскопических веществ) независимо от того, где мы начинаем. В отличие от этого, если g_0 (начальное значение g) больше, чем критическое g_c, то для $D = 3g(L)$ стремится к бесконечности (предположительно этот бег обрезается физикой, которую мы не включили), и вещество является металлом; тогда как, если $g_0 < g_c$, вещество является изолятором. Кстати, специалисты по теории конденсированных сред часто говорят о критической размерности D_c, при которой поведение системы на больших расстояниях радикально изменяется; в данном случае это $D_c = 2$.

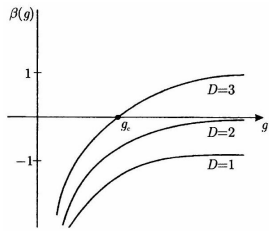

Рис. VI.8.2

Эффективное описание

В некотором смысле ренорм-группа берет начало от основного понятия физики, которое заключается в том, что эффективное описание может и должно изменяться по мере перехода от одного масштаба длин к другому. Например, в гидродинамике не надо детально отслеживать взаимодействие между молекулами воды. Таким же образом, когда ренорм-групповой поток используется для сильного взаимодействия, начиная с высоких энергий и двигаясь к низким энергиям, эффективное описание переходит от теории кварков и глюонов к теории нуклонов и мезонов. Тогда в этой более общей картине мы рассматриваем потоки не в пространстве констант связи, а в «пространстве гамильтонианов», о котором любят говорить некоторые теоретики в области физики конденсированных сред.

Упражнения

VI.8.1. Покажите, что решением $dg/dt = -bg^3 + \ldots$ будет

$$\frac{1}{\alpha(t)} = \frac{1}{\alpha(0)} + 8\pi bt + \ldots$$

где мы определили $\alpha(t) = g(t)^2/4\pi$.

VI.8.2. При рассмотрении ренорм-группы в $\lambda\varphi^4$-теории или в КЭД мы приняли для простоты, что масса m частицы гораздо меньше, чем μ, и поэтому приравняли m к нулю. Но в понятии ренорм-группы ничто не говорится о том, что нельзя переходить к масштабу массы меньше m. Действительно, в физике элементарных частиц масса t кварка m_t отличается от массы и кварка m_u на много порядков. Мы могли бы изучить, как изменяется константа связи сильного взаимодействия при переходе от некоторого масштаба массы, намного превышающего m_t, к некоторому масштабу массы μ, который намного меньше m_t, но все еще велик по сравнению с m_u. Довольно часто в качестве грубого приближения любую массу m, меньшую μ, приравнивают нулю, а любую массу m, большую μ, приравнивают к бесконечности (т. е. без вклада в ренорм-групповой поток). В действительности, по мере того как μ приближается m сверху, частица начинает давать меньший вклад и исчезает, когда μ становится меньше m. Изучите этот так называемый пороговый эффект, используя либо $\lambda\varphi^4$-теорию, либо КЭД.

VI.8.3. Покажите, что уравнение (10) является инвариантным относительно так называемого преобразования Галилея

$$h(\vec{x},t) \to h'(\vec{x},t) = h(\vec{x}+g\vec{u}t,t) + \vec{u}\cdot\vec{x} + \frac{g}{2}u^2 t.$$

Покажите, что в силу этой симметрии в (17) появляются только два параметра α и β.

VI.8.4. В выражении для $\widetilde{S}(h)$ могут появляться только производные поля h, а само поле не может. (Поскольку преобразованис имеет вид $h(\vec{x},t) \to h(\vec{x},t)+c$, где константа c соответствует тривиальному сдвигу точки, где измеряется высота поверхности, физический процесс должен быть инвариантным относительно этого преобразования.) Члены, содержащие h в первой степени, не могут появляться, так как все они являются полными производными. Таким образом, выражение $\widetilde{S}(h)$ должно начинаться с членов второй степени по h. Проверьте, что выражение $\widetilde{S}(h)$, приведенное в (17), действительно является наиболее общим. Член, пропорциональный $(\nabla h)^2$, также разрешен симметриями и действительно генерируется. Однако этот член можно устранить путем преобразования к движущейся системе координат $h \to h+ +ct$.

VI.8.5. Покажите, что g имеет размерность (длина $)^{\frac{1}{2}(D-2)}$, известную нам из школьного учебника по физике. [Указание: вид $S(h)$ означает, что t имеет размерность длины в квадрате, и поэтому h имеет размерность (длина) $^{\frac{1}{2}(2-D)}$. Сравнивая члены $\nabla^2 h$ и $\nabla^2 h$, определяем размерность g.]

VI.8.6. Вычислите пропагатор h в однопетлевом приближении. Извлеките коэффициенты членов ω^2 и k^4 в разложении по низким частотам и волновым числам обратного пропагатора и определите α и β.

VI.8.7. Изучите ренорм-групповой поток g для $D = 1, 2, 3$.

30.3.9 Nonequilibrium Field Theory in Matter: Introduction

(An Introduction to Kamenev's book, see note on kinetics for now about it)

30.4 Zi.VII Grand Unification

30.4.1 Zi.VII.1 Quantization of Yang–Mills Theory and Lattice Gauge Theory

Одна из причин, по которой теория Янга-Миллса не была сразу же принята физиками, заключается в том, что они не знали, как в ней проводить вычисления. По крайней мере, следует сформулировать правила Фейнмана и уметь проводить пертурбативные вычисления. Фейнман сам взялся за эту проблему и после рассмотрения различных диаграмм пришел к заключению, что, для того чтобы теория была согласованной, необходимо ввести дополнительные поля с духовыми свойствами. Теперь известно, как получить этот результат, используя более систематический подход.

Рассмотрим чистую теорию Янга-Миллса, а поля материи легко добавить позже. Воспользуемся нашими знаниями. Как обычно, разобьем лагранжиан $\mathcal{L} = \mathcal{L}_0 + \mathcal{L}_1$ на две части (мы также переопределяем $A \to gA$):

$$\mathcal{L}_0 = -\frac{1}{4}\left(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu\right)^2$$

и

$$\mathcal{L}_1 = -\frac{1}{2}g\left(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu\right) f^{abc} A^{n\mu} A^{c\nu} - \frac{1}{4}g^2 f^{abc} f^{ade} A^b_\mu A^c_\nu A^{d\mu} A^{r\nu}.$$

Затем обращаем дифференциальный оператор в квадратичной части выражения (1), чтобы получить пропагатор. Эта часть аналогична соответствующей процедуре для квантовой электродинамики, за исключением того, что появляется индекс a. Так же, как в

электродинамике, обратного оператора в нашем случае не существует, поэтому необходимо фиксировать калибровку.

Для квантования квантовой электродинамики я использовал сложный метод Фаддеева-Попова, и, как уже отмсчалось, в рассматриваемом контексте это было несколько излишне. Однако теперь мы от этого только вы- играем. Вспомним из главы III.4, что метод Фаддеева-Попова ведет к результату

$$\mathcal{Z} = \int DAe^{iS(A)}\Delta(A)\delta[f(A)]$$

где $\Delta(A) \equiv \left\{\int Dg\delta\left[f\left(A_g\right)\right]\right\}^{-1}$ и $S(A) = \int d^4x\mathcal{L}$ является действием Янга-Миллса. (Как и в главе III. 4, $A_g \equiv gAg^{-1} - i(\partial g)g^{-1}$ обозначает калибровочное преобразование A. Здесь $g \equiv g(x)$ обозначает элемент группы, который определяет калибровочное преобразование в точке x, и его, конечно, нельзя путать с константой связи.)

Поскольку $\Delta(A)$ в (3) умножается на $\delta[f(A)]$, следует ожидать, что в интеграле по g при разумном выборе $f(a)$ вклад дадут только бесконечно малые g. Пусть $f(A) = \partial A - \sigma$. При инфинитезимальном преобразовании имеет место $A^a_\mu \to A^a_\mu - f^{abc}\theta^b A^c_\mu + \partial_\mu\theta^a$, следовательно:

$$\Delta(A) = \left\{\int D\theta\delta\left[\partial A^a - \sigma^a - \partial^\mu\left(f^{abc}\theta^b A^c_\mu - \partial_\mu\theta^a\right)\right]\right\}^{-1} \ll=$$
$$= \left\{\int D\theta\delta\left[\partial^\mu\left(f^{abc}\theta^b A^c_\mu - \partial_\mu\theta^a\right)\right]\right\}^{-1}$$

где присутствует «фактически знак равенства», поскольку $\Delta(A)$ потом умножается на $\delta[f(A)]$.

Запишем формально

$$\delta^\mu\left(f^{abc}\theta^b A^c_\mu - \delta_\mu\theta^a\right) = \int d^4y K^{ab}(x,y)\theta^b(y)$$

определяя таким образом оператор $K^{ab}(x,y) = \partial^\mu\left(f^{abc}A^c_\mu - \partial_\mu\delta^{ab}\right)\delta^{(4)}(x\text{ - }-y)$. Отметим, что здесь, в отличие от электродинамики, K зависит от калибровочного поля. Простой результат $\int d\theta\delta(K\theta) = 1/K$ для действительных чисел θ и K может быть сведен к выражению $\int d\theta\delta(K\theta) = 1/\det K$ для действительного вектора θ и невырожденной матрицы K. Рассматривая $K^{ab}(x,y)$ как матрицу, получаем $\Delta(A) = \det K$, но из главы II.5 известно, как представить детерминант в виде функционального интеграла по грассмановым переменным. Запишем уравнение $\Delta(A) = \int DcDc^\dagger e^{iS_{.1yx}\left(c^\dagger,c\right)}$, где

$$S_{\text{дух}}\left(c^\dagger,c\right) = \int d^4xd^4yc^\dagger_a(x)K^{ab}(x,y)c_b(y) =$$
$$= \int d^4x\left[\partial c^\dagger_a(x)\partial c_a(x) - \partial^\mu c^\dagger_a(x)f^{abc}A^c_\mu(x)c_b(x)\right] =$$
$$= \int d^4x\partial c^\dagger_a(x)Dc_a(x)$$

а D - ковариантная производная для присоединенного представления, к которому принадлежат поля c_a и $c^\dagger_a$, так же, как A^a_μ. Поля c_a и $c^\dagger_a$ называют духовыми полями, поскольку они нарушают связь спина со статистикой. Хотя эти поля скалярные, их рассматривают как антикоммутирующие. Такое «нарушение» приемлемо, поскольку духовые поля не связаны с физическими частицами и вводятся только для того, чтобы представить $\Delta(A)$ в удобном виде.

Таким образом, вопрос с множителем $\Delta(A)$ в уравнении (3) рсшен. Для множителя $\delta[f(A)]$ используем тот же прием, что и в главе III.4, и интегрируем $\mathcal{Z}$ по $\sigma^a(x)$ с гауссовым весом $e^{-(i/2\xi)\int d^4x\sigma^a(x)^2}$, так что $\delta[f(A)]$ заменяется на $e^{-(i/2\xi)\int d^4x(\partial A^a)^2}$.

Объединяя все вместе, получаем

$$\mathcal{Z} = \int DADcDc^\dagger e^{iS(A)-(i/2\xi)\int d^4x(\partial A)^2+iS_{\text{Iyx}}\left(c^\dagger,c\right)},$$

где ξ - параметр калибровки. Из сравнения с соответствующим выражением для абелевой калибровочной теории, приведенным в главе III.4, следует, что в неабелевых калибровочных теориях в дополнение к действию ЯнгаМиллса есть действие для духов $S_{\text{дух}}$. Таким образом, $\mathcal{L}_0$ и $\mathcal{L}_1$ изменяются на

$$\mathcal{L}_0 = -\frac{1}{4}\left(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu\right)^2 - \frac{1}{2\xi}\left(\partial^\mu A^a_\mu\right)^2 + \partial c^\dagger_a \partial c_a$$

и

$$\mathcal{L}_1 = -\frac{1}{2}g\left(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu\right) f^{abc} A^{b\mu} A^{c\nu} + \frac{1}{4}g^2 f^{abc} f^{ade} A^b_\mu A^c_\nu A^{d\mu} A^{e\nu} -$$
$$- \partial^\mu c^\dagger_a g f^{abc} A^c_\mu c_b$$

Теперь из (8) можно сразу получить пропагаторы для калибровочного бозона и духового поля. В частности, легко видеть, что за исключением группового индекса a квадратичные по калибровочному полю члены являются такими же, как и квадратичные по электромагнитному полю члены в уравнении (III.4.8). Таким образом, пропагатор калибровочного бозона имеет вид

$$\frac{(-i)}{k^2}\left[g_{\nu\lambda} - (1-\xi)\frac{k_\nu k_\lambda}{k^2}\right]\delta_{ab}.$$

Сравним с выражением (III.4.9). Из члсна $\partial c^\dagger_a(x)\partial c_a(x)$ в уравнении (8) находим, что духовой пропагатор имеет вид $(i/k^2)\,\delta_{ab}$. Из $\mathcal{L}_1$ следует, что между калибровочными бозонами существует взаимодействие третей и четвертой степени, а также взаимодействие между калибровочным бозоном и духовым полем, как показано на рис. VII.1.1. Взаимодействия третьей и четвертой степени можно легко представить в виде

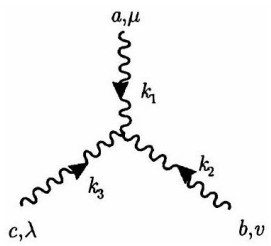
$$g f^{abc}\left[g_{\mu\nu}\left(k_1-k_2\right)_\lambda + g_{\nu\lambda}\left(k_2-k_3\right)_\mu + g_{\lambda\mu}\left(k_3-k_1\right)_\nu\right]$$

и

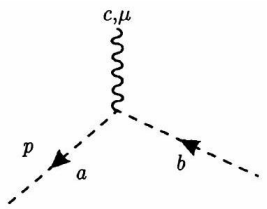
$$-ig^2\left[f^{abe}f^{cde}\left(g_{\mu\lambda}g_{\nu\rho}-g_{\mu\rho}g_{\nu\lambda}\right) + f^{ade}f^{cbe}\left(g_{\mu\lambda}g_{\nu\rho}-g_{\mu\nu}g_{\rho\lambda}\right) + \right.$$
$$\left. + f^{ace}f^{bde}\left(g_{\mu\nu}g_{\lambda\rho}-g_{\mu\rho}g_{\nu\lambda}\right)\right]$$

соответственно. Взаимодействие с духовым полем имеет вид

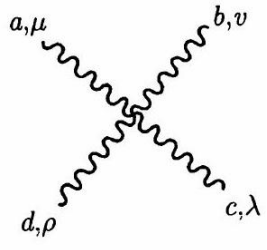
$$g f^{abc} p^\mu$$



(a)



(c)



(b)
Рис. VII.1.1

Очевидно, что для этой записи справедливы различные перестановочные симметрии. Например, второй член в (12) получается из первого путем пе- рестановки $\{c, \lambda\} \leftrightarrow \{d, \rho\}$, а третий и четвертый члены получаются из первого и второго путем перестановки $\{a, \mu\} \rightarrow \{c, \lambda\}$.

Неестественный шаг

В теории с высокой симметрией, такой как теория Янга-Миллса, теория возмущений, очевидно, является неестественным действием, так как оно включает грубое расщепление $\mathcal{L}$ на две части: квадратичную относительно полей и остальную часть. Рассмотрим, например, точно решаемую квантово-механическую задачу для одной частицы, такую как уравнение Шредингера с $V(x) = 1 - (1/\operatorname{ch} x)^2$. Представим себе запись $V(x) = \frac{1}{2}x^2 + + W(x)$ и рассмотрим $W(x)$ как возмущение гармонического осциллятора. Воспроизводить точный спектр было бы очень трудно, но именно так безжалостно мы обходимся с теорией Янга-Миллса в пертурбативном подходе. Мы взяли «целостный элемент» $\operatorname{tr} F_{\mu\nu}F^{\mu\nu}$ и разделили его на «гармонический осциллятор» $\operatorname{tr}(\partial_\mu A_\nu - \partial_\nu A_\mu)^2$ и «возмущение».

Если когда-либо окажется, что теория Янга-Миллса точно решаема, то точно не в рамках пертурбативного подхода, не сохраняющего калибровочную инвариантность.

Калибровочная теория на решетке

Вильсон предложил выход из положения: нарушать лоренц-инвариантность, а не калибровочную инвариантность. Сформулируем теорию ЯнгаМиллса на гиперкубической решетке в четырехмерном евклидовом пространстве-времени. Поскольку период решетки $a \rightarrow 0$, мы надеемся восстановить инвариантность относительно четырехмерных поворотов и (путем виковского поворота) лоренц-инвариантность. Формулировку Вильсона, известную как калибровочная теория на решетке, понять легко, но ее запись несколько громоздкая из-за отсутствия вращательной инвариантности. Обозначим положение узлов решетки вектором x_i. Каждому ребру, скажем от x_i до ближайшего соседнего x_j, ставим в соответствие унитарную $N \times N$-матрицу U_{ij}. Рассмотрим квадрат, называемый плакетом, который ограничен четырьмя вершинами x_i, x_j, x_k и x_l (ближайшими соседними друг к другу). Посмотрим на рис. VII.1.2. Каждому плакету P поставлена в соответствие величина $S(P) = \operatorname{Re}\operatorname{tr} U_{ij}U_{jk}U_{kl}U_{li}$, построенная так, чтобы быть инвариантной относительно локального преобразования

$$U_{ij} \to V_i^\dagger U_{ij} V_j$$

Симметрия является локальной, поскольку каждому узлу x_i можно поставить в соответствие независимую V_i.

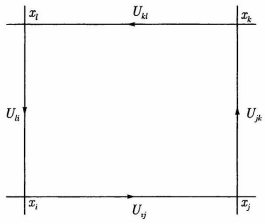


Рис. VII.1.2

Вильсон определил теорию Янга-Миллса в следующим виде:

$$\mathcal{Z} = \int \Pi dU^{\left(1/2f^2\right)\sum\limits_P S(P)}$$

где сумма берется по всем плакетам в решетке. Константа связи f определяет, насколько сильно флуктуируют унитарные матрицы U_{ij}. Для малых f предпочтительны большие значения $S(P)$, и поэтому все U_{ij} приближенно равны единичной матрице (с точностью до несущественного глобального преобразования).

Без всяких вычислений, из симметрийных соображений можно показать, что в непрерывном пределе $a \to 0$ должна появиться теория ЯнгаМиллса такая, какой мы ее знаем. Это действие явно инвариантно относительно локальных $SU(N)$-преобразований. Чтобы действительно это увидеть, определим поле $A_\mu(x)$ с $\mu = 1, 2, 3, 4$, живущим в четырехмерном евклидовом пространстве, где находится решетка, уравнением

$$U_{ij} = V_i^\dagger e^{iaA_\mu(x)} V_j$$

где $x = \frac{1}{2}(x_i + x_j)$ (это средняя точка ребра, где находится U_{ij}) и μ - направление, связывающее x_i с x_j (то есть $\widehat{\mu} \equiv (x_j - x_i)/a$ является единичным вектором в направлении μ). Параметры V отражают только калибровочную свободу в (14) и по построению, конечно, не входят в действие на плакете $S(P)$. Я вас попрошу показать в качестве упражнения, что

$$U_{ij}U_{jk}U_{kl}U_{li} = e^{ia^2F_{\mu\nu}+O\left(a^3\right)},$$

где $F_{\mu\nu}$ - напряженность поля Янга-Миллса, определенная в центре плакета. Мы действительно могли бы таким образом найти напряженность поля Янга-Миллса. Я надеюсь, что вы начинаете понимать глубокое геометрическое значение $F_{\mu\nu}$. Продолжая решать упражнение, вы найдете, что действие на каждом плакете имеет вид

$$\begin{aligned} S(P) &= \operatorname{Re}\operatorname{tr} e^{ia^2F_{\mu\nu}+O\left(a^3\right)} = \\ &= \operatorname{Re}\operatorname{tr}\left[1 + ia^2F_{\mu\nu} - \frac{1}{2}a^4F_{\mu\nu}F_{\mu\nu} + O\left(a^5\right)\right] = \operatorname{tr} 1 - \frac{1}{2}a^4 \operatorname{tr} F_{\mu\nu}F_{\mu\nu} + ..., \end{aligned}$$

и, таким образом, с точностью до несущественной аддитивной постоянной мы восстанавливаем в (15) действие Янга-Миллса в непрерывном пределе. Еще раз следует подчеркнуть, что без всяких вычислений можно зафиксировать в (18) член a^4 (с точностью до общего множителя) из анализа размерностей и калибровочной инвариантности [1].

Формулировка Вильсона хороша тем, что, для того чтобы (15) имело смысл, не нужна ни фиксация калибровки, ни детерминант Фаддеева-Попова, ни духовые поля и прочее. Вспоминая главу V.3, вы видите, что (15) определяет как одну из задач статистической механики. Вместо интегрирования, скажем, по некоторым спиновым переменным,

проинтегрируем по группе $SU(N)$ для каждого ребра. Важнее всего то, что формулировка калибровочной теории на решетке открывает возможность численного определения свойств сильно нетривиальной квантовой теории поля. Калибровочная теория на решетке является бурно развивающейся областью исследований. Попробуйте свои силы и попытайтесь включить фермионы в калибровочную теорию на решетке. Это весьма непростая задача, которая стоит на повестке дня, поскольку фермионы и спинорные поля естественным образом связаны с $SO(4)$, которая не очень хорошо переносится на решетку.

Петля Вильсона

Специалисты по теории поля обычно имеют дело с локальными наблюдаемыми, то есть наблюдаемыми, которые определены в точке x про-

[1] Знак можно легко проверить на соответствие абелеву случаю. странства-времени, такими как $J^\mu(x)$ или $\operatorname{tr} F_{\mu\nu}(x)F^{\mu\nu}(x)$. Но можно, конечно, также иметь дело с нелокальными наблюдаемыми, такими как $e^{i\oint dx^\mu A_\mu}$ в электродинамике, где интеграл вычисляется по замкнутой кривой C. Калибровочно-инвариантная величина в экспоненте равна электромагнитному потоку, проходящему через поверхность, ограниченную кривой C. (В самом деле, вспомните главу IV.4.)

Вильсон показал, что калибровочная теория на решетке содержит естественную калибровочно-инвариантную, но нелокальную наблюдаемую величину, равную $W(C) \equiv \operatorname{tr} U_{ij}U_{jk}...U_{nm}U_{mi}$, где набор звеньев, соединяющих x_i с x_j, x_j с x_k и т. д., и, наконец, с x_m и вновь с x_i, очерчивает петлю, называемую C. Возвращаясь к выражению (16), видим, что $W(C)$, называемая петлей Вильсона, является следом произведения многих множителей e^{iaA_μ}. Таким образом, в непрерывном пределе $a \to 0$ очевидным образом получаем

$$W(C) \equiv \operatorname{tr} P e^{i\oint dx^\mu A_\mu}$$

где C теперь является произвольной кривой в евклидовом пространстве-времени. Здесь P обозначает упорядоченность траектории, что, конечно, необходимо, поскольку A_μ, связанные с различными сегментами кривой C, будучи матрицами, не коммутируют друг с другом. [Действительно, P определяется заданием решетки $W(C)$.]

Чтобы понять физический смысл петли Вильсона, обратимся к главам I.4 и I.5. Для получения потенциальной энергии E между двумя противоположно заряженными тяжелыми частицами необходимо вычислить

$$\lim_{T\to\infty} \frac{1}{\mathcal{Z}} \int DA e^{iS_{\text{Maxwell}}(A) + i\int d^4x A_\mu J^\mu} = e^{iET}.$$

Для двух частиц, находящихся на расстоянии R друг от друга, подставляем

$$J^\mu(x) = \eta^{\mu 0}\left\{\delta^{(3)}(\vec{x}) - \delta^{(3)}[\vec{x} - (R,0,0)]\right\}$$

и видим, что на самом деле мы вычисляем вакуумное среднее $\left\langle e^{i\left(\int\limits_{C_1} dx^\mu A_\mu - \int\limits_{C_2} dx^\mu A_\mu\right)} \right\rangle$ во флуктуирующем электромагнитном поле, где C_1 и C_2 обозначают два прямолинейных сегмента при $\vec{x} = (0,0,0)$ и $\vec{x} = (R,0,0)$ соответственно. Удобно представить сближение двух частиц в далеком будущем (и аналогично в далеком прошлом). Тогда мы явно имеем дело с калибровочно-инвариантной величиной $\left\langle e^{i\oint dx^\mu A_\mu}\right\rangle$, где C является прямоугольником, как показано на рис. VII.1.3. Заметим, что для большого T имеет место $\log\left\langle e^{i\oint dx^\mu A_\mu}\right\rangle \sim iE(R)T$, который существенно пропорционален периметру прямоугольника C.

Как будет рассмотрено в главе VII.3 и как вы, несомненно, слышали, принятая в настоящее время теория сильного взаимодействия включает кварки, взаимодействующие с неабелевым калибровочным полем Янга-Миллса A_μ. Таким образом, чтобы определить

потенциальную энергию $E(R)$ между кварком и антикварком, удерживаемых на расстоянии R друг от друга, нужно просто вычислить вакуумное среднее петли Вильсона

$$\langle W(C)\rangle = \frac{1}{\mathcal{Z}}\int \Pi dU e^{-\left(1/2f^2\right)\sum_P S(P)} W(C).$$

В калибровочной теории на решетке можно численно определить $\log\langle W(C)\rangle$ для большого прямоугольника C на рис. VII.1.3 и извлечь $E(R)$. (Мы потеряли i, потому что в рассматриваемом случае находимся в евклидовом пространстве-времени.)

Рис. VII.1.3

Конфайнмент кварков

Я уверен, вы слышали, что, поскольку свободные кварки никто никогда не видел, полагают, что они постоянно удерживаются. В частности, предполагается, что потенциальная энергия между кварком и антикварком растет линейно с расстоянием $E(R) \sim \sigma R$. Представим себе струну, соединяющую кварк и антикварк с натяжением струны σ. Если это правильное представление, то соотношение $\log\langle W(C)\rangle \sim \sigma RT$ должно иметь место, когда область RT ограничивается петлей C. Вильсон называет такое поведение законом площадей, а не законом периметров, характерным для известных теорий, таких как электродинамика. Доказательство закона площадей в теории Янга-Миллса являстся одной из выдающихся нерешенных проблем теоретической физики.

Упражнения

VII.1.1. Выведите (17) и сопоставьте f с константой связи g в формулировке теории Янга-Миллса. [Указание: используйте формулу Бейкера-КэмпбеллаХаусдорфа

$$e^A e^B = e^{A+B+\frac{1}{2}[A,B]+\frac{1}{12}([A,[A,B]])+[B,(B,A]])+\cdots}.\Big]$$

VII.1.2. Рассмотрите калибровочную теорию на решетке в $(D+1)$-мерном пространстве с периодом решетки a в D-мерном пространстве и b в дополнительном измерении. Получите D-мерную теорию поля непрерывного спектра в пределе $a \to 0$ при фиксированном b.

VII.1.3. Изучите в выражении (2) альтернативный предел $b \to 0$ при фиксированном a и получите тем самым теорию на пространственной решетке, но с непрерывным временем.

VII.1.4. Покажите, что для калибровочной теории на решетке закон площадей Вильсона сохраняется в пределе сильной связи. [Указание: разложите выражение (20) по степеням f^{-2}.]

30.4.2 Zi.VII.2 Electroweak Unification

Бич безмассовых частиц со спином 1

Учитывая опыт прошлого, мы теперь знаем, что Природа предпочитает теорию Янга-Миллса. В конце 1960-х и начале 1970-х годов электромагнитное и слабое взаимодействия были объединены в электрослабое взаимодействие, описываемое неабелевой калибровочной теорией, которая основана на группе $SU(2) \otimes U(1)$. Несколько позже, в начале 1970 - х годов, стало понятно, что сильное взаимодействие можно описать, пользуясь неабелевой

калибровочной теорией, основанной на группе $SU(3)$. Природа буквально состоит из сети взаимодействующих полей Янга-Миллса.

Но когда в 1954 году эта теория была впервые предложена, она казалась совершенно несовместимой с наблюдениями в интерпретации того времени. Янг и Миллс сами показали в своей статье, что их теория содержит безмассовые частицы со спином 1, которые, конечно, не были экспериментально известны. Поэтому эта теория постепенно была предана забвению и в 1960-х годах не входила в обязательную университетскую программу по физике элементарных частиц. Исключение составляли только некоторые теоретики (Швингер, Глэшоу, Бладмен и др.), которые считали такую изящную математическую структуру привлекательной и были убеждены, что неабелева калибровочная теория должна иметь какое-то отношение к слабому взаимодействию.

И опять же, оглядываясь назад, мы, по-видимому, можем найти только два логических объяснения того, почему экспериментаторы не видят никаких безмассовых частиц со спином 1 за исключением фотона: (1) частицы Янга-Миллса каким-то образом приобретают массу, или (2) частицы Янга-Миллса действительно являются безмассовыми, но почему-то не могут наблюдаться в экспериментах. Теперь мы знаем, что первая возможность была реализована в электрослабом взаимодсйствии, а вторая - в сильном взаимодействии.

Построение теории электрослабых взаимодействий

Теперь рассмотрим электрослабое объединение. Возможно, с педагогической точки зрения следует мотивировать шаги, приводящие к построению этой теории. Но, как отмечено выше, это не учебник по физике элементарных частиц, и обсуждение этого предмета я вынужден свести к самому минимуму. В главе IV.2 дано краткое введение в структуру слабого взаимодействия. Как говорилось в главе II.1, существенным обстоятельством здесь является то, что слабое взаимодействие нарушает четность. В частности, левое поле электрона e_L и правое поле электрона e_R, которые переходят друг в друга при преобразовании четности, участвуют в слабом взаимодействии совсем по-разному.

Начнем со слабого распада мюона $\mu^- \to e^- + \bar{\nu} + \nu'$, где ν и ν' - электронное нейтрино и мюонное нейтрино соответственно. Подходящим членом в лагранжиане является $\bar{\nu}'_L \gamma^\mu \mu_L \bar{e}_L \gamma_\mu \nu_L$, где e_L - левое поле электрона, ν_L - поле электронного нейтрино (которое является левым) и т. д. Поле μ_L уничтожает мюон, поле $\bar{e}_L$ создает электрон и т. д. (Впредь будем опускать слово «поле».) Вам, возможно, известно, что элементарные составляющие материи образуют три семейства, первое из которых состоит из двух лептонов $-\nu, e$ и двух кварков - верхнего u и нижнего d, второе семейство - из двух лептонов ν', μ и двух кварков - очарованного c и странного s, и т. д. Для наших целей ограничимся рассмотрением первого семейства. Итак, начнем с $\bar{\nu}_L \gamma^\mu e_L \bar{e}_L \gamma_\mu \nu_L$.

Как говорилось в главе III.2, подобного рода взаимодействие Ферми может порождаться в результате обмена промежуточным векторным бозоном W^+с взаимодействием $W^+_\mu \bar{\nu}_L \gamma^\mu e_L + W^-_\mu \bar{e}_L \gamma_\mu \nu_L$.

Идея состоит в том, чтобы рассмотреть калибровочную теорию $SU(2)$ с триплетом калибровочных бозонов, которые обозначим W^a_μ, где $a = 1, 2, 3$. Поместим ν_L и e_L в дублетное представление, а правое поле электрона e_R в синглетное представление, тогда

$$\psi_L \equiv \begin{pmatrix} \nu \\ e \end{pmatrix}_L, \quad e_R$$

(В этой записи верхней компонентой ψ_L является ν_L, а нижней компонентой e_L.)

Поля ν_L и e_L, но не поле e_R взаимодействуют с калибровочными бозонами W^a_μ. Действительно, согласно (IV.5.21) лагранжиан содержит

$$W^a_\mu \bar{\psi}_L \tau^a \gamma^\mu \psi_L = \left(W^{1-i2}_\mu \bar{\psi}_L \frac{1}{2} \tau^{1+i2} \gamma^\mu \psi_L + \text{ э.с. } \right) + W^3_\mu \bar{\psi}_L \tau^3 \gamma^\mu \psi_L$$

где $W^{1-i2}_\mu \equiv W^1_\mu - iW^2_\mu$ и т. д. Мы видим, что $\tau^{1+i2} \equiv \tau^1 + i\tau^2$ является повышающим

оператором, а первые два слагаемых равны $\left(W_\mu^{1-i2}\bar{\nu}_L\gamma^\mu e_L+\ +\ \text{э. с.}\right)$, именно то, что нам нужно. По замыслу обмен полем $W_\mu^\pm$генерирует искомый член $\bar{\nu}_L\gamma^\mu e_L\bar{e}_L\gamma_\mu\nu_L$.

Нам нужно больше места

Мы надеялись, что бозон W^3, который было необходимо ввести, окажется фотоном, так что будет включен электромагнетизм. Но увы, W^3 взаимодействует с током $\bar{\psi}_L\tau^3\gamma^\mu\psi_L = (\bar{\nu}_L\gamma^\mu\nu_L - \bar{e}_L\gamma_\mu e_L)$, а не с электромагнитным током $-(\bar{e}_L\gamma_\mu e_L + \bar{e}_R\gamma_\mu e_R)$. Проблема!

Есть еще одна проблема. Чтобы генерировать массовый член для электрона, нужно иметь дублет полей Хигтса $\varphi \equiv \begin{pmatrix} \varphi^+ \\ \varphi^0 \end{pmatrix}$ для построения $SU(2)$-инвариантного члена $f\bar{\psi}_L\varphi e_R$ в лагранжиане, так что, когда φ приобретет вакуумное среднее $\begin{pmatrix} 0 \\ v \end{pmatrix}$, мы получим

$$\bar{\psi}_L\varphi e_R \to f(\bar{\nu},\bar{e})_L\begin{pmatrix} 0 \\ v \end{pmatrix}e_R = fv\bar{e}_L e_R$$

Но ни одно из преобразований $SU(2)$ не оставляет $\begin{pmatrix} 0 \\ v \end{pmatrix}$ инвариантным. Вакуумное среднее поля φ спонтанно нарушает симметрию $SU(2)$, оставляя массивными все три бозона W. В этой несовершенной теории нет места для фотона. Вот в чем дело!

Нам нужно больше места. Замечательно, что обе проблемы можно избежать путем расширения калибровочной симметрии до $SU(2)\otimes U(1)$. Обозначая генератор $U(1)$ как $\frac{1}{2}Y$ (называемый гиперзарядом), соответствующий калибровочный потенциал как B_μ (а их эквивалентные величины для $SU(2)$ как T^a и W_μ^a), получаем ковариантную производную $D_\mu = \partial_\mu$ - $-igW_\mu^aT^a - ig'B_\mu\frac{Y}{2}$. Имея четыре калибровочных бозона, можно надеяться, что один из них окажется фотоном.

Калибровочные поля нормируются с помощью соответствующих членов кинетической энергии в $\mathcal{L} = -\frac{1}{4}(B_{\mu\nu})^2 - \frac{1}{4}\left(W_{\mu\nu}^a\right)^2 + ...$, где $B_{\mu\nu} = \partial_\mu B_\nu - \partial_\nu B_\mu$ - напряженность абелева поля и $W_{\mu\nu}^a = \partial_\mu W_\nu^a - \partial_\nu W_\mu^a + +\varepsilon^{abc}W_\mu^bW_\nu^c$ - напряженность неабелева поля. Генераторы T^a, естественно, нормируются с помощью коммутационных соотношений, которые определяют $SU(2)$. В абелевой алгебре $U(1)$, напротив, нет коммутационного соотношения, чтобы зафиксировать нормировку генератора $\frac{1}{2}Y$. Пока она не зафиксирована, не зафиксирована и нормировка $U(1)$-калибровочного взаимодействия g'.

Как же зафиксировать нормировку генератора $\frac{1}{2}Y$? Мы хотим, чтобы, по построению, спонтанное нарушение симметрии оставляло линейную комбинацию T_3 и $\frac{1}{2}Y$ инвариантной и чтобы эта комбинация отождествлялась с генератором, взаимодействующим с безмассовым фотоном, а именно с оператором заряда Q. Итак, запишем

$$Q = T_3 + \frac{1}{2}Y$$

Если мы знаем T_3 и $\frac{1}{2}Y$ для произвольного поля, то из этого уравнения мы знаем его заряд. Например, $Q(\nu_L) = \frac{1}{2} + \frac{1}{2}Y(\nu_L)$ и $Q(e_L) = -\frac{1}{2} + \frac{1}{2}Y(e_L)$. В частности, легко видеть, что коэффициент при T_3 в уравнении (3) должен быть равен 1, поскольку заряды ν_L и e_L отличаются на 1. Соотношение (3) фиксирует нормировку $\frac{1}{2}Y$.

Чему равен гиперзаряд?

Следующий шаг заключается в определении гиперзаряда различных мультиплетов в теории, что в свою очередь определяет то, как с этими мультиплетами взаимодействует B_μ.

Рассмотрим дублет ψ_L. Чтобы получить заряд -1 для поля e_L, дублет ψ_L должен иметь $\frac{1}{2}Y = -\frac{1}{2}$. В противоположность этому поле e_R имеет $\frac{1}{2}Y = -1$, поскольку $T_3 = 0$ для e_R.

Имея гиперзаряд дублета ψ_L и поля e_R, легко видеть, что инвариантность члена $f\bar{\psi}_L\varphi e_R$ относительно $SU(2) \otimes U(1)$ заставляет поле Хиггса φ иметь $\frac{1}{2}Y = +\frac{1}{2}$. Таким образом, согласно (3) верхняя компонента поля φ имеет электрический заряд $Q = +\frac{1}{2} + \frac{1}{2} = +1$, а нижняя компонента $Q = -\frac{1}{2} + \frac{1}{2} = 0$. Итак, запишем $\varphi = \begin{pmatrix} \varphi^+ \\ \varphi^0 \end{pmatrix}$. Напомним, что поле φ имеет вакуумное среднее $\begin{pmatrix} 0 \\ v \end{pmatrix}$. Утверждение о том, что электрически нейтральное поле φ^0 приобретает вакуумное среднее, а заряженное поле φ^+нет, является проверкой на согласованность теории.

Теория создается сама

Теперь, когда определены взаимодействия калибровочных бозонов с различными полями, в частности, с полем Хигтса, можно легко определить спектр масс калибровочных бозонов, что (позвольте напомнить) вы уже делали при решении упражнения IV.6.3!

При спонтанном нарушении симметрии $\varphi \to (1/\sqrt{2}) \begin{pmatrix} 0 \\ v \end{pmatrix}$ (обычная нормировка): просто подставим в

$$\mathcal{L} = (D_\mu\varphi)^\dagger (D^\mu\varphi) \to \frac{g^2v^2}{4} W_\mu^+ W^{-\mu} + \frac{v^2}{8} \left(gW_\mu^3 - g'B_\mu\right)^2.$$

Полагаю, именно такой результат вы и получили! Таким образом, линейная комбинация $gW_\mu^3 - g'B_\mu$ становится массивной, тогда как ортогональная комбинация остается безмассовой и ее можно отождествить с фотоном. Разумеется, угол θ удобно определить с помощью $\operatorname{tg}\theta = g'/g$. Тогда уравнение

$$Z_\mu = \cos\theta W_\mu^3 - \sin\theta B_\mu$$

описывает массивный калибровочный бозон, называемый Z-бозоном, а электромагнитное поле задается выражением $A_\mu = \sin\theta W_\mu^3 + \cos\theta B_\mu$. Объединим (4) и (5) и проверим, что возведенная в квадрат масса Z-бозона имеет вид $M_z^2 = v^2 (g^2 + g^2)/4$; таким образом, используя элементарную тригонометрию, получаем соотношение

$$M_W = M_Z \cos\theta.$$

Обмен W-бозоном порождает слабое взаимодействие Ферми

$$\mathcal{L} = -\frac{g^2}{2M_W^2} \bar{\nu}_L\gamma^\mu e_L \bar{e}_L\gamma_\mu\nu_L = -\frac{4G}{\sqrt{2}} \bar{\nu}_L\gamma^\mu e_L \bar{e}_L\gamma_\mu\nu_L$$

где второе равенство просто является историческим определением взаимодействия Ферми G. Таким образом,

$$\frac{G}{\sqrt{2}} = \frac{g^2}{8M_W^2}.$$

Далее запишем соответствующую часть ковариантной производной

$$gW_\mu^3 T^3 + {}'B_\mu \frac{Y}{2} = g\left(\cos\theta Z_\mu + \sin\theta A_\mu\right) T^3 + g'\left(-\sin\theta Z_\mu + \cos\theta A_\mu\right) \frac{Y}{2}$$

в терминах физически наблюдаемых Z и A. Коэффициент при A_μ преобразуется к виду $g\sin\theta T^3+g'\cos\theta(Y/2)=g\sin\theta\,(T^3+Y/2)$; тот факт, что возникает комбинация $Q=T^3+Y/2$, является прекрасной проверкой формализма. Кроме того, получаем

$$e=g\sin\theta$$

Между тем удобно записать $g\cos\theta T^3-g'\sin\theta(Y/2)$ - коэффициент при Z_μ в ковариантной производной - через физически знакомый электрический заряд Q, а не теоретический гиперзаряд Y. Таким образом,

$$g\cos\theta T^3-g'\sin\theta\left(Q-T^3\right)=\frac{g}{\cos\theta}\left(T^3-\sin^2\theta Q\right).$$

Другими словами, мы определили взаимодействие Z-бозона с произволь-

ным фермионным полем Ψ в теории:

$$\mathcal{L}=\frac{g}{\cos\theta}Z_\mu\bar{\Psi}\gamma^\mu\left(T^3-\sin^2\theta Q\right)\Psi$$

Используя (9), можно, например, сразу же описать взаимодействие Z-бозона с лептонами:

$$\mathcal{L}=\frac{g}{\cos\theta}Z_\mu\left[\frac{1}{2}\left(\bar{\nu}_L\gamma^\mu\nu_L-\bar{e}_L\gamma^\mu e_L\right)+\sin^2\theta\bar{e}\gamma^\mu e\right]$$

Включение кварков

Теперь становится очевидным, как включить адроны. Учитывая, что в слабом взаимодействии принимают участие только левые поля, поместим кварки первого поколения в мультиплеты $SU(2)\otimes U(1)$ следующим обра30м:

$$q_L^\alpha\equiv\begin{pmatrix}u^\alpha\\d^\alpha\end{pmatrix}_L,\quad u_R^\alpha,d_R^\alpha$$

гдс $\alpha=1,2,3$ обозначает цветовой индекс, который обсуждается в следующей главе. Правые кварки u_R^α и d_R^α помещены в синглеты, чтобы промежуточные W^a-бозоны с ними не взаимодействовали. Напомним, что верхний u-кварк и нижний d-кварк имеют электрические заряды $\frac{2}{3}$ и $-\frac{1}{3}$ соответственно. Возвращаясь к соотношению (3), мы видим, что $\frac{1}{2}Y=\frac{1}{6}$, $\frac{2}{3}$ и $-\frac{1}{3}$ для q_R^α, u_R^α и d_R^α соответственно. Из (9) можно сразу получить взаимодействие Z-бозона с кварками:

$$\mathcal{L}=\frac{g}{\cos\theta}Z_\mu\left[\frac{1}{2}\left(\bar{u}_L\gamma^\mu u_L-\bar{d}_L\gamma^\mu d_L\right)-\sin^2\theta J_{em}^\mu\right]$$

Наконец, постарайтесь самостоятельно проверить, что из четырех степеней свободы, заключенных в φ (поскольку φ^+и φ^0 комплексны), три «съедаются» W - и Z-бозонами, и остается одна физическая степень свободы H, относящаяся к неуловимой хиггсовской частице, которую экспериментаторы все еще ищут на момент написания этой книги.

Нейтральный ток

Благодаря изящно экономной структуре калибровочной группы, электрослабая $SU(2)\otimes U(1)$-теория Глэшоу, Салама и Вайнберга привела к последней великой эре предсказаний в теоретической физике элементарных частиц. Записывая (10) и (12) в виде

$$\mathcal{L}=\frac{g}{\cos\theta}Z_\mu\left(J_{\text{пегтоны}}^\mu+J_{\text{кварки}}^\mu\right)$$

и используя (6), мы видим, что обмен Z-бозоном порождает до сих пор неизвестное взаимодействие нейтральных токов

$$\mathcal{L}_{\text{нейтральный ток}} = -\frac{g^2}{2M_W^2}\left(J_{\text{лептоны}} + J_{\text{кварки}}\right)^{\mu}\left(J_{\text{лептоны}} + J_{\text{кварки}}\right)_{\mu}$$

между лептонами и кварками. Изучая различные процессы, описываемые нейтральными токами $\hat{C}_{\text{нейтр. ток}}$, можно определить слабый угол θ. Если угол θ определен, из уравнения (8) можно предсказать g. Если определена g, из (7) можно предсказать M_W. Если определена M_W, из (6) можно иредсказать M_Z.

Заключение

Как я упомянул, в Природе существуют три поколения лептонов и кварков, состоящие из (ν_e, e, u, d), (ν_μ, μ, c, s) и (ν_τ, τ, t, b) соответственно. Появление этой повторяющейся структуры поколений, о которой $SU(2) \otimes U(1)$-теория ничего не может сказать, представляет одну из важных нерешенных задач физики элементарных частиц. Эти три семейства просто встраиваются в теорию с соответствующими углами поворота между собой путем повторения того, что записано выше.

Более логический подход, по сравнению с приведенным выше, заключается в том, чтобы начать с $SU(2) \otimes U(1)$-теории с дублетным полем Хиггса, имеющим некоторый гиперзаряд, и сказать: «Заметьте, что при спонтанном нарушении симметрии одна линейная комбинация генераторов остается ненарушенной с соответствующим безмассовым калибровочным полем». Но я думаю, что наш квазиисторический подход яснее.

Как уже неоднократно упоминалось, теория слабых взаимодействий Ферми является неперенормируемой. В 1999 году 't Хоофт и Вельтман получили Нобелевскую премию за доказательство того, что электрослабая $SU(2) \otimes U(1)$-теория является перенормируемой, проложив тем самым путь к торжеству неабелевых калибровочных теорий при описании сильных, электромагнитных и слабых взаимодействий. Я не могу здесь вдаваться в подробности их доказательства, но хочу отметить, что ключ к нему лежит в следующем: надо начинать с неабелева аналога унитарной калибровки (вспомним главу IV.6) и перейти к калибровке R_ξ. При больших импульсах пропагаторы массивного калибровочного бозона в унитарной калибровке ведут себя как $\sim (k_\mu k_\nu/k^2)$, а в калибровке R_ξ - как $\sim (1/k^2)$. Тогда из подсчета степеней следует что теория перенормируема.

Упражнения

VII.2.1. К сожалению, масса неуловимой хиггсовской частицы H зависит от параметров двухъямного потенциала $V = -\mu^2\varphi^\dagger\varphi + \lambda\left(\varphi^\dagger\varphi\right)^2$, ответственного за спонтанное нарушение симметрии. Полагая, что H достаточно массивна, чтобы распасться на $W^+ + W^-$и $Z + Z$, определите скорость распада H на различные моды.

VII.2.2. Покажите, что можно оставаться с калибровочной группой $SU(2)$ и отождествлять W^3 с фотоном A за счет введения некоторых экспериментально ненаблюдаемых лептонных полей. Эта теория не описывает наш мир прежде всего потому, что в нее невозможно включить кварки. Покажите это! [Указание: поместите лептоны в триплет $SU(2)$ вместо дублета.]

30.4.3 Zi.VII.3 Quantum Chromodynamics

Кварки

Существуют шесть типов кварков - верхний, нижний, странный, очарованный, боттом и топ, которые обозначаются как u, d, s, c, b и t. Например, протон состоит из двух верхних кварков и нижнего кварка $\sim (uud)$, тогда как нейтральный пион соответствует $\sim (u\bar{u} - d\bar{d})/\sqrt{2}$. Детали можно найти в любом учебнике по физике элементарных частиц.

К концу 1960-х годов понятие кварков стало широко принятым, но существовали два независимых друг от друга свидетельства, указывающие на отсутствие важного элемента.

Когда установили, что адроны состоят из кварков, стало понятно, что волновая функция кварков в нуклоне не оказывается антисимметричной относительно перестановки любой пары кварков, как того требует принцип запрета Паули. Примерно в то же время также стало понятно, что в идеальном мире, который используется для получения соотношения Голдбергера-Треймана и где пион является безмассовым, можно вычислить скорость распада для процесса $\pi^0 \to \gamma + \gamma$, как упомянуто в главе IV.7. Довольно странно, что при этом вычисленная скорость оказалась в $9 = 3^2$ раз меньше экспериментальной.

Обе загадки можно было решить одним махом, наделяя кварки до этого неизвестной внутренней степенью свободы, которую Гелл-Манн назвал цветом. Кварк любого типа имеет один из трех цветов. Таким образом, верхний кварк может быть красным, синим или желтым. Тогда в нуклоне волновая функция трех кварков будет содержать множитель, относящийся к цвету, помимо множителей, относящихся к орбитальному движению, спину и т. д. Нужно только сделать цветовую часть волновой функции антисимметричной; на самом деле просто взять ее в виде $\varepsilon^{\alpha\beta\gamma}$, где α, β и γ обозначают цвета, которые несут три кварка. Имея кварки трех цветов, нужно умножить амплитуду π^0-распада на множитель 3, тем самым точно устраняя расхождение между теорией и экспериментом.

Асимптотическая свобода

Как говорилось в главе VI.6, в результате изучения глубоко неупругого рассеяния электронов на нуклонах был получен важный ключ к пониманию. Экспериментаторы сделали любопытное открытие, что при сильном ударе кварки в нуклонах ведут себя так, как будто они почти не взаимодействуют друг с другом; другими словами, как будто они свободны. С другой стороны, поскольку кварки никогда не наблюдаются как изолированные объекты, они оказываются тесно связанными друг с другом в нуклоне. Как я объяснил, такое загадочное и явно противоречивое поведение кварков можно понять, если константа связи сильного взаимодействия стремится к нулю в пределе большого импульса (ультрафиолетового) и к бесконечности или по крайней мере к некоторому большому значению в пределе малого импульса (инфракрасного). Ряд теоретиков предложили поискать теории, в которых связи стремились бы к нулю в ультрафиолетовом пределе. В настоящее время такие теории называют асимптотически свободными. Со временем Гросс, Вильчек и Политцер обнаружили, что теория ЯнгаМиллса является асимптотически свободной.

Этот результат прекрасно согласуется с представлением о том, что кварки несут цвет. Неабелево калибровочное преобразование меняет кварк одного цвета на кварк другого цвета. Таким образом, чтобы записать теорию сильного взаимодействия, нужно просто взять результат решения упражнения IV.5.6

$$\mathcal{L} = -\frac{1}{4g^2} F^a_{\mu\nu} F^{a\mu\nu} + \bar{q}\left(i\gamma^\mu D_\mu - m\right) q$$

с ковариантной производной $D_\mu = \partial_\mu - iA_\mu$. Калибровочной группой является $SU(3)$ с кварковым полем q в фундаментальном представлении. Другими словами, калибровочные поля $A_\mu = A^a_\mu T^a$, где $T^a (a = 1, ..., 8)$, являются бесследовыми эрмитовыми 3×3-матрицами. Очевидно, что $(A_\mu q)^\alpha = A^a_\mu \left(T^a\right)^\alpha_\beta q^\beta$, где $\alpha, \beta = 1, 2, 3$. Эта теория известна как квантовая хромодинамика или кратко КХД, а неабелевы калибровочные бозоны известны как глюоны. Чтобы учесть аромат кварка, для второго члена в (1) просто записываем $\sum_{j=1}^{f} \bar{q}_j \left(i\gamma^\mu D_\mu - m_j\right) q_j$, где индекс j определяет один из f аромат. Заметим, что кварки разных ароматов имеют разные массы.

Инфракрасная неволя

Обратной стороной асимптотической свободы является инфракрасная неволя. Мы не можем следовать за ренорм-групповым потоком все время до малого масштаба импульсов,

характерного для кварков, заключенных внутри адронов, поскольку константа связи g становится все больше и вычисление $\beta(g)$ с помощью теории возмущений уже неприемлемо. Тем не менее вероятно (хотя пока не доказано), что g стремится к бесконечности и что глюоны удерживают себя и кварки в постоянном конфайнменте. Петля Вильсона, описанная в главе VII.1, является параметром порядка для конфайнмента.

В элементарной физике силы уменьшаются с увеличением расстояния между взаимодействующими объектами, поэтому постоянный конфайнмент является довольно странным понятием. Существуют ли какие-либо другие примеры постоянного конфайнмента? Рассмотрим магнитный монополь в сверхпроводнике. Мы собираем воедино результаты, полученные в главах IV.4 и V.4 (и даже VI.2)! Из монополя исходит квантованное количество магнитного потока, но согласно эффекту Мейсснера сверхпроводник выталкивает магнитный поток. Таким образом, один магнитный монополь не может жить внутри сверхпроводника.

Теперь рассмотрим антимонополь, находящийся на расстоянии R (рис. VII.3.1). Магнитный поток, исходящий из монополя, может входить в антимонополь, образуя трубку, соединяющую монополь с антимонополем, и вынуждая сверхпроводник потерять свои сверхпроводящие свойства в области трубки потока. На языке, использованном в главе V.4, это означает, что полю или параметру порядка поля φ больше энергетически невыгодно быть всюду постоянным; вместо этого в области трубки потока оно исчезает. Затраты энергии на такую конфитурацию явно растут с увеличением расстояния R (в соответствии с законом площадей Вильсона).

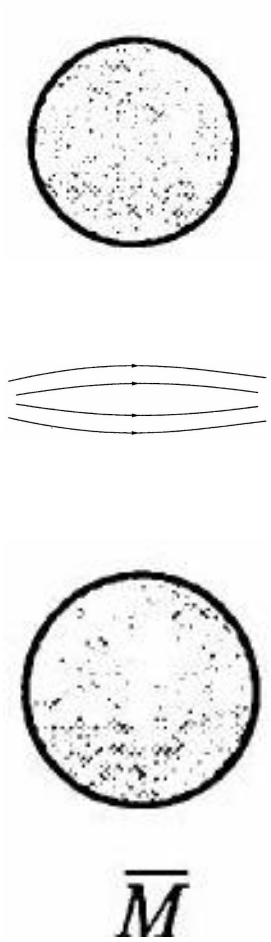

Рис. VII.3.1

Другими словами, экспериментатор, находящийся внутри сверхпроводника, обнаружил бы, что для разделения монополя и антимонополя требуется все больше и больше энергии. Такой конфайнмент монополей внутри сверхпроводника часто берется в качестве модели

конфайнмента кварков, который еще нужно доказать. Пользуясь электромагнитной дуальностью, можно представить магнитный, а не обычный электрический сверхпроводник. Внутри магнитного сверхпроводника электрические заряды будут постоянно удерживаться. Нашу Вселенную можно сравнить с цветным магнитным сверхпроводником, в котором удерживаются кварки (аналог электрических зарядов).

На масштабах расстояний, больших по сравнению с радиусом цветной трубки потока, соединяющей кварк с антикварком, трубка может рассматриваться как струна. Именно так исторически возникла теория струн. Задача, молодые люди, заключается в том, чтобы доказать, что основное состояние или вакуум в теории (1) является цветным магнитным сверхпроводником.

Симметрии сильного взаимодействия

Теперь, когда у нас есть теория сильного взаимодействия, можно понять происхождение симметрий сильного взаимодействия, а именно изоспиновой симметрии Гейзенберга и киральной симметрии, которая при спонтанном нарушении приводит к появлению пиона в виде намбу-голдстоуновского бозона (как обсуждалось в главах IV.2 и VI.4).

Рассмотрим мир с двумя ароматами; это все, что существенно для обсуждения пиона. Введем обозначения $u \equiv q_1, d \equiv q_2$ и $q = \begin{pmatrix} u \\ d \end{pmatrix}$ так, чтобы лагранжиан можно было записать в виде

$$\mathcal{L} = -\frac{1}{4g^2} F^a_{\mu\nu} F^{a\mu\nu} + \bar{q}\left(i\gamma^\mu D_\mu - m\right) q$$

с

$$m = \begin{pmatrix} m_u & 0 \\ 0 & m_d \end{pmatrix}$$

где m_u и m_d - массы верхнего и нижнего кварков соответственно. Если $m_u = m_d$, то лагранжиан является инвариантным относительно $q \to e^{i\theta\cdot\tau} q$, что соответствует изоспиновой симметрии Гейзенберга.

В пределе, когда m_u и m_d равны нулю, лагранжиан является инвариантным относительно $q \to e^{i\vec{\varphi}\cdot\tau\gamma_5} q$ и известен как киральная симметрия $SU(2)$; киральная потому, что правые кварки q_R и левые кварки q_L преобразуются по-разному. Если m_u и m_d намного меньше масштаба энергии сильного взаимодействия, киральная симметрия $SU(2)$ является приближенной.

Пион является намбу-голдстоуновским бозоном, связанным со спонтанным нарушением киральной симметрии $SU(2)$. Это, несомненно, является примером нарушения динамической симметрии, поскольку под рукой нет простейшего скалярного поля, чтобы получить вакуумное среднее. Вместо этого предполагается, что динамика сильных взаимодействий заставляет комплексные скалярные поля $\bar{u}u$ и $\bar{d}d$ «конденсироваться в вакуум» с тем, чтобы $\langle 0|\bar{u}u|0\rangle = \langle 0|\bar{d}d|0\rangle$ стали неисчезающими, где равенство между двумя вакуумными средними гарантирует, что изоспин Гейзенберга не нарушается спонтанно; это экспериментальный факт, так как соответствующих намбу-голдстоуновских бозонов не существует. Предполагается, что вакуум КХД, в терминах дублета q, должен быть таким, что $\langle 0|\bar{q}q|0\rangle \neq 0$, тогда как $\langle 0|\bar{q}\vec{\tau}q|0\rangle = 0$.

Ренорм-групповой поток

Ренорм-групповой поток для константы связи КХД определяется выражением

$$\frac{dg}{dt} = \beta(g) = -\frac{11}{3} T_2(G) \frac{g^3}{16\pi^2}$$

с обязательным знаком минус. Здесь

$$T(G)\delta^{ab} = f^{acd}f^{bcd}$$

Я не стану вычислять $\beta(g)$, но, прочитав главы VI.8 и VII.1, вы должны быть уверены, что сможете, если захотите, сделать это самостоятельно 1. Как минимум вы должны понять смысл множителя g^3 и $T_2(G)$, нарисовав соответствующие фейнмановские диаграммы.

Если добавить фермионы, то

$$\frac{dg}{dt} = \beta(g) = \left[-\frac{11}{3}T_2(G) + \frac{4}{3}T_2(F)\right]\frac{g^3}{16\pi^2}$$

где

$$T_2(F)\delta^{ab} = \mathrm{tr}\left[T^a(F)T^b(F)\right]$$

Я оставляю вам получить (4) из (2). Для группы $SU(N)$ для каждого фермиона в фундаментальном представлении $T_2(F) = \frac{1}{2}$. Обратите внимание, что асимптотическая свобода теряется, когда фермионов слишком много.

В упражнении VI.8.1 вы уже решали уравнение типа (4). По аналогии с квантовой электродинамикой определим $\alpha_S(\mu) \equiv g(\mu)^2/4\pi$ - сильное

[1] Подробное вычисление см.. например. С. Вайнберг: Квантовая теория поля. Т. 2. П. 18.7.

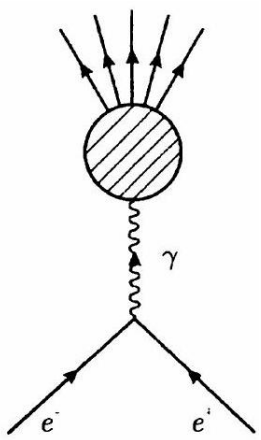

Рис. VII.3.2

взаимодействие на масштабе импульсов μ. Из (4) получаем выражение [2]

$$\alpha_S(Q) = \frac{\alpha_S(\mu)}{1 + (1/4\pi)\left(11 - \frac{2}{3}n_f\right)\alpha_S(\mu)\log\left(Q^2/\mu^2\right)}$$

откуда следует, что $\alpha_S(Q) \to 0$ логарифмически при $Q \to \infty$.

Электрон-позитронная аннигиляция

Объем книги позволяет мне продемонстрировать только одно физическое приложение. Экспериментаторы измерили сечение σ аннигиляции e^+e^-с образованием адронов как функцию общей энергии E в системе центра масс. Амплитуда показана на рис. VII.3.2. Чтобы вычислить сечение через амплитуду, нужно проделать то, что некоторые называют «скучной кинематикой»; например, все правильно нормировать, разделить на поток двух пучков и т. д. Вы, конечно, должны проделать такого рода вычисление, по крайней мере, один раз ради собственного блага. Поверьте, я делал это большее число раз, чем могу вспомнить. Но к счастью, этого неприятного занятия можно избежать, и сейчас я это продемонстрирую. Прежде всего, рассмотрим соотношение

$$R(E) \equiv \frac{\sigma\left(e^+e^- \to \text{ адроны }\right)}{\sigma\left(e^+e^- \to \mu^+\mu^-\right)}$$

2 Экспериментальные данные $\alpha_S(Q)$ можно найти на рис. 14.3 в работе F. Wilczek, in: V. Fitch et al., eds.. Critical Problems in Physics, p. 281. Кинематическая часть сокращается. На рис. VII.3.2 половина диаграммы, содержащая электрон-позитронные линии и фотонный пропагатор, появляется также в фейнмановской диаграмме $e^+e^- \to \mu^+\mu^-$(рис. VII.3.3) и поэтому исчезает в $R(E)$. Круг на рис. VII.3.2, за которым скрывается вся сложность сильного взаимодействия, дается выражением $\langle 0\,|J^\mu(0)|\,h\rangle$, где J^μ - электромагнитный ток, а состояние $|h\rangle$ может содержать любое число адронов. Чтобы получить сечение, нужно возвести в квадрат амплитуду, учесть δ-функцию, ответственную за сохранение импульса, и просуммировать по всем $|h\rangle$, получая в результате

$$\sum_h (2\pi)^4\delta^4\left(p_h - p_{e^+} - p_{e^-}\right)\langle 0\,|J^\mu(0)|\,h\rangle\,\langle h\,|J^\nu(0)|\,0\rangle$$

(где $q \equiv p_{e^+} + p_{e^-} = (E,\,\overrightarrow{0})\Big)$. Эту величину можно записать в виде

$$\int d^4x e^{iqx}\,\langle 0\,|J^\mu(x)J^\nu(0)|\,0\rangle = \int d^4x e^{iqx}\,\langle 0\,|[J^\mu(x), J^\nu(0)]|\,0\rangle = \\ = 2\,\mathrm{Im}\left(i\int d^4x e^{iqx}\,\langle 0\,|TJ^\mu(x)J^\nu(0)|\,0\rangle\right).$$

(Первое равенство следует из $E > 0$, а второе - из упражнения I.8.5). Чтобы определить эту величину, нужно вычислить бесконечное число фейнмановских диаграмм, включающих множество кварков и глюонов. Типичная диаграмма показана на рис. VII.3.4. Это совершенно безнадежно!

На помощь приходит асимптотическая свобода! Из главы VI.7 известно, что соответствующей силой взаимодействия для процесса с энергией E является $g(E)$. Но когда энергия E увеличивается, $g(E)$ постепенно уменьшается. Таким образом, все диаграммы из показанных на рис. VII.3.4, которые включают много степеней $g(E)$, исчезают; остаются диаграммы без степени $g(E)$ (рис. VII.3.5a) и с двумя степенями $g(E)$ (рис. VII.3.5b,c,d). Чтобы получить главный член в $R(E)$, никакие вычисления не нужны, поскольку диаграмма на рис. VII.3.5a аналогична той, что входит в $e^+e^- \to \mu^+\mu^-$. Нужно просто заменить кварковый пропагатор на мюонный пропагатор (массы кварка и мюона пренебрежимо малы по сравнению с E). При высокой энергии кварки свободны, а $R(E)$ просто подсчитывает квадрат заряда Q_a различных кварков, вносящих вклад в эту энергию. Можно ожидать, что

$$R(E) \underset{E\to\infty}{\longrightarrow} 3\sum_a Q_a^2$$

Множитель 3 учитывает цвет.

(b)

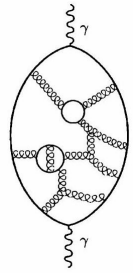

Рис. VII.3.4

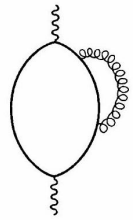
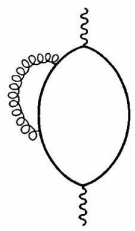


(c)



(d)
Рис. VII.3.5

КХД не только отключает себя при высоких энергиях, но и указывает нам на то, как быстро она отключается. Таким образом, можно определить, как достигается предел в (8):

$$R(E) = \left(3\sum_a Q_a^2\right)\left(1 + C\frac{2}{\left(11 - \frac{2}{3}n_f\right)\log(E/\mu)} + \ldots\right)$$

Вычислите C самостоятельно.

Мечты о точном решении

Для многих специалистов в области теории поля аналитическое решение квантовой хромодинамики является своего рода «священным граалем» (граалем, за который обещан приз в миллион долларов: см. www.ams.org/claymath/). Многие специалисты по теории поля мечтали о точном решении, по крайней мере «чистой» КХД, то есть КХД без кварков. Если все-таки какую-то четырехмерную квантовую теорию поля удастся точно решить, то, вероятнее всего, это будет чистая теория Янга-Миллса со всеми ее удивительными симметриями. (Возможно даже, что более вероятным кандидатом на такое решение является суперсимметричная теория Янга-Миллса. Мы коснемся вопроса о суперсимметрии в главе VIII.4.)

Я объясню точнее, что означает решить КХД. Рассмотрим мир, где есть только верхние и нижние кварки, массы которых m_u и m_d берутся равными нулю; а именно мир, который описывается лагранжианом

$$\mathcal{L} = -\frac{1}{4g^2}F^a_{\mu\nu}F^{a\mu\nu} + \bar{q}i\gamma^\mu D_\mu q$$

Наша цель заключается в том, чтобы вычислить нечто, подобное отношению массы ρ-мезона m_ρ к массе протона m_P.

Для успешного решения физикам-теоретикам в таком случае, как правило, нужен малый параметр разложения, но при попытке немедленного решения (10) возникает трудность, связанная с отсутствием такого параметра. Можно было бы считать таким параметром g, но это неправильно. Ренорм-групповой анализ учит нас, что $g(\mu)$ является функцией масштаба энергии μ, на котором она измеряется. Таким образом, нет такого безразмерного числа, про которое можно сказать, что оно измеряет силу КХД. Поэтому самое лучшее, что можно сделать, это указать на значение μ, при котором $\left(g\left(\mu^2\right)/4\pi\right)$ становится порядка 1. Это есть энергия, известная как Λ_{QCD}, при которой сильное взаимодействие становится сильным, когда мы уходим вниз от высокой энергии (рис. VII.3.6). Но Λ_{QCD} попросту определяет шкалу, относительно которой должны измеряться другие величины. Другими словами, если вам удастся вычислить массу m_P, то хорошо бы, чтобы она была пропорциональна Λ_{QCD}, поскольку Λ_{QCD} является единственной величиной с размерностью массы. То же относится и к массе m_ρ. Скажем прямо, если вы опубликуете статью с формулой, определяющей m_ρ/m_P в виде отвлеченных чисел, таких как 2 и π, сообщество специалистов по теории поля назовет вас героем-победителем, сумевшим получить точное решение КХД.

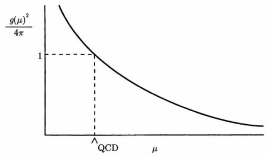


Рис. VII.3.6

Очевидный обмен безразмерной константы связи g на размерный массовый масштаб Λ_{QCD} известен как размерная трансмутация, - еще один пример который приведен в следующей главе.

Упражнения

VII.3.1. Вычислите C в (9). [Указание: за помощью обращайтесь к статьям T. Appelquist and H. Georgi, Phys. Rev. D8: 4000, 1973; и A. Zee, Phys. Rev. D8: 4038, 1973.]

VII.3.2. Вычислите (2).

30.4.4 Zi.VII.4 Large-N Expansion

Изобретение параметра разложения

Квантовая хромодинамика является теорией без параметров, поэтому трудно получить даже первое приближение. В отчаянии теоретики придумали параметр, по которому можно разлагать КХД. Допустим, что вместо трех цветов имеется N цветов. 'т Хоофт' заметил, что при $N \to \infty$ происходят поразительные упрощения. Идея состоит в том, что если вычислить m_ρ/m_P, например, в пределе больших N, то результат может быть близок к действительному значению. Иногда шутят, что специалисты в области физики элементарных частиц считают 3 большим числом, но на самом деле поправка к пределу больших N составляет обычно порядка $1/N^2$, что в реальном мире соответствует примерно 10%. Специалисты в области физики элементарных частиц были бы чрезвычайно рады, если бы смогли с такой степенью точности вычислить массы адронов.

Так же, как нарушение спонтанной симметрии и ряд других важных понятий, разложение по большим N пришло из физики конденсированных сред, но теперь оно регулярно используется в самых разных контекстах. Например, делались попытки использовать разложение по большим N для решения проблемы высокотемпературной сверхпроводимости и для того, чтобы свернуть РНК.

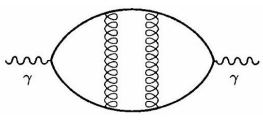
Масштабирование константы связи в КХЛ

Итак, пусть цветной группой будет $U(N)$, тогда лагранжиан запишется в виде

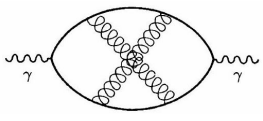
$$\mathcal{L} = -\frac{N^a}{2g^2}\,\mathrm{tr}\,F_{\mu\nu}F^{\mu\nu} + \bar{\psi}[i(\not{\partial} - i\not{\mathcal{A}}) - m]\psi$$

'G. 't Hooft, Under the Spell of the Gauge Principle, p. 378. Обратите внимание, что мы заменили g^2 на g^2/N^a. Для конечного N такое изменение не имеет существенного значения. Дело в том, что нужно выбрать степень a так, чтобы в пределе $N \to \infty$ происходили интересные упрощения при фиксированном g^2. Вершины взаимодействия третьего и четвертого порядка для глюонов пропорциональны N^a.С другой стороны, поскольку глюонный пропагатор является обратным к квадратичным членам в $\mathcal{L}$, он пропорционален $1/N^a$. Взаимодействие глюона с кварком не зависит от N.

Чтобы зафиксировать a, сосредоточим внимание на конкретном приложении - вычислении $\sigma\,(e^+e^- \to$ адроны) из предыдущей главы. Предположим, мы хотим вычислить это сечение при низких энергиях. Рассмотрим диаграммы с обменом двумя глюонами, показанные на рис. VII. 4.1a и b. Эти две диаграммы имеют порядок g^2, и нам нужно их вычислить. Заметим, что рис. VII.4.1b неплоский. Поскольку один глюон пересекает другой, эту диаграмму нельзя изобразить на плоскости, если мы считаем, что линии не могут проходить сквозь друг друга.



(a)



(b)

Рис. VII.4.1

Теперь настала очередь формализма двойных линий, описанного в главе IV.5. Диаграммы, приведенные на рис. VII.4.1a и b, изображаются в этом формализме по-другому (рис. VII.4.2a и b). Два глюонных пропагатора, общие для обеих диаграмм, дают множитель $1/N^{2a}$. Теперь мы приблизились к кульминационному моменту. Просуммируем по трем независимым цветовым индексам на рис. VII.4.2a, получая таким образом множитель N^3. Возьмите несколько цветных карандашей и попытайтесь раскрасить каждую линию на рис. VII.4.2a разным цветом: вам понадобятся три цветных карандаша. Вместо этого просуммируем только по одному независимому индексу на рис. VII.4.2b, получая тем самым множитель N. Другими словами, рис. VII.4.2a доминирует над рис. VII.4.2b в N^2 раз. В пределе больших N рис. VII.4.2b можно отбросить.

Очевидно, что это правило должно связывать один множитель N с каждой петлей. Таким образом, диаграмма наинизшего порядка, показан- ная на рис. VII.4.2c, с присутствующими на ней различными цветами N, масштабируется как N; а диаграмма на рис. VII.4.2a масштабируется как N^3/N^{2a}. Мы хотим, чтобы диаграммы рис. VII.4.2a и c масштабировались одинаково, поэтому выбираем $a = 1$.

Рисуя еще больше диаграмм [например, рис. VII.4.2d, который масштабируется как $N\,(1/N^4)\,N^4$ с тремя множителями, обусловленными взаимодействием четвертого порядка, пропагаторами и суммой по цветам соответственно], можно убедиться в том, что планарные диаграммы доминируют в пределе больших N и все масштабируются как N. Для пробы сил попытайтесь это доказать. Очевидно, что за всем этим стоит определенная топологическая структура.

Приведение диаграмм к планарному виду является значительным упрощением, но при этом все еще остается бесконечное число диаграмм. На данном этапе владения теорией поля все еще невозможно решить КХД для больших N. (Когда я начал писать эту книгу, существовала надежда, основанная на интуиции и методах, разработанных в теории струн, что решение КХД для больших N уже близко. Но теперь, когда я просматриваю окончательную корректуру, надежда эта исчезла.)

У формализма двойных линий есть естественное объяснение. С точки зрения теории групп калибровочное поле матрицы A^i_j преобразуется как $\bar{q}^i q_j$ (но мы, конечно, не считаем, что глюон является связанным состоянием кварк-антикварк). В этом случае можно считать, что две линии описы-

Рис. VII.4.2 вают распространяющиеся вдоль друг друга кварк и антикварк, а стрелки линий указывают направление, в котором течет цвет.

Теория случайных матриц

Есть теория, структурно подобная КХД для больших N, но более простая, которую, как ни удивительно, можно решить. Я имею в виду теорию случайных матриц.

Чуть преувеличивая, можно сказать, что квантовая механика заключается в написании матрицы, известной как гамильтониан, а затем нахождении ее собственных значений и собственных векторов. В начале 1950-х годов, столкнувшись с проблемой изучения свойств сложных атомных ядер, Ю. Вигнер разработал своего рода статистическую квантовую механику, в которой вместо решения истинного гамильтониана в некотором сомнительном приближении можно случайным образом создавать большие матрицы и изучать распределение собственных значений. С тех пор теория случайных матриц стала обширной и развивающейся темой с огромным и постоянно растущим числом публикаций; она применяется в многочисленных областях теоретической физики и даже чистой математики (таких как операторная алгебра и теория чисел) [2]. Эта теория имеет наглядные применения к разупорядоченным системам конденсированных сред и менее наглядные применения к случайным поверхностям и, следовательно, даже к теории струн. Здесь я ограничусь тем, что покажу, как наблюдение 't Хоофта, касающееся планарных диаграмм, работает в контексте теории случайных матриц.

Сгенерируем случайным образом эрмитовы $N \times N$-матрицы φ с вероятностью

$$P(\varphi) = \frac{1}{Z} e^{-N \operatorname{tr} V(\varphi)}$$

где $V(\varphi)$ - полином по φ. Например, пусть $V(\varphi) = \frac{1}{2} m^2 \varphi^2 + g\varphi^4$. Нормировка $\int D\varphi P(\varphi)$ фиксирует

$$Z = \int D\varphi e^{-N \operatorname{tr} V(\varphi)}$$

Везде подразумевается предел $N \to \infty$.

[2] Беглый просмотр математических публикаций см. в D. Voiculescu, ed., Free Probabilit?, Theory. Как и в главе VI.7, нас интересует $\rho(E)$ - плотность собственных значений φ. Чтобы вы действительно поняли, что это означает, я опишу, что нужно бы сделать для численного определения $\rho(E)$. Для некоторого большого целого числа N с помощью компьютера сгенерируем эрмитову матрицу φ с вероятностью $P(\varphi)$ и затем решим уравнение для собственных Значений $\varphi v = Ev$. После многократного повторения этой процедуры компьютер может построить распределение собственных значений в виде гистограммы, которая в итоге приближается к гладкой кривой, которая называется плотностью собственных значений $\rho(E)$.

Мы уже развили формализм для вычисления $\rho(E)$, в упражнении VI.7.1. Вычислим вещественно-аналитическую функцию $G(z) \equiv \langle (1/N) \operatorname{tr}[1/z - \varphi] \rangle$ и $\rho(E) = -(1/\pi) \lim_{\varepsilon \to 0} \operatorname{Im} G(E + i\varepsilon)$. Среднее $\langle ... \rangle$ взято с вероятностью $P(\varphi)$:

$$\langle O(\varphi) \rangle = \frac{1}{Z} \int D\varphi e^{-N \operatorname{tr} V(\varphi)} O(\varphi)$$

Вы понимаете, что мой выбор φ в качестве обозначения матрицы и $V(\varphi) = \frac{1}{2} m^2 \varphi^2 + g\varphi^4$ в качестве примера является провоцирующим. Вычисление Z подобно вычислению интеграла

по траекториям, но для действия $S(\varphi) = N \operatorname{tr} V(\varphi)$ оно не включает $\int d^d x$. Теорию случайных матриц можно представить как квантовую теорию поля в $(0 + 0)$-мерном пространстве-времени!

Разнообразные методы теории поля, такие как фейнмановские диаграммы, можно применить к теории случайных матриц. Но жить в $(0+ + 0)$-мерном пространстве-времени очень приятно: там нет пространства, времени, энергии и импульса, а значит нет интеграла, который нужно вычислять при нахождении фейнмановских диаграмм.

Полукруговый закон Вигнера

Давайте посмотрим, как все это работает в простом случае $V(\varphi) = \frac{1}{2}m^2\varphi^2$ (m всегда можно включить в φ, но мы не будем это делать). Вместо $G(z)$ несколько легче вычислить

$$G^i_j(z) \equiv \left\langle \left(\frac{1}{z - \varphi} \right)^i_j \right\rangle = \delta^i_j G(z).$$

I Iоследнее равенство следует из инвариантности относительно унитарных преобразований:

$$P(\varphi) = P\left(U^\dagger \varphi U\right)$$

Разложим функцию

$$G^i_j(z) = \sum_{n=0}^{\infty} \frac{1}{z^{2n+1}} \left\langle \left(\varphi^{2n}\right)^i_j \right\rangle$$

Возьмем гауссов интеграл

$$\frac{1}{Z}\int D\varphi e^{-N \operatorname{tr} \frac{1}{2}m^2\varphi^2} \varphi^i_k \varphi^l_j = \frac{1}{Z}\int D\varphi e^{-N\frac{1}{2}m^2 \sum\limits_{p,4} \varphi^p_q \varphi^q_p} \varphi^i_k \varphi^l_j = \delta^i_j \delta^l_k \frac{1}{Nm^2}$$

Полагая $k = l$ и суммируя, находим, что член $n = 1$ в уравнении (5) равен $(1/z^3)\,\delta^i_j\,(1/m^2)$

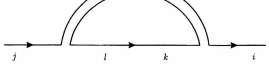

Рис. VII.4.3

Так же, как в любой теории поля, с каждым из членов в уравнении (5) можно сопоставить фейнмановскую диаграмму. Для члена $n = 1$ у нас есть рис. VII.4.3. Матричный характер поля φ естественным образом приводит к формализму двойных линий 'т Хоофта, так что мы с легкостью можем говорить о кварковом и глюонном пропагаторах. Правила Фейнмана приведены на рис. VII.4.4. Мы видим, что φ - это глюонное поле, а выражение (6) - глюонный пропагатор. В самом деле, нашу задачу можно сформулировать следующим образом: имея голый кварковый пропагатор $1/z$, надо вычислить истинный кварковый пропагатор $G(z)$ с учетом всех эффектов взаимодействия.

Теперь посмотрим на член $n = 2$ в (5) $1/z^5 \left\langle \varphi^i_h \varphi^h_k \varphi^k_l \varphi^l_j \right\rangle$, который представлен на рис. VII.4.5a. Немного подумав, можно понять, что индекс i можно свернуть с k, l или j, в результате чего появляются рис. VII.4.5b, c, d. Суммируя по цветовым индексам так же, как в КХД, видим, что планарные диаграммы на рис. VII.4.5b и рис. VII.4.5d доминируют над диаграммой рис. VII.4.5c в N^2 раз. Итак, мы соглашаемся с наблюдением 'т Хоофта,

что планарные диаграммы доминируют.

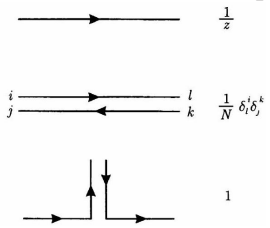

Рис. VII.4.4

Кстати, на этом примере понятно, какую важную роль играют большие N, позволяя избавиться от непланарных диаграмм. Ведь если я попрошу вычислить плотность собственных значений, скажем, для $N = 7$, вы, конечно, возразите и скажите, что для решения полиномиального уравнения 7-й степени неизвестно даже общее выражение.

Простой пример на рис. VII.4.5 указывает еще на то, как можно было бы построить всевозможные диаграммы. На рис. VII.4.5b повторяется тот же «элемент», тогда как на рис. VII.4.5d этот «элемент» вложен внутрь более базовой диаграммы. На рис. VII.4.5e показан более сложный пример. Можно убедиться, что для $N = \infty$ все диаграммы, которые вносят вклад в $G(z)$, могут быть образованы либо при помощи «вложения» существующих диаграмм внутрь образующего арку глюонного пропагатора, либо путем многократного «повторения» существующей структуры. Преобразуйте предыдущее предложение в два уравнения: «повторение» (см. рис. VII.4.6a),

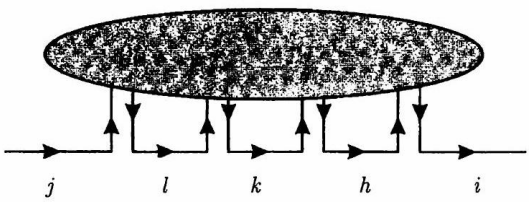
$$G(z) = \frac{1}{z} + \frac{1}{z}\Sigma(z)\frac{1}{z} + \frac{1}{z}\Sigma(z)\frac{1}{z}\Sigma(z)\frac{1}{z} + \ldots = \frac{1}{z - \Sigma(z)},$$

и «вложение» (см. рис. VII.4.6b),

$$\Sigma(z) = \frac{1}{m^2}G(z).$$

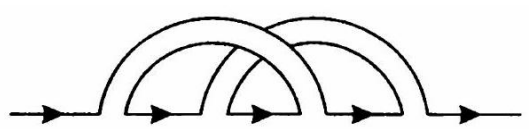
Объединяя эти два уравнения, получаем простое квадратное уравнение для $G(z)$, которое можно немедленно решить и получить

$$G(z) = \frac{m^2}{2}\left(z - \sqrt{z^2 - \frac{4}{m^2}}\right).$$

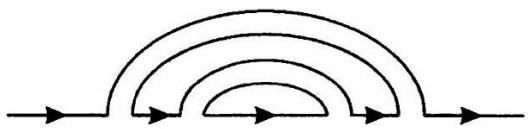


(a)

(b)



(c)



(d)

(e)
Рис. VII.4.5
(Из определения $G(z)$ следует, что для больших $zG(z) \to 1/z$, и поэтому выбираем отрицательный корень.) Сразу получаем

$$\rho(E) = \frac{2}{\pi a^2}\sqrt{a^2 - E^2}$$

где $a^2 = 4/m^2$. Это известный результат, называемый полукруговым законом Вигнера.

Рис. VII.4.7

Дайсоновский газ

Надеюсь, вы оценили элегантность подхода больших N и планарных диаграмм. Однако вы могли заметить, что глюоны не взаимодействуют. Это как если бы мы решили задачу квантовой электродинамики, когда нужно было решать задачу квантовой хромодинамики. А что, если нам приходится иметь дело с $V(\varphi) = \frac{1}{2}m^2\varphi^2 + g\varphi^4$? Слагаемое $g\varphi^4$ заставляет глюоны взаимодействовать друг с другом, образуя ужасные диаграммы такого вида, как показано на рис. VII.4.7. Ясно, что число диаграмм растет, и, насколько мне известно, никто никогда не смог вычислить $G(z)$, используя фейнмановские диаграммы. К счастью, $G(z)$ можно вычислить по-другому, используя так называемый метод дайсоновского газа. Для этого нужно записать выражение

$$\varphi = U^\dagger \Lambda U$$

где Λ обозначает диагональную $N \times N$-матрицу с диагональными элементами, равными λ_i, где $i = 1, ..., N$. Заменим переменную интегрирования в уравнении (3) с φ на U и Λ:

$$Z = \int dU \int (\Pi_i d\lambda_i)\, J e^{-N\sum_k V(\lambda_k)}$$

где J - якобиан. Поскольку подынтегральное выражение не зависит от U, интеграл по U можно отбросить. Получаем объем группы $SU(N)$. Не напоминает ли это вам главу VII.1? В самом деле, в уравнении (11) U соответствует степеням свободы нефизической калибровки: нужными степенями свободы являются собственные значения $\{\lambda_i\}$. В качестве упражнения вы можете использовать для вычисления J метод Фаддеева-Попова.

Мы же воспользуемся вместо этого более изящным способом определения J исходя из общих принципов. Замена переменных в (11) плохо определена, если произвольные два значения λ_i совпадают; в этом случае J должен занулиться. (Напомним, что переход от декартовых координат к сферическим плохо определен у Северного и Южного полюсов, и якобиан в $\sin\theta d\theta d\varphi$ действительно равен нулю при $\theta = 0$ и π.) значения λ_i эквивалентны, симметрия относительно перестановок требует, чтобы $J = \left[\Pi_{m>n}\left(\lambda_m - \lambda_n\right)\right]^\beta$. Степень β можно найти, используя анализ размерностей. CN^2-матричными элементами $d\varphi$ явно имеет размерность λ^{N^2}, тогда как $\left(\Pi_i d\lambda_i\right) J$ имеет размерность $\lambda^N \lambda^{\beta N(N-1)/2}$; таким образом, $\beta = 2$

Определив J, перепишем выражение (12) в виде

$$Z = \int \left(\Pi_i d\lambda_i\right) \left[\Pi_{m>n}\left(\lambda_m - \lambda_n\right)\right]^2 e^{-N\sum\limits_k V(\lambda_k)} =$$
$$= \int\limits_2 \left(\Pi_i d\lambda_i\right) e^{-N\sum\limits_k V(\lambda_k) + \sum\limits_{m>n} \log\left((\lambda_{mn}-\lambda_n)^2\right)}$$

Дайсон показал, что в таком виде $Z = \int \left(\Pi_i d\lambda_i\right) e^{-NE(\lambda_1,\ldots,\lambda_N)}$ является статистической суммой классического одномерного газа (вспомним главу V.2). Представьте вещественное число λ_i как положение i-й молекулы.

Энергия конфигурации

$$E\left(\lambda_1, \ldots, \lambda_N\right) = \sum_k V\left(\lambda_k\right) - \frac{1}{N} \sum_{m>n} \log\left(\lambda_m - \lambda_n\right)^2$$

состоит из двух членов с явным физическим смыслом. Газ заключен в потенциальной яме $V(x)$, и молекулы отталкивают [3] друг друга за счет двухчастичного потенциала $-(1/N)\log(x-y)^2$. Заметим, что эти два члена в E имеют одинаковый порядок по N, поскольку в каждой сумме учитывается степень N. В пределе больших N (N можно представить как обратную температуру) вычисляем Z методом наискорейшего спуска и минимизируя E, получая уравнение

$$V'\left(\lambda_k\right) = \frac{2}{N} \sum_{n\neq k} \frac{1}{\lambda_k - \lambda_n}$$

которое в непрерывном пределе, когда полюсы в (15) сливаются в разрез, имеет вид $V'(\lambda) = 2\mathcal{P}\int d\mu[\rho(\mu)/(\lambda-\mu)]$, где $\rho(\lambda)$ - неизвестная функция, для которой мы хотим найти решение, а $\mathcal{P}$ - главное значение.

Определяя, как и раньше, $G(\lambda) = \int d\mu[\rho(\mu)/(\lambda-\mu)]$, видим, что рассматриваемое уравнение для $\rho(\mu)$ можно записать в виде $\mathrm{Re}\, G(\lambda + i\varepsilon) = \frac{1}{2}V'(\lambda)$. Другими словами, $G(z)$ является вещественно-аналитической функцией с разрезами вдоль действительной оси. Нам дана действительная часть $G(z)$ на разрезе, и нужно получить решение для мнимой части. Брезан, Ициксон, Паризи и Зюбер предложили остроумное решение этой задачи. Предположим для простоты, что $V(z)$ является четным полиномом и что есть только один разрез (см. упражнение VII.4.7). Используем симметрию и постулируем следующую форму:

$$G(z) = \frac{1}{2}\left[V'(z) - P(z)\sqrt{z^2 - a^2}\right]$$

с неизвестным четным полиномом $P(z)$. Примечательно, что требование $G(z) \to 1/z$ для больших z полностью определяет $P(z)$. Разумеется, что с педагогической точки зрения следует обратиться к конкретному примеру, скажем $V(z) = \frac{1}{2}m^2z^2 + gz^4$. Поскольку $V'(z)$ является многочленом третьей степени по $z, P(z)$ должен быть квадратным (четным) многочленом по z. Беря предел $z \to \infty$ и требуя, чтобы коэффициенты при z^3 и z в $G(z)$

3Заметим, что это соответствует отталкиванию мсжду энергетическими уровнями в квантовой механике. исчезли, а коэффициент при l/z был равен 1, получаем три уравнения на три неизвестные [а именно a и двух неизвестных в $P(z)$]. Тогда плотность собственных значений определяется в виде $\rho(E) = (1/\pi)P(E)\sqrt{a^2 - E^2}$.

Я полагаю, что из этого можно извлечь урок, который заключается в том, что эффективность фейнмановских диаграмм несколько переоценивается, несмотря на их исторически важную роль в квантовой электродинамике и полезность для наглядного описания происходящего. Никто, конечно, и не думает, что КХД, даже КХД больших N, будет когда-нибудь решена путем суммирования фейнмановских диаграмм. Что необходимо, так это аналог метода дайсоновского газа для КХД больших N. С другой стороны, если моим читателям удастся вычислить $G(z)$ путем суммирования планарных диаграмм (ведь ответ известен!), то полученная при этом информация, возможно, могла бы быть полезной для понимания того, как обращаться с планарными диаграммами в КХД при больших N.

Теории поля в пределе больших N

Ряд теорий поля был также решен с использованием разложения по большим N. Я приведу в качестве примера модель Гросса-Невье отчасти потому, что она несколько напоминает КХД. Эта модель определяется выражением

$$S(\psi) = \int d^2x \left[\sum_{a=1}^{N} \bar{\psi}_a i\not{\partial} \psi_a + \frac{g^2}{2N} \left(\sum_{a=1}^{N} \bar{\psi}_a \psi_a \right)^2 \right].$$

Напомним, что согласно главе III.3 эта теория должна быть перенормируемой в $(1+1)$-мерном пространстве-времени. Для некоторого конечного N, скажем $N = 3$, наверняка окажется, что такую теорию решить не легче, чем любую другую теорию поля с полным взаимодействием. Но, как мы увидим, при $N \to \infty$ из модели можно извлечь интересную физику.

Используя тождество (A.14), теорию можно переписать в виде

$$S(\psi, \sigma) = \int d^2x \left[\sum_{a=1}^{N} \bar{\psi}_a (i\not{\partial} - \sigma) \psi_a - \frac{N}{2g^2}\sigma^2 \right].$$

Вводя скалярное поле $\sigma(x)$, получаем «незаконченное» четырехфермионное взаимодействие. (Вспомним, что аналогичный прием мы использовали в главе III.5.) Вы узнаете, что физика в этом случае подобна той, которая лежит в основе введения промежуточного бозона с целью генерирования взаимодействия Ферми. С учетом того что известно из глав II.5 и IV.3, можно сразу же проинтегрировать по фермионным полям и получить действие, записанное только в терминах поля σ.

$$S(\sigma) = -\int d^2x \frac{N}{2g^2}\sigma^2 - iN \operatorname{tr} \log(i\not{\partial} - \sigma).$$

Обратим внимание на множитель N перед логарифмическим членом следа, который получается в результате интегрирования по фермионным полям N. С заранее обдуманным намерением мы или, вернее, Гросс и Невье, ввели в (16) явный множитель $1/N$ в выражение для силы взаимодействия, с тем чтобы оба члена в (18) масштабировались как N. Таким

образом, интеграл по траектории $\mathcal{Z} = \int D\sigma e^{iS(\sigma)}$ можно вычислить методом перевала или стационарной фазы в пределе больших N. Мы просто находим экстремумы $S(\sigma)$.

Кстати, таким же образом можно объяснить разумность выбора $a = 1$ в КХД больших N. Интегрируя по кваркам в (1), получаем

$$S = -\int d^4x \frac{N}{2g^2} \operatorname{tr} F_{\mu\nu}F^{\mu\nu} + N \operatorname{tr} \log(i(\not{\partial} - iA) - m)$$

и, следовательно, оба пропорциональны N и могут уравновешивать друг друга. Увеличение числа степеней свободы должно компенсироваться ослаблением взаимодействия.

Чтобы изучить поведение основного состояния теории, ограничимся рассмотрением не зависящих от x конфигураций поля $\sigma(x)$. (Другими словами, мы не ожидаем, что трансляционная симметрия будет спонтанно нарушаться.) Можно сразу взять результат, полученный при решении упражнения IV.3.3, и записать эффективный потенциал в виде

$$\frac{1}{N}V(\sigma) = \frac{1}{2g(\mu)^2}\sigma^2 + \frac{1}{4\pi}\sigma^2\left(\log\frac{\sigma^2}{\mu^2} - 3\right).$$

Мы наложили условие $(1/N)\left[d^2V(\sigma)/d\sigma^2\right]|_{\sigma=\mu} = 1/g(\mu)^2$ как определение константы связи $g(\mu)$, зависящей от масштаба (сравните с уравнением (IV.3.18)). Утверждение, что $V(\sigma)$ не зависит от μ, сразу же приводит к выражению

$$\frac{1}{g(\mu)^2} - \frac{1}{g\left(\mu'\right)^2} = \frac{1}{\pi}\log\frac{\mu}{\mu'}$$

Если $\mu \to \infty$, то $g(\mu) \to 0$. Примечательно, что эта теория является асимптотически свободной, как и КХД. При желании можно двигаться в обратном направлении, чтобы найти уравнение ренорм-группы

$$\mu\frac{d}{d\mu}g(\mu) = -\frac{1}{2\pi}g(\mu)^3 + \ldots$$

Эта теория в различных воплощениях - (16), (17) и (18) - обладает дискретной симметрией Z_2, под действием которой $\psi_a \to \gamma^5\psi_a$ и $\sigma \to -\sigma$. Как показано в главе IV.3, эта симметрия динамически нарушается квантовыми флуктуациями. Минимум $V(\sigma)$ имеет место при $\sigma_{\min} = \mu e^{1-\pi/g(\mu)^2}$, и тогда в соответствии с уравнением (17) фермионы приобретают массу

$$m_F = \sigma_{\min} = \mu e^{1-\pi/g(\mu)^2}.$$

Заметим, что этот весьма нетривиальный результат едва ли можно увидеть, глядя на выражение (16), и мы никоим образом не можем его доказать для конечных N. Однако, как и при разложении по большим N, можно ожидать, что масса фермионов может иметь вид $m_F = \mu e^{1-\pi/g(\mu)^2} + O\left(1/N^2\right)$, так что уравнение (22) было бы хорошим приближением даже, скажем, для $N = 3$. Поскольку m_F - физически измеримая величина, она не должна зависеть от μ. Можете это проверить.

В этой теории также возникает размерная трансмутация, описанная в предыдущей главе. Мы стартуем с теории с безразмерной константой связи g и имеем в итоге теорию с размерной массой фермиона m_F. В самом деле, любая другая величина с размерностью массы должна быть пропорциональна m_F.

Динамически генерируемые кинки

Существование кинков и солитонов рассмотрено в главе V.1. Вы хорошо усвоили, что существование таких объектов следует из общих соображений симметрии и топологии, а не из конкретной динамики. Здесь мы имеем (1+1)-мерную теорию с дискретной симметрией Z_2, поэтому можно, несомненно, ожидать появление кинка, а именно не зависящей от

времени конфигурации $\sigma(x)$ (впредь x будет обозначать только пространственную координату и не будет определять общую точку в пространстве-времени) такую, что $\sigma(-\infty) = -\sigma_{\min}$ и $\sigma(+\infty) = \sigma_{\min}$. [Очевидно, что существует также антикинк с $\sigma(-\infty) = \sigma_{\min}$ и $\sigma(+\infty) = -\sigma_{\min}$.] На первый взгляд, определение точной формы кинка может показаться почти невозможным. По существу, нужно определить $\operatorname{tr}\log[i\not\partial - \sigma(x)]$ для произвольной функции $\sigma(x)$, так что $\sigma(+\infty) = -\sigma(-\infty)($ и, как говорится в главе IV.3, это включает в себя вычисление всех собственных значений оператора $i\not\partial - \sigma(x)$, суммирование по логарифму собственных значений), и затем следует проварьировать этот функционал от $\sigma(x)$, чтобы найти оптимальную форму кинка.

Примечательно, что эту форму действительно можно найти, опираясь на одно нетривиальное наблюдение [4]. По аналогии с шагами, приведшими к (IV.3.24), заметим, что

$$\operatorname{tr}\log[i\not\partial - \sigma(x)] = \operatorname{tr}\log\gamma^5[i\not\partial - \sigma(x)]\gamma^5 = \operatorname{tr}\log(-1)[i\not\partial + \sigma(x)]$$

и, следовательно, с точностью до несущественной аддитивной постоянной получаем

$$\operatorname{tr}\log(i\not\partial - \sigma(x)) = \frac{1}{2}\operatorname{tr}\log[[\not\partial - \sigma(x)][i\not\partial + \sigma(x)]] = \\ = \frac{1}{2}\operatorname{tr}\log\left\{-\partial^2 + i\gamma^1\sigma'(x) - [\sigma(x)]^2\right\}$$

Поскольку γ^1 имеет собственные значения $\pm i$, последнее выражение будет равно

$$\frac{1}{2}\left\{\operatorname{tr}\log\left\{-\partial^2 + \sigma'(x) - [\sigma(x)]^2\right\} + \operatorname{tr}\log\left\{-\partial^2 - \sigma'(x) - [\sigma(x)]^2\right\}\right\}$$

но в силу четности (пространственного отражения) эти два слагаемых равны и поэтому

$$\operatorname{tr}\log[i\not\partial - \sigma(x)] = \operatorname{tr}\log\left\{-\partial^2 - \sigma'(x) - [\sigma(x)]^2\right\}$$

Возвращаясь к выражению (18), видим, что $S(\sigma)$ является суммой двух членов - члена второго порядка по $\sigma(x)$ и члена, который зависит только от комбинации $\sigma'(x) + [\sigma(x)]^2$. Но нам известно, что $\sigma_{\min}$ минимизирует $S(\sigma)$. Таким образом, солитон определяется путем решения обычного дифференциального уравнения вида

$$\sigma'(x) + [\sigma(x)]^2 = \sigma_{\min}^2$$

[4] C. Callan, S. Coleman, D. Gross, and A. Zee. (неоиубликовано). See D. J. Gross. «Applications of the Renormalization Group to High-Energy Physics», in: R. Balian and J. Zinn-Justin. eds., Methods in Field Theory, p. 247. Кстати. я рекомснцую эту книгу студентам. занимающимся теорией поля. а именно $\sigma(x) = \sigma_{\min}\operatorname{th}\sigma_{\min}x$. Солитон наблюдался бы как объект размером $1/\sigma_{\min} = 1/m_F$. Я оставляю вам показать, что его масса дается выражением

$$m_S = \frac{N}{\pi}m_F$$

В точном соответствии с теоретическим рассмотрением, приведенным в последней главе, отношение m_S/m_F оказывается равным просто числу N/π, как и следовало ожидать.

Используя еще более удачный метод, для описания которого здесь нет места, Дашен, Хасслахер и Невье смогли исследовать зависящие от времени конфигурации σ и определить спектр масс этой модели.

Упражнения

VII.4.1. Поскольку число глюонов отличается только на единицу, обычно утверждают, что нет никакой разницы в том, чтобы изучать $U(N)$-теорию или $SU(N)$-теорию. Рассмотрите, чем глюонный пропагатор в $U(N)$-теории отличается от глюонного пропагатора в $SU(N)$-теории, и решите, какой из них проще.

VII.4.2. Попробуйте свои силы и решите КХД больших N в $(1+1)$-мерном пространстве-времени. [Указание: ключ к решению состоит в том, что в (1+ +1)-мерном пространстве-времени при выборе подходящей калибровки можно отынтегрировать калибровочное поле A_μ.] Если нужна помощь, см. 't Hooft, Under the Spell of the Gauge Principle, p. 443.

VII.4.3. Покажите, что если бы мы решили вычислить $G(z) \equiv \langle (1/N)\,\mathrm{tr}(1/z-\varphi)\rangle$, нужно было бы соединить два открытых конца кваркового пропагатора. Видим, что рис. VII.4.5b и d приводят к одной и той же диаграмме. Завершите таким способом вычисление $G(z)$.

VII.4.4. Предположим, что матрица случайных величин φ является вещественной симметричной, а не эрмитовой. Покажите, что правила Фейнмана в этом случае более сложные. Вычислите плотность собственных значений. [Указание: пропагатор, представленный двойной линией, может закручиваться.]

VII.4.5. Для эрмитовой случайной матрицы φ вычислите

$$G_c(z,w) \equiv \left\langle \frac{1}{N}\,\mathrm{tr}\,\frac{1}{z-\varphi}\,\frac{1}{N}\,\mathrm{tr}\,\frac{1}{w-\varphi}\right\rangle - \left\langle \frac{1}{N}\,\mathrm{tr}\,\frac{1}{z-\varphi}\right\rangle \left\langle \frac{1}{N}\,\mathrm{tr}\,\frac{1}{w-\varphi}\right\rangle$$

для $V(\varphi) = \frac{1}{2}m^2\varphi^2$, используя фейнмановские диаграммы. [Заметим, что этот объект гораздо проще для изучения, чем тот, который нам нужно изучить, чтобы узнать, что такое локализация (см. упражнение VI.6.1.).] По- кажите, что, выбирая подходящие мнимые части, можно получить корреляцию плотности собственных значений с собой. Если нужна помощь, см. E. Brzin and A. Zee, Phys. Rev. E51: p. 5442, 1995.

VII.4.6. Используйте метод Фаддеева-Попова, чтобы вычислить J методом дайсоновского газа.

VII.4.7. Найдите $\rho(E)$ для $V(\varphi) = \frac{1}{2}m^2\varphi^2 + g\varphi^4$. Для достаточно большой отрицательной m^2 (снова двухъямный потенциал) ожидается, что плотность собственных значений разделится на две части. Это следует из представления дайсоновского газа. Найдите критическое значение m_c^2. При $m^2 < m_c^2$ использованное в тексте предположение, что $G(z)$ имеет только один разрез, неверно. Покажите, как в этом случае вычислить $\rho(E)$.

VII.4.8. Вычислите массу солитона (25).

30.4.5 Zi.VII.5 Grand Unification

Острая необходимость в объединении

Калибровочная теория определяется группой и представлениями, которым принадлежат поля материи. Вернемся к главе VII.2 и составим каталог для теории $SU(3)\otimes SU(2)\otimes U(1)$. Например, левые верхний и нижний кварки образуют дублет $\begin{pmatrix} u^\alpha \\ d^\alpha \end{pmatrix}_L$ с гиперзарядом $\frac{1}{2}Y = \frac{1}{6}$. Обозначим его как $\left(3,2,\frac{1}{6}\right)_L$ с тремя числами, указывающими на то, как эти поля преобразуются относительно $SU(3)\otimes SU(2)\otimes U(1)$. Аналогичным образом обозначим правый кварк как $\left(3,1,\frac{2}{3}\right)_R$. Записывая все это, мы видим, что кварки и лептоны каждого семейства помещены в

$$\left(3,2,\frac{1}{6}\right)_L, \left(3,1,\frac{2}{3}\right)_R, \left(3,1,-\frac{1}{3}\right)_L, \left(1,2,-\frac{1}{2}\right)_L \quad \text{и} \quad (1,1,-1)_R.$$

По сути, этот пестрый набор представлений остро нуждается в дальнейшем объединении. Кто бы мог построить Вселенную, выбросив этот странный на вид список?

Что мы хотели бы получить, так это большую калибровочную группу G, содержащую $SU(3)\otimes SU(2)\otimes U(1)$, чтобы этот длинный список представлений объединился (в идеале) в одно внушительное большое представление. Калибровочные бозоны в G [но, конечно, не в $SU(3)\otimes SU(2)\otimes U(1)$] будут связывать друг с другом представления в (1).

Прежде чем начать поиск G, заметим, что, поскольку калибровочные преобразования коммутируют с группой Лоренца, искомые калибровочные преобразования не могут изменить левые поля на правые поля. Поэтому заменим все поля в (1) на левые поля. Напомним из

упражнения II.1.8, что зарядовые сопряжения изменяют левые поля на правые и наоборот. Таким образом, вместо (1) можно записать

$$\left(3,2,\frac{1}{6}\right),\left(3^*,1,-\frac{2}{3}\right),\left(3^*,1,\frac{1}{3}\right),\left(1,2,-\frac{1}{2}\right)\ \text{и}\ (1,1,1).$$

Теперь опустим подстрочные индексы L и R: все поля становятся левыми.

Идеальная подгонка

Самой малой группой, содержащей $SU(3)\otimes SU(2)\otimes U(1)$, является $SU(5)$. (Если вы недостаточно хорошо знаете теорию групп, ознакомьтесь для начала с приложением B). Напомним, что $SU(5)$ имеет 24 генератора ($5^2-1=24$). Эти генераторы явно представлены эрмитовыми бесследовыми 5×5-матрицами, действующими на пять объектов, которые обозначим как ψ^μ, где $\mu=1,2,...,5$. [Эти пять объектов образуют фундаментальное, или определяющее, представление $SU(5)$.

Теперь понятно, как можно поместить $SU(3)$ и $SU(2)$ в $SU(5)$. Из 24-х матриц, которые генерируют $SU(5)$, восемь имеют вид $\begin{pmatrix} A & 0\\ 0 & 0\end{pmatrix}$, а три вид $\begin{pmatrix} 0 & 0\\ 0 & B\end{pmatrix}$, где A представляет собой эрмитовы бесследовые 3×3-матрицы (из которых $3^2-1=8$ - так называемые матрицы Гелл-Манна), а B представляет собой эрмитовы бесследовые 2×2-матрицы (из которых $2^2-1=3$ - матрицы Паули). Ясно, что матрицы первого типа генерируют $SU(3)$, а матрицы второго типа - SU(2). Кроме того, эрмитова бесследовая 5×5-матрица

$$\frac{1}{2}Y=\begin{pmatrix} -\frac{1}{3} & 0 & 0 & 0 & 0\\ 0 & -\frac{1}{3} & 0 & 0 & 0\\ 0 & 0 & -\frac{1}{3} & 0 & 0\\ 0 & 0 & 0 & \frac{1}{2} & 0\\ 0 & 0 & 0 & 0 & \frac{1}{2}\end{pmatrix}$$

генерирует $U(1)$. Без лишней скромности мы уже назвали эту матрицу гиперзарядом $\frac{1}{2}Y$.

Другими словами, если разбить индекс $\mu=\{\alpha,i\}$ с $\alpha=1,2,3$ и $i=4,5$, то $SU(3)$ будет действовать на индекс α, а $SU(2)$ будет действовать на индекс i. Таким образом, три объекта ψ^α преобразуются как трехмерное представление относительно $SU(3)$, и, следовательно, могут быть 3 или 3^*. Выберем ψ^α, преобразующиеся как 3 ; далее мы увидим, что это правильный выбор, если $Y/2$ задано в таком виде, как в (3). Три объекта ψ^α не преобразуются относительно $SU(2)$, и, следовательно, каждый из них принадлежит представлению 1 синглета. Кроме того, они несут гиперзаряд $-\frac{1}{3}$, как видно из (3). В итоге ψ^α преобразуются как $\left(3,1,-\frac{1}{3}\right)$ относительно $SU(3)\otimes SU(2)\otimes U(1)$. С другой стороны, два объекта ψ^i преобразуются как 1 относительно $SU(3)$, как 2 относительно $SU(2)$ и несут гиперзаряд $\frac{1}{2}$; таким образом, они преобразуются как $\left(1,2,\frac{1}{2}\right)$. Другими словами, мы вкладываем $SU(3)\otimes SU(2)\otimes U(1)$ в $SU(5)$, определяя тем самым, как фундаментальное представление $SU(5)$ разлагается на представления $SU(3)\otimes SU(2)\otimes U(1)$

$$5\to\left(3,1,-\frac{1}{3}\right)\oplus\left(1,2,\frac{1}{2}\right).$$

Сопрягая, видим, что

$$5^*\to\left(3^*,1,\frac{1}{3}\right)\oplus\left(1,2,-\frac{1}{2}\right)$$

Сравнивая с (2), видим, что в списке появляются $\left(3*,1,\frac{1}{3}\right)$ и $\left(1,2,-\frac{1}{2}\right)$. Мы на правильном пути! Поля в этих двух представлениях хорошо помещаются в 5^*.

Таким образом, учтены пять полей из содержащихся в (2); но остаются еще десять полей

$$\left(3,2,\frac{1}{6}\right),\left(3^*,1,-\frac{2}{3}\right) \text{ и } (1,1,1).$$

Рассмотрим следующее по размеру представление $SU(5)$, а именно представление антисимметричного тензора $\psi^{\mu\nu}$. Его размер равен $(5\times 4)/2 = 10$. Именно такое число нам и нужно, только если получаются квантовые числа относительно $SU(3)\otimes SU(2)\otimes U(1)$!

Поскольку известно, что $5 \to \left(3,1,-\frac{1}{3}\right)\oplus\left(1,2,\frac{1}{2}\right)$, нужно просто (см. приложение B!) найти антисимметричное произведение $\left(3,1,-\frac{1}{3}\right)\oplus\left(1,2,\frac{1}{2}\right)$ с самим, то есть найти прямую сумму вида (где $\otimes_A$ обозначает антисимметричное произведение)

$$\left(3,1,-\frac{1}{3}\right)\otimes_A\left(3,1,-\frac{1}{3}\right)=\left(3^*,1,-\frac{2}{3}\right)$$
$$\left(3,1,-\frac{1}{3}\right)\otimes_A\left(1,2,\frac{1}{2}\right)=\left(3,2,-\frac{1}{3}+\frac{1}{2}\right)=\left(3,2,\frac{1}{6}\right)$$

и

$$\left(1,2,\frac{1}{2}\right)\otimes_A\left(1,2,\frac{1}{2}\right)=(1,1,1).$$

[Я помогу вам разобраться с (7): в $SU(3)3\otimes_A 3 = 3^*$ (помните ε_{ijk} из приложения B?), в $SU(2)1\otimes_A 1 = 1$ и в $U(1)$ гиперзаряды складываются $-\frac{1}{3}-\frac{1}{3}=-\frac{2}{3}$.]

Посмотрите, эти представления $SU(3)\otimes SU(2)\otimes U(1)$ образуют такой же набор представлений в (6). Другими словами,

$$10\to\left(3,2,\frac{1}{6}\right)\oplus\left(3^*,1,-\frac{2}{3}\right)\oplus(1,1,1)$$

Известные кварковые и лептонные поля в данном поколении идеально укладываются в представления 5^* и 10 группы $SU(5)$!

Я только что описал $SU(5)$-теорию великого объединения ДжорджиГлэшоу. Несмотря на то что эта теория до сих пор прямо не проверена на эксперименте, мне и многим другим физикам очень трудно не поверить, что группа $SU(5)$ является по меньшей мере структурно правильной, учитывая идеальное теоретико-групповое вложение.

Часто удобно представить состав представлений 5^* и 10, используя названия, которые различные поля получили в прошлом. Запишем представление 5^* в виде вектор-столбца

$$\psi_\mu=\begin{pmatrix}\psi_\alpha\\ \psi_\beta\end{pmatrix}=\begin{pmatrix}\bar{d}_\alpha\\ \nu\\ e\end{pmatrix}$$

а представление 10 в виде антисимметричной матрицы

$$\psi^{\mu\nu}=\left\{\psi^{\alpha\beta},\psi^{\alpha i},\psi^{ij}\right\}=\begin{pmatrix}0 & \bar{u} & -\bar{u} & u & d\\ -\bar{u} & 0 & \bar{u} & u & d\\ \bar{u} & -\bar{u} & 0 & u & d\\ -u & -u & -u & 0 & \bar{e}\\ -d & -d & -d & -\bar{e} & 0\end{pmatrix}$$

(Цветовые индексы опущены.)

Углубляя наше понимание физики

Помимо эстетической привлекательности, великое объединение значительно углубляет наше понимание физики.

1. Вы когда-нибудь размышляли о том, почему электрический заряд квантуется? Почему мы не видим частиц с зарядом, в $\sqrt{\pi}$ раз большим заряда электрона? В квантовой электродинамике вполне можно было бы записать

$$\mathcal{L} = \bar{\psi}[i(\not{\partial} - iA) - m]\psi + \bar{\psi}'\left[i(\not{\partial} - i\sqrt{\pi}A) - m'\right]\psi' + ...$$

В теории великого объединения, наоборот, A_μ взаимодействует с генератором калибровочной группы великого объединения. А как вы знаете, генераторы любой простой группы, такой как $SU(N)$ (считается, что группа, не образующаяся путем прямого произведения $U(1)$ на другие группы, является простой), должны через нетривиальные коммутационные соотношения $[T_a, T_b] = if_{abc}T_c$ допускать квантованные значения. Например, собственные значения T_3 в $SU(2)$, которые, конечно, зависят от представления, должны быть кратными $\frac{1}{2}$. В пределах группы $SU(3) \otimes SU(2) \otimes U(1)$, которая не является простой, квантование заряда понять нельзя. Генератор $U(1)$ не квантуется. Но при великом объединении в $SU(5)$ (или, в более общем случае, в любую простую группу) электрический заряд квантуется.

Здесь этот результат глубоко связан с замечанием Дирака (см. главу IV.4), согласно которому электрический заряд квантуется, если существует магнитный монополь. Из главы V.8 известно, что спонтанно нарушенные неабелевы калибровочные теории, такие как теория $SU(5)$, содержат монополь.

2. Вы когда-нибудь размышляли о том, почему заряд протона точно равен по величине и противоположен по знаку заряда электрона? Этот важный факт позволяет построить Вселенную в известном нам виде. Чтобы работала обычная космология, атомы должны быть электрически нейтральны с фантастической степенью точности; иначе электростатические силы, действующие в макроскопическом веществе, разорвали бы Вселенную.

Этот поразительный факт прекрасно вписывается в $SU(5)$. Наблюдение за тем, как это происходит, доставляет истинное удовольствие. Из вычисления $\operatorname{tr} Q = 0$ по представлению 5^* следует, что $3Q_{\bar{d}} = -Q_{e^-}$ЗЗесь использовано то, что сильное взаимодействие коммутирует с электромагнетизмом, и поэтому кварки различного цвета имеют одинаковый заряд. Теперь вычислим заряд протона

$$Q_p = 2Q_u + Q_d = 2\left(Q_d + 1\right) + Q_d = 3Q_d + 2 = Q_{e^-} + 2$$

Если $Q_{e^-} = -1$, то $Q_P = -Q_{e^-}$, как и есть на самом деле!

3. Напомним, что в теории электрослабых взаимодействий мы определили $\operatorname{tg}\theta = g_1/g_2$ с взаимодействием калибровочных бозонов $g_2 A_\mu^a T_a +$ $+ g_1 B_\mu (Y/2)$. Поскольку нормировка A_μ^a и B_μ фиксирована их соответствующим членом кинетической энергии, относительная величина g_2 и g_1 определяется нормировкой $Y/2$ относительно T_3. Вычислим $\operatorname{tr} T_3$ и $\operatorname{tr}(Y/2)^2$ в фундаментальном представлении 5: $\operatorname{tr} T_3^2 = \left(\frac{1}{2}\right)^2 + \left(\frac{1}{2}\right)^2 = \frac{1}{2}$ и $\operatorname{tr}(Y/2)^2 = \left(\frac{1}{3}\right)^2 3 + \left(\frac{1}{2}\right)^2 2 = \frac{5}{6}$.

Таким образом, T_3 и $\sqrt{3/5}(Y/2)$ нормированы одинаково. Итак, правильной комбинацией великого объединения является $A_\mu^a T_a + B_\mu\sqrt{3/5}(Y/2)$, и поэтому $\operatorname{tg}\theta = g_1/g_2 = \sqrt{3/5}$ или

$$\sin^2\theta = \frac{3}{8}$$

на масштабе великого объединения. Чтобы сравнить с экспериментальным значением $\sin^2\theta$, необходимо установить, как бегут константы взаимодействия g_2 и g_1 под действиcм ренорм-группы в направлении низких энергий. Отложим это рассмотрение до следующей главы.

Свобода от аномалий

Напомним, что, как описано в главе VII.2, ключом к доказательству перенормируемости неабелевой калибровочной теории является возможность свободного перехода между унитарной калибровкой и калибровкой R_ξ. Принципиальным элементом здесь является калибровочная инвариантность и получающиеся в результате тождества Уорда-Такахаши (см. главу II.7).

Внезапно у нас возникает беспокойство. Присутствует ли киральная аномалия? Существование такой аномалии означает, что некоторые тождества Уорда-Такахаши не могут выполняться. Чтобы наши теории имели смысл, им лучше не иметь аномалий. В главе IV.7 говорилось, что историческое название «аномалия» звучит так, как какая-то болезнь. В некотором смысле это так.

Теорию $SU(3)\otimes SU(2)\otimes U(1)$ пора уже было проверить на аномалии, но мы это не сделали. В качестве упражнения сделайте это самостоятельно. Здесь же я покажу, что теория $SU(5)$ безаномальна. Если в теории $SU(5)$ аномалии отсутствуют, то, значит, их также нет в теории $SU(3)\otimes SU(2)\otimes U(1)$

В главе IV.7 мы вычислили аномалию в абелевой теории, но, как там говорилось, все, что нужно сделать для обобщения до неабелевой теории, это ввести генератор T_a калибровочной группы для каждой вершины треугольной диаграммы на рис. IV.7.1. Суммируя по различным фермионам, бегущим по петле, легко видеть, что эта аномалия пропорциональна $A_{abc}(R) \equiv \operatorname{tr}(T_a\{T_b,T_c\})$, где R обозначает представление, которому принадлежат фермионы. Нужно просуммировать $A_{abc}(R)$ по всем представлениям в теории, не забывая связать противоположные знаки с левыми и правыми фермионными полями. (Полезно вспомнить о замечании 3 и упражнении 6 из главы IV.7.)

Теперь мы готовы проверить, не больна ли теория $SU(5)$. Во-первых, все фермионные поля в (2) левые. Во-вторых, можно проверить (просто представьте себе вычисление A_{abc} для всех возможных abc), что достаточно положить все T_a, T_b и T_c равными

$$T \equiv \begin{pmatrix} 2 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & -3 & 0 \\ 0 & 0 & 0 & 0 & -3 \end{pmatrix}$$

мультиплету гиперзаряда. Теперь вычислим $\operatorname{tr} T^3$ в представлении 5^*:

$$\operatorname{tr} T^3\big|_{5^*} = 3(-2)^3 + 2(+3)^3 = 30$$

и в представлении 10:

$$\operatorname{tr} T^2\big|_{10} = 3(+4)^3 + 6(-1)^3 + (-6)^3 = -30.$$

Явное чудо! Аномалия сократилась.

Это поразительное сокращение сумм кубов из странного списка чисел убедительно свидетельствует о том, что группа $SU(5)$ - еще не конец истории. Кроме того, было бы хорошо, если бы представления 5^* и 10 можно было объединить в одно представление.

Упражнения

VII.5.1. Запишите оператор заряда Q, действующий на представление 5, т. е. определяющее представление ψ^μ. Найдите заряды для представления $10 = \psi^{\mu\nu}$ и идентифицируйте содержащиеся там различные поля.

VII.5.2. Покажите, что для любой теории великого объединения, если она основана на простой группе, на масштабе объединения получаем

$$\sin^2\theta = \frac{\sum T_3^2}{\sum Q^2},$$

где сумма берется по всем фермионам. VII.5.3. Проверьте, что в теории $SU(3)\otimes SU(2)\otimes U(1)$ отсутствует аномалия. [Указание: вычисление является более сложным, чем в $SU(5)$ из-за присутствия большего числа независимых генераторов. Сначала докажите, что достаточно определить $\mathrm{tr}\, Y\,\{T_a, T_b\}$ и $\mathrm{tr}\, Y^3$ с генераторами T_a и Y для $SU(2)$ и $U(1)$ соответственно.]

VII.5.4. Постройте теории великого объединения, основанные на $SU(6), SU(7), SU(8), ...$, пока вам не надоест это занятие. Обычно такое занятие увлекает. [Указание: нужно придумать фермионы, которые еще предстоит открыть экспериментально.]

30.4.6 Zi.VII.6 Protons Are Not Eternal (???)

(??? or maybe they are???)

Распад протона

Сохранение заряда гарантирует устойчивость электрона, но как же обстоит дело с устойчивостью протона? Сохранение заряда допускает распад $p \to \pi^0 + e^+$. Ни один фундаментальный принцип не гласит, что протон живет вечно, но, однако же, протон известен своей долговечностью. По существу, так было со времени возникновения Вселенной.

Стабильность протона должна была быть декларирована авторитетной личностью. Юджин Вигнер первым обнаружил закон сохранения барионного числа. Говорят, что когда Вигнера спросили, откуда он знает, что протон живет вечно, он усмехнулся: «Я чувствую это своими костями». Я трактую эту фразу следующим образом: из одного только факта, что мы не светимся в темноте, можно сделать приемлемый вывод о нижнем пределе продолжительности существования протона.

Приступая к великому объединению, мы начинаем беспокоиться. В общем, в моделях великого объединения мы помещаем кварки и лептоны в одно и то же представление некоторой калибровочной группы [см. (VII.5.11) и (VII.5.12)]. Такое смешение сразу же предполагает, что существуют калибровочные бозоны, преобразующие кварки в лептоны и наоборот. Комбинация из трех кварков, известная как протон, могла бы вполне превратиться в лептоны при обмене этими калибровочными бозонами. Другими словами, протон, будучи опорой, на которой построен наш мир, может оказаться не вечным! Таким образом, теория великого объединения рискует тотчас же оказаться несостоятельной.

Пусть в общем случае M_X обозначает массы тех калибровочных бозонов, которые превращают кварки в лептоны и наоборот. Тогда амплитуда распада протона имеет порядок g^2/M_X^2, где g - константа взаимодействия калибровочной группы великого объединения, а скорость распада протона Γ определяется выражением $(g^2/M_X^2)^2$, умноженным на фактор фазового пространства, который определяется, по сути, массой протона m_P, поскольку массы пиона и позитрона незначительны по сравнению с массой прото- на. С помощью анализа размерностей определяем, что $\Gamma \sim (g^2/M_X^2)^2\, m_P^5$. Поскольку известно, что протон живет по крайней мере 10^{31} лет, лучше, чтобы масса M_X была намного больше тех масштабов энергии, которые можно достичь экспериментально.

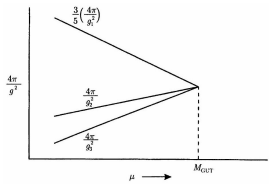

Рис. VII.6.1

Масса M_X имеет тот же порядок, что и массовый масштаб $M_{\rm GUT}$, на котором теория великого объединения спонтанно нарушается вплоть до $SU(3)\otimes SU(2)\otimes U(1)$. В частности, в теории $SU(5)$ поле Хиггса H^μ_ν, преобразующееся как сопряженное 24, с вакуумным средним $\langle H^\mu_\nu\rangle$, равным диагональной матрице с элементами $\left(-\frac{1}{3},-\frac{1}{3},-\frac{1}{3},\frac{1}{2},\frac{1}{2}\right)$, умноженными на некоторое v, может привести к необходимому результату, как обсуждалось в главе IV.6. Калибровочные бозоны в $SU(3)\otimes SU(2)\otimes U(1)$ остаются безмассовыми, тогда как другие калибровочные бозоны приобретают массу M_X порядка gv.

Чтобы определить $M_{\rm GUT}$, применим ренорм-групповой поток к g_3, g_2 и g_1 - константам взаимодействий в $SU(3), SU(2)$ и $U(1)$ соответственно. Идея заключается в том, что при движении вверх по масштабу массы или энергии μ две асимптотически свободные константы взаимодействия $g_3(\mu)$ и $g_2(\mu)$ уменьшаются, тогда как $g_1(\mu)$ увеличивается. Таким образом, при некотором массовом масштабе $M_{\rm GUT}$ они встретятся, и именно там $SU(3)\otimes SU(2)\otimes U(1)$ объединятся в $SU(5)$ (см. рис. VII.6.1). Из-за исключительно медленного логарифмического бега (который нужно бы называть продвижением или даже ползанием, но опять же по историческим причинам мы говорим о беге) константы связи, мы ожидаем, что массовый масштаб $M_{\rm GUT}$ объединения окажется намного больше любого масштаба, который использовался в физике элементарных частиц до великого объединения. На самом деле оказывается, что $M_{\rm GUT}$ имеет огромное значение порядка $10^{14}-10^{15}$Г эВ, и идея великого объединения преодолевает первое препятствие.

Устойчивость Вселенной предполагает слабость электромагнетизма

Используя результат решения упражнения VI.8.1, получаем (здесь $\alpha_S \equiv g_3^2/4\pi$ и $\alpha_{\rm GUT} = g^2/4\pi$ обозначают аналоги постоянной тонкой структуры α для случая сильного взаимодействия и великого объединения соответственно, а F - количество поколений)

$$\frac{4\pi}{[g_3(\mu)]^2}\equiv\frac{1}{\alpha_S(\mu)}=\frac{1}{\alpha_{\rm GUT}}+\frac{1}{6\pi}(4F-33)\log\frac{M_{\rm GUT}}{\mu},$$
$$\frac{4\pi}{[g_2(\mu)]^2}\equiv\frac{\sin^2\theta(\mu)}{\alpha_S(\mu)}=\frac{1}{\alpha_{\rm GUT}}+\frac{1}{6\pi}(4F-22)\log\frac{M_{\rm GUT}}{\mu},$$
$$\frac{3}{5}\frac{4\pi}{[g_1(\mu)]^2}\equiv\frac{3}{5}\frac{\cos^2\theta(\mu)}{\alpha_S(\mu)}=\frac{1}{\alpha_{\rm GUT}}+\frac{1}{6\pi}4F\log\frac{M_{\rm GUT}}{\mu}.$$

Под $\theta(\mu)$ понимается значение θ на масштабе μ. При $\mu = M_{\rm GUT}$ три константы взаимодействия связаны друг с другом через $SU(5)$.

Вычислим эти уравнения для некоторого экспериментально доступного значения μ, подставляя измеренные значения α_S и α. Имея три уравнения, можно не только определить шкалу объединения $M_{\rm GUT}$ и взаимодействие $\alpha_{\rm GUT}$, но также предсказать θ. Другими словами, если отношение g_1 к g_2 не является точно правильным, три линии на рис. VII.6.1 не пересекутся в одной точке.

Заметим, что число поколений фермионов F входит одинаково в уравнения (1), (2) и (3). Так и должно быть, поскольку при нашем вычислении фермионы эффективно считаются безмассовыми и не «знают», что объединяющая группа нарушена до $SU(3)\otimes SU(2)\otimes U(1)$. Эти уравнения выведены исходя из предположения, что все фермионные массы малы по сравнению с μ. Несколько преобразуя эти уравнения, находим

$$\sin^2\theta=\frac{1}{6}+\frac{5\alpha(\mu)}{9\alpha_S(\mu)},$$
$$\frac{\sin^2\theta}{\alpha(\mu)}=\frac{1}{\alpha_S(\mu)}+\frac{1}{6\pi}11\log\frac{M_{\rm GUT}}{\mu},$$
$$\frac{1}{\alpha(\mu)}=\frac{8}{3}\frac{1}{\alpha_{GUT}}+\frac{1}{6\pi}\left(\frac{32}{3}F-22\right)\log\frac{M_{\rm GUT}}{\mu}.$$

Уравнение (4) позволяет предсказать значение $\sin^2\theta(\mu)$, которое не зависит от $M_{\rm GUT}$ и числа поколений.

Заметим, что уравнение (5) дает ограничение на

$$\frac{1}{\alpha(\mu)} \geqslant \frac{1}{6\pi} 11 \log \frac{M_{\rm GUT}}{\mu}.$$

Нижняя граница времени жизни протона (и следовательно, шкалы $M_{\rm GUT}$) преобразуется в верхнюю границу для константы тонкой структуры. Занятно, что устойчивость Вселенной предполагает слабость электромагнетизма.

Как говорилось ранее, подставляя в измеренное значение α_S, получаем огромное значение для $M_{\rm GUT}$. Я считаю это торжеством великого объединения. Масштаб $M_{\rm GUT}$ мог бы получиться намного меньше, что сразу привело бы к противоречию с наблюдаемой стабильностью протона, но этого не произошло. Взглянем на ситуацию по-другому: если нам каким-то образом известны $M_{\rm GUT}$ и $\alpha_{\rm GUT}$, то великое объдинение фиксирует константы связи всех трех негравитационных взаимодействий! Дело не в том, что это простейшее испытание великого объединения не совсем согласуется с экспериментом. Удивительно то, что оно вообще работает.

Подробное рассмотрение того, как уравнения (4), (5) и (6) согласуются с экспериментом, выходит за рамки настоящей книги. Для глубокого феноменологического рассмотрения необходимо включить пороговые эффекты (см. упражнение VII.6.1), поправки более высокого порядка и т. д. Короче говоря, появление теории великого объединения вызвало огромное волненис в связи с возможностью распада протона. Увы, экспсримснтально полученная нижняя граница времени жизни протона в итоге оказалась выше предсказанной. Это, конечно, не означает кончину идеи великого обьдинения. В самом деле, как я отметил ранее, идеального вложения достаточно, чтобы убедить большинство теоретиков, занимающихся физикой элементарных частиц, в существенной правильности этой идеи. С годами люди предложили добавить к теории различные гипотетические частицы, чтобы увеличить продолжительность жизни протона. Идея состоит в том, что такие частицы воздействовали бы на ренорм-групповой поток и, следовательно, на $M_{\rm GUT}$. Время жизни протона на самом деле не является самым критическим вопросом. При более точных измерениях α_S и θ было установлено, что три взаимодействия не совсем пересекаются в одной точке. Действительно, вера сторонников суперсимметрии при малых энергиях частично основана на том, что при включении суперсимметричных частиц три константы связи в самом деле встречаются'. Но скептики, конечно, могут утверждать, что существует дополнительная свобода действий.

Относительные вероятности

Вы, должно быть, осознаете, что уравнения (1), (2) и (3) не являются специфичными для $SU(5)$: они сохраняются до тех пор, пока $SU(3) \otimes SU(2) \otimes U(1)$ объединяется в некоторую простую группу (настолько простую, что существует только одно калибровочное взаимодействие g).

Теперь сосредоточимся на $SU(5)$. Вспомним, что мы делим $SU(5)$-индекс μ, который может принимать пять значений, на два типа. Другими словами, индекс μ обозначается как $\{\alpha, i\}$, где α принимает три значения, а i принимает два значения. Калибровочные бозоны в $SU(5)$ соответствуют 24 независимым составляющим бесследового эрмитова поля A^μ_ν $(\mu, \nu = 1, 2, ..., 5)$, преобразующегося как присоединенное представление. Фокусируясь на теоретико-групповых свойствах $SU(5)$, опустим лоренцевы индексы, спинорные индексы и т. д. Ясно, что восемь калибровочных бозонов в $SU(3)$ преобразуют индекс типа α в индекс типа α, тогда как три калибровочных бозона в $SU(2)$ преобразуют индекс типа i в индекс типа i. Еще существует калибровочный бозон $U(1)$, который взаимодействует с гиперзарядом $\frac{1}{2}Y$. (Вы, конечно, понимаете, что я имею в виду, когда использую несколько вольный стиль изложения. Калибровочные бозоны $SU(3)$ преобразуют поля, несущие цветовой индекс, в поле, несущее цветовой индекс.)

Интересная ситуация возникает, когда калибровочные бозоны A_i^α и A_α^i преобразуют индекс α в индекс i и наоборот. Поскольку на α приходится три значения, а на i два значения, в итоге имеем $6+6=12$ таких калибровочных бозонов, учитывая, таким образом, все калибровочные бозоны в $SU(5)$. Другими словами, $24 \to (8,1)+(1,3)+(1,1)+(3,2)+(3^*,2)$. Теперь ясно видно, что обмен этими бозонами между кварками и лептонами ведет к распаду протона.

[1] См., например, F. Wilczek, in: V. Fitch et al., eds., Critical Problems in Physics, p. 297.

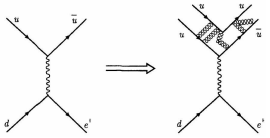

Рис. VII.6.2

Нужно просто записать в лагранжиане члены, включающие взаимодействие бозонов A_i^α и A_α^i с фермионами, и нарисовать соответствующие фейнмановские диаграммы. Я частично выполню теоретико-групповой анализ, но остальное оставлю за вами. Сворачивая индексы, легко видеть, что бозон A_ν^μ, действуя на ψ_μ, преобразует его к виду ψ_ν, а действуя на $\psi^{\nu\rho}$, преобразует его к виду $\psi^{\mu\rho}$. Используя полученное вами решение упражнения VII.5.1, посмотрим, что делает A_α^5. Он приводит к следующим переходам:

$$\psi_5 = e^- \to \psi_\alpha = \bar{d}$$
$$\psi^{\alpha\beta} = \bar{u} \to \psi^{5\beta} = u$$

К

$$\psi^{\alpha 4} = d \to \psi^{54} = e^+$$

Таким образом, обмен A_α^5 генерирует процесс (рис. VII.6.2) $u+d \to \bar{u}+e^+$, ведущий к распаду протона $p(uud) \to \pi^0(u\bar{u})+e^+$. Обратите внимание, что хотя распад $p \to \pi^0 + e^+$нарушает как барионное число B, так и лептонное число L, он сохраняет комбинацию $B-L$.

