Вы, надеюсь, согласитесь, что довольно глупо таскать с собой множитель $\prod_{a=1}^{4}\left(\frac{i}{k_a^2-m^2+i\varepsilon}\right)$, общий для всех диаграмм, в которых два мезона рассеиваются в два мезона. Поэтому мы дополним правила Фейнмана еще одним, утверждающим, что с внешними линиями пропагатор ассоциировать не надо. (На профессиональном языке это называется «ампутацией внешних концов».) Поскольку всегда присутствует общий множитель, отвечающий за сохранение импульса, нам также не стоит таскать за собой общую дельта-функцию. Таким образом, получаем еще два правила:

6. Со внешними линиями пропагатор не сопоставлять.

7. Предполагать наличие дельта-функции, отвечающей за сохранение общего импульса.

Амплитуда для диаграммы на рис. I.7.7b равна $-i\lambda$.

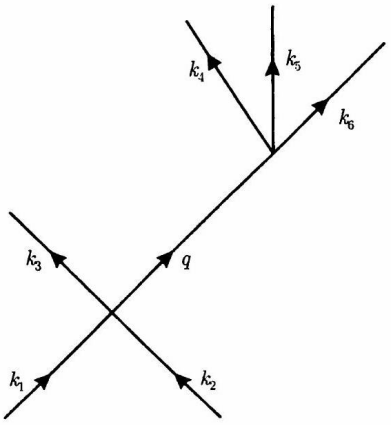

Рис. I.7.9

Рождение частиц

Как объясняется в главе I.1, одной из мотиваций для построения квантовой теории поля явилась необходимость описать рождение частиц. Теперь мы в состоянии описать, как два мезона образуют четыре. Диаграмма Фейнмана на рис. I.7.9 (сравните с рис. I.7.2a) может появиться в теории возмущений с порядком λ^2. Ампутируя внешние концы, мы опускаем множитель $\prod_{a=1}^{6}\left[i/k_a^2 - m^2 + i\varepsilon\right]$, сопоставленный с шестью внешними линиями, оставляя при этом лишь пропагатор, связанный с одной внутренней линией. Для каждой вершины включаем множитель $(-i\lambda)$ и дельта-функцию, отвечающую за сохранение импульса (правило 3). Затем интегрируем по внутреннему импульсу q (правило 4) и получаем

$$(-i\lambda)^2 \int \frac{d^4q}{(2\pi)^4} \frac{i}{q^2 - m^2 + i\varepsilon} (2\pi)^4 \delta^{(4)}\left(k_1 + k_2 - k_3 - q\right) \times \\ \times (2\pi)^4 \delta^{(4)}\left[q - (k_4 + k_5 + k_6)\right]$$

Интеграл по q трудности нс вызывает, его вычисление приводит к

$$(-i\lambda)^2 \frac{i}{\left(k_4 + k_5 + k_6\right)^2 - m^2 + i\varepsilon} (2\pi) \delta^{(4)}\left[k_1 + k_2 - (k_3 + k_4 + k_5 + k_6)\right]$$

Ранее мы договорились (правило 7) не писать каждый раз общую дельта-функцию. Из примера видно, что нет необходимости писать дельта-функции, которые затем исчезают (все кроме одной) при интегрировании. На рис. I.7.9 мы могли с самого начала использовать закон сохранения импульса и обозначить внутреннюю линию суммой $k_4+k_5+k_6$, а не символом q.

Если бы у вас были практические навыки, вы бы легко записали амплитуду

$$(-i\lambda)^2 \frac{i}{\left(k_4 + k_5 + k_6\right)^2 - m^2 + i\varepsilon}$$

с самого начала: просто запомните, что мы ассоциируем константу $(-i\lambda)$ с каждой вершиной и пропагатор - с каждой внутренней (но не внешней) линией. Довольно просто, если понять суть.

Чего стоит быть ненастоящим

Лежащая в основе наших действий физика довольно проста: внутренней линии соответствует виртуальная частица, у которой квадрат релятивистского 4-импульса $k_4 + k_5 + k_6$ не обязательно равен m^2, как должно быть в случае с реальной частицей. Чем дальше импульс виртуальной частицы от массовой поверхности, тем меньше амплитуда. Такова плата за нереальность.

Согласно квантовым правилам для тождественных частиц, полная амплитуда находится симметризацией по четырем конечным импульсам. Другими словами, мы должны заметить, что линия, помеченная как k_3 на рис. I.7.9, могла бы быть также помечена как k_4, k_5 или k_6, так что необходимо добавить все четыре вклада. Чтобы удостовериться в том, что вы понимаете правила Фейнмана, я настоятельно рекомендую вам получить (21) из (12) и (13), вычислив интеграл по траекториям.

Еще раз повторю (думаю, это того стоит), что в диаграммах Фейнмана нет ничего магического.

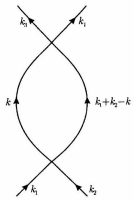

Рис. I.7.10

Петли и первое знакомство с расходимостями

Как и в нашей младенческой задаче, существуют древесные и петлевые диаграммы. До сих пор мы рассматривали только древесные диаграммы. Нашим следующим примером будет петлевая диаграмма на рис. I.7.10 (сравните с рис. I.7.3а). Применяя правила Фейнмана, получаем

$$\frac{1}{2}(-i\lambda)^2 \int \frac{d^4k}{(2\pi)^4} \frac{i}{k^2-m^2+i\varepsilon} \frac{i}{(k_1+k_2-k)^2-m^2+i\varepsilon}.$$

Как и ранее, лежащая в основе (23) физика проста: при изменении k подынтегральное выражение является большим только тогда, когда первая или вторая (или обе вместе) виртуальные частицы, ассоциированные с двумя внутренними линиями, близки к реальным. Еще раз повторяю, что за свою нереальность частицы должны платить (см. упражнение I.7.4). На больших k подынтегральное выражение ведет себя как $1/k^4$. Интеграл оказывается бесконечным! Он расходится как $\int d^4k\,(1/k^4)$. Мы вернемся к этому явному бедствию в главе III.1.

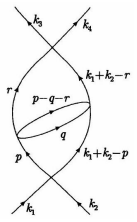

Рис. I.7.11

Получив некоторые практические навыки, вы сможете записывать амплитуду с первого взгляда. В качестве другого примера рассмотрим трехпетлевую диаграмму на рис. I.7.11, дающую вклад $O(\lambda^4)$ в мезон-мезонное рассеяние. Для начала выберем в каждой петле по одной внутренней линии и обозначим бегущий по ней импульс (символами p, q и r в нашем примере). На этом этапе у нас есть большая свобода выбора - ваш выбор может отличаться от моего, но физика, разумеется, от этого не зависит. После этого импульсы, бегущие по другим внутренним линиям, фиксируются законом сохранения импульса, как указано на рисунке. Запишем для каждой вершины константу связи, а для каждой внутренней линии - пропагатор и проинтегрируем по внутренним импульсам p, q и r. Таким образом, без учета симметрийных множителей получаем амплитуду

$$(-i\lambda)^4 \int \frac{d^4p}{(2\pi)^4}\frac{d^4q}{(2\pi)^4}\frac{d^4r}{(2\pi)^4}\frac{i}{p^2-m^2+i\varepsilon}\frac{i}{(k_1+k_2-p)^2-m^2+i\varepsilon}\times$$
$$\times\frac{i}{q^2-m^2+i\varepsilon}\frac{i}{(p-q-r)^2-m^2+i\varepsilon}\times$$
$$\times\frac{i}{r^2-m^2+i\varepsilon}\frac{i}{(k_1+k_2-r)^2-m^2+i\varepsilon}.$$

Этот тройной интеграл снова расходится: он ведет себя как $\int d^{12}P\,(1/P^{12})$.

Мое заверение

Когда я преподаю квантовую теорию поля, именно в этом месте некоторые студенты по непонятным причинам испытывают страх перед диаграммами Фейнмана. Мне бы хотелось заверить читателей, что все это на самом деле довольно просто. Диаграммы Фейнмана можно представлять себе как пространственно-временные картинки поведения частиц, которые собираются вместе, сталкиваются и порождают другие частицы, и так далее. Один студент был озадачен тем, что частицы не распространяются по прямым линиям. Помните, что квантовая частица распространяется как волна: $D(x-y)$ описывает амплитуду распространения частицы из x в y. Очевидно, что гораздо удобнее рассматривать частицы в импульсном пространстве: так нам сказал Фурье. Мы увидим еще много примеров фейнмановских диаграмм, и вскоре вы с ними хорошо познакомитесь. Другой студент был обеспокоен вычислением интегралов (23) и (24). Пока я вас этому еще не учил, но со временем обучу. Хорошей новостью является то, что на передовых рубежах современных исследований лишь немногим теоретикам приходится вычислять диаграммы Фейнмана с учетом всех множителей 2. В большинстве случаев достаточно понять лишь общее поведение интеграла. Но, конечно, всегда почетно получить точный результат. В главах II.6, III.6 и III.7 я приведу детальные вычисления диаграмм Фейнмана, правильно получив численные множители, чтобы можно было сравнить с экспериментами.

Вакуумные флуктуации

Давайте вернемся к членам, которые я опустил в (18) и которые вы должны были найти сами. Например, четыре $[\delta/\delta J(w)]$ должны были подействовать на J_c, J_d, J_g и J_h в (18) и дать что-то вроде

$$-i\lambda \iiiint \int D_{ae}D_{bf}J_aJ_bJ_eJ_f\left(\int_w D_{ww}D_{ww}\right).$$

Коэффициент при $J(x_1)\,J(x_2)\,J(x_3)\,J(x_4)$ оказывается равным $D_{13}\times$ $\times D_{24}\left(-i\lambda\int_w D_{ww}D_{ww}\right)$ плюс члены, полученные с помощью перестановок.

Соответствующий физический процесс легко описать как словесно, так и графически (см. рис. I.7.12). Источник в x_1 порождает частицу, которая безо всякого взаимодействия свободно распространяется до x_3, где

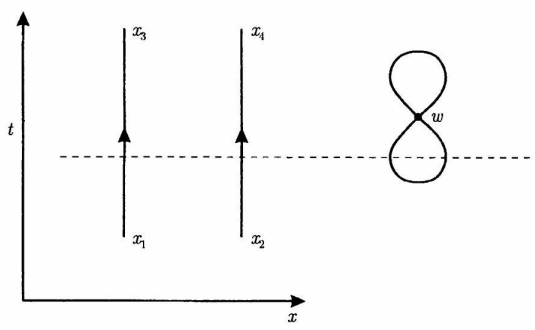

Рис. I.7.12

она спокойно умирает. Частица, рожденная в x_2, живет той же небогатой событиями жизнью, прежде чем исчезнуть в x_4. Эти две частицы совсем не взаимодействуют. Где-то там в точке w, которая может находиться абсолютно где угодно во Вселенной, происходит взаимодействие с амплитудой $-i\lambda$. Это называется вакуумной флуктуацией: как говорилось в главе I.1, квантовая механика и специальная теория относительности неизбежно ведут к появлению частиц из вакуума, которые могут даже взаимодействовать, прежде чем вновь исчезнуть в вакууме. Посмотрите на различные временные срезы (один из которых обозначен пунктирной линией) на рис. I.7.12. В далеком прошлом во Вселенной частицы отсутствовали. Потом там было две, потом четыре, потом снова две и, наконец, в отдаленном будущем, ни одной частицы. Более подробно об этих флуктуациях мы поговорим в главе VIII.2. Отмечу, что вакуумные флуктуации также присутствуют в задачах для младенца и ребенка (см., например, рис. I.7.1c, I.7.2f,g, I.7.3f,g и так далее).

Упражнения

I.7.1. Вычислите амплитуду, соответствующую рисунку I.7.12 в (18).

I.7.2. Выведите (23) из первых принципов, то есть с выражения (12). Это несколько утомительно, хотя и прямолинейно. Найдите симметрийный множитель $\frac{1}{2}$.

I.7.3. Нарисуйте все диаграммы, описывающие процесс рождения четырех мезонов из двух, до порядка λ^2 включительно. Выпишите соответствующие фейнмановские амплитуды.

1.7.4. В силу лоренц-инвариантности мы всегда можем выбрать $k_1 + k_2 = (E, \vec{0})$ в (23). Интеграл можно изучать как функцию от E. Покажите, что, для того чтобы обе внутренние частицы стали реальными, E должна быть больше $2m$. Дайте этому физическую интерпретацию.

14.2.13 4.3 Wick's Theorem

Wick's Theorem

We have now reduced the problem of calculating correlation functions to that of evaluating expressions of the form

$$\langle 0|T\left\{\phi_I\left(x_1\right)\phi_I\left(x_2\right)\cdots\phi_I\left(x_n\right)\right\}|0\rangle$$

that is, vacuum expectation values of time-ordered products of finite (but arbitrary) numbers of free field operators. For $n = 2$ this expression is just the Feynman propagator. For higher n you could evaluate this object by brute force, plugging in the expansion of ϕ_I in terms of ladder

operators. In this section and the next, however, we will see how to simplify such calculations immensely.

Consider again the case of two fields, $\langle 0|T\{\phi_I(x)\phi_I(y)\}|0\rangle$. We already know how to calculate this quantity, but now we would like to rewrite it in a form that is easy to evaluate and also generalizes to the case of more than two fields. To do this we first decompose $\phi_I(x)$ into positive- and negativefrequency parts:

$$\phi_I(x) = \phi_I^+(x) + \phi_I^-(x), \tag{4.32}$$

where

$$\phi_I^+(x) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}a_{\mathbf{p}}e^{-ip\cdot x}; \quad \phi_I^-(x) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}a_{\mathbf{p}}^\dagger e^{+ip\cdot x}$$

This decomposition can be done for any free field. It is useful because

$$\phi_I^+(x)|0\rangle = 0 \quad \text{and} \quad \langle 0|\phi_I^-(x) = 0.$$

For example, consider the case $x^0 > y^0$. The time-ordered product of two fields is then

$$\begin{aligned} T\phi_I(x)\phi_I(y) &\underset{x^0>y^0}{=} \phi_I^+(x)\phi_I^+(y) + \phi_I^+(x)\phi_I^-(y) + \phi_I^-(x)\phi_I^+(y) + \phi_I^-(x)\phi_I^-(y) \\ &= \phi_I^+(x)\phi_I^+(y) + \phi_I^-(y)\phi_I^+(x) + \phi_I^-(x)\phi_I^+(y) + \phi_I^-(x)\phi_I^-(y) \\ &\quad + \left[\phi_I^+(x), \phi_I^-(y)\right]. \end{aligned} \tag{4.33}$$

In every term except the commutator, all the $a_{\mathbf{p}}$'s are to the right of all the $a_{\mathbf{p}}^\dagger$'s. Such a term (e.g., $a_{\mathbf{p}}^\dagger a_{\mathbf{q}}^\dagger a_{\mathbf{k}} a_{\mathbf{l}}$) is said to be in normal order, and has vanishing vacuum expectation value. Let us also define the normal ordering symbol $N()$ to place whatever operators it contains in normal order, for example,

$$N\left(a_{\mathbf{p}}a_{\mathbf{k}}^\dagger a_{\mathbf{q}}\right) \equiv a_{\mathbf{k}}^\dagger a_{\mathbf{p}} a_{\mathbf{q}} \tag{4.34}$$

The order of $a_{\mathbf{p}}$ and $a_{\mathbf{q}}$ on the right-hand side makes no difference since they commute.*

If we had instead considered the case $y^0 > x^0$, we would get the same four normal-ordered terms as in (4.33), but this time the final commutator would be $\left[\phi_I^+(y), \phi_I^-(x)\right]$. Let us therefore define one more quantity, the contraction of two fields, as follows:

This quantity is exactly the Feynman propagator:

$$\overrightarrow{\phi(x)}\phi\,(y) = D_F(x-y) \tag{4.36}$$

(From here on we will often drop the subscript I for convenience; contractions will always involve interaction-picture fields.)

The relation between time-ordering and normal-ordering is now extremely simple to express, at least for two fields:

$$T\{\phi(x)\phi(y)\} = N\{\phi(x)\phi(y) + \overbrace{\phi(x)}^{\square}\phi(y)\} \tag{4.37}$$

[6]* In the literature one often sees the notation: $\phi_1\phi_2$: instead of $N(\phi_1\phi_2)$.

But now that we have all this new notation, the generalization to arbitrarily many fields is also easy to write down:

$$\begin{aligned} &T\left\{\phi\left(x_1\right)\phi\left(x_2\right)\cdots\phi\left(x_m\right)\right\} \\ &\quad = N\left\{\phi\left(x_1\right)\phi\left(x_2\right)\cdots\phi\left(x_m\right) + \text{ all possible contractions }\right\} \end{aligned} \tag{4.38}$$

This identity is known as Wick's theorem, and we will prove it in a moment. For $m = 2$ it is identical to (4.37). The phrase all possible contractions means there will be one term for each possible way of contracting the m fields in pairs. Thus for $m = 4$ we have (writing $\phi\left(x_a\right)$ as ϕ_a for brevity)

$$\begin{aligned} T\left\{\phi_1\phi_2\phi_3\phi_4\right\} = N\Big\{&\phi_1\phi_2\phi_3\phi_4 + \phi_1\phi_2\phi_3\phi_4 + \sqrt{\phi_1\phi_2\phi_3\phi_4 + \phi_1\phi_2\phi_3\phi_4} \\ &+\sqrt{\square} \\ &+\phi_1\phi_2\phi_3\phi_4 + \phi_1\phi_2\phi_3\phi_4 + \phi_1\phi_2\phi_3\phi_4 \\ &\square \\ &+\phi_1\phi_2\phi_3\phi_4 + \sqrt{\square}\phi_1\phi_2\phi_3\phi_4 + \phi_1\phi_2\phi_3\phi_4\Big\} \end{aligned} \tag{4.39}$$

When the contraction symbol connects two operators that are not adjacent, we still define it to give a factor of D_F. For example,

$$N\Big\{\phi_1\phi_2\phi_3\phi_4\Big\} \quad \text{means} \quad \overrightarrow{D_F}\left(x_1 - x_3\right)\cdot N\left\{\phi_2\phi_4\right\}\ldots\,.$$

In the vacuum expectation value of (4.39), any term in which there remain uncontracted operators gives zero (since $\langle 0|N$ (any operator) $|0\rangle = 0$). Only the three fully contracted terms in the last line survive, and they are all cnumbers, so we have

$$\begin{aligned} \langle 0|T\left\{\phi_1\phi_2\phi_3\phi_4\right\}|0\rangle = &D_F\left(x_1 - x_2\right)D_F\left(x_3 - x_4\right) \\ &+ D_F\left(x_1 - x_3\right)D_F\left(x_2 - x_4\right) \\ &+ D_F\left(x_1 - x_4\right)D_F\left(x_2 - x_3\right) \end{aligned} \tag{4.40}$$

Now let us prove Wick's theorem. Naturally the proof is by induction on m, the number of fields. We have already proved the case $m = 2$. So assume the theorem is true for $m - 1$ fields, and let's try to prove it for m fields. Without loss of generality, we can restrict ourselves to the case $x_1^0 \geq x_2^0 \geq \cdots x_m^0$; if this is not the case we can just relabel the points, without affecting either side of (4.38). Then applying Wick's theorem to $\phi_2\cdots\phi_m$, we have

$$\begin{aligned} T\left\{\phi_1\cdots\phi_m\right\} &= \phi_{\mathbf{1}}\cdots\phi_m \\ &= \phi_{\mathbf{1}}N\left\{\phi_2\cdots\phi_m + \begin{pmatrix}\text{all contractions}\\ \text{not involving }\phi_1\end{pmatrix}\right\} \\ &= \left(\phi_1^+ + \phi_1^-\right)N\left\{\phi_2\cdots\phi_m + \begin{pmatrix}\text{all contractions}\\ \text{not involving }\phi_1\end{pmatrix}\right\}. \end{aligned} \tag{4.41}$$

We want to move the $\phi_1^+$and ϕ_1^-inside the $N\{\}$. For the ϕ_1^-term this is easy: Just move it in, since (being on the left) it is already in normal order. The term with ϕ_1^+must be put in normal order by commuting it to the right past all the other ϕ 's. Consider, for example, the term with no contractions:

$$\begin{aligned}\phi_1^+ N\left(\phi_2 \cdots \phi_m\right) =& N\left(\phi_2 \cdots \phi_m\right) \phi_1^+ + \left[\phi_1^+, N\left(\phi_2 \cdots \phi_m\right)\right] \\ =& N\left(\phi_1^+ \phi_2 \cdots \phi_m\right) \\ &+ N\left(\left[\phi_1^+, \phi_2^-\right] \phi_3 \cdots \phi_m + \phi_2\left[\phi_1^+, \phi_3^-\right] \phi_4 \cdots \phi_m + \cdots\right) \\ =& N\left(\phi_1^+ \phi_2 \cdots \phi_m + \phi_1 \phi_2 \phi_3 \cdots \phi_m + \phi_1 \phi_2 \phi_3 \cdots + \cdots\right).\end{aligned}$$

The first term in the last line combines with part of the ϕ_1^-term from (4.41) to give $N\{\phi_1\phi_2\cdots\phi_m\}$, so we now have the first term on the right-hand side of Wick's theorem, as well as all possible terms involving a single contraction of ϕ_1 with another field. Similarly, a term in (4.41) involving one contraction will produce all possible terms involving both that contraction and a contraction of ϕ_1 with one of the other fields. Doing this with all the terms of (4.41), we eventually get all possible contractions of all the fields, including ϕ_1. Thus the induction step is complete, and Wick's theorem is proved.

суть теоремы Вика

Тут интересная теория, думаю, важно понять, как она работает: https://physics.stackexchange.com/questions/304869/systematic-way-to-draw-all-inequivalent-feynman-diagrams (по идее должен понимать, но что-то пробелы еще остаются в понимании)

https://physics.stackexchange.com/questions/297035/symmetry-factor-via-wicks-theorem я что это тоже не понимаю еще?

вывод теоремы Вика

В случае рассмотрения вакуум-вакуумных переходов для затравочного действия,

квадратичного по полю,

в формализме интеграла по траекториям легко получить выражение для функции Грина функционала $Z(j)$

$$\mathcal{D}^{(n)}\left(x_1, ..., x_n\right) = \langle \text{in}|\hat{\text{T}}\left\{\hat{\varphi}\left(x_1\right) ... \hat{\varphi}\left(x_n\right)\right\}|\text{in}\rangle$$

где мы опустили индекс,

обозначающий представление Гейзенберга для операторов, зависящих от времени.

Для квадратичного действия,

$$Z(j) = \exp\left\{\frac{\mathrm{i}}{\hbar}\frac{1}{2} j_x \mathcal{G}^{(2)}_{xy} j_y\right\}$$

или при помощи введения вспомогательного поля $\tilde{\varphi}$

$$Z(j) = \exp\left\{-\frac{\mathrm{i}\hbar}{2}\mathcal{G}^{(2)}_{xy}\frac{\delta^2}{\delta\tilde{\varphi}_x \delta\tilde{\varphi}_y}\right\} e^{\frac{\mathrm{i}}{\hbar} j_{x'}\tilde{\varphi}_{x'}}\Big|_{\tilde{\varphi}=0}$$

Для (4.49) находим

$$\mathcal{D}^{(n)}_{1\ldots n} = (-\mathrm{i}\hbar)^n \frac{\delta^n Z(j)}{\delta j_1 \ldots \delta j_n}\bigg|_{j=0} = \exp\left\{-\frac{\mathrm{i}\hbar}{2}\mathcal{G}^{(2)}_{xy}\frac{\delta^2}{\delta\tilde{\varphi}_x\delta\tilde{\varphi}_y}\right\}\tilde{\varphi}_1\ldots\tilde{\varphi}_n\bigg|_{\tilde{\varphi}=0}$$

При нечетном $n = 2p+1$, (????????),

$$\mathcal{D}^{(n)}_{1\ldots n} = 0.$$

Введем понятие «спаривания полей»

$$\underbrace{\tilde{\varphi}_k\tilde{\varphi}_{k'}} \cong -\mathrm{i}\hbar\mathcal{G}^{(2)}_{kk'} = \mathcal{D}^{(2)}_{kk'}$$

Тогда при четном $n = 2p$ функция Грина сводится к сумме всевозможных спариваний полей что и составляет суть теоремы Вика.

В приведенном выводе оказывается, что знак тильды не меняет дела: спаривание полей в точности отвечает расчету пропагатора частиц поля.

физический смысл спаривания и овалы (??)

Однако в операторной формулировке задается физический смысл спаривания.

Это позволит нам установить правила графического изображения для корреляторов.

В самом деле, для свободных полей,

первая ненулевая функция Грина $\mathcal{D}^{(2)}_{12}$ отвечает траектории частицы между точками 1 и 2, так что естественно изобразить эту функцию Грина в виде линии,

соединяющей эти точки,

причем,

графическому изображению соответствует вполне определенное функциональное выражение.

Для высшей функции Грина каждая точка в аргументе этой функции также отвечает концу или началу линии распространения частицы,

поскольку все возможные спаривания также отвечают соединениям точек линиями движения частиц.

(переформулирую) Всю совокупность этих спариваний можно обозначить в виде множества точек,

отвечающих аргументам функции,

причем,

из этих точек исходят линии, которые входят в область, скажем, овал, обозначающий все варианты попарного соединения точек линиями.

При отсутствии взаимодействий, овалы расшифровываются в указанном элементарном смысле.

пример: двухточечная функция свободных полей

Для примера, у свободных полей двухточечная функция -

(тут у Киселева картинки-расшифровки)

В последнем случае диаграммы не являются связными,

и эти несвязные диаграммы отсутствуют для функций Грина порядка выше двух для производящего функционала $G(j)$.

Важно подчеркнуть, что вариационная производная производяшего функционала - это линия, которая отвечает распространению частицы из овала в точку прескрипции вариационной производной!

При наличии взаимодействий можно начать рассмотрение с построения ведущего приближения теории возмущений и его графического представления, чтобы выяснить, какие варианты могут скрываться за овалом, из которого исходят линии распространения частиц, кроме элементарного соединения двух точек в свободной теории.

примеры использования теоремы Вика

(?)

14.2.14 Wick's Theorem by Mandl & Shawl

Обсудим подробно теорему Вика.

$$\underbrace{A(x_1)B}(x_2) = \langle 0|T....$$

Теория

We must now see how to obtain from the S-matrix expansion (6.23) the transition amplitude $\langle f|S|i\rangle$ for a particular transition $|i\rangle \to |f\rangle$ in a given order of perturbation theory. The Hamiltonian density $\mathscr{H}_{\rm I}(x)$ in Eq. (6.23) involves the interacting fields, each linear in creation and absorption operators. Hence the expansion (6.23) will describe a large number of different processes. However, only certain terms of the S-matrix will contribute to a given transition $|i\rangle \to |f\rangle$. For these terms must contain just the right absorption operators to destroy the particles present in $|i\rangle$, and they must contain the right creation operators to emit the particles present in $|f\rangle$. They may also contain additional creation and absorption operators, which create particles which are subsequently re-absorbed. These particles are only present in intermediate states and are called virtual particles.

Calculations can be greatly simplified by avoiding the explicit introduction of virtual intermediate particles. This can be achieved by writing the S-matrix expansion as a sum of normal products, since, in a normal product, all absorption operators stand to the right of all creation operators. Such an operator first absorbs a certain number of particles and then emits some particles. It does not cause emission and re-absorption of intermediate particles. Each of these normal products will effect a particular transition $|i\rangle \to |f\rangle$, which can be represented by a Feynman graph, similar to those introduced in Chapters 3 and 4. Consider, for example, Compton scattering ($e^- + \gamma \to e^- + \gamma$). The QED interaction Hamiltonian density is, from Eq. (6.10),

$$\mathscr{C}_{\rm I}(x) = -\mathscr{L}_{\rm I}(x) = -e\ {\rm N}\left[\bar{\psi}(x)A_A(x)\psi(x)\right].$$

Since the negative (positive) frequency parts $A^-, \bar{\psi}^-, \psi^-$ $\left(A^+, \psi^+\bar{\psi}^+\right)$are linear in creation (absorption) operators for photons, electrons and positrons respectively, the only normal product which contributes to Compton scattering is

$$\bar{\psi}^- A^- \psi^+ A^+$$

The method for expanding the S-matrix as a sum of normal products, which we shall now describe, is due to Dyson and Wick.

We first of all summarize the general definition of a normal product. Let $Q, R, ..., W$ be operators of the type $\psi^{\pm}, A^{\pm}$, etc., i.e. each is linear in either creation or absorption operators, then

$$\mathrm{N}(QR...W) = (-1)^P (Q'R'...W')$$

The S-Matrix Expansion 95 Here $Q', R', ..., W'$ are the operators $Q, R, ..., W$ reordered, so that all absorption operators (i.e. positive frequency parts) stand to the right of all creation operators (i.e. negative frequency parts). The exponent P is the number of interchanges of neighbouring fermion operators required to change the order $(QR...W)$ into $Q'R'...W')$. We generalize the definition (6.25a) by requiring the normal product to obey the distributive law

$$\mathrm{N}(RS... + VW...) = \mathrm{N}(RS...) + \mathrm{N}(VW...).$$

The QED interaction (6.24) is a normal product of field operators. We shall find that in other cases too, the interaction Hamiltonian density can be written as a normal product, i.e.

$$"\mathrm{I}(x) = \mathrm{N}\{A(x)B(x)...\}$$

where each of the fields $A(x), B(x), ...$, is linear in creation and absorption operators. Hence, we must consider the expansion into a sum of normal product of 'mixed' T-product (i.e. a T-product whose factors are normal products), such as occurs in the S-matrix expansion (6.23).

From the definition of the normal product, we have, for two field operators $A \equiv A(x_1)$ and $B \equiv B(x_2)$, that

$$AB - \mathrm{N}(AB) = \left\{ \begin{array}{ll} [A^+, B^-]_+ . & \text{for two fermion fields} \\ [A^+, B^-], & \text{otherwise} \end{array} \right\}$$

For two fermion fields, the anticommutators, and in all other cases, the commutators, are c-numbers, i.e. they do not involve creation or annihilation operators. [We had examples in Eqs. (3.40) and (4.53a).] Hence, the right-hand side of Eq. (6.27) is always a c-number. It is given by $\langle 0|AB|0\rangle$, as follows by taking the vacuum expectation value of Eq. (6.27). Hence Eq. (6.27) becomes:

$$AB = \mathrm{N}(AB) + \langle 0|AB|0\rangle.$$

Since

$$\mathrm{N}(AB) = \pm \mathrm{N}(BA),$$

the minus sign applying in the case of two fermion fields, the plus sign in all other cases, it follows from Eq. (6.28) that for $x_1^0 \neq x_2^0$

$$\mathrm{T}\{A(x_1) B(x_2)\} = \mathrm{N}\{A(x_1) B(x_2)\} + \langle 0 |\ \mathrm{T}\{A(x_1) B(x_2)\} |\, 0\rangle .$$

The case of equal times, $x_1^0 = x_2^0$, will be considered below.

The special notation

$$\underbrace{A(x_1)B}(x_2) \equiv \langle 0 |\ \mathrm{T}\{A(x_1) B(x_2)\} |\, 0\rangle$$

contractions are, of course, just the Feynman propagators, e.g. Eqs. (3.59), (3.60), (4.61) and (5.26):

$$\phi(x_1)\phi(x_2) = \mathrm{i}\Delta_{\mathrm{F}}(x_1 - x_2)$$
$$\psi_\alpha(x_1)\bar{\psi}_\beta(x_2) = -\bar{\psi}_\beta(x_2)\psi_\alpha(x_1) = \mathrm{i}S_{\mathrm{F}\alpha\beta}(x_1 - x_2)$$
$$\phi^\dagger(x_2)\phi(x_1) = \mathrm{i}\Delta_{\mathrm{F}}(x_1 - x_2)$$
$$A^\mu(x_1) A^v(x_2) = \mathrm{i}D_{\mathrm{F}}^{\mu v}(x_1 - x_2)$$

To generalize Eq. (6.30) to several operators $A \equiv A(x_1), ..., M \equiv M(x_m), ...$, the generalized normal product is defined by where P is the number of interchanges of neighbouring fermion operators required to change the order $(ABC...)$ to $(AKB...)$; for example

$$\begin{aligned}&\mathrm{N}\left(\psi_\alpha(x_1)\ \psi_\beta(x_2)\, A^\mu(x_3)\, \bar{\psi}_\gamma(x_4)\, \bar{\psi}_\delta(x_5)\right)\\ &\qquad = (-1)\psi_\beta(x_2)\, \bar{\psi}_\delta(x_5)\, \mathrm{N}\left(\psi_\alpha(x_1)\, A^\mu(x_3)\, \bar{\psi}_\gamma(x_4)\right).\end{aligned}$$

On the right-hand side of this equation appears the sum of all possible generalized normal products that can be formed from $(ABCD...WXYZ)$, the first, second and third lines representing all terms with no, one and two contractions, and so on. Each term on the righthand side of this equation contains all the factors in the same order in which they occur in the T-product on the left-hand side.

Eq. (6.35) states Wick's theorem. We shall not reproduce its proof, which is by induction, and so not very illuminating. [3] [3] G. C. Wick, Phys. Rev. 80 (1950) 268. The S-Matrix Expansion 97 With the interaction (6.26), the S-matrix expansion (6.23) contains the mixed T-products

$$\mathrm{T}\left\{\mathscr{H}_{\mathrm{I}}(x_1) ... \mathscr{X}_{\mathrm{I}}(x_n)\right\} = \mathrm{T}\left\{\mathrm{N}(AB...)_{x_1} ... \mathrm{N}(AB...)_{x_n}\right\}.$$

Wick extended the theorem (6.35) to include such mixed T-products. In each factor $\mathrm{N}(AB...)_{x_r}$ we replace $x_r = (x_r^0, \mathbf{x}_r)$ by $\xi_r = (x_r^0 \pm \varepsilon, \mathbf{x}_r), (\varepsilon < 0)$, depending on whether the substitution is made in the creation or absorption part of the field. Hence

$$\mathrm{T}\left\{\mathrm{N}(AB...)_{x_1} ... \mathrm{N}(AB...)_{x_n}\right\} = \lim_{\varepsilon \to 0}\ \mathrm{T}\left\{(AB...)_{\xi_1} ... (AB...)_{\xi_n}\right\},$$

the normal and chronological orderings within each group $(AB...)_{\xi_r}$ being the same on account of the $\pm\varepsilon$ in ξ_r^0. On expanding the right-hand side of Eq. (6.37) by Wick's theorem before going to the limit $\varepsilon \to 0$, contractions within one group $(AB...)\xi_t$ (i.e. over equaltimes operators when $\varepsilon \to 0$) vanish as the group is already in normal order. We thus have the desired result: the mixed T-product (6.36) can be expanded according to Eq. (6.35), provided contractions over equal times are omitted:

$$\mathrm{T}\left\{\mathrm{N}(AB...)_{x_1} ... \mathrm{N}(AB...)_{x_n}\right\} = \mathrm{T}\left\{(AB...)_{x_1} ... (AB...)_{x_n}\right\}_{\text{no e.t.c.}}$$

where 'no e.t.c.' stands for 'no equal-times contractions'. Eqs. (6.35) and (6.38) represent the desired result, enabling us to expand each term in the S-matrix expansion (6.23) into a sum of generalized normal products. Each of these normal products corresponds to a definite process, characterized by the operators not contracted, which absorb and create the particles present in the initial and final states respectively. The non-vanishing contractions which occur in these generalized normal products are the Feynman propagators (6.32), corresponding to virtual particles being emitted and re-absorbed in intermediate states. In the next chapter we shall see how to evaluate these individual contributions to $\langle f|S|i\rangle$, which result from the application of Wick's theorem.

14.3 4.4 Feynman Diagrams

Wick's theorem allows us to turn any expression of the form

$$\langle 0|T\left\{\phi_I(x_1)\, \phi_I(x_2) \cdots \phi_I(x_n)\right\}|0\rangle$$

into a sum of products of Feynman propagators. Now we are ready to develop a diagrammatic interpretation of such expressions. Consider first the case of four fields, all at different spacetime

points, which we worked out in Eq. (4.40). Let us represent each of the points x_1 through x_4 by a dot, and each factor
$D_F(x-y)$ by a line joining x to y. Then Eq. (4.40) can be represented as the sum of three diagrams (called Feynman diagrams):

$\langle 0|\, T\{\phi_1\phi_2\phi_3\phi_4\}\,|0\rangle =$ 
Although this isn't exactly a measurable quantity, the diagrams do suggest an interpretation: Particles are created at two spacetime points, each propagates to one of the other points, and then they are annihilated. This can happen in three ways, corresponding to the three ways to connect the points in pairs, as shown in the three diagrams. The total amplitude for the process is the sum of the three diagrams.

Things get more interesting when the expression contains more than one field at the same spacetime point. So let us now return to the evaluation of the two-point function $\langle\Omega|T\{\phi(x)\phi(y)\}|\Omega\rangle$, and put formula (4.31) to use. We will ignore the denominator until the very end of this section. The numerator, with the exponential expanded as a power series, is

$$\langle 0|T\left\{\phi(x)\phi(y)+\phi(x)\phi(y)\left[-i\int dtH_I(t)\right]+\cdots\right\}|0\rangle. \tag{4.43}$$

The first term gives the free-field result, $\langle 0|T\{\phi(x)\phi(y)\}|0\rangle = D_F(x-y)$. The second term, in ϕ^4 theory, is

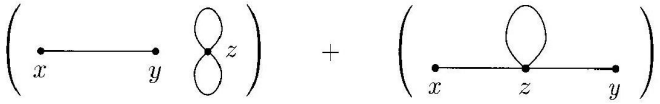
$$\begin{aligned}&\langle 0|T\left\{\phi(x)\phi(y)(-i)\int dt\int d^3z\frac{\lambda}{4!}\phi^4\right\}|0\rangle\\ &\quad=\langle 0|T\left\{\phi(x)\phi(y)\left(\frac{-i\lambda}{4!}\right)\int d^4z\phi(z)\phi(z)\phi(z)\phi(z)\right\}|0\rangle\end{aligned}$$

Now apply Wick's theorem. We get one term for every way of contracting the six ϕ operators with each other in pairs. There are 15 ways to do this, but (fortunately) only two of them are really different. If we contract $\phi(x)$ with $\phi(y)$, then there are three ways to contract the four $\phi(z)$'s with each other, and all three give identical expressions. The other possibility is to contract $\phi(x)$ with one of the $\phi(z)$'s (four choices), $\phi(y)$ with one of the others (three choices), and the remaining two $\phi(z)$'s with each other (one choice). There are twelve ways to do this, and all give identical expressions. Thus we have

$$\begin{aligned}&\langle 0|T\left\{\phi(x)\phi(y)(-i)\int dt\int d^3z\frac{\lambda}{4!}\phi^4\right\}|0\rangle\\ &\quad=3\cdot\left(\frac{-i\lambda}{4!}\right)D_F(x-y)\int d^4zD_F(z-z)D_F(z-z)\\ &\qquad+12\cdot\left(\frac{-i\lambda}{4!}\right)\int d^4zD_F(x-z)D_F(y-z)D_F(z-z).\end{aligned} \tag{4.44}$$

We can understand this expression better if we represent each term as a Feynman diagram. Again we draw each contraction D_F as a line, and each point as a dot. But this time we must distinguish between the "external" points, x and y, and the "internal" point z; each internal point

is associated with a factor of $(-i\lambda)\int d^4z$. We will worry about the constant factors in a moment. Using these rules, we see that the above expression (4.44) is equal to the sum of two diagrams:



We refer to the lines in these diagrams as propagators, since they represent the propagation amplitude D_F. Internal points, where four lines meet, are called vertices. Since $D_F(x-y)$ is the amplitude for a free Klein-Gordon particle to propagate between x and y, the diagrams actually interpret the analytic formula as a process of particle creation, propagation, and annihilation which takes place in spacetime.

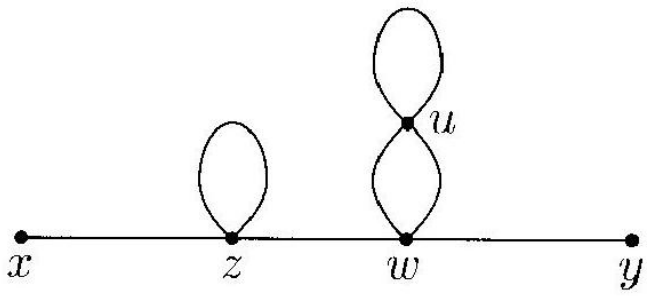
Now let's try a more complicated contraction, from the λ^3 term in the expansion of the correlation function:

$$\begin{aligned}&\langle 0|\phi(x)\phi(y)\frac{1}{3!}\left(\frac{-i\lambda}{4!}\right)^3\int d^4z\phi\phi\phi\phi\int d^4w\phi\phi\phi\phi\int d^4u\phi\phi\phi\phi|0\rangle\\&=\frac{1}{3!}\left(\frac{-i\lambda}{4!}\right)^3\int d^4zd^4wd^4uD_F(x-z)D_F(z-z)D_F(z-w)\\&\qquad\times D_F(w-y)D_F^2(w-u)D_F(u-u)\end{aligned}\tag{4.45}$$

The number of "different" contractions that give this same expression is large:

$$\underbrace{3!}_{\substack{\text{interchange}\\\text{of vertices}}}\times\underbrace{4\cdot3}_{\substack{\text{placement of}\\\text{contractions}\\\text{into } z \text{ vertex}}}\times\underbrace{4\cdot3\cdot2}_{\substack{\text{placement of}\\\text{contractions}\\\text{into } w \text{ vertex}}}\times\underbrace{4\cdot3}_{\substack{\text{placement of}\\\text{contractions}\\\text{into } u \text{ vertex}}}\times\underbrace{1/2}_{\substack{\text{interchange}\\\text{of } w-u\\\text{contractions}}}$$

The product of these combinatoric factors is 10,368 , roughly 1/13 of the total of 135,135 possible full contractions of the 14 operators. The structure of this particular contraction can be represented by the following "cactus" diagram:



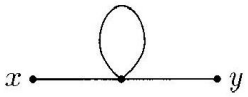
It is conventional, for obvious reasons, to let this one diagram represent the sum of all 10,368 identical terms.

In practice one always draws the diagram first, using it as a mnemonic device for writing down the analytic expression. But then the question arises, What is the overall constant? We could, of course, work it out as above: We could associate a factor $\int d^4z(-i\lambda/4\ !)$ with each vertex, put in the $1/n\ !$ from the Taylor series, and then do the combinatorics by writing out the product of fields as in (4.45) and counting. But the $1/n\ !$ from the Taylor series will almost always cancel the $n\ !$

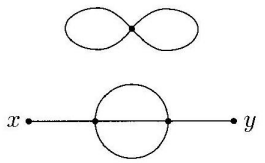
from interchanging the vertices, so we can just forget about both of these factors. Furthermore, the generic vertex has four lines coming in from four different places, so the various placements of these contractions into $\phi\phi\phi\phi$ generates a factor of 4! (as in the w vertex above), which cancels the denominator in $(-i\lambda/4\,!)$. It is therefore conventional to associate the expression $\int d^4z(-i\lambda)$ with each vertex. (This was the reason for the factor of 4 ! in the ϕ^4 coupling.)

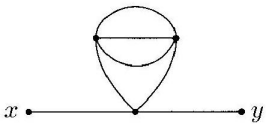
In the above diagram, this scheme gives a constant that is too large by a factor of $8 = 2 \cdot 2 \cdot 2$, the symmetry factor of the diagram. Two factors of 2 come from lines that start and end on the same vertex: The diagram is symmetric under the interchange of the two ends of such a line. The other factor of 2 comes from the two propagators connecting w to u: The diagram is symmetric under the interchange of these two lines with each other. A third possible type of symmetry is the equivalence of two vertices. To get the correct overall constant for a diagram, we divide by its symmetry factor, which is in general the number of ways of interchanging components without changing the diagram.

Most people never need to evaluate a diagram with a symmetry factor greater than 2 , so there's no need to worry too much about these technicalities. But here are a few examples, to make some sense out of the above rules:



$S = 2$





$S = 2 \cdot 2 \cdot 2 = 8$

$S = 3! = 6$

$S = 3! \cdot 2 = 12$

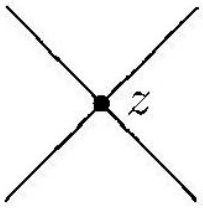
When in doubt, you can always determine the symmetry factor by counting equivalent contractions, as we did above.

We are now ready to summarize our rules for calculating the numerator of our expression (4.31) for $\langle\Omega|T\phi(x)\phi(y)|\Omega\rangle$:
$\langle 0|T\left\{\phi_I(x)\phi_I(y)\exp\left[-i\int dtH_I(t)\right]\right\}|0\rangle = \left(\begin{smallmatrix}\text{sum of all possible diagrams}\\ \text{with two external points}\end{smallmatrix}\right)$,
where each diagram is built out of propagators, vertices, and external points. The rules for associating analytic expressions with pieces of diagrams are called the Feynman rules. In ϕ^4 theory the rules are:

1. For each propagator,

$= D_F(x-y);$

2. For each vertex,



$$= (-i\lambda) \int d^4z$$

3. For each external point, x

4. Divide by the symmetry factor.

One way to interpret these rules is to think of the vertex factor $(-i\lambda)$ as the amplitude for the emission and/or absorption of particles at a vertex. The integral $\int d^4z$ instructs us to sum over all points where this process can occur. This is just the superposition principle of quantum mechanics: When a process can happen in alternative ways, we add the amplitudes for each possible way. To compute each individual amplitude, the Feynman rules tell us to multiply the amplitudes (propagators and vertex factors) for each independent part of the process.

Since these rules are written in terms of the spacetime points x, y, etc., they are sometimes called the position-space Feynman rules. In most calculations, it is simpler to express the Feynman rules in terms of momenta, by introducing the Fourier expansion of each propagator:

$$D_F(x-y) = \int \frac{d^4p}{(2\pi)^4} \frac{i}{p^2 - m^2 + i\epsilon} e^{-ip\cdot(x-y)} \tag{4.46}$$

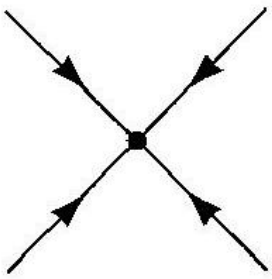
Represent this in the diagram by assigning a 4 -momentum p to each propagator, indicating the direction with an arrow. (Since $D_F(x-y) = D_F(y-x)$, the direction of p is arbitrary.) Then when four lines meet at a vertex, the z-dependent factors of the diagram are

$$\longleftrightarrow \quad \begin{array}{l} \int d^4z e^{-ip_1 z} e^{-ip_2 z} e^{-ip_3 z} e^{+ip_4 z} \\ = (2\pi)^4 \delta^{(4)}\left(p_1 + p_2 + p_3 - p_4\right) \end{array} , \$p_2 \tag{4.47}$$

In other words, momentum is conserved at each vertex. The delta functions
from the vertices can now be used to perform some of the momentum integrals from the propagators. We are left with the following momentum-space Feynman rules:

1. For each propagator, $\longrightarrow p = \frac{i}{p^2 - m^2 + i\epsilon}$;

2. For each vertex,



$$= -i\lambda$$

3. For each external point, $x\bullet \longleftarrow\!= e^{-ip\cdot x}$;

4. Impose momentum conservation at each vertex;

5. Integrate over each undetermined momentum: $\int \frac{d^4p}{(2\pi)^4}$;

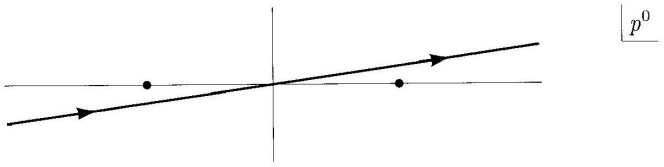
6. Divide by the symmetry factor.

Again, we can interpret each factor as the amplitude for that part of the process, with the integrations coming from the superposition principle. The exponential factor for an external point is just the amplitude for a particle at that point to have the needed momentum, or, depending on the direction of the arrow, for a particle with a certain momentum to be found at that point.

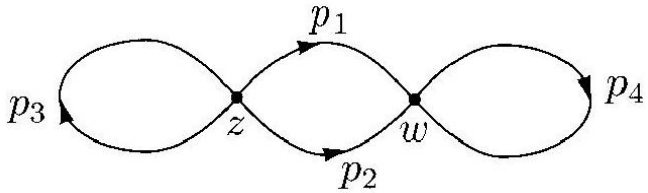
This nearly completes our discussion of the computation of correlation functions, but there are still a few loose ends. First, what happened to the large time T that was taken to $\infty(1-i\epsilon)$? We glossed over it completely in this section, starting with Eq. (4.43). The place to put it back is Eq. (4.47), where instead of just integrating over d^4z, we should have

$$\lim_{T\to\infty(1-i\epsilon)} \int_{-T}^{T} dz^0 \int d^3z e^{-i(p_1+p_2+p_3-p_4)\cdot z}.$$

The exponential blows up as $z^0 \to \infty$ or $z^0 \to -\infty$ unless its argument is purely imaginary. To achieve this, we can take each p^0 to have a small imaginary part: $p^0 \propto (1+i\epsilon)$. But this is precisely what we do in following the Feynman boundary conditions for computing D_F: We integrate along a contour that is rotated slightly away from the real axis, so that $p^0 \propto (1+i\epsilon)$:



The explicit dependence on T seems to disappear when we take the limit $T \to \infty$ in (4.46). But consider the diagram

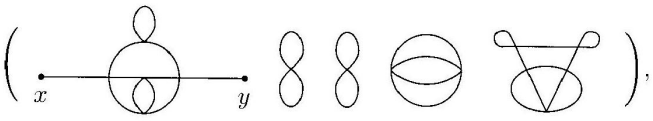


The delta function for the left-hand vertex is $(2\pi)^4\delta(p_1+p_2)$, so momentum conservation at the right-hand vertex is automatically satisfied, and we get $(2\pi)^4\delta(0)$ there. This awkward factor is easy to understand by going back to position space. It is simply the integral of a constant over d^4w:

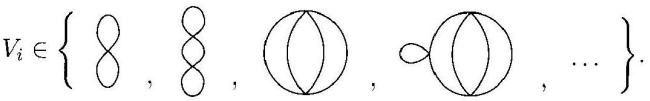
$$\int d^4w(\text{ const }) \propto (2T)\cdot(\text{ volume of space }) \tag{4.49}$$

This just tells us that the spacetime process (4.48) can happen at any place in space, and at any time between $-T$ and T. Every disconnected piece of a diagram, that is, every piece that is not connected to an external point, will have one such $(2\pi)^4\delta(0) = 2T\cdot V$ factor.

The contributions to the correlation function coming from such diagrams can be better understood with the help of a very pretty identity, the exponentiation of the disconnected diagrams. It works as follows. A typical diagram has the form



with a piece connected to x and y, and several disconnected pieces. (Since each vertex has an even number of lines coming into it, x and y must be connected to each other.) Label the various possible disconnected pieces by V_i:



The elements V_i are connected internally, but disconnected from external points. Suppose that a diagram (such as (4.50)) has n_i pieces of the form V_i, for each i, in addition to its one piece that is connected to x and y. (In any given diagram, only finitely many of the n_i will be nonzero.) If we also let V_i denote the value of the piece V_i, then the value of such a diagram is

$$(\text{value of connected piece}) \prod_i \frac{1}{n_i!} (V_i)^{n_i}$$

The $1/n_i$! is the symmetry factor coming from interchanging the n_i copies of V_i. The sum of all diagrams, representing the numerator of our formula for
the two-point correlation function, is then

$$\sum_{\substack{\text{all possible} \\ \text{connected} \\ \text{pieces}}} \sum_{\{n_i\}} \left(\begin{array}{c} \text{value of} \\ \text{connected piece} \end{array} \right) \times \left(\prod_i \frac{1}{n_i!} (V_i)^{n_i} \right)$$

where "all $\{n_i\}$ " means "all ordered sets $\{n_1, n_2, n_3, ...\}$ of nonnegative integers." The sum of the connected pieces factors out of this expression, giving

$$= \left(\sum \text{ connected} \right) \times \sum_{\text{all } \{n_i\}} \left(\prod_i \frac{1}{n_i!} (V_i)^{n_i} \right)$$

where $(\sum$ connected$)$ is an abbreviation for the sum of the values of all connected pieces. It is not too hard to see that the rest of the expression can also be factored (try working backwards):

$$\begin{aligned} &= \left(\sum \text{ connected} \right) \times \left(\sum_{n_1} \frac{1}{n_1!} V_1^{n_1} \right) \left(\sum_{n_2} \frac{1}{n_2!} V_2^{n_2} \right) \left(\sum_{n_3} \frac{1}{n_3!} V_3^{n_3} \right) \cdots \\ &= \left(\sum \text{ connected} \right) \times \prod_i \left(\sum_{n_i} \frac{1}{n_i!} V_i^{n_i} \right) \\ &= \left(\sum \text{ connected} \right) \times \prod_i \exp(V_i) \\ &= \left(\sum \text{ connected} \right) \times \exp\left(\sum_i V_i \right) \end{aligned} \tag{4.52}$$

We have just shown that the sum of all diagrams is equal to the sum of all connected diagrams, times the exponential of the sum of all disconnected diagrams. (We should really say "pieces" rather than "diagrams" on the righthand side of the equality, but from now on we will often just call a single piece a "diagram.") Pictorially, the identity is

$$\lim_{T\to\infty(1-i\epsilon)}\langle 0|T\left\{\phi_I(x)\phi_I(y)\exp\left[-i\int_{-T}^{T}dtH_I(t)\right]\right\}|0\rangle$$
$$= \left(\begin{matrix}\dot{y}\\ x\end{matrix} + \underset{\dot{y}}{\overset{\dot{x}}{\bigotimes}} + \cdots\right)$$
$$\times \exp[\therefore + 8 + (\square). \tag{4.53}$$

Now consider the denominator of our formula (4.31) for the two-point function. By an argument identical to the above, it is just

$$\langle 0|T\left\{\exp\left[-i\int_{-T}^{T}dtH_I(t)\right]\right\}|0\rangle = \exp[\}+\Big\} + (\square) + \cdots\Big]$$

which cancels the exponential of the disconnected diagrams in the numerator. This is the final simplification of the formula, which now reads

$$\langle\Omega|T[\phi(x)\phi(y)]|\Omega\rangle$$
$$= \text{ sum of all connected diagrams with two external points} \tag{4.54}$$

We have come a long way from our original formula, Eq. (4.31).
Having gotten rid of the disconnected diagrams in our formula for the correlation function, we might pause a moment to go back and interpret them physically. The place to look is Eq. (4.30), which can be written

$$\lim_{T\to\infty(1-i\epsilon)}\langle 0|T\left\{\phi_I(x)\phi_I(y)\exp\left[-i\int_{-T}^{T}dtH_I(t)\right]\right\}|0\rangle$$
$$= \langle\Omega|T\phi(x)\phi(y)|\Omega\rangle\cdot\lim_{T\to\infty(1-i\epsilon)}\left(|\langle 0|\Omega\rangle|^2 e^{-iE_0(2T)}\right)$$

Looking only at the T-dependent parts of both sides, this implies

$$\exp\left[\sum_i V_i\right] \propto \exp\left[-iE_0(2T)\right] \tag{4.55}$$

Since each disconnected diagram V_i contains a factor of $(2\pi)^4\delta^{(4)}(0) = 2T\cdot V$, this gives us a formula for the energy density of the vacuum (relative to the zero of energy set by $H_0|0\rangle = 0$):

$$\frac{E_0}{\text{volume}} = i[\bigcup + \zeta + (\square)]/\left[(2\pi)^4\delta^{(4)}(0)\right] \tag{4.56}$$

We should emphasize that the right-hand side is independent of T and (volume); in particular it is reassuring to see that E_0 is proportional to the volume of space. In Chapter 11 we will find that this formula is actually useful.

This completes our present analysis of the two-point correlation function. The generalization to higher correlation functions is easy:

$$\langle\Omega|T\left[\phi\left(x_1\right)\cdots\phi\left(x_n\right)\right]|\Omega\rangle=\left(\begin{array}{c}\text{sum of all connected diagrams}\\ \text{with } n \text{ external points}\end{array}\right) \tag{4.57}$$

The disconnected diagrams exponentiate, factor, and cancel as before, by the same argument. There is now a potential confusion in terminology, however. By "disconnected" we mean "disconnected from all external points"-exactly the same diagrams as in (4.51). (They are sometimes called "vacuum bubbles"
or "vacuum to vacuum transitions".) In higher correlation functions, diagrams can also be disconnected in another sense. Consider, for example, the fourpoint function:

$$\begin{aligned}&\langle\Omega|T\phi_1\phi_2\phi_3\phi_4|\Omega\rangle\\ &=-\quad+1+\quad 1+\lambda+\underline{0}+0\mid+\cdots\\ &+X+\varnothing\mid+\underline{00}+\cdots\\ &+\wp+\cdots+\not{+}\cdots+\cdots\,.\end{aligned} \tag{4.58}$$

In many of these diagrams, external points are disconnected from each other. Such diagrams do not exponentiate or factor; they contribute to the amplitude just as do the fully connected diagrams (in which any point can be reached from any other by traveling along the lines).

Note that in ϕ^4 theory, all correlation functions of an odd number of fields vanish, since it is impossible to draw an allowed diagram with an odd number of external points. We can also see this by going back to Wick's theorem: The interaction Hamiltonian H_I contains an even number of fields, so all terms in the perturbation expansion of an odd correlation function will contain an odd number of fields. But it is impossible to fully contract an odd number of fields in pairs, and only fully contracted terms have nonvanishing vacuum expectation value.

14.4 4.5 Cross Sections and the S-Matrix

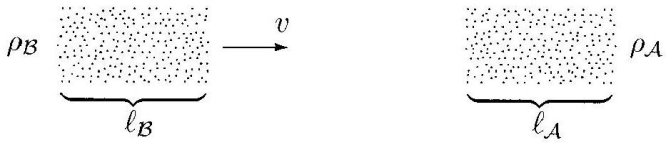
We now have an extremely beautiful formula, Eq. (4.57), for computing an extremely abstract quantity: the n-point correlation function. Our next task is to find equally beautiful ways of computing quantities that can actually be measured: cross sections and decay rates. In this section, after briefly reviewing the definitions of these objects, we will relate them (via a rather technical but fairly careful derivation) to a more primitive quantity, the S-matrix. In the next section we will learn how to compute the matrix elements of the S-matrix using Feynman diagrams.

The Cross Section

The experiments that probe the behavior of elementary particles, especially in the relativistic regime, are scattering experiments. One collides two beams of particles with well-defined momenta, and observes what comes out. The likelihood of any particular final state can be expressed in terms of the cross section, a quantity that is intrinsic to the colliding particles, and therefore
allows comparison of two different experiments with different beam sizes and intensities.

The cross section is defined as follows. Consider a target, at rest, of particles of type $\mathcal{A}$, with density $\rho_{\mathcal{A}}$ (particles per unit volume). Aim at this target a bunch of particles of type $\mathcal{B}$, with

number density $\rho_{\mathcal{B}}$ and velocity v:



Let $\ell_{\mathcal{A}}$ and $\ell_{\mathcal{B}}$ be the lengths of the bunches of particles. Then we expect the total number of scattering events (or scattering events of any particular desired type) to be proportional to $\rho_{\mathcal{A}}, \rho_{\mathcal{B}}, \ell_{\mathcal{A}}, \ell_{\mathcal{B}}$, and the cross-sectional area A common to the two bunches. The cross section, denoted by σ, is just the total number of events (of whatever type desired) divided by all of these quantities:

$$\sigma \equiv \frac{\text{Number of scattering events}}{\rho_{\mathcal{A}}\ell_{\mathcal{A}}\rho_{\mathcal{B}}\ell_{\mathcal{B}}A} \tag{4.59}$$

The definition is symmetric between the $\mathcal{A}$'s and $\mathcal{B}$'s, so of course we could have taken the $\mathcal{B}$'s to be at rest, or worked in any other reference frame.

The cross section has units of area. In fact, it is the effective area of a chunk taken out of one beam, by each particle in the other beam, that subsequently becomes the final state we are interested in.

In real beams, $\rho_{\mathcal{A}}$ and $\rho_{\mathcal{B}}$ are not constant; the particle density is generally larger at the center of the beam than at the edges. We will assume, however, that both the range of the interaction between the particles and the width of the individual particle wavepackets are small compared to the beam diameter. We can then consider $\rho_{\mathcal{A}}$ and $\rho_{\mathcal{B}}$ to be constant in what follows, and remember that, to compute the event rate in an actual accelerator, one must integrate over the beam area:

$$\text{Number of events } = \sigma\ell_{\mathcal{A}}\ell_{\mathcal{B}} \int d^2x \rho_{\mathcal{A}}(x)\rho_{\mathcal{B}}(x) \tag{4.60}$$

If the densities are constant, or if we use this formula to compute an effective area A of the beams, then we have simply

$$\text{Number of events } = \frac{\sigma N_{\mathcal{A}} N_{\mathcal{B}}}{A}, \tag{4.61}$$

where $N_{\mathcal{A}}$ and $N_{\mathcal{B}}$ are the total numbers of $\mathcal{A}$ and $\mathcal{B}$ particles.

Cross sections for many different processes may be relevant to a single scattering experiment. In e^+e^-collisions, for example, one can measure the cross sections for production of $\mu^+\mu^-, \tau^+\tau^-, \mu^+\mu^-\gamma, \mu^+\mu^-\gamma\gamma$, etc., and countless processes involving hadron production, not to mention simple e^+e^- scattering. Usually, of course, we wish to measure not only what the final-state particles are, but also the momenta with which they come out. In this case our definition (4.59) of σ still works, but if we specify the exact momenta desired, σ will be infinitesimal. The solution is to define the differential cross section, $d\sigma/\left(d^3p_1 \cdots d^3p_n\right)$. It is simply the quantity that, when integrated over any small $d^3p_1 \cdots d^3p_n$, gives the cross section for scattering into that region of final-state momentum space. The various final-state momenta are not all independent: Four components will always be constrained by 4 -momentum conservation. In the simplest case, where there are only two final-state particles, this leaves only two unconstrained momentum components, usually taken to be the angles θ and ϕ of the momentum of one of the particles. Integrating $d\sigma/\left(d^3p_1 d^3p_2\right)$ over the four constrained momentum components then leaves us with the usual differential cross section $d\sigma/d\Omega$.

A somewhat simpler measurable quantity is the decay rate Γ of an unstable particle $\mathcal{A}$ (assumed to be at rest) into a specified final state (of two or more particles). It is defined as

$$\Gamma \equiv \frac{\text{Number of decays per unit time}}{\text{Number of } \mathcal{A} \text{ particles present}} \tag{4.62}$$

The lifetime τ of the particle is then the reciprocal of the sum of its decay rates into all possible final states. (The particle's half-life is $\tau \cdot \ln 2$.)

In nonrelativistic quantum mechanics, an unstable atomic state shows up in scattering experiments as a resonance. Near the resonance energy E_0, the scattering amplitude is given by the Breit-Wigner formula

$$f(E) \propto \frac{1}{E - E_0 + i\Gamma/2}. \tag{4.63}$$

The cross section therefore has a peak of the form

$$\sigma \propto \frac{1}{(E - E_0)^2 + \Gamma^2/4}$$

The width of the resonance peak is equal to the decay rate of the unstable state.

The Breit-Wigner formula (4.63) also applies in relativistic quantum mechanics. In particular, it gives the scattering amplitude for processes in which initial particles combine to form an unstable particle, which then decays. The unstable particle, viewed as an excited state of the vacuum, is a direct analogue of the unstable nonrelativistic atomic state. If we call the 4 -momentum of the unstable particle p and its mass m, we can make a relativistically invariant generalization of (4.63):

$$\frac{1}{p^2 - m^2 + im\Gamma} \approx \frac{1}{2E_{\mathbf{p}}\left(p^0 - E_{\mathbf{p}} + i\left(m/E_{\mathbf{p}}\right)\Gamma/2\right)} \tag{4.64}$$

The decay rate of the unstable particle in a general frame is $(m/E_{\mathbf{p}})\,\Gamma$, in accord with relativistic time dilation. Although the two expressions in (4.64) are equal in the vicinity of the resonance, the left-hand side, which is manifestly Lorentz invariant, is much more convenient.

The S-Matrix

How, then, do we calculate a cross section? We must set up wavepackets representing the initial-state particles, evolve this initial state for a very long time with the time-evolution operator $\exp(-iHt)$ of the interacting field theory, and overlap the resulting final state with wavepackets representing some desired set of final-state particles. This gives the probability amplitude for producing that final state, which is simply related to the cross section. We will find that, in the limit where the wavepackets are very narrow in momentum space, the amplitude depends only on the momenta of the wavepackets, not on the details of their shapes. †

A wavepacket representing some desired state $|\phi\rangle$ can be expressed as

$$|\phi\rangle = \int \frac{d^3k}{(2\pi)^3} \frac{1}{\sqrt{2E_{\mathbf{k}}}} \phi(\mathbf{k})|\mathbf{k}\rangle \tag{4.65}$$

where $\phi(\mathbf{k})$ is the Fourier transform of the spatial wavefunction, and $|\mathbf{k}\rangle$ is a one-particle state of momentum $\mathbf{k}$ in the interacting theory. In the free theory, we would have $|\mathbf{k}\rangle = \sqrt{2E_{\mathbf{k}}}\, a^\dagger_{\mathbf{k}}|0\rangle$. The factor of $\sqrt{2E_{\mathbf{k}}}$ converts our relativistic normalization of $|\mathbf{k}\rangle$ to the conventional normalization in which the sum of all probabilities adds up to 1:

$$\langle\phi|\phi\rangle = 1 \quad \text{if} \quad \int \frac{d^3k}{(2\pi)^3}|\phi(\mathbf{k})|^2 = 1 \tag{4.66}$$

The probability we wish to compute is then

$$\mathcal{P} = |\langle\underbrace{\phi_1\phi_2\cdots}_{\text{future}}|\underbrace{\phi_{\mathcal{A}}\phi_{\mathcal{B}}}_{\text{past}}\rangle|^2, \tag{4.67}$$

where $|\phi_{\mathcal{A}}\phi_{\mathcal{B}}\rangle$ is a state of two wavepackets constructed in the far past and $\langle\phi_1\phi_2\cdots|$ is a state of several wavepackets (one for each final-state particle) constructed in the far future. The wavepackets are localized in space, so each can be constructed independently of the others. States constructed in this way are called in and out states. Note that we use the Heisenberg picture: States are time-independent, but the name we give a state depends on the eigenvalues or expectation values of time-dependent operators. Thus states with different names constructed at different times have a nontrivial overlap, which depends on the time dependence of the operators.

If we set up $|\phi_{\mathcal{A}}\phi_{\mathcal{B}}\rangle$ in the remote past, and then take the limit in which the wavepackets $\phi_i(\mathbf{k}_i)$ become concentrated about definite momenta $\mathbf{p}_i$, this defines an *in* state $|\mathbf{p}_{\mathcal{A}}\mathbf{p}_{\mathcal{B}}\rangle_{\text{in}}$ with definite initial momenta. It is useful to view $|\phi_{\mathcal{A}}\phi_{\mathcal{B}}\rangle$ as a linear superposition of such states. It is important, however, to

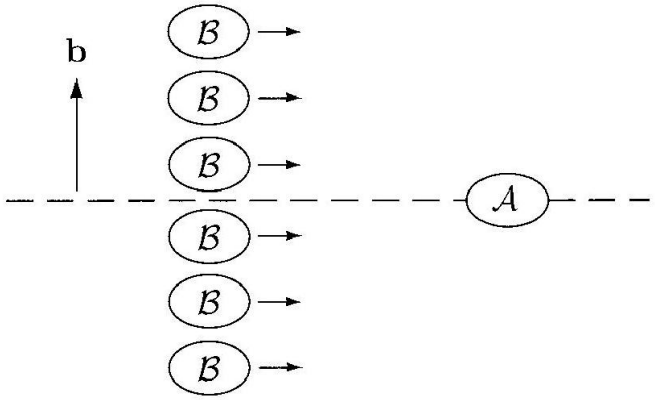


Figure 4.2. Incident wavepackets are uniformly distributed in impact parameter $\mathbf{b}$.

take into account the transverse displacement of the wavepacket $\phi_{\mathcal{B}}$ relative to $\phi_{\mathcal{A}}$ in position space (see Fig. 4.2). Although we could leave this implicit in the form of $\phi_{\mathcal{B}}(\mathbf{k}_{\mathcal{B}})$, we instead adopt the convention that our reference momentum-space wavefunctions are collinear (that is, have impact parameter $\mathbf{b} = 0$), and write $\phi_{\mathcal{B}}(\mathbf{k}_{\mathcal{B}})$ with an explicit factor $\exp(-i\mathbf{b}\cdot\mathbf{k}_{\mathcal{B}})$ to account for the spatial translation. Then, since $\phi_{\mathcal{A}}$ and $\phi_{\mathcal{B}}$ are constructed independently at different locations, we can write the initial state as

$$|\phi_{\mathcal{A}}\phi_{\mathcal{B}}\rangle_{\text{in}} = \int \frac{d^3k_{\mathcal{A}}}{(2\pi)^3}\int \frac{d^3k_{\mathcal{B}}}{(2\pi)^3}\frac{\phi_{\mathcal{A}}(\mathbf{k}_{\mathcal{A}})\,\phi_{\mathcal{B}}(\mathbf{k}_{\mathcal{B}})\,e^{-i\mathbf{b}\cdot\mathbf{k}_{\mathcal{B}}}}{\sqrt{(2E_{\mathcal{A}})(2E_{\mathcal{B}})}}|\mathbf{k}_{\mathcal{A}}\mathbf{k}_{\mathcal{B}}\rangle_{\text{in}} \tag{4.68}$$

We could expand $\langle\phi_1\phi_2\cdots|$ in terms of similarly defined out states of definite momentum formed in the asymptotic future: ‡

[6†] Much of this section is based on the treatment of nonrelativistic scattering given in Taylor (1972), Chapters 2, 3, and 17. We concentrate on the additional complications of the relativistic theory, glossing over many subtleties, common to both cases, which Taylor explains carcfully.

$$_{\text{out}}\,\langle\phi_1\phi_2\cdots| = \left(\prod_f \int \frac{d^3p_f}{(2\pi)^3}\frac{\phi_f\left(\mathbf{p}_f\right)}{\sqrt{2E_f}}\right) \text{out}\,\langle\mathbf{p}_1\mathbf{p}_2\cdots|\,.$$

It is much easier, however, to use the out states of definite momentum as the final states in the probability amplitude (4.67), and to multiply by the various normalization factors after squaring the amplitude. This is physically reasonable as long as the detectors of final-state particles mainly measure momentum - that is, they do not resolve positions at the level of de Broglie wavelengths.

We can now relate the probability of scattering in a real experiment to an idealized set of transition amplitudes between the asymptotically defined in and out states of definite momentum,

$$_{\text{out}}\,\langle\mathbf{p}_1\mathbf{p}_2\cdots|\mathbf{k}_\mathcal{A}\mathbf{k}_\mathcal{B}\rangle_{\text{in}}\ . \tag{4.69}$$

To compute the overlap of in states with out states, we note that the conventions for defining the two sets of states are related by time translation:

$$\begin{aligned} _{\text{out}}\,\langle\mathbf{p}_1\mathbf{p}_2\cdots|\mathbf{k}_\mathcal{A}\mathbf{k}_\mathcal{B}\rangle_{\text{in}} &= \lim_{T\to\infty}\langle\underbrace{\mathbf{p}_1\mathbf{p}_2\cdots}_{T}|\,\underbrace{\mathbf{k}_\mathcal{A}\mathbf{k}_\mathcal{B}}_{-T}\rangle \\ &= \lim_{T\to\infty}\langle\mathbf{p}_1\mathbf{p}_2\cdots|\,e^{-iH(2T)}\,|\mathbf{k}_\mathcal{A}\mathbf{k}_\mathcal{B}\rangle \end{aligned} \tag{4.70}$$

In the last line, the states are defined at any common reference time. Thus, the in and out states are related by the limit of a sequence of unitary operators. This limiting unitary operator is called the S-matrix:

$$_{\text{out}}\,\langle\mathbf{p}_1\mathbf{p}_2\cdots|\mathbf{k}_\mathcal{A}\mathbf{k}_\mathcal{B}\rangle_{\text{in}} \equiv \langle\mathbf{p}_1\mathbf{p}_2\cdots|\,S\,|\mathbf{k}_\mathcal{A}\mathbf{k}_\mathcal{B}\rangle \tag{4.71}$$

The S-matrix has the following structure: If the particles in question do not interact at all, S is simply the identity operator. Even if the theory contains interactions, the particles have some probability of simply missing one another. To isolate the interesting part of the S-matrix-that is, the part due to interactions-we define the T-matrix by

$$S = \mathbf{1} + iT \tag{4.72}$$

Next we note that the matrix elements of S should reflect 4-momentum conservation. Thus S or T should always contain a factor $\delta^{(4)}\left(k_\mathcal{A}+k_\mathcal{B}-\sum p_f\right)$. Extracting this factor, we define the invariant matrix element $\mathcal{M}$, by

$$\langle\mathbf{p}_1\mathbf{p}_2\cdots|\,iT\,|\mathbf{k}_\mathcal{A}\mathbf{k}_\mathcal{B}\rangle = (2\pi)^4\delta^{(4)}\left(k_\mathcal{A}+k_\mathcal{B}-\sum p_f\right)\cdot i\mathcal{M}\left(k_\mathcal{A},k_\mathcal{B}\to p_f\right) \tag{4.73}$$

We have written this expression in terms of 4-momenta p and k, but of course all 4-momenta are on mass-shell: $p^0=E_\mathbf{p}, k^0=E_\mathbf{k}$. (Note that our entire treatment is specific to the case where the initial state contains only two particles. For $3\to$ many or many $\to$ many interactions, one can invent analogous constructions, but we will not consider such complicated experiments in this book.)

The matrix element $\mathcal{M}$ is analogous to the scattering amplitude f of one-particle quantum mechanics. It is useful because it allows us to separate all the physics that depends on the details

[6]‡ Here and below, the product symbol applies (symbolically) to the integral as well as the other factors in parentheses; the integrals apply to what is outside the parentheses as well.

of the interaction Hamiltonian ("dynamics") from all the physics that doesn't ("kinematics"). In the next section we will discuss how to compute $\mathcal{M}$ using Feynman diagrams. But first, we must figure out how to reconstruct the cross section σ from $\mathcal{M}$.

To do this, let us calculate, in terms of $\mathcal{M}$, the probability for the initial state $|\phi_A\phi_B\rangle$ to scatter and become a final state of n particles whose momenta lie in a small region $d^3p_1 \cdots d^3p_n$. In our normalization, this probability is

$$\mathcal{P}(\mathcal{AB} \to 12...n) = \left(\prod_f \frac{d^3p_f}{(2\pi)^3}\frac{1}{2E_f}\right)\Bigg|_{\text{out}} \langle \mathbf{p}_1 \cdots \mathbf{p}_n | \phi_A\phi_B\rangle_{\text{in}}\Bigg|^2 \tag{4.74}$$

For a single target ($\mathcal{A}$) particle and many incident ($\mathcal{B}$) particles with different impact parameters $\mathbf{b}$, the number of scattering events is

$$N = \sum_{\substack{\text{all incident}\\ \text{particles } i}} \mathcal{P}_i = \int d^2b n_{\mathcal{B}} \mathcal{P}(\mathbf{b})$$

where $n_{\mathcal{B}}$ is the number density (particles per unit area) of $\mathcal{B}$ particles. Since we are assuming that this number density is constant over the range of the interaction, $n_{\mathcal{B}}$ can be taken outside the integral. The cross section is then

$$\sigma = \frac{N}{n_{\mathcal{B}} N_{\mathcal{A}}} = \frac{N}{n_{\mathcal{B}} \cdot 1} = \int d^2b \mathcal{P}(\mathbf{b}) \tag{4.75}$$

Deriving a simple expression for σ in terms of $\mathcal{M}$ is now a fairly straightforward calculation. Combining (4.75), (4.74), and (4.68), we have (writing $d\sigma$ rather than σ since this is an infinitesimal quantity)

$$\begin{aligned} d\sigma = &\left(\prod_f \frac{d^3p_f}{(2\pi)^3}\ \frac{1}{2E_f}\right)\int d^2b \left(\prod_{i=\mathcal{A},\mathcal{B}} \int \frac{d^3k_i}{(2\pi)^3}\frac{\phi_i(\mathbf{k}_i)}{\sqrt{2E_i}} \int \frac{d^3\bar{k}_i}{(2\pi)^3}\frac{\phi_i^*(\bar{\mathbf{k}}_i)}{\sqrt{2\bar{E}_i}}\right) \\ &\times e^{i\mathbf{b}\cdot\left(\bar{\mathbf{k}}_{\mathcal{B}} - \mathbf{k}_{\mathcal{B}}\right)} \left({}_{\text{out}}\ \langle\{\mathbf{p}_f\} \mid \{\mathbf{k}_i\}\rangle_{\text{in}}\right)\left({}_{\text{out}}\ \left\langle\{\mathbf{p}_f\} \mid \left\{\bar{\mathbf{k}}_i\right\}\right\rangle_{\text{in}}\right)^* \end{aligned} \tag{4.76}$$

where we have used $\bar{k}_{\mathcal{A}}$ and $\bar{k}_{\mathcal{B}}$ as dummy integration variables in the second half of the squared amplitude. The d^2b integral can be performed to give a factor of $(2\pi)^2\delta^{(2)}\left(k_{\mathcal{B}}^{\perp} - \bar{k}_{\mathcal{B}}^{\perp}\right)$. We get more delta functions by writing the final two factors of (4.76) in terms of $\mathcal{M}$. Assuming that we are not interested in the trivial case of forward scattering where no interaction takes place, we can drop the 1 in Eq. (4.72) and write these factors as

$$\begin{aligned} \left({}_{\text{out}}\ \left(\{\mathbf{p}_f\} \mid \{\mathbf{k}_i\}\right\rangle_{\text{in}}\right) &= i\mathcal{M}\left(\{k_i\} \to \{p_f\}\right)(2\pi)^4\delta^{(4)}\left(\sum k_i - \sum p_f\right) \\ \left({}_{\text{out}}\ \left\langle\{\mathbf{p}_f\} \mid \left\{\bar{\mathbf{k}}_i\right\}\right\rangle_{\text{in}}\right)^* &= -i\mathcal{M}^*\left(\left\{\bar{k}_i\right\} \to \{p_f\}\right)(2\pi)^4\delta^{(4)}\left(\sum \bar{k}_i - \sum p_f\right) \end{aligned}$$

We can use the second of these delta functions, together with the $\delta^{(2)}\left(k_{\mathcal{B}} - \bar{k}_{\mathcal{B}}\right)$, to perform all six of the $\bar{k}$ integrals in (4.76). Of the six integrals, only those over $\bar{k}_{\mathcal{A}}^z$ and $\bar{k}_{\mathcal{B}}^z$ require some work:

$$\begin{aligned}
&\int d\bar{k}^z_{\mathcal{A}} d\bar{k}^z_{\mathcal{B}} \delta\left(\bar{k}^z_{\mathcal{A}} + \bar{k}^z_{\mathcal{B}} - \sum p^z_f\right) \delta\left(\bar{E}_{\mathcal{A}} + \bar{E}_{\mathcal{B}} - \sum E_f\right) \\
&= \int d\bar{k}^z_{\mathcal{A}} \delta\left(\sqrt{\bar{k}^2_{\mathcal{A}} + m^2_{\mathcal{A}}} + \sqrt{\bar{k}^2_{\mathcal{B}} + m^2_{\mathcal{B}}} - \sum E_f\right)\Big|_{\bar{k}^z_{\mathcal{B}} = \Sigma p^z_f - \bar{k}^z_{\mathcal{A}}} \\
&= \frac{1}{\left|\frac{\bar{k}^z_{\mathcal{A}}}{\bar{E}_{\mathcal{A}}} - \frac{\bar{k}^z_{\mathcal{B}}}{\bar{E}^z_{\mathcal{B}}}\right|} \equiv \frac{1}{|v_{\mathcal{A}} - v_{\mathcal{B}}|}
\end{aligned} \tag{4.77}$$

In the last line and in the rest of Eq. (4.76) it is understood that the constraints $\bar{k}^z_{\mathcal{A}} + \bar{k}^z_{\mathcal{B}} = \sum p^z_f$ and $\bar{E}_{\mathcal{A}} + \bar{E}_{\mathcal{B}} = \sum E_f$ now apply (in addition to the constraints $\bar{k}^\perp_{\mathcal{A}} = k^\perp_{\mathcal{A}}$ and $\bar{k}^\perp_{\mathcal{B}} = k^\perp_{\mathcal{B}}$ coming from the other four integrals).

The difference $|v_A - v_B|$ is the relative velocity of the beams as viewed from the laboratory frame.

Now recall that the initial wavepackets are localized in momentum space, centered on $\mathbf{p}_{\mathcal{A}}$ and $\mathbf{p}_{\mathcal{B}}$. This means that we can evaluate all factors that are smooth functions of $\mathbf{k}_{\mathcal{A}}$ and $\mathbf{k}_{\mathcal{B}}$ at $\mathbf{p}_{\mathcal{A}}$ and $\mathbf{p}_{\mathcal{B}}$, pulling them outside the integrals. These factors include $E_{\mathcal{A}}, E_{\mathcal{B}}, |v_{\mathcal{A}} - v_{\mathcal{B}}|$, and $\mathcal{M}$-everything except the remaining delta function. After doing this, we arrive at the expression

$$\begin{aligned}
d\sigma = &\left(\prod_f \tfrac{d^3p_f}{(2\pi)^3} \tfrac{1}{2E_f}\right) \tfrac{\left|\mathcal{M}\left(p_{\mathcal{A}}, p_{\mathcal{B}} \to \{p_f\}\right)\right|^2}{2E_{\mathcal{A}} 2E_{\mathcal{B}} |v_{\mathcal{A}} - v_{\mathcal{B}}|} \int \tfrac{d^3k_{\mathcal{A}}}{(2\pi)^3} \int \tfrac{d^3k_{\mathcal{B}}}{(2\pi)^3} \\
&\times \left|\phi_{\mathcal{A}}\left(\mathbf{k}_{\mathcal{A}}\right)\right|^2 \left|\phi_{\mathcal{B}}\left(\mathbf{k}_{\mathcal{B}}\right)\right|^2 (2\pi)^4 \delta^{(4)}\left(k_{\mathcal{A}} + k_{\mathcal{B}} - \sum p_f\right)
\end{aligned} \tag{4.78}$$

To simplify this formula further, we should think a bit more about the properties of real particle detectors. We have already noted that real detectors project mainly onto eigenstates of momentum. But real detectors have finite resolution; that is, they sum incoherently over momentum bites of finite size. Normally, the measurement of the final-state momentum is not of such high quality that it can resolve the small variation of this momentum that results from the momentum spread of the initial wavepackets $\phi_{\mathcal{A}}, \phi_{\mathcal{B}}$. In that case, we may treat even the momentum vector $k_{\mathcal{A}} + k_{\mathcal{B}}$ inside the delta function as being well approximated by its central value $p_{\mathcal{A}} + p_{\mathcal{B}}$. With this further approximation, we can perform the integrals over $k_{\mathcal{A}}$ and $k_{\mathcal{B}}$ using the normalization condition (4.66). This produces the final form of the relation between S-matrix elements and cross sections,

$$\begin{aligned}
d\sigma = &\frac{1}{2E_{\mathcal{A}} 2E_{\mathcal{B}} \left|v_{\mathcal{A}} - v_{\mathcal{B}}\right|} \left(\prod_f \frac{d^3p_f}{(2\pi)^3} \frac{1}{2E_f}\right) \\
&\times \left|\mathcal{M}\left(p_{\mathcal{A}}, p_{\mathcal{B}} \to \{p_f\}\right)\right|^2 (2\pi)^4 \delta^{(4)}\left(p_{\mathcal{A}} + p_{\mathcal{B}} - \sum p_f\right)
\end{aligned} \tag{4.79}$$

All dependence on the shapes of the wavepackets has disappeared.
The integral over final-state momenta in (4.79) has the structure

$$\int d\Pi_n = \left(\prod_f \int \frac{d^3p_f}{(2\pi)^3} \frac{1}{2E_f}\right) (2\pi)^4 \delta^{(4)}\left(P - \sum p_f\right) \tag{4.80}$$

with P the total initial 4-momentum. This integral is manifestly Lorentz invariant, since it is built up from invariant 3 -momentum integrals constrained by a 4 -momentum delta function. This integral is known as relativistically invariant n-body phase space. Of the other ingredients in

(4.79), the matrix element $\mathcal{M}$ is also Lorentz invariant. The Lorentz transformation property of (4.79) therefore comes entirely from the prefactor

$$\frac{1}{E_{\mathcal{A}}E_{\mathcal{B}}\left|v_{\mathcal{A}}-v_{\mathcal{B}}\right|}=\frac{1}{\left|E_{\mathcal{B}}p_{\mathcal{A}}^{z}-E_{\mathcal{A}}p_{\mathcal{B}}^{z}\right|}=\frac{1}{\left|\epsilon_{\mu xy\nu}p_{\mathcal{A}}^{\mu}p_{\mathcal{B}}^{\nu}\right|}$$

This is not Lorentz invariant, but it is invariant to boosts along the z-direction. In fact, this expression has exactly the transformation properties of a crosssectional area.

For the special case of two particles in the final state, we can simplify the general expression (4.79) by partially evaluating the phase-space integrals in the center-of-mass frame. Label the momenta of the two final particles p_1 and p_2. We first choose to integrate all three components of $\mathbf{p}_2$ over the delta functions enforcing 3 -momentum conservation. This sets $\mathbf{p}_2=-\mathbf{p}_1$ and converts the integral over two-body phase space to the form

$$\int d\Pi_2=\int\frac{dp_1p_1^2d\Omega}{(2\pi)^3 2E_1 2E_2}(2\pi)\delta\left(E_{\mathrm{cm}}-E_1-E_2\right) \tag{4.81}$$

where $E_1=\sqrt{p_1^2+m_1^2}, E_2=\sqrt{p_1^2+m_2^2}$, and E_{cm} is the total initial energy. Integrating over the final delta function gives

$$\begin{aligned}\int d\Pi_2&=\int d\Omega\frac{p_1^2}{16\pi^2E_1E_2}\left(\frac{p_1}{E_1}+\frac{p_1}{E_2}\right)^{-1}\\&=\int d\Omega\frac{1}{16\pi^2}\frac{|\mathbf{p}_1|}{E_{\mathrm{cm}}}\end{aligned} \tag{4.82}$$

For reactions symmetric about the collision axis, two-body phase space can be written simply as an integral over the polar angle in the center-of-mass frame:

$$\int d\Pi_2=\int d\cos\theta\frac{1}{16\pi}\frac{2\left|\mathbf{p}_1\right|}{E_{\mathrm{cm}}} \tag{4.83}$$

The last factor tends to 1 at high energy.
Applying this simplification to (4.79), we find the following form of the cross section for two final-state particles:

$$\left(\frac{d\sigma}{d\Omega}\right)_{\mathrm{CM}}=\frac{1}{2E_{\mathcal{A}}2E_{\mathcal{B}}\left|v_{\mathcal{A}}-v_{\mathcal{B}}\right|}\frac{|\mathbf{p}_1|}{(2\pi)^2 4E_{\mathrm{cm}}}\left|\mathcal{M}\left(p_{\mathcal{A}},p_{\mathcal{B}}\to p_1,p_2\right)\right|^2 \tag{4.84}$$

In the special case where all four particles have identical masses (including the commonly seen limit $m\to 0$), this reduces to the formula quoted in Chapter 1,

$$\left(\frac{d\sigma}{d\Omega}\right)_{\mathrm{CM}}=\frac{|\mathcal{M}|^2}{64\pi^2E_{\mathrm{cm}}^2}\quad\text{(all four masses identical).} \tag{4.85}$$

To conclude this section, we should derive a formula for the differential decay rate, $d\Gamma$, in terms of $\mathcal{M}$. The correct expression is only a slight modification of (4.79), and is quite easy to guess: Just remove from (4.79) the factors that do not make sense when the initial state consists of a single particle. The definition of Γ assumes that the decaying particle is at rest, so the normalization factor $(2E_{\mathcal{A}})^{-1}$ becomes $(2m_{\mathcal{A}})^{-1}$. (In any other frame, this factor would give the usual time dilation.) Thus the decay rate formula is

$$d\Gamma = \frac{1}{2m_{\mathcal{A}}}\left(\prod_f \frac{d^3p_f}{(2\pi)^3}\frac{1}{2E_f}\right)|\mathcal{M}\left(m_{\mathcal{A}} \to \{p_f\}\right)|^2 (2\pi)^4\delta^{(4)}\left(p_{\mathcal{A}} - \sum p_f\right) \tag{4.86}$$

Unfortunately, the meaning of this formula is far from clear. Since an unstable particle cannot be sent into the infinitely distant past, our definition (4.73)
of $\mathcal{M}\left(m_{\mathcal{A}} \to \{p_f\}\right)$ in terms of the S-matrix makes no sense in this context. Nevertheless formula (4.86) is correct, when $\mathcal{M}$ is computed according to the Feynman rules for S-matrix elements that we will present in the following section. We postpone the further discussion of these matters, and the proof of Eq. (4.86), until Section 7.3. Until then, an intuitive notion of $\mathcal{M}$ as a transition amplitude should suffice.

Equations (4.79) and (4.86) are completely general, whether or not the final state contains several identical particles. (The computation of $\mathcal{M}$, of course, will be quite different when identical particles are present, but that is another matter.) When integrating either of these formulae to obtain a total cross section or decay rate, however, we must be careful to avoid counting the same final state several times. If there are n identical particles in the final state, we must either restrict the integration to inequivalent configurations, or divide by n ! after integrating over all sets of momenta.

14.5 4.6 Computing S-Matrix Elements from Feynman Diagrams

Now that we have formulae for cross sections and decay rates in terms of the invariant matrix element $\mathcal{M}$, the only remaining task is to find a way of computing $\mathcal{M}$ for various processes in various interacting field theories. In this section we will write down (and try to motivate) a formula for $\mathcal{M}$ in terms of Feynman diagrams. We postpone the actual proof of this formula until Section 7.2 , since the proof is somewhat technical and will be much easier to understand after we have seen how the formula is used.

Recall from its definition, Eq. (4.71), that the S-matrix is simply the time-evolution operator, $\exp(-iHt)$, in the limit of very large t:

$$\langle \mathbf{p}_1\mathbf{p}_2\cdots|\, S\,|\mathbf{k}_{\mathcal{A}}\mathbf{k}_{\mathcal{B}}\rangle = \lim_{T\to\infty}\langle \mathbf{p}_1\mathbf{p}_2\cdots|\, e^{-iH(2T)}\,|\mathbf{k}_{\mathcal{A}}\mathbf{k}_{\mathcal{B}}\rangle \tag{4.87}$$

To compute this quantity we would like to replace the external plane-wave states in (4.87), which are eigenstates of H, with their counterparts in the unperturbed theory, which are eigenstates of H_0. We successfully made such a replacement for the vacuum state $|\Omega\rangle$ in Eq. (4.27):

$$|\Omega\rangle = \lim_{T\to\infty(1-i\epsilon)}\left(e^{-iE_0T}\langle\Omega|0\rangle\right)^{-1} e^{-iHT}|0\rangle$$

This time we would like to find a relation of the form

$$|\mathbf{k}_{\mathcal{A}}\mathbf{k}_{\mathcal{B}}\rangle \propto \lim_{T\to\infty(1-i\epsilon)} e^{-iHT}\,|\mathbf{k}_{\mathcal{A}}\mathbf{k}_{\mathcal{B}}\rangle_0 \tag{4.88}$$

where we have omitted some unknown phases and overlap factors like those in (4.27). To find such a relation would not be easy. In (4.27), we used the fact that the vacuum was the state of absolute lowest energy. Here we can use only the much weaker statement that the external states with well-separated initial and final particles have the lowest energy consistent with the predetermined
nonzero values of momentum. The problem is a deep one, and it is associated with one of the most

fundamental difficulties of field theory, that interactions affect not only the scattering of distinct particles but also the form of the single-particle states themselves.

If the formula (4.88) could somehow be justified, we could use it to rewrite the right-hand side of (4.87) as

$$\begin{aligned}&\lim_{T\to\infty(1-i\epsilon)} {}_0\left\langle \mathbf{p}_1\cdots\mathbf{p}_n\right| e^{-iH(2T)}\left|\mathbf{p}_{\mathcal{A}}\mathbf{p}_{\mathcal{B}}\right\rangle_0 \\ &\quad\propto \lim_{T\to\infty(1-i\epsilon)} {}_0\left\langle \mathbf{p}_1\cdots\mathbf{p}_n\right| T\left(\exp\left[-i\int_{-T}^{T} dt H_I(t)\right]\right)\left|\mathbf{p}_{\mathcal{A}}\mathbf{p}_{\mathcal{B}}\right\rangle_0 \end{aligned} \tag{4.89}$$

In the evaluation of vacuum expectation values, the awkward proportionality factors between free and interacting vacuum states cancelled out of the final formula, Eq. (4.31). In the present case those factors are so horrible that we have not even attempted to write them down; we only hope that a similar dramatic cancellation will take place here. In fact such a cancellation does take place, although it is not easy to derive this conclusion from our present approach. Up to one small modification (which is unimportant for our present purposes), the formula for the nontrivial part of the S-matrix can be simplified to the following form:

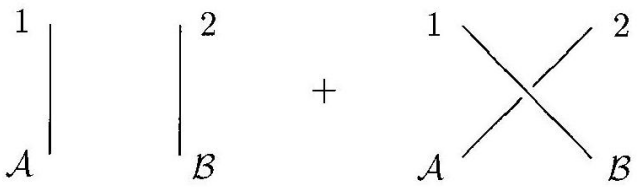
$$\begin{aligned}&\left\langle \mathbf{p}_1\cdots\mathbf{p}_n\right| iT\left|\mathbf{p}_{\mathcal{A}}\mathbf{p}_{\mathcal{B}}\right\rangle \\ &\quad=\lim_{T\to\infty(1-i\epsilon)}\left({}_0\left\langle \mathbf{p}_1\cdots\mathbf{p}_n\right| T\left(\exp\left[-i\int_{-T}^{T} dt H_I(t)\right]\right)\left|\mathbf{p}_{\mathcal{A}}\mathbf{p}_{\mathcal{B}}\right\rangle_0\right)_{\substack{\text{connected,}\\ \text{amputated}}}\end{aligned} \tag{4.90}$$

The attributes "connected" and "amputated" refer to restrictions on the class of possible Feynman diagrams; these terms will be defined in a moment. We will prove Eq. (4.90) in Section 7.2. In the remainder of this section, we will explain this formula and motivate the new restrictions that we have added.

First we must learn how to represent the matrix element in (4.90) as a sum of Feynman diagrams. Let us evaluate the first few terms explicitly, in ϕ^4 theory, for the case of two particles in the final state. The first term is

$$\begin{aligned}\left\langle \mathbf{p}_1\mathbf{p}_2|\mathbf{p}_{\mathcal{A}}\mathbf{p}_{\mathcal{B}}\right\rangle_0 =&\sqrt{2E_1 2E_2 2E_{\mathcal{A}} 2E_{\mathcal{B}}}\langle 0|a_1 a_2 a^\dagger_{\mathcal{A}} a^\dagger_{\mathcal{B}}|0\rangle \\ =&2E_{\mathcal{A}}2E_{\mathcal{B}}(2\pi)^6\left(\delta\left(\mathbf{p}_{\mathcal{A}}-\mathbf{p}_1\right)\delta\left(\mathbf{p}_{\mathcal{B}}-\mathbf{p}_2\right)\right. \\ &\left.+\delta\left(\mathbf{p}_{\mathcal{A}}-\mathbf{p}_2\right)\delta\left(\mathbf{p}_{\mathcal{B}}-\mathbf{p}_1\right)\right)\end{aligned} \tag{4.91}$$

The delta functions force the final state to be identical to the initial state, so this term is part of the ' 1 ' in $S = 1 + iT$, and does not contribute to the
scattering matrix element $\mathcal{M}$. We can represent it diagrammatically as



The next term in $\left\langle \mathbf{p}_1\mathbf{p}_2\right| S\left|\mathbf{p}_{\mathcal{A}}\mathbf{p}_{\mathcal{B}}\right\rangle$ is

$$
\begin{aligned}
&{}_0\langle \mathbf{p}_1\mathbf{p}_2|\, T\left(-i\frac{\lambda}{4!}\int d^4x\phi_I^4(x)\right)|\mathbf{p}_\mathcal{A}\mathbf{p}_\mathcal{B}\rangle_0 \\
&\quad = {}_0\langle \mathbf{p}_1\mathbf{p}_2|\, N\left(-i\frac{\lambda}{4!}\int d^4x\phi_I^4(x) + \text{ contractions }\right)|\mathbf{p}_\mathcal{A}\mathbf{p}_\mathcal{B}\rangle_0
\end{aligned}
\tag{4.92}
$$

using Wick's theorem. Since the external states are not $|0\rangle$, terms that are not fully contracted do not necessarily vanish; we can use an annihilation operator from $\phi_I(x)$ to annihilate an initial-state particle, or a creation operator from $\phi_I(x)$ to produce a final-state particle. For example,

$$
\begin{aligned}
\phi_I^+(x)|\mathbf{p}\rangle_0 &= \int \frac{d^3k}{(2\pi)^3}\frac{1}{\sqrt{2E_\mathbf{k}}}a_\mathbf{k}e^{-ik\cdot x}\sqrt{2E_\mathbf{p}}a_\mathbf{p}^\dagger|0\rangle \\
&= \int \frac{d^3k}{(2\pi)^3}\frac{1}{\sqrt{2E_\mathbf{k}}}e^{-ik\cdot x}\sqrt{2E_\mathbf{p}}(2\pi)^3\delta(\mathbf{k}-\mathbf{p})|0\rangle \\
&= e^{-ip\cdot x}|0\rangle
\end{aligned}
\tag{4.93}
$$

An uncontracted ϕ_I operator inside the N-product of (4.92) has two terms: ϕ_I^+on the far right and ϕ_I^-on the far left. We get one contribution to the S-matrix element for each way of commuting the a of ϕ_I^+past an initial-state $a^\dagger$, and one contribution for each way of commuting the $a^\dagger$ of ϕ_I^-past a finalstate a. It is natural, then, to define the contractions of field operators with external states as follows:

$$
(wickcontrlosthere)\ \phi_I(x)|\mathbf{p}\rangle = e^{-ip\cdot x};\quad {}^{p|\phi_I}(x) = e^{+ip\cdot x}
\tag{4.94}
$$

To evaluate an S-matrix element such as (4.92), we simply write down all possible full contractions of the ϕ_I operators and the external-state momenta.

To see that this prescription is correct, let us evaluate (4.92) in detail. The N-product contains terms of the form

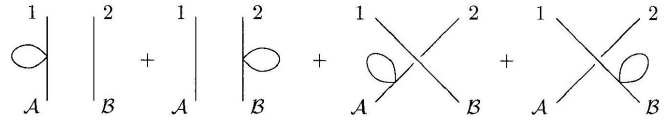
$$
\phi\phi\phi\phi; \qquad \overset{\sqcap}{\phi\phi\phi\phi}; \qquad \overset{\sqcap\ \sqcap}{\phi\phi\phi\phi}.
$$

The last term, in which the ϕ operators are fully contracted with each other, is equal to a vacuum bubble diagram times the value of (4.91) calculated above:

$$
\begin{aligned}
-i\tfrac{\lambda}{4!}\textstyle\int d^4x_0\,\langle \mathbf{p}_1\mathbf{p}_2|\,\phi\phi\phi\phi\,|\mathbf{p}_\mathcal{A}\mathbf{p}\mathcal{B}\rangle_0 \quad &= \bigotimes_\mathcal{A}^{\sqcap\sqcap}\times\big(|^1_\mathcal{B}\,| \\
&\times\,|^2_\mathcal{A}+1 \\
\mathcal{B}\qquad\qquad\qquad

$$\phi_I(\vec{x})|\mathbf{p}\Big\rangle = \Big\rangle_x \qquad \vec{p} \qquad \langle\mathbf{p}|\phi_I(x) = \overset{x\backslash}{\underset{x}{\overset{p}{}}} \tag{4.97}$$

Feynman diagrams for S-matrix elements will always contain external lines, rather than the external points of diagrams for correlation functions. The second term of (4.95) thus yields four diagrams:



The integration $\int d^4x$ produces a momentum-conserving delta function at each vertex (including the external momenta), so these diagrams again describe trivial processes in which the initial and final states are identical. This illustrates a general principle: Only fully connected diagrams, in which all external lines are connected to each other, contribute to the T-matrix.

Finally, consider the term of (4.95) in which none of the ϕ operators are contracted with each other. Our prescription tells us to contract two of the ϕ 's with $|\mathbf{p}_\mathcal{A}\mathbf{p}_\mathcal{B}\rangle$ and the other two with $\langle\mathbf{p}_1\mathbf{p}_2|$. There are 4 ! ways to do this.

Thus we obtain the diagram

$$\begin{aligned} &= (4!)\cdot\left(-i\tfrac{\lambda}{4!}\right)\int d^4x e^{-i(p_\mathcal{A}+p_\mathcal{B}-p_1-p_2)\cdot x} \\ &= -i\lambda(2\pi)^4\delta^{(4)}\left(p_\mathcal{A}+p_\mathcal{B}-p_1-p_2\right) \end{aligned} \tag{4.98}$$

This is exactly of the form $i\mathcal{M}(2\pi)^4\delta^{(4)}\left(p_\mathcal{A}+p_\mathcal{B}-p_1-p_2\right)$, with $\mathcal{M}=-\lambda$.
Before continuing our discussion of Feynman diagrams for S-matrix elements, we should certainly pause to turn this result into a cross section. For scattering in the center-of-mass frame, we can simply plug $|\mathcal{M}|^2=\lambda^2$ into Eq. (4.85) to obtain

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{CM}} = \frac{\lambda^2}{64\pi^2E_{\text{cm}}^2} \tag{4.99}$$

We have just computed our first quantum field theory cross section. It is a rather dull result, having no angular dependence at all. (This situation will be remedied when we consider fermions in the next section.) Integrating over $d\Omega$, and dividing by 2 since there are two identical particles in the final state, we find the total cross section,

$$\sigma_{\text{total}} = \frac{\lambda^2}{32\pi E_{\text{cm}}^2} \tag{4.100}$$

In practice, one would probably use this result to measure the value of λ.
Returning to our general discussion, let us consider some higher-order contributions to the T-matrix for the process $\mathcal{A},\mathcal{B}\to 1,2$. If we ignore, for the moment, the "connected and amputated" prescription, we have the formula

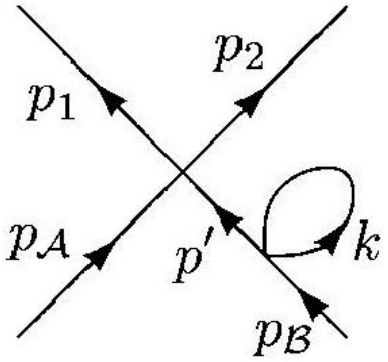
$$\begin{aligned} &\langle\mathbf{p}_1\mathbf{p}_2|\,iT\,|\mathbf{p}_\mathcal{A}\mathbf{p}_\mathcal{B}\rangle \overset{?}{=} \searrow + \chi + \chi + \infty + \cdots \\ &+ (\searrow 8) + \cdots + (\searrow 0) + \cdots \\ &+ > 0 + \cdots \end{aligned} \tag{4.101}$$

plus diagrams in which the four external lines are not all connected to each other. We have already seen that this last class of diagrams gives no contribution to the T-matrix. The first

diagram shown in (4.101) gives the lowest-order contribution to T, which we calculated above. The next three diagrams give
expected corrections to this amplitude, involving creation and annihilation of additional "virtual" particles.

The diagrams in the second line of (4.101) contain disconnected "vacuum bubbles". By the same argument as at the end of Section 4.4, the disconnected pieces exponentiate to an overall phase factor giving the shift of the energy of the interacting vacuum state upon which the scattering takes place. Thus they are irrelevant to S. We have now seen that only fully connected diagrams give sensible contributions to S-matrix elements.

The last diagram is more problematical; let us evaluate it. After integrating over the two vertex positions, we obtain

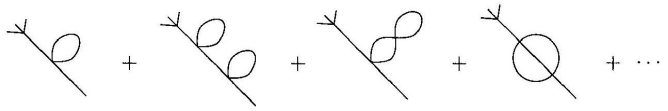


$$
\begin{aligned}
= \frac{1}{2} \int \frac{d^4p'}{(2\pi)^4} \frac{i}{p'^2 - m^2} \int \frac{d^4k}{(2\pi)^4} \frac{i}{k^2 - m^2} \\
\times (-i\lambda)(2\pi)^4 \delta^{(4)}\left(p_{\mathcal{A}} + p' - p_1 - p_2\right) \\
\times (-i\lambda)(2\pi)^4 \delta^{(4)}\left(p_{\mathcal{B}} - p'\right).
\end{aligned}
\tag{4.102}
$$

We can integrate over p' using the second delta function. It tells us to evaluate

$$
\left. \frac{1}{p'^2 - m^2} \right|_{p'=p_{\mathcal{B}}} = \frac{1}{p_{\mathcal{B}}^2 - m^2} = \frac{1}{0}.
$$

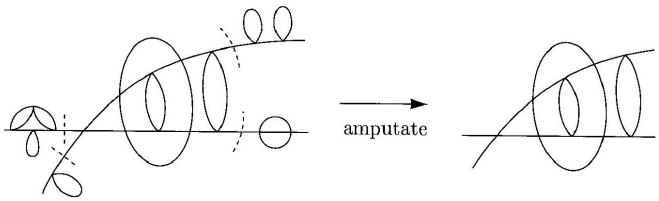
We get infinity, since $p_{\mathcal{B}}$, being the momentum of an external particle, is onshell: $p_{\mathcal{B}}^2 = m^2$. This is a disaster. Clearly, our formula for S makes sense only if we exclude diagrams of this form, that is, diagrams with loops connected to only one external leg. Fortunately, this is physically reasonable: In the same way that the vacuum bubble diagrams represent the evolution of $|0\rangle$ into $|\Omega\rangle$, these external leg corrections,



represent the evolution of $|\mathbf{p}\rangle_0$ into $|\mathbf{p}\rangle$, the single-particle state of the interacting theory. Since these corrections have nothing to do with the scattering process, we should exclude them from the computation of S.

For a general diagram with external legs, we define amputation in the following way. Starting from the tip of each external leg, find the last point at which the diagram can be cut by removing a single propagator, such that this operation separates the leg from the rest of the diagram. Cut

there. For example:



Let us summarize our prescription for calculating scattering amplitudes. Our formula for S-matrix elements, Eq. (4.90), can be rewritten

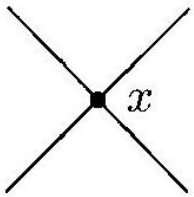
$$\begin{aligned} &i\mathcal{M}\cdot(2\pi)^4\delta^{(4)}\left(p_{\mathcal{A}}+p_{\mathcal{B}}-\sum p_f\right) \\ &\qquad = \left(\begin{array}{l}\text{sum of all connected, amputated Feynman} \\ \text{diagrams with } p_{\mathcal{A}}, p_{\mathcal{B}} \text{ incoming, } p_f \text{ outgoing}\end{array}\right). \end{aligned} \tag{4.103}$$

By 'connected', we now mean fully connected, that is, with no vacuum bubbles, and all external legs connected to each other. The Feynman rules for scattering amplitudes in ϕ^4 theory are, in position space,

1. For each propagator,

$$= D_F(x-y);$$

2. For each vertex,



$$= (-i\lambda)\int d^4x$$

3. For each external line,

$$= e^{-ip\cdot x};$$

4. Divide by the symmetry factor.

Notice that the factor for an ingoing line is just the amplitude for that particle to be found at the vertex it connects to, i.e., the particle's wavefunction. Similarly, the factor for an outgoing line is the amplitude for a particle produced at the vertex to have the desired final momentum.

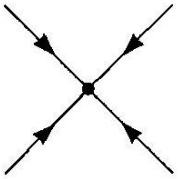
Just as with the Feynman rules for correlation functions, it is usually simpler to introduce the momentum-space representation of the propagators, carry out the vertex integrals to obtain

momentum-conserving delta functions, and use these delta functions to evaluate as many momentum integrals as possible. In a scattering amplitude, however, there will always be an overall delta function, which can be used to cancel the one on the left-hand side of Eq. (4.103). We are then left with

$$i\mathcal{M} = \text{ sum of all connected, amputated diagrams,} \tag{4.104}$$

where the diagrams are evaluated according to the following rules:

1. For each propagator, $\longrightarrow p = \frac{i}{p^2 - m^2 + i\epsilon}$;
2. For each vertex,



$= -i\lambda;$

3. For each external line,

$= 1;$

4. Impose momentum conservation at each vertex;
5. Integrate over each undetermined loop momentum: $\int \frac{d^4p}{(2\pi)^4}$;
6. Divide by the symmetry factor.

This is our final version of the Feynman rules for ϕ^4 theory; these rules are also listed in the Appendix, for reference.

Actually, Eq. (4.103) still isn't quite correct. One more modification is necessary, involving the proportionality factors that were omitted from Eq. (4.89). But the modification affects only diagrams containing loops, so we postpone its discussion until Chapters 6 and 7 , where we first evaluate such diagrams. We will prove the corrected formula (4.103) in Section 7.2, by relating S matrix elements to correlation functions, for which we have actually derived a formula in terms of Feynman diagrams.

14.6 4.7 Feynman Rules for Fermions

So far in this chapter we have discussed only ϕ^4 theory, in order to avoid unnecessary complication. We are now ready to generalize our results to theories containing fermions.

Our treatment of correlation functions in Section 4.2 generalizes without difficulty. Lorentz invariance requires that the interaction Hamiltonian H_I be a product of an even number of spinor fields, so no difficulties arise in defining the time-ordered exponential of H_I.

To apply Wick's theorem, however, we must generalize the definitions of the time-ordering and normal-ordering symbols to include fermions. We saw at the end of Section 3.5 that the time-ordering operator T acting on two spinor fields is most conveniently defined with an additional minus sign:

$$T(\psi(x)\bar{\psi}(y)) \equiv \begin{cases} \psi(x)\bar{\psi}(y) \text{ for } x^0 > y^0 \\ -\bar{\psi}(y)\psi(x) \text{ for } x^0 < y^0 \end{cases} \tag{4.105}$$

With this definition, the Feynman propagator for the Dirac field is

$$S_F(x-y) = \int \frac{d^4p}{(2\pi)^4} \frac{i(\not{p}+m)}{p^2 - m^2 + i\epsilon} e^{-ip\cdot(x-y)} = \langle 0|T\psi(x)\bar{\psi}(y)|0\rangle. \tag{4.106}$$

For products of more than two spinor fields, we generalize this definition in the natural way: The time-ordered product picks up one minus sign for each interchange of operators that is necessary to put the fields in time order. For example,

$$T\left(\psi_1\psi_2\psi_3\psi_4\right) = (-1)^3\psi_3\psi_1\psi_4\psi_2 \quad \text{if} \quad x_3^0 > x_1^0 > x_4^0 > x_2^0$$

The definition of the normal-ordered product of spinor fields is analogous: Put in an extra minus sign for each fermion interchange. The anticommutation properties make it possible to write a normal-ordered product in several ways, but with our conventions these are completely equivalent:

$$N\left(a_{\mathbf{p}}a_{\mathbf{q}}a_{\mathbf{r}}^\dagger\right) = (-1)^2 a_{\mathbf{r}}^\dagger a_{\mathbf{p}} a_{\mathbf{q}} = (-1)^3 a_{\mathbf{r}}^\dagger a_{\mathbf{q}} a_{\mathbf{p}}$$

Using these definitions, it is not hard to generalize Wick's theorem. Consider first the case of two Dirac fields, say $T[\psi(x)\bar{\psi}(y)]$. In analogy with (4.37), define the contraction of two fields by

$$T[\psi(x)\bar{\psi}(y)] = N[\psi(x)\bar{\psi}(y)] + \overrightarrow{\psi(x)}\,\bar{\psi}(y) \tag{4.107}$$

Explicitly, for the Dirac field,

$$\overrightarrow{\psi(x)}\bar{\psi}\,(y) \equiv \left\{ \begin{array}{ll} \left\{\psi^+(x), \bar{\psi}^-(y)\right\} & \text{for } x^0 > y^0 \\ -\left\{\bar{\psi}^+(y), \psi^-(x)\right\} & \text{for } x^0 < y^0 \end{array} \right\} = S_F(x-y); \tag{4.108}$$

$$\overrightarrow{\psi(x)}\psi\,(y) = \overrightarrow{\bar{\psi}}(x)\bar{\psi}(y) = 0 \tag{4.109}$$

Define contractions under the normal-ordering symbol to include minus signs for operator interchanges:

$$N\left(\psi_1\psi_2\bar{\psi}_3\bar{\psi}_4\right) = -\overset{\psi}{\bar{\psi}}_{13} N\left(\psi_2\bar{\psi}_4\right) = -S_F\left(x_1 - x_3\right) N\left(\psi_2\bar{\psi}_4\right) \tag{4.110}$$

With these conventions, Wick's theorem takes the same form as before:

$$T\left[\psi_1\bar{\psi}_2\psi_3\cdots\right] = N\left[\psi_1\bar{\psi}_2\psi_3\cdots + \text{ all possible contractions }\right] \tag{4.111}$$

The proof is essentially unchanged from the bosonic case, since all extra minus signs are accounted for by the above definitions.

Yukawa Theory

Writing down the Feynman rules for fermion correlation functions would now be easy, but instead let's press on and discuss scattering processes. For definiteness, we begin by analyzing the Yukawa theory:

$$H = H_{\text{Dirac}} + H_{\text{Klein-Gordon}} + \int d^3x g\bar{\psi}\psi\phi \tag{4.112}$$

This is a simplified model of Quantum Electrodynamics. In this section we will carefully work out the rules of calculation for Yukawa theory, so that in the next section we can guess the rules for QED without too much difficulty.

To be even more specific, consider the two-particle scattering reaction

$$\text{fermion } (p) + \text{ fermion } (k) \longrightarrow \text{ fermion } (p') + \text{ fermion } (k')$$

The leading contribution comes from the H_I^2 term of the S-matrix:

$${}_0\langle \mathbf{p}', \mathbf{k}'| T\left(\frac{1}{2!}(-ig)\int d^4x \bar{\psi}_I\psi_I\phi_I \quad (-ig)\int d^4y \bar{\psi}_I\psi_I\phi_I\right)|\mathbf{p},\mathbf{k}\rangle_0 \tag{4.113}$$

To evaluate this expression, use Wick's theorem to reduce the T-product to an N -product of contractions, then act the uncontracted fields on the initialand final-state particles. Represent this latter process as the contraction

$$\begin{aligned} {}^{\ulcorner\psi_I(x)|\mathbf{p},s\rangle} &= \int \frac{d^3p'}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}'}}}\sum_{s'} a^{s'}_{\mathbf{p}'}u^{s'}(p')\, e^{-ip'\cdot x}\sqrt{2E_{\mathbf{p}}}a^{s\dagger}_{\mathbf{p}}|0\rangle \\ &= e^{-ip\cdot x}u^s(p)|0\rangle \end{aligned} \tag{4.114}$$

Similar expressions hold for the contraction of $\bar{\psi}_I$ with a final-state fermion, and for contractions of ψ_I and $\bar{\psi}_I$ with antifermion states. Note that ψ_I can be contracted with a fermion on the right or an antifermion on the left; the opposite is true for $\bar{\psi}_I$.

We can write a typical contribution to the matrix element (4.113) as the contraction

$$\langle \mathbf{p}', \mathbf{k}'|\tfrac{1}{2!}(-ig)\textstyle\int d^4x\, \bar{\psi}\psi\phi\ (-ig)\int d^4y\, \bar{\psi}\psi\phi\, |\mathbf{p},\mathbf{k}\rangle.$$

Up to a possible minus sign, the value of this quantity is

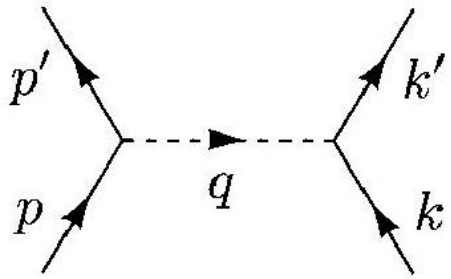
$$\begin{aligned} &(-ig)^2\int \frac{d^4q}{(2\pi)^4}\frac{i}{q^2-m_\phi^2}(2\pi)^4\delta(p'-p-q) \\ &\times(2\pi)^4\delta(k'-k+q)\,\bar{u}(p')u(p)\bar{u}(k')u(k) \end{aligned}$$

(We have dropped the factor 1/2 ! because there is a second, identical term that comes from interchanging x and y in (4.115).) Using either delta function to perform the integral, we find that this expression takes the form $i\mathcal{M}(2\pi)^4\delta(\Sigma p)$, with

$$i\mathcal{M} = \frac{-ig^2}{q^2-m_\phi^2}\bar{u}(p')u(p)\bar{u}(k')u(k) \tag{4.116}$$

When writing it in this way, we must remember to impose the constraints $p-p'=q=k'-k$.

Instead of working from (4.115), we could draw a Feynman diagram:



We denote scalar particles by dashed lines, and fermions by solid lines. The S matrix element could then be obtained directly from the following momentumspace Feynman rules.

1. Propagators:

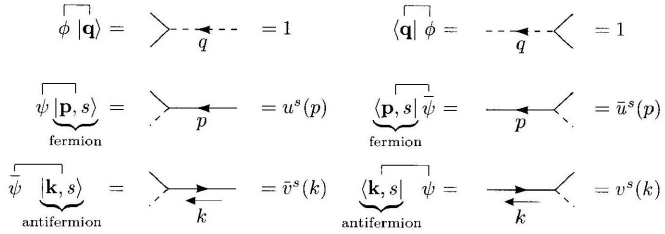
$$\phi(\overrightarrow{x})\phi\,(y) = \cdots = \frac{i}{q^2 - m_\phi^2 + i\epsilon}$$

$$\sqrt{\psi(x)\bar{\psi}(y)} = \xrightarrow[p]{p} = \frac{i(\not{p} + m)}{p^2 - m^2 + i\epsilon}$$

ces:

2. Vertices:

3. External leg contractions:



4. Impose momentum conservation at each vertex.

5. Integrate over each undetermined loop momentum.

6. Figure out the overall sign of the diagram.

Several comments are in order regarding these rules.
First, note that the $1/n\,!$ from the Taylor series of the time-ordered exponential is always canceled by the $n\,!$ ways of interchanging vertices to obtain the same contraction. The diagrams of Yukawa theory never have symmetry factors, since the three fields $(\bar{\psi}\psi\phi)$ in H_I cannot substitute for one another in contractions.

Second, the direction of the momentum on a fermion line is always significant. On external lines, as for bosons, the direction of the momentum is always
ingoing for initial-state particles and outgoing for final-state particles. This follows immediately from the expansions of ψ and $\bar{\psi}$, where the annihilation operators $a_{\mathbf{p}}$ and $b_{\mathbf{p}}$ both multiply $e^{-ip\cdot x}$ and the creation operators $a_{\mathbf{p}}^\dagger$ and $b_{\mathbf{p}}^\dagger$ both multiply $e^{+ip\cdot x}$. On internal fermion lines (propagators), the momentum must be assigned in the direction of particle-number flow (for electrons, this is the

direction of negative charge flow). This requirement is most easily seen by working out an example from first principles. Consider the annihilation of a fermion and an antifermion into two bosons:

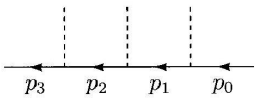
$$\ddots$$

$$\sim \int d^4x \int d^4y \bar{v}\,(p')\, e^{-ip'\cdot x} \int \frac{d^4q}{(2\pi)^4} \frac{i(d+m)}{q^2-m^2} e^{-iq\cdot(x-y)} u(p) e^{-ip\cdot y}$$

The integrals over x and y give delta functions that force q to flow from y to x, as shown. On internal boson lines the direction of the momentum is irrelevant and may be chosen for convenience, since $D_F(x-y) = D_F(y-x)$.

It is conventional to draw arrows on fermion lines, as shown, to represent the direction of particle-number flow. The momentum assigned to a fermion propagator then flows in the direction of this arrow. For external antiparticles, however, the momentum flows opposite to the arrow; it helps to show this explicitly by drawing a second arrow next to the line.

Third, note that in our examples the Dirac indices contract together along the fermion lines. This will also happen in more complicated diagrams:



$$\sim \bar{u}(p_3) \cdot \frac{i(\not{p}_2 + m)}{p_2^2 - m^2} \cdot \frac{i(\not{p}_1 + m)}{p_1^2 - m^2} \cdot u(p_0).$$

Finally, let's take a moment to worry about fermion minus signs. Return to the example of the fermion-fermion scattering process. We adopt a sign convention for the initial and final states:

$$|\mathbf{p},\mathbf{k}\rangle \sim a^\dagger_{\mathbf{p}} a^\dagger_{\mathbf{k}} |0\rangle, \quad \langle \mathbf{p}',\mathbf{k}'| \sim \langle 0| a_{\mathbf{k}'} a_{\mathbf{p}'} \tag{4.118}$$

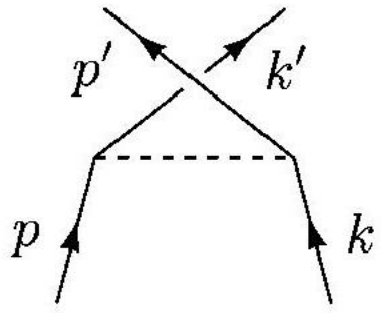
so that $(|p,k\rangle)^\dagger = \langle p,k|$. Then the contraction

$$\langle \mathbf{p}',\mathbf{k}'|(\bar\psi\psi)_x\,(\bar\psi\psi)_y|\mathbf{p},\mathbf{k}\rangle \sim \langle 0|\, a_{\mathbf{k}'} a_{\mathbf{p}'}\, \bar\psi_x \psi_x\, \bar\psi_y \psi_y\, a^\dagger_{\mathbf{p}} a^\dagger_{\mathbf{k}}\, |0\rangle$$

can be untangled by moving $\bar\psi_y$ two spaces to the left, and so picks up a factor of $(-1)^2 = +1$. But note that in the contraction

$$\langle \mathbf{p}',\mathbf{k}'|\,(\bar\psi\psi)_x(\bar\psi\psi)_y|\mathbf{p},\mathbf{k}\rangle \sim \langle 0|a_{\mathbf{k}'}a_{\mathbf{p}'}\bar\psi_x\psi_x\bar\psi_y\psi_y a^\dagger_{\mathbf{p}} a^\dagger_{\mathbf{k}}|0\rangle$$

it is sufficient to move the $\bar\psi_y$ one space to the left, giving a factor of -1 . This contraction corresponds to the diagram



The full result, to lowest order, for the S-matrix element for this process is therefore

$$
\begin{aligned}
i\mathcal{M} &= p' \\
&= \left(-ig^2\right)\left(\bar{u}\left(p'\right)u(p)\frac{1}{\left(p'-p\right)^2-m_\phi^2}\bar{u}\left(k'\right)u(k)\right. \\
&\quad \left.-\bar{u}\left(p'\right)u(k)\frac{1}{\left(p'-k\right)^2-m_\phi^2}\bar{u}\left(k'\right)u(p)\right).
\end{aligned} \tag{4.119}
$$

The minus sign difference between these diagrams is a reflection of Fermi statistics. Turning this expression into an explicit cross section would require some additional work; we postpone such calculations until Chapter 5 , when we can work with QED instead of the less interesting Yukawa theory.

In complicated diagrams, one can often simplify the determination of the minus signs by noting that the product $(\bar{\psi}\psi)$, or any other pair of fermions, commutes with any operator. Thus,

$$
\begin{aligned}
\cdots(\bar{\psi}\psi)_x(\bar{\psi}\psi)_y(\bar{\psi}\psi)_z(\bar{\psi}\psi)_w\cdots &= \cdots(+1)(\bar{\psi}\psi)_x(\bar{\psi}\psi)_z(\bar{\psi}\psi)_y(\bar{\psi}\psi)_w\cdots \\
&= \cdots S_F(x-z)S_F(z-y)S_F(y-w)\cdots
\end{aligned}
$$

But note that in a closed loop of n fermion propagators we have

$$
\begin{aligned}
=&\sqrt{\psi}\psi\sqrt{\psi}\sqrt{}\sqrt{\psi}\psi\sqrt{\psi}\psi \\
&= (-1)\,\mathrm{tr}[\sqrt{\psi}\bar{\psi}\bar{\psi}\psi\bar{\psi}\psi\bar{\psi}] \\
&= (-1)\,\mathrm{tr}\left[S_F S_F S_F S_F\right]
\end{aligned}
$$

A closed fermion loop always gives a factor of -1 and the trace of a product of Dirac matrices.

The Yukawa Potential

We now have all the formal rules we need to compute scattering amplitudes in Yukawa theory. Before going on to discuss QED, let us briefly descend from abstraction to concrete physics, and consider one very simple application of these rules: the scattering of distinguishable fermions, in the nonrelativistic limit. By comparing the amplitude for this process to the Born approximation formula from nonrelativistic quantum mechanics, we can determine the potential $V(r)$ created by the Yukawa interaction.

If the two interacting particles are distinguishable, only the first diagram in (4.119) contributes. To evaluate the amplitude in the nonrelativistic limit, we keep terms only to lowest order in the 3 -momenta. Thus, up to $\mathcal{O}\left(\mathbf{p}^2,\mathbf{p}'^2,\ldots\right)$,

$$
\begin{aligned}
p &= (m,\mathbf{p}), & k &= (m,\mathbf{k}), \\
p' &= (m,\mathbf{p}'), & k' &= (m,\mathbf{k}')
\end{aligned} \tag{4.121}
$$

Using these expressions, we have

$$
\begin{aligned}
\left(p'-p\right)^2 &= -\left|\mathbf{p}'-\mathbf{p}\right|^2+\mathcal{O}\left(\mathbf{p}^4\right), \\
u^s(p) &= \sqrt{m}\begin{pmatrix}\xi^s\\ \xi^s\end{pmatrix}, \quad \text{etc.}
\end{aligned}
$$

where ξ^s is a two-component constant spinor normalized to $\xi^{s'\dagger}\xi^s = \delta^{ss'}$. The spinor products in (4.119) are then

$$\begin{aligned} \bar{u}^{s'}(p')\,u^s(p) &= 2m\xi^{s'\dagger}\xi^s = 2m\delta^{ss'} \\ \bar{u}^{r'}(k')\,u^r(k) &= 2m\xi^{r'\dagger}\xi^r = 2m\delta^{rr'} \end{aligned} \tag{4.122}$$

So our first physical conclusion is that the spin of each particle is separately conserved in this nonrelativistic scattering interaction-a pleasing result.

Putting together the pieces of the scattering amplitude (4.119), we find

$$i\mathcal{M} = \frac{ig^2}{|\mathbf{p}'-\mathbf{p}|^2 + m_\phi^2} 2m\delta^{ss'} 2m\delta^{rr'} \tag{4.123}$$

This should be compared with the Born approximation to the scattering amplitude in nonrelativistic quantum mechanics, written in terms of the potential function $V(\mathbf{x})$:

$$\langle p'|\, iT|p\rangle = -i\widetilde{V}(\mathbf{q})(2\pi)\delta\left(E_{\mathbf{p}'} - E_{\mathbf{p}}\right), \quad (\mathbf{q} = \mathbf{p}' - \mathbf{p}) \tag{4.124}$$

So apparently, for the Yukawa interaction,

$$\widetilde{V}(\mathbf{q}) = \frac{-g^2}{|\mathbf{q}|^2 + m_\phi^2} \tag{4.125}$$

(The factors of $2m$ in (4.123) arise from our relativistic normalization conventions, and must be dropped when comparing to (4.124), which assumes conventional nonrelativistic normalization of states. The additional $\delta^{(3)}(\mathbf{p}'-\mathbf{p})$ goes away when we integrate over the momentum of the target.)

Inverting the Fourier transform to find $V(\mathbf{x})$ requires a short calculation:

$$\begin{aligned} V(\mathbf{x}) &= \int \frac{d^3q}{(2\pi)^3} \frac{-g^2}{|\mathbf{q}|^2 + m_\phi^2} e^{i\mathbf{q}\cdot\mathbf{x}} \\ &= \frac{-g^2}{4\pi^2} \int_0^\infty dq q^2 \frac{e^{iqr} - e^{-iqr}}{iqr} \frac{1}{q^2 + m_\phi^2} \\ &= \frac{-g^2}{4\pi^2 ir} \int_{-\infty}^\infty dq \frac{qe^{iqr}}{q^2 + m_\phi^2} \end{aligned} \tag{4.126}$$

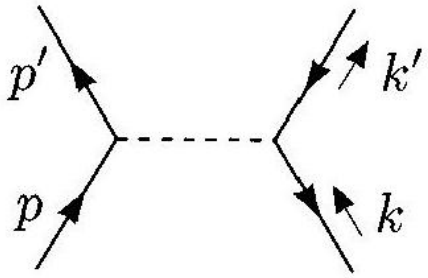
The contour of this integral can be closed above in the complex plane, and we pick up the residue of the simple pole at $q = +im_\phi$. Thus we find

$$V(r) = -\frac{g^2}{4\pi}\frac{1}{r}e^{-m_\phi r} \tag{4.127}$$

an attractive "Yukawa potential", with range $1/m_\phi = \hbar/m_\phi c$, the Compton wavelength of the exchanged boson. Yukawa made this potential the basis for his theory of the nuclear force, and worked backwards from the range of the force (about 1 fm) to predict the mass (about 200 MeV) of the required boson, the pion.

What happens if instead we scatter particles off of antiparticles? For the process

$$f_1(p)\bar{f}_2(k) \longrightarrow f_1(p')\,\bar{f}_2(k')$$



we need to evaluate (nonrelativistically)

$$\bar{v}^s(k)v^{s'}(k') \approx m\left(\xi^{s\dagger}, -\xi^{s\dagger}\right)\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} \xi^{s'} \\ -\xi^{s'} \end{pmatrix} = -2m\delta^{ss'} \tag{4.128}$$

We must also work out the fermion minus sign. Using $|\mathbf{p},\mathbf{k}\rangle = a^\dagger_{\mathbf{p}} b^\dagger_{\mathbf{k}}|0\rangle$ and $\langle \mathbf{p}',\mathbf{k}'| = \langle 0|b_{\mathbf{k}'}a_{\mathbf{p}'}$, we can write the contracted matrix element as

$$\langle \mathbf{p}',\mathbf{k}'|\,\bar{\psi}\psi\;\bar{\psi}\psi\,|\mathbf{p},\mathbf{k}\rangle = \langle 0|\,b_{\mathbf{k}'}a_{\mathbf{p}'}\;\bar{\psi}\psi\;\bar{\psi}\psi\;a^\dagger_{\mathbf{p}}b^\dagger_{\mathbf{k}}\,|0\rangle\,.$$

To untangle the contractions requires three operator interchanges, so there is an overall factor of -1 . This cancels the extra minus sign in (4.128), and therefore we see that the Yukawa potential between a fermion and an antifermion is also attractive, and identical in strength to that between two fermions.

The remaining case to consider is scattering of two antifermions. It should not be surprising that the potential is again attractive; there is an additional minus sign from changing the other $\bar{u}u$ into $\bar{v}v$, and the number of interchanges necessary to untangle the contractions is even. Thus we conclude that the Yukawa potential is universally attractive, whether it is between a pair of fermions, a pair of antifermions, or one of each.

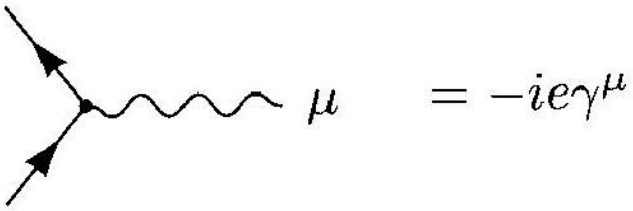
14.7 4.8 Feynman Rules for Quantum Electrodynamics

Now we are ready to step from Yukawa theory to Quantum Electrodynamics. To do this, we replace the scalar particle ϕ with a vector particle A_μ, and replace the Yukawa interaction Hamiltonian with

$$H_{\text{int}} = \int d^3x e\bar{\psi}\gamma^\mu\psi A_\mu \tag{4.129}$$

How do the Feynman rules change? The answer, though difficult to prove, is easy to guess. In addition to the fermion rules from the previous section, we have

New vertex:



Photon propagator:

$$\mu \smile\!\!\!\!\!\!\sim\!\!\!\!\!\!\sim \nu = \frac{-ig_{\mu\nu}}{q^2 + i\epsilon}$$

External photon lines:

$$\overleftarrow{A_\mu|\mathbf{p}\rangle} = \widetilde{\sim}\mu = \epsilon_\mu(p)$$
$$\rightarrow_{\mathbf{p}|A_\mu} = \mu\widetilde{\sim} \,| = \epsilon^*_\mu(p)$$

Photons are conventionally drawn as wavy lines. The symbol $\epsilon_\mu(p)$ stands for the polarization vector of the initial- or final-state photon.

To justify these rules, recall that in Lorentz gauge (which we employ to retain explicit relativistic invariance) the field equation for A_μ is

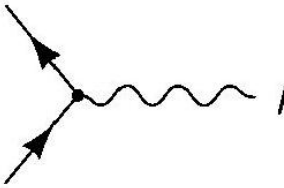
$$\partial^2 A_\mu = 0 \tag{4.130}$$

Thus each component of A separately obeys the Klein-Gordon equation (with $m = 0$). The momentum-space solutions of this equation are $\epsilon_\mu(p)e^{-ip\cdot x}$, where $p^2 = 0$ and $\epsilon_\mu(p)$ is any 4 - vector. The interpretation of ϵ as the polarization vector of the field should be familiar from classical electromagnetism. If we expand the quantized electromagnetic field in terms of classical solutions of the wave equation, as we did for the Klein-Gordon field, we find

$$A_\mu(x) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\sum_{r=0}^{3}\left(a^r_{\mathbf{p}}\epsilon^r_\mu(p)e^{-ip\cdot x} + a^{r\dagger}_{\mathbf{p}}\epsilon^{r*}_\mu(p)e^{ip\cdot x}\right) \tag{4.131}$$

where $r = 0, 1, 2, 3$ labels a basis of polarization vectors. The external line factors in the Feynman rules above follow immediately from this expansion, just as we obtained u 's and v 's as the external line factors for Dirac particles. The only subtlety is that we must restrict initial- and final-state photons to be transversely polarized: Their polarization vectors are always of the form $\epsilon^\mu = (0, \boldsymbol{\epsilon})$, where $\mathbf{p}\cdot\boldsymbol{\epsilon} = 0$. For $\mathbf{p}$ along the z-axis, the right- and left-handed polarization vectors are $\epsilon^\mu = (0, 1, \pm i, 0)/\sqrt{2}$.

The form of the QED vertex factor is also easy to justify, by simply looking at the interaction Hamiltonian (4.129). Note that the γ matrix in a QED amplitude will sit between spinors or other γ matrices, with the Dirac indices contracted along the fermion line. Note also that this interaction term is specific to the case of an electron (and its antiparticle, the positron). In general, for a Dirac particle with electric charge $Q|e|$,



$$= -iQ|e|\gamma^\mu.$$

For example, an electron has $Q = -1$, an up quark has $Q = +2/3$, and a down quark has $Q_d = -1/3$.

There is no easy way to derive the form of the photon propagator, so for now we will settle for a plausibility argument. Since the electromagnetic field in Lorentz gauge obeys the massless Klein-Gordon equation, it should come as no surprise that the photon propagator is nearly identical to the massless Klein-Gordon propagator. The factor of $-g_{\mu\nu}$, however, requires explanation.

Lorentz invariance dictates that the photon propagator be an isotropic secondrank tensor that can dot together the γ^μ and γ^ν from the vertices at each end. The simplest candidate is $g^{\mu\nu}$. To understand the overall sign of the propagator, evaluate its Fourier transform:

$$\int \frac{d^4q}{(2\pi)^4}\frac{-ig_{\mu\nu}}{q^2+i\epsilon}e^{-iq\cdot(x-y)} = \int \frac{d^3q}{(2\pi)^3}\frac{1}{2|\mathbf{q}|}e^{-iq\cdot(x-y)}\cdot(-g_{\mu\nu}) \tag{4.132}$$

Presumably this is equal to $\langle 0|T\left[A_\mu(x)A_\nu(y)\right]|0\rangle$. Now set $\mu=\nu$, and take the limit $x^0 \to y^0$ from the positive direction. Then this quantity becomes the norm of the state $A_\mu(x)|0\rangle$, which should be positive. We see that our choice of signs in the propagator implies that the three states created by A_i, with with $i=1,2,3$, indeed have positive norm. These states include all real (nonvirtual) photons, which always have spacelike polarizations. Unfortunately, because $g_{\mu\nu}$ is not positive definite, the states created by A_0 inevitably have negative norm. This is potentially a serious problem for any theory with vector particles. For Quantum Electrodynamics, we will show in Section 5.5 that the negative-norm states created by A_0 are never produced in physical processes. In Section 9.4 we will give a careful derivation of the photon propagator.

The Coulomb Potential

As a simple application of these Feynman rules, and to better understand the sign of the propagator, let us repeat the nonrelativistic scattering calculation of the previous section, this time for QED. The leading-order contribution is

$i\mathcal{M} =$ 
$= (-ie)^2\bar{u}(p')\gamma^\mu u(p)\frac{-ig_{\mu\nu}}{(p'-p)^2}\bar{u}(k')\gamma^\nu u(k).$

In the nonrelativistic limit,

$$\bar{u}\left(p'\right)\gamma^0 u(p) = u^\dagger\left(p'\right)u(p) \approx +2m\xi'^\dagger\xi$$

You can easily verify that the other terms, $\bar{u}\left(p'\right)\gamma^i u(p)$, vanish if $p=p'=0$; they can therefore be neglected compared to $\bar{u}\left(p'\right)\gamma^0 u(p)$ in the nonrelativistic limit. Thus we have

$$\begin{aligned} i\mathcal{M} &\approx \frac{+ie^2}{-\left|\mathbf{p}'-\mathbf{p}\right|^2}\left(2m\xi'^\dagger\xi\right)_p\left(2m\xi'^\dagger\xi\right)_k\cdot g_{00} \\ &= \frac{-ie^2}{\left|\mathbf{p}'-\mathbf{p}\right|^2}\left(2m\xi'^\dagger\xi\right)_p\left(2m\xi'^\dagger\xi\right)_k \end{aligned} \tag{4.134}$$

Comparing this to the Yukawa case (4.123), we see that there is an extra factor of -1 ; the potential is a repulsive Yukawa potential with $m=0$, that is, a repulsive Coulomb potential:

$$V(r) = \frac{e^2}{4\pi r} = \frac{\alpha}{r} \tag{4.135}$$

where $\alpha = e^2/4\pi \approx 1/137$ is the fine-structure constant.
For particle-antiparticle scattering, note first that

$$\bar{v}(k)\gamma^0 v\left(k'\right) = v^\dagger(k)v\left(k'\right) \approx +2m\xi^\dagger\xi'$$

The presence of the γ^0 eliminates the minus sign that we found in the Yukawa case. The nonrelativistic scattering amplitude is therefore

$$i\mathcal{M} = p^{p'}{}_{k'} = (-1) \cdot \frac{-ie^2}{|\mathbf{p}' - \mathbf{p}|^2} \left(+2m\xi'^{\dagger}\xi\right)_p \left(+2m\xi^{\dagger}\xi'\right)_k \tag{4.136}$$

where the (-1) is the same fermion minus sign we saw in the Yukawa case. This is an attractive potential. Similarly, for antifermion-antifermion scattering one finds a repulsive potential. We have just verified that in quantum field theory, when a vector particle is exchanged, like charges repel while unlike charges attract.

Note that the repulsion in fermion-fermion scattering came entirely from the extra factor $-g_{00} = -1$ in the vector boson propagator. A tensor boson, such as the graviton, would have a propagator

$$\mu\nu \curvearrowright\sim\sim\sim \rho\sigma = \frac{1}{2}\left((-g_{\mu\rho})(-g_{\nu\sigma}) + (-g_{\mu\sigma})(-g_{\nu\rho})\right)\left(\frac{i}{q^2 + i\epsilon}\right)$$

which in nonrelativistic collisions gives a factor $(-g_{00})^2 = +1$; this will result in a universally attractive potential. It is reassuring to see that quantum field theory does indeed reproduce the obvious features of the electric and gravitational forces:

Exchanged particle	ff and $\bar{f}\bar{f}$	$f\bar{f}$
scalar (Yukawa)	attractive	attractive
vector (electricity)	repulsive	attractive
tensor (gravity)	attractive	attractive

Problems

4.1 Let us return to the problem of the creation of Klein-Gordon particles by a classical source. Recall from Chapter 2 that this process can be described by the Hamiltonian

$$H = H_0 + \int d^3x(-j(t,\mathbf{x})\phi(x))$$

where H_0 is the free Klein-Gordon Hamiltonian, $\phi(x)$ is the Klein-Gordon field, and $j(x)$ is a c-number scalar function. We found that, if the system is in the vacuum state before the source is turned on, the source will create a mean number of particles

$$\langle N\rangle = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}|\tilde{j}(p)|^2$$

In this problem we will verify that statement, and extract more detailed information, by using a perturbation expansion in the strength of the source.
(a) Show that the probability that the source creates no particles is given by

$$P(0) = \left|\langle 0|T\left\{\exp\left[i\int d^4x j(x)\phi_I(x)\right]\right\}\right| 0\Big\rangle\,|^2$$

(b) Evaluate the term in P(0) of order j^2, and show that $P(0) = 1 - \lambda + \mathcal{O}(j^4)$, where λ equals the expression given above for $\langle N\rangle$.
(c) Represent the term computed in part (b) as a Feynman diagram. Now represent the whole pertubation series for $P(0)$ in terms of Feynman diagrams. Show that this series exponentiates, so that it can be summed exactly: $P(0) = \exp(-\lambda)$.
(d) Compute the probability that the source creates one particle of momentum k. Perform this

computation first to $\mathcal{O}(j)$ and then to all orders, using the trick of part (c) to sum the series.
(e) Show that the probability of producing n particles is given by

$$P(n) = (1/n!)\lambda^n \exp(-\lambda).$$

This is a Poisson distribution.
(f) Prove the following facts about the Poisson distribution:

$$\sum_{n=0}^{\infty} P(n) = 1; \quad \langle N \rangle = \sum_{n=0}^{\infty} nP(n) = \lambda$$

The first identity says that the $P(n)$'s are properly normalized probabilities, while the second confirms our proposal for $\langle N \rangle$. Compute the mean square fluctuation $\langle (N - \langle N \rangle)^2 \rangle$.
4.2 Decay of a scalar particle. Consider the following Lagrangian, involving two real scalar fields Φ and ϕ:

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu \Phi\right)^2 - \frac{1}{2}M^2\Phi^2 + \frac{1}{2}\left(\partial_\mu \phi\right)^2 - \frac{1}{2}m^2\phi^2 - \mu\Phi\phi\phi.$$

The last term is an interaction that allows a Φ particle to decay into two ϕ 's, provided that $M > 2m$. Assuming that this condition is met, calculate the lifetime of the Φ to lowest order in μ.
4.3 Linear sigma model. The interactions of pions at low energy can be described by a phenomenological model called the linear sigma model. Essentially, this model consists of N real scalar fields coupled by a ϕ^4 interaction that is symmetric under rotations of the N fields. More specifically, let $\Phi^i(x), i = 1, ..., N$ be a set of N fields, governed by the Hamiltonian

$$H = \int d^3x \left(\frac{1}{2}\left(\Pi^i\right)^2 + \frac{1}{2}\left(\nabla\Phi^i\right)^2 + V\left(\Phi^2\right) \right)$$

where $\left(\Phi^i\right)^2 = \mathbf{\Phi} \cdot \mathbf{\Phi}$, and

$$V\left(\Phi^2\right) = \frac{1}{2}m^2\left(\Phi^i\right)^2 + \frac{\lambda}{4}\left(\left(\Phi^i\right)^2\right)^2$$

is a function symmetric under rotations of $\mathbf{\Phi}$. For (classical) field configurations of $\Phi^i(x)$ that are constant in space and time, this term gives the only contribution to H; hence, V is the field potential energy.
(What does this Hamiltonian have to do with the strong interactions? There are two types of light quarks, u and d. These quarks have identical strong interactions, but different masses. If these quarks are massless, the Hamiltonian of the strong interactions is invariant to unitary transformations of the 2-component object (u, d):

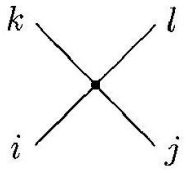
$$\begin{pmatrix} u \\ d \end{pmatrix} \to \exp(i\boldsymbol{\alpha} \cdot \boldsymbol{\sigma}/2) \begin{pmatrix} u \\ d \end{pmatrix}$$

This transformation is called an isospin rotation. If, in addition, the strong interactions are described by a vector "gluon" field (as is true in QCD), the strong interaction Hamiltonian is invariant to the isospin rotations done separately on the left-handed and right-handed components of the quark fields. Thus, the complete symmetry of QCD with two massless quarks is $SU(2) \times SU(2)$. It happens that $SO(4)$, the group of rotations in 4 dimensions, is isomorphic to $SU(2) \times SU(2)$, so for $N = 4$, the linear sigma model has the same symmetry group as the strong interactions.)
(a) Analyze the linear sigma model for $m^2 > 0$ by noticing that, for $\lambda = 0$, the Hamiltonian given

above is exactly N copies of the Klein-Gordon Hamiltonian. We can then calculate scattering amplitudes as perturbation series in the parameter λ. Show that the propagator is

$$^{\Phi^i(x)}\,\Phi^j(y) = \delta^{ij} D_F(x-y)$$

where D_F is the standard Klein-Gordon propagator for mass m, and that there is one type of vertex given by



$$= -2i\lambda(\delta^{ij}\delta^{kl} + \delta^{il}\delta^{jk} + \delta^{ik}\delta^{jl}).$$

(That is, the vertex between two Φ^1 S_S and two Φ^2 S has the value $(-2i\lambda)$; that between four $\Phi^{\mathbf{1}}$s has the value $(-6i\lambda)$.) Compute, to leading order in λ, the differential cross sections $d\sigma/d\Omega$, in the center-of-mass frame, for the scattering processes

$$\Phi^1\Phi^2 \to \Phi^1\Phi^2, \quad \Phi^1\Phi^1 \to \Phi^2\Phi^2, \quad \text{and} \quad \Phi^1\Phi^1 \to \Phi^1\Phi^1$$

as functions of the center-of-mass energy.

(b) Now consider the case $m^2 < 0 : m^2 = -\mu^2$. In this case, V has a local maximum, rather than a minimum, at $\Phi^i = 0$. Since V is a potential energy, this implies that the ground state of the theory is not near $\Phi^i = 0$ but rather is obtained by shifting Φ^i toward the minimum of V. By rotational invariance, we can consider this shift to be in the N th direction. Write, then,

$$\Phi^i(x) = \pi^i(x), \quad i = 1, ..., N-1,$$
$$\Phi^N(x) = v + \sigma(x),$$

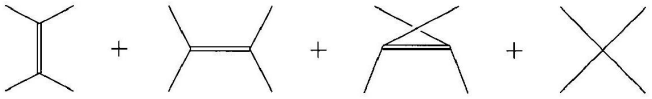
where v is a constant chosen to minimize V. (The notation π^i suggests a pion field and should not be confused with a canonical momentum.) Show that, in these new coordinates (and substituting for v its expression in terms of λ and μ), we have a theory of a massive σ field and $N-1$ massless pion fields, interacting through cubic and quartic potential energy terms which all become small as $\lambda \to 0$. Construct the Feynman rules by assigning values to the propagators and vertices:

$$\bar{\pi}^i \pi^j = i \longrightarrow \quad j$$

(c) Compute the scattering amplitude for the process

$$\pi^i(p_1)\,\pi^j(p_2) \to \pi^k(p_3)\,\pi^l(p_4)$$

to leading order in λ. There are now four Feynman diagrams that contribute:



Show that, at threshold ($\mathbf{p}_i = 0$), these diagrams sum to zero. (Hint: It may be easiest to first consider the specific process $\pi^1\pi^1 \to \pi^2\pi^2$, for which only the first and fourth diagrams are nonzero, before tackling the general case.) Show that, in the special case $N = 2$ (1 species of pion), the term of $\mathcal{O}(p^2)$ also cancels.

(d) Add to V a symmetry-breaking term,

$$\Delta V = -a\Phi^N$$

where a is a (small) constant. (In QCD, a term of this form is produced if the u and d quarks have the same nonvanishing mass.) Find the new value of v that minimizes V, and work out the content of the theory about that point. Show that the pion acquires a mass such that $m_\pi^2 \sim a$, and show that the pion scattering amplitude at threshold is now nonvanishing and also proportional to a.

4.4 Rutherford scattering. The cross section for scattering of an electron by the Coulomb field of a nucleus can be computed, to lowest order, without quantizing the electromagnetic field. Instead, treat the field as a given, classical potential $A_\mu(x)$. The interaction Hamiltonian is

$$H_I = \int d^3x e\bar{\psi}\gamma^\mu\psi A_\mu$$

where $\psi(x)$ is the usual quantized Dirac field.

(a) Show that the T-matrix element for electron scattering off a localized classical potential is, to lowest order,

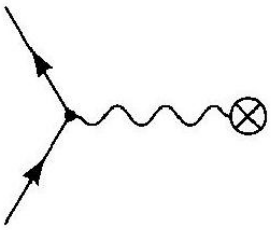
$$\langle p'|\, iT|p\rangle = -ie\bar{u}\,(p')\,\gamma^\mu u(p)\cdot\widetilde{A}_\mu\,(p'-p)\,,$$

where $\widetilde{A}_\mu(q)$ is the four-dimensional Fourier transform of $A_\mu(x)$.

(b) If $A_\mu(x)$ is time independent, its Fourier transform contains a delta function of energy. It is then natural to define

$$\langle p'|\, iT|p\rangle \equiv i\mathcal{M}\cdot(2\pi)\delta\,(E_f - E_i)$$

where E_i and E_f are the initial and final energies of the particle, and to adopt a new Feynman rule for computing $\mathcal{M}$:



$$= -ie\gamma^\mu\widetilde{A}_\mu(\mathbf{q}),$$

where $\widetilde{A}_\mu(\mathbf{q})$ is the three-dimensional Fourier transform of $A_\mu(x)$. Given this definition of $\mathcal{M}$, show that the cross section for scattering off a time-independent,
localized potential is

$$d\sigma = \frac{1}{v_i}\frac{1}{2E_i}\frac{d^3p_f}{(2\pi)^3}\frac{1}{2E_f}\left|\mathcal{M}\,(p_i\to p_f)\right|^2(2\pi)\delta\,(E_f - E_i)$$

where v_i is the particle's initial velocity. This formula is a natural modification of (4.79). Integrate over $|p_f|$ to find a simple expression for $d\sigma/d\Omega$.

(c) Specialize to the case of electron scattering from a Coulomb potential ($A^0 = Ze/4\pi r$). Working in the nonrelativistic limit, derive the Rutherford formula,

$$\frac{d\sigma}{d\Omega} = \frac{\alpha^2Z^2}{4m^2v^4\sin^4(\theta/2)}$$

(With a few calculational tricks from Section 5.1, you will have no difficulty evaluating the general cross section in the relativistic case; see Problem 5.1.)

14.7.1 5. Feynman Rules for QED

Рассмотренные два примера для амплитуд (63) и (71) помогают понять правила Фейнмана для диаграммной техники при вычислении амплитуды рассеяния iM (в импульсном представлении). Эти правила выводятся при помощи выражения для S-матрицы (58).

1. Приближению n-ого порядка ТВ отвечают диаграммы с n вершинами, в каждой из которых сходятся одна входящая и одна выходящая электронные (сплошные) и одна фотонная (волнистая) линии. В амплитуду процесса рассеяния входят все диаграммы, имеющие свободные концы (внешние линии) в числе, равном числу начальных и конечных частиц.

2. Каждой внешней входящей сплошной линии сопоставляется амплитуда начального электрона u_p или конечного позитрона u_{-p} (p − 4-импульс частицы). Каждой выходящей сплошной линии сопоставляется амплитуда конечного электрона $\bar{u}_p$ или начального позитрона $\bar{u}_{-p}$.

3. Каждой вершине сопоставляется 4 -вектор $(-ie\gamma^\mu)$.

4. Каждой внешней входящей волнистой линии сопоставляется амплитуда начального фотона $\sqrt{4\pi}e^\mu$, а выходящей линии - амплитуда $\sqrt{4\pi}e^*_\mu$ конечного фотона (e − 4-вектор поляризации фотона). Векторный индекс μ совпадает с индексом матрицы γ^μ в соответствующей вершине (так что возникает скалярное произведение $\gamma^\mu e_\mu$ или $\gamma^\mu e^*_\mu$).

5. Каждой внутренней сплошной линии сопоставляется множитель $iS_c(p) = i(\not{p} - m + i\varepsilon)^{-1}$, а внутренней волнистой линии - множитель $\left(-iD^\alpha_{\mu\nu}(p)\right) = (-i)\frac{4\pi}{p^2+i\varepsilon}\left[\eta_{\mu\nu} - \frac{(1-\alpha)p_\mu p_\nu}{p^2+i\varepsilon}\right]$. Тензорные индексы $\mu\nu$ совпадают с индексами матриц γ^μ, γ^ν в вершинах, соединяемых волнистой линией.

6. Вдоль каждой непрерывной последовательности электронных линий стрелки имеют неизменное направление, а расположение биспинорных индексов вдоль них соответствует записи матриц слева направо при движении против стрелок. Замкнутой электронной петле отвечает след произведения расположенных вдоль неё матриц.

7. В каждой вершине 4-импульсы пересекающихся в ней линий удовлетворяют закону сохранения, то есть сумма импульсов входящих линий равна сумме импульсов выходящих линий. Импульсы свободных концов - заданные (с соблюдением общего закона сохранения 4-импульса) величины, причём позитронной линии приписывается 4 -импульс $(-p)$. По импульсам внутренних линий, остающимся нефиксированными после учёта законов сохранения во всех вершинах, производится интегрирование (по $\mathrm{d}^{(4)}p/(2\pi)^4$).

8. Входящему свободному концу, отвечающему внешнему электромагнитному полю, сопоставляется множитель $A^{(e)}(q) = \int \mathrm{d}^{(4)}x e^{ikx} A^{(e)}(x)$; 4-вектор q связан с 4-импульсами сплошных электрон-позитронных линий в этой же вершине законом

сохранения. Если поле не зависит от времени, свободному концу сопоставляется множитель $A^{(e)}(\mathbf{q}) = \int \mathrm{d}^{(3)}x e^{-i\mathbf{qx}} A^{(e)}(\mathbf{x})$, а по остающимся нефиксированными трёхмерным импульсам внутренних линий производится интегрирование по $\mathrm{d}^{(3)}p/(2\pi)^3$.

9. Дополнительный множитель (-1) привносится в выражение для iM каждой замкнутой электронной петлёй и каждой парой позитронных внешних концов, если эти концы - начало и конец одной последовательности сплощных линий. Если среди начальных или среди конечных частиц имеется несколько электронов или позитронов, то относительный знак диаграмм, различающихся нечётным числом перестановок пар тождественных частиц (т. е. соответствующих им внешних концов), должен быть противоположным.

Последнее правило означает, в частности, что одинаковыми знаками должны обладать диаграммы с одинаковыми сплошными линиями, т. е. диаграммы, которые оказались бы тождественными после снятия с них всех фотонных линий. Укажем также, что при наличии тождественных фермионов общий знак амплитуды условен. Однонаправленность стрелок вдоль фермионных линий (правило 6) очевидно из того, что любая фермионная линия даёт в диаграмму множитель вида

$$...\gamma^{\mu} S_c(x-y)\gamma^{\nu} S_c(y-z)\gamma^{\lambda} S_c(z-u)...$$

Если определить направление стрелки фермионногой линии совпадающим с направлением распространения электрона, то в пропагаторе $S_c(x-y)$ стрелка направлена от точки y к точке x. Действительно, согласно задаче 1.в) при $x^0 > y^0$ величина $S_c(x-y)$ является амплитудой распространения электрона из точки y к точке x и при $x^0 < y^0$ - амплитудой распространения позитрона от точки x к точке y. Так как направление стрелки пропагатора не зависит от значения его аргументов, то мы видим, что вдоль стрелок электрон-позитронной линии распространяется электрон, а против стрелок -позитрон.

Задачи

1. Определим хронологически упорядоченное произведение от любого числа дираковских полей в представлении Гейзенберга

$$\left(T\psi_{a_1}(x_1)...\psi_{a_l}(x_l)\,\bar{\psi}_{a_{l+1}}(x_{l+1})...\psi_{a_m}(x_m)\right)$$

как произведение всех этих операторов, расположенных справа налево в порядке возрастания их временных аргументов, причём знак этого произведения определяется чётностью перестановки, которую нужно произвести, чтобы получить этот порядок из порядка, указанного под знаком T произведения.

а) Показать, что

$$\left\langle 0 \left| \left(T\psi_{a_1}(x_1)...\psi_{a_l}(x_l)\,\bar{\psi}_{a_{l+1}}(x_{l+1})...\bar{\psi}_{a_m}(x_m)\right) \right| 0 \right\rangle =$$
$$= \frac{1}{Z}\left(\frac{1}{i}\right)^m (-1)^{m-l} \frac{\delta}{\delta\bar{\eta}_{a_1}(x_1)} \cdots \frac{\delta}{\delta\bar{\eta}_{a_l}(x_l)} \frac{\delta}{\delta\eta_{a_{l+1}}(x_{l+1})} \cdots \frac{\delta}{\delta\eta_{a_m}(x_m)} Z \Big|_{J,\bar{\eta},\eta=0}$$

б) Показать, что этот коррелятор не равен нулю лишь если $m = 2l$.

Указание. В функциональном интеграле (55) (под знаком которого имеются усредняемые поля) сделать глобальное преобразование полей

$$\psi \to e^{i\alpha}\psi, \quad \bar{\psi} \to e^{-i\alpha}\bar{\psi}, \quad \eta \to e^{i\alpha}\eta, \quad \bar{\eta} \to e^{-i\alpha}\bar{\eta}$$

и учесть, что при этом мера $D\bar{\psi}D\psi$ инвариантна.

в) Показать, что в свободной теории

$$iS_c(x-y) = \langle 0|T\psi(x)\bar{\psi}(y)|0\rangle$$

2. Сформулировать и доказать теорему Вика для фермиевских операторов рождения и уничтожения.

3*. Вычислить сечение рассеяния фотона на электроне (эффект Комптона) в наинизшем приближении, считая начальные частицы неполяризованными и не фиксируя спины конечных частиц. Используя формулу (A22) выписать ответ через инвариантные переменные Мандельстама и затем перейти в систему отсчёта покоя электрона. Рассмотреть случай $\omega \ll m$ (здесь ω - энергия начального фотона, m - энергия покоя электрона) и сравнить ответ с классической нерелятивистской формулой Томсона.

Ответ:
$\mathrm{d}\sigma = 8\pi \left(\frac{e^2}{m}\right)^2 \frac{m^2\ \mathrm{d}t}{(s-m^2)^2} \left\{ \left(\frac{m^2}{s-m^2} + \frac{m^2}{u-m^2}\right)^2 + \left(\frac{m^2}{s-m^2} + \frac{m^2}{u-m^2}\right) - \frac{1}{4}\left(\frac{s-m^2}{u-m^2} + \frac{u-m^2}{s-m^2}\right) \right\}$.

4. Используя ответ предыдущей задачи, получить ответ для дифференциального сечения процесса аннигиляции электрон-позитронной пары в два фотона. Считать начальные частицы неполяризованными и спины конечных частиц нефиксированными.

14.8 Series Expansion in QFT

(I'll add theory here from the above!)

14.8.1 Mathematics of Series Expansion for QFT and Regions of Convergence (!!!)

(очень хочется именно такой раздел, где четко математически обосновывается, где граница сходимости тех рядов, в которые мы раскладываем? Почему бы в другие ряды не разложить, а не только в Тейлора?)

14.8.2 Quantum Amplitudes and External Fields by Kiselev (!!!!)

общие соображения

(перекину в запись про популярное КТП эти идеи)

После квантования поля в операторном подходе можно ставить задачу об эволюции квантовой системы, которая описывается состояниями в фоковском пространстве.

Для этого необходимо задать гамильтониан с учетом взаимодействий, чтобы эволюция не оставалась элементарной, каковой она является для свободных полей.

Тогда при наличии взаимодействий самих полей и взаимодействий с внешними источниками нужно будет построить оператор эволюции и вычислить амплитуды квантовых переходов между асимптотическими состояниями.

Но мы так делать не будем и просто забьем на все это и построим новую теорию.

Наряду с операторным подходом можно пойти по пути, который предложили Швингер и Фейнман, что мы и будем делать в этом курсе квантовой теории поля.

Этот подход, совершенно эквивалентен операторному подходу, но идеологически он опирается на рассмотрение взаимодействия полей с внешними источниками и на диаграммную технику Фейнмана при вычислении все тех же амплитуд квантовых переходов.

На примере вещественного скалярного поля $\varphi(x)$ мы сначала рассмотрим классические уравнения поля при наличии внешнего источника и покажем, как при помощи преобразования Лежандра от действия $G(j)$, зависящего от источников, к эффективному действию $\Gamma(\varphi_{\mathrm{cl}})$ происходит переход от понятия внешнего источника $j(x)$ к эквивалентному понятию классического внешнего поля $\varphi_{\mathrm{cl}}(x)$.

Такое новое понятие соответствует более прозрачной постановке задачи о воздействии на систему полей внешних сил или о зависимости характеристик системы от внешних параметров, которые как раз допускают стандартное описание в терминах классического внешнего поля φ_{cl}.

Например, в задаче рассеяния внешнее поле может описывать частицы в пучке, которые падают на мишень, или частицы, которые попадают в детектор после рассеяния.

При таком описании, внешние источники j и внешние поля φ_{cl} - это дуальные понятия в смысле преобразования Лежандра.

При этом для классического поля φ, которое является решением уравнений движения при наличии источников, мы вводим понятие амплитуды вероятности наблюдать это поле $Z(j)$.

Вероятность такого наблюдения, конечно, равна единице, $|Z(j)|^2 = 1$, но для этой амплитуды мы сформулируем вариационные уравнения Швингера-Дайсона, которые совершенно эквивалентны уравнениям Эйлера-Лагранжа для классического поля φ.

В квантовом случае поле флуктуирует, так что при вычислении амплитуды вероятности $Z(j)$ наблюдать поле с флуктуациями необходимо провести суммирование амплитуд по всем возможным флуктуациям с учетом того, что эти флуктуации согласуются с теми же уравнениями Эйлера-Лагранжа, так что в итоге мы придем к квантовым уравнениям Швингера-Дайсона для $Z(j)$.

В принципе, эти квантовые уравнения как раз и являются методом построения оператора эволюции, а поскольку оператор эволюции строится с помощью упорядочивания по времени бесконечно малых интервалов эволюции, которые следуют друг за другом, мы установим связь вариационных производных квантовой амплитуды $Z(j)$ с T-произведением операторов поля, которые, как мы уже видели, имеют вполне определенную интерпретацию в терминах рождения и уничтожения частиц, являющихся квантами локального поля.

Изящность подхода Швингера-Фейнмана заключается в том, что для вычисления квантовых амплитуд перехода можно зафиксировать внешние классические поля в начальном и конечном состояниях φ_{cl}, которые отвечают условиям поставленной задачи, и тогда для квантовых полей необходимо положить, что они при эволюции остаются в вакуумном состоянии. Поэтому говорят, что рассматривается вакуум-вакуумная амплитуда квантового перехода $Z(j)$ при наличии внешних источников j, которые, как мы уже понимаем, совершенно эквивалентны (по Лежандру) соответствующим внешним классическим полям φ_{cl}.

Суммирование по флуктуциям поля можно описывать вполне конструктивно, точно так же, как это было сделано в квантовой механике для одной нерелятивистской частицы.

При этом, в силу того, что матричный элемент оператора эволюции вычисляется по вакууму, необходимо учесть это условие в явном виде при формулировке континуального интеграла Фейнмана.

Важно, что суммирование по флуктуациям существенно влияет на форму эффективного действия $\Gamma(\varphi_{\mathrm{cl}})$. Само эффективное действие можно раскладывать в вариационный ряд по внешним полям (аналог ряда Тейлора для функций), что приводит в рамках квантовой операторной интерпретации коэффициентов разложения - функций Грина - к построению диаграммной техники Фейнмана.

Классическое поле и флуктуации

Рассмотрим классическую теорию вещественного скалярного поля с действием

$$S = \int \mathrm{d}^4 x \mathcal{L}\left(\varphi, \partial_\mu \varphi\right)$$

где можно выделить вклад свободного поля

$$S_0 = \int \mathrm{d}^4 x \frac{1}{2}\left\{\left(\partial_\mu \varphi\right)^2 - m^2 \varphi^2\right\}$$

и взаимодействия

$$S_{\mathrm{int}} = -\int \mathrm{d}^4 x V(\varphi)$$

так что

$$S = S_0 + S_{\mathrm{int}} \,,$$

а $V(\varphi)$ - это потенциал самодействия поля, который построен в виде полинома с младшей степенью, больше двух, чтобы можно было рассуждать о S_0 в терминах свободных полей, т. е. квадратичного по полю лагранжиана. К примеру, в теории «лямбда-фи-в-четвертой» $V = \lambda\varphi^4/4!$

Добавим к действию член с внешним током $j(x)$

$$S_{\mathrm{ext}}(j) = \int \mathrm{d}^4 x j(x)\varphi(x)$$

Для краткости записи договоримся о стандартных обозначениях для аргументов: поле или ток с номером - это поле или ток, которые зависят от набора координат с тем же номером, например, $\varphi\left(x_1\right) \equiv \varphi_1, j\left(x_1\right) \equiv j_1$.

Более того, повторение номера аргумента - это интегрирование по этому аргументу, так что $S_{\mathrm{ext}}(j) \equiv j_1\varphi_1$, например.

Ясно, что номер набора координат следует отличать от компонент в наборе, так что номер набора бы станем обозначать либо конкретной цифрой, либо латинской буквой, в отличие от греческих символов для компонент координат.

15 Other Fundamental Methods of QFT

(если тут окажется что-то типичное, что очень важно знать, то перенесу в 2ю часть. пока тут, потому что скорее всего это только в специфических вопросах понадобится.)

15.1 Some Well-known General Properties

15.1.1 Ward–Takahashi–Slavnov–Taylor Identities

мотивация

Theory

Квантовые флуктуации могут быть несовместимы с симметрией классического действия.

Эта несовместимость бывает обусловлена необходимостью регуляризации петлевых вкладов.

Напомним, что число петель отвечает степени $\hbar$, так что квантовые поправки могут потребовать наложения условий, которые позволят трактовать эти поправки как конечные величины.

Однако эти условия могут вступить в неустранимое противоречие с калибровочной инвариантностью,

например, из-за необходимости удовлетворять исходным принципам,

которые не зависят от модели взаимодействий, в том числе на квантовом уровне, скажем, принципу запрета Паули для фермионов. Тогда возникает ситуация квантовой аномалии: флуктуации нарушают закон сохранения тока!

В физических моделях требование сокращения квантовых аномалий является одним из ключевых.

Это может быть условие на сумму квантовых чисел полей, например.

Поэтому мы будем считать, что имеем дело с теорией, в которой нет квантовых аномалий. Тогда квантовые флуктуации оставляют амплитуды калибровочно инвариантными.

На примере неабелевой теории калибровочного поля в калибровке Лоренца с внешними источниками рассмотрим вариацию подынтегрального выражения для $Z(j)$ по локальному калибровочному параметру $u(x)$.

Возникающий при этом фактор нам уже известен, и в силу калибровочной инвариантности он равен нулю

$$-\frac{1}{\xi}(\partial^\mu \mathcal{A}_\mu)(\mathcal{M}_L(\mathcal{A})u) + j^\mu\left(-\left[\nabla_\mu, u\right]\right) = 0$$

Подставим в это выражение $u(x) = \mathcal{M}_L^{-1}(\mathcal{A})_{xy}\tilde{u}(y)$, где обратный оператор, как мы понимаем, задает пропагатор для духов при ненулевых источниках:

$$\langle 0|\ \mathrm{T}\{\mathfrak{c}(x)\overline{\mathfrak{c}}(y)\}|0\rangle = (-\mathrm{i})^2\frac{\delta^2 Z(j,\zeta,\bar{\zeta})}{\delta\bar{\zeta}(x)\delta\zeta(y)} = \mathcal{D}_{\mathfrak{c}}(x,y) = \mathrm{i}M_L^{-1}\left(-\mathrm{i}\frac{\delta Z}{\delta j^\mu}\right)$$

причем обратный оператор - это интегральный оператор с определенным ядром, зависящим от калибровочного поля,

$$\mathcal{M}_L(\mathcal{A})_x\mathcal{M}_L^{-1}(\mathcal{A})_{xy}\tilde{u}(y) = \delta_{xy}\tilde{u}(y) = \tilde{u}(x)$$

Тогда

$$\frac{1}{\xi}\left(\partial^\mu\mathcal{A}_\mu\right)\tilde{u} + j^\mu\left[\nabla_\mu(\mathcal{A}), \mathcal{M}_L^{-1}(\mathcal{A})_{xy}\tilde{u}(y)\right] = 0$$

Если теперь вынести это подынтегральное равенство из-под знака континуального интеграла и продифференцировать по $\tilde{u}$, то получится следующее уравнение в

вариационных производных

$$\frac{1}{\xi}\partial_x^\mu\left(-\mathrm{i}\frac{\delta Z}{\delta j^\mu}\right)+j^\mu(x')\left[\nabla_\mu^{x'}\left(-\mathrm{i}\frac{\delta Z}{\delta j^\mu}\right),\mathcal{M}_L^{-1}\left(-\mathrm{i}\frac{\delta Z}{\delta j^\mu}\right)_{x'x}\right]=0$$

Это - обобщенное тождество Уорда-Такахаши-Славнова-Тейлора в неабелевых калибровочных теориях без спинорных и других полей.

Оно содержит бесконечное число связей между многоточечными корреляторами.

Для иллюстрации продифференцируем обобщенное тождество Уорда-Такахаши-Славнова-Тейлора по $\mathrm{i}j^\nu(y)$ и положим $j=0$, так что в краткой записи

$$\frac{1}{\xi}\partial_x^\mu(-\mathrm{i})^2\frac{\delta^2 Z}{\delta j^\nu(y)\delta j^\mu(x)}-\mathrm{i}\delta_\nu^\mu\nabla_\mu\mathcal{M}_L^{-1}=0,\quad\text{при } j=0$$

В это выражение входит причинный пропагатор калибровочного поля

$$(-\mathrm{i})^2\frac{\delta^2 Z}{\delta j^\nu(y)\delta j^\mu(x)}=\mathcal{D}_{\nu\mu}(y,x)$$

так что, если взять 4-дивергенцию и по второму индексу этого пропагатора, то найдем

$$\frac{1}{\xi}\partial_y^\nu\partial_x^\mu\mathcal{D}_{\nu\mu}(y,x)-\mathrm{i}\delta_\nu^\mu\partial^\nu\nabla_\mu\mathcal{M}_L^{-1}=0,\quad\text{при } j=0.$$

Но поскольку $\mathcal{M}_L=-\partial^\mu\nabla_\mu$

$$-\partial^\mu\nabla_\mu\mathcal{M}_L^{-1}=\delta_{xy}$$

так что

$$\partial_y^\nu\partial_x^\mu\mathcal{D}_{\nu\mu}(y-x)=-\mathrm{i}\xi\delta_{xy}$$

что в импульсном пространстве означает равенство продольной части пропагатора его исходному выражению в исходном свободном лагранжиане, несмотря на квантовые флуктуации,

$$k^\mu k^\nu\frac{\mathrm{i}}{k^2+\mathrm{i}0}\left(Z_{\mathcal{A}}^\perp(k)\left(-g_{\mu\nu}+\frac{k_\mu k_\nu}{k^2}\right)+Z_{\mathcal{A}}^\parallel(k)\frac{k_\mu k_\nu}{k^2}\right)=-\mathrm{i}\xi\quad\to\quad Z_{\mathcal{A}}^\parallel(k)=-\xi$$

В случае электродинамики с внешними токами оператор $\mathcal{M}_{L_4}$ становится очень простым $\mathcal{M}_L^{\mathrm{QED}}=-\partial^2=-\Box$, так что тождество (10.1) означает следующее: продольное поле остается нулевым при внешних токах, которые сохраняются, $\partial_\mu j^\mu=0$. Это упражнение мы предлагаем читателю проделвть самостоятельно с использованием подстановки для продольного поля $\mathcal{A}_\mu^\parallel=\partial_\mu\mathcal{B}$

Тождества (10.1) могут быть получены и путем применения BRST-преобразования.

Воспользуемся эти способом для случая с фермионными полями ψ, например.

Тогда единственными членами в действии, которые получают преобразования, - это слагаемые с источниками,

$$\delta\mathcal{L}_{\text{ext.}}=\delta\left(j^\mu\mathcal{A}_\mu+\bar{\mathfrak{c}}_\zeta+\bar{\zeta}\mathfrak{c}+\bar{\psi}\eta+\bar{\eta}\psi\right)=j^\mu\delta\mathcal{A}_\mu+\delta\bar{\mathfrak{c}}\zeta+\bar{\zeta}\delta\mathfrak{c}+\delta\bar{\psi}\eta+\bar{\eta}\delta\psi$$

Выпишем в явном виде преобразования полей

$$\begin{aligned}
\delta\mathcal{A}_\mu &= \varepsilon\left(-\partial_\mu\mathfrak{c} + \mathrm{i}e\left[\mathfrak{c},\mathcal{A}_\mu\right]\right) = -\varepsilon\left[\nabla_\mu,\mathfrak{c}\right]\\
\delta\mathfrak{c}_c &= -\frac{1}{2}\varepsilon\mathrm{i}e\mathfrak{c}^a\mathfrak{c}^b\mathrm{i}f_{abc} = \frac{1}{2}\varepsilon e f_{abc}\mathfrak{c}^a\mathfrak{c}^b\\
\delta\bar{\mathfrak{c}} &= \frac{1}{\xi}\varepsilon\left(\partial_\mu\mathcal{A}^\mu\right)\\
\delta\psi &= \mathrm{i}e_\psi\varepsilon\mathfrak{c}^a t_a\\
\delta\bar{\psi} &= -\mathrm{i}e_\psi\bar{\psi}\varepsilon\mathfrak{c}^a t_a
\end{aligned}$$

откуда

$$\delta\mathcal{L}_{\text{ext.}} = -j^\mu\varepsilon\left[\nabla_\mu,\mathfrak{c}\right] + \frac{1}{\xi}\varepsilon\left(\partial_\mu\mathcal{A}^\mu\right)_\zeta + \bar{\zeta}^c\frac{1}{2}\varepsilon e f_{abc}\mathfrak{c}^a\mathfrak{c}^b - \mathrm{i}e_\psi\bar{\psi}\varepsilon\mathfrak{c}^a t_a\eta + \bar{\eta}\mathrm{i}e_\psi\varepsilon\mathfrak{c}^a t_a\psi$$

Переставляя грассманов параметр ε налево с учетом антикоммутации с другими грассмановыми переменными, мы может затем продифференцировать по ε и получить равенство

$$\frac{\partial}{\partial\varepsilon}\delta\mathcal{L}_{\text{ext.}} = -j^\mu\left[\nabla_\mu,\mathfrak{c}\right] + \frac{1}{\xi}\left(\partial_\mu\mathcal{A}^\mu\right)\zeta + \bar{\zeta}^c\frac{1}{2}e f_{abc}\mathfrak{c}^a\mathfrak{c}^b + \mathrm{i}e_\psi\bar{\psi}\mathfrak{c}^a t_a\eta - \bar{\eta}\mathrm{i}e_\psi\mathfrak{c}^a t_a\psi$$

Далее, положим теперь источник $\bar{\zeta} = 0$, что даст

$$\frac{\partial}{\partial\varepsilon}\delta\mathcal{L}_{\text{ext.}}\Big|_{\bar{\zeta}=0} = -j^\mu\left[\nabla_\mu,\mathfrak{c}\right] + \frac{1}{\xi}\left(\partial_\mu\mathcal{A}^\mu\right)\zeta + \mathrm{i}e_\psi\bar{\psi}\mathfrak{c}^a t_a\eta - \bar{\eta}\mathrm{i}e_\psi\mathfrak{c}^a t_a\psi$$

Если вместо полей теперь иметь ввиду соответствующие вариационные производные, то действие приведенного выражения на амплитуду Z,конечно, обращается в нуль вследствие калибровочной инвариантности континуального интеграла,

$$\frac{\partial}{\partial\varepsilon}\delta\mathcal{L}_{\text{ext.}}\Big|_{\bar{\zeta}=0} Z(j,\zeta,\eta,\bar{\eta}) = 0$$

при любых значениях источников. Избавимся от источников духов с. Для этого возьмем вариационную производную по i c и положим их равными нулю. тогда в подынтегральном выражении появятся вклады

$$\bar{\mathfrak{c}}\frac{\partial}{\partial\varepsilon}\delta\mathcal{L}_{\text{ext.}}\Big|_{\bar{\zeta}=\zeta=0} - \mathrm{i}\frac{\partial^2}{\delta\zeta\partial\varepsilon}\delta\mathcal{L}_{\text{ext.}}\Big|_{\bar{\zeta}=\mathrm{s}=0} = 0$$

что эквивалентно

$$-j^\mu\left[\nabla_\mu,\mathfrak{c}\right]\bar{\mathfrak{c}} + \mathrm{i}e_\psi\bar{\psi}\mathfrak{c}^a t_a\eta\bar{\mathfrak{c}} - \bar{\eta}\mathrm{i}e_\psi\mathfrak{c}^a t_a\psi\bar{\mathfrak{c}} - \mathrm{i}\frac{1}{\xi}\left(\partial_\mu\mathcal{A}^\mu\right) = 0$$

Спаривание полей духов дает

$$\underbrace{\mathfrak{c}\bar{\mathfrak{c}}} = \mathrm{i}\mathcal{M}_L^{-1}$$

так что с учетом перестановок антикоммутирующих переменных найдем обобщенные тождества Уорда-Такахаши-Славнова-Тейлора для калибровочной теории с фермионами, если иметь ввиду операторное действие полей на амплитуду Z,

$$\begin{aligned}
j_a^\mu\left(\nabla_\mu\mathcal{M}_L^{-1}\right)^{ab} + \frac{1}{\xi}\left(\partial_\mu\mathcal{A}^\mu\right)^b -\\
- e_\psi\bar{\psi}t_a\eta\left(\mathcal{M}_L^{-1}\right)^{ab} + e_\psi\bar{\eta}t_a\psi\left(\mathcal{M}_L^{-1}\right)^{ab} = 0
\end{aligned}$$

Если в этом выражении положить равными нулю источники для фермионных полей, то мы, как и следовало ожидать, воспроизведем тождества Уорда для случая динамики калибровочных полей с источниками, проведя вывод теперь с использованием BRST-инвариантности.

Соотношения (10.2) позволяют связать квантовые поправки для функций Грина в разном порядке по константе взаимодействия при условии калибровочной инвариантности теории без квантовых аномалий.

Это становится особенно существенным,

когда речь идет о регуляризации петлевых вкладов в теории перенормировок.

(???????)

примеры использования

В этой лекции предполагается, что функциональный интеграл (55 Л9) вычисляется при $d = 4 - \varepsilon$ и, таким образом, является регуляризованным.

15.1.2 1. Furry's Theorem

Докажем теорему Фарри, утверждающую, что диаграммы, содержащие хотя бы один нечётный замкнутый спинорный цикл (петлю), взаимно аннулируются. Рассмотрим некую фермионную петлю, изображённую на рис. 15.

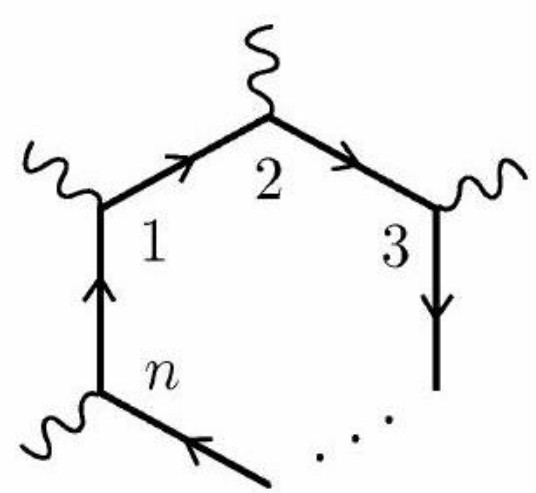


Рис. 15

Пусть при обходе петли в направлении стрелок индекс j следует за индексом i и k_{ji} есть 4 -импульс линии, соединяющей вершины i и j и направленный от вершины i к вершине j. Кроме петли на рис. 15, содержащейся в некой диаграмме, обозначаемой L_+, имеется диаграмма L_-, отличающаяся от L_+лишь тем, что она содержит такую же петлю с обращёнными стрелками. Сумма этих двух диаграмм (а точнее - самих петель) равна нулю при нечётном числе n вершин этих петель.

Множитель в диаграмме L_+, соответствующий петле на рис. 15 (до проведения интегрирования по импульсам), равен

$$l_+ = (-1)\,\mathrm{tr}\left[\gamma S_c\left(k_{n(n-1)}\right)...\gamma S_c\left(k_{21}\right)\gamma S_c\left(k_{1n}\right)\right] \tag{1}$$

Воспользуемся тем, что ни один результат теории Дирака не изменяется при замене (см. (79 Л9))

$$\gamma^{\mu} \to -\gamma^{\mu t} = U_C^{-1}\gamma^{\mu}U_C \tag{2}$$

Действительно, при замене (2) остаются инвариантными как фундаментальные соотношения γ матриц (5 Л8), так и вся алгебра матриц Дирака, включая значения следов произведения матриц Дирака, Поэтому в результате замены (2) находим:

$$\begin{gathered} l_+ = -(-1)^n \operatorname{tr}\left[\gamma^t S_c^t\left(k_{(n-1)n}\right) ... \gamma^t S_c^t\left(k_{12}\right)\gamma^t S_c^t\left(k_{n1}\right)\right] = \\ = -(-1)^n \operatorname{tr}\left[\gamma S_c\left(k_{n1}\right)\gamma S_c\left(k_{12}\right) ... \gamma S_c\left(k_{(n-1)n}\right)\right] = (-1)^n l_- \end{gathered}$$

где l_-−соответствующая петля в диаграмме L_-. Отсюда видно, что при нечётном n $l_+ + l_- = 0 \longrightarrow L_+ + L_- = 0$, что и требовалось доказать.

15.1.3 2. Ward–Takahashi Identity

Сделаем в функциональном интеграле (55 Л9) замену переменных

$$\psi(x) = e^{i\alpha(x)}\psi'(x), \quad \bar{\psi}(x) = \bar{\psi}'(x)e^{-i\alpha(x)} \tag{3}$$

и будем считать поле $\alpha(x)$ бесконечно малым. Учитывая вклад в интеграл лишь первого порядка относительно поля α и тот факт, что $D\bar{\psi}D\psi = D\bar{\psi}'D\psi'$, получаем следующее равенство

$$\frac{1}{N}\int (\exp iS\{A,\psi,\bar{\psi};J,\eta,\bar{\eta}\})DAD\bar{\psi}D\psi =$$

$$= \frac{1}{N}\int \left(\exp iS\left\{A,\psi',\bar{\psi}';J,\eta,\bar{\eta}\right\}\right)\left\{1 + i\int \mathrm{d}^{(d)}x\alpha\left[\partial_\mu J'^{\mu} + i\left(\bar{\eta}\psi' - \bar{\psi}'\eta\right)\right]\right\} DAD\bar{\psi}'D\psi' \tag{4}$$

Здесь $S\left\{A,\psi',\bar{\psi}';J,\eta,\bar{\eta}\right\}$ - действие в экспоненте в интеграле (55 Л9), $J'^{\mu} = \bar{\psi}'\gamma^{\mu}\psi'$, а нормировочный множитель N - такой же функциональный интеграл, как в (4), но с нулевыми источниками. Сравнивая обе части последнего равенства, мы видим, что равна нулю та величина, которая пропорциональна полю $\alpha(x)$. Так как поле $\alpha(x)$ - произвольно, то мы имеем в каждой точке x следующее равенство:

$$\frac{\partial}{\partial x^{\mu}}\langle J^{\mu}(x)\rangle = -i\bar{\eta}(x)\langle\psi(x)\rangle + i\langle\bar{\psi}(x)\rangle\eta(x) \tag{5}$$

Теперь вычислим повторные функциональные производные $\left(\delta/\delta\bar{\eta}\left(x_1\right)\right)\left(\delta/\delta\eta\left(x_2\right)\right)$ от равенства (5), затем положим источники равными нулю. При этом следует учесть, что обе части равенства (5) являются рядами по источникам, коэффициентные функции при степенях которых есть хронологически упорядоченные средние, и операторы частных производных $\partial/\partial x^{\mu}$, $\delta/\delta\eta\left(x_1\right)$, $\delta/\delta\bar{\eta}\left(x_2\right)$ взаимно (анти)коммутируют. В результате находим:

$$\begin{gathered} \frac{\partial}{\partial x^{\mu}}\left\langle 0\left|TJ^{\mu}(x)\psi\left(x_1\right)\bar{\psi}\left(x_2\right)\right|0\right\rangle = \\ = -\delta^{(d)}\left(x - x_1\right)\left\langle 0\left|T\psi\left(x_1\right)\bar{\psi}\left(x_2\right)\right|0\right\rangle + \delta^{(d)}\left(x - x_2\right)\left\langle 0\left|T\psi\left(x_1\right)\bar{\psi}\left(x_2\right)\right|0\right\rangle \end{gathered} \tag{6}$$

Заметим, что вследствие трансляционной инвариантности все корреляторы зависят лишь от разностей координат. Поэтому

$$\left\langle 0 \left| T J^{\mu}(x) \psi\left(x_1\right) \bar{\psi}\left(x_2\right) \right| 0 \right\rangle \equiv$$
$$\equiv \int \mathrm{d}^{(d)} y_1 \; \mathrm{d}^{(d)} y_2 \left[i \mathfrak{S}\left(x_1 - y_1\right) \right] \Gamma^{\mu}\left(y_1 - x, x - y_2\right) \left[i \mathfrak{S}\left(y_2 - x_2\right) \right] \tag{7}$$

где

$$\mathfrak{S}(x-y) = -i \langle 0 | T \psi(x) \bar{\psi}(y) | 0 \rangle \tag{8}$$

- точный электрон-позитронный пропагатор, а $\Gamma^{\mu}\left(y_1 - x, x - y_2\right)$ - вериинный оператор (в координатном пространстве).

Приведём все диаграммы вершинного оператора с точностью до величин пятого порядка:

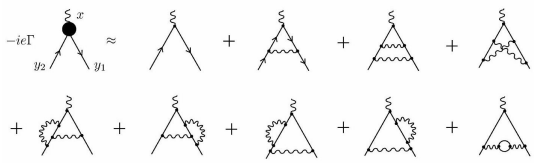

Рис. 16

Из определения вершинного оператора (7) видно, что первое слагаемое справа на рис. 16 равно $-ie\gamma^{\mu}\delta^{(d)}\left(y_1 - x\right)\delta^{(d)}\left(x - y_2\right)$. Таким образом, вершинный оператор есть сумма всех диаграмм с двумя фермионными и одной фотонной внешними ампутированными линиями.

Выразим обе части уравнения (6) при помощи формул (7) и (8) и затем проинтегрируем с весом $\int \mathrm{d}^{(4)} x_1 \; \mathrm{d}^{(4)} x_2 \exp\left[i(p+k)x_1 - ipx_2\right]$. С учётом того, что

$$\mathfrak{S}(k) = \int \mathrm{d}^{(d)} x \mathfrak{S}(x) e^{ikx}, \quad \Gamma^{\mu}(q,p) \equiv \int \mathrm{d}^{(d)} x_1 \; \mathrm{d}^{(d)} x_2 e^{iqx_1 + ipx_2} \Gamma^{\mu}\left(x_1, x_2\right) \tag{9}$$

(так что в наинизшем порядке $\Gamma^{\mu}(q,p) = \gamma^{\mu}$) находим соотношение

$$\mathfrak{S}(p) - \mathfrak{S}(p+k) = \mathfrak{S}(p+k)\left[k_{\mu}\Gamma^{\mu}(p+k,p)\right]\mathfrak{S}(p)$$

откуда получается равенство

$$k_{\mu}\Gamma^{\mu}(p+k,p) = \mathfrak{S}^{-1}(p+k) - \mathfrak{S}^{-1}(p) \tag{10}$$

При $k \to 0$ из (10) получаем также:

$$\frac{\partial \mathfrak{S}^{-1}(p)}{\partial p_{\mu}} = \Gamma^{\mu}(p,p) \tag{11}$$

15.1.4 3. Index of Divergence of Diagrams

Для произвольной диаграммы введём следующие обозначения:
L_e - число внешних электронных линий;
L_γ - число внешних фотонных линий;
N_e - число внутренних электронных линий;
N_γ - число внутренних фотонных линий;
n - число вершин;
l - число петель.
Тогда индекс расходимости диаграммы

$$\omega = dl - N_e - 2N_\gamma \tag{12}$$

Для числа петель имеем:

$$l = N_e + N_\gamma - n + 1 \tag{13}$$

так как каждому пропагатору соответствует интегрирование (по своему d-импульсу), но каждая вершина содержит δ-функцию по входящим импульсам, однако одна δ-функция даёт общий закон сохранения. Для числа вершин имеем:

$$n = L_\gamma + 2N_\gamma = \frac{1}{2}\left(L_e + 2N_e\right) \tag{14}$$

Теперь подставим l из (13) в (12) и при помощи уравнений (14) исключим N_γ и N_e. Таким образом получим:

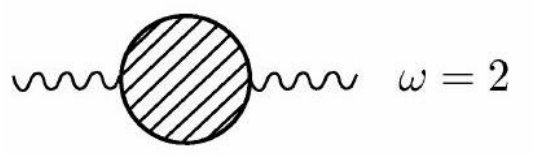
$$\omega = \frac{n}{2}(d-4) + d - \frac{d-1}{2}L_e - \frac{d-2}{2}L_\gamma \tag{15}$$

Отсюда видно, что при $d > 4$ теория заведомо неперенормируема, а при $d = 4$

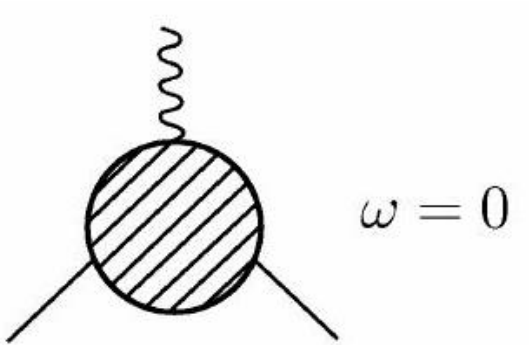
$$\omega = 4 - L_\gamma - \frac{3}{2}L_e \tag{16}$$

то есть формальная расходимость диаграммы зависит лишь от числа внешних концов. Диаграмма расходится при $\omega \geq 0$. Подчеркнём, что импульсы внешних концов диаграмм не предполагаются находящимися на массовой поверхности.

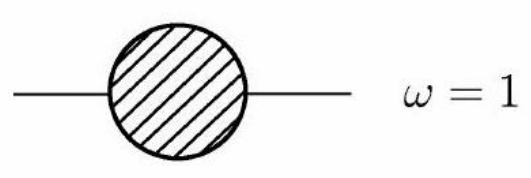
Укажем сразу, что суммы диаграмм при фиксированном порядке по e с нечётным числом L_γ и $L_e = 0$ согласно теореме Фарри равны нулю. Действительно, в таких диаграммах полное число вершин нечётно (см. (14)), и потому имеется хотя бы одна фермионная петля с нечётным числом вершин. Вакуумные пузырьки ($L_\gamma = L_e = 0$) нет смысла рассматривать, так как они дают ненаблюдаемый сдвиг энергии вакуумного состояния. Поэтому имеется всего 4 расходящихся диаграммы:



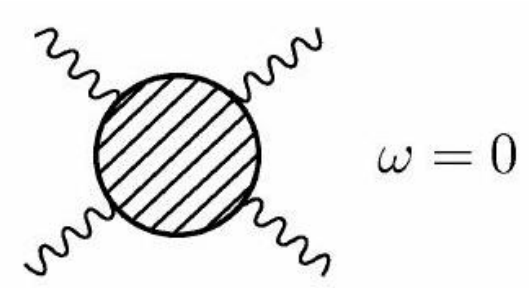
(a)



(*c*)



(b)



(*d*)
Рис. 17
Покажем, что диаграмма (*d*) на рис. 17 конечна.
Прежде всего заметим, что имеют место равенства

$$\frac{\partial}{\partial x^{\mu}} \langle 0 \left| T J^{\mu}(x) J^{\mu_1}(x_1) \ldots J^{\mu_n}(x_n) \right| 0 \rangle = 0 \tag{17}$$

Действительно, если бы мы рассмотрели вместо интеграла (55 Л9) этот же интеграл со вставкой под функциональный интеграл выражения $(J^{\mu_1}(x_1) \ldots J^{\mu_n}(x_n))$ и проделали бы манипуляции, приводящие к (5), то мы получили бы вместо (5) равенство, отличающееся лишь вставкой во все средние выражения $(J^{\mu_1}(x_1) \ldots J^{\mu_n}(x_n))$. Таким образом после зануления внешних источников получается равенство (17). В импульсном пространстве равенство (17) означает, что

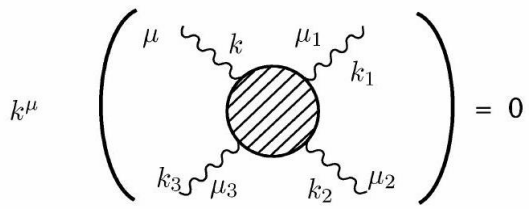


Рис. 18

Равенство, изображённое на рис. 18, возможно, лишь если диаграмма в круглых скобках на рис. 18 пропорциональна структуре вида $(\eta^{\mu\mu_1}k^{\mu_2} - \eta^{\mu\mu_2}k^{\mu_1})$. Аналогичные множители содержатся в остальных трёх вершинах. Каждый из указанных множителей линеен и однороден относительно импульсов, которые "вытягиваются"из пропагаторов внутренних линий. Поэтому некоторым внутренним линиям соответствуют множители, убывающие быстрее при возрастании импульсов, чем при формальном подсчёте. В результате оказывается, что степень расходимости диаграммы (d) на рис. 17$\omega = -4$ и она конечна.

Подчеркнём, что внешние импульсы входят в диаграммы лишь в неотрицательных степенях, поскольку по их отношениям к большим промежуточным импульсам интегрирования производится разложение.

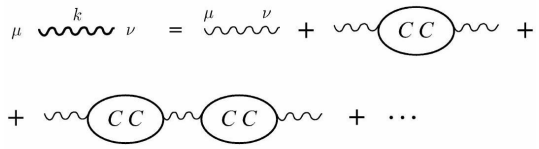
Рассмотрим диаграммы вида (a) на рис. 17. Обозначим через $i\mathcal{P}^{\mu\nu}/4\pi$ сумму всех сильно связанных диаграмм вида (a) на рис. 17. Функция $\mathcal{P}_{\mu\nu}(k)$ называется поляризационным оператором. Рассуждения, аналогичные применённым при рассмотрении диаграмм вида (d) на рис. 17, показывают, что

$$\underbrace{\mu}_{k} \sim CC \sim\sim\sim \frac{\mathcal{P}^{\mu\nu}(k)}{4\pi} = i\frac{\mathcal{P}(k)}{4\pi}\left(k^2\eta^{\mu\nu} - k^\mu k^\nu\right) \tag{18}$$

где оператор $\mathcal{P}\left(k^2\right)$ расходится лишь логарифмически. Обозначим точный фотонный пропагатор

$$\mathcal{D}_{\mu\nu}(x-y) = i\left\langle 0\left|TA_\mu(x)A_\nu(y)\right|0\right\rangle \tag{19}$$

жирной волнистой линией. Тогда на диаграммном языке имеем:



а аналитически (в импульсном пространстве)

$$\mathcal{D}^\alpha_{\mu\nu}(k) = D^\alpha_{\mu\nu}(k) + D^\alpha_{\mu\mu_1}(k)\frac{\mathcal{P}^{\mu_1\mu_2}(k)}{4\pi}D^\alpha_{\mu_2\mu}(k) + ...$$

При помощи формул (53 Л7) и (18) эта геометрическая прогрессия легко суммируется:

$$\mathcal{D}^\alpha_{\mu\nu}(k) = \frac{4\pi}{k^2(1-\mathcal{P}(k))}\left(\eta_{\mu\nu} - \frac{k_\mu k_\nu}{k^2}\right) + \frac{4\pi\alpha k_\mu k_\nu}{\left(k^2\right)^2} \tag{20}$$

Обозначим через $(-i\mathcal{M})$ сумму всех сильно связанных диаграмм вида (b) на рис. 17 и назовём эту функцию массовым оператором. Для точного фермионного пропагатора (8) имеет место разложение, аналогичное разложению точного фотонного пропагатора:

$$\mathfrak{S}(k) = S_c(k) + S_c(k)\mathcal{M}(k)S_c(k) + ... = S_c(k)(1 + \mathcal{M}(k)\mathfrak{S}(k)) = \frac{1}{\not{k} - m_0 - \mathcal{M}(k)} \tag{21}$$

где m_0 - затравочная масса

Общий вид массового оператора таков:

$$\mathcal{M}(k) = a_0 m_0 + a_1\not{k} + m(k) \tag{22}$$

где $m(k)$ - конечная функция. Из размерностных соображений очевидно, что константы a_0 и a_1 расходятся логарифмически. Важно, что в правой части (22) не может быть слагаемого a_2, не обращающегося в нуль при $m_0 = 0$ и $k^\mu = 0$ и потому расходящегося линейно. Согласно (21) такое слагаемое a_2 давало бы ненулевую массу фермионам даже в случае $m_0 = 0$ и потому нарушало бы глобальную γ^5-симметрию

$$\psi \to e^{i\alpha\gamma^5}\psi, \quad \bar{\psi} \to \bar{\psi}e^{i\alpha\gamma^5}, \quad \alpha = \text{ const} \tag{23}$$

При $m_0 = 0$ имеет место глобальная γ^5-симметрия (23) и она не может быть нарушена квантовыми поправками, т.е. точный фермионный пропагатор антикоммутирует с γ^5:

$$\gamma^5\mathfrak{S}(k) + \mathfrak{S}(k)\gamma^5 = 0 \longleftrightarrow \gamma^5\mathcal{N}(k) + \mathcal{M}(k)\gamma^5 = 0$$

Действительно, любая диаграмма, дающая вклад в точный пропагатор, представляется как одна сплошная фермионная линия с внешними концами и некоторое количество фермионных петель, соединённых между собою фотонными пропагаторами. Так как каждая фермионная петля находится под знаком спинорного следа, то спинорная структура всей диаграммы определяется произведением свободных пропагаторов S_c и γ-матриц вдоль единственной фермионной линии с внешними концами. Очевидно, что спинорная структура этой линии определяется произведением

$$S_c(k)\left[\gamma^{\mu_1}S_c\left(p_1\right)\right]...\left[\gamma^{\mu_n}S_c\left(p_n\right)\right]\left[\gamma^{\mu}S_c(k)\right], \quad n = 1, 2, ...$$

которое антикоммутирует с γ^5 в случае $m_0 = 0$. Отсюда видно, что в случае $m_0 = 0$ упомянутого слагаемого a_2 не может появиться при учёте квантовых поправок.

Мы видим, что в квантовой электродинамике имеются лишь логарифмические расходимости, которые, как мы покажем, могут быть устранены при помощи перенормировки полей и затравочных констант m_0 и e_0.

Пусть исходный (затравочный) лагранжиан КЭД равен

$$\mathcal{L} = -\frac{1}{16\pi}F_{\mu\nu}^2 + \bar{\psi}\left(i\partial\!\!\!/ - m_0\right)\psi - e_0\bar{\psi}\gamma^\mu\psi A_\mu \tag{24}$$

Вычислим с помощью этого лагранжиана в размерности $d = 4 - \varepsilon$ точные электронный (8) и фотонный (19) пропагаторы, которые вблизи полюсов ведут себя как

$$\mathfrak{S}(k) = \frac{Z_2}{\not{k} - m} + s(k) \tag{25}$$

$$\mathcal{D}_{\mu\nu}^{\perp}(k) = \frac{4\pi Z_3}{k^2}\left(\eta_{\mu\nu} - \frac{k_\mu k_\nu}{k^2}\right) + d_{\mu\nu}(k) \tag{26}$$

В (25) и (26) операторы $s(k)$ и $d_{\mu\nu}(k)$ конечны при стремлении $k^2 \to m^2$ и $k^2 \to 0$, соответственно.

15.1.5 4. Renormalization Conditions

Займёмся перенормировкой внешних линий. Рассмотрим выходящую внешнюю линию электрона с импульсом p и спиновым состоянием s. Пусть эта линия является единственной выходящей линией амплитуды $M_{(ps)i}$, изображённой на рис. 20.

Здесь все входящие и выходящие линии - жирные, которым соответствуют точные величины с учётом всех радиационных

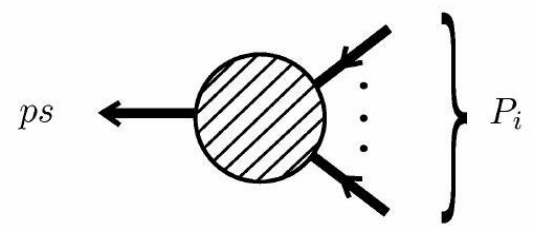


Рис. 20 поправок. В КЭД все 4-импульсы входящих линий в амплитуде на рис. 20 не могут находиться на массовой поверхности, если выходящий электрон - реальный с $p^2 = m^2$, поскольку законы сохранения 4 -импульса и заряда не допускают этого. Однако именно случай $p^2 = m^2$ нас интересует, поэтому входящие линии амплитуды $M_{(ps)i}$ не соответствуют, вообще говоря, реальным частицам. Такая ситуация может быть получена путём аналитического продолжения некоторой амплитуды с массовой поверхности в нужную область её переменных. Множитель в $M_{(ps)i}$, соответствующий выходящему электрону и обозначаемый $\overline{\mathfrak{U}}_{ps}$, получается так же, как точный электронный пропагатор с той лишь разницей, что в разложении (21) во всех слагаемых самый левый пропагатор S_c заменяется на биспинор $\bar{u}_p$, который содержится в разложении затравочного дираковского поля в (24) и удовлетворяет условиям нормировки (20 Л8), (56 Л8) и (57 Л8):

$$\overline{\mathfrak{U}}_p = \bar{u}_p(1 + \mathcal{M}\mathfrak{S}) \tag{27}$$

Таким образом имеем:

$$M_{(ps)i} = \overline{\mathfrak{U}}_{ps} M'_{pi} \tag{28}$$

где M'_{pi} является дираковским спинором - 4-рядной матрицей-столбцом. Сопрягая комплексно равенство (28) и заменяя состояние $|i\rangle$ на $|f\rangle$, получаем:

$$M^*_{(ps)f} = \bar{M}'_{pf} \mathfrak{U}_{ps} \tag{29}$$

Теперь воспользуемся формулой (38 Л5) для значения амплитуды M_{fi} при $P_i^2 = P_f^2 = p^2 \to m^2$, которая была получена из общего требования унитарности теории:

$$iM_{fi} = -\bar{M}'_{pf} \frac{i \sum\limits_s \mathfrak{U}_{ps} \overline{\mathfrak{U}}_{ps}}{p^2 - m^2 + i\varepsilon} M'_{pi} \tag{30}$$

Амплитуда (30) является аналитическим выражением процесса, изображённого на рис. 21:

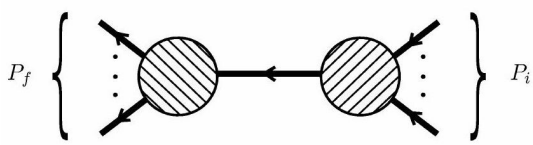

Рис. 21

В силу Лоренц-инвариантности для биспиноров $\mathfrak{U}_{ps}$ имеют место те же соотношения, что и для затравочных биспиноров u_{ps}, кроме нормировки. Следовательно (сравни с (56 Л8)):

$$\sum_s \mathfrak{U}_{ps} \overline{\mathfrak{U}}_{ps} = Z'(\not{p} + m)$$

и потому при $p^2 \to m^2$

$$iM_{fi} = -\bar{M}'_{pf} \frac{iZ'(\not{p} + m)}{p^2 - m^2 + i\varepsilon} M'_{pi} \tag{31}$$

С другой стороны, вычисление этой же амплитуды непосредственно по диаграмме на рис. 21 даёт (учтём, что в рассматриваемой области переменных у амплитуды $M_{f(ps)}$ нет реальных промежуточных состояний, и потому согласно (36 Л5) имеем $M_{f(ps)} = M^*_{(ps)f} = \bar{M}'_{pf}\mathfrak{U}_{ps}$; следовательно, левой части амплитуды на рис. 21 сопоставляется амплитуда $\left(i\bar{M}'_{pf}\right)$, пропагатору $-(i\mathfrak{S}(p))$, а правой части $-\left(iM'_{pi}\right)$)

$$iM_{fi} = \left(i\bar{M}'_{pf}\right)(i\mathfrak{S}(p))iM'_{pi} \tag{32}$$

Сопоставляя формулы (31), (32) и (25), находим $Z' = Z_2$. Поэтому

$$\mathfrak{U}_{ps} = \sqrt{Z_2}u_{ps} \tag{33}$$

где u_{ps} - дираковский биспинор, удовлетворяющий всем соотношениям, приведенным в лекции 8.

Аналогичные вычисления показывают, что точный вектор поляризации фотона $\mathcal{E}_{\mathrm{k}\alpha}$ связан с нормированным согласно (55Ω7) вектором поляризации $\mathbf{e_k}\alpha$ формулой

$$\mathcal{E}_{\mathbf{k}\alpha} = \sqrt{Z_3}\mathbf{e}_{\mathbf{k}\alpha} \tag{34}$$

Теперь введём перенормированные поля при помощи формул

$$\psi = \sqrt{Z_2}\psi_r, \quad A^\mu = \sqrt{Z_3}A^\mu_r \tag{35}$$

В результате этой замены лагранжиан принимает вид

$$\mathcal{L} = -\frac{1}{16\pi}Z_3\left(F^{\mu\nu}_r\right)^2 + Z_2\bar{\psi}_r\left(i\not{\partial} - m_0\right)\psi_r - e_0Z_2\sqrt{Z_3}\bar{\psi}_r\gamma^\mu\psi_rA_{r\mu} \tag{36}$$

Константа m в (25) является физической массой. Пусть e обозначает физический заряд, измеряемый на больших расстояниях. Определим масштабный множитель Z_1 как

$$e_0Z_2\sqrt{Z_3} = eZ_1 \tag{37}$$

Теперь разобьём лагранжиан (36) на две части:

$$\begin{gathered}\mathcal{L} = \left[-\frac{1}{16\pi}\left(F^{\mu\nu}_r\right)^2 + \bar{\psi}_r(i\not{\partial} - m)\psi_r - e\bar{\psi}_r\gamma^\mu\psi_rA_{r\mu}\right] + \\ + \left[-\frac{1}{16\pi}\delta_3\left(F^{\mu\nu}_r\right)^2 + \bar{\psi}_r\left(i\delta_2\not{\partial} - \delta_m\right)\psi_r - e\delta_1\bar{\psi}_r\gamma^\mu\psi_rA_{r\mu}\right] \\ \delta_3 = Z_3 - 1, \quad \delta_2 = Z_2 - 1, \quad \delta_m = Z_2m_0 - m, \quad \delta_1 = Z_1 - 1 = \left(\frac{e_0}{e}\right)Z_2\sqrt{Z_3} - 1\end{gathered} \tag{38}$$

Здесь первое слагаемое в лагранжиане даёт правила Фейнмана, описанные в лекции 9, а слагаемое в квадратной скобке - контрчлены.

Перепишем равенство (7) для перенормированных полей:

$$\left\langle 0\left|TJ^{\mu}(x)\psi\left(x_1\right)\bar{\psi}\left(x_2\right)\right|0\right\rangle = Z_2^2\left\langle 0\left|TJ_r^{\mu}(x)\psi_r\left(x_1\right)\bar{\psi}_r\left(x_2\right)\right|0\right\rangle =$$
$$= Z_2^2\int \mathrm{d}^{(4)}y_1\ \mathrm{d}^{(4)}y_2\left[i\mathfrak{S}_r\left(x_1-y_1\right)\right]\Gamma_r^{\mu}\left(y_1-x,x-y_2\right)\left[i\mathfrak{S}_r\left(y_2-x_2\right)\right]$$

где $\mathfrak{S}_r(x)$ - точный перенормированный фермионный пропагатор, построенный из перенормированных ферми-полей при помощи формулы (8), а Γ_r^{μ} - перенормированный вершинный оператор. Так как $Z_2\mathfrak{S}_r = \mathfrak{S}$, то из сравнения последнего равенства с равенством (7) мы видим, что $\Gamma_r^{\mu} = \Gamma^{\mu}$.

Теперь точный электронный (8) и точный фотонный (19) пропагаторы вблизи полюсов ведут себя как

$$\mathfrak{S}_r(k) = \frac{1}{\not{k} - m - \mathcal{M}_r(k)} \approx \frac{1}{\not{k} - m}$$
$$\mathfrak{D}_{r\mu\nu}^{\perp}(k) = \frac{4\pi}{k^2\left(1-\mathcal{P}_r\left(k^2\right)\right)}\left(\eta_{\mu\nu} - \frac{k_\mu k_\nu}{k^2}\right) \approx \frac{4\pi}{k^2}\left(\eta_{\mu\nu} - \frac{k_\mu k_\nu}{k^2}\right) \tag{39}$$

Отсюда вытекают следующие условия нормировки:

$$\mathcal{M}_r(k) = (\not{k} - m)g(k)(\not{k} - m) \tag{40a}$$
$$\mathcal{P}_r\left(k^2 = 0\right) = 0 \tag{40b}$$

При помощи (39), (40) и (38 а Л8) получаем:

$$\bar{u}_p \frac{\partial}{\partial p_\mu}\left[Z_2^{-1}\mathfrak{S}_r^{-1}(p)\right] u_p\Big|_{p^2=m^2} = Z_2^{-1}\bar{u}_p\gamma^{\mu}u_p \tag{41}$$

Так как тождества Уорда (11) имеют место для неперенормированных величин, то при помощи (41) находим тождество Уорда для перенормированных величин:

$$\bar{u}_p\Gamma^{\mu}(p,p)u_p|_{p^2=m^2} = Z_2^{-1}\bar{u}_p\gamma^{\mu}u_p \tag{42}$$

Рассмотрим диаграмму

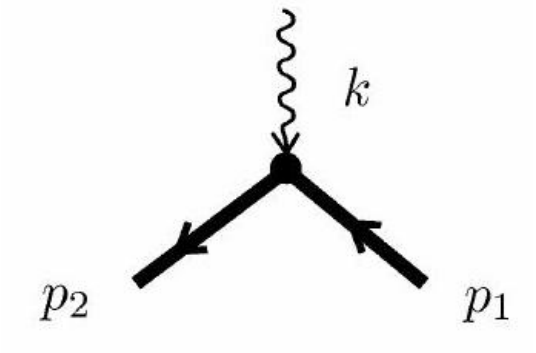

Рис. 22

описывающую рассеяние электрона во внешнем поле $A^{(e)}(k)$ (в первом порядке по полю) с учётом всех радиационных поправок. В пределе $k \to 0, p_2 \to p_1 \equiv p$ этой диаграмме соответствует амплитуда

$$iM_{fi} = -ie\bar{u}_p\gamma^\mu u_p A^{(e)}_{r\mu}(k\to 0) \tag{43}$$

Здесь все величины - перенормированные и e - физически наблюдаемый заряд на больших расстояниях.

Теперь рассмотрим эту же амплитуду в неперенормированной теории:

$$\begin{aligned} iM_{fi} &= -ie_0\overline{\mathfrak{U}}_p\Gamma^\mu(p,p)\big|_{p^2=m^2}\,\mathfrak{U}_p A^{(e)}_\mu(k\to 0) = \\ &= -ie_0 Z_2 Z_3^{1/2}\bar{u}_p\Gamma^\mu(p,p)\Big|_{p^2=m^2}\,u_p A^{(e)}_{r\mu}(k\to 0) = -iZ_1Z_2^{-1}e\bar{u}_p\gamma^\mu u_p A^{(e)}_{r\mu}(k\to 0) \end{aligned} \tag{44}$$

Мы воспользовались определением (37) тождеством Уорда (42). Сравнивая (43) и (44), мы видим, что для того чтобы константа e действительно была физическим зарядом, необходимо

$$Z_1 = Z_2, \quad e = \sqrt{Z_3}e_0 \tag{45}$$

Воспользуемся неопределённостью, возникающей из-за расходимостей, содержащихся в Γ, и потребуем, чтобы имело место равенство

$$\Gamma^\mu(p,p)\big|_{\not p=m} = \gamma^\mu \tag{46}$$

то есть $Z_1 = Z_2 = 1$. (Подразумевается, что равенство (46) имеет место в обкладках $\bar{u}_p ... u_p$, когда $\not p = m$.) Удобство этого определения состоит в том, что отпадает необходимость введения поправок во внешние электронные линии, так как теперь (см (33)) $\mathfrak{U}_{ps} = u_{ps}$, и перенормированный фермионный пропагатор совпадает с неперенормированным. Кроме того, в силу (34) и (45) $e\mathbf{e}_{\mathbf{k}\alpha} = e_0\mathcal{E}_{\mathbf{k}\alpha}$, а также $[e^2\mathfrak{D}_{r\mu\nu}] = e_0^2\mathfrak{D}_{\mu\nu}$ (здесь справа стоят неперенормированные величины). Поэтому, хотя в неперенормированной теории используется затравочный заряд e_0, внешней фотонной линии соответствует вектор поляризации $\mathcal{E}_{\mathbf{k}\alpha}$, а в качестве точного фотонного пропагатора используется функция $\mathfrak{D}_{\mu\nu}$, вместо них можно использовать физический заряд e, стандартные
вектора поляризации (см. лекцию 7) $\mathbf{e}_{\mathbf{k}}\alpha$ и перенормированные пропагаторы $\mathfrak{D}_{r\mu\nu}$. В результате такой замены значения амплитуд не изменяются.

Таким образом, если в диаграммной технике используется физический заряд, физическая масса и перенормированные величины с условиями нормировки (40), (46), то внешним линиям сопоставляются стандартные биспиноры $u_{\pm ps}, \bar{u}_{\pm ps}$ и вектора поляризации $\sqrt{4\pi}\mathbf{e}_{\mathbf{k}}\alpha$, удовлетворяющие естественным условиям нормировки, данным в лекциях 7 и 8. Указанное правило предполагает, что если какая либо внешняя линия диаграммы находится на массовой поверхности, то соответствующая "нога"ампутирована (поскольку все радиационные поправки уже учтены). Асимптотические состояния нормированы обычным способом. Например, для одноэлектронного состояния $|\mathbf{p}s\rangle$ имеем $\langle\mathbf{q}s'|\mathbf{p}s\rangle = (2\pi)^3\omega_{\mathbf{p}}\delta_{ss'}\delta^{(3)}(\mathbf{q}-\mathbf{p})$.

Далее индекс r у перенормированных величин опускается.

Задачи

1. а) Сформулировать теорию Дираковских спиноров в двумерном пространстве-времени Минковского.

Указание. Исходить из необходимости реализации алгебры Дирака $\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2\eta^{\mu\nu}$ в двумерном пространстве Минковского.

б) Рассмотреть в двумерном пространстве Минковского модель Тирринга с действием

$$\mathcal{S} = \int \mathrm{d}^{(2)}x \left\{ \bar{\psi}\left(i\gamma^\mu\partial_\mu - m\right)\psi - \frac{g}{2}\left(\bar{\psi}\gamma^\mu\psi\right)\left(\bar{\psi}\gamma_\mu\psi\right) \right\}$$

Здесь g - константа связи. Сформулировать правила диаграммной техники Фейнмана для модели Тирринга. Исследовать модель на предмет перенормируемости.

2. Доказать, что

$$\begin{gathered}(\partial/\partial x^\mu)\,\langle 0|T J^\mu(x) J^{\mu_1}(x_1)\ldots J^{\mu_m}(x_m)\, J^{5\nu_1}(y_1)\ldots J^{5\nu_n}(y_n) \\ (\bar{\psi}\psi)(z_1)\ldots(\bar{\psi}\psi)(z_l)\,|0\rangle = \\ = \langle 0|T\left(\partial_\mu J^\mu(x)\right) J^{\mu_1}(x_1)\ldots J^{\mu_m}(x_m)\, J^{5\nu_1}(y_1)\ldots J^{5\nu_n}(y_n) \\ (\bar{\psi}\psi)(z_1)\ldots(\bar{\psi}\psi)(z_l)\,|0\rangle = 0\end{gathered}$$

15.2 Schwinger–Dyson Equations

(потом сгруппирую в одно место про эти уравнения, скорее всего в одину из первой главы в этом раздеел)

Уравнения Швингера-Дайсона по Киселеву

Уравнения Эйлера-Лагранжа с учетом всех вкладов в лагранжиан, включая член с внешним током, т. е. для суммы лагранжианов $\mathcal{L}(j) = \mathcal{L} + \mathcal{L}_{\text{int}} + \mathcal{L}_{\text{ext}}$

$$\partial_\mu\left(\frac{\partial\mathcal{L}(j)}{\partial\partial_\mu\varphi}\right) = \frac{\partial\mathcal{L}_{(j)}}{\partial\varphi}$$

примут вид

$$\left(\partial^2 + m^2\right)\varphi(x) + V'(\varphi) = j(x)$$

Если поле удовлетворяет уравнениям Эйлера-Лагранжа, то можно ввести амплитуду вероятности наблюдать такое поле

$$Z(j) = e^{\mathrm{i}S + \mathrm{i}S_{\text{ext}}(j)}$$

причем в силу вещественности действия,

$$|Z(j)| = 1$$

так что вероятность наблюдать классическое поле, которое удовлетворяет уравнениям движения при наличии источников, $W = |Z(j)|^2$ равна единице.

Уравнения движения легко переписать в эквивалентном виде как уравнения для амплитуды $Z(j)$, если заметить, что поле выражается через вариационную производную

$$\frac{\delta Z(j)}{\delta j(x)} = \mathrm{i}\varphi(x)Z(j) \quad \leftrightarrow \quad \varphi(z)Z(j) = -\mathrm{i}\frac{\delta Z(j)}{\delta j(x)}$$

Тогда, например, если $S_{\text{int}} = 0$, то

$$\left(\partial^2 + m^2\right)(-\mathrm{i})\frac{\delta Z(j)}{\delta j(x)} = j(x)Z(j) \quad \leftrightarrow \quad \left(\partial^2 + m^2\right)\varphi(x)Z(j) = j(x)Z(j)$$

При наличии степенного самодействия поля уравнения движения в вариационных производных принимают вид

$$-\mathrm{i}\left(\partial^2 + m^2\right)\frac{\delta Z(j)}{\delta j(x)} + V'\left(-\mathrm{i}\frac{\delta}{\delta j(x)}\right)Z = j(x)Z(j)$$

Это - уравнения Швингера-Дайсона.

(применять бы их уметь...)

(запишу позже алгоритм их решений)

При подстановке в (3.40) амплитуды $Z(j)$ в виде $Z(j) = e^{\mathrm{i}S + \mathrm{i}S_{\text{ext}}(j)}$ уравнения эквивалентны уравнениям Эйлера-Лагранжа в классической теории поля с внешним источником, конечно.

Если эту подстановку не делать, то решение уравнений приобретает более общий смысл, который требует определенной физической интерпретации.

Мы установим, что решение уравнений Швингера-Дайсона $Z(j)$ - это амплитуда квантовых переходов при воздействии на систему внешних источников, если провести суммирование $Z(j) = e^{\mathrm{i}S + \mathrm{i}S_{\text{ext}}(j)}$ по всем флуктуациям, которые имеют место для полей в квантовой механике.

Но прежде, чем заняться описанием квантовых флуктуаций, введем еще несколько понятий, которые также обобщаются с классической теории на квантовую.

Именно, запишем

$$Z(j) = e^{\mathrm{i}G(j)}$$

где $G(j)$ называют производящим функционалом связных функций Грина.

Подставляя $Z(j)$ в уравнения Швингера-Дайсона и умножая их на Z^{-1}, получим эквивалентные уравнения для $G(j)$

$$\left(\partial^2 + m^2\right)\frac{\delta G(j)}{\delta j(x)} + e^{-\mathrm{i}G}V'\left(-\mathrm{i}\frac{\delta}{\delta j(x)}\right)e^{\mathrm{i}G} = j(x)$$

В классической теории поля элементарно находим, что

$$G(j) = S + S_{\text{ext}}$$

а это значит, что в классической теории отлична от нуля только первая вариационная производная, для которой в общем случае вводят обозначение

$$\frac{\delta G}{\delta j(x)} = \varphi_{\text{cl}}(x)$$

Тогда в классике уравнение Швингера-Дайсона в форме (3.42) сводится к виду

$$\left(\partial^2 + m^2\right)\varphi_{\text{cl}}(x) + V'\left(\varphi_{\text{cl}}\right) = j(x)$$

что оправдывает такое наименование $\varphi_{\text{cl}}(x)$, поскольку это поле удовлетворяет классическим уравнениям Эйлера-Лагрнажа.

Определение (3.44) позволяет построить преобразование Лежандра с переходом от функциональных переменных внешних источников j к классическим внешним полям $\varphi_{\rm cl}$, так что вводится функционал эффективного действия

$$\Gamma\left(\varphi_{\rm cl}\right) = G(j) - \int \mathrm{d}^4 x j(x)\varphi_{\rm cl}(x)$$

причем, конечно,

$$\frac{\delta\Gamma\left(\varphi_{\rm cl}\right)}{\delta\varphi_{\rm cl}(x)} = -j(x)$$

В классической теории поля с подстановкой (3.43) эффективное действие сводится к исходному действию на внешних классических полях

$$\Gamma\left(\varphi_{\rm cl}\right) \mapsto S\left(\varphi_{\rm cl}\right)$$

Отметим, что вместо внешних источников мы теперь можем оперировать внешними классическими полями. Эти поля в асимптотической области становятся свободными.

Эффективное действие $\Gamma\left(\varphi_{\rm cl}\right)$ называют также производящим функционалом сильносвязных функций Грина: когда речь идет о производящем функционале имеют ввиду разложение этого функционала в вариационный ряд Тейлора, причем, вариационные коэффициенты в этом разложении и являются функциями Грина,

$$\Gamma\left(\varphi_{\rm cl}\right) = \Gamma_0 + \int \mathrm{d}^4 x_1 \Gamma_1\left(x_1\right)\varphi_{\rm cl}\left(x_1\right) + \frac{1}{2!}\varphi_{\rm cl}^{(1)}\Gamma_{12}\varphi_{\rm cl}^{(2)} + \ldots$$

где, напомним, повторяющиеся номера отвечают интегрированию по соответствующим наборам координат.

Для физической интерпретации введенных понятий нам потребуется сформулировать их определения в терминах операторов и квантов поля - частиц. Однако для начала в качестве наводящих соображений проведем неформальные рассуждения, опираясь на концепцию флуктуаций наблюдаемых величин при их квантовом описании. При таком подходе амплитуду (3.39) следует просуммировать по квантовым флуктуациям поля, а значит, определить суперпозицию амплитуд с различными конфигурациями поля

$$Z(j) = \sum_{\varphi_{\rm conf}} \mathcal{A}_{\rm conf}\, e^{\mathrm{i}S_{\rm conf} + \mathrm{i}S_{\rm ext}\,(j)} = \sum_{\varphi_{\rm conf}} Z_{\rm conf}\,(j)$$

где индекс conf в явном виде указывает номер конфигурации, от которого зависят и действие, и относительная амплитуда $\mathcal{A}$.

Сама сумма по континууму полевых конфигураций будет нами определена позже в терминах когерентных состояний поля.

Важно, что эта сумма существует и конечна: это утверждение эквивалентно выделению класса физически осмысленных теорий поля среди всех возможных.

Следовательно, амплитуду для физической теории поля всегда можно нормировать, так что мы сейчас не будем уделять пристальное внимание нормировке.

Каждая амплитуда под знаком суммы в (3.47) должна описывать поле, удовлетворяющее уравнениям Эйлера-Лагрнажа, как это мы уже установили выше.

Но это означает что для каждого вклада в $Z(j)$вариационная производная даст фактор поля, специфического для каждой конфигурации, так что резонно определить оператор поля в следующем виде.

$$\hat{\varphi}(x)Z(j) = -\mathrm{i}\frac{\delta Z(j)}{\delta j(x)} = \sum_{\varphi_{\rm conf}} -\mathrm{i}\frac{\delta Z_{\rm conf}\,(j)}{\delta j(x)} = \sum_{\varphi_{\rm conf}} \varphi_{\rm conf}\,(x) Z_{\rm conf}\,(j)$$

Поскольку все эти построения линейны по $Z(j)$ уравнения Швингера-

функционала связных функций Грина $G(j)$ остаются в силе! Но теперь эти уравнения становятся сутью задачи квантовой теории поля: их нужно решить, чтобы определить сумму по полям с квантовыми флуктуациями в (3.47).

В частности, теперь, за исключением простейших случаев без взаимодействий, не удастся утверждать, что эффективное действие совпадает с исходным действием, а также, что высшие вариационные производные $G(j)$ равны нулю и т.

п.

Амплитуду $Z(j)$ можно записать после применения преобразования Лежандра в терминах внешних классических полей

$$Z = \exp\left\{\mathrm{i}\Gamma\left(\varphi_{\mathrm{cl}}\right) - \mathrm{i}\int \mathrm{d}^4x\varphi_{\mathrm{cl}}(x)\frac{\delta\Gamma}{\delta\varphi_{\mathrm{cl}}(x)}\right\}$$

а это значит, что в ней присутствует элементарный вклад в отсутствие всяких внешних полей при $\varphi_{\mathrm{cl}} = 0$, а также вклады, каждый из которых характеризуется строго фиксированным числом этих полей, если мы применяем разложение в вариационный ряд Тейлора.

Если мы теперь в качестве граничьх условий для квантовых полей установим вакуум, то все квантовые амплитуды будут соответствовать точно известным условиям в терминах внешних полей, которые порождают из вакуума квантовые поля в начальном состоянии и уничтожают квантовые поля, чтобы конечное квантовое состояние также было вакуумом.

В частности, при $\varphi_{\mathrm{cl}} = 0$ происходит эволюция вакуума в вакуум без какого-либо внешнего воздействия, а значит, при условии стабильности вакуума, которое выделяет физически осмысленные теории поля, мы должны получать амплитуду в виде фазового фактора

$$Z(0) = e^{\mathrm{i}\Gamma(0)} = e^{\mathrm{i}G(0)}$$

Поэтому часто рассматривают величину со шляпкой

$$\hat{Z}(j) = \frac{Z(j)}{Z(0)}$$

чтобы разложение в ряд по источникам или внешним полям начиналось с единицы.

Отметим также, что Z в (3.49) включает в себя, как мы увидим, вклад разного графического типа: связные и не связные диаграммы, а также сильносвязные, которые мы определим ниже, но выражение в терминах внешнего поля позволит нам при операторной интерпретации определить связь между этими типами в удобной форме, которая носит название редукционных соотношений.

Затем мы установим связь амплитуды $Z(j)$ и ее вариационных производных с Т-произведением операторов.

И в качестве вводной части повторим, как был построен матричный элемент оператора эволюции в квантовой механике нерелятивистских частиц с заданными граничными точками траектории, а затем, рассмотрим вакуумные переходы в голоморфном представлении, т.е.

в терминах когерентных состоняний осциллятора, что допускает прямое обощение для когерентных состояний свободного поля.

Это позволит нам как установить общие свойства и интерпретацию в терминах квантов поля для функций Грина, так и сформулировать фейнмановские правила для вычисления амплитуд квантовых переходов,

используя диаграммы.

мотивация

Theory

Как мы помним, классические уравнения движения полей в квантовом случае за счет квантовых флуктуаций переходят в вариационные уравнения для амплитуды Z, причем в эти уравнения можно включить и внешние источники.

Например, уравнения для электромагнитного поля уравнения $\mathcal{A}_\mu$ с внешними источниками j^μ и источниками за счет фермионного дираковского поля ψ имеют вид

$$\partial_\nu F^{\nu\mu} + \frac{1}{\xi}\partial^\mu\partial_\nu\mathcal{A}^\nu = -j^\mu + e\bar{\psi}\gamma^\mu\psi, \quad F^{\nu\mu} = \partial^\nu\mathcal{A}^\mu - \partial^\mu\mathcal{A}^\nu$$

Согласно общей процедуре, это уравнение необходимо домножить на $Z(j,\eta,\bar{\eta})$,

а поля необходимо заменить на вариационные операторы

$$\hat{\mathcal{A}}^\mu = -\mathrm{i}\frac{\delta}{\delta j_\mu}, \quad \hat{\bar{\psi}} = +\mathrm{i}\frac{\delta}{\delta\eta}, \quad \hat{\psi} = -\mathrm{i}\frac{\delta}{\delta\bar{\eta}}$$

Тогда с учетом стандартного обозначения для дифференциальных операторов $\hat{k}_\mu = \mathrm{i}\partial_\mu$ получим

$$\hat{k}^2\left(-g^{\mu\nu} + \frac{\hat{k}^\mu\hat{k}^\nu}{\hat{k}^2}\left(1-\frac{1}{\xi}\right)\right)\hat{\mathcal{A}}_\nu Z = -j^\mu Z + e\hat{\bar{\psi}}\gamma^\mu\hat{\psi}Z$$

Дифференциальный оператор нам в левой части нам хорошо известен, поскольку пропагатор фотона связан с обратным к нему элементарной формулой

$$\mathcal{D}^{(2)}_{\mu\nu} = \mathrm{i}\left\{\hat{k}^2\left(-g^{\mu\nu} + \frac{\hat{k}^\mu\hat{k}^\nu}{\hat{k}^2}\left(1-\frac{1}{\xi}\right)\right)\right\}^{-1} = \frac{\mathrm{i}}{k^2+\mathrm{i}0}\left(-g^{\mu\nu} + \frac{\hat{k}^\mu\hat{k}^\nu}{\hat{k}^2}(1-\xi)\right)$$

так что умножение операторного уравнения движения на $-\mathrm{i}\mathcal{D}^{(2)}$ дает опера- торное тождество

$$\hat{\mathcal{A}}_\nu Z = \mathrm{i}\mathcal{D}^{(2)}_{\mu\nu}j^\mu Z - \mathrm{i}e\mathcal{D}^{(2)}_{\mu\nu}\hat{\bar{\psi}}\gamma^\mu\hat{\psi}Z$$

которое представляет собой вариационное уравнение Швингера-Дайсона, которое можно бесконечное число раз вариационно дифференцировать по внешним источникам. К примеру, умножение на вариационный оператор $\hat{\mathcal{A}}_\mu = -\mathrm{i}\delta/\delta j^\mu$ и условие $j=\eta=\bar{\eta}=0$ дают

$$\hat{\mathcal{A}}_\mu\hat{\mathcal{A}}_\nu Z\Big|_{j=\eta=\bar{\eta}=0} = \mathcal{D}^{(2)}_{\mu\nu} - \mathrm{i}e\mathcal{D}^{(2)}_{\mu'\nu}\hat{\bar{\psi}}\gamma^{\mu'}\hat{\psi}\hat{\mathcal{A}}_\mu Z\Big|_{j=\eta=\bar{\eta}=0^*}$$

В этом выражении мы замечаем пропагатор фотона в теории возмущений)норным током - ie γ^μ, а также полный причинный двухточечный корелятор фотона

$$\mathcal{D}_{\mu\nu}(x,y) = \hat{\mathcal{A}}_\mu(x)\hat{\mathcal{A}}_\nu(y)Z\Big|_{j=\eta=\bar{\eta}=0} = (-\mathrm{i})^2\frac{\delta^2 Z}{\delta j^\mu(x)\delta j^\nu(y)}\Big|_{j=\eta=\bar{\eta}=0}$$

и полную трехточечную функцию взаимодействия фотона с фермионами

$$(\Gamma_\mu)^a_b(x,x',y) = (-\mathrm{i})^3\frac{\delta^3 Z}{\delta\eta^b(x)\delta j^\mu(y)\delta\bar{\eta}_a(x')}\Big|_{j=\eta=\bar{\eta}=0}$$

где мы указали координатные и спинорные аргументы. Тогда уравнение (10.7) приобретает вид

$$\mathcal{D}_{\mu\nu}(x,y) = \mathcal{D}^{(2)}_{\mu\nu}(x,y) - \mathrm{i}e\left(\gamma^{\mu'}\right)^{b}_{a}\int \mathrm{d}^4x'\mathcal{D}^{(2)}_{\mu'\nu}\left(x,x'\right)\left(\Gamma_{\mu}\right)^{a}_{b}\left(x',x',y\right)$$

Сущность этого уравнения легко понять: полная причинная двухточечная функция Грина фотона представляет собой сумму пропагатора Фейнмана и вклада за счет квантовых поправок с учетом «голой» и полной трехточечной функции Грина взаимодействия фотона с фермионами. При этом, согласно принятых нами правил, распространение частиц изображается следующим обраЗом:

(рисунок)

Петлевой вклад в пропагатор фотона после перехода к квадратичному по полю вкладу в эффективном действии называют поляризацией вакуума $\Pi\left(k^2\right)$. Как видим, поляризация вакуума отвечает, вообще говоря, изменению закона дисперсии фотона: $k^2 \mapsto k^2 + \Pi\left(k^2\right)$, - вне массовой поверхности, конечно.

Действуя совершенно аналогично с уравнением для поля Дирака с подстановкой вариационных операторов поля

$$\left(\gamma^{\mu}\mathrm{i}\partial_{\mu} - m\right)\hat{\psi}Z - e\gamma^{\mu}\hat{\mathcal{A}}_{\mu}\hat{\psi}Z + \eta Z = 0$$

после действия обратным оператором, связанным с «голым" пропагатором поля Дирака

$$\mathcal{S}^{(2)} = \mathrm{i}\left(\gamma^{\mu}\mathrm{i}\partial_{\mu} - m\right)^{-1}$$

найдем уравнение Швингера-Дайсона в квантовой электродинамике для поля Дирака

$$\hat{\psi}Z = \mathrm{i}\mathcal{S}^{(2)}\eta Z - \mathrm{i}e\mathcal{S}^{(2)}\gamma^{\mu}\hat{\mathcal{A}}_{\mu}\hat{\psi}Z$$

Умножение на оператор сопряженного поля Дирака $\hat{\bar{\psi}} = \mathrm{i}\delta/\delta\eta$ после наложения условия нулевых значений внешних полей даст уравнение на полный пропагатор поля Дирака

$$\mathcal{S}(x,y) = \mathcal{S}^{(2)}(x,y) - \mathrm{i}e\int \mathrm{d}^4x'\mathcal{S}^{(2)}\left(x,x'\right)\gamma^{\mu}\Gamma_{\mu}\left(x',y,x'\right)$$

где мы подразумеваем тамричное умножение величин со спинорными индексами. Очевидно, чтоэто уравнение графически представляется в следующем виде:

(рисунок)

Опять же, как и в случае фотона, квантовые поправки возникают за счет петли с голой и полной вершиной взаимодействия поля Дирака с фотонами. Подчеркнем, что полную вершину можно построить, например, в теории возмущений. Петлевой вклад в эффективное действие, квадратичное по полю Дирака, называют собственной энергией, например, электрона Σ: $\gamma^{\mu}p_{\mu} - m \mapsto \gamma^{\mu}p_{\mu} - m - \Sigma(p)$, - причем, собственная энергия - это матрица.

примеры использования

15.3 Bethe–Salpeter Equation

мотивация

Theory

Родственником уравнений Швингера-Дайсона является уравнение БетеСолпитера, которое описывает «4-точку» для фермионного поля. Физически «4-точка» - это амплитуда

рассеяния, скажем, электрона на электроне или электрона на позитроне в зависимости от исследуемой задачи. Уравнение

Бете-Солпитера, конечно, можно вывести из общего уравнения ШвингераДайсона с источниками, если в нем провести достаточное количество вариационного дифференцирования по внешним источникам. В самом деле, указывая аргументы в виде численных индексов, из уравнения $\sqrt{10.9}$)

$$\hat{\psi}_1 Z = \mathrm{i}\mathcal{S}^{(2)}_{11'}\eta_{1'}Z - \mathrm{i}e\mathcal{S}^{(2)}_{11'}\gamma^{\mu}_{1'}\hat{\mathcal{A}}^{1'}_{\mu}\hat{\psi}_{1'}Z$$

умножение на вариационные операторы поля с учетом смены знака при перестановке $\psi_1\hat{\bar{\psi}}_2$, с которой мы уже встречались при выводе уравнения Швингера-Дайсона для поля Дирака, дает

$$\hat{\psi}_3\hat{\bar{\psi}}_4\hat{\psi}_1\hat{\bar{\psi}}_2 Z = -\mathrm{i}\mathcal{S}^{(2)}_{11'}\hat{\psi}_3\hat{\bar{\psi}}_4\hat{\bar{\psi}}_2\eta_{1'}Z - \mathrm{i}e\mathcal{S}^{(2)}_{11'}\gamma^{\mu}_{1'}\hat{\mathcal{A}}^{1'}_{\mu}\hat{\psi}_3\hat{\bar{\psi}}_4\hat{\psi}_{1'}\hat{\bar{\psi}}_2 Z$$

Если теперь занулить источники $j = \eta = \bar{\eta} = 0$, то в левой части этого равенства окажется 4-точечная функция Грина для рассеяния полей в процессе $13 \mapsto 24$, т. е. заявленный нами объект исследования в уравнении Бете - Солпитера.

В правой части равенства есть вариационное дифференцирование источника $\eta_{1'}$. Тогда, если это дифференцирование производится за счет $\hat{\bar{\psi}}_2 = \mathrm{i}\delta/\delta\eta_2$, то возникает, во-первых, $\delta_{1'2}$, которая снимает интегрирование по $\mathrm{d}^4x_{1'}$, а вовторых, другие операторы поля действуют на Z, что дает полный пропагатор фермиона с учетом квантовых поправок. Если же дифференцирование $\eta_{1'}$ производится за счет $\hat{\bar{\psi}}_2 = \mathrm{i}\delta/\delta\eta_4$, то возникает дополнительный минус за счет перестановки грассмановых переменных, а также аналогичный вклад от полного пропагатора фермиона с другими конечными точками. В итоге, эти вклады группируются в виде

$$\mathcal{S}^{(2)}_{12}\mathcal{S}_{34} - \mathcal{S}^{(2)}_{14}\mathcal{S}_{32}$$

и возникает диаграмма на рис. 9, где мы включили также и вклад 5-точечной функции Грина.

Однако 5 -точечная функция, очевидно, содержит и несвязные вклады, которые в точности совпадают с петлевыми вкладами в полный пропагатор дираковского поля, как это становится ясно из графического представления на рис. 10

Это означает, что в действительности несвязные вклады - линии невзаимодействующих фермионов - на рис. 9 уже отвечают полным пропагаторам в силу уравнения Швингера-Дайсона для двухточечного фермионного коррелятора:

$$\mathcal{S}^{(2)}_{12}\mathcal{S}_{34} - \mathcal{S}^{(2)}_{14}\mathcal{S}_{32} \mapsto \mathcal{S}_{12}\mathcal{S}_{34} - \mathcal{S}_{14}\mathcal{S}_{32}$$

На основе анализа теории возмущений Бете и Солпитер пришли к выводу, что оставшаяся связная часть 5-точечной функции представима в виде свертки 4-точечного ядра V с исследуемой 4-точечной функцией Грина. Ядро на рис. 10 обозначено прямоугольником. Утверждение о ядре в некотором смысле элементарно: с одной стороны, связные диаграммы с двумя входящими внешними и двумя исходящими внешними линиями всегда можно отнести к свертке ядра со свободным вкладом от 4-точки, а с другой стороны, повторение таких диаграмм, соединенных двумя внутренними линиями, как раз, отвечает вкладу свертки ядра уравнения Бете- Солпиитера с 4-точкой. В итоге, уравнение Бете-Солпитера приобретает симовлический вид

$$\mathcal{S}_{13\to 24} = \mathcal{S}_{12}\mathcal{S}_{34} - \mathcal{S}_{14}\mathcal{S}_{32} + V_{13\to 2'4'}\mathcal{S}_{2'4'\to 24}$$

Неприятности с определением ядра можно обойти в теории возмущений или задавая ядро моделью, имеющую под собой какие-либо основания физического или математического рода.

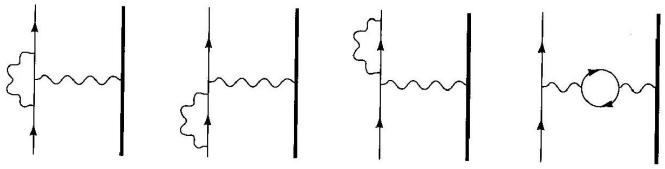
16 Radiative Corrections: Introduction

Now that we have acquired some experience at performing QED calculations, let us move on to some more complicated problems. Chapter 5 dealt only with tree-level processes, that is, with diagrams that contain no loops. But all such processes receive higher-order contributions, known as radiative corrections, from diagrams that do contain loops. Another source of radiative corrections in QED is bremsstrahlung, the emission of extra final-state photons during a reaction. In this chapter we will investigate both types of radiative corrections, and find that it is inconsistent to include one without also including the other.

Throughout this chapter, in order to illustrate these ideas in the simplest possible context, we will consider the process of electron scattering from another, very heavy, particle. We analyzed this process at tree level in Section 5.4 and Problem 5.1. At the next order in perturbation theory, we encounter the following four diagrams:



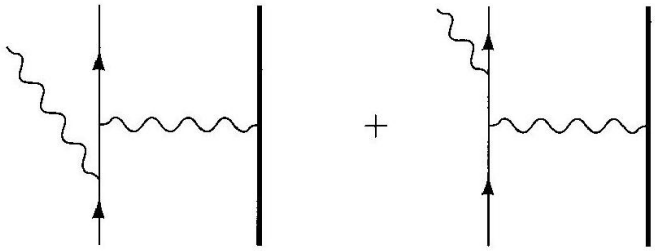
The order- α correction to the cross section comes from the interference term between these diagrams and the tree-level diagram. There are six additional one-loop diagrams involving the heavy particle in the loop, but they can be neglected in the limit where that particle is much heavier than the electron, since the mass appears in the denominator of the propagator. (Physically, the heavy particle accelerates less, and therefore radiates less, during the collision.)

Of the four diagrams in (6.1), the first (known as the vertex correction) is the most intricate and gives the largest variety of new effects. For example, it gives rise to an anomalous magnetic moment for the electron, which we will compute in Section 6.3.

The next two diagrams of (6.1) are external leg corrections. We will neglect them in this chapter because they are not amputated, as required by our formula (4.90) for S-matrix elements. We will discuss these diagrams in more
detail when we prove that formula in Section 7.2.
The final diagram of (6.1) is called the vacuum polarization. Since it requires more computational machinery than the others, we will not evaluate this diagram until Section 7.5.

Our study of these corrections will be complicated by the fact that they are ill-defined. Each diagram of (6.1) involves an integration over the undetermined loop momentum, and in each case the integral is divergent in the $k \to \infty$ or ultraviolet region. Fortunately, the infinite parts of these integrals will always cancel out of expressions for observable quantities such as cross sections.

The first three diagrams of (6.1) also contain infrared divergences: infinities coming from the $k \to 0$ end of the loop-momentum integrals. We will see in Section 6.4 that these divergences are canceled when we also include the following bremsstrahlung diagrams:



These diagrams are divergent in the limit where the energy of the radiated photon tends to zero.

In this limit, the photon cannot be observed by any physical detector, so it makes sense to add the cross section for producing these low-energy photons to the cross section for scattering without radiation. The bremsstrahlung diagrams are thus an essential part of the radiative correction, in this and any other QED process.

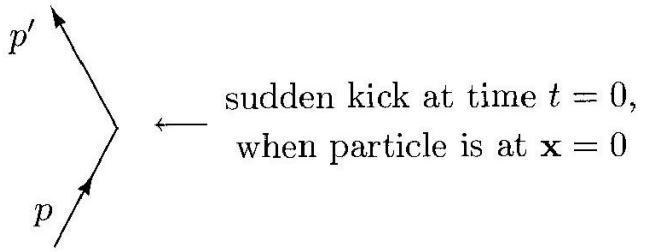
Our main goals in the present chapter are to understand bremsstrahlung of low-energy photons, the vertex correction diagram, and the cancellation of infrared divergences between these two types of radiative corrections.

16.1 6.1 Soft Bremsstrahlung

Let us begin our study of radiative corrections by analyzing the bremsstrahlung process. In this section we will first do a classical computation of the intensity of the low-frequency bremsstrahlung radiation when an electron undergoes a sudden acceleration. We will then compute a closely related quantity in quantum field theory: the cross section for emission of one very soft photon, given by diagrams (6.2). We would like to understand how the classical result arises as a limiting case of the quantum result.

Classical Computation

Suppose that a classical electron receives a sudden kick at time $t = 0$ and position $\mathbf{x} = 0$, causing its 4 -momentum to change from p to p'. (An infinitely sudden change of momentum is of course an unrealistic idealization. The precise form of the trajectory during the acceleration does not affect the low-frequency radiation, however. Our calculation will be valid for radiation with a frequency less than the reciprocal of the scattering time.)



We can find the radiation field by writing down the current of this electron, and considering that current as a source for Maxwell's equations.

What is the current density of such a particle? For a charged particle at rest at $\mathbf{x} = 0$, the current would be

$$\begin{aligned} j^\mu(x) &= (1,\mathbf{0})^\mu \cdot e\delta^{(3)}(\mathbf{x}) \\ &= \int dt (1,\mathbf{0})^\mu \cdot e\delta^{(4)}(x - y(t)), \qquad \text{with } y^\mu(t) = (t,\mathbf{0})^\mu \end{aligned}$$

From this we can guess the current for an arbitrary trajectory $y^\mu(\tau)$:

$$j^\mu(x) = e\int d\tau \frac{dy^\mu(\tau)}{d\tau}\delta^{(4)}(x - y(\tau)) \tag{6.3}$$

Note that this expression is independent of the precise way in which the curve $y^\mu(\tau)$ is parametrized: Changing variables from τ to $\sigma(\tau)$ gives a factor of $d\tau/d\sigma$ in the integration measure, which combines with $dy^\mu/d\tau$ via the chain rule to give $dy^\mu/d\sigma$. We can also prove from

(6.3) that the current is automatically conserved: For any "test function" $f(x)$ that falls off at infinity, we have

$$\begin{aligned}\int d^4x f(x)\partial_\mu j^\mu(x) &= \int d^4x f(x) e \int d\tau \frac{dy^\mu(\tau)}{d\tau}\partial_\mu \delta^{(4)}(x-y(\tau)) \\ &= -e\int d\tau \frac{dy^\mu(\tau)}{d\tau}\frac{\partial}{\partial x^\mu} f(x)\Big|_{x=y(\tau)} \\ &= -e\int d\tau \frac{d}{d\tau} f(y(\tau)) \\ &= -ef(y(\tau))|_{-\infty}^{\infty} = 0\end{aligned}$$

For our process the trajectory is

$$y^\mu(\tau) = \begin{cases} (p^\mu/m)\,\tau & \text{for } \tau < 0 \\ (p'^\mu/m)\,\tau & \text{for } \tau > 0 \end{cases}$$

Thus the current can be written

$$j^\mu(x) = e\int_0^\infty d\tau \frac{p'^\mu}{m}\delta^{(4)}\left(x - \frac{p'}{m}\tau\right) + e\int_{-\infty}^0 d\tau \frac{p^\mu}{m}\delta^{(4)}\left(x-\frac{p}{m}\tau\right)$$

In a moment we will need to know the Fourier transform of this function. Inserting factors of $e^{-\epsilon\tau}$ and $e^{\epsilon\tau}$ to make the integrals converge, we have

$$\begin{aligned}\tilde{j}^\mu(k) &= \int d^4x e^{ik\cdot x} j^\mu(x) \\ &= e\int_0^\infty d\tau \frac{p^\mu}{m} e^{i(kp'/m + i\epsilon)\tau} + e\int_{-\infty}^0 d\tau \frac{p^\mu}{m} e^{i(kp/m - i\epsilon)\tau} \\ &= ie\left(\frac{p'^\mu}{k\cdot p' + i\epsilon} - \frac{p^\mu}{k\cdot p - i\epsilon}\right)\end{aligned} \tag{6.4}$$

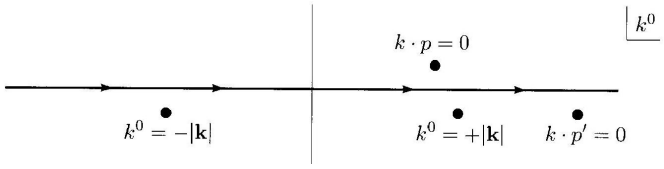
We are now ready to solve Maxwell's equations. In Lorentz gauge ($\partial^\mu A_\mu = 0$) we must solve $\partial^2 A^\mu = j^\mu$, or in Fourier space,

$$\widetilde{A}^\mu(k) = -\frac{1}{k^2}\tilde{j}^\mu(k).$$

Plugging in (6.4), we obtain a formula for the vector potential:

$$A^\mu(x) = \int \frac{d^4k}{(2\pi)^4} e^{-ik\cdot x}\frac{-ie}{k^2}\left(\frac{p'^\mu}{k\cdot p' + i\epsilon} - \frac{p^\mu}{k\cdot p - i\epsilon}\right). \tag{6.5}$$

The k^0 integral can be performed as a contour integral in the complex plane. The locations of the poles are as follows:



We place the poles at $k^0 = \pm|\mathbf{k}|$ below the real axis so that (as we shall soon confirm) the radiation field will satisfy retarded boundary conditions.

For $t < 0$ we close the contour upward, picking up the pole at $k \cdot p = 0$, that is, $k^0 = \mathbf{k} \cdot \mathbf{p}/p^0$. The result is

$$A^\mu(x) = \int \frac{d^3k}{(2\pi)^3} e^{i\mathbf{k}\cdot\mathbf{x}} e^{-i(\mathbf{k}\cdot\mathbf{p}/p^0)t} \frac{(2\pi i)(+ie)}{(2\pi)k^2} \frac{p^\mu}{p^0}.$$

In the reference frame where the particle is initially at rest, its momentum vector is $p^\mu = (p^0, \mathbf{0})$ and the vector potential reduces to

$$A^\mu(x) = \int \frac{d^3k}{(2\pi)^3} e^{i\mathbf{k}\cdot\mathbf{x}} \frac{e}{|\mathbf{k}|^2} \cdot (1, \mathbf{0})$$

This is just the Coulomb potential of an unaccelerated charge. As we would expect, there is no radiation field before the particle is scattered.

After scattering ($t > 0$), we close the contour downward, picking up the three poles below the real axis. The pole at $k^0 = \mathbf{k} \cdot \mathbf{p}'/p'^0$ gives the Coulomb potential of the outgoing particle. Thus the other two poles are completely responsible for the radiation field. Their contribution gives

$$\begin{aligned} A^\mu_{\text{rad}}(x) &= \int \frac{d^3k}{(2\pi)^3} \frac{-e}{2|\mathbf{k}|} \left\{ e^{-ik\cdot x} \left(\frac{p'^\mu}{k \cdot p'} - \frac{p^\mu}{k \cdot p} \right) + \text{ c.c. } \right\} \Bigg|_{k^0 = |\mathbf{k}|} \\ &= \text{Re} \int \frac{d^3k}{(2\pi)^3} \mathcal{A}^\mu(\mathbf{k}) e^{-ik\cdot x} \end{aligned} \tag{6.6}$$

where the momentum-space amplitude $\mathcal{A}(\mathbf{k})$ is given by

$$\mathcal{A}^\mu(\mathbf{k}) = \frac{-e}{|\mathbf{k}|} \left(\frac{p'^\mu}{k \cdot p'} - \frac{p^\mu}{k \cdot p} \right) \tag{6.7}$$

(The condition $k^0 = |\mathbf{k}|$ is implicit here and in the rest of this calculation.)
To calculate the energy radiated, we must find the electric and magnetic fields. It is easiest to write $\mathbf{E}$ and $\mathbf{B}$ as the real parts of complex Fourier integrals, just as we did for A^μ:

$$\begin{aligned} \mathbf{E}(x) &= \text{Re} \int \frac{d^3k}{(2\pi)^3} \mathcal{E}(\mathbf{k}) e^{-ik\cdot x} \\ \mathbf{B}(x) &= \text{Re} \int \frac{d^3k}{(2\pi)^3} \boldsymbol{\mathcal{B}}(\mathbf{k}) e^{-ik\cdot x} \end{aligned} \tag{6.8}$$

The momentum-space amplitudes $\mathcal{E}(\mathbf{k})$ and $\mathcal{B}(\mathbf{k})$ of the radiation fields are then simply

$$\begin{aligned} \mathcal{E}(\mathbf{k}) &= -i\mathbf{k}\mathcal{A}^0(\mathbf{k}) + ik^0 \mathcal{A}(\mathbf{k}) \\ \mathcal{B}(\mathbf{k}) &= i\mathbf{k} \times \mathcal{A}(\mathbf{k}) = \hat{k} \times \mathcal{E}(\mathbf{k}) \end{aligned} \tag{6.9}$$

Using the explicit form (6.7) of $\mathcal{A}^\mu(\mathbf{k})$, you can easily check that the electric field is transverse: $\mathbf{k} \cdot \mathcal{E}(\mathbf{k}) = 0$.

Having expressed the fields in this way, we can compute the energy radiated:

$$\text{Energy } = \frac{1}{2}\int d^3x \left(|\mathbf{E}(x)|^2 + |\mathbf{B}(x)|^2\right) \tag{6.10}$$

The first term is

$$\begin{aligned}&\frac{1}{8}\int d^3x \int \frac{d^3k}{(2\pi)^3}\int \frac{d^3k'}{(2\pi)^3}\left(\mathcal{E}(\mathbf{k})e^{-ikx} + \mathcal{E}^*(\mathbf{k})e^{ikx}\right)\cdot\left(\mathcal{E}\left(\mathbf{k}'\right)e^{-ik'x} + \mathcal{E}^*\left(\mathbf{k}'\right)e^{ik'x}\right)\\ &\quad = \frac{1}{8}\int \frac{d^3k}{(2\pi)^3}\left(\mathcal{E}(\mathbf{k})\cdot\mathcal{E}(-\mathbf{k})e^{-2ik^0t} + 2\mathcal{E}(\mathbf{k})\cdot\mathcal{E}^*(\mathbf{k}) + \mathcal{E}^*(\mathbf{k})\cdot\mathcal{E}^*(-\mathbf{k})e^{2ik^0t}\right)\end{aligned}$$

A similar expression involving $\boldsymbol{\mathcal{B}}(\mathbf{k})$ holds for the second term. Using (6.9) and the fact that $\mathcal{E}(\mathbf{k})$ is transverse, you can show that the time-dependent terms cancel between $\mathcal{E}$ and $\mathcal{B}$, while the remaining terms add to give

$$\text{Energy } = \frac{1}{2}\int \frac{d^3k}{(2\pi)^3}\mathcal{E}(\mathbf{k})\cdot\mathcal{E}^*(\mathbf{k}) \tag{6.11}$$

Since $\mathcal{E}(\mathbf{k})$ is transverse, let us introduce two transverse unit polarization vectors $\boldsymbol{\epsilon}_\lambda(\mathbf{k}), \lambda = 1, 2$. We can then write the integrand as

$$\mathcal{E}(\mathbf{k})\cdot\mathcal{E}^*(\mathbf{k}) = \sum_{\lambda=1,2}|\boldsymbol{\epsilon}_\lambda(\mathbf{k})\cdot\mathcal{E}(\mathbf{k})|^2 = |\mathbf{k}|^2\sum_{\lambda=1,2}|\epsilon_\lambda(\mathbf{k})\cdot\mathcal{A}(\mathbf{k})|^2$$

Using the explicit form of $\boldsymbol{\mathcal{A}}(\mathbf{k})$ (6.7), we finally arrive at an expression for the energy radiated*:

$$\text{Energy } = \int \frac{d^3k}{(2\pi)^3}\sum_{\lambda=1,2}\frac{e^2}{2}\left|\boldsymbol{\epsilon}_\lambda(\mathbf{k})\cdot\left(\frac{\mathbf{p}'}{k\cdot p'} - \frac{\mathbf{p}}{k\cdot p}\right)\right|^2 \tag{6.12}$$

We can freely change $\boldsymbol{\epsilon}, \mathbf{p}'$, and $\mathbf{p}$ into 4 -vectors in this expression. Then, noting that substituting k^μ for ϵ^μ would give zero,

$$k_\mu\left(\frac{p'^\mu}{k\cdot p'} - \frac{p^\mu}{k\cdot p}\right) = 0$$

we find that we can perform the sum over polarizations using the trick of Section 5.5, replacing $\sum\epsilon_\mu\epsilon_\nu^*$ by $-g_{\mu\nu}$. Our result then becomes

$$\begin{aligned}\text{Energy } &= \int \frac{d^3k}{(2\pi)^3}\frac{e^2}{2}\left(-g_{\mu\nu}\right)\left(\frac{p'^\mu}{k\cdot p'} - \frac{p^\mu}{k\cdot p}\right)\left(\frac{p'^\nu}{k\cdot p'} - \frac{p^\nu}{k\cdot p}\right)\\ &= \int \frac{d^3k}{(2\pi)^3}\frac{e^2}{2}\left(\frac{2p\cdot p'}{(k\cdot p')\,(k\cdot p)} - \frac{m^2}{(k\cdot p')^2} - \frac{m^2}{(k\cdot p)^2}\right)\end{aligned} \tag{6.13}$$

To make this formula more explicit, choose a frame in which $p^0 = p'^0 = E$. Then the momenta are

$$k^\mu = (k, \mathbf{k}), \quad p^\mu = E(1, \mathbf{v}), \quad p'^\mu = E\,(1, \mathbf{v}')$$

*This result is also derived in Jackson (1975), p. 703.

In such a frame our formula becomes

$$\text{Energy } = \frac{e^2}{(2\pi)^2}\int dk\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right) \tag{6.14}$$

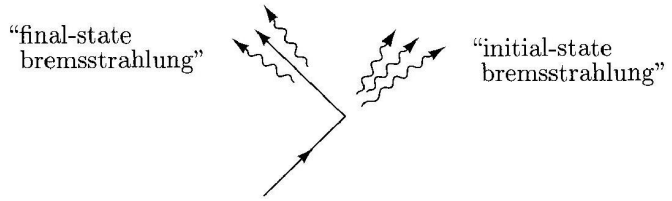
where $\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right)$ (which is essentially the differential intensity d (Energy) $/dk$) is given by

$$\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right)=\int\frac{d\Omega_{\hat{k}}}{4\pi}\left(\frac{2\left(1-\mathbf{v}\cdot\mathbf{v}'\right)}{\left(1-\hat{k}\cdot\mathbf{v}\right)\left(1-\hat{k}\cdot\mathbf{v}'\right)}-\frac{m^2/E^2}{\left(1-\hat{k}\cdot\mathbf{v}'\right)^2}-\frac{m^2/E^2}{(1-\hat{k}\cdot\mathbf{v})^2}\right) \tag{6.15}$$

Since $\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right)$ does not depend on k, we see that the integral over k in (6.14) is trivial but divergent. This divergence comes from our idealization of an infinitely sudden change in momentum. We expect our formula to be valid only for radiation whose frequency is less than the reciprocal of the scattering time. For a relativistic electron, another possible cutoff would take effect when individual photons carry away a sizable fraction of the electron's energy. In either case our formula is valid in the low-frequency limit, provided that we cut off the integral at some maximum frequency $k_{\max}$. We then have

$$\text{Energy } = \frac{\alpha}{\pi}\cdot k_{\max}\cdot\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right) \tag{6.16}$$

The integrand of $\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right)$ peaks when $\hat{k}$ is parallel to either $\mathbf{v}$ or $\mathbf{v}'$:



In the extreme relativistic limit, most of the radiated energy comes from the two peaks in the first term of (6.15). Let us evaluate $\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right)$ in this limit, by concentrating on the regions around these peaks. Break up the integral into a piece for each peak, and let $\theta=0$ along the peak in each case. Integrate over a small region around $\theta=0$, as follows:

$$\begin{aligned}\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right)\approx&\int_{\hat{k}\cdot\mathbf{v}=\mathbf{v}'\cdot\mathbf{v}}^{\cos\theta=1}d\cos\theta\frac{1-\mathbf{v}\cdot\mathbf{v}'}{\left(1-v\cos\theta\right)\left(1-\mathbf{v}\cdot\mathbf{v}'\right)}\\&+\int_{\hat{k}\cdot\mathbf{v}'=\mathbf{v}'\cdot\mathbf{v}}^{\cos\theta=1}d\cos\theta\frac{1-\mathbf{v}\cdot\mathbf{v}'}{\left(1-\mathbf{v}\cdot\mathbf{v}'\right)\left(1-v'\cos\theta\right)}\end{aligned}$$

(The lower limits on the integrals are not critical; an equally good choice would be $\hat{k}\cdot\mathbf{v}=1-x\left(1-\mathbf{v}\cdot\mathbf{v}'\right)$, as long as x is neither too close to 0 nor too much bigger than 1 . It is then easy to show that the leading term in the
relativistic limit does not depend on x.) The integrals are easy to perform, and we obtain

$$\begin{aligned}\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right)&\approx\log\left(\frac{1-\mathbf{v}'\cdot\mathbf{v}}{1-|\mathbf{v}|}\right)+\log\left(\frac{1-\mathbf{v}'\cdot\mathbf{v}}{1-|\mathbf{v}'|}\right)=\log\left(\frac{\left(E^2-\mathbf{p}\cdot\mathbf{p}'\right)^2}{E^2(E-p)^2}\right)\\&\approx 2\log\left(\frac{p\cdot p'}{\left(E^2-p^2\right)/2}\right)=2\log\left(\frac{-q^2}{m^2}\right)\end{aligned} \tag{6.17}$$

where $q^2 = (p' - p)^2$.
In conclusion, we have found that the radiated energy at low frequencies is given by

$$\text{Energy } = \frac{\alpha}{\pi} \int_0^{k_{\max}} dk \mathcal{I}\left(\mathbf{v}, \mathbf{v}'\right) \underset{E \gg m}{\longrightarrow} \frac{2\alpha}{\pi} \int_0^{k_{\max}} dk \log\left(\frac{-q^2}{m^2}\right) \tag{6.18}$$

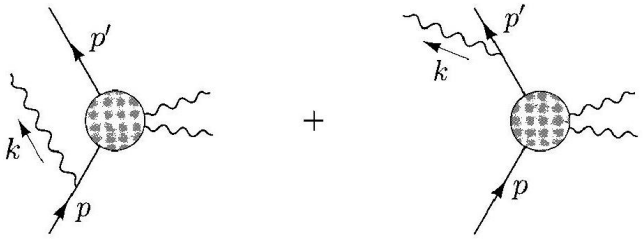
If this energy is made up of photons, each photon contributes energy k. We would then expect

$$\text{Number of photons } = \frac{\alpha}{\pi} \int_0^{k_{\max}} dk \frac{1}{k} \mathcal{I}\left(\mathbf{v}, \mathbf{v}'\right) \tag{6.19}$$

We hope that a quantum-mechanical calculation will confirm this result.

Quantum Computation

Consider now the quantum-mechanical process in which one photon is radiated during the scattering of an electron:



Let $\mathcal{M}_0$ denote the part of the amplitude that comes from the electron's interaction with the external field. Then the amplitude for the whole process is

$$\begin{aligned} i\mathcal{M} = -ie\bar{u}\left(p'\right) \Bigg(& \mathcal{M}_0\left(p', p-k\right) \frac{i(\not{p} - \not{k} + m)}{(p-k)^2 - m^2} \gamma^\mu \epsilon_\mu^*(k) \\ & + \gamma^\mu \epsilon_\mu^*(k) \frac{i\left(\not{p}' + \not{k} + m\right)}{\left(p'+k\right)^2 - m^2} \mathcal{M}_0\left(p'+k, p\right) \Bigg) u(p) \end{aligned} \tag{6.20}$$

Since we are interested in connecting with the classical limit, assume that the photon radiated is soft: $|\mathbf{k}| \ll |\mathbf{p}' - \mathbf{p}|$. Then we can approximate

$$\mathcal{M}_0\left(p', p-k\right) \approx \mathcal{M}_0\left(p'+k, p\right) \approx \mathcal{M}_0\left(p', p\right) \tag{6.21}$$

and we can ignore $\not{\angle} x$ in the numerators of the propagators. The numerators can be further simplified with some Dirac algebra. In the first term we have

$$\begin{aligned} (\not{p} + m)\gamma^\mu \epsilon_\mu^* u(p) &= \left[2p^\mu \epsilon_\mu^* + \gamma^\mu \epsilon_\mu^* (-\not{p} + m)\right] u(p) \\ &= 2p^\mu \epsilon_\mu^* u(p) \end{aligned}$$

Similarly, in the second term,

$$\bar{u}\left(p'\right) \gamma^\mu \epsilon_\mu^* \left(\not{p}' + m\right) = \bar{u}\left(p'\right) 2p'^\mu \epsilon_\mu^*.$$

The denominators of the propagators also simplify:

$$(p-k)^2 - m^2 = -2p \cdot k; \quad \left(p'+k\right)^2 - m^2 = 2p' \cdot k$$

So in the soft-photon approximation, the amplitude becomes

$$i\mathcal{M} = \bar{u}\left(p'\right)\left[\mathcal{M}_0\left(p', p\right)\right] u(p) \cdot \left[e\left(\frac{p' \cdot \epsilon^*}{p' \cdot k} - \frac{p \cdot \epsilon^*}{p \cdot k}\right)\right]. \tag{6.22}$$

This is just the amplitude for elastic scattering (without bremsstrahlung), times a factor (in brackets) for the emission of the photon.

The cross section for our process is also easy to express in terms of the elastic cross section; just insert an additional phase-space integration for the photon variable k. Summing over the two photon polarization states, we have

$$d\sigma\left(p \to p' + \gamma\right) = d\sigma\left(p \to p'\right) \cdot \int \frac{d^3k}{(2\pi)^3} \frac{1}{2k} \sum_{\lambda=1,2} e^2 \left|\frac{p' \cdot \epsilon^{(\lambda)}}{p' \cdot k} - \frac{p \cdot \epsilon^{(\lambda)}}{p \cdot k}\right|^2 \tag{6.23}$$

Thus the differential probability of radiating a photon with momentum k, given that the electron scatters from p to p', is

$$d(\text{ prob }) = \frac{d^3k}{(2\pi)^3} \sum_{\lambda} \frac{e^2}{2k} \left|\boldsymbol{\epsilon}_\lambda \cdot \left(\frac{\mathbf{p}'}{p' \cdot k} - \frac{\mathbf{p}}{p \cdot k}\right)\right|^2 \tag{6.24}$$

This looks very familiar; if we multiply by the photon energy k to compute the expected energy radiated, we recover the classical expression (6.12).

But there is a problem. Equation (6.24) is an expression not for the expected number of photons radiated, but for the probability of radiating a single photon. The problem becomes worse if we integrate over the photon momentum. As in (6.16), we can integrate only up to the energy at which our soft-photon approximations break down; a reasonable estimate for this energy is $|\mathbf{q}| = |\mathbf{p} - \mathbf{p}'|$. The integral is therefore

$$\text{Total probability } \approx \frac{\alpha}{\pi} \int_0^{|\mathbf{q}|} dk \frac{1}{k} \mathcal{I}\left(\mathbf{v}, \mathbf{v}'\right) \tag{6.25}$$

Since $\mathcal{I}\left(\mathbf{v}, \mathbf{v}'\right)$ is independent of k, the integral diverges at its lower limit (where all our approximations are well justified). In other words, the total
probability of radiating a very soft photon is infinite. This is the famous problem of infrared divergences in QED perturbation theory.

We can artificially make the integral in (6.25) well-defined by pretending that the photon has a very small mass μ. This mass would then provide a lower cutoff for the integral, allowing us to write the result of this section as

$$\begin{aligned} d\sigma\left(p \to p' + \gamma(k)\right) &= d\sigma\left(p \to p'\right) \cdot \frac{\alpha}{2\pi} \log\left(\frac{-q^2}{\mu^2}\right) \mathcal{I}\left(\mathbf{v}, \mathbf{v}'\right) \\ &\underset{-q^2 \to \infty}{\approx} d\sigma\left(p \to p'\right) \cdot \frac{\alpha}{\pi} \log\left(\frac{-q^2}{\mu^2}\right) \log\left(\frac{-q^2}{m^2}\right). \end{aligned} \tag{6.26}$$

The q^2 dependence of this result, known as the Sudakov double logarithm, is physical and will appear again in Section 6.4. The dependence on μ, however, presents a problem that we must solve. It is not hard to guess that the resolution of this problem will involve reinterpreting (6.24) as the expected number of radiated photons, rather than the probability of radiating a single photon. We will see in Sections 6.4 and 6.5 how this reinterpretation follows from the Feynman diagrams.

To prepare for that discussion, however, we need to improve our understanding of the amplitude for scattering without radiation.

16.2 6.2 The Electron Vertex Function: Formal Structure

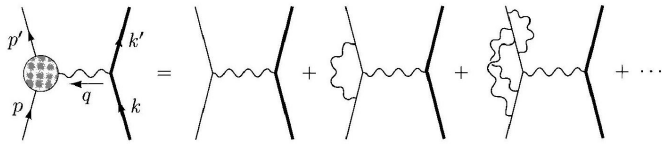
Having briefly discussed QED radiative corrections due to emission of photons (bremsstrahlung), let us now study the correction to electron scattering that comes from the presence of an additional virtual photon:

(add the diagram here!!)

This will be our first experience with a Feynman diagram containing a loop. Such diagrams give rise to significant and profound complications in quantum field theory.

The result of computing this diagram will be rather complicated, so it will be useful to think ahead about what form we expect this correction to take and how to interpret its various possible terms. In this section, we will consider the general properties of vertex correction diagrams. We will see that the basic requirements of Lorentz invariance, the discrete symmetries of QED, and the Ward identity strongly constrain the form of the vertex.

Consider, then, the class of diagrams



where the gray circle indicates the sum of the lowest-order electron-photon vertex and all amputated loop corrections. We will call this sum of vertex diagrams $-ie\Gamma^{\mu}\left(p',p\right)$. Then, according to our master formula (4.103) for S matrix elements, the amplitude for electron scattering from a heavy target is

$$i\mathcal{M}=ie^{2}\left(\bar{u}\left(p'\right)\Gamma^{\mu}\left(p',p\right)u(p)\right)\frac{1}{q^{2}}\left(\bar{u}\left(k'\right)\gamma_{\mu}u(k)\right). \tag{6.28}$$

More generally, the function $\Gamma^{\mu}\left(p',p\right)$ appears in the S-matrix element for the scattering of an electron from an external electromagnetic field. As in Problem 4.4, add to the Hamiltonian of QED the interaction

$$\Delta H_{\text{int}}=\int d^{3}xeA_{\mu}^{\text{cl}}j^{\mu} \tag{6.29}$$

where $j^{\mu}(x)=\bar{\psi}(x)\gamma^{\mu}\psi(x)$ is the electromagnetic current and A_{μ}^{cl} is a fixed classical potential. In the leading order of perturbation theory, the S-matrix element for scattering from this field is

$$i\mathcal{M}(2\pi)\delta\left(p^{0\prime}-p^{0}\right)=-ie\bar{u}\left(p'\right)\gamma^{\mu}u(p)\cdot\widetilde{A}_{\mu}^{\text{cl}}\left(p'-p\right)$$

where $\widetilde{A}_{\mu}^{\text{cl}}(q)$ is the Fourier transform of $A_{\mu}^{\text{cl}}(x)$. The vertex corrections modify this expression to

$$i\mathcal{M}(2\pi)\delta\left(p^{0\prime}-p^{0}\right)=-ie\bar{u}\left(p'\right)\Gamma^{\mu}\left(p',p\right)u(p)\cdot\widetilde{A}_{\mu}^{\text{cl}}\left(p'-p\right) \tag{6.30}$$

In writing (6.28) and (6.30), we have deliberately omitted the contribution of vacuum polarization diagrams, such as the fourth diagram of (6.1). The reason for this omission is that these

diagrams should be considered corrections to the electromagnetic field itself, while the diagrams included in Γ^μ represent corrections to the electron's response to a given applied field. †

We can use general arguments to restrict the form of $\Gamma^\mu(p', p)$. To lowest order, $\Gamma^\mu = \gamma^\mu$. In general, Γ^μ is some expression that involves p, p', γ^μ, and constants such as m, e, and pure numbers. This list is exhaustive, since no other objects appear in the Feynman rules for evaluating the diagrams that contribute to Γ^μ. The only other object that could appear in any theory is $\epsilon^{\mu\nu\rho\sigma}$ (or equivalently, γ^5); but this is forbidden in any parity-conserving theory.

We can narrow down the form of Γ^μ considerably by appealing to Lorentz invariance. Since Γ^μ transforms as a vector (in the same sense that γ^μ does), it must be a linear combination of the vectors from the list above: γ^μ, p^μ, and p'^μ. Using the combinations $p' + p$ and $p' - p$ for convenience, we have

$$\Gamma^\mu = \gamma^\mu \cdot A + (p'^\mu + p^\mu) \cdot B + (p'^\mu - p^\mu) \cdot C \tag{6.31}$$

The coefficients A, B, and C could involve Dirac matrices dotted into vectors, that is, $\not{p}$ or $\not{p}'$. But since $\not{p}u(p) = m \cdot u(p)$ and $\bar{u}(p')\not{p}' = \bar{u}(p') \cdot m$, we can write the coefficients in terms of ordinary numbers without loss of generality. The only nontrivial scalar available is $q^2 = -2p' \cdot p + 2m^2$, so A, B, and C must be functions only of q^2 (and of constants such as m).

The list of allowed vectors can be further shortened by applying the Ward identity (5.79): $q_\mu \Gamma^\mu = 0$. (Note that our arguments for this identity in Section 5.5 - and the proof in Section 7.4 - do not require $q^2 = 0$.) Dotting q_μ into (6.31), we find that the second term vanishes, as does the first when sandwiched between $\bar{u}(p')$ and $u(p)$. The third term does not automatically vanish, so C must be zero.

We can make no further simplifications of (6.31) on general principles. It is conventional, however, to rewrite (6.31) by means of the Gordon identity (see Problem 3.2):

$$\bar{u}(p')\gamma^\mu u(p) = \bar{u}(p')\left[\frac{p'^\mu + p^\mu}{2m} + \frac{i\sigma^{\mu\nu}q_\nu}{2m}\right]u(p) \tag{6.32}$$

This identity allows us to swap the $(p' + p)$ term for one involving $\sigma^{\mu\nu}q_\nu$. We write our final result as

$$\Gamma^\mu(p', p) = \gamma^\mu F_1\left(q^2\right) + \frac{i\sigma^{\mu\nu}q_\nu}{2m}F_2\left(q^2\right) \tag{6.33}$$

where F_1 and F_2 are unknown functions of q^2 called form factors.
To lowest order, $F_1 = 1$ and $F_2 = 0$. In the next section we will compute the one-loop (order- α) corrections to the form factors, due to the vertex correction diagram (6.27). In principle, the form factors can be computed to any order in perturbation theory.

Since F_1 and F_2 contain complete information about the influence of an electromagnetic field on the electron, they should, in particular, contain the electron's gross electric and magnetic couplings. To identify the electric charge of the electron, we can use (6.30) to compute the amplitude for elastic Coulomb scattering of a nonrelativistic electron from a region of nonzero electrostatic potential. Set $A^{\rm cl}_\mu(x) = (\phi(\mathbf{x}), \mathbf{0})$. Then $\widetilde{A}^{\rm cl}_\mu(q) = \Big((2\pi)\delta(q^0)\,\tilde{\phi}(\mathbf{q}), \mathbf{0}\Big)$. Inserting this into (6.30), we find

$$i\mathcal{M} = -ie\bar{u}(p')\,\Gamma^0(p', p)\,u(p) \cdot \tilde{\phi}(\mathbf{q})$$

[6†] To justify this statement, we must give a careful definition of an applied external field in a quantum field theory. We will do this in Chapter 11.

If the electrostatic field is very slowly varying over a large (perhaps macroscopic) region, $\phi(\mathbf{q})$ will be concentrated about $\mathbf{q} = 0$; then we can take the
limit $\mathbf{q} \to 0$ in the spinor matrix element. Only the form factor F_1 contributes. Using the nonrelativistic limit of the spinors,

$$\bar{u}\,(p')\,\gamma^0 u(p) = u^\dagger\,(p')\,u(p) \approx 2m\xi'^\dagger\xi$$

the amplitude for electron scattering from an electric field takes the form

$$i\mathcal{M} = -ieF_1(0)\tilde{\phi}(\mathbf{q}) \cdot 2m\xi'^\dagger\xi \tag{6.34}$$

This is the Born approximation for scattering from a potential

$$V(\mathbf{x}) = eF_1(0)\phi(\mathbf{x})$$

Thus $F_1(0)$ is the electric charge of the electron, in units of e. Since $F_1(0) = 1$ already in the leading order of perturbation theory, radiative corrections to $F_1\,(q^2)$ should vanish at $q^2 = 0$.

By repeating this analysis for an electron scattering from a static vector potential, we can derive a similar connection between the form factors and the electron's magnetic moment. ‡ Set $A^{\rm cl}_\mu(x) = \big(0, \mathbf{A}^{\rm cl}(\mathbf{x})\big)$. Then the amplitude for scattering from this field is

$$i\mathcal{M} = +ie\left[\bar{u}\,(p')\left(\gamma^i F_1 + \frac{i\sigma^{i\nu}q_\nu}{2m}F_2\right)u(p)\right]\widetilde{A}^i_{\rm cl}(\mathbf{q}). \tag{6.35}$$

The expression in brackets vanishes at $\mathbf{q} = 0$, so we must carefully extract from it a contribution linear in q^i. To do this, insert the nonrelativistic expansion of the spinors $u(p)$, keeping terms through first order in momenta:

$$u(p) = \begin{pmatrix}\sqrt{p\cdot\sigma}\xi\\ \sqrt{p\cdot\bar{\sigma}}\xi\end{pmatrix} \approx \sqrt{m}\begin{pmatrix}(1-\mathbf{p}\cdot\boldsymbol{\sigma}/2m)\xi\\ (1+\mathbf{p}\cdot\boldsymbol{\sigma}/2m)\xi\end{pmatrix}. \tag{6.36}$$

Then the F_1 term can be simplified as follows:

$$\bar{u}\,(p')\,\gamma^i u(p) = 2m\xi'^\dagger\left(\frac{\mathbf{p}'\cdot\boldsymbol{\sigma}}{2m}\sigma^i + \sigma^i\frac{\mathbf{p}\cdot\boldsymbol{\sigma}}{2m}\right)\xi$$

Applying the identity $\sigma^i\sigma^j = \delta^{ij} + i\epsilon^{ijk}\sigma^k$, we find a spin-independent term, proportional to $(\mathbf{p}' + \mathbf{p})$, and a spin-dependent term, proportional to $(\mathbf{p}' - \mathbf{p})$. The first of these terms is the contribution of the operator $[\mathbf{p}\cdot\mathbf{A} + \mathbf{A}\cdot\mathbf{p}]$ in the standard kinetic energy term of nonrelativistic quantum mechanics. The second is the magnetic moment interaction we are seeking. Retaining only the latter term, we have

$$\bar{u}\,(p')\,\gamma^i u(p) = 2m\xi'^\dagger\left(\frac{-i}{2m}\epsilon^{ijk}q^j\sigma^k\right)\xi$$

The F_2 term already contains an explicit factor of q, so we can evaluate it using the leading-order term of the expansion of the spinors. This gives

$$\bar{u}\,(p')\left(\frac{i}{2m}\sigma^{i\nu}q_\nu\right)u(p) = 2m\xi'^\dagger\left(\frac{-i}{2m}\epsilon^{ijk}q^j\sigma^k\right)\xi$$

[6‡] The following argument contains numerous factors of (-1) from raising and lowering spacelike indices. Be careful in verifying the algebra.

Thus, the complete term linear in q^j in the electron-photon vertex function is

$$\bar{u}(p')\left(\gamma^i F_1 + \frac{i\sigma^{i\nu}q_\nu}{2m}F_2\right)u(p) \underset{q\to 0}{\approx} 2m\xi'^\dagger\left(\frac{-i}{2m}\epsilon^{ijk}q^j\sigma^k\left[F_1(0)+F_2(0)\right]\right)\xi$$

Inserting this expression into (6.35), we find

$$i\mathcal{M} = -i(2m)\cdot e\xi'^\dagger\left(\frac{-1}{2m}\sigma^k\left[F_1(0)+F_2(0)\right]\right)\xi\tilde{B}^k(\mathbf{q})$$

where

$$\widetilde{B}^k(\mathbf{q}) = -i\epsilon^{ijk}q^i\widetilde{A}^j_{\rm cl}(\mathbf{q})$$

is the Fourier transform of the magnetic field produced by $\mathbf{A}^{\rm cl}(\mathbf{x})$.
Again we can interpret $\mathcal{M}$ as the Born approximation to the scattering of the electron from a potential well. The potential is just that of a magnetic moment interaction,

$$V(\mathbf{x}) = -\langle\boldsymbol{\mu}\rangle\cdot\mathbf{B}(\mathbf{x})$$

where

$$\langle\boldsymbol{\mu}\rangle = \frac{e}{m}\left[F_1(0)+F_2(0)\right]\xi'^\dagger\frac{\boldsymbol{\sigma}}{2}\xi.$$

This expression for the magnetic moment of the electron can be rewritten in the standard form

$$\boldsymbol{\mu} = g\left(\frac{e}{2m}\right)\mathbf{S}$$

where $\mathbf{S}$ is the electron spin. The coefficient g, called the Land g-factor, is

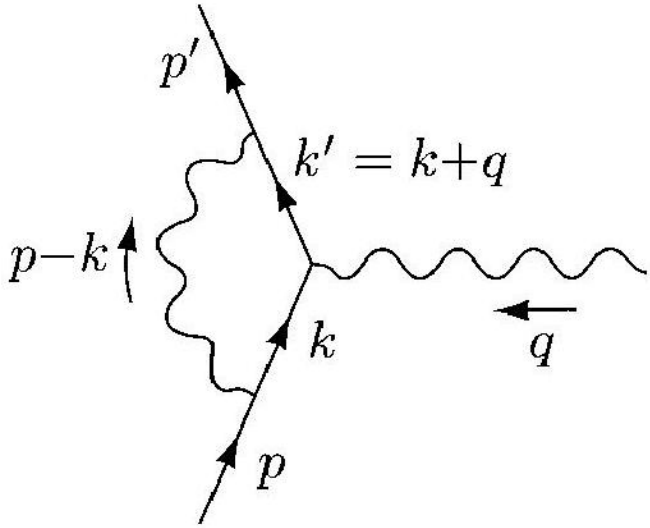
$$g = 2\left[F_1(0)+F_2(0)\right] = 2+2F_2(0). \tag{6.37}$$

Since the leading order of perturbation theory gives no F_2 term, QED predicts $g = 2+\mathcal{O}(\alpha)$. The leading term is the standard prediction of the Dirac equation. In higher orders, however, we will find a nonzero F_2 and thus a small difference between the electron's magnetic moment and the Dirac value. We will compute the order- α contribution to this anomalous magnetic moment in the next section.

Since our derivation of the structure (6.33) for the vertex function used only general symmetry principles, we expect this formula to apply not only to the electron but to any fermion with electromagnetic interactions. For example, the electromagnetic scattering amplitude of the proton should also be described by two invariant functions of q^2. Since the proton is not an elementary particle, we should not expect the Dirac equation values $F_1 = 1$ and $F_2 = 0$ to be good approximations to the form factors of the proton. In fact, both proton form factors depend strongly on q^2. However, the description of the vertex function in term of form factors provides a useful summary of data on scattering at many energies and angles. The precise transcription between form factors and cross sections is worked out in Problem 6.1. In addition, the general constraints at $q^2 = 0$ that we have just derived apply to the proton: $F_1(0) = 1$, and $2F_2(0) = (g_p - 2)$, though the g-factor of the proton differs by 40% from the Dirac value.

16.3 6.3 The Electron Vertex Function: Evaluation

Now that we know what form the answer is to take (Eq. (6.33)), we are ready to evaluate the one-loop contribution to the electron vertex function. Assign momenta on the diagram as follows:



Applying the Feynman rules, we find, to order α, that $\Gamma^\mu = \gamma^\mu + \delta\Gamma^\mu$, where

$$\begin{aligned}
&\bar{u}(p')\,\delta\Gamma^\mu(p',p)\,u(p) \\
&\quad = \int \frac{d^4k}{(2\pi)^4}\frac{-ig_{\nu\rho}}{(k-p)^2+i\epsilon}\bar{u}(p')(-ie\gamma^\nu)\frac{i(\not{l}'+m)}{k'^2-m^2+i\epsilon}\gamma^\mu\frac{i(\not{k}+m)}{k^2-m^2+i\epsilon}(-ie\gamma^\rho)\,u(p) \\
&\quad = 2ie^2\int\frac{d^4k}{(2\pi)^4}\frac{\bar{u}(p')\left[\not{k}\gamma^\mu\ \not{l}'+m^2\gamma^\mu-2m(k+k')^\mu\right]u(p)}{((k-p)^2+i\epsilon)(k'^2-m^2+i\epsilon)(k^2-m^2+i\epsilon)}.
\end{aligned} \tag{6.38}$$

In the second line we have used the contraction identity $\gamma^\nu\gamma^\mu\gamma_\nu = -2\gamma^\mu$. Note that the $+i\epsilon$ terms in the denominators cannot be dropped; they are necessary for proper evaluation of the loop-momentum integral.

The integral looks impossible, and in fact it will not be easy. The evaluation of such integrals requires another piece of computational technology, known as the method of Feynman parameters (although a very similar method was introduced earlier by Schwinger).

Feynman Parameters

The goal of this method is to squeeze the three denominator factors of (6.38) into a single quadratic polynomial in k, raised to the third power. We can then shift k by a constant to complete the square in this polynomial and evaluate the remaining spherically symmetric integral without difficulty. The price will be the introduction of auxiliary parameters to be integrated over.

It is easiest to begin with the simpler case of two factors in the denominator. We would then use the identity

$$\frac{1}{AB} = \int_0^1 dx\frac{1}{[xA+(1-x)B]^2} = \int_0^1 dxdy\delta(x+y-1)\frac{1}{[xA+yB]^2} \tag{6.39}$$

An example of its use might look like this:

$$\frac{1}{(k-p)^2\left(k^2-m^2\right)} = \int_0^1 dxdy\delta(x+y-1)\frac{1}{\left[x(k-p)^2+y\left(k^2-m^2\right)\right]^2}$$
$$= \int_0^1 dxdy\delta(x+y-1)\frac{1}{\left[k^2-2xk\cdot p+xp^2-ym^2\right]^2}$$

If we now let $\ell \equiv k - xp$, we see that the denominator depends only on ℓ^2. Integrating over d^4k would now be much easier, since $d^4k = d^4\ell$ and the integrand is spherically symmetric with respect to ℓ. The variables x and y that make this transformation possible are called Feynman parameters.

Our integral (6.38) involves a denominator with three factors, so we need a slightly better identity. By differentiating (6.39) with respect to B, it is easy to prove

$$\frac{1}{AB^n} = \int_0^1 dxdy\delta(x+y-1)\frac{ny^{n-1}}{[xA+yB]^{n+1}} \tag{6.40}$$

But this still isn't quite good enough. The formula we need is

$$\frac{1}{A_1A_2\cdots A_n} = \int_0^1 dx_1\cdots dx_n\delta\left(\sum x_i - 1\right)\frac{(n-1)!}{\left[x_1A_1+x_2A_2+\cdots x_nA_n\right]^n} \tag{6.41}$$

The proof of this identity is by induction. The case $n = 2$ is just Eq. (6.39); the induction step is not difficult and involves the use of (6.40).

By repeated differentiation of (6.41), you can derive the even more general identity

$$\frac{1}{A_1^{m_1}A_2^{m_2}\cdots A_n^{m_n}} = \int_0^1 dx_1\cdots dx_n\delta\left(\sum x_i - 1\right)\frac{\prod x_i^{m_i-1}}{\left[\sum x_iA_i\right]^{\Sigma m_i}}\frac{\Gamma\left(m_1+\cdots+m_n\right)}{\Gamma\left(m_1\right)\cdots\Gamma\left(m_n\right)} \tag{6.42}$$

This formula is true even when the m_i are not integers; in Section 10.5 we will apply it in such a case.

Evaluation of the Form Factors

Now let us apply formula (6.41) to the denominator of (6.38):

$$\frac{1}{\left((k-p)^2+i\epsilon\right)\left(k'^2-m^2+i\epsilon\right)\left(k^2-m^2+i\epsilon\right)} = \int_0^1 dxdydz\delta(x+y+z-1)\frac{2}{D^3},$$

where the new denominator D is

$$D = x\left(k^2-m^2\right)+y\left(k^2-m^2\right)+z(k-p)^2+(x+y+z)i\epsilon$$
$$= k^2+2k\cdot(yq-zp)+yq^2+zp^2-(x+y)m^2+i\epsilon. \tag{6.43}$$

In the second line we have used $x + y + z = 1$ and $k' = k + q$. Now shift k to complete the square:

$$\ell \equiv k+yq-zp$$

After a bit of algebra we find that D simplifies to

$$D = \ell^2 - \Delta + i\epsilon,$$

where

$$\Delta \equiv -xyq^2 + (1-z)^2 m^2 \tag{6.44}$$

Since $q^2 < 0$ for a scattering process, Δ is positive; we can think of it as an effective mass term.

Next we must express the numerator of (6.38) in terms of ℓ. This task is simplified by noting that since D depends only on the magnitude of ℓ,

$$\int \frac{d^4\ell}{(2\pi)^4}\frac{\ell^\mu}{D^3} = 0 \tag{6.45}$$

$$\int \frac{d^4\ell}{(2\pi)^4}\frac{\ell^\mu \ell^\nu}{D^3} = \int \frac{d^4\ell}{(2\pi)^4}\frac{\frac{1}{4}g^{\mu\nu}\ell^2}{D^3} \tag{6.46}$$

The first identity follows from symmetry. To prove the second, note that the integral vanishes by symmetry unless $\mu = \nu$. Lorentz invariance therefore requires that we get something proportional to $g^{\mu\nu}$. To check the coefficient, contract each side with $g_{\mu\nu}$. Using these identities, we have

$$\begin{aligned}
&\text{Numerator } = \bar{u}(p')\left[\not{\ell}\gamma^\mu \not{\ell}'\right.\\
&\left.+m^2\gamma^\mu - 2m(k+k')^\mu\right] u(p)\\
&\to \bar{u}(p')\left[-\frac{1}{2}\gamma^\mu\ell^2 + (-y\not{q} + z\not{p})\gamma^\mu((1-y)\not{q} + z\not{p})\right.\\
&\left.+m^2\gamma^\mu - 2m((1-2y)q^\mu + 2zp^\mu)\right] u(p).
\end{aligned}$$

(Remember that $k' = k + q$.)

Putting the numerator into a useful form is now just a matter of some tedious Dirac algebra (about a page or two). This is where our work in the last section pays off, since it tells us what kind of an answer to expect. We eventually want to group everything into two terms, proportional to γ^μ and $i\sigma^{\mu\nu}q_\nu$. The most straightforward way to accomplish this is to aim instead for an expression of the form

$$\gamma^\mu \cdot A + (p'^\mu + p^\mu)\cdot B + q^\mu \cdot C$$

just as in (6.31). Attaining this form requires only the anticommutation relations (for example, $\not{p}\gamma^\mu = 2p^\mu - \gamma^\mu \not{p}$) and the Dirac equation ($\not{p}u(p) = mu(p)$

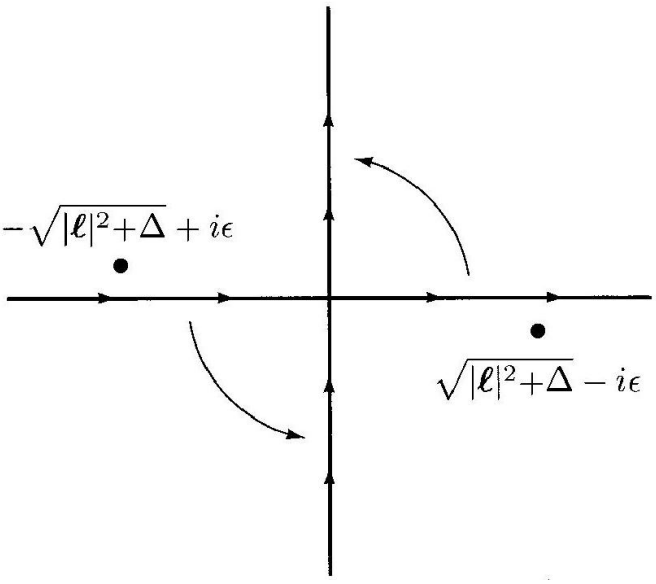


Figure 6.1. The contour of the ℓ^0 integration can be rotated as shown.

and $\bar{u}(p')\not{p}'' = \bar{u}(p')\,m$; note that this implies $\bar{u}(p')\not{q}u(p) = 0$). It is also useful to remember that $x + y + z = 1$. When the smoke clears, we have

$$\begin{aligned}\text{Numerator} &= \bar{u}(p')\left[\gamma^\mu \cdot \left(-\frac{1}{2}\ell^2 + (1-x)(1-y)q^2 + \left(1-2z-z^2\right)m^2\right)\right.\\ &\left. + (p'^\mu + p^\mu)\cdot mz(z-1) + q^\mu \cdot m(z-2)(x-y)\right]u(p)\end{aligned}$$

The coefficient of q^μ must vanish according to the Ward identity, as discussed after Eq. (6.31). To see that it does, note from (6.44) that the denominator is symmetric under $x \leftrightarrow y$. The coefficient of q^μ is odd under $x \leftrightarrow y$ and therefore vanishes when integrated over x and y.

Still following our work in the previous section, we now use the Gordon identity (6.32) to eliminate $(p' + p)$ in favor of $i\sigma^{\mu\nu}q_\nu$. Our entire expression for the $\mathcal{O}(\alpha)$ contribution to the electron vertex then becomes

$$\begin{aligned}\bar{u}(p')\,\delta\Gamma^\mu(p',p)\,u(p) &= 2ie^2\int\frac{d^4\ell}{(2\pi)^4}\int_0^1 dxdydz\delta(x+y+z-1)\frac{2}{D^3}\\ &\times\bar{u}(p')\left[\gamma^\mu\cdot\left(-\frac{1}{2}\ell^2+(1-x)(1-y)q^2+\left(1-4z+z^2\right)m^2\right)\right.\\ &\left.+\frac{i\sigma^{\mu\nu}q_\nu}{2m}\left(2m^2z(1-z)\right)\right]u(p)\end{aligned}\tag{6.47}$$

where as before,

$$D = \ell^2 - \Delta + i\epsilon, \quad \Delta = -xyq^2 + (1-z)^2m^2 > 0$$

The decomposition into form factors is now manifest.

With most of the work behind us, our main remaining task is to perform the momentum integral. It is not difficult to evaluate the ℓ^0 integral as a

contour integral, then do the spatial integrals in spherical coordinates. We will use an even easier method, making use of a trick called Wick rotation. Note that if it were not for the minus signs in the Minkowski metric, we could perform the entire four-dimensional integral in four-dimensional

"spherical" coordinates. To remove the minus signs, consider the contour of integration in the ℓ^0-plane (see Fig. 6.1). The locations of the poles, and the fact that the integrand falls off sufficiently rapidly at large $|\ell^0|$, allow us to rotate the contour counterclockwise by 90°. We then define a Euclidean 4 -momentum variable ℓ_E:

$$\ell^0 \equiv i\ell_E^0; \quad \ell = \ell_E \tag{6.48}$$

Our rotated contour goes from $\ell_E^0 = -\infty$ to ∞. By simply changing variables to ℓ_E, we can now evaluate the integral in four-dimensional spherical coordinates.

Let us first evaluate

$$\begin{aligned}\int \frac{d^4\ell}{(2\pi)^4}\frac{1}{[\ell^2-\Delta]^m} &= \frac{i}{(-1)^m}\frac{1}{(2\pi)^4}\int d^4\ell_E \frac{1}{[\ell_E^2+\Delta]^m} \\ &= \frac{i(-1)^m}{(2\pi)^4}\int d\Omega_4 \int_0^\infty d\ell_E \frac{\ell_E^3}{[\ell_E^2+\Delta]^m}\end{aligned}$$

(Here we need only the case $m = 3$, but the more general result will be useful for other loop calculations.) The factor $\int d\Omega_4$ is the surface "area" of a fourdimensional unit sphere, which happens to equal $2\pi^2$. (One way to compute this area is to use four-dimensional spherical coordinates,

$$x = (r\sin\omega\sin\theta\cos\phi, r\sin\omega\sin\theta\sin\phi, r\sin\omega\cos\theta, r\cos\omega)$$

The integration measure is then $d^4x = r^3\sin^2\omega\sin\theta d\phi d\theta d\omega dr$.) The rest of the integral is straightforward, and we have

$$\int \frac{d^4\ell}{(2\pi)^4}\frac{1}{[\ell^2-\Delta]^m} = \frac{i(-1)^m}{(4\pi)^2}\frac{1}{(m-1)(m-2)}\frac{1}{\Delta^{m-2}} \tag{6.49}$$

Similarly,

$$\int \frac{d^4\ell}{(2\pi)^4}\frac{\ell^2}{[\ell^2-\Delta]^m} = \frac{i(-1)^{m-1}}{(4\pi)^2}\frac{2}{(m-1)(m-2)(m-3)}\frac{1}{\Delta^{m-3}} \tag{6.50}$$

Note that this second result is valid only when $m > 3$. When $m = 3$, the Wick rotation cannot be justified, and the integral is in any event divergent. But it is just this case that we need for (6.47).