В упражнении VII.6.2 вы получите относительные вероятности для различных мод распада. Нерадивые экспериментаторы их еще не измерили.

Массы фермионов

Можно было надеяться, что с великим объединением у нас возникнет новое понимание масс кварков и лептонов. К сожалению, ситуация с массами фермионов в $SU(5)$ запутана, и до сегодняшнего дня никто не понимает происхождение масс кварков и лептонов. Вводя поле Хиггса φ^μ, преобразующееся как представление 5 (это видно из обозначения), можно записать взаимодействие

$$\psi_\mu C \psi^{\mu\nu} \varphi_\nu$$

К

$$\psi^{\mu\nu} C \psi^{\lambda\rho} \varphi^\sigma \varepsilon_{\mu\nu\lambda\rho\sigma}$$

(где φ_ν - сопряженное представление 5^*), отражающее теоретико-групповой факт (см. приложение С), что $5^* \otimes 10$ содержит представление 5, а $10 \otimes 10$ содержит представление 5^*.

Поскольку $5 \to \left(3,1,-\frac{1}{3}\right) \oplus \left(1,2,\frac{1}{2}\right)$, легко видеть, что поле Хиггса является просто естественным расширением $SU(2) \otimes U(1)$-дублета Хиггса $\left(1,2,\frac{1}{2}\right)$. Не желая нарушать электромагнетизм, мы допускаем, чтобы вакуумное среднее приобрела только электрически нейтральная четвертая компонента φ. Задавая $\langle\varphi^4\rangle = v$, получаем (с точностью до несущественных общих постоянных)

$$\psi_\alpha C \psi^{\alpha 4} + \psi_5 C \psi^{54} \Rightarrow m_d = m_e$$

K

$$\psi^{\alpha\beta}C\psi^{\gamma^5}\varepsilon_{\alpha\beta\gamma} \Rightarrow m_u \neq 0$$

Более высокая симметрия дает отношение масс $m_d = m_e$ на масштабе объединения; мы еще раз должны использовать ренорм-групповой поток. Следует отметить, что отношение масс $m_d = m_e$ возникает потому, что, когда речь идет о фермионах, $SU(5)$ нарушается только до $SU(4)$ из-за φ. Трудность в том, что мы получаем более или менее одинаковое отношение для каждого из трех поколений, поскольку большая часть пробега происходит между $M_{\rm GUT}$ масштаба объединения и массой верхнего кварка, так что пороговые эффекты дают только малую поправку. Подставляя числа, получаем примерно следующее:

$$\frac{m_b}{m_\tau} \sim \frac{m_s}{m_\mu} \sim \frac{m_d}{m_e} \sim 3$$

Используем полученный результат для предсказания масс кварков нижнего сектора через массы лептонов. Соотношение $m_b \sim 3m_\tau$ работает достаточно хорошо и косвенно доказывает, что могут существовать только три поколения, поскольку ренорм-групповой поток зависит от F. Соотношение $m_s \sim 3m_\mu$ более или менее верно в зависимости от того, какое взять «экспериментальное» значение для m_s. С другой стороны, выражение для m_d явно не входит ни в какие рамки. Одни приговаривают при этом, что первое поколение очень легкое, и поэтому важное значение могут иметь другие эффекты, такие как однопетлевые поправки. Другие, делая теорию более уродливой, придумывают также разные схемы, вводя большее число полей Хиггса, например 45, чтобы наделить фермионы массой.

Заметим, что в одном отношении $SU(5)$ не так экономна, как $SU(2)\otimes U(1)$, в которой поле Хигтса, которое дает массу калибровочным бозонам, также наделяет массой фермионы.

Вселенная не пуста, а почти пуста

Я расскажу об еще одном триумфе великого объединения: о его способности объяснить происхождение вещества во Вселенной. Физикам понадобилось много времени, чтобы понять два принципиальных факта, касающихся Вселенной: во-первых, Вселенная не пуста, и, во-вторых, Вселенная почти пуста. Для физиков первое означает, что во Вселенной нет симметрии между веществом и антивеществом, то есть барионное число N_B не равно нулю; а второй факт количественно выражается в поразительно малой наблюдаемой величине отношения числа барионов к числу фотонов $N_B/N_\gamma \sim 10^{-10}$.

Допустим, мы начинаем со Вселенной с равным количеством вещества и антивещества. Чтобы Вселенная развивалась в такую, где доминирует наблюдаемое вещество, должны соблюдаться три условия. (1) Законы Вселенной должны быть асимметричными между веществом и антивеществом. (2) Соответствующие физические процессы должны были быть неравновесными, чтобы была стрела времени. (3) Должно нарушаться барионное число.

Нам достоверно известно, что условия (1) и (2) действительно соблюдаются во Вселенной: в слабом взаимодействии есть нарушение комбинированной четности CP, и ранняя Вселенная расширялась быстро. Что касается условия (3), великое объединение естественным образом нарушает барионное число. Кроме того, хотя распад протонов (сдерживаемый множителем $1/M^2_{\rm GUT}$ в амплитуде) происходит с мучительно медленной скоростью (для тех, кто участвует в эксперименте по распаду протона!), в ранней Вселенной, когда X - и Y-бозонов образовывалось в изобилии, их быстрые распады легко могли приводить к нарушению барионного числа. Сдерживающий множитель $1/M^2_{\rm GUT}$ не появляется. Я не сомневаюсь, что в конечном счете число 10^{-10}, измеряющее «количество грязи во Вселенной» будет вычислено в какой-то теории великого объединения.

Иерархия

Я обещал, что явление Вайскопфа вернется и будет нас преследовать. То, что массовый масштаб великого объединения $M_{\rm GUT}$ естественным образом получается таким большим, считается триумфом, но это также создает проблему, известную как проблема иерархии.

Иерархия связана с огромным значением отношения $M_{\rm GUT}/M_{\rm EW}$, где $M_{\rm EW}$ обозначает шкалу электрослабого объединения порядка 10^2 ГэВ. Я опишу этот довольно туманный предмет в общих чертах. Посмотрим на поле Хиггса φ, ответственного за нарушение электрослабой теории. Его ренормированная или физическая масса точно неизвестна, но известно, что она имеет порядок $M_{\rm EW}$. Представим вычисление затравочного ряда возмущений в некой теории великого объединения (сама теория не обсуждается), начиная с некоторой затравочной массы μ_0 для φ. Из явления Вайскопфа следует, что квантовая поправка смещает μ_0^2 на огромную величину, квадратично зависящую от параметра обрезания, $\delta\mu_0^2 \sim f^2\Lambda^2 \sim f^2 M_{\rm GUT}^2$, где единственный естественный массовый масштаб заменяется на Λ, а именно $M_{\rm GUT}$, и где f обозначает некоторое безразмерное взаимодействие. Чтобы физическая масса в квадрате $\mu^2 = \mu_0^2 + \delta\mu_0^2$ имела порядок $M_{\rm EW}^2$, что примерно на 28 порядков меньше $M_{\rm GUT}^2$, потребовалось бы исключительно тонкое и весьма неестественное сокращение между μ_0^2 и $\delta\mu_0^2$. Как это может произойти «естественным образом» - серьезная задача для физиков-теоретиков.

Натуральность

Проблема иерархии тесно связана с дорогим сообществу физиков-теоретиков понятием натуральности. Мы, естественно, ожидаем, что безразмерные отношения параметров в наших теориях должны быть порядка единицы, где «порядок единицы» свободно трактуется между коллегами, скажем, где-то от 10^{-2} или 10^{-3} до 10^2 или 10^3. Малость безразмерного параметра η рассматривается как естественная, если только в пределе $\eta \to 0$ появляется симметрия. Таким образом, массы фермионов могли бы быть естественно малыми, поскольку, как вы помните из главы II.1, киральная симметрия появляется, когда масса фермиона полагается равной нулю. С другой стороны, никакая конкретная симметрия не появляется, когда мы задаем равной нулю либо затравочную, либо ренормированную массу скалярного поля. В этом состоит суть проблемы иерархии.

Упражнения

VII.6.1. Предположим, существуют новые поколения F' кварков и лептонов с массами порядка M'. Используя грубое приближение, описанное в упражнении VI.8.2 и заключающееся в пренебрежении этими поколениями для μ, меньших M', и рассмотрении M' как пренебрежимо малой для μ, больших M', примените ренорм-групповой поток и рассмотрите, как изменяются различные предсказания, такие как время жизни протона.

VII.6.2. Проведите все вычисления для распада протона. Выведите соотношения между следующими ширинами: $\Gamma\left(p \to \pi^0 e^+\right), \Gamma\left(p \to \pi^+ \bar{\nu}\right), \Gamma\left(n \to \pi^- e^+\right)$ и $\Gamma\left(n \to \pi^0 \bar{\nu}\right)$.

VII.6.3. Покажите, что $SU(5)$ сохраняет комбинацию $B - L$. Попробуйте свои силы и придумайте теорию великого объединения, которая нарушает $B - L$.

30.4.7 Zi.VII.7 $SO(10)$ Unification

Каждое поколение в одном представлении

В конце главы VII.5 мы полагали, что есть достаточно оснований считать, что объединение $SU(5)$ не окончательное. Зададимся вопросом, можно ли вложить представления 5 и 10^* в одно представление большей группы G, содержащей $SU(5)$?

Оказывается, что существует естественное вложение $SU(5)$ в ортогональную группу $SO(10)$[1], но чтобы это объяснить, я должен немного рассказать вам о теории групп. Начало может показаться несколько неожиданным. Вернемся к главе II.3, где описано, что группа Лоренца $SO(3,1)$ или ее евклидов родственник $SO(4)$ имеют спинорные представления. Теперь обобщим спиноры на d-мерное евклидово пространство. Я подробно опишу конструкцию для четных d, а спиноры в нечетных размерностях оставляю вам в качестве упражнения. Возможно, вам сейчас стоит также обратиться к приложению B.

Алгебра Клиффорда и спинорные представления

Начнем с утверждения. Мы утверждаем, что для любого целого числа n можно найти $2n$ эрмитовых матриц $\gamma_i (i = 1, 2, ..., 2n)$, которые удовлетворяют алгебре Клиффорда

$$\{\gamma_i, \gamma_j\} = 2\delta_{ij}$$

Другими словами, чтобы доказать наше утверждение, нужно построить $2n$ эрмитовых матриц γ_i, которые антикоммутируют друг с другом и квадрат которых равен единичной матрице. Будем называть γ_i-матрицы как γ-матрицы для $SO(2n)$.

Для $n = 1$ задача проста: $\gamma_1 = \tau_1$ и $\gamma_2 = \tau_2$. Вот и все.

[1] Говард Джорджи говорил мне, что он фактически нашел $SO(10)$ раньше $SU(5)$. Теперь выполним итерацию: имея $2n\gamma$-матриц для $SO(2n)$, построим $(2n+2)\gamma$-матриц для $SO(2n+2)$ следующим образом:

$$\gamma_j^{(n+1)} = \gamma_j^{(n)} \otimes \tau_3 = \begin{pmatrix} \gamma_j^{(n)} & 0 \\ 0 & -\gamma_j^{(n)} \end{pmatrix}, \quad j = 1, 2, ..., 2n,$$

$$\gamma_{2n+1}^{(n+1)} = 1 \otimes \tau_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

$$\gamma_{2n+2}^{(n+1)} = 1 \otimes \tau_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}.$$

(В этой книге 1 обозначает единичную матрицу соответствующего размера.) Очевидно, верхний индекс в круглых скобках нужен, чтобы знать, о каком наборе γ-матриц идет речь. Проверим, что если матрицы $\gamma^{(n)}$ удовлетворяют алгебре Клиффорда, тогда то же относится к матрицам $\gamma^{(n+1)}$. Например,

$$\left\{\gamma_j^{(n+1)}, \gamma_{2n+1}^{(n+1)}\right\} = \left(\gamma_j^{(n)} \otimes \tau_3\right) \cdot (1 \otimes \tau_1) + (1 \otimes \tau_1) \cdot \left(\gamma_j^{(n)} \otimes \tau_3\right) =$$
$$= \gamma_j^{(n)} \otimes \{\tau_3, \tau_1\} = 0.$$

Эта итерационная конструкция дает для $SO(2n)\gamma$-матрицы

$$\gamma_{2k-1} = 1 \otimes 1 \otimes ... \otimes 1 \otimes \tau_1 \otimes \tau_3 \otimes \tau_3 \otimes ... \otimes \tau_3$$

и

$$\gamma_{2k} = 1 \otimes 1 \otimes ... \otimes 1 \otimes \tau_2 \otimes \tau_3 \otimes \tau_3 \otimes ... \otimes \tau_3$$

где 1 появляется $k-1$ раз, а τ_3 появляется $n-k$ раз. Очевидно, что γ-матрицы имеют размер $2^n \times 2^n$. Если вы чувствуете, что сбиваетесь с толку в каком-либо месте наших рассуждений, вам следует получить решения в явном виде для $SO(4), SO(6)$ и т. д.

По аналогии с группой Лоренца определяем $2n(2n-1)/2 = n(2n-1)$ эрмитовых матриц

$$\sigma_{ij} \equiv \frac{i}{2}[\gamma_i, \gamma_j]$$

Заметим, что σ_{ij} равна $i\gamma_i\gamma_j$ при $i \neq j$ и зануляется при $i = j$. Таким образом, легко получить коммутаторы σ друг с другом. Например,

$$[\sigma_{12}, \sigma_{23}] = -[\gamma_1\gamma_2, \gamma_2\gamma_3] = -\gamma_1\gamma_2\gamma_2\gamma_3 + \gamma_2\gamma_3\gamma_1\gamma_2 = -[\gamma_1, \gamma_3] = 2i\sigma_{13}$$

Грубо говоря, γ_2-матрицы в σ_{12} и σ_{23} выбивают друг друга. Таким образом, видно, что $\frac{1}{2}\sigma_{ij}$ удовлетворяют тем же коммутационным соотношениям, что и J^{ij}-генераторы $SO(2n)$ (как приведено в приложении B). Матрицы $\frac{1}{2}\sigma_{ij}$ представляют собой J^{ij}.

Как и $2^n \times 2^n$-матрицы, σ действуют на объект ψ с 2^n компонентами, который назовем спинором ψ. Рассмотрим унитарное преобразование $\psi \to e^{i\omega_{ij}\sigma_{ij}}\psi$, с набором действительных чисел $\omega_{ij} = -\omega_{ji}$. Тогда

$$\psi^\dagger \gamma_k \psi \to \psi^\dagger e^{-i\omega_{ij}\sigma_{ij}\sigma_{ij}}\gamma_k e^{i\omega_{ij}\sigma_{ij}}\psi = \psi^\dagger\gamma_k\psi - i\omega_{ij}\psi^\dagger\left[\sigma_{ij},\gamma_k\right]\psi + ...$$

для бесконечно малого ω_{ij}. Используя алгебру Клиффорда, легко вычислить коммутатор в виде $[\sigma_{ij},\gamma_k] = -2i\left(\delta_{ik}\gamma_j - \delta_{jk}\gamma_k\right)$. (Если k не равно i или j, то ясно, что γ_k коммутирует с σ_{ij}, а если k равно i или j, то используем $\gamma_k^2 = = 1$.) Видно, что набор объектов $v_k \equiv \psi^\dagger\gamma_k\psi, k = 1, ..., 2n$ преобразуется как вектор в $2n$-мерном пространстве с бесконечно малым углом поворота $4\omega_{ij}$ в плоскости ij:

$$v_k \to v_k - 2\left(\omega_{kj}v_j - \omega_{ik}v_i\right) = v_k - 4\omega_{kj}v_j$$

(что полностью аналогично $\bar{\psi}\gamma^\mu\psi$, преобразующемуся как вектор относительно группы Лоренца). Мы другим способом доказали, что $\frac{1}{2}\sigma_{ij}$ представляет собой генераторы $SO(2n)$.

Определим матрицу $\gamma^{\text{FIVE}} = (-i)^n\gamma_1\gamma_2...\gamma_{2n}$, которая в используемом нами базисе имеет явный вид

$$\gamma^{\text{FIVE}} = \tau_3 \otimes \tau_3 \otimes ...\tau_3$$

где τ_3 появляется n раз. По аналогии с группой Лоренца определяем «левый» спинор как $\psi_L \equiv \frac{1}{2}\left(1 - \gamma^{\text{FIVE}}\right)\psi$ и «правый» спинор как $\psi_R \equiv \frac{1}{2}(1+ \ +\gamma^{\text{FIVE}})\,\psi$, так что $\gamma^{\text{FIVE}}\psi_L = -\psi_L$ и $\gamma^{\text{FIVE}}\psi_R = \psi_R$. При $\psi \to e^{i\omega_{ij}\sigma_{ij}}\psi$ получаем $\psi_L \to e^{i\omega_{ij}\sigma_{ij}}\psi_L$ и $\psi_R \to e^{i\omega_{ij}\sigma_{ij}}\psi_R$, поскольку γ^{FIVE} коммутирует с σ_{ij}. Проекция на левый и правый спиноры делит число компонент пополам, и, таким образом, мы приходим к важному выводу, согласно которому два неприводимых спинорных представления $SO(2n)$ имеют размерность 2^{n-1}. (Убедитесь в том, что это представление нельзя еще более упростить.) В частности, спинорное представление $SO(10)$ является 16-мерным $\left(2^{10/2-1} = 2^4 = 16\right)$. Мы увидим, что представления 5^* и 10 группы $SU(5)$ можно поместить в 16 состояний группы $SO(10)$.

Вложение унитарных групп в ортогональные группы

Унитарная группа $SU(5)$ может быть естественным образом вложена в ортогональную группу $SO(10)$. В самом деле, я сейчас покажу, что вложить $SU(n)$ в $SO(2n)$ так же легко, как $z = x + iy$.

Рассмотрим $2n$-мерные действительные векторы $x = (x_1, ..., x_n, \ y_1, ..., y_n)$ и $x' = (x'_1, , ..., x'_n, y'_1, ..., y'_n)$. По определению, $SO(2n)$ состоит из линейных преобразований этих двух действительных векторов, оставляя их скалярное произведение $x'x = \sum\limits_{j=1}^{n}\left(x'_jx_j + y'_jy_j\right)$ инвариантным.

Теперь из этих двух действительных векторов можно построить два n-мерных комплексных вектора $z = (x_1 + iy_1, ..., x_n + iy_n)$ и $z' = (x'_1 + \ +iy'_1, ..., x'_n + iy'_n)$. Группа $U(n)$ состоит из преобразований двух n-мерных комплексных векторов z и z', оставляя инвариантным их скалярное произведение

$$(z')^*\,z = \sum_{j=1}^{n}\left(x'_j + iy'_j\right)^*\left(x_j + iy_j\right) = \sum_{j=1}^{n}\left(x'_jx_j + y'_jy_j\right) + i\sum_{j=1}^{n}\left(x'_jy_j - y'_jx_j\right).$$

Другими словами, $SO(2n)$ оставляет инвариантной $\sum\limits_{j=1}^{n}\left(x'_jx_j + y'_jy_j\right)$, но $U(n)$ состоит из подмножества таких преобразований в $SO(2n)$, что оставляет инвариантной не только $\sum\limits_{j=1}^{n}\left(x'_jx_j + y'_jy_j\right)$, но также $\sum\limits_{j=1}^{n}\left(x'_jy_j - \ -y'_jx_j\right)$.

Теперь, когда мы осознаем смысл естественного вложения $U(n)$ в $SO(2n)$, легко видеть, что определяющее или векторное представление $SO(2n)$, которое назовем просто $2n$, разлагается при ограничении на $U(n)$ на два фундаментальных представления $U(n)-n$ и n^*; таким образом,

$$2n \to n \oplus n^*$$

Другими словами, $(x_1, ..., x_n, y_1, ..., y_n)$ можно переписать в виде $(x_1 + \ + iy_1, ..., x_n + iy_n)$ и $(x_1 - iy_1, ..., x_n - iy_n)$. Заметим, что это есть аналог (VII.5.4) и, значит, фундаментальное представление $SU(5)$ разлагается на представления группы $SU(3) \otimes SU(2) \otimes U(1)$:

$$5 \to \left(3^*, 1, \frac{1}{3}\right) \oplus \left(1, 2, -\frac{1}{2}\right).$$

С законом разложения представлений (10) мы можем найти, как разлагаются другие представления $SO(2n)$, когда они ограничены естественной подгруппой $U(n)$. Тензорные представления $SO(2n)$ просто устроены, поскольку они построены из векторного представления. [Именно это мы делали, переходя от (VII.5.4) к (VII.5.7), (VII.5.8) и (VII.5.9).] Например, присоединенное представление $SO(2n)$, имеющее размерность $2n(2n-1)/2 = n(2n-1)$, преобразуется как антисимметричный тензор с двумя индексами $2n \otimes_A 2n$ и поэтому разлагается на

$$2n \otimes_A 2n \to (n \oplus n^*) \otimes_A (n \oplus n^*)$$

в соответствии с (10). Антисимметричное произведение $\otimes_A$ в правой части, конечно, должно браться по $U(n)$. Например, $n \otimes_A n$ является $n(n-1)/2$ представлением $U(n)$. Таким образом, видно, что

$$\begin{aligned} n(2n-1) \to & n^2 - 1 \text{ (присоединенное представление)} \oplus \\ & \oplus 1 \text{ (синглет)} \oplus \\ & \oplus n(n-1)/2 \oplus \\ & \oplus (n(n-1)/2)^*. \end{aligned}$$

Проверим: общая размерность представлений $U(n)$ в правой части составляет $(n^2-1) + 1 + 2n(n-1)/2 = n(2n-1)$. В частности, для $SO(10) \supset SU(5)$ имеем $45 \to 24 \oplus 1 \oplus 10 \oplus 10^*$ и, конечно, $24 + 1 + 10 + 10 = 45$.

Разложение спинора

Труднее представить, как спинорное представление $SO(2n)$ разлагается при ограничении до $U(n)$. Здесь приведено эвристическое рассмотрение, которое убеждает большинство физиков, но, конечно, не математиков. Я получу только $SO(10) \supset SU(5)$ и предоставлю вам возможность рассмотреть общий случай. Вопрос в том, как разлагаются 16 состояний. Непосредственно из нумерологии и знания размерностей меньших представлений $SU(5)(1, 5, 10, 15)$ следует, что существует очень много возможностей, некоторые из которых довольно маловероятны, например, разложение 16 на 16 единиц.

Изобразим 16-компонентный спинор группы $SO(10)$ распадающимся на набор представлений группы $SU(5)$. По определению, 45 генераторов $SO(10)$ смешивают все эти представления вместе. Спросим себя, что делают с этими представлениями различные части 45, а именно $24 \oplus 1 \oplus 10 \oplus 10^*$?

Из них 24 преобразуют каждое из представлений $SU(5)$ в само себя, конечно, потому что они являются 24 генераторами $SU(5)$, и это то, что должны делать генераторы. Генератор 1 может только умножить каждое из этих представлений на вещественное число. (Другими словами, соответствующий элемент группы умножает каждое из представлений на фазовый множитель.)

Что делает с этими представлениями 10, которое, как вы помните из главы VII.5, представлено как антисимметричный тензор с двумя верхними индексами и поэтому

известно также как [2]? Предположим, что набор представлений, на которые распадается S, содержит синтлет $[0] = 1$ группы $SU(5).10 = [2]$, действуя на $[0]$, дает $[2] = 10$. (Это настолько очевидно, что не требует объяснений! Антисимметричный тензор с двумя индексами, объединенный с тензором без индексов, является антисимметричным тензором с двумя индексами.) А что происходит с $10 = [2]$, действующим на $[2]$? Результатом является тензор с четырьмя верхними индексами. Он, конечно, содержит $[4]$, что эквивалентно $[1]^* = 5^*$. Но $1 \oplus 10 \oplus 5^*$ уже составляет в сумме 16. Таким образом, все учтено. Больше уже быть не может. Поэтому мы делаем следующий вывод:

$$S^+ \to [0] \oplus [2] \oplus [4] = 1 \oplus 10 \oplus 5^*$$

Представления 5^* и 10 группы $SU(5)$ вмещаются в 16^+группы $SO(10)$!

Дальше мы узнаем, что два спинорных представления $SO(10)$ сопряжены друг другу. Действительно, вы, возможно, заметили, что я незаметно убрал верхний индекс «плюс» у символа S. Сопряженный спинор S^-распадается на сопряженные представления в (14):

$$S^- \to [1] \oplus [3] \oplus [5] = 5 \oplus 10^* \oplus 1^*$$

Давно потерянное антинейтрино

Вложение было бы идеальным, если бы мы ввели еще одно поле, преобразующееся как 1, то есть синглет относительно $SU(5)$, и, следовательно, синглет относительно $SU(3) \otimes SU(2) \otimes U(1)$. Другими словами, это поле не участвует в сильном, слабом и электромагнитном взаимодействиях, или, попросту говоря, оно описывает лептон, не имеющий электрического заряда и не участвующий в известном слабом взаимодействии. Таким образом, это поле можно определить как поле «давно потерянного» антинейтрино ν_L^c. Оно не чувствует ни один из известных калибровочных бозонов.

Напомним, что мы используем правило, по которому все фермионные поля являются левыми, и поэтому мы записали ν_L^c. В соответствии с сопряженным преобразованием, как говорилось ранее, такая запись эквивалентна правому полю нейтрино ν_R. Поскольку ν_R является синглетом $SU(5)$, ему можно присвоить майорановскую массу M, не нарушая $SU(5)$. Поэтому можно ожидать, что M больше или порядка масштаба нарушения $SU(5)$, который, как следует из главы VII.5, намного больше масштабов, исследованных экспериментально. Это объясняет, почему ν_R не наблюдалось.

С другой стороны, в присутствии ν_R у нас может быть и дираковская масса $m\,(\bar{\nu}_L \nu_R +$ э. с.). Поскольку этот член нарушает $SU(2) \otimes U(1)$ подобно известным массовым членам для кварков и лептонов, ожидается, что m будет иметь тот же порядок величины [2], что и известные массы кварков и лептонов (которые по неизвестным причинам охватывают огромный диапазон).

Таким образом, в пространстве с базисом (ν, ν^c) есть матрица (майорановской) массы

$$\mathcal{M} = \begin{pmatrix} 0 & m \\ m & M \end{pmatrix},$$

где $M \gg m$. Поскольку следом и детерминантом $\mathcal{M}$ являются соответственно M и $-m^2$, $\mathcal{M}$ имеет большое собственное значение $\sim M$ и малое собственное значение $\sim m^2/M$. Крошечная масса $\sim m^2/M$, уменьшенная в m/M раз относительно обычных масс кварков и лептонов, естественным образом генерируется для (наблюдаемого) левого нейтрино. Этот довольно привлекательный сценарий, известный, по понятной причине, как механизм «качели» [3], был открыт независимо друг от друга Янагидой и Гелл-Манном, а также Рамоном и Сланским.

Опять-таки плотное вложение представлений 5^* и 10 группы $SU(5)$ в представление 16^+группы $SO(10)$ убедило многих физиков, что это, безусловно, правильно.

ДвоичнЬй Код для Вселенной

Для прямого произведения γ-матриц в (5) и (6) и, значит, матриц σ_{ij} можно записать состояния спинорных представлений в виде

$$|\varepsilon_1\varepsilon_2...\varepsilon_n\rangle$$

[2] Очевидно, что теперь, имея ν_R, в теорию $SU(5)\otimes U(1)$. рассмотренную в главе VII.2, можно добавить член $f'\widetilde{\varphi}\bar{\nu}_R\psi_L$. где $\widetilde{\varphi}\equiv\tau^2\varphi^\dagger$. Если нет каких-либо других указаний, можно предположить, что константа f' имеет тот же порядок величины, что и f, которая приводит к массе электрона.

[3] В русскоязычной литературе отсутствует общепринятый термин для «seesaw mechanism». Имеется в виду доска, уравновешенная в центре: когда одно собственное значение матрицы стремится к бесконечности. другое стремится к нулю. - Прим. ред. где каждое ε принимает значение \pm 1. Из (9) легко видеть, что

$$\gamma^{\text{FIVE}}\,|\varepsilon_1\varepsilon_2...\varepsilon_n\rangle=\left(\Pi_{j=1}^n\varepsilon_j\right)|\varepsilon_1\varepsilon_2...\varepsilon_n\rangle$$

Правый спинор S^+состоит из состояний $|\varepsilon_1\varepsilon_2...\varepsilon_n\rangle$ с $\left(\Pi_{j=1}^n\varepsilon_j\right)=+1$, а левый спинор S^-–из состояний с $\left(\Pi_{j=1}^n\varepsilon_j\right)=-1$. Действительно, спинорные представления имеют размерность $2n-1$.

Таким образом, в объединении $SO(10)$ фундаментальные кварки и лептоны описываются пятиразрядным двоичным кодом с такими состояниями, как $|++--+\rangle$ и $|-+---\rangle$. Лично я нахожу такую картину Вселенной довольно привлекательной.

Получим эти состояния в явном виде. При этом у меня будет возможность убедиться в том, что вы понимаете теорию групп, описанную в этой главе. Начнем с гораздо более простого случая $SO(4)$. Спинор S^+состоит из $|++\rangle$ и $|--\rangle$, а спинор S^-–из $|+-\rangle$и $|-+\rangle$. Как рассматривалось в главе II.3, $SO(4)$ содержит две различные подгруппы $SU(2)$. Удаляя из приведенного в главе II. 3 рассмотрения несколько множителей i, видим, что третий генератор $SU(2)$, назовем его σ_3, может иметь вид либо $\sigma_{12}\sigma_{34}$, либо $\sigma_{12}+\sigma_{34}$. Эти два варианта соответствуют двум разным подгруппам $SU(2)$. Выбираем (произвольно) $\sigma_3=\frac{1}{2}\left(\sigma_{12}-\sigma_{34}\right)$. Из (5) и (6) получаем $\sigma_{12}=i\gamma_1\gamma_2=i\left(\tau_1\otimes\tau_3\right)\left(\tau_2\otimes\tau_3\right)=-\tau_3\otimes 1$ и $\sigma_{34}=-1\otimes\tau_3$, тогда $\sigma_3=\frac{1}{2}(\ -\ -\tau_3\otimes 1+1\otimes\tau_3)$. Чтобы представить преобразование четырех состояний $|++\rangle,|--\rangle,|+-\rangle$ и $|-+\rangle$ относительно выбранной группы $SU(2)$, подействуем на них с помощью σ_3. Например,

$$\sigma_3|++\rangle=\frac{1}{2}\left(-\tau_3\otimes 1+1\otimes\tau_3\right)|++\rangle=\frac{1}{2}(-1+1)|++\rangle=0$$

и

$$\sigma_3|-+\rangle=\frac{1}{2}\left(-\tau_3\otimes 1+1\otimes\tau_3\right)|-+\rangle=\frac{1}{2}(1+1)|-+\rangle=|-+\rangle$$

Итак, $|++\rangle$ и $|--\rangle$ являются двумя синглетами относительно группы $SU(2)$, тогда как $|+-\rangle$ и $|-+\rangle$ образуют дублет.

Заметим, что полученный вывод согласуется с обобщением (14) и (15), а именно с тем, что при ограничении $SO(2n)$ на $U(n)$ спиноры разлагаются как

$$S^+\to[0]\oplus[2]\oplus...$$

И

$$S^-\to[1]\ ()\ [3|\ (\mathrm{D})...$$

Я не показал, чем заканчиваются эти две последовательности. Легко сообразить, что они зависят от того, четным или нечетным является n. В рассматриваемом примере $n=2$, и поэтому $2^+\to[0]\oplus[2]=1\oplus 1$ и $2^-\to[1]=2$. Аналогично для $n=3$ при ограничении $SO(6)$

на $U(3)$ $4^+ \to [0] \oplus [2] = 1 \oplus 3^*$ и $4^- \to [1] \oplus [3] = 3 \oplus 1$. (Какое триплетное представление $U(3)$ назвать 3, а какое 3^*, зависит от того, будет ли это соответствовать традиционному употреблению. Убедимся в этом позже.)

Теперь мы готовы идентифицировать каждое из 16 состояний, таких как $|++--+\rangle$, в $SO(10)$-объединении. Прежде всего, выражение (18) указывает на то, что в подгруппе $SO(4) \otimes SO(6)$ группы $SO(10)$ спинор 16^+ разлагается следующим образом (поскольку $\Pi_{j=1}^5 \varepsilon_j = +1$ предполагает, что $\varepsilon_1\varepsilon_2 = \varepsilon_3\varepsilon_4\varepsilon_5$):

$$16^+ \to \left(2^+, 4^+\right) \oplus \left(2^-, 4^-\right)$$

Определим естественную группу $SU(2)$ подгруппы $SO(4)$ как $SU(2)$ электрослабого взаимодействия, а естественную группу $SU(3)$ подгруппы $SO(6)$ как цветную $SU(3)$ сильного взаимодействия. Таким образом, согласно предыдущему рассмотрению $(2^+, 4^+)$являются $SU(2)$-синглетами стандартной модели $U(1) \otimes SU(2) \otimes SU(3)$, тогда как $(2^-, 4^-)$являются $SU(2)$-дублетами. Такое построение имеет вид (все поля при этом, как обычно, левые):

$SU(2)$-дублеты:

$$\begin{aligned}
\nu &= |-+--\!-\rangle, \\
e^- &= |+---\!-\rangle, \\
u &= |-+++\!-\rangle, |-++-\!+\rangle \text{ и } |-+-+\!+\rangle, \\
d &= |+-++\!-\rangle, |+-+-\!+\rangle \text{ и } |+--+\!+\rangle;
\end{aligned}$$

$SU(2)$-синглеты:

$$\begin{aligned}
\nu^c &= |+++\!+\!+\rangle, \\
e^+ &= |--++\!+\rangle, \\
u^c &= |+++\!--\rangle, |++-+\!-\rangle \text{ и } |++--\!+\rangle, \\
d^c &= |--+-\!-\rangle, |---+\!-\rangle \text{ и } |---\!-\!+\rangle.
\end{aligned}$$

Уверяю вас, что процесс получения этого очень занимателен, и советую вам восстановить таблицу, не глядя на нее. Если нужна помощь, ниже дано несколько указаний. Из рассмотрения $SU(2)$ мне известно, что $\nu = 1-+\ +\varepsilon_3\varepsilon_4\varepsilon_5\rangle$ и $e^- = |+-\varepsilon_3\varepsilon_4\varepsilon_5\rangle$, но откуда мне известно, что $\varepsilon_3 = \varepsilon_4 = \varepsilon_5 = 1$? Во-первых, я знаю, что $\varepsilon_3\varepsilon_4\varepsilon_5 = -1$. Мне также известно, что $4^- \to 3 \oplus 1$ при ограничении $SO(6)$ на цветную $SU(3)$. Итак, из четырех состояний $|--\!-\rangle, |+\!+\!-\rangle, |+-\!+\rangle$ и $|-++\rangle$ лишним явно является $|--\!-\rangle$. В соответствии с тем же эвристическим рассуждением, из 16 возможных состояний лишним является $|+++\!+\!+\rangle$ и таким же должно быть ν^c.

Существует множество проверок на согласованность. Например, если определить $\nu = 1-+--\!-\rangle, e^- = |+---\!-\rangle$и $\nu^c = |+++\!+\!+\rangle$, то можно представить электрический заряд Q, который, преобразовываясь как синтлет относительно цветовой группы $SU(3)$, должен иметь значение $Q = a\varepsilon_1 + b\varepsilon_2 + c\left(\varepsilon_3 + \varepsilon_4 + \varepsilon_5\right)$ при действии на состояние $|\varepsilon_1\varepsilon_2\varepsilon_3\varepsilon_4\varepsilon_5\rangle$. Константы a, b и c можно определить из трех уравнений $Q(\nu) = -a + b$ - $-3c = 0, Q\left(e^-\right) = -1$ и $Q\left(\nu^c\right) = 0$. Таким образом, $Q = -\frac{1}{2}\varepsilon_1 + \frac{1}{6}\left(\varepsilon_3 + \varepsilon_4 + \varepsilon_5\right)$.

Живя в век компьютеров, меня интригует тот факт, что фундаментальные составляющие вещества имеют пятиразрядный двоичный код. Можете сказать своим коллегам, занимающимся физикой конденсированных сред, что их любимый электрон состоит из двоичных цепочек $+\!-\!-$- и $-\!+\ +\!+\!+$. Занятная возможность [4] сама по себе предполагает, что кварки и лептоны могут состоять из пяти разных видов фундаментальных фермионных объектов. Мы строим составные объекты, записывая $+$, если такой вид присутствует, и -, если он отсутствует. Например, из приведенного выше выражения для Q следует, что разновидность 1 несет электрический заряд $-\frac{1}{2}$, разновидность 2 - нейтральный, а разновидности 3,4 и 5 несут заряд $\frac{1}{6}$. Можно даже представить более или менее конкретную модель, связывая эти фундаментальные фермионные объекты с магнитным монополем.

Размышление о происхождении поколений

Одной из фундаментальных нерешенных загадок физики элементарных частиц является проблема поколений. Почему кварки и лептоны появляются в трех поколениях $\{\nu_e, e, u, d\}, \{\nu_\mu, \mu, c, s\}$ и $\{\nu_\tau, \tau, t, b\}$? То, как этот экспериментальный факт включается в сегодняшнюю теорию, можно считать просто жалким. Мы повторяем три раза фермионную часть лагранжиана без всякого на то понимания. Три живущих вместе поколения порождают мучительную для нас проблему поколений.

Наше представление мира в двоичном коде наводит на мысль об исключительно спекулятивном подходе к проблеме поколений (возможно,

[4] Более подробную информацию можно найти в работе F. Wilczek and A. Zee. Phys. Rev. D25: 553, 1982, Section IV. слишком спекулятивном, чтобы его упоминать в учебнике?): мы добавляем больше битов. Для меня разумной возможностью является «гиперобъединение» в теорию $SO(18)$, когда все фермионы помещаются в одно спинорное представление $S^+ = 256^+$, которое при нарушении $SO(18)$ до $SO(10) \otimes SO(8)$ разлагается следующим образом:

$$256^+ \to \left(16^+, 8^+\right) \oplus \left(16^-, 8^-\right)$$

У нас есть много состояний 16^+.К сожалению, видно, что теория групп [см. также (21)] предписывает нам получение также целого букета нежелательных состояний 16^-. Одно из предположений заключается в том, что Природа может повторить этот прием. Она использует цветовую группу $SU(3)$, сильное взаимодействие которой удерживает поля, не являющиеся цветовыми синглетами (глава VII.3). Интересно, что можно использовать удивительную особенность группы $SO(8)$, которую некоторые считают самой красивой из всех групп. В частности, два спинорных представления $8^\pm$ имеют такую же размерность, как и векторное представление 8^v (уравнение $2^{n-1} = 2n$ имеет единственное решение $n = 4$). Существует преобразование, которое циклически вращает три представления $8^+, 8^-$и 8^v друг в друга (переходя на жаргон, скажу, что группа $SO(8)$ допускает внешний автоморфизм). Таким образом, существует подгруппа $SO(5)$ группы $SO(8)$ такая, что когда $SO(8)$ нарушается до $SO(5)$, то 8^+ведет себя как 8^v, а 8^- ведет себя как спинор, то есть

$$8^+ \to 5 \oplus 1 \oplus 1 \oplus 1 \quad \text{и} \quad 8^- \to 4 \oplus 4^*$$

Если назвать эту группу [5]$SO(5)$ гиперцветовой и предположить, что связанное с ней сильное взаимодействие удерживает все поля, которые не являются гиперцветовыми синглетами, то остаются только три состояния 16^+! К сожалению, поскольку соответствующий физический процесс происходит в режиме энергий, превышающих энергию великого объединения, наше знание динамики нарушения симметрии является слишком жалким, чтобы можно было делать еще какие-либо предположения.

Зарядовое сопряжение

Используемая здесь запись прямого произведения $\otimes$ позволяет в явном виде построить матрицу сопряжения C. По определению, $C^{-1}\sigma_{ij}^* C = -\sigma_{ij}$

5Читатель, знакомый с теорией групп, поймет. что $SO(5)$ является изоморфной симплектической группе $Sp(4)$ и что схема Дынкина для группы $SO(8)$ является самой симметричной из всех. (так что C изменяет $e^{i\theta_{ij}\sigma_{ij}}$ на комплексно сопряженный). Из (2), (3) и (4) легко видеть, что можно построить

$$C^{(n+1)} = \begin{cases} C^{(n)} \otimes \tau_1, & \text{если } n \text{ нечетно} \\ C^{(n)} \otimes \tau_2, & \text{если } n \text{ четно.} \end{cases}$$

Проверьте, что это дает $C^{-1}\gamma_j^* C = (-1)^n \gamma_j$, и, следовательно, искомый результат.

Очевидно, что C является прямым произведением знакопеременной последовательности τ_1 и τ_2, и мы получаем важное свойство. Действуя на $|\varepsilon_1\varepsilon_2 ... \varepsilon_n\rangle$, C изменяет знак всех ε. Таким образом, C изменяет знак $\left(\Pi_{j=1}^n \varepsilon_j\right)$ для нечетных n и не изменяет его для четных n.

Для нечетных n два спинорных представления S^+и S^-сопряжены друг с другом, тогда как для четных n они сопряжены сами с собой, или, другими словами, они являются вещественными. Это же можно увидеть непосредственно из $C^{-1}\gamma^{\rm FIVE}\,C = (-1)^n\gamma^{\rm FIVE}$. Убедитесь в этом на всех явных примерах, с которыми мы сталкивались: $SO(2), SO(4), SO(6), SO(8), SO(10)$ и $SO(18)$. См. также упражнение (3).

Аномалии

Что же происходит с аномалиями в $SO(2n)$ великом объединении? Согласно рассмотрению, приведенному в главе VII.5, необходимо вычислить $A^{ijklmn} \equiv \mathrm{tr}\left(J^{ij}\left\{J^{kl}, J^{mn}\right\}\right)$ по фермионному представлению. Используя $SO(2n)$-преобразование $J^{ij} \to O^T J^{ij} O$, легко видеть, что A^{ijklmn} является инвариантным тензором. Можно ли построить в $SO(2n)$ инвариантный тензор шестого ранга с соответствующими свойствами симметрии (например, $A^{ijklmn} = -A^{\rm jiklmn}$? Этого сделать нельзя, за исключением группы $SO(6)$, для которой есть ε^{ijklmn}. Таким образом, A^{ijklmn} исчезает, за исключением группы $SO(6)$, где этот тензор пропорционален ε^{ijklmn}. Таково элегантное и краткое доказательство того, что любая теория великого объединения, основанная на $SO(2n)$, если $n \neq 3$, свободна от аномалий!

Исчезновение аномалии между представлениями 5^* и 10 в конце главы VII.5 больше не кажется каким-то чудом. По мере углубления наших знаний чудеса, как правило, исчезают.

Забавно, что при обсуждении физического вопроса, а именно является ли калибровочная теория перенормируемой или нет, мы пришли к математическому результату. Какой особенностью отличается группа $SO(6)$? См. упражнение VII.7.5.

Упражнения

VII.7.1. Получите алгебру Клиффорда в d-мерном пространстве для нечетных d.

VII.7.2. Получите алгебру Клиффорда в d-мерном пространстве Минковского.

VII.7.3. Покажите, что алгебра Клиффорда для $d = 4k$ и для $d = 4k + 2$ имеет несколько различные свойства. (Если нужна помощь для решения этой и двух предыдущих задач, прочтите F. Wilczek and A. Zee, Phys. Rev. D25: 553, 1982.

VII.7.4. Рассмотрите хиггсовскую часть группы $SO(10)$. Что требуется, чтобы дать массу кварки и лептоны?

VII.7.5. Группа $SO(6)$ имеет 15 генераторов $[6(6-1)/2 = 15]$. Заметьте, что группа $SU(4)$ также имеет 15 генераторов $[4^2 - 1 = 15]$. Обоснуйте предположение, что $SU(4)$ и $SO(6)$ изоморфны. Отождествите представления малой размерности.

VII.7.6. Покажите, что (к сожалению) число поколений, которое мы получаем в $SO(18)$, зависит от того, какую подгруппу $SO(8)$ считать гиперцветовой.

VII.7.7. Если вы хотите стать специалистом в области теории струн, вы должны знать уравнение Дирака в различных размерностях, и особенно в размерности 10. Для разминки изучите уравнение Дирака в 2-мерном пространстве-времени. Затем перейдите к уравнению Дирака в 10-мерном пространстве-времени.

30.5 Частb VIII Gravity and Beyond

30.5.1 What Does It Mean, To Quantize Gravity?

(??? this question is left???)

30.5.2 Zi.VIII. Gravity as a Field Theory and the Kaluza–Klein Picture

Учитывая гравитацию

В книгах по теории поля, написанных поколение назад, как правило, даже не упоминается гравитация. Гравитационное взаимодействие настолько слабее трех других взаимодействий, что его не включали в учебные программы по физике элементарных частиц. Сейчас ситуация в корне изменилась: главной задачей теоретической физики высоких энергий стало объединение гравитации с тремя другими видами взаимодействия, а теория струн - главным претендентом на звание единой теории.

Из курса общей теории относительности вы знаете о гравитационном действии Гильберта-Эйнштейна

$$S = \frac{1}{16\pi G}\int d^4x\sqrt{-g}R \equiv \int d^4x\sqrt{-g}M_P^2 R,$$

где $g = \det g_{\mu\nu}$ - детерминант криволинейной метрики $g_{\mu\nu}$ пространства-времени, R - скалярная кривизна, G - постоянная Ньютона. Напомню, что тензор кривизны Римана

$$R^{\lambda}_{\mu\nu\kappa} = \partial_\nu\Gamma^{\lambda}_{\mu\kappa} - \partial_\kappa\Gamma^{\lambda}_{\mu\nu} + \Gamma^{\sigma}_{\mu\kappa}\Gamma^{\lambda}_{\nu\sigma} - \Gamma^{\sigma}_{\mu\nu}\Gamma^{\lambda}_{\kappa\sigma}$$

выражается через символы Римана-Кристоффеля (см. главу I.10):

$$\Gamma^{\lambda}_{\mu\nu} = \frac{1}{2}g^{\lambda\rho}\left(\partial_\nu g_{\rho\mu} + \partial_\mu g_{\rho\nu} - \partial_\rho g_{\mu\nu}\right).$$

Тензор Риччи определяется как $R_{\mu\kappa} = R^{\nu}_{\mu\nu\kappa}$, а скалярная кривизна - как $R = g^{\mu\nu}R_{\mu\nu}$. Варьируя S, получаем [1] эйнштейновское уравнение поля

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = -8\pi G T_{\mu\nu}.$$

'См.. например. С. Вейнберг. Гравитация и космология. С. 364. Действие Гильберта-Эйнштейна однозначно определяется условием того, что действие координатно-инвариантно и содержит пространственно-временные производные второй степени. Из уравнений (2) и (3) видим, что скалярная кривизна R содержит производные второй степени и безразмерное поле $g_{\mu\nu}$, поэтому его размерность равна 2. Следовательно, размерность G^{-1} должна равняться 2. В современных работах по гравитации чаще всего используют вторую форму представления (1). (Модифицированная масса Планка $M_P \equiv 1/\sqrt{16\pi G}$ отличается от обычной массы Планка наличием тривиального множителя как в соотношении h и $\hbar$.)

Теория возникла из интуитивного представления Эйнштейна о кривизне пространства-времени и была сформулирована в геометрических терминах. Во многих учебниках теория Эйнштейна строится (и это справедливо) на чисто геометрических понятиях.

С другой стороны, гравитацию можно рассматривать в том же ключе, что и другие виды взаимодействия. В конце концов, гравитон можно считать еще одной элементарной частицей, подобной фотону. Действие (1), однако, не похоже ни на одну формулу из теории поля, с которыми мы до сих пор имели дело. Сейчас я продемонстрирую, что оно в самом деле имеет такую же структуру.

Гравитация как теория поля

Запишем $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$, где $\eta_{\mu\nu}$ - плоская метрика Минковского, а $h_{\mu\nu}$ - отклонение от плоской метрики. Разложим действие в ряд по степеням $h_{\mu\nu}$. Чтобы не запутаться в лоренцевых индексах, для начала опустим их. Зная, что по определению скалярная кривизна R включает в себя две производные ∂, приходим к выводу, что разложение должно быть следующим (после исключения полных производных):

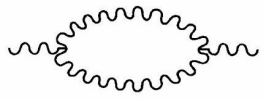
$$S = \int d^4x \frac{1}{16\pi G} \left(\partial h \partial h + h \partial h \partial h + h^2 \partial h \partial h + ...\right)$$

В главе I.10 говорилось, что поле $h^{\mu\nu}(x)$ описывает гравитон в плоском пространстве и должно рассматриваться как любое другое поле. Первый член $\partial h \partial h$ характеризует распространение гравитона и концептуально ничем не отличается от первого члена в действии для скалярного поля $\partial\varphi\partial\varphi$ или фотонного поля $\partial A \partial A$. Члены третьей и выше степеней по h описывают самодействие гравитации.

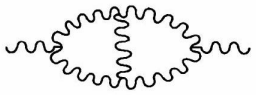
Действие Гильберта-Эйнштейна, записанное в виде разложения по слабому полю, напоминает своей структурой действие Янга-Миллса, ко- торое схематично можно представить в виде $S = \int d^4x \,(1/g^2)\,(\partial A \partial A + \ + A^2 \partial A + A^4)$. В главе IV.5 приводилось физическое обоснование самодействия бозонов Янга-Миллса: бозоны сами несут заряд, с которым они взаимодействуют. Самодействие гравитации имеет тот же смысл: гравитон взаимодействует со всем, что обладает зарядом и импульсом, при этом он сам несет заряд и импульс. Фотон, напротив, не взаимодействует с собой.

Говорят, что теории Янга-Миллса и Эйнштейна нелинейны, тогда как теория Максвелла линейна. Первые две теории сложны, а вторая проста.

Однако, в то время как действие Янга-Миллса содержит конечное число членов, действие Гильберта-Эйнштейна из-за наличия $\sqrt{-g}$ и обратной к $g_{\mu\nu}$ метрики представляет собой бесконечный ряд по гравитонному полю $h_{\mu\nu}$.



(a)



(b)

Рис. VIII. 1.1

Другим существенным отличием является тот факт, что теория ЯнгаМиллса перенормируема, тогда как хорошо известно, что гравитация неперенормируема, что следовало из анализа размерностей в главе III.2. Сейчас мы можем показать это явно. Рассмотрим собственно-энергетическую поправку к гравитонному пропагатору на рис. VIII.1.1a. Из второго члена в (5) мы видим, что взаимодействие трех гравитонов включает в себя импульс второй степени. Следовательно, фейнмановский интеграл будет иметь вид $\int d^4k\,(kkkk/k^2k^2)$, где четвертая степень по k в числителе обусловлена двумя вершинами, а четвертая степень по k в знаменателе - пропагаторами. Используя из них две степени для выделения коэффициента при $\partial h \partial h$, видим, что поправка к $1/G$ квадратично расходится. Поскольку взаимодействие явно содержит степени импульса, расходимость будет тем сильнее, чсм выше порядок. Сравните рис. VIII.1.1b с 1a: в нем больше на три пропагатора, что дает $\sim 1/k^6$, на одно интегрирование по петле $\int d^4k$ и на две вершины, дающие $\sim k^4$. Степень расходимости увеличивается на два. Все то мы уже знали из анализа размерностей.

Как говорилось в главе I.10, из фундаментального определения

$$T^{\mu\nu}(x) = -\frac{2}{\sqrt{-g}} \frac{\delta S_M}{\delta g_{\mu\nu}(x)}$$

следует, что взаимодействие гравитона с материей (в пределе слабого поля) можно учесть, добавляя в действие член

$$-\int d^4x \frac{1}{2} h_{\mu\nu} T^{\mu\nu}$$

Здесь $T^{\mu\nu}$ - тензор энергии-импульса всех полей материи (в плоском пространстве-времени), причем, под полем материи понимается любое поле, отличное от гравитона. Таким образом, действие (5) с учетом материи выглядит схематически как [2]:

$$S = \int d^4x \left[\frac{1}{16\pi G} \left(\partial h \partial h + h \partial h \partial h + h^2 \partial h \partial h + ... \right) + \left(hT + ... \right) \right]$$

В главе IV.5 мы говорили, что теорию Янга-Миллса можно привести к виду, аналогичному теории Максвелла, если сделать простое масштабирование $A \to gA$. Аналогичным образом можно привести теорию Эйнштейна к такому же виду, если масштабировать гравитонное поле $h^{\mu\nu} \to \sqrt{16\pi G} h^{\mu\nu}$ и выразить действие как

$$S = \int d^4x \left(\partial h \partial h + \sqrt{16\pi G} h \partial h \partial h + 16\pi G h^2 \partial h \partial h + ... + \sqrt{16\pi G} hT \right)$$

Отсюда очевидно, что $\sqrt{16\pi G} = 1/M_P$ характеризует величину взаимодействия гравитона с собой и всеми другими полями. Поскольку значение M_P очень велико (например, по сравнению с масштабом сильных взаимодействий), сила гравитационного взаимодействия чрезвычайно мала.

Мы раскладывали $g_{\mu\nu}$ относительно плоской метрики, хотя могли бы разложить как $g_{\mu\nu} = \bar{g}_{\mu\nu} + h_{\mu\nu}$, где $\bar{g}_{\mu\nu}$ - искривленная метрика, например, черной дыры (см. главу V.7).

Действие в пределе слабого поля

Теперь восстановим опущенные ранее индексы. Для нахождения первого члена $\partial h \partial h$ в (7), необходимого для вычисления гравитонного пропагатора, разложим действие $S \equiv M_P^2 \int d^4x \sqrt{-g} g^{\mu\nu} R_{\mu\nu}$ до членов второго порядка h^2 включительно. Из (2) и (3) следует, что тензор Риччи $R_{\mu\nu}$

[2] Если записать в разложении действия Гильберта-Эйнштейна члены третьей и четвертой степеней по h, то, строго говоря, мы должны также включить в него вклады с членами более высокого порядка по h, содержащиеся в выражении $T^{\mu\nu}(x) = -(2/\sqrt{-g}) \left(\delta S_M \right) / \left(\delta g_{\mu\nu}(x) \right)$. начинается с $O(h)$, поэтому достаточно вычислить $\sqrt{-g} g^{\mu\nu}$ с точностью до $O(h)$. Это несложно: из главы I.10 мы знаем, что $g = -\left[1 + \eta^{\mu\nu} h_{\mu\nu} + \ + O\left(h^2 \right) \right]$ и $g^{\mu\nu} = \eta^{\mu\nu} - h^{\mu\nu} + O\left(h^2 \right)$, так что $\sqrt{-g} g^{\mu\nu} = \eta^{\mu\nu} - h^{\mu\nu} + \frac{1}{2} \eta^{\mu\nu} h + + O\left(h^2 \right)$, где определено $h \equiv \eta^{\mu\nu} h_{\mu\nu}$. Теперь необходимо вычислить $R_{\mu\nu}$ с точностью до $O\left(h^2 \right)$. Это довольно громоздкое, хотя и прямое вычисление, берущее начало с (2) и (3).

Чтобы не противоречить своей концепции избегать в книге громоздких вычислений, покажу, как избежать их и сейчас. Воспользуемся соображениями симметрии!

При общем координатном преобразовании $x^\mu \to x'^\mu = x^\mu - \varepsilon^\mu(x)$ изменение метрики имеет вид $g'^{\mu\nu} = \left(\partial x'^\mu / \partial x^\sigma \right) \left(\partial x'^\nu / \partial x^\tau \right) g^{\sigma\tau}$. Подставляя метрику в виде $g^{\mu\nu} = \eta^{\mu\nu} - h^{\mu\nu} + ...$, опуская индексы (с помощью $\eta_{\mu\nu}$ в этом порядке) и учитывая, что $\left(\partial x'^\mu / \partial x^\sigma \right) = \delta^\mu_\sigma - \partial_\sigma \varepsilon^\mu$, находим, считая, что $\partial_\mu \varepsilon_\nu$ одного порядка с $h^{\mu\nu}$:

$$h'_{\mu\nu} = h_{\mu\nu} + \partial_\mu \varepsilon_\nu + \partial_\nu \varepsilon_\mu$$

Мы считаем, что порядок $\partial_\mu \varepsilon_\nu$ совпадает с порядком $h^{\mu\nu}$. Обратите внимание на структурное подобие с электромагнитным калибровочным преобразованием $A'_\mu = A_\mu - \partial_\mu \Lambda$. Очень хорошо! В каком смысле гравитацию можно рассматривать как калибровочную теорию, мы обсудим позже.

Найдем члены второго порядка по h и ∂ в выражении для действия. Согласно лоренцевской инвариантности существует четыре возможных члена (чтобы убедиться в этом, запишите сначала члены с совпадающими индексами для двух ∂, а затем члены с совпадающими индексами для одного ∂ и одного h, и т. Д.):

$$S = \int d^4x \left(a \partial_\lambda h^{\mu\nu} \partial^\lambda h_{\mu\nu} + b \partial_\lambda h^\nu_\mu \partial^\lambda h^\nu_\nu + c \partial_\lambda h^{\lambda\nu} \partial^\mu h_{\mu\nu} + d h^\lambda_\lambda \partial^\mu \partial^\nu h_{\mu\nu} \right)$$

где a, b, c и d - четыре неизвестных коэффициента. Теперь проварьируем S по $\delta h_{\mu\nu} = \partial_\mu \varepsilon_\nu + \partial_\nu \varepsilon_\mu$, интегрируя, где нужно, по частям. Например,

$$\delta\left(\partial_\lambda h^{\mu\nu}\partial^\lambda h_{\mu\nu}\right) = 2\left[\partial_\lambda\left(2\partial^\mu\varepsilon^\nu\right)\right]\left(\partial^\lambda h_{\mu\nu}\right) = 4\varepsilon^\nu\partial^2\partial^\mu h_{\mu\nu}$$

[Iоскольку имеется три объекта, линейных по h и ε и кубических по ∂ (это $\varepsilon^\nu\partial^2\partial_\nu h, \varepsilon^\nu\partial_\nu\partial^\lambda\partial^\mu h_{\lambda\mu}$ и еще один, приведенный ранее), условие $\delta S = 0$ дает три уравнения, что достаточно для фиксирования действия с точностью до общего коэффициента, соответствующего постоянной Ньютона. Их инвариантная комбинация равна

$$\mathcal{J} \equiv \frac{1}{2}\partial_\lambda h^{\mu\nu}\partial^\lambda h_{\mu\nu} - \frac{1}{2}\partial_\lambda h^\mu_\mu \partial^\lambda h^\nu_\nu - \partial_\lambda h^{\lambda\nu}\partial^\mu h_{\mu\nu} + \partial^\nu h^\lambda_\lambda \partial^\mu h_{\mu\nu}$$

Таким образом, даже если вы никогда не слышали о действии Гильберта-Эйнштейна, вы сможете определить действие для гравитации в пределе слабого поля, если потребовать инвариантность действия относительно преобразования (8). В этом нет ничего удивительного, поскольку инвариантность относительно координатных преобразований и определяет действие Гильберта-Эйнштейна. К тому же, приятно ведь сформулировать теорию гравитации «с нуля».

Нам не нужно разлагать R до $O\left(h^2\right)$, чтобы записать с учетом (6) разложение S по слабому полю:

$$S_{\text{wfg}} = \int d^4x \left(\frac{1}{32\pi G}\mathcal{J} - \frac{1}{2}h_{\mu\nu}T^{\mu\nu}\right)$$

Коэффициент при $\mathcal{J}$ фиксируется требованием, что мы воспроизводим обычную ньютоновскую гравитацию (см. далее).

Гравитонный пропагатор

Как следует из (5), действие S_{wfg} действительно имеет такую же квадратичную структуру, как и все теории поля, которые мы изучали, поэтому гравитонный пропагатор является обратным к дифференциальному оператору. Но точно так же, как в теории Максвелла и теории Янга-Миллса, соответствующий дифференциальный оператор в теории Эйнштейна-Гильберта не имеет обратного вследствие «калибровочной инвариантности» (8).

Ничего страшного. С данной трудностью справляется метод ФаддееваПопова. Более того, для нашей ограниченной цели - построения гравитонного пропагатора в плоском пространстве-времени, нет необходимости использовать формализм Фаддеева-Попова в полном объеме, включая духи и т. д [3]. Действительно, из главы III.4 известно, что для фейнмановской калибровки ($\xi = 1$) мы просто добавляем $(\partial A)^2$ в инвариант

$$\frac{1}{2}F^{\mu\nu}F_{\mu\nu} = \partial^\mu A^\nu\left(\partial_\mu A_\nu - \partial_\nu A_\mu\right) \ll= \; - A^\mu\eta_{\mu\nu}\partial^2 A^\nu - (\partial A)^2$$

в результате чего сокращается последний член. Обращая дифференциальный оператор $-\eta_{\mu\nu}\partial^2$, получаем фотонный пропагатор в фейнмановской

[3] Причина в том, что, как и в теории Максвелла. но в отличие от теории Янга-Миллса. уравнение (8) не содержит поле $h_{\mu\nu}$. Раз нам не надо вычислять петлевые диаграммы в квантовой гравитации, мы не будем использовать всю мощь метода Фаддеева-Попова. калибровке $-i\eta_{\mu\nu}/k^2$. Такой же «трюк» проделываем для гравитации. Начав с выражения

$$\mathcal{J} = \frac{1}{2}\partial_\lambda h^{\mu\nu}\partial^\lambda h_{\mu\nu} - \frac{1}{2}\partial_\lambda h^\nu_\mu \partial^\lambda h^n_\nu u - \partial_\lambda h^{\lambda\nu}\partial^\mu h_{\mu\nu} + \partial^\nu h^\lambda_\lambda \partial^\mu h_{\mu\nu}$$

и добавив в него член $\left(\partial^\mu h_{\mu\nu} - \frac{1}{2}\partial_\nu h^\lambda_\lambda\right)^2$, мы сокращаем последние два члена, так что S_{cnr} сводится к виду:

$$S_{\rm cnr} = \int d^4x \frac{1}{2}\left[\frac{1}{32\pi G}\left(\partial_\lambda h^{\mu\nu}\partial^\lambda h_{\mu\nu} - \frac{1}{2}\partial_\lambda h \partial^\lambda h\right) - h_{\mu\nu}T^{\mu\nu}\right].$$

Другими словами, свобода выбора $h_{\mu\nu}$ в (8) позволяет нам наложить так называемое условие гармонической калибровки

$$\partial_\mu h^\mu_\nu = \frac{1}{2}\partial_\nu h^\lambda_\lambda$$

(Это линеаризованная версия $\partial_\mu\left(\sqrt{-g}g^{\mu\nu}\right) = 0$.)

Записав (10) в форме

$$S = \frac{1}{32\pi G}\int d^4x \left[h^{\mu\nu}K_{\mu\nu;\lambda\sigma}\left(-\partial^2\right)h^{\lambda\sigma} + O\left(h^3\right)\right]$$

видим, что должны обратить матрицу

$$K_{\mu\nu;\lambda\sigma} \equiv \frac{1}{2}\left(\eta_{\mu\lambda}\eta_{\nu\sigma} + \eta_{\mu\sigma}\eta_{\nu\lambda} - \eta_{\mu\nu}\eta_{\lambda\sigma}\right)$$

в которой $\mu\nu$ и $\lambda\sigma$ - это два индекса. Обратите внимание, что мы должны сохранять симметрию $h^{\mu\nu}$. Иначе говоря, мы оперируем матрицами, действующими в линейном пространстве, образованном симметричными двухиндексными тензорами. Итак, единичная матрица равна

$$I_{\mu\nu;\lambda\sigma} \equiv \frac{1}{2}\left(\eta_{\mu\lambda}\eta_{\nu\sigma} + \eta_{\mu\sigma}\eta_{\nu\lambda}\right)$$

Можете проверить, что $K_{\mu\nu;\lambda\sigma}K^{\lambda\sigma}_{;\rho\omega} = I_{\mu\nu;\rho\omega}$ и, следовательно, $K^{-1} = K$. Таким образом, в гармонической калибровке гравитонный пропагатор в плоском пространстве-времени (положив постоянную Ньютона равной единице) задается в виде

$$D_{\mu\nu,\lambda\sigma}(k) = \frac{1}{2}\frac{\eta_{\mu\lambda}\eta_{\nu\sigma} + \eta_{\mu\sigma}\eta_{\nu\lambda} - \eta_{\mu\nu}\eta_{\lambda\sigma}}{k^2 + i\varepsilon}$$

От Эйнштейна к Ньютону

Варьируя (10) по $h_{\mu\nu}$, получаем уравнение движения Эйлера-Лагранжа [4] $\frac{1}{32\pi G}\left(-2\partial^2 h_{\mu\nu} + \eta_{\mu\nu}\partial^2 h\right) - T_{\mu\nu} = 0$. Вычислив след, найдем $\partial^2 h = 16\pi G T$ (где $T \equiv \eta_{\mu\nu}T^{\mu\nu}$) и в конечном итоге получим [5]

$$\partial^2 h_{\mu\nu} = -16\pi G\left(T_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}T\right).$$

В статическом пределе T_{00} является доминирующей компонентой [6] тензора энергии импульса, поэтому (13) сводится к виду $\vec{\nabla}^2\phi = 4\pi G T_{00}$, где $\phi \equiv \frac{1}{2}h_{00}$ - ньютоновский гравитационный потенциал (см. главу I.5). Мы только что вывели уравнение Пуасона для ϕ.

Кстати, есть еще один способ избежать трудоемкого разложения действия Гильберта-Эйнштейна (и, следовательно, R) до порядка $O\left(h^2\right)$ в случае, когда вы используете эйнштейновское уравнение поля (4). Необходимо разложить $R_{\mu\nu}$ лишь до порядка $O(h)$ и получить (13) из (4). Затем из (13) можно построить уравнение действия до порядка $O\left(h^2\right)$. Действительно, из выражений (2) и (3) следует, что

$R_{\mu\nu} = \frac{1}{2}\left(-\partial^2 h_{\mu\nu} + \partial_\mu\partial_\lambda h^\lambda_\nu + \partial_\nu\partial_\lambda h^\lambda_\mu - \partial_\mu\partial_\nu h^\lambda_\lambda\right) + O\left(h^2\right) \to -\frac{1}{2}\partial^2 h_{\mu\nu} + O\left(h^2\right)$.

Возможно дальнейшее упрощение в гармонической калибровке. Однако такой подход недостаточно хорош в связи с трудностью [7] вывода (4) из (1) (необходимо использовать тождество Палатини и все остальное).

Теория Эйнштейна и отклонение света

Рассмотрим две частицы с тензорами энергии импульса $T^{\mu\nu}_{(1)}$ и $T^{\mu\nu}_{(2)}$, взаимодействующие путем обмена гравитоном. Амплитуда рассеяния будет равна (с точностью до некоторой константы, несущественной для наших целей):

$$GT^{\mu\nu}_{(1)}D_{\mu\nu,\lambda\sigma}(k)T^{\lambda\sigma}_{(2)} = \frac{G}{2k^2}\left(2T^{\mu\nu}_{(1)}T_{(2)\mu\nu} - T_{(1)}T_{(2)}\right).$$

[4] Заметим, что сохранение энергии импульса в плоском пространстве-времени $\partial^\mu T_{\mu\nu} = 0$ вместе с уравнением движения означают, что $\partial^2\left(\partial^\mu h_{\mu\nu} - \frac{1}{2}\partial_\nu h\right) = 0$.

[5] Уравнение Эйнштейна в вакууме $R_{\mu\nu} = 0$ сводится к виду $\partial^2 h_{\mu\nu} = 0$; отсюда название «гармоническая».

[6] Заметим. что. в отличие от T_{00}, компонента h_{00} не является доминирующим среди остальных компонент $h_{\mu\nu}$.

[7] С. Вейнберг. Гравитаиия и космология. С. 290 и 364. Для нерелятивистской материи $T^{(00)}$ гораздо больше значений остальных компонент T^{0j} и T^{ij} (я уже говорил об этом), поэтому амплитуда рассеяния между двумя нерелятивистскими телами (скажем, Землей и вами) равна:

$$\frac{G}{2k^2}\left(2T^{00}_{(1)}T^{00}_{(2)} - T^{00}_{(1)}T^{00}_{(2)}\right) = \frac{G}{2k^2}T^{00}_{(1)}T^{00}_{(2)}$$

Как говорилось в главах I.4 и I.5, потенциал взаимодействия определяется фурье-преобразованием амплитуды рассеяния, а именно:

$$G\iint d^3x d^3x' T^{(1)(00)}(x)T^{(2)(00)}(x')\int d^3k e^{i\vec{k}\cdot(\vec{x}-\vec{x}')}\frac{1}{\vec{k}^2}.$$

Таким образом, для двух удаленных объектов ньютоновский потенциал равен $GM_{(1)}M_{(2)}/r$.

Теперь вернемся к вопросу, сформулированному в конце главы I.5. Допустим, теоретик в области элементарных частиц, доктор Грэвити, решил построить теорию гравитации, альтернативную теории Эйнштейна. Доктор Г. утверждает, что гравитация обусловлена обменом частицей со спином 2 и малой массой m_G, связанной с тензором энергии импульса $T^{\mu\nu}$. В главе I.5 мы получили пропагатор массивной частицы со спином 2, он равен

$$D^{\text{cnhH}}_{\mu\nu,\lambda\sigma}\,2(k) = \frac{1}{2}\left(G_{\mu\lambda}G_{\nu\sigma} + G_{\mu\sigma}G_{\nu\lambda} - \frac{2}{3}G_{\mu\nu}G_{\lambda\sigma}\right)/\left(k^2 - m_G^2 + i\varepsilon\right),$$

где $G_{\mu\nu} = \eta_{\mu\nu} - k_\mu k_\nu/m_G^2$ (после приведения в соответствие условных обозначений). Поскольку эта частица взаимодействует с сохраняющимся источником $k_\mu T^{\mu\nu} = 0$, можно заменить $G_{\mu\nu}$ на $\eta_{\mu\nu}$. В пределе $m_G \to 0$ пропагатор будет иметь вид:

$$D^{\text{cnuH2}}_{\mu\nu,\lambda\sigma}(k) = \frac{1}{2}\frac{\eta_{\mu\lambda}\eta_{\nu\sigma} + \eta_{\mu\sigma}\eta_{\nu\lambda} - \frac{2}{3}\eta_{\mu\nu}\eta_{\lambda\sigma}}{k^2 + i\varepsilon}$$

Сравните с выражением (12). Предложенный доктором Г. пропагатор отличается от пропагатора, полученного Эйнштейном, множителем $\frac{2}{3}$ вместо 1. Удивительно, но гравитация вовсе не порождается почти безмассовой ча-

стицей со спином 2. «Разницу в $\frac{2}{3}$» между пропагаторами (12) и (14) об-

наружили в 1970 году независимо друг от друга Ивасаки, Дам и Вельтман, а также Захаров.

В теории доктора . (с его собственной гравитационной константой связи G_G) взаимодействие двух частиц задается уравнением:

$$G_G T^{\mu\nu}_{(1)}D_{\mu\nu,\lambda\sigma}(k)T^{\lambda\sigma}_{(2)} = \frac{G_G}{2k^2}\left(2T^{\mu\nu}_{(1)}T_{(2)\mu\nu} - \frac{2}{3}T_{(1)}T_{(2)}\right)$$

Для случая двух объектов нерелятивистской материи уравнение сводится к виду:

$$\frac{G_G}{2k^2}\left(2T^{00}_{(1)}T^{00}_{(2)} - \frac{2}{3}T^{00}_{(1)}T^{00}_{(2)}\right) = \frac{4}{3}\frac{G_G}{2k^2}T^{00}_{(1)}T^{00}_{(2)}$$

Доктор Г. просто определяет $G_G = \frac{3}{4}G$, после чего его теория проходит все экспериментальные проверки.

Но подождите, хорошо известно наблюдение 1919 года, когда ученые зафиксировали отклонение света звезд Солнцем, хотя фотон не является нерелятивистским телом. Действительно, из главы I.10 (или из курса электромагнетизма) известно, что для фотона равен нулю след $T \equiv T^{\mu}_{\mu}$. Значит, принимая $T^{\mu\nu}_{(1)}$ и $T^{\mu\nu}_{(2)}$ за тензоры энергии импульса для Солнца и фотона соответственно, Эйнштейн получил бы амплитуду рассеяния $(G/2k^2)\,2T^{\mu\nu}_{(1)}T_{(2)\mu\nu}$, тогда как амплитуда рассеяния в теории доктора Г. оказалась бы равной $(G_G/2k^2)\,2T^{\mu\nu}_{(1)}T_{(2)\mu\nu} = \frac{3}{4}G/2k^2\Big)\,2T^{\mu\nu}_{(1)}T_{(2)\mu\nu}$. Доктор Г. оценил бы угол отклонения как $3GM/R$, вместо $4GM/R$ (здесь M и R - масса и радиус Солнца). Так в 1919 году на бразильском острове Собрал Эйнштейн победил доктора Г.

В главе I.5 говорилось, что массивная частица со спином 2 имеет 5 степеней свободы, тогда как безмассовый гравитон - всего 2 степени свободы. (В приложении 2 приводится анализ \pm 2 -спиральной структуры обмена одним гравитоном.) Пять степеней свободы можно рассматривать как состоящие из \pm 2 -спиральных степеней свободы, двух \pm 1 -спиральных степеней свободы и одной 0-спиральной степени свободы. Взаимодействие \pm 1 -спиральных степеней свободы исчезает вследствие условия $k_\mu T^{\mu\nu} = 0$. В результате остается дополнительное скалярное взаимодействие со следом $T \equiv T^{\mu}_{\nu}\eta_{\mu\nu}$ тензора энергии импульса; это расхождение сводится к отличию в последних членах выражений (12) и (14).

Если измерить отклонение света звезд, то придем к выводу, что физическая величина, характеризующая массу гравитона m_G, точно равна нулю, а вовсе не принимается меньшей некоторого малого значения. Этот парадокс разрешил в 1971 году Вайнштейн [8]. Он обнаружил, что в теории доктора Г. масштаб расстояний в гравитационном поле вокруг тела массой M равен

$$f_V = \left(\frac{GM}{m_G^4}\right)^{\frac{1}{5}}$$

[8] A. I. Vainshtein, Phys. Lett. 39B:393, 1977; см. также C. Defayet. G. Dvali. G. Gabadadze. and A. I. Vainshtein, Phys. Rev. D65:044026, 2002. 0-спиральная степень свободы становится эффективной лишь на масштабах расстояний $r \gg r_V$. В пределах радиуса Вайнштейна r_V гравитационное поле идентично полю в теории Эйнштейна, и результаты экспериментов для теорий Эйнштейна и доктора Г. ничем не отличаются между собой. Если использовать текущий астрофизический предел $m_G \ll (10^{24}\text{ cm})^{-1}$ и массу Солнца для параметра M, значение r_V окажется гораздо больше размера Солнечной системы. Иначе говоря, парадокс обуславливается заменой пределов: сначала можно устремить к бесконечности либо характеристическое

расстояние измерения $r_{\text{изм.}}$ (радиус Солнца при отклонении света звезд),

либо радиус Вайнштейна r_V.

Итак, все хорошо: теория доктора Г. не противоречит результатам измерений, если он выберет m_G достаточно малой. Что ему не нельзя делать в этой теории, так это использовать приближение одногравитонного обмена. Вместо этого ему следует решать массовный аналог эйнштейновского уравнения поля (4) вблизи массивного тела, например Солнца, что и проделал в 1972 году Вайнштейн. Данный подход эквивалентен разложению в ряд по гравитонному полю h до всех порядков и повторному суммированию: у нас есть бесконечное количество фейнмановских диаграмм, соответствующих испусканию Солнцем $1, 2, 3, ..., \infty$ гравитонов соответственно. Парадокс формально разрешается вследствие того, что при $m_G \to 0$ высшие порядки по h становятся все более сингулярными.

Гравитационное взаимодействие света

На данном этапе вы готовы к расчетам в пертурбативной квантовой гравитации: у вас есть гравитонный пропагатор (12) и вы можете найти взаимодействия между гравитонами из детальной версии (7)) и взаимодействия между гравитоном и любым другим полем, которое задается членом $-\frac{1}{2}h_{\mu\nu}T^{\mu\nu}$. Единственной трудностью может послужить «целое море индексов», среди которых вы легко запутаетесь, если не будете особо бдительными.

Мне известно одно вычисление (одно из моих любимых в теоретической физике), позволяющее запросто избавиться от индексов. Эйнштейн говорил, что свет отклоняется массивным объектом. Отсюда вопрос: происходит ли гравитационное отклонение света другим светом? Толман, Эренфест и Подольский пришли к выводу, что в пределе слабого поля два луча света, падающие в одном направлении, не взаимодействуют гравитационно, а два луча света, падающие в противоположных направлениях, взаимодействуют. Удивительно, не правда ли? Рассеяние двух фотонов $k_1 + k_2 \to p_2 + p_2$ за счет обмена гравитоном описывается фейнмановской диаграммой на рис. VIII.1.2, где $q \equiv p_1 - k_1$ - перенос импульса, и другой диаграммой, в которой p_1 и p_2 поменяны местами. Правило Фейнмана, описывающее взаимодействие гравитона с двумя фотонами, получается из уравнения

$$h^{\mu\nu}T_{\mu\nu} = -h^{\mu\nu}\left(F_{\mu\lambda}F^{\lambda}_{\nu} - \frac{1}{4}\eta_{\mu\nu}F_{\rho\lambda}F^{\rho\lambda}\right).$$

Нас интересует только то обстоятельство, что взаимодействие включает в себя пространственно-временные производные второй степени ∂, действующие на электромагнитное поле A_μ, так что вершина гравитон-фотон-фотон содержит импульс во второй степени, по одному на каждый фотон. Таким образом, амплитуда рассеяния (без учета лоренцевых индексов) схематично равна $\sim (k_1p_1)\, D\, (k_2p_2)$. Параметр η в гравитонном пропагаторе D связывает между собой индексы от (k_1p_1) и (k_2p_2). (Мы опустили векторы поляризации фотонов, поскольку они усредняются в выражении для квадрата амплитуды.) С учетом (12) видим, что амплитуда равна сумме трех членов: $\sim (k_1 \cdot p_1)(k_2 \cdot p_2)/q^2, \sim (k_1 \cdot k_2)(p_1 \cdot p_2)/q^2$ и $\sim (k_1 \cdot p_2)(k_2 \cdot p_1)/q^2$. Вследствие того что, согласно Фурье, составляющая потенциала взаимодействия, описывающая взаимодействие на длинных расстояниях, определяется поведением амплитуды рассеяния при малом значении q, достаточно найти эти члены в пределе $q \to 0$. От них почти ничего не остается. Смотрите:

$$k_1 \cdot p_1 \to k_1 \cdot k_1 = 0, \quad k_1 \cdot p_2 = k_1 \cdot (k_1 + k_2 - p_1) \to k_1 \cdot k_2.$$

Получаем амплитуду $\sim (k_1 \cdot k_2)(p_1 \cdot p_2)/q^2$.

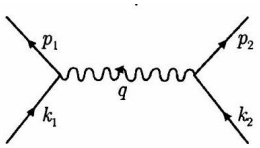


Рис. VIII. 1.2

Если направления k_1 и k_2 совпадают, то $k_1 \cdot k_2 \propto k_1 \cdot k_1 = 0$. Два фотона, движущихся в одном направлении, не взаимодействуют гравитационно.

К сожалению, полученный результат не представляет никакой практической пользы, поскольку электромагнитные эффекты в жизни имеют гораздо большее значение, но эта книга не является руководством для инженеров. В приложении 1 приводится другой вывод этого удивительного результата.

Компактификация Калуцы-Клейна

Вы, должно быть, читали, какое сильное впечатление произвело на Эйнштейна предложение Калуцы и Клейна расширить пространство-время до пяти измерений и тем самым объединить электромагнетизм с гравитацией. Пятое измерение считается компактифицированным на малую окружность с радиусом a, невидимым глазу экспериментатора; другими словами, x^5 есть угловая переменная, такая что $x^5 = x^5 + 2\pi a$. Я уверен, вы слышали, что теория струн, по крайней мере в оригинальной версии, построена на идее Калуцы-Клейна. Струны живут в 10-мерном пространстве-времени, шесть из которых компактифицированы.

Теперь продемонстрирую, как работает механизм Калуцы-Клейна. Начнем с действия в 5-мерном пространстве-времени

$$S = \frac{1}{16\pi G_5}\int d^5x\sqrt{-g_5}R_5$$

Подстрочный индекс 5 служит для обозначения 5-мерных величин. Индексы A и B 5-мерной метрики g_{AB} могут принимать значения $0, 1, 2, 3, 5$.

Пусть метрика g_{AB} не зависит от x^5. Подставим ее в выражение для S, проинтегрируем по x^5 и вычислим эффективное 4-мерное действие. Поскольку R_5 и 4-мерная скалярная кривизна R содержат производную ∂ второй степени, а g_{AB} содержит $g_{\mu\nu}$, имеем (упражнение VIII.1.5) $R_5 = R + ...$. Таким образом, уравнение (15) описывает действие Гильберта-Эйнштейна с ньютоновской гравитационной константой $G \sim G_5/a$.

Что еще мы получаем? Нам далее не нужно делать никаких выкладок. Воспользуемся симметриями. Для 5-мерного координатного преобразования $x^A \to x^A = x^A + \varepsilon^A(x)$ справедливо [см. (8)] $h'_{AB} = h_{AB} - \partial_A\varepsilon_B$ - $-\partial_B\varepsilon_A$. Пусть $\varepsilon_\mu = 0$, а $\varepsilon_5(x)$ не зависит от x_5: мы чуть-чуть поворачиваем каждую из малых окружностей, прикрепленных ко всем точкам нашего пространства-времени. Итак, имеем $h'_{\mu\nu} = h_{\mu\nu}$ и $h'_{55} = h_{55}$, но $h'_{\mu5} = h_{\mu5}$ - $-\partial_\mu\varepsilon_5$. Если назвать лоренцев 4-вектор $h_{\mu5}$ и 4-скаляр ε_5 н A_μ и Λ, получим обычное электромагнитное калибровочное преобразование $A'_\mu = A_\mu - \partial_\mu\Lambda$.

Известно, что 5-мерное действие (15) инвариантно относительно преобразования $x^A \to x^A = x^A + \varepsilon^A(x)$. Отсюда следует, что 4-мерное действие должно быть инвариантно относительно $A_\mu \to A'_\mu = A_\mu - \partial_\mu\Lambda$ и потому содержать действие Максвелла. Еще раз обращаю ваше внимание на эффективность симметрийных аргументов, которая позволяет избежать громоздких вычислений.

Электромагнетизм возникает из гравитации!

Дифференциальная геометрия римановых многообразий

Ранее я указывал на глубокую связь между общим координатным преобразованием и калибровочным преобразованием. Поясним это утверждение на примере дифференциальной геометрии и гравитации. Здесь мы будем рассматривать локальные евклидовы пространства (а не пространства Минковского).

Дифференциальная геометрия риманова многообразия может быть изящно описана в терминах дифференциальньх форм. Рассмотрим риманово многообразие (например, сферу) с метрикой $g_{\mu\nu}(x)$. По определению, многообразие является локально евклидовым, т. е.

$$g_{\mu\nu}(x) = e^a_\mu(x)\delta_{ab}e^b_\nu(x)$$

где матрицу $e(x)$ можно рассматривать в качестве преобразования подобия, которое диагонализирует матрицу $g_{\mu\nu}$ и масштабирует ее до единичной матрицы. Следовательно, для D-мерного многообразия существует D «мировых векторов» $e^a_\mu(x)$, зависящих от x и обозначаемых индексами $a = 1, 2, ..., D$. Функции $e^a_\mu(x)$ называют «тетрадами» (многоножками понемецки) (тетрадами для $D = 4$, триадами для $D = 3$ и т. д.). В некотором смысле тетрады можно считать «квадратным корнем» из метрики.

Поясним на простом примере. Обычная 2-сфера (единичного радиуса) характеризуется линейным элементом [9]$ds^2 = d\theta^2 + \sin^2\theta d\varphi^2$. Из метрики $\left(g_{\theta\theta} = 1, g_{\varphi,\varphi}\sin^2\theta\right)$ следует, что $e^1_\theta = 1$ и $e^2_\varphi = \sin\theta$ (все остальные компоненты равны нулю). Теперь определим 1-формы $e^a = e^a_\mu dx^\mu$ в количестве D. (В нашем примере $e^1 = d\theta, e^2 = \sin\theta d\varphi$.)

На искривленном многообразии, при параллельном переносе, вектор в локальной евклидовой системе координат меняет свои координаты. (Нам уже знакомо утверждение, согласно которому на искривленном многообразии, подобном поверхности Земли, понятие вектора, направленного строго на север, является локальным: если продвинуться на бесконечно малое расстояние вдоль нашего «северного вектора», придерживаясь первоначального направления, то в результате мы повернемся на бесконечно малый угол относительно «северного вектора», заданного в точке, из которой мы только что вышли.) Этот инфинитезимальный поворот тетрад описывается уравнением:

$$de^a = -\omega^{ab}e^b$$

9 Замечу, что он представляет из себя квадрат бесконечно малопо элемента расстояния, а не элемент площади, т. е. величина $d\theta^2$ есть буквально квадрат $d\theta$, а не антисимметризованное произведение $d\theta d\theta$ (из главы IV.4), тождественно равное нулю. Обратите внимание, что ω является антисимметричной матрицей, поскольку осуществляет инфинитезимальный поворот: $\omega^{ab} = -\omega^{ba}$. Поскольку de^a есть 2-форма, то ω будет 1-формой, называемой связностью: она «связывает» локальные евклидовы системы координат в соседних точках. (Индексы a, b и т. д. ассоциируются с евклидовой метрикой δ_{ab}, поэтому мы не проводим различий между верхними и нижними индексами. Символы a, b и т. д. в качестве верхних или нижних индексов используются из соображений типографического удобства.) В простом примере со сферой $de^1 = 0$ и $de^2 = \cos\theta d\theta$, поэтому связность имеет только одну ненулевую компоненту $\omega^{12} = -\omega^{21} = -\cos\theta d\varphi$.

Мы можем свободно вращать тетрады в любой точке пространства. Если вы используете функции e^a_μ, я могу использовать вместо них другие функции e'^a_μ, так как мои функции связаны с вашими поворотом $e^a_\mu(x) = O^a_b(x)e'^b_\mu(x)$. [Убедитесь, что $g_{\mu\nu}(x) = e^a_\mu(x)\delta_{ab}e^b_\nu(x) = e'^a_\mu(x)\delta_{ab}e'^b_\nu(x)$ при условии, что $O^TO = 1$.] Связность ω' задается как $de'^a = -\omega'^{ab}e'^b$. Проверьте (опустив индексы), что

$$\omega = O\omega'O^T - (dO)O^T.$$

Локальная кривизна многообразия является мерой того, как меняется связность от точки к точке. Нам бы хотелось, чтобы кривизна была инвариантна относительно локального вращения O (или, по крайней мере, чтобы она преобразовывалась как тензор и, сворачиваясь с векторами, давала скаляр.) Этому условию удовлетворяет 2-форма $R^{ab} = d\omega^{ab} + \omega^{ac}\omega^{cb}$. Проверьте, что $R = OR'O^T$. (Для сферы имеем $R^{12} = d\omega^{12} + \omega^{1c}\omega^{c2} = \sin\theta d\theta d\varphi$.) Если записать в компонентах, получим $R^{ab} = R^{ab}_{\mu\nu}dx^\mu dx^\nu$. Попробуйте самостоятельно проверить, что $R^{ab}_{\mu\nu}\lambda^\lambda_a e^\sigma_b$ - обычный тензор кривизны Римана $R^{\lambda\sigma}_{\mu\nu}$, в котором e^λ_a - матрица, обратная матрице e^a_λ. В частности, $R^{ab}_{\mu\nu}e^\mu_a e^\nu_b$ есть скалярная кривизна, равная для сферы $+1$.

Таким образом, риманову геометрию можно элегантно описать двумя выражениями (снова опуская индексы):

$$de + \omega e = 0$$

Y

$$R = d\omega + \omega^2$$

Кажется знакомым? Вы, должно быть, поражены тому, что (20) выглядит так же, как напряженность поля в неабелевых калибровочных теориях $F = dA + A^2$. Замечу, что ω преобразовывается [см. выражение (20)] в точности так же, как калибровочное поле A. Но одно различие, а именно отсутствие в калибровочной теории аналога e, долго беспокоило

физиков-теоретиков (но признанное в конце концов большинством как несущественное).Также не забывайте, что теория Эйнштейна линейна по R, тогда как теория Янга-Миллса квадратична по F.

В завершение сделаю одно техническое замечание, касающееся взаимодействия гравитации и полей спина $\frac{1}{2}$. Сначала мы, естественно, должны осуществить виковский поворот, чтобы тетрада e^a_μ относилась не к евклидовой, а локальной системе координат Минковского. Индексы a, b и т. д. теперь сворачиваются с метрикой Минковского η_{ab}. Тонкость состоит в том, что дираковские гамма-матрицы γ^a ассоциируются с лоренцевым поворотом тетрады $e^a_\mu(x) = O^a_b(x)e'^b_\mu(x)$ и, следовательно, несут лоренцев индекс a, вместо «мирового» индекса μ. Таким образом, дираковское действие в плоском пространстве $\int d^4x\bar{\psi}\left(i\gamma^\mu\partial_\mu - m\right)\psi$ должно быть обобщено до вида $\int d^4x\sqrt{-g}\bar{\psi}\left(i\gamma^a\eta_{ab}e^b_\mu g^{\mu\nu}\partial_\nu - m\right)\psi$. В отличие от действия для полей с целым спином в искривленном пространстве-времени (см. главу I.10), дираковское действие в искривленном пространстве-времени явным образом включает в себя тетраду.

Приложение 1. Свет на свете

Тензор энергии импульса $T^{\mu\nu}$ светового луча, движущегося в x-направлении, имеет четыре ненулевые компоненты: плотности энергии T^{00}, затем $T^{0x} = T^{00}$ вследствие того, что фотоны несут одну энергию и импульс, затем $T^{x0} = T^{0x}$ вследствие симметрии и, наконец, $T^{xx} = T^{00}$ вследствие того, что тензор энергии импульса электромагнитного поля дается матрицей с нулевым следом (глава I.10). Даже не решая уравнения Эйнштейна в пределе слабого поля (уравнение (13)), мы знаем, что $h^{00} = h^{0x} = h^{x0} = h^{xx} \equiv h$. Вокруг светового луча задается метрика $g_{00} = 1 + h, g_{0x} = g_{x0} = -h$ и $g_{xx} = -1 + h$ (и, естественно, $g_{yy} = g_{zz} = -1$; остальные компоненты равны нулю). Рассмотрим фотон, движущийся параллельно световому лучу. Его мировая линия определяется выражением (см. главу I.10):

$$\frac{d^2x^\rho}{d\zeta^2} = -\Gamma^\rho_{\mu\nu}\frac{dx^\mu}{d\zeta}\frac{dx^\nu}{d\zeta}$$

Вычислим $d^2y/d\zeta^2$ и $d^2z/d\zeta^2$ при условии $(dy/d\zeta), (dz/d\zeta) \ll (dt/d\zeta), (dx/d\zeta)$. Используя (3), находим (μ, ν принимают значения только $0, x$)

$$\begin{aligned}\frac{d^2y}{d\zeta^2} =& \frac{1}{2}\left(\partial_\nu g_{y\mu} + \partial_\mu g_{y\nu} - \partial_y g_{mu\nu}\frac{dx^\mu}{d\zeta}\frac{dx^\nu}{d\zeta}\right) = \\ &= -\frac{1}{2}\left(\partial_y h\right)\left[\left(\frac{dt}{d\zeta}\right)^2 + \left(\frac{dx}{d\zeta}\right)^2 - 2\frac{dt}{d\zeta}\frac{dx}{d\zeta}\right] = -\frac{1}{2}\left(\partial_y h\right)\left(\frac{dt}{d\zeta} - \frac{dx}{d\zeta}\right)^2\end{aligned}$$

Для фотона, движущегося в одном направлении с лучом света, $dt = dx$ и $d^2y/d\zeta^2 = d^2z/d\zeta^2 = 0$. Мы снова получили эффект Толмана-Эренфеста-Подольского. Обратите внимание, что мы не вычисляли при этом h.

Если вы сомневаетесь в справедливости $dt = dx$, то знайте, что условие $ds = 0$ для луча света, падающего в направлении x, сводится к виду $(1 + h)dt^2 - 2hdtdx$ - $-(1 - h)dx^2 = 0$. Делением на dt^2 получаем $-(1 + h) + 2hv + (1 - h)v^2 = 0$, где $v \equiv dx/dt$. У квадратного уравнения два корня $v = \mp(1 \pm h)/(a - h)$. Отрицательный корень дает $v = 1$, поэтому для фотона, движущегося в одном направлении с лучом света, $dx/dt = 1$. Положительный корень дает $v = -(1+ +h)/(1 - h)$, что соответствует случаю, когда фотон движется в противоположном направлении.

Приложение 2. Спиральная структура гравитации

Чтобы еще глубже понять разницу между теориями Эйнштейна и доктора Г., обратим внимание на спиральную структуру взаимодействия в двух случаях. Сначала рассмотрим взаимодействие между двумя сохраняющимися токами, обусловленное обменом частицей со

спином 1, импульсом k и массой m : $J^{\mu}_{(1)}J_{(2)\mu} = J^{0}_{(1)}J^{0}_{(2)}$ - - $J^{i}_{(1)}J^{i}_{(2)}$. Воспользуемся сохранением тока $k_\mu J^\mu = 0$, чтобы исключить $J^0 = k^i J^i/\omega$ (где $\omega \equiv k^0$). Получаем $\left(k^i k^j/\omega^2 - \delta^{ij}\right) J^i_{(1)} J^j_{(2)}$. Примем, что направление вектора $\vec{k}$ совпадает с направлением 3, выразим $\vec{k}^2 = \omega^2 - m^2$ и перепишем выражение в виде $-\left[\left(m^2/\omega^2\right) J^3_{(1)}J^3_{(2)} + J^1_{(1)}J^1_{(2)} + J^2_{(1)}J^2_{(2)}\right]$. Видим, что при $m \to 0$ продольная компонента тока J^3 действительно отщепляется, как было объяснено в главе II.7, и мы получаем $-\frac{1}{2}\left(J^{1+i2}_{(1)}J^{1-i2}_{(2)} + J^{1-i2}_{(1)}J^{1+i2}_{(2)}\right)$. Отсюда следует, что фотон имеет спиральность \pm 1. (Мы сделали очевидное обозначение: $J^{1+i2} \equiv J^1 + iJ^2$ и т. д.) Обратимся к гравитации. Рассмотрим взаимодействие $T^{\mu\nu}_{(1)}T_{(2)\mu\nu} - \xi T_{(1)}T_{(2)}$, где $\xi = \frac{1}{2}$ в теории Эйнштейна и $\xi = \frac{1}{3}$ в теории доктора Г. Для упрощения записи опустим индексы (1) и (2). Условие сохранения $k_\mu T^{\mu\nu} = 0$ позволяет нам исключить $T^{0i} = k^j T^{ji}/\omega$ и $T^{00} = k^j k^l T^{jl}/\omega^2$. Примем, что направление вектора $\vec{k}$ совпадает с направлением 3, тогда получим громоздкое выражение

$$\left(\frac{m}{\omega}\right)^4 T^{33}T^{33} + 2\left(\frac{m}{\omega}\right)^2 \left(T^{13}T^{13} + T^{23}T^{23}\right) + T^{11}T^{11} + T^{22}T^{22} + 2T^{12}T^{12} - \\ - \xi\left[\left(\frac{m}{\omega}\right)^2 T^{33} + T^{11} + T^{22}\right]\left[\left(\frac{m}{\omega}\right)^2 T^{33} + T^{11} + T^{22}\right]$$

которое в пределе $m \to 0$ упрощается до:

$$T^{11}T^{11} + T^{22}T^{22} + 2T^{12}T^{12} - \xi\left(T^{11} + T^{22}\right)\left(T^{11} + T^{22}\right).$$

В теории Эйнштейна $\xi = \frac{1}{2}$, поэтому выражение принимает вид:

$$\frac{1}{2}\left(T^{11} - T^{22}\right)\left(T^{11} - T^{22}\right) + 2T^{12}T^{12}$$

и в конечном итоге - вид $\frac{1}{2}\left(T^{1+i2,1+i2}T^{1-i2,1-i2} + T^{1-i2,1-i2}T^{1+i2,1+i2}\right)$, что доказывает следующее: гравитон действительно несет спиральность \pm 2.

Упражнения

VIII.1.1. Найдите $T^{\mu\nu}$ для скалярного поля. Нарисуйте фейнмановскую диаграмму, описывающую вклад одногравитонного обмена в рассеяние двух скалярных мезонов. Вычислите амплитуду и энергию взаимодействия между двумя мезонами, находящимися в состоянии покоя, получив тем самым ньютоновский закон гравитации.

VIII.1.2. Найдите $T^{\mu\nu}$ дя поля Янга-Миллса.

VIII.1.3. Покажите, что если $h_{\mu\nu}$ не удовлетворяет гармонической калибровке, всегда можно осуществить калибровочное преобразование при условии, что ε_ν определяется выражением $\partial^2\varepsilon_\nu = \partial_\mu h^\mu_\nu - \frac{1}{2}\partial_\nu h^\lambda_\lambda$. После этого $h_{\mu\nu}$ будет удовлетворять гармонической калибровке. Все это вам уже известно из курса электродинамики.

VIII.1.4. Подсчитайте количество степеней поляризации гравитона. [Указание: рассмотрите плоскую волну $h_{\mu\nu}(x) = h_{\mu\nu}(k)e^{ikx}$, поскольку работать в пространстве импульсов несколько легче. Симметричный тензор имеет 10 компонент, а гармоническая калибровка $k_\mu h^\mu_\nu = \frac{1}{2}k_\nu h^\lambda_\lambda$ накладывает 4 условия. Как так, у нас осталось 6 степеней свободы. Что происходит?] [Указание: продолжите калибровочное преобразование и останьтесь в гармонической калибровке. Гравитон должен иметь всего 2 степени поляризации.]

VIII.1.5. Результат Калуцы-Клейна, к которому мы пришли, из симметрийных соображений, можно получить явным вычислением. Предлагаю вам следующий план действий. Рассмотрите метрику

$$ds^2 = g_{\mu\nu}dx^\mu dx^\nu - a^2\left[d\theta + A_\mu(x)dx^\mu\right]^2$$

где θ - угловая переменная, $0 \leqslant \theta < 2\pi$. При $A_\mu = 0$ она соответствует метрике искривленного пространства-времени, к каждой точке которого прикреплена окружность радиуса a. Преобразование $\theta \to \theta + \Lambda(x)$ оставляет ds инвариантным при условии, что мы также преобразовываем $A_\mu(x) \to A_\mu(x) - \partial_\mu \Lambda(x)$. Вычислите 5-мерную скалярную кривизну R_5 и докажите, что $R_5 = R_4 - \frac{1}{4}a^2 F_{\mu\nu}F^{\mu\nu}$. Если не считать коэффициента $\frac{1}{4}$, полученный результат полностью совпадает с результатом, полученным на основе соображений симметрии и того факта, что R_5 включает две производные по 5-мерной метрике. После подходящего масштабирования получаем обычное действие для гравитации плюс электромагнетизм. Обратите внимание, что 5-мерная метрика в явном виде равна

$$g^5_{AB} = \begin{pmatrix} g_{\mu\nu} - a^2 A_\mu A_\nu & -a^2 A_\mu \\ -a^2 A_\nu & -a^2 \end{pmatrix}$$

VIII.1.6. Обобщите схему Калуцы-Клейна, заменив окружности сферами большей размерности. Покажите, что появляются поля Янга-Миллса.

VIII.1.7. Тетрады для пространства-времени с метрикой Минковского задаются в виде $g_{\mu\nu}(x) = e^a_\mu(x)\eta_{ab}e^b_\nu(x)$, где метрика Минковского η_{ab} используется вместо евклидовой метрики δ_{ab}. Индексы a и b следует сворачивать с η_{ab}. Например, $R^{ab} = d\omega^{ab} + \omega^{ac}\eta_{cd}\omega^{ab}$. Покажите, что все, как и ожидалось, работает.

30.5.3 Zi.VIII.2 The Cosmological Constant Problem and the Cosmic Coincidence Problem

Сила, которая слишком много знает

Понятие парадокса обесценено неправильным употреблением в физической литературе. Настоящий парадокс должен содержать существенное и ясное расхождение между теоретическим предсказанием и экспериментальными данными. Ультрфиолетовая катастрофа, например, является парадоксом, решение которого на заре двадцатого века привело к созданию квантовой физики. Теперь поговорим о самом большом парадоксе современной физики.

Электромагнитная сила знает о частицах, несущих заряд, сильное взаимодействие знает о частицах, несущих цвет. А как насчет гравитационной силы? Она знает всех! Точнее, всех, кто несет энергию и импульс.

С точки зрения физики элементарных частиц, а именно с этой точки зрения мы исследуем фундаментальную структуру физики, гравитон можно рассматривать как еще одну частицу. Стартуя с безмассовой частицы со спином 2, взаимодействующей с тензором энергии импульса, можно воссоздать теорию Эйнштейна.

Однако такое представление мира оставляет у нас неоднозначные чувства. Гравитация имеет дело с кривизной пространства-времени, ареной в которой живут все поля и частицы. Гравитон не просто еще одна частица.

В этом состоит суть и корень парадокса космологической постоянной. Гравитон не просто частица - он слишком много знает!

Космологическая постоянная

В отсутствие гравитации добавление константы Λ в лагранжиан $\mathcal{L} \to \mathcal{L} - \Lambda$ ни к чему не приводит. В классической физике уравнения движения Эйлера-Лагранжа зависят исключительно от вариации лагранжиана. В квантовой теории поля нужно вычислять интеграл по траекториям $Z = \int D\varphi e^{i\int d^4x \mathcal{L}(x)}$, который после добавления Λ просто умножается на множитель. Мы неоднократно видели, что мультипликативный фактор Z не участвует в вычислениях функции Грина и амплитуд рассеяния.

Гравитация, однако, знает о Λ. С физической точки зрения включение Λ соответствует сдвигу в гамильтониане $H \to H + \int d^3x \Lambda$. Следовательно, «космологическая постоянная» Λ

характеризует постоянную энергию или массу на единицу объема, проникающую во Вселенную, и, естественно, гравитация ее знает.

С технической точки зрения член $-\int d^4x\Lambda$ в действии, не инвариантен относительно координатного преобразования $x \to x'(x)$. Если учитывать гравитацию, то вследствие инвариантности относительно общего координатного преобразования член $-\int d^4x\Lambda$ в выражении для действия S должен модифицироваться к виду $-\int d^4x\sqrt{g}\Lambda$, как говорилось в главе I.10. Таким образом, гравитационное поле $g_{\mu\nu}$ знает о Λ, печально известной космологической постоянной, введенной Эйнштейном, который сам считал ее самой большой своей ошибкой. Но ссылаться на его слова будет само по себе ошибкой. Введение космологической постоянной не является ошибкой, она должна присутствовать.

Нарушение симметрии генерирует энергию вакуума

В нашем обсуждении спонтанного нарушения симметрии мы все время пренебрегали членом $\mu^4/4\lambda$, появляющимся в лагранжиане.

Физика элементарных частиц построена на ряде спонтанных нарушений симметрии. По мере охлаждения Вселенной происходит спонтанное нарушение симметрии великого объединения, за которой следует нарушение электрослабой симметрии, киральной симметрии (это только из тех видов симметрии, которые мы обсуждали). На каждой стадии в лагранжиане появляется член вида $\mu^4/4\lambda$, что не остается не замеченным гравитацией.

Насколько большой должна быть космологическая постоянная? Далее мы увидим, что для наших целей достаточно использовать самое грубое приближение. Пусть значение λ имеет порядок 1. Что касается параметра μ, то для трех упомянутых мною нарушений симметрии его значение будет порядка $10^{17}, 10^2$ и 1 ГэВ соответственно. Отсюда величину космологической постоянной Λ можно принять равной $\mu^4 = \mu/\left(-\mu^{-1}\right)^3$. Последняя форма записи μ^4 отражает тот факт, что Λ есть плотность массы или энергии: энергия порядка μ содержится в кубе размером μ^{-1}. Однако данная оценка слишком преувеличена, даже если использовать наименьшее значение для μ. Мы знаем, что плотность массы Вселенной вовсе не порядка 1 ГэВ на каждый куб, размером $1\,(\Gamma\ \text{В})^{-1}$. Нам не нужны реальные значения, чтобы увидеть, что между теоретическими оценками и экспериментальными данными существует огромная разница. Если вам нужны числа, скажу, что существующее экспериментальное ограничение сверху равно $\lesssim (10^{-3}\ \text{В})^4$. С масштабом великого объединения мы ошибаемся на $(17+9+3)\times 4 = 116$ порядков. В этом кроется причина всех расхождений!

С массой Планка $M_{Pl} \sim 10^{19}$ ГэВ, естественным масштабом гравитации и допуская гравитационное происхождение космологической постоянной, можно ожидать, что $\Lambda \sim M_{Pl}^4$. Теперь мы расходимся на 124 порядка. Мы говорим не об ординарном вычислении какого-нибудь несчастного теоретика, у которого расхождение с экспериментальными данными в 2 раза.

Мы можем представить, что, Вселенная, возникшая с отрицательным значением космологической постоянной, тонко подстраивается рядом спонтанных нарушений симметрии так, что космологическая постоянная зануляется. Либо должен существовать динамический механизм, который подстраивает космологическую постоянную к нулю.

Обратите внимание, что я говорю «к нулю», потому что задача о космологической постоянной обуславливается несоответствием между естественными единицами в космологии и единицами, естественными в физике элементарных частиц. Если измерять космологическую постоянную в ГэВ, то она окажется настолько крошечной, что специалисты в области физики элементарных частиц должны бы традиционно принять, что она должна быть равной нулю, и вели напрасные поиски правдоподобного механизма ее зануления. Одним из недостатков теории струн является неразрешимость с ее помощью проблемы космологической постоянной. При написании этой главы около 2000 г. появились сценарии бранных миров, которые дали нам надежду на решение проблемы. Грубо говоря, идея состоит в том, что гравитационная динамика большего пространства, куда вложена наша вселенная, может сократить эффект космологической постоянной.

Космическое совпадение

Природа приготовила нам большой сюрприз. В то время, когда теоретики пытались найти выход из затруднительного положения поиском аргументов почему $\Lambda = 0$, специалисты по наблюдательной космологии последовательно уточняли свои измерения и недавно заменили ограничение сверху на примерное значение

$$\Lambda \sim \left(10^{-3}\text{эВ}\right)^4 !!!$$

Парадокс космологической постоянной еще более усугубился. Теоретически нам легче объяснить, почему какая-то величина равна строго нулю, чем тот факт, почему она оказывается равной $\sim 10^{-124}$ в естественных (?) для этой проблемы единицах.

Хуже того, значение $(10^{-3}$ эВ $)^4$ имеет тот же порядок, что и плотность материи во Вселенной ρ_M сегодня. Это явление иногда называют проблемой космического совпадения.

На сегодняшний день космологическую постоянную Λ мы считаем параметром лагранжиана. С другой стороны, поскольку большая часть плотности Вселенной складывается из массы барионов, то по мере расширения Вселенной значение $\rho_M(t)$ уменьшается по закону $[1/R(t)]^3$, где R - масштаб Вселенной [1]. В далеком прошлом значение ρ_M было гораздо больше Λ, а в отдаленном будущем оно будет гораздо меньше, чем Λ. Так уж сложилось, что мы с вами живем в эпоху такой Вселенной, когда $\rho_M \sim \Lambda$. Или менее антропоцентрично, скажу, что эпоха $\rho_M \sim \Lambda$ совпадает по времени с завершающей стадией образования галактики.

Очень странно!

В отчаянии некоторые теоретики вынуждены даже опираться на антропный принцип.

'Простое введение в космологию читайте в книге А.Зи (A.Zee. Unity of Forces in the Universe, vol.II, chap.10).

30.5.4 Zi.VIII.3 Effective Field Theory as an Approach to Understanding Nature

Низкоэнергетическое проявление

Основоположники квантовой теории поля, например Дирак, склонны были рассматривать теорию поля как внутренне замкнутое фундаментальное описание Природы. Я уже неоднократно упоминал, что в 1950-х гг. после успеха квантовой электродинамики многие ведущие физики в области элементарных частиц отказались от квантовой теории поля, как неспособной описать сильное и слабое взаимодействия, не говоря уж о гравитации. Затем в начале 1970-х гг. наступил великий триумф теории поля. Но после того как теоретики достали теорию поля из мусорного пакета теоретческой физики, они осознали, что теории поля, которые они изучали, могут быть всего лишь низкоэнергетическим проявлением более глубокой структуры, которую сначала отождествляли с теорией великого объединения и позже с теорией струн. Так была развита точка зрения, известная как эффективная теория поля, с позволения Дирака.

В основе подхода лежит идея, согласно которой мы можем использовать теорию поля для описания, скажем, физики низких энергий или, что тоже самое, физики больших расстояний даже в том случае, если не имеем представлений о всеобщей теории, будь то теория струн или любая другая неизвестная теория. Важным следствием этого изменения парадигмы явился тот факт, что неперенормируемые теории теперь стали приемлемыми. Я проиллюстрирую эти соображения на частных примерах.

Появление философии эффективной теории поля, развитой Вильсоном, стало еще одним примером «перекрестного опыления» между физикой конденсированного состояния и физикой элементарных частиц.

К концу 1960-х гг. Вильсон совместно с другими учеными разработали мощный подход к пониманию критических явлений, основанный на эффективной теории поля. За свой труд

он был удостоен Нобелевской премии. Ситуация в физике конденсированных сред во многом противопо- ложна ситуации в физике элементарных частиц, по крайней мере так, как она понималась в 1960-е годы. Физики, занимающиеся конденсированным состоянием, знают физику на малых расстояниях - квантовую механику электронов и ионов. Но, конечно, уравнение Шредингера для электронов и ионов не помогает решить задачу. Напротив, хотелось бы иметь эффективное описание того, как система откликнется на пробные воздействия с малой частотой и волновым вектором. Ярким примером является эффективная теория квантовой холловской жидкости (глава VI.2). Релевантная степень свободы - калибровочное поле совсем не похоже на лежащий в основе электрон. Следует отметить, как и при σ-модельном описаний квантовой хромодинамики (глава VI.4), без экспериментальной поддержки теоретику было бы ужасно тяжело выяснить, какие будут релевантные низкоэнергетические степени свободы. Вы видели и другие многочисленные примеры в физике конденсированного состояния, начиная с теории сверхпроводимости Гинзбурга-Ландау и заканчивая неустойчивостью Пайерлса.

Граница неведения

В нашем обсуждении перенормировок моя философия состояла в том, что квантовая теория поля обеспечивает эффективное описание физических явлений до определенного масштаба энергии Λ-границы неведения. В неперенормируемой теории многие физические величины, которые мы бы хотели вычислить, оказываются зависимыми от Λ. Это означает, что для понимания физики низких энергий, которую мы исследуем, существенной в этом случае оказывается физика за пределами масштаба Λ. Недостатком неперенормируемых теорий является их неполная предсказательность, тем не менее они могут оказаться полезными. В конце концов, теория слабых взаимодействий Ферми смогла описать результаты экспериментов и даже предсказать свою собственную гибель.

В перенормируемой теории физические величины оказываются не зависящими от Λ, если выразить результаты вычислений через физические константы связи и физические массы, а не в терминах ничего не значащих затравочных констант связи и затравочных масс. Низкоэнергетическая физика не чувствительна к тому, что происходит на высоких энергиях, поэтому мы параметризуем наше отсутствие знаний в отношении высоэнергетической физики с помощью нескольких физических констант.

С конца 1960-х гг. до 1970-х гг. одной из главных задач фундаментальной физики была классификация и исследование перенормируемых теорий. Мы знаем, что ее итоги оказались «более чем впечатляющими». Она позволила нам установить теорию сильных, слабых и электромагнитных взаимодействий.

Ренорм-групповой поток и анализ размерностей

Философия эффективной теории поля неразрывно связана ренормгрупповым потоком. Для данной теории поля, если мы движемся в сторону низких энергий, одни константы связи стремятся к нулю, а другие нет (если они при этом стремятся к бесконечности, как в КХД, нам не удается построить эффективную теорию без использования экспериментальных данных). Таким образом, на первом шаге необходимо вычислить ренорм-групповой поток. Простой пример дается в упражнении VIII.3.1.

Во многих случаях мы можем просто воспользоваться анализом размерностей. Ранее, при обсуждении теории перенормировок, я говорил, что константы связи с отрицательной размерностью массы не важны в низкоэнергетическом пределе. Для определенности добавим член $g\varphi^6$ в теорию $\lambda\varphi^4$. Константа связи g имеет размерность, обратную квадрату массы. Определим $M^2 \equiv 1/g$. При низких энергиях вклад члена $g\varphi^6$ подавляется фактором $(E/M)^2$.

Как мы должны понимать вычисление Швингера аномального магнитного момента электрона в эффективной теории поля?

Сначала отвечу на вопрос с традиционной (довильсоновской) точки зрения. Допустим, студент спрашивает: «Профессор Швингер, почему вы не включили в лагранжиан член $(1/M)\bar{\psi}\sigma^{\mu\nu}\psi F_{\mu\nu}$?»

Профессор отвечает, что иначе мы не могли бы предсказать величину аномального магнитного момента, поскольку она бы зависела от M. Вспомним, что $[\psi] = \frac{3}{2}$ и $[A_\mu] = 1$. Следовательно, размерность $\bar{\psi}\sigma^{\mu\nu}\psi F_{\mu\nu}$ равна $\frac{3}{2} + \frac{3}{2} + 1 + 1 = 5 > 4$. Условие перенормируемости, при котором лагранжиан должен содержать лишь операторы размерности 4 или ниже, позволяет обоснованно исключить этот член.

На самом деле сам Швингер, наверное, не стал бы отвечать на поставленный вопрос. Всем известно, что тогда студентам было запрещено задавать вопросы. Швингер просто проигнорировал бы поднятую руку студента. И после занятий тоже не было возможности задать вопрос. Как только Швингер произносил последнее предложение своей неизменно блестяще подготовленной лекции, он величественно покидал аудиторию. Дирак иначе обходился с вопросами. Я был слишком молод и не мог быть тому свидетелем, но история гласит, что на фразы типа «Профессор Дирак, я не понимаю...» он отвечал: «Это не вопрос, а утверждение». Современное изложение сюжета об аномальном магнитном моменте сильно отличается. Сейчас мы рассматриваем лагранжиан квантовой электродинамики как эффективный лагранжиан, который должен включать в себя бесконечную последовательность членов все более высоких порядков с коэффициентами, параметризующими границу нашего неведения. Член $(1/M)\bar{\psi}\sigma^{\mu\nu}\psi F_{\mu\nu}$ тоже присутствует в лагранжиане с неизвестным коэффициентом M, имеющим размерность массы. Таким образом, результат Швингера, согласно которому квантовые флуктуации порождают член $(\alpha/2\pi)\,(1/2m_e)\,\bar{\psi}\sigma^{\mu\nu}\psi F_{\mu\nu}$, интерпретируется следующим образом: предсказанное значение аномального магнитного момента электрона равно $[(\alpha/2\pi)\,(1/2m_e) + 1/M]$. Хорошее совпадение $(\alpha/2\pi)\,(1/2m_e)$ с экспериментальным значением аномального магнитного момента позволяет установить ограничение снизу на $M \gg (4\pi/\alpha)m_e$.

Иначе, результат Швингера предсказывает аномальный магнитный момент электрона, если у нас есть независимые основания считать, что M гораздо больше $[(\alpha/2\pi)\,(1/2m_e)]^{-1}$. Особо обращаю ваше внимание, что все это имеет глубокий физический смысл. Например, если вы считаете, что электрон имеет конечный размер a, то можно ожидать, что $M \sim 1/a$. Вычисление аномального магнитного момента электрона дает верхнюю границу для a, т. е. электрон должен выглядеть как точка до некоторого малого масштаба. В качестве альтернативы мы можем иметь независимые основания полагать, например, из рассеяния электронов, что а должна быть меньше определенной длины. Отсюда следует ограничение снизу на M.

Чтобы подчеркнуть это место, представим, что в 1948 году мы, следуя Швингеру, быстро вычисляем аномальный магнитный момент протона. Мы можем сделать это буквально за 3 секунды, заменив в лагранжиане m_e на m_p и получив тем самым выражение $(\alpha/2\pi)\,(1/2m_p)\,\bar{\psi}\sigma^{\mu\nu}\psi F_{\mu\nu}$, которое в корне противоречит эксперименту. Такое противоречие говорит нам, что мы не в полной мере учли физику рассматриваемого явления, а именно что протон не точечный и сильно взаимодействует. Действительно, мы сейчас знаем, что в аномальный магнитный момент протона вносят вклады аномальные магнитные моменты кварков и их орбитальное движение внутри протона.

Эффективная теория распада протона

Может показаться, что в подходе на основе эффективной теории поля мы теряем предсказательную способность. Эффективные теории поля моIут также на удивление хорошо предсказывать результаты. Приведу один ример. Допустим, нам ничего не известно о теории великого объединения. Все, что мы знаем, - это $SU(3) \otimes SU(2) \otimes U(1)$-теория. Экспериментатор нам сообщил, что планирует проверить, распадается ли протон.

Без малейших представлений о том, что могло бы привести к распаду протона, мы все равно сможем записать теорию поля, описывающую его распад. Лагранжиан $\mathcal{L}$ должен содержать поля кварка q и лептона l, а также удовлетворять известным нам симметриям. Три кварка исчезают, так что схематично записываем qqq, но три спинора не образуют лоренцевый скаляр. Мы должны включить поле лептона и записать qqql.

Поскольку задействованы четыре фермионных поля, размерность члена $qqql$ равна 6 и в лагранжиан он входит в виде $(1/M^2)\,qqql$, где M некоторая масса, соответствующая масштабу

физических процессов, ответственных за распад протона. Экспериментальное ограничение снизу на время жизни протона устанавливает ограничение снизу на M.

Предположим, мы проводим анализ распада протона с помощью эффективной теории поля в докварковую эпоху. В этом случае мы построим лагранжиан из имеющихся полей, т. е. протонного поля p, электронного поля e и пионного поля π. В итоге получим что-то вроде $g\pi^-\bar{e}p$, где g - некоторая константа. Обратите внимание, что размерность $\pi^-\bar{e}p$ равна 4 и, следовательно, g безразмерна. Поскольку $\pi^-\bar{e}p$ нарушает изоспиновую инвариантность, можно предположить, что g порядка некоторой величины изоспинового нарушения, то есть порядка электромагнитной константы связи α, но которая, однако, дает неприемлемо короткое время жизни протона. Нам придется тогда положить g равным очень малому числу, что будет казаться неестественным. Таким образом, по крайней мере задним числом мы можем сказать, что исключительно большое время жизни протона почти указывает на существование кварков. (Можно ли решить подобным образом загадку космологической постоянной?)

Иначе говоря, $SU(3) \otimes SU(2) \otimes U(1)$-теория и ее перенормируемость позволяет предсказать одно из самых поразительных явлений Вселенной стабильность протона. Старая пион-нуклонная теория, напротив, очевидно, не смогла объяснить этот экспериментальный факт.

В соответствии с нашей философией, лагранжиан $\mathcal{L}$ должен быть инвариантен относительно группы $SU(3) \otimes SU(2) \otimes U(1)$, при которой поля кварка и лептона преобразуются довольно специфически (см. главу VII.5). Чтобы построить лагранжиан, нам придется сесть и выписать все лоренц-инвариантные члены $SU(3) \otimes SU(2) \otimes U(1)$ вида $qqql$.

За этим занятием мы обнаружим, что если для простоты рассмотреть только одно поколение кварков и лептонов, то распад протона будет описываться всего четырьмя членами, которые я приведу здесь для полноты: $\left(\tilde{l}_L C q_L\right)(u_R C d_R)$, $(e_R C u_R)\left(\widetilde{q}_L C q_L\right)$, $\left(\widetilde{l}_L C q_L\right)\left(\widetilde{q}_L C q_L\right)$ и $(e_R C u_R)(u_R C d_R)$. Здесь $l_L = \begin{pmatrix} \nu \\ e \end{pmatrix}_L$ и $q_L = \begin{pmatrix} u \\ d \end{pmatrix}_L$ обозначают дублеты лептона и кварка для $SU(2) \otimes U(1)$, знак тильды определяется как $\widetilde{l^j} = l_i \varepsilon^{ij}$ с $SU(2)$-индексами $i, j = 1, 2$ (см. приложение B), а C обозначает зарядово-сопряженную матрицу. Цветовые индексы кварковых полей сворачиваются единственно возможным способом. Таким образом, эффективный лагранжиан дается суммой этих четырех членов с четырьмя неизвестными коэффициентами.

Эффективная теория поля сообщает нам, что все возможные распады с нарушением барионного числа можно выразить через четыре неизвестные. Предполагаемая точность наших предсказаний будет порядка $(M_W/M)^2$. (Если M_W равны нулю, то $SU(3)\otimes SU(2)\otimes U(1)$ является точной.)

Конечно, можно усилить наши предсказательные способности за счет дополнительных допущений. Например, если считать, что распад протона происходит за счет обмена векторной частицей, как в универсальной теории великого объединения, то разрешены только два первых члена из вышеприведенного списка. В конкретной теории великого объединения, такой как $SU(5)$, два неизвестных коэффициента выражаются через константу связи великого объединения и массу X-бозона.

Чтобы оценить эффективную теорию поля с точки зрения способности к предсказанию, проанализируем четыре возможных оператора. Сразу можно сказать, что, хотя распад протона нарушает как барионное число B, так и лептонное число L, он сохраняет комбинацию $B - L$. Замечу, что это вовсе не очевидно без специального анализа. Могли бы вы заранее сказать экспериментатору, какую из двух возможных мод $n \to e^+\pi^-$или $n \to e^-\pi^+$ сму следует ожидать? Априори могла бы сохраняться комбинация $B + L$.

Обратите внимание, что теорию слабых взаимодействий Ферми сегодня мы бы назвали эффективной теорией поля. Конечно, бета-распад, в отличие от распада протона, можно наблюдать явным образом, поэтому результаты предсказания на основе такого сорта симметрийного анализа, а именно предсказания существования нейтрино, триумфально подтвердились.

Аналогичным образом можно построить эффективную теорию поля для масс нейтрино. Безусловно, одним из самых ярких экспериментальных открытий в области физики элементарных частиц за последние годы послужило открытие того, что нейтрино не безмассовы. Построим эффективную теорию, инвариантную относительно $SU(2) \otimes U(1)$. Поскольку ν_L входит в состав l_L, то даже без какого-либо детального анализа мы видим псобходимость включения 5-мерного оператора: схематично член $l_L l_L$ содержит требуемую нейтринную билинейность, но несет гиперзаряд $Y/2 = -1$; с другой стороны, дублет Хиггса φ несет гиперзаряд $\frac{1}{2}$, так что оператор низшей размерности имеет форму $ll\varphi\varphi$ и размерность $\frac{3}{2} + \frac{3}{2} + +1 + 1 = 5$. Следовательно, эффективный лагранжиан $\mathcal{L}$ должен включать член $(1/M)ll\varphi\varphi$, где M - массовый масштаб новой физики, ответственной за массу нейтрино. Значит, с помощью анализа размерностей мы можем оценить $m_\nu \sim m_l^2/M$, где m_l - некоторая типичная масса заряженного

лептона. Если взять m_l равной массе мюона $\sim 10^8$ МэВ, а $m_\nu \sim 10^{-1}$ эВ,

то получим $M \sim (10^2\text{МВ})^2 / 10^{-1} (10^{-6}\text{МВ}) = 10^8$ ГэВ.

Философия эффективных теорий поля, справедливых до определенного масштаба энергии Λ, кажется сегодня настолько очевидной, что с трудом верится, что когда-то многие великие физики ждали от квантовой теории поля гораздо большего: чтобы она была фундаментальной до произвольно высоких энергий.

Упражнения

VIII.3.1. Рассмотрим лагранжиан

$$\mathcal{L} = \frac{1}{2}\left[(\partial\varphi_1)^2 + (\partial\varphi_2)^2\right] - \lambda\left(\varphi_1^4 + \varphi_2^4\right) - g\varphi_1^2\varphi_2^2.$$

Мы взяли $O(2)$-теорию из главы I.9 и явно нарушили симметрию. Найдите ренорм-групповой поток на плоскости $(\lambda - g)$ и сделайте собственные выводы.

VIII.3.2. Предполагая, что правого нейтрино ν_R не существует (т. е. минимальный состав частиц в стандартной модели), запишите все члены, инвариантные относительно $SU(2) \otimes U(1)$, которые изменяют лептонное число на 2, и таким образом постройте эффективную теорию поля для массы нейтрино. Конечно, с помощью конкретной теории можно получить более сильные предсказания. Из произведения $l_L l_L$ можно построить лоренцев скаляр, преобразующийся относительно группы преобразований $SU(2)$ как синглет или триплет. Рассмотрите синглетный случай и сформулируйте для него теорию. [Указание: за помощью обращайтесь A. Zee, Phys. Lett. 93B: p. 389, 1980.

VIII.3.3. Пусть A, B, C, D - четыре поля со спином $\frac{1}{2}$. Обозначим их киральность подстрочным индексом: $\gamma^5 A_h = hA_h$ при $h = \pm 1$. То есть A_+−правое поле, A_-−левое поле и т. д. Покажите, что

$$(A_h B_h)(C_{-h} D_{-h}) = -\frac{1}{2}(A_h \gamma^\mu D_{-h})(C_{-h}\gamma_\mu B_h).$$

Это одно из многочисленных тождеств Фирца (некоторые из них нам понадобятся при обсуждении суперсимметрии). Покажите, что в том слу- чае, когда распад протона в низшем порядке идет за счет обмена векторной частицей, в лагранжиане разрешены лишь члены $\left(\widetilde{l}_L C q_L\right)(u_R C d_R)$ и $(e_R C u_R)(\widetilde{q}_L C q_L)$.

VIII.3.4. С учетом выводов из предыдущего упражнения покажите, что ширины распадов для процессов $p \to \pi^+ + \bar{\nu}, p \to \pi^0 + e^+, n \to \pi^0 + \bar{\nu}$ и $n \to \pi^- + +e^+$пропорциональны друг другу, а коэффициенты пропорциональности определяются единственной неизвестной константой [равной отношению коэффициентов для членов $\left(\widetilde{l}_L C q_L\right)(u_R C d_R)$ и $(e_R C u_R)(\widetilde{q}_L C q_L)$].

За помощью при решении последних трех упражнений обращайтесь к работам Вайнберга (S. Weinberg, Phys. Rev. Lett. 43, page 1566, 1979), Вильчека и Зи (F. Wilczek and A. Zee, ibid. p.1571), Велдона и Зи (H. A. Weldon and A. Zee, Nucl. Phys. B173:269, 1980).

30.5.5 Zi.VIII.4 Supersymmetry: A Very Brief Introduction

Объединяя бозоны и фермионы

Начну с изложения некоторых мотиваций к открытию суперсимметрии. Во-первых, все экспериментально установленные симметрии связывают бозоны с бозонами, а фермионы с фермионами. Хорошо бы, если бы некая суперсимметрия связывала бозоны с фермионами. Во-вторых, для фермионов естественно не иметь массы (вспомните главу VII.6), тогда как бозоны имеют ее. Возможно, объединяя в пару поле Хиггса с фермионным полем, получится разрешить проблему иерархий, упомянутую в главе VII.6. В-третьих, из главы II.5 известно, что фермионы создают отрицательный вклад в энергию вакуума, поэтому нельзя ли за счет фермионного вклада компенсировать вклад бозонов в энергию вакуума и решить тем самым задачу о космологической постоянной?

К сожалению, уже более 30 лет [1] никто не может опытным путем получить явное подтверждение суперсимметрии (первую суперсимметричную теорию поля построили в 1971 году Гольфанд и Лихтман). Все существующие суперсимметричные теории связывают известные бозоны с неизвестными фермионами, а известные фермионы с неизвестными бозонами. Суперсимметрия должна нарушаться на некотором масштабе массы M, находящемся вне уже исследованной экспериментально области. Тогда можно ожидать, что космологическая постоянная будет порядка M^4 (см. главу VIII.2).

Как бы то ни было, суперсимметричные теории поля обладают множеством хороших свойств (что не удивительно, поскольку симметрия таких теорий гораздо больше). Таким образом, суперсимметрия привлекает к себе внимание множества поклонников. Постараюсь как можно более кратко познакомить вас с понятием суперсимметрии, избегая упоминания о ее

[1] О ранней истории суперсимметрии читайте в книге Кейна и Шифмана (G. Kane and M. Shifman, eds., The Supersymmetric World: The Beginning of the Theory.) тонкостях и спорных моментах. Надеюсь, мое введение окажется для студентов полезным, прежде чем они возьмутся за изучение соответствующих монографий.

Открытие суперсимметрии

Представьте, что однажды вы просыпаетесь с желанием построить теорию поля с симметрией, связывающей бозоны с фермионами. Первое, что вам понадобится, - это одинаковое число фермионных и бозонных степеней свободы. Простейшим фермионным полем является двухкомпонентный спинор Вейля ψ. Теперь у вас есть одна комплексная степень свободы [2], так что вы должны включить комплексное скалярное поле φ. Далее вы можете действовать методом проб и ошибок: запишите лагранжиан, включая в него все члены с размерностью не выше четвертой, и подгоните значения различных параметров лагранжиана так, чтобы он удовлетворял желаемому условию симметрии. Например, можно так подобрать значение μ в массовых членах $\mu^2\varphi^\dagger\varphi + m(\psi\psi + \bar{\psi}\bar{\psi})$, чтобы бозон и фермион имели одинаковую массу и теория стала бы более симметричной.

Если бы вы решили использовать дираковский спинор Ψ и комплексный скаляр φ, то потерпели бы неудачу на первых шагах, поскольку получили бы в два раза больше фермионных степеней свободы, чем бозонных степеней свободы. Хочется верить, что открытие суперсимметрии откладывалось так долго исключительно из-за того, что до начала 1970-х гг. большинство теоретиков-полевиков, выросших на дираковских спинорах, имели лишь небольшое представление о вейлевских спинорах. Теперь для вас настало время познакомиться с пунктирными и непунктирными спинорами из приложения Е. Для дальнейшего изучения этой главы вы должны хорошо понимать обозначения.

Суперсимметричная алгебра

Достаточно просто построить суперсимметричную теорию поля, известную как модель Весса-Зумино, методом проб и ошибок. Однако сначала я продемонстрирую вам, как работает один изящный, но более абстрактный подход, именуемый суперпространственный

и суперполевой формализм. Этот формализм изобрели Салам и Стратди. Нам понадобится достаточно сложный формальный аппарат. Все супер в этой главе.

2 Одна комплексная степень свободы на массовой поверхности и две комплексные степени свободы вне массовой поверхности. См. ниже суериюлевой формализм. Запишем генератор суперсимметрии, переводящий φ в ψ_α, как Q_α (известный как суперзаряд). Тот факт, что Q_α преобразуется как вейлевский спинор, означает $[J^{\mu\nu}, Q_\alpha] = -i\left(\sigma^{\mu\nu}\right)_\alpha{}^\beta Q_\beta$, где $J^{\mu\nu}$ - генераторы группы Лоренца. Очевидно, что $[P^\mu, Q_\alpha] = 0$ вследствие независимости Q_α от координат пространства-времени. Обозначим величину, сопряженную Q_α, как $\bar{Q}_{\dot\alpha}$ (см. приложение Е) и получим $\left[J^{\mu\nu}, \bar{Q}^{\dot\alpha}\right] = -i\left(\bar\sigma^{\mu\nu}\right)^{\dot\alpha}{}_{\dot\beta'}\bar{Q}^{\dot\beta}$.

Запишем антикоммутационное соотношение между грассмановыми объектами Q_α и $\bar{Q}_{\dot\beta}$, при этом в полной мере учтем материал приложения Е. Алгебра суперсимметрий задается выражением

$$\left\{Q_\alpha, \bar{Q}_{\dot\beta}\right\} = 2\left(\sigma^\mu\right)_{\alpha\dot\beta} P_\mu.$$

Мы воспользовались методом «чем еще это может быть»? Правая часть выражения должна идти с индексами α и $\dot\beta$, а мы знаем, что единственным объектом, несущим эти индексы, может быть σ^μ. Лоренцев индекс μ нужно свернуть и единственный подходящий вектор - это P_μ. Множитель 2 фиксирует нормировку Q.

Аналогичным образом получаем $\left\{Q_\alpha, Q^\beta\right\} = c_1\left(\sigma^{\mu\nu}\right)_\alpha{}^\beta J_{\mu\nu} + c_2\delta_\alpha^\beta$. Коммутируя с P^λ, видим, что константа c_1 равна нулю. С учетом $Q_\gamma = \varepsilon_{\gamma\beta}Q^\beta$ приходим $\kappa\left\{Q_\alpha, Q_\gamma\right\} = c_2\varepsilon_{\gamma\alpha}$; вследствие симметричности левой части последнего выражения относительно α и γ получаем $c_2 = 0$. Таким образом, $\{Q_\alpha, Q_\beta\} = 0$ и $\left\{\bar{Q}_{\dot\alpha}, \bar{Q}_{\dot\beta}\right\} = 0$ (см. упражнение VIII.4.2).

Основная теорема

Из соотношения (1) следует важный физический факт. Сворачивая с $\left(\bar\sigma^\nu\right)^{\dot\beta\alpha}$, получаем

$$4P^\nu = \left(\bar\sigma\right)^{\dot\beta\alpha}\left\{Q_\alpha, \bar{Q}_{\dot\beta}\right\}.$$

В частности, временная компонента говорит о том, что гамильтониан равен:

$$4H = \sum_\alpha\left\{Q_\alpha, \bar{Q}_{\dot\alpha}\right\} = \sum_\alpha\left\{Q_\alpha, \bar{Q}_\alpha^\dagger\right\} = \sum_\alpha\left(Q_\alpha Q_\alpha^\dagger + Q_\alpha^\dagger Q_\alpha\right)$$

Приходим к важной теореме, которая гласит, что в суперсимметричной теории поля любое физическое состояние $|S\rangle$ должно иметь неотрицательную энергию:

$$\langle S|H|S\rangle = \frac{1}{2}\sum_\alpha\sum_{S'}\left|\langle S'\left|Q_\alpha\right|\left|S\right\rangle\right|^2 \geqslant 0.$$

Суперпространство

Теперь, когда мы построили суперсимметричную алгебру, обратимся к нашей цели построить суперсимметричные теории поля. Для этого мы должны выяснить, как преобразуются поля при действии суперсимметричной алгебры. Нам придется использовать формализмом, необходимость которого станет очевидной позднее.

Представьте, что мы пытаемся построить формализм суперпространства. Начнем с основного соотношения (1) $\left\{Q_\alpha, \bar{Q}_{\dot\beta}\right\} = 2\left(\sigma^\mu\right)_{\alpha\dot\beta}P_\mu$. Суперсимметричное преобразование Q, вместе с $\bar{Q}$, генерирует трансляцию P_μ. Гм, давайте посмотрим, $P_\mu \equiv i\left(\partial/\partial x^\mu\right)$ генерирует трансляцию в x^μ, значит, Q_α, возможно, будучи грассмановым, генерирует трансляцию в некоторой абстрактной грассмановой координате θ^α. (Аналогично $\bar{Q}_{\dot\beta}$ генерирует трансляцию в $\bar\theta^{\dot\beta}$.)

Салам и Стратди ввели понятие суперпространства с бозонными и фермионными координатами $\left\{x^\mu, \theta^\alpha \cdot \bar{\theta}^{\dot{\beta}}\right\}$ с алгеброй суперсимметрий, представленной трансляциями в этом пространстве.

Пусть Q_α и $\bar{Q}_{\dot{\beta}}$ будут чем-то типа $\partial/\partial\theta^\alpha$ и $\partial/\partial\bar{\theta}^{\dot{\beta}}$ соответственно. Тогда $\left\{Q_\alpha, \bar{Q}_{\dot{\beta}}\right\} = 0$ и мы не получим соотношение (1). Продолжим наши игры и модифицируем Q_α и $\bar{Q}_{\dot{\beta}}$. Вы, возможно, уже знаете, что мы ищем. Если добавить в $\bar{Q}_{\dot{\beta}}$ член вида $\theta\sigma^\mu\partial_\mu$, то $\partial/\partial\theta^\alpha$, действующий в Q_α на $\theta\sigma^\mu\partial_\mu$, приведет к выражению, напоминающему правую часть уравнения (1). Аналогичным образом мы решаем добавить в Q_α член вида $\bar{\theta}\sigma^\mu\partial_\mu$. (Напоминаю, что система пунктирных обозначений фиксирует, что мы должны записывать, а именно $(\sigma^\mu)_{\alpha\dot{\alpha}}\,\bar{\theta}^{\dot{\alpha}}\partial_\mu$, так что сворачиваемые индексы подчиняются правилу «от юго-запада к северо-востоку».) Итак, суперзаряды мы представляем как

$$Q_\alpha = \frac{\partial}{\partial\theta^\alpha} - i\,(\sigma^\mu)_{\alpha\dot{\alpha}}\,\bar{\theta}^{\dot{\alpha}}\partial_\mu$$

Н

$$\bar{Q}_{\dot{\beta}} = -\frac{\partial}{\partial\theta^{\dot{\beta}}} + i\theta^\beta\,(\sigma^\mu)_{\beta\dot{\beta}}\,\partial_\mu$$

Геперь уравнение (1) имеет место. Интсресно, что, когда мы сдвигаем в фермионном направлении, приходится также слегка сдвигать в бозонном паправлении.

Суперполе

Суперполе $\Phi\left(x^\mu, \theta^\alpha, \bar{\theta}^{\dot{\beta}}\right)$, как следует из названия, есть поле, живущее в суперпространстве. Инфинитезимальное преобразование суперсимметрии сводится к виду:

$$\Phi \to \Phi' = \left(1 + i\xi^\alpha Q_\alpha + i\bar{\xi}_{\dot{\alpha}}\bar{Q}_{\dot{\alpha}}\right)\Phi$$

где ξ и $\bar{\xi}$ - два грассмановых параметра.

Оказывается, можно наложить на Φ условие и тем самым несколько ограничить его широкое определение. Пристально вглядевшись в (5) и (6), вы обнаружите, что можно определить другие два объекта:

$$D_\alpha = \frac{\partial}{\partial\theta^\alpha} - i\,(\sigma^\mu)_{\alpha\dot{\alpha}}\,\bar{\theta}^{\dot{\alpha}}\partial_\mu$$

и

$$\bar{D}_{\dot{\beta}} = -\left[\frac{\partial}{\partial\theta^{\dot{\beta}}} + i\theta^\beta\,(\sigma^\mu)_{\beta\dot{\beta}}\,\partial_\mu\right],$$

которые являются комбинациями, ортогональными к Q_α и $\bar{Q}_{\dot{\beta}}$. Очевидно, что D_α и $\bar{D}_{\dot{\beta}}$ антикоммутируют с Q_α и $\bar{Q}_{\dot{\beta}}$. Следовательно, если наложить на суперполе Φ условие $\tilde{D}_{\dot{\beta}}\Phi = 0$, то его преобразованная форма Φ' также будет удовлетворять этому условию.

Суперполе Φ, удовлетворяющее условию $\bar{D}_{\dot{\beta}}\Phi = 0$, известно как киральное суперполе. На самом деле условие легко выполнить [3]. Смотрите, если мы определим $y^\mu \equiv \left(x^\mu + i\theta^\alpha\,(\sigma^\mu)_{\alpha\dot{\alpha}}\,\bar{\theta}^{\dot{\alpha}}\right)$ (обратите внимание, что мы складываем две бозонные величины), то

$$\bar{D}_{\dot{\beta}}y^\mu = -\left[\frac{\partial}{\partial\bar{\theta}^{\dot{\beta}}} + i\theta^\beta\,(\sigma^\nu)_{\beta\dot{\beta}}\,\partial_\nu\right]y^\mu = -\left[-i\theta^\alpha\,(\sigma^\mu)_{\alpha\dot{\beta}} + i\theta^\beta\,(\sigma^\mu)_{\beta\dot{\beta}}\right] = 0.$$

Таким образом, суперполе $\Phi(y,\theta)$, зависящее только от y и θ, является киральным суперполем.

Разложим Φ в ряд по степеням θ при фиксированном y. Вспомним, что θ содержит две компоненты (θ^1,θ^2). Значит, можно построить объект с θ максимум второй степени, т. е. $\theta\theta$, что вы проделали в упражнении E.3.

З'Эо аналогично задаче нахождения функции $f(x,y)$, удовлетворяющей условию $Lf=0$, где $L\equiv[x(\partial/\partial y)-y(\partial/\partial x)]$. Тогда любая f, зависящая только от r, будет удовлетворять заданному условию. Как обычно, степенной ряд по грассмановым переменным обрывается и мы получаем:

$$\Phi(y.\theta)=\varphi(y)+\sqrt{2}\theta\psi(y)+\theta\theta F(y)$$

где $\varphi(y),\psi(y)$ и $F(y)$ - пока просто коэффициенты ряда. Можно осуществить повторное разложение в ряд Тейлора в x:

$$\begin{aligned}\Phi(y,\theta)=\varphi(x)+\sqrt{2}\theta\psi(x)+\theta\theta F(x)+\\ +i\theta\sigma^\mu\bar\theta\partial_\mu\varphi(x)-\frac{1}{2}\theta\sigma^\mu\bar\theta\theta\sigma^\nu\bar\theta\partial_\mu\partial_\nu\varphi(x)+\sqrt{2}\theta i\theta\sigma^\mu\bar\theta\partial_\mu\psi(x).\end{aligned}$$

Видим, что киральное суперполе Φ включает в себя вейлевское фермионное поле ψ и два комплексных скалярных поля φ и F.

Нахождение полной производной

Сделаем небольшой анализ размерностей для пользы и удовольствия. Известно, что P_μ имеет размерность массы и, применяя обозначения из главы III.2, мы можем записать $[P_\mu]=1$. Тогда из выражений (1), (5) и (6) следует, что $[Q]=[\bar Q]=\frac{1}{2}$ и $[\theta]=[\bar\theta]=-\frac{1}{2}$. Известно, что $[\varphi]=1$, тогда из уравнения (8) следует, что $[\psi]=\frac{3}{2}$ (это мы уже знаем) и $[F]=2$ (этого мы не знали). В действительности мы никогда не встречали лоренцево скалярное поле с размерностью 2. Как может кинетический член для F в лагранжиане $\mathcal{L}$ иметь размерность 4? Никак. Член $F^\dagger F$ уже имеет размерность 4, а любая производная может лишь увеличить ее. Кроме того, разве мы не говорили, что с помощью φ и ψ уравниваем количество бозонных и фермионных степеней свободы?

С полем $F(x)$ определенно связано что-то странное. Что оно делает в нашей теории?

При инфинитезимальном суперсимметричном преобразовании суперполе изменяется на величину $\delta\Phi=i(\xi Q+\bar\xi\bar Q)\Phi$. Используя уравнения (8), (5) и (6), вы можете определить, как именно преобразуются поля φ,ψ и F (см. упражнение 5). Но пойдем более длинным путем, применяя принцип симметрии и анализ размерностей. Например, функция δF линейна относительно ξ или $\bar\xi$, поэтому вследствие $[F]=2$ и $[\xi]=[\bar\xi]=-\frac{1}{2}$ она должна умножаться на что-то с размерностью $\left[\frac{5}{2}\right]$. Единственным объектом с размсрностью $\left[\frac{5}{2}\right]$ является $\partial_\mu\psi$ с непунктирным индексом. Обратите внимание, что в качестве этого объекта не может выступать $\partial_\mu\bar\psi$, поскольку Φ не содержит поля $\bar\psi$. Согласно лоренцевской инвариантности необходимо найти такой объект, который имеет индекс μ. Это может быть только $(\sigma^\mu)_{\alpha\dot\alpha}$. Пунктирный индекс, имеющийся у $(\sigma^\mu)_{\alpha\dot\alpha}$, можно свернуть только с $\bar\xi$. Таким образом, все параметры фиксированы, за исключением общей константы:

$$\delta F\sim\partial_\mu\psi^\alpha\,(\sigma^\mu)_{\alpha\dot\alpha}\,\bar\xi^{\dot\alpha}$$

Аналогичным образом можно легко показать, что $\delta\varphi\sim\xi\psi$ и $\delta\psi\sim\xi F+{}+\partial_\mu\varphi\sigma^\mu\bar\xi$

Главное здесь - это не общая константа (9), а тот факт, что δF является полной производной.

Обозначим через $[\Phi]_F$ коэффициент при $\theta\theta$ в разложении произвольного суперполя Φ (как в (8)). Мы уже знаем, что при суперсимметричном преобразовании $\delta\left([\Phi]_F\right)$ есть полная производная, поэтому $\int d^4x[\Phi]_F$ инвариантно относительно преобразования суперсимметрии.

Наше следующее наблюдение состоит в том, что если $\bar{D}_{\dot{\beta}}\Phi = 0$, то $\bar{D}_{\dot{\beta}}\Phi^2 = 0$. Иначе говоря, если Φ есть киральное суперполе, то Φ^2 также является киральным суперполем (а еще Φ^3, Φ^4 и т. д.).

Суперсимметричное действие

Чего бы мы хотели в любом случае? Мы бы хотели получить действие, инвариантное относительно суперсимметрии.

Наконец, мы получили готовый формализм. Из материала последних двух параграфов почти очевидно, что выражение $\int d^4x \left[\frac{1}{2}m\Phi^2 + \frac{1}{3}g\Phi^3 + \ +...\right]_F$ инвариантно относительно преобразования суперсимметрии. Если возвести в квадрат (8) и взять из получившегося выражения коэффициент при $\theta\theta$, то увидим, что $[\Phi^2]_F = (2F\varphi - \psi\psi)$. Аналогично $[\Phi^3]_F = 3\,(F\varphi^2 - \ -\varphi\psi\psi)$. Теперь выполните упражнение VIII.4.6.

Создается впечатление, что мы построили массовый член для вейлевского фермиона ψ и нашли его взаимодействие со скалярным полем φ. Где же члены кинетической энергии, такие как $\bar{\psi}_{\dot{\alpha}}\left(\bar{\sigma}^{\mu}\right)^{\dot{\alpha}\alpha}\partial_{\mu}\psi_{\alpha}$?

Векторное суперполе

Члены кинетической энергии содержат $\bar{\psi}_{\dot{\alpha}}$, которого нет в Φ. Чтобы получить сопряженное поле $\bar{\psi}_{\dot{\alpha}}$, мы, очевидно, должны использовать член $\Phi^{\dagger}\Phi$. Еще немного формализма! Суперполе $V(x,\theta,\theta)$ мы называем векторным, если $V = V^{\dagger}$. Так, $\Phi^{\dagger}\Phi$ есть векторное суперполе.

Представим, что мы раскладываем $\Phi^{\dagger}\Phi = \varphi\,\dagger\,\varphi + ...$ или любое векторное суперполе V в ряд по степеням θ и $\bar{\theta}$. Старшей степенью однозначно является $\bar{\theta}\bar{\theta}\theta\theta$, так как единственный объект, который мы можем построить с учетом свойств грассмановых переменных, - это $\bar{\theta}^{\dot{1}}\bar{\theta}^{\dot{2}}\theta_1\theta_2$. Любой объект квадратичный по θ и $\bar{\theta}$, такой как $\left(\theta\sigma^{\mu}\bar{\theta}\right)\left(\theta\sigma_{\mu}\bar{\theta}\right)$, можно свести к виду $\bar{\theta}\bar{\theta}\theta\theta$, если воспользоваться одним из тождеств, которые вы нашли в упражнениях из приложения Е. Пусть $[V]_D$ обозначает коэффициент при $\bar{\theta}\bar{\theta}\theta\theta$ в разложении V.

Снова воспользуемся анализом размерностей. Если размерность V равна n, то размерность $[V]_D$ равна $n+2$, поскольку размерности θ и $\bar{\theta}$ равны $-\frac{1}{2}$. Посмотрим, как изменяется $[V]_D$ при инфинитезимальном преобразовании суперсимметрии $\delta V = i(\xi Q + \bar{\xi}\bar{Q})V$. Функция $\delta\left([V]_D\right)$ линейна относительно ξ и $\bar{\xi}$, поэтому она должна умножаться на что-то с размерностью $n + \frac{5}{2}$, ибо $[\xi] = [\bar{\xi}] = -\frac{1}{2}$. В качестве подходящего объекта может выступать лишь производная ∂ с размерностью $n + \frac{3}{2}$, а именно коэффициенты при $\bar{\theta}\bar{\theta}\theta$ и $\bar{\theta}\theta\theta$ в разложении V. Заключаем, что $\delta\left([V]_D\right)$ должна иметь форму $\partial_{\mu}(...)$. Отсюда функция $\delta\left([V]_D\right)$ есть полная производная.

Следовательно, действие $\int d^4x \left[\Phi^{\dagger}\Phi\right]_D$ инвариантно относительно преобразования суперсимметрии.

Посмотрим еще раз на уравнение (8), которое я приведу еще раз для вашего удобства:

$$\Phi(y,\theta) = \varphi(x) + \sqrt{2}\theta\psi(x) + \theta\theta F(x) + \\ + i\theta\sigma^{\mu}\bar{\theta}\partial_{\mu}\varphi(x) - \frac{1}{2}\theta\sigma^{\mu}\bar{\theta}\theta\sigma^{\nu}\bar{\theta}\partial_{\mu}\partial_{\nu}\varphi(x) + \sqrt{2}\theta i\theta\sigma^{\mu}\bar{\theta}\partial_{\mu}\psi(x).$$

Видим, что $\int d^4x \left[\Phi^{\dagger}\Phi\right]$ содержит $\int d^4x\varphi^{\dagger}\partial^2\varphi$ (если умножить первый член в $\Phi^{\dagger}$ на пятый член в Φ), $\int d^4x\partial\varphi^{\dagger}\partial\varphi$ (если умножить четвертый член в $\Phi^{\dagger}$ на четвертый член в Φ), $\int d^4x\bar{\psi}\bar{\sigma}^{\mu}\partial_{\mu}\psi$ (если умножить второй член в $\Phi^{\dagger}$ на шестой член в Φ) и, наконец, $\int d^4xF^{\dagger}F$ (если умножить третий член в $\Phi^{\dagger}$ на третий член в Φ). Поражает, как появляются производные полей в суперсимметричных теориях поля. Обратите внимание, что действие $\int d^4x \left[\Phi^{\dagger}\Phi\right]_D$ не включает в себя явные производные.

Подведем итог. Для заданного суперполя Φ мы построили суперсимметричное действие

$$S = \int d^4x \left\{ \left[\Phi^\dagger \Phi\right]_D - \left([W(\Phi)]_F + \text{ э. с. }\right)\right\}$$

Выбирая $W(\Phi) = \frac{1}{2}m\Phi^2 + \frac{1}{3}g\Phi^3$, получаем в явном виде

$$S = \int d^4x \{\partial\varphi^\dagger\partial\varphi + i\bar{\psi}\bar{\sigma}^\mu\partial_\mu\psi + F^\dagger F - \\ - \left(mF\varphi - \frac{1}{2}m\psi\psi + gF\varphi^2 - gF\varphi^2 - g\varphi\psi\psi + \text{ э. с. }\right)\Big\}.$$

Вспомогательное поле

С самого начала поле F казалось нам странным. Из условия $[F] = 2$ мы сделали вывод, что оно не может иметь члена кинетической энергии с размерностью 4, и это действительно так. Мы знаем, что оно не является динамическим полем, которое распространяется - оно является вспомогательным полем (в точности как σ в главе III.5 и ξ_μ в главе VI.3) и может быть отынтегрировано в интеграле по траекториям $\int DF^\dagger DF e^{iS}$. В самом деле, в выражении для S сгруппируем члены, зависящие от F:

$$F^\dagger F - F\left(m\varphi + g\varphi^2\right) - F^\dagger\left(m\varphi^\dagger + g\varphi^{\dagger 2}\right) = \left|F - \left(m\varphi + g\varphi^2\right)^\dagger\right|^2 - \left|m\varphi + g\varphi^2\right|^2.$$

Проинтегрируем по F и $F^\dagger$:

$$S = \int d^4x \left\{\partial\varphi^\dagger\partial\varphi + i\bar{\psi}\bar{\sigma}^\mu\partial_\mu\psi - \left|m\varphi + g\varphi^2\right|^2 + \left(\frac{1}{2}m\psi\psi - g\varphi\psi\psi + \text{ э.с. }\right)\right\}$$

Замечу, что в соответствии с (4) скалярный потенциал равен $V\left(\varphi^\dagger, \varphi\right) = \left|m\varphi + g\varphi^2\right|^2 \geqslant 0$, в минимуме он равен нулю, что обеспечивает нулевую космологическую постоянную. Обратите внимание, что мы больше не можем добавить в $V\left(\varphi^\dagger, \varphi\right)$ произвольную константу, как в несуперсимметричных теориях поля.

Как и следовало ожидать, суперсимметричные теории оказались гораздо более ограниченными, по сравнению с обычными теориями поля, но гораздо более симметричными. Используемый для их описания формализм можно обобщить до суперсимметричной теории Янга-Миллса. Ранее я говорил, что если какая-нибудь нетривиальная 4-мерная квантовая теория поля окажется точно решаемой, то это, скорее всего, будет $N = 4$ суперсимметричная теория Янга-Миллса (упражнение VIII.4.3).

Надеюсь, что это краткое введение передало вам дух суперсимметрии и поможет вам перейти к более серьзным трудам по этому предмету.

Упражнения

VIII.4.1. Постройте лагранжиан Весса-Зумино методом проб и ошибок.

VIII.4.2. В общем случае могут существовать N суперзарядов $Q^I_\alpha, I = 1, ..., N$. Покажите, что можно получить $\left\{Q^I_\alpha, Q^J_\beta\right\} = \varepsilon_{\alpha\beta}Z^{IJ}$, где Z^{IJ} – c-числа, называемые центральными зарядами.

VIII.4.3. С учетом того что мы не знаем, как записывать непротиворечивые квантовые теория поля со спином, большим двух, докажите, что значение N из предыдущего упражнения не превышает 8. Теории с суперсимметрией $N = 8$ называют максимально суперсимметричными. Докажите, что, если не включать гравитацию, значение N не должно превышать 4. Суперсимметричная теория Янга-Миллса при $N = 4$ обладает многими замечательными свойствами.

VIII.4.4. Покажите, что $\partial\theta_\alpha/\partial\theta^\beta = \varepsilon_{\alpha\beta}$.

VIII.4.5. Найдите $\delta\varphi, \delta\psi$ и δF из вариации $\delta\Phi = i\left(\xi^\alpha Q_\alpha + \bar{\xi}_{\dot{\alpha}}\bar{Q}^{\dot{\alpha}}\right)\Phi$.

VIII.4.6. Для любого многочлена $W(\Phi)$ покажите, что $[W(\Phi)]_F = F[dW(\varphi)/d\varphi] +$ + члены, не содержащие F. Покажите, что для теории (11) потенциальная энергия равна $V\left(\varphi^\dagger, \varphi\right) = |\partial W(\varphi)/\partial\varphi|^2$.

VIII.4.7. Постройте теорию поля, в которой суперсимметрия спонтанно нарушена. [Указание: вам понадобятся как минимум три киральных суперполя.]

VIII.4.8. Если мы можем построить суперсимметричную квантовую теорию поля, то определенно сможем построить суперсимметричную квантовую механику. Действительно, рассмотрим $Q_1 \equiv \frac{1}{2}\left[\sigma_1 P + \sigma_2 W(x)\right]$ и $Q_2 \equiv \frac{1}{2}\left[\sigma_2 P - -\sigma_1 W(x)\right]$, где, как обычно, $P = -i(d/dx)$ - оператор импульса. Определите $Q \equiv Q_1 + iQ_2$. Изучите свойства гамильтониана H, определяемого как $\left\{Q, Q^\dagger\right\} = 2H$.

30.5.6 Zi.VIII.5 A Bit About String Theory as a 2D Field Theory

Геометрическое действие для бозонной струны

В этой заключительной главе я постараюсь дать вам небольшое представление о теории струн. Разумеется, вы получите лишь минимальное представление о предмете. К счастью, существуют действительно замечательные книги и, я надеюсь, что эта книга подготовила вас для их изучения. Главной своей целью я считаю показать вам, что теория струн естественно формулируется в терминах 2-мерной теории поля.

В главе I.10 мы описывали точечную частицу, с мировой линией $X^\mu(\tau)$ в D-мерном пространстве-времени. Вспомним, что действие дается геометрически длиной мировой линии:

$$S = -m\int d\tau\sqrt{\frac{dX^\mu}{d\tau}\frac{dX_\mu}{d\tau}}$$

При репараметризации $\tau \to \tau'(\tau)$ действие остается неизменным. Вспомним также, что в классическом случае S эквивалентно действию

$$S_{\text{imp}} = -\frac{1}{2}\int d\tau\left(\frac{1}{\gamma}\frac{dX^\mu}{d\tau}\frac{dX_\mu}{d\tau} + \gamma m^2\right).$$

Теперь рассмотрим струну, заметающую мировой лист $X^\mu(\tau,\sigma)$ в D-мерном пространстве-времени, что мы уже проделывали в главе IV.4, когда изучали дифференциальные формы. По аналогии с (1) Намбу и Гото предложили задавать действие геометрически как площадь мирового листа:

$$S_{NG} = T\int d\tau d\sigma\sqrt{\det\left(\partial_a X^\mu \partial_b X_\mu\right)}$$

где $\partial_1 X^\mu \equiv \partial X^\mu/\partial\tau, \partial_2 X^\mu \equiv \partial X^\mu/\partial\sigma$ и $(\partial_a X^\mu \partial_b X_\mu)$ обозначают элемент ab матрицы 2×2. Здесь (как и в (1)) μ может принимать D значений: $0, 1, ..., D-1$. Константа T ($\equiv 1/2\pi\alpha'$, где α' - наклон реджевской траектории в феноменологии элементарных частиц) соответствует натяжению струны, поскольку растяжение струны для увеличения мирового листа требует дополнительного действия, пропорционального T.

Точно так же, как и для точечной частицы, желательно избавиться от квадратного корня и взамен использовать действие

$$S = \frac{1}{2}T\int d\tau d\sigma\gamma^{\frac{1}{2}}\gamma^{ab}\left(\partial_a X^\mu \partial_b X_\mu\right)$$

где $\gamma = \det\gamma_{ab}$ в интеграле по траекториям при квантовании струны. Мы сейчас покажем, что классически S эквивалентно S_{NG}.

Как и для (2), проварьируем S по вспомогательной переменной γ_{ab}, которую затем исключим. Для матрицы M имеем $\delta M^{-1} = -M^{-1}(\delta M)M^{-1}$ и

$\delta \det M = \delta e^{\operatorname{tr}\log M} = e^{\operatorname{tr}\log M} \operatorname{tr} M^{-1}\delta M = (\det M) \operatorname{tr} M^{-1}\delta M$. Следовательно, $\delta\gamma^{ab} = -\gamma^{ac}\delta\gamma_{cd}\gamma^{db}$ и $\delta\gamma = \gamma\gamma^{ba}\delta\gamma_{ab}$. Для упрощения записи введем обозначение $h_{ab} \equiv \partial_a X^\mu \partial_b X_\mu$. Тогда варьирование подынтегрального выражения в (4) даст в результате:

$$\delta\left[\gamma^{\frac{1}{2}}\gamma^{ab}h_{ab}\right] = \gamma^{\frac{1}{2}}\left[\frac{1}{2}\gamma^{dc}\delta\gamma_{cd}\left(\gamma^{ab}h_{ab}\right) - \gamma^{ac}\delta\gamma_{cd}\gamma^{db}h_{ab}\right]$$

Полагая коэффициент при $\delta\gamma_{cd}$ равным нулю, получаем:

$$h_{cd} = \frac{1}{2}\gamma_{cd}\left(\gamma^{ab}h_{ab}\right)$$

где индексы h поднимаются и опускаются метрикой γ. Умножая (5) на h^{dc} (и суммируя по повторяющимся индексам), получаем $\gamma^{ab}h_{ab} = 2$ и, следовательно, $\gamma_{cd} = h_{cd}$. Подставляя полученное выражение в (4), находим, что $S = T\int d\tau d\sigma (\det h)^{\frac{1}{2}}$. Значит, действия S и S_{NG} действительно эквивалентны в классическом случае. Действие (4), впервые полученное Бринком, Ди Веккиа и Хау, а также Дезером и Зумино, известно как действие Полякова.

Обратите внимание, что (5) определяет γ_{ab} с точностью до произвольного локального изменения масштаба, известного как преобразование Вейля:

$$\gamma_{ab}(\tau,\sigma) \to e^{2\omega(\tau,\sigma)}\gamma_{ab}(\tau,\sigma)$$

32.3.1 1. Introduction

В этой лекции мы рассматриваем безмассовую электродинамику ($m = 0$). В безмассовом случае имеются две глобальные симметрии: дираковское действие инвариантно относительно двух непрерывных глобальных преобразований:

$$\psi = e^{i\alpha}\psi', \bar{\psi} = \bar{\psi}' e^{-i\alpha} \tag{1}$$

$$\psi = e^{i\beta\gamma^5}\psi', \bar{\psi} = \bar{\psi}' e^{i\beta\gamma^5} \tag{2}$$

Здесь α, β - вещественные числа.

Если в пункте 2 лекции 10 $\partial_\mu \alpha = 0$, то преобразование (3 Л10) сводится к преобразованию (1). Согласно теореме Нётер в классической теории поля каждой непрерывной симметрии соответствует сохраняющийся ток. Таким образом, в безмассовой классической электродинамике имеется два сохраняющихся тока: векторный и аксиально-векторный:

$$\partial_\mu J^\mu = 0, \tag{3}$$
$$J^\mu = \bar{\psi}\gamma^\mu\psi \tag{4}$$
$$\partial_\mu J^{5\mu} = 0, \quad J^{5\mu} = \bar{\psi}\gamma^\mu\gamma^5\psi$$

В квантовой теории поля теорема Нётер не может оставаться автоматически справедливой вследствие расходимостей. Действительно, рассмотрим амплитуду перехода Z из вакуума в вакуум. Для получения, например, закона сохранения (3), в континуальном интеграле для Z следует сделать бесконечно близкую к тождественной замену переменных вида (3 Л10) и провести все те манипуляции, которые привели к равенству (5 Л10). Если затем положить $\eta = \bar{\eta} = 0$, то из (5 Л10) следует закон сохранения

$$\partial_\mu \langle J^\mu(x)\rangle = 0 \tag{5}$$

Чрезвычайно важно, что равенство (5) получается не в четырёхмерном, а в комплексном d-мерном пространстве, в котором амплитуда перехода регуляризована и все те свойства теории, на которых основывается получение равенства (5), остаются справедливыми при комплексной размерности пространства. Поэтому после получения равенства (5) мы можем перейти к пределу $d \to 4$ и провести перенормировку. Тем самым закон сохранения (5) остаётся справедливым в уже перенормированной теории.

Аналогичный подход для получения закона сохранения аксиально-векторного тока оказывается несостоятельным. Это видно, в частности, из того, что в предположении аналитичности относительно размерности пространства d и справедливости формул (61 Л9) имеем:

$$\operatorname{tr}\left(\gamma^5\gamma^{\mu_1}...\gamma^{\mu_{2n}}\right) = 0 \tag{6}$$

для всех n. Это входит в противоречие с (68 Л8). Равенство (6) означает, что размерная регуляризация неудовлетворительна, когда исследуются аксиальные преобразования (2). Более того, не существует такой регуляризации в рамках теории S-матрицы, которая сохраняет аксиальную инвариантность (инвариантность относительно преобразования (2)). Поэтому аксиально-векторный ток не сохраняется в квантовой безмассовой электродинамике, что далее показывается.

Для доказательства равенства (6) вставим под знак следа тождество $\gamma_\mu\gamma^\mu = d$, затем "протащим"по циклу одну из матриц γ^μ под знаком следа, используя правила антикоммутации (5 Л8). В результате получим:

$$(d-2n)\operatorname{tr}\left(\gamma^5\gamma^{\mu_1}...\gamma^{\mu_{2n}}\right) + ... = 0 \tag{7}$$

Здесь многоточие означает сумму таких же следов с $(2n-2)$ дираковскими матрицами. В частности, для $n = 0$ имеем $d\operatorname{tr}\gamma^5 = 0$, т.е. $\operatorname{tr}\gamma^5 = 0$. Теперь равенство (6) следует из равенства (7) по индукции.

Покажем, что если бы не было ультрафиолетовых расходимостей, то аксиальная аномалия (несохранение аксиально-векторного тока) также отсутствовала бы. Для наших целей достаточно рассмотреть распространение квантованного дираковского поля на фоне неквантованного, но произвольного электромагнитного поля. На языке функционального интеграла такая ситуация реализуется, если сначала вычисляется функциональный интеграл по дираковскому полю, и лишь после этого вычисляется интеграл по электромагнитному полю. Тогда внутренний фермионный интеграл, который обозначим $Z\{A\}$, и описывает амплитуду перехода дираковского поля в заданном электромагнитном поле. Заметим, что согласно (26 Л9)

$$Z\{A\} = \det\left(i\gamma^\mu\nabla_\mu\right) \tag{8}$$

Формула (8) верна, если внешние источники равны нулю. В противном случае эта формула должна быть исправлена за счёт соответствующей экспоненты.

Рассмотрим эту же задачу на операторном языке.

Пусть $\{\psi_N(t,\mathbf{x})\}$ образует в каждый момент времени t полный ортонормированный набор дираковских мод, т.е.

$$\int \mathrm{d}^{(3)}x\psi^\dagger_M(t,\mathbf{x})\psi_N(t,\mathbf{x}) = \delta_{M,N} \quad \longleftrightarrow \sum_N \psi_N(t,\mathbf{x})\psi^\dagger_N(t,\mathbf{y}) = \delta^{(3)}(\mathbf{x}-\mathbf{y}) \tag{9}$$

Для упрощения записи мы ввели дискретный индекс N, нумерующий моды. Кроме того предполагается, что эти моды являются решениями уравнения Дирака в заданном электромагнитном поле:

$$i\gamma^\mu\nabla_\mu\psi_N = 0, \quad i\nabla_\mu\bar{\psi}_N\gamma^\mu = 0 \tag{10}$$

Удобно считать, что в момент времени $t = t_0$ набор мод $\{\psi_N\}$ является полным ортонормированным набором следующего эрмитового оператора:

$$\left(-i\alpha^i\nabla_i\right)\big|_{t=t_0}\psi_N = \epsilon_N\psi_N \tag{11}$$

Уравнение Дирака (10) может быть записано в виде

$$i\frac{\partial}{\partial t}\psi_N = \mathcal{H}_\psi\psi_N, \quad \mathcal{H}_\psi = -i\alpha^i\nabla_i + eA_0 \tag{12}$$

Так как оператор $\mathcal{H}_\psi$ является эрмитовым (сравни с (33 Л8)), то условия (9)-(11) совместны. Если в (11) $\epsilon_N > 0\,(\epsilon_N < 0)$, то соответствующая мода называется положительно-(отрицательно-) частотной и обозначается $\psi^{(+)}_N\left(\psi^{(-)}_N\right)$. Имеется взаимно однозначное соответствие между положительнои отрицательно-частотными модами, так как преобразование $\psi_N \to \gamma^0\gamma^5\psi_N$ меняет их местами. Поэтому будем считать, что индекс N нумерует лишь положительно-частотные моды. Представим квантованное дираковское поле в виде (сравни с (46 Л8))

$$\begin{aligned}\psi(t,\mathbf{x}) &= \sum_N\left(a_N\psi^{(+)}_N(t,\mathbf{x}) + b^\dagger_N\psi^{(-)}_N(t,\mathbf{x})\right)\\ \psi^\dagger(t,\mathbf{x}) &= \sum_N\left(b_N\psi^{(-)\dagger}_N(t,\mathbf{x}) + a^\dagger_N\psi^{(+)\dagger}_N(t,\mathbf{x})\right)\end{aligned} \tag{13}$$

Чтобы дираковские поля удовлетворяли каноническому антикоммутационному соотношению (52 Л8) должны выполняться следующие антикоммутационные соотношения (как обычно, выписываются лишь ненулевые соотношения):

$$\left\{a_M, a^\dagger_N\right\} = \left\{b_M, b^\dagger_N\right\} = \delta_{M,N} \tag{14}$$

Подчеркнём, что операторы рождения и уничтожения в разложениях (13) не зависят от времени. Поэтому квантованные дираковские поля удовлетворяют уравнению Дирака:

$$i\gamma^\mu\nabla_\mu\psi = 0, \quad i\nabla_\mu\bar{\psi}\gamma^\mu = 0 \tag{15}$$

и, таким образом, они являются гейзенберговыми операторами во внешнем электромагнитном поле. Вакуумное состояние естественно определить как

$$a_N|0\rangle = b_N|0\rangle = 0 \tag{16}$$

Составим из квантованных полей векторный $J^\mu = \bar{\psi}\gamma^\mu\psi$ и аксиально-векторный $J^{5\mu} = \bar{\psi}\gamma^\mu\gamma^5\psi$ токи. Формально в силу уравнений Дирака-Гейзенберга (15) оба эти тока сохраняются, т.е. они удовлетворяют уравнениям (3) и (4), соответственно. Однако в

данном случае мы имеем дело с неопределённостями, которые требуют тщательного рассмотрения. Выпишем вакуумные средние рассматриваемых токов:

$$\langle 0\,|J^{\mu}(x)|\,0\rangle = -i\,\mathrm{tr}\,S(x,x+\varepsilon)\gamma^{\mu}, \quad \varepsilon^{\mu}=(\varepsilon,0,0,0), \quad \varepsilon\to+0 \tag{17}$$

$$\left\langle 0\,\middle|J^{5\mu}(x)\right|\,0\rangle = -i\,\mathrm{tr}\,S(x,x+\varepsilon)\gamma^{\mu}\gamma^{5}, \tag{18}$$

$$S(x,y)\equiv -i\langle 0|T\psi(x)\bar{\psi}(y)|0\rangle, \quad -iS(x,y)|_{y^0>x^0}=\sum_N \psi_N^{(-)}(x)\bar{\psi}_N^{(-)}(y) \tag{19}$$

Из (19) видно, что средние (17), (18) сингулярны. Поэтому непосредственное вычисление дивергенций правых частей в (17), (18) невозможно до проведения регуляризации. Регуляризация, в свою очередь, должна быть согласована с условиями квантования теории. В КЭД регуляризация должна

(i) сохранять возможность виковского поворота в евклидово пространство;

(ii) сохранять калибровочную инвариантность.

Мы видели, что условие (i) означает, что за бесконечное время вакуум переходит в вакуум и вакуумы при $t\to\pm\infty$ различаются не более чем фазовым множителем. Нарушение условия (ii) означало бы нарушение свойства перенормируемости КЭД, поскольку свойство перенормируемости основывается, в частности, на тождествах Уорда, отражающих калибровочную инвариантность.

Например, регуляризация по энергиям, заключающаяся в отбрасывании высокочастотных мод с такими N, для которых $|\epsilon_N|>\Lambda\to\infty$, удовлетворяет условию (ii), но не удовлетворяет условию (i). Действительно, оператор Дирака в евклидовом пространстве относится к операторам эллиптического типа первого порядка. Поэтому все решения уравнения Дирака (10) в евклидовом пространстве растут на пространственной бесконечности. Так как при регуляризации по энергии после поворота Вика уравнения Дирака в евклидовом пространстве для регуляризованных полей по прежнему имеют место, то мы видим, что в данном случае поворот Вика приводит к неприемлемым с физической точки зрения решениям. Поэтому поворот Вика несовместен с регуляризацией по энергии. Стоит, однако, заметить, что при регуляризации по энергии оба закона сохранения (3) и (4) выполняются.

Размерностная регуляризация сохраняет оба требования (i) и (ii). Однако вследствие парадокса (6) использовать этот метод для вычисления дивергенции аксиально-векторного тока затруднительно. Поэтому мы будем использовать другие подходы.

32.3.2 2. Diagrammatic Method of Computing the Axial Anomaly

Легко увидеть, что пропагатор (19) удовлетворяет уравнению

$$i\gamma^{\mu}\nabla_{\mu}S(x,y)=\delta^{(4)}(x-y) \tag{20}$$

Действительно, если $x^0\neq y^0$, то в силу уравнения (15) имеем $i\gamma^{\mu}\nabla_{\mu}S=0$. При $x^0=y^0$ пропагатор испытывает разрыв

$$[S(x+\varepsilon,y)-S(x-\varepsilon,y)]|_{\varepsilon\to+0}=-i\left\{\psi\left(x^0,\mathbf{x}\right),\bar{\psi}\left(x^0,\mathbf{y}\right)\right\}=-i\gamma^0\delta^{(3)}(\mathbf{x}-\mathbf{y}) \tag{21}$$

Поэтому производная $\partial/\partial x^0$ в (20) даёт дополнительный вклад, равный $i\gamma^0\delta\left(x^0-y^0\right)\times($ разрыв пропагатора). Таким образом уравнение (20) проверено.

Заметим, что пропагатор свободного безмассового дираковского поля удовлетворяет уравнению (ср. с (49 Л9))

$$i\gamma^{\mu}\partial_{\mu}S_c(x-y)=\delta^{(4)}(x-y) \tag{22}$$

Поэтому

$$S(x,y) = \left(i\gamma^\mu\partial_\mu - e\gamma^\mu A_\mu\right)^{-1}(x,y) = S_c(x-y) + \int \mathrm{d}^{(4)}z_1 S_c\left(x-z_1\right)\left(e\gamma^\mu A_\mu\left(z_1\right)\right)S_c\left(z_1-y\right) +$$
$$+ \int \mathrm{d}^{(4)}z_1\ \mathrm{d}^{(4)}z_2 S_c\left(x-z_1\right)\left(e\gamma^\mu A_\mu\left(z_1\right)\right)S_c\left(z_1-z_2\right)\left(e\gamma^\nu A_\nu\left(z_2\right)\right)S_c\left(z_2-y\right) + \ldots \tag{23}$$

Далее мы изучаем среднее от аксиально-векторного тока (18). Так как $\operatorname{tr}\gamma^5\gamma^\mu\gamma^\nu = 0$, то первое слагаемое в правой части (23) не даёт вклада в (18). Второе слагаемое в правой части (23) также не даёт вклада в (18), поскольку оно, согласно (68 Л8) и (49 Л9), пропорционально $\varepsilon_{\mu\nu\lambda\rho}\left(x-z_1\right)^\lambda\left(x-z_1\right)^\rho = 0$. Поэтому начнём с изучения третьего слагаемого в правой части (23), которое перепишем через Фурье-образы соответствующих величин:

$$e^2\int\frac{\mathrm{d}^{(4)}p\ \mathrm{d}^{(4)}q}{(2\pi)^8}\int\frac{\mathrm{d}^{(4)}r}{(2\pi)^4}A_\nu(p)A_\lambda(q)e^{ir(y-x)}e^{-ipx-iqy}S_c(r+p)\gamma^\nu S_c(r)\gamma^\lambda S_c(r-q) \tag{24}$$

Подставим (24) в (18):

$$\left\langle 0\left|J^{5\mu}(x)\right|0\right\rangle = \frac{1}{2}\int\frac{\mathrm{d}^{(4)}p\ \mathrm{d}^{(4)}q}{(2\pi)^8}e^{-i(p+q)x}A_\nu(p)A_\lambda(q)\times$$
$$\times\left\{ie^2\int\frac{\mathrm{d}^{(4)}r}{(2\pi)^4}e^{i\varepsilon r^0}\operatorname{tr}\gamma^5\gamma^\mu\left[S_c(r+p)\gamma^\nu S_c(r)\gamma^\lambda S_c(r-q) + S_c(r+q)\gamma^\lambda S_c(r)\gamma^\nu S_c(r-p)\right]\right\} + \ldots \tag{25}$$

В правой части множитель $1/2$ перед интегралом появился вследствие бозе-симметризации квадратной скобки в (25): лишь симметричная часть квадратной скобки в (25) относительно перестановки $(p,\nu) \longleftrightarrow (q,\lambda)$ даёт вклад в интеграл. Далее будем изучать выражение в фигурной скобке в (25), которое изображается суммой двух диаграмм на рис. 30.

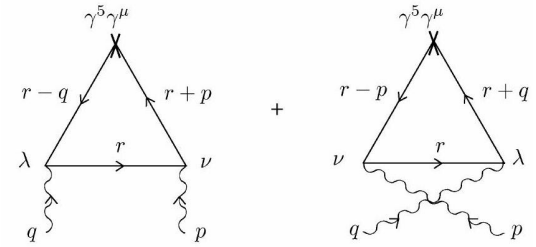

Рис. 30

Крестик в вершинах диаграмм означает, что в этих вершинах вместо множителя $(-ie\gamma^\mu)$ имеется множитель $(\gamma^5\gamma^\mu)$. В (25) можно положить $\varepsilon = 0$ ещё до вычисления интеграла, так как это не влияет на результат (те величины, которые зависят от порядка устремления ε к нулю, не дают вклада в изучаемое среднее).

Обозначим через $T^{\mu\nu\lambda}(p,q)$ величину в фигурной скобке в (25) и

$$T^{\mu\nu\lambda}(p,q) = \Gamma^{\mu\nu\lambda}(p,q) + \Gamma^{\mu\lambda\nu}(q,p) \tag{26}$$

где $\Gamma^{\mu\nu\lambda}(p,q)$ и $\Gamma^{\mu\lambda\nu}(q,p)$ изображаются первой и второй диаграммами на рис. 30, соответственно.

Диаграммы на рис. 30 расходятся линейно. Поэтому сдвиг переменной интегрирования изменяет эти диаграммы. При изучении диаграмм, встречавшихся в предыдущих лекциях, такого рода неопределённости устранялись условиями нормировки. В настоящем же случае никаких условий, кроме условия (ii), мы не имеем (условие (i) выполнено автоматически, так

как используются фейнмановские пропагаторы). Таким образом, мы должны рассмотреть семейство величин $\Gamma^{\mu\nu\lambda}(p,q|a)$, зависящих от сдвигового параметра 4 -вектора a^μ:

$$\Gamma^{\mu\nu\lambda}(p,q|a) = \tilde{\Gamma}^{\mu\nu\lambda}(p,q) + \Delta^{\mu\nu\lambda}(p,q|a) \tag{27}$$

$$\tilde{\Gamma}^{\mu\nu\lambda}(p,q) = ie^2 \int \frac{\mathrm{d}^{(4)}r}{(2\pi)^4} \operatorname{tr} \gamma^5\gamma^\mu S_c(r+p)\gamma^\nu S_c(r)\gamma^\lambda S_c(r-q) \tag{28}$$

$$\Delta^{\mu\nu\lambda}(p,q|a) = ie^2 \int \frac{\mathrm{d}^{(4)}r}{(2\pi)^4} \operatorname{tr} \gamma^5\gamma^\mu \times$$

$$\times \left\{ S_c(r+a+p)\gamma^\nu S_c(r+a)\gamma^\lambda S_c(r+a-q) - S_c(r+p)\gamma^\nu S_c(r)\gamma^\lambda S_c(r-q) \right\} \tag{29}$$

Для прояснения ситуации рассмотрим одномерный интеграл

$$\Delta(a) = \int\limits_{-\infty}^{+\infty} \mathrm{d}x [f(x+a) - f(x)] \tag{30}$$

Если $f(x)$ - интегрируемая функция на всей прямой, то при помощи сдвига переменной интегрирования устанавливается, что $\Delta(a) = 0$. Теперь разложим подынтегральное выражение:

$$\Delta(a) = \int\limits_{-\infty}^{+\infty} \mathrm{d}x \left[af'(x) + \frac{a^2}{2} f''(x) + ... \right] = a[f(+\infty) - f(-\infty)] + \frac{a^2}{2} \left[f'(+\infty) - f'(-\infty) \right] + ...$$

Отсюда видно, что если $f(x)$ стремится к разным пределам при $x \to +\infty$ и $x \to -\infty$, то

$$\Delta(a) = a[f(+\infty) - f(-\infty)] \neq 0 \tag{31}$$

Аналогично вычисляется в задаче 1 величина (29):

$$\Delta^{\mu\nu\lambda}(p,q|a) = \frac{ie^2}{8\pi^2} \varepsilon^{\mu\nu\lambda\rho} a_\rho, \quad a_\rho = (a+b)p_\rho + bq_\rho \tag{32}$$

Мы ограничили класс векторов a_ρ тем требованием, чтобы вектор a_ρ зависел лишь от векторов p, q, уже имеющихся в задаче. В (32) a и b - некие числа. Тогда наиболее общий вид величины (26) таков:

$$T^{\mu\nu\lambda}(p,q) = \left(\tilde{\Gamma}^{\mu\nu\lambda}(p,q) + \tilde{\Gamma}^{\mu\lambda\nu}(q,p) \right) + a \frac{ie^2}{8\pi^2} \varepsilon^{\mu\nu\lambda\rho} (p_\rho - q_\rho) \tag{33}$$

Комбинируя (25) и (26) и вычисляя дивергенцию, находим:

$$\left\langle 0 \left| \partial_\mu J^{5\mu}(x) \right| 0 \right\rangle = -\frac{i}{2} \int \frac{\mathrm{d}^{(4)}p\ \mathrm{d}^{(4)}q}{(2\pi)^8} e^{-i(p+q)x} A_\nu(p) A_\lambda(q) \left[(p+q)_\mu T^{\mu\nu\lambda}(p,q) \right] + ... \tag{34}$$

При помощи явной формулы (28) получаем:

$$(p+q)_\mu \tilde{\Gamma}^{\mu\nu\lambda}(p,q) \sim \int \frac{\mathrm{d}^{(4)}r}{(2\pi)^4} \operatorname{tr} \gamma^5 \left[(\not{r}+\not{p}) S_c(r+p)\gamma^\nu S_c(r)\gamma^\lambda S_c(r-q) + \right.$$

$$\left. + S_c(r+p)\gamma^\nu S_c(r)\gamma^\lambda S_c(r-q)(\not{r}-\not{q}) \right] =$$

$$= \int \frac{\mathrm{d}^{(4)}r}{(2\pi)^4} \operatorname{tr} \gamma^5 \left[\gamma^\nu S_c(r)\gamma^\lambda S_c(r-q) + S_c(r+p)\gamma^\nu S_c(r)\gamma^\lambda \right] = 0 \tag{35}$$

Здесь в последнем интеграле каждое из слагаемых является двухиндексным псевдотензором в 4мерном пространстве, составленным при помощи одного единственного вектора (q или p), что невозможно. Отсюда следует обращение в нуль величины (35). Поэтому согласно (33) и (35)

$$(p+q)_\mu T^{\mu\nu\lambda}(p,q) = -a\frac{ie^2}{4\pi^2}\varepsilon^{\nu\lambda\mu\rho}p_\mu q_\rho \tag{36}$$

Далее следует учесть, что калибровочная инвариантность не нарушена. Очевидно, что оба изучаемых тока (17) и (18) инвариантны относительно калибровочных преобразований. Поэтому так же, как в лекции 10 при выводе тождества Уорда, находим тождество

$$\frac{\partial}{\partial y^\nu}\left\langle 0\left|TJ^{5\mu}(x)J^\nu(y)J^\lambda(z)\right|0\right\rangle = 0$$

из которого в наинизшем приближении следует равенство

$$p_\nu T^{\mu\nu\lambda}(p,q) = 0 \tag{37}$$

Из (28) находим:

$$p_\nu\tilde\Gamma^{\mu\nu\lambda}(p,q) = ie^2\int\frac{\mathrm{d}^{(4)}r}{(2\pi)^4}\,\mathrm{tr}\,\gamma^5\gamma^\mu S_c(r+p)[(\not r+\not p)-\not x]S_c(r)\gamma^\lambda S_c(r-q) =$$
$$= ie^2\int\frac{\mathrm{d}^{(4)}r}{(2\pi)^4}\,\mathrm{tr}\,\gamma^5\gamma^\mu\left[S_c(r)\gamma^\lambda S_c(r-q) - S_c(r+p)\gamma^\lambda S_c(r-q)\right] \tag{38}$$

Первый интеграл в правой части (38) исчезает, так как невозможно построить псевдотензор с двумя индексами из одного единственного 4 -вектора. Аналогичное вычисление даёт:

$$p_\nu\tilde\Gamma^{\mu\lambda\nu}(q,p) = ie^2\int\frac{\mathrm{d}^{(4)}r}{(2\pi)^4}\,\mathrm{tr}\,\gamma^5\gamma^\mu S_c(r+q)\gamma^\lambda S_c(r-p) \tag{39}$$

Нам нужна сумма интегралов (38) и (39):

$$p_\nu\left(\tilde\Gamma^{\mu\nu\lambda}(p,q)+\tilde\Gamma^{\mu\lambda\nu}(q,p)\right)\equiv\Delta^{\mu\lambda}(p,q) =$$
$$= ie^2\int\frac{\mathrm{d}^{(4)}r}{(2\pi)^4}\,\mathrm{tr}\,\gamma^5\gamma^\mu\left[S_c(r+p+a)\gamma^\lambda S_c(r-q+a) - S_c(r+p)\gamma^\lambda S_c(r-q)\right],\quad a=q-p \tag{40}$$

В задаче 2 эта величина вычислена:

$$\Delta^{\mu\lambda}(p,q) = \frac{ie^2}{4\pi^2}\varepsilon^{\mu\lambda\nu\rho}p_\nu q_\rho \tag{41}$$

При помощи (26), (27), (32) и (41) находим:

$$p_\nu T^{\mu\nu\lambda}(p,q) = \frac{ie^2}{4\pi^2}\varepsilon^{\mu\lambda\nu\rho}p_\nu q_\rho\left(1+\frac{a}{2}\right) \tag{42}$$

Отсюда видно, что для выполнения калибровочной инвариантности теории необходимо

$$a = -2 \tag{43}$$

Согласно (36) такое значение параметра a означает несохранение аксиально-векторного тока. С другой стороны, если потребовать сохранение аксиально-векторного тока, для чего

необходимо положить $a = 0$, то нарушается калибровочная инвариантность и векторный ток не сохраняется. Поэтому теория самосогласована лишь при выполнении равенства (43).

Важно, что многоточие в (34) может быть опущено, так как все слагаемые, обозначенные многоточием, не содержат ультрафиолетовых расходимостей и потому, как это было указано во введении, не могут дать вклад в аномальную дивергенцию каких либо величин. Этот факт даёт возможность переписать с учётом равенств (36) и (43) соотношение (34) как точное равенство вида

$$\left\langle 0 \left| \partial_\mu J^{5\mu}(x) \right| 0 \right\rangle = -\frac{e^2}{16\pi^2}\varepsilon^{\mu\nu\lambda\rho} \int \frac{\mathrm{d}^{(4)}p\ \mathrm{d}^{(4)}q}{(2\pi)^8} e^{-i(p+q)x} \left[p_\mu A_\nu(p) - p_\nu A_\mu(p)\right] \left[q_\lambda A_\rho(q) - q_\rho A_\lambda(q)\right] =$$
$$= \frac{e^2}{16\pi^2}\varepsilon^{\mu\nu\lambda\rho} F_{\mu\nu}(x) F_{\lambda\rho}(x) \tag{44}$$

Равенство (44) было получено Ю. Швингером (1951) и затем ещё раз открыто С. Л. Адлером (1969) и Ю. С. Беллом и Р. Джекивом (1969).

32.3.3 3. Non-Invariance of the Functional Measure as the Source of Anomaly

Рассмотрим задачу об аксиальной аномалии непосредственно в евклидовом пространстве. Тем самым условие (i) автоматически выполнено.

Формулировка фотодинамики в евклидовом пространстве очевидна. Поэтому мы лишь прокомментируем формулировку теории Дирака в евклидовом пространстве размерности d.

Пусть $\{\gamma^\mu\}, \mu = 1, ..., d$ - набор эрмитовых матриц Дирака таких, что

$$\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2\delta^{\mu\nu}, \quad \gamma^5 = \gamma^1\gamma^2\gamma^3\gamma^4 = \left(\gamma^5\right)^\dagger \quad (d = 4) \tag{45}$$

где $\delta^{\mu\nu}$ - символ Кронекера. Дираковское действие в безмассовом случае имеет вид

$$\mathcal{S}_\psi = -\int \mathrm{d}^{(d)}x \bar\psi i\gamma^\mu \nabla_\mu \psi, \quad \nabla_\mu = \frac{\partial}{\partial x^\mu} + ieA_\mu \tag{46}$$

Здесь поля ψ и $\bar\psi$ взаимно эрмитовски сопряжены и поэтому действие (46) эрмитово. Рассмотрим фермионный функциональный интеграл (аналог величины (8))

$$Z\{A_\mu\} = \int D\bar\psi D\psi \exp\left(-\mathcal{S}_\psi\right) \tag{47}$$

В функциональном интеграле (47) переменные $\{\psi, \bar\psi\}$ рассматриваются как независимые.

Определим математически строго функциональную меру в интеграле (47) следующим образом. Предположим, во-первых, что x-пространство является компактным множеством (например, это может быть тор, на котором для полей заданы периодические граничные условия). Пусть $\{\psi_N\}$ - полный ортонормированный набор собственных функций оператора Дирака:

$$i\gamma^\mu\nabla_\mu\psi_N = \epsilon_N\psi_N \tag{48}$$

Заметим, что $(i\gamma^\mu\nabla_\mu)$ - эрмитов оператор и индекс N вследствие компактности x-пространства пробегает счётное неограниченное множество. Разложим фермионные поля по этому полному набору функций:

$$\psi(x) = \sum_N{}' \eta_N\psi_N(x), \quad \bar\psi(x) = \sum_N{}' \bar\eta_N\bar\psi_N(x) \tag{49}$$

где $\{\eta, \bar{\eta}\}$ - множество независимых грассмановых переменных и переменные $\eta_N, \bar{\eta}_N$ взаимно комплексно сопряжены. В разложениях (49) штрих над знаком суммы означает, что суммирование ограничено теми значениями N, для которых

$$|\epsilon_N| < \Lambda \to \infty \tag{50}$$

где Λ - импульс обрезания. Таким образом фермионные поля оказываются регуляризованными и при этом они разложены по конечному числу мод.

Обычно подразумевается, что континуальная фермионная мера в интеграле (47) представляется в виде

$$D\bar{\psi}D\psi = \prod_{x,a} \mathrm{d}\bar{\psi}_a(x)\mathrm{d}\psi_a(x) = \prod_N \mathrm{d}\bar{\eta}_N \, \mathrm{d}\eta_N \tag{51}$$

Здесь все равенства являются формальными, поскольку произведение континуального или счётного бесконечного числа дифференциалов не является корректно и однозначно определённой величиной. Поэтому определим регуляризованную фермионную меру при помощи следующей формулы:

$$(D\bar{\psi}D\psi)_{reg} = \prod_N{}' \mathrm{d}\bar{\eta}_N \, \mathrm{d}\eta_N = \prod_{|\epsilon_N|<\Lambda} \mathrm{d}\bar{\eta}_N \, \mathrm{d}\eta_N \tag{52}$$

Определение (52) является вторым моментом в определении регуляризованной дираковской континуальной меры. Мера (52) является калибровочно инвариантной. Действительно, при калибровочных преобразованиях

$$\psi_N(x) \to e^{-ie\alpha(x)}\psi_N(x), \quad \psi(x) \to e^{-ie\alpha(x)}\psi(x), \quad A_\mu(x) \to A_\mu(x) + \partial_\mu\alpha(x)$$

собственные значения ϵ_N, а также грассмановы переменные $\{\eta, \bar{\eta}\}$ остаются инвариантными.

Далее мы используем регуляризованную меру (52), которая определена математически строго. Таким образом условие квантования (ii) также выполнено.

Совершим бесконечно малое аксиальное преобразование фермионных полей:

$$\psi(x) \to \tilde{\psi}(x) = \psi(x) + i\alpha(x)\gamma^5\psi(x)$$

$$\bar{\psi}(x) \to \tilde{\bar{\psi}}(x) = \bar{\psi}(x) + i\alpha(x)\bar{\psi}(x)\gamma^5 \tag{53}$$

В терминах переменных η_N и $\bar{\eta}_N$ преобразование (53) переписывается следующим образом:

$$\eta_N \to \tilde{\eta}_N = \eta_N + i\sum_M{}' \eta_M \int \mathrm{d}^{(d)}x\alpha(x)\bar{\psi}_N(x)\gamma^5\psi_M(x)$$
$$\bar{\eta}_N \to \tilde{\bar{\eta}}_N = \bar{\eta}_N + i\sum_M{}' \bar{\eta}_M \int \mathrm{d}^{(d)}x\alpha(x)\bar{\psi}_M(x)\gamma^5\psi_N(x) \tag{54}$$

Преобразование (54) изменяет меру (52) в первом порядке по α (см. (23 Л9)):

$$\prod_N{}' \mathrm{d}\bar{\eta}_N \, \mathrm{d}\eta_N = \left(1 + 2i\int \mathrm{d}^{(d)}x\alpha \sum_M{}' \bar{\psi}_M\gamma^5\psi_M\right) \prod_N{}' \mathrm{d}\tilde{\eta}_N \, \mathrm{d}\tilde{\eta}_N \tag{55}$$

Используя в выражении (47) регуляризованную и калибровочно инвариантную фермионную меру (52), произведём в этом функциональном интеграле замену переменных согласно формулам (53), (54):

$$\prod_N{}' \mathrm{d}\bar{\eta}_N \; \mathrm{d}\eta_N e^{-\mathcal{S}_\psi} = \int \prod_N{}' \mathrm{d}\tilde{\eta}_N \; \mathrm{d}\tilde{\eta}_N e^{-\tilde{\mathcal{S}}_\psi}$$
$$\left[1 + 2i \int \mathrm{d}^{(d)}x \alpha \sum_M{}' \bar{\psi}_M \gamma^5 \psi_M + i \int \mathrm{d}^{(d)}x \alpha \partial_\mu \tilde{J}^{5\mu}\right] \tag{56}$$

Здесь $J^{5\mu} = i\bar{\psi}^\mu \gamma^\mu \gamma^5 \psi$ - эрмитовский аксиальный ток. Все функции или функционалы, над которыми стоит волна, выражены через переменные с волной по обычным правилам. Полагая в (56) $\alpha(x) \sim \delta^{(d)}(x-y)$, получаем:

$$\left\langle \partial_\mu J^{5\mu} \right\rangle = -2 \sum_N{}' \bar{\psi}_N \gamma^5 \psi_N \tag{57}$$

В уравнении (57)... означает усреднение по фермионному вакууму. Правая часть в уравнении (57) возникла вследствие неинвариантности регуляризованной фермионной меры (52) относительно преобразований (54). Правая часть в (57) легко вычисляется, если обрезание в сумме сделать "мягким", то есть вместо обрезанной суммы $\sum_N{}'$ использовать регуляризованную сумму $\sum_N \exp\left(-\tau\epsilon_N^2\right), \tau \to +0$. Таким образом, перепишем равенство (57) в виде

$$\left\langle \partial_\mu J^{5\mu}(x) \right\rangle = -2 \operatorname{tr} \gamma^5 K(x,x|\tau), \quad \tau \to +0 \tag{58}$$
$$K(x,y|\tau) = \theta(\tau) \sum_N e^{-\tau\epsilon_N^2} \psi_N(x) \bar{\psi}_N(y) = \theta(\tau) \left\{ \exp\left[-\tau \left(i\gamma^\mu \nabla_\mu\right)^2\right] \right\}_{xy} \tag{59}$$

Для оператора K имеем уравнение:

$$\left[\frac{\partial}{\partial\tau} + \left(i\gamma^\mu \nabla_\mu\right)^2\right] K(x,y|\tau) = \delta(\tau)\delta^{(d)}(x-y) \tag{60}$$

Воспользуемся равенством

$$\gamma^\mu \gamma^\nu = \delta^{\mu\nu} + 2\sigma^{\mu\nu}, \quad \sigma^{\mu\nu} = \frac{1}{4}\left[\gamma^\mu, \gamma^\nu\right]$$

и запишем оператор $\left(i\gamma^\mu \nabla_\mu\right)^2$ в виде

$$\left(i\gamma^\mu \nabla_\mu\right)^2 = -\nabla_\mu^2 - ie\sigma^{\mu\nu} F_{\mu\nu} \tag{61}$$

Теперь уравнение (60) принимает вид

$$\left[\frac{\partial}{\partial\tau} - \nabla_\mu^2 - ie\sigma^{\mu\nu} F_{\mu\nu}\right] K(x,y|\tau) = \delta(\tau)\delta^{(d)}(x-y) \tag{62}$$

Будем вычислять оператор $K(x,y|\tau)$ в пределе $\tau \to +0$ при помощи ТВ. В нулевом приближении оператор $K^{(0)}(x,y|\tau)$ удовлетворяет уравнению

$$\left[\frac{\partial}{\partial\tau} - \partial_\mu^2\right] K^{(0)}(x,y|\tau) = \delta(\tau)\delta^{(d)}(x-y) \tag{63}$$

и он равен при $d = 4$

$$K^{(0)}(x,y|\tau)=K^{(0)}(x-y|\tau)=\frac{\theta(\tau)}{16\pi^2\tau^2}\exp\left[-\frac{(x-y)^2}{4\tau}\right] \tag{64}$$

Это выражение проще всего получить, переходя в импульсное представление, в котором

$$K^{(0)}(k|\tau)=\theta(\tau)e^{-\tau k^2},\quad K^{(0)}(x-y|\tau)=\int\frac{\mathrm{d}^{(4)}k}{(2\pi)^4}e^{ik(x-y)}K^{(0)}(k|\tau)$$

Таким образом имеем:

$$\begin{aligned}K(x,x|\tau)=K^{(0)}(0|\tau)+\int\limits_0^\tau \mathrm{d}\tau_1\int \mathrm{d}^{(4)}yK^{(0)}\left(x-y|\tau-\tau_1\right)\left[ie\sigma^{\mu\nu}F_{\mu\nu}(y)\right]K^{(0)}\left(y-x|\tau_1\right)+\\ +\int\limits_0^\tau \mathrm{d}\tau_1\int\limits_0^{\tau_1}\mathrm{d}\tau_2\int \mathrm{d}^{(4)}y\int \mathrm{d}^{(4)}zK^{(0)}\left(x-y|\tau-\tau_1\right)\left[ie\sigma^{\mu\nu}F_{\mu\nu}(y)\right]\\ \cdot K^{(0)}\left(y-z|\tau_1-\tau_2\right)\left[ie\sigma^{\lambda\rho}F_{\lambda\rho}(z)\right]K^{(0)}\left(z-x|\tau_2\right)+\ldots\end{aligned} \tag{65}$$

Невыписанные здесь слагаемые, обозначенные многоточием, либо исчезают под знаком следа в (58), либо исчезают в пределе $\tau\to+0$. Так как

$$\operatorname{tr}\gamma^5=0,\quad \operatorname{tr}\gamma^5\gamma^\mu\gamma^\nu=0,\quad \operatorname{tr}\gamma^5\gamma^\mu\gamma^\nu\gamma^\lambda\gamma^\rho=4\varepsilon^{\mu\nu\lambda\rho} \tag{66}$$

то вклад в (58) даёт лишь третье слагаемое в (65). Из (64) видно, что при $\tau\to+0$ интегралы по y и z насыщаются при $y\to x, z\to x$ и потому гладкие величины $F_{\mu\nu}(y)$ и $F_{\lambda\rho}(z)$ могут быть вынесены из под знака интеграла и взяты в точке x. После этого все свёртки между функциями $K^{(0)}$ следует вычислять при помощи тривиальной формулы

$$\int \mathrm{d}^{(4)}zK^{(0)}\left(x-z|\tau-\tau_1\right)K^{(0)}\left(z-y|\tau_1\right)=K^{(0)}(x-y|\tau)$$

Таким образом находим, что третье слагаемое в (65) равно

$$-\frac{e^2}{16\pi^2}\sigma^{\mu\nu}\sigma^{\lambda\rho}F_{\mu\nu}(x)F_{\lambda\rho}(x)\left(\frac{1}{\tau^2}\int\limits_0^\tau \mathrm{d}\tau_1\int\limits_0^{\tau_1}\mathrm{d}\tau_2\right) \tag{67}$$

Из проведенного вычисления видно, что если бы мы учли более высокие члены разложения в (65), то они были бы пропорциональны, например (в следующем порядке)

$$\frac{1}{\tau^2}\int\limits_0^\tau \mathrm{d}\tau_1\int\limits_0^{\tau_1}\mathrm{d}\tau_2\int\limits_0^{\tau_2}\mathrm{d}\tau_3=\frac{\tau}{6}\to 0$$

Все такие слагаемые стремятся к нулю в пределе $\tau\to+0$. Поэтому, подставляя (67) в (58) и используя (66), окончательно находим:

$$\left\langle\partial_\mu J^{5\mu}(x)\right\rangle=\frac{e^2}{16\pi^2}\varepsilon^{\mu\nu\lambda\rho}F_{\mu\nu}(x)F_{\lambda\rho}(x) \tag{68}$$

Замечание. Строго говоря, преобразованные поля (53) должны быть спроектированы на регуляризованное пространство фермионных полей (49) с базисом мод $\{\psi_N\},|\epsilon_N|<\Lambda$. Иными словами, для преобразованных полей также должны иметь место разложения (49):

$$\tilde{\psi}(x) = \sum_N{}' \tilde{\eta}_N \psi_N(x), \quad \tilde{\bar{\psi}}(x) = \sum_N{}' \tilde{\bar{\eta}}_N \bar{\psi}_N(x) \tag{69}$$

В противном случае действие

$$\tilde{\mathcal{S}}_\psi = -\int \mathrm{d}^{(d)}x \tilde{\bar{\psi}} i\gamma^\mu \nabla_\mu \tilde{\psi}$$

в (56) как функция переменных $\{\tilde{\bar{\eta}}_M, \tilde{\eta}_M\}$ оказалось бы отличным от действия $\mathcal{S}$ в (47) как функции переменных $\{\bar{\eta}_M, \eta_M\}$, и из (56) не следовало бы соотношение (57). Однако вследствие того, что моды в разложениях (49) и (69) являются собственными для оператора Дирака $i\gamma^\mu\nabla_\mu$, мы имеем:

$$\tilde{\mathcal{S}}_\psi = \sum_{|\epsilon_N|<\Lambda} \epsilon_N \tilde{\bar{\eta}}_N \tilde{\eta}_N + \sum_{|\epsilon_N|>\Lambda} \epsilon_N \tilde{\bar{\eta}}_N \tilde{\eta}_N$$

Здесь второе слагаемое имеет порядок $O(\alpha^2)$ и потому не играет роли в приведенном выше вычислении. Мы видим, что в фермионном действии проектирование преобразованных фермионных полей на регуляризованное фермионное подпространство происходит автоматически. Подчеркнём, что этот факт является следствием использования собственных функций оператора Дирака для регуляризации фермионных полей. Поэтому корректность перехода от равенства (56) между регуляризованными фермионными интегралами к соотношению (57) очевидна.

Вычисление аномальной расходимости аксиально-векторного тока путём учёта неинвариантности фермионной меры впервые было проделано С. Н. Вергелесом (1978). Вскоре этот же метод был открыт К. Фуджикавой (1979).

Вывод: Не все сохраняющиеся величины в классической теории поля остаются сохраняющимися в квантовой теории. Этому препятствуют квантовые аномалии. В частности, в безмассовой КЭД векторнъй ток сохраняется, а аксиалъно-векторный ток не сохраняется вследствие квантовой аномалии.

Задачи

1. Вычислить интеграл (29).

   Ответ:

$$\Delta^{\mu\nu\lambda}(p,q|a) = \frac{ie^2}{8\pi^2}\varepsilon^{\mu\nu\lambda\rho}a_\rho$$

2. Вычислить интеграл (40).

Ответ:

$$\Delta^{\mu\lambda}(p,q) = \frac{ie^2}{4\pi^2}\varepsilon^{\mu\lambda\nu\rho}p_\nu q_\rho$$

3. Сформулировать и выписать действие для двумерной электродинамики (электромагнитное + дираковское поля). В безмассовом случае решить задачу также и в евклидовом пространстве. Вычислить аномалию в дивергенции аксиально-векторного тока в безмассовой евклидовой теории.

4*. Вычислить в двумерной безмассовой электродинамике (модель Швингера) величину $\ln Z\{A\}$.

Указание. Действовать в евклидовом пространстве и принять во внимание следующие факты:
а)

$$\delta_A \ln Z\{A\} = -e \int \mathrm{d}^{(2)}x \delta A_\mu \langle J^\mu \rangle$$

где $J^\mu = \bar{\psi}\gamma^\mu\psi$ - векторный ток.
б) Кинематическое соотношение

$$J^\mu = \varepsilon_{\mu\nu}J^{5\nu}, \quad J^{5\mu} = -\varepsilon_{\mu\nu}J^\nu, \quad J^{5\mu} = i\bar{\psi}\gamma^\mu\gamma^5\psi$$

в) Равенства $\partial_\mu \langle J^\mu \rangle = 0$ и $\partial_\mu \langle J^5\mu \rangle = -\frac{e}{2\pi}\varepsilon_{\mu\nu}F_{\mu\nu}$.

32.4 L15 Spontaneous Symmetry Breaking

32.4.1 1. Spontaneous Symmetry Breaking in Classical Theory

Рассмотрим теорию скалярного вещественного поля с лагранжианом

$$\mathcal{L} = \frac{1}{2}(\partial_\mu\phi)^2 + \frac{\mu^2}{2}\phi^2 - \frac{\lambda}{4!}\phi^4 \tag{1}$$

Гамильтониан такой теории

$$\mathcal{H} = \int \mathrm{d}^{(d-1)}x \left[\frac{1}{2}\pi^2 + \frac{1}{2}(\nabla\phi)^2 - \frac{\mu^2}{2}\phi^2 + \frac{\lambda}{4!}\phi^4\right] \tag{2}$$

В теории (1) - (2) имеется дискретная симметрия $\phi \to -\phi$.

Энергия классической системы (2) принимает минимальное значение в том случае, когда $\phi = \text{const}$ и потенциал

$$V(\phi) = -\frac{\mu^2}{2}\phi^2 + \frac{\lambda}{4!}\phi^4 \tag{3}$$

минимален, что имеет место при

$$\phi_0 = \pm v = \pm\sqrt{\frac{6}{\lambda}}\mu \neq 0 \tag{4}$$

Константа v называется вакуумным средним поля ϕ.

Предположим, что система находится вблизи одного из минимумов потенциала, совершая вблизи него малые колебания. Поэтому естественно разложить поле ϕ вблизи вакуумного среднего:

$$\phi = \phi_0 + \sigma \tag{5}$$

Подставим (5) в лагранжиан (1):

$$\mathcal{L} = \frac{1}{2}(\partial_\mu\sigma)^2 - \frac{(2\mu^2)}{2}\sigma^2 - \frac{\lambda\phi_0}{3!}\sigma^3 - \frac{\lambda}{4!}\sigma^4 \tag{6}$$

Мы учли, что линейное слагаемое относительно σ автоматически исчезает в (6) и опустили $\mathcal{L}(\phi_0) = \text{const}$. Лагранжиан (6) описывает скалярное поле σ с массой $m = \sqrt{2}\mu$. Симметрия $\phi \to -\phi$ теперь проявляется лишь в соотношении между тремя коэффициентми теории с лагранжианом (6).

Теперь рассмотрим линейную сигма-модель (см. задачу 3 к лекции 3) с лагранжианом

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu \phi^i\right)^2 + \frac{\mu^2}{2}\left(\phi^i\right)^2 - \frac{\lambda}{4}\left[\left(\phi^i\right)^2\right]^2,$$
$$i = 1, ..., n, \quad \left(\phi^i\right)^2 \equiv \left(\phi^1\right)^2 + \left(\phi^2\right)^2 + ... \tag{7}$$

Лагранжиан (7) инвариантен относительно преобразований

$$\phi^i \to \mathcal{O}^i_j \phi^j, \quad \mathcal{O}\mathcal{O}^t = 1 \tag{8}$$

Таким образом $\mathcal{O}$ - элемент ортогональной группы вращений n-мерного евклидового пространства.

Также как и в вышеприведенном случае классическая конфигурация с минимальной энергией есть постоянное поле ϕ^i_0, минимизирующее потенциал

$$V\left(\phi^i\right) = -\frac{\mu^2}{2}\left(\phi^i\right)^2 + \frac{\lambda}{4}\left[\left(\phi^i\right)^2\right]^2 \tag{9}$$

Этот минимум достигается, если

$$\left(\phi^i_0\right)^2 = \frac{\mu^2}{\lambda} \tag{10}$$

Условие (10) определяет лишь длину вектора ϕ^i_0, но не его направление. Для удобства будем считать, что

$$\phi^i_0 = (0, ..., v), \quad v = \frac{\mu}{\sqrt{\lambda}} \tag{11}$$

Аналогично (5) теперь имеем:

$$\phi^i = \left(\pi^k(x), v + \sigma(x)\right), \quad k = 1, ..., n-1 \tag{12}$$

Перепишем лагранжиан (7) в терминах новых полей:

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu \pi^k\right)^2 + \frac{1}{2}\left(\partial_\mu \sigma\right)^2 - \frac{1}{2}\left(2\mu^2\right)\sigma^2 - \sqrt{\lambda}\mu\sigma^3 - \sqrt{\lambda}\mu\left(\pi^k\right)^2\sigma - \frac{\lambda}{4}\sigma^4 - \frac{\lambda}{2}\left(\pi^k\right)^2\sigma^2 - \frac{\lambda}{4}\left(\left(\pi^k\right)^2\right)^2 \tag{13}$$

Лагранжиан (13) описывает динамику массивного поля σ и $(n-1)$ безмассовых полей π^k. Исходная $O(n)$ симметрия оказывается нарушенной, от неё остаётся подгруппа $O(n-1)$ вращений полей π в своём пространстве. Колебания поля σ происходят вдоль длины вектора ϕ^i, изменяя эту длину. Поэтому вторая производная лагранжиана по σ отлична от нуля и масса этого поля не равна нулю. Масса π-частиц равна нулю, так как π-частицы деформируют поле ϕ^i в $(n-1)$ направлениях, ортогональных вакуумному среднему.

32.4.2 2. Goldstone's Theorem

Заметим, что группа симметрии исходного лагранжиана (7) инвариантна относительно группы Ли $O(n)$, размерность которой $n(n-1)/2$ (число различных двумерных плоскостей, в которых можно делать независимые друг от друга повороты). Когда исходная симметрия нарушена до симметрии, содержащейся в лагранжиане (13), остаточная симметрия описывается группой $O(n-1)$ с $(n-1)(n-2)/2$ независимыми преобразованиями. Таким образом, утрачены

$$\frac{n(n-1)}{2} - \frac{(n-1)(n-2)}{2} = (n-1)$$

преобразований симметрии и вместе с тем появились $(n-1)$ безмассовые частицы, которые называются голдстоуновскими бозонами.

Теорема Голдстоуна утверждает, что для каждой спонтанно нарушенной непрерывной симметрии в теории содержится безмассовая частица.

Доказательство теоремы Голдстоуна проведём в самом общем случае.

Рассмотрим теорию, содержащую несколько полей ϕ^i с лагранжианом

$$\mathcal{L} = (\text{ члены с производными }) - V(\phi). \tag{14}$$

Пусть ϕ_0^i - постоянное поле, минимизирующее V:

$$\frac{\partial}{\partial \phi^i} V \Big|_{\phi^2(x)=\phi_0^2} = 0 \tag{15}$$

Разложим V в окрестности этого минимума:

$$V(\phi) = V(\phi_0) + \frac{1}{2}(\phi-\phi_0)^i (\phi-\phi_0)^j \left(\frac{\partial^2}{\partial\phi^i \partial\phi^j} V\right)_{\phi_0} + \ldots \tag{16}$$

Коэффициент при квадратичном слагаемом

$$m_{ij}^2 = \left(\frac{\partial^2}{\partial\phi^i \partial\phi^j} V\right)_{\phi_0} \tag{17}$$

является симметричной матрицей, собственные значения которой дают массы полей. Они неотрицательны, так как V минимален при $\phi = \phi_0$. Для доказательства теоремы Голдстоуна необходимо показать, что всякая непрерывная симметрия лагранжиана (14), не являющаяся симметрией (т.е. изменяющая) поле ϕ_0, приводит к нулевому собственному значению матрицы (17).

Произвольное преобразование непрерывной симметрии имеет вид

$$\phi^i \longrightarrow \phi^i + \alpha \Delta^i(\phi), \quad \alpha \to 0 \tag{18}$$

где $\Delta^i(\phi)$ - некие функции поля ϕ, определяющие данное преобразование симметрии. Достаточно рассмотреть поля, постоянные в пространстве-времени. Тогда потенциал V инвариантен сам по себе относительно преобразования (18):

$$V\left(\phi^i\right) = V\left(\phi^i + \alpha\Delta^i(\phi)\right) \longrightarrow \Delta^i(\phi)\frac{\partial}{\partial\phi^i} V(\phi) = 0 \longrightarrow$$

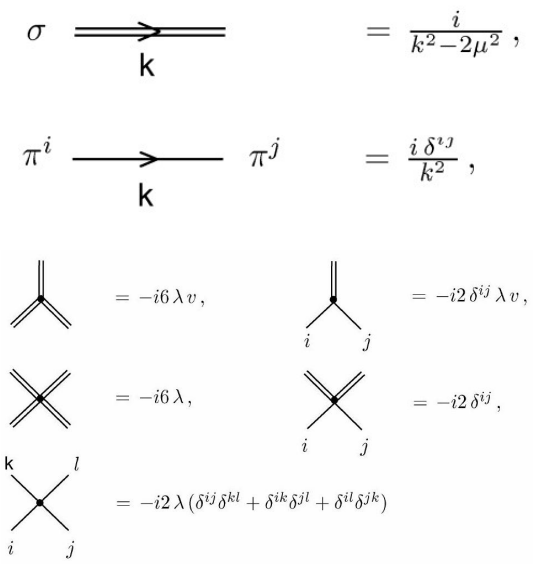
$$\frac{\partial}{\partial\phi^j}\left[\Delta^i(\phi)\frac{\partial}{\partial\phi^i}V(\phi)\right]\Big|_{\phi=\phi_0} = \frac{\partial\Delta^i}{\partial\phi^j}\Big|_{\phi=\phi_0} \frac{\partial V}{\partial\phi^i}\Big|_{\phi=\phi_0} + \Delta^i(\phi_0)\, m_{ij}^2 = 0$$

Вследствие (15)

$$m_{ij}^2 \Delta^j(\phi_0) = 0 \tag{19}$$

Заметим, что если $\Delta^i(\phi_0) = 0$, то $\phi_0^i + \Delta^i(\phi_0) = \phi_0^i$. Это означает, что вакуумное среднее инвариантно относительно относительно рассматриваемого преобразования. Наоборот, если $\Delta^i(\phi_0) \neq 0$, то мы имеем преобразование, изменяющее ϕ_0^i. Соответствующая симметрия отсутствует в лагранжиане вида (13). Но равенство (19) означает, что такому преобразованию соответствует нулевая масса. Тем самым теорема Голдстоуна доказана.

Вернёмся к линейной σ-модели с лагранжианом (13) и построим соответствующую квантовую теорию поля. Обозначим пропагаторы σ - и π-частиц соответственно двойной и одинарной линиями. Тогда элементы диаграммной техники Фейнмана представлены на рис. 31:



$$= -i2\lambda \left(\delta^{ij}\delta^{kl} + \delta^{ik}\delta^{jl} + \delta^{il}\delta^{jk}\right)$$

Рис. 31

Очевидно, что теория с указанной на рис. 31 диаграммной техникой перенормируема, так как перенормируема теория с лагранжианом (7), а ультрафиолетовые расходимости не могут зависеть от того, как "растасованы"и обозначены отдельные поля теории. Однако имеют место гораздо более сильные утверждения:

а) Для устранения ультрафиолетовых расходимостей в теории (13) с диаграммной техникой, представленной на рис. 31, достаточно введение контрчленов того же вида, что и в лагранжиане (13).

б) Теорема Голдстоуна остаётся справедливой с учётом квантовых поправок.

Ввиду громоздкости мы не доказываем здесь этих утверждений. Укажем лишь удобные условия перенормировки, фиксирующие все константы теории:

$$CBA = \quad = 0$$

$$\frac{\mathrm{d}}{\mathrm{d}k^2}\,(= CB = |_{k^2=0} = 0 \tag{20}$$

32.4.3 3. Effective Action

Рассмотрим для некоторой скалярной теории поля с лагранжианом $\mathcal{L}(\phi)$ производящий функционал (см. (16 ЛЗ))

$$e^{-iE(\eta)} \equiv Z(\eta) = \int D\phi \exp\left[i \int \mathrm{d}^{(d)}x(\mathcal{L}(\phi) + \eta\phi)\right] \tag{21}$$

Имеем:

$$\frac{\delta}{\delta\eta(x)}E(\eta) = i\frac{\delta}{\delta\eta(x)}\ln Z = -\frac{\int D\phi e^{i\int(\mathcal{L}+\eta\phi)}\phi(x)}{\int D\phi e^{i\int(\mathcal{L}+\eta\phi)}} \equiv -\langle\phi(x)\rangle_\eta \tag{22}$$

Здесь правая часть - среднее по вакууму в присутствии внешнего источника $\eta(x)$. Определим классическое поле

$$\phi_{cl}(x) \equiv \langle\phi(x)\rangle_\eta \tag{23}$$

и эффективное действие

$$\Gamma\left(\phi_{cl}\right) \equiv -E(\eta) - \int \mathrm{d}^{(d)} y \eta(y) \phi_{cl}(y) \tag{24}$$

Тот факт, что эффективное действие зависит лишь от классического поля, но не от внешнего источника, устанавливается вычислением полной вариации величины (24):

$$\delta\Gamma = -\int \frac{\delta E}{\delta\eta(y)} \delta\eta(y) \mathrm{d}^{(d)} y - \int \phi_{cl}(y) \delta\eta(y) \mathrm{d}^{(d)} y - \int \eta(y) \delta\phi_{cl}(y) \mathrm{d}^{(d)} y$$

С учётом (22) здесь первые два слагаемых взаимно сокращаются. Поэтому

$$\frac{\delta\Gamma\left(\phi_{cl}\right)}{\delta\phi_{cl}(x)} = -\eta(x) \tag{25}$$

Если внешний источник обратить в нуль, то из (25) получаем:

$$\frac{\delta\Gamma\left(\phi_{cl}\right)}{\delta\phi_{cl}(x)} = 0 \tag{26}$$

Решения последнего уравнения являются значениями $\langle\phi(x)\rangle$ в стабильных квантовых состояниях теории. Для трансляционно-инвариантного вакуума ϕ_{cl} также не зависит от x. Именно такой случай далее мы будем рассматривать. Заметим лишь, что в случае трансляционно- и лоренцинвариантного вакуума иногда могут быть дополнительные решения уравнения (26), нарушающие симметрию вакуума и соответствующие локализованным сгусткам поля, удерживаемым за счёт самодействия и топологических факторов. В случае, когда действие таких сгустков конечно, они называются инстантонами, а если конечен гамильтониан, то они называются солитонами. Солитоны являются частицами, которые отсутствуют при наивном изучении теории с помощью теории возмущений.

Если $\phi_{cl} = \mathrm{const}$, то поскольку $\Gamma\left(\phi_{cl}\right)$ есть экстенсивная величина - она пропорциональна объёму пространства-времени - мы имеем:

$$\Gamma\left(\phi_{cl}\right) = -(VT) V_{eff}\left(\phi_{cl}\right) \tag{27}$$

Здесь T - временная протяжённость пространства-времени, а V - объём. $V_{eff}\left(\phi_{cl}\right)$ в (27) называется эффективным потенциалом. В терминах эффективного потенциала уравнение (26) записывается как

$$\frac{\partial V_{eff}\left(\phi_{cl}\right)}{\partial\phi_{cl}} = 0 \tag{28}$$

Так как $\Gamma = -E$ при $\eta = 0$, то V_{eff}, вычисленное в точке (28), является плотностью энергии в этом состоянии.

Будем вычислять V_{eff} при помощи ТВ. Разобьём лагранжиан, как обычно, на слагаемое, зависящее от перенормированных параметров, и слагаемое, содержащее лиишь контрчлены:

$$\mathcal{L} = \mathcal{L}_1 + \delta\mathcal{L} \tag{29}$$

Наша цель - вычисление функции $\Gamma\left(\phi_{cl}\right)$, в то время как $Z(\eta)$ зависит от ϕ_{cl} косвенно через источник η. Попробуем найти, хотя бы неявно, связь между η и ϕ_{cl}. В наинизшем порядке ТВ эта связь задаётся уравнением (см. (25))

$$\left.\frac{\delta \int \mathrm{d}^{(d)} y \mathcal{L}}{\delta\phi(x)}\right|_{\phi=\phi_{cl}} = -\eta(x) \quad \text{(в низшем порядке)} \tag{30}$$

Тогда уравнение

$$\left.\frac{\delta\int \mathrm{d}^{(d)}y\mathcal{L}_\infty}{\delta\phi(x)}\right|_{\phi=\phi_{cl}} = -\eta_1(x) \tag{30}$$

определяет "перенормированный"источник $\eta_1(x)$, так что

$$\eta(x) = \eta_1(x) + \delta\eta(x) \tag{32}$$

"Контрчлен" $\delta\eta(x)$ определяется последовательно при помощи ТВ и уравнений (23), (31), (32). Перепишем формулу (21) следующим образом:

$$e^{-iE(\eta)} = \int D\phi \left\{\exp\left[i\int \mathrm{d}^{(d)}x\left(\mathcal{L}_1(\phi)+\eta_1\phi\right)\right]\right\}\left\{\exp\left[i\int \mathrm{d}^{(d)}x(\delta\mathcal{L}(\phi)+\delta\eta\phi)\right]\right\} \tag{33}$$

В первой экспоненте справа разложим показатель вблизи ϕ_{cl} : $\phi(x) = \phi_{cl}(x)+\rho(x)$. Имеем:

$$\begin{aligned}\int \mathrm{d}^{(d)}x\left(\mathcal{L}_1(\phi)+\eta_1\phi\right) = \int \mathrm{d}^{(d)}x\left(\mathcal{L}_1\left(\phi_{cl}\right)+\eta_1\phi_{cl}\right) + \int \mathrm{d}^{(d)}x\rho(x)\left(\left.\frac{\delta\mathcal{L}_1}{\delta\phi}\right|_{\phi=\phi_{cl}}+\eta_1\right)+\\ +\frac{1}{2}\int \mathrm{d}^{(d)}x\ \mathrm{d}^{(d)}y\rho(x)\rho(y)\left.\frac{\delta^2\mathcal{L}_1}{\delta\phi(x)\delta\phi(y)}\right|_{\phi=\phi_{cl}}+\\ +\frac{1}{3!}\int \mathrm{d}^{(d)}x\ \mathrm{d}^{(d)}y\ \mathrm{d}^{(d)}z\rho(x)\rho(y)\rho(z)\left.\frac{\delta^3\mathcal{L}_1}{\delta\phi(x)\delta\phi(y)\delta\phi(z)}\right|_{\phi=\phi_{cl}}+\ldots\end{aligned} \tag{34}$$

Вследствие (30) линейное по ρ слагаемое в (34) исчезает. Таким образом, следует вычислить гауссов интеграл по полю ρ, а нелинейности учесть при помощи ТВ в соответствии с разработанной схемой.

В низшем приближении вторая экспонента справа в (33) не даёт вклада, а первая экспонента даёт гауссов интеграл:

$$\begin{aligned}\int D\rho\exp\left\{i\left[\int\left(\mathcal{L}_1\left(\phi_{cl}\right)+\eta_1\phi_{cl}\right)+\frac{1}{2}\int\rho\frac{\delta^2\mathcal{L}_1}{\delta\phi\delta\phi}\rho\right]\right\} =\\ =\exp\left\{i\int\left(\mathcal{L}_1\left(\phi_{cl}\right)+\eta_1\phi_{cl}\right)\right\}\cdot\left(\det\left[-\frac{\delta^2\mathcal{L}_1}{\delta\phi\delta\phi}\right]\right)^{-1/2}\end{aligned} \tag{35}$$

Отсюда видно, что при дальнейшем учёте квантовых поправок возникают фейнмановские диаграммы, в которых в качестве пропагатора используется оператор

$$-i\left(\frac{\delta^2\mathcal{L}_1}{\delta\phi\delta\phi}\right)^{-1} \tag{36}$$

а вершинами являются третья и т.д. функциональные производные $\mathcal{L}_1$.

Вторая экспонента в (33) также разлагается вблизи ϕ_{cl} по полю ρ и даёт контрчлены. Как обычно в аналогичных вычислениях (см. (14 Л6)), получаем:

$$\begin{aligned}-iE(\eta) = i\int \mathrm{d}^{(d)}x\left(\mathcal{L}_1\left(\phi_{cl}\right)+\eta_1\phi_{cl}\right) - \frac{1}{2}\ln\det\left(-\frac{\delta^2\mathcal{L}_1}{\delta\phi\delta\phi}\right)+\\ +(\text{ связные диаграммы }) + i\int \mathrm{d}^{(d)}x\left(\delta\mathcal{L}\left(\phi_{cl}\right)+\delta\eta\cdot\phi_{cl}\right)\end{aligned} \tag{37}$$

Здесь последнее слагаемое является нулевым приближением при разложении по ρ показателя второй экспоненты в (33). Сопоставляя (24) и (37), находим:

$$\Gamma\left(\phi_{cl}\right)=\int \mathrm{d}^{(d)}x\mathcal{L}_1\left(\phi_{cl}\right)+\frac{i}{2}\ln\det\left(-\frac{\delta^2\mathcal{L}_1}{\delta\phi\delta\phi}\right)-i(\text{ связные диаграммы })+\int \mathrm{d}^{(d)}x\delta\mathcal{L}\left(\phi_{cl}\right) \quad (38)$$

Здесь все слагаемые зависят явно от ϕ_{cl}. Важно также то, что каждая связная диаграмма в (38) не имеет внешних линий и потому является не ниже чем двухпетлевой. Таким образом однопетлевой вклад содержится во втором слагаемом в (38).

Отметим, что контрчлен $\delta\eta$ определяется из того требования, чтобы во всех порядках было $\langle\phi\rangle=\phi_{cl}$: если в процессе вычислений возникает ненулевой вклад в $\langle\rho\rangle$, то его "убивают", добавляя соответствующий вклад в $\delta\eta$.

Вычислим эффективное действие (38) для линейной сигма-модели в однопетлевом приближении, т.е. учитывая в (38) лишь первые два слагаемых. При помощи (7) мы находим:

$$\left.\frac{\delta^2\mathcal{L}_1}{\delta\phi^i\delta\phi^j}\right|_{\phi=\phi_{cl}}=\delta^{ij}\left(-\partial^2+\mu^2\right)-\lambda\left[\left(\phi_{cl}^k\right)^2\delta^{ij}+2\phi_{cl}^i\phi_{cl}^j\right] \quad (39)$$

Предположим, что $\phi_{cl}^i=\text{const}$ и

$$\phi_{cl}^i=(0,0,...,0,\phi_{cl}) \quad (40)$$

Тогда оператор (39) совпадает с диагональной матрицей $n\times n$, на диагонали которой находятся операторы Клейна-Гордона-Фока $(-\partial^2-m_i^2)$, где

$$m_i^2=\left\{\begin{array}{ll}\lambda\phi_{cl}^2-\mu^2 & \text{при действии на } \rho^1,...,\rho^{n-1}\\ 3\lambda\phi_{cl}^2-\mu^2 & \text{при действии на } \rho^n\end{array}\right. . \quad (41)$$

Поэтому детерминант в (38) равен произведению детерминантов этих операторов:

$$\det\left(-\frac{\delta^2\mathcal{L}_1}{\delta\phi^i\delta\phi^j}\right)=\left\{\det\left[\partial^2+\left(\lambda\phi_{cl}^2-\mu^2\right)\right]\right\}^{n-1}\cdot\det\left[\partial^2+\left(3\lambda\phi_{cl}^2-\mu^2\right)\right] \quad (42)$$

Воспользуемся известной формулой

$$\ln\det A=\mathrm{tr}\ln A$$

где A - линейный оператор. Имеем:

$$\ln\det\left(\partial^2+m^2\right)=\mathrm{tr}\ln\left(\partial^2+m^2\right) \quad (43)$$

Сделаем поворот Вика в Евклидово пространство. При помощи (7), (38), (42), (43) получаем:

$$V_{eff}\left(\phi_{cl}\right)=-\frac{1}{2}\mu^2\phi_{cl}^2+\frac{\lambda}{4}\phi_{cl}^4+\frac{1}{VT}\cdot\frac{1}{2}\cdot\sum_{i=1}^{n}\mathrm{tr}\ln\left(-\partial^2+m_i^2\right)+\frac{1}{2}\delta_\mu\phi_{cl}^2+\frac{1}{4}\delta_\lambda\phi_{cl}^4 \quad (44)$$

Здесь набор масс m_i задаётся согласно (41), $\partial^2=\sum\limits_{\mu=1}^{d}\left(\partial_\mu\right)^2$, а два последние слагаемые - возможные контрчлены. Задача свелась к вычислению величины $\mathrm{tr}\ln\left(-\partial^2+m^2\right)$. В ортонормированном базисе $\left\{e^{ikx}\right\}$ матричные элементы оператора $\ln\left(-\partial^2+m^2\right)$ равны

$$\left\langle p\left|\ln\left(-\partial^2+m^2\right)\right|k\right\rangle=\int\limits_E \mathrm{d}^{(d)}xe^{i(k-p)x}\ln\left(k_E^2+m^2\right)$$

Поэтому

$$\operatorname{tr}\ln\left(-\partial^2+m^2\right)=(VT)\int\limits_E\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\ln\left(k_E^2+m^2\right) \tag{45}$$

Но

$$\begin{aligned}\int\limits_E\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\ln\left(k_E^2+m^2\right)&=-\frac{\partial}{\partial\alpha}\int\limits_E\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\frac{1}{\left(k_E^2+m^2\right)^\alpha}\Bigg|_{\alpha=0}=\\ =-\frac{\partial}{\partial\alpha}\left[\alpha\cdot\frac{\left(m^2\right)^{d/2-\alpha}}{(4\pi)^{d/2}}\cdot\frac{\Gamma(\alpha-d/2)}{\Gamma(1+\alpha)}\right]\Bigg|_{\alpha=0}&=-\frac{\left(m^2\right)^{d/2}}{(4\pi)^{d/2}}\Gamma(-d/2)\end{aligned} \tag{46}$$

Теперь при помощи (41), (42), (44), (46) получаем:

$$\begin{aligned}V_{eff}\left(\phi_{cl}\right)=-\frac{1}{2}\mu^2\phi_{cl}^2+\frac{\lambda}{4}\left(\phi_{cl}^2\right)^2-\frac{1}{2}\cdot\frac{\Gamma(-d/2)}{(4\pi)^{d/2}}\left\{(n-1)\left(\lambda\phi_{cl}^2-\mu^2\right)^{d/2}+\left(3\lambda\phi_{cl}^2-\mu^2\right)^{d/2}\right\}+\\ +\frac{1}{2}\delta_\mu\phi_{cl}^2+\frac{1}{4}\delta_\lambda\left(\phi_{cl}^2\right)^2\end{aligned} \tag{47}$$

Здесь $\phi_{cl}^2=\left(\phi_{cl}^i\right)^2$. Эффективное действие (47), конечно, $O(n)$-инвариантно. Выражение (47) конечно при $d\to 4$ (т.е. конечны коэффициенты при при степенях ϕ_{cl}), если

$$\begin{aligned}\delta_\mu&=-\lambda\mu^2(n+2)\frac{\Gamma(2-d/2)}{(4\pi)^2}+\text{ конечные члены}\\ \delta_\lambda&=\lambda^2(n+8)\frac{\Gamma(2-d/2)}{(4\pi)^2}+\text{ конечные члены}\end{aligned} \tag{48}$$

Конечные члены в (48) регулируются условиями нормировки. Подберём их так, чтобы

$$\begin{aligned}V_{eff}\left(\phi_{cl}\right)=-\frac{1}{2}\mu^2\phi_{cl}^2+\frac{\lambda}{4}\left(\phi_{cl}^2\right)^2+\\ +\frac{1}{4(4\pi)^2}\left\{(n-1)\left(\lambda\phi_{cl}^2-\mu^2\right)^2\ln\frac{\lambda\phi_{cl}^2-\mu^2}{M^2}+\left(3\lambda\phi_{cl}^2-\mu^2\right)^2\ln\frac{3\lambda\phi_{cl}^2-\mu^2}{M^2}\right\}\end{aligned} \tag{49}$$

Здесь M - точка нормировки. На рис. 32 пунктирной линией изображён график классического
эффективного потенциала, а сплошной линией - потенциала с квантовой поправкой (49). Сплошная линия рвётся там, где поправка не определена. Из (49) видно, что при $\mu^2>0$ симметрия спонтанно нарушена, при $\mu^2=-m^2=-M^2<0$ имеется один тривиальный минимум потенциала при $\phi_{cl}=0$.

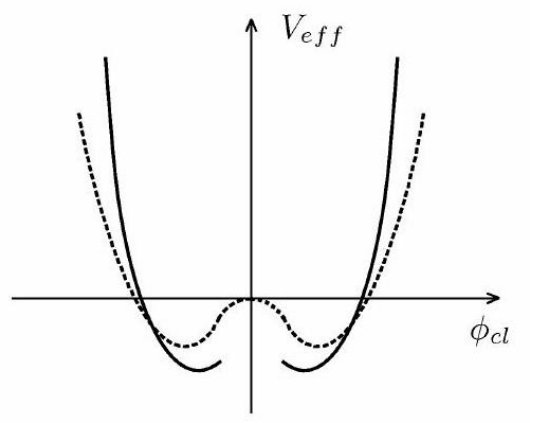


Рис. 32.

Рассмотрим $V_{eff}(49)$ в случае $\mu^2 = 0$:

$$V_{eff}\left(\phi_{cl}\right) = \frac{1}{4}\left(\phi_{cl}^2\right)^2 \left\{\lambda + \frac{\lambda^2}{(4\pi)^2}\left[(n+8)\ln\frac{\lambda\phi_{cl}^2}{M^2} + 9\ln 3\right]\right\} \tag{50}$$

Интересен вопрос: имеет ли потенциал (50) нетривиальный минимум? Легко найти, что $\mathrm{d}V_{eff}/\mathrm{d}\phi_{cl}^2 = 0$ при

$$\phi_{cl}^2 \sim \frac{M^2}{\lambda}\exp\left[-\frac{(4\pi)^2}{(n+8)\lambda}\right] \neq 0 \tag{51}$$

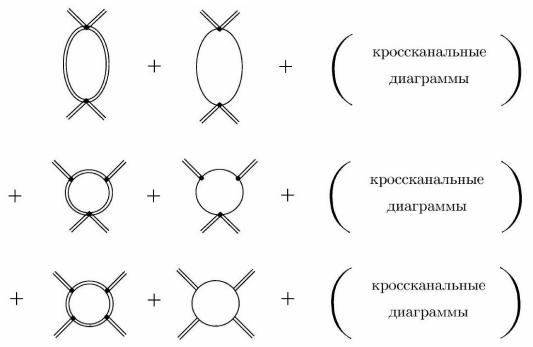
Однако при таком значении ϕ_{cl}^2 второе слагаемое в фигурной скобке в (50) почти сокращает первое слагаемое, т.е. поправки имеют тот же порядок, что и нулевое приближение. Это означает, что что для решения поставленной задачи ТВ непригодна.

Задачи

1. Нарисовать все однопетлевые диаграммы, дающие поправки к вершине туду рассеяния двух σ-частиц в линейной сигма-модели.

, дающей ампли-

Ответ:



2. Имеет место равенство

$$\frac{\delta^n \Gamma\left(\phi_{cl}\right)}{\delta\phi_{cl}\left(x_1\right)...\delta\phi_{cl}\left(x_n\right)} = -i\left\langle T\phi\left(x_1\right)...\phi\left(x_n\right)\right\rangle_{CC} \tag{52}$$

где индекс CC означает, что этот коррелятор сильно связан и его ноги ампутированы.
а) Доказать, что

$$\frac{\delta^2 \Gamma\left(\phi_{cl}\right)}{\delta\phi_{cl}(x)\delta\phi_{cl}(y)} = -[D(x,y)]^{-1}$$

гДе

$$-D(x,y) \equiv \frac{\delta^2 E(\eta)}{\delta\eta(x)\delta\eta(y)} = -i\left[\langle T\phi(x)\phi(y)\rangle - \phi_{cl}(x)\phi_{cl}(y)\right] \equiv -i\langle T\phi(x)\phi(y)\rangle_{\text{свзн}}$$

Индекс "связн"означает, что коррелятор является связным. Если вакуум трансляционно инвариантен, то согласно (13 Л5) и (22 Л5)

$$D(x,y) = \int \frac{\mathrm{d}^{(4)}k}{(2\pi)^4} \frac{e^{-ik(x-y)}}{-k^2 + m^2 + \Sigma\left(k^2\right)}, \quad -D^{-1}(k) = k^2 - m^2 - \Sigma\left(k^2\right)$$

где $\Sigma\left(k^2\right)$ - сумма сильно связных диаграмм с двумя концами.
б) Доказать формулу (52) для $n = 3$.

32.5 K-l.VIII: Anomalies

The gauge invariance leads to numerous relations between various operators and their vacuum averages, i.e., the Green functions. We have already come across such relations called the Ward or the Slavnov-Taylor identities. They are the consequences of the gauge symmetry of the classical theory. In case when one has divergences in a theory and is bound to use some regularization, the validity of these identities depends on invariance of the regularization. However, one can always perform the subtraction of divergences in such a way that the finite parts obey these relations.

The exception from this rule is the so-called *anomalies*. By anomalies one usually means the violation in quantum theory of some relation, for instance, the conservation of the current or the Ward identity following from the symmetry properties of a classical theory. The well-known examples of quantum anomalies is the anomaly of the trace of the energy-momentum tensor or the axial anomaly. The characteristic feature of the anomaly is the impossibility of its removing by the redefinition of any quantities or parameters.

32.5.1 The axial anomaly

Consider quantum electrodynamics. Let us define the vector and the axial vector currents

$$j_\mu = \bar{\psi}\gamma^\mu\psi, \quad j^5_\mu = \bar{\psi}\gamma^\mu\gamma^5\psi. \tag{32.1}$$

In classical theory the equations of motion lead to the conservation or partial conservation of the current

$$\partial_\mu j_\mu = 0, \quad \partial_\mu j^5_\mu = 2imj^5, \tag{32.2}$$

where $j^5 = \bar{\psi}\gamma^5\psi$.

On the other hand, as a consequence of the gauge invariance, the vector and the axial vertices obey the Ward identities

$$(p-p')^\mu\Gamma_\mu(p,p') = S^{-1}(p) - S^{-1}(p'), \tag{32.3}$$

$$(p-p')^\mu\Gamma^5_\mu(p,p') = S^{-1}(p)\gamma^5 + \gamma^5 S^{-1}(p') + 2m\Gamma^5(p,p'), \tag{32.4}$$

where Γ_μ, Γ^5_μ and Γ^5 are the vector, axial and pseudoscalar vertices, respectively, and S is the fermion propagator.

If one looks how the identities (32.3,32.4) are fulfilled in perturbation theory, one first of all has to introduce some regularization due to the presence of the ultraviolet divergences. If the regularization is gauge invariant, then the vector Ward identity is satisfied in any order of PT. For the axial identity there are two types of diagrams: in the first one the axial current is in the outgoing fermion line, and in the second one the axial current is in the internal loop (see Fig.32.1). For the first type of a diagram the identity (32.4) is satisfied, and for the second type

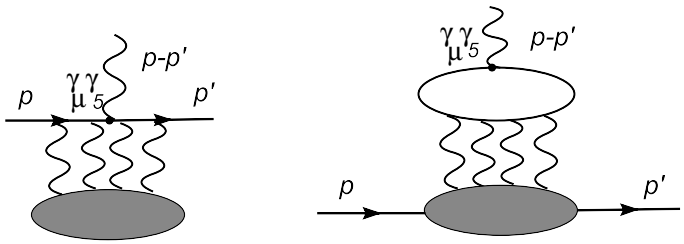


Figure 32.1: The diagrams with the axial current in external and internal fermion lines

there exists one famous triangle diagram (see Fig.32.2) where it is violated due to the ultraviolet divergence of the integral.

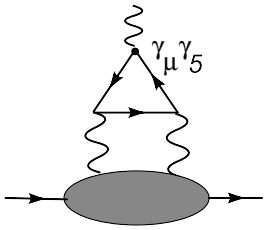

Figure 32.2: The anomalous triangle diagram for the axial current

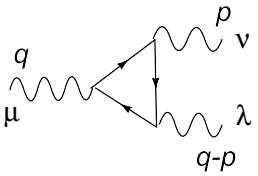
Indeed, the corresponding integral in momentum space looks like



$$= (-)(-ie)^2 \int \frac{d^4k}{(2\pi)^4} Tr\left[\gamma^\mu\gamma^5 \frac{i\hat{k}}{k^2}\gamma^\nu \frac{i(\hat{k}+\hat{p})}{(p+k)^2}\gamma^\lambda \frac{i(\hat{k}+\hat{q})}{(q+k)^2}\right] \tag{32.5}$$

and is formally divergent requiring the regularization.

To preserve the conservation of the gauge invariance, it is useful to introduce the dimensional regularization; however, here we for the first time face a problem since the γ^5 matrix has no natural and consistent continuation to non-integer dimension. Two properties of the γ^5 matrix, namely, the anticommutation with all γ^μ, $\mu = 0, 1, 2, 3$ and the property of the trace $Tr(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = -4i\epsilon^{\mu\nu\rho\sigma}$ are in contradiction if the dimension is noninteger. To calculate the axial anomaly, we use the following trick: we use the formula for the trace but reject the property of anticommutativity of γ^5. This allows one to perform al the calculations in a consistent and unambiguous way.

The divergence of the axial current can be obtained by multiplication of (32.5) by iq^μ which gives

$$e^2 \int \frac{d^4k}{(2\pi)^4} \frac{Tr\left[\hat{q}\gamma^5\hat{k}\gamma^\nu(\hat{k}+\hat{p})\gamma^\lambda(\hat{k}+\hat{q})\right]}{k^2(k+p)^2(k+q)^2} \tag{32.6}$$

Using the cyclic property of the trace we move $\hat{q}$ to the right and write it as $\hat{q} = (\hat{q}+\hat{k}) - \hat{k}$. Then the first term multiplied by $\hat{k}+\hat{q}$ gives $(k+q)^2$ and cancels with the denominator. As a result, one gets the integral

$$\int \frac{d^4k}{(2\pi)^4} \frac{Tr\left[\hat{q}\gamma^5\hat{k}\gamma^\nu(\hat{k}+\hat{p})\gamma^\lambda\right]}{k^2(k+p)^2},$$

which depends only on p and after the integration turns to zero due to the antisymmetry of the trace with the γ^5 matrix.

In the second term we will drag $\hat{k}$ to the left until it is multiplied by $\hat{k}$ giving k^2. As a result, at each step we always get the trace of four γ-matrices with γ^5 for which we have the formula with the ϵ-tensor. We obtain in the numerator

$$-4i\epsilon^{\alpha\nu\beta\lambda}k^\alpha(k+p)^\beta[(k+q)^2-q^2] + 8i\epsilon^{\alpha\nu\beta\rho}k^\alpha(k+p)^\beta q^\rho k^\lambda - 4i\epsilon^{\alpha\nu\lambda\rho}k^\alpha q^\rho[(k+p)^2-p^2]$$

$$-4i\epsilon^{\nu\alpha\lambda\rho}p^\alpha q^\rho k^2 + 8i\epsilon^{\alpha\beta\lambda\rho}k^\alpha p^\beta q^\rho k^\nu.$$

Despite the fact that the integral is formally divergent, using a dimensional regularization and collecting all terms together we finally get the finite answer equal to

$$-\frac{e^2}{4\pi^2}\epsilon^{\mu\nu\rho\lambda}p^\mu q^\rho = -\frac{e^2}{4\pi^2}\epsilon^{\mu\nu\rho\lambda}p^\mu(q-p)^\rho, \tag{32.7}$$

One has to add to this expression the same diagram but with the replacement $p \leftrightarrow q-p, \nu \leftrightarrow \lambda$ and take the sum, but the answer is already invariant with respect to this replacement. Multiplying (32.7) by $A_\nu(p)A_\lambda((q-p)$ and transforming to the coordinate representation, one gets

$$\partial_\mu j^5_\mu = \frac{e^2}{4\pi^2}\epsilon^{\mu\nu\rho\lambda}\partial_\mu A_\nu \partial_\rho A_\lambda = \frac{e^2}{16\pi^2}\epsilon^{\mu\nu\rho\lambda}F_{\mu\nu}F_{\rho\lambda}. \tag{32.8}$$

As a result one has the following modification of equations for the divergence of the axial current and the axial vertex

$$\partial_\mu j^5_\mu = 2imj^5 + \frac{\alpha}{4\pi}F_{\mu\nu}F_{\rho\sigma}\epsilon^{\mu\nu\rho\sigma}, \tag{32.9}$$

$$(p-p')^\mu\Gamma^5_\mu(p,p') = S^{-1}(p)\gamma^5 + \gamma^5 S^{-1}(p') + 2m\Gamma^5(p,p') - i\frac{\alpha}{4\pi}F(p,p'), \tag{32.10}$$

where $F(p,p')$ is the vertex with insertion of the operator $F\tilde{F}$. The appearance of the r.h.s in these equations is called *anomaly* known as the Adler-Bell-Jackiw or triangle anomaly.

The most essential here is not the violation of the Ward identity but the fact that subtracting the anomaly and restoring the "normal" Ward identity for the axial vertex we violate the conservation of the vector current. In other words, it is impossible to satisfy the conservation of axial and vector currents *simultaneously*.

Notice that the violation of the conservation of the axial current preserving the conservation of the vector current (32.9) can be obtained by accurately calculating the matrix element for the divergence of the axial current in x-space splitting the arguments of the field operators. Consider the vacuum average of the divergence of the axial current, and to avoid the singularity for the product of two operators at coinciding points, split the arguments. Then to preserve the gauge invariance, we have to insert between the operators the exponent of the Wilson line. The axial current then takes the form

$$j^5_\mu(x) = \lim_{\varepsilon\to 0}\{\bar\psi(x+\varepsilon/2)\gamma^\mu\gamma^5 \exp[-ie\int\limits_{x-\varepsilon/2}^{x+\varepsilon/2} dz^\nu A_\nu(z)]\psi(x-\varepsilon/2)\}, \tag{32.11}$$

and for the divergence we get

$$\begin{aligned}
\partial_\mu j^5_\mu(x) &= \lim_{\varepsilon\to 0}\{\partial_\mu\bar\psi(x+\varepsilon/2)\gamma^\mu\gamma^5 \exp[-ie\int\limits_{x-\varepsilon/2}^{x+\varepsilon/2} dz^\nu A_\nu(z)]\psi(x-\varepsilon/2) \\
&+ \bar\psi(x+\varepsilon/2)\gamma^\mu\gamma^5 \exp[-ie\int\limits_{x-\varepsilon/2}^{x+\varepsilon/2} dz^\nu A_\nu(z)]\partial_\mu\psi(x-\varepsilon/2) \\
&+ \bar\psi(x+\varepsilon/2)\gamma^\mu\gamma^5[-ie\varepsilon^\nu\partial_\mu A_\nu(x)] \exp[-ie\int\limits_{x-\varepsilon/2}^{x+\varepsilon/2} dz^\nu A_\nu(z)]\psi(x-\varepsilon/2)\}.
\end{aligned} \tag{32.12}$$

Using the equations of motion

$$\gamma^\mu\partial_\mu\psi = -ie\hat{A}\psi, \quad \partial_\mu\bar\psi\gamma^\mu = ie\bar\psi\hat{A}$$

and keeping the terms of the order of ε we find

$$\begin{aligned}
\partial_\mu j^5_\mu(x) &= \lim_{\varepsilon\to 0}\{\partial_\mu\bar\psi(x+\varepsilon/2)[-ie\hat{A}(x+\varepsilon/2) - ie\hat{A}(x-\varepsilon/2) \\
&\qquad -ie\varepsilon^\nu\gamma^\mu\partial_\mu A_\nu(x)]\gamma^5\psi(x-\varepsilon/2)\} \\
&= \lim_{\varepsilon\to 0}\{\bar\psi(x+\varepsilon/2)[-ie\varepsilon^\nu\gamma^\mu(\partial_\mu A_\nu - \partial_\nu A_\mu)]\gamma^5\psi(x-\varepsilon/2)\}
\end{aligned} \tag{32.13}$$

Now we have to calculate the vacuum average over the fermion vacuum (the photon field is assumed to be external) which means that we have to permute the fermion operators. The permutation function of the fermion operators is singular and this is the reason for appearance of a nonzero term similarly to the appearance of triangle anomaly due to divergency of the integral. Indeed, calculating the propagator of the fermion in external field and keeping the terms linear in the photon field, we get

$$S(y-z) = \int\frac{d^4k}{(2\pi)^4}e^{ik(y-z)}\frac{i\hat{k}}{k^2} + \int\frac{d^4k}{(2\pi)^4}\frac{d^4p}{(2\pi)^4}e^{i(k+p)y}e^{-ikz}\frac{i(\hat{k}+\hat{p})}{(k+p)^2}(-ie\hat{A}(p)\frac{i\hat{k}}{k^2} + ... \tag{32.14}$$

The propagator (32.14) is singular as $y \to z$; however, the first term does not give a contribution to the divergence, while the second one leads to

$$\begin{aligned}
&\langle\bar\psi(x+\varepsilon/2)\gamma^\mu\gamma^5\psi(x-\varepsilon/2)\rangle = \\
&= \int \frac{d^4k}{(2\pi)^4}\frac{d^4p}{(2\pi)^4}e^{ipx}e^{-ik\varepsilon}Tr[\frac{i(\hat k+\hat p)}{(k+p)^2}(-ie\hat A(p))\frac{i\hat k}{k^2}\gamma^\mu\gamma^5] \\
&= \int \frac{d^4k}{(2\pi)^4}\frac{d^4p}{(2\pi)^4}e^{ipx}e^{-ik\varepsilon}\frac{4e\epsilon^{\mu\nu\rho\sigma}(k+p)_\nu A_\rho(p)k_\sigma}{(k+p)^2k^2}.
\end{aligned} \tag{32.15}$$

To find the limit as $\varepsilon \to 0$, one can expand the integrand for large k, which gives

$$\begin{aligned}
\langle\bar\psi(x+\varepsilon/2)\gamma^\mu\gamma^5\psi(x-\varepsilon/2)\rangle &= 4e\epsilon^{\mu\nu\rho\sigma}\int\frac{d^4p}{(2\pi)^4}e^{ipx}p_\nu A_\rho(p)\int\frac{d^4k}{(2\pi)^4}e^{-ik\varepsilon}\frac{k_\sigma}{k^4} \\
&= -4e\epsilon^{\mu\nu\rho\sigma}i\partial_\nu A_\rho(x)\frac{2\varepsilon_\sigma}{16\pi^2\varepsilon^2} = -e\epsilon^{\mu\nu\rho\sigma}iF_{\nu\rho}(x)\frac{\varepsilon_\sigma}{4\pi^2\varepsilon^2},
\end{aligned} \tag{32.16}$$

Substituting this expression into (32.13) we find

$$\partial_\mu j^5_\mu = \lim_{\varepsilon\to0}\{-e\epsilon^{\mu\nu\rho\sigma}iF_{\nu\rho}(x)\frac{\varepsilon_\sigma}{4\pi^2\varepsilon^2}(-ie\varepsilon^\tau F_{\mu\tau})\} = \frac{e^2}{16\pi^2}\epsilon^{\mu\nu\rho\sigma}F_{\nu\rho}F_{\sigma\mu}, \tag{32.17}$$

that coincides with (32.9).

The axial anomaly has one very important property: the obtained formulas (32.9) and (32.10) are *exact* in all orders of perturbation theory, i.e., have no radiative corrections. More rigorous statement is: there exists such a renormalization scheme (and it was constructed explicitly) that the radiative corrections to the axial anomaly are absent. This statement is the subject of the Adler-Bardeen theorem. Graphically, this means the cancellation of the contributions of the diagrams shown in Fig.32.3, which was checked by explicit calculation.

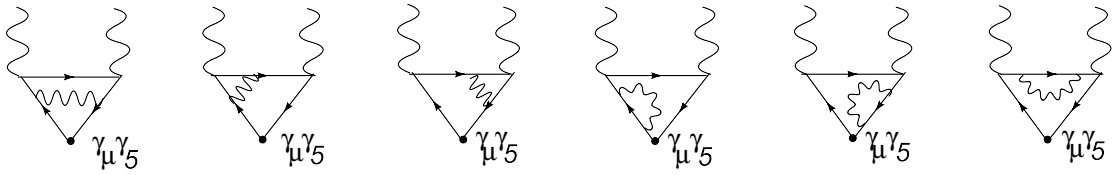


Figure 32.3: Cancellation of radiative corrections to the axial anomaly

The Adler-Bardeen theorem is valid also in non-Abelian theories. It has important consequences: if the anomaly is compensated in the lowest order, it will not appear further.

32.5.2 Consequences of the axial anomaly

Let us ask the question what are the consequences of the axial anomaly? Here one has to distinguish two cases: when the operator of the axial current is an external operator with respect to the Lagrangian and when it is present in the interaction Lagrangian.

In the first case, the presence of anomaly does not lead to any troubles and even may be useful. Thus, for instance, in the current algebra which describes the low energy hadron interactions, the axial anomaly is responsible for the neutral pion decay $\pi^0 \to 2\gamma$ and is in agreement with the experiment.

In the second case, the triangle anomaly leads to that the ultraviolet renormalizations of the vector vertex do not remove all divergences from the axial vertex. This has destructive consequences for the renormalizability of the whole theory. To see this, compare the two processes of

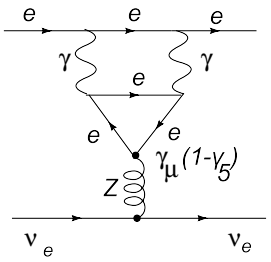

Figure 32.4: The anomaly in the process of lepton scattering in the Standard Model

the elastic scattering of leptons: $\nu_e + e \to \nu_e + e$ and $\nu_\mu + e \to \nu_e + \mu$ in the Standard Model. Graphically, in the lowest order they differ by one diagram containing the triangle anomaly (See Fig.32.4).

As a result, after the renormalization the amplitude of $\nu_\mu e$-scattering has finite radiative corrections, while that of ν_e-scattering is divergent. This led to nonrenormalizability of the theory and was a serious problem for the left-right nonsymmetric model with $SU_L(2) \times U(1)$ symmetry before the introduction of the

$$-quark. Remarkably, the$$

-quark introduced by Glashow, Iliopoulos and Maiani for suppression of the neutral current changing strangeness leads to the compensation of the contributions of quarks and leptons to triangle anomaly and restores the renormalizability of the theory.

In the Standard Model due to its left-right asymmetry the presence of the axial currents for quarks and leptons leads to several kinds of triangle anomalies where all three gauge fields may be in the vertices of the triangle. However, not all of them lead to anomalies. In general, the anomaly is proportional to the trace

$$Tr\ T^a\{T^b, T^c\},$$

where the matrix T^a is the generator of the corresponding gauge group in the representation corresponding to the fields that run inside the triangle. The necessary condition of the existence of anomaly is the presence of the complex representations and the nontrivial anticommutator of the generators of the group. Among the simple Lie groups which satisfy this requirement, only the groups $SU(n)$, $SO(4n+2)$ and E_6 have complex representations and out of them only the $SU(n), n > 2$ and $SO(6)$ groups have a symmetric invariant needed for the construction of the anomaly. The gauge theories built on other groups are free from anomalies.

The non-vanishing anomalies corresponding to the symmetry group of the Standard Model $SU_c(3) \times SU_L(2) \times U_Y(1)$ are presented in Fig.32.5 where the gauge fields adjusted to the groups $U(1)$ and $SU(2)$ are shown prior to mixing. The particles that run over the triangle can be either left or right quarks and leptons. Particles of different helicity give the opposite sign contribution to the axial anomaly.

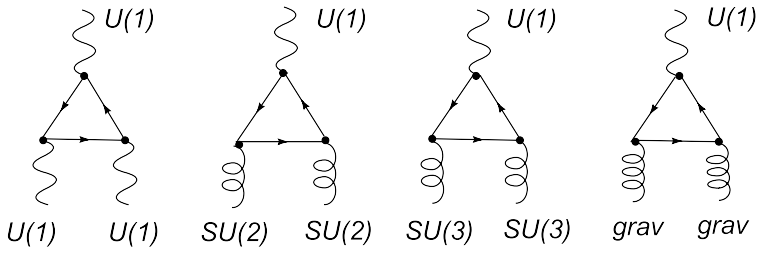

Figure 32.5: The triangle anomaly in the Standard Model

In the first case, the anomaly is proportional to the trace of the cube of hypercharge $TrY^3 = TrY_L^3 - TrY_R^3$ and its absence is achieved by the cancellation of the contributions of quarks and

leptons in each generation

$$\begin{aligned} TrY^3 = \; = \; & 3\left[(\frac{1}{3})^3+(\frac{1}{3})^3-(\frac{4}{3})^3-(-\frac{2}{3})^3\right]+(-1)^3+(-1)^3-(-2)^3=0. \\ & \uparrow \quad \uparrow \qquad \uparrow \qquad \uparrow \qquad \uparrow \qquad \uparrow \qquad \uparrow \qquad \uparrow \\ & colour \;\; u_L \quad d_L \quad u_R \quad d_R \quad \nu_L \quad e_L \quad e_R. \end{aligned} \tag{32.18}$$

In further diagrams the anomaly is proportional to, respectively,

$$\begin{aligned} TrY_L &= 3\left(\frac{1}{3}+\frac{1}{3}\right)-1-1=0, \\ TrY_q &= 3\left(\frac{1}{3}+\frac{1}{3}-\frac{4}{3}-(-\frac{2}{3})\right)=0, \\ TrY &= 3\left(\frac{1}{3}+\frac{1}{3}-\frac{4}{3}-(-\frac{2}{3})\right)-1-1-(-2)=0. \end{aligned} \tag{32.19}$$

This way the anomaly is miraculously canceled in all the cases and does not break the renormalizability of the SM.

32.5.3 The conformal anomaly

Another example of quantum anomaly is the conformal anomaly or the anomaly of the trace of the energy-momentum tensor. The requirement of conformal (scale) invariance means the invariance of the action with respect to the transformation

$$x_\mu \to x_\mu e^{-\sigma}, \quad \phi(xe^{-\sigma}) \to e^{\Delta\sigma}\phi(x), \tag{32.20}$$

where Δ is the dimension of a field. This condition is fulfilled in the classical Lagrangian if it has no dimensional parameters. In this case, according to the Noether theorem, there exists a conserved current called the dilatation current $D^\mu = \Theta^{\mu\nu}x_\nu$, so that

$$\partial_\mu D^\mu = \Theta^\mu_\mu,$$

where Θ^μ_ν is the symmetric energy-momentum tensor.

The easiest way to see it is to define the energy-momentum tensor as a variation of the action of the matter fields with respect to the space-time metric in the external gravitational filed

$$\Theta^{\mu\nu} = 2\frac{\delta}{\delta g_{\mu\nu}}\int d^4x\ \mathcal{L}(x). \tag{32.21}$$

The scale transformation can be realized as a variation of the metric

$$g_{\mu\nu}(x) \to e^{2\sigma}g_{\mu\nu}(x). \tag{32.22}$$

This means that the variation of the Lagrangian under this transformation is the trace of $\Theta^{\mu\nu}$. The deviation of the trace of the energy-momentum tensor from zero indicates the violation of the scale (and hence conformal) invariance.

In the quantum case, due the presence of the ultraviolet divergences the new scale appears. This is the same phenomenon of dimensional transmutation discussed above. Therefore, the scale invariance of the action is violated.

Since the coupling constant becomes scale dependent, its variation with the scale (32.20) takes the form

$$\delta g = \sigma\mu\frac{dg}{d\mu} = \sigma\beta(g). \tag{32.23}$$

Hence, for the variation of the Lagrangian we get

$$\delta\ \mathcal{L} = \sigma \frac{\delta \mathcal{L}}{\delta g_i} \beta_i(\{g\}), \tag{32.24}$$

i.e.,

$$\partial_\mu D^\mu = \Theta^\mu_\mu = \frac{\delta \mathcal{L}}{\delta g_i} \beta_i(\{g\}). \tag{32.25}$$

This relation is known as *the trace anomaly* of the energy-momentum tensor.

Similarly to the axial anomaly, relation (32.25) can be checked by perturbation theory. However, in this case the result is defined by the full β-function calculated in all orders of PT.

32.6 K-l.IX: Infrared Divergences

One more problem that we encounter on the way of calculating the finite expressions for the probabilities of physical processes is the presence of the so-called *infrared divergences*. They appear when calculating the matrix elements of the scattering matrix on shell, i.e., when the squares of external momenta are equal to the corresponding masses squared and the theory contains massless particles like photons or gluons. The infrared divergences can be of two types: the divergences for small values of momenta (the genuine infrared divergences) and the divergences at parallel momenta (the collinear divergences). Contrary to the ultraviolet divergences, the infrared divergences have a clear physical meaning: a massless particle with a very small momentum can not be registered and with momentum parallel to another particle cannot be distinguished. For this reason in the theories with massless particles one has to define the physical process to be evaluated in a proper way.

32.6.1 The double logarithmic asymptotics

For illustration consider the process of creation of a muon pair in the e^+e^- annihilation. The leading diagrams for this process are shown in Fig.32.6.

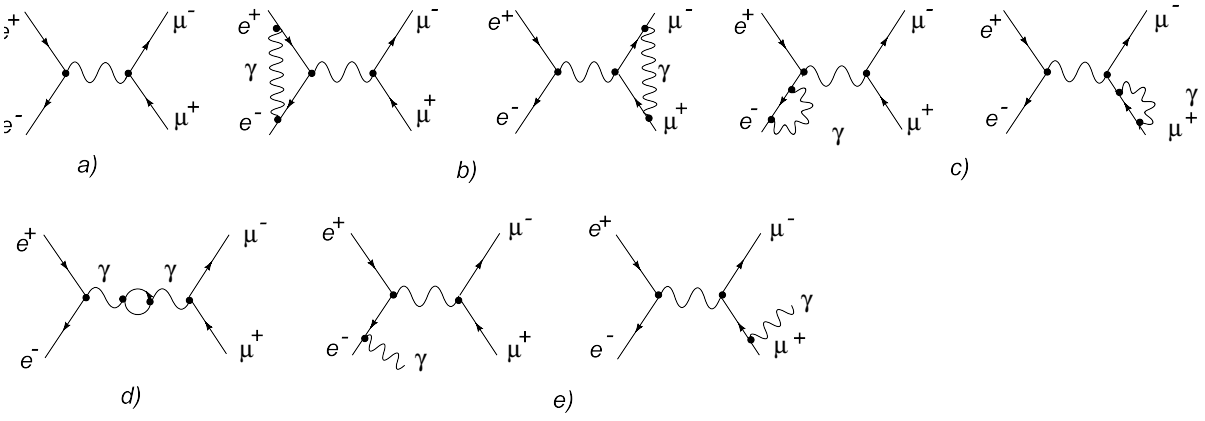

Figure 32.6: The diagrams contributing to the process $e^+e^- \to \mu^+\mu^-$ in QED: a) the leading order, b)- d) the virtual corrections of the order of α, e) the real corrections of the order of α.

The first diagram is the tree amplitude, it gives the contribution in the leading order. The radiative corrections due to emission of virtual photons (Fig.32.6 b)) are the corrections to the vertex function considered above (see (18.40)). It is easy to see that if one puts in this formula all fermion momenta on mass shell, i.e. $p^2 = (p-q)^2 = m^2$, then in the second integral in the denominator one gets $[-m^2x^2 + q^2y(x-y)]$. Performing the change of variables $y \to yx$ so that

all the integrations are performed within the limits [0,1], we get $[-m^2x^2 + q^2x^2y(1-y)]$, and the integral (with account of the Jacobian = x) is logarithmically divergent as $x \to 0$.

The appeared divergence has the infrared nature. Like the ultraviolet one it can be regularized, for instance, by introducing the nonzero photon mass or cutting the integral over momenta at the lower limit, or with the help of dimensional regularization but it cannot be removed by any renormalization.

Let us calculate this diagram on mass shell introducing the nonzero photon mass m_{ph} into the virtual photon line. This will not break the gauge invariance since, as it will be clear later, after the cancellation of the IR divergences one can put the mass of a photon equal to zero.

Let us go back to eq.(18.40), remove the UV divergence by the minimal subtraction and go to the mass shell for the fermion fields taking into account that the external fermion operators obey the Dirac equation $(\hat{p} - m)u(p) = 0$ and $\bar{u}(p-q)(\hat{p} - \hat{q} - m) = 0$. Then after some exercise we obtain for the vertex function the following expression:

$$\Gamma_1^R(p,q) = ie\left[F_1(q^2)\gamma^\mu + iF_2(q^2)\frac{\sigma^{\mu\nu}q^\nu}{2m}\right], \qquad \sigma^{\mu\nu} \equiv i\frac{\gamma^\mu\gamma^\nu - \gamma^\nu\gamma^\mu}{2}, \tag{32.26}$$

where the form-factors $F_i(q^2)$ have the form

$$\begin{aligned} F_1(q^2) &= \frac{e^2}{16\pi^2}\left[-2 - 2\int\limits_0^1 dx\int\limits_0^1 dy\ x\ \log\left(\frac{-m^2x^2 + q^2x^2y(1-y)}{-\mu^2}\right)\right. \\ &+ \left.\int\limits_0^1 dx\int\limits_0^1 dy\ x\ \frac{2m^2(2-2x-x^2) - 2q^2(1-xy)(1-x+xy)}{-m^2x^2 + q^2x^2y(1-y) - m_{ph}^2(1-x)}\right], \end{aligned} \tag{32.27}$$

$$F_2(q^2) = \frac{e^2}{16\pi^2}\left[\int\limits_0^1 dx\int\limits_0^1 dy\ x\ \frac{-4m^2x(1-x)}{-m^2x^2 + q^2x^2y(1-y) - m_{ph}^2(1-x)}\right]. \tag{32.28}$$

The form factor F_2 is IR convergent and does not need any regularization. Substituting $m_{ph} = 0$, we get

$$F_2(q^2) = \frac{\alpha}{4\pi}\int\limits_0^1 dy\frac{2m^2}{m^2 - q^2y(1-y)}. \tag{32.29}$$

For $q^2 = 0$ it can be easily calculated and equals

$$F_2(q^2 = 0) = \frac{\alpha}{2\pi}, \tag{32.30}$$

which is nothing else but the first correction to the g-factor, which is called the anomalous magnetic moment of electron (muon).

As for the form factor F_1, it is IR divergent. We calculate its divergent part in the limit $m_{ph} \to 0$. It comes only from the second integral in (32.27). To simplify the integration, we notice that the divergence is defined by the region of the parameter $x \sim 0$. Therefore, we put $x = 0$ everywhere in the numerator and in the coefficient of m_{ph} in the denominator. Then one gets

$$F_1(q^2) \simeq \frac{e^2}{16\pi^2}\int\limits_0^1 dy\int\limits_0^1 xdx\frac{2(2m^2 - q^2)}{[-m^2 + q^2y(1-y)]x^2 - m_{ph}^2}. \tag{32.31}$$

The integral over x is now easily evaluated

$$F_1(q^2) \simeq \frac{\alpha}{4\pi}\int\limits_0^1 dy\frac{2m^2 - q^2}{[-m^2 + q^2y(1-y)]}\log\left(\frac{-m^2 + q^2y(1-y) - m_{ph}^2}{-m_{ph}^2}\right). \tag{32.32}$$

The remaining integral over y is also simple. We calculate it in the limit $-q^2 \to \infty$. Then it takes the form

$$F_1(q^2) \simeq -\frac{\alpha}{4\pi}\int\limits_0^1 dy \frac{q^2}{[-m^2+q^2y(1-y)]}\log\left(\frac{-q^2}{m_{ph}^2}\right) \simeq -\frac{\alpha}{2\pi}\log\left(\frac{-q^2}{m^2}\right)\log\left(\frac{-q^2}{m_{ph}^2}\right). \qquad (32.33)$$

The obtained double logarithmic behaviour of the form-factor is called *the Sudakov* double logarithm. It contains the infrared cutoff in the form of the photon mass. In the amplitude of creation of the muon pair there are two of such form factors for the electron and the muon vertices, respectively. The corrections to the fermion and the photon propagators do not contain the IR divergences. Thus, the cross-section of the process $e^+e^- \to \mu^+\mu^-$ is logarithmically divergent. In order to understand the reason of appearance of the IR divergence and to find the method of its elimination, consider the process of creation of the muon pair from the point of view of an observer.