We will eventually explore the physical meaning of this divergence, but for the moment we simply introduce an artificial prescription to make our integral finite. Go back to the original expression for the Feynman integral in
(6.38), and replace in the photon propagator

$$\frac{1}{(k-p)^2+i\epsilon} \longrightarrow \frac{1}{(k-p)^2+i\epsilon} - \frac{1}{(k-p)^2-\Lambda^2+i\epsilon} \tag{6.51}$$

where Λ is a very large mass. The integrand is unaffected for small k (since Λ is large), but cuts off smoothly when $k \gtrsim \Lambda$. We can think of the second term as the propagator of a fictitious heavy photon, whose contribution is subtracted from that of the ordinary photon. In terms involving the heavy photon, the numerator algebra is unchanged and the denominator is altered by

$$\Delta \longrightarrow \Delta_\Lambda = -xyq^2 + (1-z)^2m^2 + z\Lambda^2 \tag{6.52}$$

The integral (6.50) is then replaced with a convergent integral, which can be Wick-rotated and evaluated:

$$\int \frac{d^4\ell}{(2\pi)^4}\left(\frac{\ell^2}{\left[\ell^2-\Delta\right]^3}-\frac{\ell^2}{\left[\ell^2-\Delta_\Lambda\right]^3}\right)=\frac{i}{(4\pi)^2}\int_0^\infty d\ell_E^2\left(\frac{\ell_E^4}{\left[\ell_E^2+\Delta\right]^3}-\frac{\ell_E^4}{\left[\ell_E^2+\Delta_\Lambda\right]^3}\right)$$
$$=\frac{i}{(4\pi)^2}\log\left(\frac{\Delta_\Lambda}{\Delta}\right) \tag{6.53}$$

The convergent terms in (6.47) are modified by terms of order Λ^{-2}, which we ignore.

This prescription for rendering Feynman integrals finite by introducing fictitious heavy particles is known as Pauli-Villars regularization. Please note that the fictitious photon has no physical significance, and that this method is only one of many for defining the divergent integrals. (We will discuss other methods in the next chapter; see especially Problem 7.2.) We must hope that the new parameter Λ will not appear in our final results for observable cross sections.

Using formulae (6.49) and (6.53) to evaluate the integrals in (6.47), we obtain an explicit, though complicated, expression for the one-loop vertex correction:

$$\left\{\begin{array}{l}\left\{\begin{array}{l}2\pi\dfrac{\alpha}{2}dxdydz\delta(x+y+z-1)\\ \quad\times\bar{u}\left(p'\right)\left(\gamma^\mu\left[\log\dfrac{z\Lambda^2}{\Delta}+\dfrac{1}{\Delta}\left((1-x)(1-y)q^2+\left(1-4z+z^2\right)m^2\right)\right]\right.\\ \qquad\left.+\dfrac{i\sigma^{\mu\nu}q_\nu}{2m}\left[\dfrac{1}{\Delta}2m^2z(1-z)\right]\right)u(p).\end{array}\right.\end{array}\right.$$

The bracketed expressions are our desired corrections to the form factors.

Before we try to interpret this result, let us summarize the calculational methods we used. The techniques are common to all loop calculations:

1. Draw the diagram(s) and write down the amplitude.

2. Introduce Feynman parameters to combine the denominators of the propagators.

3. Complete the square in the new denominator by shifting to a new loop momentum variable, ℓ.

4. Write the numerator in terms of ℓ. Drop odd powers of ℓ, and rewrite even powers using identities like (6.46).

5. Perform the momentum integral by means of a Wick rotation and fourdimensional spherical coordinates.
   The momentum integral in the last step will often be divergent. In that case we must define (or regularize) the integral using the Pauli-Villars prescription or some other device.

Now that we have parametrized the ultraviolet divergence in (6.54), let us try to interpret it. Notice that the divergence appears in the worst possible place: It corrects $F_1\left(q^2=0\right)$, which should (according to our discussion at the end of the previous section) be fixed at the value 1 . But this is the only effect of the divergent term. We will therefore adopt a simple but completely ad hoc fix for this difficulty: Subtract from the above expression a term proportional to the zeroth-order

vertex function $(\bar{u}(p')\gamma^\mu u(p))$, in such a way as to maintain the condition $F_1(0) = 1$. In other words, make the substitution

$$\delta F_1\left(q^2\right) \to \delta F_1\left(q^2\right) - \delta F_1(0) \tag{6.55}$$

(where δF_1 denotes the first-order correction to F_1). The justification of this procedure involves the minor correction to our S-matrix formula (4.103) mentioned in Section 4.6. In brief, the term we are subtracting corrects for our omission of the external leg correction diagrams of (6.1). We postpone the justification of this statement until Section 7.2.

There is also an infrared divergence in $F_1(q^2)$, coming from the $1/\Delta$ term. For example, at $q^2 = 0$ this term is

$$\begin{aligned}\int_0^1 dxdydz\delta(x+y+z-1)\frac{1-4z+z^2}{\Delta(q^2=0)} &= \int_0^1 dz\int_0^{1-z} dy\frac{-2+(1-z)(3-z)}{m^2(1-z)^2} \\ &= \int^1 dz\frac{-2}{m^2(1-z)} + \text{ finite terms.}\end{aligned}$$

We can cure this disease by pretending that the photon has a small nonzero mass μ. Then in the denominator of the photon propagator, $(k-p)^2$ would become $(k-p)^2-\mu^2$. This denominator was multiplied by z in (6.43), so the net effect is to add a term $z\mu^2$ to Δ. We will discuss the infrared divergence further in the next two sections.

With both of these provisional modifications, the form factors are

$$\begin{aligned}&F_1(q^2) = 1+ \\ &+\tfrac{\alpha}{2\pi}\int_0^1 dxdydz\delta(x+y+z-1) \\ &\times\left[\log\left(\tfrac{m^2(1-z)^2}{m^2(1-z)^2-q^2xy}\right) + \tfrac{m^2\left(1-4z+z^2\right)+q^2(1-x)(1-y)}{m^2(1-z)^2-q^2xy+\mu^2z}\right. \\ &\left.\quad -\tfrac{m^2\left(1-4z+z^2\right)}{m^2(1-z)^2+\mu^2z}\right] + \mathcal{O}(\alpha^2)\end{aligned} \tag{6.56}$$

Note that neither the ultraviolet nor the infrared divergence affects $F_2(q^2)$. We can therefore evaluate unambiguously

$$\begin{aligned}F_2\left(q^2=0\right) &= \frac{\alpha}{2\pi}\int_0^1 dxdydz\delta(x+y+z-1)\frac{2m^2z(1-z)}{m^2(1-z)^2} \\ &= \frac{\alpha}{\pi}\int_0^1 dz\int_0^{1-z} dy\frac{z}{1-z} = \frac{\alpha}{2\pi}\end{aligned} \tag{6.58}$$

Thus, we get a correction to the g-factor of the electron:

$$a_e \equiv \frac{g-2}{2} = \frac{\alpha}{2\pi} \approx .0011614 \tag{6.59}$$

This result was first obtained by Schwinger in 1948.* Experiments give $a_e = .0011597$. Apparently, the unambiguous value that we obtained for $F_2(0)$ is also, up to higher orders in α, unambiguously correct.

Precision Tests of QED

Building on the success of the order- α QED prediction for a_e, successive generations of physicists have improved the accuracy of both the theoretical and the experimental determination of this quantity. The coefficients of the QED formula for a_e are now known through order α^4. The calculation of the order- α^2 and higher coefficients requires a systematic treatment of ultraviolet divergences.

These challenging theoretical calculations have been matched by increasingly imaginative experiments. The most recent measurement of a_e uses a technique, developed by Dehmelt and collaborators, in which individual electrons are trapped in a system of electrostatic and magnetostatic fields and

excited to a spin resonance. [†] Today, the best theoretical and experimental values of a_e agree to eight significant figures.

High-order QED calculations have also been carried out for several other quantities. These include transition energies in hydrogen and hydrogen-like atoms, the anomalous magnetic moment of the muon, and the decay rates of singlet and triplet positronium. Many of these quantities have also been measured to high precision. The full set of these comparisons gives a detailed test of the validity of QED in a variety of settings. The results of these precision tests are summarized in Table 6.1.

There is some subtlety in reporting the results of precision comparisons between QED theory and experiment, since theoretical predictions require an extremely precise value of α, which can only be obtained from another precision QED experiment. We therefore quote each comparison between theory and experiment as an independent determination of α. Each value of α is assigned an error that is the composite of the expected uncertainties from theory and experiment. QED is confirmed to the extent that the values of α from different sources agree.

The first nine entries in Table 6.1 refer to QED calculations in atomic physics settings. Of these, the hydrogen hyperfine splitting, measured using Ramsey's hydrogen maser, is the most precisely known quantity in physics. Unfortunately, the influence of the internal structure of the proton leads to uncertainties that limit the accuracy with which this quantity can be predicted theoretically. The same difficulty applies to the Lamb shift, the splitting between the $j = 1/22S$ and $2P$ levels of hydrogen. The most accurate QED tests now come from systems that involve no strongly interacting particles, the electron $g - 2$ and the hyperfine splitting in the $e^-\mu^+$atom, muonium. The last entry in this group gives a new method for determining α, by converting a very accurate measurement of the neutron Compton wavelength, using accurately known mass ratios, to a value of the electron mass. This can be combined with the known value of the Rydberg energy and accurate QED formulae to determine α. The only serious discrepancy among these numbers comes in the triplet positronium decay rate; however, there is some evidence that diagrams of relative order α^2 give a large correction to the value quoted in the table.

The next two entries are determinations of α from higher-order QED reactions at high-energy electron colliders. These high-energy experiments typically achieve only percent-level accuracy, but their results are consistent with the precise information available at lower energies.

Finally, the last two entries in the table give two independent measurements of α from exotic quantum interference phenomena in condensed-matter systems. These two effects provide a standard resistance and a standard frequency, respectively, which are believed to measure the charge of the electron

Each value of α displayed in this table is obtained by fitting an experimental measurement to a theoretical expression that contains α as a parameter. The numbers in parentheses are the standard errors in the last displayed digits, including both theoretical and experimental uncertainties. This table is based on results presented in the survey of precision QED of Kinoshita (1990). That book contains a series of lucid reviews of the remarkable theoretical and experimental technology that has been developed for the detailed analysis of QED processes. The five most accurate values are updated as given by T. Kinoshita in History of Original Ideas and Basic Discoveries in Particle Physics, H. Newman and T. Ypsilantis, eds. (Plenum Press, New York, 1995). This latter paper also gives an interesting perspective on the future of precision QED experiments.

with corrections that are strictly zero for macroscropic systems. ‡

The entire picture fits together well beyond any reasonable expectation. On the evidence presented in this table, QED is the most stringently tested- and the most dramatically successful-of all physical theories.

[6‡] For a discussion of these effects, and their exact relation to α, see D. R. Yennie, Rev. Mod. Phys. 59, 781 (1987).

16.4 6.4 The Electron Vertex Function: Infrared Divergence

Now let us confront the infrared divergence in our result (6.56) for $F_1(q^2)$. The dominant part, in the $\mu \to 0$ limit, is

$$F_1(q^2) \approx \tfrac{\alpha}{2\pi} \int_0^1 dxdydz\delta(x+y+z-1) \left[\frac{m^2\left(1-4z+z^2\right)+q^2(1-x)(1-y)}{m^2(1-z)^2-q^2xy+\mu^2 z} - \frac{m^2\left(1-4z+z^2\right)}{m^2(1-z)^2+\mu^2 z} \right] \tag{6.60}$$

To understand this expression we must do some work to simplify it, extracting and evaluating the divergent part of the integral. Throughout this section we will retain only terms that diverge in the limit $\mu \to 0$.

First note that the divergence occurs in the corner of Feynman-parameter space where $z \approx 1$ (and therefore $x \approx y \approx 0$). In this region we can set $z = 1$ and $x = y = 0$ in the numerators of (6.60). We can also set $z = 1$ in the μ^2 terms in the denominators. Using the delta function to evaluate the x-integral, we then have

$$F_1\left(q^2\right) = \frac{\alpha}{2\pi} \int_0^1 dz \int_0^{1-z} dy \left[\frac{-2m^2+q^2}{m^2(1-z)^2 - q^2 y(1-z-y)+\mu^2} - \frac{-2m^2}{m^2(1-z)^2+\mu^2} \right]$$

(The lower limit on the z-integral is unimportant.) Making the variable changes

$$y = (1-z)\xi, \quad w = (1-z)$$

this expression becomes

$$\begin{aligned} F_1\left(q^2\right) &= \frac{\alpha}{2\pi} \int_0^1 d\xi \frac{1}{2} \int_0^1 d\left(w^2\right) \left[\frac{-2m^2+q^2}{\left[m^2 - q^2\xi(1-\xi)\right] w^2 + \mu^2} - \frac{-2m^2}{m^2 w^2 + \mu^2} \right] \\ &= \frac{\alpha}{4\pi} \int_0^1 d\xi \left[\frac{-2m^2+q^2}{m^2 - q^2\xi(1-\xi)} \log\left(\frac{m^2 - q^2\xi(1-\xi)}{\mu^2} \right) + 2\log\left(\frac{m^2}{\mu^2} \right) \right] \end{aligned}$$

In the limit $\mu \to 0$ we can ignore the details of the numerators inside the logarithms; anything proportional to m^2 or q^2 is effectively the same. We therefore write

$$F_1\left(q^2\right) = 1 - \frac{\alpha}{2\pi} f_{\text{IR}}\left(q^2\right) \log\left(\frac{-q^2 \text{ or } m^2}{\mu^2} \right) + \mathcal{O}\left(\alpha^2\right) \tag{6.61}$$

where the coefficient of the divergent logarithm is

$$f_{\text{IR}}\left(q^2\right) = \int_0^1 \left(\frac{m^2 - q^2/2}{m^2 - q^2\xi(1-\xi)} \right) d\xi - 1 \tag{6.62}$$

Since q^2 is negative and $\xi(1-\xi)$ has a maximum value of $1/4$, the first term is greater than 1 and hence $f_{\text{IR}}(q^2)$ is positive.

How does this infinite term affect the cross section for electron scattering off a potential? Since $F_1(q^2)$ is just the quantity that multiplies γ^μ in the matrix element, we can find the new cross section by making the replacement $e \to e \cdot F_1(q^2)$. The cross section for the process $\mathbf{p} \to \mathbf{p}'$ is therefore

$$\frac{d\sigma}{d\Omega} \simeq \left(\frac{d\sigma}{d\Omega}\right)_0 \cdot \left[1 - \frac{\alpha}{\pi} f_{\mathrm{IR}}\left(q^2\right) \log\left(\frac{-q^2 \text{ or } m^2}{\mu^2}\right) + \mathcal{O}\left(\alpha^2\right)\right] \tag{6.63}$$

where the first factor is the tree-level result. Note that the $\mathcal{O}(\alpha)$ correction to the cross section is not only infinite, but negative. Something is terribly wrong.

To gain a better understanding of the divergence, let us evaluate the coefficient of the divergent logarithm, $f_{\mathrm{IR}}\left(q^2\right)$, in the limit $-q^2 \to \infty$. In this limit, we find a second logarithm:

$$\begin{aligned}\int_0^1 d\xi \frac{-q^2/2}{-q^2\xi(1-\xi)+m^2} &\simeq \frac{1}{2}\int_0 d\xi \frac{-q^2}{-q^2\xi+m^2} + \begin{pmatrix}\text{equal contribution}\\ \text{from } \xi \approx 1\end{pmatrix} \\ &= \log\left(\frac{-q^2}{m^2}\right)\end{aligned} \tag{6.64}$$

The form factor in this limit is therefore

$$F_1\left(-q^2 \to \infty\right) = 1 - \frac{\alpha}{2\pi}\log\left(\frac{-q^2}{m^2}\right)\log\left(\frac{-q^2}{\mu^2}\right) + \mathcal{O}\left(\alpha^2\right) \tag{6.65}$$

Note that the numerator in the second logarithm is $-q^2$, not m^2; this expression contains not only the correct coefficient of $\log\left(1/\mu^2\right)$, but also the correct coefficient of $\log^2\left(q^2\right)$.

The same double logarithm of $-q^2$ appeared in the cross section for soft bremsstrahlung, Eq. (6.26). This correspondence points to a resolution of the infrared divergence problem. Comparing (6.65) with (6.26), we find in the limit $-q^2 \to \infty$

$$\begin{aligned}\frac{d\sigma}{d\Omega}\left(p \to p'\right) &= \left(\frac{d\sigma}{d\Omega}\right)_0 \left[1 - \frac{\alpha}{\pi}\log\left(\frac{-q^2}{m^2}\right)\log\left(\frac{-q^2}{\mu^2}\right) + \mathcal{O}\left(\alpha^2\right)\right] \\ \frac{d\sigma}{d\Omega}\left(p \to p' + \gamma\right) &= \left(\frac{d\sigma}{d\Omega}\right)_0 \left[+\frac{\alpha}{\pi}\log\left(\frac{-q^2}{m^2}\right)\log\left(\frac{-q^2}{\mu^2}\right) + \mathcal{O}\left(\alpha^2\right)\right]\end{aligned} \tag{6.66}$$

The separate cross sections are divergent, but their sum is independent of μ and therefore finite.

In fact, neither the elastic cross section nor the soft bremsstrahlung cross section can be measured individually; only their sum is physically observable. In any real experiment, a photon detector can detect photons only down to
some minimum limiting energy E_ℓ. The probability that a scattering event occurs and this detector does not see a photon is the sum

$$\frac{d\sigma}{d\Omega}\left(p \to p'\right) + \frac{d\sigma}{d\Omega}\left(p \to p' + \gamma\left(k < E_\ell\right)\right) \equiv \left(\frac{d\sigma}{d\Omega}\right)_{\text{measured}} \tag{6.67}$$

The divergent part of this "measured" cross section is

$$\begin{aligned}\left(\frac{d\sigma}{d\Omega}\right)_{\text{measured}} \approx \left(\frac{d\sigma}{d\Omega}\right)_0 \Bigg[1 &- \frac{\alpha}{\pi} f_{\mathrm{IR}}\left(q^2\right)\log\left(\frac{-q^2 \text{ or } m^2}{\mu^2}\right) \\ &+ \frac{\alpha}{2\pi}\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right)\log\left(\frac{E_\ell^2}{\mu^2}\right) + \mathcal{O}\left(\alpha^2\right)\Bigg]\end{aligned}$$

We have just seen that $\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right) = 2f_{\mathrm{IR}}\left(q^2\right)$ when $-q^2 \gg m^2$. If the same relation holds for general q^2, the measured cross section becomes

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{measured}} \approx \left(\frac{d\sigma}{d\Omega}\right)_0 \left[1 - \frac{\alpha}{\pi} f_{\text{IR}}\left(q^2\right) \log\left(\frac{--q^2 \text{ or } m^2}{E_\ell^2}\right) + \mathcal{O}\left(\alpha^2\right)\right] \tag{6.68}$$

which depends on the experimental conditions, but no longer on μ^2. The infrared divergences from soft bremsstrahlung and from $F_1\left(q^2\right)$ cancel each other, yielding a finite cross section for the quantity that can actually be measured.

We must still verify the identity $\mathcal{I}\left(\mathbf{v}, \mathbf{v}'\right) = 2 f_{\text{IR}}\left(q^2\right)$ for arbitrary values of q^2. From (6.13) we have

$$\mathcal{I}\left(\mathbf{v}, \mathbf{v}'\right) = \int \frac{d\Omega_{\mathbf{k}}}{4\pi} \left(\frac{2p \cdot p'}{\left(\hat{k} \cdot p'\right)\left(\hat{k} \cdot p\right)} - \frac{m^2}{\left(\hat{k} \cdot p'\right)^2} - \frac{m^2}{\left(\hat{k} \cdot p\right)^2} \right) \tag{6.69}$$

The last two terms are easy to evaluate:

$$\int \frac{d\Omega_{\mathbf{k}}}{4\pi} \frac{1}{\left(\hat{k} \cdot p\right)^2} = \frac{1}{2} \int_{-1}^{1} d\cos\theta \frac{1}{\left(p^0 - p\cos\theta\right)^2} = \frac{1}{p^2} = \frac{1}{m^2}$$

In the first term, we can combine the denominators with a Feynman parameter and perform the integral in the same way:

$$\begin{aligned} \int \frac{d\Omega_{\mathbf{k}}}{4\pi} \frac{1}{\left(\hat{k} \cdot p'\right)\left(\hat{k} \cdot p\right)} &= \int_0^1 d\xi \int \frac{d\Omega_{\mathbf{k}}}{4\pi} \frac{1}{\left[\xi \hat{k} \cdot p' + (1-\xi)\hat{k} \cdot p\right]^2} \\ &= \int_0^1 d\xi \frac{1}{\left[\xi p' + (1-\xi)p\right]^2} = \int_0^1 d\xi \frac{1}{m^2 - \xi(1-\xi)q^2} \end{aligned}$$

(In the last step we have used $2p \cdot p' = 2m^2 - q^2$.) Putting all the terms of (6.69) together, we find

$$\mathcal{I}\left(\mathbf{v}, \mathbf{v}'\right) = \int_0^1 \left(\frac{2m^2 - q^2}{m^2 - \xi(1-\xi)q^2} \right) d\xi - 2 = 2 f_{\text{IR}}\left(q^2\right) \tag{6.70}$$

just what we need to cancel the infrared divergence.

Although Eq. (6.68) demonstrates the cancellation of the infrared divergence, this result has little practical use. An experimentalist would want to know the precise dependence on q^2, which we did not evaluate carefully. Recall from (6.65), however, that we were careful to obtain the correct coefficient of $\log^2\left(-q^2\right)$ in the limit $-q^2 \gg m^2$. In that limit, therefore, (6.68) becomes

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{measured}} \approx \left(\frac{d\sigma}{d\Omega}\right)_0 \left[1 - \frac{\alpha}{\pi} \log\left(\frac{-q^2}{m^2}\right) \log\left(\frac{-q^2}{E_\ell^2}\right) + \mathcal{O}\left(\alpha^2\right)\right] \tag{6.71}$$

This result is unambiguous and useful. Note that the $\mathcal{O}(\alpha)$ correction again involves the Sudakov double logarithm.

16.5 6.5 Summation and Interpretation of Infrared Divergences

The discussion of infrared divergences in the previous section suffices for removing the infinities from our bremsstrahlung and vertex-correction calculations. There are still, however, three points that we have not addressed:

1. We have not demonstrated the cancellation of infrared divergences beyond the leading order.

2. The correction to the measured cross section that we found after the infrared cancellation (Eqs. (6.68) and (6.71)) can be made arbitrarily negative by making photon detectors with a sufficiently low threshold E_ℓ.

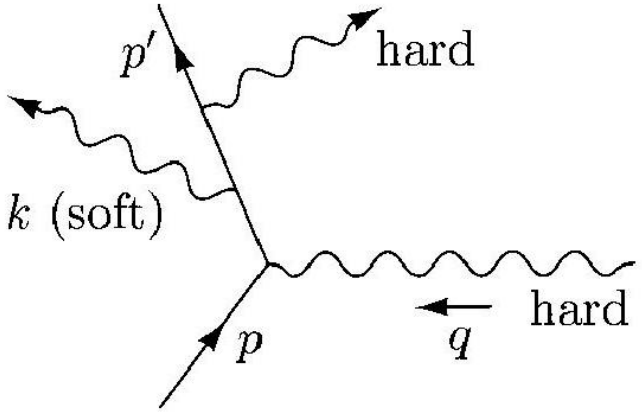
3. We have not yet reproduced the classical result (6.19) for the number of photons radiated during a collision.
   The solutions of the second and third problems will follow immediately from that of the first, to which we now turn.

A complete treatment of infrared divergences to all orders is beyond the scope of this book.* We will discuss here only the terms with the largest logarithmic enhancement at each order of perturbation theory. In general, these terms are of order

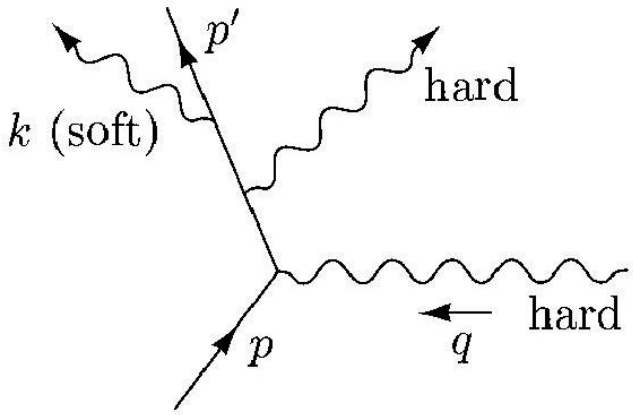
$$\left[\frac{\alpha}{\pi}\log\left(\frac{-q^2}{\mu^2}\right)\log\left(\frac{-q^2}{m^2}\right)\right]^n \tag{6.72}$$

in the nth order of perturbation theory. Our final physical conclusions were first presented by Bloch and Nordsieck in a prescient paper written before the invention of relativistic perturbation theory. † We will follow a modern, and simplified, version of the analysis due to Weinberg. ‡

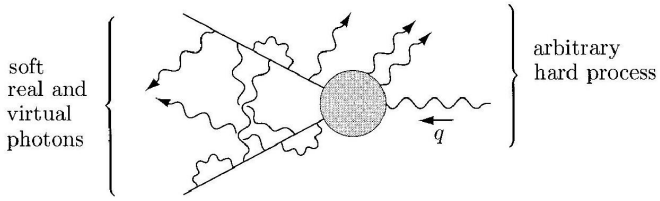
Infrared divergences arise from photons with "soft" momenta: real photons with energy less than some cutoff E_ℓ, and virtual photons with (after Wick rotation) $k^2 < E_\ell^2$. A typical higher-order diagram will involve numerous real and virtual photons. But to find a divergence, we need more than a soft photon; we need a singular denominator in an electron propagator. Consider, for example, the following two diagrams:



[6]*The definitive treatment is given in D. Yennie, S. Frautschi, and H. Suura, Ann. Phys. 13, 379 (1961).
† F. Bloch and A. Nordsieck, Phys. Rev. 52, 54 (1937).
‡ S. Weinberg, Phys. Rev. 140, B516 (1965).

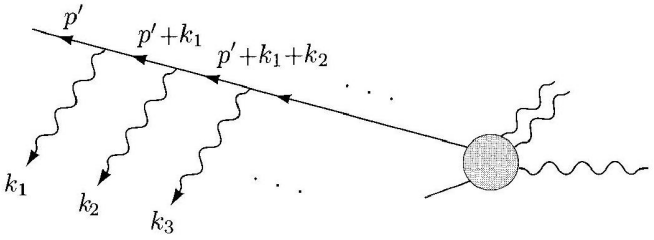


The first diagram, in which the electron emits a soft photon followed by a hard photon, has no infrared divergence, since the momenta in both electron propagators are far from the mass shell. If the soft photon is emitted last, however, the denominator of the adjacent propagator is $(p'+k)^2 - m^2 = 2p'\cdot k$, which vanishes as $k \to 0$. Thus the second diagram does contain a divergence. We would like, then, to consider diagrams in which an arbitrary hard process, possibly involving emission of hard and soft photons, is modified by the addition of soft real and virtual photons on the electron legs:



Following Weinberg, we will add up the contributions of all such diagrams. The only new difficulty in this calculation will be in the combinatorics of counting all the ways in which the photons can appear.

First consider the outgoing electron line:



We attach n photons to the line, with momenta $k_1 \ldots k_n$. For the moment we do not care whether these are external photons, virtual photons connected to each other, or virtual photons connected to vertices on the incoming electron line. The Dirac structure of this diagram is

$$\begin{aligned}
&\bar{u}(p')(-ie\gamma^{\mu_1})\frac{i(\not{p}'+\not{k}_1+m)}{2p'\cdot k_1}(-ie\gamma^{\mu_2})\frac{i(\not{p}'+\not{k}_1+\not{k}_2+m)}{2p'\cdot(k_1+k_2)+\mathcal{O}(k^2)} \\
&\cdots(-ie\gamma^{\mu_n})\frac{i(\not{p}'+\not{k}_1+\cdots+\not{k}_n+m)}{2p'\cdot(k_1+\cdots k_n)+\mathcal{O}(k^2)}(i\mathcal{M}_{\text{hard}})\cdots
\end{aligned} \tag{6.73}$$

We will assume that all the k_i are small, dropping the $\mathcal{O}(k^2)$ terms in the denominators. We will also drop the $\not{p}_i$ terms in the numerators, just as in our treatment of bremsstrahlung

in Section 6.1. Also, as we did there, we can push the factors of $(\not{p}' + m)$ to the left and use $\bar{u}(p')(-\not{p}' + m) = 0$:

$$\begin{aligned}\bar{u}(p')\gamma^{\mu_1}(\not{p}' + m)\gamma^{\mu_2}(\not{p}' + m)\cdots &= \bar{u}(p')\,2p^{\mu_1}\gamma^{\mu_2}(\not{p}' + m)\cdots \\ &= \bar{u}(p')\,2p'^{\mu_1}2p'^{\mu_2}\cdots\end{aligned}$$

This turns expression (6.73) into

$$\bar{u}(p')\left(e\frac{p'^{\mu_1}}{p'\cdot k_1}\right)\left(e\frac{p'^{\mu_2}}{p'\cdot(k_1+k_2)}\right)\cdots\left(e\frac{p'^{\mu_n}}{p'\cdot(k_1+\cdots+k_n)}\right)\cdots \tag{6.74}$$

Still working with only the outgoing electron line, we must now sum over all possible orderings of the momenta $k_1 \ldots k_n$. (This procedure will overcount when two of the photons are attached together to form a single virtual photon. We will deal with this overcounting later.) There are $n\,!$ different diagrams to sum, corresponding to the $n\,!$ permutations of the n photon momenta. Let π denote one such permutation, so that $\pi(i)$ is the number between 1 and n that i is taken to. (For example, if π denotes the permutation that takes $1 \to 3$, $2 \to 1$ and $3 \to 2$, then $\pi(1) = 3, \pi(2) = 1$, and $\pi(3) = 2$.)

Armed with this notation, we can perform the sum over permutations by means of the following identity:

$$\begin{aligned}\sum_{\substack{\text{all permu-}\\ \text{tations } \pi}} &\frac{1}{p\cdot k_{\pi(1)}}\frac{1}{p\cdot\left(k_{\pi(1)}+k_{\pi(2)}\right)}\cdots\frac{1}{p\cdot\left(k_{\pi(1)}+k_{\pi(2)}+\cdots+k_{\pi(n)}\right)} \\ &= \frac{1}{p\cdot k_1}\frac{1}{p\cdot k_2}\cdots\frac{1}{p\cdot k_n}\end{aligned} \tag{6.75}$$

The proof of this formula proceeds by induction on n. For $n = 2$ we have

$$\begin{aligned}\sum_{\pi}\frac{1}{p\cdot k_{\pi(1)}}\frac{1}{p\cdot\left(k_{\pi(1)}+k_{\pi(2)}\right)} &= \frac{1}{p\cdot k_1}\frac{1}{p\cdot(k_1+k_2)} + \frac{1}{p\cdot k_2}\frac{1}{p\cdot(k_2+k_1)} \\ &= \frac{1}{p\cdot k_1}\frac{1}{p\cdot k_2}\end{aligned}$$

For the induction step, notice that the last factor on the left-hand side of (6.75) is the same for every permutation π. Pulling this factor outside the sum, the left-hand side becomes

$$\text{LHS} = \frac{1}{p\cdot\sum k}\sum_{\pi}\frac{1}{p\cdot k_{\pi(1)}}\frac{1}{p\cdot\left(k_{\pi(1)}+k_{\pi(2)}\right)}\cdots\frac{1}{p\cdot\left(k_{\pi(1)}+\cdots+k_{\pi(n-1)}\right)}.$$

For any given π, the quantity being summed is independent of $k_{\pi(n)}$. Letting $i = \pi(n)$, we can now write

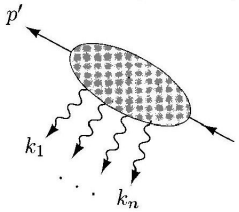
$$\sum_{\pi} = \sum_{i=1}^{n}\sum_{\pi'(i)}$$

where $\pi'(i)$ is the set of all permutations on the remaining $n-1$ integers. Assuming by induction that (6.75) is true for $n-1$, we have

$$\text{LHS} = \frac{1}{p \cdot \sum k} \sum_{i=1}^{n} \frac{1}{p \cdot k_1} \frac{1}{p \cdot k_2} \cdots \frac{1}{p \cdot k_{i-1}} \frac{1}{p \cdot k_{i+1}} \cdots \frac{1}{p \cdot k_n}$$

If we now multiply and divide each term in this sum by $p \cdot k_i$, we easily obtain our desired result (6.75).

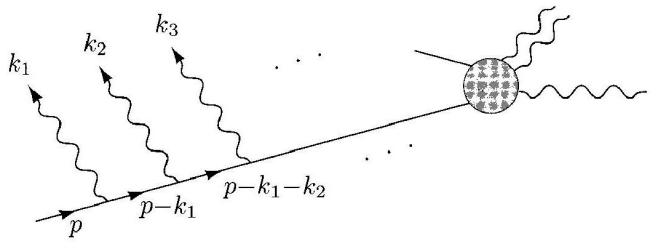
Applying (6.75) to (6.74), we find



$$= \bar{u}(p')\Big(e\frac{p'^{\mu_1}}{p' \cdot k_1}\Big)\Big(e\frac{p'^{\mu_2}}{p' \cdot k_2}\Big) \cdots \Big(e\frac{p'^{\mu_n}}{p' \cdot k_n}\Big),$$

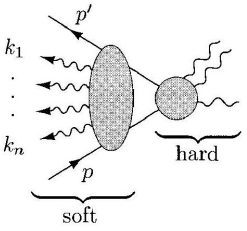
where the blob denotes a sum over all possible orders of inserting the n photon lines.

A similar set of manipulations simplifies the sum over soft photon insertions on the initial electron line. There, however, the propagator momenta are $p - k_1, p - k_1 - k_2$, and so on:



We therefore get an extra minus sign in the factor for each photon, since $(p - \Sigma k)^2 - m^2 \approx -2p \cdot \Sigma k$.

Now consider diagrams containing a total of n soft photons, connected in any possible order to the initial or final electron lines. The sum over all such diagrams can be written



$$= \bar{u}(p')\, i\mathcal{M}_{\text{hard}}\, u(p)$$
$$\cdot e\Big(\frac{p'^{\mu_1}}{p' \cdot k_1} - \frac{p^{\mu_1}}{p \cdot k_1}\Big) \cdot e\Big(\frac{p'^{\mu_2}}{p' \cdot k_2} - \frac{p^{\mu_2}}{p \cdot k_2}\Big)$$
$$\cdots e\Big(\frac{p'^{\mu_n}}{p' \cdot k_n} - \frac{p^{\mu_n}}{p \cdot k_n}\Big).$$

By multiplying out all the factors, you can see that we get the correct term for each possible way of dividing the n photons between the two lines.

Next we must decide which photons are real and which are virtual.
We can make a virtual photon by picking two photon momenta k_i and k_j, setting $k_j = -k_i \equiv k$, multiplying by the photon propagator, and integrating over k. For each virtual photon we then obtain the expression

$$\frac{e^2}{2} \int \frac{d^4k}{(2\pi)^4} \frac{-i}{k^2 + i\epsilon} \left(\frac{p'}{p' \cdot k} - \frac{p}{p \cdot k}\right) \cdot \left(\frac{p'}{-p' \cdot k} - \frac{p}{-p \cdot k}\right) \equiv \mathbf{X} \tag{6.78}$$

The factor of $1/2$ is required because our procedure has counted each Feynman diagram twice: interchanging k_i and k_j gives back the same diagram. It is possible to evaluate this expression by careful contour integration, but there is an easier way. Notice that this approximation scheme assigns to the diagram with one loop and no external photons the value

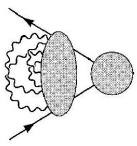
$$\bar{u}\left(p'\right)\left(i\mathcal{M}_{\text{hard}}\right)u(p)\cdot\mathbf{X}$$

Thus, $\mathbf{X}$ must be precisely the infrared limit of the one-loop correction to the form factor, as displayed in (6.61):

$$\mathbf{X}=-\frac{\alpha}{2\pi}f_{\text{IR}}\left(q^2\right)\log\left(\frac{-q^2}{\mu^2}\right) \tag{6.79}$$

A direct derivation of this result from (6.78) is given in Weinberg's paper cited above. Note that result (6.79) followed in our argument of the previous section only after the subtraction at $q^2=0$, and so we should worry whether (6.79) is consistent with the corresponding subtraction of the n th-order diagram. In addition, some of the diagrams we are summing contain external-leg corrections, which we have not discussed. Here we simply remark that neither of these subtleties affects the final answer; the proof requires the heavy machinery in the paper of Yennie, Frautschi, and Suura.

If there are m virtual photons we get m factors like (6.79), and also an additional symmetry factor of $1/m$! since interchanging virtual photons with each other does not change the diagram. We can then sum over m to obtain
the complete correction due to the presence of arbitrarily many soft virtual photons:



$$=\quad\times\sum_{m=0}^{\infty}\frac{\mathbf{X}^m}{m!}=\bar{u}(p')\big(i\mathcal{M}_{\text{hard}}\big)u(p)\exp(\mathbf{X}).$$

If in addition to the m virtual photons we also emit a real photon, we must multiply by its polarization vector, sum over polarizations, and integrate the squared matrix element over the photon's phase space. This gives an additional factor

$$\int\frac{d^3k}{(2\pi)^3}\frac{1}{2k}e^2\left(-g_{\mu\nu}\right)\left(\frac{p'^{\mu}}{p'\cdot k}-\frac{p^{\mu}}{p\cdot k}\right)\left(\frac{p'^{\nu}}{p'\cdot k}-\frac{p^{\nu}}{p\cdot k}\right)\equiv\mathbf{Y} \tag{6.81}$$

in the cross section. Assuming that the energy of the photon is greater than μ and less than E_ℓ (the detector threshold), this expression is simply

$$\mathbf{Y}=\frac{\alpha}{\pi}\mathcal{I}\left(\mathbf{v},\mathbf{v}'\right)\log\left(\frac{E_\ell}{\mu}\right)=\frac{\alpha}{\pi}f_{\text{IR}}\left(q^2\right)\log\left(\frac{E_\ell^2}{\mu^2}\right) \tag{6.82}$$

If n real photons are emitted we get n such factors, and also a symmetry factor of $1/n!$ since there are n identical bosons in the final state. The cross section for emission of any number of soft photons is therefore

$$\sum_{n=0}^{\infty}\frac{d\sigma}{d\Omega}\left(\mathbf{p}\to\mathbf{p}'+n\gamma\right)=\frac{d\sigma}{d\Omega}\left(\mathbf{p}\to\mathbf{p}'\right)\cdot\sum_{n=0}^{\infty}\frac{1}{n!}\mathbf{Y}^n=\frac{d\sigma}{d\Omega}\left(\mathbf{p}\to\mathbf{p}'\right)\cdot\exp(\mathbf{Y}) \tag{6.83}$$

Combining our results for virtual and real photons gives our final result for the measured cross section, to all orders in α, for the process $\mathbf{p}\to\mathbf{p}'+$ (any number of photons with $k<E_\ell$):

$$\begin{aligned}\left(\frac{d\sigma}{d\Omega}\right)_{\text{meas.}} &= \left(\frac{d\sigma}{d\Omega}\right)_0 \times \exp(2\mathbf{X}) \times \exp(\mathbf{Y}) \\ &= \left(\frac{d\sigma}{d\Omega}\right)_0 \times \exp\left[-\frac{\alpha}{\pi} f_{\text{IR}}\left(q^2\right) \log\left(\frac{-q^2}{\mu^2}\right)\right] \times \exp\left[\frac{\alpha}{\pi} f_{\text{IR}}\left(q^2\right) \log\left(\frac{E_\ell^2}{\mu^2}\right)\right] \\ &= \left(\frac{d\sigma}{d\Omega}\right)_0 \times \exp\left[-\frac{\alpha}{\pi} f_{\text{IR}}\left(q^2\right) \log\left(\frac{-q^2}{E_\ell^2}\right)\right] \end{aligned} \tag{6.84}$$

The correction factor depends on the detector sensitivity E_ℓ, but is independent of the infrared cutoff μ. Note that if we expand this result to $\mathcal{O}(\alpha)$, we recover our earlier result (6.68). Now, however, the correction factor is controlled in magnitude-always between 0 and 1 .

In the limit $-q^2 \gg m^2$, our result becomes

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{meas.}} = \left(\frac{d\sigma}{d\Omega}\right)_0 \times \left|\exp\left[-\frac{\alpha}{2\pi} \log\left(\frac{-q^2}{m^2}\right) \log\left(\frac{-q^2}{E_\ell^2}\right)\right]\right|^2 \tag{6.85}$$

In this limit, the probability of scattering without emitting a hard photon decreases faster than any power of q^2. The exponential correction factor, containing the Sudakov double logarithm, is known as the Sudakov form factor.

To conclude this section, let us calculate the probability, in the same approximation, that some hard scattering process is accompanied by the production of n soft photons, all with energies between $E_-$and E_+. The phase-space integral for these photons gives $\log\left(E_+/E_-\right)$instead of $\log\left(E_\ell/\mu\right)$. If we assign photons with energy greater than $E_+$to the "hard" part of the process, we find that the cross section is given by (6.84), times the additional factor

$$\begin{aligned}\text{Prob}\left(n\gamma \text{ with } E_- < E < E_+\right) = \frac{1}{n!}\Big[\frac{\alpha}{\pi}\ f_{\text{IR}}\left(q^2\right) \log\left(\frac{E_+^2}{E_-^2}\right)\Big]^n \\ \times \exp\left[-\frac{\alpha}{\pi} f_{\text{IR}}\left(q^2\right) \log\left(\frac{E_+^2}{E_-^2}\right)\right]\end{aligned} \tag{6.86}$$

This expression has the form of a Poisson distribution,

$$P(n) = \frac{1}{n!}\lambda^n e^{-\lambda},$$

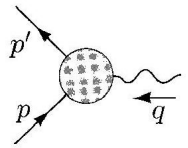
with

$$\lambda = \langle n \rangle = \frac{\alpha}{\pi} \log\left(\frac{E_+}{E_-}\right) \mathcal{I}\left(\mathbf{v}, \mathbf{v}'\right)$$

This is precisely the semiclassical estimate of the number of radiated photons that we made in Eq. (6.19).

Problems

6.1 Rosenbluth formula. As discussed Section 6.2, the exact electromagnetic interaction vertex for a Dirac fermion can be written quite generally in terms of two form factors $F_1\left(q^2\right)$ and $F_2\left(q^2\right)$:



$$= \bar{u}(p')\left[\gamma^\mu F_1(q^2) + \frac{i\sigma^{\mu\nu}q_\nu}{2m}F_2(q^2)\right]u(p),$$

where $q = p' - p$ and $\sigma^{\mu\nu} = \frac{1}{2}i\left[\gamma^\mu, \gamma^\nu\right]$. If the fermion is a strongly interacting particle such as the proton, the form factors reflect the structure that results from the strong interactions and so are not easy to compute from first principles. However, these form factors can be determined experimentally. Consider the scattering of an electron with energy $E \gg m_e$ from a proton initially at rest. Show that the above expression for the vertex leads to the following expression (the Rosenbluth formula) for the elastic scattering cross section, computed to leading order in α but to all orders in the strong interactions:

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2\left[\left(F_1^2 - \frac{q^2}{4m^2}F_2^2\right)\cos^2\frac{\theta}{2} - \frac{q^2}{2m^2}\left(F_1 + F_2\right)^2\sin^2\frac{\theta}{2}\right]}{2E^2\left[1 + \frac{2E}{m}\sin^2\frac{\theta}{2}\right]\sin^4\frac{\theta}{2}},$$

where θ is the lab-frame scattering angle and F_1 and F_2 are to be evaluated at the q^2 associated with elastic scattering at this angle. By measuring $(d\sigma/d\cos\theta)$ as a function of angle, it is thus possible to extract F_1 and F_2. Note that when $F_1 = 1$ and $F_2 = 0$, the Rosenbluth formula reduces to the Mott formula (in the massless limit) for scattering off a point particle (see Problem 5.1).

6.2 Equivalent photon approximation. Consider the process in which electrors of very high energy scatter from a target. In leading order in α, the electron is connected to the target by one photon propagator. If the initial and final encrgies of the electron are E and E', the photon will carry momentum q such that $q^2 \approx -2EE'(1 - \cos\theta)$. In the limit of forward scattering, whatcver the energy loss, the photon momentum approaches $q^2 = 0$; thus the reaction is highly peaked in the forward direction. It is tempting to guess that, in this limit, the virtual photon becomes a real photon. Let us investigate in what sense that is true.

(a) The matrix element for the scattering process can be written as

$$\mathcal{M} = (-ie)\bar{u}\left(p'\right)\gamma^\mu u(p)\frac{-ig_{\mu\nu}}{q^2}\widehat{\mathcal{M}}^\nu(q),$$

where $\widehat{\mathcal{M}}^\nu$ represents the (in general, complicated) coupling of the virtual photon to the target. Let us analyze the structure of the piece $\bar{u}\left(p'\right)\gamma^\mu u(p)$. Let $q = (q^0, \mathbf{q})$, and define $\tilde{q} = (q^0, -\mathbf{q})$. We can expand the spinor product as:

$$\bar{u}\left(p'\right)\gamma^\mu u(p) = A \cdot q^\mu + B \cdot \tilde{q}^\mu + C \cdot \epsilon_1^\mu + D \cdot \epsilon_2^\mu,$$

where A, B, C, D are functions of the scattering angle and energy loss and ϵ_i are two unit vectors transverse to $\mathbf{q}$. By dotting this expression with q_μ, show that the coefficient B is at most of order θ^2. This will mean that we can ignore it in the rest of the analysis. The coefficient A is large, but it is also irrelevant, since, by the Ward identity, $q^\mu\widehat{\mathcal{M}}_\mu = 0$.

(b) Working in the frame where $p = (E, 0, 0, E)$, compute explicitly

$$\bar{u}\left(p'\right)\boldsymbol{\gamma}\cdot\boldsymbol{\epsilon}_i u(p)$$

using massless electrons, $u(p)$ and $u\left(p'\right)$ spinors of definite helicity, and $\boldsymbol{\epsilon}_1, \boldsymbol{\epsilon}_2$ unit vectors parallel and perpendicular to the plane of scattering. We need this quantity only for scattering near the forward direction, and we need only the term of order θ. Note, however, that for ϵ in the plane of scattering, the small $\hat{3}$ component of ϵ also gives a term of order θ which must be taken

into account.
(c) Now write the expression for the electron scattering cross section, in terms of $\left|\widehat{\mathcal{M}}^{\mu}\right|^2$ and the integral over phase space on the target side. This expression must be integrated over the final electron momentum p'. The integral over p'^3 is an integral over the energy loss of the electron. Show that the integral over $p'_\perp$ diverges logarithmically as $p'_\perp$ or $\theta \to 0$.
(d) The divergence as $\theta \to 0$ appears because we have ignored the electron mass in too many places. Show that reintroducing the electron mass in the expression for q^2,

$$q^2 = -2\left(EE' - pp'\cos\theta\right) + 2m^2,$$

cuts off the divergence and yields a factor of $\log\left(s/m^2\right)$ in its place.
(e) Assembling all the factors, and assuming that the target cross sections are independent of the photon polarization, show that the largest part of the electrontarget scattering cross section is given by considering the electron to be the source of a beam of real photons with energy distribution ($x = E_\gamma/E$):

$$N_\gamma(x)dx = \frac{dx}{x}\frac{\alpha}{2\pi}\left[1 + (1-x)^2\right]\log\left(\frac{s}{m^2}\right)$$

This is the Weizsacker-Williams equivalent photon approximation. This phenomenon allows us, for example, to study photon-photon scattering using e^+e^- collisions. Notice that the distribution we have found here is the same one that appeared in Problem 5.5 when we considered soft photon emission before electron scattering. It should be clear that a parallel general derivation can be constructed for that case.
6.3 Exotic contributions to $\boldsymbol{g-2}$. Any particle that couples to the electron can produce a correction to the electron-photon form factors and, in particular, a correction to $g-2$. Because the electron $g-2$ agrees with QED to high accuracy, these corrections allow us to constrain the properties of hypothetical new particles.
(a) The unified theory of weak and electromagnetic interactions contains a scalar particle h called the Higgs boson, which couples to the electron according to

$$H_{\text{int}} = \int d^3x \frac{\lambda}{\sqrt{2}} h\bar{\psi}\psi$$

Compute the contribution of a virtual Higgs boson to the electron $(g-2)$, in terms of λ and the mass m_h of the Higgs boson.
(b) QED accounts extremely well for the electron's anomalous magnetic moment. If $a = (g-2)/2$,

$$|a_{\text{expt.}} - a_{\text{QED}}| < 1 \times 10^{-10}$$

What limits does this place on λ and m_h? In the simplest version of the electroweak theory, $\lambda = 3\times10^{-6}$ and $m_h > 60\text{GeV}$. Show that these values are not excluded. The coupling of the Higgs boson to the muon is larger by a factor (m_μ/m_e): $\lambda = 6 \times 10^{-4}$. Thus, although our experimental knowledge of the muon anomalous magnetic moment is not as precise,

$$|a_{\text{expt.}} - a_{\text{QED}}| < 3 \times 10^{-8},$$

one can still obtain a stronger limit on m_h. Is it strong enough?
(c) Some more complex versions of this theory contain a pseudoscalar particle called the axion, which couples to the electron according to

$$H_{\rm int} = \int d^3x \frac{i\lambda}{\sqrt{2}} a\bar{\psi}\gamma^5\psi$$

The axion may be as light as the electron, or lighter, and may couple more strongly than the Higgs boson. Compute the contribution of a virtual axion to the $g-2$ of the electron, and work out the excluded values of λ and m_a.

16.6 K-l.I: Radiative corrections. General analysis of divergent integrals

Preface

Today there exist many excellent textbooks on quantum field theory. The most popular ones are listed in the bibliography to the present lectures. Nevertheless, everyone who gives lectures on quantum field theory faces the problem of selection of material and writing the lecture notes for students. The present text is just the lecture notes devoted to the radiative corrections in QFT. On this way, one encounters two problems, namely, the ultraviolet and the infrared divergences. Our task is to demonstrate how one can get rid of these divergences and obtain finite corrections to the cross-sections of elementary processes. During the course we describe the methods of Feynman diagram evaluation and regularization of divergences. In more detail, we consider the renormalization theory and elimination of ultraviolet divergencies in the Green functions off mass shell, as exemplified by scalar and gauge theories. In connection with the renormalization procedure we describe also the renormalization group formalism in QFT. As for the infrared divergences, in the literature one can find mainly the discussion of the IR divergencies in quantum electrodynamics. In non-Abelian theories as well as in QED with massless particles the situation is much more involved as there arise collinear divergences as well. In the last lecture, we show how one can get rid of these divergences using the methods developed in quantum chromodynamics. One more topic also related to divergences is the so-called anomalies. They also lead to unwanted ultraviolet divergent contributions. Therefore, a separate lecture is dedicated to the axial and conformal anomalies.

The presented text overlaps with many textbooks and is partly borrowed from there. However, the composition of the material and most of the calculations belong to the author, so we omit the direct references to any textbooks. It should be admitted that the style of presentation in different textbooks varies very much and the reader can choose the book according to his preferences. We mostly used the classical monograph by N.Bogoliubov and D.Shirkov when describing the renormalization theory and more modern book by M.Peskin and D.Schreder which we followed when discussing the infrared divergences.

Our experience in giving lectures on quantum field theory, the renormalization theory and the renormalization group tells us that this material is still complicated for perception and is not always presented clearly enough. One often meets with the lack of understanding of the complicated structure of the field theory which manifests itself in renormalization theory. Sometimes the nonrenormalizable theories are simplistically treated as the field theories with a dimensional coupling constant which otherwise have no difference from the renormalizable ones. The collinear divergences arising in theories with massless particles, despite a long history, have not also become the well-known part of the QFT course. Here we make an attempt of a simplified presentation of this complicated material. Of course, this means that one has to sacrifice some rigorousness and completeness. We hope that together with the existing literature the present lectures will serve the goal of clarification and mastering of quantum field theory and its applications to particle physics.

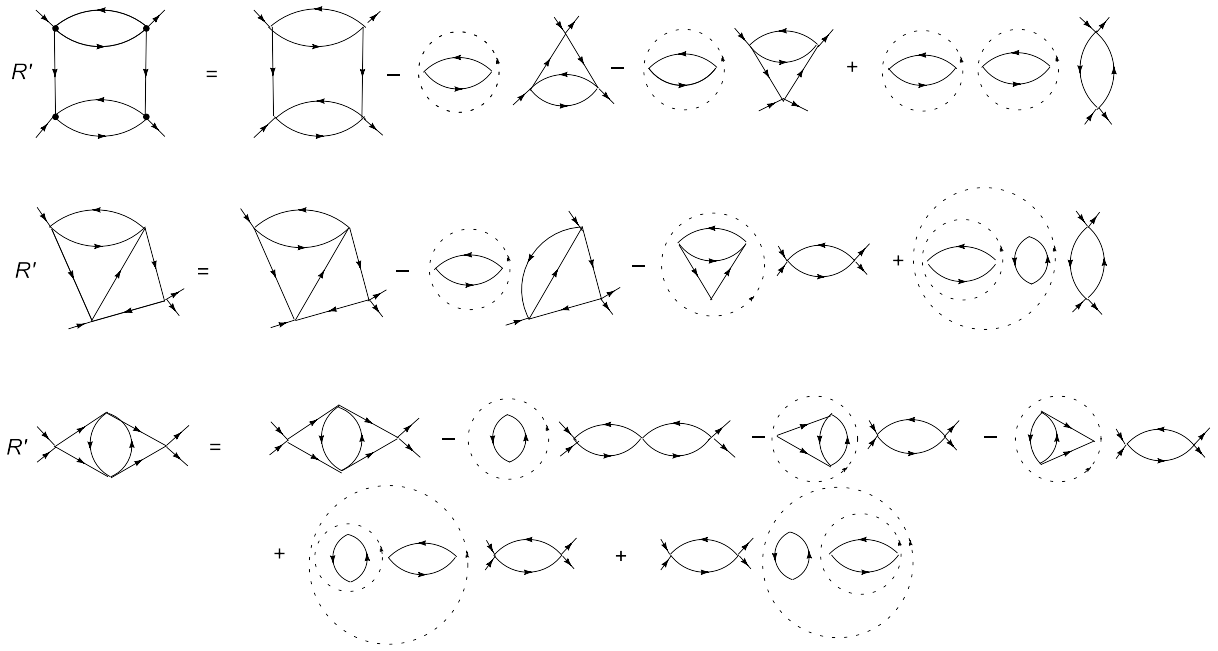


Figure 16.1: The $\mathcal{R}'$-operation for the multiloop diagrams

Afterword

Local quantum field theory, being the mathematical basis of elementary particle physics, is the logical continuation of quantum mechanics. It exploits the same basic ideas, but describing the system with an infinite number of degrees of freedom permits the creation and annihilation of particles in the course of the interaction. The modern formulation is based on the interaction representation which assumes the existence of the asymptotic states of the free fields. In the S-matric approach we presume that these fields interact in a local way in the space-time, and calculating the S-matrix elements one can find the probabilities of various processes. The most developed and reliable method of these calculations is the perturbation theory in the coupling constant which is similar to the one in quantum mechanics. However, due to a much more complicated structure of the field theory, the methods of perturbation theory encounter problems which have no analogy in quantum mechanics, namely the divergence of the appearing integrals for the radiative corrections. We have shown in these lectures how one can deal with these divergences which have the ultraviolet and the infrared nature and how to get the finite answers for the probabilities of the physical processes. We did not aim to prove the main theorems like the Bogoliubov-Parasiuk or the Kinoshita-Lee-Nauenberg theorem, but have exemplified how they work. The explicit calculations allow one to convince himself in the validity of the final conclusions.

It should be noted that the formalism of quantum field theory contains the physical principles which we have to follow sometimes not realizing it. Thus, for example, the ultraviolet divergences restrict the type of the interaction and, contrary to quantum mechanics, there are only a few types of allowed Lagrangians. Not without reason the renormalizability played such an important role in the formation of the Standard Model. The other example is the notion of the asymptotic states. Even starting with the free fields within the perturbation theory, from the requirement of the cancellation of the infrared divergences we come to the definition of the physical initial and final states which are essentially the coherent states.

The very fact that the gravitational interaction does not fit to the general scheme probably

means that local quantum field theory has a limited applicability and should be replaced by a more general construction. It might be nonlocal like in the string theory, or multidimensional one like in the brane-world theory. However, in any case, in the low energy limit one has the local quantum field theory though possibly going beyond the Standard Model that we considered here.

16.6.1 Radiative corrections

The formalism of quantum field theory, being the generalization of quantum mechanics to the case of an infinite number of degrees of freedom with nonconservation of the number of particles, allows one to describe the processes of scattering, annihilation, creation and decay of particles with the help of the set of well-defined rules. As in quantum mechanics the cross-section of any process is given by the square of the modulus of the probability amplitude calculated according to the Feynman rules for the corresponding Lagrangian integrated over the phase space. Since the exact calculations of the probability amplitudes seem to be impossible, one is bound to use the perturbation theory with a small parameter - the coupling constant - and get the result in the form of a power series. The leading terms of this series can be presented by Feynman diagrams without loops, the so-called tree diagrams. The examples of such diagrams for some typical processes in QED are shown in Fig.16.2.

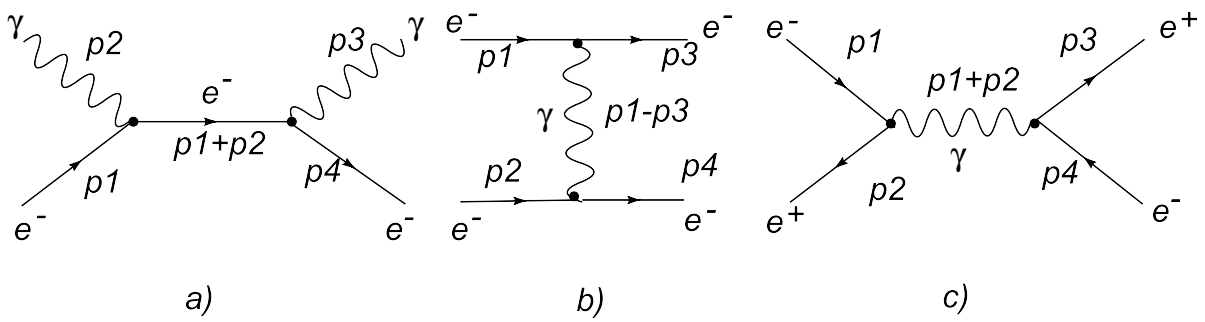

Figure 16.2: The examples of tree diagrams of different processes in QED:) the Compton scattering, b) the Mueller scattering, c) the annihilation of the particle-antiparticle pair. Shown are the momenta of external (real) and internal (virtual) particles

All the diagrams shown in Fig.16.2 are proportional to the square of the coupling constant e^2. They are constructed according to the well-known Feynman rules and do not contain any integration over momenta (when working in momentum representation) since due to the conservation of four-momentum all momenta are defined uniquely.

The situation changes when considering the next order of perturbation theory. As an example, in Fig.16.3 we show the corresponding diagrams for the Compton scattering.

They got the name of *radiative corrections* since in electrodynamics they correspond to the emission and absorption of photons. This name is also accepted in other theories for perturbative corrections. All these diagrams are proportional to the fourth power of the coupling constant e^4 and, hence, are the next order perturbations with respect to the tree diagrams. However, contrary to the tree diagrams, they contain a closed loop which requires the integration over the four-momenta running through the loop. Any loop corresponds to the bifurcation of momenta similarly to the bifurcation of the electric current, according to the Kirchhoff rules, so that the total momentum is conserved but the momentum running along each line is arbitrary. Therefore, one has to integrate over it.

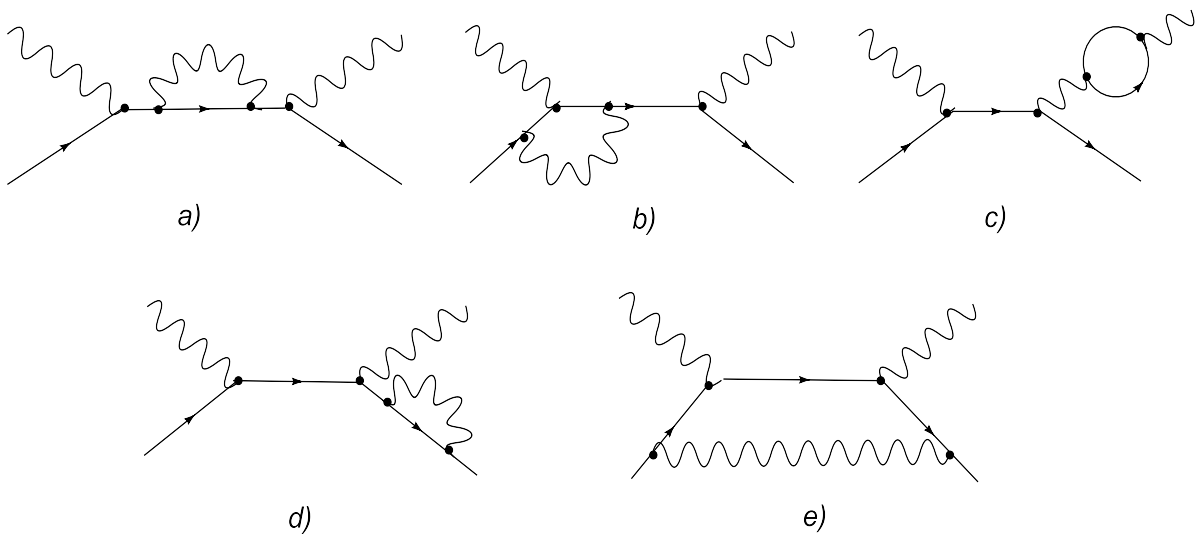

Figure 16.3: The one-loop diagrams for the process of the Compton scattering

16.6.2 Divergence of integrals

Prior to calculating the radiative corrections let us consider the behaviour of the integrand and the integral as a whole. As an example we take the diagrams of the Compton scattering shown in Fig.16.3. The integral corresponding to the diagram shown in Fig.16.3.a) has the form

$$\int d^4k \frac{\gamma^\mu(\hat{p}-\hat{k}+m)\gamma^\mu}{[k^2+i\varepsilon][(p-k)^2-m^2+i\varepsilon]}, \tag{16.1}$$

where the photon propagator is written in Feynman gauge and the integration takes place in Minkowskian space. We shall not calculate explicitly this integral now (we shall do it later) but consider the integrand from the point of view of the presence of singularities as well as the behaviour at small and large momenta.

The presence of poles in the propagators for momentum equal to the mass squared does not create any problem for the integration since according to the Feynman rules the denominator contains the infinitesimal imaginary term $\sim \varepsilon \to 0$, which defines the way to bypass the pole. The choice accepted in (16.1) corresponds to the causal Green function.

Consider now the case of $k_\mu \to 0$, the so-called *infrared* behaviour. Despite the presence of k^2 in the denominator, the singularity is absent due to the measure of the 4-dimensional integration which is also proportional to k^4. This is true for all such integrals. The singularities appear only for certain external momenta which are on mass shell and have a physical reason. Off shell the singularities are absent. For this reason we shall not discuss the infrared behaviour of the integrals so far.

Consider at last the case of $k_\mu \to \infty$, the so-called *ultraviolet* behaviour. Notice that in the denominator one has 4 powers of momenta, while in the numerator one has 1 plus 4 powers in the measure of integration. Hence one has 5-4=1, i.e. the integral is linearly divergent as $k_\mu \to \infty$. Is it the property of a particular integral or is it a general situation? What happens with the other diagrams?

Consider the integral corresponding to the diagram shown in Fig.16.3.). One has, according to

the Feynman rules

$$\int d^4k \frac{\gamma^\mu(\hat{p_1}-\hat{k})+m)\gamma^\nu(\hat{p_2}-\hat{k})+m)\gamma^\mu}{k^2[(p_1-k)^2-m^2][(p_2-k)^2-m^2]}. \tag{16.2}$$

We are again interested in the behaviour for $k_\mu \to \infty$. The counting of the powers of momenta in the numerator and the denominator gives: 6 in the denominator and 2 in the numerator plus 4 in the integration measure. Altogether one has 6-6=0, i.e., the integral is logarithmically divergent as $k_\mu \to \infty$.

Here we met the difficulty called the ultraviolet divergence of the integrals for the radiative corrections. The examples considered above are not exceptional but the usual ones. The corrections are infinite, which makes perturbation theory over a small parameter meaningless. The way out of this trouble was found with the help of the renormalization theory which will be considered later and now we try to estimate the divergence of the integrals in a theory with an arbitrary Lagrangian.

16.6.3 General analysis of ultraviolet divergences

Consider an arbitrary Feynman diagram G shown in Fig.16.4. and try to find out whether

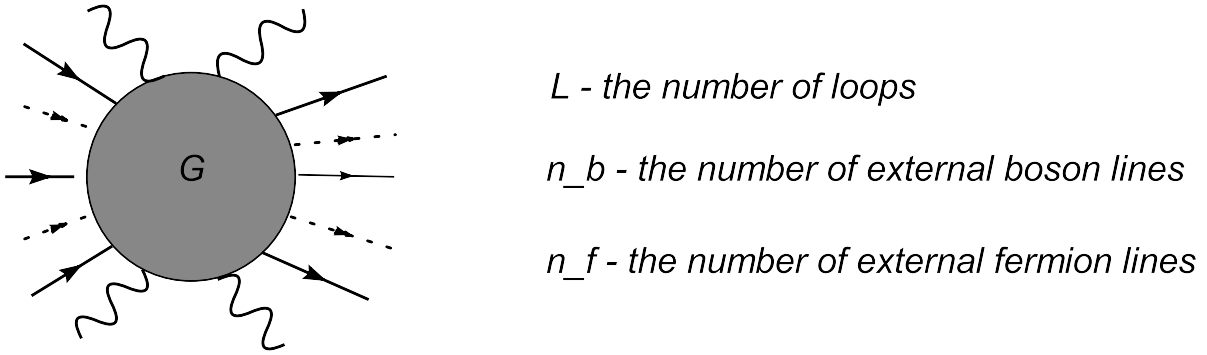

Figure 16.4: An arbitrary diagram containing L integrations

it is ultraviolet divergent or not. For this purpose we have to calculate the number of powers of momenta in the integrand: each internal loop leads to integration d^4p that gives 4 powers of momenta; each derivative in the vertex gives the momentum in p-space, i.e., 1; each internal line gives a propagator which behaves as p^{r_l}/p^2, i.e., $r_l - 2$ powers of momenta, where $r_l = 0, 1, 2$ for various fields. Combining all these powers together we get the quantity called *the index of divergence of the diagram* (UV)

$$\omega(G) = 4L + \sum_{vertices} \delta_v + \sum_{internal\ lines} (r_l - 2), \tag{16.3}$$

where L is the number of loops and δ_v is the number of derivatives in a vertex v.

The absence of the ultraviolet divergences means that $\omega(G) < 0$. However, one has to be careful, there might be subdivergences in some subgraphs. Hence, the necessary condition for finiteness is

$$\text{The finiteness condition (UV):}\ \ \omega(\gamma_i) < 0, \quad \forall \gamma_i \subset G,$$

where γ_i are all possible subgraphs of the graph G including the graph G itself.

There exists, however, a simpler way to answer the same question which does not need to analyse all the diagrams. One can see it directly from the form of the Lagrangian. To see this, let us introduce the quantity called *the index of the vertex* (UV)

$$\omega_v = \delta_v + b_v + \frac{3}{2} f_v - 4, \tag{16.4}$$

where δ_v, b_v and f_v are the number of derivatives, internal boson and fermion lines, respectively. Then the index of a diagram (16.3) can be written as

$$\omega(G) = \sum_{vertices} \omega_v^{max} + 4 - n_b - \frac{3}{2} n_f, \tag{16.5}$$

where ω_v^{max} corresponds to the vertex where all the lines are internal, n_b and n_f are the number of external boson and fermion lines, and we have used the fact that usually $r_l(boson) = 0$ and $r_l(fermion) = 1$.

Equation (16.5) tells us that the finiteness ($\omega(G) < 0$) can take place if $\omega_v \leq 0$ and the number of external lines is big enough. Prior to the formulation of conditions when it happens, let us consider some examples.

Example 1: The scalar theory $\mathcal{L}_{int} = -\lambda\varphi^4$.

In this case $\delta_v = 0$, $f_v = 0$, $b_v = 4$ and, hence, $\omega_v^{max} = 0$. Thus, according to (16.5), $\omega(G) = 4 - n_b - \frac{3}{2} n_f$ and everything is defined by the number of external lines. The situation is illustrated in Fig.16.5.

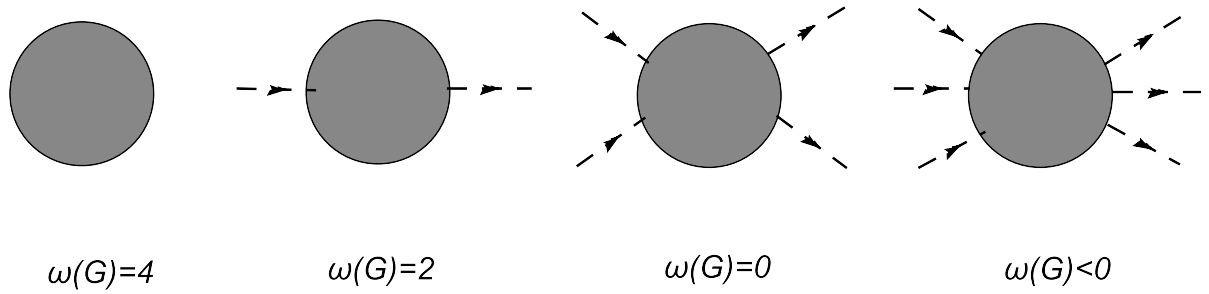

Figure 16.5: The indices of divergence of the diagrams in the scalar theory

We see that there exists a limited number of divergent structures in the φ^4 theory. These are the vacuum graphs, the two- and four-point functions. All the other diagrams having more than 4 external lines are convergent (though may have divergent subgraphs).

Example 2: Quantum Electrodynamics $\mathcal{L}_{int} = \bar{\psi}\hat{A}\psi$.

In this case $\delta_v = 0, f_v = 2, b_v = 1$, $\omega_v^{max} = 0$. Hence, $\omega(G) = 4 - n_b - \frac{3}{2} n_f$ and the situation is similar to the previous example, everything is defined by external lines. Divergent are the vacuum diagrams ($\omega(G) = 4$), the photon propagator ($\omega(G) = 2$), the electron propagator ($\omega(G) = 1$) and the triple vertex ($\omega(G) = 0$). All the other diagrams are convergent.

Example 3: Four-fermion interaction $\mathcal{L}_{int} = G\bar{\psi}\psi\bar{\psi}\psi$.

Here $\delta_v = 0, f_v = 4, b_v = 0,\ \omega_v^{max} = 2$ and, hence, $\omega(G) = 2N - \frac{3}{2}n_f$. Therefore, increasing the number of vertices we get new divergent diagrams independently of the number of external lines. The number of divergent structures happens to be infinite.

Thus, the key role is played by the maximal index of the vertex. All the theories may be classified according to the value of $\omega_v^{\max}$:

$$\omega_v^{\max} = \begin{cases} < 0 & \textit{Finite number of divergent diagrams}, \\ 0 & \textit{Finite number of divergent structures}, \\ > 0 & \textit{Infinite number of divergent structures}. \end{cases} \tag{16.6}$$

Below we show that for the first two types of theories we can handle the ultraviolet divergences with the help of the renormalization procedure. The theories with $\omega_v^{\max} = 0$ are called *renormalizable*, the theories with $\omega_v^{\max} > 0$ are called *nonrenormalizable*, and the theories with $\omega_v^{\max} < 0$ are called *superrenormalizable*.

16.6.4 The analysis of dimensions

The property of a theory with respect to ultraviolet divergences can be reformulated in terms of dimensions. Consider for this purpose an arbitrary term of the interaction Lagrangian which is the product of the field operators and their derivatives

$$\mathcal{L}_I(x) = g \prod_{i,j} \varphi_i(x) \partial \varphi_j(x). \tag{16.7}$$

Consider the action which is the four-dimensional integral of the Lagrangian density

$$A = \int d^4x \mathcal{L}(x), \tag{16.8}$$

and find the dimensions of parameters in eq.(16.7). As a unit of measure we take the dimension of a mass equal to 1. Then the dimension of length $[L] = -1$, the dimension of time is also $[T] = -1$, the dimension of derivative $[\partial_\mu] = 1$, the dimension of momenta $[p_\mu] = 1$. Since the action is dimensionless (we use the natural units where $\hbar = c = 1$)

$$[A] = 0,$$

the dimension of the Lagrangian is

$$[\mathcal{L}] = 4, \quad (D - \text{in D dimensional space.})$$

This gives us the dimensions of the fields. Indeed, from the kinetic term for the scalar field one finds

$$[(\partial\phi)^2] = 4 \to [\phi] = 1, \quad (\frac{D-2}{2} \text{ in D dimensional space}),$$

for the spinor field

$$[\bar{\psi}\hat{\partial}\psi] = 4 \to [\psi] = \frac{3}{2}, \quad (\frac{D-1}{2} \text{ in D dimensional space}),$$

for the vector field

$$[(\partial_\mu A_\nu - \partial_\nu A_\mu)^2] = 4 \to [A_\mu] = 1, \quad (\frac{D-2}{2} \text{ in D dimensional space}).$$

This allows one to find the dimension of the coupling constant in (16.7)

$$[g] = 4 - \delta_v - b_v - \frac{3}{2} f_v = -\omega_v^{max}. \tag{16.9}$$

Then the classification of interactions (16.6) can be written as

$$[g] = \begin{cases} > 0 & \textit{Superrenormalizable theories}, \\ 0 & \textit{Renormalizable theories}, \\ < 0 & \textit{Nonrenormalizable thoeries}. \end{cases} \tag{16.10}$$

Consider which category various theories belong to. For this purpose we have to calculate the dimensions of the couplings.

Illustration

$$\begin{array}{lll} \mathcal{L}_{\varphi^3} = -\lambda\varphi^3 & \Rightarrow & [\lambda] = 1, \quad SuperRen. \\ \mathcal{L}_{\varphi^4} = -\lambda\varphi^4 & \Rightarrow & [\lambda] = 0, \quad Ren. \\ \mathcal{L}_{QED} = e\overline{\psi}\gamma^\mu A_\mu \psi & \Rightarrow & [e] = 0, \quad Ren. \\ \mathcal{L}_{gauge} = -\frac{1}{4}F_{\mu\nu}^2 = -\frac{1}{4}\left[\partial_\mu A_\nu^a - \partial_\nu A_\mu^a + g f^{abc} A_\mu^b A_\nu^c\right]^2 & \Rightarrow & [g] = 0, \quad Ren. \\ \mathcal{L}_{Yukawa} = y\overline{\psi}\varphi\psi & \Rightarrow & [y] = 0. \quad Ren. \end{array}$$

Thus, all these models are renormalizable.

$$\begin{array}{lll} \mathcal{L} = -h\varphi^6 & \Rightarrow & [h] = -2, \quad Nonren. \\ \mathcal{L} = G\overline{\psi}\psi\overline{\psi}\psi & \Rightarrow & [G] = -2 \quad Nonren. \\ \mathcal{L} = \kappa\overline{\psi}\partial_\mu V_\mu \psi & \Rightarrow & [\kappa] = -1 \quad Nonren. \\ \mathcal{L} = \gamma\overline{\psi}\partial_\mu\varphi\gamma^\mu\psi & \Rightarrow & [\gamma] = -1. \quad Nonren. \end{array}$$

All these models on the contrary are nonrenormalizable. Notice that they include the four-fermion or current-current interaction which was previously used in the theory of weak interactions.

Hence, we come to the following conclusion: the only renormalizable interactions in four dimensions are:

i) the φ^4 interaction;

ii) the Yukawa interaction;

iii) the gauge interaction;

iv) the theory φ^3 is superrenormalizable. It contains only two divergent diagrams shown in Fig.16.6.

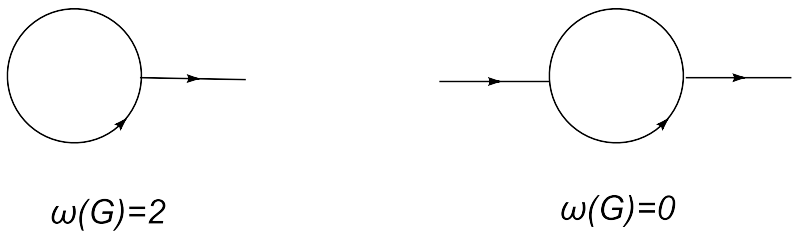

Figure 16.6: The only divergent diagrams in the ϕ^3 theory

If one looks at the spins of particles involved in the interactions, one finds out that they are strongly restricted. The renormalizable interactions contain only the fields with spins 0, 1/2 and

1. All the models with spins 3/2, 2, etc. are nonrenormalizable. The latter include also gravity. Indeed, the coupling constant in this case is the Newton constant which has dimension equal to $[G] = -2$, i.e., quantum gravity is nonrenormalizable.

Since we do not know how to handle the nonrenormalizable interactions because the ultraviolet divergences are out of control, there are only three types of interactions which are used in the construction of the Standard Model of fundamental interactions, namely the φ^4, the Yukawa and the gauge interactions with the scalar, spinor and vector particles.

Here one has to make a comment concerning the vector fields with $M \neq 0$. Remind the form of the propagator of the massive vector field

$$\overline{V_\mu V_\nu} = i\frac{g_{\mu\nu} - k_\mu k_\nu/M^2}{M^2 - k^2 - i\epsilon}.$$

It gives $r_l = 2$, which leads to some modification of the formulas used above and finally to the nonrenormalizability of the theory. The only known way to avoid this difficulty is the spontaneous breaking of symmetry. In this case,

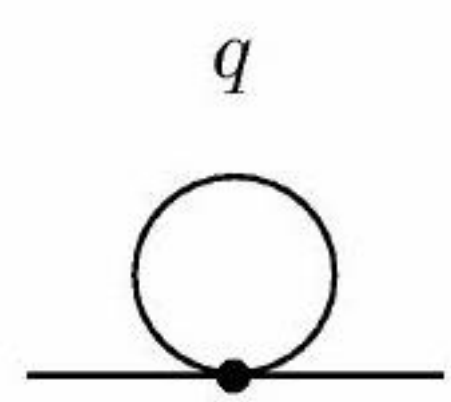
$$\overline{V_\mu V_\nu} = i\frac{g_{\mu\nu} - k_\mu k_\nu/k^2}{M^2 - k^2 - i\epsilon},$$

that gives $r_l = 0$ and the theory happens to be renormalizable. This mechanism is used in the Standard Model to give masses to the intermediate weak bosons without breaking the renormalizability of the theory.

16.7 L4 Ultraviolet Divergences and Regularization

16.7.1 1. Dimensional Regularization of Divergences

Попробуем вычислить простейшую диаграмму (f) на рис. 3:



Соответствующий вклад в iM, обозначаемый $-i\Sigma$, равен

$$-i\Sigma^{(1)} = -\frac{\lambda_0\mu^{4-d}}{2}\int\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\frac{1}{-\left(k^0\right)^2 + \mathbf{k}^2 + m_0^2 - i\varepsilon}$$

Здесь μ - константа, имеющая размерность массы, так что λ_0 - безразмерная константа. При интегрировании по k^0 сделаем поворот Вика (см. рис. 1, 2 в лекции 1) $k^0 = ik^d$:

$$-i\Sigma^{(1)} = -\frac{i\lambda_0\mu^{4-d}}{2}\int\limits_E \frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\frac{1}{k^2+m_0^2} \tag{1}$$

Обозначение $\int\limits_E \mathrm{d}^{(d)}k$ указывает на то, что интегрирование идёт по d-мерному евклидову пространству, в котором $k^2 = \left(k^1\right)^2 + \ldots + \left(k^d\right)^2$. Интеграл (1) при $d \geq 2$ расходится, при $d < 2$ - сходится. Мы видим, что сходимость диаграмм Фейнмана существенно зависит от размерности d пространства-времени. С другой стороны, большинство симметрий теории поля не зависят от d. Важнейшими из таких симметрий являются лоренц- и калибровочная инвариантности. Поэтому возникла идея (Ж. 't Хоофт, М. Вельтман) вычислять диаграммы Фейнмана при произвольной комплексной размерности пространства, устремляя в конце вычислений параметр d к нужному значению.

Для дальнейших вычислений нам понадобятся следующие формулы и интегралы.

Пусть $V_R^{(d)} = S^{(d)}R^d$ - объём шара радиуса R в d-мерном евклидовом пространстве. Вычислим $S^{(d)}$ - объём единичного шара в d-мерном пространстве. Имеем:

$$\pi^{d/2} = \int \mathrm{d}^{(d)}x e^{-\left(x_1^2+\ldots+x_d^2\right)} = \int\limits_0^\infty e^{-R^2}\,\mathrm{d}V_R^{(d)} = dS^{(d)}\int\limits_0^\infty e^{-R^2}R^{d-1}\,\mathrm{d}R =$$

$$= \frac{d}{2}S^{(d)}\int\limits_0^\infty e^{-t}t^{d/2-1}\,\mathrm{d}t = S^{(d)}\Gamma\left(\frac{d}{2}\right)\left(\frac{d}{2}\right)$$

Таким образом

$$S^{(d)} = \frac{\pi^{d/2}}{\Gamma\left(\frac{d}{2}\right)\left(\frac{d}{2}\right)} = \frac{\pi^{d/2}}{\Gamma\left(\frac{d}{2}+1\right)} \tag{2}$$

Везде $\Gamma(z)$ - гамма-функция. При $c > 0$ и $\alpha > d/2$ имеем:

$$\int\limits_E \frac{\mathrm{d}^{(d)}k}{\left(k^2+c\right)^\alpha} = dS^{(d)}\int\limits_0^\infty \frac{k^{d-1}\,\mathrm{d}k}{\left(k^2+c\right)^\alpha} = \left(\frac{d}{2}\right)S^{(d)}\int\limits_0^\infty \frac{t^{d/2-1}\,\mathrm{d}t}{(t+c)^\alpha} = \left(\frac{d}{2}\right)S^{(d)}\left[c^{d/2-\alpha}\frac{\Gamma\left(\frac{d}{2}\right)\Gamma\left(\alpha-\frac{d}{2}\right)}{\Gamma(\alpha)}\right]$$

Теперь при помощи (2) получаем:

$$\int\limits_E \frac{\mathrm{d}^{(d)}k}{\left(k^2+c\right)^\alpha} = \pi^{d/2}c^{d/2-\alpha}\frac{\Gamma\left(\alpha-\frac{d}{2}\right)}{\Gamma(\alpha)} \tag{3}$$

Интеграл (3) был вычислен при условии $d < 2\alpha$. Однако правая часть в (3) является аналитической функцией всех параметров. Поэтому при произвольных комплексных значениях параметров d. α и с будем считать правую часть уравнения (3) определением интеграла, стоящего в левой части равенства (3).

При помощи (3) вычисляем интеграл (1):

$$-i\Sigma^{(1)} = -\frac{i\lambda_0\mu^{4-d}m_0^{d-2}}{2^{d+1}\pi^{d/2}}\Gamma\left(1-\frac{d}{2}\right) \tag{4}$$

Нас интересует значение $d = 4$ или значения d, близкие к числу 4. Поэтому введём обозначения

$$d = 4 - \varepsilon, \quad \ln \frac{\Lambda}{\mu} = \frac{1}{\varepsilon}, \quad \varepsilon \to +0 \tag{5}$$

Как будет видно из дальнейших вычислений, параметр $\Lambda \to \infty$ играет роль максимально допустимого импульса в теории - импульса обрезания. Перепишем (4) в новых обозначениях:

$$-i\Sigma^{(1)} = -\frac{i\lambda_0 \mu^{\varepsilon} m_0^{2-\varepsilon}}{2^{(5-\varepsilon)}\pi^{(2-\varepsilon/2)}} \Gamma\left(-1 + \frac{\varepsilon}{2}\right) \tag{6}$$

При помощи формул

$$\Gamma(z) = \frac{\Gamma(z+1)}{z}, \quad \Gamma(1) = 1 \tag{7}$$

находим, что величина (6)

$$-i\Sigma^{(1)} \underset{\varepsilon \to +0}{} \frac{i\lambda_0 m_0^2}{2^4 \pi^2} \left(\frac{1}{\varepsilon}\right) + \text{ const} \tag{8}$$

где const - конечная величина при $\varepsilon \to 0$.

Теперь займёмся вычислением однопетлевых диаграмм на рис. 7 (n-петлевой диаграммой называется такая диаграмма, у которой имеется n нефиксированных импульсов, по которым идёт интегрирование). Каждая из этих трёх диаграмм представляется интегралом

$$I = \frac{1}{2}\lambda_0^2 \mu^{2(4-d)} \int \frac{\mathrm{d}^{(d)} q}{(2\pi)^d} D_c(q) D_c(p-q) \tag{9}$$

Сначала оценим интеграл (9) непосредственно в 4 -мерном пространстве-времени. Рассмотрим этот интеграл в ультрафиолетовой области ($q \to \infty$). Так как внешние импульсы и масса фиксированы, то ими можно пренебречь при вычислении расходящейся части. Это можно сделать не всегда, но в данном случае, когда степень расходимости интеграла не выше логарифмической, внешними импульсами и массами можно пренебречь: учёт поправок к интегралу (9), пропорциональных m и p, приводит к сходящимся интегралам.

Сделаем поворот Вика. Тогда расходящаяся часть суммы трёх интегралов в (15 Л3) равна

$$iM_{div}^{(2)} = \frac{3i\lambda_0^2}{32\pi^4} \int\limits_E \frac{\mathrm{d}^{(4)} q}{(q^2)^2} = \frac{3i\lambda_0^2}{16\pi^2} \int\limits_{\mu}^{\Lambda} \frac{\mathrm{d}q}{q}, \quad \Lambda \to \infty \tag{10}$$

Здесь Λ - промежуточный импульс обрезания, μ - нижний предел интегрирования, имеющий порядок физической массы частицы или внешних импульсов, который называется точкой нормировки.

Мы опять видим, что амплитуды перехода в квантовой теории поля содержат расходящиеся вклады.

Приведём ещё один пример.

Диаграмма (g) на рис. 3 даёт вклад в амплитуду перехода частицы в эту же частицу, аналогично диаграмме (f) на рис. 3:

$$-i\Sigma^{(2)} = -\frac{i\lambda_0^2}{6}\int \frac{\mathrm{d}^{(4)}q_1\ \mathrm{d}^{(4)}q_2}{(2\pi)^8} D_c\left(q_1\right) D_c\left(q_2\right) D_c\left(k-q_1-q_2\right) \tag{11}$$

Интеграл (11), так же как и интеграл (1), при $d = 4$ расходится квадратично.

16.7.2 2. Index of Divergence of Diagrams

Вычислим индекс расходимости произвольной диаграммы. Для этого сделаем масштабное преобразование всех импульсов в диаграмме, а также массы частицы: $k_i, p_f, q, m \ \rightarrow \ \alpha k_i, \alpha p_f, \alpha q, \alpha m$. При таком преобразовании подынтегральное выражение умножается на α^ω, где ω и есть индекс диаграммы. Очевидно, что все внутренние линии дают вклад в число ω, равный $(-2L_{in})$. Легко увидеть, что число d-мерных дифференциалов от внутренних независимых импульсов равно $L = [L_{in} - (n-1)]$, где n - число вершин диаграммы. Действительно, независимых внутренних импульсов в диаграмме с n вершинами имеется на $(n-1)$ меньше, чем внутренних линий, так как в каждой из n вершин имеет место закон сохранения d-импульса. Однако совокупность n законов сохранения содержит в себе один закон сохранения совокупности внешних входящих и выходящих d-импульсов. Этим объясняется уменьшение независимых d-импульсов не на n, а на $(n-1)$. Поэтому имеем для числа ω

$$\omega = d\left(L_{in} - n + 1\right) - 2L_{in} \tag{12}$$

Обозначим через L_{ex} суммарное число внешних линий. Имеем:

$$L_{ex} + 2L_{in} = 4n \tag{13}$$

Действительно, к каждой вершине подходит 4 линии, но каждая внутренняя линия подходит к двум вершинам. Исключим из (12) число n при помощи равенства (13):

$$\omega = \frac{1}{2}(d-4)L_{in} + d\left(1 - \frac{L_{ex}}{4}\right) \tag{14}$$

Диаграмма является формально сходящейся, если $\omega < 0$.

Мы рассмотрели расходимости диаграмм f и g на рис. 3 с $L_{ex} = 2$ и однопетлевые диаграммы на рис. 7 с $L_{ex} = 4$ при $d = 4$. Согласно (14) при $d = 4$ диаграммы с двумя внешними линиями расходятся квадратично, однако в них содержатся также и логарифмические расходимости. Это будет показано ниже. Диаграммы с четырьмя внешними линиями расходятся лишь логарифмически, что и было выяснено на примере однопетлевых диаграмм на рис. 7. Подчеркнём, что в рассматриваемой модели при $d = 4$ степень расходимости диаграммы зависит не от её числа петелъ, а от числа внешних линий. Фактически это свойство является следствием безразмерности константы связи λ_0, по которой идёт разложение. Действительно, лишь при $d = 4$ константа λ_0 безразмерна. При $d > 4$ её размерность такова, что степень расходимости диаграммы возрастает по мере её усложнения (см. (14)). Такие теории называются неперенормируемыми. При $d < 4$ теория ϕ^4 относится к так называемым сверхперенормируемым, поскольку в теории содержится лишь конечное число расходящихся диаграмм.

16.7.3 3. Diagram with Four External Lines

Теперь займёмся вычислением интеграла (9) при произвольном комплексном значении параметра d. Причинные гриновские функции допускают следующее представление:

$$D_c(q) = i\int\limits_0^\infty \exp\left[i\alpha\left(q^2 - m_0^2 + i\varepsilon\right)\right]\mathrm{d}\alpha \tag{15}$$

Делая поворот Вика и используя (15), переписываем (9) в виде

$$I = -i\frac{\lambda_0^2\mu^{2(4-d)}}{2(2\pi)^d}\int\limits_0^\infty \mathrm{d}\alpha\int\limits_0^\infty \mathrm{d}\beta\int\limits_E \mathrm{d}^{(d)}q\exp\left\{-i\alpha\left(q^2+m_0^2\right) - i\beta\left[(p-q)^2+m_0^2\right] - \varepsilon(\alpha+\beta)\right\}$$

Здесь интеграл по q является гауссовым и вычисляется при помощи формулы (13 Л1), где следует сделать замены $N \to d, \mathcal{M} \to -[2(\alpha+\beta)]^{-1}, \xi \to 2\beta p$. После вычисления этого интеграла возвращаемся в пространство Минковского:

$$I = -\frac{i}{2}\lambda_0^2\mu^{2(4-d)}(4\pi i)^{-d/2}\int\limits_0^\infty \mathrm{d}\alpha\int\limits_0^\infty \mathrm{d}\beta\frac{1}{(\alpha+\beta)^{d/2}}\exp\left\{i\frac{\alpha\beta}{\alpha+\beta}p^2 - i(\alpha+\beta)\left(m_0^2 - i\varepsilon\right)\right\} \tag{16}$$

Перепишем интеграл (16) в новых переменных интегрирования $\alpha = \lambda t, \beta = (1-\lambda)t, \quad 0 < \lambda < 1,\ 0 < t < \infty$:

$$I = -\frac{i}{2}\lambda_0^2\mu^{2(4-d)}(4\pi i)^{-d/2}\int\limits_0^1 \mathrm{d}\lambda\int\limits_0^\infty \mathrm{d}t t^{(1-d/2)}\exp\left\{-t\left[-i\lambda(1-\lambda)p^2 + im_0^2 + \varepsilon\right]\right\} \tag{17}$$

Внутренний интеграл в (17) вычисляется при помощи формулы

$$\int\limits_0^\infty \mathrm{d}t t^{z-1}e^{-kt} = k^{-z}\Gamma(z), \quad \operatorname{Re} k > 0 \tag{18}$$

В нашем случае $z = 2 - d/2, \quad k = i\left[m_0^2 - \lambda(1-\lambda)p^2\right] + \varepsilon$. Поэтому имеем:

$$\frac{I}{\mu^{4-d}} = \frac{i\lambda_0^2\mu^{(4-d)}\Gamma\left(2-\frac{d}{2}\right)}{2(4\pi)^{d/2}}\int\limits_0^1 \mathrm{d}\lambda\left[m_0^2 - \lambda(1-\lambda)p^2\right]^{d/2-2} \tag{19}$$

Разложим (с учётом (7)) правую часть (19) в ряд Лорана вблизи точки $d = 4$:

$$\frac{I}{\mu^{4-d}} = \frac{i\lambda_0^2}{(4\pi)^2(4-d)} + \frac{i\lambda_0^2[\psi(1) + \ln 4\pi]}{8(2\pi)^2} -$$
$$-\frac{i\lambda_0^2}{8(2\pi)^2}\int\limits_0^1 \mathrm{d}\lambda\ln\frac{m_0^2 - \lambda(1-\lambda)p^2 - i\varepsilon}{\mu^2}, \quad \psi(\alpha) = \frac{\mathrm{d}}{\mathrm{d}\alpha}\ln\Gamma(\alpha) \tag{20}$$

Отсюда мы видим, что расходящаяся часть в $iM^{(2)}$ равна

$$iM^{(2)}_{div} = \frac{3i\lambda_0^2}{16\pi^2}\frac{1}{4-d} \tag{21}$$

Сравнивая (21) и (10), мы оправдываем соотношение (5):

$$\frac{1}{4-d} = \frac{1}{\varepsilon} = \ln\frac{\Lambda}{\mu} \tag{22}$$

Укажем на следующее важное обстоятельство: метод размерностной регуляризации учитывает лишь логарифмические расходимости. Действительно, если $d > 2\alpha$, то полагая $c = 0$ в (3), получаем:

$$\int\limits_E \frac{\mathrm{d}^d k}{(k^2)^\alpha} = 0 \quad \text{при } d > 2\alpha \tag{23}$$

Равенство (23) означает, что в методе размерностной регуляризации при $d > 2\alpha$ интеграл (23) определён и он равен нулю. Отсюда следует автоматическое устранение расходимостей степени выше логарифмической. Это же видно, в частности, из формулы (8).

16.7.4 4. Elimination of Divergences

Предположим, что в теории возмущений, описываемой рядом диаграмм Фейнмана, содержатся расходимости в диаграммах с ограниченным числом внешних линий. Таким примером является рассматриваемая теория ϕ^4 при $d = 4$. Более того, в этой теории расходятся лишь диаграммы с двумя и четырьмя внешними линиями, а действие содержит слагаемые, пропорциональные ϕ^2 и ϕ^4. В такой ситуации для устранения расходимостей вводится промежуточная регуляризация, смысл которой заключается в обрезании петлевых интегралов по нефиксированным импульсам неким параметром Λ, стремящимся к бесконечности, Это обрезание проводится таким образом, чтобы была сохранена Лоренц-инвариантность, а также, по возможности, все прочие симметрии, имеющиеся в теории. Размерностная регуляризация является наиболее используемым методом такой регуляризации. Оказывается, что в некоторых случаях (как в теории ϕ^4 при $d = 4$) исходные параметры
теории (затравочные константы) можно выбрать такими функциями параметра обрезания Λ, что при $\Lambda \to \infty$ все расходимости в теории сокращаются. В рассматриваемой нами скалярной теории поля способ действий таков: если в неком порядке теории возмущений расходимости уже устранены, то в следующем порядке ТВ расходятся диаграммы с двумя и с четырьмя внешними линиями. В первом случае расходимость устраняется переделкой (перенормировкой) затравочной массы, а во втором случае - перенормировкой затравочной константы связи. При этом может оказаться, что затравочные константы не имеют конечного предела при устремлении промежуточного импульса обрезания к бесконечности. Но в процедуре перенормировки наблюдаемые (или физические, или перенормированные) величины (массы частиц, константы взаимодействия физических частиц, амплитуды перехода) должны стремиться к определённому пределу при устремлении промежуточного импульса обрезания к бесконечности. Затравочные константы теории разлагаются в ряд по перенормированным константам, причём коэффициенты в этом разложении являются функциями параметра обрезания.

Теории, допускающие подобную процедуру перенормировки, называются перенормируемыми теориями.

Продемонстрируем сказанное на примере перенормировки констант в теории ϕ^4 в четырёхмерном пространстве-времени. Мы увидим, что эта теория является перенормируемой. Пусть затравочная константа связи λ_0, входящая в исходное (затравочное) действие, разлагается в ряд по физической константе связи λ. Далее мы увидим, что физическая константа связи может быть определена через значение амплитуды перехода двух частиц в две частицы при некоторых значениях импульсов частиц. Пусть во втором порядке

$$\lambda_0 = \lambda + \frac{3\lambda^2}{16\pi^2} \ln \frac{\Lambda}{\mu}, \quad \lambda_0^2 = \lambda^2 + O\left(\lambda^3\right) \tag{24}$$

Тогда согласно (10) и (24) в сумме диаграмм на рис. 7 расходимости сокращаются по крайней мере с точностью $O\left(\lambda^3\right)$ и амплитуда $2 \to 2$ является конечным выражением, зависящим от физической безразмерной константы λ.

16.7.5 5. Mandelstam Invariant Variables

В заключение лекции дадим определение удобных лоренц-инвариантных переменных, при помощи которых удобнее всего описывать амплитуды перехода двух частиц в две частицы.

Прежде всего заметим, что построенная ТВ явно лоренц-инвариантна. Это значит, что все амплитуды перехода как функции внешних 4-импульсов являются лоренц-инвариантами, то есть они зависят лишь от лоренц-инвариантов, построенных из внешних 4-импульсов. Это замечание остаётся в силе для диаграмм Фейнмана, внешние импульсы которых не находятся на массовой поверхности.

Пусть в реакции участвует всего 4 частицы с массами m_1, m_2, m_3, m_4, причём при $t \to -\infty$ имелось 2 частицы и при $t \to +\infty$ имеется также 2 частицы. Обобщённый закон сохранения 4 -импульса запишем в виде

$$k_1 + k_2 + k_3 + k_4 = 0 \tag{25}$$

При этом предполагается, что, если, например, идёт реакция $1 + 2 \to 3 + 4$, то

$$k_1^0 > 0, k_2^0 > 0, k_3^0 < 0, k_4^0 < 0 \tag{26}$$

и т.д.

Из четырёх 4-импульсов, находящихся на массовой поверхности и удовлетворяющих уравнению (25), можно составить всего 2 независимых инвариантных переменных. Действительно, в силу (25) всего три импульса независимы, например, k_1, k_2, k_3. Из них можно составить всего 6 инвариантов: $k_1^2 = m_1^2, \quad k_2^2 = m_2^2, k_3^2 = m_3^2, k_1k_2, k_1k_3, k_2k_3$. Лишь последние 3 из них являются переменными. Кроме того, так как $\left(k_1 + k_2 + k_3\right)^2 = k_4^2 = m_4^2$, то независимых переменных остаётся 2.

Удобно ввести три лоренц-инвариантных переменных Мандельстама:

$$\begin{aligned} s &= \left(k_1 + k_2\right)^2 = \left(k_3 + k_4\right)^2 \\ t &= \left(k_1 + k_3\right)^2 = \left(k_2 + k_4\right)^2 \\ u &= \left(k_1 + k_4\right)^2 = \left(k_2 + k_3\right)^2 \end{aligned} \tag{27}$$

Легко проверить, что

$$s+t+u=m_1^2+m_2^2+m_3^2+m_4^2 \tag{28}$$

Теперь рассмотрим самый простой случай $m_1=m_2=m_3=m_4=m$ и реакцию

$$1+2\longrightarrow 3+4 \tag{29}$$

для которой переменные мандельстама принимают значения в следующих областях:

$$s\geq 4m^2,\quad t\leq 0,\quad u\leq 0 \tag{30}$$

О реакции (29) говорят, что это - s-канальная реакция. Амплитуда реакции в t-канале

$$1+3\longrightarrow 2+4 \tag{31}$$

получается аналитическим продолжением амплитуды в s-канале в область переменных

$$t\geq 4m^2,\quad s\leq 0,\quad u\leq 0 \tag{32}$$

Это возможно, так как в теории S-матрицы амплитуды являются аналитическими функциями инвариантных переменных.

Введём обозначение

$$iM^{(2)}(s)=\frac{1}{2}\lambda_0^2\int\frac{\mathrm{d}^dq}{(2\pi)^d}D_c(q)D_c\left(k_1+k_2-q\right) \tag{33}$$

Тогда амплитуда в (15 ЛЗ) представляется симметричным образом:

$$iM^{(2)}=i\left[M^{(2)}(s)+M^{(2)}(t)+M^{(2)}(u)\right] \tag{34}$$

Укажем ещё один удобный способ параметризации петлевых интегралов, отличный от параметризации (14)-(15).

Очевидно имеем:

$$\frac{1}{AB}=\int\limits_0^1\frac{\mathrm{d}x}{[xA+(1-x)B]^2}=\int\limits_{x,y\geq 0}\frac{\mathrm{d}x\ \mathrm{d}y\delta(x+y-1)}{(xA+yB)^2} \tag{35}$$

Дифференцируя (35) по B, получаем

$$\frac{1}{AB^{n-1}}=\int\limits_{x,y\geq 0}\mathrm{d}x\ \mathrm{d}y\delta(x+y-1)\frac{(n-1)y^{n-2}}{[xA+yB]^n} \tag{36}$$

Задачи

1. Доказать по индукции, что

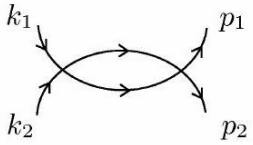
$$\frac{1}{A_1A_2...A_n}=\int\limits_{x_i\geq 0}\mathrm{d}x_1...\mathrm{d}x_n\delta\left(\sum_{i=1}^n x_i-1\right)\frac{(n-1)!}{(x_1A_1+...+x_nA_n)^n} \tag{37}$$

Переменные $\{x_i\}$ в этом интеграле называются фейнмановскими параметрами.

Указание. Использовать равенства (35) и (36).

Вергелес 4.2

Вычислить s-канальную однопетлевую диаграмму



при помощи параметризации Фейнмана. Указать, при каких значениях s эта диаграмма вещественна.

Ответ:

$$iM = \frac{i\lambda_0^2 \mu^{4-d} \Gamma(2-d/2)}{2(4\pi)^{d/2}} \int\limits_0^1 \mathrm{d}x \left[m^2 - x(1-x)s - i\varepsilon\right]^{d/2-2}$$

M вещественна при $s \leq 4m^2$.

16.8 L6 Renormalization Group

16.8.1 1. Wilsonian Approach to Renormalization Theory

Вильсоновский метод основан на описании теории поля с помощью функционального интеграла, в котором степени свободы квантового поля являются переменными интегрирования. При этом подходе происходит разделение переменных интегрирования на длинноволновые и коротковолновые. Предполагается, что длинноволновые флуктуации описывают реальные физические процессы, а учёт коротковолновых флуктуаций (то есть интегрирование по коротковолновым степеням свободы) даёт эффективное действие для описания длинноволновой физики.

Такая идеология возникла из понятия перенормируемости в квантовой теории поля. Мы видели, что суть перенормируемой квантовой теории в том, что в ней на процессы с энергией $\sim M$ степени свободы с энергией $\sim \Lambda \gg M$ влияют лишь косвенно: через перенормировку констант теории. В канонической квантовой теории поля импульс обрезания Λ является конечным лишь в промежуточных вычислениях и в конце вычислений он устремляется к бесконечности. Вильсоновский анализ основан на противоположной точке зрения, согласно которой любая квантовая теория на фундаментальном уровне определена с обрезанием Λ, которое имеет некоторое физическое значение. В приложениях к статистической механике этот масштаб импульсов равен обратному межатомному расстоянию. В КЭД и других фундаментальных квантовых теориях поля обрезание может быть связано с фундаментальной зернистостью пространства-времени, природа которой, по-видимому, может быть изучена лишь вместе с построением квантовой теории гравитации. Во всяком случае этот элементарный масштаб очень далёк от масштабов, экспериментально достижимых в настоящее время.

Продемонстрируем вильсоновский подход на примере теории ϕ^4 в евклидовом d-мерном пространстве, поскольку в пространстве Минковского ограниченное значение квадрата d-импульса не означает ограниченности его компонент, если d-импульс изотропен, что внесло бы дополнительные усложнения.

Разложим вещественное скалярное поле в интеграл Фурье:

$$\phi(x) = \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\phi(k)e^{ikx} \tag{1}$$

Равенство

$$\int \mathrm{d}^{(d)}x\phi_1(x)\phi_2(x) = \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\phi_1^*(k)\phi_2(k) \tag{2}$$

показывает, что преобразование Фурье является унитарным в пространстве полей с метрикой (2). Поэтому функциональные меры $\prod_x \mathrm{d}\phi(x)$ и $\prod_k \mathrm{d}\phi(k)$ можно считать равными. Это даёт возможность определения регуляризованной функциональной меры:

$$[D\phi]_\Lambda = \prod_{|k|<\Lambda} \mathrm{d}\phi(k) \tag{3}$$

Регуляризованная статистическая сумма скалярного поля (сравни с (34 Л1)) представляется интегралом

$$Z = \int [D\phi]_\Lambda \exp\left\{-\int \mathrm{d}^{(d)}x \left[\frac{1}{2}\left(\partial_\mu\phi\right)^2 + \frac{m^2}{2}\phi^2 + \frac{\lambda}{4!}\phi^4\right]\right\} \tag{4}$$

Здесь мы положили внешний источник равным нулю. В (4) m и λ являются голыми параметрами или параметрами на масштабе Λ.

Разделим в (4) переменные интегрирования на две группы. Пусть $0 < b < 1$ и

$$\hat{\phi}(k) = \begin{cases} \phi(k), & \text{для} \quad b\Lambda \le |k| < \Lambda \\ 0, & \text{для} \quad |k| < b\Lambda, \end{cases}$$

$$\phi(k) = \begin{cases} 0, & \text{для} \quad b\Lambda \le |k| < \Lambda \\ \phi(k), & \text{для} \quad |k| < b\Lambda \end{cases} \tag{5}$$

Тогда в (4) следует заменить $\phi(k)$ на $(\phi(k) + \hat{\phi}(k))$:

$$\begin{aligned} Z = \int [D\phi]_{b\Lambda} \int D\hat{\phi} \exp\left\{-\int \mathrm{d}^{(d)}x \left[\frac{1}{2}\left(\partial_\mu\phi + \partial_\mu\hat{\phi}\right)^2 + \frac{m^2}{2}(\phi+\hat{\phi})^2 + \frac{\lambda}{4!}(\phi+\hat{\phi})^4\right]\right\} = \\ = \int [D\phi]_{b\Lambda} e^{-\int \mathcal{L}(\phi)} \int D\hat{\phi} \exp\left\{-\int \mathrm{d}^{(d)}x \left[\frac{1}{2}\left(\partial_\mu\hat{\phi}\right)^2 + \frac{m^2}{2}(\hat{\phi})^2 + \right.\right. \\ \left.\left. + \lambda\left(\frac{1}{6}\phi^3\hat{\phi} + \frac{1}{4}\phi^2\hat{\phi}^2 + \frac{1}{6}\phi\hat{\phi}^3 + \frac{1}{4!}\hat{\phi}^4\right)\right]\right\} \end{aligned} \tag{6}$$

В (6) лагранжиан $\mathcal{L}(\phi)$ зависит лишь от поля ϕ и он имеет тот же вид, что и в (4). Квадратичные слагаемые вида $\phi\hat{\phi}$ исчезают в (6) вследствие равенства (2) и определения полей ϕ и $\hat{\phi}$ согласно (5).

Проинтегрируем (6) по полю $\hat{\phi}$:

$$Z = \int [D\phi]_{b\Lambda} \exp\left\{-\int \mathrm{d}^{(d)}x\mathcal{L}_{eff}(\phi)\right\} \tag{7}$$

Здесь $\mathcal{L}_{eff}(\phi)$ содержит только те фурье-компоненты $\phi(k)$, для которых $|k| < b\Lambda$. Если вычислять интеграл по $\hat{\phi}$ при помощи ТВ, разлагая по константе λ, то окажется, что $\mathcal{L}_{eff}(\phi)$ отличается от $\mathcal{L}(\phi)$ на поправки, пропорциональные степеням λ и ϕ и их производным. Эти поправочные члены компенсируют отсутствующие фурье-компоненты $\hat{\phi}$.

Поправки в $\mathcal{L}_{eff}$ могут быть представлены в диаграммной форме. Все слагаемые в (6), пропорциональные степеням λ, рассматриваются как возмущение. Поскольку предполагается, что $m^2 \ll \Lambda^2$, то слагаемое $(1/2)m^2\hat{\phi}^2$ также считается возмущением. Тогда слагаемое старшего порядка в последней экспоненте в (6) имеет вид

$$\int \hat{\mathcal{L}}_0 = \int\limits_{b\Lambda<|k|<\Lambda} \frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\hat{\phi}^*(k)k^2\hat{\phi}(k) \tag{8}$$

Это слагаемое приводит к пропагатору

$$\langle\hat{\phi}(k)\hat{\phi}(p)\rangle = \frac{\int D\hat{\phi}e^{-\int\hat{\mathcal{L}}_0}\hat{\phi}(k)\hat{\phi}(p)}{\int D\hat{\phi}e^{-\int\hat{\mathcal{L}}_0}} = \frac{1}{k^2}(2\pi)^d\delta^{(d)}(k+p)\theta(k)$$
$$\theta(k) = \begin{cases}1, & \text{если } b\Lambda < |k| < \Lambda\\ 0, & \text{если } |k| < b\Lambda\end{cases} \tag{9}$$

Оставшиеся в (6) $\hat{\phi}$-слагаемые рассматриваются как возмущения и их учёт осуществляется путём разложения и использования теоремы Вика (см. конец лекции 1). При этом правильная нормировка достигается, когда интеграл по полю $\hat{\phi}$ в (6) заменяется на

$$1 + \text{ поправки.} \tag{10}$$

Разложим сначала (6) относительно $\phi^2\hat{\phi}^2$ и учтём, что

$$\langle\hat{\phi}(x)\hat{\phi}(y)\rangle = \int\limits_{b\Lambda<|k|<\Lambda} \frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\frac{e^{ik(x-y)}}{k^2} \tag{11}$$

При помощи (11) легко находим эту поправку:

$$-\frac{\lambda}{4}\int \mathrm{d}^{(d)}x\phi^2\left\langle\hat{\phi}^2\right\rangle = -\frac{1}{2}\delta m^2\int \mathrm{d}^{(d)}x\phi^2 \tag{12}$$

$$\delta m^2 = \frac{\lambda}{2}\int\limits_{b\Lambda<|k|<\Lambda}\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\frac{1}{k^2} = \frac{\lambda\Lambda^{d-2}}{(4\pi)^{d/2}\Gamma(d/2)}\frac{1-b^{d-2}}{d-2} \tag{13}$$

Представим пропагатор (9) двойной линией. Поля ϕ представим как одинарные внешние линии.

Тогда вклад (12) изображается следующей диаграммой:

Рис. 10

Второй порядок относительно $\phi^2\hat{\phi}^2$ даёт вклад, соответствующий двум диаграммам:

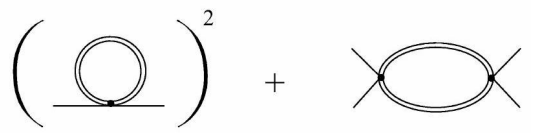


Рис. 11

Первое слагаемое на рис. 11 равно (1/2) (величина (12))^2, причём множитель (1/2) - комбинаторного происхождения. Если учесть все степени величины (12), возникающие во всех порядках, то окажется, что все эти слагаемые соберутся в экспоненту. Аналогичное утверждение справедливо в отношении любой связной диаграммы. Поэтому имеем следующий результат:

$$\mathcal{L}_{eff} = \frac{1}{2}\left(\partial_\mu\phi\right)^2 + \frac{m^2}{2}\phi^2 + \frac{\lambda}{4!}\phi^4 + (\text{ сумма связных диаграмм }). \tag{14}$$

Вычислим вторую диаграмму на рис. 11. При помощи теоремы Вика находим:

$$\frac{\lambda^2}{16}\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2\phi^2\left(x_1\right)\left[\int\limits_{b\Lambda<|k|<\Lambda}\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\frac{e^{ik(x_1-x_2)}}{k^2}\right]^2\phi^2\left(x_2\right) \tag{15}$$

Введём новые переменные

$$x_1 = x + \frac{y}{2}, \quad x_2 = x - \frac{y}{2} \tag{16}$$

в которых (15) принимает вид

$$\frac{\lambda^2}{16}\int \mathrm{d}^{(d)}x\ \mathrm{d}^{(d)}y\phi^2\left(x+\frac{y}{2}\right)\left[\int\limits_{b\Lambda<|k|<\Lambda}\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\frac{e^{iky}}{k^2}\right]^2\phi^2\left(x-\frac{y}{2}\right) \tag{17}$$

Рассмотрим предельный случай, когда импульсы, переносимые полем ϕ, исчезающе малы по сравнению с $(b\Lambda)$. Тогда (17) переходит в

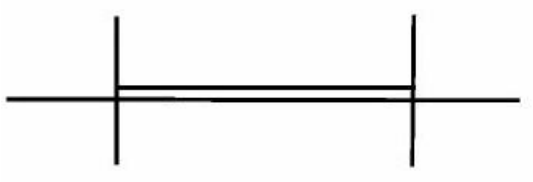
$$-\frac{\Delta\lambda}{4!}\int \mathrm{d}^{(d)}x\phi^4 \tag{18}$$

$$\Delta\lambda = -4!\frac{\lambda^2}{16}\int\limits_{b\Lambda<|k|<\Lambda}\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\frac{1}{\left(k^2\right)^2} = -\frac{3\lambda^2\Lambda^{d-4}\left(1-b^{d-4}\right)}{(4\pi)^{d/2}\Gamma(d/2)(d-4)} \quad \xrightarrow[d\to 4]{} -\frac{3\lambda^2}{16\pi^2}\ln\frac{1}{b} \tag{19}$$

Описанная диаграммная теория возмущений генерирует не только вклады в $\mathcal{L}_{eff}$, пропорциональные ϕ^2 и ϕ^4, но и вклады высших степеней ϕ, а также вклады от производных поля ϕ. Например, в (17) содержится слагаемое, пропорциональное

$$\int \mathrm{d}^{(d)}x\phi^2\left(\partial_\mu\phi\right)^2 \tag{20}$$

Вклад, пропорциональный $\left(\frac{\lambda}{\Lambda}\right)^2\int \mathrm{d}^{(d)}x\phi^6$, получается из диаграммы



Вообще говоря, вильсоновская процедура генерирует все возможные взаимодействия поля ϕ и их производных.

При помощи формулы (6) легко увидеть, что поправки с точностью $O(\lambda)$ дают

$$\mathcal{L}_{eff} = \frac{1}{2}\left(\partial_\mu\phi\right)^2 + \frac{(\tilde{m})^2}{2}\phi^2 + \frac{\tilde{\lambda}}{4!}\phi^4, \quad \tilde{m}^2 = m^2 + \Delta m^2, \quad \tilde{\lambda} = \lambda - \frac{3\lambda^2}{16\pi^2}\ln\frac{1}{b} \tag{21}$$

Здесь Δm^2 задаётся согласно (13). (Последнее равенство в (21) сравни с (24 Л4).)

Для более детального сравнения нового интеграла (7) с исходным интегралом (4) изменим в (7) масштаб расстояний и импульсов по следующему правилу:

$$x' = bx, \quad k' = \frac{k}{b}, \quad |k'| < \Lambda \tag{22}$$

Теперь импульсы в (7) изменяются в тех же пределах, что и в (4). Имеем (сравни с (29 Л5)):

$$\begin{gathered}\int \mathrm{d}^{(d)}x\mathcal{L}_{\text{eff}} = \\ = \int \mathrm{d}^{(d)}x\left[\frac{1}{2}(1+\Delta Z)\left(\partial_\mu\phi\right)^2 + \frac{1}{2}\left(m^2+\Delta m^2\right)\phi^2 + \frac{1}{4!}(\lambda+\Delta\lambda)\phi^4 + \Delta B\left(\partial_\mu\phi\right)^4 + \Delta C\phi^6 + \ldots\right] = \\ = \int \mathrm{d}^{(d)}x' b^{-d}\left[\frac{1}{2}(1+\Delta Z)b^2\left(\partial'_\mu\phi\right)^2 + \frac{1}{2}\left(m^2+\Delta m^2\right)\phi^2 + \frac{1}{4!}(\lambda+\Delta\lambda)\phi^4 + \right. \\ \left. + \Delta B b^4\left(\partial'_\mu\phi\right)^4 + \Delta C\phi^6 + \ldots\right]\end{gathered} \tag{23}$$

Чтобы в новом функциональном интеграле пропагатор сохранил прежний вид (9), изменим масштаб поля ϕ по правилу

$$\phi' = \left[b^{2-d}(1+\Delta Z)\right]^{1/2}\phi \tag{24}$$

после чего эффективное действие приобретает первоначальную форму

$$\int \mathrm{d}^{(d)}x\mathcal{L}_{eff} = \int \mathrm{d}^{(d)}x'\left[\frac{1}{2}\left(\partial'_\mu\phi'\right)^2 + \frac{1}{2}m'^2\phi'^2 + \frac{1}{4!}\lambda'\phi'^4 + B'\left(\partial'_\mu\phi'\right)^4 + C'\phi'^6 + \ldots\right] \tag{25}$$

с новыми параметрами

$$\begin{gathered}m'^2 = \left(m^2+\Delta m^2\right)(1+\Delta Z)^{-1}b^{-2} \\ \lambda' = (\lambda+\Delta\lambda)(1+\Delta Z)^{-2}b^{d-4} \\ B' = (B+\Delta B)(1+\Delta Z)^{-2}b^{d} \\ C' = (C+\Delta C)(1+\Delta Z)^{-3}b^{2d-6}\end{gathered} \tag{26}$$

и т.д. Заметим, что в исходном лагранжиане $B = C = 0$, но если бы эти константы отличались от нуля, то мы имели бы формулы (26).

Теперь повторим ещё и ещё раз описанную процедуру интегрирования по коротковолновым флуктуациям с последующими масштабными преобразованиями (22)-(26). Получаемые таким образом преобразования лагранжиана называются преобразованиями под действием ренормализаиионной группы (сокращённо - ренормгруппы). Это не есть группа в математическом смысле, поскольку при усреднении по коротковолновым флуктуациям теряется информация, эта процедура необратима.

Рассмотрим сначала с этой точки зрения простейший пример свободной теории, когда в затравочном лагранжиане $m^2 = \lambda = B = C = ... = 0$ и все возмущения исчезают. Тогда на всех этапах описанной рекурсионной процедуры Вильсона эффективный лагранжиан остаётся свободным. Поэтому говорят, что свободный лагранжиан

$$\mathcal{L}_0 = \frac{1}{2}\left(\partial_\mu \phi\right)^2 \tag{27}$$

является фиксированной точкой преобразований ренормгруппы.

Если мы находимся в непосредственной близости фиксированной точки, то можно отбросить в итерационных формулах $\Delta m^2, \Delta\lambda$, и т.д. Тогда при помощи (26) получаем:

$$m'^2 = m^2 b^{-2}, \quad \lambda' = \lambda b^{d-4}, \quad B' = B b^d, \quad C' = C b^{2d-6} \tag{28}$$

и т.д. Так как $b < 1$, то параметры, которые умножаются на отрицательные степени b, растут, и наоборот. Если лагранжиан содержит растущие коэффициенты, они уводят его от точки $\mathcal{L}_0$.

Отдельные слагаемые в квадратной скобке в (25) называются локальными операторами. Операторы, коэффициенты которых растут (вымирают) при рекурсионной процедуре, называются *cy* щественными (несущественными). Если коэффициент оператора умножается на b^0 (например, оператор ϕ^4 при $d = 4$), мы называем его маргиналъным. Для выяснения того, растёт ли или уменьшается его коэффициент, требуется вычисление высших поправок.

Из (26) и (28) видно, что массовый оператор ϕ^2 является существенным, а два последних слагаемых в (25) при $d = 4$ являются несущественными операторами. Этим и объясняется, что теория ϕ^4 является перенормируемой при $d = 4$, так как фактически и при вильсоновской процедуре перенормировок эта теория восстанавливает свой исходный вид. Это же утверждение справедливо в отношении любой перенормируемой теории.

Так как в порядке $O(\lambda) \quad \Delta Z = 0$, то при помощи (26) и (21) находим, что с точностью $O\left(\lambda^2\right)$ при $d = 4$

$$\lambda' = \lambda - \frac{3\lambda^2}{16\pi^2} \ln \frac{1}{b} \tag{29}$$

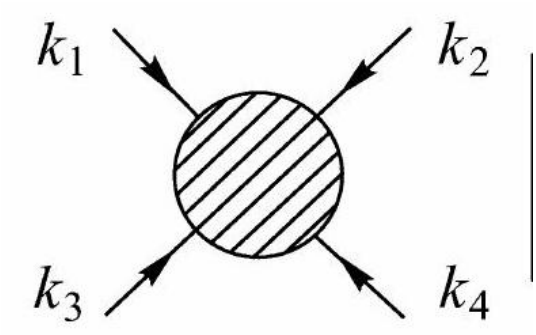
Отсюда видно, что коэффициент при маргинальном операторе ϕ^4 уменьшается, то есть константа связи уменьшается по логарифмическому закону. Соотношение (29) является аналогом соотношения (24 Л4), разница лишь в том, что в (29) и (24 Л4) представлены взаимно обратные функции. Из сказанного следует, что при $d = 4$ теория ϕ^4 в результате вильсоновской процедуры перенормировок стремится к свободной теории. Эта картина справедлива, конечно, лишь до тех пор, пока массовый оператор не становится преобладающим.

16.8.2 2. Callan–Symanzik Equation

На языке Вильсона перенормируемая квантовая теория поля с произвольно большим обрезанием отвечает эффективной теории, испытавшей большое число ренормгрупповых операций Вильсона и которая проэволюционировала до большой величины массового параметра. Такая траектория должна пройти произвольно близко от фиксированной точки. В результате этой эволюции несущественные операторы в первоначальном лагранжиане вымирают и остаются только существенные и маргинальные операторы. Коэффициенты при оставшихся операторах находятся во взаимно однозначном соответствии с наблюдаемыми параметрами, а информация об эволюции несущественных операторов утрачивается полностью в перенормируемой теории поля. Информацию же об эволюции параметров при существенных и маргинальных операторах можно восстановить, изучая их зависимость от нормировочного масштаба.

Для конкретности рассмотрим теорию ϕ^4 в четырёхмерном пространстве Минковского, изученную нами, и ограничимся случаем $m^2 = 0$. Поскольку физический размерностный оператор отсутствует, то для проведения программы перенормировок необходимо ввести размерностный параметр $\mu^2 > 0$. Поскольку условия перенормировки (30Ω5) приводят к сингулярностям при $m^2 \to 0$ (см. (32 Л5)), то наложим эти же условия перенормировки, но при пространственноподобных значениях импульсов $p^2 = -\mu^2$:

$$\Sigma\left(k^2\right)\big|_{k^2=0} = 0, \quad \frac{\mathrm{d}}{\mathrm{d}k^2}\Sigma\left(k^2\right)\Big|_{k^2=-\mu^2} = 0$$



амputированная

$$= -i\lambda \tag{30}$$

$(k_1 + k_2)^2 = (k_1 + k_3)^2 = (k_1 + k_4)^2 = -\mu^2$

Заметим, что в (30) импульсы k_a не предполагаются находящимися на массовой поверхности и потому условия (30) совместны. Таким образом, теория определена на масштабе μ^2.

Обозначим через $\phi_0(x)$ и $\phi(x)$ - затравочное и перенормированное поля, соответственно, и пусть $G_0^{(n)}(x_1, ..., x_n)$ - связная корреляционная функция (хронологическое среднее) неперенормированных полей, определяемая согласно (19 Л5), а

$$G^{(n)}(x_1, ..., x_n) = \langle 0 \,|T\phi(x_1) ...\phi(x_n)|\, 0\rangle \tag{31}$$

- связный коррелятор перенормированных полей (для удобства мы сменили обозначения, сделав замены $\phi \to \phi_0, \phi_r \to \phi$). Так как согласно (26 Л5) $\phi_0 = \sqrt{Z}\phi$, то

$$Z^{n/2}G^{(n)}\left(x_1,...,x_n;\mu,\lambda(\mu)\right)=G_0^{(n)}\left(x_1,...,x_n\right) \tag{32}$$

Обозначение $G^{(n)}\left(x_1,...,x_n;\mu,\lambda(\mu)\right)$ подчёркивает, что этот коррелятор зависит от точки нормировки μ и перенормированной константы связи $\lambda(\mu)$.

Теперь изменим точку нормировки $\mu\to\mu'$, константу связи λ и константу перенормировки Z, но оставим неизменными импульс обрезания Λ, а также затравочные константы. Это означает, что мы продвинулись вдоль траектории ренормгруппы. Ясно, что при этом "голые" (неперенормированные) гриновские функции (32) остаются неизменными, поскольку они зависят лишь от затравочных параметров и импульса обрезания Λ. Поэтому производная по параметру μ от обоих частей равенства (32) равна нулю:

$$\left[\mu\frac{\partial}{\partial\mu}+\beta(\lambda)\frac{\partial}{\partial\lambda}+n\gamma(\lambda)\right]G^{(n)}\left(\{x_i\};\mu,\lambda\right)=0 \tag{33}$$

Здесь

$$\beta(\lambda)\equiv\mu\frac{\partial\lambda}{\partial\mu},\quad \gamma(\lambda)\equiv\frac{1}{2Z}\mu\frac{\partial}{\partial\mu}Z \tag{34}$$

Функции $\beta(\lambda)$ и $\gamma(\lambda)$ - одни и те же для всех корреляторов в теории и они не могут зависеть от импульса обрезания, поскольку перенормированные корреляторы не зависят от обрезания. Следовательно, по размерным соображениям, они не могут зависеть и от μ. Поэтому функции (34) могут зависеть лишь от перенормированной константы связи λ.

Уравнение (33) называется уравнением Каллана-Симанчика.

Вычислим функцию β в наинизшем неисчезающем приближении при $d=4$. Так как $Z=1+O\left(\lambda^2\right)$, то с точностью $O\left(\lambda^2\right)$ перенормированный четырёхточечный коррелятор в импульсном представлении (см. рис. 7 и (20 Л4)) равен

$$G^{(4)}\left(k_1,...,k_4\right)=\left[-i\lambda-\frac{i\lambda^2}{32\pi^2}\left(\ln\frac{-s-i\varepsilon}{\mu^2}+\ln\frac{-t-i\varepsilon}{\mu^2}+\ln\frac{-u-i\varepsilon}{\mu^2}\right)\right]\prod_{i=1}^{4}\frac{i}{k_i^2} \tag{35}$$

Так как $\gamma=O\left(\lambda^2\right)$, то в порядке $O\left(\lambda^2\right)$ функция γ выпадает из уравнения Каллана-Симанчика. Поэтому, подставляя (35) в (33), получаем:

$$\beta(\lambda)=\frac{3\lambda^2}{16\pi^2}+O\left(\lambda^3\right) \tag{36}$$

16.8.3 3. Evolution of the Running Coupling Constant

Сопоставим уравнения (34) и (34):

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\ln\mu}=\beta(\lambda)=\frac{3\lambda^2}{16\pi^2} \tag{37}$$

Здесь первое равенство является точным по определению, а второе - приближённое. Проинтегрируем явно второе равенство в (37):

$$\lambda(\mu)=\frac{\lambda(m)}{1-\frac{3\lambda(m)}{16\pi^2}\ln\frac{\mu}{m}} \tag{38}$$

Будем считать, что m - некий масштаб порядка физической массы. Тогда следует считать, что $\mu \gg m$, так что на масштабах $\sim \mu$ теория фактически безмассовая и уравнения (34)-(37) справедливы. Тогда уравнение (38) показывает, что эффективная константа связи растёт при возрастании импульса согласно формуле (38). При этом $\lambda(m)$ - константа связи при импульсах, стремящихся к нулю.

Мы видим, что квантовая теория поля приводит к новому понятию: бегущей константе связи. При этом в теории ϕ^4 при $d = 4$ бегущая (эффективная) константа связи уменьшается, если нас интересуют всё меньшие и меньшие энергии взаимодействия (вплоть до масштаба физической массы частиц). Мы увидим, что константа взаимодействия в электродинамике (электрический заряд) также уменьшается при понижении энергии взаимодействия. Такие теории называются нульзарядными и в них β-функции положительны. Однако существуют такие теории (например, теория Янга-Миллса и построенная на её основе теория сильного взаимодействия - квантовая хромодинамика), в которых эффективная константа связи растёт при уменьшении энергии взаимодействующих частиц. Такие теории называются асимптотически свободными, β-функции в этих теориях отрицательны.

β-функция в уравнениях (33), (34) называется функиией Гелл-мана и Лоу.

Напоследок сделаем следующую оценку. Рассмотрим двухточечный коррелятор при высоких энергиях, когда можно пренебречь массой. Согласно сказанному выше имеем:

$$G(k) \sim \frac{Z\left(k^2\right)}{k^2} \tag{39}$$

Но при помощи (34) находим, что

$$Z\left(k^2\right) \sim \left(\frac{k^2}{m^2}\right)^{\gamma} \tag{40}$$

если $\gamma\left(k^2\right)$ изменяется медленно. Комбинируя (39) и (40), получаем:

$$G(k) \sim \frac{1}{\left(m^2\right)^{\gamma}\left(k^2\right)^{1-\gamma}}, \tag{41}$$

откуда

$$G(x) \sim \int \mathrm{d}^{(d)} k e^{ikx} G(k) \sim \frac{1}{|x|^{d-2+2\gamma}} \tag{42}$$

Таким образом, функции γ ответственны за появление аномальных размерностей полей.

Задачи

1. Показать, что при $d < 4$ в теории ϕ^4 имеется фиксированная точка ренормгруппы с ненулевой константой связи λ_0 и найти это значение константы связи в однопетлевом приближении.

Ответ:

$$\lambda_0 = \frac{(4-d)(4\pi)^{d/2}\Gamma(D/2)}{3}(\Lambda b)^{4-d}$$

2. Используя уравнение Каллана-Симанчика, вычислить в безмассовой теории ϕ^4 при $d = 4$ функцию $\gamma(\lambda)$ в наинизшем приближении.

3. Вычислить β-функцию в первом неисчезающем порядке в теории с лагранжианом (см. задачу 3 к лекции 3)

$$\mathcal{L} = \frac{1}{2}\sum_{i=1}^{n} \partial_\mu \phi^i \partial^\mu \phi^i - \frac{\lambda}{4}\left(\sum_{i=1}^{n} \left(\phi^i\right)^2\right)^2$$

16.9 L5 General Scheme of Renormalizations

16.9.1 1. Källén–Lehmann Spectral Representation of the Two-Point Function

(???? why is it here, what does it has to do with renormalization????)

Согласно (27 ЛЗ) фурье-образ вакуумного среднего $\langle 0|T\phi(x)\phi(0)|0\rangle$ для свободного квантованного поля ϕ имеет вид

$$\int \mathrm{d}x e^{ikx} \langle 0|T\phi(x)\phi(0)|0\rangle = \frac{i}{k^2 - m_0^2 + i\varepsilon} = -iD_c(k) \tag{1}$$

Теперь попробуем вычислить это же среднее во взаимодействующей теории. Мы будем опираться только на общие принципы теории относительности и квантовой механики; при этом вид взаимодействия, специфика ряда ТВ и другие детали не существенны. Предполагается лишь, что в теории имеются частицы с определённой массой (и, возможно, другими квантовыми числами), динамика которых лоренц-инвариантна и описывается согласно законам квантовой механики. Поэтому результаты, полученные в этой лекции, справедливы для очень широкого класса квантовых теорий поля.

Обозначим через $\mathcal{P}^\mu$ оператор d-импульса теории, так что $\mathcal{P}^0 = \mathcal{H}$ - гамильтониан теории, а $\mathcal{P}^i, \quad i = 1, ..., (d-1)$ - компоненты импульса. В свободной скалярной теории оператор $\mathcal{P}^\mu$ представляется согласно (32 Л2) и (42 Л2). Согласно самому определению d-импульса для любого локального поля $\phi(x)$ имеем:

$$\phi(x) = e^{i\mathcal{P}x}\phi(0)e^{-i\mathcal{P}x} \tag{2}$$

По определению основного состояния

$$\mathcal{P}^\mu|0\rangle = 0 \tag{3}$$

Согласно алгебре Пуанкаре (см. Ю. Швингер, "Частицы, источники, поля, Т.1) все компоненты d импульса взаимно коммутируют. Поэтому можно считать, что каждое состояние имеет определённое значение d-импульса. Обозначим через $|\lambda_{\mathbf{k}}\rangle$ какое либо из таких состояний, так что

$$\mathcal{H}\,|\lambda_{\mathbf{k}}\rangle = E_{\mathbf{k}}(\lambda)\,|\lambda_{\mathbf{k}}\rangle\,, \quad \mathcal{P}\,|\lambda_{\mathbf{k}}\rangle = \mathbf{k}\,|\lambda_{\mathbf{k}}\rangle \tag{4}$$

Вследствие Лоренц-инвариантности

$$E_{\mathbf{k}}(\lambda) = \sqrt{m_\lambda^2 + \mathbf{k}^2} > 0 \tag{5}$$

где m_λ - энергия состояния в той системе отсчёта, в которой суммарный пространственный импульс равен нулю. Неравенство в (5) означает, что энергия вакуума является наименьшей энергией в теории, которая согласно (3) равна нулю. Мы часто будем выделять из совокупности состояний $\{|\lambda_{\mathbf{k}}\rangle\}$ одночастичные состояния $\{|\mathbf{k}\rangle\}$. Тогда $|\lambda_{\mathbf{k}}\rangle$ обозначает многочастичное состояние. Состояние $|\mathbf{k}\rangle$ имеет импульс $\mathbf{k}$ и энергию $\omega_{\mathbf{k}} = \sqrt{m^2 + \mathbf{k}^2}$. Подчеркнём, что в случае одночастичного состояния импульс $\mathbf{k}$ полностью определяет энергию состояния, в то время как энергия неодночастичного состояния $|\lambda_{\mathbf{k}}\rangle$ не определяется параметром $\mathbf{k}$. Предположим, что все возбуждённые состояния принадлежат линейной оболочке одно-, двух- и т.д. частичных состояний, то есть состояния с определённым числом частиц образуют базис пространства состояний. Если в теории имеется всего один сорт частиц с массой m, то для n-частичного состояния

$$m_\lambda^2 \geq (nm)^2 \tag{6}$$

причём m_λ^2 - непрерывный параметр. Мы предполагаем также, что состояния $|\lambda_{\mathbf{k}}\rangle$ нормированы лоренц-инвариантным образом (см. (43 Л2), (45 Л2)), так что разложение единичного оператора имеет вид

$$\mathbf{1} = |0\rangle \left\langle 0 \right| + \sum_\lambda \int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}} \frac{1}{2E_{\mathbf{k}}(\lambda)} \left| \lambda_{\mathbf{k}} \right\rangle \langle \lambda_{\mathbf{k}}| \tag{7}$$

где суммирование идёт по всем многочастичным состояниям с нулевым суммарным импульсом $|\lambda_0\rangle$. Справедливость формулы (7) очевидна, если заметить, что в одночастичном секторе, согласно (38 Л2), (39 Л2)

$$\boldsymbol{I} = \int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}} \frac{1}{2\omega_{\mathbf{k}}} |\mathbf{k}\rangle\langle\mathbf{k}| \tag{8}$$

Будем считать, что $x^0 > y^0$ и вставим разложение единицы (7) между полями в среднее $\langle 0|\phi(x)\phi(y)|0\rangle$. Пренебрежём постоянной величиной $\langle 0|\phi(x)|0\rangle\langle 0|\phi(y)|0\rangle$, которая в большинстве случаев равна нулю. Таким образом получаем:

$$\langle 0|\phi(x)\phi(y)|0\rangle = \sum_\lambda \int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}} \frac{1}{2E_{\mathbf{k}}(\lambda)} \langle 0|\phi(x)|\lambda_{\mathbf{k}}\rangle \langle \lambda_{\mathbf{k}}|\phi(y)|0\rangle \tag{9}$$

Преобразуем матричные элементы в (9) при помощи формул (2)-(4):

$$\begin{aligned} \langle 0|\phi(x)|\lambda_{\mathbf{k}}\rangle = \left\langle 0 \left| e^{i\mathcal{P}x}\phi(0)e^{-i\mathcal{P}x} \right| \lambda_{\mathbf{k}} \right\rangle = \langle 0|\phi(0)|\lambda_{\mathbf{k}}\rangle\, e^{-ikx}\big|_{k^0=E_{\mathbf{k}}(\lambda)} = \\ = \langle 0|\phi(0)|\lambda_0\rangle\, e^{-ikx}\big|_{k^0=E_{\mathbf{k}}(\lambda)} \end{aligned} \tag{10}$$

Последнее равенство является следствием следующих соотношений:

$$|\lambda_{\mathbf{k}}\rangle = U\,|\lambda_0\rangle\,, \quad U^{-1}\phi(0)U = \phi(0), \quad \langle 0|U^{-1} = \langle 0|$$

где унитарный оператор U генерирует соответствующее преобразование Лоренца. Такие операторы называются бустами. Подставим (10) в (9):

$$\langle 0|\phi(x)\phi(y)|0\rangle = \sum_\lambda \int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}} \frac{1}{2E_{\mathbf{k}}(\lambda)} e^{-ik(x-y)}\, |\langle 0|\phi(0)|\lambda_0\rangle|^2 \Big|_{k^0=E_{\mathbf{k}}(\lambda)}$$

Так как $x_0 > y_0$, то можно воспользоваться формулой (23 Л1). Таким образом получаем:

$$\langle 0|\phi(x)\phi(y)|0\rangle = \sum_\lambda \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d} \frac{ie^{-ik(x-y)}}{k^2 - m_\lambda^2 + i\varepsilon} \left|\langle 0|\phi(0)|\lambda_0\rangle\right|^2$$

В случае $x^0 < y^0$ имеет место аналогичная формула. Обе формулы объединяются в следующем выражении:

$$\langle 0|T\phi(x)\phi(y)|0\rangle = \int\limits_0^\infty \frac{\mathrm{d}M^2}{2\pi} \rho\left(M^2\right) \left[-iD_c\left(x-y; M^2\right)\right]$$

$$D_c\left(x; M^2\right) = \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d} \frac{e^{-ikx}}{-k^2 + M^2 - i\varepsilon} \tag{11}$$

где $\rho\left(M^2\right)$ - положительная спектральная плотность

$$\rho\left(M^2\right) = \sum_\lambda (2\pi)\delta\left(M^2 - m_\lambda^2\right) \left|\langle 0|\phi(0)|\lambda_0\rangle\right|^2 \tag{12}$$

График спектральной плотности $\rho\left(M^2\right)$ для типичной теории поля показан на рис. 8.

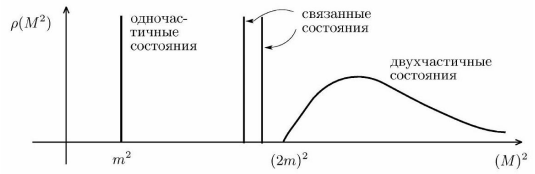


Рис. 8.

Одночастичные состояния вносят в спектральную плотность вклад в виде изолированных δ функций:

$$\rho\left(M^2\right) = 2\pi Z\delta\left(M^2 - m^2\right) + \left(\text{ ничего другого вплоть до } M^2 \gtrsim (2m)^2\right) \tag{13}$$

где

$$Z = \left|\langle 0|\phi(0)|\mathbf{k} = 0\rangle\right| \tag{14}$$

Константа Z называется константой перенормировки поля ϕ. Величина m есть физически наблюдаемая масса элементарных возбуждений поля ϕ, а m_0 в (53 Л2) является затравочной или "голой"массой, причём $m \neq m_0$. Непосредственно наблюдаемой является физическая масса m, а не затравочная масса.

С помощью (11) и (13) находим во взаимодействующей теории фурье-образ хронологического парного среднего, являющегося аналогом величины (1) в свободной теории:

$$\int \mathrm{d}x e^{ikx} \langle 0|T\phi(x)\phi(0)|0\rangle = \int\limits_0^\infty \frac{\mathrm{d}M^2}{2\pi} \rho\left(M^2\right) \frac{i}{k^2 - M^2 + i\varepsilon} =$$

$$= \frac{iZ}{k^2 - m^2 + i\varepsilon} + \int\limits_{\sim 4m^2}^\infty \frac{\mathrm{d}M^2}{2\pi} \rho\left(M^2\right) \frac{i}{k^2 - M^2 + i\varepsilon} \tag{15}$$

Аналитическая структура этой функции в комплексной k^2-плоскости показана на рис. 9.

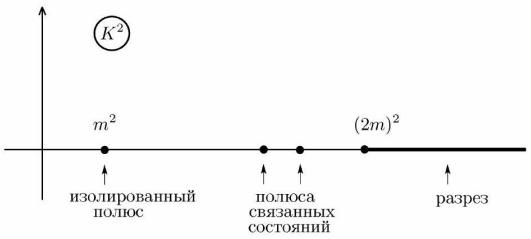

Рис. 9.

Первое слагаемое в (15) соответствует изолированному полюсу при $k^2 = m^2$, а второе - разрезу, начинающемуся в точке $4\,\mathrm{m}^2$. Если существуют двухчастичные связанные состояния, то в (15) возникают дополнительные полюса.

Сравнивая (1) и (15) мы видим, что взаимодействующее поле, в отличие от свободного, рождает из вакуума не только одночастичное, но и многочастичные состояния. Кроме того, в первом полюсном слагаемом содержится константа перенормировки поля (14), то есть вероятность того, что $\phi(0)$ родит данное одночастичное состояние из вакуума.

Проводя вычисления, аналогичные приведенным выше, легко получаем также:

$$\langle 0|[\phi(x),\phi(y)]|0\rangle = \int\limits_0^\infty \frac{\mathrm{d}M^2}{2\pi}\rho\left(M^2\right)\int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\frac{e^{-ik(x-y)}-e^{ik(x-y)}}{2k^0}\Bigg|_{k^0=\sqrt{M^2+\mathbf{k}^2}} =$$

$$= \int\limits_0^\infty \frac{\mathrm{d}M^2}{2\pi}\rho\left(M^2\right)\left[\frac{1}{i}D(x-y;M)\right] \tag{16}$$

Здесь $x^0 \neq y^0$ и введена перестановочная функция Паули-Йордана

$$D(x;M) \equiv i\int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\frac{e^{-ikx}-e^{ikx}}{2k^0}\Bigg|_{k^0=\sqrt{M^2+\mathbf{k}^2}} = i\int \frac{\mathrm{d}^{(d)}k}{(2\pi)^{d-1}}\theta\left(k^0\right)\delta\left(k^2-M^2\right)\left(e^{-ikx}-e^{ikx}\right)$$

которая удовлетворяет однородному уравнению Клейна-Гордона

$$\left(\partial_\mu\partial^\mu + M^2\right)D(x;M) = 0$$

а также соотношению

$$\frac{\partial}{\partial x^0}D(x;M)\Big|_{x^0=0} = \delta^{(3)}(\mathbf{x})$$

Поэтому из (16) находим, что

$$\langle 0|[\phi(x),\dot{\phi}(y)]|0\rangle\Big|_{x^0=y^0} = \int\limits_0^\infty \frac{\mathrm{d}M^2}{2\pi}\rho\left(M^2\right)\left[i\delta^{(3)}(\mathbf{x}-\mathbf{y})\right]$$

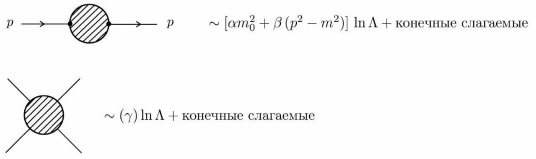
С другой стороны, левая часть этого равенства по определению равна $\left[i\delta^{(3)}(\mathbf{x}-\mathbf{y})\right]$, и потому

$$\int_0^\infty \frac{\mathrm{d}M^2}{2\pi}\rho\left(M^2\right) = 1 \longrightarrow 0 < Z < 1 \tag{17}$$

Последние неравенства получаются при учёте представления (13).

16.9.2 2. Renormalizations

Теперь опишем индуктивную процедуру, при помощи которой из расходящихся диаграмм выделяются различные физические величины, остающиеся конечными в пределе $\Lambda \to \infty$. Будем пользоваться размерностной регуляризацией, которая выделяет лишь логарифмические расходимости. Кроме того, вакуумные пузырьки, как ненаблюдаемые поправки, мы не рассматриваем. Таким образом, расходящимися являются лишь два типа диаграмм:



$\sim (\gamma)\ln\Lambda+$ конечные слагаемые

Здесь α, β, γ - безразмерные ряды по λ. Мы не предполагаем, что импульсы внешних концов диаграмм лежат на массовой поверхности. Очевидно, степень расходимости диаграмм не зависит от значений внешних импульсов.

Рассмотрим сначала n-точечную корреляционную функцию

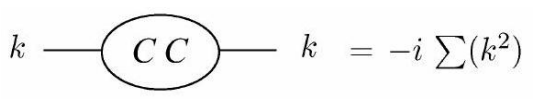
$$G\left(x_1, ..., x_n\right) = \left\langle 0 \left| T\phi\left(x_1\right) ...\phi\left(x_n\right) \right| 0 \right\rangle \tag{19}$$

Любая диаграмма, дающая вклад в коррелятор (19), содержит расходящиеся поддиаграммы указанных двух типов. Для устранения расходимостей действуют последовательно. этот процесс начинается с однопетлевых диаграмм. Так, согласно (8 Л4) в $\Sigma^{(1)}$ имеется расходящаяся часть. Она устраняется путём введения в затравочную массу соответствующей добавки:

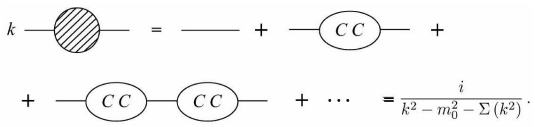
$$m_0^2 = m^2 + \delta_m, \quad \delta_m + \Sigma^{(1)} = 0 \tag{20}$$

Здесь m_0^2 - квадрат затравочной массы в однопетлевом приближении. Легче всего это установить следующим образом.

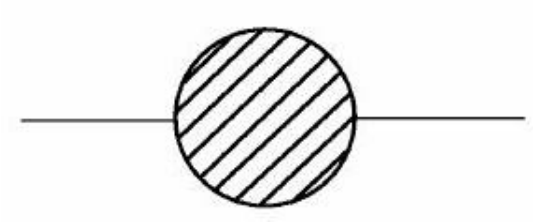
Назовём диаграмму сильно связной, если её нельзя разделить на две отдельные диаграммы путём разрезания всего лишь одной внутренней линии. Обозначим через



сумму всех сильно связных вставок в двухточечную корреляционную функцию (13) или сумму всех сильно связных диаграмм с двумя внешними линиями и ампутированными ногами. Тогда полная
функция (13) определяется геометрической прогрессией



В первом порядке по λ величина Σ задаётся согласно (6 Л4). Поэтому с учётом (20) в этом приближении



$$= \frac{i}{k^2 - m^2 + i\varepsilon} \tag{23}$$

и полюс корреляционной функции (13) находится при $k^2 = m^2$, то есть там, где и должен быть.

Устранение логарифмической расходимости в однопетлевом приближении из четырёхточечного коррелятора было проведено в предыдущей лекции (см. (24 Л4)).

Предположим, что во всех s-петлевых диаграммах при описанном способе действий устранены ультрафиолетовые расходимости. Покажем, что действуя так же, можно устранить расходимости в $(s+1)$-петлевых диаграммах. Действительно, по предположению в любой $(s+1)$-петлевой диаграмме все s-петлевые поддиаграммы уже конечны. Поэтому $(s+1)$-петлевые диаграммы с двумя и четырьмя внешними линиями расходятся лишь в той области интегрирования, где все $(s+1)$ промежуточных импульсов стремятся к бесконечности. Эти новые расходимости можно устранить и сделать диаграммы конечными путём соответствующего подбора величин $\delta_m^{(s+1)}(\lambda), \lambda_0^{(s+1)}(\lambda)$ и константы перенормировки поля $Z^{(s+1)}(\lambda)$, являющихся полиномами относительно физической константы связи λ. Очевидно, что $\delta_m^{(s+1)}(\lambda) \quad \left(\lambda_0^{(s+1)}(\lambda), Z^{(s+1)}(\lambda)\right)$ отличается от $\delta_m^{(s)}(\lambda)\left(\lambda_0^{(s)}(\lambda), Z^{(s)}(\lambda)\right)$ лишь более высокими степенями константы λ, чем степень полинома $\delta_m^{(s)}(\lambda)\left(\lambda_0^{(s)}(\lambda), Z^{(s)}(\lambda)\right)$. Действительно, диаграммы с четырьмя внешними концами расходятся лишь логарифмически и притом $(s+1)$-петлевые расходимости набегают в области, где все импульсы интегрирования стремятся к бесконечности. Поэтому расходящиеся части таких диаграмм являются числами, не зависящими от внешних импульсов и их можно поглотить за счёт подбора $\lambda_0^{(s+1)}(\lambda)$. Аналогично (см. первую диаграмму в (18)), для устранения $(s+1)$-петлевых расходимостей диаграмм с двумя внешними концами достаточно подобрать соответствующим образом константы $m_0^2(\lambda)$ и $Z(\lambda)$ в нужном порядке по физической константе связи, причём второе слагаемое в первой диаграмме в (18) вносит вклад в константу перенормировки поля. Оказывается, что n-точечный коррелятор полей (19) равен $Z^{n/2}\times$ (конечная часть) (см. ниже). Таким образом устраняются расходимости во всех $(s+1)$ петлевых диаграммах.

Замечание. Если бы оказалось, что в теории ϕ^4 имеются расходящиеся диаграммы, например, с шестью внешними линиями, то такие расходимости было бы невозможно устранить путём переопределения массы и константы связи. Для устранения таких

расходимостей потребовалось бы введение в теорию членов нового типа, пропорциональных ϕ^6. Это означало бы, что теория неперенормируема.

Можно показать, что имеет место соотношение

$$\prod_{i=1}^{n}\int \mathrm{d}^4x_i e^{ip_ix_2}\prod_{j=1}^{m}\int \mathrm{d}^4y_j e^{-ik_jy_j}\left\langle 0\left|\phi\left(x_1\right)...\phi\left(x_n\right)\phi\left(y_1\right)...\phi\left(y_m\right)\right|0\right\rangle \sim$$
$$\sim\left(\prod_{i=1}^{n}\frac{i\sqrt{Z}}{p_i^2-m^2+i\varepsilon}\right)\left(\prod_{j=1}^{m}\frac{i\sqrt{Z}}{k_j^2-m^2+i\varepsilon}\right)\langle \mathbf{p}_1...\mathbf{p}_n|S|\mathbf{k}_1...\mathbf{k}_m\rangle \tag{24}$$

Здесь в обоих частях равенства $k_j^0, p_i^0 \to \omega_k, \omega_p\left(\omega_k=\sqrt{m^2+\mathrm{k}^2}\right), Z$ - константа перенормировки поля. Знак $\sim$ в (24) означает, что обе части равенства ведут себя одинаково вблизи полюсов. Формула (24) называется редукиионной формулой Лемана-Симанчика-Циммермана.

Описанную процедуру перенормировки можно технически упростить и работать непосредственно с перенормированными физическими величинами. Начнём рассуждение с записи затравочного лагранжиана:

$$\mathcal{L}=\frac{1}{2}\left(\partial_\mu\phi\right)^2-\frac{1}{2}m_0^2\phi^2-\frac{\lambda_0}{4!}\phi^4 \tag{25}$$

Устраним множитель Z в значении вычета в полюсе хронологического парного среднего поля ϕ (см. (17)). Для этого введём перенормированное поле ϕ_r согласно равенству

$$\phi=\sqrt{Z}\phi_r \tag{26}$$

Корреляторы, построенные из полей ϕ_r, содержат столько дополнительных (по сравнению с аналогичными корреляторами полей ϕ) множителей $Z^{-1/2}$, сколько полей стоит под знаком коррелятора. Теперь лагранжиан (25) принимает вид

$$\mathcal{L}=\frac{1}{2}Z\left(\partial_\mu\phi_r\right)^2-\frac{1}{2}m_0^2Z\phi_r^2-\frac{\lambda_0}{4!}Z^2\phi_r^4 \tag{27}$$

Определим константы

$$\delta_Z=Z-1,\quad \delta_m=m_0^2Z-m^2,\quad \delta_\lambda=\lambda_0Z^2-\lambda \tag{28}$$

где m и λ - физические константы. При помощи введенных констант лагранжиан переписывается следующим образом:

$$\mathcal{L}=\left[\frac{1}{2}\left(\partial_\mu\phi_r\right)^2-\frac{1}{2}m^2\phi_r^2-\frac{\lambda}{4!}\phi_r^4\right]+\left[\frac{1}{2}\delta_Z\left(\partial_\mu\phi_r\right)^2-\frac{1}{2}\delta_m\phi_r^2-\frac{\delta_\lambda}{4!}\phi_r^4\right] \tag{29}$$

Первая квадратная скобка в правой части (29) теперь выглядит как стандартный лагранжиан в теории ϕ^4, но записанный через перенормированные величины и поля. Слагаемые во второй квадратной скобке называются контрчленами, они поглощают расходимости в ТВ. Всё что было сделано - это проведено разбиение затравочного действия (25) так, чтобы было удобно проводить дальнейшие вычисления. Мы имеем следующие условия перенормировки

$$= \int \mathrm{d}x e^{ikx} \langle 0 \,|T\phi_r(x)\phi_r(0)|\, 0\rangle = \frac{i}{k^2 - m^2 - \Sigma\left(k^2\right)} =$$

$$= \frac{i}{k^2 - m^2 + i\varepsilon} + \left(\text{ слагаемые, регулярные при } k^2 = m^2\right)$$

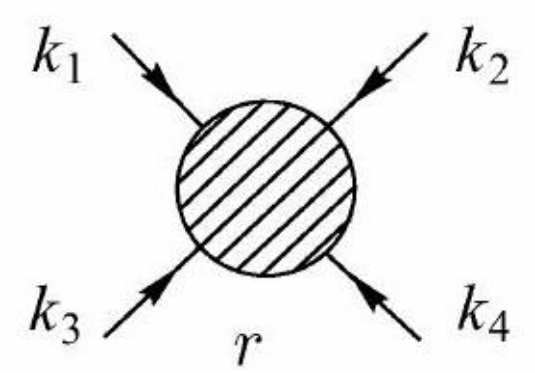
Последнее равенство означает, что

$$\Sigma\left(k^2\right)\big|_{k^2=m^2} = 0, \quad \frac{\mathrm{d}}{\mathrm{d}k^2}\Sigma\left(k^2\right)\bigg|_{k^2=m^2} = 0 \tag{30a}$$

Индекс r на диаграммах указывает на то, что эти величины - перенормированные. Однако этот факт далее как правило не отмечается, что не ведёт к недоразумениям. Условия (30a) означают, что на каждом следующем шаге индуктивной вычислительной процедуры следует сделать замену (провести вычитание)

$$\Sigma\left(k^2\right) \longrightarrow \Sigma\left(k^2\right) - \Sigma\left(m^2\right) - \left(k^2 - m^2\right)\left(\frac{\mathrm{d}}{\mathrm{d}k^2}\Sigma\left(k^2\right)\bigg|_{k^2=m^2}\right)$$

Имеет место также условие, фиксирующее константу связи:



$$\big|_{\text{амputированная}} = -\,i\lambda\big|_{\text{при } s=4m^2, t=u=0} \tag{30b}$$

Описываемая процедура перенормировки называется перенормировкой на xy.

Продемонстрируем эту процедуру перенормировки при вычислении $iM^{(2)}$. Согласно (20 Л4), (314) и (34 Л4) без учёта контрчленов в (29)

$$i\tilde{M}^{(2)}(s,t,u) = \text{ const } - i\frac{\lambda^2}{32\pi^2}\int\limits_0^1 \mathrm{d}x \left\{\ln\frac{m^2 - x(1-x)s - i\varepsilon}{\mu^2} + \ln\frac{m^2 - x(1-x)t - i\varepsilon}{\mu^2} + \right.$$
$$\left. + \ln\frac{m^2 - x(1-x)u - i\varepsilon}{\mu^2}\right\} \tag{31}$$

Здесь const - расходящаяся константа, не зависящая от переменных Мандельстама. Для выполнения условия нормировки (30 b) следует провести одно вычитание:

$$iM^{(2)}(s,t,u) = i\left[\tilde{M}^{(2)}(s,t,u) - \tilde{M}^{(2)}\left(4m^2,0,0\right)\right] =$$

$$= -i\frac{\lambda^2}{32\pi^2}\int\limits_0^1 \mathrm{d}x\left\{\ln\frac{m^2-x(1-x)s-i\varepsilon}{m^2[1-4x(1-x)-i\varepsilon]} + \ln\frac{m^2-x(1-x)t-i\varepsilon}{m^2} + \ln\frac{m^2-x(1-x)u-i\varepsilon}{m^2}\right\} \tag{32}$$

16.9.3 3. Unitarity Condition

Согласно (2 ЛЗ), S-матрица представляется как $S = 1 + iT$. Из условия унитарности $S^\dagger S = 1$ следуют важные соотношения для амплитуд. Имеем:

$$\left(T - T^\dagger\right) = iT^\dagger T \tag{33}$$

Пусть бра-вектор $\langle f|$ - конечное, а кет-вектор $|i\rangle$ - начальное состояние. Поместим равенство (33) в обкладки $\langle f|...|i\rangle$ и между операторами $T^\dagger$ и T в правой части (33) вставим единичный оператор в форме (7). Кроме того, перейдём к амплитуде M_{fi} согласно (4 ЛЗ). Таким образом получим:

$$M_{fi} - M^*_{if} = (2\pi)^4 i\sum_\lambda \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3 2E_{\mathbf{k}}(\lambda)}\delta^{(4)}\left(P_f - k\right) M^*_{\lambda_{\mathbf{k}}f} M_{\lambda_{\mathbf{k}}i} \tag{34}$$

Множитель $\delta^{(4)}\left(P_f - P_i\right)$ в обеих частях равенства (34) сокращается.

Равенство (34) полезно переписать также в виде

$$M_{fi} - M^*_{if} = (2\pi)^4 i\sum_n \sum_s \frac{1}{D}\prod_{\alpha=1}^n \left(\int \frac{\mathrm{d}^{(3)}k_\alpha}{(2\pi)^3 2\omega^{(\alpha)}_{k_\alpha}}\right)\delta^{(4)}\left(P_f - \sum_{\alpha=1}^n k_\alpha\right) M^*_{\lambda_{\mathbf{k}}f} M_{\lambda_{\mathbf{k}}i}$$

где n - число частиц в состоянии $|\lambda_{\mathbf{k}}\rangle, k_\alpha$ – 4-импульс, $\omega^{(\alpha)}_{k_\alpha} = k^0_\alpha$ - частота частицы с номером α, $\sum\limits_s$ - сумма по спинам промежуточных частиц и D - множитель, учитывающий тождественность частиц. Например, если промежуточное состояние содержит всего две тождественные частицы, то $D = 2$.

Рассмотрим важный частный случай, когда промежуточное состояние является одночастичным с массой M. Тогда суммирование $\sum\limits_\lambda$ в (34) ограничивается суммой по спинам промежуточной частицы $\sum\limits_s, E_{\mathbf{k}}(\lambda) = \sqrt{\mathbf{k}^2 + M^2}$ и

$$\frac{\mathrm{d}^3k}{2E_{\mathbf{k}}(\lambda)} = \theta\left(k^0\right)\delta\left(k_\mu k^\mu - M^2\right)\mathrm{d}^4k \tag{35}$$

Подставляя (35) в (34) и интегрируя по d^4k, находим:

$$M_{fi} - M^*_{if} = 2\pi i\delta\left(p^2 - M^2\right)\sum_s M^*_{(ps)f} M_{(ps)i} \tag{36}$$

где $|ps\rangle$ - состояние частицы с массой M, спином s и импульсом $p = P_i = P_f$.

Предположим, что теория T - и P-инвариантна. Тогда $M_{if} = M_{f'i'}$, где штрихованные состояния могут отличаться от соответствующих нештрихованных не более чем ориентацией

спина. Если начальное и конечное состояния усреднены по спину, то $M_{if} = M_{fi}$, и равенство (36) означает:

$$\operatorname{Im} M_{fi} = \pi\delta\left(p^2 - M^2\right) \sum_s M^*_{(ps)f} M_{(ps)i} \tag{37}$$

Отсюда следует, что при $p^2 \to M^2$

$$M_{fi} \to -\frac{\sum\limits_s M^*_{(ps)f} M_{(ps)i}}{p^2 - M^2 + i\varepsilon} \tag{38}$$

В этом случае говорят, что при переходе из состояния $|i\rangle$ в состояние $|f\rangle$ процесс идёт через промежуточную виртуальную частицу с массой M.

Задачи

1. Вычислить в безмассовой теории ϕ^4 при $d \to 4$ оператор собственной энергии $-i\Sigma\left(k^2\right)$ (21) в двухпетлевом приближении.

Указание. В безмассовом случае ($m^2 = 0$) вместо условий нормировки (30) при $k^2 = 0$, которые оказываются бессмысленными, используют следующие нормировочные условия:

$$\Sigma\left(k^2\right)\big|_{k^2=0} = 0 \quad \text{(отсутствие массы)} , \quad \frac{\mathrm{d}}{\mathrm{d}k^2}\Sigma\left(k^2\right)\bigg|_{k^2=-M^2} = 0$$

Применить параметризацию Фейнмана.

2. Вычислить при помощи условия унитарности мнимую часть амплитуды рассеяния $2 \to 2$ при $s > 4m^2$ в однопетлевом приближении.

17 Radiative Corrections: Some Formal Developments 1

We cheated four times in the last three chapters,* stating (and sometimes motivating) a result but postponing its proof. Those results were:

1. The formula for decay rates in terms of S-matrix elements, Eq. (4.86).
2. The master formula for S-matrix elements in terms of Feynman diagrams, Eq. (4.103).
3. The Ward identity, Eq. (5.79).
4. The *adhoc* subtraction to remove the ultraviolet divergence in the vertexcorrection diagram, Eq. (6.55).
   It is time now to return to these issues and give them a proper treatment. In Sections 7.2 through 7.4 we will derive all four of these results. The knowledge we gain along the way will help us interpret the three remaining loop corrections for electron scattering from a heavy target shown in (6.1): the external leg corrections and the vacuum polarization. We will evaluate the former in Section 7.1 and the latter in Section 7.5.

This chapter will be more abstract than the two preceding ones. Its main theme will be the singularities of Feynman diagrams viewed as analytic functions of their external momenta. We will find, however, that this apparently esoteric subject is rich in physical implications, and that it illuminates the relation between Feynman diagrams and the general principles of quantum theory.

17.1 7.1 Field-Strength Renormalization

In this section we will investigate the analytic structure of the two-point correlation function,

$$\langle\Omega|T\phi(x)\phi(y)|\Omega\rangle \quad \text{or} \quad \langle\Omega|T\psi(x)\bar{\psi}(y)|\Omega\rangle$$

In a free field theory, the two-point function $\langle 0|T\phi(x)\phi(y)|0\rangle$ has a simple interpretation: It is the amplitude for a particle to propagate from y to x. To what extent does this interpretation carry over into an interacting theory?

Our analysis of the two-point function will rely only on general principles of relativity and quantum mechanics; it will not depend on the nature of the interactions or on an expansion in perturbation theory. We will, however, restrict our consideration to scalar fields. Similar results can be obtained for correlation functions of fields with spin; we will display the analogous result for Dirac fields at the end of the analysis.

To dissect the two-point function $\langle\Omega|T\phi(x)\phi(y)|\Omega\rangle$ we will insert the identity operator, in the form of a sum over a complete set of states, between $\phi(x)$ and $\phi(y)$. We choose these states to be eigenstates of the full interacting Hamiltonian, H. Since the momentum operator $\mathbf{P}$ commutes with H, we can also choose the states to be eigenstates of $\mathbf{P}$. But we can also make a stronger use of Lorentz invariance. Let $|\lambda_0\rangle$ be an eigenstate of H with momentum zero: $\mathbf{P}\,|\lambda_0\rangle = 0$. Then all the boosts of $|\lambda_0\rangle$ are also eigenstates of H, and these have all possible 3 -momenta. Conversely, any eigenstate of H with definite momentum can be written as the boost of some zero-momentum eigenstate $|\lambda_0\rangle$. The eigenvalues of the 4 -momentum operator $P^\mu = (H, \mathbf{P})$ organize themselves into hyperboloids, as shown in Fig. 7.1.

Recall from Chapter 2 that the completeness relation for the one-particle states is

$$(\mathbf{1})_{1-\text{ particle}} = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}|\mathbf{p}\rangle\langle\mathbf{p}| \tag{7.1}$$

We can write an analogous completeness relation for the entire Hilbert space with the aid of a bit of notation. Let $|\lambda_{\mathbf{p}}\rangle$ be the boost of $|\lambda_0\rangle$ with momentum $\mathbf{p}$, and assume that the states $|\lambda_{\mathbf{p}}\rangle$, like the one-particle states $|\mathbf{p}\rangle$, are relativistically normalized. Let $E_{\mathbf{p}}(\lambda) \equiv \sqrt{|\mathbf{p}|^2 + m_\lambda^2}$, where m_λ is the "mass" of the states $|\lambda_{\mathbf{p}}\rangle$, that is, the energy of the state $|\lambda_0\rangle$. Then the desired completeness relation is

$$\mathbf{1} = |\Omega\rangle\langle\Omega| + \sum_\lambda \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}(\lambda)}\,|\lambda_{\mathbf{p}}\rangle\,\langle\lambda_{\mathbf{p}}| \tag{7.2}$$

where the sum runs over all zero-momentum states $|\lambda_0\rangle$.

We now insert this expansion between the operators in the two-point function. Assume for now that $x^0 > y^0$. Let us drop the uninteresting constant term $\langle\Omega|\phi(x)|\Omega\rangle\langle\Omega|\phi(y)|\Omega\rangle$. (This term is usually zero by symmetry; for higher-spin fields, it is zero by Lorentz invariance.) The two-point function is then

$$\langle\Omega|\phi(x)\phi(y)|\Omega\rangle = \sum_\lambda \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}(\lambda)}\langle\Omega|\phi(x)\,|\lambda_{\mathbf{p}}\rangle\,\langle\lambda_{\mathbf{p}}|\,\phi(y)|\Omega\rangle \tag{7.3}$$

[6] *A fifth cheat, postulating rather than deriving the photon propagator, will be remedied in Chapter 9.

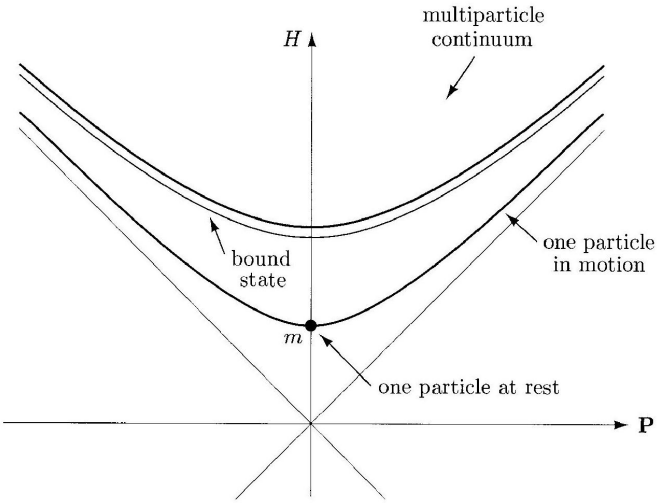


Figure 7.1. The eigenvalues of the 4 -momentum operator $P^\mu = (H, \mathbf{P})$ occupy a set of hyperboloids in energy-momentum space. For a typical theory the states consist of one or more particles of mass m. Thus there is a hyperboloid of one-particle states and a continuum of hyperboloids of two-particle states, three-particle states, and so on. There may also be one or more boundstate hyperboloids below the threshold for creation of two free particles.

We can manipulate the matrix elements as follows:

$$\begin{aligned} \langle\Omega|\phi(x)\,|\lambda_{\mathbf{p}}\rangle &= \langle\Omega|e^{iP\cdot x}\phi(0)e^{-iP\cdot x}\,|\lambda_{\mathbf{p}}\rangle \\ &= \langle\Omega|\phi(0)\,|\lambda_{\mathbf{p}}\rangle\, e^{-ip\cdot x}\big|_{p^0=E_{\mathbf{p}}} \\ &= \langle\Omega|\phi(0)\,|\lambda_0\rangle\, e^{-ip\cdot x}\big|_{p^0=E_{\mathbf{p}}} \end{aligned} \tag{7.4}$$

The last equality is a result of the Lorentz invariance of $\langle\Omega|$ and $\phi(0)$: Insert factors of $U^{-1}U$, where U is the unitary operator that implements a Lorentz boost from $\mathbf{p}$ to 0 , and use $U\phi(0)U^{-1} = \phi(0)$. (For a field with spin, we would need to keep track of its nontrivial Lorentz transformation.) Introducing an integration over p^0, our expression for the two-point function (still for $x^0 > y^0$) becomes

$$\langle\Omega|\phi(x)\phi(y)|\Omega\rangle = \sum_\lambda \int \frac{d^4p}{(2\pi)^4}\frac{i}{p^2 - m_\lambda^2 + i\epsilon}e^{-ip\cdot(x-y)}|\langle\Omega|\phi(0)|\lambda_0\Big\rangle|^2 \tag{7.5}$$

Note the appearance of the Feynman propagator, $D_F(x-y)$, but with m replaced by m_λ.

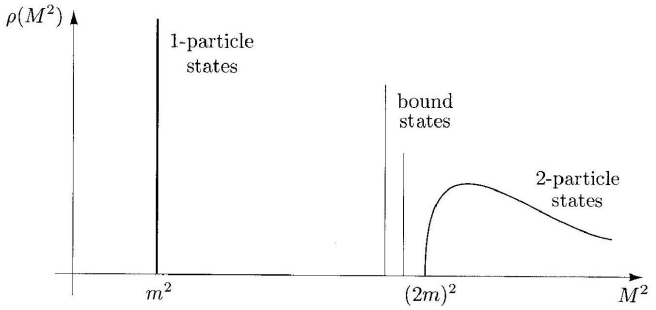

Figure 7.2. The spectral function $\rho\,(M^2)$ for a typical interacting field theory. The one-particle states contribute a delta function at m^2 (the square of the particle's mass). Multiparticle states have a continuous spectrum beginning at $(2m)^2$. There may also be bound states.

Analogous expressions hold for the case $y^0 > x^0$. Both cases can be summarized in the following general representation of the two-point function (the Klln-Lehmann spectral representation):

$$\langle \Omega | T\phi(x)\phi(y)|\Omega\rangle = \int_0^\infty \frac{dM^2}{2\pi}\rho\left(M^2\right) D_F\left(x-y; M^2\right) \tag{7.6}$$

where $\rho\left(M^2\right)$ is a positive spectral density function,

$$\rho\left(M^2\right) = \sum_\lambda (2\pi)\delta\left(M^2 - m_\lambda^2\right) |\langle \Omega|\phi(0)|\lambda_0\rangle|^2 \tag{7.7}$$

The spectral density $\rho\left(M^2\right)$ for a typical theory is plotted in Fig. 7.2. Note that the one-particle states contribute an isolated delta function to the spectral density:

$$\rho\left(M^2\right) = 2\pi\delta\left(M^2 - m^2\right)\cdot Z + \left(\text{ nothing else until } M^2 \gtrsim (2m)^2\right) \tag{7.8}$$

where Z is some number given by the squared matrix element in (7.7). We refer to Z as the field-strength renormalization. The quantity m is the exact mass of a single particle - the exact energy eigenvalue at rest. This quantity will in general differ from the value of the mass parameter that appears in the Lagrangian. We will refer to the parameter in the Lagrangian as m_0, the bare mass, and refer to m as the physical mass of the ϕ boson. Only the physical mass m is directly observable.

The spectral decomposition (7.6) yields the following form for the Fourier

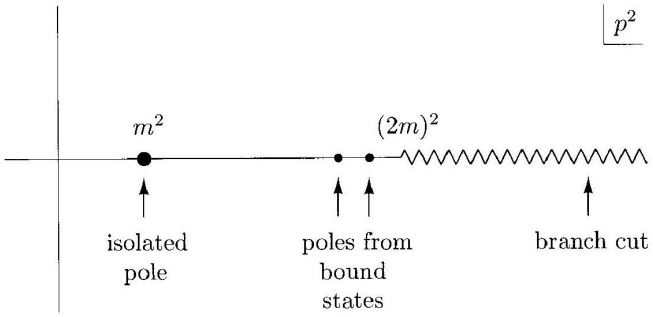

Figure 7.3. Analytic structure in the complex p^2-plane of the Fourier transform of the two-point function for a typical theory. The one-particle states contribute an isolated pole at the square of the particle mass. States of two or more free particles give a branch cut, while bound states give additional poles.

transform of the two-point function:

$$\int d^4x e^{ip\cdot x}\langle \Omega|T\phi(x)\phi(0)|\Omega\rangle = \int_0^\infty \frac{dM^2}{2\pi}\rho\left(M^2\right)\frac{i}{p^2 - M^2 + i\epsilon} \tag{7.9}$$
$$= \frac{iZ}{p^2 - m^2 + i\epsilon} + \int_{\sim 4m^2}^\infty \frac{dM^2}{2\pi}\rho\left(M^2\right)\frac{i}{p^2 - M^2 + i\epsilon}$$

The analytic structure of this function in the complex p^2-plane is shown in Fig. 7.3. The first term gives an isolated simple pole at $p^2 = m^2$, while the second term contributes a branch cut beginning at $p^2 = (2m)^2$. If there are any two-particle bound states, these will appear as additional delta functions in $\rho\left(M^2\right)$ and thus as additional poles below the cut.

In Section 2.4, we found an explicit result for the two-point correlation function in the theory of a free scalar field:

$$\int d^4x e^{ip\cdot x}\langle 0|T\phi(x)\phi(0)|0\rangle = \frac{i}{p^2 - m^2 + i\epsilon} \tag{7.10}$$

We interpreted this formula, for $x^0 > 0$, as the amplitude for a particle to propagate from 0 to x. Equation (7.9) shows that the two-point function takes a similar form in the most general theory of an interacting scalar field. The general expression is essentially a sum of scalar propagation amplitudes for states created from the vacuum by the field operator $\phi(0)$. There are two differences between (7.9) and (7.10). First, Eq. (7.9) contains the fieldstrength renormalization factor $Z = |\langle\lambda_0|\,\phi(0)|\,\Omega\rangle\,|^2$, the probability for $\phi(0)$ to create a given state from the vacuum. In (7.10), this factor is included implicitly, since $\langle p|\phi(0)|0\rangle = 1$ in free field theory. Second, Eq. (7.9) contains
contributions from multiparticle intermediate states with a continuous mass spectrum. In free field theory, $\phi(0)$ can create only a single particle from the vacuum. With these two differences, (7.9) is a direct generalization of (7.10).

It will be important in our later analysis that the contributions to (7.9) from one-particle and multiparticle intermediate states can be distinguished by the strength of their analytic singularities. The poles in p^2 come only from one-particle intermediate states, while multiparticle intermediate states give weaker branch cut singularities. We will see in the next section that this rather formal observation generalizes to higher-point correlation functions and plays a crucial role in our derivation of the diagrammatic formula for S-matrix elements.

The analysis of this section generalizes directly to two-point functions of higher-spin fields. The main complication comes in the generalization of the manipulation (7.4), since now the field has a nontrivial transformation law under boosts. In general, several invariant spectral functions are required to represent the multiparticle states. But this complication does not affect the major result that a pole in p^2 can arise only from the contribution of a singleparticle state created by the field operator. The two-point function of Dirac fields, for example, has the structure

$$\begin{aligned}\int d^4x e^{ip\cdot x}\langle\Omega|T\psi(x)\bar\psi(0)|\Omega\rangle &= \frac{iZ_2\sum_s u^s(p)\bar u^s(p)}{p^2 - m^2 + i\epsilon} + \cdots \\ &= \frac{iZ_2(\not p + m)}{p^2 - m^2 + i\epsilon} + \cdots\end{aligned} \tag{7.11}$$

where the omitted terms give the multiparticle branch cut. As in the scalar case, the constant Z_2 is the probability for the quantum field to create or annihilate an exact one-particle eigenstate of H:

$$\langle\Omega|\psi(0)|p,s\rangle = \sqrt{Z_2}u^s(p) \tag{7.12}$$

(For an antiparticle, replace u with $\bar v$.) At the pole, the Dirac two-point function is exactly that of a free field with the physical mass, aside from the rescaling factor Z_2.

An Example: The Electron Self-Energy

This nonperturbative analysis of the two-point correlation function has been very different from our usual direct analysis of Feynman diagrams. But since this derivation was done in complete generality, the singularity structure of the two-point function that it implies ought also to be visible in a Feynman diagram computation. In the rest of this section we will explicitly check our results for the electron two-point function in QED.

The electron two-point function is equal to the sum of diagrams

$$\langle\Omega|T\psi(x)\bar{\psi}(y)|\Omega\rangle = \bar{x} + \frac{r\sim}{x} + \cdots \tag{7.13}$$

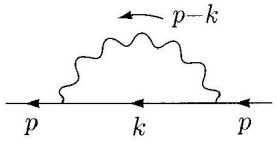
Each of these diagrams, according to the Feynman rules for correlation functions, contains a factor of $e^{ip\cdot(x-y)}$ for the two external points and an integration $\int (d^4p/(2\pi)^4)$ over the momentum p carried by the initial and final propagators. We will consistently omit these factors in this section; in other words, each diagram will denote the corresponding term in the Fourier transform of the two-point function.

The first diagram is just the free-field propagator:

$$\bar{p} = \frac{i\,(\not{p} + m_0)}{p^2 - m_0^2 + i\epsilon} \tag{7.14}$$

Throughout this calculation, we will write m_0 instead of m as the mass in the electron propagator. This makes explicit the fact noted above that the mass appearing in the Lagrangian differs, in general, from the observable rest energy of a particle. However, if a perturbation expansion is applicable, the leadingorder expression for the propagator should approximate the exact expression. Indeed, the function (7.14) has a pole, of just the form of (7.11), at $p^2 = m_0^2$. We therefore expect that the complete expression for the two-point function also has a pole of this form, at a slightly shifted location $m^2 = m_0^2 + \mathcal{O}(\alpha)$.

The second diagram in (7.13), called the electron self-energy, is somewhat more complicated:



$$= \frac{i(\not{p} + m_0)}{p^2 - m_0^2}\left[-i\Sigma_2(p)\right]\frac{i(\not{p} + m_0)}{p^2 - m_0^2},$$

where

$$-i\Sigma_2(p) = (-ie)^2 \int \frac{d^4k}{(2\pi)^4}\gamma^\mu \frac{i\,(\not{k} + m_0)}{k^2 - m_0^2 + i\epsilon}\gamma_\mu \frac{-i}{(p-k)^2 - \mu^2 + i\epsilon}. \tag{7.16}$$

(The notation Σ_2 indicates that this is the second-order (in e) contribution to a quantity Σ that we will define below.) The integral Σ_2 has an infrared divergence, which we have regularized by adding a small photon mass μ. Outside this integral, the diagram seems to have a double pole at $p^2 = m_0^2$. All in all, the form of this correction is quite unpleasant. But let us press on and try to evaluate $\Sigma_2(p)$ using the calculational techniques developed for the vertex correction in the Section 6.3.

First introduce a Feynman parameter to combine the two denominators:

$$\frac{1}{k^2 - m_0^2 + i\epsilon}\frac{1}{(p-k)^2 - \mu^2 + i\epsilon} = \int_0^1 dx \frac{1}{\left[k^2 - 2xk\cdot p + xp^2 - x\mu^2 - (1-x)m_0^2 + i\epsilon\right]^2}$$

Now complete the square and define a shifted momentum $\ell \equiv k - xp$. Dropping the term linear in ℓ from the numerator, we have

$$-i\Sigma_2(p) = -e^2 \int_0^1 dx \int \frac{d^4\ell}{(2\pi)^4}\frac{-2x\ \not{p} + 4m_0}{\left[\ell^2 - \Delta + i\epsilon\right]^2} \tag{7.17}$$

where $\Delta = -x(1-x)p^2 + x\mu^2 + (1-x)m_0^2$. The integral over ℓ is divergent. To evaluate it, we first regulate it using the Pauli-Villars procedure (6.51):

$$\frac{1}{(p-k)^2-\mu^2+i\epsilon} \to \frac{1}{(p-k)^2-\mu^2+i\epsilon} - \frac{1}{(p-k)^2-\Lambda^2+i\epsilon}$$

The second term will have the same form as (7.17), but with μ replaced by Λ. As in Section 6.3, we now Wick-rotate and substitute the Euclidean variable $\ell_E^0 = -i\ell^0$. This gives

$$\begin{aligned}\int \frac{d^4\ell}{(2\pi)^4}\frac{1}{\left[\ell^2-\Delta\right]^2} &\to \frac{i}{(4\pi)^2}\int_0^\infty d\ell_E^2 \left(\frac{\ell_E^2}{\left[\ell_E^2+\Delta\right]^2} - \frac{\ell_E^2}{\left[\ell_E^2+\Delta_\Lambda\right]^2}\right) \\ &= \frac{i}{(4\pi)^2}\log\left(\frac{\Delta_\Lambda}{\Delta}\right) \end{aligned} \tag{7.18}$$

where

$$\Delta_\Lambda = -x(1-x)p^2 + x\Lambda^2 + (1-x)m_0^2 \underset{\Lambda\to\infty}{\longrightarrow} x\Lambda^2$$

The final result is therefore

$$\Sigma_2(p) = \frac{\alpha}{2\pi}\int_0^1 dx\,(2m_0 - x\not{p})\log\left(\frac{x\Lambda^2}{(1-x)m_0^2 + x\mu^2 - x(1-x)p^2}\right) \tag{7.19}$$

Before discussing the divergences in this expression, let us work out its analytic behavior as a function of p^2. The logarithm in (7.19) has a branch cut when its argument becomes negative, and for any fixed x this will occur for sufficiently large p^2. More exactly, the cut begins at the point where

$$(1-x)m_0^2 + x\mu^2 - x(1-x)p^2 = 0$$

Solving this equation for x, we find

$$\begin{aligned} x &= \frac{1}{2} + \frac{m_0^2}{2p^2} - \frac{\mu^2}{2p^2} \pm \sqrt{\frac{\left(p^2+m_0^2-\mu^2\right)^2}{4p^4} - \frac{m_0^2}{p^2}} \\ &= \frac{1}{2} + \frac{m_0^2}{2p^2} - \frac{\mu^2}{2p^2} \pm \frac{1}{2p^2}\sqrt{\left[p^2-(m_0+\mu)^2\right]\left[p^2-(m_0-\mu)^2\right]} \end{aligned} \tag{7.20}$$

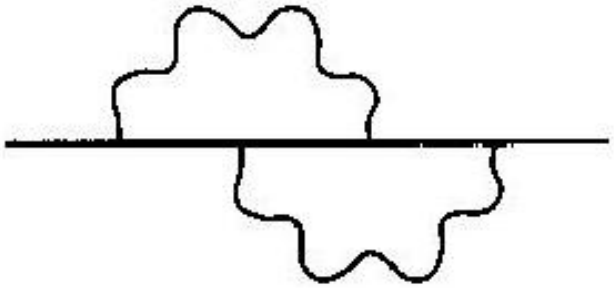
The branch cut of $\Sigma_2\left(p^2\right)$ begins at the minimum value of p^2 such that this equation has a real solution for x between 0 and 1 . This occurs when $p^2 = (m_0+\mu)^2$, that is, at the threshold for creation of a two-particle (electron
plus photon) state. In fact, it is a simple exercise in relativistic kinematics to show that the square root in (7.20), written in the form

$$k = \frac{1}{2\sqrt{p^2}}\sqrt{\left[p^2-(m_0+\mu)^2\right]\left[p^2-(m_0-\mu)^2\right]}$$

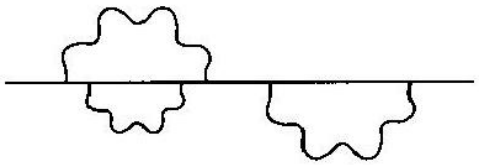
is precisely the momentum in the center-of-mass frame for two particles of mass m_0 and μ and total energy $\sqrt{p^2}$. It is natural that this momentum becomes real at the two-particle threshold. The location of the branch cut is exactly where we would expect from the Klln-Lehmann spectral representation. †

We have now located the two-particle branch cut predicted by the KllnLehmann representation, but we have not found the expected simple pole at $p^2 = m^2$. To find it we must actually include an infinite series of Feynman diagrams. Fortunately, this series will be easily summed.

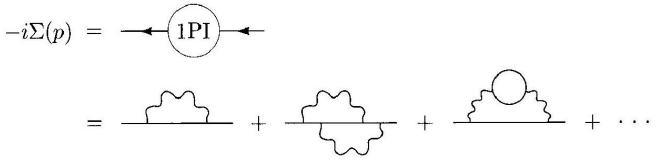
Let us define a one-particle irreducible (1PI) diagram to be any diagram that cannot be split in two by removing a single line:



is 1 PI , while



Let $-i\Sigma(p)$ denote the sum of all 1PI diagrams with two external fermion lines:



(Although each diagram has two external lines, the Feynman propagators for these lines are not to be included in the expression for $\Sigma(p)$.) To leading order in α we see that $\Sigma = \Sigma_2$.

The Fourier transform of the two-point function can now be written as

$$\begin{aligned}
&\int d^4x \langle \Omega | T\psi(x)\bar{\psi}(0)|\Omega\rangle e^{ip\cdot x} = \\
&= \frac{\text{1PI}}{\leftarrow} + \cdots + \text{1PI} - \text{1PI} + \cdots \\
&= \frac{i\,(\not{p} + m_0)}{p^2 - m_0^2} + \frac{i\,(\not{p} + m_0)}{p^2 - m_0^2}(-i\Sigma)\frac{i\,(\not{p} + m_0)}{p^2 - m_0^2} + \cdots
\end{aligned} \tag{7.22}$$

The first diagram has a simple pole at $p^2 = m_0^2$. Each diagram in the second class has a double pole at $p^2 = m_0^2$. Each diagram in the third class has a triple pole. The behavior near $p^2 = m_0^2$ gets worse and worse as we include more and more diagrams. But fortunately, the sum of all the diagrams forms a geometric series. Note that $\Sigma(p)$ commutes with $\not{p}$, since $\Sigma(p)$ is a function only of pure numbers and $\not{p}$. In fact, we can consider $\Sigma(p)$ to be a function of $\not{p}$, writing $p^2 = (\not{p})^2$. Then we can rewrite each electron propagator as $i/(\not{p} - m_0)$ and express the above series as

[6†] In real QED, $\mu = 0$ and the two-particle branch cut merges with the one-particle pole. This subtlety plays a role in the full treatment of the cancellation of infrared divergences, but it is beyond the scope of our present analysis.

$$\int d^4x \langle \Omega | T\psi(x)\bar{\psi}(0)|\Omega\rangle e^{ip\cdot x}$$
$$= \frac{i}{\not p - m_0} + \frac{i}{\not p - m_0}\left(\frac{\Sigma(\not p)}{\not p - m_0}\right) + \frac{i}{\not p - m_0}\left(\frac{\Sigma(\not p)}{\not p - m_0}\right)^2 + \cdots$$
$$= \frac{i}{\not p - m_0 - \Sigma(\not p)}. \tag{7.23}$$

The full propagator has a simple pole, which is shifted away from m_0 by $\Sigma(\not p)$. The location of this pole, the physical mass m, is the solution of the equation

$$[\not p - m_0 - \Sigma(\not p)]\big|_{\not p = m} = 0 \tag{7.24}$$

Notice that, if $\Sigma(pp)$ is defined by the convention (7.21), then a positive contribution to Σ yields a positive shift of the electron mass. Close to the pole, the denominator of (7.23) has the form

$$(\not p - m)\cdot\left(1 - \frac{d\Sigma}{d\not p}\bigg|_{\not p = m}\right) + \mathcal{O}\left((\not p - m)^2\right). \tag{7.25}$$

Thus the full electron propagator has a single-particle pole of just the form (7.11), with m given by (7.24) and

$$Z_2^{-1} = 1 - \frac{d\Sigma}{d\not p}\bigg|_{\not p = m} \tag{7.26}$$

Our explicit calculation of Σ_2 allows us to compute the first corrections to m and Z_2. Let us begin with m. To order α, the mass shift is

$$\delta m = m - m_0 = \Sigma_2(\not p = m) \approx \Sigma_2(\not p = m_0) \tag{7.27}$$

Thus, using (7.19),

$$\delta m = \frac{\alpha}{2\pi} m_0 \int_0^1 dx (2-x) \log\left(\frac{x\Lambda^2}{(1-x)^2 m_0^2 + x\mu^2}\right) \tag{7.28}$$

The mass shift is ultraviolet divergent; the divergent term has the form

$$\delta m \underset{\Lambda\to\infty}{\longrightarrow} \frac{3\alpha}{4\pi} m_0 \log\left(\frac{\Lambda^2}{m_0^2}\right) \tag{7.29}$$

Is it a problem that m differs from m_0 by a divergent quantity? This question has two levels, those of concept and practice.

On the conceptual level, we should fully expect the mass of the electron to be modified by its coupling to the electromagnetic field. In classical electrodynamics, the rest energy of any charge is increased by the energy of its electrostatic field, and this energy shift diverges in the case of a point charge:

$$\int d^3r \frac{1}{2}|\mathbf{E}|^2 = \int d^3r \frac{1}{2}\left(\frac{e}{4\pi r^2}\right)^2 = \frac{\alpha}{2}\int \frac{dr}{r^2} \sim \alpha\Lambda \tag{7.30}$$

In fact, it is puzzling why the divergence in (7.29) is so weak, logarithmic in Λ rather than linear as in (7.30). To understand this feature, suppose that m_0 were set to 0 . Then the two helicity components of the electron field ψ_L and ψ_R would not be coupled by any term in the QED Hamiltonian. This would imply that perturbative corrections could never induce a coupling of ψ_L and ψ_R, nor, in particular, an electron mass term. In other words, δm must vanish when $m_0 = 0$. The mass shift must therefore be proportional to m_0, and so, by dimensional analysis, it can depend only logarithmically on Λ.

On a practical level, the infinite mass shift casts doubt on our perturbative calculations. For example, all of the theoretical results in Chapter 5 should technically involve m_0 rather than m. To compare theory to experiment we must eliminate m_0 in favor of m, using the relation $m_0 = m + \mathcal{O}(\alpha)$. Since the "small" $\mathcal{O}(\alpha)$ correction is infinite, the validity of this procedure is far from obvious. The validity of perturbation theory would be more plausible if we could compute Feynman diagrams using the propagator $i/(pp - m)$, which has the correct pole location, instead of $i/(\not{p} - m_0)$. In Chapter 10 we will see how to rearrange the perturbation series in such a way that m_0 is systematically eliminated in favor of m and the zeroth-order propagator has its pole at the physical mass. In the remainder of this chapter, we will continue to simply replace m_0 by m in expressions for order- α corrections.

Finally, let us examine the perturbative correction to Z_2. From (7.26), we find that the order-α correction $\delta Z_2 = (Z_2 - 1)$ is

$$\begin{aligned}\delta Z_2 &= \left.\frac{d\Sigma_2}{d\ \not{p}p}\right|_{\not{p}=m} \\ &= \frac{\alpha}{2\pi}\int_0^1 dx\left[-x\log\frac{x\Lambda^2}{(1-x)^2m^2+x\mu^2} + 2(2-x)\frac{x(1-x)m^2}{(1-x)^2m^2+x\mu^2}\right] \end{aligned} \tag{7.31}$$

This expression is also logarithmically ultraviolet divergent. We will discuss the observability of this divergent term at the end of Section 7.2. However, it is interesting to note, even before that discussion, that (7.31) is very similar in form to the value of the ad hoc subtraction that we made in our calculation of the electron vertex correction in Section 6.3. From Eq. (6.56), the value of this subtraction was

$$\begin{aligned}\delta F_1(0) =& \frac{\alpha}{2\pi}\int_0^1 dxdydz\delta(x+y+z-1) \\ &\times\left[\log\left(\frac{z\Lambda^2}{(1-z)^2m^2+z\mu^2}\right) + \frac{(1-4z+z^2)\,m^2}{(1-z)^2m^2+z\mu^2}\right] \\ =& \frac{\alpha}{2\pi}\int_0^1 dz(1-z)\left[\log\left(\frac{z\Lambda^2}{(1-z)^2m^2+z\mu^2}\right) + \frac{(1-4z+z^2)\,m^2}{(1-z)^2m^2+z\mu^2}\right] \end{aligned} \tag{7.32}$$

Using the integration by parts

$$\begin{aligned}\int_0^1 dz(1-2z)\log\left(\frac{\Lambda^2}{(1-z)^2m^2+z\mu^2}\right) &= -\int_0^1 dzz(1-z)\frac{2(1-z)m^2-\mu^2}{(1-z)^2m^2+z\mu^2} \\ &= \int_0^1 dz\left[(1-z) - \frac{(1-z)\,(1-z^2)\,m^2}{(1-z)^2m^2+z\mu^2}\right]\end{aligned}$$

it is not hard to show that $\delta F_1(0) + \delta Z_2 = 0$. This identity will play a crucial role in justifying the ad hoc subtraction of Section 6.3.

17.2 7.2 The LSZ Reduction Formula

In the last section we saw that the Fourier transform of the two-point correlation function, considered as an analytic function of p^2, has a simple pole at the mass of the one-particle state:

$$\int d^4x e^{ip\cdot x}\langle\Omega|T\phi(x)\phi(0)|\Omega\rangle \underset{p^2\to m^2}{\sim} \frac{iZ}{p^2-m^2+i\epsilon} \tag{7.33}$$

(Here and throughout this section we use the symbol $\sim$ to mean that the poles of both sides are identical; there are additional finite terms, given in this case by Eq. (7.9).) In this section we will generalize this result to higher correlation functions. We will derive a general relation between correlation functions and S-matrix elements first obtained by Lehmann, Symanzik, and Zimmermann and known as the LSZ reduction formula. ‡ This result, combined with our Feynman rules for computing correlation functions, will justify Eq. (4.103), our master formula for S-matrix elements in terms of Feynman diagrams. For simplicity, we will carry out the whole analysis for the case of scalar fields.

The strategy of the argument will be as follows. To calculate the S-matrix element for a 2-body $\to$ n-body scattering process, we begin with the correlation function of $n+2$ Heisenberg fields. Fourier-transforming with respect to the coordinate of any one of these fields, we will find a pole of the form (7.33) in the Fourier-transform variable p^2. We will argue that the one-particle states associated with these poles are in fact asymptotic states, that is, states given by the limit of well-separated wavepackets as they become concentrated around definite momenta. Taking the limit in which all $n+2$ external particles go on-shell, we can then interpret the coefficient of the multiple pole as an S-matrix element.

To begin, let us Fourier-transform the $(n+2)$-point correlation function with respect to one argument x. We must then analyze the integral

$$\int d^4x e^{ip\cdot x}\langle\Omega|T\left\{\phi(x)\phi\left(z_1\right)\phi\left(z_2\right)\cdots\right\}|\Omega\rangle$$

We would like to identify poles in the variable p^0. To do this, divide the integral over x^0 into three regions:

$$\int dx^0 = \int_{T_+}^{\infty} dx^0 + \int_{T_-}^{T_+} dx^0 + \int_{-\infty}^{T_-} dx^0 \tag{7.34}$$

where $T_+$is much greater than all the z_i^0 and $T_-$is much less than all the z_i^0. Call these three intervals regions I, II, and III. Since region II is bounded and the integrand depends on p^0 through the analytic function $\exp\left(ip^0x^0\right)$, the contribution from this region will be analytic in p^0. However, regions I and III, which are unbounded, may develop singularities in p^0.

Consider first region I. Here x^0 is the latest time, so $\phi(x)$ stands first in the time ordering. Insert a complete set of intermediate states in the form of (7.2):

$$\mathbf{1} = \sum_{\lambda}\int \frac{d^3q}{(2\pi)^3}\frac{1}{2E_{\mathbf{q}}(\lambda)}\left|\lambda_{\mathbf{q}}\right\rangle\left\langle\lambda_{\mathbf{q}}\right|$$

The integral over region I then becomes

[6‡] H. Lehmann, K. Symanzik, and W. Zimmermann, Nuovo Cimento 1, 1425 (1955).

$$\int_{T_+}^{\infty} dx^0 \int d^3x e^{ip^0x^0} e^{-i\mathbf{p}\cdot\mathbf{x}} \sum_\lambda \int \frac{d^3q}{(2\pi)^3} \frac{1}{2E_{\mathbf{q}}(\lambda)} \langle\Omega|\phi(x)\,|\lambda_{\mathbf{q}}\rangle \times \langle\lambda_{\mathbf{q}}|\,T\left\{\phi\left(z_1\right)\phi\left(z_2\right)\cdots\right\}|\Omega\rangle \tag{7.35}$$

Using Eq. (7.4),

$$\langle\Omega|\phi(x)\,|\lambda_{\mathbf{q}}\rangle = \langle\Omega|\phi(0)\,|\lambda_0\rangle\, e^{-iq\cdot x}\big|_{q^0=E_{\mathbf{q}}(\lambda)}$$

and including a factor $e^{-\epsilon x^0}$ to insure that the integral is well defined, this integral becomes

$$\begin{aligned}
&\sum_\lambda \int_{T_+}^{\infty} dx^0 \int \frac{d^3q}{(2\pi)^3} \frac{1}{2E_{\mathbf{q}}(\lambda)} e^{ip^0x^0} e^{-iq^0x^0} e^{-\epsilon x^0} \langle\Omega|\phi(0)\,|\lambda_0\rangle\,(2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q}) \\
&\times \langle\lambda_{\mathbf{q}}|\,T\left\{\phi\left(z_1\right)\cdots\right\}|\Omega\rangle \\
&= \sum_\lambda \frac{1}{2E_{\mathbf{p}}(\lambda)} \frac{ie^{i\left(p^0-E_{\mathbf{p}}+i\epsilon\right)T_+}}{p^0-E_{\mathbf{p}}(\lambda)+i\epsilon} \langle\Omega|\phi(0)\,|\lambda_0\rangle\,\langle\lambda_{\mathbf{p}}|\,T\left\{\phi\left(z_1\right)\cdots\right\}|\Omega\rangle
\end{aligned} \tag{7.36}$$

The denominator is just that of Eq. (7.5): $p^2 - m_\lambda^2$. There is an analytic singularity in p^0; as in Section 7.1 , this singularity will be either a pole or a branch cut depending upon whether or not the rest energy m_λ is isolated. The one-particle state corresponds to an isolated energy value $p^0 = E_{\mathbf{p}} = \sqrt{|\mathbf{p}|^2 + m^2}$, and at this point Eq. (7.36) has a pole:

$$\begin{aligned}
&\int d^4x e^{ip\cdot x} \langle\Omega|T\left\{\phi(x)\phi\left(z_1\right)\cdots\right\}|\Omega\rangle \\
&\qquad \underset{p^0\to+E_{\mathbf{p}}}{\sim} \frac{i}{p^2-m^2+i\epsilon} \sqrt{Z}\langle\mathbf{p}|T\left\{\phi\left(z_1\right)\cdots\right\}|\Omega\rangle
\end{aligned} \tag{7.37}$$

The factor $\sqrt{Z}$ is the same field strength renormalization factor as in Eq. (7.8), since it replaces the same matrix element as in (7.7).

To evaluate the contribution from region III, we would put $\phi(x)$ last in the operator ordering, then insert a complete set of states between $T\left\{\phi\left(z_1\right)\cdots\right\}$ and $\phi(x)$. Repeating the above argument produces a pole as $p^0 \to -E_{\mathbf{p}}$:

$$\begin{aligned}
&\int d^4x e^{ip\cdot x} \langle\Omega| \\
&\qquad T\left\{\phi(x)\phi\left(z_1\right)\cdots\right\}|\Omega\rangle \\
&\qquad \sim \underset{p^0\to-E_{\mathbf{p}}}{\sim} \langle\Omega|T\left\{\phi\left(z_1\right)\cdots\right\}|-\mathbf{p}\rangle\sqrt{Z}\frac{i}{p^2-m^2+i\epsilon}
\end{aligned} \tag{7.38}$$

Next we would like to Fourier-transform with respect to the remaining field coordinates. To keep the various external particles from interfering, however, we must isolate them from each other in space. Let us therefore repeat the preceding calculation using a wavepacket rather than a simple Fourier transform. In Eq. (7.35), replace

$$\int d^4x e^{ip^0x^0} e^{-i\mathbf{p}\cdot\mathbf{x}} \to \int \frac{d^3k}{(2\pi)^3} \int d^4x e^{ip^0x^0} e^{-i\mathbf{k}\cdot\mathbf{x}} \varphi(\mathbf{k}) \tag{7.39}$$

where $\varphi(\mathbf{k})$ is a narrow distribution centered on $\mathbf{k} = \mathbf{p}$. This distribution constrains x to lie within a band, whose spatial extent is that of the wavepacket, about the trajectory of a particle with momentum $\mathbf{p}$. With this modification, the right-hand side of (7.36) has a more complicated singularity structure:

$$\begin{aligned}\sum_\lambda \int \frac{d^3k}{(2\pi)^3} \varphi(\mathbf{k}) \frac{1}{2E_{\mathbf{k}}(\lambda)} \frac{i}{p^0 - E_{\mathbf{k}}(\lambda) + i\epsilon} \langle\Omega|\phi(0)\,|\lambda_0\rangle\,\langle\lambda_{\mathbf{k}}|\,T\left\{\phi\left(z_1\right)\cdots\right\}|\Omega\rangle \\ \underset{p^0\to+E_{\mathbf{p}}}{\sim} \int \frac{d^3k}{(2\pi)^3} \varphi(\mathbf{k}) \frac{i}{\tilde{p}^2 - m^2 + i\epsilon} \sqrt{Z} \langle\mathbf{k}|T\left\{\phi\left(z_1\right)\cdots\right\}|\Omega\rangle,\end{aligned} \tag{7.40}$$

where, in the second line, $\tilde{p} = (p_0, \mathbf{k})$. The one-particle singularity is now a branch cut, whose length is the width in momentum space of the wavepacket $\varphi(\mathbf{k})$. However, if $\varphi(\mathbf{k})$ defines the momentum narrowly, this branch cut is very short, and (7.40) has a well-defined limit in which $\varphi(\mathbf{k})$ tends to $(2\pi)^3\delta^{(3)}(\mathbf{k}-\mathbf{p})$ and the singularity of (7.40) sharpens up to the pole of (7.36). The singularity due to single-particle states in the far past, Eq. (7.38), is modified in the same way.

Now consider integrating each of the coordinates in the $(n+2)$-point correlation function against a wavepacket, to form*

$$\left(\prod_i \int \frac{d^3k_i}{(2\pi)^3} \int d^4x_i e^{i\tilde{p}_i\cdot x_i} \varphi_i\left(\mathbf{k}_i\right)\right) \langle\Omega|T\left\{\phi\left(x_1\right)\phi\left(x_2\right)\cdots\right\}|\Omega\rangle \tag{7.41}$$

The wavepackets should be chosen to overlap in a region around $x = 0$ and to separate in the far past and the far future. To analyze this integral, we choose a large positive time T_+such that all of the wavepackets are well separated for $x_i^0 > T_+$, and we choose a large negative time T_-such that all of the wavepackets are well separated for $x_i^0 < T_-$. Then we can break up each of of the integrals over x_i^0 into three regions as in (7.34). The integral of any x_i^0 over the bounded region II leads to an expression analytic in the corresponding energy p_0^i, so we can concentrate on the case in which all of the x_i^0 are placed at large past or future times.

For definiteness, consider the contribution in which only two of the time coordinates, x_1^0 and x_2^0, are in the future. In this case, the fields $\phi\left(x_1\right)$ and $\phi\left(x_2\right)$ stand to the left of the other fields in time order. Inserting a complete set of states $|\lambda_{\mathbf{K}}\rangle$, the integrations in (7.41) over the coordinates of these two fields take the form

$$\begin{aligned}\sum_\lambda \int \frac{d^3K}{(2\pi)^3} \frac{1}{2E_{\mathbf{K}}} \left(\prod_{i=1,2} \int \frac{d^3k_i}{(2\pi)^3} \int d^4x_i e^{i\tilde{p}_i\cdot x_i} \varphi_i\left(\mathbf{k}_i\right)\right) \\ \times \langle\Omega|T\left\{\phi\left(x_1\right)\phi\left(x_2\right)\right\}|\lambda_{\mathbf{K}}\rangle\,\langle\lambda_{\mathbf{K}}|\,T\left\{\phi\left(x_3\right)\cdots\right\}|\Omega\rangle\end{aligned}$$

The state $|\lambda_{\mathbf{K}}\rangle$ is annihilated by two field operators constrained to lie in distant wavepackets. It must therefore consist of two distinct excitations of the vacuum at two distinct locations. If these excitations are well separated,

they should be independent of one another, so we can approximate

$$

[6]*As in Section 4.5, the product symbol applies symbolically to the integrations as well as to the other factors within the parentheses; the x_i integrals apply to what lies outside the parentheses as well.

$$\sum_{\lambda} \int \frac{d^3K}{(2\pi)^3} \frac{1}{2E_{\mathbf{K}}} \langle \Omega | T \left\{ \phi(x_1) \phi(x_2) \right\} | \lambda_{\mathbf{K}} \rangle \langle \lambda_{\mathbf{K}} |$$
$$= \sum_{\lambda_1, \lambda_{\mathbf{2}}} \int \frac{d^3q_1}{(2\pi)^3} \frac{1}{2E_{\mathbf{q}_1}} \int \frac{d^3q_2}{(2\pi)^3} \frac{1}{2E_{\mathbf{q}_2}} \langle \Omega | \phi(x_1) | \lambda_{\mathbf{q}_1} \rangle \langle \Omega | \phi(x_2) | \lambda_{\mathbf{q}_2} \rangle \langle \lambda_{\mathbf{q}_1} \lambda_{\mathbf{q}_2} |$$

$$

The sums over λ_1 and λ_2 in the this equation run over all zero-momentum states, but only single-particle states will contribute the poles we are looking for. In this case, the integrals over x_1^0 and $\mathbf{q}_1$ produce a sharp singularity in p_1^0 of the form of (7.40), and the integrals over x_2^0 and $\mathbf{q}_2$ produce the same singular behavior in p_2^0. The term in (7.41) with both singularities is

$$\left(\prod_{i=1,2} \int \frac{d^3k_i}{(2\pi)^3} \varphi_i(\mathbf{k}_i) \frac{i}{\tilde{p}_i^2 - m^2 + i\epsilon} \cdot \sqrt{Z} \right) \langle \mathbf{k}_1 \mathbf{k}_2 | T \left\{ \phi(x_3) \cdots \right\} | \Omega \rangle$$

In the limit in which the wavepackets tend to delta functions concentrated at definite momenta $\mathbf{p}_1$ and $\mathbf{p}_2$, this expression tends to

$$\left(\prod_{i=1,2} \frac{i}{p_i^2 - m^2 + i\epsilon} \cdot \sqrt{Z} \right)_{\text{out}} \langle \mathbf{p}_1 \mathbf{p}_2 | T \left\{ \phi(x_3) \cdots \right\} | \Omega \rangle$$

The state $\langle \mathbf{p}_1 \mathbf{p}_2 |$ is precisely an out state as defined in Section 4.5, since it is the definite-momentum limit of a state of particles constrained to wellseparated wavepackets. Applying the same analysis to the times x_i^0 in the far past gives the result that the coefficient of the maximally singular term in the corresponding p_i^0 is a matrix element with an in state. This most singular term in (7.41) thus has the form

$$\left(\prod_{i=1,2} \frac{i}{p_i^2 - m^2 + i\epsilon} \cdot \sqrt{Z} \right) \left(\prod_{i=3,\ldots} \frac{i}{p_i^2 - m^2 + i\epsilon} \cdot \sqrt{Z} \right)_{\text{out}} \langle \mathbf{p}_1 \mathbf{p}_2 \mid -\mathbf{p}_3 \cdots \rangle_{\text{in}}$$

The last factor is just an S-matrix element.

We have now shown that we can extract the value of an S-matrix element by folding the corresponding vacuum expectation value of fields with wavepackets, extracting the leading singularities in the energies p_i^0, and then taking the limit as these wavepackets become delta functions of momenta. However, the computation would be made much simpler if we could do these operations in the reverse order-first letting the wavepackets become delta functions, returning us to the simple Fourier transform, and then extracting the singularities. In fact, the result for the leading singularity is not changed by this switch of the order of operations. It is, however, rather subtle to argue this point. Roughly, the explanation is the following: In the language of the analysis just completed, new singularities might arise because, in the Fourier transform, x_1 and x_2 can become close together in the far future. However, in this region, the exponential factor is close to $\exp\left[i\left(p_1 + p_2\right) \cdot x_1\right]$, and thus the new singularities are single poles in the variable $(p_1^0 + p_2^0)$, rather than

being products of poles in the two separate energy variables. A more careful argument (unfortunately, couched in a rather different language) can be found in the original paper of Lehmann, Symanzik, and Zimmermann cited at the beginning of this section.

Given the ability to make this reversal in the order of operations, we obtain a precise relation between Fourier transforms of correlation functions and S-matrix elements. This is the LSZ reduction formula:

$$\begin{array}{c}\prod_1^n \int d^4x_i e^{ip_i\cdot x_i} \prod_1^m \int d^4y_j e^{-ik_j\cdot y_j} \langle\Omega|T\left\{\phi\left(x_1\right)\cdots\phi\left(x_n\right)\phi\left(y_1\right)\cdots\phi\left(y_m\right)\right\}|\Omega\rangle \\ \underset{\substack{\text{each } p_i^0\to+E_{\mathbf{p}_i}\\ \text{each } k_j^0\to+E_{\mathbf{k}_j}}}{\sim} \left(\prod_{i=1}^n \frac{\sqrt{Z}i}{p_i^2-m^2+i\epsilon}\right)\left(\prod_{j=1}^m \frac{\sqrt{Z}i}{k_j^2-m^2+i\epsilon}\right)\langle\mathbf{p}_1\cdots\mathbf{p}_n|\,S\,|\mathbf{k}_1\cdots\mathbf{k}_m\rangle\end{array}$$

The quantity Z that appears in this equation is exactly the field-strength renormalization constant, defined in Section 7.1 as the residue of the singleparticle pole in the two-point function of fields. Each distinct particle will have a distinct renormalization factor Z, obtained from its own two-point function. For higher-spin fields, each factor of $\sqrt{Z}$ comes with a polarization factor such as $u^s(p)$, as in Eq. (7.12). The polarization s must be summed over in the second line of (7.42).

In words, the LSZ formula says that an S-matrix element can be computed as follows. Compute the appropriate Fourier-transformed correlation function, look at the region of momentum space where the external particles are near the mass shell, and identify the coefficient of the multiparticle pole. For fields with spin, one must also multiply by a polarization spinor (like $u^s(p)$) or vector (like $\epsilon^r(k)$) to project out the desired spin state.

Our next goal is to express this procedure in the language of Feynman diagrams. Let us analyze the relation between the diagrammatic expansion of the scalar field four-point function and the S-matrix element for 2-particle $\to$ 2-particle scattering. We will consider explicitly the fully connected Feynman diagrams contributing to the correlator. By a similar analysis, it is easy to confirm that disconnected diagrams should be disregarded because they do not have the singularity structure, with a product of four poles, indicated on the right-hand side of (7.42).

The exact four-point function

$$\left(\prod_1^2 \int d^4x_i e^{ip_i\cdot x_i}\right)\left(\prod_1^2 \int d^4y_i e^{-ik_i\cdot y_i}\right)\langle\Omega|T\left\{\phi\left(x_1\right)\phi\left(x_2\right)\phi\left(y_1\right)\phi\left(y_2\right)\right\}|\Omega\rangle$$

has the general form shown in Fig. 7.4. In this figure, we have indicated explicitly the diagrammatic corrections on each leg; the shaded circle in the center represents the sum of all amputated four-point diagrams.

We can sum up the corrections to each external leg just as we did for the electron propagator in the previous section. Let $-iM^2\left(p^2\right)$ denote the sum of

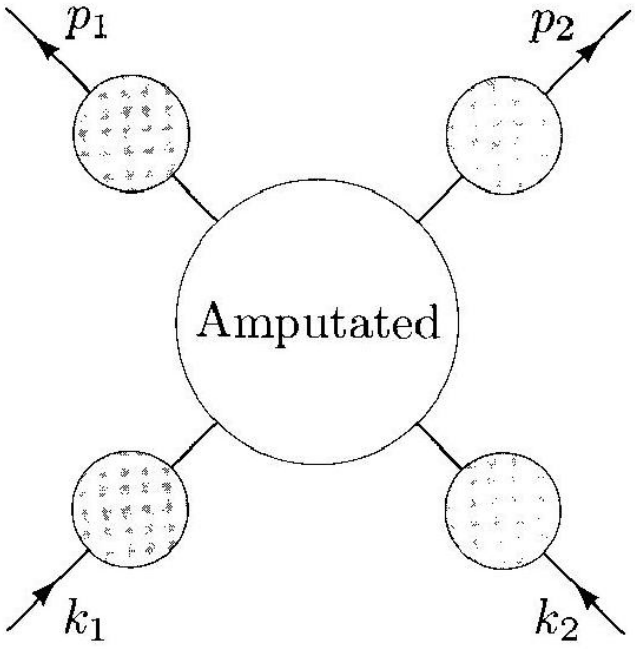


Figure 7.4. Structure of the exact four-point function in scalar field theory.
all one-particle-irreducible (1PI) insertions into the scalar propagator:

$$-iM^2\left(p^2\right) = -Q + \square + \cdots =$$

Then the exact propagator can be written as a geometric series and summed as in Eq. (7.23):

$$\begin{aligned} & 1 - 1\mathrm{PI} + 1\mathrm{PI} - 1\mathrm{PI} - \cdots \\ & = \frac{i}{p^2 - m_0^2} + \frac{i}{p^2 - m_0^2}\left(-iM^2\right)\frac{i}{p^2 - m_0^2} + \cdots \\ & = \frac{i}{p^2 - m_0^2 - M^2\left(p^2\right)} \end{aligned} \tag{7.43}$$

Notice that, as in the case of the electron propagator, our sign convention for the 1PI self-energy $M^2\left(p^2\right)$ implies that a positive contribution to $M^2\left(p^2\right)$ corresponds to a positive shift of the scalar particle mass. If we expand each resummed propagator about the physical particle pole, we see that each external leg of the four-point amplitude contributes

$$\frac{i}{p^2 - m_0^2 - M^2} \underset{p^0 \to E_{\mathbf{p}}}{\sim} \frac{iZ}{p^2 - m^2} + (\text{ regular }) \tag{7.44}$$

Thus, the sum of diagrams contains a product of four poles:

$$\frac{iZ}{p_1^2 - m^2}\frac{iZ}{p_2^2 - m^2}\frac{iZ}{k_1^2 - m^2}\frac{iZ}{k_2^2 - m^2}$$

This is exactly the singularity on the second line of (7.42). Comparing the coefficients of this product of poles, we find the relation

$$\left\langle \mathbf{p}_1\mathbf{p}_2\right| S\left|\mathbf{k}_1\mathbf{k}_2\right\rangle = (\sqrt{Z})^4 \underbrace{p_1}_{k_1}$$

where the shaded circle is the sum of amputated four-point diagrams and Z is the field-strength renormalization factor.

An identical analysis can be applied to the Fourier transform of the $(n+2)$-point correlator in a general field theory. The relation between S-matrix elements and Feynman diagrams then takes the form

$$\langle \mathbf{p}_1 \ldots \mathbf{p}_n | \, S \, | \mathbf{k}_1 \mathbf{k}_2 \rangle = (\sqrt{Z})^{n+2} \tag{7.45}$$

(If the external particles are of different species, each has its own renormalization factor $\sqrt{Z}$; if the particles have nonzero spin, there will be additional polarization factors such as $u^s(k)$ on the right-hand side.) This is almost precisely the diagrammatic formula for the S-matrix that we wrote down in Section 4.6. The only new feature is the appearance of the renormalization factors $\sqrt{Z}$. The Z factors are irrelevant for calculations at the leading order of perturbation theory, but are important in the calculation of higher-order corrections.

Up to this point, we have performed only one full calculation of a higherorder correction, the computation of the order- α corrections to the electron form factors. We did not take into account the effects of the electron fieldstrength renormalization. Let us now add in this factor and examine its effects.

Since the expressions (6.28) and (6.30) for electron scattering from a heavy target were derived using our previous, incorrect formula for S-matrix elements, we should correct these formulae by inserting factors of $\sqrt{Z_2}$ for the initial and final electrons. Equation (6.33) for the structure of the exact vertex should then read

$$Z_2 \Gamma^\mu (p', p) = \gamma^\mu F_1 \left(q^2\right) + \frac{i \sigma^{\mu\nu} q_\nu}{2m} F_2 \left(q^2\right) \tag{7.46}$$

with $\Gamma^\mu (p', p)$ the sum of amputated electron-photon vertex diagrams.
We can use this equation to reevaluate the form factors to order α. Since $Z_2 = 1 + \mathcal{O}(\alpha)$ and F_2 begins in order α, our previous computation of F_2 is unaffected. To compute F_1, write the left-hand side of (7.46) as

$$Z_2 \Gamma^\mu = (1 + \delta Z_2) (\gamma^\mu + \delta \Gamma^\mu) = \gamma^\mu + \delta \Gamma^\mu + \gamma^\mu \cdot \delta Z_2$$

where δZ_2 and $\delta \Gamma^\mu$ denote the order- α corrections to these quantities. Comparing to the right-hand side of (7.46), we see that $F_1 (q^2)$ receives a new
contribution equal to δZ_2. Now let $\delta F_1 (q^2)$ denote the (unsubtracted) correction to the form factor that we computed in Section 6.3, and recall from the end of Section 7.1 that $\delta Z_2 = -\delta F_1(0)$. Then

$$F_1 \left(q^2\right) = 1 + \delta F_1 \left(q^2\right) + \delta Z_2 = 1 + \left[\delta F_1 \left(q^2\right) - \delta F_1(0)\right]$$

This is exactly the result we claimed, but did not prove, in Section 6.3. The inclusion of field-strength renormalization justifies the subtraction procedure that we applied on an ad hoc basis there.

At this level of analysis, it is difficult to see how the cancellation of divergences in F_1 will persist to higher orders. Worse, though we argued in Section 6.3 for the general result $F_1(0) = 1$, our verification of this result in order α seems to depend on a numerical coincidence.

We can state this problem carefully as follows: Define a second rescaling factor Z_1 by the relation

$$\Gamma^\mu (q = 0) = Z_1^{-1} \gamma^\mu \tag{7.47}$$

where Γ^μ is the complete amputated vertex function. To find $F_1(0) = 1$, we must prove the identity $Z_1 = Z_2$, so that the vertex rescaling exactly compensates the electron field-strength renormalization. We will prove this identity to all orders in perturbation theory at the end Section 7.4.

We conclude our discussion of the LSZ reduction formula with one further formal observation. The LSZ formula distinguishes in and out particles only by the sign of the Fourier transform momentum p_i^0 or k_i^0. This means that, by analytically continuing the residue of the pole in p^2 from positive to negative p^0, we can convert the S-matrix element with $\phi(\mathbf{p})$ in the final state into the S-matrix element with the antiparticle $\phi^*(-\mathbf{p})$ in the initial state. This is exactly the statement of crossing symmetry, which we derived diagrammatically in Section 5.4:

$$\langle \cdots \phi(p)|S|\cdots\rangle\big|_{p=-k} = \langle \cdots |S\,|\phi^*(k)\cdots\rangle$$

Since the proof of the LSZ formula does not depend on perturbation theory, we see that the crossing symmetry of the S-matrix is a general result of quantum theory, not merely a property of Feynman diagrams.

17.3 7.3 The Optical Theorem

In Section 7.1 we saw that the two-point correlation function of quantum fields, viewed as an analytic function of the momentum p^2, has branch cut singularities associated with multiparticle intermediate states. This conclusion should not be surprising to those familiar with nonrelativistic scattering theory, since it is already true there that the scattering amplitude, as a function of energy, has a branch cut on the positive real axis. The imaginary part of the scattering amplitude appears as a discontinuity across this branch cut. By the optical theorem, the imaginary part of the forward scattering amplitude is

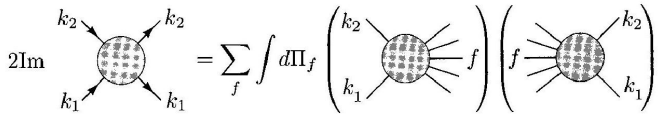

Figure 7.5. The optical theorem: The imaginary part of a forward scattering amplitude arises from a sum of contributions from all possible intermediatestate particles.

proportional to the total cross section. We will now prove the field-theoretic version of the optical theorem and illustrate how it arises in Feynman diagram calculations.

The optical theorem is a straightforward consequence of the unitarity of the S-matrix: $S^\dagger S = 1$. Inserting $S = 1 + iT$ as in (4.72), we have

$$-i\left(T - T^\dagger\right) = T^\dagger T \tag{7.48}$$

Let us take the matrix element of this equation between two-particle states $|\mathbf{p}_1\mathbf{p}_2\rangle$ and $|\mathbf{k}_1\mathbf{k}_2\rangle$. To evaluate the right-hand side, insert a complete set of intermediate states:

$$\langle \mathbf{p}_1\mathbf{p}_2|\,T^\dagger T\,|\mathbf{k}_1\mathbf{k}_2\rangle = \sum_n \left(\prod_{i=1}^n \int \frac{d^3q_i}{(2\pi)^3}\frac{1}{2E_i}\right) \langle \mathbf{p}_1\mathbf{p}_2|\,T^\dagger\,|\{\mathbf{q}_i\}\rangle\,\langle\{\mathbf{q}_i\}|\,T\,|\mathbf{k}_1\mathbf{k}_2\rangle$$

Now express the T-matrix elements as invariant matrix elements $\mathcal{M}$ times 4 -momentum-conserving delta functions. Identity (7.48) then becomes

$$
\begin{aligned}
&- i\left[\mathcal{M}\left(k_1 k_2 \to p_1 p_2\right) - \mathcal{M}^*\left(p_1 p_2 \to\ k_1 k_2\right)\right] \\
&= \sum_n \left(\prod_{i=1}^{n} \int \frac{d^3 q_i}{(2\pi)^3} \frac{1}{2E_i} \right) \mathcal{M}^*\left(p_1 p_2 \to \{q_i\}\right) \mathcal{M}\left(k_1 k_2 \to \{q_i\}\right) \\
&\times (2\pi)^4 \delta^{(4)} \left(k_1 + k_2 - \sum_i q_i \right)
\end{aligned}
$$

times an overall delta function $(2\pi)^4 \delta^{(4)}\left(k_1 + k_2 - p_1 - p_2\right)$. Let us abbreviate this identity as

$$
-i\left[\mathcal{M}(a \to b) - \mathcal{M}^*(b \to a)\right] = \sum_f \int d\Pi_f \mathcal{M}^*(b \to f) \mathcal{M}(a \to f) \tag{7.49}
$$

where the sum runs over all possible sets f of final-state particles. Although we have so far assumed that a and b are two-particle states, they could equally well be one-particle or multiparticle asymptotic states.

For the important special case of forward scattering, we can set $p_i = k_i$ to obtain a simpler identity, shown pictorially in Fig. 7.5. Supplying the kinematic factors required by (4.79) to build a cross section, we obtain the standard form of the optical theorem,

$$
\operatorname{Im} \mathcal{M}\left(k_1, k_2 \to k_1, k_2\right) = 2 E_{\mathrm{cm}} p_{\mathrm{cm}} \sigma_{\mathrm{tot}}\left(k_1, k_2 \to\ \text{anything }\right) \tag{7.50}
$$

where E_{cm} is the total center-of-mass energy and p_{cm} is the momentum of either particle in the center-of-mass frame. This equation relates the forward scattering amplitude to the total cross section for production of all final states. Since the imaginary part of the forward scattering amplitude gives the attenuation of the forward-going wave as the beam passes through the target, it is natural that this quantity should be proportional to the probability of scattering. Identity (7.50) gives the precise connection.

The Optical Theorem for Feynman Diagrams

Let us now investigate how this identity for the imaginary part of an S matrix element arises in the Feynman diagram expansion. It is easily checked (in QED, for example) that each diagram contributing to an S-matrix element $\mathcal{M}$ is purely real unless some denominators vanish, so that the $i\epsilon$ prescription for treating the poles becomes relevant. A Feynman diagram thus yields an imaginary part for $\mathcal{M}$ only when the virtual particles in the diagram go onshell. We will now show how to isolate and compute this imaginary part.

For our present purposes, let us define $\mathcal{M}$ by the Feynman rules for perturbation theory. This allows us to consider $\mathcal{M}(s)$ as an analytic function of the complex variable $s = E_{\mathrm{cm}}^2$, even though S-matrix elements are defined only for external particles with real momenta.

We first demonstrate that the appearance of an imaginary part of $\mathcal{M}(s)$ always requires a branch cut singularity. Let s_0 be the threshold energy for production of the lightest multiparticle state. For real s below s_0 the intermediate state cannot go on-shell, so $\mathcal{M}(s)$ is real. Thus, for real $s < s_0$, we have the identity

$$
\mathcal{M}(s) = \left[\mathcal{M}\left(s^*\right)\right]^* \tag{7.51}
$$

Each side of this equation is an analytic function of s, so it can be analytically continued to the entire complex s plane. In particular, near the real axis for $s > s_0$, Eq. (7.51) implies

$$\mathrm{Re}\,\mathcal{M}(s+i\epsilon) = \mathrm{Re}\,\mathcal{M}(s-i\epsilon)$$
$$\mathrm{Im}\,\mathcal{M}(s+i\epsilon) = -\,\mathrm{Im}\,\mathcal{M}(s-i\epsilon)$$

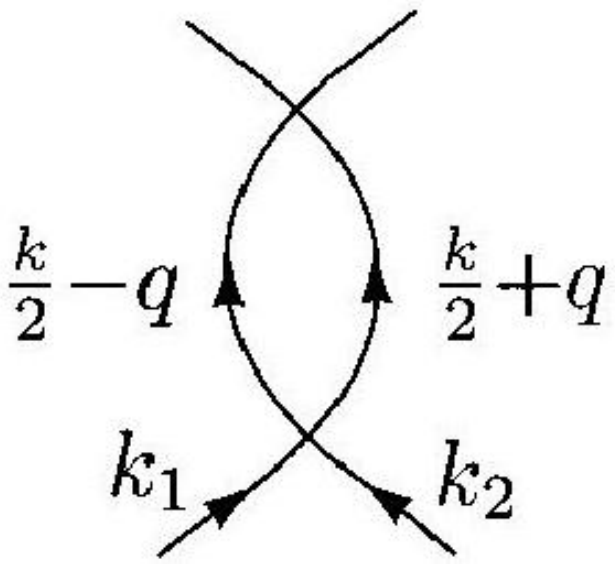
There is a branch cut across the real axis, starting at the threshold energy s_0; the discontinuity across the cut is

$$\mathrm{Disc}\,\mathcal{M}(s) = 2i\,\mathrm{Im}\,M(s+i\epsilon)$$

Usually it is easier to compute the discontinuity of a diagram than to compute the imaginary part directly. The $i\epsilon$ prescription in the Feynman propagator indicates that physical scattering amplitudes should be evaluated above the cut, at $s + i\epsilon$.

We already saw in Section 7.1 that the electron self-energy diagram has a branch cut beginning at the physical electron-photon threshold. Let us now study more general one-loop diagrams, and show that their discontinuities
give precisely the imaginary parts required by (7.49). The generalization of this result to multiloop diagrams has been proven by Cutkosky, † who showed in the process that the discontinuity of a Feynman diagram across its branch cut is always given by a simple set of cutting rules. ‡

We begin by checking (7.49) in ϕ^4 theory. Since the right-hand side of (7.49) begins in order λ^2, we expect that $\mathrm{Im}\,\mathcal{M}$ should also receive its first contribution from higher-order diagrams. Consider, then, the order- λ^2 diagram



$$k = k_1 + k_2$$

with a loop in the s-channel. (It is easy to check that the corresponding t - and u-channel diagrams have no branch cut singularities for s above threshold.) The total momentum is $k = k_1 + k_2$, and for simplicity we have chosen the symmetrical routing of momenta shown above. The value of this Feynman diagram is

$$i\delta\mathcal{M} = \frac{\lambda^2}{2}\int \frac{d^4q}{(2\pi)^4}\,\frac{1}{(k/2-q)^2 - m^2 + i\epsilon}\,\frac{1}{(k/2+q)^2 - m^2 + i\epsilon} \tag{7.52}$$

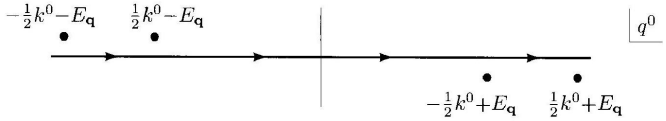
When this integral is evaluated using the methods of Section 6.3, the Wick rotation produces an extra factor of i, so that, below threshold, $\delta\mathcal{M}$ is purely real.

We would like to verify that the integral (7.52) has a discontinuity across the real axis in the physical region $k^0 > 2m$. It is easiest to identify this discontinuity by computing the integral for $k^0 < 2m$, then increasing k^0 by analytic continuation. It is not difficult to compute the integral directly using Feynman parameters (see Problem 7.1). However, it is illuminating to use a less direct approach, as follows.

Let us work in the center-of-mass frame, where $k = (k^0, \mathbf{0})$. Then the integrand of (7.52) has four poles in the integration variable q^0, at the locations

$$q^0 = \frac{1}{2}k^0 \pm (E_{\mathbf{q}} - i\epsilon)\,, \quad q^0 = -\frac{1}{2}k^0 \pm (E_{\mathbf{q}} - i\epsilon)$$

Two of these poles lie above the real q^0 axis and two lie below, as shown:



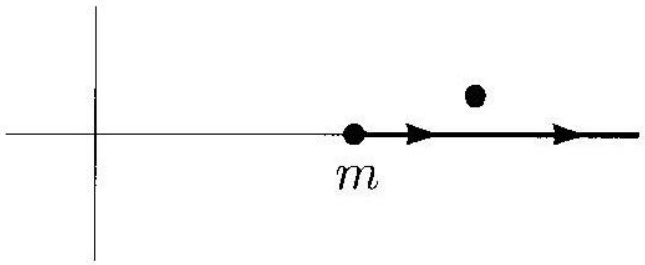
We will close the integration contour downward and pick up the residues of the poles in the lower half-plane. Of these, only the pole at $q^0 = -(1/2)k^0 + E_{\mathbf{q}}$ will contribute to the discontinuity. Note that picking up the residue of this pole is equivalent to replacing

$$\frac{1}{(k/2+q)^2 - m^2 + i\epsilon} \to -2\pi i\delta\left((k/2+q)^2 - m^2\right) \tag{7.53}$$

under the dq^0 integral.
The contribution of this pole yields the integral

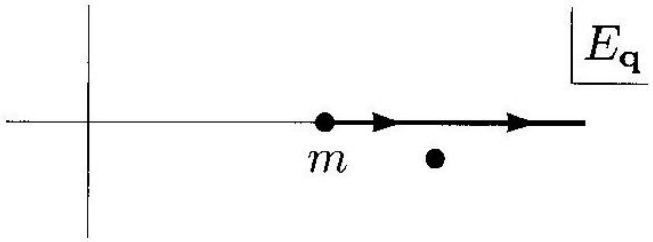
$$\begin{aligned} i\delta\mathcal{M} &= -2\pi i\frac{\lambda^2}{2}\int\frac{d^3q}{(2\pi)^4}\frac{1}{2E_{\mathbf{q}}}\frac{1}{\left(k^0 - E_{\mathbf{q}}\right)^2 - E_{\mathbf{q}}^2} \\ &= -2\pi i\frac{\lambda^2}{2}\frac{4\pi}{(2\pi)^4}\int_m^\infty dE_{\mathbf{q}}E_{\mathbf{q}}|\mathbf{q}|\frac{1}{2E_{\mathbf{q}}}\frac{1}{k^0\left(k^0 - 2E_{\mathbf{q}}\right)} \end{aligned} \tag{7.54}$$

The integrand in the second line has a pole at $E_{\mathbf{q}} = k^0/2$. When $k^0 < 2m$, this pole does not lie on the integration contour, so $\delta\mathcal{M}$ is manifestly real. When $k^0 > 2m$, however, the pole lies just above or below the contour of integration, depending upon whether k^0 is given a small positive or negative imaginary part:



[6†] R. E. Cutkosky, J. Math. Phys. 1, 429 (1960).
‡ These rules are simple only for singularities in the physical region. Away from the physical region, the singularities of three- and higher-point amplitudes can become quite intricate. This subject is reviewed in R. J. Eden, P. V. Landshoff, D. I. Olive, and J. C. Polkinghorne, The Analytic S-Matrix (Cambridge University Press, 1966).

or



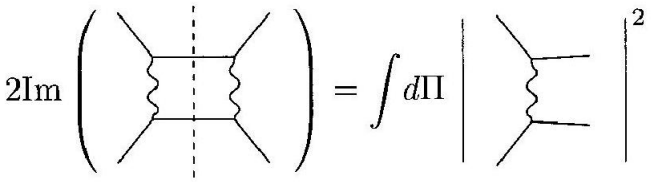
Thus the integral acquires a discontinuity between $k^2 + i\epsilon$ and $k^2 - i\epsilon$. To compute this discontinuity, apply

$$\frac{1}{k^0 - 2E_{\mathbf{q}} \pm i\epsilon} = P\frac{1}{k^0 - 2E_{\mathbf{q}}} \mp i\pi\delta\left(k^0 - 2E_{\mathbf{q}}\right)$$

(where P denotes the principal value). The discontinuity is given by replacing the pole with a delta function. This in turn is equivalent to replacing the original propagator by a delta function:

$$\frac{1}{(k/2-q)^2 - m^2 + i\epsilon} \to -2\pi i\delta\left((k/2-q)^2 - m^2\right). \tag{7.55}$$

(a)



(b)

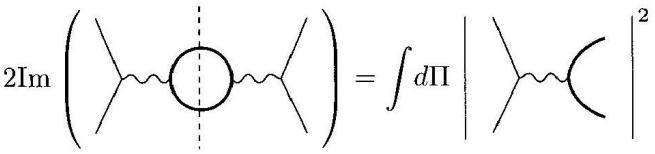


Figure 7.6. Two contributions to the optical theorem for Bhabha scattering.

Let us now retrace our steps and see what we have proved. Go back to the original integral (7.52), relabel the momenta on the two propagators as p_1, p_2 and substitute

$$\int \frac{d^4q}{(2\pi)^4} = \int \frac{d^4p_1}{(2\pi)^4}\int \frac{d^4p_2}{(2\pi)^4}(2\pi)^4\delta^{(4)}\left(p_1 + p_2 - k\right)$$

We have shown that the discontinuity of the integral is computed by replacing each of the two propagators by a delta function:

$$\frac{1}{p_i^2 - m^2 + i\epsilon} \to -2\pi i\delta\left(p_i^2 - m^2\right) \tag{7.56}$$

The discontinuity of $\mathcal{M}$ comes only from the region of the d^4q integral in which the two delta functions are simultaneously satisfied. By integrating over the delta functions, we put the momenta p_i on shell and convert the integrals d^4p_i into integrals over relativistic phase space. What is left over in expression (7.52) is just the factor λ^2, the square of the leading-order scattering amplitude, and the symmetry factor (1/2), which can be reinterpreted as the symmetry factor for identical

bosons in the final state. Thus we have shown that, to order λ^2 on each side of the equation, $\text{Disc}\,\mathcal{M}(k) = 2i\,\text{Im}\,\mathcal{M}(k)$

$$= \frac{i}{2}\int \frac{d^3p_1}{(2\pi)^3}\frac{1}{2E_1}\frac{d^3p_2}{(2\pi)^3}\frac{1}{2E_2}|\mathcal{M}(k)|^2(2\pi)^4\delta^{(4)}\left(p_1+p_2-k\right).$$

This explicitly verifies (7.49) to order λ^2 in ϕ^4 theory.
The preceding argument made no essential use of the fact that the two propagators in the diagram had equal masses, or of the fact that these propagators connected to a simple point vertex. Indeed, the analysis can be applied to an arbitrary one-loop diagram. Whenever, in the region of momentum integration of the diagram, two propagators can simultaneously go on-shell, we can follow the argument above to compute a nonzero discontinuity of $\mathcal{M}$. The value of this discontinuity is given by making the substitution (7.56) for
each of the two propagators. For example, in the order- α^2 Bhabha scattering diagrams shown in Fig. 7.6, we can compute the imaginary parts by cutting through the diagrams as shown and putting the cut propagators on shell using (7.56). The poles of the additional propagators in the diagrams do not contribute to the discontinuities. By integrating over the delta functions as in the previous paragraph, we derive the indicated relations between the imaginary parts of these diagrams and contributions to the total cross section.

Cutkosky proved that this method of computing discontinuities is completely general. The physical discontinuity of any Feynman diagram is given by the following algorithm:

1. Cut through the diagram in all possible ways such that the cut propagators can simultaneously be put on shell.

2. For each cut, replace $1/\left(p^2-m^2+i\epsilon\right) \to -2\pi i\delta\left(p^2-m^2\right)$ in each cut propagator, then perform the loop integrals.

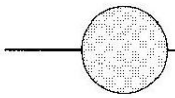
3. Sum the contributions of all possible cuts.

Using these cutting rules, it is possible to prove the optical theorem (7.49) to all orders in perturbation theory.

Unstable Particles

The cutting rules imply that the generalized optical theorem (7.49) is true not only for S-matrix elements, but for any amplitudes $\mathcal{M}$ that we can define in terms of Feynman diagrams. This fact is extremely useful for dealing with unstable particles, which never appear in asymptotic states.

Recall from Eq. (7.43) that the exact two-point function for a scalar particle has the form



$$= \frac{i}{p^2-m_0^2-M^2(p^2)}.$$

We defined the quantity $-iM^2\left(p^2\right)$ as the sum of all 1PI insertions into the boson propagator, but we can equally well think of it as the sum of all amputated diagrams for 1-particle $\to$ 1-particle "scattering". The LSZ formula then implies

$$\mathcal{M}(p\to p) = -ZM^2\left(p^2\right) \tag{7.57}$$

We can use this relation and the generalized optical theorem (7.49) to discuss the imaginary part of $M^2\left(p^2\right)$.

First consider the familiar case where the scalar boson is stable. In this case, there is no possible final state that can contribute to the right-hand side of (7.49). Thus $M^2(p^2)$ is real. The position of the pole in the propagator is determined by the equation $m^2 - m_0^2 - M^2(m^2) = 0$, which has a real-valued solution m. The pole therefore lies on the real p^2 axis, below the multiparticle branch cut.

Often, however, a particle can decay into two or more lighter particles. In this case $M^2(p^2)$ will acquire an imaginary part, so we must modify our
definitions slightly. Let us define the particle's mass m by the condition

$$m^2 - m_0^2 - \operatorname{Re} M^2\left(m^2\right) = 0 \tag{7.58}$$

Then the pole in the propagator is displaced from the real axis:

$$-\left(\sim \frac{iZ}{p^2 - m^2 - iZ \operatorname{Im} M^2(p^2)}.\right.$$

If this propagator appears in the s channel of a Feynman diagram, the cross section one computes, in the vicinity of the pole, will have the form

$$\sigma \propto \left| \frac{1}{s - m^2 - iZ \operatorname{Im} M^2(s)} \right|^2 \tag{7.59}$$

This expression closely resembles the relativistic Breit-Wigner formula (4.64) for the cross section in the region of a resonance:

$$\sigma \propto \left| \frac{1}{p^2 - m^2 + im\Gamma} \right|^2 \tag{7.60}$$

The mass m defined by (7.58) is the position of the resonance. If $\operatorname{Im} M^2(m^2)$ is small, so that the resonance in (7.59) is narrow, we can approximate $\operatorname{Im} M^2(s)$ as $\operatorname{Im} M^2(m^2)$ over the width of the resonance; then (7.59) will have precisely the Breit-Wigner form. In this case, we can identify

$$\Gamma = -\frac{Z}{m} \operatorname{Im} M^2\left(m^2\right) \tag{7.61}$$

If the resonance is broad, it will show deviations from the Breit-Wigner shape, generally becoming narrower on the leading edge and broader on the trailing edge.

To compute $\operatorname{Im} M^2$, and hence Γ, we could use the definition of M^2 as the sum of 1PI insertions into the propagator. The imaginary parts of the relevant loop diagrams give the decay rate. But the optical theorem (7.49), generalized to Feynman diagrams by the Cutkosky rules, simplifies this procedure. If we take (7.57) as the definition of the matrix element $\mathcal{M}(p \to p)$, and similarly define the decay matrix elements $\mathcal{M}(p \to f)$ through their Feynman diagram expansions, then (7.49) implies

$$Z \operatorname{Im} M^2\left(p^2\right) = -\operatorname{Im} \mathcal{M}(p \to p) = -\frac{1}{2} \sum_f \int d\Pi_f |\mathcal{M}(p \to f)|^2 \tag{7.62}$$

where the sum runs over all possible final states f. The decay rate is therefore

$$\Gamma = \frac{1}{2m} \sum_f \int d\Pi_f |\mathcal{M}(p \to f)|^2 \tag{7.63}$$

as quoted in Eq. (4.86).
We stress once again that our derivation of this equation applies only to the case of a long-lived unstable particle, so that $\Gamma \ll m$. For a broad resonance, the full energy dependence of $M^2(p^2)$ must be taken into account.

17.4 7.4 The Ward-Takahashi Identity

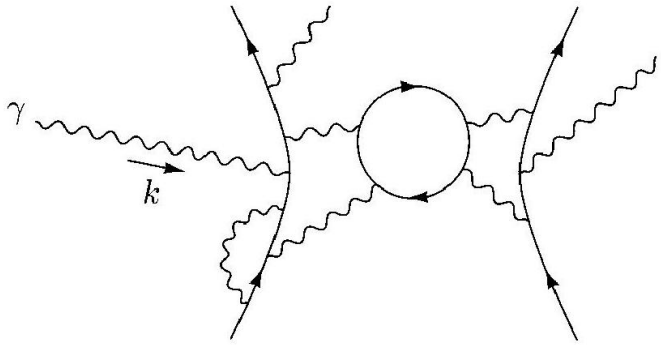
Of the loose ends listed at the beginning of this chapter, only one remains, the proof of the Ward identity. Recall from Section 5.5 that this identity states the following: If $\mathcal{M}(k) = \epsilon_\mu(k)\mathcal{M}^\mu(k)$ is the amplitude for some QED process involving an external photon with momentum k, then this amplitude vanishes if we replace ϵ_μ with k_μ:

$$k_\mu \mathcal{M}^\mu(k) = 0 \tag{7.64}$$

To prove this assertion, it is useful to prove a more general identity for QED correlation functions, called the Ward-Takahashi identity. To discuss this more general case we will let $\mathcal{M}$ denote a Fourier-transformed correlation function, in which the external momenta are not necessarily on-shell. The right-hand side of (7.64) will contain nonzero terms in this case; but when we apply the LSZ formula to extract an S-matrix element, those terms will not contribute.

We will prove the Ward-Takahashi identity order by order in α, by looking directly at the Feynman diagrams that contribute to $\mathcal{M}(k)$. The identity is generally not true for individual Feynman diagrams; we must sum over the diagrams for $\mathcal{M}(k)$ at any given order.

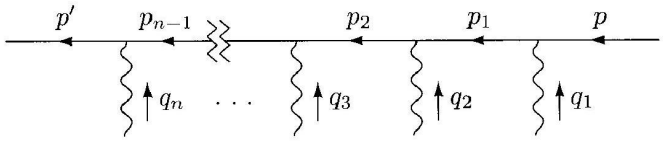
Consider a typical diagram for a typical amplitude $\mathcal{M}(k)$:



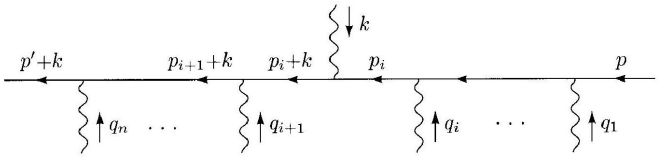
If we remove the photon $\gamma(k)$, we obtain a simpler diagram which is part of a simpler amplitude $\mathcal{M}_0$. If we reinsert the photon somewhere else inside the simpler diagram, we again obtain a contribution to $\mathcal{M}(k)$. The crucial observation is that by summing over all the diagrams that contribute to $\mathcal{M}_0$, then summing over all possible points of insertion in each of these diagrams, we obtain $\mathcal{M}(k)$. The Ward-Takahashi identity is true individually for each diagram contributing to $\mathcal{M}_0$, once we sum over insertion points; this is what we will prove.

When we insert our photon into one of the diagrams of $\mathcal{M}_0$, it must attach either to an electron line that runs out of the diagram to two external points, or to an internal electron loop. Let us consider each of these cases in turn.

First suppose that the electron line runs between external points. Before we insert our photon $\gamma(k)$, the line looks like this:



The electron propagators have momenta $p, p_1 = p + q_1, p_2 = p_1 + q_2$, and so on up to $p' = p_{n-1} + q_n$. If there are n vertices, we can insert our photon in $n + 1$ different places. Suppose we insert it after the i th vertex:



The electron propagators to the left of the new photon then have their momenta increased by k.

Let us now look at the values of these diagrams, with the polarization vector $\epsilon_\mu(k)$ replaced by k_μ. The product of k_μ with the new vertex is conveniently written:

$$-iek_\mu\gamma^\mu = -ie\left[(\not{p}_i + \not{k} - m) - (\not{p}_i - m)\right].$$

Multiplying by the adjacent electron propagators, we obtain

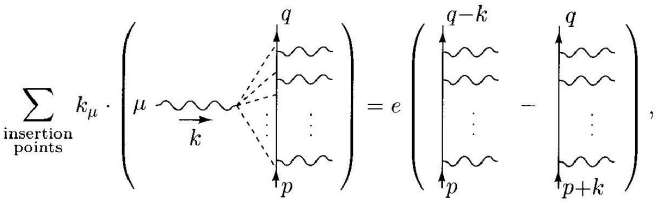
The diagram with the photon inserted at position i therefore has the structure

$$\times \left(\frac{i}{\not{p}_{i-1} - m}\right)\gamma^{\lambda_{i-1}} \cdots .$$

Similarly, the diagram with the photon inserted at position $i - 1$ has the structure

$$\times \left(\frac{i}{\not{p}_{i-1} - m} - \frac{i}{\not{p}_{i-1} + \not{k} - m}\right)\gamma^{\lambda_{i-1}} \cdots .$$

Note that the first term of this expression cancels the second term of the previous expression. A similar cancellation occurs between any other pair of
diagrams with adjacent insertions. When we sum over all possible insertion points along the line, everything cancels except the unpaired terms at the ends. The unpaired term coming from insertion after the last vertex (on the far left) is just e times the value of the original diagram; the other unpaired term, from insertion before the first vertex, is identical except for a minus sign and the replacement of p by $p + k$ everywhere. Diagrammatically, our result is



where we have renamed $p' + k \to q$ for the sake of symmetry.

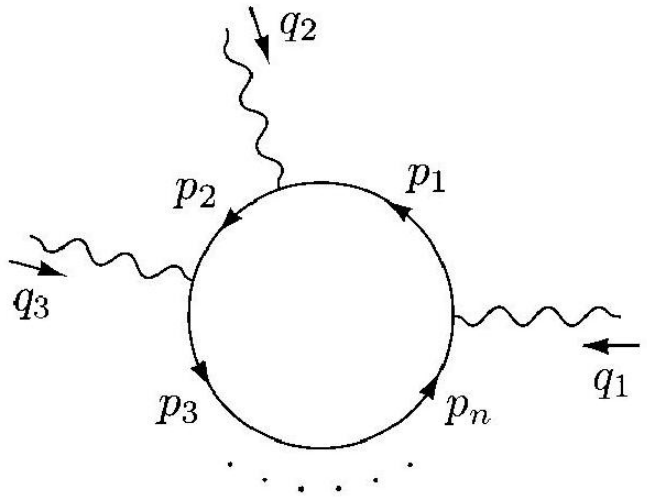
In each diagram on the left-hand side of (7.66), the momentum entering the electron line is p and the momentum exiting is q. According to the LSZ formula, we can extract from each diagram a contribution to an S-matrix element by taking the coefficient of the product of poles

$$\left(\frac{i}{\not{q} - m}\right)\left(\frac{i}{\not{p} - m}\right)$$

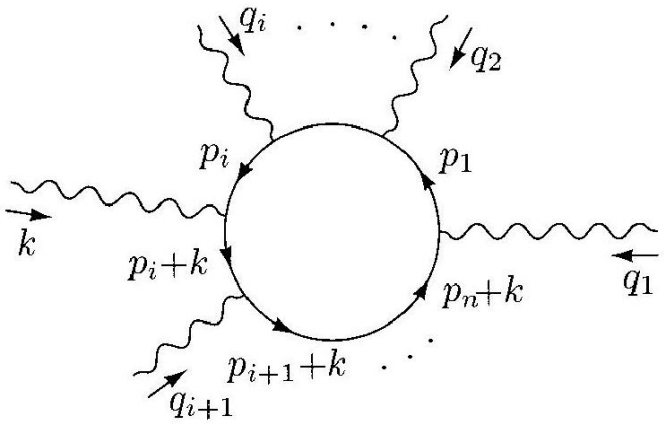
The terms on the right-hand side of (7.66) each contain one of these poles, but neither contains both poles. Thus the right-hand side of (7.66) contributes nothing to the S-matrix.*

To complete the proof of the Ward-Takahashi identity, we must consider the case in which our photon attaches to an internal electron loop. Before the insertion of the photon, a typical loop

looks like this:



The electron propagators have momenta $p_1, p_1 + q_2 = p_2$, and so on up to p_n. Suppose now that we insert the photon $\gamma(k)$ between vertices i and $i+1$:



We now have an additional momentum k running around the loop from the new vertex; by convention, this momentum exits at vertex 1 .

To evaluate the sum over all such insertions into the loop, apply identity (7.65) to each diagram. For the diagram in which the photon is inserted between vertices 1 and 2 , we obtain

$$-e\int\frac{d^4p_1}{(2\pi)^4}\,\mathrm{tr}\left[\left(\frac{i}{\not p_n+\not k-m}\right)\gamma^{\lambda_n}\cdots\left(\frac{i}{\not p_2+\not q_2-m}\right)\gamma^{\lambda_2}\right.$$
$$\left.\times\left(\frac{i}{\not p_1-m}-\frac{i}{\not p_1+\not k-m}\right)\gamma^{\lambda_1}\right].$$

The first term will be canceled by one of the terms from the diagram with the photon inserted between vertices 2 and 3 . Similar cancellations take place between terms from other pairs of adjacent insertions. When we sum over all n insertion points we are left with

[6]*This step of the argument is straightforward only if we have arranged the perturbation series so that the propagator contains m rather than m_0. We will do this in Chapter 10.

$$-e\int\frac{d^4p_1}{(2\pi)^4}\,\mathrm{tr}\left[\left(\frac{i}{\not p_n-m}\right)\gamma^{\lambda_n}\left(\frac{i}{\not p_{n-1}-m}\right)\gamma^{\lambda_{n-1}}\cdots\left(\frac{i}{\not p_1-m}\right)\gamma^{\lambda_1}\right.$$
$$\left.-\left(\frac{i}{\not p_n+\not k-m}\right)\gamma^{\lambda_n}\left(\frac{i}{\not p_{n-1}+\not b-m}\right)\gamma^{\lambda_{n-1}}\cdots\left(\frac{i}{\not p_1+\not b-m}\right)\gamma^{\lambda_1}\right]. \tag{7.67}$$

Shifting the integration variable from p_1 to p_1+k in the second term, we see that the two remaining terms cancel. Thus the diagrams in which the photon is inserted along a closed loop add up to zero.

We are now ready to assemble the pieces of the proof. Suppose that the amplitude $\mathcal{M}$ has $2n$ external electron lines, n incoming and n outgoing. Label
the incoming momenta p_i and the outgoing momenta q_i:

$\mathcal{M}(k;p_1\cdots p_n;q_1\cdots q_n)=$ 
(The amplitude can also involve an arbitrary number of additional external photons.) The amplitude $\mathcal{M}_0$ lacks the photon $\gamma(k)$ but is otherwise identical. To form $k_\mu\mathcal{M}^\mu$ from $\mathcal{M}_0$ we must sum over all diagrams that contribute to $\mathcal{M}_0$, and for each diagram, sum over all points at which the photon could be inserted. Summing over insertion points along an internal loop in any diagram gives zero. Summing over insertion points along a through-going line in any diagram gives a contribution of the form (7.66). Summing over all insertion points for any particular diagram, we obtain

$\sum_{\substack{\text{insertion}\\\text{points}}} k_\mu\cdot$ 
where the shaded circle represents any particular diagram that contributes to $\mathcal{M}_0$. Summing over all such diagrams, we finally obtain

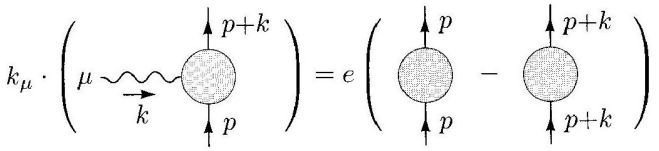
$$k_\mu\mathcal{M}^\mu(k;p_1\cdots p_n;q_1\cdots q_n)=e\sum_i[\mathcal{M}_0(p_1\cdots p_n;q_1\cdots(q_i-k)\cdots) \tag{7.68}$$
$$-\mathcal{M}_0(p_1\cdots(p_i+k)\cdots;q_1\cdots q_n)].$$

This is the Ward-Takahashi identity for correlation functions in QED. We saw below (7.66) that the right-hand side does not contribute to the S-matrix; thus in the special case where $\mathcal{M}$ is an S-matrix element, Eq. (7.68) reduces to the Ward identity (7.64).

Before discussing this identity further, we should mention a potential flaw in the above proof. In order to find the necessary cancellation in Eq. (7.67), we had to shift the integration variable by a constant. If the integral diverges, however, this shift is not permissible. Similarly, there may be divergent loopmomentum integrals in the expressions leading to Eq. (7.66). Here there is no explicit shift in the proof, but in practice one does generally perform a shift while evaluating the

integrals. In either case, ultraviolet divergences can potentially invalidate the Ward-Takahashi identity. We will see an example of this problem, as well as a general solution to it, in the next section.

The simplest example of the Ward-Takahashi identity involves, on the lefthand side, the three-point function with one entering and one exiting electron and one external photon:



The quantities on the right-hand side are exact electron propagators, evaluated at p and $(p+k)$ respectively. Label these quantities $S(p)$ and $S(p+k)$; from Eq. (7.23),

$$S(p) = \frac{i}{\not{p} - m - \Sigma(p)}.$$

The full three-point amplitude on the left-hand side can be rewritten, just as in Eq. (7.44), as a product of full propagators for the entering and exiting electrons, times an amputated scattering diagram. In this case, the amputated function is just the vertex $\Gamma^\mu(p+k, p)$. Then the Ward-Takahashi identity reads:

$$S(p+k)\left[-ie k_\mu \Gamma^\mu(p+k, p)\right] S(p) = e(S(p) - S(p+k))$$

To simplify this equation, multiply, on the left and right respectively, by the Dirac matrices $S^{-1}(p+k)$ and $S^{-1}(p)$. This gives

$$-ik_\mu \Gamma^\mu(p+k, p) = S^{-1}(p+k) - S^{-1}(p) \tag{7.69}$$

Often the term Ward-Takahashi identity is used to mean only this special case.

We can use identity (7.69) to obtain the general relation between the renormalization factors Z_1 and Z_2. We defined Z_1 in (7.47) by the relation

$$\Gamma^\mu(p+k, p) \to Z_1^{-1}\gamma^\mu \quad \text{as} \quad k \to 0$$

We defined Z_2 as the residue of the pole in $S(p)$:

$$S(p) \sim \frac{iZ_2}{\not{p} - m}$$

Setting p near mass shell and expanding (7.69) about $k = 0$, we find for the first-order terms on the left and right

$$-iZ_1^{-1} \not{k} = -iZ_2^{-1} \not{k},$$

that is,

$$Z_1 = Z_2 \tag{7.70}$$

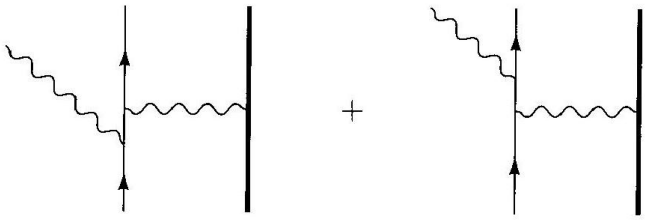
Thus, the Ward-Takahashi identity guarantees the exact cancellation of infinite rescaling factors in the electron scattering amplitude that we found at the end of Section 7.2. When combined with the correct formal expression

(7.46) for the electron form factors, this identity guarantees that $F_1(0) = 1$ to all orders in perturbation theory.

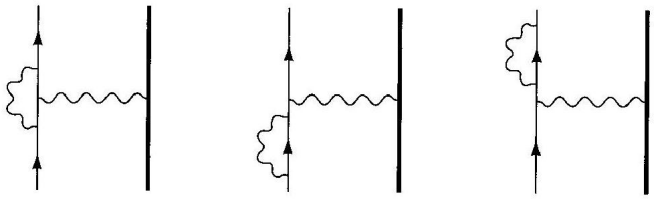
Often, in the literature, the terms Ward identity, current conservation, and gauge invariance are used interchangeably. This is quite natural, since the Ward identity is the diagrammatic expression of the conservation of the electric current, which is in turn a consequence of gauge invariance. In this book, however, we will distinguish these three concepts. By gauge invariance we mean the fundamental symmetry of the Lagrangian; by current conservation we mean the equation of motion that follows from this symmetry; and by the Ward identity we mean the diagrammatic identity that imposes the symmetry on quantum mechanical amplitudes.

17.5 7.5 Renormalization of the Electric Charge

At the beginning of Chapter 6 we set out to study the order- α radiative corrections to electron scattering from a heavy target. We evaluated (at least in the classical limit) the bremsstrahlung diagrams,

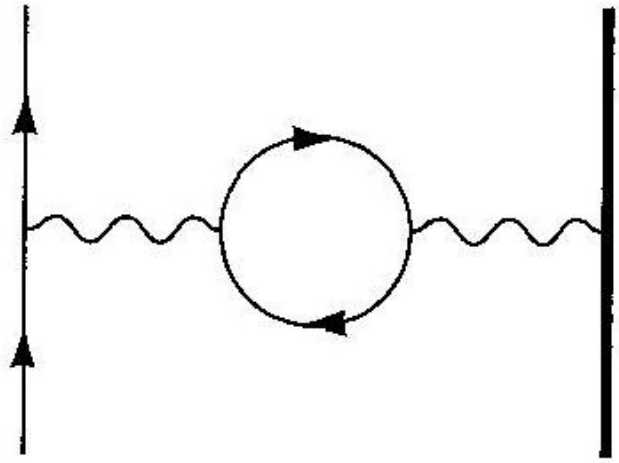


and also the corrections due to virtual photons:



Our discussion of field-strength renormalization in this chapter has finally clarified the role of the last two diagrams. In particular, we have seen that the Ward identity, through the relation $Z_1 = Z_2$, insures that the sum of the virtual photon corrections vanishes as the momentum transfer q goes to zero.

There is one remaining type of radiative correction to this process:

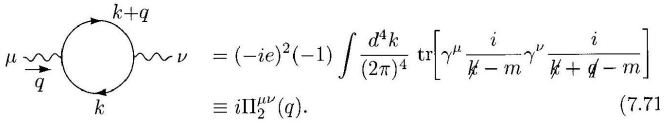


This is the order- α vacuum polarization diagram, also known as the photon self-energy. It can

be viewed as a modification to the photon structure by a
virtual electron-positron pair. This diagram will alter the effective field $A^\mu(x)$ seen by the scattered electron. It can potentially shift the overall strength of this field, and can also change its dependence on x (or in Fourier space, on q). In this section we will compute this diagram, and see that it has both of these effects.

Overview of Charge Renormalization

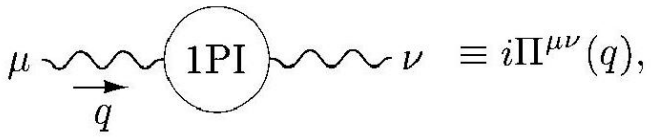
Before beginning a detailed calculation, let's ask what kind of an answer we expect and what its interpretation will be. The interesting part of the diagram is the electron loop:



$$= (-ie)^2(-1)\int \frac{d^4k}{(2\pi)^4}\,\mathrm{tr}\left[\gamma^\mu \frac{i}{\not k - m}\gamma^\nu \frac{i}{\not k + \not q - m}\right]$$

$$\equiv i\Pi_2^{\mu\nu}(q). \qquad (7.71$$

(The fermion loop factor of (-1) was derived in Eq. (4.120).) More generally, let us define $i\Pi^{\mu\nu}(q)$ to be the sum of all 1-particle-irreducible insertions into the photon propagator,



$$\equiv i\Pi^{\mu\nu}(q),$$

so that $\Pi_2^{\mu\nu}(q)$ is the second-order (in e) contribution to $\Pi^{\mu\nu}(q)$.
The only tensors that can appear in $\Pi^{\mu\nu}(q)$ are $g^{\mu\nu}$ and $q^\mu q^\nu$. The Ward identity, however, tells us that $q_\mu \Pi^{\mu\nu}(q) = 0$. This implies that $\Pi^{\mu\nu}(q)$ is proportional to the projector $(g^{\mu\nu} - q^\mu q^\nu/q^2)$. Furthermore, we expect that $\Pi^{\mu\nu}(q)$ will not have a pole at $q^2 = 0$; the only obvious source of such a pole would be a single-massless-particle intermediate state, which cannot occur in any 1 PI diagram. [†] It is therefore convenient to extract the tensor structure from $\Pi^{\mu\nu}$ in the following way:

$$\Pi^{\mu\nu}(q) = \left(q^2 g^{\mu\nu} - q^\mu q^\nu\right)\Pi\left(q^2\right) \qquad (7.73)$$

where $\Pi\left(q^2\right)$ is regular at $q^2 = 0$.
Using this notation, the exact photon two-point function is

$$\begin{aligned}
\sim_\mu = &\sim\sim\sim\sim \text{ 1PI } \sim + \sim \text{ 1PI } \sim \text{ 1PI } \sim + \cdots \\
&= \frac{-ig_{\mu\nu}}{q^2} + \frac{-ig_{\mu\rho}}{q^2}\left[i\left(q^2 g^{\rho\sigma} - q^\rho q^\sigma\right)\Pi\left(q^2\right)\right]\frac{-ig_{\sigma\nu}}{q^2} + \cdots \\
&= \frac{-ig_{\mu\nu}}{q^2} + \frac{-ig_{\mu\rho}}{q^2}\Delta_\nu^\rho \Pi\left(q^2\right) + \frac{-ig_{\mu\rho}}{q^2}\Delta_\sigma^\rho \Delta_\nu^\sigma \Pi^2\left(q^2\right) + \cdots
\end{aligned}$$

where $\Delta_\nu^\rho \equiv \delta_\nu^\rho - q^\rho q_\nu/q^2$. Noting that $\Delta_\sigma^\rho \Delta_\nu^\sigma = \Delta_\nu^\rho$, we can simplify this expression to
$$

$$\begin{aligned}
\widetilde{\mu}_\nu &= \frac{-ig_{\mu\nu}}{q^2} + \frac{-ig_{\mu\rho}}{q^2}\left(\delta_\nu^\rho - \frac{q^\rho q_\nu}{q^2}\right)\left(\Pi\left(q^2\right) + \Pi^2\left(q^2\right) + \cdots\right) \\
&= \frac{-i}{q^2\left(1 - \Pi\Pi\left(q^2\right)\right)}\left(g_{\mu\nu} - \frac{q_\mu q_\nu}{q^2}\right) + \frac{-i}{q^2}\left(\frac{q_\mu q_\nu}{q^2}\right) \qquad (7.74)
\end{aligned}$$

[6†] One can prove that there is no such pole, but the proof is nontrivial. Schwinger has shown that, in two spacetime dimensions, the singularity in Π_2 due to a pair of massless fermions is a pole rather than a cut; this is a famous counterexample to our argument. There is no such problem in four dimensions.

$$

In any S-matrix element calculation, at least one end of this exact propagator will connect to a fermion line. When we sum over all places along the line where it could connect, we must find, according to the Ward identity, that terms proportional to q_μ or q_ν vanish. For the purposes of computing S-matrix elements, therefore, we can abbreviate

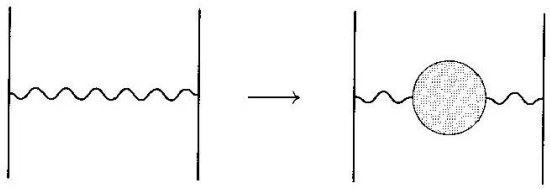
$$\widetilde{\mu}\sim\sim = \frac{-ig_{\mu\nu}}{q^2\left(1-\Pi\left(q^2\right)\right)} \tag{7.75}$$

Notice that as long as $\Pi\left(q^2\right)$ is regular at $q^2=0$, the exact propagator always has a pole at $q^2=0$. In other words, the photon remains absolutely massless at all orders in perturbation theory. This claim depends strongly on our use of the Ward identity in (7.73). If, for example, $\Pi^{\mu\nu}(q)$ contained a term $M^2g^{\mu\nu}$ (with no compensating $q^\mu q^\nu$ term), the photon mass would be shifted to M.

The residue of the $q^2=0$ pole is

$$\frac{1}{1-\Pi(0)} \equiv Z_3$$

The amplitude for any low- q^2 scattering process will be shifted by this factor, relative to the tree-level approximation:



or $\quad \cdots \dfrac{e^2 g_{\mu\nu}}{q^2} \cdots \longrightarrow \cdots \dfrac{Z_3\, e^2 g_{\mu\nu}}{q^2} \cdots .$

Since a factor of e lies at each end of the photon propagator, we can conveniently account for this shift by making the replacement $e \to \sqrt{Z_3}e$. This replacement is called charge renormalization; it is in many ways analogous to the mass renormalization introduced in Section 7.1. Note in particular that the "physical" electron charge measured in experiments is $\sqrt{Z_3}e$. We will therefore shift our notation and call this quantity simply e. From now on we
will refer to the "bare" charge (the quantity that multiplies $A_\mu\bar{\psi}\gamma^\mu\psi$ in the Lagrangian) as e_0. We then have

$$\text{(physical charge)} \;= e = \sqrt{Z_3}e_0 = \sqrt{Z_3}\cdot(\text{ bare charge }). \tag{7.76}$$

To lowest order, $Z_3=1$ and $e=e_0$.
In addition to this constant shift in the strength of the electric charge, $\Pi\left(q^2\right)$ has another effect. Consider a scattering process with nonzero q^2, and suppose that we have computed $\Pi\left(q^2\right)$ to leading order in α : $\Pi\left(q^2\right) \approx \Pi_2\left(q^2\right)$. The amplitude for the process will then involve the quantity

$$\frac{-ig_{\mu\nu}}{q^2}\left(\frac{e_0^2}{1-\Pi\left(q^2\right)}\right) \underset{\mathcal{O}(\alpha)}{=} \frac{-ig_{\mu\nu}}{q^2}\left(\frac{e^2}{1-\left[\Pi_2\left(q^2\right)-\Pi_2(0)\right]}\right)$$

(Swapping e^2 for e_0^2 does not matter to lowest order.) The quantity in parentheses can be interpreted as a q^2-dependent electric charge. The full effect of replacing the tree-level photon propagator with the exact photon propagator is therefore to replace

$$\alpha_0 \to \alpha_{\text{eff}}\left(q^2\right) = \frac{e_0^2/4\pi}{1-\Pi\left(q^2\right)} \underset{\mathcal{O}(\alpha)}{=} \frac{\alpha}{1-\left[\Pi_2\left(q^2\right)-\Pi_2(0)\right]} \tag{7.77}$$

(To leading order we could just as well bring the Π-terms into the numerator; but we will see in Chapter 12 that in this form, the expression is true to all orders when Π_2 is replaced by Π.)

Computation of Π_2

Having worked so hard to interpret $\Pi_2\left(q^2\right)$, we had better calculate it. Going back to (7.71), we have

$$\begin{aligned} i\Pi_2^{\mu\nu}(q) &= -(-ie)^2 \int \frac{d^4k}{(2\pi)^4}\,\mathrm{tr}\left[\gamma^\mu \frac{i(\not{k}+m)}{k^2-m^2}\gamma^\nu \frac{i(\not{k}+\not{q}+m)}{(k+q)^2-m^2}\right] \\ &= -4e^2 \int \frac{d^4k}{(2\pi)^4} \frac{k^\mu(k+q)^\nu + k^\nu(k+q)^\mu - g^{\mu\nu}\left(k\cdot(k+q)-m^2\right)}{\left(k^2-m^2\right)\left((k+q)^2-m^2\right)} \end{aligned} \tag{7.78}$$

We have written e and m instead of e_0 and m_0 for convenience, since the difference would give only an order- α^2 contribution to $\Pi^{\mu\nu}$.

Now introduce a Feynman parameter to combine the denominator factors:

$$\begin{aligned} \frac{1}{\left(k^2-m^2\right)\left((k+q)^2-m^2\right)} &= \int_0^1 dx \frac{1}{\left(k^2+2xk\cdot q+xq^2-m^2\right)^2} \\ &= \int_0^1 dx \frac{1}{\left(\ell^2+x(1-x)q^2-m^2\right)^2} \end{aligned}$$

where $\ell = k + xq$. In terms of ℓ, the numerator of (7.78) is

$$\begin{aligned} \text{Numerator } &= 2\ell^\mu\ell^\nu - g^{\mu\nu}\ell^2 - 2x(1-x)q^\mu q^\nu + g^{\mu\nu}\left(m^2+x(1-x)q^2\right) \\ &\quad + (\text{ terms linear in } \ell) \end{aligned}$$

Performing a Wick rotation and substituting $\ell^0 = i\ell_E^0$, we obtain

$$\begin{aligned} i\Pi_2^{\mu\nu}(q) = -4ie^2 \int_0^1 dx \int \frac{d^4\ell_E}{(2\pi)^4} \\ \times \frac{-\frac{1}{2}g^{\mu\nu}\ell_E^2 + g^{\mu\nu}\ell_E^2 - 2x(1-x)q^\mu q^\nu + g^{\mu\nu}\left(m^2+x(1-x)q^2\right)}{\left(\ell_E^2+\Delta\right)^2} \end{aligned} \tag{7.79}$$

where $\Delta = m^2 - x(1-x)q^2$. This integral is very badly ultraviolet divergent. If we were to cut it off at $\ell_E = \Lambda$, we would find for the leading term,

$$i\Pi_2^{\mu\nu}(q) \propto e^2\Lambda^2 g^{\mu\nu}$$

with no compensating $q^\mu q^\nu$ term. This result violates the Ward identity; it would give the photon an infinite mass $M \propto e\Lambda$.

Our proof of the Ward identity has failed, in precisely the way anticipated at the end of the previous section: The shift of the integration variable in (7.67) is not permissible when the integral is divergent. In our present calculation, the failure of the Ward identity is catastrophic: It leads

to an infinite photon mass, [‡] in conflict with experiment. Fortunately, there is a way to rescue the Ward identity.

In the above analysis we regulated the divergent integral in the most straightforward and most naive way: by cutting it off at a large momentum Λ. But other regulators are possible, and some will in fact preserve the Ward identity. In our computations of the vertex and electron self-energy diagrams, we used a Pauli-Villars regulator. This regulator preserved the relation $Z_1 = Z_2$, a consequence of the Ward identity; a naive cutoff does not (see Problem 7.2). We could fix our present computation by introducing Pauli-Villars fermions. Unfortunately, several sets of fermions are required, making the method rather complicated.* We will use a simpler method, dimensional regularization, due to 't Hooft and Veltman. [†] Dimensional regularization preserves the symmetries of QED and also of a wide class of more general theories.

The question of which regulator to use has no a priori answer in quantum field theory. Often the choice has no effect on the predictions of the theory.

When two regulators give different answers for observable quantities, it is generally because some symmetry (such as the Ward identity) is being violated by one (or both) of them. In these cases we take the symmetry to be fundamental and demand that it be preserved by the regulator. But the validity of this choice cannot be proven; we are adopting the symmetry as a new axiom.

Dimensional Regularization

The idea of dimensional regularization is very simple to state: Compute the Feynman diagram as an analytic function of the dimensionality of spacetime, d. For sufficiently small d, any loop-momentum integral will converge and therefore the Ward identity can be proved. The final expression for any observable quantity should have a well-defined limit as $d \to 4$.

Let us do a practice calculation to see how this technique works. We consider spacetime to have one time dimension and $(d-1)$ space dimensions. Then we can Wick-rotate Feynman integrals as before, to give integrals over a d-dimensional Euclidean space. A typical example is

$$\int \frac{d^d \ell_E}{(2\pi)^d} \frac{1}{\left(\ell_E^2 + \Delta\right)^2} = \int \frac{d\Omega_d}{(2\pi)^d} \cdot \int_0^\infty d\ell_E \frac{\ell_E^{d-1}}{\left(\ell_E^2 + \Delta\right)^2} \tag{7.80}$$

The first factor in (7.80) contains the area of a unit sphere in d dimensions. To compute it, use the following trick:

$$\begin{aligned}
(\sqrt{\pi})^d &= \left(\int dx e^{-x^2}\right)^d = \int d^d x \exp\left(-\sum_{i=1}^d x_i^2\right) \\
&= \int d\Omega_d \int_0^\infty dx x^{d-1} e^{-x^2} = \left(\int d\Omega_d\right) \cdot \frac{1}{2} \int_0^\infty d\left(x^2\right) \left(x^2\right)^{\frac{d}{2}-1} e^{-\left(x^2\right)} \\
&= \left(\int d\Omega_d\right) \cdot \frac{1}{2} \Gamma(d/2)
\end{aligned}$$

So the area of a d-dimensional unit sphere is

[6‡] We could still make the observed photon mass zero by adding a compensating infinite photon mass term to the Lagrangian. More generally, we could add terms to the Lagrangian to make the Ward identity valid for any n-point correlation function. This procedure would give the same results as the one we are about to follow, but would be much more complicated.

*This method is presented in Bjorken and Drell (1964), p. 154.

[†] G. 't Hooft and M. J. G. Veltman, Nucl. Phys. B44, 189 (1972).

$$\int d\Omega_d = \frac{2\pi^{d/2}}{\Gamma(d/2)} \tag{7.81}$$

This formula reproduces the familiar special cases:

d	$\Gamma(d/2)$	$\int d\Omega_d$
1	$\sqrt{\pi}$	2
2	1	2π
3	$\sqrt{\pi}/2$	4π
4	1	$2\pi^2$

The second factor in (7.80) is

$$\begin{aligned}\int_0^\infty d\ell \frac{\ell^{d-1}}{\left(\ell^2+\Delta\right)^2} &= \frac{1}{2}\int_0^\infty d\left(\ell^2\right)\frac{\left(\ell^2\right)^{\frac{d}{2}-1}}{\left(\ell^2+\Delta\right)^2} \\ &= \frac{1}{2}\left(\frac{1}{\Delta}\right)^{2-\frac{d}{2}}\int_0^1 dx x^{1-\frac{d}{2}}(1-x)^{\frac{d}{2}-1}\end{aligned}$$

where we have substituted $x = \Delta/\left(\ell^2+\Delta\right)$ in the second line. Using the definition of the beta function,

$$\int_0^1 dx x^{\alpha-1}(1-x)^{\beta-1} = B(\alpha,\beta) = \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha+\beta)} \tag{7.82}$$

we can easily evaluate the integral over x. The final result for the d-dimensional integral is

$$\int \frac{d^d\ell_E}{(2\pi)^d}\frac{1}{\left(\ell_E^2+\Delta\right)^2} = \frac{1}{(4\pi)^{d/2}}\frac{\Gamma\left(2-\frac{d}{2}\right)}{\Gamma(2)}\left(\frac{1}{\Delta}\right)^{2-\frac{d}{2}}$$

Since $\Gamma(z)$ has isolated poles at $z = 0, -1, -2, ...$, this integral has isolated poles at $d = 4, 6, 8, ...$ To find the behavior near $d = 4$, define $\epsilon = 4 - d$, and use the approximation ‡

$$\Gamma\left(2-\frac{d}{2}\right) = \Gamma(\epsilon/2) = \frac{2}{\epsilon} - \gamma + \mathcal{O}(\epsilon) \tag{7.83}$$

where $\gamma \approx .5772$ is the Euler-Mascheroni constant. (This constant will always cancel in observable quantities.) The integral is then

$$\int \frac{d^d\ell_E}{(2\pi)^d}\frac{1}{\left(\ell_E^2+\Delta\right)^2} \underset{d\to 4}{\longrightarrow} \frac{1}{(4\pi)^2}\left(\frac{2}{\epsilon} - \log\Delta - \gamma + \log(4\pi) + \mathcal{O}(\epsilon)\right) \tag{7.84}$$

When we defined this integral with a Pauli-Villars regulator in Eq. (7.18), we found

$$\int \frac{d^4\ell_E}{(2\pi)^4}\frac{1}{\left(\ell_E^2+\Delta\right)^2} \underset{\Lambda\to\infty}{\longrightarrow} \frac{1}{(4\pi)^2}\left(\log\frac{x\Lambda^2}{\Delta} + \mathcal{O}\left(\Lambda^{-1}\right)\right)$$

Thus the $1/\epsilon$ pole in dimensional regularization corresponds to a logarithmic divergence in the momentum integral. Note the curious fact that (7.84)

‡ This expansion follows immediately from the infinite product representation

$$\frac{1}{\Gamma(z)} = ze^{\gamma z}\prod_{n=1}^{\infty}\left(1+\frac{z}{n}\right)e^{-z/n}$$

involves the logarithm of Δ, a dimensionful quantity. The scale of the logarithm is hidden in the $1/\epsilon$ term, and appears explicitly when the divergence is canceled.

You can easily verify the more general integration formulae,

$$\int \frac{d^d\ell_E}{(2\pi)^d}\frac{1}{(\ell_E^2+\Delta)^n} = \frac{1}{(4\pi)^{d/2}}\frac{\Gamma\left(n-\frac{d}{2}\right)}{\Gamma(n)}\left(\frac{1}{\Delta}\right)^{n-\frac{d}{2}} \tag{7.85}$$

$$\int \frac{d^d\ell_E}{(2\pi)^d}\frac{\ell_E^2}{(\ell_E^2+\Delta)^n} = \frac{1}{(4\pi)^{d/2}}\frac{d}{2}\frac{\Gamma\left(n-\frac{d}{2}-1\right)}{\Gamma(n)}\left(\frac{1}{\Delta}\right)^{n-\frac{d}{2}-1} \tag{7.86}$$

In d dimensions, $g^{\mu\nu}$ obeys $g_{\mu\nu}g^{\mu\nu} = d$. Thus, if the numerator of a symmetric integrand contains $\ell^\mu\ell^\nu$, we should replace

$$\ell^\mu\ell^\nu \to \frac{1}{d}\ell^2 g^{\mu\nu} \tag{7.87}$$

in analogy with Eq. (6.46). In QED, the Dirac matrices can be manipulated as a set of d matrices satisfying

$$\{\gamma^\mu,\gamma^\nu\} = 2g^{\mu\nu}, \quad \mathrm{tr}[\mathbf{1}] = 4 \tag{7.88}$$

In manipulating Eq. (7.78), these rules give the same result as the purely four-dimensional rules. However, in the evaluation of other diagrams, there are additional contributions of order ϵ. In particular, the contraction identities (5.9) are modified in $d = 4-\epsilon$ to

$$\begin{aligned}\gamma^\mu\gamma^\nu\gamma_\mu &= -(2-\epsilon)\gamma^\nu\\ \gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu &= 4g^{\nu\rho} - \epsilon\gamma^\nu\gamma^\rho\\ \gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\mu &= -2\gamma^\sigma\gamma^\rho\gamma^\nu + \epsilon\gamma^\nu\gamma^\rho\gamma^\sigma\end{aligned} \tag{7.89}$$

These extra terms can contribute to the final value of the Feynman diagram if they multiply a factor ϵ^{-1} from a divergent integral. In QED at one-loop order, such extra terms appear in the vertex and self-energy diagrams but cancel when these diagrams are combined to compute an observable quantity.

Computation of Π_2, Continued

Now let us apply these dimensional regularization formulae to the momentum integral in (7.79). The unpleasant terms with ℓ^2 in the numerator give

$$\begin{aligned}\int \frac{d^d\ell_E}{(2\pi)^d}\frac{\left(-\frac{2}{d}+1\right)g^{\mu\nu}\ell_E^2}{\left(\ell_E^2+\Delta\right)^2} &= \frac{-1}{(4\pi)^{d/2}}\left(1-\frac{d}{2}\right)\Gamma\left(1-\frac{d}{2}\right)\left(\frac{1}{\Delta}\right)^{1-\frac{d}{2}}g^{\mu\nu}\\ &= \frac{1}{(4\pi)^{d/2}}\Gamma\left(2-\frac{d}{2}\right)\left(\frac{1}{\Delta}\right)^{2-\frac{d}{2}}\cdot(-\Delta g^{\mu\nu})\end{aligned}$$

We would have expected a pole at $d = 2$, since the quadratic divergence in 4 dimensions becomes a logarithmic divergence in 2 dimensions. But the pole cancels. The Ward identity is working.

Evaluating the remaining terms in (7.79) and using $\Delta = m^2 - x(1-x)q^2$, we obtain

$$\begin{aligned} i\Pi_2^{\mu\nu}(q) =& -4ie^2 \int_0^1 dx \frac{1}{(4\pi)^{d/2}} \frac{\Gamma\left(2-\frac{d}{2}\right)}{\Delta^{2-d/2}} \\ & \times \left[g^{\mu\nu}\left(-m^2 + x(1-x)q^2\right) + g^{\mu\nu}\left(m^2 + x(1-x)q^2\right) - 2x(1-x)q^\mu q^\nu\right] \\ =& \left(q^2 g^{\mu\nu} - q^\mu q^\nu\right) \cdot i\Pi_2\left(q^2\right) \end{aligned}$$

where

$$\begin{aligned} \Pi_2\left(q^2\right) =& \frac{-8e^2}{(4\pi)^{d/2}} \int_0^1 dx x(1-x) \frac{\Gamma\left(2-\frac{d}{2}\right)}{\Delta^{2-d/2}} \\ \xrightarrow[d\to 4]{} & -\frac{2\alpha}{\pi} \int_0^1 dx x(1-x) \left(\frac{2}{\epsilon} - \log\Delta - \gamma + \log(4\pi)\right) \quad (\epsilon = 4-d) \end{aligned} \tag{7.90}$$

With dimensional regularization, $\Pi_2^{\mu\nu}(q)$ indeed takes the form required by the Ward identity. But it is still logarithmically divergent.

We can now compute the order- α shift in the electric charge:

$$\frac{e^2 - e_0^2}{e_0^2} = \delta Z_3 \overset{\mathcal{O}(\alpha)}{=} \Pi_2(0) \approx -\frac{2\alpha}{3\pi\epsilon}$$

The bare charge is infinitely larger than the observed charge. But this difference is not observable. What can be observed is the q^2 dependence of the effective electric charge (7.77). This quantity depends on the difference

$$\widehat{\Pi}_2\left(q^2\right) \equiv \Pi_2\left(q^2\right) - \Pi_2(0) = -\frac{2\alpha}{\pi} \int_0^1 dx x(1-x) \log\left(\frac{m^2}{m^2 - x(1-x)q^2}\right) \tag{7.91}$$

which is independent of ϵ in the limit $\epsilon \to 0$. For the rest of this section we will investigate what physics this expression contains.

Interpretation of Π_2

First consider the analytic structure of $\widehat{\Pi}_2\left(q^2\right)$. For $q^2 < 0$, as is the case when the photon propagator is in the t - or u-channel, $\widehat{\Pi}_2\left(q^2\right)$ is manifestly real and analytic. But for an s-channel process, q^2 will be positive. The logarithm function has a branch cut when its argument becomes negative, that is, when

$$m^2 - x(1-x)q^2 < 0$$

The product $x(1-x)$ is at most $1/4$, so $\widehat{\Pi}_2\left(q^2\right)$ has a branch cut beginning at

$$q^2 = 4m^2$$

at the threshold for creation of a real electron-positron pair.

Let us calculate the imaginary part of $\widehat{\Pi}_2$ for $q^2 > 4m^2$. For any fixed q^2, the x-values that contribute are between the points $x = \frac{1}{2} \pm \frac{1}{2}\beta$, where $\beta = \sqrt{1 - 4m^2/q^2}$. Since $\mathrm{Im}[\log(-X \pm i\epsilon)] = \pm\pi$, we have

$$\begin{aligned}
\mathrm{Im}\left[\widehat{\Pi}_2\left(q^2 \pm i\epsilon\right)\right] &= -\frac{2\alpha}{\pi}(\pm\pi)\int_{\frac{1}{2}-\frac{1}{2}\beta}^{\frac{1}{2}+\frac{1}{2}\beta} dx x(1-x) \\
&= \mp 2\alpha \int_{-\beta/2}^{\beta/2} dy \left(\frac{1}{4} - y^2\right) \quad \left(y \equiv x - \frac{1}{2}\right) \\
&= \mp\frac{\alpha}{3}\sqrt{1 - \frac{4m^2}{q^2}}\left(1 + \frac{2m^2}{q^2}\right)
\end{aligned} \tag{7.92}$$

This dependence on q^2 is exactly the same as in Eq. (5.13), the cross section for production of a fermion-antifermion pair. That is just what we would expect from the unitarity relation shown in Fig. 7.6(b); the cut through the diagram for forward Bhabha scattering gives the total cross section for $e^+e^- \to f\bar{f}$. The parameter β is precisely the velocity of the fermions in the center-of-mass frame.

Next let us examine how $\widehat{\Pi}_2(q^2)$ modifies the electromagnetic interaction, as determined by Eq. (7.77). In the nonrelativistic limit it makes sense to compute the potential $V(r)$. For the interaction between unlike charges, we have, in analogy with Eq. (4.126),

$$V(\mathbf{x}) = \int \frac{d^3q}{(2\pi)^3} e^{i\mathbf{q}\cdot\mathbf{x}} \frac{-e^2}{|\mathbf{q}|^2\left[1 - \widehat{\Pi}_2\left(-|\mathbf{q}|^2\right)\right]} \tag{7.93}$$

Expanding $\widehat{\Pi}_2$ for $|q^2| \ll m^2$, we obtain

$$V(\mathbf{x}) = -\frac{\alpha}{r} - \frac{4\alpha^2}{15m^2}\delta^{(3)}(\mathbf{x}) \tag{7.94}$$

The correction term indicates that the electromagnetic force becomes much stronger at small distances. This effect can be measured in the hydrogen atom, where the energy levels are shifted by

$$\Delta E = \int d^3x |\psi(\mathbf{x})|^2 \cdot \left(-\frac{4\alpha^2}{15m^2}\delta^{(3)}(\mathbf{x})\right) = -\frac{4\alpha^2}{15m^2}|\psi(0)|^2$$

The wavefunction $\psi(\mathbf{x})$ is nonzero at the origin only for s-wave states. For the $2S$ state, the shift is

$$\Delta E = -\frac{4\alpha^2}{15m^2} \cdot \frac{\alpha^3 m^3}{8\pi} = -\frac{\alpha^5 m}{30\pi} = -1.123 \times 10^{-7}\mathrm{eV}$$

This is a (small) part of the Lamb shift splitting listed in Table 6.1.

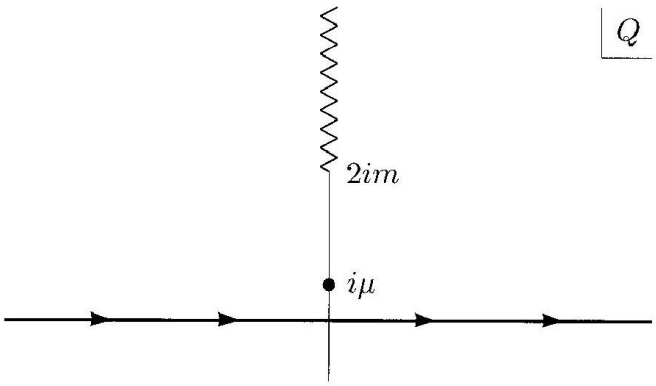


Figure 7.7. Contour for evaluating the effective strength of the electromagnetic interaction in the nonrelativistic limit. The pole at $Q = i\mu$ gives the Coulomb potential. The branch cut gives the order- α correction due to vacuum polarization.

The delta function in Eq. (7.94) is only an approximation; to find the true range of the correction term, we write Eq. (7.93) in the form

$$V(\mathbf{x}) = \frac{ie^2}{(2\pi)^2 r} \int_{-\infty}^{\infty} dQ \frac{Qe^{iQr}}{Q^2 + \mu^2} \left[1 + \widehat{\Pi}_2\left(-Q^2\right)\right] \quad (Q \equiv |\mathbf{q}|)$$

where we have inserted a photon mass μ to regulate the Coulomb potential. To perform this integral we push the contour upward (see Fig. 7.7). The leading contribution comes from the pole at $Q = i\mu$, giving the Coulomb potential, $-\alpha/r$. But there is an additional contribution from the branch cut, which begins at $Q = 2mi$. The real part of the integrand is the same on both sides of the cut, so the only contribution to the integral comes from the imaginary part of $\widehat{\Pi}_2$. Defining $q = -iQ$, we find that the contribution from the cut is

$$\begin{aligned}
\delta V(r) &= \frac{-e^2}{(2\pi)^2 r} \cdot 2 \int_{2m}^{\infty} dq \frac{e^{-qr}}{q} \operatorname{Im}\left[\widehat{\Pi}_2\left(q^2 - i\epsilon\right)\right] \\
&= -\frac{\alpha}{r}\frac{2}{\pi} \int_{2m}^{\infty} dq \frac{e^{-qr}}{q} \frac{\alpha}{3} \sqrt{1 - \frac{4m^2}{q^2}} \left(1 + \frac{2m^2}{q^2}\right)
\end{aligned}$$

When $r \gg 1/m$, this integral is dominated by the region where $q \approx 2m$. Approximating the integrand in this region and substituting $t = q - 2m$, we find

$$\begin{aligned}
\delta V(r) &= -\frac{\alpha}{r} \cdot \frac{2}{\pi} \int_0^{\infty} dt \frac{e^{-(t+2m)r}}{2m} \frac{\alpha}{3} \sqrt{\frac{t}{m}} \left(\frac{3}{2}\right) + \mathcal{O}(t) \\
&\approx -\frac{\alpha}{r} \cdot \frac{\alpha}{4\sqrt{\pi}} \frac{e^{-2mr}}{(mr)^{3/2}}
\end{aligned}$$

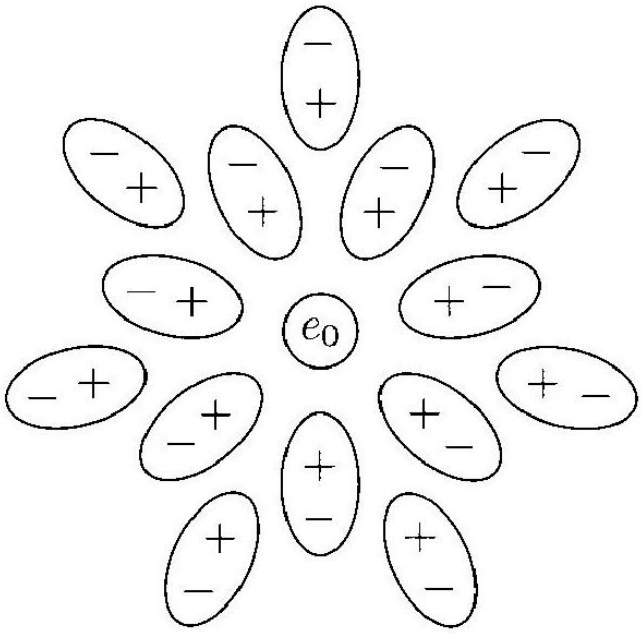

Figure 7.8. Virtual e^+e^-pairs are effectively dipoles of length $\sim 1/m$, which screen the bare charge of the electron.

so that

$$V(r) = -\frac{\alpha}{r}\left(1 + \frac{\alpha}{4\sqrt{\pi}}\frac{e^{-2mr}}{(mr)^{3/2}} + \cdots\right) \tag{7.95}$$

Thus the range of the correction term is roughly the electron Compton wavelength, $1/m$. Since hydrogen wavefunctions are nearly constant on this scale, the delta function in Eq. (7.94) was a good approximation. The radiative correction to $V(r)$ is called the Uehling potential.

We can interpret the correction as being due to screening. At $r \gtrsim 1/m$, virtual e^+e^-pairs make the vacuum a dielectric medium in which the apparent charge is less than the true charge (see Fig. 7.8). At smaller distances we begin to penetrate the polarization cloud and see the bare charge. This phenomenon is known as vacuum polarization.

Now consider the opposite limit: small distance or $-q^2 \gg m^2$. Equation (7.91) then becomes

$$\begin{aligned}\widehat{\Pi}_2\left(q^2\right) &\approx \frac{2\alpha}{\pi}\int_0^1 dx x(1-x)\left[\log\left(\frac{-q^2}{m^2}\right) + \log(x(1-x)) + \mathcal{O}\left(\frac{m^2}{q^2}\right)\right] \\ &= \frac{\alpha}{3\pi}\left[\log\left(\frac{-q^2}{m^2}\right) - \frac{5}{3} + \mathcal{O}\left(\frac{m^2}{q^2}\right)\right].\end{aligned}$$

The effective coupling constant in this limit is therefore

$$\alpha_{\text{eff}}\left(q^2\right) = \frac{\alpha}{1 - \frac{\alpha}{3\pi}\log\left(\frac{-q^2}{Am^2}\right)} \tag{7.96}$$

where $A = \exp(5/3)$. The effective electric charge becomes much larger at small distances, as we penetrate the screening cloud of virtual electronpositron pairs.

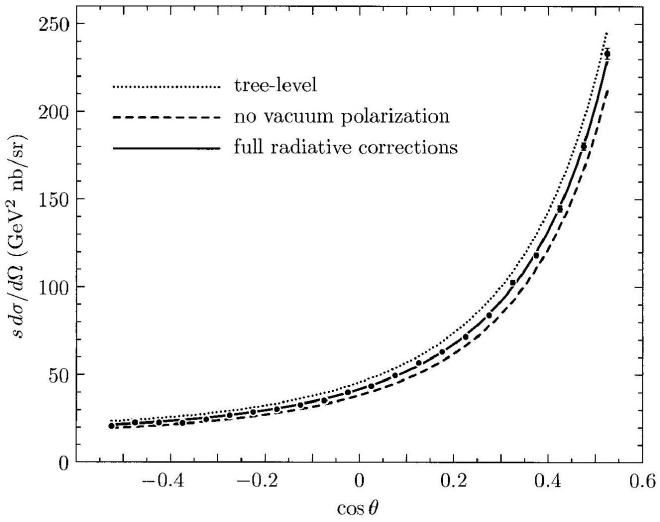

Figure 7.9. Differential cross section for Bhabha scattering, $e^+e^- \to e^+e^-$, at $E_{\rm cm} = 29$GeV, as measured by the HRS collaboration, M. Derrick, et. al., Phys. Rev. D34, 3286 (1986). The upper curve is the order- α^2 prediction derived in Problem 5.2, plus a very small ($\sim 2\%$) correction due to the weak interaction. The lower curve includes all QED radiative corrections to order α^3 except the vacuum polarization contribution; note that these corrections depend on the experimental conditions, as explained in Chapter 6. The middle curve includes the vacuum polarization contribution as well, which increases the effective value of α^2 by about 10% at this energy.

The combined vacuum polarization effect of the electron and of heavier quarks and leptons causes the value of $\alpha_{\rm eff}\ (q^2)$ to increase by about 5% from $q = 0$ to $q = 30$GeV, and this effect is observed in high-energy experiments. Figure 7.9 shows the cross section for Bhabha scattering at $E_{\rm cm} = 29$GeV, and a comparison to QED with and without the vacuum polarization diagram.

We can write $\alpha_{\rm eff}$ as a function of r by setting $q = 1/r$. The behavior of $\alpha_{\rm eff}\,(r)$ for all r is sketched in Fig. 7.10. The idea of a distance-dependent (or "scale-dependent" or "running") coupling constant will be a major theme of the rest of this book.

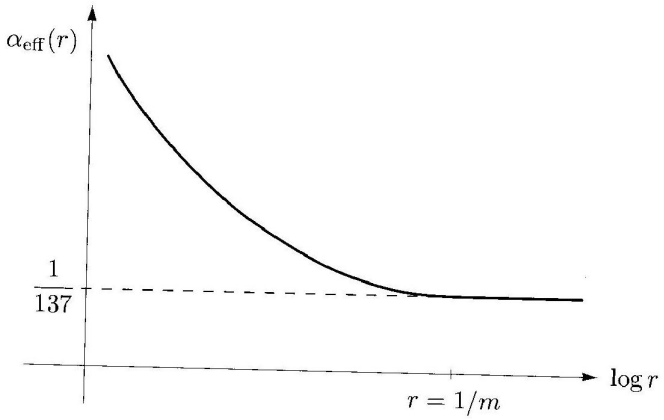

Figure 7.10. A qualitative sketch of the effective electromagnetic coupling constant generated by the one-loop vacuum polarization diagram, as a function of distance. The horizontal scale covers many orders of magnitude.

Problems

7.1 In Section 7.3 we used an indirect method to analyze the one-loop s-channel diagram for boson-boson scattering in ϕ^4 theory. To verify our indirect analysis, evaluate all three one-loop

diagrams, using the standard method of Feynman parameters. Check the validity of the optical theorem.

7.2 Alternative regulators in QED. In Section 7.5, we saw that the Ward identity can be violated by an improperly chosen regulator. Let us check the validity of the identity $Z_1 = Z_2$, to order α, for several choices of the regulator. We have already verified that the relation holds for Pauli-Villars regularization.

(a) Recompute δZ_1 and δZ_2, defining the integrals (6.49) and (6.50) by simply placing an upper limit Λ on the integration over ℓ_E. Show that, with this definition, $\delta Z_1 \neq \delta Z_2$.

(b) Recompute δZ_1 and δZ_2, defining the integrals (6.49) and (6.50) by dimensional regularization. You may take the Dirac matrices to be 4×4 as usual, but note that, in d dimensions,

$$g_{\mu\nu}\gamma^\mu\gamma^\nu = d.$$

Show that, with this definition, $\delta Z_1 = \delta Z_2$.

7.3 Consider a theory of elementary fermions that couple both to QED and to a Yukawa field ϕ:

$$H_{\text{int}} = \int d^3x \frac{\lambda}{\sqrt{2}}\phi\bar{\psi}\psi + \int d^3x e A_\mu \bar{\psi}\gamma^\mu\psi$$

(a) Verify that the contribution to Z_1 from the vertex diagram with a virtual ϕ equals the contribution to Z_2 from the diagram with a virtual ϕ. Use dimensional regularization. Is the Ward identity generally true in this theory?

(b) Now consider the renormalization of the $\phi\bar{\psi}\psi$ vertex. Show that the rescaling of this vertex at $q^2 = 0$ is not canceled by the correction to Z_2. (It suffices to compute the ultraviolet-divergent parts of the diagrams.) In this theory, the vertex and field-strength rescaling give additional shifts of the observable coupling constant relative to its bare value.