32.6.2 The soft photon emission

During the process of electron-positron annihilation the muon pair is created with momenta that satisfy the conservation law and can be measured. However, they are registered with some accuracy, and momentum smaller than some value which depends on a particular detector is not registered. Therefore, if besides the muon pair the photon with momentum smaller than this value is created, then this process with emission of the "soft" γ-quantum $e^+e^- \to \mu^+\mu^-\gamma$ is experimentally indistinguishable from the initial process $e^+e^- \to \mu^+\mu^-$. The diagrams corresponding to the process $e^+e^- \to \mu^+\mu^-\gamma$ are shown in Fig.32.6 e). They contain an additional vertex and hence additional coupling, but being squared give a correction to the main process of the order of α, exactly as the radiative corrections due to the virtual photon.

Let us compare the differential cross-sections of the precess $e^+e^- \to \mu^+\mu^-$ in the one-loop approximation and $e^+e^- \to \mu^+\mu^-\gamma$ in the tree approximation. We have, respectively,

$$\frac{d\sigma}{d\Omega}(e^+e^- \to \mu^+\mu^-) = \left(\frac{d\sigma}{d\Omega}\right)_0\left[1-\frac{\alpha}{\pi}\log\left(\frac{-q^2}{m_{e,\mu}^2}\right)\log\left(\frac{-q^2}{m_{ph}^2}\right)+...+\mathcal{O}(\alpha^2)\right] \qquad (32.34)$$

$$\frac{d\sigma}{d\Omega}(e^+e^- \to \mu^+\mu^-\gamma) = \left(\frac{d\sigma}{d\Omega}\right)_0\left[+\frac{\alpha}{\pi}\log\left(\frac{-q^2}{m_{e,\mu}^2}\right)\log\left(\frac{-q^2}{m_{ph}^2}\right)+...+\mathcal{O}(\alpha^2)\right] \qquad (32.35)$$

where the second cross-section is written down without derivation which we will perform later. As follows from eqs.(32.34,32.35), each of these cross-sections is IR divergent, but in the sum the divergences cancel and one gets the finite answer.

What is observable after all? In fact, neither the first nor the second process is observable separately. In a real detector with limited sensitivity one observes the process of creation of the muon pair plus an arbitrary number of soft photons with the total energy below the sensitivity threshold. In a given order of perturbation theory we have to sum the cross-sections of the two processes in order to get the observed cross-section

$$\left(\frac{d\sigma}{d\Omega}\right)_{observable} = \left(\frac{d\sigma}{d\Omega}\right)(e^+e^- \to \mu^+\mu^-) + \left(\frac{d\sigma}{d\Omega}\right)(e^+e^- \to \mu^+\mu^-\gamma, E < E_{min}). \qquad (32.36)$$

The latter cross-section is given by the same formula (32.35) with the replacement in the second logarithm of the photon energy by E_{min}. Thus, we get

$$\left(\frac{d\sigma}{d\Omega}\right)_{observable} = \left(\frac{d\sigma}{d\Omega}\right)_0\left[1-\frac{\alpha}{\pi}\log\left(\frac{-q^2}{m_{e,\mu}^2}\right)\log\left(\frac{-q^2}{E_{min}^2}\right)+...+\mathcal{O}(\alpha^2)\right]. \qquad (32.37)$$

As one can see, for the proper statement of the problem the cross-section of the observable process is finite and does not depend on the IR regulator. At the same time, it depends on the

sensitivity of the detector E_{min} and for improved sensitivity tends to infinity. However, this infinity also is not physical and is the artefact of perturbation theory: when the logarithm becomes large we go beyond the scope of applicability of perturbation theory and it is necessary to perform the summation of these corrections by analogy with what happens with the ultraviolet logarithms within the renormalization group method.

Thus, the IR divergences appear due to the contributions of the photons with "soft" momenta: real with the energy smaller than E_{min} and virtual with momenta $k^2 < E^2_{min}$. What is important is that the momenta of fermions are on mass shell, otherwise the singularities in the propagator do not arise. The typical diagram of higher order contains a big amount of real and virtual photon lines (see Fig.32.7).

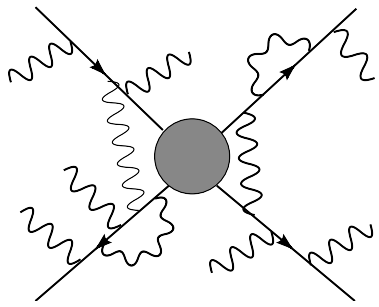

Figure 32.7: The hard process with creation of the soft photons

Let us try to sum up the contributions of these soft photons. Consider first the external fermion line with the outgoing photons (real and virtual).

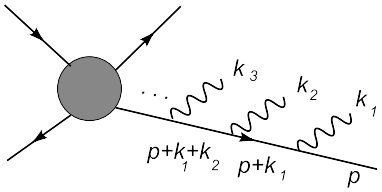

Figure 32.8: The emission of the soft photons from the fermion line

It corresponds to the following expression:

$$\bar{u}(p)\ (-ie\gamma^{\mu_1})\ \frac{i(\hat{p}+\hat{k}_1+m)}{2pk_1}\ (-ie\gamma^{\mu_2})\ \frac{i(\hat{p}+\hat{k}_1+\hat{k}_2+m)}{2p(k_1+k_2)+O(k^2)}\ \cdots \tag{32.38}$$
$$\cdots\ (-ie\gamma^{\mu_n})\ \frac{i(\hat{p}+\hat{k}_1+\cdots+\hat{k}_n+m)}{2p(k_1+\cdots k_n)+O(k^2)}\ \ iM_{hard}.$$

We use now the fact that the operator $\bar{u}(p)$ obeys the Dirac equation $\bar{u}(p)(\hat{p}-m)=0$ and omit the momenta $k_i \ll p$ in the numerator. Then we get

$$\bar{u}(p)\gamma^{\mu_1}(\hat{p}+m)\gamma^{\mu_2}(\hat{p}+m)\cdots = \bar{u}(p)2p^{\mu_1}\gamma^{\mu_2}(\hat{p}+m)\cdots = \bar{u}(p)2p^{\mu_1}2p^{\mu_2}\cdots . \tag{32.39}$$

Hence, eq.(32.38) takes the form

$$\bar{u}(p)\ (e\frac{p^{\mu_1}}{pk_1})(e\frac{p^{\mu_2}}{p(k_1+k_2)})\cdots(e\frac{p^{\mu_n}}{p(k_1+\cdots+k_n)}). \tag{32.40}$$

The next step is the summation over all the permutations of the photon lines and the permutations of momenta k_i. (So far we have not distinguished between the real and virtual photons, we will

do it later.) This operation is non-trivial but leads to the simple result. One has

$$\sum_{permutations} \frac{1}{pk_1}\,\frac{1}{p(k_1+k_2)}\,\cdots\,\frac{1}{p(k_1+k_2+\cdots+k_n)} = \frac{1}{pk_1}\,\frac{1}{pk_2}\,\cdots\,\frac{1}{pk_n}. \tag{32.41}$$

The same procedure can be applied to the incoming fermion line. The difference is that the fermion momentum has the opposite direction which leads to the replacement of $(p+k_i)^2$ to $(p-k_i)^2$ in the propagator, i.e., the change of the sign $p \to -p$ in the denominator. Collecting both factors together we get the following expression for the amplitude of emission of soft photons from arbitrary points of the incoming and the outgoing line (Fig.32.9):

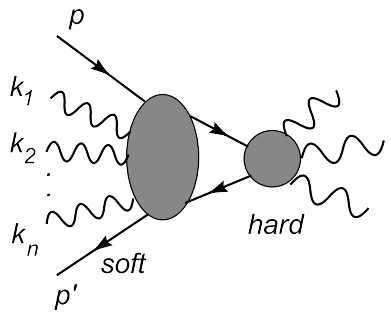

Figure 32.9: The emission of soft photons from arbitrary points of the incoming and the outgoing lines

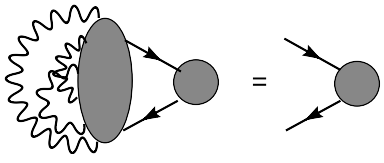
$$\mathcal{M} = \bar{u}(p')\; i\mathcal{M}_{hard}\; u(p)\; e\left(\frac{p'^{\mu_1}}{p'k_1} - \frac{p^{\mu_1}}{pk_1}\right) e\left(\frac{p'^{\mu_2}}{p'k_2} - \frac{p^{\mu_2}}{pk_2}\right)\cdots e\left(\frac{p'^{\mu_n}}{p'k_n} - \frac{p^{\mu_n}}{pk_n}\right). \tag{32.42}$$

Now we have to decide which photons are real and which are virtual. The virtual photon can be obtained by joining the two photon momenta k_i and k_j, taking $k_i = -k_j = k$, multiplying by the photon propagator and integrating over k. In this way for any virtual photon we get the expression:

$$\frac{e^2}{2}\int \frac{d^4k}{(2\pi)^4}\frac{-i}{k^2}\left(\frac{p'}{p'k} - \frac{p}{pk}\right)\left(\frac{p'}{-p'k} - \frac{p}{-pk}\right), \tag{32.43}$$

where the factor $1/2$ compensates the double counting due to permutation of k_i and k_j. The obtained integral is nothing else but the vertex function in the one-loop approximation, i.e., the form factor $F_1(q^2)$.

If the number of virtual photons equals n, one gets the product of n expressions like (32.43) and the factor $1/n!$ taking into account the permutations which do not change the result. The full answer is obtained with the help of summation over the soft virtual photons, which gives



$$\times \sum_{n=0}^{\infty} \frac{F_1^n}{n!} = \bar{u}(p')\; i\mathcal{M}_{hard}\; u(p)\exp(F_1). \tag{32.44}$$

At the same time, if the real photon is emitted, then instead of the propagator one has to multiply the amplitude by the polarization operator, sum up over all polarizations and integrate the square of the matrix element over the photon phase space. In this case, one gets the following expression:

$$I(q^2) = e^2\int \frac{d^3k}{(2\pi)^3}\frac{-g^{\mu\nu}}{2|k|}\left(\frac{p'^{\mu}}{p'k} - \frac{p^{\mu}}{pk}\right)\left(\frac{p'^{\nu}}{p'k} - \frac{p^{\nu}}{pk}\right), \tag{32.45}$$

which is the element of the cross-section of the process $e^+e^- \to \mu^+\mu^-\gamma$. The integration over the modulus of the three-vector $\vec{k}$ has to be performed within the limits (m_{ph}, E_{min}). Contracting the indices one gets

$$I(q^2) = -\frac{e^2}{(2\pi)^3}\int \frac{d^3k}{2|k|}\left(\frac{p'^2}{(p'k)^2} - 2\frac{p'p}{(pk)(p'k)} + \frac{p^2}{(pk)^2}\right). \tag{32.46}$$

The first and the last integrals are equal to each other. Let us consider the last one and choose the frame where $\vec{p} = 0$. This gives

$$I_1 = -\frac{e^2}{(2\pi)^3}4\pi \int\limits_{m_{ph}}^{E_{min}} \frac{k^2dk}{2k}\frac{m^2}{(mk)^2} = -\frac{\alpha}{2\pi}\log(\frac{E^2_{min}}{m^2_{ph}}). \tag{32.47}$$

As for the second integral, we proceed in the following way: first we also choose the frame $\vec{p} = 0$, and then we covariantize the answer. One has

$$\begin{aligned} I_2 &= \frac{e^2}{(2\pi)^3}2\pi \int\limits_{m_{ph}}^{E_{min}} \frac{k^2dk}{k}\int\limits_{-1}^{1} d\cos\theta \frac{m\sqrt{\vec{p'}^2+m^2}}{(mk)(\sqrt{\vec{p'}^2+m^2}k - |\vec{p'}|k\cos\theta)} \\ &= \frac{\alpha}{2\pi}\log(\frac{E^2_{min}}{m^2_{ph}})\frac{\sqrt{\vec{p'}^2+m^2}}{|\vec{p'}|}\log\left(\frac{\sqrt{\vec{p'}^2+m^2}-|\vec{p'}|}{\sqrt{\vec{p'}^2+m^2}+|\vec{p'}|}\right). \end{aligned} \tag{32.48}$$

Covariantizing this answer and having in mind that $q = p - p'$, $p^2 = p'^2 = m^2$ and, hence, $q^2 = 2m^2 - 2m\sqrt{\vec{p'}^2+m^2}$ one gets

$$I_2(q^2) = \frac{\alpha}{2\pi}\log(\frac{E^2_{min}}{m^2_{ph}})\frac{2m^2-q^2}{\sqrt{-q^2(4m^2-q^2)}}\log\left(\frac{2m^2-q^2-\sqrt{-q^2(4m^2-q^2}}{2m^2-q^2+\sqrt{-q^2(4m^2-q^2}}\right). \tag{32.49}$$

Thus,

$$I(q^2) = \frac{\alpha}{2\pi}\log(\frac{E^2_{min}}{m^2_{ph}})\left[\frac{2m^2-q^2}{\sqrt{-q^2(4m^2-q^2)}}\log\left(\frac{2m^2-q^2-\sqrt{-q^2(4m^2-q^2}}{2m^2-q^2+\sqrt{-q^2(4m^2-q^2}}\right)-2\right]. \tag{32.50}$$

In the limit $-q^2 \to \infty$ we get the desired answer

$$I(q^2) \to \frac{\alpha}{\pi}\log(\frac{E^2_{min}}{m^2_{ph}})\log(\frac{-q^2}{m^2}), \tag{32.51}$$

coinciding with (32.35).

If there are n real photons, there are n such contributions and the symmetry factor $1/n!$ taking into account the identity of the final particles. The cross-section of the process with emission of an arbitrary number of photons with the energy smaller than E_{min} hence equals

$$\sum_{n=0}^{\infty}\frac{d\sigma}{d\Omega}(e^+e^-\to\mu^+\mu^-+n\gamma) = \frac{d\sigma}{d\Omega}(e^+e^-\to\mu^+\mu^-)\times\sum_{n=0}^{\infty}\frac{I^n}{n!} = \frac{d\sigma}{d\Omega}(e^+e^-\to\mu^+\mu^-)e^I. \tag{32.52}$$

Combining the results for the real and virtual photons one gets the final expression for the observable cross-section with emission of an arbitrary number of photons with the energy smaller

than E_{min}

$$\left(\frac{d\sigma}{d\Omega}\right)_{observable} = \left(\frac{d\sigma}{d\Omega}\right)_0 \times \exp\left(2F_1\right) \times \exp\left(I\right)$$
$$= \left(\frac{d\sigma}{d\Omega}\right)_0 \exp\left[-\frac{\alpha}{\pi}\log(\frac{-q^2}{m_{e,\mu}^2})\log(\frac{-q^2}{m_{ph}^2})\right] \exp\left[\frac{\alpha}{\pi}\log(\frac{-q^2}{m_{e,\mu}^2})\log(\frac{E_{min}^2}{m_{ph}^2})\right]$$
$$= \left(\frac{d\sigma}{d\Omega}\right)_0 \exp\left[-\frac{\alpha}{\pi}\log(\frac{-q^2}{m_{e,\mu}^2})\log(\frac{-q^2}{E_{min}^2})\right]. \quad (32.53)$$

The obtained expression is valid in all orders of perturbation theory. The exponential factor does not depend on the IR cutoff but on the sensitivity of the detector. It is called the *Sudakov form factor*. When E_{min} tends to zero, the form factor decreases and in the limit $E_{min} \to 0$ vanishes. This is the manifestation of the statement that he amplitude of creation of the fermion pair without accompanying soft photons indeed vanishes: the charged particle inevitably emits the low frequency electromagnetic waves. This means that the cross-section of elastic electron scattering without inclusion of emission of bremsstrahlung quanta should vanish, precisely as it follows from eq.(32.53).

Let us estimate the value of the Sudakov form factor for some real process. A good example is the cross-section of e^+e^- annihilation into hadrons which in the leading order in the fine structure constant is described by one diagram with Z-boson exchange in the s-channel. The cross-section has a maximum in the Z-boson peak where it is described by the Breit-Wigner resonance formula. The energy is equal to the Z-boson mass M_Z and the energy resolution is defined by the Z-boson width Γ_Z. Substituting the values $M_Z = 91.187$ GeV, $\Gamma_Z = 2.496$ GeV, $m_e = 0.5$ MeV, $\alpha = 1/128$ into the form factor (32.53) we get

$$\exp\left[-\frac{\alpha}{\pi}\log(\frac{M_Z^2}{m_e^2})\log(\frac{M_Z^2}{\Gamma_Z^2})\right] \approx 0.648.$$

As one can see, the form factor, despite the smallness of the fine structure constant, considerably departs from unity and has to be taken into account when analysing the experimental data.

32.6.3 The cancellation of the infrared divergences

The considered example is typical of the QED and one can make the general statement concerning the infrared divergences for the elements of the S-matrix.

The infrared divergences in radiative corrections to the cross-section of any physical process in QED are cancelled in every order of perturbation theory if to the cross-section of the elastic process one adds the inelastic cross-section of the process with emission of an arbitrary number of additional photons integrated over the phase space with the requirement that the total photon energy does not exceed some value E_{min}.

This statement is also valid for the cross-sections of the processes in non-Abelian gauge theories like the electroweak theory and some processes in QCD, though in this case, due to the self-interaction of the non-Abelian gauge fields, there is no full factorization with the exponentiation, and the proof of this statement presents some problem. Nevertheless, for many processes the result has the same form. Thus, for example, the electromagnetic form-factor in QCD has the same Sudakov form (32.53) but with the replacement $\alpha \to C_F\alpha_s$.

Thus, one can say that the problem of obtaining the ultraviolet and the infrared finite radiative corrections to the cross-sections of the physical processes is solved in two steps: first, with the help of the renormalization procedure one gets rid of the ultraviolet divergences, which is under full control in renormalizable theories; second, defining the correct physical process including the emission of the soft quanta, the cancellation of the infrared divergences takes place.

As we will see below, this is not sufficient in non-Abelian gauge theories with massless gauge fields. They contain additional divergences which require some ads-inn to the described procedure. We will consider this question in the last lecture.

32.7 K-l.X: Collinear Divergences

32.7.1 The collinear divergences in massless theory

The obtained result (32.53) for the cross-section of creation of the muon pair in the process of e^+e^--annihilation with emission of additional soft photons is typical of the theories with a massive fermion and massless photons. It can be generalized to non-Abelian theories with massless gluon, though the gluon interactions cause some problems in proving the cancellation of the IR divergences. Note, however, that eq. (32.53) contains the logarithmic singularity with respect to the fermion mass, and if the latter tends to zero, one has the new divergence. This would not cause any problem since all the fermions are massive but the masses of the electron and the light quarks are so small compared to the characteristic energies of the scattering process that with good precision it is reasonable to neglect them. As for the QCD, considering the processes with gluons in initial states due to the self-interaction of the gluons we face this problem for the gluon amplitudes.

Let us analyse what is the reason for the appearance of the new divergence after the IR divergence at small photon momenta if regularized by introducing the photon mass. Consider for this purpose eq. (32.42) for the contribution of the real or virtual photons. The difference is that in one case the integration goes over the four-momentum of the virtual photon; and in the other case, over the three-momentum of the real photon, but what is essential that for the massless electron its propagator takes the form

$$\frac{1}{2pk} = \frac{1}{2(p^0k^0 - \vec{p}\vec{k})} \simeq \frac{1}{2(|\vec{p}||\vec{k}| - |\vec{p}||\vec{k}|\cos\theta)} = \frac{1}{2|\vec{p}||\vec{k}|(1-\cos\theta)}, \tag{32.54}$$

where θ is the angle between the electron and photon momenta. (In the case of a virtual photon we use the fact that the contribution to the singularity comes from the region of photon momentum close to the mass shell.)

Thus, the divergence appearing in the massless case comes from the integration over the angles and not over the modulus, as in the case of the IR divergence, and is related to the collinearity of momenta of two particles. For this reason it is called *the collinear divergence*. To get rid of these divergences, one can introduce the angular sensitivity of the detector analogously to the IR divergence. This would reflect the fact that two massless particles having almost parallel momenta are not distinguishable from a single particle with the same total momentum. Hence, the observed cross-section should include besides the main process the process of emission of the soft photons and the process of emission of the collinear photons with the kinematically allowed absolute values of momenta.

However, in real life the quarks and leptons are massive though their masses are very small; therefore, the problem of collinear divergences occurs for the processes with the gluon fields. Since the gluons are not free particles but exist inside hadrons, any process with the gluons has a similar process with quarks and it is reasonable to consider them together. For this reason, one usually speaks about *the inclusive* processes where besides the particles of the main process one includes the creation of all kinematically allowed particles, in particular the gluons. In this case, we do not impose any restriction on the gluon energy, we do not introduce any detector sensitivity to the energy or the angle, but sum over all the possibilities. It happens, however, that this is not sufficient to get the finite answer. It is necessary to take into account the possibility of existence of collinear gluons in the initial state, and only after this one can get the finite answer for the cross-section of the observable process.

The multiloop analysis in this case is much more complicated and is the subject of the Kinoshita-Lee-Nauenberg theorem which states:

The infrared and collinear divergences in a massless theory are cancelled in the cross-section of any process if one takes into account the existence in the initial and final states of an arbitrary number of the soft quanta as well as the particles having the parallel momenta with the same total momentum. The probabilities of these processes integrated over the phase space of these additional soft (collinear) quanta in the initial and final states should be added to the probability

of the initial process.

As an illustration we consider the model example of the electron-proton (quark) scattering and put all the masses equal to zero. We will be interested in the radiative corrections in the first order with respect to the strong coupling α_s. The corresponding diagrams are shown in Fig.32.10.

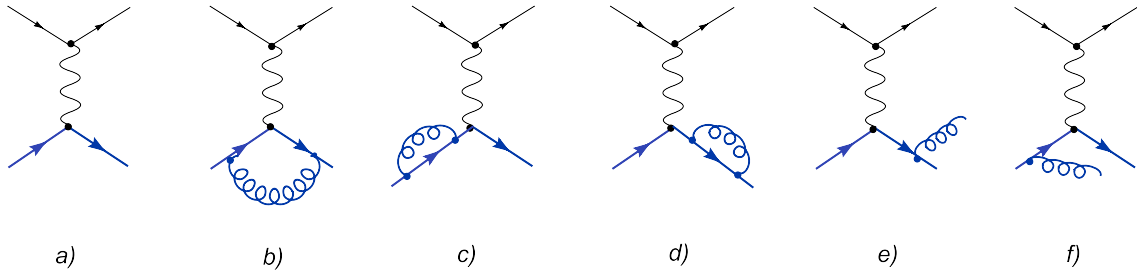


Figure 32.10: The process of electron-quark scattering in the first order in α_s:) the Born diagram, b)-d) the corrections due to the virtual gluons, e)-f) the corrections due to the real gluons

We have already calculated the matrix elements corresponding to these diagrams, but now we proceed in a different way. Since the ultraviolet divergences which appear in the diagrams b)-d) are compensated due to the Ward identity in QED ($Z_1 = Z_2$), all the arising divergences are solely infrared and collinear. To extract them we will use the dimensional regularization. Then both the divergences are manifested in the form of the poles over ε and, since we have both of them, there will be poles of the first and the second order.

We start with the virtual corrections. The diagrams of self-energy c) and d) in the massless case are identically zero due to the above-mentioned property of a massless integral depending on one argument equal to zero ($p^2 = 0$ on the mass shell). As we explained, here one has the cancellation of the UV and the IR divergences. Therefore, all divergences in the vertex diagram b) may be considered as infrared. (The UV divergences should cancel with the UV ones from the self-energy diagrams and the latter in their turn cancel with the IR). The integral for the vertex part is defined by two form factors $F_1(q^2)$ and $F_2(q^2)$ (32.26). Taking the expression for the vertex function (18.39) as the starting point, we put $m = 0$ and go to the mass shell. The result is

$$F_1(q^2) = -C_F \frac{\alpha_s}{4\pi} \left(\frac{\mu^2}{-q^2}\right)^{\varepsilon} \left(\frac{2}{\varepsilon^2} + \frac{3}{\varepsilon} + 8\right), \tag{32.55}$$

$$F_2(q^2) = 0, \tag{32.56}$$

where instead of the logarithm of the photon mass as the IR regulator we have the pole over ε. In order to avoid the transcendental numbers, we used the helpful definition of the angular measure in the space of $4 - 2\varepsilon$ dimensions and multiplied the standard expression by $\Gamma(1-\varepsilon)/(4\pi)^{\varepsilon}$. Then the constants like γ_E, $log(4\pi)$ and $\zeta(2)$ disappear from the intermediate expressions. Due to the cancellation of divergences in the final expressions, this redefinition does not influence the answer.

Thus, the cross-section for the diagrams with virtual gluon has the form

$$\left(\frac{d\sigma}{d\Omega}\right)_{virt} = \left(\frac{d\sigma}{d\Omega}\right)_0 \left[1 - 2C_F \frac{\alpha_s}{4\pi} \left(\frac{\mu^2}{-t}\right)^{\varepsilon} \left(\frac{2}{\varepsilon^2} + \frac{3}{\varepsilon} + 8\right)\right], \tag{32.57}$$

where the differential cross-section in the Born approximation is given by

$$\left(\frac{d\sigma}{d\Omega}\right)_0 = \frac{\alpha^2}{2E^2} \left(\frac{s^2 + u^2 - \varepsilon t^2}{t^2}\right) \left(\frac{\mu^2}{s}\right)^{\varepsilon}. \tag{32.58}$$

In the c.m. frame $s = E^2, t = -E^2/2(1 - \cos\theta), u = -E^2/2(1 + \cos\theta)$, where the angle θ is the electron scattering angle.

Consider now the diagrams with the emission of the real gluons e) and f). Besides the squares of each of the diagrams one should also take into account the interference term. The calculation in fact repeats that in QED but instead of the photon mass we again use the dimensional regularization and do not restrict the integration region over the momentum of additional gluon. The calculation is a bit tedious, after contracting all the indices the phase integral takes the form

$$
\begin{aligned}
d\sigma_{2\to 3} &= \frac{1}{2\pi E^2}\int d^D p_3 \delta^+(p_3^2)\int \frac{d^D k}{(2\pi)^D}\delta^+(k^2)\delta^+((p_4-k)^2)|M|^2_{p_4=p_1+p_2-p_3} \qquad (32.59)\\
|M|^2 &= \frac{e^4 g^2}{4} 8\frac{M_0+\epsilon M_1+\epsilon^2 M_2}{t(s+t+u)},\\
M_0 &= 4s-8p_1k-4p_2k+\frac{-8(p_1k)^2+4(2s+t)p_1k-(3s^2+t^2+u^2+2st)}{p_2k},\\
M_1 &= -4(s+u)+8p_1k+8p_2k+\frac{8(p_1k)^2-4(s+t+u)p_1k+2)s+t+u)^2-2(u+s)t}{p_2k}\\
M_2 &= 4(s+t+u)-4p_2k-\frac{(s+t+u)^2}{p_2k}=-\frac{(s+t+u+2p_2k)^2}{p_2k}.
\end{aligned}
$$

It is useful to pass to the spherical coordinates and use the c.m. frame. After the integration over the phase volume the result can be represented in the form

$$
\left(\frac{d\sigma}{d\Omega}\right)_{real}=\left(\frac{d\sigma}{d\Omega}\right)_0\left[2C_F\frac{\alpha_s}{4\pi}\left(\frac{\mu^2}{-t}\right)^{\varepsilon}\left(\frac{2}{\varepsilon^2}+\frac{3}{\varepsilon}+8\right)\right]+C_F\frac{\alpha^2}{E^2}\frac{\alpha_s}{4\pi}\left(\frac{\mu^2}{s}\right)^{\varepsilon}\left(\frac{\mu^2}{-t}\right)^{\varepsilon}\left(\frac{f_1}{\varepsilon}+f_2\right), \qquad (32.60)
$$

where the functions f_1 and f_2 in the c.m. frame are ($x=\cos\theta$)

$$
\begin{aligned}
f_1 &= -2\frac{(1-x)(x^3+5x^2-3x+5)\log(\frac{1-x}{2})-(x-1)^2(x+1)(x-11)/4}{(1-x)^2(1+x)^2}, \qquad (32.61)\\
f_2 &= -\frac{1}{(1-x)^2(1+x)^2}\left[(1-x)(x^3+5x^2-3x+5)\log^2(\frac{1-x}{2})\right.\\
&\quad +\frac{1}{2}(1-x)(3x^3+15x^2+77x-31)\log(\frac{1-x}{2})+(1+x)^2(x^2+5x+3)\pi^2\\
&\quad \left.-12(9x^2+2x+5)Li_2(\frac{1+x}{2})+\frac{1}{2}(1-x)(1+x)(5x^2-42x-23)\right]. \qquad (32.62)
\end{aligned}
$$

As one can see from the comparison of the cross-sections of the processes with the virtual (32.57) and the real gluons (32.60), in the sum the second order poles cancel. However, the total cancellation of divergences does not happen. The remaining divergences in the form of a single pole have a collinear nature. As was already mentioned, for their cancellation one has to define properly the initial states. The point is that the massless quark can emit the collinear gluon which will carry part of the initial momentum and in this case, it is impossible to distinguish one particle propagating with the speed of light from the two flying parallel.

32.7.2 The quark distributions and the splitting functions

To take into account this possibility, let us come back to the scattering process and assume that the initial quark has emitted the parallel gluon (see Fig.32.11). The two particles can be almost parallel with small relative transverse momentum. The three four-momenta can be chosen in the form:

$$
p=(p;0,0,p),\quad q\approx(zp;p_\perp,0,zp),\quad k\approx((1-z)p;-p_\perp,0,(1-z)p),
$$

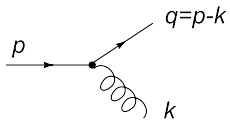

Figure 32.11: The diagram corresponding to the splitting of the quark into the quark and the gluon

so that all of them obey the condition $p^2 = q^2 = k^2 = 0$ with the accuracy up to $p_\perp^2$. It is helpful, however, to use another method, namely to choose the momenta in such a way that they obey the mass shell condition with the accuracy up to $p_\perp^4$, but to give up the energy conservation in the order of $p_\perp^2$. The advantage of this approach consists in the use of formulas for the spinors and the polarization vectors on mass shell. Therefore, we choose the momenta as follows:

$$p = (p; 0, 0, p),\ q \approx (zp + \frac{p_\perp^2}{2zp}; p_\perp, 0, zp),\ k \approx ((1-z)p + \frac{p_\perp^2}{2(1-z)p}; -p_\perp, 0, (1-z)p).$$

The square of the matrix element corresponding to the process of splitting on mass shell in this case can be written in the standard form

$$|M(q \to qG)|^2 = \frac{g^2}{2}_F Tr(\gamma^\mu \hat{p} \gamma^\nu \hat{q}) \sum_{pol} \epsilon^{*\mu} \epsilon^\nu, \tag{32.63}$$

where the factor $1/2$ comes from the averaging over the spin states. Here we must take into account the physical polarizations of the gluon only, i.e.

$$\sum_{pol} \epsilon^{*\mu} \epsilon^\nu \to \delta^{ij} - \frac{k^i k^j}{(\vec{k})^2},$$

which gives

$$|M(q \to qG)|^2 = 4 g_F^2 \left[p^0 q^0 - \frac{(\vec{p}\vec{k})(\vec{q}\vec{k})}{(\vec{k})^2} \right], \tag{32.64}$$

or, substituting the values of momenta,

$$|M(q \to qG)|^2 = C_F \frac{2g^2 p_\perp^2}{z(1-z)} \frac{1+z^2}{1-z}, \qquad z < 1. \tag{32.65}$$

The obtained expression does not depend on the choice of momenta and has a universal character.

Now one can calculate the cross-section of the process of interest. Graphically, it will be the same diagram Fig.32.10); however, the additional gluon will be referred not to the final state but to the initial one. Here we use the standard Feynman rules when the energy conservation law is not violated, but the massless particle is slightly off shell. Since in the case of interest the quark with momentum q is virtual, it is useful to choose the momenta like

$$p = (p; 0, 0, p), q \approx (zp - \frac{p_\perp^2}{2(1-z)p}; p_\perp, 0, zp), k \approx ((1-z)p + \frac{p_\perp^2}{2(1-z)p}; -p_\perp, 0, (1-z)p).$$

In this case,

$$q^2 = -\frac{p_\perp^2}{1-z}. \tag{32.66}$$

Then the cross-section of the process can be written in the factorized form

$$d\sigma(p) = \frac{1}{(2\pi)^3}\int \frac{d^3k}{2k^0}|M_{q\to qG}|^2(\frac{1}{q^2})^2(\frac{p^0z}{p^0})d\sigma(pz), \tag{32.67}$$

where the factor $(\frac{p^0z}{p^0})$ is due to fact that the cross-section is normalized to the energy of initial particles, and we have replaced the quark with the energy p^0 by the quark with the energy zp^0.

Rewriting the differential d^3k in terms of the new variables

$$d^3k = pdzd^2p_\perp = pdz\pi dp_\perp^2,$$

and substituting the value of the matrix element (32.65) and q^2 from (32.66), we get

$$\begin{aligned} d\sigma(p) &= C_F\frac{^2}{16\pi^2}\int \frac{pdzdp_\perp^2}{(1-z)p}\frac{(1-z)^2}{p_\perp^4}\frac{2p_\perp^2}{z(1-z)}\frac{1+z^2}{1-z}zd\sigma(pz) \\ &= C_F\frac{\alpha_s}{2\pi}\int \frac{dzdp_\perp^2}{p_\perp^2}\frac{1+z^2}{1-z}d\sigma(pz). \end{aligned} \tag{32.68}$$

The integral over the transverse momentum is divergent at zero and this is nothing else but the manifestation of the collinear divergence. The upper limit is not of great importance, it is restricted by kinematic considerations. We assume that the integration over $p_\perp^2$ goes from zero to some scale Q^2. Later, we will see that one can change this scale analogously to the change of the ultraviolet scale μ^2.

To extract the divergence we use the dimensional regularization. Changing the dimension of transverse integration from 2 to $2-2\varepsilon$ one gets

$$\begin{aligned} d\sigma(p) &= C_F\frac{\alpha_s}{2\pi}\int\limits_0^1 dz\frac{1+z^2}{1-z}\int\limits_0^{Q^2}\frac{(p_\perp^2)^{-\varepsilon}(-\mu^2)^\varepsilon dp_\perp^2}{p_\perp^2}d\sigma(pz) \\ &= C_F\frac{\alpha_s}{2\pi}\int\limits_0^1 dz\frac{1+z^2}{1-z}\,\frac{1}{\varepsilon}\left(-\frac{\mu^2}{Q^2}\right)^\varepsilon d\sigma(pz). \end{aligned} \tag{32.69}$$

At first sight the obtained expression still contains the pole in the integrand as $z\to 1$. However, it only looks like a singularity. It came from the matrix element (32.65), which we have calculated only for $z<1$ and it needs to be redefined for $z\to 1$. We will come back to this question below and, at first, discuss the interpretation of relation (32.69).

Let us introduce the notion of distribution of the initial quark with respect to the fraction of the carried momentum z: $q(z)$. Then the initial distribution corresponds to $q(z)=\delta(1-z)$, and the emission of a gluon leads to the splitting: the quark carries the fraction of momentum equal z, while the gluon - $(1-z)$. The probability of this event is given by the so-called *splitting functions* $P_{qq}(z)$ and $P_{qG}(1-z)$. In the lowest order of perturbation theory in α_s the quark and gluon distributions can be written in the form

$$q(z,Q^2) = \delta(1-z)+\frac{\alpha_s}{2\pi}\frac{1}{\varepsilon}\left(\frac{\mu^2}{Q^2}\right)^\varepsilon P_{qq}(z), \tag{32.70}$$

$$G(z,Q^2) = \frac{\alpha_s}{2\pi}\frac{1}{\varepsilon}\left(\frac{\mu^2}{Q^2}\right)^\varepsilon P_{qG}(1-z), \tag{32.71}$$

where the splitting functions are defined by the corresponding matrix elements one of which for $P_{qq}(z)$ has been calculated in the leading order in α_s earlier (see (32.65)). The result has the

following form:

$$P_{qq}(z) = C_F\left(\frac{1+z^2}{(1-z)_+}+\frac{3}{2}\delta(1-z)\right), \tag{32.72}$$

$$P_{qG}(z) = \frac{z^2+(1-z)^2}{2}. \tag{32.73}$$

Note that eq. (32.72) contains the redefinition of the function $P_{qq}(z)$ at the point $z=1$ mentioned above, namely the sign " $+$ " should be understood as the following integration rule:

$$\int\limits_0^1 dz\frac{f(z)}{(1-z)_+} \equiv \int\limits_0^1 dz\frac{f(z)-f(1)}{(1-z)},$$

and the coefficient of the δ-function is defined from the requirement of conservation of the number of quarks

$$\int\limits_0^1 q(x,Q^2)dz = 1 \quad \Rightarrow \int\limits_0^1 P_{qq}(z)dz = 0.$$

Thus, eq. (32.69) together with the Born diagram can be written as

$$d\sigma(p) = \int\limits_0^1 dz\ q(z,Q^2)\ d\sigma(pz), \tag{32.74}$$

where the quark distribution $q(z,Q^2)$ is given by (32.70).

It seems strange at first sight that the answer depends on the scale Q^2 which defines the quark distribution. However, it has the physical interpretation. This is the measure of collinearity of the emitted gluons that can be distinguished, i.e., it refers to the definition of the initial state. In fact, in the massless case one cannot define the initial state that contains just the quark, it exists together with the set of collinear gluons. (The same is true for the massless electron with collinear photons.) This scale is sometimes called the factorization scale, at this scale the scattering cross-section (32.74) takes the factorized form. The factorization scale can be varied. The dependence of the quark and the gluon distributions on the scale is governed by the so-called DGLAP equations well known in QCD.

32.7.3 The finite answers

Thus, besides the two contributions to the cross-section from the virtual and the real gluons there is one more contribution related to the splitted initial state (32.69). In the lowest order of perturbation theory in α_s it can be written as

$$\left(\frac{d\sigma}{d\Omega}\right)_{split} = \frac{1}{\varepsilon}\frac{\alpha_s}{2\pi}\int\limits_0^1 dz\left(\frac{\mu^2}{Q_f^2}\right)^{\varepsilon} P_{qq}(z)\frac{d\sigma_0}{d\Omega}(pz), \tag{32.75}$$

where the Born cross-section is given by (32.58) with the replacement of the initial quark momentum p by pz, and the factorization scale Q_f^2 is an arbitrary quantity associated with the quark distribution function. Note that the scale Q_f^2 may depend on z. It is quite natural to choose the factorization scale equal to the characteristic scale of the process of interest. Thus, in our case this

choice corresponds to $Q_f^2 = -\hat{t}$, where $\hat{t}$ is the Mandelstam parameter t for the process where p is replaced by pz. One has $\hat{t} = t\frac{2z}{(z+1)+(z-1)x}$. This leads to the following result:

$$\left(\frac{d\sigma}{d\Omega}\right)_{split} = C_F \frac{\alpha^2}{2E^2}\frac{\alpha_s}{2\pi}\left(\frac{\mu^2}{s}\right)^{\varepsilon}\left(\frac{\mu^2}{-t}\right)^{\varepsilon}(-\frac{f_1}{\varepsilon} + f_3), \tag{32.76}$$

where f_1 is given by (32.61) and

$$\begin{aligned} f_3 &= -\frac{1}{(1-x)^2(1+x)^2}\left[2(1-x)(x^3+x^2-33x+7)\log(\frac{1-x}{2})\right. \\ &+12(9x^2+2x+5)Li_2(\frac{1+x}{2}) - (1+x)^2(x^2+5x+3)\pi^2 \\ &\left.-\frac{1}{2}(1-x)(1+x)(11x^2-19)\right]. \end{aligned} \tag{32.77}$$

Comparing the obtained expression with (32.57) and (32.60) we see that the last divergence cancels and the final expression for the cross-section of the electron-quark scattering with account of possible creation of the gluon in the initial and final states takes the form ($x = \cos\theta$)

$$\begin{aligned} \left(\frac{d\sigma}{d\Omega}\right) &= \left(\frac{d\sigma}{d\Omega}\right)_{virt} + \left(\frac{d\sigma}{d\Omega}\right)_{real} + \left(\frac{d\sigma}{d\Omega}\right)_{split} \\ &= \frac{\alpha^2}{2E^2}\left\{\frac{x^2+2x+5}{(1-x)^2} - \frac{\alpha_s}{2\pi}\frac{C_F}{(1-x)(1+x)^2}\left[(x^3+5x^2-3x+5)\log^2\frac{1-x}{2}\right.\right. \\ &\left.\left.+\frac{1}{2}(7x^3+19x^2-55x-3)\log\frac{1-x}{2} - (1+x)(3x^2+21x+2)\right]\right\}. \end{aligned} \tag{32.78}$$

This expression is our final answer for the cross-section of the physical process of electron-quark scattering where the initial and the final state include the soft and collinear gluons. It includes also the definition of the initial state and can be recalculated for the alternative choice of the factorization scale similar to what happens to the ultraviolet scale which defines the coupling constant. Thus, we practically deal with the scattering not of individual particles but rather with coherent states with a fixed total momentum. Only this process has a physical meaning.

In Fig.34.169, we show the differential cross-section of this process as a function of the electron scattering angle: $\frac{E^2}{\alpha^2}\frac{d\sigma}{d\Omega}(\cos\theta)$. We have chosen here the strong coupling $\alpha_s = 0.2$, and $C_F = 4/3$. As one can see, the inclusion of the radiative correction $\sim \alpha_s$ practically does not change the result, the difference from the Born approximation is less than a per cent, that justifies the use of perturbation theory.

Let us stress once more that the obtained answer for the cross-section of the observable process depends on: a) the ultraviolet subtraction scheme that manifests itself, in particular, in the appearance of the ultraviolet scale μ^2 (canceled in our case in the lowest order of perturbation theory) and b) the definition of the initial coherent state, which manifests itself in the appearance of the factorization scale Q_f^2. The universality in the description of the physical processes is based on the fact that choosing the UV and the IR scale one way or another and fitting the experimental data of some process, one can then recalculate the obtained values of the running coupling and of the quark (lepton) distribution for any other choice of the scales. This way the result for the observable quantities does not depend on a particular choice of these scales and is universal.

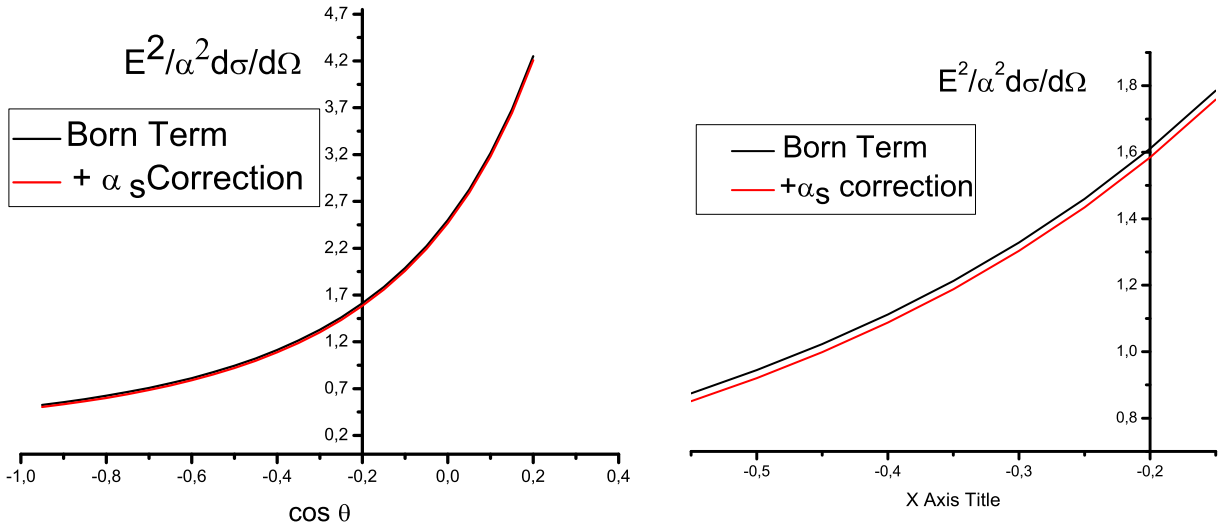

Figure 32.12: The differential cross-section of *eq* scattering in the Born approximation and with allowance for the α_s correction. On the right plane the same plot is shown in the bigger scale

33 Quantum Chromodynamics

или элетродинамика адронов
(хромо - цвет)
(пока из ЛЛ4 выгрзуки)

33.1 Fundamentals of Quantum Chromodynamics

33.1.1 Essence of QCD

(думаю, это правильнее тут писать, супер не скоро в 1ю часть буду переносить, потому что не до этого)

33.1.2 Overview of Applications of QCD

(тоже важно это выделить)

33.1.3 Popular Overview of QCD

(такое тоже есть, много видео, пропишу потом, много разных аналогий.)

33.2 QCD by Landau

33.2.1 Electromagnetic Form Factors of Hadrons

(лл4 пока что, потом буду думать и разбирать)

Теория (??)

До сих пор в этой книге речь шла о квантовой электродинамике частиц, не способных к сильным взаимодействиям, - электронов, позитронов и мюонов. Существует также большое число частиц, участвующих в сильных взаимодействиях; их называют адронами).

Адронами являются, например, протоны и нейтроны, имеющие спин $1/2, \pi$ -мезоны со спином 0 и другие частицы. Адронами, разумеется, являются и атомные ядра, так как они состоят из протонов и нейтронов.

Построение исчерпывающей электродинамики адронов в рамках существующей теории невозможно. Ясно, что нельзя составить уравнений, определяющих электромагнитные взаимодействия адронов без учета значительно более интенсивных сильных взаимодействий.

В частности, без учета последних нельзя установить и явный вид адронного тока, с помощью которого должны описываться взаимодействия в квантовой электродинамике.

В этой ситуации адронный ток вводится как феноменологическая величина, структура которой устанавливается лишь исходя из обших кинематических требований, не связанных с какимилибо предположениями о динамике взаимодействий [2]). Оператор же электромагнитного взаимодействия будет иметь по-прежнему вид

$$e(\widehat{J}\widehat{A})$$

где теперь ток обозначен прописной буквой J (в отличие от электронного тока j). Поскольку порядок величины этого взаимодействия задается тем же элементарным зарядом e, можно попрежнему пользоваться методами теории возмущений [3]).

Установим вид тока перехода между двумя состояниями свободно движущегося адрона (не сопровождающегося каким-либо

превращением самого адрона). Этот ток входит в «треххвостку»

которая сама может входить как часть в какую-либо более сложную диаграмму (например, упругого рассеяния электрона на адроне). Штриховая линия в диаграмме (138.2) изображает виртуальный фотон; она не может отвечать реальному фотону, так как свободная частица не может поглотить (или испустить) такой фотон. При этом $q^2 = (p_2 - p_1)^2 < 0$.

Рассмотрим сначала адрон со спином 0. Пусть u_1 и u_2 - волновые амплитуды начального и конечного состояний адрона, в которых он имеет 4-импульсы p_1 и p_2; для частицы со спином 0 эти амплитуды - скаляры (или псевдоскаляры)). Адронный ток перехода J_{fi} между этими двумя состояниями должен быть билинеен по u_1, и u_2^*. Запишем его в виде

$$J_{fi} = u_2^* \Gamma u_1$$

где 4-вектор Γ - неизвестный вершинный оператор (кружок на диаграмме (138.2)). Если положить $u_1 = u_2 = 1$, то будет просто $J_{fi} = \Gamma$ Универсальным свойством тока в электродинамике, связанным с калибровочной инвариантностью теории, является его сохранение. В импульсном представлении оно выражается ортогональностью тока перехода 4-импульсу фотона $q = p_2 - p_1$:

$$qJ_{fi} = 0$$

В данном случае это значит, что оператор Γ должен иметь вид

$$\Gamma = PF\left(q^2\right)$$

где $P = p_1 + p_2, F\left(q^2\right)$ - скалярная функция единственной инвариантной независимой переменной - квадрата q^2. Поскольку род адрона при переходе не меняется, то $p_1^2 = p_2^2 = M^2$(M - масса адрона), и потому $Pq = 0$.

Матричные элементы (138.3) сΓ из (138.5)(а с ними и сам оператор J) - истинные 4-векторы. Поэтому оператор взаимодействия (138.1) - истинный скаляр. Таким образом, электромагнитное взаимодействие адронов со спином 0 оказывается P -инвариантным автоматически. Оно оказывается также и T -инвариантным. Действительно, обращение времени, во-первых, переставляет начальный и конечный 4-импульсы; при этом сумма

$P = p_1 + p_2$ не меняется. Во-вторых, обращение времени меняет знак пространственных компонент 4-импульсов, не меняя их временных компонент; но таким же образом преобразуются и компоненты 4-потенциала A, так что произведение $\widehat{J}\widehat{A}$ не меняется.

Инвариантную функцию $F(q^2)$ называют электромагитны.м формфактором адрона. В рамках феноменологической теории ее вид, разумеется, не может быть установлен. Можно, однако, утверждать, что эта функция вещественна (в рассматриваемой области $q^2 < 0$). Это следует из тех же соображений, которые были применены в \$116 к формфакторам электрона: при $q^2 < 0$ во всяком случае отсутствуют промежуточные состояния, которые могли бы фигурировать в правой стороне соотношения унитарности; поэтому матрица M_{fi}, а с нею и J_{fi} оказываются эрмитовыми.

При $q = 0$ начальное и конечное состояния совпадают, так что J_{fi} становится диагональным матричным элементом. В частности, $e(J^0)_{ii}/2\varepsilon_i = eF(0)$ есть плотность заряда, совпадающая

(нормировка на одну частицу в единичном объеме!) с полным зарядом частицы Ze.

Для электрически нейтральной частицы $F(0) = 0$. Подчеркнем, однако, что это отнюдь не означает еще истинной нейтральности частицы. Если частица истинно нейтральна и обладает определенной зарядовой четностью, то $F(q^2) \equiv 0$ при всех q^2: так как оператор тока зарядово-нечетен (см. §13), его матричные элементы между двумя состояниями одного и того же адрона равны нулю).

Перейдем к адронам со спином 1/2. В этом случае волновые амплитуды u_1, u_2 - биспиноры и адронный ток имеет вид

$$J_{fi} = \bar{u}_2 \Gamma u_1$$

Из билинейных комбинаций $\bar{u}_2$ и u_1 и 4 -векторов p_1, p_2 можно составить как истинные 4-векторные, так и псевдовекторные величины (удовлетворяющие условию (138.4)). Поэтому условие P -инвариантности взаимодействия не удовлся автоматически и должно быть поставлено дополнительно). Как было показано в пар 116, при этом условии вершинный оператор содержит два независимых вещественных (при $q^2 < 0$) формфактора.

Запишем его теперь в виде

$$\Gamma^\mu = 2M(F_e - F_m)\frac{P^\mu}{P^2} + F_m\gamma^\mu = 2M\left(F_e - \frac{q^2}{4M^2}F_m\right)\frac{P^\mu}{P^2} - \frac{F_m}{2M}\sigma^{\mu\nu}q_\nu =$$
$$= (4M^2F_e - q^2F_m)\frac{\gamma^\mu}{P^2} + \frac{2M}{P^2}(F_e - F_m)\sigma^{\mu\nu}q_\nu, \quad (138.7)$$

где $F_e(q^2)$ и $F_m(q^2)$ - инвариантные формфакторы (M - масса адрона); в эквивалентности трех написанных выражений легко убедиться с помощью равенств $P^2 + q^2 = 4M^2$ и $(116.5)^2$).

Электромагнитные формфакторы относятся к категории инвариантных амплитуд, понятие о которых было введено в §70. Их можно рассматривать как амплитуды «реакции», представляющей собой (в своем аннигиляционном канале) распад виртуального фотона на адрон и антиадрон. Виртуальный фотон - «частица» со спином 1. В том, что ее распад на две частицы со спином 1/2 должен описываться двумя независимыми амплитудами,

легко убедиться и подсчетом соответствующих спиральных амплитуд $\langle \lambda_b\lambda_c | S^J | \lambda_a \rangle$ (см. § 69). Действительно, в силу P -инвариантности четыре отличных от нуля элемента S -матрицы попарно равны друг другу:

$$\langle 1/21/2 | S^1 | 1 \rangle = \langle -1/2 - 1/2 | S^1 | -1 \rangle$$
$$\langle 1/2 - 1/2 | S^1 | 0 \rangle = \langle -1/2^1/2 | S^1 | 0 \rangle$$

Требование T -инвариантности)или C -инвариантности -в аннигиляционном канале) не добавляет новых связей между эти-

ми элементами. С этим обстоятельством связан тот факт, что взаимодействие, описываемое вершинным оператором (138.7), автоматически оказывается также и T -инвариантным (такая ситуация, однако, не имеет уже места для частиц с более высокими спинами).

При $q \to 0$ члены нулевого и первого (по q) порядка в (138.7):

$$\Gamma^{\mu} = F_e(0)\gamma^{\mu} - \frac{1}{2M}\left[F_m(0) - F_e(0)\right]\sigma^{\mu\nu}q_{\nu}$$

Отсюда видно (см. §116), что $F_e(0) \equiv Z$ - электрический заряд частицы (в единицах e), а $F_m(0) - F_e(0)$ - ее аномальный магнитный момент (в единицах $e/2M$)).

До сих пор мы пользовались только формфакторами в импульсном пространстве. Этого, разумеется, достаточно для описания наблюдаемых явлений. С чисто иллюстративной целью, однако, можно дать формфакторам и несколько более наглядную интерпретацию, рассматривая их как фурье-образы некоторых функций от координат.

Для этого удобно выбрать систему отсчета, в которой $\mathbf{P} =$ (так называемая система Брейта); это всегда возможно, поскольку $P^2 > 4M^2 > 0$. В этой системе $\varepsilon_1 = \varepsilon_2 \equiv \varepsilon$, так что $P^0 = 2\varepsilon$, а составляющие 4-вектора q равны $q^0 = 0, \mathbf{q} = 2\mathbf{p}_2 = -2\mathbf{p}_1$ Для адрона со спином 0 ток перехода принимает в системе

Брейта особенно простую форму:

$$\frac{J^0_{fi}}{2\varepsilon} = F\left(-\mathbf{q}^2\right), \quad \mathbf{J} = 0$$

Отсюда видно, что $F\left(-\mathbf{q}^2\right)$ можно истолковать как фурье-образ статического распределения зарядов с плотностью

$$e\rho(\mathbf{r}) = e\frac{1}{(2\pi)^3}\int F\left(-\mathbf{q}^2\right)e^{i\mathbf{q}\mathbf{r}}d^3q$$

В этом смысле говорят о пространственной электромагнитной структуре частицы: при $F =$ const $= Z$ было бы $\rho(\mathbf{r}) = Z\delta(\mathbf{r})$; зависимость же формфактора от q интерпретируется как отклонение распределения заряда от точечного. Подчеркнем, однако, что этой интерпретации не следует придавать буквального смысла. Функция $\rho(\mathbf{r})$ вообще не относится к какой-либо определенной системе отсчета, так как каждому значению q отвечает своя система.

Лишь в нерелятивистском пределе $\mathbf{q}^2 \ll M^2$, когда изменением энергии частицы при рассеянии можно пренебречь, система Брейта совпадает с системой покоя частицы и не зависит от q.

Начальные и конечные состояния частицы в этом приближении одинаковы, так что ток перехода становится диагональным матричным элементом и функция ρ(r) приобретает реальный смысл пространственного распределения зарядов. Для элементарных частиц, однако, характерные значения |q|, на которых существенно меняются формфакторы, лишь немногим меньше M. Поэтому в нерелятивистском пределе для них можно вообще заменить $F\left(-q^2\right)$ на $F(0)$, т. е. рассматривать частицу как точечную. Иная ситуация для ядер. Масса ядра M пропорциональна числу A нуклонов в нем, а характерное значение $|\mathbf{q}| \sim 1/R$, т. е. пропорционально $A^{-1/3}$(R - радиус ядра). Поэтому для достаточно тяжелых ядер характерные $\mathbf{q}^2 \ll M^2$, и, таким образом, нерелятивистское рассмотрение допустимо во всем существенном интервале; тем самым понятие электромагнитной структуры ядра приобретает вполне определенный смысл.

Для частицы со спином 1/2 из (138.7) получим в системе Брейта

$$J^0_{fi} = (F_e - F_m)\,\tfrac{M}{\varepsilon}\,(\bar{u}_2 u_1) + F_m\,(\bar{u}_2\gamma^0 u_1) = F_e\,(\bar{u}_2\gamma^0 u_1)$$
$$\mathbf{J}_{fi} = -\tfrac{1}{2M}F_m\,[i\mathbf{q}\,(\bar{u}_2\boldsymbol{\Sigma}u_1)$$

где $\boldsymbol{\Sigma}$ -трехмерный оператор (матрица) спина (21.21), а в (138.10) использовано равенство $\varepsilon\,(\bar{u}_2\gamma^0 u_1) = M\,(\bar{u}_2 u_1)$, которое легко проверить с помощью уравнений Дирака для u_1 и $\bar{u}_2$ при

$\mathbf{p}_1 = -\mathbf{p}_2$ Временная компонента тока перехода (138.10) отличается от выражения для «точечной частицы»-электрона множителем $F_e\,(-\mathbf{q}^2)$. Поэтому можно сказать, что

формфактор F_e (его называют зарядовым) описывает «пространственное распределение заряда» согласно (138.9).

Аналогичным образом трехмерному вектору (138.11) можно привести в соответствие «пространственное распределение» плотности токов $e\mathbf{j}(\mathbf{r}) = \operatorname{rot} \boldsymbol{\mu}(\mathbf{r})$, где

$$\boldsymbol{\mu}(\mathbf{r}) = \frac{e}{2M}\boldsymbol{\Sigma} \int F_m\left(-\mathbf{q}^2\right) e^{i\mathbf{qr}} d^3q$$

представляет собой «плотность магнитного момента». Таким образом, формфактор F_m (его называют магнитны. м) можно интерпретировать как плотность пространственного распределения магнитного момента - разумеется, с теми же оговорками, которые были сделаны выше по поводу распределения заряда. При этом F_m включает в себя как «нормальный» дираковский магнитный момент, так и специфический для адрона «аномальный» момент; «плотности» последнего отвечает разность $F_m - F_e$.

Естественно считать, что особые точки адронных электромагнитных формфакторов, как и электронных, лежат при вещественных положительных значениях аргумента $t = q^2 = -\mathbf{q}^2$. Это позволяет сделать определенные заключения об асимптотическом поведении распределения $\rho(r)$ (и $\boldsymbol{\mu}(r)$) при $r \to \infty$. Именно, такое же преобразование интеграла (138. 9), которое было применено в §114 для перехода от (114. 3) к (114.4), приведет к результату, что при больших r будет $\rho(r) \propto e^{-x_0 r}$, где x_0^2 - абсцисса первой особой точки формфактора $F\left(q^2\right)$ (ср. также примеч. на с. 564). Если ближайшая особенность дается порогом образования виртуальным фотоном пары адронов (массы M_0 каждый), то $\mathcal{X}_0 = 2M_0$

33.2.2 Scattering of Electrons by Hadrons

обзор и мотивация

Theory

Применим полученные в предыдущем параграфе формулы к упругому рассеянию электрона на адроне. Обозначим начальный и конечный 4-импульсы адрона через p_h и p'_h, а 4-импульсы электрона через p_e и p'_e; при этом

$$p_e + p_h = p'_e + p'_h$$

Рассматриваемый процесс изображается диаграммой

(тут рис)

Испусканию виртуального фотона электроном отвечает обычный вершинный оператор γ; поглощению его адроном - операТор Γ

Рассмотрим наибилее интересный случай адрона со спином 1/2 (например, рассеяние электрона протоном или нейтроном). Диаграмме (139.2) соответствует амплитуда рассеяния

$$M_{fi} = -4\pi e^2 \frac{1}{q^2}\left(\bar{u}'_e \gamma^\mu u_e\right)\left(\bar{u}'_h \Gamma_\mu u_h\right)$$

(в этой главе заряд электрона есть - e!). Вычисление сечения по этой амплитуде не представляет принципиальных отличий от произведенных в §81 вычислений; при том оператор Γ удобно писать в виде первого из выражений (138.7).

Для рассеяния неполяризованных частиц получается следующий результат:

$$d\sigma = \frac{\pi\alpha^2 dt}{[s-(M+m)^2][s-(M-m)^2]t^2(1-t/4M^2)} \times$$
$$\times \left\{F_e^2\left[(s-u)^2 + (4M^2-t)\,t\right] - \frac{t}{4M^2}F_m^2\left[(s-u)^2 - (4M^2-t)\left(4m^2+t\right)\right]\right\}$$

Здесь M - масса адрона, m - масса электрона,

$$s = (p_e + p_h)^2\,, \quad t = q^2 = (p_e - p'_e)^2\,, \quad u = (p_e - p'_h)^2$$
$$s + t + u = 2m^2 + 2M^2$$

Рассмотрим некоторые предельные случаи.

Для рассеяния электронов на тяжелом ядре представляет интерес случай, когда передача импульса электроном ядру $|\mathbf{q}|$ мала по сравнению с массой ядра,

но не мала по сравнению с $1/R$(R - радиус ядра), так что ядро нельзя рассматривать как точечное.

В таком случае система центра инерции приближенно совпадает с системой покоя ядра, отдачей ядра можно пренебречь и энергия электрона не меняется. При этом

$$-t = \mathbf{q}^2 \ll M^2, \quad \pi|dt| = \mathbf{p}_e^2 do'_e, \quad s - M^2 \approx M^2 - u \approx 2M\varepsilon_e$$

и формула (139.4) принимает вид

$$d\sigma = \frac{\alpha^2 do'_e}{q^4}\left(4\varepsilon_e^2 - q^2\right) F_e^2\left(-\mathbf{q}^2\right)$$

В этом приближении в сечении остается лишь член с электрическим формфактором и (139.5) соответствует формуле (80.5),

справедливой для рассеяния электрона на статическом распределении зарядов.

При рассеянии электрона на неподвижном нейтроне в том же предельном случае $\varepsilon_e \ll M$(M - масса нейтрона) формфакторы можно заменить их значениями при $\mathbf{q} = 0$, поскольку,

как уже отмечалось, для отдельного нуклона характерный «радиус» распределения зарядов сравним с $1/M$[1]). В силу электрической нейтральности нейтрона $F_e(0) = 0$, и сечение принимает вид

$$d\sigma = \alpha\mu^2\left[\frac{4\left(\varepsilon_e^2 - m^2\right)}{\mathbf{q}^2} + 1\right] do'_e = \alpha\mu^2\left(\frac{1}{\sin^2(\vartheta/2)} + 1\right) do'_e$$

где $\mu = \frac{e}{2M}F_m(0)$ - магнитный момент нейтрона, ϑ - угол рассеяния.

Эта формула отвечает рассеянию электрона на неподвижном точечном магнитном моменте.

Наконец, напишем формулу для сечения рассеяния ультрарелятивистского электрона на нуклоне при $|\mathbf{q}| \gg m$.

Под $\mathbf{q}^2$ мы попрежнему понимаем квадрат передачи импульса в системе центра инерции, так что инвариант $t = -\mathbf{q}^2$. В системе же покоя начального нуклона (лабораторная система) имеем

$$-t \approx 2\left(p_e p'_e\right) = 2\varepsilon_e\varepsilon'_e(1 - \cos\vartheta)$$

где $\varepsilon_e, \varepsilon'_e$ - начальная и конечная энергия электрона, а ϑ - угол рассеяния в этой системе.

В ультрарелятивистском случае ε'_e связана с ϑ той же формулой, что и при рассеянии фотона (ср. (86.8)):

$$\frac{1}{\varepsilon'_e} - \frac{1}{\varepsilon_e} = \frac{1}{M}(1 - \cos\vartheta)$$

Поэтому имеем

$$-t = \frac{4\varepsilon_e^2 \sin^2\frac{\vartheta}{2}}{1 + \frac{2\varepsilon_e}{M}\sin^2\frac{\vartheta}{2}}$$

$$\pi d|t| = \frac{\varepsilon_e^2 do'_e}{\left(1 + \frac{2\varepsilon_e}{M}\sin^2\frac{\vartheta}{2}\right)^2}$$

где $do'_e = 2\pi\sin\vartheta d\vartheta$. В формуле (139.4) можно везде опустить массу электрона m; выразив все величины через t и $s - M^2 =$

$$d\sigma = \frac{\pi\alpha^2 d|t|}{\varepsilon_e^2 t^2}\left\{F_e^2(t)\left[\frac{(4M\varepsilon_e + t)^2}{4M^2 - t} + t\right] - \frac{t}{4M^2}F_m^2(t)\left[\frac{(4M\varepsilon_e + t)^2}{4M^2 - t} - t\right]\right\},$$

или, используя что-то выше

$$d\sigma = do'_e \frac{\alpha^2}{4\varepsilon_e^2} \frac{\cos^2\frac{\vartheta}{2}}{\sin^4\frac{\vartheta}{2}} \frac{1}{1+\frac{2\varepsilon_e}{M}\sin^2\frac{\vartheta}{2}} \left\{ \frac{F_e^2 - \frac{t}{4M^2}F_m^2}{1-\frac{t}{4M^2}} - \frac{t}{2M^2}F_m^2 \operatorname{tg}^2\frac{\vartheta}{2} \right\}$$

(норм формула, да?)

Обратим внимания на то, что формфакторы F_e и F_m дают независимые вклады в сечение, интерференционные члены отсутствуют. Это оправдывает целесообразность сделанного выбора формфакторов.

ЛЛ4-? Найти сечение рассеяния электрона на адроне со спином 0

(зачем она?)

Решение следующее:

Используя (138.5), имеем вместо (139.3)

$$M_{fi} = -\frac{4\pi e^2}{q^2} \left(\bar{u}'_e \left(\gamma P_h\right) u_e\right) F\left(q^2\right)$$

Для сечения получаем

$$d\sigma = \frac{\pi\alpha^2 dt \left[(s-u)^2 + (4M^2 - t)\, t\right]}{\left[s-(M+m)^2\right]\left[s-(M-m)^2\right] t^2} F^2(t)$$

(обозначения те же, что и в (139.4)). При $|t| \gg m^2$

$$d\sigma = do'_e \frac{\alpha^2}{4\varepsilon_e^2} \frac{\cos^2\frac{\vartheta}{2}}{\sin^4\frac{\vartheta}{2}} \frac{F^2(t)}{1+\frac{2\varepsilon_e}{M}\sin^2\frac{\vartheta}{2}}$$

(обозначения те же, что и в (139.10)).

33.2.3 Low-Energy Theorem for Bremsstrahlung

обзор и мотивация

Theory

В $ 98 был исследован процесс испускания фотона при столкновении частиц в пределе, когда частота фотона стремится к нулю. Оказалось, что амплитуда процесса обратно пропорциональна ω и простым образом выражается через амплитуду того же столкновения без испускания мягкого фотона (об этой последней мы будем снова говорить условно как об амплитуде «упругого» рассеяния и обозначать ее как $M_{fi}^{\text{упр}}$) .В следующем по ω приближении будет

$$M_{fi} = M_{fi}^{(-1)} + M_{fi}^{(0)}$$

где к главному члену ($\propto \omega^{-1}$) добавляется не зависящий от ω ($\propto \omega^0$) поправочный член. Мы увидим, что и этот поправочный (как и главный) член может быть выражен через $M_{fi}^{(\text{упр})}$, причем независимо от деталей электромагнитной структуры адрона. Это утверждение называют низкоэнергетической теоремой для тормозного излучения (*F.E.Low*, 1958).

Мы видели в §98, что основной вклад в амплитуду испускания мягкого фотона (отвечающий первому члену в (140.1)) возникает от диаграмм, в которых фотон излучается непосредственно начальной или конечной частицей. Это - диаграммы вида

(тут диаграммы с кругом в центре)

в противоположность диаграммам вида
(тут диаграмма с кругом в центре)
которых фотонная линия выходит из внутренних частей диа- диаграммы. Для графиков А40.2) характерно, что они могут быть рассечены на две части путем пересечения одной линии вирту- виртуального адрона (начального или конечного). Другими словами,
они иллюстрируют существенное в данном аспекте свойство: на- наличие одночастичного промежуточного состояния с одним ад- роном. Мы видели в пар 79, что в силу требований унитарности это свойство уже само по себе приводит к появлению полюсной особенности в амплитуде.

Предположим для простоты, что из двух сталкивающихся ад- ронов электрически заряжен (и потому может излучать) лишь один (первый) и что оба адрона не имеют спина. Волновые амплитуды и таких адронов — скаляры, которые полагаем рав- равными 1.

Тогда вклад в амплитуду от полюсной части диаграммы А40.2,а) имеет вид
Тогда вклад в амплитуду от полюсной части диаграммы $(140.2, a)$ имеет вид

$$iM_{fi}^{(a)} = \sqrt{4\pi} e_\mu^* \left(2p_1^\mu - k^\mu\right) eF \frac{1}{\left(p_1 - k\right)^2 - M^2} i\Gamma$$

Первый множитель отвечает фотону k (e_μ— его 4-вектор поляризации). Второй множитель отвечает электромагнитной адронной вершине (жирная точка на диаграмме); она записана в форме (138.5), F - формфактор адрона. Третий множитель - пропагатор виртуального адрона $p_1 - k$(M - его масса). Наконец, множитель i Γ обозначает весь остальной блок. Последний отличается от амплитуды упругого процесса

заменой реального адрона p_1 виртуальным $p_1 - k$. Среди первых членов разложения выражения (140.4) по степеням ω будут члены: 1) обратно пропорциональные $\omega, 2)$ не зависяшие от ω, но зависящие от направления $\mathbf{k}, 3)$ не зависящие от ω, k вовсе. Члены третьего (и только такого) рода возникнут также от «неособых» диаграмм - диаграмм вида (140.3),
не содержащих полюсной особенности, и от неполюсных частей диаграмм (140.2). Мы увидим, что все такие члены вместе однозначно определяются по членам первых двух типов условием калибровочной инвариантности и потому не требуют специального вычисления.

Амплитуда упругого процесса (140.5) зависит лишь от двух инвариантных переменных:

$$s = \left(p_1 + p_2\right)^2 = \left(p_1' + p_2'\right)^2, \quad t = \left(p_2' - p_2\right)^2$$

Замена p_1 на $p_1 - k$ не только превращает s в $\left(p_1 - k + p_2\right)^2$, но вводит еще и зависимость от новой переменной

$$\left(p_1 - k\right)^2 - M^2 = -2\left(p_1 k\right)$$

характеризующей «нефизичность» импульса $p_1 - k$. Но уже пер- вый член разложения по этой новой (малой) переменной устраняет особенность в амплитуде (140.4) и потому может дать в ней лишь не зависящие от k члены, которые, согласно сказанному выше, нас пока не интересуют. Таким образом, мы приходим к важному заключению, что вместо величины Γ в (140.4) можно подставить физическую амплитуду $M_{fi}^{(\text{упр})}(s,t)$, лишь заменив в ней

$$s \to \left(p_1 + p_2 - k\right)^2 = s - 2k\left(p_1 + p_2\right)$$

Первые члены ее разложения:

$$\Gamma \to M_{fi}^{(\text{упр})}(s,t) - 2\left(kp_1 + kp_2\right)\left(\frac{\partial M_{fi}^{(\text{упр})}}{\partial s}\right)_t$$

По такой же причине несуществен тот факт, что электромагнитный формфактор F относится здесь к вершине, в которой из двух адронных концов (p_1 и $p_1 - k$) лишь один физический. Его можно поэтому заменить рассмотренным в §138 формфактором вершины

с двумя физическими концами, а поскольку фотон k в данном случае реальный, то $F(k^2) = F(0) = Z_1$, где eZ_1 - заряд адрона. Таким образом, находим из (140.8)

$$M_{fi}^a = Z_1 \quad e\sqrt{4\pi}\frac{2(e^*p_1)}{-2(kp_1)}M_{fi}^{(\text{упр})} - \\ -Z_1 e\sqrt{4\pi}2\,(e^*p_1)\,\frac{1}{-2(kp_1)}\cdot 2\,(p_2k)\,\frac{\partial M_{fi}^{(\text{упр})}}{\partial s} + \ldots$$

где многоточие означает члены, не зависящие от k вовсе (между тем как второй член в (140.8) зависит от направления $\mathbf{k}$). Аналогичным образом найдем, что вклад в M_{fi} диаграммы (140.2,6)

отличается от (140.8) заменой p_1, p_2, k на $p_1', p_2', -k$. Для главного члена разложения получим в результате известное уже нам выражение

$$M_{fi}^{(-1)} = Z_1 e\sqrt{4\pi}\left(\frac{(p_1'e^*)}{(p_1'k)} - \frac{(p_1e^*)}{(p_1k)}\right)M_{fi}^{(\text{угр})}$$

(ср.(98.5)) Не зависящие же от k члены можно определить из требования, чтобы амплитуда в целом была калибровочно-инвариантна. Именно, она не должна меняться при замене $e^* \to e^* + \text{const}\cdot k$, т. е. должна иметь вид $M_{fi} = e_\mu^* J^\mu$, причем $k_\mu J^\mu = 0$. Легко видеть, что для этого нужно добавить к (140.8) не зависящий от k член

$$-2Z_1 e\sqrt{4\pi}\,(p_2e^*)$$

и аналогично для диаграммы $(140.2, 6)$. В результате получим окончательно

$$M_{fi}^{(0)} = 2Z_1 e\sqrt{4\pi}e_\mu^*\left[p_1^\mu\frac{(p_2k)}{(p_1k)} - p_2^\mu + p_1^\mu\frac{(p_2'k)}{(p_1'k)} - p_2'^\mu\right]\frac{\partial M_{fi}^{\text{упр}}}{\partial s}$$

Эта формула решает поставленную задачу. Ее можно представить в более компактном виде, заменив тождественно

$$2p_{2\nu}\left(\frac{\partial}{\partial s}\right)_t = \left(\frac{\partial}{\partial p_1^\nu}\right)_{p_1', p_2, p_2'}$$

(и аналогично для $\partial/\partial p_1'$) и введя дифференциальные операторы

$$\widehat{d}_{1\mu} = \frac{p_{1\mu}}{(p_1k)}k^\nu\frac{\partial}{\partial p_1^\nu} - \frac{\partial}{\partial p_1^\mu}$$

(и аналогично $\widehat{d}_{1\mu}'$). Тогда

$$M_{fi}^{(0)} = Z_1 e\sqrt{4\pi}e_\mu^*\left(\widehat{d}_1^\mu + \widehat{d}_1'^\mu\right)M_{fi}^{(\text{упр})}$$

Сечение определяется квадратом $|M_{fi}|^2$ с требуемой точноСТЬЮ

$$|M_{fi}|^2 = \left|M_{fi}^{(-1)}\right|^2 + 2\,\text{Re}\left(M_{fi}^{(-1)}M_{fi}^{(0)*}\right)$$

Второй член дает искомую поправку к сечению излучения. Просуммировав по поляризациям фотона, получим для этой поправки следующее выражение:

$$-4\pi\,(Z_1e)^2\left(\frac{p'}{(p'k)} - \frac{p}{(pk)}\right)^\mu\left(\widehat{d}_1' + \widehat{d}_1\right)_\mu\left|M_{fi}^{(\text{упр})}\right|^2$$

Таким образом, поправка к сечению излучения выражается через сечение упругого процесса и его производную по s.

Если заряженный адрон имеет спин 1/2, то вся принципи- принципиальная сторона вычислений остается прежней. Меняется лишь конкретный вид вершин и пропагаторов. При этом оказывается,

что после усреднения по поляризациям адронов и фотона оста- остается справедливой формула A40.14) (T. N. Burnett, N. M. Kroll,

1968).

33.2.4 Low-Energy Theorem for Photon-Hadron Scattering

обзор и мотивация

Theory

В пределе малых частот сечение рассеяния фотона на всякой неподвижной заряженной частице стремится к своему классическому значению, даваемому формулой Томсона.

Этому пределу соответствует не зависящая от частоты фотона ω амплитуда, которую обозначим через $M_{fi}^{(0)}$. Оказывается, однако, что и для рассеяния фотона (как и для рассмотренного в предыдущем параграфе тормозного излучения) от деталей электромагнитной структуры адрона не зависит не только этот первый, но и следующий член разложения амплитуды по степеням ω:

$$M_{fi} = M_{fi}^{(0)} + M_{fi}^{(1)}$$

где $M^{(1)} \sim \omega$(*F.E.* Low, 1954; M. Gell-Mann, *M.* L. Goldberger, 1954) Рассматриваемый процесс изображается диаграммами трех видов:

(диаграммы)

из которых первые две снова характеризуются наличием одноча- стичного промежуточного состояния и потому обладают полюс- полюсной особенностью.

Аргументация и принципиальная сторона вычислений оста- остаются теми же, что и в § 140. Достаточно фактически вычис- вычислить лишь вклад от полюсных частей диаграмм A41.2,а—б"),

причем электромагнитные вершины в них выражаются через статические формфакторы (заряд Ze и аномальный магнитный момент μ).

Однако, в отличие от случая тормозного излучения, интере- интересующие нас теперь поправки к сечению комптон-эффекта суще- существуют лишь для частиц со спином. Дело в том, что в случае тормозного излучения кроме поправок, связанных со спином,

имеются также поправки, связанные с энергетической зависимо- зависимостью амплитуды «упругого» процесса. Но в данном случае роль последней играют формфакторы, которые для «физических кон- концов» сводятся к постоянным и от энергии не зависят. Поэтому для рассеяния фотона поправки возникают только за счет маг- магнитного момента, отсутствующего у частиц без спина. Ниже мы рассмотрим рассеяние фотона на адроне со спином 1/2.

Понимая под M_{fi} вклад в амплитуду рассеяния от полюсных диаграмм, имеем (ср. (86.3),(86.4))

$$M_{fi} = -4\pi(Ze)^2 e'^*_\mu e_\nu \,(\bar{u}' Q^{\mu\nu} u)$$

где

$$Q^{\mu\nu} = (\gamma^\mu + S'^\mu)\,\tfrac{\gamma p+\gamma k+M}{s-M^2}\,(\gamma^\nu - S^\nu) + \\ + (\gamma^\nu - S^\nu)\,\tfrac{\gamma p-\gamma k'+M}{u-M^2}\,(\gamma^\mu + S'^\mu)$$

$$s = (p+k)^2 = (p'+k')^2\,, \quad u = (p-k')^2 = (p'-k)^2$$

и для краткости введены обозначения

$$\mu_{\text{ан}}\sigma^{\mu\lambda}k_\lambda = ZeS^\mu, \quad \mu_{\text{ан}}\sigma^{\mu\lambda}k'_\lambda = ZeS'^\mu$$

Переставляя операторы $\gamma p + M$ и учитывая уравнения

$$\bar{u}'(\gamma p' - M) = (\gamma p - M)u = 0$$

можно преобразовать выражение (141.4) к виду

$$\begin{aligned} Q^{\mu\nu} = &\left[(\gamma^\mu + S'^\mu)\frac{(\gamma k)\gamma^\nu + 2p^\nu}{2(pk)} + \frac{\gamma^\nu(\gamma k) - 2p'^\nu}{2(p'k)}(\gamma^\mu + S'^\mu)\right] - \\ &- \left[\frac{\gamma^\mu(\gamma k') + 2p'^\mu}{2(p'k')}S^\nu + S^\nu\frac{\gamma^\mu(\gamma k') - 2p^\mu}{2(pk')}\right] - \\ &- \left[S'^\mu\frac{\gamma p + \gamma k + M}{2(pk)}S^\nu - S^\nu\frac{\gamma p - \gamma k' + M}{2(pk)'}S'^\mu\right] \end{aligned}$$

Такая форма записи (и аналогичная с переставленными k и k') делает очевидной калибровочную инвариантность выражения (141.3), условием которой являются равенства

$$k'_\mu(\bar{u}'Q^{\mu\nu}u) = (\bar{u}'Q^{\mu\nu}u)k_\nu = 0$$

(при проверке надо помнить, что $(\gamma k)(\gamma k) = 0, kS = k'S' = 0$).

Поскольку полюсная часть амплитуды рассеяния оказывается, таким образом, калибровочно-инвариантной уже сама по себе, должна быть инвариантной сама по себе также и регулярная часть амплитуды, включающая в себя и вклад диаграммы (141.2, 6). Отсюда в свою очередь следует, что разложение этой части по степеням k и k' должно начинаться с квадратичных членов (ср. аналогичное замечание в связи с условием (127.5)). Другими словами, регулярная часть амплитуды содержит лишь члены, начиная с пропорциональных $\omega\omega'$ т. е. не дает никакого вклада в интересующие нас члены, пропорциональные ω^0 и ω^1. Все последние содержатся, следовательно, в выражении (141.3) Для их фактического вычисления выбираем лабораторную систему отсчета, в которой покоится начальный адрон. Для фотонов же выбираем трехмерно поперечную калибровку, в которой $e_0 = e'_0 = 0$. Тогда $(pe) = 0, (p'e'^*) \sim |\mathbf{p}'| \sim \omega$, и из (141.6) видно, что первые члены разложения M_{fi} будут пропорциональны ω^0, а члены, содержащие $\mu_{\text{ан}}$, дадут вклад лишь в члены пропорциональные ω^1.

Волновые амплитуды начального и конечного адронов в лабораторной системе отсчета с нужной точностью имеют вид

$$u = \sqrt{2M}\begin{pmatrix} w \\ 0 \end{pmatrix}, \quad \bar{u}' = \sqrt{2M}\left(w'^*, -\frac{w'^*}{2M}(\mathbf{k} - \mathbf{k}')\sigma\right)$$

где w, w' – 3 -спиноры. Прямое вычисление приводит к следующему результату:

$$\begin{gathered} M_{fi}^{(0)} = -8\pi(Ze)^2(\mathbf{e}'^*\mathbf{e})(w'^*w) \\ M_{fi}^{(1)} = -16\pi i M\mu_{\text{aH}}^2\omega(w'^*\sigma w)[[\mathbf{n}'\mathbf{e}'^*][\mathbf{ne}]] - \\ -4\pi i Ze\mu_{\text{ar}}\omega(w'^*\boldsymbol{\sigma}w)\{\mathbf{n}([\mathbf{ne}]\mathbf{e}'^*) + [\mathbf{ne}](\mathbf{ne}'^*) - \\ -\mathbf{n}'([\mathbf{n}'\mathbf{e}'^*]\mathbf{e}) - [\mathbf{n}'\mathbf{e}'^*](\mathbf{ne}) - 2[\mathbf{e}'^*\mathbf{e}]\}, \end{gathered}$$

где $\mathbf{n} = \mathbf{k}/\omega, \mathbf{n}' = \mathbf{k}'/\omega'$ Сечение рассеяния

$$d\sigma = \frac{1}{64\pi^2}|M_{fi}|^2\frac{\omega'^2}{M^2\omega^2}do'$$

(см. (64.19)). Для рассеяния на заряженной частице отличны от нуля как $M_{fi}^{(1)}$, так и $M_{fi}^{(0)}$. Принятая точность допускает при этом сохранение в квадрате $|M_{fi}|^2$ членов $\left|M_{fi}^{(0)}\right|^2$ и $\text{Re}\left(M_{fi}^{(0)}M_{fi}^{(1)*}\right)$. Первый дает томсоновское сечение. Второй же обращается в нуль

при усреднении по поляризациям фотонов и адронов. Поэтому при рассеянии на заряженном адроне рассматриваемые поправки проявляются только в поляризационных эффектах.

Для рассеяния же на электрически нейтральном адроне $M_{fi}^{(0)} = 0$ и сечение определяется квадратом $\left|M_{fi}^{(1)}\right|^2$. После усреднения по поляризациям начальных и суммирования по поляризациям конечных частиц оно оказывается равным (в обычных единицах)

$$d\sigma = \frac{2\mu^4\omega^2}{\hbar^2 c^4}\left(2 + \sin^2\vartheta\right) do'$$

где ϑ - угол рассеяния фотона, а аномальный магнитный момент совпадает с полным моментом μ. Отметим, что по своей угловой зависимости это сечение соответствует случаю антисимметрического рассеяния (см. задачу 2 к §60).

33.2.5 Multipole Moments of Hadrons

обзор и мотивация

Theory

Рассмотрим теперь ток перехода, соответствующий такой же как A38. 2), диаграмме, в которой, однако, линии p_1 и p_2 отвечают разным частицам (массы M_1 и M_2); фотонную линию $k = p_1 - p_2$ удобнее представлять Здесь исходящей из вершины. При этом фотон может быть теперь как виртуальным, так и реальным: должно быть лишь $k^2 < (M_1 - M_2)^2$, так что значение $k^2 = 0$ допустимо. Таким образом, применения рассматриваемой диаграммы включают в себя, в частности, процессы испускания фотона при превращениях частиц, в том числе ядер (в последнем случае начальной и конечной частицами является ядро в различных состояниях). В связи с поставленным вопросом наиболее интересен случай, когда длина волны фотона велика по сравнению с характерными «размерами» частицы (т. е. размерами, входящими в ее формфакторы; для ядра они совпадают, конечно, с его «радиусом»). Тогда ток перехода может быть разложен по степеням k^1). Отметим прежде всего, что должно быть

$$J_{fi} = 0 \quad \text{при} \quad k = 0$$

Действительно, пределу $k \to 0$ отвечает постоянный в пространстве и времени потенциал. Но такой потенциал не имеет физического значения и не может являться причиной каких-либо реальных процессов. К этому же выводу можно подойти и с более формальной точки зрения: рассмотренные в §138 токи были отличны от нуля при $k = 0$ за счет членов, пропорциональных 4-вектору $P = p_1 + p_2$; но при $M_1 \neq M_2$ произведение $(Pk) \neq 0$, так что такие члены запрещены условием поперечности тока. Запишем условие поперечности тока $J_{fi} = (\rho_{fi}, \mathbf{J}_{fi})$ в трехмерном виде:

$$\mathbf{k}\mathbf{J}_{fi} = \omega\rho_{fi}$$

Этому условию можно удовлетворить двумя способами:

$$\mathbf{J}_{fi} = \omega\mathbf{v}(\mathbf{k},\omega), \quad \rho_{fi} = \mathbf{k}\mathbf{v}(\mathbf{k},\omega)$$

или

$$\mathbf{J}_{fi} = [\mathbf{k}\mathbf{a}(\mathbf{k},\omega)], \quad \rho_{fi} = 0$$

Здесь $\mathbf{v}$ - некоторый полярный, а а - аксиальный векторы. В первом случае говорят о токе электрического, а во втором - магнитного типа. Согласно (142. 2) $\mathbf{v}$ и а при $\mathbf{k}, \omega \to 0$ остаются конечными или обращаются в нуль.

Пусть энергия фотона $\omega \ll M_1$. Тогда можно пренебречь эффектом отдачи и считать покоящейся (в системе покоя частицы M_1) также и конечную частицу M_2; при этом ω

становится заданной величиной: $\omega = M_1 - M_2$. Состояния покоящихся частиц M_1 и M_2 характеризуются трехмерными спинорами w_1 и w_2 рангов $2s_1$ и $2s_2$, где s_1 и s_2 - спины частиц. Ток перехода должен быть билинейной комбинацией w_1 и w_2^*. Из произведений компонент этих спиноров можно составить неприводимые тензоры рангов $l = s_1 + s_2, ..., |s_1 - s_2|$ (при заданном l это будет истинный или псевдотензор в зависимости от внутренних четностей частиц M_1 и M_2). Кроме этих тензоров в нашем распоряжении имеется только вектор $\mathbf{k}$. Чтобы построить первый член разложения тока по степеням $\mathbf{k}$, надо с помощью этих величин составить вектор как можно более низкой степени по k. Мы достигнем этой цели взяв тензор наименьшего ранга и умножив его скалярно $l-1$ раз на вектор к. Это и будет полярный вектор $\mathbf{v}$ или аксиальный вектор a.

Пусть Q_{lm} - сферические компоненты тензора, составленного из волновых амплитуд частиц. Сферические же компоненты тензора ранга $l-1$, составленного из компонент $\mathbf{k}$, равны $|\mathbf{k}|^{l-1}Y_{l-1,m}(\mathbf{n})$, где $\mathbf{n} = \mathbf{k}/\omega$. По общему правилу сложения сфе- рических тензоров (см. III, (107,3)) сферические компоненты,

вектора $\mathbf{v}$ можно написать в виде

$$\mathbf{v}_\lambda = (-1)^{\lambda+1} i^l \frac{\sqrt{4\pi}}{(2l-1)!!}\sqrt{\frac{2l+1}{l}}|\mathbf{k}|^{l-1}\times \\ \times \sum_m \begin{pmatrix} l-1 & 1 & l \\ \lambda+m & -\lambda & -m \end{pmatrix} Q_{l,-m} Y_{l-1,\lambda+m}(\mathbf{n}),$$

где λ пробегает значения 0,±1 (о выборе общего множителя см. ниже). Используя формулы (7.16), можно выразить $\mathbf{v}$ через шаровые векторы:

$$\mathbf{v} = i^l \frac{\sqrt{4\pi}|\mathbf{k}|^{l-1}}{(2l-1)!!\sqrt{l(2l+1)}} \sum_m ((-1)^{l-m} Q_{l,-m}\times \\ \times \left[\sqrt{l+1}\mathbf{Y}^{(\ni)}_{lm}(\mathbf{n}) + \sqrt{l}\mathbf{Y}^{(\mathrm{n})}_{lm}(\mathbf{n})\right].$$

Подставив в (142. 4), найдем El-ток перехода: $\mathbf{J}_{fi} = i^l \frac{\sqrt{4\pi}\omega|\mathbf{k}|^{l-1}}{(2l-1)!!\sqrt{l(2l+1)}} \sum_m (-1)^{l-m} Q^{(\ni)}_{l,-m}\times$

$$\times \left[\sqrt{l+1}\mathbf{Y}^{(\ni)}_{lm}(\mathbf{n}) + \sqrt{l}\mathbf{Y}^{(\mathrm{m})}_{lm}(\mathbf{n})\right]$$

Подставив в (142. 4), найдем El-ток перехода:

$$\mathbf{J}_{fi} = i^l \frac{\sqrt{4\pi}\omega|\mathbf{k}|^{l-1}}{(2l-1)!!\sqrt{l(2l+1)}} \sum_m (-1)^{l-m} Q^{(\ni)}_{l,-m}\times \\ \times \left[\sqrt{l+1}\mathbf{Y}^{(\ni)}_{lm}(\mathbf{n}) + \sqrt{l}\mathbf{Y}^{(\mathrm{n})}_{lm}(\mathbf{n})\right] \\ \rho_{fi} = i^l \frac{\sqrt{4\pi|\mathbf{k}|^l}}{(2l-1)!!\sqrt{l(2l+1)}} \sum_m (-1)^{l-m} Q^{(9)}_{l,-m} Y_{lm}(\mathbf{n})\Big]$$

(мы различаем везде $|\mathbf{k}|$ и ω, имея в виду возможные применения как к реальным, так и к виртуальным фотонам, для которых эти величины не совпадают).

В (142. 7),(142. 8) подразумевается, что сферический тензор Q_{lm} (обозначенный здесь $Q^{(\ni)}_{lm}\Big)$ - истинный тензор. Если же это псевдотензор (в таком случае обозначим его $Q^{(\mathrm{M})}_{\mathrm{lm}}$), то формула (142. 6) определит псевдовектор a. Подстановка в (142. 5) дает тогда Ml -ток перехода:

$$\mathbf{J}_{fi} = i^l \frac{\sqrt{4\pi}}{(2l-1)!!}\sqrt{\frac{l+1}{l(2l+1)}}|\mathbf{k}|^l \sum_m (-1)^{l-m} Q^{(\mathrm{M})}_{l,-m}\mathbf{Y}^{(\mathrm{M})}_{lm}(\mathbf{n}), \\ \rho_{fi} = 0$$

Величины $Q_{lm}^{()}$ и $Q_{lm}^{(\mathrm{M})}$ представляют собой адронные электрические и магнитные мультипольные моменты перехода. Их роль в электродинамике адронов вполне аналогична роли соответствующих величин в электродинамике электронов. В то время, однако,

как для электронных систем эти моменты могут быть, в принципе, вычислены по волновым функциям (как матричные элементы соответствующих операторов), в электродинамике адронов они выступают как феноменологические величины, значения которых находятся из опыта.

Нормировка этих величин в (142.7) – (142.9) выбрана в соответствии с их определением в §46. В этом можно убедиться, рассматривая токи (142.7) – (142.9) как компоненты Фурье тока перехода в координатном представлении. Так, разложив множитель $e^{-i\mathbf{kr}}$ в интеграле

$$\rho_{fi}(\mathbf{k}) = \int \rho_{fi}(\mathbf{r}) e^{-i\mathbf{kr}} d^3x$$

с помощью формулы (46. 3), получим

$$\rho_{fi}(\mathbf{k}) = 4\pi i^l \sum_{l,m} Y_{lm}(\mathbf{n}) \int \rho_{fi}(\mathbf{r}) Y_{lm}^* \left(\frac{\mathbf{r}}{r}\right) g_l(|\mathbf{k}|r) d^3x$$

Оставив здесь член с наименьшим l, для которого интеграл отличен от нуля, и заменив функцию $g_l(|\mathbf{k}|r)$ при $|\mathbf{k}|r \ll 1$ ее первым членом разложения (46.5), мы вернемся к формуле (142.9), причем

$$Q_{lm}^{(\ni)} = \sqrt{\frac{4\pi}{2l+1}} \int r^l \rho_{fi}(\mathbf{r}) Y_{lm} \left(\frac{\mathbf{r}}{r}\right) d^3x$$

в соответствии с определением (46. 7). Покажем также, что при применении к испусканию реального фотона полученные формулы приводят к уже известным нам результатам.

Амплитуда перехода с испусканием фотона с импульсом $\mathbf{k} = \omega\mathbf{n}$ и поляризацией $e = (0, \mathbf{e})$:

$$M_{fi} = -e\sqrt{4\pi}\mathbf{e}^* \mathbf{J}_{fi}$$

Если в начальном и конечном состояниях ядро обладает определенным значением проекции момента (M_i и M_f), то в сумме по m в (142.7) – (142.9) остается лишь по одному члену: $m = M_i$ - $-M_f$. Поскольку согласно (16. 23) произведения $\mathbf{Y}_{lm}^{(\ni)}\mathbf{e}^{(\lambda)*}$ или $\mathbf{Y}_{lm}^{(\mathrm{M})}\mathbf{e}^{(\lambda)*}$ ($\lambda = \pm 1-$ спиральность фотона, $e^{(\lambda)} \perp \mathbf{n}$) пропорци- ональны $D_{\lambda m}^l$, мы возвращаемся к формулам, рассмотренным в $48

Дифференциальная вероятность излучения [1])

$$dw = 2\pi\delta\left[\omega - (E_i - E_f)\right] |M_{fi}|^2 \frac{d^3k}{2\omega(2\pi)^3}$$

($E_i, E_f -$ начальная и конечная энергия ядра). Полная вероятность получится суммированием по поляризациям и интегрированием no d^3k. Подставив (142. 7) или (142. 9) в (142. 12) и затем в (142. 13) и произведя указанные действия, мы вернемся к формуле (46.9)(или (47. 2)). Формулы (142.7) – (142.9) включают в себя все случаи, которые могут иметь место для испускания реального фотона. Для виртуальных же фотонов возможен еще и другой случай, не описываемый этими формулами (*R.* H. Fowler, 1930).

Если спины и четности начального и конечного состояний ядра одинаковы, то из их волновых амплитуд можно составить скаляр Q_0, а с его помощью - ток перехода вида

$$\rho_{fi} = Q_0\mathbf{k}^2, \quad \mathbf{J}_{fi} = Q_0\omega\mathbf{k}$$

Величину Q_0 называют монопольны. м ($E0$) моментом перехода. Для испускания реального фотона соответствующая амплитуда перехода обращается в нуль (так как $\mathbf{e}^*\mathbf{k} = 0$).

Монопольный ток, однако, может быть источником переходов, связанных с испусканием виртуального фотона. Более того, он является единственным таким источником при $s_1 = s_2 = 0$, когда все мульти-

По своей зависимости от ω и $\mathbf{k}$ монопольный ток (142. 14) аналогичен электрическому квадрупольному. Соответственно и момент Q_0 представляет собой величину того же порядка, что и квадрупольный момент. К этому заключению можно прийти также и путем истолкования (142. 14) как компоненты Фурье тока в координатном представлении. Разложив в (142. 10) множитель $e^{-i\mathbf{kr}}$ по степеням kr и положив функцию $\rho_{fi}(\mathbf{r})$ сфсрическисимметричной, получим

$$\rho_{fi}(\mathbf{k}) = -\frac{1}{6}\mathbf{k}^2 \int \rho_{fi}(r) r^2 d^3x$$

Сравнив с (142. 14), найдем

$$Q_0 = -\frac{1}{6} \int \rho_{fi}(r) r^2 d^3x$$

Сходство этой величины с квадрупольным моментом очевидно.

ЛЛ4-? вероятность ионизации атома из K -оболочки при ядерном Ml -переходе

Найти вероятность ионизации атома из K -оболочки за счет энергии возбуждения ядра ω (так называемая внутренняя конверсия γ -излучения) при ядерном Ml -переходе в пренебрежении энергией связи электрона в атоме и влиянием поля ядра на его волновые функции).

Процесс описывается диаграммой где p_1 и p_2 относятся к неподвижному ядру в различных состояниях, а $p = (m, 0)$ и $p' = (m + \omega, \mathbf{p}') - 4$ -импульсы начального и конечного электронов. Этой диаграмме отвечает амплитуда

$$M_{fi} = -e^2 \frac{4\pi}{q^2} \bar{u}\left(p'\right) \left(\gamma J_{fi}\right) u(p)$$

где J_{fi} - ток перехода ядра. После суммирования по конечным и усреднения по начальным поляризациям электрона получим

$$\frac{1}{2} \sum_{\text{поляр}} |M_{fi}|^2 = e^4 \frac{16\pi^2}{\left(q^2\right)^2} \left\{ q^2 \left(J_{fi} J_{fi}^*\right) + 4 \left(J_{fi} p\right) \left(J_{fi}^* p\right) \right\}$$

(использовано, что $J_{fi} q = 0$ и поэтому $J_{fi} p = J_{fi} p'$) . Вероятность конверсии вычисляется как

$$dw_{\text{конв}} = 2 \left|\psi_i(0)\right|^2 \left(\frac{|\mathbf{p}|}{m} d\sigma \right)_{\mathbf{p} \to 0}$$

(ср. примеч. на с. 710). Для Ml -переходов ток J_{fi} надо взять из (142.9). Интегрирование $dw_{\text{конв}}$ по $d\varepsilon'$ устраняет δ -функцию, а ингегрирование по do' обращает квадрат $\left|\mathbf{Y}_{lm}^{(\mathrm{m})}\right|^2$ в 1. В результате вероятность конверсии окажется выраженной через квадрат $\left|Q_{l,-m}^{(\mathrm{M})}\right|^2$. Но через эту же величину выражается согласно (46. 9) вероятность w_γ спонтанного излучения фотона при том же ядерном переходе. Окончательно получается

$$\frac{w_{\text{конв}}}{w_\gamma} = 2\alpha (Z\alpha)^3 \frac{m}{\omega} \left(1 + \frac{2m}{\omega}\right)^{l+1/2}$$

(это отношение называют коэффициентом конверсии).

ЛЛ4-? То же для ядерного *El* -перехода.

Тем же способом с током перехода из (142.7),(142.8) получается

$$\frac{w_{\text{конв}}}{w_\gamma} = 2\alpha(Z\alpha)^3 \left(1 + \frac{4l}{l+1}\frac{m^2}{\omega^2}\right)^{l-1/2} \frac{m}{\omega}$$

ЛЛ4-? То же для монопольного перехода ядра.

С током перехода из (142.14) получается

$$w_{\text{конв}} = 4\alpha^2(Z\alpha)^3 m^3\omega^2 \left(1 + \frac{2m}{\omega}\right)^{3/2} |Q_0|^2$$

Поскольку монопольное испускание фотона невозможно, исключить отсюда $|Q_0|^2$ нельзя

33.2.6 Inelastic Scattering of Electrons by Hadrons

обзор и мотивация

Theory

В §139 было рассмотрено упругое рассеяние электронов адронами. Аналогичным образом может быть поставлена задача о неупругом рассеянии. Отличие состоит в том, что конечное адронное состояние будет теперь отвечать другому адрону или же совокупности адронов. Закон сохранения импульса (139. 1) останется в силе, если под p'_h подразумевать 4-импульс конечного адрона или суммарный 4-импульс всей образовавшейся в процессе рассеяния совокупности адронов. Таким образом, теперь $p_h'^2 \neq p_h^2 \neq M^2$, где M - масса начального адрона.

С этим отличием процесс неупругого рассеяния описывается той же диаграммой (139. 2). Нижнюю вершину этой диаграммы мы обозначим через J_{fi}, как это делалось в §138. Однако в отличие от (138. 3) или (138. 6) мы не будем выражать ток перехода через вершинный оператор и амплитуды состояний, чтобы не фиксировать заранее характер конечного адронного состояния. Теперь можно записать амплитуду рассеяния в аналогичном (139. 3) виде

$$M_{fi} = -\frac{4\pi e^2}{(p_e - p'_e)^2} (\bar{u}'_e \gamma_\mu u_e) J^\mu_{fi}$$

(такая амплитуда уже использовалась в задаче 1 к §142, где рассматривалась передача энергии электрону; аналогичную структуру имеет амплитуда в задаче о возбуждении ядер электронами)

Будем считать энергию начального электрона достаточно большой, чтобы в конечном состоянии могло образоваться боль- большое число адронов. Мы будем интересоваться так называемым инклюзивным сечением, отвечающим тому,

что в конечном состоянии фиксируется только импульс электрона, а по всем адронным состояниям произведено суммирование.

Такое дифференциальное сечение запишем, в соответствии формулами §64, в виде

$$d\sigma = \frac{d^3p'_e}{4I(2\pi)^3 2\varepsilon'_e} \sum_f (2\pi)^4 \delta^{(4)} (p_h + p'_h - p_e - p'_e) |M_{fi}|^2$$

Инклюзивное сечение может зависеть лишь от трех кинематических инвариантов, которые могут быть определены путем измерений, производимых только над электронами. Таких инвариантов существует три:

$$t = q^2 \equiv (p_e - p'_e)^2, \quad s = (p_e + p_h)^2$$

и $p_h'^2$. Необходимость учета третьего инварианта связана с тем, что в отличие от упругого рассеяния p'^2 - «масса» конечного адронного состояния - теперь не задана. Вместо $p_h'^2$ удобно, однако, пользоваться инвариантом

$$\nu = qp_h$$

Связь между ν и ${p'^2}_h$ следует из равенства $p_h' = p_h + q$:

$$p_h'^2 = M^2 + t + 2\nu$$

Если начальный адрон стабилен (например, протон), то энергия

электрона в начальном и конечном состояниях ε_e и ε_e и угол рас сеяния θ. Ниже будем считать электрон ультрарелятивистским ($\varepsilon_e \gg m, \varepsilon_e' \gg m$) и пренебрегать его массой. Тогда в системе покоя начального адрона (лабораторная система) получим

$$t = -4\varepsilon_e\varepsilon_e' \sin^2(\theta/2), \quad \nu = M\left(\varepsilon_e - \varepsilon_e'\right), \quad s - M^2 = 2M\varepsilon$$

Подставив (143.1) в (143.2) и выполнив обычным образом суммирование по поляризациям электронов, получим сечение рассеяния неполяризованных электронов. Запишем его в виде

$$d\sigma = \frac{\alpha^2}{(q^2)^2}\frac{d^3p_e'}{(2\pi)^3 \cdot 8M\varepsilon_e\varepsilon_e'} w_{\mu\nu}W^{\mu\nu}$$

или

$$d\sigma = \frac{\alpha^2}{(q^2)^2}\frac{dtd\nu}{4\left(p_hp_e\right)^2} w_{\mu\nu}W^{\mu\nu}$$

где

$$w_{\mu\nu} = 4p_{e\mu}p_{e\nu}' - 2\left(p_{e\mu}q_\nu + p_{e\nu}q_\mu\right) + q^2g_{\mu\nu}$$
$$W^{\mu\nu} = \sum_f (2\pi)^4\delta^{(4)}\left(p_h' - p_h - q\right) J_{fi}^\mu J_{fi}^{\nu *}$$

Тензор $W^{\mu\nu}$, конечно, существенно зависит от свойств адронных токов, и мы можем в общем случае только поставить задачу о его феноменологической структуре, аналогичную задаче о формфакторах адронов. Прежде всего, воспользуемся тем, что тензорная структура $W^{\mu\nu}$ должна определяться только 4-векторами, имеющими отношение к нижней вершине диаграммы (139.2), т. е. p_h и q. Из них (а также метрического тензора $g_{\mu\nu}$) можно составить всего пять независимых тензоров. Требование инвариантности относительно обращения времени сводится к требованию симметричности тензора; таких тензоров можно построить четыре. Наконец, условие сохранения тока, т. е.

$$W^{\mu\nu}q_\nu = 0, \quad W^{\mu\nu}q_\mu = 0$$

сводит число независимых тензоров к двум. Их можно выбрать в виде

$$\tau_{\mu\nu}^{(1)} = \frac{q_\mu q_\nu}{q^2} - g_{\mu\nu}, \quad \tau_{\mu\nu}^{(2)} = \left(p_{h\mu} - \frac{\nu}{t}q_\mu\right)\left(p_{h\nu} - \frac{\nu}{t}q_\nu\right)$$

и записать $W_{\mu\nu}$ как

$$W_{\mu\nu} = 4\pi MW_1\tau_{\mu\nu}^{(1)} + \frac{4\pi}{M}W_2\tau_{\mu\nu}^{(2)}$$

Подставив в (143.8) выражения (143.10) и (143.13), представим сечение в виде

$$d\sigma = \left(W_2 + 2W_1\,\mathrm{tg}^2\,\frac{\theta}{2}\right)d\varepsilon_e'd\sigma_{\text{упр}}$$

где

$$d\sigma_{\text{упр}} = \frac{\alpha^2}{4\varepsilon_e^2}\frac{\cos^2(\vartheta/2)}{\sin^4(\vartheta/2)}do'$$

- сечение рассеяния ультрарелятивистского электрона в кулоновом поле)ср. (80. 7))

Мы видим, что сечение определяется двумя структурными функциями, зависящими от двух инвариантов t и ν. Если при больших энергиях физика адронов не содержит характерных величин размерности массы (гипотеза масштабной инвариантно*сти*), то можно ожидать, что структурные функции будут зависеть при больших энергиях от единственного безразмерного параметра t/ν. Тогда функции W_1, W_2 должны иметь вид функций одной переменной:

$$W_1 = \frac{M}{\nu} F_1\left(\frac{t}{\nu}\right), \quad W_2 = \frac{M}{\nu} F_2\left(\frac{t}{\nu}\right)$$

(заметим, что отношение M/ν не зависит от M).

33.2.7 Electron-Positron Pair Conversion into Hadrons

обзор и мотивация

(а что, мне интересно почитать это.)

Theory

Рассмотрим теперь процесс превращения электрон-позитронной пары в адроны. Обозначим 4-импульсы электрона и позитрона через p_- и p_+, а 4 -импульс (суммарный) совокупности образующихся адронов через p_h; при этом $p_- + p_+ = p_h$. Процесс изображается диаграммой

Нижней вершине этой диаграммы отвечает ток перехода из ва- куума в некоторое адронное состояние $|n\rangle$, который обозначим, как это делалось в §104, через $\langle n|J|0\rangle$. Диаграмме (144.1) соответствует амплитуда рассеяния

$$M_n = -\frac{4\pi\alpha}{q^2} \bar{u}\left(-p_+\right) \gamma_\mu u\left(p_-\right) \langle n \left|J^\mu\right| 0\rangle$$

Мы будем интересоваться полным сечением аннигиляции в адроны σ_h, т. е. просуммируем по всем конечным состояниям $|n\rangle$. Тогда, в соответствии с (64.18),

$$\sigma_h = \frac{1}{4I} \sum_n \left|M_n\right|^2 (2\pi)^4 \delta^{(4)}\left(p_h - q\right)$$

где $q = p_- + p_+$. В дальнейшем будем пренебрегать массой электрона; тогда $q^2 = 2\left(p_- p_+\right), I = q^2/2$. Аналогично тому, как мы поступали в §143, запишем сечение в виде

$$\sigma_h = \frac{(4\pi)^2}{2t^3} w^{\mu\nu} W_{\mu\nu}$$

где

$$w^{\mu\nu} = \alpha\left(p_-^\mu q^\nu + p_-^\nu q^\mu - 2p_-^\mu p_-^\nu - 1/2 q^2 g^{\mu\nu}\right)$$
$$W_{\mu\nu} = \alpha \sum_n (2\pi)^4 \delta^{(4)}\left(p_h - q\right) \langle 0 \left|J_\nu\right| n\rangle \langle n \left|J_\mu\right| 0\rangle$$

и $t = q^2 > 0$ Заметим, что t является единственным кинематическим инвариантом рассматриваемой задачи («треххвостой» диаграммы (144.1)) и q - единственным 4 -вектором, от которого может зависеть $W_{\mu\nu}$. Поэтому с учетом требования сохранения тока тензор $W_{\mu\nu}$ можно представить в виде

$$W_{\mu\nu} = \frac{1}{2} \rho_h(t) \left(\frac{q_\mu q_\nu}{q^2} - g_{\mu\nu}\right)$$

где $\rho_h(t)$ - единственная инвариантная функция, зависяшая от свойств адронного тока и определяющая сечение аннигиляции. Подставив (144.5) – (144.7) в (144.4), получим

$$\sigma_h = \frac{4\pi^2\alpha}{t^2}\rho_h(t)$$

Обратим внимание на то, что функция $\rho_h(t) = -2W^\mu_\mu/3$ в точности совпадает с определенной в (104. 9) функцией $\rho(t)$, если в последней формуле понимать под токами адронные токи. Напомним также, что $\rho(t)$ является спектральной плотностью фотонной собственно-энергетической функции $\Pi(t)$: $\operatorname{Im}\Pi(t) = -\pi\rho(t)$. В рассматриваемом низшем приближении по α функция Π совпадает с поляризационным оператором $\mathcal{P}$. В этом приближении, следовательно, $\rho_h(t)$ является также и спектральной плотностью адронного вклада в поляризационный оператор:

$$\operatorname{Im}\mathcal{P}_h(t) = -\pi\rho_h(t)$$

Использовав дисперсионное соотношение (111.13) и выразив ρ_h через σ_h согласно (144.8), получим формулу

$$\mathcal{P}_h(t) = -\frac{t^2}{4\pi^2\alpha}\int\limits_0^\infty \frac{\sigma_h(t')\,dt'}{t'-t-i0}$$

выражающую адронный вклад в поляризацию вакуума через измеряемое на опыте сечение аннигиляции в адроны.

Заметим, что таким же точно способом можно было бы решить задачу об аннигиляции электрон-позитронной пары в мюонную пару (в первом приближении по α может образоваться только одна такая пара). Аналогично результату (144.8) мы получили бы

$$\sigma_\mu = \frac{4\pi^2\alpha}{t^2}\rho_\mu(t)$$

где $\rho_\mu(t)$ - спектральная плотность мюонной поляризации вакуума. Она отличается от электронной поляризации лишь заменой массы электрона m массой мюона μ и согласно (113.8) дается выражением

$$\rho_\mu(t) = \frac{\alpha}{3\pi}\left(t+2\mu^2\right)\sqrt{1-\frac{4\mu^2}{t}}$$

Подставив его в (144.11), мы воспроизведем результат, полученный уже в задаче 8 к §81.

33.3 Some Experiments for Testing QCD

(отдельную неделю потом подумаю про эксперименты!)

33.4 Other Topics of QCD

(наверняка еще что-то про это есть.)

34 Lectures on the Infrared Structure of Gravity and Gauge Theory

This is a redacted transcript of a course given by the author at Harvard in spring semester 2016. It contains a pedagogical overview of recent developments connecting the subjects of soft theorems, the memory effect and asymptotic symmetries in four-dimensional QED, nonabelian gauge theory and gravity with applications to black holes.

34.1 Introduction

34.1.1 The Infrared Triangle

These lectures concern a triangular equivalence relation that governs the infrared (IR) dynamics of all physical theories with massless particles. Each of the three corners of the triangle, illustrated in figure 34.1, represents an old and central subject in physics on which hundreds or even thousands (in the case of soft theorems) of papers have been written. Over the past few years we have learned that these three seemingly unrelated subjects are actually the same subject, arrived at from very different starting points and expressed in very different notations.

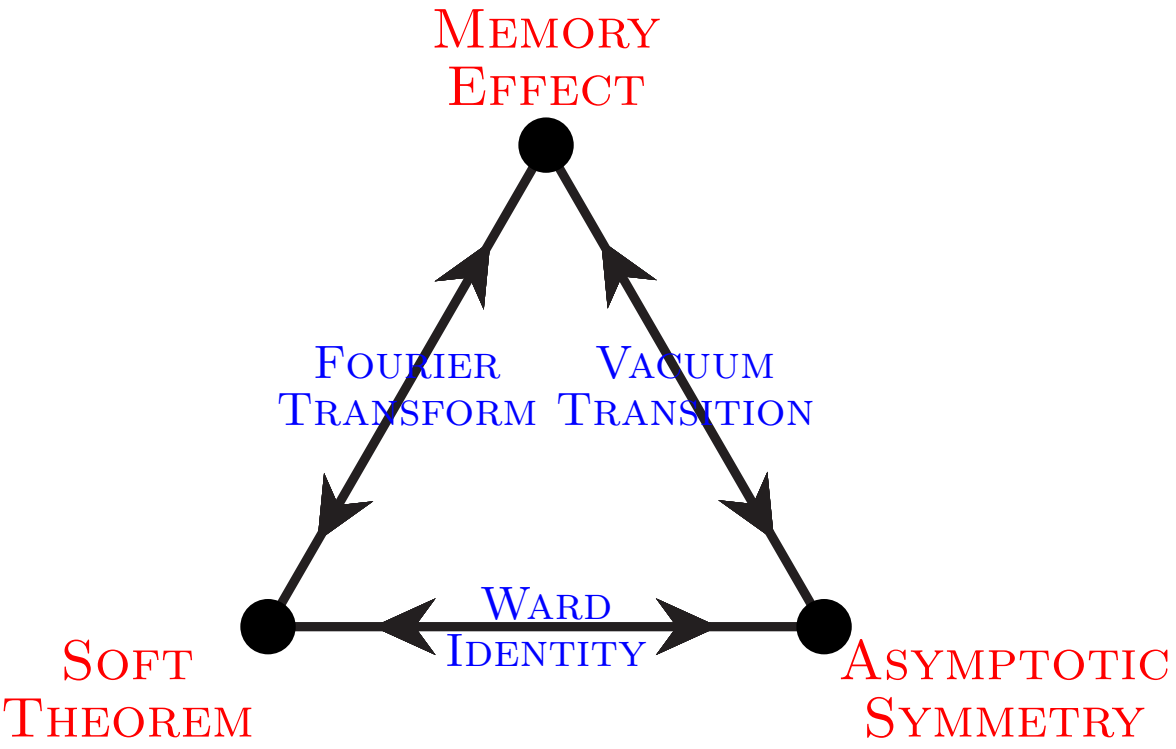

Figure 34.1: **The infrared triangle.**

The first corner is the topic of soft theorems. These originated in quantum electrodynamics (QED) in 1937 with the work of Bloch and Nordsieck [1], were significantly developed in 1958 by Low and others[2, 3, 4, 5**?**], and were generalized to gravity in 1965 by Weinberg [7]. Soft theorems characterize universal properties of Feynman diagrams and scattering amplitudes when a massless external particle becomes *soft* (i.e., its energy is taken to zero). These theorems tell us that a surprisingly large — in fact, infinite — number of soft particles are produced in any physical process, but in a highly controlled manner that is central to the consistency of quantum field theory.

The second corner is the subject of asymptotic symmetries. This is the study of the nontrivial exact symmetries or conserved charges of any system with an asymptotic region or boundary. One of the earliest examples appears in the pioneering work of Bondi, van der Burg, Metzner, and Sachs (BMS) [8, 9], who sought to recover the Poincaré group of special relativity as the symmetry group of asymptotically flat spacetimes in general relativity (GR). Instead, in a spectacular failure of their original program, they discovered the infinite-dimensional BMS group whose deep implications are still being unravelled today. In contrast, analogous asymptotic symmetries in QED and nonabelian gauge theory were discovered only recently [10, 11, 12, 13, 14] and are a subject of ongoing research [15, 16, 17, 18, 19, 20, 21, 22].

The third corner of the triangle is the memory effect, investigated in the context of gravitational physics in 1974 by Zel'dovich and Polnarev [23], and significantly developed by Christodoulou and others [24, 25, 26, 27, 28, 29, 30, 31, 32, 33]. This is a subtle DC effect, in which the passage of gravitational waves produces a permanent shift in the relative positions of a pair of inertial detectors. Detection of the memory effect has been proposed at LIGO [34] or via a pulsar timing array [35, 36]. It is an exciting experimental prospect for the coming decades. Again, the gauge theory analog appeared only recently [37, 38, 39, 40]. This memory corner of the triangle provides an important physical realization of the more abstractly formulated results of the other two corners, giving direct observational consequences of the infinite number of symmetries and conservation laws.

Figure 34.1 also depicts the mathematical equivalence relations connecting the three corners. Perhaps the simplest is the connection between the soft theorem and the memory effect [41]. The former is a statement about momentum space poles in scattering amplitudes, while the latter concerns a DC shift in asymptotic data between late and early times. These are the same thing, because the Fourier transform of a pole in frequency space is a step function in time. The step function in turn can be understood as a domain wall connecting two inequivalent vacua that are related by an asymptotic symmetry [41]. Hence the memory effect both physically manifests and directly measures the action of the asymptotic symmetries. The triangle in figure 34.1 is closed by noting that every symmetry has a Ward identity that equates scattering amplitudes of symmetry-related states.[184] These Ward identities turn out to be nothing but the soft theorems — which relate amplitudes with and without soft particles — in disguise [42, 10, 11, 43].

It is a testimony to the unity of physics that these three seemingly disparate avenues of investigation led to the same mathematical structures. We will see in section 34.5 that Weinberg's 1965 soft graviton theorem reproduced the 1962 results of BMS, but in the wildly different language and notation of Feynman diagrams as opposed to asymptotic structures at null infinity. We will further see in section 34.6 that the 1987 Braginsky-Thorne formula for the gravitational memory effect is a Fourier transform of the Weinberg soft graviton theorem. Of course, Weinberg was scattering elementary particles, while Braginsky and Thorne were scattering black holes, but this distinction is irrelevant in the deep infrared!

The bigger picture emerging from the triangle is that deep IR physics is extremely rich, perhaps richer than previously appreciated. Every time we breathe, an infinite number of soft photons and gravitons are produced. Quantum field theory analyses tend to treat this as a technical problem to be overcome by resorting to carefully constructed inclusive cross sections. IR regulators are often used that explicitly break the symmetries, and it is difficult to see them emerge as the regulator is removed.[185] GR analyses tend to treat the BMS discovery that the deep IR limit of GR is not special relativity as a problem to be avoided by the ad hoc imposition of extra boundary conditions at infinity. In fact, BMS discovered the classical version of infinite graviton production, an equivalent indication of the richness of the deep IR. Here we will see that, far from being technicalities, these IR phenomena are associated with fundamental symmetries of nature whose fascinating consequences we are just beginning to unravel.

34.1.2 New Developments

New developments in this area go beyond demonstrating the equivalence of previously known phenomena. The three-dimensional perspective afforded by the triangle has led to better conceptual understanding of each old corner, discovery of new corners, and new research programs searching for and exploring new triangles. We now mention a few of the many new results that have emerged in the past few years.

Until recently, one corner of the triangle — asymptotic symmetries — was essentially unknown for any example in four-dimensional Minkowski space. The best understood case was the BMS action in gravity. BMS showed that infinite-dimensional subgroups $\mathrm{BMS}^{\pm}$ of the diffeomorphism

[184] Alternately, these identities can be derived as the vanishing of all matrix elements of the associated charge conservation laws.

[185] BMS_3 has been recovered as the large radius limit of gravity in AdS_3[44, 45, 46], but efforts [45] to recover BMS_4 in the large radius limit of AdS_4 have so far not succeeded.

group act nontrivially at future and past null infinity $\mathcal{I}^{\pm}$, transforming one set of Cauchy data to a physically inequivalent one. The full group $\text{BMS}^+ \times \text{BMS}^-$, however, is clearly not a symmetry of gravitational scattering. For example, it includes elements that boost the past but not the future. It was widely held (in part due to misconceptions about asymptotic falloffs cleared up only recently by Christodoulou and Klainerman [47]) that there is no nontrivial infinite-dimensional symmetry of gravitational scattering; see [48] for further discussion. However, the equivalence to the soft graviton theorem was used in [42] to show that, in a generic physical setting, a certain 'antipodal' subgroup of $\text{BMS}^+ \times \text{BMS}^-$ is an exact asymptotic symmetry of gravitational scattering. This discovery is detailed in section 34.5.2.

The triangular perspective further led to the conclusion that the vacuum in GR (as well as in gauge theory) is not unique, as it transforms nontrivially under the antipodal symmetries.[186] In particular, distinct vacua are found to have different angular momenta [51]. Ignoring the vacuum degeneracy leads to the false conclusion that angular momentum is not conserved (see figure 34.9)! This degeneracy resolves the so-called problem of angular momentum in GR. The electromagnetic analog is discussed in section 34.2.11, and the gravity version in section 34.5.

Another new development from the triangle involves a conjectured extension of the BMS group involving *superrotations*, a Virasoro-like symmetry that acts on the sphere at $\mathcal{I}$ [52, 53, 54, 55]. Because of certain singularities in the generators, standard asymptotic symmetry analyses could not establish whether these are bona fide symmetries. However, the result was established [56, 57] using Feynman diagrams and proving the equivalent soft theorem, as discussed in section 34.5.3.

In abelian and nonabelian gauge theories, various soft theorems have long been known. New symmetries in gauge theory, precise analogs of the antipodal subgroup of BMS in gravity, have been discovered using the triangular equivalence, as discussed in sections 34.2 and 34.4.

Given one corner of a triangle, others can be systematically determined. Insights from gravity can be applied to gauge theory and vice versa. One or more triangles potentially exists for every type of massless particle. Let us now discuss a few of these triangular variations.

34.1.3 Echoing Triangles

The IR triangle in figure 34.1 has many copies, which echo throughout much of physics, as illustrated in figure 34.2. Here are some examples.

QED, Yang-Mills Theory, Gravity, Massless Particles, ...

The simplest cases of the triangle involve massless particles associated with local gauge symmetries, such as the photon, which will be our first example. However, whenever there is a massless particle, one can consider the soft limit of the scattering amplitude. A full triangle, including symmetry and memory, is often found to emerge, even when no underlying local gauge symmetry exists. A simple example of this discussed here is the soft photino theorem [58], which lies at the corner of a triangle including an infinite number of asymptotic fermionic symmetries. Potentially, a triangle exists for every type of massless particle, many of which have yet to be studied from this perspective.

Leading, Subleading, Sub-Subleading, ...

Soft theorems are statements about the behavior of an amplitude at zero or low energy. In an expansion in powers of the soft energy, universal behavior may appear in the leading as well as the subleading or even sub-subleading orders. Indeed, Low [2, 4, 59] already discussed a subleading soft theorem in QED. Recent research derived the symmetry based on Low's subleading theorem [60, 61, 62]. The associated memory effect remains to be analyzed. In gravity, a new subleading soft theorem was proven at tree-level [63, 64, 65, 56] and was shown to imply [57, 66, 67, 68] superrotation symmetry [52, 53, 54, 55], a recently conjectured asymptotic symmetry. The third corner of the triangle, the spin memory effect, was derived in [69]. A proposal for measuring it using

[186] This result was partially anticipated in prescient work of Ashtekar [49]; see also Balachandran and Vaidya [50].

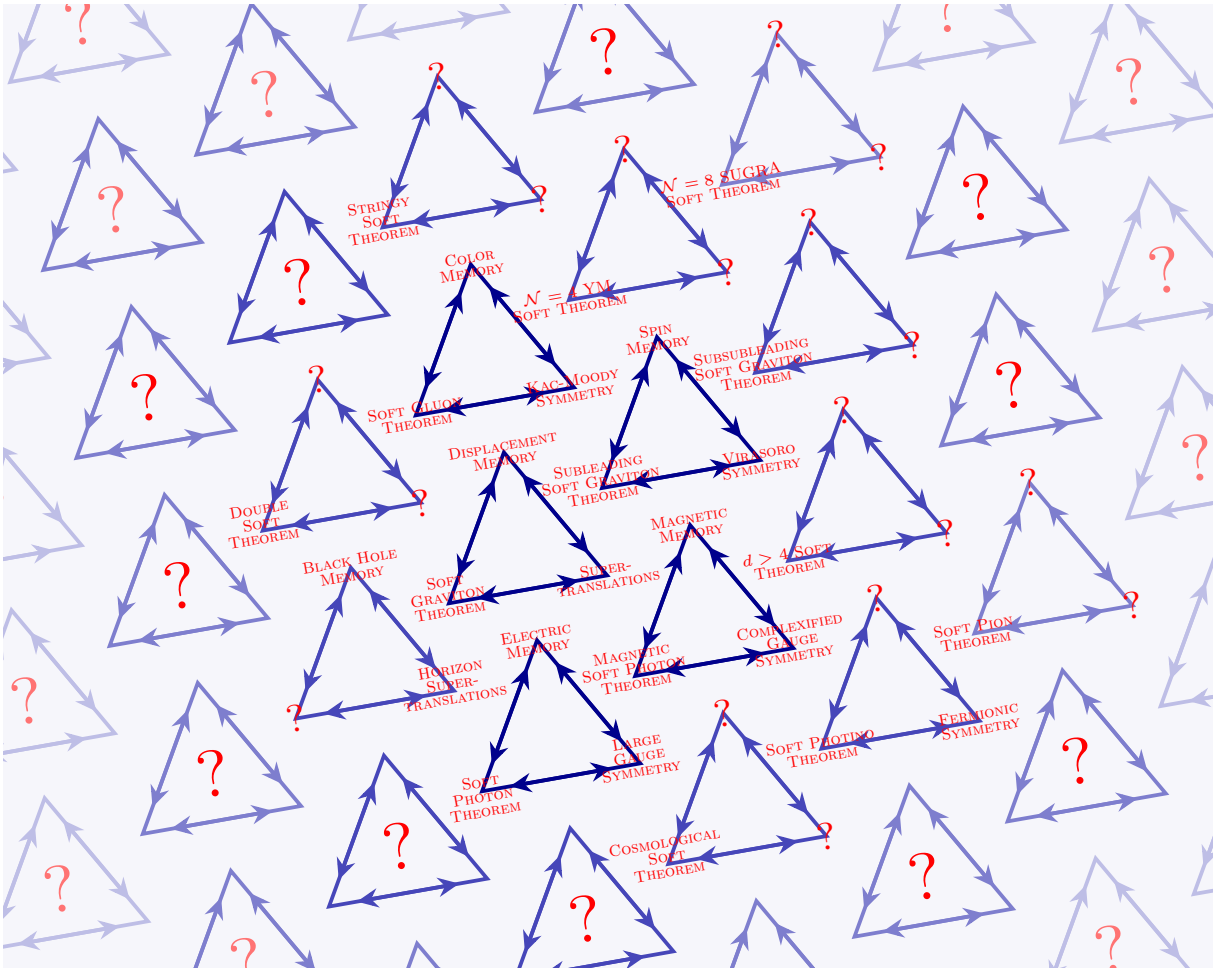

Figure 34.2: **The infrared triangle echoes throughout disparate areas of physics.**

the Einstein Telescope appears in Nichols [**?**]. A gravitational sub-subleading soft theorem has also been proven [56, 71, 72, 73, 74, 75, 76, 77], and the associated symmetry has been discussed in [78]. A complete classification of all possible soft theorems at various orders of the soft expansion has not appeared, although some discussion of it exists [79, 80]. New soft theorems at various orders have recently been discovered in nonabelian gauge theories [81, 82, 20, 77], supersymmetric theories [83, 84, 85], nonlinear sigma models [86], string theories [87, 88, 89, 90, 91, 92, 76, 93], and in other contexts [94, 95, 96, 97, 98].

Double Soft Theorems, ...

Interesting universal structures are known for limits when two or more external particles are taken to be soft. For example, for soft moduli in $\mathcal{N}=8$ supergravity, the structure constants of the hidden $E_{7(7)}$ symmetry algebra appear [99]. In recent years, double-soft limits have been further examined in gravity [100, 101], gauge theories [102, 103, 100, 104, 105], supersymmetric theories [83, 106, 103, 100], nonlinear sigma models [104, 86, 107], and string theory [103, 108, 93]. This behavior is presumably at the corner of yet another unexplored triangle and is perhaps related to structure constants or central charges of an asymptotic symmetry group.

Classical, Quantum, ...

There is a purely classical triangle involving tree-level soft theorems and classical symmetries. This regime is where these lectures begin. In the simplest cases, the soft theorem is uncorrected, and the quantum triangle is similar to the classical one. In general, however, an interesting story involving anomalies may appear [109, 110, 111, 112, 113, 114, 115, 116, 117].

Minkowski, $\boldsymbol{D < 4}$*,* $\boldsymbol{D > 4}$*, Cosmology, ...*

In these lectures, we consider only the physical case of four-dimensional Minkowski space. However, the triangle also appears in both higher dimensions [118, 119, 95] and in cosmology, where there are also soft theorems [120, 121, 122] and asymptotic symmetries [123]. The sub-subleading soft graviton theorem has been explored in arbitrary dimensions [72, 73]. The case of three-dimensional gravity, where there is generally better control, is especially interesting[44, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135]. However, since three-dimensional gravitons do not propagate, this case has no soft theorem. This feature gives the problem a rather different flavor, and I do not review it in these lectures.

Supersymmetry, $\boldsymbol{\mathcal{N} = 1, 2, ...}$

For many reasons it is also of interest to consider supersymmetric theories. The local $\mathcal{N} = 1$ case has been worked out [136, 137], as has the global one in [58]. New features should appear with soft scalars and R-symmetries for $\mathcal{N} = 4$ Yang-Mills and $\mathcal{N} = 8$ supergravity. Soft theorems in various supersymmetric theories have been worked out [109, 84, 116] and sometimes give rise to recursion relations [138]. At present, even the asymptotic symmetry group for these interesting higher-$\mathcal{N}$ cases is unknown.

Every one of the combined possibilities mentioned here can potentially result in a new triangle. So far, each story has its own unique and surprising features, which need to be worked out case by case. Most have yet to be explored. This subject is still in its infancy, which makes it a lot of fun to talk about!

34.1.4 Motivation and Applications

Why is this interesting? What are the motivations and applications? While the development of this subject heavily borrows some insights from modern string theory, it directly pertains to the real world. It has interwoven motivations and applications, which we now discuss.

Connecting Disparate Subjects

Given a concrete mathematical relation between two different subjects, results in one can be translated into what are often new results in the other. New methods of calculation, new physical phenomena and insights, and new avenues of investigation are often suggested. The current context is no exception. Soft theorems, memory effects, and asymptotic symmetries are three different ways of characterizing the behavior of the universe around us at very long distance scales. This equivalence has led to the realization that physics in the deep infrared is much richer, more subtle, and certainly much less understood than we previously believed. Notably, looking at IR structure from all three corners of the triangle has led to the realization that the vacuum in all gauge and gravitational theories is best described as infinitely degenerate. Prior to the past several years, there was no case in which all three corners were understood. Now that we know about these triangles, once we find one corner of one triangle, we can work out the other two. As a result, numerous surprising discoveries have been made, some of which are covered in these lectures.

Flat Space Holography

A central motivation for these IR investigations is to understand the holographic structure of quantum gravity in four-dimensional asymptotically flat spacetimes, which is a good approximation to the real world. This is how I came into the subject. A very beautiful story has unfolded over the past twenty years concerning the holographic structure of quantum gravity in anti-de Sitter space. The story begins [139] with the identification of the symmetries in anti-de Sitter space with those of its proposed holographic dual. Following this successful example, the very first question we should ask in attempting a holographic formulation of flat space quantum gravity is: "What are the symmetries?" Up until three years ago, the answer to this question was unknown. At the very least we now know [42] that the symmetry group is infinite dimensional and includes a certain subgroup of, but not all of, the BMS group on past and future null infinity. In addition, good evidence [57, 67, 117] indicates a conjectured Virasoro (or superrotation) symmetry [52, 53, 54, 55] that acts on the sphere at null infinity, referred to as the celestial sphere $\mathcal{CS}^2$. The Lorentz group $SL(2,\mathbb{C})$ acts as the global conformal group on this sphere, and the Virasoro action enhances the global to the local conformal group. This suggests that the holographic dual of four-dimensional flat-space quantum gravity might be realized as an exotic two-dimensional conformal field theory (CFT) on $\mathcal{CS}^2$ [12, 140, 141, 142, 143, 144].

The Gauge Theory $\mathcal{S}$-Matrix

The study of soft particles and infrared divergences in QED, Yang-Mills theory, and collider physics is a large and central enterprise in quantum field theory. Notable recent progress includes the development of soft collinear effective theory (SCET) [145], in which infinite-dimensional symmetries likely related to those discussed here make an appearance [146]. SCET has important practical applications for understanding jet structure and interpreting LHC and other collider events. From a more formal point of view, it is disturbing that generically no IR finite $\mathcal{S}$-matrix[187] exists in gauge theories, even if suitable inclusive cross sections are finite [151]. While this does not pose an obstacle for collider predictions, it is a big elephant in the room for mathematical quantum field theory. Surely the central object of study in these theories must somehow be mathematically well defined! Our hope is that the discovery of new symmetries in the deep IR will enable us to formulate the soft part of the $\mathcal{S}$-matrix in a more satisfactory way. Moreover, the symmetries might be exploited to develop more efficient computational methods, perhaps via a connection with the SCET program.