Radiation of Gluon Jets

Although we have discussed QED radiative corrections at length in the last two chapters, so far we have made no attempt to compute a full radiatively corrected cross section. The reason is of course that such calculations are quite lengthy. Nevertheless it would be dishonest to pretend that one understands radiative corrections after computing only isolated effects as we have done. This "final project" is an attempt to remedy this situation. The project is the computation of one of the simplest, but most important, radiatively corrected cross sections. You should finish Chapter 6 before starting this project, but you need not have read Chapter 7.

Strongly interacting particles-pions, kaons, and protons-are produced in e^+e^-annihilation when the virtual photon creates a pair of quarks. If one ignores the effects of the strong interactions, it is easy to calculate the total cross section for quark pair production. In this final project, we will analyze the first corrections to this formula due to the strong interactions.

Let us represent the strong interactions by the following simple model: Introduce a new massless vector particle, the gluon, which couples universally to quarks:

$$\Delta H = \int d^3x g \bar{\psi}_{fi}\gamma^\mu\psi_{fi}B_\mu$$

Here f labels the type ("flavor") of the quark (u, d, s, c, etc.) and $i = 1, 2, 3$ labels the color. The strong coupling constant g is independent of flavor and color. The electromagnetic coupling of quarks depends on the flavor, since the u and c quarks have charge $Q_f = +2/3$ while the d and s quarks have charge $Q_f = -1/3$. By analogy to α, let us define

$$\alpha_g = \frac{g^2}{4\pi}$$

In this exercise, we will compute the radiative corrections to quark pair production proportional to α_g.

This model of the strong interactions of quarks does not quite agree with the currently accepted theory of the strong interactions, quantum chromodynamics (QCD). However, all of the results that we will derive here are also
correct in QCD with the replacement

$$\alpha_g \to \frac{4}{3}\alpha_s$$

We will verify this claim in Chapter 17.
Throughout this exercise, you may ignore the masses of quarks. You may also ignore the mass of the electron, and average over electron and positron polarizations. To control infrared divergences, it will be necessary to assume that the gluons have a small nonzero mass μ, which can be taken to zero only at the end of the calculation. However (as we discussed in Problem 5.5), it is consistent to sum over polarization states of this massive boson by the replacement:

$$\sum \epsilon^\mu \epsilon^{\nu *} \to -g^{\mu\nu}$$

this also implies that we may use the propagator

$$B^\mu \overset{\Gamma}{B^\nu} = \frac{-ig^{\mu\nu}}{k^2 - \mu^2 + i\epsilon}$$

(a) Recall from Section 5.1 that, to lowest order in α and neglecting the effects of gluons, the total cross section for production of a pair of quarks of flavor f is

$$\sigma\left(e^+e^- \to \bar{q}q\right) = \frac{4\pi\alpha^2}{3s} \cdot 3Q_f^2$$

Compute the diagram contributing to $e^+e^- \to \bar{q}q$ involving one virtual gluon. Reduce this expression to an integral over Feynman parameters, and renormalize it by subtraction at $q^2 = 0$, following the prescription used in Eq. (6.55). Notice that the resulting expression can be considered as a correction to $F_1\left(q^2\right)$ for the quark. Argue that, for massless quarks, to all orders in α_g, the total cross section for production of a quark pair unaccompanied by gluons is

$$\sigma\left(e^+e^- \to \bar{q}q\right) = \frac{4\pi\alpha^2}{3s} \cdot 3\left|F_1\left(q^2 = s\right)\right|^2,$$

with $F_1\left(q^2 = 0\right) = Q_f$.
(b) Before we attempt to evaluate the Feynman parameter integrals in part (a), let us put this contribution aside and study the process $e^+e^- \to \bar{q}qg$, quark pair production with an additional gluon emitted. Before we compute the cross section, it will be useful to work out some kinematics. Let q be the total 4 -momentum of the reaction, let k_1 and k_2 be the 4 momenta of the final quark and antiquark, and let k_3 be the 4 -momentum of the gluon. Define

$$x_i = \frac{2k_i \cdot q}{q^2}, \quad i = 1, 2, 3$$

this is the ratio of the center-of-mass energy of particle i to the maximum available energy. Then show (i) $\sum x_i = 2$, (ii) all other Lorentz scalars involving only the final-state momenta can be computed in terms of the x_i and the particle masses, and (iii) the complete integral over 3-body phase space can be written as

$$\int d\Pi_3 = \prod_i \int \frac{d^3k_i}{(2\pi)^3}\frac{1}{2E_i}(2\pi)^4\delta^{(4)}\left(q - \sum_i k_i\right) = \frac{q^2}{128\pi^3}\int dx_1 dx_2$$

Find the region of integration for x_1 and x_2 if the quark and antiquark are massless but the gluon has mass μ.

(c) Draw the Feynman diagrams for the process $e^+e^- \to \bar{q}qg$, to leading order in α and α_g, and compute the differential cross section. You may throw away the information concerning the correlation between the initial beam axis and the directions of the final particles. This is conveniently done as follows: The usual trace tricks for evaluating the square of the matrix element give for this process a result of the structure

$$\int d\Pi_3 \frac{1}{4}\sum |\mathcal{M}|^2 = L_{\mu\nu}\int d\Pi_3 H^{\mu\nu}$$

where $L_{\mu\nu}$ represents the electron trace and $H^{\mu\nu}$ represents the quark trace. If we integrate over all parameters of the final state except x_1 and x_2, which are scalars, the only preferred 4 -vector characterizing the final state is q^μ. On the other hand, $H_{\mu\nu}$ satisfies

$$q^\mu H_{\mu\nu} = H_{\mu\nu}q^\nu = 0$$

Why is this true? (There is an argument based on general principles; however, you might find it a useful check on your calculation to verify this property explicitly.) Since, after integrating over final-state vectors, $\int H^{\mu\nu}$ depends only on q^μ and scalars, it can only have the form

$$\int d\Pi_3 H^{\mu\nu} = \left(g^{\mu\nu} - \frac{q^\mu q^\nu}{q^2}\right)\cdot H$$

where H is a scalar. With this information, show that

$$L_{\mu\nu}\int d\Pi_3 H^{\mu\nu} = \frac{1}{3}\left(g^{\mu\nu}L_{\mu\nu}\right)\cdot\int d\Pi_3\left(g^{\rho\sigma}H_{\rho\sigma}\right)$$

Using this trick, derive the differential cross section

$$\frac{d\sigma}{dx_1 dx_2}\left(e^+e^- \to \bar{q}qg\right) = \frac{4\pi\alpha^2}{3s}\cdot 3Q_f^2\cdot\frac{\alpha_g}{2\pi}\frac{x_1^2 + x_2^2}{(1-x_1)(1-x_2)}$$

in the limit $\mu \to 0$. If we assume that each original final-state particle is realized physically as a jet of strongly interacting particles, this formula gives the probability for observing three-jet events in e^+e^-annihilation and the kinematic distribution of these events. The form of the distribution in the x_i is an absolute prediction, and it agrees with experiment. The
normalization of this distribution is a measure of the strong-interaction coupling constant.

(d) Now replace $\mu \neq 0$ in the formula of part (c) for the differential cross section, and carefully integrate over the region found in part (b). You may assume $\mu^2 \ll q^2$. In this limit, you will find infrared-divergent terms of order $\log(q^2/\mu^2)$ and also $\log^2(q^2/\mu^2)$, finite terms of order 1 , and terms explicitly suppressed by powers of (μ^2/q^2). You may drop terms of the last type throughout this calculation. For the moment, collect and evaluate only the infrared-divergent terms.

(e) Now analyze the Feynman parameter integral obtained in part (a), again working in the limit $\mu^2 \ll q^2$. Note that this integral has singularities in the region of integration. These should be controlled by evaluating the integral for q spacelike and then analytically continuing into the physical region. That is, write $Q^2 = -q^2$, evaluate the integral for $Q^2 > 0$, and then carefully analytically continue the result to $Q^2 = -q^2 - i\epsilon$. Combine the result with the answer from part (d) to form the total cross section for $e^+e^- \to$ strongly interacting particles, to order α_g. Show that all infrareddivergent logarithms cancel out of this quantity, so that this total cross section is well-defined in the limit $\mu \to 0$.
(f) Finally, collect the terms of order 1 from the integrations of parts (d) and (e) and combine them. To evaluate certain of these terms, you may find the following formula useful:

$$\int_0^1 dx \frac{\log(1-x)}{x} = -\frac{\pi^2}{6}$$

(It is not hard to prove this.) Show that the total cross section is given, to this order in α_g, by

$$\sigma\left(e^+e^- \to \bar{q}q \text{ or } \bar{q}qg\right) = \frac{4\pi\alpha^2}{3s} \cdot 3Q_f^2 \cdot \left(1 + \frac{3\alpha_g}{4\pi}\right)$$

This formula gives a second way of measuring the strong-interaction coupling constant. The experimental results agree (within the current experimental errors) with the results obtained by the method of part (c). We will discuss the measurement of α_s more fully in Section 17.6.

17.6 Chapter 8 Invitation to Renormalization: Ultraviolet Cutoffs and Critical Fluctuations

The main purpose of Part II of this book is to develop a general theory of renormalization. This theory will explain the origin of ultraviolet divergences in field theory and will indicate when these divergences can be removed systematically. It will also give a way to convert the divergences of Feynman diagrams from a problem into a tool. We will apply this tool to study the asymptotic large- or small-momentum behavior of field theory amplitudes.

When we first encountered an ultraviolet divergence in the calculation of the one-loop vertex correction in Section 6.3, it seemed an aberration that ought to disappear before it caused us too much discomfort. In Chapter 7 we saw further examples of ultraviolet-divergent diagrams, enough to convince us that such divergences occur ubiquitously in Feynman diagram computations. Thus it is necessary for anyone studying field theory to develop a point of view toward these divergences. Most people begin with the belief that any theory that contains divergences must be nonsense. But this viewpoint is overly restrictive, since it excludes not only quantum field theory but even the classical electrodynamics of point particles.

With some experience, one might adopt a more permissive attitude of peaceful coexistence with the divergences: One can accept a theory with divergences, as long as they do not appear in physical predictions. In Chapter 7 we saw that all of the divergences that appear in the one-loop radiative corrections to electron scattering from a heavy target can be eliminated by consistently eliminating the bare values of the mass and charge of the electron in favor of their measured physical values. In Chapter 10, we will argue that all of the ultraviolet divergences of QED, in all orders of perturbation theory, can be eliminated in this way. Thus, as long as one is willing to consider the mass and charge of the electron as measured parameters, the predictions of QED perturbation theory will always be free of divergences. We will also show in Chapter 10 that QED

belongs to a well-defined class of field theories in which all ultraviolet divergences are removed after a fixed small number of physical parameters are taken from experiment. These theories, called renormalizable quantum field theories, are the only ones in which perturbation theory gives well-defined predictions.

Ideally, though, one should take the further step of trying to understand
physically why the divergences appear and why their effects are more severe in some theories than in others. This direct approach to the divergence problem was pioneered in the 1960s by Kenneth Wilson. The crucial insights needed to solve this problem emerged from a correspondence, discovered by Wilson and others, between quantum field theory and the statistical physics of magnets and fluids. Wilson's approach to renormalization is the subject of Chapter 12. The present chapter gives a brief introduction to the issues in condensed matter physics that have provided insight into the problem of ultraviolet divergences.

Formal and Physical Cutoffs

Ultraviolet divergences signal that quantities calculated in a quantum field theory depend on some very large momentum scale, the ultraviolet cutoff. Equivalently, in position space, divergent quantities depend on some very small distance scale.

The idea of a small-distance cutoff in the continuum description of a system occurs in classical field theories as well. Typically the cutoff is at the scale of atomic distances, where the continuum description no longer applies. However, the size of the cutoff manifests itself in certain parameters of the continuum theory. In fluid dynamics, for instance, parameters such as the viscosity and the speed of sound are of just the size one would expect by combining typical atomic radii and velocities. Similarly, in a magnet, the magnetic susceptibility can be estimated by assuming that the energy cost of flipping an electron spin is on the order of a tenth of an eV , as we would expect from atomic physics. Each of these systems possesses a natural ultraviolet cutoff at the scale of an atom; by understanding the physics at the atomic scale, we can compute the parameters that determine the physics on larger scales.

In quantum field theory, however, we have no precise knowledge of the fundamental physics at very short distance scales. Thus, we can only measure parameters such as the physical charge and mass of the electron, not compute them from first principles. The presence of ultraviolet divergences in the relations between these physical parameters and their bare values is a sign that these parameters are controlled by the unknown short-distance physics.

Whether we know the fundamental physics at small distance scales or not, we need two kinds of information in order to write an effective theory for large-distance phenomena. First, we must know how many parameters from the small distance scale are relevant to large-distance physics. Second, and more importantly, we must know what degrees of freedom from the underlying theory appear at large distances.

In fluid mechanics, it is something of a miracle, from the atomic point of view, that any large-distance degrees of freedom even exist. Nevertheless, the equations that express the transport of energy and mass over large distances do have smooth, coherent solutions. The large-distance degrees of freedom are
the flows that transport these conserved quantities, and sound waves of long wavelength.

In quantum field theory, the large-distance physics involves only those particles that have masses that are very small compared to the fundamental cutoff scale. These particles and their dynamics are the quantum analogues of the large-scale flows in fluid mechanics. The simplest way to naturally arrange for such particles to appear is to make use of particles that naturally have zero

mass. So far in this book, we have encountered two types of particles whose mass is precisely zero, the photon and the chiral fermion. (In Chapter 11 we will meet one further naturally massless particle, the Goldstone boson.) We might argue that QED exists as a theory on scales much larger than its cutoff because the photon is naturally massless and because the left- and right-handed clectrons are very close to being chiral fermions.

There is another way that particles of zero or almost zero mass can arise in quantum field theory: We can simply tune the parameters of a scalar field theory so that the scalar particles have masses small compared to the cutoff. This method of introducing particles with small mass seems arbitrary and unnatural. Nevertheless, it has an analogue in statistical mechanics that is genuinely interesting in that discipline and can teach us some important lessons.

Normally, in a condensed matter system, the thermal fluctuations are correlated only over atomic distances. Under special circumstances, however, they can have much longer range. The clearest example of this phenomenon occurs in a ferromagnet. At high temperature, the electron spins in a magnet are disorganized and fluctuating; but at low temperature, these spins align to a fixed direction.* Let us think about how this alignment builds up as the temperature of the magnet is lowered. As the magnet cools from high temperature, clusters of correlated spins become larger and larger. At a certain point the temperature of magnetization–the entire sample becomes a single large cluster with a well-defined macroscopic orientation. Just above this temperature, the magnet contains large clusters of spins with a common orientation, which in turn belong to still larger clusters, such that the orientations on the very largest scale are still randomized through the sample. This situation is illustrated in Fig. 8.1. Similar behavior occurs in the vicinity of any other second-order phase transition, for example, the order-disorder transition in binary alloys, the critical point in fluids, or the superfluid transition in Helium-4.

The natural description of these very long wavelength fluctuations is in terms of a fluctuating continuum field. At the lowest intuitive level, we might

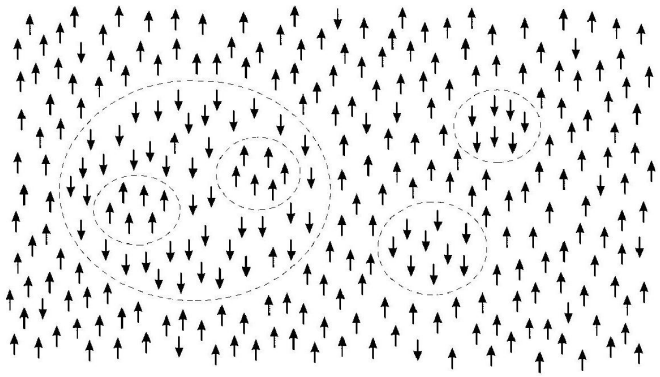

Figure 8.1. Clusters of oriented spins near the critical point of a ferromagnet.

substitute quantum for statistical fluctuations and try to describe this system as a quantum field theory. In Section 9.3 we will derive a somewhat more subtle relation that makes a precise connection between the statistical and the quantum systems. Through this connection, the behavior of any statistical system near a second-order phase transition can be translated into the behavior of a particular quantum field theory. This quantum field theory has a field with a mass that is very small compared to the basic atomic scale and that goes to zero precisely at the phase transition.

But this connection seems to compound the problem of ultraviolet divergences in quantum field

[6]*In a real ferromagnet, the long-range magnetic dipole-dipole interaction causes the state of uniform magnetization to break up into an array of magnetic domains. In this book, we will ignore this interaction and think of a magnetic spin as a pure orientation. It is this idealized system that is directly analogous to a quantum field theory.

theory: If the wealth of phase transitions observed in Nature generates a similar wealth of quantum field theories, how can we possibly define a quantum field theory without detailed reference to its origins in physics at the scale of its ultraviolet cutoff? Saying that a quantum field theory makes predictions independent of the cutoff would be equivalent to saying that the statistical fluctuations in the neighborhood of a critical point are independent of whether the system is a magnet, a fluid, or an alloy. But is this statement so obviously incorrect? By reversing the logic, we would find that quantum field theory makes a remarkably powerful prediction for condensed matter systems, a prediction of universality for the statistical fluctuations near a critical point. In fact, this prediction is verified experimentally.

A major theme of Part II of this book will be that these two ideas -cutoff independence in quantum field theory and universality in the theory of critical phenomena-are naturally the same idea, and that understanding either of these ideas gives insight into the other.

Landau Theory of Phase Transitions

To obtain a first notion of what could be universal in the phenomena of phase transitions, let us examine the simplest continuum theory of second-order phase transitions, due to Landau.

First we should review a little thermodynamics and clarify our nomenclature. In thermodynamics, a first-order phase transition is a point across which some thermodynamic variable (the density of a fluid, or the magnetization of a ferromagnet) changes discontinuously. At a phase transition point, two quite distinct thermodynamic states (liquid and gas, or magnetization parallel and antiparallel to a given axis) are in equilibrium. The thermodynamic quantity that changes discontinuously across the transition, and that characterizes the difference of the two competing phases, is called the order parameter. In most circumstances, it is possible to change a second thermodynamic parameter in such a way that the two competing states move closer together in the thermodynamic space, so that at some value of this parameter, these two states become identical and the discontinuity in the order parameter disappears. This endpoint of the line of first-order transitions is called a second-order phase transition, or, more properly, a critical point. Viewed from the other direction, a critical point is a point at which a single thermodynamic state bifurcates into two macroscopically distinct states. It is this bifurcation that leads to the long-ranged thermal fluctuations discussed in the previous section.

A concrete example of this behavior is exhibited by a ferromagnet. Let us assume for simplicity that the material we are discussing has a preferred axis of magnetization, so that at low temperature, the system will have its spins ordered either parallel or antiparallel to this axis. The total magnetization along this axis, M, is the order parameter. At low temperature, application of an external magnetic field H will favor one or the other of the two possible states. At $H = 0$, the two states will be in equilibrium; if H is changed from a small negative to a small positive value, the thermodynamic state and the value of M will change discontinuously. Thus, for any fixed (low) temperature, there is a first-order transition at $H = 0$. Now consider the effect of raising the temperature: The fluctuation of the spins increases and the value of $|M|$ decreases. At some temperature T_C the system ceases to be magnetized at $H = 0$. At this point, the first-order phase transition disappears and the two competing thermodynamic states coalesce. The system thus has a critical point at $T = T_C$. The location of these various transitions in the $H - T$ plane is shown in Fig. 8.2.

Landau described this behavior by the use of the Gibbs free energy G; this is the thermodynamic potential that depends on M and T, such that

$$\left.\frac{\partial G}{\partial M}\right|_T = H \tag{8.1}$$

He suggested that we concentrate our attention on the region of the critical

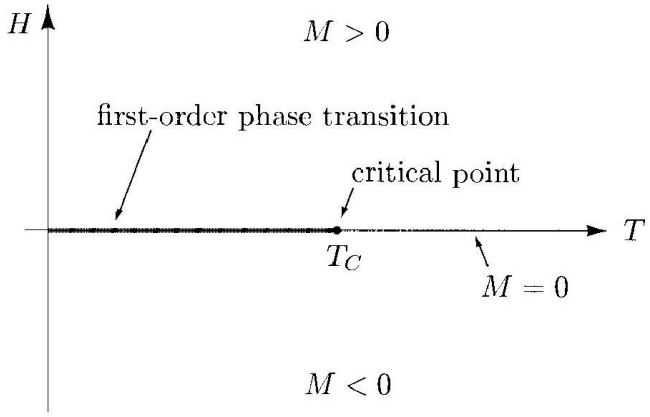

Figure 8.2. Phase diagram in the $H - T$ plane for a uniaxial ferromagnet.

point: $T \approx T_C, M \approx 0$. Then it is reasonable to expand $G(M)$ as a Taylor series in M. For $H = 0$, we can write

$$G(M) = A(T) + B(T)M^2 + C(T)M^4 + \cdots . \tag{8.2}$$

Because the system has a symmetry under $M \to -M, G(M)$ can contain only even powers of M. Since M is small, we will ignore the higher terms in the expansion. Given Eq. (8.2), we can find the possible values of M at $H = 0$ by solving

$$0 = \frac{\partial G}{\partial M} = 2B(T)M + 4C(T)M^3 \tag{8.3}$$

If B and C are positive, the only solution is $M = 0$. However, if $C > 0$ but B is negative below some temperature T_C, we have a nontrivial solution for $T < T_C$, as shown in Fig. 8.3. More concretely, approximate for $T \approx T_C$:

$$B(T) = b\,(T - T_C)\,, \quad C(T) = c \tag{8.4}$$

Then the solution to Eq. (8.3) is

$$M = \begin{cases} 0 & \text{for } T > T_C \\ \pm\left[(b/2c)\,(T_C - T)\right]^{1/2} & \text{for } T < T_C \end{cases} \tag{8.5}$$

This is just the qualitative behavior that we expect at a critical point.

To find the value of M at nonzero external field, we could solve Eq. (8.1) with the left-hand side given by (8.2). An equivalent procedure is to minimize a new function, related to (8.2). Define

$$G(M, H) = A(T) + B(T)M^2 + C(T)M^4 - HM \tag{8.6}$$

Then the minimum of $G(M, H)$ with respect to M at fixed H gives the value of M that satisfies Eq. (8.1). The minimum is unique except when $H = 0$ and $T < T_C$, where we find the double

minimum in the second line of (8.5). This is consistent with the phase diagram shown in Fig. 8.2.

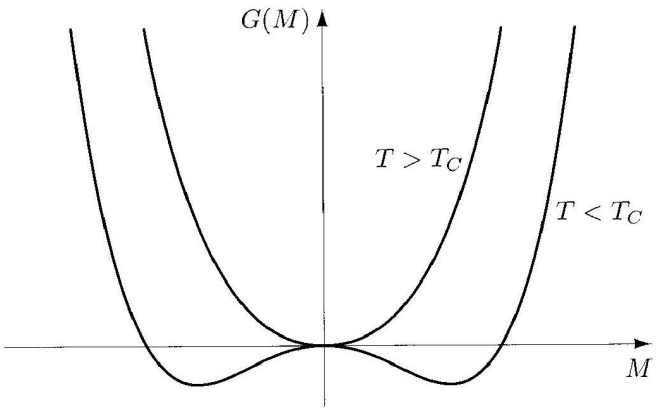

Figure 8.3. Behavior of the Gibbs free energy $G(M)$ in Landau theory, at temperatures above and below the critical temperature.

To study correlations in the vicinity of the phase transition, Landau generalized this description further by considering the magnetization M to be the integral of a local spin density:

$$M = \int d^3x s(\mathbf{x}) \tag{8.7}$$

Then the Gibbs free energy (8.6) becomes the integral of a local function of $s(\mathbf{x})$,

$$G = \int d^3x \left[\frac{1}{2} (\boldsymbol{\nabla} s)^2 + b\,(T - T_C)\, s^2 + c s^4 - H s \right] \tag{8.8}$$

which must be minimized with respect to the field configuration $s(\mathbf{x})$. The first term is the simplest possible way to introduce the tendency of nearby spins to align with one another. We have rescaled $s(\mathbf{x})$ so that the coefficient of this term is set to $1/2$. In writing this free energy integral, we could even consider H to vary as a function of position. In fact, it is useful to do that; we can turn on $H(\mathbf{x})$ near $x = 0$ and see what response we find at another point.

The minimum of the free energy expression (8.8) with respect to $s(\mathbf{x})$ is given by the solution to the variational equation

$$0 = \delta G[s(\mathbf{x})] = -\nabla^2 s + 2b\,(T - T_C)\, s + 4cs^3 - H(\mathbf{x}) \tag{8.9}$$

For $T > T_C$, where the macroscopic magnetization vanishes and so $s(\mathbf{x})$ should be small, we can find the qualitative behavior by ignoring the s^3 term. Then $s(\mathbf{x})$ obeys a linear equation,

$$\left(-\nabla^2 + 2b\,(T - T_C) \right) s(\mathbf{x}) = H(\mathbf{x}) \tag{8.10}$$

To study correlations of spins, we will set

$$H(\mathbf{x}) = H_0 \delta^{(3)}(\mathbf{x}) \tag{8.11}$$

The resulting configuration $s(\mathbf{x})$ is then the Green's function of the differential operator in Eq. (8.10), so we call it $D(\mathbf{x})$:

$$\left(-\nabla^2 + 2b\,(T - T_C) \right) D(\mathbf{x}) = H_0 \delta^{(3)}(\mathbf{x}) \tag{8.12}$$

This Green's function tells us the response at $\mathbf{x}$ when the spin at $\mathbf{x} = 0$ is forced into alignment with H. In Sections 9.2 and 9.3 we will see that $D(\mathbf{x})$ is also proportional to the zero-field spin-spin correlation function in the thermal ensemble,

$$D(\mathbf{x}) \propto \langle s(\mathbf{x})s(0)\rangle \equiv \sum_{\text{all } s(\mathbf{x})} s(\mathbf{x})s(0)e^{-\mathbf{H}/kT} \tag{8.13}$$

where $\mathbf{H}$ is the Hamiltonian of the magnetic system.
The solution to Eq. (8.12) can be found by Fourier transformation:

$$D(\mathbf{x}) = \int \frac{d^3k}{(2\pi)^3} \frac{H_0 e^{i\mathbf{k}\cdot\mathbf{x}}}{|\mathbf{k}|^2 + 2b\,(T - T_C)} \tag{8.14}$$

This is just the integral we encountered in our discussion of the Yukawa potential, Eq. (4.126). Evaluating it in the same way, we find

$$D(\mathbf{x}) = \frac{H_0}{4\pi}\frac{1}{r}e^{-r/\xi} \tag{8.15}$$

where

$$\xi = [2b\,(T - T_C)]^{-1/2} \tag{8.16}$$

is the correlation length, the range of correlated spin fluctuations. Notice that this length diverges as $T \to T_C$.

The main results of this analysis, Eqs. (8.5) and (8.16), involve unknown constants b, c that depend on physics at the atomic scale. On the other hand, the power-law dependence in these formulae on $(T - T_C)$ follows simply from the structure of the Landau equations and is independent of any details of the microscopic physics. In fact, our derivation of this dependence did not even use the fact that G describes a ferromagnet; we assumed only that G can be expanded in powers of an order parameter and that G respects the reflection symmetry $M \to -M$. These assumptions apply equally well to many other types of systems: binary alloys, superfluids, and even (though the reflection symmetry is less obvious here) the liquid-gas transition. Landau theory predicts that, near the critical point, these systems show a universal behavior in the dependence of M, ξ, and other thermodynamic quantities on $(T - T_C)$.

Critical Exponents

The preceding treatment of the Landau theory of phase transitions emphasizes its similarity to classical field theory. We set up an appropriate free energy and found the thermodynamically preferred configuration by solving a classical variational equation. This gives only an approximation to the full statistical problem, analogous to the approximation of replacing quantum by classical dynamics in field theory. In Chapter 13, we will use methods of quantum field theory to account properly for the fluctuations about the preferred Landau thermodynamic state. These modifications turn out to be profound, and rather counterintuitive.

To describe the form of these modifications, let us write Eq. (8.15) more generally as

$$\langle s(\mathbf{x})s(0)\rangle = A\frac{1}{r^{1+\eta}}f(r/\xi) \tag{8.17}$$

where A is a constant and $f(y)$ is a function that satisfies $f(0) = 1$ and $f(y) \to 0$ as $y \to \infty$. Landau theory predicts that $\eta = 0$ and $f(y)$ is a simple exponential. This expression has a form

strongly analogous to that of a Green's function in quantum field theory. The constant A can be absorbed into the field-strength renormalization of the field $s(\mathbf{x})$. The correlation length ξ is, in general, a complicated function of the atomic parameters, but in the continuum description we can simply trade these parameters for ξ. It is appropriate to consider ξ as a cutoff-independent, physical parameter, since it controls the large-distance behavior of a physical correlation. In fact, the analogy between Eq. (8.15) and the Yukawa potential suggests that we should identify ξ^{-1} with the physical mass in the associated quantum field theory. Then Eq. (8.17) gives a cutoff-independent, continuum representation of the statistical system.

If we were working in quantum field theory, we would derive corrections to Eq. (8.17) as a perturbation series in the parameter c multiplying the nonlinear term in (8.9). This would generalize the Landau result to

$$\langle s(\mathbf{x})s(0)\rangle = \frac{1}{r}F(r/\xi, c). \tag{8.18}$$

The perturbative corrections would depend on the properties of the continuum field theory. For example, $F(y, c)$ would depend on the number of components of the field $s(\mathbf{x})$, and its series expansion would differ depending on whether the magnetization formed along a preferred axis, in a preferred plane, or isotropically. For order parameters with many components, the expansion would also depend on higher discrete symmetries of the problem. However, we expect that systems described by the same Landau free energy (for example, a single-axis ferromagnet and a liquid-gas system) should have the same perturbation expansion when this expansion is written in terms of the physical mass and coupling. The complete universality of Landau theory then becomes a more limited concept, in which systems have the same large-distance correlations if their order parameters have the same symmetry. We might say that statistical systems divide into distinct universality classes, each with a characteristic large-scale behavior.

If this were the true behavior of systems near second-order phase transitions, it would already be a wonderful confirmation of the ideas required to formulate cutoff-independent quantum field theories. However, the true behavior of statistical systems is still another level more subtle. What one finds experimentally is a dependence of the form of Eq. (8.17), where the function $F(y)$ is the same within each universality class. There is no need for an auxiliary parameter c. On the other hand, the exponent η takes a specific nonzero value in each universality class. Other power-law relations of Landau theory are also modified, in a specific manner for each universality class. For example, Eq. (8.5) is changed, for $T < T_C$, to

$$M \propto (T_C - T)^{\beta} \tag{8.19}$$

where the exponent β takes a fixed value for all systems in a given universality class. For three-dimensional single-axis magnets and for fluids, $\beta = 0.313$. The powers in these nontrivial scaling relations are called critical exponents.

The modification from Eq. (8.18) to Eq. (8.17) does not imperil the idea that a condensed matter system, in the vicinity of a second-order phase transition, has a well-defined, cutoff-independent, continuum behavior. However, we would like to understand why Eq. (8.17) should be expected as the correct representation. The answer to this question will come from a thorough analysis of the ultraviolet divergences of the corresponding quantum field theory. In Chapter 12, when we finally conclude our cxplication of the ultraviolet divergences, we will find that we have in hand the tools not only to justify Eq. (8.17), but also to calculate the values of the critical exponents using Feynman diagrams. In this way, we will uncover a bcautiful application of quantum field

theory to the domain of atomic physics. The success of this application will guide us, in Part III, to cven more powerful tools, which we will need in the relativistic domain of elementary particles.

17.7 L11 Electron and Photon Propagators at One-Loop

17.7.1 1. Mass Operator

В наинизшем приближении массовый оператор $-i\mathcal{N}(p)$ определяется диаграммой

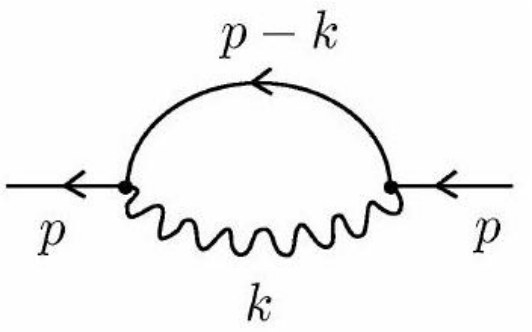

Рис. 23

аналитическое выражение которой даётся выражением

$$-i\mathcal{M}(p) = (-ie)^2 \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d} \gamma^\mu i S_c(p-k) \gamma^\nu \left(-iD^\alpha_{\mu\nu}(k)\right)$$

Проще всего вычисление проводится в калибровке Фейнмана $\alpha = 1$, в которой

$$-i\mathcal{M}(p) = -4\pi e^2 \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d} \frac{\gamma^\mu[(\not{p}-\not{k})+m]\gamma_\mu}{(p-k)^2-m^2} \frac{1}{k^2-\lambda^2}$$

Мы ввели массу фотона $\lambda^2 \ll m^2$, необходимую (см. ниже) для удовлетворения условий нормировки. Разумеется, масса фотона выпадает из физически наблюдаемых величин (см. лекцию 13). Пусть $d = 4-\varepsilon$. Тогда $\gamma^\mu \not{p} \gamma_\mu = -(2-\varepsilon)\not{p}$, $\quad \gamma^\mu\gamma_\mu = d = 4-\varepsilon$, и

$$\mathcal{M}(p) = -\frac{4\pi i e^2}{(2\pi)^d} \int \mathrm{d}^{(d)}k \frac{(4-\varepsilon)m - (2-\varepsilon)(\not{p}-\not{k})}{[(p-k)^2-m^2]\,(k^2-\lambda^2)}$$

Воспользуемся формулой (35 Л4), положив $A = (p-k)^2 - m^2, \quad B = k^2 - \lambda^2$:

$$\mathcal{M}(p) = -\frac{4\pi i e^2}{(2\pi)^d} \int \mathrm{d}^{(d)}k \int\limits_0^1 \mathrm{d}x \frac{(4-\varepsilon)m - (2-\varepsilon)(\not{p}-\not{k})}{\left[(k-xp)^2 - a^2\right]^2}$$

$$a^2 = -x(1-x)p^2 + xm^2 + (1-x)\lambda^2$$

После сдвига переменной интегрирования $k \to k + xp$ интеграл переписывается как

$$\mathcal{M}(p) = -\frac{4\pi i e^2}{(2\pi)^d} \int\limits_0^1 \mathrm{d}x \int \mathrm{d}^{(d)}k \frac{(4-\varepsilon)m - (2-\varepsilon)(1-x)\not{p}}{\left(k^2-a^2\right)^2}$$

причём линейное относительно $\not{\varepsilon}$слагаемое в числителе теперь может быть опущено, так как интегрирование по углам обращает его в нуль. Интеграл в импульсном пространстве берётся при помощи поворота Вика и формулы (3 Л4):

$$\mathcal{N}(p) = \frac{e^2\Gamma(\varepsilon/2)}{(4\pi)^{1-\varepsilon/2}} \int\limits_0^1 \mathrm{d}x[(4-\varepsilon)m - (2-\varepsilon)(1-x)\not{p}] \cdot \left[-x(1-x)p^2 + xm^2 + (1-x)\lambda^2\right]^{-\varepsilon/2}$$

Последнее выражение разложим по ε с точностью $O\left(\varepsilon^0\right)$:

$$\mathcal{N}(p) = \frac{e^2}{2\pi\varepsilon}(4m - \not{p}) + \frac{e^2}{2\pi}\left[\frac{1}{2}(\ln 4\pi + \psi(1))(4m - \not{p}) + \left(-m + \frac{1}{2}\not{p}\right)\right] -$$

$$-\frac{e^2}{2\pi}\int\limits_0^1 \mathrm{d}x[(1+x)m - (1-x)(\not{p} - m)] \cdot \ln\left[-x(1-x)p^2 + xm^2 + (1-x)\lambda^2\right] \tag{1}$$

Обратим внимание на то, что в точках нормировки оператор $\mathcal{M}$ используется в обкладках $\bar{u}_p\mathcal{M}u_p$, причём $p^2 = m^2$ и $\not{p}u_p = mu_p, \bar{u}_p\not{p} = m\bar{u}_p$ (см. (41 Л10) и (42 Л10)). Поэтому для приведения оператора $\mathcal{M}$ к виду (40 а Л10) следует, во первых, сделать вычитание

$$\mathcal{M}(\not{p}) \longrightarrow \mathcal{M}(\not{p}) - \mathcal{M}(\not{p})|_{\not{p}=m, p^2=m^2} \equiv (\not{p} - m)\mathcal{M}'(\not{p}) \tag{2}$$

Затем операцию вычитания следует повторить для величины $\mathcal{M}'^1$. В результате двух таких вычитаний первые два слагаемых в (1) исчезают. Последнее слагаемое в (1) переписываем как

$$\mathcal{M} = \mathcal{M}_1 + \mathcal{M}_2$$

$$\mathcal{M}_1 = \frac{e^2}{2\pi}(\not{p} - m)\int\limits_0^1 \mathrm{d}x(1-x)\ln\left[m^2(1-\rho)\,(x-x_1)\,(x-x_2)\right]$$

$$\mathcal{M}_2 = -\frac{e^2 m}{2\pi}\int\limits_0^1 \mathrm{d}x(1+x)\ln\left[m^2(1-\rho)\,(x-x_1)\,(x-x_2)\right] \tag{3}$$

где введены параметры

$$\rho = \frac{m^2 - p^2}{m^2}, \quad \beta = \frac{\lambda^2}{m^2}, \quad x_{1,2} = \frac{1}{2}\left[-\frac{\rho-\beta}{1-\rho} \pm \sqrt{\left(\frac{\rho-\beta}{1-\rho}\right)^2 - \frac{4\beta}{1-\rho}}\right] \tag{4}$$

Вычисления проводятся в предположении

$$\rho > 0, \longrightarrow x_{1,2} < 0 \tag{5}$$

Напомним, что m^2 имеет бесконечно малую отрицательную мнимую часть. Поэтому

$$\lim_{\rho\to+0} x_{1,2} \equiv \tilde{x}_{1,2} = \frac{1}{2}\beta \mp i\sqrt{\beta} \tag{6}$$

Проведём одно вычитание (2) для $\mathcal{M}_2$:

$$\mathcal{M}_2 = -\frac{e^2 m}{2\pi}\int\limits_0^1 \mathrm{d}x(1+x)\ln\frac{(1-\rho)(x-x_1)(x-x_2)}{(x-\tilde{x}_1)(x-\tilde{x}_2)} =$$

$$= \frac{e^2 m}{2\pi}\cdot\frac{1}{2}\int\limits_0^1 \mathrm{d}x\left(x^2+2x\right)\left[\frac{1}{x-x_1}+\frac{1}{x-x_2}-\frac{1}{x-\tilde{x}_1}-\frac{1}{x-\tilde{x}_2}\right] \tag{7}$$

При преобразовании интеграла (7) было учтено, что

$$(1-\rho)(1-x_1)(1-x_2) = 1 \longrightarrow (1-\tilde{x}_1)(1-\tilde{x}_2) = 1$$

Последний интеграл вычисляется при помощи формулы

$$\frac{x^2+ax}{x-x_i} = x + (x_i+a) + \frac{x_i(x_i+a)}{x-x_i} \tag{8}$$

Имеем:

$$\mathcal{M}_2 = \frac{e^2 m}{2\pi}\cdot\frac{1}{2}(-\rho)\left\{\frac{1-\beta}{1-\rho} - \frac{1}{\rho}\sum_{i=1,2}\left[x_i(x_i+2)\ln\frac{1-x_i}{-x_i} - \tilde{x}_i(\tilde{x}_i+2)\ln\frac{1-\tilde{x}_i}{-\tilde{x}_i}\right]\right\} \tag{9}$$

Так как

$$-\rho = \frac{1}{m^2}(\not{p}-m)(\not{p}+m) \tag{10}$$

то

10

$$\mathcal{M}_2'(\not{p}) = (\not{p}+m)\mathcal{M}_2''(\rho)$$

$$\mathcal{M}_2''(\rho) = \frac{e^2}{2\pi}\frac{1}{2m}\left\{\frac{1-\beta}{1-\rho} - \frac{1}{\rho}\sum_{i=1,2}\left[x_i(x_i+2)\ln\frac{1-x_i}{-x_i} - \tilde{x}_i(\tilde{x}_i+2)\ln\frac{1-\tilde{x}_i}{-\tilde{x}_i}\right]\right\} \tag{11}$$

Для приведения вклада в $\mathcal{M}$ от $\mathcal{M}_2$ к окончательному виду следует вместо $\mathcal{M}_2'(\not{p})$ использовать величину

$$(\not{p}+m)\mathcal{M}_2''(\rho) - (2m)\mathcal{M}_2''(0) + 2m\mathcal{M}_2''(\rho) - 2m\mathcal{M}_2''(\rho) = (\not{p}-m)\mathcal{M}_2''(\rho) + 2m\rho\left\{\frac{1}{\rho}\left[\mathcal{M}_2''(\rho) - \mathcal{M}_2''(0)\right]\right\} \tag{12}$$

Заметим, что в пределе $\lambda^2 \to 0, \rho > 0$

$$\tilde{x}_1 = \tilde{x}_2 = 0, \quad x_1 = 0, \quad x_2 = -\frac{\rho}{1-\rho}, \quad \mathcal{M}_2''(\rho) = \frac{e^2}{2\pi}\frac{1}{2m(1-\rho)}\left[1 - \frac{2-3\rho}{1-\rho}\ln\rho\right] \tag{13}$$

[61] Заметим, что согласно данным определениям $1 - \mathcal{M}'(\not{p})|_{p^2=m^2,\not{p}=m} = Z_2^{-1}$

Поэтому первое слагаемое в (12) определено корректно в пределе нулевой массы фотона. Для вычисления второго слагаемого в (12) следует вычислить $\mathcal{M}_2''(0)$, для чего необходимо в (11) перейти к пределу $\rho \to 0$ при фиксированном значении $0 < \lambda^2 \ll m^2$. В результате несложных вычислений находим:

$$\mathcal{M}_2''(0) = -\frac{e^2}{2\pi}\frac{1}{2m}\left(1 + 2\ln\frac{\lambda}{m}\right) \tag{14}$$

В (14) все коэффициенты, зависящие от β, берутся в точке $\beta = 0$, поскольку при этом не возникает неопределённостей и расходимостей. Собирая формулы (2), (12), (13) и (14), получаем для $\mathcal{M}_2$:

$$\mathcal{M}_2 = \frac{e^2}{2\pi m}(\not{p} - m)^2 \left\{ \frac{1}{2(1-\rho)}\left[1 - \frac{2-3\rho}{1-\rho}\ln\rho\right] - \frac{\not{x} + m}{m\rho}\left[\frac{1}{1-\rho} - \frac{(2-3\rho)}{(1-\rho)^2}\ln\rho + 1 + 2\ln\frac{\lambda}{m}\right]\right\} \tag{15}$$

Действуя аналогично и делая вычитание (2) для

$$\mathcal{M}_1'(\not{p}) = \frac{e^2}{2\pi}\cdot\frac{1}{2}\left\{ \text{ const } + \sum_{i=1,2}\left[x_i + x_i\,(x_i - 2)\ln\frac{1-x_i}{-x_i}\right]\right\} \tag{16}$$

находим:

$$\mathcal{M}_1 = \frac{e^2}{2\pi m}(\not{p} - m)^2\frac{\not{p} + m}{m}\frac{1}{2(1-\rho)}\left(1 + \frac{2-\rho}{1-\rho}\ln\rho\right) \tag{17}$$

Складывая (15) и (17), окончательно находим:

$$\mathcal{M} = \frac{e^2}{2\pi m}(\not{p} - m)^2\left\{\frac{1}{2(1-\rho)}\left(1 - \frac{2-3\rho}{1-\rho}\ln\rho\right) - \right.$$
$$\left. -\frac{\not{p} + m}{m\rho}\left[\frac{1}{2(1-\rho)}\left(2 - \rho + \frac{\rho^2 + 4\rho - 4}{1-\rho}\ln\rho\right) + 1 + 2\ln\frac{\lambda}{m}\right]\right\} \tag{18}$$

Оператор (18) вычислен в предположении $\rho > 0, \rho \gg \lambda/m$. При аналитическом продолжении в область $\rho < 0$ следует помнить, что точка ветвления $\rho = 0$ обходится снизу, так как m^2 содержит отрицательную бесконечно малую мнимую часть. Поэтому при $\rho < 0$

$$\ln\rho = \ln|\rho| - i\pi, \quad \rho < 0 \tag{19}$$

Из (18) видно, что при нулевой массе фотона массовый оператор не определён, если используются условия нормировки (40 а Л10).

При $p^2 \gg m^2$ из (18) получаем следующую оценку:

$$\mathcal{M} \approx \frac{e^2}{4\pi}\not{p}\ln\frac{p^2}{m^2} \tag{20}$$

Так как (20) есть поправка к \$\not\$10 (см. (39 Л10)), то для того чтобы ТВ была справедливой, должно быть

$$\frac{e^2}{4\pi}\ln\frac{p^2}{m^2} \ll 1 \tag{21}$$

Поскольку $e^2 = 1/137$, то условие (21) нарушается лишь при чрезвычайно больших импульсах.

Заметим, что массовый оператор калибровочно не инвариантен. В этом нет противоречий, поскольку массовый оператор не является непосредственно наблюдаемой величиной. В частности, в калибровке $\alpha = 3$ удовлетворение условиям нормировки (40 а Л10) не требует введения массы фотона

17.7.2 2. Polarization Operator

Можно существенно облегчить вычисления, если сначала найти мнимую часть диаграммы и затем восстановить всю диаграмму при помощи дисперсионного соотношения. Продемонстрируем этот метод на примере вычисления поляризационного оператора. В первом приближении ТВ он даётся петлёй в диаграмме

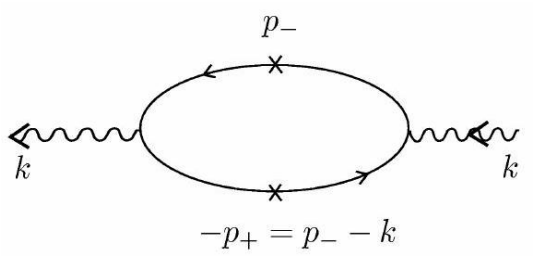

Рис. 24

Здесь внешняя линия виртуального фотона формально рассматривается как отвечающая реальной частице - векторному бозону массы $M^2 = k^2$, взаимодействующему с электрон-позитронным полем по тому же закону, что и фотон. При этом все соотношения условия унитарности остаются справедливыми. Диаграмма представляет диагональный элемент амплитуды iM_{ii}, дающей переход бозона самого в себя через распад на электрон-позитронную пару. Крестики на диаграмме показывают, по каким линиям она должна быть рассечена на две части так, чтобы дать реальное промежуточное состояние, фигурирующее при применении соотношения унитарности. Это состояние содержит электрон и позитрон с 4 -импульсами $p_- = p$ и $p_+ = (k - p)$, соответственно.

Для вычисления мнимой части M_{ii} при помощи условия унитарности в соотношении (34′5) в данном случае следует использовать меру

$$\sum_\lambda \int \frac{\mathrm{d}^3 p_-}{(2\pi)^3 2p_-^0} \frac{\mathrm{d}^3 p_+}{(2\pi)^3 2p_+^0}$$

причём далее $\sum\limits_\lambda$ означает сумму лишь по поляризациям промежуточных частиц, $p_-^2 = p_+^2 = m^2$ и в сумме по промежуточным состояниям 3 -вектора $\mathbf{p}_-$и $\mathbf{p}_+$считаются независимыми. Имеем:

$$2\,\mathrm{Im}\, M_{ii} = (2\pi)^4 \sum_\lambda \int \frac{\mathrm{d}^3 p_-}{(2\pi)^3 2p_-^0} \frac{\mathrm{d}^3 p_+}{(2\pi)^3 2p_+^0} \delta^{(4)}\left(k - p_- - p_+\right) |M_{\lambda i}|^2 \tag{22}$$

где амплитуда $M_{\lambda i}$ даётся частью диаграммы на рис. 24 правее крестиков:

$$iM_{\lambda i} = \bar{u}_{p_-} \left(-ie\gamma^\mu\right) u_{-p_+} \sqrt{4\pi} e_\mu \tag{23}$$

Введём параметр

$$t = k^2 = (p_- + p_+)^2 = 2\left(p_- p_+ + m^2\right)$$

В процессе вычисления будем предполагать, что $t > 4m^2$. Так как интеграл в (22) лоренцинвариантен, то вычислим его в системе отсчёта, где $\mathbf{k} = 0, k^0 = \sqrt{t}$. Сначала проинтегрируем по $\mathbf{p}_+$:

$$2\operatorname{Im} M_{ii} = \frac{1}{(4\pi)^2}\sum_\lambda \int \mathrm{d}o_{\mathbf{p}} \int\limits_0^\infty \frac{|\mathbf{p}|^2\ \mathrm{d}|\mathbf{p}|}{\left(p^0\right)^2}\delta\left(\sqrt{t} - 2p^0\right)|M_{\lambda i}|^2$$

Так как $|\mathbf{p}|\mathrm{d}|\mathbf{p}| = p^0\ \mathrm{d}p^0$, то

$$2\operatorname{Im} M_{ii} = \frac{1}{(4\pi)^2}\cdot\frac{|\mathbf{p}|}{2p^0}\int \mathrm{d}o\mathbf{p}\sum_\lambda |M_{\lambda i}|^2 \tag{24}$$

В (24) $p^0 = (1/2)\sqrt{t}, |\mathbf{p}| = (1/2)\sqrt{t-4m^2}$, d $o_{\mathbf{p}}$ - дифференциал телесного угла, внутри которого находится вектор $\mathbf{p} = \mathbf{p}_-$. С учётом (23)

$$\sum_\lambda |M_{\lambda i}|^2 = 4\pi e^2 e^*_\mu e_\nu \sum_\lambda \operatorname{tr}\gamma^\mu u_{-p_+}\bar{u}_{-p_+}\gamma^\nu u_{p_-}\bar{u}_{p_-} \tag{25}$$

В (25) $\sum\limits_\lambda$ означает независимое суммирование по поляризациям электрона и позитрона. Поэтому при помощи (56 Л8) находим:

$$\sum_\lambda |M_{\lambda i}|^2 = 4\pi e^2 e^*_\mu e_\nu \operatorname{tr}\gamma^\mu\left(\not{p}_+ - m\right)\gamma^\nu\left(\not{p}_- + m\right) = 16\pi e^2 e^*_\mu e_\nu\left[p^\mu_- p^\nu_+ + p^\nu_- p^\mu_+ - \left(p_+p_- + m^2\right)\eta^{\mu\nu}\right] \tag{26}$$

Здесь второе равенство получено при помощи формул (65 Л8) и (66 Л8). Так как $k = p_- + p_+$и

$$k_\mu\left[p^\mu_- p^\nu_+ + p^\nu_- p^\mu_+ - \left(p_+p_- + m^2\right)\eta^{\mu\nu}\right] \equiv 0$$

то

$$\int \mathrm{d}o_{\mathbf{p}}\left[p^\mu_- p^\nu_+ + p^\nu_- p^\mu_+ - \left(p_+p_- + m^2\right)\eta^{\mu\nu}\right] = 4\pi a\left(k^2\eta^{\mu\nu} - k^\mu k^\nu\right) \tag{27}$$

Коэффициент a в (27) находится путём вычисления свёртки по векторным индексам в (27):

$$a = -\frac{t + 2m^2}{3t} \tag{28}$$

С другой стороны,

$$iM_{ii} = \sqrt{4\pi}e^*_\mu\sqrt{4\pi}e_\mu\frac{i\mathcal{P}^{\mu\nu}}{4\pi} \tag{29}$$

Если считать вектора поляризации бозона вещественными, то сопоставляя формулы (24), (26), (27), (28) и (29), получаем:

$$2e_\mu e_\nu \operatorname{Im}\mathcal{P}^{\mu\nu} = -\frac{2e^2}{3} e_\mu e_\nu \sqrt{\frac{t-4m^2}{t}} \cdot \frac{t+2m^2}{t} \left(k^2\eta^{\mu\nu} - k^\mu k^\nu\right)$$

Теперь можно отбросить вектора поляризации бозона и использовать определение (18 Л10). Окончательно находим:

$$\operatorname{Im}\mathcal{P}(t) = -\frac{e^2}{3}\sqrt{\frac{t-4m^2}{t}} \cdot \frac{t+2m^2}{t} \tag{30}$$

Очевидно, $\operatorname{Im}\mathcal{P}(t) = 0$ при $t < 4m^2$. Поэтому по мнимой части (30) при помощи дисперсионного соотношения восстанавливается вся функция:

$$\mathcal{P}(t) = -\frac{e^2}{3\pi}\int\limits_{4m^2}^{\infty} \frac{\mathrm{d}t'}{t'-t-i\varepsilon}\sqrt{\frac{t'-4m^2}{t'}} \cdot \frac{t'+2m^2}{t'} \tag{31}$$

Этот интеграл является представлением Челлена-Лемана (см. (15 Л5)). Величина (30) является значением мнимой части поляризационного оператора на верхнем берегу разреза. Окончательное выражение для поляризационного оператора получается при учёте условия нормировки (40b Л10), согласно которому необходимо сделать замену $\mathcal{P}(t) \to \mathcal{P}(t) - \mathcal{P}(0)$:

$$\mathcal{P}(t) = -\frac{e^2}{3\pi}t\int\limits_{4m^2}^{\infty} \frac{\mathrm{d}t'}{t'-t-i\varepsilon}\sqrt{\frac{t'-4m^2}{t'}} \cdot \frac{t'+2m^2}{t'^2} \tag{32}$$

Будем считать, что $t < 0$. Тогда интеграл (32) берётся при помощи подстановки $t'/4m^2 = 1/\left(1-x^2\right), \quad 0 < x < 1$:

$$\mathcal{P}(t) = \frac{e^2}{3\pi}\left[-\frac{5}{3} + \frac{4\xi}{(1-\xi)^2} - \left(\xi^2 - 4\xi + 1\right)\frac{1+\xi}{(1-\xi)^3}\ln\xi\right] \tag{33}$$

Мы выразили $\mathcal{P}$ через переменную

$$t/m^2 = -(1-\xi)^2/\xi \tag{34}$$

Значение $\mathcal{P}(t)$ в предельном случае малых t легче всего ищется непосредственно из (32). Для этого следует положить под интегралом $t = 0$:

$$\mathcal{P}(t) = -\frac{e^2}{15\pi}\cdot\frac{t}{m^2}, \quad |t| \ll 4m^2 \tag{35}$$

Из (34) видно, что при стремлении переменной ξ к единице снизу t стремится к нулю. Чтобы продвинуться далее от $t = 0$ до $t = 4m^2$ следует положить $\xi = e^{i\varphi}$. Тогда согласно (34)

$$t = 4m^2\sin^2\frac{\varphi}{2}, \quad 0 \le \varphi \le \pi \tag{36}$$

В области $t > 4m^2$ переменная ξ заключена в интервале $-1 < \xi < 0$. Из (36) следует, что в этом интервале $\ln\xi = \ln|\xi| + i\pi$. Из (34) получаем также, что при больших $|t|$

$$t\xi = -m^2, \quad |t| \gg 4m^2 \tag{37}$$

Поэтому из (33) получаем асимптотику при больших $|t|$:

$$\mathcal{P}(t) = \begin{cases} \frac{e^2}{3\pi} \ln \frac{|t|}{m^2}, & \text{если } -t \gg 4m^2 \\ \frac{e^2}{3\pi} \left(\ln \frac{t}{m^2} - i\pi \right), & \text{если } t \gg 4m^2 \end{cases} \tag{38}$$

Мнимые части $\mathcal{P}(t)$, полученные при помощи (30) и (38), совпадают. Это подтверждает равенство $\ln \xi = \ln |\xi| + i\pi$ при $-1 < \xi < 0$.

По смыслу ТВ полученные формулы справедливы до тех пор пока $|\mathcal{P}| \ll 1$ (см. (20 Л10)). Поэтому ТВ справедлива до тех пор пока

$$\frac{e^2}{3\pi} \ln \frac{|t|}{m^2} \ll 1$$

Мы опять пришли к ограничению (21).

Константа перенормировки Z_3 получается, если в (20 Л10) подставить неперенормированный оператор (31) и устремить t к нулю. Обрезая интеграл в (31) масштабом $\Lambda \to \infty$, находим с точностью $O(e^2)$:

$$Z_3^{-1}(\Lambda) \equiv 1 - \mathcal{P}(t=0;\Lambda) \approx 1 + \frac{2e^2}{3\pi} \ln \frac{\Lambda}{m} \tag{39}$$

Теперь в соотношении (45 Л10) $e_0^2(\Lambda) = Z_3^{-1}(\Lambda) e^2$ сделаем подстановку $\Lambda \to M, e_0^2(\Lambda) \to e^2(M)$, где M - масштаб нормировки, $M \gg m$, а $e^2(M)$ - бегущая константа связи. Таким образом

$$e^2(M) = \left[1 + \frac{2e^2}{3\pi} \ln \frac{M}{m} \right] e^2$$

Отсюда с точностью $O(e^3)$ получаем:

$$M \frac{\mathrm{d}e(M)}{\mathrm{d}M} \equiv \beta(e(M)) = \frac{e^3(M)}{3\pi} \tag{40}$$

Решая это дифференциальное уравнение, находим:

$$e^2(M) = \frac{e^2}{1 - \frac{e^2}{3\pi} \ln \frac{M^2}{m^2}} \tag{41}$$

Формула (41) показывает, что эффективная константа связи растёт при продвижении в ультрафиолетовую область. Это свойство является общим для скалярной теории и КЭД.

17.7.3 3. Radiative Corrections to Coulomb's Law

Рассмотрим квантовые поправки к кулоновскому полю неподвижного сверхмассивного точечного заряда e_1, потенциал которого (без учёта поправок)

$$\varphi_0(r) \equiv A_0^{(e)}(r) = \frac{e_1}{r}, \quad \mathbf{A}^{(e)} = 0 \tag{42}$$

В импульсном пространстве

$$\varphi_0(\mathbf{k}) = \frac{4\pi e_1}{\mathbf{k}^2} \tag{43}$$

С учётом квантовых поправок потенциал (42) заменяется на

$$\varphi = A_0^{(e)} + \mathcal{D}_{0\mu}\frac{\mathcal{P}^{\mu\nu}}{4\pi}A_\nu^{(e)} \tag{44}$$

Получим первую поправку. Для этого поляризационный оператор возьмём в (32) и заменим точный фотонный пропагатор на свободный. С учётом того что $k^0 = 0$ получаем:

$$\varphi(\mathbf{k}) = \varphi_0(\mathbf{k}) + \mathcal{P}\left(-\mathbf{k}^2\right)\varphi_0(\mathbf{k}) \tag{45}$$

Отсюда видно, что возмущение потенциала есть

$$\delta\varphi(\mathbf{k}) = \frac{4\pi e_1}{\mathbf{k}^2}\mathcal{P}\left(-\mathbf{k}^2\right) = \frac{4\pi e_1}{y^2}\mathcal{P}\left(-y^2\right) \equiv \delta\varphi\left(-y^2\right)$$
$$\delta\varphi(r) = \int e^{i\mathbf{kr}}\delta\varphi(\mathbf{k})\frac{\mathrm{d}^{(3)}k}{(2\pi)^3} = \frac{1}{2\pi^2}\int\limits_0^\infty \delta\varphi\left(-y^2\right)\frac{\sin yr}{r}y\ \mathrm{d}y \tag{46}$$

Так как подынтегральное выражение чётно, то

$$\delta\varphi(r) = \frac{1}{4\pi^2 r}\operatorname{Im}\int\limits_{-\infty}^{+\infty}\delta\varphi\left(-y^2\right)e^{iry}y\ \mathrm{d}y \tag{47}$$

Теперь сместим контур интегрирования с вещественной оси переменной y в верхнюю полуплоскость так, показано на рис. 25.

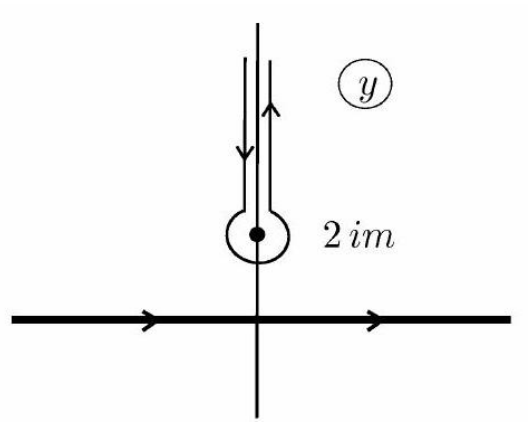

Рис. 25

На рис. 25 $\operatorname{Im}\mathcal{P}$ на левом берегу разреза задаётся при помощи (30). Положим $y = ix$. Тогда (47) переписывается как

$$\delta\varphi(r) = \frac{e_1}{r}\left[-\frac{2}{\pi}\int\limits_{2m}^\infty \operatorname{Im}\mathcal{P}\left(t = x^2\right)\frac{e^{-rx}}{x}\ \mathrm{d}x\right]$$

Теперь выпишем потенциал (45):

$$\varphi(r) = \frac{e_1}{r} + \delta\varphi(r) = \frac{e_1}{r}\left[1 + \frac{2e^2}{3\pi}\int\limits_1^\infty e^{-2mr\zeta}\left(1 + \frac{1}{2\zeta^2}\right)\frac{\sqrt{\zeta^2-1}}{\zeta^2}\ \mathrm{d}\zeta\right] \tag{48}$$

Оценим $\varphi(r)$ в двух предельных случаях.

а) $mr \gg 1$.

Интеграл (48) легко оценивается при помощи подстановки $\zeta = 1 + \xi$:

$$\varphi(r) = \frac{e_1}{r}\left[1 + \frac{e^2}{4\sqrt{\pi}} \cdot \frac{e^{-2mr}}{(mr)^{3/2}}\right], \quad r \gg \frac{1}{m} \tag{49}$$

б) $mr \ll 1$.

Опуская вычисления, приводим ответ (см. Л. Д. Ландау, Е. М. Лифшиц. Теоретическая физика. Т. 4, §114):

$$\varphi(r) = \frac{e_1}{r}\left[1 + \frac{2e^2}{3\pi}\left(\ln\frac{1}{mr} - C - \frac{5}{6}\right)\right], \quad r \ll \frac{1}{m} \tag{50}$$

где $C = 0,577...$ - постоянная Эйлера.

Мы видим, что поляризация вакуума искажает кулоново поле точечного заряда в области $r \lesssim 1/m (= \hbar/mc)$, где m - масса электрона. Вне этой области искажение поля убывает по экспоненциальному закону.

Задачи

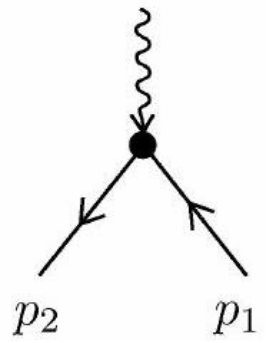
1. Вычислить в однопетлевом приближении константу перенормировки дираковского поля Z_2.

2*. Установить путём прямого вычисления что в калибровке $\alpha = 3$ для удовлетворения массовым оператором условий нормировки ($40a\Omega 10$) не требуется введение массы фотона.

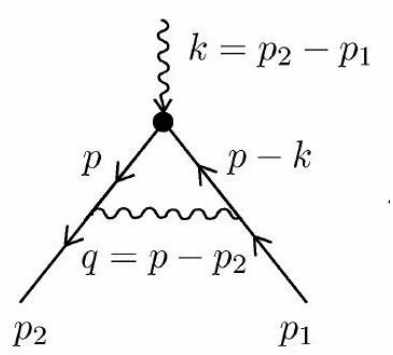
17.8 L12 Vertex Operator and Anomalous Magnetic Moment of the Electron

17.8.1 1. Electron Form Factors

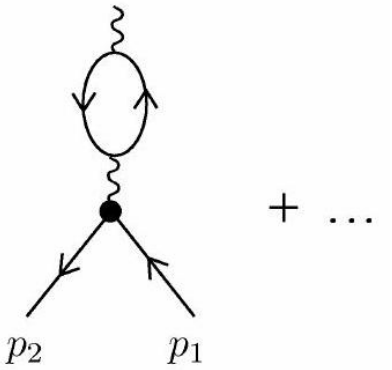
Рассмотрим вершинный оператор $\Gamma^\mu(p_2, p_1)$ в случае, когда две электронные линии являются внешними, а фотонная - внутренней с 4 -импульсом $k = p_2 - p_1$ (если рассматривать её как входящую). Электронным внешним линиям отвечают множители $u_1 = u_{p_1}$ и $\bar{u}_2 = \bar{u}_{p_2}$, так что Γ входит в выражение для диаграмм в виде $J^\mu_{fi} = \bar{u}_2 \Gamma^\mu u_1$. Амплитуда перехода, описывающая рас-



(a)



(b)



(c)
Рис. 26

сеяние электрона во внешнем поле в первом порядке по этому полю представляется как

$$M_{fi} = -eJ^{\mu}_{fi}\mathcal{A}^{(e)}_{\mu}(k) \tag{1}$$

где $\mathcal{A}^{(e)}_{\mu}$ - эффективное (с учётом поляризации вакуума) внешнее поле. Однопетлевой вклад в эффективное внешнее поле задаётся диаграммой (c) на рис. 26. Поскольку эта амплитуда является скаляром (а не псевдоскаляром), а $\mathcal{A}^{(e)}_{\mu}$ - вектором, то величина J^{μ}_{fi} является вектором во всех приближениях и она может быть выражена лишь через истинные векторы, которые могут быть составлены из имеющихся в нашем распоряжении 4 -векторов p_1 и $p_2\,(k = p_2 - p_1)$ и биспиноров u_1 и u_2. Всего имеется три таких вектора:

$$\bar{u}_2\gamma^{\mu}u_1, \quad (\bar{u}_2u_1)\,P^{\mu}, \quad (\bar{u}_2u_1)\,k^{\mu} \tag{2}$$

где $P^{\mu} = p^{\mu}_1 + p^{\mu}_2$. Вследствие тождества Уорда (10 Л10), формул (39 Л10), (40 а Л10) и равенства (38 а Л8) имеем:

$$k_{\mu}J^{\mu}_{fi} = 0 \tag{3}$$

Так как 4 -импульсы p_1 и p_2 находятся на массовой поверхности, то $k_{\mu}P^{\mu} = 0$, но $k_{\mu}k^{\mu} \neq 0$. Кроме того, вследствие (38 а Л8) $k_{\mu}\bar{u}_2\gamma^{\mu}u_1 = 0$. Поэтому

$$J^{\mu}_{fi} = f_1 \cdot (\bar{u}_2u_1)\,P^{\mu} + f_2 \cdot (\bar{u}_2\gamma^{\mu}u_1) \tag{4}$$

где f_1 и f_2 - инварианты, которые называются электромагнитными формфакторами электрона. Из двух векторов p_1 и $p_2\,(p_1^2 = p_2^2 = m^2)$ можно составить лишь одну инвариантную величину, в качестве которой возьмём k^2. Формфакторы являются функциями лишь k^2.

При помощи формул (5 Л8), (10 Л8) и (38 Л8) получаем:

$$(\bar{u}_2\sigma^{\mu\nu}u_1)\,k_\nu = -m\,(\bar{u}_2\gamma^\mu u_1) + \frac{1}{2}\,(\bar{u}_2 u_1)\,P^\mu \tag{5}$$

Поэтому представление (4) может быть переписано как

$$J^\mu_{fi} = f\left(k^2\right)(\bar{u}_2\gamma^\mu u_1) - \frac{1}{m}g\left(k^2\right)(\bar{u}_2\sigma^{\mu\nu}u_1)\,k_\nu \tag{6}$$

где f и g - другие формфакторы.

Член в амплитуде рассеяния (1), пропорциональный $g\,(k^2)$, имеет вид

$$\delta M_{fi} = \frac{e}{m}g\left(k^2\right)(\bar{u}_2\sigma^{\mu\nu}u_1)\,k_\nu\mathcal{A}^{(e)}_\mu \tag{7}$$

Рассмотрим чисто магнитное поле $\mathcal{A}^{(0)\mu} = (0, \mathbf{A})$ и пусть $k^\mu = (0, \mathbf{k}), \mathbf{k} \to 0$. Это значит, что поле не зависит от времени и оно медленно изменяется в пространстве. Поэтому далее в (7) можно заменить "одетое"поле $\mathcal{A}^{(e)}_\mu$ на "голое"поле $A^{(e)}_\mu 1$. Перепишем (7) с учётом того, что в данном случае имеются лишь пространственно-пространственные компоненты тензора электромагнитного поля и $H^i(\mathbf{k}) = i\varepsilon_{ijk}k_jA^{(e)}_k(\mathbf{k})$:

$$\delta M_{fi} = \frac{e}{m}g(0)\bar{u}_2\left(\frac{i}{2}\varepsilon_{ijk}\sigma^{jk}\right)u_1H^i$$

Такой же вклад в амплитуду даст добавка к гамильтониану

$$\delta\mathcal{H} = \int \mathrm{d}^{(3)}x\bar{\psi}\left[-\frac{e}{m}g(0)\left(\frac{i}{2}\varepsilon_{ijk}\sigma^{jk}\right)H^i\right]\psi \longrightarrow \int \mathrm{d}^{(3)}x\varphi^\dagger\left[-\frac{e}{m}g(0)\mathbf{sH}\right]\varphi \tag{8}$$

Последнее выражение в (8) получается из предыдущего в нерелятивистском пределе в стандартном представлении. Сравнение (8) с уравнениями (28 Л8) и (30 Л8) показывает, что радиационные поправки дают дополнительный вклад в магнитный момент электрона, так что его полный магнитный момент (в обычных единицах

$$\mu = \frac{e\hbar}{2mc}(1 + g(0)) \tag{9}$$

Очевидно, что первое слагаемое в (6) не может дать вклад в аномальный магнитный момент. Действительно, при $k \to 0$ для первого слагаемого в (6) имеем $f\,(k^2)\,(\bar{u}_2\gamma^\mu u_1) \to 2f(0)p^\mu$, где p^μ - импульс электрона.

17.8.2 2. Analytical Properties of Form Factors

Амплитуда (1) описывает два канала реакции. В канале рассеяния переменная

$$t \equiv k^2 = (p_2 - p_1)^2 \leq 0 \tag{10}$$

Путём замены $p_2 \to p_-, p_1 \to -p_+$мы приходим к аннигиляционному каналу, отвечающему рождению электрон-позитронной пары с 4 -импульсами p_-и p_+. В этом канале

$$t = (p_- + p_+)^2 \geq 4m^2 \tag{11}$$

Область значений $0 < t < 4m^2$ - нефизическая.

Применим условие унитарности (34 Л5). В канале рассеяния ($t < 0$) нет физических промежуточных состояний: один свободный электрон не может изменить свой импульс или родить какие либо другие реальные (не виртуальные) частицы; в нефизической области их также нет. Поэтому при $t < 4m^2$ правая сторона равенства (34 Л5) отсутствует, так что

$$M_{fi} = M_{if}^* \tag{12}$$

Равенство (12) справедливо, конечно, во всех приближениях. Перестановка начального и конечного состояний означает перестановку p_1 и p_2, а тем самым замену $k \to -k$. Из соотношения (12) для выражения (1) вытекает, что

$$J_{fi}^\mu \mathcal{A}_\mu^{(e)}(k) = J_{if}^{\mu *} \mathcal{A}_\mu^{(e)*}(-k)$$

Но вследствие вещественности электромагнитного поля $\mathcal{A}_\mu^{(e)}(k) = \mathcal{A}_\mu^{(e)*}(-k)$, и потому

$$J_{fi}^\mu = J_{if}^{\mu *}, \quad t < 4m^2 \tag{13}$$

Легко проверить, что (см. (8 Л8) и (11 Л8))

$$(\bar{u}_2 \gamma^\mu u_1) = (\bar{u}_1 \gamma^\mu u_2)^*, \quad (\bar{u}_2 \sigma^{\mu\nu} u_1) = -(\bar{u}_1 \sigma^{\mu\nu} u_2)^*$$

Поэтому f_{if}^* отличается от f_{fi} лишь заменой функций $f(t)$ и $g(t)$ их комплексно сопряжёнными. Тогда из (13) следует, что

$$\operatorname{Im} f(t) = \operatorname{Im} g(t) = 0, \quad t < 4m^2 \tag{14}$$

Из диаграмм (b) и (c) на рис. 26 видно, что в аннигиляционном канале ($t > 4m^2$) уже в однопетлевом приближении существуют реальные промежуточные частицы. Поэтому правая часть условия унитарности для амплитуды (1) отлична от нуля и формфакторы f и g комплексны. Аналитические свойства функций $f(t)$ и $g(t)$ аналогичны свойствам функций $\mathcal{P}(t)$. Эти функции аналитичны в комплексной плоскости переменной t, разрезанной вдоль положительной вещественной оси $t > 4m^2$, причём

$$f^*(t) = f(t^*), \quad g^*(t) = g(t^*) \tag{15}$$

Условие перенормируемости (46 Л10), применённое к (6), даёт

$$f(0) = 1 \tag{16}$$

Это условие учитывается автоматически, если в дисперсионном соотношении использовать не $f(t)$, а $(f(t) - 1)/t$. Таким образом

$$f(t) - 1 = \frac{t}{\pi} \int\limits_{4m^2}^{\infty} \frac{\operatorname{Im} f(t') \, \mathrm{d}t'}{t' (t' - t - i\varepsilon)} \tag{17}$$

[6] 1 1 Действительно, в конце лекции 11 было показано, что (в однопетлевом приближении) слабое медленно меняющееся "одетое"кулоново поле фактически совпадает с "голым". Это же утверждение во всех порядках ТВ имеет место в отношении любого слабого и медленно изменяющегося электромагнитного поля.

Для формфактора $g(t)$ условие перенормировки (46 Л10) не даёт ограничений аналогичная формула имеет вид

$$g(t) = \frac{1}{\pi} \int\limits_{4m^2}^{\infty} \frac{\operatorname{Im} g\left(t'\right) \mathrm{d}t'}{t' - t - i\varepsilon} \tag{18}$$

В (17), (18) мнимые части функций, как и обычно, берутся на верхних берегах разреза.

Рассмотрение, проведенное до сих пор, справедливо во всех порядках ТВ.

17.8.3 3. Calculation of Imaginary Parts Using the Feynman Integral

Выпишем амплитуду, соответствующую диаграмме (b) на рис. 26 в аннигиляционном канале $(p_2 \to p_-, p_1 \to -p_+, q \to p - p_-, k = p_- + p_+)$:

$$-ie\bar{u}_{p_-}\Gamma^{\mu}u_{-p_+} = (-ie)^3\bar{u}_{p_-}\gamma^{\nu}i\int \frac{\mathrm{d}^{(4)}p}{(2\pi)^4}S_c(p)\gamma^{\mu}S_c(p-k)\gamma^{\lambda}u_{-p_+}D^{\alpha}_{\lambda\nu}\left(p-p_-\right) \tag{19}$$

Далее обкладки $\bar{u}_{p_-}...u_{-p_+}$во всех формулах опускаются для сокращения записи, но равенства $\bar{u}_{p_-}\not{p}_- = m\bar{u}_{p_-}$и $\not{p}_+u_{-p_+} = -mu_{-p_+}$используются в вычислениях. В калибровке Фейнмана $\alpha = 1$ имеем:

$$f\left(k^2\right)\gamma^{\mu} - \frac{1}{m}g\left(k^2\right)\sigma^{\mu\nu}k_{\nu} = \int \frac{i\varphi^{\mu}\left(p^0,\mathbf{p}\right)\mathrm{d}^{(4)}p}{\left(p^2-m^2\right)\left[(p-k)^2-m^2\right]} \tag{20}$$

где

$$\varphi^{\mu}\left(p^0,\mathbf{p}\right) = -\frac{e^2}{4\pi^3}\cdot\frac{\gamma^{\nu}(\not{p}+m)\gamma^{\mu}(\not{p}-\not{k}+m)\gamma_{\nu}}{\left[\left(p-p_-\right)^2-\lambda^2\right]} \tag{21}$$

Здесь опять введена бесконечно малая масса фотона λ в фотонный пропагатор.

Разрез проходит в t-плоскости при $t > 4m^2$. При таких значениях $t = k^2$ существует система отсчёта K_0, в которой $k = (k^0, \mathbf{0})$. В системе K_0

$$(p-k)^2 = \left(p^0-k^0\right)^2 - \mathbf{p}^2, \quad p^0_- = p^0_+ = \frac{1}{2}k^0 = \frac{\sqrt{t}}{2}, \quad \mathbf{p}_- = -\mathbf{p}_+, \quad |\mathbf{p}_-| = \frac{1}{2}\sqrt{t-4m^2} \tag{22}$$

Введём обозначение $\omega = +\sqrt{|\mathbf{p}|^2+m^2}$. Тогда

$$\mathrm{d}^4p = |\mathbf{p}|\omega\mathrm{d}p^o\ \mathrm{d}\omega\mathrm{d}o_{\mathbf{p}} \tag{23}$$

В системе отсчёта K_0 знаменатель в интеграле (20) имеет полюса по p^0 в точках

$$\begin{array}{ll} \text{a)}\ p_0 = \omega - i\varepsilon, & a')\ p_0 = -\omega + i\varepsilon \\ \text{b)}\ p_0 = k_0 - \omega + i\varepsilon, & b')\ p_0 = k_0 + \omega - i\varepsilon \end{array} \tag{24}$$

Для определённости считаем $k^0 > 0$, что отвечает процессу рождения пары (ответ не зависит от этого предположения, поскольку является функцией $\left(k^0\right)^2$). Ясно, что лишь полюса a) и b) могут совпасть при интегрировании в (20), что происходит при $\omega = (1/2)k^0$ (это возможно лишь при $k^0 > 2m$). На рис. 27 показано расположение полюсов в комплексной плоскости p^0.

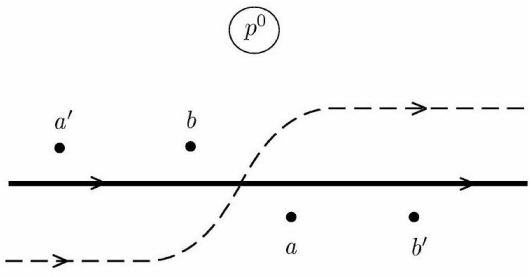


Рис. 27

При замене в интеграле (20) $k^2 \to k^2 - i\delta, \delta \to +0$, интеграл изменяется скачкообразно, поскольку при такой замене мы попадаем на нижний берег разреза. Однако из рис. 27 видно, что если полюса a) и b) не совпадают, то при указанной замене параметра скачка быть не может, поскольку контур интегрирования может быть плавно изменён (на рис. 27 новый контур интегрирования изображён пунктиром). Поэтому бесконечно малое смещение полюсов не переводит их на другую сторону контура интегрирования. Отсюда видно, что мнимая часть (или скачок интеграла) появляется лишь при условии совпадения полюсов a) и b). Такое совпадение происходит лишь при одновременном обращении в нуль обоих сомножителей в знаменателе интеграла (20). Это значит, что для нахождения скачка в интеграле (20) следует вставить под интеграл вместо знаменателя множитель $\delta\left(p^2 - m^2\right)\delta\left[(p-k)^2 - m^2\right]$. Для вычисления коэффициента при этом множителе заменим исходный контур интегрирования C на два других C' и C'' так, как показано на рис. 28.

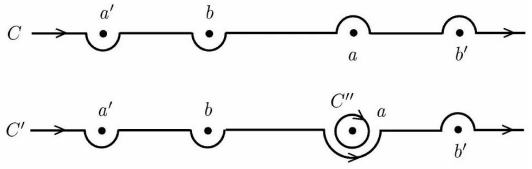

Рис. 28

Интеграл по контуру C' уводится от полюсов a) и b) и потому не даёт скачка. Интеграл по контуру C'' легко вычисляется взятием вычета, что эквивалентно замене под интегралом (20)

$$\frac{1}{p^2 - m^2} \to (-2\pi i)\delta\left(p^2 - m^2\right) \tag{25}$$

Знак "-" в (25) имеет место вследствие отрицательной ориентации контура C''. Теперь очевидно, что разность значений интеграла (20) на верхнем и нижнем берегах разреза даётся величиной

$$\int\limits_{p_0>0} \mathrm{d}^{(4)}pi\varphi^\mu\left(p^0, \mathbf{p}\right)\left[-2\pi i\delta\left(p^2 - m^2\right)\right]\left[\frac{1}{(p-k)^2 - m^2 + i\delta} - \frac{1}{(p-k)^2 - m^2 - i\delta}\right] =$$

$$= \int\limits_{p_0>0} \mathrm{d}^{(4)}pi\varphi^\mu\left(p^0, \mathbf{p}\right)\left[-2\pi i\delta\left(p^2 - m^2\right)\right]\left[-2\pi i\delta\left((p-k)^2 - m^2\right)\right] \tag{26}$$

Можно доказать общее правило Каткосского для отыскания скачка диаграмм:

[61] Совпадение полюсов внутренних фотонной и одной из фермионных линий невозможно, поскольку вследствие сохранения 4 -импульса электрон не может излучить частицу.

1. разобьём диаграмму на две всеми возможными способами путём разрезания её пропагаторов;

2. для каждого разрезанного пропагатора частицы массы m делаем замену $(p^2-m^2+i\varepsilon)^{-1}\to(-2\pi i)\delta(p^2-m^2)$, затем вычисляем петлевые интегралы;

3. суммируем вклады от всех возможных разрезаний.

В результате интегрирования в системе K_0 δ-функции в (26) легко снимаются. При помощи (22) и (23) и (26) находим для скачка интеграла (20):

$$\mathrm{Disc}\int\frac{i\varphi^\mu \mathrm{d}^4p}{(p^2-m^2)\left[(p-k)^2-m^2\right]}=\int\limits_{p_0>0}|\mathbf{p}|\omega\mathrm{d}p^o\ \mathrm{d}\omega\mathrm{d}o_{\mathbf{p}}i\varphi^\mu\times$$

$$\times\left[-2\pi i\delta\left(p_0^2-\omega^2\right)\right]\left[-2\pi i\delta\left(\left(p_0-k_0\right)^2-\omega^2\right)\right]=-i\frac{\pi^2}{2}\sqrt{\frac{t-4m^2}{t}}\int\mathrm{d}o_{\mathbf{p}}\varphi^\mu\left(\frac{\sqrt{t}}{2},\mathbf{p}\right)\tag{27}$$

$$p^0=\frac{\sqrt{t}}{2},\quad |\mathbf{p}|=\frac{1}{2}\sqrt{t-4m^2}\tag{28}$$

Вычислим интеграл в (27) в системе центра инерции K_0, в которой

$$p_-=\left(\frac{\sqrt{t}}{2},0,0,\frac{\sqrt{t-4m^2}}{2}\right),\quad p=\left(\frac{\sqrt{t}}{2},\mathbf{p}\right),\quad \mathbf{p}=\frac{\sqrt{t-4m^2}}{2}(\sin\theta\cos\phi,\sin\theta\sin\phi,\cos\theta)\tag{29}$$

При помощи формул (62 Л8), (22), (28) и (29) величина (21) переписывается в виде

$$\varphi^\mu=\frac{e^2}{\pi^3\rho}\left(-2p^\mu\not{p}+\not{k}\gamma^\mu\not{p}+4mp^\mu-2mk^\mu\right),\quad \rho=\left(t-4m^2\right)(1-\cos\theta)+2\lambda^2\tag{30}$$

Введём обозначения

$$\varkappa^\mu=\int\mathrm{d}o_{\mathbf{p}}\frac{p^\mu}{\rho},\quad \varkappa^{\mu\nu}=\int\mathrm{d}o_{\mathbf{p}}\frac{p^\mu p^\nu}{\rho}\tag{31}$$

Приведём ненулевые значения компонент этих величин:

$$\begin{aligned}\varkappa^0&=\tfrac{\pi\sqrt{t}}{t-4m^2}\ln\tfrac{t-4m^2}{\lambda^2},&\qquad \varkappa^3&=\tfrac{\pi}{\sqrt{t-4m^2}}\left[-2+\ln\tfrac{t-4m^2}{\lambda^2}\right]\\ \varkappa^{00}&=\tfrac{\pi t}{2(t-4m^2)}\ln\tfrac{t-4m^2}{\lambda^2},&\qquad \varkappa^{03}&=\tfrac{\pi}{2}\sqrt{\tfrac{t}{t-4m^2}}\left[-2+\ln\tfrac{t-4m^2}{\lambda^2}\right]\end{aligned}\tag{32}$$

$$\varkappa^{33}=\tfrac{\pi}{2}\left[-2+\ln\tfrac{t-4m^2}{\lambda^2}\right],\quad \varkappa^{\alpha\beta}=\tfrac{\pi}{2}\delta^{\alpha\beta},\quad \alpha,\beta=1,2$$

Из (22), (28) и (30) следует, что

$$\varphi^0=0\tag{33}$$

Далее в этом пункте обозначаем символом $\approx$ те равенства, которые имеют место лишь в обкладках $\bar u_{p_-}\ldots u_{-p_+}$. Например,

$$\gamma^0\approx 0,\quad \not{k}\gamma^3\not{p}_-=-\not{p}_-\not{k}\gamma^3\approx m\gamma^3\not{k}\tag{34}$$

При помощи формул (32) и (34) находим:

$$\int \mathrm{d}o_{\mathbf{p}}\varphi^3 \approx \frac{2e^2}{\pi^2}\left\{\frac{m}{\sqrt{t-4m^2}}\left[-2+\ln\frac{t-4m^2}{\lambda^2}\right]+\frac{m}{t-4m^2}\left(\ln\frac{t-4m^2}{\lambda^2}\right)\gamma^3\not{K}\right\} \tag{35}$$

Теперь воспользуемся формулой (5), которая в аннигиляционном канале имеет вид

$$\sigma^{\mu\nu}k_\nu \approx -m\gamma^\mu+\frac{1}{2}\left(p_-^\mu-p_+^\mu\right) \tag{36}$$

При $\mu=3$ с учётом (22) отсюда следует, что

$$\frac{1}{2}\sqrt{t-4m^2}\approx\frac{1}{2}\gamma^3\not{K}+m\gamma^3 \tag{37}$$

и (35) переписывается как

$$\int \mathrm{d}o_{\mathbf{p}}\varphi^3 = \frac{2e^2}{\pi^2}\left\{\frac{2m}{t-4m^2}\left(-1+\ln\frac{t-4m^2}{\lambda^2}\right)\gamma^3\not{K}+\frac{2m^2}{t-4m^2}\left(-2+\ln\frac{t-4m^2}{\lambda^2}\right)\gamma^3\right\} \tag{38}$$

Так как $\gamma^0\approx 0$, то (см. (34), (22) и (29)):

$$m\gamma^3\not{K}\approx -\not{p}_-\not{K}\gamma^3\approx-\frac{1}{2}t\gamma^3 \tag{39}$$

Поэтому наиболее общий вид левой части в равенстве (38), допустимый структурой (20), таков:

$$\begin{aligned}\int \mathrm{d}o_{\mathbf{p}}\varphi^3 = \frac{e^2}{\pi^2\left(t-4m^2\right)}\Bigg\{&4m^2\left(-2+\ln\frac{t-4m^2}{\lambda^2}\right)\gamma^3+\\ &+4m\left(-1+\ln\frac{t-4m^2}{\lambda^2}\right)\gamma^3\not{K}+x\left(\frac{1}{2}t\gamma^3+m\gamma^3\not{K}\right)\Bigg\}\end{aligned} \tag{40}$$

где x - некое вещественное число, которое будет определено ниже.

Теперь займёмся вычислением величин $\left(\int \mathrm{d}o_{\mathbf{p}}\varphi^\alpha\right)$ с $\alpha=1,2$. При помощи формул (30) и (32) находим:

$$\int \mathrm{d}o_{\mathbf{p}}\varphi^\alpha=\frac{e^2}{\pi^2}\left\{\gamma^\alpha+\frac{2}{t-4m^2}\left(\ln\frac{t-4m^2}{\lambda^2}\right)\not{K}\gamma^\alpha\not{p}_-+\frac{2}{\sqrt{t-4m^2}}\not{K}\gamma^\alpha\gamma^3\right\} \tag{41}$$

Теперь учтём, что

$$\not{p}_-=\not{K}-\not{p}_+,\quad \gamma^3=\frac{2\not{p}_+-\not{K}}{\sqrt{t-4m^2}} \tag{42}$$

Поэтому

$$\int \mathrm{d}o_{\mathbf{p}}\varphi^\alpha\approx\frac{e^2}{\pi^2\left(t-4m^2\right)}\left\{\left[\left(3t-4m^2\right)-2t\left(\ln\frac{t-4m^2}{\lambda^2}\right)\right]\gamma^\alpha+\left[4m-2m\left(\ln\frac{t-4m^2}{\lambda^2}\right)\right]\gamma^\alpha\not{K}\right\} \tag{43}$$

В случае $\mu=1,2$ равенство (36) принимает вид

$$\frac{1}{2}\gamma^\alpha \not{k} \approx -m\gamma^\alpha \tag{44}$$

Поэтому имеем наиболее общий вид левой части равенства (43), совместимый со структурой (20):

$$\int \mathrm{d}o_{\mathbf{p}}\varphi^\alpha = \frac{e^2}{\pi^2\left(t-4m^2\right)}\left\{\left(3t-4m^2-2t\ln\frac{t-4m^2}{\lambda^2}\right)\gamma^\alpha + \right.$$
$$\left. + \left(4m-2m\ln\frac{t-4m^2}{\lambda^2}\right)\gamma^\alpha \not{k} + y\left(m\gamma^\alpha + \frac{1}{2}\gamma^\alpha \not{k}\right)\right\} \tag{45}$$

Здесь y - некое вещественное число. Чтобы все выражения (33), (40) и (45) собирались в выражение вида (6), коэффициенты при γ^3 и $\gamma^3\not{k}$ в (40) должны быть равны коэффициентам при γ^α и $\gamma^\alpha \not{1}$ в (45), соответственно. Это требование однозначно определяет числа x и y:

$$x = 6 - 4\ln\frac{t-4m^2}{\lambda^2}, \quad y = -4m + 4m\ln\frac{t-4m^2}{\lambda^2}$$

Подставляя эти числа в соответствующие величины, окончательно находим:

$$\int \mathrm{d}o_{\mathbf{p}}\varphi^\mu \approx -\frac{e^2}{\pi^2\left(t-4m^2\right)}\left\{\left[-3t+8m^2+2\left(t-2m^2\right)\ln\frac{t-4m^2}{\lambda^2}\right]\gamma^\mu - 4m\sigma^{\mu\nu}k_\nu\right\} \tag{46}$$

Теперь, сопоставляя формулы (20), (27) и (46), находим мнимые части формфакторов:

$$\mathrm{Im}\, g(t) = \frac{e^2m^2}{\sqrt{t\left(t-4m^2\right)}}$$
$$\mathrm{Im}\, f(t) = \frac{e^2}{4\sqrt{t\left(t-4m^2\right)}}\left[-3t+8m^2+2\left(t-2m^2\right)\ln\frac{t-4m^2}{\lambda^2}\right] \tag{47}$$

Инфракрасная расходимость имеется только в $f(t)$.

Формфакторы могут быть вычислены точно по их мнимым частям при помощи уже использовавшейся подстановки $t' = 4m^2/\left(1-x^2\right)$ (см. Л. Д. Ландау, Е. М. Лифшиц. Теоретическая физика. Т. 4, §117). Однако мы ограничимся их асимптотическими значениями.

Согласно (18) и (47)

$$g(0) = \frac{e^2m^2}{\pi}\int\limits_{4m^2}^{\infty}\frac{\mathrm{d}t}{t\sqrt{t\left(t-4m^2\right)}} = \frac{e^2}{2\pi} \tag{48}$$

При $|t| \ll 4m^2$ можно пренебречь параметром t под знаком интеграла в (17):

$$f(t)-1 = \frac{e^2t}{8\pi m^2}\int\limits_0^1 \mathrm{d}x\left[-1-2x^2+\left(1+x^2\right)\ln\frac{4x^2}{1-x^2}+\left(1+x^2\right)\ln\frac{m^2}{\lambda^2}\right] = \frac{e^2t}{3\pi m^2}\left(\ln\frac{m}{\lambda}-\frac{3}{8}\right)$$

Поэтому

$$f(t)-1=\frac{e^2t}{3\pi m^2}\left(\ln\frac{m}{\lambda}-\frac{3}{8}\right),\quad g(t)=\frac{e^2}{2\pi},\quad |t|\ll 4m^2 \tag{49}$$

При $t'\gg 4m^2$ из (47) получаем, что $\operatorname{Im} f\left(t'\right)=(e^2/2)\ln\left(t'/\lambda^2\right)$. Оценим сначала $f(t)$ при $-t\gg 4m^2$. Делая соответствующие пренебрежения, сводим интеграл в (17) к интегралу

$$f(t)-1=\frac{e^2t}{2\pi}\int\limits_{4m^2}^{\infty}\frac{\ln\frac{t'}{\lambda^2}\,\mathrm{d}t'}{t'\left(t'+|t|\right)}$$

который легко оценивается при помощи подстановки $t'=4m^2e^x, 0<x<\infty$:

$$f(t)-1=\frac{e^2t}{2\pi}\int\limits_{0}^{\infty}\frac{\left(x+\ln\frac{4m^2}{\lambda^2}\right)\mathrm{d}x}{\left(|t|+4m^2e^x\right)}$$

Знаменатель в подынтегральном выражении почти равен $|t|$ при $x<x_0$ и быстро падает при $x>x_0$, где $x_0=\ln\left[|t|/4m^2\right]$. Поэтому при $-t\gg 4m^2$

$$f(t)-1=-\frac{e^2}{2\pi}\left(\frac{1}{2}\ln^2\frac{|t|}{m^2}+2\ln\frac{m}{\lambda}\ln\frac{|t|}{m^2}\right) \tag{50}$$

При больших положительных $|t|$ этот формфактор приобретает мнимую часть, а вещественная остаётся прежней. Легко сделать аналогичную оценку для $g(t)$. Таким образом

$$f(t)-1=-\frac{e^2}{2\pi}\left(\frac{1}{2}\ln^2\frac{|t|}{m^2}+2\ln\frac{m}{\lambda}\ln\frac{|t|}{m^2}\right)+\begin{cases} i\frac{e^2}{2}\ln\frac{|t|}{\lambda^2}, & \text{если } t\gg 4m^2\\ 0, & \text{если } -t\gg 4m^2\end{cases} \tag{51}$$

$$g(t)=-\frac{e^2m^2}{\pi t}\ln\frac{|t|}{m^2}+\begin{cases} i\frac{e^2m^2}{t}, & \text{если } t\gg 4m^2\\ 0, & \text{если } -t\gg 4m^2\end{cases} \tag{52}$$

17.8.4 4. Anomalous Magnetic Moment of the Electron

Согласно (9) и (48) в однопетлевом приближении магнитный момент электрона

$$\mu=\frac{e\hbar}{2mc}\left(1+\frac{e^2}{2\pi\hbar c}\right) \tag{53}$$

Эта формула впервые была получена Ю. Швингером в 1949 году.

17.9 L13 Infrared Problem. Lamb Shift of Energy Levels

Мы видели, что некоторые величины в КЭД вследствие инфракрасных расходимостей не могут быть вычислены без конечной массы фотона. В этой лекции будет показано, что в физически наблюдаемых величинах (в отличие от ненаблюдаемых величин) нефизическая масса фотона может быть устремлена к нулю и при этом наблюдаемые величины имеют конечный предел.

17.9.1 1. Massive Vector Field

Поскольку массивное векторное поле имеет (для каждого импульса) три физических степени свободы (а не две - как в случае фотонного поля), то для корректного обращения с массивным векторным полем следует внести исправления в некоторые формулы

Действие массивного векторного поля имеет вид

$$\mathcal{S} = -\frac{1}{4\pi}\int \mathrm{d}^{(4)}x \left\{ \frac{1}{4}\left(\partial_\mu A_\nu - \partial_\nu A_\mu\right)^2 - \frac{\lambda^2}{2}A_\mu^2 \right\} \tag{1}$$

Мы выбрали нормировку, совпадающую с нормировкой электромагнитного поля (сравни с (16 Л7)) для облегчения дальнейшего предельного перехода. Действие (1) приводит к следующему уравнению движения:

$$\partial_\nu\left(\partial^\mu A^\nu - \partial^\nu A^\mu\right) - \lambda^2 A^\mu = 0 \tag{2}$$

Из (2) следует условие

$$\partial_\mu A^\mu = 0 \tag{3}$$

В результате уравнение движения (2) упрощается:

$$\left(\partial_\nu\partial^\nu + \lambda^2\right) A^\mu = 0 \tag{4}$$

При помощи уравнения движения (2) находим пропагатор (сравни с (53 Л7))

$$D_{\mu\nu}(k) = \frac{4\pi}{k^2-\lambda^2}\left(\eta_{\mu\nu} - \frac{k_\mu k_\nu}{\lambda^2}\right) \tag{5}$$

Сумма по поляризациям векторной частицы даёт правило (сравни с (33 Л7)):

$$\sum_{\alpha=1}^{3} e_\alpha^\mu e_\alpha^{\nu\star} = -\left(\eta^{\mu\nu} - \frac{k^\mu k^\nu}{\lambda^2}\right) \tag{6}$$

Эта формула вытекает из равенств $k_\mu e_\alpha^\mu = 0$ и $k^2 = \lambda^2$.

Взаимодействие векторного поля с электрон-позитронным полем описывается тем же действием $\mathcal{S}_{\text{int}} = -e\int \mathrm{d}^{(4)}x A_\mu J^\mu$, что и в случае фотонного поля. Поэтому вследствие калибровочной инвариантности, то есть независимости физических величин от продольной части пропагатора, мы можем опустить в (5) продольную часть и пользоваться пропагатором

$$D_{\mu\nu}(k) = \frac{4\pi}{k^2-\lambda^2}\eta_{\mu\nu} \tag{7}$$

Именно пропагатор (7) использовался в предыдущих лекциях.

17.9.2 2. Emission of Soft Photons

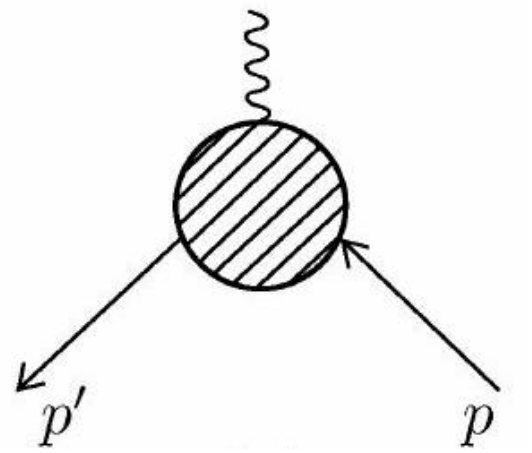
Для определённости рассмотрим процесс рассеяния электрона внешним электромагнитным полем. Например, это может быть неподвижное массивное ядро. На рис. 29 (а) изображена диаграмма упругого процесса рассеяния электрона, в результате которого электрон переходит из состояния с импульсом p в состояние с импульсом p'. Диаграммы на рис. 29$(b), (c)$ изображают процесс

PSfrag неупругого рассеяния, отличающийся от упругого процесса испусканием дополнительного мягкого фотона ($k \to 0$).

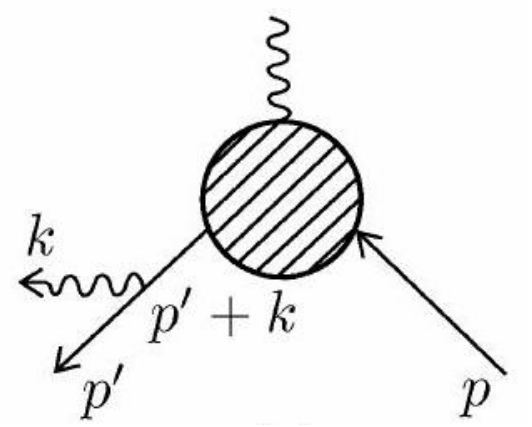
Диаграмма на рис. 29 (a) аналитически представляется в виде

$$M_{fi}^{(elas)} = \bar{u}_{p'} M u_p \tag{8}$$

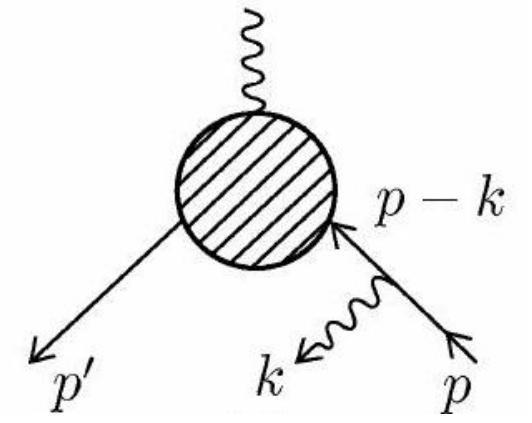
Рассмотрим амплитуду, изображённую на рис. 29 (c). Эта амплитуда получается из амплитуды,



(a)



(b)



(c)
Рис. 29
изображённой на рис. 29(a), путём замены

$$u_p \to \sqrt{4\pi}eS_c(p-k)\gamma^\mu e^*_\mu u_p = \sqrt{4\pi}e\frac{\not p - \not k + m}{(p-k)^2-m^2}^{\ *} u_p \approx -\sqrt{4\pi}e\frac{\not p + m}{2pk-\lambda^2}\phi^* u_p \tag{9}$$

Здесь было учтено, что $k^2=\lambda^2$ и $k\to 0$. Так как

$$\not p\phi^* = 2pe^* - \phi^*\not p, \quad \not p u_p = m u_p$$

то (9) переписывается как

$$u_p \to -\sqrt{4\pi}e u_p \frac{pe^*}{pk-\lambda^2/2} \tag{10}$$

Аналогичное рассмотрение показывает, что диаграмма, изображённая на рис. 29 (b), получается из диаграммы, изображённой на рис. 29 (a), путём замены

$$\bar u_{p'} \to \sqrt{4\pi}e\frac{p'e^*}{p'k+\lambda^2/2}\bar u_{p'} \tag{11}$$

Таким образом, сумма амплитуд (b) и (c) на рис. 29

$$M_{fi} = M_{fi}^{(elas)}\left[\sqrt{4\pi}e\left(\frac{p'e^*}{p'k+\lambda^2/2} - \frac{pe^*}{pk-\lambda^2/2}\right)\right] \tag{12}$$

а соответствующее неупругое сечение

$$\mathrm{d}\sigma_1 = \mathrm{d}\sigma^{(elas)} 4\pi e^2 \left|\frac{p'e}{p'k+\lambda^2/2} - \frac{pe}{pk-\lambda^2/2}\right|^2 \cdot \frac{\mathrm{d}^{(3)}k}{(2\pi)^3 2\omega_k}, \quad \omega_k = \sqrt{\mathbf{k}^2+\lambda^2} \tag{13}$$

Из формулы (13) видна причина, по которой следует учитывать лишь фотоны, излучённые внешними электронными линиями, но не учитывать мягкие фотоны, излучённые внутренними линиями: внешние электронные линии дают в амплитуде дополнительный множитель - электронный пропагатор, импульс которого при $k\to 0$ находится очень близко к массовой поверхности. Такой пропагатор находится вблизи своего полюса и он численно велик. Поэтому при $k\to 0$ дифференциальное сечение (13) стремится к бесконечности. Если же мягкий фотон излучается внутренней линией, то численно большого множителя не появляется, так как по импульсу виртуального электрона происходит интегрирование и потому можно считать, что он находится вдали от массовой поверхности.

Просуммируем в (13) по поляризациям векторной частицы при помощи (6). Легко увидеть, что второе слагаемое в (6) даёт относительный вклад в сечение $\sim O(\lambda^2)$. Так как $\lambda^2\to 0$, то вклад
в сечение от второго слагаемого в (6) можно опустить. По этой же причине может быть опущено слагаемое λ^2 в знаменателях под знаком модуля в (13). В результате получаем:

$$\mathrm{d}\sigma_1 = -e^2\left(\frac{p'}{p'k} - \frac{p}{pk}\right)^2 \frac{\mathrm{d}^{(3)}k}{4\pi^2\omega_k}\,\mathrm{d}\sigma^{(elas)} \tag{14}$$

Пусть $\mathbf{n}=\mathbf{k}/\omega_k$, а $\mathbf{v}$ и $\mathbf{v}'$ - начальная и конечная скорости электрона. Тогда в случае $\lambda=0$ выражение (14) в трёхмерных обозначениях принимает вид [1]

$$\mathrm{d}\sigma_1 = e^2 \left(\frac{[\mathbf{v}', \mathbf{n}]}{1 - \mathbf{n}\mathbf{v}'} - \frac{[\mathbf{v}, \mathbf{n}]}{1 - \mathbf{n}\mathbf{v}} \right)^2 \cdot \frac{\mathrm{d}|\mathbf{k}|\mathrm{d}o_{\mathbf{k}}}{4\pi^2 \omega_k} \, \mathrm{d}\sigma^{(elas)} \tag{15}$$

Точно к такому же выражению для сечения мы придём, если в (13) с $\lambda = 0$ просуммировать по двум поляризациям безмассовых фотонов при помощи правила (33 Л7), справедливого для реальных безмассовых фотонов. Мы видим, что формула (14) для неупругого сечения справедлива как в случае излучения реальных безмассовых мягких фотонов, так и в случае излучения мягких векторных частиц с бесконечно малой, но ненулевой массой, и тремя поляризациями.

Обратим внимание на то, что в случае реальных фотонов ($\lambda = 0$) амплитуда (12) калибровочно инвариантна, т.е. она не изменяется при преобразовании вектора поляризации согласно (56 Л7). Таким образом, в случае реальных фотонов можно суммировать в сечении (13) по трём поляризациям фотона, включая продольную поляризацию. Это не изменит результат вследствие калибровочной инвариантности амплитуды и сечения. Но это означает, что при суммировании по поляризациям реального фотона можно пользоваться формулой (6) с последующим переходом к пределу $\lambda \to 0$. Именно такой подход и был использован при получении формулы (14). Приведенное рассуждение объясняет переход формулы (14) в формулу (15) при $\lambda \to 0$. Сама же формула (15) легче всего получается из формулы (13) при $\lambda = 0$ при помощи правила (33 Л7).

Множитель, стоящий перед $\mathrm{d}\sigma^{(\mathrm{elas})}$ в (15), совпадает с (делённой на ω_k) классической интенсивностью $\mathrm{d}\, I$ тормозного излучения малых частот (см. Л. Д. Ландау, Е. М. Лифшиц. Теоретическая физика, Т. 2, §69). Таким образом, излучение длинноволновых фотонов является, по сути, классическим процессом.

Полученные формулы применимы, конечно, при условии

$$\omega \sim |\mathbf{k}| \ll p^0 \tag{16}$$

Необходимо также, чтобы передача импульса $\mathbf{q} = \mathbf{p}' - \mathbf{p}$ рассеивающему центру (ядру) была велика по сравнению с изменением этой величины вследствие испускания мягкого фотона. Так как

$$\delta|\mathbf{p}| \sim \frac{\partial|\mathbf{p}|}{\partial p^0}\omega_k \sim \frac{\omega_k}{v}$$

то имеем ограничение

$$\omega_k/|\mathbf{q}|v \ll 1 \tag{17}$$

Полученный результат легко обобщается на случай испускания нескольких фотонов. Например, в случае испускания двух мягких фотонов с импульсами и векторами поляризации, нумеруемыми индексами 1 и 2, амплитуда (12) содержала бы вместо одного множителя в квадратной скобке два аналогичных множителя:

$$\left[\sqrt{4\pi}e \left(\frac{p'e_1^*}{p'k_1} - \frac{pe_1^*}{pk_1} \right) \sqrt{4\pi}e \left(\frac{p'e_2^*}{p'k_2} - \frac{pe_2^*}{pk_2} \right) \right] \tag{18}$$

[61] Действительно, $p = p^0(1, \mathbf{v})$, и так как при $\lambda = 0 \quad \omega_k = |\mathbf{k}|$, то $pk = p^0|\mathbf{k}|(1 - \mathbf{n}\mathbf{v}), \quad pp' = p_0 p'_0 \, (1 - \mathbf{v}\mathbf{v}')$, и потому

Простое вычисление показывает, что квадратные скобки в (*) и (**) равны одному и тому же значению $(\mathbf{n}, \mathbf{v}-\mathbf{v}')^2 \left[(1-\mathbf{nv})^2 (1-\mathbf{nv}')^2\right]^{-1}$. Отсюда следует равенство выражений (14) и (15) в случае нулевой массы фотона.

В этом нетрудно убедиться прямым вычислением. Действительно, рассмотрим диаграмму, отличающуюся от диаграммы на рис. 29(с тем, что входящий электрон с импульсом p излучает сначала мягкий фотон с импульсом k_1 и затем мягкий фотон с импульсом k_2. Будем считать фотоны безмассовыми. Вычисление, аналогичное тому, которое привело к формуле (10), теперь показывает, что в данном случае вклад в амплитуду получается из амплитуды на рис. 29 (а), если в ней сделать замену (учитываются лишь главные вклады по k_1 и k_2)

$$u_p \to u_p \frac{\left[-\sqrt{4\pi} e\,(pe_1^*)\right]\left[-\sqrt{4\pi} e\,(pe_2^*)\right]}{(pk_1+pk_2)\,(pk_1)}$$

Если с правой частью этого равенства сложить такую же величину с перестановкой $k_1 \leftrightarrow k_2$, то мы получим

$$u_p \to u_p \left[-\frac{\sqrt{4\pi} e\,(pe_1^*)}{pk_1}\right]\left[-\frac{\sqrt{4\pi} e\,(pe_2^*)}{pk_2}\right]$$

Теперь очевидно, что если учесть все возможности излучения двух мягких фотонов внешними электронными линиями, то в результате амплитуда получит множитель (18), поскольку этот множитель калибровочно инвариантен.

В случае испускания n мягких фотонов для каждого фотона имеется свой множитель в амплитуде. Поэтому сечение процесса с испусканием n мягких фотонов представляется в виде

$$\mathrm{d}\sigma_n = \mathrm{d}\sigma^{(elas)} \mathrm{d}w_1 \ldots \mathrm{d}w_n \tag{19}$$

где $\mathrm{d}w_i (i = 1 \ldots n)$ - вероятность отдельного испускания фотона k_i. Поэтому полное неупругое сечение представляется в виде

$$\mathrm{d}\sigma = \mathrm{d}\sigma^{(elas)} \sum_{n=0}^{\infty} \frac{1}{n!} \left(\int\limits_{\lambda}^{\omega_{\max}} \mathrm{d}w_\omega \right)^n \tag{20}$$

Здесь $\omega_{\max}$ - некое значение частоты, удовлетворяющее условиям (16), (17). Под знаком суммы в (20) множитель $1/n\,!$ учитывает тождественность фотонов.

Как было указано,

$$-|\mathbf{k}|^2 \left(\frac{p'}{p'k} - \frac{p}{pk}\right)^2 = -\frac{m^2}{(p_0')^2 (1-\mathbf{nv}')^2} - \frac{m^2}{p_0^2 (1-\mathbf{nv}')^2} + \frac{2(1-\mathbf{vv}')}{(1-\mathbf{nv})(1-\mathbf{nv}')} =$$

$$= \left(\frac{\mathbf{v}'^2}{(1-\mathbf{nv}')^2} + \frac{\mathbf{v}^2}{(1-\mathbf{nv})^2} - \frac{2\mathbf{vv}'}{(1-\mathbf{nv})(1-\mathbf{nv}')}\right) - \left[\frac{1}{(1-\mathbf{nv}')^2} + \frac{1}{(1-\mathbf{nv})^2} - \frac{2}{(1-\mathbf{nv})(1-\mathbf{nv}')}\right] \quad (*)$$

С другой стороны

$\left(\frac{p'}{p'k} - \frac{p}{pk}\right)^2 = \left(\frac{\mathbf{v}'^2}{(1-\mathbf{nv}')^2} + \frac{\mathbf{v}^2}{(1-\mathbf{nv})^2} - \frac{2\mathbf{vv}'}{(1-\mathbf{nv})(1-\mathbf{nv}')}\right) - \left[\frac{(\mathbf{nv}')^2}{(1-\mathbf{nv}')^2} + \frac{(\mathbf{nv})^2}{(1-\mathbf{nv})^2} - 2\frac{(\mathbf{nv})(\mathbf{nv}')}{(1-\mathbf{nv})(1-\mathbf{nv}')}\right]$. (**)

$$\mathrm{d}w_\omega = \frac{\mathrm{d}I}{\omega_k} \tag{21}$$

где d I - классическая интенсивность излучения мягких фотонов. Поэтому величина (21) может интерпретироваться как среднее число излучённых фотонов d$\bar{n}$ в заданном интервале частот. Тогда среднее число излучённых фотонов

$$\bar{n} = \int\limits_{\lambda}^{\omega_{\max}} \frac{\mathrm{d}I}{\omega_k} = \int\limits_{\lambda}^{\omega_{\max}} \mathrm{d}w_\omega \sim e^2 \ln \frac{\omega_{\max}}{\lambda} \tag{22}$$

Последняя оценка получена при помощи (15). Хотя $\omega_{\max} \ll p^0$, при $\lambda \to 0$ с логарифмической точностью имеем оценку

$$\bar{n} = e^2 \ln \frac{p^0}{\lambda} \tag{23}$$

Если $\bar{n} \sim 1$, то ТВ оказывается неприменимой, т.к. первая поправка (15) оказывается того же порядка, что и d $\sigma^{(\text{elas})}$. Однако сама формула (15) тем точнее, чем меньше энергия мягкого фотона.

Выход из этой противоречивой ситуации таков.

При $\lambda \to 0$ среднее число излучённых фотонов $\bar{n} \to \infty$. Мягкие фотоны излучаются статистически независимо. Этот факт подтверждается всеми порядками ТВ. Поэтому к процессу множественного излучения фотонов можно применить формулу Пуассона: вероятность w_n излучения n фотонов выражается через их среднее число $\bar{n}$ формулой

$$w_n = \frac{\bar{n}^n}{n!} e^{-\bar{n}} \tag{24}$$

Теперь формулу (20) можно модернизировать следующим образом:

$$\mathrm{d}\sigma = \sum_{n=0}^{\infty} \mathrm{d}\sigma_n, \qquad \mathrm{d}\sigma_n = \mathrm{d}\tilde{\sigma}^{(elas)} w_n \tag{25}$$

Так как $\sum\limits_n w_n = 1$, то согласно

$$\mathrm{d}\sigma = \mathrm{d}\tilde{\sigma}^{(elas)} \tag{25}$$

При этом, конечно, упругое сечение в формулах (25), (26) отличается от упругого сечения в (20) множителем:

$$e^{-\bar{n}}\ \mathrm{d}\tilde{\sigma}^{(elas)} = \mathrm{d}\sigma^{(elas)} \tag{27}$$

Таким образом мы видим, что сечение чисто упругого рассеяния равно нулю при $\lambda \to 0$ (или $\bar{n} \to \infty$), что видно из формулы (27). Вместе с этим обращается в нуль сечение рассеяния с излучением любого конечного числа мягких фотонов. Тем не менее те сечения, которые вычисляются при помощи ТВ, конечны во всех порядках по константе связи, если учесть также и излучение мягких фотонов. Более того, в каждом порядке по константе связи существует конечный предел для сечений при устремлении массы фотона к нулю, хотя в каждом порядке по константе связи может быть излучено лишь конечное число мягких фотонов. Этот факт демонстрируется в следующем пункте. Таким образом, сечение

рассеяния в борновском (без учёта радиационных поправок) приближении может интерпретироваться как полное сечение рассеяния с учётом излучения любого числа мягких фотонов, но в наинизшем приближении по константе связи (F. Bloch, A. Nordsieck, 1937).

17.9.3 3. Cancellation of Infrared Divergences

Для подтверждения сделанного в конце предыдущего пункта утверждения и проверки формулы (26) проследим за сокращением инфракрасной расходимости в низшем порядке ТВ.

Сначала продолжим вычисление сечения (14). Имеем:

$$\varkappa \equiv \left(\frac{p'}{p'k} - \frac{p}{pk}\right)^2 = \frac{m^2}{(p'k)^2} + \frac{m^2}{(pk)^2} - \frac{2pp'}{(pk)\,(p'k)}$$

Воспользуемся равенством

$$-2pp' = -2m^2 + (p-p')^2$$

при помощи которого находим:

$$\varkappa = \frac{m^2}{(pk)^2\,(p'k)^2}\left[(pk)^2 + (p'k)^2 - 2(pk)\,(p'k)\right] + \frac{(p-p')^2}{(pk)\,(p'k)} = \frac{m^2\left[(p'-p)\,k\right]^2}{(pk)^2\,(p'k)^2} + \frac{(p'-p)^2}{(pk)\,(p'k)} \tag{28}$$

В нерелятивистском пределе величина (28)

$$\varkappa \approx \frac{(\mathbf{qk})^2}{m^2\omega_k^4} - \frac{\mathbf{q}^2}{m^2\omega_k^2}, \quad \mathbf{q} = \mathbf{p}' - \mathbf{p} \tag{29}$$

Подставим (29) в (14) и выполним тривиальное интегрирование по углам:

$$\mathrm{d}\sigma_1 = \mathrm{d}\sigma_0 \frac{e^2\mathbf{q}^2}{\pi m^2} \int\limits_0^{\omega_{\max}} \left[1 - \frac{\mathbf{k}^2}{3\,(\mathbf{k}^2+\lambda^2)}\right] \cdot \frac{\mathbf{k}^2\,\mathrm{d}|\mathbf{k}|}{(\mathbf{k}^2+\lambda^2)^{3/2}} \tag{30}$$

где $\mathrm{d}\sigma_0$ - упругое сечение рассеяния в неком порядке по теории возмущений. В предположении $\omega_{\max}/\lambda \gg 1$ интеграл в (30) легко берётся:

$$\mathrm{d}\sigma_1 = \mathrm{d}\sigma_0 \frac{2e^2}{3\pi} \cdot \frac{\mathbf{q}^2}{m^2}\left(\ln\frac{2\omega_{\max}}{\lambda} - \frac{5}{6}\right), \quad \mathbf{q}^2 \ll m^2 \tag{31}$$

Все сечения $\mathrm{d}\sigma_n$ являются рядами относительно e^2:

$$\mathrm{d}\sigma_n = \sum_i \mathrm{d}\sigma_n^{(i)} \tag{32}$$

так что величина $\mathrm{d}\sigma_n^{(i)}$ пропорциональна e^{2i}.

Согласно формулам (1), (6) и (49) лекции 13 в однопетлевом приближении

$$\begin{aligned} iM_{fi} &= (-ieA_\mu \bar{u}_{p'}\gamma^\mu u_p)\, f\left(-\mathbf{q}^2\right) = iM_{fi}^{(1)} f\left(-\mathbf{q}^2\right) \\ f\left(-\mathbf{q}^2\right) &= 1 - \frac{e^2\mathbf{q}^2}{3\pi m^2}\left(\ln\frac{m}{\lambda} - \frac{3}{8}\right), \quad \mathbf{q}^2 \ll m^2 \end{aligned} \tag{33}$$

Нас интересуют лишь инфракрасно расходящиеся вклады. Поэтому мы не учитываем вклад в iM_{fi} от формфактора g, а также вклад от амплитуды (c) на рис. 26. В нашем приближении в (31) следует использовать $\mathrm{d}\sigma_0^{(2)}$. Это сечение строится по амплитуде первого приближения $iM_{fi}^{(1)} = -i\ \mathrm{e}\ A_\mu \bar{u}_{p'}\gamma^\mu u_p$. Согласно (33)

$$\mathrm{d}\sigma_0^{(2)} + \mathrm{d}\sigma_0^{(4)} = \mathrm{d}\sigma_0^{(2)} f^2 = \mathrm{d}\sigma_0^{(2)} \left[1 - \frac{2e^2\mathbf{q}^2}{3\pi m^2}\left(\ln\frac{m}{\lambda} - \frac{3}{8}\right)\right] \tag{34}$$

При помощи (31) и (34) находим:

$$\mathrm{d}\sigma_0^{(2)} + \mathrm{d}\sigma_0^{(4)} + \mathrm{d}\sigma_1^{(4)} = \mathrm{d}\sigma_0^{(2)} \left[1 - \frac{2e^2\mathbf{q}^2}{3\pi m^2}\left(\ln\frac{m}{2\omega_{\max}} + \frac{11}{24}\right)\right] \tag{35}$$

Теперь в (35) можно перейти к пределу $\lambda \to 0$. Однако появляется зависимость сечения от $\omega_{\max}$. Эта зависимость является следствием того, что величина $\omega_{\max}$ входит в определение рассеяния как процесса, в котором может быть испущено любое число мягких фотонов с энергиями меньше $\omega_{\max}$. Сечение такого процесса будет тем меньше, чем меньше $\omega_{\max}$. Из формулы (35) видно также, что радиационные поправки к сечению малы, если частота $\omega_{\max}$ соизмерима с энергией покоя электрона.

Сравнение (35) и (34) показывает, что в нерелятивистском пределе инфракрасно регуляризованный формфактор

$$f_{\omega_{\max}}(t) = 1 + \frac{e^2 t}{3\pi m^2}\left(\ln\frac{m}{2\omega_{\max}} + \frac{11}{24}\right), \quad |t| \ll m^2 \tag{36}$$

Замечание. Полученный результат означает следующее: в величине (35) взаимно сокращаются вклады виртуальных и реальных испущенных фотонов с энергиями, меньшими $\omega_{\max}$. Поэтому регуляризованный формфактор (36) содержит лишь вклады тех промежуточных виртуальных фотонов, энергии которых больше $\omega_{\max}$.

Доказательство сокращения инфракрасных расходимостей в сечениях в четвёртом порядке относительно константы связи при любых энергиях проводится аналогично, но при помощи более трудоёмких вычислений. Эти вычисления содержатся в (Л. Д. Ландау, Е. М. Лифшиц. Теоретическая физика, Т. 4).

Имеет место следующее утверждение: в суммах (20) и (25) инфракрасные расходимости сокращаются во всех порядках относительно константы связи.

17.9.4 4. Lamb Shift of Energy Levels

Рассмотрим многоуровневую нерелятивистскую систему, взаимодействующую с электромагнитным полем. Мы будем иметь ввиду водородоподобный атом с зарядом ядра Ze, причём

$$Ze^2 \ll 1 \tag{37}$$

Эта система имеет ряд дискретных одноэлектронных уровней. Электрон взаимодействует с квантованным фотонным полем и вследствие этого дискретные уровни сдвигаются. В этом пункте вычисляется сдвиг дискретных уровней, обусловленный этим взаимодействием.

Согласно (30 Л8) нерелятивистский гамильтониан электрона имеет вид (в рассматриваемой задаче релятивистскими поправками к гамильтониану можно пренебречь)

$$\mathcal{H} = \mathcal{H}_0 - \frac{e}{m}\mathbf{p}\mathbf{A}^{\perp}, \quad \mathcal{H}_0 = \frac{\mathbf{p}^2}{2m} + \Phi(r), \quad \mathbf{p} = -i\boldsymbol{\partial}, \quad \Phi(r) = -\frac{Ze^2}{r} \tag{38}$$

Здесь $\mathbf{A}^{\perp}(x)$ - квантованное фотонное поле (33 Л7). Спиновую составляющую гамильтониана взаимодействия с фотонным полем (см. гамильтониан Паули (30 Л8)) здесь можно опустить ввиду относительной малости ($\sim \mathbf{k}|a \sim \alpha$, где a - боровский радиус, а α - постоянная тонкой структуры) соответствующей поправки. Обозначим через $|N\rangle$ электронный уровень невозмущённого гамильтониана:

$$\mathcal{H}_0|N\rangle = E_N|N\rangle \tag{39}$$

При помощи (36 Л7) находим матричный элемент фотонного поля между фотонным вакуумом и однофотонным состоянием:

$$\left\langle \mathbf{k}, \alpha \left| \mathbf{A}^{\perp}(\mathbf{x}) \right| 0 \right\rangle = \sqrt{4\pi}\mathbf{e}^{\perp}_{\mathbf{k}\,\alpha} e^{-i\mathbf{k}\mathbf{x}} \approx \sqrt{4\pi}\mathbf{e}^{\perp}_{\mathbf{k}\,\alpha} \tag{40}$$

Последнее приближённое равенство означает, что задача решается в дипольном приближении, которое в данном случае является удовлетворительным. Воспринимая второе слагаемое в $\mathcal{H}$ как возмущение, выпишем первую неисчезающую поправку к уровням:

$$\delta E_N = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3 2|\mathbf{k}|} \sum_{\alpha} \sum_{N'} \frac{4\pi e^2}{m^2} \cdot \frac{\left|\left\langle N|\mathbf{p}\mathbf{e}^{\perp}_{\mathbf{k}}\alpha N'\right\rangle\right|^2}{E_N - E_{N'} - |\mathbf{k}|} = \frac{2e^2}{3\pi m^2} \sum_{N'} \int_0^{\infty} \mathrm{d}|\mathbf{k}| \cdot |\mathbf{k}| \frac{|\mathbf{p}_{NN'}|^2}{E_N - E_{N'} - |\mathbf{k}|} \tag{41}$$

При переходе ко второму равенству в (41) мы воспользовались правилом суммирования по векторам поляризации (33 Л7) и затем проинтегрировали по углам виртуального фотона. Интеграл по энергии виртуального фотона $|\mathbf{k}|$ в (41) расходится линейно. Необходимо выделить логарифмическую расходимость на фоне линейной. Для этого воспользуемся тождеством

$$\frac{|\mathbf{k}|}{E_N - E_{N'} - |\mathbf{k}|} = \frac{E_N - E_{N'}}{E_N - E_{N'} - |\mathbf{k}|} - 1$$

Таким образом

$$\delta E_N = -\frac{2e^2}{3\pi m^2} \left(\mathbf{p}^2\right)_{NN} \int_0 \mathrm{d}|\mathbf{k}| + \frac{2e^2}{3\pi m^2} \sum_{N'} \int_0 \mathrm{d}|\mathbf{k}| \frac{|\mathbf{p}_{NN'}|^2 (E_N - E_{N'})}{E_N - E_{N'} - |\mathbf{k}|} \tag{42}$$

Предположим, что мы рассмотрели бы эту же задачу для свободного электрона с гамильтонианом $\mathcal{H}_0 = \mathbf{p}^2/2m$. В этом случае, если состояния $|N\rangle$ - плоские волны, то $\mathbf{p}_{NN'} \sim \delta_{NN'}$ и второе слагаемое в правой части (42) обращается в нуль. Первое, линейно расходящееся слагаемое, устраняется путём перенормировки массы [1]. Действительно, пусть затравочный гамильтониан

$$\mathcal{H}_0 = \frac{\mathbf{p}^2}{2m_0} = \frac{\mathbf{p}^2}{2(m + \delta m)} = \frac{\mathbf{p}^2}{2m} - \frac{\delta m}{2m^2}\mathbf{p}^2 \tag{43}$$

где m_0 - затравочная масса. В свободной теории (43) имеются лишь непрерывне уровни $|N\rangle$ - плоские волны. Подберём δm в (43) так чтобы линейные расходимости всех уровней энергии сокращались. Согласно (42) и (43) имеем:

$$\delta E_N = -\frac{2e^2}{3\pi m^2}\left(\mathbf{p}^2\right)_{NN}\int\limits_0 \mathrm{d}|\mathbf{k}| - \frac{\delta m}{2m^2}\left(\mathbf{p}^2\right)_{NN} = 0 \longrightarrow \delta m = -\frac{4e^2}{3\pi}\int\limits_0 \mathrm{d}|\mathbf{k}|$$

Так как к гамильтониану (38) должно быть добавлено второе слагаемое из правой части (43), то мы видим, что с точностью $O\left(e^2\right)$ линейно расходящиеся поправки ко всем уровням энергии сокращаются. Поэтому сдвиг дискретного уровня энергии вследствие взаимодействия с фотонным полем определяется вторым слагаемым в (42), в котором вычислим интеграл по фотонной энергии от нуля до $\omega_{\max}$. Так как наше вычисление - нерелятивистское, то неизвестная частота $\omega_{\max}$ должна удовлетворять следующим неравенствам:

$$\left(Ze^2\right)^2 m \ll \omega_{\max} \ll m \tag{44}$$

Здесь первое неравенство означает, что учитываемые энергии фотонов в (42) много больше разности энергий дискретных уровней: $|E_N - E_{N'}| \ll \omega_{\max}$. Таким образом

$$\delta E_N = \frac{2e^2}{3\pi m^2}\sum_{N'}\left|\mathbf{p}_{NN'}\right|^2\left(E_{N'} - E_N\right)\ln\frac{\omega_{\max}}{\left|E_{N'} - E_N\right|} \tag{45}$$

Вследствие первого неравенства (44) аргумент логарифма возможно заменить на $[\omega_{\max}/\left|E_{N'} - E_N\right|]$. Перепишем (45) в виде

$$\delta E_N = \frac{2e^2}{3\pi m^2}\sum_{N'}\left|\mathbf{p}_{NN'}\right|^2\left(E_{N'} - E_N\right)\ln\frac{2\omega_{\max}}{m} + \frac{2e^2}{3\pi m^2}\sum_{N'}\left|\mathbf{p}_{NN'}\right|^2\left(E_{N'} - E_N\right)\ln\frac{m}{2\left|E_{N'} - E_N\right|} \tag{46}$$

Для дальнейших преобразований воспользуемся следующими соотношениями:

$$\mathbf{p}_{NN'}\left(E_{N'} - E_N\right) = \left[\mathbf{p}, \mathcal{H}_0\right]_{NN'} = -i(\boldsymbol{\partial}\Phi)_{NN'} \tag{47}$$

$$\sum_{N'}\left|\mathbf{p}_{NN'}\right|^2\left(E_{N'} - E_N\right) \equiv \frac{1}{2}\sum_{N'}\left\{\left[\mathbf{p}_{NN'}\left(E_{N'} - E_N\right)\right]\mathbf{p}_{N'N} - \mathbf{p}_{NN'}\left[\left(E_N - E_{N'}\right)\mathbf{p}_{N'N}\right]\right\} =$$

$$= \frac{i}{2}\sum_{N'}\left\{-(\boldsymbol{\partial}\Phi)_{NN'}\mathbf{p}_{N'N} + \mathbf{p}_{NN'}(\boldsymbol{\partial}\Phi)_{N'N}\right\} = \frac{i}{2}[\mathbf{p}, \boldsymbol{\partial}\Phi]_{NN} = \frac{1}{2}(\Delta\Phi)_{NN} \tag{48}$$

$$\mathbf{p}_{NN'} = -im\left[\mathbf{r}, \mathcal{H}_0\right]_{NN'} = -im\mathbf{r}_{NN'}\left(E_{N'} - E_N\right) \tag{49}$$

Ещё раз перепишем первое и второе слагаемые в (46) при помощи (48) и (49), соответственно:

$$\delta E_N^{(I)} = \frac{e^2}{3\pi m^2}(\Delta\Phi)_{NN}\ln\frac{2\omega_{\max}}{m} + \frac{2e^2}{3\pi}\sum_{N'}\left|\mathbf{r}_{NN'}\right|^2\left(E_{N'} - E_N\right)^3\ln\frac{m}{2\left|E_{N'} - E_N\right|} \tag{50}$$

[61] В предыдущих лекциях мы выяснили, что в дираковской теории поправки к массе электрона расходятся логарифмически. Однако изучаемый здесь гамильтониан нерелятивистской заряженной частицы в равной степени может описывать как фермиевскую, так и бозевскую частицу. Поэтому линейная расходимость перенормировки её массы вследствие взаимодействия с электромагнитным полем не противоречит полученным результатам.

Здесь верхний индекс (I) указывает на то, что соответствующий вклад получен от фотонов с частотами $\omega < \omega_{\max}$.

Зависимость сдвига уровней (50) от нефизического параметра $\omega_{\max}$ указывает на то, что формула (50) учитывает лишь часть сдвига: в дополнение к (50) следует учесть вклад от жёстких фотонов, который содержится в диаграмме (b) на рис. 26, а также вклад от поправки потенциала Φ, описываемый диаграммой (c) на рис. 26. Диаграмма (b) на рис. 26 даёт квантовые поправки к движению электрона, которые можно рассматривать как поправки вследствие изменения эффективного электронного гамильтониана. Вклад в эффективный гамильтониан от диаграммы (b) на рис. 26 следует учесть, используя инфракрасно регуляризованный формфактор f (36). При этом частота $\omega_{\max}$ в (50) и (36) - одна и та же. Действительно, в регуляризованном формфакторе (36) фактически учитывается лишь вклад от виртуальных фотонов с частотами $\omega > \omega_{\max}$ (см. замечание после (36)). Вклад в сдвиг уровней именно от такого формфактора и следует добавить к (50), поскольку в (50) уже учтён вклад от фотонов с частотами $\omega < \omega_{\max}$. Формфактор g задаётся согласно (49 Л12) и он не содержит нефизических параметров, поскольку не требует инфракрасной регуляризации. Таким образом добавка к амплитуде, описываемая диаграммой (b) на рис. 26, имеет вид

$$\delta_{(b)} M_{fi}(\mathbf{q}) = -\left\{ \left[f_{\omega_{\max}}\left(-\mathbf{q}^2\right) - 1 \right] \bar{u}_f \gamma^0 u_i - \frac{g\left(-\mathbf{q}^2\right)}{m} \left(\bar{u}_f \sigma^{0\mu} u_i \right) q_\mu \right\} \Phi(\mathbf{q}) \tag{51}$$

Здесь $q-4$-импульс, приносимый потенциалом Φ, причём $q = (0, \mathbf{q})$. Добавка к амплитуде, вытекающая из радиационных поправок к потенциалу и описываемая диаграммой (c) на рис. 26, согласно (45 Л11) равна

$$\delta_{(c)} M_{fi}(\mathbf{q}) = -\mathcal{P}\left(-\mathbf{q}^2\right) \left(\bar{u}_f \gamma^0 u_i \right) \Phi(\mathbf{q}) \tag{52}$$

Представим сумму амплитуд (51) и (52) в виде

$$\begin{gathered} \delta M_{fi} = \delta_{(b)} M_{fi} + \delta_{(c)} M_{fi} = -u_f^\dagger \Lambda \Phi u_i \\ \Lambda = \left[f_{\omega_{\max}}\left(-\mathbf{q}^2\right) - 1 \right] + \mathcal{P}\left(-\mathbf{q}^2\right) + \frac{g}{2m} \gamma \mathbf{q} \end{gathered} \tag{53}$$

Величина $\delta\mathcal{H}^{(II)} \equiv \Lambda\Phi$ должна восприниматься как высокочастотная радиационная поправка к одноэлектронному гамильтониану. При помощи (53), (36), (35 Л11) и (49 Л12) находим значение этой поправки в импульсном представлении:

$$\delta\mathcal{H}^{(II)}(\mathbf{q}) = \left\{ -\frac{e^2 \mathbf{q}^2}{3\pi m^2} \left(\ln \frac{m}{2\omega_{\max}} + \frac{11}{24} - \frac{1}{5} \right) + \frac{e^2}{4\pi m} \gamma \mathbf{q} \right\} \Phi(\mathbf{q}) \tag{54}$$

Функция, соответствующая (54) в координатном представлении, имеет вид

$$\delta\mathcal{H}^{(II)}(\mathbf{x}) = \frac{e^2}{3\pi m^2} \left(\ln \frac{m}{2\omega_{\max}} + \frac{11}{24} - \frac{1}{5} \right) \Delta\Phi(\mathbf{x}) - \frac{e^2}{4\pi m} i\gamma \boldsymbol{\partial} \Phi(\mathbf{x}) \tag{55}$$

Соответствующее смещение уровней получается усреднением оператора (55) по волновой функции невозмущённого состояния электрона в атоме:

$$\delta E_N^{(II)} = \frac{e^2}{3\pi m^2} \left(\ln \frac{m}{2\omega_{\max}} + \frac{11}{24} - \frac{1}{5} \right) \langle N | \Delta\Phi | N \rangle - i \frac{e^2}{4\pi m} \langle N | \gamma \boldsymbol{\partial} \Phi | N \rangle \tag{56}$$

Замечание. Хотя формфакторы f и g были получены для электронов на массовой поверхности, их использование в (56) является законным, хотя усреднение идёт по связанным состояниям. Действительно, формфакторы в (56) получены от вклада виртуальных фотонов с энергиями $\omega > \omega_{\max}$. С другой стороны, так как энергия связанных состояний (включая энергию покоя) $\left[1-(Ze^2)^2\right]m$ почти совпадает с энергией покоя электрона и вследствие первого неравенства (44) использование формфакторов $f_{\omega_{\max}}$ и g в (53) законно.

В первом слагаемом в (56) можно пользоваться непосредственно нерелятивистскими волновыми функциями электрона. Так как диагональные матричные элементы от спиновых операторов равны нулю, то во втором слагаемом в (56) необходимо использовать в качестве невозмущённых собственных функций $|N\rangle$ собственные функции гамильтониана Дирака (см. (33 Л8)) $\mathcal{H}_0 = -i\boldsymbol{\alpha}\boldsymbol{\partial} + m\gamma^0 + \Phi(r)$. Тогда при помощи уравнения (39), в котором E_N включает энергию покоя электрона, в стандартном представлении выражаем спинор χ через спинор ϕ. Пренебрегая энергией связи и потенциалом Φ (их учёт был бы превышением точности), находим:

$$\chi = -\frac{i}{2m}\boldsymbol{\sigma}\boldsymbol{\partial}\phi \tag{57}$$

Спинор ϕ в (57) следует рассматривать как нерелятивистскую волновую функцию. Подставляя (57) в (56), после несложных вычислений получаем:

$$\delta E_N^{(II)} = \frac{e^2}{3\pi m^2}\left(\ln\frac{m}{2\omega_{\max}} + \frac{19}{30}\right)\langle N|\Delta\Phi|N\rangle + \frac{e^2}{4\pi m^2}\left\langle N\left|(\boldsymbol{\sigma}\mathbf{l})\frac{1}{r}\cdot\frac{\mathrm{d}\Phi}{\mathrm{d}r}\right|N\right\rangle \tag{58}$$

В (58) и далее $|N\rangle$ - уже нерелятивистский вектор состояния электрона в центральном потенциале $\Phi(r)$ и $\mathbf{l}$ - оператор орбитального момента.

Складывая (50) и (58), находим полный сдвиг уровней:
$\delta E_N = \frac{2e^2}{3\pi}\sum\limits_{N'}|\mathbf{r}_{NN'}|^2\left(E_{N'}-E_N\right)^3\ln\frac{m}{2|E_{N'}-E_N|} + \frac{19}{30}\cdot\frac{e^2}{3\pi m^2}\langle N|\Delta\Phi|N\rangle + \frac{e^2}{4\pi m^2}\left\langle N\left|(\boldsymbol{\sigma}\mathbf{l})\frac{1}{r}\cdot\frac{\mathrm{d}\Phi}{\mathrm{d}r}\right|N\right\rangle$.

В (59) сокращается промежуточная частота $\omega_{\max}$, что является необходимым условием корректности вычисления. Все матричные элементы в (59) берутся по отношению к нерелятивистским волновым функциям электрона в атоме. Для водородоподобного атома эти функции зависят только от четырёх квантовых чисел: главного квантового числа n, орбитального момента l, полного момента j и его проекции M, так что $|N\rangle = |nljM\rangle$. Это состояние может быть представлено как двухкомпонентный спинор (см. (74 Л8)) $|nljM\rangle = f_n(r)\Omega_{jlM}(\theta,\phi)$.

Второе слагаемое в (59) вычисляется при помощи уравнений

$$\Delta\Phi(\mathbf{x}) = 4\pi Ze^2\delta^{(3)}(\mathbf{x})$$
$$\langle nljM|\Delta\Phi|nljM\rangle = 4\pi Ze^2\left|\psi_N(0)\right|^2 = 4m^3\left(Ze^2\right)^4 n^{-3}\delta_{l0} \tag{60}$$

Полезно ввести обозначение

$$L_{nl} = \frac{n^3}{2m\left(Ze^2\right)^4}\sum_{N'}\left|\langle N'|\mathbf{r}|N\rangle\right|^2\cdot\left(E_{n'}-E_n\right)^3\ln\frac{m\left(Ze^2\right)^2}{2\left|E_{n'}-E_n\right|} \tag{61}$$

Поскольку невозмущённые уровни энергии пропорциональны $\left(Ze^2\right)^2$, а характерный размер атома пропорционален $\left(Ze^2\right)^{-1}$, то величины L_{nl} (61) не зависят от Z и они могут

быть найдены численно для атома водорода. При помощи обозначения (61) перепишем первое слагаемое в (59) как

$$\frac{4mZ^4e^{10}}{3\pi n^3}\left[L_{nl}+\frac{n^3}{2m\left(Ze^2\right)^4}\ln\frac{1}{\left(Ze^2\right)^2}\cdot\sum_{N'}\left|\mathbf{r}_{NN'}\right|^2\left(E_{N'}-E_N\right)^3\right] \tag{62}$$

Ещё раз используя (48) и (49) преобразуем второе слагаемое в квадратной скобке в (62) к виду

$$\frac{n^3}{4m^3\left(Ze^2\right)^4}\ln\frac{1}{\left(Ze^2\right)^2}\cdot\langle nljM|\Delta\Phi|nljM\rangle=\ln\frac{1}{\left(Ze^2\right)^2}\cdot\delta_{l0} \tag{63}$$

Последнее равенство здесь получается при помощи (60). Используя (60), (62), и (63), переписываем лэмбовский сдвиг в окончательном виде:

$$\delta E_{nlj}^{(L)}=\frac{4mZ^4e^{10}}{3\pi n^3}\left\{L_{nl}+\left[\ln\frac{1}{\left(Ze^2\right)^2}+\frac{19}{30}\right]\delta_{l0}\right\}+\frac{e^2}{4\pi m^2}\left\langle nljM\left|(\boldsymbol{\sigma}\mathbf{l})\frac{1}{r}\cdot\frac{\mathrm{d}\Phi}{\mathrm{d}r}\right|nljM\right\rangle \tag{64}$$

Необходимо по отдельности рассмотреть случаи $l=0$ и $l\neq 0$.

При $l=0$ последнее слагаемое в (64) исчезает и мы имеем (в обычных единицах)

$$\delta E_{n0}^{(L)}=\frac{4mc^2Z^4\alpha^5}{3\pi n^3}\left[L_{n0}+\ln\frac{1}{(Z\alpha)^2}+\frac{19}{30}\right] \tag{65}$$

Приведём числовые значения нескольких величин L_{n0}:

n	=	1	2	3	4	∞
L_{n0}	=	$-2,984$	$-2,812$	$-2,768$	$-2,750$	$-2,721$

Так как невозмущённые уровни $E_n=-mc^2(Z\alpha)^2/\left(2n^2\right)$, то

$$\left|\frac{\delta E_{n0}}{E_{n0}}\right|\sim Z^2\alpha^3\ln\frac{1}{Z\alpha} \tag{66}$$

При $l\neq 0$ исчезает второе слагаемое в (64). Так как $(1/r)\mathrm{d}\Phi/\mathrm{d}r=Ze^2/r^3$ и

$$\begin{gathered}\langle nljM|\boldsymbol{\sigma}\mathbf{l}|nljM\rangle=j(j+1)-l(l+1)-\frac{3}{4}\\ \left\langle nljM\left|\frac{1}{r^3}\right|nljM\right\rangle=\frac{2\left(Ze^2m\right)^3}{n^3l(l+1)(2l+1)}\end{gathered} \tag{67}$$

то

$$\delta E_{nljM}^{(L)}=\frac{4mc^2Z^4\alpha^5}{3\pi n^3}\left[L_{nl}+\frac{3}{8}\cdot\frac{j(j+1)-l(l+1)-3/4}{l(l+1)(2l+1)}\right] \tag{68}$$

Согласно (110 Л8) релятивистская поправка к энергии водородоподобных атомов - энергия тонкой структуры:

$$\delta E_{nljM}=-\frac{mc^2(Z\alpha)^4}{2n^3}\left[\frac{1}{j+1/2}-\frac{3}{4n}\right] \tag{69}$$

Из сравнения формул (68) и (69) видно, что квантовая теория поля даёт вклад в сдвиг уровней по порядку величины в α раз меньше чем вклад от релятивистских поправок в одноэлектронной задаче. Однако радиационный сдвиг (68) снимает последнее вырождение, сохраняющееся в формуле (69): вырождение уровней с одинаковыми значениями n и j, но разными $l = j \pm 1/2$. Именно
поэтому лэмбовский сдвиг уровней легко отделим и потому измерим.

Задачи

1. Вычислить радиационный сдвиг уровней заряженного пространственного осциллятора.

Указание. Поскольку гармонический потенциал есть некая идеализация, то можно считать, что рассматривается движение нерелятивистского электрона в глубокой, но конечной потенциальной яме с потенциалом $\Phi(r) = m\omega^2 r^2/2, \quad r < L, \quad \Phi(r) = m\omega^2 L^2/2, \quad r > L$. Считать, что $\hbar\omega \ll m\omega^2 L^2/2 \ll mc^2$. В этом случае при вычислении радиационных поправок к нижним уровням учёт высокочастотного вклада при помощи формфакторов (51) является оправданным.

18 Radiative Corrections: Some Formal Developments 2

18.1 Renormalization and Gauge Invariance by Zi

18.1.1 Zi.III.2 Renormalizable vs. Nonrenormalizable

Старый взгляд против современной точки зрения

Теперь мы знаем, что представление амплитуды мезон-мезонного рассеяния в терминах физической константы связи λ_P ведет к исчезновению зависимости от обрезания Λ (по крайней мере до порядка λ_P^2). Неужели это простое везение?

Как оказалось, существуют квантовые теории поля, в которых это условие справедливо, и квантовые теории поля, в которых оно теряет свою силу. Таким образом, получаем два класса квантовых теорий поля. Исторически сложилось, что первый класс квантовых теорий называют «перенормируемыми теориями» и относят к «хорошим». Второй класс квантовых теорий, известных как «неперенормируемые теории», вызывает у теоретических физиков страх и отвращение.

Однако новый взгляд на теории поля как на эффективные низкоэнергетические теории, дополняющие некоторой основополагающей теории, позволил современным физикам взглянуть на неперенормируемые теории в более позитивном ключе по сравнению с предыдущим поколением. Надеюсь, я смогу пояснить это утверждение в этой и следующей главах.

Школьный анализ размерностей

Начнем с анализа размерностей, которому вас обучили в средней школе. Используя натуральные единицы, для которых $\hbar = 1$ и $c = 1$, размерность длины и времени будет одинаковой и равной обратной размерности массы (а также энергии и импульса). Специалисты в области физики элементарных частиц подсчитывают размерность в терминах массы, ибо привыкли думать в масштабах энергии. С другой стороны,

специалисты в области физики конденсированных сред обычно действуют исходя из масштаба длины. Значит, физики из упомянутых отраслей оперируют величинами с (равными и) противоположными размерностями. Мы будем пользоваться обозначениями из физики элементарных частиц.

Поскольку действие $S \equiv \int d^4x\mathcal{L}$ входит в интеграл по траекториям как e^{iS}, оно не имеет размерности и, следовательно, размерность лагранжиана (точнее, плотности лагранжиана) $\mathcal{L}$ совпадает с размерностью массы в четвертой степени. Тот факт, что размерность $\mathcal{L}$ равна 4, будем записывать как $[\mathcal{L}] = 4$. Аналогично имеем $[x] = -1$ и $[\partial] = 1$. Рассмотрим теорию скалярного поля $\mathcal{L} = \frac{1}{2}\left[(\partial\varphi)^2 - m^2\varphi^2\right] - \lambda\varphi^4$. Для 4-мерного параметра $(\partial\varphi)^2$ справедливо утверждение $[\varphi] = 1$ (поскольку $2(1 + [\varphi]) = 4$), вследствие чего $[\lambda] = 0$, т. е. параметр λ не имеет размерности. Существует простое правило, согласно которому для каждого члена $\mathcal{L}$ размерность различных составляющих, включая константу связи и массу, должна в сумме составлять 4 (т. е., к примеру, $[\lambda] + 4[\varphi] = 4$).

Как обстоит дело с фермионным полем ψ? Применяя это правило к лагранжиану $\mathcal{L} = \bar{\psi}i\gamma^\mu\partial_\mu\psi + ...$, видим, что $[\psi] = \frac{3}{2}$. (В дальнейшем будем опускать... ; и так понятно, что речь идет лишь о части лагранжиана. Более того, раз мы проводим анализ размерностей, то будем опускать некоторые несущественные коэффициенты, такие как численные коэффициенты и гамма-матрицы во взаимодействии Ферми, к которому мы вскоре придем.) Анализируя член взаимодействия $f\varphi\bar{\psi}\psi$, видим, что константа связи Юкавы f безразмерна. Однако в теории слабых взаимодействий с $\mathcal{L} = G\bar{\psi}\psi\bar{\psi}\psi$ константа связи Ферми G имеет размерность -2 (так как $-2 + 4\left(\frac{3}{2}\right) = 4$; это понятно?)

Из лагранжиана Максвелла $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$ следует, что $[A_\mu] = 1$, т. е. размсрность A_μ совпадает с размерностью ∂_μ: размерности векторного и скалярного полей одинаковы. Из электромагнитного взаимодействия $eA_\mu\bar{\psi}\gamma^\mu\psi$ следует, что e не имеет размерности. Такой же вывод мы получим, если запишем закон Кулона в естественных единицах $V(r) = \alpha/r$ с коэффициентом α, равным $\alpha = e^2/4\pi$.

Амплитуда рассеяния расходится

Теперь мы готовы дать эвристическое объяснение неперенормируемости теории. Рассмотрим теорию слабых взаимодействий Ферми. Допустим, нам надо вычислить амплитуду $\mathcal{M}$ четырехфермионного взаимодействия, скажем, рассеяния нейтрино на нейтрино с энергией, намного меньшей Λ. В низшем порядке имеем $\mathcal{M} \sim G$. Попробуем записать амплитуду в следующем порядке: $\mathcal{M} \sim G + G^2(?)$ и догадаться, что должно быть на месте (?). I оо определению, все массы и энергии пренебрежительно малы, по сравнеIию с порогом Λ, так что можно принять их равными нулю. Поскольку $[G] = -2$, из анализа размерностей следует, что неизвестный коэффициент должен иметь размерность $+2$. Единственно возможным параметром для (?) является Λ^2. Значит, амплитуда следующего порядка записывается в виде $\mathcal{M} \sim G + G^2\Lambda^2$. Чтобы удостовериться в справедливости нашего заключения, рассмотрим фейнмановскую диаграмму на рис. III.2.1: видим, что действительно $G^2 \int^{\Lambda} d^4p(1/p)(1/p) \sim G^2\Lambda^2$.

Теория без обрезания или, что эквивалентно,

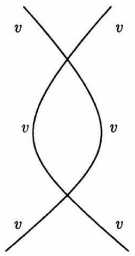


Рис. III.2.1 с Λ или принять $\Lambda = \infty$, оказывается несостоятельной: для физической величины предсказано бесконечное значение. Поэтому теорию слабых взаимодействий Ферми назвали неперенормируемой.

Поддавшись отчаянию, некоторые теоретики решили отказаться от квантовой теории поля. Другие предпринимали многочисленные попытки, чтобы «исцелить» теорию слабого взаимодействия. К примеру, они предлагали исходить из того, что ряд $\mathcal{M} \sim G\left[1 + G\Lambda^2 + \left(G\Lambda^2\right)^2 + \left(G\Lambda^2\right)^4 + \ +...\right] = Gf\left(G\Lambda^2\right)$, где неизвестная функция f обладает следующим свойством: значение $f(\infty)$ конечно. Теперь мы знаем, что данный подход нельзя было назвать плодотворным.

Зато к концу 1960-х гг. Глэшоу, Салам и Вайнберг, основываясь на результатах исследований других ученых, разработали теорию электрослабых взаимодействий, объединяющую электромагнитное и слабое взаимодействия (глава VII.2). Теория слабых взаимодействий Ферми входит в теорию электрослабых взаимодействий как эффективная низкоэнергетическая теория.

Теория Ферми оказалась несостоятельной

С современной точки зрения мы рассматриваем обрезание Λ как реально существующее, поэтому почти слышим, как жалуется теория на зависимость амплитуды четырехфермионного взаимодействия $\mathcal{M} \sim G + \ + G^2\Lambda^2$ от обрезания, ведь теория не может объяснить, что произойдет при $\Lambda \sim (1/G)^{\frac{1}{2}}$. Второй член в ряду возмущений становится сравним с первым, так что теория возмущений перестает быть применимой.

К такому выводу можно прийти иным путем. Предположим, нам ничего не известно об обрезании. Основываясь на анализе размерностей и учи- тывая тот факт, что размерность G равна -2, приходим к заключению, что амплитуда нейтрино-нейтринного рассеяния для энергии E центра масс равна $\mathcal{M} \sim G + G^2E^2 + ...$ Когда значение E достигает масштаба $\sim (1/G)^{\frac{1}{2}}$, амплитуда становится порядка единицы и должна появиться новая физика просто потому, что сечение достигает унитарного предела из обычной квантовой механики. (Помните про фазовый сдвиг и тому подобное?)

Все это восходит еще к Юкаве, который одновременно с разработкой мезонной теории для ядерных сил предложил также учитывать промежуточный векторный бозон в теории слабых взаимодействий Ферми. (В 1930-х гг. не было ясного различия между сильным и слабым взаимодействиями.) Рассмотрим кратко теорию векторного бозона массой M, взаимодействующего с фермионным полем с безразмерной константой связи g:

$$\mathcal{L} = \bar{\psi}\left(i\gamma^\mu\partial_\mu - m\right)\psi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} + M^2A_\mu A^\mu + gA_\mu\bar{\psi}\gamma^\mu\psi$$

Вычислим фермион-фермионное рассеяние. Для фейнмановской диаграммы на рис. III.2.2 амплитуда равна $(-ig)^2\left(\bar{u}\gamma^\mu u\right)\left[i/\left(k^2 - M^2 + i\varepsilon\right)\right]\left(\bar{u}\gamma_\mu u\right)$. Если переданный импульс k много меньше M, амплитуда сводится к виду $i\left(g^2/M^2\right)\left(\bar{u}\gamma^\mu u\right)\left(\bar{u}\gamma_\mu u\right)$. Но это в точности

так, если бы фермионы взаимодействуют согласно теории Ферми $G\left(\bar{\psi}\gamma^{\mu}\psi\right)\left(\bar{\psi}\gamma_{\mu}\psi\right)$, где $G = g^2/M^2$.

Если мы беспечно будем проводить расчеты на основе эффективной низкоэнергетической теории $G\left(\bar{\psi}\gamma^{\mu}\psi\right)\left(\bar{\psi}\gamma_{\mu}\psi\right)$, то в конечном итоге потерпим неудачу. Да, действительно, при энергиях $(1/G)^{\frac{1}{2}} = M/g$ появляется векторный бозон. Возникает новая физика.

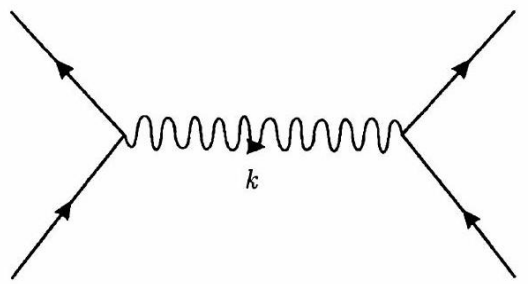

Рис. III. 2.2

Я считаю правильным, что физические теории, в отличие от других теорий человеческой мысли, в состоянии сообщить о своей области применимости, вне которой они становятся внутренне противоречивыми.

Теория Эйнштейна оказывается несостоятельной

Общеизвестно, что теория гравитации также неперенормируема. Просто сравнивая закон Ньютона $V(r) = G_N M_1 M_2/r$ с законом Кулона $V(r) = \alpha/r$, видим, то гравитационная постоянная Ньютона G_N имеет размерность массы -2. Этим все сказано. Приходим к печальному заключению, согласно которому теория гравитации, подобно теории слабых взаимодействий Ферми, является неперенормируемой. Чтобы подтвердить этот факт, попробуем вычислить гравитон-гравитонное рассеяние для энергии E. Получим ряд $\sim \left[1 + G_N E^2 + \left(G_N E^2\right)^2 + ...\right]$.

Как и для случая теории Ферми, неперенормируемость квантовой гравитации сказывается на том, что на масштабе массы Планка $(1/G_N)^{\frac{1}{2}} \equiv M_{\text{Planck}} \sim 10^{19} m_{\text{proton}}$ должна появиться новая физика. Когда обнаружилась несостоятельность теории Ферми, оказалось, что новая физика суть электрослабая теория. Окажется ли теория струн новой физикой для теории Эйнштейна? [1]

Упражнения

III.2.1. Рассмотрим теорию d-мерного скалярного поля $S = \int d^d x \left(\frac{1}{2}(\partial\varphi)^2 + \right.$ $\left. + \frac{1}{2}m^2\varphi^2 + \lambda\varphi^4 + ... + \lambda_n\varphi^n + ...\right)$. Покажите, что $[\varphi] = (d-2)/2$ и $[\lambda_n] = n(2-d)/2 + d$. Обратите внимание, что при $d = 2$ поле φ безразмерно.

'J. Polchinski, String Theory.

18.1.2 Zi.III.3 Counterterms and Physical Perturbation Theory

Перенормируемость

Из эвристических рассуждений предыдущей главы следует, что теория является неперенормируемой, если ее константа связи имеет размерность массы в отрицательной

степени. Как обстоит дело с теориями, где константа связи безразмерна, например, с квантовой электродинамикой и с φ^4-теорией? На самом деле уже доказано, что обе они являются перенормируемыми, хотя доказать, что теория перенормируема, гораздо труднее, чем неперенормируемость теории. Действительно, чтобы доказать перенормируемость неабелевой калибровочной теории (речь о которой пойдет позже), потребовались усилия многих выдающихся физиков, в частности, 't Хоофта, Вельтмана, Б. Ли, Зинн-Жюстена и многих других.

Снова рассмотрим простую φ^4-теорию. Сначала сделаем простое замечание: физическая константа связи λ_P есть функция от s_0, t_0 и u_0 [см. формулу (III.1.4)]. Для теоретических рассуждений удобнее положить s_0, t_0 и u_0 равными μ^2 и использовать вместо (III.1.4) более простое определение:

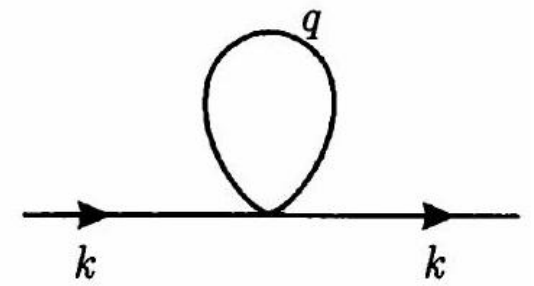
$$-i\lambda_P = -i\lambda + 3iC\lambda^2 \log\left(\frac{\Lambda^2}{\mu^2}\right) + O\left(\lambda^3\right)^1 .$$

Мы уже знаем, что до порядка λ^2 амплитуда мезон-мезонного рассеяния, выраженная через физическую константу связи λ_P, не зависит от обрезания Λ. Как доказать справедливость этого утверждения для любого порядка λ? Из анализа размерностей следует только, что до любого порядка λ зависимость амплитуды мезон-мезонного рассеяния от обрезания должна выражаться суммой членов $[\log(\Lambda/\mu)]^p$, где p - некоторая степень.

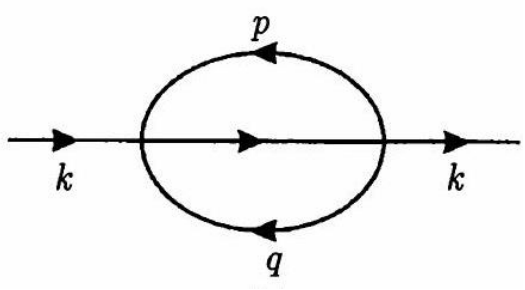
[1] В самом деле. кинематическую точку $s_0 = t_0 = u_0 = \mu^2$ нельзя достичь экспериментально. Конечно, не только амплитуда мезон-мезонного рассеяния зависит от обрезания. Рассмотрим обратный оператор к пропагатору φ до порядка λ^2 на рис. III.3.1. Для фейнмановской диаграммы на рис. III.3.1a имеем $-i\lambda \int^{\Lambda} [d^4q/(2\pi)^4]\,[i/\left(q^2 - m^2 + i\varepsilon\right)]$. Точное значение нас не интересует; заметим только, что оно квадратично зависит от Λ, а не от k^2. Для диаграммы на рис. III.3.1b справедлив двойной интеграл:

$$I(k, m, \Lambda; \lambda) \equiv (-i\lambda)^2 \int^{\Lambda}\int^{\Lambda} \frac{d^4p}{(2\pi)^4}\frac{d^4q}{(2\pi)^4} \frac{i}{p^2 - m^2 + i\varepsilon}\frac{i}{q^2 - m^2 + i\varepsilon}\frac{i}{(p+q+k)^2 - m^2 + i\varepsilon}$$

После подсчета степеней p и q обнаружим квадратичную зависимость интеграла $\sim \int (d^8P/P^6)$ и, следовательно, функции I от обрезания Λ.



(a)



(b)

Рис. III.3.1

Из лоренцевской инвариантности следует, что I есть функция от k^2, которая раскладывается в ряд $D + Ek^2 + Fk^4 + ...$ Величина D соответствует функции I с нулевым внешним импульсом k и, значит, квадратично зависит от обрезания Λ. Теперь, дважды дифференцируя I по k и приравнивая затем k к нулю, находим E. При этом в два раза уменьшается значение степеней p и q в подынтегральном выражении, так что E начинает зависеть от порога Λ лишь логарифмически. Аналогично находим значение F четырехкратным дифференцированием I по k и приравниваем k к нулю. В результате значения степеней p и q уменьшатся в 4 раза и величину F можно будет найти как интеграл $\sim \int d^8P/P^{10}$ для больших значений P. Это сходящийся интеграл, следовательно, он не зависит от обрезания. Таким образом, F и члены в (...) не зависят от обрезания при его стремлении к бесконечности, и поэтому они не должны нас заботить.

С учетом всего вышесказанного приходим к обратному пропагатору $k^2 - m^2 + a + bk^2$ с точностью $O(k^2)$, в котором параметры a и b квадратично и логарифмически зависят от обрезания. Пропагатор сводится к виду:

$$\frac{1}{k^2 - m^2} \to \frac{1}{(1+b)k^2 - (m^2 - a)}$$

Полюс в k^2 сдвигается к $m_P^2 \equiv m^2 + \delta m^2 \equiv (m^2 - a)(1+b)^{-1}$, т. е. к физической массе. Этот сдвиг называют перенормировкой. С физической точки зрения довольно естественно, что квантовые флуктуации приводят к слвигу массы.

Что можно сказать по поводу вычета в полюсе пропагатора, который теперь равен не 1, а $(1+b)^{-1}$?

Для объяснения сдвига в вычете вспомним, как мы беспечно нормировали поле φ, так что $\mathcal{L} = \frac{1}{2}(\partial\varphi)^2 + ...$ Коэффициент при k^2 в обратном пропагаторе низшего порядка $k^2 - m^2$ равен 1, следовательно, коэффициент при $\frac{1}{2}(\partial\varphi)^2$ в функции $\mathcal{L}$ также равен 1. Однако мы не можем гарантировать, что при включении поправок высшего порядка коэффициент при $\frac{1}{2}(\partial\varphi)^2$ в эффективном лагранжиане $\mathcal{L}$ останется равным 1. Действительно, он сдвигается к $(1 + b)$. Данный сдвиг получил название «перенормировки волновой функции», хотя ни о какой волновой функции речи не идет. Более современным названием мог бы послужить термин «перенормировка поля». (В нашем случае слово «перенормировка» употреблено кстати, ибо мы действительно нормируем поле, хотя сильно к этому и не стремимся.)

К тому же, гораздо проще сказать «логарифмически расходящийся», чем «логарифмически зависимый от обрезания Λ, поэтому довольно часто мы будем употреблять привычный, хотя и менее точный термин «расходящийся». В φ^4-теории перенормировка волновой функции и перенормировка константы связи являются логарифмически расходящимися, тогда как перенормировка массы расходится квадратично.

Затравочная теория возмучений против физической теории возмущений

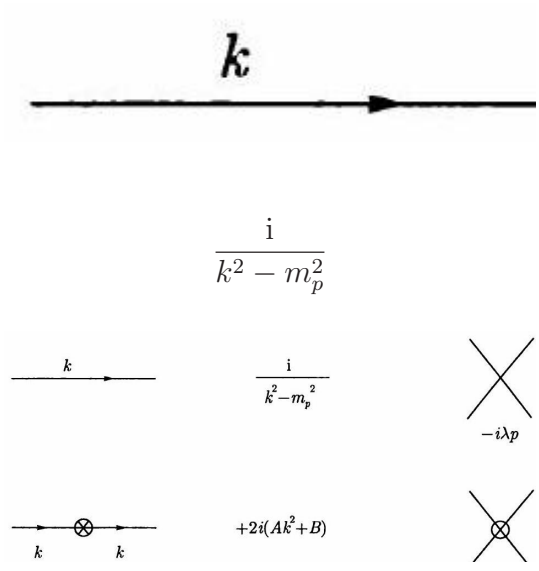
До сих пор мы занимались голой или затравочной теорией возмущений. Нам следовало добавить индекс 0 к величинам φ, m и λ. Поле φ_0 называется затравочным полем, параметры m_0 и λ_0 - затравочной массой и затравочной константой связи соответственно. Я не употреблял индекс 0 в первой части этой книги, поскольку не хотел вводить обозначения до того, как вы узнаете, что именно они обозначают.

С этой точки зрения применение затравочной теории возмущений кажется неоправданным, и это действительно так. Не лучше было бы начать с теории нулевого порядка, сразу записанной в терминах физической массы m_P и физической константы связи λ_P, которые измеряются экспериментаторами, и соответственно изучать теорию возмущений этой теории? В самом деле, это так и происходит, и такой способ вычислений называется перенормированной теорией возмущений или, как я предпочитаю ее называть, физической теорией возмущений.

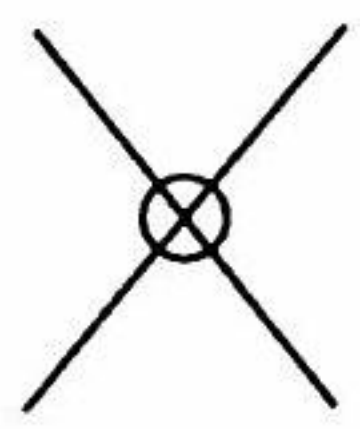
Запишем:

$$\mathcal{L} = \frac{1}{2}\left[(\partial\varphi)^2 - m_P^2\varphi^2\right] - \frac{\lambda_P}{4!}\varphi^4 + A(\partial\varphi)^2 + B\varphi^2 + C\varphi^4$$

(Пара слов об обозначениях: педант, возможно, пожелал бы употребить поле φ с индексом P, но давайте как можно реже менять обозначения.) Физическая теория возмущений работает следующим образом. Правила Фейнмана не меняются, за исключением того, что константа связи обозначается как λ_P, а пропагатор $i/\left(k^2 - m_P^2 + i\varepsilon\right)$ записывается уже с физической массой. Последние три члена в выражении (4) называют контрчленами. Коэффициенты A, B и C вычисляются итерационно (см. далее), по мере перехода к все более и более высоким порядкам теории возмущений. На фейнмановских диаграммах они обозначаются крестиками (рис. III.3.2) с соответствующими правилами Фейнмана. Все интегралы по импульсам обрезаны.



$$+2i\left(Ak^2 + B\right)$$



$4!iC$

Рис. III.3.2

Теперь объясню, почему коэффициенты A, B и C определяются итерационно. Предположим, мы вычислили их до порядка λ_P^N; обозначим их в этом порядке как A_N, B_N и C_N. Нарисуем все диаграммы для поряд- ка λ_P^{N+1}. Найдем значения A_{N+1}, B_{N+1} и C_{N+1} при условии, что вычисленный до порядка λ_P^{N+1} пропагатор имеет при m_P полюс с вычетом равным 1, и условии, что амплитуда мезон-мезонного рассеяния, для определенных значений кинематических переменных, равна $-i\lambda_P$. Иначе говоря, контрчлены фиксируются условием, согласно которому m_p и λ_P есть то, что мы о них думаем. Естественно, A, B и C будут зависимыми от обрезания. Обратите внимание, что существует точно три условия определения трех неизвестных A_{N+1}, B_{N+1} и C_{N+1}.

При таком рассуждении становится очевидным, почему работает физическая теория возмущений. Она справедлива тогда, когда все физические величины, которые мы вычисляем, не зависят от обрезания. Представьте, к примеру, что вы долго и упорно вычисляли амплитуду мезон-мезонного рассеяния до порядка λ_P^{17}. Она будет содержать как зависимые, так и независимые от обрезания члены. Вы просто добавляете в полученное выражение коэффициент C_{17} и подбираете его значение таким образом, чтобы зависимые от обрезания члены сократились.

И тут вы начинаете волноваться. Вы говорите: «Что, если я захочу вычислить амплитуду превращения двух мезонов в четыре мезона? Этой ситуации соответствуют диаграммы с шестью внешними концами. Если я получу зависимые от порога обрезания члены, что мне делать, ведь в выражении (4) нет контрчлена вида $D\varphi^6$ и нельзя устранить зависимость от обрезания?» Очень проницательно с вашей стороны, но не стоит беспокоиться по этому поводу. Проблему здесь решает теорема подсчета степеней.

Степень расходимости

Рассмотрим диаграмму с B_E внешними φ-линиями. Во-первых, определение: говорят, что диаграмма A имеет кажущуюся степень расходимости D, если она расходится как Λ^D. (Степень логарифмической расходимости $\log\Lambda$ равна $D = 0$.) Теорема гласит, что D принимает значение, равное:

$$D = 4 - B_E$$

Доказательство приведу позже, а пока объясню смысл формулы (5). Для пропагатора имеем $B_E = 2$ и, согласно формуле, $D = 2$. Действительно, расходимость получается

квадратичной. Для амплитуды мезон-мезонного рассеяния имеем $B_E = 4$ и, следовательно, $D = 0$, что как раз соответствует логарифмической расходимости.

Согласно теореме, для диаграммы с шестью внешними ветками (которую иногда формально называют шеститочечной функцией) имеем $B_E = 6$

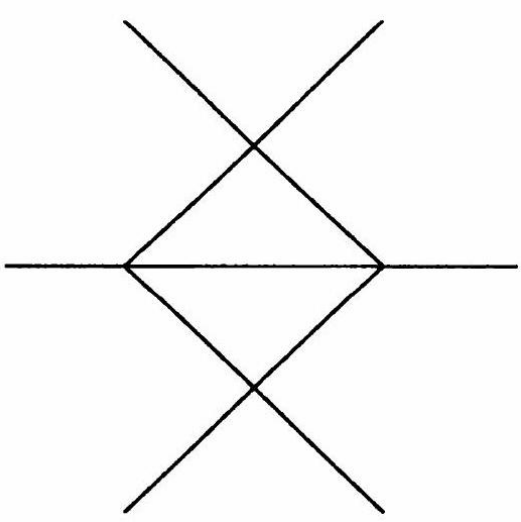


Рис. III.3.3

и $D = -2$. Получается, что по теореме диаграмма сходится или не зависит от обрезания (зависимость от обрезания исчезает при Λ^{-2}). Не сомневайтесь в этом, а просто постройте несколько диаграмм и проверьте данное утверждение. Чем больше на диаграмме внешних веток, тем лучше она сходится.

Доказательство теоремы основано на простом подсчете степеней. Кроме B_E и D, определим параметр B_I, характеризующий количество внутренних линий, параметр V - количество вершин и параметр L - количество петель. (Для удобства возьмем конкретную диаграмму на рис. III.3.3: $B_E = 6, D = -2, B_I = 5, V = 4$ и $L = 2$.)

Число петель соответствует числу интегрирований $\int [d^4k/(2\pi)^4]$, которые нужно выполнить. Каждой внутренней линии соответствует импульс, по которому надо провести интегрирование, так что получаем еще B_I интегралов. Реальное число интегрирований уменьшается за счет дельта-функций сохранения импульса, в вершинах (по одной на каждую вершину). В результате получаем V дельта-функций, одна из которых связана с сохранением общего импульса для всей диаграммы. Число петель равно

$$L = B_I - (V - 1).$$

[Если вы ставите это под сомнение, проанализируйте диаграмму на рис. III.3.3 и получите тождество $2 = 5 - (4 - 1)$.]

Из каждой вершины исходят четыре линии (или входят, в зависимости от того, как на это посмотреть). Каждая внешняя линия исходит (или входит) из одной вершины. Каждая внутренняя линия соединяет две вершины. Таким образом

$$4V = B_E + 2B_I$$

(Для рис. III. 3.3 имеем $4 \cdot 4 = 6 + 2 \cdot 5$.)

Наконец, каждой петле соответствует интеграл $\int d^4k$, а каждой внутренней линии - выражение $i/\left(k^2-m^2+i\varepsilon\right)$, что в два раза уменьшает значения степеней импульса. Получаем,

$$D = 4L - 2B_I$$

(Для рис. III. 3.3 имеем $-2 = 4 \cdot 2 - 2 \cdot 5$.)

Объединяя (6), (6) и (8), приходим к теореме (5)[2]. Теперь вы видите, что ее доказательство строится на подсчете степеней.

Степень расходимости с фермионами

Проверим, усвоили вы наши рассуждения, предшествующие доказательству теоремы (5), или нет. Для этого обратимся к теории Юкавы, с которой мы встречались в (II.5.19). (Для удобства обозначения опустим контрчлены.)

$$\mathcal{L} = \bar{\psi}\left(i\gamma^\mu\partial_\mu - m_P\right)\psi + \frac{1}{2}\left[(\partial\varphi)^2 - \mu_P^2\varphi^2\right] - \lambda_P\varphi^4 + f_P\varphi\bar{\psi}\psi$$

Теперь мы должны найти число внутренних F_I и внешних F_E фермионных линий и проследить за числом вершин V_f и V_λ, с константами связи f и λ соответственно.

У нас всего пять уравнений. Например, соотношение (7) можно разложить на два, поскольку теперь мы считаем отдельно фермионные линии и отдельно бозонные линии. Например, имеем:

$$V_f + 4V_\lambda = B_E + 2B_I$$

В итоге получаем:

$$D = 4 - B_E - \frac{3}{2}F_E$$

[2] Кажущаяся степень расходимости характеризует расходимость фейнмановской диаграммы при условии, что все внутренние импульсы масштабируются одинаково $k \to \lambda k$, где λ стремится к бесконечности. При более строгом подходе мы должны следить за импульсами в поддиаграммах (части полной диаграммы), которые стремятся к бесконечности при остальных фиксированных импульсах. Итак, для расходящихся амплитуд, т. е. класса диаграмм с $D \geqslant 0$, справедливо $(B_E, F_E) = (0,2), (2,0), (1,2)$ и $(4,0)$, что точно соответствует шести членам в лагранжиане (9). Значит, нам необходимы шесть контрчленов.

Обратите внимание, что подобный подсчет степеней расходимости доказывает факт появления всех членов с размерностью $\leqslant 4$. Например, записывая лагранжиан (9), мы забыли включить в него член $\lambda_P\varphi^4$. Согласно теореме мы должны будем включить этот член в виде контрчлена [член с $(B_E, F_E) = (4,0)$ в приведенном выше списке.]

Выражения (5) и (11) имеют одно общее свойство: они оба зависят только от числа внешних линий и не зависят от числа вершин V. Следовательно, для заданного числа внешних линий не имеет значения, до какого порядка теории возмущений мы двигаемся, поскольку кажущаяся степень расходимости остается одинаковой. Дальнейшие рассуждения приводят нас к мысли, что мы всего лишь формализуем процесс подсчета степеней из предыдущей главы. [Вспомним, что размерность поля Бозе $[\varphi]$ равна 1, а

размерность поля Ферми ψ равна $\frac{3}{2}$, что соответствует коэффициентам 1 и $\frac{3}{2}$ в уравнении (11).]

Наши рассуждения нельзя считать строгим доказательством перенормируемости таких теорий, как теория Юкавы. Для большей строгости вам придется обратиться к монографиям по теории перенормировок, в которых исчерпывающе обсуждаются такие мистические вопросы, как перекрывающиеся расходимости и «лесная» формула Циммермана.

Неперенормируемые теории поля

В контексте наших рассуждений полезно будет узнать, откуда неперенормируемые теории получили свои неприятные особенности. Рассмотрим теорию слабых взаимодействий Ферми, записанную в упрощенной форме:

$$\mathcal{L} = \bar{\psi}\left(i\gamma^{\mu}\partial_{\mu} - m_P\right)\psi + G(\bar{\psi}\psi)^2.$$

Аналогами выражений (6), (7) и (8) будут $L = F_I - (V-1), 4V = F_E + 2F_I$ и $D = 4L - F_I$. Выражая кажущуюся степень расходимости через число внешних фермионных линий, получаем:

$$D = 4 - \frac{3}{2}F_E + 2V.$$

Сравним это выражение с соответствующим уравнением (5) для перенормируемых теорий и с уравнением (11). Видим, что теперь D зависит от V. То есть при расчете, например, фермион-фермионного рассеяния ($F_E = 4$), характер расходимости будет ухудшаться по мере нашего продвижения к более высокому порядку ряда возмущений. Это подтверждает сделанные в предыдущей главе выводы. Действительно, неприятным моментом является условие, что для любого заданного F_E мы придем к расходящимся диаграммам с большим числом V, так что придется включать нескончаемый поток контрчленов $(\bar{\psi}\psi)^3, (\bar{\psi}\psi)^4, (\bar{\psi}\psi)^5$... с произвольными константами связи, которые следует определить из эксперимента. Предсказательные возможности теории сильно ограничиваются.

Одно время неперенормируемые теории считались безнадежными. С современной точки зрения, основанной на подходе эффективных теорий поля, речь о которой пойдет в главе VIII.3, они вполне приемлемы.

Зависимость от размерности

Кажущаяся степень расходимости зависит от размерности d пространства-времени, так как каждой петле сопоставляется интеграл $\int d^d k$. К примеру, рассмотрим взаимодействие Ферми $G(\bar{\psi}\psi)^2$ в $(1+1)$-мерном пространстве-времени. Из трех уравнений, приводящих к выражению (12), одно меняется на $D = 2L - F_I$, поэтому в итоге получаем:

$$D = 2 - \frac{1}{2}F_E$$

Полученное выражение есть аналог (12) для 2-мерного пространства-времени. В отличие от уравнения (12), сюда не входит параметр V, поэтому двумерные диаграммы содержат $F_E = 2$ и 4, которые сокращаются подходящими контрчленами. Взаимодействие Ферми

перенормируемо в (1+ +1)-мерном пространстве-времени. К этому вопросу мы еще вернемся в главе VII.4.

Явление Вайскопфа

В качестве заключения скажу, что поправка к массе поля Бозе и поля Ферми расходится неодинаково. Этот факт впервые обнаружил Вайскопф, поэтому я буду называть его явлением Вайскопфа. Вернемся к уравнению (11) и увидим, что B_E и F_E дают разные вклады в значение кажущейся степени расходимости D. Для $B_E = 2, F_E = 0$ имеем $D = 2$, так что поправка к массе поля Бозе расходится квадратично, что мы уже явно наблюдали [параметр a в (3)]. Однако для $F_E = 2, B_E = 0$ имеем $D = 1$. То есть масса фермиона расходится как бы линейно. В действительности в 4-мерной теории поля нельзя получить линейную зависимость от обрезания. Легче всего это увидеть на примере интеграла Фейнмана из упражнения II.5.1, соответствующего диаграмме на рис. II.5.1:

$$(if)^2 i^2 \int \frac{d^4k}{(2\pi)^4} \frac{1}{k^2-\mu^2} \frac{\not p + \not k + m}{(p+k)^2 - m^2} \equiv A\left(p^2\right) \not p + B\left(p^2\right)$$

где для удобства введены две неизвестные функции $A\left(p^2\right)$ и $B\left(p^2\right)$. (Для нас сейчас не имеет значения, придерживаемся мы затравочной или физической теории возмущений. В случае последней считайте, что я просто опустил подстрочный индекс P.)

Посмотрим на подынтегральное выражение при больших k. Видим, что интеграл будет иметь вид $\int^{\Lambda} d^4k \, (k/k^4)$ и выглядит линейно расходящимся, но, вследствие симметрии относительно отражений $k \to -k$, равен нулю в ведущем порядке. Интеграл в (14) расходится только логарифмически. Довольно часто кажущаяся степень расходимости D дает лишь оценку сверху, насколько сильны могут быть расходимости (отсюда определение «кажущаяся»). Действительно, из (14) можно доказать, что, например, $B\left(p^2\right)$ должно быть пропорционально m. В качестве упражнения попробуйте с помощью правил Фейнмана (см. главу II.5) доказать справедливость этого утверждения для квантовой электродинамики.

Для бозона квантовые флуктуации дают $\delta\mu \propto \Lambda^2/\mu$, а для фермиона (например, электрона) квантовая поправка к массе $\delta m \propto m \log(\Lambda/m)$ гораздо меньше. Интересно, что в начале двадцатого века физики рассматривали электрон как заряженный шарик радиуса a. Электростатическая энергия такого шарика, значение которой было порядка e^2/a, считалась массой электрона. Трактуя $1/a$ как Λ, мы могли бы сказать, что в классической физике масса электрона пропорциональна Λ и линейно расходится. Следовательно, приходим к одному из определений явления Вайскопфа: «Бозоны ведут себя хуже классического заряда, а фермионы - лучше».

В 1939 году Вайскопф пришел к выводу, что разницу в степенях расходимости можно объяснить эвристически на основе квантовой статистики. «Плохое» поведение бозонов связано с их стадным поведением. Фермион оттолкнул бы виртуальные фермионы, флуктуирующие в вакууме, и создал бы тем самым вокруг себя полость в вакуумном распределении заряда. Таким образом, собственная энергия фермиона менее сингулярна, чем могла бы быть без учета квантовой статистики. У бозона все наоборот.

«Плохое» поведение бозонов будет преследовать нас и дальше.

Упражнения

III.3.1. Покажите, что в $(1+1)$-мерном пространстве-времени дираковское поле ψ имеет размерность $\frac{1}{2}$, так что константа связи Ферми безразмерна.

III.3.2. Выведите (11) из (13).

III.3.3. Покажите, что $B\left(p^2\right)$ в выражении (14) равен нулю, если положить $m=0$. Покажите, что такое же явление справедливо и для квантовой электродинамики.

III.3.4. Мы показали, что вклад (14) в δm логарифмически расходится. Убедитесь, что это верно для любого конечного порядка теории возмущений.

18.1.3 Zi.III.4 Gauge Invariance: Photon Knows No Rest

Нарушение основного тождества

В главе I.7 говорилось, что интеграл по траекториям для произвольной теории поля можно формально вычислить с помощью соотношения, которое вполне заслуженно называют Центральным тождеством квантовой теории поля:

$$\int D\varphi e^{-\frac{1}{2}\varphi\cdot K\cdot\varphi - V(\varphi)+J\cdot\varphi} = e^{-V(\delta/\delta J)} e^{\frac{1}{2}J\cdot K^{-1}\cdot J}$$

Для любой теории поля мы всегда можем собрать все поля и поместить их в один гигантский вектор-столбец φ. Затем мы выделим из вектора φ квадратичный член и запишем его как $\frac{1}{2}\varphi\cdot K\cdot\varphi$; оставшийся вектор назовем $V(\varphi)$. Я пользуюсь компактным обозначением, при котором все координаты пространства-времени и все индексы полей, включая лоренцевские индексы, включены в индексы в формальной матрице K. Часто уравнение (1) будем записывать с $V=0$:

$$\int D\varphi e^{-\frac{1}{2}\varphi\cdot K\cdot\varphi + J\cdot\varphi} = e^{\frac{1}{2}J\cdot K^{-1}\cdot J}$$

Что делать, если K не имеет обратной матрицы?

Такой случай не является чем-то эзотерическим, присущим патологическим теориям поля. Он реализуется в одном из самых основных действий в физике, действии Максвелла:

$$S(A)=\int d^4x\mathcal{L}=\int d^4x\left[\frac{1}{2}A_\mu\left(\partial^2 g^{\mu\nu}-\partial^\mu\partial^\nu\right)A_\nu + A_\mu J^\mu\right]$$

Формальная матрица K в уравнении (2) пропорциональна дифференциальному оператору $\left(\partial^2 g^{\mu\nu}-\partial^\mu\partial^\nu\right)\equiv Q^{\mu\nu}$. Матрица не имеет обратной матрицы, если некоторые из ее собственных значений равны нулю, т. е. если при ее действии на вектор матрица зануляет этот вектор. Видим, что $Q^{\mu\nu}$ зануляет вектор $\partial_\nu\Lambda(x) : Q^{\mu\nu}\partial_\nu\Lambda(x)=0$. Значит, $Q^{\mu\nu}$ не имеет обратной.

В этом явлении нет ничего таинственного; мы уже встречались с ним в классической физике. Действительно, когда мы впервые изучали законы электричества, нам говорили, что только «падение напряжения» между двумя точками имеет физический смысл. На более сложном уровне мы узнали, что всегда можно добавить некоторую константу (или произвольную функцию времени) в электростатический потенциал (который, конечно, есть просто «напряжение»), поскольку по определению его градиентом является электрическое поле. На еще более сложном уровне мы видим, что, решая уравнение Максвелла (которое

получается из экстремума действия), мы находим обратную матрицу Q^{-1}. [Уравнение Максвелла $\partial_\mu F^{\mu\nu}$ я записал здесь в виде $Q_{\mu\nu}A^\nu = J_\mu$ с решением $A^\nu = (Q^{-1})^{\nu\mu}\, J_\mu$.]

Итак, Q^{-1} не существует! Что делать? Мы знаем, что следует наложить дополнительное условие на калибровочный потенциал A^μ, так называемую «фиксацию калибровки».

Простое объяснение

Чтобы подчеркнуть довольно земное происхождение фиксации калибровки (которую в старых книгах превращали во что-то таинственное и почти безнадежно сложное для понимания), рассмотрим обычный интеграл $\int\limits_{-\infty}^{+\infty} dAe^{-A\cdot K\cdot A}$, в котором $A = (a, b)$ есть двухкомпонентный вектор, а $K = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ есть матрица, не имеющая обратной. Конечно, вы понимаете, в чем состоит трудность: у нас есть $\int\limits_{-\infty}^{+\infty}\int\limits_{-\infty}^{+\infty} dadbe^{-a^2}$, в то время как интеграла по b не существует. Для определения интеграла вставим в него дельта-функцию $\delta(b-\xi)$. Теперь интеграл определен и фактически не зависит от произвольного числа ξ. В более общем виде можно ввести в интеграл дельта-функцию $\delta[f(b)]$, где f - некоторая функция на наш выбор. В случае обычного интеграла эти действия выглядят нелепыми и лишними, но мы будем пользоваться аналогом этой процедуры в других случаях.

В калибровочных теориях необходимость наложения руками связи, фиксирующей калибровку, можно объяснить с физической точки зрения. В главе I.5 мы обошли вопрос фиксации калибровки за счет того, что рассматривали вместо фотона массивный векторный мезон. В результате мы заменили $Q^{\mu\nu}$ на $(\partial^2 + m^2)\, g^{\mu\nu} - \partial^\mu\partial^\nu$, для которой существует обратная матрица (на самом деле мы даже нашли ее явным вычислением).

Рассмотрим движущийся массивный векторный мезон. С помощью лоренцевских преобразований мы всегда можем привести его в покоящуюся систему координат и применить к ней все, что знаем о группе вращений, а именно то, что мезон со спином 1 имеет три спиновых состояния (в классической физике - состояния поляризации). Однако, если векторный мезон безмассов, мы больше не можем привести его в покоящуюся систему координат. Фотон не знает покоя!

Безмассовое поле со спином 1 отличается от массивного поля со спином 1 - в этом состоит корень проблемы. Теперь у нас есть лишь вращения вокруг направлсния движения фотона, т. е. $O(2)$. У фотона всего две поляризационные степени свободы. (Из классической электродинамики вы знаете, что электромагнитная волна обладает двумя поперечными степенями свободы.) Таково истинное физическое происхождение калибровочной инвариантности.

С этой точки зрения калибровочная инвариантность является, строго говоря, не настоящей симметрией, а лишь отражением того факта, что мы пользуемся избыточным описанием: лоренцевским [1] векторным полем для описания двух физических степеней свободы.

Ограничение функционального интеграла

Теперь обратимся к методу борьбы с этой избыточностью, изобретенному Фаддеевым и Поповым. Вы увидите, что он аналогичен методу, использованному нами в разобранном выше примере. Даже в случае электромагнетизма применение этого метода кажется

излишним, однако для неабелевых калибровочных теорий и теории гравитации он имеет большое значение (в главе VII.1 вы убедитесь в этом). Я изложу метод в наиболее общем виде. В следующем разделе мы рассмотрим конкретный пример. Если у вас возникнут трудности с пониманием этого раздела, возможно, полезно будет читать эти два раздела параллельно.

Предположим, нам необходимо вычислить интеграл $I \equiv \int DAe^{iS(A)}$; это может быть обычный интеграл или интеграл по траекториям. Допустим, вследствие преобразования $A \to A_g$ подынтегральное выражение и мера не меняются, т. е. $S(A) = S(A_g)$ и $DA = DA_g$. Очевидно, что преобразования образуют группу, поскольку при преобразовании с g' подынтегральное выражение и мера не изменятся при совместном преобразовании g и g' и $A_g \to (A_g)_{g'} = A_{gg'}$. Нам бы хотелось записать интеграл I в виде $I = \left(\int Dg\right) J$, где J не зависит от g, и отфакторизовать тем самым избыточное интегрирование по g. Обратите внимание, что Dg есть инвариантная мера для группы преобразований, а $\int Dg$ есть объем группы. Не забывайте, что

[1] Четырехкомпонентным. - Прим. ред. мы пользуемся компактным обозначением интеграла по траекториям: параметры A и g есть функции координат пространства-времени x.

Подчеркну, что в наших действиях нет ничего выдающегося и мистического. Для вычисления интеграла $I = \int dxdye^{iS(x,y)}$, где $S(x,y)$ - некоторая функция от x^2+y^2, удобно перейти к полярным координатам $I = \left(\int d\theta\right) J = (2\pi)J$, где $J = \int drre^{iS(r)}$ - интеграл по радиальной координате r. Множитель 2π есть в точности объем группы вращений в двух измерениях.

Фаддеев и Попов продемонстрировали универсальный и очень элегантный способ «перехода к полярным координатам». Они предложили записывать единицу как $1 = \Delta(A)\int Dg\delta\left[f\left(A_g\right)\right]$, т. е. равенством, определяющим $\Delta(A)$. Здесь f есть некоторая функция на наш выбор, а $\Delta(A)$ - детерминант Фаддеева-Попова, зависящий от f. Обратите внимание, что $\left[\Delta\left(A_{g'}\right)\right]^{-1} = \int Dg\delta\left[f\left(A_{g'g}\right)\right] = \int Dg''\delta\left[f\left(A_{g''}\right)\right] = [\Delta(A)]^{-1}$, где второе равенство следует из определения $g'' = g'g$ и условия $Dg'' = Dg$. Другими словами, мы показали, что $\Delta(A) = \Delta\left(A_g\right)$: детерминант Фаддеева-Попова является калибровочно-инвариантным. Теперь подставим 1 в интеграл I, который необходимо вычислить, и получим:

$$\begin{aligned} I &= \int DAe^{iS(A)} = \\ &= \int DAe^{iS(A)}\Delta(A)\int Dg\delta\left[f\left(A_g\right)\right] = \\ &= \int Dg\int DAe^{iS(A)}\Delta(A)\delta\left[f\left(A_g\right)\right]. \end{aligned}$$

Раз мы физики, а не математики, можем спокойно поменять порядок интегрирования.

С точки зрения физики, всегда можно заменить переменные интегрирования, пока не будет доказано обратное, поэтому заменим A на $A_{g^{-1}}$. Получим:

$$I = \left(\int Dg\right)\int DAe^{iS(A)}\Delta(A)\delta[f(A)]$$

где учитывается условие инвариантности $DA, S(A)$ и $\Delta(A)$ относительно преобразования $A \to A_{g^{-1}}$.

Вот так. Мы отфакторизовали интегрирование по группе $\left(\int Dg\right)$.

Объем компактной группы конечен, однако в калибровочных теориях для каждой точки пространства-времени существует отдельная группа, поэтому $\left(\int Dg\right)$ является бесконечным фактором. (Это также объясняет, почему в теориях с глобальными симметриями нет необходимости в фиксации калибровки.) К счастью, как говорилось в главе I.3, в рамках теории поля мы можем не беспокоиться по поводу общих множителей в интеграле по траекториям Z, поэтому множитель $\left(\int Dg\right)$ может быть просто отброшен.

Фиксация калибровки в электродинамике

Теперь применим метод Фаддеева-Попова к электродинамике. Преобразование, относительно которого действие инвариантно, конечно же $A_\mu \to A_\mu - \partial_\mu \Lambda$, где g обозначено как Λ, а $A_g \equiv A_\mu - \partial_\mu \Lambda$. Обратите внимание, что, поскольку начальный интеграл I не зависит от f, он не будет зависеть от f, несмотря на то, что f появляется в (5). Пусть $f(A) = \partial A - \sigma$, где σ - функция от x. В частности, интеграл I не зависит от σ, поэтому можно проинтегрировать I с произвольным функционалом от σ, например, с функционалом $e^{-(i/2\xi)\int d^4x \sigma(x)^2}$.

Теперь применим метод. Сначала вычислим

$$[\Delta(A)]^{-1} \equiv \int Dg \delta\left[f\left(A_g\right)\right] = \int D\Lambda \delta\left(\partial A - \partial^2 \Lambda - \sigma\right)$$

Видим, что в интеграле (5) параметр $\Delta(A)$ умножается на $\delta[f(A)]$, так что, вычисляя (6), можно принять $f(A) = \partial A - \sigma$ равной нулю. Из уравнения (6) получаем $\Delta(A) \ll= \left[\int D\Lambda \delta\left(\partial^2 \Lambda\right)\right]^{-1}$. Правая часть этого выражения не зависит от A, поэтому его можно отбросить. С точностью до несущественных общих множителей, которые можно отбросить, интеграл I равен просто $\int DA e^{iS(A)} \delta(\partial A - \sigma)$.

Интегрируя по $\sigma(x)$ мы окончательно получаем:

$$\begin{aligned} Z &= \int D\sigma e^{-(i/2\xi)\int d^4x \sigma(x)^2} \int DA e^{iS(A)} \delta(\partial A - \sigma) = \\ &= \int DA e^{iS(A) - (i/2\xi)\int d^4x (\partial A)^2}. \end{aligned}$$

Не правда ли, изящный трюк придумали Фаддеев и Попов?

Итак, $S(A)$ в (3) эффективно заменяется выражением:

$$\begin{aligned} S_{\ni\phi.}(A) &= S(A) - \frac{1}{2\xi} \int d^4x (\partial A)^2 = \\ &= \int d^4x \left\{ \frac{1}{2} A_\mu \left[\partial^2 g^{\mu\nu} - \left(1 - \frac{1}{\xi}\right) \partial^\mu \partial^\nu \right] A_\nu + A_\mu J^\mu \right\} \end{aligned}$$

а $Q^{\mu\nu}$ заменяется на $Q^{\mu\nu}_{3.} = \partial^2 g^{\mu\nu} - (1 - 1/\xi)\partial^\mu \partial^\nu$. В импульсном пространстве матрица $Q^{\mu\nu}_{\text{эфф.}} = -k^2 g^{\mu\nu} + (1 - 1/\xi) k^\mu k^\nu$, в самом деле, имеет обратную матрицу. Можете проверить, что

$$Q^{\mu\nu}_{\exists\phi\phi.} \left[-g_{\nu\lambda} + (1 - \xi) \frac{k_\nu k_\lambda}{k^2} \right] \frac{1}{k^2} = \delta^\mu_\lambda.$$

Следовательно, фотонный пропагатор можно представить в виде:

$$\frac{(-i)}{k^2}\left[g_{\nu\lambda}-(1-\xi)\frac{k_\nu k_\lambda}{k^2}\right]$$

в согласии с выводами главы II.7.

В связи с тем что метод Фаддеева-Попова является во многом хитростью, многие физики, в том числе и я, предпочитают следовать явным аргументам Фейнмана, представленным в главе II.7. Однако, как я уже отмечал, в теории Янга-Миллса и теории Эйнштейна без метода Фаддеева-Попова не обойтись.

Размышления о калибровочной симметрии

Как мы увидим позже и как вы, возможно, слышали, многие явления в мире, выходящие за рамки электродинамики, объясняются калибровочными теориями. В некотором смысле калибровочные теории также оказываются неудовлетворительными, поскольку построены на избыточности описания. Электромагнитное калибровочное преобразование $A_\mu \to A_\mu - \partial_\mu\Lambda$ не является истинной симметрией, при которой два физических состояния наделены одинаковыми свойствами. Скорее, оно гласит, что два калибровочных потенциала A_μ и $A_\mu - \partial_\mu\Lambda$ описывают одно и то же физическое состояние. В главе IV.4 я покажу, что A_μ необходимо в первую очередь для уравнения Шредингера. В рамках классической физики можно спокойно обойтись лишь с помощью $\vec{E}$ и $\vec{B}$. Некоторые физики пытаются сформулировать квантовую электродинамику без использования A_μ, но пока не преуспели в поиске альтернативы тому, что мы имеем на данный момент. Возможно, что действительно глубокий прорыв в теоретической физике будет включать в себя формулировку квантовой электродинамики без использования A_μ.

18.1.4 Zi.III.5 Field Theory Without Relativistic Invariance

Замедляясь с возрастом

Когда появилась квантовая теория поля, она была релятивистской. С наступлением периода зрелости теория нашла свое применение в физике конденсированных сред. Можно долго говорить о роли квантовой теории поля в теории конденсированных сред, но у нас более скромная цель, заключающаяся в нахождении нерелятивистского предела квантовой теории поля.

Лоренц-инвариантная теория скалярного поля

$$\mathcal{L}=\left(\partial\Phi^\dagger\right)\left(\partial\Phi\right)-m^2\Phi^\dagger\Phi-\lambda\left(\Phi^\dagger\Phi\right)^2$$

(при условии $\lambda>0$) описывает систему взаимодействующих бозонов. Она обязательно включает в себя физику медленно движущихся бозонов. Для ясности рассмотрим сначала релятивистское уравнение Клейна-Гордона

$$\left(\partial^2+m^2\right)\Phi=0$$

для свободного скалярного поля. Мода с энергией $E=m+\varepsilon$ осциллировала бы во времени как $\Phi\propto e^{-iEt}$. В нерелятивистском пределе кинетическая энергия ε гораздо меньше массы m. Поэтому имеем право записать $\Phi(\vec{x},t)=e^{-imt}\varphi(\vec{x},t)$ при условии, что поле φ осциллирует во времени гораздо медленнее, чем e^{-imt}. Подставляя данное выражение в уравнение (2) и дважды применяя тождество $(\partial/\partial t)e^{-imt})\,(...)=e^{-imt}(-im+\partial/\partial t)(...)$, получаем $(-im+$

$\partial/\partial t)^2\varphi - \vec{\nabla}^2\varphi + m^2\varphi = 0$. Член $(\partial^2/\partial t^2)\,\varphi$ мал по сравнению со значением $-2im(\partial/\partial t)\varphi$, поэтому его можно отбросить. В результате придем к уравнению Шредингера:

$$i\frac{\partial}{\partial t}\varphi = -\frac{\vec{\nabla}^2}{2m}\varphi.$$

Кстати, уравнение Клейна-Гордона было получено раньше уравнения Шредингера.

С учетом всего вышесказанного можно легко найти нерелятивистский предел квантовой теории поля. Просто подставим в уравнение (1) выражение

$$\Phi(\vec{x},t) = \frac{1}{\sqrt{2m}}e^{-imt}\varphi(\vec{x},t)$$

(Множитель $1/\sqrt{2m}$ нужен для удобства дальнейших вычислений.) Например,

$$\frac{\partial\Phi^\dagger}{\partial t}\frac{\partial\Phi}{\partial t} - m^2\Phi^\dagger\Phi \to \frac{1}{2m}\left\{\left[\left(im + \frac{\partial}{\partial t}\right)\varphi^\dagger\right]\left[\left(-im + \frac{\partial}{\partial t}\right)\varphi\right] - m^2\varphi^\dagger\varphi\right\} \simeq$$
$$\simeq \frac{1}{2}i\left(\varphi^\dagger\frac{\partial\varphi}{\partial t} - \frac{\partial\varphi^\dagger}{\partial t}\varphi\right)$$

После интегрирования по частям приходим к выражению

$$\mathcal{L} = i\varphi^\dagger\partial_0\varphi - \frac{1}{2m}\partial_i\varphi^\dagger\partial_i\varphi - g^2\left(\varphi^\dagger\varphi\right)^2$$

где $g^2 = \lambda/4m^2$

В главе I.9 мы видели, что в теории (1) есть сохраняющийся нетеровский ток $J_\mu = i\left(\Phi^\dagger\partial_\mu\Phi - \partial_\mu\Phi^\dagger\Phi\right)$. Как и можно было ожидать, плотность J_0 сводится к $\varphi^\dagger\varphi$, тогда как J_i сводится к виду $(i/2m)\left(\varphi^\dagger\partial_i\varphi - \partial_i\varphi^\dagger\varphi\right)$. Когда вы впервые изучали квантовую механику, не задавались ли вы вопросом, почему плотность $\rho \equiv \varphi^\dagger\varphi$ и ток $J_i = (i/2m)\left(\varphi^\dagger\partial_i\varphi - \partial_i\varphi^\dagger\varphi\right)$ выглядят так по-разному? Многие выражения при редукции из более симметричной в менее симметричную теорию неизбежно становятся менее изящными.

Число сопряжено фазовому углу

Позвольте обратить ваше внимание на некоторые отличия между релятивистским и нерелятивистским случаями.

Самое большое отличие состоит в том, что релятивистская теория квадратична по производным по времени, тогда как нерелятивистская теория линейна по производным по времени. Следовательно, в нерелятивистской теории плотность импульса, сопряженная полю φ, а именно $\partial\mathcal{L}/\delta\partial_0\varphi$, равна просто $i\varphi^\dagger$, так что $\left[\varphi^\dagger(\vec{x},t), \varphi\left(\vec{x}',t\right)\right] = -\delta^{(D)}\left(\vec{x}-\vec{x}'\right)$. В физике конденсированных сред часто полезно записать $\varphi = \sqrt{\rho}e^{i\theta}$, так что:

$$\mathcal{L} = \frac{i}{2}\partial_0\rho - \rho\partial_0\theta - \frac{1}{2m}\left[\rho\left(\partial_i\theta\right)^2 + \frac{1}{4\rho}\left(\partial_i\rho\right)^2\right] - g^2\rho^2$$

Первый член является полной производной. Второй член сообщает нечто очень важное [1] из физики конденсированных сред: в каноническом формализме (глава I.8) плотность импульса, сопряженная фазовому полю $\theta(x)$, равна $\delta\mathcal{L}/\delta\partial_0\theta = -\rho$, следовательно, согласно Гейзенбергу:

$$[\rho(\vec{x},t), \theta\left(\vec{x}',t\right)] = i\delta^{(D)}\left(\vec{x}-\vec{x}'\right)$$

Проинтегрировав и введя параметр $N \equiv \int d^D x \rho(\vec{x}, t)$, равный общему количеству бозонов, получим одно из важнейших соотношений в физике конденсированных сред:

$$[N, \theta] = i$$

Число оказалось сопряженным фазовому углу, подобно тому, как импульс сопряжен с координатой. Изящно, не правда ли? Из курса физики конденсированных сред вы, может быть, знаете, что это фундаментальное соотношение лежит в основе физики контакта Джозефсона.

Вам, должно быть, известно, что система бозонов с короткодействующим отталкиванием при нулевой температуре является сверхтекучей жидкостью. В частности, Боголюбов доказал, что система содержит элементарное возбуждение с линейной дисперсией [2]. О сверхтекучести речь пойдет в главе V.1.

Знак отталкивания

В нерелятивистской теории (уравнение (7)) бозоны отталкиваются друг от друга, и этот факт очевиден. Чтобы собрать частицы в области высокой плотности, потребовалась бы энергия $g^2\rho^2$. В релятивистской теории менее очевидно, что член $\lambda\left(\Phi^\dagger\Phi\right)^2$ с положительным λ соответствует отталкиванию. В упражнении III.5.3 описывается один из возможных методов, а пока прибегнем лишь к эвристическим соображениям. Гамильтониан (плотность) включает в себя лагранжиан со знаком минус, поэтому для больших значений Φ он записывается как $\lambda\left(\Phi^\dagger\Phi\right)^2$ и не ограничен снизу при $\lambda < 0$. Мы знаем, что физически свободный Бозе-газ склонен к конденсированию и сгущению, и при притягивающем взаимодействии он обязательно сколлапсирует. Естественным образом можно предположить, что условие $\lambda > 0$ соответствует отталкиванию.

Теперь рассмотрим более надежный способ. Если применить основное тождество квантовой теории поля, можно переписать интеграл по траекто-

[1] P. Anderson, Basic Notations of Condensed Matter Physics, p. 235.

[2] Например. Л. Д. Ландау, Е. М. Лифшиц. Статистическая физика, стр. 238. риям, фигурирующий в уравнении (1), в виде:

$$Z = \int D\Phi D\sigma e^{i\int d^4x\left[\left(\partial\Phi^\dagger\right)(\partial\Phi) - m^2\Phi^\dagger\Phi + 2\sigma\Phi^\dagger\Phi + (1/\lambda)\sigma^2\right]}$$

Физики-твердотельщики называют преобразование из (1) в лагранжиан $\mathcal{L} = \left(\partial\Phi^\dagger\right)(\partial\Phi) - m^2\Phi^\dagger\Phi + 2\sigma\Phi^\dagger\Phi + (1/\lambda)\sigma^2$ преобразованием ХаббардаСтратоновича. Поле, не обладающее кинетической энергией, например σ, называется в теории поля вспомогательным, его можно отынтегрировать в интеграле по траекториям. Когда мы будем рассматривать в главе VIII.4 сверхтекучие жидкости, вспомогательные поля будут играть важную роль.

Действительно, в главе III.2 уже говорилось, как теория с промежуточным векторным бозоном генерирует теорию слабых взаимодействий Ферми. Аналогичные физические законы действуют и в нашем случае: теория (10), в которой поле Φ взаимодействует с «промежуточным σ-бозоном», может генерировать теорию (1).

Если бы σ было «нормальным скалярным полем», которые нам известны, т. е. если бы члены квадратичные по σ, в лагранжиане, имели вид $\frac{1}{2}(\partial\sigma)^2 - \frac{1}{2}M^2\sigma^2$, то пропагатор был бы $i/\left(k^2 - M^2 + i\varepsilon\right)$. Амплитуда рассеяния двух Φ-бозонов была бы в этом случае пропорциональна пропагатору. Из главы I.4 нам известно, что обмен скалярным полем приводит к притяжению.

Однако, σ не есть нормальное поле, что следует из того факта, что лагранжиан содержит единственный квадратичный член $+(1/\lambda)\sigma^2$. Следовательно, его пропагатор равен просто $i/(1\lambda) = i\lambda$, его знак (при $\lambda > 0$) противоположен знаку нормального пропагатора, получаемого при малой передаче импульса $i/\left(k^2 - M^2 + i\varepsilon\right) \simeq -i/M^2$. Заключаем, что обмен σ-бозоном приводит к отталкиванию.

Это объяснение, к тому же, показывает, что сила отталкивания имеет бесконечно малый радиус действия, типа дельта-функционного взаимодействия. В главе I.4 говорилось, что расстояние определяется соотношением членов k^2 и M^2. В нашем случае член M^2 бесконечно большой. Можно также утверждать, что взаимодействие $\lambda\left(\Phi^\dagger\Phi\right)$ включает в себя рождение двух бозонов и их уничтожение в одной и той же точке пространства-времени.

Конечная плотность

Специалисты в области физики элементарных частиц иногда забывают, что специалистов в области конденсированных сред не интересует пустое пространство и что они хотели бы иметь конечную плотность $\bar{\rho}$-бозонов. Из статистической механики известен способ, при котором в лагранжиан (6) добавляется химический потенциал $\mu\varphi^\dagger\varphi$. С точностью до несущественных (в данном контексте!) аддитивных констант перепишем лагранжиан в виде:

$$\mathcal{L} = i\varphi^\dagger\partial_0\varphi - \frac{1}{2m}\partial_i\varphi^\dagger\partial_i\varphi - g^2\left(\varphi^\dagger\varphi - \bar{\rho}\right)^2$$

Удивительно, но в релятивистской и нерелятивистской теориях поля масса появляется в разных местах. Для дальнейшего мне потребуется понятие спонтанного нарушения симметрии, поэтому на этом пока все. К вопросу о сверхтекучести вернемся в свое время.

Упражнения

III.5.1. Получите уравнение Клейна-Гордона для частицы в электростатическом потенциале (таком, как потенциал ядра), основываясь на калибровочном принципе замены $(\partial/\partial t)$ в уравнении (2) на $\partial/\partial t - ieA_0$. Покажите, что в нерелятивистском пределе оно сводится к уравнению Шредингера для частицы во внешнем потенциале.

III.5.2. Найдите нерелятивистский предел дираковского лагранжиана.

III.5.3. Для конкрстной теории поля мы можем вычислить амплитуду рассеяния двух частиц в нерелятивистском пределе. Затем потребовать существование потенциала взаимодействия $U(\vec{x})$ между двумя частицами и с помощью нерелятивистской квантовой механики вычислить амплитуду рассеяния, например, в борновском приближении. Сравнивая две амплитуды рассеяния, можно найти значение $U(\vec{x})$. Вычислите таким способом юкавский и кулоновский потенциалы. Применение этого метода к взаимодействию $\lambda\left(\Phi^\dagger\Phi\right)^2$ несколько затрудняется из-за того, что дельта-функционное взаимодействие сингулярно. Тем не менее с помощью этого метода можно определить, является сила отталкивающей или притягивающей.

18.1.5 Zi.III.6 Magnetic Moment of the Electron

Триумф Дирака

Во введении я сказал, что не собираюсь в этой книге уделять много места вычислениям, но не могу удержаться и не рассказать сейчас о величайшем триумфе квантовой теории поля.

После того как Дирак написал свое уравнение, следующим шагом был вопрос о взаимодействии электрона с электромагнитным полем. Согласно калибровочному принципу, уже примененному к уравнению Шредингера в электромагнитном поле, чтобы получить уравнение Дирака для электрона во внешнем электромагнитном поле, мы должны просто заменить обычную производную ∂_μ ковариантной производной $D_\mu = \partial_\mu - ieA_\mu$:

$$(i\gamma^\mu D_\mu - m)\,\psi = 0$$

Сравните с уравнением (II.1.27).

Действуя на это уравнение $(i\gamma^\mu D_\mu + m)$, получаем $-(\gamma^\mu\gamma^\nu D_\mu D_\nu + \ +m^2)\,\psi = 0$. Имеем $\gamma^\mu\gamma^\nu D_\mu D_\nu = \frac{1}{2}\left(\{\gamma^\mu,\gamma^\nu\} + [\gamma^\mu,\gamma^\nu]\right) D_\mu D_\nu = D_\mu D^\mu$ - $-i\sigma^{\mu\nu} D_\mu D_\nu$ и $i\sigma^{\mu\nu} D_\mu D_\nu = (i/2)\sigma^{\mu\nu}\,[D_\mu, D_\nu] = (e/2)\sigma^{\mu\nu}F_{\mu\nu}$. Таким образом,

$$\left(D_\mu D^\mu - \frac{e}{2}\sigma^{\mu\nu}F_{\mu\nu} + m^2\right)\psi = 0.$$

Теперь рассмотрим слабое постоянное магнитное поле, направленное для определенности вдоль третьей оси. Оно настолько слабо, что можно пренебречь членом $(A_i)^2$ в $(D_i)^2$. Согласно калибровочной инвариантности, мы можем выбрать $A_0 = 0, A_1 = -\frac{1}{2}Bx^2$ и $A_2 = \frac{1}{2}Bx^1$ (так что $F_{12} = \partial_1 A_2 - \partial_2 A_1 = B$). Как мы увидим, это одно из вычислений, в котором нам действительно нужно следить за множителями типа 2. Тогда

$$\begin{aligned}(D_i)^2 &= (\partial_i)^2 - ie\,(\partial_i A_i + A_i\partial_i) + O\left(A_i^2\right) = \\ &= (\partial_i)^2 - 2\frac{ie}{2}B\left(x^1\partial_2 - x^2\partial_1\right) + O\left(A_i^2\right) = \\ &= \vec{\nabla}^2 + e\vec{B}\cdot\vec{x}\times\vec{p} + O\left(A_i^2\right).\end{aligned}$$

Обратите внимание, что мы воспользовались условием $\partial_i A_i + A_i\partial_i = (\partial_i A_i) + 2A_i\partial_i$, где в $(\partial_i A_i)$ частные производные действуют только на A_i. В $\vec{L} \equiv \vec{x}\times\vec{p}$ вы, наверное, узнали оператор орбитального углового момента импульса. Таким образом, орбитальный угловой момент порождает орбитальный магнитный момент, взаимодействующий с магнитным полем.

В приведенном расчете есть определенный физический смысл. Если бы мы изучали взаимодействие заряженного скалярного поля Φ с внешним электромагнитным полем, мы бы начали с уравнения

$$\left(D_\mu D^\mu + m^2\right)\Phi = 0$$

получаемого путем замены обычной производной в уравнении КлейнаГордона ковариантными производными. Затем мы провели бы аналогичное уравнению (3) вычисление. Сравнивая выражения (4) и (2), видим, что спин электрона вносит вклад в виде $(e/2)\sigma^{\mu\nu}F_{\mu\nu}$.

Как и в главе II.1, запишем $\psi = \begin{pmatrix}\phi\\ \chi\end{pmatrix}$ в дираковском базисе и сконцентрируемся на параметре ϕ, поскольку в нерелятивистском пределе он много больше χ. Вспомним, что в этом базисе $\sigma^{ij} = \varepsilon^{ijk}\begin{pmatrix}\sigma^k & 0\\ 0 & \sigma^k\end{pmatrix}$. Значит, член $(e/2)\sigma^{\mu\nu}F_{\mu\nu}$, действующий на ϕ, равен $(e/2)\sigma^3\,(F_{12} - F_{21}) = (e/2)2\sigma^3 B = 2e\vec{B}\cdot\vec{S}$, так как $\vec{S} = (\vec{\sigma}/2)$. Убедитесь, что вы понимаете происхождение всех множителей 2 ! Между тем, согласно тому, что я говорил в главе II.1, нам следует записать $\phi = e^{-imt}\Psi$, где Ψ осциллирует гораздо медленнее, чем e^{-imt}, так что

имеет место $(\partial_0^2 + m^2)\, e^{-imt}\Psi \simeq \simeq e^{-imt}[-2im(\partial/\partial t)\Psi]$. Объединяя все выражения, приходим к уравнению:

$$\left[-2im\frac{\partial}{\partial t} - \vec{\nabla}^2 - e\vec{B}\cdot(\vec{L}+2\vec{S})\right]\Psi = 0.$$

Полюбуйтесь на него! Уравнение Дирака как по волшебству говорит нам, что спиновый момент импульса взаимодействует с магнитным полем с коэффициентом 2, по сравнению с орбитальным моментом импульса. Этот экспериментальный факт в то время сильно озадачивал физиков. Вычисление, приводящее к уравнению (5), справедливо считается одним из важнейших в истории физики.

Известна история о том, что Дирак, открыв свое уравнение, не сделал этого вычисления. Вот насколько он был уверен в справедливости своего уравнения! По другой версии, он опасался, что магнитный момент окажется неверным и что Природа не воспользовалась преимуществом его красивейшего уравнения. Существует другой способ увидеть, что уравнение Дирака содержит магнитный момент, - применить разложение Гордона, доказательство которого приведено в упражнении:

$$\bar{u}\,(p')\,\gamma^\mu u(p) = \bar{u}\,(p')\left[\frac{(p'+p)^\mu}{2m} + \frac{i\sigma^{\mu\nu}\,(p'-p)_\nu}{2m}\right]u(p).$$

Посмотрев на взаимодействие с электромагнитным полем $\bar{u}\,(p')\,\gamma^\mu u(p)\times\ \times A_\mu\,(p'-p)$, мы видим, что первый член в уравнении (6) зависит от импульса $(p'+p)^\mu$ и будет присутствовать в уравнении, даже при взаимодействии заряженной скалярной частицы с электромагнитным полем в первом порядке. Второй член содержит спин и дает магнитный момент. Иначе говоря, член $\bar{u}\,(p')\,\gamma^\mu u(p)$ содержит магнитный момент.

Аномальный магнитный момент

Совершенствование техники эксперимента позволило в конце 1940-х гг. установить, что магнитный момент электрона превышает значение, вычисленное Дираком, в $1,00118 \pm 0,00003$ раза. После этого целью любой теории квантовой электродинамики явился расчет данного аномального магнитного момента. Вы, должно быть, знаете, что впечатляющий успех, достигнутый Швингером при решении этой проблемы, позволил установить вне всяких сомнений, справедливость релятивистской квантовой теории поля, по крайней мере в том, что касается электромагнитных явлений.

Прежде чем погрузиться в вычисления, вспомним, что из лоренцевской инвариантности и сохранения тока следует (см. пример III.6.3), что матричный элемент электромагнитного тока должен иметь следующий вид (здесь $|p,s\rangle$ означает состояние электрона с импульсом p и поляризацией s):

$$\langle p',s'\,|J^\mu(0)|\,p,s\rangle = \bar{u}\,(p',s')\left[\gamma^m u F_1\left(q^2\right) + \frac{i\sigma^{\mu\nu}q_\nu}{2m}F_2\left(q^2\right)\right]u(p,s),$$

где $q \equiv (p'-p)$. Функции $F_1\,(q^2)$ и $F_2\,(q^2)$, о которых ничего не может нам сказать лоренцевская инвариантность, известны как форм-факторы. В главном порядке по переданному импульсу q выражение (7) с помощью разложения Гордона сводится к виду:

$$\bar{u}\,(p',s')\left\{\frac{(p'+p)^\mu}{2m}F_1(0) + \frac{i\sigma^{\mu\nu}q_\nu}{2m}\left[F_1(0)+F_2(0)\right]\right\}u(p,s).$$

Коэффициент в первом члене есть электрический заряд, наблюдаемый экспериментаторами и по определению равный 1. То есть $F_1(0) = 1$. Магнитный момент электрона отличается от дираковского значения на $1 + F_2(0)$.

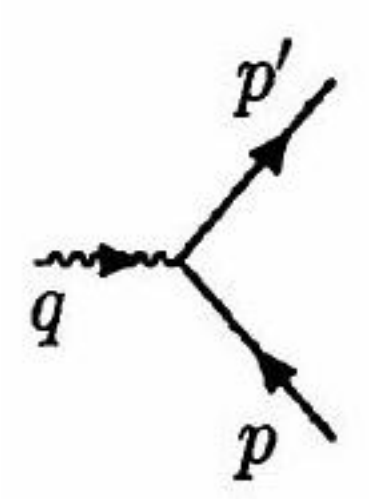
Триумф Швингера

Давайте теперь вычислим $F_2(0)$ до порядка $\alpha = e^2/4\pi$. Сначала нарисуем все соответствующие фейнмановские диаграммы в данном порядке (рис. III.6.1). За исключением диаграммы 1 b, все фейнмановские диаграммы, очевидно, пропорциональны $\bar{u}(p', s')\,\gamma^\mu u(p, s)$ и, значит, вносят свой вклад в $F_1(q^2)$, что, однако, не должно нас волновать. Как удачно! Нам необходимо будет вычислить лишь одну фейнмановскую диаграмму.

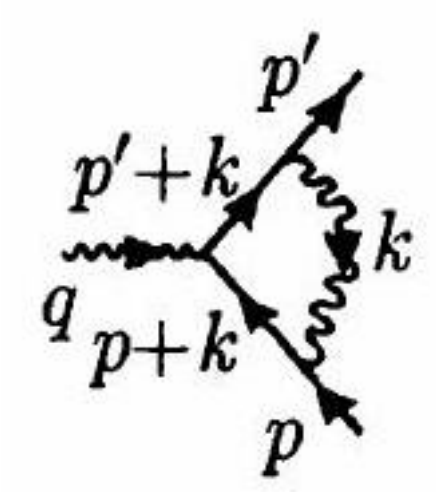
Для удобства нормируем вклад рисунка 1 b путем его сравнения со вкладом рисунка 1a низшего порядка и запишем сумму двух вкладов в виде $\bar{u}\,(\gamma^\mu + \Gamma^\mu)\,u$. Применяя правила Фейнмана, получаем:

$$\Gamma^\mu = \int \frac{d^4k}{(2\pi)^4}\frac{-i}{k^2}\left(ie\gamma^\nu \frac{i}{\not p' + \not k - m}\gamma^\mu \frac{i}{\not p + \not k - m} ie\gamma_\nu\right).$$

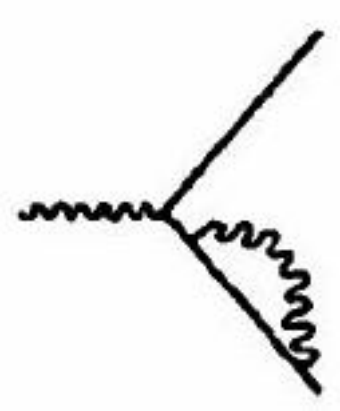
Сейчас я перехожу к довольно подробным вычислениям не только в связи с его важностью, но и потому, что мы воспользуемся несколькими изящными трюками, к которым впервые прибегли Швингер и Фейнман. Конечно, вам стоит самим проделать все выкладки.



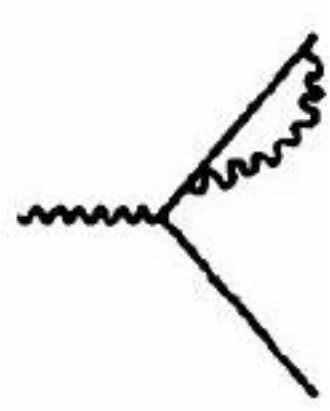
(a)



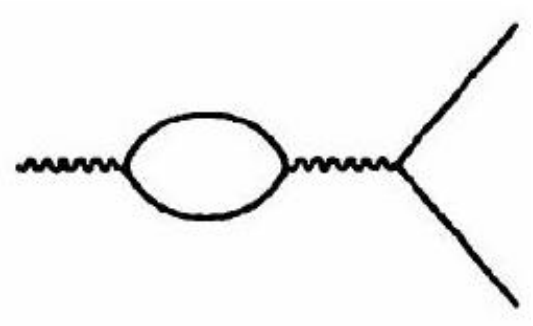
(b)



(c)



(d)



(e)
Рис. III.6.1
Сделав некоторые упрощения, получим $\Gamma^\mu = -ie^2 \int [d^4k/(2\pi)^4]\,(N^\mu/D)$, где

$$N^\mu = \gamma^\nu \left(\not{p}' + \not{k} + m\right) \gamma^\mu (\not{p} + \not{k} + m)\gamma_\nu$$

и

$$\frac{1}{D} = \frac{1}{(p'+k)^2 + m^2} \frac{1}{(p+k)^2 + m^2} \frac{1}{k^2} = 2 \int d\alpha d\beta \frac{1}{\mathcal{D}}.$$

Мы воспользовались тождеством (D.16). Интеграл вычисляется по треугольнику на плоскости (α, β), ограниченной прямыми $\alpha = 0, \beta = 0$ и $\alpha + +\beta = 1$. Имеем

$$\mathcal{D} = \left[k^2 + 2k\left(\alpha p' + \beta p\right)\right]^3 = \left[l^2 - (\alpha + \beta)^2 m^2\right]^3 + O\left(q^2\right)$$

где мы выделили полный квадрат, положив $k = l - (\alpha p' + \beta p)$.

Наша стратегия состоит в приведении N^μ к виду, состоящему из линейной комбинации γ^μ, p^μ и p'. Применяя разложение Гордона (6), запишем (7) в виде:

$$\bar{u}\left\{\gamma^\mu \left[F_1\left(q^2\right) + F_2\left(q^2\right)\right] - \frac{1}{2m}\left(p' + p\right)^\mu F_2\left(q^2\right)\right\} u$$

Следовательно, чтобы выделить $F_2(0)$, можно выкинуть все члены, пропорциональные γ^μ, которые мы учитывали, преобразуя N. Итак, продолжим. Выражая k через l в уравнении (9), получаем

$$N^\mu = \gamma^\nu \left[\not{P}' + m\right] \gamma^\mu [\not{P} + m]\gamma_\nu$$

где $P'\mu \equiv (1-\alpha)p'^\mu - \beta p^\mu$ и $P^\mu \equiv (1-\beta)p^\mu - \alpha p'$. Я буду неоднократно прибегать к тождествам из приложения D и не предупреждать вас каждый раз об этом. Удобно члены в N^μ сгруппировать по степеням m. (Далее я отказываюсь писать в виде завершенных грамматических предложений.)

1. Член m^2 : член γ^μ отбрасывается.

2. Члены m: выстраиваются по степеням l. Линейный по l член зануляется при интегрировании по соображениям симметрии. Остается член, который не зависит от l:

$$m\left(\gamma^\nu \not{P}'\gamma^\mu\gamma_\nu + \gamma^\nu\gamma^\mu \not{P}\gamma_\nu\right) = 4m\left[(1-2\alpha)p'^\mu + (1-2\beta)p^\mu\right] \to$$
$$\to 4m(1-\alpha-\beta)\left(p'+p\right)^\mu$$

На последнем шаге я воспользовался таким соображением: поскольку $\mathcal{D}$ симметрично относительно $\alpha \leftrightarrow \beta$, можно симметризовать члены в выражении для N^μ.

3. Наконец, самый сложный член m^0. Член второго порядка по l: обратите внимание на возможность эффективной замены $l^\sigma l^\tau$ внутри $\int d^4l/(2\pi)^4$ на $\frac{1}{4}\eta^{\sigma\tau}l^2$ в силу лоренцевской инвариантности (этот шаг возможен потому, что мы сдвинули переменную интегрирования; так что $\mathcal{D}$ есть лоренц-инвариантная функция от l^2.) Таким образом, член второго порядка по l приводит к появлению члена γ^μ. Отбрасываем его. Снова отбрасываем линейный по l член, оставляя в итоге [с учетом тождества (D.6)!]

$$\gamma^\nu \not{P}'\gamma^\mu\gamma_\nu = -2\not{P}\gamma^\mu\not{P}' \to$$
$$\to -2[(1-\beta)\not{p} - \alpha m]\gamma^\mu\left[(1-\alpha)\not{p}' - \beta m\right].$$

где на последнем шаге вспоминаем, что Γ^μ стоит в обкладках $\bar{u}\left(p'\right)$ и $u(p)$. Опять удобно члены в (14) сгруппировать по степеням m. Прибегая к различным, уже известным нам трюкам, находим, что член m^2 можно отбросить, член m дает $2m\left(p'+p\right)^\mu\left[\alpha(1-\alpha)+\beta(1-\beta)\right]$, а член m^0 дает нам $2m\left(p'+p\right)^\mu\left[-2(1-\alpha)(1-\beta)\right]$. Объединяя все вместе, приходим к тому, что $N^\mu \to 2m\left(p'+p\right)^\mu(\alpha+\beta)(1-\alpha-\beta)$.

Итак, теперь можно вычислить интеграл $\int\left[d^4l/(2\pi)^4\right](1/\mathcal{D})$ с учетом (D.11). В конечном итоге получим

$$\Gamma^\mu = -2ie^2\int d\alpha d\beta\left(\frac{-i}{32\pi^2}\right)\frac{1}{(\alpha+\beta)^2m^2}N^\mu =$$
$$= -\frac{e^2}{8\pi^2}\frac{1}{2m}\left(p'+p\right)^\mu$$

и, следовательно (аплодисменты, пожалуйста):

$$F_2(0) = \frac{e^2}{8\pi^2} = \frac{\alpha}{2\pi}$$

Когда в 1948 году Швингер объявил о полученном им результате, это произвело огромное впечатление на сообщество физиков-теоретиков.

В настоящей главе я рассказал не об одном, а о двух триумфах великих физиков двадцатого века, хотя первый из двух триумфов не является по своей сути результатом теории поля.

Упражнения

III.6.1. Найдите $\bar{u}\left(p'\right)\left(\not{p}'\gamma^\mu + \gamma^\mu\not{p}\right)u(p)$ двумя разными способами и докажите тем самым справедливость разложения Гордона.

III.6.2. Проверьте, что (7) согласовано с сохранением тока. [Указание: из трансляционной инвариантности (опустив спиновую переменную) следует:

$$\langle p'\left|J^\mu(x)\right|p\rangle = \langle p'\left|J^\mu(0)\right|p\rangle\, e^{i(p'-p)x}$$

и поэтому

$$\langle p' \left| \partial_\mu J^\mu(x) \right| p \rangle = i \left(p' - p\right)_\mu \langle p' \left| J^\mu(0) \right| p \rangle \, e^{i(p'-p)x}$$

Таким образом, сохранение тока означает, что $q^\mu \langle p' \left| J^\mu(0) \right| p \rangle = 0$.]

III.6.3. Согласно лоренцевской инвариантности правая часть (7) должна быть вектором. Возможны только $\bar{u}\gamma^\mu u, (p+p')^\mu \, \bar{u}u$ и $(p-p')^\mu \, \bar{u}u$. Последний член исключается, поскольку он противоречит сохранению тока. Покажите, что уравнение (7) действительно имеет самый общий вид.

18.1.6 Zi.III.7 Polarizing the Vacuum and Renormalizing the Charge

Фотон может флуктуировать в электрон и позитрон

Одним из ранних достижений квантовой электродинамики явилось понимание того, как квантовые флуктуации влияют на характер распространения фотона. Фотон всегда может превратиться в электрон и позитрон, которэе по истечении короткого промежутка времени, предписанного принципом неопределенности, аннигилируют друг с другом, снова образуя фотон. Этот процесс изображен на рис. III.7.1.

Квантовые флуктуации не ограничиваются теми процессами, что мы сейчас описали. Электрон и позитрон могут взаимодействовать друг с другом, обмениваясь фотоном, который в свою очередь может превратиться в электрон и позитрон и т. д. Этот процесс изображен на рис. III.7.2; здесь заштрихованный объект, обозначаемый как $i\Pi_{\mu\nu}(q)$ и называемый тензором поляризации вакуума, представляется бесконечным числом фейнмановских диаграмм (рис. III.7.3). Рисунок III.7.1 получается из рисунка III.7.2 приближением $i\Pi_{\mu\nu}(q)$ диаграммой низшего порядка.

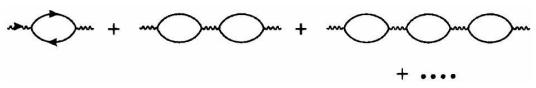


Рис. III.7.1

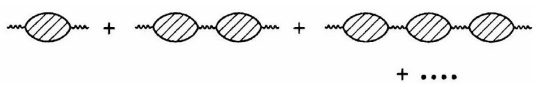

Рис. III.7.2

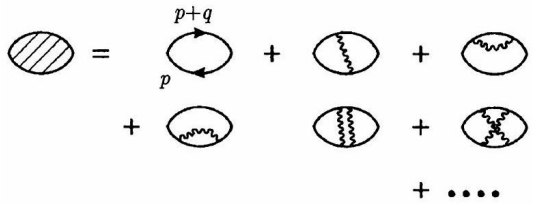

Рис. III.7.3

Удобно переписать лагранжиан $\mathcal{L} = \bar{\psi}\left[i\gamma^\mu\left(\partial_\mu - ieA_\mu\right) - m\right]\psi$ - $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$, заменяя $A \to (1/e)A$, что мы всегда имеем право сделать, в виде:

$$\mathcal{L} = \bar{\psi}\left[i\gamma^\mu\left(\partial_\mu - iA_\mu\right) - m\right]\psi - \frac{1}{4e^2}F_{\mu\nu}F^{\mu\nu}$$

Обратите внимание, что калибровочное преобразование, оставляющее $\mathcal{L}$ инвариантным, задается как $\psi \to e^{i\alpha}\psi$ и $A_\mu \to A_\mu + \partial_\mu \alpha$. Фотонный пропагатор (глава III.4), получаемый, грубо говоря, обращением $(1/4e^2)\, F_{\mu\nu}F^{\mu\nu}$, теперь пропорционален e^2:

$$iD_{\mu\nu}(q) = \frac{-ie^2}{q^2}\left[g_{\mu\nu} - (1-\xi)\frac{q_\mu q_\nu}{q^2}\right]$$

Каждый раз после обмена фотоном амплитуда умножается на e^2. Подобное изменение хотя и тривиально, но очень удобно, поскольку ни в малейшей степени не влияет на физику. Например, для фейнмановской диаграммы, которую мы вычисляли в главе II.6 для электрон-электронного рассеяния, множитель e^2 рассматривался как обусловленный не вершинами взаимодействия, а скорее фотонным пропагатором. В данной интерпретации e^2 характеризует легкость, с которой фотон распространяется в пространстве-времени. Чем меньше e^2, тем больше требуется действия, чтобы фотон распространялся. Чем труднее фотону распространяться, тем слабее эффект электромагнетизма.

Диаграммное доказательство калибровочной инвариантности, которое мы приводили в главе II.7, означает, что $q^\mu \Pi_{\mu\nu}(q) = 0$. С учетом лоренцевской инвариантности из этого условия следует:

$$\Pi_{\mu\nu}(q) = \left(q_\mu q_\nu - g_{\mu\nu}q^2\right)\Pi\left(q^2\right)$$

Физический, или ренормированный, фотонный пропагатор, изображенный на рис. III.7.2, дается в этом случае геометрической прогрессией:

$$\begin{aligned} iD^P_{\mu\nu}(q) &= iD_{\mu\nu}(q) + iD_{\mu\lambda}(q)i\Pi^{\lambda\rho}(q)iD_{\rho\nu}(q) + \\ &+ iD_{\mu\lambda}(q)i\Pi^{\lambda\rho}(q)iD^\sigma_\rho(q)i\Pi^\kappa_\sigma(q)iD_{\kappa\nu}(q) + \ldots = \\ &= \frac{-ie^2}{q^2}g_{\mu\nu}\left\{1 - e^2\Pi\left(q^2\right) + \left[e^2\Pi\left(q^2\right)\right]^2 + \ldots\right\} + q_\mu q_\nu \text{ член } = \\ &= \frac{-ie^2}{q^2}g_{\mu\nu}\frac{1}{1+e^2\Pi\left(q^2\right)} + q_\mu q_\nu \text{ член.} \end{aligned}$$

С учетом (3) член $(1-\xi)\,(q_\mu q_\lambda/q^2)$ в пропагаторе $D_{\mu\lambda}(q)$ зануляется при сворачивании с $\Pi^{\lambda\rho}(q)$. Следовательно, в пропагаторе $iD^P_{\mu\nu}$ калибровочный параметр ξ входит лишь в член $q_\mu q_\nu$ и выпадает из физических амплитуд, как было объяннено в главе II.7.

Вычет в полюсе в $iD^P_{\mu\nu}(q)$ представляет собой физический или перенормированный квадрат заряда:

$$e^2_R = e^2\frac{1}{1+e^2\Pi(0)}$$

Отдаем должное калибровочной инвариантности

Чтобы выразить e_R через e, проведем вычисление в низшем порядке

$$i\Pi_{\mu\nu}(q) = (-)\int \frac{d^4p}{(2\pi)^4}\,\mathrm{tr}\left(i\gamma_\nu\frac{i}{\not p + \not q - m}i\gamma_\mu\frac{i}{\not p - m}\right)$$

Для больших значений p подынтегральное выражение будет иметь вид $1/p^2$ с поправкой m^2/p^4, т. е. одна часть интеграла будет расходиться квадратично, а другая часть - логарифмически. (Видите, как легко перейти на плохой язык.) Это совсем не

концептуальная проблема, как я объяснил в главе III.1. Мы просто регуляризуем интеграл. Поскольку калибровочная инвариантность итрает ключевую роль мы должны проверить, что регуляризация ее не нарушает.

При регуляризации Паули-Вилларса (III.1.12) выражение (7) заменяется на:

$$i\Pi_{\mu\nu}(q) = (-)\int \frac{d^4p}{(2\pi)^4}\,\mathrm{tr}\left(i\gamma_\nu \frac{i}{\not p+\not q-m} i\gamma_\mu \frac{i}{\not p-m}\right) -$$

$$-\sum_a c_a\,\mathrm{tr}\left(i\gamma_\nu \frac{i}{\not p+\not q-m_a} i\gamma_\mu \frac{i}{\not p-m_a}\right).$$

Теперь подынтегральное выражение будет иметь вид $\left(1-\sum\limits_a c_a\right)(1/p^2)$ со вторым членом $\left(m^2-\sum\limits_a c_a m_a^2\right)(1/p^4)$. Поэтому интеграл будет сходиться, если мы выберем c_a и m_a так, что:

$$\sum_a c_a = 1$$

и

$$\sum_a c_a m_a^2 = m^2$$

Очевидно, что необходимо ввести как минимум две регуляторные массы. Мы верим, что можно пренебречь физикой выше масштаба m_a. Интеграл в (7) эффективно обрезается, когда импульс p превышает m_a.

Калибровочно-инвариантная форма (3) в действительности означает, что нам потребуется меньшее количество регуляторных членов, чем мы предполагали. Представим себе разложение (6) по степеням q. Поскольку

$$\Pi_{\mu\nu}(q) = \left(q_\mu q_\nu - g_{\mu\nu}q^2\right)[\Pi(0)+...]$$

в фейнмановском интеграле нас интересуют лишь члены $O\left(q^2\right)$ и старше. Если разложить подынтегральную функцию из уравнения (6), увидим, что член $O\left(q^2\right)$ для больших значений p ведет себя как $1/p^4$ и, следовательно, вносит логарифмически расходящийся (опять говоря на плохом языке) вклад. (Между прочим, аналогичное объяснение приводилось в главе III.3). Создается впечатление, что нам необходим только один регулятор. Этого нельзя сказать точно, ведь мы не доказали, что $\Pi\left(q^2\right)$ раскладывается в степенной ряд по q^2. Тем не менее продолжим вычисления.

Раз интеграл сходится, проходит доказательство калибровочной инвариантности из главы II.7. Вспомним схему доказательства. При вычислении $q^\mu\Pi_{\mu\nu}(q)$ мы пользовались тождеством

$$\frac{1}{\not p+\not q-m}\not q\frac{1}{\not p-m} = \frac{1}{\not p-m} - \frac{1}{\not p+\not q-m}$$

для разбиения подынтегрального выражения на две части, которые взаимно сокращаются при сдвиге переменной интегрирования $p \to p+q$. Из упражнения (II.7.2) вспомним, что в некоторых случаях сдвиг невозможен. Однако он возможен в случае, когда интеграл сходится. После регуляризации мы как раз получили сходящийся интеграл. В любом случае

не попробуешь не узнаешь, так что, проведя явное вычисление тензора поляризации вакуума $\Pi_{\mu\nu}(q)$, мы увидим, что он действительно имеет форму (3).

Выучив несколько вычислительных трюков из предыдущей главы, вы сейчас готовы взяться за вычисления. Я вам помогу их проделать. Чтобы не загромождать страницу, будем опускать регуляторные члены в (7) на промежуточных шагах. Восстановим их ближе к концу. После нескольких шагов вы должны получить

$$i\Pi_{\mu\nu}(q) = -\int \frac{d^4p}{(2\pi)^4}\frac{N_{\mu\nu}}{D}$$

где $N_{\mu\nu} = \operatorname{tr}\left[\gamma_\nu(\not{p}+\not{q}+m)\gamma_\mu(\not{p}+m)\right]$, и

$$\frac{1}{D} = \int\limits_0^1 d\alpha \frac{1}{\mathcal{D}}$$

где $\mathcal{D} = \left[l^2+\alpha(1-\alpha)q^2 - m^2 + i\varepsilon\right]^2$ и $l = p+\alpha q$. Выражая p через l, вы узнаете, что $N_{\mu\nu}$ фактически равно

$$-4\left(\frac{1}{2}g_{\mu\nu}l^2 + \alpha(1-\alpha)\left(2q_\mu q_\nu - g_{\mu\nu}q^2\right) - m^2 g_{\mu\nu}\right)$$

Интегрируя по l с учетом (D.12) и (D.13) и записывая явно вклады от регуляторов, получаем

$$\Pi_{\mu\nu}(q) = -\frac{1}{4\pi^2}\int\limits_0^1 d\alpha\left[F_{\mu\nu}(m) - \sum_a c_a F_{\mu\nu}\left(m_a\right)\right]$$

где

$$\begin{aligned}
&F_{\mu\nu}(m) = \\
=&\frac{1}{2}g_{\mu\nu}\left\{\Lambda^2 - 2\left[m^2-\alpha(1-\alpha)q^2\right]\log\frac{\Lambda^2}{m^2-\alpha(1-\alpha)q^2} + m^2 - \alpha(1-\alpha)q^2\right\} \\
&-\left[\alpha(1-\alpha)\left(2q_\mu q_\nu - g_{\mu\nu}q^2\right) - m^2 g_{\mu\nu}\right]\left[\log\frac{\Lambda^2}{m^2-\alpha(1-\alpha)q^2} - 1\right].
\end{aligned}$$

Не забывайте, что вы самостоятельно проводите вычисления, а я лишь направляю вас. В приложении D Λ вводится для придания смысла разным расходящимся интегралам. Поскольку наш интеграл сходится, нам не следует использовать параметр Λ. Действительно, благодаря (8) и (9) параметр Λ выпадает из формулы (10), так что в конечном итоге получаем формулу:

$$\begin{aligned}
\Pi_{\mu\nu}(q) = &-\frac{1}{2\pi^2}\left(q_\mu q_\nu - g_{\mu\nu}q^2\right)\int\limits_0^1 d\alpha\alpha(1-\alpha)\times \\
&\times\left\{\log\left[m^2-\alpha(1-\alpha)q^2\right] - \sum_a c_a \log\left[m_a^2-\alpha(1-\alpha)q^2\right]\right\}.
\end{aligned}$$

Вот так! Тензор поляризации вакуума действительно имеет форму $\Pi_{\mu\nu}(q) = (q_\mu q_\nu - g_{\mu\nu}q^2)\,\Pi\,(q^2)$. Наша схема регуляризации действительно уважает калибровочную инвариантность.

При $q^2 \ll m_a^2$ (желательно, чтобы интересующий нас кинематический режим был много меньше порога нашего неведения) определяем $\log M^2 \equiv \sum\limits_a c_a \log m_a^2$ в (12) и получаем:

$$\Pi\left(q^2\right)\frac{1}{2\pi^2}\int\limits_0^1 d\alpha\alpha(1-\alpha)\log\frac{M^2}{m^2-\alpha(1-\alpha)q^2}.$$

Заметим, что наши эвристические рассуждения в самом деле правильны. В конечном итоге нам нужен только один регулятор, хотя на промежуточных шагах их должно было быть два. По существу, спор о количестве регуляторов не столь важен.

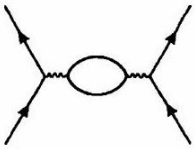
В главе III.1 я уже упоминал о размерной регуляризации как альтернативе регуляризации Паули-Вилларса. Размерную регуляризацию придумали для того, чтобы сохранить калибровочную инвариантность в неабелевых калибровочных теориях (о которых мы поговорим в следующих главах). Поучительно вычислить Π с помощью размерной регуляризации (упражнение III.7.1).

Электрический заряд

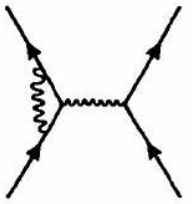
Окончательное выражение для $\Pi\,(q^2)$ содержит параметр M^2, характеризующий порог нашего неведения. Заключаем, что

$$e_R^2 = e^2\frac{1}{1+(e^2/12\pi^2)\log\left(M^2/m^2\right)} \simeq e^2\left(1-\frac{e^2}{12\pi^2}\log\frac{M^2}{m^2}\right).$$

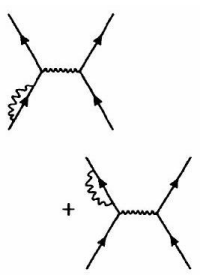
Квантовые флуктуации эффективно уменьшают заряд. Я объясню физический смысл этого явления позднее в главе, посвященной ренормализационной группе.



(a)



(b)



(c)

Рис. III.7.4

Вы скажете, что с физической точки зрения сила заряда характеризуется тем, как один электрон рассеивается на другом. До порядка e^4 строим диаграммы, как в главе II.7, и дополнительно другие диаграммы, как на рис. III.7.4a,b,c. Диаграмму на рисунке 4 a мы вычислили, но что же делать с диаграммами 4b и 4c? В книгах говорится, что вклады III.7.4b и III.7.4c в перенормировку заряда взаимно сокращаются. Заряд - это мера того, что фотон распространяется. Преимущество лагранжиана (1) в том, что это утверждение становится очевидным.

Чтобы проверить этот более или менее очевидный факт, прибегнем к физической, или ренормированной, теории возмущений (см. главу III.3). Перепишем лагранжиан в виде функции от физических, или ренормированных, полей (как и прежде, будем опускать подстрочный индекс P):

$$\begin{aligned}\mathcal{L} =&\bar{\psi}\left(i\gamma^{\mu}\left(\partial_{\mu}-iA_{\mu}\right)-m_{P}\right)\psi-\frac{1}{4e_{P}^{2}}F_{\mu\nu}F^{\mu\nu}+\\&+A\bar{\psi}i\gamma^{\mu}\left(\partial_{\mu}-iA_{\mu}\right)\psi+B\bar{\psi}\psi-CF_{\mu\nu}F^{\mu\nu}\end{aligned}$$

где коэффициенты A, B и C при контрчленах определяются итеративным методом. Дело в том, что калибровочная инвариантность гарантирует, что $\bar{\psi}i\gamma^{\mu}\partial_{\mu}\psi$ и $\bar{\psi}\gamma^{\mu}A_{\mu}\psi$ всегда идут в комбинации $\bar{\psi}i\gamma^{\mu}\left(\partial_{\mu}-iA_{\mu}\right)\psi$, т. е. силу взаимодействия A_{μ} с $\bar{\psi}\gamma^{\mu}\psi$ нельзя изменить. Мы можем изменить лишь ту легкость, с которой фотон распространяется в пространстве-времени.

Это утверждение имеет огромный физический смысл. Экспериментально установлено (с большой степенью точности), что заряды электрона и протона имеют противоположные знаки и точно равны между собой. Если бы они не равнялись друг другу, между объектами макроскопического мира действовала бы остаточная электростатическая сила. Предположим, мы открыли принцип, согласно которому голые заряды электрона и протона точно равны друг другу (в дальнейшем мы увидим, что в теориях великого объединения этот факт действительно вытекает из теории групп.) Как мы можем быть уверенными, что под воздействием квантовых флуктуаций заряды не станут несколько отличными друг от друга? Все же протон участвует в сильном взаимодействии, а электрон - нет, поэтому электромагнитное рассеяние двух протонов на больших расстояниях описывается гораздо большим количеством диаграмм. Теперь ясно, что равенство зарядов есть необходимое условие по той очевидной причине, что перенормировка заряда имеет отношение к фотону. В конце концов, все обуславливается калибровочной инвариантностью.

Аналитичность

Рассмотрим функцию П(s), определенную в (13). С помощью аналитического продолжсния сс можно задать на всей комплексной s-плоскости. Как правило, логарифм

$\log z$ задают так, чтобы он имел разрез на отрицательной действительной оси. Тогда подынтегральная функция в (13) будет иметь разрез на положительной действительной q^2-оси и простираться от $q^2 = m^2/\alpha(1-\alpha)$ до бесконечности. Поскольку максимальное значение $\alpha(1-\alpha)$ в области интегрирования равно $\frac{1}{4}$, функция $\Pi(q^2)$ есть аналитическая функция на комплексной q^2-плоскости, которая имеет разрез вдоль действительной оси, начинающийся от $q_c^2 = 4m^2$.

Представим себе виртуальный движущийся фотон с импульсом $q^\mu = \left(\sqrt{q^2}, \overrightarrow{0}\right)$. При $\sqrt{q^2} \geqslant 2m$ у него достаточно энергии для превращения в реальную пару электрон-позитрон, а не просто виртуальную пару, которая практически тут же перестает существовать. В этом состоит физический смысл разреза. (Если вы скрупулезно выполняете все упражнения, то, должно быть, уже заметили, что аналогичные выводы были получены в упражнениях I.7.5 и III.1.2.)

В связи с тем что в квантовой теории поля амплитуды вычисляются как интегралы от произведений пропагаторов, становится более или менее ясно, что амплитуды есть аналитические функции от внешних кинематических переменных. Например, амплитуда рассеяния $\mathcal{M}$ в главе III.1 представляет собой аналитическую функцию от s, t и u с несколькими разрезами. В период с конца 1950-х до начала 1960-х годов было приложено множество усилий, посвященных изучению аналитических свойств фейнмановских диаграмм 1.

[1] Техническое отступление: если восстановить в пропагаторах член $i\varepsilon$, который мы по ходу дела отбрасывали. увидим, что в интегральном представлении для $\Pi(q^2)$ мы должны написать $m^2 - i\varepsilon$. Отсюда следует, что мы должны вычислять $\Pi(q^2)$ чуть выше разреза для $q^2 \geqslant 4m^2$.

Модификация кулоновского потенциала

Основное внимание мы уделяли перенормировке заряда, которую полностью определяет $\Pi(0)$, однако в выражении (13) мы получили полную функцию $\Pi(q^2)$, которая описывает, как модифицируется зависимость фотонного пропагатора от q. Из обсуждения в главе I.5 мы знаем, что кулоновский потенциал есть фурье-преобразование фотонного пропагатора (см. также упражнение III.5.3). Следовательно, кулоновское взаимодействие модифицируется из закона $1/r$ на длине порядка $(2m)^{-1}$, обратной к характерному значению q в $\Pi(q^2)$. Эта модификация проверена экспериментально как часть лэмбовского сдвига в атомной спектроскопии, еще одного великого триумфа квантовой электродинамики.

Упражнения

III.7.1. Вычислите $\Pi_{\mu\nu}(q)$, используя размерную регуляризацию. Начните с уравнения (6), найдите след в $N_{\mu\nu}$, сдвиньте переменную интегрирования с p до l и т. д., действуя в точности как в тексте. Продолжайте до тех пор, пока не дойдете до вычисления интеграла по импульсу l в петле. На этом шаге вы «считаете», что живете в d-мерном пространстве-времени, что позволяет заменить, например, член типа $l_\mu l_\nu$ в $N_{\mu\nu}$ на $(1/d)g_{\mu\nu}l^2$. Интегрирование необходимо провести с учетом уравнения (III.1.15) и его обобщений. Покажите, что структура (3) автоматически возникает при продолжении в $d = 4$.

III.7.2. Изучите модифицированный закон Кулона, определяемый интегралом Фурье $\int d^3q \left\{1/\vec{q}^2\left[1 + e^2\Pi\left(\vec{q}^2\right)\right]\right\} e^{i\vec{q}\vec{x}}$.

18.2 K-l.II: Regularization

The divergences which appear in radiative corrections are not yet a catastrophe for a theory (remind, for example, the infinite self-energy of an electric charge in its own Coulomb field) but require a quantitative description. To get a finite difference of the two infinite quantities, one has to give them some meaning. This can be achieved by introducing a kind of regularization of divergent integrals. The most natural way of regularization is to cut off the integral on the upper or lower bound of integration. There are also different ways of regularization based on a modification of the integrand or of the measure of integration. Below we consider three most popular kinds of regularization: the ultraviolet cutoff in Euclidean space (Λ-regularization), the Pauli-Villars regularization, and the dimensional regularization.

18.2.1 Euclidean integral and the ultraviolet cutoff

All the integrals in quantum field theory are written in Minkowski space; however, the ultraviolet divergence appears for large values of modulus of momentum and it is useful to regularize it in Euclidean space. Transition to Euclidean space can be achieved by replacing the zeroth component of momentum $k_0 \to ik_4$, so that the squares of all momenta and the scalar products change the sign $k^2 = k_0^2 - \vec{k}^2 \to -k_4^2 - \vec{k}^2 = -k_E^2$ and the measure of integration becomes equal to $d^4k \to id^4k_E$, where the integration over the fourth component of momenta goes along the imaginary axis. To go to the integration along the real axis, one has to perform the (Wick) rotation of the integration contour by 90^o (see. Fig.18.1). This is possible since the integral over the big circle vanishes and during the transformation of the contour it does not cross the poles.

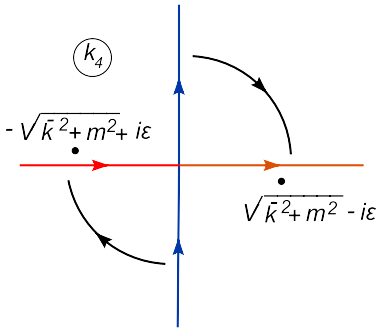


Figure 18.1: The Wick rotation of the integration contour

When transferring to Euclidean space the poles in all the propagators disappear. Now the integral in 4-dimensional Euclidean space can be evaluated in spherical coordinates and the integral over the modulus can be cut on the upper limit. Let us demonstrate how this method works in the case of the simplest scalar diagram shown in Fig.18.2. The corresponding pseudo-Euclidean integral has the form

$$I(p^2) = \frac{1}{(2\pi)^4}\int \frac{d^4k}{[k^2-m^2][(p-k)^2-m^2]}. \tag{18.1}$$

Transforming it to Euclidean space one gets

$$I(p_E^2) = \frac{i}{(2\pi)^4}\int \frac{d^4k}{[k_E^2+m^2][(p-k)_E^2+m^2]}. \tag{18.2}$$

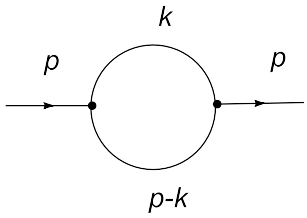

Figure 18.2: The simplest divergent diagram in a scalar theory

(in what follows the index will be omitted.)

For calculation of this kind of integrals we use the following approach. First, we transform the product of several brackets in the denominator into the single bracket with the help of the so-called Feynman parametrization. The following general formula is valid:

$$\begin{aligned}\frac{1}{A_1^{\alpha_1}A_2^{\alpha_2}\cdots A_n^{\alpha_n}} &= \frac{\Gamma(\alpha_1+\alpha_2+\cdots+\alpha_n)}{\Gamma(\alpha_1)\Gamma(\alpha_2)\cdots\Gamma(\alpha_n)}\int\limits_0^1 dx_1dx_2\cdots dx_n \\ &\cdot \frac{\delta(1-x_1-x_2-\cdots-x_n)x_1^{\alpha_1-1}x_2^{\alpha_2-1}\cdots x_n^{\alpha_n-1}}{[A_1x_1+A_2x_2+\cdots A_nx_n]^{\alpha_1+\alpha_2+\cdots+\alpha_n}}.\end{aligned} \tag{18.3}$$

Here $\Gamma(\alpha)$ is the Euler Γ-function which has the following properties:

$$\Gamma(1)=1,\ \Gamma(n+1)=n!,\ x\Gamma(x)=\Gamma(x+1),\ \Gamma(1+x)=e^{[-x\gamma_E+\sum\limits_{n=2}^{\infty}\frac{(-x)^n}{n}\zeta(n)]},$$

where γ_E is the Euler constant and $\zeta(n)$ is the Riemann zeta-function. The Γ-function is finite for positive values of the argument and has simple poles at negative integer values and at zero.

In our case, $(n=2, \alpha_1=\alpha_2=1)$ and eq.(18.3) has the form:

$$\begin{aligned}\frac{1}{[k^2+m^2][(p-k)^2+m^2]} &= \frac{\Gamma(2)}{\Gamma(1)\Gamma(1)}\int\limits_0^1 \frac{dx_1x_2\delta(1-x_1-x_2)}{[[k^2+m^2]x_1+[(p-k)^2+m^2]x_2]^2} \\ &= \int\limits_0^1 \frac{dx}{[k^2-2pkx+p^2x+m^2]^2}.\end{aligned} \tag{18.4}$$

Thus, integral (18.2) can be written as

$$I(p^2)=\frac{i}{(2\pi)^4}\int\limits_0^1 dx\int\frac{d^4k}{[k^2-2kpx+p^2x+m^2]^2}\overset{k\to k-px}{=}\frac{i}{(2\pi)^4}\int\limits_0^1 dx\int\frac{d^4k}{[k^2+p^2x(1-x)+m^2]^2} \tag{18.5}$$

Now the integral depends only on the modulus of k and one can use the spherical coordinates:

$$I(p^2)=\frac{i}{(2\pi)^4}\int\limits_0^1 dx\ \Omega_4\int\limits_0^\Lambda \frac{k^3dk}{[k^2+p^2x(1-x)+m^2]^2}, \tag{18.6}$$

where the volume of the 4-dimensional sphere equals $\Omega_4 = 2\pi^2$ (in general $\Omega_D = \frac{2\pi^{D/2}}{\Gamma(D/2)}$). The integral over the modulus can be easily calculated

$$\frac{1}{2}\int_0^{\Lambda^2} \frac{k^2 dk^2}{[k^2 + p^2 x(1-x) + m^2]^2} = \frac{1}{2}\log(\frac{\Lambda^2}{p^2 x(1-x) + m^2}) + 1, \tag{18.7}$$

and, as one can see, is logarithmically divergent at the upper limit. The full answer has the form

$$I(p^2) = \frac{i}{16\pi^2}\int_0^1 dx \left(\log(\frac{\Lambda^2}{p^2 x(1-x) + m^2}) + 1\right). \tag{18.8}$$

The last integral over x can also be evaluated and takes the simplest form in the limiting cases for $m = 0$ or $p = 0$. Now one can go back to Minkowski space $p_E^2 => -p^2$.

The regularization with the ultraviolet cut-off is quite natural and relatively simple. The drawback of this regularization is Euclidean rather than Lorentzian invariance and also the absence of the gauge invariance. Therefore, it is not useful in the gauge theories. However, one should notice that the noninvariance of a regularization is acceptable since the invariance is restored when removing the regularization. Still, this aspect complicates the calculation as one has to take care of the validity of all the identities.

18.2.2 Pauli-Villars Regularization

Another method of regularization which is called the Pauli-Villars regularization is based on the introduction of a set of additional heavy fields with a wrong sign of the kinetic term. These fields are not physical and are introduced essentially with the purpose of regularization of divergent integrals. The main trick is in the replacement

$$\frac{1}{p^2 - m^2} \to \frac{1}{p^2 - m^2} - \frac{1}{p^2 - M^2}, \tag{18.9}$$

where $M \to \infty$ is the mass of the Pauli-Villars fields. As a result, the propagator for large momenta decreases faster, which ensures the convergence of the integrals. The divergences manifest themselves as logs and powers of M^2 instead of the cutoff parameter Λ^2.

One uses sometimes the modifications of the Pauli-Villars regularization when the replacement (18.9) is performed not for each propagator but for the loop as a whole. This method of regularization is called the regularization over circles. It is used in Abelian gauge theories for the loops made of the matter fields. This way one can preserve the gauge invariance. However, in non-Abelian theories we face some problems related to the loops of the gauge fields which cannot become massive without violating the gauge invariance. This problem is often solved by introducing an additional regularization for the vector fields, for example, with the help of higher derivatives. Here we will not consider this regularization.

The positive property of the Pauli-Villars regularization is the explicit Lorentz and gauge (in abelian case) invariance, but it requires complicated calculations since one has to calculate massive diagrams, while massless integrals are much simpler.

18.2.3 Dimensional Regularization

The most popular in gauge theories is the so-called dimensional regularization. In this case, one modifies the integration measure.

The technique of dimensional regularization consists of analytical continuation from an integer to a noninteger number of dimensions. Basically one goes from some D to $D-2\epsilon$, where $\epsilon \to 0$. In particular, we will be interested in going from 4 to $4-2\epsilon$ dimensions. In this case, all the ultraviolet and infrared singularities manifest themselves as pole terms in ϵ. To perform this continuation to non-integer number of dimensions, one has to define all the objects such as the metric, the measure of integration, the γ matrices, the propagators, etc. Though this continuation is not unique, one can define a self-consistent set of rules, which allows one to perform the calculations.

The metric: $g_4^{\mu\nu} \to g_{4-2\epsilon}^{\mu\nu}$. Though it is rather tricky to define the metric in non-integer dimensions, one usually needs only one relation, namely $g^{\mu\nu}g_{\mu\nu} = \delta_\mu^\mu = D = 4-2\epsilon$.

The measure: $d^4q \to (\mu^2)^\epsilon d^{4-2\epsilon}q$, where μ is a parameter of dimensional regularization with dimension of a mass. The integration with this measure is defined by an analytical continuation from the integer dimensions.

The γ matrices: The usual anticommutation relation holds $\{\gamma^\mu, \gamma^\nu\} = 2g^{\mu\nu}$; however, some relations involving the dimension are modified:

$$\gamma^\mu\gamma_\mu = D = 4-2\epsilon; \quad Tr\gamma^\mu\gamma^\nu = g^{\mu\nu}Tr1 = g^{\mu\nu}\begin{cases} 2^{[D/2]} \\ 4 \end{cases}.$$

Usually $Tr1 = 4$ is taken. Then the γ-algebra is straightforward:

$$Tr\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma = Tr1[g^{\mu\nu}g^{\rho\sigma} + g^{\mu\sigma}g^{\nu\rho} - g^{\nu\rho}g^{\mu\sigma}],$$

$$\gamma^\mu\gamma^\nu\gamma^\mu = -\gamma^\mu\gamma^\mu\gamma^\nu + 2g^{\mu\nu}\gamma^\mu = -(4-2\epsilon)\gamma^\nu + 2\gamma^\nu = -(2-2\epsilon)\gamma^\nu, \quad \text{etc.}$$

What is not well-defined is the γ^5 since $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ and cannot be continued to an arbitrary dimension. This creates a problem in dimensional regularization since there is no consistent way of definition of γ^5.

The propagator: In momentum space the continuation is simple

$$\frac{1}{p^2-m^2} \to \frac{1}{p^2-m^2}.$$

However, in coordinate space one has: (take $m=0$ for simplicity)

$$\int \frac{d^4p}{p^2}e^{ipx} \sim \frac{1}{x^2} \Rightarrow \int \frac{d^{4-2\epsilon}p}{p^2}e^{ipx} \sim \frac{1}{[x^2]^{1-\epsilon}}.$$

The basic integrals: The main idea is to calculate the integral in the space-time dimension where it is convergent and then analytically continue the answer to the needed dimension.

Consider the earlier discussed example (18.1) and use the Euclidean representation (18.5). Let us rewrite it formally in D-dimensional space

$$\int \frac{d^Dk}{[k^2+M^2]^2} = \frac{\Omega_D}{2}\int_0^\infty \frac{(k^2)^{D/2-1}dk^2}{[k^2+M^2]^2}, \qquad M^2 \equiv p^2x(1-x)+m^2. \tag{18.10}$$

The integral over k^2 is now the table one

$$\int_0^\infty \frac{(k^2)^{D/2-1}dk^2}{[k^2+M^2]^2} \overset{k^2\to k^2M^2}{=} (M^2)^{\frac{D}{2}-2}\int_0^\infty \frac{x^{D/2-1}dx}{(x+1)^2} = (M^2)^{\frac{D}{2}-2}\,\frac{\Gamma(\frac{D}{2})\Gamma(2-\frac{D}{2})}{\Gamma(2)}, \tag{18.11}$$

where we assume that the dimension D is such that the integral exists. In this case this is 2 and 3. The main formula (18.11) allows one to perform the analytical continuation over D into the region $D = 4-2\varepsilon$. For $\varepsilon = 0$, i.e., in 4 dimensions, the integral does not exist since the Γ-function has a pole at zero argument. However, in the vicinity of zero we get a regularized expression.

Collecting all together we get

$$I(p^2) = \frac{i}{(2\pi)^D}\frac{\Omega_D}{2}\int_0^1 dx \frac{\Gamma(D/2)\Gamma(2-D/2)}{[p^2x(1-x)+m^2]^{2-D/2}}. \tag{18.12}$$

Substituting now $D = 4-2\varepsilon$ and transforming back into the pseudo-Euclidean space one finds

$$I(p^2) = \frac{i(-\pi)^{2-\varepsilon}}{(2\pi)^{4-2\varepsilon}}\Gamma(\varepsilon)\int_0^1 \frac{dx(\mu^2)^\varepsilon}{[p^2x(1-x)-m^2]^\varepsilon} \tag{18.13}$$

Expanding the denominator into the series over ε, we finally arrive at

$$I(p^2) = \frac{i}{16\pi^2}\Gamma(1+\varepsilon)\left(\frac{1}{\varepsilon} - \int_0^1 dx\log[\frac{p^2x(1-x)-m^2}{-\mu^2}] + \log(4\pi)\right). \tag{18.14}$$

Comparing it with eq.(18.8) we see that the ultraviolet divergence now takes the form of the pole over ε instead of the logarithm of the cutoff. This is less visual but much simpler in the calculations and also is automatically gauge invariant.

We present below the main integrals needed for the one-loop calculations. They can be obtained via the analytical continuation from the integer values of D. We will write them down directly in the pseudo-Euclidean space.

$$\int \frac{d^Dp}{[p^2-2kp+m^2]^\alpha} = i\frac{\Gamma(\alpha-D/2)}{\Gamma)\alpha)}\frac{(-\pi)^{D/2}}{[m^2-k^2]^{\alpha-D/2}}, \tag{18.15}$$

$$\int \frac{d^{4-2\epsilon}p}{[p^2-2kp+m^2]^2} = i\frac{\Gamma)\epsilon)}{\Gamma(2)}\frac{(-\pi)^{2-\epsilon}}{[m^2-k^2]^\epsilon}, \quad \Gamma(\epsilon)\sim\frac{1}{\epsilon}\to\infty,$$

$$\int \frac{d^{4-2\epsilon}p\ \ p_\mu}{[p^2-2kp+m^2]^2} = i\frac{\Gamma(\epsilon)}{\Gamma(2)}\frac{(-\pi)^{2-\epsilon}k_\mu}{[m^2-k^2]^\epsilon}, \tag{18.16}$$

$$\int \frac{d^{4-2\epsilon}p\ \ p_\mu p_\nu}{[p^2-2kp+m^2]^2} = i(-\pi)^{2-\epsilon}\left[\frac{\Gamma(\epsilon)}{\Gamma(2)}\frac{k_\mu k_\nu}{[m^2-k^2]^\epsilon} + \frac{g^{\mu\nu}}{2}\frac{\Gamma(\epsilon-1)}{\Gamma(2)}\frac{1}{[m^2-k^2]^{\epsilon-1}}\right]$$

The key formula is (18.15). All the rest can be obtained from it by the differentiation. Notice the singularity in the r.h.s. of (18.15) for $\alpha = D/2-n$, $n = 0,1,...$ These integrals remain non-regularized. However, they usually do not appear in the real calculations.

Let us mention one important rule used in dimensional regularization and related to the massless theories. By definition it is accepted that zero to any power is zero. Thus, for example, the following integral is zero

$$\int \frac{d^Dk}{(k^2)^\alpha} = 0, \quad \forall\ \alpha. \tag{18.17}$$

In fact, here we have a cancellation of the ultraviolet and infrared divergences which both have the form of a pole over $1/\varepsilon$. There is no any inconsistency here and this way of doing is self-consistent in the calculations of dimensionally regularized integrals.

This rule leads, in particular, to the vanishing of all the diagrams of the tad-pole type in the massless case. However, in the massive case they survive and are important for the restoration of the gauge invariance. As it will be clear later, in the Standard Model the tad-poles give their contribution to the renormalization of the quark masses and provide the transversality of the vector propagator in a theory with spontaneous symmetry breaking.

18.3 K-l.III: Examples of Calculations. One-loop Integrals

All further calculations will be performed using dimensional regularization. Below we show how the rules described above can be applied to calculate in various models of quantum field theory.

18.3.1 The scalar theory

We start with the simplest scalar case and consider the theory described by the Lagrangian

$$\mathcal{L} = \frac{1}{2}(\partial_\mu\varphi)^2 - \frac{m^2}{2}\varphi^2 - \frac{\lambda}{4!}\varphi^4. \tag{18.18}$$

The Feynman rules in this case are:

$= \dfrac{i}{p^2-m^2},$

$= -i\lambda$

First, we find the one-loop divergent diagrams. As it follows from Fig.16.5, they are the propagator of the scalar field and the quartic vertex.

The propagator: In the first order there is only one diagram of the tad-pole type shown in Fig.18.3.

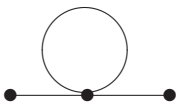

Figure 18.3: The one-loop propagator diagram

The corresponding integral is

$$J_1(p^2) = \frac{-i\lambda}{(2\pi)^{4-2\varepsilon}}\frac{i}{2}\int\frac{d^{4-2\varepsilon}k(\mu^2)^\varepsilon}{k^2-m^2}, \tag{18.19}$$

where $1/2$ is the combinatoric factor. Calculating the integral (18.19), according to (18.16), we find

$$J_1(p^2) = \frac{-i\lambda}{(4\pi)^{2-\varepsilon}}\frac{\Gamma(-1+\varepsilon)}{2\Gamma(1)}m^2(\frac{\mu^2}{m^2})^\varepsilon = \frac{i\lambda}{32\pi^2}m^2\left[\frac{1}{\varepsilon}+1-\gamma_E+\log(4\pi)-\log\frac{m^2}{\mu^2}\right] \tag{18.20}$$

The fact that the integral diverges quadratically manifests itself in the structure of the multiplier $\Gamma(-1+\varepsilon)$ which has a pole at $\varepsilon=0$ as well as at $\varepsilon=1$. However, since we are interested in the limit $\varepsilon\to 0$, we expand the answer in the Loran series in ε. As one can see, even in the case of

quadratically divergent integrals the divergence takes the form of a simple pole over ε, but the integral has the dimension equal to two. Notice, however, that for $m = 0$ the integral equals zero in accordance with the properties of dimensional regularization mentioned above.

The vertex: Here one also has only one diagram but the external momenta can be adjusted in several ways (see Fig.18.4). As a result the total contribution to the vertex function consists of

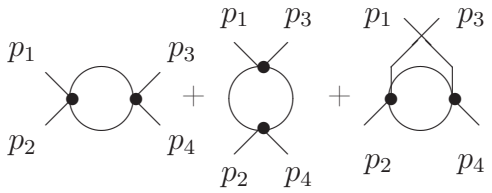

Figure 18.4: The one-loop vertex diagram

three parts

$$I_1 = I_1(s) + I_1(t) + I_1(u),$$

where we introduced the commonly accepted notation for the Mandelstam variables (we assume here that the momenta p_1 and p_2 are incoming and the momenta p_3 and p_4 are outgoing)

$$s = (p_1 + p_2)^2 = (p_3 + p_4)^2,\ t = (p_1 - p_3)^2 = (p_2 - p_4)^2,\ u = (p_1 - p_4)^2 = (p_2 - p_3)^2,$$

and the integral equals

$$I_1(s) = \frac{(-i\lambda)^2}{48} \frac{(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}} i^2 \int \frac{d^{4-2\varepsilon}k}{[k^2 - m^2][(p-k)^2 - m^2]} \tag{18.21}$$

(1/48 is the combinatoric coefficient). We have already calculated this integral and the answer has the form (18.14). Now we perform the calculation in a different and simpler way applicable to the massless integrals.

Two comments are in order. The first one concerns the evaluation of the combinatoric coefficient. It comes from the expansion of the S-matrix within the Wick theorem. In the case when all the particles are different like, for example, in QED, the combinatoric coefficient is usually 1. For identical particles their permutations are taken into account already in the Lagrangian (the factors 1/2 and /4! in (18.18)) and lead to nontrivial coefficients. There exists a simple method to calculate the combinatoric coefficient in these cases. The coefficient equals 1/Sym, where Sym is the symmetry factor of a diagram. Consider the diagram shown in Fig.18.4. If one does not distinguish the arrangement of momenta, then the diagram has the following symmetries: the permutation of external lines entering into the left vertex, the permutation of external lines entering into the right vertex, the permutation of the vertices, the permutation of internal lines. Altogether one has: $2 \times 2 \times 2 \times 2 = 16$. Hence, the combinatoric coefficient equals 1/16 but, since we distinguish three different momentum arrangements, one has 1/48. The same rule is valid for the multiloop diagrams and we will use it in the next section.

The second comment is related to the calculation of the massless integrals which are much simpler, and in some cases one can get the answer without any explicit integration. The method, which we will describe below, is applicable to a certain type of massless integrals and is based on conformal properties of the massless integrals depending on one external argument and uses the symmetry between the coordinate and momentum representations.

The key formula is the Fourier-transformation of the propagator of a massless particle

$$\int \frac{d^4p\ e^{ipx}}{p^2} = \frac{i\pi^2}{x^2}, \tag{18.22}$$

which can be generalized to an arbitrary dimension and any power of the propagator as follows:

$$\int \frac{d^D p\ e^{ipx}}{(p^2)^\alpha} = i(-\pi)^{D/2}\frac{\Gamma(D/2-\alpha)}{\Gamma(\alpha)}\frac{1}{(x^2)^{D/2-\alpha}}. \tag{18.23}$$

Obviously, this formula is also valid for the coordinate integration instead of momentum. This way the transition from momentum representation to the coordinate one and vice versa is performed with the help of (18.23) and is accompanied by the factor $\frac{\Gamma(D/2-\alpha)}{\Gamma(\alpha)}$.

Let us go back to the diagram Fig.18.4. In momentum space it corresponds to the integral over the momenta running along the loop. However, in coordinate space it is just the product of the two propagators and does not contain any integration. Therefore, the integral in momentum space can be replaced by the Fourier-transform of the square of the propagator. Since in the massless case all the propagators in both momentum and coordinate representation are just the powers of p^2 or x^2, all of them are easily calculated with the help of relation (18.23).

In the case of the integral (18.21) for $m = 0$ one first has to mentally transform both the propagators into coordinate space which, according to (18.23), gives the factor $(\frac{\Gamma(1-\varepsilon)}{\Gamma(1)})^2$, then multiply the obtained propagators (this gives $1/(x^2)^{2-2\varepsilon}$) and transform the obtained result back into momentum space that gives the factor $\frac{\Gamma(\varepsilon)}{\Gamma(2-2\varepsilon)}$ and the power of momenta $1/(p^2)^\varepsilon$ (the same as in the argument of the last Γ-function). Besides this, each loop contains the factor $i(-\pi)^{2-\varepsilon}$. Collecting all together one gets

$$I_1(s) = \frac{(-i\lambda)^2}{48}\frac{(\mu^2)^\varepsilon i^2}{(2\pi)^{4-2\varepsilon}}\int\frac{d^{4-2\varepsilon}k}{k^2(p-k)^2} = \frac{\lambda^2}{48}\frac{i\pi^{2-\varepsilon}}{(2\pi)^{4-2\varepsilon}}\left(\frac{\mu^2}{-s}\right)^\varepsilon\frac{\Gamma(1-\varepsilon)\Gamma(1-\varepsilon)\Gamma(\varepsilon)}{\Gamma(1)\Gamma(1)\Gamma(2-2\varepsilon)}$$

$$= \frac{i}{48}\frac{\lambda^2}{(4\pi)^{2-\varepsilon}}\left[\frac{\mu^2}{-s}\right]^\varepsilon\frac{1}{\varepsilon(1-2\varepsilon)}\frac{\Gamma^2(1-\varepsilon)\Gamma(1+\varepsilon)}{\Gamma(1-2\varepsilon)} = \frac{i}{48}\frac{\lambda^2}{16\pi^2}[\frac{1}{\varepsilon}+2-\gamma_E+\log 4\pi+\ln\frac{\mu^2}{-s}],$$

which coincides with (18.14) at $m = 0$.

The described method for calculation of massless integrals is applicable to any integral depending on one external momentum (propagator type) and allows one to perform the calculations in any number of loops simply writing down the corresponding factors without explicit integration. In the case when the integral depends on more than one external momentum (like for a triangle or a box) and they cannot be put equal to zero the method is not directly applicable though some modifications are available. We do not consider them here.

The four-point vertex in the one-loop approximation thus equals (we take the common factor $1/4!\phi^4$ out of the brackets):

$$\Gamma_4 = -i\lambda\left\{1-\frac{\lambda}{16\pi^2}\left(\frac{3}{2\varepsilon}+3-\frac{3}{2}\gamma_E+\frac{3}{2}\log 4\pi+\frac{1}{2}\ln\frac{\mu^2}{-s}+\frac{1}{2}\ln\frac{\mu^2}{-t}+\frac{1}{2}\ln\frac{\mu^2}{-u}\right)\right\}. \tag{18.24}$$

As one can see, the Euler constant and the logarithm of 4π always accompany the pole term $1/\varepsilon$ and can be absorbed into the redefinition of μ^2.

18.3.2 Quantum electrodynamics

Consider now the calculation of the diagrams in the gauge theories. We start with quantum electrodynamics. The QED Lagrangian has the form

$$\mathcal{L}_{QED} = -\frac{1}{4}F_{\mu\nu}^2 + \bar\psi(i\gamma^\mu\partial_\mu - m)\psi + e\bar\psi\gamma^\mu A_\mu\psi - \frac{1}{2\xi}(\partial_\mu A_\mu)^2, \tag{18.25}$$

where the electromagnetic stress tensor is $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$, and the last term in (34.2) fixes the gauge. In what follows we choose the Feynman or the diagonal gauge ($\xi = 1$).

The Feynman rules corresponding to the Lagrangian (34.2) are shown in Fig.18.5.

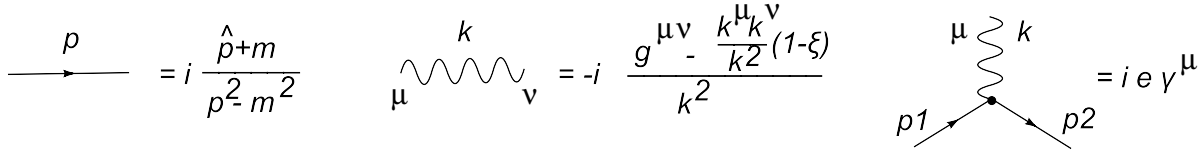

Figure 18.5: The Feynman rules for QED

In quantum electrodynamics the divergences appear only in the photon propagator, the electron propagator, and the triple vertex. The one-loop divergent diagrams are shown in Fig.18.6.

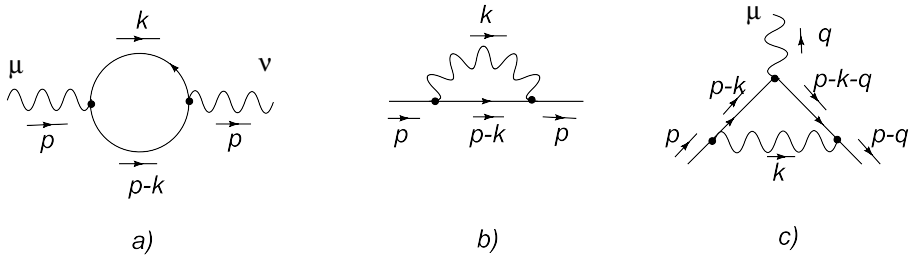

Figure 18.6: The one-loop divergent diagrams in QED

We begin with the vacuum polarization graph. It is given by the diagram shown in Fig. 18.6a). The corresponding expression looks like:

$$\Pi_{\mu\nu}(p) = (-)\frac{e^2}{(2\pi)^4}\int d^4k \frac{Tr[\gamma^\mu(m+\hat{k})\gamma^\nu(m+\hat{k}-\hat{p})]}{[m^2-k^2][m^2-(k-p)^2]}, \tag{18.26}$$

where the "-" sign comes from the fermion loop and $\hat{q} \equiv \gamma^\mu q_\mu$. We first go to dimension $4-2\epsilon$. Then the integral (18.26) becomes

$$\Pi^{Dim}_{\mu\nu}(p) = (-)\frac{e^2(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}}\int d^{4-2\varepsilon}k \frac{Tr[\gamma^\mu(m+\hat{k})\gamma^\nu(m+\hat{k}-\hat{p})]}{[m^2-k^2][m^2-(k-p)^2]}, \tag{18.27}$$

Let us put $m = 0$ for simplicity. This will allow us to get a simple answer at the end. First, we calculate the trace of the γ-matrices:

$$Tr\gamma^\mu\hat{k}\gamma^\nu(\hat{k}-\hat{p}) = Tr(\gamma^\mu\gamma^\rho\gamma^\nu\gamma^\sigma)k^\rho(k-p)^\sigma = 4k^\rho(k-p)^\sigma[g^{\mu\rho}g^{\nu\sigma}+g^{\mu\sigma}g^{\nu\rho}-g^{\mu\nu}g^{\rho\sigma}].$$

So the integral now looks like

$$I^{Dim}_{\rho\sigma}(p) = (-)\frac{(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}}\int \frac{d^{4-2\varepsilon}k k^\rho(k-p)^\sigma}{k^2(k-p)^2}.$$

Using the Feynman parametrization and performing the integration according to the formulae given above one finds

$$I^{Dim}_{\rho\sigma}(p) = (-)\frac{(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}}\int_0^1 dx \int \frac{d^{4-2\varepsilon}k k^\rho(k-p)^\sigma}{[k^2-2pkx+p^2x]^2} \tag{18.28}$$

$$= (-)i\frac{(-\mu^2)^\varepsilon \pi^{2-\varepsilon}}{(2\pi)^{4-2\varepsilon}} \left\{ -\Gamma(\varepsilon)\int_0^1 \frac{dx p^\rho p^\sigma x(1-x)}{[p^2x(1-x)]^\varepsilon} + \Gamma(\varepsilon-1)\frac{g^{\rho\sigma}}{2}\int_0^1 \frac{dx}{[p^2x(1-x)]^{\varepsilon-1}} \right\}.$$

To evaluate the remaining integrals, we use the standard integral for the Euler beta-function

$$\int_0^1 dx x^{\alpha-1}(1-x)^{\beta-1} = B(\alpha,\beta) = \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha+\beta)},$$

which gives in our case

$$\int_0^1 dx x^{1-\varepsilon}(1-x)^{1-\varepsilon} = \frac{\Gamma(2-\varepsilon)\Gamma(2-\varepsilon)}{\Gamma(4-2\varepsilon)}.$$

Thus, the integral (18.28) becomes

$$I^{Dim}_{\rho\sigma}(p) = \frac{i}{16\pi^2}(4\pi)^\varepsilon \left(-\frac{\mu^2}{p^2}\right)^\varepsilon \frac{\Gamma^2(2-\varepsilon)\Gamma(\varepsilon)}{\Gamma(4-2\varepsilon)} \left[p^\rho p^\sigma + \frac{1}{2}\frac{g^{\rho\sigma}p^2}{1-\varepsilon}\right], \tag{18.29}$$

where we have used that $\Gamma(-1+\varepsilon) = -\frac{\Gamma(\varepsilon)}{1-\varepsilon}$. Multiplying eq.(18.29) by the trace

$$[g^{\mu\rho}g^{\nu\sigma} + g^{\mu\sigma}g^{\nu\rho} - g^{\mu\nu}g^{\rho\sigma}]p^\rho p^\sigma = p^\mu p^\nu + p^\nu p^\mu - g^{\mu\nu}p^2 = 2p^\mu p^\nu - g^{\mu\nu}p^2,$$

$$[g^{\mu\rho}g^{\nu\sigma} + g^{\mu\sigma}g^{\nu\rho} - g^{\mu\nu}g^{\rho\sigma}]g^{\rho\sigma}p^2 = g^{\mu\nu}p^2 + g^{\mu\nu}p^2 - g^{\mu\nu}(4-2\varepsilon)p^2 = -(2-2\varepsilon)p^2 g^{\mu\nu},$$

we find

$$\begin{aligned}\Pi^{Dim}_{\mu\nu}(p) &= i\frac{4e^2}{16\pi^2}(4\pi)^\varepsilon \left(-\frac{\mu^2}{p^2}\right)^\varepsilon \frac{\Gamma^2(2-\varepsilon)\Gamma(\varepsilon)}{\Gamma(4-2\varepsilon)}\left[2p^\mu p^\nu - g^{\mu\nu}p^2 - g^{\mu\nu}p^2\right] \\ &= -i\frac{8e^2}{16\pi^2}(4\pi)^\varepsilon \left(-\frac{\mu^2}{p^2}\right)^\varepsilon (g^{\mu\nu}p^2 - p^\mu p^\nu)\frac{\Gamma^2(2-\varepsilon)\Gamma(\varepsilon)}{\Gamma(4-2\varepsilon)}.\end{aligned} \tag{18.30}$$

Expanding now over ε with the help of

$$\Gamma(\varepsilon) = \frac{1}{\varepsilon}\Gamma(1+\varepsilon),\ \Gamma(2-\varepsilon) = (1-\varepsilon)\Gamma(1-\varepsilon),\ \Gamma(4-2\varepsilon) = (3-2\varepsilon)(2-2\varepsilon)(1-2\varepsilon)\Gamma(1-2\varepsilon),$$

we finally get

$$\begin{aligned}\Pi^{Dim}_{\mu\nu}(p) &= -i\frac{e^2}{16\pi^2}(4\pi)^\varepsilon \left(-\frac{\mu^2}{p^2}\right)^\varepsilon (g^{\mu\nu}p^2 - p^\mu p^\nu)\frac{4(1+5/3\varepsilon)}{3\varepsilon}e^{-\gamma\varepsilon} \\ &= -ie^2\frac{g^{\mu\nu}p^2 - p^\mu p^\nu}{16\pi^2}\frac{4}{3}\left[\frac{1}{\varepsilon} - \gamma_E + \log 4\pi + \log\frac{-\mu^2}{p^2} + \frac{5}{3}\right], \\ &= i(g^{\mu\nu}p^2 - p^\mu p^\nu)\Pi^{Dim}(p^2),\end{aligned} \tag{18.31}$$

where

$$\Pi^{Dim}(p^2) = -\frac{e^2}{16\pi^2}\frac{4}{3}\left[\frac{1}{\varepsilon} - \gamma_E + \log 4\pi + \log\frac{-\mu^2}{p^2} + \frac{5}{3}\right]. \tag{18.32}$$

Given the expression for the vacuum polarization one can construct the photon propagator as shown in Fig.18.7.

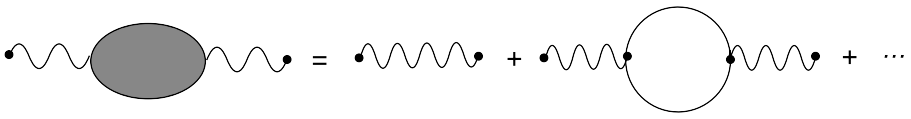

Figure 18.7: The photon propagator in QED

One has

$$\begin{aligned} G_{\mu\nu}(p) &= \frac{-i}{p^2}g^{\mu\nu} + \frac{-i}{p^2}g^{\mu\rho}\Pi_{\rho\sigma}\frac{-i}{p^2}g^{\sigma\nu} + \cdots \\ &= \frac{-i}{p^2}g^{\mu\nu} - \frac{\Pi^{\mu\nu}}{p^4} + \cdots = \frac{-i}{p^2}g^{\mu\nu} - \frac{i(g^{\mu\nu} - p^\mu p^\nu/p^2)}{p^2}\Pi(p^2) + \cdots \\ &= \frac{-i}{p^2}(g^{\mu\nu} - \frac{p^\mu p^\nu}{p^2})(1 + \Pi(p^2) + \cdots) - \frac{i}{p^2}\frac{p^\mu p^\nu}{p^2}, \end{aligned}$$

where $\Pi(p^2)$ is given by eq.(18.32). Notice that the radiative corrections are always proportional to the transverse tensor $P_{\mu\nu} = g_{\mu\nu} - p_\mu p_\nu/p^2$. This is a consequence of the gauge invariance and follows from the Ward identities.

Consider now the electron self-energy graph Fig.18.6b). The corresponding integral is

$$\Sigma(\hat{p}) = -\frac{e^2}{(2\pi)^4}\int d^4k \frac{\gamma^\mu(\hat{p} - \hat{k} + m)\gamma^\mu}{k^2[(p-k)^2 - m^2]}. \tag{18.33}$$

Acting in a usual way we go to dimension $4-2\varepsilon$, convert the indices of the γ-matrices and introduce the Feynman parametrization. The result is

$$\Sigma^{Dim}(\hat{p}) = -\frac{e^2(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}}\int_0^1 dx \int \frac{d^{4-2\varepsilon}k[-2(1-\varepsilon)(\hat{p} - \hat{k}) + (4-2\varepsilon)m]}{[k^2 - 2kpx + p^2x - m^2x]^2}. \tag{18.34}$$

The integral over k can now be evaluated according to the standard formulas

$$\Sigma^{Dim}(\hat{p}) = -i\frac{e^2}{16\pi^2}\frac{(-\mu^2)^\varepsilon}{(4\pi)^{-\varepsilon}}\Gamma(\varepsilon)\int_0^1 dx \frac{-2(1-\varepsilon)\hat{p}(1-x) + (4-2\varepsilon)m}{[p^2x(1-x) - m^2x]^\varepsilon}. \tag{18.35}$$

This expression can be expanded in series in ε

$$\begin{aligned} \Sigma^{Dim}(\hat{p}) &= -i\frac{e^2}{16\pi^2}\left[-\frac{\hat{p} - 4m}{\varepsilon} + \hat{p} - 2m - (\hat{p} - 4m)(-\gamma_E + \log(4\pi))\right. \\ &+ \left.\int_0^1 dx[2\hat{p}(1-x) - 4m]\log\frac{p^2x(1-x) - m^2x}{-\mu^2}\right]. \end{aligned} \tag{18.36}$$

Notice that the linear divergence of the integral manifests itself as a simple pole in ε, and the coefficient has the dimension equal to 1 and is Lorentz invariant (this is either $\hat{p}$ or m).

At last, consider the vertex function Fig.18.6c). The corresponding integral is

$$\Gamma_1(p,q) = \frac{e^3}{(2\pi)^4}\int d^4k \frac{\gamma^\nu(\hat{p} - \hat{k} - \hat{q} + m)\gamma^\mu(\hat{p} - \hat{k} + m)\gamma^\nu}{[(p-k-q)^2 - m^2][(p-k)^2 - m^2]k^2}. \tag{18.37}$$

Transfer to dimension $4-2\varepsilon$ and introduce the Feynman parametrization. This gives

$$\Gamma_1^{Dim}(p,q) = \frac{e^3(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}}\Gamma(3)\int\limits_0^1 dx\int\limits_0^x dy \times \int \frac{d^{4-2\varepsilon}k[\gamma^\nu(\hat{p}-\hat{k}-\hat{q}+m)\gamma^\mu(\hat{p}-\hat{k}+m)\gamma^\nu]}{[((p-k-q)^2-m^2)y+((p-k)^2-m^2)(x-y)+k^2(1-x)]^3}. \tag{18.38}$$

The integral over k is straightforward and gives

$$\Gamma_1^{Dim}(p,q) = ie\frac{e^2}{16\pi^2}\frac{(-\mu^2)^\varepsilon}{(4\pi)^{-\varepsilon}}\int\limits_0^1 dx\int\limits_0^x dy \tag{18.39}$$
$$\left\{\Gamma(1+\varepsilon)\frac{[\gamma^\nu(\hat{p}(1-x)-\hat{q}(1-y)+m)\gamma^\mu(\hat{p}(1-x)+\hat{q}y+m)\gamma^\nu]}{[(p-q)^2y(1-x)+p^2(1-x)(x-y)+q^2y(x-y)-m^2x]^{1+\varepsilon}}\right.$$
$$\left.+\frac{\Gamma(\varepsilon)}{2}\frac{\gamma^\nu\gamma^\rho\gamma^\mu\gamma^\rho\gamma^\nu}{[(p-q)^2y(1-x)+p^2(1-x)(x-y)+q^2y(x-y)-m^2x]^\varepsilon}\right\}.$$

As one can see, the first integral is finite and the second one is logarithmically divergent. Expanding in series in ε we find

$$\Gamma_1^{Dim}(p,q) = ie\frac{e^2}{16\pi^2}\left\{\frac{\gamma^\mu}{\varepsilon}-2\gamma^\mu-\gamma^\mu(\gamma_E-\log(4\pi))\right. \tag{18.40}$$
$$-\ 2\gamma^\mu\int\limits_0^1 dx\int\limits_0^x dy\ \log\left[\frac{(p-q)^2y(1-x)+p^2(1-x)(x-y)+q^2y(x-y)-m^2x}{-\mu^2}\right]$$
$$\left.+\int\limits_0^1 dx\int\limits_0^x dy\frac{\gamma^\nu(\hat{p}(1-x)-\hat{q}(1-y)+m)\gamma^\mu(\hat{p}(1-x)+\hat{q}y+m)\gamma^\nu}{(p-q)^2y(1-x)+p^2(1-x)(x-y)+q^2y(x-y)-m^2x}\right\}.$$

18.3.3 Quantum chromodynamics

Consider now the non-Abelian gauge theories and, in particular, QCD. The Lagrangian of QCD has the form

$$\mathcal{L}_{QD} = -\frac{1}{4}(F^a_{\mu\nu})^2+\bar{\psi}(i\gamma^\mu\partial_\mu-m)\psi+g\bar{\psi}\gamma^\mu A^a_\mu T^a\psi-\frac{1}{2\xi}(\partial_\mu A^a_\mu)^2$$
$$+\ \partial_\mu\bar{c}^a\partial_\mu c^2+gf^{abc}\partial_\mu\bar{c}^a A^b_\mu c^c, \tag{18.41}$$

where the stress tensor of the gauge field is now $F^a_{\mu\nu}=\partial_\mu A^a_\nu-\partial_\nu A^a_\mu+gf^{abc}A^b_\mu A^c_\nu$ and the last terms represent the Faddeev-Popov ghosts.

The Lagrangian (18.41) generates the following set of Feynman rules:

the spinor propagator  $= \frac{i}{\hat{p} - m}$

the vector propagator  $\frac{-i\delta^{ab} g^{\mu\nu}}{p^2}$

the ghost propagator  $= \frac{i\delta^{ab}}{p^2}$

the spino-gauge vertex  $-ig\gamma^{\mu} T^{a}$

the triple gauge vertex $= -gf^{abc}[(p-q)^{\rho} g^{\mu\nu}$
$+(q-k)^{\mu} g^{\rho\nu}$
$+(k-p)^{\nu} g^{\mu\rho}]$

the ghost-gauge vertex  $= -gf^{abc} q^{\mu}$

Consider the one-loop divergent diagrams. We start with the gluon propagator. Besides the diagram shown in Fig.18.6), one has additional contributions to the vacuum polarization from the diagrams shown in Fig.18.8. The first diagram takes into account the gluon self-interaction and the second one the contribution of the Faddeev-Popov ghosts. (As has already been mentioned, the tad-pole diagrams should not be included since they are automatically zero.) These diagrams depend on the choice of the gauge, and to evaluate them we have to fix the gauge. In what follows we choose the Feynman gauge (or the diagonal gauge) for the gluon field.

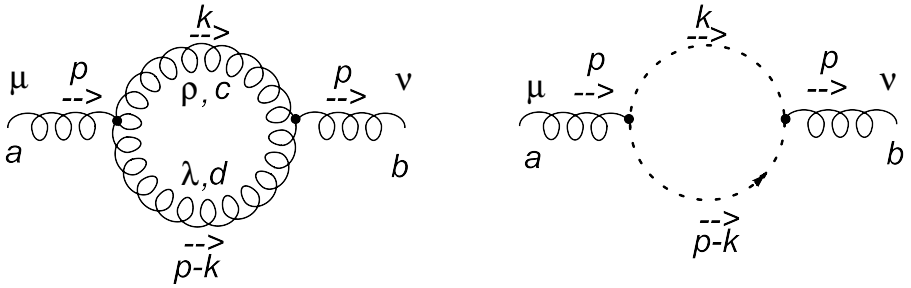

Figure 18.8: The vacuum polarization diagrams in the Yang-Mills theory

Then for the first diagram we have the expression

$$\Pi^{ab}_{\mu\nu}(p) = \frac{g^2 C_A \delta^{ab}}{2(2\pi)^4}\int \frac{d^4k}{k^2(k-p)^2}[(2p-k)^\rho g^{\mu\lambda}+(2k-p)^\mu g^{\rho\lambda}-(k+p)^\lambda g^{\mu\rho}] \times [(2p-k)^\rho g^{\lambda\nu}-(k+p)^\lambda g^{\nu\rho}+(2k-p)^\nu g^{\rho\lambda}], \quad (18.42)$$

where $1/2$ is a combinatorial factor and C_2 is the quadratic Casimir operator which for the SU(N) group equals N. It comes from the contraction of the gauge group structure constants f^{abc}

$$f^{abc}f^{dbc} = C_2\delta^{ad}.$$

Contracting the indices and going to $4-2\epsilon$ dimensions, one gets

$$\Pi^{Dim\ (ab)}_{\mu\nu}(p) = \delta^{ab}\frac{g^2C_A}{2}\frac{(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}}\int\frac{d^{4-2\varepsilon}k}{k^2(k-p)^2}\{g^{\mu\nu}[4p^2+k^2+(k-p)^2] +(3-2\varepsilon)(2k-p)^\mu(2k-p)^\nu-(2p-k)^\mu(2p-k)^\nu-(k+p)^\mu(k+p)^\nu\}. \quad (18.43)$$

To calculate the integrals, one can use the formulas given above. The first step is the Feynman parametrization, eq.(18.4), and then the momentum integration is performed according to eqs.(18.16). Applying these rules we get for the integral (18.43)

$$\Pi^{Dim\ (ab)}_{\mu\nu}(p) = i\frac{g^2C_A\delta^{ab}}{(4\pi)^{2-\varepsilon}}\left[\frac{-\mu^2}{p^2}\right]^\varepsilon\frac{\Gamma(\varepsilon)\Gamma(1-\varepsilon)\Gamma(2-\varepsilon)}{\Gamma(4-2\varepsilon)}[g^{\mu\nu}p^2(\frac{19}{2}-6\varepsilon)-p^\mu p^\nu(11-7\varepsilon)]. \quad (18.44)$$

The second diagram corresponds to the integral

$$\Pi^{Dim\ (ab)}_{\mu\nu}(p) = i\frac{g^2C_A\delta^{ab}}{(4\pi)^{2-\varepsilon}}\left[\frac{-\mu^2}{p^2}\right]^\varepsilon\frac{\Gamma(\varepsilon)\Gamma(1-\varepsilon)\Gamma(2-\varepsilon)}{\Gamma(4-2\varepsilon)}[g^{\mu\nu}p^2(\frac{19}{2}-6\varepsilon)-p^\mu p^\nu(11-7\varepsilon)]. \quad (18.45)$$

here the "-" sign comes from the Fermi statistics of the ghost fields.