Miracles in $\mathcal{N} = 4$ Yang-Mills

Scattering amplitudes in $\mathcal{N} = 4$ Yang-Mills have been a very active subject for more than 10 years e.g., [152, 153, 154, 155, 99, 156, 157, 158, 159]. Extensive computations have revealed miraculous cancellations that reduce very complicated expressions to simple ones. When many cancellations occur it is natural to suspect that they are required by an underlying symmetry. It is possible that the new IR symmetries provide an explanation of those miracles or, even better, a derivation of some of the incredibly beautiful formulas for scattering amplitudes in $\mathcal{N} = 4$ Yang-Mills theory.

Black Holes

Although I did not start this IR project with black holes in mind, as usual, all roads lead to black holes [41, 160, 48]. The IR structure has important implications for the information paradox[161]. This paradox is intertwined with the deep IR because an infinite number of soft gravitons and soft photons are produced in the process of black hole formation and evaporation. These soft

[187] In massive abelian gauge theories, the Faddeev-Kulish construction [147] yields some IR finite amplitudes. An analogous construction for nonabelian gauge theory was given in [148, 149] and references therein. It was recently revisited for gravity [150] and for QED [22]. However, Faddeev-Kulish states are not complete: for example, they exclude an incoming positron-electron pair with no incoming radiation. See section 34.2.15 for further discussion.

particles carry information with a very low energy cost. They must be carefully tracked to follow the flow of information. Tracking is hard to do without a definition of the $\mathcal{S}$-matrix! Moreover, their production is highly constrained by an infinite number of exact quantum conservation laws that correlate them with energetic hard particles and also with the quantum state of the black hole itself [162]. Thus black holes must carry an infinite number of conserved charges, described as "soft hair" in a recent collaboration with Hawking and Perry [160, 48]. The information paradox cannot be clearly stated [163], let alone solved, without accounting for soft particles. The implications of soft hair recently have been discussed [164, 165, 166, 128, 167, 168, 163, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180], for example.

These lectures both review the old material on soft theorems, asymptotic symmetries and memory as well as the new connections among them. Unsolved problems are pointed out along the way. Some exciting developments in the past year whose proper perspective has not yet been clarified are omitted. These lectures are not meant to be an exhaustive review; see other sources in the References [50, 94, 181, 182, 45, 183, 184, 185, 186, 187, 188, 51, 189, 190, 191] for interesting related developments.

34.2 QED

Since this is a book about the interconnections among many different subjects, we might start at many different places — gauge theory or gravity, soft theorems, symmetries or memories — and weave our way through the connections. Here I choose the simplest possible starting point: classical, nineteenth-century electromagnetism. Beginning from this point, we will trace out these interconnections for any theory with an abelian gauge symmetry — including, of course, QED.

We begin in section 2.1 by recalling the Liénard-Wiechert solutions for a collection of charges and noting that these solutions are discontinuous at the boundary of Minkowski space. Characterizing this discontinuity requires a careful description of the boundary, which is provided in section 2.2. In section 2.3, we show that the Liénard-Wiechert field obeys a boundary matching condition equating its values at the far past of $\mathcal{I}^+$ ($\mathcal{I}^+_-$) with those at antipodal points of the far future of $\mathcal{I}^-$ ($\mathcal{I}^-_+$). Section 2.4 describes the electromagnetic Cauchy data at $\mathcal{I}^\pm$. Using only the matching condition, an infinity of conservation laws is derived in section 2.5. Section 2.6 presents the covariant canonical formulations of the physical phase spaces at $\mathcal{I}^\pm$. In section 2.7, I show for massless fields, that the conserved charges generate (via the Dirac bracket) nontrivial large gauge transformations associated with antipodally matched angle-dependent gauge parameters that do not die off at $\mathcal{I}^\pm$. A Ward identity of this symmetry is derived in section 2.8 and shown to be equivalent to the soft photon theorem. For completeness, the standard diagrammatic derivation of the soft theorems for both photons and gravitons is reviewed in section 2.9. In section 2.10, I adapt the BMS-type analysis of asymptotic symmetries employed from studies of gravity to electromagnetism and show that it reproduces the antipodally matched large gauge symmetries. In section 2.11, it is noted that the large gauge symmetry is spontaneously broken, resulting in an infinite vacuum degeneracy with soft photons as the Goldstone bosons. The generalization to massive fields, and hence QED, is in section 2.12. This extension employs a hyperbolic slicing of Minkowski space and heavily borrows results from investigations of the anti-de Sitter/conformal field theory correspondence (AdS/CFT). In 2.13, a magnetically corrected soft photon theorem is presented and conjectured to be nonperturbatively exact. I derive a second infinity of conserved charges and symmetries arising from large magnetic gauge transformations. Section 2.14 shows that for $\mathcal{N} = 1$ supersymmetry, the soft photino theorem leads to an infinity of fermionic conservation laws and symmetries. These are surprising, as they are unrelated to any previously discussed local symmetry. In section 2.15, IR divergences are discussed and shown to disappear for some and possibly all fully charge-conserving amplitudes.

34.2.1 Liénard-Wiechert Solution

Maxwell's theory of electromagnetism is described by the action

$$S = -\frac{1}{4e^2}\int d^4x\sqrt{-g}F_{\mu\nu}F^{\mu\nu} + S_M \ , \tag{34.1}$$

where $\mu,\nu = 0,1,2,3$ and S_M denotes a general matter action. In form notation, the field strength F is related to the gauge field A by

$$F = \mathrm{d}A \ . \tag{34.2}$$

The equation of motion is

$$\mathrm{d}*F = e^2 * j \quad \Longrightarrow \quad \nabla^\mu F_{\mu\nu} = e^2 j_\nu \ , \tag{34.3}$$

where $*$ is the Hodge dual, and the charge current is

$$j^\nu = -\frac{\delta S_M}{\delta A_\nu} \ . \tag{34.4}$$

The electric charge inside a two-sphere (S^2) at infinity is defined by

$$Q_E = \frac{1}{e^2}\int_{S^2} *F = \int_\Sigma *j \in \mathbb{Z} \ . \tag{34.5}$$

The second equality is obtained using integration by parts and the constraint component of the equation of motion. It says that if we take Σ to be any slice with the S^2 boundary, the electric charge is just the normal component of the charge current integrated over that slice. For convenience, we adopt here a convention in which Q_E is an integer in the quantum theory. For example, the electron has charge $Q_E = 1$ (not e). The magnetic charge $\frac{1}{2\pi}\int F$ is also integral, and it has an associated conservation law [192]. We return to the interesting story of magnetic charges in section 2.13, but for now, assume they are absent.

The theory (34.1) is invariant under the infinitesimal gauge transformations

$$\delta_\varepsilon A = \mathrm{d}\varepsilon \ , \qquad \delta_\varepsilon \Phi_k = i\varepsilon Q_k \Phi_k \ , \tag{34.6}$$

where $\varepsilon \sim \varepsilon + 2\pi$, and Φ_k is a matter field with charge Q_k. Since $Q_k \in \mathbb{Z}$, the finite transformation

$$\Phi_k \to e^{iQ_k\varepsilon}\Phi_k \tag{34.7}$$

is invariant under $\varepsilon \to \varepsilon + 2\pi$.

Now let us solve the equation of motion. Consider a source j corresponding to n particles, each moving with constant four-velocity $U_k^\mu = \gamma_k\left(1,\vec{\beta}_k\right)$, where $U_k^2 = -1$ and $\gamma_k^2 = \frac{1}{1-\beta_k^2}$. Then we have

$$j_\mu(x) = \sum_{k=1}^n Q_k \int d\tau \ U_{k\mu}\delta^4(x^\nu - U_k^\nu\tau) \ . \tag{34.8}$$

Each particle is a point source with a worldline parametrized by τ, so that $x_k^\mu(\tau) = U_k^\mu\tau$.

Equation (34.3) determines the electromagnetic field due to this source. Liénard and Wiechert solved this problem in 1898. The solution for the radial component of the electric field is

$$F_{rt}(\vec{x},t) = \frac{e^2}{4\pi}\sum_{k=1}^n \frac{Q_k\gamma_k\left(r - t\hat{x}\cdot\vec{\beta}_k\right)}{\left|\gamma_k^2\left(t - r\hat{x}\cdot\vec{\beta}_k\right)^2 - t^2 + r^2\right|^{3/2}} \ , \tag{34.9}$$

where

$$r^2 = \vec{x} \cdot \vec{x} \ , \quad \vec{x} = r\hat{x} \ . \tag{34.10}$$

This formula is valid for either the advanced or the retarded potential. It has the peculiar property that it is not single valued and has a discontinuity at $r = \infty$. Although this fact was presumably well known to many since the nineteenth century, this basic point surprised me when I became aware of it only recently. It is crucial for all that follows, so we will go through how this happens in pedantic detail. To fully explain it, we must first digress and review the structure of infinity in Minkowski space.

34.2.2 Minkowski Space Penrose Diagram

To talk about infinity, it is useful to introduce Penrose diagrams. The Penrose diagram for four-dimensional Minkowski space is shown in figure 34.3. In this figure all of Minkowski space is pulled

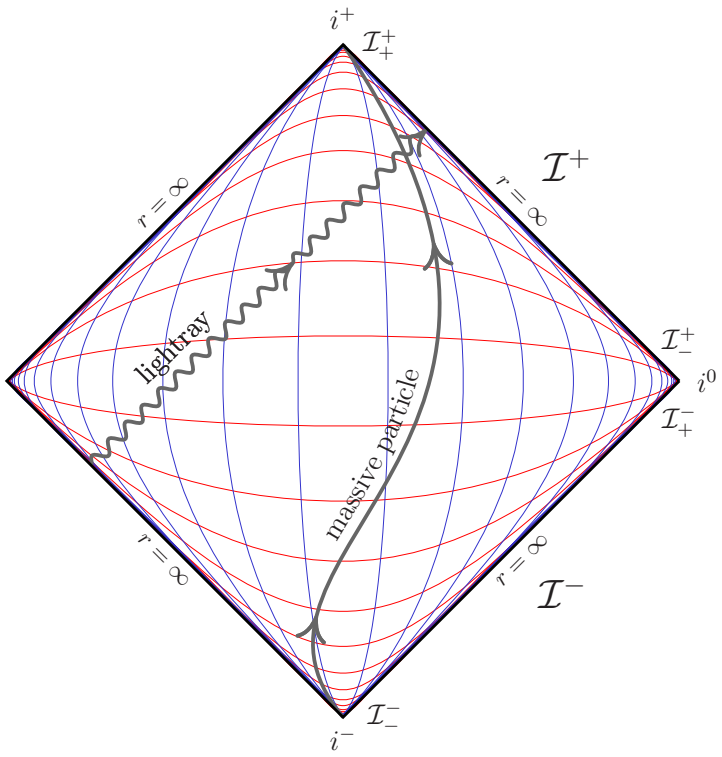

Figure 34.3: **Penrose diagram of Minkowski space. Red lines represent surfaces of constant t, while blue lines represent surfaces of constant r. The thick gray line is the worldline of a massive particle moving at constant velocity, and the thick wavy gray line is a light ray. Every two-sphere of constant $(r > 0, t)$ is represented by two points, one on the left and one on the right, which are exchanged by the antipodal map. Past and future null infinities are labelled by $\mathcal{I}^{\pm}$, and their four S^2 boundary components by $\mathcal{I}^{\pm}_{\pm}$. The points $i^{\pm}$ are past and future timelike infinity, while the point i^0 is spatial infinity.**

into a finite region by a conformal transformation that diverges at the boundaries. Distances are not faithfully represented, but the causal structure is unaffected by the conformal transformation and is clearly indicated by the rule that light rays always propagate at 45 degrees. Every left-right pair of points at the same (r, t) in figure 34.3 corresponds to an S^2 (except $r = 0$, which is a point), and the pair is interchanged by the antipodal map on S^2. Sometimes the picture is drawn differently, as in figure 34.4. Every point on this diagram represents an S^2 except for $r = 0$, which

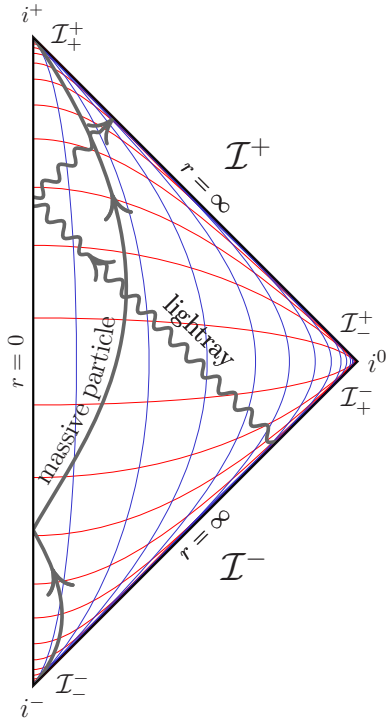

Figure 34.4: **Alternative Penrose diagram of Minkowski space in which every point except for $r = 0$ is an S^2.**

is the origin. If you have a sequence of two-spheres that are getting smaller and smaller and you add a point in the middle, you get $\mathbb{R}^3$. For our purposes (which include a study of the antipodal map), figure 34.3 will be more useful.

We want to study the electric field of n charges moving at constant velocity. The charges have worldlines that look like the thick gray line in figure 34.3. They cannot escape to $r = \infty$, because light rays move at 45 degrees on Penrose diagrams; every light ray will eventually catch up to a particle moving with constant velocity (less than c) and cross it to larger radius. As a result, massive charges always end up at the uppermost point, "called future timelike infinity" and denoted i^+ in figure 34.3. Similarly, the worldlines of (massive) charges start at past timelike infinity (i^-). Likewise, we call the place where light rays go to "future null infinity" ($\mathcal{I}^+$) and the place where light rays come from "past null infinity" ($\mathcal{I}^-$). We will be especially concerned about behavior near spatial infinity, denoted i^0. This behavior turns out to be very subtle. As we will see, almost anything, even Maxwell electromagnetism with one point particle, is singular at this point. $\mathcal{I}^+$ is the product of S^2 with a null line. It will be important to distinguish between the past of $\mathcal{I}^+$, which we call $\mathcal{I}^+_-$, and the future of $\mathcal{I}^-$, which we call $\mathcal{I}^-_+$. Both these points are near, but distinct from, the point i^0. Figures 34.3 and 34.4 also illustrate $\mathcal{I}^-_-$, which is an S^2 near but distinct from the point i^-. Likewise, near the point i^+, we have the S^2 denoted $\mathcal{I}^+_+$.

Now let us discuss the problem of scattering in Minkowski space, a central topic of this book. Whether in electrodynamics or gravity, classical or quantum, one starts by specifying initial data at $\mathcal{I}^-$. If there are stable massive particles, initial data at past timelike infinity i^- are also needed, but we suppress that for now and return to it in section 34.2.12. In the far past, fields and particles disperse, and so the theory is weakly interacting. Incoming particles or wavepackets evolve towards each other, interact in some very complicated way, and ultimately come out on $\mathcal{I}^+$. The classical version of the scattering problem is to find a classical map from the phase space defined on $\mathcal{I}^-$ to the phase space defined on $\mathcal{I}^+$. The quantum version of the scattering problem is to find the $\mathcal{S}$-matrix that evolves incoming states defined on $\mathcal{I}^-$ to outgoing states defined on $\mathcal{I}^+$.

Clearly in this setting, what goes on near i^0 is important, because we have to know how to

match on final data on $\mathcal{I}^+$ given initial data on $\mathcal{I}^-$. Specifically, we need to understand what the matching conditions are that relate the fields at $\mathcal{I}^-_+$ to the fields at $\mathcal{I}^+_-$. One might think that the fields should simply be taken to be equal, but this turns out to be completely wrong. In fact, such a matching condition is not even Lorentz invariant! We will soon see it is also not obeyed by the Liénard-Wiechert solution.

To describe $\mathcal{I}^-$, it is useful to introduce advanced time:

$$v = t + r \ . \tag{34.11}$$

To describe $\mathcal{I}^+$, we introduce retarded time:

$$u = t - r \ . \tag{34.12}$$

$\mathcal{I}^-$ is a three-dimensional surface, so four coordinates are not needed. We could try to use the usual $(t, r, \hat{x})$, $\hat{x}$ being a unit vector labeling a point on the sphere, but this choice is awkward, because t and r are both infinite on $\mathcal{I}$. However, if we follow null rays backward (in time), $t + r$ is finite, and if we follow them forward, $t - r$ is finite. So $\mathcal{I}^+$ is naturally parametrized by $(u, \hat{x})$, and $\mathcal{I}^-$ is naturally parametrized by $(v, \hat{x})$.

34.2.3 Antipodal Matching Condition

A peculiar property of the Liénard-Wiechert solution is that if we start at a point in the bulk, take the limit first to $\mathcal{I}^+$ and then to i^0, we get a different answer than if we take the limit to $\mathcal{I}^-$ and then to i^0. In fact, the Liénard-Wiechert solution takes different values at fixed angles (or $\hat{x}$) on $\mathcal{I}^+_-$ and $\mathcal{I}^-_+$, but obeys an *antipodal* matching condition.

To see this, first rewrite (34.9) in retarded coordinates $u = t - r$:

$$F_{rt} = F_{ru} = \frac{e^2}{4\pi} \sum_{k=1}^{n} \frac{Q_k \gamma_k \left(r - (u + r)\hat{x} \cdot \vec{\beta}_k \right)}{\left| \gamma_k^2 \left(u + r - r\hat{x} \cdot \vec{\beta}_k \right)^2 - (u + r)^2 + r^2 \right|^{3/2}} \ . \tag{34.13}$$

To reach $\mathcal{I}^+$, hold u fixed and take the limit $r \to \infty$:

$$F_{rt}\big|_{\mathcal{I}^+} = \frac{e^2}{4\pi r^2} \sum_{k=1}^{n} \frac{Q_k}{\gamma_k^2 (1 - \hat{x} \cdot \vec{\beta}_k)^2} \ . \tag{34.14}$$

To reach $\mathcal{I}^+_-$, we must further take $u \to -\infty$, but since the expression is u-independent, (34.14) is the final answer. Note, if we take the velocity $\vec{\beta}_k = 0$, we recover the usual Coulomb field for a static charged particle.

The leading $\frac{1}{r^2}$ component of the electric field due to moving charges is not a constant: it depends on the angle of the sphere at infinity. In standard electrodynamics texts, such as Jackson [193], one often studies the multipole expansion of static configurations. The $\frac{1}{r^2}$ component is then constant and proportional to the total electric charge, while the $\frac{1}{r^3}$ term comes from the static electric dipole moment with angular momentum $\ell = 1$. In contrast, for the case of a single charge moving at constant velocity, no electric dipole is in the picture, but there is a dipole moment in the $\frac{1}{r^2}$ term, in the sense that the $\ell = 1$ mode of the distribution over the sphere is nonzero. This $\ell = 1$ mode dipole moment of the $\frac{1}{r^2}$ term is not to be confused with what is usually called the the electric dipole moment in classical electrodynamics!

To find the electric field at $\mathcal{I}^-$, we work in advanced coordinates $v = t + r$:

$$F_{rt} = F_{rv} = \frac{e^2}{4\pi} \sum_{k=1}^{n} \frac{Q_k \gamma_k \left(r - (v - r)\hat{x} \cdot \vec{\beta}_k \right)}{\left| \gamma_k^2 \left(v - r - r\hat{x} \cdot \vec{\beta}_k \right)^2 - (v - r)^2 + r^2 \right|^{3/2}} \ . \tag{34.15}$$

To reach $\mathcal{I}^-$, we hold v fixed and take the limit $r \to \infty$:

$$F_{rt}\big|_{\mathcal{I}^-} = \frac{e^2}{4\pi r^2} \sum_{k=1}^{n} \frac{Q_k}{\gamma_k^2 (1 + \hat{x} \cdot \vec{\beta}_k)^2} \ . \tag{34.16}$$

Once again, since the expression is v-independent, this is also the value of F_{rt} at $\mathcal{I}_+^-$. Comparing equation (34.14) and equation (34.16), we find that the values of the fields do not match. Even for the case of one moving charge in Minkowski space, the radial component of the electric field is not continuous at spatial infinity. Its value depends on how one approaches spatial infinity, and it is discontinuous there. The field takes a definite value if one specifies a way of approaching i^0. Going down from $\mathcal{I}^+$, or up from $\mathcal{I}^-$, one gets a definite answer, but they are not equal as long as $\vec{\beta}_k \neq 0$.

Since the solution is Lorentz covariant and can be obtained by boosting a static charge, the discontinuity is dictated by Lorentz invariance. Indeed, Lorentz transformations themselves are not smooth at spatial infinity, because the vector fields that generate them are singular at i^0. A boost toward the north pole in the future is a boost away from the north pole in the past. The point i^0 is the dividing point of these two different behaviors.

Although the fields $F_{rt}\big|_{\mathcal{I}_+^-}$ and $F_{rt}\big|_{\mathcal{I}_-^+}$ are not equal, they have an important antipodal relation: taking $\hat{x}$ to $-\hat{x}$ takes $F_{rt}\big|_{\mathcal{I}_-^+}$ to $F_{rt}\big|_{\mathcal{I}_+^-}$. Comparison of equation (34.14) and equation (34.16) reveals the matching condition,

$$\lim_{r\to\infty} r^2 F_{ru}(\hat{x})\big|_{\mathcal{I}_-^+} = \lim_{r\to\infty} r^2 F_{rv}(-\hat{x})\big|_{\mathcal{I}_+^-} \ , \tag{34.17}$$

where we have used the relation $F_{ru} = F_{rv} = F_{rt}$. That is, the leading term in the radial electric field for a collection of n particles at any point on $\mathcal{I}_-^+$ will be equal to the value of the field at the antipodal point on $\mathcal{I}_+^-$.

So far we have been considering a relatively simple nonstatic situation, in which nothing is interacting. However, it is not hard to check (see exercise 1) that equation (34.17) holds in basically all reasonable circumstances. If we add electromagnetic waves on top of the n-particle solution (34.9), the field strengths at $\mathcal{I}^+$ and $\mathcal{I}^-$ would no longer be constant. Electromagnetic waves are radiative as opposed to Coulombic modes of the electromagnetic field. If we want them to have finite energy, they must die off in the infinite future and the infinite past. For finite energy configurations, adding radiative modes will give more complicated expressions (for example the field strength on $\mathcal{I}^+$ will depend on u) but will not affect this basic behavior of the Coulombic, deep IR part of the electric field near spatial infinity, which is what we have been studying. It is also the case that letting the charges interact or scatter off one another preserves (34.17). If one uses the retarded Liénard-Wiechert potential, one obtains equation (34.9) in a neighborhood of i^0 with $\vec{\beta}_k$ the outgoing velocities, while the advanced Liénard-Wiechert gives (34.9) in a neighborhood of i^0 with $\vec{\beta}_k$ the incoming velocities. These solutions are different, but both obey antipodal matching. In section 2.9, we will also see that in quantum theory, Feynman diagrammatics implicitly assume equation (34.17) in the standard weak field expansion. That might have been guessed from the fact that the matching condition is Lorentz and CPT invariant.

Another way of thinking about the matching condition, using the conformal invariance of electromagnetism, is to map or "conformally compactify" Minkowski space to the cylinder using a conformal rescaling of the metric (figure 34.5). This mapping is especially simple in electromagnetism, which is invariant under such rescalings, but it is also very useful in gravity, where it formed the basis of Penrose's analysis of null infinity [194, 195]. The cross sections of the cylinder are S^3, and Minkowski space is represented by the blue diamond. Null infinity $\mathcal{I}$ is the lightcone of spatial infinity i^0. The future lightcone wraps around the cylinder and meets itself at i^+, while the past lightcone meets itself at i^-. The Minkowski diamond is wrapped on the cylinder and touches itself at i^0. The null generators of $\mathcal{I}$ start at past null infinity $\mathcal{I}^-$ and pass through spatial infinity i^0 to future null infinity $\mathcal{I}^+$. The matching condition (34.17) then states that the fields are continuous along the generators of $\mathcal{I}$, including when they cross i^0, even though it is generically a singular point. It is singular, because, for example, even just one charge in the interior needs

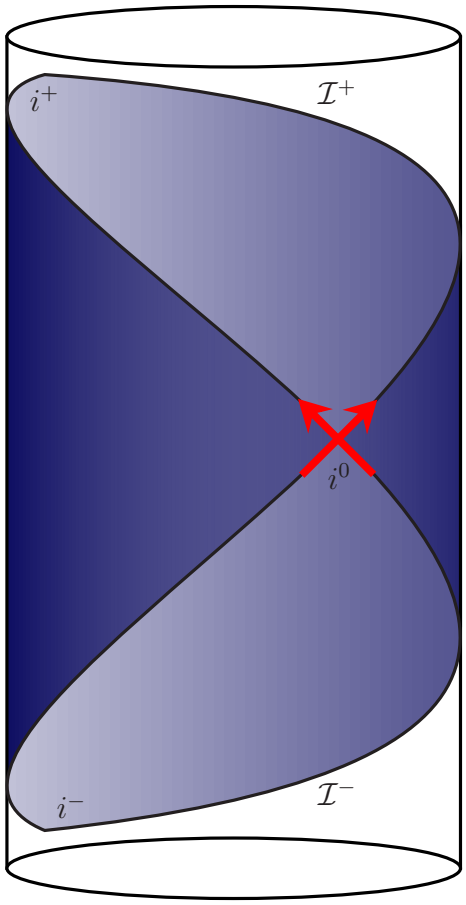

Figure 34.5: **The blue diamond represents Minkowski space conformally compactified onto the $S^3 \times \mathbb{R}$ Einstein static universe. The red arrows indicate how the generators of null infinity pass through spatial infinity.**

an image charge at i^0, which will cause the electric field to diverge there. One certainly cannot demand that the fields be smooth at spatial infinity. In the presence of multiple moving charges, the singularity can become very complicated and in general requires arbitrarily many parameters to describe. However, we are still able to consistently require, without violating Lorentz invariance (which is a conformal symmetry of the compactified geometry), that the fields are continuous along the null generators passing through i^0 as prescribed by equation (34.17).

34.2.4 Asymptotic Expansions

Before going any further, it is convenient to introduce specific advanced and retarded coordinates, illustrated in figure 34.6, and to be more precise about our large-r expansions around $\mathcal{I}^{\pm}$.

In retarded coordinates $(r, u, z, \bar{z})$, the Minkowski line element is

$$ds^2 = -du^2 - 2dudr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} \ . \tag{34.18}$$

These coordinates will be used in the neighborhood of $\mathcal{I}^+$. Here, $u = t - r$ is the retarded time coordinate introduced in equation (34.12), r is the radial coordinate, and z is a complex coordinate on the unit sphere with metric

$$\gamma_{z\bar{z}} = \frac{2}{(1 + z\bar{z})^2} \ . \tag{34.19}$$

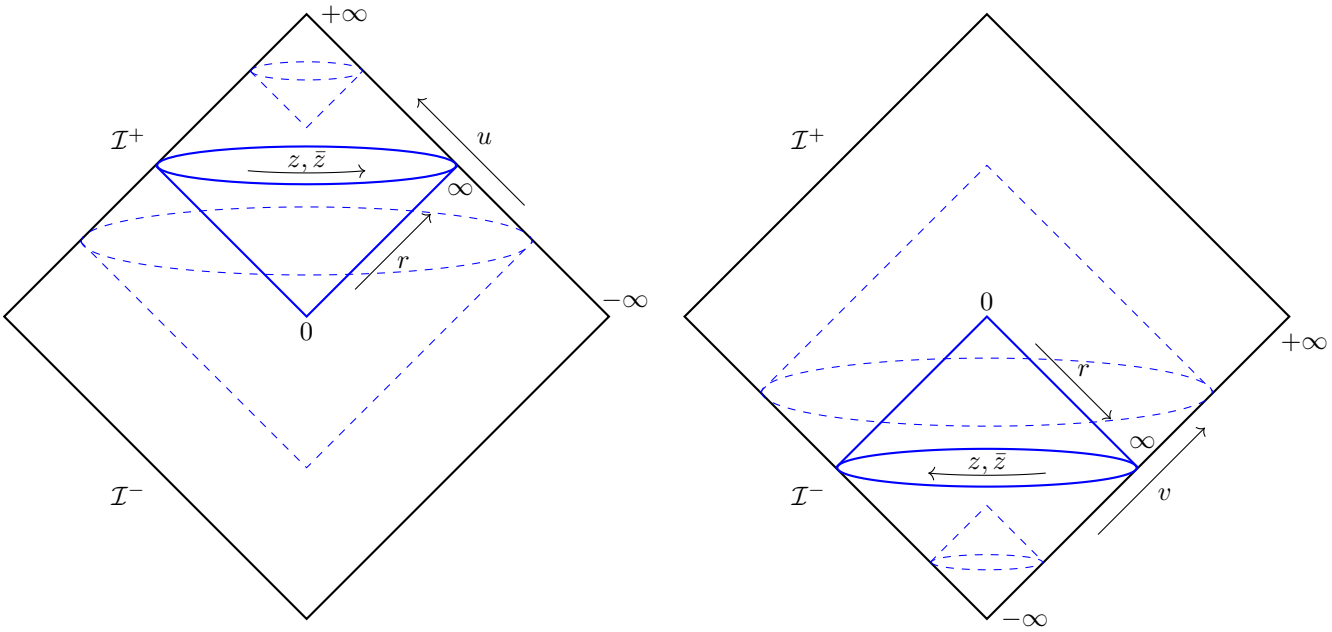

Figure 34.6: **In the left diagram, $\mathcal{I}^+$ is parametrized by retarded time u and spherical coordinates $(z, \bar{z})$ in retarded Bondi coordinates, while in the right diagram, $\mathcal{I}^-$ is parametrized by advanced time v and spherical coordinates $(z, \bar{z})$ in advanced Bondi coordinates. The advanced and retarded $(z, \bar{z})$ coordinates are chosen so that they are related by an antipodal map on spheres of constant (u, r).**

If we keep $(u, z, \bar{z})$ fixed and take the limit $r \to \infty$, we move out along a null line to $\mathcal{I}^+$. One can see that this is a null line, because along this path, $du = dz = d\bar{z} = 0$, which implies $ds^2 = 0$. The standard metric on Minkowski space,

$$ds^2 = -dt^2 + (d\vec{x})^2 \ , \tag{34.20}$$

is related to the metric in equation (34.18) by the coordinate transformations

$$(\vec{x})^2 = r^2 \ , \quad t = u + r \ , \quad x^1 + ix^2 = \frac{2rz}{1 + z\bar{z}} \ , \quad x^3 = r\frac{1 - z\bar{z}}{1 + z\bar{z}} \ . \tag{34.21}$$

The inverse transformation is

$$r^2 = (\vec{x})^2 \ , \quad u = t - r \ , \quad z = \frac{x^1 + ix^2}{x^3 + r}. \tag{34.22}$$

Here, z runs over the entire complex plane; $z = 0$ is the north pole, $z = \infty$ is the south pole, $z\bar{z} = 1$ is the equator, and $z \to -1/\bar{z}$ is the antipodal map. This is a convenient coordinate system to work in near $\mathcal{I}^+$ because, as we will see, everything falls off near $\mathcal{I}^+$, so we can expand fields in powers of $\frac{1}{r}$. However, we cannot easily use these coordinates near $\mathcal{I}^-$, because $u = -\infty$ there. To work in a neighborhood of $\mathcal{I}^-$, we introduce advanced coordinates. The advanced line element is

$$ds^2 = -dv^2 + 2dvdr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} \ . \tag{34.23}$$

This metric can be obtained from the standard Cartesian metric on Minkowski space by means of the coordinate transformations

$$(\vec{x})^2 = r^2 \ , \quad t = v - r \ , \quad x^1 + ix^2 = -\frac{2rz}{1 + z\bar{z}} \ , \quad x^3 = -r\frac{1 - z\bar{z}}{1 + z\bar{z}} \ . \tag{34.24}$$

Crucial minus signs introduced into the last two terms of (34.24) imply that the z in the advanced coordinates denotes the antipodal point on the sphere to the z in the retarded coordinates (the sign reverses under $z \to -1/\bar{z}$). If we take a light ray which crosses Minkowski space, then the value of z at which it starts in advanced coordinates will be the same as the value of z at which it ends in retarded coordinates. Moreover, z is constant along the null generators of $\mathcal{I}^-$ as they pass through i^0 to $\mathcal{I}^+$. This perhaps odd-seeming choice of notation simplifies subsequent formulas.

Now we wish to expand around $\mathcal{I}^+$. Given any field—say, the z-component of the vector potential—we can write an expansion for it as a sum

$$A_z(u, r, z, \bar{z}) = \sum_{n=0}^{\infty} \frac{A_z^{(n)}(u, z, \bar{z})}{r^n} \ , \tag{34.25}$$

where the coefficients depend only on the coordinates $(u, z, \bar{z})$ parametrizing $\mathcal{I}^+$. In exercise 2, it is shown that $A_z^{(0)}$ is the local Cauchy data. The superscript (n) will be used to denote the order in the expansion (the power of $1/r$) about $r = \infty$. In general, we are going to be expanding many fields about both $\mathcal{I}^+$ and $\mathcal{I}^-$. Using our new notation, we can finally rewrite the matching condition (34.17) as

$$F_{ru}^{(2)}(z, \bar{z})\Big|_{\mathcal{I}_-^+} = F_{rv}^{(2)}(z, \bar{z})\Big|_{\mathcal{I}_+^-} \ , \tag{34.26}$$

where $F_{ru}^{(2)}$ is the $\frac{1}{r^2}$ term in the expansion of the ru component of the field strength around $\mathcal{I}^+$. Evaluating it at $\mathcal{I}_-^+$ is equivalent to taking $u = -\infty$:

$$F_{ru}^{(2)}(z, \bar{z})\Big|_{\mathcal{I}_-^+} = F_{ru}^{(2)}(-\infty, z, \bar{z}) \ . \tag{34.27}$$

The simplicity of expression (34.26) motivated our definition of the z values on $\mathcal{I}^+$ as antipodally related to those on $\mathcal{I}^-$.

34.2.5 An Infinity of Conserved Charges

In this section we will show that the matching condition (34.26) immediately implies, without further ado, the existence of an infinite number of conserved charges in all electromagnetic theories in Minkowski space.

Consider any function ε on Minkowski space obeying the boundary condition

$$\varepsilon(z, \bar{z})|_{\mathcal{I}_-^+} = \varepsilon(z, \bar{z})|_{\mathcal{I}_+^-} \ . \tag{34.28}$$

Note that $\varepsilon(z, \bar{z})$ is not smooth near spatial infinity, but instead is antipodally identified. Now we define future and past charges:

$$Q_\varepsilon^+ = \frac{1}{e^2} \int_{\mathcal{I}_-^+} \varepsilon * F, \quad Q_\varepsilon^- = \frac{1}{e^2} \int_{\mathcal{I}_+^-} \varepsilon * F \ . \tag{34.29}$$

It then immediately follows from (34.26) that any theory involving electromagnetism has an infinite number of conservation laws, one for every function ε:

$$Q_\varepsilon^+ = Q_\varepsilon^- . \tag{34.30}$$

For example, we could take $\varepsilon|_{\mathcal{I}_+^-} = Y_{\ell m}$ to be a spherical harmonic, in which case we have one conservation law for every value of the angular momentum (ℓ, m). One way of stating this conservation law is that all the incoming multipole moments of the electromagnetic field are equal to

the antipodal outgoing multipole moments. All of these moments are nonzero in a generic time-dependent situation. In this basis, the antipodal map acts as $(-)^\ell$. The $\ell = 0$ mode is of course total charge conservation, which equates the net incoming to the net outgoing charge. Here we discover an infinite family of higher harmonics of this familiar global conservation law.

The conservation laws look even more interesting and nontrivial when we use the Gauss law to write the surface integral expression for the electric field as a volume integral expression of the incoming and outgoing fields. At this point, we make the simplifying assumption that all stable charged particles are massless, deferring the more intricate discussion of the (more realistic) massive case to section 34.2.12. We then find

$$Q^+_\varepsilon = \frac{1}{e^2}\int_{\mathcal{I}^+} \mathrm{d}\varepsilon \wedge *F + \int_{\mathcal{I}^+} \varepsilon * j + \frac{1}{e^2}\cancelto{0}{\int_{\mathcal{I}^+_+} \varepsilon * F} \,, \tag{34.31}$$

where we recall j is the charged matter current. This last term arises because $\mathcal{I}^+$ has two boundaries: we began in (34.29) with an integral over $\mathcal{I}^+_-$ and used integration by parts to get a volume integral over $\mathcal{I}^+$ plus a surface integral over $\mathcal{I}^+_+$. However, we can set this last surface integral to zero under our assumption that there are no massive charged particles, which implies that the electric field will vanish at $\mathcal{I}^+_+$. Likewise, for $\mathcal{I}^-$,

$$Q^-_\varepsilon = \frac{1}{e^2}\int_{\mathcal{I}^-} \mathrm{d}\varepsilon \wedge *F + \int_{\mathcal{I}^-} \varepsilon * j + \frac{1}{e^2}\cancelto{0}{\int_{\mathcal{I}^-_-} \varepsilon * F} \,. \tag{34.32}$$

Charge conservation, equation (34.30), is true for any ε obeying equation (34.28). However, we restrict to the special case in which

$$\partial_u \varepsilon = \partial_v \varepsilon = 0 \,. \tag{34.33}$$

Our formulas are all true for the more general case, but consideration of those cases turns out not to yield anything new. A particular case of equation (34.28) is $\varepsilon =$ constant, in which case the first term on the RHS of the $Q^\pm_\varepsilon$ equation vanishes. Equation (34.30) reduces to, for m (n) incoming (outgoing) particles with charges Q^{in}_k (Q^{out}_k)

$$\sum_{k=1}^m Q^{\text{in}}_k = \sum_{k=1}^n Q^{\text{out}}_k \,. \tag{34.34}$$

This is just the familiar statement that the sum of all the incoming charges must be equal to the sum of all the outgoing charges.

Now suppose ε is not constant. Then we get an infinite number of conserved charges that are on exactly the same footing as the usual conservation law (34.34) but with both terms in (34.32) and (34.31) contributing. The second term is still a sum over electric charges but is now weighted by an arbitrary function of the angle. The first is an additional mysterious term linear in the electromagnetic field F. We will call this a *soft photon term*, because, as we show later, when promoted to an operator it creates and annihilates zero-energy photons; for now it is just a classical integral of F. Unlike the constant ε case, whose associated charge involves only incoming matter fields, these more general conservation laws mix the charged matter and the electromagnetic field. We have an exact statement that relates various integrals, weighted by ε, of the incoming initial data to the outgoing final data. The conservation law says that, for any ε, the number obtained from the incoming integral exactly equals the number obtained from the outgoing integral.

Thus far, we have written the charges in form notation in (34.31) and (34.32). For many computations, explicit coordinate representations are useful. In retarded coordinates (34.18),

$$Q^+_\varepsilon = \frac{1}{e^2}\int_{\mathcal{I}^+_-} \varepsilon * F = \frac{1}{e^2}\int_{\mathcal{I}^+_-} d^2z \gamma_{z\bar{z}} \varepsilon F^{(2)}_{ru} \,. \tag{34.35}$$

Note there is an r^2 in the Hodge dual, which cancels the $1/r^2$ that comes with the $F^{(2)}_{ru}$ term, resulting in an integral which is finite for $r \to \infty$. This is equal, by virtue of the boundary condition (34.28), to

$$Q^-_\varepsilon = \frac{1}{e^2}\int_{\mathcal{I}^-_+} d^2z\gamma_{z\bar{z}}\varepsilon F^{(2)}_{rv} \ . \tag{34.36}$$

To integrate these formulas by parts, we need to use the constraint equations on the null surfaces $\mathcal{I}^\pm$. The constraint equation near $\mathcal{I}^+$ has an expansion in powers of $1/r$, with leading term

$$\partial_u F^{(2)}_{ru} + D^z F^{(0)}_{uz} + D^{\bar{z}} F^{(0)}_{u\bar{z}} + e^2 j^{(2)}_u = 0 \ . \tag{34.37}$$

D_z is the covariant derivative with respect to the unit round S^2 metric $\gamma_{z\bar{z}}$, and we also define $D^z = \gamma^{z\bar{z}} D_{\bar{z}}$. Choosing $\partial_u \varepsilon|_{\mathcal{I}^+} = 0$, integrating the boundary expression for Q^+_ε by parts, and using the constraint equation gives two terms,

$$Q^+_\varepsilon = \underbrace{-\frac{1}{e^2}\int_{\mathcal{I}^+} du d^2z \left(\partial_z \varepsilon F^{(0)}_{u\bar{z}} + \partial_{\bar{z}}\varepsilon F^{(0)}_{uz}\right)}_{Q^+_S} + \underbrace{\int_{\mathcal{I}^+} du d^2z \varepsilon \gamma_{z\bar{z}} j^{(2)}_u}_{Q^+_H} \ , \tag{34.38}$$

where we have defined a "soft" charge Q^+_S, which is linear in the electromagnetic field, and a "hard" charge Q^+_H, which is typically linear in the charge current but quadratic or higher in the charged matter fields. We have already seen the equation in form notation in (34.31). The term "soft" refers to objects with zero energy, while "hard" denotes energetic excitations. Q^+_H is referred to as the hard charge, because j is the matter current for energy-carrying matter fields. If ε is constant, then Q^+_S vanishes, and Q^+_ε collapses to the total charge flux through future null infinity. If ε is not constant, then the hard term is still there, but it has an unfamiliar form, because the charges that pierce null infinity are weighted by an arbitrary function that depends on the angle at which they exit the spacetime. However, we still have an overall conserved quantity, provided we compensate by including the soft term. The soft charge involves a term of the form

$$\int_{-\infty}^{\infty} du \ F^{(0)}_{uz} \equiv N_z \ , \tag{34.39}$$

convoluted with $\partial_{\bar{z}}\varepsilon$ and integrated over the sphere. Equation (34.39) is the $\omega \to 0$ limit of

$$\int_{-\infty}^{\infty} du \ F^{(0)}_{uz} e^{i\omega u} \ , \tag{34.40}$$

which is a Fourier component with nonzero energy and frequency ω of the electromagnetic field. Moreover, it is a component of the electromagnetic field that is transverse to $\mathcal{I}^+$, as the z index is transverse to a light ray passing through $\mathcal{I}^+$. Promoted to a quantum operator, (34.40) creates and annihilates outgoing photons of energy ω. However, the expression we are interested in appearing in (34.38) has no ω; rather it is an $\omega \to 0$ limit. This term creates and annihilates soft particles with zero energy, which is why we call it the soft term. Equation (34.38) indicates that these soft photons have polarization $\partial_{\bar{z}}\varepsilon$.

The soft photon mode N_z is simply related to gauge transformations at $\mathcal{I}^+_\pm$. To see this, consider the curl

$$\begin{aligned} \partial_{\bar{z}} N_z - \partial_z N_{\bar{z}} &= \int_{-\infty}^{\infty} du \ \left[\partial_{\bar{z}} F^{(0)}_{uz} - \partial_z F^{(0)}_{u\bar{z}}\right] \\ &= -\int_{-\infty}^{\infty} du \ \partial_u F^{(0)}_{z\bar{z}} = -F^{(0)}_{z\bar{z}}\Big|^{\mathcal{I}^+_+}_{\mathcal{I}^+_-} \ , \end{aligned} \tag{34.41}$$

where we have used the Bianchi identity in the second line. At this point we assume that there are no asymptotic states with magnetic charges (i.e., no magnetic monopoles), and no long-range magnetic fields, so that $F_{z\bar{z}}\big|_{\mathcal{I}^+_\pm} = 0$. Then the curl (34.41) vanishes, and we can define a real scalar N by

$$N_z \equiv e^2 \partial_z N \ . \tag{34.42}$$

Imposing the gauge condition $A^{(0)}_u = 0$, it follows that

$$e^2 \partial_z N = \int_{-\infty}^{\infty} du F^{(0)}_{uz} = A^{(0)}_z\big|_{\mathcal{I}^+_+} - A^{(0)}_z\big|_{\mathcal{I}^+_-} \ . \tag{34.43}$$

The soft photon mode (34.39) is the difference between the z-component of the gauge field at the future of $\mathcal{I}^+$ and the past of $\mathcal{I}^+$. If we want to have finite energy, the gauge field better be pure gauge at both the beginning and the end of $\mathcal{I}^+$, and the relative shift better also be pure gauge. Indeed, we have just seen that the shift is a gauge transformation with parameter $e^2 N$. The charge has a simple expression in terms of the soft photon mode:

$$Q^+_\varepsilon = 2 \int d^2 z N \partial_z \partial_{\bar{z}} \varepsilon + \int_{\mathcal{I}^+} du d^2 z \varepsilon \gamma_{z\bar{z}} j^{(2)}_u \ . \tag{34.44}$$

34.2.6 Canonical Electrodynamics at $\mathcal{I}$

We have found an infinity of conserved charges in abelian gauge theories. One expects an associated infinity of symmetries. In a canonical Hamiltonian formalism, these symmetries are easily identified as the Dirac bracket action of the charges on the phase space. (To go the other way, from symmetries to charges, one uses Noether's theorem.) In this subsection we develop this formalism, and in the next we determine the symmetry.

In a Hamiltonian formulation, one has a phase space Γ with coordinates $x^I = \{q^i, p_j\}$, where $i, j = 1, \ldots, N/2$, and N is the (even) dimension of the phase space. For example, the theory of a particle in three dimensions has a six-dimensional phase space with $i, j = 1, 2, 3$. In field theory, the index I becomes continuous, and the phase space is infinite-dimensional. The symplectic two-form Ω,

$$\Omega = \frac{1}{2} \Omega_{IJ} dx^I \wedge dx^J \ , \tag{34.45}$$

is needed to define the Hamiltonian dynamics. Ω_{IJ} is antisymmetric and must be invertible. Once the symplectic form is known, quantum commutators are constructed as

$$[A, B] = i \Omega^{IJ} \partial_I A \partial_J B \ . \tag{34.46}$$

These are related to classical Poisson brackets by a factor of i. Much in these lectures is relevant at the purely classical level, but we will always use quantum commutators to avoid writing two sets of formulas that differ only by a factor of i.

Symplectic Form

The classical phase space in electromagnetism can be defined as the allowed initial data on any Cauchy surface Σ. For a Cauchy surface Σ in Minkowski space, the symplectic form for free electrodynamics can be written as (see exercise 2 and [196, 49, 197, 198])

$$\Omega_\Sigma = -\frac{1}{e^2} \int_\Sigma \delta(*F) \wedge \delta A \ . \tag{34.47}$$

Here, δA is an on-shell variation of the gauge field A and also a 1-form on the infinite-dimensional phase space Γ on which $\wedge$ denotes the wedge product. $\delta(*F)\wedge\delta A$ is a closed 3-form in spacetime, and its integral Ω_Σ is a 2-form on Γ. Equation (34.47) gives the same value for any pair of 3-surfaces Σ with the same boundary. In particular, Σ can be chosen either to be a spacelike slice or pushed out to a null surface at $\mathcal{I}^\pm$. For Ω_Σ to be invertible, it must have no zero modes. This requires that δA be restricted by gauge conditions, constraints, and boundary conditions. Specifying all of these can be quite subtle (and may entail boundary corrections to (34.47)). Writing out the indices,

$$\Omega_\Sigma = \frac{1}{e^2}\int_\Sigma d\Sigma^\mu \delta F_{\mu\nu}\wedge\delta A^\nu \ , \tag{34.48}$$

where $d\Sigma^\mu$ is the induced measure times the unit normal vector to Σ.

Now we take $\Sigma=\mathcal{I}^+$. This choice is very nice, because at $\mathcal{I}^+$ everything spreads out, becomes very weakly interacting, and essentially reduces to free field theory. The symplectic form becomes, very simply,

$$\Omega_{\mathcal{I}^+} = \frac{1}{e^2}\int du d^2z \left(\delta F^{(0)}_{uz}\wedge\delta A^{(0)}_{\bar z} + \delta F^{(0)}_{u\bar z}\wedge\delta A^{(0)}_z\right) \ . \tag{34.49}$$

This expression typically remains exact even in interacting theories (as long as the IR theory is free), because interactions are weak near $\mathcal{I}^+$.

Now we come to a tricky point, which was incorrectly treated in some of the literature until recently. We need to be very careful about what is happening at the boundaries of $\mathcal{I}^+$ and $\mathcal{I}^-$. We begin by separating out the constant (u-independent) part of $A^{(0)}_z$ [11, 12],

$$A^{(0)}_z(u,z,\bar z) = \hat A_z(u,z,\bar z) + \partial_z\phi(z,\bar z) \ , \tag{34.50}$$

where

$$\partial_z\phi \equiv \frac{1}{2}\left[A^{(0)}_z\big|_{\mathcal{I}^+_+} + A^{(0)}_z\big|_{\mathcal{I}^+_-}\right] \ . \tag{34.51}$$

The constant piece $\partial_z\phi$ is pure gauge, because we are demanding that the magnetic field vanish at the boundaries $\mathcal{I}^+_\pm$.[188] This boundary condition is crucial in the following: without it, the charges below would fail by a factor of 2 to generate the proper symmetries. Now we can substitute (34.50) into the expression for the symplectic form and find

$$\Omega_{\mathcal{I}^+} = \frac{2}{e^2}\int du d^2z\ \partial_u\delta\hat A_z\wedge\delta\hat A_{\bar z} - 2\int d^2z\ \partial_z\delta\phi\wedge\partial_{\bar z}\delta N \ , \tag{34.52}$$

where N was defined in (34.42). We see that the radiative components of $A^{(0)}_z$ are paired with each other in the symplectic form,[189] and the soft photon mode is paired with the field ϕ, which is the sum of the boundary values.

Note that the very existence of a Hamiltonian formulation requires that we keep the mode ϕ, which is absent in a standard Fourier decomposition. Without it, there is no symplectic partner for the soft photon zero-mode N.

Commutators

The next thing to discuss is the commutators. As we see from equation (34.46), to derive the commutators one must invert the symplectic form. Since it is a sum of terms, one of which only

[188] The symplectic form in the presence of magnetic charges and fields has so far not been constructed.

[189] Since $\hat A_z$ has no constant term, the sum of its boundary values vanishes, and N therefore does not appear in the first term.

involves $\hat{A}$ and the other which only involves the boundary fields N and ϕ, we can invert them separately. Consider the first one. It implies the commutator

$$\left[\partial_u \hat{A}_z\left(u,z,\bar{z}\right),\hat{A}_{\bar{w}}\left(u',w,\bar{w}\right)\right]=-\frac{ie^2}{2}\delta\left(u-u'\right)\delta^2\left(z-w\right)\ . \tag{34.53}$$

Integrating with respect to u, we find

$$\left[\hat{A}_z\left(u,z,\bar{z}\right),\hat{A}_{\bar{w}}\left(u',w,\bar{w}\right)\right]=-\frac{ie^2}{4}\Theta\left(u-u'\right)\delta^2\left(z-w\right)\ , \tag{34.54}$$

where

$$\Theta(u)=\frac{1}{\pi i}\int\frac{d\omega}{\omega}e^{i\omega u}\ , \tag{34.55}$$

with $\Theta(u<0)=-1$ and $\Theta(u>0)=1$, and a potential integration constant in (34.54) is fixed by antisymmetry. Equation (34.54) is a standard lightcone commutator. We can also compute the commutator between the boundary fields ϕ and N, which does not depend on u:

$$[\phi(z,\bar{z}),N(w,\bar{w})]=-\frac{i}{4\pi}\log|z-w|^2+f(z,\bar{z})+g(w,\bar{w})\ . \tag{34.56}$$

At various points, one must be careful about the integration functions f and g, but we are going to ignore them for the present as the computations below require only

$$[\partial_z\phi(z,\bar{z}),\partial_{\bar{w}}N(w,\bar{w})]=-\frac{i}{4\pi}\partial_z\partial_{\bar{w}}\log|z-w|^2=\frac{i}{2}\delta^2(z-w)\ , \tag{34.57}$$

which follows from

$$\partial_{\bar{z}}\frac{1}{z-w}=2\pi\delta^2(z-w)\ . \tag{34.58}$$

34.2.7 Large Gauge Symmetry

Now we can easily compute the commutator action of Q^+_ε. Q^+_ε has a term involving the matter field and a linear term involving $\partial_z N$ and $\partial_{\bar{z}}N$ (i.e., the soft photon terms). The soft terms do not commute with $A^{(0)}_z$. We find

$$\left[Q^+_\varepsilon,A^{(0)}_z(u,z,\bar{z})\right]=i\partial_z\varepsilon(z,\bar{z})\ , \tag{34.59}$$

while a similar calculation on $\mathcal{I}^-$ yields

$$\left[Q^-_\varepsilon,A^{(0)}_z(v,z,\bar{z})\right]=i\partial_z\varepsilon(z,\bar{z})\ . \tag{34.60}$$

Some other useful commutators are

$$\left[Q^+_\varepsilon,N(z,\bar{z})\right]=0\ ,\quad\left[Q^+_\varepsilon,\hat{A}_z(u,z,\bar{z})\right]=0\ ,\quad\left[Q^+_\varepsilon,\phi(z,\bar{z})\right]=i\varepsilon(z,\bar{z})\ . \tag{34.61}$$

This leads to a remarkable conclusion in the free Maxwell theory: *the infinite number of symmetries generated by the conserved charges Q^+_ε in a canonical formalism are just gauge transformations with parameter ε!* Of course, we have long known that for constant ε, the total charge $Q^+_{\varepsilon=1}$ generates constant gauge transformations on all the fields. Here, we see that even when ε is an arbitrary function, Q^+_ε transforms A_z by a non-trivial, "large" gauge transformation that does not die off at infinity. Rather, the gauge parameter goes to an angle-dependent, but u-independent,

function at $\mathcal{I}^+$. At $\mathcal{I}^-$, Q^-_ε generates a transformation for which the gauge parameter approaches the antipodally transformed function. These are pretty weird gauge transformations! The fact that the condition $A_z = 0$ is not invariant under these symmetries implies that they are spontaneously broken and the vacuum is infinitely degenerate, but more on that story in Section 2.11.

Now suppose our theory includes charged matter. The electromagnetic field commutators above are unchanged as long as the coupling approaches a constant in the infrared. We showed that the commutator of the soft charge with the gauge field itself is a large gauge transformation. With matter added, we must check that Q^+_ε properly generates the gauge transformations on the matter fields. This is the role of the hard term. The charged matter current j_u is the conserved Noether current associated with the global U(1) matter symmetry. By the Noether construction, j_u canonically generates this symmetry on $\mathcal{I}^+$:[190]

$$\left[j^{(2)}_u(u', w, \bar{w}), \Phi_k(u, z, \bar{z})\right] = -Q_k \Phi_k(u, z, \bar{z}) \gamma^{z\bar{z}} \delta^2(z - w) \delta(u - u') \ , \tag{34.62}$$

where Φ_k is a matter field of charge Q_k. This commutator implies

$$\left[\int_{\mathcal{I}^+} \varepsilon * j, \Phi_k(u, z, \bar{z})\right] = -Q_k \varepsilon(z, \bar{z}) \Phi_k(u, z, \bar{z}) = i\delta_\varepsilon \Phi_k(u, z, \bar{z}) \tag{34.63}$$

and

$$\left[Q^+_\varepsilon, \Phi_k(u, z, \bar{z})\right] = i\delta_\varepsilon \Phi_k(u, z, \bar{z}) \ . \tag{34.64}$$

Hence, we conclude that the sum of the hard and soft term properly generates local angle-dependent gauge transformations on $\mathcal{I}^+$.

Historically, the story ran the other way around. First it was discovered [11], through an asymptotic analysis, that QED had an infinite number of nontrivially acting gauge symmetries generated by the antipodally matched functions ε. Then the generators were constructed via the Noether method and identified as conserved charges. However, the asymptotic symmetry analysis — which we will see some of in Section 2.10 — requires assumptions about asymptotic falloffs near $\mathcal{I}$. Such assumptions are unnecessary in the treatment here starting from the conserved charges. As we have seen, their existence follows directly from nineteenth-century electromagnetism.

To summarize, so far we have found that there are an infinite number of conserved charges in electromagnetism. We have further showed that these charges canonically generate an infinite number of large gauge symmetries that act nontrivially on the physical phase space.

34.2.8 Ward Identity

In this subsection we derive Ward identities, which relate quantum scattering amplitudes. These identities express the dynamical consequences of the fact that the conserved charges commute with the Hamiltonian, or equivalently, with the $\mathcal{S}$-matrix, since $\mathcal{S} \sim \exp(iHT)$ for $T \to \infty$.

Symmetries of the $\mathcal{S}$-matrix

Quantum scattering amplitudes can be written in the form

$$\langle \text{out} | \mathcal{S} | \text{in} \rangle \ . \tag{34.65}$$

Charge conservation is then

$$\langle \text{out} | \left(Q^+_\varepsilon \mathcal{S} - \mathcal{S} Q^-_\varepsilon \right) | \text{in} \rangle = 0 \ . \tag{34.66}$$

[190] Here as elsewhere in this section, we make the assumption that the charged fields are massless, so that the charge flux all goes through $\mathcal{I}^+$. It remains true in the massive case that Q^+_ε generates gauge transformations, but there are very interesting new twists; see section 34.2.12.

By the matching condition, Q^+_ε is equal to Q^-_ε, but we use Q^+_ε when acting on out-states and Q^-_ε when acting on in-states, because they are expressed in variables appropriate for acting on the out- and in-states, respectively. Exponentiating the charge to generate a finite symmetry, (34.66) becomes the statement: given an in-state X that evolves to an out-state Y, a large-gauge-transformed in-state X evolves to a large-gauge-transformed out-state Y.

The action of Q^-_ε on the in-state is

$$Q^-_\varepsilon|\text{in}\rangle = -2\int d^2z\partial_{\bar z}\varepsilon\partial_z N^-(z,\bar z)|\text{in}\rangle + \sum_{k=1}^{m} Q_k^{\text{in}}\varepsilon(z_k^{\text{in}},\bar z_k^{\text{in}})|\text{in}\rangle\ , \tag{34.67}$$

where $N^-(z,\bar z)$ denotes the incoming soft photon field on $\mathcal{I}^-$. We have assumed that the in-state can be described by m hard particles that are coming in at points on the asymptotic sphere denoted by z_k^{in}. The first term is the action of the soft charge, and the second term is the action of the hard charge. Similarly, the action of Q^+_ε on the out-state takes the form

$$\langle\text{out}|Q^+_\varepsilon = 2\int d^2z\partial_z\partial_{\bar z}\varepsilon\langle\text{out}|N(z,\bar z) + \sum_{k=1}^{n} Q_k^{\text{out}}\varepsilon(z_k^{\text{out}},\bar z_k^{\text{out}})\langle\text{out}|\ . \tag{34.68}$$

Finally, we can write the Ward identity as

$$\begin{aligned} 2\int d^2z\partial_z\partial_{\bar z}\varepsilon\langle\text{out}|\left(N(z,\bar z)\mathcal{S}-\mathcal{S}N^-(z,\bar z)\right)|\text{in}\rangle \\ = \left[\sum_{k=1}^{m} Q_k^{\text{in}}\varepsilon(z_k^{\text{in}},\bar z_k^{\text{in}}) - \sum_{k=1}^{n} Q_k^{\text{out}}\varepsilon(z_k^{\text{out}},\bar z_k^{\text{out}})\right]\langle\text{out}|\mathcal{S}|\text{in}\rangle\ . \end{aligned} \tag{34.69}$$

Equation (34.69) is an infinite number of Ward identities, one for every function ε on the sphere. They relate any $\mathcal{S}$-matrix element between any pair of incoming and outgoing states multiplied by the soft factor in square brackets, to the same $\mathcal{S}$-matrix element with the insertion of certain soft photon modes. This is a very general relation. It would be incredibly surprising if, after 90 years of studying QED, we discovered an infinite number of new relationships between scattering processes. We have not done that. Rather, we have rediscovered some relations that have been known for a long time but were derived using very different methods, namely, Feynman diagrams and mode expansions, and go under the name of "soft theorems." What we will do next is show that these identities, which we derived from charge conservation, are precisely the same thing as the well-known soft theorems in abelian gauge theories.

Before proceeding with this demonstration, as a little teaser for section 34.4, it is interesting to consider the special case in which ε is taken to be

$$\varepsilon(w,\bar w) = \frac{1}{z-w}\ . \tag{34.70}$$

Using the fact that

$$\partial_{\bar z}\frac{1}{z-w} = 2\pi\delta^2(z-w) \tag{34.71}$$

to easily perform the integral on the LHS of equation (34.69), we can rewrite the Ward identity as

$$4\pi\langle\text{out}|\left(\partial_z N\mathcal{S}-\mathcal{S}\partial_z N^-\right)|\text{in}\rangle = \left[\sum_{k=1}^{m}\frac{Q_k^{\text{in}}}{z-z_k^{\text{in}}} - \sum_{k=1}^{n}\frac{Q_k^{\text{out}}}{z-z_k^{\text{out}}}\right]\langle\text{out}|\mathcal{S}|\text{in}\rangle\ . \tag{34.72}$$

In two-dimensional CFT with a current algebra, when one inserts a $U(1)$ Kac-Moody current into a correlation function of operators of charge Q_k, one gets exactly this kind of Ward identity. More generally, it was recently shown [199] that the entire soft factor of the $\mathcal{S}$-matrix is computed by a current algebra with level determined by the cusp anomalous dimension. We will see in section 34.4, in the more general nonabelian setting, that this is in fact not a coincidence and that the large gauge symmetry is equivalent to a $U(1)$ Kac-Moody symmetry on the sphere at null infinity.

Mode Expansions

To show that the Ward identity (34.69) is in fact a soft theorem, we have to transcribe notation. Until this section, the presentation has been rather different than what is found in most quantum field theory textbooks. We have characterized particles by the points at which they came in at null infinity, used advanced and retarded coordinates, and derived conservation laws from antipodal matching conditions.

In traditional quantum field theory, one works in a basis of plane waves. To compare notations we must rewrite (34.69) in terms of a plane wave basis, using a conventional mode expansion for A_z. It is not manifestly obvious that the commutation relations (34.54) and (34.56) are equivalent to the conventional ones. One way to see that they must nevertheless be the same is to note that both follow from the slice-independent covariant symplectic form (34.47). We evaluated it by pushing the slice up to $\mathcal{I}^+$, as opposed to the conventional use of the $t = 0$ slice and a plane wave basis. Such bases employ the standard Cartesian coordinates for Minkowski space

$$ds^2 = -dt^2 + d\vec{x} \cdot d\vec{x} \ . \tag{34.73}$$

Near $\mathcal{I}^+$, A_ν has the on-shell outgoing plane wave mode expansion

$$A_\nu(x) = e \sum_{\alpha=\pm} \int \frac{d^3q}{(2\pi)^3} \frac{1}{2\omega} \left[\varepsilon_\nu^{*\alpha}(\vec{q}) a_\alpha^{\text{out}}(\vec{q}) e^{iq\cdot x} + \varepsilon_\nu^{\alpha}(\vec{q}) a_\alpha^{\text{out}}(\vec{q})^\dagger e^{-iq\cdot x} \right] \ , \tag{34.74}$$

where $q^2 = 0$, the two polarization vectors satisfy a normalization condition $\varepsilon_\alpha^\nu \varepsilon^*_{\beta\nu} = \delta_{\alpha\beta}$, and

$$\left[a_\alpha^{\text{out}}(\vec{q}), a_\beta^{\text{out}}(\vec{q}')^\dagger \right] = \delta_{\alpha\beta} (2\pi)^3 (2\omega_q) \delta^3 \left(\vec{q} - \vec{q}' \right) \ . \tag{34.75}$$

This is the standard textbook formula for commutators of modes of the free electromagnetic field.

The next step is to rewrite asymptotic quantities on $\mathcal{I}^+$ in terms of the familiar creation and annihilation operators appearing in (34.74). Near $\mathcal{I}^+$ it is convenient to use retarded coordinates, in which the metric takes the form

$$ds^2 = -du^2 - 2dudr + 2r^2 \gamma_{z\bar{z}} dz d\bar{z} \ . \tag{34.76}$$

The transformation to retarded from Cartesian coordinates was given in (34.22). A null vector q^μ, satisfying $q^\mu q_\mu = 0$, is labelled by a point on the sphere, up to its overall magnitude. Hence, there is a natural map from null vectors q^μ to points $(z, \bar{z})$ on the sphere toward which the null vector is directed. We can write this as

$$q^\mu = \frac{\omega}{1 + z\bar{z}} \left(1 + z\bar{z}, z + \bar{z}, -i(z - \bar{z}), 1 - z\bar{z} \right) = (\omega, q^1, q^2, q^3) \ . \tag{34.77}$$

As an example of this, let us suppose that z is taken to be the north pole at $z = 0$. Then we find $q^\mu = \omega(1, 0, 0, 1)$ (i.e., a null vector pointing along the x^3-axis). We may further choose the polarization vectors orthogonal to q^μ as

$$\varepsilon^{+\mu}(\vec{q}) = \frac{1}{\sqrt{2}} \left(\bar{z}, 1, -i, -\bar{z} \right) \ , \quad \varepsilon^{-\mu}(\vec{q}) = \frac{1}{\sqrt{2}} \left(z, 1, i, -z \right) \ , \quad q_\mu \varepsilon^{\pm\mu}(\vec{q}) = 0 \ , \quad \varepsilon_\alpha^\mu \varepsilon^*_{\beta\mu} = \delta_{\alpha\beta} \ . \tag{34.78}$$

Now let us consider the $\mathcal{I}^+$ field $A_z^{(0)}(u, z, \bar{z})$. By definition,

$$A_z^{(0)}(u, z, \bar{z}) = \lim_{r\to\infty} A_z(u, r, z, \bar{z}) \ . \tag{34.79}$$

Using the above formulas, we can take all the q^μs in the mode expansion and rewrite them in terms of points on the asymptotic sphere. Since $A_z(u, r, z, \bar{z})$ has an expansion in terms of creation and

annihilation operators, $A_z^{(0)}(u,z,\bar{z})$ must also have such an expansion. In particular, we expect $A_z^{(0)}(u,z,\bar{z})$ to create and annihilate photons that land at the point $(z,\bar{z})$, since it is an operator that is localized at that point on the asymptotic sphere. Moreover, rotating about the point $(z,\bar{z})$, $A_z^{(0)}$ gets one phase, while $A_{\bar{z}}^{(0)}$ gets the opposite phase. Hence we expect $A_z^{(0)}$ to create one photon helicity and annihilate the other, while $A_{\bar{z}}$ does the opposite. These expectations are realized when one evaluates (34.79) in a large-r saddle-point approximation (see exercise 3):

$$A_z^{(0)}(u,z,\bar{z}) = -\frac{i}{8\pi^2}\frac{\sqrt{2}e}{1+z\bar{z}}\int_0^\infty d\omega\left[a_+^{\text{out}}(\omega\hat{x})e^{-i\omega u} - a_-^{\text{out}}(\omega\hat{x})^\dagger e^{i\omega u}\right] , \qquad \hat{x}=\hat{x}(z,\bar{z}) . \tag{34.80}$$

The "out" creation and annihilation operators involve the three-momentum $\omega\hat{x}$; $\hat{x}$ is a unit vector that points to $(z,\bar{z})$ on the sphere, with the relationship between $\hat{x}_1$, $\hat{x}_2$, and $\hat{x}_3$ and the point $(z,\bar{z})$ as in equation (34.77). So $A_z^{(0)}(u,z,\bar{z})$ annihilates a positive helicity photon that is headed to the point $\hat{x}(z,\bar{z})$ and creates a negative helicity photon that is headed to the same point. It can create and annihilate photons of all different frequencies. Equation (34.80) is the basic relationship between the out fields in the $1/r$ expansion at $\mathcal{I}^+$ and the standard outgoing creation and annihilation operators in the plane wave expansion usually employed in quantum field theory.

The Ward identity involves $\partial_z N$, so we need to determine its mode expansion. To be precise about the zero-momentum limit, define

$$\partial_z N = \frac{1}{2e^2}\lim_{\omega\to 0^+}\int_{-\infty}^{\infty} du\left(e^{i\omega u}+e^{-i\omega u}\right)F_{uz}^{(0)} . \tag{34.81}$$

This definition ensures that $\partial_z\partial_{\bar{z}}N$ is Hermitian. Had our definition only involved either $e^{i\omega u}$ or $e^{-i\omega u}$, this would not be the case. Using (34.80), we find

$$\partial_z N = -\frac{1}{8\pi e}\frac{\sqrt{2}}{1+z\bar{z}}\lim_{\omega\to 0^+}\left[\omega a_+^{\text{out}}(\omega\hat{x}) + \omega a_-^{\text{out}}(\omega\hat{x})^\dagger\right] . \tag{34.82}$$

One might wonder why we care about this operator, since we are taking the limit $\omega\to 0$ while multiplying by ω. One might think it is just identically zero. However, if it were zero, the Ward identity would not make sense, because it would imply that the RHS of equation (34.72) would vanish. The reconciliation is that the $\mathcal{S}$-matrix elements with insertions of these operators have poles that cancel the explicit factor of ω appearing in equation (34.82).

There is a similar formula for $\partial_z N^-$:

$$\partial_z N^- = -\frac{1}{8\pi e}\frac{\sqrt{2}}{1+z\bar{z}}\lim_{\omega\to 0^+}\left[\omega a_+^{\text{in}}(\omega\hat{x}) + \omega a_-^{\text{in}}(\omega\hat{x})^\dagger\right] . \tag{34.83}$$

The Ward identity in the form (34.72) can be reexpressed as

$$\begin{aligned}\lim_{\omega\to 0}\Big[\omega\langle\text{out}|\left(a_+^{\text{out}}(\omega\hat{x})\mathcal{S} - \mathcal{S}a_-^{\text{in}}(\omega\hat{x})^\dagger\right)|\text{in}\rangle\Big] \\ = \sqrt{2}e(1+z\bar{z})\left[\sum_{k=1}^{n}\frac{Q_k^{\text{out}}}{z-z_k^{\text{out}}} - \sum_{k=1}^{m}\frac{Q_k^{\text{in}}}{z-z_k^{\text{in}}}\right]\langle\text{out}|\mathcal{S}|\text{in}\rangle .\end{aligned} \tag{34.84}$$

This is beginning to look very much like the standard soft photon theorem. There is a soft pole in the matrix element on the LHS, which we have rendered finite via explicit multiplication by ω. There are also collinear poles on the RHS for $z\to z_k$.

Soft Theorems

Now in principle to show that (34.84) is exactly equivalent to the standard soft theorem, I could take the RHS of the equation and rewrite the zs and z_ks in terms of the momenta of the particles. However, it is easier and equivalent to proceed in reverse. That is, we begin with the textbook formula for the soft photon theorem and show that it is equivalent to (34.84) by going from momentum space to points on a sphere. For the reader's benefit, the next section reviews the standard textbook derivation of the soft photon theorem. The soft theorem states

$$\begin{aligned}\lim_{\omega\to 0}\left[\omega\langle \text{out}|a_+^{\text{out}}(\vec{q})\mathcal{S}|\text{in}\rangle\right] &= e\lim_{\omega\to 0}\left[\sum_{k=1}^{m}\frac{\omega Q_k^{\text{out}} p_k^{\text{out}}\cdot\varepsilon^+}{p_k^{\text{out}}\cdot q}-\sum_{k=1}^{n}\frac{\omega Q_k^{\text{in}} p_k^{\text{in}}\cdot\varepsilon^+}{p_k^{\text{in}}\cdot q}\right]\langle \text{out}|\mathcal{S}|\text{in}\rangle \\ &= -\lim_{\omega\to 0}\left[\omega\langle \text{out}|\mathcal{S}a_-^{\text{in}\dagger}(\vec{q})|\text{in}\rangle\right] ,\end{aligned} \tag{34.85}$$

where $q^\mu=(\omega,\vec{q})$ is the momentum of the soft photon, and we are taking the in-state and out-state in plane wave bases:

$$|\text{in}\rangle = |p_1^{\text{in}},\dots,p_n^{\text{in}}\rangle , \qquad \langle\text{out}| = \langle p_1^{\text{out}},\dots,p_m^{\text{out}}| . \tag{34.86}$$

The equality of the matrix elements involving in and out soft photons is a consequence of $\mathcal{CPT}$ invariance. Equation (34.85) is not quite the standard form, as we have multiplied both sides of the equation by a factor ω in order to have a finite limit. In the limit where $\omega\to 0$ (the soft limit), the ratios appearing on the RHS are finite and depend only on the direction of $\vec{q}$, but not its magnitude. When one writes the formula without this factor of ω, there is a pole as $\omega\to 0$, which is called the "soft pole" or "Weinberg pole."

To make the comparison between equation (34.84) and equation (34.85), we note that in addition to the $\omega\to 0$ pole, there is a collinear pole, since q^μ and p_k^μ are both null vectors. When p_k^μ is proportional to q^μ, $p_k\cdot q=0$, and $\frac{1}{p_k\cdot q}$ diverges. In (34.84), collinearity implies $z_k=z$, which again gives a pole. Hence the pole structure of equation (34.84) and equation (34.85) agrees.

Now we want to turn equation (34.85) into equation (34.84) by writing the momentum of each hard particle in terms of the energy E_k and a point on the sphere $(z_k,\bar{z}_k)$. For example,

$$(p_k^{\text{in}})^\mu = E_k^{\text{in}}\left(1,\frac{z_k^{\text{in}}+\bar{z}_k^{\text{in}}}{1+z_k^{\text{in}}\bar{z}_k^{\text{in}}},\frac{-i\left(z_k^{\text{in}}-\bar{z}_k^{\text{in}}\right)}{1+z_k^{\text{in}}\bar{z}_k^{\text{in}}},\frac{1-z_k^{\text{in}}\bar{z}_k^{\text{in}}}{1+z_k^{\text{in}}\bar{z}_k^{\text{in}}}\right) . \tag{34.87}$$

Similar formulas apply to the soft photon momentum q^μ (see (34.77)) and outgoing hard particle momenta p_k^{out}. In other words, knowing that the massless charged particle is going to land at the point $(z_k,\bar{z}_k)$ determines what its momentum must be. This enables us to replace all momenta in equation (34.85) with their expressions in terms of energies and points on a sphere. Summing the contribution from an outgoing positive helicity soft photon and an incoming negative helicity soft photon then exactly reproduces equation (34.84). The straightforward but somewhat intricate algebra is left to exercise 5. The standard soft photon formula reduces to the Ward identity following from invariance under large gauge symmetries, or equivalently, the matrix element of the charge conservation law. This establishes the central result connecting the soft photon theorem to the large gauge symmetry of electromagnetism.

The story might have been told backward. Starting with the soft photon theorem, we could reverse engineer and deduce the fact that abelian gauge theories have an infinite number of conservation laws associated to antipodally identified large gauge transformations. They are mathematically equivalent statements.

34.2.9 Feynman Diagrammatics

In this section, we review the standard field theory derivation of the leading photon and graviton soft theorems in the form given by Weinberg [7, 151].

Soft Photons

The soft photon theorem states that any $\mathcal{S}$-matrix element with an additional soft ($q^\mu \to 0$) photon is equal to the original matrix element multiplied by the soft factor plus corrections of order q^0:

$$\langle \text{out}|a_+^{\text{out}}(\vec{q})\mathcal{S}|\text{in}\rangle = e\left[\sum_{k=1}^{m}\frac{Q_k^{\text{out}}p_k^{\text{out}}\cdot\varepsilon^+}{p_k^{\text{out}}\cdot q} - \sum_{k=1}^{n}\frac{Q_k^{\text{in}}p_k^{\text{in}}\cdot\varepsilon^+}{p_k^{\text{in}}\cdot q}\right]\langle \text{out}|\mathcal{S}|\text{in}\rangle + \mathcal{O}(q^0)\ . \tag{34.88}$$

The leading order term in the soft expansion is a pole.

To derive this formula, let us take any scattering process with n incoming and m outgoing particles and then consider adding to it one outgoing photon, denoted by a wavy line in figure 34.7, with momentum q. (The derivation for an incoming photon is similar.) In the soft limit, we

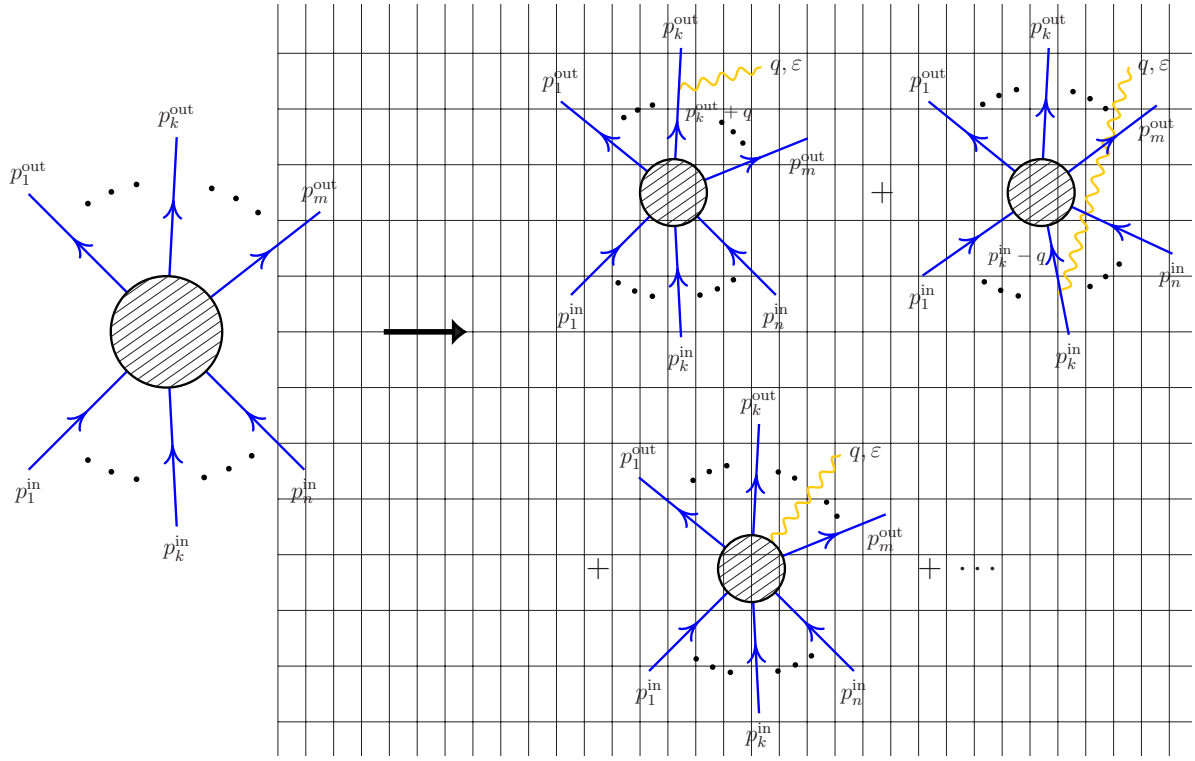

Figure 34.7: **On the left is a Feynman diagram representing $n \to m$ scattering. On the right the effect of adding an outgoing soft photon (or graviton) with momentum q and polarization ε is illustrated. In the upper diagrams the soft particle attaches to an external propagator, while in the lower one it attaches to an internal propagator.**

can write the amplitude as a sum of two types of terms, ones in which the soft photon attaches to an external line and others in which the soft photon attaches to an internal line. The soft photon can attach to any one of the $n+m$ external lines, so we must include a sum over all such terms. The full amplitude has a Laurent expansion in q with an infinite number of terms whose detailed form depends on what theory we are talking about. For the pole we need not specify what theory we are studying except that it has a photon. That is one of the beauties of this formula.

The LSZ rule for computing scattering amplitudes starts out by computing the time-ordered Green's functions using the Feynman $i\epsilon$ prescription and then amputating the external legs. The Feynman diagrams have factors for vertices and propagators. What happens when we attach the extra photon to an external leg is, since external legs are amputated, we need only add a vertex

and propagator for the particle to whose external leg the photon is added. The difference between the diagram with and without the attached external soft photon is just the vertex and propagator.

Now I have to say a little bit about the interaction vertex. Let us take the interaction to be

$$\mathcal{L}_{\text{int}} = -A^\mu j_\mu \ . \tag{34.89}$$

For a scalar field of charge Q, the charge current is

$$j_\mu = iQ(\phi\partial_\mu\phi^* - \phi^*\partial_\mu\phi) \ . \tag{34.90}$$

For a plane wave, this is just

$$j_\mu \sim 2Qp_\mu \ , \tag{34.91}$$

where we have used the normalization for single-particle states

$$\langle p|p'\rangle = 2\omega_p(2\pi)^3\delta^3(p-p') \ . \tag{34.92}$$

This is the electromagnetic current associated to a scalar field of charge Q, meaning that under gauge transformations, it acquires a phase $e^{iQ\varepsilon}$. Moreover, we take the polarization of the photon to obey $\varepsilon^\mu q_\mu = 0$, where q^μ is the momentum of the photon. The propagator for a scalar particle of mass m gives a factor

$$\frac{-i}{(p+q)^2+m^2} = \frac{-i}{p^2+2p\cdot q+q^2+m^2} = \frac{-i}{2p\cdot q} \ , \tag{34.93}$$

where we have used the fact that in a scattering amplitude, all the external lines must be on-shell, so $q^2 = 0$ and $p^2 = -m^2$. The vertex factor is, up to $\mathcal{O}(q)$ corrections,

$$ie\varepsilon^\mu 2Qp_\mu \ , \tag{34.94}$$

where ε^μ comes from A^μ and $2Qp_\mu$ comes from j_μ. The total contribution is

$$ie\varepsilon^\mu(2Qp_\mu)\frac{-i}{(p+q)^2+m^2} \to \frac{eQ\varepsilon\cdot p}{q\cdot p} \ . \tag{34.95}$$

There is one such term for every outgoing particle, while for the incoming particles there is an additional minus sign. Altogether these give

$$\sum_{k=1}^{m}\frac{eQ_k^{\text{out}}p_k^{\text{out}}\cdot\varepsilon}{p_k^{\text{out}}\cdot q} - \sum_{k=1}^{n}\frac{eQ_k^{\text{in}}p_k^{\text{in}}\cdot\varepsilon}{p_k^{\text{in}}\cdot q} \ . \tag{34.96}$$

At the end of the day, if we just consider the diagrams in which the photon attaches to an external leg, we simply multiply the $\mathcal{S}$-matrix element by the factor in equation (34.96), sometimes called the "soft factor", which you may recognize from equation (34.85).

We have not yet considered the terms coming from the photon attaching to an internal leg. The key point is that the internal propagators are never on-shell (i.e., they never have $p^2 = -m^2$). In the propagator, one then never has the cancellation between p^2 and m^2, so if we take $q^\mu \to 0$, the difference between p^2 and m^2 will dominate, and we will not get a pole. These types of diagrams are most certainly nonzero, but they do not contribute to the pole, so we can forget about them in the soft limit. This is an extremely simple derivation. Up to some signs, one finds the same thing for a soft incoming photon.

Now we note an important feature of this formula. The condition $\varepsilon^\mu q_\mu = 0$ defines the polarization vector only up to shifts of ε^μ by q^μ, because $q^2 = 0$. The physical amplitude with the soft photon should be invariant if we shift ε^μ by any multiple of q^μ. Now it is interesting to see what happens to the soft factor (34.96). If we shift ε^μ by q^μ, it shifts by

$$\sum_{k=1}^{m} eQ_k^{\text{out}} - \sum_{k=1}^{n} eQ_k^{\text{in}} = 0 \ . \tag{34.97}$$

In other words, global charge conservation guarantees that this soft factor is gauge invariant. This observation was in fact the basis of Low's derivation of the soft formula in 1958 [4].

We have only worked out the soft theorem for the case of a scalar. For a fermion or some other kind of charged particle, it is a little more complicated, but it works out to the same expression [151]. One way of seeing that this must be so is that (34.96) is the only formula with the right dimensions that is invariant under shifts $\varepsilon^\mu \to \varepsilon^\mu + q^\mu$.

Soft Gravitons

So far we have largely deferred any discussion of gravity. However, having just derived the soft formulas for quantum electrodynamics, the generalization to gravity is short and simple, so we do it now. We do not need to redraw diagrams, because we can just imagine that the wavy lines are gravitons of momentum q^μ rather than photons. We do need to specify the interaction

$$\mathcal{L}_{\rm int} = \sqrt{8\pi G} h^{\mu\nu} T_{\mu\nu} \ , \tag{34.98}$$

which couples the graviton field $h^{\mu\nu}$ in the expansion $g^{\mu\nu} = \eta^{\mu\nu} - \sqrt{32\pi G} h^{\mu\nu}$ to matter. This field is normalized so that there are no factors of G in the kinetic term. The graviton has polarization tensor $\varepsilon_{\mu\nu}$ satisfying

$$\varepsilon_{\mu\nu} q^\mu = 0 \ , \quad \varepsilon^{\mu\nu}\eta_{\mu\nu} = 0 \ . \tag{34.99}$$

For a scalar field,

$$T_{\mu\nu} = \partial_\mu\phi\partial_\nu\phi - \frac{1}{2}\eta_{\mu\nu}\partial^\rho\phi\partial_\rho\phi \ . \tag{34.100}$$

Now, we apply the same argument, which is that we multiply the $\mathcal{S}$-matrix element by a factor of the propagator and the vertex. The propagator is the same,

$$\frac{-i}{2p\cdot q} \ . \tag{34.101}$$

Whether one has added an external photon or graviton, these poles, which become the holomorphic poles on the sphere at null infinity, are ubiquitous in soft limits. For a scalar field the interaction is

$$T_{\mu\nu} \sim 2p_\mu p_\nu \ , \tag{34.102}$$

where the term in $T_{\mu\nu}$ proportional to $\eta_{\mu\nu}$ does not contribute due to $\varepsilon_{\mu\nu}$ being traceless. In total, the product of the vertex and propagator gives a factor

$$i\sqrt{32\pi G}\varepsilon^{\mu\nu}p_\mu p_\nu \frac{-i}{(p+q)^2+m^2} \to \sqrt{8\pi G}\frac{\varepsilon^{\mu\nu}p_\mu p_\nu}{p\cdot q} \ . \tag{34.103}$$

This is just the result for one external particle. More generally, if we have m outgoing and n incoming particles, we have a soft factor

$$\sqrt{8\pi G}\sum_{k=1}^{m}\frac{\varepsilon^{\mu\nu}p^{\rm out}_{k\mu}p^{\rm out}_{k\nu}}{p^{\rm out}_k\cdot q} - \sqrt{8\pi G}\sum_{k=1}^{n}\frac{\varepsilon^{\mu\nu}p^{\rm in}_{k\mu}p^{\rm in}_{k\nu}}{p^{\rm in}_k\cdot q} \ . \tag{34.104}$$

We get a very similar-looking formula to the gauge theory case with p_k replacing Q_k. Just as in the gauge theory case, we cannot get poles by coupling the soft graviton to internal lines.

The soft factor must be invariant under the shift $\varepsilon^{\mu\nu} \to \varepsilon^{\mu\nu} + \Lambda^\mu(q)q^\nu$, the analog of gauge invariance in the gravity case. Performing such a shift, we can pull the Λ^μ out from under the sum and find that the soft factor shifts by

$$\Lambda^\mu\left[\sum_{k=1}^{m}p^{\rm out}_{k\mu} - \sum_{k=1}^{n}p^{\rm in}_{k\mu}\right] = 0 \ , \tag{34.105}$$

due to global energy-momentum conservation. We saw above that global charge conservation was required for the consistency and gauge invariance of the soft photon theorem. Here we see that global energy-momentum conservation is required for the consistency and gauge invariance of the soft graviton theorem. So far we have not used global angular momentum conservation, which we will see in section 34.5.3 is responsible for a new soft theorem and set of asymptotic symmetries called "superrotations".

34.2.10 Asymptotic Symmetries

Our discussion so far began with the derivation of conserved charges. These were then shown, via a canonical formalism, to generate asymptotic symmetries. We might have instead begun (as was the case historically) with a direct analysis of the asymptotic symmetries. Such analyses are more of an art than a science, in part because of ambiguities in the choice of asymptotic falloffs and gauge conditions, which are often only a posteriori justified. However, despite the lack of rigor, this approach has been extraordinarily fruitful and the source of many physical insights. Once one has an idea of how it should go, more rigorous methods can then be developed. The fact that it is an art and not a science is not a derogatory statement. In fact, maybe art is better than science!

An asymptotic symmetry group (ASG) is defined as

$$\text{ASG} = \frac{\text{allowed gauge symmetries}}{\text{trivial gauge symmetries}} \ . \tag{34.106}$$

One studies the theory on some spacetime and imposes boundary conditions that describe how the field components behave near the boundary. The boundary conditions should be weak enough so that all physically reasonable solutions are allowed, but strong enough so that relevant charges are finite and well defined. The *allowed gauge symmetries* are any ones that respect the boundary conditions. The *trivial gauge symmetries* are the ones that act trivially on the physical data of the theory.

It can be quite subtle to decide what kind of behavior is allowed at infinity or which data is physical. Indeed, this problem remains unresolved in full generality for asymptotically flat spacetimes in GR. In many cases, part of the definition of the theory is specifying the boundary conditions. Moreover, we shall encounter examples in sections 34.2.13 and 34.2.14 for which the ASG is not even a subset of the local symmetry group, indicating that the definition (34.106) is too narrow. Nevertheless, despite the vagaries of this procedure, it has proven extraordinarily useful.

Oddly, asymptotic symmetry analyses were first carried out in the context of gravity rather than gauge theory. An early application was the seminal work of Bondi, van der Burg, Metzner and Sachs [9, 8] (BMS), who wanted to find the subgroup of diffeomorphisms of asymptotically flat spacetimes that act nontrivially on the asymptotic data. It seemed intuitively obvious that if one has an isolated system that is flat near infinity, it should be acted on non-trivially by the Poincaré group. For an asymptotically flat black hole, a boost is a diffeomorphism that should certainly be allowed but must be nontrivial, because it changes the energy. Similarly, translations move the black hole to a different place. BMS expected the asymptotic symmetry analysis would reproduce the isometries of flat spacetime itself, namely, the Poincaré group. To everyone's great surprise and consternation, what they got instead was an infinite-dimensional group, now called the BMS group. This contains the finite-dimensional Poincaré group as a subgroup but has an additional infinity of generators known as "supertranslations." This result implies that GR does *not* reduce to special relativity for weak fields and long distances, as naïvely expected. As we will see below, it is now realized that the BMS group is not the whole story: it is both too big and too small, but much more on this in section 5.

Another famous asymptotic symmetry analysis appeared in the work of Brown and Henneaux in the late 1980s on AdS_3 [200]. They found a result that no one was expecting: the asymptotic symmetry algebra is two copies of the Virasoro algebra with a computable central charge — a harbinger of AdS/CFT. This beautifully demonstrated the power of the method. It is not just a way of confirming what we already know.

What would we expect for the asymptotic symmetry group of electrodynamics? This question has been asked only in the past few years [10, 11]. In Minkowski space electromagnetism, we

are interested in boundary conditions at $\mathcal{I}^+$ or $\mathcal{I}^-$. At these null boundaries, one does not have the same freedom in choosing the boundary conditions as one does, for example, for the timelike boundary of a box. Rather one must derive the asymptotic behavior from the field equations. If we consider a sphere at large r, its surface area grows like r^2, so for the energy flux at any moment to be finite, $T_{uu} \sim \mathcal{O}(1/r^2)$. Note that we are not talking about the integrated energy flux, whose finiteness requires that fields fall off in a certain way at late and early times on $\mathcal{I}^\pm$. In electromagnetism,

$$T_{uu} \sim F_{uz} F_{u\bar{z}} \frac{\gamma^{z\bar{z}}}{r^2} + \dots \ , \tag{34.107}$$

where the factor of $\frac{1}{r^2}$ comes from inverting the metric on the sphere of radius r. This suggests that $F_{uz} \sim \mathcal{O}(1)$. However, F_{ru} is the long-range electric field, so it should go as $\mathcal{O}(1/r^2)$ to have finite charge configurations. Similarly, $F_{rz} \sim \mathcal{O}(1/r^2)$. To summarize:

$$F_{uz} \sim \mathcal{O}(1), \quad F_{ur}, F_{zr} \sim \mathcal{O}\left(\frac{1}{r^2}\right) \ . \tag{34.108}$$

This suggests we choose the boundary falloff conditions for the gauge fields to be

$$A_z \sim \mathcal{O}(1) \ , \quad A_r \sim \mathcal{O}\left(\frac{1}{r^2}\right) \ , \quad A_u \sim \mathcal{O}\left(\frac{1}{r}\right) \ . \tag{34.109}$$

If we try to impose stronger boundary conditions for A_μ, we would teleologically disallow some physically reasonable initial data configurations.

Now we ask: what kind of gauge transformations do these falloffs allow? Generic gauge transformations take the form

$$\delta A_z = \partial_z \varepsilon \ , \quad \delta A_u = \partial_u \varepsilon \ , \quad \delta A_r = \partial_r \varepsilon \ . \tag{34.110}$$

These boundary conditions are consistent with

$$\varepsilon = \varepsilon(z, \bar{z}) + \mathcal{O}\left(\frac{1}{r}\right) \ . \tag{34.111}$$

Note, the $\mathcal{O}(1)$ piece of ε cannot depend on u without violating the boundary conditions (34.109). The transformations (34.111) are the exact electrodynamic analog of the BMS transformations found much earlier for gravity. The additional necessity of an antipodal matching condition for transformations on $\mathcal{I}^+$ and $\mathcal{I}^-$ may be deduced from the need for a well-defined Lorentz invariant scattering problem.

There are several ways to see that the transformations (34.111) are nontrivial as well as allowed. One is to show that their Ward identities have nontrivial physical content and are equivalent to the soft photon theorem. Another is to note that they impart distinct phases to charged particles at different positions on $\mathcal{I}^+$. This leads to an Aharonov-Bohm type interference pattern, which could be observed for electrons stationed near $\mathcal{I}^+$. Details of how this "electromagnetic memory effect" can be observed are discussed in the literature [201, 38, 39]. We will discuss the similar gravitational analog in detail in section 34.6.

Equation (34.111) together with antipodal matching are of course exactly the large gauge symmetries discussed in section 34.2.7. This very simple asymptotic analysis quickly leads to the result that we previously arrived at in a lengthier manner starting from conserved charges. In fact, this is how the symmetries were first discovered [10]. However, if one thinks about it a little bit harder, one might ask, for example, why we did not allow A_us that are $\mathcal{O}(r^0)$ but pure gauge, since they would maintain the falloff behavior of the field strengths. Indeed, interesting new developments [61, 202, 62] suggest that pure gauge modes for which (34.108) is preserved but (34.109) is not provide an effective way to understand the subleading soft theorem [2, 4] and associated symmetries [60]. So while some basics of asymptotic symmetry analyses are firmly understood, much remains to be learned.

34.2.11 Spontaneous Symmetry Breaking, Vacuum Degeneracy, and Goldstone Bosons

As we shall now elucidate, the preceding results imply that abelian gauge theories have an infinite vacuum degeneracy and undergo spontaneous symmetry breaking. However, because of the unusual angular dependence of the symmetry parameters, the nature of the symmetry breaking and relation of the degenerate vacua are different than what we are used to.[191] Let us begin by recalling the standard case of spontaneous breaking of a global symmetry.

A classic example of spontaneous symmetry breaking is a scalar field theory with the "Mexican hat" potential

$$V(\Phi) = -m^2\Phi^*\Phi + \lambda\big(\Phi^*\Phi\big)^2 \ , \tag{34.112}$$

illustrated in figure 34.8. This theory has a global symmetry, under which

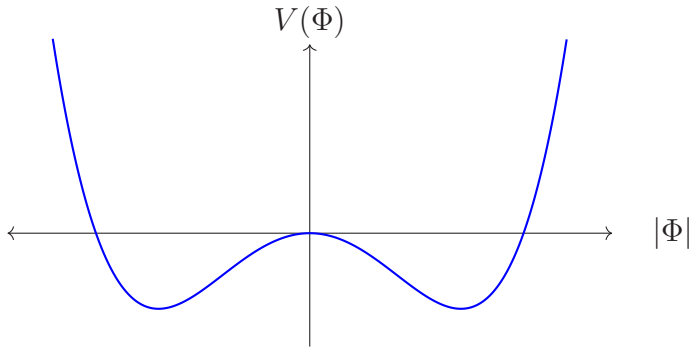

Figure 34.8: **The Mexican hat potential.**

$$\Phi \to e^{i\theta}\Phi \ , \qquad \Phi^* \to e^{-i\theta}\Phi^* \ . \tag{34.113}$$

The minimum of the potential occurs when

$$\Phi_{\rm vac}(x) = \frac{m}{\sqrt{2\lambda}}e^{i\rho} \ , \tag{34.114}$$

for arbitrary constant ρ. If we want to study excitations of this theory, we expand around $\Phi = \Phi_{\rm vac}$, not $\Phi = 0$. In the quantum theory, a particular choice $|\,\rho = \rho_0\,\rangle$ of vacuum state is made. Clearly, this state is not invariant under the global symmetry transformations (34.113), that is, if Q_θ generates (34.113), then it acts on the vacuum state as

$$e^{iQ_\theta}|\,\rho_0\,\rangle \sim |\,\rho_0 + \theta\,\rangle \neq 0 \ . \tag{34.115}$$

Hence we have a symmetry of the Lagrangian but not a symmetry of the vacuum state. In this case, we say that the symmetry (34.113) is spontaneously broken.

Goldstone's theorem states that whenever a continuous global symmetry is spontaneously broken, there exists a massless excitation about the spontaneously broken vacuum. Decomposing

[191] Large gauge symmetries are unlike any previously discussed symmetry both in their asymptotic angle dependence and in the fact that the action is described at null, not spatial, infinity. Phrases like "spontaneous symmetry breaking," "Goldstone boson," "superselection sector," and even "conservation law" are used with slightly different meanings in different physical contexts. In importing those words to the present context, I have necessarily adapted and refined their meanings. I have done so in the way I thought most natural, but other adaptations might be possible.

$\Phi(x) = |\Phi(x)|e^{i\rho(x)}$, ρ transforms as $\rho(x) \to \rho(x) + \theta$. Hence the Lagrangian can depend on ρ only via the derivative $\partial_\mu \rho$; there cannot be any mass term for ρ, and it is a massless field. ρ — identified as the field that transforms inhomogeneously under the broken symmetry — is referred to as the Goldstone boson.

Let us now relate this elementary example to our discussion in the previous sections. We have a charge Q^+_ε that generates a symmetry of the Lagrangian of any abelian gauge theory. However, this charge does not annihilate the vacuum. Instead, it creates an extra soft photon mode ϕ, which, according to (34.61), transforms inhomogeneously under the broken symmetry. Hence the soft photons are the Goldstone bosons of spontaneously broken large gauge symmetry. There is an infinite vacuum degeneracy, since we can add any number of soft photons to any vacuum state and obtain another vacuum state with the same zero energy. Classically, the infinite-dimensional space of vacua can be labeled by flat abelian connections $\partial_z \varepsilon(z, \bar{z})$ on the sphere.

There is a crucial difference between the usual Mexican hat story of spontaneous global symmetry breaking and the spontaneous breaking of the large gauge symmetries. In the usual story, the different vacua form superselection sectors (i.e., no physical finite energy operator exists that can move us from one vacuum to another). In other words, the charge Q_θ that would in principle move us between various vacua is not a normalizable operator in the Hilbert space. To see this, consider a system in a vacuum ρ_0. Now, suppose we have a bubble with a different value of ρ, say ρ_1, in the interior. Then along the surface of this bubble, Φ must have nonzero gradient. Hence the bubble carries energy proportional to its area. To change the vacuum from ρ_0 to ρ_1 everywhere, we need this bubble to grow in size and cover the entire volume of the system. In infinite volume systems, this process will take an infinite amount of energy and therefore cannot be achieved. Thus, there are no finite-energy physical processes that change the vacuum state in systems of infinite size, and the Q_θ appearing in (34.115) is not a finite energy operator on the Hilbert space. This argument relied on the area of the bubble growing with its volume. This is only true in more than one space dimension. In two spacetime dimensions the bubble wall is a point, and the area does not grow. Finite energy processes may then give rise to a change in the vacuum. In spacetime dimensions $d > 2$, scattering processes break up into superselection sectors, but in $d = 2$ they do not.

Such superselection sectors clearly do not arise for the large gauge symmetry. The vacuum state is changed by soft photon creation, which occurs in nearly all scattering processes.[192] The $\mathcal{S}$-matrix elements do not factorize into superselection sectors. One way to understand this is that, even though we are working in $d = 4$, the symmetry action in some regards mimics the $d = 2$ case. The parameter that generates the spontaneously broken symmetry is an arbitrary local function on the sphere — one parameter for every point — as opposed to the constant parameter in (34.113). Hence vacuum-to-vacuum transitions need not occur simultaneously everywhere at once on the sphere at infinity. Restricting to just one point, finite energy transitions are possible.

At the classical level, the degenerate electromagnetic vacua connected by large gauge transformations all have vanishing $F_{\mu\nu}$ and hence carry no large gauge charge. This is because the large gauge group is abelian, and hence its action commutes with the charge. As discussed in section 34.5, an analogous classical vacuum degeneracy appears in gravity. However in this case, the asymptotic symmetry group is nonabelian, and the different vacua are classically distinguished by the charges they carry (e.g., angular momentum $\vec{J}$). The existence of classically degenerate vacua is then more obvious, as it can then be deduced from charge conservation. Consider, for example, the situation depicted in figure 34.9, in which an initial configuration with angular momentum $\vec{J}_{initial}$ radiates angular momentum $\vec{J}_{rad}$ and decays to a vacuum spacetime with vanishing Riemann tensor but angular momentum $\vec{J}_{vac}$.[193] Angular momentum conservation implies

$$\vec{J}_{initial} = \vec{J}_{rad} + \vec{J}_{vac} \ . \tag{34.116}$$

Insisting on vacuum uniqueness in gravity leads to the nonsensical conclusion that angular momentum is not conserved. This is sometimes referred to as the problem of angular momentum in

[192] In the gravitational version of this story, the change in vacuum is classically measured by the gravitational memory effect, which one hopes to measure at LIGO [34] or elsewhere.

[193] Explicit solutions of this general type are studied below in section 34.7.2. Formulas for the infinitesimal change in the vacuum angular momentum under a supertranslation are in [203], and the finite case is treated in [51]. Vacua with nonzero $\vec{J}$ are also discussed in [204].

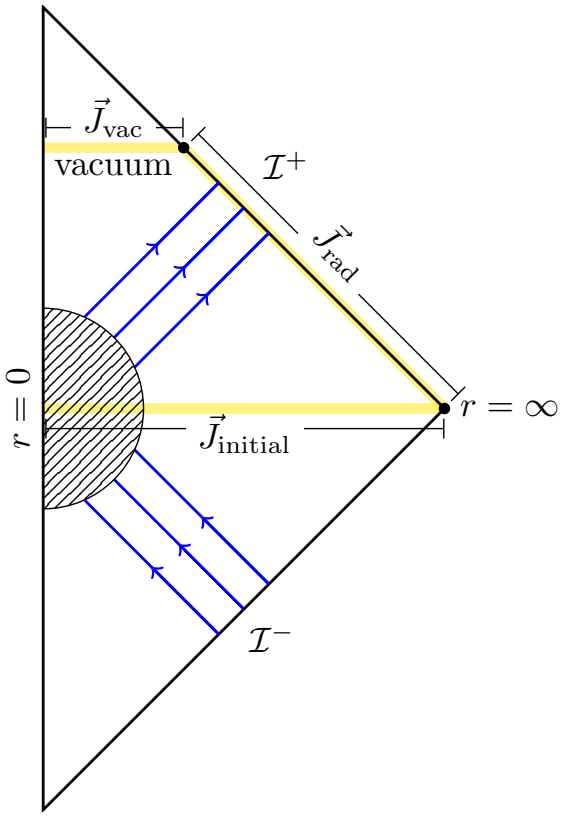

Figure 34.9: **The existence of degenerate vacua in general relativity can be deduced from angular momentum conservation. According to the Einstein equation, an initial configuration with angular momentum $\vec{J}_{initial}$ can decay to flat space while emitting total angular momentum flux $\vec{J}_{rad} \neq \vec{J}_{initial}$. Angular momentum is nevertheless conserved, because the final vacuum carries angular momentum.**

GR, but it is neatly resolved by the existence of degenerate vacua with nonzero $\vec{J}$.

34.2.12 Massive QED

In the previous sections, we have seen that massless electrodynamics has infinitely many conserved charges, and moreover that the quantum matrix elements of the conservation laws are the soft photon theorem for amplitudes with massless charged external states. Of course, in the real world, charged particles like the electron have mass. In this subsection we generalize the previous results to massive particles.

The basic obstacle is that our analysis so far has been based on $\mathcal{I}$, but massive particles never reach $\mathcal{I}$ (for discussion, see [205]). For theories that only have massless particles, $\mathcal{I}$ forms a Cauchy surface — that is, specification of initial (or final) data on $\mathcal{I}^-$ (or $\mathcal{I}^+$) is sufficient to obtain the complete evolution of the field into the interior. This no longer works for massive particles, since they do not arrive at $\mathcal{I}$. Rather, they arrive from i^- and asymptote to i^+. Interestingly, resolving this problem essentially forces one to the use of hyperbolic slices of Minkowski space employed for holographic reduction by de Boer and Solodukhin [52]. The massive formulas are a bit more complicated than the massless ones, but they have a beautiful structure and make suggestive connections to AdS/CFT.

The first step is to understand how the symmetries act near $i^\pm$. This has been discussed in two papers [13, 14]. In the first paper, the authors present a gauge invariant description of the action of the asymptotic symmetries on outgoing massive particles and show that the Ward identities

correctly imply the soft theorem. In the second paper, the authors worked in Lorenz gauge. Despite making a specific gauge choice, the discussion of the second paper is more illuminating. We now review it.

Most of the requisite machinery has already been set up in the massless analysis. The main step left is to understand how the large gauge symmetries act on massive states. Given this knowledge, we know the action of the hard part of the charge on asymptotic massive states. With this extra term in hand, we can proceed as before by transforming into momentum space to reproduce the soft theorem.

For this purpose, a prescription is needed to extend the asymptotic gauge parameter $\varepsilon(z,\bar{z})$ into the bulk interior of Minkowski space and $i^{\pm}$. While this bulk extension can be done in many different ways, due to gauge invariance, any extension should give rise to the same final result. It turns out to be very convenient to extend the gauge parameter from the boundary into the bulk using Lorenz gauge

$$\nabla^{\mu} A_{\mu} = 0 \ , \tag{34.117}$$

which implies that the gauge parameter must satisfy

$$\Box \varepsilon = 0 \ . \tag{34.118}$$

We need to solve this equation with the boundary condition that it asymptote to a specific function $\varepsilon(z,\bar{z})$ on $\mathcal{I}^{+}$. We might try to solve it by Fourier transforming. However, this gives scattering solutions that fall off like $\frac{1}{r}$ near $\mathcal{I}^{+}$ and therefore cannot satisfy our boundary condition. Fortunately, (34.118) also has solutions that have no Fourier transform and do not die off at $\mathcal{I}^{+}$ (see exercise 6). The solution that approaches $\varepsilon(z,\bar{z})$ can be written as

$$\varepsilon(x) = \int d^2\hat{q}\, G\big(x,\hat{q}\big)\varepsilon(\hat{q}) \ , \tag{34.119}$$

where we have parametrized the point on the asymptotic sphere by a unit vector $\hat{q}$ that points toward $(z,\bar{z})$, and G is a Green's function that must satisfy

$$\Box G(x,\hat{q}) = 0 \ , \qquad \lim_{\substack{r\to\infty \\ u \text{ fixed}}} G(x,\hat{q}) = \delta^2(\hat{x}-\hat{q}) \ . \tag{34.120}$$

This has the solution

$$G\big(x,\hat{q}\big) = -\frac{\sqrt{\gamma(\hat{q})}}{4\pi}\frac{x^{\mu}x_{\mu}}{(q\cdot x)^2} \ , \tag{34.121}$$

where $q^{\mu} = \big(1,\hat{q}\big)$. The first property is easy to show:

$$\begin{aligned} \Box G\big(x,\hat{q}\big) &= -\frac{\sqrt{\gamma(\hat{q})}}{4\pi}\partial_{\nu}\left[\frac{2x^{\nu}}{(q\cdot x)^2} - \frac{2x^{\mu}x_{\mu}}{(q\cdot x)^3}q^{\nu}\right] \\ &= -\frac{\sqrt{\gamma(\hat{q})}}{4\pi}\left[\frac{8}{(q\cdot x)^2} - \frac{4}{(q\cdot x)^2} - \frac{4}{(q\cdot x)^2} + \frac{6x^{\mu}x_{\mu}}{(q\cdot x)^4}q^2\right] = 0 \ . \end{aligned} \tag{34.122}$$

The second property is exhibited by writing G in retarded coordinates:

$$G\big(x,\hat{q}\big) = \frac{\sqrt{\gamma(\hat{q})}}{4\pi}\frac{u(u+2r)}{\big[u+r\,(1-\hat{q}\cdot\hat{x})\,\big]^2} \tag{34.123}$$

which at large r vanishes if $\hat{q}\neq\hat{x}$ and diverges if $\hat{q}=\hat{x}$. The overall normalization of the delta function can then be determined by integrating over $\hat{q}$.

Another important property of G can be seen by considering the limit toward $\mathcal{I}^{-}$, $r\to\infty$, keeping $v = u+2r$ constant. In this limit, G localizes to the point $\hat{q} = -\hat{x}$. Thus, we find that in the $\mathcal{I}^{-}$ limit, the large gauge parameter is antipodally related to the one obtained in the $\mathcal{I}^{+}$ limit. In other words, G "knows" about the antipodal map, which is a very convenient feature of Lorenz gauge. In hindsight, this may not be altogether surprising, since the gauge chosen here is Lorentz invariant, and the antipodal map is required by Lorentz invariance.

Hyberbolic Slices

Now we are in a position to find the limit of this bulk gauge parameter onto i^+. For this purpose, we introduce a new set of coordinates. The retarded $(u, r, z, \bar{z})$ or advanced $(v, r, z, \bar{z})$ coordinates that we have employed so far are natural when one is interested in null infinity. However, they are not good near $i^{\pm}$. To discuss these boundaries, consider a hyperbolic slicing of Minkowski space, with slices labeled by the coordinate

$$\tau^2 = -x^\mu x_\mu = t^2 - r^2 \ . \tag{34.124}$$

Hypersurfaces corresponding to constant τ are hyperbolic spaces. For $\tau^2 > 0$, the hypersurfaces are $\mathbb{H}_3$ (or Euclidean AdS_3), whereas for $\tau^2 < 0$ the hypersurfaces are three-dimensional de Sitter space dS_3, as illustrated in figure 34.10. Here we are interested in resolving the structure of $i^{\pm}$,

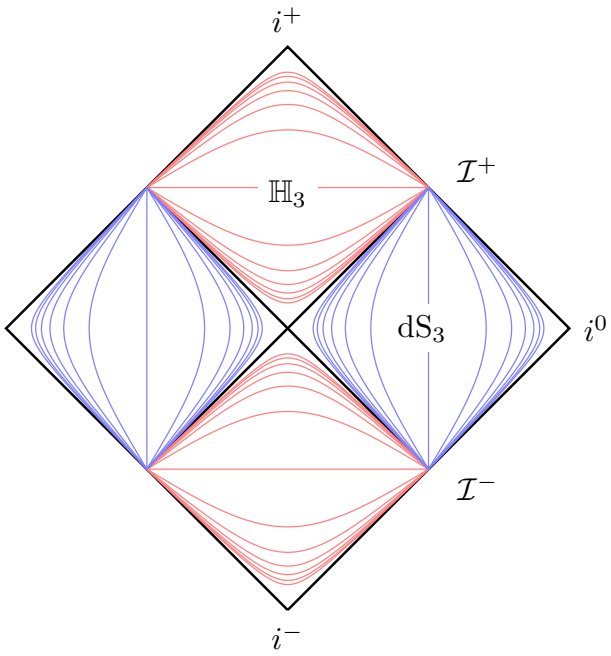

Figure 34.10: **Hyperbolic slicing of Minkowski space. The slices correspond to constant $\tau^2 = t^2 - r^2$ surfaces. The red lines correspond to $\mathbb{H}_3$ slices and have $\tau^2 > 0$, whereas the blue lines correspond to the dS_3 slices with $\tau^2 < 0$.**

for which we focus on the $\mathbb{H}_3$ slices. The dS_3 slices were used to resolve the structure of spatial infinity i^0 by Ashtekar and Romano [206] in a related context.

On the $\mathbb{H}_3$ slices, we introduce the coordinate ρ:

$$\rho = \frac{r}{\sqrt{t^2 - r^2}} \ . \tag{34.125}$$

The Minkowski metric then takes the form

$$ds^2 = -d\tau^2 + \tau^2 \left[\frac{d\rho^2}{1+\rho^2} + \rho^2 d\Omega_2^2 \right] \ . \tag{34.126}$$

The metric on the $\tau =$ constant hypersurfaces is that of $\mathbb{H}_3$, whose isometry group is $SL(2, \mathbb{C})$. These are Lorentz transformations, which in Minkowski space map each of these slices into themselves. Similarly, $SL(2, \mathbb{C})$ maps the dS_3 slices into themselves.

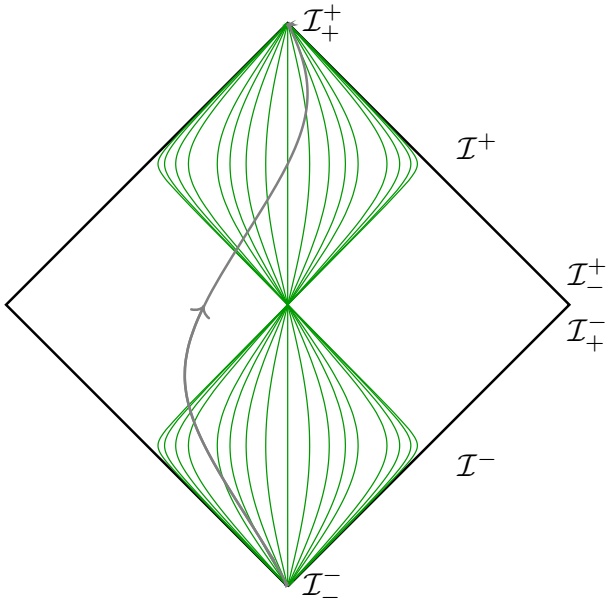

Figure 34.11: **Hypersurfaces of constant ρ are shown in green. The grey line is the worldline of a massive particle moving at constant velocity. The worldline of a particle asymptotes to a surface of constant ρ as $\tau \to \infty$.**

The Green's function (34.121) in these coordinates takes the form

$$G(\tau, \rho, \hat{x}; \hat{q}) = \frac{\sqrt{\gamma(\hat{q})}}{4\pi \left[\sqrt{1+\rho^2} - \rho \hat{q} \cdot \hat{x}\right]^2} \,. \tag{34.127}$$

Note that τ has completely dropped out of this equation (i.e., $\partial_\tau G = 0$). This implies that the gauge parameter (34.119) is independent of τ. Viewed as a three-dimensional Green's function, (34.127) has been studied extensively in the context of AdS_3 and is known as the bulk-to-boundary propagator for a massless scalar, which relates quantities on the boundary to those in the bulk. We are beginning to see the holographic structure of AdS_3 echoing in Minkowski space. Of course, this Green's function seems quite special since it does not depend on τ at all, but in other applications to flat space holography [142, 143], $\mathbb{H}_3$ Green's functions (or bulk-to-boundary propagators) for fields of any conformal weight can arise and are accompanied by τ-dependence in the full Minkowski space solutions.

Now consider a massive particle moving with constant momentum and following the trajectory $\vec{r} = \frac{1}{E}\vec{p}t + \vec{r}_0$ for some fixed $\vec{r}_0$, as illustrated in figure 34.11. $(\tau, \rho, \hat{x})$ are given by

$$\begin{aligned}
\rho &= \frac{r}{\sqrt{t^2 - r^2}} = \frac{|\frac{1}{E}\vec{p}t + \vec{r}_0|}{\sqrt{t^2 - \left(\frac{1}{E}\vec{p}t + \vec{r}_0\right)^2}} \,, \\
\tau &= \sqrt{t^2 - r^2} = \sqrt{t^2 - \left(\frac{1}{E}\vec{p}t + \vec{r}_0\right)^2} \,, \\
\hat{x} &= \frac{\vec{r}}{r} = \frac{\vec{p}t + E\vec{r}_0}{|\vec{p}t + E\vec{r}_0|} \,.
\end{aligned} \tag{34.128}$$

At late times, $t \to \infty$,

$$\rho \to \frac{|\vec{p}|}{m} , \qquad \tau \to \frac{m}{E} t , \qquad \hat{x} \to \hat{p} . \tag{34.129}$$

Hence ρ, and $\hat{x}$ asymptote to constants, and a massive particle approaches a fixed location on the unit hyperboloid at i^+. Hence in this resolution, i^+ is the hyperbola $\mathbb{H}_3$, much as $\mathcal{I}^+$ is $\mathbb{R} \times S^2$. The symplectic form for massive particles on $\mathbb{H}_3$ is worked out in exercise 7.

This construction readily gives the large gauge symmetry action on such a one-particle state at asymptotically late times. As ε is independent of the parameter τ labelling the hypersurfaces, we simply evaluate it at (34.129). Writing the hard part of the charge in a vicinity of i^+ as an integral over the asymptotic late-time $\mathbb{H}_3$, one concludes that

$$Q_\varepsilon^{+H} |\, \vec{p}\,\rangle = Q\varepsilon \left(\frac{|\vec{p}|}{m}, \hat{p} \right) |\, \vec{p}\,\rangle , \tag{34.130}$$

where ε is given by (34.119). To summarize, the action of the large gauge charge on a massive particle is proportional to the Lorenz gauge value of the gauge parameter at the $\mathbb{H}_3$ point to which the massive particle asymptotes.

Soft Theorem

We are now set to use this result to derive the quantum Ward identity. The derivation is essentially identical to the massless case. Equations (34.67) and (34.68) now include additional terms on the RHS from massive states:[194]

$$\begin{aligned} \langle \text{ out } | Q_\varepsilon^+ = -2 \int d^2w \partial_{\bar{w}} \varepsilon \langle \text{ out } | \partial_w N \\ + \sum_{k \in \text{massless}} Q_k \varepsilon(z_k, \bar{z}_k) \langle \text{ out } | + \sum_{k \in \text{massive}} Q_k \varepsilon \left(\frac{|\vec{p}_k|}{m_k}, \hat{p}_k \right) \langle \text{ out } | . \end{aligned} \tag{34.131}$$

The Ward identity becomes

$$\begin{aligned} -2 \int d^2w \partial_{\bar{w}} \varepsilon \partial_w \langle \text{ out } | \big[N(w,\bar{w}) \mathcal{S} - \mathcal{S} N^-(w,\bar{w}) \big] | \text{ in } \rangle \\ = - \left[\sum_{k \in \text{massless}} Q_k \varepsilon(z_k, \bar{z}_k) + \sum_{k \in \text{massive}} Q_k \varepsilon \left(\frac{|\vec{p}_k|}{m_k}, \hat{p}_k \right) \right] \langle \text{ out } | \mathcal{S} | \text{ in } \rangle . \end{aligned} \tag{34.132}$$

To verify that this is the soft photon theorem, set, as before, $\varepsilon(w,\bar{w}) = \frac{1}{z-w}$ and obtain

$$\begin{aligned} \frac{\sqrt{2}}{1+z\bar{z}} \lim_{\omega \to 0^+} \big[\omega \langle \text{ out } | a_+\big(\omega \hat{x}(z,\bar{z})\big) \mathcal{S} | \text{ in } \rangle \big] \\ = e \left[\sum_{k \in \text{massless}} \frac{Q_k}{z - z_k} + \sum_{k \in \text{massive}} Q_k \varepsilon \left(\frac{|\vec{p}_k|}{m_k}, \hat{p}_k \right) \right] \langle \text{ out } | \mathcal{S} | \text{ in } \rangle . \end{aligned} \tag{34.133}$$

[194] For notational brevity, we introduce here a simplified notation for n-point amplitudes with m outgoing particles and $n-m$ incoming particles. We drop the superscripts "in" and "out" on the momenta and charges and simply take the particles labeled $k = 1, \ldots, m$ to be outgoing and particles labelled $k = m+1, \ldots, n$ to be incoming. We further adopt a convention in which an incoming negative helicity photon of energy p^0 is described as a outgoing positive helicity photon with energy $-p^0$. Similarly, an incoming matter state of helicity h, charge Q, and energy p^0 is described as an outgoing matter state of helicity $-h$, charge $-Q$, and energy $-p^0$.

Using the property

$$G\left(\frac{|\vec{p_k}|}{m},\hat{p}_k;w,\bar{w}\right)=\frac{1}{2\pi}\partial_{\bar{w}}\left[\frac{\sqrt{2}}{1+w\bar{w}}\frac{p_k\cdot\varepsilon^+}{p_k\cdot\hat{q}}\right]\ , \tag{34.134}$$

we find

$$\varepsilon\left(\frac{|\vec{p_k}|}{m},\hat{p}_k\right)=\int d^2wG\left(\frac{|\vec{p_k}|}{m},\hat{p}_k;w,\bar{w}\right)\frac{1}{z-w}=\frac{\sqrt{2}}{1+z\bar{z}}\frac{p_k\cdot\varepsilon^+(z,\bar{z})}{p_k\cdot\hat{q}(z,\bar{z})}\ . \tag{34.135}$$

Plugging this into (34.133) and multiplying both sides by $\frac{1+z\bar{z}}{\sqrt{2}}$, we reproduce the soft photon theorem for massive charged particles in the standard momentum space form (34.88). It is rather satisfying to see this detailed equivalence emerge from the properties of bulk-to-boundary propagators on $\mathbb{H}_3$!

34.2.13 Magnetic Charges

In this section, we derive a new nonperturbative soft theorem and generalize the analysis to include magnetic charges [192].

In perturbation theory, it has been proven using Feynman diagrams [151] that the soft photon theorem is tree-level exact (i.e., it does not receive any loop corrections). It is natural to ask whether there can be nonperturbative corrections. To even talk about nonperturbative contributions to the soft theorem, one first needs a theory that exists nonperturbatively. QED — the theory of photons and electrons — does not exist due to the Landau pole. It must be embedded in some bigger theory — maybe one that is asymptotically free — that does exist nonperturbatively. To the best of my knowledge, all examples of such bigger theories contain magnetic monopoles.

This leads us to ask whether the soft photon theorem is corrected when magnetic monopoles are present in the asymptotic states. It is not hard to see that there must indeed be such a correction. In low-energy effective field theory, a magnetic monopole is represented by a point particle with magnetic charge. A soft photon will certainly couple to such an object, and the pole due to the nearly on-shell propagator (34.93) is still present. The only thing that changes is the coupling of the magnetic particle to the gauge field (34.94). This coupling gives rise to a different soft factor, but the pole remains.

To derive the nonperturbative corrections to the soft theorem, we begin with the perturbative electric soft factor

$$S_0^\alpha=\sum_k\frac{eQ_kp_k\cdot\varepsilon^\alpha}{q\cdot p_k}\ , \tag{34.136}$$

for a soft photon of polarization ε_α. Consider an amplitude involving asymptotic particles with integral magnetic charges M_k defined by

$$M_k=\frac{1}{2\pi}\int_{S_k^2}F\ , \tag{34.137}$$

where S_k^2 is a sphere surrounding the kth particle. Since the pole in the soft factor is unchanged, we need to simply determine the vertex factor. A trick for this purpose is to transform to dual variables

$$\tilde{F}=-\frac{2\pi}{e^2}*F\ ,\qquad \tilde{e}=\frac{2\pi}{e}\ ,\qquad \tilde{Q}_k=\frac{1}{\tilde{e}^2}\int_{S_k^2}*\tilde{F}=M_k\ ,\qquad \tilde{M}_k=\frac{1}{2\pi}\int_{S_k^2}\tilde{F}=-Q_k\ . \tag{34.138}$$

This duality interchanges the electric and magnetic charges as $(\tilde{Q}_k,\tilde{M}_k)=(M_k,-Q_k)$. Note that we are not assuming here that the theory has any kind of duality symmetry; we are simply rewriting

it in terms of the dual field strength as a shortcut to derive magnetic terms in the soft factor. It is useful to define a dual gauge potential that couples to magnetic charges in the same way that the usual gauge potential couples to electric charges:

$$\tilde{F} = \mathrm{d}\tilde{A} = -\frac{2\pi}{e^2} * \mathrm{d}A \ , \tag{34.139}$$

which determines $\tilde{A}$ in terms of A (up to magnetic gauge transformations). In the bulk four dimensions, this is a highly nonlocal relationship, but as we shall see, it becomes local on $\mathcal{I}^+$. Note that (34.139) also relates the polarization ε_α to its dual $\tilde{\varepsilon}_\alpha$ as defined by

$$A_\mu(q) = e\varepsilon^\alpha_\mu(q) \ , \qquad \tilde{A}_\mu(q) = \tilde{e}\tilde{\varepsilon}^\alpha_\mu(q) \ . \tag{34.140}$$

Since $\tilde{A}$ couples to magnetic particles in exactly the same way that A couples to electric particles, we immediately conclude that magetic charges must correct the soft formula to

$$S^\alpha_0 = \sum_k \frac{p_k \cdot (Q_k e\varepsilon^\alpha + M_k\tilde{e}\tilde{\varepsilon}^\alpha)}{q \cdot p_k} \ . \tag{34.141}$$

Electric and magnetic gauge invariance implies that the amplitude should remain invariant under separate shifts of ε^α and $\tilde{\varepsilon}^\alpha$. This indeed follows from the fact that electric and magnetic charge are each conserved. It is easy to check that this formula is invariant under electric-magnetic duality. It is conjectured to be nonperturbatively exact [192].

It is illuminating to describe the duality transformations (34.138) in retarded coordinates near $\mathcal{I}^+$. Expanding near $\mathcal{I}^+$, they simplify to

$$\tilde{F}^{(0)}_{z\bar{z}} = \frac{2\pi i}{e^2}\gamma_{z\bar{z}}F^{(2)}_{ru} \ , \qquad \tilde{F}^{(2)}_{ru} = \frac{2\pi i}{e^2}\gamma^{z\bar{z}}F^{(0)}_{z\bar{z}} \ , \qquad \tilde{F}^{(0)}_{uz} = \frac{2\pi i}{e^2}F^{(0)}_{uz} \ . \tag{34.142}$$

Integrating the last equation of (34.142) and choosing the integration constant to get a linear relation between A_z and $\tilde{A}_z$, we find

$$\tilde{A}^{(0)}_z = \frac{2\pi i}{e^2}A^{(0)}_z \ . \tag{34.143}$$

This formula is quite interesting. It states that the duality transformation is simply multiplication by i. This is unsurprising, since F_{uz} corresponds to the radiative mode of the electromagnetic field with one polarization. A multiplication by i corresponds to a phase shift by $\frac{\pi}{2}$, which is equivalent to exchanging electric and magnetic fields. The soft factor may then finally be written in the simple form for positive helicity

$$S^\alpha_0 = \sum_k \frac{(eQ_k + \frac{2\pi i}{e}M_k)p_k \cdot \varepsilon^+}{q \cdot p_k} \ , \tag{34.144}$$

while the combination $eQ_k - \frac{2\pi i}{e}M_k$ appears for the opposite helicity.

In the presence of magnetic charges, there is a second infinity of conserved charges. Let us define an outgoing charge by

$$\tilde{Q}^+_\varepsilon = \frac{1}{2\pi}\int_{\mathcal{I}^+_-} \varepsilon F = \frac{i}{2\pi}\int_{\mathcal{I}^+_-} d^2z\varepsilon F^{(0)}_{z\bar{z}} . \tag{34.145}$$

The Lorentz-invariant matching condition

$$F^{(0)}_{z\bar{z}}|_{\mathcal{I}^+_-} = -F^{(0)}_{z\bar{z}}|_{\mathcal{I}^-_+} \tag{34.146}$$

then implies that this outgoing magnetic charge is equal to the incoming magnetic charge on $\mathcal{I}^-$:

$$\tilde{Q}^+_\varepsilon = \tilde{Q}^-_\varepsilon = -\frac{i}{2\pi}\int_{\mathcal{I}^-_+} d^2z\varepsilon F^{(0)}_{z\bar{z}} \ . \tag{34.147}$$

The extra minus sign in (34.146) is present because the $(z,\bar{z})$ coordinates used on $\mathcal{I}^-$ are antipodally mapped to the ones on $\mathcal{I}^+$, reversing the orientation of the sphere.

To what symmetry is this new charge associated? In the case of the electric charges, this question was answered by constructing the asymptotic Dirac brackets and working out the action of the charge on the fields. In doing so, we assumed that $F^{(0)}_{z\bar{z}}$ vanished on the boundaries of $\mathcal{I}^+_\pm$. This boundary condition is consistent in the absence of magnetically charged particles but obviously cannot be imposed here. In fact, the correct boundary conditions and Dirac brackets in the presence of both electric and magnetic charges have not yet been worked out. It remains an important open problem.

However, without going through this long procedure, duality covariance gives an obvious guess for the final result: $\tilde{Q}^\pm_\varepsilon$ should generate *magnetic* gauge transformations on the dual gauge fields, namely

$$\tilde{\delta}_\varepsilon \tilde{A}^{(0)}_z = \partial_z\varepsilon \ . \tag{34.148}$$

Using (34.143), this can be written in terms of the gauge field A_z as

$$\tilde{\delta}_\varepsilon A^{(0)}_z = -\frac{ie^2}{2\pi}\partial_z\varepsilon \ . \tag{34.149}$$

These may be interpreted as electric gauge transformations but with an imaginary gauge parameter $\tilde{\varepsilon} = -\frac{ie^2}{2\pi}\varepsilon$. The original real $U(1)$ symmetry is now enhanced to a complex $U(1)$. This complexification enables us to simultaneously and *locally* realize both the electric and magnetic gauge symmetry on the asymptotic fields! From this point forward, showing that the Ward identity of this complexified large gauge symmetry is precisely the full nonperturbative electric+magnetic soft photon theorem follows through exactly as before. We will not work through the derivation here.

It is instructive to note here that in the standard electric presentation of abelian gauge theory, the large electric symmetries are manifest as a nontrivial subgroup of the gauge symmetry, whereas magnetic symmetries are not. In the dual magnetic description, the opposite is true. The lesson here is that not all asymptotic symmetries can be thought of as subgroups of some bulk gauge symmetry. As truly physical symmetries with measurable dynamical implications, they have a more fundamental status. Since trivial gauge symmetries correspond to redundant degrees of freedom, one may have many different presentations of a theory in which different redundant degrees of freedom appear. However, since the asymptotic symmetries are physical, they must exist in each presentation, although not necessarily describable as a subgroup of a local gauge symmetry. Indeed, we will see in the next section that the soft photino theorem in $\mathcal{N}=1$ QED implies the existence of infinitely many fermionic symmetries. These are not a subgroup of a local gauge symmetry in any known presentation of the theory.

34.2.14 Supersymmetry

In supersymmetric theories, every particle has a superpartner. The partner of the photon is called the photino. One might expect a soft photino theorem as a superpartner of the soft photon theorem. This is indeed the case. For every soft theorem, one expects an asymptotic symmetry. Furthermore, since the soft theorem can be thought of as one relationship between two $\mathcal{S}$-matrix amplitudes for every direction $(z,\bar{z})$ of the soft particle, the associated asymptotic symmetry should be infinite dimensional. The soft photino theorem is thus expected to give rise to an infinite number of fermionic symmetries of the $\mathcal{S}$-matrix.

This simple conclusion is quite surprising as, in the simplest case of $\mathcal{N} = 1$, the global supersymmetry is generated by four real fermionic parameters. Clearly, the infinitely many fermionic symmetries alluded to above cannot possibly be a subgroup of these finitely many supersymmetries! This is therefore another example, following the magnetic one, of an asymptotic symmetry that is not realized as a subgroup of any manifest local symmetry of the full bulk theory. However, in the magnetic case, we were able to construct a reformulation of the theory in terms of dual variables in which the magnetic symmetry was manifest as a subgroup of the local gauge symmetry of the dual magnetic potentials. In contrast, there is no known description of the fermionic symmetries in $\mathcal{N} = 1$ theories in which a nontrivial infinite-dimensional symmetry is manifest.[195] Hence, the fermionic symmetries that we uncover here are completely new and different.

In this section, we present the soft photino theorem and rewrite it as the matrix element of an infinite set of fermionic conservation laws, with some details referred to the original work [58]. In section 34.2.14, we review the soft photino theorem. Section 34.2.14 derives the equivalent fermionic conservation laws. Further directions involving supersymmetric asymptotic symmetries are discussed in section 34.2.14.

Soft Photino Theorem

First we review the soft photino theorem. The Lagrangian for $\mathcal{N} = 1$ supersymmetric QED with photino Λ and generic matter supercurrent $\mathcal{K}$ (the superpartner of the charged matter current j_μ) is

$$\mathcal{L} = -\frac{1}{4e^2}F_{\mu\nu}F^{\mu\nu} - \frac{i}{e^2}\bar{\Lambda}\bar{\sigma}^\mu D_\mu\Lambda + i\bar{\mathcal{K}}\bar{\Lambda} - i\Lambda\mathcal{K} + \mathcal{L}_{\text{matter}} + \ldots, \tag{34.150}$$

where we follow the spinor conventions of Wess and Bagger [207]. Here, $\mathcal{L}_{\text{matter}}$ is the full interacting matter Lagrangian and "..." denotes any higher derivative interactions. Our discussion of the soft photino theorem will not depend on the precise nature of these terms. The only important term is the linear coupling of the supercurrent to the photino. The structure of this interaction is fixed completely by gauge invariance and supersymmetry.