Calculation is now straightforward and gives

$$\Pi^{Dim\ (ab)}_{\mu\nu}(p) = i\frac{g^2C_A\delta^{ab}}{(4\pi)^{2-\varepsilon}}\left(-\frac{\mu^2}{p^2}\right)^\varepsilon\frac{\Gamma(\varepsilon)\Gamma(1-\varepsilon)\Gamma(2-\varepsilon)}{\Gamma(4-2\varepsilon)}[g^{\mu\nu}p^2/2+p^\mu p^\nu(1-\varepsilon)]. \quad (18.46)$$

Adding up the two contributions together, one finally has

$$\Pi^{Dim\ (ab)}_{\mu\nu}(p) = iC_A\frac{2g^2\delta^{ab}}{16\pi^2}(4\pi)^\varepsilon\left[\frac{-\mu^2}{p^2}\right]^\varepsilon\frac{\Gamma(\varepsilon)\Gamma(1-\varepsilon)\Gamma(2-\varepsilon)}{\Gamma(4-2\varepsilon)}(5-3\varepsilon)[g^{\mu\nu}p^2-p^\mu p^\nu] \quad (18.47)$$

or expanding in ε

$$\Pi^{Dim\ (ab)}_{\mu\nu}(p) = iC_A\delta^{ab}g^2\frac{g^{\mu\nu}p^2-p^\mu p^\nu}{16\pi^2}\frac{5}{3}\left[\frac{1}{\varepsilon}-\gamma_E+\log 4\pi+\log\frac{-\mu^2}{p^2}+\frac{31}{15}\right]. \quad (18.48)$$

Acting the same way as in QED one can calculate the contribution to the gluon propagator.

Notice that the final result for the sum of the two diagrams is again proportional to the transverse tensor $P_{\mu\nu} = g_{\mu\nu} - p_\mu p_\nu/p^2$. This is not true, however, for the diagram with the gauge fields and is valid only if one takes into account the ghost contribution. Notice also the opposite sign of the resulting expression compared to that of eq.(18.31). This is due to a non-Abelian nature of the gauge fields and has very important consequences to be discussed later.

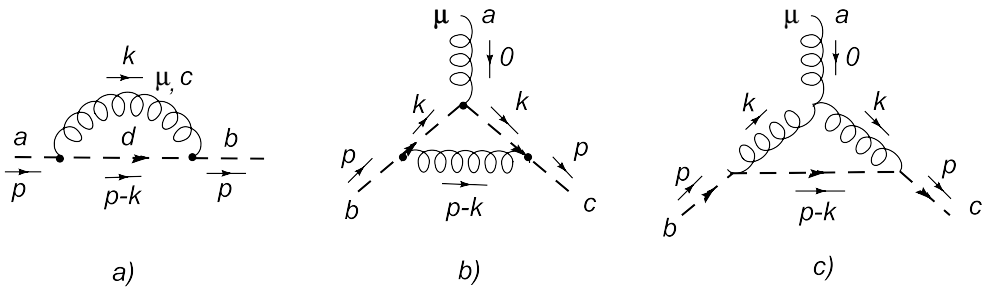

Figure 18.9: The ghost propagator and the ghost-gluon vertex diagrams in QCD

Consider also the ghost propagator. Here there is only one diagram shown in Fig.18.9a). It corresponds to the integral

$$\Pi^{Dim\ (ab)}(p) = -C_A\delta^{ab}\frac{g^2(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}}\int d^{4-2\varepsilon}k\frac{k^\mu p^\mu}{k^2(k-p)^2}, \tag{18.49}$$

which equals

$$\begin{aligned}\Pi^{Dim\ (ab)}(p) &= -iC_A\delta^{ab}\frac{g^2}{2(4\pi)^{2-\varepsilon}}\left(\frac{-\mu^2}{p^2}\right)^\varepsilon p^2\frac{\Gamma(\varepsilon)\Gamma(1-\varepsilon)\Gamma(1-\varepsilon)}{\Gamma(2-2\varepsilon)}\\ &= -iC_A\delta^{ab}\frac{g^2}{32\pi^2}p^2\left[\frac{1}{\varepsilon}-\gamma_E+\log 4\pi+\log\frac{-\mu^2}{p^2}+2\right].\end{aligned} \tag{18.50}$$

Analogously one can calculate the vertex diagrams. We consider in more detail the calculation of the ghost-gluon vertex as a simpler one. The corresponding diagrams are shown in Fig.18.9. To simplify the evaluation, we put one of the momenta equal to zero. Then the first diagram gives the integral

$$V_{1\rho}^{Dim\ (abc)}(p) = i\frac{C_A}{2}f^{abc}\frac{g^3(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}}\int d^{4-2\varepsilon}k\frac{k^\mu k^\rho p^\mu}{(k^2)^2(k-p)^2}. \tag{18.51}$$

Using the equality $kp = 1/2[k^2+p^2-(k-p)^2]$ and substituting it into (18.51) we find that the first two terms are reduced to the standard integrals and the last one leads to the tad-pole structure and is equal to zero. Adding up all together we get

$$\begin{aligned}V_{1\rho}^{Dim\ (abc)}(p) &= -C_A\frac{1}{4}f^{abc}\frac{g^3}{(4\pi)^{2-\varepsilon}}\left(-\frac{\mu^2}{p^2}\right)^\varepsilon p^\rho\frac{\Gamma(\varepsilon)\Gamma(2-\varepsilon)\Gamma(1-\varepsilon)}{\Gamma(3-2\varepsilon)}(1+2\varepsilon)\\ &= -C_A\frac{1}{8}f^{abc}\frac{g^3}{16\pi^2}p^\rho\left[\frac{1}{\varepsilon}-\gamma_E+\log 4\pi+\log\frac{-\mu^2}{p^2}+4\right].\end{aligned} \tag{18.52}$$

The second diagram gives

$$V_{2\rho}^{Dim\ (abc)}(p) = -i\frac{C_A}{2}f^{abc}\frac{g^3(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}}\int d^{4-2\varepsilon}k\frac{(p-k)^\mu p^\nu[k^\nu g^{\mu\rho}+k^\mu g^{\nu\rho}-2k^\rho g^{\mu\nu}]}{(k^2)^2(k-p)^2}. \tag{18.53}$$

Contracting the indices in the numerator we have $(p-k)^\rho kp + p^\rho k(p-k) - 2k^\rho p(p-k)$, which after integration leads to

$$\begin{aligned}V_{2\rho}^{Dim\ (abc)}(p) &= -C_A\frac{3}{8}f^{abc}\frac{g^3}{(4\pi)^{2-\varepsilon}}\left(-\frac{\mu^2}{p^2}\right)^\varepsilon p^\rho\frac{\Gamma(\varepsilon)\Gamma(1-\varepsilon)\Gamma(1-\varepsilon)}{\Gamma(2-2\varepsilon)}(1-\frac{2}{3}\varepsilon)\\ &= -C_A\frac{3}{8}f^{abc}\frac{g^3}{16\pi^2}p^\rho\left[\frac{1}{\varepsilon}-\gamma_E+\log 4\pi+\log\frac{-\mu^2}{p^2}+\frac{4}{3}\right].\end{aligned} \tag{18.54}$$

Adding up the two contributions together we find

$$V_\rho^{Dim\ (abc)}(p) = -C_A \frac{1}{2} f^{abc} \frac{g^3}{16\pi^2} p^\rho \left[\frac{1}{\varepsilon} - \gamma_E + \log 4\pi + \log \frac{-\mu^2}{p^2} + 2 \right]. \tag{18.55}$$

Having in mind that at the tree level the vertex has the form $V_\rho^{tree\ (abc)}(p) = -g f^{abc} p^\rho$ we get the vertex function in the one-loop approximation as

$$V_\rho^{(abc)}(p) = -g f^{abc} p^\rho \left\{ 1 + C_A \frac{1}{2} \frac{g^2}{16\pi^2} \left[\frac{1}{\varepsilon} - \gamma_E + \log 4\pi + \log \frac{-\mu^2}{p^2} + 2 \right] \right\}. \tag{18.56}$$

18.4 K-l.IV: Renormalization. General Idea

Thus, we have convinced ourselves that the integrals for the radiative corrections are indeed ultraviolet divergent in accordance with the naive power counting. The question then is: how to get a sensible result for the cross-sections of the scattering processes, decay widths, etc? To answer this question let us see what is the reason for divergences at large values of momenta. In coordinate space the large values of momenta correspond to the small distances. Hence, the ultraviolet divergences allow for the singularities at small distances. Indeed, the simplest divergent loop diagram (Fig.18.2) in coordinate space is the product of two propagators. Each propagator is uniquely defined in momentum as well as in coordinate space, but the square of the propagator has already an ill-defined Fourier-transform, it is ultraviolet divergent. The reason is that the square of the propagator is singular as $x^2 \to 0$ and behaves like $1/(x^2)^2$. In fact, the causal Green function (the propagator) is the so-called distribution which is defined on smooth functions. It has the δ-function like singularities and needs an additional definition for the product of several such functions at a single point. The discussed diagram is precisely this product.

The general approach to the elimination of the ultraviolet divergences known as the $\mathcal{R}$-operation was developed in the 1950s. It consists in the introduction to the initial Lagrangian of additional local (or quasi-local) terms, called the counter-terms, which serve the task of the definition of the product of distributions at the coinciding points. The counter-terms lead to additional diagrams which cancel the ultraviolet divergences. The peculiarity of this procedure, being the subject of the Bogoliubov-Parasiuk theorem, is in that the singularities are local in coordinate space, i.e., are the functions of a single point and can contain only a finite number of derivatives. In the theories belonging to the renormalizable class, where the number of divergent structures is finite, the number of types of the counter-terms is also finite, they repeat the terms of the original Lagrangian. This means that the introduction of the counter-terms in this case is equivalent to the modification of the coefficients of various terms., i.e. to the modification of the normalization of these terms. That is why this procedure was called the *renormalization* procedure.

It should be stressed that the parameters of the original Lagrangian like the masses, the coupling constants and the fields themselves are not, strictly speaking, observable. They can be infinite. It is important that the renormalized parameters which enter the final answers are meaningful.

Below we show by several examples of renormalizable theories how one introduces the counter-terms into the Lagrangian, how they lead to the renormalization of the original parameters and how the renormalization procedure allows one to get finite results for the Green functions.

18.4.1 The scalar theory. The one-loop approximation

We start with the one-loop approximation and consider for simplicity the scalar theory (18.18). It belongs to the renormalizable type and has a finite number of ultraviolet divergent structures.

The one-loop divergent diagrams in this theory were calculated in the third lecture. Here we are interested in the singular parts, i.e., the poles in ε. They are given by eqs. (18.20) and (18.24.

$$\text{The propagator}: \quad Sing\ J_1(p^2) = -im^2(\tfrac{\lambda}{16\pi^2})(-\tfrac{1}{2\varepsilon}),$$

$$\text{The vertex}: \quad Sing\ \Gamma_4(s,t,u) = -i\lambda(\tfrac{\lambda}{16\pi^2})(-\tfrac{3}{2\varepsilon}).$$

Note that the singular parts do not depend on momenta, i.e. their Fourier-transform has the form of the δ-function in coordinate space.

In order to remove the obtained singularities we add to the Lagrangian (18.18) extra terms, the counter-terms equal to the singular parts with the opposite sign (the factor i belongs to the S-matrix and does not enter into the Lagrangian), namely,

$$\Delta\mathcal{L} = \frac{1}{2\varepsilon}\frac{\lambda}{16\pi^2}\ (-\frac{m^2}{2}\phi^2) + \frac{\lambda}{16\pi^2}\frac{3}{2\varepsilon}\ (-\frac{\lambda}{4!}\phi^4). \tag{18.57}$$

These counter-terms correspond to additional vertices shown in Fig.18.10, where the cross denotes

Figure 18.10: The one-loop counter-terms in the scalar theory

the contribution corresponding to (18.57). With account taken of the new diagrams the expressions for the propagator (18.20) and the vertex (18.24) become

$$J_1(p^2) = \frac{i\lambda}{32\pi^2}m^2\left(1-\gamma_E+\log(4\pi)-\log(m^2/\mu^2)\right). \tag{18.58}$$

$$\Delta\Gamma_4 = i\lambda\left\{\frac{\lambda}{16\pi^2}\left(3-\frac{3}{2}\gamma_E+\frac{3}{2}\log(4\pi)+\frac{1}{2}\ln\frac{\mu^2}{-s}+\frac{1}{2}\ln\frac{\mu^2}{-t}+\frac{1}{2}\ln\frac{\mu^2}{-u}\right)\right\}. \tag{18.59}$$

Notice that the obtained expressions have no infinities but contain the dependence on the regularization parameter μ^2 which was absent in the initial theory. The appearance of this dependence on a dimensional parameter is inherent in any regularization and is called the dimensional transmutation, i.e., an appearance of a new scale in a theory.

What we have done is equivalent to *subtraction* of divergences from the diagrams. In doing this we have subtracted just the singular parts. This way of subtraction is called the *minimal subtraction scheme* or the MS-scheme. One can make the subtraction differently, for instance, subtract also the finite parts. It is useful to subtract the Euler constant and $\log 4\pi$ which accompany the pole terms. This subtraction scheme is called the *modified minimal subtraction scheme* or the $\overline{MS}$-scheme. It is equivalent to the redefinition of the parameter μ^2. Another popular scheme of subtraction is the so-called MOM-scheme when the subtractions are made for fixed values of momenta. For example, in the case of the vertex function one can make the subtraction at the point $s = t = u = l^2$. This subtraction is called the subtraction at a symmetric point.

The difference between various subtraction schemes is in the finite parts; in the one-loop approximation this is just the constant independent of momentum, however, in higher loops one already has momentum dependent terms. Therefore, the finite parts of the Green functions depend on a *subtraction scheme*. Note that this dependence in general is not reduced to the redefinition

of the parameter μ, since there are usually a few divergent Green functions and all of them are independent.

Thus, in the three subtraction schemes discussed above we have three different values for the vertex function

$$\begin{aligned}
\Gamma_4^{MS} &= -i\lambda\left\{1-\frac{\lambda}{16\pi^2}\left[3-\frac{3}{2}\gamma_E+\frac{3}{2}\log 4\pi+\frac{1}{2}\ln\frac{\mu^2}{-s}+\frac{1}{2}\ln\frac{\mu^2}{-t}+\frac{1}{2}\ln\frac{\mu^2}{-u}\right]\right\},\\
\Gamma_4^{\overline{MS}} &= -i\lambda\left\{1-\frac{\lambda}{16\pi^2}\left[3+\frac{1}{2}\ln\frac{\mu^2}{-s}+\frac{1}{2}\ln\frac{\mu^2}{-t}+\frac{1}{2}\ln\frac{\mu^2}{-u}\right]\right\},\\
\Gamma_4^{MOM} &= -i\lambda\left\{1-\frac{\lambda}{16\pi^2}\left[\frac{1}{2}\ln\frac{l^2}{-s}+\frac{1}{2}\ln\frac{l^2}{-t}+\frac{1}{2}\ln\frac{l^2}{-u}\right]\right\}.
\end{aligned}$$

The counter-terms are also different. It is useful to write them in the following way

$$\Delta\mathcal{L} = -(Z-1)\frac{m^2}{2}\phi^2-(Z_4-1)\frac{\lambda}{4!}\phi^4, \tag{18.60}$$

where for different subtraction schemes one has

$$\begin{aligned}
Z^{MS} &= 1+\frac{1}{2\varepsilon}\frac{\lambda}{16\pi^2},\\
Z^{\overline{MS}} &= 1+[\frac{1}{2\varepsilon}+1-\gamma_E+\log(4\pi)]\frac{\lambda}{16\pi^2},\\
Z_4^{MS} &= 1+\frac{3}{2\varepsilon}\frac{\lambda}{16\pi^2},\\
Z_4^{\overline{MS}} &= 1+[\frac{3}{2\varepsilon}-3\gamma_E+3\log(4\pi)]\frac{\lambda}{16\pi^2},\\
Z_4^{MOM} &= 1+[\frac{3}{2\varepsilon}+3-3\gamma_E+3\log(4\pi)+\frac{3}{2}\ln\frac{\mu^2}{l^2}]\frac{\lambda}{16\pi^2}.
\end{aligned} \tag{18.61}$$

The Lagrangian (18.18) together with the counter-terms (18.60) can be written as

$$\mathcal{L}+\Delta\mathcal{L} = Z_2\frac{1}{2}(\partial_\mu\varphi)^2-Z\frac{m^2}{2}\varphi^2-Z_4\frac{\lambda}{4!}\varphi^4 = \mathcal{L}_{Bare}, \tag{18.62}$$

where the renormalization constants Z and Z_4 are given by (18.61) and the renormalization constant Z_2 in the one-loop approximation equals 1.

Writing the "bare" Lagrangian in the same form as the initial one but in terms of the "bare" fields and couplings

$$\mathcal{L}_{Bare} = \frac{1}{2}(\partial_\mu\varphi_B)^2-\frac{m_B^2}{2}\varphi_B^2-\frac{\lambda_B}{4!}\varphi_B^4 \tag{18.63}$$

and comparing it with (18.62), we get the connection between the "bare" and renormalized quantities

$$\varphi_B = \sqrt{Z_2}\varphi,\quad m_B^2 = ZZ_2^{-1}m^2,\quad \lambda_B = Z_4Z_2^{-2}\lambda. \tag{18.64}$$

Equations (18.63) and (18.64) imply that the one-loop radiative corrections calculated from the Lagrangian (18.63) with parameters chosen according to (18.64,18.61) are finite.

18.4.2 The scalar theory. The two-loop approximation

Consider now the two-loop diagrams. For simplicity and in order to complete all the integrations we restrict ourselves to the massless case. Since we are going to calculate the diagrams off mass shell, no infrared divergences may appear.

The propagator: In this order of PT there is only one diagram shown in Fig.18.11.

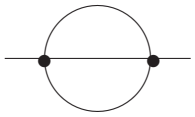

Figure 18.11: The two-loop propagator type diagram

The corresponding integral equals

$$J_2(p^2) = \frac{(-i\lambda)^2}{3!}\frac{i^3(\mu^2)^{2\varepsilon}}{(2\pi)^{8-4\varepsilon}}\int\frac{d^{4-2\varepsilon}kd^{4-2\varepsilon}q}{q^2(k-q)^2(p-k)^2},$$

(1/3! is a combinatorial coefficient). Let us use the method of evaluation of the massless diagrams described above. One has to transform each of the propagators into coordinate space, multiply them and transform back to momentum space. This reduces to writing down the corresponding transformation factors. One gets

$$J_2(p^2) = \frac{i\lambda^2}{6}\frac{(i\pi^2)^{2-\varepsilon}}{(2\pi)^{8-4\varepsilon}}p^2\left(\frac{\mu^2}{-p^2}\right)^{2\varepsilon}\frac{\Gamma(1-\varepsilon)\Gamma(1-\varepsilon)\Gamma(1-\varepsilon)\Gamma(-1+2\varepsilon)}{\Gamma(1)\Gamma(1)\Gamma(1)\Gamma(3-3\varepsilon)}$$

$$= \frac{i}{6}\frac{\lambda^2}{(16\pi^2)^2}\left[\frac{\mu^2}{-p^2}\right]^{2\varepsilon}\frac{p^2}{(2-3\varepsilon)(1-3\varepsilon)(1-2\varepsilon)2\varepsilon} = \frac{i}{24}\frac{\lambda^2}{(16\pi^2)^2}p^2\left[\frac{1}{\varepsilon}+\frac{13}{2}+2\ln\frac{\mu^2}{-p^2}\right],$$

where the Euler constant and $\log 4\pi$ are omitted.

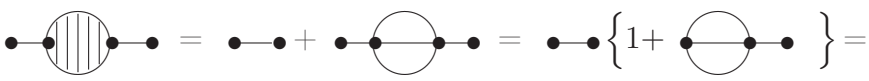
The appeared ultraviolet divergence, the pole in ε, can be removed via the introduction of the (quasi)local counter-term

$$\Delta\mathcal{L} = \frac{1}{2}(Z_2-1)(\partial\phi)^2, \tag{18.65}$$

where the wave function renormalization constant Z_2 in the $\overline{MS}$ scheme is obtained by taking the singular part of the integral with the opposite sign

$$Z_2 = 1 - \frac{1}{24\varepsilon}\left(\frac{\lambda}{16\pi^2}\right)^2. \tag{18.66}$$

After that the propagator in the massless case takes the form



$$= \frac{i}{p^2}\left\{1 - \frac{1}{24}\frac{\lambda^2}{(16\pi^2)^2}\left(\frac{13}{2}+2\ln\frac{\mu^2}{-p^2}\right)\right\}. \tag{18.67}$$

The vertex: In the given order there are two diagrams (remind that in the massless case the tad-poles equal to zero) shown in Fig.18.12.

Figure 18.12: The two-loop vertex diagrams

The first diagram by analogy with the one-loop case equals the sum of s, t and u channels

$$I_{21} = I_{21}(s) + I_{21}(t) + I_{21}(u),$$

where each integral is nothing else but the square of the one-loop integral

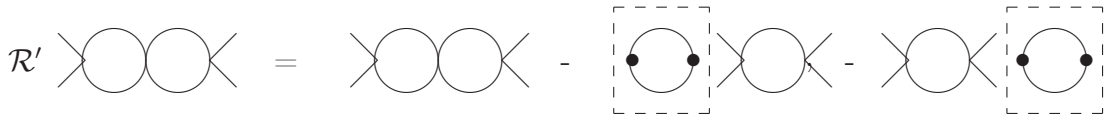
$$I_{21}(s) = \frac{(-i\lambda)^3}{96}\left(\frac{(\mu^2)^\varepsilon}{(2\pi)^{4-2\varepsilon}} i^2 \int \frac{d^{4-2\varepsilon}k}{k^2(p-k)^2}\right)^2 = -\frac{i}{96}\frac{\lambda^3}{(16\pi^2)^2}(\frac{1}{\varepsilon} + 2 + \ln\frac{\mu^2}{-s})^2. \qquad (18.68)$$

(1/96 is the combinatorial coefficient).

Opening the bracket we, for the first time here, come across the second order pole term $1/\varepsilon^2$ and the single pole $\log(-\mu^2/s)/\varepsilon$ accompanying it. This latter pole is not harmless since its Fourier-transform is not a local function of coordinates. This means that it can not be eliminated by a local counter-term. This would be an unremovable problem if it were not the one-loop counter-terms (18.57) which created the new vertices shown in Fig.18.10. In the same order of λ^3 one gets additional diagrams presented in Fig.18.13.

Figure 18.13: The diagrams with the counter-terms in the two-loop approximation

These diagrams lead to the subtraction of divergences in the subgraphs (left and right) in the first diagram of Fig.18.12. The subtraction of divergent subgraphs (the $\mathcal{R}$-operation without the last subtraction called the $\mathcal{R}'$-operation) looks like



where the subgraph surrounded with the dashed line means its singular part, and the rest of the graph is obtained by shrinking down the singular subgraph to a point. The result has the form

$$\mathcal{R}' I_{21}(s) = -\frac{i}{4}\frac{\lambda^3}{(16\pi^2)^2}\left\{(\frac{1}{\varepsilon} + 2 + \ln\frac{\mu^2}{-s})^2 - \frac{2}{\varepsilon}(\frac{1}{\varepsilon} + 2 + \ln\frac{\mu^2}{-s})\right\} =$$

$$= -\frac{i}{4}\frac{\lambda^3}{(16\pi^2)^2}\left(-\frac{1}{\varepsilon^2} + 4 + \ln^2\frac{\mu^2}{-s} + 4\ln\frac{\mu^2}{-s}\right).$$

Notice that after the subtractions of subgraphs the singular part is local, i.e. in momentum space does not contain $\ln p^2$. The terms with the single pole $1/\varepsilon$ are absent since the diagram can be factorized into two diagrams of the lower order.

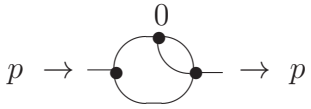
The contribution of a given diagram to the vertex function equals

$$\begin{aligned}\Delta\Gamma_4 &= -i\lambda\left\{\frac{1}{4}\frac{\lambda^2}{(16\pi^2)^2}\left(-\frac{3}{\varepsilon^2}+12\right.\right. \\ &\left.\left.+\ln^2\frac{\mu^2}{-s}+4\ln\frac{\mu^2}{-s}+\ln^2\frac{\mu^2}{-t}+4\ln\frac{\mu^2}{-t}+\ln^2\frac{\mu^2}{-u}+4\ln\frac{\mu^2}{-u}\right)\right\}\end{aligned} \tag{18.69}$$

The contribution to the renormalization constant of the four-point vertex in the $\overline{MS}$ scheme is equal to the singular part with the opposite sign

$$\Delta Z_4 = +\frac{3}{4\varepsilon^2}\left(\frac{\lambda}{16\pi^2}\right)^2. \tag{18.70}$$

The second diagram with the crossed terms contains 6 different cases. Consider one of them. Since we are interested here in the singular parts contributing to the renormalization constants, we perform some simplification of the original integral. We use a very important property of the minimal subtraction scheme that the renormalization constants depend only on dimensionless coupling constants and do not depend on the masses and the choice of external momenta. Therefore, we put all the masses equal to zero, and to avoid artificial infrared divergences, we also put equal to zero one of the external momenta. Then the diagram becomes the propagator type one:



The corresponding integral is:

$$I_{22}(p^2) = \frac{(-i\lambda)^3}{48}\frac{(\mu^2)^{2\varepsilon}}{(2\pi)^{8-4\varepsilon}}i^4\int\frac{d^{4-2\varepsilon}qd^{4-2\varepsilon}k}{q^2(k-q)^2k^2(p-k)^2},$$

(1/48 is the combinatorial coefficient). Since putting one of the momenta equal to zero we reduced the diagram to the propagator type, we can again use the advocated method to calculate the massless integral. One has

$$\begin{aligned}I_{22}(p^2) &= \frac{i\lambda^3}{48}\frac{(\mu^2)^{2\varepsilon}}{(2\pi)^{8-4\varepsilon}}i\pi^2\frac{\Gamma(1-\varepsilon)\Gamma(1-\varepsilon)\Gamma(\varepsilon)}{\Gamma(1)\Gamma(1)\Gamma(2-2\varepsilon)}\int\frac{d^{4-2\varepsilon}k}{(k^2)^{1+\varepsilon}(p-k)^2} \\ &= -\frac{i}{48}\frac{\lambda^3}{(16\pi^2)^2}\left(\frac{\mu^2}{-p^2}\right)^{2\varepsilon}\frac{\Gamma(1-\varepsilon)\Gamma(1-\varepsilon)\Gamma(\varepsilon)\Gamma(1-2\varepsilon)\Gamma(1-\varepsilon)\Gamma(2\varepsilon)}{\Gamma(1)\Gamma(1)\Gamma(2-2\varepsilon)\Gamma(1+\varepsilon)\Gamma(1)\Gamma(2-3\varepsilon)} \\ &= -\frac{i}{48}\frac{\lambda^3}{(16\pi^2)^2}\left(\frac{\mu^2}{-p^2}\right)^{2\varepsilon}\frac{1}{2\varepsilon^2(1-2\varepsilon)(1-3\varepsilon)} \\ &= -\frac{i}{48}\frac{\lambda^3}{(16\pi^2)^2}\left\{\frac{1}{2\varepsilon^2}+\frac{5}{2\varepsilon}+2+\frac{\ln(-\mu^2/p^2)}{\varepsilon}+\ln^2\frac{\mu^2}{-p^2}+5\ln\frac{\mu^2}{-p^2}\right\}.\end{aligned}$$

As one can see, in this case we again have the second order pole in ε and, accordingly, the single pole with the logarithm of momentum. The reason of their appearance is the presence of the divergent subgraph. Here we again have to look at the counter-terms of the previous order which eliminate the divergence from the one-loop subgraph. The subtraction of divergent subgraphs (the $\mathcal{R}$-operation without the last subtraction) looks like

$\mathcal{R}'$ 
or

$$\mathcal{R}'I_2(s) = -\frac{i}{2}\frac{\lambda^3}{(16\pi^2)^2}\left\{\left(\frac{\mu^2}{-p^2}\right)^{2\varepsilon}\frac{1}{2\varepsilon^2(1-2\varepsilon)(1-3\varepsilon)} - \left(\frac{\mu^2}{-p^2}\right)^{\varepsilon}\frac{1}{\varepsilon^2(1-2\varepsilon)}\right\}$$

$$= -\frac{i}{2}\frac{\lambda^3}{(16\pi^2)^2}\left\{\left(\frac{1}{2\varepsilon^2}+\frac{5}{2\varepsilon}+2+\frac{\ln(-\mu^2/p^2)}{\varepsilon}+\ln^2\frac{\mu^2}{-p^2}+5\ln\frac{\mu^2}{-p^2}\right)\right.$$

$$\left. -\left(\frac{1}{\varepsilon^2}+\frac{2}{\varepsilon}+4+\frac{\ln(-\mu^2/p^2)}{\varepsilon}+\frac{1}{2}\ln^2\frac{\mu^2}{-p^2}+2\ln\frac{\mu^2}{-p^2}\right)\right\} =$$

$$= -\frac{i}{2}\frac{\lambda^3}{(16\pi^2)^2}\left\{-\frac{1}{2\varepsilon^2}+\frac{1}{2\varepsilon}-2+\frac{1}{2}\ln^2\frac{\mu^2}{-p^2}+3\ln\frac{\mu^2}{-p^2}\right\}.$$

Once again, after the subtraction of the divergent subgraph the singular part is local, i.e. in momentum space does not depend on $\ln p^2$.

The contribution to the vertex function from this diagram is:

$$\Delta\Gamma_4 = -i\lambda\left\{\frac{1}{2}\frac{\lambda^2}{(16\pi^2)^2}\left(-\frac{3}{\varepsilon^2}+\frac{3}{\varepsilon}-12+\frac{1}{2}\ln^2\frac{\mu^2}{-p^2}+3\ln\frac{\mu^2}{-p^2}+\ldots\right)\right\} \tag{18.71}$$

and, accordingly,

$$\Delta Z_4 = (\frac{3}{2\varepsilon^2}-\frac{3}{2\varepsilon})\left(\frac{\lambda}{16\pi^2}\right)^2. \tag{18.72}$$

Thus, due to (18.61) and (18.72) in the two-loop approximation the quartic vertex renormalization constant in the $\overline{MS}$ scheme looks like:

$$Z_4 = 1+\frac{3}{2\varepsilon}\frac{\lambda}{16\pi^2}+\left(\frac{\lambda}{16\pi^2}\right)^2(\frac{9}{4\varepsilon^2}-\frac{3}{2\varepsilon}). \tag{18.73}$$

With taking account of the two-loop renormalization of the propagator (18.66) one has:

$$Z_\lambda = Z_4 Z_2^{-2} = 1+\frac{3}{2\varepsilon}\frac{\lambda}{16\pi^2}+\left(\frac{\lambda}{16\pi^2}\right)^2(\frac{9}{4\varepsilon^2}-\frac{17}{12\varepsilon}). \tag{18.74}$$

The statement is that the counter-terms introduced this way eliminate all the ultraviolet divergences up to two-loop order and make the Green functions and hence the radiative corrections finite. In the case of nonzero mass, one should also add the mass counter-term.

18.4.3 The general structure of the R-operation

We are ready to formulate now the general procedure of getting finite expressions for the Green functions off mass shell in an arbitrary local quantum field theory. It consists of:

In any order of perturbation theory in the coupling constant one introduces to the Lagrangian the (quasi) local counter-terms. They perform the subtraction of divergences in the diagrams of a given order. The subtraction of divergences in the subgraphs is provided by the counter-terms of the lower order. After the subtraction of divergences in the subgraphs the rest of the divergences

are always local. The Green functions of the given order calculated on the basis of the initial Lagrangian with account of the counter-terms are ultraviolet finite.

The structure of the counter-terms as functions of the field operators depends on the type of a theory. According to the classification discussed in the first lecture, the theories are divided into three classes: *superrenormalizable* (a finite number of divergent diagrams), *renormalizable* (a finite number of types of divergent diagrams) and *non-renormalizable* (a infinite number of types of divergent diagrams). Accordingly, in the first case one has a finite number of counter-terms; in the second case, a infinite number of counter-terms but they repeat the structure of the initial Lagrangian, and in the last case, one has an infinite number of structures with an increasing number of the fields and derivatives.

In the case of renormalizable and superrenormalizable theories, since the counter-terms repeat the structure of the initial Lagrangian, the result of the introduction of counter-terms can be represented as

$$\mathcal{L} + \Delta\mathcal{L} = \mathcal{L}_{Bare} = \mathcal{L}(\phi_B, \{g_B\}, \{m_B\}), \tag{18.75}$$

i.e., $\mathcal{L}_{Bare}$ is the same Lagrangian $\mathcal{L}$ but with the fields, masses and coupling constants being the "bare" ones related to the renormalized quantities by the multiplicative equalities

$$\phi_i^{Bare} = Z_i^{1/2}(\{g\}, 1/\varepsilon)\phi, \quad g_i^{Bare} = Z_g^i(\{g\}, 1/\varepsilon)g_i, \quad m_i^{Bare} = Z_m^i(\{g\}, 1/\varepsilon)m_i, \tag{18.76}$$

where the renormalization constants Z_i depend on the renormalized parameters and the parameter of regularization (for definiteness we have chosen $1/\varepsilon$). In some cases the renormalization can be nondiagonal and the renormalization constants become matrices.

The renormalization constants are not unique and depend on the renormalization scheme. This arbitrariness, however, does not influence the observables expressed through the renormalized quantities. We will come back to this problem later when discussing the group of renormalization. In the gauge theories Z_i may depend on the choice of the gauge though in the minimal subtraction scheme the renormalizations of the masses and the couplings are gauge invariant.

In the minimal schemes the renormalization constants do not depend on dimensional parameters like masses and do not depend on the arrangement of external momenta in the diagrams. This property allows one to simplify the calculation of the counter-terms putting the masses and some external momenta to zero, as it was exemplified above by calculation of the two-loop diagrams. In making this trick, however, one has to be careful not to create artificial infrared divergences. Since in dimensional regularization they also have the form of poles in ε, this may lead to the wrong answers.

In renormalizable theory the finite Green function is obtained from the "bare" one, i.e., is calculated from the "bare" Lagrangian by multiplication on the corresponding renormalization constant

$$\Gamma(\{p^2\}, \mu^2, g_\mu) = Z_\Gamma(1/\varepsilon, g_\mu)\Gamma_{Bare}(\{p^2\}, 1/\varepsilon, g_{Bare}), \tag{18.77}$$

where in the n-th order of perturbation theory the "bare" parameters in the r.h.s. have to be expressed in terms of the renormalized ones with the help of relations (18.76) taken in the (n-1)-th order. The remaining constant Z_Γ creates the counter-term of the n-th order of the form $\Delta\mathcal{L} = (Z_\Gamma - 1)O_\Gamma$, where the operator O_Γ reflects the corresponding Green function. If the Green function is finite by itself (for instance, has many legs), then one has to remove the divergences only in the subgraphs and the corresponding renormalization constant $Z_\Gamma = 1$.

Note that since the propagator is inverse to the operator quadratic in fields in the Lagrangian, the renormalization of the propagator is also inverse to the renormalization of the 1-particle irre-

ducible two-point Green function

$$D(p^2, \mu^2, g_\mu) = Z_2^{-1}(1/\varepsilon, g_\mu) D_{Bare}(p^2, 1/\varepsilon, g_{Bare}). \tag{18.78}$$

The propagator renormalization constant is also the renormalization constant of the corresponding field, but the fields themselves, contrary to the masses and couplings, do not enter into the expressions for observables.

We would like to stress once more that the $\mathcal{R}$-operation works independently on the fact renormalizable or non-renormalizable the theory is. In local theory the counter-terms are local anyway. But only in renormalizable theory the counter-terms are reduced to the multiplicative renormalization of the finite number of fields and parameters.

One can perform the $\mathcal{R}$-operation for each diagram separately. For this purpose one has first of all to subtract the divergences in the subgraphs and then subtract the divergence in the diagram itself which has to be local. This serves as a good test that the divergences in the subgraphs are subtracted correctly. In this case the $\mathcal{R}$-operation can be symbolically written in a factorized form

$$\mathcal{R}G = \prod_{div.subgraphs} (1 - M_\gamma) G, \tag{18.79}$$

where G is the initial diagram, M is the subtraction operator (for instance, subtraction of the singular part of the regularized diagram) and the product goes over all divergent subgraphs including the diagram itself. By a subgraph we mean here the 1-particle irreducible diagram consisting of the vertices and lines of the diagram which is UV divergent. The 1-particle irreducible is called the diagram which can not be made disconnected by deleting of one line.

We have demonstrated above the application of the $\mathcal{R}$-operation to the two–loop diagrams in a scalar theory. Consider some other examples of diagrams with larger number of loops shown in Fig.18.14. They appear in the ϕ^4 theory in the three-loop approximation.

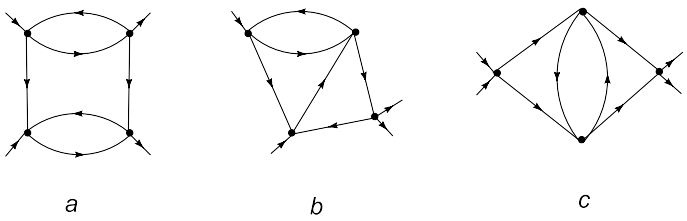


Figure 18.14: The multiloop diagrams in the ϕ^4 theory

In order to perform the $\mathcal{R}$-operation for these diagrams one first has to find out the divergent subgraphs. They are shown in Fig.18.15.

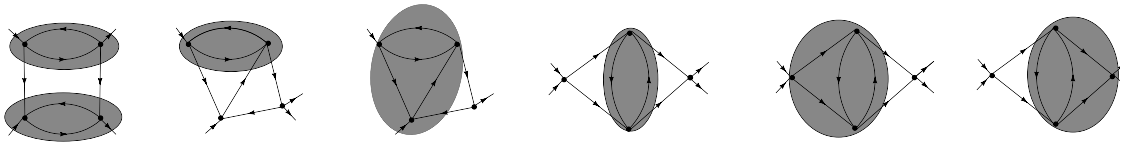

Figure 18.15: The divergent subgraphs in the diagrams of Fig.18.14

Let us use the factorized representation of the $\mathcal{R}$-operation in the form of (18.79). For the three chosen diagrams one has, respectively,

$$\begin{aligned} RG_a &= (1-M_G)(1-M_{\gamma_1})(1-M_{\gamma_1'})G_a, \\ RG_b &= (1-M_G)(1-M_{\gamma_2})(1-M_{\gamma_1})G, \\ RG_c &= (1-M_G)(1-M_{\gamma_2})(1-M_{\gamma_2'})(1-M_{\gamma_1})G, \end{aligned}$$

where γ_1 and γ_2 are the one- and two-loop divergent subgraphs shown in Fig.18.15.

The result of the application of the $\mathcal{R}$-operation without the last subtraction ($\mathcal{R}'$-operation) for the diagrams of interest graphically is as follows:

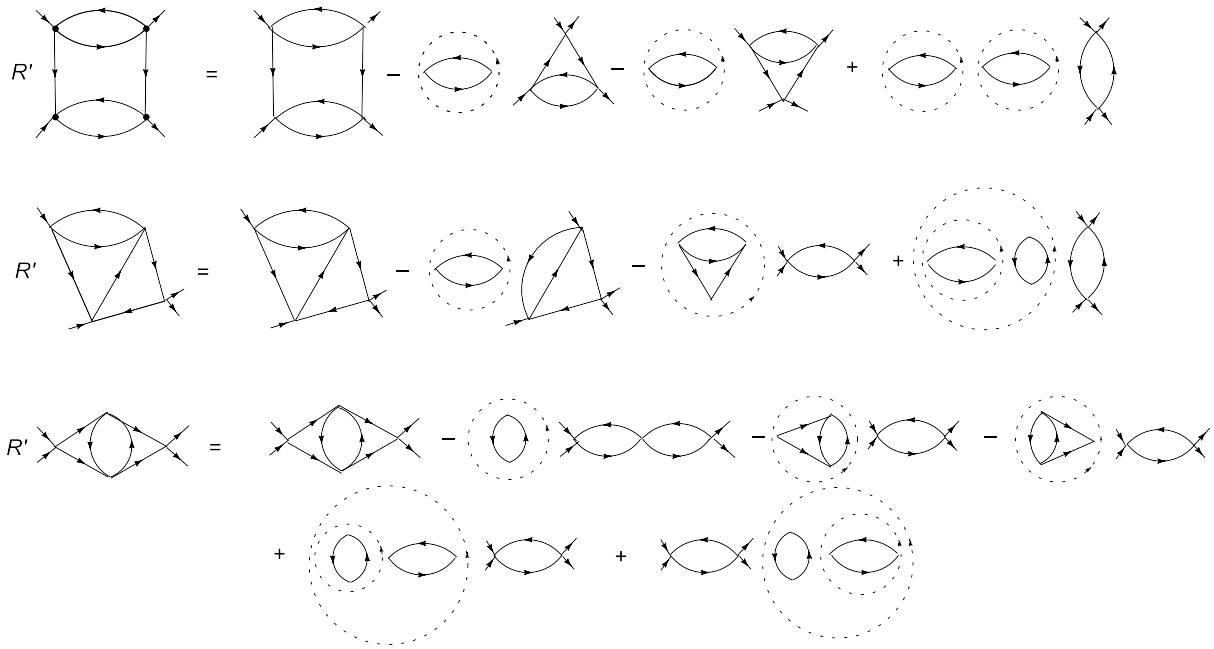

Figure 18.16: The $\mathcal{R}'$-operation for the multiloop diagrams

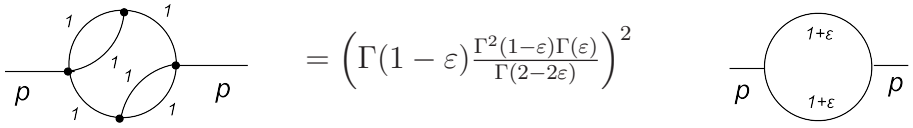
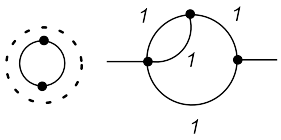
Here, as before, the graph surrounded with the dashed circle means its singular part and the remaining graph is obtained by shrinking the singular subgraph to a point.

Let us demonstrate how the $\mathcal{R}'$-operation works for the diagram Fig.18.14a). Since the result of the $\mathcal{R}'$-operation does not depend on external momenta, we put two momenta on the diagonal to be equal to zero so that the integral takes the propagator form. Then we can use the method based on Fourier-transform, as it was explained above. One has

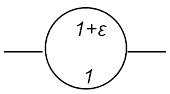


$$= \left(\Gamma(1-\varepsilon)\frac{\Gamma^2(1-\varepsilon)\Gamma(\varepsilon)}{\Gamma(2-2\varepsilon)}\right)^2 \left(\Gamma(1-\varepsilon)\frac{\Gamma^2(1-2\varepsilon)\Gamma(3\varepsilon)}{\Gamma^2(1+\varepsilon)\Gamma(2-4\varepsilon)}\right)\left(\frac{\mu^2}{p^2}\right)^{3\varepsilon} \cong \frac{1}{\varepsilon^3(1-2\varepsilon)^2(1-4\varepsilon)}\left(\frac{\mu^2}{p^2}\right)^{3\varepsilon}.$$

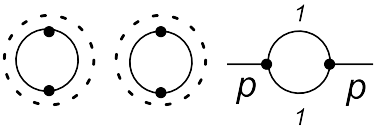
We use here the angular integration measure in the $4-2\varepsilon$ dimensional space accepted above, which results in the multiplication of the standard expression by $\Gamma(1-\varepsilon)$ in order to avoid the unwanted transcendental functions. Following the scheme shown in Fig.18.16 we get



$$= \tfrac{1}{\varepsilon}\Gamma(1-\varepsilon)\tfrac{\Gamma^2(1-\varepsilon)\Gamma(\varepsilon)}{\Gamma(2-2\varepsilon)}$$

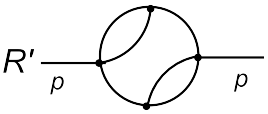


$$= \tfrac{1}{\varepsilon}\Gamma(1-\varepsilon)\tfrac{\Gamma^2(1-\varepsilon)\Gamma(\varepsilon)}{\Gamma(2-2\varepsilon)}\Gamma(1-\varepsilon)\tfrac{\Gamma(1-\varepsilon)\Gamma(1-2\varepsilon)\Gamma(2\varepsilon)}{\Gamma(1+\varepsilon)\Gamma(2-3\varepsilon)}\left(\tfrac{\mu^2}{p^2}\right)^{2\varepsilon} \cong \tfrac{1}{\varepsilon^3(1-2\varepsilon)(1-3\varepsilon)}\left(\tfrac{\mu^2}{p^2}\right)^{2\varepsilon}.$$



$$= \tfrac{1}{\varepsilon^2}\Gamma(1-\varepsilon)\tfrac{\Gamma^2(1-\varepsilon)\Gamma(\varepsilon)}{\Gamma(2-2\varepsilon)}\left(\tfrac{\mu^2}{p^2}\right)^{\varepsilon} \cong \tfrac{1}{\varepsilon^3(1-2\varepsilon)}\left(\tfrac{\mu^2}{p^2}\right)^{\varepsilon}.$$

Combining all together one finds



$$\cong \tfrac{1}{\varepsilon^3(1-2\varepsilon)^2(1-4\varepsilon)}\left(\tfrac{\mu^2}{p^2}\right)^{3\varepsilon} - 2\tfrac{1}{\varepsilon^3(1-2\varepsilon)}\left(\tfrac{\mu^2}{p^2}\right)^{\varepsilon} + \tfrac{1}{\varepsilon^3(1-2\varepsilon)}\left(\tfrac{\mu^2}{p^2}\right)^{\varepsilon}$$

$$= \frac{1-\varepsilon-\varepsilon^2}{\varepsilon^3}.$$

Note the cancellation of all nonlocal contributions. The singular part after the R'-operation is always local.

The realization of the $\mathcal{R}'$-operation for each diagram G allows one to find the contribution of a given diagram to the corresponding counter-term and, in the case of a renormalizable theory, to find the renormalization constant equal to

$$Z = 1 - \mathcal{K}\,\mathcal{R}'G, \tag{18.80}$$

where $\mathcal{K}$ means the extraction of the singular part. Adding the contribution of various diagrams we get the resulting counter-term of a given order and, accordingly, the renormalization constant.

18.5 K-l.V: Renormalization. Gauge Theories and the Standard Model

Consider now the gauge theories. The difference from the scalar case is in the relations between various renormalization constants which follow from the gauge invariance. If the regularization and the renormalization scheme do not break the symmetry these relations hold automatically. In the opposite case, this is an additional requirement imposed on the counter-terms.

18.5.1 Quantum electrodynamics

Quantum electrodynamics (34.2) is a renormalizable theory; hence, the counter-terms repeat the structure of the Lagrangian. They can be written as

$$\Delta\mathcal{L}_{QED} = -\frac{Z_3-1}{4}F_{\mu\nu}^2 + (Z_2-1)i\bar\psi\hat\partial\psi - m(Z-1)\bar\psi\psi + e(Z_1-1)\bar\psi\hat A\psi. \tag{18.81}$$

The term that fixes the gauge is not renormalized. In the leading order of perturbation theory we calculated the corresponding diagrams with the help of dimensional regularization (see

(18.32),(18.36),(18.40)). Their singular parts with the opposite sign give the proper renormalization constants. They are, respectively,

$$\begin{aligned} Z_1 &= 1-\frac{e^2}{16\pi^2}\frac{1}{\varepsilon}, \\ Z_2 &= 1-\frac{e^2}{16\pi^2}\frac{1}{\varepsilon}, \\ Z_3 &= 1-\frac{e^2}{16\pi^2}\frac{4}{3\varepsilon}, \\ Z &= 1-\frac{e^2}{16\pi^2}\frac{4}{\varepsilon}. \end{aligned} \tag{18.82}$$

Adding (18.81) with (34.2) we get

$$\begin{aligned} &\mathcal{L}_{QED}+\Delta\mathcal{L}_{QED} = -\frac{Z_3}{4}F_{\mu\nu}^2 + Z_2 i\bar\psi\hat\partial\psi - mZ\bar\psi\psi + eZ_1\bar\psi\hat A\psi - \frac{1}{2\xi}(\partial_\mu A_\mu)^2 \\ &= -\frac{1}{4}F_{\mu\nu B}^2 + i\bar\psi_B\hat\partial\psi_B - mZZ_2^{-1}\bar\psi_B\psi_B + eZ_1Z_2^{-1}Z_3^{-1/2}\bar\psi_B\hat A_B\psi_B \\ &\quad -\frac{Z_3^{-1}}{2\xi}(\partial_\mu A_{\mu B})^2, \end{aligned} \tag{18.83}$$

that gives

$$\psi_B = Z_2^{1/2}\psi, \quad A_B = Z_3^{1/2}A, \quad m_B = ZZ_2^{-1}m, \quad e_B = Z_1Z_2^{-1}Z_3^{-1/2}e, \quad \xi_B = Z_3\xi. \tag{18.84}$$

The gauge invariance here manifests itself in two places. First, the transversality of the radiative correction to the photon propagator means that the gauge fixing term is not renormalized and, hence, the gauge parameter ξ is renormalized as a gauge field. Second, the gauge invariance connects the vertex Green function and the fermion propagator (the Ward identity), which leads to the identity $Z_1 = Z_2$. Since the dimensional regularization which we use throughout the calculations does not break the gauge invariance, this identity is satisfied automatically (see (18.82)). This means that the renormalization of the coupling (18.84) is defined by the photon propagator only. Note, however, that this is not true in general in a non-Abelian theory.

18.5.2 Quantum chromodynamics

The complications which appear in non-Abelian theories are caused by the presence of many vertices with the same coupling as it follows from the gauge invariance. Hence, they have to renormalize the same way, i.e there appear new identities, called the Slavnov-Taylor identities. The full set of the counter-terms in QCD looks like

$$\begin{aligned} &\Delta\mathcal{L}_{QD} = -\frac{Z_3-1}{4}(\partial_\mu A_\nu^a - \partial_\nu A_\mu^a)^2 - g(Z_1-1)f^{abc}A_\mu^a A_\nu^b\partial_\mu A_\nu^c \\ &-(Z_4-1)\frac{g^2}{4}f^{abc}f^{ade}A_\mu^b A_\nu^c A_\mu^d A_\nu^e + (\tilde Z_3-1)\partial_\mu\bar c^a\partial_\mu c^a + g(\tilde Z_1-1)f^{abc}\partial_\mu\bar c^a A_\mu^b c^c \\ &+i(Z_2-1)\bar\psi\hat\partial\psi - m(Z-1)\bar\psi\psi + g(Z_{1\psi}-1)\bar\psi\hat A^a T^a\psi, \end{aligned} \tag{18.85}$$

that being added to the initial Lagrangian gives

$$\begin{aligned}
\mathcal{L}_{QD}+\Delta\mathcal{L}_{QD} &= -\frac{Z_3}{4}(\partial_\mu A^a_\nu-\partial_\nu A^a_\mu)^2 - gZ_1 f^{abc}A^a_\mu A^b_\nu \partial_\mu A^c_\nu \\
&-Z_4\frac{g^2}{4}f^{abc}f^{ade}A^b_\mu A^c_\nu A^d_\mu A^e_\nu - \tilde{Z}_3\partial_\mu\bar{c}^a\partial c^a - g\tilde{Z}_1 f^{abc}\partial_\mu\bar{c}^a A^b_\mu c^c \\
&+iZ_2\bar{\psi}\hat{\partial}\psi - mZ\bar{\psi}\psi + gZ_{1\psi}\bar{\psi}\hat{A}^a T^a\psi - \frac{1}{2\xi}(\partial_\mu A^a_\mu)^2 \\
&= -\frac{1}{4}(\partial_\mu A^a_{\nu B}-\partial_\nu A^a_{\mu B})^2 - gZ_1Z_3^{-3/2}f^{abc}A^a_{\mu B}A^b_{\nu B}\partial_\mu A^c_{\nu B} \\
&-Z_4Z_3^{-2}\frac{g^2}{4}f^{abc}f^{ade}A^b_{\mu B}A^c_{\nu B}A^d_{\mu B}A^e_{\nu B} + \partial_\mu\bar{c}^a_B\partial_\mu c^a_B + g\tilde{Z}_1\tilde{Z}_3^{-1}Z_3^{-1/2}f^{abc}\partial_\mu\bar{c}^a_B A^b_{\mu B}c^c_B \\
&+\frac{Z_3^{-1}}{2\xi}(\partial_\mu A^a_{\mu B})^2 + i\bar{\psi}_B\hat{\partial}\psi_B - mZZ_2^{-1}\bar{\psi}_B\psi_B + gZ_{1\psi}Z_2^{-1}Z_3^{-1/2}\bar{\psi}_B\hat{A}^a_B T^a\psi_B. \qquad (18.86)
\end{aligned}$$

This results in the relations between the renormalized and the "bare" fields and couplings

$$\begin{aligned}
&\psi_B = Z_2^{1/2}\psi, \quad A_B = Z_3^{1/2}A, \quad c_B = \tilde{Z}_3^{1/2}c, \\
&m_B = ZZ_2^{-1}m, \quad g_B = Z_1Z_3^{-3/2}g, \quad \xi_B = Z_3\xi, \qquad (18.87)\\
&Z_1Z_3^{-1} = \tilde{Z}_1\tilde{Z}_3^{-1}, \quad Z_4 = Z_1^2Z_3^{-1}, \quad Z_{1\psi}Z_2^{-1} = Z_1Z_3^{-1}.
\end{aligned}$$

The last line of equalities follows from the requirement of identical renormalization of the coupling in various vertices and represents the Slavnov-Taylor identities for the singular parts.

The explicit form of the renormalization constants in the lowest approximation follows from the one-loop diagrams calculated earlier (see (18.31), (18.36), (18.40), (18.48), (18.50), (18.56). Aa usual, one has to take the singular part with the opposite sign. One has in the $\overline{MS}$ scheme

$$\begin{aligned}
Z_2 &= 1-\frac{g^2}{16\pi^2}\frac{C_F}{\varepsilon}, \\
Z_3 &= 1+\frac{g^2}{16\pi^2}(\frac{5}{3\varepsilon}C_A-\frac{4}{3\varepsilon}T_f n_f), \\
Z &= 1-\frac{g^2}{16\pi^2}\frac{4C_F}{\varepsilon}, \\
\tilde{Z}_1 &= 1-\frac{g^2}{16\pi^2}\frac{C_A}{2\varepsilon}, \qquad (18.88)\\
\tilde{Z}_2 &= 1+\frac{g^2}{16\pi^2}\frac{C_A}{2\varepsilon}, \\
Z_g &= \tilde{Z}_1\tilde{Z}_2^{-1}Z_3^{-1/2} = 1-\frac{g^2}{16\pi^2}(\frac{11}{6\varepsilon}C_A-\frac{4}{3\varepsilon}T_f n_f),
\end{aligned}$$

where the following notation for the Casimir operators of the gauge group is used

$$f^{abc}f^{dbc} = C_A\delta^{ad}, \quad (T^aT^a)_{ij} = C_F\delta_{ij}, \quad Tr(T^aT^b) = T_F\delta^{ab}.$$

For the $SU(N)$ group and the fundamental representation of the fermion fields they are equal to

$$C_A = N, \quad C_F = \frac{N^2-1}{2N}, \quad T_F = \frac{1}{2}.$$

18.5.3 The Standard Model of fundamental interactions

In the Standard Model of fundamental interactions besides the gauge interactions and the quartic interaction of the Higgs fields there are also Yukawa type interactions of the fermion fields with the Higgs field. These interactions are also renormalizable and is characterized by the Yukawa coupling constants, one for each fermion field. The peculiarity of the SM is that the masses of the fields appear as a result of spontaneous symmetry breaking when the Higgs field develops a vacuum expectation value. As a result the masses are not independent but are expressed via the coupling constant multiplied by the vacuum expectation value. Here there are two possibilities: to treat the Yukawa couplings as independent quantities and to renormalize them in a usual way and then express the renormalized masses via the renormalized couplings or to start with the masses of particles and to treat the Yukawa couplings as secondary quantities. The first approach is usually used within the minimal subtraction scheme where the renormalizations do not depend on masses. On the contrary, in the scheme when the subtraction is carried out on mass shell (the so-called "on-shell" scheme), one usually takes masses of particles as the basis. Under this way of subtraction the pole of the propagator is not shifted and the renormalized mass coincides with the mass of a physical particle. Below we consider the renormalizations in the SM in the $\overline{MS}$ scheme and concentrate on the renormalization of the fields and the couplings.

Another property of the Standard Model is that it has the gauge group $SU_c(3)\times SU_L(2)\times U_Y(1)$ which is spontaneously broken to $SU_c(3)\times U_{EM}(1)$. In the theories with spontaneously broken symmetry, according to the Goldstone theorem there are massless particles, the goldstone bosons. These particles indeed are present in the SM but they are not the physical degrees of freedom and due to the Higgs effect are absorbed by vector bosons turning into longitudinal degrees of freedom of massive vector particles.

Thus, there are two possibilities to formulate the SM as a theory with spontaneous symmetry breaking: the *unitary* formulation in which nonphysical degrees of freedom are absent and vector bosons have three degrees of freedom, and the so-called *renormalizable* formulation in which goldstone bosons are present in the spectrum and vector fields have two degrees of freedom. These two formulations correspond to two different choices of the gauge in spontaneously broken theory.

In unitary gauge we have only physical degrees of freedom, i.e., the theory is automatically unitary, hence the name of this gauge. However, the propagator of the massive vector fields in this case has the form

$$G_{\mu\nu}(k) = -i\frac{g^{\mu\nu} - \frac{k^\mu k^\nu}{M^2}}{k^2 - M^2},$$

i.e., does nor decrease when momentum goes to infinity. This leads to the increase in the power of divergences and the theory happens to be formally nonrenormalizable despite the coupling constant being dimensionless. We have mentioned this fact in the first lecture.

On the other hand, in renormalizable gauge, where the vector fields have two degrees of freedom, the propagator behaves as

$$G_{\mu\nu}(k) = -i\frac{g^{\mu\nu} - \frac{k^\mu k^\nu}{k^2}}{k^2 - M^2},$$

which obviously leads to a renormalizable theory which explains the name of this gauge. However, the presence of the goldstone bosons calls into question the unitarity of the theory since transitions between the physical and unphysical states become possible.

Since all the gauges are equivalent, one can work in any of them but in the unitary gauge one has to prove the renormalizability while in the renormalizable gauge one has to prove unitarity.

The gauge invariance of observables preserved in a spontaneously broken theory should guarantee the fulfilment of both the requirements simultaneously. Note that in spontaneous symmetry breaking the symmetry of the Lagrangian is preserved, it is the boundary condition that breaks the symmetry.

The rigorous proof of that the theory is simultaneously renormalizable and unitary is not so obvious and eventually was awarded the Nobel prize, but can be seen by using some intermediate gauge called the R_ξ-gauge. The gauge fixing term in this case is chosen in the form

$$-\frac{1}{2\xi}(\partial_\mu A^a_\mu - \xi g F^a_i \chi_i)^2, \quad gF^a_i = \frac{v}{2}\begin{pmatrix} g & 0 & 0 \\ 0 & g & 0 \\ 0 & 0 & g \\ 0 & 0 & g' \end{pmatrix},$$

where v is the vacuum expectation value of the Higs field, and χ_i are the goldstone bosons. In this gauge the vector propagator has the form

$$G_{\mu\nu}(k) = -i\frac{g^{\mu\nu} - \frac{k^\mu k^\nu}{k^2 - \xi M^2}(1-\xi)}{k^2 - M^2},$$

and at $\xi = 0$ corresponds to the renormalizable gauge while as $\xi \to \infty$ it corresponds to the unitary one. Since all the observables do not depend on ξ, we can choose $\xi = 0$ when investigating the renormalizability properties and choose $\xi = \infty$ in examining the unitarity. Since we are interested here in the renormalizability of the SM, in what follows we will work in a renormalizable gauge.

The Lagrangian of the Standard Model consists of the following three parts:

$$\mathcal{L} = \mathcal{L}_{gauge} + \mathcal{L}_{Yukawa} + \mathcal{L}_{Higgs}, \tag{18.89}$$

The gauge part is totally fixed by the requirement of the gauge invariance leaving only the values of the couplings as free parameters

$$\begin{aligned} \mathcal{L}_{gauge} &= -\frac{1}{4}G^a_{\mu\nu}G^a_{\mu\nu} - \frac{1}{4}W^i_{\mu\nu}W^i_{\mu\nu} - \frac{1}{4}B_{\mu\nu}B_{\mu\nu} \\ &+ i\overline{L}_\alpha \gamma^\mu D_\mu L_\alpha + i\overline{Q}_\alpha \gamma^\mu D_\mu Q_\alpha + i\overline{E}_\alpha \gamma^\mu D_\mu E_\alpha \\ &+ i\overline{U}_\alpha \gamma^\mu D_\mu U_\alpha + i\overline{D}_\alpha \gamma^\mu D_\mu D_\alpha + (D_\mu H)^\dagger (D_\mu H), \end{aligned} \tag{18.90}$$

where the following notation for the covariant derivatives is used

$$\begin{aligned} G^a_{\mu\nu} &= \partial_\mu G^a_\nu - \partial_\nu G^a_\mu + g_s f^{abc} G^b_\mu G^c_\nu, \\ W^i_{\mu\nu} &= \partial_\mu W^i_\nu - \partial_\nu W^i_\mu + g\epsilon^{ijk} W^j_\mu W^k_\nu, \\ B_{\mu\nu} &= \partial_\mu B_\nu - \partial_\nu B_\mu, \\ D_\mu L_\alpha &= (\partial_\mu - i\frac{g}{2}\tau^i W^i_\mu + i\frac{g'}{2}B_\mu)L_\alpha, \\ D_\mu E_\alpha &= (\partial_\mu + ig'B_\mu)E_\alpha, \\ D_\mu Q_\alpha &= (\partial_\mu - i\frac{g}{2}\tau^i W^i_\mu - i\frac{g'}{6}B_\mu - i\frac{g_s}{2}\lambda^a G^a_\mu)Q_\alpha, \\ D_\mu U_\alpha &= (\partial_\mu - i\frac{2}{3}g'B_\mu - i\frac{g_s}{2}\lambda^a G^a_\mu)U_\alpha, \\ D_\mu D_\alpha &= (\partial_\mu + i\frac{1}{3}g'B_\mu - i\frac{g_s}{2}\lambda^a G^a_\mu)D_\alpha. \end{aligned}$$

The Yukawa part of the Lagrangian which is needed for the generation of the quark and lepton masses is also chosen in the gauge invariant form and contains arbitrary Yukawa couplings (we ignore the neutrino masses, for simplicity)

$$\mathcal{L}_{Yukawa} = y^L_{\alpha\beta}\overline{L}_\alpha E_\beta H + y^D_{\alpha\beta}\overline{Q}_\alpha D_\beta H + y^U_{\alpha\beta}\overline{Q}_\alpha U_\beta \tilde{H} + h.c., \tag{18.91}$$

where $\tilde{H} = i\tau_2 H^\dagger$.

At last the Higgs part of the Lagrangian contains the Higgs potential which is chosen in such a way that the Higgs field acquires the vacuum expectation value and the potential itself is stable

$$\mathcal{L}_{Higgs} = -V = m^2 H^\dagger H - \frac{\lambda}{2}(H^\dagger H)^2. \tag{18.92}$$

Here there are two arbitrary parameters: m^2 λ. The ghost fields and the gauge fixing terms are omitted.

The Lagrangian of the SM contains the following set of free parameters:

- 3 gauge couplings g_s, g, g';
- 3 Yukawa matrices $y^L_{\alpha\beta}, y^D_{\alpha\beta}, y^U_{\alpha\beta}$;
- Higgs coupling constant λ;
- Higgs mass parameter m^2;
- the number of the matter fields (generations).

All particles obtain their masses due to spontaneous breaking of the $SU_{left}(2)$ symmetry group via a nonzero vacuum expectation value (v.e.v.) of the Higgs field

$$< H >= \begin{pmatrix} v \\ 0 \end{pmatrix}, \qquad v = m/\sqrt{\lambda}. \tag{18.93}$$

As a result, the gauge group of the SM is spontaneously broken down to

$$SU_c(3) \otimes SU_L(2) \otimes U_Y(1) \Rightarrow SU_c(3) \otimes U_{EM}(1).$$

The physical weak intermediate bosons are linear combinations of the gauge ones

$$W^\pm_\mu = \frac{W^1_\mu \mp iW^2_\mu}{\sqrt{2}}, \qquad Z_\mu = -\sin\theta_W B_\mu + \cos\theta_W W^3_\mu \tag{18.94}$$

with masses

$$m_W = \frac{1}{\sqrt{2}} gv, \qquad m_Z = m_W/\cos\theta_W, \qquad \tan\theta_W = g'/g, \tag{18.95}$$

while the photon field

$$\gamma_\mu = \cos\theta_W B_\mu + \sin\theta_W W^3_\mu \tag{18.96}$$

remains massless.

The matter fields acquire masses proportional to the corresponding Yukawa couplings:

$$M^u_{\alpha\beta} = y^u_{\alpha\beta} v, \; M^d_{\alpha\beta} = y^d_{\alpha\beta} v, \; M^l_{\alpha\beta} = y^l_{\alpha\beta} v, \; m_H = \sqrt{2}m. \tag{18.97}$$

The mass matrices have to be diagonalized to get the quark and lepton masses.

The explicit mass terms in the Lagrangian are forbidden because they are not $SU_{left}(2)$ symmetric. They would destroy the gauge invariance and, hence, the renormalizability of the Standard Model. To preserve the gauge invariance we use the mechanism of spontaneous symmetry breaking which, as was explained above, allows one to get the renormalizable theory with massive fields.

The Feynman rules in the SM include the ones for QED and QCD with additional new vertices corresponding to the $SU(2)$ group and the Yukawa interaction, as well as the vertices with goldstone particles if one works in the renormalizable gauge. We will not write them down due to their complexity, though the general form is obvious.

Consider the one-loop divergent diagrams in the SM. Besides the familiar diagrams in QED and QCD discussed above one has the diagrams presented in Fig.18.17. The diagrams containing the goldstone bosons are omitted. The calculation of these diagrams is similar to what we have

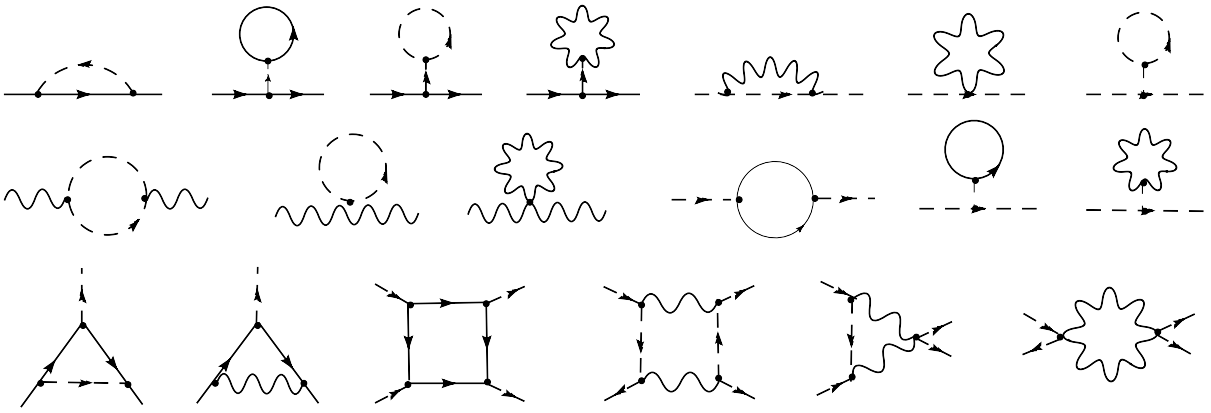


Figure 18.17: Some divergent one-loop diagrams in the SM. The dotted line denotes the Higgs field, the solid line - the quark and lepton fields, and the wavy line - the gauge fields

done above. Therefore, we show only the results for the renormalization constants of the fields

and the coupling constants. They have the form (for the gauge fields we use the Feynman gauge)

$$
\begin{aligned}
Z_{2Q_L} &= 1-\frac{1}{\varepsilon}\frac{1}{16\pi^2}[\frac{1}{36}g'^2+\frac{3}{4}g^2+\frac{4}{3}g_s^2+\frac{1}{2}y_U^2+\frac{1}{2}y_D^2],\\
Z_{2u_R} &= 1-\frac{1}{\varepsilon}\frac{1}{16\pi^2}[\frac{4}{9}g'^2+\frac{4}{3}g_s^2+y_U^2],\\
Z_{2d_R} &= 1-\frac{1}{\varepsilon}\frac{1}{16\pi^2}[\frac{1}{9}g'^2+\frac{4}{3}g_s^2+y_D^2],\\
Z_{2L_L} &= 1-\frac{1}{\varepsilon}\frac{1}{16\pi^2}[\frac{1}{4}g'^2+\frac{3}{4}g^2+\frac{1}{2}y_L^2],\\
Z_{2e_R} &= 1-\frac{1}{\varepsilon}\frac{1}{16\pi^2}[g'^2+y_L^2],\\
Z_{2H} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[\frac{1}{2}g'^2+\frac{3}{2}g^2-3y_U^2-3y_D^2-y_L^2],\\
Z_{3B} &= 1-\frac{1}{\varepsilon}\frac{1}{16\pi^2}[\frac{20}{9}N_F+\frac{1}{6}N_H]g'^2 \qquad \mathrm{U(1)_Y\ boson}\\
Z_{3A} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[3-\frac{32}{9}N_F]e^2 \qquad \mathrm{photon}\\
Z_{3W} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[\frac{10}{3}-\frac{1}{3}(N_F+3N_F)-\frac{1}{6}N_H]g^2,\\
Z_{3G} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[5-\frac{4}{3}N_F]g_s^2,\\
Z_{g_3^2} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[-11+\frac{4}{3}N_F]g_s^2,\\
Z_{g_2^2} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[-\frac{22}{3}+\frac{4}{3}N_F+\frac{1}{6}N_H]g^2,\\
Z_{g'^2} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[\frac{20}{9}N_F+\frac{1}{6}N_H]g'^2,\\
Z_{y_U^2} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[-\frac{17}{12}g'^2-\frac{9}{4}g^2-8g_s^2+\frac{9}{2}y_U^2+\frac{3}{2}y_D^2+y_L^2],\\
Z_{y_D^2} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[-\frac{5}{12}g'^2-\frac{9}{4}g^2-8g_s^2+\frac{3}{2}y_U^2+\frac{9}{2}y_D^2+y_L^2],\\
Z_{y_L^2} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[-\frac{15}{4}g'^2-\frac{9}{4}g^2+\frac{9}{4}y_L^2+3y_U^2+3y_D^2],\\
Z_\lambda &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[-\frac{3}{2}g'^2-\frac{9}{2}g^2+2)3y_U^2+3y_D^2+y_L^2)+6\lambda\\
&\quad -2)3y_U^4+3y_D^4+y_L^4)/\lambda+(\frac{3}{8}g'^4+\frac{9}{8}g^4+\frac{3}{4}g^2g'^2)/\lambda],
\end{aligned}
$$

where, for simplicity, we ignored the mixing between the generations and assumed the Yukawa matrices to be diagonal.

The difference from the expressions considered above is that the renormalization constant of the scalar coupling contains the terms of the type g^4/λ and y^4/λ. This is because writing the counter-term for the quartic vertex we factorized λ. The counter-terms themselves are proportional to g^4 and y^4 and are not equal to zero. Thus, the quantum corrections generate a new interaction even if it is absent initially. Since the gauge and Yukawa interactions belong to the renormalizable type, the number of types of the counter-terms is finite and the only new interaction which is generated this way, if it was absent, is the quartic scalar one. With allowance for this interaction the model is renormalizable.

Since the masses of all the particles are equal to the product of the gauge or Yukawa couplings and the vacuum expectation value of the Higgs field, in the minimal subtraction scheme the mass ratios are renormalized the same way as the ratio of couplings. To find the renormalization of the mass itself, one should know how the v.e.v. is renormalized or find explicitly the mass counter-term from Feynman diagrams. In this case, one has also to take into account the tad-pole diagrams shown in Fig.18.17, including the diagrams with goldstone bosons.

For illustration we present the renormalization constant of the b-quark mass in the SM

$$\begin{aligned} Z_{m_b} &= 1+\frac{1}{\varepsilon}\frac{1}{16\pi^2}[\sum_l \frac{y_l^4}{\lambda}+3\sum_q \frac{y_q^4}{\lambda}-\frac{3}{2}\lambda+\frac{3}{4}(y_b^2-y_t^2) \\ &- \frac{3}{16}\frac{(g^2+g'^2)^2}{\lambda}-\frac{3}{8}\frac{g^4}{\lambda}-3Q_b(Q_b-T_b^3)g'^2-4g_s^2]. \end{aligned} \tag{18.98}$$

The result for the t-quark can be obtained by replacing b by t. For the light quarks the Yukawa constants are very small and can be ignored in eq.(34.268).

Note that here we again have the Higgs self-interaction coupling λ in the denominator. It appears from the tad-pole diagrams but, contrary to the previous case, the renormalization constant Z_{m_q} is not multiplied by λ and the denominator is not cancelled. This does not lead to any problems in perturbation theory since by order of magnitude $\lambda \sim g^2 \sim y^2$ and the loop expansion is still valid.

18.6 K-l.VI: Renormalization Group

The procedure formulated above allows one to eliminate the ultraviolet divergences and get the finite expression for any Green function in any local quantum field theory. In renormalizable theories this procedure is reduced to the multiplicative renormalization of parameters (masses and couplings) and multiplication of the Green function by its own renormalization constant. This is true for any regularization and subtraction scheme. Thus, for example, in the cutoff regularization and dimensional regularization the relation between the "bare" and renormalized Green functions looks like

$$\Gamma(\{p^2\},\mu^2,\{g_\mu\}) = Z_\Gamma(\Lambda^2/\mu^2,\{g_\mu\})\Gamma_{Bare}(\{p^2\},\Lambda,\{g_{Bare}\}) \tag{18.99}$$

$$\Gamma(\{p^2\},\mu^2,\{g_\mu\}) = Z_\Gamma(1/\varepsilon,\{g_\mu\})\Gamma_{Bare}(\{p^2\},1/\varepsilon,\{g_{Bare}\}), \tag{18.100}$$

where $\{p^2\}$ is the set of external momenta, $\{g\}$ is the set of masses and couplings, and

$$g_{Bare} = Z_g()\Lambda^2/\mu^2,\{g_\mu\})g \quad \text{or} \quad g_{Bare} = Z_g((1/\varepsilon,\{g_\mu\})g.$$

It is obvious that the operation of multiplication by the constant Z obeys the group property. Indeed, after the elimination of divergences one can multiply the couplings, masses and the Green functions by finite constants and this will be equivalent to the choice of another renormalization scheme. Since these finite constants can be changed continuously, we have a continuous Lie group which got the name of renormalization group. The group transformations of multiplication of the couplings and the Green functions are called the Dyson transformations.

18.6.1 The group equations and solutions via the method of characteristics

In what follows we stick to dimensional regularization and rewrite relation (18.100) in the form

$$\Gamma_{Bare}(\{p^2\},1/\varepsilon,\{g_{Bare}\}) = Z_\Gamma^{-1}(1/\varepsilon,\{g_\mu\})\Gamma(\{p^2\},\mu^2,\{g_\mu\}). \tag{18.101}$$

It is obvious that the l.h.s. of this equation does not depend on the parameter of dimensional transmutation μ and, hence, the r.h.s. should not also depend on it. This allows us to write the functional equation for the renormalized Green function. Differentiating it with respect to the continuous parameter μ one can get the differential equation which has a practical value: solving this equation one can get the improved expression for the Green function which corresponds to summation of an infinite series of Feynman diagrams.

Consider an arbitrary Green function Γ obeying equation (18.100) with the normalization condition

$$\Gamma(\{p^2\}, \mu^2, 0) = 1.$$

Differentiating (18.100) with respect to μ^2 one gets:

$$\mu^2 \frac{d}{d\mu^2}\Gamma = \left(\mu^2 \frac{\partial}{\partial \mu^2} + \mu^2 \frac{\partial g}{\partial \mu^2}\frac{\partial}{\partial g}\right)\Gamma = \mu^2 \frac{d \ln Z_\Gamma}{d\mu^2} Z_\Gamma \Gamma_{Bare},$$

or

$$\left(\mu^2 \frac{\partial}{\partial \mu^2} + \beta(g)\frac{\partial}{\partial g} + \gamma_\Gamma\right)\Gamma(\{p^2\}, \mu^2, g_\mu) = 0, \tag{18.102}$$

where we have introduced the so-called beta function $\beta(g)$ and the anomaly dimension of the Green function $\gamma_\Gamma(g)$ defined as

$$\beta = \mu^2 \frac{dg}{d\mu^2}|_{g_{bare}}, \tag{18.103}$$

$$\gamma_\Gamma = -\mu^2 \frac{d \ln Z_\Gamma}{d\mu^2}|_{g_{bare}}. \tag{18.104}$$

Equation (18.102) is called the *renormalization group equation* in partial derivatives (in Ovsyannikov form). In the western literature it is also called the Callan-Simanzik equation.

The solution of the renormalization group equation can be written in terms of characteristics:

$$\Gamma\left(e^t \frac{\{p^2\}}{\mu^2}, g\right) = \Gamma\left(\frac{\{p^2\}}{\mu^2}, \bar{g}(t, g)\right) \mathrm{e}^{\int\limits_0^t \gamma_\Gamma(\bar{g}(t,g))dt}, \tag{18.105}$$

where the characteristic equation is (for definiteness we restrict ourselves to a single coupling)

$$\frac{d}{dt}\bar{g}(t, g) = \beta(\bar{g}), \quad \bar{g}(0, g) = g. \tag{18.106}$$

The quantity $\bar{g}(t, g)$ is called the *effective charge* or *effective coupling*.

We will consider the useful properties of this solution (18.105) later and we first derive several other similar equations. Since the vertex function usually comes with the coupling, one can consider the product

$$g\Gamma\left(\frac{\{p^2\}}{\mu^2}, g\right). \tag{18.107}$$

If Γ is the n-point function, then the renormalization of the coupling g is given by

$$g_{Bare} = Z_\Gamma Z_2^{-n/2} g,$$

and the product (18.107) is renormalized as

$$g\Gamma = Z_2^{n/2} g_{Bare}\Gamma_{Bare}.$$

Hence, one has the same equation as (18.100) with solution (18.105) but with $Z_\Gamma = Z_2^{n/2}$ and $\gamma_\Gamma = -n/2\gamma_2$. (Recall that the anomalous dimension γ_2 is defined with respect to the renormalization constant Z_2^{-1}.)

Furthermore, one can construct the so-called *invariant charge* by multiplying the product (18.107) by the corresponding propagators

$$\xi = g\Gamma\left(\frac{\{p^2\}}{\mu^2}, g\right)\prod_i^n D^{1/2}\left(\frac{p_i^2}{\mu^2}, g\right). \tag{18.108}$$

The invariant charge ξ, being RG-invariant, obeys the RG equation without the anomalous dimension and plays an important role in the formulation of the renormalization group together with the effective charge. In some cases, for instance in the MOM subtraction scheme, the effective and invariant charges coincide.

The usefulness of solution (18.105) is that it allows one to sum up an infinite series of logs coming from the Feynman diagrams in the infrared ($t \to -\infty$) or ultraviolet ($t \to \infty$) regime and improve the usual perturbation theory expansions. This in its turn extends the applicability of perturbation theory and allows one to study the infrared or the ultraviolet asymptotics of the Green functions.

To demonstrate the power of the RG, let us consider the invariant charge in a theory with a single coupling and restrict ourselves to the massless case. Let the perturbative expansion be

$$\xi(\frac{p^2}{\mu^2}, g) = g(1 + bg\ln\frac{p^2}{\mu^2} + ...). \tag{18.109}$$

The β function in the one-loop approximation is given by

$$\beta(g) = bg^2. \tag{18.110}$$

Notice that the coefficient b of the logarithm in eq.(18.109) coincides with that of the β function. Alternatively the β function can be defined as the derivative of the invariant charge with respect to logarithm of momentum

$$\beta(g) = p^2\frac{d}{dp^2}\xi(\frac{p^2}{\mu^2}, g)|_{p^2=\mu^2}. \tag{18.111}$$

This definition is useful in the MOM scheme where the mass is not considered as a coupling but as a parameter and the renormalization constants depend on it. We will come back to the discussion of this question below when considering different definitions of the mass.

According to eq.(18.105) (with vanishing anomalous dimension) the RG-improved expression for the invariant charge corresponding to the perturbative expression (18.109) is:

$$\xi_{RG}(\frac{p^2}{\mu^2}, g) = \xi_{PT}(1, \bar{g}(\frac{p^2}{\mu^2}, g)) = \bar{g}(\frac{p^2}{\mu^2}, g), \tag{18.112}$$

where we have put in eq.(18.105) $p^2 = \mu^2$ and then replaced t by $t = \ln p^2/\mu^2$. The effective coupling is a solution of the characteristic equation

$$\frac{d}{dt}\bar{g}(t, g) = b\bar{g}^2, \quad \bar{g}(0, g) = g, \quad t \equiv \ln\frac{p^2}{\mu^2}. \tag{18.113}$$

The solution of this equation is

$$\bar{g}(t,g) = \frac{g}{1-bgt}. \tag{18.114}$$

Being expanded over t, the geometrical progression (18.114) reproduces the expansion (18.109); however, it sums the infinite series of terms of the form $g^n t^n$. This is called the leading log approximation (LLA) in QFT. To get the correction to the LLA, one has to consider the next term in the expansion of the β function. Then one can sum up the next series of terms of the form $g^n t^{n-1}$ which is called the next to leading log approximation (NLLA), etc. This procedure allows one to describe the leading asymptotics of the Green functions for $t \to \pm\infty$.

Consider now the Green function with non-zero anomalous dimension. Let its perturbative expansion be

$$\Gamma(\frac{p^2}{\mu^2}, g) = 1 + cg \ln \frac{p^2}{\mu^2} + ... \tag{18.115}$$

Then in the one-loop approximation the anomalous dimension is

$$\gamma(g) = cg. \tag{18.116}$$

Again the coefficient of the logarithm coincides with that of the anomalous dimension. In analogy with eq.(18.111) the anomalous dimension can be defined as a derivative with respect to the logarithm of momentum

$$\gamma(g) = p^2 \frac{d}{dp^2} \ln \Gamma(\frac{p^2}{\mu^2}, g)|_{p^2=\mu^2}. \tag{18.117}$$

Substituting (18.116) into eq.(18.105), one has in the exponent

$$\int_0^t \gamma(\bar{g}(t,g)dt = \int_g^{\bar{g}} \frac{\gamma(g)}{\beta(g)} dg = \int_g^{\bar{g}} \frac{cg}{bg^2} dg = \frac{c}{b} \ln \frac{\bar{g}}{g}.$$

This gives for the Green function the improved expression

$$\Gamma_{RG} = \left(\frac{\bar{g}}{g}\right)^{-c/b} = \left(\frac{1}{1-bgt}\right)^{c/b} \approx 1 + ct + ... \tag{18.118}$$

Thus, one again reproduces the perturbative expansion, but expression (18.118) again contains the whole infinite sum of the leading logs. To get the NLLA, one has to take into account the next term in eq.(18.116) together with the next term of expansion of the β function.

All the formulas can be easily generalized to the case of multiple couplings and masses.

18.6.2 The effective coupling

By virtue of the central role played by the effective coupling in RG formulas, consider it in more detail. The behaviour of the effective coupling is determined by the β function. Qualitatively, the β function can exhibit the behaviour shown in Fig.18.18. We restrict ourselves to the region of small couplings.

In the first case, the β-function is positive. Hence, with increasing momentum the effective coupling unboundedly increases. This situation is typical of most of the models of QFT in the one-loop approximation when $\beta(g) = bg^2$ and $b > 0$. The solution of the RG equation for the effective coupling in this case has the form of a geometric progression (18.114). It is characterized

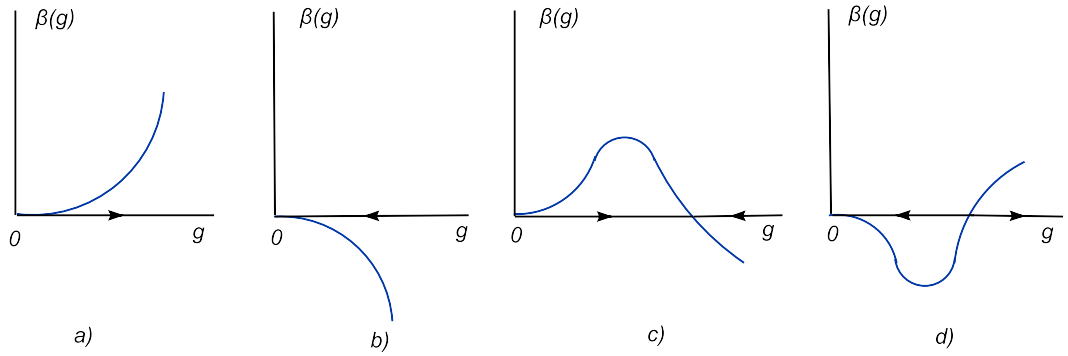

Figure 18.18: The possible form of the β-function. The arrows show the behaviour of the effective coupling in the ultraviolet regime ($t \to \infty$)

by the presence of a pole at high energies, called the Landau pole. We will consider this pole in detail later.

In the second case, the β-function is negative and, hence, the effective coupling decreases with increasing momentum. This situation appears in the one-loop approximation when $b < 0$, which takes place in the gauge theories. Here we also have a pole but in the infrared region.

In the third case, the β-function has zero: at first, it is positive and then is negative. This means that for small initial values the effective coupling increases; and for large ones, decreases. In both the cases, with increasing momentum it tends to the fixed value defined by the zero of the β-function. This is the so-called ultraviolet stable *fixed point*. It appears in some models in higher orders of perturbation theory.

Eventually, in the last case one also has the fixed point but now for the small initial coupling it decreases and for the large one it increases, i.e., with increasing momentum the effective coupling moves away from the fixed point, it is ultraviolet unstable. On the contrary, with decreasing momentum it tends to the fixed point, i.e., it is infrared stable. It appears in some models in lower dimensions, for instance, in statistical physics.

18.6.3 Dimensional regularization and the $\overline{MS}$ scheme

Consider now the calculation of the β function and the anomalous dimensions in some particular models within the dimensional regularization and the minimal subtraction scheme. Note that in transition from dimension 4 to $4 - 2\varepsilon$ the dimension of the coupling is changed and the "bare" coupling acquires the dimension $[g_B] = 2\varepsilon$. That is why the relation between the "bare" and renormalized coupling contains the factor $(\mu^2)^\varepsilon$

$$g_B = (\mu^2)^\varepsilon Z_g g. \tag{18.119}$$

Hence, even before the renormalization when $Z_g = 1$, in order to compensate this factor the dimensionless coupling g should depend on μ. Differentiating (18.119) with respect to μ^2 one gets

$$0 = \varepsilon Z_g g + \frac{d\log Z_g}{d\log\mu^2} Z_g g + Z_g \frac{dg}{d\log\mu^2},$$

i.e.,

$$\beta_{4-2\varepsilon}(g) \equiv \frac{dg}{d\log\mu^2} = -\varepsilon g + g\frac{d\log Z_g}{d\log\mu^2} = -\varepsilon g + \beta_4(g). \tag{18.120}$$

In the $\overline{MS}$ scheme the renormalization constants are given by the pole terms in $1/\varepsilon$ expansion and so does the bare coupling. They can be written as

$$Z_\Gamma = 1 + \sum_{n=1}^{\infty} \frac{c_n(g)}{\varepsilon^n} = 1 + \sum_{n=1}^{\infty} \sum_{m=n}^{\infty} \frac{c_{nm} g^m}{\varepsilon^n}. \tag{18.121}$$

And similarly

$$g_{Bare} = (\mu^2)^\varepsilon \left[g + \sum_{n=1}^{\infty} \frac{a_n(g)}{\varepsilon^n} \right] = (\mu^2)^\varepsilon \left[g + \sum_{n=1}^{\infty} \sum_{m=n}^{\infty} \frac{a_{nm} g^{m+1}}{\varepsilon^n} \right]. \tag{18.122}$$

Differentiating eq.(18.121) with respect to $\ln \mu^2$ and having in mind the definitions (18.103) and (18.104), one has:

$$-[1 + \sum_{n=1}^{\infty} \frac{c_n(g)}{\varepsilon^n}] \gamma_\Gamma(g) = [-\varepsilon g + \beta(g)] \frac{d}{dg} \sum_{n=1}^{\infty} \frac{c_n(g)}{\varepsilon^n}.$$

Equalizing the coefficients of equal powers of ε, one finds

$$\gamma_\Gamma(g) = g \frac{d}{dg} c_1(g), \tag{18.123}$$

$$g \frac{d}{dg} c_n(g) = [\gamma_\Gamma(g) + \beta(g) \frac{d}{dg}] c_{n-1}(g), \quad n \geq 2. \tag{18.124}$$

One sees that the coefficients of higher poles c_n, $n \geq 2$ are completely defined by that of the lowest pole c_1 and the β function. In its turn the β-function is also defined by the lowest pole. To see this, consider eq.(18.122). Differentiating it with respect to $\ln \mu^2$ one has

$$\varepsilon \left[g + \sum_{n=1}^{\infty} \frac{a_n(g)}{\varepsilon^n} \right] + [-\varepsilon g + \beta(g)] \left[1 + \frac{d}{dg} \sum_{n=1}^{\infty} \frac{a_n(g)}{\varepsilon^n} \right] = 0. \tag{18.125}$$

Equalizing the coefficients of equal powers of ε, one finds

$$\beta(g) = (g \frac{d}{dg} - 1) a_1(g), \tag{18.126}$$

$$(g \frac{d}{dg} - 1) a_n(g) = \beta(g) \frac{d}{dg} a_{n-1}(g), \quad n \geq 2. \tag{18.127}$$

Thus, knowing the coefficients of the lower poles one can reproduce all the higher order divergences. This means that they are not independent, all the information about them is connected in the lowest pole. In particular, substituting in (18.127) the perturbative expansion (18.122) one can solve the recurrent equation and find for the highest pole term

$$a_{nn} = a_{11}^n, \tag{18.128}$$

i.e. in the leading order one has the geometric progression

$$g_B = \mu^{2\varepsilon} \frac{g}{1 - g a_{11}/\varepsilon}, \tag{18.129}$$

which reflects the fact that the effective coupling in the LLA is also given by a geometric progression (18.114).

The pole equations are easily generalized for the multiple couplings case, the higher poles are also expressed through the lower ones though the solutions of the RG equations are more complicated.

Consider now some particular models and calculate the corresponding β-functions and the anomalous dimensions.

The ϕ^4 theory

The renormalization constants in the $\overline{MS}$ scheme up to two loops are given by eqs. (18.66,18.70,18.74). ($g \equiv \lambda/16\pi^2$)

$$Z_4 = 1 + \frac{3}{2\varepsilon}g + g^2\left(\frac{9}{4\varepsilon^2} - \frac{3}{2\varepsilon}\right), \tag{18.130}$$

$$Z_2^{-1} = 1 + \frac{g^2}{24\varepsilon}, \tag{18.131}$$

$$Z_g = 1 + \frac{3}{2\varepsilon}g + g^2\left(\frac{9}{4\varepsilon^2} - \frac{17}{12\varepsilon}\right). \tag{18.132}$$

Notice that the higher pole coefficient $a_{22} = 9/4$ in the last expression is the square of the lowest pole one $a_{11} = 3/2$ in accordance with eq.(18.128).

Applying now eqs.(18.123) and (18.126) one gets

$$\gamma_4(g) = \frac{3}{2}g - 3g^2, \tag{18.133}$$

$$\gamma_2(g) = \frac{1}{12}g^2, \tag{18.134}$$

$$\beta(g) = g(\gamma_4 + 2\gamma_2) = \frac{3}{2}g^2 - \frac{17}{6}g^2. \tag{18.135}$$

One can see from eq.(18.135) that the first coefficient of the β-function is 3/2, i.e., the ϕ^4 theory belongs to the type of theories shown in Fig.18.18a). In the leading log approximation (LLA) one has a Landau pole behaviour. In the two-loop approximation (NLLA) the β-function gets a non-trivial zero and the effective coupling possesses an UV fixed point like the one shown in Fig.18.18). However, this fixed point is unstable with respect to higher orders and is not reliable. Here we encounter the problem of divergence of perturbation series in quantum field theory, they are the so-called asymptotic series which have a zero radius of convergence.

QED

In QED in the one-loop approximation the renormalization constants in the Feynman gauge are given by eq.(18.82). Due to the Ward identities the renormalization of the coupling is defined by the photon wave function renormalization constant Z_3 and is gauge invariant. Equation (18.82) allows one to determine the anomalous dimensions and the β-function

$$\gamma_1(\alpha) = -\alpha, \tag{18.136}$$

$$\gamma_2(\alpha) = \alpha, \tag{18.137}$$

$$\gamma_3(\alpha) = \frac{4}{3}\alpha, \tag{18.138}$$

$$\gamma_m(\alpha) = -4\alpha, \tag{18.139}$$

$$\beta_\alpha(\alpha) = \frac{4}{3}\alpha^2, \tag{18.140}$$

where we use the notation $\alpha \equiv e^2/16\pi^2$.

Thus, in QED in the one-loop approximation the effective coupling behaves the same way a in the ϕ^4 theory and has a Landau pole in the LLA. In this theory, the next term of expansion of the β-function is also calculated. It has the same sign.

QCD

In QCD the calculation of the β function can be based on various vertices. The result should be the same due to the gauge invariance. To simplify the calculations, we choose the ghost-ghost-vector vertex. The renormalization constants in the one-loop approximation in the Feynman gauge are given by (18.88) and lead to the following anomalous dimensions and the β-function:

$$\tilde{\gamma}_1(\alpha) = -\frac{C_2}{2}\alpha, \tag{18.141}$$

$$\tilde{\gamma}_2(\alpha) = -\frac{C_2}{2}\alpha, \tag{18.142}$$

$$\gamma_3(\alpha) = -(\frac{5}{3}C_2 - \frac{2}{3}n_f)\alpha, \tag{18.143}$$

$$\beta_\alpha(\alpha) = \alpha(2\tilde{\gamma}_1 + 2\tilde{\gamma}_2 + \gamma_3) = -(\frac{11}{3}C_- \frac{2}{3}n_f)\alpha^2, \tag{18.144}$$

where like in QED we take $\alpha \equiv g^2/16\pi^2$, the Casimir operator C in the case of SU(3) groups is equal to 3, and n_f is the number of quark flavours.

One can see from eq.(18.144) that if the number of flavours is less than $\frac{11}{2}C_2 = \frac{33}{2}$, the β-function is negative and the effective coupling decreases and tends to zero with increasing momentum. This type of behaviour of the effective coupling is called the *asymptotic freedom*. It takes place only in gauge theories.

18.6.4 Λ_{QCD}

The solution of the characteristic equation for the effective coupling, which is a differential equation of the first order, depends on initial conditions. Therefore, the solution (18.114) depends on the choice of the initial point and the value of the coupling at this point. However, this choice is not unique and one can choose another initial point and another value of the coupling and still get the same solution, as it is shown in Fig.18.19.

In fact, every curve is not characterized by two numbers (the initial point and the coupling), but by one number and the transition from one curve to another is defined by the change of this number. To see this, consider the one-loop expression for the effective coupling in a gauge theory and rewrite it in equivalent form

$$\bar{g}(\frac{Q^2}{\mu^2}, g_\mu) = \frac{g_\mu}{1 - \beta_0 g_\mu \ln\frac{Q^2}{\mu^2}} = \frac{1}{\frac{1}{g_\mu} - \beta_0 \ln\frac{Q^2}{\mu^2}} \equiv -\frac{1}{\beta_0 \ln\frac{Q^2}{\Lambda^2}} = \bar{g}(\frac{Q^2}{\Lambda^2}), \tag{18.145}$$

where we have introduced the notation

$$\Lambda^2 = \mu^2 e^{-\frac{1}{\beta_0 \alpha_\mu}}. \tag{18.146}$$

This quantity is called Λ_{QCD} in quantum chromodynamics and can be introduced in any model. The numerical value of Λ is defined from experiment.

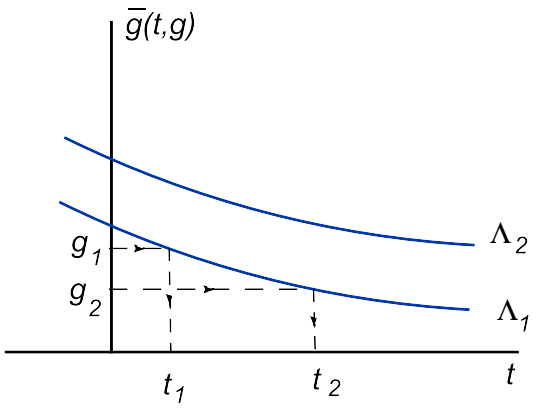

Figure 18.19: Different parametrizations of the effective coupling. Each curve is characterized by a single parameter Λ

Equation (18.146) can be generalized to any number of loops. For this purpose, let us rewrite the RG equation for the effective coupling in the Gell-Mann – Low form. One has

$$\ln \frac{Q^2}{\mu^2} = \int\limits_{g_\mu}^{g_Q} \frac{dg}{\beta_g(g)}. \tag{18.147}$$

Combining the lower limit with $\ln \mu^2$ one gets

$$\ln \frac{Q^2}{\Lambda^2} = \int^{g_Q} \frac{dg}{\beta_g(g)}, \tag{18.148}$$

where

$$\Lambda^2 = \mu^2 exp\left(\int^{g_\mu} \frac{dg}{\beta_g(g)} \right), \tag{18.149}$$

which is the generalization of eq.(18.146) for an arbitrary number of loops.

The quantity Λ, introduced this way, is μ-independent but depends on the renormalization scheme due to the scheme dependence of the β-function. However, the scheme dependence of Λ is given exactly (!) in one-loop order. Indeed, since Λ does not depend on μ, let us choose μ in such a way that $g_\mu \to 0$. Then for the β-function one can use the perturbative expansion

$$\beta_\alpha(\alpha) = \beta_0 \alpha^2 + \beta_1 \alpha^3 + ...$$

or

$$\int \frac{d\alpha}{\beta(\alpha)} = -\frac{1}{\beta_0 \alpha} + \ln \alpha + O(\alpha).$$

In this limit the ratio of two parameters Λ belonging to two different schemes is

$$\ln \frac{\Lambda_1^2}{\Lambda_2^2} = -\frac{1}{\beta_0}\left[\frac{1}{\alpha_1} - \frac{1}{\alpha_2}\right] = -\frac{1}{\beta_0}\left[c_1 - c_2\right], \tag{18.150}$$

where the coefficients c_1 and c_2 are calculated in the one-loop order. They can be found from perturbative expansion of any physical quantity in two different schemes

$$\begin{aligned} R &= g_1(1 + c_1 g_1 + ...) \\ &= g_2(1 + c_2 g_2 + ...). \end{aligned}$$

Since Λ does not depend on g, one can take any value of g, and eq.(18.150) is always valid. The difference $c_1 - c_2$ does not depend on a particular choice of R (though each of them depends) and is universal.

It should be noted that the quantities like the invariant or effective coupling, the β-function, etc. are not directly observable. Therefore, their dependence on the subtraction scheme does not contradict the independence of predictions of the method of calculations. We perform the perturbative expansion over the coupling which is scheme dependent, but the coefficients are also scheme dependent. As a result, within the given accuracy defined by the order of perturbation theory the answer is universal.

In the minimal subtraction schemes when the renormalizations depend only on dimensionless couplings, the one-loop renormalization constants and hence the anomalous dimensions and the β-function are the same in all schemes; the difference starts from two loops. The exception is the β-function in a theory with a single coupling like QED, QCD or the ϕ^4 theory, where the difference starts from three loops. Indeed, if one has two subtraction schemes M_1 and M_2 so that the couplings in two schemes are related by

$$g_2 = q(g_1) = g_1 + c g_1^2 + O(g_1^3),$$

then the β-functions $\beta_1(g_1)$ and $\beta_2(g_2)$ are connected by the relation

$$\beta_2(g_2) = \frac{dq(g_1)}{dg_1}\beta_1(g_1)$$

and their perturbative expansions are

$$\begin{aligned} \beta_1(g_1) &= \beta_0 g_1 + \beta_1 g_1^2 + \beta_2 g_1^3 + ..., \\ \beta_2(g_2) &= \beta_0 g_2 + \beta_1 g_2^2 + \beta_2' g_2^3 + ... \end{aligned}$$

so that the first two terms of the β-function are universal.

As for the further terms of expansion, they depend on the renormalization scheme and one can use this dependence as discretion, for instance, one can put all of them equal to zero. Then we would have an exact β-function. However, one should have in mind that it is not valuable by itself but rather in the aggregate with the PT expansion for the Green functions for which we construct the solution of the RG equation. This expansion in our "exact" scheme is unknown.

18.6.5 The running masses

In the minimal subtraction scheme the renormalization of the mass is performed the same way as the renormalization of the couplings, i.e., the mass is treated as an additional coupling and is renormalized multiplicatively, namely,

$$m_{Bare} = Z_m m,$$

where the mass renormalization constant Z_m is independent of the mass parameters and depends only on dimensionless couplings. Then, in full analogy with the effective coupling one can introduce the *effective* or the "running" mass

$$\frac{d}{dt}\bar{m}(t,g) = \bar{m}\gamma_m(\bar{g}), \quad \bar{m}(0,g) = m_0. \tag{18.151}$$

Solving this equation together with the equation for the effective coupling (18.106) one has

$$\bar{m}(t,g) = m_0 \mathrm{e}^{\int\limits_0^t \gamma_m(\bar{g}(t,g))dt} = m_0 \mathrm{e}^{\int\limits_g^{\bar{g}} \frac{\gamma(g)}{\beta(g)}dg}. \tag{18.152}$$

In the one-loop order

$$\beta(\alpha) = b\alpha^2, \quad \gamma_m(\alpha) = c\alpha$$

and the solution is

$$m(t) = m_0 \left(\frac{\alpha(t)}{\alpha_0}\right)^{c/b}.$$

This is the running mass!

The natural question arises: what is the physical mass measured in experiment and how is it related to the running mass and at what scale?

To answer this question, consider why the mass is running. This is due to the radiative corrections. If one considers the value of momentum which is bigger than the mass, i.e. $p^2 > m^2$, then the particles are created, they are running inside the loops and give the contribution to the running. On the contrary, if $p^2 < m^2$, particles are not created, they "decouple" and do not contribute to the running. In the MOM scheme this takes place automatically because for the momentum smaller than the mass the diagram simply disappears. In the minimal scheme, on the contrary, this does not happen. Hence, it is quite natural in this case to stop the running at the value of $p^2 = m^2$ and to identify the physical mass with the running mass at the scale of the mass, i.e

$$m^2 = \bar{m}^2(m^2).$$

However, this is true only up to finite corrections. Let us come back to the definition of the mass term in the Lagrangian. It is chosen in such a way that the propagator of a particle, which is the inverse to the quadratic form, has the pole at $p^2 = m^2$. Therefore, a more appropriate definition of the physical mass is the position of the pole of the propagator with allowance for the radiative corrections,.i.e.,

$$\text{physical mass} \equiv \text{pole mass}$$

This definition of a mass does not depend on a scale and it is also scheme independent and may have physical meaning. The pole mass can be expressed through the running mass at the scale of a mass with finite and calculable corrections.

Consider as an example the quark mass in QCD. The quark propagator is graphically presented in Fig.18.20.

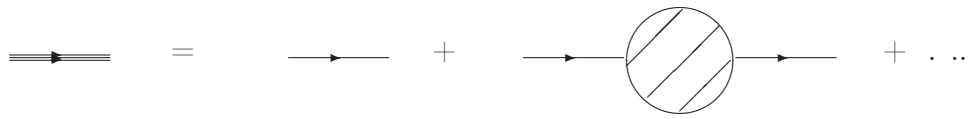

Figure 18.20: The quark propagator

The corresponding expression is

$$G(\hat{p},m) = \frac{i}{\hat{p}-m} + \frac{i}{\hat{p}-m}(iA\hat{p}+iBm)\frac{i}{\hat{p}-m} + ...$$
$$= \frac{i}{\hat{p}-m}\left[1 - \frac{A\hat{p}+Bm}{\hat{p}-m} + ...\right] = \frac{i}{\hat{p}-m}\,\frac{1}{1+\frac{A\hat{p}+Bm}{\hat{p}-m}} = \frac{i}{\hat{p}-m+A\hat{p}+Bm}.$$

The pole mass is now defined as a root of the equation

$$\hat{p}(1+A(p^2)) - m(1-B(p^2)) = 0, \tag{18.153}$$

which gives in the lowest order

$$m_{pole} = m\frac{1-B(m^2)}{1+A(m^2)} = m[1-A(m^2)-B(m^2)].$$

To calculate the functions A and B, consider the one-loop diagram shown in Fig.18.21.

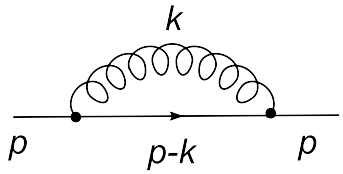

Figure 18.21: The quark propagator in one loop in QCD

The corresponding expression is

$$\Sigma = -\frac{g_s^2}{(2\pi)^4}C_F\int\frac{dk\;\gamma^\mu(\hat{p}-\hat{k}+m)\gamma^\nu}{[(p-k)^2-m^2]}\frac{g^{\mu\nu}}{k^2} \tag{18.154}$$

and was calculated earlier. The result has the form (18.36)

$$A(p^2,m^2) = \frac{g_s^2}{16\pi^2}C_F\left[\frac{1}{\varepsilon}-1-2\int\limits_0^1 dx(1-x)\log\frac{p^2x(1-x)-m^2}{-\mu^2}\right], \tag{18.155}$$

$$B(p^2,m^2) = \frac{g_s^2}{16\pi^2}C_F\left[-\frac{4}{\varepsilon}+2+4\int\limits_0^1 dx\log\frac{p^2x(1-x)-m^2}{-\mu^2}\right]. \tag{18.156}$$

After subtraction of divergences in the $\overline{MS}$-scheme one has

$$A^{\overline{MS}}(p^2,m^2) = -\frac{g_s^2}{16\pi^2}C_F\left[1+2\int\limits_0^1 dx(1-x)\log\frac{p^2x(1-x)-m^2}{-\mu^2}\right], \tag{18.157}$$

$$B^{\overline{MS}}(p^2,m^2) = \frac{g_s^2}{16\pi^2}C_F\left[2+4\int\limits_0^1 dx\log\frac{p^2x(1-x)-m^2}{-\mu^2}\right]. \tag{18.158}$$

Substituting $p^2=m^2$, one finds

$$A^{\overline{MS}}(m^2,m^2) = 2+\ln\frac{\mu^2}{m^2}, \quad B^{\overline{MS}}(m^2,m^2) = -6-4\ln\frac{\mu^2}{m^2}. \tag{18.159}$$

Thus, for the radiative correction to the pole mass we have

$$m_{pole} = m(\mu)\left[1+\frac{\alpha_s C_F}{4\pi})4+3\ln\frac{\mu^2}{m^2})\right]. \tag{18.160}$$

Substituting $C_F=4/3$ and $\mu^2=m^2$ one obtains the desired relation between the pole mass and the running mass at the mass scale

$$m_{pole} = m(m)\left[1+\frac{4}{3}\frac{\alpha_s}{\pi}\right]. \tag{18.161}$$

18.7 K-l.VII: Zero Charge and Asymptotic Freedom

Since the behaviour of the effective coupling has so essential consequences we consider two typical examples which are realized in quantum field theory in the one-loop approximation and presumably take place in a full theory. Usually, one speaks about the zero charge behaviour or the asymptotic freedom. We explain below what it means.

18.7.1 The zero charge

The notion of the zero charge appeared in QED in the leading log approximation. This is what takes place within the renormalization group method in the one-loop approximation. If one writes down the expression for the renormalized coupling as a function of the "bare" coupling, i.e. inverts eq.(18.129), one gets

$$g = \frac{g_B}{1+\beta_0 g_B/\varepsilon} = \frac{g_B}{1+\beta_0 g_B\log\Lambda^2}, \tag{18.162}$$

where the first coefficient of the β-function $\beta_0>0$. Then, removing the regularization, i.e., for $\varepsilon\to 0$ or $\Lambda\to\infty$, the renormalized coupling tends to zero independently of the value of the "bare" coupling. This is what is called the *zero charge*. For the effective coupling considered above the zero charge corresponds to the behaviour shown on the left panel of Fig.18.22 which is characterized by the Landau pole at high energies.

The zero charge behaviour is typical of QED, the ϕ^4 theory for positive quartic coupling and also the Yukawa type interactions, i.e., in those theories where the β-function is positive.

It is obvious that in the vicinity of the pole the perturbation theory does not work and, hence, the one-loop formula is not applicable. However, for small momenta transfer the one-loop

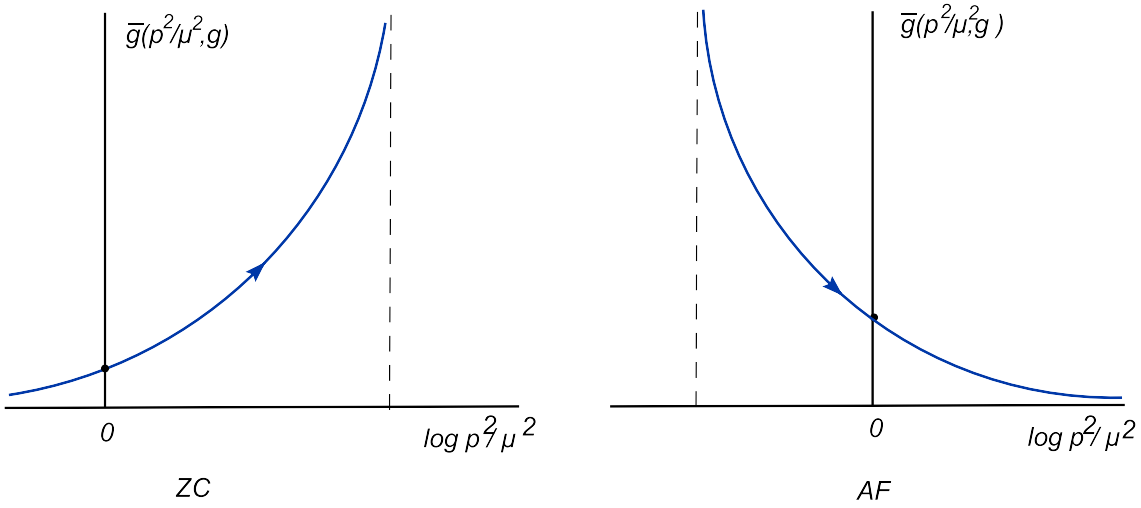

Figure 18.22: The behaviour of the effective coupling: the zero charge (left) and the asymptotic freedom (right)

approximation is reliable. For instance, in QED the effective expansion parameter is $e^2/16\pi^2 = \alpha/4\pi \approx 1/137/4\pi \approx 5.8 \cdot 10^{-4}$ and the next loop corrections (which have the same sign) do not play any essential role. The behaviour of the effective coupling in QED in the region up to 100 GeV has got the experimental confirmation in measuring the fine structure constant at the LEP accelerator. At the scale equal to the mass of the Z-boson M_Z the fine structure constant is not $1/137$ but $\alpha(M_Z) \approx 1/128$, which is in a good agreement with the one-loop formula.

The large momenta transfer in this case are limited by the pole provided the pole does not disappear in a full theory. It is still unclear how higher orders of perturbation theory influence this behaviour since the perturbation series is divergent and it is impossible to make definite conclusions without additional nonperturbative information.

The presence of the Landau pole indicates the presence of unphysical ghost states. To see this, consider the photon propagator in QED which due to the Ward identities coincides with the invariant charge and in the leading log approximation has the form of a geometric progression

$$G(p^2) = -i\frac{g^{\mu\nu} - p^\mu p^\nu/p^2}{p^2}\frac{1}{1 - \frac{4}{3}\sum Q^2 \frac{\alpha_0}{4\pi}\log(-p^2/m^2)}, \tag{18.163}$$

where Q is the electric charge of a particle (in the units of electron charge) running round the loop.

This expression has a pole in the Euclidean region at $p^2 = -m^2 exp(\frac{3\pi}{\alpha_0 Q^2 n_f})$. Substituting $m = m_e = 0.5$ MeV, $\alpha_0 \simeq 1/137$ and $\sum Q^2 = [(4/9 + 1/9)3 + 1)3] = 8$, one gets $p^2 \simeq -(5 \cdot 10^{31})^2$ GeV^2. That is the pole is very far off, even beyond the Planck scale, and at low energies one can ignore it. However, the presence of the pole indicates the presence of a new asymptotic state and the residue at the pole defines the norm of this state. In the case of the Landau pole the residue is negative, i.e., the new state is a ghost, it has the wrong sign of the kinetic term in the Lagrangian. This fact, in its turn, leads to negative probabilities, which indicates internal inconsistency of the theory.

Usually, it is assumed that there are two ways out of this trouble: either the higher order corrections improve the behaviour of the theory at high momenta so that the Landau pole disappears, or that the zero charge theory is contradictory by itself, but at high energies it is part of a more

general theory where the behaviour of the coupling is improved. The example of such a behaviour is given by the Grand Unified Theories where QED is one of the branches of a non-Abelian gauge theory with the asymptotically free behaviour. In both the cases the theory at high energies is modified. At the same time, the zero charge theory is infrared free, i.e. for small momenta transfer the coupling goes to zero.

18.7.2 The asymptotic freedom

The name *asymptotic freedom* originates from the non-Abelian gauge theories where it was found that the sign of the first coefficient of the β-function is negative. The effective coupling in this case behaves as is shown in the right panel of Fig.18.22 and tends to zero at high momenta transfer. This means that quarks in QCD are quasi-free particles, i.e., practically do not interact. This way one explains the success of the so-called parton model of the strong interactions at high energies, according to which the proton behaves as a set of free partons, and at high energies the interaction takes place with the individual partons and their interaction does not play any role.

The behaviour of the effective coupling in QCD at high energies was tested at various accelerators and in various experiments and the validity of the renormalization group formula was confirmed. The accuracy of modern measurements assumes the inclusion of the next terms of perturbative expansion. In QCD in the $\overline{MS}$ scheme the four terms of the β-function are known. Below we present the two-loop expression

$$\beta_\alpha(\alpha_s) = -\frac{1}{4\pi}[11 - \frac{2}{3}n_f]\alpha_s^2 - \frac{1}{(4\pi)^2}[102 - \frac{38}{3}n_f]\alpha_s^3 + O(\alpha_s^4). \tag{18.164}$$

As one can see, if the number of quarks in not too big, both the coefficients of the β-function are negative. All the experimental data fit a single curve for the effective coupling with the parameter $\Lambda_{QCD} \simeq 200$ MeV (see Fig.18.23)

In four-dimensional space the asymptotic freedom occurs only in non-Abelian gauge theories. But in the case when one has several interactions, like in the Standard Model, the non-Abelian coupling may draw other couplings into the asymptotically free region. Consider, for instance, the behaviour of the Yukawa couplings in the SM. For simplicity, let us take a single Yukawa coupling for the t-quark and a single gauge coupling. Then in the one-loop approximation the equations for the effective couplings look like

$$\begin{aligned} \frac{dg}{dt} &= -bg^2, \quad g \equiv \frac{g_s^2}{16\pi^2}, \\ \frac{dy}{dt} &= y(ay - cg), \quad y \equiv \frac{y_t^2}{16\pi^2}, \quad t \equiv \log\frac{q^2}{q_0^2}, \end{aligned} \tag{18.165}$$

where the coefficients b, a and c are always positive and for the SM are equal to $7, 9/2$ and 8, respectively. The solutions to these equations are

$$\begin{aligned} g &= \frac{g_0}{1 + bg_0 t}, \quad y = \frac{y_0 E}{1 - ay_0 F}, \\ E(t) &= (g/g_0)^{c/b}, \quad F(t) = \int_0^t E(t')dt'. \end{aligned} \tag{18.166}$$

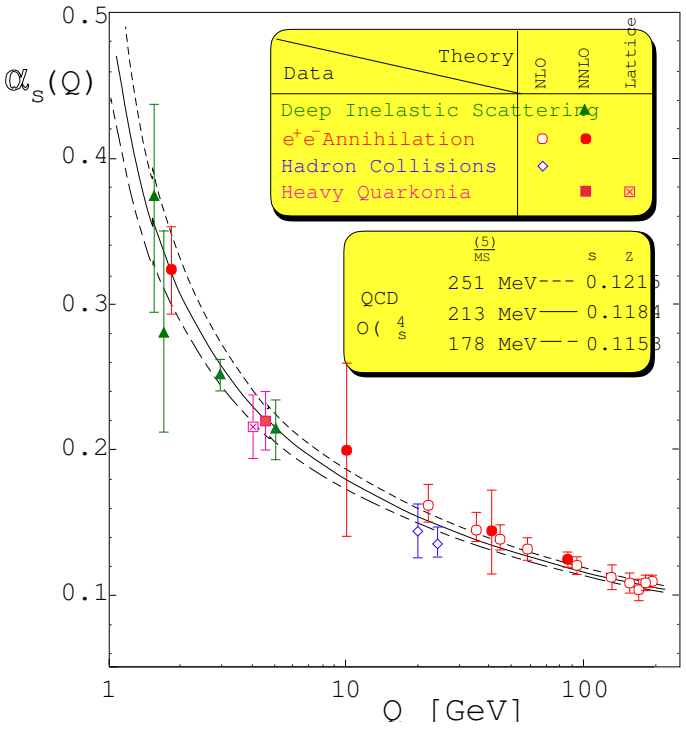

Figure 18.23: The variation of the effective coupling of the strong interactions α_s with energy

In the case of a single Yukawa coupling it can be written in an explicit form

$$y = \frac{y_0 (\frac{g}{g_0})^{c/b}}{1 + \frac{y_0}{g_0}\frac{a}{c-b}[(\frac{g}{g_0})^{c/b-1} - 1]}. \tag{18.167}$$

Graphically, it can be presented in a phase diagram shown in Fig.18.24. For the initial condition

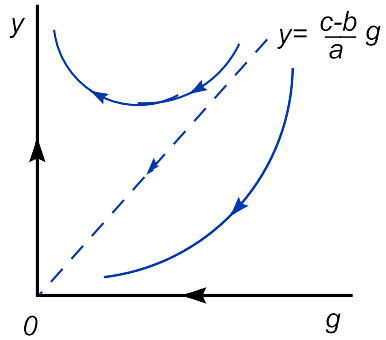

Figure 18.24: The behaviour of the Yukawa and gauge couplings for various initial conditions

such that $y_0 > (c-b)/a\ g_0$ the Yukawa coupling increases with momenta and has the Landau pole, while for $y_0 \leq (c-b)/a\ g_0$ it demonstrates the asymptotically free behaviour. In a similar way in the Grand Unified Theories one can reach the asymptotic freedom for all the couplings.

The back side of the asymptotic freedom at high energies is the presence of a pole at low energies or the infrared pole. In this region, we also go beyond the validity of perturbation theory since the coupling increases. To find the true behaviour of the coupling one has to attract independent

nonperturbative information. However, in QCD the region near the infrared pole $p \sim \Lambda_{QCD}$ is in the phase of hadronization, i.e., in this region the quark-gluon description is no more adequate. Therefore, the behaviour of the effective coupling in this region is not described by perturbative QCD.

18.7.3 The screening and anti-screening of the charge

The variation of the coupling with momenta transfer or with the scale, which is the characteristic feature of quantum field theory, has its analog in a classical theory. This analogy allows one to understand the qualitative reason for the variation of the coupling.

Indeed, let us consider the electromagnetic phenomena. Consider the dielectric medium and put the test electric charge in it. The medium will be polarized. The electric dipoles present in the medium will be rearranged in such a way as to screen the charge (see Fig.18.25). This is a consequence of the Coulomb law: the opposite charges are attracted and the same charges are repulsed. This is the essence of the electric screening phenomena.

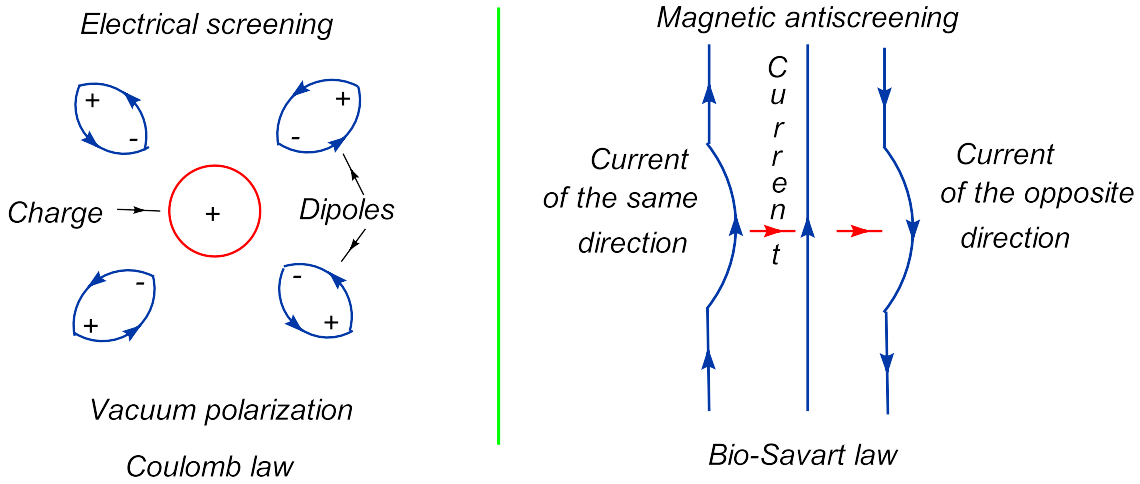

Figure 18.25: The electric screening and magnetic anti-screening

The opposite situation occurs in magnetic medium. According to the Bio-Savart law, the electric currents of the same direction are attracted and the opposite direction are repulsed (see Fig.18.25). This leads to the anti-screening in magnetic medium.

In quantum field theory the role of the medium is played by the vacuum. The vacuum is polarized in the presence of created virtual pairs. The matter particles as well as transversely polarized quanta of the gauge fields act like the electric dipoles in the dielectric and cause the screening of the charge. At the same time, the longitudinal quanta of the gauge fields behave like currents and cause the anti-screening. These two effects are in competition (see eq.(18.48) above) and, for instance, in QCD with a small number of quarks the effect of anti-screening prevails.

Thus, the couplings become the functions of the distance or momentum transfer described by the renormalization group equations.

18.7.4 Non-Abelian Gauge Transformations in QFT

Theory

Рассмотрим модель, содержащую безмассовые векторные поля B^a_μ (калибровочные поля или глюоны) и фермионы ψ_i (кварки).

Кварки преобразуются по некоторому представлению неабелевой группы с генераторами t^a и антисимметричными структурными константами f^{abc}:

$$\psi_i \to \psi_i + ig\omega^a t^a_{ij}\psi_j,$$

где g - константа связи (заряд), а $\omega^a(x)$ - локальные параметры калибровочных преобразований.

(???)

$$\left[t^a, t^b\right] = if^{abc}t^c,$$

тождество Якоби:

$$f^{\mathrm{abc}}\, f^{\mathrm{ade}} + f^{\mathrm{abd}}\, f^{\mathrm{aec}} + f^{\mathrm{abe}}\, f^{\mathrm{acd}} = 0$$

Глюоны преобразуются как:

$$B^a_\mu \to \left(B^a_\mu\right)^\omega = B^a_\mu + \partial_\mu\omega^a + gf^{abc}B^b_\mu\omega^c$$

Составленный из глюонов тензор $F^a_{\mu\nu}$ принадлежит присоединенному представлению,

$$F^a_{\mu\nu} \equiv \partial_\mu B^a_\nu - \partial_\nu B^a_\mu + gf^{abc}B^b_\mu B^c_\nu,$$

(тут какое-то не сложное доказательство может дать вид преобразования:)

$$F^a_{\mu\nu} \to F^a_{\mu\nu} + gf^{abc}F^b_{\mu\nu}\omega^c$$

Лагранжиан векторного поля глюонов включает в себя свободную часть и слагаемые, отвечающие взаимодействию глюонов, строится из калибровочно инвариантной комбинации $F^a_{\mu\nu}F^a_{\mu\nu}$:

$$\begin{aligned}\mathscr{L}(B) &= -\frac{1}{4}F^a_{\mu\nu}F^a_{\mu\nu} - \frac{1}{2\alpha}\left(\partial_\mu B^a_\mu\right)^2 = \\ &= -\frac{1}{4}\left(\partial_\mu B^a_\nu - \partial_\nu B^a_\mu\right)^2 - \frac{1}{2\alpha}\left(\partial_\mu B^a_\mu\right)^2 - \frac{g}{2}f^{abc}\left(\partial_\mu B^a_\nu - \partial_\nu B^a_\mu\right)B^b_\mu B^c_\nu - \frac{g^2}{4}f^{abc}f^{ade}B^b_\mu B^c_\nu B^d_\mu B^e_\nu\end{aligned}$$

Ковариантная производная имеет вид

$$\nabla_\mu\psi \equiv \left(\partial_\mu - igB^a_\mu t^a\right)\psi$$

Ее преобразование имеет вид:

$$\begin{aligned}\nabla_\mu\psi = \left(\partial_\mu - igB^a_\mu t^a\right)\psi &\to \left(\partial_\mu - ig\left(B^a_\mu\right)^\omega t^a\right)\left(1 + ig\omega^b t^b\right)\psi \\ &= \left(\partial_\mu - igB^a_\mu t^a - igt^a\partial_\mu\omega^a - ig^2 f^{adc}B^d_\mu t^a\omega^c\right)\left(1 + ig\omega^b t^b\right)\psi \\ &= \left(1 + ig\omega^b t^b\right)\left(\partial_\mu - igB^a_\mu t^a\right)\psi = \left(1 + ig\omega^b t^b\right)\nabla_\mu\psi\end{aligned}$$

Его усложнение по сравнению с КЭЛ обусловлено, конечно, некоммутативностью.

Коммутатор ковариантных производных, как всегда, связан с тензором $F^a_{\mu\nu}$:

$$[\nabla_\mu, \nabla_\nu] = -ig\left(\partial_\mu B^a_\nu - \partial_\nu B^a_\mu\right)t^a - g^2 B^a_\mu B^b_\nu\left[t^a, t^b\right] = -igF^a_{\mu\nu}t^a.$$

примеры

построение глюонов (????)

посмотрим, как построить глюонную теорию.
хз

применения

явное отличие неабелевых от абелевых

приведем такое сравнение, чтобы ориентроваться.

18.7.5 Faddeev–Popov Method

суть метода Фаддеева-Попова

Метод Фаддеева-Попова получает дополнительные поправки к лагранжиану??.
??? при чем тут петли??
Он основан на идее исключения “лишнего” интегрирования по полям, связанным друг с другом калибровочным преобразованием. (?????)
В квантовой электродинамике мы столкнулись с проблемой необратимости оператора

$$K_{\mu\nu} = g_{\mu\nu}\partial^2 - \partial_\mu\partial_\nu$$

в лагранжиане КЭД

$$\mathscr{L}_0(A) = -\frac{1}{4}\left(\partial_\mu A_\nu - \partial_\nu A_\mu\right)^2 = \frac{1}{2}\left(\partial_\mu A_\nu \partial_\nu A_\mu - \partial_\mu A_\nu \partial_\mu A_\nu\right) = \frac{1}{2}A_\mu K_{\mu\nu} A_\nu$$

и решили ее, введя в лагранжиан неинвариантное слагаемое с параметром α.
(???)
Аналогичное слагаемое мы, с теми эке целями, сразу включили и в лагранжиан глюонов $\mathscr{L}(B)$.

$$\mathscr{L}(B) = -\frac{1}{4}F^a_{\mu\nu}F^a_{\mu\nu} - \frac{1}{2\alpha}\left(\partial_\mu B^a_\mu\right)^2$$

Однако оказывается, что в неабелевом случае этого мало: потребуются и другие добавки к лагранжиану.
(!!!)
Метод получения дополнительных поправок, предложенный Фаллеевым и Поповым, основан на идее исключения "лишнего" интегрирования по полям, связанным друг с другом калибровочным преобразованием.

аналогия с чем-то простым, уже известным

Зи там привел ее, а я хз.
потом разберусь.

фиксация калибровки

(?? пример бы???)

Будем говорить, что условие $f(B) = 0$ фиксирует калибровку, если оно нарушается калибровочным преобразованием $B \to B^\omega$.

То есть если $\omega^a \neq 0$ влечет за собой $f\left(B^\omega\right) \neq 0$.

Реально мы ограничимся простейшими калибровочными условиями типа

$$f(B) = \partial_\mu B^a_\mu = 0.$$

?? тут примеры хочу записать

рецепт континуального интегрирования по полям

(?? то есть казалось бы, это тупо усложнение, зачем так делать?)

Имеется следующий рецепт континуального интегрирования по полям B^a_μ:

$$\int \mathscr{D}B\Phi(B) = \int \mathscr{D}B\delta(f(B))\Delta_f[B]\Phi(B)$$

(??? что за рецепт, как пользоваться???)

Предлагается запить

$$\int \mathscr{D}B \sim \int \mathscr{D}B\delta(f(B))\Delta_f[B]$$

Действительно, ведь более подробно:

$$\begin{aligned}
\int \mathscr{D}B &= \int \mathscr{D}B\mathscr{D}f\left(B^\omega\right)\delta\left(f\left(B^\omega\right)\right) = \\
&= \int \mathscr{D}B\mathscr{D}\omega \det\frac{\partial f\left(B^\omega\right)}{\partial\omega}\delta\left(f\left(B^\omega\right)\right) \\
&= \int \mathscr{D}\omega \int \mathscr{D}B\delta\left(f\left(B^\omega\right)\right)\Delta_f[B] \sim \\
&\sim \int \mathscr{D}B\delta(f(B))\Delta_f[B]
\end{aligned}$$

То есть сначала мы ввели дополнительное интегрирование по значениям функции f.

(???) Поскольку они скоррелированы со значениями ω, то на втором шаге сделана замена континуальной переменной $f \to \omega$.

Введенный на следующем шаге функционал

$$\Delta_f[B] \doteq \det\left[\frac{\partial f\left(B^\omega\right)}{\partial\omega}\right]_{f=0}$$

$$\Delta_f^{-1}[B] = \int \mathscr{D}\omega\delta\left(f\left(B^\omega\right)\right)$$

определяется видом f и по построению калибровочно инвариантен, то есть $\Delta_f\left[B^\omega\right] = \Delta_f[B]$.

Считая, что таким же свойством обладает и континуальная мера $\mathscr{D}B$, мы можем калибровочной заменой превратить B^ω в B.

Тогда интегрирование по $\mathscr{D}\omega$ даст просто числовой множитель (объем калибровочной группы), который мы, как всегда, опускаем.

В итоге получается следующий рецепт континуального интегрирования по полям B^a_μ:

$$\int \mathscr{D}B\Phi(B) = \int \mathscr{D}B\delta(f(B))\Delta_f[B]\Phi(B)$$

Здесь $\Phi(B)$ - любой калибровочно инвариантный объект.

Лишние поля из интеграла устранены условием $f(B) = 0$;

в виде платы за это пришлось внести под знак интеграла величину $\Delta_f[B]$.

Весь интеграл как целое, конечно же, от f не зависит.

вычисление детерминанта Фаддеева-Попова

Приведем рабочий метод вычисления детерминатнов.

Для нахождения $\Delta_f[B]$ на поверхности $f(B) = 0$ нужно уметь вычислять детерминант

$$\Delta_f[B] = \det\left[\frac{\partial f\left(B^\omega\right)}{\partial\omega}\right]_{f=0}$$

при $\omega = 0$.

Пусть $f(B) = \partial_\mu B^a_\mu = 0$.

Тогда

$$f\left(B^\omega\right) = \partial_\mu\left(B^a_\mu\right)^\omega = \partial^2\omega^a + gf^{acb}\partial_\mu\left(B^c_\mu\omega^b\right) = \partial^2\omega^a + gf^{acb}B^c_\mu\partial_\mu\omega^b = M^{ab}\omega^b$$

где $M^{ab} = \delta^{ab}\partial^2 + gf^{acb}B^c_\mu\partial_\mu$,

В итоге:

$$\Delta_f[B] = \det M = \int \mathscr{D}\bar{c}\mathscr{D}c\exp\left(i\bar{c}^a M^{ab}c^b\right)$$

То есть руководствуясь?????, мы представили искомый детерминант в виде континуального интеграла по фермионным полям $\bar{c}$, c.

лагранжиан гостов

Структура лагранжиана гостов $\mathscr{L}_{\text{gh}}$ (и даже сам факт их наличия) существенно зависит от вида калибровочного условия, задаваемого функцией f.

Введение функционала $\Delta_f[B]$ оказалось в данном случае эквивалентным добавлению к лагранжиану двух новых слагаемых,

$$\mathscr{L}_{\text{gh}} = -\partial_\mu\bar{c}^a\partial_\mu c^a + gf^{acb}\bar{c}^a B^c_\mu\partial_\mu c^b = -\partial_\mu\bar{c}^a\partial_\mu c^a - gf^{acb}\partial_\mu\bar{c}^a B^c_\mu c^b$$

отвечающих полям гостов.

пропагатор гостов

????

Сразу видно, что пропагатор гостов равен (с обратным знаком и множителем δ^{ab}) пропагатору скалярного поля.

и что?

(???)

Вершина взаимодействия связывает госты с глюонами.

Однако в in- и out-состояниях госты, по определению, присутствовать не должны, это частицы фиктивные и сугубо виртуальные, их единственная роль в диаграммах - образовывать замкнутые петли.

Кстати, можно было изначально свести $\Delta_f[B]$ к этим самым петлям, если раскрывать $\det M$ с помощью $\det M = \exp \operatorname{tr}(\ln M)$.

отсутствие гостов в КЭД

Отметим, что отсутствие гостов в КЭД объясняется тривиальностью оператора $M^{ab} = \delta^{ab}\partial^2$ в этом случае.

(?)

независимость интеграла от калибровочного параметра: доказательство

Нам осталось выполнить давнее обещание - доказать независимость интегралов вида (208) от калибровочного параметра α.

Для этого модифицируем калибровочное условие, положив

$$f(B) = \partial_\mu B^a_\mu - b^a.$$

Функционал $\Delta_f[B]$ удобно записать в форме

$$\Delta_f[B] = \det\left(\delta^{ab}\partial^2 + g f^{acb}\partial_\mu \cdot B^c_\mu\right),$$

одинаковой при любом выборе функции $b^a(x)$.

Формуле (209) это не противоречит, ибо $\partial_\mu \cdot B^a_\mu = B^a_\mu \partial_\mu + \partial_\mu B^a_\mu$.

Более того, оба представления для $\Delta_f[B]$ эквивалентны при любом B в силу очевидного равенства $\operatorname{tr}\ln(1+MN) = \operatorname{tr}\ln(1+NM)$, а соответствующие им выражения (210) для вклада гостов в лагранжиан - в силу $\partial^x_\mu D^c(x-y) = -\partial^y_\mu D^c(x-y)$.

Сам интеграл (208) по построению не может зависеть от f, а значит и от b, поэтому если мы подвергнем его дополнительному интегрированию по $\mathscr{D}b$ с весом $\exp\left(-ib^a b^a/2\alpha\right)$, это приведет лишь к домножению на несущественный числовой фактор:

$$\begin{aligned}\int \mathscr{D}B\Phi(B) &= \int \mathscr{D}B\delta\left(\partial_\mu B^a_\mu - b^a\right)\Delta_f[B]\Phi(B)\\ &\sim \int \mathscr{D}B\mathscr{D}b\delta\left(\partial_\mu B^a_\mu - b^a\right)\Delta_f[B]\Phi(B)\exp\left(-\frac{i}{2\alpha}b^a b^a\right)\\ &= \int \mathscr{D}B\mathscr{D}\bar{c}\mathscr{D}c\Phi(B)\exp i\left(\mathscr{L}_{\text{gh}} - \frac{1}{2\alpha}\left(\partial_\mu B^a_\mu\right)^2\right)\end{aligned}$$

мы воспроизвели слагаемое с калибровочным параметром α и показали, что континуальные интегралы вида (208) от него не зависят.

При этом интегралы от калибровочно неинвариантных величин (например, n -хвостки) вполне могут зависеть от α.

случай поперечной калибровки (???)

Отметим, что в случае поперечной калибровки $\alpha = 0$, когда $\exp\left(-\left(\partial_\mu B^a_\mu\right)^2/2\alpha\right)$ не существует, вместо него как раз появляется $\delta\left(\partial_\mu B^a_\mu\right)$ в континуальном интеграле: эту δ -функцию можно условно трактовать как предел экспоненты при $\alpha \to 0$.

калибровочная инвариантность S-матрицы (???)

Осталось сказать, что вместе с α-независимостью интегралов (208) нами установлена и калибровочная инвариантность S -матрицы.

???? я хз.

лагранжиан кварков и глюонов

Структура лагранжиана гостов $\mathscr{L}_{\text{gh}}$ (и даже сам факт их наличия) существенно зависит от вида калибровочного условия, задаваемого функцией f.

Лагранжиан не калибровочной теории кварков и глюонов имеет вид:

$$\begin{aligned}\mathscr{L}(\psi, B) =& -\frac{1}{4}F^a_{\mu\nu}F^a_{\mu\nu} + \bar\psi\left(i\gamma_\mu\nabla_\mu - m\right)\psi + \mathscr{L}_{\text{gh}} - \frac{1}{2\alpha}\left(\partial_\mu B^a_\mu\right)^2 \\ =& -\frac{1}{4}\left(\partial_\mu B^a_\nu - \partial_\nu B^a_\mu\right)^2 + \bar\psi\left(i\gamma_\mu\partial_\mu - m\right)\psi - \partial_\mu\bar c^a\partial_\mu c^a - \frac{1}{2\alpha}\left(\partial_\mu B^a_\mu\right)^2 + g\bar\psi\gamma_\mu B^a_\mu t^a\psi \\ &+ g f^{acb}\bar c^a B^c_\mu\partial_\mu c^b - \frac{g}{2}f^{abc}\left(\partial_\mu B^a_\nu - \partial_\nu B^a_\mu\right)B^b_\mu B^c_\nu - \frac{g^2}{4}f^{abc}f^{ade}B^b_\mu B^c_\nu B^d_\mu B^e_\nu\end{aligned}$$

(как его использовать???)

теория от Киселева

На примере электромагнитного поля мы убедились, что его квантование в голоморфном представлении мало чем отличается от квантования скалярного поля.

А именно, две физические моды безмассового векторного поля полностью определяют гамильтониан поля и имеют соответствующие релятивистски инвариантные амплитуды, по которым можно провести интегрирование и в континуальном интеграле.

Амплитуды квантовых переходов строятся именно для этих двух поперечных мод.

Однако сами моды определены совершенно нековариантным образом в терминах векторов поляризации,

которые имеют нулевую временную компоненты и две пространственно поперечные компоненты.

Это, в частности, означает, что пропагатор таких мод имеет совершенно нековариантный вид, а значит,

доказательство релятивистской инвариантности амплитуд квантовых переходов становится настоящей проблемой.

С другой стороны, мы убедились, что уравнения движения для безмассового векторного поля могут быть получены из принципа экстремальности калибровочно инвариантного действия.

В этом действии, однако, присутствуют нефизические калибровочные степени свободы, которые мы можем исключить, налагая связи и фиксируя калибровку, а значит, исключая

степени излишние свободы. С точки зрения континуального интеграла

$$\tilde{Z} = \int \mathcal{D}\mathcal{A} e^{\mathrm{i}S}, \quad S = \int \mathrm{d}^4 x \mathcal{L}_{\mathrm{g.f.}}, \quad \mathcal{L}_{\mathrm{g.f.}} = -\frac{1}{2} \operatorname{tr} F_{\mu\nu} F^{\mu\nu}$$

в релятивистски инвариантном интеграле по всем компонентам поля содер- жится лишнее интегрирование по параметрам локальной группы внутренней симметрии, от которых зависят компоненты поля. От этого излишнего нефи- зического фактора можно избавиться. Для этого заметим несколько фактов.

Первое, в мере интегрирования $\mathcal{D}\mathcal{A}$ можно делать замену переменных в виде калибрвочного преобразования инвариантным образом:

$$\mathcal{D}\mathcal{A} = \mathcal{D}\mathcal{A}^g$$

В самом деле, из вида калибровочного преобразования

$$\mathcal{A}^g_\mu = g\mathcal{A}_\mu g^{-1} - \frac{\mathrm{i}}{e} g \partial_\mu g^{-1}$$

ясно, сдвиг не влияет на интеграл, а якобиан замены переменных равен единице, так как $\det\left(g \cdot \mathbb{1} \cdot g^{-1}\right) = 1$. В силу калибровочной инвариантности действия такая замена переменных не меняет континуальный интеграл. Второе, на примере 2-мерного интегралая

$$\int \mathrm{d}x_1 dx_2 \delta^{(2)}\left(f^\alpha(x)\right) = \int \det\left(\frac{\partial x^\beta}{\partial f^\alpha}\right) \mathrm{d}f_1 df_2 \delta\left(f_1\right) \delta\left(f_2\right) = \det\left(\frac{\partial x^\beta}{\partial f^\alpha}\right)\Bigg|_{\boldsymbol{f}=0}$$

мы можем заключить, что использование обратной матрицы дает тождество

$$\det\left(\frac{\partial f^\alpha}{\partial x^\beta}\right)\Bigg|_{\boldsymbol{f}=0} \int \mathrm{d}x_1 dx_2 \delta^{(2)}\left(f^\alpha(x)\right) = 1$$

которое справедливо и для континуального интеграла

$$\operatorname{Det}\left(\mathcal{M}_X(\mathcal{A})\right)|_{X(\mathcal{A})=0} \int \mathcal{D}g \delta\left(X\left(\mathcal{A}^g\right)\right) = 1$$

В этом интеграле $\mathcal{D}g$ - инвариантная мера интегрирования по параметрам группы, скажем, интеграл по параметрам u, которые отсчитываются в экс-

поненциальном представлении возле единицы $\exp(\mathrm{i}eu)$, так что $\mathcal{D}g \cong \mathcal{D}u$, - так что замена в виде группового умножения $g \mapsto \tilde{g} = g \cdot g_1$ с фиксированным элементом g_1 никак не меняет параметров при разложении экспоненциального представления возле единицы, $\exp(\mathrm{i}eu) \mapsto \exp(\mathrm{i}eu)$. При заданном калибровочном поле $X\left(\mathcal{A}^g\right) = 0$ - это калибровочное условие, которое имеет единственное решение (по крайней мере в рамках теории возмущений). Матрица

$$\left(\mathcal{M}_X(\mathcal{A})\right)^a_b|_{X(\mathcal{A})=0} = \left.\frac{\partial X^a\left(\mathcal{A}^g\right)}{\partial u^b}\right|_{u=0}$$

Детерминант этой матрицы является калибровочно инвариантным в силу инвариантности метрики, поскольку при $\tilde{g} = gg_1$

$$\int \mathcal{D}g \delta\left(X\left(\mathcal{A}^{gg_1}\right)\right) = \int \mathcal{D}\tilde{g} \delta\left(X\left(\mathcal{A}^{\tilde{g}}\right)\right) = \int \mathcal{D}g \delta\left(X\left(\mathcal{A}^g\right)\right)$$

а значит,

$$\mathrm{Det}\left(\mathcal{M}_X\left(\mathcal{A}^{g_1}\right)\right)\big|_{X(\mathcal{A})=0} = \mathrm{Det}\left(\mathcal{M}_X(\mathcal{A})\right)\big|_{X(\mathcal{A})=0}$$

Тогда, вводя единицу в подынтегральное выражение

$$\tilde{Z} = \int \mathcal{D}\mathcal{A} e^{\mathrm{i}S}\,\mathrm{Det}\left(\mathcal{M}_X(\mathcal{A})\right)\Big|_{X(\mathcal{A})=0} \int \mathcal{D}g\,\delta\left(X\left(\mathcal{A}^g\right)\right)$$

мы можем выделить интеграл по параметрам калибровочной группы

$$\tilde{Z} = \int \mathcal{D}g \int \mathcal{D}\mathcal{A} e^{\mathrm{i}S}\,\mathrm{Det}\left(\mathcal{M}_X(\mathcal{A})\right)\Big|_{X(\mathcal{A})=0} \delta\left(X\left(\mathcal{A}^g\right)\right)$$

и воспользоваться заменой переменных $\mathcal{A}^g \mapsto \left(\mathcal{A}^g\right)^{g^{-1}} = \mathcal{A}$, так что калибровочно инвариантные факторы не изменятся, но изменится аргумент калибровочного условия, который теперь перестанет зависеть от параметров интегрирования по калибровочной группе, и

$$Z' = \tilde{Z}\left(\int \mathcal{D}g\right)^{-1} = \int \mathcal{D}\mathcal{A} e^{\mathrm{i}S}\,\mathrm{Det}\left(\mathcal{M}_X(\mathcal{A})\right)\Big|_{X(\mathcal{A})=0} \delta(X(\mathcal{A}))$$

Такая факторизация «объема калибровочной групыы» носит название трюка Фаддеева-Попова. Этот трюк позволяет нам избавиться в амплитуде от интегрирования по нефизическим степеням свободы, т. е. от интеграла по группе внутренней симметрии. При этом итоговая амплитуда не зависит от вида калибровки $X^a(\mathcal{A}) = 0$, поскольку $\tilde{Z}\left(\int \mathcal{D}g\right)^{-1}$ - это, как мы видели, калибровочно инвариантная величина по построению!

Третий шаг - переход от дельта-функции к более прагматическому выражению. Заменим калибровку

$$X(\mathcal{A}) \mapsto X(\mathcal{A}) - b(x)$$

При этом значение амплитуды Z' совершенно не зависит от функции $b(x)$, так что мы можем проинтегрировать по этой функции с любым весом. Например,

$$Z = \int \mathcal{D}b \exp\left(-\frac{\mathrm{i}}{2\xi}\int \mathrm{d}^4x b^2(x)\right) Z'$$

так что после поворота Вика и перехода к координатам в евклидова пространства $\mathrm{d}^4x = -\mathrm{i}\mathrm{d}^4x_E$ гауссов интеграл сходится при $\xi > 0$. Снимая интегрирование за счет континуальной дельта-функции, мы приходим к окончательному калибровочно инвариантному выражению для амплитуды

$$Z = \int \mathcal{D}\mathcal{A} e^{\mathrm{i}S_F}\,\mathrm{Det}\left(\mathcal{M}_X(\mathcal{A})\right)\Big|_{X(\mathcal{A})=0}$$

где действие с учетом калибровочного условия

$$S_F = S_{\text{g.f.}} - \frac{\mathrm{i}}{2\xi}\int \mathrm{d}^4x X^2(\mathcal{A})$$

Здесь фиксирующий калибровку вклад в лагранжиан

$$\mathcal{L}_{\text{g.fix.}} = -\frac{1}{2\xi}X^2(\mathcal{A})$$

можно теперь выбрать в явно релятивистски инвариантном виде. При введении источников j^μ для калибровочного поля необходимо сохранить калибровочную инвариантность исходного лагранжиана без $\mathcal{L}_{\text{g.fix.}}$, что конечно легко достигается требованием сохранения тока и соответствующим

законом преобразования при калибровочных преобразованиях $j^\mu \mapsto g j^\mu g^{-1}$, ТаК ЧТО

$$\mathcal{L}_{\text{int}} = \text{tr}\left(\mathcal{A}_\mu j^\mu\right)$$

строгое обоснование действия Фаддеева-Попова

В заключение укажем более строгий способ обоснования трюка Фаддева-Попова.

Калибровочно и релятивистски инвариантный лагранжиан калибровочного векторного поля с точки зрения гамильтоновой механики описывается физическими величинами - трехмерно поперечным полем и канонически сопряженным к этому полю импульсом,

а также трехмерно продольным полем и канонически сопряженным к нему импульсом,

но содержит также зависимость от временной компоненты поля $\mathcal{A}_0$, которая выделяется следующим образом: канонически сопряженный к ней импульс строится как производная лагранжиана по скорости изменения этой компоненты по времени,

т. е. по $\partial_0 \mathcal{A}_0$.

Однако, в лагранжиан не входит $\partial_0 \mathcal{A}_0$, поскольку напряженность поля не содержит этой производной, так что,

следуя формализму связи лагранжиана и гамильтониана,

мы приходим к выводу, что временная компонента калибровочного поля является множителем Лагранжа.

Обозначим в традициях механики трехмерно поперечное поле символом q, сопряженный ему импульс - p,

трехмерно продольное поле - x,

сопряженный ему импульс p_x, а временную компоненту поля $-\lambda$.

При этом в явном виде мы не пишем ни пространственные, ни групповые индексы внутренней симметрии.

Тогда лагранжиан калибровочного поля запишется в виде

$$\mathcal{L} = \dot{q}p + \dot{x}p_x - \mathcal{H}\left(q, p, x, p_x\right) - \lambda C\left(q, p, x, p_x\right)$$

где $C\left(q, p, x, p_x\right)$ - функция, которая оказывается связью: уравнение Эйлера-Лагранжа для величины λ сводятся к $C\left(q, p, x, p_x\right) = 0$.

По факту оказывается, что эта связь накладывает условие на значение продольной части канонического импульса p_x

Важно вычислить скобки Пуассона для физических величин $\{F, G\}_{\text{P}}$, которые при квантовании отвечают коммутаторам: скобка Пуассона связи с собой выражается через саму связь, а значит, связи не порождают новые связи в уравнениях движения; скобка Пуассона связи с функцией Гамильтона равна нулю, и следовательно, связь сохраняется со временем. Это также говорит о том, что связь является генератором симметрии: ее скобка Пауассона с обобщенными координатами (q, x) порождает преобразования поля, которые оставляют действие инвариантным. Это ничто иное как калибровочные преобразования, так что механическая система содержит степень свободы, от которой не зависят наблюдаемые величины. В нашем случае это трехмерно продольное поле x и соответсвующий ему импульс p_x: их можно исключить из рассмотрения и оставить только

физические моды. Это можно сделать, если ввести связи - калибровки $X\left(q,p,x,p_x\right)$, которые не инвариантны относительно действия генератора симметрии, а значит, скобки Пауассона связи и калибровки отличны от нуля, $\{C,X\}_{\mathrm{P}}\neq 0$. Сами калибровки также не должны порождать новые связи: $\{X,X\}\mathrm{p}=0$.

Допустиv, что существует каноническое преобразование переменных, при котором можно перейти от координат x к обобщенным координатам X. Тогда разрешая все связи, можно показать, что уравнения движения для физических степеней свободы - координат q и импульсов p - это уравнения гамильтоновой механики, в которой гамильтониан зависит только от физических степеней свободы (мы это знаем, поскольку для безмассового векторного поля мы как раз и построили

такой гамильтониан, исключив трехмерно продольное поле и временную компоненту поля).

Запишем амплитуду квантовых переходов в виде континуального интеграла от исходного действия с введением калиброки в виде

$$Z=\int \mathcal{D}q\mathcal{D}p\mathcal{D}x\mathcal{D}p_x\mathcal{D}\lambda\delta(X)\,\mathrm{Det}(\{C,X\}\mathrm{P})e^{\mathrm{i}\int \mathrm{d}^4x(\dot{q}p-\dot{x}p_x-\mathcal{H}-\lambda C)}$$

Интегрирвание по множителю Лагранжа выполняется элементарно и дает континуальную дельта-функцию $\delta(C)$, так что мы имеем полный аналог системы со связями: $C=X=0$ Остается рассмотреть выражение

$$\int \mathcal{D}x\mathcal{D}p_x\delta(C)\delta(X)\Big)\,\mathrm{Det}\left(\{C,X\}_{\mathrm{P}}\right)$$

которое следует сравнить с обычным интегрированием, рассмотренным ранее в (9.5): скобка Пуассона в точности соответствует якобиану перехода от одних координат к другим, так что этот интеграл следует положить равным единице и, при этом, использовать фиксированные значения x и p_x, которые в общем случае выражаются через физические переменный, но из можно просто считать равными нулю при $C=X=0$. В итоге, амплитуда сводится к интегралу по физическим степеням свободы, когда выполнены все калибровочные связи, а нединамическая компонента λ также не дает никакого вклада в действие,

$$Z=\int \mathcal{D}q\mathcal{D}pe^{\mathrm{i}\int \mathrm{d}^4x(\dot{q}p-\mathcal{H}(q,p))}$$

Именно, этого мы и добивались: построенный по физическим модам калибровочного поля континуальный интеграл эквивалентен калибровочно инвариантному континуальному интегралу,

где проводится интегрирование по всем компонентам поля с учетом фактора,

который отвечает скобке Пуассона генератора калибровочных преобразований и калировочного условия, которое фиксирует калибровку.

Эта

оператором, который вводится в трюке Фаддева-Попова.

Далее, чтобы рассматривать произвольные калибровочные условия, оставалось убедиться, что произведение дельта-функции от калибровки $\delta(X)$ на детерминант от оператора $\mathrm{Det}\left(\mathcal{M}_X\right)$, задающего производную калибровки по групповому параметру, является калибровочно инвариантным, что мы уже установили ранее.

примеры применений метода Фаддеева-Попова (!!!??)

самое интересное, я хз прямо.

примеры гостов

хз

примеры применений (!!!)

в гравитации, говорят, применяется.
как и где еще?

18.7.6 BRST Method

Более общий взгляд на происхождение и роль гостов возможен в рамках метода $BRST$, названного по именам авторов - Becchi, Rouet, Stora, Тютин и широко применяемого в теории калибровочных полей и струн.

мотивация и обзор методов

обзор применений (!!??)

вид преобразований

Соответствующие преобразования полей носят название $BRST$ -преобразований:

$$\delta\varphi = c_i t_i \varphi, \quad \delta c_i = -\frac{i}{2} f_{ijk} c_j c_k, \quad \delta \bar{c}_i = b_i, \quad \delta b_i = 0$$

объяснение метода BRST

Центральным объектом данного метода является нильпотентный оператор δ.

простейшая реализация

Рассмотрим сначала простейшую реализацию BRST метода.
Пусть нильпотентный оператор δ имеет вид:

$$\delta = c_i t_i - \frac{i}{2} f_{ijk} c_i c_j \frac{\partial}{\partial c_k}, \quad [t_i, t_j] = i f_{ijk} t_k, \quad c_i c_j = -c_j c_i$$

где t_i-генераторы некоторой группы, а c_i-грассмановы переменные (будущие госты).

Нильпотентность δ, то есть свойство $\delta^2 = 0$, доказывается прямым вычислением.
???

Например, если генераторы t_i действуют на φ, то достаточно проверить

$$\delta^2 \varphi = \delta\left(c_i t_i \varphi\right) = -\frac{i}{2} f_{jki} c_j c_k t_i \varphi + c_j c_i t_j t_i \varphi = -\frac{i}{2} f_{jki} c_j c_k t_i \varphi + \frac{1}{2} c_j c_i \left[t_j, t_i\right] \varphi = 0$$

$$\delta^2 c_i = -\frac{i}{2} f_{jki} \delta\left(c_j c_k\right) = \frac{1}{2} f_{jki} f_{mnk} c_j c_m c_n = 0$$

Последнее равенство есть следствие циклической структуры тождества Якоби.

Теперь запишем оператор δ в том виде, в котором он обычно используется в калибровочных теориях, добавив к (213), не нарушая нильпотентности, антигостые $\bar{c}_i$ (тоже грассманновы) и вспомогательные бозонные поля b_i :

$$\delta = c_i t_i - \frac{i}{2} f_{ijk} c_i c_j \frac{\partial}{\partial c_k} + b_i \frac{\partial}{\partial \bar{c}_i}, \quad \delta^2 = 0$$

Соответствующие преобразования полей носят название $BRST$ -преобразований:

$$\delta\varphi = c_i t_i \varphi, \quad \delta c_i = -\frac{i}{2} f_{ijk} c_j c_k, \quad \delta \bar{c}_i = b_i, \quad \delta b_i = 0$$

Теперь t_i -это генераторы калибровочной группы; они действуют на все поля (φ), из которых строилась исходная теория (глюоны, кварки и т.д.), производя над ними калибровочные преобразования согласно типу каждого поля.

В привычных нам обозначениях первые соотношения из BRST преобразований имели бы вид

$$\delta\psi = igc^a t^a \psi, \quad \delta B^a_\mu = \partial_\mu c^a + g f^{abc} B^b_\mu c^c, \quad \delta c^a = -\frac{g}{2} f^{abc} c^b c^c$$

Отметим, что госты и антигосты выступают в данном подходе как независимые поля, хотя в лагранжиане (210) это не бросалось в глаза; в частности, преобразования (215) у них совершенно различны.

мы ввели BRST-преобразования как калибровочные, но с гостами в качестве параметров.

метод Фаддеева-Попова на BRST языке

Переформулируем теперь метод Фаддеева-Попова на BRST языке.

Назовем $BRST$ -инвариантным объект Φ, удовлетворяющий условию $\delta\Phi = 0$.

Если выбрать полный лагранжиан квантовой неабелевой теории в виде суммы

$$\mathscr{L} = \mathscr{L}_{\text{inv}} + \delta\Lambda$$

исходного калибровочно инвариантного лагранжиана $\mathscr{L}_{\text{inv}}(\varphi)$, содержащего только поля φ, и добавки $\delta\Lambda$ с неинвариантным $\Lambda(\varphi, c, \bar{c}, b)$, то весь лагранжиан $\mathscr{L}$ будет BRST-инвариантен.

Пусть калибровка фиксируется условиями $f_i(\varphi) = 0$.

Возьмем

$$\Lambda = \left(f_i + \frac{\alpha}{2} b_i\right) \bar{c}_i \quad \Longrightarrow \quad \mathscr{L} = \mathscr{L}_{\text{inv}} + c_j t_j f_i \bar{c}_i + f_i b_i + \frac{\alpha}{2} b_i b_i$$

Тогда континуальное интегрирование по $c, \bar{c}$ выдает детерминант $\det(t_j f_i)$ матрицы калибровочного преобразования условий f_i, который в точности соответствует функционалу $\Delta_f[B]$(207).

Интегрирование по полям b порождает $\exp(-i f_i f_i / 2\alpha)$, а при $\alpha = 0$ -соответственно, $\delta(f)$, воспроизводя лагранжиан (212).

Особенно прозрачным становится в этом подходе доказательство независимост теории от неинвариантной (фиксирующей калибровку) добавки Λ.

Действительно, континуальный интеграл типа (211) с инвариантным Φ,

$$\int \mathscr{D}\phi \mathscr{D}\bar{c} \mathscr{D}c \mathscr{D}b \Phi \exp i\left(\mathscr{L}_{\text{inv}} + \delta\Lambda\right) \equiv \int \mathscr{D}\Psi \Phi \exp i\left(\mathscr{L}_{\text{inv}} + \delta\Lambda\right)$$

при малых изменениях Λ сам может измениться только на величину вида

$$\int \mathscr{D}\Psi\Phi\delta X \exp i\left(\mathscr{L}_{\text{inv}} + \delta\Lambda\right) = \int \delta\left(\mathscr{D}\Psi\Phi X \exp i\left(\mathscr{L}_{\text{inv}} + \delta\Lambda\right)\right) = 0$$

равную нулю, поскольку интеграл не меняется при заменах переменных.

пример применений???

хз, я даже сам метод не очень пока понял.

19 What If There Is Another Fundamental Effect?

(theoretical analysis of different effects)

19.0.1 Vacuum in a Uniform Gravitational Field, Excitation of a Uniformly Accelerated Detector by Ginzburg, Frolov

(see now something about it in GR, later I'll write also here from QFT perspective)

Вакуум в пространстве-времени Минковского, рассматриваемый в инерциальной и в равномерно ускоренной системах отсчета. Вакуум в статическом однородном гравитационном поле

Квантовая теория поля в инерциальной системе отсчета.

2.2. Равномерно ускоренная система отсчета и система отсчета, покоящаяся в однородном гравитационном поле.

2.3. Квантовая теория поля в равномерно ускоренной системе отсчета.

2.4. Вакуум в статическом однородном гравитационном поле.

Суть (????)

Правила Фейнмана для неабелевой теории с фермионными полями по Киселеву (!?!?)

Для определения правил Фейнмана запишем все вклады в лагранжиан неабелевых калибровочных полей, которые взаимодействую со спинорнми дираковскими полями.

Калибровочное поле с тензором напряженности

$$F^c_{\mu\nu} = \partial_\mu \mathcal{A}^c_\nu - \partial_\nu \mathcal{A}^c_\mu - e f_{abc} \mathcal{A}^a_\mu \mathcal{A}^b_\nu$$

задает

$$\mathcal{L}_{\text{g.f.}} = -\frac{1}{2} \operatorname{tr} F^2_{\mu\nu} = -\frac{1}{4} F^c_{\mu\nu} F^{\mu\nu}_c$$

где наряду с квадратичным членом свободного поля с добавлием вклада от лоренцевской калибровки

$$\mathcal{L}_0 + \mathcal{L}_{\text{g.fix.}} = -\frac{1}{4} \left(\partial_\mu \mathcal{A}^c_\nu - \partial_\nu \mathcal{A}^c_\mu\right) \left(\partial^\mu \mathcal{A}^\nu_c - \partial^\nu \mathcal{A}^\mu_c\right) - \frac{1}{2\xi} \left(\partial_\mu \mathcal{A}^\mu_c\right)^2$$

есть вклады от кубического самодействия поля, линейного по заряду e,

$$\mathcal{L}_{eA} = \frac{1}{2} e \left(\partial_\mu \mathcal{A}^c_\nu - \partial_\nu \mathcal{A}^c_\mu\right) f_{abc} \mathcal{A}^\mu_a \mathcal{A}^\nu_b$$

и самодействия четвертой степени по полю, квадратичного по заряду,

$$\mathcal{L}_{e^2A} = -\frac{1}{4}e^2 f_{abc}\mathcal{A}^a_\mu \mathcal{A}^b_\nu f_{a'b'c}\mathcal{A}^\mu_{a'}\mathcal{A}^\nu_{b'}$$

Значит, на внутренних линиях калибровочному полу соответствует волнистая линия с пропагатором, который сохраняет групповой индекс поля,

$$\frac{\mathrm{i}}{k^2+\mathrm{i}0}\delta^b_a\left(-g_{\mu\nu}+(1-\xi)\frac{k_\mu k_\nu}{k^2}\right) \quad a \quad \sim\sim\sim\sim \quad b$$

Трехточечная вершина вычисляется дифференцированием по трем полям, причем, $\frac{1}{2}$ сокращается поскольку поля без производных входят неотличимым образом, стандартный фактор перед лагранжианом i в сочетании, например, с ∂_μ дает импульс p_μ, а исходное слагаемое записывается по явному виду лагранжиана: сначала фактор с групповыми индексами, так что импульс отвечает полю с третим групповым индексом и лоренцевым индексом в соответствии с лагранжианом, а остальные вклады получаются циклической перестановкой групповых индексов в структурных константах и соответствующими заменами импульса и лоренцевых индексов,

$$\begin{array}{l} ef_{abc}\left(q_\mu g_{\lambda\nu}-q_\nu g_{\lambda\mu}\right)+ \\ ef_{bca}\left(p_\nu g_{\mu\lambda}-p_\lambda g_{\mu\nu}\right)+ \\ ef_{cab}\left(k_\lambda g_{\nu\mu}-k_\mu g_{\nu\lambda}\right) \end{array}$$

Четыреехточечная вершина имеет $4!/4 = 6$ вкладов, которые получаются перестановками лоренцеых и групповых индексов из их исходной прескрипции в явном виде лагражиана с учетом антисимметрии структурных констант f_{abc} по перестановке групповых индексов,

$$-\mathrm{i}e^2\left\{\begin{array}{l} f_{abc}f_{a'b'c}\left(g_{\mu\mu'}g_{\nu\nu'}-g_{\mu\nu'}g_{\nu\mu'}\right)+ \\ f_{aa'c}f_{bb'c}\left(g_{\mu\nu}g_{\mu'\nu'}-g_{\mu\nu'}g_{\mu'\nu}\right)+ \\ f_{ab'c}f_{a'bc}\left(g_{\mu\mu'}g_{\nu'\nu}-g_{\mu\nu}g_{\nu'\mu'}\right) \end{array}\right\}$$

Для внешних линий калибровочного полая в конечном состоянии в амплитуду входят отрицательно частотные моды ε^{*a}_μ, а в начальном состоянии − положительно частотные ε^a_μ. Лагранжиан калибровочного взаимодействия спинорного дираковского поля с групповым индексом A представления группы локальной внутренней

симметрии с эрмитово самосопряженными генераторами t^a_{AB} имеет вид

$$\mathcal{L}_D = \bar\psi_A\left(\delta_{AB}\left(\mathrm{i}\partial_\mu\gamma^\mu - m\right) - e\gamma^\mu\mathcal{A}^a_\mu t^a_{AB}\right)\psi_B$$

Отсюда элементарно воспроизводим пропагатор фермиона на внутренних линиях

(пара диаграмм)

Для внешних линий частиц в конечном состоянии в амплитуду входят отрицательно частотные моды $\bar u_{\lambda,A}$, в начальном состоянии - положительно частотные моды $u_{\lambda,A}$ для античастиц в конечном состоянии - положительно частотные $v+\lambda, A$, а в начальном - отрицательно частотные $\bar v_{\lambda,A}$

Правила Фейнмана для диаграмм с духами Фаддеева-Попова мы уже приводили в разделе 9.6.

примеры

применим эти правила к какому-то конкретному случаю.

Part VI
QFT Processes and Effects

21 Typical Phenomena of Quantum Electrodynamics (?!!!)

Обсудим подробно типичные явления КТП.

(!??!?!? Киселева еще раз переучу, там многие есть!!! ну или других, важно нарабатать классические КТП явления!!)

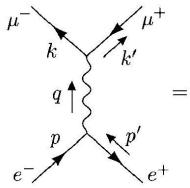
Finally, after three long chapters of formalism, we are ready to perform some real relativistic calculations, to begin working out the predictions of Quantum Electrodynamics. First we will return to the process considered in Chapter 1, the annihilation of an electron-positron pair into a pair of heavier fermions. We will study this paradigm process in extreme detail in the next three sections, then do a few more simple QED calculations in Sections 5.4 and 5.5. The problems at the end of the chapter treat several additional QED processes. More complete surveys of QED can be found in the books of Jauch and Rohrlich (1976) and of Berestetskii, Lifshitz, and Pitaevskii (1982).

21.1 5.1$e^+e^- \to \mu^+\mu^-$: Introduction

The reaction $e^+e^- \to \mu^+\mu^-$is the simplest of all QED processes, but also one of the most important in high-energy physics. It is fundamental to the understanding of all reactions in e^+e^-colliders, and is in fact used to calibrate such machines. The related process $e^+e^- \to q\bar{q}$ (a quark-antiquark pair) is extraordinarily useful in determining the properties of elementary particles.

In this section we will compute the unpolarized cross section for $e^+e^- \to \mu^+\mu^-$, to lowest order. In Chapter 1 we used elementary arguments to guess the answer (Eq. (1.8)) in the limit where all the fermions are massless. We now relax that restriction and retain the muon mass in the calculation. Retaining the electron mass as well would be easy but pointless, since the ratio $m_e/m_\mu \approx 1/200$ is much smaller than the fractional error introduced by neglecting higher-order terms in the perturbation series.

Using the Feynman rules from Section 4.8, we can at once draw the diagram and write down the amplitude for our process:



$$= \bar{v}^{s'}(p')(-ie\gamma^\mu)u^s(p)\left(\frac{-ig_{\mu\nu}}{q^2}\right)\bar{u}^r(k)(-ie\gamma^\nu)v^{r'}(k').$$

Rearranging this slightly and leaving the spin superscripts implicit, we have

$$i\mathcal{M}\left(e^-(p)e^+(p') \to \mu^-(k)\mu^+(k')\right) = \frac{ie^2}{q^2}\left(\bar{v}(p')\gamma^\mu u(p)\right)\left(\bar{u}(k)\gamma_\mu v(k')\right) \tag{5.1}$$

This answer for the amplitude $\mathcal{M}$ is simple, but not yet very illuminating.
To compute the differential cross section, we need an expression for $|\mathcal{M}|^2$, so we must find the complex conjugate of $\mathcal{M}$. A bi-spinor product such as $\bar{v}\gamma^\mu u$ can be complex-conjugated as follows:

$$(\bar{v}\gamma^\mu u)^* = u^\dagger (\gamma^\mu)^\dagger \left(\gamma^0\right)^\dagger v = u^\dagger (\gamma^\mu)^\dagger \gamma^0 v = u^\dagger \gamma^0 \gamma^\mu v = \bar{u}\gamma^\mu v$$

(This is another advantage of the 'bar' notation.) Thus the squared matrix element is

$$|\mathcal{M}|^2 = \frac{e^4}{q^4} \left(\bar{v}\left(p'\right)\gamma^\mu u(p)\bar{u}(p)\gamma^\nu v\left(p'\right)\right)\left(\bar{u}(k)\gamma_\mu v\left(k'\right)\bar{v}\left(k'\right)\gamma_\nu u(k)\right) \tag{5.2}$$

At this point we are still free to specify any particular spinors $u^s(p)$, $\bar{v}^{s'}(p')$, and so on, corresponding to any desired spin states of the fermions. In actual experiments, however, it is difficult (though not impossible) to retain control over spin states; one would have to prepare the initial state from polarized materials and/or analyze the final state using spin-dependent multiple scattering. In most experiments the electron and positron beams are unpolarized, so the measured cross section is an average over the electron and positron spins s and s'. Muon detectors are normally blind to polarization, so the measured cross section is a sum over the muon spins r and r'.

The expression for $|\mathcal{M}|^2$ simplifies considerably when we throw away the spin information. We want to compute

$$\frac{1}{2}\sum_s \frac{1}{2}\sum_{s'}\sum_r\sum_{r'} \left|\mathcal{M}\left(s,s'\to r,r'\right)\right|^2$$

The spin sums can be performed using the completeness relations from Section 3.3:

$$\sum_s u^s(p)\bar{u}^s(p) = \not{p} + m; \quad \sum_s v^s(p)\bar{v}^s(p) = \not{p} - m \tag{5.3}$$

Working with the first half of (5.2), and writing in spinor indices so we can freely move the v next to the $\bar{v}$, we have

$$\begin{aligned}\sum_{s,s'} \bar{v}_a^{s'}\left(p'\right)\gamma^\mu_{ab}u_b^s(p)\bar{u}_c^s(p)\gamma^\nu_{cd}v_d^{s'}\left(p'\right) &= \left(\not{p}'-m\right)_{da}\gamma^\mu_{ab}\left(\not{p}+m\right)_{bc}\gamma^\nu_{cd} \\ &= \operatorname{trace}\left[\left(\not{p}'-m\right)\gamma^\mu\left(\not{p}+m\right)\gamma^\nu\right]\end{aligned}$$

Evaluating the second half of (5.2) in the same way, we arrive at the desired simplification:

$$\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 = \frac{e^4}{4q^4}\operatorname{tr}\left[\left(\not{p}'-m_e\right)\gamma^\mu\left(\not{p}+m_e\right)\gamma^\nu\right]\operatorname{tr}\left[\left(\not{k}+m_\mu\right)\gamma_\mu\left(\not{p}'-m_\mu\right)\gamma_\nu\right] \tag{5.4}$$

The spinors u and v have disappeared, leaving us with a much cleaner expression in terms of γ matrices. This trick is very general: Any QED amplitude involving external fermions, when squared and summed or averaged over spins, can be converted in this way to traces of products of Dirac matrices.

Trace Technology

This last step would hardly be an improvement if the traces had to be laboriously computed by brute force. But Feynman found that they could be worked out easily by appealing to the algebraic properties of the γ matrices. Since the evaluation of such traces occurs so often in QED calculations, it is worthwhile to pause and attack the problem systematically, once and for all.

We would like to evaluate traces of products of n gamma matrices, where $n = 0, 1, 2, \ldots$ (For the present problem we need $n = 2, 3, 4$.) The $n = 0$ case is fairly easy: $\operatorname{tr}\mathbf{1} = 4$. The trace of one γ matrix is also easy. From the explicit form of the matrices in the chiral representation, we have

$$\operatorname{tr}\gamma^\mu = \operatorname{tr}\begin{pmatrix} 0 & \sigma^\mu \\ \bar\sigma^\mu & 0 \end{pmatrix} = 0$$

It is useful to prove this result in a more abstract way, which generalizes to an arbitrary odd number of γ matrices:

$$\begin{aligned}
\operatorname{tr}\gamma^\mu &= \operatorname{tr}\gamma^5\gamma^5\gamma^\mu && \text{since } \left(\gamma^5\right)^2 = 1 \\
&= -\operatorname{tr}\gamma^5\gamma^\mu\gamma^5 && \text{since } \left\{\gamma^\mu,\gamma^5\right\} = 0 \\
&= -\operatorname{tr}\gamma^5\gamma^5\gamma^\mu && \text{using cyclic property of trace} \\
&= -\operatorname{tr}\gamma^\mu.
\end{aligned}$$

Since the trace of γ^μ is equal to minus itself, it must vanish. For $n\gamma$-matrices we would get n minus signs in the second step (as we move the second γ^5 all the way to the right), so the trace must vanish if n is odd.

To evaluate the trace of two γ matrices, we again use the anticommutation properties and the cyclic property of the trace:

$$\begin{aligned}
\operatorname{tr}\gamma^\mu\gamma^\nu &= \operatorname{tr}\left(2g^{\mu\nu}\cdot 1 - \gamma^\nu\gamma^\mu\right) && \text{(anticommuatation)} \\
&= 8g^{\mu\nu} - \operatorname{tr}\gamma^\mu\gamma^\nu && \text{(cyclicity)}
\end{aligned}$$

Thus $\operatorname{tr}\gamma^\mu\gamma^\nu = 4g^{\mu\nu}$. The trace of any even number of γ matrices can be evaluated in the same way: Anticommute the first γ matrix all the way to the right, then cycle it back to the left. Thus for the trace of four γ matrices, we have

$$\begin{aligned}
\operatorname{tr}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\right) &= \operatorname{tr}\left(2g^{\mu\nu}\gamma^\rho\gamma^\sigma - \gamma^\nu\gamma^\mu\gamma^\rho\gamma^\sigma\right) \\
&= \operatorname{tr}\left(2g^{\mu\nu}\gamma^\rho\gamma^\sigma - \gamma^\nu 2g^{\mu\rho}\gamma^\sigma + \gamma^\nu\gamma^\rho 2g^{\mu\sigma} - \gamma^\nu\gamma^\rho\gamma^\sigma\gamma^\mu\right)
\end{aligned}$$

Using the cyclic property on the last term and bringing it to the left-hand side, we find

$$\begin{aligned}
\operatorname{tr}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\right) &= g^{\mu\nu}\operatorname{tr}\gamma^\rho\gamma^\sigma - g^{\mu\rho}\operatorname{tr}\gamma^\nu\gamma^\sigma + g^{\mu\sigma}\operatorname{tr}\gamma^\nu\gamma^\rho \\
&= 4\left(g^{\mu\nu}g^{\rho\sigma} - g^{\mu\rho}g^{\nu\sigma} + g^{\mu\sigma}g^{\nu\rho}\right)
\end{aligned}$$

In this manner one can always reduce a trace of $n\gamma$-matrices to a sum of traces of $(n-2)\gamma$-matrices. The case $n = 6$ is easy to work out, but has fifteen terms (the number of ways of grouping the six indices in pairs to make terms of the form $g^{\mu\nu}g^{\rho\sigma}g^{\alpha\beta}$). Fortunately, we will not need it in this book. (If you ever do need to evaluate such complicated traces, it may be easier to learn to use one of the several computer programs that can perform symbolic manipulations on Dirac matrices.)

Starting in Section 5.2, we will often need to evaluate traces involving γ^5. Since $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$, the trace of γ^5 times any odd number of other γ matrices is zero. It is also easy to show that the trace of γ^5 itself is zero:

$$\operatorname{tr}\gamma^5 = \operatorname{tr}\left(\gamma^0\gamma^0\gamma^5\right) = -\operatorname{tr}\left(\gamma^0\gamma^5\gamma^0\right) = -\operatorname{tr}\left(\gamma^0\gamma^0\gamma^5\right) = -\operatorname{tr}\gamma^5$$

The same trick works for $\operatorname{tr}\left(\gamma^\mu\gamma^\nu\gamma^5\right)$, if we insert two factors of γ^α for some α different from both μ and ν. The first nonvanishing trace involving γ^5 contains four other γ matrices. In this case the trick still works unless every γ matrix appears, so $\operatorname{tr}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^5\right) = 0$ unless $(\mu\nu\rho\sigma)$ is some permutation of (0123). From the anticommutation rules it also follows that interchanging any two

of the indices simply changes the sign of the trace, so tr $(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^5)$ must be proportional to $\epsilon^{\mu\nu\rho\sigma}$. The overall constant turns out to be $-4i$, as you can easily check by plugging in $(\mu\nu\rho\sigma) = (0123)$.

Here is a summary of the trace theorems, for convenient reference:

$$\begin{aligned}
\mathrm{tr}(\mathbf{1}) &= 4 \\
\mathrm{tr}\,(\text{ any odd \# of } \gamma'\mathrm{s}) &= 0 \\
\mathrm{tr}\,(\gamma^\mu\gamma^\nu) &= 4g^{\mu\nu} \\
\mathrm{tr}\,(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) &= 4\left(g^{\mu\nu}g^{\rho\sigma} - g^{\mu\rho}g^{\nu\sigma} + g^{\mu\sigma}g^{\nu\rho}\right) \\
\mathrm{tr}\left(\gamma^5\right) &= 0 \\
\mathrm{tr}\left(\gamma^\mu\gamma^\nu\gamma^5\right) &= 0 \\
\mathrm{tr}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^5\right) &= -4i\epsilon^{\mu\nu\rho\sigma}
\end{aligned} \tag{5.5}$$

Expressions resulting from use of the last formula can be simplified by means of the identities

$$\begin{aligned}
\epsilon^{\alpha\beta\gamma\delta}\epsilon_{\alpha\beta\gamma\delta} &= -24 \\
\epsilon^{\alpha\beta\gamma\mu}\epsilon_{\alpha\beta\gamma\nu} &= -6\delta^\mu{}_\nu \\
\epsilon^{\alpha\beta\mu\nu}\epsilon_{\alpha\beta\rho\sigma} &= -2\left(\delta^\mu{}_\rho\delta^\nu{}_\sigma - \delta^\mu{}_\sigma\delta^\nu{}_\rho\right)
\end{aligned} \tag{5.6}$$

All of these can be derived by first appealing to symmetry arguments, then evaluating one special case to determine the overall constant.

Another useful identity allows one to reverse the order of all the γ matrices inside a trace:

$$\mathrm{tr}\,(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\cdots) = \mathrm{tr}\,(\cdots\gamma^\sigma\gamma^\rho\gamma^\nu\gamma^\mu) \tag{5.7}$$

To prove this relation, consider the matrix $C \equiv \gamma^0\gamma^2$ (essentially the chargeconjugation operator). This matrix satisfies $C^2 = 1$ and $C\gamma^\mu C = -\left(\gamma^\mu\right)^T$. Thus if there are $n\gamma$-matrices inside the trace,

$$\begin{aligned}
\mathrm{tr}\,(\gamma^\mu\gamma^\nu\cdots) &= \mathrm{tr}\,(C\gamma^\mu CC\gamma^\nu C\cdots) \\
&= (-1)^n\,\mathrm{tr}\left[\left(\gamma^\mu\right)^T\left(\gamma^\nu\right)^T\cdots\right] \\
&= \mathrm{tr}\,(\cdots\gamma^\nu\gamma^\mu)
\end{aligned}$$

since the trace vanishes unless n is even. It is easy to show that the reversal identity (5.7) is also valid when the trace contains one or more factors of γ^5.

When two γ matrices inside a trace are dotted together, it is easiest to eliminate them before evaluating the trace. For example,

$$\gamma^\mu\gamma_\mu = g_{\mu\nu}\gamma^\mu\gamma^\nu = \frac{1}{2}g_{\mu\nu}\left\{\gamma^\mu,\gamma^\nu\right\} = g_{\mu\nu}g^{\mu\nu} = 4 \tag{5.8}$$

The following contraction identities, all easy to prove using the anticommutation relations, can be used when other γ matrices lie in between:

$$\begin{aligned}
\gamma^\mu\gamma^\nu\gamma_\mu &= -2\gamma^\nu \\
\gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu &= 4g^{\nu\rho} \\
\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\mu &= -2\gamma^\sigma\gamma^\rho\gamma^\nu
\end{aligned} \tag{5.9}$$

Note the reversal of order in the last identity.
All of the γ matrix identities proved in this section are collected for reference in the Appendix.

Unpolarized Cross Section

We now return to the evaluation of the squared matrix element, Eq. (5.4). The electron trace is

$$\mathrm{tr}\left[(\not{p}' - m_e)\,\gamma^\mu\,(\not{p} + m_e)\,\gamma^\nu\right] = 4\left[p'^\mu p^\nu + p'^\nu p^\mu - g^{\mu\nu}\left(p\cdot p' + m_e^2\right)\right]$$

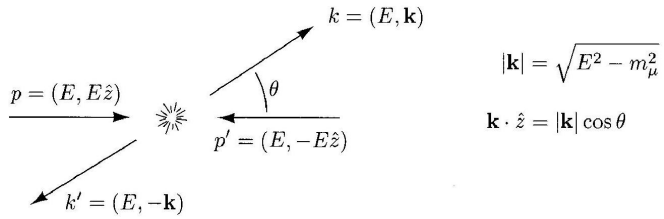
The terms with only one factor of m vanish, since they contain an odd number of γ matrices. Similarly, the muon trace is

$$\mathrm{tr}\left[(\not{k}+m_\mu)\,\gamma_\mu\,(\not{k}' - m_\mu)\,\gamma_\nu\right] = 4\left[k_\mu k'_\nu + k_\nu k'_\mu - g_{\mu\nu}\left(k\cdot k' + m_\mu^2\right)\right]$$

From now on we will set $m_e = 0$, as discussed at the beginning of this section. Dotting these expressions together and collecting terms, we get the simple result

$$\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 = \frac{8e^4}{q^4}\left[(p\cdot k)\,(p'\cdot k') + (p\cdot k')\,(p'\cdot k) + m_\mu^2\,(p\cdot p')\right] \tag{5.10}$$

To obtain a more explicit formula we must specialize to a particular frame of reference and express the vectors p, p', k, k', and q in terms of the basic kinematic variables - energies and angles- in that frame. In practice, the choice of frame will be dictated by the experimental conditions. In this book, we will usually make the simplest choice of evaluating cross sections in the center-ofmass frame. For this choice, the initial and final 4-momenta for $e^+e^- \to \mu^+\mu^-$ can be written as follows:



To compute the squared matrix element we need

$$q^2 = (p+p')^2 = 4E^2; \qquad p\cdot p' = 2E^2$$
$$p\cdot k = p'\cdot k' = E^2 - E|\mathbf{k}|\cos\theta; \quad p\cdot k' = p'\cdot k = E^2 + E|\mathbf{k}|\cos\theta$$

We can now rewrite Eq. (5.10) in terms of E and θ:

$$\begin{aligned}\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 &= \frac{8e^4}{16E^4}\left[E^2(E-|\mathbf{k}|\cos\theta)^2 + E^2(E+|\mathbf{k}|\cos\theta)^2 + 2m_\mu^2E^2\right]\\ &= e^4\left[\left(1+\frac{m_\mu^2}{E^2}\right) + \left(1-\frac{m_\mu^2}{E^2}\right)\cos^2\theta\right]\end{aligned} \tag{5.11}$$

All that remains is to plug this expression into the cross-section formula derived in Section 4.5. Since there are only two particles in the final state and we are working in the center-of-mass frame, we can use the simplified formula (4.84). For our problem $|v_{\mathcal{A}} - v_{\mathcal{B}}| = 2$ and $E_{\mathcal{A}} = E_{\mathcal{B}} = E_{\mathrm{cm}}/2$, so we have

$$\frac{d\sigma}{d\Omega} = \frac{1}{2E_{\rm cm}^2}\frac{|\mathbf{k}|}{16\pi^2 E_{\rm cm}} \cdot \frac{1}{4}\sum_{\rm spins}|\mathcal{M}|^2 \tag{5.12}$$
$$= \frac{\alpha^2}{4E_{\rm cm}^2}\sqrt{1-\frac{m_\mu^2}{E^2}}\left[\left(1+\frac{m_\mu^2}{E^2}\right)+\left(1-\frac{m_\mu^2}{E^2}\right)\cos^2\theta\right].$$

Integrating over $d\Omega$, we find the total cross section:

$$\sigma_{\rm total} = \frac{4\pi\alpha^2}{3E_{\rm cm}^2}\sqrt{1-\frac{m_\mu^2}{E^2}}\left(1+\frac{1}{2}\frac{m_\mu^2}{E^2}\right) \tag{5.13}$$

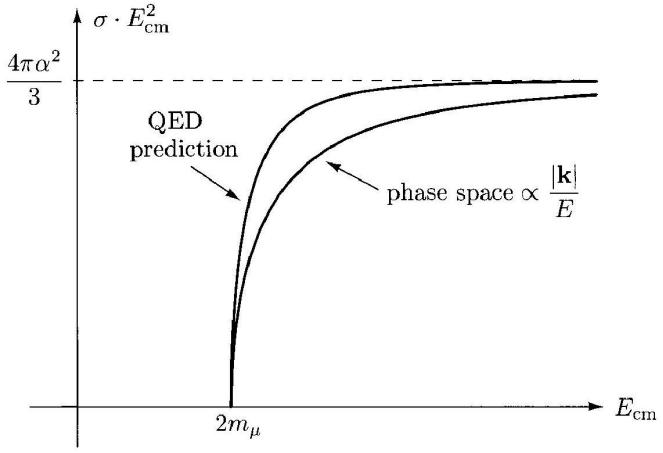


Figure 5.1. Energy dependence of the total cross section for $e^+e^- \to \mu^+\mu^-$, compared to "phase space" energy dependence.

In the high-energy limit where $E \gg m_\mu$, these formulae reduce to those given in Chapter 1:

$$\frac{d\sigma}{d\Omega} \underset{E\gg m_\mu}{\longrightarrow} \frac{\alpha^2}{4E_{\rm cm}^2}\left(1+\cos^2\theta\right)$$
$$\sigma_{\rm total} \underset{E\gg m_\mu}{\longrightarrow} \frac{4\pi\alpha^2}{3E_{\rm cm}^2}\left(1-\frac{3}{8}\left(\frac{m_\mu}{E}\right)^4-\cdots\right) \tag{5.14}$$

Note that these expressions have the correct dimensions of cross sections. In the high-energy limit, $E_{\rm cm}$ is the only dimensionful quantity in the problem, so dimensional analysis dictates that $\sigma_{\rm total} \propto E_{\rm cm}^{-2}$. Since we knew from the beginning that $\sigma_{\rm total} \propto \alpha^2$, we only had to work to get the factor of $4\pi/3$.

The energy dependence of the total cross-section formula (5.13) near threshold is shown in Fig. 5.1. Of course the cross section is zero for $E_{\rm cm} < 2m_\mu$. It is interesting to compare the shape of the actual curve to the shape one would obtain if $|\mathcal{M}|^2$ did not depend on energy, that is, if all the energy dependence came from the phase-space factor $|\mathbf{k}|/E$. To test Quantum Electrodynamics, an experiment must be able to resolve deviations from the naive phase-space prediction. Experimental results from pair production of both μ and τ leptons confirm that these particles behave as QED predicts. Figure 5.2 compares formula (5.13) to experimental measurements of the $\tau^+\tau^-$ threshold.

Before discussing our result further, let us pause to summarize how we obtained it. The method extends in a straightforward way to the calculation of unpolarized cross sections for other QED

processes. The general procedure is as follows:

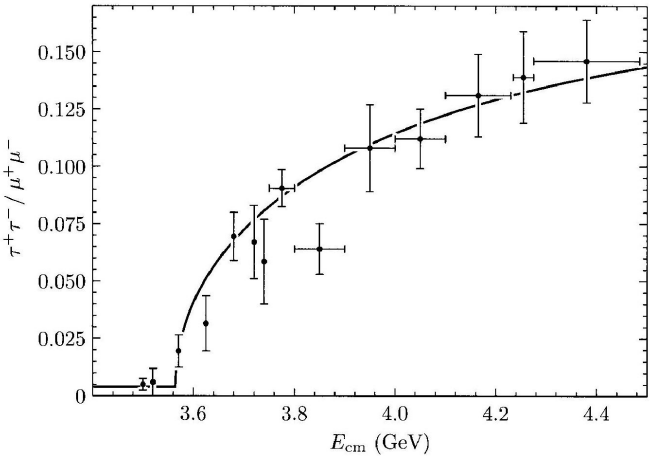

Figure 5.2. The ratio $\sigma\left(e^+e^- \to \tau^+\tau^-\right)/\sigma\left(e^+e^- \to \mu^+\mu^-\right)$of measured cross sections near the threshold for $\tau^+\tau^-$pair-production, as measured by the DELCO collaboration, W. Bacino, et. al., Phys. Rev. Lett. 41, 13 (1978). Only a fraction of τ decays are included, hence the small overall scale. The curve shows a fit to the theoretical formula (5.13), with a small energy-independent background added. The fit yields $m_\tau = 1782^{+2}_{-7}$MeV.

1. Draw the diagram(s) for the desired process.

2. Use the Feynman rules to write down the amplitude $\mathcal{M}$.

3. Square the amplitude and average or sum over spins, using the completeness relations (5.3). (For processes involving photons in the final state there is an analogous completeness relation, derived in Section 5.5.)

4. Evaluate traces using the trace theorems (5.5); collect terms and simplify the answer as much as possible.

5. Specialize to a particular frame of reference, and draw a picture of the kinematic variables in that frame. Express all 4-momentum vectors in terms of a suitably chosen set of variables such as E and θ.

6. Plug the resulting expression for $|\mathcal{M}|^2$ into the cross-section formula (4.79), and integrate over phase-space variables that are not measured to obtain a differential cross section in the desired form. (In our case these integrations were over the constrained momenta $\mathbf{k}'$ and $|\mathbf{k}|$, and were performed in the derivation of Eq. (4.84).)
   While other calculations (especially those involving loop diagrams) often require additional tricks, nearly every QED calculation will involve the basic procedures outlined here.

Production of Quark-Antiquark Pairs

The asymptotic energy dependence of the $e^+e^- \to \mu^+\mu^-$cross-section formula sets the scale for all e^+e^-annihilation cross sections. A particularly important example is the cross section for

$$e^+e^- \to \text{ hadrons },$$

that is, the total cross section for production of any number of strongly interacting particles.

In our current understanding of the strong interactions, given by the theory called Quantum Chromodynamics (QCD), all hadrons are composed of Dirac fermions called quarks. Quarks appear in a variety of types, called flavors, each with its own mass and electric charge. A quark also carries an additional quantum number, color, which takes one of three values. Color serves as the "charge" of QCD, as we will discuss in Chapter 17.

According to QCD , the simplest e^+e^-process that ends in hadrons is

$$e^+e^- \to q\bar{q}$$

the annihilation of an electron and a positron, through a virtual photon, into a quark-antiquark pair. After they are created, the quarks interact with one another through their strong forces, producing more quark pairs. Eventually the quarks and antiquarks combine to form some number of mesons and baryons.

To adapt our results for muon production to handle the case of quarks, we must make three modifications:

1. Replace the muon charge e with the quark charge $Q|e|$.

2. Count each quark three times, one for each color.

3. Include the effects of the strong interactions of the produced quark and antiquark.
   The first two changes are easy to make. For the first, it is simply necessary to know the masses and charges of each flavor of quark. For u, c, and t quarks we have $Q = 2/3$, while for d, s, and b quarks we have $Q = -1/3$. The crosssection formulae are proportional to the square of the charge of the final-state particle, so we can simply insert a factor of Q^2 into any of these formulae to obtain the cross section for production of any particular variety of quark. Counting colors is necessary because experiments measure only the total cross section for production of all three colors. (The hadrons that are actually detected are colorless.) In any case, this counting is easy: Just multiply the answer by 3 .

If you know a little about the strong interaction, however, you might think this is all a big joke. Surely the third modification is extremely difficult to make, and will drastically alter the predictions of QED. The amazing truth is that in the high-energy limit, the effect of the strong interaction on the quark production process can be completely neglected. As we will discuss in Part III, the only effect of the strong interaction (in this limit) is to dress
up the final-state quarks into bunches of hadrons. This simplification is due to a phenomenon called asymptotic freedom; it played a crucial role in the identification of Quantum Chromodynamics as the correct theory of the strong force.

Thus in the high-energy limit, we expect the cross section for the reaction $e^+e^- \to q\bar{q}$ to approach $3 \cdot Q^2 \cdot 4\pi\alpha^2/3E_{\rm cm}^2$. It is conventional to define

$$1 \text{ unit of R} \equiv \frac{4\pi\alpha^2}{3E_{\rm cm}^2} = \frac{86.8\text{nbarns}}{(E_{\rm cm} \text{ in GeV})^2} \tag{5.15}$$

The value of a cross section in units of R is therefore its ratio to the asymptotic value of the $e^+e^- \to \mu^+\mu^-$cross section predicted by Eq. (5.14). Experimentally, the easiest quantity to measure is the total rate for production of all hadrons. Asymptotically, we expect

$$\sigma\left(e^+e^- \to \text{ hadrons }\right) \underset{E_{\rm cm}\to\infty}{\longrightarrow} 3 \cdot \left(\sum_i Q_i^2\right) \text{R} \tag{5.16}$$

where the sum runs over all quarks whose masses are smaller than $E_{\rm cm}/2$. When $E_{\rm cm}/2$ is in the vicinity of one of the quark masses, the strong interactions cause large deviations from this formula. The most dramatic such effect is the appearance of bound states just below $E_{\rm cm} = 2m_q$, manifested as very sharp spikes in the cross section.

Experimental measurements of the cross section for e^+e^-annihilation to hadrons between 2.5 and 40 GeV are shown in Fig. 5.3. The data shows three distinct regions: a low-energy region in which u, d, and s quark pairs are produced; a region above the threshold for production of c quark pairs; and a region also above the threshold for b quark pairs. The prediction (5.16) is shown as a set of solid lines; it agrees quite well with the data in each region, as long as the energy is well away from the thresholds where the high-energy approximation breaks down. The dotted curves show an improved theoretical prediction, including higher-order corrections from QCD, which we will discuss in Section 17.2. This explanation of the e^+e^-annihilation cross section is a remarkable success of QCD. In particular, experimental verification of the factor of 3 in (5.16) is one piece of evidence for the existence of color.

The angular dependence of the differential cross section is also observed experimentally.* At high energy the hadrons appear in jets, clusters of several hadrons all moving in approximately the same direction. In most cases there are two jets, with back-to-back momenta, and these indeed have the angular dependence $(1 + \cos^2\theta)$.

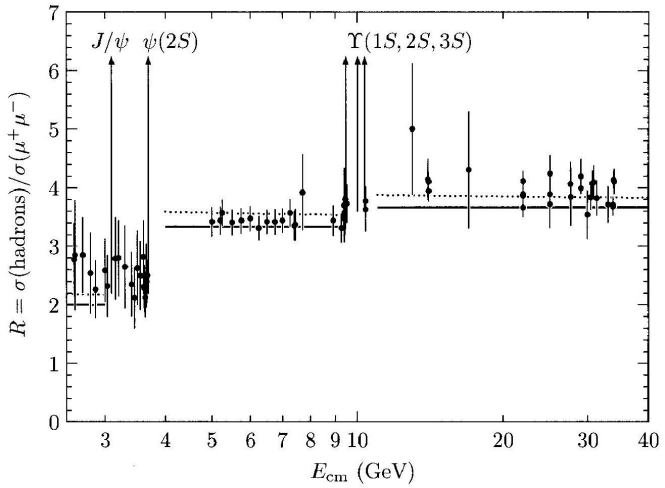

Figure 5.3. Experimental measurements of the total cross section for the reaction $e^+e^- \to$ hadrons, from the data compilation of M. Swartz, Phys. Rev. D53, 5268 (1996). Complete references to the various experiments are given there. The measurements are compared to theoretical predictions from Quantum Chromodynamics, as explained in the text. The solid line is the simple prediction (5.16).

21.2 5.2$e^+e^- \to \mu^+\mu^-$:Helicity Structure

The unpolarized cross section for a reaction is generally easy to calculate (and to measure) but hard to understand. Where does the $(1 + \cos^2\theta)$ angular dependence come from? We can answer this question by computing the $e^+e^- \to \mu^+\mu^-$cross section for each set of spin orientations separately.

First we must choose a basis of polarization states. To get a simple answer in the high-energy

[6]*The basic features of hadron production in high-energy e^+e^-annihilation are reviewed by P. Duinker, Rev. Mod. Phys. 54, 325 (1982).

limit, the best choice is to quantize each spin along the direction of the particle's motion, that is, to use states of definite helicity. Recall that in the massless limit, the left- and right-handed helicity states of a Dirac particle live in different representations of the Lorentz group. We might therefore expect them to behave independently, and in fact they do.

In this section we will compute the polarized $e^+e^- \to \mu^+\mu^-$cross sections, using the helicity basis, in two different ways: first, by using trace technology but with the addition of helicity projection operators to project out the desired left- or right-handed spinors; and second, by plugging explicit expressions for these spinors directly into our formula for the amplitude $\mathcal{M}$. Throughout this section we work in the high-energy limit where all fermions are effectively
massless. (The calculation can be done for lower energy, but it is much more difficult and no more instructive.) †

Our starting point for both methods of calculating the polarized cross section is the amplitude

$$i\mathcal{M}\left(e^-(p)e^+\left(p'\right) \to \mu^-(k)\mu^+\left(k'\right)\right) = \frac{ie^2}{q^2}\left(\bar{v}\left(p'\right)\gamma^\mu u(p)\right)\left(\bar{u}(k)\gamma_\mu v\left(k'\right)\right) \tag{5.1}$$

We would like to use the spin sum identities to write the squared amplitude in terms of traces as before, even though we now want to consider only one set of polarizations at a time. To do this, we note that for massless fermions, the matrices

$$\frac{1+\gamma^5}{2} = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}, \quad \frac{1-\gamma^5}{2} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \tag{5.17}$$

are projection operators onto right- and left-handed spinors, respectively. Thus if in (5.1) we make the replacement

$$\bar{v}\left(p'\right)\gamma^\mu u(p) \longrightarrow \bar{v}\left(p'\right)\gamma^\mu\left(\frac{1+\gamma^5}{2}\right)u(p)$$

the amplitude for a right-handed electron is unchanged while that for a lefthanded electron becomes zero. Note that since

$$\bar{v}\left(p'\right)\gamma^\mu\left(\frac{1+\gamma^5}{2}\right)u(p) = v^\dagger\left(p'\right)\left(\frac{1+\gamma^5}{2}\right)\gamma^0\gamma^\mu u(p) \tag{5.18}$$

this same replacement imposes the requirement that $v\left(p'\right)$ also be a righthanded spinor. Recall from Section 3.5, however, that the right-handed spinor $v\left(p'\right)$ corresponds to a left-handed positron. Thus we see that the annihilation amplitude vanishes when both the electron and the positron are right-handed. In general, the amplitude vanishes (in the massless limit) unless the electron and positron have opposite helicity, or equivalently, unless their spinors have the same helicity.

Having inserted this projection operator, we are now free to sum over the electron and positron spins in the squared amplitude; of the four terms in the sum, only one (the one we want) is nonzero. The electron half of $|\mathcal{M}|^2$, for a right-handed electron and a left-handed positron, is then

$$\begin{aligned}\sum_{\text{spins}}\left|\bar{v}\left(p'\right)\gamma^\mu\left(\frac{1+\gamma^5}{2}\right)u(p)\right|^2 &= \sum_{\text{spins}}\bar{v}\left(p'\right)\gamma^\mu\left(\frac{1+\gamma^5}{2}\right)u(p)\bar{u}(p)\gamma^\nu\left(\frac{1+\gamma^5}{2}\right)v\left(p'\right) \\ &= \operatorname{tr}\left[\not{p}'\gamma^\mu\left(\frac{1+\gamma^5}{2}\right)\not{p}\gamma^\nu\left(\frac{1+\gamma^5}{2}\right)\right] \\ &= \operatorname{tr}\left[\not{p}''\gamma^\mu\not{p}\gamma^\nu\left(\frac{1+\gamma^5}{2}\right)\right]\end{aligned}$$

† The general formalism for S-matrix elements between states of definite helicity is presented in a beautiful paper of M. Jacob and G. C. Wick, Ann. Phys. 7, 404 (1959).

$$= 2\left(p'^{\mu}p^{\nu} + p'^{\nu}p^{\mu} - g^{\mu\nu}p\cdot p' - i\epsilon^{\alpha\mu\beta\nu}p'_{\alpha}p_{\beta}\right) \tag{5.19}$$

The indices in this expression are to be dotted into those of the muon half of the squared amplitude. For a right-handed $\mu^-$and a left-handed μ^+, an identical calculation yields

$$\sum_{\text{spins}} \left|\bar{u}(k)\gamma_{\mu}\left(\frac{1+\gamma^5}{2}\right)v\left(k'\right)\right|^2 = 2\left(k_{\mu}k'_{\nu} + k_{\nu}k'_{\mu} - g_{\mu\nu}k\cdot k' - i\epsilon_{\rho\mu\sigma\nu}k^{\rho}k'^{\sigma}\right) \tag{5.20}$$

Dotting (5.19) into (5.20), we find that the squared matrix element for $e^-_R e^+_L \to \mu^-_R\mu^+_L$in the center-of-mass frame is

$$\begin{aligned}
|\mathcal{M}|^2 &= \frac{4e^4}{q^4}\left[2(p\cdot k)\left(p'\cdot k'\right) + 2\left(p\cdot k'\right)\left(p'\cdot k\right) - \epsilon^{\alpha\mu\beta\nu}\epsilon_{\rho\mu\sigma\nu}p'_{\alpha}p_{\beta}k^{\rho}k'^{\sigma}\right] \\
&= \frac{8e^4}{q^4}\left[(p\cdot k)\left(p'\cdot k'\right) + \left(p\cdot k'\right)\left(p'\cdot k\right) - (p\cdot k)\left(p'\cdot k'\right) + \left(p\cdot k'\right)\left(p'\cdot k\right)\right] \\
&= \frac{16e^4}{q^4}\left(p\cdot k'\right)\left(p'\cdot k\right) \\
&= e^4(1+\cos\theta)^2
\end{aligned} \tag{5.21}$$

Plugging this result into (4.85) gives the differential cross section,

$$\frac{d\sigma}{d\Omega}\left(e^-_R e^+_L \to \mu^-_R\mu^+_L\right) = \frac{\alpha^2}{4E^2_{\text{cm}}}(1+\cos\theta)^2 \tag{5.22}$$

There is no need to repeat the entire calculation to obtain the other three nonvanishing helicity amplitudes. For example, the squared amplitude for $e^-_R e^+_L \to \mu^-_L\mu^+_R$is identical to (5.20) but with γ^5 replaced by $-\gamma^5$ on the left-hand side, and thus $\epsilon_{\rho\mu\sigma\nu}$ replaced by $-\epsilon_{\rho\mu\sigma\nu}$ on the right-hand side. Propagating this sign though (5.21), we easily see that

$$\frac{d\sigma}{d\Omega}\left(e^-_R e^+_L \to \mu^-_L\mu^+_R\right) = \frac{\alpha^2}{4E^2_{\text{cm}}}(1-\cos\theta)^2 \tag{5.23}$$

Similarly,

$$\begin{aligned}
\frac{d\sigma}{d\Omega}\left(e^-_L e^+_R \to \mu^-_R\mu^+_L\right) &= \frac{\alpha^2}{4E^2_{\text{cm}}}(1-\cos\theta)^2 \\
\frac{d\sigma}{d\Omega}\left(e^-_L e^+_R \to \mu^-_L\mu^+_R\right) &= \frac{\alpha^2}{4E^2_{\text{cm}}}(1+\cos\theta)^2
\end{aligned} \tag{5.24}$$

(These two results actually follow from the previous two by parity invariance.) The other twelve helicity cross sections (for instance, $e^-_L e^+_R \to \mu^-_L\mu^+_L$) are zero, as we saw from Eq. (5.18). Adding up all sixteen contributions, and dividing by 4 to average over the electron and positron spins, we

recover the unpolarized cross section in the massless limit, Eq. (5.14).

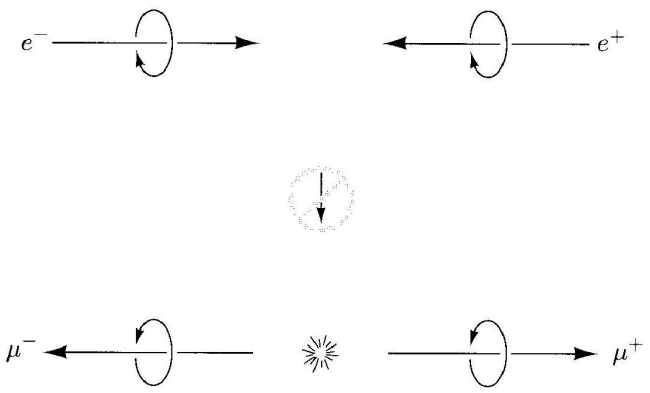

Figure 5.4. Conservation of angular momentum requires that if the z component of angular momentum is measured, it must have the same value as initially.

Note that the cross section (5.22) for $e_R^- e_L^+ \to \mu_R^- \mu_L^+$vanishes at $\theta = 180°$. This is just what we would expect, since for $\theta = 180°$, the total angular momentum of the final state is opposite to that of the initial state (see Figure 5.4).

This completes our first calculation of the polarized $e^+e^- \to \mu^+\mu^-$cross sections. We will now redo the calculation in a manner that is more straightforward, more enlightening, and no more difficult. We will calculate the amplitude $\mathcal{M}$ (rather than the squared amplitude) directly, using explicit values for the spinors and γ matrices. This method does have its drawbacks: It forces us to specialize to a particular frame of reference much sooner, so manifest Lorentz invariance is lost. More pragmatically, it is very cumbersome except in the nonrelativistic and ultra-relativistic limits.

Consider again the amplitude

$$\mathcal{M} = \frac{e^2}{q^2} \left(\bar{v}\left(p'\right) \gamma^\mu u(p)\right) \left(\bar{u}(k) \gamma_\mu v\left(k'\right)\right) \tag{5.25}$$

In the high-energy limit, our general expressions for Dirac spinors become

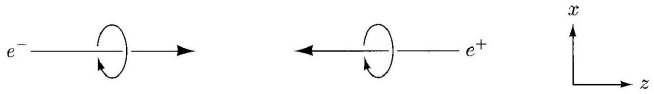
$$\begin{aligned} u(p) &= \begin{pmatrix} \sqrt{p \cdot \sigma}\xi \\ \sqrt{p \cdot \bar{\sigma}}\xi \end{pmatrix} \underset{E\to\infty}{\longrightarrow} \sqrt{2E} \begin{pmatrix} \frac{1}{2}(1 - \hat{p} \cdot \sigma)\xi \\ \frac{1}{2}(1 + \hat{p} \cdot \sigma)\xi \end{pmatrix} \\ v(p) &= \begin{pmatrix} \sqrt{p \cdot \sigma}\xi \\ -\sqrt{p \cdot \bar{\sigma}}\xi \end{pmatrix} \underset{E\to\infty}{\longrightarrow} \sqrt{2E} \begin{pmatrix} \frac{1}{2}(1 - \hat{p} \cdot \sigma)\xi \\ -\frac{1}{2}(1 + \hat{p} \cdot \sigma)\xi \end{pmatrix} \end{aligned} \tag{5.26}$$

A right-handed spinor satisfies $(\hat{p} \cdot \boldsymbol{\sigma})\xi = +\xi$, while a left-handed spinor has $(\hat{p} \cdot \boldsymbol{\sigma})\xi = -\xi$. (Remember once again that for antiparticles, the handedness of the spinor is the opposite of the handedness of the particle.) We must evaluate expressions of the form $\bar{v}\gamma^\mu u$, so we need

$$\gamma^0\gamma^\mu = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} 0 & \sigma^\mu \\ \bar{\sigma}^\mu & 0 \end{pmatrix} = \begin{pmatrix} \bar{\sigma}^\mu & 0 \\ 0 & \sigma^\mu \end{pmatrix} \tag{5.27}$$

Thus we see explicitly that the amplitude is zero when one of the spinors is left-handed and the other is right-handed. In the language of Chapter 1, the Clebsch-Gordan coefficients that couple the vector photon to the product of such spinors are zero; those coefficients are just the off-block-diagonal elements of the matrix $\gamma^0\gamma^\mu$ (in the chiral representation).

Let us choose p and p' to be in the $\pm z$-directions, and first consider the case where the electron is right-handed and the positron is left-handed:



Thus for the electron we have $\xi = \binom{1}{0}$, corresponding to spin up in the z direction, while for the positron we have $\xi = \binom{0}{1}$, also corresponding to (physical) spin up in the z-directon. Both particles have $(\hat{p}\cdot\sigma)\xi = +\xi$, so the spinors are

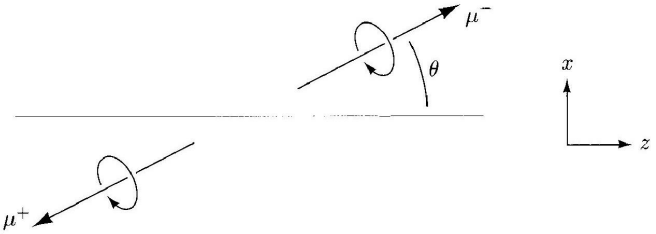
$$u(p) = \sqrt{2E}\begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix}; \qquad v\,(p') = \sqrt{2E}\begin{pmatrix} 0 \\ 0 \\ 0 \\ -1 \end{pmatrix} \tag{5.28}$$

The electron half of the matrix element is therefore

$$\bar{v}\,(p')\,\gamma^\mu u(p) = 2E(0,-1)\sigma^\mu\begin{pmatrix}1\\0\end{pmatrix} = -2E(0,1,i,0) \tag{5.29}$$

We can interpret this expression by saying that the virtual photon has circular polarization in the $+z$-direction; its polarization vector is $\epsilon_+ = (1/\sqrt{2})(\hat{x} + i\hat{y})$.

Next we must calculate the muon half of the matrix element. Let the μ^- be emitted at an angle θ to the z-axis, and consider first the case where it is right-handed (and the $\mu^+$is therefore left-handed):



To calculate $\bar{u}(k)\gamma^\mu v\,(k')$ we could go back to expressions (5.26), but then it would be necessary to find the correct spinors ξ corresponding to polarization along the muon momentum. It is much easier to use a trick: Since any expression of the form $\bar{\psi}\gamma^\mu\psi$ transforms like a 4 -vector, we can just rotate the result
(5.29). Rotating that vector by an angle θ in the xz-plane, we find

$$\begin{aligned}\bar{u}(k)\gamma^\mu v\,(k') &= [\bar{v}\,(k')\,\gamma^\mu u(k)]^* \\ &= [-2E(0,\cos\theta,i,-\sin\theta)]^* \\ &= -2E(0,\cos\theta,-i,-\sin\theta).\end{aligned} \tag{5.30}$$

This vector can also be interpreted as the polarization of the virtual photon; when it has a nonzero overlap with (5.29), we get a nonzero amplitude. Plugging (5.29) and (5.30) into (5.25), we see that the amplitude is

$$\mathcal{M}\left(e_R^- e_L^+ \to \mu_R^- \mu_L^+\right) = \frac{e^2}{q^2}(2E)^2(-\cos\theta - 1) = -e^2(1+\cos\theta), \tag{5.31}$$

in agreement with (1.6), and also with (5.21). The differential cross section for this set of helicities can now be obtained in the same way as above, yielding (5.22).

We can calculate the other three nonvanishing helicity amplitudes in an analogous manner. For a left-handed electron and a right-handed positron, we easily find

$$\bar{v}\left(p'\right)\gamma^\mu u(p) = -2E(0,1,-i,0) \equiv -2E\cdot\sqrt{2}\epsilon_-^\mu$$

Perform a rotation to get the vector corresponding to a left-handed $\mu^-$and a right-handed μ^+:

$$\bar{u}(k)\gamma^\mu v\left(k'\right) = -2E(0,\cos\theta,i,\sin\theta)$$

Putting the pieces together in various ways yields the remaining amplitudes,

$$\begin{aligned}\mathcal{M}\left(e_L^- e_R^+ \to \mu_L^- \mu_R^+\right) &= -e^2(1+\cos\theta)\\ \mathcal{M}\left(e_R^- e_L^+ \to \mu_L^- \mu_R^+\right) = \mathcal{M}\left(e_L^- e_R^+ \to \mu_R^- \mu_L^+\right) &= -e^2(1-\cos\theta)\end{aligned} \tag{5.32}$$

21.3 5.3$e^+e^- \to \mu^+\mu^-$: Nonrelativistic Limit

Now let us go to the other end of the energy spectrum, and discuss the reaction $e^+e^- \to \mu^+\mu^-$in the extreme nonrelativistic limit. When E is barely larger than m_μ, our previous result (5.12) for the unpolarized differential cross section becomes

$$\frac{d\sigma}{d\Omega} \underset{|\mathbf{k}|\to 0}{\longrightarrow} \frac{\alpha^2}{2E_{\rm cm}^2}\sqrt{1-\frac{m_\mu^2}{E^2}} = \frac{\alpha^2}{2E_{\rm cm}^2}\frac{|\mathbf{k}|}{E} \tag{5.33}$$

We can recover this result, and also learn something about the spin dependence of the reaction, by evaluating the amplitude with explicit spinors. Once again we begin with the matrix element

$$\mathcal{M} = \frac{e^2}{q^2}\left(\bar{v}\left(p'\right)\gamma^\mu u(p)\right)\left(\bar{u}(k)\gamma_\mu v\left(k'\right)\right)$$

Before:

After:

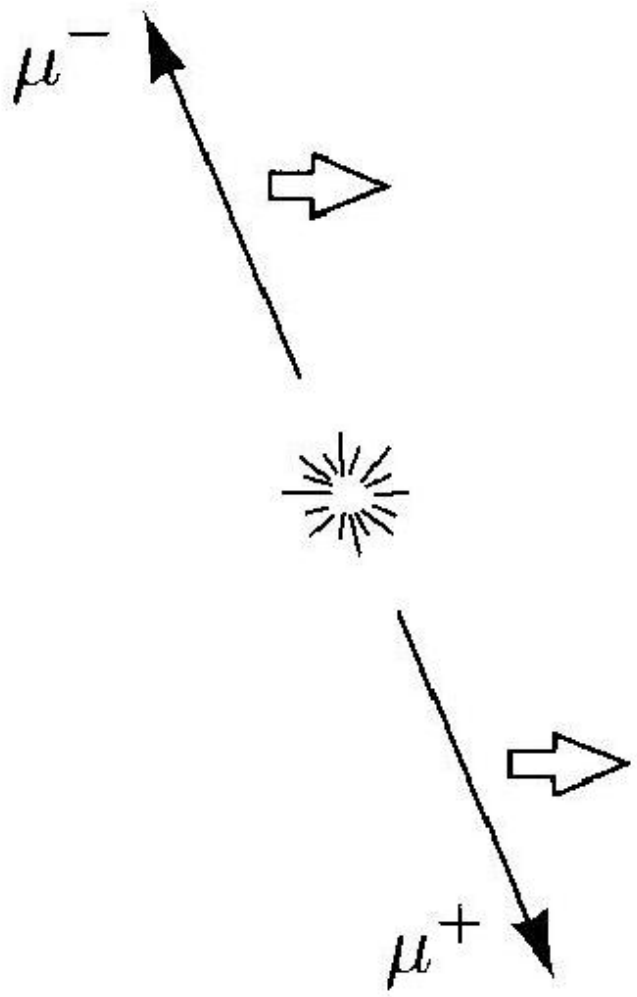


Figure 5.5. In the nonrelativistic limit the total spin of the system is conserved, and thus the muons are produced with both spins up along the z-axis.

The electron and positron are still very relativistic, so this expression will be simplest if we choose them to have definite helicity. Let the electron be righthanded, moving in the $+z$-direction, and the positron be left-handed, moving in the $-z$-direction. Then from Eq. (5.29) we have

$$\bar{v}\,(p')\,\gamma^\mu u(p) = -2E(0,1,i,0) \tag{5.34}$$

In the other half of the matrix element we should use the nonrelativistic expressions

$$u(k) = \sqrt{m}\begin{pmatrix}\xi\\ \xi\end{pmatrix}, \quad v\,(k') = \sqrt{m}\begin{pmatrix}\xi'\\ -\xi'\end{pmatrix}. \tag{5.35}$$

Keep in mind, in the discussion of this section, that the spinor ξ' gives the flipped spin of the antiparticle. Leaving the muon spinors ξ and ξ' undetermined for now, we can easily compute

$$\begin{aligned}\bar{u}(k)\gamma^\mu v\,(k') &= m\,(\xi^\dagger, \xi^\dagger)\begin{pmatrix}\bar{\sigma}^\mu & 0\\ 0 & \sigma^\mu\end{pmatrix}\begin{pmatrix}\xi'\\ -\xi'\end{pmatrix}\\ &= \begin{cases}0 & \text{for } \mu = 0,\\ -2m\xi^\dagger\sigma^i\xi' & \text{for } \mu = i\end{cases}\end{aligned} \tag{5.36}$$

To evaluate $\mathcal{M}$, we simply dot (5.34) into (5.36) and multiply by $e^2/q^2 = e^2/4m^2$. The result is

$$\mathcal{M}\left(e_R^- e_L^+ \to \mu^+\mu^-\right) = -2e^2 \xi^\dagger \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \xi' \tag{5.37}$$

Since there is no angular dependence in this expression, the muons are equally likely to come out in any direction. More precisely, they are emitted in an s-wave; their orbital angular momentum is zero. Angular momentum conservation therefore requires that the total spin of the final state equal 1 , and indeed the matrix product gives zero unless both the muon and the antimuon have spin up along the z-axis (see Fig. 5.5).

To find the total rate for this process, we sum over muon spins to obtain $\mathcal{M}^2 = 4e^4$, which yields the cross section

$$\frac{d\sigma}{d\Omega}\left(e_R^- e_L^+ \to \mu^+\mu^-\right) = \frac{\alpha^2}{E_{\rm cm}^2}\frac{|\mathbf{k}|}{E} \tag{5.38}$$

The same expression holds for a left-handed electron and a right-handed positron. Thus the spin-averaged cross section is just $2 \cdot (1/4)$ times this expression, in agreement with (5.33).

Bound States

Until now we have considered the initial and final states of scattering processes to be states of isolated single particles. Very close to threshold, however, the Coulomb attraction of the muons should become an important effect. Just below threshold, we can still form $\mu^+\mu^-$pairs in electromagnetic bound states.

The treatment of bound states in quantum field theory is a rich and complex subject, but one that lies mainly beyond the scope of this book. ‡ Fortunately, many of the familiar bound systems in Nature can be treated (at least to a good first approximation) as nonrelativistic systems, in which the internal motions are slow. The process of creating the constituent particles out of the vacuum is still a relativistic effect, requiring quantum field theory for its proper description. In this section we will develop a formalism for computing the amplitudes for creation and annihilation of two-particle, nonrelativistic bound states. We begin with a computation of the cross section for producing a $\mu^+\mu^-$bound state in e^+e^-annihilation.

Consider first the case where the spins of the electron and positron both point up along the z-axis. From the preceding discussion we know that the resulting muons both have spin up, so the only type of bound state we can produce will have total spin 1, also pointing up. The amplitude for producing free muons in this configuration is

$$\mathcal{M}\left(\uparrow\uparrow \to \mathbf{k}_1 \uparrow, \mathbf{k}_2 \uparrow\right) = -2e^2 \tag{5.39}$$

independent of the momenta (which we now call $\mathbf{k}_1$ and $\mathbf{k}_2$) of the muons.
Next we need to know how to write a bound state in terms of free-particle states. For a general two-body system with equal constituent masses, the center-of-mass and relative coordinates are

$$\mathbf{R} = \frac{1}{2}\left(\mathbf{r}_1 + \mathbf{r}_2\right), \quad \mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2 \tag{5.40}$$

These have conjugate momenta

$$\mathbf{K} = \mathbf{k}_1 + \mathbf{k}_2, \quad \mathbf{k} = \frac{1}{2}\left(\mathbf{k}_1 - \mathbf{k}_2\right) \tag{5.41}$$

The total momentum $\mathbf{K}$ is zero in the center-of-mass frame. If we know the force between the particles (for $\mu^+\mu^-$, it is just the Coulomb force), we can

solve the nonrelativistic Schrdinger equation to find the Schrdinger wavefunction, $\psi(\mathbf{r})$. The bound state is just a linear superposition of free states of definite $\mathbf{r}$ or $\mathbf{k}$, weighted by this wavefunction. For our purposes it is more convenient to build this superposition in momentum space, using the Fourier transform of $\psi(\mathbf{r})$:
$$

$$\widetilde{\psi}(\mathbf{k}) = \int d^3x e^{i\mathbf{k}\cdot\mathbf{r}}\psi(\mathbf{r}); \quad \int \frac{d^3k}{(2\pi)^3}|\widetilde{\psi}(\mathbf{k})|^2 = 1 \tag{5.42}$$

$$

If $\psi(\mathbf{r})$ is normalized conventionally, $\widetilde{\psi}(\mathbf{k})$ gives the amplitude for finding a particular value of $\mathbf{k}$. An explicit expression for a bound state with mass $M \approx 2m$, momentum $\mathbf{K} = 0$, and spin 1 oriented up is then

$$|B\rangle = \sqrt{2M}\int \frac{d^3k}{(2\pi)^3}\widetilde{\psi}(\mathbf{k})\frac{1}{\sqrt{2m}}\frac{1}{\sqrt{2m}}|\mathbf{k}\uparrow, -\mathbf{k}\uparrow\rangle \tag{5.43}$$

The factors of $(1/\sqrt{2m})$ convert our relativistically normalized free-particle states so that their integral with $\widetilde{\psi}(\mathbf{k})$ is a state of norm 1. (The factors should involve $\sqrt{2E_{\pm\mathbf{k}}}$, but for a nonrelativistic bound state, $|\mathbf{k}| \ll m$.) The outside factor of $\sqrt{2M}$ converts back to the relativistic normalization assumed by our formula for cross sections. These normalization factors could easily be modified to describe a bound state with nonzero total momentum $\mathbf{K}$.

Given this expression for the bound state, we can immediately write down the amplitude for its production:

$$\mathcal{M}(\uparrow\uparrow\to B) = \sqrt{2M}\int \frac{d^3k}{(2\pi)^3}\widetilde{\psi}^*(\mathbf{k})\frac{1}{\sqrt{2m}}\frac{1}{\sqrt{2m}}\mathcal{M}(\uparrow\uparrow\to \mathbf{k}\uparrow, -\mathbf{k}\uparrow) \tag{5.44}$$

Since the free-state amplitude from (5.39) is independent of the momenta of the muons, the integral over $\mathbf{k}$ gives $\psi^*(0)$, the position-space wavefunction evaluated at the origin. It is quite natural that the amplitude for creation of a two-particle state from a pointlike virtual photon should be proportional to the value of the wavefunction at zero separation. Assembling the pieces, we find that the amplitude is simply

$$\mathcal{M}(\uparrow\uparrow\to B) = \sqrt{\frac{2}{M}}\left(-2e^2\right)\psi^*(0) \tag{5.45}$$

In a moment we will compute the cross section from this amplitude. First, however, let us generalize this discussion to treat bound states with more general spin configurations. The analysis leading up to (5.37) will cast any S matrix element for the production of nonrelativistic fermions with momenta $\mathbf{k}$ and $-\mathbf{k}$ into the form of a spin matrix element

$$i\mathcal{M}\left(\text{ something } \to \mathbf{k}, \mathbf{k}'\right) = \xi^\dagger[\Gamma(\mathbf{k})]\xi' \tag{5.46}$$

where $\Gamma(\mathbf{k})$ is some 2×2 matrix. We now must replace the spinors with a normalized spin wavefunction for the bound state. In the example just completed,
we replaced

[6]‡ Reviews of this subject can be found in Bodwin, Yennie, and Gregorio, Rev. Mod. Phys. 57, 723 (1985), and in Sapirstein and Yennie, in Kinoshita (1990).

$$\xi'\xi^\dagger \to \begin{pmatrix}0\\1\end{pmatrix}\begin{pmatrix}1 & 0\end{pmatrix} = \begin{pmatrix}0 & 0\\1 & 0\end{pmatrix} \tag{5.47}$$

More generally, a spin-1 state is obtained by the replacement

$$\xi'\xi^\dagger \to \frac{1}{\sqrt{2}}\mathbf{n}^*\cdot\boldsymbol{\sigma} \tag{5.48}$$

where $\mathbf{n}$ is a unit vector. Choosing $\mathbf{n} = (\hat{x}+i\hat{y})/\sqrt{2}$ gives back (5.47), while the choices $\mathbf{n} = (\hat{x}-i\hat{y})/\sqrt{2}$ and $\mathbf{n} = \hat{z}$ give the other two spin- 1 states $\downarrow\downarrow$ and $(\uparrow\downarrow+\downarrow\uparrow)/\sqrt{2}$. (The relative minus sign in (5.48) for this last case comes from the rule (3.135) for the flipped spin.) Similarly, the spin-zero state $(\uparrow\downarrow-\downarrow\uparrow)/\sqrt{2}$ is given by the replacement

$$\xi'\xi^\dagger \to \frac{1}{\sqrt{2}}\mathbf{1} \tag{5.49}$$

involving the 2×2 unit matrix. With these rules, we can convert an S-matrix element of the form (5.46) quite generally into an S-matrix element for production of a bound state at rest:

$$i\mathcal{M}(\text{ something } \to B) = \sqrt{\frac{2}{M}}\int\frac{d^3k}{(2\pi)^3}\widetilde{\psi}^*(\mathbf{k})\,\mathrm{tr}\left(\frac{\mathbf{n}^*\cdot\boldsymbol{\sigma}}{\sqrt{2}}\Gamma(\mathbf{k})\right) \tag{5.50}$$

where the trace is taken over 2-component spinor indices. For a spin-0 bound state, replace $\mathbf{n}\cdot\boldsymbol{\sigma}$ by the unit matrix.

Vector Meson Production and Decay

Equation (5.45) can be straightforwardly converted into a cross section for production of $\mu^+\mu^-$bound states in e^+e^-annihilation. To make it easier to extract all the physics in this equation, let us introduce polarization vectors for the initial and final spin configurations: $\epsilon_+ = (\hat{x}+i\hat{y})/\sqrt{2}$, from Eq. (5.29), and $\mathbf{n}$, from Eq. (5.48). Then (5.45) can be rewritten in a more invariant form as

$$\mathcal{M}\left(e_R^-e_L^+ \to B\right) = \sqrt{\frac{2}{M}}\left(-2e^2\right)\left(\mathbf{n}^*\cdot\boldsymbol{\epsilon}_+\right)\psi^*(0) \tag{5.51}$$

The bound state spin polarization $\mathbf{n}$ is projected parallel to $\boldsymbol{\epsilon}_+$. Note that if the electrons are initially unpolarized, the cross section for production of B will involve the polarization average

$$\frac{1}{4}\left(|\mathbf{n}^*\cdot\boldsymbol{\epsilon}_+|^2 + |\mathbf{n}^*\cdot\boldsymbol{\epsilon}_-|^2\right) = \frac{1}{4}\left((n^x)^2+(n^y)^2\right) \tag{5.52}$$

Thus, the bound states produced will still be preferentially polarized along the e^+e^-collision axis.

Assuming an unpolarized electron beam, and summing (5.52) over the three possible directions of $\mathbf{n}$, we find the following expression for the total cross section for production of the bound state: $\sigma\left(e^+e^-\to B\right) = \frac{1}{2}\frac{1}{2m}\frac{1}{2m}\int\frac{d^3K}{(2\pi)^3}\frac{1}{2E_{\mathbf{K}}}(2\pi)^4\delta^{(4)}\left(p+p'-K\right)\cdot\frac{2}{M}\left(4e^4\right)\frac{1}{2}|\psi(0)|^2$.
Notice that the 1-body phase space integral can remove only three of the four delta functions. It is conventional to rewrite the last delta function using $\delta\left(P^0-K^0\right) = 2K^0\delta\left(P^2-K^2\right)$. Then

$$\sigma\left(e^+e^-\to B\right) = 64\pi^3\alpha^2\frac{|\psi(0)|^2}{M^3}\delta\left(E_{\mathrm{cm}}^2-M^2\right) \tag{5.54}$$

The last delta function enforces the constraint that the total center-of-mass energy must equal the bound-state mass; thus, the bound state is produced as a resonance in e^+e^-annihilation. If the bound state has a finite lifetime, this delta function will be broadened into a resonance peak. In practice, the intrinsic spread of the e^+e^-beam energy is often a more important broadening mechanism. In either case, (5.54) correctly predicts the area under the resonance peak.

If the bound state B can be produced from e^+e^-, it can also annihilate back to e^+e^-, or to any other sufficiently light lepton pair. According to (4.86), the total width for this decay mode is given by

$$\Gamma\left(B \to e^+e^-\right) = \frac{1}{2M}\int d\Pi_2 |\mathcal{M}|^2 \tag{5.55}$$

where $\mathcal{M}$ is just the complex conjugate of the matrix element (5.51) we used to compute B production. Thus

$$\Gamma = \frac{1}{2M}\int \left(\frac{1}{2\pi}\frac{d\cos\theta}{2}\right)\frac{8e^4}{M}|\psi(0)|^2\left(|\mathbf{n}\cdot\boldsymbol{\epsilon}|^2 + |\mathbf{n}\cdot\boldsymbol{\epsilon}^*|^2\right) \tag{5.56}$$

Now we must sum over electron polarization states and average over the three possible values of $\mathbf{n}$. We thus obtain

$$\Gamma\left(B \to e^+e^-\right) = \frac{16\pi\alpha^2}{3}\frac{|\psi(0)|^2}{M^2} \tag{5.57}$$

The formula for the decay width of B is very similar to that for the production cross section, and this is no surprise: Both calculations involve the square of the same matrix element, summed over initial and final polarizations. The two calculations differed only in how we formed the polarization averages, and in the phase-space factors. By this logic, the relation we have found between the two quantities,

$$\sigma\left(e^+e^- \to B\right) = 4\pi^2 \cdot \frac{3\Gamma\left(B \to e^+e^-\right)}{M} \cdot \delta\left(E_{\rm cm}^2 - M^2\right) \tag{5.58}$$

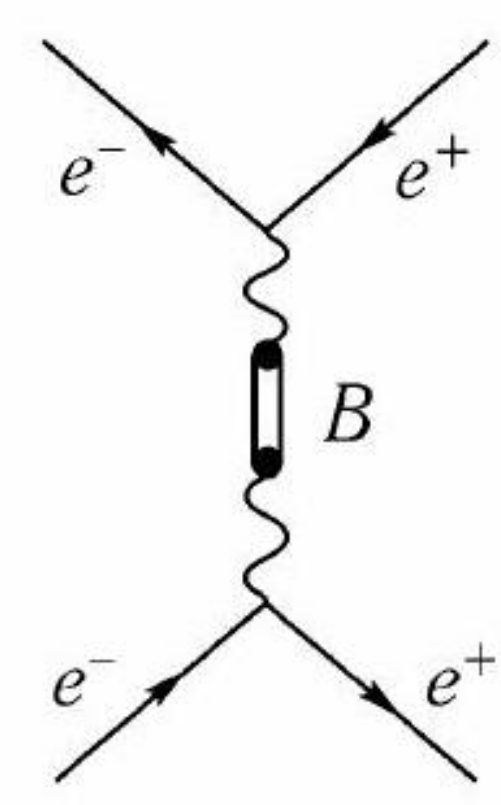
is very general and completely independent of the details of the matrix element computation. The factor 3 in (5.58) came from the orientation average for $\mathbf{n}$; for a spin- J bound state, this factor would be $(2J+1)$.

The most famous application of this formalism is to bound states not of muons but of quarks: quarkonium. We saw the experimental evidence for $q\bar{q}$ bound states (the J/ψ and Υ, for example) in Fig. 5.3. (The resonance peaks are much too high and too narrow to show in the figure, but their sizes have been carefully measured.) Equations (5.54) and (5.57) must be multiplied by a color factor of 3 to give the production cross section and decay width for a spin-1 $q\bar{q}$ bound state. The value $\psi(0)$ of the $q\bar{q}$ wavefunction at the origin cannot be computed from first principles, but can be estimated from a nonrelativistic model of the $q\bar{q}$ spectrum with a phenomenologically chosen potential. Alternatively, we can use the formula

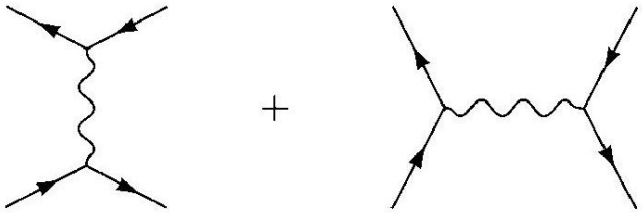
$$\Gamma\left(B(q\bar{q}) \to e^+e^-\right) = 16\pi\alpha^2 Q^2\frac{|\psi(0)|^2}{M^2} \tag{5.59}$$

to measure $\psi(0)$ for a $q\bar{q}$ bound state. For example, the $1S$ spin- 1 state of $s\bar{s}$, the ϕ meson, has an e^+e^-partial width of 1.4 keV and a mass of 1.02 GeV . From this we can infer $|\psi(0)|^2 = (1.2\text{fm})^{-3}$. This result is physically reasonable, since hadronic dimensions are typically $\sim$ 1fm.

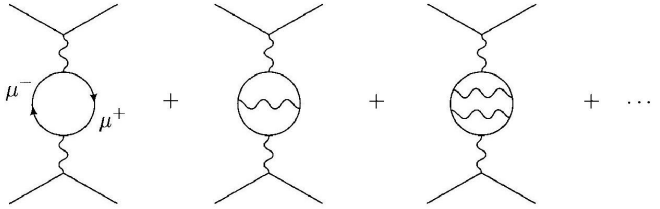
Our viewpoint in this section has been quite different from that of earlier sections: Instead of computing everything from first principles, we have pieced together an approximate formula using a bit of quantum field theory and a bit of nonrelativistic quantum mechanics. In principle, however, we could treat bound states entirely in the relativistic formalism. Consider the annihilation of an e^+e^-pair to form a $\mu^+\mu^-$bound state, which subsequently decays back into e^+e^-. In our present formalism we might represent this process by the diagram



The net process is simply $e^+e^- \to e^+e^-$(Bhabha scattering). What would happen if we tried to compute the Bhabha scattering cross section directly in QED perturbation theory? Obviously there is no $\mu^+\mu^-$contribution in the tree-level diagrams:



As we go to higher orders in the perturbation series, however, we find (among others) the following set of diagrams:

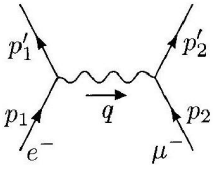


At most values of $E_{\rm cm}$, these diagrams give only a small correction to the tree-level expression. But when $E_{\rm cm}$ is near the $\mu^+\mu^-$threshold, the diagrams involving the exchange of photons within the muon loop contain the Coulomb interaction between the muons, and therefore become quite large. One must sum over all such diagrams, and it can be shown that this summation is equivalent to solving the nonrelativistic Schrdinger equation.* The final prediction is that the cross section contains a resonance peak, whose area is given by (5.54) and whose width is given by (5.57).

21.4 5.4 Crossing Symmetry

Electron-Muon Scattering

Now that we have completed our discussion of the process $e^+e^- \to \mu^+\mu^-$, let us consider a different but closely related QED process: electron-muon scattering, or $e^-\mu^- \to e^-\mu^-$. The lowest-order Feynman diagram is just the previous one turned on its side:



$$= \frac{ie^2}{q^2}\,\bar{u}(p_1')\gamma^\mu u(p_1)\,\bar{u}(p_2')\gamma_\mu u(p_2).$$

The relation between the processes $e^+e^- \to \mu^+\mu^-$and $e^-\mu^- \to e^-\mu^-$becomes clear when we compute the squared amplitude, averaged and summed over spins:
$\frac{1}{4}\sum_{\rm spins}|\mathcal{M}|^2 = \frac{e^4}{4q^4}\,\mathrm{tr}\left[(\not{p}\mathrm{l}_1 + m_e)\,\gamma^\mu\,(\not{p}_1 + m_e)\,\gamma^\nu\right]\mathrm{tr}\left[(\not{p}\mathrm{l}_2' + m_\mu)\,\gamma_\mu\,(\not{p}_2 + m_\mu)\,\gamma_\nu\right]$.
This is exactly the same as our result (5.4) for $e^+e^- \to \mu^+\mu^-$, with the replacements

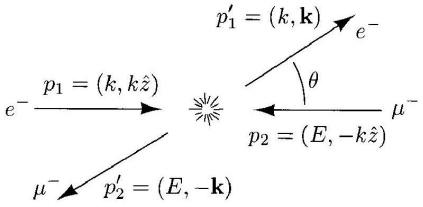
$$p \to p_1, \quad p' \to -p_1', \quad k \to p_2', \quad k' \to -p_2 \tag{5.60}$$

*This analysis is carried out in Berestetskii, Lifshitz, and Pitaevskii (1982).

So instead of evaluating the traces from scratch, we can just make the same replacements in our previous result, Eq. (5.10). Setting $m_e = 0$, we find

$$\frac{1}{4}\sum_{\rm spins}|\mathcal{M}|^2 = \frac{8e^4}{q^4}\left[(p_1\cdot p_2')\,(p_1'\cdot p_2) + (p_1\cdot p_2)\,(p_1'\cdot p_2') - m_\mu^2\,(p_1\cdot p_1')\right] \tag{5.61}$$

To evaluate this expression, we must work out the kinematics, which will be completely different. Working in the center-of-mass frame, we make the following assignments:



$$E^2 = k^2 + m_\mu^2$$
$$\mathbf{k}\cdot\hat{z} = k\cos\theta$$
$$E + k = E_{\rm cm}$$

The combinations we need are

$$p_1\cdot p_2 = p_1'\cdot p_2' = k(E+k); \quad p_1'\cdot p_2 = p_1\cdot p_2' = k(E + k\cos\theta)$$
$$p_1\cdot p_1' = k^2(1-\cos\theta); \quad q^2 = -2p_1\cdot p_1' = -2k^2(1-\cos\theta)$$

Our expression for the squared matrix element now becomes

$$\frac{1}{4}\sum_{\rm spins}|\mathcal{M}|^2 = \frac{2e^4}{k^2(1-\cos\theta)^2}\left((E+k)^2 + (E+k\cos\theta)^2 - m_\mu^2(1-\cos\theta)\right) \tag{5.62}$$

To find the cross section from this expression, we use Eq. (4.84), which in the case where one particle is massless takes the simple form

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{CM}} = \frac{|\mathcal{M}|^2}{64\pi^2(E+k)^2} \tag{5.63}$$

Thus we have our result for unpolarized electron-muon scattering in the center-of-mass frame:

$$\frac{d\sigma}{d\Omega} = \frac{\alpha^2}{2k^2(E+k)^2(1-\cos\theta)^2}\left((E+k)^2 + (E+k\cos\theta)^2 - m_\mu^2(1-\cos\theta)\right) \tag{5.64}$$

where $k = \sqrt{E^2 - m_\mu^2}$. In the high-energy limit where we can set $m_\mu = 0$, the differential cross section becomes

$$\frac{d\sigma}{d\Omega} = \frac{\alpha^2}{2E_{\text{cm}}^2(1-\cos\theta)^2}\left(4 + (1+\cos\theta)^2\right) \tag{5.65}$$

Note the singular behavior

$$\frac{d\sigma}{d\Omega} \propto \frac{1}{\theta^4} \quad \text{as } \theta \to 0 \tag{5.66}$$

of formulae (5.64) and (5.65). This singularity is the same as in the Rutherford formula (Problem 4.4). Such behavior is always present in Coulomb scattering; it arises from the nearly on-shell (that is, $q^2 \approx 0$) virtual photon.

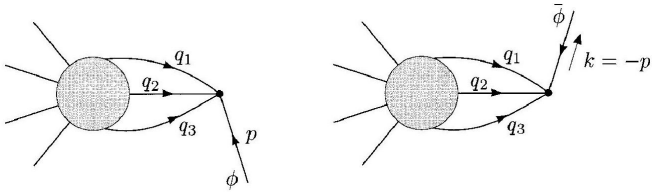
Crossing Symmetry

The trick we made use of here, namely the relation between the two processes $e^+e^- \to \mu^+\mu^-$and $e^-\mu^- \to e^-\mu^-$, is our first example of a type of relation known as crossing symmetry. In general, the S-matrix for any process involving a particle with momentum p in the initial state is equal to the S-matrix for an otherwise identical process but with an antiparticle of momentum $k = -p$ in the final state. That is,

$$\mathcal{M}(\phi(p) + \cdots \to \cdots) = \mathcal{M}(\cdots \to \cdots + \bar{\phi}(k)) \tag{5.67}$$

where $\bar{\phi}$ is the antiparticle of ϕ and $k = -p$. (Note that there is no value of p for which p and k are both physically allowed, since the particle must have $p^0 > 0$ and the antiparticle must have $k^0 > 0$. So technically, we should say that either amplitude can be obtained from the other by analytic continuation.)

Relation (5.67) follows directly from the Feynman rules. The diagrams that contribute to the two amplitudes fall into a natural one-to-one correspondence, where corresponding diagrams differ only by changing the incoming ϕ into the outgoing $\bar{\phi}$. A typical pair of diagrams looks like this:



In the first diagram, the momenta q_i coming into the vertex from the rest of the diagram must add up to $-p$, while in the second diagram they must add up to k. Thus the two diagrams are equal, except for any possible difference in the external leg factors, if $p = -k$. If ϕ is a spin-zero

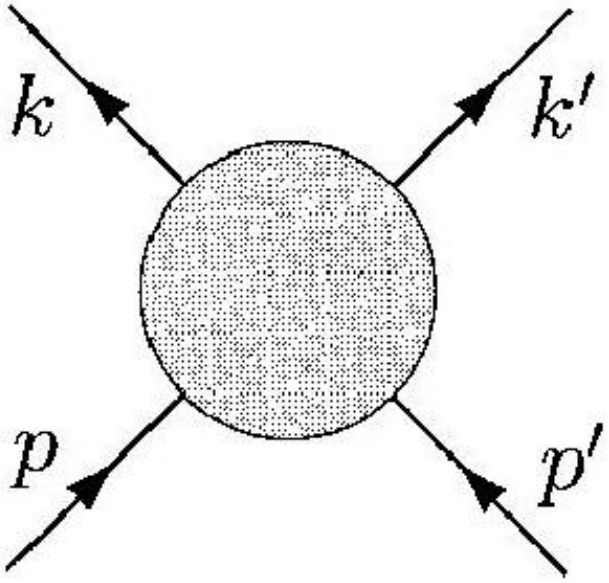
boson, there is no external leg factor, so the identity is proved. If ϕ is a fermion, the analysis becomes more subtle, since the relation depends on the relative phase convention for the external spinors u and v. If we simply replace p by $-k$ in the fermion polarization sum, we find

$$\sum u(p)\bar{u}(p) = \not{p} + m = -(\not{k} - m) = -\sum v(k)\bar{v}(k). \tag{5.68}$$

The minus sign can be compensated by changing our phase convention for $v(k)$. In practice, it is easiest to cancel by hand one minus sign for each crossed fermion. With appropriate conventions for the spinors $u(p)$ and $v(k)$, it is possible to prove the identity (5.67) without spin-averaging.

Mandelstam Variables

It is often useful to express scattering amplitudes in terms of variables that make it easy to apply crossing relations. For 2-body $\to$ 2-body processes, this can be done as follows. Label the four external momenta as

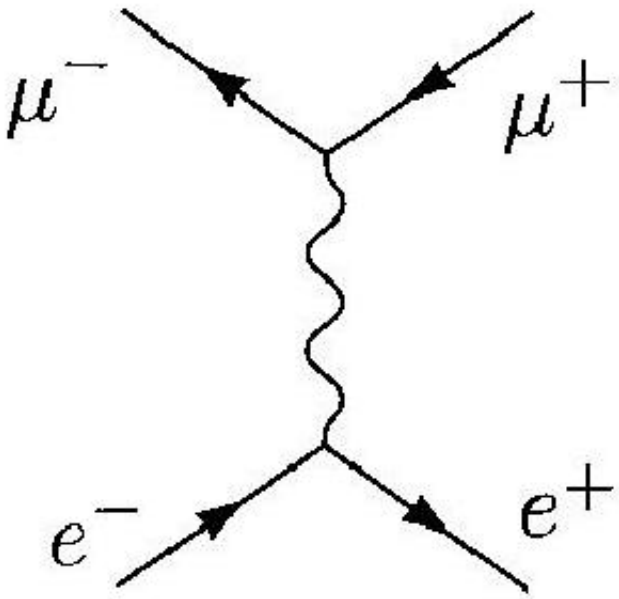


We now define three new quantities, the Mandelstam variables:

$$\begin{aligned} s &= (p + p')^2 = (k + k')^2 \\ t &= (k - p)^2 = (k' - p')^2 \\ u &= (k' - p)^2 = (k - p')^2 \end{aligned} \tag{5.69}$$

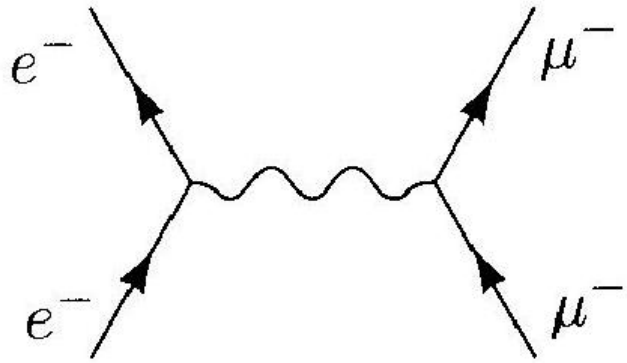
The definitions of t and u appear to be interchangeable (by renaming $k \to k'$); it is conventional to define t as the squared difference of the initial and final momenta of the most similar particles. For any process, s is the square of the total initial 4-momentum. Note that if we had defined all four momenta to be ingoing, all signs in these definitions would be $+$.

To illustrate the use of the Mandelstam variables, let us first consider the squared amplitude for $e^+e^- \to \mu^+\mu^-$, working in the massless limit for simplicity. In this limit we have $t = -2p \cdot k = -2p' \cdot k'$ and $u = -2p \cdot k' = -2p' \cdot k$, while of course $s = (p + p')^2 = q^2$. Referring to our previous result (5.10), we find



$$\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 = \frac{8e^4}{s^2}\left[\left(\frac{t}{2}\right)^2 + \left(\frac{u}{2}\right)^2\right] \tag{5.70}$$

To convert to the process $e^-\mu^- \to e^-\mu^-$, we turn the diagram on its side and make use of the crossing relations, which become quite simple in terms of Mandelstam variables. For example, the crossing relations tell us to change the sign of p', the positron momentum, and reinterpret it as the momentum of the outgoing electron. Therefore $s = (p + p')^2$ becomes what we would now call t, the difference of the outgoing and incoming electron momenta. Similarly, t becomes s, while u remains unchanged. Thus for $e^{--}\mu^- \to e^-\mu^-$,
we can immediately write down

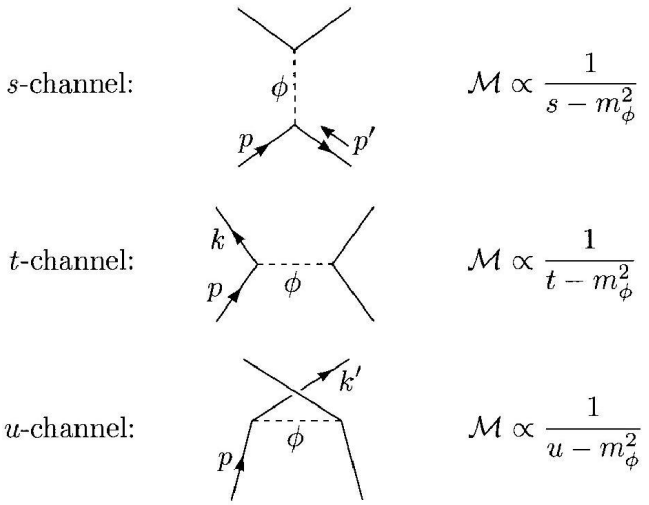


$$\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 = \frac{8e^4}{t^2}\left[\left(\frac{s}{2}\right)^2 + \left(\frac{u}{2}\right)^2\right] \tag{5.71}$$

You can easily check that this agrees with (5.61) in the massless limit. Note that while (5.70) and (5.71) look quite similar, they are physically very different: The denominator of the first is just $s^2 = E_{\text{cm}}^4$, but that of the second involves t, which depends on angles and goes to zero as $\theta \to 0$.

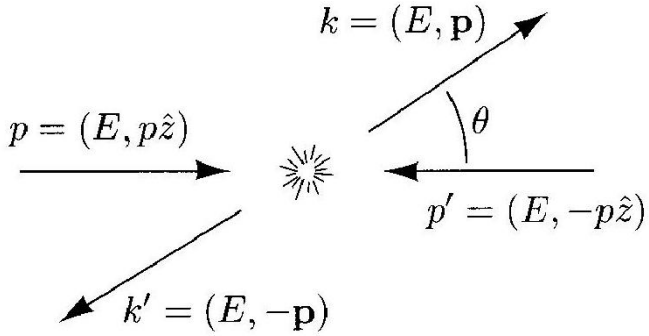
When a 2-body $\to$ 2-body diagram contains only one virtual particle, it is conventional to

describe that particle as being in a certain "channel". The channel can be read from the form of the Feynman diagram, and each channel leads to a characteristic angular dependence of the cross section:



In many cases, a single process will receive contributions from more than one channel; these must be added coherently. For example, the amplitude for Bhabha scattering, $e^+e^- \to e^+e^-$, is the sum of $s^-$and t-channel diagrams; Mller scattering, $e^-e^- \to e^-e^-$, involves t - and u-channel diagrams.

To get a better feel for s, t, and u, let us evaluate them explicitly in the center-of-mass frame for particles all of mass m. The kinematics is as usual:



Thus the Mandelstam variables are

$$\begin{aligned} s &= (p + p')^2 = (2E)^2 = E_{\text{cm}}^2 \\ t &= (k - p)^2 = -p^2 \sin^2\theta - p^2(\cos\theta - 1)^2 = -2p^2(1 - \cos\theta) \\ u &= (k' - p)^2 = -p^2 \sin^2\theta - p^2(\cos\theta + 1)^2 = -2p^2(1 + \cos\theta) \end{aligned} \tag{5.72}$$

Thus we see that $t \to 0$ as $\theta \to 0$, while $u \to 0$ as $\theta \to \pi$. (When the masses are not all equal, the limiting values of t and u will shift slightly.)

Note from (5.72) that when all four particles have mass m, the sum of the Mandelstam variables is $s + t + u = 4E^2 - 4p^2 = 4m^2$. This is a special case of a more general relation, which is often quite useful:

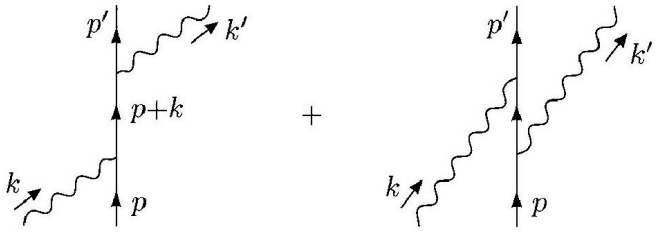
$$s + t + u = \sum_{i=1}^{4} m_i^2 \tag{5.73}$$

where the sum runs over the four external particles. This identity is easy to prove by adding up the terms on the right-hand side of Eqs. (5.69), and applying momentum conservation in the form $(p+p'-k-k')^2 = 0$.

21.5 5.5 Compton Scattering

We now move on to consider a somewhat different QED process: Compton scattering, or $e^-\gamma \to e^-\gamma$. We will calculate the unpolarized cross section for this reaction, to lowest order in α. The calculation will employ all the machinery we have developed so far, including the Mandelstam variables of the previous section. We will also develop some new technology for dealing with external photons.

This is our first example of a calculation involving two diagrams:



As usual, the Feynman rules tell us exactly how to write down an expression for $\mathcal{M}$. Note that since the fermion portions of the two diagrams are identical, there is no relative minus sign between the two terms. Using $\epsilon_\nu(k)$ and $\epsilon^*_\mu(k')$ to denote the polarization vectors of the initial and final photons, we have

$$\begin{aligned} i\mathcal{M} =& \bar{u}(p')(-ie\gamma^\mu)\epsilon^*_\mu(k')\frac{i(\not{p}+\not{k}+m)}{(p+k)^2-m^2}(-ie\gamma^\nu)\epsilon_\nu(k)u(p) \\ &+ \bar{u}(p')(-ie\gamma^\nu)\epsilon_\nu(k)\frac{i(\not{p}-\not{k}'+m)}{(p-k')^2-m^2}(-ie\gamma^\mu)\epsilon^*_\mu(k')u(p) \\ = -ie^2\epsilon^*_\mu(k')\epsilon_\nu(k)\bar{u}(p')&\left[\frac{\gamma^\mu(\not{p}+\not{k}+m)\gamma^\nu}{(p+k)^2-m^2}+\frac{\gamma^\nu(\not{p}-\not{k}'+m)\gamma^\mu}{(p-k')^2-m^2}\right]u(p). \end{aligned}$$

We can make a few simplifications before squaring this expression. Since $p^2 = m^2$ and $k^2 = 0$, the denominators of the propagators are

$$(p+k)^2 - m^2 = 2p\cdot k \quad \text{and} \quad (p-k')^2 - m^2 = -2p\cdot k'$$

To simplify the numerators, we use a bit of Dirac algebra:

$$\begin{aligned} (\not{p}+m)\gamma^\nu u(p) &= (2p^\nu - \gamma^\nu\not{p} + \gamma^\nu m)u(p) \\ &= 2p^\nu u(p) - \gamma^\nu(\not{p}-m)u(p) \\ &= 2p^\nu u(p). \end{aligned}$$

Using this trick on the numerator of each propagator, we obtain

$$i\mathcal{M} = -ie^2\epsilon^*_\mu(k')\epsilon_\nu(k)\bar{u}(p')\left[\frac{\gamma^\mu\not{p}\gamma^\nu + 2\gamma^\mu p^\nu}{2p\cdot k} + \frac{-\gamma^\nu\not{k}'\gamma^\mu + 2\gamma^\nu p^\mu}{-2p\cdot k'}\right]u(p). \tag{5.74}$$

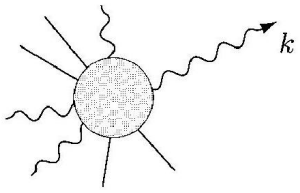
Photon Polarization Sums

The next step in the calculation will be to square this expression for $\mathcal{M}$ and sum (or average) over electron and photon polarization states. The sum over electron polarizations can be performed as before, using the identity $\Sigma u(p)\bar{u}(p) = \not{p} + m$. Fortunately, there is a similar trick for summing over photon polarization vectors. The correct prescription is to make the replacement

$$\sum_{\text{polarizations}} \epsilon_\mu^* \epsilon_\nu \longrightarrow -g_{\mu\nu} \tag{5.75}$$

The arrow indicates that this is not an actual equality. Nevertheless, the replacement is valid as long as both sides are dotted into the rest of the expression for a QED amplitude $\mathcal{M}$.

To derive this formula, let us consider an arbitrary QED process involving an external photon with momentum k:



$$= i\mathcal{M}(k) \equiv i\mathcal{M}^\mu(k)\epsilon_\mu^*(k).$$

Since the amplitude always contains $\epsilon_\mu^*(k)$, we have extracted this factor and defined $\mathcal{M}^\mu(k)$ to be the rest of the amplitude $\mathcal{M}$. The cross section will be proportional to

$$\sum_\epsilon \left|\epsilon_\mu^*(k)\mathcal{M}^\mu(k)\right|^2 = \sum_\epsilon \epsilon_\mu^* \epsilon_\nu \mathcal{M}^\mu(k)\mathcal{M}^{\nu *}(k)$$

For simplicity, we orient k in the 3 -direction: $k^\mu = (k, 0, 0, k)$. Then the two transverse polarization vectors, over which we are summing, can be chosen to be

$$\epsilon_1^\mu = (0, 1, 0, 0); \quad \epsilon_2^\mu = (0, 0, 1, 0)$$

With these conventions, we have

$$\sum_\epsilon \left|\epsilon_\mu^*(k)\mathcal{M}^\mu(k)\right|^2 = \left|\mathcal{M}^1(k)\right|^2 + \left|\mathcal{M}^2(k)\right|^2 \tag{5.77}$$

Now recall from Chapter 4 that external photons are created by the interaction term $\int d^4x e j^\mu A_\mu$, where $j^\mu = \bar{\psi}\gamma^\mu\psi$ is the Dirac vector current. Therefore we expect $\mathcal{M}^\mu(k)$ to be given by a matrix element of the Heisenberg field j^μ:

$$\mathcal{M}^\mu(k) = \int d^4x e^{ik\cdot x} \langle f|j^\mu(x)|i\rangle \tag{5.78}$$

where the initial and final states include all particles except the photon in question.

From the classical equations of motion, we know that the current j^μ is conserved: $\partial_\mu j^\mu(x) = 0$. Provided that this property still holds in the quantum theory, we can dot k_μ into (5.78) to obtain

$$k_\mu \mathcal{M}^\mu(k) = 0. \tag{5.79}$$

The amplitude $\mathcal{M}$ vanishes when the polarization vector $\epsilon_\mu(k)$ is replaced by k_μ. This famous relation is known as the Ward identity. It is essentially a statement of current conservation, which is a consequence of the gauge symmetry (4.6) of QED. We will give a formal proof of the

Ward identity in Section 7.4, and discuss a number of subtle points skimmed over in this quick "derivation".

It is useful to check explicitly that the Compton amplitude given in (5.74) obeys the Ward identity. To do this, replace $\epsilon_\nu(k)$ by k_ν or $\epsilon^*_\mu(k')$ by k'_μ, and manipulate the Dirac matrix products. In either case (after a bit of algebra) the terms from the two diagrams cancel each other to give zero.

Returning to our derivation of the polarization sum formula (5.75), we note that for $k^\mu = (k, 0, 0, k)$, the Ward identity takes the form

$$k\mathcal{M}^0(k) - k\mathcal{M}^3(k) = 0 \tag{5.80}$$

Thus $\mathcal{M}^0 = \mathcal{M}^3$, and we have

$$\begin{aligned}\sum_\epsilon \epsilon^*_\mu \epsilon_\nu \mathcal{M}^\mu(k)\mathcal{M}^{\nu*}(k) &= \left|\mathcal{M}^1\right|^2 + \left|\mathcal{M}^2\right|^2 \\ &= \left|\mathcal{M}^1\right|^2 + \left|\mathcal{M}^2\right|^2 + \left|\mathcal{M}^3\right|^2 - \left|\mathcal{M}^0\right|^2 \\ &= -g_{\mu\nu}\mathcal{M}^\mu(k)\mathcal{M}^{\nu*}(k)\end{aligned}$$

That is, we may sum over external photon polarizations by replacing $\sum \epsilon^*_\mu \epsilon_\nu$ with $-g_{\mu\nu}$.

Note that this proves (pending our general proof of the Ward identity) that the unphysical timelike and longitudinal photons can be consistently omitted from QED calculations, since in any event the squared amplitudes for producing these states cancel to give zero total probability. The negative norm of the timelike photon state, a property that troubled us in the discussion after Eq. (4.132), plays an essential role in this cancellation.

The Klein-Nishina Formula

The rest of the computation of the Compton scattering cross section is straightforward, although it helps to be somewhat organized. We want to average the squared amplitude over the initial electron and photon polarizations, and sum over the final electron and photon polarizations. Starting with expression (5.74) for $\mathcal{M}$, we find

$$\begin{aligned}\tfrac{1}{4}\textstyle\sum_{\text{spins}} |\mathcal{M}|^2 = \tfrac{e^4}{4} g_{\mu\rho}g_{\nu\sigma} \cdot \operatorname{tr}\Big\{ (\not{p}' + m)\left[\tfrac{\gamma^\mu \not{k}\gamma^\nu + 2\gamma^\mu p^\nu}{2p\cdot k} + \tfrac{\gamma^\nu \not{k}'\gamma^\mu - 2\gamma^\nu p^\mu}{2p\cdot k'}\right] \\ \cdot(\not{p} + m)\left[\tfrac{\gamma^\sigma \not{k}\gamma^\rho + 2\gamma^\rho p^\sigma}{2p\cdot k} + \tfrac{\gamma^\rho \not{k}'\gamma^\sigma - 2\gamma^\sigma p^\rho}{2p\cdot k'}\right]\Big\} \\ \equiv \tfrac{e^4}{4}\left[\tfrac{\mathbf{I}}{(2p\cdot k)^2} + \tfrac{\mathbf{II}}{(2p\cdot k)(2p\cdot k')} + \tfrac{\mathbf{III}}{(2p\cdot k')(2p\cdot k)} + \tfrac{\mathbf{IV}}{(2p\cdot k')^2}\right],\end{aligned} \tag{5.81}$$

where I, II, III, and IV are complicated traces. Note that IV is the same as I if we replace k with $-k'$. Also, since we can reverse the order of the γ matrices inside a trace (Eq. (5.7)), we see that II =III. Thus we must work only to compute I and II.

The first of the traces is

$$\mathbf{I} = \operatorname{tr}\left[(\not{p}' + m)\left(\gamma^\mu \not{k} \not{\gamma}^\nu + 2\gamma^\mu p^\nu\right)(\not{p} + m)\left(\gamma_\nu \not{k}\gamma_\mu + 2\gamma_\mu p_\nu\right)\right].$$

There are 16 terms inside the trace, but half contain an odd number of γ matrices and therefore vanish. We must now evaluate the other eight terms, one at a time. For example,

$$\begin{aligned}\mathrm{tr}\left[\not{p}'\gamma^\mu\ \not{k}\gamma^\nu\ \not{p}\gamma_\nu\ \not{k}\gamma_\mu\right] &= \mathrm{tr}\left[(-2\ \not{p}')\ \not{k}(-2\ \not{p})\ \not{\mathbb{1}}\ c\right] \\ &= \mathrm{tr}\left[4\ \not{p}'\ \not{k}(2p\cdot k - \not{k}\ \not{p})\right] \\ &= 8p\cdot k\,\mathrm{tr}\left[\not{p}'\ \not{k}x\right] \\ &= 32(p\cdot k)\,(p'\cdot k)\,.\end{aligned}$$

By similar use of the contraction identities (5.8) and (5.9), and other Dirac algebra such as $\not{p}\ \not{p} = p^2 = m^2$, each term in $\mathbf{I}$ can be reduced to a trace of no more than two γ matrices. When the smoke clears, we find

$$\mathbf{I} = 16\left(4m^4 - 2m^2 p\cdot p' + 4m^2 p\cdot k - 2m^2 p'\cdot k + 2(p\cdot k)\,(p'\cdot k)\right). \tag{5.82}$$

Although it is not obvious, this expression can be simplified further. To see how, introduce the Mandelstam variables:

$$\begin{aligned}s &= (p+k)^2 = 2p\cdot k + m^2 = 2p'\cdot k' + m^2 \\ t &= (p'-p)^2 = -2p\cdot p' + 2m^2 = -2k\cdot k' \\ u &= (k'-p)^2 = -2k'\cdot p + m^2 = -2k\cdot p' + m^2\end{aligned} \tag{5.83}$$

Recall from (5.73) that momentum conservation implies $s+t+u = 2m^2$. Writing everything in terms of s, t, and u, and using this identity, we eventually obtain

$$\mathbf{I} = 16\left(2m^4 + m^2\left(s-m^2\right) - \frac{1}{2}\left(s-m^2\right)\left(u-m^2\right)\right) \tag{5.84}$$

Sending $k \leftrightarrow -k'$, we can immediately write

$$\mathbf{IV} = 16\left(2m^4 + m^2\left(u-m^2\right) - \frac{1}{2}\left(s-m^2\right)\left(u-m^2\right)\right) \tag{5.85}$$

Evaluating the traces in the numerators II and III requires about the same amount of work as we have just done. The answer is

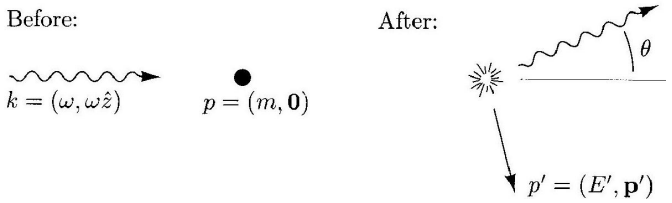
$$\mathbf{II} = \mathbf{III} = -8\left(4m^4 + m^2\left(s-m^2\right) + m^2\left(u-m^2\right)\right) \tag{5.86}$$

Putting together the pieces of the squared matrix element (5.81), and rewriting s and u in terms of $p\cdot k$ and $p\cdot k'$, we finally obtain

$$\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 = 2e^4\left[\frac{p\cdot k'}{p\cdot k} + \frac{p\cdot k}{p\cdot k'} + 2m^2\left(\frac{1}{p\cdot k} - \frac{1}{p\cdot k'}\right) + m^4\left(\frac{1}{p\cdot k} - \frac{1}{p\cdot k'}\right)^2\right] \tag{5.87}$$

To turn this expression into a cross section we must decide on a frame of reference and draw a picture of the kinematics. Compton scattering is most often analyzed in the "lab" frame, in which the electron is initially at rest:

Before:



We will express the cross section in terms of ω and θ. We can find ω', the energy of the final photon, using the following trick:

$$\begin{aligned} m^2 = (p')^2 &= (p+k-k')^2 = p^2 + 2p\cdot(k-k') - 2k\cdot k' \\ &= m^2 + 2m(\omega-\omega') - 2\omega\omega'(1-\cos\theta) \end{aligned} \tag{5.88}$$

hence, $\frac{1}{\omega'} - \frac{1}{\omega} = \frac{1}{m}(1-\cos\theta)$.

The last line is Compton's formula for the shift in the photon wavelength. For our purposes, however, it is more useful to solve for ω':

$$\omega' = \frac{\omega}{1+\frac{\omega}{m}(1-\cos\theta)} \tag{5.89}$$

The phase space integral in this frame is

$$\begin{aligned} \int d\Pi_2 &= \int \frac{d^3k'}{(2\pi)^3}\frac{1}{2\omega'}\frac{d^3p'}{(2\pi)^3}\frac{1}{2E'}(2\pi)^4\delta^{(4)}(k'+p'-k-p) \\ &= \int \frac{(\omega')^2\,d\omega' d\Omega}{(2\pi)^3}\frac{1}{4\omega' E'} \\ &\quad \times 2\pi\delta\left(\omega' + \sqrt{m^2+\omega^2+(\omega')^2-2\omega\omega'\cos\theta} - \omega - m\right) \\ &= \int \frac{d\cos\theta}{2\pi}\frac{\omega'}{4E'}\frac{1}{\left|1+\frac{\omega'-\omega\cos\theta}{E'}\right|} \\ &= \frac{1}{8\pi}\int d\cos\theta \frac{\omega'}{m+\omega(1-\cos\theta)} \\ &= \frac{1}{8\pi}\int d\cos\theta \frac{(\omega')^2}{\omega m} \end{aligned} \tag{5.90}$$

Plugging everything into our general cross-section formula (4.79) and setting $|v_{\mathcal{A}} - v_{\mathcal{B}}| = 1$, we find

$$\frac{d\sigma}{d\cos\theta} = \frac{1}{2\omega}\frac{1}{2m}\cdot\frac{1}{8\pi}\frac{(\omega')^2}{\omega m}\cdot\left(\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2\right)$$

To evaluate $|\mathcal{M}|^2$, we replace $p\cdot k = m\omega$ and $p\cdot k' = m\omega'$ in (5.87). The shortest way to write the final result is

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2}{m^2}\left(\frac{\omega'}{\omega}\right)^2\left[\frac{\omega'}{\omega} + \frac{\omega}{\omega'} - \sin^2\theta\right] \tag{5.91}$$

where ω'/ω is given by (5.89). This is the (spin-averaged) Klein-Nishina formula, first derived in 1929. †

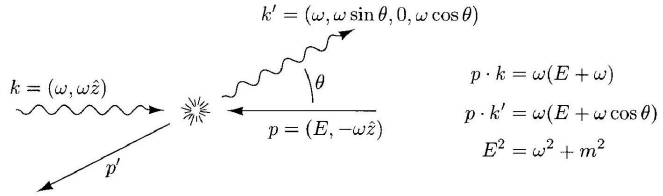
In the limit $\omega \to 0$ we see from (5.89) that $\omega'/\omega \to 1$, so the cross section becomes

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2}{m^2}\left(1+\cos^2\theta\right); \quad \sigma_{\text{total}} = \frac{8\pi\alpha^2}{3m^2} \tag{5.92}$$

This is the familiar Thomson cross section for scattering of classical electromagnetic radiation by a free electron.

High-Energy Behavior

To analyze the high-energy behavior of the Compton scattering cross section, it is easiest to work in the center-of-mass frame. We can easily construct the differential cross section in this frame from the invariant expression (5.87). The kinematics of the reaction now looks like this:



Plugging these values into (5.87), we see that for $\theta \approx \pi$, the term $p \cdot k / p \cdot k'$ becomes very large, while the other terms are all of $\mathcal{O}(1)$ or smaller. Thus for $E \gg m$ and $\theta \approx \pi$, we have

$$\frac{1}{4}\sum_{\text{spins}} |\mathcal{M}|^2 \approx 2e^4 \cdot \frac{p \cdot k}{p \cdot k'} = 2e^4 \cdot \frac{E + \omega}{E + \omega\cos\theta} \tag{5.93}$$

The cross section in the CM frame is given by (4.84):

$$\begin{aligned} \frac{d\sigma}{d\cos\theta} &= \frac{1}{2} \cdot \frac{1}{2E} \cdot \frac{1}{2\omega} \cdot \frac{\omega}{(2\pi)4(E+\omega)} \cdot \frac{2e^4(E+\omega)}{E + \omega\cos\theta} \\ &\approx \frac{2\pi\alpha^2}{2m^2 + s(1+\cos\theta)} \end{aligned} \tag{5.94}$$

Notice that, since $s \gg m^2$, the denominator of (5.94) almost vanishes when the photon is emitted in the backward direction ($\theta \approx \pi$). In fact, the electron mass m could be neglected completely in this formula if it were not necessary to cut off this singularity. To integrate over $\cos\theta$, we can drop the electron mass term if we supply an equivalent cutoff near $\theta = \pi$. In this way, we can approximate the total Compton scattering cross section by

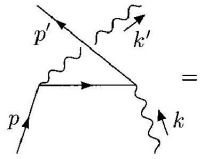
$$\int_{-1}^{1} d(\cos\theta) \frac{d\sigma}{d\cos\theta} \approx \frac{2\pi\alpha^2}{s} \int_{-1+2m^2/s}^{1} d(\cos\theta) \frac{1}{(1+\cos\theta)} \tag{5.95}$$

Thus, we find that the total cross section behaves at high energy as

$$\sigma_{\text{total}} = \frac{2\pi\alpha^2}{s} \log\left(\frac{s}{m^2}\right) \tag{5.96}$$

The main dependence α^2/s follows from dimensional analysis. But the singularity associated with backward scattering of photons leads to an enhancement by an extra logarithm of the energy.

Let us try to understand the physics of this singularity. The singular term comes from the square of the u-channel diagram,



$$= -ie^2\, \epsilon_\mu(k)\epsilon^*_\nu(k')\bar{u}(p')\gamma^\mu \frac{\not{p} - \not{k}' + m}{(p-k')^2 - m^2}\gamma^\nu u(p).$$

[6†] O. Klein and Y. Nishina, Z. Physik, 52, 853 (1929).

The amplitude is large at $\theta \approx \pi$ because the denominator of the propagator is then small ($\sim m^2$) compared to s. To be more precise, define $\chi \equiv \pi - \theta$. We will be interested in values of χ that are somewhat larger than m/ω, but still small enough that we can approximate $1 - \cos\chi \approx \chi^2/2$. For χ in this range, the denominator is

$$(p - k')^2 - m^2 = -2p \cdot k' \approx -2\omega^2 \left(\frac{m^2}{2\omega^2} + 1 - \cos\chi \right) \approx -\left(\omega^2\chi^2 + m^2\right) \tag{5.98}$$

This is small compared to s over a wide range of values for χ, hence the enhancement in the total cross section.

Looking back at (5.93), we see that for χ such that $m/\omega \ll \chi \ll 1$, the squared amplitude is proportional to $1/\chi^2$, and hence we expect $\mathcal{M} \propto 1/\chi$. But we have just seen that the denominator of $\mathcal{M}$ is proportional to χ^2, so there must be a compensating factor of χ in the numerator. We can understand the physical origin of that factor by looking at the amplitude for a particular set of electron and photon polarizations.

Suppose that the initial electron is right-handed. The dominant term of (5.97) comes from the term that involves $(\not{p} - \not{k}')$ in the numerator of the propagator. Since this term contains three γ-matrices in (5.97) between the $\bar{u}$ and the u, the final electron must also be right-handed. The amplitude is therefore

$$i\mathcal{M} = -ie^2 \epsilon_\mu(k) \epsilon^*_\nu(k')\, u^\dagger_R(p')\, \sigma^\mu \frac{\bar{\sigma} \cdot (p - k')}{-(\omega^2\chi^2 + m^2)} \sigma^\nu u_R(p) \tag{5.99}$$

where

$$u_R(p) = \sqrt{2E}\begin{pmatrix} 0 \\ 1 \end{pmatrix} \quad \text{and} \quad u_R(p') = \sqrt{2E}\begin{pmatrix} 1 \\ 0 \end{pmatrix} \tag{5.100}$$

If the initial photon is left-handed, with $\epsilon_\mu(k) = (1/\sqrt{2})(0, 1, -i, 0)$, then

$$\sigma^\mu \epsilon_\mu(k) = \begin{pmatrix} 0 & 0 \\ \sqrt{2} & 0 \end{pmatrix}$$

and the combination $u^\dagger_R(p')\, \sigma^\mu \epsilon_\mu(k)$ vanishes. The initial photon must therefore be right-handed. Similarly, the amplitude vanishes unless the final photon is right-handed. The kinematic situation for this set of polarizations is shown

Before:

After:

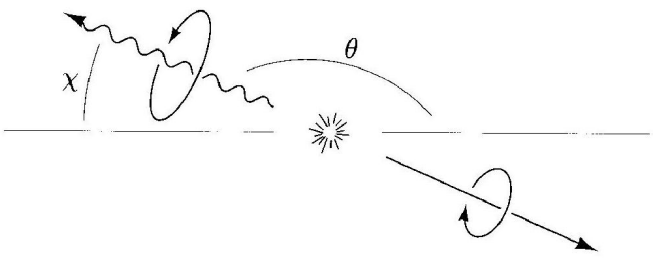


Figure 5.6. In the high-energy limit, the final photon is most likely to be emitted at backward angles. Since helicity is conserved, a unit of spin angular momentum is converted to orbital angular momentum.

in Fig. 5.6. Note that the total spin angular momentum of the final state is one unit less than that of the initial state.

Continuing with our calculation, let us consider the numerator of the propagator in (5.99). For χ in the range of interest, the dominant term is

$$-\sigma^1 \left(p - k'\right)^1 = \sigma^1 \cdot \omega\chi$$

This is the factor of χ anticipated above. It indicates that the final state is a p-wave, as required by angular momentum conservaton. Assembling all the pieces, we obtain

$$\mathcal{M}\left(e_R^- \gamma_R \to e_R^- \gamma_R\right) \approx e^2\sqrt{2E}\sqrt{2}\frac{\omega\chi}{(\omega^2\chi^2 + m^2)}\sqrt{2E}\sqrt{2} \approx \frac{4e^2\chi}{\chi^2 + m^2/\omega^2}. \tag{5.101}$$

We would find the same result in the case where all initial and final particles are left-handed.

Notice that for directly backward scattering, $\chi = 0$, the matrix element (5.101) vanishes due to the angular momentum zero in the numerator. Thus, at angles very close to backward, we should also take into account the mass term in the numerator of the propagator in (5.97). This term contains only two gamma matrices and so converts a right-handed electron into a left-handed electron. By an analysis similar to the one that led to Eq. (5.101), we can see that this amplitude is nonvanishing only when the initial photon is lefthanded and the final photon is right-handed. Following this analysis in more detail, we find

$$\mathcal{M}\left(e_R^- \gamma_L \to e_L^- \gamma_R\right) \approx \frac{4e^2 m/\omega}{\chi^2 + m^2/\omega^2} \tag{5.102}$$

The reaction with all four helicities reversed gives the same matrix element.

To compare this result to our previous calculations, we should add the contributions to the cross section from (5.101) and (5.102) and equal contributions for the reactions involving initial left-handed electrons, and divide by 4 to average over initial spins. The unpolarized differential cross section should then be

$$\begin{aligned}\frac{d\sigma}{d\cos\theta} &= \frac{1}{2}\frac{1}{2E}\frac{1}{2\omega}\frac{\omega}{(2\pi)4(E+\omega)}\left[\frac{8e^4\chi^2}{\left(\chi^2 + m^2/\omega^2\right)^2} + \frac{8e^4 m^2/\omega^2}{\left(\chi^2 + m^2/\omega^2\right)^2}\right] \\ &= \frac{4\pi\alpha^2}{s\left(\chi^2 + 4m^2/s\right)},\end{aligned} \tag{5.103}$$

which agrees precisely with Eq. (5.94).

The importance of the helicity-flip process (5.102) just at the kinematic endpoint has an interesting experimental consequence. Consider the process of inverse Compton scattering, a high-energy electron beam colliding with a low-energy photon beam (for example, a laser beam) to produce a highenergy photon beam. Let the electrons have energy E and the laser photons have energy ϖ, let the energy of the scattered photon be $E' = yE$, and assume for simplicity that $s = 4E\varpi \gg m^2$. Then the computation we have just done applies to this situation, with the highest energy photons resulting from scattering that is precisely backward in the center-of-mass frame. By computing $2k \cdot k'$ in the center-of-mass frame and in the lab frame, it is easy to show that the final photon energy is related to the center-of-mass scattering angle through

$$y \approx \frac{1}{2}(1-\cos\theta) \approx 1 - \frac{\chi^2}{4}$$

Then Eq. (5.103) can be rewritten as a formula for the energy distribution of backscattered photons near the endpoint:

$$\frac{d\sigma}{dy} = \frac{2\pi\alpha^2}{s\left((1-y)+m^2/s\right)^2}\left[(1-y)+\frac{m^2}{s}\right] \tag{5.104}$$

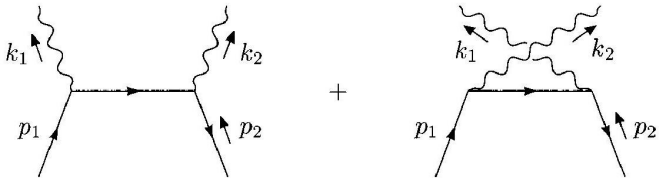
where the first term in brackets corresponds to the helicity-conserving process and the second term to the helicity-flip process. Thus, for example, if a right-handed polarized laser bearn is scattered from an unpolarized highenergy electron beam, most of the backscattered photons will be right-handed but the highest-energy photons will be left-handed. This effect can be used experimentally to measure the polarization of an electron beam or to create high-energy photon sources with adjustable energy distribution and polarization.

Pair Annihilation into Photons

We can still obtain one more result from the Compton-scattering amplitude. Consider the annihilation process

$$e^+e^- \to 2\gamma$$

given to lowest order by the diagrams



This process is related to Compton scattering by crossing symmetry; we can obtain the correct amplitude from the Compton amplitude by making the replacements

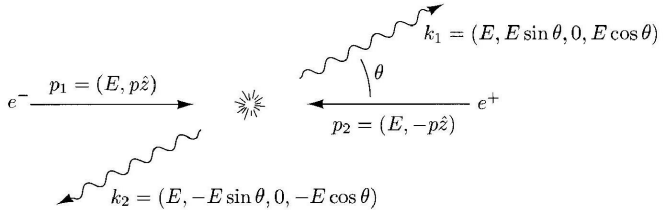
$$p \to p_1 \quad p' \to -p_2 \quad k \to -k_1 \quad k' \to k_2$$

Making these substitutions in (5.87), we find

$$\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 = -2e^4\left[\frac{p_1\cdot k_2}{p_1\cdot k_1}+\frac{p_1\cdot k_1}{p_1\cdot k_2}+2m^2\left(\frac{1}{p_1\cdot k_1}+\frac{1}{p_1\cdot k_2}\right)\right. \tag{5.105}$$
$$\left. -m^4\left(\frac{1}{p_1\cdot k_1}+\frac{1}{p_1\cdot k_2}\right)^2\right]$$

The overall minus sign is the result of the crossing relation (5.68) and should be removed.

Now specialize to the center-of-mass frame. The kinematics is



A routine calculation yields the differential cross section,

$$\frac{d\sigma}{d\cos\theta} = \frac{2\pi\alpha^2}{s}\left(\frac{E}{p}\right)\left[\frac{E^2+p^2\cos^2\theta}{m^2+p^2\sin^2\theta} + \frac{2m^2}{m^2+p^2\sin^2\theta} - \frac{2m^4}{\left(m^2+p^2\sin^2\theta\right)^2}\right] \tag{5.106}$$

In the high-energy limit, this becomes

$$\frac{d\sigma}{d\cos\theta} \underset{E\gg m}{\longrightarrow} \frac{2\pi\alpha^2}{s}\left(\frac{1+\cos^2\theta}{\sin^2\theta}\right) \tag{5.107}$$

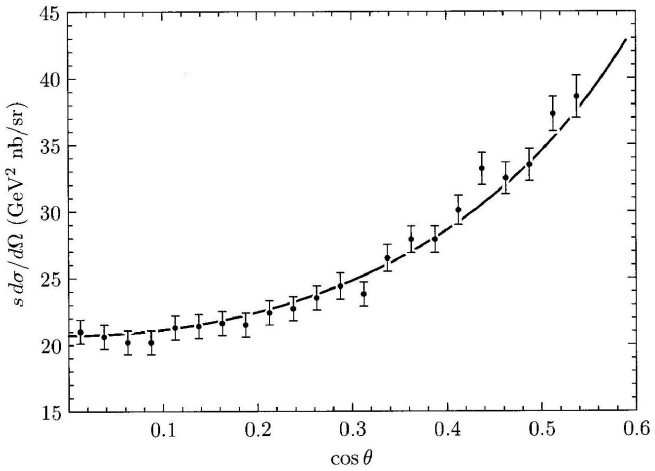


Figure 5.7. Angular dependence of the cross section for $e^+e^- \to 2\gamma$ at $E_{\rm cm} = 29$GeV, as measured by the HRS collaboration, M. Derrick, et. al., Phys. Rev. D34, 3286 (1986). The solid line is the lowest-order theoretical prediction, Eq. (5.107).

except when $\sin\theta$ is of order m/p or smaller. Note that since the two photons are identical, we count all possible final states by integrating only over $0 \le \theta \le \pi/2$. Thus the total cross section is computed as

$$\sigma_{\rm total} = \int_0^1 d(\cos\theta)\frac{d\sigma}{d\cos\theta} \tag{5.108}$$

Figure 5.7 compares the asymptotic formula (5.107) for the differential cross section to measurements of e^+e^-annihilation into two photons at very high energy.

Problems

5.1 Coulomb scattering. Repeat the computation of Problem 4.4, part (c), this time using the full relativistic expression for the matrix element. You should find, for the spin-averaged cross section,

$$\frac{d\sigma}{d\Omega} = \frac{\alpha^2}{4|\mathbf{p}|^2\beta^2\sin^4(\theta/2)}\left(1-\beta^2\sin^2\frac{\theta}{2}\right)$$

where $\mathbf{p}$ is the electron's 3 -momentum and β is its velocity. This is the Mott formula for Coulomb scattering of relativistic electrons. Now derive it in a second way, by working out the cross section for electron-muon scattering, in the muon rest frame, retaining the electron

mass but sending $m_\mu \to \infty$.

5.2 Bhabha scattering. Compute the differential cross section $d\sigma/d\cos\theta$ for Bhabha scattering, $e^+e^- \to e^+e^-$. You may work in the limit $E_{\rm cm} \gg m_e$, in which it is permissible to ignore the electron mass. There are two Feynman diagrams; these must be added in the invariant matrix element before squaring. Be sure that you have the correct relative sign between these diagrams. The intermediate steps are complicated, but the final result is quite simple. In particular, you may find it useful to introduce the Mandelstam variables s, t, and u. Note that, if we ignore the electron mass, $s+t+u=0$. You should be able to cast the differential cross section into the form

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2}{s}\left[u^2\left(\frac{1}{s}+\frac{1}{t}\right)^2 + \left(\frac{t}{s}\right)^2 + \left(\frac{s}{t}\right)^2\right]$$

Rewrite this formula in terms of $\cos\theta$ and graph it. What feature of the diagrams causes the differential cross section to diverge as $\theta \to 0$?

5.3 The spinor product formalism introduced in Problem 3.3 provides an efficient way to compute tree diagrams involving massless particles. Recall that in Problem 3.3 we defined spinor products as follows: Let u_{L0}, u_{R0} be the left- and right-handed spinors at some fixed lightlike momentum k_0. These satisfy

$$u_{L0}\bar{u}_{L0} = \left(\frac{1-\gamma^5}{2}\right)\not{0}, \quad u_{R0}\bar{u}_{R0} = \left(\frac{1+\gamma^5}{2}\right)\not{0}. \tag{1}$$

(These relations are just the projections onto definite helicity of the more standard formula $\sum u_0\bar{u}_0 = \not{p}_0$.) Then define spinors for any other lightlike momentum p by

$$u_L(p) = \frac{1}{\sqrt{2p\cdot k_0}}\not{p}u_{R0}, \quad u_R(p) = \frac{1}{\sqrt{2p\cdot k_0}}\not{p}u_{L0} \tag{2}$$

We showed that these spinors satisfy $\not{p}u(p) = 0$; because there is no m around, they can be used as spinors for either fermions or antifermions. We defined

$$s(p_1,p_2) = \bar{u}_R(p_1)\,u_L(p_2), \quad t(p_1,p_2) = \bar{u}_L(p_1)\,u_R(p_2)$$

and, in a special frame, we proved the properties

$$t(p_1,p_2) = (s(p_2,p_1))^*, \quad s(p_1,p_2) = -s(p_2,p_1), \quad |s(p_1,p_2)|^2 = 2p_1\cdot p_2 \tag{3}$$

Now let us apply these results.

(a) To warm up, give another proof of the last relation in Eq. (3) by using (1) to rewrite $|s(p_1,p_2)|^2$ as a trace of Dirac matrices, and then applying the trace calculus.

(b) Show that, for any string of Dirac matrices,

$$\mathrm{tr}\left[\gamma^\mu\gamma^\nu\gamma^\rho\cdots\right] = \mathrm{tr}\left[\cdots\gamma^\rho\gamma^\nu\gamma^\mu\right]$$

where $\mu,\nu,\rho,\ldots = 0,1,2,3$, or 5 . Use this identity to show that

$$\bar{u}_L(p_1)\,\gamma^\mu u_L(p_2) = \bar{u}_R(p_2)\,\gamma^\mu u_R(p_1)$$

(c) Prove the Fierz identity

$$\bar{u}_L(p_1)\,\gamma^\mu u_L(p_2)\,[\gamma_\mu]_{ab} = 2\left[u_L(p_2)\,\bar{u}_L(p_1) + u_R(p_1)\,\bar{u}_R(p_2)\right]_{ab}$$

where $a, b = 1, 2, 3, 4$ are Dirac indices. This can be done by justifying the following statements: The right-hand side of this equation is a Dirac matrix; thus, it can be written as a linear combination of the 16Γ matrices discussed in Section 3.4. It satisfies

$$\gamma^5[M] = -[M]\gamma^5,$$

thus, it must have the form

$$[M] = \left(\frac{1-\gamma^5}{2}\right)\gamma_\mu V^\mu + \left(\frac{1+\gamma^5}{2}\right)\gamma_\mu W^\mu$$

where V^μ and W^μ are 4 -vectors. These 4 -vectors can be computed by trace technology; for example,

$$V^\nu = \frac{1}{2}\,\mathrm{tr}\left[\gamma^\nu\left(\frac{1-\gamma^5}{2}\right)M\right].$$

(d) Consider the process $e^+e^- \to \mu^+\mu^-$, to the leading order in α, ignoring the masses of both the electron and the muon. Consider first the case in which the electron and the final muon are both right-handed and the positron and the final antimuon are both left-handed. (Use the spinor v_R for the antimuon and $\bar{u}_R$ for the positron.) Apply the Fierz identity to show that the amplitude can be evaluated directly in terms of spinor products. Square the amplitude and reproduce the result for

$$\frac{d\sigma}{d\cos\theta}\left(e_R^- e_L^+ \to \mu_R^- \mu_L^+\right)$$

given in Eq. (5.22). Compute the other helicity cross sections for this process and show that they also reproduce the results found in Section 5.2.
(e) Compute the differential cross section for Bhabha scattering of massless electrons, helicity state by helicity state, using the spinor product formalism. The average over initial helicities, summed over final helicities, should reproduce the result of Problem 5.2. In the process, you should see how this result arises as the sum of definite-helicity contributions.

5.4 Positronium lifetimes.

(a) Compute the amplitude $\mathcal{M}$ for e^+e^-annihilation into 2 photons in the extreme nonrelativistic limit (i.e., keep only the term proportional to zero powers of the electron and positron 3 -momentum). Use this result, together with our formalism for fermion-antifermion bound states, to compute the rate of annihilation of the $1S$ states of positronium into 2 photons. You should find that the spin-1 states of positronium do not annihilate into 2 photons, confirming the symmetry argument of Problem 3.8. For the spin-0 state of positronium, you should find a result proportional to the square of the $1S$ wavefunction at the origin. Inserting the value of this wavefunction from nonrelativistic quantum mechanics, you should find

$$\frac{1}{\tau} = \Gamma = \frac{\alpha^5 m_e}{2} \approx 8.03 \times 10^9 \mathrm{sec}^{-1}$$

A recent measurement [‡] gives $\Gamma = 7.994 \pm .011 \mathrm{nsec}^{-1}$; the 0.5% discrepancy is accounted for by radiative corrections.
(b) Computing the decay rates of higher-l positronium states is somewhat more difficult; in the rest of this problem, we will consider the case $l = 1$. First, work out the terms in the $e^+e^- \to 2\gamma$

amplitude proportional to one power of the 3 -momentum. (For simplicity, work in the center-of-mass frame.) Since

$$\int \frac{d^3p}{(2\pi)^3} p^i \psi(\mathbf{p}) = i \frac{\partial}{\partial x^i} \psi(\mathbf{x}) \Big|_{\mathbf{x}=0}$$

this piece of the amplitude has overlap with P-wave bound states. Show that the $S = 1$, but not the $S = 0$ states, can decay to 2 photons. Again, this is a consequence of C.
(c) To compute the decay rates of these P-wave states, we need properly normalized state vectors. Denote the three P-state wavefunctions by

$$\psi_i = x^i f(|\mathbf{x}|), \quad \text{normalized to } \int d^3x \psi_i^*(\mathbf{x}) \psi_j(\mathbf{x}) = \delta_{ij}$$

and their Fourier transforms by $\psi_i(\mathbf{p})$. Show that

$$|B(\mathbf{k})\rangle = \sqrt{2M} \int \frac{d^3p}{(2\pi)^3} \psi_i(\mathbf{p}) a^\dagger_{\mathbf{p}+\mathbf{k}/2} \Sigma^i b^\dagger_{-\mathbf{p}+\mathbf{k}/2} |0\rangle$$

is a properly normalized bound-state vector if Σ^i denotes a set of three 2×2 matrices normalized to

$$\sum_i \mathrm{tr}\left(\Sigma^{i\dagger}\Sigma^i\right) = 1$$

To build $S = 1$ states, we should take each Σ^i to contain a Pauli sigma matrix. In general, spin-orbit coupling will split the multiplet of $S = 1, L = 1$ states according to the total angular momentum J. The states of definite J are given by

$$\begin{aligned} J = 0: &\quad \Sigma^i = \tfrac{1}{\sqrt{6}} \sigma^i \\ J = 1: &\quad \Sigma^i = \tfrac{1}{2} \epsilon^{ijk} n^j \sigma^k \\ J = 2: &\quad \Sigma^i = \tfrac{1}{\sqrt{3}} h^{ij} \sigma^j \end{aligned}$$

where $\mathbf{n}$ is a polarization vector satisfying $|\mathbf{n}|^2 = 1$ and h^{ij} is a traceless tensor, for which a typical value might be $h^{12} = 1$ and all other components zero.
(d) Using the expanded form for the $e^+e^- \to 2\gamma$ amplitude derived in part (b) and the explicit form of the $S = 1, L = 1$, definite- J positronium states found in part (c), compute, for each J, the decay rate of the state into two photons.

5.5 Physics of a massive vector boson. Add to QED a massive photon field B_μ of mass M, which couples to electrons via

$$\Delta H = \int d^3x \left(g \bar{\psi} \gamma^\mu \psi B_\mu\right)$$

A massive photon in the initial or final state has three possible physical polarizations, corresponding to the three spacelike unit vectors in the boson's rest frame. These can be characterized invariantly, in terms of the boson's 4 -momentum k^μ, as the three vectors $\epsilon^{(i)}_\mu$ satisfying

$$\epsilon^{(i)} \cdot \epsilon^{(j)} = -\delta^{ij}, \quad k \cdot \epsilon^{(i)} = 0$$

[6‡] D. W. Gidley et. al., Phys. Rev. Lett. 49, 525 (1982).

The four vectors $(k_\mu/M, \epsilon_\mu^{(i)})$ form a complete orthonormal basis. Because B_μ couples to the conserved current $\bar{\psi}\gamma^\mu\psi$, the Ward identity implies that k_μ dotted into the amplitude for B production gives zero; thus we can replace:

$$\sum_i \epsilon_\mu^{(i)} \epsilon_\nu^{(i)*} \to -g_{\mu\nu}$$

This gives a generalization to massive bosons of the Feynman trick for photon polarization vectors and simplifies the calculation of B production cross sections. (Warning: This trick does not work (so simply) for "non-Abelian gauge fields".) Let's do a few of these computations, using always the approximation of ignoring the mass of the electron.
(a) Compute the cross section for the process $e^+e^- \to B$. Compute the lifetime of the B, assuming that it decays only to electrons. Verify the relation

$$\sigma\left(e^+e^- \to B\right) = \frac{12\pi^2}{M}\Gamma\left(B \to e^+e^-\right)\delta\left(M^2 - s\right)$$

discussed in Section 5.3.
(b) Compute the differential cross section, in the center-of-mass system, for the process $e^+e^- \to \gamma + B$. (This calculation goes over almost unchanged to the realistic process $e^+e^- \to \gamma + Z^0$; this allows one to measure the number of decays of the Z^0 into unobserved final states, which is in turn proportional to the number of neutrino species.)
(c) Notice that the cross section of part (b) diverges as $\theta \to 0$ or π. Let us analyze the region near $\theta = 0$. In this region, the dominant contribution comes from the t-channel diagram and corresponds intuitively to the emission of a photon from the electron line before e^+e^-annihilation into a B. Let us rearrange the formula in such a way as to support this interpretation. First, note that the divergence as $\theta \to 0$ is cut off by the electron mass: Let the electron momentum be $p^\mu = (E, 0, 0, k)$, with $k = (E^2 - m_e^2)^{1/2}$, and let the photon momentum be $k^\mu = (xE, xE\sin\theta, 0, xE\cos\theta)$. Show that the denominator of the propagator then never becomes smaller than $\mathcal{O}(m_e^2/s)$. Now integrate the cross section of part (b) over forward angles, cutting off the θ integral at $\theta^2 \sim (m_e^2/s)$ and keeping only the leading logarithmic term, proportional to $\log(s/m_e^2)$. Show that, in this approximation, the cross section for forward photon emission can be written

$$\sigma\left(e^+e^- \to \gamma + B\right) \approx \int dx f(x) \cdot \sigma\left(e^+e^- \to B \text{ at } E_{\text{cm}}^2 = (1-x)s\right)$$

where the annihilation cross section is evaluated for the collision of a positron of energy E and an electron of energy $(1-x)E$, and the function $f(x)$, the Weiszacker-Williams distribution function, is given by

$$f(x) = \frac{\alpha}{2\pi}\frac{1+(1-x)^2}{x} \cdot \log\left(\frac{s}{m_e^2}\right)$$

This function arises universally in processes in which a photon is emitted collinearly from an electron line, independent of the subsequent dynamics. We will meet it again, in another context, in Problem 6.2.
5.6 This problem extends the spinor product technology of Problem 5.3 to external photons.
(a) Let k be the momentum of a photon, and let p be another lightlike vector, chosen so that $p \cdot k \neq 0$. Let $u_R(p), u_L(p)$ be spinors of definite helicity for fermions with the lightlike momentum p, defined according to the conventions of Problem 5.3. Define photon polarization vectors as follows:

$$\epsilon_+^\mu(k) = \frac{1}{\sqrt{4p\cdot k}}\bar{u}_R(k)\gamma^\mu u_R(p), \quad \epsilon_-^\mu(k) = \frac{1}{\sqrt{4p\cdot k}}\bar{u}_L(k)\gamma^\mu u_L(p).$$

Use the identity

$$u_L(p)\bar{u}_L(p) + u_R(p)\bar{u}_R(p) = \not{p}$$

to compute the polarization sum

$$\epsilon_+^\mu\epsilon_+^{\nu*} + \epsilon_-^\mu\epsilon_-^{\nu*} = -g^{\mu\nu} + \frac{k^\mu p^\nu + k^\nu p^\mu}{p\cdot k}$$

The second term on the right gives zero when dotted with any photon emission amplitude $\mathcal{M}^\mu$, so we have

$$|\epsilon_+\cdot\mathcal{M}|^2 + |\epsilon_-\cdot\mathcal{M}|^2 = \mathcal{M}^\mu\mathcal{M}^{\nu*}(-g_{\mu\nu});$$

thus, we can use the vectors $\epsilon_+, \epsilon_-$to compute photon polarization sums.
(b) Using the polarization vectors just defined, and the spinor products and the Fierz identity from Problem 5.3, compute the differential cross section for a massless electron and positron to annihilate into 2 photons. Show that the result agrees with the massless limit derived in (5.107):

$$\frac{d\sigma}{d\cos\theta} = \frac{2\pi\alpha^2}{s}\left(\frac{1+\cos^2\theta}{\sin^2\theta}\right)$$

in the center-of-mass frame. It follows from the result of part (a) that this answer is independent of the particular vector p used to define the polarization vectors; however, the calculation is greatly simplified by taking this vector to be the initial electron 4 -vector.

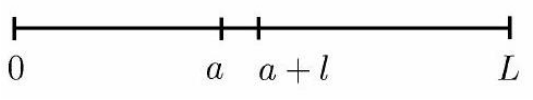
21.7.1 Casimir Effect by Vergeles

Рассмотреть свободное безмассовое скалярное поле $\phi(x)$ на отрезке длины L с граничными условиями $\phi(0) = \phi(a) = \phi(a+l) = \phi(L) = 0$, где $a \sim (1/2)L, l \ll L$ (см. рисунок).



Вычислить силу $(-\partial\mathcal{E}_0/\partial l)$, где $\mathcal{E}_0$ - энергия нулевых колебаний вакуума.