For clarity, we work with a specific example, but the discussion is completely general and applies to any supersymmetric abelian gauge theory. Consider the case where the matter content of this theory contains a single, massless charged chiral multiplet with charge Q. This multiplet contains a complex scalar field Φ and its superpartner Ψ_α. The fermionic current is

$$\mathcal{K}_\alpha = \sqrt{2}Q\bar{\Phi}\Psi_\alpha, \qquad \bar{\mathcal{K}}_{\dot{\alpha}} = \sqrt{2}Q\Phi\bar{\Psi}_{\dot{\alpha}}. \tag{34.151}$$

To describe the soft theorem, consider an amplitude with n particles with momenta p_k, $k = 1, \ldots, n$, and a photino with momentum q. Since all momenta are null, we can write them in terms of spinors as

$$p_{k\mu}\sigma^\mu_{\alpha\dot{\alpha}} = \eta_{k\alpha}\bar{\eta}_{k\dot{\alpha}}, \qquad q_\mu\sigma^\mu_{\alpha\dot{\alpha}} = \eta_\alpha\bar{\eta}_{\dot{\alpha}}. \tag{34.152}$$

The soft photino theorem (a derivation is in [58]) is then simply

$$\lim_{\eta\to 0}\langle \text{ out } |a_+(\eta)\mathcal{S}| \text{ in } \rangle = \sqrt{2}ie\sum_k \frac{1}{\eta\cdot\eta_k}\langle \text{ out } |\mathscr{F}_k\mathcal{S}| \text{ in } \rangle, \tag{34.153}$$

where $\mathscr{F}$ is the operator whose action on states is given by

$$\langle\, \Phi\,|\mathscr{F} = -Q\langle\, \Psi\,|, \qquad \langle\, \bar{\Psi}\,|\mathscr{F} = Q\langle\, \bar{\Phi}\,|, \qquad \langle\, \bar{\Phi}\,|\mathscr{F} = \langle\, \Psi\,|\mathscr{F} = 0. \tag{34.154}$$

[195] In superspace formalisms, the gauge parameter sometimes has a fermionic superpartner that is gauge fixed to zero. However, the fermionic symmetries we find here are unrelated to these superpartners. It is of course possible that alternate superspace formulations exist in which our fermionic symmetries are superpartners of gauge symmetries.

Note that the soft theorem here takes on a qualitatively different form than the examples considered so far. In the soft photon theorem, the soft factors were all simply numbers in a plane wave basis, whereas here the soft factor is an *operator* that changes external bosons into external fermions and vice versa. Going forward, we will encounter many more examples in which the soft factor is an operator acting on the external states.

Note that $\mathscr{F}$ is a fermionic operator (i.e., it takes bosonic states into fermionic states and vice versa). This is to be expected, as all nonvanishing amplitudes must have an even number of external fermions. If the LHS of (34.153) is nonvanishing, the $\mathcal{S}$-matrix $\langle \text{out} | \mathcal{S} | \text{in} \rangle$ must itself vanish. Note also that $\mathscr{F}$ only acts on charged states, and even then it does not act on all charged states, only on $\langle \Phi |$ and on $\langle \bar{\Psi} |$. This action is quite distinct from that of the supercharge itself, which acts on all states; see Exercise 8.

We will not derive the soft photino theorem in detail, but we can understand qualitatively why the soft photino theorem must involve the operator $\mathscr{F}$ as follows. The derivation of the soft theorem for the photino follows through in exactly the same way as for the photon, with the $\frac{1}{p_k \cdot q}$ pole coming from the untruncated, nearly on-shell propagator. The only new element is the coupling of the photino with the chiral fields. For an outgoing positive helicity photino, the relevant interaction term is $\bar{\mathcal{K}}_{\dot{\alpha}} = \sqrt{2} Q \Phi \bar{\Psi}_{\dot{\alpha}}$. The factor of Q indicates that one only gets a contribution to the soft factor from particles with charge, as seen in (34.153). Moreover, one only gets a nonzero soft factor from states created by fields $\bar{\Phi}$ and Ψ_α, which are precisely the states on which the operator $\mathscr{F}$ has a nonzero action.[196]

Fermionic Conservation Laws

Following the theme of these lectures, we strongly suspect that (34.153) can be recast as the quantum matrix element of a charge conservation law. There are not too many sensible possibilities for what that charge could be. Our approach will be to simply motivate an Ansatz and then establish the conservation law by checking that the corresponding Ward identity is equivalent to (34.153).

Note that the generic structure of this fermionic charge, $\mathscr{F}[\chi]$ (χ is an arbitrary angle-dependent fermionic parameter), has to be similar to the structure of the large gauge charge — namely, that there is a soft charge linear in the photino field and a hard charge containing the matter particles. Thus, we guess that the new infinity of conserved charges $\mathscr{F}[\chi]$ loosely takes the form of a $\mathcal{I}_-^+$ integral:

$$\mathscr{F}[\chi] \sim \int \chi \Lambda + \int \chi \mathcal{K}. \tag{34.155}$$

To refine this guess, we require that somehow supersymmetry should play a role in this story. This is because the soft photino theorem itself was obtained as a supersymmetrization of the soft photon theorem. Supersymmetry commutes with all gauge transformations. Thus, it cannot be possible to obtain $\mathscr{F}[\chi]$ directly by the action of supersymmetry on Q_ε^+. However, the reverse might be (and as we shall see, is) true: the action of supersymmetry on $\mathscr{F}[\chi]$ could give us Q_ε^+. Another motivation for suspecting such a relation is that it implies $\mathscr{F}[\chi]$ as an operator has mass dimension $-\frac{1}{2}$, consistent with the mass dimension of $\mathscr{F}$ as defined in (34.154).

To implement this guess, note that the supersymmetry transformations of the photino field are

$$\delta_\alpha^{\text{susy}} \Lambda_\beta = -F_{\alpha\beta} + \ldots. \tag{34.156}$$

Here, $\delta_\alpha^{\text{susy}}$ is a supersymmetry transformation with a spinor index α, and $F_{\alpha\beta} = \sigma_{\alpha\beta}^{\mu\nu} F_{\mu\nu}$. The corrections "..." depend on the precise form of the Lagrangian and of the theory under consideration. In the off-shell superfield formalism, these corrections are simply $\varepsilon_{\alpha\beta} D$, where D is an auxiliary field. In any case, these terms will not matter for our purposes, since they die off rapidly near

[196] The notation used here is that the ket state $|\Phi\rangle$ is created by the field Φ. Thus, its adjoint $\langle \Phi |$ is created by the field $\bar{\Phi}$.

$\mathcal{I}^+$. Equation (34.156) then suggests that for the supersymmetry transformation of the fermionic charge,

$$\zeta^\alpha \delta^{\text{susy}}_\alpha \mathscr{F}[\chi] = Q^+_{\zeta\chi}, \qquad \bar\zeta^{\dot\alpha} \delta^{\text{susy}}_{\dot\alpha} \mathscr{F}[\chi] = 0. \tag{34.157}$$

This equation can be used to determine the precise form of $\mathscr{F}[\chi]$. One might anticipate at this point that it is just a $\mathcal{I}^+_-$ integral of $\chi\Lambda$. This is almost right, except that Λ has a term that grows in the far past of $\mathcal{I}^+$, which we must take some care to project out.

To do so explicitly, let us describe in more detail the structure of spinors near $\mathcal{I}^+$. Define a spinor basis by

$$\sigma_z{}^z \xi^{(\pm)} = \pm \frac{1}{2} \xi^{(\pm)}, \qquad \xi^{(+)} \xi^{(-)} = 1. \tag{34.158}$$

Near $\mathcal{I}^+$, we can then expand the photino and fermionic current as

$$\begin{aligned} \Lambda_\alpha &= \frac{1}{r} \lambda_{(+)} \xi^{(+)}_\alpha + \frac{1}{r^2} \lambda_{(-)} \xi^{(-)}_\alpha + \mathcal{O}\big(r^{-3}\big), \\ \bar{\mathcal{K}}_{\dot\alpha} &= \frac{1}{r^2} \bar k_{(-)} \bar\xi^{(-)}_{\dot\alpha} + \frac{1}{r^3} \bar k_{(+)} \bar\xi^{(+)}_{\dot\alpha} + \mathcal{O}\big(r^{-4}\big). \end{aligned} \tag{34.159}$$

The constraint equation on $\mathcal{I}^+$ is

$$(1 + z\bar z) D_{\bar z} \lambda_{(+)} - 2\partial_u \lambda_{(-)} = e^2 \bar k_{(-)}. \tag{34.160}$$

This is the superpartner of the leading-order Maxwell constraint equation (34.37), and it will play the same role as that constraint in converting boundary expressions for charges into bulk ones. The supersymmetry transformation of $\lambda_{(\pm)}$ can be determined by taking the $\mathcal{I}^+$ limits of (34.156). It is convenient to define the following supersymmetry transformation

$$\delta_{(-)} = \xi^\alpha_{(-)} \delta^{\text{susy}}_\alpha. \tag{34.161}$$

Then, near $\mathcal{I}^+$, (34.156) simplifies to

$$\delta_{(-)} \lambda_{(+)} = -2(1 + z\bar z) F^{(0)}_{uz}, \qquad \delta_{(-)} \lambda_{(-)} = F^{(2)}_{ur} - \gamma^{z\bar z} F^{(0)}_{z\bar z} + \ldots, \tag{34.162}$$

where "…" are the D-term contributions. In general, $\lambda_{(+)}$ goes to a finite value at large $|u|$. Equation (34.160) then implies that $\lambda_{(-)}$ may diverge linearly in u. Thus, to define a fermionic charge as an integral over $\mathcal{I}^+_-$ of $\lambda_{(-)}$, we must project out the term linear in u:

$$\mathscr{F}[\chi] = \frac{1}{e^2} \int d^2z \gamma_{z\bar z} \chi \xi^{(-)} \left(1 - u\partial_u\right) \lambda_{(-)} \big|_{\mathcal{I}^+_-}. \tag{34.163}$$

The supersymmetry transformation (34.162) then immediately implies

$$\zeta^\alpha \delta^{\text{susy}}_\alpha \mathscr{F}[\chi] = Q^+_{\zeta^\alpha \chi_\alpha}. \tag{34.164}$$

This fermionic charge satisfies all the properties discussed above. Appropriate photino matching conditions imply that it commutes with the $\mathcal{S}$-matrix. The corresponding Ward identity states

$$\langle \text{ out} \,| \left(\mathscr{F}[\chi] \mathcal{S} - \mathcal{S} \mathscr{F}^-[\chi] \right) | \,\text{in} \rangle = 0. \tag{34.165}$$

Then, using formulas from the previous sections for rewriting boundary expressions in a plane wave basis, we find that this is indeed equivalent to the soft photino theorem (34.153).

The symmetry corresponding to this charge follows with the help of the symplectic form for fermions on $\mathcal{I}^+$. The action of the charge on the photino is found to be

$$\left\{ \mathscr{F}[\chi], \lambda_{(+)}(u, z, \bar z) \right\} = 0, \qquad \left\{ \mathscr{F}[\chi], \bar\lambda_{(-)}(u, z, \bar z) \right\} = -\partial_{\bar z} \chi. \tag{34.166}$$

We see that the photino gets an inhomogeneous shift, implying a new kind of "fermionic gauge transformation." This new and infinite set of symmetries exists for all supersymmetric abelian gauge theories, yet is not a subset of any previously considered local fermionic symmetry.

$\mathcal{N} = 4, 8$

It is an important and outstanding problem to extend this construction to gauge theories with $\mathcal{N} = 4$ supersymmetry or gravity theories with $\mathcal{N} = 8$ supersymmetry. Clearly, conceptually new features will arise from supermultiplets of soft theorems with nonabelian R-symmetry groups. Multiple soft limits are known not to commute in this more general context[99]. At this time, there is not even a conjecture for what the asymptotic symmetry group should be!

The fact that the action of supersymmetry on the fermionic charges/symmetries gives the large gauge charges/symmetries is closely related to an observation of Larkoski [94] that the leading and subleading soft theorems in QED are related by conformal symmetry. Going forward to higher supersymmetry groups, we may encounter a rich structure in which hierarchies of asymptotic symmetries related to leading, subleading, and sub-subleading soft theorems merge into a unified infinite-dimensional symmetry group. This will be interesting indeed to explore.

In Barnich et al. [125], a charge-weighted vacuum partition function that encodes the BMS-degeneracy of the vacuum in three-dimensional gravity was constructed. It would be of interest in supersymmetric theories to define and compute charge-weighted vacuum indices characterizing the degeneracy.

34.2.15 Infrared Divergences

A salient and much-studied feature of QED in the deep infrared is the appearance of IR divergences in the integral over momenta in internal loops [151]. These divergences set all conventional Fock-basis $\mathcal{S}$-matrix elements to zero. Often they are dealt with by restricting to inclusive cross sections in which physically unmeasurable photons below some IR cutoff are traced over. The trace gives a divergence, which offsets the zero and yields a finite result for the physical measurement [6, 208, 209, 7]. While this is adequate for most experimental applications, for some purposes it is nice to have an $\mathcal{S}$-matrix. For example, discussions of unitarity or asymptotic symmetries require an $\mathcal{S}$-matrix.

It is natural to ask whether the considerations of this book bear on the issue of IR divergences. We shall see that they indeed give a satisfying picture: imposing the infinity of conservation laws on amplitudes eliminates some and possibly all IR divergences. To see this, consider Bhabha scattering as illustrated in figure 34.12, in which an incoming electron-positron pair scatters to an outgoing electron-positron pair, with no incoming or outgoing radiation. To restrict attention to $\mathcal{I}$ (rather than $i^{\pm}$), we take the charged particles to be massless.[197] In this case the constraint equations on $\mathcal{I}^+$ imply (see (34.37))

$$\partial_u F^{(2)}_{ru} + \cancelto{0}{D^z F^{(0)}_{uz}} + \cancelto{0}{D^{\bar z} F^{(0)}_{u\bar z}} = -e^2 j^{(2)}_u, \tag{34.167}$$

while on $\mathcal{I}^-$,

$$\partial_v F^{(2)}_{rv} - \cancelto{0}{D^z F^{(0)}_{vz}} - \cancelto{0}{D^{\bar z} F^{(0)}_{v\bar z}} = e^2 j^{(2)}_v. \tag{34.168}$$

Here we have set $F^{(0)}_{uz} = F^{(0)}_{vz} = 0$, as this process involves no radiative modes. $j^{(2)}_v$ and $j^{(2)}_u$ are the electron and positron charge fluxes at $\mathcal{I}$. For example, an outgoing positron at $(u_0, z_0, \bar z_0)$ creates a flux

$$j^{(2)}_u = \gamma^{z\bar z}\delta(u - u_0)\delta^2(z - z_0). \tag{34.169}$$

Since the incoming (outgoing) state is taken to be the vacuum in the far past (future), we should solve (34.168) ((34.167)) with the boundary condition that the Coulomb field vanishes in the far past (future). One then finds that, as long as the scattering angle is nontrivial, the fields cannot obey the matching conditions (34.26)

$$F^{(2)}_{ru}(z, \bar z)\Big|_{\mathcal{I}^+_-} = F^{(2)}_{rv}(z, \bar z)\Big|_{\mathcal{I}^-_+} \tag{34.170}$$

[197] We suppress here the effects of loop corrections in the massless case, which make the coupling run in the deep IR. The qualitatively similar and more realistic massive case is treated in [210].

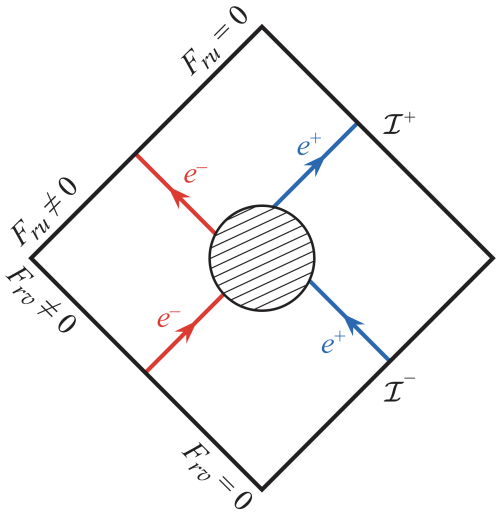

Figure 34.12: **Bhabha scattering, $e^+e^- \to e^+e^-$, involves incoming and outgoing electron-positron pairs unaccompanied by radiative photons. In the massless case depicted, the Maxwell equation implies Coulomb fields on $\mathcal{I}$ to the future of the incoming pair and the past of the outgoing pair. If the scattering angle is nonzero, these Coulomb fields cannot obey the required matching conditions where $\mathcal{I}^+$ and $\mathcal{I}^-$ meet. The amplitude for Bhabha scattering therefore vanishes identically.**

at the boundary of $\mathcal{I}$ near i^0. Therefore Bhabha scattering must vanish identically.

This may sound bizarre at first, but in fact the result is well known and is usually attributed to IR divergences. As depicted in figure 34.13, the tree level one-photon exchange is finite, but the one loop correction is infinite due to IR divergences in pairwise exchanges of soft photons between charged external legs. The source of this divergence is the $\omega \to 0$ pole in the coupling of a soft photon to a charged particle. Including arbitrary numbers of soft photon exchanges and resumming, this divergence exponentiates with a minus sign and sets the full amplitude to zero. Here we have provided a simple physical interpretation of that well-known result. IR divergences are not "real", rather they are a clever trick employed by the Feynman rules to set conservation-law-violating amplitudes to zero!

Finding a new way of computing zero, however, is not enough: we would like to use our insights to construct finite amplitudes. The problem above was the mismatched Coulomb fields produced

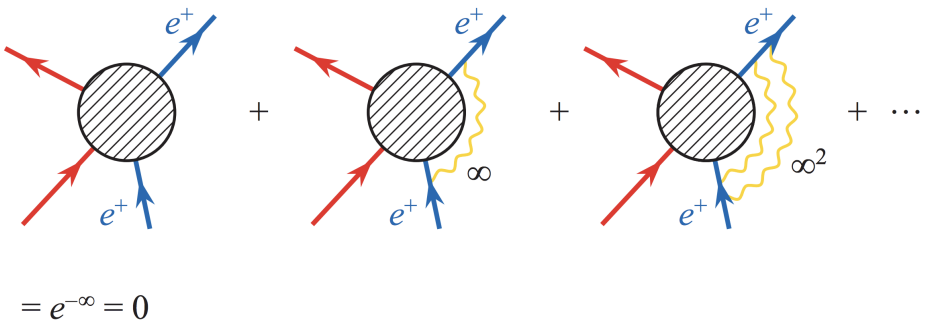

Figure 34.13: **The resummation of IR divergent processes, in which pairs of external charged legs exchange soft photons, sets the amplitude for Bhabha scattering to zero.**

by the asymptotic charge fluxes. This mismatch can be avoided by using radiative, rather than the Coulombic, modes to satisfy the constraints:

$$\begin{aligned} \cancelto{0}{\partial_u F^{(2)}_{ru}} + D^z F^{(0)}_{uz} + D^{\bar z} F^{(0)}_{u\bar z} &= -e^2 j^{(2)}_u, \\ \cancelto{0}{\partial_v F^{(2)}_{rv}} - D^z F^{(0)}_{vz} - D^{\bar z} F^{(0)}_{v\bar z} &= e^2 j^{(2)}_v. \end{aligned} \tag{34.171}$$

For a single outgoing positron, this has the radiative shock wave solution[198]

$$A^{(0)}_z = -\frac{e^2}{4\pi(z-z_0)}\theta(u-u_0). \tag{34.172}$$

The field strength has support only at at $u = u_0$, but the gauge potential is shifted by the shock wave, indicating a transition between the degenerate vacua. Its frequency space Fourier transform has the signature $\omega \to 0$ pole. The corresponding "dressed" coherent quantum state for the outgoing positron,

$$|j_0\rangle_{\text{dressed}} = e^{(\frac{i}{2\pi}\int \frac{d^2z}{z_0-z} A^{(0)}_{\bar z}(u_0,z,\bar z) - h.c.)}|j_0\rangle \ , \tag{34.173}$$

is annihilated by the $\mathcal{I}^+$ constraint equation (34.171) (with the fields promoted to operators). This state can be described as a positron surrounded by a cloud of soft photons. Dressing all the positrons and electrons in this manner, one finds for "dressed" Bhabha scattering[199]

$$F^{(2)}_{ru}(z,\bar z)\Big|_{\mathcal{I}^+_-} = 0 = F^{(2)}_{rv}(z,\bar z)\Big|_{\mathcal{I}^-_+} \ , \tag{34.174}$$

and the matching conditions (34.170) are trivially satisfied. Of course, there are many other ways to satisfy the matching condition, but the example (34.173) is particularly simple and illustrates the main point.

Since the conservation laws are satisfied, there is no reason for dressed Bhabha amplitudes to vanish and no need for IR divergences. In fact, these amplitudes are known to be completely IR finite![200] The dressed state here is a special case of the ones shown by Kulish and Faddeev in 1970 [147] to have IR finite scattering amplitudes. As shown in figure 34.14, there is a pairwise cancellation of IR divergences in soft photon exchanges between pairs of external charges and external charges and soft clouds.[201] We can now understand the role of Faddeev-Kulish clouds as inserting radiative photons to satisfy the conservation laws.

This is progress, but Faddeev-Kulish states are highly nongeneric. When the net charge is zero, they all have vanishing leading radial electric fields near spatial infinity as in (34.174). When it is not zero, the leading electric field is nonzero but is independent of the angle, because the soft photon cloud shields all the angle-dependent components. Such states are unphysical. When pairs of protons are thrown at one another at the LHC, they are not followed up with a finely tuned cloud of soft photons to shield the angle-dependent part of the electric field. The $\mathcal{S}$-matrix $\mathcal{S}_{FK}$ restricted to Faddeev Kulish states is not unitary: rather $\mathcal{S}^\dagger_{FK}\mathcal{S}_{FK} = \mathcal{P}_{FK}$ is a projection operator projecting onto such shielded states. $\mathcal{P}_{FK}$ projects out the states we scatter in accelerator experiments.

It is desirable to have IR finite scattering amplitudes for all physical states. The discussion here suggests that IR divergences arise only to enforce charge conservation. Accordingly, it was conjectured in [210] that all amplitudes allowed by charge conservation are free of IR divergences.[202] As depicted in figure 34.15, a leading order analysis corroborates this conjecture. Let us move the

[198] This solution is singular at $z = \infty$, but in the case of Bhabha scattering with zero net global charge the singularity is cancelled.

[199] When there is net global charge, this procedure sets the leading radial component of the electric field to a nonzero but angle-independent constant.

[200] There are UV divergences in this particular example, as the positrons, electrons, and shock waves are all infinitely localized. These divergences can be eliminated by smearing but are not our interest here.

[201] More generally, cloud-cloud exchanges also participate in the cancellations.

[202] This conjecture was recently proven by R. Akhoury and S. Choi [211].

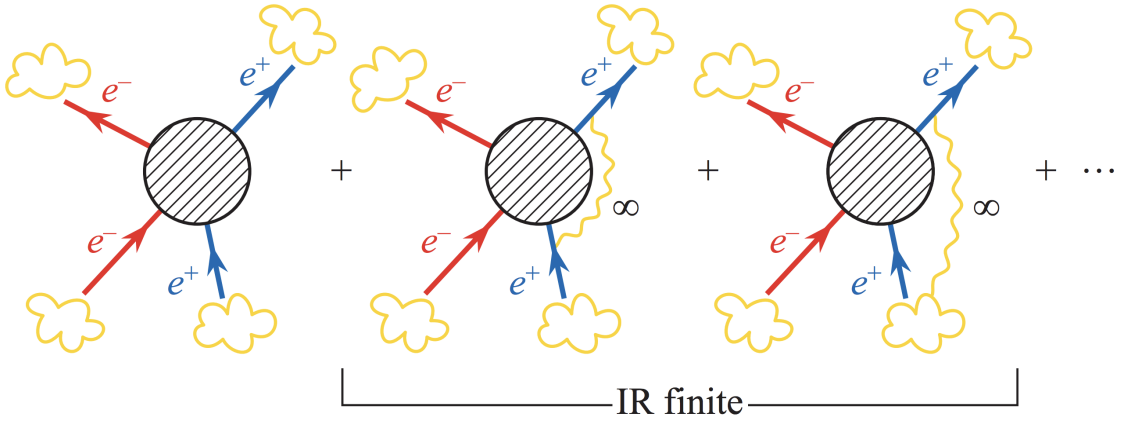

Figure 34.14: **The Faddeev-Kulish mechanism. IR divergences from soft exchanges between external charges are pairwise cancelled by exchanges between external charges and soft photon clouds surrounding each particle.**

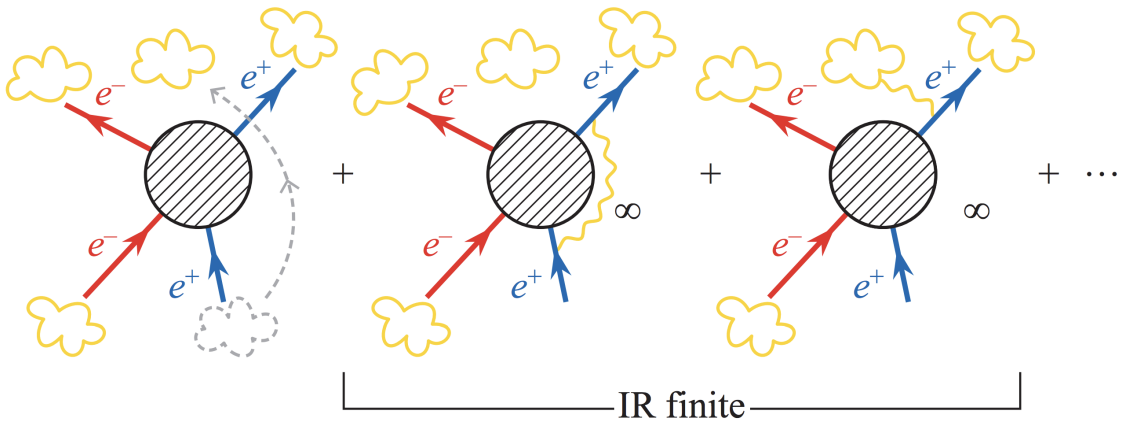

Figure 34.15: **IR divergences from soft exchanges between external charges are pairwise cancelled by exchanges between external charges and soft photon clouds associated with, but not necessarily surrounding, each particle.**

soft cloud surrounding an incoming positron to an antipodal outgoing position in a manner such that all the constraints on $\mathcal{I}$ are still satisfied. This can be done by omitting the incoming positron dressing operator and acting with its hermitian conjugate on the out state. When we move the radiative cloud from $\mathcal{I}^-$ to $\mathcal{I}^+$, the constraints imply nontrivial but matched Coulomb fields will be created near i^0. The original IR divergence from soft photon exchange between the outgoing positron and the soft cloud around the incoming positron is traded for a divergence from exchange between the outgoing positron and the new antipodally positioned outgoing cloud. The soft photon theorem, which takes the same form (up to a sign) for ingoing and outgoing photons, implies that the IR divergent parts of these diagrams are equal, and hence the pairwise cancellation of these leading divergences is still in effect with the repositioned cloud [210].

It is possible to antipodally reposition all the incoming clouds to outgoing ones while maintaining the leading Faddeev-Kulish cancellation of IR divergences. Physical scattering processes at accelerators are described by such incoming charges with no incoming soft clouds. The resulting outgoing soft clouds are then simply identified as the soft radiation inevitably produced in the scattering process.

34.3 The $\mathcal{S}$-matrix as a Celestial Correlator

So far, the framework for our discussion has been the conventional one of an $\mathcal{S}$-matrix that maps an incoming to an outgoing Hilbert space. Multiparticle states in the in- and out-Hilbert spaces are described as asymptotic, noninteracting energy-momentum eigenstates. In this section, we present an alternate description, which for some purposes is both computationally and conceptually more convenient.

The alternate description of scattering [12] is as a type of correlation function on a sphere, depicted in figure 34.16. In the massless case, "in" and "out" massless particles are labelled by

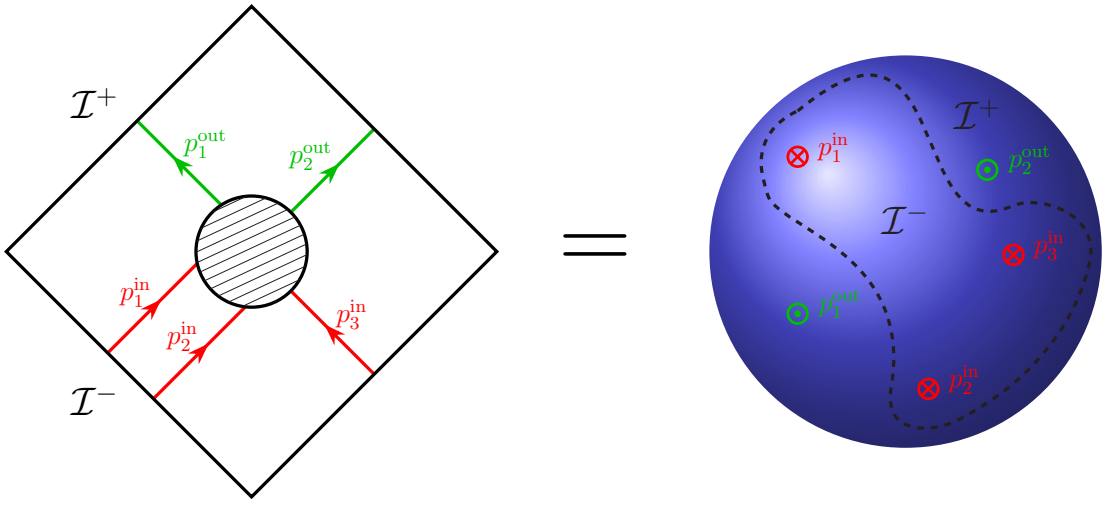

Figure 34.16: **The four-dimensional Minkowski $\mathcal{S}$-matrix for any theory can be rewritten as a two-dimensional correlator on the celestial sphere $\mathcal{CS}^2$, which is parametrized by the asymptotic angle $(z, \bar{z})$ on $\mathcal{I}$. Incoming or outgoing massless particles are represented by operators at the location where they enter $\mathcal{I}^-$ or exit $\mathcal{I}^+$, labeled by quantum numbers such as the energy or boost charge. The angles on $\mathcal{I}^+$ and $\mathcal{I}^-$ are antipodally identified so that a free massless particle enters and exits at the same point on $\mathcal{CS}^2$. The dashed line on $\mathcal{CS}^2$ separates the regions associated with incoming and outgoing particles. The four-dimensional $SL(2,\mathbb{C})$ Lorentz invariance acts as the global two-dimensional conformal group on $\mathcal{CS}^2$.**

operators denoted

$$O_k(z,\bar{z}). \tag{34.175}$$

Here,

$$z = \frac{x^1 + ix^2}{r + x^3} \tag{34.176}$$

denotes the point on the sphere at past or future null infinity where the particle of type k enters or exits the spacetime. This sphere is referred to as the celestial sphere and is denoted $\mathcal{CS}^2$. O_k may depend on other quantum numbers, such as the angular momentum, boost weight, energy, or electromagnetic charge, but we often suppress these labels. The asymptotic angle $(z,\bar{z})$ and either energy or boost weight replace the conventional three-momentum $\vec{p}$ characterizing a massless particle.

Massive particles in energy-momentum eigenstates, in contrast, do not enter or exit spacetime at a definite point on $\mathcal{CS}^2$. Rather, as discussed in section 34.2.12, they enter or exit $i^\pm$ at a definite point on the hyperboloid $\mathbb{H}_3$ in (34.129). They correspond to operators that are smeared on $\mathcal{CS}^2$ with the weighting given by (34.127). Alternately, boost-eigenstate wave functions for massive particles associated to a point on $\mathcal{CS}^2$ can be constructed using the bulk-to-boundary propagator on $\mathbb{H}_3$ [142].

It is then natural to express the n-particle scattering amplitudes in the form of a celestial correlator on $\mathcal{CS}^2$:

$$\langle \text{ out } |\mathcal{S}| \text{ in } \rangle \to \langle\, \mathcal{O}_1(z_1,\bar{z}_1)\cdots\mathcal{O}_n(z_n,\bar{z}_n)\,\rangle. \tag{34.177}$$

Note that no assumptions are being made here; we are simply rewriting the $\mathcal{S}$-matrix in a different notation.

We are interested in Lorentz invariant theories. The four-dimensional Lorentz symmetry is $SL(2,\mathbb{C})$, which acts on $\mathcal{CS}^2$ as

$$z \to \frac{az+b}{cz+d}, \quad ad-bc=1. \tag{34.178}$$

This formula is very familiar to anyone who has studied two-dimensional CFT, because $SL(2,\mathbb{C})$ is the global conformal group of the two-sphere. In quantum field theory, scattering amplitudes must transform covariantly under the Lorentz group, so these correlation functions must transform covariantly under the global conformal group. Hence they must look a lot like the familiar correlation functions in a two-dimensional CFT on the sphere. This connection becomes manifest when the external particle wave functions are taken to be $SL(2,\mathbb{C})$ primaries labeled by their conformal dimensions and location on $\mathcal{CS}^2$ rather than the traditional plane waves [68, 142, 144].

This connection becomes even more interesting later on when we get to quantum gravity. We will see that — up to currently unresolved issues involving IR finite quantum anomalies — the global conformal group gets enhanced to the full local conformal group $z \to w(z)$ that appears in two-dimensional CFT. There is even an operator constructed from soft gravitons [67, 68, 117] whose Ward identities are those of a two-dimensional stress tensor. This likely places powerful constraints on the structure of scattering amplitudes that are currently under investigation [142, 144]. More ambitiously, one may attempt to find a two-dimensional CFT whose correlators on $\mathcal{CS}^2$ reproduce the $\mathcal{S}$-matrix of a four-dimensional quantum theory of gravity. This would provide a microscopic realization of the holographic principle in four-dimensional flat space quantum gravity, or flat space holography.

At this point in the lectures, we are still considering QFT and have not started to discuss gravity in any depth. Nevertheless, if the QFT can be coupled to gravity, it suggests that the celestial correlators (34.177) are those of a two-dimensional CFT, possibly in unusual representations.[203] Indeed, as a simple example we will see in the next section that tree-level celestial correlators involving soft gluons are those of a nonabelian two-dimensional Kac-Moody algebra. A brief discussion of the abelian case already appeared around equation (34.72).

[203] The work of Pasterski et al. and Cardona and Huang [140, 141, 142, 144] suggests that the principal series plays an important role.

34.4 Nonabelian Gauge Theory

Now we turn to another type of soft theorem, namely, the soft gluon theorem. This theorem applies to theories with a nonabelian gauge group $\mathcal{G}$ which is neither confined nor higgsed. Otherwise, there are no soft gluons! Unlike the (leading) soft photon theorem, the soft gluon theorem has corrections at the loop level. These are related to the running of the gauge coupling in the infrared, which affects the coupling constant appearing in front of the hard part of the charges. However, this is not the whole story of quantum corrections. Even in $\mathcal{N} = 4$ Yang-Mills, where the coupling does not run, there are still corrections to the soft gluon theorem that are one-loop exact [110, 111, 112, 113]. I have a little bit to say about this below, but the consequences of these anomalies for the asymptotic symmetries remain to be analyzed. A related issue in gravity was recently addressed in He et al.[117].

Soft theorems are essential for controlling IR divergences and getting IR finite inclusive cross sections. The absence of an uncorrected quantum soft theorem in the nonabelian case is intertwined with the fact that there is no known unitary $\mathcal{S}$-matrix for quantum nonabelian gauge theories, although a large class of IR finite dressed states were constructed in [148, 149] and earlier references therein. For a general state, the best one can do is to define finite inclusive cross sections with an IR cutoff. This is perfectly acceptable for most or all experimental applications, which in practice have an IR cutoff from limits on detector sensitivity. However, it is a problem, for example, for the theoretical studies of $\mathcal{N} = 4$ Yang-Mills scattering amplitudes, which do not actually exist. It is hard to analyze unitarity or symmetries of the $\mathcal{S}$-matrix without an $\mathcal{S}$-matrix! The lack of an $\mathcal{S}$-matrix for these theories is an elephant in the room. We hope that understanding the IR symmetries will enable the construction of a finite unitary $\mathcal{S}$-matrix or a suitable replacement thereof.

In this section, which largely reviews He et al. [12], we sidestep these issues simply by restricting the discussion to tree level. The presentation will proceed a bit differently than that for the abelian case. Rather than discuss a canonical formalism with an in- and out-Hilbert space, it is more efficient to illustrate the physics in the language of celestial correlators discussed in section 34.3. In this language, the scattering of a soft gluon becomes the insertion of a current into a correlation function on $\mathcal{CS}^2$. In section 34.4.1, it is shown that this current obeys the Ward identities of a $\mathcal{G}$-current algebra, which provides a useful alternate representation of the asymptotic symmetry group. In section 34.4.2, we construct the infinity of nonabelian conserved charges.

34.4.1 $\mathcal{G}$-Kac-Moody Algebra

Following the discussion around expression (34.177), we adopt the language of celestial correlators, in which asymptotic particles are represented by operators $\mathcal{O}_k$ on $\mathcal{CS}^2$:

$$\langle \text{ out } | \mathcal{S} | \text{ in } \rangle = \langle \mathcal{O}_1(E_1, z_1, \bar{z}_1) \cdots \mathcal{O}_n(E_n, z_n, \bar{z}_n) \rangle. \tag{34.179}$$

The operators $\mathcal{O}_k$ are taken to be in the kth representation of the nonabelian gauge group $\mathcal{G}$, whose generators satisfy

$$\big[T^a_k, T^b_k\big] = i f^{abc} T^c_k, \tag{34.180}$$

where the f^{abc} are the real, completely antisymmetric structure constants normalized so that

$$f^{acd} f^{bcd} = \delta^{ab} = \mathrm{tr}\big[T^a T^b\big], \tag{34.181}$$

with T^a the generators in the adjoint representation, and the trace is over the suppressed color index. The field strength is constructed from the gauge field $\mathcal{A}_\mu = \mathcal{A}^a_\mu T^a$ as

$$\mathcal{F}_{\mu\nu} = \partial_\mu \mathcal{A}_\nu - \partial_\nu \mathcal{A}_\mu - i\big[\mathcal{A}_\mu, \mathcal{A}_\nu\big] = \mathcal{F}^a_{\mu\nu} T^a \tag{34.182}$$

and obeys the equations of motion

$$\nabla^\nu \mathcal{F}_{\nu\mu} - i\big[\mathcal{A}^\nu, \mathcal{F}_{\nu\mu}\big] = g_{YM}^2 j_\mu^M. \tag{34.183}$$

Here g_{YM} is the gauge coupling, and j^M is the matter color current. The nonabelian gauge transformations act on the gauge and matter fields as

$$\delta_\varepsilon \mathcal{A}_\mu = \partial_\mu \varepsilon - i\big[\mathcal{A}_\mu, \varepsilon\big] \ , \qquad \delta_\varepsilon \phi_k = i\varepsilon^a T_k^a \phi_k \ , \qquad \delta_\varepsilon j_\mu^M = -i\big[j_\mu^M, \varepsilon\big]. \tag{34.184}$$

Near $\mathcal{I}^+$, the gauge field has a large-r expansion as in the abelian case:

$$\begin{aligned} \mathcal{A}_z(u,r,z,\bar z) &= A_z(u,z,\bar z) + \mathcal{O}\left(\frac{1}{r}\right), \\ \mathcal{A}_r(u,r,z,\bar z) &= \frac{1}{r^2} A_r(u,z,\bar z) + \mathcal{O}\left(\frac{1}{r^3}\right), \\ \mathcal{A}_u(u,r,z,\bar z) &= \frac{1}{r} A_u(u,z,\bar z) + \mathcal{O}\left(\frac{1}{r^2}\right). \end{aligned} \tag{34.185}$$

The field strength then has the expansion

$$\mathcal{F}_{ur} = \frac{1}{r^2} F_{ur} + \mathcal{O}\left(\frac{1}{r^3}\right), \qquad \mathcal{F}_{uz} = F_{uz} + \mathcal{O}\left(\frac{1}{r}\right), \qquad \mathcal{F}_{z\bar z} = F_{z\bar z} + \mathcal{O}\left(\frac{1}{r}\right), \tag{34.186}$$

where the leading components are given by

$$F_{ur} = \partial_u A_r + A_u, \qquad F_{uz} = \partial_u A_z, \qquad F_{z\bar z} = \partial_z A_{\bar z} - \partial_{\bar z} A_z - i\big[A_z, A_{\bar z}\big]. \tag{34.187}$$

The asymptotics (34.185) allow large gauge transformations infinitesimally generated by

$$\delta_\varepsilon A_z(u,z,\bar z) = D_z \varepsilon(z,\bar z). \tag{34.188}$$

A finite transformation yields an arbitrary flat $\mathcal{G}$-connection over $\mathcal{CS}^2$. These flat connections label the inequivalent vacua.

In classical Yang-Mills theory, the scattering problem is to find a map from initial data on $\mathcal{I}^-$ to final data on $\mathcal{I}^+$. These data include the connection A_z, as the gauge field explicitly appears in the equations of motion and therefore must be specified as part of the initial Cauchy data on $\mathcal{I}^-$. However, the maximal Cauchy development of incoming data on $\mathcal{I}^-$ via the field equations cannot by itself fully determine the outgoing data on $\mathcal{I}^+$, because given any one solution, another can always be obtained by acting with a large gauge transformation on $\mathcal{I}^+$. As in the abelian case, when there are no long-range magnetic fields,[204] the ambiguity is eliminated, and the scattering problem becomes well defined if we impose the antipodal boundary condition

$$A_z\big|_{\mathcal{I}^+_-} = A_z\big|_{\mathcal{I}^-_+}, \tag{34.189}$$

along with $F_{ru}|_{\mathcal{I}^+_-} = F_{rv}|_{\mathcal{I}^-_+}$. This boundary condition is preserved by large gauge transformations provided the parameter on $\mathcal{I}^+$ is related to the one on $\mathcal{I}^-$ by

$$\varepsilon(z,\bar z)\big|_{\mathcal{I}^+_-} = \varepsilon(z,\bar z)\big|_{\mathcal{I}^-_+}. \tag{34.190}$$

[204] Although it has not been carefully worked out, a generalization that drops this restriction presumably exists, as it is not required in the derivation of the Kac-Moody symmetry which follows.

Hence given any one solution of the scattering problem, infinitely more may be generated by acting on both the in- and the out-data with such a transformation.

Note that the boundary condition (34.189) is required simply for the existence of a well-defined classical scattering problem. The maximal Cauchy development of data on $\mathcal{I}^-$ gives the data on $\mathcal{I}^+$ only up to large gauge transformations. Without an additional condition such as (34.189), we cannot even determine whether the final state is a color singlet. As in the abelian case, the infinity of conservation laws is an immediate consequence of the need for a matching condition, although in this section, we adopt a different approach based on celestial correlators.

The tree-level nonabelian soft theorem can be written

$$\langle\, \mathcal{O}_1(p_1)\cdots\mathcal{O}_n(p_n)\mathcal{O}^a(q,\varepsilon)\,\rangle_{U=1} = g_{YM}\sum_{k=1}^{n}\frac{p_k\cdot\varepsilon}{p_k\cdot q}\langle\, \mathcal{O}_1(p_1)\cdots T^a_k\mathcal{O}_k(p_k)\cdots\mathcal{O}_n(p_n)\,\rangle_{U=1} + \mathcal{O}(q^0). \tag{34.191}$$

Here, $\mathcal{O}^a(q,\varepsilon)$ is the soft gluon operator of momentum q and polarization ε with color index a displayed. In textbook QFT, a state with a red gluon at the south pole and an anti-red gluon at the north pole is usually said to have zero total color charge. This implicitly assumes that the color connection $A_z = U^{-1}\partial_z U$ with $U\in G$ on the S^2 is trivial ($U=1$ or constant) so that the gluon does not change color under parallel transport from the north to the south pole. This assumption is made explicit in (34.191) by the $U=1$ subscript.

In fact, given the boundary condition (34.185), it is not possible in all contexts to choose the color frame $U=1$ everywhere. Consider a generic classical solution with an initially trivial flat connection $A_z=0$ with $U=1$ and a pulse of radiation passing through $\mathcal{I}^+$. The final connection will be flat if the system decays to zero energy, but the equations of motion imply that the final flat connection will not be trivial: $A_z = U^{-1}\partial_z U \neq 0$.[205] A pair of quarks near $\mathcal{I}^+$ initially in a color singlet will generically not be a singlet at late times, due to a change in the color frame. This is the "color memory" effect. An explicit formula for the color memory in terms of a Green's function convoluted with the color flux at $\mathcal{I}^+$, analogous to the one derived for gravity in [41], is given in [40]. As in QED, the nonabelian gauge theory vacua are infinitely degenerate and labeled classically by flat connections.

We define the soft gluon operator at $\mathcal{I}^+$ just as in the abelian case:

$$N_z = \int_{-\infty}^{\infty} du F_{uz} = A_z\big|_{\mathcal{I}^+_+} - A_z\big|_{\mathcal{I}^+_-}. \tag{34.192}$$

Similarly, at $\mathcal{I}^-$,

$$N^-_z = \int_{-\infty}^{\infty} dv F^-_{vz} = A^-_z\big|_{\mathcal{I}^-_+} - A^-_z\big|_{\mathcal{I}^-_-}. \tag{34.193}$$

Finally, we define the soft gluon current

$$J_z = -\frac{4\pi}{g^2_{YM}}\left(N_z - N^-_z\right). \tag{34.194}$$

Trading the operator momenta p_k in (34.191) for z_k and q for z, the soft theorem takes the suggestive form

$$\langle\, J^a_z\mathcal{O}_1(z_1,\bar z_1)\cdots\mathcal{O}_n(z_n,\bar z_n)\,\rangle_{U=1} = \sum_{k=1}^{n}\frac{1}{z-z_k}\langle\, \mathcal{O}_1(z_1,\bar z_1)\cdots T^a_k\mathcal{O}_k(z_k,\bar z_k)\cdots\mathcal{O}_n(z_n,\bar z_n)\,\rangle_{U=1}. \tag{34.195}$$

[205] The boundary condition (34.185) prevents us from gauging this away with a time dependent gauge transformation.

This is a very familiar formula in two-dimensional CFT. It is the Ward identity of a holomorphic Kac-Moody symmetry.[206]

Consider now the weighted integral of the current around a contour $\mathcal{C}$ on $\mathcal{CS}^2$

$$J_{\mathcal{C}}[\varepsilon] = \oint_{\mathcal{C}} \frac{dz}{2\pi i} \mathrm{tr}\left[\varepsilon J_z\right], \tag{34.196}$$

where $\varepsilon(z)$ is any holomorphic function in the interior of $\mathcal{C}$. Insertions of these operators obey

$$\langle\, J_{\mathcal{C}}[\varepsilon]\mathcal{O}_1 \cdots \mathcal{O}_n \,\rangle_{U=1} = \sum_{k\in\mathcal{C}} \langle\, \mathcal{O}_1 \cdots \varepsilon^a(z_k) T^a_k \mathcal{O}_k \cdots \mathcal{O}_n \,\rangle_{U=1}. \tag{34.197}$$

That is, they generate gauge transformations ε inside $\mathcal{C}$.

So far, all the amplitudes have been constructed with the trivial connection $U = 1$ on $\mathcal{CS}^2$. Large gauge transformations change this connection, so we would like to understand the more general case. The Ward identity (34.197) relates $U = 1$ amplitudes to the more general case. Consider, for instance, an infinitesimal change in flat connection

$$\delta U(z, \bar{z}) = i\varepsilon(z, \bar{z}) + \dots . \tag{34.198}$$

Suppose we choose ε so that $\varepsilon = 0$ outside $\mathcal{C}$ and is nonzero and holomorphic in $\mathcal{C}$. Then, the change in the correlator under this shift is simply given by a large gauge transformation of the operators themselves:

$$\begin{aligned} \delta_\varepsilon \langle\, \mathcal{O}_1 \cdots \mathcal{O}_n \,\rangle_{U=1} &\equiv \langle\, \mathcal{O}_1 \cdots \mathcal{O}_n \,\rangle_{U=1+i\varepsilon} - \langle\, \mathcal{O}_1 \cdots \mathcal{O}_n \,\rangle_{U=1} \\ &= i \sum_{k\in\mathcal{C}} \langle\, \mathcal{O}_1 \cdots \varepsilon^a(z_k) T^a_k \mathcal{O}_k \cdots \mathcal{O}_n \,\rangle_{U=1} \\ &= i \langle\, J_{\mathcal{C}}[\varepsilon]\mathcal{O}_1 \cdots \mathcal{O}_n \,\rangle_{U=1}. \end{aligned} \tag{34.199}$$

We can characterize this relation by

$$J_{\mathcal{C}}[\varepsilon] = \int_{R_{\mathcal{C}}} d^2z \gamma_{z\bar{z}} \varepsilon^a \frac{\delta}{\delta U^a}, \tag{34.200}$$

where $R_{\mathcal{C}}$ is the region inside the contour $\mathcal{C}$. In other words, insertions of $J_{\mathcal{C}}[\varepsilon]$ generate locally holomorphic large gauge transformations on the boundary that are characterized by a general flat connection $A_z = U^{-1}\partial_z U$.

34.4.2 Conserved Charges

In section 34.4.1, I presented the soft gluon theorem as a Kac-Moody Ward identity. It is also possible to formulate the entire problem as an infinity of charge conservation laws. The nonabelian analogue of (34.29) is[207]

$$Q^+_\varepsilon = \frac{1}{g^2_{YM}} \int_{\mathcal{I}^+_-} \mathrm{tr}\left[\varepsilon * F\right]. \tag{34.201}$$

[206] There is also an antiholomorphic current $J_{\bar{z}}$, whose insertions are related to negative helicity gluons. One may consider the double soft limits involving either $J_z J_w$ or $J_z J_{\bar{w}}$. It turns out that the former is unambiguous, whereas the latter depends on the order of limits [12]: see exercise 9. This was not the case with photons and begs for interpretation.

[207] As in section 34.2.13, the magnetic generalization is obtained by replacing $*F$ with F in (34.201). It would be interesting to understand the action of S-duality on the electric and magnetic charges.

As before, by integrating by parts and using the nonabelian constraint equations, this can be written as an integral over all of $\mathcal{I}^+$. The final expression contains a soft term Q_ε^{+S} and a hard term Q_ε^{+H}. Similar constructions apply on $\mathcal{I}^-$. The soft term is, of course, related to the current defined here. The precise relationship turns out to be

$$J_{\mathcal{C}}[\varepsilon] = Q_\varepsilon^{-S} - Q_\varepsilon^{+S}. \tag{34.202}$$

The left-hand side depends only on the value of ε on the curve $\mathcal{C}$. This has a meromorphic extension to $\mathcal{CS}^2$. On the right-hand side, we take ε to be given by this extension inside $\mathcal{C}$ and zero outside $\mathcal{C}$. Actually, this procedure gives two possible expressions, depending on which side of $\mathcal{C}$ we regard as the interior. It is illuminating to check that the equivalence of these two expressions is a consequence of the soft theorem.

I close with a comment on loop corrections. Rather than using the soft theorem, the nonabelian conservation law $Q_\varepsilon^+ = Q_\varepsilon^-$ can be derived directly from the nonabelian matching conditions (34.189), as we did for the abelian case. As discussed, such matching conditions are classically required to determine the future color frame from the past one, and without them the scattering problem makes no sense. This suggests that the conservation laws somehow survive the one-loop quantum corrections [110, 111, 112, 113] to the soft theorem, perhaps in a modified or shifted form along the lines discussed for gravity in [117].

34.5 Gravity

Finally we turn to gravity, where the implications of the IR structure become even more far reaching. Oddly, many of the ideas herein were first understood in the gravitational rather than the seemingly simpler gauge-theoretic context. These lectures have presented the material in ahistorical order.

Section 34.5.1 reviews the basics of asymptotically flat spacetimes and Bondi coordinates. Section 34.5.2 begins with a review of the BMS analysis of asymptotic data and the discovery of supertranslations of $\mathcal{I}^+$ and $\mathcal{I}^-$. Then I present the antipodally matched subgroup of past and future supertranslations, which is a symmetry of gravitational scattering. Following the abelian gauge theory case, the conserved charges are derived from the matching condition, shown to generate the symmetry and to imply the leading soft graviton theorem. In section 34.5.3, conserved charges are derived from a matching condition for subleading metric components and their relation to superrotation symmetry (an extension of BMS symmetry), and a new subleading soft theorem are discussed.

34.5.1 Asymptotically Flat Spacetimes

In the previous sections, flat Minkowski space in retarded coordinates near $\mathcal{I}^+$ was described by the metric

$$ds^2 = -du^2 - 2dudr + 2r^2\gamma_{z\bar{z}}dzd\bar{z}. \tag{34.203}$$

We would now like to study gravitational theories in which the metric is asymptotic to, but not exactly equal to, the flat metric. We will work in Bondi coordinates $(u, r, z, \bar{z})$, and we abbreviate $\Theta^A = (z, \bar{z})$. In this gauge, the most general four-dimensional metric takes the form

$$ds^2 = -Udu^2 - 2e^{2\beta}dudr + g_{AB}\left(d\Theta^A + \frac{1}{2}U^A du\right)\left(d\Theta^B + \frac{1}{2}U^B du\right), \tag{34.204}$$

where

$$\partial_r \det\left(\frac{g_{AB}}{r^2}\right) = 0. \tag{34.205}$$

Equation (34.205) implies that r is the luminosity distance. Note that we have completely fixed here the local diffeomorphism invariance by the conditions $g_{rr} = g_{rA} = 0$ together with (34.205). We adopt these coordinates largely because they are used in most of the literature on asymptotically flat spacetimes. However, important insights have arisen in other gauges, such as the harmonic gauge [183, 184], which may ultimately prove more useful.

So far, we have not imposed any sort of asymptotic flatness condition. Any geometry can be described locally by the metric (34.204). Imposing asymptotic flatness at large r with fixed $(u, z, \bar{z})$ leads to falloff conditions on the metric components. There is no a priori preferred method of determining what these falloffs must be, and the literature discusses various options. They are typically chosen to be weak enough to allow for all interesting solutions, including gravity waves, but strong enough to rule out unphysical solutions, such as those with infinite energy. For the natural choice made by Bondi, van der Burg, Metzner, and Sachs (BMS) [9, 8], the large-r structure of the metric is constrained to be (see exercise 10)

$$\begin{aligned} ds^2 = &-du^2 - 2dudr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} \\ &+ \frac{2m_B}{r}du^2 + rC_{zz}dz^2 + rC_{\bar{z}\bar{z}}d\bar{z}^2 + D^zC_{zz}dudz + D^{\bar{z}}C_{\bar{z}\bar{z}}dud\bar{z} \\ &+ \frac{1}{r}\left(\frac{4}{3}(N_z + u\partial_z m_B) - \frac{1}{4}\partial_z(C_{zz}C^{zz})\right)dudz + c.c. + ..., \end{aligned} \tag{34.206}$$

where D_z is the covariant derivative with respect to $\gamma_{z\bar{z}}$; C_{zz}, m_B and N_z depend on $(u, z, \bar{z})$ but not on r. The first three terms in (34.206) are simply the flat Minkowski metric, and the remaining terms are the leading corrections. The ellipsis "..." involves further subleading terms at large r, whose precise structure we will not need. Near $\mathcal{I}^+$, spacetime is flat to leading order, and we can relate the retarded Bondi coordinates to the standard Minkowski coordinates $u = t - r + ...$. Equation (34.206) corresponds to the large r falloffs:

$$\begin{aligned} &g_{uu} = -1 + \mathcal{O}\left(\frac{1}{r}\right), \qquad g_{ur} = -1 + \mathcal{O}\left(\frac{1}{r^2}\right), \qquad g_{uz} = \mathcal{O}(1), \\ &g_{zz} = \mathcal{O}(r), \qquad g_{z\bar{z}} = r^2\gamma_{z\bar{z}} + \mathcal{O}(1)\ , \qquad g_{rr} = g_{rz} = 0. \end{aligned} \tag{34.207}$$

So far, no mention of Einstein's equations has been made. (34.206) is simply a geometric constraint that defines the class of spacetimes that we are interested in studying.

The quantity m_B is known as the Bondi mass aspect. For Kerr spacetimes, $m_B = GM$ is constant and proportional to the mass. However, in a generic spacetime, it will depend on both the retarded time u and on the angle $(z, \bar{z})$. Its integral over the sphere is the total Bondi mass. N_z is known as the angular momentum aspect, because its integrals over the sphere, contracted with a rotational vector field, give the total angular momentum. Our definition here of this term is shifted relative to some of the literature to simplify some formulas below. C_{zz} describes gravitational waves. It is $\frac{1}{r}$-suppressed relative to the leading metric component and is transverse to $\mathcal{I}^+$. The "Bondi news tensor" is defined by

$$N_{zz} = \partial_u C_{zz}. \tag{34.208}$$

It is the gravitational analogue of the field strength $F_{uz} = \partial_u A_z$, and its square is proportional to the energy flux across $\mathcal{I}^+$.

Eventually we will need to supplement (34.207) with additional boundary conditions near the boundaries $\mathcal{I}^+_\pm$ of $\mathcal{I}^+$. If N_{zz} does not fall off fast enough for $u \to \pm\infty$, the solution will have infinite energy. We discuss this in Section 34.5.2.

34.5.2 Supertranslations

We now turn to the asymptotic symmetries of gravitational theories in asymptotically flat spacetimes. As argued by BMS [9, 8], these are generated by diffeomorphisms that preserve both

the Bondi gauge (34.204) as well as the boundary falloffs (34.207). Since researchers were looking for symmetries that act in the asymptotic region where spacetime is almost flat, it was expected that one would reproduce the isometries of flat spacetime itself, namely, the Poincaré group. Had this been the case, GR would reduce to special relativity at large-distances and weak fields. Surprisingly, as we now review, what they got instead was an infinite-dimensional group, now called the BMS group. This contains as a subgroup the finite-dimensional Poincaré group. However, the four global translations are elevated to a whole function's worth of "supertranslations" that act independently on each point of the asymptotic sphere. Moreover, as we shall see, GR does not reduce to special relativity at large distances and weak fields. Instead, a large space of degenerate vacua remains.

BMS Analysis

We will not reproduce here the entire calculation of BMS [9, 8], which is a bit lengthy. We instead make a simplifying assumption that eliminates six Lorentz generators. Namely, we restrict consideration to diffeomorphisms that have the large-r falloffs:

$$\xi^u, \xi^r \sim \mathcal{O}(1) \ , \qquad \xi^z, \xi^{\bar{z}} \sim \mathcal{O}\left(\frac{1}{r}\right) . \tag{34.209}$$

This condition is equivalent to the statement that the vector field is $\mathcal{O}(1)$ at large r in an orthonormal frame, thereby eliminating boosts and rotations that grow with r at infinity. We return to a discussion of these in section 34.5.3.

The Lie derivative of the metric components at large r are then

$$\begin{aligned}
\mathcal{L}_\zeta g_{ur} &= -\partial_u \zeta^u + \mathcal{O}\left(\frac{1}{r}\right) , \\
\mathcal{L}_\zeta g_{zr} &= r^2 \gamma_{z\bar{z}} \partial_r \zeta^{\bar{z}} - \partial_z \zeta^u + \mathcal{O}\left(\frac{1}{r}\right) , \\
\mathcal{L}_\zeta g_{z\bar{z}} &= r \gamma_{z\bar{z}} \left[2\zeta^r + r D_z \zeta^z + r D_{\bar{z}} \zeta^{\bar{z}}\right] + \mathcal{O}(1), \\
\mathcal{L}_\zeta g_{uu} &= -2\partial_u \zeta^u - 2\partial_u \zeta^r + \mathcal{O}\left(\frac{1}{r}\right) .
\end{aligned} \tag{34.210}$$

Then, requiring that the Bondi gauge conditions (34.204) and falloffs (34.207) are both preserved implies that at large r,

$$\zeta = f\partial_u - \frac{1}{r}\left(D^z f \partial_z + D^{\bar{z}} f \partial_{\bar{z}}\right) + D^z D_z f \partial_r + \ldots, \tag{34.211}$$

where $f(z, \bar{z})$ is any function of $(z, \bar{z})$. It turns out that (34.211) also preserves all the remaining conditions. We note here that the last term in (34.211) is derived from the condition that $g_{ur} = -1 + \mathcal{O}\left(\frac{1}{r^2}\right)$. In other formulations of asymptotically flat spacetimes (for instance, the one considered by Newman and Unti [212], where $g_{ur} = -1$), this term takes on a different form. The first two terms are universal and are directly measured by the gravitational memory effect, which we discuss in Section 34.6. The transformations generated by (34.211) are called *supertranslations*, depicted in figure 34.17. They are generalizations of the four translations in Minkowski space. For instance, for $f(z, \bar{z}) =$ constant, (34.211) generates u-translations. What is less obvious, though, is that if $f(z, \bar{z})$ is taken to be the $\ell = 1$ harmonic on the sphere, we retrieve the three spatial translations. The most general f effectively allows separate translations along every null generator of $\mathcal{I}^+$.

Supertranslations transform one geometry into a new, physically inequivalent geometry, despite the fact that they are diffeomorphisms. To see this, consider a solution where an outgoing pulse of gravitational or electromagnetic waves crosses the south pole of $\mathcal{I}^+$, and another pulse crosses

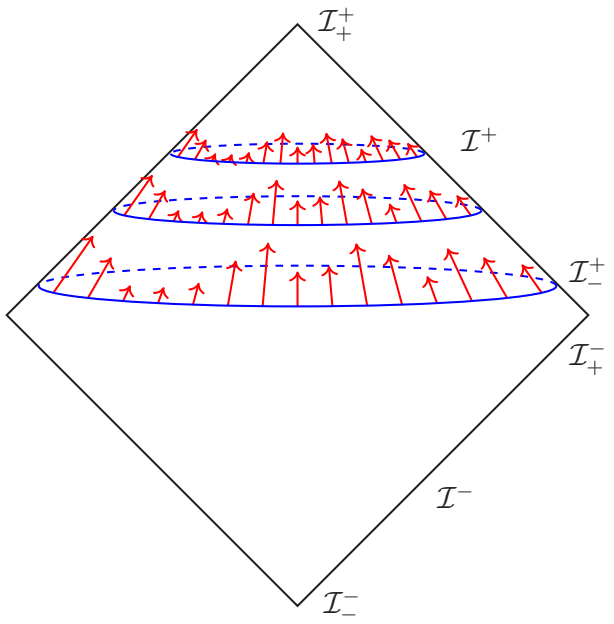

Figure 34.17: **Under a supertranslation, retarded time u is shifted independently at every angle on $\mathcal{I}$.**

the north pole of $\mathcal{I}^+$, both at retarded time $u = 100$. Now supertranslate this solution with a function $f(z, \bar{z})$ that has the property that f(south pole)=100 and f(north pole)=0. The new solution now has one outgoing pulse at the north pole only at $u = 100$ and one at the south pole only at $u = 200$. The outgoing data are measurably changed by the supertranslation.

This simple example shows that the effect of a supertranslation on a solution can be discerned even at the classical level. While the structure here follows the abelian gauge theory case quite closely, the large abelian gauge transformations only modified phases of states and therefore are somewhat quantum in nature. For this reason, it can be less confusing to discuss asymptotic symmetries in the case of gravity. Although supertranslations were not understood to be a symmetry of gravitational scattering until recently [42, 43], the fact that they act nontrivially on the phase spaces at $\mathcal{I}^\pm$ was understood fifty years ago by BMS [8, 9]. It is odd that this symmetry of gravity was at least partially understood fifty years ago, whereas the precisely analogous symmetries in electromagnetism were only understood in the past few years [10, 11, 13, 14]. This is perhaps in part due to the quantum nature of the electromagnetic symmetries.

The action of supertranslations on the $\mathcal{I}^+$ data m_B, C_{zz}, and N_{zz} can be determined by computing the Lie derivative of the appropriate component of the metric and then extracting the appropriate coefficient in the large-r expansion. This process gives (see exercise 11)

$$\begin{aligned} \mathcal{L}_f N_{zz} &= f\partial_u N_{zz}, \\ \mathcal{L}_f m_B &= f\partial_u m_B + \frac{1}{4}\left[N^{zz}D_z^2 f + 2D_z N^{zz} D_z f + c.c.\right], \\ \mathcal{L}_f C_{zz} &= f\partial_u C_{zz} - 2D_z^2 f. \end{aligned} \tag{34.212}$$

The last equation above is especially interesting. Suppose we supertranslate flat Minkowski spacetime described by $m_B = N_{zz} = C_{zz} = 0$. Equation (34.212) implies that the supertranslated spacetime will still have zero Bondi mass and Bondi news and vanishing Riemann tensor. This is consistent with the fact that a diffeomorphism cannot change the physical mass squared or create gravitational waves. However, the supertranslated spacetime does have a nonzero C_{zz}. One may check that the vanishing of the curvature in fact requires

$$C_{zz} = -2D_z^2 C, \tag{34.213}$$

for some function $C(z,\bar{z})$. Under a supertranslation,

$$\mathcal{L}_f C = f. \tag{34.214}$$

Hence C is the Goldstone boson of spontaneously broken supertranslation invariance. It parametrizes the classically inequivalent gravitational vacua. Since the $\ell = 0, 1$ modes of C are annihilated by D_z^2, the four rigid spacetime translations are not broken.

If one drops the overly restrictive falloffs (34.209) on ζ, one obtains the larger BMS$^+$ group which is a semidirect product of supertranslations with Lorentz transformations on $\mathcal{I}^+$. The four spacetime translations are an ideal of BMS$^+$ and so may be canonically identified in any BMS$^+$ frame. In general, there is no preferred Poincaré subgroup of BMS$^+$. Different subgroups are transformed into one another via conjugation by supertranslations. In particular, this implies that there is no BMS$^+$ invariant definition of angular momentum. This is sometimes referred to as "the problem of angular momentum in general relativity," although I view it as a feature, not a bug. However, given any particular classical choice of vacuum, there is a unique Poincaré subgroup of BMS$^+$ under which it is invariant.[208]

So far, we have not utilized any equations of motion. Assume that the geometry is governed by the Einstein equations

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R = 8\pi G T^M_{\mu\nu}. \tag{34.215}$$

Since we are here interested in the structure of null infinity, we assume that $T^M_{\mu\nu}$ is a matter stress tensor corresponding to massless modes.[209] Plugging in the explicit form of the metric (34.206) and expanding in large r, we find that the leading uu component of Einstein's equations is

$$\partial_u m_B = \frac{1}{4}\left[D_z^2 N^{zz} + D_{\bar{z}}^2 N^{\bar{z}\bar{z}}\right] - T_{uu}, \tag{34.216}$$

where

$$T_{uu} = \frac{1}{4} N_{zz} N^{zz} + 4\pi G \lim_{r\to\infty}\left[r^2 T^M_{uu}\right]. \tag{34.217}$$

Equations (34.216) and (34.217) constrain the leading data at $\mathcal{I}^+$. There is an additional constraint involving N_z from the uz component of the Einstein equation. However, (34.216) suffices for our current discussion on supertranslations.

The traceless Bondi news $N_{zz}(u,z,\bar{z})$ comprises two unconstrained real functions on $\mathcal{I}^+$ as expected for the two helicities of the massless graviton. We assume that near the past and future boundaries of $\mathcal{I}^+$, $\mathcal{I}^+_-$ and $\mathcal{I}^+_+$, the news falls off faster than $\frac{1}{|u|}$. These (and stronger) asymptotic boundary conditions were proven by Christodoulou and Klainerman [47] to hold in a finite neighborhood of flat space: here we shall consider spacetimes with this asymptotic behavior but do not require them to be near flat space in the deep interior.[210] The news then trivially determines C_{zz} up to an integration function by integrating (34.208). Moreover, the vanishing of the Weyl tensor at $\mathcal{I}^+_-$ requires $C_{zz}|_{\mathcal{I}^+_-} = -2D_z^2 C|_{\mathcal{I}^+_-}$[42]. Therefore we may take the integration function to be $C|_{\mathcal{I}^+_-}$. Given the news tensor and these initial data at $\mathcal{I}^+_-$, the constraints may be integrated to give the mass m_B and N_z everywhere on $\mathcal{I}^+$. Hence the Cauchy data include

$$\{N_{zz}(u,z,\bar{z}), C(z,\bar{z})|_{\mathcal{I}^+_-}, m_B(z,\bar{z})|_{\mathcal{I}^+_-}\}. \tag{34.218}$$

[208] Thus, classically, there is always an unbroken Poincaré subgroup of BMS$^+$ in flat space. In the quantum theory, a generic superposition of vacua will have only the four global translations as an unbroken symmetry.

[209] The massive case is treated by Campiglia and Laddha [183, 184].

[210] If the news is only required to fall off slowly enough to make the total energy finite, C_{zz} is not well defined at the boundaries $\mathcal{I}^+_\pm$. This is one of the reasons it was thought impossible to match the BMS frames of $\mathcal{I}^\pm$. However, the results of [47] demonstrate that the region of phase space in which the boundary values of C_{zz} are well defined and the matching (given below) is possible is a physically reasonable one.

At higher orders in $\frac{1}{r}$, more data are needed, including $N_z|_{\mathcal{I}^+_-}$. This will be important when we consider superrotations below, but is suppressed for now.

There is an analogous story at $\mathcal{I}^-$. The metric in advanced Bondi coordinates $(v, r, z, \bar{z})$ has the expansion

$$ds^2 = -dv^2 + 2dvdr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} + \frac{2m_B}{r}dv^2 + rC_{zz}dz^2 + rC_{\bar{z}\bar{z}}d\bar{z}^2 + \dots, \tag{34.219}$$

where m_B and C_{zz} depend on $(v, z, \bar{z})$ rather than on $(u, z, \bar{z})$. The angular $(z, \bar{z})$ coordinates on $\mathcal{I}^-$ are as usual antipodal to the ones on $\mathcal{I}^+$, and $v = t + r + \dots$. Supertranslations act on $\mathcal{I}^-$ as

$$\mathcal{L}_f N_{zz} = f\partial_v N_{zz}, \qquad \mathcal{L}_f C_{zz} = f\partial_v C_{zz} + 2D_z^2 f, \tag{34.220}$$

which may be enlarged with boosts and rotations to give the action of BMS$^-$ on $\mathcal{I}^-$. The constraint equation takes the form

$$\partial_v m_B = \frac{1}{4}\left(D_z^2 N^{zz} + D_{\bar{z}}^2 N^{\bar{z}\bar{z}}\right) + T_{vv}, \qquad T_{vv} = \frac{1}{4}N_{zz}N^{zz} + 4\pi G \lim_{r\to\infty}\left[r^2 T^M_{vv}\right]. \tag{34.221}$$

Defining $C_{zz}|_{\mathcal{I}^-_+} = 2D_z^2 C|_{\mathcal{I}^-_+}$, the analog of the Cauchy data (34.218) is

$$\{N_{zz}(v, z, \bar{z}), C(z, \bar{z})|_{\mathcal{I}^-_+}, m_B(z, \bar{z})|_{\mathcal{I}^-_+}\}. \tag{34.222}$$

The scattering problem

The scattering problem in classical general relativity is, roughly speaking, to find the map from Cauchy data on $\mathcal{I}^-$ to that on $\mathcal{I}^+$.[211] Such a map is not even formally determined from the maximal Cauchy development of the $\mathcal{I}^-$ data (34.218) with the Einstein equation. This determines the data on $\mathcal{I}^+$ at most up to a supertranslation, or more generally, a BMS$^+$ frame. A prescription is needed to attach $\mathcal{I}^+$, choose a future BMS$^+$ frame, and determine the initial values for integrating m_B (and N_z) along $\mathcal{I}^+$ using the constraints. *Without such a prescription, the scattering problem in GR is not defined.* In [42] it was proposed that the BMS$^+$ frame should be determined by the Lorentz- and CPT-invariant matching conditions

$$C(z, \bar{z})|_{\mathcal{I}^+_-} = C(z, \bar{z})|_{\mathcal{I}^-_+}, \quad m_B(z, \bar{z})|_{\mathcal{I}^+_-} = m_B(z, \bar{z})|_{\mathcal{I}^-_+}. \tag{34.223}$$

The matching condition for N_z is discussed below. Conditions (34.223) break the combined BMS$^+ \times$ BMS$^-$ action on $\mathcal{I}^+$ and $\mathcal{I}^-$ down to the diagonal subgroup that preserves these conditions, namely,

$$f(z, \bar{z})|_{\mathcal{I}^+_-} = f(z, \bar{z})|_{\mathcal{I}^-_+}\ . \tag{34.224}$$

This condition fixes the BMS$^+$ frame in terms of the BMS$^-$ frame. The diagonal subgroup generated by (34.224) remains as a symmetry of gravitational scattering. Given one solution of the scattering problem, this group generates infinitely many more.

With our conventions, (34.223) *antipodally* equates past and future fields near spatial infinity. We expect that it is the only Lorentz and CPT invariant choice, and it is implicit in most or all GR computations in asymptotically flat spacetimes. The matching condition (34.223) was proven [43] to be implicit to all orders in standard weak field perturbation theory by demonstrating its equivalence to Weinberg's soft graviton theorem [7]. This perturbative analysis motivates the proposal that (34.223) is part of the definition of the scattering problem whenever the fields are sufficiently weak near spatial infinity, even if the interior contains a black hole.

[211] Of course, if a black hole is formed, we need Cauchy data on $\mathcal{I}^+ \cup \mathcal{H}$, where $\mathcal{H}$ is the future horizon, but for now, we assume that black holes are absent.

Conserved Charges

The mere existence of infinitely many matching conditions, one for every point on the celestial sphere, implies an infinite number of conserved charges. Following closely the gauge theory discussion, the supertranslation charges are

$$\begin{aligned} Q_f^+ &= \frac{1}{4\pi G}\int_{\mathcal{I}^+_-} d^2z\gamma_{z\bar{z}} f m_B, \\ Q_f^- &= \frac{1}{4\pi G}\int_{\mathcal{I}^-_+} d^2z\gamma_{z\bar{z}} f m_B. \end{aligned} \tag{34.225}$$

The matching conditions (34.223) immediately imply the conservation law

$$Q_f^+ = Q_f^- \ . \tag{34.226}$$

Integrating by parts, using the constraint equation, and assuming m_B decays to zero in the far future, we can write

$$\begin{aligned} Q_f^+ &= \frac{1}{4\pi G}\int_{\mathcal{I}^+} du d^2z\gamma_{z\bar{z}} f\left[T_{uu} - \frac{1}{4}\left(D_z^2 N^{zz} + D_{\bar{z}}^2 N^{\bar{z}\bar{z}}\right)\right], \\ Q_f^- &= \frac{1}{4\pi G}\int_{\mathcal{I}^-} dv d^2z\gamma_{z\bar{z}} f\left[T_{vv} + \frac{1}{4}\left(D_z^2 N^{zz} + D_{\bar{z}}^2 N^{\bar{z}\bar{z}}\right)\right]. \end{aligned} \tag{34.227}$$

To understand the conservation law better, suppose we take $f(z,\bar{z}) = \delta^2(z-w)$. Then (34.226) implies that the integrated (over u) energy flux at a point w on $\mathcal{I}^+$ is equal to the integrated energy flux at the antipodal point w on $\mathcal{I}^-$:

$$\int_{\mathcal{I}^+} du\gamma_{z\bar{z}}\left[T_{uu} - \frac{1}{4}\left(D_z^2 N^{zz} + D_{\bar{z}}^2 N^{\bar{z}\bar{z}}\right)\right] = \int_{\mathcal{I}^-} dv\gamma_{z\bar{z}}\left[T_{vv} + \frac{1}{4}\left(D_z^2 N^{zz} + D_{\bar{z}}^2 N^{\bar{z}\bar{z}}\right)\right]. \tag{34.228}$$

Here, the local energy at a point includes not only the usual term involving the stress tensor, but also a crucial extra term that is linear in the gravitational field and is also a total u derivative (i.e., it is a soft graviton contribution to the local energy). Thus, the conservation law (34.226) is the statement that *energy is conserved at every angle.*

In the quantum theory, conserved charges commute with the $\mathcal{S}$-matrix:

$$Q_f^+\mathcal{S} - \mathcal{S}Q_f^- = 0. \tag{34.229}$$

We can now sandwich this between in- and out-states. The resulting Ward identity is of course equivalent to Weinberg's soft graviton theorem,

$$\langle \text{ out } | a_+\mathcal{S} | \text{ in } \rangle = \sqrt{8\pi G}\sum_k \frac{\varepsilon^{+\mu\nu} p_{k\mu} p_{k\nu}}{q\cdot p_k}\langle \text{ out } | \mathcal{S} | \text{ in } \rangle, \tag{34.230}$$

where a_+ annihilates a helicity $+$ graviton. We already derived this formula using Feynman diagrams in section 34.2.9. The proof [43] that (34.230) and (34.228) are equivalent is almost exactly the same as in the gauge theory case and is not repeated here.

One expects that, in a Hamiltonian formulation, supertranslation symmetries corresponding to f are generated via Dirac brackets or commutators with Q_f^+:

$$[Q_f^+, ...] = i\delta_f, \qquad [Q_f^+, H] = 0, \qquad H = Q^+_{f=1}. \tag{34.231}$$

This guess turns out to be correct, but, as in the gauge theory case, verification is quite subtle [43]. It requires computing the terms in the symplectic form involving the Goldstone mode C

and the soft graviton mode N. On the physical phase space one must impose the vanishing of the Weyl tensor as a constraint at the boundaries $\mathcal{I}^+_\pm$ of $\mathcal{I}^+$. This changes various commutators by important factors of 2, yielding exactly (34.231). These factors of 2 are, as in the gauge case, related to the fact that soft gravitons and Goldstone modes are both described by a single real scalar field, despite the existence of two polarizations of the former [43].

The existence of these conserved charges is in principle experimentally verifiable. Indeed, proposed tests of the gravitational memory effect [34, 35, 36], although not initially recognized as such, are tests of supertranslation charge conservation [41].

34.5.3 Superrotations

Our analysis so far has centered around C_{zz} and the Bondi mass m_B, which are the first nontrivial corrections to the flat metric near $\mathcal{I}$. Proceeding in the large-r expansion, at the next order we encounter the angular momentum aspect N_z, which bears the same relation to the total angular momentum that the m_B bears to the total mass. In this subsection, we see that the matching condition for N_z leads to conserved superrotation charges, just as the matching condition for m_B led to conserved supertranslation charges.

Conserved Charges

The angular momentum aspect N_z is subject to the constraint equation $G_{uz} = 8\pi G T^M_{uz}$. The leading uz component of the Einstein equations is (compare to (34.216) for the analogous constraint on m_B)

$$\partial_u N_z = \frac{1}{4}\partial_z \left(D_z^2 C^{zz} - D_{\bar{z}}^2 C^{\bar{z}\bar{z}}\right) - u\partial_u \partial_z m_B - T_{uz}. \tag{34.232}$$

Here we have introduced the (rescaled) momentum density in the z-direction of the gravitational field (compare to (34.217) for T_{uu}):

$$T_{uz} \equiv 8\pi G \lim_{r\to\infty}\left[r^2 T^M_{uz}\right] - \frac{1}{4}\partial_z\left(C_{zz}N^{zz}\right) - \frac{1}{2}C_{zz}D_z N^{zz}. \tag{34.233}$$

N_z is constrained in relation to a momentum density T_{uz}, in contrast to m_B, which was constrained in relation to the energy density T_{uu}. Once m_B and C_{zz} are fully specified, then $\partial_u N_z$ is also specified by (34.232). This fixes N_z up to an integration function. We fix this function by the matching condition [57]

$$N_z(z,\bar{z})|_{\mathcal{I}^+_-} = N_z(z,\bar{z})|_{\mathcal{I}^-_+}, \tag{34.234}$$

which is just like the matching condition for m_B. A new subleading soft graviton theorem was proven [56, 213, 214], to all orders using Feynman tree diagrams,[212] and then shown to imply (34.234) [57, 215]. Motivated by this perturbative analysis, we propose that (34.223) and (34.234) are part of the definition of the scattering problem whenever the fields are sufficiently weak near spatial infinity, even if the interior contains a black hole.

Condition (34.234) implies a second infinity of conserved charges, which can be constructed from an arbitrary vector field Y^z on the sphere. Using (34.234), we find

$$Q^+_Y = \frac{1}{8\pi G}\int_{\mathcal{I}^+_-} d^2z (Y_{\bar{z}}N_z + Y_z N_{\bar{z}}) = \frac{1}{8\pi G}\int_{\mathcal{I}^-_+} d^2z (Y_{\bar{z}}N_z + Y_z N_{\bar{z}}) = Q^-_Y. \tag{34.235}$$

[212] Quantum mechanically, (34.234) is possibly deformed by an anomaly at one-loop [110, 112, 111, 113, 79, 114]. Since *some* matching relation of the form (34.234) must exist for gravitational scattering to be defined, this reasoning suggests that these one-loop corrections deform rather than eliminate the conserved charges. This is an important open problem on which recent progress has been made [67, 117, 210].

Equation (34.235) expresses conservation of superrotation charge. The special cases for which Y^z is one of the 6 global conformal Killing vectors on S^2 are conservation of ADM angular momentum and boost charge, sometimes referred to as the BORT (Beig-O'Murchada-Regge-Teitelboim) [216, 217] center-of-mass. Choosing the vector field to be a delta function, these new conservation laws equate net "in" and "out" angular momentum flux for every angle. A recent proposal to test superrotation charge conservation via the gravitational spin memory effect [69] was made by Nichols [70].

Symmetries

Given an infinite number of conserved charges that generalizes angular momentum and boost charges, one naturally expects an infinite number of symmetries generalizing Lorentz transformations. Indeed, conjectures that such a superrotation symmetry exists have been made from several different perspectives, as reviewed in this subsection. We will see that subtleties arise in part because a finite symmetry action changes the asymptotics, the consequences of which remain to be analyzed.

Aspects of superrotation symmetry were implicit in early work of Penrose [218], but were first conjectured in their modern form in the prescient work of de Boer and Solodukhin [52], who were trying to understand holography in Minkowski space. These authors considered the hyperbolic slicing of Minkowski space, which is discussed in section 34.2.12, and argued that the parameter τ that labels the slices should be viewed as the coordinate of an internal space. This describes four-dimensional Minkowski space as a "noncompactification" to the three-dimensional hyperbolas $\mathbb{H}_3$. Because the internal space is noncompact, the effective field theory on $\mathbb{H}_3$ contains a continuum of representations of the Lorentz isometry group. De Boer and Solodukhin [52] conjecture that standard holographic arguments nevertheless apply. In particular, the asymptotic analysis of Brown and Henneaux for AdS_3[200] implies that Lorentz symmetry should be enhanced to the Virasoro symmetry, or equivalently, to superrotations.

A second line of reasoning that leads to superrotations arose while revisiting the original BMS analysis. It was suggested by Banks [53] in a footnote, and independently in greater detail by Barnich and Troessaert [54, 55, 219, 203], that some of the falloff assumptions in BMS are overly restrictive. We now review this illuminating perspective.

In the course of the derivation of the supertranslations in section 34.5.2, an important restriction was imposed: we required that the components of the vector field ζ be bounded in an orthonormal frame as the latter approaches $\mathcal{I}^+$. However, in general this is clearly too strong an assumption, because it rules out both boosts and rotations. One should (and BMS did [8, 9]) do an analysis without that assumption. We now summarize the salient points of this analysis and show along the way how the supertranslations naturally generalize to superrotations.

Lorentz Killing vectors are of the general form

$$\zeta_Y = \left(1+\frac{u}{2r}\right) Y^z \partial_z - \frac{u}{2r} D^{\bar z} D_z Y^z \partial_{\bar z} - \frac{1}{2}(u+r) D_z Y^z \partial_r + \frac{u}{2} D_z Y^z \partial_u + c.c., \tag{34.236}$$

where $(Y^z, Y^{\bar z})$ is a two-dimensional vector field on $\mathcal{CS}^2$. At null infinity ζ_Y simplifies to

$$\zeta_Y|_{\mathcal{I}^+} = Y^z \partial_z + \frac{u}{2} D_z Y^z \partial_u + c.c.. \tag{34.237}$$

The claim is (see exercise 12) that for flat Minkowski space, described by the first three terms of (34.206), if we take

$$Y^z = 1, z, z^2, i, iz, iz^2, \tag{34.238}$$

then the six real vector fields ζ_Y generate the Lorentz transformations.

Instead of restricting ourselves to $Y^z \sim 1, z, z^2$, let us instead compute, for a general Y^z, the Lie derivative with respect to ζ_Y (denoted by $\mathcal{L}_Y$) of various components of the metric. We find

that

$$\mathcal{L}_Y g_{ur} = \mathcal{O}\left(\frac{1}{r^2}\right), \tag{34.239}$$

$$\mathcal{L}_Y g_{zr} = \mathcal{O}\left(\frac{1}{r}\right), \tag{34.240}$$

$$\mathcal{L}_Y g_{z\bar{z}} = \mathcal{O}(r), \tag{34.241}$$

$$\mathcal{L}_Y g_{uu} = \mathcal{O}\left(\frac{1}{r}\right), \tag{34.242}$$

$$\mathcal{L}_Y g_{\bar{z}\bar{z}} = 2r^2\gamma_{z\bar{z}}\partial_{\bar{z}}Y^z + \mathcal{O}(r). \tag{34.243}$$

Let us focus now on the last equation, which is the most important one. The falloff conditions (34.207) are obeyed if the first $\mathcal{O}(r^2)$ term vanishes. This requires that Y^z be a holomorphic vector field. Locally this is solved by $Y^z = z^n$ for any integer n. However, only the restricted choice $Y^z \sim 1, z, z^2$ leads to globally defined vector fields, the six global conformal Killing vector fields of the sphere. BMS discarded all the rest on the grounds that equation (34.243) is violated at isolated points in the more general meromorphic case. For example, if $Y^z = \frac{1}{z-w}$, then

$$\partial_{\bar{z}}Y^z = 2\pi\delta^2(z-w) \neq 0, \tag{34.244}$$

and the falloff condition is violated at $z = w$.[213] The Lie bracket algebra of $Y^z = z^n$ for any n is the centerless Virasoro algebra.

Interestingly, exactly the same equation (34.243) was encountered some 20 years later by Belavin, Polyakov, and Zamolodchikov [221] in analyzing the symmetries of two-dimensional CFTs. However Belavin et al. chose to allow Y^z to be any meromorphic function on the sphere, allowing for analytic singularities. This was a very good idea. While every practitioner of two-dimensional CFT will agree that this is the right thing to do, different explanations are given to support it. One is that the symmetries can be analyzed in a local patch, and singularities outside the patch do not affect the local identities obtained with the symmetry. Another is that the Ward identities of these symmetries provide quick derivations of relations among correlators that can be independently derived using other, more tedious methods. This justification readily adapts to four-dimensional quantum gravity where, as shown in the next subsection, the Ward identities are equivalent to the new subleading soft theorem [56, 213, 214], as well as to the superrotation conservation laws of the previous subsection.

In any case, since allowing meromorphic vector fields was such a good idea in two-dimensional CFT, perhaps we should go beyond the six global vector fields that were retained by BMS in their original analysis and instead consider the whole infinite-dimensional local conformal group generated by $Y^z = z^n$ for all n. This is a tantalizing conjecture, because we have learned an incredible amount about two-dimensional CFTs simply by unraveling the powerful implications of the local conformal = Virasoro group. One may hope for similarly powerful insights into four-dimensional quantum gravity. Perhaps we have even gotten our foot in the door of the long-sought holographic description of quantum gravity in Minkowski space, in which bulk quantum gravity in Minkowski space is dual to an exotic CFT on $\mathcal{CS}^2$. The conjectured superrotation symmetry will be verified at linearized and tree level in section 34.5.3.

Canonical Formalism

It is natural to ask whether superrotation charges generate superrotation symmetries in a canonical formalism. We will see that the answer to this question is yes, but only at linearized order. As discussed at the end of this subsection, singularities prevent the exponentiation of the infinitesimal transformations.

[213] This violation can be physically interpreted as due to cosmic strings [220].

As with supertranslations, we begin by investigating how the boundary data specifying the geometry change under superrotations; see Barnich and Troessaert [203] for further details. The Lie derivative with respect to Y (denoted δ_Y) of the C_{zz} component of the metric is given by

$$\delta_Y C_{zz} = \frac{u}{2} D \cdot Y N_{zz} + Y \cdot D C_{zz} - \frac{1}{2} D \cdot Y C_{zz} + 2 D_z Y^z C_{zz} - u D_z^3 Y^z. \tag{34.245}$$

Taking the u derivative yields

$$\delta_Y N_{zz} = \frac{u}{2} D \cdot Y \partial_u N_{zz} + Y \cdot D N_{zz} + 2 D_z Y^z N_{zz} - D_z^3 Y^z. \tag{34.246}$$

Note that if we sit at $u = 0$, then the last three terms in (34.246) are exactly the infinitesimal transformation law of a stress tensor in a two-dimensional CFT (i.e., the linearization of the Schwarzian derivative).

Now consider the conserved superrotation charge

$$Q_Y^+ = \frac{1}{8\pi G} \int_{\mathcal{I}_-^+} d^2 z [Y_{\bar{z}} N_z + Y_z N_{\bar{z}}] \ . \tag{34.247}$$

Integrating by parts and using the constraints (34.232) gives

$$\begin{aligned} Q_Y^+ &= Q_H^+ + Q_S^+, \\ Q_S^+ &= -\frac{1}{16\pi G} \int_{\mathcal{I}^+} du d^2 z [D_z^3 Y^z u N^z{}_{\bar{z}} + D_{\bar{z}}^3 Y^{\bar{z}} u N^{\bar{z}}{}_z], \\ Q_H^+ &= \frac{1}{8\pi G} \int_{\mathcal{I}^+} du d^2 z \left(Y_{\bar{z}} T_{uz} + Y_z T_{u\bar{z}} + u \partial_z Y_{\bar{z}} T_{uu} + u \partial_{\bar{z}} Y_z T_{uu} \right), \end{aligned} \tag{34.248}$$

where the graviton stress-energy component T_{uz} was defined in (34.233). The soft charges are linear in the metric flutuation C_{zz}, while the hard charge is quadratic. To compute commutators, we need [222, 223, 224, 49]

$$[N_{\bar{z}\bar{z}}(u, z, \bar{z}), C_{ww}(u', w, \bar{w})] = 16\pi G i \gamma_{z\bar{z}} \delta^2(z - w) \delta(u - u'). \tag{34.249}$$

It follows that

$$\left[Q_S^+, C_{zz}\right] = -i u D_z^3 Y^z, \tag{34.250}$$

$$\left[Q_H^+, C_{zz}\right] = \frac{iu}{2} D \cdot Y N_{zz} + i Y \cdot D C_{zz} - \frac{i}{2} D \cdot Y C_{zz} + 2 i D_z Y^z C_{zz}. \tag{34.251}$$

Putting this together, we conclude that

$$\left[Q_Y^+, ...\right] = i \delta_Y. \tag{34.252}$$

The conserved charge generates the symmetry as expected.

However, something is not quite right. Commutators with Q_Y^+ shift the news by a function that goes to a constant at $\mathcal{I}_\pm^+$, while C_{zz} diverges linearly. Such behavior violates the boundary conditions we started off with and hence maps points in the initially defined phase space to points outside that phase space. To make good sense of this behavior, we need to define a larger phase space. This is related to the observation [220] that singularities produced by superrotations correspond to cosmic strings, which destroy asymptotic flatness. Hence, to fully understand superrotations, we will at a minimum need to consider a larger phase space that allows for such defects. This is a topic for future investigations.

Subleading Soft Theorem

Given the infinities of conserved superrotation charges and symmetries, one expects an associated soft theorem. There is of course Weinberg's soft graviton theorem, but we have already seen that this is equivalent to supertranslations. Invoking the IR triangle (Section 34.1.1) leads to the conclusion that there must be a second soft theorem in gravity. Indeed, motivated by this observation, a new subleading soft theorem was proven diagrammatically [56, 63, 64, 65] and shown [57, 66] to be equivalent to the superrotation charge conservation equation (34.235). This logic can be turned around and the subleading soft theorem used to prove (34.235).

At the level of the quantum $\mathcal{S}$-matrix, superrotation charge conservation states

$$\langle \text{out}| \left(Q_Y^+ \mathcal{S} - \mathcal{S} Q_Y^-\right) |\text{in}\rangle = 0. \tag{34.253}$$

From the decomposition (34.248) it is clear that this identity equates a soft graviton insertion to a hard term. Equation (34.253) is most directly expressed in terms of the $(z_k, \bar{z}_k)$ coordinates at which asymptotic particles pierce $\mathcal{CS}^2$. After quite a lengthy calculation [57] using relations such as (34.87) and setting $Y^z = \frac{1}{z-(q^1+iq^2/q^0+q^3)}$, one finds this equation can be reexpressed in momentum space as

$$\begin{aligned} \lim_{\omega\to 0} (1+\omega\partial_\omega) \langle p_{n+1}, p_{n+2}, ...| \, a_-(q)\mathcal{S} \, |p_1, p_2, ...\rangle = \\ \sqrt{8\pi G} S^{(1)-} \langle p_{n+1}, p_{n+2}, ...| \, \mathcal{S} \, |p_1, p_2, ...\rangle \, , \end{aligned} \tag{34.254}$$

where $a_-(q)$ is the annihilation operator for a negative helicity graviton of four-momentum $q = \omega(1, \hat{q})$, and the subleading soft factor is

$$S^{(1)-} = -i \sum_k \frac{p_{k\mu} \varepsilon^{-\mu\nu} q^\lambda J_{k\lambda\nu}}{p_k \cdot q}, \quad J_{k\mu\nu} \equiv L_{k\mu\nu} + S_{k\mu\nu}, \tag{34.255}$$

with $L_{k\mu\nu}$ the orbital angular momentum and $S_{k\mu\nu}$ the helicity of the internal spin of the kth particle. In reference [56] it was directly shown, through some diagrammatics far more tedious than Weinberg's, that this subleading expression is valid at tree level. This confirms the classical existence of an infinite number of conserved superrotation charges.

Comments about this soft relation are now in order. Recall from our discussion of supertranslations that the addition of a soft graviton to a scattering amplitude produces a Weinberg pole proportional to $1/\omega$. But here, the prefactor $(1+\omega\partial_\omega)$ projects out this pole, eliminates the leading divergence and leaves the finite, subleading $\mathcal{O}(1)$ piece (note the factors of q in both the numerator and denominator of (34.255)). We see there is a universal form not just for the leading but also for the subleading part of the amplitude in the soft limit. Although we have not discussed it, a similar (and much older) story exists for QED: there is also a subleading soft theorem discovered in 1958 by Low [4]. Following the triangle, it is also related to a new symmetry in gauge theory, as discussed in [60, 61].

The subleading soft factor $S^{(1)-}$ can be obtained from the leading soft factor by replacing p_ν with $q^\mu J_{k\mu\nu}$, in other words, by replacing translations with rotations about q. This makes sense, because the first term in the hard piece Q_H^+ is $Y^z T_{uz}$, which generates a rotation around the axis through which the particle is emerging, whereas the hard part of the supertranslation-generating charge involves fT_{uu}. This relation can be made more precise by looking at details of geodesics with nonzero angular momentum, for which it can be shown that the replacement $fT_{uu} \to Y^z T_{uz}$ is akin to the replacement $p_\nu \to q^\mu J_{k\mu\nu}$, with q the direction around which the rotation is performed. Indeed, this is how the soft formula was first guessed before it was properly derived.

While I do not reproduce the diagrammatic proof of the subleading soft graviton theorem here, I present a simple but important consistency check. Recall that the Weinberg soft graviton theorem involves the leading soft factor

$$\sum_k \frac{\varepsilon^{\mu\nu} p_{k\mu} p_{k\nu}}{p_k \cdot q}, \tag{34.256}$$

which for consistency had better vanish for pure gauge gravitons, that is, when

$$\varepsilon^{\mu\nu} = \Lambda^\mu q^\nu. \tag{34.257}$$

Indeed, with this choice, the soft factor (34.256) becomes

$$\Lambda^\mu \sum_k \frac{p_{k\mu} p_k \cdot q}{p_k \cdot q} = \Lambda^\mu \sum_k p_{k\mu} = 0, \tag{34.258}$$

where the last equality follows from energy-momentum conservation.

Consistency demands that a similar property hold for our new expression for $S^{(1)}(\epsilon_\Lambda)$. Since it is not automatically symmetric, let us now insert

$$\varepsilon_\Lambda^{\mu\nu} = q^\mu \Lambda^\nu + q^\nu \Lambda^\mu \tag{34.259}$$

and hence find that

$$iS^{(1)}(\varepsilon_\Lambda) = q^\mu \Lambda^\nu \sum_k J_{k\mu\nu} + \sum_k \frac{p_k \cdot \Lambda q^\mu q^\nu J_{k\mu\nu}}{p_k \cdot q} = 0, \tag{34.260}$$

as required. In the last step, the second term vanishes just because $J_{k\mu\nu}$ is antisymmetric while $q^\mu q^\nu$ is symmetric. Meanwhile, the first term vanishes by angular momentum conservation. We again see that angular momentum is to superrotations as energy-momentum is to supertranslations.

A powerful reformulation of superrotational invariance has recently been achieved in the celestial language of section 34.3. References [67, 68] construct a four-dimensional soft operator whose amplitudes are precisely those of a two-dimensional CFT stress tensor.

34.6 The Memory Effect

In this section, we describe the third corner of the IR triangle, the memory effect. In the case of gravity, the memory effect characterizes a pair of inertial detectors stationed near $\mathcal{I}^+$ in a region with no Bondi news at both late and early times. At intermediate times, gravity waves may pass through, causing oscillating distortions in their relative separations, which we denote $(s^z, s^{\bar{z}})$ and depict in figure 34.18. The equation of geodesic deviation implies (see exercise 13)

$$r^2 \gamma_{z\bar{z}} \partial_u^2 s^{\bar{z}} = -R_{uzuz} s^z \ , \tag{34.261}$$

where

$$R_{uzuz} = -\frac{r}{2} \partial_u^2 C_{zz} \ . \tag{34.262}$$

Integrating this equation reveals a DC effect. Namely, the initial and final separations differ by (in retarded coordinates)

$$\Delta s^{\bar{z}} = \frac{\gamma^{z\bar{z}}}{2r} \Delta C_{zz} s^z \ . \tag{34.263}$$

This is the gravitational memory effect [23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33]. The difference ΔC_{zz} between initial and final transverse metric components need not vanish, as flatness does not require $C_{zz} = 0$. Proposals to measure the gravitational memory effect with a variety of methods are given in Lasky et al. and van Haasteren and Levin [34, 35].

The effect is harder to see than gravity waves themselves but has a decent chance of being measured in the coming decades. The connection of the memory effect with basic symmetries of gravity makes this an exciting prospect.

A quick way [41] to see the equivalence of gravitational memory to the soft graviton theorem is to compare formulas in the original literature. An excerpt with the central formula for the outgoing metric fluctuation sourced by elementary particle collisions from Weinberg [7] is

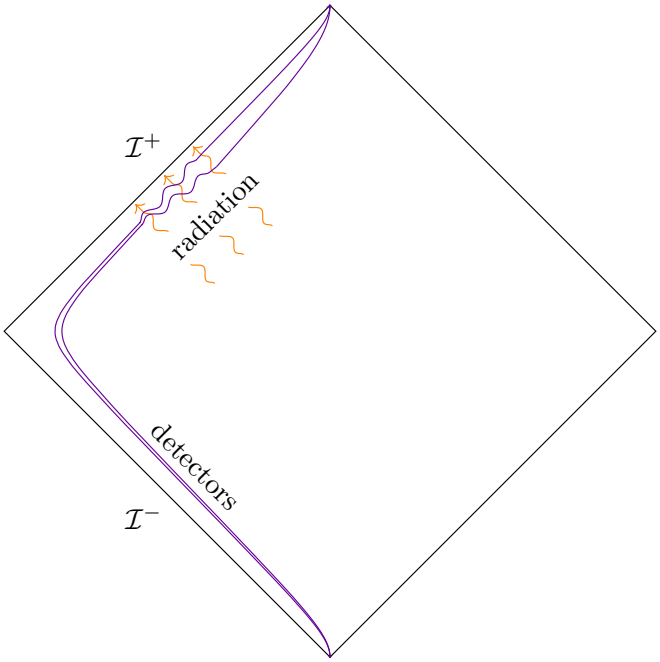

Figure 34.18: **The memory effect. The passage of gravitational radiation past a pair of inertial detectors stationed near $\mathcal{I}^+$ causes a temporary oscillation in their relative positions followed by a permanent displacement which "remembers" certain moments of the energy flux.**

The dominance of the $1/(p\cdot q)$ pole in (2.5) implies that the effect of attaching one soft-graviton line to an arbitrary diagram is to supply a factor equal to the sum of (2.5) over all external lines in the diagram

$$(8\pi G)^{1/2}\sum_n \eta_n p_n{}^\mu p_n{}^\nu/[p_n\cdot q - i\eta_n\epsilon]. \qquad (2.7)$$

It is interesting to compare this to the central equation for the DC shift in the outgoing metric sourced by black hole or neutron star collisons in Braginsky and Thorne [25]:

permanent change in the gravitational-wave field (the burst's memory) δh_{ij}^{TT} is equal to the 'transverse, traceless (TT) part'[36] of the time-independent, Coulomb-type, $1/r$ field of the final system minus that of the initial system. If $\mathbf{P}^A$ is the 4-momentum of mass A of the system and P_i^A is a spatial component of that 4-momentum in the rest frame of the distant observer, and if $\mathbf{k}$ is the past-directed null 4-vector from observer to source, then δh_{ij}^{TT} has the following form:

$$\delta h_{ij}^{TT} = \delta\left(\sum_A \frac{4P_i^A P_j^A}{\mathbf{k}\cdot\mathbf{P}^A}\right)^{TT} \qquad (1)$$

Here we use units with $G = c = 1$. In the observer's local Car-

A glance reveals that the two equations are indeed strikingly similar! In fact, to see that they are identical, not just similar, requires a conversion of notation and a Fourier transform, as follows [41]:

- Replace the four-momenta P_i^A of colliding stars or black holes with the four-momenta p_n^μ of elementary particles.
- Account for the different conventions for Newton's constant G and normalization.
- Substitute the graviton momentum q with its energy ω times the unit null vector k via $q = \omega k$.

- Act with a Fourier transform $\int dt e^{i\omega t}$ on the Weinberg momentum-space formula to obtain the Braginsky-Thorne formula for the difference between the initial and final transverse metric components.

The fact that identical formulas were independently derived, using wildly different methods, for both the collisions of black holes and the collisions of elementary particles is a testimony to the universality of the IR phenomena discussed in these lectures. At very long distances, astrophysical black holes and elementary particles are both effectively pointlike!

Universal phenomena are often related to symmetries. Since the memory effect is a Fourier transform of the soft theorem, and the soft theorem is the Ward identity of supertranslation symmetry, there should be a direct connection between memory and supertranslations that does not involve soft theorems. To derive this connection, note that if there is no energy flux or retarded time dependence of the asymptotic data at late and early times, C_{zz} must vanish up to a supertranslation:

$$C_{zz}^{\text{early}} = -2D_z^2 C^{\text{early}}, \qquad C_{zz}^{\text{late}} = -2D_z^2 C^{\text{late}} \ , \tag{34.264}$$

where $\partial_u C^{\text{early}} = \partial_u C^{\text{late}} = 0$. The early and late geometries are related by a supertranslation

$$\Delta C = C^{\text{late}} - C^{\text{early}} \ . \tag{34.265}$$

Hence we can think of a pulse of radiation passing through $\mathcal{I}^+$ as a domain wall separating diffeomorphic but BMS-inequivalent vacua. Using the constraint equation (34.216), we find

$$D_z^2 \Delta C^{zz} = 2\Delta m_B + 2\int du T_{uu} \ , \tag{34.266}$$

where the u-integral extends from the early to the late regions. Solving this differential equation, it follows that

$$\Delta C(z,\bar{z}) = -\int d^2w \gamma_{w\bar{w}} G(z,\bar{z};w,\bar{w}) \left(\int du T_{uu}(w,\bar{w}) + \Delta m_B \right) \ , \tag{34.267}$$

where the Green's function is

$$G(z,\bar{z};z',\bar{z}') = \frac{1}{\pi} \sin^2 \frac{\Delta\Theta}{2} \log \sin^2 \frac{\Delta\Theta}{2} \ , \tag{34.268}$$

with $\Delta\Theta$ the angle on $\mathcal{CS}^2$ between $(z,\bar{z})$ and $(z',\bar{z}')$. This is an explicit formula for the supertranslation induced by waves (gravity or otherwise) passing through $\mathcal{I}^+$. One of its unusual characteristics is that it is highly nonlocal on $\mathcal{CS}^2$. Indeed, if a gravity wave passes through the north pole, the effect vanishes both there and at the south pole but is large near the equator.

The relative displacements (34.263) of inertial detectors have a simple explanation in this framework. Imagine tiling $\mathcal{CS}^2$ with initially evenly spaced inertial detectors. Passage of a gravity wave will adjust the relative $(z,\bar{z})$ positions by amounts of order $\frac{1}{r}$, defining a diffeomorphism on $\mathcal{CS}^2$, as depicted in figure 34.19. This was shown [41] to be exactly the angular diffeomorphism appearing in the subleading term of the supertranslation vector field (34.211). It would be exciting indeed to observe these supertranslations in the sky!

The gravitational memory effect imparts a physical meaning to the soft graviton theorem. Soft gravitons may seem a bit unphysical, because it takes longer and longer to measure them as the energy goes to zero. Surprisingly, despite this, the memory effect can be measured in a finite time, because the Fourier transform of the Weinberg pole is a step function in retarded time.

This completes the third leg of the triangle containing Weinberg's soft graviton theorem and asymptotic BMS symmetries. Memory is connected to the soft theorem by a Fourier transform and measures transitions between BMS-inequivalent vacua. There are other kinds of memory effects associated with other triangles. Taking the Fourier transform of the subleading soft theorem led to a new gravitational memory effect called spin memory [69], which gives relative time delays to

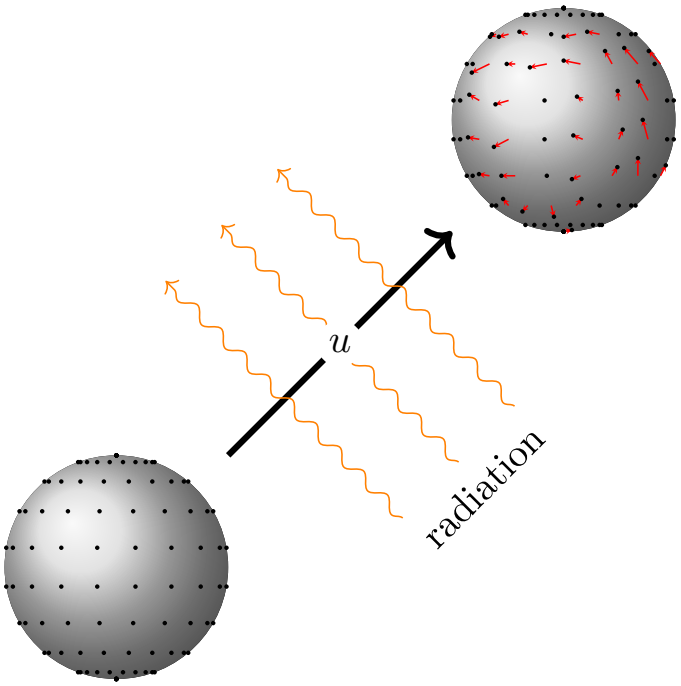

Figure 34.19: **An array of evenly spaced inertial detectors (black dots) on the sphere near $\mathcal{I}^+$ will be permanently displaced (red arrows) by the passage of gravitational radiation. The displacements are a measurement of the BMS diffeomorphism, which relates the vacua before and after the passage of the radiation.**

counterorbiting objects and might be measurable [70]. In (unconfined and unhiggsed) nonabelian gauge theory, the color memory effect rotates the relative colors of nearby quarks [40]. If a pulse of gluons passes a pair of initially singlet quarks, it will generically no longer be in a singlet. In abelian gauge theories, such as QED, the electromagnetic memory effect gives relative phases to adjacent charged particles, which can be measured by quantum interference or other experiments, as recently discussed in the literature [37, 201, 38, 39].

34.7 Black Holes

So far, black holes have barely been mentioned. It turns out that the IR triangle is highly relevant to the behavior of black holes and to the famous information paradox [161]. While many of the implications of the IR symmetries for black hole physics are topics of current investigation and remain to be fully understood, others follow straightforwardly from the groundwork laid in these lectures. Some of the latter already well understood material is described in this section, with occasional pointers to open problems.

We begin in section 34.7.1 with a lightning review of the information paradox. In section 34.7.2, it is shown that the infinity of conservation laws requires that black holes must carry corresponding "soft hair", invalidating Hawking's argument [161] that information is destroyed. In section 34.7.2, the properties of soft hair are perturbatively described at the classical level. Section 34.7.2 constructs the horizon contribution to the linearized supertranslation charge and shows that this charge generates horizon supertranslations. Quantum aspects of soft hair and its relation to soft gravitons on the horizon are discussed in section 34.7.2. The electromagnetic version involving soft photons is in section 34.7.2. Future outlook and the status of the information paradox are discussed in section 34.7.3.

34.7.1 The Information Paradox

There are many ways to characterize the information paradox, but perhaps the most striking is in the formation and total evaporation of a black hole in an asymptotically flat space. We begin with the process of black hole formation, which is classically described by the Penrose diagram in figure 34.20. One could consider a more generic collapsing geometry, but it is useful to be specific.

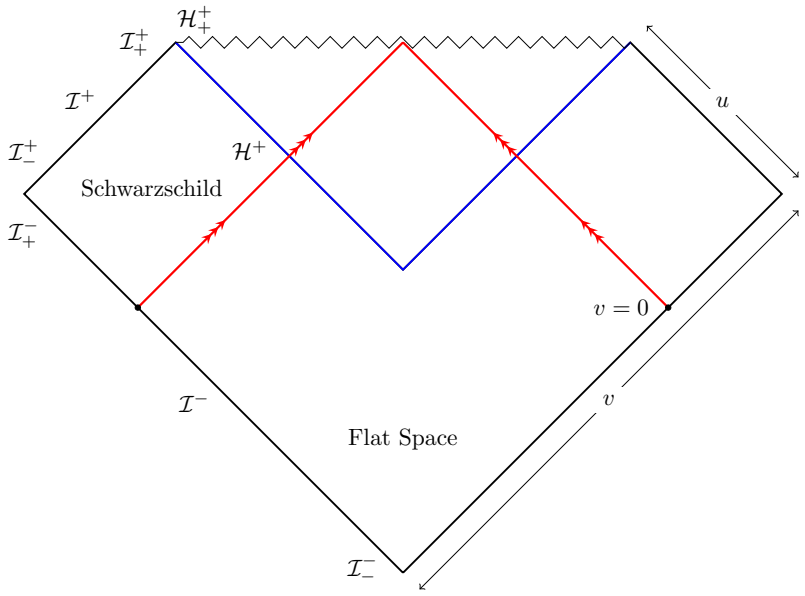

Figure 34.20: **Vaidya geometry. The red lines denote a null spherical shockwave imploding at advanced time $v = 0$. When the shockwave crosses its Schwarzschild radius, the (blue) event horizon forms. The causal future of the event horizon is the black hole and ends at the jagged singularity.**

In this picture, the far past is empty flat space. Then at advanced time $v = 0$, a null shockwave with total energy M is sent in. This infinitely thin collapsing shell of matter eventually forms a Schwarzschild black hole of mass M. The resulting spacetime geometry can be described by the Vaidya metric, which in advanced coordinates takes the form

$$ds^2 = -\left(1 - \frac{2MG\theta(v)}{r}\right) dv^2 + 2dvdr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} \ , \tag{34.269}$$

where θ denotes the step function

$$\theta(v) = \begin{cases} 0 & \text{if } v < 0 \ , \\ 1 & \text{if } v \geq 0 \ . \end{cases} \tag{34.270}$$

This metric evidently describes flat space before the passing of the shockwave and a Schwarzschild black hole after. The two regions are glued along the shockwave of infalling matter, whose collapse results in the creation of an event horizon, that is, a region from which light rays cannot escape to infinity (depicted in blue). The spacelike singularity is hidden behind the horizon.

More generally, the collapsing matter may have arbitrary multipole moments and may not be spherically symmetric. However, according to the usual interpretation (which we question below) of the no-hair theorem [225], regardless of how it is formed, after a rather short time scale (roughly speaking, the light-crossing time of the black hole), it will settle down to a stationary state that is characterized by only ten conserved Poincaré charges: the energy-momentum $(E, \vec{P})$, the total

angular momentum $\vec{J}$ and the boost charge or BORT center of mass $\vec{K}$. The standard statement is that a black hole in Einstein gravity has ten hairs, or equivalently, the phase space is ten-dimensional.[214] Of course, in the presence of gauge fields, there may be more, such as the total electric charge, but we ignore these for the moment.

Quantum mechanically, the situation differs radically. If we wait a long time, the black hole will eventually evaporate [226]. This leads to the qualitatively different picture in figure 34.21. As

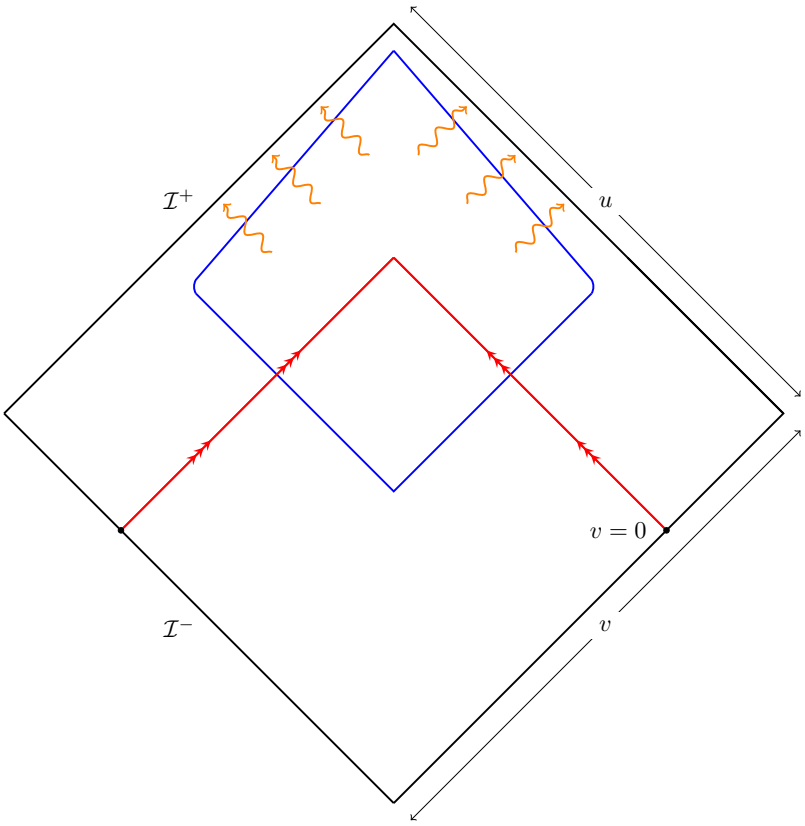

Figure 34.21: **Evaporating black hole. The red collapsing shell makes a black hole, which at early times, looks just like the classical black hole of figure 34.20. However, at late times the black hole evaporates. This process causes the horizon, depicted in blue, to become timelike, and the black hole eventually disappears. In the far future the system reverts to a vacuum state.**

before, we first throw in a shockwave to create the black hole. Then, after a very long time, the black hole begins to evaporate. Since classical black holes do not evaporate, this must take a period of time that goes to infinity as $\hbar \to 0$. As long as $\hbar > 0$, however, the black hole eventually starts to Hawking evaporate, becoming smaller and smaller until (assuming no remnants) it ultimately disappears altogether, as illustrated at the top of the diagram.

Hawking gave a semiclassical derivation of the spectrum of radiated particles in his famous 1975 paper [226]. He found a blackbody spectrum with a temperature given by the Hawking temperature,

$$T_H = \frac{\hbar}{8\pi G M} \ . \tag{34.271}$$

[214] Of these, only two — the magnitude of the intrinsic spin J and mass $M = \sqrt{E^2 - \vec{P}^2}$ — are invariant under Poincaré transformations.

Moreover, he argued that the outgoing Hawking radiation does not carry any information about what formed the black hole. The radiation results from a pair production process outside the horizon, in which a negative energy particle goes into the black hole and is correlated with a positive energy particle going out to infinity. This process is insensitive to all details concerning the interior of the black hole. The no-hair theorem is invoked in this argument to conclude that the exterior contains no information about the formation process. We could have made the black hole of red, green, or blue matter, but since the final geometry is the same in all cases, so must be the outgoing Hawking radiation. Finally, the black hole is presumed to eventually decay to the vacuum, traditionally assumed to be unique (also questioned below) and incapable of storing information. Hence, Hawking argued [161], all information falling into the black hole has no place to go and is destroyed in the formation/evaporation process.

Both in Hawking's argument and in figure 34.21, a divide is placed between the periods of black hole formation and evaporation. It is assumed that quantum effects are negligible during formation and that during evaporation the black hole can be approximated as stationary. These assumptions are justified if the mass M is large enough in Planck units. Ignoring constants, the Hawking temperature (34.271) varies like

$$T \sim \frac{\hbar}{GM} \ . \tag{34.272}$$

Thus, $T \to 0$ as $\hbar \to 0$ or as the black hole gets bigger. The Stefan-Boltzmann law then implies that the power radiated by the black hole varies as

$$P \sim \frac{AT^4}{\hbar^3} \sim \frac{\hbar}{G^2M^2} \ , \tag{34.273}$$

where A is the area of the horizon. It follows that the rate of mass loss also obeys

$$\frac{dM}{dt} \sim \frac{\hbar}{G^2M^2} \ . \tag{34.274}$$

The typical time for the black hole to lose a small fraction, say 1%, of its total mass is

$$t_{\rm typ} \sim .01\frac{G^2M^3}{\hbar} \ . \tag{34.275}$$

So we have to wait a long time of order $G^2M^3/\hbar$ to see the geometry change appreciably due to Hawking emission. Any classical transient effects that occur during the matter shell infall, such as those associated with emission of radiation to $\mathcal{I}^+$, will all clear out and settle down in timescales that cannot involve $\hbar$. Hence we have a clean division between the classical black hole formation phase and the onset of Hawking evaporation. The argument for information loss [161] applies only when M is large and such a clean division can be made.

We now revisit this argument in light of the new insights into the IR structure of gravity.

34.7.2 Soft Hair

In the standard analysis, it is *not* claimed that the Hawking radiation is *completely* uncorrelated with the quantum state of the black hole. For example, even in the semiclassical regime, it has always been presumed that the total mass is exactly conserved. If the black hole emits a quantum of Hawking radiation of energy ΔE, then it must necessarily decrease its mass by an amount exactly equal to ΔE. This holds at the level of quantum states and has never been thought to be a probabilistic statement. Instead there should exist an exact correlation for all conserved quantum numbers (such as the energy) of the black hole and the conserved quantum numbers of the outgoing radiation. This correlation is not manifest in the leading-order Hawking calculation. It must be enforced by hand when computing the backreaction of the outgoing Hawking quanta

on the geometry. The result will be exact correlations between the quantum states of the outgoing Hawking radiation and of the black hole. Not much attention has been paid to these correlations, even if they do modify the thermal spectrum and imply that some information is carried out by the radiation. The reason is they are too few in number — one for each of the ten black hole hairs — to rescue the macroscopic quantities of lost information.

This story is, however, significantly modified [41, 160, 48] by the infinite number of conserved charges discussed in these lectures. First, it is a common misconception, originating in a misinterpretation of the no-hair theorem, that black holes (in the absence of gauge fields) have only ten hairs, corresponding to the ten conserved Poincaré charges. The no-hair theorem states that all stationary solutions are diffeomorphic to Kerr spacetimes. While this statement is mathematically correct, these diffeomorphisms, if they are within BMS, need not act trivially on the black hole spacetime. Generically they map one black hole spacetime to a second, physically inequivalent one. A simple example is a boost that changes both the energy and momentum and so clearly changes the quantum state. However, we have learned that there is no canonically preferred "boost" element of the asymptotic BMS symmetry group. For the same reason that two black hole spacetimes that differ by a boost are physically inequivalent, two black hole spacetimes which differ by any BMS transformation (except Killing time translations) are also physically inequivalent. This simple observation implies that there are not merely ten, but an infinite[215] number of "soft hairs" [160] on classical black holes. We will see below that superrotation charges serve as a diagnostic distinguishing the different black hole "hairdos" and that a supertranslated Schwarzschild black hole generically carries nonzero angular momentum.

The presence of a lush head of soft hair on black holes is required for supertranslation and superrotation charge conservation. Since the conservation laws follow from the long-distance behavior of fields near spatial infinity, they should not be affected by the presence of black holes — classical or quantum. The conserved charges can be expressed as bulk integrals over any Cauchy surface. In the presence of a classical black hole, $\mathcal{I}^+$ is no longer a Cauchy surface. One must include a contribution from the future event horizon $\mathcal{H}^+$, which is the black hole contribution to the conserved charge. In the quantum theory, black holes evaporate, but one may still choose to consider a Cauchy surface — such as the green one in figure 34.22 — which crosses the spacetime before the black hole has disappeared. The integrand on such a surface will contain a contribution both from the black hole and from $\mathcal{I}^+$.

A generic massless Hawking quantum from an evaporating black hole will carry nonzero amounts of all the supertranslation, superrotation, and (if it is charged) large-gauge charges across $\mathcal{I}^+$. Exact conservation of these charges requires that the black hole decrease its supertranslation, superrotation, and large-gauge charges by an exactly compensating amount. This enforces an infinite number of correlations between the quantum state of the black hole and the quantum state of the outgoing Hawking radiation. A mere ten constraints from Poincaré charges forcing correlations cannot have a significant effect on how macroscopic quantities of information flow in and out of the black hole; an infinite number of constraints gives a very different story. It potentially significantly modifies the information flow, or equivalently, the entanglement, between the portions of the bulk quantum state on $\mathcal{I}^+$ and on the horizon. Motivated by this observation, in the next few subsections we begin a detailed perturbative analysis of soft hair. We note that it has been suggested that soft hair is an alternate description of the edge modes discussed in [227, 228, 229, 230, 231].

Classical Hair

The first and simplest thing to understand about soft hair, and the subject of this section, is classical, linearized supertranslation hair on a Schwarzschild black hole.

Our first problem is to extend the action of supertranslations from a neighborhood of $\mathcal{I}$ to the entire spacetime. The extension of an asymptotic gauge symmetry into the interior is gauge dependent. In a general time-dependent situation, there is unlikely to be a canonical choice of gauge. Quantum fluctuations further diminish the utility of specific choices. For quantum gravity

[215] In the quantum theory, it may not be sensible to discuss hairs localized to a region smaller than the Planck length, which would render the number of hairs finite[160].

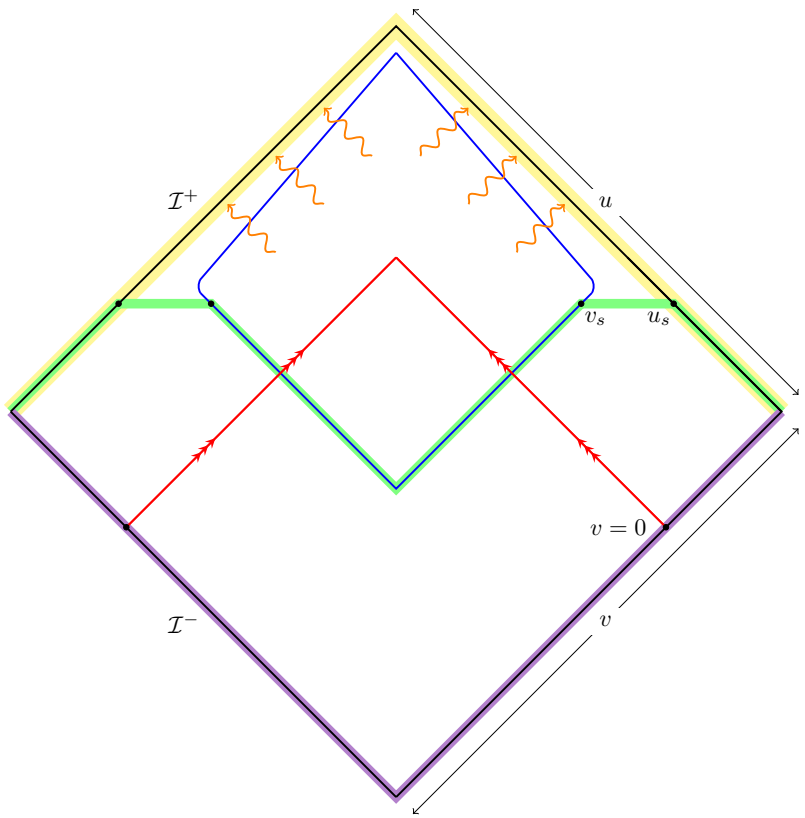

Figure 34.22: **An infinite number of conserved charges can be defined as surface integrals at $\mathcal{I}^+_-$ or $\mathcal{I}^-_+$. Integrating by parts and using the constraints, they can be written as an outgoing integral over $\mathcal{I}^+$ (yellow surface), an incoming integral over $\mathcal{I}^-$ (purple surface), or an intermediate time integral over the green surface that includes a black hole contribution. The equality of these three expressions is possible only if the black hole itself can carry an infinite number of charges, or soft hair.**

in asymptotically flat spacetimes, we expect the only fully well-defined observables are supported at the boundary at infinity. It is nevertheless sometimes possible, armed with a gauge choice, to define interior quantities, such as local gravitational energy densities, at first nontrivial order in perturbation theory around the Schwarzschild solution. This can be useful in developing a picture and intuition for the behavior of the spacetime away from its boundary. For example, one may show at leading order in perturbation theory that, at both the classical and quantum levels, the total energy comprised of linearized perturbations plus the mass of the black hole itself is conserved. Moreover, this perturbative conservation law is the linearization of an exact, nonperturbative conservation law, which can only be exactly phrased in terms of asymptotic quantities. It is in this spirit that we study the linearized action of supertranslations in the Schwarzschild solution.

Supertranslated Schwarzschild Solution. In advanced Bondi coordinates, the Schwarzschild metric is

$$ds^2 = -V dv^2 + 2dvdr + r^2 \gamma_{AB} d\Theta^A d\Theta^B \ , \quad V \equiv 1 - \frac{2m_B}{r} \ , \tag{34.276}$$

where $m_B = GM$. It is not hard to show that, for the Schwarzschild geometry, the supertranslation vector field,

$$\zeta_f = f\partial_v + \frac{1}{r} D^A f \partial_A - \frac{1}{2} D^2 f \partial_r \ , \quad f = f(z, \bar{z}) \ , \tag{34.277}$$

preserves Bondi gauge for all r, not just to leading order. Taking the Lie derivative, we find

$$\begin{aligned} ds^2 + \mathcal{L}_f ds^2 &= -\left(V - \frac{m_B D^2 f}{r^2}\right) dv^2 + 2dvdr - dvd\Theta^A D_A(2Vf + D^2 f) \\ &\quad + (r^2 \gamma_{AB} + 2r D_A D_B f - r\gamma_{AB} D^2 f) d\Theta^A d\Theta^B \ . \end{aligned} \tag{34.278}$$

The event horizon is at $r = 2m_B + \frac{1}{2}D^2 f$. This geometry describes a black hole with linearized supertranslation hair. Horizon supertranslations have been studied in other gauges [232, 233, 234].

Superrotation Charges. Supertranslating a black hole does not add supertranslation charges to the black hole, just as an ordinary translation of a black hole does not add momentum. This result follows from the fact that the supertranslation group is abelian and may also be seen at linear order directly, because m_B is unshifted in (34.278). However, as supertranslations and superrotations do not commute, a supertranslated black hole can and does carry superrotation charges, already at the classical level. In (34.235), we derived the conserved superrotation charges

$$Q_Y^- = \frac{1}{8\pi G} \int_{\mathcal{I}_+^-} d^2\Theta \sqrt{\gamma} Y^A N_A \ , \tag{34.279}$$

where Y^A is any smooth vector field on the sphere. We are interested in the differential superrotation charges carried by an infinitesimally supertranslated Schwarzschild black hole of the type considered in the previous paragraph. As seen from (34.278), under a supertranslation $\delta_f g_{\mu\nu} = \mathcal{L}_f g_{\mu\nu}$ of the Schwarzschild geometry,

$$\delta_f N_A = -3 m_B \partial_A f \ . \tag{34.280}$$

It follows immediately that [164, 48]

$$\hat{Q}_Y^-(g, h = \delta_f g) = -\frac{3}{8\pi} \int_{\mathcal{I}_+^-} d^2\Theta \sqrt{\gamma} Y^A M \partial_A f \ . \tag{34.281}$$

The hat here on $\hat{Q}_Y^-$ and on other quantities below are to remind the reader that we are doing a linearized analysis. Equation (34.281) is nonzero for a generic vector field Y^A and supertranslation f. An infinite number of superrotation charges can be independently added to the black hole by different choices of f. Hence superrotation charges classically distinguish differently supertranslated black holes. Classical black holes sport an infinite head of "supertranslation hair."

Hair implants. In the previous paragraphs we described a supertranslated eternal Schwarzschild black hole. To be certain such objects really exist, in this section we describe how one physically implants hair, or rearranges the hairdo, by throwing something into a Schwarzschild black hole. Similar conclusions were reached using the membrane paradigm [166, 169].

At advanced time v_0 in the Schwarzschild geometry, we send in a linearized shockwave with energy-momentum density

$$\hat{T}_{vv} = \frac{\mu + \hat{T}(\Theta)}{4\pi r^2} \delta(v - v_0) \tag{34.282}$$

near $\mathcal{I}^-$. Here μ is the total mass of the shockwave, and we take $\hat{T}$ to have only $\ell > 2$ components for simplicity. We wish to solve for the linearized metric in such a way that the solution is diffeomorphic to the Schwarzschild solution both before and after the shockwave. Stress-energy conservation, $\nabla_\mu \hat{T}^{\mu\nu} = 0$, then mandates subleading-in-$\frac{1}{r}$ corrections to the stress tensor for shockwaves that are not spherically symmetric. Defining

$$\hat{C}(\Theta) \equiv G \int d^2\Theta' G(\Theta, \Theta') \hat{T}(\Theta'), \tag{34.283}$$

where G is the Green's function (34.268) arising in the memory effect, the solution is

$$\hat{T}_{vv} = \frac{1}{4\pi r^2}\left[\mu + \frac{1}{4G}D^2\left(D^2+2\right)\hat{C} - \frac{3M}{2r}D^2\hat{C}\right]\delta\left(v-v_0\right) \ ,$$
$$\hat{T}_{vA} = -\frac{3M}{8\pi r^2}D_A\hat{C}\delta\left(v-v_0\right) \ . \tag{34.284}$$

Solving the linearized Einstein equation with this shockwave source then gives (see exercise 15)

$$\begin{aligned} h_{vv} &= \theta(v-v_0)\left(\frac{2G\mu}{r} - \frac{m_B D^2\hat{C}}{r^2}\right) \ , \\ h_{AB} &= -2r\theta(v-v_0)\left(D_A D_B\hat{C} - \frac{1}{2}\gamma_{AB}D^2\hat{C}\right) \ , \\ h_{vA} &= \theta(v-v_0)\partial_A\left(1 - \frac{2m_B}{r} + \frac{1}{2}D^2\right)\hat{C} \ . \end{aligned} \tag{34.285}$$

Comparing with the formula (34.278) for a supertranslation of the Schwarzschild metric, we find that (34.285) can be written

$$h_{\mu\nu} = \theta(v-v_0)\left(\mathcal{L}_{f=-\hat{C}}g_{\mu\nu} + \frac{2G\mu}{r}\delta^v_\mu\delta^v_\nu\right) \ . \tag{34.286}$$

Hence the shockwave is a domain wall interpolating between two BMS-inequivalent Schwarzschild vacua, whose mass parameters differ by μ.

The shockwave induces a shift in the transverse components of the metric perturbation on the horizon. Integrating over a null generator of the horizon, we have

$$\Delta h_{AB}(r=2m_B,\Theta) = \int_{-\infty}^{\infty} dv\partial_v h_{AB}(r=2m_B,v,\Theta) = -4m_B\left(D_A D_B\hat{C}(\Theta) - \frac{1}{2}\gamma_{AB}D^2\hat{C}(\Theta)\right) \ . \tag{34.287}$$

Hence the shockwave induces a supertranslation on the Schwarzschild horizon, which is registered by a nonzero value for the zero mode of the transverse, traceless fluctuations of the horizon metric. In the physical phase space, two black hole spacetimes that differ by any element of BMS correspond to different points. For the case of boosts, the two spacetimes have different energies. For supertranslations, they are energetically degenerate but carry different angular momenta and other superrotation charges. An important difference between boosts and supertranslations is that, as discussed in section 34.5.2, the latter act nontrivially on all the zero-energy vacua as well, imparting angular momentum and superrotation charges at quadratic order [51]. Hence the phase space of asymptotically flat geometries with nonzero energy and four Killing vectors is not a simple product of vacuum and black hole phase spaces.[216]

The formula (34.281) of superrotation charges requires only the asymptotic behavior of the black hole and hence pertains to any geometry with nonzero mass. We would like to understand how a classical black hole compares in this regard to a configuration with the same mass and many internal states, such as a star, or an elementary particle with few or no internal states. Suppose we send the supertranslating shockwave into a star or a collection of stars instead of into a black hole. The wave will excite and rearrange the interior structure of the star and, in the case of multiple stars, their relative motions. Generically gravitational radiation will carry some, but not all, of the superrotation charge back out to infinity, while some will be retained by the star(s). It is unsurprising that a star or a collection of stars (which has many internal degrees of freedom

[216] We consider here supertranslations that act in unison on the horizon and null infinity. As discussed at the end of this subsection, one may try to consider separate actions, but we do not do so here.

and possible interior states) can carry many superrotation charges. There is no no-hair theorem for a star! Now consider instead replacing the black hole by a massive, stable, "bald" elementary particle with no internal degrees of freedom. Such an object cannot carry arbitrary superrotation charges: the pre- and post-superrotation charges are generically the same (except for the $l = 1$ component). To leading order, the supertranslating shockwave will simply be reflected through the origin and scatter back up to future null infinity. The elementary particle has no mechanism to absorb all the superrotation charges. The outgoing wave will cancel the superrotation charges induced by the ingoing wave and, in the far future, the superrotation charges will revert to their initial incoming values.