Замечание. Рассмотренная ситуация даёт одномерную модель взаимодействия двух близко расположенных параллельных проводящих пластин, устанавливающих соответствующие граничные условия для электромагнитного поля.

Указание. Для решения задачи необходимо пройти следующие этапы:

а) На отрезке $[a, a+l]$ проквантовать скалярное поле с лагранжианом

$$L = \frac{1}{2}\int\limits_0^l \mathrm{d}x \left(\dot{\phi}^2 - (\phi')^2\right)$$

и граничными условиями $\phi(0) = \phi(l)$.

б) Выразить гамильтониан через бозонные операторы рождения и уничтожения и вычислить энергию вакуума $\mathcal{E}_0$.

в) Регуляризовать энергию вакуума двумя методами:

(i)

$$\mathcal{E}_{0(reg)} = \sum_n \frac{\omega_n}{2} e^{-\varepsilon\omega_n/2}, \quad \varepsilon \to +0$$

(ii) При помощи дзета-функции Римана

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}$$

формально полагая

$$\sum_{n=1}^{\infty} n = \zeta(-1) = -\frac{1}{12}$$

Сравнить оба метода.

г) Вычислить регуляризованную энергию системы $\mathcal{E}_{0(reg)}$, определённой на рис. 1, и вычислить силу

$$f = -\frac{\partial\mathcal{E}_0(reg)}{\partial l}$$

21.7.4 Vacuum polarization по Matthew Schwartz

Теория Vacuum polarization по Matthew Schwartz

In the previous lecture, we calculated the Casimir effect. We found that the energy of a system involving two plates was infinite; however the observable, namely the force on the plates, was finite. At an intermediate step in calculating the force we needed to model the inability of the plates to restrict ultra-high frequency radiation. We found that the force was independent of the model and only determined by radiation with wavelengths of the plate separation, exactly as physical intuition would suggest. More precisely, we proved the force was independent of how we modeled the interactions of the fields with the plates as long as the very short wavelength modes were effectively removed and the longest wavelength modes were not affected. Some of our models were inspired by physical arguments, as in a step-function cutoff representing an atomic spacing; others, such as the ζ-function regulator, were not. That the calculated force is independent of the model is very satisfying: macroscopic physics (the force) is independent of microscopic physics (the atoms). Indeed, for the Casimir calculation, it doesn't matter if the plates are made of atoms, aether, phlogiston or little green aliens.

The program of systematically making testable predictions about long-distance physics in spite of formally infinite short distance fluctuations is known as renormalization. Because physics at short- and long-distance decouples, we can deform the theory at short distance any way we like to get finite answers - we are unconstrained by physically justifiable models. In fact, our most calculationally efficient deformation will be analytic continuation to $d = 4 - \varepsilon$ dimensions with $\varepsilon \to 0$. In some quantum field theory applications, such as condensed matter systems or string theory, there is a real physical cutoff. The beauty of renormalization, however, is that the existence of a physical cutoff is totally irrelevant: quantitative predictions about long distance physics do not care what the short-distance cutoff really is, or even whether or not it exists. The basic principle of renormalization in quantum field theory is - Observables, such as S-matrix elements, are finite and (in principle) calculable functions of other observables.

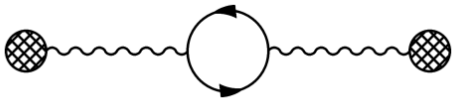
One can think of general correlation functions $\langle \Omega | T \{\phi(x_1) \cdots \phi(x_n)\} | \Omega \rangle$ as a useful proxy for observables. Most of the conceptual confusion, both historically and among students learning the subject, stems from trying to express observables in terms of non-observable quantities, such as coupling constants in a Lagrangian. In practice: - Infinite results associated with high-energy divergences may appear in intermediate steps of calculations, such as in loop graphs. - Infinities are tamed by a deformation procedure called regularization. The regulator dependence must drop out of physical predictions. - Coefficients of terms in the Lagrangian, such as coupling constants, are not observable. They can be solved for in terms of the regulator and will drop out of physical predictions. We will find that loops can produce behavior different from anything possible at tree-level. In particular, - Non-analytic behavior, such as $\ln \frac{s}{s_0}$, is characteristic of loop effects. Tree-level amplitudes are always rational polynomials in external momenta and never involve logarithms. In many cases the non-analytic behavior will comprise the entire physical prediction associated with the loop.

In the previous lecture we gave an example of renormalization in ϕ^4 theory. We found that the expression for a correlation function in terms of the coupling constant λ was infinite: $\langle \phi^4 \rangle_s = \lambda - \frac{\lambda^2}{16\pi^2} \ln\left(\frac{s}{\Lambda^2}\right) + \cdots = \infty$. However, expressing the correlation function at the scale s in terms of the correlation function at a different scale s_0 gave a finite prediction: $\langle \phi^4 \rangle_s = \langle \phi^4 \rangle_{s_0} - \frac{1}{16\pi^2} \langle \phi^4 \rangle_{s_0}^2 \ln\left(\frac{s}{s_0}\right) + \cdots$. Although ϕ^4 theory was just a toy example, renormalization in QED, which we begin in this lecture, is conceptually identical. Recall that the Coulomb potential $V(r) = \frac{e^2}{4\pi r}$

is given by the exchange of a single photon

$$= \frac{e^2}{p^2}$$

Indeed $\frac{1}{4\pi r}$ is just the Fourier transform of the propagator (cf. Lecture I-3). A one-loop correction to Coulomb's law comes from a e^+e^-loop inside the photon line:



This will give us a correction to $V(r)$ proportional to e^4. We will show that while the charge e is infinite it can be replaced by a finite renormalized charge order-by-order in perturbation theory. The physical effect will be a measurable correction to Coulomb's law predicted by quantum field theory with logarithmic scale dependence, as in the ϕ^4 toy model.

The process represented by the Feynman diagram in Eq. (2) is known as vacuum polarization. The diagram shows the creation of virtual e^+e^-pairs which act like a virtual dipole. In the same way that a dielectric material such as water would get polarized if we put it in a electric field, this vacuum polarization tells us how the vacuum itself gets polarized when it interacts with electromagnetic radiation.

Since the renormalization of the graph is no different than it was in ϕ^4 theory, the only difficult part of calculating vacuum polarization is in the evaluation of the loop. Indeed, the loop in Eq. (2) is complicated, involving photons and spinors, but we can do it exploiting some tricks developed through the hard work of our predecessors. Our approach will be to build up the

QED vacuum polarization graph in pieces, starting with ϕ^3 theory, then scalar QED, and finally real QED. For convenience, some of the more mathematical aspects of regularization are combined into one place in Appendix B, which is meant to provide a general reference. In the following, we assume familiarity with the results from that appendix. 2 Scalar ϕ^3 theory As a warm-up for the vacuum polarization calculation in QED, we will start with scalar ϕ^3 theory with Lagrangian

$$\mathcal{L} = -\frac{1}{2}\phi\left(\Box + m^2\right)\phi + \frac{g}{3!}\phi^3$$

Now we want to compute

$$i\mathcal{M}_{\text{loop}}(p) = \quad = \frac{1}{2}(ig)^2 \int \frac{d^4k}{(2\pi)^4} \frac{i}{(p-k)^2 - m^2 + i\varepsilon} \frac{i}{k^2 - m^2 + i\varepsilon}$$

which will tell us the 1-loop correction to the Yukawa potential. We will allow the initial and final line to be off-shell: $p^2 \neq m^2$, since we are calculating the correction to the initial ϕ propagator $\frac{i}{p^2-m^2}$ which also must have $p^2 \neq m^2$ to make any sense, and since we will be embedding this graph into a correction to Coulomb's law (see Eq. (14) below). First, we can use the Feynman parameter trick from Appendix B

$$\frac{1}{AB} = \int_0^1 dx \frac{1}{[A + (B-A)x]^2}$$

with $A - (p-k)^2 - m^2 + i\varepsilon$ and $B - k^2 - m^2 + i\varepsilon$. Then we complete the square

$$\begin{aligned} A + [B-A]x &= (p-k)^2 - m^2 + i\varepsilon + \left[k^2 - (p-k)^2\right] x \\ &= (k - p(1-x))^2 + p^2 x(1-x) - m^2 + i\varepsilon \end{aligned}$$

which gives

$$i\mathcal{M}_{\text{loop}}(p) = \frac{g^2}{2}\int \frac{d^4k}{(2\pi)^4}\int_0^1 dx \frac{1}{\left[(k-p(1-x))^2 + p^2x(1-x) - m^2 + i\varepsilon\right]^2}$$

Now shift $k^\mu \to k^\mu + p^\mu(1-x)$ in the integral. The measure is unchanged, and we get

$$i\mathcal{M}_{\text{loop}}(p) = \frac{g^2}{2}\int \frac{d^4k}{(2\pi)^4}\int_0^1 dx \frac{1}{\left[k^2 - (m^2 - p^2x(1-x)) + i\varepsilon\right]^2}$$

At this point, we need to introduce a regulator. We will use Pauli-Villars regularization (see Appendix B), which adds a fictitious scalar of mass Λ with fermionic statistics. This particle is an unphysical ghost particle. We can use the Pauli-Villars formula from Appendix B:

$$\int \frac{d^4k}{(2\pi)^4}\frac{1}{\left(k^2 - \Delta + i\varepsilon\right)^2} = -\frac{i}{16\pi^2}\ln\frac{\Delta}{\Lambda^2}$$

Comparing to Eq. (8), we have $\Delta = m^2 - p^2x(1-x)$ so that

$$i\mathcal{M}_{\text{loop}}(p) = -\frac{ig^2}{32\pi^2}\int_0^1 dx \ln\left(\frac{m^2 - p^2x(1-x)}{\Lambda^2}\right)$$

This integral can be done - the integrand is perfectly well behaved between $x = 0$ and $x = 1$. For $m = 0$ it has the simple form

$$\mathcal{M}_{\text{loop}}(p) = \frac{g^2}{32\pi^2}\left[2 - \ln\frac{-p^2}{\Lambda^2}\right]$$

Note that the 2 cannot be physical, because we can remove it by redefining $\Lambda^2 \to \Lambda^2 e^{-2}$. Also note that when this diagram contributes to the Coulomb potential (as in Eq. (14) below), the virtual momentum p^μ is spacelike ($p^2 < 0$) so $\ln\frac{-p^2}{\Lambda^2}$ is real. Then,

$$\mathcal{M}_{\text{loop}}(p) = -\frac{g^2}{32\pi^2}\ln\frac{Q^2}{\Lambda^2}$$

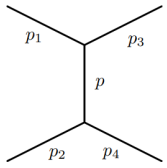
An important point is that the regulator scale Λ has to be just a number, independent of any external momenta. With the Pauli-Villars regulator we are using here, Λ is the mass of some heavy fictitious particle. It corresponds to a deformation of the theory at very high energies/short distances, like the modeling of the wall in the Casimir force. On the other hand, Q is a physical scale like the plate separation in the Casimir force. Thus Λ cannot depend on Q. In particular, the $\ln Q^2$ dependence cannot be removed by a redefinition of Λ like the 2 in Eq. (11) was. This point is so important it's worth repeating: the short distance deformation (Λ) can't depend on long-distance physical quantities (Q). This separation of scales is critical to being able to take $\Lambda \to \infty$ to make predictions by relating observables at different long-distance scales such as Q and Q_0. The coefficient of $\ln Q^2$ is in fact regulator independent and will generate the physical prediction from the loop.

2.1

Renormalization

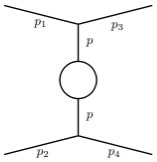
The diagram we computed is a correction to the tree level ϕ propagator. To see this, observe that the propagator is essentially the same as the t-channel scattering diagram

$$i\mathcal{M}^0(p) = \quad = (ig)^2\frac{i}{p^2}$$



If we insert our scalar bubble in the middle, we get

$$i\mathcal{M}^1(p) = \quad = (ig)^2\frac{i}{p^2}i\mathcal{M}_{\text{loop}}(p)\frac{i}{p^2} = ig^2\frac{1}{p^2}\left[-\frac{g^2}{32\pi^2}\ln\frac{-p^2}{\Lambda^2}\right]\frac{1}{p^2}$$



Since $p^2 < 0$, let us write $Q^2 = -p^2$ with $Q > 0$. Then,

$$\mathcal{M}(Q) = \mathcal{M}^0(Q) + \mathcal{M}^1(Q) = \frac{g^2}{Q^2}\left(1 - \frac{1}{32\pi^2}\frac{g^2}{Q^2}\ln\frac{Q^2}{\Lambda^2} + \mathcal{O}\left(g^4\right)\right)$$

Note that g is not a number in ϕ^3 theory but has dimensions of mass. This actually makes ϕ^3 a little more confusing than QED, but not insurmountably so. Let's just simplify things by writing the whole thing in terms of a new Q-dependent variable $\tilde{g}^2 \equiv \frac{g^2}{Q^2}$ which is dimensionless. Then

$$\mathcal{M}(Q) = \tilde{g}^2 - \frac{1}{32\pi^2}\tilde{g}^4\ln\frac{Q^2}{\Lambda^2} + \mathcal{O}\left(\tilde{g}^6\right)$$

Then we can define a renormalized coupling $\hat{g}_R$ at some fixed scale Q_0 by

$$\tilde{g}_R \equiv \mathcal{M}\left(Q_0\right)$$

This is called a renormalization condition. It is a definition, and by definition, it holds to all orders in perturbation theory. The renormalization condition defines the coupling in terms of an observable. Therefore, you can only have one renormalization condition for each parameter in the theory. This is critical to the predictive power of quantum field theory. It follows that $\tilde{g}_R^2$ is a formal power series in $\tilde{g}$

$$\tilde{g}_R = \mathcal{M}\left(Q_0\right) = \tilde{g}^2 - \frac{1}{32\pi^2}\tilde{g}^4\ln\frac{Q_0^2}{\Lambda^2} + \mathcal{O}\left(\tilde{g}^6\right)$$

which can be inverted to give $\tilde{g}$ as a power series in $\tilde{g}_R$

$$\bar{g}^2 = \tilde{g}_R^2 + \frac{1}{32\pi^2}\tilde{g}_R^4\ln\frac{Q_0^2}{\Lambda^2} + \mathcal{O}\left(\tilde{g}_R^6\right)$$

Substituting into Eq.(16) produces a prediction for the matrix element at the scale Q in terms of the matrix element at the scale Q_0

$$\mathcal{M}(Q) = \tilde{g}^2 - \frac{1}{32\pi^2}\tilde{g}^4\ln\frac{Q^2}{\Lambda^2} + \mathcal{O}\left(\tilde{g}^6\right) = \tilde{g}_R^2 + \frac{1}{32\pi^2}\tilde{g}_R^4\ln\frac{Q_0^2}{Q^2} + \mathcal{O}\left(\tilde{g}_R^6\right)$$

Thus we can measure $\mathcal{M}$ at one Q and then make a nontrivial prediction at another value of Q.

3

Vacuum polarization in QED

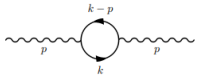
In ϕ^3 theory, we found

$$= -\frac{ig^2}{32\pi^2}\int_0^1 dx \ln\frac{m^2 - p^2x(1-x)}{\Lambda^2}$$

The integral in QED is quite similar. We will first evaluate the vacuum polarization graph in scalar QED, and then in spinor QED.

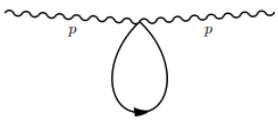
Scalar QED

In scalar QED the vacuum polarization diagram is



$$= (-ie)^2 \int \frac{d^4k}{(2\pi)^4} \frac{i}{(p-k)^2 - m^2 + i\varepsilon} \frac{i}{k^2 - m^2 + i\varepsilon} (2k^\mu - p^\mu)(2k^\nu - p^\nu)$$

For external photons, we could contract the μ and ν indices with polarization vectors, but instead we keep them free so that this diagram can be embedded in a Coulomb exchange diagram as in Eq. (14). This integral is the same as in ϕ^3 theory, except for the numerator factors. In scalar QED there is also another diagram



$$= 2ie^2 g^{\mu\nu} \int \frac{d^4k}{(2\pi)^4} \frac{i}{k^2 - m^2 + i\varepsilon}$$

So we can add them together to get

$$i\Pi_2^{\mu\nu} = -e^2 \int \frac{d^4k}{(2\pi)^4} \frac{-4k^\mu k^\nu + 2p^\mu k^\nu + 2p^\nu k^\mu - p^\mu p^\nu + 2g^{\mu\nu}\left((p-k)^2 - m^2\right)}{\left[(p-k)^2 - m^2 + i\varepsilon\right]\left[k^2 - m^2 + i\varepsilon\right]}$$

Fortunately, we do not need to evaluate the entire integral. By looking at what possible form it could have, we can isolate the part which will contribute to a correction to Coulomb's law and just calculate that part. By Lorentz invariance, the most general form that $\Pi_2^{\mu\nu}$ could have is

$$\Pi_2^{\mu\nu} = \Delta_1\left(p^2, m^2\right) p^2 g^{\mu\nu} + \Delta_2\left(p^2, m^2\right) p^\mu p^\nu$$

for some form factors Δ_1 and Δ_2. Note that $\Pi_2^{\mu\nu}$ cannot depend on k^μ, since k^μ is integrated over.

As a correction to Coulomb's law, this vacuum polarization graph will contribute to the same process that the photon propagator does. Let us define the photon propagator in momentum space by

$$\langle\Omega\left|T\left\{A^\mu(x)A^\nu(y)\right\}\right|\Omega\rangle = \int \frac{d^4p}{(2\pi)^4} e^{ip(x-y)} iG^{\mu\nu}(p)$$

Note that this expression only depends on $x-y$ by translation invariance. This is the all-orders non-perturbative definition of the propagator $G^{\mu\nu}(p)$, which is sometimes called the dressed propagator. At leading order, in Feynman gauge, the dressed propagator reduces to the free propagator

$$iG^{\mu\nu}(p) = \frac{-ig^{\mu\nu}}{p^2 + i\varepsilon} + \mathcal{O}\left(e^2\right)$$

Including the 1-loop correction, with the parametrization in Eq. (24), the propagator is (suppressing the is pieces)

$$\begin{aligned} iG^{\mu\nu}(p) &= \frac{-ig^{\mu\nu}}{p^2} + \frac{-ig^{\mu\alpha}}{p^2} i\Pi^2_{\alpha\beta} \frac{-ig^{\beta\nu}}{p^2} + \mathcal{O}\left(e^4\right) \\ &= \frac{-ig^{\mu\nu}}{p^2} + \frac{-i}{p^2}\left(\Delta_1 g^{\mu\nu} + \Delta_2 \frac{p^\mu p^\nu}{p^2}\right) + \mathcal{O}\left(e^4\right) \\ &= -i\frac{(1+\Delta_1)\, g^{\mu\nu} + \Delta_2 \frac{p^\mu p^\nu}{p^2}}{p^2 + i\varepsilon} \end{aligned}$$

Note that we are calculating loop corrections to a Green's function, not an S-matrix element, so we do not truncate the external propagators and add polarization vectors. One point of using a dressed propagator is that once we calculate Δ_1 and Δ_2 we can just use $G^{\mu\nu}(p)$ instead of the tree level propagator in QED calculations to include the loop effect.

Next note that the Δ_2 term is just a change of gauge - it gives a correction to the unphysical gauge parameter ξ in covariant gauges. Since ξ drops out of any physical process, by gauge invariance, so will Δ_2. Thus we only need to compute Δ_1. This means extracting the term proportional to $g^{\mu\nu}$ in $\Pi^{\mu\nu}$.

Most of the terms in the amplitude in Eq. (23) cannot give $g^{\mu\nu}$. For example, the $p^\mu p^\nu$ term must be proportional to $p^\mu p^\nu$ and can therefore only contribute to Δ_2, so we can ignore it. For the $p^\mu k^\nu$ term, we can pull p^μ out of the integral, so whatever the remaining integral gives, it must provide a p^ν by Lorentz invariance. So these terms can be ignored too. The $k^\mu k^\nu$ term is important - it may give a $p^\mu p^\mu$ piece, but may also give a $g^{\mu\nu}$ piece, which is what we're looking for. So we only need to consider

$$\Pi_2^{\mu\nu} = ie^2 \int \frac{d^4k}{(2\pi)^4} \frac{-4k^\mu k^\nu + 2g^{\mu\nu}\left((p-k)^2 - m^2\right)}{(p-k)^2 - m^2 + i\varepsilon]\,[k^2 - m^2 + i\varepsilon]}$$

Now we need to compute the integral. The denominator can be manipulated using Feynman parameters just as with the ϕ^3 theory

$$\Pi_2^{\mu\nu} = ie^2 \int \frac{d^4k}{(2\pi)^4} \int_0^1 dx \frac{-4k^\mu k^\nu + 2g^{\mu\nu}\left((p-k)^2 - m^2\right)}{\left[(k - p(1-x))^2 + p^2 x(1-x) - m^2 + i\varepsilon\right]^2}$$

However, now when we shift $k^\mu \to k^\mu + p^\mu(1-x)$ we get a correction to the numerator. We get

$$\Pi_2^{\mu\nu} = ie^2 \int \frac{d^4k}{(2\pi)^4} \int_0^1 dx \frac{-4\left(k^\mu + p^\mu(1-x)\right)\left(k^\nu + p^\nu(1-x)\right) + 2g^{\mu\nu}\left((xp-k)^2 - m^2\right)}{\left[k^2 + p^2 x(1-x) - m^2 + i\varepsilon\right]^2}$$

As we have said, we don't care about $p^\mu p^\nu$ pieces, or pieces linear in p^ν. Also, pieces like $p \cdot k$ are odd under $k \to -k$ while the rest of the integrand, including the measure, is even. So these terms must give zero by symmetry. All that is left is

$$\Pi_2^{\mu\nu} = 2ie^2 \int \frac{d^4k}{(2\pi)^4} \int_0^1 dx \frac{-2k^\mu k^\nu + g^{\mu\nu}\left(k^2 + x^2p^2 - m^2\right)}{\left[k^2 + p^2 x(1-x) - m^2 + i\varepsilon\right]^2}$$

It looks like this integral is much more badly divergent than the ϕ^3 theory - it is now quadratically instead of logarithmically divergent. That is, if we cut off at $k = \Lambda$ we will get something proportional to Λ^2 due to the $k^\mu k^\nu$ and k^2 terms. Quadratic divergences are not technically a problem for

renormalization. However, in Lecture III-8 we will see, on very general grounds, that in gauge theories like scalar QED, all divergences should be logarithmic. In this case, the quadratic divergence from the $k^\mu k^\nu$ term and the k^2 term precisely cancel due to gauge invariance. This cancellation can only be seen using a regulator which respects gauge invariance, such as dimensional regularization. In d dimensions (using $k^\mu k^\nu \to \frac{1}{d}k^2 g^{\mu\nu}$ from Appendix B), the integral becomes

$$\Pi_2^{\mu\nu} = 2ie^2\mu^{4-d}g^{\mu\nu}\int_0^1 dx \int \frac{d^dk}{(2\pi)^d\left[\frac{\left(1-\frac{2}{d}\right)k^2+x^2p^2-m^2}{[k^2+p^2x(1-x)-m^2+i\varepsilon]^2}\right.}$$

Using the formulas from Appendix B:

$$\int \frac{d^dk}{(2\pi)^d}\frac{k^2}{\left(k^2-\Delta+i\varepsilon\right)^2} = -\frac{d}{2}\frac{i}{(4\pi)^{d/2}}\frac{1}{\Delta^{1-\frac{d}{2}}}\Gamma\left(\frac{2-d}{2}\right)$$
$$\int \frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2-\Delta+i\varepsilon\right)^2} = \frac{i}{(4\pi)^{d/2}}\frac{1}{\Delta^{2-\frac{\pi}{2}}}\Gamma\left(\frac{4-d}{2}\right)$$

with $\Delta = m^2 - p^2x(1-x)$ we find

$$\Pi_2^{\mu\nu} = -2\frac{e^2}{(4\pi)^{d/2}}g^{\mu\nu}\mu^{4-d}\int_0^1 dx\left[\left(1-\frac{d}{2}\right)\Gamma\left(1-\frac{d}{2}\right)\left(\frac{1}{\Delta}\right)^{1-\frac{d}{2}} + \left(x^2p^2-m^2\right)\Gamma\left(2-\frac{d}{2}\right)\left(\frac{1}{\Delta}\right)^{2-\frac{d}{2}}\right]$$

Using $\Gamma\left(2-\frac{d}{2}\right) = \left(1-\frac{d}{2}\right)\Gamma\left(1-\frac{d}{2}\right)$ this simplifies to

$$\Pi_2^{\mu\nu} = -2\frac{e^2}{(4\pi)^{d/2}}p^2g^{\mu\nu}\Gamma\left(2-\frac{d}{2}\right)\mu^{4-d}\int_0^1 dx x(2x-1)\left(\frac{1}{\Delta}\right)^{2-\frac{d}{2}}$$

For completeness, we also give the result including also the $p^{\mu i}p^\nu$ terms

$$\Pi_2^{\mu\nu} = \frac{-2e^2}{(4\pi)^{d/2}}\left(p^2g^{\mu\nu}-p^\mu p^\nu\right)\Gamma\left(2-\frac{d}{2}\right)\mu^{4-d}\int_0^1 dx x(2x-1)\left(\frac{1}{m^2-p^2x(1-x)}\right)^{2-\frac{d}{2}}$$

You should verify this through direct calculation (see Problem 1), but it is the unique result consistent with Eq. (35) which satisfies the Ward identity $p_\mu\Pi_2^{m=n} = 0$. Expanding $d = 4-\varepsilon$ we get, in the $\epsilon \to 0$ limit,

$$\Pi_2^{\mu\nu} = -\frac{e^2}{8\pi^2}\left(p^2g^{\mu\nu}-p^{\mu k}p^\nu\right)\int_0^1 dx x(2x-1)\left[\frac{2}{\varepsilon}+\ln\left(\frac{4\pi e^{-\gamma\mu^2}}{m^2-p^2x(1-x)}\right)+\mathcal{O}(\varepsilon)\right]$$

The $\frac{1}{c}$ gives the infinite, regulator-dependent constant. It is also standard to define $\tilde{\mu}^2 = 4\pi e^{-\gamma_r}\mu^2$ which removes the $\ln(4\pi)$ and $e^{-\gamma x}$ factors. For $Q^2 = -p^2 > 0$ and $m\&Q$, the integral over x is easy to do and we find

$$\Pi_2^{\mu\nu} = -\frac{e^2}{48\pi^2}\left(p^2g^{\mu\nu}-p^\mu p^\nu\right)\left(\frac{2}{\varepsilon}+\ln\frac{\tilde{\mu}^2}{Q^2}+\frac{8}{3}\right), \quad m\&Q$$

At this point, rather than continue with the scalar QED calculation, let's calculate the loop in QED, as it's almost exactly the same.

3.2

Spinor QED

In spinor QED, the loop is

where the -1 in front comes from the fermion loop. Note that there is only 1 diagram in this case. Using our trace formulas (see Lecture II-6), we find

$$\mathrm{Tr}\left[\gamma^\mu(\not{k}-\not{p}+m)\gamma^\nu(\not{k}+m)\right] = 4\left[-p^\mu k^\nu - k^\mu p^\nu + 2k^\mu k^\nu + g^{\mu\nu}\left(-k^2 + p\cdot k + m^2\right)\right]$$

We can drop the p^μ and p^ν terms as before giving

$$i\Pi_2^{\mu\nu} = -4e^2\int\frac{d^4k}{(2\pi)^4}\frac{2k^\mu k^\nu + g^{\mu\nu}\left(-k^2+p\cdot k+m^2\right)}{\left[(p-k)^2-m^2+i\varepsilon\right]\left[k^2-m^2+i\varepsilon\right]}$$

Introducing Feynman parameters and changing $k^\mu \to k^\mu + p^\mu(1-x)$ and again dropping the $p^{\mu t}$ and p^ν terms we get

$$\Pi_2^{\mu\nu} = 4ie^2\int\frac{d^4k}{(2\pi)^4}\int_0^1 dx\frac{2k^\mu k^\nu - g^{\mu\nu}\left(k^2 - x(1-x)p^2 - m^2\right)}{\left[k^2+p^2x(1-x)-m^2\right]^2}$$

This integral is quite similar to the one for scalar QED, Eq. (31). The result is

$$\begin{aligned}\Pi_2^{\mu\nu} &= -8p^2g^{\mu\nu}\frac{e^2}{(4\pi)^{d/2}}\Gamma\left(2-\frac{d}{2}\right)\mu^{4-d}\int_0^1 dx x(1-x)\left(\frac{1}{m^2-p^2x(1-x)}\right)^{2-\frac{d}{2}}\\ &= -\frac{e^2}{2\pi^2}p^2g^{\mu\nu}\int_0^1 dx x(1-x)\left[\frac{2}{\varepsilon}+\ln\left(\frac{\tilde{\mu}^2}{m^2-p^2x(1-x)}\right)+\mathcal{O}(\varepsilon)\right]\end{aligned}$$

So we find (for large $Q^2 = -p^2 \gg m^2$)

$$\Pi_2^{\mu\nu} = -\frac{e^2}{12\pi^2}p^2g^{\mu\nu}\left(\frac{2}{\varepsilon}+\ln\frac{\tilde{\mu}^2}{Q^2}+\frac{5}{3}+\mathcal{O}(\varepsilon)\right),\quad m\leqslant Q$$

We see that the electron loop gives the same pole and $\ln\frac{\mu^2}{Q^2}$ terms as a scalar loop, multiplied by a factor of 4.

It is not hard to compute the $p^\mu p^\nu$ pieces as well (see Problem 1). The full result is

$$\Pi_2^{\mu\nu} = \frac{-8e^2}{(4\pi)^{d/2}}\left(p^2g^{\mu\nu}-p^\mu p^\nu\right)\Gamma\left(2-\frac{d}{2}\right)\mu^{4-d}\int_0^1 dx x(1-x)\left(\frac{1}{m^2-p^2x(1-x)}\right)^{2-\frac{d}{2}}$$

which, as in the scalar QED case, automatically satisfies the Ward identity.

4

Physics of vacuum polarization

We have found that vacuum polarization loop in QED gives

$$i\Pi_2^{\mu\nu} = i\left(-p^2 g^{\mu\nu} + p^\mu p^\nu\right) e^2 \Pi_2\left(p^2\right)$$

where

$$\Pi_2\left(p^2\right) = \frac{1}{2\pi^2}\int_0^1 dx x(1-x)\left[\frac{2}{\varepsilon} + \ln\left(\frac{\tilde{\mu}^2}{m^2 - p^2 x(1-x)}\right)\right]$$

Thus the dressed photon propagator at 1-loop in Feynman gauge is

$$= -i\frac{\left(1 - e^2\Pi_2\left(p^2\right)\right) g^{\mu\nu}}{p^2} + p^\mu p^\nu \text{ terms}$$

This directly gives the Fourier transform of the corrected Coulomb potential:

$$\tilde{V}(p) = e^2 \frac{1 - e^2\Pi_2\left(p^2\right)}{p^2}$$

Now we need to renormalize. A natural renormalization condition is that the potential between two particles at some reference scale r_0 should be $V\left(r_0\right) \equiv -\frac{e_R^2}{4\pi r_0}$ which would define a renormalized e_R. It is easier to continue working in momentum space and to define the renormalized charge as $\tilde{V}\left(p_0^2\right) \equiv e_R^2 p_0^{-2}$ exactly. So

$$e_R^2 \equiv p_0^2 \hat{V}\left(p_0^2\right) = e^2 - e^4\Pi_2\left(p_0^2\right) + \cdots$$

Solving for the bare coupling e as a function of e_R to order e_R gives

$$e^2 = e_R^2 + e_R\Pi_2\left(p_0^2\right) + \cdots$$

Since $\Pi_2\left(p_0^2\right)$ is infinite, e is infinite as well, but that is ok since e is not observable. The potential at another scale p, which is measurable, is

$$p^2\tilde{V}(p) = e^2 - e^4\Pi_2\left(p^2\right) + \cdots = e_R^2 - e_R^4\left[\Pi_2\left(p^2\right) - \Pi_2\left(p_0^2\right)\right] + \cdots$$

For concreteness, let us take $p_0 = 0$, corresponding to $r = \infty$ so that the renormalized electric charge agrees with the macroscopically measured electric charge. Then

$$\Pi_2\left(p^2\right) - \Pi_2(0) = -\frac{1}{2\pi^2}\int_0^1 dx x(1-x)\ln\left[1 - \frac{p^2}{m^2}x(1-x)\right]$$

Thus, we have

$$\tilde{V}\left(p^2\right) = \frac{e_R^2}{p^2}\left\{1 + \frac{e_R^2}{2\pi^2}\int_0^1 dx x(1-x)\ln\left[1 - \frac{p^2}{m^2}x(1-x)\right] + \mathcal{O}\left(e_R^4\right)\right\}$$

which is a totally finite correction to the Coulomb potential. It is also a well-defined perturbation expansion in terms of a small parameter e_R which is also finite. We will now study some of the physical implications of this potential

Small momentum - Lamb shift

(?? мб больший раздел про Лембовский сдвиг сделаю, пока так вот.)

Суть Лэмбовского сдвига (????)

The Lamb shift is a difference in energy between two energy levels ${}^2S_{1/2}$ and ${}^2P_{1/2}$ (in term symbol notation) of the hydrogen atom which was not predicted by the Dirac equation, according to which these states should have the same energy. Interaction between vacuum energy fluctuations and the hydrogen electron in these different orbitals is the cause of the Lamb shift, as was shown subsequent to its discovery. The Lamb shift has since played a significant role through vacuum energy fluctuations in theoretical prediction of Hawking radiation from black holes.

This effect was first measured in 1947 in the Lamb-Retherford experiment on the hydrogen microwave spectrum [1] and this measurement provided the stimulus for renormalization theory to handle the divergences. It was the harbinger of modern quantum electrodynamics developed by Julian Schwinger, Richard Feynman, Ernst Stueckelberg, Sin-ltiro Tomonaga and Freeman Dyson. Lamb won the Nobel Prize in Physics in 1955 for his discoveries related to the Lamb shift.

In 1978, on Lamb's 65th birthday, Freeman Dyson addressed him as follows: "Those years, when the Lamb shift was the central theme of physics, were golden years for all the physicists of my generation. You were the first to see that this tiny shift, so elusive and hard to measure, would clarify our thinking about particles and fields."

Теория по Schwartz-y

First, let's look at the small-momentum, large-distance limit. For $|p^2| < m$

$$\int_0^1 dx x(1-x) \ln\left[1 - \frac{p^2}{m^2}x(1-x)\right] \approx \int_0^1 dx x(1-x)\left[-\frac{p^2}{m^2}x(1-x)\right] = -\frac{p^2}{30m^2}$$

$$\text{implying } \tilde{V}(p) = \frac{e_R^2}{p^2} - \frac{e_R^4}{60\pi^2 m^2} + \cdots$$

The Fourier transform of a 1 is $\delta(r)$, so we find

$$V(r) = -\frac{e_R^2}{4\pi r} - \frac{e_R}{60\pi^2 m^2}\delta(r)$$

This agrees with the Coulomb potential up to a correction known the Uehling term [Uehling Phys. Rev. 48, 55-63 (1935)]

What is the physical effect of this extra term? One way to find out is to plug this potential into the Schrödinger equation and see how the states of the Hydrogen atom change. Equivalently, we can evaluate the effect in time-independent perturbation theory by evaluating the leading order energy shift $\Delta E = \langle\psi_i|\Delta V|\psi_i\rangle$ using $\Delta V = -\frac{e^4}{60\pi^4 m^2}\delta(r)$. Since only the $L = 0$ atomic orbitals have support at $r = 0$ this extra term will only affect the S states of the Hydrogen atom. The energy is negative, so their energies will be lowered. You might recall that, at leading order, the energy spectrum of the Hydrogen atom is determined only by the principal atomic number n, so the $2P_{1/2}$ and $2S_{1/2}$ levels (for example) are degenerate. Thus the Uehling term contributes to the splitting of these levels, known as the Lamb shift. It changes the $2S_{1/2}$ state by -27MHz which is

a measurable contribution to the −1028MHz Lamb shift. More carefully, you can show in Problem 2 that the 1-loop potential is

$$V(r) = -\frac{e^2}{4\pi r}\left(1 + \frac{e^2}{6\pi^2}\int_1^\infty dx e^{-2mrx}\frac{2x^2+1}{2x^4}\sqrt{x^2-1}\right)$$

This is known as the Uehling potential [Uehling 1935]. For $r \gg \frac{1}{m}$,

$$V(r) = -\frac{\alpha}{r}\left[1 + \frac{\alpha}{4\sqrt{\pi}}\frac{1}{(mr)^{3/2}}e^{-2mr}\right], \quad r \gg \frac{1}{m}$$

This shows that the finite correction has extent $1/m = r_e$, the Compton radius of the electron. Since r_e is much smaller than the characteristic size of the L modes, the Bohr radius $a_0 \sim \frac{m}{\alpha}$, our δ-function approximation is valid.

By the way, the measurement of the Lamb shift in 1947 by Wallis Lamb [Ref] was one of the key experiments that convinced people to take quantum field theory seriously. Measurements of the hyperfine splitting between the $2S_{1/2}$ and $2P_{1/2}$ states of the Hydrogen atom had been attempted for many years, but it was only by using microwave technology developed during the Second World War that Lamb was able to provide an accurate measurement. He found $\Delta E \simeq 1000$MHz. Shortly after his measurement, Hans Bethe calculated the dominant theoretical contribution. His calculation was of a vertex correction which was infrared divergent. Now we know that the infrared divergence is canceled when all the relevant contributions are included, but Bethe simply cut off the divergence by hand at what he argued was a natural physical scale, the electron mass. His result was that $\Delta E = -\frac{Z^4\alpha^5\ \mathrm{m}_e}{12\pi}\ln(\alpha^4 Z^4) \approx -1000$MHz in excellent agreement with Lamb's value. The next year, Feynman, Schwinger and Tomonaga all independently provided the complete calculation, including the Uehling term and the spin-orbit coupling. Due to a subtlety regarding gauge invariance, only Tomonaga got it right the first time. The full 1-loop result gives $E\left(2S_{1/2}\right) - E\left(2P_{1/2}\right) = 1051$MHz. The current best measurement of this shift is 1054 MHz. 4.2

Large momentum - logarithms of p

In the small distance limit $r \& \frac{1}{m}$ it is easier to consider the potential in momentum space. Then we have from Eq. (51)

$$\begin{aligned}
\tilde{V}\left(p^2\right) &= \frac{e_R^2}{p^2} + \frac{e_R^4}{p^2}\frac{1}{2\pi^2}\int_0^1 dx x(1-x)\ln\left[1 - \frac{p^2}{m^2}x(1-x)\right] + \mathcal{O}\left(e_R^6\right) \\
&\approx \frac{e_R^2}{p^2} + \frac{e_R^4}{p^2}\frac{1}{2\pi^2}\ln\left(-\frac{p^2}{m^2}\right)\int_0^1 dx x(1-x) + \mathcal{O}\left(e_R^6\right) \\
&= \frac{e_R^2}{p^2}\left(1 + \frac{e_R^2}{12\pi^2}\ln\frac{-p^2}{m^2}\right) + \mathcal{O}\left(e_R^6\right)
\end{aligned}$$

Recall that for t-channel exchange, $Q^2 = -p^2 > 0$ so this logarithm is real. If we compare the potential at two high energy scales $Q \gg m$ and $Q_0 > m$ we find

$$Q^2\tilde{V}\left(Q^2\right) - Q_0^2 V\left(Q_0^2\right) = \frac{e_R^4}{12\pi^2}\ln\frac{Q_0^2}{Q^2}$$

which is independent of m. Note however, that setting $m = 0$ directly in Eq. (57) results in a divergence. This kind of divergence is known as a mass singularity, which is a type of infrared divergence. In this case, the divergence is naturally regulated by $m \neq 0$. On other occasions we will have to introduce an artificial infrared regulator (like a photon mass) to produce finite answers. Infrared divergences are the subject of Lecture III-6. One way to write the radiative correction to the potential is where

$$\tilde{V}\left(Q^2\right) = \frac{e_{\text{eff}}^2(Q)}{p^2}$$

In this case, for simplicity, we have defined the renormalized charge $e_R \equiv e_{\text{eff}}\left(m\right)$ at $Q = m$ rather than at $Q = 0$. (One could also define ε_R at $Q = 0$ as with the Uehling potential; however then one would need to include the full m dependence to regulate the $m = 0$ singularity.)

Eq. (62) is to be interpreted as an effective charge in QED which grows as the distance gets smaller (momentum gets larger). Near any particular fixed value of the momentum transfer p^μ, the potential looks like a Coulomb potential with a charge $e_{\text{eff}}\left(p^2\right)$ instead of e_R. This is a useful concept because the charge depends only weakly on p^2, through a logarithm. Thus, for small variations of p around a reference scale, the same effective charge can be used. Eq. (62) only comes into play when one compares the charge at very different momentum transfers.

The sign of the coefficient of the $\ln \frac{Q}{m}$ term is very important; this sign implies the effective charge gets larger at short distances. At large distances, the charge is increasingly screened by the virtual electron-positron dipole pairs. At smaller distances, there is less room for the screening and the effective charge increases. However, the effective charge only increases at small distances very slowly. In fact taking $\alpha_R = \frac{e_R^2}{4\text{x}} = \frac{1}{137}$ so that $e_R = 0.303$ we get an effective fine structure constant of the form

$$\alpha_{e\text{eff}}\left(-p^2\right) = \frac{1}{137}\left[1 + 0.00077 \ln\left(\frac{-p^2}{m^2}\right)\right]$$

Because the coefficient of the logarithm is numerically small, one has to measure the potential at extremely high energies to see its effect. In fact, only very few high precision measurements are sensitive to this logarithm.

Despite the difficulty of probing extremely high energies in QED experimentally, one can at least ask what would happen if we attempted scattering at $t = -p^2 \gg m^2$. From Eq. (63) we can see that at some extraordinarily high energies $p \sim 10^{286}$eV, the loop correction, the logarithm, is as important as the tree-level value, the 1. Thus perturbation theory is breaking down. At these scales, the 2-loop value will also be as large as the 1-loop and tree level values, and so on. The scale where this happens is known as a Landau pole. So, - QED has a Landau Pole: perturbation theory breaks down at short distances. This means that QED is not a complete theory in the sense that it does not tell us how to compute scattering amplitudes at all energies.

4.3

Running coupling

It is not difficult to include certain higher-order corrections to the effective electric charge. Adding more loops in series, we can sum a set of graphs to all orders in the coupling constant:

These corrections to the propagator immediately translate into corrections to the momentumspace potential:

$$\tilde{V}(Q) = -\frac{e_R^2}{Q^2}\left[1 + \frac{e_R^2}{12\pi^2}\ln\frac{Q^2}{m^2} + \left(\frac{e_R^2}{12\pi^2}\ln\frac{Q^2}{m^2}\right)^2 + \cdots\right]$$
$$= -\frac{1}{Q^2}\left[\frac{e_R^2}{1 - \frac{c\hbar}{12\pi^2}\ln\frac{Q^2}{m^2}}\right]$$

So now the momentum-dependent electric charge becomes

$$e_{\text{eff}}^2(Q) = \frac{e_R^2}{1 - \frac{c_R^2}{12\pi^2}\ln\frac{Q^2}{m^2}}$$

which is known as a running coupling. Note we have defined this running coupling to have the same renormalization condition as the one-loop effective charge: $e_{\text{eff}} = e_R$ at $p^2 = -m^2$. Although the running coupling includes contributions from all orders in perturbation theory, it still has a Landau pole at $p \sim 10^{286}$eV.

Running couplings will play an increasingly important role as we study more complicated problems in quantum field theory. They are best understood through the renormalization group. As a preview of how the renormalization group works, note that Eq. (66) can be written as

$$\frac{1}{e_{eff}^2(Q)} = \frac{1}{e_R^2} - \frac{1}{12\pi^2}\ln\frac{Q^2}{m^2}$$

The renormalization group comes from the simple observation that there is nothing special about the renormalization point. Here we have defined $e_R = e_{eff}(m)$, but we could have renormalized at any other point μ^2 instead of m^2, and the results would be the same. Then we would have

$$\frac{1}{e_{eff}^2(Q)} = \frac{1}{e_{eff}^2(\mu)} - \frac{1}{12\pi^2}\ln\frac{Q^2}{\mu^2}$$

The left hand side is independent of μ. So taking the μ derivative gives Or

$$0 = -\frac{2}{e_{\text{eff}}^3}\frac{d}{d\mu}e_{\text{eff}} + \frac{1}{12\pi^2}\frac{2}{\mu}$$

$$\mu\frac{de_{\text{eff}}}{d\mu} = \frac{e_{\text{eff}}^3}{12\pi^2}$$

This is known as a renormalization group equation. We even have a special name for the right hand side of this particular equation, the $\boldsymbol{\beta}$-function. In general,

$$\mu\frac{de}{d\mu} \equiv \beta(e)$$

and we have derived that $\beta(e) = \frac{e^3}{12\pi^2}$ at 1-loop. The renormalization group is the subject of Lecture Lecture III-9.

21.8 Finding Main Fundamental Constants Using QFT

21.8.1 Testing Electron Charge

(??? how to do it???)

21.8.2 Testing Fine Structure Constant

(??? how to do it???)

21.8.3 Testing Ridberg's Constant

21.9 Finding Some Other Other Constants Using QFT

(there are many constants, so I'll also write about how some of them can be determined)

21.10 Determining Fundamental Quantities of Nature

21.10.1 Determining Proton Radius

(main theory about it, some experiments, some main discussions. I heard more than 1 hour talk about it, but have no time to write what is going on there)

21.10.2 Determining Proton Radius: Extra Understanding

(a lot of things were done about it, so there will be a lot of theory which I can write here)

24.2 Electron-Photon Interaction by Landau 1

24.2.1 86. Photon Scattering by an Electron

Сохранение 4-импульса при рассеянии фотона свободным электроном (эффект Комптона) выражается равенством

$$p + k = p' + k'$$

где p и k – 4-импульсы электрона и фотона до столкновения, а p' и k' - их 4-импульсы после столкновения. Введенные в \$66 кинематические инварианты:

$$s = (p+k)^2 = (p'+k')^2 = m^2 + 2pk = m^2 + 2p'k',$$
$$t = (p-p')^2 = (k'-k)^2 = 2\left(m^2 - pp'\right) = -2kk',$$
$$u = (p-k')^2 = (p'-k)^2 = m^2 - 2pk' = m^2 - 2p'k,$$
$$s + t + u = 2m^2.$$

Рассматриваемый процесс изображается двумя диаграммами Фейнмана $(74, 14)$, и его амплитуда

$$M_{fl} = -4\pi e^2 e'^*_\mu e_v \left(\bar{u}' Q^{\mu v} u\right),$$

$$Q^{\mu\nu} = \frac{1}{s-m^2}\gamma^\mu(\gamma p + \gamma k + m)\gamma^\nu + \frac{1}{u-m^2}\gamma^\nu\left(\gamma p - \gamma k' + m\right)\gamma^\mu.$$

$$d\sigma = \frac{\pi e^4}{4}\frac{dt}{(s-m^2)^2}\,\mathrm{Sp}\left\{\left(\gamma p' + m\right)Q^{\lambda\mu}(\gamma p + m)\bar{Q}_{\lambda\mu}\right\}$$

Аналогичным образом вычисляется g:

$$g(s,u) = \frac{2m^2}{(s-m^2)(u-m^2)}\left\{4m^2 + \left(s-m^2\right) + \left(u-m^2\right)\right\}.$$

В результате для сечения получим

$$d\sigma = 8\pi r_e^2 \frac{m^2 dt}{(s-m^2)^2}\left\{\left(\frac{m^2}{s-m^2} + \frac{m^2}{u-m^2}\right)^2 + \right.$$
$$\left. + \left(\frac{m^2}{s-m^2} + \frac{m^2}{u-m^2}\right) - \frac{1}{4}\left(\frac{s-m^2}{u-m^2} + \frac{u-m^2}{s-m^2}\right)\right\}.$$

где $r_e = e^2/m$.

(вывод потом понимать буду)

$$d\sigma = \frac{r_e^2}{2}\left(\frac{\omega'}{\omega}\right)^2\left(\frac{\omega}{\omega'} + \frac{\omega'}{\omega} - \sin^2\vartheta\right)do'$$

Наибольший член в сечении $(86, 6)$

$$d\sigma \approx 8\pi r_e^2 \frac{m^2 dt}{4(s-m^2)(m^2-u)},$$

откуда

$$d\sigma = \frac{r_B^2}{2}\frac{do'}{1 + (\pi-\theta)^2\omega^2/m^2}.$$

Сечение $d\sigma/do' \sim r_e^2$ в узком конусе $\pi - \theta \leqslant m/\omega$, а вне его уменьшается по порядку величины в ω^2/m^2 раз.

24.2.2 87. Photon Scattering by an Electron: Polarization Effects

Общие формулы

$$e^{(1)} = \frac{N}{\sqrt{-N^2}}, \quad e^{(2)} = \frac{P}{\sqrt{-P^2}},$$

где

$$P^\lambda = \left(p^\lambda + p'^\lambda\right) - K^\lambda \frac{pK + p'K}{K^2}, \quad N^\lambda = e^{\lambda\mu\nu\rho} P_\mu q_v K_\rho$$
$$K^\lambda = k^\lambda + k'^\lambda, \quad q^\lambda = k'^\lambda - k^\lambda = p^\lambda - p'^\lambda.$$

Непосредственным проецированием тензора $Q_{\mu\nu}$ находим

$$Q_0 = \frac{1}{2} Q^{\mu\nu} \left(e^{(1)}_\mu e^{(1)}_v + e^{(2)}_u e^{(2)}_v\right)$$

и т. д. Для вычисления удобно сначала выразить $Q_{\mu v}$ через взаимно ортогональные 4-векторы P, N, q, K:

$$Q^{\mu\nu} = \gamma^\mu \frac{\gamma P/2 + m}{s - m^2} \gamma^\nu + \gamma^\nu \frac{\gamma P/2 + m}{u - m^2} \gamma^\mu - \frac{1}{t} \left[\gamma^\mu (\gamma K) \gamma^\nu - \gamma^\nu (\gamma K) \gamma^\mu\right].$$

$$\bar{u}' \left(\gamma p + \gamma p'\right) u = 2m \bar{u}' u,$$
$$\bar{u}' \gamma^5 (\gamma q) u = \bar{u}' \left[\gamma^5 (\gamma p) + (\gamma p') \gamma^5\right] u = 2m \bar{u}' \gamma^5 u$$

то можно заменить в $Q^{\mu\nu}$ слагаемые

$$\gamma p + \gamma p' \to 2m, \quad \gamma^5 (\gamma q) \to 2m\gamma^5$$

Поэтому матрицы плотности начального и конечного фотонов, отнесенные к 4-ортам $e^{(1)}, e^{(2)}$, будут

$$\rho^{(\gamma)} = \tfrac{1}{2}(1 + \xi\sigma), \qquad \xi = (\xi_1, \xi_2, \xi_3);$$
$$\rho^{(\gamma)'} = \tfrac{1}{2}(1 + \xi'\sigma), \quad \xi' = (-\xi'_1, -\xi'_2, \xi'_3).$$

Теперь тензорный след

$$\rho^{(\nu')}_{\lambda\mu} Q^{\mu\nu} \rho^{(\nu)}_{\nu\rho} \tilde{\tilde{Q}}^{\rho\lambda}$$

Рассеяние на неполяризованных электронах

$$\rho^{(e)} = \frac{1}{2}(\gamma p + m), \quad \rho^{(e)'} = \frac{1}{2}\left(\gamma p' + m\right)$$

и удвоить результат, который должен быть подставлен вместо $|M_{fi}|^2$ в формулу для сечения $(64, 22)$

$$d\sigma = \frac{1}{32\pi^2} \frac{dt d\varphi}{\left(s - m^2\right)^2} |M_{fi}|^2$$

В лабораторной системе формула $(87, 11)$ принимает вид

$$d\sigma = \tfrac{r_e^2}{4} \left(\tfrac{\omega'}{\omega}\right)^2 do' \left\{F_0 + F_3 (\xi_3 + \xi'_3) + F_{11}\xi_1\xi'_1 + F_{22}\xi_2\xi'_2 + F_{33}\xi_3\xi'_3\right\}$$
$$do' = \sin\theta d\theta d\varphi, \quad (87, 12$$

где

$$F_0 = \frac{\omega}{\omega'} + \frac{\omega'}{\omega} - \sin^2\vartheta, \quad F_3 = \sin^2\vartheta$$

$$F_{11} = 2\cos\vartheta, \quad F_{22} = \left(\frac{\omega}{\omega'} + \frac{\omega'}{\omega}\right)\cos\vartheta, \quad F_{33} = 1 + \cos^2\vartheta$$

(U. Fano, 1949).

Согласно изложенным в §65 правилам величины ξ_i'' равны отношениям коэффициентов при $\xi_i'\dot{\kappa}$ члену, не содержащему ξ':

$$\xi_1^{(f)} = \frac{F_{11}}{F}\xi_1, \quad \xi_2^{(f)} = \frac{F_{22}}{F}\xi_2, \quad \xi_3^{(f)} = \frac{F_3 + F_{33}\xi_3}{F}.$$

В частности, при рассеянии неполяризованного фотона

$$\xi_1^{(f)} = \xi_2^{(f)} = 0, \quad \xi_3^{(f)} = \frac{\sin^2\theta}{\omega/\omega' + \omega'/\omega - \sin^2\theta}$$

$$d\sigma = \frac{r_e^2}{4}\left(\frac{\omega'}{\omega}\right)^2\left(\frac{\omega}{\omega'} + \frac{\omega'}{\omega} - 2 + 4\cos^2\Theta\right)do',$$

Рассеяние на поляризованных электронах

$$d\sigma = \frac{1}{2}d\sigma\left(\xi,\xi'\right) +$$

$$+ \frac{r_e^2}{8}\left(\frac{\omega'}{\omega}\right)^2 do'\left\{\mathbf{f}\xi\xi_2 + \mathbf{f}'\xi_2' + \mathbf{g}\xi'\xi_2 + \mathbf{g}'\xi'\xi_2' + G_{ik}\xi_i\xi_k' + ...\right\}.$$

фотона поляризованным электроном

$$d\sigma(\xi,\xi) = d\sigma(\xi) + \frac{1}{2}r_e^2\left(\frac{\omega'}{\omega}\right)^2\xi_2\mathrm{f}\xi do'$$

отличается от $d\sigma(\xi)$ только при наличии у фотона круговой поляризации, а у электронов-отличной от нуля проекции среднего спина на плоскость рассеяния. По той же причине электрон отдачи поляризуется только в случае, если фотон обладает круговой поляризацией; вектор же возникающей поляризации электрона лежит при этом в плоскости рассеяния:

$$\xi^{(f)} = \frac{1}{F}\xi_2\mathbf{g}.$$

Соотношения симметрии

Качественные свойства поляризационных эффектов при рассеянии фотонов на электронах следуют уже из общих требований симметрин.

Параметр ξ_2 циркулярной поляризации - псевдоскаляр (см. §8). Поэтому в силу требования P-инвариантности члены вида $\sim \xi_2$ (или $\propto \xi_2'$) в сечении рассеяния могли бы возникнуть лишь как произведение ξ_2 на какой-либо псевдоскаляр, составленный из имеющихся в нашем распоряжении векторов $\mathbf{k}$ и $\mathbf{k}'^1$). Но из двух полярных векторов нельзя составить псевдоскаляр. Отсюда и следует, что указанных членов в сечении не может быть.

Параметры линейной поляризации ξ_1 и ξ_3 связаны с компонентами двумерного (в плоскости, перпендикулярной k) симметричного тензора

$$S_{\alpha\beta} = \frac{1}{2}\left(\rho_{\alpha\beta}^{(\nu)} + \rho_{\beta\alpha}^{(\nu)}\right) = \frac{1}{2}\begin{pmatrix} 1+\xi_3 & \xi_1 \\ \xi_1 & 1-\xi_3 \end{pmatrix}.$$

24.2.3 88. Two-Photon Annihilation of an Electron Pair

Они отличаются от диаграмм рассеяния фотона на электроне заменой

$$p \to p_-, \quad p' \to -p_+, \quad k \to -k_1, \quad k' \to k_2.$$

Оба процесса - два перекрестных канала одной и той же (обобщенной) реакции. После замены (88, 2) кинематические инварианты (86, 2) приобретают следующий смысл:

$$\begin{aligned} s &= (p_- - k_1)^2, \\ t &= (p_- + p_+)^2 = (k_1 + k_2)^2, \\ u &= (p_- - k_2)^2. \end{aligned}$$

Если рассеяние фотона было s-каналом, то аннигиляция есть t-канал.

Физическая область аниигиляционного канала есть область II на рис. 7 (см. с. 300). При заданном t (заданной энергии в системе центра инерцин) интервал изменения s определяется уравнением границы $su = m^4$. Вместе с соотношением $s + t + u = 2m^2$ это дает $-\frac{t}{2} - \frac{1}{2}\sqrt{t\,(t-4m^2)} \leqslant s - m^2 \leqslant -\frac{t}{2} + \frac{1}{2}\sqrt{t\,(t-4m^2)}$. Интегрирование выражения (88, 4) элементарно; результат надо еше разделить на 2, учитывая тождественность двух конечных частиц (фотонов). Таким образом, получим

$$\sigma = \frac{\pi r_e^2}{2\tau^2(\tau-1)}\left[\left(\tau^2+\tau-\frac{1}{2}\right)\ln\frac{\sqrt{\tau}+\sqrt{\tau-1}}{\sqrt{\tau}-\sqrt{\tau-1}} - (\tau+1)\sqrt{\tau(\tau-1)}\right],$$

(88, 6) где $\tau = t/4m^2$ (P. A. M. Dirac, 1930).

В нерелятивистском пределе ($\tau \to 1$) находим отсюда

$$\sigma = \frac{\pi r_e^2}{2\sqrt{\tau-1}} \text{ (н. р.)}.$$

В системе центра инерции электрон, позитрон и оба фотона имеют одинаковые энергии $\varepsilon = \omega$. Инварианты:

$$m^2 - s = 2\varepsilon(\varepsilon - |\mathbf{p}|\cos\theta), \quad m^2 - u = 2\varepsilon(\varepsilon + |\mathbf{p}|\cos\theta),$$
$$t = 4\varepsilon^2,$$

где θ - угол между импульсами электрона и одного из фотонов. Подставив (88, 12) в (88, 4), получим угловое распределение аннигиляционных фотонов

$$d\sigma = \frac{r_e^2 m^2}{4\varepsilon|\mathrm{p}|}\left[\frac{\varepsilon^2 + \mathrm{p}^2\left(1+\sin^2\theta\right)}{\varepsilon^2 - \mathrm{p}^2\cos^2\theta} - \frac{2\mathrm{p}^4\sin^4\theta}{\left(\varepsilon^2 - \mathrm{p}^2\cos^2\theta\right)^2}\right]do.$$

В ультрарелятивистском случае оно имеет симметричные максимумы в направлениях $\theta = 0$ и $\theta = \pi$. Вблизи $\theta = 0$

$$d\sigma \approx \frac{r_e^2 m^2 do}{2\varepsilon^2\left(\theta^2 + m^2/\varepsilon^2\right)} \text{ (у. р.)}.$$

Подставив (88, 12) в (88, 4), получй угловое распределение аннигиляционных фотонов

$$d\sigma = \frac{r_e^2 m^2}{4\varepsilon|\mathrm{p}|}\left[\frac{\varepsilon^2 + \mathrm{p}^2\left(1+\sin^2\theta\right)}{\varepsilon^2 - \mathrm{p}^2\cos^2\theta} - \frac{2\mathrm{p}^4\sin^4\theta}{\left(\varepsilon^2 - \mathrm{p}^2\cos^2\theta\right)^2}\right]do.$$

В ультрарелятивистском случае оно имеет симметричные максимумы в направлениях $\theta = 0$ и $\theta = \pi$. Вблизи $\theta = 0$

$$d\sigma \approx \frac{r_e^2 m^2 do}{2\varepsilon^2 \left(\theta^2 + m^2/\varepsilon^2\right)} \text{ (у. р.).}$$

Полное сечение получается из $(88, 6)$:

$$\sigma = \pi r_e^2 \frac{1 - v^2}{4v} \left[\frac{3 - v^4}{v} \ln \frac{1 + v}{1 - v} - 2\left(2 - v^2\right)\right],$$

где $v = |\mathbf{p}|/\varepsilon = \sqrt{\varepsilon^2 - m^2}/\varepsilon$ - скорость сталкивающихся частин.

24.2.4 89. Positronium Annihilation

В нерелятивистском пределе согласно $(88, 11)$[1])

$$\overrightarrow{\sigma}_{2\gamma} = \pi \left(\frac{e^2}{mc^2}\right)^2 \frac{c}{v},$$

где v-относительная скорость частиц. Мы получим вероятность аннигиляции $\overline{\boldsymbol{\omega}}_{2\gamma}$, умножив $\bar{\sigma}_{2\gamma}$ на плотность потока, равную $v|\psi(0)|^2$. Здесь $\psi(r)$ - нормированная на 1 волновая функция основного состояния позитрония:

$$\psi(r) = \frac{1}{\sqrt{\pi a^3}} e^{-r/a}, \quad a = \frac{2\hbar^2}{me^2}$$

(боровский радиус позитрония a в два раза больше радиуса атома водорода из-за вдвое меньшей приведенной массы). Эта

Аналогичным образом найдем, что вероятность распада ортопозитрония связана с усредненным по спинам сечением трехфотонной аннигиляции свободной пары соотноением

$$w_1 = \frac{4}{3} \bar{w}_{3\gamma} = \frac{4}{3} |\psi(0)|^2 \left(v \bar{\sigma}_{3\gamma}\right)_{0 \to 0}$$

(3/4 - относительный статистический вес состояния со спином 1). Забегая вперед, укажем, что

$$\bar{\sigma}_{3\nu} = \frac{4\left(\pi^2 - 9\right) c}{3v} \alpha \left(\frac{e^2}{mc^2}\right)^2.$$

Поэтому продолжительность жизни ортопозитрония

$$\tau_1 = \frac{9\pi}{2\left(\pi^2 - 9\right)} \frac{\hbar}{mc^2 \alpha^5} = 1,4 \cdot 10^{-7} \text{с}.$$

Неравенство $\Gamma_1 \ll |E_{\text{осн}}|$ в этом случае, разумеется, выполняется еще в большей степени, чем для парапозитрония.

Вычислим сечение трехфотонной аннигиляции свободной пары (A. Ore, J. L. Powell, 1949).

Соответствующую амплитуду запишем в виде

$$M_{fi} = (4\pi)^{s/2} e_\lambda^{(3)^*} e_\mu^{(2)^*} e_v^{(1^{**})} \bar{u}\left(-p_+\right) Q^{\lambda\mu v} u\left(p_-\right),$$

где

$$Q^{\lambda\mu\nu} = \sum_{\text{пер}} \gamma^\lambda G\left(k_3 - p_+\right)\gamma^\mu G\left(p_- - k_1\right)\gamma^\nu,$$

причем сумма берется по всем перестановкам номеров фотонов $1, 2, 3$ вместе с одновременными такими же перестановками соответствующих тензорных индексов $\lambda\mu v$.

Квадрат модуля амплитуды, усредненный по поляризациям электрона и позитрона и просуммированный по поляризациям фотонов:

$$\frac{1}{4}\sum_{\text{поляр}} |M_{fi}|^2 = (4\pi)^3 \,\mathrm{Sp}\left\{\rho_+ Q^{\lambda\mu\nu}\rho_- \bar{Q}_{\lambda\mu\nu}\right\},$$

где

$$\rho_- = \frac{1}{2}\left(\gamma p_- + m\right), \quad \rho_+ = \frac{1}{2}\left(\gamma p_+ - m\right).$$

В результате все же довольно длинного вычисления пояучается

$$\frac{1}{4}\sum_{\text{поляр}} |M_{fi}|^2 = (4\pi)^3 e^6 \cdot 16\left[\left(\frac{m-\omega_1}{\omega_2\omega_3}\right)^2 + \left(\frac{m-\omega_2}{\omega_1\omega_3}\right)^2 + \left(\frac{m-\omega_3}{\omega_1\omega_2}\right)^2\right].$$

Подставив это выражение в $(89, 8)$, найдем дифференциальное сечение трехфотонной аннигиляции:

$$\begin{aligned} d\tilde{\sigma}_{3\gamma} =& \frac{e^6}{\pi^2 m^2 v}\left[\left(\frac{m-\omega_1}{\omega_2\omega_3}\right)^2 + \left(\frac{m-\omega_2}{\omega_1\omega_3}\right)^2 + \left(\frac{m-\omega_3}{\omega_1\omega_2}\right)^2\right] \times \\ & \times \delta\left(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3\right)\delta\left(\omega_1 + \omega_2 + \omega_3 - 2m\right)\frac{d^3k_1 d^3k_2 d^3k_3}{\omega_1\omega_2\omega_3}. \end{aligned}$$

Здесь надо еще исключить δ-функции. Первая нз них устраняется интегрированием по d^3k_3, после чего заменяем остальные дифференциалы:

$$d^3k_1 d^3k_2 \to 4\pi\omega_1^2 d\omega_1 \cdot 2\pi\omega_2^2 d\left(\cos\theta_{12}\right) d\omega_2$$

где θ_{12} - угол между $\mathbf{k}_1$ и $\mathbf{k}_2$; подразумевается, что уже произведено интегрирование по направлениям $\mathbf{k}_1$ и азимуту $\mathbf{k}_2$ относительно k_1. Дифференцируя равенство

$$\omega_3 = \sqrt{\omega_1^2 + \omega_2^2 + 2\omega_1\omega_2\cos\theta_{12}},$$

находим

$$d\cos\theta_{12} = \frac{\omega_3}{\omega_1\omega_2}d\omega_3$$

Полнсе сечение аннигиляции получается интегрированием $(89, 14)$ по обеим частотам:

$$\bar{\sigma}_{3y} = \frac{4\varepsilon^6}{3vm^2}3\int_0^m \int_{m-\omega_1}^m \frac{\left(\omega_1 + \omega_2 - m\right)^2}{\omega_1^2\omega_2^2}d\omega_1 d\omega_2.$$

Стояший здесь двойной интеграл равен $\left(\pi^2 - 9\right)/3$, и мы приходим к приведенной выше формуле $(89, 6)$.

24.2.5 90. Synchrotron radiation

квантовая отдача при испускании фотона. Последняя определяется отношением $\hbar\omega/\varepsilon$, и условие применимости классической теории требует его малостн. В этой связи удобно ввести параметр

$$\chi = \frac{H}{H_0}\frac{|p|}{m} \approx \frac{H\varepsilon}{H_0 m} \approx \frac{\hbar\omega_0}{\varepsilon}\left(\frac{\varepsilon}{m}\right)^3,$$

где $H_0 = m^2/|e|\hbar\,(= m^2c^3/|e|\hbar) = 4,4\cdot 10^{13}\Gamma$ с. В классической области $\chi \sim \hbar\omega/\varepsilon \ll 1$. В случае $\chi \geqslant 1$ энергия излученного фотона $\hbar\omega \sim \varepsilon$, причем при $\chi \gg 1$ (как мы увидим в дальнейшем) существенная область спектра простирается до частот, при которых энергия электрона после испускания

$$\varepsilon' \sim m\frac{H_0}{H} \ll \varepsilon.$$

Для того чтобы электрон оставался ультрарелятивистским, поле должно удовлетворять условию

$$\frac{H}{H_0} \ll 1$$

символическом виде

$$\psi = (2\hat{H})^{-1/2}u(\hat{p})\exp\left(-\frac{i}{\hbar}\hat{H}t\right)\varphi(\mathbf{r}),$$

где $\varphi(\mathbf{r}) \sim \exp(iS/\hbar)$ - квазиклассические волновые функцин бесспиновой частицы ($S(\mathbf{r})$ - ее классическое действие); $u(\hat{p})$ - операторный биспинор

$$u(\hat{p}) = \begin{pmatrix} (\hat{H}+m)^{1/2}w \\ (\hat{H}+m)^{-1/2}(\sigma\hat{p})\omega \end{pmatrix},$$

получающийся из биспинорной амплитуды плоской волны $u(p)$ $(23,9)$ заменой $\mathbf{p}$ и ε операторами [2])

$$\hat{\mathbf{p}} = \hat{\mathbf{p}} - e\mathbf{A} = -i\hbar\nabla - e\mathbf{A}, \quad \hat{H} = \left(\hat{\mathbf{p}}^2 + m^2\right)^{1/2},$$

$$V_{fi}(t) = e\sqrt{\frac{2\pi}{\hbar\omega}}\langle f|Q(t)|i\rangle e^{i\omega t},$$

где $\hat{Q}(t)$ обозначает гейзенберговский оператор

$$\widehat{Q}(t) = \frac{u_f^+(\hat{p})}{(2\hat{H})^{1/2}}\,(\alpha\mathrm{e}^*)\,e^{-i\hat{\mathrm{k}}(t)}\frac{u_i(\hat{p})}{(2\hat{H})^{1/2}},$$

$$dI = \frac{e^2}{4\pi^2}d^3k\int e^{-i\omega\tau}\left\langle i\left|Q^+\left(t+\frac{\tau}{2}\right)Q\left(t-\frac{\tau}{2}\right)\right|i\right\rangle d\tau.$$

$$\hat{\mathbf{p}}\exp(-i\mathbf{k}\hat{\mathbf{r}}) = \exp(-i\mathbf{k}\hat{\mathbf{r}})(\hat{\mathbf{p}} - \hbar\mathbf{k})$$
$$H(\hat{\mathbf{p}})\exp(-i\mathbf{k}\hat{\mathbf{r}}) = \exp(-i\mathbf{k}\hat{\mathbf{r}})H(\hat{\mathbf{p}} - \hbar\mathbf{k})$$

сдвига в импульсном пространстве. С помощью $(90,11)$. выносим в $(90,8)$ оператор $\exp(-i\mathrm{k}\hat{\mathbf{r}}(t))$ налево и записываем $\widehat{Q}(t)$ в виде

$$\hat{Q}(t) = \exp[-i\mathbf{k}\hat{\mathbf{r}}(t)]\hat{R}(t), \quad \hat{R}(t) = \frac{u_f^+\,(\hat{p}')}{\left(2\widehat{H}'\right)^{1/2}}\,(\alpha\mathrm{e}^*)\,\frac{u_i(\hat{p})}{(2\widehat{H})^{1/2}},$$

где $\hat{H}' = \hat{H} - \hbar\omega, \hat{\mathbf{p}}' = \hat{\mathbf{p}} - \hbar\mathbf{k}$. Теперь

$$\hat{Q}_2^+ \hat{Q}_1 = \hat{R}_2 \exp\left(i\mathbf{k}\hat{\mathbf{r}}_2\right) \exp\left(-i\mathbf{k}\hat{\mathbf{r}}_1\right) \hat{R}_1$$

$$L(\tau) = \exp\left\{ i \frac{\boldsymbol{\varepsilon}}{\boldsymbol{\varepsilon}'} \left(\mathbf{k}\mathbf{r}_2 - \mathbf{k}\mathbf{r}_1 - \omega\tau\right) \right\}$$

До сих пор мы не использовали конкретного вида траектории электрона. Выразим теперь $\boldsymbol{r}_2 - \mathbf{r}_1$ в $(90, 18)$ через $\mathbf{p}_1$ с помощью уравнения движения электрона в плоскости, перпендикулярной полю H (см. II, §21):

$$\mathbf{r}_2 - \mathbf{r}_1 = \frac{\mathbf{p}_1}{e\ddot{H}} \sin\frac{eH\tau}{\varepsilon} + \frac{[\mathbf{p}_1\mathbf{H}]}{eH^2} \left(1 - \cos\frac{eH\tau}{\varepsilon}\right).$$

Разлагая по степеням τ, имеем отсюда

$$\mathbf{k}\left(\mathbf{r}_2 - \mathbf{r}_1\right) - \omega\tau \approx \omega\tau \left\{ \left(\mathbf{v}_1\mathbf{n} - 1\right) + \tau \frac{e\mathbf{n}\left[\mathbf{p}_1\mathbf{H}\right]}{2\varepsilon^2} - \tau^2 \frac{e^2H^2}{6\varepsilon^2} \right\}$$

Таким образом, окончательно имеем

$$\exp(-i\omega t) \left\langle i \left| Q_2^+ Q_1 \right| i \right\rangle = R_2^* R_1 L(\tau)$$
$$R_2^* R_1 = \mathrm{Sp} \frac{1 + \xi_i \boldsymbol{\sigma}}{2} \left(\left(\mathrm{A}_2 - i\left[\mathbf{B}_2\boldsymbol{\sigma}\right]\right)\mathrm{e}\right) \frac{1 + \xi_i \boldsymbol{\sigma}}{2} \left(\left(\mathbf{A}_1 + i\left[\mathbf{B}_1\boldsymbol{\sigma}\right]\right)\mathrm{e}^*\right).$$

Множители $(1 + \xi\sigma)/2$ - двухрядные поляризационные матрицы плотности начального и конечного электронов.

$$\frac{dI}{d\omega} = \frac{ie^2\omega}{2\pi} \int\limits_{-\infty}^{\infty} \left(\frac{m^2}{\varepsilon^2\tau} + \frac{\varepsilon^2 + \varepsilon'^2}{4\varepsilon\varepsilon'} \omega_0^2 \tau \right) \exp\left\{ -\frac{i\omega\tau\varepsilon}{\boldsymbol{\varepsilon}'} \left(1 - v + \frac{\tau^2}{24}\omega_0^2\right) \right\} d\tau,$$

причем контур интегрирования выбирается указанным выше способом. Используя интегральное представление, функции Эйри Φ (см. III § b), нетрудно показать, что первый член сводится к интегралу от функции Эйри, а второй-к производной от нее. Окончательно находим

$$\frac{dI}{d\omega} = -\frac{e^2m^2\omega}{\sqrt{\pi}\varepsilon^2} \left\{ \int\limits_x^{\infty} \Phi(\xi) d\xi + \left(\frac{2}{x} + \frac{\hbar\omega}{\varepsilon}\chi x^{1/2}\right) \tilde{\Phi}'(x) \right\},$$
$$x = \left(\frac{\hbar\omega}{\varepsilon'\chi}\right)^{2/3} = \frac{m\iota^2}{\varepsilon^2} \left(\frac{\varepsilon\omega}{\varepsilon'\omega_0}\right)^{2/s}$$

(А. И. Никишов, В. И. Ритус, 1967).

Магнитотормозное излучение ириводит к возникновению поляризации движущихся электронов (А. А. Соколов, И. М. Тернов, 1963). Для рассмотрения этого вопроса надо найти всроятность радиационного перехода с обращением направления спина. Положнв в $(90, 21)\xi_i = -\xi_f \equiv \xi, |\zeta| = 1$, получим

$$R_2^* R_1 = \left(\mathbf{B}_1\mathbf{B}_2\right) - \left(\mathrm{e}^*\mathbf{B}_1\right)\left(\mathbf{e}_2\right) - \left(\mathbf{e}^*\left[\mathbf{B}_1\zeta\right]\right)\left(\mathbf{e}\left[\mathbf{B}_2\zeta\right]\right) - i\left(\zeta\mathrm{e}^*\right)\left(\mathbf{e}\left[\mathbf{B}_1\mathbf{B}_2\right]\right).$$

окончательно полную вероятность радиационного перехода с обращением спина:

$$w = \frac{5\sqrt{3}\alpha}{16}\frac{\hbar^2}{m^2}\left(\frac{\varepsilon}{m}\right)^5 \omega_0^3 \left(1 - \frac{2}{9}\zeta_\parallel^2 - \frac{8\sqrt{3}}{15}\frac{e}{|e|}\zeta_\perp\right),$$

где $\zeta_\parallel = \zeta\mathbf{v}, \zeta_\perp = \zeta\mathbf{H}/H$. Эта формула пригодна как для электронов ($e < 0$), так и для позитронов ($e > 0$).

Вероятность $(90, 30)$ не зависит от знака продольной поляризации $\zeta_\parallel$, но зависит от знака $\zeta_\perp$.

24.2.6 91. Pair Production by a Photon in a Magnetic Field

Образование электрон-позитронной пары фотоном в магнитном поле и магнитотормозное излучение - два 'перекрестных канала одной и той же реакции. Поэтому амплитуда M_{fi} процесса образования пары получается из амплитуды тормозного излучения просто путем замены

$$\varepsilon, p \to -\varepsilon_+, -p_+; \quad \varepsilon', p' \to \varepsilon_-, p_-; \quad \omega, k \to -\omega, -k \quad (91, 1)$$

(здесь ε_-, p_-и ε_+, p_+−энергии и импульсы электрона и пози трона в паре; $\boldsymbol{\varepsilon}, \mathbf{p}$ и $\boldsymbol{\varepsilon}', \mathbf{p}'$ - начальные и конечные энергии и импульсы электрона при тормозном излучении). В терминах углов и абсолютных значений преобразование импульсов есть

$$|\mathbf{p}| \to |\mathbf{p}_+|, |\mathbf{p}'| \to |\mathbf{p}_-|, \theta \to \pi - \theta_+, \theta' \to \theta_-, \varphi \to \varphi - \pi,$$

где $\theta_\pm$−углы между $\mathbf{p}_\pm$и $\mathbf{k}, \varphi$-угол между плоскостями $\mathbf{k}, \mathbf{p}_+$и $\mathbf{k}, \mathbf{p}_-$.

В случае же образования пары фотоном сечение выражается через амплитуду согласно

$$d\sigma = |M_{fi}|^2 \frac{1}{8\omega\varepsilon_-\varepsilon_+}\delta\left(\omega - \varepsilon_+ - \varepsilon_-\right)\frac{d^3p_+ d^3p_-}{(2\pi)^5}$$

или, после исключения δ-функции:

$$d\sigma = |M_{fi}|^2 \frac{|\mathrm{p}_+|\,|\mathbf{p}_-|}{8(2\pi)^5\omega} do_+ do_- d\varepsilon_+.$$

$$dw = \frac{m^2e^2}{\sqrt{\pi}}\frac{d\varepsilon_+}{\omega^2}\left\{\int_x^\infty \Phi(\xi)d\xi + \left(\frac{2}{x} - xx^{1/2}\right)\Phi'(x)\right\}.$$

где теперь

$$x = \left(\frac{m^3\omega}{|e|H{\varepsilon_+}^2-}\right)^{2/3}, \quad x = \frac{|e|H\omega}{m^3}\left(= \frac{\hbar^2|e|H\omega}{m^3c^5}\right).$$

Полная вероятность рождения пары в единицу времени получается интегрированием $(91, 8)$ по ε_+(причем, ввиду очевидной симметрии по отношению к ε_+и $\varepsilon_- = \omega - \varepsilon_+$, достаточно интегрировать от 0 до $\omega/2$ и затем удвонть результат). Производя замену переменной интегрирования ε_+на x и интегрируя первый член в $(91, 8)$ дважды по частям, получаем

$$w = -\frac{|e|^3H}{mx\sqrt{\pi}}\int_{(4/x)^{2/6}}^\infty \frac{2\left(x^{3/2} + 1/x\right)\Phi'(x)}{x^{1/4}\left(x^{3/2} - 4/x\right)^{1/2}}dx$$

(А. И. Никищов, В. И. Ритус, 1967).

Part VII
Problems in QFT

26 Problems about messing with typical QFT formalism

26.1 Problems about fundamentals of QFT

26.1.1 Problems about classical fields and mechanics for preparation to QFT

Stanford.exam-2022.2/5. Forces on external currents. (5/40p)

In problem set 7, you considered the "improved" electromagnetic stress-energy tensor,

$$\hat{T}^{\mu\nu} = -\eta_{\rho\sigma}F^{\mu\rho}F^{\nu\sigma} + \frac{1}{4}\eta^{\mu\nu}F_{\rho\sigma}F^{\rho\sigma}$$

and showed that it was conserved, $\partial_\mu \hat{T}^{\mu\nu} = 0$, when no current was present.

a) When there is a nonzero current $J^\mu = (\rho, \mathbf{J})$, the stress-energy tensor defined in (3) has divergence $\partial_\mu \hat{T}^{\mu\nu} = -K^\nu$. Find K^ν.

Solution

: The only difference is that the equation of motion is now $\partial_\mu F^{\mu\nu} = J^\nu$. We already know that when $\partial_\mu F^{\mu\nu} = 0$, the stress-energy is conserved, so to compute K^ν we only need to consider what terms appear which are proportional to J^μ. This can only occur when the derivative ∂_μ hits the factor of $F^{\mu\rho}$ in the first term, so

$$\partial_\mu \hat{T}^{\mu\nu} = -\eta_{\rho\sigma}\left(\partial_\mu F^{\mu\rho}\right)F^{\nu\sigma} = -\eta_{\rho\sigma}J^\rho F^{\nu\sigma}.$$

Thus, the answer is $K^\nu = J_\sigma F^{\nu\sigma}$.

You might be wondering why we are allowed to use the original expression for the stress-energy tensor, as rerunning the Noether/Belinfante procedure will give additional terms when J^μ is nonzero. The point is that we're trying to find the change in the energy-momentum of the electromagnetic field alone, so we shouldn't include those extra terms, which represent something like potential energy-momentum.

b) The vector $K^\mu = \left(K^0, \mathbf{K}\right)$ is the four-momentum delivered to the current by the field, per unit space and unit time. Explicitly write K^0 and $\mathbf{K}$ in terms of $\rho, \mathbf{J}, \mathbf{E}$, and $\mathbf{B}$.

Solution

Expanding the components out, we have

$$K^i = J_\sigma F^{i\sigma} = J_0 F^{i0} + J_j F^{ij} = J_0 E^i - J_j \epsilon^{ijk} B^k.$$

Noting that $J_0 = J^0 = \rho$ and $J_i = -J^i$, we conclude

$$\mathbf{K} = \rho\mathbf{E} + \mathbf{J} \times \mathbf{B}$$

which of course is just the continuous version of the Lorentz force law. Similarly, we have

$$K^0 = J_i F^{0i} = \left(-J^i\right)\left(-F^{i0}\right) = \mathbf{J} \cdot \mathbf{E}$$

which is the rate at which the electric field does work on the charges.

Асимптотическое состояние теории с простым взаимодействием полей

Пусть у нас

$$L = (Lkg1) + (Lkg2) - \tilde{m}\phi_1\phi_2.$$

Какое его асимптотическое состояние?

Solution

(нужно записать через матрицы и повращать матрицей поворота, там потом новое поле - примерно сумма и разность двух полей до. задача по сути по линалу на диагонализацию симм матрицы.)
(не очень крутая задача, выдуманная теория взаимодействия полей, по сути на линал.)

Задачи 1 на Интегралы движения как генераторы симметрии

По аналогии с классической механикой, обобщенный импульс в теории поля можно записать, как

$$\pi_i(\vec{x},t)=\frac{\delta\int d^3\vec{y}\mathcal{L}\left(\phi_k(\vec{y},t),\partial_\mu\phi_k(\vec{y},t)\right)}{\delta\dot{\phi}_i(\vec{x},t)} \tag{0.1}$$

где мы используем, что

$$\frac{\delta\dot{\phi}_k(\vec{x},t)}{\delta\dot{\phi}_i(\vec{y},t)}=\delta_{ik}\delta(\vec{x}-\vec{y}) \tag{0.2}$$

Далее, по опять же по аналогии с классической механикой, мы вводим скобку Пуассона

$$\left\{F\left(\phi_k(\vec{x},t),\pi_k(\vec{x},t)\right),G\left(\phi_k(\vec{y},t),\pi_k(\vec{y},t)\right)\right\}=\int d^3z\sum_i\left(\frac{\delta F}{\delta\phi_i(\vec{z},t)}\frac{\delta G}{\delta\pi_i(\vec{z},t)}-\frac{\delta F}{\delta\pi_i(\vec{z},t)}\frac{\delta G}{\delta\phi_i(\vec{z},t)}\right) \tag{0.3}$$

и подразумеваем, что

$$\frac{\delta\phi_k(\vec{x},t)}{\delta\phi_i(\vec{y},t)}=\delta_{ik}\delta(\vec{x}-\vec{y}),\quad \frac{\delta\pi_k(\vec{x},t)}{\delta\pi_i(\vec{y},t)}=\delta_{ik}\delta(\vec{x}-\vec{y}),\quad \frac{\delta\phi_k(\vec{x},t)}{\delta\pi_i(\vec{y},t)}=\frac{\delta\pi_k(\vec{x},t)}{\delta\phi_i(\vec{y},t)}=0. \tag{0.4}$$

Легко проверить, что

$$\{\phi_i(\vec{x},t),\phi_j(\vec{y},t)\}=\{\pi_i(\vec{x},t),\pi_j(\vec{y},t)\}=0,\quad \{\phi_i(\vec{x},t),\pi_j(\vec{y},t)\}=\delta_{ij}\delta(\vec{x}-\vec{y}). \tag{0.5}$$

Общее утверждение заключается в том, что интегралы движения (заряды)

$$Q=\int d^3\vec{x}J^0(\vec{x},t),\quad \frac{dQ}{dt}=0,\quad \partial_\mu J^\mu=0 \tag{0.6}$$

генерируют симметрию (из которой они по теореме Нетер были вычисленны), а именно

$$\{\phi_i(\vec{x},t),Q\}=\delta\phi_i(\vec{x},t), \tag{0.7}$$

где инфинитезимальное преобразование симметрии есть $\phi_i'(x)=\phi_i(x)+\epsilon\delta\phi_i(x)$.
Упражнение 1. Проверьте (0.7) для комплексного скалярного поля ($U(1)$ симметрия).
Решение 1. Как мы уже знаем $U(1)$ сохраняющийся ток

$$j^\mu=i\left(\phi\partial^\mu\phi^*-\phi^*\partial^\mu\phi\right) \tag{0.8}$$

соответствует симметрии $\phi'(x)=e^{i\alpha}\phi(x)$, что при инфинитезимальном α запишется как

$$\delta\phi=i\phi,\quad \delta\phi^*=-i\phi^* \tag{0.9}$$

С другой стороны сохраняющийся заряд равен

$$Q=i\int d^3\vec{x}\left(\pi\phi-\phi^*\pi^*\right) \tag{0.10}$$

Тогда находим,

$$\begin{aligned}\{\phi(\vec{x},t),Q\}&=\int d^3z\left(\frac{\delta\phi(\vec{x},t)}{\delta\phi(\vec{z},t)}\frac{\delta Q}{\delta\pi(\vec{z},t)}-\frac{\delta\phi(\vec{x},t)}{\delta\pi(\vec{z},t)}\frac{\delta Q}{\delta\phi(\vec{z},t)}+\frac{\delta\phi(\vec{x},t)}{\delta\phi^*(\vec{z},t)}\frac{\delta Q}{\delta\pi^*(\vec{z},t)}-\frac{\delta\phi(\vec{x},t)}{\delta\pi^*(\vec{z},t)}\frac{\delta Q}{\delta\phi^*(\vec{z},t)}\right)=\\&=\int d^3z\left(\frac{\delta Q}{\delta\pi(\vec{z},t)}\frac{\delta\phi(\vec{x},t)}{\delta\phi(\vec{z},t)}\right)=\int d^3z\left(\frac{\delta Q}{\delta\pi(\vec{z},t)}\delta(\vec{x}-\vec{z})\right)=\frac{\delta Q}{\delta\pi(\vec{x},t)}=\\&=\frac{\delta\left(i\int d^3\vec{y}(\pi(\vec{y},t)\phi(\vec{y},t))-\phi^*(\vec{y},t)\pi^*(\vec{y},t))\right)}{\delta\pi(\vec{x},t)}=i\phi(\vec{x},t).\end{aligned} \tag{0.11}$$

Аналогично найдем, что $\{\phi^*(\vec{x},t),Q\} = -i\phi^*(\vec{x},t)$.

Упражнение 2. Проверьте, на примере скалярного поля, что Гамильтониан генерирует сдвиги по времени: $\{\phi(\vec{x},t),H\} = \dot{\phi}(\vec{x},t)$

Решение 2. Для Гамильтониана имеем

$$H = \int d^3\vec{x}\left(\frac{1}{2}\pi^2 + \frac{1}{2}(\nabla\phi)^2 + \frac{1}{2}m^2\phi^2\right), \tag{0.12}$$

тогда

$$\{\phi(\vec{x},t),H\} = \int d^3z\left(\frac{\delta\phi(\vec{x},t)}{\delta\phi(\vec{z},t)}\frac{\delta H}{\delta\pi(\vec{z},t)} - \frac{\delta\phi(\vec{x},t)}{\delta\pi(\vec{z},t)}\frac{\delta H}{\delta\phi(\vec{z},t)}\right) = \frac{\delta H}{\delta\pi(\vec{x},t)} = \pi(\vec{x},t) = \dot{\phi}(\vec{x},t) \tag{0.13}$$

Откуда мы получили, что Гамильтониан генерирует сдвиги по времени. Это не удивительно, так как Гамилтониан это по сути заряд

$$H = \int d^3\vec{x}T^{00}(\vec{x},t) \tag{0.14}$$

получающийся из компоненты тензора энергии импульса $T^{\mu 0}$.

Упражнение 3. Проверьте, на примере скалярного поля, что импульс генерирует пространственные сдвиги: $\{\phi(\vec{x},t),\vec{P}\} = -\nabla\phi(\vec{x},t)$

Решение 3. Для импульса имеем

$$P^i = \int d^3xT^{0i} = -\int d^3\vec{x}\pi(\vec{x},t)\partial_i\phi(x,t), \tag{0.15}$$

тогда

$$\{\phi(\vec{x},t),\vec{P}\} = \int d^3z\left(\frac{\delta\phi(\vec{x},t)}{\delta\phi(\vec{z},t)}\frac{\delta\vec{P}}{\delta\pi(\vec{z},t)} - \frac{\delta\phi(\vec{x},t)}{\delta\pi(\vec{z},t)}\frac{\delta\vec{P}}{\delta\phi(\vec{z},t)}\right) = \frac{\delta\vec{P}}{\delta\pi(\vec{x},t)} = -\nabla\phi(\vec{x},t) \tag{0.16}$$

Упражнение 4. Проверьте, на примере скалярного поля, что момент импульса генерирует пространственные повороты: $\{\phi(\vec{x},t),L_k\} = -\epsilon_{ijk}x^i\partial_j\phi(\vec{x},t)$

Решение 4. Для момента импульса имеем (см. Листок 1)

$$L_k = \frac{1}{2}\epsilon_{ijk}\int d^3\vec{x}\left(x^iT^{0j} - x^jT^{0i}\right) = \frac{1}{2}\epsilon_{ijk}\int d^3\vec{x}\pi(\vec{x},t)\left(x^i\partial^j\phi(\vec{x},t) - x^j\partial^i\phi(\vec{x},t)\right) \tag{0.17}$$

тогда

$$\{\phi(\vec{x},t),L_k\} = \int d^3z\left(\frac{\delta\phi(\vec{x},t)}{\delta\phi(\vec{z},t)}\frac{\delta L_k}{\delta\pi(\vec{z},t)} - \frac{\delta\phi(\vec{x},t)}{\delta\pi(\vec{z},t)}\frac{\delta L_k}{\delta\phi(\vec{z},t)}\right) = \frac{\delta L_k}{\delta\pi(\vec{x},t)} = \frac{1}{2}\epsilon_{ijk}\left(x^i\partial^j - x^j\partial^i\right)\phi(\vec{x},t) =$$
$$= \epsilon_{ijk}x^i\partial^j\phi(\vec{x},t). \tag{0.18}$$

Белавин-Пархоменко**.1. Классическая теория поля**

1 Классическая Теория Поля и Теорема Нётер (100 баллов)

В этой задаче, мы будем изучать классическую Теорему Нётер, которая утверждает, что любой непрерывной симметрии действия соответствует сохраняющийся ток.

(a). В качестве разминки, рассмотрим двухмерный изотропный гармонический осциллятор с координатами x, y. В терминах комплексной координаты $\phi = x + iy$ действие имеет вид:

$$S[\phi(t)] = \int dt\left(\frac{1}{2}\dot{\phi}^*(t)\dot{\phi}(t) - \frac{1}{2}m^2\phi^*(t)\phi(t)\right) \tag{0.1}$$

Покажите, что это действие инвариантно при преобразовании $\phi(t) \to \phi'(t) = e^{i\alpha}\phi(t)$, где α действительная постоянная. Как это преобразование действует на координаты x и y? Теперь рассмотрим такое же преобразование, только с зависимой от времени функцией $\alpha(t)$,

$$\phi(t) \to \phi'(t) = e^{i\alpha(t)}\phi(t) \tag{0.2}$$

Это больше не симметрия действия. Для инфинитезимального (бесконечно маленького) $\alpha(t)$ покажите, что изменение действия есть

$$\delta S = S\left[\phi'(t)\right] - S[\phi(t)] = \int dt Q(t)\dot{\alpha}(t) + \mathcal{O}\left(\alpha^2\right) \tag{0.3}$$

и найдите $Q(t)$ в терминах $\phi(t)$. Используйте (0.3) для вывода того, что из уравнений движения следует, что $\dot{Q}(t) = 0$, т.е. Q является сохраняющимся зарядом. Какой физической величине соответствует заряд Q в данном примере?

(b). Рассмотрим классическую теорию поля с действием

$$S = \int d^4x \mathcal{L}\left(\phi_i(x), \partial_\mu \phi_i(x)\right) \tag{0.4}$$

Предположим, что S инвариантно относительно инфинитезимальных преобразований вида

$$\phi_i(x) \to \phi_i'(x) = \phi_i(x) + \alpha F_i\left(\phi_j(x), \partial_\mu \phi_j(x)\right), \quad \alpha \ll 1. \tag{0.5}$$

Если S инвариантно, то как $\mathcal{L}$ изменятся при таких преобразованиях. Теперь объявляя α функцией координаты x и действуя аналогично части (a) выше, покажите, что существует ток j^μ, такой что при учете уравнений движения можно получить $\partial_\mu j^\mu = 0$, то есть ток сохраняется (сохраняющийся ток). Найдите явную формулу для j^μ.

(c). Рассмотрим комплексное скалярное поле $\phi(x)$ с действием

$$S = \int d^4x \left(\partial^\mu \phi^* \partial_\mu \phi - V(|\phi|)\right) \tag{0.6}$$

Покажите, что действие инвариантно относительно глобальных $U(1)$ фазовых поворотов $\phi'(x) = e^{i\alpha}\phi(x)$, и найдите соответствующий Нётеровский ток. Повторите тоже самое, но для сдвигов (трансляций):

$$x^\mu \to x'^\mu = x^\mu + a^\mu, \quad \phi(x) \to \phi'\left(x'\right) = \phi(x). \tag{0.7}$$

Получите соответствующие Нётеровские токи и следовательно Тензор энергии-импульса $T_{\mu\nu}$. (Обратите внимание, что Лагранжева плотность не является инвариантной при сдвигах, в том смысле, что: $\delta\mathcal{L}(x) = \mathcal{L}\left(\phi'(x), \partial_\mu \phi'(x)\right) - \mathcal{L}\left(\phi(x), \partial_\mu \phi(x)\right) = a^\mu \partial_\mu \mathcal{L}(x)$. В данном месте может возникнуть путаница, так как иногда говорят, что Лагранжева плотность как раз инвариантна, подразумевая, что: $\mathcal{L}\left(\phi'\left(x'\right), \partial'_\mu \phi'\left(x'\right)\right) - \mathcal{L}\left(\phi(x), \partial_\mu \phi(x)\right) = 0\big)$. Теперь рассмотрите масштабное преобразование

$$x'^\mu = \lambda x^\mu, \quad \phi'\left(x'\right) = \lambda^{-1}\phi(x). \tag{0.8}$$

При каком виде потенциала $V(|\phi|)$ данное преобразование является симметрией действия? Найдите соответствующий Нётеровский ток и выразите его в терминах $T_{\mu\nu}$.

(d). Утверждение, что теория является Лоренц инвариантной, является утверждением о наличии симметрии нашей теории (Лоренц-симметрии), а следовательно мы можем в полном праве воспользоваться теоремой Нётер и найти соответствующие данной симметрии сохраняющиеся токи. Рассмотрим инфинитезимальное преобразование Лоренца для теории одного скалярного поля

$$x'^\mu = \Lambda^\mu_\nu x^\nu = x^\mu + \omega^\mu{}_\nu x^\nu, \quad \phi(x) \to \phi'\left(x'\right) = \phi(x), \quad \omega_{\mu\nu} = -\omega_{\nu\mu}. \tag{0.9}$$

Покажите, что такому преобразованию соответствуют сохраняющиеся токи вида

$$M^{\lambda\mu\nu} = x^\mu T^{\lambda\nu} - x^\nu T^{\lambda\mu}. \tag{0.10}$$

Соответственно независящий от времени тензор получается по формуле $L^{\mu\nu} = \int d^3x M^{0\mu\nu}$. А величина $L_k = \frac{1}{2}\epsilon_{ijk}L^{ij}$ в физике называется моментом импульса.

(e). Найдите сохраняющиеся токи соответствующие Лоренц симметрии для теории векторного поля A_μ с Лагранжианом $\mathcal{L}\left(A_\mu(x), \partial_\nu A_\mu(x)\right)$. В данном случае

$$x'^\mu = \Lambda^\mu{}_\nu x^\nu, \quad A_\mu(x) \to A'_\mu\left(x'\right) = \Lambda^\nu_\mu A_\nu(x). \tag{0.11}$$

Аналогично задаче (d) рассмотрите инфинитезимальное преобразование Лоренца и покажите, что у сохраняющихся токов $M^{\lambda\mu\nu}$ в данном случае появляется еще и спиновая часть

$$M^{\lambda\mu\nu} = x^\mu T^{\lambda\nu} - x^\nu T^{\lambda\mu} + S^{\lambda\mu\nu}. \tag{0.12}$$

Найдите $S^{\lambda\mu\nu}$.

(f). Покажите, что в Лоренц инвариантной теории одного скалярного поля $\phi\left(x^\mu\right)$ с Лагранжевой плотностью $\mathcal{L}\left(\phi, \partial_\mu \phi\right)$ Тензор энергии-импулься $T_{\mu\nu}$, полученный как Нётеровский ток, всегда симметричен. (В данном случае как раз удобно рассмотреть разность: $0 = \mathcal{L}\left(\phi'\left(x'\right), \partial'_\mu \phi'\left(x'\right)\right) - \mathcal{L}\left(\phi(x), \partial_\mu \phi(x)\right)\big)$.

Белавин-Пархоменко**.1. Классическая теория поля Решения**

1 Классическая Теория Поля и Теорема Нётер (100 баллов)

(a). - Преобразование имеет вид

$$\phi'(t) = e^{i\alpha}\phi(t) \quad \Rightarrow \quad \dot{\phi}'(t) = e^{i\alpha}\dot{\phi}(t). \tag{0.1}$$

Таким образом получаем для действия

$$S\left[\phi'(t)\right] = \int dt \left(\frac{1}{2}\left(e^{-i\alpha}\dot{\phi}^*(t)\right)\left(e^{i\alpha}\dot{\phi}(t)\right) - \frac{1}{2}m^2\left(e^{-i\alpha}\phi^*(t)\right)\left(e^{i\alpha}\phi(t)\right)\right) = S[\phi(t)]. \tag{0.2}$$

Далее имеем

$$\phi = x + iy \quad \Rightarrow \quad \begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} \cos\alpha & -\sin\alpha \\ \sin\alpha & \cos\alpha \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix} \tag{0.3}$$

это матрица поворота на угол α (из группы $SO(2)$).
Далее теперь имеем $\alpha(t) \ll 1$, следовательно

$$\begin{aligned} \phi'(t) &= e^{i\alpha(t)}\phi(t) = \phi(t) + i\alpha(t)\phi(t) + \mathcal{O}\left(\alpha^2\right), \\ \dot{\phi}'(t) &= \dot{\phi}(t) + i\dot{\alpha}(t)\phi(t) + i\alpha(t)\dot{\phi}(t) + \mathcal{O}\left(\alpha^2\right). \end{aligned} \tag{0.4}$$

Находим для действия

$$\begin{aligned} S\left[\phi'(t)\right] = \int dt \Bigg[\frac{1}{2}\left(\dot{\phi}^*(t) - i\dot{\alpha}(t)\phi^*(t) - i\alpha(t)\dot{\phi}^*(t)\right)\left(\dot{\phi}(t) + i\dot{\alpha}(t)\phi(t) + i\alpha(t)\dot{\phi}(t)\right) - \\ -\frac{1}{2}m^2\left(\phi^*(t) - i\alpha(t)\phi^*(t)\right)\left(\phi(t) + i\alpha(t)\phi(t)\right) + \mathcal{O}\left(\alpha^2\right)\Bigg] = \\ = S[\phi(t)] + \int dt \left[-\frac{i\dot{\alpha}(t)}{2}\left(\phi^*(t)\dot{\phi}(t) - \dot{\phi}^*(t)\phi(t)\right)\right] + \mathcal{O}\left(\alpha^2\right). \end{aligned} \tag{0.5}$$

Таким образом мы находим

$$Q(t) = -\frac{i}{2}\left(\phi^*(t)\dot{\phi}(t) - \dot{\phi}^*(t)\phi(t)\right) \tag{0.6}$$

На уравнениях движения ("on-shell") вариация действия равна нулю $\delta S = 0$ для любого $\alpha(t)$, следовательно получаем:

$$\int dt\alpha(t)\dot{Q}(t) = 0, \forall\alpha(t), \quad \Rightarrow \quad \dot{Q}(t) = 0 \quad \text{и поэтому} \quad Q(t) = Q \text{ сохраняющий заряд "on-shell".} \tag{0.7}$$

В обычных координатах x, y имеем для заряда

$$Q = -\frac{i}{2}((x - iy)(\dot{x} + i\dot{y}) - \text{ к.с. }) = x\dot{y} - y\dot{x} \tag{0.8}$$

данное выражение называется в физике моментом импульса. (аббревиатура к.с. означает комплексно сопряженная часть)

(b). - Мы предполагаем, что мера d^4x инвариантна. Из инвариантности действия S мы получаем (здесь $\alpha = \text{const}$, не зависит от x)

$$\mathcal{L}\left(\phi'(x), \partial_\mu\phi'(x)\right) = \mathcal{L}\left(\phi(x), \partial_\mu\phi(x)\right) + \alpha\partial_\mu G^\mu. \tag{0.9}$$

Последнее слагаемое есть полная производная, поэтому при интегрировании по d^4x оно исчезает. Теперь пусть (здесь уже мы ввели зависящую от x функцию $\alpha(x)$)

$$\phi_i'(x) = \phi_i(x) + \alpha(x)F_i\left(\phi(x), \partial_\mu\phi(x)\right), \tag{0.10}$$

тогда получим

$$\mathcal{L}\left(\phi_i\ +\alpha(x)F_i\left(\phi,\partial_\mu\phi\right),\partial_\mu\phi_i(x)+\partial_\mu\alpha(x)F_i+\alpha(x)\partial_\mu F_i\right)=$$
$$=\mathcal{L}\left(\phi_i,\partial_\mu\phi_i\right)+\frac{\partial\mathcal{L}}{\partial\phi_i}\alpha(x)F_i+\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi_i\right)}\left(\partial_\mu\alpha F_i+\alpha\partial_\mu F_i\right) \tag{0.11}$$

но как мы знаем (это мы бы получили если бы α не зависело от x)

$$\frac{\partial\mathcal{L}}{\partial\phi_i}F_i+\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi_i\right)}\partial_\mu F_i=\partial_\mu G^\mu \tag{0.12}$$

Поэтому можно получить, что

$$\delta S=-\int d^4x\alpha(x)\partial_\mu\left(\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi_i\right)}F_i-G^\mu\right) \tag{0.13}$$

На уравнениях движения ("on-shell") $\delta S=0$, следовательно

$$j^\mu=\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi_i\right)}F_i-G^\mu,\quad \partial_\mu j^\mu=0. \tag{0.14}$$

(c). · При $U(1)$ преобразованиях мы имеем (по аналогии с задачей (b))

$$\delta\phi=i\alpha\phi,\quad \delta\phi^*=-i\alpha\phi^*,\quad G^\mu=0 \tag{0.15}$$

откуда получаем

$$F_\phi=i\phi,\quad F_{\phi^*}=-i\phi^* \tag{0.16}$$

и следовательно сохраняющийся ток дается формулой

$$j^\mu=\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi\right)}F_\phi+\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi^*\right)}F_{\phi^*}=\left(-\partial^\mu\phi^*\right)\left(i\phi\right)+\left(-\partial^\mu\phi\right)\left(-i\phi^*\right)=i\left(\phi^*\partial^\mu\phi-\phi\partial^\mu\phi^*\right). \tag{0.17}$$

При сдвигах (трансляциях) мы имеем

$$\phi'\left(x'\right)=\phi(x)\quad\Rightarrow\quad\phi'(x)=\phi(x-a), \tag{0.18}$$

следовательно

$$\delta_{a^\mu}\phi=-a^\mu\partial_\mu\phi(x),\quad \delta_{a^\mu}\phi^*=-a^\mu\partial_\mu\phi^*(x), \tag{0.19}$$

а также

$$\delta_{a^\mu}\mathcal{L}=-a^\mu\partial_\mu\mathcal{L}=-a^\mu\partial_\nu\left(\delta^\nu_\mu\mathcal{L}\right) \tag{0.20}$$

откуда получаем, что

$$G^\nu_{a^\mu}=-a^\mu\delta^\nu_\mu\mathcal{L} \tag{0.21}$$

Таким образом для сохраняющегося тока находим (см. пункт (b))

$$j^\nu_{a^\mu}=\frac{\partial\mathcal{L}}{\partial\left(\partial_\nu\phi\right)}\delta_{a^\mu}\phi+\frac{\partial\mathcal{L}}{\partial\left(\partial_\nu\phi^*\right)}\delta_{a^\mu}\phi^*-G^\nu_{a^\mu}=$$
$$=\partial^\nu\phi^*\left(-a^\mu\partial_\mu\phi\right)+\partial^\nu\phi\left(-a^\mu\partial_\mu\phi\right)+a^\mu\delta^\nu_\mu\mathcal{L}=$$
$$=-a^\mu\left(\partial^\nu\phi^*\partial_\mu\phi+\partial_\mu\phi^*\partial^\nu\phi-\delta^\nu_\mu\mathcal{L}\right). \tag{0.22}$$

Эти сохраняющиеся токи называются тензором энергии-импульса

$$T_{\mu\nu}=\partial_\nu\phi^*\partial_\mu\phi+\partial_\mu\phi^*\partial_\nu\phi-\eta_{\mu\nu}\left(\partial^\lambda\phi^*\partial_\lambda\phi-V(|\phi|)\right). \tag{0.23}$$

Заметим, что

$$T^{00}=\dot\phi^*\dot\phi+\partial_i\phi^*\partial_i\phi+V(|\phi|)=\mathcal{H}=\ \left(\text{Гамильтонова плотность}\ \right). \tag{0.24}$$

При масштабных преобразованиях мы имеем

$$x' = \lambda x, \quad \phi'(x') = \lambda^{-1}\phi(x), \tag{0.25}$$

следовательно $d^4x' = \lambda^4 d^4x$, следовательно для инвариантности действия нам нужно, чтобы $\mathcal{L}' = \lambda^{-4}\mathcal{L}$. С другой стороны мы имеем

$$\mathcal{L}' = \lambda^{-4}\partial_\mu\phi^*\partial^\mu\phi - V\left(\lambda^{-1}|\phi|\right), \tag{0.26}$$

следовательно мы должны потребовать

$$V\left(\lambda^{-1}|\phi|\right) = \lambda^{-4}V(|\phi|) \tag{0.27}$$

откуда получаем, что

$$V(|\phi|) \sim |\phi|^4 \tag{0.28}$$

и в нашей теории не должно быть никакого массово члена $\sim |\phi|^2$. Для того чтобы найти Нетеровский ток рассмотрим вариацию

$$\delta\phi(x) = \phi'(x) - \phi(x) = \lambda^{-1}\phi\left(\lambda^{-1}x\right) - \phi(x). \tag{0.29}$$

Если $\lambda = 1 + \delta\lambda$, то мы получим

$$\delta\phi(x) = -\delta\lambda\left(\phi(x) + x^\mu\partial_\mu\phi(x)\right). \tag{0.30}$$

И аналогично

$$\partial'_\mu\phi'(x') = \lambda^{-1}\frac{\partial}{\partial(\lambda x)^\mu}\phi(x) = \lambda^{-2}\partial_\mu\phi(x) \tag{0.31}$$

следовательно

$$\delta\left(\partial_\mu\phi(x)\right) = \lambda^{-2}\partial_\mu\phi\left(\lambda^{-1}x\right) - \phi(x) = -\delta\lambda\left(2\partial_\mu\phi(x) + x^\nu\partial_\mu\partial_\nu\phi(x)\right). \tag{0.32}$$

Таким образом мы получаем

$$\begin{aligned}\delta\mathcal{L} &= \partial^\mu\phi^*(-\delta\lambda)\left(2\partial_\mu\phi + x^\nu\partial_\mu\partial_\nu\phi\right) + \partial^\mu\phi(-\delta\lambda)\left(2\partial^\mu\phi^* + x^\nu\partial_\mu\partial_\nu\phi^*\right) - 2V(|\phi|)(-\delta\lambda)\left(2 + x^\nu\partial_\nu\log|\phi|^2\right) = \\ &= -4\delta\lambda\left(\partial^\mu\phi^*\partial_\mu\phi - V(|\phi|)\right) - \delta\lambda x^\nu\partial_\nu\left(\partial^\mu\phi^*\partial_\mu\phi\right)\left(\partial^\mu\phi^*\partial_\mu\phi - V(|\phi|)\right) = -\delta\lambda\partial_\nu\left(x^\nu\left(\partial^\mu\phi^*\partial_\mu\phi - V(|\phi|)\right)\right)\end{aligned} \tag{0.33}$$

Откуда мы получаем

$$G^\mu = -x^\mu\left(\partial^\nu\phi^*\partial_\nu\phi - V(|\phi|)\right). \tag{0.34}$$

И для тока имеем

$$\begin{aligned}j^\mu &= -\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi\right)}\left(\phi + x^\nu\partial_\nu\phi\right) - \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi^*\right)}\left(\phi^* + x^\nu\partial_\nu\phi^*\right) - G^\mu = \\ &= -\partial^\mu\phi^*\left(\phi + x^\nu\partial_\nu\phi\right) - \partial^\mu\phi\left(\phi^* + x^\nu\partial_\nu\phi^*\right) + x^\mu\left(\partial^\nu\phi^*\partial_\nu\phi - V(|\phi|)\right).\end{aligned} \tag{0.35}$$

В терминах $T^{\mu\nu}$ находим

$$j^\mu = -x_\nu T^{\mu\nu} - \partial^\mu|\phi|^2. \tag{0.36}$$

Используя тот факт, что $\partial_\mu|\phi|^2$ можно записать как

$$\partial_\mu|\phi|^2 = -\frac{1}{3}x^\nu\left(\partial_\mu\partial_\nu - \eta_{\mu\nu}\partial^2\right)|\phi|^2 + \frac{1}{3}\partial^\rho\left(\left(x_\rho\partial_\mu - x_\mu\partial_\rho\right)|\phi|^2\right), \tag{0.37}$$

мы можем переписать ток в виде

$$j^\mu = -x_\nu\hat{T}^{\mu\nu} - \frac{1}{3}\partial_\rho\left(\left(x^\rho\partial^\mu - x^\mu\partial^\rho\right)|\phi|^2\right), \quad \hat{T}^{\mu\nu} = T^{\mu\nu} - \frac{1}{3}\left(\partial^\mu\partial^\nu - \eta^{\mu\nu}\partial^2\right)|\phi|^2. \tag{0.38}$$

Добавки которые получили ток и тензор энергии-импульса называются улучшающими членами ("improvement terms").

(d). В данном случае мы имеем

$$\phi'(x) = \phi\left(x^\mu - \omega^\mu{}_\nu x^\nu\right) = \phi(x) - \omega^\mu{}_\nu x^\nu \partial_\mu \phi(x),$$
$$\partial_\mu \phi'(x) = \partial_\mu \phi(x) - \omega^\lambda_\nu x^\nu \partial_\mu \partial_\lambda \phi(x) - \omega^\lambda{}_\mu \partial_\lambda \phi(x). \tag{0.39}$$

Таким образом с одной стороны для Лагранжевой плотности мы получаем

$$\mathcal{L}\left(\phi'(x), \partial_\mu \phi'(x)\right) = \mathcal{L}\left(\phi(x), \partial_\mu \phi(x)\right) - \frac{\partial \mathcal{L}}{\partial \phi}\omega^\mu{}_\nu x^\nu \partial_\mu \phi - \frac{\partial \mathcal{L}}{\partial\left(\partial_\mu \phi\right)}\omega^\lambda{}_\nu x^\nu \partial_\mu \partial_\lambda \phi - \frac{\partial \mathcal{L}}{\partial\left(\partial_\mu \phi\right)}\omega^\lambda{}_\mu \partial_\lambda \phi. \tag{0.40}$$

С другой стороны

$$\mathcal{L}\left(x^\mu - \omega^\mu{}_\nu x^\nu\right) = \mathcal{L}(x) - \omega^\mu{}_\nu x^\nu \partial_\mu \mathcal{L}. \tag{0.41}$$

Откуда получим

$$\omega^\mu{}_\nu x^\nu \partial_\mu \mathcal{L} = \frac{\partial \mathcal{L}}{\partial \phi}\omega^\mu{}_\nu x^\nu \partial_\mu \phi + \frac{\partial \mathcal{L}}{\partial\left(\partial_\mu \phi\right)}\omega^\lambda{}_\nu x^\nu \partial_\mu \partial_\lambda \phi + \frac{\partial \mathcal{L}}{\partial\left(\partial_\mu \phi\right)}\omega^\lambda{}_\mu \partial_\lambda \phi \tag{0.42}$$

Далее используя уравнение движения (Эйлера-Лагранжа):

$$\frac{\partial \mathcal{L}}{\partial \phi} = \partial_\lambda \frac{\partial \mathcal{L}}{\partial\left(\partial_\lambda \phi\right)} \tag{0.43}$$

можно получить

$$\omega^\mu{}_\nu \left(\partial_\lambda \frac{\partial \mathcal{L}}{\partial\left(\partial_\lambda \phi\right)} x^\nu \partial_\mu \phi + \frac{\partial \mathcal{L}}{\partial\left(\partial_\lambda \phi\right)} x^\nu \partial_\mu \partial_\lambda \phi + \frac{\partial \mathcal{L}}{\partial\left(\partial_\nu \phi\right)} \partial_\mu \phi - x^\nu \partial_\mu \mathcal{L}\right) = 0. \tag{0.44}$$

Далее заметим, что полученное выражение можно записать в виде

$$\omega^\mu{}_\nu \partial_\lambda \left(x^\nu \left(\frac{\partial \mathcal{L}}{\partial\left(\partial_\lambda \phi\right)} \partial_\mu \phi - \delta^\lambda_\mu \mathcal{L}\right)\right) = \omega_{\mu\nu} \partial_\lambda \left(x^\nu T^{\lambda\mu}\right) = 0 \tag{0.45}$$

Так как $\omega_{\mu\nu} = -\omega_{\nu\mu}$ мы можем окончательно записать

$$\omega_{\mu\nu} \partial_\lambda \left(x^\nu T^{\lambda\mu} - x^\mu T^{\lambda\nu}\right) = 0. \tag{0.46}$$

Это равенство выполняется для произвольного антисимметричного $\omega_{\mu\nu}$, следовательно мы получаем сохраняющийся Нетеровский ток

$$M^{\lambda\mu\nu} = x^\mu T^{\lambda\nu} - x^\nu T^{\lambda\mu} \tag{0.47}$$

Заметим, что то, что данный ток сохраняется сразу дает ответ на пункт (f), так как

$$0 = \partial_\lambda M^{\lambda\mu\nu} = T^{\mu\nu} - T^{\nu\mu} \tag{0.48}$$

но мы решим пункт (f) похожим, но немного другим способом.
(e). В данном случае для векторного поля A_μ мы получаем

$$A'_\mu(x) = \left(\delta^\nu_\mu + \omega^\nu_\mu\right) A_\nu\left(x^\lambda - \omega^\lambda_\rho x^\rho\right) = A_\mu(x) - \omega^\lambda_\rho x^\rho \partial_\lambda A_\mu(x) + \omega_\mu{}^\nu A_\nu(x),$$
$$\partial_\nu A'_\mu(x) = \partial_\nu A_\mu(x) - \omega^\lambda_\nu \partial_\lambda A_\mu(x) - \omega^\lambda_\rho x^\rho \partial_\lambda \partial_\nu A_\mu(x) + \omega_\mu{}^\lambda \partial_\nu A_\lambda(x). \tag{0.49}$$

Ход решения аналогичен пункту (d), за исключением того, что векторное поле приобретает дополнительные поправки, связанные с "векторностью", или можно сказать, связанные со спином $s = 1$. Лагранжева плотность, являясь скаляром, преобразуется как и раньше:

$$\mathcal{L}\left(x^\mu - \omega^\mu{}_\nu x^\nu\right) = \mathcal{L}(x) - \omega^\mu{}_\nu x^\nu \partial_\mu \mathcal{L}. \tag{0.50}$$

Далее следуя ходу решения задачи (d) получаем

$$0 = -\omega_{\mu\nu} \partial_\lambda \left(x^\nu T^{\lambda\mu} - x^\mu T^{\lambda\nu}\right) + \frac{\partial \mathcal{L}}{\partial A_\mu}\omega_\mu{}^\lambda A_\lambda + \frac{\partial \mathcal{L}}{\partial\left(\partial_\nu A_\mu\right)}\omega_\mu{}^\lambda \partial_\nu A_\lambda \tag{0.51}$$

Используя уравнения движения

$$\frac{\partial \mathcal{L}}{\partial A_\mu} = \partial_\sigma \frac{\partial \mathcal{L}}{\partial \left(\partial_\sigma A_\mu\right)} \tag{0.52}$$

находим $\left(\omega_\mu{}^\lambda = -\omega^\lambda{}_\mu\right)$

$$\begin{aligned} 0 &= -\omega_{\mu\nu}\partial_\lambda \left(x^\nu T^{\lambda\mu} - x^\mu T^{\lambda\nu}\right) - \omega^\lambda{}_\mu \left(\partial_\sigma \frac{\partial \mathcal{L}}{\partial \left(\partial_\sigma A_\mu\right)} A_\lambda + \frac{\partial \mathcal{L}}{\partial \left(\partial_\nu A_\mu\right)} \partial_\nu A_\lambda\right) = \\ &= -\omega_{\mu\nu}\partial_\lambda \left(x^\nu T^{\lambda\mu} - x^\mu T^{\lambda\nu} + \frac{\partial \mathcal{L}}{\partial \left(\partial_\lambda A_\mu\right)} A^\nu - \frac{\partial \mathcal{L}}{\partial \left(\partial_\lambda A_\nu\right)} A^\mu\right). \end{aligned} \tag{0.53}$$

Откуда получаем

$$M^{\lambda\mu\nu} = x^\mu T^{\lambda\mu} - x^\nu T^{\lambda\mu} + S^{\lambda\mu\nu} = x^\mu T^{\lambda\mu} - x^\nu T^{\lambda\mu} + \frac{\partial \mathcal{L}}{\partial \left(\partial_\lambda A_\nu\right)} A^\mu - \frac{\partial \mathcal{L}}{\partial \left(\partial_\lambda A_\mu\right)} A^\nu \tag{0.54}$$

Изначально задача была сформулирована в очень замысловатом варианте: $M^{\lambda\mu\nu} = x^\mu \Theta^{\lambda\nu} - x^\nu \Theta^{\lambda\mu}$, где $\Theta^{\mu\nu} = T^{\mu\nu} + S^{\mu\nu}$ тензор Белинфанте. Такой подход осложняет понимание материала и может быть найден в книге Вайнберга 1 том п. 7.

(f). В данном случае мы имеем

$$\begin{aligned} &\phi'\left(x'\right) = \phi(x), \\ &\partial'_\mu \phi'\left(x'\right) = \partial_\mu \phi(x) - \omega^\nu{}_\mu \partial_\nu \phi(x). \end{aligned} \tag{0.55}$$

Тогда получим

$$0 = \mathcal{L}\left(\phi'\left(x'\right), \partial'_\mu \phi'\left(x'\right)\right) - \mathcal{L}\left(\phi(x), \partial_\mu \phi(x)\right) = -\frac{\partial \mathcal{L}}{\partial \left(\partial_\mu \phi\right)} \omega^\nu{}_\mu \partial_\nu \phi = -\omega_{\nu\mu}\left(T^{\mu\nu} - T^{\nu\mu}\right), \tag{0.56}$$

откуда

$$T^{\mu\nu} = T^{\nu\mu} \tag{0.57}$$

МФТИ-Киселев-2020.**3**.^{C}

Найти поток частиц с релятивистской нормировкой состояний

$$\left\langle \boldsymbol{k} | \boldsymbol{k}' \right\rangle = 2\epsilon(\boldsymbol{k})(2\pi)^3 \delta\left(\boldsymbol{k} - \boldsymbol{k}'\right)$$

Solution

Релятивистская нормировка задает число частиц, которое равно

$$\mathcal{N} = \langle \boldsymbol{k} | \boldsymbol{k} \rangle = 2\varepsilon(\boldsymbol{k})(2\pi)^3 \delta(\boldsymbol{k})\big|_{k=0} = 2\varepsilon(\boldsymbol{k}) V_{[3]}$$

Для свободных частиц вектор потока направлен по волновому вектору $j = j \cdot n$, где $n = \boldsymbol{k}/k$. Тогда за время $T \to \infty$ через площадь $S = S \cdot n$ с нормалью, параллельной потоку, пройдет число частиц

$$\mathcal{N} = j \cdot ST = jST$$

Но если v - скорость движения частицы, то

$$T = \frac{L}{v}, \quad V_{[3]} = SL$$

и, следовательно,

$$\mathcal{N} = \frac{1}{v} j V_{[3]}$$

а значит,

$$j = 2\varepsilon(k) \cdot v$$

26.1.2 Problems about free quantum fields 1

Stanford.exam-2022.1/5. Field uncertainties. (10/40p)

Quantum field theories have states with definite numbers of particles, in analogy with the number states $|n\rangle$ of a quantum harmonic oscillator. However, there also exist states with definite field profiles, in analogy with the position states $|x\rangle$. A general state is a superposition of such field eigenstates, and thus can have an uncertain field value.

a) Consider a free real scalar field ϕ of mass m in the vacuum state. The variance of the field value at $\mathbf{x}$ is

$$\sigma^2_{\phi(\mathbf{x})} = \left\langle 0 \left| \phi(\mathbf{x})^2 \right| 0 \right\rangle - (\langle 0|\phi(\mathbf{x})|0\rangle)^2.$$

Show that this quantity is infinite.

b) There's nothing wrong with the result in part (a), because in practice we can never measure the field value at a point. We only measure "smeared" field values averaged over some length scale a, such as

$$\phi_a(\mathbf{x}) = \frac{1}{a^3\pi^{3/2}} \int d^3y \phi(\mathbf{y}) e^{-|\mathbf{x}-\mathbf{y}|^2/a^2}.$$

Write $\sigma^2_{\phi_a(\mathbf{x})}$ in the form of an integral over a single variable.

c) The standard deviation of the smeared field is finite. Find expressions for $\sigma^2_{\phi_a(\mathbf{x})}$ in the limits $a \ll 1/m$ and $a \gg 1/m$.

(Hint: in each regime, your answer should have the form αa^β for some values of α and β. If you're having trouble doing the final integral in one of these cases, you can start from the result $\int_{-\infty}^{\infty} e^{-x^2} dx = \sqrt{\pi}$.)

d) Consider a cubical copper microwave cavity of volume $V = 1\ \mathrm{m}^3$. The electric field in the cavity does not have a definite value, due to the quantization of the electromagnetic field. Find a rough, order of magnitude estimate for the standard deviation of the average electric field in the cavity in its ground state, and evaluate it in volts per meter. (Hint: you will need to go from natural units back to SI units using $\hbar = 10^{-34}\mathrm{Js}, c = 3 \times 10^8$ m/s, and $e = 1.6 \times 10^{-19}\mathrm{C}$.)

Solution a)

The expectation value is

$$\langle 0|\phi(\mathbf{x})|0\rangle = 0$$

while the expectation value of the square is

$$\begin{aligned}
\left\langle 0 \left| \phi(\mathbf{x})^2 \right| 0 \right\rangle &= \int \frac{d\mathbf{p}}{(2\pi)^3} \frac{d\mathbf{q}}{(2\pi)^3} \frac{1}{\sqrt{2E(\mathbf{p})}\sqrt{2E(\mathbf{q})}} \\
&\quad \times \langle 0| \left(a(\mathbf{p}) e^{i\mathbf{x}\cdot\mathbf{p}} + a^\dagger(\mathbf{p}) e^{-i\mathbf{x}\cdot\mathbf{p}} \right) \left(a(\mathbf{q}) e^{i\mathbf{x}\cdot\mathbf{q}} + a^\dagger(\mathbf{q}) e^{-i\mathbf{x}\cdot\mathbf{q}} \right) \\
&= \int \frac{d\mathbf{p}}{(2\pi)^3} \frac{d\mathbf{q}}{(2\pi)^3} \frac{1}{\sqrt{2E(\mathbf{p})}\sqrt{2E(\mathbf{q})}} \left\langle 0 \left| a(\mathbf{p}) a^\dagger(\mathbf{q}) e^{i\mathbf{x}\cdot(\mathbf{p}-\mathbf{q})} \right| 0 \right\rangle \\
&= \int \frac{d\mathbf{p}}{(2\pi)^3} \frac{d\mathbf{q}}{(2\pi)^3} \frac{1}{\sqrt{2E(\mathbf{p})}\sqrt{2E(\mathbf{q})}} (2\pi)^3 \delta^{(3)}(\mathbf{p}-\mathbf{q}) e^{i\mathbf{x}\cdot(\mathbf{p}-\mathbf{q})} \\
&= \int \frac{d\mathbf{p}}{(2\pi)^3} \frac{1}{2E(\mathbf{p})} \\
&= \frac{1}{2\pi^2} \int_0^\infty d|\mathbf{p}| \frac{|\mathbf{p}|^2}{\sqrt{|\mathbf{p}|^2 + m^2}}
\end{aligned}$$

which is infinite.

Solution b)

The expectation value still vanishes, but now we have

$$\begin{aligned}\left\langle 0\left|\phi_a(\mathbf{x})^2\right|0\right\rangle &= \frac{1}{a^6\pi^3}\int d\mathbf{y}d\mathbf{z}e^{-\frac{|\mathbf{x}-\mathbf{y}|^2}{a^2}}e^{-\frac{|\mathbf{x}-\mathbf{z}|^2}{a^2}}\langle 0|\phi(\mathbf{y})\phi(\mathbf{z})|0\rangle \\ &= \frac{1}{a^6\pi^3}\int d\mathbf{y}d\mathbf{z}\frac{d\mathbf{p}}{(2\pi)^3}\frac{1}{2E(\vec{p})}e^{i\mathbf{p}(\mathbf{y}-\mathbf{z})}e^{-\frac{|\mathbf{x}-\mathbf{y}|^2}{a^2}}e^{-\frac{|\mathbf{x}-\mathbf{z}|^2}{a^2}}.\end{aligned}$$

Next, we perform the shifts $\mathbf{z}\to \mathrm{z}+\mathrm{x}$ and $\mathbf{y}\to\mathbf{y}+\mathrm{x}$. Then the integral

$$\begin{aligned}\int d\mathbf{y}e^{i\mathbf{p}(\mathbf{y})}e^{-\frac{|\mathbf{y}|^2}{a^2}} &= \int d\mathbf{y}e^{i|\mathbf{p}||\mathbf{y}|\cos\theta}e^{-\frac{|\mathbf{y}|^2}{a^2}} \\ &= (2\pi)\int_0^\infty d|\mathbf{y}||\mathbf{y}|^2\int_{-1}^1 d\cos\theta|\mathbf{y}|e^{i|\mathbf{p}|\cos\theta}e^{-\frac{|\mathbf{y}|^2}{a^2}} \\ &= \frac{(4\pi)}{|\mathbf{p}|}\int_0^\infty d|\mathbf{y}||\mathbf{y}|\sin(|\mathbf{y}||\mathbf{p}|)e^{-\frac{|\mathbf{y}|^2}{a^2}} \\ &= a^3\pi^{3/2}e^{-\frac{|\mathbf{p}|^2a^2}{4}}\end{aligned}$$

Inserting this above, we find

$$\left\langle 0\left|\phi_a(\mathbf{x})^2\right|0\right\rangle = \int\frac{d\mathbf{p}}{(2\pi)^3}\frac{1}{2E(\vec{p})}e^{-\frac{|\mathbf{p}|^2a^2}{2}}$$

Simplifying, we thus conclude that

$$\sigma^2_{\phi_a(\mathbf{x})} = \left\langle 0\left|\phi_a(\mathbf{x})^2\right|0\right\rangle = \frac{1}{4\pi^2}\int_0^\infty d|\mathbf{p}|\frac{|\mathbf{p}|^2}{\sqrt{|\mathbf{p}|^2+m^2}}e^{-\frac{|\mathbf{p}|^2a^2}{2}}$$

Solution c)

Changing to the variable $t=a|\mathbf{p}|$, we have

$$\sigma^2_{\phi_a(\mathbf{x})} = \frac{1}{4\pi^2a^2}\int_0^\infty dt\frac{t^2}{\sqrt{t^2+a^2m^2}}e^{-\frac{t^2}{2}}$$

Expanding around $ma\ll 1$, we find

$$\lim_{ma\to 0}\sigma^2_{\phi_a(\mathbf{x})} = \frac{1}{4\pi^2a^2}\int_0^\infty dtte^{-\frac{t^2}{2}} = \frac{1}{4\pi^2a^2}.$$

Expanding around $ma\gg 1$, we find

$$\lim_{1/(ma)\to 0}\sigma^2_{\phi_a(\mathbf{x})} = \frac{1}{4\pi^2a^3m}\int_0^\infty dtt^2e^{-\frac{t^2}{2}} = \frac{1}{4\pi^{3/2}a^3m\sqrt{2}}.$$

Solution d)

In part (c), we showed that for a massless vector field, the standard deviation of the field average over a region of size a is $\sigma\sim 1/a$. The same logic applies to a massless vector field A_μ. The electric field in the cavity is related to A_μ by one spatial or temporal derivative, which by dimensional analysis also gives a factor of $1/a$. Thus, we expect $\sigma_E\sim 1/a^2\sim 1/V^{2/3}$. (We could also have jumped directly to this result. We already know $[E]=2$ from problem set 1, and part (**c**) tells us the answer is neither zero nor infinity, so by dimensional analysis, $1/a^2$ is the only possible answer.)

Going from natural units back to SI units, we have

$$\sigma_E \sim \frac{\hbar c}{e a^2} \sim 10^{-7}\ \text{V/m}.$$

This might be surprisingly large if you haven't seen it before, but it lines up with typical "quantum noise" scales in precision electronics. Any answer within a few orders of magnitude of this is acceptable.

Белавин-Пархоменко.2. Квантование поля Клейна-Гордона и эффект Казимира

Квантование комплексного поля Клейна-Гордона (задача 2.2. П-Ш) (50 баллов)

Рассмотрим комплексное скалярное поле $\phi(x)$ с действием

$$S = \int d^4x \left(\partial^\mu \phi^* \partial_\mu \phi - m^2 \phi^* \phi\right) \tag{0.1}$$

(a). Найдите сопряженные импульсы к $\phi(x)$ и $\phi^*(x)$ и канонические коммутационные соотношения. Покажите, что Гамильтониан дается формулой

$$H = \int d^3x \left(\pi^* \pi + \nabla \phi^* \cdot \nabla \phi + m^2 \phi^* \phi\right). \tag{0.2}$$

Вычислите Гейзенберговское уравнение движения для поля $\phi(x)$ и покажите, что это действительно уравнение движения для поля Клейна-Гордона.

(b). Диагонализуйте H введя операторы рождения и уничтожения:

$$\phi(x) = \int \frac{d^3p}{(2\pi)^3 \sqrt{2E_p}} \left(a_p e^{-ipx} + b_p^\dagger e^{ipx}\right), \quad E_p = \sqrt{p^2 + m^2}. \tag{0.3}$$

Покажите, что теория содержит два набора частиц массой m.

(c). Перепишите сохраняющийся заряд

$$Q = \int d^3x \frac{i}{2} \left(\phi^* \pi^* - \pi \phi\right) \tag{0.4}$$

в терминах операторов рождения и уничтожения и вычислите заряд частиц каждого типа.

(d). Рассмотрите случай двух комплексных полей Клейна-Гордона одинаковой массы. Обозначим поля ϕ_a, где $a = 1, 2$. Покажите, что теперь есть четыре сохраняющихся заряда. Один дается обобщением части (c), а другие три даются формулой

$$Q^i = \int d^3x \frac{i}{2} \left(\phi_a^* \left(\sigma^i\right)_{ab} \pi_b^* - \pi_a \left(\sigma^i\right)_{ab} \phi_b\right), \tag{0.5}$$

где σ^i матрицы Паули. Обобщите результат на случай n комплексных скалярных полей. Для решения этой задачи, нужно вспомнить из первой лекции, что сохраняющиеся заряды получаются из сохраняющихся токов, а те в свою очередь по теореме Нетер возникают вследствие некоторой симметрии. В данном случае мы имеем дело с симметрией $U(n) = U(1) \times SU(n)$:

$$\phi_a(x) \to \phi'_a(x) = U_{ab} \phi_b(x). \tag{0.6}$$

Сохраняющийся заряд для $U(1)$ это заряд в пункте (c). Для группы $SU(n)$ введем генераторы симметрии $\left(T^i\right)_{ab}$, тогда

$$\delta \phi_a = i \alpha^i \left(T^i\right)_{ab} \phi_b, \quad \delta \phi_a^* = -i \alpha^i \phi_b^* \left(T^i\right)_{ba}, \tag{0.7}$$

Дальше постарайтесь продолжить сами.

2 Эффект Казимира (50 баллов)

(a). В данной задаче мы изучим немного иной подход (чем который был на лекции) к эффекту Казимира. Рассмотрите безмассовое скалярное поле в пространстве размерности $d+1$. Пусть само пространство представляет из себя огромный d-мерный куб с длиной стороны D (+ время). В этом пространстве находятся две пластины на расстоянии L друг от друга. Выберем координаты так, чтобы одна пластина находилась в $x_1 = 0$, а вторая в $x_1 = L$. Мы подразумеваем отражающие граничные условия для поля

$$\phi(\vec{x}, t) = 0, \quad \text{при} \quad x_1 = 0, L. \tag{0.8}$$

Также будем считать, что $\phi(\vec{x}, t) = \phi(\vec{x} + D\vec{n}, t)$, где $\vec{n} = (1, 0, ...0)$, то есть у нас переодические граничные условия на гранях огромного ($D \gg L$, в силу этого условия считайте, что спектр вне пластин и вдоль пластин непрерывный) пространства-куба. Таким образом полная энергия вакуума складывается из энергии вакуума между пластинами $E(L)$ и из энергии вакуума вне пластин $E(D-L)$:

$$E = E(L) + E(D - L). \tag{0.9}$$

Покажите, что энергия Казимира на единицу площади дается формулой (здесь A это площадь)

$$\frac{E(L)}{A} = -\frac{\Gamma(-d/2)\zeta(-d)}{2(4\pi)^{d/2}} \left(\frac{\pi}{L}\right)^d \tag{0.10}$$

При вычислении используйте регуляризацию дзета-функцией:

$$\zeta(s) = \sum_{n=1}^{\infty} n^{-s} \tag{0.11}$$

Например: $\zeta(-1) = \sum\limits_{n=1}^{\infty} n = -\frac{1}{12}$, (не удивляйтесь, это формальный математический метод регуляризации, часто оказывающийся весьма удобным). Также Г-функция определяется как

$$\Gamma(x) = \int_0^{\infty} t^{x-1} e^{-t} dt \tag{0.12}$$

Объясните почему наличие квантового поля приводит к силе между пластинами.
(b). Изучите эффект Казимира в трех пространственных измерениях для поля Клейна-Гордона в случае когда масса m не равна нулю. Граничные условия для ϕ и ход решения точно такие же как на лекции. Используйте, выведенную на лекции, формулу Абеля-Плана:

$$\sum_{n=1}^{\infty} f(n) - \int_0^{\infty} f(\tau) d\tau = -\frac{1}{2} f(0) + i \int_0^{\infty} dt \frac{f(it) - f(-it)}{e^{2\pi t} - 1} \tag{0.13}$$

(из которой в свою очередь получалась формула Эйлера-Маклорена). Обратите внимание на то, что у подынтегральной функции есть точки ветвления и поэтому $f(it)$ не на всей области интегрирования равна $f(-it)$. Найдите силу на единицу площади $F(a, m)$, где a - растояние между пластинами (не ожидайте, что ответ будет элементарной функцией!) Найдите асимптотики $F(a, m)$ для $am \ll 1$ и $am \gg 1$. (Обратите внимание, что если в этой задаче наивно использовать формулу Эйлера-Маклорена, а не Абеля-Плана, то мы получим для энергии Казимира ноль, что очевидно физически неверно!)

Белавин-Пархоменко.2. Квантование поля Клейна-Гордона и эффект Казимира Решения

Квантование комплексного поля Клейна-Гордона (задача 2.2. П-Ш) (50 баллов)

$$S = \int d^4x \left(\partial^\mu \phi^* \partial_\mu \phi + m^2 |\phi|^2\right) \tag{0.1}$$

получаем

$$\pi = \frac{\delta S}{\delta \dot{\phi}} = \dot{\phi}^*, \quad \pi^* = \frac{\delta S}{\delta \dot{\phi}^*} = \dot{\phi} \tag{0.2}$$

Для Гамильтониана находим

$$\mathcal{H}(x)=\int d^3x\left(\pi^*\cdot\pi+\nabla\phi^*\cdot\nabla\phi+m^2|\phi|^2\right) \tag{0.3}$$

Используем

$$[\phi(x),\pi(y)]|_{x^0=y^0}=i\delta^{(3)}(\vec{x}-\vec{y}) \tag{0.4}$$

и получаем

$$\begin{aligned}\dot{\pi}\left(x^0,\vec{x}\right)&=-i\left[\pi\left(x^0,\vec{x}\right),\int d^3y\left(\pi^*\left(x^0,\vec{y}\right)\pi\left(x^0,\vec{y}\right)+\nabla\phi^*\left(x^0,\vec{y}\right)\nabla\phi\left(x^0,\vec{y}\right)+m^2\left|\phi\left(x^0,\vec{y}\right)\right|^2\right)\right]=\\&=-i\int d^3y\left(-\nabla^2\phi^*\left(x^0,\vec{y}\right)(-i)\delta^{(3)}(\vec{x}-\vec{y})-im^2\phi^*\left(x^0,\vec{y}\right)\delta^{(3)}(\vec{x}-\vec{y})\right)=\\&=\left(\nabla^2-m^2\right)\phi^*\left(x^0,\vec{x}\right).\end{aligned} \tag{0.5}$$

В итоге находим $\left(\dot{\pi}=\ddot{\phi}^*\right)$

$$\ddot{\phi}^*-\nabla^2\phi^*+m^2\phi^*=\left(-\partial^2+m^2\right)\phi^*=0. \tag{0.6}$$

(b). Так как $\phi(x)$ комплексное поле, то в его разложении по модам участвуют два разных типа оператора рождения и уничтожения a_p,b_p:

$$\phi(x)=\int\frac{d^3p}{(2\pi)^3\sqrt{2E_{\vec{p}}}}\left(a_{\vec{p}}e^{i\vec{p}\vec{x}}+b^\dagger_{\vec{p}}e^{-i\vec{p}\vec{x}}\right) \tag{0.7}$$

Для импульса получаем

$$\pi(x)=i\int\frac{d^3p}{(2\pi)^3}\sqrt{\frac{E_{\vec{p}}}{2}}\left(a^\dagger_{\vec{p}}e^{-i\vec{p}\vec{x}}-b_{\vec{p}}e^{i\vec{p}\vec{x}}\right) \tag{0.8}$$

где коммутационные соотношения для операторов рождения и уничтожения даются формулами:

$$\left[a_{\vec{p}},a^\dagger_{\vec{q}}\right]=\left[b_{\vec{p}},b^\dagger_{\vec{q}}\right]=(2\pi)^3\delta^{(3)}(\vec{p}-\vec{q}) \tag{0.9}$$

Далее получаем (пусть $x^0=0$)

$$\begin{aligned}\int d^3x\pi^*(x)\pi(x)&=\int\frac{d^3xd^3pd^3q}{(2\pi)^6}\frac{\sqrt{E_{\vec{p}}E_{\vec{q}}}}{2}\left(a_{\vec{p}}e^{i\vec{p}\vec{x}}-b^\dagger_{\vec{p}}e^{-i\vec{p}\vec{x}}\right)\left(a^\dagger_{\vec{q}}e^{-i\vec{q}\vec{x}}-b_{\vec{q}}e^{i\vec{q}\vec{x}}\right)=\\&=\int\frac{d^3p}{(2\pi)^3}\frac{E_{\vec{p}}}{2}\left(a_{\vec{p}}a^\dagger_{\vec{p}}-a_{\vec{p}}b_{-\vec{p}}-b^\dagger_{\vec{p}}a^\dagger_{-\vec{p}}+b^\dagger_{\vec{p}}b_{\vec{p}}\right),\\\int d^3x\nabla\phi^*(x)\nabla\phi(x)&=\int\frac{d^3xd^3pd^3q}{(2\pi)^6}\frac{1}{2\sqrt{E_{\vec{p}}E_{\vec{q}}}}\left(-ia^\dagger_{\vec{p}}\vec{p}e^{-i\vec{p}\vec{x}}+i\vec{p}b_{\vec{p}}e^{i\vec{p}\vec{x}}\right)\left(i\vec{q}a_{\vec{q}}e^{i\vec{q}\vec{x}}-i\vec{q}b^\dagger_{\vec{q}}e^{-i\vec{q}\vec{x}}\right)=\\&=\int\frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\vec{p}}}\left(\vec{p}^2a^\dagger_{\vec{p}}a_{\vec{p}}+\vec{p}^2a^\dagger_{\vec{p}}b^\dagger_{-\vec{p}}+\vec{p}^2b_{\vec{p}}a_{-\vec{p}}+\vec{p}^2b_{\vec{p}}b^\dagger_{\vec{p}}\right),\\\int d^3xm^2|\phi|^2&=\int\frac{d^3xd^3pd^3q}{(2\pi)^6}\frac{m^2}{2\sqrt{E_{\vec{p}}E_{\vec{p}}}}\left(a^\dagger_{\vec{p}}a_{\vec{p}}+a^\dagger_{\vec{p}}b^\dagger_{-\vec{p}}+b_{\vec{p}}a_{-\vec{p}}+b_{\vec{p}}b^\dagger_{\vec{p}}\right).\end{aligned} \tag{0.10}$$

В итоге получаем для Гамильтониана

$$\begin{aligned}H&=\int\frac{d^3p}{(2\pi)^3}\left[\frac{E_{\vec{p}}}{2}\left(a_{\vec{p}}a^\dagger_{\vec{p}}+a^\dagger_{\vec{p}}a_{\vec{p}}+b^\dagger_{\vec{p}}b_{\vec{p}}+b_{\vec{p}}b^\dagger_{\vec{p}}\right)+\frac{E_{\vec{p}}}{2}\left(a^\dagger_{\vec{p}}b^\dagger_{-\vec{p}}+b_{\vec{p}}a_{-\vec{p}}-a_{-\vec{p}}b_{\vec{p}}-b^\dagger_{-\vec{p}}a^\dagger_{\vec{p}}\right)\right]=\\&=\int\frac{d^3p}{(2\pi)^3}E_{\vec{p}}\left(a^\dagger_{\vec{p}}a_{\vec{p}}+b^\dagger_{\vec{p}}b_{\vec{p}}\right)+(\text{ бесконечная константа }),\end{aligned} \tag{0.11}$$

где $E_{\vec{p}}=\sqrt{p^2+m^2}$. Таким образом теория описывает две частицы (a и b) массой m.

(c). Для заряда получаем

$$\begin{aligned}
Q &= \frac{i}{2}\int d^3x\phi^*\pi^* + (\text{ к.с. }) = \\
&= \frac{i}{2}\int \frac{d^3xd^3pd^3q}{(2\pi)^6}\frac{(-i)}{2}\sqrt{\frac{E_{\vec{q}t}}{E_{\vec{p}}}}\left(a^\dagger_{\vec{p}}e^{-i\vec{p}\vec{x}}+b_{\vec{p}}e^{i\vec{p}\vec{x}}\right)\left(a_{\vec{q}}e^{i\vec{q}\vec{x}}-b^\dagger_{\vec{q}}e^{-i\vec{q}\vec{x}}\right)+(\text{ к.с. }) = \\
&= \frac{1}{4}\int \frac{d^3p}{(2\pi)^3}\left(a^\dagger_{\vec{p}}a_{\vec{p}}-a^\dagger_{\vec{p}}b^\dagger_{-\vec{p}}+b_{\vec{p}}a_{-\vec{p}}-b_{\vec{p}}b^\dagger_{\vec{p}}+a^\dagger_{\vec{p}}a_{\vec{p}}-b_{-\vec{p}}a_{\vec{p}}+a^\dagger_{-\vec{p}}b^\dagger_{\vec{p}}-b_{\vec{p}}b^\dagger_{\vec{p}}\right) = \\
&= \frac{1}{2}\int \frac{d^3p}{(2\pi)^3}\left(a^\dagger_{\vec{p}}a_{\vec{p}}-b^\dagger_{\vec{p}}b_{\vec{p}}\right)+(\text{ бесконечная константа }).
\end{aligned} \tag{0.12}$$

В итоге получаем, что $Q(a)=\frac{1}{2}$ и $Q(b)=-\frac{1}{2}$.
(d). Итак вариации полей даются формулами

$$\delta\phi_a = i\alpha^i\left(T^i\right)_{ab}\phi_b,\quad \delta\phi^*_a = -i\alpha^i\phi^*_b\left(T^i\right)_{ba}. \tag{0.13}$$

Откуда для сохраняющегося тока получаем (см. решение Листка 1)

$$\begin{aligned}
j^\mu_i &= \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi_a\right)}\left(-i\left(T_i\right)_{ab}\phi_b\right)+(\text{ к.с. }) = \\
&= i\partial^\mu\phi^*_a\left(T_i\right)_{ab}\phi_b - i\phi^*_b\left(T_i\right)_{ba}\partial^\mu\phi_a.
\end{aligned} \tag{0.14}$$

В итоге получаем

$$Q_i = \int d^3xj^0_i = -i\int d^3x\dot{\phi}^*_a\left(T_i\right)_{ab}\phi_b + i\int d^3x\phi^*_b\left(T_i\right)_{ba}\dot{\phi}_a. \tag{0.15}$$

Далее замечая, что импульсы равны $\pi_a=\dot{\phi}^*_a, \pi^*_a=\dot{\phi}_a$, получаем для зарядов

$$Q_i = i\int d^3x\left[\phi^*_a\left(T_i\right)_{ab}\pi^*_b - \pi_a\left(T_i\right)_{ab}\phi_b\right] \tag{0.16}$$

В частном случае группы $SU(2)$ мы имеем

$$\left(T^i\right)_{ab} = \frac{1}{2}\left(\sigma^i\right)_{ab} \tag{0.17}$$

2 Эффект Казимира (50 баллов)

(a). Итак спектр поля между пластинами

$$\omega_{n,p_2,...,p_d} = \left[\left(\frac{\pi n}{L}\right)^2+p_2^2+...+p_d^2\right]^{1/2} = \left[\left(\frac{\pi n}{L}\right)^2+\vec{p}^{\,2}_{\|}\right]^{1/2},\quad n=1,2,3,... \tag{0.18}$$

Для энергии на единицу площади получаем

$$\begin{aligned}
\frac{E(L)}{A} &= \sum_{n=1}^{\infty}\int\frac{d^{d-1}p_{\|}}{(2\pi)^{d-1}}\frac{1}{2}\left[\left(\frac{\pi n}{L}\right)^2+\vec{p}^{\,2}_{\|}\right]^{1/2} = \\
&= \frac{1}{2}\sum_{n=1}^{\infty}\frac{\Omega_{d-1}}{(2\pi)^{d-1}}\int\limits_0^\infty p_{\|}^{d-2}dp_{\|}\left[\left(\frac{\pi n}{L}\right)^2+\vec{p}^{\,2}_{\|}\right]^{1/2}
\end{aligned} \tag{0.19}$$

где $\Omega_{d-1}=\frac{2\pi^{\frac{d-1}{2}}}{\Gamma\left(\frac{d-1}{2}\right)}$ - площадь $d-2$-мерного шара. Далее делая замену переменных в интеграле $p_{\|}=\left(\frac{\pi n}{L}\right)t$ получаем

$$\frac{E(L)}{A}=\frac{1}{2}\sum_{n=1}^{\infty}\left(\frac{\pi n}{L}\right)^{d}\frac{\Omega_{d-1}}{(2\pi)^{d-1}}\int\limits_{0}^{\infty}dtt^{d-2}\sqrt{1+t^2}=\frac{1}{2}\frac{\Omega_{d-1}}{(2\pi)^{d-1}}\frac{\pi^d}{L^d}\zeta(-d)\int\limits_{0}^{\infty}dtt^{d-2}\sqrt{1+t^2}\tag{0.20}$$

Далее для интеграла находим

$$\int\limits_{0}^{\infty}dtt^{d-2}\sqrt{1+t^2}\overset{u=1+t^2}{=}\frac{1}{2}\int\limits_{1}^{\infty}duu^{1/2}(u-1)^{\frac{d-3}{2}}\overset{v=\frac{1}{u}}{=}\frac{1}{2}\int\limits_{0}^{1}dvv^{-\frac{d}{2}-1}(1-v)^{\frac{d}{2}-\frac{3}{2}}=$$
$$=\frac{1}{2}B\left(-\frac{d}{2},\frac{d-1}{2}\right)=\frac{\Gamma(-d/2)\Gamma\left(\frac{d-1}{2}\right)}{2\Gamma(-1/2)}.\tag{0.21}$$

В итоге получаем

$$\frac{E(L)}{A}=-\frac{1}{2^{d+1}}\zeta(-d)\frac{\pi^{d/2}}{L^d}\Gamma\left(-\frac{d}{2}\right)\tag{0.22}$$

И для силы на единицу площади находим

$$\frac{F}{A}=-\frac{\partial}{\partial L}\left(\frac{E(L)}{A}+\frac{E(D-L)}{A}\right)\overset{D\to\infty}{=}\left(-\frac{d}{2}\right)\Gamma\left(-\frac{d}{2}\right)\frac{\zeta(-d)\pi^{d/2}}{2^dL^{d+1}}=\frac{\pi^{d/2}\Gamma(1-d/2)\zeta(-d)}{2^dL^{d+1}}\tag{0.23}$$

Мы видим, что пластины притягиваются.
(b). Итак в данном случае мы имеем

$$\frac{E-E_0}{L^2}=\sum_{n=1}^{\infty}f(n)-\int\limits_{0}^{\infty}f(\tau)d\tau\tag{0.24}$$

где

$$f(\tau)=\frac{1}{2}\int\frac{d^2p_{\|}}{(2\pi)^2}\sqrt{\vec{p}_{\|}^2+\frac{\pi^2\tau^2}{a^2}+m^2}\Phi\left(\frac{\vec{p}_{\|}^2+\frac{\pi^2\tau^2}{a^2}+m^2}{\Lambda^2}\right).\tag{0.25}$$

Используя формулу Абеля-Плана находим

$$\sum_{n=1}^{\infty}f(n)-\int\limits_{0}^{\infty}f(\tau)d\tau=-\frac{1}{2}f(0)+i\int\limits_{0}^{\infty}dt\frac{f(it)-f(-it)}{e^{2\pi t}-1}.\tag{0.26}$$

Для функции $F(z)=\sqrt{z^2+a^2}$, мы имеем

$$F(iy)=\begin{cases}\sqrt{a^2-y^2}, & |y|<a\\ i\sqrt{y^2-a^2}, & y>a\\ -i\sqrt{y^2-a^2}, & y<a\end{cases}\tag{0.27}$$

В итоге получаем

$$\frac{E-E_0}{L^2}=-\frac{1}{2}f(0)+i\frac{1}{2}\int\frac{d^2p_{\|}}{(2\pi)^2}\int\limits_{\sqrt{\frac{a^2}{\pi^2}\left(p_{\|}^2+m^2\right)}}^{\infty}dt\frac{2i\sqrt{\frac{\pi^2}{a^2}t^2-p_{\|}^2-m^2}}{e^{2\pi t}-1}\tag{0.28}$$

где мы уже убрали ультрафиолетовый регулятор $\Phi\left(p^2/\Lambda^2\right)$, так как получившееся выражение сходится. Далее делая замену координат $t=\frac{a}{\pi}\sqrt{p_{\|}^2+m^2}x$, получаем

$$\frac{E-E_0}{L^2}=-\frac{1}{2}f(0)-\frac{a}{\pi}\int\frac{d^2p_{\|}}{(2\pi)^2}\left(p_{\|}^2+m^2\right)\int\limits_{1}^{\infty}dx\frac{\sqrt{x^2-1}}{e^{2ax\sqrt{p_{\|}^2+m^2}}-1}\tag{0.29}$$

Далее для интеграла в правой части формулы делая замену $p_{\|}^2=ym^2$ имеем

$$I(am) = \frac{am^4}{4\pi^2}\int\limits_0^\infty dy(y+1)\int\limits_1^\infty dx\frac{\sqrt{x^2-1}}{e^{2(am)x\sqrt{y+1}-1}} = \frac{am^4}{2\pi^2}\iint\limits_1^\infty dydx\frac{y^3\sqrt{x^2-1}}{e^{2(am)xy}-1} \tag{0.30}$$

Таким образом для силы на единицу площади получаем получаем

$$\frac{F(am)}{L^2} = mI'(am) \tag{0.31}$$

Теперь если $am \ll 1$, мы находим

$$\begin{aligned} I(am) &= \frac{am^4}{2\pi^2}\iint\limits_1^\infty dydx\frac{y^3\sqrt{x^2-1}}{e^{2(am)xy}-1} \overset{t=amy}{=} \frac{am^4}{2\pi^2}\frac{1}{(am)^4}\int\limits_1^\infty dx\sqrt{x^2-1}\int\limits_{am}^\infty dt\frac{t^3}{e^{2tx}-1} \approx \\ &\approx \frac{1}{2\pi^2a^3}\int\limits_1^\infty dx\sqrt{x^2-1}\int\limits_0^\infty dt\frac{t^3}{e^{2tx}-1} = \frac{1}{2\pi^2a^3}\int\limits_1^\infty dx\sqrt{x^2-1}\frac{\pi^4}{240x^4} = \frac{1}{2\pi^2a^3}\frac{\pi^4}{240}\cdot\frac{1}{3} = \\ &= \frac{\pi^2}{1440a^3}. \end{aligned} \tag{0.32}$$

Откуда для энергии находим в случаем $am \ll 1$:

$$\frac{E-E_0}{L^2} = -\frac{1}{2}f(0) - \frac{\pi^2}{1440a^3}, \quad \text{откуда} \quad \frac{F}{L^2} = \frac{\pi^2}{480a^4} \tag{0.33}$$

что как раз является ответом для безмассового случая, который был разобран на лекции.
Теперь если $am \gg 1$, мы получаем

$$\begin{aligned} I(am) &= \frac{am^4}{2\pi^2}\iint\limits_1^\infty dydx\frac{y^3\sqrt{x^2-1}}{e^{2(am)xy}-1} \approx \frac{am^4}{2\pi^2}\iint\limits_1^\infty dydxy^3\sqrt{x^2-1}e^{-2(am)xy} = \frac{am^4}{2\pi^2}\int\limits_1^\infty dyy^3\frac{K_1(2yam)}{2yam} = \\ &= \frac{m^3}{4\pi^2}\int\limits_1^\infty dyy^2K_1(2yam). \end{aligned} \tag{0.34}$$

Далее используя асимптотику для функции бесселя $K_1(x)$ при $x \gg 1$:

$$K_1(x) \approx \sqrt{\frac{\pi}{2x}}e^{-x} \tag{0.35}$$

получаем

$$I(am) \approx \frac{m^3}{4\pi^2}\int\limits_1^\infty dyy^2K_1(2yam) = \frac{m^{5/2}}{8\pi^{3/2}a^{1/2}}\int\limits_1^\infty dyy^{3/2}e^{-2yam} \approx \frac{m^3}{16(\pi am)^{3/2}}e^{-2am} \tag{0.36}$$

Откуда для энергии находим в случаем $am \gg 1$:

$$\frac{E-E_0}{L^2} = -\frac{1}{2}f(0) - \frac{m^3}{16(\pi am)^{3/2}}e^{-2am}, \quad \text{откуда} \quad \frac{F}{L^2} = \frac{m^4}{8(\pi am)^{3/2}}e^{-2am} \tag{0.37}$$

То есть взаимодействие (притяжение) пластин экспоненциально подавленно.

Белавин-Пархоменко.3. Функции Грина

1 Функции Грина для Простого Гармонического Осциллятора (ПГО)

В этом упражнении мы будем изучать несколько разных функций Грина для одномерного ПГО. Обозначим координату ϕ, тогда Лагранжиан дается формулой

$$L = \frac{1}{2}\dot{\phi}^2 - \frac{1}{2}m^2\phi^2. \tag{0.1}$$

(a). Используйте выражение для Гейзенберговского оператора $\phi(t)$ в терминах операторов рождения и уничтожения, чтобы вычислить следующие функции Грина

$$\begin{aligned} G_R(t) &= \theta(t)\langle 0|[\phi(t),\phi(0)]|0\rangle, \\ G_A(t) &= -\theta(-t)\langle 0|[\phi(t),\phi(0)]|0\rangle, \\ G_F(t) &= \theta(t)\langle 0|\phi(t)\phi(0)|0\rangle + \theta(-t)\langle 0|\phi(0)\phi(t)|0\rangle. \end{aligned} \tag{0.2}$$

Индексы R, A, F означают запаздывающая ("retarted"), опережающая ("advanced") и Фейнмановская ("Feynman") функции Грина, соответственно.

(b). Покажите непосредственно из формул (0.2), что все функции G_R, G_A и G_F удовлетворяют уравнению

$$\left(\partial_t^2 + m^2\right) G_{R,A,F}(t) = -i\delta(t). \tag{0.3}$$

Поэтому они являются действительно функциями Грина для дифференциального оператора $\partial_t^2 +$ m^2. Покажите, что все эти три функции Грина отличаются друг от друга решением однородного уравнения и что они могут быть классифицированы по их поведению при $t \to \pm\infty$.

(c). Используйте преобразование Фурье $\tilde{G}(\omega) = \int\limits_{-\infty}^{\infty} dt e^{i\omega t} G(t)$, чтобы решить (0.3). Заметьте, что у $\tilde{G}(\omega)$ много разных неопределенностей. Проанализируйте их и покажите, что они соответствуют добавлению решений однородного уравнения для $G(t)$. Используя это знание, запишите явное Фурье представление для функций Грина G_R, G_A и G_F.

Пропагатор Фейнмана Применяя дифференциальный оператор $\partial_\mu\partial^\mu +$ m^2 к определению пропагатора Фейнмана $D_F(x)$:

$$D_F(\vec{x},t) = \theta(t)\langle 0|\phi(\vec{x},t)\phi(0,0)|0\rangle + \theta(-t)\langle 0|\phi(0,0)\phi(\vec{x},t)|0\rangle \tag{0.4}$$

и используя коммутационные соотношения, получите уравнение

$$\left(\partial_\mu\partial^\mu + m^2\right) D_F(x) = -i\delta^{(4)}(x). \tag{0.5}$$

(30 баллов) Амплитуда для частицы поля Клейна-Гордона (П-Ш, з. 2.3) Вычислите явно в терминах функции Бесселя, амплитуду перехода из точки y в точку x:

$$\langle 0|\phi(x)\phi(y)|0\rangle = D(x-y) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\vec{p}}} e^{-ip\cdot(x-y)}, \quad E_{\vec{p}} = \sqrt{p^2+m^2} \tag{0.6}$$

для $(x-y)$ пространственно подобного, т.е. $(x-y)^2 = -r^2$.

Белавин-Пархоменко.исток3. Функции Грина Решения

1 Функции Грина для Простого Гармонического Осциллятора (ПГО)

(a). - Координата $\phi(t)$ в данном случае записывается через операторы рождения и уничтожения как

$$\phi(t) = \frac{1}{\sqrt{2m}}\left(ae^{-imt} + a^\dagger e^{imt}\right) \tag{0.1}$$

Тогда для коммутатора полей находим $\left(\left[a, a^\dagger\right] = 1\right)$:

$$[\phi(t),\phi(0)] = \frac{1}{2m}\left[ae^{-imt} + a^\dagger e^{imt}, a + a^\dagger\right] = \frac{1}{2m}\left(e^{-imt} - e^{imt}\right) = -\frac{i}{m}\sin(mt) \tag{0.2}$$

Откуда получаем для $G_R(t)$ и $G_A(t)$:

$$G_R(t) = -\frac{i}{m}\theta(t)\sin(mt),$$
$$G_A(t) = \frac{i}{m}\theta(-t)\sin(mt). \tag{0.3}$$

И для пропагатора $G_F(t)$ получаем

$$G_F(t) = \theta(t)\frac{1}{2m}\left\langle 0\left|\left(ae^{-imt}+a^\dagger e^{imt}\right)\left(a+a^\dagger\right)\right|0\right\rangle + \theta(-t)\frac{1}{2m}\left\langle 0\left|\left(a+a^\dagger\right)\left(ae^{-imt}+a^\dagger e^{imt}\right)\right|0\right\rangle =$$
$$= \theta(t)\frac{1}{2m}e^{-imt} + \theta(-t)\frac{1}{2m}e^{imt} = \frac{1}{2m}e^{-im|t|}. \tag{0.4}$$

(b). Мы покажем для G_F (для $G_{R,A}$ аналогично):

$$\left(\partial_t^2+m^2\right)G_F(t) =$$
$$\left(\partial_t^2+m^2\right)\left[\theta(t)\langle 0|\phi(t)\phi(0)|0\rangle + \theta(-t)\langle 0|\phi(0)\phi(t)|0\rangle\right] = \delta'(t)\langle 0|\phi(t)\phi(0)|0\rangle - \delta'(t)\langle 0|\phi(0)\phi(t)|0\rangle +$$
$$+ 2\delta(t)\langle 0|\dot\phi(t)\phi(0)|0\rangle - 2\delta(t)\langle 0|\phi(0)\dot\phi(t)|0\rangle + \theta(t)\left\langle 0\left|\left(\partial_t^2+m^2\right)\phi(t)\phi(0)\right|0\right\rangle +$$
$$+ \theta(-t)\left\langle 0\left|\phi(0)\left(\partial_t^2+m^2\right)\phi(t)\right|0\right\rangle. \tag{0.5}$$

Используя то, что $\delta'(t)f(t) = -\delta(t)f'(t)$, а также то, что $\left(\partial_t^2+m^2\right)\phi(t) = 0$, получаем

$$\left(\partial_t^2+m^2\right)G_F(t) = \delta(t)\langle 0|[\dot\phi(t),\phi(0)]|0\rangle = -i\delta(t) \tag{0.6}$$

Далее, например, имеем

$$G_F(t) - G_R(t) = \frac{e^{imt}}{2m} = f(t) \tag{0.7}$$

что является однородным решением уравнения: $\left(\partial_t^2+m^2\right)f(t) = 0$. Аналогично для других разностей. Далее имеем при $t\to\pm\infty$:

$$G_R(t) \to \begin{cases} \sim\left(e^{imt}-e^{-imt}\right), & t\to+\infty \\ 0, & t\to-\infty \end{cases},$$
$$G_A(t) \to \begin{cases} 0, & t\to+\infty \\ \sim\left(e^{imt}-e^{-imt}\right), & t\to-\infty \end{cases},$$
$$G_F(t) \to \begin{cases} \sim e^{-imt}, & t\to+\infty \\ \sim e^{imt}, & t\to-\infty \end{cases}, \tag{0.8}$$

и мы видим, что все функции имееют разное поведение при $t\to\pm\infty$.
(c). Для фурье образа получаем

$$\left(-\omega^2+m^2\right)\tilde G(\omega) = -i \tag{0.9}$$

откуда

$$\tilde G(\omega) = \frac{i}{\omega^2-m^2} \tag{0.10}$$

Для обратного преобразования имеем:

$$G(t) = i\int\limits_C \frac{d\omega}{2\pi}\frac{e^{-i\omega t}}{\omega^2-m^2} \tag{0.11}$$

Мы видим, что на действительной оси есть два полюса в точках $\omega_1 = -m$ и $\omega_2 = m$. Ответ для функции Грина завит от выбора контура интегрирования C. Если контур C идет вдоль действительной оси, чуть выше полюсов, то при интегрировании мы получим, что $G(t) = G_R(t)$. Если контур C идет вдоль действительной

оси, чуть ниже полюсов, то при интегрировании мы получим, что $G(t) = G_A(t)$. Если контур C идет ниже полюса $\omega_1 = -m$, но выше полюса $\omega_2 = m$, то при интегрировании мы получим, что $G(t) = G_F(t)$.

Пропагатор Фейнмана По аналогии с пунктом (b) задачи 1, получаем

$$\begin{aligned}\left(\partial_\mu\partial^\mu + m^2\right) D_F(\vec{x},t) =& \delta'(t)\langle 0|\phi(\vec{x},t)\phi(0,0)|0\rangle - \delta'(t)\langle 0|\phi(0,0)\phi(\vec{x},t)|0\rangle + \\ &+ 2\delta(t)\langle 0|\dot{\phi}(\vec{x},t)\phi(0,0)|0\rangle - 2\delta(t)\langle 0|\phi(0,0)\dot{\phi}(\vec{x},t)|0\rangle = \\ =&\delta(t)\langle 0|[\dot{\phi}(\vec{x},0),\phi(0,0)]|0\rangle = i\delta(t)\langle 0|[\pi(\vec{x},0),\phi(0,0)]|0\rangle = -i\delta(t)\delta^{(3)}(\vec{x}) = \\ =&-i\delta^{(4)}(x). \end{aligned} \tag{0.12}$$

(30 баллов) Амплитуда для частицы поля Клейна-Гордона (П-Ш, з. 2.3) Пусть $\left(x^0 - y^0\right) = t$ и $\vec{x} - \vec{y} = \vec{r}$, и $(x-y)^2 = t^2 - r^2 < 0$. Так как амплитуда Лоренц инвариантна (докажите как упражнение), то мы можем перейти в систему координат в которой $x^0 - y^0 = 0$ и $\vec{x} - \vec{y} = \vec{r}$. Тогда для амплитуды получаем

$$\begin{aligned} D(x-y) =& \int \frac{d^3p}{(2\pi)^3}\frac{1}{2\sqrt{p^2+m^2}}e^{i\vec{p}\vec{r}} = \frac{2\pi}{(2\pi)^3}\int\limits_0^\infty dp\frac{p^2}{2\sqrt{p^2+m^2}}\int\limits_{-1}^{1} d\cos\theta e^{ipr\cos\theta} = \\ =& \frac{1}{8\pi^2}\int\limits_0^\infty dp\frac{p^2}{\sqrt{m^2+p^2}}\frac{e^{ipr}-e^{-ipr}}{ipr} = -\frac{i}{8\pi^2 r}\int\limits_{-\infty}^{\infty} dp\frac{pe^{ipr}}{\sqrt{p^2+m^2}} \end{aligned} \tag{0.13}$$

У интеграла есть две точки ветвления $p = \pm im$. Изогнем контур так, чтобы он сел на вертикальный разрез, идущий от im до $+i\infty$, тогда получим для амплитуды, делая замену $\rho = -ip$:

$$\begin{aligned} D(x-y) =& \frac{1}{4\pi^2 r}\int\limits_m^\infty d\rho\frac{\rho e^{-\rho r}}{\sqrt{\rho^2-m^2}} \overset{\rho = m\,\mathrm{ch}\,\xi}{=} \frac{m}{4\pi^2 r}\int\limits_0^\infty d\xi\,\mathrm{ch}\,\xi e^{-mr\,\mathrm{ch}\,\xi} = \frac{mK_1(mr)}{4\pi^2 r} = \\ =& \frac{m}{4\pi^2\sqrt{-(x-y)^2}}K_1\left(m\sqrt{-(x-y)^2}\right) \end{aligned} \tag{0.14}$$

где $K_1(x)$ функция Макдональда.

Белавин-Пархоменко.4. Континуальный интеграл в Квантовой Механике

Евклидова корреляционная функция

(a). Как мы знаем, если сделать поворот контура интегрирования по времени (поворот Вика) для пропагатора Фейнмана в пространстве Минковского: $t = -ix_4$, где x_4 действительная переменная, то мы получим выражение для Евклидового пропагатора:

$$D\left(x_E\right) = \int \frac{d^4p_E}{(2\pi)^4}\frac{e^{ip_E x_E}}{p_E^2+m^2} \tag{0.1}$$

где $p_E^2 = \vec{p}^2 + p_4^2$ и $x_E^2 = \vec{x}^2 + x_4^2$. Иногда удобно воспользоваться следующим приемом (Швингеровское представление), а именно записать $D\left(x_E\right)$, как

$$D\left(x_E\right) = \int\limits_0^\infty d\tau \int \frac{d^4p_E}{(2\pi)^4}e^{-\tau\left(p_E^2+m^2\right)}e^{ip_E x_E} \tag{0.2}$$

Покажите, что при $|x_E| \gg m^{-1}$:

$$D\left(x_E\right) \sim \frac{m^{1/2}}{|x_E|^{3/2}}e^{-m|x_E|} \tag{0.3}$$

(b). Используя представление Швингера вычислите $D\left(x_E\right)$ явно в терминах функций Бесселя.

Оператор эволюции (в мнимом времени $\tau = it$) По определению, оператор эволюции $\hat{U}(\tau, \tau_0)$ удовлетворяет уравнению

$$-\frac{\partial}{\partial\tau}\hat{U}(\tau,\tau_0) = \hat{H}(\tau)U(\tau,\tau_0), \quad \hat{U}(\tau_0,\tau_0) = \hat{I} \tag{0.4}$$

где $\hat{H}(\hat{p},\hat{q},\tau)$ - Гамильтониан нашей квантово-механической системы. Мы предполагаем, что спектр Гамильтониана ограничен снизу. Оператор эволюции существует только при $\tau \geqslant \tau_0$.

(a). Проверьте, что оператор эволюции удовлетворяет свойству композиции:

$$\hat{U}(\tau,\tau_0) = \hat{U}(\tau,\tau_1)\hat{U}(\tau_1,\tau_0), \quad \tau \geqslant \tau_1 \geqslant \tau_0 \tag{0.5}$$

(b). В координатном представлении $|q\rangle$ и для Гамильтониана вида $\hat{H} = \frac{1}{2}p^2 + V(q,\tau)$, уравнение для оператора эволюции запишется как

$$-\frac{\partial}{\partial\tau}\left\langle q\left|\hat{U}(\tau,\tau_0)\right|q'\right\rangle = \left(-\frac{1}{2}\frac{\partial^2}{\partial q^2} + V(q,\tau)\right)\left\langle q\left|\hat{U}(\tau,\tau_0)\right|q'\right\rangle, \quad \left\langle q\left|\hat{U}(\tau_0,\tau_0)\right|q'\right\rangle = \delta(q-q') \tag{0.6}$$

Рассмотрим $\tau - \tau_0 = \Delta \to 0$, и записывая $\left\langle q\left|\hat{U}(\tau,\tau_0)\right|q'\right\rangle = e^{-\sigma(q,q'|\tau_0)}$, будем искать $\sigma(q,q'|\tau_0)$ в виде

$$\sigma(q,q'|\tau_0) = \frac{1}{\Delta}\sigma_0(q,q'|\tau_0) + a\log\Delta + b + \Delta\sigma_1(q,q'|\tau_0) + O\left(\Delta^2\right) \tag{0.7}$$

где a, b - некоторые константы. Используя уравнения для оператора эволюции, покажите, что

$$\sigma_0(q,q'|\tau_0) = \frac{1}{2}(q-q')^2, \quad a = 1/2, \quad \sigma_1(q,q'|\tau_0) = \frac{1}{q-q'}\int_{q'}^{q} V(y|\tau_0)\,dy \tag{0.8}$$

а также, что $b = \frac{1}{2}\log 2\pi$, которая определяется из условия $\left\langle q\left|\hat{U}(\tau_0,\tau_0)\right|q'\right\rangle = \delta(q-q')$.

Stanford.Zhou.2022.1.1. natural units

In this course, we will work in "natural" units, where $\hbar = k_B = c = \mu_0 = \epsilon_0 = 1$. As a result, any physical quantity $\mathcal{A}$ has the same dimensions as $(1\text{eV})^n$ for some n, which we write as $[\mathcal{A}] = n$. For example, we have

$$[\text{ energy }] = [\text{ momentum }] = [\text{ mass }] = [\text{ temperature }] = 1$$

and

$$[\text{ length }] = [\text{ time }] = -1.$$

These results immediately imply, e.g., [frequency] = 1, [speed] = 0, and [volume] = −3. If the mass of a particle in natural units is $m = 1\text{eV}$, that means its mass in SI units is

$$m = \frac{1\text{eV}}{c^2} = 1.8 \times 10^{-36}\ \text{kg}$$

One physical interpretation is that a particle of this mass has rest energy 1eV.

a) Find the wavelength and period of a photon of energy 1eV in SI units.

Solution:

Since $E = \hbar\omega$, the period is

$$T = \frac{2\pi\hbar}{1\text{eV}} = 4 \times 10^{-15}\ \text{s}$$

Since $\lambda = cT$, the wavelength is

$$\lambda = \frac{2\pi\hbar c}{1\text{eV}} = 1.2 \times 10^{-6}\ \text{m}$$

b) Express the temperature $T = 1\text{eV}$ in SI units.

Solution:

Since energy has dimensions of $k_B T$, the temperature is

$$T = \frac{1\text{eV}}{k_B} = 12000 \text{ K}$$

This is the temperature where the typical thermal energy of a degree of freedom is $\sim$ 1eV, which would be sufficient to break apart molecules and ionize most atoms.

If you commit the above results to memory, you should always be able to recover numeric values in SI units. The other skill you need is going from SI units to natural units.

c) Find $[G]$, where G is Newton's constant.

Solution:

You can do this part, and all the parts below, by brute force. But it's faster and more fun to get the answers by thinking about equations you already know.

For example, the gravitational potential energy formula implies $[E] = \left[GM^2/R\right]$, so $[G] = [R/M] = -2$. (In natural units, $G \sim 1/M_{\text{pl}}^2$ where M_{pl} is the Planck mass.)

d) Find $[n], [P]$, and $[\rho]$, where n is number density, P is pressure, and ρ is mass density.

Solution:

Since n is a dimensionless number per volume, $[n] = [1/\text{ volume }] = 3$. Noting that $dU = PdV$ for thermodynamic work, $[P] = [\text{ energy / volume }] = 4$. Similarly, $[\rho] = [\text{ mass / volume }] = 4$.

e) Find $[\phi]$, where ϕ is a real scalar field.

Solution:

Note that the action S is the integral of a Lagrangian (with units of energy) over time, so

$$[S] = [\text{ energy } \cdot \text{ time }] = 0$$

In field theory, the action is the integral over 4-dimensional spacetime of a Lagrangian density $\mathcal{L}$, which implies $[\mathcal{L}] = 4$. Examining the kinetic term, we have

$$\left[(\partial_\mu \phi)^2\right] = 4$$

and we have $[\partial_\mu] = 1$, which implies $[\phi] = 1$.

f) Find $[q], [A], [E]$ and $[B]$, where q is electric charge, A is vector potential, and E and B are electric and magnetic fields.

Solution:

In natural units, the force between charges is $F = q^2/4\pi r^2$. Since $[F] = [dp/dt] = 2$, we conclude $[q] = 0$, i.e. charge is dimensionless. (In case you were wondering, the specific value of the electron charge is about -0.3. This result is more commonly expressed in terms of the "fine structure constant" $\alpha = e^2/4\pi \approx 1/137$, and later, the fact that $\alpha \ll 1$ will tell us that electromagnetic interactions in QFT can be treated in perturbation theory.)

For the vector potential, one could recall the Lorenz gauge equation of motion $\partial^2 A^\mu = J^\mu$ where J^μ is the current density. We have $\left[\partial^2\right] = 2$ and $[J] = [\text{ charge/volume }] = 3$, so we conclude $[A] = 1$.

The electric and magnetic fields are spatial or time derivatives of the vector potential, so $[E] = [B] = 2$.

Once you're comfortable with natural units, they'll be an incredibly convenient tool for making rough estimates. For example, the mass of the proton is $m_p \sim$ GeV, and everything in nuclear physics is roughly governed by this scale. From this, we can immediately conclude that the radius of the proton is roughly $r \sim \text{GeV}^{-1}$, in natural units.

g) Write down rough expressions for the density and electric field within a nucleus, and the temperature above which nuclei melt into quark-gluon plasma, in natural units.

Solution:

It's just $\rho \sim \text{GeV}^4, E \sim \text{GeV}^2$, and $T \sim \text{GeV}$. These are all very rough estimates, dropping dimensionless factors like $\alpha \sim 1/137$ or dependence on the pion mass, but they're all within a few orders of magnitude.

Technically, all of the estimates here will be a bit off, because some of these quantities are actually determined by the pion mass $m_\pi \sim 10^{-1}\text{GeV}$, as the pion governs the forces between nucleons. For a more careful treatment, see Astronomical reach of fundamental physics by Burrows and Ostriker.

Stanford.Zhou.2022.1. The harmonic oscillator in quantum mechanics. (15/45p)

This exercise reviews the quantum harmonic oscillator, which has Hamiltonian

$$H = \frac{p^2}{2m} + \frac{m\omega^2 x^2}{2}.$$

a) Write the Hamiltonian in terms of the ladder operators a and $a^\dagger$, where

$$a = \frac{1}{\sqrt{2}}\left(\sqrt{m\omega}x + i\frac{p}{\sqrt{m\omega}}\right).$$

Solution:

Of course, we have

$$a^\dagger = \frac{1}{\sqrt{2}}\left(\sqrt{m\omega}x - i\frac{p}{\sqrt{m\omega}}\right).$$

Following the usual textbook steps, you should find

$$H = \omega\left(a^\dagger a + \frac{1}{2}\right)$$

Equivalent forms, such as having $a^\dagger a + aa^\dagger$ in parentheses, are also acceptable.

b) The normalized vacuum state $|0\rangle$ is defined to satisfy $a|0\rangle = 0$. The number states are then defined by $a^\dagger|n\rangle = \sqrt{n+1}|n+1\rangle$ for any integer n. Show that $\left[a, a^\dagger\right] = 1$, and use this fact alone to show that the number states are properly normalized.

Solution:

Using the fact that $[x, p] = i$, we have

$$\begin{aligned}\left[a, a^\dagger\right] &= \frac{1}{2}\left[\sqrt{m\omega}x + i\frac{p}{\sqrt{m\omega}}, \sqrt{m\omega}x - i\frac{p}{\sqrt{m\omega}}\right] \\ &= \frac{1}{2}([x, -ip] + [ip, x]) = 1\end{aligned}$$

as desired.

Now, by repeatedly using the definition of the number states, we have

$$|n\rangle = \frac{1}{\sqrt{n!}}\left(a^\dagger\right)^n|0\rangle$$

Note that we have

$$\left[a, \left(a^\dagger\right)^n\right] = n\left(a^\dagger\right)^{n-1}.$$

The intuition is that to convert $a\left(a^\dagger\right)^n$ into $\left(a^\dagger\right)^n a$, we need to move an a through an $a^\dagger$ a total of n times. For each move, we use the identity $aa^\dagger = a^\dagger a + \left[a, a^\dagger\right] = a^\dagger a + 1$, and therefore pick up a factor of $\left(a^\dagger\right)^{n-1}$. The factor of n in the final result is because we need to do n such moves.

To check the normalization, we just compute

$$\begin{aligned}\langle n|n\rangle &= \frac{1}{n!}\left\langle 0\left|a^n\left(a^\dagger\right)^n\right|0\right\rangle \\ &= \frac{1}{n!}\left\langle 0\left|a^{n-1}a\left(a^\dagger\right)^n\right|0\right\rangle \\ &= \frac{1}{n!}\left\langle 0\left|a^{n-1}\left(\left(a^\dagger\right)^n a + n\left(a^\dagger\right)^{n-1}\right)\right|0\right\rangle \\ &= \frac{1}{(n-1)!}\left\langle 0\left|a^{n-1}\left(a^\dagger\right)^{n-1}\right|0\right\rangle \\ &= \langle n-1|n-1\rangle.\end{aligned}$$

This shows that the norms of all the number states are equal, so they're all normalized because $|0\rangle$ is.

c) Calculate the expectation values of x, p, and the number operator $N = a^\dagger a$ in the number state $|n\rangle$.

Solution:

We can write x and p in terms of ladder operators as

$$x = \frac{1}{\sqrt{2m\omega}}\left(a^\dagger + a\right), \quad p = i\sqrt{\frac{m\omega}{2}}\left(a^\dagger - a\right).$$

Then $\langle n|x|n\rangle$ has two terms, one proportional to $\langle n|n+1\rangle$ and the other proportional to $\langle n|n-1\rangle$, which both vanish. Thus, $\langle n|x|n\rangle = 0$, and by similar reasoning $\langle n|p|n\rangle = 0$. As for the number operator,

$$\langle n|N|n\rangle = \left\langle n\left|a^\dagger a\right|n\right\rangle = \langle n-1|\sqrt{n}\sqrt{n}|n-1\rangle = n.$$

d) Calculate the standard deviations $\Delta x, \Delta p$ and ΔN in the number state $|n\rangle$. For what n is the Heisenberg uncertainty product $\Delta x \Delta p$ minimal?

Solution:

For a given state, the standard deviation of any operator A is defined by

$$\Delta A = \sqrt{\langle A^2\rangle - \langle A\rangle^2}$$

where the expectation values are taken with respect to the state. Now first, we note that

$$\begin{aligned}\left\langle n\left|x^2\right|n\right\rangle &= \frac{1}{2m\omega}\left\langle n\left|\left(a + a^\dagger\right)\left(a + a^\dagger\right)\right|n\right\rangle \\ &= \frac{1}{2m\omega}\left\langle n\left|a^\dagger a + aa^\dagger\right|n\right\rangle \\ &= \frac{1}{2m\omega}(n + (n+1)) \\ &= \frac{2n+1}{2m\omega}.\end{aligned}$$

From this and the previous part, we conclude

$$\Delta x = \sqrt{\frac{2n+1}{2m\omega}}.$$

A very similar computation for p gives

$$\Delta p = \sqrt{\frac{m\omega(2n+1)}{2}}.$$

Clearly the Heisenberg uncertainty product is minimal for $n = 0$, in which case $\Delta x \Delta p = 1/2$, saturating the uncertainty relation.

Finally, we have

$$\left\langle n\left|N^2\right|n\right\rangle = n\langle n|N|n\rangle = n^2$$

from which we conclude $\Delta N = 0$, as expected.

e) Suppose the particle begins in the vacuum state $|0\rangle$, and at time $t = 0$, we apply an impulse α. This can be modeled by a Hamiltonian term $-\alpha x \delta(t)$, and the state immediately after the impulse is

$$|\alpha\rangle = e^{i\alpha x}|0\rangle.$$

Show that $|\alpha\rangle$ is an eigenvector of a, and find the eigenvalue.

Solution:

For simplicity, let's define $\beta = \alpha/\sqrt{2m\omega}$, so that

$$|\alpha\rangle = e^{i\beta\left(a+a^\dagger\right)}|0\rangle.$$

We'll show a direct solution. First, note that $\left[a, a + a^\dagger\right] = 1$. This implies that

$$\left[a, \left(a + a^\dagger\right)^n\right] = n\left(a + a^\dagger\right)^{n-1}$$

where the factor of n comes from commuting the a past each copy of $a + a^\dagger$. Now we have

$$\begin{aligned}
a|\alpha\rangle &= a\sum_{n=0}^{\infty}\frac{(i\beta)^n}{n!}\left(a + a^\dagger\right)^n|0\rangle \\
&= \sum_{n=0}^{\infty}\frac{(i\beta)^n}{n!}\left(\left[a, \left(a + a^\dagger\right)^n\right] + \left(a + a^\dagger\right)^n a\right)|0\rangle \\
&= \sum_{n=0}^{\infty}\frac{(i\beta)^n}{n!}\left(n\left(a + a^\dagger\right)^{n-1}\right)|0\rangle \\
&= \sum_{n=0}^{\infty}\frac{(i\beta)^n}{(n-1)!}\left(a + a^\dagger\right)^{n-1}|0\rangle \\
&= \sum_{n=0}^{\infty}\frac{(i\beta)^{n+1}}{n!}\left(a + a^\dagger\right)^n|0\rangle \\
&= i\beta|\alpha\rangle
\end{aligned}$$

where we Taylor expanded the exponential, used the definition of the commutator, used $a|0\rangle = 0$ and Eq. (S28), and shifted the variable n. Thus, $|\alpha\rangle$ is an eigenvector of a with eigenvalue $i\beta = i\alpha/\sqrt{2m\omega}$.

f) Find the expectation values of x, p, and N, and their standard deviations, for all $t > 0$. (Hint: after you find the answers for the initial state $|\alpha\rangle$, it is easiest to generalize to arbitrary t using Heisenberg picture.)

Solution:

First, let's calculate the expectation values in the initial state $|\alpha\rangle$. Since x commutes with $e^{i\alpha x}$, we have

$$\langle\alpha|x|\alpha\rangle = \left\langle 0\left|e^{-i\alpha x}xe^{i\alpha x}\right|0\right\rangle = \langle 0|x|0\rangle = 0.$$

Similarly, we have

$$\left\langle\alpha\left|x^2\right|\alpha\right\rangle = \left\langle 0\left|x^2\right|0\right\rangle = \frac{1}{2m\omega}$$

where we used Eq. (S24). This gives a standard deviation

$$\Delta x = \frac{1}{\sqrt{2m\omega}}$$

Next, for p it's useful to use the decomposition into ladder operators, as

$$\langle\alpha|a|\alpha\rangle = \langle\alpha|i\beta|\alpha\rangle = i\beta, \quad \left\langle\alpha\left|a^\dagger\right|\alpha\right\rangle = (a|\alpha\rangle)^\dagger|\alpha\rangle = -i\beta$$

where we used the result of part (e). We therefore have

$$\langle\alpha|p|\alpha\rangle = i\sqrt{\frac{m\omega}{2}}\left\langle\alpha\left|\left(a^\dagger - a\right)\right|\alpha\right\rangle = (-2i\beta)i\sqrt{\frac{m\omega}{2}} = \alpha$$

which is unsurprising, as the state $|\alpha\rangle$ as defined by exerting an impulse α on the ground state. Next,

$$\begin{aligned}\left\langle\alpha\left|p^2\right|\alpha\right\rangle &= -\frac{m\omega}{2}\left\langle\alpha\left|\left(a^\dagger - a\right)^2\right|\alpha\right\rangle \\ &= -\frac{m\omega}{2}\left\langle\alpha\left|\left(a^\dagger a^\dagger + aa - aa^\dagger - a^\dagger a\right)\right|\alpha\right\rangle \\ &= \frac{m\omega}{2}\left\langle\alpha\left|\left(-a^\dagger a^\dagger - aa + 2a^\dagger a + 1\right)\right|\alpha\right\rangle \\ &= \frac{m\omega}{2}\left(4\beta^2 + 1\right) \\ &= \frac{m\omega}{2} + \alpha^2.\end{aligned}$$

Therefore, the standard deviation is

$$\Delta p = \sqrt{\frac{m\omega}{2}}$$

which is unchanged from the ground state. Finally, for the number states,

$$\langle\alpha|N|\alpha\rangle = \left\langle\alpha\left|a^\dagger a\right|\alpha\right\rangle = \beta^2 = \frac{\alpha^2}{2m\omega}$$

and

$$\begin{aligned}\left\langle\alpha\left|N^2\right|\alpha\right\rangle &= \left\langle\alpha\left|a^\dagger a a^\dagger a\right|\alpha\right\rangle \\ &= \beta^2\left\langle\alpha\left|aa^\dagger\right|\alpha\right\rangle \\ &= \beta^2\left\langle\alpha\left|\left(1 + a^\dagger a\right)\right|\alpha\right\rangle \\ &= \beta^2 + \beta^4\end{aligned}$$

from which we conclude

$$\Delta N = \beta = \frac{\alpha}{\sqrt{2m\omega}}$$

You could also derive all of the above results using the Baker-Campbell-Hausdorff theorem, but such machinery isn't necessary. We simply leaned on the result of part **(e)** to get all of the results, and the solution to part **(e)** is effectively a proof of that theorem in the simple case we need.

Now let's consider how these expectation values and uncertainties evolve over time. The evolution of an expectation value of any operator $\mathcal{O}$ is

$$\langle\mathcal{O}\rangle(t) = \left\langle\psi\left|e^{iHt}\mathcal{O}e^{-iHt}\right|\psi\right\rangle$$

Since N commutes with H, this implies that N and ΔN just stay constant over time. As for x and p, the easiest way is to compute the "Heisenberg" operators $\mathcal{O}_H(t) = e^{iHt}\mathcal{O}e^{-iHt}$. The basic result is that Heisenberg operators satisfy Hamilton's equations, which here imply

$$\frac{dp_H}{dt} = -m\omega^2 x_H, \quad \frac{dx_H}{dt} = \frac{p_H}{m}$$

The solution of this pair of equations is

$$p_H(t) = p\cos\omega t - m\omega x\sin\omega t, \quad x_H(t) = x\cos\omega t + \frac{p}{m\omega}\sin\omega t$$

This means the expectation values we're after follow immediately from those we already calculated. We know that $\langle\alpha|x|\alpha\rangle = 0$ and $\langle\alpha|p|\alpha\rangle = \alpha$, from which we conclude

$$\langle x\rangle(t) = \frac{\alpha}{m\omega}\sin\omega t, \quad \langle p\rangle(t) = \alpha\cos\omega t$$

Similarly, we have

$$\begin{aligned}\left\langle x^2\right\rangle(t) &= \left\langle \alpha \left| x^2\cos^2\omega t + \frac{(xp+px)}{m\omega}\cos\omega t\sin\omega t + \frac{p^2}{m^2\omega^2}\sin^2\omega t \right| \alpha \right\rangle \\ &= \cos^2\omega t\left\langle \alpha\left|x^2\right|\alpha\right\rangle + \frac{\sin^2\omega t}{m^2\omega^2}\left\langle \alpha\left|p^2\right|\alpha\right\rangle \\ &= \left(\frac{\alpha\sin\omega t}{m\omega}\right)^2 + \frac{1}{2m\omega}\end{aligned}$$

which implies that the position uncertainty does not change over time,

$$\Delta x(t) = \frac{1}{\sqrt{2m\omega}}$$

By an extremely similar computation, we find the momentum uncertainty doesn't change over time either,

$$\Delta p(t) = \sqrt{\frac{m\omega}{2}}$$

Your result in part (**e**) shows that $|\alpha\rangle$ is a so-called coherent state. You might have heard that they are important because they are the "most classical" states. A more important reason is that they are the states you automatically get when you drive a quantum system. As you can see from your results, in the limit of strong driving, Δx and Δp become negligible compared to x and p, and we recover classical physics. Later we will see how a similar result allows quantum fields to behave like classical fields.

26.1.3 Problems about free quantum fields 2

Stanford.Zhou.2022.1. The relativistic classical point particle. (12/45p)

The spacetime trajectory of a relativistic point particle is $x^\mu(\tau) = \left(x^0(\tau), \mathbf{x}(\tau)\right)$, where τ is an arbitrary parameter. The corresponding action is proportional to the relativistic "length" of the trajectory, where the relativistic line element is

$$ds^2 = \eta_{\mu\nu}dx^\mu dx^\nu = dt^2 - dx^2 - dy^2 - dz^2$$

The action is therefore

$$S = -\alpha\int_{\mathcal{P}} ds = -\alpha\int_{\tau_1}^{\tau_2} d\tau\sqrt{\eta_{\mu\nu}\frac{dx^\mu}{d\tau}\frac{dx^\nu}{d\tau}}$$

where α is a constant, and τ_1 and τ_2 are the initial and final values of the parameter.

a) The easiest way to understand the nonrelativistic limit $\left|\partial_t x^i\right| \ll 1$ is to set $\tau = t$. By demanding that the action reduces to that of a free nonrelativistic particle of mass m (plus a constant), determine the value of the constant α.

Solution:

Setting $\tau = t$, we have

$$S = -\alpha\int dt\sqrt{\eta_{\mu\nu}\frac{dx^\mu}{dt}\frac{dx^\nu}{dt}} = -\alpha\int dt\sqrt{1-v(t)^2}$$

where $v(t)$ is the ordinary speed. In the nonrelativistic limit $v \ll 1$,

$$S \approx -\alpha\int dt\left(1 - \frac{v^2}{2} + O\left(v^4\right)\right)$$

The first term is just an irrelevant constant, while the next gives a Lagrangian $\alpha v^2/2$. On the other hand, we know the Lagrangian for a free nonrelativistic particle is $mv^2/2$, so we conclude $\alpha = m$.

If we don't just set $\tau = t$, there are four Euler-Lagrange equations and canonical momenta,

$$\frac{dp^\mu}{d\tau} = \frac{\partial L}{\partial x_\mu}, \quad p^\mu = \frac{\partial L}{\partial\left(dx_\mu/d\tau\right)}$$

b) Find the Euler-Lagrange equations for a general parameter τ, then show that they are equivalent to the conservation of the physical four-momentum of the particle.

Solution:

For simplicity, let a dot denote a derivative with respect to τ, so that

$$L = -m\sqrt{\eta_{\mu\nu}\dot{x}^\mu \dot{x}^\nu} = -m\sqrt{\dot{x}^2}.$$

The canonical momenta are

$$p^\mu = \frac{\partial L}{\partial \dot{x}_\mu} = -\frac{m}{2\sqrt{\dot{x}^2}}\left(2\dot{x}^\mu\right) = -\frac{m\dot{x}^\mu}{\sqrt{\dot{x}^2}}.$$

The Lagrangian has no direct dependence on x^μ, so the Euler-Lagrange equations just state that p^μ is conserved, $dp^\mu/d\tau = 0$.

This isn't the end of the problem, though; we still need to show how the canonical momentum p^μ is related to physical four-momentum. One way to do this is to let τ be the proper time s of the particle. Then $\dot{x}^2 = 1$, and $p^\mu = -m dx^\mu/ds$-momentum. Alternatively, we can let τ be the coordinate time t, in which case $p^\mu = -m\left(dx^\mu/dt\right)/\sqrt{1-v^2}$. In both cases, it's clear that p^μ is the negative of the physical four-momentum. (This negative sign is weird, but harmless, since the physical results are the same. It occurs because we used a mostly negative metric, which will pay off later in the course.)

c) A simple local, Lorentz invariant way to include a force on the particle is to add

$$S_{\text{int}} = -q\int_{\mathcal{P}} A_\mu\left(x^\mu\right) dx^\mu = -q\int_{\tau_1}^{\tau_2} A_\mu\left(x^\mu\right)\frac{dx^\mu}{d\tau}d\tau$$

to the action, where $A^\mu\left(x^\mu\right)$ is a given four-vector field. Calculate p^μ and $\partial L/\partial x^\mu$, continuing to assume general τ.

Solution:

There are a lot of μ 's floating around, so to avoid confusion, let's use the fact that we can always rename a dummy index to rewrite the interaction as

$$S_{\text{int}} = -q\int A_\nu\left(x^\mu\right)\dot{x}^\nu d\tau$$

First, the canonical momenta are changed to

$$p^\mu = \frac{\partial L}{\partial \dot{x}_\mu} = -\frac{m\dot{x}^\mu}{\sqrt{\dot{x}^2}} - qA^\mu\left(x^\mu\right)$$

Next, the right-hand side of the Euler-Lagrange equations is now nontrivial,

$$\frac{\partial L}{\partial x_\mu} = -q\dot{x}^\nu \partial^\mu A_\nu\left(x^\mu\right)$$

where the partial derivative on the right is with respect to x^μ.

A common issue with this part was mismatched indices (having μ up on one side and down on the other side), which can be avoided by taking care to make the index positions consistent at each step. Another issue was duplicated indices (having more than two copies of μ, which is meaningless), which can be avoided by renaming dummy indices when required.

d) Now set τ to be the proper time s experienced by the particle (so that $ds = d\tau$) and evaluate the Euler-Lagrange equations, simplifying as much as possible.

Solution:

From this point on, we'll leave the x^μ argument of the vector potential implicit. Specializing the proper time, the canonical momenta are

$$p^\mu = -m\dot{x}^\mu - qA^\mu$$

We therefore have

$$\frac{dp^\mu}{ds} = -m\ddot{x}^\mu - q\frac{dA^\mu}{ds} = -m\ddot{x}^\mu - q\dot{x}^\nu \partial_\nu A^\mu$$

Equating this with Eq. (S67) gives

$$m\ddot{x}^\mu = -q\dot{x}^\nu \left(\partial_\nu A^\mu - \partial^\mu A_\nu\right) = q\dot{x}_\nu \left(\partial^\mu A^\nu - \partial^\nu A^\mu\right)$$

This is an acceptable final answer; the right-hand side can also be written as $q\dot{x}_\nu F^{\mu\nu}$ where F is the electromagnetic field strength tensor. If you treat A^μ as a vector potential and plug in the definitions of the electric and magnetic fields, you'll recover the Lorentz force law.

A warning: if you set τ to proper time before doing part (c), and apply the Euler-Lagrange equations anyway, you'll get nonsense. The reason is that the derivation of the EulerLagrange equation assumes all the variables $x^\mu(\tau)$ can be varied independently, but when $d\tau = ds$ we automatically have the constraint $\sqrt{\eta_{\mu\nu}\left(dx^\mu/d\tau\right)\left(dx^\nu/d\tau\right)} = 1$. Lagrangians with constraints are subtle and important, but beyond the scope of this course. For much more about them, see Quantization of Gauge Systems by Henneaux and Teitelboim.

Stanford.Zhou.2022.1. The complex scalar field. (5/45p)

The Lagrangian density for a canonically normalized free real scalar field of mass m is

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu\phi\right)\left(\partial^\mu\phi\right) - \frac{1}{2}m^2\phi^2.$$

Now consider a theory of two free real scalar fields ϕ_1 and ϕ_2, both with mass m.

a) Write their Lagrangian density in terms of the complex scalar field $\Phi = \left(\phi_1 + i\phi_2\right)/\sqrt{2}$ and its complex conjugate Φ^*.

Solution:

The mass terms involve $\phi_1^2 + \phi_2^2$, which clearly indicates the answer involves the complex norm $\Phi^*\Phi$. Treating the kinetic term the same way, and fixing the numeric constants, gives

$$\mathcal{L} = \left(\partial_\mu\Phi^*\right)\left(\partial^\mu\Phi\right) - m^2\Phi^*\Phi$$

Complex fields are always equivalent to a pair of equal mass real fields, and are useful because such pairs occur frequently in nature, for reasons we'll see later. (At low energies, we actually don't know of any complex scalar fields, but the electron is described by a Dirac field, which is a complex fermion field built from two equal mass real fermion fields.)

Complex fields are convenient once you get to know them, but they come with an annoying problem: it is not obvious how to vary the action with respect to Φ, because any change in Φ also changes Φ^*. It turns out that you will always get the right results (i.e. results that are equivalent to what you'd get working in terms of the two real fields) by treating Φ and Φ^* as if they were independent real fields, even though they clearly aren't. (For an explanation why, see page 56 of Sidney Coleman's lecture notes.)

b) Compute the conjugate momenta Π and Π^* of Φ and Φ^*, and the Euler-Lagrange equations for Φ and Φ^*.

Solution:

Note that the kinetic term contains $\dot{\Phi}^*\dot{\Phi}$, where a dot denotes a time derivative. Thus, the canonical momenta are

$$\Pi = \frac{\partial\mathcal{L}}{\partial\dot{\Phi}} = \dot{\Phi}^*, \quad \Pi^* = \frac{\partial\mathcal{L}}{\partial\dot{\Phi}^*} = \dot{\Phi}$$

The Euler-Lagrange equations are

$$\partial_\mu \frac{\partial \mathcal{L}}{\partial\left(\partial^\mu \Phi\right)}-\frac{\partial \mathcal{L}}{\partial \Phi}=0, \quad \partial_\mu \frac{\partial \mathcal{L}}{\partial\left(\partial^\mu \Phi^*\right)}-\frac{\partial \mathcal{L}}{\partial \Phi^*}=0$$

from which we read off

$$\left(\partial^2+m^2\right) \Phi^*=0, \quad \left(\partial^2+m^2\right) \Phi=0$$

which is just the Klein-Gordan equation.

c) Show that the action is invariant under the transformation $\Phi \rightarrow e^{i\alpha}\Phi$, for any real α. What is the equivalent symmetry in terms of the real scalar fields ϕ_1 and ϕ_2?

Solution:

Each term in the Lagrangian has one power of Φ and one power of Φ^*, and $\Phi^* \rightarrow e^{-i\alpha}\Phi$, so the phase cancels out. In terms of the real scalar fields, an equivalent symmetry is a rotation,

$$\phi_1 \rightarrow \phi_1 \cos\alpha - \phi_2 \sin\alpha, \quad \phi_2 \rightarrow \phi_2 \cos\alpha + \phi_1 \sin\alpha$$

Stanford.Zhou.2022.2. Quantization of the complex scalar field. (30/45p)

In problem set 1 we considered a complex scalar field Φ with Lagrangian density

$$\mathcal{L}=\left(\partial_\mu \Phi^*\right)\left(\partial^\mu \Phi\right)-m^2 \Phi^* \Phi$$

and found the canonical fields Φ and Φ^* and momenta Π and Π^*. Letting $\omega_{\mathbf{k}}=\sqrt{|\mathbf{k}|^2+m^2}$, introduce the following mode expansion for the canonical fields and momenta:

$$\begin{aligned}
\Phi(\mathbf{x}) &= \int \frac{d^3k}{(2\pi)^3}\frac{1}{\sqrt{2\omega_{\mathbf{k}}}}\left[a(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{x}}+b^\dagger(\mathbf{k})e^{-i\mathbf{k}\cdot\mathbf{x}}\right], \\
\Phi^*(\mathbf{x}) &= \int \frac{d^3k}{(2\pi)^3}\frac{1}{\sqrt{2\omega_{\mathbf{k}}}}\left[b(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{x}}+a^\dagger(\mathbf{k})e^{-i\mathbf{k}\cdot\mathbf{x}}\right], \\
\Pi(\mathbf{x}) &= -i\int \frac{d^3k}{(2\pi)^3}\sqrt{\frac{\omega_{\mathbf{k}}}{2}}\left[b(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{x}}-a^\dagger(\mathbf{k})e^{-i\mathbf{k}\cdot\mathbf{x}}\right], \\
\Pi^*(\mathbf{x}) &= -i\int \frac{d^3k}{(2\pi)^3}\sqrt{\frac{\omega_{\mathbf{k}}}{2}}\left[a(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{x}}-b^\dagger(\mathbf{k})e^{-i\mathbf{k}\cdot\mathbf{x}}\right]
\end{aligned}$$

We quantize the fields by imposing the canonical commutation relations

$$[\Phi(\mathbf{x}),\Pi(\mathbf{y})]=[\Phi^*(\mathbf{x}),\Pi^*(\mathbf{y})]=i\delta^{(3)}(\mathbf{x}-\mathbf{y})$$

with all other commutators between these fields vanishing. (Technically, we should write Hermitian conjugates $\Phi^\dagger$ and $\Pi^\dagger$ here, since Φ and Π are now operators, but we'll continue to use stars to emphasize the links between the classical and quantum theories.)

a) Show that the operators $a(\mathbf{k}), a^\dagger(\mathbf{k}), b(\mathbf{k})$ and $b^\dagger(\mathbf{k})$ obey

$$\left[a(\mathbf{k}),a^\dagger(\mathbf{p})\right]=\left[b(\mathbf{k}),b^\dagger(\mathbf{p})\right]=(2\pi)^3\delta^{(3)}(\mathbf{k}-\mathbf{p})$$

with all other commutators between these operators vanishing. This implies that we have two sets of independent creation and annihilation operators for each $\mathbf{k}$.

Solution:

In order to keep the expressions as simple as possible, we'll define

$$d\mathbf{x}=d^3x, \quad d\mathbf{p}=\frac{d^3p}{(2\pi)^3}, \quad \not{\delta}(\mathbf{p})=(2\pi)^3\delta^{(3)}(\mathbf{p})$$

As a simple of this notation, we have

$$\int d\mathbf{x} e^{-i\mathbf{p}\cdot\mathbf{x}} = \phi(\mathbf{p}), \quad \int d\mathbf{p} e^{i\mathbf{p}\cdot\mathbf{x}} = \delta(\mathbf{x})$$

If you just remember that every momentum delta function comes with a slash, and every momentum integral comes with a bar, all the factors of 2π will take care of themselves.

Now, we note that

$$\begin{aligned}\int d\mathbf{x} e^{i\mathbf{k}\cdot\mathbf{x}}\Phi(\mathbf{x}) &= \int \frac{d\mathbf{x}d\mathbf{k}'}{\sqrt{2\omega_{\mathbf{k}'}}}\left[a(\mathbf{k})e^{i\left(\mathbf{k}+\mathbf{k}'\right)\cdot\mathbf{x}} + b^\dagger(\mathbf{k})e^{-i\left(\mathbf{k}'-\mathbf{k}\right)\mathbf{x}}\right] \\ &= \int \frac{d\mathbf{k}'}{\sqrt{2\omega_{\mathbf{k}'}}}\left[a(\mathbf{k})\phi\left(\mathbf{k}+\mathbf{k}'\right) + b^\dagger(\mathbf{k})\phi\left(\mathbf{k}'-\mathbf{k}\right)\right] \\ &= \frac{1}{\sqrt{2\omega_{\mathbf{k}}}}\left(a(-\mathbf{k}) + b^\dagger(\mathbf{k})\right).\end{aligned}$$

By a similar argument, we have

$$\int d\mathbf{x} e^{i\mathbf{k}\cdot\mathbf{x}}(i\Pi(\mathbf{x})) = \sqrt{\frac{\omega_{\mathbf{k}}}{2}}\left(b(-\mathbf{k}) - a^\dagger(\mathbf{k})\right).$$

Combining these equations to solve for the creation and annihilation operators yields

$$\begin{aligned}a(\mathbf{k}) &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}} e^{-i\mathbf{k}\cdot\mathbf{x}}\left[\omega_{\mathbf{k}}\Phi(\mathbf{x}) + i\Pi^*(\mathbf{x})\right] \\ b(\mathbf{k}) &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}} e^{-i\mathbf{k}\cdot\mathbf{x}}\left[\omega_{\mathbf{k}}\Phi^*(\mathbf{x}) + i\Pi(\mathbf{x})\right] \\ a^\dagger(\mathbf{k}) &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}} e^{i\mathbf{k}\cdot\mathbf{x}}\left[\omega_{\mathbf{k}}\Phi^*(\mathbf{x}) - i\Pi(\mathbf{x})\right] \\ b^\dagger(\mathbf{k}) &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}} e^{i\mathbf{k}\cdot\mathbf{x}}\left[\omega_{\mathbf{k}}\Phi(\mathbf{x}) - i\Pi^*(\mathbf{x})\right]\end{aligned}$$

Let's start by considering commutators involving $a(\mathbf{k})$. We only have nonzero commutators between Φ and Π, and between Φ^* and Π^*. This automatically implies that $[a(\mathbf{k}), a(\mathbf{p})] = \left[a(\mathbf{k}), b^\dagger(\mathbf{p})\right] = 0$, leaving just two to manually check. First, we have

$$\begin{aligned}[a(\mathbf{k}), b(\mathbf{p})] &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}}\frac{d\mathbf{y}}{\sqrt{2\omega_{\mathbf{p}}}} e^{-i\mathbf{k}\cdot\mathbf{x}}e^{-i\mathbf{p}\cdot\mathbf{y}}\left[\omega_{\mathbf{k}}\Phi(\mathbf{x}) + i\Pi^*(\mathbf{x}), \omega_{\mathbf{p}}\Phi^*(\mathbf{y}) + i\Pi(\mathbf{y})\right] \\ &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}}\frac{d\mathbf{y}}{\sqrt{2\omega_{\mathbf{p}}}} e^{-i\mathbf{k}\cdot\mathbf{x}}e^{-i\mathbf{p}\cdot\mathbf{y}}\left(\delta(\mathbf{y}-\mathbf{x})\left(\omega_{\mathbf{p}} - \omega_{\mathbf{k}}\right)\right) \\ &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}\sqrt{2\omega_{\mathbf{p}}}} e^{-i\mathbf{k}\cdot\mathbf{x}}e^{-i\mathbf{p}\cdot\mathbf{x}}\left(\omega_{\mathbf{p}} - \omega_{\mathbf{k}}\right) \\ &= \not{\delta}(\mathbf{k}+\mathbf{p})\frac{\omega_{\mathbf{p}} - \omega_{\mathbf{k}}}{\sqrt{2\omega_{\mathbf{k}}}\sqrt{2\omega_{\mathbf{p}}}} = 0\end{aligned}$$

where the final step follows from $\omega_{\mathbf{k}} = \omega_{-\mathbf{k}}$. Next, we have

$$\begin{aligned}\left[a(\mathbf{k}), a^\dagger(\mathbf{p})\right] &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}}\frac{d\mathbf{y}}{\sqrt{2\omega_{\mathbf{p}}}} e^{-i\mathbf{k}\cdot\mathbf{x}}e^{i\mathbf{p}\cdot\mathbf{y}}\left[\omega_{\mathbf{k}}\Phi(\mathbf{x}) + i\Pi^*(\mathbf{x}), \omega_{\mathbf{p}}\Phi^*(\mathbf{y}) - i\Pi(\mathbf{y})\right] \\ &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}}\frac{d\mathbf{y}}{\sqrt{2\omega_{\mathbf{p}}}} e^{-i\mathbf{k}\cdot\mathbf{x}}e^{i\mathbf{p}\cdot\mathbf{y}}\left(\delta(\mathbf{y}-\mathbf{x})\left(\omega_{\mathbf{p}} + \omega_{\mathbf{k}}\right)\right) \\ &= \int \frac{d\mathbf{x}}{\sqrt{2\omega_{\mathbf{k}}}\sqrt{2\omega_{\mathbf{p}}}} e^{-i\mathbf{k}\cdot\mathbf{x}}e^{i\mathbf{p}\cdot\mathbf{x}}\left(\omega_{\mathbf{p}} + \omega_{\mathbf{k}}\right) \\ &= \not{\delta}(\mathbf{k}-\mathbf{p})\frac{\omega_{\mathbf{p}} + \omega_{\mathbf{k}}}{\sqrt{2\omega_{\mathbf{k}}}\sqrt{2\omega_{\mathbf{p}}}} = \not{\delta}(\mathbf{k}-\mathbf{p})\text{`}\end{aligned}$$

as desired. All of the other commutators can be derived similarly.

The vacuum state $|0\rangle$ is defined to be the unique state where $a(\mathbf{k})|0\rangle = b(\mathbf{k})|0\rangle = 0$ for all $\mathbf{k}$. The states $a^\dagger(\mathbf{k})|0\rangle$ and $b^\dagger(\mathbf{k})|0\rangle$ each contain one particle, while the state $a^\dagger\left(\mathbf{k}_1\right)a^\dagger\left(\mathbf{k}_2\right)|0\rangle$ contains two particles, and so on.

b) In problem set 1, you showed that the complex scalar field Lagrangian had the symmetry $\Phi \to e^{i\alpha}\Phi, \Phi^* \to e^{-i\alpha}\Phi^*$. Compute the Noether current J^μ and conserved charge Q associated with the symmetry.

Solution:

The infinitesimal transformation is $\delta\Phi = i\Phi$ and $\delta\Phi^* = -i\Phi$, so Noether's theorem gives

$$\begin{aligned} J^\mu &= \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\Phi\right)}\delta\Phi + \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\Phi^*\right)}\delta\Phi^* \\ &= i\left(\left(\partial^\mu\Phi^*\right)\Phi - \left(\partial^\mu\Phi\right)\Phi^*\right) \end{aligned}$$

The charge is just the integral of the charge density,

$$Q = i\int d\mathbf{x}\left(\left(\partial^0\Phi^*\right)\Phi - \left(\partial^0\Phi\right)\Phi^*\right)$$

Of course, if we want to evaluate this in the canonically quantized theory, we should express it in terms of the fields and canonical momenta, giving the final answer

$$Q = i\int d\mathbf{x}\left(\Pi(\mathbf{x})\Phi(\mathbf{x}) - \Pi^*(\mathbf{x})\Phi^*(\mathbf{x})\right)$$

c) Write Q in terms of the creation and annihilation operators. You should find the result is indeterminate up to a constant; resolve this by defining the vacuum to have zero charge, $Q|0\rangle = 0$. What is the charge in the three other states mentioned above?

Solution:

The fundamental reason the answer will be undetermined up to a constant is that Noether's theorem, which applies to classical fields, tells us (S30), but not the order that $\Pi(\mathbf{x})$ and $\Phi(\mathbf{x})$ are multiplied together. In the classical theory, that simply doesn't matter, but in the quantum theory it does because the fields are noncommuting operators. So without further information, the "right" answer in the quantum theory could contain $\Pi(\mathbf{x})\Phi(\mathbf{x})$, or $\Phi(\mathbf{x})\Pi(\mathbf{x})$, or even a mixture like $(\Pi(\mathbf{x})\Phi(\mathbf{x}) + \Phi(\mathbf{x})\Pi(\mathbf{x}))/2$.

This is called an ordering ambiguity, and in general there is no way to resolve it. (Ordering information is intrinsically quantum; it simply doesn't exist in the classical theory!) But in simple cases like this, all of the possible orderings give you the same operator Q, just shifted by a constant. So we can fix the ambiguity by demanding the reasonable assumption $Q|0\rangle = 0$, which is known as normal ordering.

Anyway, let's not worry about this for now, and just directly evaluate the result. First,

$$\begin{aligned} \int d\mathbf{x} i\Pi(\mathbf{x})\Phi(\mathbf{x}) &= \int \frac{d\mathbf{x}d\mathbf{k}d\mathbf{k}'}{2}\sqrt{\frac{\omega_\mathbf{k}}{\omega_{\mathbf{k}'}}}\left(b(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{x}} - a^\dagger(\mathbf{k})e^{-i\mathbf{k}\cdot\mathbf{x}}\right)\left(a\left(\mathbf{k}'\right)e^{i\mathbf{k}'\cdot\mathbf{x}} + b^\dagger\left(\mathbf{k}'\right)e^{-i\mathbf{k}'\cdot\mathbf{x}}\right) \\ &= \int \frac{d\mathbf{k}d\mathbf{k}'}{2}\sqrt{\frac{\omega_\mathbf{k}}{\omega_{\mathbf{k}'}}}\left[\left(b(\mathbf{k})a\left(\mathbf{k}'\right) - a^\dagger(\mathbf{k})b^\dagger\left(\mathbf{k}'\right)\right)\phi\left(\mathbf{k}+\mathbf{k}'\right)\right. \\ &\qquad \left. + \left(b(\mathbf{k})b^\dagger\left(\mathbf{k}'\right) - a^\dagger(\mathbf{k})a\left(\mathbf{k}'\right)\right)\phi\left(\mathbf{k}-\mathbf{k}'\right)\right] \\ &= \int \frac{d\mathbf{k}}{2}\left(b(\mathbf{k})a(-\mathbf{k}) - a^\dagger(\mathbf{k})b^\dagger(-\mathbf{k}) + b(\mathbf{k})b^\dagger(\mathbf{k}) - a^\dagger(\mathbf{k})a(\mathbf{k})\right). \end{aligned}$$

By a very similar computation, the second term is

$$\int d\mathbf{x}\left(-i\Pi^*(\mathbf{x})\right)\Phi^*(\mathbf{x}) = \int \frac{d\mathbf{k}}{2}\left(-a(\mathbf{k})b(-\mathbf{k}) + b(\mathbf{k})^\dagger a(-\mathbf{k})^\dagger - a(\mathbf{k})a(\mathbf{k})^\dagger + b(\mathbf{k})^\dagger b(\mathbf{k})\right)$$

The first term of (S33) cancels with the first term of (S34). To see this very explicitly:

$$\int d\mathbf{k}b(\mathbf{k})a(-\mathbf{k}) = \int d\mathbf{k}'a\left(\mathbf{k}'\right)b\left(-\mathbf{k}'\right) = \int d\mathbf{k}a(\mathbf{k})b\left(-\mathbf{k}'\right)$$

where we changed the integration variable to $\mathbf{k}' = -\mathbf{k}$, used the commutation relation, and then renamed $\mathbf{k}'$ to $\mathbf{k}$. Similarly, the second term of (S33) cancels with the second term of S34. This leaves

$$Q = \int \frac{d\mathbf{k}}{2}\left(b(\mathbf{k})b^\dagger(\mathbf{k}) + b(\mathbf{k})^\dagger b(\mathbf{k}) - a^\dagger(\mathbf{k})a(\mathbf{k}) - a(\mathbf{k})a(\mathbf{k})^\dagger\right)$$

At this point, we need to impose normal ordering. We will have $Q|0\rangle = 0$ if all the annihilation operators are on the right, so we move them to the right and throw out the constants this produces, giving

$$Q = \int d\mathbf{k}\left(b^\dagger(\mathbf{k})b(\mathbf{k}) - a^\dagger(\mathbf{k})a(\mathbf{k})\right)$$

Evidently, the conserved charge is the number of type b particles minus the number of type a particles. So the charges in the three states mentioned above are $-1, 1$, and -2, respectively.

d) To check that this is the same symmetry operation that we started out with, we can see how it acts on the operators of the theory. Quantum mechanically, symmetries act on operators by conjugation, and we expect to have

$$e^{i\alpha Q}\Phi(\mathbf{x})e^{-i\alpha Q} = e^{i\alpha}\Phi(\mathbf{x}), \quad e^{i\alpha Q}\Phi^*(\mathbf{x})e^{-i\alpha Q} = e^{-i\alpha}\Phi^*(\mathbf{x})$$

Show that this implies the commutation relations

$$[Q, \Phi(\mathbf{x})] = \Phi(\mathbf{x}), \quad [Q, \Phi^*(\mathbf{x})] = -\Phi^*(\mathbf{x})$$

and show that these relations hold. Thus, Q generates phase rotations of the field.

Solution:

Taking α infinitesimal, we have

$$(1 + i\alpha Q)\Phi(\mathbf{x})(1 - i\alpha Q) = (1 + i\alpha)\Phi(\mathbf{x})$$

and matching up the order α terms gives

$$iQ\Phi - i\Phi Q = i\Phi$$

which is precisely the desired result. The proof for Φ^* is similar.
To show the first commutation relation, we have

$$\begin{aligned}
[Q, \Phi(\mathbf{x})] &= \int \frac{d\mathbf{k}d\mathbf{k}'}{\sqrt{2\omega_{\mathbf{k}'}}} \left[b^\dagger(\mathbf{k})b(\mathbf{k}) - a^\dagger(\mathbf{k})a(\mathbf{k}), a\left(\mathbf{k}'\right)e^{i\mathbf{k}'\cdot\mathbf{x}} + b^\dagger\left(\mathbf{k}'\right)e^{-i\mathbf{k}'\cdot\mathbf{x}}\right] \\
&= \int \frac{d\mathbf{k}d\mathbf{k}'}{\sqrt{2\omega_{\mathbf{k}'}}} \left(\left[b^\dagger(\mathbf{k})b(\mathbf{k}), b^\dagger\left(\mathbf{k}'\right)\right]e^{-i\mathbf{k}'\cdot\mathbf{x}} - \left[a^\dagger(\mathbf{k})a(\mathbf{k}), a\left(\mathbf{k}'\right)\right]e^{i\mathbf{k}'\cdot\mathbf{x}}\right) \\
&= \int \frac{d\mathbf{k}}{\sqrt{2\omega_{\mathbf{k}}}} \left(b^\dagger(\mathbf{k})e^{-i\mathbf{k}\cdot\mathbf{x}} + a^\dagger(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{x}}\right) = \Phi(\mathbf{x})
\end{aligned}$$

as desired. The proof of the other commutation relation is similar, but we don't have to write it because it follows immediately from the result we just proved. Taking the Hermitian conjugate of both sides,

$$\Phi^*(\mathbf{x}) = [Q, \Phi(\mathbf{x})]^\dagger = (Q\Phi(\mathbf{x}) - \Phi(\mathbf{x})Q)^\dagger = \Phi^*(\mathbf{x})Q - Q\Phi^*(\mathbf{x}) = -[Q, \Phi^*(\mathbf{x})]$$

which is the desired result. (Here we used the fact that Q is Hermitian.)

e) Use Noether's theorem to find the stress-energy tensor $T^{\mu\nu}$ and the associated conserved total four-momentum P^μ.

Solution:

Using the same procedure as in class, and suppressing x arguments, we have

$$\begin{aligned}
T^{\mu\nu} &= \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\Phi\right)}\partial^\nu\Phi + \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\Phi^*\right)}\partial^\nu\Phi^* - \eta^{\mu\nu}\mathcal{L} \\
&= \partial^\mu\Phi^*\partial^\nu\Phi + \partial^\mu\Phi\partial^\nu\Phi^* - \eta^{\mu\nu}\left(\left(\partial_\rho\Phi^*\right)\left(\partial^\rho\Phi\right) - m^2\Phi^*\Phi\right)
\end{aligned}$$

The total energy is

$$\begin{aligned}
P^0 &= \int d\mathbf{x}T^{00} \\
&= \int d\mathbf{x}\partial^0\Phi\partial^0\Phi^* + \partial^0\Phi^*\partial^0\Phi - \left(\partial_\rho\Phi^*\right)\left(\partial^\rho\Phi\right) + m^2\Phi^*\Phi \\
&= \int d\mathbf{x}\Pi^*\Pi + (\nabla\Phi^*)\cdot(\nabla\Phi) + m^2\Phi^*\Phi
\end{aligned}$$

The total momentum is

$$\begin{aligned} P^i &= \int d\mathbf{x} T^{0i} \\ &= \int d\mathbf{x} \partial^0 \Phi^* \partial^i \Phi + \partial^0 \Phi \partial^i \Phi^* \\ &= \int d\mathbf{x} \Pi \partial^i \Phi + \Pi^* \partial^i \Phi^* \end{aligned}$$

f) Write the Hamiltonian $H = P^0$ and the spatial momenta $\mathbf{P}$ in terms of the creation and annihilation operators, again defining the vacuum to have zero four-momentum. What is the four-momentum in the three other states mentioned above?

Solution:

Starting with the Hamiltonian, we have three terms:

$$\begin{aligned} \int d\mathbf{x} \Pi^* \Pi &= -\int d\mathbf{x} d\mathbf{k} d\mathbf{k}' \frac{\sqrt{\omega_{\mathbf{k}} \omega_{\mathbf{k}'}}}{2} \left(a(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} - b^\dagger(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{x}} \right) \left(b\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} - a^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right) \\ \int d\mathbf{x} \left(\nabla \Phi^*\right) \cdot (\nabla \Phi) &= -\int \frac{d\mathbf{x} d\mathbf{k} d\mathbf{k}'}{2\sqrt{\omega_{\mathbf{k}} \omega_{\mathbf{k}'}}} \left(\mathbf{k} b(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} - \mathbf{k} a^\dagger(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{x}} \right) \cdot \left(\mathbf{k}' a\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} - \mathbf{k}' b^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right) \\ \int d\mathbf{x} m^2 \Phi^* \Phi &= \int \frac{d\mathbf{x} d\mathbf{k} d\mathbf{k}'}{2\sqrt{\omega_{\mathbf{k}} \omega_{\mathbf{k}'}}} m^2 \left(b(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} + a^\dagger(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{x}} \right) \left(a\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} + b^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right) \end{aligned}$$

When we do the $d\mathbf{x}$ integrations, each line gives four terms, along with appropriate delta functions,

$$\begin{aligned} \int d\mathbf{x} \Pi^* \Pi &= \int \frac{d\mathbf{k}}{2\omega_{\mathbf{k}}} \omega_{\mathbf{k}}^2 \left(-a(\mathbf{k}) b(-\mathbf{k}) + b^\dagger(\mathbf{k}) b(\mathbf{k}) + a(\mathbf{k}) a^\dagger(\mathbf{k}) - b^\dagger(\mathbf{k}) a^\dagger(-\mathbf{k}) \right) \\ \int d\mathbf{x} \left(\nabla \Phi^*\right) \cdot (\nabla \Phi) &= \int \frac{d\mathbf{k}}{2\omega_{\mathbf{k}}} |\mathbf{k}|^2 \left(b(\mathbf{k}) a(-\mathbf{k}) + a^\dagger(\mathbf{k}) a(\mathbf{k}) + b(\mathbf{k}) b^\dagger(\mathbf{k}) + a^\dagger(\mathbf{k}) b^\dagger(-\mathbf{k}) \right) \\ \int d\mathbf{x} m^2 \Phi^* \Phi &= \int \frac{d\mathbf{k}}{2\omega_{\mathbf{k}}} m^2 \left(b(\mathbf{k}) a(-\mathbf{k}) + b(\mathbf{k}) b^\dagger(\mathbf{k}) + a^\dagger(\mathbf{k}) a(\mathbf{k}) + a^\dagger(\mathbf{k}) b^\dagger(-\mathbf{k}) \right). \end{aligned}$$

Summing the terms, all the cross terms (those with one a and one b) cancel, and normal ordering leaves

$$\begin{aligned} H &= \int \frac{d\mathbf{k}}{2\omega_{\mathbf{k}}} \left(\omega_{\mathbf{k}}^2 + |\mathbf{k}|^2 + m^2 \right) \left(a^\dagger(\mathbf{k}) a(\mathbf{k}) + b^\dagger(\mathbf{k}) b(\mathbf{k}) \right) \\ &= \int d\mathbf{k} \omega_{\mathbf{k}} \left(a^\dagger(\mathbf{k}) a(\mathbf{k}) + b^\dagger(\mathbf{k}) b(\mathbf{k}) \right) \end{aligned}$$

This tells us that each one of the a-type and b-type particles has energy $\omega_{\mathbf{k}}$. Thankfully, the momentum is a little easier to deal with. We have

$$\begin{aligned} \int d\mathbf{x} \Pi \partial^i \Phi &= -i \int \frac{d\mathbf{x} d\mathbf{k} d\mathbf{k}'}{2} \sqrt{\frac{\omega_{\mathbf{k}}}{\omega_{\mathbf{k}'}}} \left(b(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} - a^\dagger(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{x}} \right) \partial^i \left(a\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} + b^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right) \\ &= \int \frac{d\mathbf{x} d\mathbf{k} d\mathbf{k}'}{2} \sqrt{\frac{\omega_{\mathbf{k}}}{\omega_{\mathbf{k}'}}} k^i \left(b(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} - a^\dagger(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{x}} \right) \left(-a\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} + b^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right) \\ &= \int \frac{d\mathbf{k}}{2} k^i \left(b(\mathbf{k}) a(-\mathbf{k}) + a^\dagger(\mathbf{k}) a(\mathbf{k}) + b^\dagger(\mathbf{k}) b(\mathbf{k}) + a^\dagger(\mathbf{k}) b^\dagger(-\mathbf{k}) \right) \end{aligned}$$

The easy way to handle the other term in P^i is to notice that when you conjugate this term, you almost get the other term, but the operators are in the reverse order. But of course, we're going to fix the ordering ambiguity with normal ordering later, so this doesn't matter. So we can treat the other term as

$$\left(\int d\mathbf{x} \Pi \partial^i \Phi \right)^\dagger = \int \frac{d\mathbf{k}}{2} k^i \left(a^\dagger(-\mathbf{k}) b^\dagger(\mathbf{k}) + a(\mathbf{k}) a^\dagger(\mathbf{k}) + b(\mathbf{k}) b^\dagger(\mathbf{k}) + b(-\mathbf{k}) a(\mathbf{k}) \right)$$

By substituting $\mathbf{k} = -\mathbf{k}'$ and then renaming $\mathbf{k}'$ back to $\mathbf{k}$, the first and last terms here cancel with the first and last terms of S62. The second and third terms add, and normal ordering gives

$$P^i = \int d\mathbf{k} k^i \left(a^\dagger(\mathbf{k}) a(\mathbf{k}) + b^\dagger(\mathbf{k}) b(\mathbf{k}) \right)$$

which tells us that a-type and b-type particles both carry momentum $\mathbf{k}$. Therefore, the states mentioned above have four-momentum $(\omega_{\mathbf{k}}, \mathbf{k})$, $(\omega_{\mathbf{k}}, \mathbf{k})$, and $(\omega_{\mathbf{k}_1} + \omega_{\mathbf{k}_2}, \mathbf{k}_1 + \mathbf{k}_2)$.

g) By definition, the operator H generates time translations of the field - this is the content of the Schrodinger equation, $i\partial_t |\Psi\rangle = H|\Psi\rangle$, which holds unchanged in quantum field theory. As for the momenta $\mathbf{P}$, we expect

$$e^{i\mathbf{a}\cdot\mathbf{P}} \Phi(\mathbf{x}) e^{-i\mathbf{a}\cdot\mathbf{P}} = \Phi(\mathbf{x} - \mathbf{a})$$

for any vector a, with a similar result for all the other fields. Show that this implies

$$\left[P^i, \Phi(\mathbf{x}) \right] = -i\partial^i \Phi(\mathbf{x})$$

and show that this relation holds. Thus, $\mathbf{P}$ generates spatial translations.

Solution:

We again take infinitesimal a and expand, giving

$$(1 + i\mathbf{a}\cdot\mathbf{P})\Phi(\mathbf{x})(1 - i\mathbf{a}\cdot\mathbf{P}) = \Phi(\mathbf{x}) - \mathbf{a}\cdot\nabla\Phi(\mathbf{x})$$

Equating the order a components and taking care to remember that $\partial^i = -\partial_i$ gives the desired result.

By the way, you might wonder why we're treating the Hamiltonian and momentum slightly differently. The reason is that in this problem set, we're still working in Schrodinger picture, where the operators $\Phi(\mathbf{x})$ depend on space but not time. In Heisenberg picture, the Heisenberg equation of motion for operators gives the analogous result $[H, \Phi(\mathbf{x}, t)] = -i\partial^0 \Phi(\mathbf{x}, t)$, so that in general we have $[P^\mu, \Phi(x)] = -i\partial^\mu \Phi(x)$.

Now, evaluating the commutator, we have

$$\begin{aligned}
\left[P^i, \Phi(\mathbf{x}) \right] &= \int d\mathbf{k} d\mathbf{k}' \frac{k^i}{\sqrt{2\omega_{\mathbf{k}'}}} \left[a^\dagger(\mathbf{k}) a(\mathbf{k}) + b^\dagger(\mathbf{k}) b(\mathbf{k}), a\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} + b^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right] \\
&= \int d\mathbf{k} d\mathbf{k}' \frac{k^i}{\sqrt{2\omega_{\mathbf{k}'}}} \left[a^\dagger(\mathbf{k}) a(\mathbf{k}) + b^\dagger(\mathbf{k}) b(\mathbf{k}), a\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} + b^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right] \\
&= \int d\mathbf{k} \frac{k^i}{\sqrt{2\omega_{\mathbf{k}}}} \left(a(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} - b^\dagger(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{x}} \right) \\
&= -i\partial^i \int \frac{d\mathbf{k}}{\sqrt{2\omega_{\mathbf{k}}}} \left(a(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} + b^\dagger(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{x}} \right) = -i\partial^i \Phi(\mathbf{x}).
\end{aligned}$$

Stanford.Zhou.2022.3.1. Locality in relativistic quantum field theory. (20/45 p)

The vacuum two-point correlation function of a real scalar field is

$$D(x - y) = \langle 0 | \phi(x) \phi(y) | 0 \rangle.$$

It only depends on the difference of positions $z = x - y$, by translational invariance, and it quantifies correlations between the field values at x and y in the vacuum state.

a) Show that

$$D(z) = \int \frac{d^4 p}{(2\pi)^4} (2\pi) \delta\left(p^2 - m^2\right) \theta\left(p^0\right) e^{-ip\cdot z}$$

where the Heaviside step function θ is 1 if the argument is positive and 0 otherwise.

Solution:

Using the same d and ϕ notation as in the solutions to the second problem set,

$$\begin{aligned}\langle 0|\phi(x)\phi(y)|0\rangle &= \int \frac{d\mathbf{p}d\mathbf{q}}{\sqrt{2\omega_\mathbf{p}}\sqrt{2\omega_\mathbf{q}}} e^{i\mathbf{p}\cdot\mathbf{x}} e^{-i\omega_p x^0} e^{-i\mathbf{q}\cdot\mathbf{y}} e^{i\omega_q y^0} \left\langle 0 \left| a(\mathbf{q}) a^\dagger(\mathbf{p}) \right| 0 \right\rangle \\ &= \int \frac{d\mathbf{p}d\mathbf{q}}{\sqrt{2\omega_\mathbf{p}}\sqrt{2\omega_\mathbf{q}}} e^{i\mathbf{p}\cdot\mathbf{x}} e^{-i\omega_p x^0} e^{-i\mathbf{q}\cdot\mathbf{y}} e^{i\omega_q y^0} \phi(\mathbf{p}-\mathbf{q}) \\ &= \int \frac{d\mathbf{p}}{2\omega_\mathbf{p}} e^{-i\omega_p z^0} e^{i\mathbf{p}\cdot\mathbf{z}}.\end{aligned}$$

On the other hand, starting from the desired expression, we have

$$\begin{aligned}D(z) &= \int d\mathbf{p} e^{i\mathbf{p}\cdot\mathbf{z}} \int_0^\infty \frac{dp^0}{2\pi} (2\pi)\delta\left(p^2 - m^2\right) e^{-ip^0 z^0} \\ &= \int \frac{d\mathbf{p}}{2\omega_\mathbf{p}} e^{-i\omega_p z^0} e^{i\mathbf{p}\cdot\mathbf{z}}\end{aligned}$$

which matches.

b) Show that if $z'^\mu = \Lambda^\mu{}_\nu z^\nu$ for a proper orthochronous Lorentz transformation Λ, then $D\left(z'\right) = D(z)$. (Hint: show that d^4p and $\delta\left(p^2 - m^2\right)\theta\left(p^0\right)$ are each Lorentz invariant.)

Solution:

For $D\left(z'\right)$, let's change the integration variable from p to $p'^\mu = \Lambda^\mu_\nu p^\nu$. Then

$$\begin{aligned}D\left(z'\right) &= \int \frac{d^4p'}{(2\pi)^4} (2\pi)\delta\left(p'^2 - m^2\right)\theta\left(p'^0\right) e^{-ip'\cdot z'} \\ &= \int \frac{d^4p'}{(2\pi)^4} (2\pi)\delta\left(p^2 - m^2\right)\theta\left(p'^0\right) e^{-ip\cdot z}\end{aligned}$$

which is precisely the same thing as $D(z)$ provided that

$$d^4p'\delta\left(p'^2 - m^2\right)\theta\left(p'^0\right) = d^4p\delta\left(p^2 - m^2\right)\theta\left(p^0\right)$$

Lorentz transformations always preserve inner products, $p^2 = p^2$, so the two delta functions are the same. Furthermore, for timelike momenta (which are the only ones that contribute to the integral, because of the presence of the delta functions), orthochronous Lorentz transformations always preserve the sign of the time component, by definition. Physically this corresponds to the fact that you can't boost a particle from positive energy to negative energy, and you can check it by explicitly computing the effects of Lorentz boosts. (Of course, Lorentz boosts certainly can change the sign of the time component of spacelike vectors.)

The tricky part is to show that proper orthochronous Lorentz transformations preserve spacetime volume, $d^4p' = d^4p$. There are a few different ways to show this. The most formal way is to just compute the Jacobian determinant. The Jacobian matrix for the transformations between the variables is just

$$\frac{\partial p'^\mu}{\partial p^\nu} = \Lambda^\mu_\nu$$

and its determinant is

$$J = -\frac{1}{24}\epsilon_{\mu\nu\rho\sigma}\Lambda^\mu_{\mu'}\Lambda^\nu_{\nu'}\Lambda^\rho_{\rho'}\Lambda^\sigma_{\sigma'}\epsilon^{\mu'\nu'\rho'\sigma'}$$

as you can show by expanding out the definition of the determinant and using the antisymmetry of ϵ. On the other hand, we know the Levi-Civita symbol is an invariant tensor, so we just get

$$J = -\frac{1}{24}\epsilon_{\mu\nu\rho\sigma}\epsilon^{\mu\nu\rho\sigma} = 1$$

Another method is to note that in terms of matrix multiplications, $\eta = \Lambda^T\eta\Lambda$, which implies

$$\det\eta = \left(\det\Lambda^T\right)(\det\eta)(\det\Lambda)$$

and therefore $J = \det\Lambda = \pm 1$. Since the proper orthochronous Lorentz transformations are connected to the identity, we must have $J = 1$. Finally, you could just manually show that $J = 1$ when Λ^μ_ν is a rotation or a boost, i.e. by showing that the matrices

$$\Lambda^\mu_\nu = \begin{pmatrix} \cosh\gamma & \sinh\gamma & & \\ \sinh\gamma & \cosh\gamma & & \\ & & 1 & \\ & & & 1 \end{pmatrix}, \quad \Lambda^\mu_\nu = \begin{pmatrix} 1 & & & \\ & 1 & & \\ & \cos\theta & \sin\theta & \\ & & -\sin\theta & \cos\theta \end{pmatrix}$$

have unit determinant. This is sufficient, since any proper orthochronous Lorentz transformation can be built out of rotations and boosts.

c) Show that for spacelike separation, $z^2 < 0$, the correlation function is exponentially decaying but nonzero. You can do this in two ways. First, you can show that

$$D(z) = \frac{m}{4\pi^2\sqrt{-z^2}} K_1\left(\sqrt{-z^2}m\right)$$

where K_1 is a modified Bessel function of the second kind. Alternatively, you may numerically integrate $D(z)$ and graph the result. In both cases you may use any books or computer programs needed, such as Mathematica or Abramowitz and Stegun.

Solution:

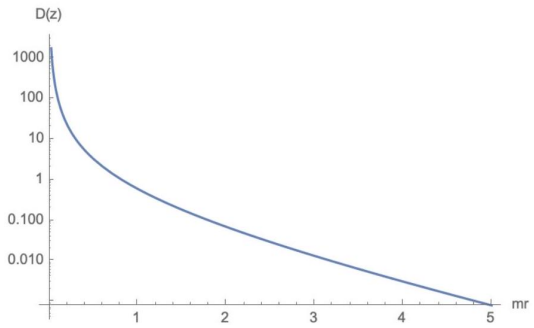
By our result from part (b), we can choose a frame where $z^\mu = (0, \mathbf{z})$, and set up spherical coordinates with the axis aligned with $\mathbf{z}$. Defining $r = \sqrt{-z^2} = |\mathbf{z}|$ and $p = |\mathbf{p}|$, we have

$$\begin{aligned} D(z) &= \int \frac{d\mathbf{p}}{2\omega_\mathbf{p}} e^{i\mathbf{p}\cdot\mathbf{z}} \\ &= \frac{1}{(2\pi)^3} \int_0^\infty dp \int_{-1}^1 d\cos\theta \int_0^{2\pi} d\phi \frac{p^2}{2\sqrt{p^2+m^2}} e^{ipr\cos\theta} \\ &= \frac{1}{(2\pi)^2} \int_0^\infty dp \frac{p}{\sqrt{p^2+m^2}} \frac{\sin(pr)}{r} \end{aligned}$$

At this point we can straightforwardly evaluate the integral numerically, e.g. in Mathematica.

```
Dz[r_, m_] := NIntegrate[p Sin[p r] / (r Sqrt[p^2 + m^2]),
  {p, 0, Infinity}]

LogPlot[Dz[r, 1], {r, 0, 5}, AxesLabel → {"mr", "D(z)"}]
```



Alternatively, if we want to stay analytic to the end, a little more work is necessary. First, we replace the integral with an equivalent complex integral over the entire real axis,

$$D(z) = -\frac{i}{8\pi^2 r} \int_{-\infty}^\infty dp \frac{pe^{ipr}}{\sqrt{p^2+m^2}}$$

To evaluate the integral, we deform the contour so that it wraps around the vertical branch cut that starts at $p = im$. Across this branch cut, the square root flips sign, so the contour integral going down the left end of the branch cut is equal to the contour integral going up the right end, giving

$$D(z) = \frac{1}{4\pi^2 r}\int_m^\infty dx \frac{xe^{-xr}}{\sqrt{x^2-m^2}}$$

where $p = ix$. Finally, looking up this integral in a book or Mathematica yields the final result,

$$D(z) = \frac{m}{4\pi^2 r}K_1(mr)$$

A key requirement for a relativistic theory is that it is local, meaning that effects don't propagate faster than the speed of light. That means any change applied to the field at x should only affect observable results at y if x and y aren't spacelike separated, $(y-x)^2 \geq 0$.

You might thus be concerned about part (c), which implies a field in the vacuum "knows" about the values of the field at spacelike separation. But there's nothing wrong with this. For example, to define a reference frame in special relativity, one synchronizes the clocks by sending light pulses throughout all space. After synchronization, all the clocks "know" about the values on the other clocks, even at spacelike separation. But that doesn't mean that changes propagate faster than light; it's just a consequence of how we set up the system. Similarly, ensuring a field is in the vacuum state requires absorbing all particles throughout all space, and this process sets up correlations between field values.

To test if our theory is local, we must see whether changes in the state propagate faster than light; that is the subject of the rest of the question.

d) One way to interact with a quantum field is to measure its value at a point, a process which changes the state. From quantum mechanics, we know that measurements of two operators $\mathcal{O}_1$ and $\mathcal{O}_2$ do not affect each other if $[\mathcal{O}_1, \mathcal{O}_2] = 0$. Show that

$$\langle 0|[\phi(x), \phi(y)]|0\rangle = 0$$

for spacelike separation, $(x-y)^2 < 0$, as expected from locality.

Solution:

We have

$$\langle 0|[\phi(x), \phi(y)]|0\rangle = D(z) - D(-z).$$

On the other hand, when z is spacelike, it can always be transformed into $-z$ by a Lorentz transformation. (A simple way to see this is to note that both z and $-z$ can be transformed into a standard four-vector like $\left(0, 0, 0, \sqrt{-z^2}\right)$, by first boosting to get rid of the time component, and rotating to get the spatial component pointing the right way.) Therefore, $D(z) = D(-z)$, so the commutator vanishes.

Note that when z is timelike, you can't Lorentz transform it into $-z$, so the argument that $D(z) = D(-z)$ fails. That makes sense because the commutator should be nonzero for timelike separations; if it was zero for all separations, then the theory would be trivial, as no measurements would ever affect anything.

e) Another way to interact with a field is to couple it to a classical source $J(x)$, which for a real scalar field corresponds to taking the Lagrangian

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu\phi\right)\left(\partial^\mu\phi\right) - \frac{1}{2}m^2\phi^2 + \phi(x)J(x)$$

This is the scalar analogue of driving the electromagnetic field with a current $J^\mu(x)$. For simplicity, we'll treat $\phi(x)$ as a classical field for now, though similar conclusions will hold when it is a quantum field. Show that the classical equation of motion is

$$\left(\partial_\mu\partial^\mu + m^2\right)\phi(x) = J(x).$$

Solution:

The Euler-Lagrange equations are

$$\partial_\mu \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi\right)} - \frac{\partial\mathcal{L}}{\partial\phi} = 0$$

where we now have

$$\partial_\mu \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi\right)} = \partial_\mu\partial^\mu\phi, \quad \frac{\partial\mathcal{L}}{\partial\phi} = -m^2\phi + J$$

which together give the desired result.
f) Show that the equation of motion is solved by

$$\phi(x) = i \int d^4y G(x-y) J(y)$$

where G is a Green's function of the Klein-Gordan operator, which means

$$\left(\partial_\mu \partial^\mu + m^2\right) G(z) = -i\delta^{(4)}(z)$$

The factors of $-i$ here are purely conventional, and will simplify results later.

Solution:

We have

$$\begin{aligned}\left(\partial^2 + m^2\right)\phi(x) &= i\left(\partial^2 + m^2\right)\int d^4y G(x-y)J(y) \\ &= i\int d^4y \left(-i\delta^{(4)}(x-y)\right) J(y) \\ &= J(x)\end{aligned}$$

as desired. Note that there is no term from the derivatives acting on the current because the derivatives are with respect to x, while J is a function of y. g) By taking Fourier transforms, we may heuristically write the Green's function as

$$G(z) = \int \frac{d^4p}{(2\pi)^4} \frac{ie^{-ip\cdot z}}{p^2 - m^2}$$

which formally obeys Eq. (8). However, this expression is not mathematically welldefined because the integral blows up when $p^2 = m^2$. To get a definite result, we must add " $i\epsilon$ " terms to the denominator to keep it from vanishing. There are multiple ways to do this, which physically corresponds to the fact that there are multiple possible Green's functions, depending on the field's boundary conditions. Three key examples are the retarded, advanced, and Feynman Green's functions,

$$\begin{aligned}G_R(z) &= \lim_{\epsilon\to 0^+} \int \frac{d^4p}{(2\pi)^4} \frac{ie^{-ip\cdot z}}{\left(p^0 + i\epsilon\right)^2 - |\mathbf{p}|^2 - m^2} \\ G_A(z) &= \lim_{\epsilon\to 0^+} \int \frac{d^4p}{(2\pi)^4} \frac{ie^{-ip\cdot z}}{\left(p^0 - i\epsilon\right)^2 - |\mathbf{p}|^2 - m^2} \\ G_F(z) &= \lim_{\epsilon\to 0^+} \int \frac{d^4p}{(2\pi)^4} \frac{ie^{-ip\cdot z}}{p^2 - m^2 + i\epsilon}\end{aligned}$$

where the limit notation means ϵ approaches zero from the positive end. By using the residue theorem to perform the integral over p^0, show that

$$\begin{aligned}G_R(z) &= \theta\left(z^0\right)\left(D(z) - D(-z)\right) \\ G_A(z) &= \theta\left(-z^0\right)\left(D(-z) - D(z)\right) \\ G_F(z) &= \theta\left(z^0\right) D(z) + \theta\left(-z^0\right) D(-z)\end{aligned}$$

Solution:

Applying partial fractions, we have

$$G_R(z) = i\int \frac{d^3p dp^0}{(2\pi)^4} \frac{1}{2\omega_p}\left[\frac{1}{\left(p^0 - \omega_p + i\epsilon\right)} - \frac{1}{\left(p^0 + \omega_p + i\epsilon\right)}\right] e^{-ip\cdot z}$$

which implies both poles are shifted below the real p^0 axis. Now we perform the integral over p^0. When $z^0 > 0$, the integrand is exponentially damped below the real p^0 axis, so it makes no difference if we replace the contour over the real line with a closed contour which additionally includes a semicircle (of infinite radius) below the real axis, as shown.

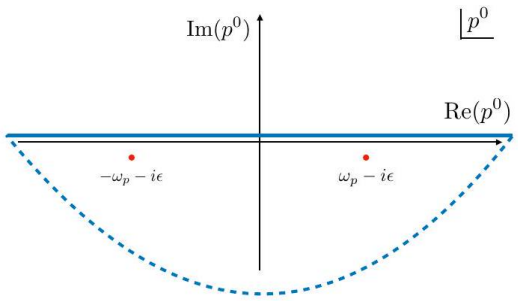


Figure 1: Contour for the retarded propagator for $z^0 > 0$.

This closed contour integral can be calculated using the residue theorem. Each pole contributes $-2\pi i$ times its residue (where the minus sign is because the contour goes around the poles clockwise), giving

$$G_R(z) = \int \frac{d^3p}{(2\pi)^3}\left[\frac{1}{2\omega_p}e^{-i\omega_p z^0 + i\mathbf{p}\cdot\mathbf{z}} - \frac{1}{2\omega_p}e^{i\omega_p z^0 + i\mathbf{p}\cdot\mathbf{z}}\right]$$

Reindexing $\mathbf{p} \to -\mathbf{p}$ in the second term gives

$$\begin{aligned} G_R(z) &= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2\omega_p}\left[e^{-i\omega_p z^0 + i\mathbf{p}\cdot\mathbf{z}} - e^{i\omega_p z^0 - i\mathbf{p}\cdot\mathbf{z}}\right] \\ &= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2\omega_p}\left[e^{-ip\cdot z} - e^{ip\cdot z}\right] = D(z) - D(-z) \end{aligned}$$

where here we are defining $p = (\omega_p, \mathbf{p})$. On the other hand, when $z^0 < 0$, the integral is exponentially damped above the real p^0 axis. We can thus close the contour above the real axis, and it encircles no poles, so the integral vanishes. Thus,

$$G_R(z) = \theta\left(z^0\right)\left(D(z) - D(-z)\right)$$

as desired. The proof for $G_A(z)$ is extremely similar, but now with both poles above the real axis.

Finally, the Feynman propagator is

$$\begin{aligned} G_F(z) &= i\int \frac{d^4p}{(2\pi)^4}\left[\frac{1}{(p^0 - \omega_p + i\epsilon)(p^0 + \omega_p - i\epsilon)}\right]e^{-ip\cdot z} \\ &= i\int \frac{d^3p dp^0}{(2\pi)^4}\frac{1}{2\omega_p}\left[\frac{1}{(p^0 - \omega_p + i\epsilon)} - \frac{1}{(p^0 + \omega_p - i\epsilon)}\right]e^{-ip\cdot z} \end{aligned}$$

which has one pole above the real axis, and one pole below. In figure 2 we show the contours of integration

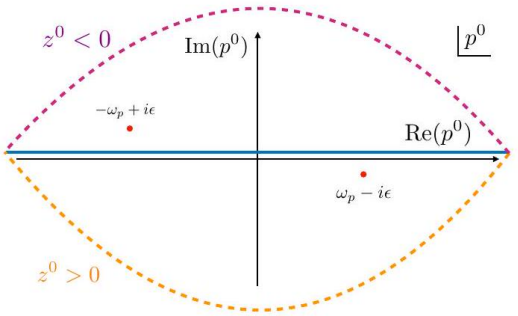

Figure 2: Contour for the Feynman propagator.

for the p^0 integral. If $z^0 > 0$ the dashed, orange line in fig. 2 represents a contour of a semi-circle with infinite radius in the lower half of the complex plane and does not contribute to the integral. The integral along the the real p^0 axis consequently yields minus one times the residue at $p^0 = \omega_p + i\epsilon$ and the other residue does not contribute. Conversely, if $z^0 < 0$, the purple dashed contour in the positive imaginary half-plane contributes zero to the integral and the integral along the real axis yields the residue at $p^0 = -\omega_p + i\epsilon$. We thus conclude

$$G_F(z) = \int \frac{d^4p}{(2\pi)^4} \frac{1}{2\omega_p} \left[\theta\left(z^0\right) e^{-ipz} + \theta\left(-z^0\right) e^{ipz}\right]$$
$$= \theta\left(z^0\right) D(z) + \theta\left(-z^0\right) D(-z)$$

h) The retarded Greens function applies when the field is zero before the source acts. Show that $G_R(x-y)$ vanishes for spacelike separation, as expected from locality.

Solution:

When z^0 is negative, $G_R(z)$ is just zero by the definition of the step function. When z^0 is positive, $G_R(z)$ is just the same thing as $\langle 0|[\phi(x), \phi(y)]|0\rangle$, which we showed was zero for spacelike separation in part (d).

i) The Feynman propagator will play a crucial role when we introduce Feynman diagrams because it is equal to $\langle 0|T\phi(x)\phi(y)|0\rangle$. Does it vanish for spacelike separation?

Solution:

It doesn't vanish for spacelike separation. For example, when z^0 is positive, the Feynman propagator is just $D(z)$, and we already showed in part **(c)** that this can be nonzero for spacelike separations. For this reason, the Feynman propagator has little use in classical field theory (which is why it doesn't show up in electromagnetism classes, while the retarded and advanced propagators do). But it will be useful when we set up perturbation theory.

Some students tried to solve this problem by setting $z^0 = 0$, but this is a bit tricky because the step functions are discontinuous there. There's no need to do this, because we already showed that $D(z)$ can be nonzero for general spacelike separation, not just when $z^0 = 0$.

Stanford.Zhou.2022.3.2 Recovering classical field theory. (10/45p)

If an operator $\mathcal{O}$ is time-independent in Schrodinger picture, then in Heisenberg picture,

$$\frac{d\mathcal{O}(t)}{dt} = i[H(t), \mathcal{O}(t)]$$

In quantum field theory, working in the Heisenberg picture allows fields to depend on spacetime, making results look more Lorentz invariant. For example, we saw that in Heisenberg picture, a real scalar field obeys the Klein-Gordan equation $\left(\partial^2 + m^2\right)\phi = 0$. Now consider the Lagrangian of Eq. (5), which additionally includes a source term $J(x)$. In this case, the Hamiltonian is explicitly time-dependent,

$$H(t) = H_0 - \int d^3\mathbf{x}\phi(\mathbf{x}, t)J(\mathbf{x}, t)$$

where H_0 is the free Hamiltonian.

a) Show that in Heisenberg picture, the field $\phi(x)$ obeys Eq. (6). (Thus, by the logic of problem 1, expectation values of a quantum field $\phi(x)$ respond locally to sources.)

b) The impulse causes operators to instantaneously shift in value at $t = 0$. Show that

$$\phi\left(\mathbf{x}, 0^+\right) = \phi\left(\mathbf{x}, 0^-\right), \quad \pi\left(\mathbf{x}, 0^+\right) = \pi\left(\mathbf{x}, 0^-\right) + j(\mathbf{x}).$$

Here, 0^+means a time right after $t = 0$, and 0^-means a time right before, i.e.

$$f\left(0^+\right) - f\left(0^-\right) = \lim_{\epsilon \to 0^+} \int_{-\epsilon}^{\epsilon} \frac{df(t)}{dt} dt$$

for any function of time.

c) Show that this is equivalent to the annihilation operators shifting by

$$a\left(\mathbf{p}, 0^+\right) = a\left(\mathbf{p}, 0^-\right) + \frac{i}{\sqrt{2\omega_{\mathbf{p}}}} \tilde{j}(\mathbf{p})$$

where $\tilde{j}$ is the Fourier transform of j.

d) Show that the field is in a coherent state after the impulse, in the sense that the state is an eigenvector of $a\left(\mathbf{p}, 0^+\right)$. Then evaluate $\left\langle 0 \left| a^\dagger\left(\mathbf{p}, 0^+\right) a\left(\mathbf{p}, 0^+\right) \right| 0 \right\rangle$, which gives the number of particles of momentum $\mathbf{p}$ produced, per unit volume of momentum space.

Solution:

Note that the new term in the Hamiltonian commutes with $\phi(\mathbf{y},t)$ for any $\mathbf{y}$. Therefore, the Heisenberg equation of motion for ϕ is exactly the same as before,

$$\dot{\phi}(x) = \pi(x)$$

As for the canonical momentum, we have

$$\begin{aligned}\dot{\pi}(x) &= \nabla^2\phi(x) - m^2\phi(x) + i\left[-\int d^3\mathbf{y}\phi(\mathbf{y},t)J(\mathbf{y},t), \pi(\mathbf{x},t)\right] \\ &= \nabla^2\phi(x) - m^2\phi(x) + (-i)(i)\int d^3\mathbf{y}\delta^{(3)}(\mathbf{y}-\mathbf{x})J(\mathbf{y},t) \\ &= \nabla^2\phi(x) - m^2\phi(x) + J(x).\end{aligned}$$

Combining these two equations gives the result.

With the source, quantum fields can evolve in time nontrivially. Suppose we start in the vacuum state $|0\rangle$, and at time $t = 0$ apply an impulse to the field via

$$J(x) = \delta(t)j(\mathbf{x})$$

This is the scalar analogue of suddenly turning an electric current on and off in electromagnetism. It is also closely related to the last half of problem 2 of problem set 1.

Solution:

Integrating the Heisenberg equation of motion for an infinitesimal time centered at $t = 0$,

$$\phi\left(\mathbf{x},0^+\right) - \phi\left(\mathbf{x},0^-\right) = -i\left[\int d^3\mathbf{y}\phi(\mathbf{y},0)j(\mathbf{y}), \phi(\mathbf{x},0)\right] = 0$$

On the other hand, we have

$$\begin{aligned}\pi\left(\mathbf{x},0^+\right) - \pi\left(\mathbf{x},0^-\right) &= -i\left[\int d^3\mathbf{y}\phi(\mathbf{y},0)j(\mathbf{y}), \pi(\mathbf{x},0)\right] \\ &= -i\int d^3\mathbf{y}i\delta(\mathbf{y}-\mathbf{x})j(\mathbf{y}) \\ &= j(\mathbf{x})\end{aligned}$$

Solution to c:

First, note that

$$a^\dagger\left(\mathbf{p},0^+\right) = a^\dagger\left(\mathbf{p},0^-\right) - \frac{i}{\sqrt{2\omega_\mathbf{p}}}\tilde{j}^*(\mathbf{p})$$

Furthermore, because $j(\mathbf{x})$ is real, we have

$$\tilde{j}^*(\mathbf{p}) = \left(\int d\mathbf{x}j(\mathbf{x})e^{-i\mathbf{p}\cdot\mathbf{x}}\right)^* = \int d\mathbf{x}j(\mathbf{x})e^{i\mathbf{p}\cdot\mathbf{x}} = \tilde{j}(-\mathbf{p})$$

The change in the field operator is

$$\phi\left(\mathbf{x},0^+\right) - \phi\left(\mathbf{x},0^-\right) = \int \frac{d\mathbf{k}}{\sqrt{2\omega_\mathbf{k}}}\left(\frac{i\tilde{j}(\mathbf{k})}{\sqrt{2\omega_\mathbf{k}}}e^{i\mathbf{k}\cdot\mathbf{x}} - \frac{i\tilde{j}^*(\mathbf{k})}{\sqrt{2\omega_\mathbf{k}}}e^{-i\mathbf{k}\cdot\mathbf{x}}\right)$$

Substituting $\mathbf{k}' = -\mathbf{k}$ in the second term and renaming $\mathbf{k}'$ to $\mathbf{k}$ gives

$$\phi\left(\mathbf{x},0^+\right) - \phi\left(\mathbf{x},0^-\right) = i\int \frac{d\mathbf{k}}{\sqrt{2\omega_\mathbf{k}}}\left(\frac{\tilde{j}(\mathbf{k})}{\sqrt{2\omega_\mathbf{k}}}e^{i\mathbf{k}\cdot\mathbf{x}} - \frac{\tilde{j}^*(-\mathbf{k})}{\sqrt{2\omega_\mathbf{k}}}e^{i\mathbf{k}\cdot\mathbf{x}}\right) = 0.$$

On the other hand, we have

$$\begin{aligned}\pi\left(\mathbf{x},0^{+}\right)-\pi\left(\mathbf{x},0^{-}\right) &= -i\int d\mathbf{k}\sqrt{\frac{\omega_{\mathbf{k}}}{2}}\left(\frac{i\tilde{j}(\mathbf{k})}{\sqrt{2\omega_{\mathbf{k}}}}e^{i\mathbf{k}\cdot\mathbf{x}}-\frac{-i\tilde{j}^{*}(\mathbf{k})}{\sqrt{2\omega_{\mathbf{k}}}}e^{-i\mathbf{k}\cdot\mathbf{x}}\right)\\ &= \frac{1}{2}\int d\mathbf{k}\left(\tilde{j}(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{x}}+\tilde{j}^{*}(\mathbf{k})e^{-i\mathbf{k}\cdot\mathbf{x}}\right)\\ &= \frac{1}{2}\int d\mathbf{k}\left(\tilde{j}(\mathbf{k})+\tilde{j}^{*}(-\mathbf{k})\right)e^{i\mathbf{k}\cdot\mathbf{x}}\\ &= j(\mathbf{x})\end{aligned}$$

as desired.

Solution to d:

Because we are in the vacuum state before the impulse, $a\left(\mathbf{p},0^{-}\right)|0\rangle=0$, we have

$$a\left(\mathbf{p},0^{+}\right)|0\rangle=\frac{i}{\sqrt{2\omega_{\mathbf{p}}}}\tilde{j}(\mathbf{p})|0\rangle$$

which implies the field is in a coherent state after the impulse. Then we have

$$\left\langle 0\left|a^{\dagger}\left(\mathbf{p},0^{+}\right)a\left(\mathbf{p},0^{+}\right)\right|0\right\rangle=\left\langle 0\left|\frac{(-i)\tilde{j}^{*}(\mathbf{p})}{\sqrt{2\omega_{\mathbf{p}}}}\frac{i\tilde{j}(\mathbf{p})}{\sqrt{2\omega_{\mathbf{p}}}}\right|0\right\rangle=\frac{|\tilde{j}(\mathbf{p})|^{2}}{2\omega_{\mathbf{p}}}$$

Incidentally, the fact that the field is in a coherent state implies that the number of particles in a given range of momenta is Poisson distributed.

As you saw in problem set 1, coherent states of the quantum harmonic oscillator have the same position and momentum uncertainties as the vacuum state. Similarly, in quantum field theory, coherent states of the field have the same ϕ and π uncertainties as the vacuum, while their expectation values behave classically. When the driving is strong, the uncertainties become negligible compared to the expectation values, and the number of particles becomes large so that we can no longer see their discreteness. We therefore recover a classical field.

Stanford.Zhou.2022.3.3 Practice with time-ordered exponentials. (10/45p)

Suppose the Hamiltonian is $H=H_0+H_{\text{int}}$, where H_0 is a time-independent free Hamiltonian, and H_{int} is an interaction which could be time-dependent. In interaction picture, operators evolve under the free Hamiltonian H_0 alone, and the states are $|\psi(t)\rangle_I$. Let's first review some results derived in lecture.

a) Show that

$$i\partial_t|\psi(t)\rangle_I=H_{\text{int},I}(t)|\psi(t)\rangle_I$$

where $H_{\text{int},I}(t)$ is the interaction Hamiltonian in the interaction picture.

Solution:

By definition, matrix elements of operators are the same in all pictures, so for any states $|\psi\rangle$ and $|\psi'\rangle$, and any operator $\mathcal{O}$, we have

$${}_I\left\langle\psi'(t)\left|\mathcal{O}_I(t)\right|\psi(t)\right\rangle_I={}_S\left\langle\psi'(t)\left|\mathcal{O}_S\right|\psi(t)\right\rangle_S$$

On the other hand, we know that

$$\mathcal{O}_I(t)=e^{iH_0t}\mathcal{O}_Se^{-iH_0t}$$

so comparing the expressions gives

$$|\psi(t)\rangle_I=e^{iH_0t}|\psi(t)\rangle_S$$

Applying $i\partial_t$ to both sides gives

$$\begin{aligned}i\partial_t|\psi(t)\rangle_I &= -H_0e^{iH_0t}|\psi(t)\rangle_S+ie^{iH_0t}\partial_t|\psi(t)\rangle_S\\ &= -H_0|\psi(t)\rangle_I+e^{iH_0t}H_S|\psi(t)\rangle_S\\ &= -e^{iH_0t}H_0e^{-iH_0t}|\psi(t)\rangle_I+e^{iH_0t}H_Se^{-iH_0t}|\psi(t)\rangle_I\\ &= H_{\text{int},I}(t)|\psi(t)\rangle_I\end{aligned}$$

as desired.
b) Show that if the interaction picture time evolution operator is defined as

$$|\psi(t_f)\rangle_I = U(t_f, t_i)\,|\psi(t_i)\rangle_I$$

for $t_f > t_i$, then it is given by Dyson's formula,

$$U(t_f, t_i) = T\exp\left(-i\int_{t_i}^{t_f} dt H_{\text{int},I}(t)\right)$$

where T denotes time ordering.

Solution:

Abbreviating $H_{\text{int},I}(t)$ as $H(t)$, note that the time-ordered exponential is

$$U(t_f, t_i) = \sum_{n=0}^{\infty}\frac{(-i)^n}{n!}\int_{t_i}^{t_f} dt_n \int_{t_i}^{t_f} dt_{n-1}\cdots\int_{t_i}^{t_f} dt_1 T\left(H(t_n)\,H(t_{n-1})\cdots H(t_1)\right).$$

We can incorporate the effect of the time ordering by changing the integration bounds,

$$U(t_f, t_i) = \sum_{n=0}^{\infty}(-i)^n\int_{t_i}^{t_f} dt_n \int_{t_i}^{t_n} dt_{n-1}\cdots\int_{t_i}^{t_2} dt_1 H(t_n)\,H(t_{n-1})\cdots H(t_1)$$

where the factor of $1/n\,!$ cancelled because the new integration region has $1/n\,!$ times the volume of the original one. Now, part **(a)** tells us that we want to prove

$$i\partial_{t_f} U(t_f, t_i) = H(t_f)\,U(t_f, t_i).$$

When we differentiating Eq. (S61) with respect to t_f, we only pick up one term from the upper bound of the outer integral, giving

$$i\partial_{t_f} U(t_f, t_i) = H(t_f)\sum_{n=1}^{\infty}(-i)^{n-1}\int_{t_i}^{t_f} dt_{n-1}\cdots\int_{t_i}^{t_2} dt_1 H(t_{n-1})\cdots H(t_1)$$

Shifting the sum in n downward by one recovers $U(t_f, t_i)$, as desired.
Now let's do some concrete calculations with the time evolution operator.
c) Suppose the interaction is only turned on for two moments, i.e. it has the form

$$H_{\text{int},I}(t) = g\left(h_1\delta(t - t_1) + h_2\delta(t - t_2)\right)$$

Write out $U(t_f, t_i)$ up to and including terms of order g^2, assuming $t_i < t_1 < t_2 < t_f$.

Solution:

We have

$$\int_{t_i}^{t_f} dt H_{\text{int},I}(t) = g(h_1 + h_2)$$

so the exponential without the time-ordering would be

$$1 - ig(h_1 + h_2) - \frac{g^2}{2}(h_1 + h_2)^2 + O\left(g^3\right).$$

The time-ordering puts contributions that occur later on the left, which means all the h_2 terms are to the left of the h_1 terms, giving

$$1 - ig\left(h_1 + h_2\right) - \frac{g^2}{2}\left(h_1^2 + 2h_2h_1 + h_2^2\right) + O\left(g^3\right)$$

d) Now consider a general $H_{\text{int},I}(t)$ which is proportional to a coupling g. It is generally true that $U\left(t_3,t_2\right)U\left(t_2,t_1\right) = U\left(t_3,t_1\right)$. Explicitly show that this result is true, up to and including terms of order g^2, in the case $t_1 < t_2 < t_3$.

Solution:

The desired right-hand side is

$$U\left(t_3,t_1\right) = 1 - ig\int_{t_1}^{t_3} dt H(t) - g^2\int_{t_1}^{t_3} dt\int_{t_1}^{t} dt' H(t)H\left(t'\right) + O\left(g^3\right)$$

On the left-hand side, expanding the product of the two terms gives

$$\begin{aligned} U\left(t_3,t_2\right)U\left(t_2,t_1\right) &= 1 - ig\int_{t_1}^{t_2} dt H(t) - ig\int_{t_2}^{t_3} dt H(t) \\ &- g^2\int_{t_1}^{t_2} dt\int_{t_2}^{t_3} dt' H(t)H\left(t'\right) - g^2\int_{t_1}^{t_2} dt\int_{t_1}^{t} dt' H(t)H\left(t'\right) - g^2\int_{t_2}^{t_3} dt\int_{t_2}^{t} dt' H(t)H\left(t'\right) + O\left(g^3\right). \end{aligned}$$

Clearly, the constant and $O(g)$ terms agree, so the tricky part is showing the equality of the $O\left(g^2\right)$ terms,

$$\int_{t_1}^{t_3} dt\int_{t_1}^{t} dt' H(t)H\left(t'\right) = \int_{t_1}^{t_2} dt\int_{t_2}^{t_3} dt' H(t)H\left(t'\right) + \int_{t_1}^{t_2} dt\int_{t_1}^{t} dt' H(t)H\left(t'\right) + \int_{t_2}^{t_3} dt\int_{t_2}^{t} dt' H(t)H\left(t'\right)$$

The left-hand side integrates over all $t_1 < t' < t < t_3$, and t_2 is between t_1 and t_3. All terms on the right-hand side enforce $t' < t$. The second term includes the region where both t and t' are less than t_2, the third term includes the regions where both are greater than t_2, and the first term corresponds to when t_2 is between t and t'.

26.1.4 Problems about free quantum fields 3

Stanford.Zhou.2022 4.1. Wick's theorem. (7/45 p)

For both parts of this problem, you can use Wick's theorem for two real scalar fields.
a) Show that $T\left(\phi\left(x_1\right)\phi\left(x_2\right)\right)$ and: $\phi\left(x_1\right)\phi\left(x_2\right)$: both remain the same when x_1 and x_2 are exchanged. Using these results, explain why $D_F\left(x_1 - x_2\right) = D_F\left(x_2 - x_1\right)$.

Solution:

For the time ordered product this is true by definition; it puts the later operator on the left no matter what their original order was. As for the normal ordered product, we can split each field into parts with only creation and annihilation operators,

$$\phi\left(x_i\right) = \phi_i^+ + \phi_i^-, \quad 0 = \phi_i^-|0\rangle = \langle 0|\phi_i^+.$$

The normal ordered product is defined by

$$:\phi_1\phi_2: = \phi_1^+\phi_2^+ + \phi_1^+\phi_2^- + \phi_2^+\phi_1^- + \phi_1^-\phi_2^-.$$

Since $\left[\phi_i^+,\phi_j^+\right] = \left[\phi_i^-,\phi_j^-\right] = 0$, this expression is identical if we exchange x_1 and x_2. Finally, Wick's theorem tells us that the Feynman propagator is the difference of a time ordered product and a normal ordered product, so it is also symmetric in its arguments.
b) Prove Wick's theorem for a time ordered product of three scalar fields,

$$\begin{aligned} T\left(\phi\left(x_1\right)\phi\left(x_2\right)\phi\left(x_3\right)\right) =: \phi\left(x_1\right)\phi\left(x_2\right)\phi\left(x_3\right): &+ \phi\left(x_1\right)D_F\left(x_2 - x_3\right) \\ &+ \phi\left(x_2\right)D_F\left(x_3 - x_1\right) + \phi\left(x_3\right)D_F\left(x_1 - x_2\right). \end{aligned}$$

Solution:

We simply work through the cases for the time ordering of x_1, x_2, and x_3. By definition,

$$T\left(\phi\left(x_1\right)\phi\left(x_2\right)\phi\left(x_3\right)\right) = \phi_1 T\left\{\phi_2\phi_3\right\}\big|_{t_1>t_2,t_3} + \phi_2 T\left\{\phi_1\phi_3\right\}\big|_{t_2>t_1,t_3} + \phi_3 T\left\{\phi_1\phi_2\right\}\big|_{t_3>t_2,t_1}$$

Now let's apply Wick's theorem to the last term,

$$\phi_3 T\left\{\phi_1\phi_2\right\}\big|_{t_3>t_2,t_1} = \left(\phi_3^+ + \phi_3^-\right)\left(\phi_1^+\phi_2^+ + \phi_1^+\phi_2^- + \phi_2^+\phi_1^- + \phi_1^-\phi_2^- + D_F\left(x_2 - x_3\right)\right)\big|_{t_3>t_2,t_1}$$

A term is normal ordered if all the ϕ_i^+'s are to the left of all the ϕ_i^-'s, so

$$:\phi_1\phi_2\phi_3: = \left(\phi_3^+ + \phi_3^-\right)\left(\phi_1^+\phi_2^+ + \phi_1^+\phi_2^- + \phi_2^+\phi_1^- + \phi_1^-\phi_2^-\right)\big|_{t_3>t_2,t_1} + \left[\phi_3^-, \phi_2^+\right]\phi_1 + \left[\phi_3^-, \phi_1^+\right]\phi_2\big|_{t_3>t_2,t_1}$$

We have therefore shown that

$$\phi_3 T\left\{\phi_1\phi_2\right\}\big|_{t_3>t_2,t_1} = \left(:\phi_1\phi_2\phi_3: + \phi_1\left[\phi_3^-, \phi_2^+\right] + \phi_2\left[\phi_3^-, \phi_1^+\right] + \phi_3 D_F\left(x_1 - x_2\right)\right) \times \theta\left(x_3^0 - x_2^0\right)\theta\left(x_3^0 - x_1^0\right).$$

When we add the other two terms, the first terms of each one combine to give: $\phi_1\phi_2\phi_3$: with no step functions. In addition, pairs of commutator terms combine into Feynman propagators by

$$D_F(x,y) = \theta\left(x^0 - y^0\right)\left[\phi^-(x), \phi^+(y)\right] + \theta\left(y^0 - x^0\right)\left[\phi^-(y), \phi^+(x)\right]$$

To see how this works, let's consider the terms that eventually combine to yield $\phi\left(x_3\right) D_F\left(x_1 - x_2\right)$,

$$\phi_3\left(D_F\left(x_1 - x_2\right)\theta\left(t_3 - t_2\right)\theta\left(t_3 - t_1\right) + \left[\phi_1^-, \phi_2^+\right]\theta\left(t_1 - t_3\right)\theta\left(t_1 - t_2\right) + \left[\phi_2^-, \phi_1^+\right]\theta\left(t_2 - t_1\right)\theta\left(t_2 - t_3\right)\right).$$

The first term here is the desired term when t_3 is the latest time. The second and third terms combine to give the Feynman propagator for any ordering of t_1 and t_2, under the condition that t_3 is not the latest. So the sum is $\phi\left(x_3\right) D_F\left(x_1 - x_2\right)$, and the logic for the other terms is similar.

Stanford.Zhou.2022 4.2 Diagrams in ϕ^3 theory. (18/45p)

Consider a real scalar field ϕ of mass m with a cubic self-interaction, so that

$$\mathcal{L}_0 = \frac{1}{2}\left(\partial_\mu\phi\right)\left(\partial^\mu\phi\right) - \frac{1}{2}m^2\phi^2, \quad \mathcal{L}_{\text{int}} = \frac{\lambda}{3!}\phi^3.$$

Let $|0\rangle$ denote the free vacuum, the interaction Hamiltonian density is $\mathcal{H}_{\text{int}} = -\mathcal{L}_{\text{int}}$, and H_I is the interaction Hamiltonian in interaction picture.

a) Using Wick's theorem, evaluate the vacuum correlation function

$$\left\langle 0\left|T\exp\left(-i\int dt H_I(t)\right)\right|0\right\rangle$$

up to and including terms of order λ^2. Your result should be an explicit expression in terms of integrals of the position-space Feynman propagator. (You will run into terms proportional to $D_F(0)$, which is infinite. Don't worry about this for now; we'll come back to this issue when we discuss renormalization.)

b) Draw all distinct diagrams that contribute to the vacuum correlation function at order λ^3 and λ^4. For this part, you do not need to evaluate the diagrams or compute any symmetry factors, but you should neatly display all of your diagrams in one box.

c) Now consider the two-point correlation function

$$\langle\Omega\left|T\left(\phi_H(x)\phi_H(y)\right)\right|\Omega\rangle = \frac{\left\langle 0\left|T\left(\phi_I(x)\phi_I(y)\exp\left(-i\int dt H_I\right)\right)\right|0\right\rangle}{\left\langle 0\left|T\exp\left(-i\int dt H_I\right)\right|0\right\rangle}$$

where ϕ_H and ϕ_I are Heisenberg and interaction picture fields. As discussed in class, only connected diagrams contribute to the left-hand side, i.e. diagrams where all fields are connected to at least one of the external points. Find all diagrams that contribute up to and including order λ^4, along with their symmetry factors, which you can compute with any method. Again, give your answer by drawing everything neatly inside one box. (Hint: there are 13 fully connected diagrams, i.e. diagrams where all fields are connected to both of the external points.)

Solution to a:

Let the desired correlation function be $c_0 + \lambda c_1 + \lambda^2 c_2 + \mathcal{O}\left(\lambda^3\right)$. Then

$$c_0 = \langle 0|0\rangle = 1$$

and

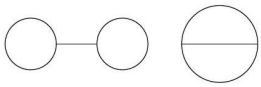
$$c_1 = \frac{i}{3!}\left\langle 0\left|T\left(\int d^4x\phi(x)\phi(x)\phi(x)\right)\right|0\right\rangle = 0$$

because we have an odd number of copies of ϕ.

Then,

$$\begin{aligned} c_2 &= \frac{1}{2!}\left(\frac{i}{3!}\right)^2\left\langle 0\left|T\left(\int d^4xd^4y\phi(x)\phi(x)\phi(x)\phi(y)\phi(y)\phi(y)\right)\right|0\right\rangle \\ &= -\frac{1}{72}\int d^4xd^4y\left[3\cdot 3\cdot D_F(x-x)D_F(x-y)D_F(y-y) + 3!\cdot D_F(x-y)^3\right] \\ &= -\int d^4xd^4y\left(\frac{1}{8}D_F(0)^2D_F(x-y) + \frac{1}{12}D_F(x-y)^3\right). \end{aligned}$$

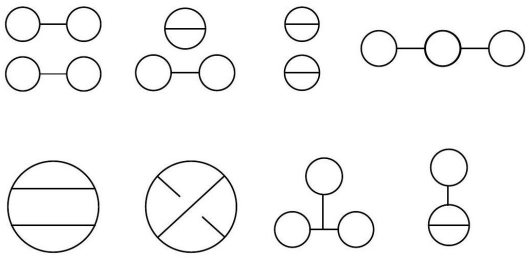
The terms in c_2 correspond to the diagrams shown below:



(??? интересно, тут как раз эти 8 и 12 это перестановки вершин и пара других правил симметрий? вроде да, так и получается, впишу эти рассуждения потом)

Solution to b:

There are no diagrams at any odd order. The 8 diagrams at order λ^4 are shown below.



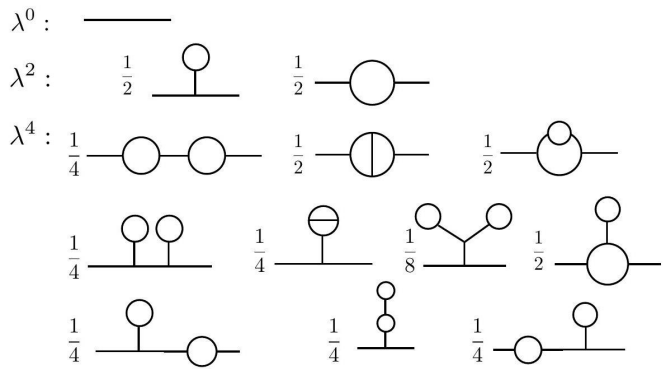
Solution c: (??????????????)

(??? пока вообще не понял, почему такие симм. факторы???? научусь выводить еще это потом!!!)

Again, odd orders in λ always yield correlation functions on the right-hand side with an odd number of fields, which vanish since $\langle 0|\phi|0\rangle = 0$. The fully connected diagrams that contribute at orders λ^0, λ^2, and λ^4 are shown below, along with their symmetry factors.

These symmetry factors can all be found with the following rules:

- $1/2$ for every vertex connected to itself.
- $1/k!$ for k propagators connecting the same two vertices.
- $1/2$ for two interchangeable vertices.



(??? почему именно такое их количество????)

For λ^2:

1) vertex connected to itself, 2) 2 propagators connecting the same two vertices

For the first line in λ^4:

1) Two elements of "two propagators connecting the same two vertices", 2) two interchangeable vertices, 3) 2 propagators connecting the same two vertices.

For the second line in λ^4:

1) Two elements of "vertex connected to itself", 2) two interchangeable vertices and 2 propagators connecting the same two vertices, 3) two elements of "vertex connected to itself" and two interchangeable vertices, 4) vertex connected to itself.

For the third line in λ^4:

1) Vertex connected to itself and two propagators connecting the same two vertices, 2) vertex connected to itself and two propagators connecting the same two vertices, 3) vertex connected to itself and two propagators connecting the same two vertices.

Here is some computation by hand if one wants to make sure:

(????!!! сделаю это, а то пока не уверен!!!)

(to do: also include the four non-fully connected diagrams) (?????)

Stanford.Zhou.2022 4.3 Recovering nonrelativistic quantum mechanics. (15/45p)

A free complex scalar field Φ of mass m satisfies the Klein-Gordan equation, so its plane wave modes $e^{-ip\cdot x}$ satisfy $\omega^2 = |\mathbf{k}|^2 + m^2$. This implies we have plane waves with both positive and negative ω, which is universal in relativistic theories. Upon quantization, excitations of these modes correspond to matter and antimatter, with opposite charges.

The nonrelativistic limit is $|\mathbf{k}| \ll m$, but since antimatter is inherently a feature of relativistic theories, we should also throw away the negative ω modes. To do this, take

$$\Phi(x) = e^{-imt}\chi(x)/\sqrt{2m}$$

and assume $|\dot{\chi}| \ll m\chi$, so that only nonrelativistic positive ω modes are excited. The $\sqrt{2m}$ factor transfers us back to nonrelativistic normalization.

a) Simplify the complex scalar field action to

$$S = \int d^4x \left(i\chi^*\dot{\chi} - \frac{1}{2m}\nabla\chi^* \cdot \nabla\chi \right)$$

by dropping a term that is small for $|\dot{\chi}| \ll m\chi$.

b) Find the Euler-Lagrange equations for χ and χ^*, and the conserved current $J^\mu = (\rho, \mathbf{J})$ corresponding to the symmetry $\chi \to e^{-i\alpha}\chi$ and $\chi^* \to e^{i\alpha}\chi^*$. (Be careful to account for minus signs from the relativistic metric.)

For the relativistic complex scalar field, we had to canonically quantize Φ, Π, Φ^*, and Π^* as two pairs of phase space variables. But for this nonrelativistic field, the canonical momentum for χ is just $i\chi^*$, so we only have one pair. This is because we threw away the negative ω solutions, and it implies the canonical commutation relations are

$$[\chi(\mathbf{x}), \chi^*(\mathbf{y})] = \delta^{(3)}(\mathbf{x} - \mathbf{y})$$

with all other commutators vanishing. These can be satisfied with the mode expansion

$$\chi(\mathbf{x}) = \int \frac{d^3\mathbf{p}}{(2\pi)^3} a(\mathbf{p}) e^{-i\mathbf{p}\cdot\mathbf{x}}, \quad \chi^*(\mathbf{x}) = \int \frac{d^3\mathbf{p}}{(2\pi)^3} a^\dagger(\mathbf{p}) e^{i\mathbf{p}\cdot\mathbf{x}}$$

c) Show that $\left[a(\mathbf{p}), a^\dagger(\mathbf{q})\right] = (2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})$. (Of course, the other commutators vanish.) Then show that the single-particle states $|\mathbf{x}\rangle = \chi^*(\mathbf{x})|0\rangle$ and $|\mathbf{p}\rangle = a^\dagger(\mathbf{p})|0\rangle$ behave like nonrelativistic position and momentum states, obeying

$$\langle\mathbf{y}|\mathbf{x}\rangle = \delta^{(3)}(\mathbf{y}-\mathbf{x}), \quad \langle\mathbf{q}|\mathbf{p}\rangle = (2\pi)^3\delta^{(3)}(\mathbf{q}-\mathbf{p}), \quad \langle\mathbf{p}|\mathbf{x}\rangle = e^{i\mathbf{p}\cdot\mathbf{x}}$$

The factors of 2π are just due to our Fourier transform convention.

d) A general single-particle state takes the form

$$|\psi(t)\rangle = \int d^3\mathbf{x}\psi(\mathbf{x},t)|\mathbf{x}\rangle$$

where $\psi(\mathbf{x},t)$ is the particle's position-space wavefunction at time t. As always in quantum theories, the state evolves over time as $i\partial_t|\psi\rangle = H|\psi\rangle$, where H is the Hamiltonian. Write this equation as a partial differential equation involving $\psi(\mathbf{x},t)$.

e) Take the term in the action you dropped in part (**a)** and simplify it by applying the Euler-Lagrange equations you found in part (b). Find how the Hamiltonian in part (**d)** changes when this term is added. What is its physical interpretation?

Solution to a:

The Lagrangian is

$$\begin{aligned}\mathcal{L} &= (\partial_\mu\Phi)(\partial^\mu\Phi)^* - m^2\Phi^*\Phi \\ &= \frac{1}{2m}\left(\partial_\mu\left(e^{-imt}\chi\right)\right)\left(\partial^\mu\left(e^{imt}\chi^*\right)\right) - \frac{m}{2}\chi^*\chi \\ &= -\frac{1}{2m}\nabla\chi\cdot\nabla\chi^* + \frac{1}{2m}\left(\partial_t\left(e^{-imt}\chi\right)\right)\left(\partial_t\left(e^{imt}\chi^*\right)\right) - \frac{m}{2}\chi^*\chi\end{aligned}$$

The middle term is

$$\frac{1}{2m}(\dot\chi - im\chi)(\dot\chi^* + im\chi^*) = \frac{\dot\chi^*\dot\chi}{2m} + \frac{i}{2}(\dot\chi\chi^* - \dot\chi^*\chi) + \frac{m}{2}\chi^*\chi$$

Of these terms, the first is negligible in the nonrelativistic limit, and the last term cancels with the last term of Eq. S16). To get the second term in the desired form, we integrate the action by parts,

$$\frac{i}{2}\int d^4x\,(\dot\chi\chi^* - \dot\chi^*\chi) = i\int d^4x\chi^*\dot\chi$$

Solution to b:

As usual, we treat χ and χ^* as independent variables. For both parts of this question, we need to compute the derivatives of $\mathcal{L}$ with respect to $\partial_\mu\chi$ and $\partial_\mu\chi^*$. These are

$$\frac{\partial\mathcal{L}}{\partial\dot\chi} = i\chi^*, \quad \frac{\partial\mathcal{L}}{\partial(\nabla\chi)} = -\frac{1}{2m}\nabla\chi^*$$

and

$$\frac{\partial\mathcal{L}}{\partial\dot\chi^*} = 0, \quad \frac{\partial\mathcal{L}}{\partial(\nabla\chi^*)} = -\frac{1}{2m}\nabla\chi$$

The Euler-Lagrange equation for χ is

$$\frac{\partial\mathcal{L}}{\partial\chi} = \partial_\mu\frac{\partial\mathcal{L}}{\partial(\partial_\mu\chi)} = \partial_t\frac{\partial\mathcal{L}}{\partial\dot\chi} + \nabla\cdot\frac{\partial\mathcal{L}}{\partial(\nabla\chi)}$$

The left-hand side is zero, and plugging in the results for the right-hand side gives

$$i\dot\chi^* = \frac{1}{2m}\nabla^2\chi^*$$

Similarly, the Euler-Lagrange equation for χ^* is

$$\frac{\partial\mathcal{L}}{\partial\chi^*} = \partial_t\frac{\partial\mathcal{L}}{\partial\dot\chi^*} + \nabla\cdot\frac{\partial\mathcal{L}}{\partial(\nabla\chi^*)}$$

Now the left-hand side is nonzero, but the first term on the right-hand side is zero, giving

$$i\dot{\chi} = -\frac{1}{2m}\nabla^2\chi$$

As expected, the two Euler-Lagrange equations are conjugates of each other, and the equation of motion for χ is just the Schrodinger equation.

For infinitesimal α, the change in the fields is $\delta\chi = -i\alpha\chi$ and $\delta\chi^* = i\alpha\chi^*$, so Noether's theorem gives

$$J^\mu = -i\chi\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\chi\right)} + i\chi^*\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\chi^*\right)}$$

The density of the conserved charge is

$$\rho = -i\chi\frac{\partial\mathcal{L}}{\partial\dot{\chi}} + i\chi^*\frac{\partial\mathcal{L}}{\partial\dot{\chi}^*} = \chi^*\chi$$

The current density is

$$\mathbf{J} = -i\chi\frac{\partial\mathcal{L}}{\partial(\nabla\chi)} + i\chi^*\frac{\partial\mathcal{L}}{\partial\left(\nabla\chi^*\right)} = \frac{i}{2m}\left(\chi\nabla\chi^* - \chi^*\nabla\chi\right)$$

These are the same form as the probability density and probability current in nonrelativistic quantum mechanics. (But here they don't mean the same thing: we're still talking about classical field theory, not quantum mechanics.)

Solution to c:

We use the same d and ϕ notation as in the solutions to the second problem set. Inverting the Fourier transform gives

$$a(\mathbf{p}) = \int d\mathbf{x}\chi(\mathbf{x})e^{-i\mathbf{p}\cdot\mathbf{x}}$$

which implies

$$\left[a(\mathbf{p}), a^\dagger(\mathbf{q})\right] = \int d\mathbf{x}d\mathbf{y}\left[\chi(\mathbf{x}), \chi^*(\mathbf{y})\right]e^{-i\mathbf{p}\cdot\mathbf{x}}e^{i\mathbf{q}\cdot\mathbf{y}} = \int d\mathbf{x}e^{-i\mathbf{p}\cdot\mathbf{x}}e^{i\mathbf{q}\cdot\mathbf{x}} = \not{\delta}(\mathbf{p}-\mathbf{q})$$

Now, we have

$$\langle\mathbf{y}|\mathbf{x}\rangle = \langle 0\left|\chi^*(\mathbf{y})\chi(\mathbf{x})\right|0\rangle = \delta(\mathbf{y}-\mathbf{x})$$

where we applied the commutation relation and used $\chi^*(\mathbf{y})|0\rangle = 0$. Next,

$$\langle\mathbf{q}|\mathbf{p}\rangle = \left\langle 0\left|a(\mathbf{q})a^\dagger(\mathbf{p})\right|0\right\rangle = \not{\delta}(\mathbf{q}-\mathbf{p})$$

where we applied the commutation relation and used $a(\mathbf{q})|0\rangle = 0$. Finally,

$$\langle\mathbf{p}|\mathbf{x}\rangle = \left\langle 0\left|a(\mathbf{p})\int d\mathbf{q}a^\dagger(\mathbf{q})e^{i\mathbf{q}\cdot\mathbf{x}}\right|0\right\rangle = e^{i\mathbf{p}\cdot\mathbf{x}}$$

Solution to d:

First, we need to find the Hamiltonian. Applying the Legendre transform (or equivalently considering the element T^{00} of the stress-energy tensor),

$$\mathcal{H} = \dot{\chi}\frac{\partial\mathcal{L}}{\partial\dot{\chi}} - \mathcal{L} = \frac{1}{2m}\nabla\chi^*\cdot\nabla\chi$$

Therefore, in terms of creation and annihilation operators, the Hamiltonian is

$$\begin{aligned} H &= \frac{1}{2m}\int d\mathbf{x}\nabla\chi^*\cdot\nabla\chi \\ &= \frac{1}{2m}\int d\mathbf{x}\int d\mathbf{p}d\mathbf{q}a^\dagger(\mathbf{p})e^{i\mathbf{p}\cdot\mathbf{x}}(i\mathbf{p}\cdot(-i\mathbf{q}))a(\mathbf{q})e^{-i\mathbf{q}\cdot\mathbf{x}} \\ &= \frac{1}{2m}\int d\mathbf{x}\int d\mathbf{p}d\mathbf{q}(\mathbf{p}\cdot\mathbf{q})e^{i(\mathbf{p}-\mathbf{q})\cdot\mathbf{x}}a^\dagger(\mathbf{p})a(\mathbf{q}) \\ &= \frac{1}{2m}\int d\mathbf{p}|\mathbf{p}|^2a^\dagger(\mathbf{p})a(\mathbf{p}). \end{aligned}$$

The Hamiltonian acts on position eigenstates as

$$\begin{aligned} H|\mathbf{x}\rangle &= \frac{1}{2m}\int d\mathbf{p}|\mathbf{p}|^2a^\dagger(\mathbf{p})a(\mathbf{p})\int d\mathbf{q}a^\dagger(\mathbf{q})e^{i\mathbf{q}\cdot\mathbf{x}}|0\rangle \\ &= \frac{1}{2m}\int d\mathbf{p}|\mathbf{p}|^2a^\dagger(\mathbf{p})e^{i\mathbf{p}\cdot\mathbf{x}}|0\rangle \\ &= -\frac{\nabla^2}{2m}\int d\mathbf{p}a^\dagger(\mathbf{p})e^{i\mathbf{p}\cdot\mathbf{x}}|0\rangle \\ &= -\frac{\nabla^2}{2m}|\mathbf{x}\rangle \end{aligned}$$

Finally, the time evolution equation is

$$\int d\mathbf{x}i\dot{\psi}|\mathbf{x}\rangle = \int d\mathbf{x}\psi H|\mathbf{x}\rangle = -\frac{1}{2m}\int d\mathbf{x}\psi\nabla^2|\mathbf{x}\rangle = -\frac{1}{2m}\int d\mathbf{x}\left(\nabla^2\psi\right)|\mathbf{x}\rangle$$

where we integrated by parts in the last step. Matching the coefficients of $|\mathbf{x}\rangle$ gives

$$i\dot{\psi} = -\frac{\nabla^2\psi}{2m}$$

which is of course the nonrelativistic single-particle Schrodinger equation. Thus, our nonrelativistic quantum scalar field theory contains single-particle nonrelativistic quantum mechanics. In addition, it naturally contains states with arbitrarily many particles.

Notice that the single-particle quantum wavefunction ψ obeys the same equation of motion as the classical field χ, and both have a conserved current of the same form. This formal correspondence is a general structural feature of quantum field theory, and one of the original clues used to construct it. It is also the reason the pioneers of quantum field theory called it "second quantization," under the mistaken impression they were quantizing ψ a second time rather than χ for a first time.

Solution to e:

We had dropped the term $\dot{\chi}^*\dot{\chi}/2m$, and plugging in the Euler-Lagrange equations gives

$$\mathcal{L} \supset \frac{1}{8m^3}\nabla^2\chi^*\nabla^2\chi$$

This contributes an additional term to the Hamiltonian,

$$H \supset -\frac{1}{8m^3}\int d\mathbf{x}\nabla^2\chi^*\nabla^2\chi$$

and following the same steps as in part (d) yields

$$H \supset -\frac{1}{8m^3}\int d\mathbf{p}|\mathbf{p}|^4a^\dagger(\mathbf{p})a(\mathbf{p})$$

This is simply the leading relativistic correction to the kinetic energy, which you often see, e.g. when computing the fine structure of the hydrogen atom. Applying a similar (but more technically complex) procedure to the Dirac equation, known as the Foldy-Wouthuysen transformation, one can derive the fine structure corrections for the hydrogen atom. You can continue turning the crank to get relativistic corrections at all orders.

Stanford.Zhou.2022 4.4.⋆ The force between sources. (5/45p)

Correlation functions often do not have a direct physical interpretation. For example, the vacuum correlation function $\langle 0 \left| T \exp\left(-i \int dt H_I(t)\right) \right| 0 \rangle$ can be used to find the energy of the interacting vacuum relative to the free vacuum, but this isn't directly measurable because we can't turn off the interaction in real life.

Instead, let's again consider a free real scalar field with source $J(x)$,

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu \phi\right)\left(\partial^\mu \phi\right) - \frac{1}{2}m^2\phi^2 + \phi(x)J(x).$$

If we change the vacuum by including a static source $J(x)$, the resulting shift in vacuum energy can be directly interpreted as the energy of the source, which is measurable.

a) Using Wick's theorem, show that

$$\left\langle 0 \left| T \exp\left(i \int d^4x \phi(x) J(x)\right) \right| 0 \right\rangle = \exp\left(-\frac{1}{2}\int d^4x d^4y J(x) D_F(x-y) J(y)\right).$$

b) Now consider the case where two point sources are turned on for a long time T,

$$J(x) = g f(t)\left(\delta^{(3)}(\mathbf{x}) + \delta^{(3)}(\mathbf{x}-\mathbf{R})\right), \quad f(t) = \begin{cases} 1 & -T/2 < t < T/2 \\ 0 & \text{otherwise} \end{cases}.$$

If you plug this into Eq. (12), you'll get infinite terms involving $D_F(0)$, reflecting the fact that point sources have infinite energy. Discarding these terms so we can focus on the sources' interaction energy, evaluate Eq. (12) assuming $T \gg R \gg 1/m$.

c) Relate your answer to the interaction energy $V(R)$ between the sources, and find it. Is the force between them attractive or repulsive?

Solution to a:

Again, odd-order terms vanish, so the left-hand side is

$$\sum_n \frac{i^{2n}}{(2n)!}\int d^4x_1 \cdots d^4x_{2n} J\left(x_1\right) \cdots J\left(x_{2n}\right) \left\langle 0 \left| T\phi\left(x_1\right) \cdots \phi\left(x_{2n}\right) \right| 0 \right\rangle$$

There are $(2n-1)(2n-3)\cdots(3)(1)$ possible Wick contractions, all of which yield the same thing, giving

$$\sum_n \frac{i^{2n}}{(2n)(2n-2)\cdots(2)}\left(\int d^4x d^4y J(x) D_F(x-y) J(y)\right)^n$$

Simplifying the numeric factors gives

$$\sum_n \frac{1}{n!}\left(-\frac{1}{2}\int d^4x d^4y J(x) D_F(x-y) J(y)\right)^n$$

which is indeed the Taylor series of the desired right-hand side.

Solution to b:

It's helpful to go to momentum space, where we get

$$\exp\left(-\frac{i}{2}\int d^4x d^4y J(x) J(y) \int \frac{d^4p}{(2\pi)^4}\frac{e^{-ip\cdot(x-y)}}{p^2 - m^2 + i\epsilon}\right)$$

Taking only the two interaction terms and imposing the position-space delta functions gives

$$\exp\left(-ig^2 \int dx^0 dy^0 f\left(x^0\right) f\left(y^0\right) \int \frac{d^4p}{(2\pi)^4}\frac{e^{-ip^0\left(x^0-y^0\right)}e^{-i\mathbf{p}\cdot\mathbf{R}}}{p^2 - m^2 + i\epsilon}\right)$$

At this point, we can perform the temporal integrals; they are a representation of the delta function,

$$\int_{-T/2}^{T/2} dx^0 \int_{-T/2}^{T/2} dy^0 e^{-ip^0\left(x^0-y^0\right)} = 2\pi T\delta\left(p^0\right)$$

for large T, where the normalization can be found by integrating both sides against p^0. We thus get

$$\exp\left(ig^2T\int\frac{d^3p}{(2\pi)^3}\frac{e^{-i\mathbf{p}\cdot\mathbf{R}}}{|\mathbf{p}|^2+m^2}\right)$$

where we dropped the $i\epsilon$ since the denominator won't vanish. This is a standard integral you can look up or do with spherical coordinates and contour integration (we'll see it again later in the course), so

$$\exp\left(ig^2T\frac{e^{-mr}}{4\pi r}\right)$$

Solution to c:

If the interaction energy is V, then the correlation function should be e^{-iVT}, reflecting the change in energy of the vacuum. Comparing with above expression gives

$$V(r) = -\frac{g^2e^{-mr}}{4\pi r}$$

The force falls off exponentially on the scale $1/m$, and it is attractive. (Incidentally, since we just have a free field theory and classical sources, we could have done this all much more easily in classical field theory. But the approach we've just taken is much more powerful and general.)

Stanford.Zhou.2022 5.1. Mandelstam variables. (4/45 p)

Consider any $2 \to 2$ scattering process, where the two incoming particles have momenta p_1 and p_2, and the two outgoing particles have momenta p_3 and p_4. By momentum conservation, $p_1 + p_2 = p_3 + p_4$, and $p_i^2 = m_i^2$ where m_i is the mass of particle i. In this situation, it is often useful to work in terms of the Mandelstam variables

$$s = (p_1+p_2)^2, \quad t = (p_1-p_3)^2, \quad u = (p_1-p_4)^2$$

a) Show that $s + t + u = m_1^2 + m_2^2 + m_3^2 + m_4^2$.
b) In the center of mass frame, the total energy is E_{cm} and the angle of $\mathbf{p}_1$ to $\mathbf{p}_3$ is θ. Write s, t, and u in terms of E_{cm} and θ, assuming all four particles are massless.