So we see that, in its ability to absorb superrotation charges, a black hole acts more like a complex "hairy" star with many internal degrees of freedom than a massive "bald" elementary particle. The observer at infinity can confirm this by sending in shockwaves and watching what comes out. This is a classical signal that black holes are not bald.

However, there are also intriguing differences, yet to be fully understood, between the supertranslation hair on a black hole as described above and the internal states of a star. Bondi gauge supertranslations change the metric of the spacetime everywhere, including both at the event horizon and at infinity, while internal states of a star can be changed with possibly[217] no effect at infinity. It is interesting to ask whether horizon supertranslations can be untethered from supertranslations of null infinity. There has been discussion of this point [128, 166, 48, 170, 173], but as it remains unsettled, I do not go into detail here. A related point is that we do not know how to describe supertranslation hair (one proposal is edge modes [227, 228, 229]) on a classical stationary black hole in AdS, whose asymptotic boundary does not support supertranslation symmetry. In contrast, a star in AdS clearly retains many internal degrees of freedom, which, however, AdS/CFT tells us are recorded on the boundary. Evidently this issue goes to the heart of the holographic structure of spacetime. We will not settle it here. The next subsection sheds some light on it by constructing the intrinsic horizon contribution to the supertranslation charge without reference to infinity.

Horizon Charges

In the absence of eternal black holes or massive fields, we saw in section 34.5.2 that the linearized supertranslation charges $\hat{Q}_f^+$ can be written as volume integrals of local operators over $\mathcal{I}^+$. However, for the Schwarzschild geometry this is clearly impossible, as $\mathcal{I}^+$ is not a Cauchy surface. Instead, for massless fields, $\mathcal{I}^+ \cup \mathcal{H}^+$ is a Cauchy surface. Hence one expects a relation of the form

$$\hat{Q}_f^+ = \hat{Q}_f^{\mathcal{I}^+} + \hat{Q}_f^{\mathcal{H}^+}. \tag{34.288}$$

The second term, $\hat{Q}_f^{\mathcal{H}^+}$, is the horizon supertranslation charge. In general (for example, with Hawking radiation), supertranslation charge can be exchanged between the horizon and $\mathcal{I}^+$, and one does not expect them to be separately conserved.

The literature [223, 196, 235, 197, 198, 236, 237] on the covariant canonical formalism, symplectic forms, and conserved charges in GR contains general expressions for the charges associated with diffeomorphisms of a surface Σ as an integral over its boundary $\partial\Sigma$. In our case, $\mathcal{H}^+$ has past and future boundaries, $\mathcal{H}^+_\pm$, which is the key reason it is possible to have a nontrivial horizon charge.[218] The precise form of the horizon contribution $\hat{Q}_f^{\mathcal{H}^+}$ will depend on the coordinate choice used to extend the supertranslations in from infinity to the horizon. Adopting the Bondi gauge,

[217] I add the caveat "possibly" because in full quantum gravity, the holographic principle may ultimately imply that the internal states of the star are recorded at the boundary at infinity. However, ignoring this, it is at least true semiclassically.

[218] In the quantum theory, the black hole evaporates, and the horizon (however it is defined) may not have a boundary. This suggests there cannot be a quantum exact notion of horizon charges independently of those at infinity.

one finds the boundary expression [48]

$$\hat{Q}_f^{\mathcal{H}^+} = \frac{M}{8\pi}\int d^2\Theta\sqrt{\gamma}f\left[D^A\partial_r h_{Av} + 2h_{vv} + D^2 h_{vr}\right]_{\mathcal{H}_-^+}^{\mathcal{H}_+^+} . \tag{34.289}$$

Integrating by parts and using the constraints gives the horizon integral

$$\begin{aligned}\hat{Q}_f^{\mathcal{H}^+} = \frac{1}{8\pi G}\int_{\mathcal{H}^+} d^2\Theta\sqrt{\gamma}dvf\Bigg(&\frac{1}{4m_B}D^AD^B\partial_v h_{BA}\\ &+\frac{1}{2}D^2h_{vv} + m_BD^2\partial_r h_{vv} + \frac{1}{2}D^2h_{vr} - \frac{1}{4m_B}D^Ah_{Av}\Bigg) .\end{aligned} \tag{34.290}$$

As a check, we would like to see that (34.290) generates supertranslations of the horizon components of the metric via the inverted symplectic form. However, this is still not quite possible, because the Bondi gauge allows residual trivial diffeomorphisms that vanish at the boundaries $\mathcal{H}_\pm^+$ of the horizon and are zero modes of the symplectic form. We must first eliminate these modes and reduce to the physical horizon phase space $\Gamma_{\mathcal{H}^+}$, which is parametrized by h_{AB}. After some effort [48], $\hat{Q}_f^{\mathcal{H}^+}$ reduces to

$$\hat{Q}_f^{\mathcal{H}^+} = \frac{1}{32\pi G m_B}\int_{\mathcal{H}^+} dvd^2\Theta\sqrt{\gamma}D^AD^Bf\partial_v h_{AB} . \tag{34.291}$$

This charge is nothing but a soft graviton on $\mathcal{H}^+$, just as the linearized charge $\hat{Q}_f^{\mathcal{I}^+}$ is a soft graviton on $\mathcal{I}^+$. The symplectic form can now be inverted, and the commutator is

$$\left[\hat{Q}_f^{\mathcal{H}^+}, h_{AB}\right] = i2m_B(2D_AD_Bf - \gamma_{AB}D^2f) . \tag{34.292}$$

This relation is the desired linearized supertranslation action on the horizon metric fluctuations.

This construction makes sense only in leading-order perturbation theory: in the general case the classical horizon is defined only nonlocally, and in the quantum case it evaporates altogether. In the presence of interactions it is unlikely that a clean separation can be made between the two terms on the right-hand side of (34.288). Nevertheless, it provides a starting point for an analysis of horizon supertranslations.

We note that the construction requires the charges $\hat{Q}_f^{\mathcal{H}^+}$ (i.e., the soft graviton modes) to be incorporated as symplectic partners of the v-independent part of h_{AB} in the physical phase space $\Gamma_{\mathcal{H}^+}$. Moreover, the analysis is fully intrinsic to the horizon and does not require any properties of asymptotic infinity. Because the classical horizon has boundaries, it is possible for pure diffeomorphisms that do not vanish at these boundaries to be nonzero eigenvectors of the symplectic form. This is the basic reason that supertranslations act nontrivially on the black hole horizon.

Quantum Hair

Let $|M\rangle$ denote a quantum state corresponding to a Schwarzschild black hole. Then an infinitesimally supertranslated black hole corresponds to the quantum state

$$|M_f\rangle = |M\rangle + iQ_f^+|M\rangle . \tag{34.293}$$

In section 34.7.2 it was noted that, because the supertranslation group is abelian, a classically supertranslated black hole does not carry classical supertranslation hair. The quantum version of this statement is that to linear order in f

$$\langle M_f|Q_{f'}^+|M_f\rangle = 0 \tag{34.294}$$

for any non-constant f'. However, it does not imply that the supertranslation charge Q_f^+ annihilates $|M\rangle$. Instead, Q_f^+ adds a soft graviton to $|M\rangle$, leaving its energy unchanged but adding angular momentum and more general superrotation charges. According to the decomposition (34.288), the soft part of the charge has two terms, one that acts on $\mathcal{H}^+$ and the other on $\mathcal{I}^+$. Hence the soft graviton may be either a soft mode on $\mathcal{H}^+$ or a soft mode on $\mathcal{I}^+$.

Similar statements apply to the quantum vacuum. The supertranslated vacuum carries no classical supertranslation charge, as $m_B = 0$. However, the soft part Q_f^{+S} acts nontrivially on the vacuum, turning it into an orthogonal vacuum with an extra soft graviton and different superrotation charges.

Electric Hair

In this section, we repeat the discussion in the context of abelian gauge theories, replacing supertranslations with large gauge transformations and soft gravitons with soft photons. Technically, the discussion is much simpler, both because there are fewer indices and because there is less ambiguity in the extension of boundary quantities into the bulk. However, conceptually it is more subtle, because the action of large gauge transformations on charged particles is only a phase, which is most naturally detected by quantum interference experiments. The quantum nature of the large gauge symmetry action contrasts with that of supertranslations, which has a clear classical interpretation as advancing or delaying the arrival times of massless particles at $\mathcal{I}^+$. Moreover, in the gauge theory case, there is no analog of superrotation charge that provides a classical measurement of the supertranslation hairdo on the black hole. Because the large gauge symmetry is abelian, classical large gauge charges of large gauge transformed black holes must vanish. It is for these conceptual reasons that we discussed the gravity case before the gauge theory one. However, the gauge theory case is also illuminating, as it displays many of the basic concepts in simpler forms that are uncluttered by proliferating indices.

To begin, let us briefly recall the argument for conservation of the total electric charge. The total charge may be written as a surface integral at infinity,

$$\hat{Q}^+_{\varepsilon=1} = \frac{1}{e^2}\int_{\mathcal{I}^+_-} *F \ , \tag{34.295}$$

where again the hat on $\hat{Q}$ serves to remind the reader that in this section, we linearize around a fixed background. Equivalently, using integration by parts, we may write it as an integral of the charged matter current on a bulk slice Σ that ends at $\mathcal{I}^+_-$:

$$\hat{Q}^+_{\varepsilon=1} = \int_\Sigma *j_M \ . \tag{34.296}$$

The result must be the same regardless of which slice Σ through the bulk we choose, as illustrated in the context of black hole formation and evaporation depicted in figure 34.22. For instance, we could compute $\hat{Q}^+_{\varepsilon=1}$ by integrating over the purple slice hugging $\mathcal{I}^-$ at the bottom of the diagram before we create the black hole. Alternately, we could use the yellow slice at the top of the diagram after the black hole has evaporated or the green slice that runs into the horizon of the black hole. In the latter case, we can either continue the slice along the horizon as depicted, or we could end the slice at the horizon with an extra boundary term that tells us about the charge carried by the black hole itself. Either way, the black hole typically contributes to the electric charge. This contribution is required to ensure that the total $\hat{Q}^+_{\varepsilon=1}$ is conserved throughout the entire bulk evolution.

This argument may be applied to the infinite number of such conserved electric charges that generalize the total charge. That is, given any function ε on $\mathcal{CS}^2$, there is a conserved charge (34.29),

$$\hat{Q}^+_\varepsilon = \frac{1}{e^2}\int_{\mathcal{I}^+_-} \varepsilon * F = \frac{1}{e^2}\int_\Sigma \left(\mathrm{d}\varepsilon \wedge *F + e^2 \varepsilon * j_M\right) \ , \tag{34.297}$$

where Σ again is an arbitrary three-dimensional slice of the bulk ending on $\mathcal{I}^+_-$, and ε on the slice is any function with the prescribed boundary value at $\mathcal{I}^+_-$. Clearly, as we vary this slice and let it end at different surfaces on the black hole horizon, there will be different amounts of large gauge charge that pass through the horizon portion of the slice. This amount will vary in a complicated way as we change the time at which the slice meets the horizon. Therefore, to ensure charge conservation, it must be the case that black holes are capable of storing $\hat{Q}^+_\varepsilon$ charge, just as they store global charge. That is, the black hole must carry an infinite amount of soft electric hair.

We wish to analyze the linearized charges in perturbation theory about a fixed black hole background. For the case of supertranslations, we linearized around the eternal Schwarzschild black hole. It should also be possible to do a linearized analysis around the more physical geometry of a black hole formed by gravitational collapse. In practice, for supertranslations, the equations become unwieldy in a time-dependent background. However, for the large gauge transformations, the algebra simplifies and such an analysis is both instructive and possible, as we shall now see.

Consider a Vaidya black hole formed by a neutral null incoming shockwave at $v = 0$. Then at some later time v_0, we send in a linearized null shockwave with an asymmetric null charge current j, so that the higher large gauge charges are excited. This situation is depicted in figure 34.23. To

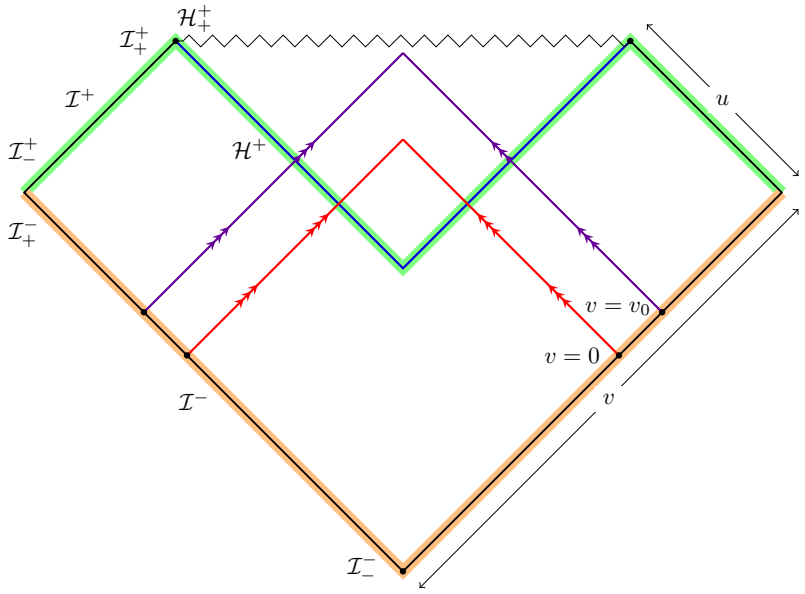

Figure 34.23: **A black hole formed by the spherically symmetric red shockwave at $v = 0$ is classically supertranslated at a later time $v = v_0$ by the asymmetric purple shockwave. The solution is diffeomorphic to the Schwarzschild geometry or vacuum away from the shockwaves but generically carries arbitrary superrotation charges in the region $v > v_0$. The charges computed on the orange and green surfaces must agree, but the latter adds contributions from the horizon and null infinity.**

be explicit, let us take

$$j_v = \frac{Y_{\ell m}(z, \bar{z})}{r^2} \delta(v - v_0) \ . \tag{34.298}$$

It takes only one line to check that this current is conserved. We are going to examine the effects of this shell of charge in linearized perturbation theory, neglecting its backreaction on the geometry. Note that since it has an angular profile $Y_{\ell m}$, the net charge is zero. If the net charge were nonzero, we would need to discuss a transition from a Schwarzschild to a Reissner-Nördstrom black hole instead of just a Schwarzschild to a Schwarzschild one.

Now we solve the sourced Maxwell equation. The leading constraint equation at $\mathcal{I}^-$ (34.37) says that

$$\partial_v F^{(2)}_{rv} + \gamma^{z\bar{z}} \left(\partial_z F^{(0)}_{\bar{z}v} + \partial_{\bar{z}} F^{(0)}_{zv} \right) = e^2 Y_{\ell m}(z,\bar{z}) \delta(v - v_0) \ . \tag{34.299}$$

There are many different ways of solving this constraint equation, as it is one equation for the four components of the vector potential. The one that most simply illustrates the physics is obtained by stipulating that the radial electric field vanish on $\mathcal{I}^-$,

$$F^{(2)}_{vr} = 0 \ , \tag{34.300}$$

and the initial connection is $A_z|_{\mathcal{I}^-_-} = 0$. These initial data on $\mathcal{I}^-$ then determine the full solution. Explicitly in $A_v = 0$ gauge, we have

$$A_z = \partial_z \left[\theta(v - v_0) \frac{e^2}{\ell(\ell+1)} Y_{\ell m}(z,\bar{z}) \right] \ , \tag{34.301}$$

as in equation (34.172). It is easy to check that this potential is indeed a solution by using $\partial_v \theta(v - v_0) = \delta(v - v_0)$ and

$$D^2 Y_{\ell m}(z,\bar{z}) = -\ell(\ell+1) Y_{\ell m}(z,\bar{z}) \ . \tag{34.302}$$

If we ignore the factor $\theta(v - v_0)$, A_z is manifestly just a pure gauge transformation, so F is identically zero both before and after the shockwave. We sent in a complicated angle-dependent charge distribution but dressed it with photons in just such a way that no electric field was produced. After the shockwave passes, the entire spacetime (including both the black hole and null infinity) is acted on by a gauge transformation $A \to A + \mathrm{d}\varepsilon$, with gauge parameter

$$\varepsilon = \frac{e^2}{\ell(\ell+1)} Y_{\ell m}(z,\bar{z}) \ . \tag{34.303}$$

Hence, the effect of this shockwave is to induce a large gauge transformation. It is a domain wall connecting a black hole spacetime to a large gauge transformation thereof.

The large gauge transformation (34.303) depends only on the data of the charge current and not the further choice of electric field data (34.300). In Hawking et al. [160], for instance, it was not assumed that $F^{(2)}_{vr} = 0$, but the same conclusion was reached. To see why, integrate the constraint along the horizon:

$$\int_{\mathcal{H}^+} dv \left[\partial_v F^{(2)}_{rv} + \gamma^{z\bar{z}} \left(\partial_z F^{(0)}_{\bar{z}v} + \partial_{\bar{z}} F^{(0)}_{zv} \right) \right] = e^2 Y_{\ell m}(z,\bar{z}) \ . \tag{34.304}$$

If the radial electric field eventually decays near $\mathcal{H}^+_+$, $\int_{\mathcal{H}^+} dv \partial_v F^{(2)}_{vr} = 0$. In the more general case, the gauge field is a Heun function and does not have a simple analytic expression. We nevertheless learn that the zero-modes of the transverse components of the field strength are always excited when charge is asymmetrically thrown in.

Equation (34.304) can be rewritten as

$$\int_{\mathcal{H}^+} dv d^2z Y_{\ell' m'} \left(\partial_z F^{(0)}_{\bar{z}v} + \partial_{\bar{z}} F^{(0)}_{zv} \right) = e^2 \delta_{\ell,\ell'} \delta_{m,m'} \ . \tag{34.305}$$

This expresses the fact that the classical soft photon mode is excited by the asymmetric charge shell or, for that matter, by any charged object that is thrown into the black hole. In the quantum theory, the quantum state of the soft photons on the horizon will be a coherent state in which the

expectation value of the transverse electric field obeys (34.305). We note that, in contrast, horizon soft photons cannot be excited by throwing in photons from $\mathcal{I}^-$, because the relevant greybody factors vanish at zero momentum. Nevertheless, it follows from (34.305) that soft photons on the horizon can be excited by throwing in charges and are needed for a perturbative description of black hole dynamics.

The incoming charge $\hat{Q}^-_\varepsilon$ can be written as an integral over the orange slice hugging $\mathcal{I}^-$ in figure 34.23. This slice is punctured by i^-, past timelike infinity. In general, one must be careful about contributions from the i^- puncture, but for the present case of massless fields they vanish. This conclusion follows from the mathematical fact that $\mathcal{I}^-$ by itself constitutes a complete Cauchy surface for massless fields. Physically, it means massless fields decay before reaching timelike infinity.

Likewise, the integral for the charge $\hat{Q}^+_\varepsilon$ can be extended up along $\mathcal{I}^+$, giving an integral $\hat{Q}^{\mathcal{I}^+}_\varepsilon$ along $\mathcal{I}^+$. Clearly, this term is no longer on its own equal to $\hat{Q}^-_\varepsilon$, because $\mathcal{I}^+$ no longer constitutes a Cauchy surface. To apply Gauss's law, we need a complete Cauchy slice. We may obtain one by following the green slice hugging the event horizon $\mathcal{H}^+$. This additional portion of the surface gives the black hole contribution to the charge. Again if we do not include massive particles, $\mathcal{H}^+$ and null infinity $\mathcal{I}^+$ together form a Cauchy surface for massless fields, so there should be no contributions from i^+.

The conservation law thus takes the form

$$\hat{Q}^-_\varepsilon = \hat{Q}^{\mathcal{I}^+}_\varepsilon + \hat{Q}^{\mathcal{H}^+}_\varepsilon \ . \tag{34.306}$$

This equation says that the large gauge charge computed along the green slice has two pieces: one from null infinity (the outgoing charge $\hat{Q}^{\mathcal{I}^+}_\varepsilon$) and one from the black hole (the horizon charge $\hat{Q}^{\mathcal{H}^+}_\varepsilon$). Moreover, the sum of these two charges equals the single term obtained by computing $\hat{Q}^-_\varepsilon$ on the single incoming orange slice.

We have already seen in section 34.2.6 that in a canonical formalism, $\hat{Q}^{\mathcal{I}^+}_\varepsilon$ generates large gauge transformations on the data at $\mathcal{I}^+$. It is not hard to see that $\hat{Q}^{\mathcal{H}^+}_\varepsilon$ similarly generates large gauge transformations on the data at $\mathcal{H}^+$. Integrating by parts, we find

$$\hat{Q}^{\mathcal{H}^+}_\varepsilon = \frac{1}{e^2}\int_{\mathcal{H}^+_+} \varepsilon * F = \frac{1}{e^2}\int_{\mathcal{H}^+} \left(\mathrm{d}\varepsilon \wedge *F + e^2 \varepsilon * j_M\right) \ . \tag{34.307}$$

In exercise 14, the interested reader is invited to show, following the same steps as in section 34.2.6, that in advanced gauge $A_v = 0$,[219]

$$\left[\hat{Q}^{\mathcal{H}^+}_\varepsilon, A_z\right]_{\mathcal{H}^+} = i\partial_z \varepsilon|_{\mathcal{H}^+} \ , \tag{34.308}$$

which are large gauge transformations on the horizon. This equation also states that the soft part of the horizon charge — the soft photons — are symplectically paired with the Goldstone bosons of spontaneously broken large gauge transformations on the horizon.

In general, a necessary condition for a gauge mode to be physical is that it have a nonvanishing symplectic form. From the general formula for the symplectic form, this is possible only if the surface has a boundary. The boundary of the future horizon $\mathcal{H}^+$ is $\mathcal{H}^+_+$,[220] and v-independent gauge transformations are indeed nonvanishing there.

Note that classically, in an asymptotically stationary situation, $\hat{Q}^{\mathcal{H}^+}_\varepsilon$ always vanishes, because the electromagnetic fields (except for the $\ell = 0$ mode) go to zero at late times. We already saw this in our linearized analysis: equation (34.304) says that the hard and soft part of the charge

[219] $A_v = 0$ gauge is natural for analyzing how excitations from $\mathcal{I}^-$, such as our shockwave, affect $\mathcal{H}^+$, because advanced Bondi coordinates cover both regions. However, they do not cover $\mathcal{I}^+$. For this reason, it would be interesting to analyze the problem in harmonic gauge, as considered by Campiglia and Laddha [215].

[220] For eternal black holes there is also a past boundary $\mathcal{H}^+_-$.

are classically equal and opposite. However, it is not zero as an operator, as we have just seen its commutators create large gauge transformations. Moreover, when we pass to the quantum theory and expand in creation/annihilation operators, the associated charges will create and annihilate soft photons on the horizon. Acting on the horizon Hilbert space with the operator $\hat{Q}_\varepsilon^{\mathcal{H}^+}$ will not change the energy, since it commutes with the Hamiltonian (as we know, because we can write the charge as a boundary integral at infinity), but it nonetheless inserts a soft photon, which will change the angular momentum of the black hole by one unit. Thus, a black hole with a soft photon is different from a black hole without one. The action of this infinitesimal symmetry is nontrivial:

$$\hat{Q}_\varepsilon^{\mathcal{H}^+} |M\rangle = \left(\frac{1}{e^2} \int_{\mathcal{H}^+} \mathrm{d}\varepsilon \wedge *F \right) |M\rangle \neq 0 \ , \tag{34.309}$$

where we use $|M\rangle$ to denote the portion of the black hole quantum state on the null surface $\mathcal{H}^+$. The classical vanishing of the linearized horizon charge holds at the level of expectation values:

$$\langle M| \hat{Q}_\varepsilon^{\mathcal{H}^+} |M\rangle = 0 \ . \tag{34.310}$$

A similar situation was already encountered in the electromagnetic vacuum in the absence of black holes. Since the field strength vanishes, the charges $\hat{Q}_\varepsilon^+$ are all classically zero. However, they are not zero as operators. Instead, they create and annihilate photons, mapping one classical vacuum to another with different angular momenta.

In conclusion, black holes have an infinite electromagnetic degeneracy that can be described at both the classical and quantum levels. At the classical level, the degeneracy arises from nontrivially-acting gauge transformations. At the quantum level, there is an alternate perturbative description in terms of zero-energy soft photons on the horizon.

34.7.3 Discussion

The no-hair theorem tells us that Einstein-Maxwell gravity has a three-parameter[221] family of black hole solutions labeled by the mass M, charge Q, and total angular momentum J, up to diffeomorphisms and gauge transformations. It has long been accepted that a few diffeomorphisms (for example, boosts or translations) act nontrivially on the physical phase space and impart a sparse head of hair on black holes. We have shown that there are in fact an infinite number of diffeomorphisms, including an antipodal subgroup of $\mathrm{BMS}^+ \times \mathrm{BMS}^-$, that act nontrivially and thereby impart a lush head of soft hair on black holes. The soft hairdo is classically measured by conserved superrotation charges at infinity. More hair is supplied by large gauge transformations. The hairdo is rearranged whenever anything is thrown into the black hole, and it thereby stores partial information about how the black hole is formed. Exactly how much information is stored, and how it is transmitted to the outgoing Hawking radiation, is presently unknown. At the very least, understanding black hole information requires understanding the properties of soft hair and more generally keeping careful track of how much information flows into or is stored in the deep infrared [163].

Our analysis reveals two subtly flawed assumptions underlying the argument given in Hawking [161] that there is an information paradox:

- The adage “black holes have no hair" is misleading at best. In reality they carry an infinite number of conserved charges which generalize the ten Poincaré and one electric charges. These provide some memory of how the black hole was formed. Moreover, since these charges are exactly conserved, they must affect the quantum state of the outgoing Hawking radiation, correlating it with both the quantum state of the black hole and outgoing soft radiation [162]. The argument in Hawking [161] incorrectly assumed such correlations do not exist.

[221] We suppress possible magnetic charge.

- "When the black hole evaporates completely, there is no place where the information can be stored" is a second incorrect assumption in Hawking [161]. We have seen that the vacuum itself is infinitely degenerate and hence can store information. In particular, from what is understood so far, it is a logical possibility that the final vacuum state and or the outgoing soft quanta could be correlated with the outgoing Hawking radiation in such a way as to maintain quantum purity.

Of course, it is always possible that these assumptions are ultimately inessential and the paradox can be resolved without taking them into account. This does not seem to be the case so far, but much remains to be understood.

To phrase the issue more generally, soft gravitons are produced in every scattering process. The IR pole in the soft theorem says that their production is more ubiquitous than might have been expected. In fact, infinitely many are produced in any physical process. The soft modes are correlated highly with the hard modes [162, 238] and can store information at little or no cost in energy. Many are made in any process of black hole formation/evaporation in a manner that is highly regulated by an infinite number of conservation laws. It strikes me as implausible that we could solve the information paradox in asymptotically flat spacetime without a good understanding of these modes.

What would it actually mean to solve the black hole information paradox? First, a convincing solution must microscopically reproduce the Bekenstein-Hawking entropy $S_{BH} = \frac{\text{Area}}{4G}$ with the right factor of 1/4 in front, not just a squiggly line. As we now understand them, soft modes on the horizon are both too many and too few for this purpose (although see Donnay et al. [170]). They are too many because there is no UV cutoff. Presumably, modes that are localized to shorter than the Planck length on the horizon should be thrown out, but we do not know how to do this systematically. They are too few because of a variant of the flavor problem: there are many different ways of throwing things into the black hole that produce the same soft hairdo. Second, a satisfactory understanding of black hole information should not be merely verbal but should enable explicit computations. In particular, one would like an algorithm for computing the rate at which the information is returned to infinity [239].

The last 40 plus years of contemplating the wonders of quantum black holes have been truly amazing. It has led us to unexpected and fundamental new insights about the structure of classical spacetime, exotic quantum states of matter, quantum chaos, nonperturbative string theory, and a potentially revolutionary holographic reformulation of the laws of nature! At the same time, clearly much more is to come, as the basic paradox in Hawking [161] remains unresolved, while the current literature is replete with promising ideas and directions. The adventure continues!

34.8 Exercises *with Prahar Mitra and Monica Pate*

This section contains exercises. We set $G = 1$ in all exercises and solutions.

1. Exercise 1. (Section 2)

   Consider a scattering process in which an incoming null shockwave of the form

   $$j_v(v, r, z, \bar{z}) = \frac{1}{r^2}\delta(v)Y_{\ell m}(z, \bar{z}) \ , \qquad j_r = j_z = 0 \ , \tag{34.311}$$

   scatters at the origin $u = v = 0$ into an outgoing null shockwave

   $$j_u(u, r, z, \bar{z}) = \frac{1}{r^2}\delta(u)Y_{\ell' m'}(z, \bar{z}) \ , \qquad j_r = j_z = 0 \ , \tag{34.312}$$

   where $Y_{\ell m}\big(z, \bar{z}\big)$ are the usual spherical harmonics on S^2.

   (a) Find a solution for the field strength sourced by the null shockwave described above, assuming that

   $$F_{vr}^{(2)} = \lim_{r\to\infty}\big[r^2 F_{vr}\big] = 0 \ , \tag{34.313}$$

and that $F_{vz}^{(0)} = \lim_{r\to\infty} F_{vz}$ only has support at the source $v = 0$.

(b) Using the result of part (a), compute $A_z^{(0)}$ on $\mathcal{I}^+$ and $\mathcal{I}^-$ assuming $A_z^{-(0)}\big|_{\mathcal{I}_-^-} = 0$ and $A_z^{(0)}\big|_{\mathcal{I}_-^+} = A_z^{-(0)}\big|_{\mathcal{I}_+^-}$.

2. Exercise 2. (Section 2)

Working in Lorenz gauge $\nabla^\mu A_\mu = 0$ and, using a large-r expansion, show that in pure abelian gauge theory, the four-dimensional gauge field $A_\mu(u, r, z, \bar{z})$ is determined, up to u-independent integration constants by the equations of motion with boundary data (initial conditions)

$$A_z^{(0)}(u, z, \bar{z}) = \lim_{r\to\infty} A_z(u, r, z, \bar{z}) \ . \tag{34.314}$$

Hint: Use the residual gauge freedom to set $A_u^{(1)} = 0$.

3. Exercise 3. (Section 2)

(a) Starting from the usual action for free abelian gauge theories

$$S = -\frac{1}{2e^2}\int F \wedge *F \ , \tag{34.315}$$

use the formalism in [198] to derive the symplectic form (34.47).

(b) Work out the symplectic form explicitly on $\Sigma = \mathcal{I}^+$, and derive the commutators (34.54) and (34.56).

4. Exercise 4. (Section 2)

Starting from the free field mode expansion

$$A_\mu(x) = e\sum_{\alpha=\pm}\int \frac{d^3q}{(2\pi)^3}\frac{1}{2\omega_q}\left[\varepsilon_\mu^{\alpha *}(\vec{q})a_\alpha(\vec{q})e^{iq\cdot x} + \varepsilon_\mu^{\alpha}(\vec{q})a_\alpha^\dagger(\vec{q})e^{-iq\cdot x}\right] , \tag{34.316}$$

show that

$$e^2\partial_z N(z, \bar{z}) = -\frac{1}{8\pi}\frac{\sqrt{2}e}{1 + z\bar{z}}\lim_{\omega\to 0^+}\left[\omega a_+(\omega\hat{x}) + \omega a_-(\omega\hat{x})^\dagger\right] \ , \tag{34.317}$$

where $\hat{x}$ is the unit three-vector

$$\hat{x} = \left(\frac{z + \bar{z}}{1 + z\bar{z}}, \frac{-i(z - \bar{z})}{1 + z\bar{z}}, \frac{1 - z\bar{z}}{1 + z\bar{z}}\right) \ . \tag{34.318}$$

5. Exercise 5. (Section 2)

In this problem, you will show that the soft photon theorem for a single outgoing photon,

$$\langle \text{out}|\, a_\pm^{\text{out}}(\vec{q})\mathcal{S}\,|\text{in}\rangle \to e\left(\sum_{k=1}^m Q_k^{\text{out}}\frac{p_k^{\text{out}}\cdot\varepsilon_\pm}{p_k^{\text{out}}\cdot q} - \sum_{k=1}^n Q_k^{\text{in}}\frac{p_k^{\text{in}}\cdot\varepsilon_\pm}{p_k^{\text{in}}\cdot q}\right)\langle \text{out}|\,\mathcal{S}\,|\text{in}\rangle \, , \tag{34.319}$$

is equivalent to the Ward identity for large gauge transformations.

(a) For massless momenta, use parameterizations of the type (34.77), namely,

$$p^\mu = E\left(1\,,\frac{z+\bar{z}}{1+z\bar{z}}\,,\frac{-i(z-\bar{z})}{1+z\bar{z}}\,,\frac{1-z\bar{z}}{1+z\bar{z}}\right)\,, \tag{34.320}$$

and rewrite the soft theorem (34.319) in terms of z, $z_k^{\rm in}$, $z_k^{\rm out}$, and N_z.

(b) For massive particles of mass m, use the momentum parameterization (34.129),

$$\vec{p} = m\rho\hat{x}\,, \tag{34.321}$$

while keeping the parameterization $q = \omega(1,\hat{q})$ for the photon momentum, and rewrite the soft theorem for a scattering amplitude of massive particles in the $(\rho,\hat{x})$ coordinates.

6. Exercise 6. (Section 2)

In this problem, we study large gauge transformations in Lorenz gauge, $\nabla^\mu A_\mu = 0$. These are gauge transformations that are nonzero on $\mathcal{I}^\pm$ and satisfy $\nabla^\mu\nabla_\mu\varepsilon = 0$. We will work in coordinates (ν, r, θ, ϕ), where $\nu = \frac{t}{r}$.

(a) On a Penrose diagram, draw lines of constant ν and lines of constant r.

(b) Determine the scalar wave equation in these coordinates.

(c) Find the most general non singular r-independent solution that is of the form $\varepsilon_{\ell m}(\nu,\theta,\phi) = A_\ell(\nu)Y^\ell_m(\theta,\phi)$. Be sure to demand that the solution is continuous and finite at both $\nu = \pm 1$ and the origin $\nu = \pm\infty$ (by choosing appropriate branch cuts at $\nu = \pm 1$).

(d) Determine the near-$\mathcal{I}^+$ expansion of $\varepsilon_{2m}(u, r, \theta, \phi)$ to $\mathcal{O}(r^{-1})$.

(e) Verify from a large-r expansion around $\mathcal{I}^+$ (in retarded radial coordinates) that the form of the subleading behavior obtained in part (d) is required for any solution of the wave equation whose limit on $\mathcal{I}^+$ is an arbitrary nonvanishing and nonsingular function on S^2.

7. Exercise 7. (Section 2)

In this problem, you will derive the symplectic form for massive scalar fields near future timelike infinity. To resolve i^+, work in the coordinates (34.126) [14],

$$\tau = \sqrt{t^2 - r^2}\,, \qquad \rho = \frac{r}{\sqrt{t^2-r^2}}\,. \tag{34.322}$$

(a) Start with the free field mode expansion for a real massive scalar

$$\phi(x) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2\omega_p}\left[a(\vec{p})e^{ip\cdot x} + a^\dagger(\vec{p})e^{-ip\cdot x}\right]\,, \tag{34.323}$$

and determine the leading order term in the asymptotic expansion of the field in the limit $\tau \to \infty$.

(b) Determine the symplectic form on a Cauchy surface Σ for a free massive real scalar, governed by the action

$$S = -\frac{1}{2}\int d^4x\sqrt{-g}\left[(\partial_\mu\phi)^2 + m^2\phi^2\right]\,. \tag{34.324}$$

(c) Now take Σ to be a constant-τ slice in the coordinates defined in (34.322), and determine the symplectic form in the limit $\tau \to \infty$.

(d) Verify that the commutation relations determined by this symplectic form are the standard free field commutation relations:

$$[a(\vec{p}), a^\dagger(\vec{p}')] = (2\pi)^3(2\omega_p)\delta^3(\vec{p}-\vec{p}') \ . \tag{34.325}$$

8. Exercise 8. (Section 2)

Consider the hard part $\mathscr{F}^h[\chi]$ of the fermionic charge that generates the soft-photino theorem,

$$\mathscr{F}^h[\chi] = \frac{1}{4}\int du d^2z \gamma_{z\bar{z}}\chi(z,\bar{z})u\partial_u \bar{k}_- \ , \tag{34.326}$$

where $\bar{k}_-$ is the large-r limit of the fermionic current. For minimally coupled $\mathcal{N}=1$ supersymmetric QED, $\bar{k}_- = \sqrt{2}Q\phi\bar{\psi}_-$, where ϕ and $\bar{\psi}_-$ are the boundary values of the bulk fields Φ and $\bar{\Psi}_{\dot{\alpha}}$, respectively:

$$\begin{aligned} \Phi(u,r,z,\bar{z}) &= \frac{1}{r}\phi(u,z,\bar{z}) + \mathcal{O}(r^{-2}) \ , \\ \bar{\Psi}_{\dot{\alpha}}(u,r,z,\bar{z}) &= \frac{1}{r}\bar{\psi}_-(u,z,\bar{z})\bar{\xi}^-_{\dot{\alpha}} + \mathcal{O}(r^{-2}) \ . \end{aligned} \tag{34.327}$$

$\xi^\pm_\alpha$ and $\bar{\xi}^\mp_{\dot{\alpha}}$ are commuting two-component helicity basis spinors (i.e., they are eigenspinors of ${\sigma_z}^z$)

$$({\sigma_z}^z\xi^\pm)_\alpha = \pm\frac{1}{2}\xi^\pm_\alpha \ , \qquad \left(\xi^\pm_\alpha\right)^* = \bar{\xi}^\mp_{\dot{\alpha}} \ . \tag{34.328}$$

Using the form above, derive the action of $\mathscr{F}^h[\chi]$ on the radiative modes $\partial_u\bar{\phi}$ and ψ_+. Note that the action of $\mathscr{F}^h[\chi]$ mimics that of the superconformal generators S_α except that it acts only on charged matter.

Hint: You can either derive the symplectic form on $\mathcal{I}^+$ for scalars and fermions or rewrite the fields on $\mathcal{I}^+$ in terms of the usual creation and annihilation operators.

9. Exercise 9. (Section 4)

(a) Consider an amplitude $\mathcal{A}^{a_1,a_2}_{n+2}(q_1,\varepsilon_1,q_2,\varepsilon_2;p_1,\cdots,p_n)$ containing two outgoing gluons with color, momentum, and polarization (a_1,q_1,ε_1) and (a_2,q_2,ε_2), and n particles charged under the gauge group. Derive the following double-soft limit

$$\left[\lim_{q_1\to 0}, \lim_{q_2\to 0}\right] \mathcal{A}^{a_1,a_2}_{n+2}(q_1,\varepsilon_1,q_2,\varepsilon_2;p_1,\cdots,p_n) \ . \tag{34.329}$$

(b) Show that when the two gluons have the same helicity the above quantity vanishes.

10. Exercise 10. (Section 5)

Any four-dimensional Lorentzian metric can be written in Bondi gauge as

$$ds^2 = -Udu^2 - 2e^{2\beta}dudr + g_{AB}\left(dx^A + \frac{1}{2}U^A du\right)\left(dx^B + \frac{1}{2}U^B du\right) \ . \tag{34.330}$$

Asymptotically flat spacetimes are defined by the following falloff conditions for the Weyl tensor:

$$C_{rzrz} \sim \mathcal{O}(r^{-3}) \ , \qquad C_{rurz}, C_{rur\bar{z}} \sim \mathcal{O}(r^{-3}) \qquad \text{at large } r, \tag{34.331}$$

along with some other assumptions of uniform smoothness that will not be considered here. In (34.206), asymptotically flat spacetimes are described by the large-r expansion

$$ds^2 = -du^2 - 2dudr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} + \frac{2m_B}{r}du^2 + rC_{zz}dz^2 + U_z dudz + c.c. + \cdots \ . \quad (34.332)$$

Show that this metric satisfies the first equation of (34.331). Use the second equation to derive a constraint on U_z and $U_{\bar{z}}$.

11. Exercise 11. (Section 5)

In retarded Bondi gauge, a four-dimensional Lorentzian spacetime can be written as

$$ds^2 = -Udu^2 - 2e^{2\beta}dudr + g_{AB}\left(dx^A + \frac{1}{2}U^A du\right)\left(dx^B + \frac{1}{2}U^B du\right) \ , \quad (34.333)$$

where $\det g = r^4 \det \gamma$, and γ_{AB} is the two-dimensional metric on the round sphere, S^2. As discussed in section 34.5.1, the asymptotic falloff conditions for the component fields are

$$\begin{aligned} U &= 1 - \frac{2m_B}{r} + \mathcal{O}(r^{-2}) \ , \qquad \beta = \mathcal{O}(r^{-2}) \ , \\ U_A &= \frac{1}{r^2}D^B C_{BA} + \mathcal{O}(r^{-3}) \ , \qquad g_{AB} = r^2\gamma_{AB} + rC_{AB} + \mathcal{O}(1) \ , \end{aligned} \quad (34.334)$$

where γ_{AB} is the round metric on S^2, D_A is its covariant derivative, and all indices $(A, B, C, \cdots)$ are raised and lowered with respect to γ_{AB}.

(a) Show that the coordinate condition $\partial_r \det\left(\frac{g_{AB}}{r^2}\right) = 0$ implies that C_{AB} is traceless.

(b) Find the most general diffeomorphism ξ that preserves the form of this metric and that satisfies the asymptotic falloffs $\xi^u, \xi^r \sim \mathcal{O}(1)$ and $\xi^z, \xi^{\bar{z}} \sim \mathcal{O}(r^{-1})$ at large r. *Be sure to keep track of the leading and the first subleading terms in the large-r expansion.*

(c) The diffeomorphism in part (b) is parametrized by a function $f(x^A)$ on the sphere. Show that, to leading order, the Lie algebra of supertranslations is abelian:

$$[\xi(f_1), \xi(f_2)] = \mathcal{O}(r^{-1}) \ . \quad (34.335)$$

(d) Show that the action of $\xi(f)$ on m_B, C_{AB}, and $N_{AB} = \partial_u C_{AB}$ is

$$\begin{aligned} \mathcal{L}_f C_{AB} &= f\partial_u C_{AB} - 2D_A D_B f + \gamma_{AB} D^2 f \ , \\ \mathcal{L}_f N_{AB} &= f\partial_u N_{AB} \ , \\ \mathcal{L}_f m_B &= f\partial_u m_B + \frac{1}{4}\left(N^{AB}D_A D_B f + 2D_A N^{AB} D_B f\right) \ . \end{aligned} \quad (34.336)$$

Note that the traceless condition on C_{AB} is preserved under supertranslations.

(e) The function $f(x^A)$ can be expanded in spherical harmonics on the sphere. Show that the $\ell = 0$ and $\ell = 1$ modes in this expansion correspond to the standard global translations in Minkowski spacetime. Find the action of these modes on C_{AB}, N_{AB}, and m_B.

12. Exercise 12. (Section 5)

In addition to the supertranslations, the four-dimensional BMS algebra also contains generators of an (extended) Lorentz group. We will study these in this problem.

(a) Determine the Killing vector ζ that generates Lorentz transformations in flat spacetime in the $(u, r, z, \bar{z})$ coordinates. Show that it can be parametrized in terms of a global CKV Y^A on S^2, and find $\zeta(Y)$.[222]

(b) Show that $[\zeta(Y_1), \zeta(Y_2)] = \zeta([Y_1, Y_2])$. This shows that the Lorentz algebra is isomorphic to $SL(2, \mathbb{C})$, the algebra of global CKVs of S^2.

(c) Show that $\zeta(Y)$ preserves the asymptotic form of the metric in asymptotically flat spacetimes even when Y is a local CKV of S^2, except at possibly isolated analytic singularities. Find the action of $\zeta(Y)$ on C_{AB}. These diffeomorphisms are called superrotations.

13. Exercise 13. (Section 6)

In this problem, we study the gravitational memory effect experienced by inertial observers due to supertranslations.

(a) Working in retarded Bondi coordinates, determine the first subleading correction to the component of the four-velocity of an inertial time-like observer that is stationary with respect to retarded time at leading order (i.e., $v^\mu = \delta^\mu_u + \mathcal{O}(r^{-1})$). Then determine the trajectory with this four-velocity that passes through the point $(u_0, r_0, z_0, \bar{z}_0)$ and is valid for $|u - u_0| \ll r_0$. Be sure to determine any subleading corrections needed to reproduce the subleading corrections to the four-velocity.

(b) Now consider a nearby inertial observer, who at $u = u_0$ is located at the same radius r_0 but at a different point $(z_1, \bar{z}_1)$ on the asymptotic S^2, where $|z_1 - z_0| \sim \mathcal{O}(r_0^{-1})$. Determine the proper distance between the observers at retarded time $u > u_0$ to leading order in the large-r_0 limit. Assume $u - u_0 \ll r_0$, so you can use the trajectory determined in part (a).

(c) A burst of radiation of the following form passes the observers:

$$T^M_{uu}(u, r, z, \bar{z}) = \frac{\mu}{4\pi r^2}\delta(u - u_{\rm rad})\gamma^{z\bar{z}}\delta^2(z - z_{\rm rad}) \ , \tag{34.337}$$

where

$$u_{\rm rad} > u_0 \ , \qquad \frac{|u_{\rm rad} - u_0|}{r_0} \ll 1 \ . \tag{34.338}$$

Determine the change in proper distance between the observers as a result of the passage of this radiation. You will need to work consistently to an order at which this change is nonzero. Also, assume that the Bondi mass m_B is independent of $(z, \bar{z})$.

(d) Find the supertranslation f that gives rise to the same change in proper distance as calculated in part (c).

14. Exercise 14. (Section 7)

Consider a Schwarzschild black hole with mass M perturbed by a null shockwave at $v = v_0$ described by the stress tensor

$$\begin{aligned} T_{vv} &= \frac{1}{4\pi r^2}\left[\mu + \frac{1}{4}D^2\left(D^2 + 2\right)f\right]\delta\left(v - v_0\right) - \frac{3M}{8\pi r^3}D^2 f\delta\left(v - v_0\right) \ , \\ T_{vA} &= -\frac{3M}{8\pi r^2}D_A f\delta\left(v - v_0\right) \ . \end{aligned} \tag{34.339}$$

(a) Solve the linearized Einstein's equations about the initial Schwarzschild solution in Bondi gauge. Assume that only the zero mode of the Bondi mass aspect m_B on $\mathcal{I}^-$ changes under this perturbation.

[222] A conformal Killing vector (CKV) on S^2 is one that satisfies $D_A Y_B + D_B Y_A = \gamma_{AB} D_C Y^C$. In the $(z, \bar{z})$ coordinates, this equation reads $\partial_{\bar{z}} Y^z = \partial_z Y^{\bar{z}} = 0$, implying that any holomorphic vector field $Y^z(z)$ is locally a CKV. The ones that are defined globally on the sphere S^2 take the special form $Y^z(z) = a + bz + cz^2$ for $a, b, c \in \mathbb{C}$.

(b) Show that the final black hole (after $v > v_0$) can be obtained instead by sending a spherically symmetric null shockwave with stress tensor

$$T_{vv} = \frac{\mu}{4\pi r^2}\delta\left(v - v_0\right) \ , \tag{34.340}$$

followed by an infinitesimal supertranslation.

15. Exercise 15. (Section 7)

Consider the Vaidya black hole created by a spherically symmetric null shockwave at $v = 0$. We define the horizon large gauge charge as

$$Q_\varepsilon^{\mathcal{H}^+} \equiv \frac{1}{e^2}\int_{\mathcal{H}_+^+} \varepsilon * F \ , \tag{34.341}$$

where $\mathcal{H}_+^+$ is the future of the horizon of the Vaidya black hole.

(a) Using the constraints derived from Maxwell's equations on the horizon $\mathcal{H}^+$, rewrite $Q_\varepsilon^{\mathcal{H}^+}$ as an integral over $\mathcal{H}^+$, and determine the soft and hard parts of this charge. Write the soft charge explicitly in the $(v, r, z, \bar{z})$ coordinates.

(b) Determine the symplectic form for the gauge fields on $\mathcal{H}^+$. (Hint: You can use the symplectic form Ω_Σ derived in exercise 3 and set $\Sigma = \mathcal{H}^+$). Write it out explicitly in $(v, r, z, \bar{z})$ coordinates.

(c) By using the explicit forms of the charge and symplectic form derived in parts (a) and (b), show that $\hat{Q}_\varepsilon^{\mathcal{H}^+}$ generates large gauge transformations on the horizon, that is,

$$\left[\hat{Q}_\varepsilon^{\mathcal{H}^+}, A_z\right]_{\mathcal{H}^+} = i\partial_z\varepsilon\big|_{\mathcal{H}^+} \ . \tag{34.342}$$

34.9 Solutions *with Prahar Mitra and Monica Pate*

1(a). First consider the electric field produced by an incoming null shockwave. We work in the $(v, r, z, \bar{z})$ coordinates. Maxwell's equations take the explicit form

$$\begin{aligned} \left(\partial_v + \partial_r\right)\left(r^2 F_{rv}\right) - \gamma^{z\bar{z}}\left(\partial_z F_{v\bar{z}} + \partial_{\bar{z}} F_{vz}\right) &= e^2\delta(v) Y_{\ell m} \ , \\ \partial_r\left(r^2 F_{rv}\right) + \gamma^{z\bar{z}}\left(\partial_z F_{r\bar{z}} + \partial_{\bar{z}} F_{rz}\right) &= 0 \ , \\ r^2\left(\partial_v + \partial_r\right) F_{rz} + r^2\partial_r F_{vz} - \partial_z\left(\gamma^{z\bar{z}} F_{z\bar{z}}\right) &= 0 \ . \end{aligned} \tag{34.343}$$

We also have the Bianchi identities, namely,

$$\begin{aligned} \partial_v F_{z\bar{z}} + \partial_{\bar{z}} F_{vz} - \partial_z F_{v\bar{z}} &= 0 \ , \\ \partial_r F_{z\bar{z}} + \partial_{\bar{z}} F_{rz} - \partial_z F_{r\bar{z}} &= 0 \ , \\ \partial_v F_{rz} - \partial_z F_{rv} - \partial_r F_{vz} &= 0 \ . \end{aligned} \tag{34.344}$$

A simple solution satisfying the boundary conditions is

$$F_{vz} = -e^2\delta(v)\partial_z\varepsilon_{\ell m} \ , \qquad F_{vr} = F_{rz} = F_{z\bar{z}} = 0 \ , \tag{34.345}$$

where

$$\varepsilon_{\ell m} = \begin{cases} \log\left(1 + z\bar{z}\right) Y_{00} \ , & \ell = 0 \ , \\ -\frac{1}{\ell(\ell+1)} Y_{\ell m} \ , & \ell \neq 0 \ , \end{cases} \tag{34.346}$$

and $Y_{\ell m}$ satisfies

$$2\gamma^{z\bar{z}}\partial_z\partial_{\bar{z}}Y_{\ell m} = -\ell(\ell+1)Y_{\ell m} \ . \tag{34.347}$$

This implies

$$2\gamma^{z\bar{z}}\partial_z\partial_{\bar{z}}\varepsilon_{\ell m} = Y_{\ell m} \ . \tag{34.348}$$

Any other solution differs from this one by a solution to the homogeneous Maxwell equation. Similarly, for the outgoing null shockwave, the solution is

$$F_{uz} = -e^2\delta(u)\partial_z\varepsilon_{\ell' m'} \ , \qquad F_{ur} = F_{rz} = F_{z\bar{z}} = 0 \ . \tag{34.349}$$

1(b). We have $F^{(0)}_{vz} = \partial_v A_z^{-(0)}$ and the boundary condition $A_z^{-(0)}\big|_{\mathcal{I}^-_-} = 0$, we find

$$A_z^{-(0)}(v,z,\bar{z}) = -e^2\theta(v)\partial_z\varepsilon_{\ell m}(z,\bar{z}) \ , \tag{34.350}$$

where θ is the Heaviside step function. Then, using the antipodal matching condition, we find

$$A_z^{(0)}\big|_{\mathcal{I}^+_-} = -e^2\partial_z\varepsilon_{\ell m}(z,\bar{z}) \ . \tag{34.351}$$

Finally, integrating $F^{(0)}_{uz} = \partial_u A^{(0)}_z$ and using the above boundary condition, we find

$$A^{(0)}_z(u,z,\bar{z}) = -e^2\partial_z\varepsilon_{\ell m}(z,\bar{z}) - e^2\theta(u)\partial_z\varepsilon_{\ell' m'}(z,\bar{z}) \ . \tag{34.352}$$

2(a). In the $(u,r,z,\bar{z})$ coordinates, the Lorenz gauge condition and Maxwell equations take the form

$$\begin{aligned}
(\partial_u - \partial_r)\left(r^2F_{ru}\right) + \gamma^{z\bar{z}}\left(\partial_z F_{u\bar{z}} + \partial_{\bar{z}}F_{uz}\right) &= 0 \ , \\
-\partial_r\left(r^2F_{ru}\right) + \gamma^{z\bar{z}}\left(\partial_z F_{r\bar{z}} + \partial_{\bar{z}}F_{rz}\right) &= 0 \ , \\
r^2\left(\partial_u - \partial_r\right)F_{rz} + r^2\partial_r F_{uz} + \partial_z\left(\gamma^{z\bar{z}}F_{z\bar{z}}\right) &= 0 \ , \\
-\partial_u\big(r^2A_r\big) - \partial_r\big(r^2A_u\big) + \partial_r\big(r^2A_r\big) + \gamma^{z\bar{z}}\left(\partial_z A_{\bar{z}} + \partial_{\bar{z}}A_z\right) &= 0 \ .
\end{aligned} \tag{34.353}$$

To impose the Bianchi identity, express the Maxwell equations in terms of the gauge field A_μ, and in addition, substitute the Lorenz gauge condition into each Maxwell equation:

$$\begin{aligned}
-2r\partial_r(r\partial_u A_u) + \partial_r(r^2\partial_r A_u) + 2\gamma^{z\bar{z}}\partial_z\partial_{\bar{z}}A_u &= 0 \ , \\
-2\partial_r(rA_u) - 2\partial_u\partial_r(r^2A_r) + \partial_r^2(r^2A_r) + 2\gamma^{z\bar{z}}\partial_z\partial_{\bar{z}}A_r &= 0 \ , \\
-2r^2\partial_u\partial_r A_z + r^2\partial_r^2 A_z + 2r\partial_z(A_r - A_u) + 2\partial_z(\gamma^{z\bar{z}}\partial_{\bar{z}}A_z) &= 0 \ .
\end{aligned} \tag{34.354}$$

The gauge field can be expanded at large r as

$$A_u = \sum_{n=2}^{\infty}\frac{A_u^{(n)}}{r^n} \ , \qquad A_r = \sum_{n=2}^{\infty}\frac{A_r^{(n)}}{r^n} \ , \qquad A_z = \sum_{n=0}^{\infty}\frac{A_z^{(n)}}{r^n} \ . \tag{34.355}$$

Note that A_u has a slightly different expansion than what was given in section 34.2, namely, $A_u^{(1)} = 0$. The Lorenz gauge condition leaves unfixed a set of residual gauge transformations satisfying $\Box\varepsilon = 0$. Among these are a set of trivial gauge transformations with falloff behavior $\mathcal{O}(1/r)$ near $\mathcal{I}^+$. This set of residual trivial gauge transformations has precisely the degrees

of freedom of a massless scalar field with the usual falloff near $\mathcal{I}^+$, and thus, the residual trivial gauge symmetry can be used to set $A_u^{(1)} = 0$. Then the Lorenz gauge condition has the following expansion:

$$\begin{aligned}
\partial_u A_r^{(2)} &= \gamma^{z\bar{z}} \left(\partial_z A_{\bar{z}}^{(0)} + \partial_{\bar{z}} A_z^{(0)} \right) \ , \\
\partial_u A_r^{(3)} &= \gamma^{z\bar{z}} \left(\partial_z A_{\bar{z}}^{(1)} + \partial_{\bar{z}} A_z^{(1)} \right) \ , \\
\partial_u A_r^{(n+2)} &= (n-1)(A_u^{(n+1)} - A_r^{(n+1)}) + \gamma^{z\bar{z}} \left(\partial_z A_{\bar{z}}^{(n)} + \partial_{\bar{z}} A_z^{(n)} \right) \ , \qquad n > 1 \ .
\end{aligned} \tag{34.356}$$

Using the leading order equation, one can determine $A_r^{(2)}$ up to integration constants in terms of the boundary data $A_z^{(0)}$. The first equation in (34.354) has the following expansion:

$$\begin{aligned}
\partial_u A_u^{(2)} &= 0 \ , \\
\partial_u A_u^{(n+1)} &= -\frac{1}{2n} \left[n(n-1) + 2\gamma^{z\bar{z}} \partial_z \partial_{\bar{z}} \right] A_u^{(n)} \ , \qquad n > 1 \ .
\end{aligned} \tag{34.357}$$

Hence, we can determine all $A_u^{(n)}$ up to integration constants. The second equation in (34.354) has the following expansion:

$$\begin{aligned}
\partial_u A_r^{(3)} &= -A_u^{(2)} - \gamma^{z\bar{z}} \partial_z \partial_{\bar{z}} A_r^{(2)} \ , \\
\partial_u A_r^{(n+1)} &= -A_u^{(n)} - \left[\frac{1}{2}(n-2) + \frac{1}{n-1} \gamma^{z\bar{z}} \partial_z \partial_{\bar{z}} \right] A_r^{(n)} \ , \qquad n > 2 \ .
\end{aligned} \tag{34.358}$$

Hence, with the previously determined set of $A_u^{(n)}$ and $A_r^{(2)}$, we can determine all $A_r^{(n)}$ up to integration constants. Finally, the third equation in (34.354) has the following expansion:

$$\begin{aligned}
\partial_u A_z^{(1)} &= -\partial_z (\gamma^{z\bar{z}} \partial_{\bar{z}} A_z^{(0)}) \ , \\
\partial_u A_z^{(n+1)} &= \frac{1}{n+1} \left[-\partial_z A_r^{(n+1)} + \partial_z A_u^{(n+1)} - \frac{1}{2} n(n+1) A_z^{(n)} - \partial_z (\gamma^{z\bar{z}} \partial_{\bar{z}} A_z^{(n)}) \right] ,
\end{aligned} \tag{34.359}$$

for $n > 0$. With the previously determined sets of $A_u^{(n)}$ and $A_r^{(n)}$ plus the boundary data $A_z^{(0)}$, we can determine all $A_z^{(n)}$, up to integration constants. Therefore, we have determined the full four-dimensional gauge field entirely in terms of $A_z^{(0)}$ up to integration constants. Note the remaining (seemingly unused) equations in (34.357) give rise to additional constraints on the integration constants.

3(a). Varying the action, we find

$$\delta S = -\frac{1}{e^2} \int d\delta A \wedge *F = \frac{1}{e^2} \int (d * F) \wedge \delta A - \frac{1}{e^2} \int d \left(*F \wedge \delta A \right) \ . \tag{34.360}$$

The equations of motion are $d*F = 0$. Following [198], the (pre) symplectic potential current density can be read off as

$$\boldsymbol{\Theta} \left(A, \delta A \right) = -\frac{1}{e^2} \left(*F \right) \wedge \delta A \ . \tag{34.361}$$

The symplectic form is then

$$\Omega_\Sigma = \int_\Sigma \boldsymbol{\omega} \left(A, \delta_1 A, \delta_2 A \right) = -\frac{1}{e^2} \int_\Sigma \left[\delta_1 \left(*F \right) \wedge \delta_2 A - \delta_2 \left(*F \right) \wedge \delta_1 A \right] \ . \tag{34.362}$$

In terms of a wedge product of differential forms on the symplectic manifold, this can be written as

$$\Omega_\Sigma = -\frac{1}{e^2}\int_\Sigma \delta\,(*F)\wedge\delta A\ . \tag{34.363}$$

3(b). For $\Sigma = \mathcal{I}^+$, we are interested in the $uz\bar{z}$ component of the above three-form. We find

$$\begin{aligned}\boldsymbol{\omega}_{uz\bar{z}}\big|_{\mathcal{I}^+} &= -\frac{1}{e^2}\left[\delta(*F)_{uz}\wedge\delta A_{\bar{z}} + \delta(*F)_{\bar{z}u}\wedge\delta A_z + \delta(*F)_{z\bar{z}}\wedge\delta A_u\right]_{\mathcal{I}^+}\\ &= -\frac{i}{e^2}\left[\delta F^{(0)}_{uz}\wedge\delta A^{(0)}_{\bar{z}} + \delta F^{(0)}_{u\bar{z}}\wedge\delta A^{(0)}_z\right]\ ,\end{aligned} \tag{34.364}$$

where

$$(*F)_{uz} = \varepsilon_{uzr\bar{z}}F^{r\bar{z}} = i\,(F_{uz}-F_{rz})\ ,\qquad (*F)_{z\bar{z}} = ir^2\gamma_{z\bar{z}}F_{ru}\ . \tag{34.365}$$

This implies

$$\Omega_{\mathcal{I}^+} = \frac{1}{e^2}\int du d^2z\left[\delta F^{(0)}_{uz}\wedge\delta A^{(0)}_{\bar{z}} + \delta F^{(0)}_{u\bar{z}}\wedge\delta A^{(0)}_z\right]\ . \tag{34.366}$$

We now use this to write everything in terms of $\hat{A}_z$, ϕ, and N. To do this, we write

$$A^{(0)}_z = \hat{A}_z + \partial_z\phi\ ,\qquad \int_{-\infty}^{\infty} du F^{(0)}_{uz} = e^2\partial_z N\ , \tag{34.367}$$

which gives

$$\Omega_{\mathcal{I}^+} = \frac{2}{e^2}\int du d^2z\partial_u\delta\hat{A}_z\wedge\delta\hat{A}_{\bar{z}} - 2\int d^2z\delta\partial_z\phi\wedge\partial_{\bar{z}}\delta N\ . \tag{34.368}$$

We can then derive the brackets

$$\begin{aligned}-\frac{2}{e^2}\left[\partial_u\hat{A}_z(u,z,\bar{z}),\hat{A}_{\bar{w}}(u',w,\bar{w})\right] &= i\delta(u-u')\delta^2(z-w)\ ,\\ 2\left[\partial_z\phi(z,\bar{z}),\partial_{\bar{w}}N(w,\bar{w})\right] &= i\delta^2(z-w)\ .\end{aligned} \tag{34.369}$$

Integrating the above, we find

$$\begin{aligned}\left[\hat{A}_z(u,z,\bar{z}),\hat{A}_{\bar{w}}(u',w,\bar{w})\right] &= -\frac{ie^2}{4}\Theta(u-u')\delta^2(z-w)\ ,\\ [\phi(z,\bar{z}),N(w,\bar{w})] &= -\frac{i}{4\pi}\log|z-w|^2 + f(z,\bar{z}) + g(w,\bar{w})\ .\end{aligned} \tag{34.370}$$

4. The free field mode expansion can be written as

$$\begin{aligned}A_\mu(x) &= e\sum_{\alpha=\pm}\int\frac{d^3q}{(2\pi)^3}\frac{1}{2\omega_q}\left[\varepsilon^{*\alpha}_\mu(\vec{q})a_\alpha(\vec{q})e^{-i\omega_q u - i\omega_q r(1-\hat{q}\cdot\hat{x})}\right.\\ &\qquad\left.+\varepsilon^\alpha_\mu(\vec{q})a^\dagger_\alpha(\vec{q})e^{i\omega_q u + i\omega_q r(1-\hat{q}\cdot\hat{x})}\right]\\ &= \frac{e}{8\pi^2}\sum_{\alpha=\pm}\int_0^\infty d\omega_q\omega_q\int_0^\pi d\theta\sin\theta\left[\varepsilon^{*\alpha}_\mu(\vec{q})a_\alpha(\vec{q})e^{-i\omega_q u - i\omega_q r(1-\cos\theta)}\right.\\ &\qquad\left.+\varepsilon^\alpha_\mu(\vec{q})a^\dagger_\alpha(\vec{q})e^{i\omega_q u + i\omega_q r(1-\cos\theta)}\right]\ .\end{aligned} \tag{34.371}$$

At large r, we use the saddle point approximation. The exponent is stationary at $\theta = 0, \pi$. The saddle point at $\theta = \pi$ does not contribute due to the Riemann-Lebesgue lemma (the assumptions of the lemma hold here as operator statements due to the cluster decomposition principle that all $\mathcal{S}$-matrices satisfy). Then, expanding the integrand around $\theta = 0$, we find

$$\begin{aligned} A_\mu(x) &= \frac{e}{8\pi^2}\sum_{\alpha=\pm}\int_0^\infty d\omega_q \omega_q \varepsilon_\mu^{*\alpha}(\omega_q\hat{x}) a_\alpha(\omega_q\hat{x}) e^{-i\omega_q u}\int_0^\pi d\theta\theta e^{-i\omega_q r\theta^2/2} + c.c. + \mathcal{O}(r^{-2}) \\ &= -\frac{ie}{8\pi^2 r}\sum_{\alpha=\pm}\int_0^\infty d\omega_q \left[\varepsilon_\mu^{*\alpha}(\omega_q\hat{x}) a_\alpha(\omega_q\hat{x}) e^{-i\omega_q u} - c.c.\right] + \mathcal{O}(r^{-2}) \ . \end{aligned} \tag{34.372}$$

We are interested first in $A_z = \partial_z x^\mu A_\mu$. To determine this, note that

$$\partial_z x^\mu \varepsilon_\mu^+(\omega_q\hat{x}) = 0 \ , \qquad \partial_z x^\mu \varepsilon_\mu^-(\omega_q\hat{x}) = \frac{\sqrt{2}r}{1+z\bar{z}} \ . \tag{34.373}$$

Using this, we find

$$A_z = -\frac{i}{8\pi^2}\frac{\sqrt{2}e}{1+z\bar{z}}\int_0^\infty d\omega_q \left[a_+(\omega_q\hat{x})e^{-i\omega_q u} - a_-^\dagger(\omega_q\hat{x})e^{i\omega_q u}\right] + \mathcal{O}(r^{-1}) \ . \tag{34.374}$$

Finally, we can immediately read off from this equation the large-r mode:

$$A_z^{(0)} = -\frac{i}{8\pi^2}\frac{\sqrt{2}e}{1+z\bar{z}}\int_0^\infty d\omega_q \left[a_+(\omega_q\hat{x})e^{-i\omega_q u} - a_-^\dagger(\omega_q\hat{x})e^{i\omega_q u}\right] \ . \tag{34.375}$$

From this, we find

$$\begin{aligned} e^2\partial_z N &= \frac{1}{2}\lim_{\omega\to 0^+}\int_{-\infty}^\infty du \left(e^{i\omega u} + e^{-i\omega u}\right)\partial_u A_z^{(0)} \\ &= -\frac{1}{8\pi}\frac{\sqrt{2}e}{1+z\bar{z}}\lim_{\omega\to 0^+}\left[\omega a_+(\omega\hat{x}) + \omega a_-^\dagger(\omega\hat{x})\right] \ . \end{aligned} \tag{34.376}$$

5(a). Rewriting expression (34.319) is a simple problem of algebra. We are required to substitute

$$\begin{aligned} q^\mu &= \frac{\omega}{1+z\bar{z}}\left(1+z\bar{z}, z+\bar{z}, -i(z-\bar{z}), 1-z\bar{z}\right) \ , \\ p_k^\mu &= \frac{E_k}{1+z_k\bar{z}_k}\left(1+z_k\bar{z}_k, z_k+\bar{z}_k, -i(z_k-\bar{z}_k), 1-z_k\bar{z}_k\right) \ , \\ \varepsilon_+^\mu(q) &= \frac{1}{\sqrt{2}}\left(\bar{z}, 1, -i, -\bar{z}\right) \ , \\ \varepsilon_-^\mu(q) &= \frac{1}{\sqrt{2}}\left(z, 1, i, -z\right) \ . \end{aligned} \tag{34.377}$$

To simplify the algebra a little, note that the polarizations satisfy the property

$$\varepsilon_+^\mu(q) = \frac{1}{\sqrt{2}\omega}\partial_z\left[(1+z\bar{z})\,q^\mu\right] \ , \qquad \varepsilon_-^\mu(q) = \frac{1}{\sqrt{2}\omega}\partial_{\bar{z}}\left[(1+z\bar{z})\,q^\mu\right] \ . \tag{34.378}$$

Then the soft factor for the kth particle takes the form

$$\begin{aligned}\frac{p_k\cdot\varepsilon_+}{p_k\cdot q}&=\frac{1}{\sqrt{2}\omega}\frac{\partial_z\left[(1+z\bar{z})\,p_k\cdot q\right]}{p_k\cdot q}\\&=\frac{1}{\sqrt{2}\omega}\,(1+z\bar{z})\,\partial_z\log\left[(1+z\bar{z})\,p_k\cdot q\right]\ .\end{aligned}\tag{34.379}$$

A similar formula for negative helicity holds with $\partial_z\to\partial_{\bar{z}}$. Finally, compute

$$p_k\cdot q=-\frac{2\omega E_k}{(1+z\bar{z})\,(1+z_k\bar{z}_k)}|z-z_k|^2\ .\tag{34.380}$$

Then the soft factor is

$$\begin{aligned}\frac{p_k\cdot\varepsilon_+}{p_k\cdot q}&=\frac{1}{\sqrt{2}\omega}\,(1+z\bar{z})\,\partial_z\log|z-z_k|^2=\frac{1}{\sqrt{2}\omega}\frac{1+z\bar{z}}{z-z_k}\ ,\\\frac{p_k\cdot\varepsilon_-}{p_k\cdot q}&=\frac{1}{\sqrt{2}\omega}\,(1+z\bar{z})\,\partial_{\bar{z}}\log|z-z_k|^2=\frac{1}{\sqrt{2}\omega}\frac{1+z\bar{z}}{\bar{z}-\bar{z}_k}\ .\end{aligned}\tag{34.381}$$

Thus, the soft-theorem can be written as

$$\begin{aligned}&\lim_{\omega\to0^+}\left[\omega\,\langle\text{out}|\,a_+^{\text{out}}(\omega\hat{x})\mathcal{S}\,|\text{in}\rangle\right]\\&\qquad=\frac{e}{\sqrt{2}}\,(1+z\bar{z})\left[\sum_{k\in\text{out}}\frac{Q_k}{z-z_k}-\sum_{k\in\text{in}}\frac{Q_k}{z-z_k}\right]\langle\text{out}|\,\mathcal{S}\,|\text{in}\rangle\ .\end{aligned}\tag{34.382}$$

A similar formula is true for the negative helicity photon. Finally, note that we can write the limit in terms of an insertion of N_z, by using formula (34.317) derived in exercise 4, namely,

$$e^2\partial_z N=-\frac{1}{8\pi^2}\frac{\sqrt{2}e}{1+z\bar{z}}\lim_{\omega\to0^+}\left[\omega a_+\left(\omega\hat{x}\right)+\omega a_-^\dagger\left(\omega\hat{x}\right)\right]\ .\tag{34.383}$$

This gives for an insertion of N_z,

$$\langle\text{out}|\,\partial_z N\ \mathcal{S}\,|\text{in}\rangle=-\frac{1}{8\pi^2}\left[\sum_{k\in\text{out}}\frac{Q_k}{z-z_k}-\sum_{k\in\text{in}}\frac{Q_k}{z-z_k}\right]\langle\text{out}|\,\mathcal{S}\,|\text{in}\rangle\ .\tag{34.384}$$

5(b). Again, it will be convenient to write the soft factor

$$\frac{p_k\cdot\varepsilon_+}{p_k\cdot q}=-\frac{1}{\sqrt{2}\omega}\,(1+z\bar{z})\,\partial_z\log\frac{(1+z\bar{z})^{-1}}{p_k\cdot q}\ .\tag{34.385}$$

However, now we parametrize $p_k^\mu=m_k\left(\sqrt{1+\rho_k^2}\ ,\rho_k\hat{x}_k\right)$ and $q^\mu=\omega\,(1,\hat{q})$. Then, we find

$$\frac{p_k\cdot\varepsilon_+}{p_k\cdot q}=-\frac{1}{2\sqrt{2}\omega}\,(1+z\bar{z})\,\partial_z\log\frac{\gamma_{z\bar{z}}}{\left(\sqrt{1+\rho_k^2}-\rho_k\hat{q}\cdot\hat{x}_k\right)^2}\ .\tag{34.386}$$

Note that the mass m_k drops out of the formula. Now, recall the scalar propagator (34.127):

$$G\left(\rho,\hat{x};\hat{q}\right)=\frac{1}{4\pi}\frac{\gamma_{z\bar{z}}}{\left(\sqrt{1+\rho^2}-\rho\hat{q}\cdot\hat{x}\right)^2}\ .\tag{34.387}$$

This is precisely the term in the logarithm in the soft factor. Thus, we find

$$\frac{p_k \cdot \varepsilon_+}{p_k \cdot q} = -\frac{1}{2\sqrt{2}\omega}\left(1 + z\bar{z}\right)\partial_z \log G\left(\rho_k, \hat{x}_k; \hat{q}\right) \ . \tag{34.388}$$

Then the soft theorem can be written as

$$\langle \text{out}| \, \partial_z N \, \mathcal{S} \, |\text{in}\rangle = \langle \text{out}| \, \mathcal{S} \, |\text{in}\rangle \left[\sum_{k\in\text{out}} - \sum_{k\in\text{in}}\right] \frac{Q_k}{16\pi^2}\partial_z \log G\left(\rho_k, \hat{x}_k; \hat{q}\right) \ . \tag{34.389}$$

6(a). The compactified coordinates on the Penrose diagram of Minkowski space are given by

$$\begin{aligned} T &= \tan^{-1}\left(t + r\right) + \tan^{-1}\left(t - r\right) \ , \\ R &= \tan^{-1}\left(t + r\right) - \tan^{-1}\left(t - r\right) \ , \end{aligned} \tag{34.390}$$

with the coordinate range $R + |T| < \pi$ and $R \geq 0$. Setting $t = \nu r$, we find

$$\begin{aligned} T &= \tan^{-1}\left[r\left(\nu + 1\right)\right] + \tan^{-1}\left[r\left(\nu - 1\right)\right] \ , \\ R &= \tan^{-1}\left[r\left(\nu + 1\right)\right] - \tan^{-1}\left[r\left(\nu - 1\right)\right] \ . \end{aligned} \tag{34.391}$$

Lines of constant ν and constant r are shown in figure 34.24 .

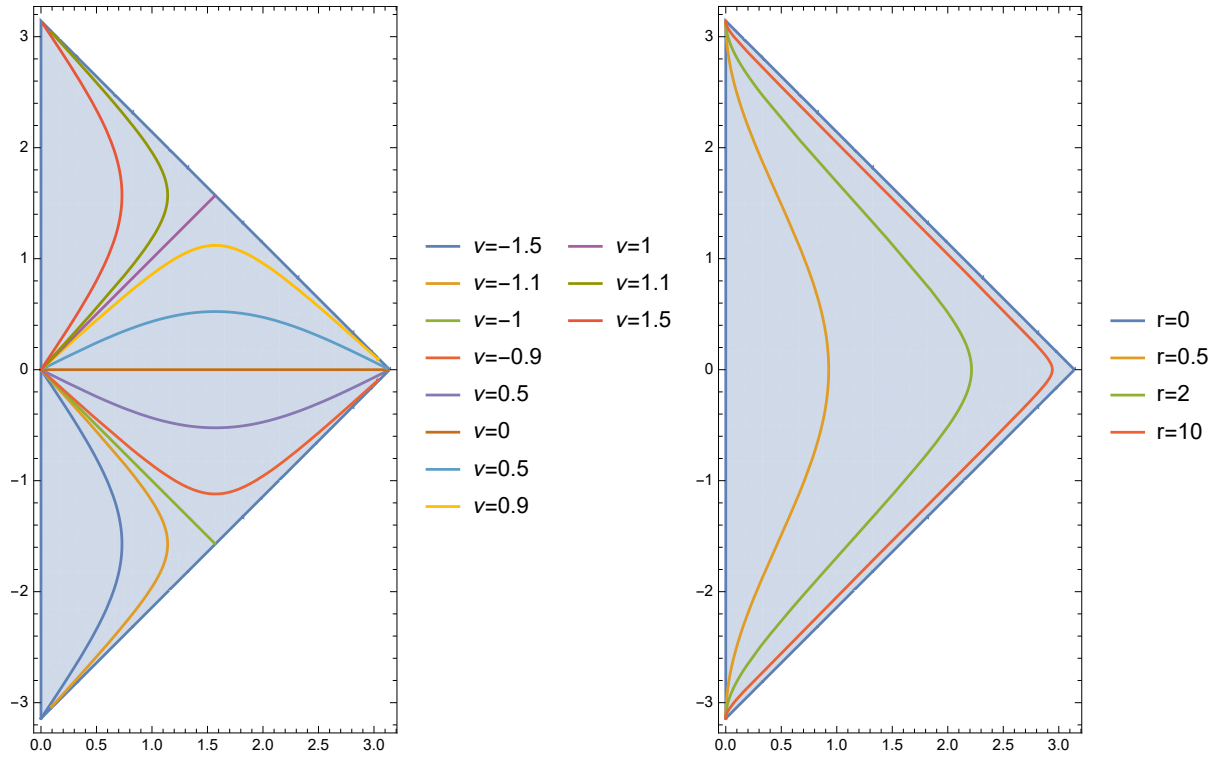

Figure 34.24: Lines of constant ν (left) and constant r (right).

6(b). Let us first determine the metric in these coordinates. We start from the metric of Minkowski space in the standard spherical coordinates

$$ds^2 = -dt^2 + dr^2 + r^2 d\Omega_2^2 \ . \tag{34.392}$$

Substituting in $t = \nu r$, we find

$$\begin{aligned} ds^2 &= -(rd\nu + \nu dr)^2 + dr^2 + r^2 d\Omega_2^2 \\ &= -r^2 d\nu^2 - 2\nu r d\nu dr + \left(1-\nu^2\right) dr^2 + r^2 d\Omega_2^2 \ . \end{aligned} \tag{34.393}$$

The inverse metric is

$$g^{\mu\rho} = \frac{1}{r^2} \begin{pmatrix} -\left(1-\nu^2\right) & -r\nu & 0 \\ -\nu r & r^2 & 0 \\ 0 & 0 & \gamma^{AB} \end{pmatrix} \ , \tag{34.394}$$

where $x^A = (\theta, \phi)$, and γ^{AB} is the inverse metric on the unit S^2. Note that $\sqrt{-g} = r^3\sqrt{\gamma}$. The scalar wave equation is then

$$\begin{aligned} 0 = D^2\varepsilon &= \frac{1}{\sqrt{-g}} \partial_\mu \left(\sqrt{-g} g^{\mu\rho} \partial_\rho \varepsilon\right) \\ &= -\frac{1}{r^2}\left(1-\nu^2\right)\partial_\nu^2 \varepsilon - \frac{2\nu}{r}\partial_\nu\partial_r\varepsilon + \frac{2}{r}\partial_r\varepsilon + \partial_r^2\varepsilon + \frac{1}{r^2} D^2\varepsilon \ , \end{aligned} \tag{34.395}$$

where D^2 is the Laplacian operator on S^2.

6(c). For r-independent solutions, the scalar wave equation reduces to

$$\left(1-\nu^2\right)\partial_\nu^2\varepsilon = D^2\varepsilon \ . \tag{34.396}$$

Now consider solutions of the form $\varepsilon_{\ell m}(\nu, x^A) = A_\ell(\nu) Y_m^\ell(x^A)$. By noting that $Y_m^\ell(x^A)$ satisfies $D^2 Y_m^\ell = -\ell\left(\ell+1\right) Y_m^\ell$, we find the following equation for $A_\ell(\nu)$:

$$\left(1-\nu^2\right)\partial_\nu^2 A_\ell(\nu) = -\ell\left(\ell+1\right) A_\ell(\nu) \ . \tag{34.397}$$

When $\ell = 0$, the most general solution is $A_0(\nu) = d_1\nu + d_2$. Requiring that the function be well defined at the origin, $\nu \to \pm\infty$ requires $d_1 = 0$. We also normalize the solution so that $A_\ell(1) = 1$. Thus, we must have $d_2 = 1$. So, for $\ell = 0$, the solution is

$$A_0(\nu) = 1 \ . \tag{34.398}$$

We now come to the less trivial case $\ell > 0$, which will be our assumption for the rest of this problem. The first step is to note that by taking a derivative of the equation above we arrive at

$$\left(1-\nu^2\right) A_\ell'''(\nu) - 2\nu A_\ell''(\nu) + \ell\left(\ell+1\right) A_\ell'(\nu) = 0 \ , \tag{34.399}$$

which is the Legendre equation for $A_\ell'(\nu)$. Thus, we must have

$$A_\ell'(\nu) = c_1 P_\ell(\nu) + c_2 Q_\ell(\nu) \ . \tag{34.400}$$

Integrating this equation yields

$$A_\ell(\nu) = \frac{c_1}{2\ell+1}\left[P_{\ell+1}(\nu) - P_{\ell-1}(\nu)\right] + \frac{c_2}{2\ell+1}\left[Q_{\ell+1}(\nu) - Q_{\ell-1}(\nu)\right] + c_3 \ , \tag{34.401}$$

where we have used the formula

$$\int d\nu P_\ell(\nu) = \frac{P_{\ell+1}(\nu) - P_{\ell-1}(\nu)}{2\ell+1} \ , \tag{34.402}$$

and similarly for Q_ℓ. Note that we originally started out with a second order differential equation, whereas our final answer for $A_\ell(\nu)$ contains three unknown constants. This is because we took a derivative of the original differential equation (34.397) in the process. To fix one of the constants, let us plug in our ansatz for the solution into the original differential equation. To do this, we use the property

$$\begin{aligned}\left[\left(1-\nu^2\right)\partial_\nu^2+\ell\left(\ell+1\right)\right]\left[P_{\ell+1}(\nu)-P_{\ell-1}(\nu)\right]=0\,,\\ \left[\left(1-\nu^2\right)\partial_\nu^2+\ell\left(\ell+1\right)\right]\left[Q_{\ell+1}(\nu)-Q_{\ell-1}(\nu)\right]=0\,.\end{aligned} \tag{34.403}$$

Thus, for (34.401) to satisfy the differential equation, we must have $c_3 = 0$. So, we find the solution

$$A_\ell(\nu)=c_1\left[P_{\ell+1}(\nu)-P_{\ell-1}(\nu)\right]+c_2\left[Q_{\ell+1}(\nu)-Q_{\ell-1}(\nu)\right]\,. \tag{34.404}$$

We are interested in studying the properties of this function at $\nu = \pm 1$ and $\nu = \pm\infty$. For this purpose, a more convenient representation of $Q_\ell(\nu)$ is

$$Q_\ell(\nu)=\frac{1}{2}P_\ell(\nu)\log\frac{1+\nu}{1-\nu}+F_\ell(\nu)\,,\qquad |\nu|<1\,, \tag{34.405}$$

where

$$F_\ell(\nu)=-\sum_{k=0}^{\lfloor\frac{\ell-1}{2}\rfloor}\frac{2\ell-4k-1}{(2k+1)\left(\ell-k\right)}P_{\ell-2k-1}(\nu)\,. \tag{34.406}$$

Note that $F_\ell(\nu)$ is a polynomial in ν. Then we have

$$A_\ell(\nu)=\left[c_1+\frac{c_2}{2}\log\frac{1+\nu}{1-\nu}\right]\left[P_{\ell+1}(\nu)-P_{\ell-1}(\nu)\right]+c_2\left[F_{\ell+1}(\nu)-F_{\ell-1}(\nu)\right], \tag{34.407}$$

for $|\nu| < 1$. Due to the logarithm in the parenthesis above, $A_\ell(\nu)$ has a branch point at $\nu = \pm 1$. Thus, we must choose an appropriate branch cut. We would like to choose the branch cut so that $A_\ell(\nu)$ is defined for all $\nu \in \mathbb{R}$ and so that it does not diverge at both $\nu \to \pm\infty$. As a result, the branch cuts must be chosen as follows. First, we choose an arbitrary branch cut at $\nu = +1$. This determines a particular way of defining $A_\ell(\nu)$ for $\nu > 1$ and in the process also specifies the asymptotic behavior of $A_\ell(\nu)$ at $\nu \to \infty$. Requiring that this is finite will fix c_1 in terms of c_2. Once this has been done, the choice of branch at $\nu = -1$ is fixed by requiring that the same solution (namely, for the same choice of c_1 and c_2) also be finite at $\nu \to -\infty$. We choose the branch cut at $\nu = 1$ so that it extends along $\nu = 1 + it$ for $t > 0$. With this choice of the branch cut, the extension of $A_\ell(\nu)$ to $\nu > 1$ is fixed as

$$A_\ell(\nu)=\left[c_1-\frac{ic_2\pi}{2}+\frac{c_2}{2}\log\frac{\nu+1}{\nu-1}\right]\left[P_{\ell+1}(\nu)-P_{\ell-1}(\nu)\right]+c_2\left[F_{\ell+1}(\nu)-F_{\ell-1}(\nu)\right]\,. \tag{34.408}$$

This extension can be seen by writing $\nu = 1 - re^{i\theta}$ near the branch point. Note that as θ goes from 0 to π, we move from $\nu < 1$ to $\nu > 1$ without crossing the branch cut. Plugging $\nu = 1 - re^{i\theta}$ into (34.407), then setting $\theta = \pi$, and finally setting $r = \nu - 1$, we reproduce (34.408). We can now study the asymptotics of this function at large ν. The leading term in the large ν expansion arises from $P_{\ell+1}(\nu)$, which goes like

$$P_{\ell+1}(\nu)\quad\to\quad\frac{2^{-\ell-1}(2\ell+2)!}{(\ell+1)!^2}\nu^{\ell+1}\qquad\text{as}\qquad\nu\to\infty\,. \tag{34.409}$$

Then we find

$$A_\ell(\nu) \to \left(c_1 - \frac{ic_2\pi}{2}\right) \frac{2^{-\ell-1}(2\ell+2)!}{(\ell+1)!^2}\nu^{\ell+1} + \cdots \ . \tag{34.410}$$

The quantity above is divergent unless $c_1 = \frac{ic_2\pi}{2}$. A proper check requires that we also verify that the subleading divergent powers also do not contribute in this limit. The subleading divergent powers do not contribute because

$$\frac{1}{2}\log\frac{\nu+1}{\nu-1}P_\ell(\nu) + F_\ell(\nu) = \mathcal{O}\left(\nu^{-\ell-1}\right) \qquad \text{at large } \nu \ . \tag{34.411}$$

Thus, we have determined that for the choice $c_1 = \frac{ic_2\pi}{2}$, $A_\ell(\nu)$ is completely finite at large ν. We now consider the extension of $A_\ell(\nu)$ to $\nu < -1$. Since the asymptotics of the Legendre polynomials is the same at $\nu \to -\infty$ as it is for $\nu \to +\infty$, it is clear that a branch cut must be chosen so that $A_\ell(\nu)$ takes exactly the form (34.408) for $\nu < -1$. This requires choosing a branch that starts at $\nu = -1$ and extends along $\nu = -1 + it$ for $t > 0$. The branch cuts for the function in the complex ν plane are shown in figure 34.25. In summary, we have so far

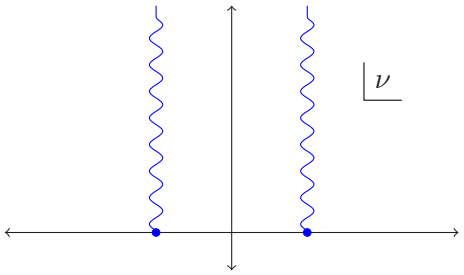

Figure 34.25: Branch cuts for $A_\ell(\nu)$.

constructed branch cuts so that the function is well defined at $\nu = \pm\infty$. In doing so, we have defined the function everywhere except at $\nu = \pm 1$. Indeed, due to the presence of the branch point, it is not a priori evident that the function can be defined at these points. However, note that this is not the case. The only divergence at $\nu = \pm 1$ arises from the logarithm. This is multiplied by $P_{\ell+1}(\nu) - P_{\ell-1}(\nu)$, which vanishes polynomially near $\nu = \pm 1$. Thus, $A_\ell(\pm 1)$ is finite and well defined. In fact, the function is also continuous at this point, since the only nonvanishing term in this limit arises from $F_\ell(\nu)$, which is a polynomial and continuous everywhere. Explicitly, we have

$$A_\ell(\pm 1) = \lim_{h\to 0^\pm} A_\ell(\pm 1 + h) = c_2\left[F_{\ell+1}(\pm 1) - F_{\ell-1}(\pm 1)\right] = -(\pm 1)^\ell \frac{c_2\,(2\ell+1)}{\ell\,(\ell+1)} \ . \tag{34.412}$$

As before, we normalize the function so that $A_\ell(1) = 1$. This fixes

$$c_2 = -\frac{\ell(\ell+1)}{2\ell+1} \ . \tag{34.413}$$

In summary, for $|\nu| < 1$, we have

$$A_\ell(\nu) = -\frac{\ell(\ell+1)}{2\ell+1}\left[\frac{1}{2}\log e^{i\pi}\frac{1+\nu}{1-\nu}\left[P_{\ell+1}(\nu) - P_{\ell-1}(\nu)\right] + F_{\ell+1}(\nu) - F_{\ell-1}(\nu)\right] \ , \tag{34.414}$$

whereas for $|\nu| > 1$, we have

$$A_\ell(\nu) = -\frac{\ell(\ell+1)}{2\ell+1}\left[\frac{1}{2}\left[P_{\ell+1}(\nu) - P_{\ell-1}(\nu)\right]\log\frac{\nu+1}{\nu-1} + F_{\ell+1}(\nu) - F_{\ell-1}(\nu)\right] \ . \tag{34.415}$$

6(d). For $\ell = 2$, the solution in part (c) (when $\nu > 1$) takes the form

$$A_2(\nu) = 3\nu^2 - 2 + \frac{3}{2}\nu\left(1-\nu^2\right)\log\frac{\nu+1}{\nu-1}\ . \tag{34.416}$$

Plugging in $\nu = \frac{t}{r} = 1 + \frac{u}{r}$ and expanding in powers of r, we find

$$A_2\left(1+\frac{u}{r}\right) = 1 + \frac{3u}{r}\left(2+\log\frac{u}{2r}\right) + \frac{3u^2}{2r^2}\left(1+3\log\frac{u}{2r}\right) + \mathcal{O}\big(r^{-3}\big)\ . \tag{34.417}$$

This implies that the expansion of the full solution is

$$\begin{aligned}\varepsilon_{2m}(u,r,\theta,\phi) = Y^2_m(\theta,\phi)\Bigg[1 + \frac{3u}{r}\left(2+\log\frac{u}{2r}\right)\\ +\frac{3u^2}{2r^2}\left(1+3\log\frac{u}{2r}\right) + \mathcal{O}\big(r^{-3}\big)\Bigg]\ .\end{aligned} \tag{34.418}$$

6(e). We now solve the scalar wave equation at large r in the retarded radial coordinates. The answer to part (d) of the problem shows that we must have a large-r falloff of the form

$$\begin{aligned}\varepsilon(u,r,z,\bar z) = \varepsilon^{(0)}(u,z,\bar z) + \frac{1}{r}\varepsilon^{(1)}(u,z,\bar z) + \frac{1}{r}f^{(1)}(u,z,\bar z)\log\frac{u}{2r}\\ + \frac{1}{r^2}\varepsilon^{(2)}(u,z,\bar z) + \frac{1}{r^2}f^{(2)}(u,z,\bar z)\log\frac{u}{2r} + \mathcal{O}\big(r^{-3}\big)\ .\end{aligned} \tag{34.419}$$

The scalar wave equation in the retarded radial coordinates is

$$\left[\partial_r^2 - 2\partial_u\partial_r + \frac{2}{r}\left(\partial_r - \partial_u\right) + \frac{2}{r^2}\gamma^{z\bar z}\partial_z\partial_{\bar z}\right]\varepsilon(u,r,z,\bar z) = 0\ . \tag{34.420}$$

Plugging in the expansion (34.419) and expanding in large r, we find the following equations order-by-order in large r:

$$\begin{aligned}&\partial_u\varepsilon^{(0)} = 0\ , \qquad \partial_u f^{(1)} + \frac{1}{2}D^2\varepsilon^{(0)} = 0\ , \qquad \partial_u f^{(2)} + \frac{1}{2}D^2 f^{(1)} = 0\ ,\\ &\partial_u\varepsilon^{(2)} = \frac{1}{2}D^2 f^{(1)} - \frac{1}{2}D^2\varepsilon^{(1)} - \frac{1}{2}f^{(1)} - \frac{1}{u}f^{(2)}\ .\end{aligned} \tag{34.421}$$

The solutions to these equations are

$$\begin{aligned}f^{(1)} &= -\frac{u}{2}D^2\varepsilon^{(0)} + g^{(1)}\ ,\\ f^{(2)} &= \frac{u^2}{8}\big(D^2\big)^2\varepsilon^{(0)} - \frac{u}{2}D^2 g^{(1)} + g^{(2)}\ ,\\ \varepsilon^{(2)} &= -\frac{3u^2}{16}\big(D^2\big)^2\varepsilon^{(0)} + \frac{u^2}{8}D^2\varepsilon^{(0)} + uD^2 g^{(1)} - \frac{u}{2}g^{(1)}\\ &\qquad - g^{(2)}\log u - \frac{1}{2}D^2\int du\varepsilon^{(1)} + h^{(2)}\ ,\end{aligned} \tag{34.422}$$

where all functions on the RHS are functions of $(z,\bar z)$, except for $\varepsilon^{(1)}$, which is an arbitrary function of $(u,z,\bar z)$. The solution is indeed the form of the solution ε_{2m} obtained in part (d). We can see this by choosing

$$\varepsilon^{(0)} = Y^2_m\ , \qquad \varepsilon^{(1)} = 6uY^2_m\ , \qquad g^{(1)} = g^{(2)} = h^{(2)} = 0\ . \tag{34.423}$$

In this case, we have

$$f^{(1)} = 3uY_m^2 \ , \qquad f^{(2)} = \frac{9u^2}{2}Y_m^2 \ , \qquad \varepsilon^{(2)} = \frac{3u^2}{2}Y_m^2 \ , \tag{34.424}$$

which is precisely the expansion (34.418).

7(a). Inverting the coordinates, we have $r = \rho\tau$ and $t = \tau\sqrt{1+\rho^2}$. We parametrize the massive momentum as $p^\mu = (\omega_p, \vec{p})$. Then we have

$$p \cdot x = \tau \left[-\sqrt{p^2+m^2}\sqrt{1+\rho^2} + \rho\vec{p}\cdot\hat{x} \right] = -\tau f(\vec{p}) \ . \tag{34.425}$$

In the mode expansion, we perform an integral over $\vec{p}_i$. In the limit of large τ, the value of the integral is dominated by the integrand at the minimum of the function $f(\vec{p})$:

$$\frac{\partial f}{\partial p_i} = 0 \qquad \Longrightarrow \qquad \frac{\vec{p}}{\sqrt{p^2+m^2}} = \frac{\rho}{\sqrt{1+\rho^2}}\hat{x} \ . \tag{34.426}$$

Let us simplify this expression a little more. Squaring both sides, we find

$$\frac{p^2}{p^2+m^2} = \frac{\rho^2}{1+\rho^2} \qquad \Longrightarrow \qquad \rho = \frac{|\vec{p}|}{m} \qquad \Longrightarrow \qquad \omega_p = m\sqrt{1+\rho^2} \ . \tag{34.427}$$

Then we find that the saddle point is at

$$\vec{p} = m\rho\hat{x} \ . \tag{34.428}$$

Next, in the saddle point approximation, we must evaluate the function f and its second derivative at this value. We find

$$f(m\rho\hat{x}) = m \ , \qquad \frac{\partial}{\partial p_i}\frac{\partial}{\partial p_j} f\Big|_{\vec{p}=m\rho\hat{x}} = \frac{1}{m}\left[\delta_{ij} - \frac{\rho^2}{1+\rho^2}\hat{x}_i\hat{x}_j \right] = \mathcal{P}_{ij} \ . \tag{34.429}$$

Then around the saddle point, expand

$$p \cdot x = -m\tau - \frac{\tau}{2}\mathcal{P}_{ij}(p_i - m\rho\hat{x}_i)(p_j - m\rho\hat{x}_j) + \mathcal{O}(p^3) \ . \tag{34.430}$$

At large τ, we can then write the mode expansion as

$$\begin{aligned} \phi(x) &= \frac{1}{2m(2\pi)^3\sqrt{1+\rho^2}} \Bigg[a(m\rho\hat{x})e^{-im\tau} \int d^3p e^{-i\frac{\tau}{2}\mathcal{P}_{ij}p_ip_j} \\ &\qquad\qquad + a^\dagger(m\rho\hat{x})e^{im\tau} \int d^3p e^{i\frac{\tau}{2}\mathcal{P}_{ij}p_ip_j} \Bigg] \\ &= \frac{\sqrt{\frac{(2\pi)^3}{\tau^3 \det\mathcal{P}}}}{2m(2\pi)^3\sqrt{1+\rho^2}} \left[a(m\rho\hat{x})e^{-im\tau}e^{-3i\pi/4} + a^\dagger(m\rho\hat{x})e^{im\tau}e^{3i\pi/4} \right] \ , \end{aligned} \tag{34.431}$$

where we used

$$\int_{-\infty}^{\infty} dx \ e^{ikx^2} = \sqrt{\frac{\pi}{k}}e^{i\pi/4} \ . \tag{34.432}$$

Next we must evaluate $\det \mathcal{P}$. An explicit computation shows

$$\det \mathcal{P} = \frac{1}{m^3 \left(1+\rho^2\right)} \ . \tag{34.433}$$

Using equation (34.433), we find

$$\phi(\tau, \rho, \hat{x}) = \frac{\sqrt{m}}{2(2\pi\tau)^{3/2}} \left[a(m\rho\hat{x}) e^{-im\tau} e^{-3i\pi/4} + a^\dagger(m\rho\hat{x}) e^{im\tau} e^{3i\pi/4}\right] \ . \tag{34.434}$$

7(b). We start with the action

$$S = -\frac{1}{2} \int d^4x \sqrt{-g} \left[(\partial_\mu \phi)^2 + m^2 \phi^2\right] \ . \tag{34.435}$$

Varying (34.435) with respect to ϕ, we find

$$\delta S = \int d^4x \sqrt{-g} \left(\Box - m^2\right) \phi \delta\phi - \int d^4x \sqrt{-g} \nabla_\mu \left(\nabla^\mu \phi \delta\phi\right) \ . \tag{34.436}$$

The first term gives the equations of motion. The canonical one-form (symplectic potential current density) can be read off as $\Theta^\mu(\phi, \delta\phi) = -\nabla^\mu \phi \delta\phi$. The symplectic form is then

$$\begin{aligned} \Omega_\Sigma &= \int d\Sigma_\mu \omega^\mu = \int d\Sigma_\mu \left[\delta_1 \Theta^\mu \left(\phi, \delta_2 \phi\right) - 1 \leftrightarrow 2\right] \\ &= -\int d\Sigma_\mu \left[\nabla^\mu \delta_1 \phi \delta_2 \phi - \nabla^\mu \delta_2 \phi \delta_1 \phi\right] \ . \end{aligned} \tag{34.437}$$

7(c). The Minkowskian metric in $(\rho, \tau, \theta, \phi)$ coordinates is

$$ds^2 = -d\tau^2 + \tau^2 \left[\frac{d\rho^2}{1+\rho^2} + \rho^2 \gamma_{AB} dx^A dx^B\right] \ . \tag{34.438}$$

We consider the hypersurface Σ to be $\tau =$ constant. Then the unit normal is

$$n_\mu = \partial_\mu \tau = \delta^\tau_\mu \ . \tag{34.439}$$

The volume element is

$$d\Sigma_\mu = d^3V \tau^3 \delta^\tau_\mu \ , \tag{34.440}$$

where d^3V is the volume element on the unit hyperboloid. Using this volume element, we find

$$\Omega_\tau = \int d^3V \tau^3 \partial_\tau \delta\phi \wedge \delta\phi \ . \tag{34.441}$$

To simplify this, we can now insert the large-τ expression for ϕ. We then find at $\tau = \infty$ that

$$\Omega_{\tau\to\infty} = -\frac{im^2}{2(2\pi)^3} \int d^3V \ \delta a(m\rho\hat{x}) \wedge \delta a^\dagger(m\rho\hat{x}) \ . \tag{34.442}$$

7(d). The commutation relation obtained from equation (34.442) is

$$\left[a(m\rho\hat{x}), a^\dagger(m\rho'\hat{x}')\right] = \frac{2\,(2\pi)^3}{m^2}\delta\left(\rho-\rho'\right)\delta^2\left(\hat{x}-\hat{x}'\right)\ , \tag{34.443}$$

where the δ-functions are normalized so that

$$\int d^3V\delta\left(\rho-\rho'\right)\delta^2\left(\hat{x}-\hat{x}'\right) = 1\ . \tag{34.444}$$

To match (34.443) to the standard commutation relations in momentum space, we have to transform the δ-functions above to the standard three-vector notation. We do this as follows. Recall that we are parameterizing

$$\vec{p} = m\rho\hat{x} = \frac{m\rho}{1+z\bar{z}}\left(z+\bar{z}, -i(z-\bar{z}), 1-z\bar{z}\right)\ . \tag{34.445}$$

Then the standard volume form in momentum space is $dp^1\wedge dp^2\wedge dp^3$. Using the parameterization above, we find

$$dp^1\wedge dp^2\wedge dp^3 = im^3\rho^2\gamma_{z\bar{z}}d\rho\wedge dz\wedge d\bar{z}\ . \tag{34.446}$$

From equation (34.446), we find

$$\begin{aligned} 1 &= \int d^3p\delta^3\left(\vec{p}-\vec{p'}\right) \\ &= \int d\rho d^2z m^3\rho^2\gamma_{z\bar{z}}\delta^3\left(\vec{p}-\vec{p'}\right) \\ &= \int d^3V m^2\omega_p\delta^3\left(\vec{p}-\vec{p'}\right)\ . \end{aligned} \tag{34.447}$$

From equation (34.447), we can read off

$$m^2\omega_p\delta^3\left(\vec{p}-\vec{p'}\right) = \delta\left(\rho-\rho'\right)\delta^2\left(\hat{x}-\hat{x}'\right)\ . \tag{34.448}$$

Plugging this form into our commutation relations, we find

$$\left[a(m\rho\hat{x}), a^\dagger(m\rho'\hat{x}')\right] = (2\pi)^3\left(2\omega_p\right)\delta^3\left(\vec{p}-\vec{p'}\right)\ . \tag{34.449}$$

8. To determine the action of the charge, we first determine the symplectic form on $\mathcal{I}^+$. We do so by determining the boundary fields ϕ and ψ_+ on $\mathcal{I}^+$ using large-r limits of the bulk mode expansions. For this, we will use the saddle point approximation. We start by determining the boundary field of a scalar. Bulk scalar fields have mode expansions

$$\Phi(x) = \int\frac{d^3q}{(2\pi)^3}\frac{1}{2\omega_q}\left[a(\vec{q})e^{iq\cdot x}+\tilde{a}^\dagger(\vec{q})e^{-iq\cdot x}\right]\ . \tag{34.450}$$

Here a and $\tilde{a}$ satisfy the usual creation-annihilation commutation relations. Then, taking a large-r limit and doing the usual saddle point procedure, we find

$$\phi(u,z,\bar{z}) = -\frac{i}{8\pi^2}\int_0^\infty d\omega\left[a(\omega\hat{x})e^{-i\omega u}-\tilde{a}^\dagger(\omega\hat{x})e^{i\omega u}\right]\ . \tag{34.451}$$

Using the standard commutators, we find

$$\left[\phi(u,z,\bar{z}),\bar{\phi}(u',z',\bar{z}')\right] = -\frac{i}{4}\gamma^{z\bar{z}}\Theta(u-u')\delta^2(z-z') \ . \tag{34.452}$$

Bulk spinors[223] have the mode expansion

$$\Psi_\alpha(x) = \int \frac{d^3q}{(2\pi)^3}\frac{1}{2\omega_q}\eta_\alpha(\vec{q})\left[b(\vec{q})e^{iq\cdot x} + \tilde{b}^\dagger(\vec{q})e^{-iq\cdot x}\right] \ , \tag{34.453}$$

where $\eta_\alpha(\vec{p})\bar{\eta}_{\dot{\alpha}}(\vec{p}) = p_\mu(\sigma^\mu)_{\alpha\dot{\alpha}}$, and b and $\tilde{b}$ satisfy the standard fermionic creation-annihilation commutation relations. To perform the large-r expansion, we will first have to convert the conventions of Wess and Bagger [207] to the $(u,r,z,\bar{z})$ coordinate system. First, we determine the basis spinors. In the $(u,r,z,\bar{z})$ coordinates used here, we have

$$\sigma_z{}^z = \frac{1}{r^2}\gamma^{z\bar{z}}\partial_z x^\mu \partial_{\bar{z}} x^\nu \sigma_{\mu\nu} = \begin{pmatrix} \frac{1-z\bar{z}}{2(1+z\bar{z})} & \frac{\bar{z}}{1+z\bar{z}} \\ \frac{z}{1+z\bar{z}} & -\frac{1-z\bar{z}}{2(1+z\bar{z})} \end{pmatrix} \ . \tag{34.454}$$

The eigenvalues of this matrix are $\pm\frac{1}{2}$ with eigenvectors

$$\xi^{(+)}_\alpha = \sqrt{\frac{1}{1+z\bar{z}}}\begin{pmatrix}1\\ z\end{pmatrix} \ , \qquad \xi^{(-)}_\alpha = \sqrt{\frac{1}{1+z\bar{z}}}\begin{pmatrix}\bar{z}\\ -1\end{pmatrix} \ . \tag{34.455}$$

The normalization of the eigenvectors is chosen so that $\xi^{(+)\alpha}\xi^{(-)}_\alpha = 1$. Since $\eta_\alpha(\vec{p})$ is a two-component spinor, it can be expanded in this basis. If we parametrize the momentum as

$$p^\mu = \frac{\omega}{1+z\bar{z}}\left(1+z\bar{z}, z+\bar{z}, -i(z-\bar{z}), 1-z\bar{z}\right) \ , \tag{34.456}$$

then $\eta_\alpha(p) = \sqrt{2\omega}\xi^{(+)}_\alpha$. With all the explicit formulas determined, we can go ahead and take the large-r expansion of Ψ_α:

$$\psi_{(+)}(u,z,\bar{z}) = -\frac{i}{8\pi^2}\int_0^\infty d\omega_q\sqrt{2\omega_q}\left[b(\omega_q\hat{x})e^{-i\omega_q u} - \tilde{b}^\dagger(\omega_q\hat{x})e^{i\omega_q u}\right] \ . \tag{34.457}$$

Using the commutation relations for b and $\tilde{b}$, we find

$$\left\{\psi_{(+)}(u,z,\bar{z}),\bar{\psi}_{(-)}(u',z',\bar{z}')\right\} = \gamma^{z\bar{z}}\delta(u-u')\delta^2(z-z') \ . \tag{34.458}$$

Now we are ready to determine the action of the hard charge on the fields. The hard charge is

$$\mathscr{F}^h[\chi] = \frac{Q}{2\sqrt{2}}\int du d^2z\gamma_{z\bar{z}}\chi u\partial_u\left(\phi\bar{\psi}_{(-)}\right) \ . \tag{34.459}$$

It is clear that this acts trivially on ϕ and $\bar{\psi}_{(-)}$. However, we have

$$\begin{aligned}
\left[\mathscr{F}^h[\chi],\partial_u\bar{\phi}(u,z,\bar{z})\right] &= \frac{Q}{2\sqrt{2}}\int du'd^2z'\gamma_{z'\bar{z}'}\chi u'\partial_{u'}\partial_u\left(\left[\phi(u',z',\bar{z}'),\bar{\phi}(u,z,\bar{z})\right]\bar{\psi}_{(-)}\right) \\
&= -i\frac{Q}{4\sqrt{2}}\chi(z,\bar{z})\bar{\psi}_{(-)}(z,\bar{z}) \ , \\
\left\{\mathscr{F}^h[\chi],\psi_{(+)}(u,z,\bar{z})\right\} &= \frac{Q}{2\sqrt{2}}\int du'd^2z'\gamma_{z'\bar{z}'}\chi u'\partial_{u'}\left(\phi\left\{\bar{\psi}_{(-)},\psi_{(+)}(u,z,\bar{z})\right\}\right) \\
&= -\frac{Q}{2\sqrt{2}}\chi(z,\bar{z})\phi(u,z,\bar{z}) \ ,
\end{aligned} \tag{34.460}$$

which determines the action of the hard charge on the fields.

[223] Spinor conventions of Wess and Bagger [207] are used here.

9(a). We consider an $(n+2)$-point amplitude $\mathcal{A}_{n+2}^{a_1,a_2}(q_1,\varepsilon_1;q_2,\varepsilon_2)$. The amplitude also depends on the other external momenta, but we suppress the dependence for convenience. Taking first the limit $q_2 \to 0$ and using the soft gluon theorem, we find

$$\begin{aligned}\lim_{q_2\to 0}\mathcal{A}_{n+2}^{a_1,a_2}(q_1,\varepsilon_1;q_2,\varepsilon_2) \to g_{YM}\sum_{k=1}^{n}\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2}T_k^{a_2}\mathcal{A}_{n+1}^{a_1}(q_1,\varepsilon_1)\\ + g_{YM}\frac{q_1\cdot\varepsilon_2}{q_1\cdot q_2}\left(T_{\text{adj.}}^{a_2}\right)^{a_1 b}\mathcal{A}_{n+1}^{b}(q_1,\varepsilon_1)\ ,\end{aligned} \tag{34.461}$$

where we have used the fact that the gluon transforms in the adjoint representation. The matrix elements of the adjoint representations are $\left(T_{\text{adj.}}^{a_2}\right)^{a_1 b} = -if^{a_2 a_1 b} = if^{a_1 a_2 b}$. Using this, we find

$$\begin{aligned}\lim_{q_2\to 0}\mathcal{A}_{n+2}^{a_1,a_2}(q_1,\varepsilon_1;q_2,\varepsilon_2) \to g_{YM}\sum_{k=1}^{n}\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2}T_k^{a_2}\mathcal{A}_{n+1}^{a_1}(q_1,\varepsilon_1)\\ + ig_{YM}f^{a_1 a_2 b}\frac{q_1\cdot\varepsilon_2}{q_1\cdot q_2}\mathcal{A}_{n+1}^{b}(q_1,\varepsilon_1)\ .\end{aligned} \tag{34.462}$$

Let us now take the second limit, $q_1 \to 0$:

$$\begin{aligned}\lim_{q_1\to 0}\lim_{q_2\to 0}\mathcal{A}_{n+2}^{a_1,a_2}(q_1,\varepsilon_1;q_2,\varepsilon_2) \to g_{YM}^2\sum_{k=1}^{n}\sum_{k'=1}^{n}\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2}\frac{p_{k'}\cdot\varepsilon_1}{p_{k'}\cdot q_1}T_k^{a_2}T_{k'}^{a_1}\mathcal{A}_n\\ + ig_{YM}^2 f^{a_1 a_2 b}\frac{q_1\cdot\varepsilon_2}{q_1\cdot q_2}\sum_{k=1}^{n}\frac{p_k\cdot\varepsilon_1}{p_k\cdot q_1}T_k^{b}\mathcal{A}_n\ .\end{aligned} \tag{34.463}$$

When the limits are taken in the opposite order, we find

$$\begin{aligned}\lim_{q_2\to 0}\lim_{q_1\to 0}\mathcal{A}_{n+2}^{a_1,a_2}(q_1,\varepsilon_1;q_2,\varepsilon_2) \to g_{YM}^2\sum_{k=1}^{n}\sum_{k'=1}^{n}\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2}\frac{p_{k'}\cdot\varepsilon_1}{p_{k'}\cdot q_1}T_{k'}^{a_1}T_k^{a_2}\mathcal{A}_n\\ - ig_{YM}^2 f^{a_1 a_2 b}\frac{q_2\cdot\varepsilon_1}{q_2\cdot q_1}\sum_{k=1}^{n}\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2}T_k^{b}\mathcal{A}_n\ .\end{aligned} \tag{34.464}$$

Now subtract the two. Note that in the double sum, when $k \neq k'$ the two quantities are equal, since the generators T_k are acting on different sets of indices. The only nontrivial contribution to the difference occurs when $k = k'$. Thus, we find

$$\begin{aligned}\left[\lim_{q_1\to 0},\lim_{q_2\to 0}\right]\mathcal{A}_{n+2}^{a_1,a_2}(q_1,\varepsilon_1;q_2,\varepsilon_2) &\to g_{YM}^2\sum_{k=1}^{n}\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2}\frac{p_k\cdot\varepsilon_1}{p_k\cdot q_1}\left[T_k^{a_2},T_k^{a_1}\right]\mathcal{A}_n\\ &\quad + ig_{YM}^2 f^{a_1 a_2 b}\frac{q_1\cdot\varepsilon_2}{q_1\cdot q_2}\sum_{k=1}^{n}\frac{p_k\cdot\varepsilon_1}{p_k\cdot q_1}T_k^{b}\mathcal{A}_n\\ &\quad + ig_{YM}^2 f^{a_1 a_2 b}\frac{q_2\cdot\varepsilon_1}{q_2\cdot q_1}\sum_{k=1}^{n}\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2}T_k^{b}\mathcal{A}_n\\ &\to ig_{YM}^2 f^{a_1 a_2 b}\sum_{k=1}^{n}\left(\frac{q_1\cdot\varepsilon_2}{q_1\cdot q_2}\frac{p_k\cdot\varepsilon_1}{p_k\cdot q_1}\right.\\ &\quad \left.+\frac{q_2\cdot\varepsilon_1}{q_2\cdot q_1}\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2} - \frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2}\frac{p_k\cdot\varepsilon_1}{p_k\cdot q_1}\right)T_k^{b}\mathcal{A}_n\ .\end{aligned} \tag{34.465}$$

This can be written in a more concise way by adding to it a fourth term that is identically zero:

$$-ig_{YM}^2 f^{a_1 a_2 b} \sum_{k=1}^{n} \frac{q_1\cdot\varepsilon_2}{q_1\cdot q_2}\frac{q_2\cdot\varepsilon_1}{q_2\cdot q_1} T_k^b \mathcal{A}_n = -ig_{YM}^2 f^{a_1 a_2 b} \frac{q_1\cdot\varepsilon_2}{q_1\cdot q_2}\frac{q_2\cdot\varepsilon_1}{q_2\cdot q_1} \sum_{k=1}^{n} T_k^b \mathcal{A}_n \ . \tag{34.466}$$

The last term vanishes due to global color charge conservation. Adding this, we can write the double-soft limit as

$$\begin{aligned}\left[\lim_{q_1\to 0}\ ,\ \lim_{q_2\to 0}\right] &\mathcal{A}_{n+2}^{a_1,a_2}(q_1,\varepsilon_1;q_2,\varepsilon_2) \\ &\to ig_{YM}^2 f^{a_1 a_2 b} \sum_{k=1}^{n} \left(\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2} - \frac{q_1\cdot\varepsilon_2}{q_1\cdot q_2}\right)\left(\frac{q_2\cdot\varepsilon_1}{q_2\cdot q_1} - \frac{p_k\cdot\varepsilon_1}{p_k\cdot q_1}\right) T_k^b \mathcal{A}_n \ .\end{aligned} \tag{34.467}$$

9(b). All we have to do here is to plug in the explicit forms of the momenta in the z parametrization. Recall that when the helicity is positive,

$$\frac{p_k\cdot\varepsilon}{p_k\cdot q} \propto \frac{1}{z-z_k} \ . \tag{34.468}$$

Then the soft factor is

$$\begin{aligned}\left(\frac{p_k\cdot\varepsilon_2}{p_k\cdot q_2} - \frac{q_1\cdot\varepsilon_2}{q_1\cdot q_2}\right)\left(\frac{q_2\cdot\varepsilon_1}{q_2\cdot q_1} - \frac{p_k\cdot\varepsilon_1}{p_k\cdot q_1}\right) &\propto \left(\frac{1}{w-z_k} - \frac{1}{w-z}\right)\left(\frac{1}{z-w} - \frac{1}{z-z_k}\right) \\ &= \frac{z_k - z}{(w-z_k)(w-z)}\frac{w-z_k}{(z-w)(z-z_k)} \\ &= \frac{1}{(z-w)^2} \ .\end{aligned} \tag{34.469}$$

This factor does not depend on z_k at all. Thus, we can pull this factor out of the sum to get

$$\left[\lim_{q_1\to 0}\ ,\ \lim_{q_2\to 0}\right] \mathcal{A}_{n+2}^{a_1,a_2}(q_1,\varepsilon_1;q_2,\varepsilon_2) \propto \frac{ig_{YM}^2 f^{a_1 a_2 b}}{(z-w)^2} \sum_{k=1}^{n} T_k^b \mathcal{A}_n = 0 \ . \tag{34.470}$$

The argument follows through in the same way when the helicity is negative (just take all z's to $\bar{z}$'s).

10. We take the metric to be of the form

$$\begin{aligned}ds^2 = -du^2 - 2dudr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} + \frac{2m_B}{r}du^2 + rC_{zz}dz^2 + rC_{\bar{z}\bar{z}}d\bar{z}^2 \\ + U_z dudz + U_{\bar{z}}dud\bar{z} + \cdots \ .\end{aligned} \tag{34.471}$$

The four-dimensional Weyl tensor of a spacetime is given by

$$C_{\mu\nu\rho\sigma} = R_{\mu\nu\rho\sigma} + \frac{1}{2}\left(g_{\nu\rho}R_{\sigma\mu} + g_{\mu\sigma}R_{\rho\nu} - g_{\nu\sigma}R_{\rho\mu} - g_{\mu\rho}R_{\sigma\nu}\right) + \frac{1}{6}R\left(g_{\mu\rho}g_{\sigma\nu} - g_{\mu\sigma}g_{\rho\nu}\right) \ . \tag{34.472}$$

We are interested in computing the following components:

$$C_{rzrz} = R_{rzrz} - \frac{1}{2}g_{zz}R_{rr} \ , \qquad C_{rurz} = R_{rurz} + \frac{1}{2}\left(g_{ur}R_{rz} - g_{uz}R_{rr}\right) \ . \tag{34.473}$$

For the metric of interest, we then find

$$C_{rzrz} = \mathcal{O}(r^{-3}) \ , \qquad C_{rurz} = -\frac{1}{4r^2}\left(U_z - D^z C_{zz}\right) + \mathcal{O}(r^{-3}) \ , \tag{34.474}$$

where D_z is the covariant derivative with respect to $\gamma_{z\bar{z}}$. Thus, to have an asymptotically flat spacetime, we must have

$$U_z = D^z C_{zz} \ . \tag{34.475}$$

11(a). We will show that $\partial_r \det\left(\frac{g_{AB}}{r^2}\right) = 0$ implies that C_{AB} is traceless.

$$\begin{aligned} \det\left(\frac{g_{AB}}{r^2}\right) &= \det\left(\gamma_{AB} + \frac{C_{AB}}{r} + \mathcal{O}(r^{-2})\right) \\ &= \det\gamma\left(1 + \frac{C^A{}_A}{r} + \mathcal{O}(r^{-2})\right) \ . \end{aligned} \tag{34.476}$$

Hence,

$$\partial_r \det\left(\frac{g_{AB}}{r^2}\right) = -\det\gamma\ \frac{C^A{}_A}{r^2} + \mathcal{O}(r^{-3}) \ . \tag{34.477}$$

Therefore,

$$\partial_r \det\left(\frac{g_{AB}}{r^2}\right) = 0 \qquad \Longrightarrow \qquad C^A{}_A = 0 \ . \tag{34.478}$$

11(b). First, we must determine the variation of the metric under a diffeomorphism generated by the vector field ξ, where $\xi^u, \xi^r \sim \mathcal{O}(1)$ and $\xi^A \sim \mathcal{O}(r^{-1})$. The variation of the metric under a diffeomorphism is given by

$$\mathcal{L}_\xi g_{\mu\nu} = \xi^\rho \partial_\rho g_{\mu\nu} + g_{\mu\rho}\partial_\nu \xi^\rho + g_{\nu\rho}\partial_\mu \xi^\rho \ . \tag{34.479}$$

By definition, the asymptotic symmetries must preserve the falloff conditions for the fields:

$$\begin{aligned} g_{uu} &= -U + \frac{1}{4} g_{AB} U^A U^B = -1 + \frac{2m_B}{r} + \mathcal{O}(r^{-2}) \ , \\ g_{ur} &= -e^{2\beta} = -1 + \mathcal{O}(r^{-2}) \ , \\ g_{uA} &= \frac{1}{2} g_{AB} U^B = \frac{1}{2} D^B C_{BA} + \mathcal{O}(r^{-1}) \ , \\ g_{rA} &= g_{rr} = 0 \ , \\ g_{AB} &= r^2 \gamma_{AB} + r C_{AB} + h^{(0)}_{AB} + \mathcal{O}(r^{-1}) \ . \end{aligned} \tag{34.480}$$

In Bondi gauge,

$$\mathcal{L}_\xi g_{rr} = 2\partial_r \xi^u g_{ur} \ , \tag{34.481}$$

which implies ξ^u must be independent of r

$$\xi^u = \xi^u(u, x^A) \ . \tag{34.482}$$

To leading order in the asymptotic expansion, we have

$$\mathcal{L}_\xi g_{ur} = \partial_u \xi^u g_{ur} + \mathcal{O}(r^{-1}) \ . \tag{34.483}$$

Hence, ξ^u must also be independent of u:

$$\xi^u = f(x^A) \ . \tag{34.484}$$

Then the remaining components have the following variations under ξ, with $\xi^u = f$:

$$\begin{aligned}
\mathcal{L}_\xi g_{uu} &= f\partial_u g_{uu} + \xi^r \partial_r g_{uu} + \xi^A \partial_A g_{uu} + 2\partial_u \xi^r g_{ru} + 2\partial_u \xi^A g_{Au} \ , \\
\mathcal{L}_\xi g_{rA} &= \partial_r \xi^C g_{CA} + g_{ur}\partial_A f \ , \\
\mathcal{L}_\xi g_{AB} &= f\partial_u g_{AB} + \xi^r \partial_r g_{AB} + \xi^C \partial_C g_{AB} + g_{uB}\partial_A f + \partial_A \xi^C g_{CB} \\
&\qquad + g_{uA}\partial_B f + \partial_B \xi^C g_{CA} \ .
\end{aligned} \tag{34.485}$$

Let us consider the asymptotic expansion of the vector field

$$\xi = f\partial_u + \sum_{n=0}^{\infty} \frac{\xi^{r(n)}}{r^n}\partial_r + \sum_{n=1}^{\infty} \frac{\xi^{A(n)}}{r^n}\partial_A \ . \tag{34.486}$$

The Lie derivative of the metric is then

$$\begin{aligned}
\mathcal{L}_\xi g_{uu} &= -2\partial_u \xi^{r(0)} + \frac{-2\partial_u \xi^{r(1)} + 2f\partial_u m_B + \partial_u \xi^{A(1)} D^B C_{BA}}{r} + \mathcal{O}(r^{-2}) \ , \\
\mathcal{L}_\xi g_{rA} &= -\gamma_{AB}\left(\xi^{B(1)} + D^B f\right) - \frac{2\gamma_{AB}\xi^{B(2)} + C_{AB}\xi^{B(1)}}{r} + \mathcal{O}(r^{-2}) \ , \\
\mathcal{L}_\xi g_{AB} &= r\Big(f\partial_u C_{AB} + 2\gamma_{AB}\xi^{r(0)} + D_A \xi_B^{(1)} + D_B \xi_A^{(1)}\Big) \\
&\quad + f\partial_u h_{AB}^{(0)} + C_{AB}\xi^{r(0)} + 2\gamma_{AB}\xi^{r(1)} + \frac{1}{2}D^C C_{CA} D_B f \\
&\quad + \frac{1}{2}D^C C_{CB} D_A f + \xi^{C(1)} D_C C_{AB} + D_A \xi_B^{(2)} \\
&\quad + C_{BC} D_A \xi^{C(1)} + D_B \xi_A^{(2)} + C_{AC} D_B \xi^{C(1)} + \mathcal{O}(r^{-1}) \ .
\end{aligned} \tag{34.487}$$

From $\mathcal{L}_\xi g_{rA}$ at $\mathcal{O}(1)$, we find

$$\xi^{A(1)} = -D^A f \ . \tag{34.488}$$

From $\mathcal{L}_\xi g_{rA}$ at $\mathcal{O}(r^{-1})$, we find

$$\xi^{A(2)} = \frac{1}{2}C^{AB} D_B f \ . \tag{34.489}$$

We require that the $\mathcal{O}(r)$ term of $\mathcal{L}_\xi g_{AB}$ be traceless, which implies

$$\xi^{r(0)} = \frac{1}{2} D_A D^A f \ . \tag{34.490}$$

Finally, to determine the $\mathcal{O}(r^{-2})$ piece of ξ^r, we need to consider a higher order expansion of g_{AB}:

$$g_{AB} = r^2 \gamma_{AB} + r C_{AB} + h_{AB}^{(0)} + \mathcal{O}(r^{-1}). \tag{34.491}$$

Then

$$\begin{aligned}
\det\left(\frac{g_{AB}}{r^2}\right) &= \det\gamma \exp \mathrm{tr}\left[\log\left(\delta_A^B + \frac{1}{r}C_A{}^B + \frac{1}{r^2}h_A^{(0)B} + \mathcal{O}(r^{-3})\right)\right] \\
&= \det\gamma\left[1 + \frac{1}{r}C_A{}^A \right. \\
&\qquad \left. + \frac{1}{r^2}\left(h_A^{(0)A} - \frac{1}{2}C_A{}^B C_B{}^A + \frac{1}{2}C_A{}^A C_B{}^B\right) + \mathcal{O}(r^{-3})\right] \ .
\end{aligned} \tag{34.492}$$

Assuming that $C_A{}^A = 0$ to satisfy the $\mathcal{O}(r^{-1})$ constraint, we additionally find that

$$h_A^{(0)A} = \frac{1}{2} C_{AB} C^{AB} \ . \tag{34.493}$$

This imposes the following constraint on the variations of the metric components

$$\delta h_A^{(0)A} = C_{AB} \delta C^{AB} \ . \tag{34.494}$$

An explicit computation reveals

$$\begin{aligned} \delta h_A^{(0)A} &= f \partial_u h_A^{(0)A} + 4\xi^{r(1)} + 2 D_A f D_B C^{AB} - C^{AB} D_A D_B f \ , \\ C_{AB} \delta C^{AB} &= \frac{f}{2} \partial_u (C^{AB} C_{AB}) - 2 C^{AB} D_A D_B f \ . \end{aligned} \tag{34.495}$$

Equating these terms, we find

$$\xi^{r(1)} = -\frac{1}{2} D_A f D_B C^{AB} - \frac{1}{4} C^{AB} D_A D_B f \ . \tag{34.496}$$

Therefore, the most general diffeomorphism ξ that preserves the metric to leading order is given by

$$\begin{aligned} \xi(f) = f \partial_u &+ \left[-\frac{D^A f}{r} + \frac{\frac{1}{2} C^{AB} D_B f}{r^2} + \mathcal{O}\left(\frac{1}{r^3}\right) \right] \partial_A \\ &+ \left[\frac{1}{2} D^2 f + \frac{-\frac{1}{2} D_A f D_B C^{AB} - \frac{1}{4} C^{AB} D_A D_B f}{r} + \mathcal{O}\left(\frac{1}{r^2}\right) \right] \partial_r \ , \end{aligned} \tag{34.497}$$

where $f = f(x^A)$.

11(c). We will show that the Lie algebra of the supertranslations at leading order is abelian, that is,

$$[\xi(f_1), \xi(f_2)] = \mathcal{O}(r^{-1}) \ . \tag{34.498}$$

Using the definition of the Lie bracket, we find

$$\begin{aligned} [\xi(f_1), \xi(f_2)]^u &= \xi(f_1)^\mu \partial_\mu f_2 - \xi(f_2)^\mu \partial_\mu f_1 \\ &= \frac{-D^A f_1 D_A f_2}{r} + \frac{\frac{1}{2} C^{AB} D_A f_1 D_B f_2}{r^2} - (f_1 \leftrightarrow f_2) \\ &= 0 \ , \\ [\xi(f_1), \xi(f_2)]^r &= \xi(f_1)^\mu \partial_\mu \left(\frac{1}{2} D^2 f_2 \right) - (f_1 \leftrightarrow f_2) + \mathcal{O}(r^{-2}) \\ &= \frac{1}{2r} D_A \left(-D^A f_1 D^2 f_2 + D^A f_2 D^2 f_1 \right) + \mathcal{O}(r^{-2}) \\ &= \mathcal{O}(r^{-1}) \ , \\ [\xi(f_1), \xi(f_2)]^A &= \xi(f_1)^\mu \partial_\mu \left[-\frac{D^A f_2}{r} \right] - (f_1 \leftrightarrow f_2) + \mathcal{O}(r^{-3}) \\ &= \frac{1}{2} \frac{D^2 f_1 D^A f_2}{r^2} + \frac{D^B f_1 D_B D^A f_2}{r^2} - 1 \leftrightarrow 2 + \mathcal{O}(r^{-3}) \\ &= \mathcal{O}(r^{-2}) \ . \end{aligned} \tag{34.499}$$

11(d). Recall in part (b), Eq.(34.487), we found

$$\begin{aligned}\mathcal{L}_\xi g_{uu} &= -2\partial_u \xi^{r(0)} + \frac{-2\partial_u \xi^{r(1)} + 2f\partial_u m_B + \partial_u \xi^{A(1)} D^B C_{BA}}{r} + \mathcal{O}(r^{-2}) \ , \\ \mathcal{L}_\xi g_{AB} &= r\Big(f\partial_u C_{AB} + 2\gamma_{AB}\xi^{r(0)} + D_A \xi^{(1)}_B + D_B \xi^{(1)}_A\Big) + \mathcal{O}(1) \ .\end{aligned} \tag{34.500}$$

Using the solution for part (b) and the variations above, we can calculate the action of $\xi(f)$ on m_B, C_{AB} and N_{AB}:

$$\begin{aligned}\mathcal{L}_f C_{AB} &= f\partial_u C_{AB} + \gamma_{AB} D^2 f - 2D_A D_B f \ , \\ \mathcal{L}_f N_{AB} &= f\partial_u N_{AB} \ , \\ \mathcal{L}_f m_B &= f\partial_u m_B + \frac{1}{4}\Big(N^{AB} D_A D_B f + 2D_A f D_B N^{AB}\Big) \ .\end{aligned} \tag{34.501}$$

Note that $\gamma^{AB}\mathcal{L}_f C_{AB} = 0$.

11(e). Let us now evaluate the vector field $\xi(f)$ on the $\ell = 0$ and $\ell = 1$ spherical harmonics.

$$\begin{aligned}\xi(Y_0^0) &= Y_0^0 \partial_u \ , \\ \xi(Y_1^m) &= Y_1^m \partial_u - \frac{\gamma^{AB}\partial_B Y_1^m}{r}\partial_A + \frac{1}{2}D^2 Y_1^m \partial_r \ .\end{aligned} \tag{34.502}$$

Consider the following normalization for the spherical harmonics:

$$Y_0^0 = 1, \qquad Y_1^1 = \frac{z}{1+z\bar{z}} \ , \qquad Y_1^0 = \frac{1-z\bar{z}}{1+z\bar{z}} \ , \qquad Y_1^{-1} = \frac{\bar{z}}{1+z\bar{z}} \ . \tag{34.503}$$

Then we have

$$\begin{aligned}\xi(Y_0^0) &= \partial_u \ , \\ \xi(Y_1^1) &= \frac{z}{1+z\bar{z}}(\partial_u - \partial_r) + \frac{z^2}{2r}\partial_z - \frac{1}{2r}\partial_{\bar{z}} \ , \\ \xi(Y_1^0) &= \frac{1-z\bar{z}}{1+z\bar{z}}(\partial_u - \partial_r) + \frac{z}{r}\partial_z + \frac{\bar{z}}{r}\partial_{\bar{z}} \ , \\ \xi(Y_1^{-1}) &= \frac{\bar{z}}{1+z\bar{z}}(\partial_u - \partial_r) - \frac{1}{2r}\partial_z + \frac{\bar{z}^2}{2r}\partial_{\bar{z}} \ .\end{aligned} \tag{34.504}$$

To compare with the standard global translations in Minkowski space, we begin with these translations in Cartesian coordinates:

$$T = \partial_t \ , \qquad X_i = \partial_i \ . \tag{34.505}$$

In Bondi coordinates, the global translations take the following form:

$$\begin{aligned}T &= \partial_u \ , \\ X_1 &= -\frac{z+\bar{z}}{1+z\bar{z}}\partial_u + \frac{z+\bar{z}}{1+z\bar{z}}\partial_r + \frac{1-z^2}{2r}\partial_z + \frac{1-\bar{z}^2}{2r}\partial_{\bar{z}} \ , \\ X_2 &= \frac{i(z-\bar{z})}{1+z\bar{z}}\partial_u - \frac{i(z-\bar{z})}{1+z\bar{z}}\partial_r + \frac{i(1+z^2)}{2r}\partial_z - \frac{i(1+\bar{z}^2)}{2r}\partial_{\bar{z}} \ , \\ X_3 &= -\frac{1-z\bar{z}}{1+z\bar{z}}\partial_u + \frac{1-z\bar{z}}{1+z\bar{z}}\partial_r - \frac{z}{r}\partial_z - \frac{\bar{z}}{r}\partial_{\bar{z}} \ .\end{aligned} \tag{34.506}$$

We then find

$$\begin{aligned}\xi(Y_0^0) &= T \ , \\ \xi(Y_1^1) &= -\frac{1}{2}(X_1 + iX_2) \ , \\ \xi(Y_1^0) &= -X_3 \ , \\ \xi(Y_1^{-1}) &= -\frac{1}{2}(X_1 - iX_2) \ .\end{aligned} \tag{34.507}$$

The action of the $\ell = 0$ mode on the fields is given by

$$\begin{aligned}\mathcal{L}_{\xi(Y_0^0)} C_{AB} &= Y_0^0 \partial_u C_{AB} \ , \\ \mathcal{L}_{\xi(Y_0^0)} N_{AB} &= Y_0^0 \partial_u N_{AB} \ , \\ \mathcal{L}_{\xi(Y_0^0)} m_B &= Y_0^0 \partial_u m_B \ .\end{aligned} \tag{34.508}$$

The action of the $\ell = 1$ modes on the fields is given by

$$\begin{aligned}\mathcal{L}_{\xi(Y_1^m)} C_{AB} &= Y_1^m \partial_u C_{AB} \ , \qquad \mathcal{L}_{\xi(Y_1^m)} N_{AB} = Y_1^m \partial_u N_{AB}, \\ \mathcal{L}_{\xi(Y_1^1)} m_B &= Y_1^1 \partial_u m_B + \frac{1}{4}\Big(D^{\bar{z}} N_{\bar{z}\bar{z}} - z^2 D^z N_{zz} \Big) \ , \\ \mathcal{L}_{\xi(Y_1^0)} m_B &= Y_1^0 \partial_u m_B - \frac{1}{2}\Big(z D^z N_{zz} + \bar{z} D^{\bar{z}} N_{\bar{z}\bar{z}} \Big) \ , \\ \mathcal{L}_{\xi(Y_1^{-1})} m_B &= Y_1^{-1} \partial_u m_B + \frac{1}{4}\Big(D^z N_{zz} - \bar{z}^2 D^{\bar{z}} N_{\bar{z}\bar{z}} \Big) \ ,\end{aligned} \tag{34.509}$$

where we have used the fact that $D_z D_z Y_1^m = 0$.