Solution:

Just directly using the definitions,

$$\begin{aligned} s+t+u &= p_1^2 + 2p_1\cdot p_2 + p_2^2 + p_1^2 - 2p_1\cdot p_3 + p_3^2 + p_1^4 - 2p_1\cdot p_4 + p_4^2 \\ &= m_1^2 + m_2^2 + m_3^2 + m_4^2 + 2p_1\cdot(p_1+p_2-p_3-p_4) \\ &= m_1^2 + m_2^2 + m_3^2 + m_4^2 \end{aligned}$$

Solution:

This is easiest if we use concrete coordinate expressions. Aligning the z-axis with $\mathbf{p}_1$,

$$p_1^\mu = \frac{E_{\text{cm}}}{2}(1,0,0,1), \quad p_2^\mu = \frac{E_{\text{cm}}}{2}(1,0,0,-1)$$

where the spatial momenta are opposite because we're working in the center of mass frame, and equal in magnitude to the energy because the particles are massless. After the scattering, we have

$$p_3^\mu = \frac{E_{\text{cm}}}{2}(1,0,\sin\theta,\cos\theta), \quad p_4^\mu = \frac{E_{\text{cm}}}{2}(1,0,-\sin\theta,-\cos\theta).$$

At this point we can just compute the Mandelstam variables explicitly, giving

$$s = E_{\text{cm}}^2, \quad t = -E_{\text{cm}}^2 \frac{1-\cos\theta}{2} = -E_{\text{cm}}^2 \sin^2\frac{\theta}{2}, \quad u = -E_{\text{cm}}^2 \frac{1+\cos\theta}{2} = -E_{\text{cm}}^2 \cos^2\frac{\theta}{2}.$$

Note that they sum to zero, as expected from part (a).

МФТИ-Киселев-2020.4.^{C}

Показать, что для свободного комплексного скалярного поля электрический заряд выражается через лоренц-инвариантные амплитуды $a(\boldsymbol{k})$ и $a_c(\boldsymbol{k})$ в виде

$$Q = \int \mathrm{d}^3 r j^0 = \int \frac{\mathrm{d}^3 k}{(2\pi)^3 2k_0} e \left\{ a^*(\boldsymbol{k}) a(\boldsymbol{k}) - a_c^*(\boldsymbol{k}) a_c(\boldsymbol{k}) \right\}$$

Solution

Как известно, из теоремы Нетер для действия скалярного комплексного поля, при глобальных калибровочных преобразованиях, сохраняется ток:

$$j^\mu = -ie(\partial_\mu \varphi^* \varphi - \varphi^* \partial_\mu \varphi)$$

где поле, как известно, имеет вид:

$$\varphi(k) = \frac{c\hbar}{\sqrt{\hbar\omega}} \hat{\mathfrak{q}}(k) = \frac{e}{2\omega} \left\{ e^{\mathrm{i}kx} \hat{\mathfrak{a}}^\dagger(k) + e^{-\mathrm{i}kx} \hat{\mathfrak{a}}(k) \right\}$$

Всё, осталось подставить, и просто посчитать.
В итоге у нас слагаемые преобразуются и

$$Q = \int \mathrm{d}^3 r j^0 = \int \frac{\mathrm{d}^3 k}{(2\pi)^3 2k_0} e \left\{ a^*(\boldsymbol{k}) a(\boldsymbol{k}) - a_c^*(\boldsymbol{k}) a_c(\boldsymbol{k}) \right\}$$

МФТИ-Киселев-2020.5 Energy-momentum tensor for a scalar field

Для решения в виде плоской монохроматической волны для скалярного поля $\phi \mapsto \frac{1}{\sqrt{2k_0}} e^{\mp \mathrm{i}kx}$ proof that компоненты тензора энергии-импульса

$$T_0^0 \mapsto k_0, \quad T_0^\alpha \mapsto \boldsymbol{k}$$

Solution

$$T_\nu^\mu := \frac{\partial L}{\partial \partial_\mu \varphi} \partial_\nu \varphi + \frac{\partial L}{\partial \partial_\mu \varphi^*} \partial_\nu \varphi^* - \delta_\nu^\mu L; \qquad L = \partial_\mu \varphi \partial^\mu \varphi^* - m^2 \varphi \varphi^*$$

$$T_\mu^\nu = \partial^\nu \varphi^* \partial_\mu \varphi + \partial_\mu \varphi^* \partial^\nu \varphi - \delta_\mu^\nu (\partial_\mu \varphi \partial^\mu \varphi^* - m^2 \varphi \varphi^*)$$

$\phi \mapsto \frac{1}{\sqrt{2k_0}} e^{\mp \mathrm{i}kx}$.
(?? I'll check again later)
s

$$T_0^0 = \frac{2}{2k_0} (\pm ik_0)(\mp ik_0) = k_0$$

$$T_0^\alpha = \frac{1}{2k_0} (\pm ik_0^\alpha (-ik_0) + (\pm ik_0)(\mp ik^\alpha) = k^\alpha$$

26.1.5 Problems about free quantum fields 4

МФТИ-Киселев-2020.6 Current for a scalar field

Для решения в виде плоской монохроматической волны для скалярного поля $\phi \mapsto \frac{1}{\sqrt{2k_0}} e^{\mp \mathrm{i}kx}$ Найти, что компоненты тока

$$j_0 \mapsto \pm e, \quad j_\alpha \mapsto \pm e\boldsymbol{k}$$

Solution

$j^\mu = -ie(\partial_\mu \varphi^* \varphi - \varphi^* \partial_\mu \varphi)$
$\phi \mapsto \frac{1}{\sqrt{2k_0}} e^{\mp \mathrm{i} kx}$

$$j_0 = ie\left(\frac{1}{\sqrt{2k_0}}\right)^2 (\pm ik_0 - (\mp ik_0)) = \pm e$$

$$j_\alpha = ie\left(\frac{1}{\sqrt{2k_0}}\right)^2 (\mp ik_\alpha - (\pm ik_0)) = \pm ek_\alpha$$

МФТИ-Киселев-2020.7.^{C} Invariant energy-momentum tensor

Какой вид имеет тензор энергии-импульса релятивистски инвариантного вакуума?

Solution

Этот объект удовлетворяет:
Для баланса энергии-импульса должно выполняться $\partial_\mu T^\mu_\nu = 0$.
симметричность.
во всех системах отсчета он должен иметь один и тот же вид.
А вообще тензор энергии-импульса в теории поля в пространстве Минковского: $T_{\mu\nu} = 2\frac{\partial \mathcal{L}}{\partial g^{\mu\nu}} - g_{\mu\nu}\mathcal{L}$ где лагранжиан $\mathcal{L}$ является плотностью функции Лагранжа

$$\frac{1}{c}L = \int \mathrm{d}^3 x \mathcal{L}$$

Тогда для вещественного скалярного поля лагранжиан

$$c\mathcal{L} = \frac{1}{2}\left\{ g^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi - \frac{m^2c^2}{\hbar^2}\varphi^2 \right\}$$

И тензор энергии-импульса

$$cT_{\mu\nu} = \partial_\mu\varphi\partial_\nu\varphi - g_{\mu\nu}\frac{1}{2}\left\{ g^{\mu'\nu'}\partial_{\mu'}\varphi\partial_{\nu'}\varphi - \frac{m^2c^2}{\hbar^2}\varphi^2 \right\}$$

26.1.6 Problems about relativity and Poincare group 1

МФТИ-Киселев-2020.1 4-вектор как спинор (?!??!)

Рассмотреть вещественный 4-вектор в представлении группы Лоренца $\left(\frac{1}{2},\frac{1}{2}\right)$

Solution

Рассмотрим произвольную эрмитово сопряженную величину $\hat{V}$ в представлении $\left(\frac{1}{2},\frac{1}{2}\right)$.

$\hat{V}$ несет пару индексов $\{\alpha\dot{\alpha}\}$, может быть разложена по базису матриц σ^ν :

$$(\hat{V})_{\alpha\dot{\alpha}} = \sigma^\nu_{\alpha\dot{\alpha}} V_\nu$$

причем

$$V^\mu = \frac{1}{2}\operatorname{tr}\left\{\bar{\sigma}^\mu \hat{V}\right\} = \frac{1}{2}\operatorname{tr}\left\{\hat{V}\bar{\sigma}^\mu\right\}$$

так как по определению в (1.58) и (1.59), очевидно,

что антисимметричная по пространственным индексам часть произведения матриц не дает вклада в след, ввиду бесследовости обычных 3 -мерных матриц Паули,

$$\operatorname{tr}\{\bar{\sigma}^\mu\sigma^\nu\} = 2g^{\mu\nu}$$

Согласно установленным нами законам преобразования верхних и нижних спинорных индексов,

преобразования группы $\mathrm{SL}(2,\mathbb{C})$ переводят $\hat{V}$ в эрмитову величину

$$\hat{V}' = \Lambda_- \hat{V} \Lambda_-^\dagger$$

которая опять может быть разложена по исходному базису релятивистских матриц Паули:

$$V'^\mu = \frac{1}{2}\operatorname{tr}\left\{\bar{\sigma}^\mu \hat{V}'\right\} = \frac{1}{2}\operatorname{tr}\left\{\hat{V}'\bar{\sigma}^\mu\right\}$$

Заметим, что

$$\det \hat{V}' = \det\left\{\Lambda_- \hat{V} \Lambda_-^\dagger\right\} = |\det \Lambda_-|^2 \det \hat{V} = \det \hat{V}$$

При этом

$$\hat{V} = \begin{pmatrix} V_0+V_3 & V_1-\mathrm{i}V_2 \\ V_1+\mathrm{i}V_2 & V_0-V_3 \end{pmatrix}$$

так что

$$\det \hat{V} = V_0^2 - \boldsymbol{V}^2$$

а равенство детерминантов $\det \hat{V}' = \det \hat{V}$ означает, что преобразование сохраняет лоренц-инвариантную длину 4-вектора,

т. е. представляет собой элемент группы Лоренца на 4-векторах.

Это представление является двузначным, так как матрицы Λ_- и $-\Lambda_-$ приводят к идентичным преобразованиям 4-вектора.

В случае инфинитезимальных преобразований $\omega^{\lambda\rho} \to 0$,

$$\Lambda_- = \mathbb{1} - \frac{\mathrm{i}}{2}\sigma_{\lambda\rho}\omega^{\lambda\rho}, \quad \Lambda_-^\dagger = \mathbb{1} + \frac{\mathrm{i}}{2}\bar{\sigma}_{\lambda\rho}\omega^{\lambda\rho}$$

находим, что

$$V'^{\mu} = V^{\mu} + \frac{\mathrm{i}}{4}\,\mathrm{tr}\left\{\bar{\sigma}_{\lambda\rho}\bar{\sigma}^{\mu}\sigma^{\nu} - \sigma_{\lambda\rho}\sigma^{\nu}\bar{\sigma}^{\mu}\right\}\omega^{\lambda\rho}V_{\nu}$$

где, например, разложение на симметричную и антисимметричную по перестановке индексов части

$$\bar{\sigma}^{\mu}\sigma^{\nu} = g^{\mu\nu} - 2\mathrm{i}\bar{\sigma}^{\mu\nu}$$

приводит к

$$\mathrm{tr}\left\{\bar{\sigma}_{\lambda\rho}\bar{\sigma}^{\mu}\sigma^{\nu}\right\} = -2\mathrm{i}\,\mathrm{tr}\left\{\bar{\sigma}_{\lambda\rho}\bar{\sigma}^{\mu\nu}\right\}$$

и затем, как легко заметить, в силу симметрийных свойств по перестановке пространственных индексов выражение для следа матриц должно иметь определенную тензорную структуру,

$$\mathrm{tr}\left\{\bar{\sigma}_{\lambda\rho}\bar{\sigma}^{\mu\nu}\right\} = A\left\{\delta^{\mu}_{\lambda}\delta^{\nu}_{\rho} - \delta^{\nu}_{\lambda}\delta^{\mu}_{\rho}\right\} + B\hat{\varepsilon}^{\mu\nu}_{\lambda\rho}$$

а коэффициенты A, B можно определить, используя явный вид генераторов при определенном выборе пространственных индексов, так что в итоге полу- чаем

$$\mathrm{tr}\left\{\bar{\sigma}_{\lambda\rho}\bar{\sigma}^{\mu\nu}\right\} = \frac{1}{2}\left\{\delta^{\mu}_{\lambda}\delta^{\nu}_{\rho} - \delta^{\nu}_{\lambda}\delta^{\mu}_{\rho}\right\} - \frac{\mathrm{i}}{2}\hat{\varepsilon}^{\mu\nu}_{\lambda\rho}$$

Совершенно аналогично

$$\mathrm{tr}\left\{\sigma_{\lambda\rho}\sigma^{\mu\nu}\right\} = \frac{1}{2}\left\{\delta^{\mu}_{\lambda}\delta^{\nu}_{\rho} - \delta^{\nu}_{\lambda}\delta^{\mu}_{\rho}\right\} + \frac{\mathrm{i}}{2}\hat{\varepsilon}^{\mu\nu}_{\lambda\rho}$$

В итоге приведение подобных членов дает

$$V'^{\mu} = V^{\mu} + \omega^{\mu\nu}V_{\nu}$$

т. е. инфинитезимальное преобразование 4-вектора.

МФТИ-Киселев-2020.**2**

Доказать равенства

$$(\sigma^{\mu}\bar{\sigma}^{\nu} + \sigma^{\nu}\bar{\sigma}^{\mu})^{\alpha}_{\beta} = 2g^{\mu\nu}\delta^{\alpha}_{\beta}$$
$$(\bar{\sigma}^{\mu}\sigma^{\nu} + \bar{\sigma}^{\nu}\sigma^{\mu})^{\dot{\alpha}}_{\dot{\beta}} = 2g^{\mu\nu}\delta^{\dot{\alpha}}_{\dot{\beta}}$$

Solution

По определению $\sigma^{\mu} = (1, \sigma^{i}), \bar{\sigma}^{\mu} = (1, -\sigma^{i})$.
Посчитаем отдельно

$$\left(\sigma^{0}\bar{\sigma}^{i} + \sigma^{i}\bar{\sigma}^{0}\right) = (-\sigma^{i} + \sigma^{i}) = 0$$
$$\left(\sigma^{i}\bar{\sigma}^{j} + \sigma^{j}\bar{\sigma}^{i}\right) = -(\sigma^{i}\sigma^{j} + \sigma^{j}\sigma^{i}) = -2\delta^{ij}$$

Поэтому

$$(\sigma^{\mu}\bar{\sigma}^{\nu} + \sigma^{\nu}\bar{\sigma}^{\mu})^{\alpha}_{\beta} = 2g^{\mu\nu}\delta^{\alpha}_{\beta}$$

Аналогично доказывается второе.

МФТИ-Киселев-2020.**3**

Доказать равенства

$$\mathrm{tr}\left\{\bar{\sigma}_{\lambda\rho}\bar{\sigma}^{\mu\nu}\right\} = \tfrac{1}{2}\left\{\delta^{\mu}_{\lambda}\delta^{\nu}_{\rho} - \delta^{\nu}_{\lambda}\delta^{\mu}_{\rho}\right\} - \tfrac{\mathrm{i}}{2}\hat{\epsilon}^{\mu\nu}_{\lambda\rho}$$
$$\mathrm{tr}\left\{\sigma_{\lambda\rho}\sigma^{\mu\nu}\right\} = \tfrac{1}{2}\left\{\delta^{\mu}_{\lambda}\delta^{\nu}_{\rho} - \delta^{\nu}_{\lambda}\delta^{\mu}_{\rho}\right\} + \tfrac{\mathrm{i}}{2}\hat{\epsilon}^{\mu\nu}_{\lambda\rho}$$

Solution

По определению

$$\sigma^{\mu\nu} = -\sigma^{\nu\mu} = \frac{i}{4}(\sigma^\mu\bar{\sigma}^\nu - \sigma^\nu\bar{\sigma}^\mu)$$
$$\bar{\sigma}^{\mu\nu} = -\bar{\sigma}^{\nu\mu} = \frac{i}{4}(\bar{\sigma^\mu}\sigma^\nu - \bar{\sigma^\nu}\sigma^\mu)$$

Посмотрим, как можно их расписать через компоненты.

$$\sigma^{00} = 0$$
$$\sigma^{0i} = -\sigma^{\nu\mu} = \frac{i}{4}(\sigma^0(-\sigma^i) - \sigma^i\sigma^0) = -\frac{i}{2}\sigma^i$$
$$\bar{\sigma^{0i}} = \frac{i}{2}\sigma^i$$
$$\bar{\sigma}^{ij} = \frac{i}{4}(-\sigma^i\sigma^j - (-\sigma^j)\sigma^i) = -\frac{i}{4}\cdot 2i\varepsilon_{ijk}\sigma^k = \frac{1}{2}\varepsilon_{ijk}\sigma^k$$
$$\bar{\sigma}^{ij} = \frac{1}{2}\varepsilon_{ijk}\sigma^k$$

В последних равенствах использовалось соотношение на матрицы Паули:

$$\sigma^i\sigma^j = i\varepsilon_{ijk}\sigma^k + \delta_{ij}\sigma^0$$

Таким образом, исходное уравнение для пространственных индексов $\operatorname{tr}\{\sigma_{\lambda\rho}\sigma^{\mu\nu}\}$ можно переписать как:

$$\operatorname{tr}\left\{\sigma_{ij}\sigma^{kl}\right\} = \operatorname{tr}\left\{\frac{1}{2}\varepsilon_{ijm}\sigma^m\frac{1}{2}\varepsilon_{kln}\sigma^n\right\} = \frac{1}{4}\varepsilon_{ijm}\varepsilon_{kln}\operatorname{tr}\{\sigma_m\sigma^n\} = \frac{1}{4}\varepsilon_{ijm}\varepsilon_{kln}\operatorname{tr}\{2\delta^{mn}\}$$

И дальше просто преобразуем до конца:

$$\operatorname{tr}\left\{\sigma_{ij}\sigma^{kl}\right\} = \frac{1}{2}\varepsilon_{ijm}\varepsilon_{kln} = 1\frac{1}{2}(\delta_{ik}\delta_{jl} - \delta_{il}\delta_{jk})$$

А если есть временной индекс, то

$$\operatorname{tr}\left\{\sigma_{ij}\sigma^{k0}\right\} = \operatorname{tr}\left\{\frac{1}{2}\varepsilon_{ijk}\sigma^n\frac{i}{2}\sigma^k\right\} = \frac{i}{2}\varepsilon_{ijk} = -\frac{i}{2}\varepsilon_{ijk0} = \frac{i}{2}\varepsilon_{ij}^{k0}$$

В последнем переходе показано как от трехмерного символа Леви-Чевиты перейти к четырехмерному. Также при подъеме пространственной части метрика домножилась на (-1), а при подъеме временной - на 1.

Осталось разобрать случай

$$\operatorname{tr}\left\{\sigma_{i0}\sigma^{k0}\right\} = -\left(\frac{i}{2}\right)^2\operatorname{tr}\left\{\sigma^i\sigma^k\right\} = \frac{1}{2}\delta_{ik} \equiv \frac{1}{2}[\delta_i^k\delta_0^0 - \delta_i^0\delta_0^k]$$

Собирая все вместе, получаем

$$\operatorname{tr}\{\sigma_{\lambda\rho}\sigma^{\mu\nu}\} = \frac{1}{2}\left\{\delta_\lambda^\mu\delta_\rho^\nu - \delta_\lambda^\nu\delta_\rho^\mu\right\} + \frac{\mathrm{i}}{2}\hat{\epsilon}_{\lambda\rho}^{\mu\nu}$$

Теперь то же самое для $\operatorname{tr}\{\bar{\sigma}_{\lambda\rho}\bar{\sigma}^{\mu\nu}\}$
действуя аналогично, получаем:

$$\operatorname{tr}\{\sigma_{\lambda\rho}\sigma^{\mu\nu}\} = \frac{1}{2}\left\{\delta_\lambda^\mu\delta_\rho^\nu - \delta_\lambda^\nu\delta_\rho^\mu\right\} + \frac{\mathrm{i}}{2}\hat{\epsilon}_{\lambda\rho}^{\mu\nu}$$

МФТИ-Киселев-2020.**4**

Показать, что величины

$$\theta\sigma^\mu\bar{\chi} = \theta^\alpha\sigma^\mu_{\alpha\dot{\alpha}}\bar{\chi}^{\dot{\alpha}} \quad \text{и} \quad \bar{\theta}\bar{\sigma}^\mu\chi = \bar{\theta}_{\dot{\alpha}}\left(\bar{\sigma}^\mu\right)^{\dot{\alpha}\alpha}\chi_\alpha$$

ведут себя так же, как 4-векторы.

Solution

То есть нужно доказать, что
В самом деле, воспользуемся стандартным способом: построим, например, величину

$$V_\mu \theta \sigma^\mu \bar{\chi} = V_\mu \theta^\alpha \sigma^\mu_{\alpha\dot{\alpha}} \bar{\chi}^{\dot{\alpha}}$$

и покажем, что она является инвариантом.
Действительно, преобразование из группы $SL(2,\mathbb{C})$ дает

$$\theta^\alpha \mapsto \theta^{\alpha_1} \left(\Lambda^{-1}\right)^\alpha_{\alpha_1}, \quad \bar{\chi}^{\dot{\alpha}} \mapsto \bar{\chi}^{\dot{\alpha}_1} \left(\Lambda_+\right)^{\dot{\alpha}}_{\dot{\alpha}_1}, \quad V_\mu \mapsto V_\nu \left(\Lambda^{-1}\right)^\nu_\mu$$

где Λ^ν_μ - матрица преобразований координат, так что ковектор преобразуется обратной матрицей, а также, как мы показали,

$$\hat{V}_{\alpha\dot{\alpha}} = V_\mu \left(\sigma^\mu\right)_{\alpha\dot{\alpha}} \mapsto \left(\Lambda_-\right)^{\alpha_1}_\alpha \hat{V}_{\alpha_1\dot{\alpha}_1} \left(\Lambda^{-1}_+\right)^{\dot{\alpha}_1}_{\dot{\alpha}}$$

Поэтому величина в явном виде

$$V_\mu \theta^\alpha \sigma^\mu_{\alpha\dot{\alpha}} \bar{\chi}^{\dot{\alpha}}$$

в явном виде переходит сама в себя, а значит, является инвариантом.
С другой стороны, этот инвариант - скалярное линейное отображение 4-ковектора на числа, и, стало быть, по определению оно представляет собой 4-вектор, что и доказывает наше утверждение о характере преобразований билинейной по киральным полям форме $\theta\sigma^\mu\bar{\chi}$.

МФТИ-Киселев-2020.5

Доказать, что $(\theta_\alpha)^\dagger = \bar{\theta}_{\dot{\alpha}}$ и $\left(\bar{\chi}^{\dot{\alpha}}\right)^\dagger = \chi^\alpha$.

Solution

Напомним, что по определению $(\theta_\alpha)^\dagger = (\theta_{\dot{\alpha}})^*$,
то есть мы совершаем комплексное сопряжение над спинором, а также заменяем точечный индекс на неточечный. (????)
Совершим преобразования поднятия индексов и перехода из сопряженного спинора к обычному над $\bar{\theta}_{\dot{\alpha}}$:

$$\bar{\theta}_{\dot{\alpha}} = \varepsilon_{\dot{\alpha}\dot{\beta}} \bar{\theta}^{\dot{\beta}} = \varepsilon_{\dot{\alpha}\dot{\beta}} [i\sigma_2^{\alpha\dot{\beta}} \theta_\alpha]^* = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \cdot i \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \theta^*_\alpha = \delta^\alpha_{\dot{\alpha}} \theta^*_\alpha = (\theta_\alpha)^\dagger$$

Однако то, что компоненты равны не значит, что это один и тот же объект, потому что они могут преобразовываться по-разному. Поэтому проверим, что они преобразуются одинаково:

$$(\theta')^\dagger_\alpha = ((\Lambda_-)^\beta_\alpha \theta_\beta)^\dagger = \exp\left(\frac{i}{2}\sigma^{\mu\nu}\omega_{\mu\nu}\right)^\beta_\alpha \theta^\dagger_\beta$$

а кстати легко показать, записывая в явном виде, что $(\sigma^{\mu\nu})^\dagger = \bar{\sigma}^{\mu\nu}$, поэтому

$$\bar{\theta}_{\dot{\alpha}} = \varepsilon_{\dot{\alpha}\dot{\beta}} \bar{\theta}^{\dot{\alpha}} = \varepsilon_{\dot{\alpha}\dot{\beta}} (\Lambda_+)^{\dot{\beta}}_{\dot{\gamma}} \bar{\theta}^{\dot{\gamma}} = \varepsilon_{\dot{\alpha}\dot{\beta}} \exp\left(\frac{i}{2}\sigma^{\mu\nu}\omega_{\mu\nu}\right)^{\dot{\beta}}_{\dot{\alpha}} \bar{\theta}_{\dot{\beta}}$$

В итоге $(\theta_\alpha)^\dagger$ и $\bar{\theta}_{\dot{\alpha}}$ преобразуются одинаково, так что это один и тот же объект.
Аналогично доказывается, что $\left(\bar{\chi}^{\dot{\alpha}}\right)^\dagger = \chi^\alpha$

МФТИ-Киселев-2020.6*

Покажите, что представления группы Лоренца со спином $s = 1$: $(1,0)$ и $(0,1)$ отвечают самодуальным и антисамодуальным тензорным полям второго ранга в пространстве-времени Минковского, т.е. при определении поля, дуального к $B_{\mu\nu}$, как

$$\tilde{B}^{\mu\nu} = \frac{1}{2}\hat{\epsilon}^{\mu\nu\mu'\nu'} B_{\mu'\nu'}$$

имеют место соотношения самодуальности и антисамодуальности в пространстве-времени Минковского:

$$\tilde{B}^{\mu\nu} = \pm \mathrm{i} B^{\mu\nu}$$

[Hint: При выводе учесть, что представления (1,0) и $(0,1)$ - это бесследовые матрицы в индексах с точками и без точек.]

Solution

МФТИ-Киселев-2020.**7**

Доказать, что квадрат псевдовектора Паули-Любанского имеет вид

$$W^2 = -\frac{1}{2}\left\{p^2 S^2 - 2p_\nu p^\mu S_{\mu\lambda} S^{\nu\lambda}\right\}$$

Solution

Просто запишем W^2 квадрат в тензорном виде, вспомнив, что произведение двух символов Леви-Чивиты запишутся через определитель матрицы ниже:

$$W^2 = -\frac{1}{4}\begin{vmatrix} \delta^\nu_{\nu'} & \delta^\nu_{\lambda'} & \delta^\nu_{\rho'} \\ \delta^\lambda_{\nu'} & \delta^\lambda_{\lambda'} & \delta^\lambda_{\rho'} \\ \delta^\rho_{\nu'} & \delta^\rho_{\lambda'} & \delta^\rho_{\rho'} \end{vmatrix} p_\nu p^{\nu'} S_{\lambda\rho} S^{\lambda'\rho'}$$

что можно представить в виде

$$W^2 = -\frac{1}{4}\left\{p_\nu p^\nu S_{\lambda\rho} S^{\lambda\rho} + p_\nu p^\rho S_{\lambda\rho} S^{\nu\lambda} + p_\nu p^\lambda S_{\lambda\rho} S^{\rho\nu} - -p_\nu p^\rho S_{\lambda\rho} S^{\lambda\nu} - p_\nu p^\lambda S_{\lambda\rho} S^{\nu\rho} - p_\nu p^\nu S_{\lambda\rho} S^{\rho\lambda}\right\}$$

и после использования антисимметрии тензора спина получаем

$$W^2 = -\frac{1}{2}\left\{p^2 S^2 - 2p_\nu p^\lambda S_{\lambda\rho} S^{\nu\rho}\right\}$$

МФТИ-Киселев-2020.**1**.^{C}

Доказать, что компоненты псевдовектора Паули–Любанского для безмассовых полей равны

$$W_0 = \hbar \boldsymbol{p}\cdot\boldsymbol{s}, \quad W^\alpha = \hbar\left\{p_0 \boldsymbol{s}^\alpha \mp \mathrm{i}(\boldsymbol{p}\times\boldsymbol{s})^\alpha\right\}$$

Solution

В искомом базисе поля удовлетворяют уравнению на собственные значения оператора W^2. Но у повышающего оператора в группе SU(2) существуют только два собственных вектора: во-первых, это «вакуум» с нулевым моментом

$$\mathcal{J}^\pm|0\rangle = 0$$

а во-вторых, это старший вектор с нулевым собственным значением

$$\mathcal{J}^+_+ |\lambda_+, \lambda_+\rangle = 0$$

Точно так же для понижающего оператора есть два собственных вектора: вакуум (2.8) и младший вектор с нулевым собственным значением

$$\mathcal{J}^-_- |\lambda_-, -\lambda_-\rangle = 0$$

При этом, конечно, на этих полях (т. е. при действии операторов на поля) проекция спина на ось импульса или, как говорят, спиральность имеет значения

$$\frac{p\cdot\mathcal{J}^\pm}{p_0} = \mathcal{J}^\pm_3 = \pm\lambda_\pm$$

причем на физических полях $W^2 = 0$.

Таким образом, среди безмассовых полей со спином базис составляют так называемые киральные поля полуцелого спина и поляризованные поля целого спина: правые поля с положительной киральностью и спиральностью $\mathfrak{s} = \lambda_+$:

$$\mathcal{J}^- \equiv 0 \to \mathcal{K} = -\mathrm{i}s, \quad \mathcal{J}^+ = s$$

левые поля с отрицательной киральностью и спиральностью $\mathfrak{s} = -\lambda_-$:

$$\mathcal{J}^+ \equiv 0 \to \mathcal{K} = \mathrm{i}s, \quad \mathcal{J}^- = s$$

а также их произведения и вакуум. При этом произведения полей, конечно, могут оказаться приводимыми представлениями.

Рассмотрим компоненты псевдовектора Паули- -Любанского для киральных и поляризованных полей в представлениях, отвечающим полям группы Лоренца $(\lambda_+, 0)$ и $(0, \lambda_-)$, в которых генераторы $\mathcal{J}^{(\pm)}$, отличные от нуля конечно, совпадают со спином s. С учетом

$$S_{\beta\gamma} = \hbar\varepsilon_{\beta\gamma\rho}s^\rho$$

нулевая компонента

$$W_0 = -\frac{1}{2}\hat{\varepsilon}^{0\alpha\beta\gamma}p_\alpha S_{\beta\gamma} = \hbar p\cdot s = \pm p_0\hbar\lambda_\pm$$

Половина задачи решена!

При вычислении пространственной компоненты необходимо использовать то, Что

$$\frac{1}{\hbar}S_{0\gamma} = \mathcal{K}^\gamma = \mp\mathrm{i}s^\gamma$$

откуда

$$W^\alpha = -\frac{1}{2}\hat{\varepsilon}^{\alpha 0\beta\gamma}p_0 S_{\beta\gamma} - \frac{1}{2}2\hat{\varepsilon}^{\alpha\beta 0\gamma}p_\beta S_{0\gamma} = \hbar\left\{p_0 s^\alpha \mp \mathrm{i}(p\times s)^\alpha\right\}$$

Вот и вся задача решена.

26.1.7 Problems about relativity and Poincare group 2

МФТИ-Киселев-2020.**2**.^{C}

Доказать, что квадрат псевдовектора Паули-Любанского для безмассовых полей имеет вид

$$W^2 = -4p_0^2\hbar^2\left\{\partial^+\cdot\partial^- - \frac{1}{p_0^2}\left(\boldsymbol{p}\cdot\boldsymbol{\jmath}^+\right)\left(\boldsymbol{p}\cdot\boldsymbol{\jmath}^-\right) - \frac{\mathrm{i}}{p_0}\boldsymbol{p}\cdot\left(\boldsymbol{J}^+\times\boldsymbol{\jmath}^-\right)\right\}$$

Solution

Псевдовектор Паули-Любанского определяется как

$$W^m = -\frac{1}{2}\hat{\epsilon}^{mnkl}p_n S_{kl}$$

При $p^2 = 0$

$$\begin{aligned}W^2 &= p_n p^k S_{kl}S^{nl} = p_n p^k S_{k0}S^{n0} + p_n p^k S_{k\alpha}S^{n\alpha}\\ &= -p^\alpha p^\beta S_{0\alpha}S^{0\beta} + p_0^2 S^{0\alpha}S_{0\alpha} - p^\gamma p^\beta S^{\gamma\alpha}S_{\beta\alpha} + p_0 p^\beta\left(S_{\beta\alpha}S^{0\alpha} - S_{0\alpha}S^{\beta\alpha}\right)\\ &= \hbar^2\left\{(\boldsymbol{p}\cdot\mathcal{K})^2 - p_0^2\mathcal{K}^2 - (\boldsymbol{p}\times s)^2 + p_0\boldsymbol{p}\cdot\left\{(\boldsymbol{s}\times\mathcal{K}) - (\mathcal{K}\times\boldsymbol{s})\right\}\right\}\end{aligned}$$

Раскрывая квадрат векторного произведения $(p\times s)^2 = p^2s^2 - (p\cdot s)^2$, находим

$$\frac{1}{\hbar^2}W^2 = -p_0^2\left(s^2 + \mathcal{K}^2\right) + (\boldsymbol{p}\cdot\boldsymbol{s})^2 + (\boldsymbol{p}\cdot\boldsymbol{\mathcal{K}})^2 + p_0\boldsymbol{p}\cdot\left\{(\boldsymbol{s}\times\mathcal{K}) - (\mathcal{K}\times\boldsymbol{s})\right\}$$

Выражая генераторы спина и бустов через эрмитовы векторы $\mathcal{J}^+$ и $\mathcal{J}^-$, $s = \mathcal{J}^+ + \mathcal{J}^-$, $\quad \mathrm{i}\mathcal{K} = \mathcal{J}^+ - \mathcal{J}^-$, получаем

$$W^2 = -4p_0^2\hbar^2\left\{\boldsymbol{\jmath}^+\cdot\boldsymbol{\jmath}^- - \frac{1}{p_0^2}\left(\boldsymbol{p}\cdot\boldsymbol{\jmath}^+\right)\left(\boldsymbol{p}\cdot\boldsymbol{\jmath}^-\right) - \frac{\mathrm{i}}{p_0}\boldsymbol{p}\cdot\left(\boldsymbol{\jmath}^+\times\boldsymbol{\jmath}^-\right)\right\}$$

задача решена.

Упражнения к лекции 3. Лоренц инвариантность

(Параграф 2 в книжке Средницкого)
Итак преобразование Лоренца это линейная однородная замена координат

$$x'^{\mu} = \Lambda^{\mu}_{\nu} x^{\nu} \tag{0.1}$$

которая сохраняет интервал $x^2 = x^{\mu} x_{\mu} = \eta_{\mu\nu} x^{\mu} x^{\nu}$, где $\eta_{\mu\nu} = \mathrm{diag}(1, -1, -1, -1)$. Это означает, что

$$\eta_{\mu\nu} \Lambda^{\mu}{}_{\rho} \Lambda^{\nu}_{\sigma} = \eta_{\rho\sigma}. \tag{0.2}$$

Заметим, преобразования Лоренца включают в себя обычные пространственные вращения: для это возьмем $\Lambda^0_0 = 1, \Lambda^0{}_i = \Lambda^i{}_0 = 0$, и $\Lambda^i{}_j = R_{ij}$, где R_{ij} ортогональная матрица поворотов трехмерного пространства.
Для инфинитезимальных преобразования Лоренца мы можем записать

$$\Lambda^{\mu}{}_{\nu} = \delta^{\mu}{}_{\nu} + \omega^{\mu}{}_{\nu}, \tag{0.3}$$

где

$$\omega_{\mu\nu} = -\omega_{\nu\mu} \tag{0.4}$$

То есть есть 6 независимых инфинитезимальных преобразований Лоренца. Это три поворота $\omega_{ij} = -\epsilon_{ijk} \hat{n}_k \delta\theta$ на угол $\delta\theta$ относительно оси $\hat{n}$ и три буста $\omega_{i0} = \hat{n}_i \delta\eta$ в направлении $\hat{n}$ с быстротой $\delta\eta$.
Упражнение 1. Проверьте, что (0.4) следует из (0.2).
Решение: Подставляем (0.3) в (0.2) и получаем

$$\eta_{\mu\nu} \left(\delta^{\mu}{}_{\rho} + \omega^{\mu}{}_{\rho}\right) \left(\delta^{\nu}{}_{\sigma} + \omega^{\nu}{}_{\sigma}\right) = \eta_{\rho\sigma}, \tag{0.5}$$

откуда

$$\eta_{\sigma\rho} + \omega_{\sigma\rho} + \omega_{\rho\sigma} + O\left(\omega^2\right) = \eta_{\sigma\rho} \tag{0.6}$$

и находим $\omega_{\sigma\rho} = -\omega_{\rho\sigma}$. $\bigcirc$
В квантовой теории поля симметрии представляются унитарными (или антиунитарными) операторами. Это значит, что мы сопоставляем оператор $U(\Lambda)$ каждому правильному ортохроному преобразованию Лоренца $\Lambda \left(\Lambda^0_0 \geqslant 1, \det \Lambda = 1\right)$. Эти операторы должны удовлетворять свойству

$$U\left(\Lambda' \Lambda\right) = U\left(\Lambda'\right) U(\Lambda) \tag{0.7}$$

Для инфинитезимальных преобразований Лоренца мы можем записать

$$U(1 + \omega) = I + \frac{i}{2} \omega_{\mu\nu} M^{\mu\nu} \tag{0.8}$$

где $M^{\mu\nu} = -M^{\nu\mu}$ набор эрмитовых операторов, которые называются генераторами группы Лоренца. Теперь рассмотрим $U(\Lambda)^{-1} U\left(\Lambda'\right) U(\Lambda) = U\left(\Lambda^{-1} \Lambda' \Lambda\right)$, и пусть $\Lambda' = 1 + \omega'$, и разложим обе части этого равенства до линейных по ω членов. Мы получим

$$\omega_{\mu\nu} U(\Lambda)^{-1} M^{\mu\nu} U(\Lambda) = \omega_{\mu\nu} \Lambda^{\mu}{}_{\rho} \Lambda^{\nu}{}_{\sigma} M^{\rho\sigma}. \tag{0.9}$$

Далее, так как $\omega_{\mu\nu}$ произвольно, то анитисимметричная часть ее сомножителей на каждой стороне уравнения должна быть одинаковой. В данном случае, так как $M^{\mu\nu}$ уже само антисимметрично мы получаем

$$U(\Lambda)^{-1} M^{\mu\nu} U(\Lambda) = \Lambda^{\mu}_{\rho} \Lambda^{\nu}_{\sigma} M^{\rho\sigma}. \tag{0.10}$$

Упражнение 2. Проверьте, что (0.10) следует из $U(\Lambda)^{-1} U\left(\Lambda'\right) U(\Lambda) = U\left(\Lambda^{-1} \Lambda' \Lambda\right)$.
Решение: Имеем

1. $U(\Lambda)^{-1} U\left(1 + \omega'\right) U(\Lambda) = U(\Lambda)^{-1} \left(I + \frac{i}{2} \omega_{\mu\nu} M^{\mu\nu}\right) U(\Lambda) = I + \frac{i}{2} \omega_{\mu\nu} U(\Lambda)^{-1} M^{\mu\nu} U(\Lambda)$
2. $U\left(\Lambda^{-1}(1 + \omega)\Lambda\right) = U\left(\delta^{\rho}{}_{\sigma} + \left(\Lambda^{-1}\right)^{\rho}{}_{\mu} \omega^{\mu}{}_{\nu} \Lambda^{\nu}{}_{\sigma}\right) = U\left(\delta^{\rho}{}_{\sigma} + \omega^{\mu}{}_{\nu} \Lambda_{\mu}{}^{\rho} \Lambda^{\nu}{}_{\sigma}\right) = U\left(\delta^{\rho}{}_{\sigma} + \omega_{\mu\nu} \Lambda^{\mu\rho} \Lambda^{\nu}{}_{\sigma}\right) =$

$$= I + \frac{i}{2} \omega_{\mu\nu} \Lambda^{\mu}{}_{\rho} \Lambda^{\nu}{}_{\sigma} M^{\rho\sigma}, \tag{0.11}$$

откуда получаем сначала (0.9), а потом уже (0.10).

То есть мы видим, что каждый векторный индекс у $M^{\mu\nu}$ преобразуется по его собственному преобразованию Лоренца. Это общий результат: любой оператор который несет один или более векторных индексов должен преобразовываться подобным образом. Например, рассмотрим оператор момента $P^\mu = \int d^3x T^{0\mu}$, где $P^0 = H$ - гамильтониан, а P^i компоненты оператора полного импульса. Мы ожидаем, что

$$U(\Lambda)^{-1} P^\mu U(\Lambda) = \Lambda^\mu{}_\nu P^\nu. \tag{0.12}$$

Теперь пусть $\Lambda = 1 + \omega$ в уравнении (0.10), тогда раскладывая его до линейных по ω членов мы получим коммутационное соотношения на операторы $M^{\mu\nu}$:

$$[M^{\mu\nu}, M^{\rho\sigma}] = i\left(\eta^{\mu\sigma} M^{\nu\rho} - \eta^{\mu\rho} M^{\nu\sigma} + \eta^{\nu\rho} M^{\mu\sigma} - \eta^{\nu\sigma} M^{\mu\rho}\right) \tag{0.13}$$

Эти коммутационные соотношения определяют алгебру Ли группы Лоренца.
Упражнение 3. Проверьте, что (0.13) следует из (0.10).
Решение: Имеем

$U(1+\omega)^{-1} M^{\mu\nu} U(1+\omega) = \left(I - \frac{i}{2}\omega_{\sigma\rho} M^{\sigma\rho}\right) M^{\mu\nu} \left(I + \frac{i}{2}\omega_{\lambda\delta} M^{\lambda\delta}\right) = M^{\mu\nu} + \frac{i}{2}\omega_{\sigma\rho}\left[M^{\mu\nu}, M^{\sigma\rho}\right] + O\left(\omega^2\right)$,
$\left(\delta^\mu{}_\rho + \omega^\mu{}_\rho\right)\left(\delta^\nu{}_\sigma + \omega^\nu{}_\sigma\right) M^{\rho\sigma} = M^{\mu\nu} + \omega^\mu{}_\rho M^{\rho\nu} + \omega^\nu{}_\sigma M^{\mu\sigma} + O\left(\omega^2\right) = M^{\mu\nu} + \omega_{\sigma\rho}\eta^{\mu\sigma} M^{\rho\nu} - \omega_{\sigma\rho}\eta^{\nu\rho} M^{\mu\sigma}$.
После антисимметризации части 2. получаем (0.13).
Введем компоненты оператора момента импульса $\boldsymbol{J}$ по формуле $J_i = \frac{1}{2}\epsilon_{ijk} M^{jk}$ и компоненты оператора буста $\boldsymbol{K}$ по формуле $K_i = M^{i0}$. Тогда мы можем найти используя (0.13):

$$\begin{aligned} &[J_i, J_j] = i\epsilon_{ijk} J_k \\ &[J_i, K_j] = i\epsilon_{ijk} K_k \\ &[K_i, K_j] = -i\epsilon_{ijk} J_k \end{aligned} \tag{0.15}$$

Упражнение 4. Выведите уравнения (0.15).
Решение: Покажем, что $[J_i, J_j] = i\epsilon_{ijk} J_k$ $\left(\epsilon_{123} = -\epsilon^{123} = 1\right)$. Имеем

$$\begin{aligned} [J_i, J_j] &= \frac{1}{4}\epsilon_{imn}\epsilon_{jst}\left[M^{mn}, M^{st}\right] = \frac{i}{4}\epsilon_{imn}\epsilon_{jst}\left(\eta^{mt} M^{ns} - \eta^{ms} M^{nt} + \eta^{ns} M^{mt} - \eta^{nt} M^{ms}\right) = \\ &= -\frac{i}{4}\epsilon_{imn}\epsilon_{jst}\left(\delta^{mt} M^{ns} - \delta^{ms} M^{nt} + \delta^{ns} M^{mt} - \delta^{nt} M^{ms}\right) \end{aligned} \tag{0.16}$$

Далее заметим, что $M^{ij} = -\epsilon^{ijk} J_k$ (мы поднимаем и опускаем индексы с помощью $\eta_{\mu\nu} = \mathrm{diag}(1, -1, -1, -1)$, поэтому так как здесь мы работаем с индексами $i = 1, 2, 3$, с каждым поднятием индекса мы зарабатываем фактор)-1)), откуда получаем

$$[J_i, J_j] = \frac{i}{4}\left(\epsilon_{imn}\epsilon_{jsm}\epsilon^{nsk} J_k - \epsilon_{imn}\epsilon_{jmt}\epsilon^{ntk} J_k + \epsilon_{imn}\epsilon_{jnt}\epsilon^{mtk} J_k - \epsilon_{imn}\epsilon_{jsn}\epsilon^{msk} J_k\right) \tag{0.17}$$

Далее используя, что $\epsilon_{ijs}\epsilon_{mns} = \delta_{im}\delta_{jn} - \delta_{im}\delta_{jm}$, находим

$$\begin{aligned} &[J_i, J_j] = \\ &= \frac{i}{4}\left(\left(\delta_{is}\delta_{nj} - \delta_{ij}\delta_{ns}\right)\epsilon^{nsk} J_k - \left(\delta_{ij}\delta_{nt} - \delta_{it}\delta_{nj}\right)\epsilon^{ntk} J_k + \left(\delta_{it}\delta_{mj} - \delta_{ij}\delta_{mt}\right)\epsilon^{mtk} J_k - \left(\delta_{ij}\delta_{ms} - \delta_{is}\delta_{mj}\right)\epsilon^{msk} J_k\right) = \\ &= \frac{i}{4}\left(\epsilon^{jik} J_k + \epsilon^{jik} J_k + \epsilon^{jik} J_k + \epsilon^{jik} J_k\right) = -i\epsilon^{ijk} J_k = i\epsilon_{ijk} J_k. \end{aligned} \tag{0.18}$$

В итоге мы получили, что $[J_i, J_j] = i\epsilon_{ijk} J_k$.
Далее из уравнения (0.12), мы можем получить при $\Lambda = 1 + \omega$:

$$[P^\mu, M^{\rho\sigma}] = i\left(\eta^{\mu\rho} P^\sigma - \eta^{\mu\sigma} P^\rho\right) \tag{0.19}$$

Упражнение 5. Выведите (0.19) из (0.12).
Решение: Имеем

$$1.\ \left(I-\frac{i}{2}\omega_{\sigma\rho}M^{\sigma\rho}\right)P^{\mu}\left(I+\frac{i}{2}\omega_{\sigma\rho}M^{\sigma\rho}\right)=P^{\mu}+\frac{i}{2}\omega_{\sigma\rho}\left[P^{\mu},M^{\sigma\rho}\right]+O\left(\omega^{2}\right)$$

$$2.\ \left(\delta^{\mu}{}_{\nu}+\omega^{\mu}{}_{\nu}\right)P^{\nu}=P^{\mu}+\omega^{\mu}{}_{\nu}P^{\nu}=P^{\mu}+\omega_{\sigma\rho}\eta^{\mu\sigma}P^{\rho}=P^{\mu}+\frac{1}{2}\omega_{\sigma\rho}\left(\eta^{\mu\sigma}P^{\rho}-\eta^{\mu\rho}P^{\sigma}\right) \tag{0.20}$$

Сравнивая выражения 1. и 2. получаем (0.19).
Из формулы (0.19) можно получить

$$\begin{aligned}&[J_i,H]=0\\&[J_i,P_j]=i\epsilon_{ijk}P_k\\&[K_i,H]=iP_i\\&[K_i,P_j]=i\delta_{ij}H\end{aligned} \tag{0.21}$$

Упражнение 6. Выведите уравнения (0.21) из (0.19).
Решение: Получим, что $[K_i,H]=iP_i$. Имеем:

$$[K_i,H]=\left[M^{i0},P^{0}\right]=-i\left(\eta^{0i}P^{0}-\eta^{00}P^{i}\right)=iP^{i} \tag{0.22}$$

Остальные выражения получаются аналогично.
Также компоненты P^{μ} должны коммутировать с друг другом

$$\begin{aligned}&[P_i,P_i]=0\\&[P_i,H]=0\end{aligned} \tag{0.23}$$

Уравнения (0.15), (0.21), и (0.23) образуют алгебру Ли группы Пуанкаре.
Упражнение 7. Покажите, что мера

$$d\mu(p)=\frac{d^{3}\vec{p}}{(2\pi)^{3}2E_{\vec{p}}},\quad E_{\vec{p}}=\sqrt{\vec{p}^{2}+m^{2}} \tag{0.24}$$

Лоренц инвариантна
Решение:

$$d\mu(p)=\frac{d^{3}p}{(2\pi)^{3}2E_{p}}=\int\limits_{p_0>0}dp^{0}\delta\left(\left(p^{0}\right)^{2}-E_{p}^{2}\right)\frac{d^{3}\vec{p}}{(2\pi)^{3}}=\int\limits_{p_0>0}\frac{d^{4}p}{(2\pi)^{3}}\delta\left(p^{2}-m^{2}\right) \tag{0.25}$$

далее очевидно, что если мы перейдем к $p^{\mu}=\Lambda^{\mu}{}_{\nu}p^{\nu}$, то $p^{2}=p^{2}$ и $d^{4}p=d^{4}p'$ и соответственно $d\mu(p)=d\mu\left(p'\right)$.

Stanford.Zhou.2022.2.1. Lorentz transformations. (10/45 p)

Lorentz transformations $x^{\mu}\rightarrow x^{\mu}=\Lambda^{\mu}{}_{\nu}x^{\nu}$ are linear transformations that leave inner products invariant, meaning that $x^{\mu}y_{\mu}=x'^{\mu}y'_{\mu}$ for any four-vectors x and y.

a) Show that this implies

$$\eta_{\mu\nu}=\eta_{\rho\sigma}\Lambda^{\rho}_{\mu}\Lambda^{\sigma}_{\nu}$$

Solution:

Since the inner product stays the same, we have

$$\eta_{\mu\nu}x^{\mu}y^{\nu}=\eta_{\rho\sigma}x'^{\rho}y'^{\sigma}=\eta_{\rho\sigma}\Lambda^{\rho}_{\mu}\Lambda^{\sigma}_{\nu}x^{\mu}y^{\nu}$$

In other words, we have

$$\left(\eta_{\mu\nu}-\eta_{\rho\sigma}\Lambda^{\rho}_{\mu}\Lambda^{\sigma}_{\nu}\right)x^{\mu}y^{\nu}=0$$

for any four-vectors x and y, which implies the quantity in parentheses vanishes. (Concretely, we could take $x^\mu = \delta_0^\mu$ and $y^\nu = \delta_0^\nu$ to show the $\mu = \nu = 0$ component vanishes, and so on for all 16 pairs of values.)

b) All proper, orthochronous Lorentz transformations (i.e. all those which preserve the orientation of space and the direction of time) can be decomposed into infinitesimal Lorentz transformations. These take the form

$$x^\mu \to x'^\mu = x^\mu + \epsilon \omega^\mu{}_\nu x^\nu$$

where ϵ is infinitesimal. Show that $\omega_{\mu\nu} = -\omega_{\nu\mu}$.

Solution:

Plugging $\Lambda^\mu{}_\nu = \delta^\mu_\nu + \epsilon\omega^\mu{}_\nu$ into Eq. (1) yields

$$\eta_{\mu\nu} = \eta_{\rho\sigma}\left(\delta^\rho_\mu\delta^\sigma_\nu + \epsilon\omega^\rho_\mu\delta^\sigma_\nu + \epsilon\delta^\rho_\mu\omega^\sigma_\nu\right)$$

where we dropped a term of order ϵ^2. Contracting the indices on the right-hand side,

$$\eta_{\mu\nu} = \eta_{\mu\nu} + \epsilon\omega^\rho_\mu\eta_{\rho\nu} + \epsilon\eta_{\mu\sigma}\omega^\sigma_\nu$$

from which we conclude $\omega_{\nu\mu} + \omega_{\mu\nu} = 0$, as desired.

c) The elements of any infinitesimal Lorentz transformation $\omega^\mu{}_\nu$ can be written as a 4×4 matrix, where μ and ν index the row and column, respectively. For an infinitesimal rotation $\epsilon = d\theta$ about the z-axis, write out this matrix, and denote it by iJ^3 for later. What exponential of J^3 corresponds to a finite rotation by an angle θ?

Solution:

An infinitesimal rotation keeps t and z the same, and maps $x \to x + \epsilon y$ and $y \to y - \epsilon x$, so we can immediately write down

$$iJ^3 = \begin{pmatrix} & 1 & \\ -1 & & \end{pmatrix}$$

The appropriate matrix exponential is $e^{i\theta J^3}$. The purpose of the factor of i in the definition is to ensure J^3 is a Hermitian matrix, in accordance with how it's treated in quantum mechanics.

d) Write down the matrix iK^1 corresponding to an infinitesimal boost by $\epsilon = dv$ about the x-axis. What exponential of K^1 corresponds to a finite boost by a velocity v?

Solution:

An infinitesimal boost keeps y and z the same, and maps $x \to x + \epsilon t$ and $t \to t + \epsilon x$, so

$$iK^1 = \begin{pmatrix} 1 & 1 & \\ & & \\ & & \end{pmatrix}$$

Note that this is not an antisymmetric matrix. The quantity that is antisymmetric is $\omega_{\mu\nu}$, with two indices down, but raising an index to get $\omega^\mu{}_\nu$ produces some signs. The appropriate exponential for a finite boost is $e^{i\alpha K^1}$, where $\alpha = \tanh^{-1} v$ is the rapidity. (The most common mistake was instead writing e^{ivK^1}.)

There's a minor subtlety: the usual taught form of the Lorentz transformation has $x' = \gamma(x - vt)$, which suggests the matrix should have minus signs. But in that form, we're keeping the situation the same, and x' denotes the coordinate seen by an observer moving to the right. In this problem, we're considering the case where there's just one observer but physical objects are boosted to the right. Nonetheless, if you used the "passive" convention instead, it's no big deal since none of the other results in this problem will be affected.

Note that the factor of i in the definition of K^1 is a common convention, but it implies K^1 is not Hermitian. This is also sensible, as K^1 doesn't actually correspond to a physical observable. At a deeper level, it is related to the fact that non-compact non-Abelian Lie groups don't have finite-dimensional unitary representations, which will be discussed in section.

e) Defining J^1, J^2, K^2, and K^3 similarly, the generators obey commutation relations

$$\left[J^i, J^j\right] = i\epsilon^{ijk}J^k, \quad \left[J^i, K^j\right] = i\epsilon^{ijk}K^k, \quad \left[K^i, K^j\right] = -i\epsilon^{ijk}J^k$$

This is the Lie algebra of the Lorentz group. Physically, these results tells us that infinitesimal rotations and boosts are vectors (i.e. angular velocity and velocity are vectors), and that composing boosts can yield a rotation. Prove these results for the cases $(i, j) = (1, 1)$ and $(i, j) = (1, 2)$. (The proofs for other cases are similar.)

Solution:

The full set of generators is, up to a factor of i,

$$iJ^1 = \begin{pmatrix} & & \\ & -1 & 1 \\ & & \end{pmatrix} \quad iJ^2 = \begin{pmatrix} & & \\ & & -1 \\ & & \end{pmatrix} \quad iJ^3 = \begin{pmatrix} & & \\ & -1 & \\ & & 1 \end{pmatrix}$$
$$iK^1 = \begin{pmatrix} & & \\ & & 1 \\ & 1 & \end{pmatrix} \quad iK^2 = \begin{pmatrix} & & \\ & & 1 \\ & 1 & \end{pmatrix} \quad iK^3 = \begin{pmatrix} & & \\ & & 1 \\ & 1 & \end{pmatrix}$$

For the case $(i, j) = (1, 1)$, the first and third relations are clearly satisfied, because the right-hand side is just zero, and $\left[J^1, K^1\right] = 0$ because these matrices are nonzero only in independent blocks. For the case $(i, j) = (1, 2)$, we need to check $\left[J^1, J^2\right] = iJ^3$, $\left[J^1, K^2\right] = iK^3$, and $\left[K^1, K^2\right] = -iJ^3$, which is straightforward to do manually.

Stanford.Zhou.2022.2.3.* Conserved currents of Lorentz transformations. (10/45p)

This somewhat tricky problem combines the ideas of the first two. It is completely optional: the problem set will be graded out of 40 points, so that you will receive up to 100% credit if you don't do this problem, and up to 125% credit if you do.

Under a Lorentz transformation, a scalar field profile ϕ gets mapped to ϕ', so that $\phi'(x') = \phi(x)$. This implies that

$$\phi'(x) = \phi\left(\Lambda^{-1}x\right).$$

For an infinitesimal Lorentz transformation (2), this corresponds to

$$\phi'(x) = \phi(x) - \epsilon\omega^{\mu\nu}x_\nu\partial_\mu\phi(x)$$

to first order in ϵ. Because an infinitesimal Lorentz transformation is parametrized by a rank 2 tensor $\omega^{\mu\nu}$, the corresponding Noether current will be a rank 3 tensor $J^{\mu\nu\rho}$, where the first index is the usual index that comes from Noether's theorem, and the last two describe the Lorentz transformation. For simplicity, you can do the entire problem for a real scalar field. (This corresponds to a complex scalar field with $a(\mathbf{k}) = b(\mathbf{k})$, which in turn implies $\Phi = \Phi^*$ and $\Pi = \Pi^*$.)

a) Show that for a scalar field,

$$J^{\mu\nu\rho} = x^\nu T^{\mu\rho} - x^\rho T^{\mu\nu}$$

where $T^{\mu\nu}$ is the stress-energy tensor. Let the associated conserved charges be $M^{\mu\nu}$.

Solution:

This is just like the derivation of the stress-energy tensor, except that the constant displacement a^μ is replaced with $\omega^{\mu\nu}x_\nu$. Thus, the current for a given ω is

$$J^\mu = \omega^{\rho\nu}x_\nu T^\mu_\rho = \frac{1}{2}\omega_{\rho\nu}\left(T^{\mu\rho}x^\nu - T^{\mu\nu}x^\rho\right)$$

where we used the antisymmetry of ω in the second step. The general rank-three conserved tensor can be found by "stripping off" the $\omega_{\rho\nu}$, giving

$$J^{\mu\nu\rho} = T^{\mu\rho}x^\nu - T^{\mu\nu}x^\rho$$

as desired.

b) Since $M^{\mu\nu}$ is antisymmetric, there are six independent conserved charges. The three independent M^{ij} physically correspond to the angular momentum of the field. What is the physical meaning of the other three conserved quantities M^{0i}?

Solution:

We have

$$M^{0i} = \int d\mathbf{x}J^{00i} = \int d\mathbf{x}T^{0i}x^0 - T^{00}x^i$$

The first term is just the total momentum P^i times the time t. The second term is an integral of the energy density times x^i, so it is proportional to the location of the "center of energy",

$$X^i_{\rm CE} = \frac{\int d\mathbf{x} T^{00} x^i}{\int d\mathbf{x} T^{00}} = \frac{\int d\mathbf{x} T^{00} x^i}{E}$$

where E is the total energy. Plugging in these definitions, we have

$$M^{0i} = P^i t - E X^i_{\rm CE}$$

Since this is conserved, its time derivative vanishes, giving

$$\frac{P^i}{E} = \frac{dX^i_{\rm CE}}{dt}$$

In other words, the conservation of M^{0i} means that the center of energy moves at constant speed. This is a very general principle in relativistic theories.

c) Show that after normal ordering, the angular momentum is

$$M^{ij} = i \int \frac{d^3k}{(2\pi)^3} a(\mathbf{k})^\dagger \left(k^j \frac{\partial}{\partial k_i} - k^i \frac{\partial}{\partial k_j} \right) a(\mathbf{k})$$

The form of this answer implies that the particles created and annihilated by scalar fields do not carry any intrinsic angular momentum (i.e. spin).

Solution:

We have

$$M^{ij} = \int d\mathbf{x} J^{0ij} = \int d\mathbf{x} x^i T^{0j} - x^j T^{0i}$$

The resulting integrals look very similar to those we already did in 2(f), but the factor of x^i complicates things: it means we can no longer do the $d\mathbf{x}$ integral trivially. The trick is to convert the factor of x^i into a momentum derivative. From a starting point much like (S60), we have

$$\begin{aligned}
\int d\mathbf{x} x^i \pi \partial^j \phi &= -\frac{i}{2} \int d\mathbf{x} d\mathbf{k} d\mathbf{k}' \sqrt{\frac{\omega_{\mathbf{k}}}{\omega_{\mathbf{k}'}}} x^i \left(a(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} - a^\dagger(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{x}} \right) \partial^j \left(a\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} + a^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right) \\
&= \frac{1}{2} \int d\mathbf{x} d\mathbf{k} d\mathbf{k}' \sqrt{\frac{\omega_{\mathbf{k}}}{\omega_{\mathbf{k}'}}} x^i k'^j \left(a(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}} - a^\dagger(\mathbf{k}) e^{-i\mathbf{k}\cdot\mathbf{x}} \right) \left(-a\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} + a^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right) \\
&= -\frac{i}{2} \int d\mathbf{x} d\mathbf{k} d\mathbf{k}' \sqrt{\frac{\omega_{\mathbf{k}}}{\omega_{\mathbf{k}'}}} k'^j \left(a(\mathbf{k}) \partial_{k_i} e^{i\mathbf{k}\cdot\mathbf{x}} + a^\dagger(\mathbf{k}) \partial_{k_i} e^{-i\mathbf{k}\cdot\mathbf{x}} \right) \\
&\quad \times \left(-a\left(\mathbf{k}'\right) e^{i\mathbf{k}'\cdot\mathbf{x}} + a^\dagger\left(\mathbf{k}'\right) e^{-i\mathbf{k}'\cdot\mathbf{x}} \right) \\
&= -\frac{i}{2} \int d\mathbf{k} d\mathbf{k}' \sqrt{\frac{\omega_{\mathbf{k}}}{\omega_{\mathbf{k}'}}} k'^j \left(\left(a(\mathbf{k}) a\left(\mathbf{k}'\right) - a^\dagger(\mathbf{k}) a^\dagger\left(\mathbf{k}'\right) \right) \partial_{k_i} \phi\left(\mathbf{k} + \mathbf{k}'\right) \right. \\
&\left. + \left(a(\mathbf{k}) a^\dagger\left(\mathbf{k}'\right) - a^\dagger(\mathbf{k}) a\left(\mathbf{k}'\right) \right) \partial_{k_i} \phi\left(\mathbf{k} - \mathbf{k}'\right) \right).
\end{aligned}$$

To evaluate the delta function, we need to integrate by parts, which causes the ∂_{k_i}'s to hit the rest of the integrand. Now, the ∂_{k_i} can either act on $\sqrt{\omega_{\mathbf{k}}}$ or the ladder operators. If it hits the $\sqrt{\omega_{\mathbf{k}}}$, it produces a factor of k^i which makes the integrand proportional to $k^i k'^j$. However, since M^{ij} involves an antisymmetrization in i and j, these terms don't contribute to the final answer. We only care about the terms where ∂_{k_i} acts on the ladder operators, giving

$$\begin{aligned}
M^{ij} = \frac{i}{2} \int d\mathbf{k} k^j \left(-\left(\partial_{k_i} a(\mathbf{k})\right) a(-\mathbf{k}) + \left(\partial_{k_i} a^\dagger(\mathbf{k})\right) a^\dagger(-\mathbf{k}) \right. \\
\left. + \left(\partial_{k_i} a(\mathbf{k})\right) a^\dagger(\mathbf{k}) - \left(\partial_{k_i} a^\dagger(\mathbf{k})\right) a(\mathbf{k}) \right) - (i \leftrightarrow j \text{ term }).
\end{aligned}$$

Let's first show that the first term vanishes. For convenience we define

$$I^{ij} = \int d\mathbf{k} k^j a(-\mathbf{k}) \partial_{k_i} a(\mathbf{k})$$

Integrating by parts again, we have

$$\begin{aligned} I^{ij} &= -\int d\mathbf{k}\partial_{k_i}\left(k^j a(-\mathbf{k})\right) a(\mathbf{k}) \\ &= -\int d\mathbf{k}\delta^{ij} a(-\mathbf{k})a(\mathbf{k}) + k^j\left(\partial_{k_i} a(-\mathbf{k})\right) a(\mathbf{k}) \\ &= -\int d\mathbf{k}\delta^{ij} a(-\mathbf{k})a(\mathbf{k}) + k^j\left(\partial_{k_i} a(\mathbf{k})\right) a(-\mathbf{k}) \\ &= -I^{ij} - \int d\mathbf{k}\delta^{ij} a(-\mathbf{k})a(\mathbf{k}) \end{aligned}$$

where we did the usual $\mathbf{k} \to -\mathbf{k}$ trick in the third step. This shows that I^{ij} is proportional to δ^{ij}. Since the final answer M^{ij} involves an antisymmetrization in i and j, this shows the first term does not contribute to M^{ij}. Similarly, the second term doesn't contribute either.

You might be worried about what happens to the boundary terms when we integrate by parts. Usually, we justify throwing away boundary terms by saying the integrand goes to zero at infinity. But here, it doesn't: the integrand is always a nonzero operator, for any $\mathbf{k}$. However, as the integrand goes to infinity, we get creation and annihilation operators for extremely high momentum particles. These operators have zero matrix elements if you sandwich them between any two physically accessible states, so they might as well just be zero.

We are now left with the last two terms in S81. Normal ordering now gives

$$\begin{aligned} M^{ij} &= \frac{i}{2}\int d\mathbf{k}k^j\left(a^\dagger(\mathbf{k})\partial_{k_i} a(\mathbf{k}) - \left(\partial_{k_i} a^\dagger(\mathbf{k})\right) a(\mathbf{k})\right) - (i \leftrightarrow j \text{ term }) \\ &= \frac{i}{2}\int d\mathbf{k}k^j\left(a^\dagger(\mathbf{k})\partial_{k_i} a(\mathbf{k}) + a^\dagger(\mathbf{k})\partial_{k_i} a(\mathbf{k})\right) - (i \leftrightarrow j \text{ term }) \\ &= i\int d\mathbf{k}a^\dagger(\mathbf{k})\left(k^j\partial_{k_i} - k^i\partial_{k_j}\right) a(\mathbf{k}) \end{aligned}$$

where we integrated by parts again. This is the final result.

The only reason this result looks more complicated than our result for the spatial momentum is that we expanded the field in plane wave modes, which are eigenfunctions of translations but not rotations. Alternatively, we could have expanded the field in spherical waves (i.e. equal to a spherical Bessel function in r times a spherical harmonic), in which case the angular momentum expansion looks simple and the momentum expansion looks complicated. Plane waves are useful for describing the initial states in a particle physics experiment, but spherical waves can be useful in other situations, such as the emission of photons from a excited atom.

Stanford.Zhou.2022 6.1. The Lorentz algebra. (10/45 p)

You previously showed the rotation and boost generators obey commutation relations

$$\left[J^i, J^j\right] = i\epsilon^{ijk}J^k, \quad \left[J^i, K^j\right] = i\epsilon^{ijk}K^k, \quad \left[K^i, K^j\right] = -i\epsilon^{ijk}J^k$$

These are Euclidean indices, which is why pairs of upstairs indices can be contracted.

a) Defining $J^i_\pm = \left(J^i \pm iK^i\right)/2$, show that

$$\left[J^i_+, J^j_-\right] = 0, \quad \left[J^i_\pm, J^j_\pm\right] = i\epsilon^{ijk}J^k_\pm$$

so that the Lorentz algebra is just two copies of the algebra of the rotation group.

Solution:

In general, for any numbers a and b,

$$\begin{aligned} \frac{1}{4}\left[J^i + iaK^i, J^j + ibK^j\right] &= \frac{1}{4}\left(\left[J^i, J^j\right] + ia\left[K^i, J^j\right] + ib\left[J^i, K^j\right] - ab\left[K^i, K^j\right]\right) \\ &= \frac{i}{4}\epsilon^{ijk}\left((1 + a\mathbf{b})J^k + i(a + \mathbf{b})K^k\right) \end{aligned}$$

For $a = -b = 1$ we find

$$\left[J^i_+, J^j_-\right] = 0$$

as desired. For $a = b = \pm 1$ we find

$$\left[J_{\pm}^{i}, J_{\pm}^{j}\right] = i\epsilon^{ijk} J_{\pm}^{k}$$

also as desired.

The commutation relations can be expressed more concisely if we collect all six generators into the antisymmetric Lorentz tensor $J^{\mu\nu}$, where

$$J^{ij} = \epsilon^{ijk} J^{k}, \quad J^{0i} = K^{i}$$

The commutation relations (1) can then all be written together as

$$[J^{\mu\nu}, J^{\rho\sigma}] = i\left(\eta^{\nu\rho} J^{\mu\sigma} - \eta^{\mu\rho} J^{\nu\sigma} - \eta^{\nu\sigma} J^{\mu\rho} + \eta^{\mu\sigma} J^{\nu\rho}\right).$$

By definition, a representation of the Lorentz algebra is a choice of $J^{\mu\nu}$ that satisfies these commutation relations. The simplest example is the trivial representation $J^{\mu\nu} = 0$, which describes the action of Lorentz transformations on scalars.

b) In the vector representation, each generator $J^{\mu\nu}$ is a 4×4 matrix, with elements

$$\left(J^{\mu\nu}\right)_{\alpha\beta} = i\left(\delta_{\alpha}^{\mu}\delta_{\beta}^{\nu} - \delta_{\alpha}^{\nu}\delta_{\beta}^{\mu}\right)$$

This describes the action of Lorentz transformations on four-vectors V^{β}, as you've already seen. Starting from (5), verify the generators satisfy the Lorentz algebra (4). (Hint: upper and lower indices should be contracted in pairs to perform matrix multiplication. For example, $\left(J^{01}J^{23}\right)_{\alpha\beta} = \left(J^{01}\right)_{\alpha}^{\gamma}\left(J^{23}\right)_{\gamma\beta}$. If you get confused, start by plugging in specific values for the indices and doing the sums explicitly.)

Solution:

We just directly evaluate the commutator,

$$[J^{\mu\nu}, J^{\rho\sigma}]_{\alpha\delta} = \eta^{\beta\gamma}\left[-\left(\delta_{\alpha}^{\mu}\delta_{\beta}^{\nu} - \delta_{\alpha}^{\nu}\delta_{\beta}^{\mu}\right)\left(\delta_{\gamma}^{\rho}\delta_{\delta}^{\sigma} - \delta_{\gamma}^{\sigma}\delta_{\delta}^{\rho}\right) + \delta_{\alpha}^{\rho}\delta_{\beta}^{\sigma} - \delta_{\alpha}^{\sigma}\delta_{\beta}^{\rho}\right)\left(\delta_{\gamma}^{\mu}\delta_{\delta}^{\nu} - \delta_{\gamma}^{\nu}\delta_{\delta}^{\mu}\right)\Big]$$

There are 8 terms in total, each of which has the form $\eta^{\beta\gamma}$ times a product of four delta functions. For each one, we can apply the identity $\delta_{\alpha}^{\mu}\delta_{\beta}^{\nu}\eta^{\alpha\beta} = \eta^{\mu\nu}$ to reduce the term to a product of two delta functions times a metric tensor. Collecting the terms in four pairs yields the desired result.

This is tedious to write out. An easier way is to note that $\left(J^{\mu\nu}\right)_{\alpha\beta} = i\left(\delta_{\alpha}^{\mu}\delta_{\beta}^{\nu} - \delta_{\alpha}^{\nu}\delta_{\beta}^{\mu}\right)$ is antisymmetric in μ and ν, and in ρ and σ, which means the result also has to be antisymmetric in these pairs of indices. In this way, you can reduce the amount of algebra needed by a factor of 4, though you have to be a bit careful with signs.

c) The gamma matrices are 4×4 matrices defined to satisfy

$$\{\gamma^{\mu}, \gamma^{\nu}\} = 2\eta^{\mu\nu}$$

Show that

$$[\gamma^{\mu}\gamma^{\nu}, \gamma^{\rho}\gamma^{\sigma}] = 2\left(\eta^{\nu\rho}\gamma^{\mu}\gamma^{\sigma} - \eta^{\mu\rho}\gamma^{\nu}\gamma^{\sigma} + \eta^{\nu\sigma}\gamma^{\rho}\gamma^{\mu} - \eta^{\mu\sigma}\gamma^{\rho}\gamma^{\nu}\right)$$

Solution:

We just directly use the definition of the commutator, and then use (6) repeatedly to get the two terms in the same form, picking up factors of the metric with each anticommutation:

$$\begin{aligned}
[\gamma^{\mu}\gamma^{\nu}, \gamma^{\rho}\gamma^{\sigma}] &= \gamma^{\mu}\gamma^{\nu}\gamma^{\rho}\gamma^{\sigma} - \gamma^{\rho}\gamma^{\sigma}\gamma^{\mu}\gamma^{\nu} \\
&= \gamma^{\mu}\left\{\gamma^{\nu}, \gamma^{\rho}\right\}\gamma^{\sigma} - \gamma^{\mu}\gamma^{\rho}\gamma^{\nu}\gamma^{\sigma} - \gamma^{\rho}\gamma^{\sigma}\gamma^{\mu}\gamma^{\nu} \\
&= 2\eta^{\nu\rho}\gamma^{\mu}\gamma^{\sigma} - \gamma^{\mu}\gamma^{\rho}\left\{\gamma^{\nu}, \gamma^{\sigma}\right\} + \gamma^{\mu}\gamma^{\rho}\gamma^{\sigma}\gamma^{\nu} - \gamma^{\rho}\gamma^{\sigma}\gamma^{\mu}\gamma^{\nu} \\
&= 2\eta^{\nu\rho}\gamma^{\mu}\gamma^{\sigma} - 2\eta^{\nu\sigma}\gamma^{\mu}\gamma^{\rho} + \left\{\gamma^{\mu}, \gamma^{\rho}\right\}\gamma^{\sigma}\gamma^{\nu} - \gamma^{\rho}\gamma^{\mu}\gamma^{\sigma}\gamma^{\nu} - \gamma^{\rho}\gamma^{\sigma}\gamma^{\mu}\gamma^{\nu} \\
&= 2\eta^{\nu\rho}\gamma^{\mu}\gamma^{\sigma} - 2\eta^{\nu\sigma}\gamma^{\mu}\gamma^{\rho} + 2\eta^{\mu\rho}\gamma^{\sigma}\gamma^{\nu} - \gamma^{\rho}\left\{\gamma^{\mu}, \gamma^{\sigma}\right\}\gamma^{\nu} \\
&= 2\eta^{\nu\rho}\gamma^{\mu}\gamma^{\sigma} - 2\eta^{\nu\sigma}\gamma^{\mu}\gamma^{\rho} + 2\eta^{\mu\rho}\gamma^{\sigma}\gamma^{\nu} - 2\eta^{\mu\sigma}\gamma^{\rho}\gamma^{\nu} \\
&= 2\eta^{\nu\rho}\gamma^{\mu}\gamma^{\sigma} + 2\eta^{\nu\sigma}\gamma^{\rho}\gamma^{\mu} - 2\eta^{\mu\rho}\gamma^{\nu}\gamma^{\sigma} - 2\eta^{\mu\sigma}\gamma^{\rho}\gamma^{\nu}
\end{aligned}$$

Note that in the last step, we used the anticommutation relation on each of the middle two terms; the factors of $\eta^{\nu\sigma}\eta^{\mu\rho}$ cancel between the two terms.

d) In the Dirac spinor representation, the generators are the 4×4 matrices

$$S^{\mu\nu} = \frac{i}{4}\left[\gamma^\mu, \gamma^\nu\right]$$

This describes the action of Lorentz transformations on Dirac spinors. Show that these generators satisfy the Lorentz algebra (4).

Solution:

Plugging in the definitions, we have

$$\begin{aligned}
[S^{\mu\nu}, S^{\rho\sigma}] &= -\frac{1}{16}\left[\gamma^\mu\gamma^\nu - \gamma^\nu\gamma^\mu, \gamma^\rho\gamma^\sigma - \gamma^\sigma\gamma^\rho\right] \\
&= -\frac{1}{16}\left([\gamma^\mu\gamma^\nu, \gamma^\rho\gamma^\sigma] - [\gamma^\nu\gamma^\mu, \gamma^\rho\gamma^\sigma] - [\gamma^\mu\gamma^\nu, \gamma^\sigma\gamma^\rho] + [\gamma^\nu\gamma^\mu, \gamma^\sigma\gamma^\rho]\right) \\
&= -\frac{1}{4}\left[\gamma^\mu\gamma^\nu, \gamma^\rho\gamma^\sigma\right] \\
&= -\frac{1}{2}\left(\eta^{\nu\rho}\gamma^\mu\gamma^\sigma + \eta^{\nu\sigma}\gamma^\rho\gamma^\mu - \eta^{\mu\rho}\gamma^\nu\gamma^\sigma - \eta^{\mu\sigma}\gamma^\rho\gamma^\nu\right)
\end{aligned}$$

In the third step, we used the anticommutation relations on the last three terms, and in the fourth step we used the result of part (c). To finish the problem, we note that

$$\gamma^\mu\gamma^\nu = \frac{1}{2}\left[\gamma^\mu, \gamma^\nu\right] + \frac{1}{2}\left\{\gamma^\mu, \gamma^\nu\right\} = -2iS^{\mu\nu} + \eta^{\mu\nu}$$

Applying this to all four terms, the factors of the metric all cancel out, leaving the desired result

$$[S^{\mu\nu}, S^{\rho\sigma}] = i\eta^{\nu\rho}S^{\mu\sigma} + i\eta^{\nu\sigma}S^{\rho\mu} - i\eta^{\mu\rho}S^{\nu}\sigma - i\eta^{\mu\sigma}S^{\rho\nu}$$

Stanford.Zhou.2022 6.2 Properties of gamma matrices. (15/45p)

In this problem, you should only use the defining property (6) of the gamma matrices. Below, $\mathbb{1}_4$ denotes a 4×4 identity matrix.

a) Show that contractions of gamma matrices satisfy

$$\begin{aligned}
\gamma^\mu\gamma_\mu &= 4\mathbb{1}_4 \\
\gamma^\mu\gamma^\nu\gamma_\mu &= -2\gamma^\nu \\
\gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu &= 4\eta^{\nu\rho}\mathbb{1}_4 \\
\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\mu &= -2\gamma^\sigma\gamma^\rho\gamma^\nu
\end{aligned}$$

Solution:

Since γ^μ and γ_μ commute, we have

$$\gamma^\mu\gamma_\mu = \frac{1}{2}\left(\gamma^\mu\gamma_\mu + \gamma_\mu\gamma^\mu\right) = \frac{1}{2}\left\{\gamma^\mu, \gamma_\mu\right\} = \eta^\mu_\mu = 4$$

where the right-hand side has an implicit 4×4 spinor identity matrix. Now, the proofs of the other three statements are very similar, but we use the defining anticommutation relation (6) to get the γ^μ and γ_μ next to each other, so we can use (9). The results are:

$$\begin{aligned}
\gamma^\mu\gamma^\nu\gamma_\mu &= \gamma^\mu\left\{\gamma^\nu,\gamma_\mu\right\} - \gamma^\mu\gamma_\mu\gamma^\nu \\
&= 2\gamma^\mu\eta_\mu^\nu - 4\gamma^\nu \\
&= -2\gamma^\nu \\
\gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu &= \gamma^\mu\gamma^\nu\left\{\gamma^\rho,\gamma_\mu\right\} - \gamma^\mu\gamma^\nu\gamma_\mu\gamma^\rho \\
&= 2\eta_\mu^\rho\gamma^\mu\gamma^\nu - \gamma^\mu\left\{\gamma^\nu,\gamma_\mu\right\}\gamma^\rho + \gamma^\mu\gamma_\mu,\gamma^\nu\gamma^\rho \\
&= 2\gamma^\rho\gamma^\nu - 2\gamma^\nu\gamma^\rho + 4\gamma^\nu\gamma^\rho \\
&= 4\eta^{\rho\nu} \\
\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\mu &= 2\eta_\mu^\sigma\gamma^\mu\gamma^\nu\gamma^\rho - \gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu\gamma^\sigma \\
&= 2\gamma^\sigma\gamma^\nu\gamma^\rho - 2\eta_\mu^\rho\gamma^\mu\gamma^\nu\gamma^\sigma + \gamma^\mu\gamma^\nu\gamma_\mu\gamma^\rho\gamma^\sigma \\
&= 2\gamma^\sigma\gamma^\nu\gamma^\rho - 2\gamma^\rho\gamma^\nu\gamma^\sigma + 2\eta_\mu^\nu\gamma^\mu\gamma^\rho\gamma^\sigma - \gamma^\mu\gamma_\mu\gamma^\nu\gamma^\rho\gamma^\sigma \\
&= 2\gamma^\sigma\gamma^\nu\gamma^\rho - 2\gamma^\rho\gamma^\nu\gamma^\sigma - 2\gamma^\nu\gamma^\rho\gamma^\sigma \\
&= 2\gamma^\sigma\left\{\gamma^\nu,\gamma^\rho\right\} - 2\gamma^\sigma\gamma^\rho\gamma^\nu - 2\gamma^\rho\gamma^\nu\gamma^\sigma - 2\left\{\gamma^\nu,\gamma^\rho\right\}\gamma^\sigma \\
&= 2\gamma^\sigma\left\{\gamma^\nu,\gamma^\rho\right\} - 2\gamma^\sigma\gamma^\rho\gamma^\nu - 2\gamma^\rho\gamma^\nu\gamma^\sigma - 2\left\{\gamma^\nu,\gamma^\rho\right\}\gamma^\sigma + 2\gamma^\rho\gamma^\nu\gamma^\sigma \\
&= -2\gamma^\sigma\gamma^\rho\gamma^\nu
\end{aligned}$$

b) Show that the traces of products of gamma matrices obey

$$\begin{aligned}
\operatorname{tr}\gamma^\mu &= 0 \\
\operatorname{tr}\gamma^\mu\gamma^\nu &= 4\eta^{\mu\nu} \\
\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho &= 0 \\
\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma &= 4\left(\eta^{\mu\nu}\eta^{\rho\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}\right)
\end{aligned}$$

Solution:

We use the cyclic property of the trace,

$$\operatorname{tr} ABC...XYZ = \operatorname{tr} BC...XYZA$$

as well as the results we proved in part (a). For example, we have

$$\operatorname{tr}\gamma^\mu = \operatorname{tr}\left[\frac{1}{4}\gamma^\mu\gamma^\nu\gamma_\nu\right] = \operatorname{tr}\left[\frac{1}{4}\gamma_\nu\gamma^\mu\gamma^\nu\right] = -\frac{1}{2}\operatorname{tr}\gamma^\mu$$

where we used (9), the cyclic property of the trace, and (10). The only way this equation can be satisfied is if $\operatorname{tr}\gamma^\mu = 0$, as desired. A similar idea works for the trace of three gamma matrices,

$$\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho = \frac{1}{4}\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\sigma = \frac{1}{4}\operatorname{tr}\gamma_\sigma\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma = -\frac{1}{2}\operatorname{tr}\gamma^\rho\gamma^\nu\gamma^\mu = -\frac{1}{2}\operatorname{tr}\gamma^\mu\gamma^\rho\gamma^\nu$$

We can bring the right-hand side to the same form as the left-hand side using the anticommutation relation,

$$-\frac{1}{2}\operatorname{tr}\gamma^\mu\gamma^\rho\gamma^\nu = -\frac{1}{2}\operatorname{tr}\gamma^\mu\left\{\gamma^\rho,\gamma^\nu\right\} + \frac{1}{2}\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho = \frac{1}{2}\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho$$

where the second step uses (13). We thus conclude $\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho = 0$. One can generalize this argument to show that the trace of an odd number of gamma matrices always vanishes. (Of course, there are multiple ways to show this; you could also have done it by inserting factors of $\left(\gamma^5\right)^2 = 1$, as in Peskin.)

Now let's consider the equations with an even number of gamma matrices. For two gamma matrices, we can use the cyclic property of the trace to produce an anticommutator, giving

$$\operatorname{tr}\gamma^\mu\gamma^\nu = \frac{1}{2}\operatorname{tr}\left[\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu\right] = \operatorname{tr}\left[\eta^{\mu\nu}\right] = 4\eta^{\mu\nu}$$

For four gamma matrices, we can use a similar idea, repeatedly using the anticommutation relations to bring γ^μ to the right and then moving it back to the left using the cyclic property of the trace,

$$\begin{aligned}
\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma &= \operatorname{tr}\left\{\gamma^\mu,\gamma^\nu\right\}\gamma^\rho\gamma^\sigma - \operatorname{tr}\gamma^\nu\gamma^\mu\gamma^\rho\gamma^\sigma \\
&= 8\eta^{\mu\nu}\eta^{\rho\sigma} - \operatorname{tr}\gamma^\nu\left\{\gamma^\mu,\gamma^\rho\right\}\gamma^\sigma - \operatorname{tr}\gamma^\nu\gamma^\rho\gamma^\mu\gamma^\sigma \\
&= 8\eta^{\mu\nu}\eta^{\rho\sigma} - 8\eta^{\mu\rho}\eta^{\nu\sigma} + \operatorname{tr}\gamma^\nu\gamma^\rho\left\{\gamma^\mu,\gamma^\sigma\right\} - \operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma \\
&= 8\eta^{\mu\nu}\eta^{\rho\sigma} - 8\eta^{\mu\rho}\eta^{\nu\sigma} + 8\eta^{\mu\sigma}\eta^{\rho\nu} - \operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma
\end{aligned}$$

Adding $\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma$ to both sides and dividing by two gives the result.

While these relations might seem random, there's a very simple way to summarize what they mean. Consider an arbitrarily long product of arbitrary gamma matrices,

$$\operatorname{tr}\left(\gamma^1\gamma^3\gamma^0\gamma^0\gamma^2\gamma^3\gamma^2\gamma^1\ldots\right)$$

The defining anticommutation relations tells us that we pick up a minus sign when we swap the order of any two adjacent, distinct gamma matrices. So such a trace can always be rewritten in the form

$$\pm\operatorname{tr}\left(\left(\gamma^0\right)^{n_0}\left(\gamma^1\right)^{n_1}\left(\gamma^2\right)^{n_2}\left(\gamma^3\right)^{n_3}\right)$$

where n_0 through n_3 are nonnegative integers. The anticommutation relations also tell us that $\gamma^0\gamma^0 = 1$ and $\gamma^1\gamma^1 = \gamma^2\gamma^2 = \gamma^3\gamma^3 = -1$, which reduces the trace above (up to a sign) to

$$\pm\operatorname{tr}\left(\left(\gamma^0\right)^{m_0}\left(\gamma^1\right)^{m_1}\left(\gamma^2\right)^{m_2}\left(\gamma^3\right)^{m_3}\right)$$

where the m_i are 0 or 1, depending on the parity of the n_i. Looking back at what we've just proven, (13) says the trace of any single gamma matrix is zero, (14) says the trace of the product of any two distinct gamma matrices is zero, and (15) and (16) say the analogous results for three and four gamma matrices. Therefore, the trace S45 is automatically zero unless all of the m_i are equal to zero. The punchline is that the only way to get a nonzero trace is to multiply an even number of copies of each type of gamma matrix.

c) It will be useful to introduce the matrix $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$. Show that

$$\begin{aligned}\left\{\gamma^5,\gamma^\mu\right\} &= 0\\ \left(\gamma^5\right)^2 &= \mathbb{1}_4\\ \operatorname{tr}\gamma^5 &= 0\\ \operatorname{tr}\gamma^\mu\gamma^\nu\gamma^5 &= 0\\ \operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^5 &= -4i\epsilon^{\mu\nu\rho\sigma}.\end{aligned}$$

Solution:

We can check the first statement for each value of μ. For example, for $\mu = 0$ we have

$$\left\{\gamma^5,\gamma^0\right\} = i\gamma^0\gamma^1\gamma^2\gamma^3\gamma^0 + i\gamma^0\gamma^0\gamma^1\gamma^2\gamma^3$$

The second term can be brought to the first term by performing three anticommutations, each of which flips the sign. Thus, the sum of the two terms is zero. The logic for $\mu = 1, 2, 3$ is similar.

To prove the second statement, we note that

$$\begin{aligned}\left(\gamma^5\right)^2 &= -\gamma^0\gamma^1\gamma^2\gamma^3\gamma^0\gamma^1\gamma^2\gamma^3\\ &= \gamma^1\gamma^2\gamma^3\gamma^1\gamma^2\gamma^3\\ &= -\gamma^2\gamma^3\gamma^2\gamma^3\\ &= -\gamma^3\gamma^3\\ &= 1\end{aligned}$$

where we just used the anticommutation relations, which imply $\gamma^0\gamma^0 = 1$ and $\gamma^1\gamma^1 = \gamma^2\gamma^2 = \gamma^3\gamma^3 = -1$.

To prove the third statement, we can simply use (16),

$$\operatorname{tr}\gamma^5 = i\operatorname{tr}\gamma^0\gamma^1\gamma^2\gamma^3 = 4i\left(\eta^{01}\eta^{23} - \eta^{02}\eta^{13} + \eta^{03}\eta^{12}\right) = 0$$

For the fourth statement, we can do some casework on the values of μ and ν. If $\mu = \nu$, then the γ^μ and γ^ν multiply to give \pm 1, leaving us with $\operatorname{tr}\gamma^5 = 0$. On the other hand, suppose $\mu \neq \nu$, then we can bring the factors of γ^μ and γ^ν within γ^5 to the left, by performing anticommutations. Multiplying them with $\gamma^\mu\gamma^\nu$ yields \pm 1 and leaves the trace of a product of two different gamma matrices, which is zero.

Finally, for the last statement, let's first show that the left-hand side is totally antisymmetric in its four indices. For the μ and ν indices, note that

$$\operatorname{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^5 = 2\eta^{\mu\nu}\operatorname{tr}\gamma^\rho\gamma^\sigma\gamma^5 - \operatorname{tr}\gamma^\nu\gamma^\mu\gamma^\rho\gamma^\sigma\gamma^5 = -\operatorname{tr}\gamma^\nu\gamma^\mu\gamma^\rho\gamma^\sigma\gamma^5$$

By similar reasoning, we get a sign flip when we exchange the ν and ρ indices, and the ρ and σ indices, which suffices to show that the left-hand side is antisymmetric in all four indices. Thus, it must be equal to $A\epsilon^{\mu\nu\rho\sigma}$ for some constant A. To find the constant, we just consider a special case,

$$\operatorname{tr}\gamma^0\gamma^1\gamma^2\gamma^3\gamma^5 = A\epsilon^{0123} = A$$

The left-hand side is just

$$-i\operatorname{tr}\left(\gamma^5\right)^2 = -4i$$

which yields the desired result.

Stanford.Zhou.2022 6.3 Invariance of the Dirac Lagrangian. (15/45p)

The Dirac Lagrangian is

$$\mathcal{L} = \bar{\Psi}\left(i\not{\partial} - m\mathbb{1}_4\right)\Psi$$

where $\bar{\Psi} = \Psi^\dagger\gamma^0$ and $\not{\partial} = \gamma^\mu\partial_\mu$. The four-component spinor Ψ is acted on by the gamma matrices. In general, a Lorentz transformation Λ will change a spinor according to

$$\Psi(x) \to \Psi'(x') = U(\Lambda)\Psi(x)$$

where $U(\Lambda)$ is some 4×4 matrix, not necessarily unitary.
a) Show that the Dirac Lagrangian is invariant under Lorentz transformations if

$$U^{-1}(\Lambda) = \gamma^0 U^\dagger(\Lambda)\gamma^0, \quad U^{-1}(\Lambda)\gamma^\mu U(\Lambda) = \Lambda^\mu_\nu\gamma^\nu$$

Solution:

From basic special relativity, we know that under a Lorentz transformation,

$$x^\mu \to x^\mu = \Lambda^\mu_\nu x^\nu, \quad \frac{\partial}{\partial x_\mu} \to \frac{\partial}{\partial x'_\mu} = \Lambda^\mu_\nu\frac{\partial}{\partial x^\nu}$$

Now let's show that each term in the Dirac Lagrangian is invariant. The mass term is invariant because

$$\bar{\Psi}\Psi = \Psi^\dagger\gamma^0\Psi \to \Psi^\dagger U^\dagger\gamma^0 U\Psi = \Psi^\dagger\gamma^0 U^{-1}U\Psi = \bar{\Psi}\Psi$$

To show the kinetic term is invariant, note that

$$\begin{aligned}
\bar{\Psi}\not{\partial}\Psi &\to \Psi^\dagger U^\dagger\gamma^0\gamma_\mu\Lambda^\mu_\nu\partial^\nu U\Psi \\
&= \Psi^\dagger\gamma^0 U^{-1}\gamma_\mu\Lambda^\mu_\nu U\partial^\nu\Psi \\
&= \bar{\Psi}\Lambda_{\mu\rho}\gamma^\rho\Lambda^\mu_\nu\partial^\nu\Psi \\
&= \bar{\Psi}\eta_{\nu\rho}\gamma^\rho\partial^\nu\Psi \\
&= \bar{\Psi}\not{\partial}\Psi.
\end{aligned}$$

b) Show that for an infinitesimal Lorentz transformation $\Lambda^{\mu\nu} = \eta^{\mu\nu} + \omega^{\mu\nu}$ the above relations are satisfied for

$$U(\Lambda) = \mathbb{1}_4 - \frac{i}{2}\omega^{\mu\nu}S_{\mu\nu}$$

where $S^{\mu\nu}$ is the Lorentz generator defined by (8). (Hint: use $\gamma^0\gamma^\mu\gamma^0 = (\gamma^\mu)^\dagger$, which holds in every representation of the gamma matrices.)

Solution:

Expanding out the definitions, we have

$$U = \mathbb{1} + \frac{1}{8}\left[\gamma^\mu,\gamma^\nu\right]\omega_{\mu\nu}$$

which implies

$$U^{-1} = \mathbb{1} - \frac{1}{8}\left[\gamma^\mu,\gamma^\nu\right]\omega_{\mu\nu}$$

since we're considering infinitesimal translations. To prove the first result note that

$$\begin{aligned}\gamma^0 U^\dagger \gamma^0 &= \mathbb{1} + \frac{1}{8}\gamma^0 \left[(\gamma^\nu)^\dagger, (\gamma^\mu)^\dagger\right] \gamma^0 \omega_{\mu\nu} \\ &= \mathbb{1} + \frac{1}{8}\gamma^0 \left[\gamma^0\gamma^\nu\gamma^0, \gamma^0\gamma^\mu\gamma^0\right] \gamma^0 \omega_{\mu\nu} \\ &= \mathbb{1} - \frac{1}{8}\left[\gamma^\mu, \gamma^\nu\right] \omega_{\mu\nu} \\ &= U^{-1}\end{aligned}$$

In the first step, we used the fact that $[A,B]^\dagger = \left[B^\dagger, A^\dagger\right]$, in the second step we used $\gamma_\mu^\dagger = \gamma^0\gamma_\mu\gamma^0$, and in the third step we used $\gamma^0\gamma^0 = 1$.

For the second relation, note that

$$\gamma_\mu \left[\gamma_\rho, \gamma_\sigma\right] = 4\left(\eta_{\mu\rho}\gamma_\sigma - \eta_{\mu\sigma}\gamma_\rho\right) + \left[\gamma_\rho, \gamma_\sigma\right]\gamma_\mu$$

Next,

$$\gamma^\mu U = \gamma^\mu \left(\mathbb{1} + \frac{1}{8}\left[\gamma_\rho, \gamma_\sigma\right]\omega^{\rho\sigma}\right) = U\gamma^\mu + \frac{1}{2}\left(\omega^{\mu\sigma}\gamma_\sigma - \omega^{\sigma\mu}\gamma_\sigma\right) = U\gamma^\mu + \omega^{\mu\sigma}\gamma_\sigma$$

Finally, we find

$$U^{-1}\gamma_\mu U = U^{-1}\left(U\gamma_\mu + \omega_{\mu\sigma}\gamma^\sigma\right) = \left(\eta_{\mu\nu} + \omega_{\mu\nu}\right)\gamma^\nu = \Lambda_{\mu\nu}\gamma^\nu$$

as desired. Note that in the penultimate step, we dropped a term of order ω^2 since the Lorentz transformation is infinitesimal. **c)** A finite Lorentz transformation is given by exponentiating a generator,

$$U(\Lambda) = \exp\left(-\frac{i}{2}\omega^{\mu\nu}S_{\mu\nu}\right)$$

Explicitly write down the 4×4 matrix $U(\Lambda)$ for a rotation about the x-axis by an angle θ, and a boost along the z axis with rapidity ϕ. Use the Dirac representation of the gamma matrices, as this will yield simple results in the nonrelativistic limit.

Solution:

For rotations around the x-axis by an angle θ we have $\omega^{23} = -\omega^{32} = \theta$ and all other entries zero. In the Dirac representation, we find

$$\left[\gamma^2, \gamma^3\right] = \left[\begin{pmatrix} 0 & \sigma_2 \\ -\sigma_2 & 0 \end{pmatrix}, \begin{pmatrix} 0 & \sigma_2 \\ -\sigma_2 & 0 \end{pmatrix}\right] = -\begin{pmatrix} [\sigma_2,\sigma_3] & 0 \\ 0 & [\sigma_2,\sigma_3] \end{pmatrix} = 2i\begin{pmatrix} \sigma_1 & 0 \\ 0 & \sigma_1 \end{pmatrix}$$

Consequently,

$$U(\Lambda(\theta)) = \exp\left\{\frac{i\theta}{2}\begin{pmatrix} \sigma_1 & 0 \\ 0 & \sigma_1 \end{pmatrix}\right\} = \cos\frac{\theta}{2}\mathbb{1} + i\sin\frac{\theta}{2}\begin{pmatrix} \sigma_1 & 0 \\ 0 & \sigma_1 \end{pmatrix}$$

This makes sense, because it just says that both of the two-component spinors that make up a Dirac spinor transform like spin 1/2 particles in ordinary quantum mechanics.

For boosts along the z direction we have $\omega^{03} = -\omega^{30} = \phi$ and all other entries zero, and

$$\left[\gamma^0, \gamma^3\right] = \left[\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \begin{pmatrix} 0 & \sigma_3 \\ -\sigma_3 & 0 \end{pmatrix}\right] = 2\begin{pmatrix} 0 & \sigma_3 \\ \sigma_3 & 0 \end{pmatrix}$$

Consequently,

$$U(\Lambda(\phi)) = \exp\left\{\frac{\phi}{2}\begin{pmatrix} 0 & \sigma_3 \\ \sigma_3 & 0 \end{pmatrix}\right\} = \cosh\frac{\phi}{2}\mathbb{1} + \begin{pmatrix} 0 & \sigma_3 \\ \sigma_3 & 0 \end{pmatrix}\sinh\frac{\phi}{2}$$

In other words, boosts mix the two two-component spinors, while keeping the spin state the same.

d) Show that the Dirac Lagrangian is invariant under $\Psi \to e^{-i\alpha}\Psi$, and find the associated conserved current J_V^μ. Then show explicitly that $\partial_\mu J_V^\mu = 0$ using the Dirac equation.

Solution:

The Lagrangian is invariant because we also have $\bar{\Psi} \to e^{i\alpha}\bar{\Psi}$, so the phases cancel out. Now, to avoid confusion when applying Noether's theorem, let's explicitly write out the spinor indices. The changes in the spinors are

$$(\delta\Psi)_a = -i\Psi_a, \quad (\delta\bar{\Psi})_a = (i\bar{\Psi})_a$$

and Noether's theorem states

$$J_V^\mu = \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\Psi\right)_a}(\delta\Psi)_a + \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\bar{\Psi}\right)_a}(\delta\bar{\Psi})_a$$

where there is an implicit sum over the spinor index a. (It ranges from 0 to 3, covering the four elements of the spinor, but it is not a Lorentz index.) The second term is just zero, so we get

$$J_V^\mu = \left(i\bar{\Psi}\gamma^\mu\right)_a(-i\Psi)_a$$

We can rewrite this without explicit spinor indices as

$$J_V^\mu = \bar{\Psi}\gamma^\mu\Psi$$

where there are now implicit spinor matrix multiplications. To check this is conserved, note that

$$\partial_\mu J_V^\mu = \left(\partial_\mu\bar{\Psi}\right)\gamma^\mu\Psi + \bar{\Psi}\gamma^\mu\partial_\mu\Psi = im\bar{\Psi}\Psi - im\bar{\Psi}\Psi = 0$$

e) Show that when $m = 0$, the Dirac Lagrangian is also invariant under $\Psi \to e^{-i\alpha\gamma^5}\Psi$, and find the associated conserved current J_A^μ. What is $\partial_\mu J_A^\mu$ when m is nonzero?

Solution:

Using the fact that γ^5 anticommutes with all gamma matrices, we have

$$\bar{\Psi} = \Psi^\dagger\gamma^0 \to \Psi^\dagger e^{i\alpha\gamma^5}\gamma^0 = \Psi^\dagger\gamma^0 e^{-i\alpha\gamma^5} = \bar{\Psi}e^{-i\alpha\gamma^5}$$

Thus, the Lagrangian becomes

$$\Psi^\dagger e^{-i\alpha\gamma^5}\not{\partial}e^{-i\alpha\gamma^5}\Psi.$$

Moving the $e^{-i\alpha\gamma^5}$ past the $\not{\partial}$ flips the sign of the exponential, so we end up with a factor of $e^{i\alpha\gamma^5}e^{-i\alpha\gamma^5} = 1$. Now, the changes in the spinors per α, for infinitesimal α, are

$$\delta\Psi = -i\gamma^5\Psi, \quad \delta\bar{\Psi} = -i\bar{\Psi}\gamma^5$$

which means the Noether current is

$$J_A^\mu = \bar{\Psi}\gamma^\mu\gamma^5\Psi$$

For nonzero m, the divergence of the current is

$$\begin{aligned}\partial_\mu J_A^\mu &= \left(\partial_\mu\bar{\Psi}\right)\gamma^\mu\gamma^5\Psi + \bar{\Psi}\gamma^\mu\gamma^5\partial_\mu\Psi \\ &= \left(\partial_\mu\bar{\Psi}\right)\gamma^\mu\gamma^5\Psi - \bar{\Psi}\gamma^5\gamma^\mu\partial_\mu\Psi \\ &= im\bar{\Psi}\gamma^5\Psi + im\bar{\Psi}\gamma^5\Psi \\ &= 2im\bar{\Psi}\gamma^5\Psi\end{aligned}$$

Stanford.Zhou.2022 6.4.* Spinors in three dimensions. (5/45p)

In this course, we focus on spinors in four dimensions for good reason. In this optional problem, you'll see how the same mathematical structures appear in three dimensions.

a) Consider spinors in three spacetime dimensions. What are the smallest nonzero matrices that can satisfy (6)? Write down three such matrices γ^0, γ^1, and γ^2 explicitly.

Solution:

The minimum size is 2×2, and one example set is

$$\gamma^0 = \sigma^2, \quad \gamma^1 = i\sigma^1, \quad \gamma^2 = i\sigma^3$$

where the σ^i are the Pauli matrices.

b) We define the spinor Lorentz generators by (8) in any dimension. Since there are now only two spatial dimensions, there is only one rotation generator S^{12}. What phase does a spinor pick up after a 2π rotation?

Solution:

We have
Then a 2π rotation yields

$$S^{12} = \frac{i}{4}\left[i\sigma^1, i\sigma^3\right] = -\frac{\sigma^2}{2}$$

$$\exp\left(-\pi\sigma^2\right) = -I$$

and therefore a phase of π, just like in 4 dimensions.

c) How does the tensor product of two spinor representations decompose into irreducible representations of the Lorentz group?

Solution:

By the exact same logic as in 4 dimensions, we can extract a Lorentz scalar by $\bar{\psi}\psi$, and a Lorentz vector (which only has three components) by $\bar{\psi}\gamma^\mu\psi$. Since spinors have 2 components, the tensor product has 4 components, so this decomposition is complete: there isn't anything else. For instance, you might consider putting $[\gamma^\mu, \gamma^\nu]$ in the middle, but in three dimensions the commutator of two gamma matrices is just another gamma matrix, so you don't get anything new. Similarly, you can't use γ^5 to get anything new, as its analogue here, $i\gamma^0\gamma^1\gamma^2$, is just proportional to the identity.

In two spatial dimensions there are exotic particles called anyons, which can pick up an arbitrary phase after a 2π rotation. However, they can't be described by the conventional quantum fields covered in this course.

26.1.8 Problems about spinors and Dirac equation

33 Решения уравнения Дирака для свободных частиц.

11

Покажите, что $\exp\left[\begin{pmatrix} 0 & \eta \\ \eta & 0 \end{pmatrix}\right] = \begin{pmatrix} \operatorname{ch}\eta & \operatorname{sh}\eta \\ \operatorname{sh}\eta & \operatorname{ch}\eta \end{pmatrix}$, и

$$\exp\left[\begin{pmatrix} -\eta\sigma^3/2 & 0 \\ 0 & \eta\sigma^3/2 \end{pmatrix}\right] = \begin{pmatrix} \operatorname{ch}(\eta/2) - \sigma^3\operatorname{sh}(\eta/2) & 0 \\ 0 & \operatorname{ch}(\eta/2) + \sigma^3\operatorname{sh}(\eta/2) \end{pmatrix}$$

Решение: Имеем

$$\begin{pmatrix} 0 & \eta \\ \eta & 0 \end{pmatrix}^{2n} = \begin{pmatrix} \eta^{2n} & 0 \\ 0 & \eta^{2n} \end{pmatrix}, \quad \begin{pmatrix} 0 & \eta \\ \eta & 0 \end{pmatrix}^{2n+1} = \begin{pmatrix} 0 & \eta^{2n+1} \\ \eta^{2n+1} & 0 \end{pmatrix} \tag{0.14}$$

В итоге получим

$$\exp\left[\begin{pmatrix} 0 & \eta \\ \eta & 0 \end{pmatrix}\right] = \sum_{k=0}^{\infty}\frac{1}{k!}\begin{pmatrix} 0 & \eta \\ \eta & 0 \end{pmatrix}^k = \sum_{n=0}^{\infty}\frac{1}{(2n)!}\begin{pmatrix} \eta^{2n} & 0 \\ 0 & \eta^{2n} \end{pmatrix} + \sum_{n=0}^{\infty}\frac{1}{(2n+1)!}\begin{pmatrix} 0 & \eta^{2n+1} \\ \eta^{2n+1} & 0 \end{pmatrix} =$$
$$= \begin{pmatrix} \operatorname{ch}\eta & \operatorname{sh}\eta \\ \operatorname{sh}\eta & \operatorname{ch}\eta \end{pmatrix}. \tag{0.15}$$

Также имеем

$$\begin{pmatrix} -\eta\sigma^3/2 & 0 \\ 0 & \eta\sigma^3/2 \end{pmatrix}^{2n} = \begin{pmatrix} \left(\frac{\eta}{2}\right)^{2n} & 0 \\ 0 & \left(\frac{\eta}{2}\right)^{2n} \end{pmatrix}, \quad \begin{pmatrix} -\eta\sigma^3/2 & 0 \\ 0 & \eta\sigma^3/2 \end{pmatrix}^{2n+1} = \begin{pmatrix} -\left(\frac{\eta}{2}\right)^{2n+1}\sigma^3 & 0 \\ 0 & \left(\frac{\eta}{2}\right)^{2n+1}\sigma^3 \end{pmatrix}. \tag{0.16}$$

И аналогично получаем

$$\exp\left[\begin{pmatrix} -\eta\sigma^3/2 & 0 \\ 0 & \eta\sigma^3/2 \end{pmatrix}\right] = \begin{pmatrix} \operatorname{ch}(\eta/2) - \sigma^3\operatorname{sh}(\eta/2) & 0 \\ 0 & \operatorname{ch}(\eta/2) + \sigma^3\operatorname{sh}(\eta/2) \end{pmatrix} \tag{0.17}$$

что и требовалось показать.

12

Докажите, что $(p\cdot\sigma)(p\cdot\bar{\sigma}) = p^2 = m^2$, где $\sigma = (1, \boldsymbol{\sigma})$ и $\bar{\sigma} = (1, -\boldsymbol{\sigma})$.
Решение: Имеем

$$(p\cdot\sigma)(p\cdot\bar{\sigma}) = p_\mu p_\nu \sigma^\mu\bar{\sigma}^\nu = p_\mu p_\nu \frac{1}{2}\left(\sigma^\mu\bar{\sigma}^\nu + \sigma^\nu\bar{\sigma}^\mu\right) = p_\mu p_\nu g^{\mu\nu} = p^2 = m^2 \tag{0.18}$$

где мы использовали, что $\sigma^\mu\bar{\sigma}^\nu + \sigma^\nu\bar{\sigma}^\mu = 2g^{\mu\nu}$, что легко проверить прямым вычислением и учитывая, что $\left\{\sigma^i, \sigma^j\right\} = 2\delta^{ij}$.$\bigcirc$

13*.

Найдите собственные числа и общий вид матрицы $\sqrt{p\cdot\sigma}$.
Решение: Имеем

$$p\cdot\sigma = g_{\mu\nu}p^\mu\sigma^\nu = p^0\sigma^0 - \boldsymbol{p}\boldsymbol{\sigma} = \begin{pmatrix} p^0 - p^3 & -p^1 + ip^2 \\ -p^1 - ip^2 & p^0 + p^3 \end{pmatrix}. \tag{0.19}$$

Находя собственные значения $\lambda_{1,2} = p^0 \pm |\boldsymbol{p}|$, легко переписать данную матрицу в виде

$$p\cdot\sigma = S\Lambda S^{-1} = \begin{pmatrix} -p^3 - |\boldsymbol{p}| & -p^3 + |\boldsymbol{p}| \\ -p^1 - ip^2 & -p^1 - ip^2 \end{pmatrix}\begin{pmatrix} p^0 - |\boldsymbol{p}| & 0 \\ 0 & p^0 + |\boldsymbol{p}| \end{pmatrix}\begin{pmatrix} -\frac{1}{2|\boldsymbol{p}|} & \frac{p^3 - |\boldsymbol{p}|}{2|\boldsymbol{p}|(p^1+ip^2)} \\ \frac{1}{2|\boldsymbol{p}|} & -\frac{p^3+|\boldsymbol{p}|}{2|\boldsymbol{p}|(p^1+ip^2)} \end{pmatrix}. \tag{0.20}$$

Тогда для $\sqrt{p\cdot\sigma}$ получим

$$\begin{aligned}\sqrt{p\cdot\sigma} = S\sqrt{\Lambda}S^{-1} &= \begin{pmatrix} -p^3 - |\boldsymbol{p}| & -p^3 + |\boldsymbol{p}| \\ -p^1 - ip^2 & -p^1 - ip^2 \end{pmatrix}\begin{pmatrix} \sqrt{p^0 - |\boldsymbol{p}|} & 0 \\ 0 & \sqrt{p^0 + |\boldsymbol{p}|} \end{pmatrix}\begin{pmatrix} -\frac{1}{2|\boldsymbol{p}|} & \frac{p^3 - |\boldsymbol{p}|}{2|\boldsymbol{p}|(p^1+ip^2)} \\ \frac{1}{2|\boldsymbol{p}|} & -\frac{p^3+|\boldsymbol{p}|}{2|\boldsymbol{p}|(p^1+ip^2)} \end{pmatrix} = \\ &= \begin{pmatrix} \frac{|\boldsymbol{p}|\mathfrak{s} - p^3\mathfrak{r}}{2|\boldsymbol{p}|} & -\frac{\mathfrak{r}}{2|\boldsymbol{p}|}\left(p^1 - ip^2\right) \\ -\frac{\mathfrak{r}}{2|\boldsymbol{p}|}\left(p^1 + ip^2\right) & \frac{|\boldsymbol{p}|\mathfrak{s} + \mathfrak{r}p^3}{2|\boldsymbol{p}|} \end{pmatrix} = g_{\mu\nu}\tilde{p}^\mu\sigma^\mu = \tilde{p}\cdot\sigma, \quad \tilde{p} = \left(\frac{\mathfrak{s}}{2}, \frac{\mathfrak{r}}{2}\frac{\boldsymbol{p}}{|\boldsymbol{p}|}\right),\end{aligned} \tag{0.21}$$

где $\mathfrak{s} = \sqrt{p^0 + |\boldsymbol{p}|} + \sqrt{p^0 - |\boldsymbol{p}|}$, а $\mathfrak{r} = \sqrt{p^0 + |\boldsymbol{p}|} - \sqrt{p^0 - |\boldsymbol{p}|}$.

14

Проверить, что $\psi(x) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar{\sigma}}\xi \end{pmatrix} e^{-ipx}$ есть решение уравнения Дирака.
Решение: Мы должны проверить, что

$$\left(\gamma^\mu p_\mu - m\right)u(p) = \left(g_{\mu\nu}\gamma^\mu p^\nu - m\right)u(p) = \left(\gamma^0 p^0 - \gamma^i p^i - m\right)u(p) = 0 \tag{0.22}$$

где спинор $u(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar{\sigma}}\xi \end{pmatrix}$, а γ-матрицы взяты в киральном (Вейлевском) представлении:

$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}\cdot$ Имеем

$$\begin{aligned}(\gamma^\mu p_\mu - m)\, u(p) &= \begin{pmatrix} -m & p^0\sigma^0 - p^i\sigma^i \\ p^0\sigma^0 + p^i\sigma^i & -m \end{pmatrix} u(p) = \begin{pmatrix} -m & p\cdot\sigma \\ p\cdot\bar\sigma & -m \end{pmatrix}\begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar\sigma}\xi \end{pmatrix} = \\ &= \begin{pmatrix} (-m\sqrt{p\cdot\sigma} + p\cdot\sigma\sqrt{p\cdot\bar\sigma})\xi \\ (-m\sqrt{p\cdot\bar\sigma} + p\cdot\bar\sigma\sqrt{p\cdot\sigma})\xi \end{pmatrix} = \begin{pmatrix} (-m\sqrt{p\cdot\sigma} + \sqrt{p\cdot\sigma}\sqrt{p\cdot\sigma}\sqrt{p\cdot\bar\sigma})\xi \\ (-m\sqrt{p\cdot\bar\sigma} + \sqrt{p\cdot\bar\sigma}\sqrt{p\cdot\bar\sigma}\sqrt{p\cdot\sigma})\xi \end{pmatrix} = \\ &= \begin{pmatrix} (-m\sqrt{p\cdot\sigma} + \sqrt{p\cdot\sigma}m)\xi \\ (-m\sqrt{p\cdot\bar\sigma} + \sqrt{p\cdot\bar\sigma}m)\xi \end{pmatrix} = 0, \end{aligned} \tag{0.23}$$

что и требовалось показать.

15

Покажите, что $\bar u u = 2m\xi^\dagger\xi$, где $u(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar\sigma}\xi \end{pmatrix}$, а $\bar u(p) = u^\dagger(p)\gamma^0$.

Решение: Имеем

$$\bar u(p) = u^\dagger(p)\gamma^0 = \begin{pmatrix} \xi^\dagger\sqrt{p\cdot\sigma} & \xi^\dagger\sqrt{p\cdot\bar\sigma} \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} \xi^\dagger\sqrt{p\cdot\bar\sigma} & \xi^\dagger\sqrt{p\cdot\sigma} \end{pmatrix} \tag{0.24}$$

где мы использовали, что $(\sqrt{p\cdot\sigma})^\dagger = \sqrt{p\cdot\sigma}$ и $(\sqrt{p\cdot\bar\sigma})^\dagger = \sqrt{p\cdot\bar\sigma}$. Далее получаем

$$\bar u(p)u(p) = \begin{pmatrix} \xi^\dagger\sqrt{p\cdot\bar\sigma}\xi^\dagger\sqrt{p\cdot\sigma} \end{pmatrix}\begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar\sigma}\xi \end{pmatrix} = 2\xi^\dagger\sqrt{p\cdot\bar\sigma}\sqrt{p\cdot\sigma}\xi = 2m\xi^\dagger\xi \tag{0.25}$$

что и требовалось показать.

16

Покажите, что $\bar v^r(p)v^s(p) = -2m\delta^{rs}$, $v^{r\dagger}(p)v^s(p) = 2E_{\mathbf{p}}\delta^{rs}$, где $v^s(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\eta^s \\ -\sqrt{p\cdot\bar\sigma}\eta^s \end{pmatrix}$ и $\eta^{r\dagger}\eta^s = \delta^{rs}, s, r = 1, 2$.

Решение: Имеем

$$\bar v^r(p)v^s(p) = \begin{pmatrix} -\eta^{r\dagger}\sqrt{p\cdot\bar\sigma} & \eta^{r\dagger}\sqrt{p\cdot\sigma} \end{pmatrix}\begin{pmatrix} \sqrt{p\cdot\sigma}\eta^s \\ -\sqrt{p\cdot\bar\sigma}\eta^s \end{pmatrix} = -2m\eta^{r\dagger}\eta^s = -2m\delta^{rs}. \tag{0.26}$$

Далее

$$\begin{aligned} v^{r\dagger}(p)v^s(p) &= \begin{pmatrix} \eta^{r\dagger}\sqrt{p\cdot\sigma} - \eta^{r\dagger}\sqrt{p\cdot\bar\sigma} \end{pmatrix}\begin{pmatrix} \sqrt{p\cdot\sigma}\eta^s \\ -\sqrt{p\cdot\bar\sigma}\eta^s \end{pmatrix} = \eta^{r\dagger}(p\cdot\sigma + p\cdot\bar\sigma)\eta^s = \eta^{r\dagger}\left(2p^0\sigma^0\right)\eta^s = \\ &= 2p^0\eta^{r\dagger}\eta^s = 2E_{\boldsymbol{p}}\delta^{rs} \end{aligned} \tag{0.27}$$

что и требовалось показать.

17

Проверьте, что $\bar u^r(p)v^s(p) = \bar v^r(p)u^s(p) = 0$ и $u^{r\dagger}(\mathbf{p})v^s(-\mathbf{p}) = v^{r\dagger}(-\mathbf{p})u^s(\mathbf{p}) = 0$.

Решение: Имеем

$$\bar{u}^r(p)v^s(p) = \begin{pmatrix} \xi^{r\dagger}\sqrt{p\cdot\bar{\sigma}} & \xi^{r\dagger}\sqrt{p\cdot\sigma} \end{pmatrix} \begin{pmatrix} \sqrt{p\cdot\sigma}\eta^s \\ -\sqrt{p\cdot\bar{\sigma}}\eta^s \end{pmatrix} = \xi^{r\dagger}(\sqrt{p\cdot\bar{\sigma}}\sqrt{p\cdot\sigma} - \sqrt{p\cdot\sigma}\sqrt{p\cdot\bar{\sigma}})\eta^s =$$
$$= \xi^{r\dagger}(m-m)\eta^s = 0,$$
$$\bar{v}^r(p)u^s(p) = \begin{pmatrix} -\eta^{r\dagger}\sqrt{p\cdot\bar{\sigma}} & \eta^{r\dagger}\sqrt{p\cdot\sigma} \end{pmatrix} \begin{pmatrix} \sqrt{p\cdot\sigma}\xi^s \\ \sqrt{p\cdot\bar{\sigma}}\xi^s \end{pmatrix} = \eta^{r\dagger}(-\sqrt{p\cdot\bar{\sigma}}\sqrt{p\cdot\sigma} + \sqrt{p\cdot\sigma}\sqrt{p\cdot\bar{\sigma}})\xi^s =$$
$$= \eta^{r\dagger}(-m+m)\xi^s = 0. \tag{0.28}$$

Далее имеем

$$u^{r\dagger}(\mathbf{p})v^s(-\mathbf{p}) = \begin{pmatrix} \xi^{r\dagger}\sqrt{p\cdot\sigma} & \xi^{r\dagger}\sqrt{p\cdot\bar{\sigma}} \end{pmatrix} \begin{pmatrix} \sqrt{p\cdot\bar{\sigma}}\eta^s \\ -\sqrt{p\cdot\sigma}\eta^s \end{pmatrix} = 0 \tag{0.29}$$

для $v^{r\dagger}(-\mathbf{p})u^s(\mathbf{p}) = 0$ проверяется аналогично.

18

Докажите формулу $\sum\limits_{s=1,2}\xi^s\xi^{s\dagger} = \mathbf{1} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$, где $\xi^{r\dagger}\xi^s = \delta^{rs}$ и покажите, что $\sum\limits_s u^s(p)\bar{u}^s(p) = \gamma\cdot p + m$, а $\sum\limits_s v^s(p)\bar{v}^s(p) = \gamma\cdot p - m$

Решение: Так как $\xi^s, s = 1,2$ образуют ортонормированный базис: $\xi^{r\dagger}\xi^s = \delta^{rs}$, то взяв произвольный вектор $\boldsymbol{e} = e_1\xi^1 + e_2\xi^2$, имеем

$$\left(\sum_{s=1,2}\xi^s\xi^{s\dagger}\right)\boldsymbol{e} = e_1\sum_{s=1,2}\xi^s\xi^{s\dagger}\xi^1 + e_2\sum_{s=1,2}\xi^s\xi^{s\dagger}\xi^2 = e_1\sum_{s=1,2}\xi^s\delta^{s1} + e_2\sum_{s=1,2}\xi^s\delta^{s2} = e_1\xi^1 + e_2\xi^2 = \boldsymbol{e}, \tag{0.30}$$

откуда следует, что $\sum\limits_{s=1,2}\xi^s\xi^{s\dagger} = \mathbf{1}$. Далее получаем

$$\sum_s u^s(p)\bar{u}^s(p) = \sum_s \begin{pmatrix} \sqrt{p\cdot\sigma}\xi^s \\ \sqrt{p\cdot\bar{\sigma}}\xi^s \end{pmatrix} \begin{pmatrix} \xi^{s\dagger}\sqrt{p\cdot\bar{\sigma}} & \xi^{s\dagger}\sqrt{p\cdot\sigma} \end{pmatrix} = \begin{pmatrix} m & p\cdot\sigma \\ p\cdot\bar{\sigma} & m \end{pmatrix} = \gamma\cdot p + m$$
$$\sum_s v^s(p)\bar{v}^s(p) = \sum_s \begin{pmatrix} \sqrt{p\cdot\sigma}\eta^s \\ -\sqrt{p\cdot\bar{\sigma}}\eta^s \end{pmatrix} \begin{pmatrix} -\eta^{s\dagger}\sqrt{p\cdot\bar{\sigma}} & \eta^{s\dagger}\sqrt{p\cdot\sigma} \end{pmatrix} = \begin{pmatrix} -m & p\cdot\sigma \\ p\cdot\bar{\sigma} & -m \end{pmatrix} = \gamma\cdot p - m$$

что и требовалось показать.

34 Матрицы Дирака и билинейные формы Дирака.

Проверьте, что $\gamma^5 \equiv i\gamma^0\gamma^1\gamma^2\gamma^3 = -\frac{i}{4!}\varepsilon^{\mu\nu\rho\sigma}\gamma_\mu\gamma_\nu\gamma_\rho\gamma_\sigma$, и $\varepsilon^{0123} = -\varepsilon_{0123} = 1$.

Решение: Так как $\gamma_\mu\gamma_\nu = 2g_{\mu\nu} - \gamma_\nu\gamma_\nu$, и $g_{\mu\nu}$ симметричный тензор, и при свертке с $\varepsilon^{\mu\nu\rho\sigma}$ он равен нулю, то при свертке с $\varepsilon^{\mu\nu\rho\sigma}$ можно считать, что $\gamma_\mu\gamma_\nu \sim -\gamma_\nu\gamma_\mu$. Тогда $\gamma_\mu\gamma_\nu\gamma_\rho\gamma_\sigma \sim \varepsilon_{\mu\nu\rho\sigma}\gamma^0\gamma^1\gamma^2\gamma^3$. Таким образом получаем

$$-\frac{i}{4!}\varepsilon^{\mu\nu\rho\sigma}\gamma_\mu\gamma_\nu\gamma_\rho\gamma_\sigma = -\frac{i}{4!}\varepsilon^{\mu\nu\rho\sigma}\varepsilon_{\mu\nu\rho\sigma}\gamma^0\gamma^1\gamma^2\gamma^3 = i\gamma^0\gamma^1\gamma^2\gamma^3 \tag{0.32}$$

где мы воспользовались тем, что $\varepsilon^{\mu\nu\rho\sigma}\varepsilon_{\mu\nu\rho\sigma} = -4$!.

Проверьте, что $\gamma^{\mu\nu\rho} = i\varepsilon^{\mu\nu\rho\sigma}\gamma_\sigma\gamma^5$, где $\gamma^{\mu\nu\rho} = \gamma^{[\mu}\gamma^\nu\gamma^{\rho]} = \frac{1}{3!}\left(\gamma^\mu\gamma^\nu\gamma^\rho - \gamma^\nu\gamma^\mu\gamma^\rho - \gamma^\mu\gamma^\rho\gamma^\nu + \gamma^\nu\gamma^\rho\gamma^\mu + \gamma^\rho\gamma^\mu\gamma^\nu - \gamma^\rho\gamma^\nu\gamma^\mu\right)$.

Решение: Очевидно, что если два каких-либо индекса совпадают, то $\gamma^{\mu\nu\rho} = 0$. Рассмотрим случай, когда все индексы μ, ν, ρ разные. Тогда гамма-матрицы антикоммутируют между собой, откуда $\gamma^{\mu\nu\rho} = \gamma^\mu\gamma^\nu\gamma^\rho$. Далее пусть σ есть индекс, который не равен индексам μ, ν, ρ (например $\mu = 2, \nu = 3, \rho = 0$, тогда $\sigma = 1$), тогда мы можем записать, используя, что $\gamma_\sigma\gamma^\sigma = 1$ (здесь нет суммирования по индексу σ)

$$\gamma^{\mu\nu\rho} = \gamma^\mu\gamma^\nu\gamma^\rho\gamma_\sigma\gamma^\sigma = -\gamma_\sigma\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma = i\varepsilon^{\mu\nu\rho\sigma}\gamma_\sigma\left(i\gamma^0\gamma^1\gamma^3\gamma^4\right) = i\varepsilon^{\mu\nu\rho\sigma}\gamma_\sigma\gamma^5 \tag{0.33}$$

где мы использовали, что $\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma = \varepsilon^{\mu\nu\rho\sigma}\gamma^0\gamma^1\gamma^3\gamma^4$, так как все индексы разные.

Проверьте, что $\left(\gamma^5\right)^\dagger = \gamma^5, \quad \left(\gamma^5\right)^2 = 1, \quad \left\{\gamma^5, \gamma^\mu\right\} = 0$.

Решение: Используя, что $\left(\gamma^0\right)^\dagger = \gamma^0$, а $\left(\gamma^i\right)^\dagger = -\gamma^i, i = 1, 2, 3$, имеем:

$$\left(\gamma^5\right)^\dagger = \left(i\gamma^0\gamma^1\gamma^2\gamma^3\right)^\dagger = -i\left(\gamma^3\right)^\dagger\left(\gamma^2\right)^\dagger\left(\gamma^1\right)^\dagger\left(\gamma^0\right)^\dagger = i\gamma^3\gamma^2\gamma^1\gamma^0 = i\gamma^0\gamma^1\gamma^2\gamma^3 = \gamma^5 \tag{0.34}$$

Также

$$\left(\gamma^5\right)^2 = i\gamma^0\gamma^1\gamma^2\gamma^3 i\gamma^0\gamma^1\gamma^2\gamma^3 = \gamma^1\gamma^2\gamma^3\gamma^1\gamma^2\gamma^3 = -\gamma^2\gamma^3\gamma^2\gamma^3 = -\gamma^3\gamma^3 = 1 \tag{0.35}$$

И в итоге

$$\left\{\gamma^5, \gamma^\mu\right\} = i\gamma^0\gamma^1\gamma^2\gamma^3\gamma^\mu + i\gamma^\mu\gamma^0\gamma^1\gamma^2\gamma^3 = -i\gamma^\mu\gamma^0\gamma^1\gamma^2\gamma^3 + i\gamma^\mu\gamma^0\gamma^1\gamma^2\gamma^3 = 0 \tag{0.36}$$

так как при переносе γ^μ через произведение $\gamma^0\gamma^1\gamma^2\gamma^3$, она антикоммутирует с тремя гамма-матрицами и коммутирует с собой, откуда и появляется знак минус.

Покажите, что $\partial_\mu j^\mu = 0, \partial_\mu j^{\mu 5} = 2im\bar{\psi}\gamma^5\psi$, где $j^\mu(x) = \bar{\psi}(x)\gamma^\mu\psi(x), \quad j^{\mu 5}(x) = \bar{\psi}(x)\gamma^\mu\gamma^5\psi(x)$, учитывая уравнения движения.

Решение: Уравнения движения есть

$$\begin{aligned}&\left(i\gamma^\mu\partial_\mu - m\right)\psi = 0\\ &\left(i\left(\partial_\mu\bar{\psi}\right)\gamma^\mu + m\bar{\psi}\right) = 0\end{aligned} \tag{0.37}$$

далее получаем

$$\partial_\mu j^\mu = \partial_\mu\left(\bar{\psi}(x)\gamma^\mu\psi(x)\right) = \left(\partial_\mu\bar{\psi}(x)\right)\gamma^\mu\psi(x) + \bar{\psi}(x)\gamma^\mu\partial_\mu\psi(x) = im\bar{\psi}(x)\psi(x) - m\bar{\psi}(x)\psi(x) = 0 \tag{0.38}$$

аналогично имеем

$$\partial_\mu j^{\mu 5} = \partial_\mu\left(\bar{\psi}\gamma^\mu\gamma^5\psi\right) = \left(\partial_\mu\bar{\psi}\right)\gamma^\mu\gamma^5\psi + \bar{\psi}\gamma^\mu\gamma^5\partial_\mu\psi = im\bar{\psi}\gamma^5\psi + im\bar{\psi}\gamma^5\psi = 2im\bar{\psi}\gamma^5\psi \tag{0.39}$$

что и требовалось показать.

Покажите, что $j^\mu(x)$ и $j^{\mu 5}(x)$ являются нетеровскими токами, соответствующими преобразованиям $\psi(x) \to e^{i\alpha}\psi(x)$ и $\psi(x) \to e^{i\alpha\gamma^5}\psi(x)$.

Решение: Имеем $\mathcal{L} = \bar{\psi}\left(i\gamma^\mu\partial_\mu - m\right)\psi$ и $\psi \to (1+i\alpha)\psi$, откуда $\delta\psi = i\psi$, и получим

$$j^\mu = -\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\psi\right)}\delta\psi = \bar{\psi}\gamma^\mu\psi \tag{0.40}$$

далее $\psi \to \left(1+i\alpha\gamma^5\right)\psi$, откуда $\delta\psi = i\gamma^5\psi$ и получим

$$j^{\mu 5} = -\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\psi\right)}\delta\psi = \bar{\psi}\gamma^\mu\gamma^5\psi \tag{0.41}$$

что и требовалось показать.

Используя тождество Фирца $\left(\sigma^\mu\right)_{\alpha\beta}\left(\sigma_\mu\right)_{\gamma\delta} = 2\varepsilon_{\alpha\gamma}\varepsilon_{\beta\delta}$, покажите, что

$$\left(\bar{u}_{1R}\sigma^\mu u_{2R}\right)\left(\bar{u}_{3R}\sigma_\mu u_{4R}\right) = -\left(\bar{u}_{1R}\sigma^\mu u_{4R}\right)\left(\bar{u}_{3R}\sigma_\mu u_{2R}\right)$$
$$\left(\bar{u}_{1L}\bar{\sigma}^\mu\sigma^\nu\bar{\sigma}^\lambda u_{2L}\right)\left(\bar{u}_{3L}\bar{\sigma}_\mu\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right) = 16\left(\bar{u}_{1L}\bar{\sigma}^\mu u_{2L}\right)\left(\bar{u}_{3L}\bar{\sigma}_\mu u_{4L}\right)$$

Решение: Используем, что $\left(\sigma^\mu\right)_{\alpha\beta}\left(\sigma_\mu\right)_{\gamma\delta} = 2\varepsilon_{\alpha\gamma}\varepsilon_{\beta\delta} = -2\varepsilon_{\alpha\gamma}\varepsilon_{\delta\beta} = -\left(\sigma^\mu\right)_{\alpha\delta}\left(\sigma_\mu\right)_{\gamma\beta}$, откуда

$$\begin{aligned}\left(\bar{u}_{1R}\sigma^\mu u_{2R}\right)\left(\bar{u}_{3R}\sigma_\mu u_{4R}\right) &= \bar{u}_{1R\alpha}u_{2R\beta}\bar{u}_{3R\gamma}u_{4R\delta}\left(\sigma^\mu\right)_{\alpha\beta}\left(\sigma_\mu\right)_{\gamma\delta} = -\bar{u}_{1R\alpha}u_{2R\beta}\bar{u}_{3R\gamma}u_{4R\delta}\left(\sigma^\mu\right)_{\alpha\delta}\left(\sigma_\mu\right)_{\gamma\beta} = \\ &= -\left(\bar{u}_{1R}\sigma^\mu u_{4R}\right)\left(\bar{u}_{3R}\sigma_\mu u_{2R}\right).\end{aligned} \tag{0.42}$$

Далее имеем

$$\left(\bar{u}_{1L}\bar{\sigma}^\mu\sigma^\nu\bar{\sigma}^\lambda u_{2L}\right)\left(\bar{u}_{3L}\bar{\sigma}_\mu\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right) = 2\epsilon_{\alpha\gamma}\bar{u}_{1L\alpha}\bar{u}_{3L\gamma}\epsilon_{\beta\delta}\left(\sigma^\nu\bar{\sigma}^\lambda u_{2L}\right)_\beta\left(\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right)_\delta. \tag{0.43}$$

Теперь рассмотрим отдельно

$$\begin{aligned}\epsilon_{\beta\delta}\left(\sigma^\nu\bar{\sigma}^\lambda u_{2L}\right)_\beta\left(\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right)_\delta &= \epsilon_{\beta\delta}\left(\sigma^\nu\right)_{\beta\rho}\left(\bar{\sigma}^\lambda\right)_{\rho\sigma}u_{2L\sigma}\left(\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right)_\delta = -\epsilon_{\delta\beta}\left(\sigma^\nu\right)_{\beta\rho}\left(\bar{\sigma}^\lambda\right)_{\rho\sigma}u_{2L\sigma}\left(\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right)_\delta = \\ &= -\left(\bar{\sigma}^\nu\right)_{\beta\delta}\epsilon_{\beta\rho}\left(\bar{\sigma}^\lambda\right)_{\rho\sigma}u_{2L\sigma}\left(\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right)_\delta = -\left(\bar{\sigma}^\nu\right)_{\beta\delta}\left(\sigma^\lambda\right)_{\rho\beta}\epsilon_{\rho\sigma}u_{2L\sigma}\left(\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right)_\delta = \\ &= -\epsilon_{\rho\sigma}u_{2L\sigma}\left(\sigma^\lambda\right)_{\rho\beta}\left(\bar{\sigma}^\nu\right)_{\beta\delta}\left(\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right)_\delta = \epsilon_{\sigma\rho}u_{2L\sigma}\left(\sigma^\lambda\bar{\sigma}^\nu\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right)_\rho = \\ &= (4)^2\epsilon_{\sigma\rho}u_{2L\sigma}u_{4L\rho},\end{aligned} \tag{0.44}$$

где мы использовали, что $\epsilon_{\alpha\beta}\left(\sigma^\mu\right)_{\beta\gamma} = \left(\bar{\sigma}^\mu\right)_{\beta\alpha}\epsilon_{\beta\gamma}$ и $\sigma^\mu\bar{\sigma}_\mu = \bar{\sigma}^\mu\sigma_\mu = 4$. Теперь получаем

$$\begin{aligned}\left(\bar{u}_{1L}\bar{\sigma}^\mu\sigma^\nu\bar{\sigma}^\lambda u_{2L}\right)\left(\bar{u}_{3L}\bar{\sigma}_\mu\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right) &= 2\epsilon_{\alpha\gamma}\bar{u}_{1L\alpha}\bar{u}_{3L\gamma}\epsilon_{\beta\delta}\left(\sigma^\nu\bar{\sigma}^\lambda u_{2L}\right)_\beta\left(\sigma_\nu\bar{\sigma}_\lambda u_{4L}\right)_\delta = \\ &= 2\cdot(4)^2\epsilon_{\alpha\gamma}\bar{u}_{1L\alpha}\bar{u}_{3L\gamma}\epsilon_{\sigma\rho}u_{2L\sigma}u_{4L\rho} = \\ &= 16\bar{u}_{1L\alpha}\bar{u}_{3L\gamma}u_{2L\sigma}u_{4L\rho}\left(\bar{\sigma}^\mu\right)_{\alpha\sigma}\left(\bar{\sigma}_\mu\right)_{\gamma\rho} = \\ &= 16\left(\bar{u}_{1L}\bar{\sigma}^\mu u_{2L}\right)\left(\bar{u}_{3L}\bar{\sigma}_\mu u_{4L}\right),\end{aligned} \tag{0.45}$$

что и требовалось показать.

Белавин-Пархоменко.6. Поле Дирака

Все задачи в этом листке взяты из книги Пескина Шредера, глава 3.

Белавин-Пархоменко.6.1 Представления группы Лоренца

Итак коммутационные соотношения для генераторов алгебры Лоренца:

$$[J^{\mu\nu}, J^{\rho\sigma}] = i\left(g^{\nu\rho}J^{\mu\sigma} - g^{\mu\rho}J^{\nu\sigma} - g^{\nu\sigma}J^{\mu\rho} + g^{\mu\sigma}J^{\nu\rho}\right). \tag{0.1}$$

(a). Определим генераторы поворотов и бустов по формулам

$$L^i = \frac{1}{2}\epsilon^{ijk}J^{jk}, \quad K^i = J^{0i} \tag{0.2}$$

где $i, j, k = 1, 2, 3$.

Инфинитезимальное преобразование Лоренца может быть записано как

$$\Phi \to (1 - i\boldsymbol{\theta}\cdot\boldsymbol{L} - i\boldsymbol{\beta}\cdot\boldsymbol{K})\Phi. \tag{0.3}$$

Запишите коммутационные соотношения для L^i и K^i явно. Покажите, что комбинации

$$\boldsymbol{J}_+ = \frac{1}{2}(\boldsymbol{L} + i\boldsymbol{K}), \quad \boldsymbol{J}_- = \frac{1}{2}(\boldsymbol{L} - i\boldsymbol{K}) \tag{0.4}$$

коммутируют друг с другом, и по отдельности удовлетворяют коммутационным соотношениям момента импульса.

(b). Конечномерные представления группы вращений нумеруются допустимыми значениям орбитального момента: целыми и полуцелыми числами. Из результата части (a) следуют, что все конечномерные представления группы Лоренца соответствуют парам целых или полуцелых чисел, (j_+, j_-), которые в свою очередь соответствуют паре представлений группы поворотов. Используя то, что $\boldsymbol{J} = \boldsymbol{\sigma}/2$ для представления спина- 1/2, запишите явно закон преобразования для 2 -компонентных объектов преобразующихся по представлениям $\left(\frac{1}{2}, 0\right)$ и $\left(0, \frac{1}{2}\right)$ группы Лоренца. Покажите, что это есть в точности преобразования для ψ_L и ψ_R:

$$\psi_L \to \left(1 - i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} - \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_L, \quad \psi_R \to \left(1 - i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} + \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_R. \tag{0.5}$$

(c). Тождество $\boldsymbol{\sigma}^T = -\sigma^2\boldsymbol{\sigma}\sigma^2$ позволяет переписать преобразование для ψ_L в эквивалентной форме

$$\psi' \to \psi'\left(1 + i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} + \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right), \tag{0.6}$$

где $\psi' = \psi_L^T\sigma^2$. Используя этот закон, мы можем записать объект, который преобразуется по представлению $\left(\frac{1}{2}, \frac{1}{2}\right)$ как 2×2 матрица, которая преобразуется по закону ψ_R с левой стороны и одновременно преобразуется по закону транспонированного ψ_L с правой. Запишите эту матрицу в виде

$$\begin{pmatrix} V^0 + V^3 & V^1 - iV^2 \\ V^1 + iV^2 & V^0 - V^3 \end{pmatrix}. \tag{0.7}$$

Покажите, что объект V^μ преобразуется как 4-вектор.

Белавин-Пархоменко.6.2 Тождество Гордона

Выведите тождество

$$\bar{u}(p')\gamma^\mu u(p) = \bar{u}(p')\left[\frac{p'^\mu + p^\mu}{2m} + \frac{i\sigma^{\mu\nu}q_\nu}{2m}\right]u(p) \tag{0.8}$$

где $q = (p' - p)$.

Белавин-Пархоменко.6.3 Произведение спиноров

Пусть k_0^μ, k_1^μ фиксированные 4-векторы, удовлетворяющие $k_0^2 = 0, k_1^2 = -1, k_0 \cdot k_1 = 0$. Определим базис спиноров следующим способом: Пусть u_{L0} будет левополяризованным спинором для фермиона с импульсом k_0. Пусть $u_{R0} = k_1 u_{L0}$. Тогда для любого светоподобного импульса $p\,(p^2 = 0)$, определим:

$$u_L(p) = \frac{1}{\sqrt{2p\cdot k_0}}\not{p}u_{R0}, \quad u_R(p) = \frac{1}{\sqrt{2p\cdot k_0}}\not{p}u_{L0} \tag{0.9}$$

Такой набор условий определяет спиноры однозначно (кроме случая, когда p параллелен k_0).
(a). Покажите, что $\ell_0 u_{R0} = 0$. Покажите, что для любого светоподобного p $\not{u}_L(p) = \not{u}_R(p) = 0$.
(b). Для $k_0 = (E, 0, 0, -E), k_1 = (0, 1, 0, 0)$, постройте $u_{L0}, u_{R0}, u_L(p)$ и $u_R(p)$ явно.
(c). Определим спинорные произведения $s\left(p_1, p_2\right)$ и $t\left(p_1, p_2\right)$, для светоподоных p_1, p_2, по формулам

$$s\left(p_1, p_2\right) = \bar{u}_R\left(p_1\right) u_L\left(p_2\right), \quad t\left(p_1, p_2\right) = \bar{u}_L\left(p_1\right) u_R\left(p_2\right) \tag{0.10}$$

Используя явные выражения для u_λ в части (b), вычислите спинорные произведения явно и покажите, что $t\left(p_1, p_2\right) = \left(s\left(p_2, p_1\right)\right)^*$ и $s\left(p_1, p_2\right) = -s\left(p_2, p_1\right)$. Также покажите, что

$$\left|s\left(p_1, p_2\right)\right|^2 = 2 p_1 \cdot p_2 \tag{0.11}$$

Откуда видно, что спиноры это квадратные корни из скалярного произведения 4-векторов.

Белавин-Пархоменко.6.4 Майорановские фермионы

Релятивистское уравнение для безмассового 2-компонентного фермионного поля, которое преобразутеся как верхние две компоненты Дираковского спинора (ψ_L) можно записать как:

$$i\left(\partial_0 - \boldsymbol{\sigma} \cdot \boldsymbol{\nabla}\right) \psi_L = 0 \tag{0.12}$$

Обозначим такое двухкомпонентное поле $\chi_a(x), a = 1, 2$.
(a). Покажите, что можно записать уравнение для $\chi(x)$, как для массивного поля в следующем виде

$$i\bar{\sigma} \cdot \partial \chi - im\sigma^2 \chi^* = 0 \tag{0.13}$$

То есть, покажите вначале, что это уравнение является релятивистски инвариантным, а затем, что из него можно получить уравнение Клейна-Гордона $\left(\partial^2 + m^2\right) \chi = 0$. Такая форма фермионной массы называется Майорановское массовое слагаемое.
(b). Следует ли уравнение Майорана из лагранжиана? Казалось бы, массовое слагаемое, получается варьированием выражения $\left(\sigma^2\right)_{ab} \chi_a^* \chi_b^*$; Однако, так как σ^2 - антисимметричная матрица, это выражение обратилось бы в нуль, если бы $\chi(x)$ было бы обычным c-числовым полем. Известно, что при переходе к квантовой теории поля $\chi(x)$ становится антикоммутирующим квантовым полем. Следовательно, имеет смысл развивать классическую теорию поля, рассматривая $\chi(x)$ как классическое антикоммутирующее поле, то есть как поле, которое принимает значения в грассмановых числах, удовлетворяющих условиям:

$$\alpha\beta = -\beta\alpha, \quad \text{для любых } \alpha, \beta. \tag{0.14}$$

Заметим, что из этих соотношений следует, что $\alpha^2 = 0$. Грассманово поле $\xi(x)$ может быть разложено по базису функций как

$$\xi(x) = \sum_n \alpha_n \phi_n(x) \tag{0.15}$$

где $\phi_n(x)$ - ортогональные c-числовые функции и α_n - набор независимых грассмановых чисел. Определим комплексное сопряжение произведения грассмановых чисел как обращающее их порядок:

$$(\alpha\beta)^* \equiv \beta^* \alpha^* = -\alpha^* \beta^*. \tag{0.16}$$

Это правило по форме совпадает с эрмитовым сопряжением квантовых полей. Покажите, что классическое действие

$$S = \int d^4x \left[\chi^\dagger i\bar{\sigma} \cdot \partial \chi + \frac{im}{2}\left(\chi^T \sigma^2 \chi - \chi^\dagger \sigma^2 \chi^*\right)\right] \tag{0.17}$$

(где $\chi^\dagger = \left(\chi^*\right)^T$) является вещественным ($S^* = S$) и варьирование S относительно χ и χ^* приводит к уравнению Майорана.
(c). Запишем 4-компонентное дираковское поле

$$\psi(x) = \begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix} \tag{0.18}$$

и напомним, что нижняя компонента ψ преобразуется по представлению, унитарно эквивалентному комплексно-сопряженному представлению ψ_L. Таким образом, можно переписать 4 -компонетное дираковское поле в терминах двух 2-компонентных спиноров:

$$\psi_L(x) = \chi_1(x), \quad \psi_R(x) = i\sigma^2 \chi_2^*(x). \tag{0.19}$$

Перепешите лагранжиан Дирака в терминах χ_1 и χ_2 и обратите внимание на форму массового слагаемого.
(d). Покажите, что действие пункта (c) имеет глобальную симметрию. Вычислите дивергенции токов

$$J^\mu = \chi^\dagger \bar{\sigma}^\mu \chi, \quad J^\mu = \chi_1^\dagger \bar{\sigma}^\mu \chi_1 - \chi_2^\dagger \bar{\sigma}^\mu \chi_2 \tag{0.20}$$

для теорий пунктов (b) и (c) соответственно, и свяжите результаты с симметриями этих теорий. Постройте теорию из N свободных массивных 2-компонентных фермионных полей с $O(N)$ симметрией (то есть с вращательной симметрией в N-мерном пространстве).
(e). Проквантуйте теорию Майорана пунктов (a) и (b). Иными словами, рассмотрите $\chi(x)$ как квантовое поле, удовлетворяющее каноническому антикоммутационному соотношению

$$\left\{\chi_a(\boldsymbol{x}), \chi_b^\dagger(\boldsymbol{y})\right\} = \delta_{ab}\delta^{(3)}(\boldsymbol{x}-\boldsymbol{y}) \tag{0.21}$$

Постройте эрмитовый гамильтониан и найдите представление канонических коммутационных соотношений, которое диагонализует гамильтониан в терминах набора операторов рождения и уничтожения. (Подсказка: сравните поле $\chi(x)$ с двумя верхними компонентами проквантованного дираковского поля)

Упражнения к Лекции 6. Поле Дирака

Упражнения идут по ходу главы 3 Пескина Шредера, каждое упражнение оценивается в 2.5 балла.

31 Лоренц инвариантность волновых уравнений.

31

Исходя из формулы для генераторов вращения $J^{\mu\nu} = i\left(x^\mu \partial^\nu - x^\nu \partial^\mu\right)$, показать, что для них выполняются следующие коммутационные соотношения алгебры Лоренца

$$[J^{\mu\nu}, J^{\rho\sigma}] = i\left(g^{\nu\rho}J^{\mu\sigma} - g^{\mu\rho}J^{\nu\sigma} - g^{\nu\sigma}J^{\mu\rho} + g^{\mu\sigma}J^{\nu\rho}\right).$$

Решение: Используем, что $\partial_\mu x^\nu = \delta_\mu^\nu$, откуда $\partial^\mu x^\nu = g^{\mu\nu}$, имеем

$$\begin{aligned}
[J^{\mu\nu}, J^{\rho\sigma}] &= -\left[\left(x^\mu\partial^\nu - x^\nu\partial^\mu\right), \left(x^\rho\partial^\sigma - x^\sigma\partial^\rho\right)\right] = -\left[x^\mu\partial^\nu, x^\rho\partial^\sigma\right] + \ldots = \\
&= -g^{\nu\rho}x^\mu\partial^\sigma + g^{\mu\sigma}x^\rho\partial^\nu + \ldots = ig^{\nu\rho}\left(ix^\mu\partial^\rho + \ldots\right) + ig^{\mu\sigma}\left(\ldots - ix^\rho\partial^\nu\right) + \ldots = \\
&= i\left(g^{\nu\rho}J^{\mu\sigma} - g^{\mu\rho}J^{\nu\sigma} - g^{\nu\sigma}J^{\mu\rho} + g^{\mu\sigma}J^{\nu\rho}\right),
\end{aligned} \tag{0.1}$$

что и тербовалось показать.

26.1.9 Problems about spinors and Dirac equation 2

32 Уравнение Дирака.

2

Показать, что генераторы алгебры Лоренца в представлении гамма-матриц: $S^{\mu\nu} = \frac{i}{4}[\gamma^\mu, \gamma^\nu]$, удовлетворяет коммутационным соотношениям алгебры Лоренца:

$$[S^{\mu\nu}, S^{\rho\sigma}] = i\left(g^{\nu\rho}S^{\mu\sigma} - g^{\mu\rho}S^{\nu\sigma} - g^{\nu\sigma}S^{\mu\rho} + g^{\mu\sigma}S^{\nu\rho}\right).$$

Решение: Используем, что $\{\gamma^\mu, \gamma^\nu\} = 2g^{\mu\nu}$, имеем

$$\begin{aligned}
[S^{\mu\nu}, S^{\rho\sigma}] &= -\frac{1}{16}\left[\gamma^\mu\gamma^\nu, \gamma^\rho\gamma^\sigma\right] + \ldots = -\frac{1}{16}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma - \gamma^\rho\gamma^\sigma\gamma^\mu\gamma^\nu\right) + \ldots = \\
&= -\frac{1}{16}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma + \gamma^\rho\gamma^\mu\gamma^\sigma\gamma^\nu - 2g^{\mu\sigma}\gamma^\rho\gamma^\nu\right) + \ldots = \\
&= -\frac{1}{16}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma - \gamma^\mu\gamma^\rho\gamma^\sigma\gamma^\nu + 2g^{\mu\rho}\gamma^\sigma\gamma^\nu - 2g^{\mu\sigma}\gamma^\rho\gamma^\nu\right) + \ldots = \\
&= -\frac{1}{16}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma + \gamma^\mu\gamma^\rho\gamma^\nu\gamma^\sigma - 2g^{\nu\sigma}\gamma^\mu\gamma^\rho + 2g^{\mu\rho}\gamma^\sigma\gamma^\nu - 2g^{\mu\sigma}\gamma^\rho\gamma^\nu\right) + \ldots = \\
&= -\frac{1}{16}\left(2g^{\nu\rho}\gamma^\mu\gamma^\sigma - 2g^{\nu\sigma}\gamma^\mu\gamma^\rho + 2g^{\mu\rho}\gamma^\sigma\gamma^\nu - 2g^{\mu\sigma}\gamma^\rho\gamma^\nu\right) + \ldots = \\
&= i\left(g^{\nu\rho}S^{\mu\sigma} - g^{\mu\rho}S^{\nu\sigma} - g^{\nu\sigma}S^{\mu\rho} + g^{\mu\sigma}S^{\nu\rho}\right)
\end{aligned} \tag{0.2}$$

3

Покажите, что в киральном представлении гамма-матриц: $\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}$, генераторы алгебры Лоренца $S^{\mu\nu}$, даются выражениями

$$S^{0i} = \frac{i}{4}\left[\gamma^0, \gamma^i\right] = -\frac{i}{2}\begin{pmatrix} \sigma^i & 0 \\ 0 & -\sigma^i \end{pmatrix}, \quad S^{ij} = \frac{i}{4}\left[\gamma^i, \gamma^j\right] = \frac{1}{2}\varepsilon^{ijk}\begin{pmatrix} \sigma^k & 0 \\ 0 & \sigma^k \end{pmatrix} \equiv \frac{1}{2}\varepsilon^{ijk}\Sigma^k.$$

Решение: Имеем

$$\begin{aligned} S^{0i} = \frac{i}{4}\left[\gamma^0, \gamma^i\right] = \frac{i}{4}\left(\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix} - \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\right) = \\ = \frac{i}{4}\left(\begin{pmatrix} -\sigma^i & 0 \\ 0 & \sigma^i \end{pmatrix} - \begin{pmatrix} \sigma^i & 0 \\ 0 & -\sigma^i \end{pmatrix}\right) = -\frac{i}{2}\begin{pmatrix} \sigma^i & 0 \\ 0 & -\sigma^i \end{pmatrix} \end{aligned} \tag{0.3}$$

И также находим

$$\begin{aligned} S^{ij} = \frac{i}{4}\left[\gamma^i, \gamma^j\right] = \frac{i}{4}\left(\begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}\begin{pmatrix} 0 & \sigma^j \\ -\sigma^j & 0 \end{pmatrix} - \begin{pmatrix} 0 & \sigma^j \\ -\sigma^j & 0 \end{pmatrix}\begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}\right) = \\ = \frac{i}{4}\left(\begin{pmatrix} -\sigma^i\sigma^j & 0 \\ 0 & -\sigma^i\sigma^j \end{pmatrix} - \begin{pmatrix} -\sigma^j\sigma^i & 0 \\ 0 & -\sigma^j\sigma^i \end{pmatrix}\right) = -\frac{i}{4}\begin{pmatrix} \left[\sigma^i, \sigma^j\right] & 0 \\ 0 & \left[\sigma^i, \sigma^j\right] \end{pmatrix} = \\ = \frac{1}{2}\varepsilon^{ijk}\begin{pmatrix} \sigma^k & 0 \\ 0 & \sigma^k \end{pmatrix} \equiv \frac{1}{2}\varepsilon^{ijk}\Sigma^k, \end{aligned} \tag{0.4}$$

где мы использовали то, что $\left[\sigma^i, \sigma^j\right] = 2i\varepsilon^{ijk}\sigma^k$ и $\varepsilon^{123} = 1$.◯

4

Покажите, что $[\gamma^\mu, S^{\rho\sigma}] = (\mathcal{J}^{\rho\sigma})^\mu_\nu \gamma^\nu$, где $(\mathcal{J}^{\rho\sigma})_{\alpha\beta} = i\left(\delta^\rho_\alpha\delta^\sigma_\beta - \delta^\rho_\beta\delta^\sigma_\alpha\right)$.
Решение: Имеем

$$\begin{aligned} [\gamma^\mu, S^{\rho\sigma}] = \frac{i}{4}\left[\gamma^\mu, [\gamma^\rho, \gamma^\sigma]\right] = \frac{i}{4}\left[\gamma^\mu, \gamma^\rho\gamma^\sigma - \gamma^\sigma\gamma^\rho\right] = \frac{i}{4}\left([\gamma^\mu, \gamma^\rho\gamma^\sigma] - [\gamma^\mu, \gamma^\sigma\gamma^\rho]\right) = \\ = \frac{i}{4}\left(\gamma^\mu\gamma^\rho\gamma^\sigma - \gamma^\rho\gamma^\sigma\gamma^\mu - \gamma^\mu\gamma^\sigma\gamma^\rho + \gamma^\sigma\gamma^\rho\gamma^\mu\right) = \\ = \frac{i}{4}\left(-\gamma^\rho\gamma^\mu\gamma^\sigma + 2g^{\mu\rho}\gamma^\sigma - \gamma^\rho\gamma^\sigma\gamma^\mu + \gamma^\sigma\gamma^\mu\gamma^\rho - 2g^{\mu\sigma}\gamma^\rho + \gamma^\sigma\gamma^\rho\gamma^\mu\right) = \\ = \frac{i}{4}\left(-2g^{\mu\sigma}\gamma^\rho + 2g^{\mu\rho}\gamma^\sigma + 2g^{\mu\rho}\gamma^\sigma - 2g^{\mu\sigma}\gamma^\rho\right) = i\left(g^{\mu\rho}\gamma^\sigma - g^{\mu\sigma}\gamma^\rho\right) = \\ = i\left(g^{\rho\mu}\delta^\sigma_\nu - g^{\sigma\mu}\delta^\rho_\nu\right)\gamma^\nu = (\mathcal{J}^{\rho\sigma})^\mu_\nu\gamma^\nu. \end{aligned} \tag{0.5}$$

5

Покажите, что верно равенство

$$\left(1 + \frac{i}{2}\omega_{\rho\sigma}S^{\rho\sigma}\right)\gamma^\mu\left(1 - \frac{i}{2}\omega_{\rho\sigma}S^{\rho\sigma}\right) = \left(1 - \frac{i}{2}\omega_{\rho\sigma}\mathcal{J}^{\rho\sigma}\right)^\mu_\nu\gamma^\nu$$

Решение: Имеем
$\left(1 + \frac{i}{2}\omega_{\rho\sigma}S^{\rho\sigma}\right)\gamma^\mu\left(1 - \frac{i}{2}\omega_{\rho\sigma}S^{\rho\sigma}\right) = \gamma^\mu + \frac{i}{2}\omega_{\rho\sigma}\left[S^{\rho\sigma}, \gamma^\mu\right] + O\left(\omega^2\right) = \left(1 - \frac{i}{2}\omega_{\rho\sigma}\mathcal{J}^{\rho\sigma}\right)^\mu_\nu\gamma^\nu + O\left(\omega^2\right)$,
где мы использовали результат предыдущего упражнения.

6

Проверьте, что $\left(S^{ij}\right)^{\dagger}=S^{ij},\left(S^{0i}\right)^{\dagger}=-S^{0i},\quad \left(S^{ij}\right)^{\dagger}\gamma^{0}=\gamma^{0}S^{ij},\quad \left(S^{0i}\right)^{\dagger}\gamma^{0}=-\gamma^{0}S^{0i}$.

Решение: Используя результат упражнения 3, а также $\left(\sigma^{i}\right)^{\dagger}=\sigma^{i}$, очевидно, что $\left(S^{ij}\right)^{\dagger}=S^{ij},\left(S^{0i}\right)^{\dagger}=-S^{0i}$. Далее, используя, что $\left(\gamma^{0}\right)^{\dagger}=\gamma^{0}$, можно получить остальные равенства. Также все можно было получить непостредственно из определения $S^{\mu\nu}$ и из того, что $\left(\gamma^{0}\right)^{\dagger}=\gamma^{0}$ и $\left(\gamma^{i}\right)^{\dagger}=-\gamma^{i}$.

7

Покажите, что $\bar{\psi}\psi$ есть лоренцевский скаляр, а $\bar{\psi}\gamma^{\mu}\psi$ лоренцевский вектор, где $\bar{\psi}\equiv\psi^{\dagger}\gamma^{0}$.
Решение: При преобразовании Лоренца $x^{\mu}\to\Lambda_{\nu}^{\mu}x^{\nu}$, спинор преобразуется как

$$\psi(x)\to\Lambda_{\frac{1}{2}}\psi(x),\qquad \text{где}\qquad \Lambda_{\frac{1}{2}}=\exp\left(-\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu}\right) \tag{0.7}$$

тогда имеем для $\bar{\psi}$

$$\bar{\psi}=\psi^{\dagger}\gamma^{0}\to\psi^{\dagger}\exp\left(\frac{i}{2}\omega_{\mu\nu}\left(S^{\mu\nu}\right)^{\dagger}\right)\gamma^{0}=\psi^{\dagger}\gamma^{0}\exp\left(\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu}\right)=\bar{\psi}\Lambda_{\frac{1}{2}}^{-1} \tag{0.8}$$

где мы использовали результаты упражнения 6. Далее имеем

$$\bar{\psi}\psi\to\bar{\psi}\Lambda_{\frac{1}{2}}^{-1}\Lambda_{\frac{1}{2}}\psi=\bar{\psi}\psi \tag{0.9}$$

и также

$$\bar{\psi}\gamma^{\mu}\psi\to\bar{\psi}\Lambda_{\frac{1}{2}}^{-1}\gamma^{\mu}\Lambda_{\frac{1}{2}}\psi=\Lambda_{\nu}^{\mu}\bar{\psi}\gamma^{\nu}\psi \tag{0.10}$$

где мы использовали результат упражнения 5.

8

Покажите, что уравнения Эйлера-Лагранжа для $\bar{\psi}$ (или $\psi^{\dagger}$) для лагранжиана $\mathcal{L}_{\text{Dirac}}=\bar{\psi}\left(i\gamma^{\mu}\partial_{\mu}-m\right)\psi$ приводят к уравнению Дирака $\left(i\gamma^{\mu}\partial_{\mu}-m\right)\psi(x)=0$.
Решение: Получаем из $\frac{\partial\mathcal{L}}{\partial\bar{\psi}}=0$:

$$\left(i\gamma^{\mu}\partial_{\mu}-m\right)\psi(x)=0 \tag{0.11}$$

32 Вейлевские спиноры.

9

Проверьте, что для левого ψ_{L} и правого ψ_{R} вейлевских спиноров, при бесконечно мылых вращениях $\boldsymbol{\theta}\left(\theta_{i}=\frac{1}{2}\varepsilon^{ijk}\omega_{jk}\right)$ и бустах $\boldsymbol{\beta}\left(\beta_{i}=\omega_{0i}\right)$, преобразования имеют вид

$$\psi_{\text{L}}\to\left(1-i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2}-\boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_{L}$$
$$\psi_{\text{R}}\to\left(1-i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2}+\boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_{R}.$$

Решение: Имеем

$$\begin{aligned}\begin{pmatrix}\psi_{L}\\ \psi_{R}\end{pmatrix}=\psi\to\left(1-\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu}\right)\psi&=\left(1-i\omega_{0i}S^{0i}-\frac{i}{2}\omega_{ij}S^{ij}\right)\begin{pmatrix}\psi_{L}\\ \psi_{R}\end{pmatrix}=\\ &=\left(1-\frac{1}{2}\begin{pmatrix}\omega_{0i}\sigma^{i} & 0\\ 0 & -\omega_{0i}\sigma^{i}\end{pmatrix}-\frac{i}{4}\omega_{ij}\varepsilon^{ijk}\begin{pmatrix}\sigma^{k} & 0\\ 0 & \sigma^{k}\end{pmatrix}\right)\begin{pmatrix}\psi_{L}\\ \psi_{R}\end{pmatrix}=\\ &=\left(1-\begin{pmatrix}\beta_{i}\frac{\sigma^{i}}{2}+i\theta_{i}\frac{\sigma^{i}}{2} & 0\\ 0 & -\beta_{i}\frac{\sigma^{i}}{2}+i\theta_{i}\frac{\sigma^{i}}{2}\end{pmatrix}\right)\begin{pmatrix}\psi_{L}\\ \psi_{R}\end{pmatrix}.\end{aligned} \tag{0.12}$$

В итоге получим преобразование $\psi_{\text{L}}\to\left(1-i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2}-\boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_{L}$, и $\psi_{\text{R}}\to\left(1-i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2}+\boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_{R}\cdot\bigcirc$

10

Докажите тождество $\sigma^2\boldsymbol{\sigma}^* = -\boldsymbol{\sigma}\sigma^2$, и покажите, что величина $\sigma^2\psi_{\mathrm{L}}^*$ преобразуется подобно правому спинору.

Решение: Используя, что $\left(\sigma^1\right)^* = \sigma^1, \left(\sigma^2\right)^* = -\sigma^2, \left(\sigma^3\right)^* = \sigma^3$, а также $\left\{\sigma^i, \sigma^j\right\} = 2\delta^{ij}$, легко проверить, что $\sigma^2\boldsymbol{\sigma}^* = -\boldsymbol{\sigma}\sigma^2$. Далее получаем

$$\sigma^2\psi_{\mathrm{L}}^* \to \sigma^2\left(1 + i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} - \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_L^* = \left(1 - i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} + \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\sigma^2\psi_L^* \tag{0.13}$$

В итоге видим, что $\sigma^2\psi_{\mathrm{L}}^* \to \left(1 - i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} + \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\sigma^2\psi_L^*$, как и $\psi_{\mathrm{R}} \to \left(1 - i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} + \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_R$.

35 Квантование Дираковского поля.

25

Покажите, что плотность Дираковского гамильтониана дается выражением $\mathcal{H} = \bar{\psi}(-i\gamma.\ \nabla + m)\psi$.
Решение: Для канонического момента p имеем

$$p = \frac{\partial\mathcal{L}}{\partial_0\psi} = \bar{\psi}i\gamma^0 = i\psi^\dagger\gamma^0\gamma^0 = i\psi^\dagger \tag{0.46}$$

Далее для Гамильтоновой плотности получаем

$$\mathcal{H} = p\partial_0\psi - \mathcal{L} = i\bar{\psi}\gamma^0\partial_0\psi - \bar{\psi}\left(i\gamma^0\partial_0 + i\gamma^i\partial_i - m\right)\psi = \bar{\psi}(-i\gamma\cdot\nabla + m)\psi, \tag{0.47}$$

что и требовалось показать.

Покажите, что для данного "неправильного"дираковского поля

$$\psi(\mathbf{x}) = \int\frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}e^{i\mathbf{px}}\sum_{s=1,2}\left(a_{\mathbf{p}}^s u^s(\mathbf{p}) + b_{-\mathbf{p}}^s v^s(-\mathbf{p})\right)$$

выполняются соотношения $\left[\psi(\mathbf{x}), \psi^\dagger(\mathbf{y})\right] = \delta^{(3)}(\mathbf{x}-\mathbf{y})\times\mathbf{1}_{4\times4}$. Используйте коммутационные соотношения $\left[a_{\boldsymbol{p}}^r, a_{\boldsymbol{q}}^{s\dagger}\right] = \left[b_{\boldsymbol{p}}^r, b_{\boldsymbol{q}}^{s^\dagger}\right] = (2\pi)^3\delta^{(3)}(\boldsymbol{p}-\boldsymbol{q})\delta^{rs}$.
Решение: Имеем

$$\begin{aligned}\left[\psi(\mathbf{x}), \psi^\dagger(\mathbf{y})\right] &= \int\frac{d^3pd^3q}{(2\pi)^6}\frac{1}{\sqrt{2E_{\boldsymbol{p}}2E_{\boldsymbol{q}}}}e^{i(\boldsymbol{p}\cdot\boldsymbol{x}-\boldsymbol{q}\cdot\boldsymbol{y})}\times\sum_{r,s}\left(\left[a_{\boldsymbol{p}}^r, a_{\boldsymbol{q}}^{s\dagger}\right]u^r(\boldsymbol{p})\bar{u}^s(\boldsymbol{q}) + \left[b_{-\boldsymbol{p}}^r, b_{-\boldsymbol{q}}^{s\dagger}\right]v^r(-\boldsymbol{p})\bar{v}^s(-\boldsymbol{q})\right)\gamma^0 = \\ &= \int\frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}e^{i\boldsymbol{p}\cdot(\boldsymbol{x}-\boldsymbol{y})}\left[\left(\gamma^0E_{\boldsymbol{p}} - \gamma\cdot\boldsymbol{p} + m\right) + \left(\gamma^0E_{\boldsymbol{p}} + \gamma\cdot\boldsymbol{p} - m\right)\right]\gamma^0 = \\ &= \delta^{(3)}(\boldsymbol{x}-\boldsymbol{y})\times\mathbf{1}_{4\times4},\end{aligned} \tag{0.48}$$

что и требовалось показать.

27

Покажите, что для волновой функции из пункта 26, гамильтониан дается выражением

$$H = \int\frac{d^3p}{(2\pi)^3}\sum_s\left(E_{\mathbf{p}}a_{\mathbf{p}}^{s\dagger}a_{\mathbf{p}}^s - E_{\mathbf{p}}b_{\mathbf{p}}^{s\dagger}b_{\mathbf{p}}^s\right).$$

Решение: Имеем

$$H = \int d^3x\bar{\psi}(-i\boldsymbol{\gamma}\cdot\boldsymbol{\nabla} + m)\psi \tag{0.49}$$

где

$$\psi(\mathbf{x}) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}e^{i\mathbf{px}}\sum_{s=1,2}\left(a^s_{\mathbf{p}}u^s(\mathbf{p}) + b^s_{-\mathbf{p}}v^s(-\mathbf{p})\right),$$
$$\bar{\psi}(\boldsymbol{y}) = \psi^\dagger(\mathbf{y})\gamma^0 = \int \frac{d^3q}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{q}}}}e^{-i\mathbf{qy}}\sum_{r=1,2}\left(a^{r\dagger}_{\mathbf{q}}\bar{u}^r(\mathbf{q}) + b^{r\dagger}_{-\mathbf{q}}\bar{v}^r(-\mathbf{q})\right). \tag{0.50}$$

Далее получаем

$$H = \int d^3x\bar{\psi}(-i\boldsymbol{\gamma}\cdot\boldsymbol{\nabla} + m)\psi =$$
$$= \int \frac{d^3pd^3q}{(2\pi)^6}\frac{1}{\sqrt{2E_{\boldsymbol{p}}2E_{\boldsymbol{q}}}}(2\pi)^3\delta(\boldsymbol{p}-\boldsymbol{q})\sum_{r,s=1}^{2}\left(a^{r\dagger}_{\mathbf{q}}\bar{u}^r(\mathbf{q}) + b^{r\dagger}_{-\mathbf{q}}\bar{v}^r(-\mathbf{q})\right)(\boldsymbol{\gamma}\cdot\boldsymbol{p} + m)\left(a^s_{\mathbf{p}}u^s(\mathbf{p}) + b^s_{-\mathbf{p}}v^s(-\mathbf{p})\right) =$$
$$= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}\sum_{r,s=1}^{2}\left(a^{r\dagger}_{\mathbf{p}}\bar{u}^r(\mathbf{p}) + b^{r\dagger}_{-\mathbf{p}}\bar{v}^r(-\mathbf{p})\right)(\boldsymbol{\gamma}\cdot\boldsymbol{p} + m)\left(a^s_{\mathbf{p}}u^s(\mathbf{p}) + b^s_{-\mathbf{p}}v^s(-\mathbf{p})\right) \tag{0.51}$$

далее используем из уравнений движения, что $(\boldsymbol{\gamma}\cdot\boldsymbol{p} + m)u^s(\boldsymbol{p}) = \gamma^0E_{\boldsymbol{p}}u^s(\boldsymbol{p})$ и $(\boldsymbol{\gamma}\cdot\boldsymbol{p} + m)v^s(-\boldsymbol{p}) = -\gamma^0E_{\boldsymbol{p}}v^s(-\boldsymbol{p})$ получим

$$H = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2}\sum_{r,s=1}^{2}\left(a^{r\dagger}_{\mathbf{p}}u^{r\dagger}(\mathbf{p}) + b^{r\dagger}_{-\mathbf{p}}v^{r\dagger}(-\mathbf{p})\right)\left(a^s_{\mathbf{p}}u^s(\mathbf{p}) - b^s_{-\mathbf{p}}v^s(-\mathbf{p})\right) \tag{0.52}$$

теперь используем, что $u^{r\dagger}(\mathbf{p})v^s(-\mathbf{p}) = v^{r\dagger}(-\mathbf{p})u^s(\mathbf{p}) = 0$ и получим

$$H = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2}\sum_{r,s=1}^{2}\left(a^{r\dagger}_{\mathbf{p}}a^s_{\mathbf{p}}u^{r\dagger}(\mathbf{p})u^s(\mathbf{p}) - b^{r\dagger}_{-\mathbf{p}}b^s_{-\mathbf{p}}v^{r\dagger}(-\mathbf{p})v^s(-\mathbf{p})\right) \tag{0.53}$$

далее используя, что $u^{r\dagger}(\boldsymbol{p})u^s(\boldsymbol{p}) = v^{r\dagger}(\boldsymbol{p})v^s(\boldsymbol{p}) = 2E_{\boldsymbol{p}}\delta^{rs}$, в итоге находим

$$H = \int \frac{d^3p}{(2\pi)^3}\sum_s\left(E_{\mathbf{p}}a^{s\dagger}_{\mathbf{p}}a^s_{\mathbf{p}} - E_{\mathbf{p}}b^{s\dagger}_{\mathbf{p}}b^s_{\mathbf{p}}\right) \tag{0.54}$$

что и требовалось показать.

Покажите, что $\left[\psi_a(x), \bar{\psi}_b(y)\right] = \left(i\partial\!\!\!/_x + m\right)_{ab}\left[\phi(x), \phi(y)\right]$, где $\phi(x), \phi(y)$ - поля Клейна-Гордона, а ψ_a и $\bar{\psi}_b$ поля из пункта 26 в Гейзенберговском представлении.

Решение: Имеем

$$\psi(x) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\boldsymbol{p}}}}\sum_{s=1,2}\left(a^s_{\boldsymbol{p}}u^s(p)e^{-ip\cdot x} + b^s_{\boldsymbol{p}}v^s(p)e^{ip\cdot x}\right)$$
$$\bar{\psi}(x) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\boldsymbol{p}}}}\sum_{s=1,2}\left(a^{s\dagger}_{\boldsymbol{p}}\bar{u}^s(p)e^{ip\cdot x} + b^{s\dagger}_{\boldsymbol{p}}\bar{v}^s(p)e^{-ip\cdot x}\right) \tag{0.55}$$

тогда получим

$$\begin{aligned}\left[\psi_a(x),\bar{\psi}_b(y)\right] &= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}\sum_{s=1,2}\left(u_a^s(p)\bar{u}_b^s(p)e^{-ip\cdot(x-y)}+v_a^s(p)\bar{v}_b^s(p)e^{ip\cdot(x-y)}\right)= \\ &= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}\left((\not{p}+m)_{ab}e^{-ip\cdot(x-y)}+(\not{p}-m)_{ab}e^{ip\cdot(x-y)}\right)= \\ &= \left(i\not{\partial}_x+m\right)_{ab}\int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}\left(e^{-ip\cdot(x-y)}-e^{ip\cdot(x-y)}\right)= \\ &= \left(i\not{\partial}_x+m\right)_{ab}[\phi(x),\phi(y)], \end{aligned} \tag{0.56}$$

что и требовалось показать.

29

Покажите, что для "правильно"квантованного Дираковского поля

$$\psi(x)=\int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\sum_s\left(a_{\mathbf{p}}^s u^s(p)e^{-ip\cdot x}+b_{\mathbf{p}}^{s\dagger}v^s(p)e^{ip\cdot x}\right)$$
$$\bar{\psi}(x)=\int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\sum_s\left(b_{\mathbf{p}}^s \bar{v}^s(p)e^{-ip\cdot x}+a_{\mathbf{p}}^{s\dagger}\bar{u}^s(p)e^{ip\cdot x}\right)$$

гамильтониан дается выражением

$$H=\int \frac{d^3p}{(2\pi)^3}\sum_s\left(E_{\mathbf{p}}a_{\mathbf{p}}^{s\dagger}a_{\mathbf{p}}^s+E_{\mathbf{p}}b_{\mathbf{p}}^{s\dagger}b_{\mathbf{p}}^s\right)$$

где операторы антикоммутируют как $\left\{a_{\boldsymbol{p}}^r,a_{\boldsymbol{q}}^{s\dagger}\right\}=\left\{b_{\boldsymbol{p}}^r,b_{\boldsymbol{q}}^{s\dagger}\right\}=(2\pi)^3\delta^{(3)}(\boldsymbol{p}-\boldsymbol{q})\delta^{rs}$.
Решение: Имеем

$$H=\int d^3x\bar{\psi}(-i\boldsymbol{\gamma}\cdot\boldsymbol{\nabla}+m)\psi \tag{0.57}$$

далее получаем

$$\begin{aligned} H &= \int d^3x\bar{\psi}(-i\boldsymbol{\gamma}\cdot\boldsymbol{\nabla}+m)\psi= \\ &= \int \frac{d^3pd^3q}{(2\pi)^6}\frac{1}{\sqrt{2E_{\boldsymbol{p}}2E_{\boldsymbol{q}}}}(2\pi)^3\delta(\boldsymbol{p}-\boldsymbol{q})\sum_{r,s=1}^{2}\left(a_{\mathbf{q}}^{r\dagger}\bar{u}^r(\mathbf{q})+b_{-\mathbf{q}}^r\bar{v}^r(-\mathbf{q})\right)(\boldsymbol{\gamma}\cdot\boldsymbol{p}+m)\left(a_{\mathbf{p}}^s u^s(\mathbf{p})+b_{-\mathbf{p}}^{s\dagger}v^s(-\mathbf{p})\right)= \\ &= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}\sum_{r,s=1}^{2}\left(a_{\mathbf{p}}^{r\dagger}\bar{u}^r(\mathbf{p})+b_{-\mathbf{p}}^r\bar{v}^r(-\mathbf{p})\right)(\boldsymbol{\gamma}\cdot\boldsymbol{p}+m)\left(a_{\mathbf{p}}^s u^s(\mathbf{p})+b_{-\mathbf{p}}^{s\dagger}v^s(-\mathbf{p})\right) \end{aligned} \tag{0.58}$$

далее используем из уравнений движения, что $(\boldsymbol{\gamma}\cdot\boldsymbol{p}+m)u^s(\boldsymbol{p})=\gamma^0E_{\boldsymbol{p}}u^s(\boldsymbol{p})$ и $(\boldsymbol{\gamma}\cdot\boldsymbol{p}+m)v^s(-\boldsymbol{p})=-\gamma^0E_{\boldsymbol{p}}v^s(-\boldsymbol{p})$ получим

$$H=\int \frac{d^3p}{(2\pi)^3}\frac{1}{2}\sum_{r,s=1}^{2}\left(a_{\mathbf{p}}^{r\dagger}u^{r\dagger}(\mathbf{p})+b_{-\mathbf{p}}^r v^{r\dagger}(-\mathbf{p})\right)\left(a_{\mathbf{p}}^s u^s(\mathbf{p})-b_{-\mathbf{p}}^{s\dagger}v^s(-\mathbf{p})\right) \tag{0.59}$$

теперь используем, что $u^{r\dagger}(\mathbf{p})v^s(-\mathbf{p})=v^{r\dagger}(-\mathbf{p})u^s(\mathbf{p})=0$ и получим

$$H=\int \frac{d^3p}{(2\pi)^3}\frac{1}{2}\sum_{r,s=1}^{2}\left(a_{\mathbf{p}}^{r\dagger}a_{\mathbf{p}}^s u^{r\dagger}(\mathbf{p})u^s(\mathbf{p})-b_{-\mathbf{p}}^r b_{-\mathbf{p}}^{s\dagger}v^{r\dagger}(-\mathbf{p})v^s(-\mathbf{p})\right) \tag{0.60}$$

далее используя, что $u^{r\dagger}(\boldsymbol{p})u^s(\boldsymbol{p})=v^{r\dagger}(\boldsymbol{p})v^s(\boldsymbol{p})=2E_{\boldsymbol{p}}\delta^{rs}$, в итоге находим
$H=\int\frac{d^3p}{(2\pi)^3}\sum_s\left(E_{\mathbf{p}}a_{\mathbf{p}}^{s\dagger}a_{\mathbf{p}}^s-E_{\mathbf{p}}b_{\mathbf{p}}^s b_{\mathbf{p}}^{s\dagger}\right)=\int\frac{d^3p}{(2\pi)^3}\sum_s\left(E_{\mathbf{p}}a_{\mathbf{p}}^{s\dagger}a_{\mathbf{p}}^s+E_{\mathbf{p}}b_{\mathbf{p}}^{s\dagger}b_{\mathbf{p}}^s\right)+$ (бесконечная константа),
что и требовалось показать.

30

Покажите, что унитарный оператор $U(\Lambda)$, преобразует $a^s_{\mathbf{p}}$ по правилу $U(\Lambda)a^s_pU^{-1}(\Lambda) = \sqrt{\frac{E_{\Lambda p}}{E_p}}a^s_{\Lambda p}$.

Решение: Имеем для одночастичного состояния $|\boldsymbol{p},s\rangle = \sqrt{2E_{\boldsymbol{p}}}a^{s\dagger}_{\boldsymbol{p}}|0\rangle$:

$$U(\Lambda)|\boldsymbol{p},s\rangle = |\Lambda\boldsymbol{p},s\rangle = \sqrt{2E_{\Lambda\boldsymbol{p}}}a^{s\dagger}_{\Lambda\boldsymbol{p}}|0\rangle \tag{0.62}$$

откуда получаем

$$U(\Lambda)|\boldsymbol{p},s\rangle = \sqrt{2E_{\boldsymbol{p}}}U(\Lambda)a^{s\dagger}_{\boldsymbol{p}}|0\rangle = \sqrt{2E_{\boldsymbol{p}}}U(\Lambda)a^{s\dagger}_{\boldsymbol{p}}U^{-1}(\Lambda)U(\Lambda)|0\rangle = \sqrt{2E_{\Lambda\boldsymbol{p}}}a^{s\dagger}_{\Lambda\boldsymbol{p}}|0\rangle, \tag{0.63}$$

учитывая, что $U(\Lambda)|0\rangle = |0\rangle$, получаем, что

$$\sqrt{2E_{\boldsymbol{p}}}U(\Lambda)a^{s\dagger}_{\boldsymbol{p}}U^{-1}(\Lambda) = \sqrt{2E_{\Lambda\boldsymbol{p}}}a^{s\dagger}_{\Lambda\boldsymbol{p}}, \tag{0.64}$$

откуда находим $U(\Lambda)a^{s\dagger}_pU^{-1}(\Lambda) = \sqrt{\frac{E_{\Lambda p}}{E_p}}a^{s\dagger}_{\Lambda\boldsymbol{p}}$.

31

Рассматривая маленький поворот вокруг оси z, покажите, что $\Lambda_{\frac12} \approx 1 - \frac{i}{2}\omega_{\mu\nu}S^{\mu\nu} = 1 - \frac{i}{2}\theta\Sigma^3$.

Решение: При повороте вокруг оси $z, \omega_{12} = -\omega_{21} = \theta$, остальные компоненты $\omega_{\mu\nu}$ равны нулю. Также $S^{ij} = \frac12\varepsilon^{ijk}\Sigma^k$, следовательно

$$\Lambda_{\frac12} \approx 1 - \frac{i}{2}\omega_{\mu\nu}S^{\mu\nu} = 1 - \frac{i}{2}\left(\omega_{12}S^{12} + \omega_{21}S^{21}\right) = 1 - \frac{i}{2}\left(\theta\frac12\Sigma^3 - \theta\left(-\frac12\Sigma^3\right)\right) = 1 - \frac{i}{2}\theta\Sigma^3, \tag{0.65}$$

что и требовалось показать.

32*.

Оператор углового момента для поля Дирака равен $\boldsymbol{J} = \int d^3x\psi^\dagger\left(-i\boldsymbol{x}\times\boldsymbol{\nabla} + \frac12\boldsymbol{\Sigma}\right)\psi$. Упростите отдельно выражение для спиновой i компоненты $J^i_{\text{spin}} = \int d^3x\psi^\dagger\left(\frac12\Sigma^i\right)\psi$ оператора углового момента и затем для орбитальной $J^i_{\text{orbit}} = \int d^3x\psi^\dagger\left(-i(\boldsymbol{x}\times\boldsymbol{\nabla})^i\right)\psi$. Покажите, что оператор $\boldsymbol{J} = \boldsymbol{J}_{\text{orbit}} + \boldsymbol{J}_{\text{spin}}$ уничтожает вакуум, то есть $\boldsymbol{J}|0\rangle = 0$. Покажите, что $\boldsymbol{J}a^{s\dagger}_0|0\rangle = \sum\limits_r\left(\xi^{r\dagger}\frac{\boldsymbol{\sigma}}{2}\xi^s\right)a^{r\dagger}_0|0\rangle$.

Решение: Используем, что

$$\psi(\boldsymbol{x}) = \int\frac{d^3p}{(2\pi)^3}\frac{e^{i\boldsymbol{p}\boldsymbol{x}}}{\sqrt{2E_{\boldsymbol{p}}}}\sum_{s=1,2}\left(a^s_{\boldsymbol{p}}u^s(\boldsymbol{p}) + b^{s\dagger}_{-\boldsymbol{p}}v^s(-\boldsymbol{p})\right),$$
$$\psi^\dagger(\boldsymbol{x}) = \int\frac{d^3p}{(2\pi)^3}\frac{e^{-i\boldsymbol{p}\boldsymbol{x}}}{\sqrt{2E_{\boldsymbol{p}}}}\sum_{s=1,2}\left(a^{s\dagger}_{\boldsymbol{p}}u^{s\dagger}(\boldsymbol{p}) + b^s_{-\boldsymbol{p}}v^{s\dagger}(-\boldsymbol{p})\right), \tag{0.66}$$

а также, что $u^s(p) = \begin{pmatrix}\sqrt{p\cdot\sigma}\xi^s\\ \sqrt{p\cdot\bar\sigma}\xi^s\end{pmatrix}$ и $v^s(p) = \begin{pmatrix}\sqrt{p\cdot\sigma}\eta^s\\ -\sqrt{p\cdot\bar\sigma}\eta^s\end{pmatrix}$, и $u^{r\dagger}(\boldsymbol{p})v^s(-\boldsymbol{p}) = v^{r\dagger}(-\boldsymbol{p})u^s(\boldsymbol{p}) = 0$, и $\sqrt{p\cdot\sigma}\sqrt{p\cdot\bar\sigma} = m$, и $\sqrt{p\cdot\sigma} = \begin{pmatrix}\frac{|\boldsymbol{p}|\mathfrak{s}-p^3\mathfrak{r}}{2|\boldsymbol{p}|} & -\frac{\mathfrak{r}}{2|\boldsymbol{p}|}\left(p^1-ip^2\right)\\ -\frac{\mathfrak{r}|\boldsymbol{p}|}{2|p^1+ip^2)} & \frac{|\boldsymbol{p}|\mathfrak{s}+\mathfrak{r}p^3}{2|\boldsymbol{p}|}\end{pmatrix} = g_{\mu\nu}\tilde p^\mu\sigma^\mu = \tilde p\cdot\sigma,\quad \tilde p = \left(\frac{\mathfrak{s}}{2},\frac{\mathfrak{r}}{2}\frac{\boldsymbol{p}}{|\boldsymbol{p}|}\right)$, где $\mathfrak{s} = \sqrt{p^0+|\boldsymbol{p}|}+\sqrt{p^0-|\boldsymbol{p}|}$, а $\mathfrak{r} = \sqrt{p^0+|\boldsymbol{p}|}-\sqrt{p^0-|\boldsymbol{p}|}$ (отметим, что $\mathfrak{s},\mathfrak{r}$ скаляры, а не векторы!).

Спиновая часть: Для спиновой части имеем

$$\begin{aligned}J^i_{\text{spin}} &= \int d^3x\frac{d^3pd^3q}{(2\pi)^6}\frac{e^{-ix(\boldsymbol{q}-\boldsymbol{p})}}{\sqrt{2E_{\mathbf{p}}2E_{\mathbf{q}}}}\sum_{r,s=1,2}\left(a^{s\dagger}_{\mathbf{q}}u^{s\dagger}(\mathbf{q}) + b^s_{-\mathbf{q}}v^{s\dagger}(-\mathbf{q})\right)\frac{\Sigma^i}{2}\left(a^r_{\mathbf{p}}u^r(\mathbf{p}) + b^{r\dagger}_{-\mathbf{p}}v^r(-\mathbf{p})\right) =\\ &= \int d^3x\frac{d^3pd^3q}{(2\pi)^6}\frac{e^{-ix(\boldsymbol{q}-\boldsymbol{p})}}{\sqrt{2E_{\mathbf{p}}2E_{\mathbf{q}}}}\sum_{r,s=1,2}\Big(u^{s\dagger}(\boldsymbol{q})\tfrac{\Sigma^i}{2}u^r(\boldsymbol{p})a^{s\dagger}_{\boldsymbol{q}}a^r_{\boldsymbol{p}} + u^{s\dagger}(\boldsymbol{q})\tfrac{\Sigma^i}{2}v^r(-\boldsymbol{p})a^{s\dagger}_{\boldsymbol{q}}b^{r\dagger}_{-\boldsymbol{p}} +\\ &\qquad + v^{s\dagger}(-\boldsymbol{q})\tfrac{\Sigma^i}{2}u^r(\boldsymbol{p})b^s_{-\boldsymbol{q}}a^r_{\boldsymbol{p}} + v^{s\dagger}(-\boldsymbol{q})\tfrac{\Sigma^i}{2}v^r(-\boldsymbol{p})b^s_{-\boldsymbol{q}}b^{r\dagger}_{-\boldsymbol{p}}\Big).\end{aligned} \tag{0.67}$$

Далее используя, что $\int d^3x e^{-ix(\boldsymbol{q}-\boldsymbol{p})} = (2\pi)^3\delta(\boldsymbol{q}-\boldsymbol{p})$, получим

$$\begin{aligned} J^i_{\text{spin}} = \int \tfrac{d^3p d^3q}{(2\pi)^3}\tfrac{\delta^{(3)}(\boldsymbol{p}-\boldsymbol{q})}{\sqrt{2E_{\mathbf{p}}2E_{\mathbf{q}}}} \sum_{r,s=1,2} \Big(& u^{s\dagger}(\boldsymbol{q})\tfrac{\Sigma^i}{2}u^r(\boldsymbol{p})a^{s\dagger}_{\boldsymbol{q}}a^r_{\boldsymbol{p}} + u^{s^\dagger}(\boldsymbol{q})\tfrac{\Sigma^i}{2}v^r(-\boldsymbol{p})a^{s\dagger}_{\boldsymbol{q}}b^{r\dagger}_{-\boldsymbol{p}} + \\ & + v^{s\dagger}(-\boldsymbol{q})\tfrac{\Sigma^i}{2}u^r(\boldsymbol{p})b^s_{-\boldsymbol{q}}a^r_{\boldsymbol{p}} + v^{s\dagger}(-\boldsymbol{q})\tfrac{\Sigma^i}{2}v^r(-\boldsymbol{p})b^s_{-\boldsymbol{q}}b^{r\dagger}_{-\boldsymbol{p}}\Big) = \\ = \int \tfrac{d^3p}{(2\pi)^3}\tfrac{1}{2E_{\mathbf{p}}} \sum_{r,s=1,2} \Big(& u^{s\dagger}(\boldsymbol{p})\tfrac{\Sigma^i}{2}u^r(\boldsymbol{p})a^{s\dagger}_{\boldsymbol{p}}a^r_{\boldsymbol{p}} + u^{s^\dagger}(\boldsymbol{p})\tfrac{\Sigma^i}{2}v^r(-\boldsymbol{p})a^{s\dagger}_{\boldsymbol{p}}b^{r\dagger}_{-\boldsymbol{p}} + \\ & + v^{s\dagger}(-\boldsymbol{p})\tfrac{\Sigma^i}{2}u^r(\boldsymbol{p})b^s_{-\boldsymbol{p}}a^r_{\boldsymbol{p}} + v^{s\dagger}(-\boldsymbol{p})\tfrac{\Sigma^i}{2}v^r(-\boldsymbol{p})b^s_{-\boldsymbol{p}}b^{r\dagger}_{-\boldsymbol{p}}\Big). \end{aligned} \tag{0.68}$$

Теперь вычисляем (используем, что $\sigma^i\sigma^j = \delta^{ij} + i\varepsilon^{ijk}\sigma^k$ и $\left[\sigma^i,\sigma^j\right] = 2i\varepsilon^{ijk}\sigma^k$ и $\mathfrak{sr} = 2|\boldsymbol{p}|, \varepsilon^{123} = 1$):

$$\begin{aligned} & u^{s^\dagger}(\boldsymbol{p})\frac{\Sigma^i}{2}v^r(-\boldsymbol{p}) = \frac{1}{2}\begin{pmatrix} \xi^{s\dagger}\sqrt{p\cdot\sigma} & \xi^{s\dagger}\sqrt{p\cdot\bar\sigma}\end{pmatrix}\begin{pmatrix}\sigma^i & 0\\ 0 & \sigma^i\end{pmatrix}\begin{pmatrix}\sqrt{p\cdot\bar\sigma}\eta^r\\ -\sqrt{p\cdot\sigma}\eta^r\end{pmatrix} = \\ & = \frac{1}{2}\xi^{s\dagger}\left(\sqrt{p\cdot\sigma}\sigma^i\sqrt{p\cdot\bar\sigma} - \sqrt{p\cdot\bar\sigma}\sigma^i\sqrt{p\cdot\sigma}\right)\eta^r = \\ & = \frac{1}{2}\xi^{s\dagger}\left(\left(\frac{\mathfrak{s}}{2}\sigma^0 - \frac{\mathfrak{r}}{2}\frac{\boldsymbol{\sigma}\cdot\boldsymbol{p}}{|\boldsymbol{p}|}\right)\sigma^i\left(\frac{\mathfrak{s}}{2}\sigma^0 + \frac{\mathfrak{r}}{2}\frac{\boldsymbol{\sigma}\cdot\boldsymbol{p}}{|\boldsymbol{p}|}\right) - \left(\frac{\mathfrak{s}}{2}\sigma^0 + \frac{\mathfrak{r}}{2}\frac{\boldsymbol{\sigma}\cdot\boldsymbol{p}}{|\boldsymbol{p}|}\right)\sigma^i\left(\frac{\mathfrak{s}}{2}\sigma^0 - \frac{\mathfrak{r}}{2}\frac{\boldsymbol{\sigma}\cdot\boldsymbol{p}}{|\boldsymbol{p}|}\right)\right)\eta^r = \\ & = \frac{1}{2}\xi^{s\dagger}\left(2\frac{\mathfrak{sr}}{4|\boldsymbol{p}|}\left[\sigma^i,\boldsymbol{\sigma}\boldsymbol{p}\right]\right)\eta^r = \frac{1}{2}\xi^{s\dagger}\left(2i\epsilon_{ijk}\sigma^k p^j\right)\eta^r = i\xi^{s\dagger}(\boldsymbol{p}\times\boldsymbol{\sigma})^i\eta^r, \\ & v^{s^\dagger}(-\boldsymbol{p})\frac{\Sigma^i}{2}u^r(\boldsymbol{p}) = \frac{1}{2}\begin{pmatrix}\eta^{s\dagger}\sqrt{p\cdot\bar\sigma} & -\xi^{s\dagger}\sqrt{p\cdot\sigma}\end{pmatrix}\begin{pmatrix}\sigma^i & 0\\ 0 & \sigma^i\end{pmatrix}\begin{pmatrix}\sqrt{p\cdot\sigma}\xi^r\\ \sqrt{p\cdot\bar\sigma}\xi^r\end{pmatrix} = \\ & = \frac{1}{2}\eta^{s\dagger}\left(\sqrt{p\cdot\bar\sigma}\sigma^i\sqrt{p\cdot\sigma} - \sqrt{p\cdot\sigma}\sigma^i\sqrt{p\cdot\bar\sigma}\right)\xi^r = -i\eta^{s\dagger}(\boldsymbol{p}\times\boldsymbol{\sigma})^i\xi^r. \end{aligned}$$

Далее имеем

$$\begin{aligned} & u^{s^\dagger}(\boldsymbol{p})\frac{\Sigma^i}{2}u^r(\boldsymbol{p}) = \frac{1}{2}\begin{pmatrix} \xi^{s\dagger}\sqrt{p\cdot\sigma} & \xi^{s\dagger}\sqrt{p\cdot\bar\sigma}\end{pmatrix}\begin{pmatrix}\sigma^i & 0\\ 0 & \sigma^i\end{pmatrix}\begin{pmatrix}\sqrt{p\cdot\sigma}\xi^r\\ \sqrt{p\cdot\bar\sigma}\xi^r\end{pmatrix} = \\ & = \frac{1}{2}\xi^{s\dagger}\left(\sqrt{p\cdot\sigma}\sigma^i\sqrt{p\cdot\sigma} + \sqrt{p\cdot\bar\sigma}\sigma^i\sqrt{p\cdot\bar\sigma}\right)\xi^r = \\ & = \frac{1}{2}\xi^{s\dagger}\left(\left(\frac{\mathfrak{s}}{2}\sigma^0 - \frac{\mathfrak{r}}{2}\frac{\boldsymbol{\sigma}\cdot\boldsymbol{p}}{|\boldsymbol{p}|}\right)\sigma^i\left(\frac{\mathfrak{s}}{2}\sigma^0 - \frac{\mathfrak{r}}{2}\frac{\boldsymbol{\sigma}\cdot\boldsymbol{p}}{|\boldsymbol{p}|}\right) + \left(\frac{\mathfrak{s}}{2}\sigma^0 + \frac{\mathfrak{r}}{2}\frac{\boldsymbol{\sigma}\cdot\boldsymbol{p}}{|\boldsymbol{p}|}\right)\sigma^i\left(\frac{\mathfrak{s}}{2}\sigma^0 + \frac{\mathfrak{r}}{2}\frac{\boldsymbol{\sigma}\cdot\boldsymbol{p}}{|\boldsymbol{p}|}\right)\right)\xi^r = \\ & = \frac{1}{2}\xi^{s\dagger}\left(\frac{\mathfrak{s}^2}{2}\sigma^i + \frac{\mathfrak{r}^2}{2|\boldsymbol{p}|^2}\boldsymbol{\sigma}\boldsymbol{p}\sigma^i\boldsymbol{\sigma}\boldsymbol{p}\right)\xi^r = \xi^{s\dagger}\left(m\sigma^i + (E_{\boldsymbol{p}} - m)\frac{\boldsymbol{\sigma}\boldsymbol{p}}{|\boldsymbol{p}|^2}p^i\right)\xi^r, \\ & v^{s^\dagger}(-\boldsymbol{p})\frac{\Sigma^i}{2}v^r(-\boldsymbol{p}) = \frac{1}{2}\begin{pmatrix}\eta^{s\dagger}\sqrt{p\cdot\bar\sigma} & -\eta^{s\dagger}\sqrt{p\cdot\sigma}\end{pmatrix}\begin{pmatrix}\sigma^i & 0\\ 0 & \sigma^i\end{pmatrix}\begin{pmatrix}\sqrt{p\cdot\bar\sigma}\eta^r\\ -\sqrt{p\cdot\sigma}\eta^r\end{pmatrix} = \\ & = \frac{1}{2}\eta^{s\dagger}\left(\sqrt{p\cdot\bar\sigma}\sigma^i\sqrt{p\cdot\bar\sigma} + \sqrt{p\cdot\sigma}\sigma^i\sqrt{p\cdot\sigma}\right)\eta^r = \eta^{s\dagger}\left(m\sigma^i + (E_{\boldsymbol{p}} - m)\frac{\boldsymbol{\sigma}\boldsymbol{p}}{|\boldsymbol{p}|^2}p^i\right)\eta^r \end{aligned}$$

где мы использовали, что $\mathfrak{s}^2 = 2\left(E_{\boldsymbol{p}} + m\right)$ и $\mathfrak{r}^2 = 2\left(E_{\boldsymbol{p}} - m\right)$, а также

$$\begin{aligned} \boldsymbol{\sigma}\boldsymbol{p}\sigma^i\boldsymbol{\sigma}\boldsymbol{p} &= \sigma^j\sigma^i\sigma^k p^j p^k = \left(\delta^{ji} + i\varepsilon^{jil}\sigma^l\right)\sigma^k p^j p^k = p^i\boldsymbol{\sigma}\boldsymbol{p} + i\varepsilon^{jil}\sigma^l\sigma^k p^j p^k = \\ &= p^i\boldsymbol{\sigma}\boldsymbol{p} + i\varepsilon^{jil}\left(\delta^{lk} + i\varepsilon^{lkm}\sigma^m\right)p^j p^k = p^i\boldsymbol{\sigma}\boldsymbol{p} + i\varepsilon^{jil}p^j p^l - \varepsilon^{jil}\varepsilon^{lkm}\sigma^m p^j p^k = \\ &= p^i\boldsymbol{\sigma}\boldsymbol{p} - \left(\delta^{jk}\delta^{im} - \delta^{jm}\delta^{ik}\right)\sigma^m p^j p^k = 2p^i\boldsymbol{\sigma}\boldsymbol{p} - |\boldsymbol{p}|^2\sigma^i. \end{aligned} \tag{0.71}$$

В итоге получаем

$$\begin{aligned} J^i_{\text{spin}} = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}\sum_{r,s=1,2}\Big(& \xi^{s\dagger}\left(m\sigma^i + (E_{\boldsymbol{p}} - m)\frac{\boldsymbol{\sigma}\boldsymbol{p}}{|\boldsymbol{p}|^2}p^i\right)\xi^r a^{s\dagger}_{\boldsymbol{p}}a^r_{\boldsymbol{p}} + i\xi^{s\dagger}(\boldsymbol{p}\times\boldsymbol{\sigma})^i\eta^r a^{s\dagger}_{\boldsymbol{p}}b^{r\dagger}_{-\boldsymbol{p}} - \\ & - i\eta^{s\dagger}(\boldsymbol{p}\times\boldsymbol{\sigma})^i\xi^r b^s_{-\boldsymbol{p}}a^r_{\boldsymbol{p}} + \eta^{s\dagger}\left(m\sigma^i + (E_{\boldsymbol{p}} - m)\frac{\boldsymbol{\sigma}\boldsymbol{p}}{|\boldsymbol{p}|^2}p^i\right)\eta^r b^s_{-\boldsymbol{p}}b^{r\dagger}_{-\boldsymbol{p}}\Big) \end{aligned} \tag{0.72}$$

Орбитальная часть: Для орбитальной компоненты имеем

$$
\begin{aligned}
J^i_{\text{orbit}} &= \int d^3x \psi^\dagger(x) \left(-i(\boldsymbol{x}\times\boldsymbol{\nabla})^i\right)\psi(x) = \\
&= \int d^3x \frac{d^3q d^3p}{(2\pi)^6}\frac{e^{-i\boldsymbol{xq}}}{\sqrt{2E_{\boldsymbol{p}}2E_{\boldsymbol{q}}}}\sum_{s,r=1,2}\left(a^{s\dagger}_{\boldsymbol{q}}u^{s\dagger}(\boldsymbol{q})+b^s_{-\boldsymbol{q}}v^{s\dagger}(-\boldsymbol{q})\right)\left(-i\varepsilon^{ijk}x^j\frac{\partial}{\partial x^k}\right)e^{i\boldsymbol{px}}\left(a^r_{\boldsymbol{p}}u^r(\boldsymbol{p})+b^{r\dagger}_{-\boldsymbol{p}}v^r(-\boldsymbol{p})\right) = \\
&= \int \frac{d^3q d^3p}{(2\pi)^6}d^3x\frac{\varepsilon^{ijk}x^j e^{i\boldsymbol{x}(\boldsymbol{p}-\boldsymbol{q})}}{\sqrt{2E_{\boldsymbol{p}}2E_{\boldsymbol{q}}}}\sum_{s,r=1,2}\left(a^{s\dagger}_{\boldsymbol{q}}u^{s\dagger}(\boldsymbol{q})+b^s_{-\boldsymbol{q}}v^{s\dagger}(-\boldsymbol{q})\right)p^k\left(a^r_{\boldsymbol{p}}u^r(\boldsymbol{p})+b^{r\dagger}_{-\boldsymbol{p}}v^r(-\boldsymbol{p})\right) = \\
&= \int \frac{d^3q d^3p}{(2\pi)^6}\frac{-i(2\pi)^3\varepsilon^{ijk}\frac{\partial\delta^{(3)}(\boldsymbol{p}-\boldsymbol{q})}{\partial p^j}}{\sqrt{2E_{\boldsymbol{p}}2E_{\boldsymbol{q}}}}\sum_{s,r=1,2}\left(a^{s\dagger}_{\boldsymbol{q}}u^{s\dagger}(\boldsymbol{q})+b^s_{-\boldsymbol{q}}v^{s\dagger}(-\boldsymbol{q})\right)p^k\left(a^r_{\boldsymbol{p}}u^r(\boldsymbol{p})+b^{r\dagger}_{-\boldsymbol{p}}v^r(-\boldsymbol{p})\right) = \\
&= i\int \frac{d^3q}{(2\pi)^3}\frac{1}{\sqrt{2E_{\boldsymbol{q}}}}\sum_{s,r=1,2}\left(a^{s\dagger}_{\boldsymbol{q}}u^{s\dagger}(\boldsymbol{q})+b^s_{-\boldsymbol{q}}v^{s\dagger}(-\boldsymbol{q})\right)\varepsilon^{ijk}\frac{\partial}{\partial q^j}\left(q^k\frac{1}{\sqrt{2E_{\boldsymbol{q}}}}\left(a^r_{\boldsymbol{q}}u^r(\boldsymbol{q})+b^{r\dagger}_{-\boldsymbol{q}}v^r(-\boldsymbol{q})\right)\right), \quad (0.73)
\end{aligned}
$$

далее мы используем, что $\varepsilon^{ijk}\frac{\partial}{\partial q^j}q^k = \varepsilon^{ijk}\delta^{jk} = 0$ и также $\varepsilon^{ijk}q^k\frac{\partial}{\partial q^j}f(|\boldsymbol{q}|) = \varepsilon^{ijk}q^k\frac{q^j}{|\boldsymbol{q}|}f'(|\boldsymbol{q}|) = 0$, где f - произвольная функция. Отсюда в частности следует, что $\varepsilon^{ijk}q^k\frac{\partial}{\partial q^j}\frac{1}{\sqrt{2E_q}} = 0$, так как $E_{\boldsymbol{q}} = \sqrt{m^2+|\boldsymbol{q}|^2}$. В итоге мы получаем (заменяя $\boldsymbol{q}$ на $\boldsymbol{p}$)

$$
J^i_{\text{orbit}} = -i\int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}\sum_{s,r=1,2}\left(a^{s\dagger}_{\boldsymbol{p}}u^{s\dagger}(\boldsymbol{p})+b^s_{-\boldsymbol{p}}v^{s\dagger}(-\boldsymbol{p})\right)\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\left(a^r_{\boldsymbol{p}}u^r(\boldsymbol{p})+b^{r\dagger}_{-\boldsymbol{p}}v^r(-\boldsymbol{p})\right), \quad (0.74)
$$

далее используя, что $u^{s\dagger}(\boldsymbol{p})u^r(\boldsymbol{p}) = v^{s\dagger}(-\boldsymbol{p})v^r(-\boldsymbol{p}) = 2E_{\boldsymbol{p}}\delta^{rs}$, и $u^{s\dagger}(\boldsymbol{p})v^r(-\boldsymbol{p}) = v^{s\dagger}(-\boldsymbol{p})u^r(\boldsymbol{p}) = 0$, получаем

$$
\begin{aligned}
J^i_{\text{orbit}} &= -i\int \frac{d^3p}{(2\pi)^3}\sum_{s=1,2}\varepsilon^{ijk}\left(a^{s\dagger}_{\boldsymbol{p}}p^j\frac{\partial a^s_{\boldsymbol{p}}}{\partial p^k}+b^s_{-\boldsymbol{p}}p^j\frac{\partial b^{s\dagger}_{-\boldsymbol{p}}}{\partial p^k}\right) - \\
&- i\int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}\sum_{s,r=1,2}\varepsilon^{ijk}\left(u^{s\dagger}(\boldsymbol{p})p^j\frac{\partial u^r(\boldsymbol{p})}{\partial p^k}a^{s\dagger}_{\boldsymbol{p}}a^r_{\boldsymbol{p}}+u^{s\dagger}(\boldsymbol{p})p^j\frac{\partial v^r(-\boldsymbol{p})}{\partial p^k}a^{s\dagger}_{\boldsymbol{p}}b^{r\dagger}_{-\boldsymbol{p}}+\right. \\
&\left.+v^{s\dagger}(-\boldsymbol{p})p^j\frac{\partial u^r(\boldsymbol{p})}{\partial p^k}b^s_{-\boldsymbol{p}}a^r_{\boldsymbol{p}}+v^{s\dagger}(-\boldsymbol{p})p^j\frac{\partial v^r(-\boldsymbol{p})}{\partial p^k}b^s_{-\boldsymbol{p}}b^{r\dagger}_{-\boldsymbol{p}}\right). \quad (0.75)
\end{aligned}
$$

Используя, что $\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\mathfrak{s} = \varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\frac{\mathfrak{r}}{2|\boldsymbol{p}|} = 0$, где $\mathfrak{s} = \sqrt{p^0+|\boldsymbol{p}|}+\sqrt{p^0-|\boldsymbol{p}|}$, а $\mathfrak{r} = \sqrt{p^0+|\boldsymbol{p}|}$ - $\sqrt{p^0-|\boldsymbol{p}|}$, получим

$$
\begin{aligned}
\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\sigma} &= \varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\left(\frac{\mathfrak{s}}{2}\sigma^0-\frac{\mathfrak{r}}{2|\boldsymbol{p}|}p^l\sigma^l\right) = -\frac{\mathfrak{r}}{2|\boldsymbol{p}|}\varepsilon^{ijk}p^j\sigma^k = -\frac{\mathfrak{r}}{2|\boldsymbol{p}|}(\boldsymbol{p}\times\boldsymbol{\sigma})^i, \\
\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\bar{\sigma}} &= \frac{\mathfrak{r}}{2|\boldsymbol{p}|}\varepsilon^{ijk}p^j\sigma^k = \frac{\mathfrak{r}}{2|\boldsymbol{p}|}(\boldsymbol{p}\times\boldsymbol{\sigma})^i, \quad (0.76)
\end{aligned}
$$

откуда находим

$$
\begin{aligned}
u^{s\dagger}(\boldsymbol{p})\varepsilon^{ijk}p^j\frac{\partial v^r(-\boldsymbol{p})}{\partial p^k} &= \xi^{s\dagger}\left(\sqrt{p\cdot\sigma}\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\bar{\sigma}}-\sqrt{p\cdot\bar{\sigma}}\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\sigma}\right)\eta^r = \\
&= \xi^{s\dagger}\left(\frac{\mathfrak{s}\mathfrak{r}}{2|\boldsymbol{p}|}\varepsilon^{ijk}p^j\sigma^k\right)\eta^r = \xi^{s\dagger}\left(\varepsilon^{ijk}p^j\sigma^k\right)\eta^r = \xi^{s\dagger}(\boldsymbol{p}\times\boldsymbol{\sigma})^i\eta^r, \\
v^{s\dagger}(-\boldsymbol{p})\varepsilon^{ijk}p^j\frac{\partial u^r(\boldsymbol{p})}{\partial p^k} &= \eta^{s\dagger}\left(\sqrt{p\cdot\bar{\sigma}}\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\sigma}-\sqrt{p\cdot\sigma}\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\bar{\sigma}}\right)\xi^r = \\
&= -\eta^{s\dagger}\left(\frac{\mathfrak{s}\mathfrak{r}}{2|\boldsymbol{p}|}\varepsilon^{ijk}p^j\sigma^k\right)\xi^r = -\eta^{s\dagger}\left(\varepsilon^{ijk}p^j\sigma^k\right)\xi^r = -\eta^{s\dagger}(\boldsymbol{p}\times\boldsymbol{\sigma})^i\xi^r. \quad (0.77)
\end{aligned}
$$

Далее находим

$$
\begin{aligned}
u^{s\dagger}(\boldsymbol{p})\varepsilon^{ijk}p^j\frac{\partial u^r(\boldsymbol{p})}{\partial p^k} &= \xi^{s\dagger}\left(\sqrt{p\cdot\sigma}\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\sigma}+\sqrt{p\cdot\bar{\sigma}}\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\bar{\sigma}}\right)\xi^r = \\
&= \xi^{s\dagger}\left(\frac{\mathfrak{r}^2}{2|\boldsymbol{p}|^2}(\boldsymbol{\sigma p})(\boldsymbol{p}\times\boldsymbol{\sigma})^i\right)\xi^r = i\xi^{s\dagger}\left((E_{\boldsymbol{p}}-m)\,\sigma^i-(E_{\boldsymbol{p}}-m)\,\frac{\boldsymbol{\sigma p}}{|\boldsymbol{p}|^2}p^i\right)\xi^r, \\
v^{s\dagger}(-\boldsymbol{p})\varepsilon^{ijk}p^j\frac{\partial v^r(-\boldsymbol{p})}{\partial p^k} &= \eta^{s\dagger}\left(\sqrt{p\cdot\bar{\sigma}}\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\bar{\sigma}}+\sqrt{p\cdot\sigma}\varepsilon^{ijk}p^j\frac{\partial}{\partial p^k}\sqrt{p\cdot\sigma}\right)\eta^r = \\
&= \eta^{s\dagger}\left(\frac{\mathfrak{r}^2}{2|\boldsymbol{p}|^2}(\boldsymbol{\sigma p})(\boldsymbol{p}\times\boldsymbol{\sigma})^i\right)\eta^r = i\eta^{s\dagger}\left((E_{\boldsymbol{p}}-m)\,\sigma^i-(E_{\boldsymbol{p}}-m)\,\frac{\boldsymbol{\sigma p}}{|\boldsymbol{p}|^2}p^i\right)\eta^r, \qquad (0.78)
\end{aligned}
$$

где мы использовали, что $\mathfrak{r}^2 = 2\,(E_{\boldsymbol{p}}-m)$, а также

$$
\begin{aligned}
(\boldsymbol{\sigma p})(\boldsymbol{p}\times\boldsymbol{\sigma})^i &= \varepsilon^{ijk}\sigma^l\sigma^k p^l p^j = \varepsilon^{ijk}\left(\delta^{lk}+i\varepsilon^{lkm}\sigma^m\right)p^l p^j = i\varepsilon^{ijk}\varepsilon^{mlk}\sigma^m p^l p^j = \\
&= i\left(\delta^{im}\delta^{jl}-\delta^{il}\delta^{jm}\right)\sigma^m p^l p^j = i\left(|\boldsymbol{p}|^2\sigma^i - p^i\boldsymbol{\sigma p}\right). \qquad (0.79)
\end{aligned}
$$

В итоге получаем

$$
\begin{aligned}
J^i_{\text{orbit}} &= -\,i\int\frac{d^3p}{(2\pi)^3}\sum_{s=1,2}\varepsilon^{ijk}\left(a^{s\dagger}_{\boldsymbol{p}}p^j\frac{\partial a^s_{\boldsymbol{p}}}{\partial p^k}+b^s_{-\boldsymbol{p}}p^j\frac{\partial b^{s\dagger}_{-\boldsymbol{p}}}{\partial p^k}\right)+ \\
&+\int\frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}}\sum_{s,r=1,2}\left(\xi^{s\dagger}\left((E_{\boldsymbol{p}}-m)\,\sigma^i-(E_{\boldsymbol{p}}-m)\,\frac{\boldsymbol{\sigma p}}{|\boldsymbol{p}|^2}p^i\right)\xi^r a^{s\dagger}_{\boldsymbol{p}}a^r_{\boldsymbol{p}} - i\xi^{s\dagger}(\boldsymbol{p}\times\boldsymbol{\sigma})^i\eta^r a^{s\dagger}_{\boldsymbol{p}}b^{r\dagger}_{-\boldsymbol{p}}+\right. \\
&\left.+i\eta^{s\dagger}(\boldsymbol{p}\times\boldsymbol{\sigma})^i\xi^r b^s_{-\boldsymbol{p}}a^r_{\boldsymbol{p}}+\eta^{s\dagger}\left((E_{\boldsymbol{p}}-m)\,\sigma^i-(E_{\boldsymbol{p}}-m)\,\frac{\boldsymbol{\sigma p}}{|\boldsymbol{p}|^2}p^i\right)\eta^r b^s_{-\boldsymbol{p}}b^{r\dagger}_{-\boldsymbol{p}}\right). \qquad (0.80)
\end{aligned}
$$

В итоге находи для J^i:

$$
\begin{aligned}
J^i = J^i_{\text{spin}} + J^i_{\text{orbit}} &= -\,i\int\frac{d^3p}{(2\pi)^3}\sum_{s=1,2}\varepsilon^{ijk}\left(a^{s\dagger}_{\boldsymbol{p}}p^j\frac{\partial a^s_{\boldsymbol{p}}}{\partial p^k}+b^s_{-\boldsymbol{p}}p^j\frac{\partial b^{s\dagger}_{-\boldsymbol{p}}}{\partial p^k}\right)+ \\
&+\int\frac{d^3p}{(2\pi)^3}\sum_{s,r=1,2}\left(\xi^{s\dagger}\frac{\sigma^i}{2}\xi^r a^{s\dagger}_{\boldsymbol{p}}a^r_{\boldsymbol{p}}+\eta^{s\dagger}\frac{\sigma^i}{2}\eta^r b^s_{-\boldsymbol{p}}b^{r\dagger}_{-\boldsymbol{p}}\right). \qquad (0.81)
\end{aligned}
$$

Антикоммутируя $b^s_{-p}b^{r\dagger}_{-p}$ и выкидывая бесконечные константы, а также заменяя в данных членах $\boldsymbol{p}\to-\boldsymbol{p}$, получаем

$$
J^i = -i\int\frac{d^3p}{(2\pi)^3}\sum_{s=1,2}\varepsilon^{ijk}\left(a^{s\dagger}_{\boldsymbol{p}}p^j\frac{\partial a^s_{\boldsymbol{p}}}{\partial p^k}+b^{s\dagger}_{\boldsymbol{p}}p^j\frac{\partial b^s_{\boldsymbol{p}}}{\partial p^k}\right)+\int\frac{d^3p}{(2\pi)^3}\sum_{s,r=1,2}\left(\xi^{s\dagger}\frac{\sigma^i}{2}\xi^r a^{s\dagger}_{\boldsymbol{p}}a^r_{\boldsymbol{p}}-\eta^{s\dagger}\frac{\sigma^i}{2}\eta^r b^{r\dagger}_{\boldsymbol{p}}b^s_{\boldsymbol{p}}\right). \qquad (0.82)
$$

Это выражение можно переписать как

$$
\boldsymbol{J} = \int\frac{d^3p}{(2\pi)^3}\sum_{s,r=1,2}\left(a^{s\dagger}_{\boldsymbol{p}}\xi^{s\dagger}\left(\frac{\boldsymbol{\sigma}}{2}-i\delta^{rs}\boldsymbol{p}\times\frac{\partial}{\partial\boldsymbol{p}}\right)\xi^r a^r_{\boldsymbol{p}} - b^{r\dagger}_{\boldsymbol{p}}\eta^{s\dagger}\left(\frac{\boldsymbol{\sigma}}{2}+i\delta^{rs}\boldsymbol{p}\times\frac{\partial}{\partial\boldsymbol{p}}\right)\eta^r b^s_{\boldsymbol{p}}\right). \qquad (0.83)
$$

Далее, очевидно, что $\boldsymbol{J}|0\rangle = 0$. Теперь, так как $\boldsymbol{J}|0\rangle = 0$, имеем $\boldsymbol{J}a^{s\dagger}_0|0\rangle = \left[\boldsymbol{J}, a^{s\dagger}_0\right]|0\rangle$. Вычисляя коммутатор $\left[a^{r'\dagger}_{\boldsymbol{p}}a^r_{\boldsymbol{p}}, a^{s\dagger}_0\right] = (2\pi)^3\delta^{(3)}(\boldsymbol{p})a^{r'\dagger}_0\delta^{rs}$, мы видим, что должны взять все в точке $\boldsymbol{p}=0$, откуда находим, что $\boldsymbol{J}a^{s\dagger}_0|0\rangle = \sum\limits_{r'}\left(\xi^{r'\dagger}\frac{\boldsymbol{\sigma}}{2}\xi^s\right)a^{r'\dagger}_0|0\rangle$.

33

Покажите, что запаздывающая функция Грина для уравнения Дирака есть $S_R^{ab}(x-y) = \left(i\partial\!\!\!/_x + m\right)_{ab} D_R(x-y)$, где $D_R(x-y)$ запаздывающая функция Грина для уравнения Клейна-Гордона.

Решение: С одной стороны мы имеем

$$S_R^{ab}(x-y) \equiv \theta\left(x^0-y^0\right)\right) \left\langle 0 \left| \left\{ \psi_a(x), \bar{\psi}_b(y) \right\} \right| 0 \right\rangle, \tag{0.84}$$

с другой стороны можно вычислить

$$\begin{aligned}
\left\langle 0 \left| \psi_a(x)\bar{\psi}_b(y) \right| 0 \right\rangle &= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}} \sum_{s=1,2} u_a^s(p)\bar{u}_b^s(p)e^{-ip\cdot(x-y)} = \left(i\partial_x + m\right)_{ab} \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}} e^{-ip\cdot(x-y)}, \\
\left\langle 0 \left| \bar{\psi}_b(y)\psi_a(x) \right| 0 \right\rangle &= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}} \sum_{s=1,2} v_a^s(p)\bar{v}_b^s(p)e^{-ip\cdot(y-x)} = -\left(i\partial\!\!\!/_x + m\right)_{ab} \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}} e^{-ip\cdot(y-x)},
\end{aligned} \tag{0.85}$$

откуда

$$\left\langle 0 \left| \left\{ \psi_a(x), \bar{\psi}_b(y) \right\} \right| 0 \right\rangle = \left(i\partial\!\!\!/_x + m\right)_{ab} \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\boldsymbol{p}}} \left(e^{-ip\cdot(x-y)} - e^{-ip\cdot(y-x)} \right) = \left(i\partial\!\!\!/_x + m\right)_{ab} \langle 0|[\phi(x),\phi(y)]|0\rangle. \tag{0.86}$$

В итоге получаем

$$\begin{aligned}
S_R^{ab}(x-y) &\equiv \theta\left(x^0-y^0\right)\right) \left\langle 0 \left| \left\{ \psi_a(x), \bar{\psi}_b(y) \right\} \right| 0 \right\rangle = \left(i\partial\!\!\!/_x + m\right)_{ab} \theta\left(x^0-y^0\right)\right) \langle 0|[\phi(x),\phi(y)]|0\rangle = \\
&= \left(i\partial\!\!\!/_x + m\right)_{ab} D_R(x-y),
\end{aligned} \tag{0.87}$$

что и требовалось показать.

Покажите, что $\partial\!\!\!/\partial\!\!\!/ = \partial^2$.

Решение: Имеем

$$\partial\!\!\!/\partial\!\!\!/ = \gamma^\mu\partial_\mu\gamma^\nu\partial_\nu = \gamma^\mu\gamma^\nu\partial_\mu\partial_\nu = \frac{1}{2}\left(\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu\right)\partial_\mu\partial_\nu = g^{\mu\nu}\partial_\mu\partial_\nu = \partial^2 \tag{0.88}$$

что и требовалось показать.

36 Дискретные симметрии в теории Дирака.

Проверьте, что все величины: $\bar{\psi}\psi, \bar{\psi}\gamma^\mu\psi, i\bar{\psi}\left[\gamma^\mu,\gamma^\nu\right]\psi, \bar{\psi}\gamma^\mu\gamma^5\psi, i\bar{\psi}\gamma^5\psi$ являются эрмитовыми.

Решение: Используя то, что $\left(\gamma^0\right)^\dagger = \gamma^0, \left(\gamma^5\right)^\dagger = \gamma^5$, а $\left(\gamma^i\right)^\dagger = -\gamma^i, i = 1,2,3$, а также, что $\left\{\gamma^5,\gamma^\mu\right\} = 0, \left\{\gamma^\mu,\gamma^\nu\right\} = 2g^{\mu\nu}$ имеем:

$$\begin{aligned}
&(\bar{\psi}\psi)^\dagger = \left(\psi^\dagger\gamma^0\psi\right)^\dagger = \psi^\dagger\left(\gamma^0\right)^\dagger\psi = \psi^\dagger\gamma^0\psi = \bar{\psi}\psi \\
&\left(\bar{\psi}\gamma^\mu\psi\right)^\dagger = \left(\psi^\dagger\gamma^0\gamma^\mu\psi\right)^\dagger = \psi^\dagger\left(\gamma^\mu\right)^\dagger\left(\gamma^0\right)^\dagger\psi = \psi^\dagger\gamma^0\gamma^\mu\psi = \bar{\psi}\gamma^\mu\psi, \\
&\left(i\bar{\psi}\left[\gamma^\mu,\gamma^\nu\right]\psi\right)^\dagger = \left(i\psi^\dagger\gamma^0\left[\gamma^\mu,\gamma^\nu\right]\psi\right)^\dagger = -i\psi^\dagger\left(\left(\gamma^\nu\right)^\dagger\left(\gamma^\mu\right)^\dagger - \left(\gamma^\mu\right)^\dagger\left(\gamma^\nu\right)^\dagger\right)\gamma^0\psi = i\bar{\psi}\left[\gamma^\mu,\gamma^\nu\right]\psi, \\
&\left(\bar{\psi}\gamma^\mu\gamma^5\psi\right)^\dagger = \psi^\dagger\left(\gamma^5\right)^\dagger\left(\gamma^\mu\right)^\dagger\gamma^0\psi = \psi^\dagger\gamma^5\gamma^0\gamma^\mu\psi = \bar{\psi}\gamma^\mu\gamma^5\psi, \\
&\left(i\bar{\psi}\gamma^5\psi\right)^\dagger = -i\psi^\dagger\left(\gamma^5\right)^\dagger\left(\gamma^0\right)^\dagger\psi = -i\psi^\dagger\gamma^5\gamma^0\psi = i\bar{\psi}\gamma^5\psi,
\end{aligned} \tag{0.89}$$

что и требовалось проверить.

35

Покажите, что

$$\gamma^0\gamma^\mu\gamma^0 = \begin{cases} +\gamma^\mu, & \mu = 0 \\ -\gamma^\mu, & \mu = 1,2,3 \end{cases}$$

Решение: Используя то, что $\left(\gamma^0\right)^2 = 1$, а также $\left\{\gamma^0, \gamma^i\right\} = 0, i = 1,2,3$, получаем

$$\gamma^0\gamma^0\gamma^0 = \gamma^0, \quad \gamma^0\gamma^i\gamma^0 = -\gamma^i\gamma^0\gamma^0 = -\gamma^i \tag{0.90}$$

что и требовалось показать.

36

Проверьте, что

$$T\bar{\psi}\gamma^\mu\psi T = \begin{cases} +\bar{\psi}\gamma^\mu\psi(-t,\mathbf{x}), & \mu = 0 \\ -\bar{\psi}\gamma^\mu\psi(-t,\mathbf{x}), & \mu = 1,2,3 \end{cases}$$

Решение: Используя, что $T(c \text{ - число }) = (c - \text{ число })^* T$, и также $T\psi(t,\boldsymbol{x})T = \gamma^1\gamma^3\psi(-t,\boldsymbol{x})$, получим

$$\begin{aligned} T\bar{\psi}\gamma^\mu\psi T = T\bar{\psi}T\left(\gamma^\mu\right)^* T\psi T = \psi^\dagger(-t,\boldsymbol{x})\left[\gamma^1\gamma^3\right]^\dagger(\gamma)^0\left(\gamma^\mu\right)^*\gamma^1\gamma^3\psi(-t,\boldsymbol{x}) = \\ = \bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^1\gamma^3\right)\left(\gamma^\mu\right)^*\gamma^1\gamma^3\psi(-t,\boldsymbol{x}) \end{aligned} \tag{0.91}$$

Теперь используя, что $\left(\gamma^0\right)^* = \gamma^0, \left(\gamma^1\right)^* = \gamma^1, \left(\gamma^3\right)^* = \gamma^3$ и $\left(\gamma^2\right)^* = -\gamma^2, \{\gamma^\mu, \gamma^\nu\} = 2g^{\mu\nu}$, получим

$$\begin{aligned} T\bar{\psi}\gamma^0\psi T &= \bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^1\gamma^3\right)\gamma^0\gamma^1\gamma^3\psi(-t,\boldsymbol{x}) = \bar{\psi}\gamma^0\psi(-t,\boldsymbol{x}), \\ T\bar{\psi}\gamma^1\psi T &= \bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^1\gamma^3\right)\gamma^1\gamma^1\gamma^3\psi(-t,\boldsymbol{x}) = -\bar{\psi}\gamma^1\psi(-t,\boldsymbol{x}), \\ T\bar{\psi}\gamma^2\psi T &= -\bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^1\gamma^3\right)\gamma^2\gamma^1\gamma^3\psi(-t,\boldsymbol{x}) = -\bar{\psi}\gamma^2\psi(-t,\boldsymbol{x}), \\ T\bar{\psi}\gamma^3\psi T &= \bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^1\gamma^3\right)\gamma^3\gamma^1\gamma^3\psi(-t,\boldsymbol{x}) = -\bar{\psi}\gamma^3\psi(-t,\boldsymbol{x}), \end{aligned} \tag{0.92}$$

что и требовалось проверить.

37

Найдите чему равно преобразование зарядового сопряжения для биллинейных форм:
$C\bar{\psi}\psi C, C\bar{\psi}\gamma^\mu\psi C, Ci\bar{\psi}\left[\gamma^\mu,\gamma^\nu\right]\psi C, C\bar{\psi}\gamma^\mu\gamma^5\psi C, Ci\bar{\psi}\gamma^5\psi C$.
Решение: Используя, что $C\psi(x)C = -i\left(\bar{\psi}\gamma^0\gamma^2\right)^T$, и также $C\bar{\psi}C = \left(-i\gamma^0\gamma^2\psi\right)^T$ имеем:
$C\bar{\psi}\psi C = \left(-i\gamma^0\gamma^2\psi\right)^T\left(-i\bar{\psi}\gamma^0\gamma^2\right)^T = -\gamma^0_{ab}\gamma^2_{bc}\psi_c\bar{\psi}_d\gamma^0_{de}\gamma^2_{ea} = \bar{\psi}_d\gamma^0_{de}\gamma^2_{ea}\gamma^0_{ab}\gamma^2_{bc}\psi_c = -\bar{\psi}\gamma^2\gamma^0\gamma^0\gamma^2\psi = \bar{\psi}\psi$,
$Ci\bar{\psi}\gamma^5\psi C = i\left(-i\gamma^0\gamma^2\psi\right)^T\gamma^5\left(-i\bar{\psi}\gamma^0\gamma^2\right)^T = i\bar{\psi}\gamma^5\psi$,
аналогично можно проверить для остальных выражений.

26.1.10 Problems about spinors and Dirac equation 3

Stanford.Zhou.2022.7.1. Plane wave solutions of the Dirac equation. (10/45 p)

In the Weyl representation the gamma matrices are given by

$$\gamma^\mu = \begin{pmatrix} 0 & \sigma^\mu \\ \bar{\sigma}^\mu & 0 \end{pmatrix}, \quad \sigma^\mu = \left(\mathbb{1}_2, \sigma^1, \sigma^2, \sigma^3\right), \quad \bar{\sigma}^\mu = \left(\mathbb{1}_2, -\sigma^1, -\sigma^2, -\sigma^3\right)$$

Here, $\mathbb{1}_n$ denotes an $n \times n$ identity matrix.
a) Show that $(p\cdot\sigma)(p\cdot\bar{\sigma}) = p^2\mathbb{1}_2$.

Solution:

Inserting the definitions and suppressing the factors of the identity, the expression is

$$\left(p^0 - \mathbf{p}\cdot\boldsymbol{\sigma}\right)\left(p^0 + \mathbf{p}\cdot\boldsymbol{\sigma}\right) = \left(p^0\right)^2 - \frac{1}{2}p^i p^j\left\{\sigma^i,\sigma^j\right\} = \left(p^0\right)^2 - |\mathbf{p}|^2 = p^2$$

as desired, where we used $\left\{\sigma^i,\sigma^j\right\} = 2\delta^{ij}$.

b) Show that the Dirac equation has positive-frequency plane wave solutions

$$\psi(x) = u_s(p)e^{-ip\cdot x}, \quad u_s(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi_s \\ \sqrt{p\cdot\bar{\sigma}}\xi_s \end{pmatrix}$$

where ξ_s is a two-component spinor, i.e. a complex vector with two elements. (Formally, given a matrix A with a complete basis of eigenvectors, with eigenvalues λ_i, we can define a matrix square root $\sqrt{A}$ to have the same eigenvectors, with eigenvalues $\sqrt{\lambda_i}$. But the only thing you need to know to do this problem is $\sqrt{A}\sqrt{A} = A$.)

Solution:

By the definition of the matrix square root and the result of part (a), we have

$$\sigma\cdot p = \sqrt{\sigma\cdot p}\cdot\sqrt{\sigma\cdot p}, \quad \bar{\sigma}\cdot p = \sqrt{\bar{\sigma}\cdot p}\cdot\sqrt{\bar{\sigma}\cdot p}, \quad m\mathbb{1}_2 = \sqrt{\sigma\cdot p}\cdot\sqrt{\bar{\sigma}\cdot p} = \sqrt{\bar{\sigma}\cdot p}\cdot\sqrt{\sigma\cdot p}$$

where we used $p^2 = m^2$. To show the Dirac equation is satisfied, note that the derivative ∂_μ just pulls down a factor of $-ip^\mu$. Thus, it suffices to show that

$$\left(p_\mu\gamma^\mu - m\mathbb{1}_4\right)u_s(p) = 0$$

To show this, we just plug in the definitions, giving

$$\begin{aligned}
\left(p_\mu\gamma^\mu - m\mathbb{1}_4\right)u_s(p) &= \begin{pmatrix} -m\mathbb{1}_2 & \sqrt{p\cdot\sigma}\sqrt{p\cdot\sigma} \\ \sqrt{p\cdot\bar{\sigma}}\sqrt{p\cdot\bar{\sigma}} & -m\mathbb{1}_2 \end{pmatrix}\begin{pmatrix} \sqrt{p\cdot\sigma}\xi_s \\ \sqrt{p\cdot\bar{\sigma}}\xi_s \end{pmatrix} \\
&= \begin{pmatrix} \sqrt{p\cdot\sigma}\left(-m\mathbb{1}_2 + \sqrt{p\cdot\sigma}\sqrt{p\cdot\bar{\sigma}}\right)\xi_s \\ \sqrt{p\cdot\bar{\sigma}}\left(\sqrt{p\cdot\bar{\sigma}}\sqrt{p\cdot\sigma} - m\mathbb{1}_2\right)\xi_s \end{pmatrix} \\
&= \begin{pmatrix} \sqrt{p\cdot\sigma}\left(-m\mathbb{1}_2 + \sqrt{p^2}\mathbb{1}_2\right)\xi_s \\ \sqrt{p\cdot\bar{\sigma}}\left(\sqrt{p^2}\mathbb{1}_2 - m\mathbb{1}_2\right)\xi_s \end{pmatrix} \\
&= 0
\end{aligned}$$

where we used $p^2 = m^2$ in the last step.

c) Show that if we pick an orthonormal basis of two-component spinors ξ_s with $s\in\{1,2\}$, satisfying $\left(\xi_r\right)^\dagger\xi_s = \delta_{rs}$, then the Dirac spinors satisfy the orthogonality relations

$$u_r(p)^\dagger u_s(p) = 2p_0\delta_{rs}, \quad \bar{u}_r(p)u_s(p) = 2m\delta_{rs}$$

Solution:

To take the Hermitian conjugate, note that $\left(\sigma^\mu\right)^\dagger = \sigma^\mu$. Then we simply have

$$\begin{aligned}
u_s^\dagger(p)u_r(p) &= \begin{pmatrix} \xi_s^\dagger\sqrt{\sigma\cdot p} & \xi_s^\dagger\sqrt{\bar{\sigma}\cdot p} \end{pmatrix}\cdot\begin{pmatrix} \sqrt{\sigma\cdot p}\xi_r \\ \sqrt{\bar{\sigma}\cdot p}\xi_r \end{pmatrix} \\
&= \xi_s^\dagger(p\cdot\sigma + p\cdot\bar{\sigma})\xi_r = 2p^0\xi_s^\dagger\xi_r = 2p^0\delta_{rs}
\end{aligned}$$

The proof of the second orthogonality relation is similar:

$$\begin{aligned}
\bar{u}_s(p)u_r(p) = u_s^\dagger(p)\gamma^0u_r(p) &= \begin{pmatrix} \xi_s^\dagger\sqrt{\bar{\sigma}\cdot p} & \xi_s^\dagger\sqrt{\sigma\cdot p} \end{pmatrix}\cdot\begin{pmatrix} \sqrt{\sigma\cdot p}\xi_r \\ \sqrt{\bar{\sigma}\cdot p}\xi_r \end{pmatrix} \\
&= 2\xi_s^\dagger(\sqrt{p\cdot\sigma}\sqrt{p\cdot\bar{\sigma}})\xi_r = 2m\xi_s^\dagger\xi_r = 2m\delta_{rs}.
\end{aligned}$$

d) Similarly, the Dirac equation has negative-frequency plane wave solutions

$$\psi(x) = v_s(p)e^{ip\cdot x}, \quad v_s(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi_s \\ -\sqrt{p\cdot\bar{\sigma}}\xi_s \end{pmatrix}$$

Show that these solve the Dirac equation, and satisfy the orthogonality relations

$$v_r(p)^\dagger v_s(p) = 2p_0\delta_{rs}, \quad \bar{v}_r(p)v_s(p) = -2m\delta_{rs}$$

Solution:

The proof that these plane waves solve the Dirac equation is very similar to that of part (b), except that now the derivative ∂_μ pulls down a factor of ip^μ, so we want to show

$$(p_\mu\gamma^\mu + m\mathbb{1}_4)\, v_s(p) = 0$$

This holds because

$$\begin{aligned}(p_\mu\gamma^\mu + m\mathbb{1}_4)\, v_s(p) &= \begin{pmatrix} m\mathbb{1}_2 & \sqrt{p\cdot\sigma}\sqrt{p\cdot\sigma} \\ \sqrt{p\cdot\bar{\sigma}}\sqrt{p\cdot\bar{\sigma}} & m\mathbb{1}_2 \end{pmatrix}\begin{pmatrix} \sqrt{p\cdot\sigma}\xi_s \\ -\sqrt{p\cdot\bar{\sigma}}\xi_s \end{pmatrix} \\ &= \begin{pmatrix} \sqrt{p\cdot\sigma}\left(m\mathbb{1}_2 - \sqrt{p\cdot\sigma}\sqrt{p\cdot\bar{\sigma}}\right)\xi_s \\ \sqrt{p\cdot\bar{\sigma}}\left(\sqrt{p\cdot\bar{\sigma}}\sqrt{p\cdot\sigma} - m\mathbb{1}_2\right)\xi_s \end{pmatrix} \\ &= \begin{pmatrix} \sqrt{p\cdot\sigma}\left(m\mathbb{1}_2 - \sqrt{p^2}\mathbb{1}_2\right)\xi_s \\ \sqrt{p\cdot\bar{\sigma}}\left(\sqrt{p^2}\mathbb{1}_2 - m\mathbb{1}_2\right)\xi_s \end{pmatrix} \\ &= 0.\end{aligned}$$

The proofs of the orthogonality relations are very similar to part (c),

$$\begin{aligned}v_s^\dagger(p)v_r(p) &= \begin{pmatrix} \xi_s^\dagger\sqrt{\sigma\cdot p} & -\xi_s^\dagger\sqrt{\bar{\sigma}\cdot p} \end{pmatrix}\cdot\begin{pmatrix} \sqrt{\sigma\cdot p}\xi_r \\ -\sqrt{\bar{\sigma}\cdot p}\xi_r \end{pmatrix} \\ &= \xi_s^\dagger(p\cdot\sigma + p\cdot\bar{\sigma})\xi_r = 2p^0\xi_s^\dagger\xi_r = 2p^0\delta_{rs}\end{aligned}$$

and

$$\begin{aligned}\bar{v}_s(p)v_r(p) = v_s(p)\gamma^0 v_r(p) &= -\begin{pmatrix} \xi_s^\dagger\sqrt{\bar{\sigma}\cdot p} & \xi_s^\dagger\sqrt{\sigma\cdot p} \end{pmatrix}\cdot\begin{pmatrix} \sqrt{\sigma\cdot p}\xi_r \\ \sqrt{\bar{\sigma}\cdot p}\xi_r \end{pmatrix} \\ &= -2\xi_s^\dagger(\sqrt{p\cdot\sigma}\sqrt{p\cdot\bar{\sigma}})\xi_r = -2m\xi_s^\dagger\xi_r = -2m\delta_{rs}.\end{aligned}$$

e) Show the completeness relations for the Dirac spinors,

$$\sum_{s=1}^{2} u_s(p)\bar{u}_s(p) = \not{p} + m\mathbb{1}_4, \quad \sum_{s=1}^{2} v_s(p)\bar{v}_s(p) = \not{p} - m\mathbb{1}_4$$

Solution:

This follows straightforwardly from plugging in the definitions,

$$\sum_{s=1}^{2} u_s(p)\bar{u}_s(p) = \sum_{s=1}^{2}\begin{pmatrix} \sqrt{p\cdot\sigma}\xi_s \\ \sqrt{p\cdot\bar{\sigma}}\xi_s \end{pmatrix}\begin{pmatrix} \xi_s^\dagger\sqrt{p\cdot\bar{\sigma}} & \xi_s^\dagger\sqrt{p\cdot\sigma} \end{pmatrix} = \begin{pmatrix} m & p\cdot\sigma \\ p\cdot\bar{\sigma} & m \end{pmatrix} = p_\mu\gamma^\mu + m\mathbb{1}_4$$

$$\sum_{s=1}^{2} v_s(p)\bar{v}_s(p) = \sum_{s=1}^{2}\begin{pmatrix} \sqrt{p\cdot\sigma}\xi_s \\ -\sqrt{p\cdot\bar{\sigma}}\xi_s \end{pmatrix}\begin{pmatrix} -\xi_s^\dagger\sqrt{p\cdot\bar{\sigma}} & \xi_s^\dagger\sqrt{p\cdot\sigma} \end{pmatrix} = \begin{pmatrix} -m & p\cdot\sigma \\ p\cdot\bar{\sigma} & -m \end{pmatrix} = p_\mu\gamma^\mu - m\mathbb{1}_4$$

In both cases we used the completeness relation for the two-component spinors, $\sum_{s=1}^{2}\xi_s\xi_s^\dagger = \mathbb{1}_2$.

Stanford.Zhou.2022.7.2 Useful spinor identities. (10/45p)

a) Prove the Gordon identity,

$$\bar{u}_r\left(p'\right)\gamma^\mu u_s(p)=\bar{u}_r\left(p'\right)\left(\frac{p'^\mu+p^\mu}{2m}+\frac{i\sigma^{\mu\nu}\left(p'_\nu-p_\nu\right)}{2m}\right)u_s(p)$$

where $\sigma^{\mu\nu}=\frac{i}{2}\left[\gamma^\mu,\gamma^\nu\right]$.

(Hint: this can be done using only the Dirac equation and the defining property of the gamma matrices.)

b) Show the completeness relation for the Γ matrices,

$$\delta_{ac}\delta_{db}=\frac{1}{4}\sum_I\tilde{\Gamma}^I_{dc}\Gamma^I_{ab}$$

(Hint: it suffices to show that both sides give the same result when multiplied by a general matrix M_{cd}.)

c) Using (10), show the Fierz identity

$$\tilde{\Gamma}^I_{ab}\Gamma^J_{cd}=\frac{1}{16}\sum_{KL}\mathrm{tr}\left[\tilde{\Gamma}^I\tilde{\Gamma}^K\Gamma^J\Gamma^L\right]\tilde{\Gamma}^L_{ad}\Gamma^K_{cb}$$

d) Find the Fierz transformations for $\left(\bar{u}_1u_2\right)\left(\bar{u}_3u_4\right)$ and $\left(\bar{u}_1\gamma^\mu u_2\right)\left(\bar{u}_3\gamma_\mu u_4\right)$ explicitly. (Your final result should only contain the spinors and gamma matrices, not the Γ^I.)

Solution to (a)

It's easiest to start from the second term on the right-hand side. Note that

$$\begin{aligned}\bar{u}_r\left(p'\right)\left[\gamma^\mu,\gamma^\nu\right]\left(p'-p\right)_\nu u_s(p)&=\bar{u}_r\left(p'\right)\left(\gamma^\mu\gamma^\nu-\gamma^\nu\gamma^\mu\right)\left(p'-p\right)_\nu u_s(p)\\&=\bar{u}_r\left(p'\right)\left[2\left(p'+p\right)^\mu-2\left(p'\gamma^\mu+\gamma^\mu\not{p}\right)\right]u_s(p)\\&=\bar{u}_r\left(p'\right)\left(-4m\gamma^\mu+2\left(p'^\mu+p^\mu\right)\right)u_s(p)\end{aligned}$$

where we used the Dirac equation (S33)(??) in the last step. Plugging this into the right hand side of (7) gives the desired result.

Combinations of gamma matrices can be used to produce a basis Γ^I for the space of 4×4 matrices, where I ranges from 1 to 16. Concretely, we have

$$\begin{aligned}&\Gamma^{11}=(i/2)\left[\gamma^0,\gamma^1\right]\\&\Gamma^3=\gamma^0\quad\Gamma^7=i\gamma^5\gamma^0\quad\Gamma^{12}=(i/2)\left[\gamma^0,\gamma^2\right]\\&\Gamma^1=\mathbb{1}_4\quad\Gamma^4=\gamma^1\quad\Gamma^8=i\gamma^5\gamma^1\quad\Gamma^{13}=(i/2)\left[\gamma^0,\gamma^3\right]\\&\Gamma^2=\gamma^5\quad\Gamma^5=\gamma^2\quad\Gamma^9=i\gamma^5\gamma^2\quad\Gamma^{14}=(i/2)\left[\gamma^1,\gamma^2\right]\\&\Gamma^6=\gamma^3\quad\Gamma^{10}=i\gamma^5\gamma^3\quad\Gamma^{15}=(i/2)\left[\gamma^1,\gamma^3\right]\\&\Gamma^{16}=(i/2)\left[\gamma^2,\gamma^3\right]\end{aligned}$$

We define the matrices $\tilde{\Gamma}^I$ similarly, but with lowered Lorentz indices; for example, $\tilde{\Gamma}^4=\gamma_1=-\gamma^1=-\Gamma^4$. (This ensures the equations below won't have annoying extra signs due to the signs in the metric.) An inner product for 4×4 matrices can be defined by

$$\mathrm{tr}(AB)=\sum_{ab}A_{ab}B_{ba}$$

Under this inner product, the matrices given above are orthogonal, in the sense that

$$\mathrm{tr}\left(\tilde{\Gamma}^I\Gamma^J\right)=4\delta^{IJ}$$

which implies they are linearly independent, and thus indeed form a basis. (You don't have to check (9), but it follows directly from the results you proved in problem set 6.)

Solution to (b)

We consider a general matrix M, where

$$M_{cd} = \sum_I m^I \Gamma^I_{cd}$$

Multiplying both sides with M_{cd}, the left-hand side is just M_{ab}, while the right-hand side is

$$\frac{1}{4}\sum_I \tilde{\Gamma}^I_{dc}\Gamma^I_{ab}\sum_J m^J\Gamma^J_{cd} = \sum_{IJ}\Gamma^I_{ab}m^J \operatorname{tr}\left(\tilde{\Gamma}^I\Gamma^J\right) = \sum_I \Gamma^I_{ab}m^I = M_{ab}$$

Since the two sides match for any matrix M, the completeness relation holds.

Solution to (c)

We note that

$$\begin{aligned}\tilde{\Gamma}^I_{ab}\Gamma^J_{cd} &= \tilde{\Gamma}^I_{ef}\Gamma^J_{gh}\delta_{ae}\delta_{fb}\delta_{cg}\delta_{hd}\\ &= \frac{1}{16}\tilde{\Gamma}^I_{ef}\Gamma^J_{gh}\sum_{KL}\tilde{\Gamma}^L_{ad}\Gamma^L_{he}\tilde{\Gamma}^K_{fg}\Gamma^K_{cb}\\ &= \frac{1}{16}\sum_{KL}\operatorname{tr}\left[\tilde{\Gamma}^I\tilde{\Gamma}^K\Gamma^J\Gamma^L\right]\tilde{\Gamma}^L_{ad}\Gamma^K_{cb}\end{aligned}$$

where we applied the completeness relation twice, and then used the definition of the trace.
Contracting both sides of the Fierz identity with four spinors $\bar{u}_{1a}u_{2b}\bar{u}_{3c}u_{4d}$ yields

$$\left(\bar{u}_1\tilde{\Gamma}^I u_2\right)\left(\bar{u}_3\Gamma^J u_4\right) = \frac{1}{16}\sum_{KL}\operatorname{tr}\left[\tilde{\Gamma}^I\tilde{\Gamma}^K\Gamma^J\Gamma^L\right]\left(\bar{u}_1\tilde{\Gamma}^L u_4\right)\left(\bar{u}_3\Gamma^K u_2\right)$$

In other words, the Fierz identity relates the product of a contraction of $\bar{u}_1$ with u_2 and a contraction of $\bar{u}_3$ and u_4 (with arbitrary gamma matrices in the middle) to a combination of contractions of $\bar{u}_1$ with u_4 and $\bar{u}_3$ with u_2. This "Fierz transformation" rearranges how the spinors are contracted with each other, which can be useful in calculations.

Solution to (d)

For the first case, we can apply the Fierz identity with $\tilde{\Gamma}^I = \Gamma^J = \mathbb{1}_4$. Then the right-hand side becomes

$$\begin{aligned}\frac{1}{16}\sum_{KL}\operatorname{tr}\left[\tilde{\Gamma}^I\tilde{\Gamma}^K\Gamma^J\Gamma^L\right]\tilde{\Gamma}^L_{ad}\Gamma^K_{cb} &= \frac{1}{16}\sum_{KL}\operatorname{tr}\left[\tilde{\Gamma}^K\Gamma^L\right]\tilde{\Gamma}^L_{ad}\Gamma^K_{cb}\\ &= \frac{1}{4}\sum_{KL}\delta^{KL}\tilde{\Gamma}^L_{ad}\Gamma^K_{cb}\\ &= \frac{1}{4}\sum_K \tilde{\Gamma}^K_{ad}\Gamma^K_{cb}.\end{aligned}$$

Contracting both sides with the spinors, we conclude

$$\begin{aligned}\left(\bar{u}_1u_2\right)\left(\bar{u}_3u_4\right) =& \frac{1}{4}\Big[\left(\bar{u}_1u_4\right)\left(\bar{u}_3u_2\right) + \left(\bar{u}_1\gamma^5u_4\right)\left(\bar{u}_3\gamma^5u_2\right) + \left(\bar{u}_1\gamma^\mu u_4\right)\left(\bar{u}_3\gamma_\mu u_2\right)\\ &- \left(\bar{u}_1\gamma^5\gamma^\mu u_4\right)\left(\bar{u}_3\gamma^5\gamma_\mu u_2\right) - \frac{1}{8}\left(\bar{u}_1\left[\gamma^\mu,\gamma^\nu\right]u_4\right)\left(\bar{u}_3\left[\gamma_\mu,\gamma_\nu\right]u_2\right)\Big].\end{aligned}$$

Note that there is an extra factor of $1/2$ in the final term to avoid double counting. This result is admittedly rather complex, but it's indeed rearranged as desired.

For the second case, we take $\tilde{\Gamma}^I = \gamma_\mu$ and $\Gamma^J = \gamma^\mu$. Computing the right-hand side requires some casework, and use of the trace identities derived in problem set 6. The results are

$$\begin{aligned}
\tilde{\Gamma}^K = \mathbb{1}_4 : &\sum_L \operatorname{tr}\left[\gamma_\mu \gamma^\mu \Gamma^L\right] \tilde{\Gamma}^L_{ad} \delta_{cb} = 16 \delta_{cb} \delta_{ad}, \\
\tilde{\Gamma}^K = \gamma_\nu : &\sum_L \operatorname{tr}\left[\gamma_\mu \gamma_\nu \gamma^\mu \Gamma^L\right] \tilde{\Gamma}^L_{ad} \gamma^\nu_{cb} = -8 \gamma_{\nu ad} \gamma^\nu_{cb}, \\
\tilde{\Gamma}^K = \gamma^5 : &\sum_L \operatorname{tr}\left[\gamma_\mu \gamma^5 \gamma^\mu \Gamma^L\right] \tilde{\Gamma}^L_{ad} \gamma_{5cb} = -16 \gamma_{5ad} \gamma_{5cb}, \\
\tilde{\Gamma}^K = i\gamma^5 \gamma_\nu : &- \sum_L \operatorname{tr}\left[\gamma_\mu \gamma^5 \gamma_\nu \gamma^\mu \Gamma^L\right] \tilde{\Gamma}^L_{ad} \left(\gamma_5 \gamma^\nu\right)_{cb} = 8 \left(i\gamma_5 \gamma_\nu\right)_{ad} \left(i\gamma_5 \gamma^\nu\right)_{cb}, \\
\tilde{\Gamma}^K = \frac{i}{2} \sum_L \left[\gamma_\nu, \gamma_\rho\right] : &\quad \frac{i}{2} \operatorname{tr}\left[\gamma_\mu \left[\gamma_\nu, \gamma_\rho\right] \gamma^\mu \Gamma^L\right] \tilde{\Gamma}^L_{ad} \left(\frac{i}{2}\left[\gamma_\nu, \gamma_\rho\right]\right)_{cb} = 0.
\end{aligned}$$

Putting this all together yields

$$\left(\bar{u}_1 \gamma_\mu u_2\right)\left(\bar{u}_3 \gamma^\mu u_4\right) = \left(\bar{u}_1 u_4\right)\left(\bar{u}_3 u_2\right) - \frac{1}{2}\left(\bar{u}_1 \gamma_\mu u_4\right)\left(\bar{u}_3 \gamma^\mu u_2\right) - \left(\bar{u}_1 \gamma^5 u_4\right)\left(\bar{u}_3 \gamma^5 u_2\right) - \frac{1}{2}\left(\bar{u}_1 \gamma^5 \gamma_\mu u_4\right)\left(\bar{u}_3 \gamma^5 \gamma^\mu u_2\right)$$

Stanford.Zhou.2022.7.3 Electromagnetism in relativistic notation. (20/45p)

In electromagnetism, the Lagrangian is a function of the four-potential $A^\mu = (\phi, \mathbf{A})$,

$$\mathcal{L} = -\frac{1}{4} F_{\mu\nu} F^{\mu\nu} - J^\mu A_\mu, \quad \text{where} \quad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$$

and $J^\mu = (\rho, \mathbf{J})$ is a classical current density.

a) Show that if the current is conserved, $\partial_\mu J^\mu = 0$, then the action remains the same under the gauge symmetry $A_\mu \to A_\mu + \partial_\mu \alpha$, for any smooth function α.

Solution:

The kinetic term is gauge invariant because $F_{\mu\nu}$ is,

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu \to \partial_\mu A_\nu + \partial_\nu \partial_\mu \alpha - \partial_\nu A_\mu - \partial_\nu \partial_\mu \alpha = \partial_\mu A_\nu - \partial_\nu A_\mu$$

The interaction term is gauge invariant when the current is conserved because

$$J^\mu A_\mu \to J^\mu A_\mu + J^\mu \partial_\mu \alpha = J^\mu A_\mu + \partial_\mu \left(J^\mu \alpha\right)$$

where the change is a total derivative term, which does not affect the action.

b) Show that the Euler-Lagrange equation for A^μ is

$$\partial_\mu F^{\mu\nu} = J^\nu$$

Solution:

The Euler-Lagrange equation is

$$\partial_\mu \frac{\partial \mathcal{L}}{\partial\left(\partial_\mu A_\nu\right)} = \frac{\partial \mathcal{L}}{\partial A_\nu}$$

The right-hand side is clearly $-J^\nu$. As for the left-hand side, we use the product rule, giving

$$\begin{aligned}
\partial_\mu \frac{\partial \mathcal{L}}{\partial\left(\partial_\mu A_\nu\right)} &= -\frac{1}{2} \partial_\mu \left(F^{\rho\sigma} \frac{\partial F_{\rho\sigma}}{\partial\left(\partial_\mu A_\nu\right)}\right) \\
&= -\frac{1}{2} \partial_\mu \left(F^{\rho\sigma}\left(\delta^\mu_\rho \delta^\nu_\sigma - \delta^\mu_\sigma \delta^\nu_\rho\right)\right) \\
&= -\frac{1}{2} \partial_\mu \left(F^{\mu\nu} - F^{\nu\mu}\right) \\
&= -\partial_\mu F^{\mu\nu}
\end{aligned}$$

This gives the desired result.

c) Defining the electric and magnetic fields by $E^i = F^{i0}$ and $\epsilon^{ijk}B^k = -F^{ij}$, show that (14) is equivalent to two of Maxwell's equations.

Solution:

First set $\nu = 0$. Since $F^{00} = 0$, we have $\partial_i F^{i0} = J^0$, which in vector calculus notation is Gauss's law, $\nabla \cdot \mathbf{E} = \rho$. Next set $\nu = j$. Here we have

$$J^j = \partial_0 F^{0j} + \partial_i F^{ij} = -\dot{E}^j - \partial_i \epsilon^{ijk} B^k$$

which in vector calculus notation is

$$\mathbf{J} = -\dot{\mathbf{E}} + \nabla \times \mathbf{B}$$

which is Ampere's law.

d) The other two of Maxwell's equations are

$$\epsilon^{\mu\nu\rho\sigma}\partial_\mu F_{\nu\rho} = 0$$

which follows directly from the definition of $F_{\mu\nu}$. Interestingly, all four of Maxwell's equations can be written as a single spinor equation. Show that the equation

$$\gamma^\nu\gamma^\rho\gamma^\sigma\partial_\nu F_{\rho\sigma} = 2\gamma^\nu J_\nu$$

contains both (14) and (15). (This is just a mathematical trick with no physical meaning, but it's a nice application of the properties of gamma matrices.)

Solution:

To recover (14), we want to get the current by itself on the right-hand side. Thus, multiply both sides by γ^μ and take the trace, giving

$$\operatorname{tr}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\right)\partial_\nu F_{\rho\sigma} = 2\operatorname{tr}\left(\gamma^\mu\gamma^\nu\right)J_\nu = 8J^\mu$$

Simplifying the left-hand side, we have

$$\begin{aligned}\operatorname{tr}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\right)\partial_\nu F_{\rho\sigma} &= 4\left(\eta^{\mu\nu}\eta^{\rho\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}\right)\partial_\nu F_{\rho\sigma} \\ &= 4\left(-\partial_\nu F^{\mu\nu} + \partial_\nu F^{\nu\mu}\right) \\ &= 8\partial_\nu F^{\nu\mu}\end{aligned}$$

where we used the fact that F is antisymmetric, so $\eta^{\rho\sigma}F_{\rho\sigma} = 0$. Equating the two sides and renaming the indices recovers 14.

To recover (15), we want to get a factor of $\epsilon^{\mu\nu\rho\sigma}$ on the left-hand side. Therefore, multiply both sides by $\gamma^5\gamma^\mu$ and take the trace. By the results we've derived previously, the right-hand side vanishes and the trace on the left-hand side is proportional to $\epsilon^{\mu\nu\rho\sigma}$, as desired.

e) In the Lagrangian (13), we could have also included a term of the form $\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$, which is Lorentz invariant and gauge invariant. What is it in terms of $\mathbf{E}$ and $\mathbf{B}$? Show that this term is a total derivative, and thus does not contribute to the action.

Solution:

To write this term in terms of $\mathbf{E}$ and $\mathbf{B}$, we just expand out the contractions. There are 24 terms, corresponding to the cases where μ, ν, ρ, and σ are all distinct. However, the antisymmetry of F means that groups of eight of them all give the same thing, e.g.

$$\begin{aligned}&\epsilon^{0123}F_{01}F_{23} = \epsilon^{1023}F_{10}F_{23} = \epsilon^{0132}F_{01}F_{32} = \epsilon^{1032}F_{10}F_{32} \\ &= \epsilon^{2301}F_{23}F_{01} = \epsilon^{2310}F_{23}F_{10} = \epsilon^{3201}F_{32}F_{01} = \epsilon^{3210}F_{32}F_{10}\end{aligned}$$

There are thus only three distinct terms to write down. Adjusting the index position for convenience,

$$\begin{aligned}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} &= 8\left(\epsilon_{0123}F^{01}F^{23}+\epsilon_{0213}F^{02}F^{13}+\epsilon_{0312}F^{03}F^{12}\right)\\ &= 8\left(-F^{01}F^{23}+F^{02}F^{13}-F^{03}F^{12}\right)\\ &= 8\left(F^{10}F^{23}+F^{20}F^{31}+F^{30}F^{12}\right)\\ &= 8\left(F^{10}F^{23}+F^{20}F^{31}+F^{30}F^{12}\right)\\ &= -8\mathbf{E}\cdot\mathbf{B}.\end{aligned}$$

Now, to show the term is a total derivative, we note that

$$\begin{aligned}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} &= \epsilon^{\mu\nu\rho\sigma}\left[\partial_\mu A_\nu\partial_\rho A_\sigma-\partial_\nu A_\mu\partial_\rho A_\sigma-\partial_\mu A_\nu\partial_\sigma A_\rho+\partial_\nu A_\mu\partial_\sigma A_\rho\right]\\ &= 4\epsilon^{\mu\nu\rho\sigma}\partial_\mu A_\nu\partial_\rho A_\sigma\\ &= 4\epsilon^{\mu\nu\rho\sigma}\partial_\mu\left(A_\nu\partial_\rho A_\sigma\right)-4\epsilon^{\mu\nu\rho\sigma}A_\nu\partial_\mu\left(\partial_\rho A_\sigma\right)\\ &= \partial_\mu\left(4\epsilon^{\mu\nu\rho\sigma}A_\nu\partial_\rho A_\sigma\right)\end{aligned}$$

which is a total derivative as desired. Note that the second and third steps in this derivation just follow from the antisymmetry of $\epsilon^{\mu\nu\rho\sigma}$.

For the rest of this problem suppose there is no current, $J^\mu = 0$.

f) Construct the stress-energy tensor by directly applying Noether's theorem.

Solution:

Applying Noether's theorem as usual, we have

$$T^{\mu\nu} = \frac{\partial\mathcal{L}}{\partial\left(\partial_\mu A_\rho\right)}\partial^\nu A_\rho - \eta^{\mu\nu}\mathcal{L} = -F^{\mu\rho}\partial^\nu A_\rho + \frac{1}{4}\eta^{\mu\nu}F_{\rho\sigma}F^{\rho\sigma}$$

g) The stress-energy tensor you found in part (**e**) is conserved, but neither symmetric nor gauge invariant. However, we can define an "improved" stress-energy tensor,

$$\hat{T}^{\mu\nu} = T^{\mu\nu} + \partial_\rho\left(F^{\mu\rho}A^\nu\right)$$

Assuming the equations of motion hold, show that $\hat{T}^{\mu\nu}$ is symmetric, gauge invariant, conserved $\left(\partial_\mu\hat{T}^{\mu\nu}=0\right)$, and traceless $\left(\eta_{\mu\nu}\hat{T}^{\mu\nu}=0\right)$. Furthermore, show that it contains the familiar electromagnetic energy and momentum densities,

$$\hat{T}^{00} = \frac{1}{2}\left(|\mathbf{E}|^2+|\mathbf{B}|^2\right), \quad \hat{T}^{0i} = (\mathbf{E}\times\mathbf{B})^i$$

Solution:

Adding on the new term gives

$$\hat{T}^{\mu\nu} = \left(\partial_\rho F^{\mu\rho}\right)A^\nu + F^{\mu\rho}F^\nu_\rho + \frac{1}{4}\eta^{\mu\nu}F_{\rho\sigma}F^{\rho\sigma}$$

When the equations of motion hold, $\partial_\rho F^{\mu\rho}=0$, so we may simply drop the first term, giving

$$\hat{T}^{\mu\nu} = -\eta_{\rho\sigma}F^{\mu\rho}F^{\nu\sigma} + \frac{1}{4}\eta^{\mu\nu}F_{\rho\sigma}F^{\rho\sigma}$$

where we cleaned up the indices a bit. In this form, the stress-energy tensor is clearly symmetric, and it is gauge invariant because it is written in terms of the gauge invariant F alone. To show conservation, it is easiest to note that

$$\partial_\mu\hat{T}^{\mu\nu} = \partial_\mu T^{\mu\nu} + \partial_\mu\partial_\rho\left(F^{\mu\rho}A^\nu\right) = 0$$

where the first term vanishes by Noether's theorem, and the second term vanishes by the antisymmetry of F. Finally, to show tracelessness, we note that

$$\eta_{\mu\nu}\hat{T}^{\mu\nu} = -\eta_{\mu\nu}\eta_{\rho\sigma}F^{\mu\rho}F^{\nu\sigma} + \frac{1}{4}\eta_{\mu\nu}\eta^{\mu\nu}F_{\rho\sigma}F^{\rho\sigma} = -F_{\nu\sigma}F^{\nu\sigma} + F_{\rho\sigma}F^{\rho\sigma} = 0$$

Now let's consider the components. For the energy density, we have

$$\begin{aligned}\hat{T}^{00} &= -\eta_{\rho\sigma}F^{0\rho}F^{0\sigma} + \frac{1}{4}\eta^{00}F_{\rho\sigma}F^{\rho\sigma} \\ &= F^{01}F^{01} + F^{02}F^{02} + F^{03}F^{03} + \frac{1}{4}F_{\rho\sigma}F^{\rho\sigma} \\ &= |\mathbf{E}|^2 + \frac{1}{2}\left(F_{01}F^{01} + F_{02}F^{02} + F_{03}F^{03} + F_{12}F^{12} + F_{23}F^{23} + F_{31}F^{31}\right) \\ &= |\mathbf{E}|^2 + \frac{1}{2}\left(-|\mathbf{E}|^2 + |\mathbf{B}|^2\right) \\ &= \frac{1}{2}\left(|\mathbf{E}|^2 + |\mathbf{B}|^2\right)\end{aligned}$$

as desired. For the momentum density, we have

$$\hat{T}^{0i} = -\eta_{\rho\sigma}F^{0\rho}F^{i\sigma} = F^{0j}F^{ij} = E^j\epsilon^{ijk}B^k = (\mathbf{E}\times\mathbf{B})^i.$$

In general, the improved stress-energy tensor considered here is called the Belinfante tensor; it is this stress-energy tensor that sources gravity in general relativity. We didn't see it earlier because the improvement terms are related to the spin angular momentum of the field, which is zero for scalar fields.

36 Дискретные симметрии в теории Дирака.

Проверьте, что все величины: $\bar{\psi}\psi, \bar{\psi}\gamma^\mu\psi, i\bar{\psi}\left[\gamma^\mu,\gamma^\nu\right]\psi, \bar{\psi}\gamma^\mu\gamma^5\psi, i\bar{\psi}\gamma^5\psi$ являются эрмитовыми.

Решение: Используя то, что $\left(\gamma^0\right)^\dagger = \gamma^0, \left(\gamma^5\right)^\dagger = \gamma^5$, а $\left(\gamma^i\right)^\dagger = -\gamma^i, i = 1,2,3$, а также, что $\left\{\gamma^5,\gamma^\mu\right\} = 0, \left\{\gamma^\mu,\gamma^\nu\right\} = 2g^{\mu\nu}$ имеем:

$$\begin{aligned}&(\bar{\psi}\psi)^\dagger = \left(\psi^\dagger\gamma^0\psi\right)^\dagger = \psi^\dagger\left(\gamma^0\right)^\dagger\psi = \psi^\dagger\gamma^0\psi = \bar{\psi}\psi \\ &\left(\bar{\psi}\gamma^\mu\psi\right)^\dagger = \left(\psi^\dagger\gamma^0\gamma^\mu\psi\right)^\dagger = \psi^\dagger\left(\gamma^\mu\right)^\dagger\left(\gamma^0\right)^\dagger\psi = \psi^\dagger\gamma^0\gamma^\mu\psi = \bar{\psi}\gamma^\mu\psi, \\ &\left(i\bar{\psi}\left[\gamma^\mu,\gamma^\nu\right]\psi\right)^\dagger = \left(i\psi^\dagger\gamma^0\left[\gamma^\mu,\gamma^\nu\right]\psi\right)^\dagger = -i\psi^\dagger\left(\left(\gamma^\nu\right)^\dagger\left(\gamma^\mu\right)^\dagger - \left(\gamma^\mu\right)^\dagger\left(\gamma^\nu\right)^\dagger\right)\gamma^0\psi = i\bar{\psi}\left[\gamma^\mu,\gamma^\nu\right]\psi, \\ &\left(\bar{\psi}\gamma^\mu\gamma^5\psi\right)^\dagger = \psi^\dagger\left(\gamma^5\right)^\dagger\left(\gamma^\mu\right)^\dagger\gamma^0\psi = \psi^\dagger\gamma^5\gamma^0\gamma^\mu\psi = \bar{\psi}\gamma^\mu\gamma^5\psi, \\ &\left(i\bar{\psi}\gamma^5\psi\right)^\dagger = -i\psi^\dagger\left(\gamma^5\right)^\dagger\left(\gamma^0\right)^\dagger\psi = -i\psi^\dagger\gamma^5\gamma^0\psi = i\bar{\psi}\gamma^5\psi,\end{aligned} \tag{0.89}$$

что и требовалось проверить.

35

Покажите, что

$$\gamma^0\gamma^\mu\gamma^0 = \begin{cases}+\gamma^\mu, & \mu = 0 \\ -\gamma^\mu, & \mu = 1,2,3\end{cases}$$

Решение: Используя то, что $\left(\gamma^0\right)^2 = 1$, а также $\left\{\gamma^0,\gamma^i\right\} = 0, i = 1,2,3$, получаем

$$\gamma^0\gamma^0\gamma^0 = \gamma^0, \quad \gamma^0\gamma^i\gamma^0 = -\gamma^i\gamma^0\gamma^0 = -\gamma^i \tag{0.90}$$

что и требовалось показать.

36

Проверьте, что

$$T\bar{\psi}\gamma^\mu\psi T = \begin{cases}+\bar{\psi}\gamma^\mu\psi(-t,\mathbf{x}), & \mu = 0 \\ -\bar{\psi}\gamma^\mu\psi(-t,\mathbf{x}), & \mu = 1,2,3\end{cases}$$

Решение: Используя, что $T(c\text{ - число }) = (c-\text{ число })^*T$, и также $T\psi(t,\boldsymbol{x})T = \gamma^1\gamma^3\psi(-t,\boldsymbol{x})$, получим

$$T\bar{\psi}\gamma^{\mu}\psi T = T\bar{\psi}T\left(\gamma^{\mu}\right)^{*}T\psi T = \psi^{\dagger}(-t,\boldsymbol{x})\left[\gamma^{1}\gamma^{3}\right]^{\dagger}(\gamma)^{0}\left(\gamma^{\mu}\right)^{*}\gamma^{1}\gamma^{3}\psi(-t,\boldsymbol{x}) = \\ = \bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^{1}\gamma^{3}\right)\left(\gamma^{\mu}\right)^{*}\gamma^{1}\gamma^{3}\psi(-t,\boldsymbol{x}) \tag{0.91}$$

Теперь используя, что $\left(\gamma^{0}\right)^{*} = \gamma^{0}, \left(\gamma^{1}\right)^{*} = \gamma^{1}, \left(\gamma^{3}\right)^{*} = \gamma^{3}$ и $\left(\gamma^{2}\right)^{*} = -\gamma^{2}, \{\gamma^{\mu},\gamma^{\nu}\} = 2g^{\mu\nu}$, получим

$$T\bar{\psi}\gamma^{0}\psi T = \bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^{1}\gamma^{3}\right)\gamma^{0}\gamma^{1}\gamma^{3}\psi(-t,\boldsymbol{x}) = \bar{\psi}\gamma^{0}\psi(-t,\boldsymbol{x}), \\ T\bar{\psi}\gamma^{1}\psi T = \bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^{1}\gamma^{3}\right)\gamma^{1}\gamma^{1}\gamma^{3}\psi(-t,\boldsymbol{x}) = -\bar{\psi}\gamma^{1}\psi(-t,\boldsymbol{x}), \\ T\bar{\psi}\gamma^{2}\psi T = -\bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^{1}\gamma^{3}\right)\gamma^{2}\gamma^{1}\gamma^{3}\psi(-t,\boldsymbol{x}) = -\bar{\psi}\gamma^{2}\psi(-t,\boldsymbol{x}), \\ T\bar{\psi}\gamma^{3}\psi T = \bar{\psi}(-t,\boldsymbol{x})\left(-\gamma^{1}\gamma^{3}\right)\gamma^{3}\gamma^{1}\gamma^{3}\psi(-t,\boldsymbol{x}) = -\bar{\psi}\gamma^{3}\psi(-t,\boldsymbol{x}), \tag{0.92}$$

что и требовалось проверить.

37

Найдите чему равно преобразование зарядового сопряжения для биллинейных форм:
$C\bar{\psi}\psi C, C\bar{\psi}\gamma^{\mu}\psi C, Ci\bar{\psi}\left[\gamma^{\mu},\gamma^{\nu}\right]\psi C, C\bar{\psi}\gamma^{\mu}\gamma^{5}\psi C, Ci\bar{\psi}\gamma^{5}\psi C$.
Решение: Используя, что $C\psi(x)C = -i\left(\bar{\psi}\gamma^{0}\gamma^{2}\right)^{T}$, и также $C\bar{\psi}C = \left(-i\gamma^{0}\gamma^{2}\psi\right)^{T}$ имеем:
$C\bar{\psi}\psi C = \left(-i\gamma^{0}\gamma^{2}\psi\right)^{T}\left(-i\bar{\psi}\gamma^{0}\gamma^{2}\right)^{T} = -\gamma^{0}_{ab}\gamma^{2}_{bc}\psi_{c}\bar{\psi}_{d}\gamma^{0}_{de}\gamma^{2}_{ea} = \bar{\psi}_{d}\gamma^{0}_{de}\gamma^{2}_{ea}\gamma^{0}_{ab}\gamma^{2}_{bc}\psi_{c} = -\bar{\psi}\gamma^{2}\gamma^{0}\gamma^{0}\gamma^{2}\psi = \bar{\psi}\psi$,
$Ci\bar{\psi}\gamma^{5}\psi C = i\left(-i\gamma^{0}\gamma^{2}\psi\right)^{T}\gamma^{5}\left(-i\bar{\psi}\gamma^{0}\gamma^{2}\right)^{T} = i\bar{\psi}\gamma^{5}\psi$,
аналогично можно проверить для остальных выражений.

МФТИ-Киселев-2020.8 Тождество вейлевского спинора

Для правого вейлевского спинора покажите, что из уравнения движения следует тождество

$$\frac{1}{\hbar}\boldsymbol{W}\bar{\chi} = \frac{1}{2}\boldsymbol{p}\bar{\chi}$$

Solution

(?? вроде типичная по теории задача? напишу теорию точнее!!!)
Правое киральное безмассовое поле $\bar{\chi}^{\dot{\alpha}}(x)$, преобразующееся по представлению $\left(\frac{1}{2},0\right)$ группы $\mathrm{SL}(2,\mathbb{C})$, согласно общему формализму удовлетворяет уравнению

$$\mathfrak{s}p^{\mu}\bar{\chi} = \frac{1}{\hbar}W^{\mu}\bar{\chi},$$

где спиральность $\mathfrak{s} = \frac{1}{2}$, а оператор W^{k} задается покомпонентно, так что для временно́й компоненты

$$\frac{1}{\hbar}W^{0} = \frac{1}{2}p\cdot\sigma$$

а уравнения для пространственных компонент, как мы показали, являются следствием заданного представления для безмассового поля. В явном виде уравнение для p_0 принимает вид

$$p_{0}\bar{\chi} = p\cdot\sigma\bar{\chi}$$

или с учетом определения 4-вектора сигма-матриц

$$p_{\mu}\sigma^{\mu}\bar{\chi} = 0 \leftrightarrow p_{\mu}\sigma^{\mu}_{\alpha\dot{\alpha}}\bar{\chi}^{\dot{\alpha}} = 0$$

МФТИ-Киселев-2020.9 Отраженный спинор (???)

Показать, что если χ удовлетворяет уравнению

$$\boldsymbol{p}\cdot\boldsymbol{\sigma}\bar{\chi}(\boldsymbol{p}) = |\boldsymbol{p}|\bar{\chi}(\boldsymbol{p}),$$

то спинор $\chi_{cp}(-\boldsymbol{p}) = -\mathrm{i}\sigma_2\bar{\chi}^*(\boldsymbol{p})$ удовлетворяет уравнению

$$-\boldsymbol{p}\cdot\boldsymbol{\sigma}\chi_{cp}(-\boldsymbol{p}) = |\boldsymbol{p}|\chi_{cp}(-\boldsymbol{p})$$

Solution

(???? доучу скоро. суть - что решаем ур движения, да? Тут как раз то самое сопряжение, напишу в 1й части тоже про это!)

Найдем решения уравнения для спинора (6.1) в импульсном представлении, т. е. в виде плоской волны

$$\bar{\chi}(x) = e^{-\frac{\mathrm{i}}{\hbar}p\cdot x}\sum_{\lambda}\bar{\chi}_{(\lambda)}(\boldsymbol{p})$$

где $p\cdot x = p_0x_0 - \boldsymbol{p}\cdot\boldsymbol{x}$. Как нам известно, матрица $p\cdot\sigma = \sigma_p$ имеет пару собственных векторов-столбцов, так что в их базисе

$$\boldsymbol{p}\cdot\boldsymbol{\sigma} = |\boldsymbol{p}|\sigma_3 = |\boldsymbol{p}|\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}$$

и, принимая условие нормировки $\bar{\chi}^\dagger\bar{\chi} = 2|p|$

$$\bar{\chi}(\boldsymbol{p}) = \sqrt{2|\boldsymbol{p}|}\begin{pmatrix}1\\0\end{pmatrix},\quad \boldsymbol{p}\cdot\boldsymbol{\sigma}\bar{\chi}(\boldsymbol{p}) = |\boldsymbol{p}|\bar{\chi}(\boldsymbol{p})$$
$$\chi_{cp}(\boldsymbol{p}) = \sqrt{2|p|}\begin{pmatrix}0\\1\end{pmatrix},\quad -\boldsymbol{p}\cdot\boldsymbol{\sigma}\chi_{cp}(-\boldsymbol{p}) = |\boldsymbol{p}|\chi_{cp}(-\boldsymbol{p})$$

МФТИ-Киселев-2020. Гамильтониан спиноров

Вычислить гамильтониан правого вейлевского спинора в терминах амплитуд релятивистски нормированных мод.

Solution

Обобщенный импульс равен $\frac{\delta L_{\mathrm{R}}}{\delta\dot{\bar{\chi}}(x)} = \mathrm{i}\hbar\chi\sigma^0$, поэтому гамильтониан вейлевского классического поля: (??? проверю!)

$$H_{\mathrm{R}} = \int \mathrm{d}^3x\left\{\mathrm{i}\hbar\chi\sigma^0\dot{\bar{\chi}} - c\chi p_\mu\sigma^\mu\bar{\chi}\right\} = c\int \mathrm{d}^3x\{\chi\boldsymbol{p}\cdot\sigma\bar{\chi}\}$$

В итоге разложение классического правого спинорного поля по модам принимает вид

$$\bar{\chi}(x) = \int\frac{\mathrm{d}^3p}{2p_0(2\pi\hbar)^3}\left\{e^{-\frac{1}{\hbar}p\cdot x}\bar{\chi}(p)\vartheta(p) + e^{\frac{1}{\hbar}p\cdot x}\chi_{cp}(p)\bar{v}(p)\right\}$$

где уже энергия p_0 принимает только положительные значения $p_0 = |p|, p\cdot x = p_0x_0 - p\cdot\boldsymbol{x}$, а $\vartheta(p)$ и $v(p)$ - комплекснозначные параметры. С учетом ортогональности базисных спиноров находим для гамильтониана

$$H_{\mathrm{R}} = \int\varepsilon(p)\frac{\mathrm{d}^3p}{2p_0(2\pi\hbar)^3}\{\bar{\vartheta}(p)\vartheta(p) - v(p)\bar{v}(p)\}$$

где $\varepsilon(p) = c|p| = cp_0 > 0$ - положительно определенная энергия спинорной моды.

МФТИ-Киселев-2020.11^C Заряд

Вычислить заряд правого вейлевского спинора в терминах амплитуд релятивистски нормированных мод.

Solution

Аналогично предыдущему пункту, заряд классического поля

$$Q = e\int \frac{\mathrm{d}^3 p}{2p_0(2\pi\hbar)^3}\{\bar{\vartheta}(\boldsymbol{p})\vartheta(\boldsymbol{p}) + v(\boldsymbol{p})\bar{v}(\boldsymbol{p})\}$$

Просто подставили разложение спинорного поля по модам в формулу для тока.

МФТИ-Киселев-2020.12 Проекторы

Показать, что проекторы на состояния с заданной проекцией спина частицы на вектор поляризации имеют вид

$$P_\pm = \frac{1}{2}\left(1 + \lambda\gamma_5 \not{\epsilon}\right)$$

а для античастиц -

$$P^c_\pm = \frac{1}{2}\left(1 - \lambda\gamma_5 \not{\epsilon}\right)$$

где λ — направление спина вдоль вектора поляризации ε^μ, ортогонального 4-импульсу p:

$$\lambda = \pm 1, \quad \epsilon^2 = -1, \quad \epsilon \cdot p = 0$$

Solution

(?? очень известная из теории тема, напишу потом)

МФТИ-13 Сумма по поляризациям дираковских частиц и античастиц

Вычислить сумму по поляризациям дираковских частиц и античастиц:

$$\Pi(\boldsymbol{p}) = \sum_\lambda u_\lambda(\boldsymbol{p})\bar{u}_\lambda(\boldsymbol{p}) = \not{p} + mc, \quad \Pi^c(\boldsymbol{p}) = \sum_\lambda v_\lambda(\boldsymbol{p})\bar{v}_\lambda(\boldsymbol{p}) = \not{p} - mc$$

Solution

Для покоящихся спиноров сумму по поляризациям или матрицу

$$\Pi(0) := \sum_\lambda u_\lambda(0)\bar{u}_\lambda(0)$$

можно вычислить в явном виде как прямое произведение строк и столбцов

$$\Pi(\mathbf{0}) = mc(1,0,1,0)\begin{pmatrix}1\\0\\1\\0\end{pmatrix} + mc(0,1,0,1)\begin{pmatrix}0\\1\\0\\1\end{pmatrix} = mc\begin{pmatrix}1&0&1&0\\0&1&0&1\\1&0&1&0\\0&1&0&1\end{pmatrix}$$

или в ковариантном виде

$$\Pi(0) = mc\left(\gamma_0 + 1\right) = \left(p' + mc\right), \qquad p' = (mc, 0)$$

Поскольку преобразование Лоренца для матрицы A сводятся к преобразованию 4-вектора A^ν в движущуюся систему отсчета:

$$\Lambda \not{A} \Lambda^{-1} \to \not{A}$$

сумма по поляризациям для движущихся частиц

$$\Pi(p) = (\not{p} + mc)$$

и аналогично для античастиц

$$\Pi^c(p) = \sum_\lambda v_\lambda(p)\bar{v}_\lambda(p) = (\not{p} - mc)$$

(?? нам что-то нужно подставить, для этого пишем то, что ниже, я забыл, что?)
Запишем уравнение Дирака

$$(\mathrm{i}\gamma^\mu\partial_\mu - m)\,\psi = 0$$

Рассмотрим для начала положительно частотные решения уравнения (16.1). Для этого запипем ψ в виде

$$\psi = u(\mathbf{p})e^{-ip\cdot x}$$

где $u(\mathbf{p})$ - четырёхкомпонентных спинор, зависящий только от $\mathbf{p}$. С учётом (16.2), уравнение Дирака примет вид

$$(\gamma^\mu p_\mu - m)\,u(\mathbf{p}) = \begin{pmatrix} -m & p_\mu\sigma^\mu \\ p_\mu\bar\sigma^\mu & -m \end{pmatrix} u(\mathbf{p}) = 0$$

Здесь мы использовали следующие обозначения: $\sigma^\mu = \left(1, \sigma^i\right), \bar\sigma^\mu = \left(1, -\sigma^i\right)$. Найдём общий вид $u(\mathbf{p})$. Для этого запишем спинор $u(\mathbf{p})$ как

$$u(\mathbf{p}) = \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}$$

Тогда имеем

$$(p\cdot\sigma)u_2 = mu_1, \quad (p\cdot\bar\sigma)u_1 = mu_2$$

Заметим, что $(p\cdot\sigma)(p\cdot\bar\sigma) = m^2$. Действительно,

$$(p\cdot\sigma)(p\cdot\bar\sigma) = p_0^2 - p_ip_j\sigma^i\sigma^j = p_0^2 - p_ip_j\delta^{ij} = p_0^2 - \mathbf{p}^2 = p^2 = m^2$$

Всвязи с этим, представим двухкомпонентный спинор u_1 в виде $u_1 = (p\cdot\sigma)\xi'$. В таком случае спинор u_2 примет вид: $u_2 = m\xi'$. Значит,

$$u(\mathbf{p}) = A\begin{pmatrix} (p\cdot\sigma)\xi' \\ m\xi' \end{pmatrix}$$

Выбирая $A = \frac{1}{m}, \xi' = \sqrt{p\cdot\bar\sigma}\xi\ \left(\xi^\dagger\xi = 1\right)$, получаем

$$u(\mathbf{p}) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar\sigma}\xi \end{pmatrix}$$

Аналогично можно рассмотреть и отрицательно частотные решения уравнения Дирака:

$$\psi = v(\mathbf{p})e^{\mathrm{i}p\cdot x}$$
$$(\gamma^\mu p_\mu + m)\,v(\mathbf{p}) = \begin{pmatrix} m & p_\mu\sigma^\mu \\ p_\mu\bar\sigma^\mu & m \end{pmatrix} v(\mathbf{p}) = 0$$

Решение имеет вид:

$$v(\mathbf{p}) = \begin{pmatrix} \sqrt{p\cdot\sigma}\eta \\ -\sqrt{p\cdot\bar\sigma}\eta \end{pmatrix}$$

где η - некоторый постоянный двухкомпонентный спинор с нормировкой $\eta^\dagger\eta = 1$. Вычислим теперь суммы по поляризациям $\sum\limits_s u_s(\mathbf{p})\bar u_s(\mathbf{p}), \sum\limits_s v_s(\mathbf{p})\bar v_s(\mathbf{p})$:

$$\sum_s u_s(\mathbf{p})\bar u_s(\mathbf{p}) = \sum_s \begin{pmatrix} \sqrt{p\cdot\sigma}\xi_s \\ \sqrt{p\cdot\bar\sigma}\xi_s \end{pmatrix}\left(\xi_s^\dagger\sqrt{p\cdot\bar\sigma}, \xi_s^\dagger\sqrt{p\cdot\sigma}\right) = \begin{pmatrix} m & p_\mu\sigma^\mu \\ p_\mu\bar\sigma^\mu & m \end{pmatrix} = p\gamma + m = \not{p} + m$$

Здесь учтено, что $\sum\limits_s \xi_s\xi_s^\dagger = 1$. Аналогично находим, что

$$\sum_s v_s(\mathbf{p})\bar v_s(\mathbf{p}) = \sum_s \begin{pmatrix} \sqrt{p\cdot\sigma}\eta_s \\ -\sqrt{p\cdot\bar\sigma}\eta_s \end{pmatrix}\left(-\eta_s^\dagger\sqrt{p\cdot\bar\sigma}, \eta_s^\dagger\sqrt{p\cdot\sigma}\right) = \begin{pmatrix} -m & p_\mu\sigma^\mu \\ p_\mu\bar\sigma^\mu & -m \end{pmatrix} = p\gamma - m = \not{p} - m$$

МФТИ-Мусаев-2023. 7. Оператор спиральности

Доказать, что оператор спиральности $\chi = \frac{1}{2}\vec\Sigma\vec n$ (где $\vec\Sigma = \gamma_0\gamma_5\vec\gamma$, $\vec n$ - единичный вектор вдоль импульса частицы, $\gamma_5 = -i\gamma_0\gamma_1\gamma_2\gamma_3$) коммутирует со свободным дираковским гамильтонианом. Найти собственные значения оператора спиральности.

МФТИ-Мусаев-2023**.8. Суммы произведений биспиноров**

Вычислить суммы произведений биспиноров

$$\sum_{\sigma} u(\sigma, \pm E, \vec{p})\bar{u}(\sigma, \pm E, \vec{p}), \qquad \text{где} \qquad E = \sqrt{p^2 + m^2} > 0.$$

по спиральности частиц $\sigma = \pm\frac{1}{2}$.

МФТИ-Мусаев-2023**.9**/19 **Гамма матрицы**

Пусть $A = A_\mu\gamma_\mu$, а R - произвольное матричное выражение. Доказать равенство

$$\gamma_\mu A R \gamma_\mu + A\gamma_\mu R\gamma_\mu = 2RA$$

МФТИ-Мусаев-2023**.10**/19

Найти сохраняющийся оператор, соответствующий инвариантности лагранжиана дираковского поля относительно лоренцевых бустов и трехмерных поворотов. Выразить его в терминах операторов рождения и уничтожения электронов и позитронов. Вычислить спин возбуждений дираковского поля, при условии, что спин безмассового векторного поля равен 1.

МФТИ-Мусаев-2023**.11**/19

Показать, что при унитарных преобразованиях

$$UU^+ = U^+U = 1$$

не меняются нормировка состояний, средние значения операторов, коммутационные соотношения, свойство эрмитовости операторов, собственные значения операторов.

26.2 Problems about Useful QFT Formalism

26.2.1 Problems about operators in QFT

26.2.2 Problems about propagators in QFT

МФТИ-Мусаев-2023**.1**/19 **Причинность**

Показать, что фейнмановская функция Грина свободного действительного скалярного поля является причинной. В каком смысле следует понимать причинность?

МФТИ-Мусаев-2023**.2**/19 **Смысл пропагатора**

Показать, что пропагатор скалярной частицы

$$D(x-y) = i\langle 0|\mathbf{T}\{\phi(x)\phi(y)\}|0\rangle$$

описывает следующие последовательности событий: **a)** при $t_x > t_y$ в точке y рождается частица, которая затем уничтожается в точке x; **b)** при $t_x < t_y$ частица рождается в точке x и уничтожается в точке y;
Проверить в x - и p-представлениях, что D пропорциональна функции Грина оператора д'Аламбера $\Box$.

26.2.3 Problems about path integral formalism in QFT 1

Белавин-Пархоменко**.7.1 Действие мировой линии и пропагатор Фейнмана**

(a).

Классическое действие для релятивистской частицы массы m дается произведением m с собственным временем вдоль мировой линии частицы

$$S[x] = -m \int d\tau = -m \int_0^1 ds \sqrt{-\dot{x}^\mu \dot{x}_\mu}, \tag{0.1}$$

где $\dot{A} = \frac{\partial A}{\partial s}$. Такое релятивисткое действие мировой линии инвариантно относительно репараметризаций $s \to s'(s)$, где $s'(0) = 0, s'(1) = 1$, and $ds'/ds > 0$. Введем множитель Лагранжа $\lambda(s) > 0$. Покажите, что следующее действие

$$S[x, \lambda] = \frac{1}{2} \int_0^1 ds \left(\frac{\dot{x}^2(s)}{\lambda(s)} - m^2 \lambda(s) \right) \tag{0.2}$$

классически эквивалентно (в итоге дает тоже самое уравнение движения для x^μ) действию (0.1). (Подсказка: Исключите $\lambda(s)$ из уравнений движения.) Теперь в добавок, мы введем импульс p_μ. Покажите, что

$$S[x, \lambda, p] = - \int_0^1 ds \left(\dot{x}^\mu p_\mu + \frac{\lambda}{2} \left(p^2 + m^2 \right) \right) \tag{0.3}$$

классически эквивалентно действию (0.1).

(b).

Покажите, что действие (0.3) инвариантно относительно репараметризаций, если $\lambda(s)$ преобразуется определенным образом. Используя эту инвариантность, покажите, что можно фиксировать $\lambda(s) = \tau$, где $\tau > 0$ и не зависит от s.

Теперь мы определим пропагатор Фейнмана $G_F(x, y)$ как интеграл по путям из одной точки пространства x в другую y:

$$G_F(x, y) = \int_x^y [dx] \int [d\lambda][dp] e^{\frac{i}{\hbar} S[x, \lambda, p]} \tag{0.4}$$

(c).

Используя эквивалентность между инегралом по путям и Шредингеровской формулировкой квантовой механики, покажите, что

$$G_F(x, y) = \int_0^\infty d\tau \left\langle y \left| e^{-\frac{i}{\hbar} \hat{H} \tau} \right| x \right\rangle \tag{0.5}$$

с $\hat{H} = \hat{p}^2 + m^2$.

Интеграл по τ, как мы уже знаем, называется интегралом Швингера по собственному времени. Чтобы сделать этот интеграл формально хорошо определенным - сходящимся, мы добаляем маленькую мнимую часть к Гамильтониану $\hat{H} \to \hat{H} - i\epsilon$.

(d). Покажите, что это требование сходимости, по сути эквивалентно $i\epsilon$ прескрипции для пропагатора Фейнмана:

$$G_F(x, y) = \int \frac{d^4 p}{(2\pi)^4} \frac{e^{ip(x-y)}}{p^2 + m^2 - i\epsilon} \tag{0.6}$$

Белавин-Пархоменко.7.1 Действие мировой линии и пропагатор Фейнмана

(a). Классическое действие для релятивистской частицы массы m дается произведением m с собственным временем вдоль мировой линии частицы

$$S[x] = -m \int d\tau = -m \int_0^1 ds \sqrt{-\dot{x}^\mu \dot{x}_\mu} \tag{0.1}$$

где $\dot{A} = \frac{\partial A}{\partial s}$. Такое релятивисткое действие мировой линии инвариантно относительно репараметризаций $s \to s'(s)$, где $s'(0) = 0, s'(1) = 1$, and $ds'/ds > 0$. Введем множитель Лагранжа $\lambda(s) > 0$. Покажем, что следующее действие

$$S[x, \lambda] = \frac{1}{2} \int\limits_0^1 ds \left(\frac{\dot{x}^2(s)}{\lambda(s)} - m^2 \lambda(s) \right) \tag{0.2}$$

классически эквивалентно)- в итоге дает тоже самое уравнение движения для x^μ) действию (0.1). С одной стороны для уравнения (0.1) получаем следующие уравнения движения

$$\delta_x S[x] = 0, \quad \text{откуда:} \quad \frac{d}{ds} \left(\frac{m \dot{x}^\mu}{\sqrt{-\dot{x}^\mu \dot{x}_\mu}} \right) = 0 \tag{0.3}$$

С другой стороны уравнения движения для уравнения (0.2) следующие

$$\delta_\lambda S[x, \lambda] = 0, \quad \text{откуда:} \quad \frac{\dot{x}^2}{\lambda^2} + m^2 = 0, \tag{0.4}$$

и мы находим $\lambda = \frac{1}{m}\sqrt{-\dot{x}^2}$. Теперь подставляя это в действие (0.2) мы получим

$$S[x, \lambda] = \frac{1}{2} \int\limits_0^1 ds \left(-m \frac{-\dot{x}^2}{\sqrt{-\dot{x}^2}} - m^2 \frac{1}{m} \sqrt{-\dot{x}^2} \right) = -m \int\limits_0^1 ds \sqrt{-\dot{x}^\mu \dot{x}_\mu} = S[x] \tag{0.5}$$

Альтернативно мы можем также найти уравнения движения для x у уравнения (0.2), имеем

$$\delta_x S[x, \lambda] = 0, \quad \text{откуда:} \quad \frac{d}{ds} \left(\frac{\dot{x}^\mu}{\lambda} \right) = 0 \tag{0.6}$$

подставляя в него $\lambda = \frac{1}{m}\sqrt{-\dot{x}^2}$, получим

$$\frac{d}{ds} \left(\frac{m \dot{x}^\mu}{\sqrt{-\dot{x}^\mu \dot{x}_\mu}} \right) = 0 \tag{0.7}$$

что совпадает с уравнениями движения для исходного действия $S[x]$. Теперь в добавок, мы введем импульс p_μ. Покажем, что

$$S[x, \lambda, p] = - \int\limits_0^1 ds \left(\dot{x}^\mu p_\mu + \frac{\lambda}{2} \left(p^2 + m^2 \right) \right) \tag{0.8}$$

классически эквивалентно действию (0.1). Аналогично находим уравнения движения, из вариации действия по импульсу:

$$\delta_p S[x, \lambda, p] = 0, \quad \text{откуда:} \quad \dot{x}^\mu + \lambda p^\mu = 0 \tag{0.9}$$

откуда мы находим, что $p^\mu = -\frac{1}{\lambda}\dot{x}^\mu$ и подставляя это в действие (0.8) имеем

$$S[x, \lambda, p] = - \int\limits_0^1 ds \left(-\dot{x}^\mu \frac{1}{\lambda} \dot{x}_\mu + \frac{\lambda}{2} \left(\frac{1}{\lambda^2} \dot{x}^2 + m^2 \right) \right) = \frac{1}{2} \int\limits_0^1 ds \left(\frac{\dot{x}^2(s)}{\lambda(s)} - m^2 \lambda(s) \right) = S[x, \lambda]. \tag{0.10}$$

То есть мы пришли к действию $S[x, \lambda]$, которое как мы уже показали эквивалентно действию $S[x]$.
(b). Покажем, что действие (0.8) инвариантно относительно репараметризаций, если $\lambda(s)$ преобразуется определенным образом. Имеем, при преобразовании $s' = s'(s)$:

$$ds' = \frac{ds'}{ds} ds, \quad \frac{dx^\mu}{ds} = \frac{dx^\mu}{ds'} \frac{ds'}{ds} \tag{0.11}$$

и теперь если мы определим преобразование для $\lambda(s)$ как $\lambda(s) = \lambda'(s') \frac{ds'}{ds}$, то мы получим

$$S[x,\lambda,p] = -\int ds\left(\dot{x}^\mu p_\mu + \frac{\lambda}{2}\left(p^2+m^2\right)\right) = -\int\limits_0^1 ds'\frac{ds}{ds'}\left(\frac{ds'}{ds}\frac{dx^\mu}{ds'}p_\mu + \frac{ds'}{ds}\frac{\lambda'(s')}{2}\left(p^2+m^2\right)\right) =$$

$$= -\int\limits_0^1 ds'\left(\frac{dx^\mu}{ds'}p_\mu + \frac{\lambda'(s')}{2}\left(p^2+m^2\right)\right) = S[x,\lambda,p]. \tag{0.12}$$

Используя эту инвариантность, покажем, что можно фиксировать $\lambda(s)=\tau$, где $\tau>0$ и не зависит от s. Имеем

$$\lambda'(s') = \frac{ds}{ds'}\lambda(s) \tag{0.13}$$

и пусть $\lambda'(s')=\tau>0$, тогда мы получаем уравнение для $s'(s)$:

$$\frac{ds}{ds'}\lambda(s)=\tau, \quad \text{откуда} \quad \frac{ds'}{ds}=\frac{1}{\tau}\lambda(s) \tag{0.14}$$

и решение данного уравнения

$$s'(s) = \frac{1}{\tau}\int\limits_0^s \lambda(x)dx, \quad \text{где} \quad \tau = \int\limits_0^1 \lambda(s)ds \tag{0.15}$$

То есть мы явно построили преобразование $s'(s)$ при котором $\lambda'(s')=\tau$.
Теперь мы определим пропагатор Фейнмана $G_F(x,y)$ как интеграл по путям из одной точки пространства x в другую y:

$$G_F(x,y) = \int\limits_x^y [dx]\int [d\lambda][dp]e^{\frac{i}{\hbar}S[x,\lambda,p]} \tag{0.16}$$

(c). Используя эквивалентность между инегралом по путям и Шредингеровской формулировкой квантовой механики, покажем, что

$$G_F(x,y) = \int\limits_0^\infty d\tau\left\langle y\left|e^{-\frac{i}{\hbar}\hat{H}\tau}\right|x\right\rangle \tag{0.17}$$

с $\hat{H}=\hat{p}^2+m^2$. Имеем

$$\int [d\lambda] = \text{Vol(diff)}\times\int\limits_0^\infty d\tau \tag{0.18}$$

где Vol(diff) - объем группы репараметризаций. (На самом деле данная формула требует уточнения и более детального вывода, но здесь мы опустим эти детали). В итоге получаем

$$G_F(x,y) = \int\limits_x^y [dx]\int [d\lambda][dp]e^{\frac{i}{\hbar}S[x,\lambda,p]} = \int\limits_0^\infty d\tau\int\limits_x^y [dx][dp]e^{-\frac{i}{\hbar}\int\limits_0^1 ds\left(\dot{x}^\mu p_\mu+\frac{\tau}{2}\left(p^2+m^2\right)\right)}. \tag{0.19}$$

С другой стороны мы знаем, что

$$\left\langle y\left|e^{-\frac{iHT}{\hbar}}\right|x\right\rangle = \int [dx][dp]e^{\frac{i}{\hbar}\int\limits_0^T dt(p_\mu\dot{x}^\mu - H(x,p))} \tag{0.20}$$

откуда получим

$$\int\limits_x^y [dx][dp]e^{-\frac{i}{\hbar}\int\limits_0^1 ds\left(\dot{x}^\mu p_\mu+\frac{\tau}{2}\left(p^2+m^2\right)\right)} = \left\langle y\left|e^{\frac{i}{\hbar}\left(-\frac{\tau}{2}\left(p^2+m^2\right)\right)}\right|x\right\rangle = \left\langle y\left|e^{-\frac{i}{\hbar}\hat{H}\frac{\tau}{2}}\right|x\right\rangle. \tag{0.21}$$

Далее переобозначим τ, как $\tau \to 2\tau$, чтобы избавиться от лишнего фактора $1/2$. Такой скейлинг приведет к коэффициенту 2 перед всем интегралом, но у нас уже и так есть численный коэффициент, равный объему группы репараметризаций, так что все вычисления которые мы делаем, определены с точностью до константы. В итоге находим

$$G_F(x,y) = \int\limits_0^\infty d\tau \left\langle y \left| e^{-\frac{i}{\hbar}\hat{H}\tau} \right| x \right\rangle \tag{0.22}$$

Интеграл по τ, как мы уже знаем, называется интегралом Швингера по собственному времени. Чтобы сделать этот интеграл формально хорошо определенным - сходящимся, мы добаляем маленькую мнимую часть к Гамильтониану $\hat{H} \to \hat{H} - i\epsilon$.