12(a). The Lorentz transformations in Cartesian coordinates are given by

$$K_i = x^0 \partial_i + x^i \partial_0, \qquad J_{ij} = x^i \partial_j - x^j \partial_i \ , \tag{34.510}$$

where K_i are the boosts and J_{ij} are the rotations. The Cartesian coordinates are related to the $(u, r, z, \bar{z})$ coordinates by the coordinate transformations

$$u = t - \sqrt{x^i x_i} \ , \qquad r = \sqrt{x^i x_i} \ , \qquad z = \frac{x^1 + i x^2}{x^3 + \sqrt{x^i x_i}} \ . \tag{34.511}$$

In these coordinates, the boosts and rotations take the following form:

$$\begin{aligned}K_1 &= -\frac{u(z+\bar{z})}{1+z\bar{z}} \partial_u + \frac{(r+u)(z+\bar{z})}{1+z\bar{z}} \partial_r \\ &\qquad - \frac{(z^2-1)\,(r+u)}{2r} \partial_z - \frac{(\bar{z}^2-1)\,(r+u)}{2r} \partial_{\bar{z}} \ , \\ K_2 &= \frac{iu(z-\bar{z})}{1+z\bar{z}} \partial_u - \frac{i(r+u)(z-\bar{z})}{1+z\bar{z}} \partial_r \\ &\qquad + \frac{i\,(z^2+1)\,(r+u)}{2r} \partial_z - \frac{i\,(\bar{z}^2+1)\,(r+u)}{2r} \partial_{\bar{z}} \ , \\ K_3 &= -\frac{u(1-z\bar{z})}{1+z\bar{z}} \partial_u + \frac{(r+u)(1-z\bar{z})}{1+z\bar{z}} \partial_r - \frac{z(r+u)}{r} \partial_z - \frac{\bar{z}(r+u)}{r} \partial_{\bar{z}} \ , \\ J_{12} &= iz\partial_z - i\bar{z}\partial_{\bar{z}} \ , \\ J_{23} &= \frac{1}{2} i \left(z^2-1\right) \partial_z - \frac{1}{2} i \left(\bar{z}^2-1\right) \partial_{\bar{z}} \ , \\ J_{31} &= \frac{1}{2} \left(z^2+1\right) \partial_z + \frac{1}{2} \left(\bar{z}^2+1\right) \partial_{\bar{z}} \ .\end{aligned} \tag{34.512}$$

Then in Bondi gauge, a generic Lorentz transformation is generated by the vector field ζ, with components

$$\begin{aligned}\zeta^u &= \frac{u}{2}\,\frac{2z(c-a^*)+2\bar{z}(c^*-a)+(b+b^*)(1-z\bar{z})}{1+z\bar{z}}\,,\\ \zeta^r &= -\frac{u+r}{2}\,\frac{2z(c-a^*)+2\bar{z}(c^*-a)+(b+b^*)(1-z\bar{z})}{1+z\bar{z}}\,,\\ \zeta^z &= a+bz+cz^2+\frac{u}{2r}\left((a-c^*)+(b+b^*)z+(c-a^*)z^2\right)\,.\end{aligned} \tag{34.513}$$

In particular, the individual rotations and boosts are reproduced for specific choices of a, b, and c:

$$\begin{aligned} J_{12} &= \zeta|_{\substack{a=0\\b=i\\c=0}}\,, & J_{23} &= \zeta|_{\substack{a=-\frac{i}{2}\\b=0\\c=\frac{i}{2}}}\,, & J_{31} &= \zeta|_{\substack{a=\frac{1}{2}\\b=0\\c=\frac{1}{2}}}\,,\\ K_1 &= \zeta|_{\substack{a=\frac{1}{2}\\b=0\\c=-\frac{1}{2}}}\,, & K_2 &= \zeta|_{\substack{a=\frac{i}{2}\\b=0\\c=\frac{i}{2}}}\,, & K_3 &= \zeta|_{\substack{a=0\\b=-1\\c=0}}\,. \end{aligned} \tag{34.514}$$

We now express this vector in terms of the global CKV on the sphere $Y^z = a + bz + cz^2$. Using the identities

$$\begin{aligned} D_z Y^z + D_{\bar{z}} Y^{\bar{z}} &= \frac{2z(c-a^*)+2\bar{z}(c^*-a)+(b+b^*)(1-z\bar{z})}{1+z\bar{z}}\,,\\ D^z\left(D_z Y^z + D_{\bar{z}} Y^{\bar{z}}\right) &= -\left((a-c^*)+(b+b^*)z+(c-a^*)z^2\right)\,, \end{aligned} \tag{34.515}$$

we find

$$\zeta(Y) = \frac{u}{2} D_A Y^A \partial_u - \frac{u+r}{2} D_A Y^A \partial_r + \left[Y^A - \frac{u}{2r} D^A D_B Y^B\right]\partial_A\,. \tag{34.516}$$

Comparing (34.515) with (34.503), we have $D\cdot Y \sim Y_1^m$. Noting that $D^z D_z Y^z = -Y^z$, we can write this vector field as presented in section 34.5.3

$$\begin{aligned}\zeta(Y) = &\frac{u}{2}\left(D_z Y^z + D_{\bar{z}} Y^{\bar{z}}\right)\partial_u - \frac{u+r}{2}\left(D_z Y^z + D_{\bar{z}} Y^{\bar{z}}\right)\partial_r\\ &+\left[Y^z + \frac{u}{2r}\left(Y^z - D^z D_{\bar{z}} Y^{\bar{z}}\right)\right]\partial_z\\ &+\left[Y^{\bar{z}} + \frac{u}{2r}\left(Y^{\bar{z}} - D^{\bar{z}} D_z Y^z\right)\right]\partial_{\bar{z}}\,.\end{aligned} \tag{34.517}$$

12(b). We show that the Lorentz algebra is isomorphic to the algebra of the global CKVs of S^2. First note that, since the r and u components of ζ are linear in r and u, the terms of the form $\zeta^\mu \partial_\mu \zeta^\nu$ will always cancel when $\mu, \nu = u, r$:

$$\begin{aligned}[\zeta(Y_1), \zeta(Y_2)]^u &= \zeta(Y_1)^A D_A \zeta(Y_2)^u - \zeta(Y_2)^A D_A \zeta(Y_1)^u\\ &= \frac{u}{2}\left[Y_1^A D_A D_B Y_2^B - Y_2^A D_A D_B Y_1^B\right]\\ &= \frac{u}{2} D_B\left[Y_1^A D_A Y_2^B - Y_2^A D_A Y_1^B\right]\\ &= \frac{u}{2} D_A\left[Y_1, Y_2\right]^A\,.\end{aligned} \tag{34.518}$$

In a similar way, we have

$$\begin{aligned}
[\zeta(Y_1),\zeta(Y_2)]^r &= \zeta(Y_1)^A D_A \zeta(Y_2)^r - \zeta(Y_2)^A D_A \zeta(Y_1)^r \\
&= -\frac{u+r}{2}\left[Y_1^A D_A D_B Y_2^B - Y_2^A D_A D_B Y_1^B\right] \\
&= -\frac{u+r}{2} D_A \left[Y_1, Y_2\right]^A \ , \\
[\zeta(Y_1),\zeta(Y_2)]^A &= [Y_1,Y_2]^A + \frac{u^2}{4r^2}\Big[D\cdot Y_2 D^A D\cdot Y_1 - D\cdot Y_1 D^A D\cdot Y_2 \\
&\qquad + D^C D\cdot Y_1 D_C D^A D\cdot Y_2 - D^C D\cdot Y_2 D_C D^A D\cdot Y_1\Big] \\
&\qquad - \frac{u}{2r}\Big[D^A D\cdot [Y_1,Y_2] - (D^A Y_1^C + D^C Y_1^A) D_C D\cdot Y_2 \\
&\qquad\quad + (D^A Y_2^C + D^C Y_2^A) D_C D\cdot Y_1 + D\cdot Y_1 D^A D\cdot Y_2 \\
&\qquad\quad - D\cdot Y_2 D^A D\cdot Y_1\Big] \\
&= [Y_1,Y_2]^A - \frac{u}{2r} D^A D\cdot [Y_1,Y_2] \ ,
\end{aligned} \tag{34.519}$$

where we have used the identities $D_A Y_B + D_B Y_A = \gamma_{AB} D\cdot Y$ and $D_A D_B (D\cdot Y) = \frac{1}{2}\gamma_{AB} D^2 D\cdot Y = -\gamma_{AB} D\cdot Y$.

12(c). The diffeomorphism generated by ζ induces the following variations in the metric components:

$$\begin{aligned}
\mathcal{L}_\zeta g_{uu} &= \frac{D\cdot Y(u\partial_u m_B + 3m_B) + 2Y^A\partial_A m_B - \frac{1}{2}D^B C_{BA} D^A D\cdot Y}{r} + \mathcal{O}(r^{-2}) \ , \\
\mathcal{L}_\zeta g_{ur} &= \mathcal{O}(r^{-2}) \ , \\
\mathcal{L}_\zeta g_{rr} &= 0 \ , \\
\mathcal{L}_\zeta g_{uA} &= \mathcal{O}(1) \ , \\
\mathcal{L}_\zeta g_{rA} &= \frac{u}{2}\left(\frac{g_{AB}\gamma^{BC}}{r^2} + g_{ur}\delta_A^C\right) D_C D\cdot Y \ , \\
\mathcal{L}_\zeta g_{AB} &= \frac{u}{2}\left(D\cdot Y\partial_u g_{AB} - D\cdot Y\partial_r g_{AB} + g_{uB} D_A D\cdot Y + g_{uA} D_B D\cdot Y\right) \\
&\quad - \frac{u}{2r}\left[D^C D\cdot Y D_C g_{AB} + g_{CB} D_A D^C D\cdot Y + g_{CA} D_B D^C D\cdot Y\right] \\
&\quad - \frac{r}{2} D\cdot Y\partial_r g_{AB} + \mathcal{L}_Y g_{AB} \ .
\end{aligned} \tag{34.520}$$

The first four equations in (34.520) indicate that ζ preserves the asymptotic form of the components g_{uu}, g_{rr}, g_{ur}, and g_{uA}. We now check the leading and subleading terms in the variations of g_{rA} and g_{AB}, using the asymptotic expansion $g_{AB} = r^2\gamma_{AB} + rC_{AB} + \mathcal{O}(1)$:

$$\begin{aligned}
\mathcal{L}_\zeta g_{rA} &= \frac{u}{2}\left(\gamma_{AB}\gamma^{BC} - \delta_A^C + \mathcal{O}(r^{-1})\right) D_C D\cdot Y \ , \\
\mathcal{L}_\zeta g_{AB} &= r^2\left(\mathcal{L}_Y\gamma_{AB} - \gamma_{AB} D\cdot Y\right) + r\Big[\frac{u}{2}\left(D\cdot Y\partial_u C_{AB} - 2\gamma_{AB} D\cdot Y\right. \\
&\qquad \left. -2D_A D_B D\cdot Y\right) - \frac{1}{2} C_{AB} D\cdot Y + \mathcal{L}_Y C_{AB}\Big] + \mathcal{O}(1) \ .
\end{aligned} \tag{34.521}$$

At order $\mathcal{O}(r^2)$, $\mathcal{L}_\zeta g_{AB}$ vanishes, due to the conformal Killing equation $\mathcal{L}_Y \gamma_{AB} = D_A Y_B + D_B Y_A = \gamma_{AB} D \cdot Y$. The $\mathcal{O}(r)$ term gives the variation of C_{AB}:

$$\begin{aligned}\delta C_{AB} = \frac{u}{2}\left(D\cdot Y \partial_u C_{AB} - 2\gamma_{AB} D\cdot Y - 2D_A D_B D\cdot Y\right) \\ - \frac{1}{2} C_{AB} D\cdot Y + \mathcal{L}_Y C_{AB}\ .\end{aligned} \tag{34.522}$$

Note that

$$\gamma^{AB}\delta C_{AB} = \frac{u}{2}\left(-4D\cdot Y - 2D^2 D\cdot Y\right) + C^{AB}\left(D_A Y_B + D_B Y_A\right) = 0\ , \tag{34.523}$$

where $D^2 D\cdot Y = -2D\cdot Y$, and $C^{AB}\left(D_A Y_B + D_B Y_A\right) = C^{AB}\gamma_{AB} D\cdot Y$. Hence, C_{AB} remains traceless under the diffeomorphism generated by ζ.

13(a). In the limit $r\to\infty$, the metric in Bondi gauge is flat, and $v^\mu = (1,0,0,0)$ is a solution for the four-velocity of a timelike observer. At finite but large r, an inertial observer's four-velocity must have subleading corrections, generically of the form

$$\begin{aligned} v^u &= 1 + \frac{1}{r} v^{u(1)} + \mathcal{O}(r^{-2})\ , \\ v^r &= \frac{1}{r} v^{r(1)} + \mathcal{O}(r^{-2})\ , \\ v^z &= \frac{1}{r} v^{z(1)} + \frac{1}{r^2} v^{z(2)} + \mathcal{O}(r^{-3})\ , \\ v^{\bar z} &= \frac{1}{r} v^{\bar z(1)} + \frac{1}{r^2} v^{\bar z(2)} + \mathcal{O}(r^{-3})\ . \end{aligned} \tag{34.524}$$

To compute the norm, we use the asymptotic form of the metric:

$$\begin{aligned} ds^2 = -du^2 - 2dudr + 2r^2\gamma_{z\bar z}dzd\bar z + \frac{2m_B}{r}du^2 \\ + D^z C_{zz} dudz + D^{\bar z} C_{\bar z\bar z} dud\bar z + rC_{zz}dz^2 + rC_{\bar z\bar z}d\bar z^2 + \cdots\ . \end{aligned} \tag{34.525}$$

By requiring that $v^\mu v_\mu = -1 + \mathcal{O}(r^{-2})$, we find

$$v^{z(1)} = v^{\bar z(1)} = 0\ , \qquad m_B = v^{u(1)} + v^{r(1)}\ . \tag{34.526}$$

Hence, we will study a four-velocity of the asymptotic form

$$\begin{aligned} v^u &= 1 + \frac{m_0(u,z,\bar z)}{r} + \mathcal{O}(r^{-2})\ , \\ v^r &= \frac{m_B(u,z,\bar z) - m_0(u,z,\bar z)}{r} + \mathcal{O}(r^{-2})\ , \\ v^z &= \frac{1}{r^2} v^{z(2)} + \mathcal{O}(r^{-3})\ , \\ v^{\bar z} &= \frac{1}{r^2} v^{\bar z(2)} + \mathcal{O}(r^{-3})\ . \end{aligned} \tag{34.527}$$

We require that $v^\mu \nabla_\mu v^{u,r} = \mathcal{O}(r^{-2})$ and $v^\mu \nabla_\mu v^{z,\bar z} = \mathcal{O}(r^{-3})$. Explicitly, these conditions are given by

$$\begin{aligned} \frac{\partial_u m_0}{r} + \Gamma^u_{\alpha\beta} v^\alpha v^\beta = \mathcal{O}(r^{-2})\ , \\ \frac{\partial_u m_B - \partial_u m_0}{r} + \Gamma^r_{\alpha\beta} v^\alpha v^\beta = \mathcal{O}(r^{-2})\ , \\ \frac{\partial_u v^{z(2)}}{r^2} + \Gamma^z_{\alpha\beta} v^\alpha v^\beta = \mathcal{O}(r^{-3})\ . \end{aligned} \tag{34.528}$$

Next, we need to compute the large-r expansion of the Christoffel connection. The only nonzero components at this order are

$$\Gamma^r_{uu} = -\frac{\partial_u m_B}{r} + \mathcal{O}(r^{-2}) \ , \qquad \Gamma^z_{uu} = \frac{D_z N^{zz}}{2r^2} + \mathcal{O}(r^{-3}) \ . \tag{34.529}$$

Substituting (34.529) into the geodesic equation, we find the following constraints:

$$\partial_u m_0 = 0 \ , \qquad \partial_u v^{z(2)} = -\tfrac{1}{2} D_z N^{zz} \ . \tag{34.530}$$

Integrating the second condition, we find

$$v^{z(2)}(u,z,\bar{z}) = -\tfrac{1}{2}\left(D_z C^{zz}(u,z,\bar{z}) - D_z C^{zz}(u_0,z,\bar{z})\right) \ . \tag{34.531}$$

Moreover, since m_0 is simply a function of $(z,\bar{z})$, we can also interpret it as a boundary condition. Hence, we have

$$\begin{aligned} v^\mu = \Bigg(1 + \tfrac{m_B(u_0,z,\bar{z})}{r} + \mathcal{O}(r^{-2}) \ , \ \tfrac{\Delta m_B(u,z,\bar{z})}{r} + \mathcal{O}(r^{-2}) \ , \\ - \tfrac{D_z \Delta C^{zz}(u,z,\bar{z})}{2r^2} + \mathcal{O}(r^{-3}), - \tfrac{D_{\bar{z}} \Delta C^{\bar{z}\bar{z}}(u,z,\bar{z})}{2r^2} + \mathcal{O}(r^{-3})\Bigg) \ , \end{aligned} \tag{34.532}$$

where

$$\begin{aligned} \Delta m_B(u,z,\bar{z}) &\equiv m_B(u,z,\bar{z}) - m_B(u_0,z,\bar{z}) \ , \\ \Delta C^{zz}(u,z,\bar{z}) &\equiv C^{zz}(u,z,\bar{z}) - C^{zz}(u_0,z,\bar{z}) \ . \end{aligned} \tag{34.533}$$

To leading order in r_0 and for small λ, the trajectory of an observer with this four-velocity is

$$X^\mu(\lambda) = (u_0 + \lambda, r_0, z_0, \bar{z}_0) \ . \tag{34.534}$$

The first correction to the four-velocity may now be approximated as

$$\begin{aligned} v^\mu(\lambda) = \Bigg(1 + \frac{m_B(u_0,z,\bar{z})}{r_0} \ , \ \frac{\lambda \partial_u m_B(u_0,z,\bar{z})}{r_0} \ , \\ - \frac{\lambda D_z N^{zz}(u_0,z,\bar{z})}{2r_0^2} \ , \ - \frac{\lambda D_{\bar{z}} N^{\bar{z}\bar{z}}(u_0,z,\bar{z})}{2r_0^2}\Bigg) \ . \end{aligned} \tag{34.535}$$

The trajectory with these subleading corrections is

$$\begin{aligned} X^\mu(\lambda) &= \Bigg(u_0 + \lambda\left(1 + \frac{m_B(u_0,z,\bar{z})}{r_0}\right), r_0 + \frac{\lambda^2 \partial_u m_B(u_0,z,\bar{z})}{2r_0}, \\ &\quad z_0 - \frac{\lambda^2 D_z N^{zz}(u_0,z,\bar{z})}{4r_0^2}, \bar{z}_0 - \frac{\lambda^2 D_{\bar{z}} N^{\bar{z}\bar{z}}(u_0,z,\bar{z})}{4r_0^2}\Bigg) + \cdots \\ &= \Bigg(u, r_0\left(1 + \frac{(u-u_0)^2 \partial_u m_B(u_0,z,\bar{z})}{2r_0^2}\right), \\ &\quad z_0 - \frac{(u-u_0)^2 D_z N^{zz}(u_0,z,\bar{z})}{4r_0^2}, \bar{z}_0 - \frac{(u-u_0)^2 D_{\bar{z}} N^{\bar{z}\bar{z}}(u_0,z,\bar{z})}{4r_0^2}\Bigg) + \cdots \ . \end{aligned} \tag{34.536}$$

13(b). Since both inertial observers pass through the point (u_0, r_0), we can use the trajectory found in part (a), and simply modify the angular dependence. To leading order in the large-r_0 limit, assuming $|u - u_0| \ll r_0$, we find

$$\Delta X^\mu \equiv X_1^\mu - X_0^\mu = (0, 0, z_1 - z_0, \bar{z}_1 - \bar{z}_0) + \cdots \ . \tag{34.537}$$

The leading order proper distance between the observers is then

$$L \approx \sqrt{2r_0^2 \gamma_{z_0\bar{z}_0} \delta z \delta \bar{z}} = \frac{2r_0|\delta z|}{1 + z_0\bar{z}_0} \ , \qquad \delta z \equiv z_1 - z_0 \ . \tag{34.538}$$

13(c). Due to the burst of radiation, the metric undergoes a transition. Inverting the leading order constraint equation, we find that the leading order change in the zz-component is given by

$$\begin{aligned} \Delta C_{zz}(z, \bar{z}) &\equiv C_{zz}(z, \bar{z})\big|_{u=u_f} - C_{zz}(z, \bar{z})\big|_{u=u_0} \\ &= 2 \int d^2 z' \ \gamma_{z'\bar{z}'} D_z^2 G(z, \bar{z}; z', \bar{z}') \left[\int_{u_0}^{u_f} du \ T_{uu}(u, z', \bar{z}') + \Delta m_B(z', \bar{z}') \right] , \end{aligned} \tag{34.539}$$

where $u_f > u_{\rm rad}$, $\frac{|u_f - u_0|}{r_0} \ll 1$, and

$$\begin{aligned} G(z, \bar{z}; z', \bar{z}') &= \frac{1}{\pi} \frac{|z - z'|^2}{(1 + z\bar{z})(1 + z'\bar{z}')} \log \left(\frac{|z - z'|^2}{(1 + z\bar{z})(1 + z'\bar{z}')} \right) \ , \\ \Delta m_B &= m_B(u_f, z, \bar{z}) - m_B(u_0, z, \bar{z}) \ . \end{aligned} \tag{34.540}$$

Henceforth we assume m_B is independent of $(z, \bar{z})$. To check this, note that

$$D_{\bar{z}}^2 D_z^2 G(z, \bar{z}; z', \bar{z}') = \gamma_{z\bar{z}} \delta^2(z - z') + \cdots \ . \tag{34.541}$$

To determine Δm_B, we used the constraint equation

$$\partial_u m_B = \frac{1}{4} \left[D_z^2 N^{zz} + D_{\bar{z}}^2 N^{\bar{z}\bar{z}} \right] - T_{uu} \ . \tag{34.542}$$

We can extract the zero mode of this equation by integrating over the two-sphere

$$\partial_u m_B = -\frac{1}{4\pi} \int d^2 z \ \gamma_{z\bar{z}} T_{uu} \ . \tag{34.543}$$

Integrating over u, we find

$$\Delta m_B = -\frac{1}{4\pi} \int_{u_0}^{u_f} \int d^2 z \ \gamma_{z\bar{z}} \ T_{uu} \ . \tag{34.544}$$

Then the change in C_{zz} takes the modified form

$$\begin{aligned} \Delta C_{zz}(z, \bar{z}) = 2 \int d^2 z' \ \gamma_{z'\bar{z}'} D_z^2 G(z, \bar{z}; z', \bar{z}') \\ \times \left[\int_{u_0}^{u_f} du \ \left(T_{uu}(u, z', \bar{z}') - \frac{1}{4\pi} \int d^2 z'' \gamma_{z''\bar{z}''} T_{uu}(u, z'', \bar{z}'') \right) \right] \ . \end{aligned} \tag{34.545}$$

T_{uu} due to the burst of radiation is given by

$$T_{uu}(u, z, \bar{z}) = \mu \delta(u - u_{\rm rad}) \frac{\delta^2(z - z_{\rm rad})}{\gamma_{z\bar{z}}} \ . \tag{34.546}$$

The change in C_{zz} due to the burst in radiation is then as follows:

$$\begin{aligned}\Delta C_{zz}(z,\bar{z}) &= 2\mu \int d^2z'\ D_z^2 G(z,\bar{z};z',\bar{z}')\left[\delta^2(z'-z_{\rm rad}) - \frac{\gamma_{z'\bar{z}'}}{4\pi}\right] \\ &= 2\mu D_z^2 G(z,\bar{z};z_{\rm rad},\bar{z}_{\rm rad}) \\ &\quad - \frac{\mu}{2\pi}\int d^2z'\ \gamma_{z'\bar{z}'} D_z^2 G(z,\bar{z};z',\bar{z}')\ .\end{aligned} \tag{34.547}$$

Since this component of the metric never contributed to the proper distance between inertial observers at leading order, to leading order the separation between the observers after the burst of radiation remains unchanged:

$$L \approx \frac{2r_0|\delta z|}{1+z_0\bar{z}_0} \equiv L_0\ . \tag{34.548}$$

However, this component of the metric does play a role in subleading corrections. Note that to calculate the first subleading correction to L, we can safely neglect any corrections to ΔX, since they will not contribute at this order. Hence, the first subleading correction comes from the metric used to compute the inner product of ΔX^μ. At a given time u, the distance is given by

$$\begin{aligned}L &\approx \sqrt{2r_0^2\gamma_{z_0\bar{z}_0}\delta z\delta\bar{z} + r_0 C_{zz}(u,z_0,\bar{z}_0)\delta z^2 + r_0 C_{\bar{z}\bar{z}}(u,z_0,\bar{z}_0)\delta\bar{z}^2} \\ &= L_0\sqrt{1+\frac{r_0}{L_0^2}\left[C_{zz}(u,z_0,\bar{z}_0)\delta z^2 + C_{\bar{z}\bar{z}}(u,z_0,\bar{z}_0)\delta\bar{z}^2\right]} \\ &\approx L_0 + \frac{r_0}{2L_0}\left[C_{zz}(u,z_0,\bar{z}_0)\delta z^2 + C_{\bar{z}\bar{z}}(u,z_0,\bar{z}_0)\delta\bar{z}^2\right]\ .\end{aligned} \tag{34.549}$$

Hence, the change in distance between u_0 and u_f is given by the difference in the subleading term at u_f and u_0:

$$\Delta L = \frac{r_0}{2L_0}\left[\Delta C_{zz}(z_0,\bar{z}_0)\delta z^2 + \Delta C_{\bar{z}\bar{z}}(z_0,\bar{z}_0)\delta\bar{z}^2\right]\ . \tag{34.550}$$

13(d). To determine the supertranslation that would give rise to the same change in proper distance as equation (34.550), recall that under a supertranslation parametrized by a function on the sphere f, we have

$$\mathcal{L}_f C_{zz} = f N_{zz} - 2D_z^2 f\ . \tag{34.551}$$

The change in the metric is related to the Lie derivative

$$\Delta C_{zz} = -\mathcal{L}_f C_{zz} = 2D_z^2 f\ , \tag{34.552}$$

where N_{zz} has been set to zero, since the region of $\mathcal{I}^+$ before and after the radiation has passed is in a vacuum state. Then, using equation (34.547), we find

$$f(z,\bar{z}) = \mu G(z,\bar{z};z_{\rm rad},\bar{z}_{\rm rad}) - \frac{\mu}{4\pi}\int d^2z'\ \gamma_{z'\bar{z}'} G(z,\bar{z};z',\bar{z}')\ . \tag{34.553}$$

14(a). To determine the linearized Einstein's equation, note that

$$\begin{aligned}R_{\mu\nu}[g+h] &= R_{\mu\nu}[g] + \frac{1}{2}\left(\nabla_\rho\nabla_\mu h_\nu{}^\rho + \nabla_\rho\nabla_\nu h_\mu{}^\rho - \nabla^2 h_{\mu\nu} - \nabla_\mu\nabla_\nu h\right) \\ &\quad + \mathcal{O}\left(h^2\right)\ , \\ R[g+h] &= R[g] - R_{\mu\nu}[g]h^{\mu\nu} + \nabla_\mu\nabla_\nu h^{\mu\nu} - \nabla^2 h + \mathcal{O}\left(h^2\right)\ ,\end{aligned} \tag{34.554}$$

where ∇_μ is the covariant derivative w.r.t. $g_{\mu\nu}$. Using this, we find

$$\begin{aligned} G_{\mu\nu}[g+h] = G_{\mu\nu}[g] &+ \frac{1}{2}\left(\nabla_\rho\nabla_\mu h_\nu{}^\rho + \nabla_\rho\nabla_\nu h_\mu{}^\rho - \nabla^2 h_{\mu\nu} - \nabla_\mu\nabla_\nu h\right) \\ &+ \frac{1}{2}g_{\mu\nu}h^{\rho\sigma}R_{\rho\sigma}[g] - \frac{1}{2}g_{\mu\nu}\nabla_\rho\nabla_\sigma h^{\rho\sigma} + \frac{1}{2}g_{\mu\nu}\nabla^2 h \\ &- \frac{1}{2}h_{\mu\nu}R[g] + \mathcal{O}\left(h^2\right) \ . \end{aligned} \tag{34.555}$$

We are interested in the linearized equations about the Schwarzschild background. In this case, $R_{\mu\nu}[g] = R[g] = 0$, which implies that the linearized Einstein equations are

$$\nabla_\rho\nabla_\mu h_\nu{}^\rho + \nabla_\rho\nabla_\nu h_\mu{}^\rho - \nabla^2 h_{\mu\nu} - \nabla_\mu\nabla_\nu h - g_{\mu\nu}\nabla_\rho\nabla_\sigma h^{\rho\sigma} + g_{\mu\nu}\nabla^2 h = 0 \ . \tag{34.556}$$

To solve the linearized Einstein's equations about the initial Schwarzschild solution in Bondi gauge, we consider a line element of the form

$$ds^2 = -\left(1 - \frac{2M}{r}\right)dv^2 + 2dvdr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} + h_{\mu\nu}dx^\mu dx^\nu \ , \tag{34.557}$$

where $h_{\mu\nu}$ is a small perturbation of the metric. We require that $h_{\mu\nu}$ preserve the Bondi gauge condition and the Bondi mass only shifts by a constant. In particular, since the metric describes a spacetime that is perturbed by a null shockwave at $v = v_0$, we can take $h_{\mu\nu}$ to be of the following form:

$$\begin{aligned} h_{vv}(v,r,z,\bar{z}) &= \theta(v-v_0)\left(\frac{2\delta m}{r} + \frac{1}{r^2}\tilde{h}_{vv}(r,z,\bar{z})\right) \ , \\ h_{vr}(v,r,z,\bar{z}) &= \frac{\theta(v-v_0)}{r^2}\tilde{h}_{vr}(r,z,\bar{z}) \ , \\ h_{vz}(v,r,z,\bar{z}) &= \theta(v-v_0)\tilde{h}_{vz}(r,z,\bar{z}) \ , \\ h_{zz}(v,r,z,\bar{z}) &= r\theta(v-v_0)\tilde{h}_{zz}(r,z,\bar{z}) \ , \\ h_{rr} &= h_{rz} = h_{z\bar{z}} = 0 \ , \end{aligned} \tag{34.558}$$

where $\tilde{h}_{\mu\nu}(r,z,\bar{z})$ must approach a finite function on the two-sphere as $r \to \infty$. Note that at linear order, the Bondi condition $\partial_r \det \frac{g_{AB}}{r^2}$ implies $\gamma^{AB}h_{AB} = 0$. Consider the rr-component of Einstein's equation,

$$G_{rr} = \frac{2\theta(v-v_0)\left(r\partial_r\tilde{h}_{vr} - 2\tilde{h}_{vr}\right)}{r^4} = 0 \tag{34.559}$$

which implies that

$$\tilde{h}_{vr} = r^2 c_{1vr}(z,\bar{z}) \ . \tag{34.560}$$

However, to satisfy the boundary condition that $\tilde{h}_{vr}$ is finite as $r \to \infty$, we must have $c_{1vr}(z,\bar{z}) = 0$. Using this result, next consider the zz-component of Einstein's equations:

$$\begin{aligned} G_{zz} = &-r\delta(v-v_0)\partial_r\tilde{h}_{zz} + \frac{1}{2r^2}\theta(v-v_0)\Big(2r^2\partial_r D_z\tilde{h}_{vz} - 2Mr\partial_r\tilde{h}_{zz} \\ &+r^2(2M-r)\partial_r^2\tilde{h}_{zz} + 2M\tilde{h}_{zz}\Big) \\ = &\ 0 \ , \end{aligned} \tag{34.561}$$

where D_z is the covariant derivative w.r.t. the two-sphere. From the first term, we find that $\tilde{h}_{zz}$ must be r-independent. Using these results, we have

$$G_{rz} = -\theta(v-v_0)\left(\frac{-2r^2\partial_r^2\tilde{h}_{vz} + 4\tilde{h}_{vz} + 2D^z\tilde{h}_{zz}}{4r^2}\right) = 0 \ . \tag{34.562}$$

If we take a derivative of the numerator with respect to r, we find a differential equations for only $\tilde{h}_{vz}$ with the general solution

$$\tilde{h}_{vz}(r,z,\bar{z}) = \frac{c_{1vz}(z,\bar{z})}{r} + c_{2vz}(z,\bar{z}) + c_{3vz}(z,\bar{z})r^2 \ . \tag{34.563}$$

The boundary conditions force $c_{3vz}(z,\bar{z}) = 0$. Moreover, substituting back into (34.562) implies that $c_{2vz} = -\frac{1}{2}D^z\tilde{h}_{zz}$. From the second term in (34.561), we learn that $\tilde{h}_{zz} = \frac{1}{M}D_z c_{1vz}$. Using these results, we have

$$G_{z\bar{z}} = \theta(v-v_0)\left(\frac{2D^z c_{1vz} + 2D^{\bar{z}}c_{1v\bar{z}} - 2r^2\partial_r^2\tilde{h}_{vv} + 4r\partial_r\tilde{h}_{vv} - 4\tilde{h}_{vv}}{2r^2(1+z\bar{z})^2}\right) = 0 \ . \tag{34.564}$$

Again, taking an r-derivative of the numerator, we can solve for the r-dependence of $\tilde{h}_{vv}$. The most general solution consistent with the boundary conditions is

$$\tilde{h}_{vv}(r,z,\bar{z}) = \frac{1}{2}\left(D^z c_{1vz} + D^{\bar{z}}c_{1v\bar{z}}\right). \tag{34.565}$$

Using these results, the vz-component is of the form

$$G_{vz} = \frac{3\delta(v-v_0)c_{1vz}}{2r^2} + \theta(v-v_0)G'_{vz}(r,z,\bar{z}) \ , \tag{34.566}$$

where $G'_{vz}(r,z,\bar{z})$ is defined to be the coefficient of the $\theta(v-v_0)$ term in G_{vz}. Using the Einstein's equations, we find

$$c_{1vz} = -2MD_z f \ . \tag{34.567}$$

Finally, we can compute

$$G_{vv} = \delta(v-v_0)\left(\frac{2\delta m}{r^2} + \frac{D^2(D^2+2)f}{2r^2} - \frac{3MD^2 f}{r^3}\right) \ . \tag{34.568}$$

Using Einstein's equations, we find $\delta m = \mu$. At this point, we have completely determined the metric to be

$$\begin{aligned}
g_{vv} &= -1 + \frac{2(M+\mu\theta(v-v_0))}{r} - \frac{\theta(v-v_0)MD^2 f}{r^2} \ , \\
g_{vr} &= 1 \ , \\
g_{vz} &= \theta(v-v_0)D_z\left[\left(1-\frac{2M}{r}\right) + \frac{1}{2}D^2\right] f \ , \\
g_{zz} &= -2r\theta(v-v_0)D_z^2 f \ , \\
g_{z\bar{z}} &= r^2\gamma_{z\bar{z}} \ , \\
g_{rr} &= g_{rz} = 0 \ .
\end{aligned} \tag{34.569}$$

One can check that this metric satisfies $G_{vr} = 0$, as desired.

14(b). Note that a spherically symmetric shockwave with stress tensor

$$T_{vv} = \frac{\mu\delta(v-v_0)}{4\pi r^2} \ , \tag{34.570}$$

is a particular case of equation (34.568) part (a) with $f = 0$, so that for $v > v_0$ the metric will take the form

$$ds^2 = -\left(1 - \frac{2(M+\mu)}{r}\right) dv^2 + 2dvdr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} \ . \tag{34.571}$$

The exact form of the generator of supertranslations in a Schwarzschild background is given by

$$\xi = f\partial_v + \frac{1}{r}D^A f\partial_A - \frac{1}{2}D^2 f\partial_r \ , \tag{34.572}$$

where $f = f(z,\bar{z})$. Under the supertranslation, the components of the metric have the following variations:

$$\begin{aligned} &\mathcal{L}_f g_{vv} = \frac{D^2 fM}{r^2} \ , \qquad \mathcal{L}_f g_{vr} = \mathcal{L}_f g_{rr} = \mathcal{L}_f g_{rz} = \mathcal{L}_f g_{z\bar{z}} = 0 \ , \\ &\mathcal{L}_f g_{vz} = -\frac{1}{2}D_z D^2 f - D_z f + \frac{2D_z fM}{r} \ , \qquad \mathcal{L}_f g_{zz} = 2rD_z^2 f \ . \end{aligned} \tag{34.573}$$

The change in the metric is related to the Lie derivative by $\delta g_{\mu\nu} = -\mathcal{L}_f g_{\mu\nu}$. Hence, the resulting metric is given by

$$\begin{aligned} g_{vv} &= -1 + \frac{2(M+\mu)}{r} - \frac{D^2 fM}{r^2} \ , \\ g_{vr} &= 1 \ , \\ g_{vz} &= \frac{1}{2}D_z D^2 f + D_z f - \frac{2D_z fM}{r} \ , \\ g_{zz} &= -2rD_z^2 f \ , \\ g_{z\bar{z}} &= r^2\gamma_{z\bar{z}} \ , \\ g_{rr} &= g_{rz} = 0 \ , \end{aligned} \tag{34.574}$$

which matches the metric found in part (a) when $v > v_0$.

15(a). Maxwell's equations are

$$d * F = e^2 * j \ . \tag{34.575}$$

Then, using Stokes' law, we can write

$$\hat{Q}^{\mathcal{H}}_{\varepsilon} = \frac{1}{e^2}\int_{\mathcal{H}} d\left[\varepsilon * F\right] = \frac{1}{e^2}\int_{\mathcal{H}} d\varepsilon \wedge *F + \int_{\mathcal{H}} \varepsilon * j \ . \tag{34.576}$$

The first term in this equation is the soft charge. To determine its explicit form, we need to determine the projection of the two-form $*F$ onto $\mathcal{H}$. To do this, note that the Vaidya metric takes the form

$$ds^2 = -\left[1 - \frac{2M\theta(v)}{r}\right] dv^2 + 2dvdr + 2r^2\gamma_{z\bar{z}}dzd\bar{z} \ . \tag{34.577}$$

Using this form, we can determine $*F$ as

$$\begin{aligned} *F = iF^z{}_z dv \wedge dr - ir^2 \gamma_{z\bar{z}} F_{vr} dz \wedge d\bar{z} \\ + \left[iF_{rz} dr \wedge dz - i \left[F_{vz} + \left[1 - \frac{2M}{r} \theta(v) \right] F_{rz} \right] dv \wedge dz + c.c. \right] . \end{aligned} \tag{34.578}$$

This is derived using

$$(*F)_{\mu\nu} = \frac{1}{2} \varepsilon_{\mu\nu\rho\sigma} F^{\rho\sigma} \ . \tag{34.579}$$

We must now project equation (34.579) onto $\mathcal{H}$. To do so, we note that the event horizon of the Vaidya shockwave metric is located at

$$r_H(v) = \begin{cases} \frac{v}{2} + 2M \ , & v \leq 0 \ , \\ 2M \ , & v > 0 \ . \end{cases} \tag{34.580}$$

Then, setting $r = r_H(v)$ in (34.578), we find

$$(*F) \big|_{\mathcal{H}} = -ir_H^2 \gamma_{z\bar{z}} F^{(0)}_{vr} dz \wedge d\bar{z} + \left\{ -i \left[F^{(0)}_{vz} + \frac{1}{2} \theta(-v) F^{(0)}_{rz} \right] dv \wedge dz + c.c. \right\} \ , \tag{34.581}$$

where here the superscript (0) indicates the projection of the corresponding component of the field strength onto $\mathcal{H}$. Now we are finally ready to compute the charge. We take ε to be extended onto $\mathcal{H}$ so that it is constant along null generators (i.e., $\partial_v \varepsilon = 0$). Then we find

$$\hat{Q}^{S,\mathcal{H}}_{\varepsilon} = \frac{1}{e^2} \int d^2z \varepsilon \left(\partial_z N_{\bar{z}} + \partial_{\bar{z}} N_z \right) \ , \tag{34.582}$$

where

$$N_z = \int dv \left(F^{(0)}_{vz} + \frac{1}{2} \theta(-v) F^{(0)}_{rz} \right) \ . \tag{34.583}$$

Here N_z is the analog of the zero mode on $\mathcal{I}^+$. Just like on $\mathcal{I}^+$, it is also a boundary term and only gets contributions from $\mathcal{H}^+$. To see this, we move to the advanced radial gauge:

$$A_r = 0 \ , \qquad A_v \big|_{\mathcal{H}} = 0 \ . \tag{34.584}$$

In this gauge, we have

$$F^{(0)}_{vz} + \frac{1}{2} \theta(-v) F^{(0)}_{rz} = \left(\partial_v + \frac{1}{2} \theta(-v) \partial_r \right) A_z \big|_{r=r_H} = \partial_v A^{(0)}_z \ . \tag{34.585}$$

In the second equality, we first take the appropriate derivatives and *then* set $r = r_H$ in A_z. By the chain rule, this is equal to first setting $r = r_H$ in A_z and then taking a v-derivative. Thus, we have

$$N_z = \int dv \partial_v A^{(0)}_z = A^+_z - A^-_z \ . \tag{34.586}$$

The past boundary of $\mathcal{H}$ is really a point at $v = -4M, r = 0$, where there is a coordinate singularity. To regulate this, we take the boundary to be at $v = -4M + \epsilon$ and then take $\epsilon \to 0$.

15(b). We recall the symplectic form determined in exercise 3:

$$\Omega_\Sigma = -\frac{1}{e^2}\int_\Sigma \delta(*F)\wedge\delta A\ . \tag{34.587}$$

Plugging in the explicit forms of $*F$ and A in the advanced radial gauge, we find

$$\Omega_{\mathcal{H}} = \frac{1}{e^2}\int_{\mathcal{H}} dvd^2z\left(\partial_v\delta A_z^{(0)}\wedge\delta A_{\bar z}^{(0)} + \partial_v\delta A_{\bar z}^{(0)}\wedge\delta A_z^{(0)}\right)\ . \tag{34.588}$$

Note that the symplectic form as well as the soft charge take exactly the same form as on $\mathcal{I}^+$. We can therefore proceed as we did there. Define

$$\hat A_z = A_z^{(0)} - \frac{1}{2}\left(A_z^+ + A_z^-\right) = A_z^{(0)} - \partial_z\phi\ . \tag{34.589}$$

Using this, we find

$$\Omega_{\mathcal{H}} = \frac{2}{e^2}\int dvd^2z\partial_v\delta\hat A_z\wedge\delta\hat A_{\bar z} - \frac{1}{e^2}\int d^2z\left[\delta\partial_z\phi\wedge\delta N_{\bar z} + \delta\partial_{\bar z}\phi\wedge\delta N_z\right]\ . \tag{34.590}$$

15(c). Just as on $\mathcal{I}^+$, we can write out the commutators from (34.590) as

$$\begin{aligned}\left[\hat A_z(v),\hat A_{\bar w}(v')\right] &= -\frac{ie^2}{4}\Theta(v-v')\delta^2(z-w)\ ,\\ [\partial_z\phi, N_{\bar w}] &= ie^2\delta^2(z-w)\ .\end{aligned} \tag{34.591}$$

Using this, we find

$$\left[Q_\varepsilon^{S,\mathcal{H}},\hat A_z\right] = \left[Q_\varepsilon^{S,\mathcal{H}},N_z\right] = 0\ ,\qquad \left[Q_\varepsilon^{S,\mathcal{H}},\partial_z\phi\right] = i\partial_z\varepsilon\ . \tag{34.592}$$

Уравнение Клейна - Фока - Гордона во внешних гравитационном и электромагнитном полях

Уравнение Клейна - Фока - Гордона в римановом пространстве - времени приводится к специальной форме, удобной для исследования нерелятивистского приближения в этом уравнении.

Уравнение для скалярной частицы в пространстве-времени с метрикой $dS^2 = g_{\alpha\beta}dx^\alpha dx^\beta$ выберем в виде

$$\left[\left(i\hbar\nabla_\alpha + \frac{e}{c}A_\alpha\right) g^{\alpha\beta}(x) \left(i\hbar\nabla_\beta + \frac{e}{c}A_\beta\right) - \frac{\hbar^2}{6}R - m^2c^2\right]\Psi(x) = 0$$

На время проведения вычислений, чтобы не загромождать формулы, будем использовать сокращенные обозначения

$$\frac{e}{\hbar c} \Longrightarrow e, \quad \frac{mc}{h} \Longrightarrow m;$$

тогда основное уравнение примет вид

$$\left[\left(i\nabla_\alpha + eA_\alpha\right) g^{\alpha\beta}(x) \left(i\nabla_\beta + eA_\beta\right) - \frac{1}{6}R - m^2\right] \quad \Psi(x) = 0$$

Представляем его как

$$\left[i^2\nabla_\alpha g^{\alpha\beta}(x)\nabla_\beta + ie\left(\nabla_\alpha g^{\alpha\beta}(x)A_\beta\right) + 2ieA_\alpha g^{\alpha\beta}(x)\nabla_\beta + \right.$$
$$\left. e^2 A_\alpha g^{\alpha\beta}(x)A_\beta - \tfrac{1}{6}R - m^2\right]\Psi(x) = 0$$

Пользуясь известными формулами для общековариатных оператора Лапласа и дивергенции:

$$\nabla_\alpha g^{\alpha\beta}(x)\nabla_\beta\Phi = \tfrac{1}{\sqrt{-g}}\tfrac{\partial}{\partial x^\alpha}\sqrt{-g}g^{\alpha\beta}\tfrac{\partial}{\partial x^\beta}\Psi$$
$$\nabla_\alpha g^{\alpha\beta}A_\beta = \tfrac{1}{\sqrt{-g}}\tfrac{\partial}{\partial x^\alpha}\sqrt{-g}g^{\alpha\beta}A_\beta, \quad g = \det\left(g_{\alpha\beta}\right)$$

предыдущее уравнение переписываем в виде

$$\left[i^2\tfrac{1}{\sqrt{-g}}\tfrac{\partial}{\partial x^\alpha}\sqrt{-g}g^{\alpha\beta}(x)\tfrac{\partial}{\partial x^\beta} + \tfrac{1}{\sqrt{-g}}\tfrac{\partial}{\partial x^\alpha}\sqrt{-g}g^{\alpha\beta}(x)A_\beta + \right.$$
$$\left. 2\text{ie}\ \ A_\alpha g^{\alpha\beta}\tfrac{\partial}{\partial_\beta} + e^2 A_\alpha g^{\alpha\beta}(x)A_\beta - \tfrac{1}{6}R - m^2\right]\Psi(x) = 0$$

или

$$\left[\frac{1}{\sqrt{-g}}\left(i\frac{\partial}{\partial x^\alpha} + eA_\alpha\right)\sqrt{-g}g^{\alpha\beta}(x)\left(i\frac{\partial}{\partial x^\beta} + eA_\beta\right) - \frac{1}{6}R - m^2\right]\Psi(x) = 0$$

В обычных единицах это уравнение записывается как

$$\left[\frac{1}{\sqrt{-g}}\left(i\hbar\frac{\partial}{\partial x^\alpha} + \frac{e}{c}A_\alpha\right)\sqrt{-g}g^{\alpha\beta}(x)\left(i\hbar\frac{\partial}{\partial x^\beta} + \frac{e}{c}A_\beta\right) - \frac{\hbar^2}{6}R - m^2c^2\right]\Psi(x) = 0$$

35.2.4 Introduction to QFT in Curved Space by Hollands, Wald

Обсудим основные идеи полей в искривленном пространстве. Эти идеи отдельно развиваются в соответствующей части и скорее всего очень большими будут, поэтому выгодно выделить главу с основами.

(из Quantum fields in curved spacetime см литературу)

1.

The nature of quantum field theory in curved spacetime Quantum field theory in curved spacetime (QFTCS) is the theory of quantum fields propagating in a background, classical, curved spacetime $(\mathscr{M}, g)$. On account of its classical treatment of the metric, QFTCS cannot be a fundamental theory of nature. However, QFTCS is expected to provide an accurate description of quantum phenomena in a regime where the effects of curved spacetime may be significant, but effects of quantum gravity itself may be neglected. In particular, it is expected that QFTCS should be applicable to the description of quantum phenomena occurring in the early universe and near (and inside of black holes-provided that one does not attempt to describe phenomena occurring so near to singularities that curvatures reach Planckian scales and the quantum nature of the spacetime metric would have to be taken into account. It should be possible to derive QFTCS by taking a suitable limit of a more fundamental theory wherein the spacetime metric is treated in accord with the principles of quantum theory. However, this has not been done - except in formal and/or heuristic ways - simply because no present quantum theory of gravity has been developed to the point where such a well defined limit can be taken. Rather, the framework of QFTCS that we shall describe in this review has been obtained by suitably merging basic principles of classical general relativity with the basic principles of quantum field theory in Minkowski spacetime. As we shall explain further below, the basic principles of classical general relativity are relatively easy to identify and adhere to, but it is far less clear what to identify as the "basic principles" of quantum field theory in Minkowski spacetime. Indeed, many of the concepts normally viewed as fundamental to quantum field theory in Minkowski spacetime, such as Poincare invariance, do not even make sense in the context of curved spacetime, and therefore cannot be considered as "fundamental" from the viewpoint of QFTCS. By forcing one to re-think basic concepts, such as the notions of "vacuum state" and "particles", QFTCS has led to deep insights into the nature of quantum field theory-and one may hope that it will provide significant guidance towards the development of quantum gravity itself.

The fundamental ideas upon which classical general relativity is based are that (i) all aspects of spacetime structure are described by the topological and differential (i.e., manifold) properties of events together with a Lorentz signature metric g, and (ii) the metric and matter fields are

dynamical; furthermore their evolution is locally determined. More precisely, the metric and the tensor (and/or spinor) fields describing matter satisfy partial differential equations - namely, Einstein's equation together with the equations of motion for the matter fields - that have a well posed initial value formulation, so that these fields are uniquely determined (up to "gauge") from their initial data within a suitable domain of dependence. In particular, in classical general relativity, there is no non-dynamical, "background structure" in the laws of physics apart from the manifold structure of events. This lack of background structure in classical general relativity is usually referred to as the "covariance" or "coordinate invariance" of the theory; a "preferred set of coordinates" defined independently of the metric would provide non-dynamical, background structure.

It is much more difficult to identify the fundamental ideas upon which quantum field theory in Minkowski spacetime is based. One can attempt to formulate the quantum theory of a field in Minkowski spacetime by decomposing the field into modes and applying the rules of quantum mechanics to each mode. For a free field, each mode is an independent harmonic oscillator and one can obtain a mathematically sensible quantum field theory in this manner, although even here one encounters infinite expressions for quantities that are nonlinear in the fields. A well known example of this general phenomenon is that one obtains an infinite expression for the total energy (and energy density) of the field, as can be seen by adding the zero-point energies and/or energy densities of the infinite number of modes. The situation is considerably worse for interacting (i.e., nonlinear) fields, wherein one immediately encounters ill defined and/or infinite expressions in the calculation of essentially all physical quantities, arising from the fact that modes of arbitrarily high energies seemingly contribute to low energy processes. Historically, it appears to have been generally assumed in its earliest days that the quantum field theory description of nature would break down at, say, the energy scale of elementary particles, and there was no reason to presume that it was a mathematically consistent theory. However, starting from the early 1950 s, it was gradually understood how to give mathematically consistent rules to produce well defined expressions for physical quantities to all orders in perturbation theory for renormalizable theories such as quantum electrodynamics. This process culminated in the works of Bogoliubov, Parasiuk and of Hepp and Zimmermann, with important practical improvements (dimensional regularization) being given later by 't Hooft and Veltmann. It was also seen that the predictions of quantum field theory give truly excellent agreement with experiment-as they have continued to do through the present, LHC era. In the 1950 s and 1960 s, major progress was made towards putting quantum field on a mathematically sound footing via the development of the axiomatic [73], algebraic [40], and constructive [39] approaches. Nevertheless, the prevailing attitude towards quantum field theory today is not very different from what it was in its earliest days, namely, that it is not a fundamental theory but merely a valid description of quantum field modes up to some cutoff in energy (now assumed to be at a much higher energy scale than would have been assumed in its earliest days). At the present time, relatively little attention is generally paid to the issue of whether quantum field theory can be given a mathematically precise and consistent formulation-as compared with such issues as the "fine tuning" that would be necessary to give small values to the cosmological constant and Higgs mass if one views quantum field theory as the quantum theory of the modes of fields lying below some energy cutoff.

Our view is that it is very important to determine if quantum field theory can be given a mathematically precise and consistent formulation as a theory in its own right-and to provide such a formulation if it can be given. This is not because we believe that quantum field theory should be a "final" theory of nature; indeed, we do not believe that a quantum theory of the spacetime metric can be formulated within the existing framework of quantum field theory. However, even if quantum field theory has only a limited domain of validity, it is important to understand precisely what questions are well posed within its framework and how the answers to these questions are to be obtained. In this way, the predictions of quantum field theory can be made with clarity and precision, and hints may be provided for some of the features that might be expected to survive in a more fundamental theory that supersedes quantum field theory.

What are the "basic principles" of quantum field theory in Minkowski spacetime? The observables of the theory are the tensor fields representing the fundamental constituents of matter, together with "composite fields", such as the stress-energy tensor, derived from these matter fields. A key basic principle of quantum field theory is that each observable field, $\Phi(x)$, at each spacetime

point x should be represented as an operator. These operators will satisfy nontrivial algebraic relations, such as commutation relations. However, there are two important caveats to this statement that $\Phi(x)$ is represented as an operator.

The first caveat is that, even in the case of a free Klein-Gordon scalar field ϕ - where, as already mentioned above, a quantum field theory can be formulated by ordinary quantization of the independent modes - it can be seen that one cannot make mathematical sense of $\phi(x)$ as an operator at a sharply defined point x, since modes of arbitrarily high frequency and short wavelength contribute to $\phi(x)$. However, $\phi(x)$ does make sense as a distribution, i.e., by "averaging" $\phi(x)$ with a smooth function of compact support, $f(x)$, one effectively eliminates the arbitrarily high frequency and short wavelength oscillations and thereby obtains a well defined expression for the quantum field. Thus, quantum fields are operator-valued distributions. The distributional nature of quantum fields is the source of most, if not all, of the mathematical difficulties arising in quantum field theory. Nonlinear operations involving distributions are intrinsically ill defined, and one will typically get infinite answers if one attempts to evaluate nonlinear functions of a distribution via mode expansions or other procedures.

The second caveat is that the word "operator" presumes that there is some unique underlying Hilbert space of states on which this operator will act. However, even for a free field, there are an infinite number of unitarily inequivalent representations of the fundamental commutation relations. (This contrasts sharply with the situation for a quantum mechanical system with a finite number of degrees of freedom, where the Stone-von Neumann theorem asserts that, under mild additional assumptions, all such representations are unitarily equivalent.) In Minkowski spacetime, a preferred representation normally can be chosen based upon the additional requirement that the representation contain a Poincare invariant state ("the vacuum"). However, no criterion analogous to this can be applied in a general curved spacetime. As discussed further at the end of this section, it would therefore seem much more natural to view the algebraic relations satisfied by the field observables - rather than the choice of representation - to be fundamental. Thus, in quantum field theory, we will take as a basic principle that the quantum fields $\Phi(x)$ are distributions valued in an algebra.

Another basic principle of quantum field theory in Minkowski spacetime that the fields should "transform covariantly" under Poincare transformations. The Poincare group is the isometry group of the metric, η, of Minkowski spacetime, but a general, curved spacetime will not admit any isometries. Nevertheless, "Poincare invariance" may be viewed as a special relativistic version of the above general relativistic requirement of "covariance", i.e., that quantum field theory in curved spacetime be constructed out of the classical spacetime metric g and the fundamental quantum fields ϕ, without any additional "background structure". Furthermore, this construction should be local in nature. We will take as a basic principle that quantum field theory should be locally and covariantly constructed. We will give precise meaning to this statement in Section 3.

An additional basic principle of quantum field theory in Minkowski spacetime is the requirement of positivity of energy. Since the notion an energy operator for a quantum field theory in Minkowski spacetime is normally defined in terms of the transformation properties of the field under time translations, this requirement cannot be straightforwardly generalized to QFTCS. Nevertheless, one can formulate local conditions on the quantum field theory - known as microlocal spectral conditions - that correspond to positivity of energy in Minkowski spacetime and make sense in curved spacetime. We will take as a basic principle that the quantum field theory should satisfy suitable microlocal spectral conditions. We will give precise meaning to this statement in the Appendix.

Finally, an additional principle of quantum field theory in Minkowski spacetime that is usually taken to be fundamental is the existence of a unique, Poincare invariant state. However, this condition has no analog in a general curved spacetime as a condition on existence or uniqueness of states, [2] and we will not attempt to impose any condition of this nature.

Thus, we seek a formulation of quantum field theory in curved spacetime that implements the three basic principles written in italics above. In the remainder of this section, we briefly describe some of the standard approaches that have been used to formulate quantum field theory in Minkowski spacetime and explain why they do not appear suitable for the formulation of QFTCS. We will then describe the approach that we shall adopt.

Many discussions of quantum field theory are based upon a notion of "particles", and focus

almost entirely on the calculation of the S-matrix, describing the scattering of particles. For a free field in Minkowski spacetime, a notion of "vacuum state" and "particles" can be defined in a natural and precise manner. If an interacting field behaves like a free field in the asymptotic past and future, one can define asymptotic particle states. The S-matrix provides the relationship between the "in" and "out" particle descriptions of the states, and thereby directly yields the dynamical information about the interacting field that is most relevant to laboratory experiments in high energy physics. However, the use of an S -matrix description as a fundamental ingredient in the formulation of QFTCS is unsuitable for the following reasons. Although natural notions of "vacuum state" and "particles" can be defined for a free field in stationary spacetimes, no such natural notions exist in a general curved spacetime. The difficulty is not that a notion of "particles" cannot be defined at all in a general curved spacetime but rather that many notions exist and none appears preferred. Although it may be possible (and useful) to define an S-matrix in spacetimes that become asymptotically stationary in a suitable manner in the past and future, many of the spacetimes of greatest interest in QFTCS are cosmological spacetimes or spacetimes describing gravitational collapse, where singularities occur in the asymptotic past and/or future. If one wishes to apply QFTCS to such spacetimes, it clearly would be preferable to formulate it in a manner that does not require one to define a notion of "particles" near singularities before one can even pose a well defined question. Furthermore, even if the spacetime of interest is suitably asymptotically stationary in the past and future, many of the most interesting physical questions are concerned with the local dynamical behavior of the fields at finite times rather than the particle-like description of states at asymptotically early and late times. For example, one may wish to know the expected stress-energy tensor of a quantum field in order to estimate the "back reaction" effects of the quantum field on the dynamics of the spacetime. An S-matrix would not be useful for such a calculation.

In many discussions of quantum field theory in Minkowski spacetime, Euclidean methods play an important role in both the formulation of the theory and in calculational techniques. Minkowski spacetime can be viewed as a real 4 -dimensional section of a complex 4-dimensional manifold with complex metric, which contains another 4 -real-dimensional section (of "imaginary time") on which the metric is positive definite. If one can define a quantum field theory in a suitable manner on this "Euclidean section", a quantum field theory on Minkowski spacetime can then be obtained via analytic continuation. Since it is much easier to make sense of formal expressions in the Euclidean setting than in the Lorentzian setting, Euclidean methods have been employed in most of the attempts to rigorously define interacting quantum field theories and in most of the methods employed to regularize and renormalize quantities in perturbative quantum field theory [39]. Euclidean methods can be generalized so as to apply to static, curved spacetimes, where the transformation " $t \rightarrow$ it" takes one from a static Lorentzian spacetime to a Riemannian space. However, a general curved spacetime will not be a real section of a complex manifold that also contains a real section on which the metric is Riemannian. Thus, although it should be possible to define "Euclidean quantum field theory" on curved Riemannian spaces [62], there is no obvious way to connect such a theory with quantum field theory on Lorentzian spacetimes. Thus, if one's goal is to define quantum field theory on general Lorentzian spacetimes, it does not appear fruitful to attempt to formulate the theory via a Euclidean approach.

Finally, by far the most prevalent approach taken towards the formulation of quantum field theory in Minkowski spacetime is to write down a formal functional integral expression for an effective action. Suitable functional derivatives of this expression are then interpreted as providing the correlation functions of the quantum field in its vacuum state. Thus, one will have defined the quantum field theory if one can make sense of this functional integral and its functional derivatives. The difficulty with using a functional integral approach to formulate QFTCS is that, in effect, it requires one to single out a preferred state in order to define the theory-namely, the state for which the correlation functions are being given. This is not a difficulty in Minkowski spacetime, where Poincare invariance naturally selects a preferred state and, furthermore, Euclidean methods are available to make sense of the functional integral for this preferred state. However, as previously indicated above, no analogous notion of a preferred state exists in a general curved spacetime without symmetries. As in the above discussion of S -matrix approaches to the formulation of QFTCS, we do not believe that it will be fruitful to formulate QFTCS via an approach that requires one to define a preferred state in order to define the theory. [3]

For the above reasons, we shall adopt the "algebraic viewpoint" for the formulation of QFTCS. The basic idea of this approach is to take the relations satisfied by the quantum fields - such as commutation relations and field equations - as the fundamental starting point of the theory. To define the theory, one must specify the complete set of algebraic relations satisfied by the fundamental field and composite fields. As we shall see, this can be done for a free field. In addition, we can naturally define time ordered products, enabling one to give a perturbative construction of interacting quantum field theory. However, it is far less clear as to how to define appropriate algebraic relations so as to give a non-perturbative definition of interacting quantum field theory; we will return to this issue in Section 4.1. Once the algebraic relations have been given, states are defined to be positive linear functions on the algebra of quantum fields. The GNS construction then shows that every state in this sense arises as a vector in a Hilbert space that carries a representation of the field algebra, thus connecting the algebraic notion of states with usual notions of states in quantum theory. The key point is that one can formulate QFTCS via the algebraic approach in a manner that does not require one to single out a preferred state in order to define the theory. We begin the next section by formulating QFTCS for a free scalar field, taking into account only the fundamental field observables. We also discuss some key applications, including the Hawking and Unruh effects and quantum effects arising from inflation. In Section 3, we show how a wide class of nonlinear field observables can be defined for a free scalar field.

We then describe the perturbative construction of QFTCS for interacting fields. We also discuss the construction of QFTCS for gauge fields. Finally, in Section 4 we discuss ideas that may lead towards a nonperturbative formulation of interacting QFTCS and we make some remarks on the formulation of quantum gravity from the perspective of QFTCS. 2. Free quantum fields In this section, we provide a precise formulation of the theory of a free Klein-Gordon field in curved spacetime, insofar as the fundamental field observable, ϕ, is concerned. (Observables that are nonlinear in ϕ - i.e., "composite fields" - will be introduced in the next section.) We then discuss some key applications of the theory, namely, the Unruh effect, quantum field theory in deSitter spacetime, the Hawking effect, and cosmological perturbations.

Formulation of linear QFTCS via the algebraic approach (without nonlinear observables)

2.1.

We now describe how to define the quantum field theory of a real, linear Klein-Gordon field ϕ on a d -dimensional, curved, Lorentzian spacetime $(\mathscr{M}, g)$ along the lines sketched in the previous section. We begin with the classical Klein-Gordon field, which satisfies

$$\left(\Box_g - m^2\right)\phi = 0$$

where $\Box_g = g^{\mu v}\nabla_\mu\nabla_v$ is the D'Alembertian operator associated with g. In order that (1) have a well-posed initial value formulation, we restrict consideration - here and throughout this article - to globally hyperbolic spacetimes. By definition, a globally hyperbolic spacetime is a time oriented spacetime that possesses a "Cauchy surface", Σ, i.e., a smoothly embedded $(d-1)$-dimensional spacelike submanifold with the property that if $\gamma : \mathbb{R} \to \mathscr{M}$ is any inextendible causal curve, then γ intersects Σ precisely once. [4] The classical Klein-Gordon equation with source j $(\Box_g - m^2)\,\phi = j$ (where j is an arbitrary, fixed, smooth function on spacetime) has a well posed initial value formulation on globally hyperbolic spacetimes in the following sense. Let n denote the unit normal to Σ. Then, given any pair (f_0, f_1) of smooth functions on Σ, there exists a unique solution ϕ to the Klein-Gordon equation (2) such that $\phi|_\Sigma = f_0, \quad n^\mu\nabla_\mu\phi|_\Sigma = f_1$ Furthermore, solutions to the initial value problem have a causal dependence upon the initial data and the source in the sense that if $x \in J^+(\Sigma)$, then the solution ϕ to the above initial value problem will not change at x if we change the initial data (f_0, f_1) outside $J^-(x) \cap \Sigma$, or if we change the source outside of $J^-(x) \cap J^+(\Sigma)$. Here

$J^\pm(S) \equiv \{x \in \mathscr{M} \quad | \exists$ causal future/past directed curve from $y \in S$ to $x\}$ denotes the "causal future/past" of a set $S \subset \mathscr{M}$. Similarly, if $x \in J^-(\Sigma)$, then $\phi(x)$ will not change if we change the initial data (f_0, f_1) outside $J^+(x) \cap \Sigma$, or if we change the source outside of $J^+(x) \cap J^-(\Sigma)$. Finally, the solution ϕ depends continuously on (f_0, f_1) and j in a suitable sense.

We can define the retarded and advanced propagators $E^{\pm}$ of the Klein-Gordon equation as follows. For $j \in C_0^\infty(\mathscr{M})$ the advanced solution $E^- j$ is the unique solution to the Klein-Gordon equation with source j such that $E^- f(x) = 0$ for all $x \notin J^-(\mathrm{supp}\, j)$, with the opposite definition for the retarded solution $E^+ j$. The propagators may be viewed as maps $E^{\pm} : C_0^\infty(\mathscr{M}) \to C^\infty(\mathscr{M})$ or alternatively as distributional kernels on $\mathscr{M} \times \mathscr{M}$. As distributions, $E^{\pm}$ satisfy the differential equation $(\Box_g - m^2)\, E^{\pm}(x,y) = \delta(x,y)$ where the Klein-Gordon operator acts on the first variable, x, in the sense of distributions. The support properties are $\mathrm{supp}\, E^{\pm} \subset \{(y,x) \in \mathscr{M} \times \mathscr{M} | x \in J^{\pm}(y)\}$ The advanced and retarded propagators are related by exchanging x with y. The anti-symmetric combination $E = E^+ - E^-$ is called "commutator function". As described in the Introduction, we will formulate QFTCS for a Klein-Gordon field by defining a suitable algebra, $\mathscr{A}(\mathscr{M}, g)$ of quantum observables. In this section, we will consider only the algebra of observables generated by the funda-

mental field ϕ. An enlarged algebra that includes "composite fields" will be defined in the next section. The construction of $\mathscr{A}(\mathscr{M}, g)$ will take into account: (1) the distributional nature of the field $\phi(x)$, (2) the field equation, (3) the real character of ϕ and (4) the symplectic structure of the classical phase space of this theory. We construct $\mathscr{A}(\mathscr{M}, g)$ by starting with the free * -algebra generated by a unit 1 and elements $\phi(f)$, with $f \in C_0^\infty(\mathscr{M})$, and factoring by the following relations: (1) Linearity: $\phi(c_1 f_1 + c_2 f_2) = c_1 \phi(f_1) + c_2 \phi(f_2)$ for all $c_1, c_2 \in \mathbb{C}$, (2) Field equation: $\phi((\Box_g - m^2) f) = 0$ (3) Hermitian field: $\phi(f)^* = \phi(\bar{f})$, (4) Commutator: $[\phi(f_1), \phi(f_2)] = iE(f_1, f_2)\, 1$. Item (1) incorporates the distributional character of the field; informally we write

$$\phi(f) = \int_{\mathscr{H}} \phi(x) f(x) dv_g$$

and we think of $\phi(x)$ as an $\mathscr{A}$ -valued distribution. We refer to the algebra $\mathscr{A}$ as "abstract", because no reference has been made to any representation. In fact, we are not supposed to think, a priori, of the elements of $\mathscr{A}$ as operators on a particular Hilbert space, in the same way as an abstract Lie-algebra is defined irrespective of a particular representation. (2) incorporates the field equation in a distributional sense. (3) expresses that the field is real, and (4) implements the usual quantum mechanical relationship between classical Poisson-brackets and commutators. It also incorporates Einstein causality, because $E(x,y) = 0$ if x, y are spacelike related.

Rather than working with fields $\phi(f)$ that are smeared with test functions f on $\mathscr{M}$, we can also equivalently view ϕ as being "symplectically smeared" with solutions, F, having initial data of compact support on some Cauchy surface Σ. The correspondence is the following. If $f \in C_0^\infty(\mathscr{M})$, then $F = Ef$ is a source free solution having initial data (3) of compact support. Conversely, given a solution F with initial data of compact support, there exists a test function f - unique up to addition of $(\Box_g - m^2)\, h$ for $h \in C_0^\infty$ - such that $F = Ef$. Defining $\phi[F] = \phi(f)$ under this correspondence between F and f, we can then informally write the field as

$$\phi[F] = \int_\Sigma (F \nabla_\mu \phi - (\nabla_\mu F)\, \phi)\, n^\mu dS$$

We can think of $\pi = n^\mu \nabla_\mu \phi|_\Sigma, \varphi = \phi|_\Sigma$ as canonically conjugate variables and the commutation relation (4) then corresponds to $[\pi(x), \varphi(y)] = i\delta_\Sigma(x,y)\mathbf{1}$; for details, see, e.g. [23] or lemma 3.2.1 of [79].

A physical state, ω, is simply an "expectation value functional", i.e., a linear map $\omega : \mathscr{A}(\mathscr{M}, g) \to \mathbb{C}$ satisfying the normalization condition $\omega(\mathbf{1}) = 1$, and positivity, $\omega(a^* a) \geq 0$ for all $a \in \mathscr{A}$. Any state is, by construction, specified by the collection $(W_n)_{n \geq 1}$ of its "n-point functions",

$$W_n(f_1, ..., f_n) \equiv \omega(\phi(f_1) \cdots \phi(f_n))$$

The KG-equation, condition (2), is translated into the fact that W_n is a distributional solution in each entry. Condition (1) implies that W_n is an n -times multilinear functional on $C_0^\infty(\mathscr{M})$, which one normally requires to be distributional (i.e. continuous in the appropriate sense). The commutator condition (4) is translated into a linear condition which in the simplest case $n = 2$

is $W_2(x,y) - W_2(y,x) = iE(x,y)$ Positivity is translated into a rather complicated hierarchy of conditions on the multi-linear functionals W_n, the simplest of which is

$$W_2(\bar{f}, f) \geq 0 \text{ for all } f \in C_0^\infty$$

Given two states ω, ω', one can form a new state by forming any convex linear combination $\lambda\omega + (1-\lambda)\omega'$, where $0 \leq \lambda \leq 1$. A state which cannot be written as a non-trivial convex linear combination of others is called pure.

The notion of algebraic state is in principle sufficient to answer all physical questions about the field observables. In particular, the specification of a state ω directly yields the expected values of all powers of $\phi(f)$ for all, say real, test functions f. It follows from the classical "Hamburger moment problem" (see e.g. [67]) that there is a probability measure $dv(\lambda)$ such that

$$\int_{\mathbb{R}} \lambda^n dv(\lambda) = \omega(\underbrace{\phi(f)...\phi(f)}_{n}) \equiv m_n \text{ for all } n \geq 1.$$

The probability that an observation of $\phi(f)$ will yield a value within $[a,b]$ when the field is in state ω is then given by $P_{a,b} = \int_{[a,b]} \lambda dv(\lambda)$ The relationship between states in the algebraic sense as defined above and the usual notion of states as vectors in a Hilbert space can be seen as follows: First, assume that we have a representation $\pi : \mathscr{A}(\mathscr{M}, g) \to \mathscr{H}$ on a Hilbert space with dense invariant domain $\mathscr{D} \subset \mathscr{H}$. If Ψ is a non-zero vector in this domain, then

$$\omega_\Psi(a) = \frac{(\Psi, \pi(a)\Psi)}{(\Psi, \Psi)}$$

defines a state in the algebraic sense. More generally, any sufficiently regular (with respect to $\mathscr{D}$) density matrix on $\mathscr{H}$ - i.e., a non-negative, trace-class operator $\rho \in \mathscr{I}_1(\mathscr{H})$ - defines an algebraic state ω_ρ. Conversely, given any algebraic state ω, there is a simple construction - known as the GNS-construction, or Wightman reconstruction argument - that yields a Hilbert space $\mathscr{H}$, a representation π of $\mathscr{A}$ on $\mathscr{H}$ with invariant domain $\mathscr{D} \subset \mathscr{H}$, and a vector $\Omega \in \mathscr{D}$ such that the algebraic state corresponding to Ω is ω. As we shall explain further below, for the case of a Gaussian state, the GNS construction yields a Fock representation of $\mathscr{A}$, with Ω being the vacuum vector of this Fock space.

The above correspondences show that the algebraic and Hilbert space formulations of QFTCS are essentially equivalent. However, there is one important difference: There are many unitarily inequivalent representations of the field algebra $\mathscr{A}$. (Two representations are said to be unitarily equivalent if there is an isometry $U : \mathscr{H} \to \mathscr{H}'$ such that $U\pi(a)U^* = \pi'(a)$ for all $a \in \mathscr{A}$.) The Hilbert space formulation requires one to chose a "preferred representation" at the outset, while the algebraic formulation does not. For this reason, we feel that the formulation of QFTCS via the algebraic approach is conceptually superior.

The algebra $\mathscr{A}$ admits states with rather pathological properties of their n -point functions W_n. However, there is a natural criterion to select physically reasonable states that is motivated from a variety of closely related considerations, including that (i) the ultra-high-frequency modes of the field should be essentially in their ground state, (ii) the short distance singular structure of the n -point functions W_n should be similar to that of the n -point functions of the vacuum state in Minkowski spacetime, and (iii) the singular structure of the W_n 's should be of "positive frequency type". A mathematically precise implementation of these requirements in a general curved spacetime can be formulated in the language of wave front sets discussed in the Appendix, as first proposed in [65,66,15]. The criterion is that the 2 -point function have a wavefront set of the form

$$\mathrm{WF}\left(W_2\right) \subset \left\{(x_1, k_1; x_2, k_2) \in T^*\mathscr{M}^2 \backslash 0 | k_1 \in \dot{V}^+, k_2 \in \dot{V}^-, k_1 \sim -k_2\right\}$$

and that each "connected n -point function" $\omega_n^c\left(\phi\left(x_1\right), ..., \phi\left(x_n\right)\right)$ for $n \neq 2$ (defined below in Eq. (19)) is smooth. Here $V^+ \subset T^*\mathscr{M}$ is the collection of all non-zero, future directed time-like

or null co-vectors (and similarly V^-), and the relation $\sim$ holds between two covectors if they are tangent to a null geodesic in $(\mathscr{M}, g)$ and are parallel transported into each other. Such states are called "Hadamard states". As we will see in the next section, it will be necessary to restrict to Hadamard states in order to extend the action of the state to an enlarged algebra of field observables that includes all polynomials in the field and its derivatives at the same spacetime point. In particular, it will be necessary to restrict to Hadamard states when considering the perturbative expansion of interacting QFTCS.

One can prove [65,66] that the above definition of a Hadamard state is equivalent to the following local condition [58] on the 2 -point function together with the requirement that, globally, there be no singularities at spacelike separations: For every convex, normal neighborhood $U \subset \mathscr{M}$, the two-point function has the form (in $d = 4$ dimensions; similar expressions hold in arbitrary d):

$$W_2 = \frac{1}{4\pi^2}\left[\frac{u}{\sigma + i0^+ t} + \left(\sum_{n=0}^{N} v_n \sigma^n\right)\log\left(\sigma + i0^+ t\right)\right] + f \equiv H_N + R_{N,\omega}.$$

f - some N -times continuously differentiable function $R_{N,\omega}$.

Here, the spacetime arguments are understood as $(x, y) \in U \times U$, and we mean that the above formula should hold for every N, with (different) remainders $R_{N,\omega} \in C^N(U \times U)$.$\sigma$ is the signed squared geodesic distance, and $t = T(x) - T(y)$ for some (in fact, any) global time function $T : \mathscr{M} \to \mathbb{R}$. The functions u, v_n are determined by certain local "transport equations" [19] and also appear in similar local forms of the advanced and retarded Green's function for the operator $\Box_g - m^2$. In particular, H_N is locally and covariantly defined in terms of the metric, and is hence the same for any Hadamard state. By contrast, the remainder $R_{N,\omega}$ depends on the state.

The Hadamard condition does not single out a particular state, but a class of states. Existence of a large class of Hadamard states on any globally hyperbolic spacetime can be established by a deformation argument [37] combined with microlocal techniques, or by methods from the theory of pseudo-differential operators [57,38].

We now discuss two important classes of states: Gaussian states and thermal states. Gaussian States: Gaussian states (also called "quasi-free states") are defined by the condition that the "connected n -point functions" $\omega_n^c\left(\phi\left(f_1\right), ..., \phi\left(f_n\right)\right)$ vanish for all $n > 2$, where $\omega_n^c : \mathscr{A} \times \cdots \times \mathscr{A} \to \mathbb{C}$ is defined by [8]

$$\omega_n^c\left(a_1, ..., a_n\right) \equiv \frac{\partial^n}{\partial t_1 ... \partial t_n} \log\left\{\omega\left(e^{t_1 a_1} \cdots e^{t_n a_n}\right)\right\}\Big|_{t_i = 0}, \quad a_i \in \mathscr{A}.$$

Thus, the n -point functions of Gaussian states can be expressed entirely in terms of their 1 - and 2 -point functions. For a Gaussian state, positivity will hold if and only if (13) is satisfied. Thus, there exists a wide class of Gaussian states.

Any Gaussian state, ω, can be expressed as the "vacuum state" in a Fock representation of $\mathscr{A}$. To see this explicitly, let W_2 be the 2 -point function of ω. On the complex linear space $C_0^\infty(\mathscr{M}, \mathbb{C})$ of smooth complex-valued functions on $\mathscr{M}$ of compact support, define the inner product $\langle f | h \rangle = W_2(\bar{f}, h)$. This is hermitian and positive, $\langle f | f \rangle \geq 0$, but contains degenerate vectors, such as elements of the form $f = (\Box_g - m^2)\, h$. Let $\mathfrak{h}$ be the factor space of $C_0^\infty(\mathscr{M}, \overline{\mathbb{C}})$, divided by the degenerate vectors. The elements in this space can be identified more concretely with a subspace of complex valued smooth solutions to the KG-equation, corresponding to "positive frequency modes", see below. The completion of $\mathfrak{h}$, denoted by the same symbol, is a Hilbert space, usually referred to as the "1-particle space". Let $\mathscr{H}$ be the bosonic Fock space over $\mathfrak{h}$, $\mathscr{H} = \mathbb{C} \oplus \bigoplus_{n \geq 1} \underbrace{(\mathfrak{h} \otimes_S \cdots \otimes_S \mathfrak{h})}_{n}$, where $\otimes_s$ is the symmetrized tensor product. A representation, π, of $\mathscr{A}$ on $\mathscr{H}$ can then be defined by $\pi[\phi(f)] = a([f])^\dagger + a([f])$ where $a([f])$ is the annihilation operator associated with the equivalence class of f in $\mathfrak{h}$. The vacuum vector Ω given by the element $|1, 0, 0, ...\rangle$ in Fock-space then corresponds to ω, and, as already mentioned above, $(\mathscr{H}, \pi, \Omega)$ is precisely the GNS triple arising from the GNS construction.

A closely related construction often used in practice to construct Gaussian pure states is the following. Suppose that we have a set of smooth, complex-valued "mode functions" $u_\xi(x)$ that are solutions to Eq. (1), and which are labeled by $\xi \in X$ in some measure space $(X, d\mu)$. We assume that for each $f \in C_0^\infty(\mathscr{M}, \mathbb{R})$, the map

$$X \ni \xi \mapsto Kf(\xi) \equiv \int_{\mathscr{M}} \overline{u_\xi(x)} f(x) dv_g \in \mathbb{C}$$

is in $L^2(X, d\mu)$, and in fact that the (real linear) span of such vectors is dense in $L^2(X, d\mu)$. We also assume that the mode functions are such that

$$\mathrm{Im}\, \langle Kf_1 | Kf_2 \rangle_{L^2(X,d\mu)} = \frac{1}{2} E(f_1, f_2) \text{ for all } f_1, f_2 \in C_0^\infty(\mathscr{M})$$

(These properties are equivalent to the statement that the collection of modes $(u_\xi)_{\xi \in X}$ is "complete in the KG-norm".) Then, clearly

$$W_2(f_1, f_2) = \langle Kf_1 | Kf_2 \rangle_{L^2(X,d\mu)} \to W_2(x, y) = \int_X d\mu(\xi) u_\xi(x) \overline{u_\xi(y)}$$

defines the 2 -point function of a Gaussian state, which can be shown to be pure. Its GNS-representation is thus constructed as above. K is clearly well-defined on the equivalence classes $[f]$, and it can also be shown that it provides a bounded isomorphism $K : \mathfrak{h} \to L^2(X, d\mu)$. Hence, in this case, we may consider $\mathscr{H}$ as the bosonic Fock-space over $L^2(X, d\mu)$, and we may informally write the representative of the field on this Fock space as

$$\pi(\phi(x)) = \int_X d\mu(\xi) \left[u_\xi(x) a_\xi + \overline{u_\xi(x)} a_\xi^\dagger \right]$$

This is the usual form of the field in the vacuum representation on Minkowski space, where $\xi = \mathbf{k} \in \mathbb{R}^3 = X, d\mu(\mathbf{k}) = d^3\mathbf{k}/(2\pi)^3$, and $u_\mathbf{k}(\mathbf{x}, t) = e^{-i\omega_\mathbf{k} t + i\mathbf{l}\mathbf{x}}/\sqrt{2\omega_\mathbf{k}}$. In this example, the mode functions have positive frequency with respect to the global time translations, and similar constructions are available also on other spacetimes with a globally defined time-like isometry.

Given two pure Gaussian states ω and ω' with 2 -point functions W_2 respectively W_2' and vanishing 1 -point functions, one may ask when their associated GNS-representations are unitarily equivalent. A necessary condition is that there be a constant c such that

$$c^{-1} \mu(f, f) \leq \mu'(f, f) \leq c\mu(f, f)$$

for all $f \in C_0^\infty(\mathscr{M}, \mathbb{R})$, where μ and μ' denote the symmetric parts of W_2 and W_2'. Since it is easy to construct states violating this condition, one sees that there is in general a large class of inequivalent representations. Suppose the condition is satisfied. It immediately follows that the positive, sesquilinear [9] forms μ, μ' induce the same topology on the complex vector space $\mathcal{K}$ which is defined as $C_0^\infty(\mathscr{M}, \mathbb{C})$ modulo elements of the form $f = (\Box_g - m^2) h.\mathcal{K}$ may be thought of as the space of complex valued, spatially compact smooth solutions to the Klein-Gordon equation, and the bilinear forms μ and μ' are well-defined on $\mathcal{K}$ and positive definite. Furthermore, it is easy to see that the closure of this space (relative to either μ or μ') can be decomposed into "positive and negative frequency solutions" as $\mathcal{K} \cong \mathfrak{h} \oplus \overline{\mathfrak{h}} \cong \mathfrak{h}' \oplus \overline{\mathfrak{h}'}$, where an overbar means the complex conjugate Hilbert space, and where $\mathfrak{h}$ respectively $\mathfrak{h}'$ are the 1 -particle spaces corresponding to W_2 respectively W_2'. The Riesz representation theorem guarantees that there is a bounded map S on $\mathscr{K}$ such that $\mu(F_1, F_2) = \mu'(F_1, SF_2)$ for all $F_1, F_2 \in \mathscr{K}$. A necessary and sufficient criterion that the two states give rise to unitarily equivalent representations is [76] $\mathrm{tr}_\mathcal{K} |1 - S| < \infty$ where $|1 - S|$ is the absolute value of the operator defined using μ'. The operator $1 - S$ characterizes the

difference between the 2 -point functions. It is therefore plausible that if their difference is smooth - as happens e.g. if both states are Hadamard - and the manifold $\mathscr{M}$ has compact slices, then (27) should hold, and the representations should be unitarily equivalent. This can indeed be shown [10] [77]. On the other hand, for the case of a non-compact Cauchy surface, the representations can be unitarily inequivalent if the 2 -point functions have sufficiently different long-range behavior. Similarly, the representations can fail to be unitarily inequivalent if the states are not Hadamard and have a sufficiently different short range behavior.

(и там дальше еще целая куча всего, просто пока что все равно это выгрузки, так что нет смысла это писать, начало разобрать бы.)

(из Quantum fields in curved spacetime см литературу)

35.3 Integrable Models of QFT

У лашкевича аж полно лекций про это, чисто теорфизная такая заморочка, мб займусь этим тоже потом.

35.4 QFT on Lattices

(отдельный важный раздел, про который много докладов. соберу потом)

35.4.1 Basics of QFT on Lattices

Основы описания

(там много инфы, не до нее)

Пример вычисления интеграла Фейнмана по решетке

(напишу потом, давно про это вопрос есть.)

35.5 Other Special Topics in a Nutshell

35.5.1 Visualization of Quantum Fields (??)

(это большой вопрос, потому что внятного ответа я не находил. Пока нет времени разбираться в этом.)

35.5.2 Quantum Fields in Curved Space in a Nutshell

пока хз, квантовую механику там бы сперва изучить.

35.6 Overview of Attempts of Quantization of Gravity

(all about this is in this part of the note)

35.7 Some Special Applications of QFT

(пока раздел мелкий, потом мб увеличу, если будет нужно.)

35.7.1 Quantum Field Theory in Economics

я слышал, что есть такая книга, на самом деле никогда не занимался этим.

35.7.2 Applications of QFT in Kinetics

(Там Пригожин и другие что-то многое писали про это, пока не до этого. maybe Kamenev's book it exactly about it)

35.7.3 On Applications of QFT to Life Problems (??)

??? пока не знаю вообще.

Part IX
Adds

Обсудим используемые в КТП основы и отдельные конструкции других разделов физики.

A Introduction and Overview of QFT

A.1 Motivation for QFT

Обсудим, что нас мотивирует изучать классическую теорию поля.

A.1.1 Extra Motivation

Фундаментальные законы природы раскрываются в квантовой теории поля

Часто можно слышать, что на многие принципиальные вопросы физики вместо ответа идет отсылка к КТП.

И вот, наконец-то мы на этом уровне! Мы можем раскрыть самую настоящую суть природы. Вот в первую очередь зачем КТП изучать круто.

Многие величайшие физики человечества специализировались именно на КТП

Типа Фейнман, типа Ландау. Именно КТП и его приложениями они и занимались.

Круто владеть диаграммами

тоже аргумент изучать ее, но слабоватый конечно.

Открывает понимание квантовой гравитации и теории струн

Типа они есть использование КТП в более единых теориях.

Много связей с более простыми предметами

квантовая механика и теория поля при многих рассуждениях переходят в КТП
так что если там не знаешь основы, то тупиковое будет дело.

даже как-то другие предметы не назвать выученными, потому что задаешь вопрос о связях с КТП, и если этот вопрос не отвечен, то сама природа явлений не ясна.

Используются продвинутые математические методы

Поэтому, изучая правильно КТП, появится углубленная подготовка по математике, а также сам стиль работы станет заметно более профессиональным.

Верная ли вообще квантовая электродинамика (?!?!?!?!??!?)

(приведу видео из Ютуба, где доказывается, что КЭД это плохо!?!??! и что вот делать?)

Что такое уровень теормина, если КЭД не работал в 1948м году, а Ландау его с 33го года проводил?

Мы знаем, что КЭД - важная часть теормина. Видно, тогда не было КЭД в теормине.

A.1.2 Phenomena Deeply Understood from the Point of View of QFT

Углубленное понимание света

КТП (? по идее, пока хз) сполна ответит на вопросы о том, что есть свет и как он работает? Отражения, преломления. См. на Ютубе видео чуть что. Пока этих ответов я не нашел.

A.1.3 Overview of QFT Applications

неплохо бы выписать вопросы, которые перед нами появляются, когда мы начинаем КТП заниматься.

Физика элементарных частиц

вроде там она используется, но дорасти нужно сперва до этого.

когда КТП не нужно

(важный вопрос)
в квантмехе ввели бы как-то взаимодействие частиц, да и все.
решали бы квантовомеханические задачи про частицы.
зачем к полям переходить?

характеристики квантовых явлений, в которых не хватает квантовой механики

да хз вот...

A.1.4 Amazing Facts

(??? collect them???)

A.1.5 Results of QFT

объяснен аномальный магнитный момент

Швингер это сделал.
где-то у меня про это будет, Зи хорошо про это написал.

A.1.6 The Physical World with QFT

обсудим, как решаются вопросы, которые без КТП были не решенными.

Сравнение методов квантования

понятия частиц или квантов полей

супер частый вопрос, КТП на многообразиях изучу - впишу.
Кванты поля обладают всеми физическими свойствами самого поля.
да?
(тут в том числе выжимка Киселева про то, что квант это именно частица)

усовершенствование квантовой механики теорией поля

конкретные простые примеры эффективности подхода квантовых полей

решение проблемы принципа причинности

(как он решается?)

квантовая механика это КТП во временном пространстве (??)

это пока не пойму!
но там уравнение Клейна напоминает как раз осциллятор...
(???? не пойму вообще это)

A.2 How Professionals in QFT Think?

(это все еще раз перепишу с опытом! (мб и не раз))

A.2.1 What is Quantum Field Theory in General? (?!)

(напишу нормальный ответ для меня! пока как-то не готов писать это. формулы тоже добавлю.)

Суть квантовой теории поля

(?? как на этот вопрос ответить? в чем она?)

QFT in a nutshell is just a little number of basic fields and formalism for their interaction, which gives matrix elements

(допишу подробнее, как видеть КТП, чтобы не парится про тысячи страниц непоятно какой теории, потому что так или иначе, общая картина происходящего очень небольшая. так профессионалы и видят КТП, ничего особо там нет сложного, а практически все темы можно ине понимать, просто по потребности можно их дочитывать. Поэтому вообще ничего и нет сложного, хотя, казалось бы, сотни страниц уходят на обсуждение формализма.)

квантовые поля - это примененный аппарат квантования к классическим полям

пока думаю так.
тут вот интересно, что все-таки а почему это так?
там же тонна методов отдельных, а также как-то даже аппарат квантовой механики сперва отдельно выделить нужно, чтобы им пользоваться.
в общем, позже можно подумать, но пока останавливаюсь на этом.

О бесконечностях в КТП

(пока мелкий раздел, потом мб буду расширять)

О ответах на принципиально сложные вопросы квантовой теории поля

(На начальных этапах это лучше отложить. Тут обсуждение, когда ими стоит заниматься и сколько внимания уделять.)

КТП - суть всего материального мира (??)

По сути на квантовом уровне у нас первичны поля, они же проявляют себя как частицы. (?)
тоже пока что далеко не настолько я зрел, чтобы сказать про это точно.
так что они принципиально важны для понимания природы.
однако мб это абсолютно не так, пока еще предстоит разобраться в этом.

Map of QFT

(add picture and discussion about it!!!)

What is Quantum Field Theory?

(с опытом напишу, тут пока ответ Тонга.)

Having told you why QFT is necessary, I should really tell you what it is. The clue is in the name: it is the quantization of a classical field, the most familiar example of which is the electromagnetic field. In standard quantum mechanics, we're taught to take the classical degrees of freedom and promote them to operators acting on a Hilbert space. The rules for quantizing a field are no different. Thus the basic degrees of freedom in quantum field theory are operator valued functions of space and time. This means that we are dealing with an infinite number of degrees of freedom - at least one for every point in space. This infinity will come back to bite on several occasions.

It will turn out that the possible interactions in quantum field theory are governed by a few basic principles: locality, symmetry and renormalization group flow (the decoupling of short distance phenomena from physics at larger scales). These ideas make QFT a very robust framework: given a set of fields there is very often an almost unique way to couple them together.

What is Quantum Field Theory Good For?

(с опытом напишу, Тонг писал, что для всего, но вряд ли это так. потом когда-то свое мнение появится.)

Появление КТП в нашей картине мира

Суть КТП за 2 часа

Обсудим, что из себя представляет предмет наиболее кратко, выделяя самую суть.

обзор квантовой хромодинамики

(??)

Обзор лагранжианов КТП

(тут будет список лагранжианов с комментариями. не такой важный раздел, но прикольно было бы его иметь.)

Что за непертубативные эффекты? (????????)

(пока не дошел до них, потом дойду.)

Основные методы КТП за 2 часа

Наиболее прикладные темы КТП

обсудим, какие темы на самом деле самые важные тут.

обзор теоретических подходов

такие-то есть, такие полезные, такие - нет.

Нетипичные применения КТП

Обсудим применения, которые скорее всего не встретятся, однако видеть их очень полезно

применения в математической статистике

очень актуально кстати.
по идее мы когда там считаем разные усреднения и поправки, там же это делается.

применения в экономике

такие тоже есть, но до этого абсолютно не дойти, пока сам формализм не будет досконально понят.
хотя мб тут именно континуальный интеграл будет применяться, а не сами методы КТП.
пока рано писать.

Обзор дальнейших развитий КТП

пока не готов писать

хромодинамика

теория струн

Список физических величин

Посмотрим, какие величины и зачем нужно нам помнить?
масса планка

A.2.2 Attitude Toward QFT

(сомнительное название раздела, потом перенозову или удалю)

Стоит ли заниматься КТП?

Стоит ли заниматься КТП обычным физикам?

Однозначно, да, но ограничить себя по объему работы, иначе увязнешь! Потому что если говорить про фундаментальные взаимодействия, нано масштаб (?? какой конкретно масштаб???), то там если не знать КТП, то и сказать не будет чего в принципе.

Стоит ли заниматься КТП тем, кто специализируется в другой области физики (!?!)

Думаю, да, но если у человека нормальный подход в принципе к науке, а также нет чего-то горящего. Просто без проблем можно раз в пару недель досматривать формализм или прорешивать модели, это было бы совершенно не сложно. Самое главное тут иметь общий уровень развития и подход к физике, если они есть - нет проблем спокойно досматривать КТП, это было бы очень интересно и полезно. Но если нет развития - тут слишком много будет проблем, так что возможности получить пользу будет мало, так что особой важности в занятиях КТП нету.

A.2.3 Which Problems of QFT Are Important And Which Are Not?

(there are a lot of problems, but many of them looks useless. the discussion of this will be here. which problems solving is a good idea and which is just a waste of time? Maybe Kiselev doesn't know this)

A.2.4 Is QFT Really a Good Theory After All?

(с опытом напишу, важная часть обзора. вообще, мб и вряд ли, но пока рано это писать)

О строгости КТП

говорят, она не строгая математически, это плохо. да?
не знаю.
есть мнение, что для математиков это вызов, КТП можно сделать более строгой.
То есть ничего страшного, просто потом будут новые формулировки ее, более четкие.
А с этим появятся новые идеи.

A.2.5 “So Many Formulas, What is Going On?”

Типичный вопрос изучающего КТП это вопрос в духе “Столько формул, я вообще не понимаю, что с чем связано. Какие-то методы, какие-то параметры, что-то, что я даже не понимаю, к чему относится. Можно упрощенно понять, что вообще происходит?” Это типичный вопрос и часто нужна просто пара лет, чтобы все уложилось в голове. Тем не менее, я попробую на него ответить, потому что такой ответ очень может помочь все уложить в голове, в то же время моя первая часть тоже об этом.

(напишу просто очень упрощенно)

О том, что мы хотим найти и какие физические параметры у нас итоговые

(сечения рассеяния, ширины распадов.)
(мб что-то еще напишу, пока нет потребности в этом.)

Еще раз быстрый вывод амплитуды рассеяния простого процесса?

(в теории про это подробно, в 1й части - указаний много хороших, а тут - чисто для распутывания запутавшегося. просто иллюстрация метода. но мб это же в 1ю часть добавлю, просто там идея в нормальных указаниях, а не в указаниях для распутывания)

A.2.6 Which Method to Chose for a Given Problem?

(про это много вопросов, тут все это обсуждение. когда это полезно, а когда нет?)

Мотивация работать с интегралом по траекториям

Сохранение Лоренц инвариантности

Минусы работы с интегралом по траекториям

с амплитудой могут быть проблемы

A.2.7 How to Study of QFT Effectively?

Особая важность хорошего понимания основ (!)

В других предметах основы интуитивно понятны, но не в КТП. тут нужно очень ответственно подойти к тому, чтобы понять, откуда появляются диаграммы и как ими пользоваться!!! если в этом налажать, то весь предмет не зайдет. раскрою эту мысль подробнее.

Необходимые темы

теория поля

потом пропишу связь

квантовая механика

потом пропишу связь

минимальная теория групп

потому что в этом ориентироваться прямо обязательно!
представления, разные переходы!
позже всё пропишу.

Дополнительные темы

да вроде особо ничего и не нужно, там по ходу разобраться можно.
потом напишу с точки зрения мышления, пока хз.

физика элементарных частиц

потому что там приложений много

дифференциальная геометрия

потому что КТП на многообразиях мы любим смотреть.

теория струн

Теория струн напрямую связана с КТП и по сути обобщает ее.

Особенности эффективного изучения

КТП изучается по сути так же как и другой предмет, однако есть некоторые особенности, сильно увеличивающие эффективность его изучения.

мышление для КТП играет первостепенную роль

да уж, тут порой приходится полгода непонятно что учить, подготовительные предметы улучшать, и только ради того, чтобы создать работающее мышление, с которым изучение будет проходить не сложно.

по сути предмет простой, разве что необходимые темы не должны вызывать принципиальные вопросы, а также необходимо иметь силы и отдельное время на предмет.

и всё, далее всё получится. особенно если пользоваться методами этого раздела.

Очень хорошо было бы найти профессионала в КТП и приятного в общении, это ускорит обучение раз в 10

Это будет огромным плюсом, который будет стоить того, даже если этот человек будет немного фигни нести и приколы иметь в плане своего видения мира.

Как найти? Не знаю, потому что у нас полно своих дел, нам не до бегания и поиска их. Знаю, что просто идя вперед по жизни такого и встретишь, сразу будет видно, что ему особо интересно про КТП общаться и он понимает задачи и подход к ней. Так или иначе, двигаясь в науке, однажды и найдешь такого человека, вот и общайся с ним периодически.

Конечно же, не все профессионалы хороши в общении, очень много ни о чем людей. Обычный фильтр от не тех людей решает полностью эту проблему.

Обход типичных тупиков при изучении

Посмотрим на изучение с точки зрения выхода из тупиков, порой это куда полезнее, чем рассуждения о правильном подходе.
(пропишиу позже)

если книга не понятна - возьми новую книгу

Большинство книг написаны очень неплохо, в то же время если на данном этапе она для тебя непонятная - закрывай и открой новую!!
это решит полностью остановку и даст кучу сил идти вперед.
просто начинаешь заново и все.

О разных подходах к изучению КТП

(потом обсужу, лень писать пока, не нужно это почти)

О строгом подходе к КТП по типу Вайнберга или Боголюбова (???)

тоже есть такой

A.2.8 Is QFT Overcomplicated and Should Be Used Only if There Is No Way Without It?

(this is a big discussion, that sometimes yes, it is abstract theoretical mathematical and useless, but sometimes no, it is exactly what should be used. it is an important question, so a big discussion will be here)

A.2.9 Ways to Guess All the Main Ideas

незаменимая часть нормального понимания предмета.

Глубокое понимание концепции частиц

(что типа все квантутеся. так эйнштейн свою модель теплоемкости предложил. и так мы не все смотрим, что каждому полю обязательно должна соответствовать частица. это важный вывод из КТП, который пропишу тут. пока его не понимаю. но это важная концепция, которую точно нужно прописать нормально.)

В чем были основные ошибки и непонимания ученых в прошлом, когда не было КТП и до этих методов не могли догадаться? (!?!??!??!?)

(для профессионального уровня очень важно ответить на этот вопрос подробно!!)

A.2.10 How not to Turning into Pseudoscience by Doing QFT?

(они особо важны для КТП, потому что фигня тут какя-то часто происходит, и большая потребность в четких критериях, как отличить фигню от обоснованной теории.)

A.3 Acknowledgements

Currently, no one except me has worked on the sections of this note (with the exception of sections taken from books).

A.4 Literature on QFT

A.4.1 Main literature

Основная обучающая

[1] Tong D. Quantum Field Theory Part I, II
Небольшие лекции про основы квантовых полей, не многие темы раскрыты, тем не менее, много важных идей.

[2] Kevin Zhou Lecture Notes on Quantum Field Theory https://knzhou.github.io/
Хороший конспект сути в КТП.

[3] Зи Э. Квантовая теория поля в двух словах
Замечательная книга, очень многие вопросы обсуждаются в примерно свободном формате.

[4] Mandl F., Shaw G. Quantum Field Theory
Хорошая книга, много тем разобрано, много формул написано, но понять КТП по ней невозможно, можно разве что посмотреть примеры и найти местами хорошее изложение.

[5] Вергелес С. Н. Лекции по квантовой электродинамике
Хорошие лекции, очень важные темы разобраны, многому можно научиться, но многое написано вообще непонятно.

David ATKINSON Porter Wear JOHNSON "Exercises in Quantum Field Theory A Self-Contained Book of Questions and Answers Volume 4"
A really great book with problems and solutions. Covers QM, field theory, QFT, Standard Model. Top 5 book to read in free time for one who knows QFT.

Основная профессиональная

[6] Matthew D. Schwartz Quantum Field Theory and the Standard Model
Очень крутая книга, очень много неповторимо хорошо написано. Можно было бы считать ее основной обучающей, просто она очень большая.

[7] М. Е. Пескин, Д. В. Шредер Введение в квантовую теорию поля
Очень большая и хорошая книга, где очень подробно многое обсуждается. Не все, тем не менее, в основном по ней семестр учиться квантовой теории поля - очень хорошая идея. Можно было бы считать ее основной обучающей, просто она очень большая.

Zhong-Zhi Xianyu A Complete Solution to Problems in "An Introduction to Quantum Field Theory" by Peskin and Schroeder
Greate and very useful solutions.

Collection of books, which have many problems with solutions

Some of them will be also mentioned in another lists of literature. They are selected here to make them easier to be found.

David ATKINSON Porter Wear JOHNSON “Exercises in Quantum Field Theory A Self-Contained Book of Questions and Answers Volume 4”
A really great book with problems and solutions. Covers QM, field theory, QFT, Standard Model. Top 5 book to read in free time for one who knows QFT.

https://old.mccme.ru/ium//f13/f13-belavin-parhomenko.html Лекции и задачи с лекций Белавина
Очень крутые задачи, разберу потом!!!

A.4.2 Additional and professional literature

Дополнительная обучающая

[8] Казаков Д. И. Радиационные поправки, расходимости, ренормализация и все такое в квантовой теории поля
Хорошая книга про эти темы, много формул и примеров, по ней можно очень хорошо тренироваться. Примерно эти лекции и составляют типичную КТП 2 (из 3). Просто есть книги лучше, проще, подробнее, а также эти темы не первые, которые следует тренировать и они не так часто нужны.

[9] Dreiner, Herbi K. and Haber, Howard E. and Martin, Stephen P. Two-component spinor techniques and Feynman rules for quantum field theory and supersymmetry
A very good article with clear explanation and many examples.

[10] Киселев В. В. Квантовая теория поля элементарные основы (advanced)
Неплохая книга на тренировку, но считать ее основным учебником не вижу смысла, слишком особая теория, слишком в сыром виде все написано и слишком перегружено.

[11] Andrey Grozin Lectures on QED and QCD https://arxiv.org/abs/hep-ph/0508242
Выглядят очень крутыми лекции по КТП, много формул, 1ю часть скорее всего по ним буду создавать, очень вероятно, что неделю потренируюсь по этим лекциям.

Brian Hatfield Quantum Field Theory of Point Particles and Strings
Maybe, it is the best book to make a transition from QFT to string theory? Looks like there are a lot of detailed explanations of basics.

Hugh Osborn Advanced Quantum Field Theory (typeset by Steffen Gielen in 2007, revised by Carl Turner in 2013)
Можно подумать про темы и мелочи из этих лекций в течение недели, это будет полезно и интересно. В качестве основного лекционного учебника - и близко не тянет.

Matthew Schwartz Lecture “III-2: Vacuum polarization”, 2012
Выглядят как очень хорошо написанные лекции про поляризацию вакуума. Скорее всего это одна из его лекций в Гарварде, в интернете этот файл качается с сайта Гарварда, но откуда он - неизвестно.

[12] Robert Harlander Feynman diagrams From complexity to simplicity and back
Небольшая методичка про то, что я скорее всего уже знаю, обзор диаграмм Фейнмана. Будет свободное время - прочитаю, по идее тоже несколько полезных мыслей должно быть.

[13] Владимиров А. А. Введение в КТП
Компактная книга, которая мало что объясняет, но интересно посмотреть на взгляд автора, очень многое большое в пару страниц написал. Учиться по ней в принципе невозможно, просто когда нормальные книги уже прочитаны, можно посмотреть пару утверждений и подумать про них.

Michel Bellac Thermal field theory
Here, there is a discussion of thermal field theory, as is written in the title. Maybe 2 weeks will be enough to understand basics, how it works? QFT is needed a lot for it.

Углубленная и другая профессиональная

[14] Ландау Л. Д. Том 4, Квантовая электродинамика
Много тем КТП, акцент на электродинамику. Хорошая книга для доработки своего понимания, что есть некоторые разделы. Пока про адроны из нее у меня многое написано.

[15] Боголюбов Н. Н., Широков Д. В. Квантовые поля, 1980.
Многие ее очень много изучают, потому что говорят, что хорошо многое там написано. Поизучаю потом тоже, наверное, пока книги есть интереснее и проще.

[16] Боголюбов Ширков Введение в квантовую теорию поля 1984 link
Еще одна книга Боголюбова, которая многое скажет о КТП. Наверное, минимум на 2 недели тренировок в ней, чтобы усвоить ее.

[17] Oliver Consa The Unpublished Feynman Diagram IIc
Статья про то, что ассистенты Фейнмана неправильно посчитали диаграмму, так это или нет, так и не понял?

[18] Steven Weinberg What is Quantum Field Theory, and What Did We Think It Is?
Мировой эксперт обсуждает, что вообще такое КТП, очень интересно на досуге познакомиться с его мыслями.

[19] Aoyama, Tatsumi and Hayakawa, Masashi and Kinoshita, Toichiro and Nio, Makiko Complete Tenth-Order QED Contribution to the Muon
Еще одна статья про какие-то диаграммы и их вычисления, очень интересно, всего 5 страниц. Когда-то раз подумаю про это!
Thomas Borne, Georges Lochak, Harald Stumpf Nonperturbative Quantum Field Theory and the Structure of Matter
A discussion of special constructions in QFT and field theory. Very special methods. I don't know, if they are important or now, but specialists in QFT, maybe, know some of them.

[20] Каку М. Введение в теорию суперструн
Много для КТП деталей объяснено, да и скорее всего крутая книга, так что во многом добавлю.

Поляков А. М. Калибровочные поля и струны
Книга профессионала, поэтому есть смысл на нее и равняться.

[21] Вайнберг Квантовая теория поля 1
когда сделаю основы - дополнять буду его методами, ибо это профессионализм. Там даны подробно основы представлений группы Лоренца, так что во многом по нему буду писать. Ну и вообще, много деталей раскрыто.

[?] Вайнберг Квантовая теория поля 2

[22] Райдер Л. Квантовая теория поля
Пара хороших моделей, схожих со Стандартной моделью описывается. мб и нормальная книга, просто мб это же и в других дается, тут не знаю...

Волошин М. Б., Тер-Мартиросяи К. А. Теория калибровочных взаимодействий элементарных частиц. М.: Энергоатомиздат, 1984, 296 с.

Книга профессионалов и для профессионалов, очень концентрированная, минимум 2 месяца нужно на понимание основных ее тем, для минимального уровня можно и не открывать. Качается с либ-мипта.

[23] Шварц А. С. Квантовая теория поля и топология
интересная книга, пока не до нее. Пройду сперва основы, вдали раздел по топологическим явлениям во многом по ней создавать буду.

[24] Завьялов О. И. Перенормированные диаграммы Фейнмана
Перенормировки, возможно, буду по ней смотреть, вроде интересно написано. пока не до этого просто.

Фейнман Р. Квантовая электродинамика
Типичная книга, которую все читают. Когда-то тоже пройду, мб узнаю подход Фейнмана лучше, его образ мышления. Пока не актуально и не до этого.

Shvarts A S Matematicheskie osnovy kvantovoi teorii polya
Нет желания открывать, но судя по названию, очень хорошо там основы будут рассказаны.

Швебер ктп.pdf
Мб когда-то открыл и закрыл, еще какая-то известная книга.

Гриб А. А., Мамаев С. Г., Мостепаненко В. М. Вакуумные квантовые эффекты в сильных полях. — 2-е изд., перераб. и доп. — М.: Энергоатомиздат, 1988.—288 с—ISBN 5-283-03955-2.
Книга профессионалов про вакуум, очень известная. Чего только там не происходит! Если начну изучать, отдельные 3 недели на эти явления уйдут, в минимум знаний они не входят. Одним словом, черт ногу сломит разбираться, что там за явления в вакууме.

[?] Вайнберг Квантовая теория поля 3 суперсимметрия
Возможно, тоже хорошая книга, но не думаю, что это нужно кому-то, кроме энтузиастов.

[25] Volovik, Grigory The Universe in a Helium Droplet
Более 480 страниц (более 530 страниц с цитатами) большой теории и размышлений про вакуум, квантовые жидкости, всякие явления с ними. Очень интересная книга, в то же время это специфика, никак не для обязательного изучения.

Литература про важные особенности математики для КТП

[26] Jegerlehner, F. Facts of life with γ_5
Обсуждаются ее особенности, всяких много интересных мыслей, когда-то продумаю.

Про разные процессы в физике элементарных частиц в рамках КТП и вычисления диаграмм

[27] Sergey Volkov Calculation of lepton magnetic moments in quantum electrodynamics: a justification of the flexible divergence elimination method
Статья про вычисление магнитного момента. Когда-то почитаю, разберу хотя бы одну диаграмму!!!! Проверю, могу ли???

Про КТП в физике конденсированных сред

(тоже ее много, потом обсудим.)
[28] Левитов Шитов Функция Грина. Задачи и решения.
крутая книга с примерами КТП к твердотельным явлениям. Очень скоро буду его добирать и вписывать, очень важная книга.

Абрикосов Горьков Дзялошинский
Известная тоже книга, многими считающаяся одной из лучших.

Moritz Helias Lecture notes: Statistical physics 2018
Лекции из Ахена про всякие сложные темы. Выглядят крутыми, содержательными, много диаграмм. Отдельный курс, месяц примерно изучать только их нужно.

По квантовой механике и теории поля в помощь для КТП

[29] Тахтаджян Л. А. Квантовая механика для математиков
прекраснейшая книга, где прекрасные определения, которыми я и пользуюсь (буду пользоваться) просто шикарная структура.

[30] Зинн-Жюстен, Жан Континуальный интеграл в квантовой механике
самая прекрасная книга, по которой и буду создавать изначально запись. книга настолько прекрасна, что ничего другого перед ней читать не хочу! и уже многее выгрузки по ней сделаны!

A.4.3 Selected articles about applications and special phenomena

Статьи о проверке типичных явлений

[31] Levi, M. E. and Blocker, C. A. and Strait, J. and others Weak Neutral Currents in e^+e^- Collisions at $\sqrt{s} = 29$ GeV
Маленькая статья, где хороший график приведен сравнения сечений. Когда-то научусь его выводить.

О других темах и особых редких методах КТП

(потом группировку мб сделаю)
Mukhanov Quant Effects
многим известная книга, до которой пока мне нет дела.
[32] Schwinger, Julian Quantum Electrodynamics. I. A Covariant Formulation
Известная статья Швингера 1948 года, крутое развлечение на вечер, когда будет сделана работа - попробовать прочесть и понять все там. По идее на современном уровне 2 дня хватит на нее. Но не актуально пока что.

Ronald Kleiss Quantum Field Theory A Diagrammatic Approach https://agenda.irmp.ucl.ac.be/event/3340/contributions/4015/attachments/2087/2506/qft.pdf
Странная книга со многими диаграммами, странными формулами, пока не думаю, что мне такое нужно, ну и точно про нее много задуматься придется. Но выглядит она, конечно, круто очень.

[33] Stefan Hollands, Robert M. Waldb Quantum fields in curved spacetime
Интересная статья, как описывать квантовые поля в искривленном пространстве времени. (в неискривленном бы научиться сперва!) Много добавлений из нее выгружено, потом буду разбирать

[34] Редьков В. М. Поля частиц в римановом пространстве и группа Лоренца
прекрасно про искривленное пространство дана тонна теории. сделаю основы - буду дополнять ей. очень уж крутые и интересные темы!!! скорее бы собрать основы! Может, потом и другие его книги добавлю, не до него сейчас.

[35] Robert Karplus and Maurice. Neuman The Scattering of Light by Light

9 страниц про рассеяние света на свете. Такое чувство, что менее, чем за 3 дня это не пойму, так что отложил, интересно, но не актуально. Доступна через lib.mipt, в интернете в открытом доступе нет ее.

Kiryl Piasotski Mikhail Pletyukhov Diagrammatic approach to scattering of multiphoton states in waveguide QED
Применили КТП к волноводам, написали кучу сложных диаграммных формул. Скоро пойму, как это связано с обычной теорией, на первый взгляд кажется, что нужно долго подумать, прежде, чем это станет понятно.
(???? про теорию струн неплохо тоже написать будет потом книгу, пока не так особо читал это.)

Статьи о разных редких эффектах и явлениях

Про суперсимметрию в КТП

A.5 Description of This Note

A.5.1 List of QFT Parameters and Functions

(уже это все написано и в теории и в 1й части, но тут именно с обзорной стороны, чтобы точно было усвоено, что от чего зависит)

***W* эффективный производящий функционал (!!!)**

***J* токи (!!!)**

Коррелятор (!??!??!?)

(про него важные формулы, с ними и работаем ведь!)

Г дифференциальный оператор

$\hat{Z}(j)$ производящий функционал

замкнутым петлям в диаграммах соответствуют интеграции по *dp*

.

О пропагаторах

Пропагатор фотона (массивного векторного мезона) в двух словах (!??!?)

$$D_{\nu\lambda}(k) = \frac{-g_{\nu\lambda} + k_\nu k_\lambda / m^2}{k^2 - m^2}$$

(тут много важных формул будет!)

смысл пропагаторов и их применения

вкратце, зачем они нужны и как используются?
их суть тут запишу.
(пока не очень представляю, как конкретно они нужны...)

О двухточечной корреляционной функции

свойства

Двухточечная корреляционная функция имеет вид:

$$\langle\Omega|T\phi(x)\phi(y)|\Omega\rangle \quad \text{или} \quad \langle\Omega|T\psi(x)\bar{\psi}(y)|\Omega\rangle.$$

$$\int d^4x e^{ip\cdot x}\langle\Omega|T\phi(x)\phi(0)|\Omega\rangle \underset{p^2\to m^2}{\sim} \frac{iZ}{p^2-m^2+i\varepsilon}.$$

В свободной теории поля двухточечная функция $\langle 0|T\phi(x)\phi(y)|0\rangle$ имеет простую интерпретацию.

Она является амплитудой вероятности того, что частица распространяется из точки y в точку x.

В какой степени такая интерпретация является справедливой В теории с взаимодействием?

примеры

связь с другими параметрами

двухточечная корреляционная функция в случае свободного скалярного поля

раздел 2.4 ПШ

Точное выражение для двухточечной корреляционной функции в случае свободного скалярного поля:

$$\int d^4x e^{ip\cdot x}\langle 0|T\phi(x)\phi(0)|0\rangle = \frac{i}{p^2-m^2+i\varepsilon}$$

константа связи

разберем, что есть она и зачем нужна.

***Z* производящий функционал (!!!)**

О многоточечной корреляционной функции

$$\int d^4x e^{ip\cdot x}\left\langle\Omega\left|T\left\{\phi(x)\phi\left(z_1\right)\phi\left(z_2\right)\cdots\right\}\right|\Omega\right\rangle$$

$$\int dx^0 = \int_{T_+}^{\infty} dx^0 + \int_{T_-}^{T_+} dx^0 + \int_{-\infty}^{T_-} dx^0,$$

$$\int_{T_+}^{\infty} dx^0 \int d^3x e^{ip^0x^0}e^{-i\mathbf{p}\cdot\mathbf{x}}\sum_\lambda \int \frac{d^3q}{(2\pi)^3}\frac{1}{2E_{\mathbf{q}}(\lambda)}\left\langle\Omega|\phi(x)|\lambda_{\mathbf{q}}\right\rangle\left\langle\lambda_{\mathbf{q}}\left|T\left\{\phi\left(z_1\right)\phi\left(z_2\right)\cdots\right\}\right|\Omega\right\rangle$$

ведь $\mathbf{1} = \sum_\lambda \int \frac{d^3q}{(2\pi)^3}\frac{1}{2E_{\mathbf{q}}(\lambda)}\left|\lambda_{\mathbf{q}}\right\rangle\left\langle\lambda_{\mathbf{q}}\right|$.

$$\langle\Omega|\phi(x)|\lambda_{\mathbf{q}}\rangle = \langle\Omega|\phi(0)|\lambda_0\rangle\, e^{-iq\cdot x}\big|_{q^0=E_{\mathbf{q}}(\lambda)}$$

$$\int d^4x e^{ip\cdot x}\left\langle\Omega\left|T\left\{\phi(x)\phi\left(z_1\right)\cdots\right\}\right|\Omega\right\rangle \underset{p^0\to -E_{\mathbf{p}}}{\sim} \left\langle\Omega\left|T\left\{\phi\left(z_1\right)\cdots\right\}\right|-\mathbf{p}\right\rangle\sqrt{Z}\frac{i}{p^2-m^2+i\varepsilon}.$$

$$\sum_\lambda \int \tfrac{d^3k}{(2\pi)^3}\varphi(\mathbf{k})\tfrac{1}{2E_{\mathbf{k}}(\lambda)}\tfrac{i}{p^0-E_{\mathbf{k}}(\lambda)+i\varepsilon}\left\langle\Omega|\phi(0)|\lambda_0\right\rangle\left\langle\lambda_{\mathbf{k}}\left|T\left\{\phi\left(z_1\right)\cdots\right\}\right|\Omega\right\rangle \underset{p^0\to +E_{\mathbf{p}}}{\sim}$$
$$\underset{p^0\to +E_{\mathbf{p}}}{\sim} \int \tfrac{d^3k}{(2\pi)^3}\varphi(\mathbf{k})\tfrac{i}{\tilde{p}^2-m^2+i\varepsilon}\sqrt{Z}\left\langle\mathbf{k}\left|T\left\{\phi\left(z_1\right)\cdots\right\}\right|\Omega\right\rangle,$$

$$\left(\prod_i\int\frac{d^3k_i}{(2\pi)^3}\int d^4x_i e^{i\tilde{p}_i\cdot x_i}\varphi_i\left(\mathbf{k}_i\right)\right)\left\langle\Omega\left|T\left\{\phi\left(x_1\right)\phi\left(x_2\right)\cdots\right\}\right|\Omega\right\rangle.$$

$$\left(\prod_{i=1,2}\int\frac{d^3k_i}{(2\pi)^3}\varphi_i\left(\mathbf{k}_i\right)\frac{i}{\tilde{p}_i^2-m^2+i\varepsilon}\cdot\sqrt{Z}\right)\left\langle\mathbf{k}_1\mathbf{k}_2\left|T\left\{\phi\left(x_3\right)\cdots\right\}\right|\Omega\right\rangle$$

Наиболее сингулярное слагаемое:

$$\left(\prod_{i=1,2}\frac{i}{p_i^2-m^2+i\varepsilon}\cdot\sqrt{Z}\right)\left(\prod_{i=3,\ldots}\frac{i}{p_i^2-m^2+i\varepsilon}\cdot\sqrt{Z}\right)_{\text{out}}\left(\mathbf{p}_1\mathbf{p}_2\left|-\mathbf{p}_3\cdots\right\rangle_{\text{in}}\right.\cdot$$

Итак, мы показали, что элемент S-матрицы можно получить, рассматривая соответствующее вакуумное среднее по волновым пакетам полей, выделяя главные сингулярности по энергиям p_i^0 и затем переходя к пределу, в котором волновые пакеты становятся дельта-функциями от импульсов.

A.5.2 Features of This Note

описание глав и разделов

описание записи в целом

(когда-то очень не скоро напишу)

первая часть

(когда-то очень не скоро напишу)

приложения

какие вообще приложения я разбирал?
(когда-то очень не скоро напишу)

Особенности структуры по КТП

(когда-то очень не скоро напишу)

Важность раздела в дополнениях с физическими основами (!!!)

(потом подробнее опишу, насколько он важен)

Именно эти знания предполагаются известными для начала изучения КТП

обозначения

В отличие от многих других разделов физики, в КТП есть много соврешенно непривычных обозначений, в которых можно запутаться, так что приведем их сводку, чтобы не останавливаться на этом.

цифровые индексы

хз, но такое есть. вроде, обозначают номер координаты, но я не уверен.

Константы

Системы единиц

Натуральная система единиц

Иногда в этой записи постоянная Планка $\hbar$ и скорость света c существенно загромождают формулы, поэтому я использую систему единиц, в которой $\hbar = c = 1$.

в ней нет отличий между импульсом и энергией, частотойи энергией, массой и импульсом и т.п.

....

A.6 Puzzles of QFT for Different Cases in Life

(особенно из Зи добавлю многое!!)

A.6.1 Puzzles for Motivation to Study Fundamental Physics

Раздел вдали, потому что не всегда занятие фундаментальной физикой приведет к результатам, так что не всегда полезно иметь мотивацию к ней. Однако, тем не менее, убирание этого полностью приведет к абсолютному непониманию происходящего, что очень не круто.

(в многом из Зи это будет)

Как так, что один и тот же метод представлений группы Пуанкаре - и такие принципиально разные поля, стоит только спин поменять?

(не знаю, вопрос о глубоком понимании пространства-времени, не мой уровень, нужно несколько лет думать про это, чтобы понять это, не актуально такое.)

Как вообще проквантовать поля?

(вопрос номер 1 из КТП. хз, мб я уже это ответил, пока пусть повесит вопрос)

когда электрон считаем полем, а когда частицей?

самый актуальный вопрос.

почему без слабого взаимодействия мы бы испарялись в полной темноте?

Если бы не было слабого взаимодействия, регулирующего горение звезд, то вы бы проваливались или воспаряли в полной темноте.

почему без связи спина со статистикой метрия бы коллапсировала?

Без связи спина со статистикой электрон не подчинялся бы принципу Паули. Материя просто коллапсировала бы.

(Зи говорит, это так)

мб посмотрю Доказательство устойчивости материи, данное Дайсоном и Ленардом, которое существенно опирается на принцип Паули.

почему если частица это поле,то на трековых детекторах видим только треки частиц?

A.6.2 Puzzles for Pleasant Conversation About Fundamental Physics

Тут то, что прикольно, но скорее для приятного проведения времени, подумать об интересном, а не для того, чтобы всерьез потом пойти и изучать это. Еще раз уточню, что имеется в виду именно случай, когда рядом есть собеседник, которому интересно и который что-то изучал про это.

m-th.1 В чем состоит истинная природа физического мира? (????)

(все-таки по факту именно КТП из типичной физике наиболее близка к ответу на этот вопрос. тут укажу коротко вопрос и суть ответа, указав на темы из теории. так-то можно много писать про это.)

m-th.1 Что на самом деле такое фотон?

. Вот и напишу. Укажу, что отговорки - не ответ.

(пока что остановился на том, что вообще неизвестно, но много разных свойств в разных случаях можно указать)

m-th.1 Верна ли КТП в принципе и можно ли избавляться так просто от бесконечностей?

Как так получается, что у нас теория предсказывает бесконечности, что является признаком ее провала, но в то же время есть многие задачи, которые решаются ей?

(потом распишу подробнее. так или иначе, это очень мотивирует все-таки понять, в чем суть метода?)

m-th.1 Почему в физике конденсированных сред могут применяться те же методы, которые в физике элементарных частиц используются?

Казалось бы, два разных раздела.

(распишу потом. формулы добавлю для полноты.)

Благодаря электромагнетизму мы не проваливаемся сквозь пол, это так?

(Зи)

Иногда говорят, что благодаря электромагнетизму вы не проваливаетесь сквозь пол

почему?

О квантовании массы

Вопрос: квантуется ли масса
(вроде никому это не интересно, типа ну квантуется, у каждого кванта своя масса, и что? мб что-то тут разное есть, не знаю.)

A.6.3 Puzzles for Motivation to Study QFT Methods

Тут больше про явления и приложения, где нужны методы.

Если увеличивать энергию электрона, то представляя его как волновую функцию, как объяснить, что распад возможен?

(задача из зи)
Запишем теперь уравнение Шредингера для рассеяния электрона на протоне.
Уравнение описывает волновую функцию одного электрона, и, как бы вы ни упражнялись с теорией дифференциальных уравнений в частных производных, электрон, за которым ведется наблюдение, всегда остается одним-единственным электроном.
Однако, согласно специальной теории относительности, энергия может быть преобразована в материю: если электрон обладает достаточной энергией, могут родиться электрон и позитрон («антиэлектрон»).
Уравнение Шредингера просто не в состоянии описать это явление, что свидетельствует о несостоятельности нерелятивистской квантовой механики.
Давайте рассуждать эвристически. В квантовой механике есть принцип неопределенности, который гласит, что энергия может испытывать резкие флуктуации за малый промежуток времени. Согласно же специальной теории относительности, энергию можно преобразовать в массу и наоборот.
Если объединить принципы квантовой механики и специальной теории относительности, то придем к выводу, что флуктуирующая энергия может превращаться в массу, то есть в ранее не существовавшие частицы.

Пусть два электрона летят друг на друга, как объяснить их взаимодействие с точки зрения КТП?

с точки зрения классической электродинамики все понятно (нужно только это сделать мне еще, пока осознанно не делал)
а вот с точки зрения КТП?
взаимодействие дираковских полей включаем что ли?
и почему оно внезапно электромагнитное?

Если я хорошо знаю релятивистскую механику, можно ли с помощью нее посчитать сечение рассеяния с образованием виртуальной частицы? Будет ли оно совпадать с сечением, расчитанным для этого процесса методами КТП? (?????)

(не знаю, но интересно будет поисследовать.)

А вихревое электрическое поле квантуется так же, как плоское?

Хочу на примере посмотреть.
хз

Почему электрон стабилен?

(?? напишу с формулами, пока не знаю.)

A.6.4 Selected Technical Problems

Приведу задачи для того, чтобы потренироваться/проверить уровень собеседника/продемонстрировать свой уровень.

Покажите, что если в формализме теории рассеяния положить $\hbar = 0$, то получим классическую механику?

(хороший вопрос)

как вывести аномальный магнитный момент?

что за перенормировка заряда?

а я вот сам не знаю еще, хотя и читал.

О типичных интегралах КТП

КТП известно тем, что там любят давать диаграммы и сказать, как быстро их считать? даже развлекаться этим можно.
так что соберем эти вопросы.
(см книгу казакова)

посчитать диаграмму “арбуз”

посчитать диаграмму “закат”

посчитать диаграмму “рыба”

тут во Казаков быстрый методы какой-то сказал, я в него не въехал.

посчитать диаграмму “треугольник”

там типа что-то такое быстрое не прокатывает, тогда другое быстрое приходит.

посчитать диаграмму “пингвин”

(?? как такую задачу задавать?? так и не научился такое считать.)

О типичных распадах КТП

(мб подподглавой сделаю)

О лептонном распаде пи-мезона

(типичная задача, посмотрю семинар Киселева, пропишу сюда суть её. чисто на проверку знаний.)

A.6.5 Puzzles for Those Claiming to Know QFT

A.6.6 Puzzles for Mastering Typical Concepts

Допустим, видим человека, который в принципе хотел бы понять суть, опишем, какие в какой последовательности будем задавать, чтобы в типичном случае ему было бы интереснее въезжать. В частности это могут быть младшие студенты или редко школьники.

Головоломки для освоения КТП уровня теормина

Головоломки для знакомства с понятием диаграмм (!??!??!??!!?)

(самое важное, что может быть, потому что КТП очень часто чисто в диаграммы и упирается.)

Головоломки для освоения других особенностей КТП

A.6.7 Puzzles About Fantastic Phenomena

Как проквантовать Вселенную? (??)

см. работу Розена "Квантовая механика мини Вселенной"
Под вселенной понимаем метрику Фридмана.

A.7 Connection of QFT and Other Parts of Science

A.7.1 QFT, Mechanics and Quantum Mechanics

Явные формулы сравнения законов механики и КТП (????)

(в частности формулы для задач по механике и задачи по КТП. Хочу написать просто как список: там такая формула - тут аналог - такая формула. это не так полезно, просто для более глубокого понимания.)
(!!! a very good question, I'll write it very very later!)

Явное обобщение квантмеха на КТП (??????)

(ну вот пропишу это потом, пока оба предмета доделывать нужно.)

A.7.2 QFT and Field Theory

(I think, it might be a good idea to write this connection explicitly here. it is not obvious!!! and in theory, we are not so much focused on this general and useless for application overview. because it is a comparison of theories!)

A.7.3 QFT and Solid State, Condensed Matter

Очень много применений КТП находит в нем.
(порешаю - пропишу)

A.7.4 QFT and Cosmology

Подсчет обратной реакции рождения частиц в черных дырах

ты не сможешь посчитать обратную реакцию рождения частиц в черных дырах или в расширяющейся вселенной без перенормировок квантовополевого ТЭИ
получить: космологический фактор и плотности энергии материи и пр во Вселенной

A.7.5 QFT and Special Parts of Mathematics

Связь с вычислительной математикой

(мы вычисляем что-то многое разное)

Про КТП на решетках

(такое есть, потом подумаю, хз)

A.7.6 QFT and Hypothetical High Energy Physics Theories

Связи тут большие.
пропишу позже, когда по теории струн разовьюсь.

A.8 Short Historical Overview

Посмотрим вкратце, как развивалось КТП и сделаем нужные выводы из этого.

О попытках подумать про КТП до 20го века

(если такие были, то напишу сюда)

О Фейнмане

Биография в двух словах

Основные выводы из биографии

О Швингере

Биография в двух словах

Основные выводы из биографии

B Physics and Mathematics for QFT

Обсудим коротко некоторые важные для КТП темы других разделов физики.
(??? I'll write it later!! only what is really additional, but still used sometimes)

B.1 Physics and Mathematics for Basic QFT

B.1.1 Some Mathematics for Path Integral

Лемма о трюке Швингера (???)

Lemma

$$G\left(\frac{\partial}{\partial \underline{b}}\right) F(\underline{b}) = F\left(\frac{\partial}{\partial \underline{x}}\right) G(\underline{x}) e^{\underline{x}\cdot\underline{b}}\Big|_{\underline{x}=\underline{0}}.$$

Proof We will show this for a special case: Let $G(\underline{x}) = e^{\underline{x}\cdot\underline{\alpha}}, F(\underline{b}) = e^{\underline{\beta}\,\underline{\underline{b}}}$. Then the left-hand side is

$$G\left(\frac{\partial}{\partial \underline{b}}\right) F(\underline{b}) = e^{\frac{\partial}{\partial \underline{b}}\cdot\underline{\alpha}} F(\underline{b}) = F(\underline{b}+\underline{\alpha}) = e^{\underline{\beta}\cdot(\underline{b}+\underline{\alpha})}.$$

Let us attempt to consider the right-hand side:

$$F\left(\frac{\partial}{\partial \underline{x}}\right) G(\underline{x}) e^{\underline{x}\cdot\underline{b}}\Big|_{\underline{x}=\underline{0}} = e^{\underline{\beta}\cdot\frac{\partial}{\partial \underline{x}}} e^{\underline{x}\cdot(\underline{\alpha}+\underline{b})}\Big|_{\underline{x}=\underline{0}} = e^{(\underline{x}+\underline{\beta})\cdot(\underline{\alpha}+\underline{b})}\big|_{\underline{x}=\underline{0}} = e^{\underline{\beta}\cdot(\underline{\alpha}+\underline{b})}.$$

The result is then true for any F and G as one may express F and G as a Fourier series.

B.1.2 Some Special Functions

(I'll read LL4 and write it here after it)

B.1.3 Some Methods for Matrices

(I'll read LL4 and write it here after it)

B.1.4 Some Numerical Methods

(maybe I'll make many sections here about it)

B.2 Physics and Mathematics for Exotic QFT Models

B.2.1 Some Special Algebra

(in algebra, there are some important ideas, which will be also good to mention)

B.2.2 Mathematics for Supersymmetry

(ok, I'll add also some this later)

C Bibliography