(d). Покажем, что это требование сходимости, по сути эквивалентно $i\epsilon$ прескрипции для пропагатора Фейнмана:

$$G_F(x,y) = \int \frac{d^4p}{(2\pi)^4} \frac{e^{ip(x-y)}}{p^2 + m^2 - i\epsilon}. \tag{0.23}$$

Вставим два раза полный набор состояний $1 = \int \frac{d^4p}{(2\pi)^4} |p\rangle\langle p|$ в формулу для $G_F(x,y)$, получим

$$\begin{aligned} G_F(x,y) &= \int\limits_0^\infty d\tau \left\langle y \left| e^{-\frac{i}{\hbar}(\hat{H}-i\epsilon)\tau} \right| x \right\rangle = \int\limits_0^\infty d\tau \int \frac{d^4p d^4q}{(2\pi)^8} \langle y|q\rangle \left\langle q \left| e^{-\frac{i}{\hbar}(\hat{H}-i\epsilon)\tau} \right| p \right\rangle \langle p|x\rangle = \\ &= \int\limits_0^\infty d\tau \int \frac{d^4p d^4q}{(2\pi)^8} e^{-iqy} (2\pi)^4 \delta(p-q) e^{-\frac{i}{\hbar}\left(p^2+m^2-i\epsilon\right)\tau} e^{ipx} = \\ &= \int \frac{d^4p}{(2\pi)^4} e^{ip(x-y)} \int\limits_0^\infty d\tau e^{-\frac{i}{\hbar}\left(p^2+m^2-i\epsilon\right)\tau} = \int \frac{d^4p}{(2\pi)^4} e^{ip(x-y)} \frac{\hbar}{i\left(p^2+m^2-i\epsilon\right)} \end{aligned} \tag{0.24}$$

Но, так как мы вычисляем все с точностью до константы, то мы действительно можем написать, что

$$G_F(x,y) = \int \frac{d^4p}{(2\pi)^4} \frac{e^{ip(x-y)}}{p^2 + m^2 - i\epsilon}. \tag{0.25}$$

Белавин-Пархоменко.7.2 Сходимость теории возмущений в 0 -мерной КТП

Большое понимание КТП может быть получено из изучения интеграла

$$Z(j) = \int\limits_{-\infty}^{\infty} dx e^{-\frac{1}{2}x^2 - \frac{\lambda}{4!}x^4 + jx} \tag{0.7}$$

где $\lambda \geqslant 0$ и $j \in \mathbb{R}$. Этот интеграл может рассматриваться как производящий функционал для Евклидовой КТП в $d = 0$ пространстве времени. Заметим, что данный интеграл быстро сходится.

(a). Положите $\lambda = 0$ и вычислите $Z(j)$ в этом случае. Используйте это, чтобы вычислить свободные "функции Грина":

$$\langle x^n \rangle = \frac{\int\limits_{-\infty}^{\infty} dx x^n e^{-\frac{1}{2}x^2}}{\int dx e^{-\frac{1}{2}x^2}} \tag{0.8}$$

где $n \geqslant 1$. Дайте интерпретацию результата в терминах диаграмм Фейнмана и покажите, что для $n = 2, 4, 6, 8$ функции Грина корректно даются их симметрийным фактором.

(b). Теперь рассмотрим $Z(0)$ для $\lambda > 0$. Предполагая, что λ достаточно мало, разложите $Z(0)$ по теории возмущений $Z(0) = \sum\limits_{n=0}^{\infty} \lambda^n Z_n$ и вычислите Z_n. Покажите, что Z_n растет факториально с $n \to \infty$ и по этому теория возмущений (ряд Тейлора) имеет нулевой радиус сходимости. Объясните этот результат в терминах интегрального представления для $Z(0)$.

Казалось бы результат пункта (b) является катастрофой для нашей уверенности в теории возмущений для КТП. На самом деле, такая ситуация закономерна и в Квантовой механике и в КТП, по причинам подобным

тем, что мы наблюдали на нашем примере. Эта ситуация не безнадежна по двум причинам. Первая причина состоит в том, что теория возмущений все равно имеет смысл как асимптотическое разложение: покуда мы ограничиваем наше разложение до порядка $n \lesssim \lambda^{-1}$ в теории возмущений, пертурбативный ответ дает нам хорошее приближение к полному ответу. Вторая причина в том, что существуют разные методы (такие как преобразование Бореля), которые позволяют получить полный ответ из знания коэффициентов Z_n теории возмущений, даже если такой ряд формально расходится.

Белавин-Пархоменко .7.2 Сходимость теории возмущений в 0 -мерной Квантовой теории поля (КТП)

Большое понимание КТП может быть получено из изучения интеграла

$$Z(j) = \int\limits_{-\infty}^{\infty} dx e^{-\frac{1}{2}x^2 - \frac{\lambda}{4!}x^4 + jx} \tag{0.26}$$

где $\lambda \geqslant 0$ и $j \in \mathbb{R}$. Этот интеграл может рассматриваться как производящий функционал для Евклидовой КТП в $d = 0$ пространстве времени. Заметим, что данный интеграл быстро сходится.

(a). Положим $\lambda = 0$ и вычислим $Z(j)$ в этом случае. Имеем

$$Z(j) = \int\limits_{-\infty}^{\infty} dx e^{-\frac{1}{2}x^2 + jx} = \int dx e^{-\frac{1}{2}(x-j)^2 + \frac{j^2}{2}} = \sqrt{2\pi} e^{\frac{1}{2}j^2} \tag{0.27}$$

Используем это, чтобы вычислить свободные "функции Грина":

$$\langle x^n \rangle = \frac{\int\limits_{-\infty}^{\infty} dx x^n e^{-\frac{1}{2}x^2}}{\int dx e^{-\frac{1}{2}x^2}} \tag{0.28}$$

где $n \geqslant 1$. Очевидно, что если $n = 2k+1$ то $\left\langle x^{2k+1} \right\rangle = 0$. Для $n = 2k$ получим

$$\left\langle x^{2k} \right\rangle = \left(\frac{d}{dj} \right)^{2k} e^{\frac{j^2}{2}} \Bigg|_{j=0} = (2k-1)!! \tag{0.29}$$

В итоге получаем

$$\langle x^n \rangle = \begin{cases} 0, & n \text{ нечетное} \\ (n-1)!!, & n \text{ четное.} \end{cases} \tag{0.30}$$

В терминах диаграмм Фейнмана, $\left\langle x^{2k} \right\rangle$ есть число способов соединить $2k$ точек попарно:

(b). Теперь рассмотрим $Z(0)$ для $\lambda > 0$. Предполагая, что λ достаточно мало, разложим $Z(0)$ по теории возмущений $Z(0) = \sum\limits_{n=0}^{\infty} \lambda^n Z_n$ и вычислим Z_n. Имеем

$$\begin{aligned} Z(0) &= \int dx e^{-\frac{1}{2}x^2 - \frac{\lambda}{4!}x^4} = \int dx \sum_{n=0}^{\infty} \frac{1}{n!} \left(-\frac{\lambda}{4!} x^4 \right)^n e^{-\frac{1}{2}x^2} = \sum_{n=0}^{\infty} \frac{1}{n!} \left(-\frac{\lambda}{4!} \right)^n \int dx x^{4n} e^{-\frac{1}{2}x^2} = \\ &= \sqrt{2\pi} \sum_{n=0}^{\infty} \frac{1}{n!} \left(-\frac{\lambda}{4!} \right)^n \left\langle x^{4n} \right\rangle . \end{aligned} \tag{0.31}$$

В итоге получаем для Z_n:

$$Z_n = \sqrt{2\pi} \frac{(-1)^n}{n!(4!)^n} \left\langle x^{4n} \right\rangle = \sqrt{2\pi}(-1)^n \frac{(4n-1)!!}{n!(4!)^n} = \sqrt{2\pi}(-1)^n \frac{(4n)!}{2^{2n}(2n)!n!(4!)^n} = \frac{\sqrt{2\pi}(-1)^n}{2^{5n}3^n} \frac{(4n)!}{n!(2n)!} \tag{0.32}$$

Покажем, что Z_n растет факториально с $n \to \infty$, для этого используем формулу Стирлинга:

$$n! \approx \sqrt{2\pi n}\left(\frac{n}{e}\right)^n \tag{0.33}$$

откуда получаем

$$Z_n = \frac{\sqrt{2\pi}(-1)^n}{2^{5n}3^n}\frac{(4n)!}{n!(2n)!} \sim \frac{1}{2^{5n}3^n}\frac{(4n)^{4n}}{n^n(2n)^{2n}}\frac{e^n e^{2n}}{e^{4n}} = \frac{2^n}{3^n}\frac{n^n}{e^n} \sim \left(\frac{2}{3}n\right)! \tag{0.34}$$

и по этому теория возмущений (ряд Тейлора) имеет нулевой радиус сходимости. Если бы данный ряд имел ненулевой радиус сходимости $R > 0$, то мы бы получили

$$Z(0) = \sum_{n=0}^{\infty} \lambda^n Z_n \leqslant \sum_{n=0}^{\infty} R^n Z_n \tag{0.35}$$

для $|\lambda| < R$, но тогда $Z(0)$ было бы конечным при $\lambda < 0$, но очевидно, что при $\lambda < 0$ наш интеграл $Z(0)$ расходится.

Казалось бы результат пункта (b) является катастрофой для нашей уверенности в теории возмущений для КТП. На самом деле, такая ситуация закономерна и в Квантовой механике и в КТП, по причинам подобным тем, что мы наблюдали на нашем примере. Эта ситуация не безнадежна по двум причинам. Первая причина состоит в том, что теория возмущений все равно имеет смысл как асимптотическое разложение: покуда мы ограничиваем наше разложение до порядка $n \lesssim \lambda^{-1}$ в теории возмущений, пертурбативный ответ дает нам хорошее приближение к полному ответу. Вторая причина в том, что существуют разные методы (такие как преобразование Бореля), которые позволяют получить полный ответ из знания коэффициентов Z_n теории возмущений, даже если такой ряд формально расходится.

Белавин-Пархоменко.7.3 Уравнение Швингера-Дайсона и петлевое разложение

В интеграле по путям мы тоже можем интегрировать по частям. В этой задаче вы покажите, что это позволяет получить так называемые уравнения Швингера-Дайсона, которые утверждают, что классические уравнения движения выполняются внутри корреляционных функций, с точностью до контактных членов.

(a).

Для разминки, рассмотрите интеграл $I[J] = \int\limits_{-\infty}^{\infty} dx e^{-s(x)-Jx}$ с $s(x) = \frac{1}{2}x^2 + \frac{\lambda}{4!}x^4$. Покажите, что $I[J]$ удовлетворяет дифференциальному уравнению $\left(J + s'\left[-\frac{\partial}{\partial J}\right]\right) I[J] = 0$. Это уравнение Швингера-Дайсона для интеграла $I[J]$ - игрушечной модели производящего функционала в КТП.

(b).

Теперь, рассмотрите статистическую сумму $Z[J] = \int [d\phi] e^{\frac{i}{\hbar}S[\phi(x)] + \frac{i}{\hbar}\int d^d x J(x)\phi(x)}$, для взаимодействующей теории поля

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu \phi\right)^2 - \frac{1}{2}m^2\phi^2 - \frac{g}{3!}\phi^3, \tag{0.9}$$

с источником $J(x)$. Выведите уравнение Швингера-Дайсона для $Z[J]$.

Теперь возьмем оператор, среднее которого мы хотим найти, например произведение полей. Обозначим такой оператор $f[\phi]$. Определим среднее такого оператора $f[\phi]$ как

$$\langle f[\phi] \rangle = \frac{\int [d\phi] f[\phi] e^{\frac{i}{\hbar}S[\phi]}}{\int [d\phi] e^{\frac{i}{\hbar}S[\phi]}} \tag{0.10}$$

(c).

Выведите следующее уравнение:

$$\left\langle \frac{\delta f[\phi]}{\delta \phi(x)} + \frac{i}{\hbar} f[\phi] \frac{\delta S[\phi]}{\delta \phi(x)} \right\rangle = 0 \tag{0.11}$$

(d).

Рассмотрите разложение $Z[J]$ в терминах статистической суммы свободной теории $Z_0[J]$. Покажите, что такое разложение может быть записанно как ряд по $\hbar$. Также рассмотрите Z[0] как разложение по диаграммам Фейнмана. Покажите, что каждая связная диаграмма Фейнмана пропорциональна $\hbar^{L-1}$, где L - количество петель в диаграмме (количество незафиксированных импульсов у пропагаторов). Чтобы показать это, изучите как зависят пропагаторы и вершины от $\hbar$. А затем покажите, что число петель L в связной диаграмме Фейнмана связанно с количеством пропагаторов P и вершин V по формуле $L = P - V + 1$. (Подсказка: используйте то, что в каждой вершине должен выполняться закон сохранения импульса)

Белавин-Пархоменко.7.3 Уравнение Швингера-Дайсона и петлевое разложение

В интеграле по путям мы тоже можем интегрировать по частям. В этой задаче мы покажем, что это позволяет получить так называемые уравнения Швингера-Дайсона, которые утверждают, что классические уравнения движения выполняются внутри корреляционных функций, с точностью до контактных членов.

(a). Для разминки, рассмотрим интеграл $I[J] = \int\limits_{-\infty}^{\infty} dx e^{-s(x)-Jx}$ с $s(x) = \frac{1}{2}x^2 + \frac{\lambda}{4!}x^4$. Покажем, что $I[J]$ удовлетворяет дифференциальному уравнению $\left(J + s'\left[-\frac{\partial}{\partial J}\right]\right) I[J] = 0$. Это уравнение Швингера-Дайсона для интеграла $I[J]$ - игрушечной модели производящего функционала в КТП. Имеем

$$\int\limits_{-\infty}^{\infty} dx \frac{d}{dx}\left(e^{-s(x)-Jx}\right) = e^{-s(x)-Jx}\Big|_{-\infty}^{\infty} = 0 \tag{0.36}$$

с другой стороны

$$0 = \int\limits_{-\infty}^{\infty} dx \frac{d}{dx}\left(e^{-s(x)-Jx}\right) = \int\limits_{-\infty}^{\infty} dx \left(-J - s'(x)\right) e^{-s(x)-Jx} = -\left(J + s'\left[-\frac{\partial}{\partial J}\right]\right) I[J] \tag{0.37}$$

Так как $s'(x) = x + \frac{\lambda}{6}x^3$, получим

$$\left(\frac{\lambda}{6}\frac{\partial^3}{\partial J^3} + \frac{\partial}{\partial J} - J\right) I[J] = 0 \tag{0.38}$$

(b). Теперь, рассмотрим статистическую сумму $Z[J] = \int [d\phi] e^{\frac{i}{\hbar}S[\phi(x)] + \frac{i}{\hbar}\int d^d x J(x)\phi(x)}$, для взаимодействующей теории поля

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu \phi\right)^2 - \frac{1}{2}m^2\phi^2 - \frac{g}{3!}\phi^3, \tag{0.39}$$

с источником $J(x)$. Выведим уравнение Швингера-Дайсона для $Z[J]$. Имеем

$$\begin{aligned} 0 = \int [d\phi] \frac{\delta}{\delta\phi(y)}\left(e^{\frac{i}{\hbar}S[\phi(x)] + \frac{i}{\hbar}\int d^d x J(x)\phi(x)}\right) = \int [d\phi]\left(\frac{i}{\hbar}\frac{\delta S[\phi]}{\delta\phi(y)} + \frac{i}{\hbar}J(y)\right) e^{\frac{i}{\hbar}S[\phi(x)] + \frac{i}{\hbar}\int d^d x J(x)\phi(x)} = \\ = \frac{i}{\hbar}\left(J(y) + \frac{\delta S\left[\frac{\hbar}{i}\frac{\delta}{\delta J(x)}\right]}{\delta\phi(y)}\right) Z[J] = 0 \end{aligned} \tag{0.40}$$

Далее находим $\frac{\delta S}{\delta\phi(y)} = -\left(\partial^2 + m^2\right)\phi(y) - \frac{g}{2}\phi^2(y)$. И мы получим

$$\left(\frac{g}{2}\left(\frac{\hbar}{i}\frac{\delta}{\delta J(y)}\right)^2 + \left(\partial^2 + m^2\right)\left(\frac{\hbar}{i}\frac{\delta}{\delta J(y)}\right) - J(y)\right) Z[J] = 0 \tag{0.41}$$

Теперь возьмем оператор, среднее которого мы хотим найти, например произведение полей. Обозначим такой оператор $f[\phi]$. Определим среднее такого оператора $f[\phi]$ как

$$\langle f[\phi]\rangle = \frac{\int [d\phi] f[\phi] e^{\frac{i}{\hbar}S[\phi]}}{\int [d\phi] e^{\frac{i}{\hbar}S[\phi]}} \tag{0.42}$$

(c). Выведим следующее уравнение:

$$\left\langle \frac{\delta f[\phi]}{\delta\phi(x)} + \frac{i}{\hbar} f[\phi] \frac{\delta S[\phi]}{\delta\phi(x)} \right\rangle = 0 \tag{0.43}$$

Имеем

$$0 = \frac{\int [d\phi] \frac{\delta}{\delta\phi(x)} \left(f[\phi] e^{\frac{i}{\hbar} S[\phi]} \right)}{\int [d\phi] e^{\frac{i}{\hbar} S[\phi]}} = \left\langle \frac{\delta f[\phi]}{\delta\phi(x)} + \frac{i}{\hbar} f[\phi] \frac{\delta S[\phi]}{\delta\phi(x)} \right\rangle \tag{0.44}$$

(d). Рассмотрим разложение $Z[J]$ в терминах статистической суммы свободной теории $Z_0[J]$. Покажем, что такое разложение может быть записанно как ряд по $\hbar$. Имеем

$$Z[J] = \int [d\phi] e^{\frac{i}{\hbar} \int d^d x \left(\frac{1}{2} (\partial_\mu \phi)^2 - \frac{1}{2} m^2 \phi^2 - \frac{g}{3!} \phi^3 \right) + \frac{i}{\hbar} \int d^d x J(x) \phi(x)} \tag{0.45}$$

Сделаем замену $\phi \to \sqrt{\hbar}\phi$ и $J \to \sqrt{h} J$, тогда получим

$$\begin{aligned} Z[J] &= \int [d\phi] e^{i \int d^d x \left(\frac{1}{2} (\partial_\mu \phi)^2 - \frac{1}{2} m^2 \phi^2 - \frac{g\sqrt{\hbar}}{3!} \phi^3 \right) + i \int d^d x J(x) \phi(x)} = \\ &= \int [d\phi] \sum_{n=0}^{\infty} \left(\int d^d x \frac{-ig\sqrt{\hbar}\phi^3}{3!} \right)^n e^{iS_0[\phi] + i \int d^d x J(x) \phi(x)} = \sum_{n=0}^{\infty} \hbar^{n/2} \left(\int d^d x \frac{g}{3!} \frac{\delta^3}{\delta J(x)^3} \right)^n Z_0[J] \end{aligned} \tag{0.46}$$

Также рассмотрим $Z[0]$ как разложение по диаграммам Фейнмана. Покажем, что каждая связная диаграмма Фейнмана пропорциональна $\hbar^{L-1}$, где L - количество петель в диаграмме (количество незафиксированных импульсов у пропагаторов). Имеем

$$\text{Пропагатор } = \langle \phi(x)\phi(y) \rangle = \hbar \int \frac{d^d p}{(2\pi)^d} \frac{i}{p^2 - m^2 + i\epsilon} e^{-ip(x-y)}, \quad \text{Вершина } = \frac{1}{\hbar} \int d^d x \left(-\frac{ig}{3!} \phi^3 \right). \tag{0.47}$$

В фурье пространстве, каждая вершина дает фактор $\sim \frac{1}{\hbar} \delta^{(d)} \left(\sum k_i \right)$, где дельта функция накладывает условия сохранения энергии и импульса в вершине. Каждый пропагатор дает фактор $\sim \hbar \frac{i}{k^2 - m^2}$. Таким образом выражение для диаграммы общего вида с P пропагаторами и V вершинами будет иметь вид

$$\int \frac{d^d k_1 ... d^d k_P}{(2\pi)^{dP}} \frac{\hbar^P i^P}{(k_1^2 - m^2) ... (k_P^2 - m^2)} \frac{1}{\hbar^V} \delta^{(d)} \left(\sum k_{i_1} \right) ... \delta^{(d)} \left(\sum k_{i_V} \right) \sim \hbar^{P-V} \tag{0.48}$$

С другой стороны при интегрировании, дельта функции вершин сократят число интегралов до $L = P - V + 1$. Дополнительная единица в этой формуле происходит из-за того, что остается одна дельта функция, обеспечивающая сохранение входящих и выходящих из диаграммы энергии и импульса. В итоге мы видим, что разложение по петлям идет как $\hbar^{L-1}$, где L - число петель.

Белавин-Пархоменко.8. Функциональный интеграл для фермионных полей

1. Интегралы по Грассмановым переменным

(a). Show that

$$\left(\prod_i \int d\theta_i^* d\theta_i \right) e^{-\theta_i^* B_{ij} \theta_j} = \det B \tag{0.1}$$

где B - Эрмитова матрица, θ_i - комплексные Грассмановые переменные.

b) Compute the Grassman integral

$$\int d\psi_n ... d\psi_1 e^{\frac{1}{2} \sum\limits_{i,j=1}^{n} \psi_i M_{ij} \psi_j} \tag{0.3}$$

где M антисимметричная комплексная матрица коммутирующих чисел (обычная антисимметричная комплексная матрица), а ψ_i - Грассмановы числа.

Solution to a)

Имеем

$$\left(\prod_i \int d\theta_i^* d\theta_i\right) e^{-\theta_i^* B_{ij} \theta_j} = \left(\prod_i \int d\theta_i'^* d\theta_i'\right) e^{-\theta_i'^* b_i \theta_j'} = \prod_i b_i = \det B \tag{0.2}$$

Solution to b)

Данная матрица M может быть приведена к виду

$$M = \begin{pmatrix} 0 & m_1 & & & \\ -m_1 & 0 & & & \\ & & 0 & m_2 & \\ & & -m_2 & 0 & \\ & & & & \ddots \end{pmatrix} \tag{0.4}$$

причем если матрица имеет нечетный размер, то на диагонали вместо последнего блока 2×2 стоит ноль. Таким образом в случае матрицы нечетного размера данный интеграл равен нулю. Для матрицы четного размера $n = 2k$ находим

$$\int d\psi_n ... d\psi_1 e^{\frac{1}{2} \sum\limits_{i,j=1}^{n} \psi_i M_{ij} \psi_j} = \int d\psi'_{2k} d\psi'_{2k-1} ... d\psi'_2 d\psi'_1 e^{m_1 \psi'_1 \psi'_2 + ... m_k \psi'_{2k-1} \psi'_{2k}} = \prod_{i=1}^{k} m_i = \sqrt{\det M} \tag{0.5}$$

2. Теорема Вика для фермионных полей

Выведим формулу для свободного Дираковского поля:

$$\left\langle \psi(x_1) ... \psi(x_n) \bar{\psi}(y_1) ... \bar{\psi}(y_n) \right\rangle = \sum_{i=1}^{n} (-1)^{n+i} S(x_1 - y_i) \left\langle \psi(x_2) ... \psi(x_n) \bar{\psi}(y_1) ... \widehat{\bar{\psi}(y_i)} ... \bar{\psi}(y_n) \right\rangle \tag{0.6}$$

где $\langle \psi(x) \bar{\psi}(y) \rangle = S(x-y)$, а шляпка $\widehat{...}$ над полем означает, что этого поля нет в корреляционной функции.

(Подсказка: Рассмотрите функциональный интеграл: $\langle ... \rangle = \frac{1}{Z} \int D\psi' D\bar{\psi}' ... e^{i \int d^4x \bar{\psi}' (i\not{\partial} - m) \psi'}$. Сделайте сдвиг полей: $\psi'(x) = \psi(x), \bar{\psi}'(x) = \bar{\psi}(x) + \bar{\epsilon}(x)$, где $\bar{\epsilon}(x)$ - инфинитезимальная Грассманова функция. Такой сдвиг не изменит значение функционального интеграла, поэтому можно получить дифференциальное уравнение на корреляционную функцию, решение которого и есть формула (0.3).)

Solution

Рассмотрим функциональный интеграл:

$$\frac{1}{Z} \int D\psi' D\bar{\psi}' \psi'(x_2) ... \psi'(x_n) \bar{\psi}'(y_1) ... \bar{\psi}'(y_n) e^{i \int d^4x \bar{\psi}' (i\not{\partial} - m) \psi'} \tag{0.7}$$

Теперь сделаем замену переменных

$$\psi'(x) = \psi(x), \quad \bar{\psi}'(x) = \bar{\psi}(x) + \bar{\epsilon}(x) \tag{0.8}$$

где $\bar{\epsilon}(x)$ - произвольная инфинитезимальная Грассманова функция, быстро затухающая при $x \to \infty$. Имеем

$$\begin{aligned} &\frac{1}{Z} \int D\psi' D\bar{\psi}' \ \psi'(x_2) ... \psi'(x_n) \bar{\psi}'(y_1) ... \bar{\psi}'(y_n) e^{i \int d^4x \bar{\psi}' (i\not{\partial} - m) \psi'} = \\ &= \frac{1}{Z} \int D\psi D\bar{\psi} \ \psi(x_2) ... \psi(x_n) \left(\bar{\psi}(y_1) ... \bar{\psi}(y_n) + \sum_{i=1}^{n} (-1)^{i-1} \bar{\epsilon}(y_i) \bar{\psi}(y_1) ... \widehat{\bar{\psi}(y_i)} ... \bar{\psi}(y_n) \right) e^{i \int d^4x (\bar{\psi} + \bar{\epsilon}) (i\not{\partial} - m) \psi}, \end{aligned} \tag{0.9}$$

где мы использовали то, что $\bar{\epsilon}$ антикоммутирует со всеми полями. Теперь раскладывая данное выражение до линейных членов по $\bar{\epsilon}$ и учитывая очевидное равенство

$$\frac{1}{Z}\int D\psi' D\bar{\psi}'\psi'\left(x_2\right)...\psi'\left(x_n\right)\bar{\psi}'\left(y_1\right)...\bar{\psi}'\left(y_n\right)e^{i\int d^4x\bar{\psi}'(i\not{\partial}-m)\psi'}= \\ =\frac{1}{Z}\int D\psi D\bar{\psi}\psi\left(x_2\right)...\psi\left(x_n\right)\bar{\psi}\left(y_1\right)...\bar{\psi}\left(y_n\right)e^{i\int d^4x\bar{\psi}(i\not{\partial}-m)\psi} \tag{0.10}$$

получим

$$0=\sum_{i=1}^{n}(-1)^{n+i}\bar{\epsilon}\left(y_i\right)\left\langle\psi\left(x_2\right)...\psi\left(x_n\right)\bar{\psi}\left(y_1\right)...\widehat{\bar{\psi}\left(y_i\right)}...\bar{\psi}\left(y_n\right)\right\rangle+ \\ +i\int d^4x\left(i\not{\partial}_x-m\right)\left\langle\psi\left(x_2\right)...\psi\left(x_n\right)\bar{\psi}\left(y_1\right)...\bar{\psi}_n\left(y_n\right)\bar{\epsilon}(x)\psi(x)\right\rangle, \tag{0.11}$$

откуда, из произвольности $\bar{\epsilon}(x)$, следует, что

$$0=\sum_{i=1}^{n}(-1)^{n+i}\delta^{(4)}\left(x-y_i\right)\left\langle\psi\left(x_2\right)...\psi\left(x_n\right)\bar{\psi}\left(y_1\right)...\widehat{\bar{\psi}\left(y_i\right)}...\bar{\psi}\left(y_n\right)\right\rangle+ \\ +i\left(i\not{\partial}_x-m\right)\left\langle\psi(x)\psi\left(x_2\right)...\psi\left(x_n\right)\bar{\psi}\left(y_1\right)...\bar{\psi}_n\left(y_n\right)\right\rangle \tag{0.12}$$

и мы в итоге получаем уравнение

$$\left(i\not{\partial}_x-m\right)\left\langle\psi(x)\psi\left(x_2\right)...\psi\left(x_n\right)\ \bar{\psi}\left(y_1\right)...\bar{\psi}_n\left(y_n\right)\right\rangle= \\ =\sum_{i=1}^{n}(-1)^{n+i}i\delta^{(4)}\left(x-y_i\right)\left\langle\psi\left(x_2\right)...\psi\left(x_n\right)\bar{\psi}\left(y_1\right)...\widehat{\bar{\psi}\left(y_i\right)}...\bar{\psi}\left(y_n\right)\right\rangle. \tag{0.13}$$

Используя то, что $\left(i\not{\partial}_x-m\right)S(x-y)=\left(i\not{\partial}_x-m\right)\langle\psi(x)\bar{\psi}(y)\rangle=i\delta^{(4)}(x-y)$, мы видим, что решение данного уравнения есть

$$\left\langle\psi(x)...\psi\left(x_n\right)\bar{\psi}\left(y_1\right)...\bar{\psi}\left(y_n\right)\right\rangle=\sum_{i=1}^{n}(-1)^{n+i}S\left(x-y_i\right)\left\langle\psi\left(x_2\right)...\psi\left(x_n\right)\bar{\psi}\left(y_1\right)...\widehat{\bar{\psi}\left(y_i\right)}...\bar{\psi}\left(y_n\right)\right\rangle$$

что и требовалось показать.

3. Задача из Пескина Шредера 9.2 пункт (d)

Пусть $\psi(t)$ и $\bar{\psi}(t)$ два Грассмановых (фермионных) поля. Определим фермионный осциллятор следующим Лагранжианом:

$$L_E=\bar{\psi}\dot{\psi}+\omega\bar{\psi}\psi \tag{0.15}$$

Данный Лагранжиан соответствует Гамильтониану

$$H=\omega\bar{\psi}\psi,\qquad\text{где}\qquad\{\bar{\psi},\psi\}=1 \tag{0.16}$$

то есть это простая двух-уровневая система. Вычислим функциональный интеграл, предполагая что фермионные (Грассмановы) поля удовлетворяют следующим граничным условиям $\psi(t+\beta)=-\psi(t)$

$$Z=\int\limits_{\psi(0)=-\psi(\beta)}D\psi D\bar{\psi}\exp\left(-\int\limits_0^{\beta}dtL_E(\psi(t),\bar{\psi}(t))\right) \tag{0.17}$$

(Подсказка: Используйте разложение в ряд Фурье). Покажите, что ваш результат воспроизводит статистическую сумму квантово-механической двух-уровневой системы - то есть частица может сидеть либо на одном уровне, либо на другом, а расстояние между уровнями ω и температура $T=1/\beta$.

Раскладывая $\psi(t)$ в ряд Фурье

$$\psi(t) = \sum_{n=-\infty}^{\infty} \theta_n \frac{e^{\frac{\pi i t}{\beta}(2n+1)}}{\sqrt{\beta}} \tag{0.18}$$

где θ_n - Грассмановы числа, находим для статистической суммы:

$$Z = \prod_n \int d\bar{\theta}_n d\theta_n e^{-\sum\limits_n \bar{\theta}_n \theta_n \left(\frac{\pi i(2n+1)}{\beta}+\omega\right)} = \prod_{n=-\infty}^{\infty} \left(\frac{\pi i(2n+1)}{\beta}+\omega\right) = \prod_{n=0}^{\infty} \left(\omega^2 + \frac{\pi^2(2n+1)^2}{\beta^2}\right), \tag{0.19}$$

затем мы, беря логарифм, получаем:

$$\ln Z = \sum_{n=0}^{\infty} \ln\left(\omega^2 + \frac{\pi^2(2n+1)^2}{\beta^2}\right) \tag{0.20}$$

Дифференцируя данное выражение по ω, находим

$$\frac{\partial \ln Z}{\partial \omega} = \sum_{n=0}^{\infty} \frac{2\omega}{\omega^2 + \frac{\pi^2(2n+1)^2}{\beta^2}} = \frac{1}{2}\beta \tanh\left(\frac{\beta\omega}{2}\right). \tag{0.21}$$

Теперь находим

$$\ln Z[\omega] = \ln Z[0] + \ln\cosh\frac{\beta\omega}{2} \tag{0.22}$$

и в конечном итоге

$$Z[\omega] = Z[0]\cosh\frac{\beta\omega}{2} \tag{0.23}$$

В свою очередь для двух-уровневой системы с щелью ω мы получаем

$$Z[\omega] = e^{-\beta\omega/2} + e^{\beta\omega/2} = 2\cosh\frac{\beta\omega}{2}. \tag{0.24}$$

Теперь разберемся почему в данном случае мы использовали антипериодические граничные условия. Наша цель записать подходящее выражение для следа некоторого оператора:

$$\mathrm{tr}[\hat{O}] \stackrel{\mathrm{def}}{=} O_{\downarrow\downarrow} + O_{\uparrow\uparrow} \tag{0.25}$$

Во первых, вспомним определение и свойства Грассмановых состояний и операторов. Для Грассманового понижающего оператора $\hat{\psi}$ мы имеем

$$\hat{\psi}|\downarrow\rangle = 0, \quad \hat{\psi}|\uparrow\rangle = |\downarrow\rangle \tag{0.26}$$

где состояние системы $|\uparrow\rangle$ и $|\downarrow\rangle$ удовлетворяют

$$\langle\downarrow|\downarrow\rangle = \langle\uparrow|\uparrow\rangle = 1, \quad \langle\uparrow|\downarrow\rangle = 0. \tag{0.27}$$

Общий вид собственного вектора для такого оператора есть:

$$|\psi\rangle = |\downarrow\rangle + \psi|\uparrow\rangle, \quad \langle\psi| = -\langle\uparrow| + \langle\downarrow|\psi \tag{0.28}$$

и можно проверить, что

$$\hat{\psi}|\psi\rangle = \psi|\psi\rangle, \quad \langle\psi|\hat{\psi} = -\langle\psi|\psi, \quad \langle\psi|\psi'\rangle = \psi - \psi' \tag{0.29}$$

Следует заметить, что у $\langle\psi| = -\langle\uparrow| + \langle\downarrow|\psi$, есть знак минус перед $\langle\uparrow|$! Такое определение для бра состояния нужно, чтобы сделать Грассмановы переменные подобными обычным бозонным, т.е. чтобы иметь

$$1 = \int |\psi\rangle d\psi\langle\psi|, \quad \langle\psi|\psi'\rangle = \delta(\psi - \psi') = \psi - \psi' \tag{0.30}$$

Тогда для любого оператора $\hat{O}$ мы получаем

$$\hat{O}|\uparrow\rangle = |\uparrow\rangle O_{\uparrow\uparrow} + |\downarrow\rangle O_{\downarrow\uparrow}, \quad \hat{O}|\downarrow\rangle = |\downarrow\rangle O_{\downarrow\downarrow} + |\uparrow\rangle O_{\uparrow\downarrow} \tag{0.31}$$

и мы моголи бы ожидать, что формула $\int d\psi \langle\psi|\hat{O}|\psi\rangle$ и есть выражение для следа оператора $\hat{O}$, но

$$\int d\psi \langle\psi|\hat{O}|\psi\rangle = \int d\psi \left(\psi \left(O_{\downarrow\downarrow} - O_{\uparrow\uparrow}\right) - O_{\uparrow\downarrow}\right) = O_{\downarrow\downarrow} - O_{\uparrow\uparrow} = \mathrm{tr}\left[(-1)^{\hat{F}}\hat{O}\right] \tag{0.32}$$

где $(-1)^F$ действует как

$$\langle\uparrow|(-1)^F = -\langle\uparrow|, \quad \langle\downarrow|(-1)^F = \langle\downarrow|. \tag{0.33}$$

То есть мы видим, что такое наивное определение следа не приводит нас к желаемому результату, поэтому, чтобы получить след поератора $\hat{O} : O_{\downarrow\downarrow} + O_{\uparrow\uparrow}$, нам нужно записать выражение как

$$\mathrm{tr}[\hat{O}] = O_{\downarrow\downarrow} + O_{\uparrow\uparrow} = \int d\psi \left\langle \psi \left| (-1)^{\hat{F}}\hat{O} \right| \psi \right\rangle \tag{0.34}$$

где мы использовали, что $(-1)^{\hat{F}} \cdot (-1)^{\hat{F}} = 1$. Теперь, используя, что $\langle\psi|(-1)^{\hat{F}} = -\langle -\psi|$ мы имеем

$$\mathrm{tr}[\hat{O}] = -\int d\psi \langle -\psi|\hat{O}|\psi\rangle \tag{0.35}$$

С другой стороны, используя тот же самый метод вывода континуального интеграла, что и для бозонных полей, т.е. вставляя полные наборы из Грассмановым переменных в матричный элемент через каждый небольшой промежуток времени ϵ, мы получаем

$$\left\langle \psi_f \left| e^{-\beta H} \right| \psi_i \right\rangle = - \int\limits_{\substack{\psi(0)=\psi_i \\ \psi(\beta)=\psi_f}} D\bar{\psi}D\psi \exp\left(- \int\limits_0^\beta dt L_E(\psi(t), \bar{\psi}(t)) \right) \tag{0.36}$$

и поэтому для статистической суммы находим

$$Z = \mathrm{tr}\left[e^{-\beta H}\right] = -\int d\psi \left\langle -\psi \left| e^{-\beta H} \right| \psi \right\rangle = \int\limits_{\psi(\beta)=-\psi(0)} D\bar{\psi}D\psi \exp\left(- \int\limits_0^\beta dt L_E(\psi(t), \bar{\psi}(t)) \right) \tag{0.37}$$

что и требовалось показать.

Также сделаем небольшое замечание о фермионных переменных. По существу мы имеем два разных разложения фермионного поля $\psi(t)$:

$$\begin{aligned} &1.\ \psi(t) = \left\{ \psi_n, \quad \psi_n^2 = 0, \quad n = 0, ..., N, \quad t_n = \beta\frac{n}{N}, \quad N \to \infty \right\}, \\ &2.\ \psi(t) = \left\{ \sum_{k=-\infty}^{\infty} \theta_k e^{\frac{i\pi k t}{\beta}}, \quad \theta_k^2 = 0 \right\}. \end{aligned} \tag{0.38}$$

Причем, как мы видим для вывода континуального интеграла из матричного элемента (мы не проделали данный вывод, а лишь указали путь к нему, оставив это как упражнение) мы использовали первое разложение, а для вычисления континуального интеграла для нашего конкретного Лагранжиана мы пользовались вторым разложением. На первый взгляд два данных разложени выглядят по-разному, но если мы сделаем время дискретным во втором разложении, то мы получим

$$\psi_n = \sum_{k=0}^{N} \theta_k e^{i\pi k \frac{n}{N}} \tag{0.39}$$

Из этого выражения мы можем видеть, что ψ_n и θ_k связанны просто унитарной матрицей, поэтому это всего лишь унитарное преобразование, которое обычно называют преобразованием Фурье. В нашем конкретном случае

$$\psi_n = \sum_{k=0}^{N} \theta_k e^{i\pi(2k+1)\frac{n}{N}} \tag{0.40}$$

и можно получить

$$\psi_0 = \sum_{k=0}^{N} \theta_k, \quad \psi_N = -\sum_{k=0}^{N} \theta_k \tag{0.41}$$

откуда можно видеть, что $\psi_0 = -\psi_N$.

Белавин-Пархоменко.9.1. Диаграммы Фейнмана для теории ϕ^4

Интегралы вычислять не надо, нужно только их уметь записать, используя теорему Вика для свободного поля, а также, что

$$\langle\phi(x)\phi(y)\rangle_0 := \frac{\int D\phi\phi(x)\phi(y)e^{iS_0}}{\int D\phi e^{iS_0}} = G(x-y) \tag{0.1}$$

где $S_0 = \frac{1}{2}\int d^dx\left(\partial_\mu\phi\partial^\mu\phi - m^2\phi^2\right)$. Обратите внимание на индекс $\langle ...\rangle_0$, который означает, что усреднение идет по свободному полю! Каждый такой пропагатор $G(x-y)$ представляется графически как линия между точками x и y:

$$G(x-y) = \quad x \bullet\!\!\!

Что можно сказать про $\langle\phi(x)\rangle, \langle\phi(x)\phi(y)\phi(z)\rangle$ и $\langle\phi(x_1)...\phi(x_{2n+1})\rangle$?

(d). Нарисуйте диаграммы Фейнмана и напишите выражения для них до λ^2 включительно для корреляционной функции

$$\langle\phi(x)\phi(y)\phi(z)\phi(w)\rangle. \tag{0.7}$$

Solution

Рассмотрим теорию ϕ^4 с взаимодействием $S_I = -\int dd^dx\frac{\lambda}{4!}\phi^4(x)$. Если мы хотим найти среднее какого-то числа полей по теории возмущений

$$\langle\phi(x_1)\phi(x_2)...\phi(x_n)\rangle := \frac{\int D\phi\phi(x_1)\phi(x_2)...\phi(x_n)e^{iS_0+iS_I}}{\int D\phi e^{iS_0+iS_I}} \tag{0.2}$$

мы раскладываем возмущение в ряд Тейлора $e^{iS_I} = e^{-i\int d^4x\frac{\lambda}{4!}\phi^4(x)} = \sum\limits_{k=0}^{\infty}\frac{(iS_I)^k}{k!}$, и дальше усредняем все (берем функциональный интеграл) по свободному полю. То есть на деле мы просто применяем уже доказанную нами теорему Вика, то есть находим все возможные попарные свертки полей. Каждый множитель iS_I генерирует на языке диаграмм Фейнмана вершину - узел из которого в теории ϕ^4 торчат 4 отрезка:

$$\frac{\lambda}{4!}\phi^4(x) =>$$

Выражение вида $\frac{(iS_I)^k}{k!}$ пропорционально λ^k, и мы говорим о нем, как о k порядке в теории возмущений.

(a). Начнем с простого рассмотрения вакуумных диаграмм. Рассмотрим функциональный интеграл

$$\int D\phi e^{iS_0+iS_I} \tag{0.3}$$

и найдем выражения для диаграмм Фейнмана до второго порядка включительно $\left(\lambda^2\right)$. Имеем

$$\int D\phi e^{iS_0+iS_I} = \int D\phi\sum_{k=0}^{\infty}\frac{(iS_I)^k}{k!}e^{iS_0} \tag{0.4}$$

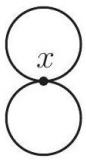
В нулевом порядке по λ получаем просто свободную статсумму

$$\int D\phi e^{iS_0} = Z_0 \tag{0.5}$$

В первом пордяке по λ мы имеем

$$\begin{aligned}\int D\phi(iS_I)e^{iS_0} = -i\int D\phi\int d^dx\frac{\lambda}{4!}\phi^4(x)e^{iS_0} = -\frac{i\lambda}{4!}Z_0\int d^dx\langle\phi(x)\phi(x)\phi(x)\phi(x)\rangle_0 = \\ = -\frac{i\lambda}{4!}Z_0\int d^dx3G^2(0) = -\frac{i\lambda}{8}Z_0G^2(0)\cdot V_d,\end{aligned} \tag{0.6}$$

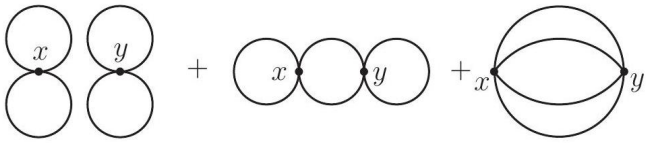
где $V_d = \int d^dx$. В данном случае мы имеем только одну диаграмму вида:



Мы не включаем в выражение для диагрммы множитель Z_0. Во втором порядке мы имеем

$$\int D\phi \frac{1}{2!}\left(iS_I\right)^2 e^{iS_0} = -\frac{1}{2!}\int D\phi \int d^dx \frac{\lambda}{4!}\phi^4(x) \int d^dy \frac{\lambda}{4!}\phi^4(y) e^{iS_0} = -\frac{\lambda^2}{2!(4!)^2} Z_0 \int d^dx d^dy \left\langle \phi^4(x)\phi^4(y)\right\rangle_0 =$$
$$= -\frac{\lambda^2}{2!(4!)^2} Z_0 \int d^dx d^dy \left(\left(3G^2(0)\right)^2 + 72G(0)G^2(x-y)G(0) + 4!G^4(x-y)\right) =$$
$$= \frac{1}{2!}\left(-\frac{i\lambda}{8}\right)^2 Z_0 G^4(0)\cdot V_d^2 - \frac{\lambda^2}{16} Z_0 G^2(0) \int d^dx d^dy G^2(x-y) - \frac{\lambda^2 Z_0}{2!(4!)} \int d^dx d^dy G^4(x-y) \tag{0.7}$$

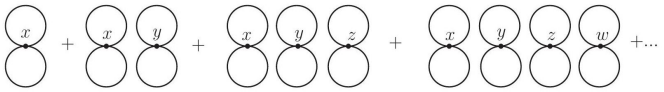
В данном случае мы имеем три диаграммы вида:



(b). Покажем, что вакуумные диаграммы "экспоненцируются", то есть можно написать

$$\int D\phi e^{iS_0+iS_I} = \exp(\text{ сумма по всем связным вакуумным диаграммам }), \tag{0.8}$$

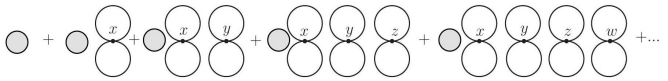
где связными называются диаграммы, которые представляют собой один связный граф. Из предыдущего пункта уже видно, что в разложении возмущения в ряд Тейлора мы можем выделить из бесконечной суммы диаграмм, например, ряд диаграмм вида:



Данный ряд равен

$$-\frac{i\lambda}{8}G^2(0)\cdot V_d + \frac{1}{2!}\left(-\frac{i\lambda}{8}\right)^2 \left(G^2(0)\right)^2 \cdot V_d^2 + + \frac{1}{3!}\left(-\frac{i\lambda}{8}\right)^3 \left(G^2(0)\right)^3 \cdot V_d^3 + ... =$$
$$= \exp\left(-\frac{i\lambda}{8}G^2(0)\cdot V_d\right) - 1 \tag{0.9}$$

Далее можно заметить, что $\int D\phi e^{iS_I} e^{iS_0}$ можно представить как следующий ряд



где заштрихованный кружочек означает сумму все остальных диграмм (отличных по структуре, то есть не равных "двум склееным кружочкам"). Как мы видим, выделенные диаграммы могут быть "экспоненциированы", то есть в итоге мы можем написать:

$$\int D\phi\, e^{iS_I} e^{iS_0} = \exp\,($$ $$)$$

Далее рассуждая алогично, мы можем “экспоненциировать" диаграммы следующего типа и записать

$$\int D\phi\, e^{iS_I} e^{iS_0} = \exp\Big($$  $$\Big)$$

где более маленький заштрихованный кружочек означает сумму все остальных диграмм, отличных уже от тех двух которые стоят в экспоненте. В итоге повторяя процедуру экспоненциирования диаграмм каждого типа, мы получим

$$\int D\phi\, e^{iS_I} e^{iS_0} = Z_0 \exp\Big($$  $$+\ldots\Big)$$

(c). Следствием пункта (b) является то, что мы можем написать

$$\langle \phi(x_1)\,\phi(x_2)\ldots\phi(x_n)\rangle = \frac{\int D\phi\phi(x_1)\,\phi(x_2)\ldots\phi(x_n)\,e^{iS_0+iS_I}}{\int D\phi e^{iS_0+iS_I}} =$$

$$= \sum_{k=0}^{\infty}\frac{1}{k!}\left(\left\langle \phi(x_1)\ldots\phi(x_n)\,(iS_I)^k\right\rangle_0\right)_{\text{все диаграммы без вакуумных пузырьков}}, \qquad (0.10)$$

то есть это означает, что мы должны раскладывать взаимодействие в ряд тейлора по λ, находить все возможные свертки полученных корреляторов по теореме Вика, но из полученного множества всех Фейнмановских диаграм, мы должны взять только те диаграммы, которые не содержат отдельных кусков (вакуумных пузырьков), которые не связанны с внешними точками $x_1,\ldots,x_n$. Далее, пользуясь этим следствием, нарисуем диаграммы Фейнмана и напишим выражения для них до λ^2 включительно для корреляционной функции $\langle\phi(x)\phi(y)\rangle$. Имеем

$$\begin{aligned}\langle\phi(x)\phi(y)\rangle =& \langle\phi(x)\phi(y)\rangle_0 + \frac{(-i\lambda)}{4!}\left\langle\phi(x)\phi(y)\int d^dz\phi^4(z)\right\rangle_{0,\text{ связ}} + \\ &+\frac{(-i\lambda)^2}{2!(4!)^2}\left\langle\phi(x)\phi(y)\int d^dz\phi^4(z)\int d^dw\phi^4(w)\right\rangle_{0,\text{ связ}} + O\left(\lambda^3\right) = \\ =& G(x-y) - \frac{i\lambda}{2}\int d^dz G(x-z)G(0)G(z-y) + \\ &+\left(\frac{-i\lambda}{2}\right)^2\int d^dz d^dw G(x-z)G(0)G(z-w)G(0)G(w-y) - \\ &-\frac{\lambda^2}{4}\int d^dz d^dw G(x-z)G^2(w-z)G(0)G(z-y) - \\ &-\frac{\lambda^2}{6}\int d^dz d^dw G(x-z)G^3(z-w)G(w-y) + O\left(\lambda^3\right). \end{aligned} \qquad (0.11)$$

На диаграммном языке мы имеем:

$\langle\phi(x)\phi(y)\rangle =$ 
Коррелятор $\langle\phi(x_1)\ldots\phi(x_{2n+1})\rangle = 0$ в силу симметрии действия: $S[\phi] = S[-\phi]$, также это можно заметить из того факта, что в каждом порядке теории возмущений будет возникать усреднение по свободному полю (по S_0) нечетного числа полей, а такие корреляторы в свободной теории поля равны нулю.

(d). Нарисуем диаграммы Фейнмана и напишим выражения для них до λ^2 включительно для корреляционной функции $\langle\phi(x)\phi(y)\phi(z)\phi(w)\rangle$. Имеем

$\lambda^0:\ \langle\phi(x)\phi(y)\phi(z)\phi(w)\rangle_0 =$ 
Все остальные диаграммы выглядят как диаграммы первого порядка по λ у которых пропагаторы перенормированны еще одной дополнительной петлей.

Белавин-Пархоменко.9.2. Диаграммы Фейнмана для теории ϕ^3

Рассмотрим теперь теорию скалярного поля с взаимодействие $S_I = -\int d^dx\lambda\frac{\phi^3(x)}{3!}$. Проделайте пункты (a)-(d) из Задачи 1.

Данная задача разобрана в параграфе 9 книги Средницкого.

Белавин-Пархоменко.**4. Континуальный интеграл в Квантовой Механик Решения**

1 Евклидова корреляционная функция

(a). Имеем для $D\left(x_E\right)$

$$D\left(x_E\right)=\int\limits_0^\infty d\tau\int\frac{d^4p_E}{(2\pi)^4}e^{-\tau\left(p_E^2+m^2\right)}e^{ip_Ex_E}=\int\limits_0^\infty d\tau\frac{1}{16\pi^2\tau^2}e^{-\frac{x_E^2}{4\tau}-\tau m^2\tau=\frac{|x_E|}{2m}t}$$
$$=\frac{m}{8\pi^2\left|x_E\right|}\int\limits_0^\infty\frac{dt}{t^2}e^{-\frac{1}{2}m|x_E|\left(t+\frac{1}{t}\right)}. \tag{0.1}$$

Далее, так как $m\left|x_E\right|\gg1$, мы можем воспользоваться методом перевала. Для этого находим для седловой точки:

$$\left(t+\frac{1}{t}\right)'=1-\frac{1}{t^2}=0,\quad \text{откуда}\quad t_0=1 \tag{0.2}$$

Далее подставляя $t=t_0+\delta t$, получаем

$$D\left(x_E\right)=\frac{m}{8\pi^2\left|x_E\right|}\int\limits_0^\infty\frac{dt}{t^2}e^{-\frac{1}{2}m|x_E|\left(t+\frac{1}{t}\right)}\approx\frac{m}{8\pi^2\left|x_E\right|}e^{-m|x_E|}\int\limits_{-\infty}^\infty d(\delta t)e^{-\frac{1}{2}m|x_E|(\delta t)^2}=$$
$$=\frac{m}{8\pi^2\left|x_E\right|}e^{-m|x_E|}\sqrt{\frac{2\pi}{m\left|x_E\right|}}\sim\frac{m^{1/2}}{\left|x_E\right|^{3/2}}e^{-m|x_E|}. \tag{0.3}$$

(b). Имеем

$$D\left(x_E\right)=\int\limits_0^\infty d\tau\frac{1}{16\pi^2\tau^2}e^{-\frac{x_E^2}{4\tau}-\tau m^2} \tag{0.4}$$

Используя формулу

$$K_\nu(2\sqrt{pq})=\frac{1}{2}\left(\frac{p}{q}\right)^{\nu/2}\int\limits_0^\infty x^{\nu-1}e^{-px-q/x}dx \tag{0.5}$$

находим $\left(p=m^2,q=x_E^2/4,\nu=-1\right)$

$$D\left(x_E\right)=\frac{m}{4\pi^2\left|x_E\right|}K_{-1}\left(m\left|x_E\right|\right)=\frac{m}{4\pi^2\left|x_E\right|}K_1\left(m\left|x_E\right|\right). \tag{0.6}$$

2 Оператор эволюции (в мнимом времени $\tau=it$)

(a). Мы можем записать решение уравнения

$$-\frac{\partial}{\partial\tau}\hat{U}\left(\tau,\tau_0\right)=\hat{H}(\tau)U\left(\tau,\tau_0\right),\quad\hat{U}\left(\tau_0,\tau_0\right)=\hat{I} \tag{0.7}$$

в форме (см. Пескин Шредер, глава 4)

$$\hat{U}\left(\tau,\tau_0\right)=\hat{I}-\int\limits_{\tau_0}^\tau d\tau_1\hat{H}\left(\tau_1\right)+\int\limits_{\tau_0}^\tau d\tau_1\int\limits_{\tau_0}^{\tau_1}d\tau_2\hat{H}\left(\tau_1\right)\hat{H}\left(\tau_2\right)-...=$$
$$=\hat{I}-\int\limits_{\tau_0}^\tau d\tau_1\hat{H}\left(\tau_1\right)+\frac{1}{2!}\int\limits_{\tau_0}^\tau d\tau_1d\tau_2T\left\{\hat{H}\left(\tau_1\right)\hat{H}\left(\tau_2\right)\right\}-...\equiv T\left\{e^{-\int\limits_{\tau_0}^\tau d\tau'\hat{H}\left(\tau'\right)}\right\}, \tag{0.8}$$

где символ T означает временное упорядочение, т.е. оператор с большим временем ставится слева от оператора с меньшим. Далее имеем

$$T\left\{\left(\int\limits_{\tau_0}^{\tau} d\tau' \hat{H}\left(\tau'\right)\right)^n\right\} = C_n^k T\left\{\left(\int\limits_{\tau_1}^{\tau} d\tau' \hat{H}\left(\tau'\right)\right)^k \left(\int\limits_{\tau_0}^{\tau_1} d\tau' \hat{H}\left(\tau'\right)\right)^{n-k}\right\} = \\ = C_n^k T\left\{\left(\int\limits_{\tau_1}^{\tau} d\tau' \hat{H}\left(\tau'\right)\right)^k\right\} T\left\{\left(\int\limits_{\tau_0}^{\tau_1} d\tau' \hat{H}\left(\tau'\right)\right)^{n-k}\right\}, \tag{0.9}$$

где $C_n^k = \frac{n!}{k!(n-k)!}$. В итоге получаем, что

$$\hat{U}\left(\tau,\tau_0\right) = T\left\{e^{-\int\limits_{\tau_0}^{\tau} d\tau' \hat{H}(\tau')}\right\} = T\left\{e^{-\int\limits_{\tau_1}^{\tau} d\tau' \hat{H}(\tau')}\right\} T\left\{e^{-\int\limits_{\tau_0}^{\tau_1} d\tau' \hat{H}(\tau')}\right\} = \hat{U}\left(\tau,\tau_1\right)\hat{U}\left(\tau_1,\tau_0\right) \tag{0.10}$$

(b). Имеем $\left\langle q\left|\hat{U}\left(\tau,\tau_0\right)\right|q'\right\rangle = e^{-\sigma\left(q,q'|\tau_0\right)}$, где

$$\sigma\left(q,q'|\tau_0\right) = \frac{1}{\Delta}\sigma_0\left(q,q'|\tau_0\right) + a\log\Delta + b + \Delta\sigma_1\left(q,q'|\tau_0\right) + O\left(\Delta^2\right) \tag{0.11}$$

тогда ($\Delta = \tau - \tau_0$):

$$-\frac{\partial}{\partial\tau}e^{-\sigma\left(q,q'|\tau_0\right)} = -\frac{\partial}{\partial\Delta}e^{-\sigma\left(q,q'|\tau_0\right)} = \left(-\frac{1}{\Delta^2}\sigma_0\left(q,q'|\tau_0\right) + \frac{a}{\Delta} + \sigma_1\left(q,q'|\tau_0\right) + O(\Delta)\right)e^{-\sigma\left(q,q'|\tau_0\right)}, \\ -\frac{1}{2}\partial_q^2 e^{-\sigma\left(q,q'|\tau_0\right)} = \left(-\frac{1}{2\Delta^2}\left(\partial_q\sigma_0\left(q,q'|\tau_0\right)\right)^2 + \frac{1}{2\Delta}\partial_q^2\sigma_0\left(q,q'|\tau_0\right) - \partial_q\sigma_0\left(q,q'|\tau_0\right)\partial_q\sigma_1\left(q,q'|\tau_0\right)\right)e^{-\sigma\left(q,q'|\tau_0\right)} \tag{0.12}$$

Получаем в порядке $1/\Delta^2$

$$\left(\partial_q\sigma_0\left(q,q'|\tau_0\right)\right)^2 = 2\sigma_0\left(q,q'|\tau_0\right) \tag{0.13}$$

откуда

$$\sigma_0\left(q,q'|\tau_0\right) = \frac{1}{2}\left(q-q_0\right)^2 \tag{0.14}$$

Далее в порядке $1/\Delta$ находим

$$a = \frac{1}{2} \tag{0.15}$$

Далее имеем

$$e^{-\sigma\left(q,q'|\tau_0\right)} = \frac{1}{e^b\sqrt{\Delta}}e^{-\frac{(q-q_0)^2}{2\Delta}} \xrightarrow{\Delta} \frac{\sqrt{2\pi}}{e^b}\delta\left(q-q_0\right) \tag{0.16}$$

и используя граничное условие $\left\langle q\left|\hat{U}\left(\tau_0,\tau_0\right)\right|q'\right\rangle = \delta\left(q-q'\right)$ мы находим

$$q_0 = q', \quad b = \frac{1}{2}\log 2\pi. \tag{0.17}$$

Далее в порядке Δ^0 получаем уравнение

$$\sigma_1\left(q,q'|\tau_0\right) = -\partial_q\sigma_0\left(q,q'|\tau_0\right)\partial_q\sigma_1\left(q,q'|\tau_0\right) + V(q,\tau) \tag{0.18}$$

откуда

$$\sigma_1\left(q,q'|\tau_0\right) + \left(q-q'\right)\partial_q\sigma_1\left(q,q'|\tau_0\right) = V(q,\tau) \tag{0.19}$$

Далее получаем

$$\partial_q\left(\left(q-q'\right)\sigma_1\left(q,q'|\tau_0\right)\right)=V(q,\tau),\qquad \text{откуда}\qquad \sigma_1\left(q,q'|\tau_0\right)=\frac{1}{q-q'}\int\limits_{q'}^{q}V\left(y|\tau_0\right)dy \tag{0.20}$$

В конечном итоге мы получили

$$\left\langle q\left|\hat{U}\left(\tau,\tau_0\right)\right|q'\right\rangle=\frac{1}{\sqrt{2\pi\Delta}}e^{-\frac{(q-q')^2}{2\Delta}-\frac{\Delta}{q-q'}\int\limits_{q'}^{q}V(y|\tau_0)dy} \tag{0.21}$$

26.2.4 Problems about path integral formalism in QFT 3

Белавин-Пархоменко.5. Связь континуального интеграла и классической статфизики

1 Полубесконечная струна

Рассмотрим полубесконечную струну в некотором потенциале V, положения точек которой задается функцией $q(\tau)$, где $\tau\in[0,+\infty)$. Граничное условие для левого конца струны $q(0)=q_0$. А статистический вес конфигурации задается формулой

$$[Dq(\tau)]\exp(-\beta W[q(\tau)])=[Dq(\tau)]\exp\left(-\beta\int d\tau\left(V(q(\tau))+\frac{1}{2}\left(\frac{dq(\tau)}{d\tau}\right)^2\right)\right) \tag{0.1}$$

где член $\frac{1}{2}\left(\frac{dq(\tau)}{d\tau}\right)^2$ представляет упругую энергию деформации. Покажите, что q_0-зависимость для статистической суммы

$$Z\left(q_0\right)=\ \text{const}\ \cdot\Psi_0\left(q_0\right), \tag{0.2}$$

где $\Psi_0(q)$ - волновая функция основного состояния Гамильтониана

$$\hat{H}=\frac{1}{2}\hat{p}^2+V(\hat{q}). \tag{0.3}$$

2. Временное упорядочение

На лекции мы нашли, что корреляционная функция координат струны ($A[q(\tau)]=\beta W[q(\tau)]$):

$$G\left(\tau_1,...,\tau_N\right)\overset{\text{def}}{=}\left\langle q\left(\tau_1\right)...q\left(\tau_N\right)\right\rangle=\frac{1}{Z}\int[Dq(\tau)]q\left(\tau_1\right)...q\left(\tau_N\right)e^{-A[q(\tau)]} \tag{0.4}$$

может быть представлена как

$$\left\langle q\left(\tau_1\right)...q\left(\tau_N\right)\right\rangle=\left\langle 0\left|\hat{q}_E\left(\tau_N\right)\hat{q}_E\left(\tau_{N-1}\right)...\hat{q}_E\left(\tau_1\right)\right|0\right\rangle, \tag{0.5}$$

где $\hat{q}_E(\tau)=e^{\hat{H}\tau}\hat{q}e^{-\hat{H}\tau}$ - оператор координаты в представлении Гейзенберга в мнимом времени, и $\hat{q}\left|q_0\right\rangle=q_0\left|q_0\right\rangle$ (Вопрос на засыпку (5 баллов): как выглядит собственная волновая функция $\psi_{q_0}(q)=\langle q|q_0\rangle$ оператора координаты q, в координатном представлении, с собственным значением q_0 : $\hat{q}\psi_{q_0}(q)=q_0\psi_{q_0}(q)$?). Важно, что все операторы поставлены в порядке убывания времени: $\tau_N\geqslant\tau_{N-1}\geqslant...\geqslant\tau_1$. Далее, если мы хотим аналитически продолжить функцию $G\left(\tau_1,...,\tau_N\right)$, то есть рассмотреть ее значения для комплексных чисел $\tau_1,...,\tau_N$, то это имеет смысл только если выполняется неравенство

$$\operatorname{Re}\tau_N\geqslant\operatorname{Re}\tau_{N-1}\geqslant...\geqslant\operatorname{Re}\tau_1 \tag{0.6}$$

то есть $G\left(\tau_1,...,\tau_N\right)$ аналитична только в этой области. Покажите, что делая Виковский поворот: $\tau_k=e^{i\alpha}t_k$, где $\alpha\to\frac{\pi}{2}-0$, мы получим соотношение

$$\left\langle q\left(\tau_1\right)...q\left(\tau_N\right)\right\rangle=\left\langle 0\left|T\left(\hat{q}\left(t_1\right)...\hat{q}\left(t_N\right)\right)\right|0\right\rangle, \tag{0.7}$$

где $\tau_k=(i-0)t_k$ и $\hat{q}\left(t_k\right)$ обычный оператор Гейзенберга в реальном времени и символ T означает временное упорядочение - то есть операторы с большим временем ставятся слева от операторов с меньшим.

3 Теорема Вика для ПГО (Простого Гармонического Осциллятора)

(a). Пусть $\phi(t)$ координата обычного гармонического осциллятора, то есть

$$\phi(t)=\frac{1}{\sqrt{2m}}\left(ae^{-imt}+a^{\dagger}e^{imt}\right) \tag{0.8}$$

Докажите, что

$$T\left(\phi(t)\phi\left(t'\right)\right)=G_F\left(t-t'\right)+:\phi(t)\phi\left(t'\right): \tag{0.9}$$

где:: обозначает нормальное упорядочение - то есть мы должны все операторы уничтожения поставить справа от операторов рождения (например: $aa^{\dagger}aa^{\dagger}:=\left(a^{\dagger}\right)^2a^2$), и где пропагатор Фейнмана дается формулой

$$G_F(t)=\langle 0|T(\phi(t)\phi(0))|0\rangle \tag{0.10}$$

Обобщите (0.9) на произведение $2n$ полей и используйте это для доказательства теоремы Вика:

$$\langle 0\left|T\left(\phi\left(t_1\right)\phi\left(t_2\right)...\phi\left(t_{2n}\right)\right)\right|0\rangle=\sum_{\text{по всем парам}}G_F\left(t_{i_1}-t_{i_2}\right)...G_F\left(t_{i_{2n-1}}-t_{i_{2n}}\right). \tag{0.11}$$

(b). Вычислите явно

$$\langle 1\left|T\left(\phi\left(t_1\right)\phi\left(t_2\right)\phi\left(t_3\right)\phi\left(t_4\right)\right)\right|1\rangle \tag{0.12}$$

где $|1\rangle$ - первое возбужденное состояние ПГО, и проверьте, что теорема Вика не работает. Что не так в этом случае?

Белавин-Пархоменко .5. Связь континуального интеграла и классической статфизики Решения

1 Полубесконечная струна

Данную статистическую сумму можно записать как:

$$Z\left(q_0\right)=\lim_{T\to\infty}\int dq_f\int\limits_{q(0)=q_0}^{q(T)=q_f}[Dq(\tau)]e^{-\beta\int\limits_0^T d\tau\left(\frac{1}{2}\left(\frac{dq}{d\tau}\right)^2+V(q)\right)} \tag{0.1}$$

Далее, как мы знаем, интеграл по путям равен матричному элементу от оператора эволюции в квантовой механике $\left(\beta=\frac{1}{\hbar}=1\right)$:

$$Z\left(q_0\right)=\lim_{T\to\infty}\int dq_f\left\langle q_f|U(T,0)|q_0\right\rangle=\lim_{T\to\infty}\int dq_f\left\langle q_f\left|e^{-TH}\right|q_0\right\rangle \tag{0.2}$$

где $\hat{H}=\frac{1}{2}\hat{p}^2+V(q)$. Вставляя полный набор собственных состояний Гамильтониана: $1=\sum\limits_{n=0}^{\infty}|n\rangle\langle n|$, мы получаем

$$Z\left(q_0\right)=\lim_{T\to\infty}\int dq_f\sum_{n=0}^{\infty}\left\langle q_f|n\right\rangle e^{-TE_n}\left\langle n|q_0\right\rangle\to\left(\lim_{T\to\infty}\int dq_f\Psi_0\left(q_f\right)e^{-E_0T}\right)\Psi_0^*\left(q_0\right)=\text{const}\cdot\Psi_0^*\left(q_0\right). \tag{0.3}$$

Так как статсумма является вещественной функцией, можно записать

$$Z\left(q_0\right)=\text{ const }\cdot\Psi_0\left(q_0\right). \tag{0.4}$$

С одной стороны мы видим, что константа при $E_0>0$ стремится к нулю, но мы всегда можем нормировать нашу статистическую сумму так, чтобы сократить эту константу. В общем случае мы также не придаем значения бесконечным константам перед функциональным интегралом или интегралом по путям, так как обычно при подсчете физических величин такие бесконечные константы сокращаются.

2. Временное упорядочение

Ответ на вопрос на засыпку: $\psi_{q_0}(q) = \langle q|q_0\rangle = \delta(q-q_0)$.
Сама задача была по сути очевидной, так как мы уже получили равенство на лекции:

$$\langle q(\tau_1)...q(\tau_N)\rangle = \langle 0|T\left(\hat{q}_E(\tau_1)\hat{q}_E(\tau_2)...\hat{q}_E(\tau_N)\right)|0\rangle \tag{0.5}$$

Далее, делая Виковский поворот $\left(\tau_k = e^{i\alpha}t_k, \alpha \to \frac{\pi}{2}-0\right) : \tau_k = (i-0)t_k$ мы не нарушаем T упорядочение (т. е. если изначально $\tau_i > \tau_j$, то и $t_i > t_j$), поэтому получим

$$\langle q(\tau_1)...q(\tau_N)\rangle = \langle 0|T\left(\hat{q}(t_1)\hat{q}(t_2)...\hat{q}(t_N)\right)|0\rangle \tag{0.6}$$

4. Теорема Вика для ПГО (Простого Гармонического Осциллятора)

(a). Итак мы имеем

$$\phi(t) = \frac{1}{\sqrt{2m}}\left(ae^{-imt} + a^\dagger e^{imt}\right) \tag{0.7}$$

Пусть теперь $t > t'$ откуда получаем

$$\begin{aligned}
&T(\phi(t)\phi(t')) = \phi(t)\phi(t') = \frac{1}{2m}\left(ae^{-imt} + a^\dagger e^{imt}\right)\left(ae^{-imt'} + a^\dagger e^{imt'}\right) = \\
&= \frac{1}{2m}\left(a^2e^{-imt-imt'} + a^\dagger a e^{imt}e^{-imt'} + \left(a^\dagger\right)^2 e^{imt+imt'} + aa^\dagger e^{-imt+imt'}\right) = \\
&= \frac{1}{2m}\left(a^2e^{-imt-imt'} + a^\dagger a e^{imt}e^{-imt'} + \left(a^\dagger\right)^2 e^{imt+imt'} + \left(1+a^\dagger a\right)e^{-imt+imt'}\right) = \\
&=: \phi(t)\phi(t') : + \frac{1}{2m}e^{-im\left(t-t'\right)}.
\end{aligned} \tag{0.8}$$

Аналогично, если $t < t'$, то

$$T(\phi(t)\phi(t')) =: \phi(t)\phi(t') : + \frac{1}{2m}e^{im\left(t-t'\right)}. \tag{0.9}$$

Откуда получаем

$$T(\phi(t)\phi(t')) =: \phi(t)\phi(t') : + \frac{1}{2m}e^{-im|t-t'|} =: \phi(t)\phi(t') : + G_F(t-t'). \tag{0.10}$$

Обобщение на случай $2n$ полей тривиально следует из метода индукции примененного к утверждению (см. Пескин Шредер параграф 4.3):

$$T(\phi(t_1)\phi(t_2)...\phi(t_m)) =: \phi(t_1)\phi(t_2)...\phi(t_m) + \text{ все возможные свертки:}, \tag{0.11}$$

где каждая свертка дает пропагатор G_F.
(b). В данном случае имеем

$$\begin{aligned}
T(\phi_1\phi_2\phi_3\phi_4) =& G_{12}G_{34} + G_{13}G_{24} + G_{14}G_{23} + \\
&+ G_{12} : \phi_3\phi_4 : + G_{14} : \phi_2\phi_2 : + G_{13} : \phi_2\phi_4 : + G_{23} : \phi_1\phi_4 : + \\
&+ G_{24} : \phi_1\phi_3 : + G_{34} : \phi_1\phi_2 : + :: \phi_1\phi_2\phi_3\phi_4 :
\end{aligned} \tag{0.12}$$

Теорема Вика работает, когда все нормально-упорядоченные слагаемые исчезают. Очевидно это происходит, когда мы берем матричный элемент по вакуумным состояниям $\langle 0|...|0\rangle$. Но в нашем случае имеем, например

$$\langle 1|: \phi_1\phi_2 :|1\rangle = \frac{1}{2m}\left\langle 1\left|a^\dagger a\left(e^{-imt_1}e^{imt_2} + e^{-imt_2}e^{imt_1}\right)\right|1\right\rangle = \frac{1}{2m}\cos\left(m\left(t_1-t_2\right)\right) \neq 0, \tag{0.13}$$

так как $\left\langle 1\left|a^\dagger a\right|1\right\rangle = 1$, в случае вакуума мы бы получили $\left\langle 0\left|aa^\dagger\right|0\right\rangle = 0$.

МФТИ-Киселев-2020.14 Уравнения Швингера–Дайсона для Юкавской теории

Вывести уравнения Швингера–Дайсона и графическое представление для двухточечной вершинной функции для биспинора Дирака с юкавским взаимодействием с вещественным скалярным полем.

Записать правила Фейнмана.

Solution

МФТИ-Киселев-2020.15^C Уравнения Швингера–Дайсона для скалярной электродинамики

Вывести уравнения Швингера–Дайсона и графическое представление для двухточечной вершинной функции для скалярной электродинамики. Записать правила Фейнмана.

Solution

(???????)

Правила Фейнмана для вычисления амплитуд квантовых переходов в теории со скалярными полями при заданных начальных и конечных состояниях.

Эти правила зависят, конечно, от исходного (bare) лагранжиана, что подразумевает определение состава полей и их взаимодействий. Для (нейтрального) вещественного поля φ и заряженного (комплексного) поля Φ, лагранжиан свободных полей имеет стандартный вид

$$\mathcal{L}_0 = \frac{1}{2}\left(\partial_\mu\varphi\partial^\mu\varphi - M^2\varphi^2\right) + \partial_\mu\Phi^\dagger\partial^\mu\Phi - m^2\Phi^\dagger\Phi$$

где M -масса нейтрального поля, а m - масса заряженного поля, а лагранжиан взаимодействия имеет вид

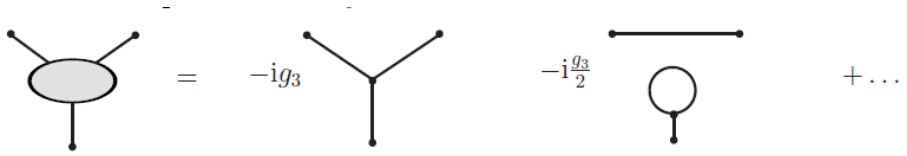
$$\mathcal{L}_{\text{int}} = -\Lambda\varphi\Phi^\dagger\Phi - \frac{\lambda}{4}\left(\Phi^\dagger\Phi\right)^2$$

где Λ - размерная постоянная юкавского взаимодействия полей, а λ константа самодействия заряженного поля.

В импульсном представлении амплитуда квантового перехода строится по диаграмме с учетом закона сохранения 4-импульса, которые приписываются всем линиям,

$$\mathrm{i}\mathcal{M} = (2\pi)^4\delta\left(\sum p\right)\mathrm{i}\mathfrak{M}$$

причем в $\mathfrak{M}$ внутренним линиям отвечают следующие пропагаторы: вещественное поля φ - штриховая линия -



Вершина, как мы убедились, получаются из затравочного действия путем дифференцирования лагранжиана $\mathcal{L}_{\text{int}}$ по полям и домножением на мнимую единицу. Внешним линиям в конечном состоянии отвечают следующие моды:

заряженная частица - отрицательно частотная мода поля $\hat{\Phi}^\dagger$,

заряженная античастица - отрицательно частотная мода поля $\hat{\Phi}$,

нейтральная частица - отрицательно частотная мода поля $\hat{\varphi}$.

Внешним линиям в начальном состоянии отвечают следующие моды: заряженная античастица - положительно частотная мода поля $\hat{\Phi}^\dagger$, заряженная частица - положительно частотная мода поля $\hat{\Phi}$, нейтральная частица - положительно частотная мода поля $\hat{\varphi}$. Для скалярных частиц в принятой релятивистски ковариантной нормировке состояний все эти моды в координатном представлении отвечают волнам де Бройля с соответствующей прескрипцией для импульсов и энергий в начальных и конечных состояниях,

чтобы выполнялся закон сохранения 4 импульса. В импульсном же представлении эти моды оказываются равными 1. Однако понимание того, как они были получены, упростит нам задачу в случае полей с ненулевым спином, когда моды - это многокомпонентные строки или столбцы, а не единицы.

При наличии в диаграмме петель закон сохранения 4-импульса приводит к дополнительному интегрированию по 4-импульсу, который может принимать произвольные значения,

$$\int \frac{\mathrm{d}^4 p}{(2\pi)^4}$$

для каждой петли. Подчеркнем, что при наличии тождественных полей необходимо учесть симметрийный фактор: для внешних полей провести симметризацию по тождественным частицам и сосчитать варианты прескрипции 4-импульсов этим полям, для внутренних линий сосчитать число графических вариантов возникновения одних и тех же диаграмм по заданному набору линий и вершин. Пример расчета симметрийного фактора мы видели в теории кубического самодействия нейтрального поля.

И наконец, повторим, как связана амплитуда с дифференциальной шириной распада частицы массой M с 4 -импульсм p

$$\mathrm{d}\Gamma = \frac{|\mathfrak{M}|^2}{2M} d\mathfrak{p}_f$$

где релятивистски инвариантный фазовый объем частиц в конечном состоя- нии

$$\mathrm{d}\mathfrak{p}_f = (2\pi)^4 \delta\left(p - \sum_{n=1}^{n_f} k_{(n)}\right) \prod_{n=1}^{n_f} \frac{\mathrm{d}^3 k_{(n)}}{2E_{(n)}}$$

и дифференциальным сечением рассеяния частиц с 4-импульсами p и $\tilde{p}$

$$\mathrm{d}\sigma = \frac{|\mathfrak{M}|^2}{4\sqrt{(p\cdot\tilde{p})^2 - m^2\tilde{m}^2}} d\mathfrak{p}_f$$

где фазовый объем в конечном состоянии $\mathrm{d}\mathfrak{p}_f = (2\pi)^4 \delta\left(p + \tilde{p} - \sum_{n=1}^{n_f} k_{(n)}\right) \prod_{n=1}^{n_f} \frac{\mathrm{d}^3 k_{(n)}}{2E_{(n)}}$. Отметим, что эти правила относятся к случаю, когда одноточечная функция Грина поля равна нулю. Однако, легко сообразить, что ненулевое

вакуумное значение поля $v = \langle 0|\hat{\varphi}(x)|0\rangle$ отвечает просто случаю внешнего поля с нулевым импульсом. Такую внешнюю линию обычно изображают с символом $\otimes$ на конце.

При этом вершины взаимодействия внешнего вакуумного поля легко определить, если в исходном лагранжиане произвести замену поля, скажем, $\varphi \mapsto v + \varphi$, так что новое поле уже не имеет вакуумного среднего.

МФТИ-Киселев-2020.16.C Уравнение Швингера-Дайсона для $\lambda\phi^4/4!$ (????)

Вывести уравнения Швингера–Дайсона и графическое представление для двухточечной вершинной функции для массивного скалярного поля с самодействием $\lambda\phi^4/4!$. Записать правила Фейнмана.

Solution

(???????)
Правила Фейнмана:
1. точный пропагатор дается суммой всех связных диаграмм
2. каждой вершине отвечает $-i\lambda\int d^4x$
3. Свободный пропагатор $D_0^F(x,y) = \int \frac{d^4k}{(2\pi)^4} \frac{e^{ik(x-y)}}{k^2-m^2+i\varepsilon}$
4. Комбинаторные множители.

МФТИ-Киселев-2020.17 Количество петель, внутренних линий и связных компонент

Доказать, что число петель N_L в диаграмме с N_V степенями действия взаимодействия V, числом связных компонент диаграммы N_c и числом внутренних линий N_I связано соотношением

$$N_L = N_I + N_c - N_V$$

Привести примеры одно- и двухпетлевых диаграмм с одно- и двухсвязными компонентами в теории с взаимодействием $V \sim \lambda\phi^4$

Solution

(?? в чем идея - тут напишу)
Внутренняя линия добавляет $\int d^4x$, а петля снимает.
Для одной связной петли

$$N_V = N_I - N_L + 1$$

Поэтому для нескольких:

$$\sum N_v = \sum N_I - \sum N_L + N_C = N_v = N_I - N_L + N_C$$

Амплитуду квантовых переходов $\hat{Z}(j) = \int \mathcal{D}\varphi \exp\left\{\frac{\mathrm{i}}{\hbar}\left(S_0(\varphi) + j_{x'}\varphi_{x'}\right) + \frac{\mathrm{i}}{\hbar}S_{\mathrm{int}}(\varphi)\right\}$ можно выразить с помощью действия оператора поля на функционал, построенный для свободных полей:

$$\hat{Z}(j) = \exp\left\{\frac{\mathrm{i}}{\hbar}S_{\mathrm{int}}\left(-\mathrm{i}\hbar\frac{\delta}{\delta j}\right)\right\}\int \mathcal{D}\varphi \exp\left\{\frac{\mathrm{i}}{\hbar}\left(S_0(\varphi) + j_{x'}\varphi_{x'}\right)\right\}$$

Этот функционал позволяет найти общее соотношение для числа петель, степени возмущения и числа внутренних линий в связной диаграмме.

Действительно, если N_V - степень вклада возмущения в функцию Грина, и значит, N_V - это число внутренних вершин в диаграмме, то вклад вершин в число интегрирований по координатам равен N_V (vertex, number of vertecies).

Если в диаграмме есть внутренняя линия, то она соединяет 2 точки, т. е. каждой внутренней линии отвечает одно интегрирование по координатам на конце внутренней линии, так что при наличии N_I внутренних линий (internal lines) N_I интегрирований относятся именно к этим линиям, и нужно добавить еще одну начальную точку, так что при последовательном счете, если рассматривать связную цепочку внутренних линий, имеется $N_I + 1$ число интегрирований в цепочке.

При этом, поскольку внутренняя линия соединяет именно вершины,

по сути мы полагаем, что в диаграмме столько же и вершин.

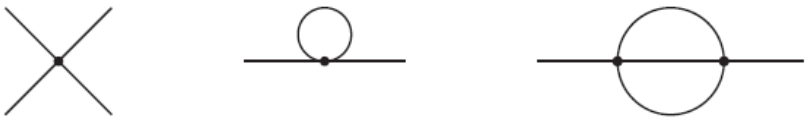
Однако если диаграмма связная, то некоторые начальные и конечные точки в цепочке внутренних линий могут совпасть.

Каждое такое совпадение означает наличие замкнутой петли.

Число петель N_L (number of loops) определяет число точек посчитанных дважды, так что общее число интегрирований по внутренним вершинам или просто число вершин в действительности равно

$$N_V = N_I + 1 - N_L, \quad N_L = N_I + 1 - N_V$$

В справедливости данной формулы читатель может наглядно убедиться на примере четырех- и двухточечной функции Грина в теории «фи-в-четвертой», как это показано на рис. ниже



МФТИ-Киселев-2020.18^C Разложение диаграмм по петлям

Докажите, что разложение связных диаграмм по петлям совпадает с разложением по постоянной Планка $\hbar$.

Solution

(?? в чем идея - тут напишу. ничего сейчас не понимаю!!!)
Заметим, что связные функции Грина $\mathrm{i}G(j)/\hbar$ с фиксированным числом петель получаются суммированием диаграмм с N_V степенями возмущения и N_I внутренними линиями, причем каждое возмущение дает фактор $1/\hbar$, а каждая внутренняя линия отвечает обратному оператору на квадратичном по траектории свободном действии, т. е. вносит фактор $\hbar$(cm. связь связной двухточечной функции Грина со связной частью двухточечной функции Грина для амплитуды вероятности $Z(j)$).

В итоге связные функции Грина с петлями имеют следующий масштаб по $\hbar$:

$$\frac{1}{\hbar}G^{(L)} \sim \sum_{N_V,N_I} \left(\frac{1}{\hbar}\right)^{N_V} \hbar^{N_I}\Bigg|_{N_L \text{ fixed}} \sim \hbar^{N_L-1}$$

Таким образом, разложение связных функций Грина по петлям совпадает с разложением по степеням $\hbar$. Это означает, что в классическом пределе $\hbar \to 0$ среди связных диаграмм остаются только диаграммы без петель или, как говорят, древесные диаграммы.

Example (???)

(хочется еще пример, потом приведу.)

26.2.5 Problems about path integral formalism in QFT 4

KUL-aqft-2023-hw2.1/3 Identity for Grassmann integral

Assume that $\left\{\theta_i, \bar{\theta}_i, \eta_i, \bar{\eta}_i\right\}$ is a collection of independent Grassmann variables with $i = 1, ..., n$, and B_{ij} is an invertible $n \times n$ matrix. Show that the following identity is true

$$Z[B, \eta, \bar{\eta}] \equiv \int \prod_{i=1}^{n} d\bar{\theta}_i d\theta_i \exp\left(-\bar{\theta}_i B_{ij} \theta_j + \bar{\eta}_i \theta_i + \bar{\theta}_i \eta_i\right) = \det(B) \exp\left(\bar{\eta}_i \left(B^{-1}\right)_{ij} \eta_j\right).$$

Using this result compute the "two-point function" $\left\langle \theta_i \bar{\theta}_j \right\rangle$. Express your result in two alternative ways, one explicit expression in terms of the matrix B_{ij} and one in terms of derivatives of the "path integral" $Z[B, \eta, \bar{\eta}]$.

Solution

KUL-aqft-2023-hw2.2/3 Value of Grassmann integral (?????)

Assume that $w_i(x)$ are functions of the n real variables x_i. Take θ_i and $\bar{\theta}_i$ to be n independent Grassmann variables. Compute the integral

$$Z[w] \equiv \frac{1}{(2\pi)^{n/2}} \int d^n x \prod_{i=1}^{n} d\bar{\theta}_i d\theta_i \exp\left(-\bar{\theta}_i \partial_j w_i(x) \theta_j - \frac{1}{2} w_i(x) w_i(x)\right).$$

Assume that $\det\left[\partial_i w_j(x)\right] > 0$.

Now take

$$w_i(x) := x_i + \frac{1}{2} g_{ijk} x_j x_k, \qquad \text{with} \qquad g_{ijk} = g_{ikj} = g_{kij}.$$

Assume that all g_{ijk} are small and find the Feynman rules for this perturbative expansion. Evaluate the one- and two-loop contributions to the "path integral" $Z[g]$.

Solution

(??? вроде хорошая задача, подумаю потом!!! не до этого все еще.)

KUL-aqft-2023-hw1.1 Typical integral

Consider the integral

$$Z(\lambda) = \frac{1}{\sqrt{2\pi}} \int\limits_{-\infty}^{\infty} dx e^{-\frac{x^2}{2!} - \frac{\lambda}{4!} x^4}$$

This is a simple toy model for the path integral in quantum field theory.

1. What is the range of λ such that $Z(\lambda)$ converges?

2. Find a compact expression for the series expansion of $Z(\lambda)$ for small λ of the form

$$Z_N(\lambda) = \sum_{n=0}^{N} c_n \lambda^n$$

Is your series convergent? What is the radius of convergence?

3. Use your favorite computer program or www.wolframalpha.com to compute $Z(0.1)$. Evaluate your series expression $Z_N(\lambda)$ for $\lambda = 0.1$ and for $N = 1, 5, 10, 50$. Discuss and interpret your results.

4. Find a series expansion for $Z(\lambda)$ for $\lambda \gg 1$ of the form

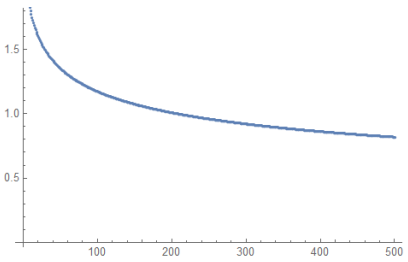
$$\hat{Z}_N(\lambda) = \sum_{n=0}^{N} d_n \lambda^{-(2n+1)/4}$$

Is this series convergent? For what value of N will you obtain a value for $\hat{Z}_N(0.1)$ which is close to the exact value $Z(0.1)$.

Solution

I'll check with Wolfram:

```
f[l_] = Integrate[ Exp[-x^2/2 - l x^4/24], {x, - \ [Infinity], \ [Infinity]}]
ListPlot[Table[f[n], {n, 500}]]
```



So indeed there is no reason to worry about it.

1.

What is the range of λ such that $Z(\lambda)$ converges?

It converges for $\lambda \geq 0$, since for it it behaves like $\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} dx e^{-\frac{x^2}{2}}$, which converges. For $\lambda < 0$, integral behaves like $\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} dx e^{|\lambda| \frac{x^4}{4!}}$ and it diverges.

1. Another solution

A Series Use Eq. 1.131 from Osborn to express Z with two exponential Taylor series.

$$\begin{aligned} Z &= \exp\left(\frac{1}{2}\frac{\partial^2}{\partial x^2}\right) \exp\left(-\frac{\lambda}{4!}x^4\right)\Big|_{x=0} \\ &= \sum_{m=0}^{\infty}\sum_{n=0}^{\infty} \frac{(-\lambda)^n}{m!n!}\left(\frac{1}{2}\frac{\partial^2}{\partial x^2}\right)^m \left(\frac{x^4}{4!}\right)^n\Big|_{x=0} \\ &= \sum_{m=0}^{\infty}\sum_{n=0}^{\infty} \frac{(-\lambda)^n}{m!n!} 2^{-m}(4!)^{-n}\left(\frac{\partial^2}{\partial x^2}\right)^m x^{4n}\Big|_{x=0} \end{aligned}$$

Only the $4n$-th derivative of x^{4n} is nonvanishing, so restrict to $m = 2n$. This derivative equals $(4n)!$.

$$\begin{aligned} Z &= \sum_{n=0}^{\infty} \frac{(-\lambda)^n}{(2n)!n!} 2^{-2n} (4!)^{-n} (4n)! \\ &= \sum_{n=0}^{\infty} (-\lambda)^n \frac{(4!4)^{-n}(4n)!}{n!(2n)!} \\ &= \sum_{n=0}^{\infty} (-\lambda)^n \frac{6^{-n}\Gamma\left(2n+\frac{1}{2}\right)}{\sqrt{\pi}\Gamma(n+1)} \end{aligned}$$

This is of that power series form with $c_n = (-1)^n \frac{6^{-n}\Gamma(2n+1/2)}{\sqrt{\pi}\Gamma(n+1)}$. This is divergent because the $(4n)$! grows faster than everything else. This can be seen from the Stirling formula, $\mathcal{O}(n!) = \mathcal{O}\left(\sqrt{n}\left(\frac{n}{e}\right)^n\right)$. The radius of convergence is 0. But that's normal.

2.

Well, I have no idea how to implement mathematical analysis for this problem and it will take me a lot of time to revise mathematical tools for it. But the problem is about the results, so I can just use a numerical method from paragraph below. The result is that if diverges at around $N \approx 42$.

3.

I write:

```
g[numb_]:= Series[f[1] // Normal, {1, 0, numb}, Assumptions->{1 \[Element] Reals, 1 > 0}]//Normal
g[1] /. 1 -> 0.1
g[5] /. 1 -> 0.1
g[10] /. 1 -> 0.1
g[50] /. 1 -> 0.1
```

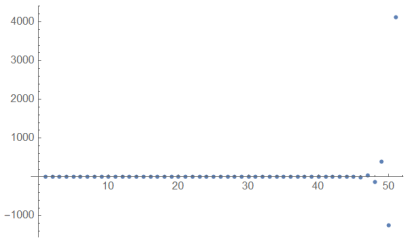
I get:

$$Z(0.1) = 2.47732 \quad Z_1(0.1) = 2.4753 \quad Z_5(0.1) = 2.47731 \quad Z_{10}(0.1) = 2.47732 \quad Z_{50}(0.1) = 4112.56$$

Wow, it diverges at big N...

Let's analyse more:

```
TableForm[N[Table[g[numb], {numb, 0, 5}] ] ]
ListPlot[%, PlotRange -> All]
```



4.

I will use Watson's lemma from Mathematical Analysis II by Vladimir A. Zorich (page 741 in russian version). This lemma is as follows.

Let's $\alpha > 0, \beta > 0, 0 < a \leqslant \infty$, $f \in C([0,a],\mathbb{R})$. Then for $W(\lambda) := \int\limits_0^a x^{\beta-1} f(x) e^{-\lambda x^\alpha} dx$

$$\lim_{\lambda \to +\infty} W(\lambda) \sim \frac{1}{\alpha} f(0) \Gamma(\beta/\alpha) \lambda^{-\frac{\beta}{\alpha}} + O\left(\lambda^{-\frac{\beta+1}{\alpha}}\right),$$

if $f(x) = f(0) + O(x)$ with $x \to 0$.

b) If $f(x) = a_0 + a_1 x + ... + a_n x^n + O\left(x^{n+1}\right)$ with $x \to 0$, then

$$W(\lambda) = \frac{1}{\alpha} \sum_{k=0}^{n} a_k \Gamma\left(\frac{k+\beta}{\alpha}\right) \lambda^{-\frac{k+\beta}{\alpha}} + O\left(\lambda^{-\frac{n+\beta+1}{\alpha}}\right)$$

c) If f infinitely differentiable in $x = 0$, then

$$W(\lambda) \simeq \frac{1}{\alpha} \sum_{k=0}^{\infty} \frac{f^{(k)}(0)}{k!} \Gamma\left(\frac{k+\beta}{\alpha}\right) \lambda^{-\frac{k+\beta}{\alpha}}.$$

So in our case we will have only terms for even terms, because for odd ones $f^{(k)}(0) = 0$. And in notation above we have $\beta = 1, \alpha = 4, \lambda \to \frac{\lambda}{4!}, f(x) = e^{-x^2/2}$, so we will get:

I checked with Wolfram, $f^{(2k)}(0) = (-1)^{k/2}(2k)!!$, so

$$Z_N = \frac{1}{4} \sum_{2k=0}^{N} \frac{(-1)^{k/2}(2k)!!}{(2k)!} \Gamma\left(\frac{2k+1}{4}\right) \lambda^{-\frac{2k+1}{4}}$$

I suppose that this series are convergent and better then above ones.

О смысле этого интеграла и результатов (?????)

(напишу потом, оставался вопрос, потом подумаю.)

МФТИ-Мусаев-2023.18/19 Функциональный интеграл фермионов

Рассмотрим квантовую механику, заданную лагранжианом

$$L_E = \bar{\psi}\dot{\psi} + \omega\bar{\psi}\psi$$

где $\bar{\psi}, \psi$ - грассмановы переменные и $\{\bar{\psi}, \psi\} = 1$. Считая, что переменные удовлетворяют антипериодическим граничным условиям $\psi(t + \beta) = -\psi(t)$, вычислить функциональный интеграл теории. Почему осмысленны именно антипериодические условия?

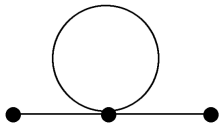
Интеграл для "головастика" ϕ^4

Вычислить интеграл для диаграммы "головастик":



Solution (????)

(в теории уже это написано, там напишу лучше еще, сюда потом буду писать.)

27 Problems about physics in QFT

27.1 Problems about decays and scatterings

27.1.1 Problems about typical scatterings in QED

Stanford.Zhou.2022.8.1. Magnetic moments in QED. (15/45 p)

The interaction Hamiltonian in quantum electrodynamics for a Dirac field of charge q is

$$H_I = q \int d^3x \bar{\Psi} \gamma^\mu \Psi A_\mu$$

To understand the physical meaning of this expression, we can evaluate its matrix elements in states $|p,s\rangle = \sqrt{2E_p} a_s^\dagger(p)|0\rangle$ with a single fermion. We assume the electromagnetic field is in a quantum state with negligible field uncertainty, so that its field operator A_μ can be replaced with a time-independent classical expectation value $A_\mu^{\mathrm{cl}}(\mathbf{x})$.

a) Show that the matrix elements of the Schrodinger picture Hamiltonian are

$$\langle p,s\,|H_I|\,p',s'\rangle = q\int d^3x e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}} \bar{u}_s(p)\gamma^\mu u_{s'}(p')\, A_\mu^{\mathrm{cl}}(\mathbf{x})$$

when $|p',s'\rangle \neq |p,s\rangle$.

b) Evaluate both sides of (4) in a static electric field, corresponding to general $A^0(\mathbf{x})$ and $\mathbf{A}=0$. Show that they agree when $q'=q$, as one would expect.

c) Show that if the fermion was a classical spinning ball with uniform mass and charge density, then its g-factor would be 1. This strongly disagrees with the measured value.

d) Evaluate both sides of (4) in a static magnetic field, corresponding to $A^0=0$ and $\nabla\times\mathbf{A}=\mathbf{B}(\mathbf{x})$, and infer the value of g. (Hint: to relate spin in the Dirac theory to spin in the nonrelativistic theory, recall that in the nonrelativistic theory, spinors ξ_s have two components and the spin operator is $\mathbf{S}=\boldsymbol{\sigma}/2$. You already showed in problem set 7 how the Dirac spinors $u_s(p)$ are built from ξ_s. You will have to integrate by parts, so assume $\mathbf{A}$ and $\mathbf{B}$ vanish at infinity.)

Solution:

Plugging in the Schrodinger picture mode expansion of the Dirac field, and using the abbreviated notation introduced in the solutions to problem set 2,

$$\begin{aligned}\langle p,s\,|H_I|\,p',s'\rangle &= q\sum_{r,r'}\int d\mathbf{x}\frac{d\mathbf{q}}{\sqrt{2E_q}}\frac{d\mathbf{q}'}{\sqrt{2E_{q'}}}\sqrt{2E_p 2E_{p'}}\\ &\times\left\langle 0\left|a_s(\mathbf{p})\left(a_r^\dagger(\mathbf{q})e^{-i\mathbf{q}\cdot\mathbf{x}}\bar{u}_r(q)+b_r(\mathbf{q})e^{i\mathbf{q}\cdot\mathbf{x}}\bar{v}_r(q)\right)\mathcal{A}\left(a_{r'}(\mathbf{q}')\,e^{i\mathbf{q}'\cdot\mathbf{x}}u_{r'}(q)+b_{r'}^\dagger(\mathbf{q}')\,e^{-i\mathbf{q}'\cdot\mathbf{x}}v_{r'}(q')\right)a_{s'}^\dagger(\mathbf{p}')\right|0\right\rangle.\end{aligned}$$

Now let's think about the structure of this matrix element. We can only get nonzero contributions from the terms $a_r^\dagger(\mathbf{q})a_{r'}(\mathbf{q}')$ and $b_r(\mathbf{q})b_{r'}^\dagger(\mathbf{q}')$. On the other hand, the latter term yields

$$\left\langle 0\left|a_s(\mathbf{p})b_r(\mathbf{q})b_{r'}^\dagger(\mathbf{q}')\,a_{s'}^\dagger(\mathbf{p}')\right|0\right\rangle = \delta_{ss'}\delta_{rr'}\phi(\mathbf{p}-\mathbf{p}')\,\phi(\mathbf{q}-\mathbf{q}')$$

and therefore cannot contribute matrix elements with $|p',s'\rangle\neq|p,s\rangle$. Discarding this term, we're left with

$$\begin{aligned}\langle p,s\,|H_I|\,p',s'\rangle &= q\int d\mathbf{x}d\mathbf{q}d\mathbf{q}'\frac{\sqrt{2E_p2E_{p'}}}{\sqrt{2E_q2E_{q'}}}e^{-i(\mathbf{q}-\mathbf{q}')\cdot\mathbf{x}}\sum_{r,r'}\bar{u}_r(q)\not{A}u_{r'}(q')\left\langle 0\left|a_s(\mathbf{p})a_r^\dagger(\mathbf{q})a_{r'}(\mathbf{q}')\,a_{s'}^\dagger(\mathbf{p}')\right|0\right\rangle\\ &= q\int d\mathbf{x}d\mathbf{q}'\frac{\sqrt{2E_{p'}}}{\sqrt{2E_{q'}}}e^{-i(\mathbf{p}-\mathbf{q}')\cdot\mathbf{x}}\sum_{r'}\bar{u}_s(p)\not{A}u_{r'}(q')\left\langle 0\left|a_{r'}(\mathbf{q}')\,a_{s'}^\dagger(\mathbf{p}')\right|0\right\rangle\\ &= q\int d\mathbf{x}e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}}\bar{u}_s(p)\not{A}u_{s'}(p').\end{aligned}$$

This is the desired result. Using the Gordon identity we find

$$\langle p,s\left|H_I\right|p',s'\rangle = \frac{q}{2m}\int d\mathbf{x}e^{-i\left(\mathbf{p}-\mathbf{p}'\right)\cdot\mathbf{x}}\bar{u}_s(p)\left(p'_\mu+p_\mu+i\sigma_{\mu\nu}\left(p'^\nu-p^\nu\right)\right)u_{s'}\left(p'\right)A^\mu(x)$$

In nonrelativistic quantum mechanics, the single-particle states are $|\mathbf{p},s\rangle$. If the particle has charge q' and g-factor g, then its magnetic moment is $\mu=(gq'/2m)\,\mathbf{S}$ where $\mathbf{S}$ is the spin. In terms of the particle's position $\mathbf{x}$, the Hamiltonian contains the terms

$$H_I^{\text{nr}} = q'A^0(\mathbf{x}) - \boldsymbol{\mu}\cdot\mathbf{B}(\mathbf{x})$$

To find the values of q' and g, we equate matrix elements in the nonrelativistic limit,

$$\langle p,s\left|H_I\right|p',s'\rangle = 2m\left\langle\mathbf{p},s\left|H_I^{\text{nr}}\right|\mathbf{p}',s'\right\rangle \text{ when } |\mathbf{p}|,|\mathbf{p}'|\ll m$$

where the factor of $2m$ converts between relativistic and nonrelativistic normalization. We could evaluate both sides for general $A_\mu^{\text{cl}}(\mathbf{x})$, but it is easier to consider two special cases. In both cases it will be helpful to use the Gordon identity from set 7.

Solution:

If we set $\mathbf{A}=0$, then the matrix element above reduces to

$$\langle p,s\left|H_I\right|p',s'\rangle = \frac{q}{2m}\int d\mathbf{x}e^{-i\left(\mathbf{p}-\mathbf{p}'\right)\cdot\mathbf{x}}\bar{u}_s(p)\left(p'_0+p_0+i\sigma_{0i}\left(p^i-p^i\right)\right)u_{s'}\left(p'\right)A^0(x)$$

since σ_{00} vanishes. In the nonrelativistic limit, $p_0,p'_0\approx m$ are much greater than p^i,p^i, so we may simply drop the latter terms, giving

$$\begin{aligned}\langle p,s\left|H_I\right|p',s'\rangle &= q\int d\mathbf{x}e^{-i\left(\mathbf{p}-\mathbf{p}'\right)\cdot\mathbf{x}}\bar{u}_s(p)u_{s'}\left(p'\right)A^0(x)\\ &= 2mq\delta_{ss'}\int d\mathbf{x}e^{-i\left(\mathbf{p}-\mathbf{p}'\right)\cdot\mathbf{x}}A^0(x)\end{aligned}$$

On the other hand, in nonrelativistic quantum mechanics we have

$$\begin{aligned}2m\left\langle\mathbf{p},s\left|q'A^0(\hat{\mathbf{x}})\right|\mathbf{p}',s'\right\rangle &= 2mq'\delta_{ss'}\left\langle\mathbf{p}\left|A^0(\hat{\mathbf{x}})\right|\mathbf{p}'\right\rangle\\ &= 2mq'\delta_{ss'}\int d\mathbf{y}d\mathbf{z}\langle\mathbf{p}|\mathbf{y}\rangle\left\langle\mathbf{y}\left|A^0(\hat{\mathbf{x}})\right|\mathbf{z}\right\rangle\langle\mathbf{z}|\mathbf{p}'\rangle\\ &= 2mq'\delta_{ss'}\int d\mathbf{y}d\mathbf{z}e^{-i\mathbf{p}\cdot\mathbf{y}}e^{i\mathbf{p}'\cdot\mathbf{z}}\delta(\mathbf{y}-\mathbf{z})A^0(\mathbf{z})\\ &= 2mq'\delta_{ss'}\int d\mathbf{y}e^{-i\left(\mathbf{p}-\mathbf{p}'\right)\cdot\mathbf{y}}A^0(\mathbf{y})\\ &= 2mq'\delta_{ss'}\int d\mathbf{x}e^{-i\left(\mathbf{p}-\mathbf{p}'\right)\cdot\mathbf{x}}A^0(\mathbf{x})\end{aligned}$$

The two matrix elements match if $q=q'$, as desired.

Solution:

For simplicity, let's consider a thin ring of radius r, angular velocity ω, mass m, and charge q. Then the angular momentum is

$$S = mvr = m\omega r^2$$

and the magnetic moment is

$$\mu = IA = \frac{q}{2\pi/\omega}\left(\pi r^2\right) = \frac{q\omega r^2}{2}$$

Therefore, the ring has $\mu/S=q/2m$, corresponding to a g-factor of 1. Since a ball is just a superposition of such rings, this shows that $g=1$ for a ball, or more generally any spinning object with axial symmetry.

Solution:

In this case, since A^0 vanishes, we have

$$\langle p,s\,|H_I|\,p',s'\rangle = \frac{q}{2m}\int d\mathbf{x}e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}}\bar{u}_s(p)\left(p'_i+p_i+i\sigma_{i\nu}\left(p'^{\nu}-p^{\nu}\right)\right)u_{s'}\left(p'\right)A^i(x)$$

This might look more complicated than what we had before using the Gordon identity, but this form is useful because it lets us isolate the physically distinct effects of different terms, and figure out which to keep in the nonrelativistic limit. (Though of course you could also do the problem without using the Gordon identity too.) Now, we need to choose which term to keep within the parentheses.

- The p_i and p'_i terms are order mv.
- The term $\sigma_{i0}\left(p'^0-p^0\right)$ is not order m, since the m 's cancel. Instead, it's order mv^2.
- The term $\sigma_{ij}\left(p^j-p^j\right)$ is order mv.

The second contribution is therefore negligible in the nonrelativistic limit. The first contribution is not negligible, but it also has nothing to do with spin: it will just yield the $\mathbf{p}\cdot\mathbf{A}$ term in the nonrelativistic Hamiltonian that physically corresponds to the magnetic force on a charged particle. (Considering it won't tell us anything new, because we already know that $q'=q$ from part (b).) We therefore focus on the third term, giving

$$\begin{aligned}\langle p,s\,|H_I|\,p',s'\rangle &\supset \frac{q}{2m}\int d\mathbf{x}e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}}\bar{u}_s(p)\left(i\sigma_{ij}\left(p'^j-p^j\right)\right)u_{s'}\left(p'\right)A^i(x)\\ &= \frac{q}{2m}\int d\mathbf{x}e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}}\left(p^j-p'^j\right)\left(\bar{u}_s(p)\frac{\left[\gamma^i,\gamma^j\right]}{2}u_{s'}\left(p'\right)\right)A^i(x)\end{aligned}$$

To make further progress, we use the results we derived in the Weyl representation in problem set 7. First, because we're only considering the leading term in the nonrelativistic limit, it suffices to expand the spinor solutions to lowest order in m,

$$u_s(p)=\begin{pmatrix}\sqrt{p\cdot\sigma}\xi_s\\ \sqrt{p\cdot\bar{\sigma}}\xi_s\end{pmatrix}\approx\sqrt{m}\begin{pmatrix}\xi_s\\ \xi_s\end{pmatrix}$$

We can also explicitly evaluate the commutators. For example, we have

$$\left[\gamma^1,\gamma^2\right]=-2i\begin{pmatrix}\sigma^3 & \\ & \sigma^3\end{pmatrix}$$

from which we conclude in general that

$$\left[\gamma^i,\gamma^j\right]=-2i\epsilon^{ijk}\begin{pmatrix}\sigma^k & \\ & \sigma^k\end{pmatrix}$$

Plugging these results in and simplifying, we find

$$\langle p,s\,|H_I|\,p',s'\rangle \supset q\int d\mathbf{x}e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}}(-i)\left(p^j-p'^j\right)\left(\epsilon^{ijk}\xi_s^\dagger\sigma^k\xi_{s'}\right)A^i(x)$$

To handle the $p^j-p'^j$, we write it as a derivative and integrate by parts, dropping a boundary term,

$$\begin{aligned}\langle p,s\,|H_I|\,p',s'\rangle &\supset q\int d\mathbf{x}\frac{\partial}{\partial x_j}\left(e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}}\right)\left(\epsilon^{ijk}\xi_s^\dagger\sigma^k\xi_{s'}\right)A^i(x)\\ &= q\xi_s^\dagger\sigma^k\xi_{s'}\int d\mathbf{x}e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}}\epsilon^{ijk}\partial^j A^i(x)\\ &= -q\xi_s^\dagger\sigma^k\xi_{s'}\int d\mathbf{x}e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}}B^k.\end{aligned}$$

We can now compare this to the nonrelativistic result,

$$2m\left\langle\mathbf{p},s\right|(-\boldsymbol{\mu}\cdot\mathbf{B})\left|\mathbf{p}',s'\right\rangle=-gq'\xi_s^\dagger S^k\xi_{s'}\int d\mathbf{x}e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}}B^k$$

by the same logic as in part (b). Since $q'=q$ and $\mathbf{S}=\boldsymbol{\sigma}/2$, we conclude that $g=2$.

The agreement of this value you found in part **(d)** with the experimentally measured value for the electron was one of the early triumphs of the Dirac equation.

Stanford.Zhou.2022.8.3. Electron-positron annihilation to muons. (15/45p)

One of the key successes of quantum electrodynamics is its description of particle creation and annihilation processes at relativistic energies. In this exercise we will consider the process $e^+e^- \to \mu^+\mu^-$, where the electron and muon are Dirac fields of charge e, and mass m_e and m_μ respectively.

a) Let the initial momenta be $p^\mu_{e^+}$ and $p^\mu_{e^-}$ and the final momenta be $p^\mu_{\mu^+}$ and $p^\mu_{\mu^-}$. Find the scattering matrix element $\mathcal{M}$ for this process, to leading nonvanishing order in e.

b) Let $|\overline{\mathcal{M}}|^2$ be the square of the matrix element, summed over final spin states and averaged over initial spin states. Compute $|\overline{\mathcal{M}}|^2$ in terms of e, m_e, m_μ, and the Mandelstam variables s and t, where

$$s = (p_{e^+} + p_{e^-})^2, \quad t = \left(p_{e^-} - p_{\mu^-}\right)^2, \quad u = \left(p_{e^-} - p_{\mu^+}\right)^2$$

c) Rewrite $|\overline{\mathcal{M}}|^2$ in terms of e, m_e, m_μ, s, and the angle θ between $\mathbf{p}_{e^-}$and $\mathbf{p}_{\mu^-}$.

d) Starting from equation (4.84) of Peskin and Schroeder, compute the differential cross section $d\sigma/d\Omega$ and the total cross section.

Solution:

There is one relevant Feynman diagram, which gives

$\mathcal{M}_{e^+e^-\to\mu^+\mu^-} =$ 
$$= \bar{u}_t(p_\mu^-)(-ie\gamma^\mu_{tu})v_u(p_{\mu^+})\left(\frac{-i\eta_{\mu\nu}}{(p_{e^+}+p_{e^-})^2}\right)\bar{v}_r(p_{e^+})(-ie\gamma^\nu_{rs})u_s(p_{e^-}).$$

Solution:

Before starting, we note that the Mandelstam variables are simply related to inner products,

$$\frac{s}{2} = m_e^2 + p_{e^+}\cdot p_{e^-} = m_{\mu^2} + p_{\mu^+}\cdot p_{\mu^-}$$

and

$$t = m_e^2 + m_\mu^2 - p_{e^-}\cdot p_{\mu^-} = m_e^2 + m_\mu^2 - p_{e^+}\cdot p_{\mu^+}$$
$$u = m_e^2 + m_\mu^2 - p_{e^-}\cdot p_{\mu^+} = m_e^2 + m_\mu^2 - p_{e^+}\cdot p_{\mu^-}$$

Now, squaring, summing over final spins and averaging over initial spins yields

$$|\overline{\mathcal{M}}|^2 = \frac{e^4}{s^2}\frac{1}{4}\sum_{\text{spins}} \bar{u}_t\left(p_\mu^-\right)\gamma^\mu_{tu}v_u\left(p_{\mu^+}\right)\bar{v}_{u'}\left(p_\mu^+\right)\gamma^\nu_{u't'}u_{t'}\left(p_{\mu^-}\right)\bar{v}_r\left(p_{e^+}\right)\left(\gamma_\mu\right)_{rs}u_s\left(p_{e^-}\right)\bar{u}_{s'}\left(p_{e^-}\right)\left(\gamma_\nu\right)_{s'r'}v_{r'}\left(p_{e^+}\right)$$
$$= \frac{e^4}{s^2}\frac{1}{4}\operatorname{tr}\left[\left(\not{p}_{\mu^-} + m_\mu\right)\gamma^\mu\left(\not{p}_{\mu^+} - m_\mu\right)\gamma^\nu\right]\operatorname{tr}\left[\left(\not{p}_{e^-} + m_e\right)\gamma_\mu\left(\not{p}_{e^+} - m_e\right)\gamma_\nu\right].$$

Both traces have the same form, and can be evaluated using the results from problem set 6,

$$\operatorname{tr}\left[(\not{p} + m)\gamma^\mu\left(\not{p}_2 - m\right)\gamma^\nu\right] = \operatorname{tr}\left[\not{p}_1\gamma^\mu\not{p}_2\gamma^\nu\right] - m^2\operatorname{tr}\left[\gamma^\mu\gamma^\nu\right]$$
$$= 4\left(p_1^\mu p_2^\nu + p_1^\nu p_2^\mu - (p_1\cdot p_2)\,\eta^{\mu\nu}\right) - 4m^2\eta^{\mu\nu}$$
$$= 4\left(p_1^\mu p_2^\nu + p_1^\nu p_2^\mu - \frac{s}{2}\eta^{\mu\nu}\right)$$

where in the last step we used (S44). Inserting this result twice above, we have

$$|\overline{\mathcal{M}}|^2 = \frac{4e^4}{s^2}\left(p^\mu_{e^+}p^\nu_{e^-} + p^\mu_{e^-}p^\nu_{e^+} - \frac{s}{2}\eta^{\mu\nu}\right)\left(p_{\mu^+,\mu}p_{\mu^-,\nu} + p_{\mu^-,\mu}p_{\mu^+,\nu} - \frac{s}{2}\eta_{\mu\nu}\right)$$
$$= \frac{4e^4}{s^2}\left(s^2 - s\left(p_{\mu^+}\cdot p_{\mu^-} + p_{e^+}\cdot p_{e^-}\right) + 2\left(p_{e^+}\cdot p_{\mu^+}\right)\left(p_{e^-}\cdot p_{\mu^-}\right) + 2\left(p_{e^+}\cdot p_{\mu^-}\right)\left(p_{e^-}\cdot p_{\mu^+}\right)\right)$$

We can then write the inner products in terms of s, t, and u using (S44) and (S45). There are many possible forms for the answer, since

$$s + t + u = 2m_e^2 + 2m_\mu^2.$$

If we eliminate u, then we get

$$|\overline{\mathcal{M}}|^2 = \frac{2e^4}{s^2}\left[(s+t)^2 + t^2 - 4t\left(m_e^2 + m_\mu^2\right) + 2\left(m_e^2 + m_\mu^2\right)^2\right]$$

Alternatively, if we eliminate s inside the brackets, then we get

$$|\overline{\mathcal{M}}|^2 = \frac{2e^4}{s^2}\left[\left(u - 2\left(m_e^2 + m_\mu^2\right)\right)^2 + \left(t - 2\left(m_e^2 + m_\mu^2\right)\right)^2 - 2\left(m_e^2 + m_\mu^2\right)^2\right]$$

For the rest of this problem, we specialize to the center of mass frame.

Solution:

In the centre-of-mass frame we have

$$E_{e^-} = E_{e^+}, \quad E_{\mu^-} = E_{\mu^+}, \quad \mathbf{p}_{e^-} = -\mathbf{p}_{e^+}, \quad \mathbf{p}_{\mu^-} = -\mathbf{p}_{\mu^+}$$

which implies that

$$s = 4E_{e^-}^2 = 4E_{\mu^-}^2.$$

Furthermore, we have $E_{e^\pm}^2 = |\mathbf{p}_{e^\pm}|^2 + m_e^2$ and $E_{\mu^\pm}^2 = |\mathbf{p}_{\mu^\pm}|^2 + m_\mu^2$.
Starting from S55, we need to eliminate t in favor of θ. Starting from the definition of t,

$$\begin{aligned} t &= m_e^2 + m_\mu^2 - 2E_{e^-}E_{\mu^-} + 2\,|\mathbf{p}_{e^-}|\,|\mathbf{p}_{\mu^-}|\cos\theta \\ &= \frac{1}{2}\left(2m_e^2 + 2m_\mu^2 - s + \sqrt{s - 4m_e^2}\sqrt{s - 4m_\mu^2}\cos\theta\right) \end{aligned}$$

Plugging this into S55 and simplifying gives

$$|\overline{\mathcal{M}}|^2 = e^4\left[1 + \frac{4\left(m_e^2 + m_\mu^2\right)}{s} + \left(1 - 4m_e^2/s\right)\left(1 - 4m_\mu^2/s\right)\cos^2\theta\right]$$

Also note that solving (S60) for $\cos\theta$ gives

$$\cos\theta = 2\frac{t - m_e^2 - m_\mu^2 + \frac{s}{2}}{\sqrt{s - 4m_e^2}\sqrt{s - 4m_\mu^2}}$$

Solution:

Equation (4.84) of Peskin and Schroeder is

$$\frac{d\sigma}{d\Omega} = \frac{1}{2E_{e^-}2E_{e^+}\,|\mathbf{v}_{e^-} - \mathbf{v}_{e^+}|}\frac{|\mathbf{p}_{\mu^-}|}{(2\pi)^2 4E_{\mathrm{cm}}}|\overline{\mathcal{M}}|^2$$

Our first task is to write the phase space factors in the same variables we've been using above. We note that $\sqrt{s} = E_{\mathrm{cm}} = 2E_{e^-} = 2E_{e^+}$in the center of mass frame. Furthermore,

$$|\mathbf{v}_{e^-} - \mathbf{v}_{e^+}| = 2\,|\mathbf{v}_{e^-}| = 2\frac{|\mathbf{p}_{e^-}|}{E_{e^-}} = 2\frac{\sqrt{E_{e^-}^2 - m_{e^-}^2}}{E_{e^-}} = 2\sqrt{1 - 4m_e^2/s}$$

and similarly

$$|\mathbf{p}_{\mu^-}| = \frac{\sqrt{s}}{2}\sqrt{1 - 4m_\mu^2/s}$$

Plugging these results in and simplifying gives

$$\frac{d\sigma}{d\Omega} = \frac{1}{64\pi^2 s}\frac{\sqrt{1-4m_\mu^2/s}}{\sqrt{1-4m_e^2/s}}|\overline{\mathcal{M}}|^2$$

To find the total cross section, we integrate over solid angle, noting that

$$\int d\Omega = 4\pi, \quad \int \cos^2\theta d\Omega = \int_0^{2\pi} d\phi \int_0^{\pi} d\theta \sin\theta\cos^2\theta = \frac{4\pi}{3}$$

The final result is

$$\begin{aligned}\sigma &= \frac{e^4}{16\pi s}\frac{\sqrt{1-4m_\mu^2/s}}{\sqrt{1-4m_e^2/s}}\left[1+\frac{4\left(m_e^2+m_\mu^2\right)}{s}+\frac{\left(1-4m_e^2/s\right)\left(1-4m_\mu^2/s\right)}{3}\right] \\ &= \frac{e^4}{12\pi s}\frac{\sqrt{1-4m_\mu^2/s}}{\sqrt{1-4m_e^2/s}}\left(1+2m_e^2/s\right)\left(1+2m_\mu^2/s\right).\end{aligned}$$

As a check, we recover the expected result in the ultrarelativistic limit,

$$\sigma \approx \frac{e^4}{12\pi s} = \frac{4\pi\alpha^2}{3s}$$

which matches the result in Peskin and Schroeder.

You can see section 5.1 of Peskin and Schroeder to get started or check your answer. But note that the book neglects the mass of the electron, while here we account for it.

Stanford.Zhou.2022.9.1. $e^+e^- \to \mu^+\mu^-$ at one loop. (8/45p)

This problem set guides you through the calculation of loop diagrams and their application to the renormalization of QED. Unlike previous problem sets, it is ordered sequentially: each problem is easiest to approach after completing the previous problems. For reference, you may find it useful to consult sections 6.3 and 7.5 of Peskin and Schroeder, but this problem set is self-contained and its results are somewhat more general.

We will use dimensional regularization with $d = 4 - 2\epsilon$. To avoid confusion, we will rename the $i\epsilon$ in the Feynman propagator to $i0$ in this problem set.

In the previous problem set, you considered the leading order (or "tree level") contribution to the scattering matrix element for $e^+e^- \to \mu^+\mu^-$,

$\mathcal{M}^{\mathrm{LO}} =$ 
$$= \bar{u}_s(p_3)(-ie\gamma^\nu)v_t(p_4)\frac{-i\eta_{\mu\nu}}{(p_1+p_2)^2+i0}\bar{v}_{s'}(p_2)(-ie\gamma^\mu)u_{t'}(p_1)$$

which is proportional to e^2. The next-to-leading order contribution $\mathcal{M}^{\mathrm{NLO}}$ is of order e^4, and contains Feynman diagrams with one loop.

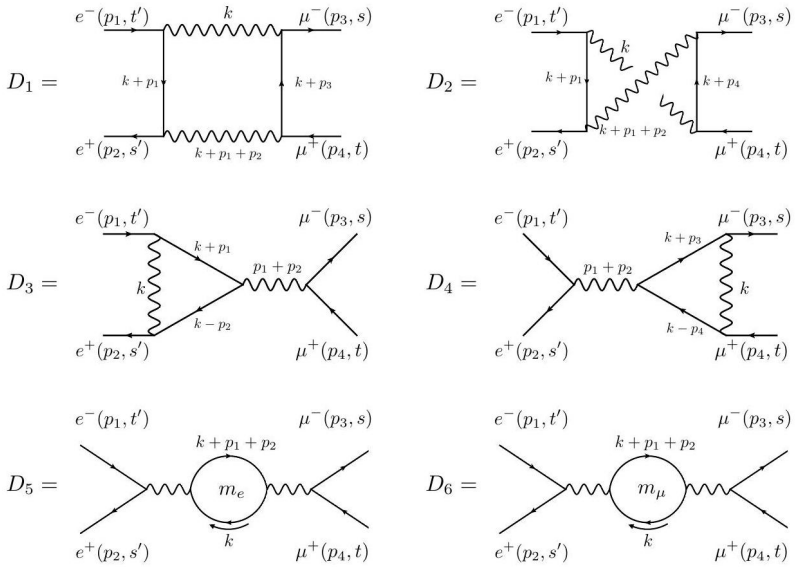
a) Draw all Feynman diagrams that contribute to $\mathcal{M}^{\mathrm{NLO}}$.

b) Write down $\mathcal{M}^{\mathrm{NLO}}$ using the Feynman rules. You don't have to evaluate the loop integrals; this is just to show you examples of their typical form.

Solution to a:

The matrix element at next-to-leading order (NLO) is given by

$$M^{\mathrm{NLO}} = D_1 + D_2 + D_3 + D_4 + D_5 + D_6$$



Solution to b:

(!???!! проделаю это еще раз и перепишу)

$$D_1 = \int \frac{d^dk}{(2\pi)^d} \bar{u}_s(p_3)(-ie\gamma^\mu) \frac{i\left(\not{k}+\not{p}_3+m_\mu\right)}{(k+p_3)^2-m_\mu^2+i0}(-ie\gamma^\nu) v_t(p_4) \frac{-i\eta_{\mu\sigma}}{k^2+i0}$$
$$\times \bar{v}_{s'}(p_2)(-ie\gamma^\rho) \frac{i\left(\not{k}+\not{p}_1+m_e\right)}{(k+p_1)^2-m_e^2+i0}(-ie\gamma^\sigma) u_{t'}(p_1) \frac{-i\eta_{\nu\rho}}{(k+p_1+p_2)^2+i0}.$$

$$D_2 = \int \frac{d^dk}{(2\pi)^d} \bar{u}_s(p_3)(-ie\gamma^\mu) \frac{i\left(\not{k}+\not{p}_4+m_\mu\right)}{(k+p_4)^2-m_\mu^2+i0}(-ie\gamma^\nu) v_t(p_4) \frac{-i\eta_{\mu\sigma}}{k^2+i0}$$
$$\times \bar{v}_{s'}(p_2)(-ie\gamma^\sigma) \frac{i\left(k+\not{p}_1+m_e\right)}{(k+p_1)^2-m_e^2+i0}(-ie\gamma^\rho) u_{t'}(p_1) \frac{-i\eta_{\nu\rho}}{(k+p_1+p_2)^2+i0}.$$

$$D_3 = \int \frac{d^dk}{(2\pi)^d} \bar{u}_s(p_3)(-ie\gamma^\mu) v_t(p_4) \frac{-i\eta_{\mu\nu}}{(p_3+p_4)^2+i0} \frac{-i\eta_{\sigma\rho}}{k^2+i0}$$
$$\times \bar{v}_{s'}(p_2)(-ie\gamma^\rho) \frac{i\left(\not{k}-\not{p}_2+m_e\right)}{(k-p_2)^2-m_e^2+i0}(-ie\gamma^\nu) \frac{i\left(\not{k}+\not{p}_1+m_e\right)}{(k+p_1)^2-m_e^2+i0}(-ie\gamma^\sigma) u_{t'}(p_1).$$

$$D_4 = \int \frac{d^dk}{(2\pi)^d} \bar{v}_{s'}(p_2)(-ie\gamma^\mu) u_{t'}(p_1) \frac{-i\eta_{\mu\nu}}{(p_1+p_2)^2+i0} \frac{-i\eta_{\sigma\rho}}{k^2+i0}$$
$$\times \bar{u}_s(p_3)(-ie\gamma^\rho) \frac{i\left(k+\not{p}_3+m_\mu\right)}{(k+p_3)^2-m_\mu^2+i0}(-ie\gamma^\nu) \frac{i\left(k\not{k}-\not{p}_4+m_\mu\right)}{(k-p_4)^2-m_\mu^2+i0}(-ie\gamma^\sigma) v_t(p_4).$$

$$D_5 = \int \frac{d^dk}{(2\pi)^d} \bar{u}_s(p_3)(-ie\gamma^\nu) v_t(p_4) \bar{v}_{s'}(p_2)(-ie\gamma^\mu) u_{t'}(p_1)$$
$$\times \frac{-i\eta_{\mu\rho}}{(p_1+p_2)^2+i0} \frac{\operatorname{tr}\left[(-ie\gamma^\rho) i\left(\not{k}+m_\mu\right)(-ie\gamma^\sigma) i\left(\not{k}+\not{p}_1+\not{p}_2+m_\mu\right)\right]}{\left(k_1+m_\mu^2+i0\right)(k+p_1+p_2)^2-m_\mu^2+i0} \frac{-i\eta_{\sigma\nu}}{(p_1+p_2)^2+i0}.$$

$$D_6 = \int \frac{d^dk}{(2\pi)^d} \bar{u}_s(p_3)(-ie\gamma^\nu) v_t(p_4) \bar{v}_{s'}(p_2)(-ie\gamma^\mu) u_{t'}(p_1)$$
$$\times \frac{-i\eta_{\mu\rho}}{(p_1+p_2)^2+i0} \frac{\operatorname{tr}\left[(-ie\gamma^\rho) i\left(\not{k}+m_\mu\right)(-ie\gamma^\sigma) i\left(\not{k}+\not{p}_1+\not{p}_2+m_\mu\right)\right]}{\left(k^2-m_\mu^2+i0\right)(k+p_1+p_2)^2-m_\mu^2+i0} \frac{-i\eta_{\sigma\nu}}{(p_1+p_2)^2+i0}$$

If you collect all factors of i, e and (-1), the common pre-factor is $i^8(-1)^6e^4 = (4\pi\alpha)^2$.

Stanford.Zhou.2022.9.5.* The scalar triangle integral. (5/45p)

a) Evaluate the scalar triangle integral $I_{\triangle}(a,b,c;p_1,p_2)$ when $p_1^2=p_2^2=0$, but for general a,b,c, and d, and give your answer in terms of $s=(p_1+p_2)^2$.

Solution:

(!! write again, from what we start?)

Introducing $s=(p_1+p_2)^2$, Feynman parameters and shifting the loop momentum $k\to k+(1-x_1-x_2)\,p_2-x_2p_1$ we find

$$I_T(a,b,c;s)=\frac{\Gamma(a+b+c)}{\Gamma(a)\Gamma(b)\Gamma(c)}\int\frac{d^dk}{(2\pi)^d}\int\limits_0^1 dx_1x_1^{a-1}dx_2x_2^{b-1}\left(1-x_1-x_2\right)^{c-1}\frac{1}{\left[k^2+sx_2\left(1-x_1-x_2\right)\right]^{a+b+c}}.$$

Next, we perform the Wick rotation $k^0=ik_E^0$ and integrate out k_E. We find

$$I_T(a,b,c;s)=i(-1)^{a+b+c}\pi^{d/2}(-s-i0)^{-a-b-c+\frac{d}{2}}\frac{\Gamma\left(a+b+c-\frac{d}{2}\right)}{(2\pi)^d\Gamma(a)\Gamma(b)\Gamma(c)}\int\limits_0^1 dx_1\int\limits_0^{1-x_1}dx_2$$
$$\times x_1^{a-1}x_2^{-a-c+\frac{d}{2}-1}\left(1-x_1-x_2\right)^{-a-b+\frac{d}{2}-1}$$

Next, we perform the transformation $x_2=(1-x_1)\,x_2$ and subsequently integrate out the parameter integrals over x_1 and x_2. We find

$$I_T(a,b,c;s)=i(4\pi)^{-\frac{d}{2}}(-1)^{a+b+c}(-s-i0)^{-a-b-c+\frac{d}{2}}\frac{\Gamma\left(-a-b+\frac{d}{2}\right)\Gamma\left(-a-c+\frac{d}{2}\right)\Gamma\left(a+b+c-\frac{d}{2}\right)}{\Gamma(b)\Gamma(c)\Gamma(-a-b-c+d)}.$$

b) It turns out there is a simple relation between the triangle and bubble integrals,

$$I_{\triangle}(1,1,1;p_1,p_2)|_{p_1^2=p_2^2=0}=CI_B\left(1,1;(p_1+p_2)^2\right)$$

Find the coefficient C in terms of d and s.

Solution:

By comparing our previous results, we conclude

$$C=-\frac{2(d-3)}{(d-4)s}$$

Рассеяние $e^+e^-\to\mu^+\mu^-$

(решу скоро!!)

Рассеяние $e^+e^-\to\pi^+\pi^-$

В ведущем порядке теории возмущений квантовой электродинамики вычислить дифференциальное и полное сечения элеткрон-позитронной аннигиляции в пион-антипион,

считая пионы точечными скалярными частицами: $e^+e^-\to\pi^+\pi^-$. Сравнить распределение по углами в системе центра масс с распределением в случае образования мюонов.

сечение рождения очарованных кварков

(задача их ктп киселева)

в глюон-глюоннном слиянии: g g cc. Рассмотреть синглетный и октетный по цвету вклады в сечение.

распад мюона $\mu^- \to e^- \bar{\nu}_e \nu_\mu$

Вычислить ширину трёхчастичного распада мюона на электрон и нейтрино: $\mu^- \to e^- \bar{\nu}_e \nu_\mu$

время распада заряженного пиона $\pi^- \to \mu^- \bar{\nu}_\mu$.

Вычислить время двухчастичного распада заряженного пиона: $\pi^- \to \mu^- \bar{\nu}_\mu$. Сравнить ширину распада пиона на электрон и мюон.

время распада нейтрона $n \to p e^- \bar{\nu}_e$

Распад Z-бозона на нейтрино

Вычислить ширину двухчастичного распада Z -бозона на нейтрино $Z \to \nu\bar{\nu}$

сечение $\bar{q}q \to \bar{c}c$

В ведушем порядке теории возмушений КХД вычислить сечение $\bar{q}q \to \bar{c}c$

ПШ-5.1. Кулоновское рассеяние.

Повторите решение задачи 4.4, часть (c), на этот раз используя для матричного элемента полное релятивистское выражение. Необходимо показать, что усредненное по спинам сечение равно

$$\frac{d\sigma}{d\Omega} = \frac{\alpha^2}{4|\mathbf{p}|^2\beta^2 \sin^4(\theta/2)} \left(1 - \beta^2 \sin^2 \frac{\theta}{2}\right)$$

где $\mathbf{p}$ - 3-импульс электрона, а β - его скорость. Это формула получила название формулы Мотта для кулоновского рассеяния релятивистских электронов. Выведите эту формулу другим способом, используя сечение рассеяния электрона на мюоне, в системе покоя мюона и в пределе $m_\mu \to \infty$.

Solution

(пишу коротко, потому что есть как раз теор часть для всяких деталей этого)

ПШ-5.2. Рассеяние Баба.

Вычислите дифференциальное сечение $d\sigma/d\cos\theta$ процесса $e^+e^- \to e^+e^-$. Вычисления можно сделать в пределе $E_{\text{cm}} \gg m_e$, то есть пренебречь массой электрона. Процесс описывается двумя фейнмановскими диаграммами. Вклады от них следует сложить, прежде чем находить квадрат инвариантного матричного элемента. Убедитесь, что вы получили правильный относительный знак между вкладами диаграмм. Вычисления довольно сложны, но окончательный результат очень прост. В частности, его удобно записать, используя мандельстамовские переменные s, t, u. Заметим, что в пределе нулевой массы электрона $u + s + t = 0$. Попробуйте привести дифференциальное сечение к виду:

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2}{s}\left[u^2\left(\frac{1}{s}+\frac{1}{t}\right)^2 + \left(\frac{t}{s}\right)^2 + \left(\frac{s}{t}\right)^2\right]$$

Перепишите эту формулу через $\cos\theta$ и постройте соответствующий график. Почему сечение расходится при $\theta \to 0$?

Solution

(пишу коротко, потому что есть как раз теор часть для всяких деталей этого)

ПШ-5.3.Куча вопросов о времени жизни позитрония

(мб много сделаю параграфов из этой задачи)

(a) Вычислите амплитуду $\mathscr{M}$ аннигиляции электрон-позитронной пары с образованием двух фотонов в нерелятивистском пределе (т. е. оставьте только слагаемые, пропорциональные нулевым степеням 3-импульсов электрона и позитрона). Используя этот результат и формализм связанных состояний фермион-антифермион, исследуйте аннигиляцию 1S-состояния позитрония с образованием двух фотонов. Покажите, что состояния позитрония со спином 1 не могут аннигилировать в два фотона (что подтверждает соображения симметрии, высказанные в задаче 3.8). Для состояния позитронов со спином 0 покажите, что результат пропорционален квадрату волновой функции 1 S - состояния в нуле. Подставив волновую функцию, известную из нерелятивистской квантовой механики, нужно получить следующий ответ:

$$\frac{1}{\tau} = \Gamma = \frac{\alpha^5 m_e}{2} \approx 8.03 \times 10^9 \mathrm{c}^{-1}.$$

Последние измерения* дают $\Gamma = 7.994 \pm 0.011$ нс $^{-1}$; расхождение в 0.5% говорит о необходимости учета радиационных поправок.

(b) Вычисление вероятностей распада состояний с большими значениями l - несколько более сложная задача. Мы рассмотрим случай $l = 1$. Прежде всего, выделим слагаемые в амплитуде $e^+e^- \to 2\gamma$, которые пропорциональны первой степени 3-импульса (для простоты ведем расчет в системе центра инерции). Так как

$$\int \frac{d^3p}{(2\pi)^3} p^i \psi(\mathbf{p}) = i \frac{\partial}{\partial x^i} \psi(\mathbf{x}) \bigg|_{\mathbf{x}=0}$$

эта часть амплитуды будет «перекрываться» со связанными P-состояниями. Покажите, что состояния со спином 1 (а не со спином 0) могут аннигилировать в два фотона. Это снова есть следствие C-инвариантности.

(c) Чтобы вычислить вероятности распада P-состояний, нам нужны соответствующим образом отнормированные волновые функции. Обозначим три волновые функции P-состояний как

$$\psi_i = x^i f(|\mathbf{x}|), \quad \text{причем они нормированы условием } \int d^3x \psi_i^*(\mathbf{x}) \psi_j(\mathbf{x}) = \delta_{ij},$$

а их фурье-образы как $\psi_i(\mathbf{p})$. Покажите, что

$$|B(\mathbf{k})\rangle = \sqrt{2M} \int \frac{d^3p}{(2\pi)^3} \psi_i(\mathbf{p}) a^\dagger_{\mathbf{p}+\mathbf{k}/2} \Sigma^i b^\dagger_{-\mathbf{p}+\mathbf{k}/2} |0\rangle$$

правильно нормированный вектор связанного состояния, если Σ^i обозначает набор трех матриц 2×2, нормированных условием:

$$\sum_i \mathrm{tr}\left(\Sigma^{i\dagger}\Sigma^i\right) = 1$$

* D. W. Gidley et. al., Phys. Rev. Lett. 49, 525 (1982).

Чтобы построить состояния с $S = 1$, нужно сделать так, чтобы каждая Σ^i содержала матрицу Паули. Вообще говоря, спин-орбитальное взаимодействие расщепит мультиплет с $S = 1, L = 1$ в соответствии с полным моментом J. Состояния с определенным J таковы:

$$\begin{aligned} J = 0: &\quad \Sigma^i = \tfrac{1}{\sqrt{6}} \sigma^i \\ J = 1: &\quad \Sigma^i = \tfrac{1}{2} \varepsilon^{ijk} n^j \sigma^k, \\ J = 2: &\quad \Sigma^i = \tfrac{1}{\sqrt{3}} h^{ij} \sigma^j \end{aligned}$$

где $\mathbf{n}$ - вектор поляризации, удовлетворяющий $|\mathbf{n}|^2 = 1$, а h^{ij} - тензор с нулевым следом, типичное значение которого $h^{12} = 1$, а все остальные компоненты равняются нулю.

(d) Используя выражение для амплитуды аннигиляции, выведенное в (b), и явное выражение в (c) для состояний позитрона с $S = 1, L = 1$ и определенным J, вычислите для каждого J вероятность аннигиляции состояния с образованием двух фотонов.

ПШ-5.5. Физика массивного векторного бозона.

Введем в КЭД массивное фотонное поле B_μ массой M, которое взаимодействует с электроном по закону

$$\Delta H = \int d^3x \left(g \bar{\psi} \gamma^\mu \psi B_\mu\right)$$

Массивный фотон в начальном и конечном состоянии имеет три возможные физические поляризации, соответствующие трем пространственноподобным единичным векторам в системе покоя бозона. Они могут быть инвариантно описаны (через 4-импульс бозона k^μ) как три вектора $\varepsilon_\mu^{(i)}$, Удовлетворяющие условиям:

$$\varepsilon^{(i)} \cdot \varepsilon^{(j)} = -\delta^{ij}, \quad k \cdot \varepsilon^{(i)} = 0.$$

Четыре вектора $\left(k_\mu/M, \varepsilon_\mu^{(i)}\right)$ образуют ортогональный базис. Так как B_μ связано с сохраняющемся током $\bar{\psi}\gamma^\mu\psi$, то из тождества Уорда вытекает, что произведение k_μ на амплитуду рождения B равно нулю. Поэтому мы можем заменить

$$\sum_i \varepsilon_\mu^{(i)} \varepsilon_\nu^{(i)*} \to -g_{\mu\nu}$$

Это обобщает фейнмановский прием с векторами поляризации фотона на случай массивных бозонов и упрощает вычисление сечений процессов рождения B. (Внимание! Этот прием не работает (по крайней мере, столь просто) в случае неабелевых калибровочных полей.) Выполните некоторые вычисления, во всех случаях пренебрегая массой электрона.

(a) Вычислите сечение процесса $e^+e^- \to B$. Найдите время жизни B, предполагая, что он распадается только на электроны. Проверьте соотношение

$$\sigma\left(e^+e^- \to B\right) = \frac{12\pi^2}{M}\Gamma\left(B \to e^+e^-\right)\delta\left(M^2 - s\right)$$

(оно обсуждалось в разделе 5.3).

(b) Вычислите дифференциальное сечение процесса $e^+e^- \to \gamma + B$ в системе центра масс. (Аналогичный процесс, действительно имеющий место, - это $e^+e^- \to \gamma + Z^0$. Полученный результат позволяет измерить число распадов Z_0 в ненаблюдаемые конечные состояния, которое в свою очередь оказывается пропорциональным числу типов нейтрино.)

(c) Заметьте, что сечение из (b) расходится при $\theta \to 0$ или π. Проанализируем область вблизи $\theta = 0$. Здесь главный вклад дает t-канал. Интуитивно это соответствует тому, что фотон излучается с электронной линии до момента аннигиляции. Преобразуйте формулу так, чтобы показать, что такая интерпретация действительно правильна. Прежде всего, заметьте, что расходимость при $\theta \to 0$ обрезается электронной массой. Положите импульс электрона равным $(E, 0, 0, k)$, где $k = \left(E^2 - m_e^2\right)^{1/2}$, а импульс фотона - $k^\mu = (xE, xE\sin\theta, 0, xE\cos\theta)$. Покажите, что знаменатель пропагатора никогда не становится меньше, чем $\mathcal{O}\left(m_e^2/s\right)$. Теперь проинтегрируйте сечение из (b) по углам, обрезая интеграл по θ при $\theta^2 \sim \left(m_e^2/s\right)$ и оставляя только ведущий логарифмический вклад, пропорциональный $\ln\left(s/m_e^2\right)$. Покажите, что в этом приближении сечение для излучения фотона в направлении вперед может быть записано как

$$\sigma\left(e^+e^- \to \gamma + B\right) \approx \int dx f(x) \cdot \sigma\left(e^+e^- \to B \text{ при } E_{\text{ци}}^2 = (1-x)s\right),$$

где сечение аннигиляции вычислено для случая столкновения позитрона с энергией E и электрона с энергией $(1-x)E$, а $f(x)$, а функция распределения Вайцзеккера -Вильямса $f(x)$ равна

$$f(x) = \frac{\alpha}{2\pi}\frac{1+(1-x)^2}{x} \cdot \ln\left(\frac{s}{m_e^2}\right)$$

Эта функция всегда возникает в тех процессах, где фотон излучается коллинеарно с электронной линии. Мы встретимся с ней снова в задаче 6.2.

ПШ-5.6 О спинорах и фотонах (???)

5.6. В этой задаче формализм спинорного произведения распространяется на внешние фотоны.

(a) Пусть k - импульс фотона, а p - другой светоподобный вектор, выбранный так, что $p \cdot k \neq 0$. Введем $u_R(p)$ и $u_L(p)$ - спиноры с определенной спиральностью, соответствующие фермионам со светоподобным импульсом p, определенные в соответствии с соглашением из задачи 5.3. Определим векторы поляризации фотона:

$$\varepsilon_+^\mu(k) = \frac{1}{\sqrt{4p\cdot k}}\bar{u}_R(k)\gamma^\mu u_R(p), \quad \varepsilon_-^\mu(k) = \frac{1}{\sqrt{4p\cdot k}}\bar{u}_L(k)\gamma^\mu u_L(p)$$

Воспользуйтесь тождеством

$$u_L(p)\bar{u}_L(p) + u_R(p)\bar{u}_R(p) = \not{p}$$

и вычислите сумму по поляризациям:

$$\varepsilon_+^\mu \varepsilon_+^{\nu *} + \varepsilon_-^\mu \varepsilon_-^{\nu *} = -g^{\mu\nu} + \frac{k^\mu p^\nu + k^\nu p^\mu}{p \cdot k}.$$

Второе слагаемое справа даст нуль, если его свернуть с любой амплитудой излучения фотона $\mathscr{M}^\mu$, так что

$$|\varepsilon_+ \cdot \mathscr{M}|^2 + |\varepsilon_- \cdot \mathscr{M}|^2 = \mathscr{M}^\mu \mathscr{M}^{\nu *} \left(-g_{\mu\nu}\right);$$

Таким образом, векторы $\varepsilon_+, \varepsilon_-$можно использовать для вычисления сумм по поляризациям фотонов.
(b) Используя только что введенные поляризации и тождество Фирца из задачи 5.3, вычислите дифференциальное сечение аннигиляции безмассовых электрона и позитрона с образованием двух фотонов. Покажите, что в системе центра инерции результат совпадает с безмассовым пределом (5.107):

$$\frac{d\sigma}{d\cos\theta} = \frac{2\pi\alpha^2}{s}\left(\frac{1+\cos^2\theta}{\sin^2\theta}\right)$$

Из результатов (a) следует, что ответ не зависит от вектора p, который использовался для определения поляризационных векторов; однако вычисление сильно упрощается, если выбрать этот вектор равным первоначальному 4-вектору электрона.

27.1.2 Problems about other, special decays and scatterings

Stanford.Zhou.2022.8.2. Decays of the Higgs boson. (10/45p)

The Standard Model contains three charged leptons, the electron e, muon μ, and tau τ, which are described by Dirac fields and differ only by their mass. It also contains a spinless particle called the Higgs boson, described by a real scalar field h. The free Lagrangian is

$$\mathcal{L}_0 = \frac{1}{2}\left(\partial_\mu h\right)\left(\partial^\mu h\right) - \frac{1}{2}m_h^2 h^2 + \sum_i \bar{\Psi}_i \left(i\partial\!\!\!/ - m_i\right)\Psi_i$$

where $i \in \{e, \mu, \tau\}$, and the numeric values of the masses are

$$m_h = 125\text{GeV}, \quad m_e = 511\text{keV}, \quad m_\mu = 105.7\text{MeV}, \quad m_\tau = 1777\text{MeV}$$

The Higgs field couples to the charged leptons by a Yukawa coupling proportional to mass,

$$\mathcal{L}_{\text{int}} = -\sum_i \frac{m_i}{v} h \bar{\Psi}_i \Psi_i$$

Here, v is a constant associated with the breaking of electroweak symmetry, but for this problem you will only need its value, $v = 246\text{GeV}$. For this problem, all of your final answers should be numeric, and given to at least two significant figures.
a) Compute the partial decay rate for a Higgs boson to an electron-positron pair $\Gamma_{H\to e^+e^-}$ at leading non-vanishing order in perturbation theory, giving your answer in eV. (Hint: sum over final spin states, and reuse results from problem set 5.)
b) Find the ratios $\Gamma_{H\to\mu^+\mu^-}/\Gamma_{H\to e^+e^-}$and $\Gamma_{H\to\tau^+\tau^-}/\Gamma_{H\to e^+e^-}$.
c) Find the probability a Higgs boson decays to $\tau^+\tau^-$, also known as the branching ratio

$$\text{BR}_{H\to\tau^+\tau^-} = \frac{\Gamma_{H\to\tau^+\tau^-}}{\sum_X \Gamma_{H\to X}}$$

The denominator is the total decay rate of the Higgs boson, equal to 4.1 MeV. (To check your answer, you can consult the so-called Yellow Report.)

Solution:

There is one Feynman diagram, giving matrix element

$$\mathcal{M}_{h\to e^+e^-} = \quad \text{  } \quad = \bar{u}_s(p_{e^-})\left(-i\frac{m_e}{v}\right)v_r(p_{e^+}).$$

Squaring the matrix element and summing over final spin states gives

$$\begin{aligned}
\left|\overline{\mathcal{M}}_{h\to e^+e^-}\right|^2 &= \frac{m_e^2}{v^2}\sum_{r,s}\bar{u}_s\left(p_{e^-}\right)v_r\left(p_{e^+}\right)\bar{v}_r\left(p_{e^+}\right)u_s\left(p_{e^-}\right) \\
&= \frac{m_e^2}{v^2}\,\mathrm{tr}\left[\left(\not{p}_{e^-}+m_e\right)\left(\not{p}_{e^+}-m_e\right)\right] \\
&= \frac{m_e^2}{v^2}\left(\mathrm{tr}\left[\not{p}_{e^-}\not{p}_{e^+}\right]-4m_e^2\right) \\
&= 2\frac{m_e^2}{v^2}\left(2p_{e^-}\cdot p_{e^+}-2m_e^2\right) \\
&= 2\frac{m_e^2}{v^2}\left(m_h^2-4m_e^2\right).
\end{aligned}$$

In the last line we used the fact that

$$m_h^2 = p_h^2 = \left(p_{e^-}+p_{e^+}\right)^2 = 2m_e^2+2p_{e^+}\cdot p_{e^-}.$$

The decay width of a Higgs to leptons $l^+l^-$is defined by

$$\Gamma_{h\to l^+l^-} = \frac{1}{2m_h}\int\frac{d^4p_{l^-}}{(2\pi)^4}(2\pi)\delta_+\left(p_{l^-}^2-m_l^2\right)\frac{d^4p_{l^+}}{(2\pi)^4}(2\pi)\delta_+\left(p_{l^+}^2-m_l^2\right)(2\pi)^4\delta^{(4)}\left(p_h-p_{l^-}-p_{l^+}\right)\left|\overline{\mathcal{M}}_{h\to e^+e^-}\right|^2$$

By reusing results from problem set 5, we immediately find

$$\Gamma_{h\to l^+l^-} = \frac{1}{16\pi m_h^2}\sqrt{m_h^2-4m_e^2}\left|\overline{\mathcal{M}}_{h\to e^+e^-}\right|^2 = \frac{m_e^2m_h}{8\pi v^2}\left(1-4m_e^2/m_h^2\right)^{3/2} = 0.021\text{eV}$$

Solution:

Note that since m_e, m_μ, and m_τ are all much less than m_h, we have

$$\Gamma_{h\to l^+l^-} \approx \frac{m_l^2m_h}{8\pi v^2}$$

for each charged lepton. That is, the decay rate is proportional to the mass squared, so the Higgs boson is much more likely to decay to heavier leptons,

$$\frac{\Gamma_{H\to\mu^+\mu^-}}{\Gamma_{H\to e^+e^-}} \approx \frac{m_\mu^2}{m_e^2} = 4.3\times10^4, \quad \frac{\Gamma_{H\to\tau^+\tau^-}}{\Gamma_{H\to e^+e^-}} \approx \frac{m_\tau^2}{m_e^2} = 1.2\times10^7$$

Solution:

Plugging in the numbers gives $\mathrm{BR}_{H\to\tau^+\tau^-} = 6.3\%$. (The Yellow Report gives a slightly different value because it accounts for higher-order corrections.)

The decay of Higgs bosons to taus was confirmed experimentally only recently [1][2], and first evidence for the Higgs coupling to muons has been detected [34]. Establishing the coupling of the Higgs to electrons remains a monumental experimental challenge.

Stanford.exam-2022.3/5. Pseudoscalar and vector decays. (10/40p)

In this problem we will consider decays of particles to pairs of electrons. As usual, the electron is described by a Dirac field Ψ of mass m_e. All decay rates should be computed in the rest frame of the decaying particle, and you can reuse results from problem sets.

a) Consider a pseudoscalar particle, described by a real scalar field ϕ of mass M, where $M > 2m_e$. Write down the Feynman rule for the interaction

$$\mathcal{L}_{\text{int}} = ig\phi\bar{\Psi}\gamma^5\Psi.$$

Then find the decay rate for $\phi \to e^+e^-$to leading nontrivial order in g.

Solution

: As usual, the Feynman rule comes from $-iH_{\text{int}} = iL_{\text{int}}$, so the vertex factor is $-g\gamma^5$. (This looks unusual, but it's correct: there had to be an i in L_{int} to ensure the action is real when g is.) Then

$$\mathcal{M} = -g\bar{u}_r\left(p_1\right)\gamma^5 v_s\left(p_2\right).$$

Squaring and summing over final spin states gives

$$\begin{aligned}
|\overline{\mathcal{M}}|^2 &= g^2\sum_{r,s}\bar{u}_r\left(p_1\right)\gamma^5 v_s\left(p_2\right)v_s^\dagger\left(p_2\right)\left(\gamma^5\right)^\dagger\left(\gamma^0\right)^\dagger u_r\left(p_1\right) \\
&= -g^2\,\mathrm{tr}\left(\left(\not{p}_1 + m_e\right)\gamma^5\left(\not{p}_2 - m_e\right)\gamma^5\right) \\
&= g^2\,\mathrm{tr}\left(\left(\not{p}_1 + m_2\right)\left(\not{p}_2 + m_e\right)\gamma^5\gamma^5\right) \\
&= 4g^2\left(p_1\cdot p_2 + m_e^2\right) \\
&= 2g^2M^2.
\end{aligned}$$

Plugging this into the decay rate result derived in problem set 5 gives

$$\Gamma = \frac{g^2}{8\pi}\sqrt{M^2 - 4m_e^2}.$$

b) Now consider a vector particle, described by a massive vector field A_μ of mass M, where $M > 2m_e$. Write down the Feynman rule for the interaction

$$\mathcal{L}_{\text{int}} = g\bar{\Psi}\gamma^\mu A_\mu\Psi.$$

Then find the decay rate for $A_\mu \to e^+e^-$to leading nontrivial order in g. (Hint: the Feynman rule for an incoming massive vector is $\epsilon_\mu(p)$, where ϵ_μ is its polarization. The polarization satisfies $\epsilon\cdot\epsilon = -1$ and $p\cdot\epsilon = 0$, since $\partial_\mu A^\mu = 0$. By rotational symmetry, the decay rate doesn't depend on the vector's polarization, so you can compute it by either averaging over possible polarizations using

$$\sum_\lambda \epsilon^\mu(p,\lambda)\epsilon^{*\nu}(p,\lambda) = -\eta^{\mu\nu} + \frac{p^\mu p^\nu}{M^2}$$

or by picking any specific polarization.)

Solution

The Feynman rule for the vertex is $ig\gamma^\mu$, as in ordinary QED, so

$$\mathcal{M} = ig\epsilon_\mu^\lambda\bar{u}_r\left(p_1\right)\gamma^\mu v_s\left(p_2\right).$$

Summing over final spin states and averaging over the initial three spin states, we have

$$|\overline{\mathcal{M}}|^2 = \frac{g^2}{3}\left(-\eta_{\mu\nu} + \frac{p_\mu p_\nu}{M^2}\right)\sum_{rs}\bar{u}_r\left(p_1\right)\gamma^\mu v_s\left(p_2\right)\bar{v}_2\left(p_2\right)\gamma^\nu u_r\left(p_1\right).$$

Note that the $p_\mu p_\nu$ terms won't contribute anything, as by the Dirac equation,

$$\bar{u}_r\left(p_1\right)pv_s\left(p_2\right) = \bar{u}_r\left(p_1\right)\left(\not{p}_1 + \not{p}_2\right)v_s\left(p_2\right) = \bar{u}_r\left(p_1\right)\left(m_e - m_e\right)v_s\left(p_2\right) = 0.$$

Thus, keeping just the metric term and rewriting the spinor sum as a trace,

$$\begin{aligned}|\overline{\mathcal{M}}|^2 &= -\frac{g^2}{3}\eta_{\mu\nu}\,\mathrm{tr}\left(\left(p_1+m_e\right)\gamma^\mu\left(p_2-m_e\right)\gamma^\nu\right)\\ &= -\frac{4g^2}{3}\eta_{\mu\nu}\left(p_1^\mu p_2^\nu + p_2^\mu p_1^\nu - \left(p_1\cdot p_2 - m_e^2\right)\eta^{\mu\nu}\right)\\ &= \frac{8g^2}{3}\left(p_1\cdot p_2 + 2m_e^2\right)\\ &= \frac{4g^2M^2}{3}\left(1+\frac{2m_e^2}{M^2}\right).\end{aligned}$$

Plugging this into our decay rate result gives

$$\Gamma = \frac{g^2}{12\pi}\left(1+\frac{2m_e^2}{M^2}\right)\sqrt{M^2-4m_e^2}.$$

Stanford.exam-2022.4/5. Higgs boson production at a muon collider. (15/40p)

The high energy physics community is currently debating how to best study the Higgs boson with future particle accelerators. One idea is to build a machine that collides muons and anti-muons at very high energies and produces Higgs bosons in their annihilation. You should treat the muon, Higgs, and photon in the same way as in problem set 8, and neglect any other particles or interactions. That is, consider the free Lagrangian

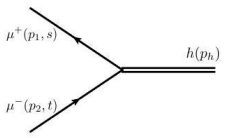
$$\mathcal{L}_0 = \frac{1}{2}\left(\partial_\mu h\right)^2 - \frac{1}{2}m_h^2h^2 + \bar{\Psi}\left(i\not{\partial} - m_\mu\right)\Psi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu}$$

with interactions

$$\mathcal{L}_{\text{int}} = -\frac{m_\mu}{v}h\bar{\Psi}\Psi - e\bar{\Psi}A\Psi.$$

We first consider the case where a muon and anti-muon annihilate to produce a Higgs boson, $\mu^+\left(p_1\right)\mu^-\left(p_2\right)\to h\left(p_h\right)$.

a) Compute the scattering amplitude $\mathcal{M}_{p_1p_2\to p_h}$ for this process at lowest nontrivial order in perturbation theory, by explicitly using Wick's theorem. Then show that you get the same answer if you simply apply the Feynman rules, where the vertex is



$$= -\frac{im_\mu}{v}.$$

Solution a)

The initial and final states are

$$\begin{aligned}\left|\mu^+\left(p_1,s\right),\mu^-\left(p_2,t\right)\right\rangle &= \sqrt{2E\left(\overrightarrow{p_1}\right)}\sqrt{2E\left(\overrightarrow{p_2}\right)}b_s^\dagger\left(p_1\right)a_t^\dagger\left(p_2\right)|0\rangle,\\ |h\rangle &= \sqrt{2E\left(\overrightarrow{p_h}\right)}a^\dagger\left(p_h\right)|0\rangle.\end{aligned}$$

We can then compute for example the S-matrix element

$$\begin{aligned}\left\langle\mu^+\left(p_1,s\right),\mu^-\left(p_2,t\right)\left|\int d^4x i\mathcal{L}_{int}\right|h\right\rangle &= \left\langle\mu^+\left(p_1,s\right),\mu^-\left(p_2,t\right)\left|\int d^4x i\frac{m_h}{v}h(x)\bar{\Psi}_i(x)\Psi_i(x)\right|h\right\rangle\\ &= \frac{-im_\mu}{v}\sqrt{8E\left(p_h\right)E\left(p_1\right)E\left(p_2\right)}\left\langle 0\left|\int d^4x b_s\left(p_1\right)a_t\left(p_2\right)h(x)\bar{\Psi}_i(x)\Psi_i(x)a^\dagger\left(p_h\right)\right|0\right\rangle\end{aligned}$$

We find for example for

$$
\begin{aligned}
h(x)a^{\dagger}\left(p_h\right) &= \int \frac{d\mathbf{p}}{(2\pi)^3}\frac{1}{\sqrt{2E(p)}}\left[a(p)e^{-ipx}+a^{\dagger}(p)e^{ipx}\right]a^{\dagger}\left(p_h\right)\\
&= a^{\dagger}\left(p_h\right)h(x)+\int \frac{d\mathbf{p}}{(2\pi)^3}\frac{1}{\sqrt{2E(p)}}\left[a(p),a^{\dagger}\left(p_h\right)\right]e^{-ipx}\\
&= a^{\dagger}\left(p_h\right)h(x)+\int \frac{d\mathbf{p}}{(2\pi)^3}\frac{1}{\sqrt{2E(p)}}(2\pi)^3\delta^{(3)}\left(\vec{p}-\vec{p_h}\right)e^{-ipx}\\
&= a^{\dagger}\left(p_h\right)h(x)+\frac{1}{\sqrt{2E\left(p_h\right)}}e^{-ip_hx}
\end{aligned}
$$

In our vacuum expectation value of S40, the creation operator of the scalar field then acts directly on the vacuum state on the left and annihilates it and only the commutator term remains. Similarly, we find

$$
\begin{aligned}
a_t\left(p_2\right)\Psi_i(x) &= u_i^t\left(p_2\right)\frac{e^{ip_2x}}{\sqrt{2E\left(p_2\right)}}-\Psi_i(x)a_t\left(p_2\right).\\
b_s\left(p_1\right)\bar{\Psi}_i(x) &= \bar{v}_i^s\left(p_1\right)\frac{e^{ip_1x}}{\sqrt{2E\left(p_1\right)}}-\bar{\Psi}_i(x)b_s\left(p_1\right).
\end{aligned}
$$

As

$$
\left\{b_s^{\dagger}\left(p_1\right),\Psi(x)\right\}=\left\{\bar{\Psi}_i(x),a_t^{\dagger}\left(p_2\right)\right\}=0,
$$

only the anti-commutator terms survive. We find

$$
\begin{aligned}
&\left\langle \mu^{+}\left(p_1,s\right),\mu^{-}\left(p_2,t\right)\left|\int d^4x i\mathcal{L}_{int}\right|h\right\rangle = -\frac{im_{\mu}}{v}\int d^4x e^{-ix\left(p_h-p_1-p_2\right)}\bar{v}_i^s\left(p_1\right)\delta_{ij}u_j^t\left(p_2\right)\\
&=(2\pi)^4\delta^{(4)}\left(p_h-p_1-p_2\right)\bar{v}_i^s\left(p_1\right)\left(-\frac{im_{\mu}}{v}\delta_{ij}\right)u_j^t\left(p_2\right).
\end{aligned}
$$

The scattering matrix elements are defined by

$$
S_{fi}=\delta_{fi}+(2\pi)^4\delta\left(p_f-p_i\right)\mathcal{M},
$$

and we associate $u_i^t\left(p_2\right)$ with an ingoing muon and $\bar{v}_j^s\left(p_1\right)$ with an ingoing anti-muon. We thus conclude

$$
\mathcal{M}_{p_1p_2\to p_h}=\bar{v}_i^s\left(p_1\right)\left(-i\frac{m_{\mu}}{v}\right)u_i^t\left(p_2\right)
$$

which is clearly also what we get from the Feynman rules.
The scattering cross section of particles a and b with masses m_a and m_b to produce N final state particles is

$$
\begin{aligned}
\sigma_{p_ap_b\to q_1\ldots q_N} &= \frac{1}{2\sqrt{\left(2p_ap_b\right)^2-4m_a^2m_b^2}}\int\prod_{i=1}^{N}\left(\frac{d^4q_i}{(2\pi)^4}(2\pi)\delta\left(q_i^2-m_i^2\right)\theta\left(q_i^0-m_i\right)\right)\\
&\times(2\pi)^4\delta^{(4)}\left(p_a+p_b-q_1-\cdots-q_N\right)\left|\overline{\mathcal{M}}_{p_ap_b\to q_1\ldots q_N}\right|^2
\end{aligned}
$$

where $\left|\overline{\mathcal{M}}_{p_ap_b\to q_1\ldots q_N}\right|^2$ is the modulus squared of the scattering amplitude, summed over final state spins and averaged over initial state spins.

b) Compute $\left|\overline{\mathcal{M}}_{p_1p_2\to p_h}\right|^2$ and write it in terms of the constants defined in (7) and (8).

Solution

: Using the result of part (a), we have

$$\begin{aligned}\left|\overline{\mathcal{M}}_{p_1p_2\to p_h}\right|^2 &= \frac{1}{4}\sum_{s,t}\bar{u}_i^t\left(p_2\right)\left(i\frac{m_\mu}{v}\right)v_i^s\left(p_1\right)\bar{v}_j^s\left(p_1\right)\left(-i\frac{m_\mu}{v}\right)u_j^t\left(p_2\right)\\ &= \frac{m_\mu^2}{4v^2}\,\mathrm{tr}\left[\left(\not{p}_1-m_\mu\right)\left(\not{p}_2+m_\mu\right)\right]\\ &= \frac{m_\mu^2}{4v^2}\,\mathrm{tr}\left[\not{p}_1\not{p}_2\right]-4m_\mu^2\\ &= \frac{m_\mu^2}{2v^2}\left(m_h^2-4m_\mu^2\right).\end{aligned}$$

The factor of 1/4 arises due to averaging over 2 spin states per initial state fermion.

c) Using this result and (10, compute the total cross section for this process. Your result should contain distributions - what is their interpretation?

Solution

Introducing $s=\left(p_1+p_2\right)^2$, we find

$$\begin{aligned}\sigma_{p_1p_2\to p_h} &= \frac{\pi}{\sqrt{s\left(s-4m_\mu^2\right)}}\int d^4p_h\delta\left(p_h^2-m_h^2\right)\theta\left(p_h^0-m_h\right)\delta^{(4)}\left(p_1+p_2-p_h\right)\left|\overline{\mathcal{M}}_{p_1p_2\to p_h}\right|^2\\ &= \frac{\pi}{\sqrt{s\left(s-4m_\mu^2\right)}}\delta\left(s-m_h^2\right)\theta\left(p_1^0+p_2^0-m_h\right)\left|\overline{\mathcal{M}}_{p_1p_2\to p_h}\right|^2\\ &= \frac{\pi m_\mu^2}{2v^2}\sqrt{1-\frac{4m_\mu^2}{m_h^2}}\delta\left(s-m_h^2\right)\theta\left(p_1^0+p_2^0-m_h\right).\end{aligned}$$

The distributions forces the center-of-mass energy s to be exactly equal to the Higgs boson mass, which makes sense by energy-momentum conservation. (There is something weird about this result, though: in physics you can never have two things be exactly equal to each other, so this would suggest Higgs bosons are never produced this way at all. The resolution is that all unstable particles actually have a slightly indefinite mass (heuristically due to the energy-time uncertainty principle applied to their finite decay time) so the delta function is replaced with a narrow peak.)

It is also possible to produce additional particles in the final state. For the rest of this problem, we consider the process $\mu^+\left(p_1\right)\mu^-\left(p_2\right)\to\gamma\left(p_3\right)h\left(p_h\right)$ at leading nontrivial order in perturbation theory.

d) Draw all the relevant Feynman diagrams and use the Feynman rules to write down the corresponding amplitude $\mathcal{M}_{p_1p_2\to p_3p_h}$.

Solution

: There are two relevant diagrams:

$D_1 =$ 
$$= \bar{v}_s(p_1)\left(-i\frac{m_\mu}{v}\right)\frac{i(\not{p}_1 - \not{p}_h + m_\mu)}{(p_1-p_h)^2 - m_\mu^2}(-ie\gamma^\mu)u_t(p_2)\epsilon_\mu(p_3,\lambda).$$

$D_2 =$ 
$$= \bar{v}_s(p_1)(-ie\gamma^\mu)\frac{i(\not{p}_1 - \not{p}_3 + m_\mu)}{(p_1-p_3)^2 - m_\mu^2}\left(-i\frac{m_\mu}{v}\right)u_t(p_2)\epsilon_\mu(p_3,\lambda).$$

The amplitude is $D_1 + D_2$. All other diagrams are suppressed by more powers of m_μ/v, or more powers of e, or both.

e) Since a muon collider would operate at a center-of-mass energy much higher than the muon mass, we can treat m_μ as a small quantity. Compute $\left|\overline{\mathcal{M}}_{p_1p_2\to p_3p_h}\right|^2$ to leading nontrivial order in m_μ, and write it in terms of the Mandelstam invariants

$$s = (p_1+p_2)^2, \quad t = (p_1-p_h)^2, \quad u = (p_1-p_3)^2$$

and the constants defined in (7) and (8). (Hint: your expression will contain a sum over photon polarizations of the form

$$\sum_\lambda \epsilon^\mu(p_3,\lambda)\,\epsilon^{*\nu}(p_3,\lambda)$$

which you can simply replace with $-\eta^{\mu\nu}$.)

Solution

: First, we find the leading term in m_μ for our diagrams:

$$D_1 = \frac{-iem_\mu}{vt}\bar{s}_s(p_1)(p_1 - \not{p}_h)\gamma^\mu u_t(p_2)\epsilon_\mu(p_3,\lambda),$$
$$D_2 = \frac{-iem_\mu}{vu}\bar{v}_s(p_1)\gamma^\mu(p_h - \not{p}_2)u_t(p_2)\epsilon_\mu(p_3,\lambda).$$

$D_1 =$ 
Since these quantities already have a factor of m_μ in front, and we only want the lowest order in m_μ, we can set m_μ to zero when evaluating what's left. The Dirac equation for the spinors becomes $\bar{v}_s(p_1)\not{p}_1 = 0 = \not{p}_2 u_t(p_2)$, from which we find

$$D_1 = \frac{iem_\mu}{vt}\bar{v}_s(p_1)\not{p}_h\gamma^\mu u_t(p_2)\epsilon_\mu(p_3,\lambda),$$
$$D_2 = \frac{-iem_\mu}{vu}\bar{v}_s(p_1)\gamma^\mu p_h u_t(p_2)\epsilon_\mu(p_3,\lambda).$$

Next, we compute the terms in the square of the total amplitude,

$$\frac{1}{4}\sum_{s,t,\lambda} D_1 D_1^\dagger = -\frac{e^2 m_\mu^2}{4v^2 t^2}\,\mathrm{tr}\left[p_1 \not{p}_4 \gamma_\mu \not{p}_2 \gamma^\mu \not{p}_4\right] = \frac{e^2 m_\mu^2}{2v^2 t^2}\,\mathrm{tr}\left[\not{p}_1 \not{p}_4 \not{p}_2 \not{p}_4\right] = \frac{e^2 m_\mu^2 u}{v^2 t}.$$

$$\frac{1}{4}\sum_{s,t,\lambda} D_1 D_2^\dagger = \frac{e^2 m_\mu^2}{4v^2 tu}\,\mathrm{tr}\left[\not{p}_1 \not{p}_4 \gamma_\mu \not{p}_2 \not{p}_4 \gamma^\mu\right] = \frac{4e^2 m_\mu^2}{v^2 tu}\left(p_1 p_4\right)\left(p_2 p_4\right) = \frac{e^2 m_\mu^2}{v^2 tu}\left(m_h^2 - t\right)\left(m_h^2 - u\right).$$

$$\frac{1}{4}\sum_{s,t,\lambda} D_2 D_2^\dagger = -\frac{e^2 m_\mu^2}{4v^2 u^2}\,\mathrm{tr}\left[\not{p}_1 \gamma_\mu \not{p}_4 \not{p}_2 \not{p}_4 \gamma^\mu\right] = \frac{e^2 m_\mu^2}{2v^2 u^2}\,\mathrm{tr}\left[p_1 \not{p}_4 \not{p}_2 \not{p}_4\right] = \frac{e^2 m_\mu^2 t}{v^2 u}.$$

Above, we used the identities

$$\begin{aligned}
\gamma^\mu \not{p} \gamma_\mu &= -2\not{p} \\
\gamma^\mu \not{p} \not{q} \gamma_\mu &= 4pq \\
\mathrm{tr}[\not{p}\not{q}] &= 4pq \\
p_1 p_4 &= \frac{m_h^2 - t}{2} \\
p_2 p_4 &= \frac{m_h^2 - u}{2}, \\
m_h^2 &= s + t + u, \\
\mathrm{tr}\left[p_1 \not{p}_4 \not{p}_2 \not{p}_4\right] &= 4\left[2\left(p_1 p_4\right)\left(p_2 p_4\right) - \left(p_1 p_2\right) p_4^2\right] = 2tu
\end{aligned}$$

several of which follow from neglecting m_μ. After some algebra, we find

$$\left|\overline{\mathcal{M}}_{p_1 p_2 \to p_3 p_h}\right|^2 = \frac{1}{4}\sum_{s,t,\lambda}\left[D_1 D_1^\dagger + 2\,\mathrm{Re}\left(D_1 D_2^\dagger\right) + D_2 D_2^\dagger\right] = \frac{e^2 m_\mu^2}{v^2 tu}\left(s^2 + m_h^4\right).$$

f) Using this result and (10, compute the differential cross section $d\sigma/d\cos\theta$ for this process in the center-of-mass frame, where θ is the angle between the three-momenta of the muon and the photon. You may again work to leading nontrivial order in m_μ. Express your result in terms of s, θ, and the constants defined in (7) and (8).

Solution

Starting from 10, we have

$$\begin{aligned}
\sigma_{p_1 p_2 \to p_3 p_h} = \frac{1}{2(2\pi)^2 s}\int d^4 p_3 d^4 p_h \delta\left(p_3^2\right)\delta\left(p_h^2 - m_h^2\right)\theta\left(p_3^0\right)\theta\left(p_h^0 - m_h\right) \\
\times \delta^{(4)}\left(p_1 + p_2 - p_3 - p_h\right)\left|\overline{\mathcal{M}}_{p_1 p_2 \to p_3 p_h}\right|^2.
\end{aligned}$$

We work in the center-of-mass frame where $s = E_{CM}^2$ and do the p_h integral, giving
$\sigma_{p_1 p_2 \to p_3 p_h} = \frac{1}{2(2\pi)^2 s}\int d^4 p_3 \delta\left(p_3^2\right)\delta\left(E_{CM}^2 - 2E_{CM} p_3^0 - m_h^2\right)\theta\left(p_3^0\right)\theta\left(E_{CM} - p_3^0 - m_h\right)\left|\overline{\mathcal{M}}_{p_1 p_2 \to p_3 p_h}\right|^2$.
We parametrize the p_3 integral by writing

$$\begin{aligned}
\int d^4 p_3 \delta\left(p_3^2\right) &= \int_0^\infty dp_3^0 \frac{d\left|\vec{p}_3\right|^2}{2}\left|\overrightarrow{p_3}\right|\int d\cos\theta d\phi \delta\left(\left(p_3^0\right)^2 - \left|\vec{p}_3\right|^2\right) \\
&= \pi\int_0^\infty dp_3^0 p_3^0 \int d\cos\theta
\end{aligned}$$

We can integrate over p_3^0 using the remaining delta function,

$$\delta\left(E_{CM}^2 - 2E_{CM} p_3^0 - m_h^2\right) = \frac{1}{2E_{CM}}\delta\left(p_3^0 - \frac{1}{2}\left(E_{CM} - \frac{m_h^2}{E_{CM}}\right)\right).$$

Since we want a differential cross section, we simply drop the last integral over $\cos\theta$. Using

$$\begin{aligned}
t &= \left(p_2 - p_3\right)^2 = -2p_2 p_3 = -E_{CM} p_3^0 (1 - \cos\theta) \\
u &= \left(p_1 - p_3\right)^2 = -2p_1 p_3 = -E_{CM} p_3^0 (1 + \cos\theta)
\end{aligned}$$

we find

$$\frac{d\sigma_{p_1p_2\to p_3p_h}}{d\cos\theta} = \frac{s-m_h^2}{32s^2\pi}\left|\overline{\mathcal{M}}_{p_1p_2\to p_3p_h}\right|^2 = \frac{e^2m_\mu^2}{8\pi v^2 s^2}\frac{s^2+m_h^4}{(s-m_h^2)\left(1-\cos^2\theta\right)}.$$

Рассеяние электронов на мюонном нейтрино

Вычислить сечение рассеяния электронов на мюонном нейтрино в модели с четырёхфермионном взаимодействием: $e^-\nu_\mu \to \nu_e\mu^-$

МФТИ-Мусаев-2023.**12**/19

Найти дифференциальное сечение рассеяния электрона в кулоновском поле точечного ядра с зарядом Z.

МФТИ-Мусаев-2023.**13**/19

Показать, что амплитуды комптон-эффекта, соответствующие каждой из двух возможных фейнмановских диаграмм, порознь не являются калибровочно-инвариантными. Проверить калибровочную инвариантность суммарной амплитуды процесса.

МФТИ-Мусаев-2023.**14**/19

Показать, что при малых энергиях позитрона сечение аннигиляции пары электрон-позитрон в два фотона обратно пропорционально относительной скорости частиц, а вероятность аннигиляции не зависит от скорости.

МФТИ-Мусаев-2023.**15**/19 **Эффективный потенциал**

Получить из амплитуды рассеяния эффективный потенциал взаимодействия в борновском приближении для электронов и позитронов при обмене **a)** безмассовыми векторными бозонами (КЭД) **b)** скалярными частицами (потенциал Юкавы). Отдельно рассмотреть случаи массивных и безмассовых скалярных частиц.

МФТИ-Мусаев-2023.**16**/19 **Ограниченин на массу бозона Хиггса**

Экспериментальное значение аномального магнитного момента отличается от вычисления КЭД

$$|a_{\text{exp}} - a_{QED}| < 10^{-10}.$$

Вычислить ограничения, которые задает это значение на массу бозона Хиггса m_h и константу взаимодействия λ, если

$$H_{int} = \frac{\lambda}{\sqrt{2}}\int d^3x h\bar{\psi}\psi.$$

МФТИ-Мусаев-2023.**17**/19 **Эффект Швингера**

Получить выражение для плотности числа рожденных электрон-позитронных пар постоянным во времени однородным электрическим полем (эффект Швингера). Показать, что результат непертурбативен по напряженности поля.

27.2 Problems about Pure QED

(in spirit of LL4. there are a lot of problems in that book, so all of them will be collected here)

27.3 Problems about important methods and relations in QFT

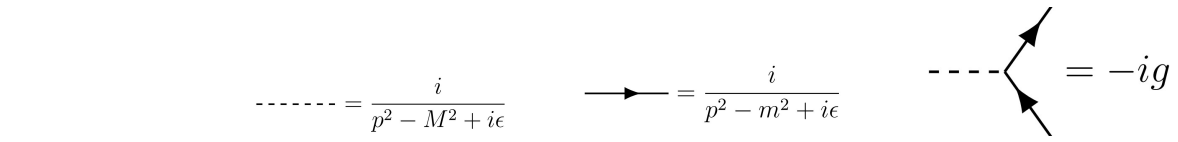
27.3.1 Problems about properties of QED (?!?!)

Stanford.Zhou.2022**5.2 Scalar Yukawa amplitudes. (7/45p)**

Let ϕ be a real scalar field of mass M, and ψ be a complex scalar field of mass m, with

$$\mathcal{L}_{\text{int}} = -g\psi^*\psi\phi$$

The field ψ can annihilate a particle, or create a particle with opposite $U(1)$ charge; these particles are conventionally called the ψ and ψ^*, respectively. Similarly, the field ϕ can create or annihilate a ϕ particle. (That is, particles are named after the field that annihilates them.) As discussed in section, the Feynman rules are



where a dashed line stands for ϕ and a solid line stands for ψ.

a) Assuming $M > 2m$, calculate the decay rate of a ϕ particle to leading order in g.

Start from equation

$$d\Gamma = \frac{1}{2m_{\mathscr{A}}}\left(\prod_f \frac{d^3p_f}{(2\pi)^3}\frac{1}{2E_f}\right)\left|\mathscr{M}\left(m_{\mathscr{A}} \to \{p_f\}\right)\right|^2 (2\pi)^4\delta^{(4)}\left(p_{\mathscr{A}} - \sum p_f\right)$$

and do the phase space integrals.

b) Find the amplitude for $\psi(p_1)\,\psi^*(p_2) \to \psi(p_3)\,\psi^*(p_4)$ scattering to leading order in g, in terms of Mandelstam variables.

c) Suppose the energies we can reach in an experiment are higher than m, but much lower than M. In this case, we might not know that ϕ particles exist, since we can't produce them, so we would have to describe the scattering process in part (**b)** using an "effective" field theory in terms of ψ alone. Show that at leading order,

$$\mathcal{L}_{\text{int}} = -\lambda\psi^*\psi\psi^*\psi$$

will yield the same answer for part (**b)** for some value of λ, and find that value in terms of g and M. Assume all elements of the momenta p_i are much less than M.

Solution to a:

The Feynman diagram is just one copy of the interaction vertex, so $i\mathcal{M} = -ig$. Let the initial momentum be $k^\mu = (M, \mathbf{0})$ and the final momenta be p_1^μ and p_2^μ. Then

$$\begin{aligned}
\Gamma &= \frac{1}{2M}\int \frac{d^3\mathbf{p}_1}{(2\pi)^3 2E_1}\frac{d^3\mathbf{p}_2}{(2\pi)^3 2E_2}|-ig|^2(2\pi)^4\delta^{(4)}(k - p_1 - p_2) \\
&= \frac{g^2}{32\pi^2 M}\int \frac{d^3\mathbf{p}_1}{E_1}\frac{d^3\mathbf{p}_2}{E_2}\delta^{(4)}(k - p_1 - p_2) \\
&= \frac{g^2}{32\pi^2 M}\int \frac{d^3\mathbf{p}_1}{E_1^2}\delta(M - 2E_1) \\
&= \frac{g^2}{8\pi M}\int_0^\infty d|\mathbf{p}_1|\,\frac{|\mathbf{p}_1|^2}{E_1^2}\delta(M - 2E_1) \\
&= \frac{g^2}{8\pi M}\int_m^\infty dE_1\,\frac{|\mathbf{p}_1|}{E_1}\delta(M - 2E_1) \\
&= \frac{g^2}{16\pi M}\sqrt{1 - (2m/M)^2}.
\end{aligned}$$

Solution to b:

There are two Feynman diagrams, giving amplitude

$$i\mathcal{M} = \quad + \quad$$

$$= (-ig)^2 \left(\frac{i}{(p_1+p_2)^2 - M^2 + i\epsilon} + \frac{i}{(p_1-p_3)^2 - M^2 + i\epsilon} \right)$$

$$= -g^2 \left(\frac{i}{s - M^2 + i\epsilon} + \frac{i}{t - M^2 + i\epsilon} \right).$$

Solution to c:

The Feynman rule for the interaction in the effective theory is just

$$= -4i\lambda.$$

The factor of 4 comes about because there are 2 ways to choose which copy of ψ contracts with what, and similarly 2 ways for ψ^*.

This is also the amplitude for the scattering process in the effective theory. On the other hand, we have $s, t \ll M$, so the answer to part **(b)** becomes $2ig^2/M^2$. Equating these results gives $\lambda = -g^2/2M^2$. (The fact that λ is suppressed by powers of M is a generic feature of effective field theory.)

Stanford.Zhou.2022.5.3 Solving a trivial theory. (4/45p)

Consider a free real scalar field of mass m, but treat the mass term as the perturbation,

$$\mathcal{L}_0 = \frac{1}{2} \left(\partial_\mu \phi\right) \left(\partial^\mu \phi\right), \qquad \mathcal{L}_{\text{int}} = -\frac{1}{2} m^2 \phi^2$$

a) Write down the Feynman rules for this theory.
b) Evaluate the momentum-space propagator exactly, summing all of the (infinitely many) connected Feynman diagrams.

Solution to a:

The Feynman rules are:

propagator $\qquad$ $= \dfrac{i}{p^2 + i\epsilon}$

interaction vertex $\qquad$ $= -im^2.$

Solution to b:

The diagrams are

$$+ \quad + \quad + \ldots$$

which correspond to

$$\frac{i}{p^2+i\epsilon}+\frac{i}{p^2+i\epsilon}\left(-im^2\right)\frac{i}{p^2+i\epsilon}+\frac{i}{p^2+i\epsilon}\left(-im^2\right)\frac{i}{p^2+i\epsilon}\left(-im^2\right)\frac{i}{p^2+i\epsilon}+\ldots$$

This is a geometric series where the ratio between terms is $m^2/\left(p^2+i\epsilon\right)$, so the sum is

$$\frac{i}{p^2+i\epsilon}\frac{1}{1-\frac{m^2}{p^2+i\epsilon}}=\frac{i}{p^2-m^2+i\epsilon}$$

Of course, this is just the familiar propagator for a free massive scalar field. But still this problem is a good illustration.

Stanford.Zhou.2022**5.4 Pion scattering in the linear sigma model. (25/45p)**

Consider a theory with N free real scalar fields $\Phi_i(x)$ of equal mass m,

$$\mathcal{L}_0=\sum_{i=1}^{N}\frac{1}{2}\partial_\mu\Phi_i\partial^\mu\Phi_i-\frac{m^2}{2}\Phi_i\Phi_i$$

This Lagrangian is symmetric under rotations of the scalar fields among themselves. We can show this more clearly by defining an N-element vector $\mathbf{\Phi}$ with elements of Φ_i, so

$$\mathcal{L}_0=\frac{1}{2}\left(\partial_\mu\mathbf{\Phi}\right)^2-\frac{m^2}{2}\mathbf{\Phi}\cdot\mathbf{\Phi}$$

This is just shorthand for Eq. (6). Note that the index on Φ_i is not a spatial index (such as on ∂_i). It is a "flavor" index, meaning it just identifies which field we're talking about.

a) We quantize the theory by imposing the equal time commutation relations

$$[\Pi_i(\mathbf{x},0),\Phi_j(\mathbf{y},0)]=i\delta_{ij}\delta^{(3)}(\mathbf{x}-\mathbf{y}),\quad \Pi_i(x)=\partial_t\Phi_i(x)$$

with all other commutators vanishing. Show that the propagator is

$$\langle 0\left|T\left\{\Phi_i(x)\Phi_j(y)\right\}\right|0\rangle=\text{W. contr.}(\Phi_i(x)\Phi_j(y))=\delta_{ij}D_F(x-y).$$

where δ_{ij} is 1 if $i=j$, and 0 otherwise. The momentum space Feynman rule is

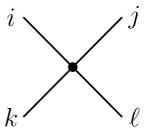
$$i\text{————}j=\frac{i\delta_{ij}}{p^2-m^2+i\epsilon}$$

where the i and j are flavor indices.

b) The linear sigma model additionally contains the interaction

$$\mathcal{L}_{\text{int}}\ =-\frac{\lambda}{4}(\mathbf{\Phi}\cdot\mathbf{\Phi})^2$$

which is also symmetric under rotations of $\mathbf{\Phi}$. Show that this interaction corresponds to the momentum space Feynman rule



$$=-2i\lambda\left(\delta_{ij}\delta_{k\ell}+\delta_{ik}\delta_{j\ell}+\delta_{i\ell}\delta_{jk}\right).$$

(Hint: consider the cases where all four fields have the same flavor, and when two pairs of fields have the same flavor.)

e) Show that in terms of these fields, the Lagrangian is

$$\begin{aligned}\mathcal{L}=\frac{1}{2})\ \partial_\mu\boldsymbol{\pi})^2+\frac{1}{2}\left(\partial_\mu\sigma\right)^2-\frac{1}{2}m_\sigma^2\sigma^2\\ -\frac{\lambda_{4\pi}}{4}(\boldsymbol{\pi}\cdot\boldsymbol{\pi})^2-\lambda_{3\sigma}\sigma^3-\frac{\lambda_{4\sigma}}{4}\sigma^4-\lambda_{\pi\sigma1}(\boldsymbol{\pi}\cdot\boldsymbol{\pi})\sigma-\lambda_{\pi\sigma2}(\boldsymbol{\pi}\cdot\boldsymbol{\pi})\sigma^2+C.\end{aligned}$$

and give expressions for $m_\sigma, \lambda_{4\pi}, \lambda_{3\sigma}, \lambda_{4\sigma}, \lambda_{\pi\sigma 1}, \lambda_{\pi\sigma 2}$ and C in terms of μ and λ. We see that σ is massive, but we have $N-1$ massless pion fields π_i.

f) Write the momentum-space Feynman rules in terms of μ and λ. Draw the pions with a solid line and flavor index i, and the σ particle with a double solid line. (Hint: if you've seen the pattern from the other Feynman rules in the problem set, it should be possible to write down the answer with some thought, but no explicit calculation. There is no Feynman rule corresponding to the constant C, which has no effect here.)

g) Compute the decay rate of a σ particle to leading order in λ, and give the corresponding lifetime in seconds if $\lambda = 0.1, \mu = 10\text{GeV}$ and $N = 3$.

h) Find the amplitude for $\pi_i(p_1)\,\pi_j(p_2) \to \pi_k(p_3)\,\pi_\ell(p_4)$ scattering to leading order in λ, in terms of Mandelstam variables. (Hint: there are four Feynman diagrams.)

i) Show that the amplitude in part (h) vanishes when all spatial momenta $\mathbf{p}_i$ go to zero.

j) We can see a similar phenomenon in the linear sigma model. Show that when we add a small term $a\Phi_N$ to the Lagrangian, the pion fields get a mass term m_π^2 proportional to a, and find this term. (Hint: to keep things from getting messy, work to lowest order in a as much as possible.)

Solution to a:

The commutation relations imply that the mode expansion of the field Φ_i involves a set of creation and annihilation operators $a_i^\dagger(\mathbf{k})$ and $a_i(\mathbf{k})$, whose commutators vanish for $i \neq j$. Therefore, when $i \neq j$, the contraction of two fields vanishes because Φ_i^+ and Φ_j^- automatically commute. When $i = j$, the derivation of the propagator is just the same as for a single real scalar field.

Solution to b:

Expanding out the interaction explicitly gives

$$\mathcal{L}_{\text{int}} = -\frac{\lambda}{4}\left(\sum_i \Phi_i\Phi_i\right)^2 = -\frac{\lambda}{4}\sum_{i,j}\Phi_i\Phi_i\Phi_j\Phi_j = -\frac{\lambda}{4}\sum_i \Phi_i^4 - \frac{\lambda}{2}\sum_{i<j}\Phi_i^2\Phi_j^2$$

The first term yields a vertex for four fields of the same flavor. Whenever we introduce a copy of this vertex, we get a factor of $4! = 24$ because of the ways to choose how to contract the copies of Φ_i with other things, so the overall vertex factor is $-6i\lambda$.

The second term yields a vertex for four fields where two pairs have the same flavor. These come with an extra factor of $2 \cdot 2 = 4$ because of the two copies of Φ_i and two copies of Φ_j, and thus the overall vertex factor is $-2i\lambda$.

Now let's check if this is compatible with the provided Feynman rule. When $i = j = k = \ell$, all the Kronecker deltas are equal to 1, so we get $-6i\lambda$. When $i = j$ and $k = \ell$, but $i \neq k$, then only the first Kronecker delta is equal to 1, and the others are equal to 0, so we get $-2i\lambda$.

c) Find the total cross section in the centre of mass frame for the processes

$$\Phi_1\Phi_2 \to \Phi_1\Phi_2, \quad \Phi_1\Phi_1 \to \Phi_2\Phi_2, \quad \Phi_1\Phi_1 \to \Phi_1\Phi_1$$

to leading order in λ, in terms of E_{cm}. (Hint: start from equation (4.85) of Peskin and Schroeder, and be careful with factors of 2.)

Solution to c:

The Feynman diagrams for all three of these processes are just one copy of the interaction vertex, and the amplitudes are just $-2i\lambda$, $-2i\lambda$, and $-6i\lambda$ respectively. Because all four masses are identical, we may use equation (4.85), which states

$$\frac{d\sigma}{d\Omega} = \frac{|\mathcal{M}|^2}{64\pi^2 E_{\text{cm}}^2}$$

The scattering is isotropic, so the angular integrals are trivial.

For the first process, the angular integral just gives a factor of 4π, so

$$\sigma(\Phi_1\Phi_2 \to \Phi_1\Phi_2) = \frac{4\pi\lambda^2}{16\pi^2 E_{\text{cm}}^2} = \frac{\lambda^2}{4\pi E_{\text{cm}}^2}$$

For the second process, the angular integral only gives a factor of 2π because the particles in the final state are identical. (The state where the first Φ_2 exits left and the second exits right is exactly the same as the state where

the first Φ_2 exits right and the second exits left. So integrating over all possible directions for the momentum of the first Φ_2 would be double counting.) Thus,

$$\sigma\left(\Phi_1\Phi_1 \to \Phi_2\Phi_2\right) = \frac{\lambda^2}{8\pi E_{\text{cm}}^2}$$

Finally, the last cross section is 9 times bigger, giving

$$\sigma\left(\Phi_1\Phi_1 \to \Phi_1\Phi_1\right) = \frac{9\lambda^2}{8\pi E_{\text{cm}}^2}$$

In the linear sigma model, the potential energy of a uniform classical field is

$$V(\Phi) = \frac{m^2}{2}\mathbf{\Phi}\cdot\mathbf{\Phi} + \frac{\lambda}{4}(\mathbf{\Phi}\cdot\mathbf{\Phi})^2.$$

When we quantize the harmonic oscillator, the usual definition of the creation and annihilation operators in terms of x and p only makes sense if the potential's minimum is at $x = 0$. If the minimum is somewhere else, then many things go wrong. For instance, $a|0\rangle$ won't be zero, and more generally $a^\dagger$ and a won't have simple commutation relations with H, so won't properly raise and lower the energy. Similarly, it only makes sense to quantize fields in the usual way about minima of the potential $V(\Phi)$.

If $m^2 > 0$ and $\lambda > 0$, there is a unique minimum of the potential at $\mathbf{\Phi} = \mathbf{0}$, so our treatment above makes sense. Now suppose that $m^2 < 0$ and $\lambda > 0$.

d) Defining $\mu^2 = -m^2$, show that the minima of the potential are at

$$|\Phi| = v = \sqrt{\frac{\mu^2}{\lambda}}$$

The quantum theory thus has multiple vacuum states, but all have nonvanishing $\langle\mathbf{\Phi}\rangle$.

Solution to d:

Setting $dV/d|\mathbf{\Phi}|$ to zero gives $m^2|\mathbf{\Phi}| + \lambda|\mathbf{\Phi}|^3 = 0$, which yields the desired result.

By symmetry under rotations of $\mathbf{\Phi}$, we can suppose without loss of generality that we are in a vacuum state where $\langle\Phi_N\rangle = v$, with all others vanishing. Define the new fields

$$\sigma(x) = \Phi_N(x) - v, \quad \pi_i(x) = \Phi_i(x), \quad i \in \{1, 2, ..., N-1\}$$

which all have vanishing expectation values in this vacuum.

Solution to e:

This is straightforward algebra, and the answers are

$$m_\sigma = \sqrt{2}\mu, \quad \lambda_{4\pi} = \lambda, \quad \lambda_{3\sigma} = \mu\sqrt{\lambda}, \quad \lambda_{4\sigma} = \lambda$$

and

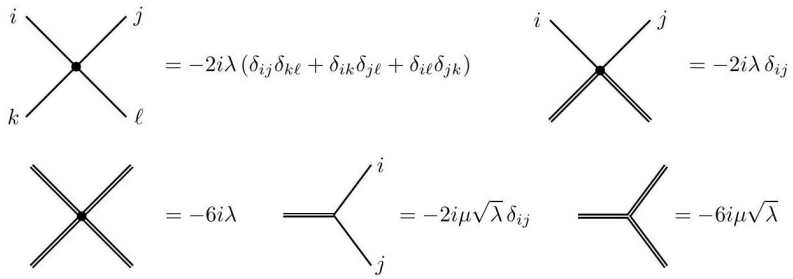
$$\lambda_{\pi\sigma 1} = \mu\sqrt{\lambda}, \quad \lambda_{\pi\sigma 2} = \frac{\lambda}{2}, \quad C = -\frac{\mu^4}{4\lambda}$$

Solution to f:

The propagators are

$$i \text{———} j = \frac{i\delta_{ij}}{p^2 + i\epsilon} \qquad \text{═══} = \frac{i}{p^2 - m_\sigma^2 + i\epsilon}$$

and the interaction vertices are



Solution to g:

The amplitude to decay to a pair of some species of pion is $i\mathcal{M} = -2i\mu\sqrt{\lambda}$, so recycling the result to problem 2(**a**) gives the decay rate

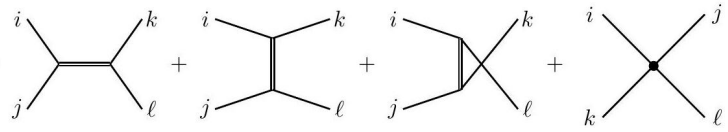
$$\Gamma = \frac{N-1}{2}\frac{(2\sqrt{\lambda}\mu)^2}{8\pi m_\sigma} = \frac{(N-1)\lambda\mu}{4\sqrt{2}\pi}.$$

where the factor of $1/2$ accounts for the two identical particles in the final state, and $N-1$ is the number of species of pion. Inverting this and converting back from natural units gives a lifetime 6×10^{-24} s.

Solution to h:

The amplitude is

$$i\mathcal{M} =$$



$$= (-2i\sqrt{\lambda}\mu)^2\left(\frac{i\delta_{ij}\delta_{k\ell}}{s-m_\sigma^2+i\epsilon} + \frac{i\delta_{ik}\delta_{j\ell}}{t-m_\sigma^2+i\epsilon} + \frac{i\delta_{i\ell}\delta_{jk}}{u-m_\sigma^2+i\epsilon}\right) - 2i\lambda\left(\delta_{ij}\delta_{k\ell} + \delta_{ik}\delta_{j\ell} + \delta_{i\ell}\delta_{jk}\right)$$
$$= (-2i\lambda)\left(\frac{2\mu^2\delta_{ij}\delta_{k\ell}}{s-2\mu^2+i\epsilon} + \frac{2\mu^2\delta_{ik}\delta_{j\ell}}{t-2\mu^2+i\epsilon} + \frac{2\mu^2\delta_{i\ell}\delta_{jk}}{u-2\mu^2+i\epsilon} + \delta_{ij}\delta_{k\ell} + \delta_{ik}\delta_{j\ell} + \delta_{i\ell}\delta_{jk}\right).$$

Solution to i:

In this limit, we have $s = t = u = 0$, so the denominators all become $-2\mu^2$. Then each of the first three diagrams cancels with one term from the last diagram.

This is another manifestation of Goldstone's theorem, discussed below. The general statement is that in the effective theory of pions alone (i.e. without σ), sometimes called the nonlinear sigma model, the Lagrangian only depends on the spatial derivatives $\partial_\mu\pi$ of the pion field. Since acting with a derivative on a field produces a factor of the particle momentum p^μ, the Feynman rules for the interactions always come with factors of momenta, so scattering amplitudes like the one we computed must vanish at zero momentum.

The theory above is an example of "spontaneous" symmetry breaking. The original theory has an $SO(N)$ rotational symmetry among the fields $\mathbf{\Phi}$. After fixing a vacuum state, we only have an $SO(N-1)$ rotational symmetry among the fields $\boldsymbol{\pi}$. The symmetries that rotate Φ_N into the π_i are still there, but operating with them moves us between different vacuum states; they tell us that the vacua all have the same energy. Thus, there is no energy cost for shifting a pion field π_i by a small constant, corresponding to the fact that there is no mass term for the pion fields. This is an example of a Goldstone's theorem, which states that each spontaneously broken continuous symmetry corresponds to a massless boson, called a Goldstone boson.

Pions are the lightest mesons, and mediate interactions between protons and neutrons. The linear sigma model was a phenomenological model which, among other things, explained why the pion was so light. The complete picture we have today is that pions are the Goldstone bosons corresponding to the spontaneous breaking of chiral symmetry, a symmetry of quantum chromodynamics which appears for massless up and down quarks.

In reality, the up and down quarks have small masses. This additional, "explicit" breaking of chiral symmetry explains why real pions have nonzero mass. In addition, the quarks differ in electric charge, which explains why the pions have different masses.

Solution to j:

The potential now includes $-a\Phi_N$, which tilts it in the Φ_N direction. There is now a unique vacuum state where only $\langle\Phi_N\rangle = v$ is nonzero. Setting the derivative of the potential to zero gives

$$-\mu^2 v + \lambda v^3 - a = 0$$

which rearranges to

$$\lambda v^2 = \mu^2 + \frac{a}{v}$$

To solve this at leading order in a, we replace the v on the right-hand side with the unperturbed expectation value $v_0 = \sqrt{\mu^2/\lambda}$. Solving for v then yields

$$v = \sqrt{\frac{\mu^2}{\lambda} + \frac{a}{\mu\sqrt{\lambda}}} = v_0 + \frac{a}{2\mu^2} + O\left(a^2\right)$$

To find the mass term for the pion, it's easiest to start with Eq. (17) and do a second shift, defining

$$\sigma' = \sigma - \frac{a}{2\mu^2}$$

The only term that will produce a pion mass term linear in a is $-\lambda_{\pi\sigma 1}(\boldsymbol{\pi}\cdot\boldsymbol{\pi})\sigma$, giving

$$\mathcal{L} \supset -\mu\sqrt{\lambda}(\boldsymbol{\pi}\cdot\boldsymbol{\pi})\frac{a}{2\mu^2} = -\frac{a\sqrt{\lambda}}{2\mu}\boldsymbol{\pi}\cdot\boldsymbol{\pi}$$

In other words, the pion mass is $\sqrt{a\sqrt{\lambda}/\mu}$.

Stanford.Zhou.2022 5.5.⋆ A contrived calculation. (5/45 p) (??????????????????)

In scalar ϕ^3 theory there is a diagram that contributes to the vacuum correlation function at order λ^8, shaped like a cube. Find its symmetry factor.
(This is somewhat involved, and the heuristic rules given in lecture will not be enough.)

Solution:

(???? вообще не знаю)
The most reliable way to do this is to simply count all the Wick contractions that yield a cube, building up the diagram one vertex at a time.
• Consider what the three copies of ϕ in the first vertex can contract with. The first has $7\cdot 3$ choices, the second has $6\cdot 3$ choices, and the third has $5\cdot 3$ choices.
• Now consider the opposite corner of the cube. There are 4 choices for which remaining uncontracted vertex is the opposite corner. Its three copies of ϕ have $3\cdot 3, 2\cdot 3$, and 3 choices for contractions.
• Finally, we attach the two halves of the cube together. There are 6 ways of choosing which vertices attach to which, and 2^6 choices for how ϕ fields are contracted to make the joining edges.
Therefore, the symmetry factor is

$$\frac{7\cdot 3\cdot 6\cdot 3\cdot 5\cdot 3\cdot 4\cdot 3\cdot 3\cdot 2\cdot 3\cdot 3\cdot 6\cdot 2^6}{8!\cdot(3!)^8} = \frac{1}{48}$$

This makes sense, as the symmetry group of the cube has 48 elements.

Stanford.Zhou.2022.9.4. Self-energy corrections in QED. (10/45p)

Loop corrections to the two-point correlation function play a key role in renormalization, and are often referred to as self-energy corrections. The one-loop self-energy corrections for the electron and photon in QED are given by the diagrams below.

$\Sigma(p^2) =$ 
$\Pi^{\mu\nu}(p^2) =$ 
Throughout this problem we will work in massless QED, $m_e = 0$.

a) Using the Feynman rules, write down $\Sigma\left(p^2\right)$ and $\Pi^{\mu\nu}\left(p^2\right)$. Since we are viewing these quantities as corrections to the electron and photon propagators, you should not include factors for the external legs, such as $u_s(p)$ or ϵ_μ, to get a scalar matrix element. Instead, Σ should be a 4×4 spinor matrix and $\Pi^{\mu\nu}$ a rank 2 Lorentz tensor.

Solution:

Using the Feynman rules, we simply read off the answers,

$$\Sigma\left(p^2\right) = \int \frac{d^dk}{(2\pi)^d}(-ie)\gamma^\mu \frac{i(\not{k}+\not{p})}{(k+p)^2+i0}(-ie)\gamma^\nu \frac{-ig_{\mu\nu}}{k^2+i0} = -4\pi\alpha \int \frac{d^dk}{(2\pi)^d} \frac{\gamma^\mu(\not{k}+\not{k})\gamma_\mu}{(k^2+i0)\left((k+p)^2+i0\right)}$$

and

$$\Pi^{\mu\nu}\left(p^2\right) = -\int \frac{d^dk}{(2\pi)^d} \frac{\operatorname{tr}\left[(-ie\gamma^\mu)\, i(\not{k}+\not{p})\,(-ie\gamma^\nu)\, i\not{k}\right]}{(k^2+i0)\left((k+p)^2+i0\right)} = -4\pi\alpha \int \frac{d^dk}{(2\pi)^d} \frac{\operatorname{tr}\left[\gamma^\mu(\not{k}+\not{p})\gamma^\nu\not{k}\right]}{(k^2+i0)\left((k+p)^2+i0\right)}$$

b) Evaluate the resulting loop integrals, expressing your final result in terms of p^2 and ϵ. (Hint: once you handle the gamma matrices, all of the integrals you get will be ones evaluated earlier in the problem set.)

Solution:

To compute Σ, we first note that $\gamma^\mu(\not{k}+\not{p})\gamma_\mu = (2-d)(\not{k}+\not{p})$. We then find that

$$\begin{aligned}
\Sigma\left(p^2\right) &= -4\pi\alpha(2-d)\left[\not{p} I_B(1,1) + \gamma_\mu I_B^\mu(1,1)\right] \\
&= -2\pi\alpha(2-d)\not{p} I_B(1,1) \\
&= \frac{\alpha}{\pi}\left(\frac{-p^2-i0}{4\pi}\right)^{-\epsilon} \not{p}\frac{i(1-\epsilon)\Gamma(1-\epsilon)^2\Gamma(1+\epsilon)}{4(1-2\epsilon)\epsilon\Gamma(1-2\epsilon)}.
\end{aligned}$$

To compute $\Pi^{\mu\nu}$ we first compute the trace in the numerator.

$$\begin{aligned}
\operatorname{tr}\left[\gamma^\mu(\not{k}+\not{p})\gamma^\nu\not{k}\right] &= 4\left(2k^\mu k^\nu + p^\mu k^\nu + k^\mu p^\nu - \eta^{\mu\nu}\left(k^2 + k\cdot p\right)\right) \\
&= 4\left(2k^\mu k^\nu + p^\mu k^\nu + k^\mu p^\nu - \eta^{\mu\nu}\left(k^2 + \frac{1}{2}\left((k+p)^2 - k^2 - p^2\right)\right)\right).
\end{aligned}$$

With this we find

$$\begin{aligned}
\Pi^{\mu\nu}\left(p^2\right) &= -16\pi\alpha\left[2I_B^{\mu\nu}\left(1,1;p^2\right) + p^\mu I_B^\nu\left(1,1;p^2\right) + p^\nu I_B^\mu\left(1,1;p^2\right) + \eta^{\mu\nu}\frac{p^2}{2} I_B\left(1,1;p^2\right)\right] \\
&= -8\pi\alpha p^2 \frac{d-2}{d-1} I_B\left(1,1;p^2\right)\left(\eta^{\mu\nu} - \frac{p^\mu p^\nu}{p^2}\right) \\
&= -\frac{\alpha}{\pi}\left(\frac{-p^2-i0}{4\pi}\right)^{-\epsilon} \frac{ip^2(1-\epsilon)\Gamma(1-\epsilon)^2\Gamma(1+\epsilon)}{(1-2\epsilon)(3-2\epsilon)\epsilon\Gamma(1-2\epsilon)}\left(\eta^{\mu\nu} - \frac{p^\mu p^\nu}{p^2}\right).
\end{aligned}$$

c) The Euler-Mascheroni constant is defined as

$$\gamma_E = -\int_0^\infty dx e^{-x}\log x \approx 0.577$$

Show that

$$\Gamma(1-\epsilon) = 1 + \gamma_E\epsilon + O\left(\epsilon^2\right)$$

Solution:

Using the definition,

$$\begin{aligned}\Gamma(1-\epsilon) &= \int_0^\infty dx x^{-\epsilon} e^{-x} \\ &= \int_0^\infty dx e^{-\epsilon \log x} e^{-x} \\ &= \int_0^\infty dx \left(1 - \epsilon \log x + O\left(\epsilon^2\right)\right) e^{-x} \\ &= 1 + \gamma_E \epsilon + O\left(\epsilon^2\right)\end{aligned}$$

as desired.
d) Using (22), expand your results from part (b), dropping terms that vanish as $\epsilon \to 0$.

Solution:

Plugging in the above result and simplifying gives

$$\Sigma = i\frac{\alpha}{\pi}\left(\frac{-p^2 - i0}{4\pi}\right)^{-\epsilon} e^{-\epsilon\gamma_E} \not{p}\left(\frac{1}{4\epsilon} + \frac{1}{4} + \mathcal{O}(\epsilon)\right)$$

and

$$\Pi^{\mu\nu}\left(p^2\right) = i\frac{\alpha}{\pi}\left(\frac{-p^2 - i0}{4\pi}\right)^{-\epsilon} e^{-\epsilon\gamma_E}\left(\eta^{\mu\nu} - \frac{p^\mu p^\nu}{p^2}\right)\left(-\frac{1}{3\epsilon} - \frac{5}{9} + \mathcal{O}(\epsilon)\right)$$

27.3.2 Basic problems about renormalization

Экзамен. Перенормировка безмассовой теории ϕ^4

Решение:
В этой задаче мы будем изучать перенормировку безмассовой теории ϕ^4 в 4 мерном Евклидовом пространстве используя метод размерной регуляризации. Статистическая сумма нашей теории записывается как

$$Z = \int D\phi_0 \exp\left(-\int d^4x \left(\frac{1}{2}\left(\partial_\mu \phi_0\right)^2 + \frac{1}{2}m_0^2\phi_0^2 + \frac{\lambda_0}{4!}\phi_0^4\right)\right) \tag{0.1}$$

где m_0 называется "затравочной" ("голой") массой и λ_0 затравочная константа связи. Мы вводим новое поле ϕ и константу связи $\lambda(\mu)$ по формулам

$$\begin{aligned}&\phi_0 = Z^{1/2}(\mu)\phi, \\ &m_0^2 = Z^{-1}(\mu)\delta m^2, \\ &\lambda_0 = Z^{-2}(\mu)(\lambda(\mu) + \delta\lambda(\mu)),\end{aligned} \tag{0.2}$$

где $\delta Z(\mu) = Z(\mu) - 1, \delta m^2 = Z(\mu)m_0^2$ и $\delta\lambda(\mu) = Z^2(\mu)\lambda_0 - \lambda(\mu)$ контрчлены, а μ вспомогательный масштаб. Статистическая сумма запишется как

$$Z = \int D\phi \exp\left(-\int d^4x \left(\frac{1}{2}\left(\partial_\mu \phi\right)^2 + \frac{\lambda(\mu)}{4!}\phi^4 + \frac{\delta Z(\mu)}{2}\left(\partial_\mu\phi\right)^2 + \frac{1}{2}\delta m^2(\mu)\phi^2 + \frac{\delta\lambda(\mu)}{4!}\phi^4\right)\right). \tag{0.3}$$

Ренормализационные условия в данном случае записываются как

$$\Gamma^{(2)}(0) = 0,$$
$$\left.\frac{d\Gamma^{(2)}}{dp^2}\right|_{p^2=\mu^2} = 1,$$
$$\left.\Gamma^{(4)}\right|_{p_i=\mu e_i} = \lambda(\mu), \tag{0.4}$$

где $e_1, e_2, .., e_4$4-вектора, такие, что $e_1+e_2+e_3+e_4 = 0$ и $p_i^2 = 3\mu^2, p_i \cdot p_j = -\mu^{21}$. Мы опять предполагаем, что все контрчлены могут быть вычисленны шаг за шагом по степеням $\lambda(\mu)$:

$$\delta Z(\mu) = z^{(2)}(\mu)\lambda^2(\mu) + ...,$$
$$\delta m^2(\mu) = b^{(1)}(\mu)\lambda(\mu) + ...$$
$$\delta\lambda(\mu) = a^{(2)}(\mu)\lambda^2(\mu) + ..., \tag{0.5}$$

с коэффициентами, которые определяются из наших ренормализационных условий.
В первой петле для $\Sigma\left(p^2\right)$ мы имеем:

Найдем коэффициенты $z^{(1)}$ и $b^{(1)}$ для контчленов δZ и δm^2, исходя из ренормализационных условий $\Sigma(0) = \Sigma'(0) = 0$. Получаем

$$-\Sigma\left(p^2\right) = -\frac{\lambda}{2}\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2} - \lambda\left(p^2z^{(1)} + b^{(1)}\right) = -\lambda\left(p^2z^{(1)} + b^{(1)}\right) \tag{0.6}$$

(Например можно взять $e_1 = (\sqrt{3}, 0, 0, 0), e_2 = \left(-\frac{1}{\sqrt{3}}, \frac{2\sqrt{2}}{\sqrt{3}}, 0, 0\right), e_3 = \left(-\frac{1}{\sqrt{3}}, -\frac{\sqrt{2}}{\sqrt{3}}, \sqrt{2}, 0\right), e_4 = \left(-\frac{1}{\sqrt{3}}, -\frac{\sqrt{2}}{\sqrt{3}}, -\sqrt{2}, 0\right)$.)
Из уравнений $\Sigma(0) = 0$ и $\Sigma'\left(\mu^2\right) = 0$ мы получаем

$$b^{(1)}(\mu) = 0, \quad z^{(1)}(\mu) = 0. \tag{0.7}$$

Во втором порядке по λ^2, для $\Gamma^{(2)}$ мы рассматриваем три диаграммы:
$-\Sigma\left(p^2\right) =$

+
Первая диаграмма равна

$$\Sigma_a\left(p^2\right) = -\frac{\lambda^2(\mu)}{3!}\int\frac{d^dkd^dq}{(2\pi)^{2d}}\frac{1}{k^2q^2(p+k+q)^2} = -\frac{\lambda^2(\mu)}{3!}\int\frac{d^dkd^dq}{(2\pi)^{2d}}\int\limits_0^\infty dt_1dt_2dt_3e^{-k^2t_1-q^2t_2-(p+k+q)^2t_3} =$$

$$= -\frac{\lambda^2(\mu)}{3!}\int\limits_0^\infty dt_1dt_2dt_3\int\frac{d^dkd^dq}{(2\pi)^{2d}}e^{-k^2(t_1+t_3)-2k(q+p)t_3-q^2(t_2+t_3)-2pqt_3-p^2t_3} =$$

$$= -\frac{\lambda^2(\mu)}{3!}\int\limits_0^\infty dt_1dt_2dt_3\int\frac{d^dq}{(2\pi)^{2d}}e^{-q^2(t_2+t_3)-2pqt_3-p^2t_3+\frac{(q+p)^2t_3^2}{t_1+t_3}}\int d^dke^{-(t_1+t_3)\left(k+\frac{(q+p)t_3}{t_1+t_3}\right)^2} =$$

$$= -\frac{\lambda^2(\mu)}{3!}\int\limits_0^\infty dt_1dt_2dt_3\int\frac{d^dq}{(2\pi)^{2d}}e^{-\frac{q^2(t_1t_2+t_2t_3+t_1t_3)+2pqt_1t_3+p^2t_1t_3}{t_1+t_3}}\left(\frac{\pi}{t_1+t_3}\right)^{d/2} =$$

$$= -\frac{\lambda^2(\mu)}{3!}\int\limits_0^\infty dt_1dt_2dt_3\frac{1}{(2\pi)^{2d}e^{-p^2\frac{t_1t_2t_3}{t_1t_2+t_2t_3+t_1t_3}}\left(\frac{\pi(t_1+t_3)}{t_1t_2+t_2t_3+t_1t_3}\right)^{d/2}\left(\frac{\pi}{t_1+t_3}\right)^{d/2t_i\to t_i/p^2}} =$$

$$= -\frac{\lambda^2(\mu)\left(p^2\right)^{d-3}}{3!(4\pi)^d}\int\limits_0^\infty\frac{dt_1dt_2dt_3}{\left(t_1t_2+t_2t_3+t_1t_3\right)^{d/2}}e^{-\frac{t_1t_2t_3}{t_1t_2+t_2t_3+t_1t_3}} =$$

$$= -\frac{\lambda^2(\mu)\left(p^2\right)^{d-3}}{3!(4\pi)^d}\frac{\Gamma-d)\Gamma^3(d/2-1)}{\Gamma(3d/2-3)}. \tag{0.8}$$

Также для второй и третьей диаграммы мы получаем

$$\Sigma_b\left(p^2\right) = -\frac{\delta\lambda(\mu)}{2}\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2} = 0$$
$$\Sigma_c\left(p^2\right) = -\left(p^2\delta Z(\mu)+\delta m^2(\mu)\right) = -\lambda^2(\mu)\left(z^{(2)}(\mu)p^2+b^{(2)}(\mu)\right) \tag{0.9}$$

Из первого ренормализационного условия $\Gamma^{(2)}(0)=0$ получаем $\left(\Gamma^{(2)}=p^2+\Sigma\left(p^2\right)\right)$:

$$b^{(2)}(\mu) = 0 \tag{0.10}$$

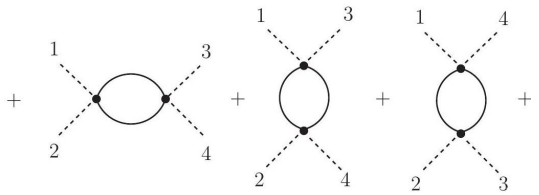
Из второго ренормализационного условия $\left.\frac{d\Gamma^{(2)}}{dp^2}\right|_{p^2=\mu^2}=1$ получаем:

$$z^{(2)}(\mu) = \frac{\left(\mu^2\right)^{d-4}\Gamma(4-d)\Gamma^3(d/2-1)}{3!(4\pi)^d\Gamma(3d/2-3)}, \tag{0.11}$$

откуда получим при $d=4-\epsilon$ и $\epsilon\to 0$:

$$\Gamma^{(2)}\left(p^2\right) = p^2+\Sigma_a\left(p^2\right)+\Sigma_b\left(p^2\right)+\Sigma_c\left(p^2\right) = p^2+\frac{1}{12}\frac{\lambda^2}{(4\pi)^4}p^2\left(\log\left(\mu^2/p^2\right)+1\right)+O\left(\lambda^3\right) \tag{0.12}$$

$-\Gamma^{(4)}\left(p_1,p_2,p_3,p_4\right) =$



Для $\Gamma^{(4)}\left(p_1,p_2,p_3,p_4\right)$ имеем получаем

$$\Gamma^{(4)}\left(p_1,p_2,p_3,p_4\right) = \lambda(\mu)-\frac{\lambda^2(\mu)}{2}\left(I\left(p_{12}^2\right)+I\left(p_{13}^2\right)+I\left(p_{14}^2\right)\right)+\lambda^2(\mu)a^{(2)}(\mu)+O\left(\lambda^3\right), \tag{0.13}$$

где $p_{12}=p_1+p_2, p_{13}=p_1+p_3, p_{14}=p_1+p_4$ и

$$I\left(q^2\right)=\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2(q+k)^2}=\int\frac{d^dk}{(2\pi)^d}\int\limits_0^1dx\frac{1}{\left(x(q+k)^2+(1-x)k^2\right)^2}=$$

$$=\int\limits_0^1dx\int\frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2+2xqk+xq^2\right)^2}=\int\limits_0^1dx\int\frac{d^dk}{(2\pi)^d}\frac{1}{\left((k+xq)^2+x(1-x)q^2\right)^2}=$$

$$=\frac{\Gamma\left(2-\frac{d}{2}\right)}{(4\pi)^{\frac{d}{2}}}\int\limits_0^1dx\left(x(1-x)q^2\right)^{\frac{d}{2}-2}=\frac{\left(q^2\right)^{\frac{d}{2}-2}}{(4\pi)^{\frac{d}{2}}}\frac{\Gamma\left(2-\frac{d}{2}\right)\Gamma^2\left(\frac{d}{2}-1\right)}{\Gamma(d-2)}. \tag{0.14}$$

Далее из условия $\Gamma^{(4)}\big|_{p_i=\mu e_i}=\lambda(\mu)$, где $e_1,e_2,..,e_4$4-вектора, такие, что $e_1+e_2+e_3+e_4=0$ и $p_i^2=3\mu^2, p_i\cdot p_j=-\mu^2$, находим $\left(p_{12}^2=p_{13}^2=p_{14}^2=4\mu^2\right)$:

$$a^{(2)}(\mu)=\frac{3}{2}I\left(4\mu^2\right) \tag{0.15}$$

Затем находим, что

$$I\left(q^2\right)-I\left(\mu^2\right)\overset{d\to4}{=}-\frac{1}{(4\pi)^2}\log\frac{q^2}{4\mu^2} \tag{0.16}$$

И таким образом мы получаем

$$\Gamma^{(2)}\left(p^2\right)=p^2+\frac{1}{12}\frac{\lambda^2}{(4\pi)^4}p^2\left(\log\left(\mu^2/p^2\right)+1\right)+O\left(\lambda^3\right),$$
$$\Gamma^{(4)}\left(p^2\right)=\lambda+\frac{1}{2}\frac{\lambda^2}{(4\pi)^2}\left(\log\left(p_{12}^2/4\mu^2\right)+\log\left(p_{13}^2/4\mu^2\right)+\log\left(p_{14}^2/4\mu^2\right)\right)+O\left(\lambda^3\right), \tag{0.17}$$

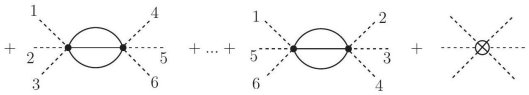
где $p_{12}^2=\left(p_1+p_2\right)^2$ и т.д.

2 Бета-функция безмассовой теории ϕ^6

Рассмотрим безмассовую теорию ϕ^6 в $d=3$ Евклидовом пространстве. Действие теории

$$S=\int d^3x\left(\frac{1}{2}\left(\partial_\mu\phi\right)^2+\frac{\lambda}{6!}\phi^6+\text{ контрчлены }\right). \tag{0.18}$$

Вычислим ведущий член в бета-функции $\beta(\lambda)$. Для $\Gamma^{(6)}\left(p_1,...,p_6\right)$ имеем
$-\Gamma^{(6)}\left(p_1,...,p_6\right)=$



И мы получаем

$$\Gamma^{(6)}\left(p_1,...,p_6\right)=\lambda-\frac{(-\lambda)^2}{6}\left(J\left(p_{123}^2\right)+...+J\left(p_{156}^2\right)\right)+\lambda^2a^{(2)}+O\left(\lambda^3\right) \tag{0.19}$$

где $p_{ijk}=p_i+p_j+p_k$ и в сумме имеется 10 слагаемых вида $J\left(p^2\right)$ и

$$J\left(p^2\right)=\int\frac{d^dqd^dk}{(2\pi)^{2d}}\frac{1}{k^2q^2(p+k+q)^2}=\frac{\left(p^2\right)^{d-3}}{(4\pi)^d}\frac{\Gamma(3-d)\Gamma^3(d/2-1)}{\Gamma(3d/2-3)}. \tag{0.20}$$

Теперь используя ренормальзационное условие

$$\Gamma^{(6)}\left(p_1,...,p_6\right)\Big|_{p_i=\mu e_i}=\lambda(\mu), \tag{0.21}$$

где $e_1, ..., e_6$ - какие-то произвольные 3 -вектора с условием $\sum_{i=1}^{6} e_i = 0$, мы найдем, что

$$a^{(2)}(\mu) = \frac{1}{6}\left(J\left(\mu^2 e_{123}^2\right) + ... + J\left(\mu^2 e_{156}^2\right)\right) \tag{0.22}$$

Далее замечая, что

$$J\left(p^2\right) - J\left(\mu^2\right) \overset{d\to 3}{=} -\frac{1}{2(4\pi)^2}\log\frac{p^2}{\mu^2} \tag{0.23}$$

получим

$$\Gamma^{(6)}\left(p_1, ..., p_6\right) = \lambda + \frac{\lambda^2}{12(4\pi)^2}\left(\log\frac{p_{123}^2}{\mu^2 e_{123}^2} + ... + \log\frac{p_{156}^2}{\mu^2 e_{156}^2}\right) + O\left(\lambda^3\right) \tag{0.24}$$

Далее подставляя $\Gamma^{(6)}\left(p_1, ..., p_6\right)$ в уравнение Каллана-Симанчика:

$$\left(\mu\frac{\partial}{\partial\mu} + \beta(\lambda)\frac{\partial}{\partial\lambda} - 6\gamma(\lambda)\right)\Gamma^{(6)}\left(p_1, ..., p_6\right) = 0 \tag{0.25}$$

находим

$$-\frac{10\lambda^2}{12(4\pi)^2}\left(\mu\frac{\partial}{\partial\mu}\log\mu^2\right) + \beta(\lambda) - 6\gamma(\lambda)\lambda + O\left(\lambda^3\right) = 0 \tag{0.26}$$

затем, используем, что $\gamma(\lambda) = O\left(\lambda^2\right)^2$, а следовательно слагаемое $\gamma(\lambda)\lambda = O\left(\lambda^3\right)$ и может не рассматриваться во втором порядке по λ, поэтому мы в итоге получаем:

$$\beta(\lambda) = \frac{10\lambda^2}{12(4\pi)^2}\left(\mu\frac{\partial}{\partial\mu}\log\mu^2\right) = \frac{5\lambda^2}{48\pi^2}. \tag{0.27}$$

(Строго говоря, это нужно было бы проверить, но в данном случае мы оставим это как упражнение.)

3 Задача 11.1 из Пескина-Шредера.

(a). Итак у нас есть свободное скалярное поле $\phi(x)$ с пропагатором

$$\langle T\phi(x)\phi(0)\rangle = D(x). \tag{0.28}$$

и конечно мы можем использовать теорему Вика. Можно использовать комбинаторные методы, но наипростейший путь использовать функциональный интеграл

$$\begin{aligned}
&\left\langle Te^{i\phi(x_0)}e^{-i\phi(0)}\right\rangle = \int D\phi e^{i(\phi(x_0)-\phi(0))}e^{\int d^dxd^dy\frac{1}{2}\phi(x)D^{-1}(x-y)\phi(y)} = \\
&= \int D\phi e^{\int d^dxd^dy\frac{1}{2}\phi(x)D^{-1}(x-y)\phi(y)+i\int d^dx\phi(x)(\delta(x-x_0)-\delta(x))} = \\
&= e^{-\frac{1}{2}\int d^dxd^dy(\delta(x-x_0)-\delta(x))D(x-y)(\delta(y-x_0)-\delta(y))} = e^{-\frac{1}{2}\int d^dx(\delta(x-x_0)-\delta(x))(D(x-x_0)-D(x))} = \\
&= e^{-\frac{1}{2}((D(0)-D(x_0)-(D(-x_0)-D(0)))} = e^{D(x_0)-D(0)}.
\end{aligned} \tag{0.29}$$

(b). У нас есть только производные ϕ, т.е. члены вида $\lambda_{n_1...n_m}^{k_1...k_m}\left(\nabla^{n_1}\phi\right)^{k_1}...\left(\nabla^{n_m}\phi\right)^{k_m}$. И мы находим ($\phi$ есть фаза и поэтому $[\phi] = 1$)

$$[\phi] = 1, \quad [\rho] = L^{2-d}, \quad \left[\lambda_{n_1...n_m}^{k_1...k_m}\right] = L^{\sum_i k_i n_i - d} \tag{0.30}$$

Принимая во внимание то, что $n_i, k_i \geqslant 1$ можно показать, что

$$P = \sum_{i=1}^{m} k_i n_i - d \geqslant m - d \tag{0.31}$$

Если $m = 1$, мы получим линейный член, что есть просто источник и это не интересно. Для $m = 2$ мы имеем $P = 2 - d$, только когда $k_1 = k_2 = n_1 = n_2 = 1$ и в этом случае мы получим $\rho(\nabla\phi)^2$. В остальных случаях мы имеем $P > 2 - d$, поэтому эти члены ростут быстрее, чем член с ρ, и они будут релевантными.

(c). Мы имеем

$$\langle s(x)s^*(0)\rangle = \left\langle Ae^{i\phi(x)}Ae^{-i\phi(0)}\right\rangle = A^2e^{D(x)-D(0)} \tag{0.32}$$

и для Лагранжиана $L = \frac{1}{2}\rho(\nabla\phi)^2$ получим

$$D(x) = \frac{1}{\rho}\int\frac{d^dk}{(2\pi)^d}\frac{i}{k^2}e^{ikx} = \frac{1}{\rho}\int\frac{d^dk_E}{(2\pi)^d}\frac{1}{k_E^2}e^{-ik_Ex} = \frac{1}{\rho}\int\frac{d^dk_E}{(2\pi)^d}\int\limits_0^\infty dte^{-tk_E^2-ik_Ex} =$$

$$= \frac{1}{\rho}\int\limits_0^\infty dt\frac{t^{-d/2}}{(4\pi)^{d/2}}e^{-\frac{x^2}{4t}} \overset{t=1/s}{=} \frac{1}{(4\pi)^{d/2}\rho}\int\limits_0^\infty dss^{d/2-2}e^{-s\frac{x^2}{4}} = \frac{\Gamma(d/2-1)}{4\rho\pi^{d/2}|x|^{d-2}}. \tag{0.33}$$

Мы предполагаем, что $D(0) = \frac{\Gamma(d/2-1)}{4\rho\pi^{d/2}|a|^{d-2}}$, где a - размер решетки. Поэтому получаем

$$\langle s(x)s^*(0)\rangle = \left\langle Ae^{i\phi(x)}Ae^{-i\phi(0)}\right\rangle = A^2\exp\left(\frac{\Gamma(d/2-1)}{4\rho\pi^{d/2}}\left(\frac{1}{|x|^{d-2}} - \frac{1}{|a|^{d-2}}\right)\right). \tag{0.34}$$

В итоге мы можем написать для $d > 2$:

$$\langle s(x)s^*(0)\rangle = A^2e^{-\frac{\Gamma(d/2-1)}{4\rho\pi^{d/2}}\frac{1}{|a|^{d-2}}}\exp\left(\frac{\Gamma(d/2-1)}{4\rho\pi^{d/2}}\frac{1}{|x|^{d-2}}\right). \tag{0.35}$$

Для $d = 2$ мы имеем $D(x) = -\frac{1}{2\pi\rho}\log|x|$, поэтому:

$$\langle s(x)s^*(0)\rangle = \frac{A^2|a|^{2\pi\rho}}{|x|^{2\pi\rho}}. \tag{0.36}$$

Белавин-Пархоменко.10. Кактусные диаграммы Фейнмана

В этой задаче мы будем изучать перенормировку массы в теории ϕ^4 в 3 мерном Евклидовом пространстве, на примере кактусных диаграмм (также они часто называются "daisy" диаграммы в англоязычной литературе). Статистическая сумма нашей теории записывается как

$$Z = \int D\phi\exp\left(-\int d^3x\left(\frac{1}{2}\left(\partial_\mu\phi\right)^2 + \frac{1}{2}m_0^2\phi^2 + \frac{\lambda}{4!}\phi^4\right)\right) \tag{0.1}$$

где m_0 называется "затравочной")"голой") массой.

(a). (30 баллов) Рассмотрим поправку первого порядка к пропагатору поля ϕ. А именно рассмотрим первую диаграмму, которая дает вклад в собственную энергетическую часть $\tilde{\Sigma}(p)$:

$-\tilde{\Sigma}(p) =$ 
$= -\frac{\lambda}{2}\int\frac{d^3k}{(2\pi)^3}\frac{1}{k^2+m_0^2}$

Как мы видим, данный интеграл расходится. Устранить данную расходимость мы можем многими способами, например введя регулятор $\Phi_{\Lambda^2}\left(k^2\right)$:

$$\tilde{\Sigma}(p) = \frac{\lambda}{2}\int\frac{d^3k}{(2\pi)^3}\frac{1}{k^2+m_0^2}\Phi_{\Lambda^2}\left(k^2\right) \tag{0.2}$$

Другой способ устранения расходимости, есть по сути выбор регулятора в виде $\Phi_{\Lambda^2}\left(k^2\right) = \theta\left(\Lambda^2-k^2\right)$, где $\theta(x)$ - тета-функция Хевисайда ("ступенька"). Тогда мы схематически можем записать

$$\tilde{\Sigma}(p) = \frac{\lambda}{2}\int\limits^\Lambda\frac{d^3k}{(2\pi)^3}\frac{1}{k^2+m_0^2} \tag{0.3}$$

Второй оригинальный способ устранить расходимость называется регуляризацией Паули-Вилларса, а именно мы записываем

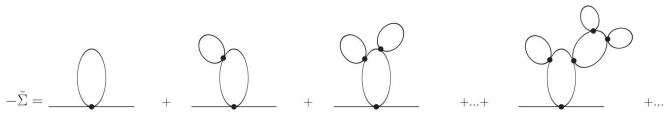
$$\frac{1}{k^2+m_0^2} \to \frac{1}{k^2+m_0^2} - \frac{1}{k^2+M^2} \tag{0.4}$$

где $M \gg m$. И последний способ, который мы рассмотрим в данном примере называется размерной регуляризацией: идея состоит в том, что мы можем рассмотреть интеграл по k в пространстве произвольной размерности d:

$$I(d) = \int \frac{d^d k}{(2\pi)^d} \frac{1}{k^2+m_0^2} \tag{0.5}$$

Очевидно, что при $d = 1$, данный интеграл сходится. Далее оказывается, что для данного интеграла $I(d)$ можно найти общий ответ в виде аналитической функции при любом действительном
d[1]. Замечательным свойством является то, что мы можем вычислить эту функцию при $d \to 3$ и получить конечный "регуляризованный" ответ. Вычислите собственную энергетическую часть $\tilde{\Sigma}(p)$ для всех трех регуляризаций.

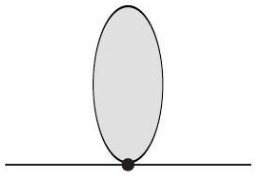
(b). Теперь рассмотрим бесконечный ряд "кактусных" диаграмм, которые дают вклад в $\tilde{\Sigma}(p)$:



Очевидно, что это далеко не все диаграммы которые дают вклад в $\tilde{\Sigma}(p)$, а только лишь их некоторое ничтожно малое подмножество [2]. Найдите сумму всех таких диаграмм. Вы должны получить самосогласованное уравнение (уравнение Дайсона) на $\tilde{\Sigma}(p)$ вида (как мы видим в данном случае $\tilde{\Sigma}$ не зависит от внешнего импульса p):

$$\tilde{\Sigma} = \frac{\lambda}{2} \int \frac{d^3 k}{k^2 + m_0^2 + \tilde{\Sigma}} \tag{0.6}$$

Нарисуйте данное самосогласованное уравнение на диаграммном языке, введя понятие перенормированного "кактуса", который по сути и есть $-\tilde{\Sigma}(p)$:



(c). Найдите $m^2 - m_0^2 = \tilde{\Sigma}(p)$ из уравнения (0.6), вычисляя интеграл с применением регуляризаций из пункта (a). Как отличаются ответы при разных регуляризациях?

Solution кактусных диаграмм Фейнмана

В этой задаче мы будем изучать перенормировку массы в теории ϕ^4 в 3 мерном Евклидовом пространстве, на примере кактусных диаграмм (также они часто называются "daisy" диаграммы в англоязычной литературе). Статистическая сумма нашей теории записывается как

$$Z = \int D\phi \exp\left(-\int d^3x \left(\frac{1}{2}(\partial_\mu \phi)^2 + \frac{1}{2} m_0^2 \phi^2 + \frac{\lambda}{4!}\phi^4\right)\right) \tag{0.1}$$

где m_0 называется "затравочной")"голой") массой.

(a). (30 баллов) Рассмотрим поправку первого порядка к пропагатору поля ϕ. А именно рассмотрим первую диаграмму, которая дает вклад в собственную энергетическую часть $\tilde{\Sigma}(p)$:

[1] Мы это уже делали в Листке 2, когда вычисляли эффект Казимира: там был интеграл, который сводился к произведению Гамма функций, на самом деле формально данный интеграл не сходился, но тем не менее мы получили для него ответ в виде аналитичекой фунции.

[2] Существуют теории, в которых данное подмножество "кактусных" диаграмм дает основной вклад в $\tilde{\Sigma}(p)$, но в нашем случае ϕ^4 это не так.

$$-\tilde{\Sigma}(p) = \quad \underset{p}{\longrightarrow} \overset{k}{\bigcirc} \underset{p}{\longrightarrow} \quad = -\frac{\lambda}{2}\int \frac{d^3k}{(2\pi)^3}\frac{1}{k^2+m_0^2}$$

Как мы видим, данный интеграл расходится. Устранить данную расходимость мы можем многими способами, например введя регулятор $\Phi_{\Lambda^2}\left(k^2\right)$:

$$\tilde{\Sigma}(p) = \frac{\lambda}{2}\int \frac{d^3k}{(2\pi)^3}\frac{1}{k^2+m_0^2}\Phi_{\Lambda^2}\left(k^2\right) \tag{0.2}$$

Другой способ устранения расходимости, есть по сути выбор регулятора в виде $\Phi_{\Lambda^2}\left(k^2\right) = \theta\left(\Lambda^2 - k^2\right)$, где $\theta(x)$ - тета-функция Хевисайда ("ступенька"). Тогда мы схематически можем записать

$$\tilde{\Sigma}(p) = \frac{\lambda}{2}\int^{\Lambda} \frac{d^3k}{(2\pi)^3}\frac{1}{k^2+m_0^2} \tag{0.3}$$

Второй оригинальный способ устранить расходимость называется регуляризацией Паули-Вилларса, а именно мы записываем

$$\frac{1}{k^2+m_0^2} \to \frac{1}{k^2+m_0^2} - \frac{1}{k^2+M^2} \tag{0.4}$$

где $M \gg m$. И последний способ, который мы рассмотрим в данном примере называется размерной регуляризацией: идея состоит в том, что мы можем рассмотреть интеграл по k в пространстве произвольной размерности d:

$$I(d) = \int \frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m_0^2} \tag{0.5}$$

Очевидно, что при $d = 1$, данный интеграл сходится. Далее оказывается, что для данного интеграла $I(d)$ можно найти общий ответ в виде аналитической функции при любом действительном
d[1]. Замечательным свойством является то, что мы можем вычислить эту функцию при $d \to 3$ и получить конечный "регуляризованный" ответ. Вычислим собственную энергетическую часть $\tilde{\Sigma}(p)$ для всех трех регуляризаций. Имеем

$$\begin{aligned}
\tilde{\Sigma}(p) &= \frac{\lambda}{2}\frac{4\pi}{8\pi^3}\int_0^{\Lambda}\frac{k^2dk}{k^2+m_0^2} = \frac{\lambda}{4\pi^2}\left(\int_0^{\Lambda}dk - \int_0^{\Lambda}\frac{m_0^2}{k^2+m_0^2}dk\right) = \\
&= \frac{\lambda}{4\pi^2}\left(\Lambda - m_0\arctan\left(\frac{k}{m_0}\right)\Big|_0^{\Lambda}\right) = \frac{\lambda}{4\pi^2}\left(\Lambda - m_0\arctan\left(\frac{\Lambda}{m_0}\right)\right) \approx \\
&\approx \frac{\lambda}{4\pi^2}\left(\Lambda - \frac{\pi}{2}m_0 + \frac{m_0^2}{\Lambda} - \frac{m_0^4}{3\Lambda^3}\right) = \frac{\lambda}{4\pi^2}\Lambda - \frac{\lambda}{8\pi}m_0 + \frac{\lambda}{4\pi^2}\frac{m_0^2}{\Lambda} - \frac{\lambda}{12\pi^2}\frac{m_0^4}{\Lambda^3} + O\left(1/\Lambda^5\right).
\end{aligned} \tag{0.6}$$

Далее имеем:

$$\begin{aligned}
\tilde{\Sigma}(p) &= \frac{\lambda}{4\pi^2}\int_0^{\Lambda}k^2dk\left(\frac{1}{k^2+m_0^2} - \frac{1}{k^2+M^2}\right) = \frac{\lambda}{4\pi^2}\left(M\arctan\frac{k}{M} - m_0\arctan\frac{k}{m_0}\right)\Big|_0^{\infty} = \\
&= \frac{\lambda}{4\pi^2}\left(\frac{\pi}{2}M - \frac{\pi}{2}m_0\right) = \frac{\lambda}{8\pi}M - \frac{\lambda}{8\pi}m_0.
\end{aligned} \tag{0.7}$$

И в последнем случае получаем:

$$\tilde{\Sigma}(p) = \frac{\lambda}{2}\int \frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m_0^2} = \frac{\lambda}{2}\frac{2\pi^{d/2}}{\Gamma\left(\frac{d}{2}\right)}\frac{1}{(2\pi)^d}\int\limits_0^\infty \frac{k^{d-1}dk}{k^2+m_0^2} = \frac{\lambda}{(4\pi)^{d/2}\Gamma\left(\frac{d}{2}\right)}\int\limits_0^\infty dt\int\limits_0^\infty dk k^{d-1}e^{-t\left(k^2+m_0^2\right)} =$$

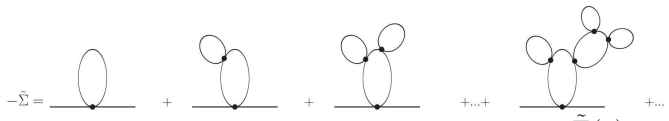
$$= \frac{\lambda}{(4\pi)^{d/2}\Gamma\left(\frac{d}{2}\right)}\int\limits_0^\infty dte^{-tm_0^2}\int\limits_0^\infty \frac{dx}{2t}(x/t)^{\frac{d-2}{2}}e^{-x} = \frac{\lambda}{2(4\pi)^{d/2}\Gamma\left(\frac{d}{2}\right)}\int\limits_0^\infty dte^{-tm_0^2}\frac{\Gamma\left(\frac{d}{2}\right)}{t^{d/2}} =$$

$$= \frac{\lambda}{2(4\pi)^{d/2}}\int\limits_0^\infty dtt^{-d/2}e^{-tm_0^2} = \frac{\lambda}{2(4\pi)^{d/2}}\left(m_0^2\right)^{\frac{d}{2}-1}\Gamma\left(1-\frac{d}{2}\right)\overset{d\to 3}{=} -\frac{\lambda}{8\pi}m_0$$

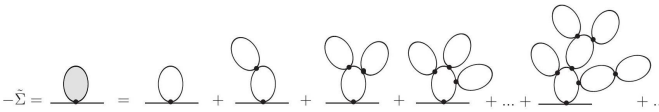
Мы видим, что размерная регуляризиация дает нам первую инвариантную константу и не содержит в данном случае расходящихся членов.

(b).

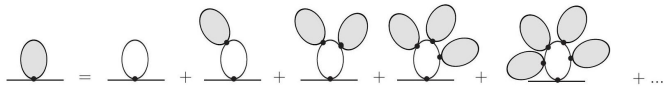
Теперь рассмотрим бесконечный ряд "кактусных" диаграмм, которые дают вклад в $\tilde{\Sigma}(p)$:



Очевидно, что это далеко не все диаграммы которые дают вклад в $\tilde{\Sigma}(p)$, а только лишь их некоторое ничтожно малое подмножество [2]. Найдем сумму всех таких диаграмм. Получим самосогласованное уравнение (уравнение Дайсона) на $\tilde{\Sigma}(p)$ вида (как мы видим в данном случае $\tilde{\Sigma}$ не зависит от внешнего импульса p). Введем понятие перенормированного "кактуса":



Тогда на такой перенормированный "кактус" можно написать самосогласованное уравнение, которое диаграммно рисуется как:



Откуда получается самосогласованное уравнение

$$-\tilde{\Sigma} = -\frac{\lambda}{2}\int d^3k\left(\frac{1}{k^2+m_0^2}+\frac{1}{k^2+m_0^2}(-\tilde{\Sigma})\frac{1}{k^2+m_0^2}+\frac{1}{k^2+m_0^2}(-\tilde{\Sigma})\frac{1}{k^2+m_0^2}(-\tilde{\Sigma})\frac{1}{k^2+m_0^2}+...\right) =$$
$$= -\frac{\lambda}{2}\int d^3k\frac{1}{k^2+m_0^2+\tilde{\Sigma}}, \tag{0.9}$$

и в итоге

$$\tilde{\Sigma} = \frac{\lambda}{2}\int d^3k\frac{1}{k^2+m_0^2+\tilde{\Sigma}} \tag{0.10}$$

(c). Найдем $m^2 - m_0^2 = \tilde{\Sigma}(p)$ из уравнения (0.10), вычисляя интеграл с применением регуляризаций из пункта (a). Имеем в первом случае

$$\tilde{\Sigma} = \frac{\lambda}{4\pi^2}\left(\Lambda - \sqrt{m_0^2+\tilde{\Sigma}}\arctan\left(\frac{\Lambda}{\sqrt{m_0^2+\tilde{\Sigma}}}\right)\right) \tag{0.11}$$

[61] Мы это уже делали в Листке 2, когда вычисляли эффект Казимира: там был интеграл, который сводился к произведению Гамма функций, на самом деле формально данный интеграл не сходился, но тем не менее мы получили для него ответ в виде аналитичекой фунции.

[2] Существуют теории, в которых данное подмножество "кактусных" диаграмм дает основной вклад в $\tilde{\Sigma}(p)$, но в нашем случае ϕ^4 это не так.

Или для перенормированной массы m^2 получим уравнение

$$m^2 = m_0^2 + \frac{\lambda}{4\pi^2}\left(\Lambda - m\arctan\left(\frac{\Lambda}{m}\right)\right) \tag{0.12}$$

В итоге получим в первом порядке ($\lambda\Lambda \gg m_0$):

$$m^2 \approx \frac{\lambda}{4\pi^2}\Lambda - \frac{\lambda^{3/2}}{16\pi^2}\Lambda^{1/2} \tag{0.13}$$

Во втором случаем получаем:

$$\tilde{\Sigma} = \frac{\lambda}{8\pi}M - \frac{\lambda}{8\pi}\sqrt{\tilde{\Sigma} + m_0^2} \tag{0.14}$$

откуда

$$\tilde{\Sigma} = \frac{\lambda}{8\pi}\left(M + \frac{\lambda}{16\pi} - \sqrt{\left(\frac{\lambda}{16\pi}\right)^2 + 2M\left(\frac{\lambda}{16\pi}\right) + m_0^2}\right). \tag{0.15}$$

Мы выбрали знак минус в решении для $\tilde{\Sigma}$, чтобы при $\lambda \to 0$ получить выражение для $\tilde{\Sigma}$ из пункта (a). Если опять $M \gg \lambda, m_0^2/\lambda$, мы получим

$$\tilde{\Sigma} \approx \frac{\lambda M}{8\pi} - \frac{\lambda^{3/2}}{16\sqrt{2}\pi^{3/2}}M^{1/2} + \frac{\lambda^2}{128\pi^2}. \tag{0.16}$$

В последнем случаем мы получаем

$$\tilde{\Sigma} = -\frac{\lambda}{8\pi}\sqrt{\tilde{\Sigma} + m_0^2} \tag{0.17}$$

откуда

$$\tilde{\Sigma} = \frac{\lambda}{8\pi}\left(\frac{\lambda}{16\pi} - \sqrt{\left(\frac{\lambda}{16\pi}\right)^2 + m_0^2}\right). \tag{0.18}$$

Белавин-Пархоменко.11 Перенормировки в теории ϕ^3

В этой задаче мы будем изучать перенормировки в теории ϕ^3 в 6 мерном Евклидовом пространстве. Статистическая сумма нашей теории записывается как

$$Z = \int D\phi_0 \exp\left(-\int d^6x\left(\frac{1}{2}\left(\partial_\mu\phi_0\right)^2 + \frac{1}{2}m_0^2\phi_0^2 + \frac{\lambda_0}{3!}\phi_0^3\right)\right) \tag{0.1}$$

где m_0 называется "затравочной" ("голой") массой и λ_0 затравочная константа связи.

Применяя размерную регуляризацию, то есть работая в $d = 6 - \epsilon$ размерности, вычислите одно-петлевые контрчлены $\delta Z, \delta m^2$ и $\delta\lambda$, где $\delta Z = Z - 1, \delta m^2 = Zm_0^2 - m^2$ и $\delta\lambda = \lambda_0 Z^{3/2} - \lambda$. Используйте следующие ренормализационные условия: трех-точечная функция $\Gamma^{(3)}(0,0,0) = \lambda$ в точке, где $p_1 = p_2 = p_3 = 0$. И для функции $\Sigma(p)$ используйте условия: $\Sigma(0) = 0$ и $\Sigma'(0) = 0$, что предполагает, что $\Gamma^{(2)}(p) = p^2 + m^2 + O\left(p^4\right)$. По сути нужно повторить все, что было сделано в лекции, для одной петли, но на примере теории ϕ^3, а не ϕ^4.

Solution 1. (100 баллов)

В этой задаче мы будем изучать перенормировки в теории ϕ^3 в 6 мерном Евклидовом пространстве. Статистическая сумма нашей теории записывается как

$$Z = \int D\phi_0 \exp\left(-\int d^6x\left(\frac{1}{2}\left(\partial_\mu\phi_0\right)^2 + \frac{1}{2}m_0^2\phi_0^2 + \frac{\lambda_0}{3!}\phi_0^3\right)\right) \tag{0.1}$$

где m_0 называется "затравочной" ("голой") массой и λ_0 затравочная константа связи.

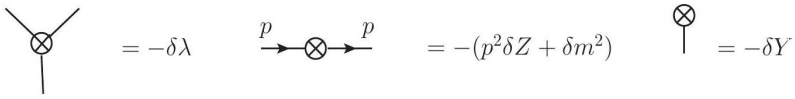
Применяя размерную регуляризацию, то есть работая в $d = 6 - \epsilon$ размерности, мы вычислим однопетлевые контрчлены $\delta Z, \delta m^2$ и $\delta\lambda$, где $\delta Z = Z - 1, \delta m^2 = Zm_0^2 - m^2$ и $\delta\lambda = \lambda_0 Z^{3/2} - \lambda$, используя следующие ренормализационные условия:

$$\begin{aligned}\Gamma^{(3)}(0,0,0) &= \lambda \\ \Gamma^{(2)}(p) &= p^2 + m^2 + O\left(p^4\right)\end{aligned} \tag{0.2}$$

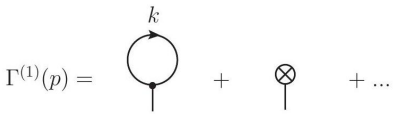
Итак мы имеем следующее действие с контр-членами

$$S = \int d^6x \left(\frac{1}{2}\left(\partial_\mu\phi\right)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{3!}\phi^3 + \frac{1}{2}\delta Z\left(\partial_\mu\phi\right)^2 + \frac{1}{2}\delta m^2\phi^2 + \frac{\delta\lambda}{3!}\phi^3 + \delta Y\phi\right), \tag{0.3}$$

где $\phi_0 = Z^{1/2}\phi$. Здесь произошел небольшой обман, а именно мы руками ввели контр-член δY, который нужен для того, чтобы сделать одноточку $\langle\phi\rangle = 0$ во всех порядках по λ и как следствие сократить все диаграммы содержащие "головастиков". Мы поясним ниже, что это значит [1]. Итак у нас есть три контр-члена:



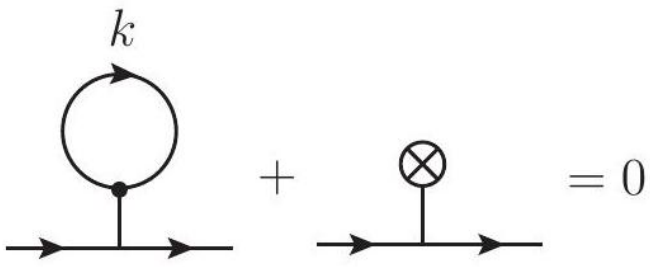
Тогда для одноточечной функции $\langle\phi\rangle$ в первом порядке по λ мы получим



И на языке формул:

$$\Gamma^{(1)}(p) = -\lambda\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2} - \delta Y = -\lambda\frac{\left(m^2\right)^{\frac{d}{2}-1}}{(4\pi)^{\frac{d}{2}}}\Gamma\left(1-\frac{d}{2}\right) - \delta Y = 0 \tag{0.4}$$

Тогда в первом порядке мы для контр-члена получим: $\delta Y = -\lambda\frac{\left(m^2\right)^{\frac{d}{2}-1}}{(4\pi)^{\frac{d}{2}}}\Gamma\left(1-\frac{d}{2}\right) + O\left(\lambda^2\right)$. Для более высоких порядков по λ мы опять выбираем контр-член δY так, чтобы в итоге получить $\langle\phi\rangle = 0$. Данный выбор контр-члена δY приводит к тому, что мы можем выкинуть все диаграммы "головастики"("tadpoles") из рассмотрения, так как их всегда можно будет сократить диаграммами с контр-членами δY. Например:



[61] Вообще говоря теория ϕ^3 является плохо определенной теорией, так как можно легко увидеть, что Гамильтониан данной теории неограничен снизу (в отличие от теории ϕ^4). Тем не менее теория возмущений не "видит" данной ужасной проблемы, и мы можем безнаказанно вычислять порядок за порядком контр-члены и перенормировки наших велечин.

Более строгое утверждение можно сформулировать так: мы ингорируем любую диаграмму, которую можно разрезать на две части, разрезав только одну линию. Причем одна из этих частей не будет содержать внешнии линии.

Теперь для собственной энергетической части мы имеем:

$$-\Sigma\left(p^2\right) = \xrightarrow{p+k} + \xrightarrow{p} \circlearrowright \xrightarrow{p} + \ldots$$

То есть на языке формул мы получаем

$$\begin{aligned}
-\Sigma\left(p^2\right) &= \frac{(-\lambda)^2}{2}\int \frac{d^dk}{(2\pi)^d}\frac{1}{(p+k)^2+m^2}\frac{1}{k^2+m^2} - \left(p^2\delta Z + \delta m^2\right) = \\
&= \frac{\lambda^2}{2}\int\limits_0^1 dx \int \frac{d^dk}{(2\pi)^d}\frac{1}{\left[(k+xp)^2+(m^2+x(1-x)p^2)\right]^2} - \left(p^2\delta Z + \delta m^2\right) = \\
&= \frac{\lambda^2\Gamma(2-d/2)}{2(4\pi)^{d/2}}\int\limits_0^1 dx \frac{1}{\left[m^2+x(1-x)p^2\right]^{2-d/2}} - \left(p^2\delta Z + \delta m^2\right), \qquad (0.5)
\end{aligned}$$

где мы использовали формулу

$$\int \frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2+\Delta\right)^n} = \frac{\Gamma\left(n-\frac{d}{2}\right)}{(4\pi)^{d/2}\Gamma(n)}\frac{1}{\Delta^{n-\frac{d}{2}}}. \qquad (0.6)$$

Далее из условий

$$\Sigma\left(p^2\right)\big|_{p^2=0} = 0, \quad \frac{d}{dp^2}\Sigma\left(p^2\right)\Big|_{p^2=0} = 0, \qquad (0.7)$$

мы находим

$$\begin{aligned}
\delta Z - \frac{\lambda^2\Gamma(2-d/2)}{2(4\pi)^{d/2}}\int\limits_0^1 dx \frac{(d/2-2)x(1-x)}{\left(m^2\right)^{3-d/2}} = 0, \\
\delta m^2 - \frac{\lambda^2\Gamma(2-d/2)}{2(4\pi)^{d/2}}\int\limits_0^1 dx \frac{1}{\left(m^2\right)^{2-d/2}} = 0, \qquad (0.8)
\end{aligned}$$

и в итоге получаем

$\delta Z = -\frac{\lambda^2\Gamma\left(2-\frac{d}{2}\right)\left(2-\frac{d}{2}\right)}{12(4\pi)^{d/2}}\frac{1}{(m^2)^{3-d/2}} = -\frac{\lambda^2\Gamma\left(3-\frac{d}{2}\right)}{12(4\pi)^{d/2}}\frac{1}{(m^2)^{3-d/2}} \overset{d=6-\epsilon}{=} \frac{\lambda^2}{6(4\pi)^3}\left(\frac{-1}{\epsilon}+\frac{1}{2}\log\frac{m^2}{4\pi}+\frac{\gamma}{2}+O(\epsilon)\right)$,

$\delta m^2 = \frac{\lambda^2\Gamma(2-d/2)}{2(4\pi)^{d/2}}\frac{1}{(m^2)^{2-d/2}} \overset{d=6-\epsilon}{=} \frac{\lambda^2 m^2}{(4\pi)^3}\left(\frac{-1}{\epsilon}+\frac{1}{2}\log\frac{m^2}{4\pi}+\frac{\gamma}{2}-\frac{1}{2}+O(\epsilon)\right)$.

Для трехточечной функции $\Gamma^{(3)}\left(p_1,p_2,p_3\right)$ мы получим

$-\Gamma^{(3)}(p_1,p_2,p_3) =$ 
И на языке формул имеем:

$$-\Gamma^{(3)}\left(p_1,p_2,p_3\right) = -\lambda + (-\lambda)^3\int\frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2+m^2\right)\left(\left(k+p_2\right)^2+m^2\right)\left(\left(k+p_2+p_3\right)^2+m^2\right)} - \delta\lambda \qquad (0.10)$$

И из условия $\Gamma^{(3)}(0,0,0) = \lambda$, получаем

$$-\lambda^3 \int \frac{d^d k}{(2\pi)^d} \frac{1}{\left(k^2+m^2\right)^3} - \delta\lambda = 0 \tag{0.11}$$

откуда

$$\delta\lambda = -\frac{\lambda^3 \Gamma(3-d/2)}{2(4\pi)^{d/2} m^{6-d}} \overset{d=6-\epsilon}{=} -\frac{\lambda^3 \Gamma(\epsilon/2)}{2(4\pi)^{3-\epsilon/2} m^{\epsilon}} = \frac{\lambda^3}{(4\pi)^3}\left(\frac{-1}{\epsilon} + \frac{1}{2}\log\frac{m^2}{4\pi} + \frac{\gamma}{2} + O(\epsilon)\right). \tag{0.12}$$

Белавин-Пархоменко.**12. Перенормировка пропагатора в теории ϕ^4**

1. (100 баллов)

В этой задаче мы будем изучать перенормировку пропагатора в теории ϕ^4 в 4 мерном Евклидовом пространстве используя метод размерной регуляризации. Статистическая сумма нашей теории записывается как

$$Z = \int D\phi_0 \exp\left(-\int d^4x \left(\frac{1}{2}\left(\partial_\mu \phi_0\right)^2 + \frac{1}{2} m_0^2 \phi_0^2 + \frac{\lambda_0}{4!}\phi_0^4\right)\right) \tag{0.1}$$

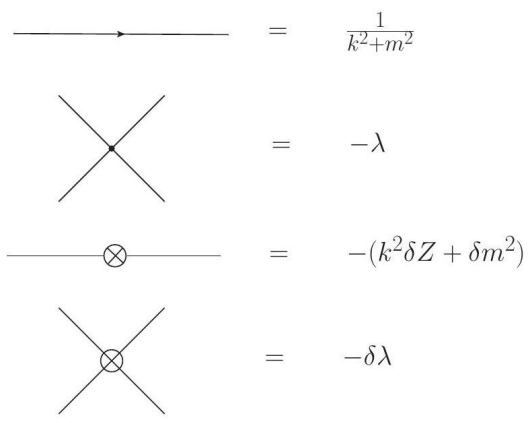
где m_0 называется "затравочной" ("голой") массой и λ_0 затравочная константа связи. Мы вводим новое поле ϕ и константы связи λ и m^2 по формулам

$$\begin{aligned} &\phi_0 = Z^{1/2}\phi, \\ &m_0^2 = Z^{-1}\left(m^2 + \delta m^2\right), \\ &\lambda_0 = Z^{-2}(\lambda + \delta\lambda) \end{aligned} \tag{0.2}$$

где $\delta Z = Z - 1, \delta m^2 = Z m_0^2 - m^2$ и $\delta\lambda = Z^2\lambda_0 - \lambda$ контрчлены. И статистическая сумма запишется как

$$Z = \int D\phi \exp\left(-\int d^4x \left(\frac{1}{2}\left(\partial_\mu\phi\right)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4 + \frac{\delta Z}{2}\left(\partial_\mu\phi\right)^2 + \frac{1}{2}\delta m^2\phi^2 + \frac{\delta\lambda}{4!}\phi^4\right)\right). \tag{0.3}$$

Нашу диаграммную технику в данном случае можно кратко записать как:



Контрчлены расскладываются по степеням взаимодействия λ:

$$\begin{aligned} &\delta Z = z^{(1)}\lambda + z^{(2)}\lambda^2 + ... \\ &\delta m^2 = b^{(1)}\lambda + b^{(2)}\lambda^2 + ... \\ &\delta\lambda = a^{(1)}\lambda + a^{(2)}\lambda^2 + ... \end{aligned} \tag{0.4}$$

с коэффициентами зависящими от $\epsilon = 4 - d$, таким образом, что корреляционные функции ренормированных полей ϕ имеют конечный предел при $\epsilon \to 0$ в каждом порядке по λ.

В этой задаче нужно будет найти перенормировку пропагатора, то есть двухточечной функции $\Gamma^{(2)}\left(p^2\right)$ до второй петли:

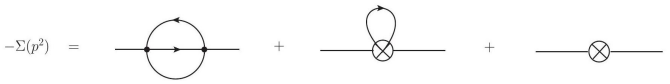
$$\Gamma^{(2)}\left(p^2\right) = p^2 + m^2 + \Sigma\left(p^2\right) \tag{0.5}$$

с ренормализационными условиями $\Sigma\left(p^2=0\right)=0$ и $\frac{d}{dp^2}\Sigma\left(p^2\right)\Big|_{p^2=0} = 0$ (кратко: $\Sigma(0)=\Sigma'(0)=0$).

(a). Однопетлевое вычисление $\Gamma^{(2)}\left(p^2\right)$ (30 баллов) В первой петле для $\Sigma\left(p^2\right)$ мы имеем:

Найдите коэффициенты $z^{(1)}$ и $b^{(1)}$ для контчленов δZ и δm^2, исходя из ренормализационных условий $\Sigma(0)=\Sigma'(0)=0$.

(b). Двухпетлевое вычисление $\Gamma^{(2)}\left(p^2\right)$ (70 баллов) Во второй петле для $\Sigma\left(p^2\right)$ мы имеем:



Вычислите первую диаграмму (I). Она дается довольно громоздким двойным интегралом. Вычислите сначала первый, а затем второй интегралы используя Фейнмановские параметры, а именно пользуясь формулой:

$$\frac{1}{A^\alpha B^\beta} = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)}\int\limits_0^1 \frac{dv v^{\alpha-1}(1-v)^{\beta-1}}{[vA+(1-v)B]^{\alpha+\beta}}. \tag{0.6}$$

В итоге вы должны получить результат вида

$$\Sigma_I\left(p^2\right) = -\frac{\lambda^2}{3!}\frac{\Gamma(3-d)}{(4\pi)^d}\times$$
$$\int\limits_0^1 dwduw^{1-\frac{d}{2}}\left((1-w)+wu(1-u)\right)^{3-\frac{3d}{2}}\left[u(1-u)w(1-w)p^2+\left((1-w)+wu(1-u)\right)m^2\right]^{d-3}. \tag{0.7}$$

Данный интеграл расходится как $1/\epsilon^2$. Вычитая из него члены вида $\Sigma_I(0)$ и $p^2\Sigma_I'(0)$, получите выражение для

$$\Sigma_r\left(p^2\right) = \Sigma_I\left(p^2\right) - \Sigma_I(0) - p^2\Sigma_I'(0). \tag{0.8}$$

Покажите, что $\Sigma_r\left(p^2\right)$ при $d\to 4$ не имеет расходимостей. С другой стороны мы имеем

$$\begin{aligned}\Sigma\left(p^2\right) &= \Sigma_I\left(p^2\right) + \Sigma_{II}\left(p^2\right) + \Sigma_{III}\left(p^2\right)\\ &= \Sigma_r\left(p^2\right) + \Sigma_I(0) + p^2\Sigma_I'(0) + \Sigma_{II}\left(p^2\right) + \Sigma_{III}\left(p^2\right)\end{aligned} \tag{0.9}$$

Найдити коэффициенты в контлченах: $z^{(2)}, a^{(2)}$ и $b^{(2)}$ исходя из условия

$$\Sigma_I(0) + p^2\Sigma_I'(0) + \Sigma_{II}\left(p^2\right) + \Sigma_{III}\left(p^2\right) = 0. \tag{0.10}$$

Откуда в конечно итоге мы получим, что

$$\Sigma\left(p^2\right) = \Sigma_r\left(p^2\right) \tag{0.11}$$

Мы не включили сюда диаграммы вида:

Покажите, что их сумма равна нулю, если использовать коэффициенты $z^{(1)}$ и $b^{(1)}$ которые мы нашли в пункте (a).

Solution Белавин-Пархоменко.12. Перенормировка пропагатора в теории ϕ^4 Решения

В этой задаче мы будем изучать перенормировку пропагатора в теории ϕ^4 в 4 мерном Евклидовом пространстве используя метод размерной регуляризации. Статистическая сумма нашей теории записывается как

$$Z = \int D\phi_0 \exp\left(-\int d^4x \left(\frac{1}{2}\left(\partial_\mu \phi_0\right)^2 + \frac{1}{2}m_0^2\phi_0^2 + \frac{\lambda_0}{4!}\phi_0^4\right)\right) \tag{0.1}$$

где m_0 называется "затравочной" ("голой") массой и λ_0 затравочная константа связи. Мы вводим новое поле ϕ и константы связи λ и m^2 по формулам

$$\begin{aligned} &\phi_0 = Z^{1/2}\phi \\ &m_0^2 = Z^{-1}\left(m^2 + \delta m^2\right), \\ &\lambda_0 = Z^{-2}(\lambda + \delta\lambda) \end{aligned} \tag{0.2}$$

где $\delta Z = Z - 1, \delta m^2 = Zm_0^2 - m^2$ и $\delta\lambda = Z^2\lambda_0 - \lambda$ контрчлены. И статистическая сумма запишется как

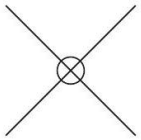
$$Z = \int D\phi \exp\left(-\int d^4x \left(\frac{1}{2}\left(\partial_\mu \phi\right)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4 + \frac{\delta Z}{2}\left(\partial_\mu\phi\right)^2 + \frac{1}{2}\delta m^2\phi^2 + \frac{\delta\lambda}{4!}\phi^4\right)\right). \tag{0.3}$$

Нашу диаграммную технику в данном случае можно кратко записать как:

$= \quad \frac{1}{k^2+m^2}$

$= \quad -\lambda$

$= \quad -(k^2\delta Z + \delta m^2)$



$= \quad -\delta\lambda$

Контрчлены расскладываются по степеням взаимодействия λ:

$$\begin{aligned} &\delta Z = z^{(1)}\lambda + z^{(2)}\lambda^2 + ... \\ &\delta m^2 = b^{(1)}\lambda + b^{(2)}\lambda^2 + ... \\ &\delta\lambda = a^{(1)}\lambda + a^{(2)}\lambda^2 + ... \end{aligned} \tag{0.4}$$

с коэффициентами зависящими от $\epsilon = 4 - d$, таким образом, что корреляционные функции ренормированных полей ϕ имеют конечный предел при $\epsilon \to 0$ в каждом порядке по λ.

В этой задаче мы найдем перенормировку пропагатора, то есть двухточечной функции $\Gamma^{(2)}\left(p^2\right)$ до второй петли:

$$\Gamma^{(2)}\left(p^2\right) = p^2 + m^2 + \Sigma\left(p^2\right) \tag{0.5}$$

с ренормализационными условиями $\Sigma\left(p^2\right)\big|_{p^2=0} = 0$ и $\frac{d}{dp^2}\Sigma\left(p^2\right)\Big|_{p^2=0} = 0$ (кратко: $\Sigma(0) = \Sigma'(0) = 0$).

(a). Однопетлевое вычисление $\Gamma^{(2)}\left(p^2\right)$ (30 баллов) В первой петле для $\Sigma\left(p^2\right)$ мы имеем:

$-\Sigma(p^2)$ =

+

Найдем коэффициенты $z^{(1)}$ и $b^{(1)}$ для контчленов δZ и δm^2, исходя из ренормализационных условий $\Sigma(0) = \Sigma'(0) = 0$. Получаем

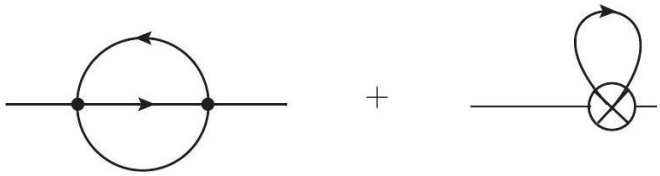
$$-\Sigma\left(p^2\right) = -\frac{\lambda}{2}\int \frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2} - \lambda\left(p^2 z^{(1)} + b^{(1)}\right) = -\frac{\lambda}{2(4\pi)^{\frac{d}{2}}}\frac{\Gamma\left(1-\frac{d}{2}\right)}{\left(m^2\right)^{1-\frac{d}{2}}} - \lambda\left(p^2 z^{(1)} + b^{(1)}\right). \tag{0.6}$$

Из уравнений $\Sigma(0) = \Sigma'(0) = 0$ мы получаем

$$b^{(1)} = -\frac{1}{2(4\pi)^{\frac{d}{2}}}\frac{\Gamma\left(1-\frac{d}{2}\right)}{\left(m^2\right)^{1-\frac{d}{2}}} \overset{d=4-\epsilon}{=} \frac{1}{(4\pi)^2}\frac{m^2}{\epsilon} - \frac{m^2}{2(4\pi)^2}\left(\log\frac{m^2}{4\pi} + \gamma - 1\right) + O(\epsilon), \quad z^{(1)} = 0. \tag{0.7}$$

(b). Двухпетлевое вычисление $\Gamma^{(2)}\left(p^2\right)$ (70 баллов) Во второй петле для $\Sigma\left(p^2\right)$ мы имеем:

$$-\Sigma\left(p^2\right) =$$



Вычислим первую диаграмму (I). Имеем

$$\begin{aligned}
-\Sigma_I\left(p^2\right) &= \frac{(-\lambda)^2}{3!}\int \frac{d^dk d^dq}{(2\pi)^{2d}}\frac{1}{k^2+m^2}\frac{1}{q^2+m^2}\frac{1}{(p+q+k)^2+m^2} = \\
&= \frac{\lambda^2}{3!}\int \frac{d^dk d^dq}{(2\pi)^{2d}}\frac{1}{k^2+m^2}\int\limits_0^1 du \frac{1}{\left[u\left(q^2+2q(p+k)+(p+k)^2\right)+(1-u)q^2+m^2\right]^2} = \\
&= \frac{\lambda^2}{3!}\int \frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2}\int\limits_0^1 du\int \frac{d^dq}{(2\pi)^d}\frac{1}{\left[(q+u(p+k))^2+m^2+u(1-u)(p+k)^2\right]^2} = \\
&= \frac{\lambda^2}{3!}\int \frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2}\int\limits_0^1 du \frac{\Gamma\left(2-\frac{d}{2}\right)}{(4\pi)^{d/2}\Gamma(2)}\frac{1}{\left[m^2+u(1-u)(p+k)^2\right]^{2-\frac{d}{2}}} = \\
&= \frac{\lambda^2}{3!}\frac{\Gamma\left(2-\frac{d}{2}\right)}{(4\pi)^{d/2}\Gamma(2)}\int \frac{d^dk}{(2\pi)^d}\int\limits_0^1 dudw w^{1-\frac{d}{2}}\frac{\Gamma^2)}{\Gamma\left(2-\frac{d}{2}\right)\Gamma(2)\left[m^2+wu(1-u)(p+k)^2+k^2(1-w)\right]^{3-\frac{d}{2}}} = \\
&= \frac{\lambda^2}{3!}\frac{\Gamma\left(3-\frac{d}{2}\right)}{(4\pi)^{d/2}}\int dudw w^{1-\frac{d}{2}}\int \frac{d^dk}{(2\pi)^d}\frac{1}{\left[k^2A+2pkwu(1-u)+m^2+p^2wu(1-u)\right]^{3-\frac{d}{2}}},
\end{aligned} \tag{0.8}$$

где $A = 1 - w + wu(1-u)$. Далее получаем

$$\begin{aligned}
-\Sigma_I\left(p^2\right) &= \frac{\lambda^2}{3!}\frac{\Gamma\left(3-\frac{d}{2}\right)}{(4\pi)^{d/2}}\int \frac{dudw w^{1-\frac{d}{2}}}{A^{3-\frac{d}{2}}}\int \frac{d^dk}{(2\pi)^d}\frac{1}{\left[\left(k+p\frac{wu(1-u)}{A}\right)^2+\frac{m^2+p^2wu(1-u)}{A}-p^2\frac{w^2u^2(1-u)^2}{A^2}\right]^{3-\frac{d}{2}}} = \\
&= \frac{\lambda^2}{3!}\frac{\Gamma\left(3-\frac{d}{2}\right)}{(4\pi)^{d/2}}\int \frac{dudw w^{1-\frac{d}{2}}}{A^{3-\frac{d}{2}}}\frac{\Gamma(3-d)}{(4\pi)^{d/2}\Gamma\left(3-\frac{d}{2}\right)}\left(\frac{A^2}{u(1-u)w(1-w)p^2+Am^2}\right)^{3-d}.
\end{aligned} \tag{0.9}$$

В итоге мы получим

$$\Sigma_I\left(p^2\right) = -\frac{\lambda^2}{3!}\frac{\Gamma(3-d)}{(4\pi)^d}\int dudww^{1-\frac{d}{2}}A^{3-\frac{3d}{2}}\left(u(1-u)w(1-w)p^2+Am^2\right)^{d-3} =$$
$$= -\frac{\lambda^2}{3!}\frac{\Gamma(3-d)}{(4\pi)^d}\left(m^2\right)^{d-3}\int dudww^{1-\frac{d}{2}}A^{-\frac{d}{2}}\left(1+Bp^2\right)^{d-3}, \tag{0.10}$$

где $B = \frac{u(1-u)w(1-w)}{Am^2}$. Данный интеграл расходится как $1/\epsilon^2$. Вычитая из него члены вида $\Sigma_I(0)$ и $p^2\Sigma_I'(0)$, получим

$$\Sigma_r\left(p^2\right) = \Sigma_I\left(p^2\right) - \Sigma_I(0) - p^2\Sigma_I'(0) =$$
$$= -\frac{\lambda^2}{3!}\frac{\Gamma(3-d)}{(4\pi)^d}\left(m^2\right)^{d-3}\int dudww^{1-\frac{d}{2}}A^{-\frac{d}{2}}\left(\left(1+Bp^2\right)^{d-3}-1-(d-3)p^2B\right) =$$
$$= -\frac{\lambda^2}{3!}\frac{\Gamma(-1+\epsilon)}{(4\pi)^{4-\epsilon}}\left(m^2\right)^{1-\epsilon}\int dudww^{1-\frac{d}{2}}A^{-\frac{d}{2}}\left(\left(1+Bp^2\right)e^{-\epsilon\log\left(1+Bp^2\right)}-1-(1-\epsilon)p^2B\right) =$$
$$= -\frac{\lambda^2}{3!}\frac{\epsilon(-1+\epsilon)}{(4\pi)^{4-\epsilon}}\left(m^2\right)^{1-\epsilon}\int dudww^{1-\frac{d}{2}}A^{-\frac{d}{2}}\left(p^2B-\left(1+p^2B\right)\log\left(1+p^2B\right)+O(\epsilon)\right)\overset{\epsilon\to 0}{=}$$
$$= \frac{\lambda^2}{3!}\frac{m^2}{(4\pi)^4}\int\limits_0^1\frac{dudw}{wA^2}\left(p^2B-\left(1+p^2B\right)\log\left(1+p^2B\right)\right). \tag{0.11}$$

Покажем, что $\Sigma_r\left(p^2\right)$ при $d\to 4$ не имеет расходимостей. Имеем при $w\to 0$

$$A\to 1,\quad B\to\frac{wu(1-u)}{m^2}\to 0 \tag{0.12}$$

поэтому мы получаем для подынтегрального выражения при $w\to 0$:

$$\frac{1}{wA^2}\left(p^2B-\left(1+p^2B\right)\log\left(1+p^2B\right)\right)\to -\frac{\left(p^2B\right)^2}{2wA^2}\to -\frac{p^4}{2m^4}wu^2(1-u)^2\to 0 \tag{0.13}$$

Откуда следует, что двойной инеграл по w и по u не имеет расходимостей при $w\to 0$. Теперь при $w\to 1$ мы имеем:

$$A\to 1-w+u(1-u)=\alpha+\beta,\quad B\to\frac{(1-w)u(1-u)}{m^2(1-w+u(1-u))}=\frac{1}{m^2}\frac{\alpha\beta}{\alpha+\beta} \tag{0.14}$$

где $\alpha = 1-w\to +0$ и $\beta = u(1-u) > 0$. Для A и B имеем следующие неравенства:

$$A\geqslant\max(\alpha,\beta),\quad B\leqslant\frac{1}{m^2}\min(\alpha,\beta)\to 0 \tag{0.15}$$

И для подынтегрального выражения получаем при $w\to 1$:

$$\left|\frac{1}{wA^2}\left(p^2B-\left(1+p^2B\right)\log\left(1+p^2B\right)\right)\right|\to\frac{\left(p^2B\right)^2}{2wA^2}\to\frac{p^4}{2}\frac{B^2}{A^2}\leqslant\frac{p^4}{2m^4}\frac{\min(\alpha,\beta)^2}{\max(\alpha,\beta)^2}\leqslant\frac{p^4}{2m^4}, \tag{0.16}$$

то есть мы опять видим, что подынтегральное выражение конечно и не содержит сингулярностей, таким образом мы видим, что $\Sigma_r\left(p^2\right)$ не имеет расходимостей.

С другой стороны мы имеем

$$\Sigma\left(p^2\right) = \Sigma_I\left(p^2\right)+\Sigma_{II}\left(p^2\right)+\Sigma_{III}\left(p^2\right)$$
$$= \Sigma_r\left(p^2\right)+\left(\Sigma_I(0)+p^2\Sigma_I'(0)+\Sigma_{II}\left(p^2\right)+\Sigma_{III}\left(p^2\right)\right) \tag{0.17}$$

Найдем коэффициенты в контлченах: $z^{(2)}, a^{(2)}$ и $b^{(2)}$ исходя из условия

$$\Sigma_I(0)+p^2\Sigma_I'(0)+\Sigma_{II}\left(p^2\right)+\Sigma_{III}\left(p^2\right)=0 \tag{0.18}$$

Итак имеем:

$$\Sigma_{II}\left(p^2\right) = -\frac{\lambda^2 a^{(2)}}{2}\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2}, \quad \Sigma_{III}\left(p^2\right) = -\lambda^2\left(z^{(2)}p^2 + b^{(2)}\right), \tag{0.19}$$

откуда находим, что

$$z^{(2)} = \frac{\Sigma_I'(0)}{\lambda^2} = \frac{1}{3!}\frac{\Gamma(4-d)}{(4\pi)^d}\left(m^2\right)^{d-4}\int\limits_0^1 dudw\frac{w^{2-\frac{d}{2}}(1-w)u(1-u)}{(1-w+wu(1-u))^{1+\frac{d}{2}}} \overset{d=4-\epsilon}{=} \frac{1}{12(4\pi)^4}\frac{1}{\epsilon}+O(1). \tag{0.20}$$

и также

$$a^{(2)}\frac{\Gamma\left(1-\frac{d}{2}\right)}{2(4\pi)^{\frac{d}{2}}\left(m^2\right)^{1-\frac{d}{2}}} + b^{(2)} = -\frac{\Gamma(3-d)\left(m^2\right)^{d-3}}{3!(4\pi)^d}\int\limits_0^1\frac{dudww^{1-\frac{d}{2}}}{(1-w+wu(1-u))^{\frac{d}{2}}} \tag{0.21}$$

и в лидирующем порядке по ϵ получаем:

$$a^{(2)}\left(-\frac{m^2}{(4\pi)^2\epsilon}+O(1)\right)+b^{(2)} = \frac{m^2}{3(4\pi)^4\epsilon^2}+O(1/\epsilon) \tag{0.22}$$

Откуда в конечно итоге мы получим, что

$$\Sigma\left(p^2\right) = \Sigma_r\left(p^2\right) = \frac{\lambda^2}{3!}\frac{m^2}{(4\pi)^4}\int\limits_0^1\frac{dudw}{wA^2}\left(p^2B-\left(1+p^2B\right)\log\left(1+p^2B\right)\right), \tag{0.23}$$

где $A = 1-w+wu(1-u)$ и $B = \frac{u(1-u)w(1-w)}{Am^2}$.
Мы не включили сюда диаграммы вида:

Покажем, что их сумма равна нулю, если использовать коэффициенты $z^{(1)}$ и $b^{(1)}$, которые мы нашли в пункте (a). Имеем

$$\begin{aligned}
&-\frac{\lambda}{2}\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2}\left(-\frac{\lambda}{2}\int\frac{d^dq}{(2\pi)^d}\frac{1}{q^2+m^2}\right)\frac{1}{k^2+m^2} - \frac{\lambda}{2}\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2}\left(-\lambda\left(k^2z^{(1)}+b^{(1)}\right)\right)\frac{1}{k^2+m^2} = \\
&= -\frac{\lambda}{2}\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2}\left(-\frac{\lambda}{2}\int\frac{d^dq}{(2\pi)^d}\frac{1}{q^2+m^2}-\lambda b^{(1)}\right)\frac{1}{k^2+m^2} = -\frac{\lambda}{2}\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2}(0)\frac{1}{k^2+m^2} = 0.
\end{aligned} \tag{0.24}$$

Белавин-Пархоменко.13. Перенормировка оператора $\phi^2(x)$ в теории ϕ^4

1. (100 баллов)

В этой задаче мы будем изучать перенормировку оператора $O(x) = \phi^2(x)$ в теории ϕ^4 в 4 мерном Евклидовом пространстве используя метод размерной регуляризации. Статистическая сумма нашей теории записывается как

$$Z = \int D\phi_0 \exp\left(-\int d^4x\left(\frac{1}{2}\left(\partial_\mu\phi_0\right)^2+\frac{1}{2}m_0^2\phi_0^2+\frac{\lambda_0}{4!}\phi_0^4\right)\right) \tag{0.1}$$

где m_0 называется "затравочной" ("голой") массой и λ_0 затравочная константа связи. Мы вводим новое поле ϕ и константы связи λ и m^2 по формулам

$$\begin{aligned}
&\phi_0 = Z^{1/2}\phi, \\
&m_0^2 = Z^{-1}\left(m^2+\delta m^2\right), \\
&\lambda_0 = Z^{-2}(\lambda+\delta\lambda)
\end{aligned} \tag{0.2}$$

где $\delta Z = Z - 1, \delta m^2 = Z m_0^2 - m^2$ и $\delta\lambda = Z^2\lambda_0 - \lambda$ контрчлены. И статистическая сумма запишется как

$$Z = \int D\phi \exp\left(-\int d^4x \left(\frac{1}{2}\left(\partial_\mu\phi\right)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4 + \frac{\delta Z}{2}\left(\partial_\mu\phi\right)^2 + \frac{1}{2}\delta m^2\phi^2 + \frac{\delta\lambda}{4!}\phi^4\right)\right). \tag{0.3}$$

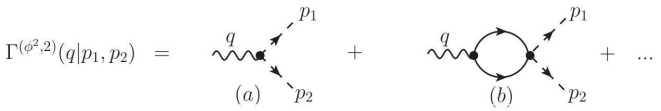
Определим $W^{\left(\phi^2,2\right)}\left(x|x_1,x_2\right)$ по формуле:

$$W^{\left(\phi^2,2\right)}\left(x|x_1,x_2\right) = \left\langle\phi^2(x)\phi\left(x_1\right)\phi\left(x_2\right)\right\rangle_{\text{связн}} = \left\langle\phi^2(x)\phi\left(x_1\right)\phi\left(x_2\right)\right\rangle - \left\langle\phi^2(x)\right\rangle\left\langle\phi\left(x_1\right)\phi\left(x_2\right)\right\rangle. \tag{0.4}$$

Удобно перейти в импульсное пространство и определить $\Gamma^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right)$:

$$\Gamma^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right) = \frac{W^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right)}{W\left(p_1\right)W\left(p_2\right)}, \quad q = p_1 + p_2 \tag{0.5}$$

где $\Gamma^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right)$ уже дается суммой всех связанных одночастично неприводимых диаграмм:



Таким обозом мы находим, что

$$\Gamma^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right) = 1 - \frac{\lambda}{2}I\left(p_{12}^2\right) + \ldots \tag{0.6}$$

где $I\left(p^2\right)$ интеграл, который мы вычисляли на предыдущих лекциях. Мы знаем, что $I\left(p_{12}^2\right) = I_r\left(p_{12}^2\right) + I(0)$, где I_r конечен при $\epsilon \to 0$, а $I(0) = \left(m^2\right)^{d/2-2}\Gamma(2-d/2)/(4\pi)^{d/2}$ сингулярная часть, то есть мы видим, что в данных диаграммах есть расходимости. Мы можем определить перенормированный оператор $\left[\phi^2\right]_R$ и $\Gamma^{\left(\left[\phi^2\right]_R,2\right)}$ по формулам:

$$\phi^2 = Z_2^{-1}\left[\phi^2\right]_R, \quad \Gamma^{\left(\phi^2,2\right)} = Z_2^{-1}\Gamma^{\left(\left[\phi^2\right]_R,2\right)}, \tag{0.7}$$

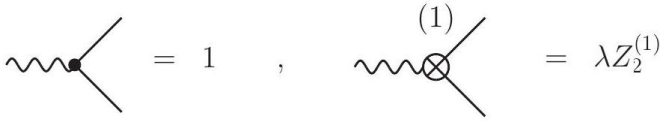
так, что $\Gamma^{\left(\left[\phi^2\right]_R,2\right)}$ имеет уже конечный предел при $\epsilon \to 0$. Удобно написать

$$\left[\phi^2\right]_R = Z_2\phi^2 \tag{0.8}$$

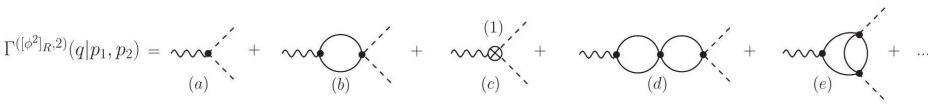
где коэффициент Z_2 находится порядок за порядком по степени λ:

$$Z_2 = 1 + \lambda Z_2^{(1)} + \lambda^2 Z_2^{(2)} + \ldots \tag{0.9}$$

Поэтому вычисление корреляционной функции с вставкой ренормированного оператора $\left[\phi^2\right]_R$, эквивалентно добавлению к нашей диаграммной технике серии контрчленных вершин:



Поэтому для корреляционной функции $\Gamma^{\left(\left[\phi^2\right]_R,2\right)}$ мы получим следующие диаграммы:



[61] Внешнии линии обозначаются здесь пунктиром, а волнистая линия просто обозначает, что в корреляционную функцию вставленна внешняя вершина-оператор с полным импульсом q.

И коэффициенты контрчленов $Z_2^{(1)}, Z_2^{(2)}, ...$ подбираются таким образом, чтобы сократить расходимости. Мы выбираем ренормализационное условие в виде [2]

$$\Gamma^{\left([\phi^2]_R,2\right)}(0|0,0)=1 \tag{0.10}$$

И мы можем легко найти, что $Z_2^{(1)}=\frac{1}{2}I(0)$ и $\Gamma^{\left([\phi^2]_R,2\right)}=1-\frac{\lambda}{2}I_r\left(p_{12}^2\right)+O\left(\lambda^2\right)$.

Покажите, что во втором порядке по λ, можно найти такое $Z_2^{(2)}$, что $\Gamma^{\left([\phi^2]_R,2\right)}$ не будет иметь сингулярностей. Помимо диаграмм (d) и (e) вам нужно найти еще три дополнительные диаграммы, которые дадут вклад в λ^2 порядке, одна из этих диаграмм есть просто операторный контрчлен $Z_2^{(2)}$. Также не забывайте, что у нас есть и обычные контрчлены. (Подсказка: Вспомните анализ двухпетлевой перенормировки для $\Gamma^{(4)}$).

Solution Белавин-Пархоменко.13. Перенормировка оператора $\phi^2(x)$ в теории ϕ^4

В этой задаче мы будем изучать перенормировку оператора $O(x)=\phi^2(x)$ в теории ϕ^4 в 4 мерном Евклидовом пространстве используя метод размерной регуляризации. Статистическая сумма нашей теории записывается как

$$Z=\int D\phi_0 \exp\left(-\int d^4x\left(\frac{1}{2}\left(\partial_\mu\phi_0\right)^2+\frac{1}{2}m_0^2\phi_0^2+\frac{\lambda_0}{4!}\phi_0^4\right)\right) \tag{0.1}$$

где m_0 называется "затравочной" ("голой") массой и λ_0 затравочная константа связи. Мы вводим новое поле ϕ и константы связи λ и m^2 по формулам

$$\begin{aligned}\phi_0&=Z^{1/2}\phi\\ m_0^2&=Z^{-1}\left(m^2+\delta m^2\right)\\ \lambda_0&=Z^{-2}(\lambda+\delta\lambda)\end{aligned} \tag{0.2}$$

где $\delta Z=Z-1, \delta m^2=Zm_0^2-m^2$ и $\delta\lambda=Z^2\lambda_0-\lambda$ контрчлены. И статистическая сумма запишется как

$$Z=\int D\phi \exp\left(-\int d^4x\left(\frac{1}{2}\left(\partial_\mu\phi\right)^2+\frac{1}{2}m^2\phi^2+\frac{\lambda}{4!}\phi^4+\frac{\delta Z}{2}\left(\partial_\mu\phi\right)^2+\frac{1}{2}\delta m^2\phi^2+\frac{\delta\lambda}{4!}\phi^4\right)\right). \tag{0.3}$$

Определим $W^{\left(\phi^2,2\right)}\left(x|x_1,x_2\right)$ по формуле:

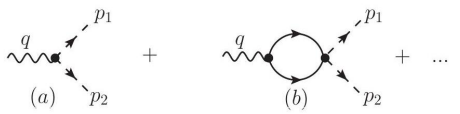
$$W^{\left(\phi^2,2\right)}\left(x|x_1,x_2\right)=\left\langle\phi^2(x)\phi\left(x_1\right)\phi\left(x_2\right)\right\rangle_{\text{связн}}=\left\langle\phi^2(x)\phi\left(x_1\right)\phi\left(x_2\right)\right\rangle-\left\langle\phi^2(x)\right\rangle\left\langle\phi\left(x_1\right)\phi\left(x_2\right)\right\rangle. \tag{0.4}$$

Удобно перейти в импульсное пространство и определить $\Gamma^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right)$:

$$\Gamma^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right)=\frac{W^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right)}{W\left(p_1\right)W\left(p_2\right)},\quad q=p_1+p_2 \tag{0.5}$$

где $\Gamma^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right)$ уже дается суммой всех связанных одночастично неприводимых диаграмм:

$\Gamma^{(\phi^2,2)}(q|p_1,p_2)$ =



Таким обозом мы находим, что

$$\Gamma^{\left(\phi^2,2\right)}\left(q|p_1,p_2\right)=1-\frac{\lambda}{2}I\left(p_{12}^2\right)+... \tag{0.6}$$

[62] Как всегда у нас есть свобода в выборе конечной части контрчленных коэффициентов. Мы фиксируем эту свободу выбором ренормализационного условия.

где $I\left(p^2\right)$ интеграл, который мы вычисляли на предыдущих лекциях. Мы знаем, что $I\left(p_{12}^2\right) = I_r\left(p_{12}^2\right) + I(0)$, где I_r конечен при $\epsilon \to 0$, а $I(0) = \left(m^2\right)^{d/2-2}\Gamma(2-d/2)/(4\pi)^{d/2}$ сингулярная часть, то есть мы видим, что в данных диаграммах есть расходимости. Мы можем определить перенормированные операторы $\left[\phi^2\right]_R$ и $\Gamma^{\left(\left[\phi^2\right]_R,2\right)}$ по формулам:

$$\phi^2 = Z_2^{-1}\left[\phi^2\right]_R, \quad \Gamma^{\left(\phi^2,2\right)} = Z_2^{-1}\Gamma^{\left(\left[\phi^2\right]_R,2\right)} \tag{0.7}$$

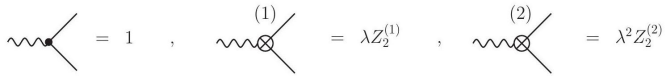
так, что $\Gamma^{\left(\left[\phi^2\right]_R,2\right)}$ имеет уже конечный предел при $\epsilon \to 0$. Удобно написать

$$\left[\phi^2\right]_R = Z_2\phi^2 \tag{0.8}$$

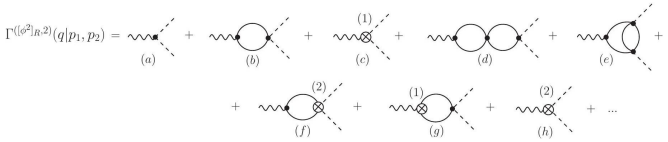
где коэффициент Z_2 находится порядок за порядком по степени λ:

$$Z_2 = 1 + \lambda Z_2^{(1)} + \lambda^2 Z_2^{(2)} + \ldots \tag{0.9}$$

Поэтому вычисление корреляционной функции с вставкой ренормированного оператора $\left[\phi^2\right]_R$, эквивалентно добавлению к нашей диаграммной технике серии контрчленных вершин:



Поэтому для корреляционной функции $\Gamma^{\left(\left[\phi^2\right]_R,2\right)}$ мы получим следующие диаграммы:



(g)
(h) ,

И коэффициенты контрчленов $Z_2^{(1)}, Z_2^{(2)}, \ldots$ подбираются таким образом, чтобы сократить расходимости. Мы выбираем ренормализационное условие в виде [2]

$$\Gamma^{\left(\left[\phi^2\right]_R,2\right)}(0|0,0) = 1 \tag{0.10}$$

Далее имеем

$$(a) = 1, \quad (b) = -\frac{\lambda}{2}\int \frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2+m^2\right)\left((q+k)^2+m^2\right)} = -\frac{\lambda}{2}I\left(q^2\right), \quad (c) = \lambda Z_2^{(1)} \tag{0.11}$$

Вычисляем интеграл $I\left(q^2\right)$ используя Фейнмановские параметры:

$$\begin{aligned} I\left(q^2\right) &= \int \frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2+m^2\right)\left((q+k)^2+m^2\right)} = \int \frac{d^dk}{(2\pi)^d}\int\limits_0^1 dx \frac{1}{\left(x(q+k)^2+(1-x)k^2+m^2\right)^2} = \\ &= \int\limits_0^1 dx \int \frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2+2xqk+m^2+xq^2\right)^2} = \int\limits_0^1 dx \int \frac{d^dk}{(2\pi)^d}\frac{1}{\left((k+xq)^2+m^2+x(1-x)q^2\right)^2} = \\ &= \frac{\Gamma\left(2-\frac{d}{2}\right)}{(4\pi)^{\frac{d}{2}}}\int\limits_0^1 dx\left(m^2+x(1-x)q^2\right)^{\frac{d}{2}-2}. \end{aligned} \tag{0.12}$$

При $d = 4$, Гамма-функция имеет полюс: $\Gamma\left(2-\frac{d}{2}\right) = \frac{2}{\epsilon} - \gamma + O(\epsilon)$, где $d = 4-\epsilon$, чтобы устранить данную сингулярность мы вычитаем из $I\left(q^2\right)$ интеграл на нулевом импульсе $I(0)$:

[61] Внешнии линии обозначаются здесь пунктиром, а волнистая линия просто обозначает, что в корреляционную функцию вставленна внешняя вершина-оператор с полным импульсом q.

[62] Как всегда у нас есть свобода в выборе конечной части контрчленных коэффициентов. Мы фиксируем эту свободу выбором ренормализационного условия.

$$I_r\left(q^2\right)=I\left(q^2\right)-I(0)=-\frac{1}{(4\pi)^2}\int\limits_0^1 dx\log\left(1+x(1-x)\frac{q^2}{m^2}\right)=$$
$$=-\frac{1}{16\pi^2}\left(\sqrt{\frac{q^2+4m^2}{q^2}}\log\frac{\sqrt{q^2+4m^2}+\sqrt{q^2}}{\sqrt{q^2+4m^2}-\sqrt{q^2}}-2\right), \tag{0.13}$$

также замечая, что очевидно $I_r(0)=0$. В итоге получаем ($q=p_1+p_2=p_{12}$):

$$\Gamma^{\left(\left[\phi^2\right]_R,2\right)}\left(q|p_1,p_2\right)=1-\frac{\lambda}{2}I_r\left(q^2\right)-\lambda\left(\frac{1}{2}I(0)-Z_2^{(1)}\right)+O\left(\lambda^2\right). \tag{0.14}$$

и из условия (0.10) следует, что $Z_2^{(1)}=\frac{1}{2}I(0)$ и $\Gamma^{\left(\left[\phi^2\right]_R,2\right)}=1-\frac{\lambda}{2}I_r\left(p_{12}^2\right)+O\left(\lambda^2\right)$.

Покажем, что во втором порядке по λ, можно найти такое $Z_2^{(2)}$, что $\Gamma^{\left(\left[\phi^2\right]_R,2\right)}$ не будет иметь сингулярностей. Имеем

$$(d)=\frac{(-\lambda)^2}{4}\left(I\left(q^2\right)\right)^2,\quad (f)=-\frac{\delta\lambda^{(2)}}{2}I\left(q^2\right)=-\frac{a^{(2)}\lambda^2}{2}I\left(q^2\right),\quad (g)=-\frac{\lambda^2Z_2^{(1)}}{2}I\left(q^2\right),\quad (h)=\lambda^2Z_2^{(2)}, \tag{0.15}$$

где $\delta\lambda=a^{(1)}\lambda+a^{(2)}\lambda^2+...$, и контрчлен $a^{(2)}=\frac{3}{2}I(0)$, находился из однопетлевой перенормировки вершины ϕ^4. Диаграмма () более сложная и дается интегралом

$$(e)=\frac{(-\lambda)^2}{2}\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2}\frac{1}{(q+k)^2+m^2}I\left(\left(k+p_1\right)^2\right) \tag{0.16}$$

Вычислим его опять используя Фейнмановские параметры

$$(e)=\frac{\lambda^2\Gamma\left(2-\frac{d}{2}\right)}{2(4\pi)^{d/2}}\int\limits_0^1 dx\int\frac{d^dk}{(2\pi)^d}\frac{1}{k^2+m^2}\frac{1}{(q+k)^2+m^2}\frac{1}{\left(m^2+x(1-x)\left(k+p_1\right)^2\right)^{2-\frac{d}{2}}}=$$
$$=\frac{\lambda^2\Gamma\left(2-\frac{d}{2}\right)}{2(4\pi)^{d/2}}\int\limits_0^1 dxdy\int\frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2+2ykq+yq^2+m^2\right)^2}\frac{z^{1-\frac{d}{2}}(1-z)}{\left(m^2+x(1-x)\left(k+p_1\right)^2\right)^{2-\frac{d}{2}}}=$$
$$=\frac{\lambda^2\Gamma\left(4-\frac{d}{2}\right)}{2(4\pi)^{d/2}}\int\limits_0^1 dxdydz\int\frac{d^dk}{(2\pi)^d}\frac{z^{1-\frac{d}{2}}(1-z)}{\left[z\left(m^2+x(1-x)\left(k+p_1\right)^2\right)+(1-z)\left(k^2+2ykq+yq^2+m^2\right)\right]^{4-\frac{d}{2}}}=$$
$$=\frac{\lambda^2\Gamma\left(4-\frac{d}{2}\right)}{2(4\pi)^{d/2}}\int\limits_0^1 dxdydz\int\frac{d^dk}{(2\pi)^d}\frac{1}{\left[A\left(k+\frac{zx(1-x)p_1+y(1-z)q}{1-z+xx(1-x)}\right)^2+P^2+m^2\right]^{4-\frac{d}{2}}}, \tag{0.17}$$

где $A=1-z+zx(1-x)$ и

$$P^2=\frac{z(1-z)x(1-x)p_1^2+y(1-z)((1-y)(1-z)+zx(1-x))q^2-2xyz(1-x)(1-z)p_1q}{1-z+zx(1-x)}. \tag{0.18}$$

В итоге получаем

$$(e)=\frac{\lambda^2\Gamma(4-d)}{2(4\pi)^d}\int\limits_0^1 dxdydz\frac{z^{1-\frac{d}{2}}(1-z)}{A^{\frac{d}{2}}}\left(m^2+P^2\right)^{d-4}. \tag{0.19}$$

Данная диаграмма расходится как $1/\epsilon^2$, одна степень ϵ появляется из Гамма-функции:

$$\Gamma(4-d)=\Gamma(\epsilon)=\frac{1}{\epsilon}-\gamma+O(\epsilon) \tag{0.20}$$

а другая степень из интеграла по z, при интегрировании вблизи $z=0$:

$$\int\limits_0^1 z^{1-\frac{d}{2}}dz=\int\limits_0^1 dzz^{-1+\frac{\epsilon}{2}}=\frac{2}{\epsilon}z^{\frac{\epsilon}{2}}\Big|_0^1=\frac{2}{\epsilon} \tag{0.21}$$

Чтобы изолировать данную сингулярность мы запишем диаграмму (e), как

$$\begin{aligned}(e)=&\frac{\lambda^2\Gamma(4-d)}{2(4\pi)^d}\int\limits_0^1 dxdydzz^{1-\frac{d}{2}}\left(m^2+y(1-y)q^2\right)^{d-4}+\\&+\frac{\lambda^2\Gamma(4-d)}{2(4\pi)^d}\int\limits_0^1 dxdydzz^{1-\frac{d}{2}}\left(\frac{(1-z)}{A^{\frac{d}{2}}}\left(m^2+P^2\right)^{d-4}-\left(m^2+y(1-y)q^2\right)^{d-4}\right)\end{aligned} \tag{0.22}$$

где мы использовали то, что $P^2(z=0)=y(1-y)q^2$ и $A(z=0)=1$. Итак, вычисляя первое слагаемое имеем:

$$\begin{aligned}&\frac{\lambda^2\Gamma(4-d)}{2(4\pi)^{d/2}}\int\limits_0^1 dxdydzz^{1-\frac{d}{2}}\left(m^2+y(1-y)q^2\right)^{d-4}=\frac{\lambda^2\Gamma(\epsilon)}{\epsilon(4\pi)^{4-\epsilon}}\int\limits_0^1 dy\left(m^2+y(1-y)q^2\right)^{-\epsilon}=\\&=\frac{\lambda^2}{\epsilon(4\pi)^4}\left(\frac{1}{\epsilon}-\gamma\right)e^{\epsilon\log 4\pi}\int\limits_0^1 dye^{-\epsilon\log\left(m^2+y(1-y)q^2\right)}=\\&=\frac{\lambda^2}{\epsilon(4\pi)^4}\left(\frac{1}{\epsilon}-\gamma\right)(1+\epsilon\log 4\pi)\int\limits_0^1 dy\left(1-\epsilon\log\left(m^2+y(1-y)q^2\right)\right)=\\&=\frac{\lambda}{\epsilon(4\pi)^4}\left(\frac{1}{\epsilon}-\gamma\right)(1+\epsilon\log 4\pi)\left(1-\epsilon\left(\log m^2-(4\pi)^2I_r\left(q^2\right)\right)\right)=\\&=\frac{\lambda^2}{(4\pi)^4}\left(\frac{1}{\epsilon^2}+\frac{1}{\epsilon}\left(\log\frac{4\pi}{m^2}-\gamma+(4\pi)^2I_r\left(q^2\right)\right)\right)+\text{ конечные члены.}\end{aligned} \tag{0.23}$$

Для того, чтобы во втором слагаемом найти член $\sim\frac{1}{\epsilon}$, интеграл достаточно вычислить при $d=4$:

$$\begin{aligned}&\frac{\lambda^2\Gamma(4-d)}{2(4\pi)^d}\int\limits_0^1 dxdydzz^{1-\frac{d}{2}}\left(\frac{(1-z)}{A^{\frac{d}{2}}}\left(m^2+P^2\right)^{d-4}-\left(m^2+y(1-y)q^2\right)^{d-4}\right)=\\&=\frac{\lambda^2\Gamma(\epsilon)}{2(4\pi)^4}\int\limits_0^1 dxdydzz^{-1}\left(\frac{(1-z)}{A^2}-1\right)+\text{ конечные члены }=\\&=\frac{\lambda^2}{2(4\pi)^4}\frac{1}{\epsilon}+\text{ конечные члены.}\end{aligned} \tag{0.24}$$

Теперь замечая, что $I(0)=\frac{2}{\epsilon(4\pi)^2}+\frac{1}{(4\pi)^2}\left(\log\frac{4\pi}{m^2}-\gamma\right)$, получаем для диграммы (e):

$$(e)=\frac{\lambda^2}{4}I^2(0)+\frac{\lambda^2}{2}I(0)I_r\left(q^2\right)+\text{ конечные члены.} \tag{0.25}$$

В итоге получаем

$$(d)+(e)+(f)+(g)+(h)=\frac{\lambda^2}{4}I^2\left(q^2\right)+\frac{\lambda^2}{4}I^2(0)+\frac{\lambda^2}{2}I(0)I_r\left(q^2\right)-\frac{3\lambda^2}{4}I(0)I\left(q^2\right)-$$
$$-\frac{\lambda^2}{4}I(0)I\left(q^2\right)+\lambda^2 Z_2^{(2)}+\text{ конечные члены }=$$
$$=\lambda^2\left(\frac{1}{4}\left(I_r\left(q^2\right)+I(0)\right)^2+\frac{1}{4}I(0)^2+\frac{1}{2}I(0)I_r\left(q^2\right)-I(0)\left(I_r\left(q^2\right)+I(0)\right)+Z_2^{(2)}+\text{ к.ч. }\right)=$$
$$=\lambda^2\left(\frac{1}{4}I_r^2\left(q^2\right)-\frac{1}{2}I^2(0)+Z_2^{(2)}+\text{ к.ч. }(p_1,p_2)\right)$$

откуда мы получаем, что $Z_2^{(2)}=\frac{1}{2}I^2(0)$ - к.ч. $(0,0)$, и в итоге

$$\Gamma^{\left([\phi^2]_R,2\right)}(q|p_1,p_2)=1-\frac{\lambda}{2}I_r\left(q^2\right)+\frac{\lambda^2}{4}\left(I_r^2\left(q^2\right)+\text{ к.ч. }(p_1,p_2)-\text{ к.ч. }(0,0)\right),\tag{0.27}$$

отметим, что интеграл $I_r\left(q^2\right)$ уже тоже входит во множество конечных членов, но мы оставили здесь его в явном виде.

28 Other problems in QFT

28.1 Problems for checking knowledge of QFT

28.1.1 Questions on Understanding the Essence of QFT

KUL-aqft-2023-hw2.3/3 О виде лагранжиана

Assume that you have a theory of a real scalar field $\phi(x)$ in d space-time dimensions. Write down the most general Lorentz invariant Lagrangian with a canonical (i.e. quadratic in the fields and the derivatives) kinetic term and polynomial interactions of degree less than or equal to 6. Analyze the mass dimensions of all terms in this Lagrangian and find the mass dimensions of all couplings. What is the maximal value of d for which this theory is renormalizable? Find out a polynomial potential (with integer powers) for this model which will render the theory renormalizable in $d=5,6,7,8$. What can you conclude about interacting scalar theories in general space-time dimensions?

Solution

В чем проблемы с уравнением КГ и как их решаем?

Answer:

(это в теории написано, еще раз вопрос про это. потому что у нас нет основного состояния в гамильтониане КГ (????), потом с причинностью разговоры, тоже в теории их напишу.)

Критерии перенормируемости

Какая теория является перенормируемой, а какая нет?

Answer:

28.1.2 Typical Problems for Checking Knowledge of Fundamentals

(! тут будет хороший список задач, которые не такие уж громоздкие, но очень типичные. как и в других всех записях.)

Количество поляризаций фотона?

Сколько у фотона поляризаций и почему?

Solution

Две. Потому что у нас изначально 4 (??), потом одна калибровкой Лоренца уходит, вторая (????) гармоническими функциями (?? как??).

Бесконечная отрицательная энергия дираковского поля?

(типичный вопрос, оформлю потом его.)

28.2 Problems about mathematical preparation

28.2.1 Problems about integrals and mathematical features for QFT

KUL-aqft-2023-hw1.2 Derivative of a function

Prove the identity

$$G\left(\frac{\partial}{\partial b}\right)F(b) = F\left(\frac{\partial}{\partial x}\right)\left[G(x)e^{xb}\right]\Big|_{x=0},$$

by assuming that the functions F and G can be expanded in a convergent power series around 0. Extend the result to the case of many variables, i.e. to the case where $(\vec{b},\vec{x})$ are vectors in $\mathbb{R}^n$.

Solution

I will show this for a special case: Let $G(\underline{x}) = e^{\underline{x}\cdot\underline{\alpha}}, F(\underline{b}) = e^{\underline{\beta}\underline{b}}$. Then the left-hand side is

$$G\left(\frac{\partial}{\partial \underline{b}}\right)F(\underline{b}) = e^{\frac{\partial}{\partial \underline{b}}\cdot\underline{\alpha}}F(\underline{b}) = F(\underline{b}+\underline{\alpha}) = e^{\underline{\beta}\cdot(\underline{b}+\underline{\alpha})}.$$

Let us attempt to consider the right-hand side:

$$F\left(\frac{\partial}{\partial \underline{x}}\right)G(\underline{x})e^{\underline{x}\cdot\underline{b}}\Big|_{\underline{x}=\underline{0}} = e^{\underline{\beta}\cdot\frac{\partial}{\partial \underline{x}}}e^{\underline{x}\cdot(\underline{\alpha}+\underline{b})}\Big|_{\underline{x}=\underline{0}} = e^{(\underline{x}+\underline{\beta})\cdot(\underline{\alpha}+\underline{b})}\Big|_{\underline{x}=0} = e^{\underline{\beta}\cdot(\underline{\alpha}+\underline{b})}.$$

The result is then true for any F and G as one may express F and G as a Fourier series.

Another Solution, for $d = 1$ Dimensional

Say

$$G(x) = \sum_{m=0}^{\infty} g_m x^m, \text{ and}$$
$$F(x) = \sum_{n=0}^{\infty} f_n x^n.$$

On one hand, we have

$$G\left(\frac{\partial}{\partial b}\right)F(b) = \sum_{m=0}^{\infty}\sum_{n=0}^{\infty} g_m f_n \frac{\partial^m}{\partial b^m} b^n$$
$$= \sum_{n=0}^{\infty}\sum_{m=0}^{n} g_m f_n \frac{n!}{(n-m)!} b^{n-m}.$$

On the other hand, we have

$$F\left(\frac{\partial}{\partial x}\right)\left\{G(x)e^{bx}\right\}\Big|_{x=0}=\sum_{n=0}^{\infty}\sum_{m=0}^{\infty}f_n g_m\frac{\partial^n}{\partial x^n}\left\{x^m e^{bx}\right\}\Big|_{x=0}.$$

To get $\frac{\partial^n}{\partial x^n}\left\{x^m e^{bx}\right\}\big|_{x=0}\neq 0$, we need m derivatives to fall on x^m, and thus $n-m$ on e^{bx}, in the Leibniz rule. This is assuming there are sufficient derivatives to share, i.e. $n\geq m$. If $n<m$, there are insufficient derivatives to get any nonzero contribution, so we may reduce the sum to $\sum_{m=0}^{n}$. There are $\left(\begin{array}{c} n \\ m \end{array}\right)$ ways to get in such a situation where the derivative does not vanish. [1] Using also $e^{bx}\big|_{x=0}=1$, we see that

$$\begin{aligned}\frac{\partial^n}{\partial x^n}\left\{x^m e^{bx}\right\}\Big|_{x=0}&=m!\left(\begin{array}{c} n \\ m \end{array}\right)b^{n-m}\\&=\frac{n!}{(n-m)!}b^{n-m}\end{aligned}$$

and thus

$$F\left(\frac{\partial}{\partial x}\right)\left\{G(x)e^{bx}\right\}\Big|_{x=0}=\sum_{n=0}^{\infty}\sum_{m=0}^{n}f_n g_m\frac{n!}{(n-m)!}b^{n-m}$$

which is identical to (1).

Another Solution, for d Dimensional

We will just write the calculation here, it's the same idea as before. Say

$$\begin{aligned}G(\underline{x})&=\sum_{m=0}^{\infty}\underline{g_m}\cdot\underline{x}^m,\ \text{and}\\F(\underline{x})&=\sum_{n=0}^{\infty}\underline{f_n}\cdot\underline{x}^n\cdot\\G\left(\frac{\partial}{\partial\underline{b}}\right)F(\underline{b})&=\sum_{m=0}^{\infty}\sum_{n=0}^{\infty}\underline{g_m}\cdot\frac{\partial^m}{\partial\underline{b}^m}\underline{f_n}\cdot\underline{b}^n\\&=\sum_{n=0}^{\infty}\sum_{m=0}^{n}\frac{n!}{(n-m)!}\underline{g_m}\cdot\underline{f_n}b^{n-m}\\F\left(\frac{\partial}{\partial\underline{x}}\right)\left\{G(\underline{x})e^{\underline{b}\cdot\underline{x}}\right\}\Big|_{\underline{x}=\underline{0}}&=\sum_{n=0}^{\infty}\sum_{m=0}^{\infty}\underline{f_n}\cdot\frac{\partial^n}{\partial\underline{x}^n}\left\{\underline{g_m}\cdot\underline{x}^m e^{\underline{b}\cdot\underline{x}}\right\}\Big|_{\underline{x}=\underline{0}}\\&=\sum_{n=0}^{\infty}\sum_{m=0}^{n}\underline{f_n}\cdot\underline{g_m}m!\left(\begin{array}{c} n \\ m \end{array}\right)b^{n-m}\\&=\sum_{n=0}^{\infty}\sum_{m=0}^{n}\underline{f_n}\cdot\underline{g_m}\frac{n!}{(n-m)!}b^{n-m}\end{aligned}$$

Stanford.Zhou.2022.9.2. Feynman parameters. (12/45p)

As you saw in problem 1, loop integrals take a few generic forms. For simplicity, let's consider a scalar theory, which doesn't have nontrivial factors in the numerator of the loop integrand. Then some generic loop integrals are the "tadpole", "bubble", and "triangle",

$$I_T\left(a;m^2\right)=\int\frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2-m^2\right)^a}$$
$$I_B\left(a,b;p^2\right)=\int\frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2\right)^a\left((k+p)^2\right)^b}$$
$$I_\triangle\left(a,b,c;p_1,p_2\right)=\int\frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2\right)^a\left(\left(k+p_1\right)^2\right)^b\left(\left(k-p_2\right)^2\right)^c}$$

named after the kinds of Feynman diagrams in which they appear. Here we have suppressed $i0$ terms, but you should keep in mind that they're implicitly there, which will be important in the last subpart. We regard a, b, and c as general real exponents, though in practice they will usually be positive integers. The dimension d is also a real parameter.

To compute the bubble and triangle integrals, it is helpful to introduce Feynman parameters, which combine the factors into the denominator into a power of a single quantity, like the tadpole integral. We will first have to build up some mathematical machinery.

a) The gamma function is defined by

$$\Gamma(z)=\int_0^\infty dx x^{z-1}e^{-x}$$

and for positive integer n, satisfies $\Gamma(n)=(n-1)\,!$. Show that for real ν,

$$\frac{1}{A^\nu}=\frac{1}{\Gamma(\nu)}\int_0^\infty dx x^{\nu-1}e^{-xA}$$

b) Show that for general ν_i,

$$\frac{1}{\prod_{i=1}^n A_i^{\nu_i}}=\frac{\Gamma\left(\sum_{i=1}^n\nu_i\right)}{\prod_{i=1}^n\Gamma\left(\nu_i\right)}\int_0^1\left(\prod_{i=1}^n dx_i\right)\delta\left(1-\sum_{i=1}^n x_i\right)\frac{\prod_{i=1}^n x_i^{\nu_i-1}}{\left[\sum_{i=1}^n x_iA_i\right]^{\sum_{i=1}^n\nu_i}}$$

Here, the x_i are called Feynman parameters.

Solution to a:

Using the result of part (a) n times yields

$$\frac{1}{\prod_{i=1}^n A_i^{\nu_i}}=\frac{1}{\prod_{i=1}^n\Gamma\left(\nu_i\right)}\int_0^\infty\prod_{i=1}^n dx_i x_i^{\nu_i-1}e^{-\sum_{i=1}^n x_iA_i}$$

This is already pretty close to the desired answer, so we now introduce an identity

$$1=\int_0^\infty dy\delta\left(y-\sum_{i=1}^n x_i\right)$$

which converts our result to

$$\frac{1}{\prod_{i=1}^n A_i^{\nu_i}}=\frac{1}{\prod_{i=1}^n\Gamma\left(\nu_i\right)}\int_0^\infty dy\prod_{i=1}^n dx_i x_i^{\nu_i-1}\delta\left(y-\sum_{i=1}^n x_i\right)e^{-\sum_{i=1}^n x_iA_i}$$

Let us rescale all the x_i by y so they sum up to 1, as required in the final answer. The result is

$$\begin{aligned}\frac{1}{\prod_{i=1}^{n} A_i^{\nu_i}} &= \frac{1}{\prod_{i=1}^{n}\Gamma(\nu_i)} \int_0^\infty dy y^{\sum_{i=1}^{n}\nu_i} \prod_{i=1}^{n} dx_i x_i^{\nu_i-1} \delta\left(y - y\sum_{i=1}^{n} x_i\right) e^{-y\sum_{i=1}^{n} x_i A_i} \\ &= \frac{1}{\prod_{i=1}^{n}\Gamma(\nu_i)} \int_0^\infty dy y^{-1+\sum_{i=1}^{n}\nu_i} \prod_{i=1}^{n} dx_i x_i^{\nu_i-1} \delta\left(1 - \sum_{i=1}^{n} x_i\right) e^{-y\sum_{i=1}^{n} x_i A_i} \\ &= \frac{\Gamma\left(\sum_{i=1}^{n}\nu_i\right)}{\prod_{i=1}^{n}\Gamma(\nu_i)} \int_0^1 \prod_{i=1}^{n} dx_i x_i^{\nu_i-1} \delta\left(1 - \sum_{i=1}^{n} x_i\right) \frac{1}{\left[\sum_{i=1}^{n} x_i A_i\right]^{\sum_{i=1}^{n}\nu_i}}\end{aligned}$$

as desired, where we performed the y integral using (7). **c)** Apply (8) to $I_B\left(a,b;p^2\right)$ to get an integrand whose denominator contains a single quantity raised to the $a+b$ power.

Solution:

$$\begin{aligned}I_B\left(a,b;p^2\right) &= \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \int \frac{d^dk}{(2\pi)^d} \int_0^\infty dx_1 x_1^{a-1} dx_2 x_2^{b-1} \frac{\delta(1-x_1-x_2)}{\left[k^2x_1 + (k+p)^2 x_2\right]^{a+b}} \\ &= \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \int \frac{d^dk}{(2\pi)^d} \int_0^\infty dx_1 x_1^{a-1} dx_2 x_2^{b-1} \frac{\delta(1-x_1-x_2)}{\left[k^2(x_1+x_2) + (2kp+p^2)x_2\right]^{a+b}} \\ &= \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \int \frac{d^dk}{(2\pi)^d} \int_0^\infty dx_1 x_1^{a-1}(1-x_1)^{b-1} \frac{1}{\left[k^2 + (2kp+p^2)(1-x_1)\right]^{a+b}}.\end{aligned}$$

d) Complete the evaluation of $I_B\left(a,b;p^2\right)$ by Wick rotating to Euclidean signature and performing all the remaining integrals. As a hint, the Euclidean integration measure is $d^dk_E = |k_E|^{d-1}\, d|k_E|\, d\Omega_d$, where the surface area of a unit sphere in d dimensions is

$$\Omega_d = \frac{2\pi^{\frac{d}{2}}}{\Gamma\left(\frac{d}{2}\right)}$$

As a second hint, you can use the result

$$\frac{\Gamma(a)\Gamma(b)}{\Gamma(a+b)} = \int_0^1 dx x^{a-1}(1-x)^{b-1}$$

To check your answer, if you set $d = 4-2\epsilon$ then you should find

$$I_B\left(1,1;p^2\right) = \left(\frac{-p^2-i0}{4\pi}\right)^{-\epsilon} \frac{i\Gamma(1-\epsilon)^2\Gamma(1+\epsilon)}{(4\pi)^2(1-2\epsilon)\epsilon\Gamma(1-2\epsilon)}$$

Solution:

Next, we perform the linear shift $k \to k - p(1-x_1)$ and find

$$I_B\left(a,b;p^2\right) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \int \frac{d^dk}{(2\pi)^d} \int_0^\infty dx_1 x_1^{a-1}(1-x_1)^{b-1} \frac{1}{\left[k^2 + p^2x_1(1-x_1)\right]^{a+b}}$$

Notice, that we dropped the " $+i0$ " Feynman prescription from the integral at the very beginning. We could have kept an infinitesimal mass term throughout. To track the infinitesimal imaginary part, we can simply associate it with the momentum, $p^2 + i0$. Next, we perform a Wick rotation $k^0 = ik_E^0$ and $\vec{k} = \vec{k}_E$.

$$
\begin{aligned}
I_B\left(a,b;p^2\right) &= i\frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)}\int\frac{d^dk_E}{(2\pi)^d}\int\limits_0^\infty dx_1x_1^{a-1}\left(1-x_1\right)^{b-1}\frac{1}{\left[-k_E^2+p^2x_1\left(1-x_1\right)\right]^{a+b}}\\
&= \frac{i(-1)^{a+b}}{2(2\pi)^d}\frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)}\int\limits_0^\infty d\left(k_E^2\right)\int d\Omega_d\left(k_E^2\right)^{\frac{d}{2}-1}\int\limits_0^\infty dx_1x_1^{a-1}\left(1-x_1\right)^{b-1}\frac{1}{\left[k_E^2-p^2x_1\left(1-x_1\right)\right]^{a+b}}\\
&= \frac{i(-1)^{a+b}}{2(2\pi)^d}\frac{\Gamma\left(\frac{d}{2}\right)\Gamma\left(-a-b-\frac{d}{2}\right)}{\Gamma(a)\Gamma(b)}\Omega_d\int\limits_0^1 dx_1x_1^{a-1}\left(1-x_1\right)^{b-1}\left(-\left(p^2+i0\right)x_1\left(1-x_1\right)\right)^{\frac{d}{2}-a-b}\\
&= \frac{i(-1)^{a+b}\left(-\left(p^2+i0\right)\right)^{\frac{d}{2}-a-b}}{2(2\pi)^d}\frac{\Gamma\left(\frac{d}{2}\right)\Gamma\left(a+b-\frac{d}{2}\right)}{\Gamma(a)\Gamma(b)}\Omega_d\int\limits_0^1 dx_1x_1^{\frac{d}{2}-b-1}\left(1-x_1\right)^{\frac{d}{2}-a-1}\\
&= \frac{i(-1)^{a+b}\left(-\left(p^2+i0\right)\right)^{\frac{d}{2}-a-b}}{(4\pi)^{\frac{d}{2}}}\frac{\Gamma\left(a+b-\frac{d}{2}\right)}{\Gamma(a)\Gamma(b)}\frac{\Gamma\left(\frac{d}{2}-a\right)\Gamma\left(\frac{d}{2}-b\right)}{\Gamma(d-a-b)}.
\end{aligned}
$$

Above we used the Euler β-function integral

$$
\frac{\Gamma(a)\Gamma(b)}{\Gamma(a+b)}=\int\limits_0^1 dxx^{a-1}(1-x)^{b-1}
$$

Stanford.Zhou.2022.9.3. Passarino-Veltman reduction. (10/45p)

More generally, loop integrands will have momenta and other factors in the numerator. However, we can often use symmetry properties and a technique called Passarino-Veltman reduction to reduce them to the simpler loop integrands considered in problem 2. For example, consider the rank 2 tadpole integral

$$
I_T^{\mu\nu}\left(a;m^2\right)=\int\frac{d^dk}{(2\pi)^d}\frac{k^\mu k^\nu}{\left(k^2-m^2\right)^a}
$$

Because the right-hand side is a Lorentz tensor, the left-hand side must be as well. As there are no momenta in the integral, the only option is the metric, so we must have

$$
I_T^{\mu\nu}\left(a;m^2\right)=\eta^{\mu\nu}A
$$

for some Lorentz scalar A. Contracting both sides with the metric, we find

$$
\begin{aligned}
A &= \frac{1}{d}\int\frac{d^dk}{(2\pi)^d}\frac{k^2}{\left(k^2-m^2\right)^a}\\
&= \frac{1}{d}\int\frac{d^dk}{(2\pi)^d}\frac{\left(k^2-m^2\right)+m^2}{\left(k^2-m^2\right)^a}
\end{aligned}
$$

This is just two "scalar" tadpole integrals, as defined in (3), so we conclude

$$
I_T^{\mu\nu}\left(a;m^2\right)=\frac{\eta^{\mu\nu}}{d}\left[I_T\left(a-1;m^2\right)+m^2I_T\left(a;m^2\right)\right]
$$

a) Apply the same reasoning to the rank 3 and rank 4 tadpole integrals,

$$
\begin{aligned}
I_T^{\mu\nu\rho}\left(a;m^2\right) &= \int\frac{d^dk}{(2\pi)^d}\frac{k^\mu k^\nu k^\rho}{\left(k^2-m^2\right)^a}\\
I_T^{\mu\nu\rho\sigma}\left(a;m^2\right) &= \int\frac{d^dk}{(2\pi)^d}\frac{k^\mu k^\nu k^\rho k^\sigma}{\left(k^2-m^2\right)^a}.
\end{aligned}
$$

Solution:

Again, only combinations of the metric tensor are available to us. There is no combination of metric tensors that would allow us to write down a tensor with 5 indices, so the first integral vanishes. (Another way of seeing this is that the integrand is odd under the transformation $k \to -k$ and the integral is consequently equal to minus itself and thus zero.)

The integrand with four Lorentz indices is symmetric under the exchange of any pair of indices, so we must have

$$I_T^{\mu\nu\rho\sigma}(a) = A\left(\eta^{\mu\nu}\eta^{\rho\sigma} + \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}\right)$$

Contracting with $\eta_{\mu\nu}\eta_{\rho\sigma}$ we find

$$\begin{aligned} I_T^{\mu\nu\rho\sigma}\eta_{\mu\nu}\eta_{\rho\sigma}(a) &= A\left(d^2+2d\right) \\ &= \int \frac{d^dk}{(2\pi)^d}\frac{\left(k^2\right)^2}{\left(k^2-m^2\right)^a} \\ &= \int \frac{d^dk}{(2\pi)^d}\frac{\left(k^2-m^2+m^2\right)^2}{\left(k^2-m^2\right)^a} \\ &= \int \frac{d^dk}{(2\pi)^d}\frac{1}{\left(k^2-m^2\right)^{a-2}} + \int \frac{d^dk}{(2\pi)^d}\frac{2m^2}{\left(k^2-m^2\right)^{a-1}} + \int \frac{d^dk}{(2\pi)^d}\frac{m^4}{\left(k^2-m^2\right)^a} \end{aligned}$$

from which we conclude

$$I_T^{\mu\nu\rho\sigma}\left(a;m^2\right) = \frac{\eta^{\mu\nu}\eta^{\rho\sigma}+\eta^{\mu\rho}\eta^{\nu\sigma}+\eta^{\mu\sigma}\eta^{\nu\rho}}{d^2+2d}\left(I_T\left(a-2;m^2\right)+2m^2I_T\left(a-1;m^2\right)+m^4I_T\left(a;m^2\right)\right)$$

b) Similarly, the rank 1 and 2 bubble integrals can be written as

$$\begin{aligned} I_B^{\mu}\left(a,b;p^2\right) &= \int \frac{d^dk}{(2\pi)^d}\frac{k^\mu}{\left(k^2\right)^a\left((k+p)^2\right)^b} = p^\mu C. \\ I_B^{\mu\nu}\left(a,b;p^2\right) &= \int \frac{d^dk}{(2\pi)^d}\frac{k^\mu k^\nu}{\left(k^2\right)^a\left((k+p)^2\right)^b} = \left(\eta^{\mu\nu}-\frac{p^\mu p^\nu}{p^2}\right)A_\perp + \frac{p^\mu p^\nu}{p^2}B_\parallel. \end{aligned}$$

Express $A_\perp$ and $B_\parallel$and C in terms of p^2 and the scalar bubble integral (4).

Solution:

$$\begin{aligned} I_B^{\mu}\left(a,b;p^2\right)p_\mu = p^2C &= \frac{1}{2}\int \frac{d^dk}{(2\pi)^d}\frac{2kp}{\left(k^2\right)^a\left((k+p)^2\right)^b} \\ C &= \frac{1}{2p^2}\int \frac{d^dk}{(2\pi)^d}\frac{(k+p)^2-k^2-p^2}{\left(k^2\right)^a\left((k+p)^2\right)^b} \\ &= \frac{1}{2p^2}\left[I_B\left(a,b-1;p^2\right)-I_B\left(a-1,b;p^2\right)-p^2I_B\left(a,b;p^2\right)\right]. \\ I_B^{\mu\nu}\left(a,b;p^2\right)\eta_{\mu\nu} &= (d-1)A_\perp + B_\parallel = I_B(a-1,b). \\ I_B^{\mu\nu}\left(a,b;p^2\right)\frac{p^\mu p^\nu}{p^2} &= B_\parallel = \frac{1}{4p^2}\int \frac{d^dk}{(2\pi)^d}\frac{(2kp)^2}{\left(k^2\right)^a\left((k+p)^2\right)^b} \\ &= \frac{1}{4p^2}\int \frac{d^dk}{(2\pi)^d}\frac{\left((k+p)^2-k^2-p^2\right)^2}{\left(k^2\right)^a\left((k+p)^2\right)^b} \\ &= \frac{1}{4p^2}\Big[I_B\left(a-2,b;p^2\right)+I_B\left(a,b-2;p^2\right)+\left(p^2\right)^2I_B\left(a,b;p^2\right) \\ &\quad -2I_B\left(a-1,b-1;p^2\right)-2p^2I_B\left(a-1,b;p^2\right)-2p^2I_B\left(a,b-1;p^2\right)\Big] \\ A_\perp &= \frac{1}{d-1}\left[I_B\left(a-1,b;p^2\right)-B_\parallel\right]. \end{aligned}$$

28.2.2 Other Problems about γ-Matrices and Other Mathematics for Spinors

(всякие особые задачи пока в отдельной записи по модиф теориям поля. простые и скучные - тоже в подготовительной записи!)

МФТИ-Киселев-2020.9.^{C} Следы

Доказать, что след нечетного числа гамма-матриц Дирака равен нулю, а для четного n имеет место соотношение редукции

$$\mathrm{tr}\left(\gamma^{\mu_1}...\gamma^{\mu_n}\right)=g^{\mu_1\mu_2}\,\mathrm{tr}\left(\gamma^{\mu_3}...\gamma^{\mu_n}\right)+g^{\mu_1\mu_3}\,\mathrm{tr}\left(\gamma^{\mu_2}\gamma^{\mu_4}...\gamma^{\mu_n}\right)+...$$

Solution

(пока такое не научился доказывать)

ПШ-5.3.Куча вопросов о спинорах

(мб много сделаю параграфов из этой задачи)
Спинорные произведения, введенные в задаче 3.3, позволяют эффективно вычислять древесные диаграммы, включающие безмассовые частицы. Вспомним, как мы определяли спинорные произведения в задаче 3.3. Пусть u_{L0} и u_{R0} являются соответственно левым и правым спинорами при некотором фиксированном светоподобном импульсе k_0. Они удовлетворяют соотношениям:

$$u_{L0}\bar{u}_{L0}=\left(\frac{1-\gamma^5}{2}\right)\not{k}_0,\qquad u_{R0}\bar{u}_{R0}=\left(\frac{1+\gamma^5}{2}\right)\not{k}_0.$$

(Эти соотношения есть просто проекции более стандартной формулы $\sum u_0\bar{u}_0=\not{k}_0$ на состояние с определенной спиральностью.) Затем определим спиноры для любого другого светоподобного импульса p как

$$u_L(p)=\frac{1}{\sqrt{2p\cdot k_0}}\not{p}u_{R0},\quad u_R(p)=\frac{1}{\sqrt{2p\cdot k_0}}\not{p}u_{L0}.$$

Мы показали, что эти спиноры удовлетворяют условию $pu(p)=0$. Так как в задачу не входит масса m, то эти спиноры можно использовать как для фермионов, так и для антифермионов. Определим

$$s\left(p_1,p_2\right)=\bar{u}_R\left(p_1\right)u_L\left(p_2\right),\quad t\left(p_1,p_2\right)=\bar{u}_L\left(p_1\right)u_R\left(p_2\right).$$

В выделенной системе отсчета доказаны тождества:

$$t\left(p_1,p_2\right)=\left(s\left(p_2,p_1\right)\right)^*,\quad s\left(p_1,p_2\right)=-s\left(p_2,p_1\right),\quad \left|s\left(p_1,p_2\right)\right|^2=2p_1\cdot p_2.$$

Теперь воспользуемся этими результатами. (a) Для разминки дайте другое доказательство последнего соотношения в (3): воспользуйтесь (1), чтобы переписать $\left|s\left(p_1,p_2\right)\right|^2$ как след от матриц Дирака, а затем вычислите след.
(b) Покажите, что для любого набора дираковских матриц

$$\mathrm{tr}\left[\gamma^\mu\gamma^\nu\gamma^\rho\cdots\right]=\mathrm{tr}\left[\cdots\gamma^\rho\gamma^\nu\gamma^\mu\right]$$

где $\mu,\nu,\rho,...=0,1,2,3$, и 5. Воспользуйтесь этим тождеством для доказательства соотношения

$$\bar{u}_L\left(p_1\right)\gamma^\mu u_L\left(p_2\right)=\bar{u}_R\left(p_2\right)\gamma^\mu u_R\left(p_1\right)$$

(c) Докажите тождество Фирца:

$$\bar{u}_L\left(p_1\right)\gamma^\mu u_L\left(p_2\right)\left[\gamma_\mu\right]_{ab}=2\left[u_L\left(p_2\right)\bar{u}_L\left(p_1\right)+u_R\left(p_1\right)\bar{u}_R\left(p_2\right)\right]_{ab},$$

где $a,b=1,2,3,4$ - дираковские индексы. Доказательство может быть проведено путем проверки следующих утверждений. Правая часть этого соотношения является матрицей Дирака; следовательно, она может быть записана как линейная комбинация -матриц, которые обсуждались в разделе 3.4. Эта правая часть удовлетворяет равенству

$$\gamma^5[M]=-[M]\gamma^5,$$

и, следовательно, должна иметь вид:

$$[M] = \left(\frac{1-\gamma^5}{2}\right)\gamma_\mu V^\mu + \left(\frac{1+\gamma^5}{2}\right)\gamma_\mu W^\mu$$

где V^μ и W^μ – 4-векторы. Их можно найти с помощью техники вычисления следов, например:

$$V^\nu = \frac{1}{2}\,\mathrm{tr}\left[\gamma^\nu\left(\frac{1-\gamma^5}{2}\right)M\right]$$

(d) Рассмотрим процесс $e^+e^- \to \mu^+\mu^-$в главном порядке по α, пренебрегая массами электрона и мюона. Сначала рассмотрим случаи, когда электрон и конечный мюон правополяризованы, а позитрон и антимюон - левополяризованы*. Используя тождество Фирца, покажите, что амплитуду можно выразить через спинорные произведения. Возведите ее в квадрат и воспроизведите выражение (5.22) для

$$\frac{d\sigma}{d\cos\theta}\left(e_R^- e_L^+ \to \mu_R^- \mu_L^+\right)$$

Вычислите сечения для других спиральностей частиц и покажите, что они идентичны приведенным в разделе 5.2.

(e) Используя формализм спинорного произведения, вычислите дифференциальное сечение рассеяния Баба для состояний с заданными спиральностями частиц в случае безмассовых электронов. Сечение, усредненное по спиральностям исходных и просуммированное по спиральностям конечных частиц, должно воспроизводить ответ задачи 5.2. Нужно обратить внимание на то, как суммируются вклады от определенных спиральностей.

* Используйте спинор v_R для антимюона и $\bar{u}_R$ для позитрона.

Solution

(пишу коротко, потому что есть как раз теор часть для всяких деталей этого)

28.3 Problems about special quantum theories

28.3.1 Problems about Non-Abelian QED

МФТИ-Мусаев-2023.3.19/19. Духи и амплитуды

Показать, что в абелевой калибровочной теории духи не дают вклада в амплитуды.

28.3.2 Problems of Typical Modifications of QFT

Stanford.Zhou.2022.7.4.* Chern-Simons theory. (5/45p)

This optional problem presents a way to produce massive gauge fields.
a) The Proca Lagrangian for a massive vector field is

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}m^2 A_\mu A^\mu$$

Find the equation of motion for A^μ and show that for $m \neq 0$, it implies

$$\left(\partial^2 + m^2\right)A^\mu = 0, \quad \partial_\mu A^\mu = 0$$

However, this action does not have a gauge symmetry.

Solution:

The derivation of the equation of motion is similar to problem 3(b), but now a new term appears on the right-hand side, giving

$$-\partial_\mu F^{\mu\nu} = m^2 A^\nu.$$

This is the equation of motion. Applying ∂_ν to both sides yields

$$m^2 \partial_\nu A^\nu = -\partial_\nu \partial_\mu F^{\mu\nu} = 0$$

by the antisymmetry of F, which shows $\partial_\mu A^\mu = 0$ when m is nonzero. Plugging this result back into the original equation of motion gives

$$-\partial_\mu \left(\partial^\mu A^\nu - \partial^\nu A^\mu\right) = -\partial^2 A^\nu = m^2 A^\nu$$

as desired.

b) On the other hand, in two spatial dimensions it is possible to have massive gauge fields. We consider a Lagrangian with a "Chern-Simons" term,

$$\mathcal{L} = -\frac{1}{4} F_{\mu\nu} F^{\mu\nu} + \frac{\alpha}{4} \epsilon^{\mu\nu\rho} F_{\mu\nu} A_\rho$$

where all indices take the values 0,1, and 2, and $\epsilon^{012} = 1$. (This new term is a relative of the term we considered in 3(e), but it is not a total derivative.) Show that the action is gauge invariant, and find the Euler-Lagrange equation for A^μ.

Solution:

The proof that the action is gauge invariant is similar to 3(e). Note that the change in the Lagrangian under a gauge transformation is

$$\delta\mathcal{L} = \frac{\alpha}{4} \epsilon^{\mu\nu\rho} F_{\mu\nu} \partial_\rho \alpha = \frac{\alpha}{2} \epsilon^{\mu\nu\rho} \left(\partial_\mu A_\nu\right) \partial_\rho \alpha = \partial_\rho \left(\frac{\alpha}{2} \epsilon^{\mu\nu\rho} \alpha \partial_\mu A_\nu\right)$$

which is a total derivative, as desired. As for the Euler-Lagrange equation, starting from our solution to 3(b), we pick up an extra term on both the left-hand and right-hand sides, giving

$$-\partial_\mu F^{\mu\nu} + \frac{\alpha}{2} \epsilon^{\mu\nu\rho} \partial_\mu A_\rho = \frac{\alpha}{4} \epsilon^{\mu\rho\nu} F_{\mu\rho}$$

We can clean this up using the antisymmetry of ϵ to give

$$\partial_\mu F^{\mu\nu} = \frac{\alpha}{2} \epsilon^{\mu\nu\rho} F_{\mu\rho}$$

c) The Chern-Simons term is sometimes called a "topological" mass term, because it doesn't depend on the metric. Show that the equation of motion implies

$$\left(\partial^2 + m^2\right) F^{\mu\nu} = 0$$

for some m you should find. Thus the field is massive, yet still has a gauge symmetry.

Solution:

This is a bit fiddly. The idea is that we want to use the equation of motion twice. But in its current form, we can't really do much to it, because of the factor of ϵ on the right-hand side which already contracts with most of the indices. However, we can clear factors of ϵ out of the way by contracting with additional copies of ϵ, and using

$$\epsilon^{\mu\nu\rho} \epsilon_{\mu\alpha\beta} = \delta^\nu_\alpha \delta^\rho_\beta - \delta^\nu_\beta \delta^\rho_\alpha.$$

To get started, we contract both sides of S82 with $\epsilon_{\nu\alpha\beta}$, giving

$$\epsilon_{\nu\alpha\beta} \partial_\mu F^{\mu\nu} = \alpha F_{\beta\alpha}$$

Now we can apply ∂^β to both sides and use the equation of motion again, giving

$$\epsilon_{\nu\alpha\beta} \partial^\beta \partial_\mu F^{\mu\nu} = \frac{\alpha^2}{2} \epsilon_{\mu\alpha\nu} F^{\mu\nu}$$

To get rid of the ϵ' s again, we contract both sides with $\epsilon^{\alpha\delta\sigma}$, giving

$$\partial^\delta \partial_\mu F^{\mu\sigma} - \partial^\sigma \partial_\mu F^{\mu\delta} = \alpha^2 F^{\sigma\delta}$$

Finally, to get the factor of ∂^2 we want, we can apply ∂_δ to both sides, giving

$$\partial^2 \partial_\mu F^{\mu\sigma} = \alpha^2 \partial_\delta F^{\sigma\delta}$$

where a term vanished due to the antisymmetry of F. Cleaning this up, we have

$$0 = \left(\partial^2 + \alpha^2\right)\left(\partial_\mu F^{\mu\nu}\right) = \left(\partial^2 + \alpha^2\right)\left(\frac{\alpha}{2}\epsilon^{\mu\nu\rho}F_{\mu\rho}\right)$$

where we used the equation of motion a final time. Now we just clear away the factor of ϵ by contracting with $\epsilon_{\nu\alpha\beta}$, which finally gives the result with $m = \alpha$.

Since there is no Chern-Simons term in three spatial dimensions, it has little role in particle physics, but it is important in the description of topological effects in two-dimensional condensed matter systems.

Stanford.Zhou.2022.8.4.* Nonminimal couplings. (5/45p)

In problem 1, you found the charge and g-factor for a Dirac fermion minimally coupled to the electromagnetic field, i.e. via the simplest possible interaction (1). However, if the fermion is composite, or interacts with heavier particles, we might need additional terms to describe the coupling. For all parts of this problem, you should adopt the formalism of problem 1 and work in the nonrelativistic limit. Detailed calculations are not needed; qualitative final answers (with justification) are sufficient.

a) The g-factors of the proton and neutron are not given by the result you found in problem 1. When the Dirac equation was invented, physicists explained this by adding an additional term to $\mathcal{H}_I$, proportional to $i\bar{\Psi}\left[\gamma^\mu, \gamma^\nu\right]\Psi F_{\mu\nu}$. Show that the physical effect of such a term is indeed to shift the magnetic dipole moment.

Solution:

If we follow the exact same logic as in problem 1, we'll end up with a term in $\langle p, s\,|H_I|\,p', s'\rangle$ proportional to

$$\int d\mathbf{x} e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}} \bar{u}_s(p)\left[\gamma^\mu, \gamma^\nu\right] u_{s'}(p') F_{\mu\nu}(x)$$

In the presence of a uniform magnetic field, this becomes

$$\begin{aligned}\int d\mathbf{x} e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}} \bar{u}_s(p)\left[\gamma^i, \gamma^j\right] u_{s'}(p') F_{ij}(x) &\propto \int d\mathbf{x} e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}} \epsilon^{ijk}\xi_s^\dagger \sigma^k \xi_{s'} F_{ij} \\ &\propto \not{\delta}\left(\mathbf{p}-\mathbf{p}'\right)\xi_s^\dagger(\boldsymbol{\sigma}\cdot\mathbf{B})\xi_{s'}\end{aligned}$$

which, as we already saw, is precisely what you would get from a magnetic dipole moment.

You might be concerned that this term also causes an interaction with electric fields, as it contains

$$\int d\mathbf{x} e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}} \bar{u}_s(p)\left[\gamma^0, \gamma^i\right] u_{s'}(p') F_{0i}(x).$$

However, we have

$$\left[\gamma^0, \gamma^i\right] = -2\begin{pmatrix} \sigma^i & \\ & -\sigma^i \end{pmatrix}$$

so that when we do the spinor contractions in the nonrelativistic limit, we get two terms that cancel in the nonrelativistic limit. So the only effect of this term is a magnetic dipole moment.

b) What is the physical effect of a term proportional to $\bar{\Psi}\left[\gamma^\mu, \gamma^\nu\right]\gamma^5\Psi F_{\mu\nu}$?

Solution:

By the same logic as before, we'll get a term in the matrix element like

$$\int d\mathbf{x} e^{-i(\mathbf{p}-\mathbf{p}')\cdot\mathbf{x}} \bar{u}_s(p) \left[\gamma^\mu, \gamma^\nu\right] \gamma^5 u_{s'}(p') F_{\mu\nu}(x)$$

where

$$\gamma^5 = \begin{pmatrix} -\mathbb{1}_2 & \\ & \mathbb{1}_2 \end{pmatrix}$$

in the Weyl representation. Recall that both $\left[\gamma^i, \gamma^j\right]$ and $\left[\gamma^i, \gamma^0\right]$ have Pauli matrices on the diagonal, but the latter has them with opposite signs. The presence of the γ^5 essentially exchanges the two. It is now the $\left[\gamma^i, \gamma^0\right]$ that contribute in the nonrelativistic limit, giving a term proportional to $\not{\delta}(\mathbf{p}-\mathbf{p}')\,\xi_s^\dagger(\boldsymbol{\sigma}\cdot\mathbf{E})\xi_{s'}$. Physically, this corresponds to giving the particle an electric dipole moment.

The presence of an electric dipole moment implies the violation of CP symmetry. Many past and ongoing experiments search for the electric dipole moment of the electron, which could arise from physics beyond the Standard Model, but so far none has been detected. The Standard Model generically predicts a sizable electric dipole moment for the neutron, which should have been easily detected decades ago, but mysteriously none has been found.

The above two are the only terms with dimension 5, and are therefore the simplest nonminimal couplings one could consider. Next, let's consider some dimension 6 terms.

c) What is the physical effect of a term proportional to $\bar{\Psi}\gamma^\mu\Psi\partial^\nu F_{\mu\nu}$?

Solution:

This is just like the coupling in problem 1, but we have replaced A_μ with $\partial^\nu F_{\mu\nu} = -J_\mu$. In the nonrelativistic limit, the leading effect is the one we found in problem 1(b), as this is the only one not suppressed by powers of v. By the same logic, the result is a term in H_I^{nr} proportional to $J^0(\mathbf{x}) = \rho(\mathbf{x})$, where ρ is the external charge density. That is, it has no effect, regardless of the fields at the particle's location, unless the particle is sitting right on top of some other charge.

This might seem rather mysterious, but it's perfectly comprehensible within classical electromagnetism. Consider a tiny spherical capacitor with places of charge $\pm q$. This charge configuration produces exactly zero electromagnetic field everywhere outside it, which means that it does not interact with external charges until they are right inside the capacitor, in which case they feel the potential inside.

If the particle already has a net charge, then superposing the above configuration spreads the charge out in space. For this reason, this term is said to produce a "charge radius". The charge radius is one way to quantify the size of particles like the proton. (The "proton radius puzzle" is the fact that two independent measurements of this quantity seemed to give different results.) When we say the electron is a pointlike particle, we mean that it has no charge radius, as far as we've detected.

d) What is the physical effect of a term proportional to $\bar{\Psi}\gamma^\mu\gamma^5\Psi\partial^\nu F_{\mu\nu}$?

Solution:

In this case the leading term in the nonrelativistic limit is that of 1(d), but with $\mathbf{B}$ replaced with $\mathbf{J}$, corresponding to an interaction of the form $\mathbf{S}\cdot\mathbf{J}(\mathbf{x})$. In other words, we have an interaction with currents directly on top of the particle.

To physically interpret this, imagine the particle is a tiny toroidal solenoid with its axis of symmetry aligned with $\mathbf{S}$. Such a configuration produces zero magnetic field outside itself, but the magnetic field affects currents that pass right over the toroid. When the current flows parallel to $\mathbf{S}$, it gets pushed directly towards (or away from) the toroid's axis, while a current flowing perpendicular to $\mathbf{S}$ experiences no net force; this therefore reproduces the $\mathbf{S}\cdot\mathbf{J}$ potential.

Depending on the field of physics, such a current configuration is called an anapole moment, or a polar toroidal dipole moment. You have probably not seen such a thing in electromagnetism classes, because it doesn't show up in the multipole expansion - it is a near field effect, not a far field effect. But anapole moments are important observables in nuclear physics.

One can keep going. The anapole moment produces a localized parity-violating magnetic field, while the so-called Schiff moment, also important in nuclear physics, produces a localized parity-violating electric field. It corresponds to a term in H_I^{nr} proportional to $\mathbf{S}\cdot\nabla\rho$.

Stanford.exam-2022.5*/5. Kaluza-Klein theory. (5/40p)

Some theories of physics beyond the Standard Model involve compactified extra spacetime dimensions. In this problem, you will see why this generically gives rise to many new particles, and why the extra dimensions are hard to detect when they are very small.

Consider a massless real scalar field on a five-dimensional spacetime, where the extra dimension is compactified on a circle of radius R. That is, points are labeled by (x, w) where $x = (t, x, y, z)$ is the usual four-dimensional spacetime coordinate, and $w \in [0, 2\pi R]$, with the points $w = 0$ and $w = 2\pi R$ identified. The metric on this spacetime is still mostly negative, so $\eta^{00} = 1$ with the other diagonal elements negative. The action is

$$S = \int d^4x \int_0^{2\pi R} dw \frac{1}{2} \left(\partial_M \phi(x, w)\right) \left(\partial^M \phi(x, w)\right)$$

where the index M ranges from 0 to 4.

a) Using Fourier series, the w-dependence of the field can be written as

$$\phi(x, w) = \sum_n \phi^{(n)}(x) e^{ik_n w}$$

where the sum is over integer n. What are the k_n, and how is $\phi^{(n)}$ related to $\phi^{(-n)}$?

b) Plug this decomposition into the action and perform the w integral to yield an ordinary four-dimensional action, written in terms of the fields $\phi^{(n)}(x)$ for $n \geq 0$. What are the physical masses m_n of these fields?

(Hint: you should rescale the fields to give the kinetic terms the usual normalizations.)

c) Show that we can use a gauge transformation to set $A_4^{(n)} = 0$ when $n \neq 0$, and explain why this is not possible when $n = 0$.

d) Using this gauge, find all the resulting four-dimensional fields and their masses.

Solution a)

Because the function is periodic in w with period $2\pi R$, we must have $k_n = n/R$.

Since the field is real, we must have $\left(\phi^{(n)}\right)^* = \phi^{(-n)}$.

Solution b)

The result is

$$\begin{aligned}
S &= \int d^4x \sum_{n,n'} \int_0^{2\pi R} dw \frac{1}{2} \partial_M \left(\phi^{(n)} e^{inw/R}\right) \partial^M \left(\phi^{(n')} e^{in'w/R}\right) \\
&= \int d^4x \sum_{n,n'} \int_0^{2\pi R} dw \frac{1}{2} \left(\partial_\mu \phi^{(n)} \partial^\mu \phi^{(n')} - \frac{in}{R}\frac{in'}{R} \phi^{(n)} \phi^{(n')}\right) e^{inw/R} e^{in'w/R} \\
&= \int d^4x \sum_{n,n'} \frac{1}{2} \left(\partial_\mu \phi^{(n)} \partial^\mu \phi^{(n')} - \frac{in}{R}\frac{in'}{R} \phi^{(n)} \phi^{(n')}\right) 2\pi R \delta_{n,-n'} \\
&= \int d^4x \sum_{n} \frac{1}{2} \left(\partial_\mu \phi^{(n)} \partial^\mu \phi^{(-n)} - \frac{n^2}{R^2} \phi^{(n)} \phi^{(-n)}\right) 2\pi R.
\end{aligned}$$

Pairing up terms with positive and negative n, we get

$$S = 2\pi R \int d^4x \frac{1}{2} \partial_\mu \phi^{(0)} \partial^\mu \phi^{(0)} + \sum_{n>0} \left(\left|\partial_\mu \phi^{(n)}\right|^2 - \frac{n^2}{R^2} \left|\phi^{(n)}\right|^2\right)$$

This is almost the action for a real scalar field and a bunch of complex scalar fields, but we need to rescale to get the right kinetic terms. Defining $\varphi^{(n)} = \sqrt{2\pi R}\phi^{(n)}$, we conclude

$$S = \int d^4x \frac{1}{2} \partial_\mu \varphi^{(0)} \partial^\mu \varphi^{(0)} + \sum_{n>0} \left(\left|\partial_\mu \varphi^{(n)}\right|^2 - \frac{n^2}{R^2} \left|\varphi^{(n)}\right|^2\right)$$

from which we see $m_0 = 0$ and $m_n = n/R$. We get an infinite tower of increasingly massive particles, whose masses are very high if R is very small.

Now consider the case of a massless vector field, which can be decomposed as

$$A_M(x,w) = \sum_n A_M^{(n)}(x) e^{ik_n w}$$

The action is the five-dimensional analogue of the usual electromagnetic action,

$$S = -\frac{1}{4}\int d^4x \int_0^{2\pi R} dw F_{MN}F^{MN}$$

and we have the five-dimensional analogue of the usual gauge symmetry, $A_M \to A_M + \partial_M \alpha$

Solution c)

We can set $A_4^{(n)} = 0$ for all $n \neq 0$ by taking

$$\alpha = -\sum_{n\neq 0} A_M^{(n)}(x)\frac{e^{ik_n w}}{ik_n}$$

This doesn't work for $n = 0$ because it would result in division by zero. Or, in gratuitously fancy language, $A_4^{(0)}$ corresponds to the constant function on the circle, which has zero derivative, yet itself is not the derivative of anything; such a function exists because of the nontrivial cohomology of the circle.

Solution d)

Since we're going to have to rescale the fields later anyway, let's preemptively define

$$A_\mu(x,w) = \sqrt{2\pi R}\sum_n A_\mu^{(n)}(x)e^{ik_n w}, \quad \phi = \sqrt{2\pi R}A_4^{(0)}.$$

The action becomes

$$S = \int d^4x \int_0^{2\pi R} dw \left(-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2}F_{\mu 4}F^{\mu 4}\right)$$

The first term is

$$\begin{aligned} S_1 &= \int d^4x \int_0^{2\pi R}\frac{dw}{2\pi R}\left(-\frac{1}{4}\sum_{n,n'} e^{i(n+n')w/R}F_{\mu\nu}^{(n)}F^{\mu\nu(n')}\right) \\ &= -\frac{1}{4}\int d^4x F_{\mu\nu}^{(0)}F^{\mu\nu(0)} - \frac{1}{2}\sum_{n>0}\int d^4x \left(F_{\mu\nu}^{(n)}\right)^* F^{\mu\nu(n)} \end{aligned}$$

which is just the kinetic term for a real vector field $A_\mu^{(0)}$ and a tower of complex vector fields $A_\mu^{(n)}$ for $n > 0$. Next, the second term is

$$\begin{aligned} S &= -\frac{1}{2}\int d^4x \int_0^{2\pi R}\frac{dw}{2\pi R}\left(\partial_\mu\phi - \sum_n \partial_4\left(A_\mu^{(n)}e^{inw/R}\right)\right)\left(-\partial^\mu\phi - \sum_{n'}\partial^4\left(A^{\mu(n')}e^{in'w/R}\right)\right) \\ &= \int d^4x \frac{1}{2}\partial_\mu\phi\partial^\mu\phi - \frac{1}{2}\int d^4x \int_0^{2\pi R}\frac{dw}{2\pi R}\sum_{n,n'} e^{i(n+n')w/R}\frac{nn'}{R^2}A_\mu^{(n)}A^{\mu(n')} \\ &= \int d^4x \frac{1}{2}\partial_\mu\phi\partial^\mu\phi + \sum_{n>0}\int d^4x \frac{n^2}{R^2}\left(A_\mu^{(n)}\right)^* A^{\mu(n)}. \end{aligned}$$

From this we conclude we have:
• One massless real scalar field ϕ.
• One massless real vector field $A_\mu^{(0)}$.
• A tower of massive complex vector fields $A_\mu^{(n)}$ with masses n/R.
By the way, if you do the analogous calculation starting with a five-dimensional metric, the massless degrees of freedom you'll get are a real scalar, a real vector, and a four-dimensional metric, suggesting a unification between electromagnetism and gravity; that's why Einstein was a big fan of this theory.

Если фотон рассеивается назад, то как так получается, что он при этом не останавливается и всегда движется со скорость света? Мы ведь всегда, чтобы пойти назад должны сперва остановиться.

Solution (?????)

(стану умнее - подумаю.)

Я. Классическая виртуальная частица

Если посчитать сечение рассеяния с передачей частицы, но только в рамках классической механики, то как будет результат отличаться от результата в рамках квантовой теории поля?

Solution (?????)

(стану умнее - подумаю.)

Я. Анизотропность рассеяния

Как так вообще получается, что две частицы если налетают друг на друга, будучи полностью одинаковыми, в одни углы рассеиваются больше, в другие меньше?

Solution (?????)

(как бы понятно, можно говорить слова, типа квантовые флуктуации, но я хотел бы количественно это тут объяснить еще, с формулами.)

Я. Квантование нелинейного поля

The FD pulse was first established as a solution to the homogenous Maxwell's equations by Hellwarth and Nouchi [13]. As space-time non-separable solutions to Maxwells equations, FD pulses can be classified in TE and TM field configurations, with the electric and magnetic fields for the TE case given in cylindrical coordinates (ρ, θ, z) as:

$$E_\theta = -4if_0\sqrt{\frac{\mu_0}{\varepsilon_0}}\frac{\rho\left(q_1+q_2-2ict\right)}{\left[\rho^2+\left(q_1+i\tau\right)\left(q_2-i\sigma\right)\right]^3}$$

$$H_\rho = 4if_0\frac{\rho\left(q_2-q_1-2iz\right)}{\left[\rho^2+\left(q_1+i\tau\right)\left(q_2-i\sigma\right)\right]^3}$$

$$H_z = -4f_0\frac{\rho^2-\left(q_1+i\tau\right)\left(q_2-i\sigma\right)}{\left[\rho^2+\left(q_1+i\tau\right)\left(q_2-i\sigma\right)\right]^3}$$

Where $\sigma = z+ct, \tau = z-ct$ and f_0 is an arbitrary normalisation constant. The parameters q_1 and q_2 have the dimensions of length and represent respectively the effective wavelength

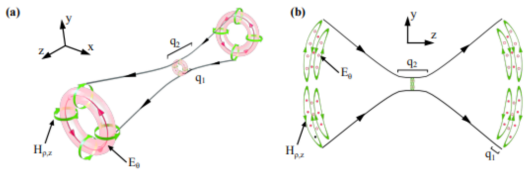

Fig. 1. Field topology and focusing properties of the "focused doughnut" pulse. The electric E and magnetic H fields are represented by green and red arrows respectively. The effective wavelength parameter q_1 and the pulse focal region depth q_2 are indicated on both diagrams, along with the region of maximum energy concentration at $z = 0, t = 0$. The pulse envelope is shown by the black lines and arrows.
Question: how to quantize it?

Solution

29 Two-component spinor techniques and Feynman rules for quantum field theory and supersymmetry by Dreiner, Haber

Abstract

Two-component spinors are the basic ingredients for describing fermions in quantum field theory in $3+1$ spacetime dimensions. We develop and review the techniques of the two-component spinor formalism and provide a complete set of Feynman rules for fermions using two-component spinor notation. These rules are suitable for practical calculations of cross-sections, decay rates, and radiative corrections in the Standard Model and its extensions, including supersymmetry, and many explicit examples are provided. The unified treatment presented in this review applies to massless Weyl fermions and massive Dirac and Majorana fermions. We exhibit the relation between the two-component spinor formalism and the more traditional four-component spinor formalism, and indicate their connections to the spinor helicity method and techniques for the computation of helicity amplitudes.

29.1 Introduction

A crucial feature of the Standard Model of particle physics is the chiral nature of fermion quantum numbers and interactions. According to the modern understanding of the electroweak interactions, the fundamental degrees of freedom for quarks and leptons are two-component Weyl-van der Waerden fermions [1], i.e. two-component Lorentz spinors that transform as irreducible representations under the gauge group $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. Furthermore, within the context of supersymmetric field theories, two-component spinors enter naturally, due to the spinorial nature of the symmetry generators themselves, and the holomorphic structure of the superpotential. Despite this, most pedagogical treatments and practical calculations in high-energy physics continue to use the four-component Dirac spinor notation, which combines distinct irreducible representations of the Lorentz symmetry algebra. Parity-conserving theories such as QED and QCD are well-suited to the four-component fermion methods. There is also a certain perceived advantage to familiarity. However, as we progress to phenomena at and above the scale of electroweak symmetry breaking, it seems increasingly natural to employ two-component fermion notation, in harmony with the irreducible transformation properties dictated by the physics.

One occasionally encounters the misconception that two-component fermion notations are somehow inherently ill-suited or unwieldy for practical use. Perhaps this is due in part to a lack of examples of calculations using two-component language in the pedagogical literature. In this review, we seek to dispel this idea by presenting Feynman rules for fermions using two-component spinor notation, intended for practical calculations of cross-sections, decays, and radiative corrections. This formalism employs a unified framework that applies equally well to Dirac fermions [2] such as the Standard Model quarks and charged leptons, and to Majorana fermions [3] such as the light neutrinos of the seesaw extension of the Standard Model [4, 5] or the neutralinos of the minimal supersymmetric extension of the Standard Model (MSSM) [6, 7, 8, 9, 10].

Spinors were introduced by E. Cartan in 1913 as projective representations of the rotation group [11, 12], and entered into physics via the Dirac equation in 1928 [2]. In the same year, H. Weyl

discussed the representations of the Lorentz group [13], including the two-component spinor representations, in terms of stereographic projective coordinates [14]. The extension of the tensor calculus (or tensor analysis) to spinor calculus (or spinor analysis) was given by B.L. van der Waerden [1], upon the instigation of P. Ehrenfest. It is in this paper that van der Waerden (not Weyl as often claimed in the literature) first introduced the notation of dotted and undotted indices for the irreducible $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ representations of the Lorentz group. Both Weyl [15] and van der Waerden independently considered the decomposition of the Dirac equation into two coupled differential equations for two-component spinors. In the 1930s, more pedagogical presentations of two-component spinors were given in refs. [16, 17, 18]. In particular, [16] was the first paper in English to employ the dotted and undotted index notation. Ref. [17] also presents the first two-component spinor analysis for general relativity. In the early 1950s, comprehensive reviews of two-component spinor techniques were published in English by Bade and Jehle [19] and in German by Cap [20]. Shortly thereafter, Bergmann reintroduced two-component spinors into the formalism of general relativity [21], which was followed by significant developments by Penrose [22].[7] Two-component spinor techniques in curved space are reviewed in refs. [23, 24], with an extensive bibliography given in [25]. A recent mathematical treatment of two-component spinors and their geometry can be found in [26]. Two-component spinors also play a central role in the covariant formulation of relativistic wave equations [27].

The formalism of two-component spinors has also been discussed in many textbooks on relativistic quantum mechanics, quantum field theory, elementary particle physics, group theoretical methods in physics, general relativity, and supersymmetry. For a guide to the non-supersymmetric literature, see for example, refs. [14, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68]. Among the early books, we would like to draw attention to [28], which has an extensive discussion of two-component spinor methods. Scheck [42] includes a short discussion of the field theory of two-component spinors, including the propagator. A more extensive field theoretic treatment, including Feynman rules and applications, is given by Ticciati [50]. A modern textbook on quantum field theory by Srednicki [66] includes a comprehensive treatment of two-component fermions and their quantization. Most textbooks and introductory reviews of supersymmetry [6, 7, 8, 9, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90] include a discussion of two-component spinors on some level, with a treatment of dotted and undotted indices and a collection of identities involving two-component spinors and the sigma matrices. Particularly extensive and useful sets of identities can be found in refs. [69, 73, 75, 78, 84, 86]. Finally, some mathematically sophisticated textbook treatments of spinors can be found in refs. [91, 92, 93].

The standard technique for computing scattering cross-sections with initial and final state fermions involves squaring the quantum S-matrix amplitude, summing over the spin states and then computing the traces of products of gamma matrices (in the four-component spinor formalism), or products of sigma matrices (in the two-component spinor formalism). We employ this latter technique throughout this paper (with a translation to the four-component formalism provided in an appendix). However, the computational effort rises rapidly as the number of interfering diagrams increases. The standard techniques typically become impractical with four or more particles in the final state. One approach to make such extensive calculations manageable is the helicity amplitude technique. Here the scattering process is decomposed into the scattering of helicity eigenstates. Then the individual amplitudes are computed analytically in terms of Lorentz scalar invariants, i.e. a complex number that can be readily computed. It is then a simple numerical task to sum all the contributing amplitudes and compute the square of the complex magnitude of the resulting sum. Such methods were first explored in refs. [94, 95, 96, 97], using four-component spinors (see also refs. [98, 99, 100, 101, 102]). Spinor techniques in the helicity formalism were also developed in ref. [103]. In fact, the natural spinor formalism for the helicity amplitude techniques makes use of the two-component Weyl-van der Waerden spinors, which we discuss in detail in this review. They were implemented in the helicity amplitude technique in refs. [104, 105, 106, 107, 108, 109, 110]. Recently, the two-component formalism has been implemented in a computer program for the numerical computation of amplitudes and cross-sections for event generators multi-particle

[7] For typographical reasons, Penrose replaced the dotted indices with primed indices, a notation still employed by most general relativists today.

processes [111].

This review is outlined as follows. In Section 2, we present our conventions and notation (with some additional discussion of our conventions in Appendix A). We also establish numerous identities involving sigma matrices, epsilon symbols and two-component spinors. In Section 3, we derive the basic properties of the quantized two-component fermion fields. For a generic collection of N two-component fermion fields with identical conserved quantum numbers, the corresponding mass matrix is an $N \times N$ complex symmetric matrix. To identify the corresponding mass eigenstates, one must perform a fermion-mass diagonalization that differs from the usual unitary similarity transformation of an hermitian matrix that is employed for a collection of scalar fields. In Section 4, we derive the Feynman rules for two-component spinors and describe how to write down amplitudes in our formalism. We demonstrate how to employ the two-component formalism for both tree-level and loop-level processes. In Section 5, we establish a naming convention for fermion and antifermion particle states and the corresponding fields. This is important as it provides an unambiguous procedure for obtaining the amplitudes for a given physical process, and for comparing these computations in the two-component and four-component spinor formalisms. In Section 6 we provide an extensive number of examples of computations using the two-component spinor formalism. This is the central part of our review.

We have relegated many details to a set of twelve appendices. In Appendix A, we summarize our metric and sigma matrix conventions and indicate how to translate between conventions with opposite metric signature. With our definition of the sigma matrices, one can switch easily between the two conventions by computing one overall sign factor. In Appendix B, we provide a comprehensive list of sigma matrix identities, and indicate which of these identities can be generalized to $d \neq 4$ dimensions required for loop computations that employ dimensional regularization. Explicit forms for the two-component spinor wave functions are given in Appendix C (where we exhibit two of the most common phase conventions employed in the literature). The mathematics of fermion mass diagonalization is discussed in Appendix D. In contrast to the unitary similarity transformation of the scalar squared-mass matrix, fermion mass diagonalization involves the Takagi diagonalization [112] of a complex symmetric matrix (for neutral fermions) or the singular value decomposition of a complex matrix (for charged fermions). In Appendix E, we review some of the basic facts of Lie groups and Lie algebras needed in the treatment of gauge theories. The two-component fermion propagators (derived in Section 4 using canonical field theory techniques) can also be obtained by path integral methods, as exhibited in Appendix F.

As most textbooks on quantum field theory and elementary particle physics employ the four-component spinor formalism for fermions, we provide in Appendix G a dictionary that allows one to translate between the two-component and four-component spinor techniques. We use the two-component spinor methods developed in this review to establish a generalization of the standard four-component spinor Feynman rules that incorporate Majorana fermions in a natural way. In Appendix H, we develop a method for computing helicity amplitudes in terms of Lorentz-invariant scalar quantities. This method, which makes use of the Bouchiat-Michel formulae [113] (originally established in the four-component spinor formalism) is developed in the language of two-component spinors. However, these methods are somewhat limited in scope and must be generalized in the case of multi-particle final states. This was accomplished by Hagiwara and Zeppenfeld (HZ) based on a two-component spinor treatment [106]. In Appendix I, we provide a translation between the HZ formalism and the two-component spinor formalism of this review. We also demonstrate that the spinor helicity method that is now commonly used in obtaining compact expressions for helicity amplitudes of multi-particle processed has a very simple development within the two-component spinor formalism. Finally, the two-component spinor Feynman rules for the Standard Model, the seesaw-extended Standard Model (which incorporates massive neutrinos), the minimal supersymmetric extension of the Standard Model (MSSM), and the R-parity-violating extension of the MSSM are given in Appendices J, K and L.

29.2 Essential conventions, notations and two-component spinor identities

We begin with a discussion of necessary conventions. The metric tensor is taken to be:[8]

$$g_{\mu\nu} = g^{\mu\nu} = \mathrm{diag}(+1, -1, -1, -1)\,, \tag{29.1}$$

where $\mu, \nu = 0, 1, 2, 3$ are spacetime vector indices. Contravariant four-vectors (e.g. positions and momenta) are defined with raised indices, and covariant four-vectors (e.g. derivatives) with lowered indices:

$$x^\mu = (t\,;\,\vec{\boldsymbol{x}})\,, \tag{29.2}$$
$$p^\mu = (E\,;\,\vec{\boldsymbol{p}})\,, \tag{29.3}$$
$$\partial_\mu \equiv \frac{\partial}{\partial x^\mu} = (\partial/\partial t\,;\,\vec{\boldsymbol{\nabla}})\,, \tag{29.4}$$

in units with $c = 1$. The totally antisymmetric pseudo-tensor $\epsilon^{\mu\nu\rho\sigma}$ is defined such that

$$\epsilon^{0123} = -\epsilon_{0123} = +1\,. \tag{29.5}$$

More details on our conventions can be found in Appendix A .

The irreducible building blocks for spin-1/2 fermions are fields that transform either under the left-handed $(\frac{1}{2}, 0)$ or the right-handed $(0, \frac{1}{2})$ representation of the Lorentz group. Hermitian conjugation interchanges these two representations. A Majorana fermion field can be constructed from either representation; this is the spin-1/2 analogue of a real scalar field. A Dirac fermion field combines two equal mass two-component fields into a reducible representation of the form $(\frac{1}{2}, 0) \oplus (0, \frac{1}{2})$; this is the spin-1/2 analogue of a complex scalar field. It is also possible to use four-component notation to describe a Majorana fermion by imposing a reality condition on the spinor in order to reduce the number of degrees of freedom in half. Details of this construction are given in Appendix G.1. However, in this review, we shall focus primarily on two-component spinor notation for all fermions. In the following, $(\frac{1}{2}, 0)$ spinors carry undotted indices $\alpha, \beta, ... = 1, 2$, and $(0, \frac{1}{2})$ spinors carry dotted indices $\dot{\alpha}, \dot{\beta}, ... = 1, 2$.

We first provide a brief introduction to the Lorentz group and its two-dimensional spinor representations. Under an active Lorentz transformation, a contravariant four-vector x^μ transforms as

$$x^\mu \to x'^\mu = \Lambda^\mu{}_\nu x^\nu\,, \tag{29.6}$$

where $\Lambda \in \mathrm{SO}(3,1)$ satisfies $\Lambda^\mu{}_\nu g_{\mu\rho} \Lambda^\rho{}_\lambda = g_{\nu\lambda}$. It then follows that the transformation of the corresponding covariant four-vector $x_\mu \equiv g_{\mu\nu} x^\nu$ satisfies:

$$x_\nu = x'_\mu \Lambda^\mu{}_\nu\,. \tag{29.7}$$

The most general proper orthochronous Lorentz transformation (which is continuously connected to the identity), corresponding to a rotation by an angle θ about an axis $\widehat{\boldsymbol{n}}$ $[\vec{\boldsymbol{\theta}} \equiv \theta\widehat{\boldsymbol{n}}]$ and a boost vector $\vec{\boldsymbol{\zeta}} \equiv \hat{\boldsymbol{v}} \tanh^{-1}\beta$ [where $\hat{\boldsymbol{v}} \equiv \vec{\boldsymbol{v}}/|\vec{\boldsymbol{v}}|$ and $\beta \equiv |\vec{\boldsymbol{v}}|$], is a 4×4 matrix given by:

$$\Lambda = \exp\left(-\tfrac{1}{2} i\theta^{\rho\sigma}\mathcal{S}_{\rho\sigma}\right) = \exp\left(-i\vec{\boldsymbol{\theta}}\cdot\vec{\boldsymbol{\mathcal{S}}} - i\vec{\boldsymbol{\zeta}}\cdot\vec{\boldsymbol{\mathcal{K}}}\right)\,, \tag{29.8}$$

[8] The published version of this paper employs the $(+,-,-,-)$ Minkowski space metric. An otherwise identical version, using the $(-,+,+,+)$ metric favored by one of the authors (SPM), may be found at http://www.niu.edu/spmartin/spinors/. It can also be constructed by changing a single macro at the beginning of the LaTeX source file [114], in an obvious way. You can tell which version you are presently reading from eq. (29.1). See Appendix A pinors for further details and rules for translating between metric conventions.

where $\theta^{\rho\sigma} = -\theta^{\sigma\rho}$ and $\mathcal{S}_{\rho\sigma} = -\mathcal{S}_{\sigma\rho}$. In particular, $\theta^i \equiv \frac{1}{2}\epsilon^{ijk}\theta_{jk}$, $\zeta^i \equiv \theta^{i0} = -\theta^{0i}$, $\mathcal{S}^i \equiv \frac{1}{2}\epsilon^{ijk}\mathcal{S}_{jk}$, $\mathcal{K}^i \equiv \mathcal{S}^{0i} = -\mathcal{S}^{i0}$, and

$$(\mathcal{S}_{\rho\sigma})^{\mu}{}_{\nu} = i(\delta^{\mu}_{\rho}\, g_{\sigma\nu} - \delta^{\mu}_{\sigma}\, g_{\rho\nu})\,. \tag{29.9}$$

Here, the indices $i, j, k = 1, 2, 3$ and $\epsilon^{123} = +1$.

Thus, an infinitesimal orthochronous Lorentz transformation is given by

$$\Lambda^{\mu}{}_{\nu} \simeq \delta^{\mu}_{\nu} - \tfrac{1}{2}i\theta^{\rho\sigma}(\mathcal{S}_{\rho\sigma})^{\mu}{}_{\nu} = \delta^{\mu}_{\nu} + \tfrac{1}{2}\theta^{\rho\sigma}(\delta^{\mu}_{\rho}\, g_{\sigma\nu} - \delta^{\mu}_{\sigma}\, g_{\rho\nu}) = \delta^{\mu}_{\nu} + \tfrac{1}{2}(\theta^{\mu}{}_{\nu} - \theta_{\nu}{}^{\mu})\,. \tag{29.10}$$

Since $\theta^{\mu}{}_{\nu} = g_{\alpha\nu}\theta^{\mu\alpha} = -g_{\alpha\nu}\theta^{\alpha\mu} = -\theta_{\nu}{}^{\mu}$, it follows that

$$\Lambda^{\mu}{}_{\nu} \simeq \delta^{\mu}_{\nu} + \theta^{\mu}{}_{\nu}\,. \tag{29.11}$$

Moreover, the infinitesimal boost parameter is $\vec{\boldsymbol{\zeta}} \equiv \hat{\boldsymbol{v}}\tanh^{-1}\beta \simeq \beta\hat{\boldsymbol{v}} \equiv \vec{\boldsymbol{\beta}}$, since $\beta \ll 1$ for an infinitesimal boost. Hence, the actions of the infinitesimal boosts and rotations on the spacetime coordinates are

$$\text{Rotations:} \qquad \begin{cases} \vec{\boldsymbol{x}} \to \vec{\boldsymbol{x}}' \simeq \vec{\boldsymbol{x}} + (\vec{\boldsymbol{\theta}} \times \vec{\boldsymbol{x}})\,, \\ t \to\ t' \simeq t\,, \end{cases} \tag{29.12}$$

$$\text{Boosts:} \qquad \begin{cases} \vec{\boldsymbol{x}} \to \vec{\boldsymbol{x}}' \simeq \vec{\boldsymbol{x}} + \vec{\boldsymbol{\beta}}\, t\,, \\ t \to\ t' \simeq t + \vec{\boldsymbol{\beta}}\cdot\vec{\boldsymbol{x}}\,, \end{cases} \tag{29.13}$$

with exactly analogous transformations for any contravariant four-vector.

With respect to the Lorentz transformation Λ, a general n-component field Φ transforms according to a representation R of the Lorentz group as $\Phi(x^\mu) \to \Phi'(x'^\mu) = M_R(\Lambda)\,\Phi(x^\mu)$, where $M_R(\Lambda)$ is the corresponding (finite) d_R-dimensional matrix representation. Equivalently, the functional form of the transformed field Φ obeys

$$\Phi'(x^\mu) = M_R(\Lambda)\Phi([\Lambda^{-1}]^{\mu}{}_{\nu}x^{\nu})\,, \tag{29.14}$$

after using eq. (29.6). For proper orthochronous Lorentz transformations,

$$M_R = \exp\left(-\tfrac{1}{2}i\theta_{\mu\nu}J^{\mu\nu}\right) \simeq \mathbb{1}_{d_R\times d_R} - i\vec{\boldsymbol{\theta}}\cdot\vec{\boldsymbol{J}} - i\vec{\boldsymbol{\zeta}}\cdot\vec{\boldsymbol{K}}\,, \tag{29.15}$$

where $\mathbb{1}_{d_R\times d_R}$ is the $d_R \times d_R$ identity matrix and $\theta_{\mu\nu}$ parameterizes the Lorentz transformation Λ [eq. (29.8)]. The six independent components of the matrix-valued antisymmetric tensor $J^{\mu\nu}$ are the d_R-dimensional generators of the Lorentz group and satisfy the commutation relations:

$$[J^{\mu\nu}\,,\, J^{\lambda\kappa}] = i(g^{\mu\kappa}\, J^{\nu\lambda} + g^{\nu\lambda}\, J^{\mu\kappa} - g^{\mu\lambda}\, J^{\nu\kappa} - g^{\nu\kappa}\, J^{\mu\lambda})\,. \tag{29.16}$$

We identify $\vec{\boldsymbol{J}}$ and $\vec{\boldsymbol{K}}$ as the generators of rotations parameterized by $\vec{\boldsymbol{\theta}}$ and boosts parameterized by $\vec{\boldsymbol{\zeta}}$, respectively, where

$$J^i \equiv \tfrac{1}{2}\epsilon^{ijk}J_{jk}\,, \qquad\qquad K^i \equiv J^{0i}\,. \tag{29.17}$$

Here we focus on the simplest non-trivial irreducible representations of the Lorentz algebra. These are the two-dimensional (inequivalent) representations: $(\frac{1}{2}, 0)$ and $(0, \frac{1}{2})$. In the $(\frac{1}{2}, 0)$ representation, $\vec{\boldsymbol{J}} = \vec{\boldsymbol{\sigma}}/2$ and $\vec{\boldsymbol{K}} = -i\vec{\boldsymbol{\sigma}}/2$ in eq. (29.15), which yields

$$M_{(\frac{1}{2},0)} \equiv M \simeq \mathbb{1}_{2\times 2} - i\vec{\boldsymbol{\theta}}\cdot\vec{\boldsymbol{\sigma}}/2 - \vec{\boldsymbol{\zeta}}\cdot\vec{\boldsymbol{\sigma}}/2\,, \tag{29.18}$$

where $\vec{\boldsymbol{\sigma}} \equiv (\sigma^1\,,\, \sigma^2\,,\, \sigma^3)$ are the Pauli matrices [cf. eq. (29.29)]. By definition M carries undotted spinor indices, as indicated by $M_\alpha{}^\beta$. A two-component $(\frac{1}{2}, 0)$ spinor is denoted by ψ_α and transforms

as $\psi_\alpha \to M_\alpha{}^\beta \psi_\beta$, omitting the coordinate arguments of the fields, which are as in eq. (29.14). In our conventions for the location of the spinor indices, we sum implicitly over a repeated index pair in which one index is lowered and one index is raised.

In the $(0, \frac{1}{2})$ representation, $\vec{\boldsymbol{J}} = -\vec{\boldsymbol{\sigma}}^*/2$ and $\vec{\boldsymbol{K}} = -i\vec{\boldsymbol{\sigma}}^*/2$ in eq. (29.15), so that its representation matrix is M^*, the complex conjugate of eq. (29.18). By definition, the indices carried by M^* are dotted, as indicated by $(M^*)_{\dot\alpha}{}^{\dot\beta}$. A two-component $(0, \frac{1}{2})$ spinor is denoted by $\psi^\dagger_{\dot\alpha}$ and transforms as $\psi^\dagger_{\dot\alpha} \to (M^*)_{\dot\alpha}{}^{\dot\beta}\psi^\dagger_{\dot\beta}$, again suppressing the coordinate arguments of the fields, which are as in eq. (29.14). We distinguish between the undotted and dotted spinor index types because they cannot be directly contracted with each other to form a Lorentz invariant quantity.

It follows that the $(\frac{1}{2}, 0)$ and $(0, \frac{1}{2})$ representations are related by hermitian conjugation. That is, if ψ_α is a $(\frac{1}{2}, 0)$ fermion, then $(\psi_\alpha)^\dagger$ transforms as a $(0, \frac{1}{2})$ fermion. This means that we can, and will, describe all fermion degrees of freedom using only fields defined as left-handed $(\frac{1}{2}, 0)$ fermions ψ_α, and their conjugates. In combining spinors to make Lorentz tensors [as in eq. (29.40)], it is useful to regard $\psi^\dagger_{\dot\alpha}$ as a row vector, and ψ_α as a column vector, with:[9] [10]

$$\psi^\dagger_{\dot\alpha} \equiv (\psi_\alpha)^\dagger. \tag{29.19}$$

The Lorentz transformation property of $\psi^\dagger_{\dot\alpha}$ then follows from $(\psi_\alpha)^\dagger \to (\psi_\beta)^\dagger (M^\dagger)^{\dot\beta}{}_{\dot\alpha}$ [with coordinate arguments of the fields again suppressed], where $(M^\dagger)^{\dot\beta}{}_{\dot\alpha} = (M^*)_{\dot\alpha}{}^{\dot\beta}$ reflects the definition of the hermitian adjoint matrix as the complex conjugate transpose of the matrix. Again the coordinate arguments of the fields have been suppressed, and are as in eq. (29.14).

In this review, we shall employ the dotted-index notation in association with the dagger to denote hermitian conjugation, as specified in eq. (29.19). This is the notation for hermitian conjugation of spinors found in most field theory textbooks (e.g., see refs. [66, 89, 115]). However, it should be noted that many references in the supersymmetry literature (e.g., see refs. [69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 88, 87]) employ the bar notation made popular by Wess and Bagger [69] where $\overline{\psi}_{\dot\alpha} \equiv \psi^\dagger_{\dot\alpha} \equiv (\psi_\alpha)^\dagger$.

Spinors labeled with one undotted or one dotted index are sometimes called spinors of rank one [or more precisely, spinors of rank $(1, 0)$ or $(0, 1)$, respectively]. One can also define spinors of higher rank, which possess more than one spinor index, with Lorentz transformation properties that depend on the number of undotted and dotted spinor indices[16, 19, 20, 23, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 51, 53, 61, 79, 116]. In particular, for a spinor of rank (m, n) denoted by $S_{\alpha_1\alpha_2\cdots\alpha_m\dot\beta_1\dot\beta_2\cdots\dot\beta_n}$, each lowered undotted α-index transforms separately according to $M_{\alpha'_i}{}^{\alpha_i}$ in eq. (29.18) and each lowered dotted $\dot\beta$-index transforms according to $(M^*)_{\dot\beta'_i}{}^{\dot\beta_i}$.

There are two additional spin-1/2 irreducible representations of the Lorentz group, $(M^{-1})^{\mathsf{T}}$ and $(M^{-1})^\dagger$, but these are equivalent representations to the $(\frac{1}{2}, 0)$ and the $(0, \frac{1}{2})$ representations, respectively. The spinors that transform under these representations have raised spinor indices, ψ^α and $\psi^{\dagger\dot\alpha}$, with transformation laws $\psi^\alpha \to [(M^{-1})^{\mathsf{T}}]^\alpha{}_\beta \psi^\beta$ and $\psi^{\dagger\dot\alpha} \to [(M^{-1})^\dagger]^{\dot\alpha}{}_{\dot\beta}\psi^{\dagger\dot\beta}$, respectively (with coordinate arguments of the fields again suppressed). It is convenient to rewrite the transformation law for the undotted spinor as $\psi^\alpha \to \psi^\beta (M^{-1})_\beta{}^\alpha$. In combining spinors to make Lorentz

[9] In the early literature that employed the van der Waerden spinor index notation (surveyed in Section 29.1), no dagger was used in conjunction with the dotted index. The advantage to attaching the dagger to the dotted spinor field is that it permits the development of a spinor-index-free notation for Lorentz-covariant spinor products [see eqs. (29.37)–(29.41) and the accompanying text].

[10] Other conventions for the dotted spinor are possible. For example, in [75], the hermitian conjugate of ψ_α yields a spinor with a *raised* dotted index, i.e. $\psi^{\dagger\,\dot\alpha} \equiv (\psi_\alpha)^\dagger$, which the authors rewrite as $\psi^{\dagger\,\dot\alpha} = \overline{\sigma}^{\dot\alpha\beta}(\psi_\beta)^\dagger$ in an attempt to maintain the same index structure on both sides of the equation. Here, $\overline{\sigma}^0 \equiv \mathbb{1}_{2\times 2}$ [defined in eq. (29.29)] appears as a formal device. This latter convention leads to a number of complications; e.g., $(M_\alpha{}^\beta)^* \neq (M^*)_{\dot\alpha}{}^{\dot\beta}$, etc. (see [75] for further details). Although this alternative convention seems self-consistent, we have adopted the more convenient eqs. (29.19) and (29.20) in this review.

tensors [as in eq. (29.41)], it is useful to regard ψ^α as a row vector, and $\psi^{\dagger\,\dot\alpha}$ as a column vector, with:

$$\psi^{\dagger\,\dot\alpha} \equiv (\psi^\alpha)^\dagger\,. \tag{29.20}$$

The Lorentz transformation property of $\psi^{\dagger\,\dot\alpha}$ then follows from $(\psi^\alpha)^\dagger \to [(M^{-1})^\dagger]^{\dot\alpha}{}_{\dot\beta}(\psi^\beta)^\dagger$.

The spinor indices are raised and lowered with the two-index antisymmetric epsilon symbol with non-zero components,[11]

$$\epsilon^{12} = -\epsilon^{21} = \epsilon_{21} = -\epsilon_{12} = 1\,, \tag{29.21}$$

and the same set of sign conventions for the corresponding dotted spinor indices. In particular, we formally define $\epsilon^{\dot\alpha\dot\beta} \equiv (\epsilon^{\alpha\beta})^*$ and $\epsilon_{\dot\alpha\dot\beta} \equiv (\epsilon_{\alpha\beta})^*$. Viewed as a 2×2 matrix, the epsilon symbol with lowered undotted [dotted] indices is the inverse of the epsilon symbol with raised undotted [dotted] indices. Thus, consistent with eqs. (29.19) and (29.20), one can write:[12] [13]

$$\psi_\alpha = \epsilon_{\alpha\beta}\psi^\beta\,, \qquad \psi^\alpha = \epsilon^{\alpha\beta}\psi_\beta\,, \qquad \psi^\dagger_{\dot\alpha} = \epsilon_{\dot\alpha\dot\beta}\psi^{\dagger\dot\beta}\,, \qquad \psi^{\dagger\dot\alpha} = \epsilon^{\dot\alpha\dot\beta}\psi^\dagger_{\dot\beta}\,, \tag{29.22}$$

which respects Lorentz covariance due to the properties of M given in eqs. (29.103) and (29.104). The epsilon symbols $\epsilon^{\alpha\beta}$ ($\epsilon_{\alpha\beta}$) and $\epsilon^{\dot\alpha\dot\beta}$ ($\epsilon_{\dot\alpha\dot\beta}$), first introduced in this context in [1], are also called the *spinor metric tensors*, as they raise (lower) the undotted and dotted spinor indices, respectively. Note that in raising or lowering an index of a spinor quantity, *adjacent* spinor indices are summed over when multiplied on the *left* by the appropriate epsilon symbol.

The epsilon symbols can also be used to raise or lower undotted or dotted indices of spinors of higher rank. For example, for an object with two undotted indices it is natural to define

$$A^{\gamma\delta} = \epsilon^{\gamma\alpha}\epsilon^{\delta\beta}A_{\alpha\beta}\,, \qquad\qquad A_{\gamma\delta} = \epsilon_{\gamma\alpha}\epsilon_{\delta\beta}A^{\alpha\beta}\,. \tag{29.23}$$

In the special case that $A^{\alpha\beta} = \psi^\alpha\chi^\beta$ is a product of rank-one spinors, eq. (29.23) is not just natural but necessary, as it follows directly from eq. (29.22). However, in other cases there can be a different sign associated (by convention) with raising and lowering spinor indices, because of the antisymmetry of the epsilon symbols (in contrast to the symmetry of the spacetime metric used to raise and lower spacetime indices). This sign convention can be defined independently for distinct higher-rank spinors (even in the case where the higher-rank spinors possess the same index

[11] For related earlier work on the epsilon symbol and its properties, see refs. [17, 16, 19, 117]. Various subsets of the subsequent identities in this section involving commuting and anticommuting two-component spinors, as well as the ϵ symbol and the sigma matrices appear in many books and reviews (e.g., see refs. [18, 69, 70, 71, 73, 72, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 86, 88, 87, 89]) and in papers (e.g., see refs. [104, 105, 106, 107, 108, 109, 110]).

[12] In the general relativity literature (see e.g., refs. [22, 23, 38, 43, 44, 47, 53, 61, 63, 65]), the more common convention for the epsilon symbol (also adopted in refs. [19, 28, 30, 37, 46, 48, 93, 110]) is $\epsilon^{\alpha\beta} = \epsilon_{\alpha\beta}$ with $\epsilon^{12} = -\epsilon^{21} = 1$, and similarly for the epsilon symbol with dotted spinor indices. In this convention, one writes $\psi^\alpha = \epsilon^{\alpha\beta}\psi_\beta$ as above, but in contrast to eq. (29.22), $\psi_\alpha = \psi^\beta\epsilon_{\beta\alpha}$, and similarly for the corresponding equations with dotted spinor indices. That is, in raising [lowering] an index of a spinor quantity, *adjacent* spinor indices are summed over when multiplied on the left [right] by the appropriate epsilon symbol. The various identities involving the epsilon symbols given in this review must then be modified by a minus sign for every epsilon symbol with lowered spinor indices. There are some benefits for this alternative convention; e.g., the minus signs appearing in eq. (29.24) are absent. However, one must keep track of other minus signs that arise because $\epsilon_{\alpha\beta}$ is the *negative* of the inverse of $\epsilon^{\alpha\beta}$. In this review, we have adopted the convention of eq. (29.21), which is consistent with most of the supersymmetry literature.

[13] In refs. [51, 70], one finds yet another convention in which the spinor indices are raised and lowered by a two-index antisymmetric quantity, $C_{\alpha\beta} = -C^{\alpha\beta} = C_{\dot\alpha\dot\beta} = -C^{\dot\alpha\dot\beta} = \left(\begin{smallmatrix} 0 & -i \\ i & 0 \end{smallmatrix}\right)$, which play the role of the epsilon symbols. As in footnote 12, $C_{\alpha\beta}$ is the negative inverse of $C^{\alpha\beta}$ in which case $\psi^\alpha = C^{\alpha\beta}\psi_\beta$ whereas $\psi_\alpha = \psi^\beta C_{\beta\alpha}$, and similarly for the corresponding equations with dotted spinor indices. However, in this convention where C is pure imaginary, if $\psi^{\dagger\,\dot\alpha} \equiv (\psi^\alpha)^\dagger$ as in eq. (29.20), then $\psi^\dagger_{\dot\alpha} = -(\psi_\alpha)^\dagger$ in contrast to eq. (29.19). We choose not to pursue the alternative epsilon symbol conventions of footnotes 12 or 13 in this review.

structure). Indeed, as a consequence of our epsilon symbol conventions of eq. (29.21), the epsilon symbols themselves satisfy:

$$\epsilon^{\gamma\delta} = -\epsilon^{\gamma\alpha}\epsilon^{\delta\beta}\epsilon_{\alpha\beta}\,, \qquad\qquad \epsilon_{\gamma\delta} = -\epsilon_{\gamma\alpha}\epsilon_{\delta\beta}\epsilon^{\alpha\beta}\,, \tag{29.24}$$

in contrast to eq. (29.23). The above results (and similar ones with dotted indices) show that some care is required [33], since the extra overall minus signs of eq. (29.24) in comparison to eq. (29.23) might otherwise have been unexpected [e.g., see eqs. (29.42) and (29.43) below].[14] This reflects an awkwardness imposed by the epsilon symbol conventions of eq. (29.21), rather than an inconsistency. Practitioners of spinor algebra in the conventions used in this review should be wary of this sign issue when using the epsilon symbols to explicitly raise or lower two or more spinor indices of higher-rank spinors.[15] Fortunately, such manipulations are quite rare in practical calculations.

We also introduce the two-index symmetric Kronecker delta symbol,

$$\delta^1_1 = \delta^2_2 = 1\,, \qquad\qquad \delta^1_2 = \delta^1_2 = 0\,, \tag{29.25}$$

and $\delta^{\dot\beta}_{\dot\alpha} \equiv (\delta^\beta_\alpha)^*$. Eq. (29.25) implies that the numerical values of the undotted and dotted Kronecker delta symbols coincide. The epsilon symbols with undotted and with dotted indices respectively satisfy:

$$\epsilon_{\alpha\beta}\epsilon^{\gamma\delta} = -\delta^\gamma_\alpha\delta^\delta_\beta + \delta^\delta_\alpha\delta^\gamma_\beta, \qquad\qquad \epsilon_{\dot\alpha\dot\beta}\epsilon^{\dot\gamma\dot\delta} = -\delta^{\dot\gamma}_{\dot\alpha}\delta^{\dot\delta}_{\dot\beta} + \delta^{\dot\delta}_{\dot\alpha}\delta^{\dot\gamma}_{\dot\beta}\,, \tag{29.26}$$

from which it follows that:

$$\epsilon_{\alpha\beta}\epsilon^{\beta\gamma} = \epsilon^{\gamma\beta}\epsilon_{\beta\alpha} = \delta^\gamma_\alpha, \qquad\qquad \epsilon_{\dot\alpha\dot\beta}\epsilon^{\dot\beta\dot\gamma} = \epsilon^{\dot\gamma\dot\beta}\epsilon_{\dot\beta\dot\alpha} = \delta^{\dot\gamma}_{\dot\alpha}\,, \tag{29.27}$$

$$\epsilon_{\alpha\beta}\epsilon_{\gamma\delta} + \epsilon_{\alpha\gamma}\epsilon_{\delta\beta} + \epsilon_{\alpha\delta}\epsilon_{\beta\gamma} = 0\,, \qquad\qquad \epsilon_{\dot\alpha\dot\beta}\epsilon_{\dot\gamma\dot\delta} + \epsilon_{\dot\alpha\dot\gamma}\epsilon_{\dot\delta\dot\beta} + \epsilon_{\dot\alpha\dot\delta}\epsilon_{\dot\beta\dot\gamma} = 0\,. \tag{29.28}$$

In the literature, eq. (29.28) is often referred to as the Schouten identities.[16]

To construct Lorentz invariant Lagrangians and observables, one needs to first combine products of spinors to make objects that transform as Lorentz tensors. In particular, Lorentz vectors are obtained by introducing the sigma matrices $\sigma^\mu_{\alpha\dot\beta}$ and $\overline{\sigma}^{\mu\,\dot\alpha\beta}$ defined by [14, 1, 17, 18]

$$\sigma^0 = \overline{\sigma}^0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}\,, \qquad\qquad \sigma^1 = -\overline{\sigma}^1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\,,$$

$$\sigma^2 = -\overline{\sigma}^2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}\,, \qquad\qquad \sigma^3 = -\overline{\sigma}^3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\,. \tag{29.29}$$

The sigma matrices are hermitian, and have been defined above with an upper (contravariant) index. We denote the 2×2 identity matrix by $\mathbb{1}_{2\times2}$ and the three-vector of Pauli matrices by $\vec{\boldsymbol{\sigma}} \equiv (\sigma^1\,,\,\sigma^2\,,\,\sigma^3)$. Hence, eq. (29.29) is equivalent to:

$$\sigma^\mu = (\mathbb{1}_{2\times2}\,;\,\vec{\boldsymbol{\sigma}})\,, \qquad\qquad \overline{\sigma}^\mu = (\mathbb{1}_{2\times2}\,;\,-\vec{\boldsymbol{\sigma}})\,. \tag{29.30}$$

[14] It would be perhaps more transparent to simply replace the symbol $\epsilon_{\alpha\beta}$ with $\epsilon^{-1}_{\alpha\beta}$, in which case $\epsilon^{\alpha\beta}$ is used to raise spinor indices and $\epsilon^{-1}_{\alpha\beta}$ is used to lower spinor indices (cf. [39]). Although this convention avoids an apparent conflict between eqs. (29.23) and (29.24), it doubles the number of distinct epsilon symbols. We shall not adopt such an approach in this review.

[15] In the alternative convention mentioned in footnote 12, this particular awkwardness is absent; the minus signs in the analogue of eq. (29.24) do not occur, in which case the rules for raising and lowering the spinor indices in eqs. (29.23) and (29.24) are identical. More generally, in the convention of footnote 12, the indices of all higher-rank spinors can be raised [lowered] via multiplication on the left [right] by the appropriate epsilon symbol, including the epsilon symbols themselves, with no extra signs.

[16] The Schouten identities also follow from the observation that a rank-four spinor must vanish if it is antisymmetric with respect to more than two undotted or dotted two-component spinor indices.

We also define the corresponding quantities with lower (covariant) indices:

$$\sigma_\mu = g_{\mu\nu}\sigma^\nu = (\mathbb{1}_{2\times 2}\,;\,-\vec{\boldsymbol{\sigma}})\,, \qquad\qquad \overline{\sigma}_\mu = g_{\mu\nu}\overline{\sigma}^\nu = (\mathbb{1}_{2\times 2}\,;\,\vec{\boldsymbol{\sigma}})\,. \tag{29.31}$$

The relations between σ^μ and $\overline{\sigma}^\mu$ are

$$\sigma^\mu_{\alpha\dot\alpha} = \epsilon_{\alpha\beta}\epsilon_{\dot\alpha\dot\beta}\overline{\sigma}^{\mu\,\dot\beta\beta}\,, \qquad\qquad \overline{\sigma}^{\mu\,\dot\alpha\alpha} = \epsilon^{\alpha\beta}\epsilon^{\dot\alpha\dot\beta}\sigma^\mu_{\beta\dot\beta}\,, \tag{29.32}$$

$$\epsilon^{\alpha\beta}\sigma^\mu_{\beta\dot\alpha} = \epsilon_{\dot\alpha\dot\beta}\overline{\sigma}^{\mu\dot\beta\alpha}\,, \qquad\qquad \epsilon^{\dot\alpha\dot\beta}\sigma^\mu_{\alpha\dot\beta} = \epsilon_{\alpha\beta}\overline{\sigma}^{\mu\dot\alpha\beta}\,. \tag{29.33}$$

Consider a spinor of rank (n,n) denoted by $S_{\alpha_1\alpha_2\ldots\alpha_n\dot\beta_1\dot\beta_2\ldots\dot\beta_n}$. The object obtained by multiplying S by $\overline{\sigma}^{\mu_1\,\dot\beta_1\alpha_1}\cdots\overline{\sigma}^{\mu_n\,\dot\beta_n\alpha_n}$ has the transformation properties of an nth rank contravariant Lorentz tensor [29, 32, 116]. For example, there is a one-to-one correspondence between each bi-spinor $V_{\alpha\dot\beta}$ and the associated Lorentz four-vector V^μ [1, 17, 19, 20, 28, 29],[17]

$$V^\mu \equiv \tfrac{1}{2}\overline{\sigma}^{\mu\dot\beta\alpha}V_{\alpha\dot\beta}\,, \qquad\qquad V_{\alpha\dot\beta} = V^\mu\sigma_{\mu\alpha\dot\beta}\,. \tag{29.34}$$

In particular, if V^μ is a real four-vector then $V_{\alpha\dot\beta}$ is hermitian (and vice versa). To clarify this last remark, consider the bi-spinor $V_{\alpha\dot\beta}$ regarded as a 2×2 matrix. Then,[18]

$$(V^{\mathsf{T}})_{\alpha\dot\beta} \equiv V_{\beta\dot\alpha}\,, \qquad (V^*)_{\alpha\dot\beta} \equiv (V_{\alpha\dot\beta})^*\,, \qquad (V^\dagger)_{\alpha\dot\beta} \equiv (V_{\beta\dot\alpha})^*\,. \tag{29.35}$$

An hermitian bi-spinor satisfies $V = V^\dagger$, or equivalently $V_{\alpha\dot\beta} = (V_{\beta\dot\alpha})^*$.

Rank-two spinors (with two undotted or with two dotted indices) can also be interpreted as 2×2 matrices. In the case of the rank-two spinor $W_\alpha{}^\beta$, it is convenient to define:

$$(W^{\mathsf{T}})^\beta{}_\alpha \equiv W_\alpha{}^\beta\,, \qquad (W^*)_{\dot\alpha}{}^{\dot\beta} \equiv (W_\alpha{}^\beta)^*\,, \qquad (W^\dagger)^{\dot\beta}{}_{\dot\alpha} \equiv (W_\alpha{}^\beta)^* = (W^*)_{\dot\alpha}{}^{\dot\beta}\,. \tag{29.36}$$

Note that the matrix transposition of $W_\alpha{}^\beta$ interchanges the rows and columns of W without altering the relative heights of the α and β indices. Similar results hold for $W_{\alpha\beta}$ and $W^{\alpha\beta}$ by either lowering or raising the relevant spinor indices with the appropriate epsilon symbol.

When constructing Lorentz tensors from fermion fields, the heights of spinor indices must be consistent in the sense that lowered indices must only be contracted with raised indices. As a convention, *descending* contracted undotted indices and *ascending* contracted dotted indices,

$$\ {}^\alpha{}_\alpha \qquad\qquad \text{and} \qquad\qquad {}_{\dot\alpha}{}^{\dot\alpha}\,, \tag{29.37}$$

can be suppressed. In all spinor products given in this paper, contracted indices always have heights that conform to eq. (29.37). For example, in an index-free notation, we define:

$$\xi\eta \equiv \xi^\alpha\eta_\alpha, \tag{29.38}$$

$$\xi^\dagger\eta^\dagger \equiv \xi^\dagger_{\dot\alpha}\eta^{\dagger\dot\alpha}, \tag{29.39}$$

$$\xi^\dagger\overline{\sigma}^\mu\eta \equiv \xi^\dagger_{\dot\alpha}\overline{\sigma}^{\mu\dot\alpha\beta}\eta_\beta, \tag{29.40}$$

$$\xi\sigma^\mu\eta^\dagger \equiv \xi^\alpha\sigma^\mu_{\alpha\dot\beta}\eta^{\dagger\dot\beta}. \tag{29.41}$$

[17] In the general relativity literature [43, 47, 61, 93], the more common normalization is $V^\mu \equiv \frac{1}{\sqrt{2}}\overline{\sigma}^{\mu\dot\beta\alpha}V_{\alpha\dot\beta}$, which yields $V_{\alpha\dot\beta} = \frac{1}{\sqrt{2}}V^\mu\sigma_{\mu\alpha\dot\beta}$. In this context, the $\frac{1}{\sqrt{2}}\sigma^\mu_{\alpha\dot\beta}$ are often called the Infeld-van der Waerden symbols.

[18] As stressed in [19], taking the transpose of $V_{\alpha\dot\beta}$ interchanges its rows and columns without altering the fact that the first spinor index is undotted and the second spinor index is dotted. Moreover, it is often useful to further simplify the notation by *defining* $V_{\dot\alpha\beta} \equiv (V_{\alpha\dot\beta})^*$. In this notation, an hermitian bi-spinor satisfies $V_{\alpha\dot\beta} = V_{\dot\beta\alpha}$.

All the spinor-index-contracted products above have natural interpretations as products of matrices and vectors by regarding η_α and $\eta^{\dagger\dot\alpha}$ as column vectors and $\xi^\dagger_{\dot\alpha}$ and ξ^α as row vectors of the two-dimensional spinor space. However, the reader is cautioned that in the index-free notation (with undotted and dotted indices suppressed), the undaggered and daggered spinors cannot be uniquely identified as column or row vectors until their locations within the spinor product are specified. Nevertheless, the proper identifications are straightforward, as any spinor on the left end of a spinor product can be identified as a row vector and any spinor on the right end of a spinor product can be identified as a column vector.

For an *anticommuting* two-component spinor ψ, the product $\psi^\alpha\psi^\beta$ is antisymmetric with respect to the interchange of the spinor indices α and β. Hence, this product of spinors must be proportional to $\epsilon^{\alpha\beta}$. Similar conclusions hold for the corresponding spinor products with raised undotted indices and with lowered and raised dotted indices, respectively. Thus,

$$\psi^\alpha\psi^\beta = -\tfrac{1}{2}\epsilon^{\alpha\beta}\psi\psi\,, \qquad \psi_\alpha\psi_\beta = \tfrac{1}{2}\epsilon_{\alpha\beta}\psi\psi\,, \tag{29.42}$$

$$\psi^{\dagger\,\dot\alpha}\psi^{\dagger\,\dot\beta} = \tfrac{1}{2}\epsilon^{\dot\alpha\dot\beta}\psi^\dagger\psi^\dagger\,, \qquad \psi^\dagger_{\dot\alpha}\psi^\dagger_{\dot\beta} = -\tfrac{1}{2}\epsilon_{\dot\alpha\dot\beta}\psi^\dagger\psi^\dagger\,, \tag{29.43}$$

where $\psi\psi \equiv \psi^\alpha\psi_\alpha$ and $\psi^\dagger\psi^\dagger \equiv \psi^\dagger_{\dot\alpha}\psi^{\dagger\,\dot\alpha}$ as in eqs. (29.38) and (29.39). Note that the minus signs above can be understood to be a consequence of the extra minus sign that arises when the indices of the epsilon symbol are lowered or raised [cf. eqs. (29.23) and (29.24)].

The behavior of the spinor products under hermitian conjugation (for quantum field operators) or complex conjugation (for classical fields) is as follows:

$$(\xi\eta)^\dagger = \eta^\dagger\xi^\dagger\,, \tag{29.44}$$

$$(\xi\sigma^\mu\eta^\dagger)^\dagger = \eta\sigma^\mu\xi^\dagger, \tag{29.45}$$

$$(\xi^\dagger\overline{\sigma}^\mu\eta)^\dagger = \eta^\dagger\overline{\sigma}^\mu\xi, \tag{29.46}$$

$$(\xi\sigma^\mu\overline{\sigma}^\nu\eta)^\dagger = \eta^\dagger\overline{\sigma}^\nu\sigma^\mu\xi^\dagger\,, \tag{29.47}$$

where we have used the hermiticity properties, $(\sigma^\mu)^\dagger = \sigma^\mu$ and $(\overline{\sigma}^\mu)^\dagger = \overline{\sigma}^\mu$. More generally,

$$(\xi\Sigma\eta)^\dagger = \eta^\dagger\Sigma_r\xi^\dagger\,, \qquad (\xi\Sigma\eta^\dagger)^\dagger = \eta\Sigma_r\xi^\dagger\,, \qquad (\xi^\dagger\Sigma\eta)^\dagger = \eta^\dagger\Sigma_r\xi\,, \tag{29.48}$$

where in each case Σ stands for any sequence of alternating σ and $\overline{\sigma}$ matrices, and Σ_r is obtained from Σ by reversing the order of all of the σ and $\overline{\sigma}$ matrices, since the sigma matrices are hermitian. Eqs. (29.44)–(29.48) are applicable both to anticommuting and to commuting spinors.

The properties of the two-component spinor fields under the discrete C, P and T transformations are elucidated in refs. [40, 118]. The corresponding behaviors of the spinor products under C, P and T are easily obtained (and are left as an exercise for the reader).

The following identities can be used to systematically simplify expressions involving products of σ and $\overline{\sigma}$ matrices:[19]

$$\sigma^\mu_{\alpha\dot\alpha}\overline{\sigma}^{\dot\beta\beta}_\mu = 2\delta_\alpha{}^\beta\delta^{\dot\beta}{}_{\dot\alpha}\,, \tag{29.49}$$

$$\sigma^\mu_{\alpha\dot\alpha}\sigma_{\mu\beta\dot\beta} = 2\epsilon_{\alpha\beta}\epsilon_{\dot\alpha\dot\beta}\,, \tag{29.50}$$

$$\overline{\sigma}^{\mu\dot\alpha\alpha}\overline{\sigma}^{\dot\beta\beta}_\mu = 2\epsilon^{\alpha\beta}\epsilon^{\dot\alpha\dot\beta}\,, \tag{29.51}$$

$$[\sigma^\mu\overline{\sigma}^\nu + \sigma^\nu\overline{\sigma}^\mu]_\alpha{}^\beta = 2g^{\mu\nu}\delta_\alpha{}^\beta\,, \tag{29.52}$$

$$[\overline{\sigma}^\mu\sigma^\nu + \overline{\sigma}^\nu\sigma^\mu]^{\dot\alpha}{}_{\dot\beta} = 2g^{\mu\nu}\delta^{\dot\alpha}{}_{\dot\beta}\,, \tag{29.53}$$

[19] Since the Kronecker delta symbol is symmetric under the interchange of its two indices, naively there is nothing gained in writing $\delta_\alpha{}^\beta$ and $\delta^{\dot\beta}{}_{\dot\alpha}$, with the spinor indices staggered as shown, instead of δ^β_α and $\delta^{\dot\beta}_{\dot\alpha}$, respectively. Nevertheless, we often prefer to employ the former rather than the latter as it provides some insight into the spinor index structure of the equation. For example, in eq. (29.52), α labels the row and β labels the column of the product of sigma matrices. Neither $\sigma^\mu\overline{\sigma}^\nu$ nor $\sigma^\nu\overline{\sigma}^\mu$ is symmetric under the interchange of the (suppressed) spinor indices (although the sum of the two is symmetric). By writing $\delta_\alpha{}^\beta$ on the right-hand side of eq. (29.52), one formally maintains the index structure of each of the separate terms of the equation.

In the literature, one sometimes sees eqs. (29.50) and (29.51) rewritten using the identity $\epsilon_{ab}\epsilon_{cd} = \delta_{ac}\delta_{bd} - \delta_{ad}\delta_{bc}$. However, as this latter result does not formally respect covariance with respect to the dotted and undotted indices, we shall not make use of it here. Products of three or more sigma matrices can be reduced to sums of terms involving at most two sigma matrices by employing the identities,

$$\sigma^\mu\overline{\sigma}^\nu\sigma^\rho = g^{\mu\nu}\sigma^\rho - g^{\mu\rho}\sigma^\nu + g^{\nu\rho}\sigma^\mu + i\epsilon^{\mu\nu\rho\kappa}\sigma_\kappa\,, \tag{29.54}$$
$$\overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho = g^{\mu\nu}\overline{\sigma}^\rho - g^{\mu\rho}\overline{\sigma}^\nu + g^{\nu\rho}\overline{\sigma}^\mu - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa\,. \tag{29.55}$$

Computations of cross-sections and decay rates generally require traces of alternating products of σ and $\overline{\sigma}$ matrices (e.g., see [105]):

$$\mathrm{Tr}[\sigma^\mu\overline{\sigma}^\nu] = \mathrm{Tr}[\overline{\sigma}^\mu\sigma^\nu] = 2g^{\mu\nu}\,, \tag{29.56}$$
$$\mathrm{Tr}[\sigma^\mu\overline{\sigma}^\nu\sigma^\rho\overline{\sigma}^\kappa] = 2\left(g^{\mu\nu}g^{\rho\kappa} - g^{\mu\rho}g^{\nu\kappa} + g^{\mu\kappa}g^{\nu\rho} + i\epsilon^{\mu\nu\rho\kappa}\right)\,, \tag{29.57}$$
$$\mathrm{Tr}[\overline{\sigma}^\mu\sigma^\nu\overline{\sigma}^\rho\sigma^\kappa] = 2\left(g^{\mu\nu}g^{\rho\kappa} - g^{\mu\rho}g^{\nu\kappa} + g^{\mu\kappa}g^{\nu\rho} - i\epsilon^{\mu\nu\rho\kappa}\right)\,. \tag{29.58}$$

Traces involving a larger even number of σ and $\overline{\sigma}$ matrices can be systematically obtained from eqs. (29.56)–(29.58) by repeated use of eqs. (29.52) and (29.53) and the cyclic property of the trace. Traces involving an odd number of σ and $\overline{\sigma}$ matrices cannot arise, since there is no way to connect the spinor indices consistently.

In addition to manipulating expressions containing anticommuting fermion quantum fields, we often must deal with products of *commuting* spinor wave functions that arise when evaluating the Feynman rules. In the following expressions we denote the generic spinor by z_i. In the various identities listed below, an extra minus sign arises when interchanging the order of two anticommuting fermion fields of a given spinor index height. It is convenient to introduce the notation:

$$(-1)^A \equiv \begin{cases} +1\,, & \text{commuting spinors,} \\ -1\,, & \text{anticommuting spinors.} \end{cases} \tag{29.59}$$

The following identities hold for the z_i:

$$z_1 z_2 = -(-1)^A z_2 z_1\,, \tag{29.60}$$
$$z_1^\dagger z_2^\dagger = -(-1)^A z_2^\dagger z_1^\dagger\,, \tag{29.61}$$
$$z_1\sigma^\mu z_2^\dagger = (-1)^A z_2^\dagger\overline{\sigma}^\mu z_1\,, \tag{29.62}$$
$$z_1\sigma^\mu\overline{\sigma}^\nu z_2 = -(-1)^A z_2\sigma^\nu\overline{\sigma}^\mu z_1\,, \tag{29.63}$$
$$z_1^\dagger\overline{\sigma}^\mu\sigma^\nu z_2^\dagger = -(-1)^A z_2^\dagger\overline{\sigma}^\nu\sigma^\mu z_1^\dagger\,, \tag{29.64}$$
$$z_1^\dagger\overline{\sigma}^\mu\sigma^\rho\overline{\sigma}^\nu z_2 = (-1)^A z_2\sigma^\nu\overline{\sigma}^\rho\sigma^\mu z_1^\dagger\,, \tag{29.65}$$

and so on.[20] The hermiticity properties of the spinor products given in eqs. (29.44)–(29.48) hold for both commuting and anticommuting spinors, with no additional sign factor.

Two-component spinor products can often be simplified by using Fierz identities. Due to the antisymmetry of the suppressed two-index epsilon symbol [or equivalently, using the Schouten identities given in eq. (29.28)], the following identities are obtained:

$$(z_1 z_2)(z_3 z_4) = -(z_1 z_3)(z_4 z_2) - (z_1 z_4)(z_2 z_3)\,, \tag{29.66}$$
$$(z_1^\dagger z_2^\dagger)(z_3^\dagger z_4^\dagger) = -(z_1^\dagger z_3^\dagger)(z_4^\dagger z_2^\dagger) - (z_1^\dagger z_4^\dagger)(z_2^\dagger z_3^\dagger)\,, \tag{29.67}$$

where we have used eqs. (29.60) and (29.61) to eliminate any residual factors of $(-1)^A$. Similarly, eqs. (29.49)–(29.51) can be used to derive additional Fierz identities,

$$(z_1\sigma^\mu z_2^\dagger)(z_3^\dagger\overline{\sigma}_\mu z_4) = -2(z_1 z_4)(z_2^\dagger z_3^\dagger)\,, \tag{29.68}$$
$$(z_1^\dagger\overline{\sigma}^\mu z_2)(z_3^\dagger\overline{\sigma}_\mu z_4) = 2(z_1^\dagger z_3^\dagger)(z_4 z_2)\,, \tag{29.69}$$

$$(z_1\sigma^\mu z_2^\dagger)(z_3\sigma_\mu z_4^\dagger) = 2(z_1 z_3)(z_4^\dagger z_2^\dagger)\,. \tag{29.70}$$

[20] In particular, if z is a *commuting* spinor, then $zz = z^\dagger z^\dagger = 0$, as emphasized in refs. [16, 19].

Having eliminated all factors of $(-1)^A$, eqs. (29.66)–(29.70) hold for both commuting and anti-commuting spinors.

From the sigma matrices, one can construct the antisymmetrized products:[21]

$$(\sigma^{\mu\nu})_\alpha{}^\beta \equiv \frac{i}{4}\left(\sigma^\mu_{\alpha\dot\gamma}\overline{\sigma}^{\nu\dot\gamma\beta} - \sigma^\nu_{\alpha\dot\gamma}\overline{\sigma}^{\mu\dot\gamma\beta}\right)\,, \tag{29.71}$$

$$(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\beta} \equiv \frac{i}{4}\left(\overline{\sigma}^{\mu\dot\alpha\gamma}\sigma^\nu_{\gamma\dot\beta} - \overline{\sigma}^{\nu\dot\alpha\gamma}\sigma^\mu_{\gamma\dot\beta}\right)\,. \tag{29.72}$$

Equivalently, we can use eqs. (29.52) and (29.53) to write:

$$(\sigma^\mu\overline{\sigma}^\nu)_\alpha{}^\beta = g^{\mu\nu}\delta_\alpha{}^\beta - 2i(\sigma^{\mu\nu})_\alpha{}^\beta\,, \tag{29.73}$$

$$(\overline{\sigma}^\mu\sigma^\nu)^{\dot\alpha}{}_{\dot\beta} = g^{\mu\nu}\delta^{\dot\alpha}{}_{\dot\beta} - 2i(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\beta}\,. \tag{29.74}$$

The components of $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$ are easily evaluated:

$$\sigma^{ij} = \overline{\sigma}^{ij} = \tfrac{1}{2}\epsilon^{ijk}\sigma^k\,, \qquad \sigma^{i0} = -\sigma^{0i} = -\overline{\sigma}^{i0} = \overline{\sigma}^{0i} = \tfrac{1}{2}i\sigma^i\,. \tag{29.75}$$

The matrices $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$ satisfy self-duality relations,

$$\sigma^{\mu\nu} = -\tfrac{1}{2}i\epsilon^{\mu\nu\rho\kappa}\sigma_{\rho\kappa}\,, \qquad \overline{\sigma}^{\mu\nu} = \tfrac{1}{2}i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_{\rho\kappa}\,. \tag{29.76}$$

The self-duality relations can be used to obtain the following two identities:

$$g^{\kappa\rho}\sigma^{\mu\nu} - g^{\nu\rho}\sigma^{\mu\kappa} + g^{\mu\rho}\sigma^{\nu\kappa} - i\epsilon^{\mu\nu\kappa}{}_\lambda\sigma^{\lambda\rho} = 0\,, \tag{29.77}$$

$$g^{\kappa\rho}\overline{\sigma}^{\mu\nu} - g^{\nu\rho}\overline{\sigma}^{\mu\kappa} + g^{\mu\rho}\overline{\sigma}^{\nu\kappa} + i\epsilon^{\mu\nu\kappa}{}_\lambda\overline{\sigma}^{\lambda\rho} = 0\,. \tag{29.78}$$

A number of useful properties and identities involving $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$ can be derived. For example, eq. (29.26) implies that:

$$(\sigma^{\mu\nu})_\alpha{}^\beta = \epsilon_{\alpha\tau}\epsilon^{\beta\gamma}(\sigma^{\mu\nu})_\gamma{}^\tau\,, \qquad (\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\beta} = \epsilon^{\dot\alpha\dot\tau}\epsilon_{\dot\beta\dot\gamma}(\overline{\sigma}^{\mu\nu})^{\dot\gamma}{}_{\dot\tau}\,, \tag{29.79}$$

$$\epsilon^{\tau\alpha}(\sigma^{\mu\nu})_\alpha{}^\beta = \epsilon^{\beta\gamma}(\sigma^{\mu\nu})_\gamma{}^\tau\,, \qquad \epsilon_{\dot\tau\dot\alpha}(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\beta} = \epsilon_{\dot\beta\dot\gamma}(\overline{\sigma}^{\mu\nu})^{\dot\gamma}{}_{\dot\tau}\,, \tag{29.80}$$

$$\epsilon_{\gamma\beta}(\sigma^{\mu\nu})_\alpha{}^\beta = \epsilon_{\alpha\tau}(\sigma^{\mu\nu})_\gamma{}^\tau\,, \qquad \epsilon^{\dot\gamma\dot\beta}(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\beta} = \epsilon^{\dot\alpha\dot\tau}(\overline{\sigma}^{\mu\nu})^{\dot\gamma}{}_{\dot\tau}\,. \tag{29.81}$$

Using eqs. (29.49)–(29.55), the following identities can be obtained:

$$(\sigma^{\mu\nu})_\alpha{}^\beta(\sigma_{\mu\nu})_\gamma{}^\tau = \epsilon_{\alpha\gamma}\,\epsilon^{\beta\tau} + \delta_\alpha{}^\tau\delta_\gamma{}^\beta = 2\delta_\alpha{}^\tau\delta_\gamma{}^\beta - \delta_\alpha{}^\beta\delta_\gamma{}^\tau\,, \tag{29.82}$$

$$(\overline{\sigma}^{\mu\nu})^{\dot\alpha}{}_{\dot\beta}(\overline{\sigma}_{\mu\nu})^{\dot\gamma}{}_{\dot\tau} = \epsilon^{\dot\alpha\dot\gamma}\,\epsilon_{\dot\beta\dot\tau} + \delta^{\dot\alpha}{}_{\dot\tau}\,\delta^{\dot\gamma}{}_{\dot\beta} = 2\delta^{\dot\alpha}{}_{\dot\tau}\,\delta^{\dot\gamma}{}_{\dot\beta} - \delta^{\dot\alpha}{}_{\dot\beta}\,\delta^{\dot\gamma}{}_{\dot\tau}\,, \tag{29.83}$$

$$(\sigma^{\mu\nu})_\alpha{}^\beta(\overline{\sigma}_{\mu\nu})^{\dot\gamma}{}_{\dot\tau} = 0\,, \tag{29.84}$$

$$\sigma^{\mu\nu}\sigma^\rho = \tfrac{1}{2}i\left(g^{\nu\rho}\sigma^\mu - g^{\mu\rho}\sigma^\nu + i\epsilon^{\mu\nu\rho\kappa}\sigma_\kappa\right)\,, \tag{29.85}$$

$$\overline{\sigma}^{\mu\nu}\overline{\sigma}^\rho = \tfrac{1}{2}i\left(g^{\nu\rho}\overline{\sigma}^\mu - g^{\mu\rho}\overline{\sigma}^\nu - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa\right)\,, \tag{29.86}$$

$$\overline{\sigma}^\mu\sigma^{\nu\rho} = \tfrac{1}{2}i\left(g^{\mu\nu}\overline{\sigma}^\rho - g^{\mu\rho}\overline{\sigma}^\nu - i\epsilon^{\mu\nu\rho\kappa}\overline{\sigma}_\kappa\right)\,, \tag{29.87}$$

$$\sigma^\mu\overline{\sigma}^{\nu\rho} = \tfrac{1}{2}i\left(g^{\mu\nu}\sigma^\rho - g^{\mu\rho}\sigma^\nu + i\epsilon^{\mu\nu\rho\kappa}\sigma_\kappa\right)\,, \tag{29.88}$$

$$\sigma^{\mu\nu}\sigma^{\rho\kappa} = -\tfrac{1}{4}\left(g^{\nu\rho}g^{\mu\kappa} - g^{\mu\rho}g^{\nu\kappa} + i\epsilon^{\mu\nu\rho\kappa}\right) + \tfrac{1}{2}i\left(g^{\nu\rho}\sigma^{\mu\kappa} + g^{\mu\kappa}\sigma^{\nu\rho} - g^{\mu\rho}\sigma^{\nu\kappa} - g^{\nu\kappa}\sigma^{\mu\rho}\right)\,, \tag{29.89}$$

$$\overline{\sigma}^{\mu\nu}\overline{\sigma}^{\rho\kappa} = -\tfrac{1}{4}\left(g^{\nu\rho}g^{\mu\kappa} - g^{\mu\rho}g^{\nu\kappa} - i\epsilon^{\mu\nu\rho\kappa}\right) + \tfrac{1}{2}i\left(g^{\nu\rho}\overline{\sigma}^{\mu\kappa} + g^{\mu\kappa}\overline{\sigma}^{\nu\rho} - g^{\mu\rho}\overline{\sigma}^{\nu\kappa} - g^{\nu\kappa}\overline{\sigma}^{\mu\rho}\right)\,. \tag{29.90}$$

[21] The reader is cautioned that $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$ are sometimes defined in the literature without the factor of i in eqs. (29.71) and (29.72) (as in [78]), or with an overall factor of $\frac{1}{2}i$ (as in [72]) instead of $\frac{1}{4}i$.

Eqs. (29.89) and (29.90) and the antisymmetry of $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$ yield the following trace formulae:

$$\mathrm{Tr}\ \sigma^{\mu\nu} = \mathrm{Tr}\ \overline{\sigma}^{\mu\nu} = 0\,, \tag{29.91}$$

$$\mathrm{Tr}[\sigma^{\mu\nu}\sigma^{\rho\kappa}] = \tfrac{1}{2}\left[g^{\mu\rho}g^{\nu\kappa} - g^{\mu\kappa}g^{\nu\rho} - i\epsilon^{\mu\nu\rho\kappa}\right]\,, \tag{29.92}$$

$$\mathrm{Tr}[\overline{\sigma}^{\mu\nu}\overline{\sigma}^{\rho\kappa}] = \tfrac{1}{2}\left[g^{\mu\rho}g^{\nu\kappa} - g^{\mu\kappa}g^{\nu\rho} + i\epsilon^{\mu\nu\rho\kappa}\right]\,. \tag{29.93}$$

The properties of spinor products involving $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$ are easily derived. Under hermitian conjugation (for quantum field operators) or complex conjugation (for classical fields),

$$(\xi\sigma^{\mu\nu}\eta)^\dagger = \eta^\dagger\overline{\sigma}^{\mu\nu}\xi^\dagger\,, \tag{29.94}$$

due to the hermiticity relation, $(\sigma^{\mu\nu})^\dagger = \overline{\sigma}^{\mu\nu}$. Next, we use eqs. (29.63) and (29.64) to obtain:

$$z_1\sigma^{\mu\nu}z_2 = (-1)^A z_2\sigma^{\mu\nu}z_1\,, \tag{29.95}$$

$$z_1^\dagger\overline{\sigma}^{\mu\nu}z_2^\dagger = (-1)^A z_2^\dagger\overline{\sigma}^{\mu\nu}z_1^\dagger\,. \tag{29.96}$$

One can also derive additional Fierz identities, which follow from eqs. (29.82)–(29.84),

$$(z_1\sigma^{\mu\nu}z_2)(z_3\sigma_{\mu\nu}z_4) = -2(z_1z_4)(z_2z_3) - (z_1z_2)(z_3z_4)\,, \tag{29.97}$$

$$(z_1^\dagger\overline{\sigma}^{\mu\nu}z_2^\dagger)(z_3^\dagger\overline{\sigma}_{\mu\nu}z_4^\dagger) = -2(z_1^\dagger z_4^\dagger)(z_2^\dagger z_3^\dagger) - (z_1^\dagger z_2^\dagger)(z_3^\dagger z_4^\dagger)\,, \tag{29.98}$$

$$(z_1\sigma^{\mu\nu}z_2)(z_3^\dagger\overline{\sigma}_{\mu\nu}z_4^\dagger) = 0\,, \tag{29.99}$$

where we have again used eqs. (29.60) and (29.61) to eliminate any residual factors of $(-1)^A$. Thus, eqs. (29.97)–(29.99) hold for both commuting and anticommuting spinors. A more comprehensive list of sigma matrix identities and their associated Fierz identities are given in Appendix B.1 (see also Appendix B of [78]).

The $\sigma^{\mu\nu}$ and $\overline{\sigma}^{\mu\nu}$ satisfy the commutation relations of the $J^{\mu\nu}$ [cf. eq. (29.16)], and thus can be identified as the generators of the Lorentz group in the $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ representations, respectively. That is, for the $(\frac{1}{2},0)$ representation with a lowered undotted index (e.g. ψ_α), $J^{\mu\nu} = \sigma^{\mu\nu}$, while for the $(0,\frac{1}{2})$ representation with a raised dotted index (e.g. $\psi^{\dagger\dot\alpha}$), $J^{\mu\nu} = \overline{\sigma}^{\mu\nu}$. In particular, the infinitesimal forms for the 4×4 Lorentz transformation matrix Λ [cf. eq. (29.11)] and the corresponding matrices M and $(M^{-1})^\dagger$ that transform the $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ spinors, respectively, are given by:

$$\Lambda^\mu{}_\nu \simeq \delta^\mu_\nu + \theta^\mu{}_\nu\,, \tag{29.100}$$

$$M \simeq \mathbb{1}_{2\times 2} - \tfrac{1}{2}i\theta_{\mu\nu}\sigma^{\mu\nu}\,, \tag{29.101}$$

$$(M^{-1})^\dagger \simeq \mathbb{1}_{2\times 2} - \tfrac{1}{2}i\theta_{\mu\nu}\overline{\sigma}^{\mu\nu}\,. \tag{29.102}$$

The inverses of these quantities are obtained (to first order in θ) by replacing $\theta\to-\theta$ in the above formulae. Using eqs. (29.79), (29.101) and (29.102), it follows that:

$$(M^{-1})_\gamma{}^\tau = \epsilon^{\tau\alpha}M_\alpha{}^\beta\epsilon_{\beta\gamma}\,, \tag{29.103}$$

$$(M^{-1\,\dagger})^{\dot\gamma}{}_{\dot\tau} = \epsilon_{\dot\tau\dot\alpha}\,(M^\dagger)^{\dot\alpha}{}_{\dot\beta}\,\epsilon^{\dot\beta\dot\gamma}\,. \tag{29.104}$$

These results can be used to demonstrate the covariance (with respect to Lorentz transformations) of the spinor index raising and lowering properties of the epsilon symbols defined in eq. (29.22). The infinitesimal forms given by eqs. (29.100)–(29.102) can also be used [with the assistance of eqs. (29.85)–(29.87)] to establish the following two results:

$$M^\dagger\overline{\sigma}^\mu M = \Lambda^\mu{}_\nu\,\overline{\sigma}^\nu\,, \tag{29.105}$$

$$M^{-1}\sigma^\mu(M^{-1})^\dagger = \Lambda^\mu{}_\nu\,\sigma^\nu\,. \tag{29.106}$$

Using the Lorentz transformation properties of the undotted and dotted two-component spinor fields, eqs. (29.105) and (29.106) can be used, respectively, to prove that the spinor products $\xi^\dagger\overline{\sigma}^\mu\eta$ and $\xi\sigma^\mu\eta^\dagger$ transform as Lorentz four-vectors.

As an example, consider a pure boost from the rest frame to a frame where $p^\mu = (E_{\boldsymbol{p}}\,, \vec{\boldsymbol{p}})$, which corresponds to $\theta_{ij} = 0$ and $\zeta^i = \theta^{i0} = -\theta^{0i}$. We assume that the mass-shell condition is satisfied, i.e. $p^0 = E_{\vec{\boldsymbol{p}}} \equiv (|\vec{\boldsymbol{p}}|^2 + m^2)^{1/2}$. The matrices $M_\alpha{}^\beta$ and $[(M^{-1})^\dagger]^{\dot\alpha}{}_{\dot\beta}$ that govern the Lorentz transformations of spinor fields with a lowered undotted index and spinor fields with a raised dotted index, respectively, are given by:

$$\exp\left(-\tfrac{1}{2}i\theta_{\mu\nu}J^{\mu\nu}\right) = \begin{cases} M = \exp\left(-\tfrac{1}{2}\vec{\boldsymbol{\zeta}}\cdot\vec{\boldsymbol{\sigma}}\right) = \sqrt{\dfrac{p\cdot\sigma}{m}}\,, & \text{for } (\tfrac{1}{2},0)\,, \\[2ex] (M^{-1})^\dagger = \exp\left(\tfrac{1}{2}\vec{\boldsymbol{\zeta}}\cdot\vec{\boldsymbol{\sigma}}\right) = \sqrt{\dfrac{p\cdot\overline{\sigma}}{m}}\,, & \text{for } (0,\tfrac{1}{2})\,, \end{cases} \tag{29.107}$$

where

$$\sqrt{p\cdot\sigma} \equiv \frac{(E_{\boldsymbol{p}} + m)\,\mathbb{1}_{2\times2} - \vec{\boldsymbol{\sigma}}\cdot\vec{\boldsymbol{p}}}{\sqrt{2(E_{\boldsymbol{p}} + m)}}\,, \tag{29.108}$$

$$\sqrt{p\cdot\overline{\sigma}} \equiv \frac{(E_{\boldsymbol{p}} + m)\,\mathbb{1}_{2\times2} + \vec{\boldsymbol{\sigma}}\cdot\vec{\boldsymbol{p}}}{\sqrt{2(E_{\boldsymbol{p}} + m)}}\,. \tag{29.109}$$

These matrix square roots are defined to be the unique non-negative definite hermitian matrices (i.e., with non-negative eigenvalues) whose squares are equal to the non-negative definite hermitian matrices $p\cdot\sigma$ and $p\cdot\overline{\sigma}$, respectively.[22]

According to eq. (29.107), the spinor index structure of $\sqrt{p\cdot\sigma}$ and $\sqrt{p\cdot\overline{\sigma}}$ corresponds to that of $M_\alpha{}^\beta$ and $[(M^{-1})^\dagger]^{\dot\alpha}{}_{\dot\beta}$, respectively. In this case, we can rewrite eqs. (29.108) and (29.109) as:

$$\left[\sqrt{p\cdot\sigma}\,\right]_\alpha{}^\beta \equiv \left[\sqrt{p\cdot\sigma\,\overline{\sigma}^0}\,\right]_\alpha{}^\beta = \frac{(p\cdot\sigma_{\alpha\dot\alpha})\overline{\sigma}^{0\,\dot\alpha\beta} + m\delta_\alpha^\beta}{\sqrt{2(E_{\boldsymbol{p}} + m)}}\,, \tag{29.110}$$

$$\left[\sqrt{p\cdot\overline{\sigma}}\,\right]^{\dot\alpha}{}_{\dot\beta} \equiv \left[\sqrt{p\cdot\overline{\sigma}\,\sigma^0}\,\right]^{\dot\alpha}{}_{\dot\beta} = \frac{(p\cdot\overline{\sigma}^{\dot\alpha\alpha})\sigma^0_{\alpha\dot\beta} + m\delta^{\dot\alpha}_{\dot\beta}}{\sqrt{2(E_{\boldsymbol{p}} + m)}}\,, \tag{29.111}$$

since $\sigma^0 = \overline{\sigma}^0 = \mathbb{1}_{2\times2}$. Using eqs. (29.54) and (29.55), one can easily verify that:

$$\left[\sqrt{p\cdot\sigma}\,\right]_\alpha{}^\gamma\left[\sqrt{p\cdot\sigma}\,\right]_\gamma{}^\beta = (p\cdot\sigma\,\overline{\sigma}^0)_\alpha{}^\beta\,, \tag{29.112}$$

$$\left[\sqrt{p\cdot\overline{\sigma}}\,\right]^{\dot\alpha}{}_{\dot\gamma}\left[\sqrt{p\cdot\overline{\sigma}}\,\right]^{\dot\gamma}{}_{\dot\beta} = (p\cdot\overline{\sigma}\,\sigma^0)^{\dot\alpha}{}_{\dot\beta}\,, \tag{29.113}$$

where implicit factors of $\overline{\sigma}^0$ and σ^0 inside the square roots of eq. (29.112) have been suppressed.

Due to the fact that $p\cdot\sigma$ and $p\cdot\overline{\sigma}$ are hermitian, we could have defined their hermitian matrix square roots by the hermitian conjugate of eq. (29.107). In this case, the spinor index structure of $\sqrt{p\cdot\sigma}$ and $\sqrt{p\cdot\overline{\sigma}}$ would correspond to that of $[(M^\dagger]^{\dot\alpha}{}_{\dot\beta}$ and $[M^{-1}]_\alpha{}^\beta$, respectively. That is, instead of eqs. (29.110) and (29.111), we would now rewrite eqs. (29.108) and (29.109) in the following form:

$$\left[\sqrt{p\cdot\sigma}\,\right]^{\dot\alpha}{}_{\dot\beta} \equiv \left[\sqrt{\overline{\sigma}^0\,p\cdot\sigma}\,\right]^{\dot\alpha}{}_{\dot\beta} = \frac{\overline{\sigma}^{0\,\dot\alpha\beta}(p\cdot\sigma_{\beta\dot\beta}) + m\delta^{\dot\alpha}_{\dot\beta}}{\sqrt{2(E_{\boldsymbol{p}} + m)}}\,, \tag{29.114}$$

$$\left[\sqrt{p\cdot\overline{\sigma}}\,\right]_\alpha{}^\beta \equiv \left[\sqrt{\sigma^0\,p\cdot\overline{\sigma}}\,\right]_\alpha{}^\beta = \frac{\sigma^0_{\alpha\dot\beta}(p\cdot\overline{\sigma}^{\dot\beta\beta}) + m\delta_\alpha^\beta}{\sqrt{2(E_{\boldsymbol{p}} + m)}}\,. \tag{29.115}$$

[22] Note that $p\cdot\sigma$ and $p\cdot\overline{\sigma}$ are non-negative matrices due to the implicit mass-shell condition satisfied by p^μ.

Using eqs. (29.54) and (29.55), one can again confirm that:

$$\big[\sqrt{p\cdot\sigma}\,\big]^{\dot\alpha}{}_{\dot\gamma}\big[\sqrt{p\cdot\sigma}\,\big]^{\dot\gamma}{}_{\dot\beta} = (\overline\sigma^0\, p\cdot\sigma)^{\dot\alpha}{}_{\dot\beta}\,, \qquad \big[\sqrt{p\cdot\overline\sigma}\,\big]_{\alpha}{}^{\gamma}\big[\sqrt{p\cdot\overline\sigma}\,\big]_{\gamma}{}^{\beta} = (\sigma^0\, p\cdot\overline\sigma)_{\alpha}{}^{\beta}\,, \tag{29.116}$$

where implicit factors of $\overline\sigma^0$ and σ^0 inside the square roots of eq. (29.116) have been suppressed.

The proper choice of the spinor index structure for $\sqrt{p\cdot\sigma}$ and $\sqrt{p\cdot\overline\sigma}$ can always be determined for any covariant expression. That is, if we employ the spinor index-free notation (and suppress the factors of σ^0 and $\overline\sigma^0$), it will always be clear from the context which spinor index structure for $\sqrt{p\cdot\sigma}$ and $\sqrt{p\cdot\overline\sigma}$ is implicit.

As an example that will prove valuable later on, consider an arbitrary four-vector S^μ, defined in a reference frame where $p^\mu = (E\,;\vec{\boldsymbol{p}})$, whose rest frame value is S^μ_R, i.e.

$$S^\mu = \Lambda^\mu{}_\nu S^\nu_R\,, \qquad \text{with} \qquad \Lambda = \begin{pmatrix} E/m & p^j/m \\ p^i/m & \delta_{ij} + \dfrac{p^i p^j}{m(E+m)} \end{pmatrix}\,. \tag{29.117}$$

Then, using eqs. (29.7), (29.106) and (29.107), it follows that:

$$\sqrt{p\cdot\sigma}\, S\cdot\overline\sigma\, \sqrt{p\cdot\sigma} = mS_R\cdot\overline\sigma\,, \qquad \sqrt{p\cdot\overline\sigma}\, S\cdot\sigma\, \sqrt{p\cdot\overline\sigma} = mS_R\cdot\sigma\,. \tag{29.118}$$

The spinor index structures of eq. (29.118) are easily established:

$$\big[\sqrt{p\cdot\sigma}\,\big]^{\dot\beta}{}_{\dot\gamma}\, S\cdot\overline\sigma^{\dot\gamma\alpha}\big[\sqrt{p\cdot\sigma}\,\big]_{\alpha}{}^{\beta} = mS_R\cdot\overline\sigma^{\dot\beta\beta}\,, \tag{29.119}$$

$$\big[\sqrt{p\cdot\overline\sigma}\,\big]_{\beta}{}^{\gamma}\, S\cdot\sigma_{\gamma\dot\alpha}\big[\sqrt{p\cdot\overline\sigma}\,\big]^{\dot\alpha}{}_{\dot\beta} = mS_R\cdot\sigma_{\beta\dot\beta}\,. \tag{29.120}$$

Using eqs. (29.110)–(29.117) and (29.54)–(29.55), one can directly verify the above results.

The two-component spinor formalism established in this section will be applied to the quantum field theory of fermions in Minkowski space of one time and three space dimensions in this review. We also direct the reader's attention to Appendices G.1 and G.2, which provide details of the correspondence between the two-component and four-component spinor notation.

For certain applications, the spinor formalism in four-dimensional Minkowski space is not sufficient. For example, in order to obtain instanton solutions [119, 120, 121], it is necessary to formulate quantum field theory in Euclidean space. One also needs the Euclidean space formalism for a rigorous definition of the path integral [122, 123]. The Green functions derived from the Euclidean path integral can be related to the Green functions of the Minkowski space theory by a Wick rotation [124]. In addition, to evaluate the loop-corrected Green functions of the theory, it is often most convenient to apply a regularization scheme that involves dimensional continuation away from $d = 4$ spacetime dimensions [125]. Thus, we also need to generalize the spinor results of this section to $d \neq 4$.

The treatment of fermions in Euclidean space is subtle [126, 127, 128, 129]. Here, we focus briefly on the mathematics of fermions in $d = 4$ Euclidean dimensions, where the relevant spacetime symmetry group is SO(4) rather than SO(3,1). The two-dimensional representations of SO(3,1)$\cong$SL(2,$\mathbb{C}$), denoted in this section by $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$, respectively, are complex representations that are related by hermitian conjugation. In contrast, the two-dimensional representations of SO(4)$\cong$SU(2)$\times$SU(2), also denoted by $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$, respectively,[23] are independent pseudo-real representations, i.e. *not* related by hermitian conjugation. A two-component spinor notation can be formulated for fields that transform respectively under the $(\frac{1}{2},0)$ and $(0,\frac{1}{2})$ representations of SO(4). Details can be found in refs. [120, 130, 131].

[23] These SO(4) representations transform as a doublet under one of the SU(2) groups and as a singlet under the other SU(2) group.

In Feynman diagram calculations, one can adopt the standard procedure for the Wick rotation in order to evaluate the loop integrals in Euclidean space. We shall employ the standard Euclidean metric $\delta^{\mu\nu}$ in computing scalar products of four-vectors. Moreover, one can define Euclidean sigma matrices, $\sigma_E^\mu = (-i\vec{\boldsymbol{\sigma}}\,, \sigma_E^4)$ and $\overline{\sigma}_E^\mu = (i\vec{\boldsymbol{\sigma}}\,, \overline{\sigma}_E^4)$, where $\sigma_E^4 = \overline{\sigma}_E^4 \equiv \mathbb{1}_{2\times 2}$. In this convention, the Wick-rotated versions of eqs. (29.52)–(29.58) are preserved [after making the replacements $g^{\mu\nu} \to \delta^{\mu\nu}$ and $i\epsilon^{ijk0} \to \epsilon^{ijk4}$, with $\epsilon^{1234} = \epsilon_{1234} = +1$].[24] Further details of our Euclidean space conventions are provided at the end of Appendix A.

The generalization of the spinor results of this section to $d \neq 4$, useful for dimensional continuation regularization schemes, is discussed in Appendix B.2 . In particular, the identities of Appendix B.1 used to derive Fierz identities [cf. eqs. (29.66)–(29.70) and (29.97)–(29.99)] and any identities involving the four-dimensional Levi-Civita ϵ-tensor are not valid unless μ is a Lorentz vector index in exactly four dimensions. In our treatment of two-component spinor identities in $d \neq 4$ dimensions given in Appendix B.2 , we take the Lorentz vector indices to formally run over d values, whereas the undotted and dotted spinor indices continue to take on two possible values. This is sufficient when used as a regularization procedure for divergent integrals that arise in loop computations. However in generic d-dimensional field theories where d is an integer greater than 4, the two-component spinor formalism of this review is no longer applicable. Suitable methods for treating spinors in diverse spacetime dimensions and signatures [132, 91, 133, 134, 135, 136, 137, 138, 139, 140, 92, 141, 142, 143, 144] are briefly presented in Appendix G.3 .

29.3 Properties of fermion fields

In this review, we refer to spin-1/2 particles as Majorana or Dirac fermions depending on the nature of the global symmetry[25] that governs the fermion Lagrangian and dictates the form of the fermion mass terms. A *Majorana fermion* is a two-component massive field that is completely neutral (i.e. a singlet with respect to the symmetry group) or transforms as a non-trivial real representation of the symmetry group (cf. footnote 37). A *Dirac fermion* consists of a pair of two-component massive fields that are oppositely charged with respect to a conserved O(2) symmetry. As shown in Section 29.3.2, Dirac fermions arise when a multiplet of two-component fermions transforms as a complex or pseudo-real representation of the symmetry group.[26]

The case of a massless fermion is special, as the absence of mass terms leads to an enhanced global symmetry group. Each physical spin-1/2 zero-mass eigenstate is fundamentally a two-component spinor. Thus, following the standard nomenclature used for massless neutrinos, it is common to employ the term *massless Weyl fermion* to describe any massless spin-1/2 particle.[27]

29.3.1 The two-component fermion field and spinor wave functions

We begin by describing the properties of a free neutral massive anticommuting spin-1/2 field, denoted $\xi_\alpha(x)$, which transforms as $(\frac{1}{2}, 0)$ under the Lorentz group. The field ξ_α therefore describes

[24] In practical computations of one-loop matrix elements, one can carry out all the sigma matrix algebra in Minkowski space *before* Wick-rotating to Euclidean space in order to perform the loop integrals.

[25] A subgroup of the global symmetry group may be gauged (and hence promoted to a local symmetry). Degrees of freedom not associated with the gauged subgroup are typically referred to as flavor degrees of freedom.

[26] Majorana and Dirac fermions can also be described in terms of four-component Majorana and Dirac spinor fields, as in Appendix G . However, keep in mind that the terms *Majorana spinor* and *Dirac spinor* are defined strictly in the context of the four-component spinor formalism as in Appendix G.1 , or in the more general context of a d-dimensional spacetime as in Appendix G.3 .

[27] Two-component fermions are often called Weyl fermions, due to their association with the two-dimensional spinor representations of the Lorentz group introduced by Weyl in refs. [14, 15]. It is now common practice to define a Weyl spinor as the left or right-handed projection of a four-component spinor [as in eq. (G.1.9)]. Of course, there is a one-to-one correspondence between these two definitions.

a Majorana fermion [3]. The free-field Lagrangian density is [16]:

$$\mathscr{L} = i\xi^\dagger\overline{\sigma}^\mu\partial_\mu\xi - \tfrac{1}{2}m(\xi\xi + \xi^\dagger\xi^\dagger)\,. \tag{29.3.1}$$

On-shell, ξ satisfies the free-field Dirac equation [2, 14, 1, 145, 146],

$$i\overline{\sigma}^{\mu\dot\alpha\beta}\partial_\mu\xi_\beta = m\xi^{\dagger\dot\alpha}\,. \tag{29.3.2}$$

Consequently after quantization, ξ_α can be expanded in a Fourier series [145]:

$$\xi_\alpha(x) = \sum_s \int \frac{d^3\vec{\boldsymbol{p}}}{(2\pi)^{3/2}(2E_{\boldsymbol{p}})^{1/2}}\left[x_\alpha(\vec{\boldsymbol{p}},s)a(\vec{\boldsymbol{p}},s)e^{-ip\cdot x} + y_\alpha(\vec{\boldsymbol{p}},s)a^\dagger(\vec{\boldsymbol{p}},s)e^{ip\cdot x}\right]\,, \tag{29.3.3}$$

where $E_{\boldsymbol{p}} \equiv (|\vec{\boldsymbol{p}}|^2 + m^2)^{1/2}$, and the creation and annihilation operators $a^\dagger$ and a satisfy anticommutation relations:

$$\{a(\vec{\boldsymbol{p}},s),\, a^\dagger(\vec{\boldsymbol{p}}',s')\} = \delta^3(\vec{\boldsymbol{p}}-\vec{\boldsymbol{p}}')\delta_{ss'}\,, \tag{29.3.4}$$

and all other anticommutators vanish. It follows that

$$\xi^\dagger_{\dot\alpha}(x) \equiv (\xi_\alpha)^\dagger = \sum_s \int \frac{d^3\vec{\boldsymbol{p}}}{(2\pi)^{3/2}(2E_{\boldsymbol{p}})^{1/2}}\left[x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)a^\dagger(\vec{\boldsymbol{p}},s)e^{ip\cdot x} + y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)a(\vec{\boldsymbol{p}},s)e^{-ip\cdot x}\right]\,. \tag{29.3.5}$$

We employ covariant normalization of the one-particle states, i.e., we act with one creation operator on the vacuum with the following convention

$$|\vec{\boldsymbol{p}},s\rangle \equiv (2\pi)^{3/2}(2E_{\boldsymbol{p}})^{1/2}a^\dagger(\vec{\boldsymbol{p}},s)\,|0\rangle\,, \tag{29.3.6}$$

so that $\langle\vec{\boldsymbol{p}},s|\vec{\boldsymbol{p}}',s'\rangle = (2\pi)^3(2E_{\boldsymbol{p}})\delta^3(\vec{\boldsymbol{p}}-\vec{\boldsymbol{p}}')\delta_{ss'}$. Therefore,

$$\langle 0|\,\xi_\alpha(x)\,|\vec{\boldsymbol{p}},s\rangle = x_\alpha(\vec{\boldsymbol{p}},s)e^{-ip\cdot x}\,, \qquad \langle 0|\,\xi^\dagger_{\dot\alpha}(x)\,|\vec{\boldsymbol{p}},s\rangle = y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)e^{-ip\cdot x}\,, \tag{29.3.7}$$

$$\langle\vec{\boldsymbol{p}},s|\,\xi_\alpha(x)\,|0\rangle = y_\alpha(\vec{\boldsymbol{p}},s)e^{ip\cdot x}\,, \qquad \langle\vec{\boldsymbol{p}},s|\,\xi^\dagger_{\dot\alpha}(x)\,|0\rangle = x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)e^{ip\cdot x}\,. \tag{29.3.8}$$

It should be emphasized that $\xi_\alpha(x)$ is an anticommuting spinor field, whereas x_α and y_α are *commuting* two-component spinor wave functions. The anticommuting properties of the fields are carried by the creation and annihilation operators.

Applying eq. (29.3.2) to eq. (29.3.3), we find that the x_α and y_α satisfy momentum space Dirac equations. These conditions can be written down in a number of equivalent ways:

$$(p\cdot\overline{\sigma})^{\dot\alpha\beta}x_\beta = my^{\dagger\dot\alpha}\,, \qquad (p\cdot\sigma)_{\alpha\dot\beta}y^{\dagger\dot\beta} = mx_\alpha\,, \tag{29.3.9}$$

$$(p\cdot\sigma)_{\alpha\dot\beta}x^{\dagger\dot\beta} = -my_\alpha\,, \qquad (p\cdot\overline{\sigma})^{\dot\alpha\beta}y_\beta = -mx^{\dagger\dot\alpha}\,, \tag{29.3.10}$$

$$x^\alpha(p\cdot\sigma)_{\alpha\dot\beta} = -my^\dagger_{\dot\beta}\,, \qquad y^\dagger_{\dot\alpha}(p\cdot\overline{\sigma})^{\dot\alpha\beta} = -mx^\beta\,, \tag{29.3.11}$$

$$x^\dagger_{\dot\alpha}(p\cdot\overline{\sigma})^{\dot\alpha\beta} = my^\beta\,, \qquad y^\alpha(p\cdot\sigma)_{\alpha\dot\beta} = mx^\dagger_{\dot\beta}\,. \tag{29.3.12}$$

Using the identities $[(p\cdot\sigma)(p\cdot\overline{\sigma})]_\alpha{}^\beta = p^2\,\delta_\alpha{}^\beta$ and $[(p\cdot\overline{\sigma})(p\cdot\sigma)]^{\dot\alpha}{}_{\dot\beta} = p^2\,\delta^{\dot\alpha}{}_{\dot\beta}$, one can check that both x_α and y_α must satisfy the mass-shell condition, $p^2 = m^2$ (or equivalently, $p^0 = E_{\boldsymbol{p}}$). We will later see that eqs. (29.3.9)–(29.3.12) are often useful for simplifying matrix elements.

The quantum number s labels the spin or helicity of the spin-1/2 fermion. We shall examine two approaches for constructing the spin-1/2 states. In the first approach, we consider the particle in its rest frame and quantize the spin along a fixed axis specified by the unit vector $\hat{\boldsymbol{s}} \equiv (\sin\theta\cos\phi\,,\, \sin\theta\sin\phi\,,\, \cos\theta)$ with polar angle θ and azimuthal angle ϕ with respect to a fixed

z-axis.[28] The corresponding spin states will be called fixed-axis spin states. The relevant basis of two-component spinors χ_s are eigenstates of $\frac{1}{2}\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}}$, i.e.,

$$\tfrac{1}{2}\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}}\,\chi_s = s\chi_s\,, \qquad s = \pm\tfrac{1}{2}\,. \tag{29.3.13}$$

Explicit forms for the two-component spinors χ_s and their properties are given in Appendix C .

The fixed-axis spin states described above are not very convenient for particles in relativistic motion. Moreover, these states cannot be employed for massless particles since no rest frame exists. Thus, a second approach is to consider helicity states and the corresponding basis of two-component helicity spinors χ_λ that are eigenstates of $\frac{1}{2}\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{p}}$, i.e.,

$$\tfrac{1}{2}\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{p}}\,\chi_\lambda = \lambda\chi_\lambda, \qquad \lambda = \pm\tfrac{1}{2}\,. \tag{29.3.14}$$

Here $\hat{\boldsymbol{p}}$ is the unit vector in the direction of the three-momentum, with polar angle θ and azimuthal angle ϕ with respect to a fixed z-axis. That is, the two-component helicity spinors can be obtained from the fixed-axis spinors by replacing $\hat{\boldsymbol{s}}$ by $\hat{\boldsymbol{p}}$ and identifying θ and ϕ as the polar and azimuthal angles of $\hat{\boldsymbol{p}}$.

For fermions of mass $m \neq 0$, one can define a spin four-vector S^μ, which reduces to $(0;\hat{\boldsymbol{s}})$ in the rest frame. For fixed-axis spin states, the unit three-vector $\hat{\boldsymbol{s}}$ corresponds to the axis of spin quantization. In an arbitrary reference frame, the spin four-vector satisfies $S\cdot p = 0$ and $S\cdot S = -1$. Boosting from the rest frame to a frame where $p^\mu = (E\,,\,\vec{\boldsymbol{p}})$ [using eq. (29.117)] yields

$$S^\mu = \left(\frac{\vec{\boldsymbol{p}}\cdot\hat{\boldsymbol{s}}}{m}\,;\,\hat{\boldsymbol{s}} + \frac{(\vec{\boldsymbol{p}}\cdot\hat{\boldsymbol{s}})\,\vec{\boldsymbol{p}}}{m(E+m)}\right)\,. \tag{29.3.15}$$

If necessary, we shall write $S^\mu(\hat{\boldsymbol{s}})$ to emphasize the dependence of S^μ on $\hat{\boldsymbol{s}}$.

The spin four-vector for helicity states is defined by taking $\hat{\boldsymbol{s}} = \hat{\boldsymbol{p}}$. Eq. (29.3.15) then reduces to

$$S^\mu = \frac{1}{m}\,(|\vec{\boldsymbol{p}}|\,;\,E\hat{\boldsymbol{p}})\,. \tag{29.3.16}$$

In the non-relativistic limit, the spin four-vector for helicity states is $S^\mu \simeq (0\,;\,\hat{\boldsymbol{p}})$, as expected.[29] In the high energy limit ($E \gg m$), $S^\mu = p^\mu/m + \mathcal{O}(m/E)$. For a massless fermion, the spin four-vector does not exist (as there is no rest frame). Nevertheless, one can obtain consistent results by working with massive helicity states and taking the $m \to 0$ limit at the end of the computation. In this case, one can simply use $S^\mu = p^\mu/m + \mathcal{O}(m/E)$; in practical computations the final result will be well-defined in the zero mass limit. In contrast, for massive fermions at rest, the helicity state does not exist without reference to some particular boost direction as noted in footnote 29.

Using eq. (29.118) with $S^\mu_R = (0\,;\,\hat{\boldsymbol{s}})$, two important formulae are obtained:

$$\sqrt{p\cdot\sigma}\,S\cdot\overline{\sigma}\,\sqrt{p\cdot\sigma} = m\,\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}}\,, \qquad \sqrt{p\cdot\overline{\sigma}}\,S\cdot\sigma\,\sqrt{p\cdot\overline{\sigma}} = -m\,\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}}\,. \tag{29.3.17}$$

These results can also be derived directly by employing the explicit form for the spin vector S^μ [eq. (29.3.15)] and the results of eqs. (29.108) and (29.109).

The two-component spinor wave functions x and y can now be given explicitly in terms of the χ_s defined in eq. (C.1.11). First, we note that eq. (29.3.9) when evaluated in the rest frame yields $x_1 = y^{\dagger 1}$ and $x_2 = y^{\dagger 2}$. That is, as column vectors, $x_\alpha(\vec{\boldsymbol{p}} = 0) = y^{\dagger\dot{\alpha}}(\vec{\boldsymbol{p}} = 0)$ can be expressed in general as some linear combination of the χ_s ($s = \pm\frac{1}{2}$). Hence, we may choose $x_\alpha(\vec{\boldsymbol{p}} = 0, s) = y^{\dagger\dot{\alpha}}(\vec{\boldsymbol{p}} = 0, s) = \sqrt{m}\chi_s$, where the factor of $\sqrt{m}$ reflects the standard relativistic

[28] In the literature, it is a common practice to choose $\hat{\boldsymbol{s}} = \hat{\boldsymbol{z}}$. However in order to be somewhat more general, we shall not assume this convention here.

[29] Strictly speaking, $\hat{\boldsymbol{p}}$ is not defined in the rest frame. In practice, helicity states are defined in some moving frame with momentum $\vec{\boldsymbol{p}}$. The rest frame is achieved by boosting in the direction of $-\vec{\boldsymbol{p}}$.

normalization of the rest frame spin states. These wave functions can be boosted to an arbitrary frame using eq. (29.107). The resulting undotted spinor wave functions are given by:[30]

$$x_\alpha(\vec{\boldsymbol{p}},s)=\sqrt{p\cdot\sigma}\,\chi_s\,,\qquad x^\alpha(\vec{\boldsymbol{p}},s)=-2s\chi^\dagger_{-s}\sqrt{p\cdot\overline{\sigma}}\,, \tag{29.3.18}$$

$$y_\alpha(\vec{\boldsymbol{p}},s)=2s\sqrt{p\cdot\sigma}\,\chi_{-s}\,,\qquad y^\alpha(\vec{\boldsymbol{p}},s)=\chi^\dagger_s\sqrt{p\cdot\overline{\sigma}}\,, \tag{29.3.19}$$

and the dotted spinor wave functions are given by

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)=-2s\sqrt{p\cdot\overline{\sigma}}\,\chi_{-s}\,,\qquad x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)=\chi^\dagger_s\sqrt{p\cdot\sigma}\,, \tag{29.3.20}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)=\sqrt{p\cdot\overline{\sigma}}\,\chi_s\,,\qquad y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)=2s\chi^\dagger_{-s}\sqrt{p\cdot\sigma}\,, \tag{29.3.21}$$

where $\sqrt{p\cdot\sigma}$ and $\sqrt{p\cdot\overline{\sigma}}$ are defined either by eqs. (29.110) and (29.111) or by eqs. (29.114) and (29.115), respectively (as mandated by the spinor index structure). Note that eqs. (29.3.18)–(29.3.21) imply that the x and y spinors are related:

$$y(\vec{\boldsymbol{p}},s)=2sx(\vec{\boldsymbol{p}},-s)\,,\qquad y^\dagger(\vec{\boldsymbol{p}},s)=2sx^\dagger(\vec{\boldsymbol{p}},-s)\,. \tag{29.3.22}$$

The phase choices in eqs. (29.3.18)–(29.3.21) are consistent with those employed for four-component spinor wave functions [see Appendix G]. We again emphasize that in eqs. (29.3.18)–(29.3.21), one may either choose χ_s to be an eigenstate of $\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}$, where the spin is measured in the rest frame along the quantization axis $\hat{\boldsymbol{s}}$, or choose χ_s to be an eigenstate of $\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{p}}$ (in this case we shall write $s=\lambda$), which yields the helicity spinor wave functions.

The following equations can now be derived:

$$(S\cdot\overline{\sigma})^{\dot\alpha\beta}x_\beta(\vec{\boldsymbol{p}},s)=2sy^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)\,,\qquad (S\cdot\sigma)_{\alpha\dot\beta}y^{\dagger\dot\beta}(\vec{\boldsymbol{p}},s)=-2sx_\alpha(\vec{\boldsymbol{p}},s)\,, \tag{29.3.23}$$

$$(S\cdot\sigma)_{\alpha\dot\beta}x^{\dagger\dot\beta}(\vec{\boldsymbol{p}},s)=-2sy_\alpha(\vec{\boldsymbol{p}},s)\,,\qquad (S\cdot\overline{\sigma})^{\dot\alpha\beta}y_\beta(\vec{\boldsymbol{p}},s)=2sx^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)\,, \tag{29.3.24}$$

$$x^\alpha(\vec{\boldsymbol{p}},s)(S\cdot\sigma)_{\alpha\dot\beta}=-2sy^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s)\,,\qquad y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)(S\cdot\overline{\sigma})^{\dot\alpha\beta}=2sx^\beta(\vec{\boldsymbol{p}},s)\,, \tag{29.3.25}$$

$$x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)(S\cdot\overline{\sigma})^{\dot\alpha\beta}=2sy^\beta(\vec{\boldsymbol{p}},s)\,,\qquad y^\alpha(\vec{\boldsymbol{p}},s)(S\cdot\sigma)_{\alpha\dot\beta}=-2sx^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s)\,. \tag{29.3.26}$$

For example, using eq. (29.3.17) and the definitions above for $x_\alpha(\vec{\boldsymbol{p}},s)$ and $y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)$, we find (suppressing spinor indices),

$$\sqrt{p\cdot\sigma}\,S\cdot\overline{\sigma}\,x(\vec{\boldsymbol{p}},s)=\sqrt{p\cdot\sigma}\,S\cdot\overline{\sigma}\,\sqrt{p\cdot\sigma}\,\chi_s=m\vec{\boldsymbol{\sigma}}\boldsymbol{\cdot}\hat{\boldsymbol{s}}\,\chi_s=2sm\,\chi_s\,. \tag{29.3.27}$$

Multiplying both sides of eq. (29.3.27) by $\sqrt{p\cdot\overline{\sigma}}$ and noting that $\sqrt{p\cdot\overline{\sigma}}\sqrt{p\cdot\sigma}=m$, we end up with

$$S\cdot\overline{\sigma}\,x(\vec{\boldsymbol{p}},s)=2s\sqrt{p\cdot\overline{\sigma}}\,\chi_s=2sy^\dagger(\vec{\boldsymbol{p}},s)\,. \tag{29.3.28}$$

All the results of eqs. (29.3.23)–(29.3.26) can be derived in this manner.

The consistency of eqs. (29.3.23)–(29.3.26) can also be checked as follows. First, each of these equations yields

$$(S\cdot\sigma)_{\alpha\dot\alpha}(S\cdot\overline{\sigma})^{\dot\alpha\beta}=-\delta^\beta_\alpha\,,\qquad (S\cdot\overline{\sigma})^{\dot\alpha\alpha}(S\cdot\sigma)_{\alpha\dot\beta}=-\delta^{\dot\alpha}_{\dot\beta}\,, \tag{29.3.29}$$

after noting that $4s^2=1$ (for $s=\pm\frac{1}{2}$). From eqs. (29.52) and (29.53) it follows that $S\cdot S=-1$, as required. Second, if one applies

$$(p\cdot\sigma\,S\cdot\overline{\sigma}+S\cdot\sigma\,p\cdot\overline{\sigma})_\alpha{}^\beta=2p\cdot S\,\delta_\alpha{}^\beta\,, \tag{29.3.30}$$

$$(p\cdot\overline{\sigma}\,S\cdot\sigma+S\cdot\overline{\sigma}\,p\cdot\sigma)^{\dot\alpha}{}_{\dot\beta}=2p\cdot S\,\delta^{\dot\alpha}{}_{\dot\beta}\,, \tag{29.3.31}$$

[30] Explicit forms for two-component spinor wave functions have been exhibited a number of times in the literature. For example, see refs. [105, 106] and Appendix I.1 .

to eqs. (29.3.9)–(29.3.12) and eqs. (29.3.23)–(29.3.26), it follows that $p\cdot S = 0$.

It is useful to combine the results of eqs. (29.3.9)–(29.3.12) and eqs. (29.3.23)–(29.3.26) as follows:

$$(p^\mu - 2smS^\mu)\overline{\sigma}_\mu^{\dot\alpha\beta}x_\beta(\vec{\boldsymbol{p}},s) = 0\,, \qquad (p_\mu - 2smS_\mu)\sigma^\mu_{\alpha\dot\beta}x^{\dagger\dot\beta}(\vec{\boldsymbol{p}},s) = 0\,, \tag{29.3.32}$$

$$(p^\mu + 2smS^\mu)\overline{\sigma}_\mu^{\dot\alpha\beta}y_\beta(\vec{\boldsymbol{p}},s) = 0\,, \qquad (p_\mu + 2smS_\mu)\sigma^\mu_{\alpha\dot\beta}y^{\dagger\dot\beta}(\vec{\boldsymbol{p}},s) = 0\,, \tag{29.3.33}$$

$$x^\alpha(\vec{\boldsymbol{p}},s)\sigma^\mu_{\alpha\dot\beta}(p_\mu - 2smS_\mu) = 0\,, \qquad x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)\overline{\sigma}_\mu^{\dot\alpha\beta}(p^\mu - 2smS^\mu) = 0\,, \tag{29.3.34}$$

$$y^\alpha(\vec{\boldsymbol{p}},s)\sigma^\mu_{\alpha\dot\beta}(p_\mu + 2smS_\mu) = 0\,, \qquad y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},s)\overline{\sigma}_\mu^{\dot\alpha\beta}(p^\mu + 2smS^\mu) = 0\,. \tag{29.3.35}$$

Eqs. (29.3.18)–(29.3.35) also apply to the helicity wave functions $x(\vec{\boldsymbol{p}},\lambda)$ and $y(\vec{\boldsymbol{p}},\lambda)$ simply by replacing s with λ and $S^\mu(\hat{\boldsymbol{s}})$ [eq. (29.3.15)] with $S^\mu(\hat{\boldsymbol{p}})$ [eq. (29.3.16)].

The above results are applicable only for massive fermions (where the spin four-vector S^μ exists). We may treat the case of massless fermions directly by employing helicity spinors in eqs. (29.3.18)–(29.3.21). Putting $E = |\vec{\boldsymbol{p}}|$ and $m = 0$, we easily obtain:

$$x_\alpha(\vec{\boldsymbol{p}},\lambda) = \sqrt{2E}\,\left(\tfrac{1}{2} - \lambda\right)\chi_\lambda\,, \qquad x^\alpha(\vec{\boldsymbol{p}},\lambda) = \sqrt{2E}\,\left(\tfrac{1}{2} - \lambda\right)\chi^\dagger_{-\lambda}\,, \tag{29.3.36}$$

$$y_\alpha(\vec{\boldsymbol{p}},\lambda) = \sqrt{2E}\,\left(\tfrac{1}{2} + \lambda\right)\chi_{-\lambda}\,, \qquad y^\alpha(\vec{\boldsymbol{p}},\lambda) = \sqrt{2E}\,\left(\tfrac{1}{2} + \lambda\right)\chi^\dagger_{\lambda}\,, \tag{29.3.37}$$

or equivalently,

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda) = \sqrt{2E}\,\left(\tfrac{1}{2} - \lambda\right)\chi_{-\lambda}\,, \qquad x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda) = \sqrt{2E}\,\left(\tfrac{1}{2} - \lambda\right)\chi^\dagger_{\lambda}\,, \tag{29.3.38}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda) = \sqrt{2E}\,\left(\tfrac{1}{2} + \lambda\right)\chi_{\lambda}\,, \qquad y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}},\lambda) = \sqrt{2E}\,\left(\tfrac{1}{2} + \lambda\right)\chi^\dagger_{-\lambda}\,. \tag{29.3.39}$$

It follows that:

$$\left(\tfrac{1}{2} + \lambda\right)x(\vec{\boldsymbol{p}},\lambda) = 0\,, \qquad \left(\tfrac{1}{2} + \lambda\right)x^\dagger(\vec{\boldsymbol{p}},\lambda) = 0\,, \tag{29.3.40}$$

$$\left(\tfrac{1}{2} - \lambda\right)y(\vec{\boldsymbol{p}},\lambda) = 0\,, \qquad \left(\tfrac{1}{2} - \lambda\right)y^\dagger(\vec{\boldsymbol{p}},\lambda) = 0\,. \tag{29.3.41}$$

The significance of eqs. (29.3.40) and (29.3.41) is clear; for massless fermions, only one helicity component of x and y is non-zero. Applying this result to neutrinos, we find that massless neutrinos are left-handed ($\lambda = -1/2$), while antineutrinos are right-handed ($\lambda = +1/2$).

Eqs. (29.3.40) and (29.3.41) can also be derived by carefully taking the $m \to 0$ limit of eqs. (29.3.32) and (29.3.33) applied to the helicity wave functions $x(\vec{\boldsymbol{p}},\lambda)$ and $y(\vec{\boldsymbol{p}},\lambda)$ [i.e., replacing s with λ]. We then replace mS^μ with p^μ, which is the leading term in the limit of $E \gg m$. Using the results of eqs. (29.3.9) and (29.3.10) and dividing out by an overall factor of m (before finally taking the $m \to 0$ limit) reproduces eqs. (29.3.40) and (29.3.41).

Having defined explicit forms for the two-component spinor wave functions, we can now write down the spin projection matrices. Noting that $\frac{1}{2}(1 + 2s\,\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}})\chi_{s'} = \frac{1}{2}(1 + 4ss')\chi_{s'} = \delta_{ss'}\chi_{s'}$ (since s, $s' = \pm\frac{1}{2}$), one can write:

$$\chi_s\chi_s^\dagger = \tfrac{1}{2}\,(1 + 2s\,\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}})\sum_{s'}\chi_{s'}\chi_{s'}^\dagger = \tfrac{1}{2}\,(1 + 2s\,\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}})\,, \tag{29.3.42}$$

where at the second step, we have employed the completeness relation given in eq. (C.1.21). Making use of eq. (29.3.17) for $\vec{\boldsymbol{\sigma}}\cdot\hat{\boldsymbol{s}}$, it follows that

$$\chi_s\chi_s^\dagger = \tfrac{1}{2}\left(1 + \frac{2s}{m}\sqrt{p\cdot\sigma}\,S\cdot\overline{\sigma}\,\sqrt{p\cdot\sigma}\right)\,. \tag{29.3.43}$$

Hence, with both spinor indices in the lowered position,

$$\begin{aligned} x(\vec{\boldsymbol{p}},s)x^\dagger(\vec{\boldsymbol{p}},s) &= \sqrt{p\cdot\sigma}\,\chi_s\chi_s^\dagger\sqrt{p\cdot\sigma} \\ &= \tfrac{1}{2}\sqrt{p\cdot\sigma}\left[1+\frac{2s}{m}\sqrt{p\cdot\sigma}S\cdot\overline{\sigma}\sqrt{p\cdot\sigma}\right]\sqrt{p\cdot\sigma} \\ &= \tfrac{1}{2}\left[p\cdot\sigma+\frac{2s}{m}p\cdot\sigma S\cdot\overline{\sigma}p\cdot\sigma\right] \\ &= \tfrac{1}{2}\left[p\cdot\sigma-2smS\cdot\sigma\right]. \end{aligned} \tag{29.3.44}$$

In the final step above, we simplified the product of three dot products by noting that $p\cdot S=0$ implies that $S\cdot\overline{\sigma}\;p\cdot\sigma=-p\cdot\overline{\sigma}\;S\cdot\sigma$. The other spin projection formulae for massive fermions can be similarly derived. The complete set of such formulae is given below:[31]

$$x_\alpha(\vec{\boldsymbol{p}},s)x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(p_\mu-2smS_\mu)\sigma^\mu_{\alpha\dot\beta}\,, \tag{29.3.45}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)y^\beta(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(p^\mu+2smS^\mu)\overline{\sigma}^{\dot\alpha\beta}_\mu\,, \tag{29.3.46}$$

$$x_\alpha(\vec{\boldsymbol{p}},s)y^\beta(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}\left(m\delta_\alpha{}^\beta-2s[S\cdot\sigma\,p\cdot\overline{\sigma}]_\alpha{}^\beta\right), \tag{29.3.47}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}\left(m\delta^{\dot\alpha}{}_{\dot\beta}+2s[S\cdot\overline{\sigma}\,p\cdot\sigma]^{\dot\alpha}{}_{\dot\beta}\right). \tag{29.3.48}$$

By taking the hermitian conjugate of the above results, one obtains an equivalent set of formulae,

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)x^\beta(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(p^\mu-2smS^\mu)\overline{\sigma}^{\dot\alpha\beta}_\mu\,, \tag{29.3.49}$$

$$y_\alpha(\vec{\boldsymbol{p}},s)y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = \tfrac{1}{2}(p_\mu+2smS_\mu)\sigma^\mu_{\alpha\dot\beta}\,, \tag{29.3.50}$$

$$y_\alpha(\vec{\boldsymbol{p}},s)x^\beta(\vec{\boldsymbol{p}},s) = -\tfrac{1}{2}\left(m\delta_\alpha{}^\beta+2s[S\cdot\sigma\,p\cdot\overline{\sigma}]_\alpha{}^\beta\right), \tag{29.3.51}$$

$$x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = -\tfrac{1}{2}\left(m\delta^{\dot\alpha}{}_{\dot\beta}-2s[S\cdot\overline{\sigma}\,p\cdot\sigma]^{\dot\alpha}{}_{\dot\beta}\right). \tag{29.3.52}$$

For the case of massless spin-1/2 fermions, we must use helicity spinor wave functions. The corresponding massless projection operators can be obtained directly from the explicit forms for the two-component spinor wave functions given in eqs. (29.3.36)–(29.3.39):

$$x_\alpha(\vec{\boldsymbol{p}},\lambda)x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}-\lambda)p\cdot\sigma_{\alpha\dot\beta}\,, \qquad x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda)x^\beta(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}-\lambda)p\cdot\overline{\sigma}^{\dot\alpha\beta}\,, \tag{29.3.53}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda)y^\beta(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}+\lambda)p\cdot\overline{\sigma}^{\dot\alpha\beta}\,, \qquad y_\alpha(\vec{\boldsymbol{p}},\lambda)y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},\lambda) = (\tfrac{1}{2}+\lambda)p\cdot\sigma_{\alpha\dot\beta}\,, \tag{29.3.54}$$

$$x_\alpha(\vec{\boldsymbol{p}},\lambda)y^\beta(\vec{\boldsymbol{p}},\lambda) = 0\,, \qquad y_\alpha(\vec{\boldsymbol{p}},\lambda)x^\beta(\vec{\boldsymbol{p}},\lambda) = 0\,, \tag{29.3.55}$$

$$y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda)x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},\lambda) = 0\,, \qquad x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},\lambda)y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},\lambda) = 0\,. \tag{29.3.56}$$

As a check, one can verify that the above results follow from eqs. (29.3.45)–(29.3.52), by replacing s with λ, setting $mS^\mu=p^\mu$, and taking the $m\to 0$ limit at the end of the computation.

Having listed the projection operators for definite spin projection or helicity, we may now sum over spins to derive the spin sum identities. These arise when computing squared matrix elements for unpolarized scattering and decay. There are only four basic identities, but for convenience we list each of them with the two-index height permutations that can occur in squared amplitudes by following the rules given in this paper. The results can be derived by inspection of the spin projection operators, since summing over $s=\pm\frac{1}{2}$ simply removes all terms linear in the spin

[31] Similar formulae for the products of two-component spinor wave functions are given in ref. [105].

four-vector S^μ.

$$\sum_s x_\alpha(\vec{\boldsymbol{p}},s)x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = p\cdot\sigma_{\alpha\dot\beta}\,, \qquad \sum_s x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)x^\beta(\vec{\boldsymbol{p}},s) = p\cdot\overline{\sigma}^{\dot\alpha\beta}\,, \tag{29.3.57}$$

$$\sum_s y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)y^\beta(\vec{\boldsymbol{p}},s) = p\cdot\overline{\sigma}^{\dot\alpha\beta}\,, \qquad \sum_s y_\alpha(\vec{\boldsymbol{p}},s)y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = p\cdot\sigma_{\alpha\dot\beta}\,, \tag{29.3.58}$$

$$\sum_s x_\alpha(\vec{\boldsymbol{p}},s)y^\beta(\vec{\boldsymbol{p}},s) = m\delta_\alpha{}^\beta\,, \qquad \sum_s y_\alpha(\vec{\boldsymbol{p}},s)x^\beta(\vec{\boldsymbol{p}},s) = -m\delta_\alpha{}^\beta\,, \tag{29.3.59}$$

$$\sum_s y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = m\delta^{\dot\alpha}{}_{\dot\beta}\,, \qquad \sum_s x^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)y^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = -m\delta^{\dot\alpha}{}_{\dot\beta}\,. \tag{29.3.60}$$

These results are applicable both to spin sums and helicity sums, and hold for both massive and massless spin-1/2 fermions.

One can generalize the above massive and massless projection operators by considering products of two-component spinor wave functions, where the spin or helicity of each spinor can be different. These are the Bouchiat-Michel formulae [113], which are derived in Appendix H.3 .

29.3.2 Fermion mass diagonalization in a general theory

Consider a collection of free anticommuting two-component spin-1/2 fields, $\hat\xi_{\alpha i}(x)$, which transform as $(\frac12,0)$ fields under the Lorentz group. Here, α is the spinor index, and i labels the distinct fields of the collection. The free-field Lagrangian is given by (e.g., see ref. [5]):

$$\mathscr{L} = i\hat\xi^{\dagger i}\overline{\sigma}^\mu\partial_\mu\hat\xi_i - \tfrac12 M^{ij}\hat\xi_i\hat\xi_j - \tfrac12 M_{ij}\hat\xi^{\dagger i}\hat\xi^{\dagger j}\,, \tag{29.3.1}$$

where

$$M_{ij} \equiv (M^{ij})^*. \tag{29.3.2}$$

Note that M is a complex symmetric matrix, since the product of anticommuting two-component fields satisfies $\hat\xi_i\hat\xi_j = \hat\xi_j\hat\xi_i$ [with the spinor contraction rule according to eq. (29.37)].

In eq. (29.3.1), we have employed the U(N)-covariant tensor calculus [45, 147] for "flavor-tensors" labeled by the flavor indices i and j. Each left-handed $(\frac12,0)$ fermion always has an index with the opposite height of the corresponding right-handed $(0,\frac12)$ fermion. Raised indices can only be contracted with lowered indices and vice versa. Flipping the heights of all flavor indices of an object corresponds to complex conjugation, as in eq. (29.3.2). In particular, we generalize eq. (29.19) as follows:[32]

$$\psi^{\dagger\,i}_\alpha \equiv (\psi_{\alpha i})^\dagger\,. \tag{29.3.3}$$

If $M = 0$, then the free-field Lagrangian is invariant under a global U(N) symmetry. That is, for a unitary matrix U, with matrix elements $U_i{}^j$, and its hermitian conjugate defined by:

$$(U^\dagger)_i{}^j = (U_j{}^i)^* \equiv U^j{}_i\,, \tag{29.3.4}$$

with $U_i{}^k(U^\dagger)_k{}^j = \delta_i^j$, the massless free-field Lagrangian is invariant under the transformations:

$$\hat\xi_i \longrightarrow U_i{}^j\hat\xi_j\,, \qquad \hat\xi^{\dagger i} \longrightarrow U^i{}_j\hat\xi^{\dagger j}\,. \tag{29.3.5}$$

[32] In the case at hand, we have more specifically chosen all of the left-handed fermions to have lowered flavor indices, which implies that all of the right-handed fermions have raised flavor indices. However, in cases where a subset of left-handed fermions transform according to some representation R of a (global) symmetry and a different subset of left-handed fermions transform according to the conjugate representation R^*, it is often more convenient to employ a raised flavor index for the latter subset of left-handed fields.

For $M \neq 0$, eq. (29.3.1) remains formally invariant under the global U(N)-symmetry if M acts as a spurion field [148] with the appropriate tensorial transformation law, $M^{ij} \longrightarrow U^i{}_k U^j{}_\ell M^{k\ell}$.

Expressions consisting of flavor-vectors and second-rank flavor-tensors have natural interpretations as products of vectors and matrices. As a result, the flavor indices can be suppressed, and the resulting expressions can be written in an index-free matrix notation. To accomplish this, one must first assign a particular flavor index structure to the matrices that will appear in the index-free expression. For example, given the second-rank flavor-tensors introduced above, we define the matrix elements of M to be M^{ij} and the matrix elements of U to be $U_i{}^j$. Note that $(U^\dagger)_i{}^j$ has the same flavor-index structure as U.[33]

As a simple example, in an index-free notation eq. (29.3.5) reads: $\hat{\xi} \longrightarrow U\hat{\xi}$ and $\hat{\xi}^\dagger \longrightarrow \hat{\xi}^\dagger U^\dagger$. A slightly more complicated example is exhibited below:

$$U^i{}_k M^{k\ell} = (U^\dagger)_k{}^i M^{k\ell} = (U^* M)^{i\ell}\,, \tag{29.3.6}$$

where we have used $(U^\dagger)^{\mathsf{T}} = U^*$ in obtaining the final result. That is, in matrix notation with suppressed indices, $U^i{}_k M^{k\ell}$ corresponds to the matrix $U^* M$. Thus, in an index-free notation, the tensorial transformation law for the spurion field M is given by $M \longrightarrow U^* M U^\dagger$.

We can diagonalize the mass matrix M and rewrite the Lagrangian in terms of mass eigenstates $\xi_{\alpha i}$ and (real non-negative) masses m_i. To do this, we introduce a unitary matrix Ω,

$$\hat{\xi}_i = \Omega_i{}^k \xi_k\,, \tag{29.3.7}$$

and demand that $M^{ij}\Omega_i{}^k\Omega_j{}^\ell = m_k \delta^{k\ell}$ (no sum over k), where the m_k are real and non-negative. Equivalently, in matrix notation with suppressed indices, $\hat{\xi} = \Omega\xi$ and[34]

$$\Omega^{\mathsf{T}} M\, \Omega = \boldsymbol{m} = \mathrm{diag}(m_1, m_2, \ldots). \tag{29.3.8}$$

This is the Takagi diagonalization [112, 149] of an arbitrary complex symmetric matrix, which is discussed in more detail in Appendix D.2 . To compute the values of the diagonal elements of $\boldsymbol{m}$, note that

$$\Omega^\dagger M^\dagger M \Omega = \boldsymbol{m}^2\,. \tag{29.3.9}$$

Indeed $M^\dagger M$ is hermitian and thus it can be diagonalized by a unitary matrix. Hence, the elements of the diagonal matrix $\boldsymbol{m}$ are the non-negative square roots of the corresponding eigenvalues of $M^\dagger M$. However, in cases where $M^\dagger M$ has degenerate eigenvalues, eq. (29.3.9) *cannot* be employed to determine the unitary matrix Ω that satisfies eq. (29.3.8). A more general technique for determining Ω that works in all cases is given in Appendix D.2 .

In terms of the mass eigenstates,

$$\mathscr{L} = i\xi^{\dagger i}\overline{\sigma}^\mu \partial_\mu \xi_i - \tfrac{1}{2} m_i(\xi_i \xi_i + \xi^{\dagger i}\xi^{\dagger i})\,, \tag{29.3.10}$$

where the sum over i is implicit. If the $m_i \neq 0$ are non-degenerate, then the corresponding field ξ_i describes a neutral Majorana fermion consisting of two on-shell real degrees of freedom. The case of mass degeneracies will be treated explicitly below. If $m_i = 0$, then we shall denote the corresponding field ξ_i as a massless Weyl fermion [15].

Each $\xi_{\alpha i}$ can now be expanded in a Fourier series, exactly as in eq. (29.3.3):

$$\xi_{\alpha i}(x) = \sum_s \int \frac{d^3\vec{\boldsymbol{p}}}{(2\pi)^{3/2}(2E_{\boldsymbol{p}i})^{1/2}} \left[x_\alpha(\vec{\boldsymbol{p}}, s) a_i(\vec{\boldsymbol{p}}, s) e^{-ip\cdot x} + y_\alpha(\vec{\boldsymbol{p}}, s) a_i^\dagger(\vec{\boldsymbol{p}}, s) e^{ip\cdot x}\right]\,, \tag{29.3.11}$$

[33] The reader should not be tempted to substitute $U^\dagger$ for U in eq. (29.3.4), as the resulting flavor-index structure for U and $U^\dagger$ would then disagree with the original flavor-index assignments.

[34] In general, the m_i are *not* the eigenvalues of M. Rather, they are the *singular values* of the matrix M, which are defined to be the non-negative square roots of the eigenvalues of $M^\dagger M$. See Appendix D for further details.

where $E_{\boldsymbol{p}i} \equiv (|\vec{\boldsymbol{p}}|^2 + m_i^2)^{1/2}$, and the creation and annihilation operators, $a_i^\dagger$ and a_i satisfy anticommutation relations:

$$\{a_i(\vec{\boldsymbol{p}}, s), a_j^\dagger(\vec{\boldsymbol{p}}', s')\} = \delta^3(\vec{\boldsymbol{p}} - \vec{\boldsymbol{p}}')\delta_{ss'}\delta_{ij}\,. \tag{29.3.12}$$

We employ covariant normalization of the one-particle states, i.e., we act with one creation operator on the vacuum with the following convention

$$|\vec{\boldsymbol{p}}, i, s\rangle \equiv (2\pi)^{3/2}(2E_{\boldsymbol{p}i})^{1/2} a_i^\dagger(\vec{\boldsymbol{p}}, s)\,|0\rangle\ , \tag{29.3.13}$$

so that $\langle \vec{\boldsymbol{p}}, i, s\,|\,\vec{\boldsymbol{p}}', j, s'\rangle = (2\pi)^3(2E_{\boldsymbol{p}i})\delta^3(\vec{\boldsymbol{p}} - \vec{\boldsymbol{p}}')\delta_{ij}\delta_{ss'}$.

In the case of two mass-degenerate massive fermion fields, $m_1 = m_2 \neq 0$, eq. (29.3.10) possesses a global internal O(2) flavor symmetry, $\xi_i \to \mathcal{O}_i{}^j\xi_j$ $(i = 1, 2)$, where $\mathcal{O}^{\mathsf{T}}\mathcal{O} = \mathbb{1}_{2\times 2}$. Corresponding to this symmetry is a conserved hermitian Noether current:

$$J^\mu = i(\xi^{\dagger 1}\overline{\sigma}^\mu\xi_2 - \xi^{\dagger 2}\overline{\sigma}^\mu\xi_1)\,, \tag{29.3.14}$$

with a corresponding conserved charge, $Q = \int J^0 d^3x$. In the ξ_1–ξ_2 basis, the Noether current is off-diagonal. However, it is convenient to define a new basis of fields:

$$\chi \equiv \frac{1}{\sqrt{2}}(\xi_1 + i\xi_2)\,, \qquad \eta \equiv \frac{1}{\sqrt{2}}(\xi_1 - i\xi_2)\,. \tag{29.3.15}$$

With respect to the χ–η basis, the Noether current is diagonal:

$$J^\mu = \chi^\dagger\overline{\sigma}^\mu\chi - \eta^\dagger\overline{\sigma}^\mu\eta\,. \tag{29.3.16}$$

That is, the fermions χ and η are eigenstates of the charge operator Q with corresponding eigenvalues ± 1. In terms of the fermion fields of definite charge, the free-field fermion Lagrangian [eq. (29.3.10) with $i = 1, 2$ and $m_1 = m_2 \equiv m$] is given by [16]:[35]

$$\mathscr{L} = i\chi^\dagger\overline{\sigma}^\mu\partial_\mu\chi + i\eta^\dagger\overline{\sigma}^\mu\partial_\mu\eta - m(\chi\eta + \chi^\dagger\eta^\dagger)\,. \tag{29.3.17}$$

On-shell, χ and η satisfy the free-field Dirac equations:

$$i\,\overline{\sigma}^\mu\partial_\mu\chi - m\eta^\dagger = 0\,, \qquad i\,\overline{\sigma}^\mu\partial_\mu\eta - m\chi^\dagger = 0\,. \tag{29.3.18}$$

In the χ–η basis, the global internal SO(2) symmetry (which is continuously connected to the identity) is realized as the U(1) symmetry $\chi \to e^{i\theta}\chi$ and $\eta \to e^{-i\theta}\eta$, where θ is the rotation angle that defines the SO(2) rotation matrix.

Together, χ and $\eta^\dagger$ constitute a single Dirac fermion. We can then write:

$$\chi_\alpha(x) = \sum_s \int \frac{d^3\vec{\boldsymbol{p}}}{(2\pi)^{3/2}(2E_{\boldsymbol{p}})^{1/2}}\left[x_\alpha(\vec{\boldsymbol{p}}, s)a(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x} + y_\alpha(\vec{\boldsymbol{p}}, s)b^\dagger(\vec{\boldsymbol{p}}, s)e^{ip\cdot x}\right]\ , \tag{29.3.19}$$

$$\eta_\alpha(x) = \sum_s \int \frac{d^3\vec{\boldsymbol{p}}}{(2\pi)^{3/2}(2E_{\boldsymbol{p}})^{1/2}}\left[x_\alpha(\vec{\boldsymbol{p}}, s)b(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x} + y_\alpha(\vec{\boldsymbol{p}}, s)a^\dagger(\vec{\boldsymbol{p}}, s)e^{ip\cdot x}\right]\ , \tag{29.3.20}$$

where $E_{\boldsymbol{p}} \equiv (|\vec{\boldsymbol{p}}|^2 + m^2)^{1/2}$, the creation and annihilation operators, $a^\dagger$, $b^\dagger$, a and b satisfy anticommutation relations:

$$\{a(\vec{\boldsymbol{p}}, s), a^\dagger(\vec{\boldsymbol{p}}', s')\} = \{b(\vec{\boldsymbol{p}}, s), b^\dagger(\vec{\boldsymbol{p}}', s')\} = \delta^3(\vec{\boldsymbol{p}} - \vec{\boldsymbol{p}}')\delta_{s,s'}\,, \tag{29.3.21}$$

[35] Although the fermion mass matrix is not diagonal in the χ–η basis, this is not an obstacle to the subsequent analysis, as one only needs a diagonal *squared*-mass matrix, $M^\dagger M$, to ensure that the denominators of propagators are diagonal. Eq. (29.3.15) provides the explicit Takagi diagonalization of the Dirac fermion matrix $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. See Appendix D.3 for the mathematical interpretation of this special case.

and all other anticommutators vanish. We now must distinguish between two types of one-particle states, which we can call fermion (F) and antifermion ($\overline{F}$):

$$|\vec{\boldsymbol{p}}, s; F\rangle \equiv (2\pi)^{3/2}(2E_{\boldsymbol{p}})^{1/2}a^\dagger(\vec{\boldsymbol{p}}, s)\,|0\rangle\ , \qquad \left|\vec{\boldsymbol{p}}, s; \overline{F}\right\rangle \equiv (2\pi)^{3/2}(2E_{\boldsymbol{p}})^{1/2}b^\dagger(\vec{\boldsymbol{p}}, s)\,|0\rangle\ . \tag{29.3.22}$$

Note that both $\eta(x)$ and $\chi^\dagger(x)$ can create $|\vec{\boldsymbol{p}}, s; F\rangle$ from the vacuum, while $\eta^\dagger(x)$ and $\chi(x)$ can create $\left|\vec{\boldsymbol{p}}, s; \overline{F}\right\rangle$. The one-particle wave functions are given by:

$$\langle 0|\,\chi_\alpha(x)\,|\vec{\boldsymbol{p}}, s; F\rangle = x_\alpha(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x}\,, \qquad \langle 0|\,\eta^\dagger_{\dot\alpha}(x)\,|\vec{\boldsymbol{p}}, s; F\rangle = y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x}\,, \tag{29.3.23}$$

$$\langle F; \vec{\boldsymbol{p}}, s|\,\eta_\alpha(x)\,|0\rangle = y_\alpha(\vec{\boldsymbol{p}}, s)e^{ip\cdot x}\,, \qquad \langle F; \vec{\boldsymbol{p}}, s|\,\chi^\dagger_{\dot\alpha}(x)\,|0\rangle = x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, s)e^{ip\cdot x}\,, \tag{29.3.24}$$

$$\langle 0|\,\eta_\alpha(x)\,\left|\vec{\boldsymbol{p}}, s; \overline{F}\right\rangle = x_\alpha(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x}\,, \qquad \langle 0|\,\chi^\dagger_{\dot\alpha}(x)\,\left|\vec{\boldsymbol{p}}, s; \overline{F}\right\rangle = y^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, s)e^{-ip\cdot x}\,, \tag{29.3.25}$$

$$\left\langle \overline{F}; \vec{\boldsymbol{p}}, s\right|\,\chi_\alpha(x)\,|0\rangle = y_\alpha(\vec{\boldsymbol{p}}, s)e^{ip\cdot x}\,, \qquad \left\langle \overline{F}; \vec{\boldsymbol{p}}, s\right|\,\eta^\dagger_{\dot\alpha}(x)\,|0\rangle = x^\dagger_{\dot\alpha}(\vec{\boldsymbol{p}}, s)e^{ip\cdot x}\,, \tag{29.3.26}$$

and the eight other single-particle matrix elements vanish.

More generally, consider a collection of free anticommuting charged Dirac fermions, which can be represented by pairs of two-component fields $\hat\chi_{\alpha i}(x)$, $\hat\eta^i_{\dot\alpha}(x)$. These fields transform in (possibly reducible) representations of the unbroken symmetry group that are conjugates of each other. This accounts for the opposite flavor index heights of $\hat\chi_i$ and $\hat\eta^i$ [cf. footnote 32]. The free-field Lagrangian is given by

$$\mathscr{L} = i\hat\chi^{\dagger i}\overline\sigma^\mu\partial_\mu\hat\chi_i + i\hat\eta^\dagger_i\overline\sigma^\mu\partial_\mu\hat\eta^i - M^i{}_j\hat\chi_i\hat\eta^j - M_i{}^j\hat\chi^{\dagger i}\hat\eta^\dagger_j\,, \tag{29.3.27}$$

where M is an arbitrary complex matrix with matrix elements $M^i{}_j$, and

$$M_i{}^j \equiv (M^i{}_j)^*\,. \tag{29.3.28}$$

If $M = 0$, then the free-field Lagrangian is invariant under a global U(N)×U(N) symmetry. That is, for a pair of unitary matrices U_L and U_R, with matrix elements given respectively by $(U_L)_i{}^j$ and $(U_R)^i{}_j$, and the corresponding hermitian conjugates defined by:

$$(U_L^\dagger)_j{}^i = [(U_L)_i{}^j]^* \equiv (U_L)^i{}_j\,, \qquad (U_R^\dagger)^j{}_i = [(U_R)^i{}_j]^* \equiv (U_R)_i{}^j\,, \tag{29.3.29}$$

the massless free-field Lagrangian is invariant under the transformations:

$$\hat\chi_i \longrightarrow (U_L)_i{}^j\hat\chi_j\,, \qquad \hat\chi^{\dagger i} \longrightarrow (U_L)^i{}_j\hat\chi^{\dagger j}\,, \qquad \hat\eta^i \longrightarrow (U_R)^i{}_j\hat\eta^j\,, \qquad \hat\eta^\dagger_i \longrightarrow (U_R)_i{}^j\hat\eta^\dagger_j\,. \tag{29.3.30}$$

For $M \neq 0$, eq. (29.3.27) remains formally invariant under the U(N)×U(N) symmetry if M acts as a spurion field [148] with the appropriate tensorial transformation law, $M^i{}_j \to (U_L)^i{}_k(U_R)_j{}^\ell M^k{}_\ell$ (or equivalently, in an index-free matrix notation with suppressed flavor indices, $M \longrightarrow U_L^* M U_R^\dagger$).

In order to diagonalize the mass matrix, we introduce the mass eigenstates χ_i and η^i and unitary matrices L and R, with matrix elements given respectively by $L_i{}^k$ and $R^i{}_k$, such that

$$\hat\chi_i = L_i{}^k\chi_k\,, \qquad \hat\eta^i = R^i{}_k\eta^k\,, \tag{29.3.31}$$

and demand that $M^i{}_jL_i{}^kR^j{}_\ell = m_k\delta^k_\ell$ (no sum over k), where the m_k are real and non-negative. Equivalently, in matrix notation with suppressed indices, $\hat\chi = L\chi$, $\hat\eta = R\eta$ and

$$L^{\mathsf T}MR = \boldsymbol{m} = \mathrm{diag}(m_1, m_2, \ldots), \tag{29.3.32}$$

with the m_i real and non-negative (cf. footnote 34). The singular value decomposition of linear algebra, discussed more fully in Appendix D.1 , states that for any complex matrix M, unitary matrices L and R exist such that eq. (29.3.32) is satisfied. It then follows that:

$$L^{\mathsf T}(MM^\dagger)L^* \;=\; R^\dagger(M^\dagger M)R \;=\; \boldsymbol{m}^2. \tag{29.3.33}$$

That is, since $MM^\dagger$ and $M^\dagger M$ are both hermitian, they can be diagonalized by unitary matrices. The diagonal elements of $\boldsymbol{m}$ are therefore the non-negative square roots of the corresponding eigenvalues of $MM^\dagger$ (or equivalently, $M^\dagger M$). In terms of the mass eigenstates,

$$\mathscr{L} = i\chi^{\dagger i}\overline{\sigma}^\mu\partial_\mu\chi_i + i\eta_i^\dagger\overline{\sigma}^\mu\partial_\mu\eta^i - m_i(\chi_i\eta^i + \chi^{\dagger i}\eta_i^\dagger)\,. \tag{29.3.34}$$

The mass matrix now consists of 2×2 blocks $\left(\begin{smallmatrix} 0 & m_i \\ m_i & 0\end{smallmatrix}\right)$ along the diagonal. More importantly, the squared-mass matrix is diagonal with doubly degenerate entries m_i^2 that will appear in the denominators of the propagators of the theory. For $m_i \neq 0$, each χ_i–η^i pair describes a charged Dirac fermion consisting of four on-shell real degrees of freedom.[36] In addition, eq. (29.3.34) yields an even number of massless Weyl fermions.

Given an arbitrary collection of two-component left-handed $(\frac{1}{2},0)$ fermions, the distinction between Majorana and Dirac fermions depends on whether the Lagrangian is invariant under a global (or local) continuous symmetry group G, and the corresponding multiplet structure of the fermion fields [150]. If no such continuous symmetry exist, then the fermion mass eigenstates will consist of Majorana fermions. If the Lagrangian is invariant under a symmetry group G, then the collection of two-component fermions will break up into a sum of multiplets that transform irreducibly under G. As described in Appendix E , a representation R can be either a real, pseudo-real, or complex representation of G. If a multiplet transforms under a real representation of G, then the corresponding fermion mass eigenstates are Majorana fermions.[37] If a multiplet transforms under a complex representation of G, then the corresponding fermion mass eigenstates are Dirac fermions. In particular [as noted above eq. (29.3.27)], if the χ_i transform under the representation R, then the η^i transform under the conjugate representation R^*.

The case where a multiplet of two-component left-handed fermions transform under a pseudo-real representation of G has not been explicitly treated above. The simplest example of this kind is a model of $2n$ multiplets (or "flavors") of two-component SU(2)-doublet[38] fermions, $\hat{\psi}_{ia}$ (where $i = 1, 2, ..., 2n$ labels the flavor index and a labels the SU(2) doublet index). The free-field Lagrangian is given by:

$$\mathscr{L} = i\hat{\psi}^{\dagger ia}\overline{\sigma}^\mu\partial_\mu\hat{\psi}_{ia} - \tfrac{1}{2}\left(M^{ij}\epsilon^{ab}\hat{\psi}_{ia}\hat{\psi}_{jb} + \text{h.c.}\right)\,, \tag{29.3.35}$$

where ϵ^{ab} is the antisymmetric SU(2)-invariant tensor, defined such that $\epsilon^{12} = -\epsilon^{21} = +1$. As $\epsilon^{ab}\hat{\psi}_{ia}\hat{\psi}_{jb}$ is antisymmetric under the interchange of flavor indices i and j, it follows that M is a complex antisymmetric matrix. To identify the fermion mass eigenstates ψ_{ja}, we introduce a unitary matrix U (with matrix elements $U_i{}^j$) such that $\hat{\psi}_{ia} = U_i{}^j\psi_{ja}$ and demand that:

$$U^{\mathsf{T}}MU = \boldsymbol{N} \equiv \text{diag}\left\{\begin{pmatrix} 0 & m_1 \\ -m_1 & 0\end{pmatrix}, \begin{pmatrix} 0 & m_2 \\ -m_2 & 0\end{pmatrix}, \cdots, \begin{pmatrix} 0 & m_n \\ -m_n & 0\end{pmatrix}\right\}, \tag{29.3.36}$$

where $\boldsymbol{N}$ is written in block-diagonal form consisting of 2×2 matrix blocks appearing along the diagonal, and the m_j are real and non-negative. Eq. (29.3.36) corresponds to the reduction of a complex antisymmetric matrix to its real normal form [151], which is discussed in more detail in Appendix D.4 . In order to compute the m_k, we first note that

$$U^\dagger M^\dagger MU = \text{diag}(m_1^2\,,\, m_1^2\,,\, m_2^2\,,\, m_2^2\,,\, \ldots\,,\, m_n^2\,,\, m_n^2)\,. \tag{29.3.37}$$

[36] Of course, one could always choose instead to treat the Dirac fermions in a non-charge-eigenstate basis with a fully diagonalized mass matrix, as in eq. (29.3.10). Inverting eq. (29.3.15) for each Dirac fermion yields $\xi_{2i-1} = (\chi_i + \eta^i)/\sqrt{2}$ and $\xi_{2i} = i(\eta_i - \chi^i)/\sqrt{2}$. However, it is rarely, if ever, convenient to do so; practical calculations only require that the squared-mass matrix $M^\dagger M$ is diagonal, and it is of course more convenient to employ fields that carry well-defined charges.

[37] This is a slight generalization of the more restrictive definition that requires Majorana fermions to transform trivially under the group G. Gluinos, which transform under the (real) adjoint representation of the color SU(3) group, are Majorana fermions according to our more general definition.

[38] The doublet representation of SU(2) is pseudo-real.

Hence, the m_j are the non-negative square roots of the corresponding eigenvalues of $M^\dagger M$. Since the dimension of the doublet representation of SU(2) provides an additional degeneracy factor of 2, eq. (29.3.37) implies that the mass spectrum consists of $2n$ pairs of mass-degenerate two-component fermions, which are equivalent to $2n$ Dirac fermions. In particular,

$$\mathscr{L} = \sum_{i=1}^{2n} i\psi^{\dagger ia}\overline{\sigma}^\mu\partial_\mu\psi_{ia} - \sum_{i=1}^{n}\left(m_i\epsilon^{ab}\psi_{2i-1,\,a}\psi_{2i,\,b} + \text{h.c.}\right) . \tag{29.3.38}$$

In the general case of a pseudo-real representation R (of dimension d_R), the SU(2)-invariant ϵ-tensor is replaced by a more general $d_R \times d_R$ unitary antisymmetric matrix, C [defined in eq. (E.1.9)]. Thus, the analysis above can be repeated virtually unchanged. By defining

$$\chi_{ia} \equiv \psi_{2i-1,\,a}\,, \qquad \eta^{ia} \equiv C^{ab}\psi_{2i,\,b}\,, \qquad i = 1, 2, ..., n\,; \quad a = 1, 2, ..., d_R\,, \tag{29.3.39}$$

with an implicit sum over the repeated index b, the resulting Lagrangian given by

$$\mathscr{L} = \sum_{i=1}^{n} i\chi^{\dagger ia}\overline{\sigma}^\mu\partial_\mu\chi_{ia} + i\eta^\dagger_{ia}\overline{\sigma}^\mu\partial_\mu\eta^{ia} - m_i\left(\chi_{ia}\eta^{ia} + \chi^{\dagger ia}\eta^\dagger_{ia}\right) , \tag{29.3.40}$$

describes a free field theory of nd_R Dirac fermions [cf. eq. (29.3.34)]. Therefore, if a multiplet of two-component left-handed fermions transforms under a pseudo-real representation of G, then the corresponding fermion mass eigenstates are Dirac fermions [150]. If eq. (29.3.35) contains an odd number of pseudo-real fermion multiplets, then the (antisymmetric) mass matrix M is odd-dimensional and thus has an odd number of zero eigenvalues [according to eq. (D.4.1)]. But as d_R must be even, it follows that the pseudo-real fermion multiplet contains an even number of massless Weyl fermions.

In conclusion, the mass diagonalization procedure of an arbitrary field theory of fermions yields (in general) a set of massless Weyl fermions, a set of massive neutral Majorana fermions [as in eq. (29.3.10)], and a set of massive charged Dirac fermions [as in eq. (29.3.34)]. The Feynman rules for these mass eigenstate two-component fermion fields are given in Section 29.4.

For completeness, we review the squared-mass matrix diagonalization procedure for scalar fields. First, consider a collection of free commuting real spin-0 fields, $\hat{\varphi}_i(x)$, where the flavor index i labels the distinct scalar fields of the collection. The free-field Lagrangian is given by[39]

$$\mathscr{L} = \tfrac{1}{2}\partial_\mu\hat{\varphi}_i\partial^\mu\hat{\varphi}_i - \tfrac{1}{2}M^2_{ij}\hat{\varphi}_i\hat{\varphi}_j\,, \tag{29.3.41}$$

where M^2 is a real symmetric matrix. We diagonalize the scalar squared-mass matrix by introducing mass eigenstates φ_i and the orthogonal matrix Q such that $\hat{\varphi}_i = Q_{ij}\varphi_j$, with $M^2_{ij}Q_{ik}Q_{j\ell} = m^2_k\delta_{k\ell}$ (no sum over k). In matrix form,

$$Q^{\mathsf{T}}M^2Q = \boldsymbol{m}^2 = \text{diag}(m_1^2, m_2^2, ...)\,, \tag{29.3.42}$$

where the squared-mass eigenvalues m_k^2 are real.[40] This is the standard diagonalization problem for a real symmetric matrix.

Next, consider a collection of free commuting complex spin-0 fields, $\hat{\Phi}_i(x)$. For complex fields, we follow the conventions for flavor indices enunciated below eq. (29.3.2) [e.g. $\hat{\Phi}^i = (\hat{\Phi}_i)^\dagger$]. The free-field Lagrangian is given by

$$\mathscr{L} = \partial_\mu\hat{\Phi}^i\partial^\mu\hat{\Phi}_i - (M^2)^i{}_j\hat{\Phi}_i\hat{\Phi}^j\,, \tag{29.3.43}$$

[39] Since the scalar fields are real, there is no need to distinguish between raised and lowered flavor indices.

[40] If the vacuum corresponds to a local minimum (or flat direction) of the scalar potential, then the squared-mass eigenvalues of M^2 are real *and* non-negative.

where M^2 is an hermitian matrix [i.e., $(M^2)^i{}_j = (M^2)_j{}^i$ in the notation of eq. (29.3.29)].

We diagonalize the scalar squared-mass matrix by introducing mass eigenstates Φ_i and the unitary matrix W such that $\hat{\Phi}_i = W_i{}^k \Phi_k$ (and $\hat{\Phi}^i = W^i{}_k \Phi^k$), with $(M^2)^i{}_j W_i{}^k W^j{}_\ell = m_k^2 \delta_\ell^k$ (no sum over k). In matrix form,

$$W^\dagger M^2 W = \boldsymbol{m}^2 = \text{diag}(m_1^2, m_2^2, \ldots)\,. \tag{29.3.44}$$

where the squared-mass eigenvalues m_k^2 are real (cf. footnote 40). This is the standard diagonalization problem for an hermitian matrix.

29.4 Feynman rules with two-component spinors

In order to systematically perform perturbative calculations using two-component spinors, we present the basic Feynman rules. The Feynman rules for the Standard Model (and its seesaw extension) and the MSSM (including possible R-parity-violating interactions) are given in Appendices J, K and L. Feynman rules for two-component spinors have also been treated in refs. [50, 107, 110].

29.4.1 External fermion and boson rules

Consider a general theory, for which we may assume that the mass matrix for fermions has been diagonalized as discussed in Section 29.3.2. The rules for assigning two-component external state spinors are then as follows:

- For an initial state (incoming) left-handed $(\frac{1}{2}, 0)$ fermion: x
- For an initial state (incoming) right-handed $(0, \frac{1}{2})$ fermion: $y^\dagger$
- For a final state (outgoing) left-handed $(\frac{1}{2}, 0)$ fermion: $x^\dagger$
- For a final state (outgoing) right-handed $(0, \frac{1}{2})$ fermion: y

where we have suppressed the momentum and spin arguments of the spinor wave functions. These rules are summarized in the mnemonic diagram of Fig. 29.4.1.

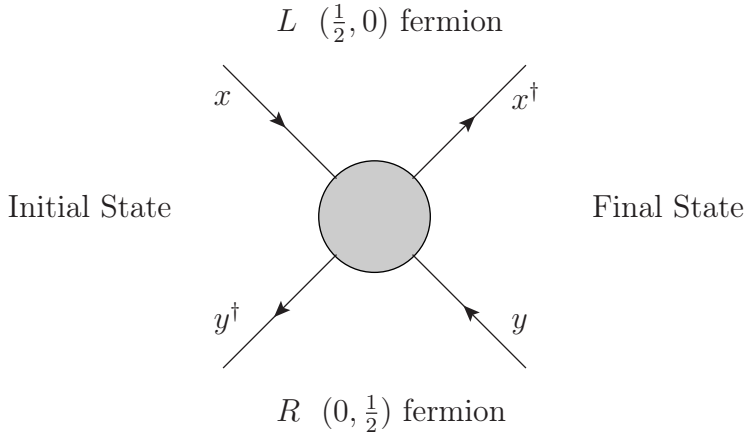

Figure 29.4.1: The external wave function spinors should be assigned as indicated here, for initial state and final state left-handed $(\frac{1}{2}, 0)$ and right-handed $(0, \frac{1}{2})$ fermions.

In general, the two-component external state fermion wave functions are distinguished by their Lorentz group transformation properties, rather than by their particle or antiparticle status as in four-component Feynman rules. This helps to explain why two-component notation is especially convenient for (i) theories with Majorana particles, in which there is no fundamental distinction

between particles and antiparticles, and (ii) theories like the Standard Model and MSSM in which the left and right-handed fermions transform under different representations of the gauge group and (iii) problems with polarized particle beams.

In contrast to four-component Feynman rules (given in Appendix G.5), the direction of the arrow does *not* correspond to the flow of charge or fermion number. The two-component Feynman rules for external fermion lines simply correspond to the formulae for the one-particle wave functions exhibited in eqs. (29.3.7) and (29.3.8) [with the convention that $|\vec{\boldsymbol{p}}, s\rangle$ is an initial state fermion and $\langle\vec{\boldsymbol{p}}, s|$ is a final state fermion]. In particular, the arrows indicate the spinor index structure, with fields of undotted indices flowing *into* any vertex and fields of dotted indices flowing *out* of any vertex.

The rules above apply to any mass eigenstate two-component fermion external wave functions. It is noteworthy that the same rules apply for the two-component fermions governed by the Lagrangians of eq. (29.3.10) [Majorana] and eqs. (29.3.34) or (29.3.40) [Dirac].

The corresponding rules for external boson lines are well-known (see, e.g [115]).

- For an initial state (incoming) or final state (outgoing) spin-0 boson : 1
- For an initial state (incoming) spin-1 boson of momentum $\vec{\boldsymbol{k}}$ and helicity λ : $\varepsilon^\mu(\vec{\boldsymbol{k}}\,,\,\lambda)$
- For a final state (outgoing) spin-1 boson of momentum $\vec{\boldsymbol{k}}$ and helicity λ : $\varepsilon^\mu(\vec{\boldsymbol{k}}\,,\,\lambda)^*$

The explicit form of the helicity ±1 (massless or massive) spin-1 polarization vector ε^μ is given in eq. (I.2.41). The helicity zero massive spin-1 polarization vector is given in eq. (I.2.43).

29.4.2 Propagators

Next we turn to the subject of fermion propagators for two-component fermions. A derivation of the two-component fermion propagators using path integral techniques is given in Appendix F . Here, we will follow the more elementary approach typically given in an initial textbook treatment of quantum field theory.

Fermion propagators are the Fourier transforms of the free-field vacuum expectation values of time-ordered products of two fermion fields. They are obtained by inserting the free-field expansion of the two-component fermion field and evaluating the spin sums using the formulae given in eqs. (29.3.57) and (29.3.60). For the case of a single neutral two-component fermion field $\xi(x)$ of mass m, eqs. (29.3.11) and (29.3.12) yield [145, 50, 152, 107, 109, 110]:

$$\langle 0|\,T\xi_\alpha(x)\xi^\dagger_{\dot\beta}(y)\,|0\rangle_{\rm FT} = \frac{i}{p^2-m^2+i\epsilon}\sum_s x_\alpha(\vec{\boldsymbol{p}},s)x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = \frac{i}{p^2-m^2+i\epsilon}\,p{\cdot}\sigma_{\alpha\dot\beta}\,, \quad (29.4.1)$$

$$\langle 0|\,T\xi^{\dagger\dot\alpha}(x)\xi^\beta(y)\,|0\rangle_{\rm FT} = \frac{i}{p^2-m^2+i\epsilon}\sum_s y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)y^\beta(\vec{\boldsymbol{p}},s) = \frac{i}{p^2-m^2+i\epsilon}\,p{\cdot}\overline{\sigma}^{\dot\alpha\beta}\,, \quad (29.4.2)$$

$$\langle 0|\,T\xi^{\dagger\dot\alpha}(x)\xi^\dagger_{\dot\beta}(y)\,|0\rangle_{\rm FT} = \frac{i}{p^2-m^2+i\epsilon}\sum_s y^{\dagger\dot\alpha}(\vec{\boldsymbol{p}},s)x^\dagger_{\dot\beta}(\vec{\boldsymbol{p}},s) = \frac{i}{p^2-m^2+i\epsilon}\,m\delta^{\dot\alpha}{}_{\dot\beta}\,, \quad (29.4.3)$$

$$\langle 0|\,T\xi_\alpha(x)\xi^\beta(y)\,|0\rangle_{\rm FT} = \frac{i}{p^2-m^2+i\epsilon}\sum_s x_\alpha(\vec{\boldsymbol{p}},s)y^\beta(\vec{\boldsymbol{p}},s) = \frac{i}{p^2-m^2+i\epsilon}\,m\delta_\alpha{}^\beta\,, \quad (29.4.4)$$

where FT indicates the Fourier transform from position to momentum space.[41] These results have a clear diagrammatic representation, as shown in Fig. 29.4.1. Note that the direction of the

[41] The Fourier transform of a translationally invariant function $f(x,y)\equiv f(x-y)$ is given by

$$f(x,y) = \int \frac{d^4p}{(2\pi)^4}\,\widehat{f}(p)\,e^{-ip\cdot(x-y)}\,, \qquad \text{where} \qquad \widehat{f}(p) = \int d^4x\,f(x)e^{ip\cdot x}\,.$$

In the notation of the text above, $f(x,y)_{\rm FT}\equiv\widehat{f}(p)$.

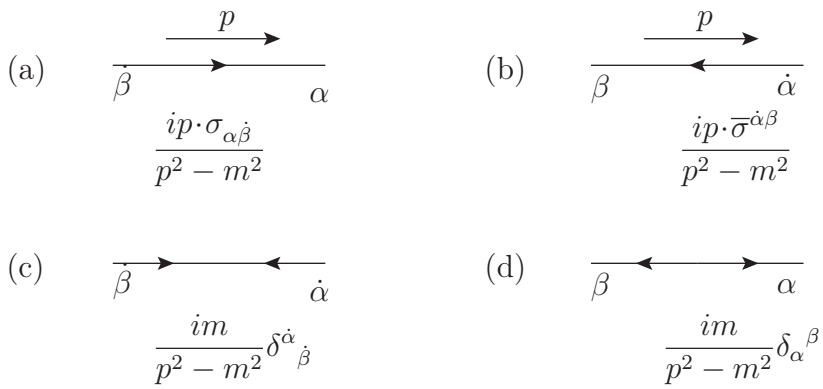

Figure 29.4.1: Feynman rules for propagator lines of a neutral two-component fermion with mass m. (For simplicity, the $+i\epsilon$ terms in the denominators are omitted in all propagator rules.)

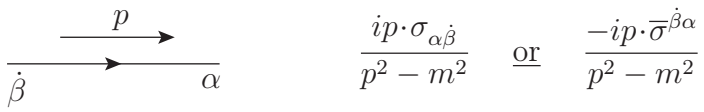

Figure 29.4.2: This rule summarizes the results of both Figs. 29.4.1(a) and (b) for a neutral two-component fermion with mass m.

momentum flow p^μ here is determined by the creation operator that appears in the evaluation of the free-field propagator. Arrows on fermion lines always run away from dotted indices at a vertex and toward undotted indices at a vertex.

There are clearly two types of fermion propagators. The first type preserves the direction of arrows, so it has one dotted and one undotted index. For this type of propagator, it is convenient to establish a convention where p^μ in the diagram is defined to be the momentum flowing in the direction of the arrow on the fermion propagator. With this convention, the two rules above for propagators of the first type can be summarized by one rule, as shown in Fig. 29.4.2. Here the choice of the σ or the $\overline{\sigma}$ version of the rule is uniquely determined by the height of the indices on the vertex to which the propagator is connected.[42] These heights should always be chosen so that they are contracted as in eq. (29.37). It should be noted that in diagrams (a) and (b) of Fig. 29.4.1 as drawn, the indices on the σ and $\overline{\sigma}$ read from right to left. In particular, the Feynman rules for the propagator can be employed with the spinor indices suppressed provided that the arrow-preserving propagator lines are traversed in the direction parallel [antiparallel] to the arrowed line segment for the $\overline{\sigma}$ [σ] version of the rule, respectively.

The second type of propagator shown in diagrams (c) and (d) of Fig. 29.4.1 does not preserve the direction of arrows, and corresponds to an odd number of mass insertions. The indices on $\delta^{\dot\alpha}{}_{\dot\beta}$ and $\delta_\alpha{}^\beta$ are staggered as shown to indicate that $\dot\alpha$ and α are to be contracted with expressions to the left, while $\dot\beta$ and β are to be contracted with expressions to the right, in accord with eq. (29.37).[43]

Starting with massless fermion propagators, one can also derive the massive fermion propagators by employing mass insertions as interaction vertices, as shown in Fig. 29.4.3. By summing up an infinite chain of such mass insertions between massless fermion propagators, one can reproduce the massive fermion propagators of both types.

The above results for the propagator of a Majorana fermion can be generalized to a multiplet of mass eigenstate Majorana fermions, $\xi_{\alpha a}(x)$ [such as a color octet of gluinos], which transforms as

[42] The second form of the rule in Fig. 29.4.2 arises when one flips diagram (b) of Fig. 29.4.1 around by a 180° rotation (about an axis perpendicular to the plane of the diagram), and then relabels $p \to -p$, $\dot\alpha \to \dot\beta$ and $\beta \to \alpha$.

[43] As in Fig. 29.4.2, alternative and equivalent versions of the rules corresponding to diagrams (c) and (d) of Fig. 29.4.1 can be given for which the indices on the Kronecker deltas are staggered as $\delta^{\dot\beta}{}_{\dot\alpha}$ and $\delta_\beta{}^\alpha$. These versions correspond to flipping the two respective diagrams by 180° and relabeling the indices $\dot\alpha \to \dot\beta$ and $\beta \to \alpha$.

Figure 29.4.3: Fermion mass insertions (indicated by the crosses) can be treated as a type of interaction vertex, using the Feynman rules shown here.

a real representation R of a (gauge or flavor) group G (where $a = 1, 2, ..., d_R$ for a representation of dimension d_R). In this case, the Feynman graphs given in Figs. 29.4.1–29.4.3 are modified simply by specifying a group index a and b at either end of the propagator line. The corresponding Feynman rules then include an additional Kronecker delta factor in the group indices. In particular, if we associate the index a with the spinor indices α, $\dot\alpha$ and the index b with the spinor indices β, $\dot\beta$, then the rules exhibited in Fig. 29.4.1(a) and (b) would include the following Kronecker delta factors:

$$(a)\quad \delta^b_a\,, \qquad\qquad (b)\quad \delta^a_b\,, \tag{29.4.5}$$

and the factors of m in the rules exhibited in Fig. 29.4.1(c) and (d) would be replaced by

$$(c)\quad \delta^a_c m^{cd}\delta^b_d = m_a\delta^{ab}\,, \qquad\qquad (d)\quad \delta^c_a m_{cd}\delta^d_b = m_a\delta_{ab}\,, \tag{29.4.6}$$

(with no sum over the repeated index a), where m^{cd} and $m_{cd} \equiv m^{cd}$ are diagonal matrices with real non-negative diagonal elements m_c. Here, we have introduced the separate symbol m_{cd} in order to maintain the convention that two repeated group indices are summed when one index is raised and one index is lowered. Of course, if the Lagrangian is invariant under the symmetry group G, then a multiplet of Majorana fermions corresponding to an irreducible representation R has a common mass $m = m_a$.

It is convenient to treat separately the case of charged massive fermions. Consider a charged Dirac fermion of mass m, which is described by a pair of two-component fields $\chi(x)$ and $\eta(x)$ [cf. eq. (29.3.17)]. Using the free-field expansions [eqs. (29.3.19) and (29.3.20)] and the spin sums [eqs. (29.3.57)–(29.3.60)], the two-component free-field propagators are obtained:

$$\langle 0|\,T\chi_\alpha(x)\chi^\dagger_{\dot\beta}(y)\,|0\rangle_{\rm FT} = \langle 0|\,T\eta_\alpha(x)\eta^\dagger_{\dot\beta}(y)\,|0\rangle_{\rm FT} = \frac{i}{p^2-m^2}\,p{\cdot}\sigma_{\alpha\dot\beta}\,, \tag{29.4.7}$$

$$\langle 0|\,T\chi^{\dagger\dot\alpha}(x)\chi^\beta(y)\,|0\rangle_{\rm FT} = \langle 0|\,T\eta^{\dagger\dot\alpha}(x)\eta^\beta(y)\,|0\rangle_{\rm FT} = \frac{i}{p^2-m^2}\,p{\cdot}\overline\sigma^{\dot\alpha\beta}\,, \tag{29.4.8}$$

$$\langle 0|\,T\chi_\alpha(x)\eta^\beta(y)\,|0\rangle_{\rm FT} = \langle 0|\,T\eta_\alpha(x)\chi^\beta(y)\,|0\rangle_{\rm FT} = \frac{i}{p^2-m^2}\,m\,\delta_\alpha{}^\beta\,, \tag{29.4.9}$$

$$\langle 0|\,T\chi^{\dagger\dot\alpha}(x)\eta^\dagger_{\dot\beta}(y)\,|0\rangle_{\rm FT} = \langle 0|\,T\eta^{\dagger\dot\alpha}(x)\chi^\dagger_{\dot\beta}(y)\,|0\rangle_{\rm FT} = \frac{i}{p^2-m^2}\,m\,\delta^{\dot\alpha}{}_{\dot\beta}\,. \tag{29.4.10}$$

For all other combinations of fermion bilinears, the corresponding two-point functions vanish. These results again have a simple diagrammatic representation, as shown in Fig. 29.4.4. Note that for Dirac fermions, the propagators with opposing arrows (proportional to a mass) necessarily change the identity (χ or η) of the two-component fermion, while the single-arrow propagators are diagonal in the fields. In processes involving such a charged fermion, one must of course distinguish between the χ and η fields.

The above results for the propagator of a Dirac fermion can be generalized to a multiplet of mass eigenstate Dirac fermions, $\chi_{\alpha i}$, η^i_α, which transform under a (gauge or flavor) group G. In this case, the Feynman graphs given in Fig. 29.4.4 are modified simply by specifying a group index i and j at either end of the propagator line. The corresponding Feynman rules then include an

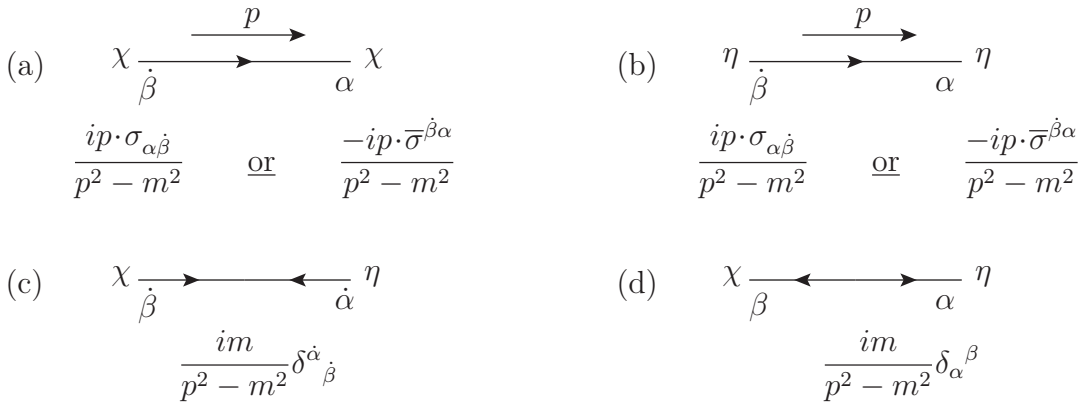

Figure 29.4.4: Feynman rules for propagator lines of a pair of charged two-component fermions with a Dirac mass m. As in Fig. 29.4.2, the direction of the momentum is taken to flow from the dotted to the undotted index in diagrams (a) and (b).

additional Kronecker delta factor in the group indices. In particular, if we associate the group index i with the spinor indices α, $\dot\alpha$ and the index j with the spinor indices β, $\dot\beta$, then the rules exhibited in Fig. 29.4.4(a) and (b) would include the following Kronecker delta factors:

$$(a)\ \ \delta_i^j \qquad\qquad (b)\ \ \delta_j^i\,, \tag{29.4.11}$$

and the factors of m in the rules exhibited in Fig. 29.4.4(c) and (d) would be replaced by

$$(c)\ \ \delta_i^\ell m_\ell{}^n \delta_n^j = m_i \delta_i^j\,, \qquad\qquad (d)\ \ \delta_\ell^i m^\ell{}_n \delta_j^n = m_i \delta_j^i\,, \tag{29.4.12}$$

where $m^\ell{}_n$ and $m_\ell{}^n \equiv m^\ell{}_n$ are diagonal matrices with real non-negative diagonal elements m_ℓ, and there is no sum over the repeated index i. (Here, we have introduced the separate symbol $m_\ell{}^n$ in order to maintain the convention that two repeated group indices are summed when one index is raised and one index is lowered.) As before, if the Lagrangian is invariant under the symmetry group G, then an irreducible multiplet of Dirac fermions has a common mass $m = m_i$.

For completeness, we exhibit in Fig. 29.4.5 the Feynman rules for the propagators of the (neutral or charged) scalar boson and gauge boson in the R_ξ gauge, with gauge parameter ξ [153].

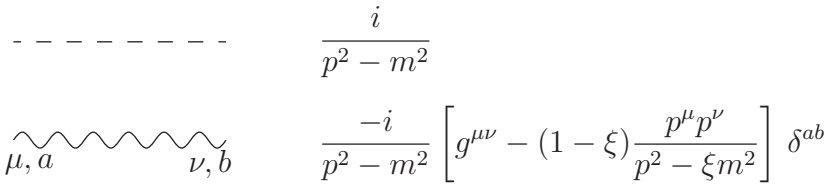

Figure 29.4.5: Feynman rules for the (neutral or charged) scalar and gauge boson propagators, in the R_ξ gauge, where p^μ is the propagating four-momentum. In the gauge boson propagator, $\xi = 1$ defines the 't Hooft-Feynman gauge, $\xi = 0$ defines the Landau gauge, and $\xi \to \infty$ defines the unitary gauge. For the propagation of a non-abelian gauge boson, one must also specify the adjoint representation indices a, b.

29.4.3 Fermion interactions with bosons

We next discuss the interaction vertices for fermions with bosons. Renormalizable Lorentz-invariant interactions involving fermions must consist of bilinears in the fermion fields, which

transform as a Lorentz scalar or vector, coupled to the appropriate bosonic scalar or vector field to make an overall Lorentz scalar quantity.

Let us write all of the two-component left-handed $(\frac{1}{2},0)$ fermions of the theory as $\hat{\psi}_i$, where i runs over all of the gauge group representation and flavor degrees of freedom. In general, the $(\frac{1}{2},0)$-fermion fields $\hat{\psi}_i$ consist of Majorana fermions $\hat{\xi}_i$, and Dirac fermion pairs $\hat{\chi}_i$ and $\hat{\eta}^i$ after mass terms (both explicit and coming from spontaneous symmetry breaking) are taken into account. Likewise, consider a multiplet of scalar fields $\hat{\phi}_I$, where I runs over all of the gauge group representation and flavor degrees of freedom. In general, the scalar fields $\hat{\phi}_I$ consist of real scalar fields $\hat{\varphi}_I$ and pairs of complex scalar fields $\hat{\Phi}_I$ and $\hat{\Phi}^I \equiv (\hat{\Phi}_I)^\dagger$. In matrix form,

$$\hat{\psi} \equiv \begin{pmatrix} \hat{\xi} \\ \hat{\chi} \\ \hat{\eta} \end{pmatrix}, \qquad \hat{\phi} \equiv \begin{pmatrix} \hat{\varphi} \\ \hat{\Phi} \\ \hat{\Phi}^\dagger \end{pmatrix}. \tag{29.4.1}$$

By dividing up the fermions into Majorana and Dirac fermions and the spin-zero fields into real and complex scalars, we are assuming implicitly that some of the indices I and i correspond to states of a definite (global) U(1)-charge (denoted in the following by q_I and q_i, respectively).

The most general set of Yukawa interactions of the scalar fields with a pair of fermion fields is then given by:

$$\mathscr{L}_{\rm int} = -\tfrac{1}{2}\hat{Y}^{Ijk}\hat{\phi}_I\hat{\psi}_j\hat{\psi}_k - \tfrac{1}{2}\hat{Y}_{Ijk}\hat{\phi}^I\hat{\psi}^{\dagger j}\hat{\psi}^{\dagger k}, \tag{29.4.2}$$

where $\hat{Y}_{Ijk} = (\hat{Y}^{Ijk})^*$ is symmetric under the interchange of j and k. We have suppressed the spinor indices; the product of two-component spinors is always performed according to the index convention indicated in eq. (29.37). The Yukawa Lagrangian [eq. (29.4.2)] must be invariant under:

$$\hat{\xi}_i \to \hat{\xi}_i\,, \qquad \hat{\chi}_i \to e^{iq_i\theta}\hat{\chi}_i\,, \qquad \hat{\eta}^i \to e^{-iq_i\theta}\hat{\eta}^i\,, \qquad \hat{\varphi}_i \to \hat{\varphi}_i\,, \qquad \hat{\Phi}_I \to e^{iq_I\theta}\hat{\Phi}_I\,, \qquad \hat{\Phi}^I \to e^{-iq_I\theta}\hat{\Phi}^I\,, \tag{29.4.3}$$

where the q_i are the U(1)-charges of the corresponding Dirac fermions and the q_I are the U(1)-charges of the corresponding complex scalars. Consequently, the form of the $\hat{Y}^{Ijk}$ is constrained:

$$\hat{Y}^{Ijk} = 0\,, \quad \text{unless} \quad q_I + q_j + q_k = 0\,. \tag{29.4.4}$$

Of course, any other conserved symmetries will impose additional selection rules on the Yukawa couplings $\hat{Y}^{Ijk}$.

The hatted fields are the interaction eigenstate fields. However, in general the mass eigenstates can be different, as discussed in Section 29.3.2. The computation of matrix elements for physical processes is more conveniently done in terms of the propagating mass eigenstate fields. The mass eigenstate basis ψ is related to the interaction eigenstate basis $\hat{\psi}$ by a unitary rotation $U_i{}^j$ on the flavor indices. In matrix form:

$$\hat{\psi} \equiv \begin{pmatrix} \hat{\xi}_i \\ \hat{\chi}_i \\ \hat{\eta}^i \end{pmatrix} = U\psi \equiv \begin{pmatrix} \Omega_i{}^j & 0 & 0 \\ 0 & L_i{}^j & 0 \\ 0 & 0 & R^i{}_j \end{pmatrix} \begin{pmatrix} \xi_j \\ \chi_j \\ \eta^j \end{pmatrix}, \tag{29.4.5}$$

where Ω, L, and R are constructed as described previously in Section 29.3.2 [see eqs. (29.3.8) and (29.3.32)]. Likewise, the mass eigenstate basis ϕ is related to the interaction eigenstate basis $\hat{\phi}$ by a unitary rotation $V_I{}^J$ on the flavor indices. In matrix form,

$$\hat{\phi} \equiv \begin{pmatrix} \hat{\varphi}_I \\ \hat{\Phi}_I \\ \hat{\Phi}^I \end{pmatrix} = V\phi \equiv \begin{pmatrix} Q_I{}^J & 0 & 0 \\ 0 & W_I{}^J & 0 \\ 0 & 0 & W^I{}_J \end{pmatrix} \begin{pmatrix} \varphi_J \\ \Phi_J \\ \Phi^J \end{pmatrix}, \tag{29.4.6}$$

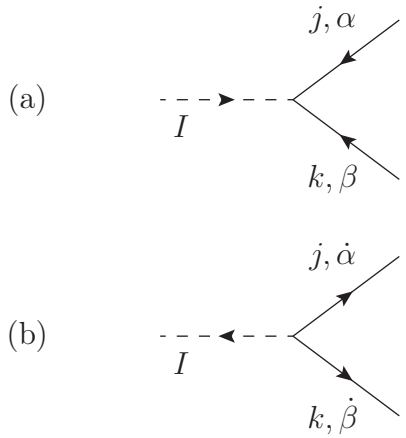

Figure 29.4.1: Feynman rules for Yukawa couplings of scalars to two-component fermions in a general field theory. The choice of which rule to use depends on how the vertex connects to the rest of the amplitude. When indices are suppressed, the spinor index part is always just proportional to the identity matrix.

where $W^I{}_J = (W_I{}^J)^*$, and Q and W are constructed according to eqs. (29.3.42) and (29.3.44).

Thus, we may rewrite eq. (29.4.2) in terms of mass eigenstate fields:

$$\mathscr{L}_{\rm int} = -\tfrac{1}{2}Y^{Ijk}\phi_I\psi_j\psi_k - \tfrac{1}{2}Y_{Ijk}\phi^I\psi^{\dagger j}\psi^{\dagger k}\,, \tag{29.4.7}$$

where

$$Y^{Ijk} = Y^{Ikj} \equiv V_J{}^I U_m{}^j U_n{}^k \hat{Y}^{Jmn}\,. \tag{29.4.8}$$

Note that eq. (29.4.4) implies that $Y^{Ijk} = 0$ unless $q_I + q_j + q_k = 0$. The corresponding Feynman rules that arise from the Yukawa interaction Lagrangian are shown in Fig. 29.4.1. If the scalar ϕ_I is complex, then one can associate an arrow with the flow of analyticity, which would point into the vertex in (a) and would point out of the vertex in (b). That is, the arrow on the scalar line keeps track of the height of the scalar flavor index entering or leaving the vertex.

In Fig. 29.4.1, two versions are given for each Feynman rule. The choice of which rule to use is dictated by the height of the indices on the fermion lines that connect to the vertex. These heights should always be chosen so that they are contracted as in eq. (29.37). However, when all spinor indices are suppressed, the scalar-fermion-fermion rules will have an identical appearance for both cases, since they are just proportional to the identity matrix of the 2×2 spinor space.

To provide a more concrete example of the above results, consider a real neutral scalar field ϕ and a (possibly) complex charged scalar field Φ (with U(1)-charge q_Φ) that interact with a multiplet of Majorana fermions ξ_i and Dirac fermion pairs χ_j and η^j (with U(1)-charges q_j and $-q_j$, respectively). We assume that all fields are given in the mass eigenstate basis. The Yukawa interaction Lagrangian is given by:

$$\begin{aligned}\mathscr{L}_{\rm int} = &-\tfrac{1}{2}(\lambda^{ij}\xi_i\xi_j + \lambda_{ij}\xi^{\dagger i}\xi^{\dagger j})\phi - \kappa^i{}_j\chi_i\eta^j\Phi + \kappa_i{}^j\chi^{\dagger i}\eta^\dagger_j\Phi^\dagger \\ &-[(\kappa_1)^i{}_j\xi_i\eta^j + (\kappa_2)_{ij}\xi^{\dagger i}\chi^{\dagger j}]\Phi - [(\kappa_2)^{ij}\xi_i\chi_j + (\kappa_1)_i{}^j\xi^{\dagger i}\eta^\dagger_j]\Phi^\dagger\,,\end{aligned} \tag{29.4.9}$$

where λ is a complex symmetric matrix, and κ, κ_1 and κ_2 are complex matrices such that $\kappa^i{}_j = 0$ unless $q_\Phi = q_j - q_i$ and $(\kappa_1)^i{}_j = (\kappa_2)_{ij} = 0$ unless $q_\Phi = q_j$ [flavor index conventions are specified in eqs. (29.3.2) and (29.3.28)]. The corresponding Feynman rules of Fig. 29.4.1(a) are obtained by identifying $Y^{Iij} = \lambda^{ij}$, $\kappa^i{}_j$, $(\kappa_1)^i{}_j$ and $(\kappa_2)^{ij}$ for the undotted fermion vertices $\phi\xi_i\xi_j$, $\Phi\chi_i\eta^j$, $\Phi\xi_i\eta^j$ and $\Phi^\dagger\xi_i\chi_j$, respectively.[44] The corresponding Feynman rules of Fig. 29.4.1(b) for the dotted fermion vertices are governed by the complex-conjugated Yukawa couplings, $Y_{Ijk} \equiv (Y^{Ijk})^*$.

[44]For the $\Phi^\dagger\xi_i\chi_j$ vertex, we should reverse the direction of the arrow on the scalar line in Fig. 29.4.1(a) [and

The renormalizable interactions of vector bosons with fermions and scalars arise from gauge interactions. These interaction terms of the Lagrangian derive from the respective kinetic energy terms of the fermions and scalars when the derivative is promoted to the covariant derivative:

$$(D_\mu)_i{}^j \equiv \delta_i{}^j\partial_\mu + ig_a A_\mu^a (\boldsymbol{T^a})_i{}^j\,, \tag{29.4.10}$$

where the index a labels the real (interaction eigenstate) vector bosons A_a^μ and is summed over. The index a runs over the adjoint representation of the gauge group,[45] and the $(\boldsymbol{T^a})_i{}^j$ are hermitian representation matrices of the generators of the Lie algebra of the gauge group acting on the left-handed fermions (for further details, see Appendix E). For a $U(1)$ gauge group, the $\boldsymbol{T^a}$ are replaced by real numbers corresponding to the U(1) charges of the left-handed $(\frac{1}{2},0)$ fermions. There is a separate coupling g_a for each simple group or U(1) factor of the gauge group G.[46]

In the gauge-interaction basis for the left-handed $(\frac{1}{2},0)$ two-component fermions the corresponding interaction Lagrangian is given by

$$\mathscr{L}_{\rm int} = -g_a A_a^\mu \hat{\psi}^{\dagger i}\,\overline{\sigma}_\mu (\boldsymbol{T}^a)_i{}^j \hat{\psi}_j\,. \tag{29.4.11}$$

In the case of spontaneously broken gauge theories, one must diagonalize the vector boson squared-mass matrix. The form of eq. (29.4.11) still applies where A_μ^a are gauge boson fields of definite mass, although in this case for a fixed value of a, $g_a\boldsymbol{T}^a$ [which multiplies A_μ^a in eq. (29.4.11)] is some linear combination of the original $g_a\boldsymbol{T}^a$ of the unbroken theory. That is, the hermitian matrix gauge field $(A_\mu)_i{}^j \equiv A_\mu^a(\boldsymbol{T^a})_i{}^j$ appearing in eq. (29.4.11) can always be re-expressed in terms of the *physical* mass eigenstate gauge boson fields.

If an unbroken U(1) (global or local) symmetry exists, then the physical gauge bosons will be eigenstates of the conserved U(1)-charge.[47] If the U(1) symmetry group is orthogonal to the gauge group under which the A_a^μ transform, then all the gauge bosons are neutral with respect to the U(1)-charge. For example, in the case of the interaction of a gluon with a pair of Majorana fermion gluinos, the gluon is a gauge boson that transforms under the SU(3) color group, which is orthogonal to the conserved $\mathrm{U}(1)_{\rm EM}$. That is, gluinos are color octet, electrically neutral fermions. In contrast, in the case of the interaction of a Z^0 with pair of Majorana neutralinos, $\mathrm{U}(1)_{\rm EM}$ is not orthogonal to the electroweak SU(2)×U(1) gauge group. Nevertheless, the Z^0-gauge boson interactions of the neutralinos are allowed as they conserve electric charge.

To obtain the desired Feynman rule, we rewrite eq. (29.4.11) in terms of mass eigenstate fermion fields. The resulting interaction Lagrangian can be rewritten as

$$\mathscr{L}_{\rm int} = -A_a^\mu \psi^{\dagger i}\,\overline{\sigma}_\mu (G^a)_i{}^j \psi_j\,, \tag{29.4.13}$$

likewise for the corresponding hermitian-conjugated vertex of Fig. 29.4.1(b)], in which case all arrows on the charged scalar and fermion lines would represent the direction of flow of the conserved U(1)-charge.

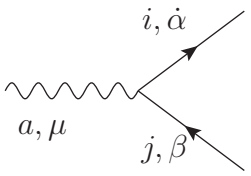
[45] Since the adjoint representation is a real representation, the height of the adjoint index a is not significant. The choice of a subscript or superscript adjoint index is based solely on typographical considerations.

[46] That is, the generators $\boldsymbol{T^a}$ separate out into distinct classes, each of which is associated with a simple group or one of the U(1) factors contained in the direct product that defines G. In particular, $g_a = g_b$ if $\boldsymbol{T^a}$ and $\boldsymbol{T^b}$ are in the same class. If G is simple, then $g_a = g$ for all a.

[47] In terms of the physical gauge boson fields, $A_\mu^a\boldsymbol{T^a}$ consists of a sum over real neutral gauge fields multiplied by hermitian generators, and complex charged gauge fields multiplied by non-hermitian generators. For example, in the electroweak Standard Model, G=SU(2)×U(1) with gauge bosons and generators W_μ^a and $\boldsymbol{T}^a = \frac{1}{2}\tau^a$ for SU(2) and B_μ and $\boldsymbol{Y}$ for U(1), where the τ^a are the usual Pauli matrices. After diagonalizing the gauge boson squared-mass matrix[153]:

$$gW_\mu^a\boldsymbol{T^a} + g'B_\mu\boldsymbol{Y} = \frac{g}{\sqrt{2}}(W_\mu^+\boldsymbol{T^+} + W_\mu^-\boldsymbol{T^-}) + \frac{g}{\cos\theta_W}\left(\boldsymbol{T^3} - \boldsymbol{Q}\sin^2\theta_W\right)Z_\mu + e\boldsymbol{Q}A_\mu\,, \tag{29.4.12}$$

where $\boldsymbol{Q} = \boldsymbol{T^3} + \boldsymbol{Y}$ is the generator of the unbroken $\mathrm{U}(1)_{\rm EM}$, $\boldsymbol{T^\pm} \equiv \boldsymbol{T^1} \pm i\boldsymbol{T^2}$, and $e = g\sin\theta_W = g'\cos\theta_W$. The massive gauge boson charge-eigenstate fields of the broken theory consist of a charged massive gauge boson pair, $W^\pm \equiv (W^1 \mp iW^2)/\sqrt{2}$, a neutral massive gauge boson, $Z \equiv W^3\cos\theta_W - B\sin\theta_W$, and the massless photon, $A \equiv W^3\sin\theta_W + B\cos\theta_W$.



$$-i(G^a)_i{}^j\,\overline{\sigma}_\mu^{\dot\alpha\beta} \quad \text{or} \quad i(G^a)_i{}^j\,\sigma_{\mu\beta\dot\alpha}$$

Figure 29.4.2: The Feynman rules for two-component fermion interactions with gauge bosons. The choice of which rule to use depends on how the vertex connects to the rest of the amplitude. The G^a are defined in eq. (29.4.14). The index a runs over both neutral and charged (mass eigenstate) gauge bosons, consistent with charge conservation at the vertex.

where the A_a^μ are the mass eigenstate gauge fields (of definite U(1)-charge, if relevant), and

$$(G^a)_i{}^j = g_a U^k{}_i (\boldsymbol{T^a})_k{}^m U_m{}^j\,, \tag{29.4.14}$$

or in matrix form, $G^a = g_a U^\dagger \boldsymbol{T^a} U$ (no sum over a). For values of a corresponding to the neutral gauge fields, the G^a are hermitian matrices. The corresponding Feynman rule is shown in Fig. 29.4.2.

The above treatment of the gauge interactions of (two-component) fermions is general. Nevertheless, it is useful to consider separately three cases where the gauge bosons couple to a pair of Majorana fermions, a pair of Dirac fermions, and a fermion pair consisting of one Majorana and one Dirac fermion.

First, consider the gauge interactions of neutral Majorana fermions. The Majorana fermions consist of left-handed $(\frac{1}{2},0)$ interaction eigenstate fermions $\hat\xi_i$ that transform under a real representation of the gauge group. After converting from the interaction eigenstates $\hat\xi_i$ to the mass eigenstates ξ_i using eq. (29.3.7), the Lagrangian for the gauge interactions of Majorana fermions is given by:

$$\mathscr{L}_{\rm int} = -A_\mu^a \xi^{\dagger i}\,\overline{\sigma}^\mu (G^a)_i{}^j \xi_j\,, \tag{29.4.15}$$

where the A_μ^a are *neutral* (real) mass eigenstate gauge fields, and

$$(G^a)_i{}^j = g_a \Omega^k{}_i (\boldsymbol{T^a})_k{}^m \Omega_m{}^j\,, \tag{29.4.16}$$

or in matrix form, $G^a = g_a \Omega^\dagger \boldsymbol{T^a} \Omega$ (no sum over a). Note that the G^a are hermitian matrices. The corresponding Feynman rule takes the same form as the generalized rule shown in Fig. 29.4.2, with a restricted to values corresponding to the neutral mass eigenstate gauge bosons.

Next, consider the gauge interactions of charged Dirac fermions. The Dirac fermions consist of pairs of left-handed $(\frac{1}{2},0)$ interaction eigenstate fermions $\hat\chi_i$ and $\hat\eta^i$ that transform as conjugate representations of the gauge group (hence the opposite flavor index heights). The fermion mass matrix couples χ and η type fields as in eq. (29.3.27). In the coupling to the interaction eigenstate gauge fields, if the $(\boldsymbol{T}^a)_i{}^j$ are matrix elements of the hermitian representation matrices of the generators acting on the $\hat\chi_i$, then the $\hat\eta^i$ transform in the complex conjugate representation with the corresponding generator matrices $-(\boldsymbol{T}^a)^* = -(\boldsymbol{T}^a)^{\sf T}$, i.e. with matrix elements $-(\boldsymbol{T}^a)_j{}^i$. Hence, the Lagrangian for the gauge interactions of Dirac fermions can be written in the form:

$$\mathscr{L}_{\rm int} = -g_a A_a^\mu \hat\chi^{\dagger i}\,\overline{\sigma}_\mu (\boldsymbol{T}^a)_i{}^j \hat\chi_j + g_a A_a^\mu \hat\eta_i^\dagger\,\overline{\sigma}_\mu (\boldsymbol{T}^a)_j{}^i \hat\eta^j\,. \tag{29.4.17}$$

We now rewrite eq. (29.4.17) in terms of mass eigenstate fermion fields using eq. (29.3.31), and express the hermitian matrix gauge field $A^\mu \equiv A_a^\mu \boldsymbol{T^a}$ in terms of mass eigenstate gauge fields (of definite U(1)-charge, if relevant). The resulting interaction Lagrangian is then given by:

$$\mathscr{L}_{\rm int} = -A_a^\mu \left[\chi^{\dagger i}\,\overline{\sigma}_\mu (G_L^a)_i{}^j \chi_j - \eta_i^\dagger\,\overline{\sigma}_\mu (G_R^a)_j{}^i \eta^j\right]\,, \tag{29.4.18}$$

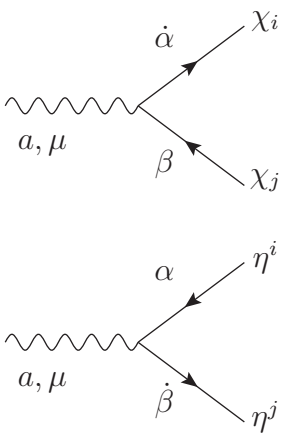


Figure 29.4.3: The Feynman rules for the interaction of a gauge boson and a pair of Dirac fermions (each formed by χ and η of the appropriate flavor index). The fermion lines are labeled by the corresponding two-component left-handed $(\frac{1}{2},0)$ fermion fields. The matrices G_L^a and G_R^a depend on the group generators for the representation carried by the χ_i according to eqs. (29.4.19) and (29.4.20). The index a runs over both neutral and charged (mass eigenstate) gauge bosons, consistent with charge conservation at the vertex.

where $A_a^\mu G_L^a$ and $A_a^\mu G_R^a$ are hermitian matrix-valued gauge fields, with:

$$(G_L^a)_i{}^j = g_a L^k{}_i (\boldsymbol{T^a})_k{}^m L_m{}^j\,, \tag{29.4.19}$$

$$(G_R^a)_j{}^i = g_a R^m{}_j (\boldsymbol{T^a})_m{}^k R_k{}^i\,. \tag{29.4.20}$$

In matrix form, eqs. (29.4.19) and (29.4.20) read: $G_L^a = g_a L^\dagger \boldsymbol{T^a} L$ and $G_R^a = g_a R^\dagger \boldsymbol{T^a} R$ (no sum over a). For values of a corresponding to the neutral gauge fields, G_L^a and G_R^a are hermitian matrices. The corresponding Feynman rules for the gauge interactions of Dirac fermions are shown in Fig. 29.4.3. Note that χ_i with its arrow pointing out of the vertex and η^i with its arrow pointing into the vertex represent the same Dirac fermion.

Finally, consider the interaction of a charged vector boson W (with U(1)-charge q_W) with a fermion pair consisting of one Majorana and one Dirac fermion. As before, we denote the Majorana fermion by ξ_i and the Dirac fermion pair by χ_j and η^j (with U(1)-charges q_j and $-q_j$, respectively). All fields are assumed to be in the mass eigenstate basis. The interaction Lagrangian is given by:[48]

$$\mathscr{L}_{\rm int} = -W_\mu[(G_1)_j{}^i \chi^{\dagger j}\overline\sigma^\mu \xi_i - (G_2)_{ij}\xi^{\dagger i}\overline\sigma^\mu\eta^j] - W_\mu^\dagger[(G_1)^j{}_i\,\xi^{\dagger i}\overline\sigma^\mu\chi_j - (G_2)^{ij}\eta_j^\dagger\overline\sigma^\mu\xi_i]\,, \tag{29.4.21}$$

where G_1 and G_2 are arbitrary complex matrices, with $(G_1)^i{}_j \equiv [(G_1)_i{}^j]^*$ and $(G_2)^{ij} \equiv [(G_2)_{ij}]^*$, such that $(G_1)_j{}^i = (G_2)_{ij} = 0$ unless $q_W = q_j$. The interactions of eq. (29.4.21) yield the Feynman rules exhibited in Fig. 29.4.4. Note that rules (c) and (d) are the complex conjugates of rules (a) and (b), respectively, corresponding to a reversal of the flow of the U(1)-charge through the interaction vertex.

In Figs. 29.4.2–29.4.4, two versions are given for each of the boson-fermion-fermion Feynman rules. The correct version to use depends in a unique way on the heights of indices used to connect each fermion line to the rest of the diagram. For example, the way of writing the vector-fermion-fermion interaction rule depends on whether we used $\psi^{\dagger i}\overline\sigma^\mu\psi_j$, or its equivalent form $-\psi_j\sigma^\mu\psi^{\dagger i}$, in eq. (29.4.11). Note the different heights of the undotted and dotted spinor indices that adorn σ^μ and $\overline\sigma^\mu$. The choice of which rule to use is thus dictated by the height of the indices on the lines that connect to the vertex. These heights should always be chosen so that they are contracted as in eq. (29.37).

The application of the rules of this subsection will be exhibited in Section 29.4.5. Many additional examples involving Standard Model and MSSM processes can be found in Section 29.6.

[48] The sign in front of G_2 is conventionally chosen to match the sign of the term proportional to G_R^a in eq. (29.4.18).

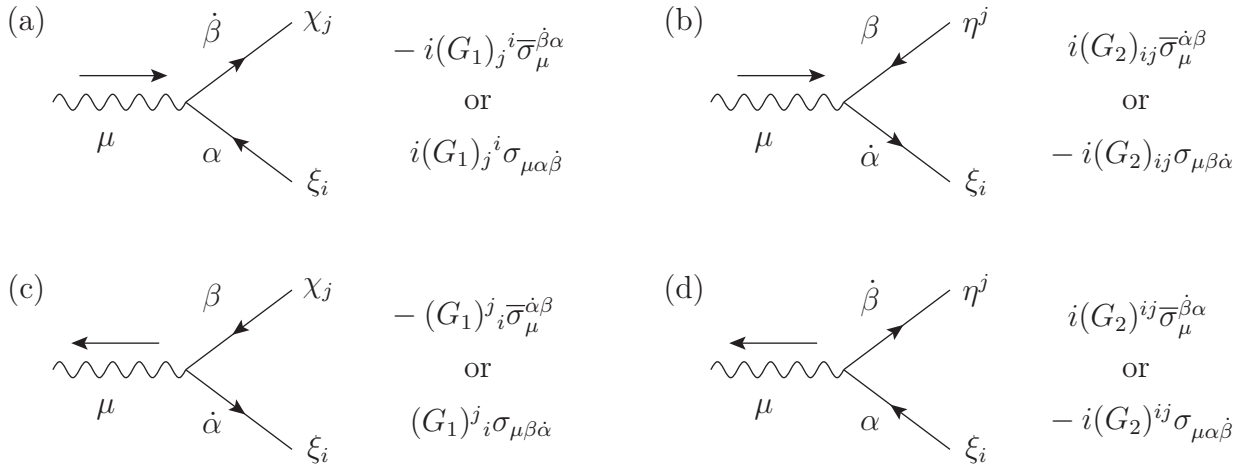

Figure 29.4.4: The Feynman rules for the interactions of a charged vector boson (with U(1)-charge q_W) with a fermion pair consisting of one Majorana fermion ξ_i and one Dirac fermion formed by χ_j and η^j (with corresponding U(1)-charges q_j and $-q_j$). The fermion lines are labeled by the corresponding two-component left-handed $(\frac{1}{2},0)$ fermion fields. The matrix couplings G_1 and G_2 are defined in eq. (29.4.21). Note that $(G_1)_j{}^i = (G_2)_{ij} = 0$ unless $q_W = q_j$. The arrows indicate the direction of flow of the U(1)-charges of the fermion and boson fields.

29.4.4 General structure and rules for Feynman graphs

When computing an amplitude for a given process, all possible diagrams should be drawn that conform with the rules given in Sections 29.4.1–29.4.3 for external wave functions, propagators, and interactions, respectively. Starting from any external wave function spinor (or from any vertex on a fermion loop), factors corresponding to each propagator and vertex should be written down from left to right, following the line until it ends at another external state wave function (or at the original point on the fermion loop). If one starts a fermion line at an x or y external state spinor, it should have a raised undotted index in accord with eq. (29.37). Or, if one starts with an $x^\dagger$ or $y^\dagger$, it should have a lowered dotted spinor index. Then, all spinor indices should always be contracted as in eq. (29.37). If one ends with an x or y external state spinor, it will have a lowered undotted index, while if one ends with an $x^\dagger$ or $y^\dagger$ spinor, it will have a raised dotted index. For arrow-preserving fermion propagators and gauge vertices, the preceding determines whether the σ or $\overline\sigma$ rule should be used.

With only a little practice, one can write down amplitudes immediately with all spinor indices suppressed. In particular, the following must be satisfied:

- For any scattering matrix amplitude, factors of σ and $\overline\sigma$ must alternate. If one or more factors of σ and/or $\overline\sigma$ are present, then x and y must be followed [preceded] by a σ [$\overline\sigma$], and $x^\dagger$ and $y^\dagger$ must be followed [preceded] by a $\overline\sigma$ [σ]. (29.4.1)

These requirements automatically dictate whether the σ or $\overline\sigma$ version of the rule for arrow-preserving fermion propagators and gauge vertices are employed in any tree-level Feynman diagram. In loop diagrams, we must add one further requirement that governs the order of the σ and $\overline\sigma$ factors as one traverses around the loop.

- Arrow-preserving propagator lines must be traversed in a direction parallel [antiparallel] to the arrowed line segment for the $\overline\sigma$ [σ] version of the propagator rule.[49] (29.4.2)

[49] This rule is simply a consequence of the order of the spinor indices in Fig. 29.4.2, as noted in Section 29.4.2.

For fermion lines that are not closed loops, this last requirement is realized automatically provided that the requirements of eq. (29.4.1) are satisfied. However, for closed fermion loops, one must use the correct fermion propagator corresponding to the direction around the loop one has chosen to follow in writing down the spinor trace with suppressed indices. For example, having employed a σ [$\overline{\sigma}$] rule at one vertex attached to the loop, one must then traverse the loop from that vertex point in a direction parallel [antiparallel] to the arrow-preserving propagator lines in the loop. Indeed, this rule is crucial for obtaining the correct sign for the triangle anomaly calculation in Section 29.6.26.

Symmetry factors for identical particles are implemented in the usual way. Fermi-Dirac statistics are implemented by the following rules:

- Each closed fermion loop gets a factor of -1.
- A relative minus sign is imposed between terms contributing to a given amplitude whenever the ordering of external state spinors (written left-to-right in a formula) differs by an odd permutation.

Amplitudes generated according to these rules will contain objects of the form:

$$a = z_1 \Sigma z_2 \tag{29.4.3}$$

where z_1 and z_2 are each commuting external spinor wave functions x, $x^\dagger$, y, or $y^\dagger$, and Σ is a sequence of alternating σ and $\overline{\sigma}$ matrices. The complex conjugate of this quantity is obtained by applying the results of eqs. (29.44)–(29.48), and is given by[50]

$$a^* = z_2^\dagger \Sigma_r z_1^\dagger \tag{29.4.4}$$

where Σ_r is obtained from Σ by reversing the order of all the σ and $\overline{\sigma}$ matrices, and using the same rule for suppressed spinor indices. [Notice that this rule for taking complex conjugates has the same form as for anticommuting spinors; cf. eqs. (29.44)–(29.48).] We emphasize that in principle, it does not matter in what direction a diagram is traversed while applying the rules. However, for each diagram one must include a sign that depends on the ordering of the external fermions. This sign can be fixed by first choosing some canonical ordering of the external fermions. Then for any graph that contributes to the process of interest, the corresponding sign is positive (negative) if the ordering of external fermions is an even (odd) permutation with respect to the canonical ordering. If one chooses a different canonical ordering, then the resulting amplitude changes by an overall phase (is unchanged) if this ordering is an odd (even) permutation of the original canonical ordering.[51] This is consistent with the fact that the S-matrix element is only defined up to an overall sign, which is not physically observable.[52]

Note that different graphs contributing to the same process will often have different external state wave function spinors, with different arrow directions, for the same external fermion. Furthermore, there are no arbitrary choices to be made for arrow directions, as there are in some four-component Feynman rules for Majorana fermions (as discussed in Appendix G .) Instead, one must add together *all* Feynman graphs that obey the rules.

[50] For Lorentz-scalar quantities of the form given by eq. (29.4.3), there is no distinction between complex conjugation and hermitian conjugation.

[51] For a process with exactly two external fermions, it is convenient to apply the Feynman rules by starting from the same fermion external state in all diagrams. That way, all terms in the amplitude have the same canonical ordering of fermions and there are no additional minus signs between diagrams. However, if there are four or more external fermions, it often happens that there is no way to choose the same ordering of external state spinors for all graphs when the amplitude is written down. Then the relative signs between different graphs must be chosen according to the relative sign of the permutation of the corresponding external fermion spinors. This guarantees that the total amplitude is antisymmetric under the interchange of any pair of external fermions.

[52] The S-matrix element is related to the invariant matrix element $\mathcal{M}_{fi}$ by $S_{fi} = \delta_{fi} + (2\pi)^4 \delta^{(4)}(p_f - p_i)\, i\mathcal{M}_{fi}$, where p_f (p_i) is the total four-momentum of the final (initial) state. If $f \neq i$ (i.e. the final and initial states are distinct), then $\delta_{fi} = 0$ in which case the invariant matrix element is only defined up to an overall (unphysical) sign. However, if $f = i$, the most convenient choice for the canonical ordering of external fermions is the one that yields $\langle f|i\rangle = \delta_{fi}$ (with no extra minus sign), which then fixes the absolute sign of the invariant matrix element.

29.4.5 Basic examples of writing down diagrams and amplitudes

Some simple examples will help clarify the rules of Section 29.4.4. In the tree-level Feynman graphs of this subsection, we label all two-component fermion lines by their corresponding left-handed $(\frac{1}{2},0)$ fields. (We shall propose a slightly different labeling convention in Section 29.5.) A larger number of examples, drawn from practical calculations, are given in Section 29.6.

Scalar boson decay to fermion pairs

Let us first consider a theory with a multiplet of uncharged, massive $(\frac{1}{2},0)$ fermions ξ_i, and a real scalar ϕ, with interaction

$$\mathscr{L}_{\rm int} = -\tfrac{1}{2}\left(\lambda^{ij}\xi_i\xi_j + \lambda_{ij}\xi^{\dagger i}\xi^{\dagger j}\right)\phi\,, \tag{29.4.1}$$

where $\lambda_{ij} \equiv (\lambda^{ij})^*$ and $\lambda^{ij} = \lambda^{ji}$. Consider the decay $\phi \to \xi_i(\vec{\boldsymbol{p}}_1, s_1)\xi_j(\vec{\boldsymbol{p}}_2, s_2)$ [for a fixed choice of i and j], where by $\xi_i(\vec{\boldsymbol{p}}, s)$ we mean the one particle state given by eq. (29.3.13).

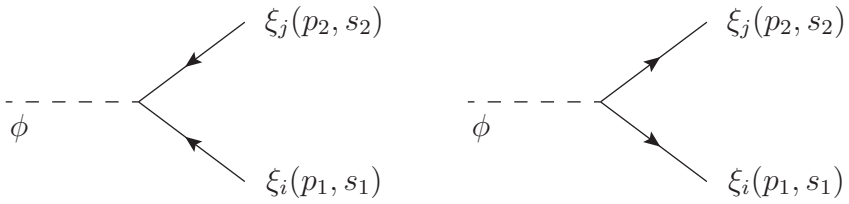

Figure 29.4.1: The two tree-level Feynman diagrams contributing to the decay of a neutral scalar into a pair of Majorana fermions.

Two diagrams contribute to this process, as shown in Fig. 29.4.1. The matrix element is:

$$\begin{aligned} i\mathcal{M} &= y(\vec{\boldsymbol{p}}_1, s_1)^\alpha(-i\lambda^{ij}\delta_\alpha{}^\beta)y(\vec{\boldsymbol{p}}_2, s_2)_\beta + x^\dagger(\vec{\boldsymbol{p}}_1, s_1)_{\dot\alpha}(-i\lambda_{ij}\delta^{\dot\alpha}{}_{\dot\beta})x^\dagger(\vec{\boldsymbol{p}}_2, s_2)^{\dot\beta} \\ &= -i\lambda^{ij}y(\vec{\boldsymbol{p}}_1, s_1)y(\vec{\boldsymbol{p}}_2, s_2) - i\lambda_{ij}x^\dagger(\vec{\boldsymbol{p}}_1, s_1)x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\,. \end{aligned} \tag{29.4.2}$$

The second line could be written down directly by recalling that the sum over suppressed spinor indices is taken according to eq. (29.37). Note that if we reverse the ordering for the external fermions, the overall sign of the amplitude changes sign. This is easily checked, since for the commuting spinor wave functions (x and y), the spinor products in eq. (29.4.2) change sign when the order is reversed [see eqs. (29.60) and (29.61)]. This overall sign is not significant and depends on the order used in constructing the two particle state. One could even make the choice of starting the first diagram from fermion 1, and the second diagram from fermion 2:

$$i\mathcal{M} = -i\lambda^{ij}y(\vec{\boldsymbol{p}}_1, s_1)y(\vec{\boldsymbol{p}}_2, s_2) - (-1)i\lambda_{ij}x^\dagger(\vec{\boldsymbol{p}}_2, s_2)x^\dagger(\vec{\boldsymbol{p}}_1, s_1)\,. \tag{29.4.3}$$

Here, the first term establishes the canonical ordering of fermions (12), and the contribution from the second diagram therefore includes the relative minus sign in parentheses. Indeed, eqs. (29.4.2) and (29.4.3) are equal. In the computation of the total decay rate for the case of $i = j$, one must multiply the integral over the total phase space by 1/2 to account for the identical particles.

Next, we consider a theory of a massive neutral scalar boson that couples to a multiplet of Dirac fermions. We denote the corresponding two-component fields by χ_i and η^i. For simplicity, we take all the U(1)-charges of the χ_i to be equal (and opposite to the charges of the η^i). The corresponding U(1)-invariant interaction is:

$$\mathscr{L}_{\rm int} = -(\kappa^i{}_j\chi_i\eta^j + \kappa_i{}^j\chi^{\dagger i}\eta^\dagger_j)\phi\,, \tag{29.4.4}$$

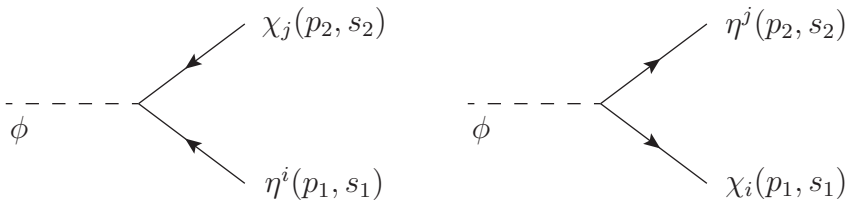

Figure 29.4.2: The two tree-level Feynman diagrams contributing to the decay of a neutral scalar into a pair of Dirac fermions. The χ_i–η^i and χ_j–η^j pairs, each with oppositely directed arrows, comprise Dirac fermion states with flavor indices i and j, respectively.

where $\kappa_i{}^j = (\kappa^i{}_j)^*$. Consider the decay $\phi \to f_i(\vec{\boldsymbol{p}}_1, s_1)\overline{f}{}^j(\vec{\boldsymbol{p}}_2, s_2)$ [for a fixed choice of i and j], where by $f(\vec{\boldsymbol{p}}, s)$ and $\overline{f}(\vec{\boldsymbol{p}}, s)$ we mean the one particle states given by eq. (29.3.22). Two diagrams contribute to this process, as shown in Fig. 29.4.2. Note that the outgoing fermion lines are distinguished by their U(1)-charges. The matrix element is then given by

$$i\mathcal{M} = -i\kappa^j{}_i y(\vec{\boldsymbol{p}}_1, s_1)y(\vec{\boldsymbol{p}}_2, s_2) - i\kappa_i{}^j x^\dagger(\vec{\boldsymbol{p}}_1, s_1)x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\,. \tag{29.4.5}$$

The matrix element for $\phi \to f_i(\vec{\boldsymbol{p}}_1, s_1)\overline{f}{}^j(\vec{\boldsymbol{p}}_2, s_2)$ is identical to that of $\phi \to \xi_i(\vec{\boldsymbol{p}}_1, s_1)\xi_j(\vec{\boldsymbol{p}}_2, s_2)$ after replacing λ^{ij} with $\kappa^i{}_j$. However for fixed $i = j$, the rate for scalar boson decay to $f_i\overline{f}{}^i$ is twice that of $\xi_i\xi_i$ due to the final state identical particles in the latter case, as noted above. One also arrives at the same conclusion if one treats a single Dirac fermion as a pair of mass-degenerate two-component fields ξ_1 and ξ_2 [cf. eq. (29.3.15)]. Due to the U(1)-symmetry, the scalar Yukawa interactions are diagonal in the ξ_1–ξ_2 basis, so the rate for scalar decay into the Dirac fermion pair is equal to the incoherent sum of the rate for decay into $\xi_1\xi_1$ and $\xi_2\xi_2$.

Fermion pair annihilation into a scalar boson

It is also instructive to consider the corresponding $2 \to 1$ scattering (annihilation) processes $\xi(\vec{\boldsymbol{p}}_1, s_1)\xi(\vec{\boldsymbol{p}}_2, s_2) \to \phi$ and $f(\vec{\boldsymbol{p}}_1, s_1)\overline{f}(\vec{\boldsymbol{p}}_2, s_2) \to \phi$, respectively. The corresponding amplitudes are given by eqs. (29.4.2) and (29.4.5) with $y \to x$ and $x^\dagger \to y^\dagger$ (for simplicity, we neglect flavor). In the computation of the cross-sections, there is no extra factor required to account for the case of identical particles in the initial state. That is, the cross-section for $f(\vec{\boldsymbol{p}}_1, s_1)\overline{f}(\vec{\boldsymbol{p}}_2, s_2) \to \phi$ is equal to the cross-section for $\xi(\vec{\boldsymbol{p}}_1, s_1)\xi(\vec{\boldsymbol{p}}_2, s_2) \to \phi$ after replacing λ with κ.

This may at first seem puzzling given that a Dirac fermion can be represented by a pair of mass-degenerate two-component fields χ_1 and χ_2. But, recall the standard procedure for the calculation of decay rates and cross-sections in field theory—*average over unobserved degrees of freedom of the initial state and sum over unobserved degrees of freedom of the final state*. This mantra is well-known for dealing with spin and color degrees of freedom, but it is also applicable to degrees of freedom associated with global internal symmetries. Thus, the cross-section for the annihilation of a Dirac fermion pair into a neutral scalar boson can be obtained by computing the *average* of the cross-sections for $\xi_1(\vec{\boldsymbol{p}}_1, s_1)\xi_1(\vec{\boldsymbol{p}}_2, s_2) \to \phi$ and $\xi_2(\vec{\boldsymbol{p}}_1, s_1)\xi_2(\vec{\boldsymbol{p}}_2, s_2) \to \phi$. Since the annihilation cross-sections for $\xi_1\xi_1$ and $\xi_2\xi_2$ are equal, we confirm the annihilation cross-section for the Dirac fermion pair obtained above in the χ–η basis. Since the latter is conceptually simpler, subsequent computations involving Dirac fermions will be performed in the χ–η basis.

The annihilation rate of fermions enters in the analysis of the event flux due to the annihilation of dark matter in the halo of our galaxy. Let us compare the rates in the case that the dark matter is either a Majorana or a Dirac fermion. Suppose the annihilation involves two fermions whose number densities are n_1 and n_2 respectively. Then the observer on Earth who integrates along the line of sight to the annihilation events that are detected sees a flux of events proportional to [154]

$$\frac{dN_{\rm events}}{dA\,dt} \sim \int n_1 n_2 \,\langle \sigma_{\rm ann} v_{\rm rel}\rangle \, d\ell\,, \tag{29.4.6}$$

where $v_{\rm rel}$ is the relative velocity of the annihilating initial state particles, $\sigma_{\rm ann}$ is the annihilation cross-section and $\langle\cdots\rangle$ refers to a thermal average [155] over the velocity distribution of dark matter particles in the halo. We now compare the case of the annihilation of a single species of Majorana particles and the annihilation of a Dirac fermion-antifermion pair (assumed to have the same mass and couplings). We assume that the number density of Dirac fermions and antifermions and the corresponding number density of Majorana fermions are all the same (and denoted by n). Above, we showed that $\sigma_{\rm ann}$ is the same for the annihilation of a single species of Majorana and Dirac fermions. For the Dirac case, $n_1n_2 = n^2$. For the Majorana case, because the Majorana fermions are identical particles, given N initial state fermions in a volume V, there are $N(N-1)/2$ possible scatterings. In the thermodynamic limit where $N, V \to \infty$ at fixed $n \equiv N/V$, we conclude that $n_1n_2 = \frac{1}{2}n^2$ for a single species of annihilating Majorana fermions.[53] Hence the event flux rate for the annihilation of a Dirac fermion-antifermion pair is double that of a single species of Majorana fermions.[54] The extra factor of $1/2$ can also be understood by noting that in the case of annihilating dark matter particles (in the large N limit), all possible scattering axes occur and are implicitly integrated over. But, integrating over 4π steradians double counts the annihilation of identical particles (in the same way it does in the computation of the decay rate of a scalar into identical fermions discussed above). Hence, one must include a factor of $\frac{1}{2}$ in this case by replacing $n_1n_2 = n^2$ by $\frac{1}{2}n^2$ in eq. (29.4.6).

The relic abundance of primordial dark matter particles in the universe is inversely proportional to $\langle\sigma_{\rm ann}v_{\rm rel}\rangle$ [157]. By similar arguments to the ones just presented, it follows that the relic abundance of a single species of Majorana fermions would be twice that of a single species of Dirac fermions.

Vector boson decay into fermion pairs

Consider next the decay of a massive neutral vector boson A_μ into a pair of Majorana fermions, $A_\mu \to \xi_i(\vec{\boldsymbol{p}}_1, s_1)\xi_j(\vec{\boldsymbol{p}}_2, s_2)$, following from the interaction,

$$\mathscr{L}_{\rm int} = -G_i{}^j A^\mu \xi^{\dagger i}\overline{\sigma}_\mu \xi_j \,, \tag{29.4.7}$$

where G is an hermitian coupling matrix. The two diagrams shown in Fig. 29.4.3 contribute.

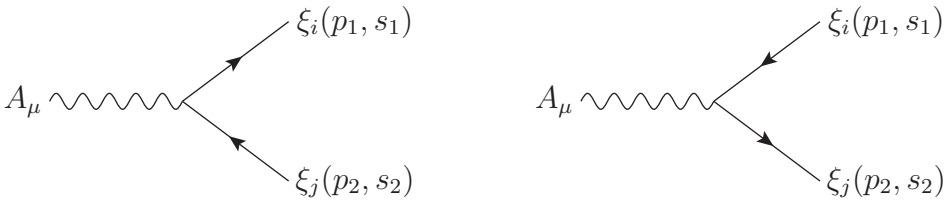

Figure 29.4.3: The two tree-level Feynman diagrams contributing to the decay of a massive neutral vector boson A_μ into a pair of Majorana fermions.

We start from the fermion with momentum p_1 and spin vector s_1 and end at the fermion with momentum p_2 and spin vector s_2, using the rules of Fig. 29.4.2. The resulting amplitude for the decay is

$$i\mathcal{M} = \varepsilon^\mu \left[-iG_i{}^j x^\dagger(\vec{\boldsymbol{p}}_1, s_1)\overline{\sigma}_\mu y(\vec{\boldsymbol{p}}_2, s_2) + iG_j{}^i y(\vec{\boldsymbol{p}}_1, s_1)\sigma_\mu x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\right] \,, \tag{29.4.8}$$

where ε^μ is the vector boson polarization vector. We have used the $\overline{\sigma}$-version of the vector-fermion-fermion rule [see Fig. 29.4.2] for the first diagram of Fig. 29.4.3 and the σ-version for the

[53] The factor of $1/2$, which has been erroneously omitted in many papers in the literature, was correctly employed and explained in footnote 1 of [156].

[54] This is also consistent with the interpretation of a Dirac fermion as a pair of mass-degenerate Majorana fermions.

second diagram of Fig. 29.4.3, as dictated by the implicit spinor indices, which we have suppressed. However, we could have chosen to evaluate the second diagram of Fig. 29.4.3 using the $\overline{\sigma}$-version of the vector-fermion-fermion rule by starting from the fermion with momentum p_2 and spin vector s_2. In that case, the term $iG_j{}^i y(\vec{\boldsymbol{p}}_1, s_1)\sigma_\mu x^\dagger(\vec{\boldsymbol{p}}_2, s_2)$ in eq. (29.4.8) is replaced by

$$(-1)[-iG_j{}^i x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\overline{\sigma}_\mu y(\vec{\boldsymbol{p}}_1, s_1)]\,. \tag{29.4.9}$$

In eq. (29.4.9), the factor of $-iG_j{}^i$ arises from the use of the $\overline{\sigma}$-version of the vector-fermion-fermion rule, and the overall factor of -1 appears because the order of the fermion wave functions has been reversed; i.e. (21) is an odd permutation of (12). This is in accord with the ordering rule stated at the end of Section 29.4.4. Thus, the resulting amplitude for the decay of the vector boson into the pair of Majorana fermions now takes the form:

$$i\mathcal{M} = \varepsilon^\mu \left[-iG_i{}^j x^\dagger(\vec{\boldsymbol{p}}_1, s_1)\overline{\sigma}_\mu y(\vec{\boldsymbol{p}}_2, s_2) + iG_j{}^i x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\overline{\sigma}_\mu y(\vec{\boldsymbol{p}}_1, s_1)\right]\,, \tag{29.4.10}$$

which coincides with eq. (29.4.8) after using $y\sigma^\mu x^\dagger = x^\dagger\overline{\sigma}^\mu y$ [cf. eq. (29.62) with commuting spinors]. Eq. (29.4.10) explicitly exhibits the property that the amplitude is antisymmetric under the interchange of the two external identical fermions. Again, the absolute sign of the total amplitude is not significant and depends on the choice of ordering of the outgoing states.

Next, we consider the decay of a massive neutral vector boson into a pair of Dirac fermions. Each Dirac fermion is described by the two-component fields χ_i and η^i, which possess equal and opposite U(1)-charges, respectively. The corresponding interaction Lagrangian is given by:

$$\mathscr{L}_{\rm int} = -A^\mu[(G_L)_i{}^j\,\chi^{\dagger i}\overline{\sigma}_\mu\chi_j - (G_R)_j{}^i\,\eta_i^\dagger\overline{\sigma}_\mu\eta^j\,]\,, \tag{29.4.11}$$

where G_L and G_R are hermitian. There are two contributing graphs, as shown in Fig. 29.4.4.

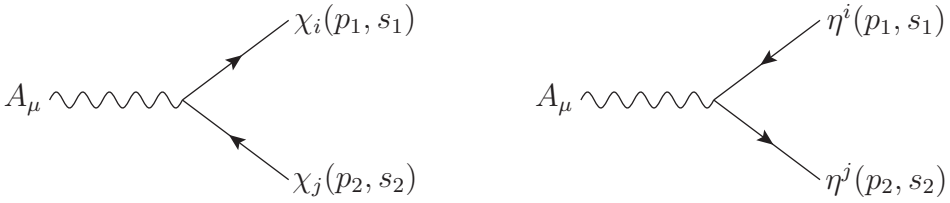

Figure 29.4.4: The two tree-level Feynman diagrams contributing to the decay of a massive neutral vector boson A_μ into a pair of Dirac fermions. The χ_i–η^i and χ_j–η^j pairs, each with oppositely directed arrows, comprise Dirac fermion states with flavor indices i and j, respectively.

To evaluate the amplitude, we start with the fermion of momentum p_1 and spin vector s_1, and end at the fermion with momentum p_2 and spin vector s_2. Note that the outgoing χ_i with the arrow pointing outward from the vertex and the outgoing η^i with the arrow pointing inward to the vertex both correspond to the same outgoing Dirac fermion. The amplitude for the decay is given by:

$$\begin{aligned} i\mathcal{M} &= \varepsilon^\mu \left[-i(G_L)_i{}^j x^\dagger(\vec{\boldsymbol{p}}_1, s_1)\overline{\sigma}_\mu y(\vec{\boldsymbol{p}}_2, s_2) - i(G_R)_i{}^j y(\vec{\boldsymbol{p}}_1, s_1)\sigma_\mu x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\right] \\ &= \varepsilon^\mu \left[-i(G_L)_i{}^j x^\dagger(\vec{\boldsymbol{p}}_1, s_1)\overline{\sigma}_\mu y(\vec{\boldsymbol{p}}_2, s_2) - i(G_R)_i{}^j x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\overline{\sigma}_\mu y(\vec{\boldsymbol{p}}_1, s_1)\right]\,. \end{aligned} \tag{29.4.12}$$

As in the case of the decay to a pair of Majorana fermions, we have exhibited a second form for the amplitude in eq. (29.4.12) in which the $\overline{\sigma}$-version of the vertex Feynman rule has been employed in both diagrams. Of course, the resulting amplitude must be the same in each method (up to a possible overall sign of the total amplitude that is not determined).

The computation of the amplitude for the decay of a charged vector boson to a fermion pair consisting of one Majorana fermion and one Dirac fermion, due to the interactions given in eq. (29.4.21), is straightforward and will not be given explicitly here.

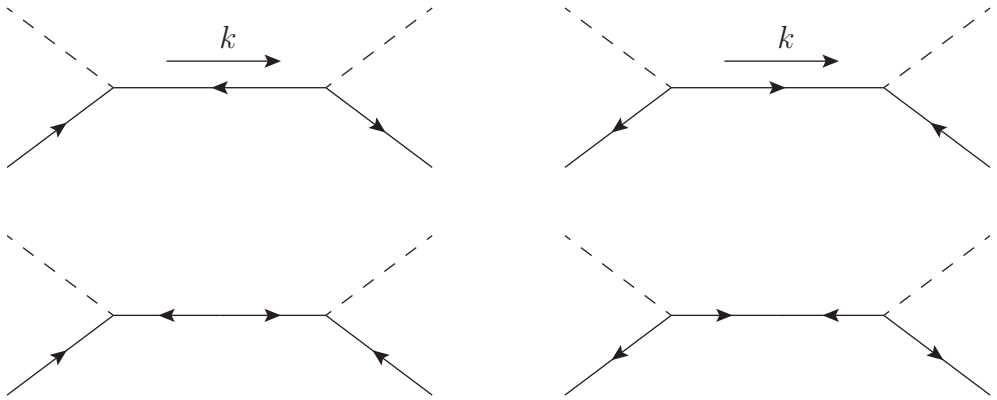

Figure 29.4.5: Tree-level Feynman diagrams contributing to the elastic scattering of a neutral scalar and a Majorana fermion. There are four more diagrams, obtained from these by crossing the initial and final scalar lines.

Two-body scattering of a boson and a neutral fermion

The next level of complexity consists of diagrams that involve fermion propagators. In the examples that follow in this and in the next subsection, we shall ignore the flavor index and consider scattering processes that involve a single flavor of Majorana or Dirac fermion. For our first example of this type, consider the tree-level matrix element for the scattering of a neutral scalar and a two-component neutral massive fermion ($\phi\xi \to \phi\xi$), with the interaction Lagrangian given above in eq. (29.4.1). Using the corresponding Feynman rules, there are eight contributing diagrams. Four are depicted in Fig. 29.4.5; there are another four diagrams (not shown) where the initial and final state scalars are crossed (i.e., the initial state scalar is attached to the same vertex as the final state fermion).

We shall write down the amplitudes for the four diagrams shown in Fig. 29.4.5, starting with the final state fermion line and moving toward the initial state fermion line. Then,

$$i\mathcal{M} = \frac{i}{k^2 - m_\xi^2}\Big\{(-i\lambda)(-i\lambda^*)\left[x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\,\overline{\sigma}\cdot k\, x(\vec{\boldsymbol{p}}_1, s_1) + y(\vec{\boldsymbol{p}}_2, s_2)\,\sigma\cdot k\, y^\dagger(\vec{\boldsymbol{p}}_1, s_1)\right] + m_\xi\left[(-i\lambda)^2 y(\vec{\boldsymbol{p}}_2, s_2)x(\vec{\boldsymbol{p}}_1, s_1) + (-i\lambda^*)^2 x^\dagger(\vec{\boldsymbol{p}}_2, s_2)y^\dagger(\vec{\boldsymbol{p}}_1, s_1)\right]\Big\} + (\text{crossed})\,, \tag{29.4.13}$$

where k^μ is the sum of the two incoming (or outgoing) four-momenta, (p_1, s_1) are the momentum and spin four-vectors of the incoming fermion, and (p_2, s_2) are those of the outgoing fermion. The notation "(crossed)" refers to the contribution to the amplitude from diagrams which have the initial and final scalars interchanged. Note that we could have evaluated the diagrams above by starting with the initial vertex and moving toward the final vertex. It is easy to check that the resulting amplitude is the negative of the one obtained in eq. (29.4.13); the overall sign change simply corresponds to swapping the order of the two fermions and has no physical consequence. The overall minus sign is a consequence of eqs. (29.60)–(29.62) and the minus sign difference between the two ways of evaluating the propagator that preserves the arrow direction.

Next, we compute the tree-level matrix element for the scattering of a neutral vector boson and a neutral massive two-component fermion ξ with the interaction Lagrangian of eq. (29.4.7). Again there are eight diagrams: the four diagrams depicted in Fig. 29.4.6 plus another four (not shown) where the initial and final state vector bosons are crossed.

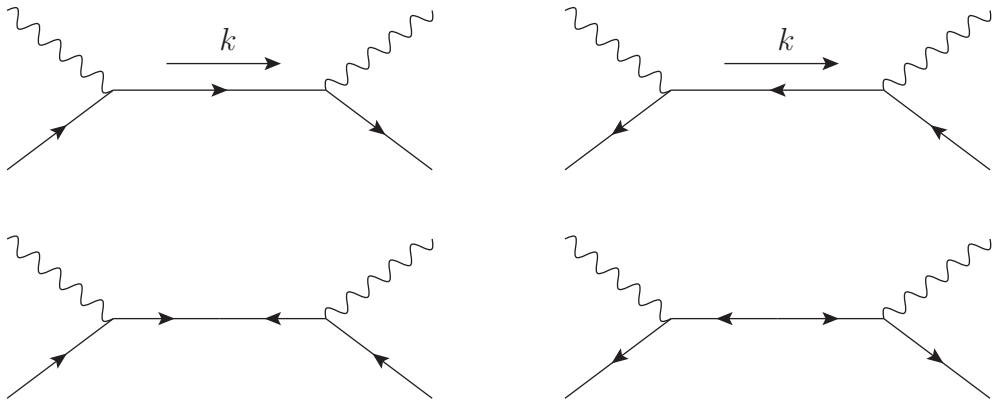

Figure 29.4.6: Tree-level Feynman diagrams contributing to the elastic scattering of a neutral vector boson and a Majorana fermion. There are four more diagrams, obtained from these by crossing the initial and final scalar lines.

Starting with the final state fermion line and moving toward the initial state, we obtain

$$i\mathcal{M} = \frac{i}{k^2 - m_\xi^2}\Big\{(-iG)^2 x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\,\overline{\sigma}\cdot\varepsilon_2^*\,\sigma\cdot k\,\overline{\sigma}\cdot\varepsilon_1\,x(\vec{\boldsymbol{p}}_1, s_1) + (iG)^2 y(\vec{\boldsymbol{p}}_2, s_2)\,\sigma\cdot\varepsilon_2^*\,\overline{\sigma}\cdot k\,\sigma\cdot\varepsilon_1 y^\dagger(\vec{\boldsymbol{p}}_1, s_1)$$
$$+(-iG)(iG)m_\xi\left[y(\vec{\boldsymbol{p}}_2, s_2)\,\sigma\cdot\varepsilon_2^*\,\overline{\sigma}\cdot\varepsilon_1\,x(\vec{\boldsymbol{p}}_1, s_1) + x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\,\overline{\sigma}\cdot\varepsilon_2^*\,\sigma\cdot\varepsilon_1\,y^\dagger(\vec{\boldsymbol{p}}_1, s_1)\right]\Big\}$$
$$+(\text{crossed})\,, \tag{29.4.14}$$

where ε_1 and ε_2 are the initial and final vector boson polarization four-vectors, respectively. As before, k^μ is the sum of the two incoming (or outgoing) four-momenta, (p_1, s_1) and (p_2, s_2) are the momentum and spin four-vectors of the incoming and outgoing fermions, respectively, and "(crossed)" indicates the terms from diagrams in which the initial and final vector bosons are interchanged. Alternatively, if one starts with an initial state fermion and moves toward the final state, the resulting amplitude is the negative of the one obtained in eq. (29.4.14), as expected.

The computation of the amplitude for the scattering of a charged scalar or vector boson and a Majorana fermion is straightforward and will not be given explicitly here.

Two-body scattering of a boson and a charged fermion

We first consider the scattering of a Dirac fermion with a neutral scalar. We denote the Dirac mass of the fermion by m_D. The left-handed fields χ and η have opposite charges (which we take to be $Q = +1$ and -1 respectively), and interact with the scalar ϕ according to

$$\mathscr{L}_{\text{int}} = -\phi[\kappa\chi\eta + \kappa^*\chi^\dagger\eta^\dagger]\,, \tag{29.4.15}$$

where κ is a coupling parameter. Then, for the elastic scattering of the $Q = +1$ fermion and a scalar, the diagrams of Fig. 29.4.7 contribute at tree level plus another four diagrams (not shown) where the initial and final state scalars are crossed. Now, these diagrams match precisely those of Fig. 29.4.5. Thus, applying the Feynman rules yields the same matrix element, eq. (29.4.13), previously obtained for the scattering of a neutral scalar and neutral two-component fermion, with the replacement of λ with κ and m_ξ with m_D.

We next examine the scattering of a Dirac fermion and a charged scalar, where both the scalar and fermion have the same absolute value of the charge. As above, we denote the charged $Q = \pm 1$ fermion by the pair of two-component fermions χ and η and the (intermediate state) neutral two-component fermion by ξ. The charged $Q = \pm 1$ scalar is represented by the complex scalar field Φ

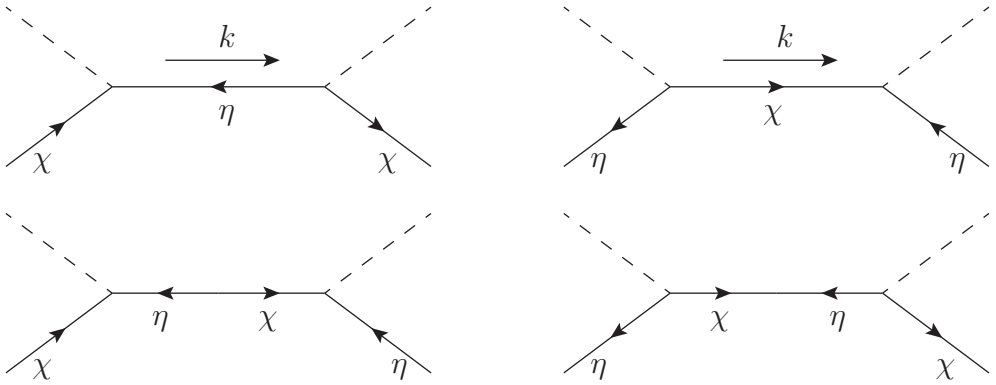

Figure 29.4.7: Tree-level Feynman diagrams contributing to the elastic scattering of a neutral scalar and a charged fermion. There are four more diagrams, obtained from these by crossing the initial and final scalar lines.

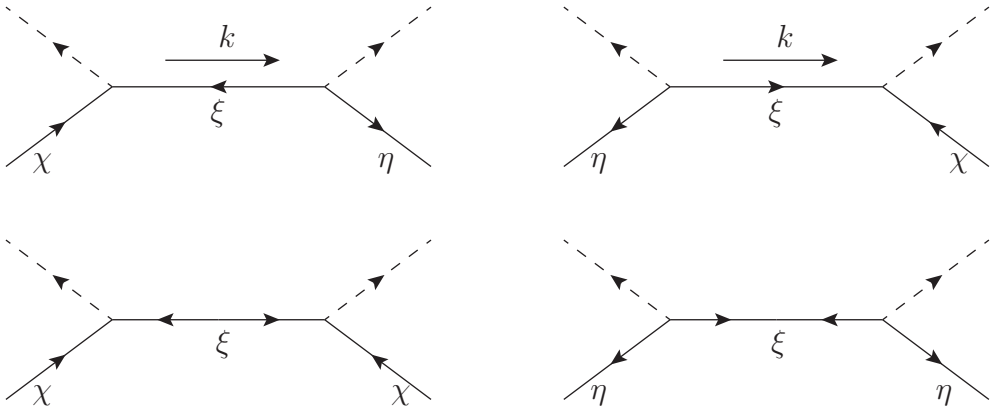

Figure 29.4.8: Tree-level Feynman diagrams contributing to the scattering of an initial charged scalar and a charged fermion into its charge-conjugated final state. The unlabeled intermediate state is a neutral fermion. There are four more diagrams, obtained from these by crossing the initial and final scalar lines.

and its hermitian conjugate. The interaction Lagrangian takes the form:

$$\mathscr{L}_{\rm int} = -\Phi[\kappa_1\eta\xi + \kappa_2^*\chi^\dagger\xi^\dagger] - \Phi^\dagger[\kappa_2\chi\xi + \kappa_1^*\eta^\dagger\xi^\dagger]\,. \tag{29.4.16}$$

Consider the scattering of an initial boson-fermion state into its charge-conjugated final state via the exchange of a neutral fermion. The relevant diagrams are shown in Fig. 29.4.8 plus the corresponding diagrams with the initial and final scalars crossed. We define the four-momentum k to be the sum of the two initial state four-momenta as shown in Fig. 29.4.8. The derivation of the amplitude is similar to the ones given previously, and we end up with

$$\begin{aligned} i\mathcal{M} = \frac{-i}{k^2 - m_\xi^2}\Big\{ &\kappa_1^*\kappa_2[x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\,\overline{\sigma}\cdot k\, x(\vec{\boldsymbol{p}}_1, s_1) + y(\vec{\boldsymbol{p}}_2, s_2)\,\sigma\cdot k\, y^\dagger(\vec{\boldsymbol{p}}_1, s_1)] \\ &+ m_\xi\left[\kappa_2^2 y(\vec{\boldsymbol{p}}_2, s_2)x(\vec{\boldsymbol{p}}_1, s_1) + (\kappa_1^*)^2 x^\dagger(\vec{\boldsymbol{p}}_2, s_2)y^\dagger(\vec{\boldsymbol{p}}_1, s_1)\right]\Big\} + (\text{crossed})\,. \end{aligned} \tag{29.4.17}$$

The scattering of a charged fermion and a neutral spin-1 vector boson can be similarly treated. For example, consider the amplitude for the elastic scattering of a charged fermion of mass m_D

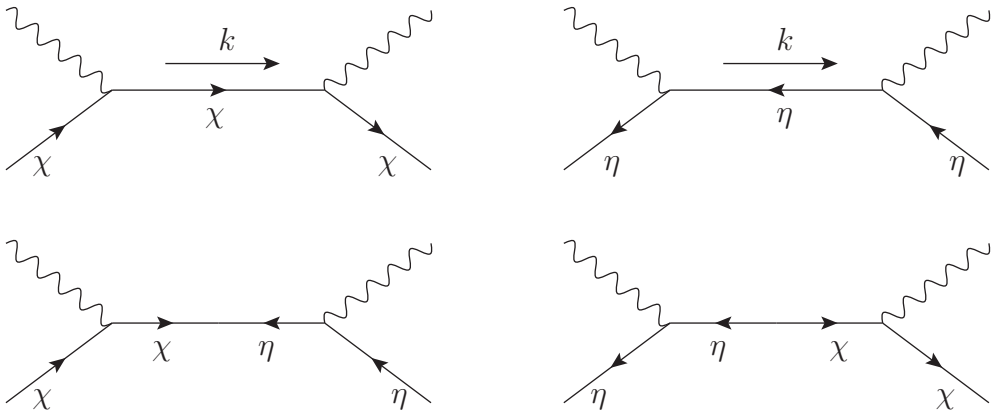

Figure 29.4.9: Tree-level Feynman diagrams contributing to the elastic scattering of a neutral vector boson and a Dirac fermion. There are four more diagrams, obtained from these by crossing the initial and final vector lines.

and a neutral vector boson. Again taking the interactions as given in eq. (29.4.11), the relevant diagrams are those shown in Fig. 29.4.9, plus four diagrams (not shown) obtained from these by crossing the initial and final state vector bosons. Applying the Feynman rules of Fig. 29.4.3, one obtains the following matrix element:

$$i\mathcal{M} = \frac{-i}{k^2 - m_D^2}\Big\{ G_L^2 x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\, \overline{\sigma}\cdot\varepsilon_2^*\, \sigma\cdot k\, \overline{\sigma}\cdot\varepsilon_1\, x(\vec{\boldsymbol{p}}_1, s_1) + G_R^2 y(\vec{\boldsymbol{p}}_2, s_2)\, \sigma\cdot\varepsilon_2^*\, \overline{\sigma}\cdot k\, \sigma\cdot\varepsilon_1 y^\dagger(\vec{\boldsymbol{p}}_1, s_1)$$
$$+ m_D G_L G_R \left[y(\vec{\boldsymbol{p}}_2, s_2)\, \sigma\cdot\varepsilon_2^*\, \overline{\sigma}\cdot\varepsilon_1\, x(\vec{\boldsymbol{p}}_1, s_1) + x^\dagger(\vec{\boldsymbol{p}}_2, s_2)\, \overline{\sigma}\cdot\varepsilon_2^*\, \sigma\cdot\varepsilon_1\, y^\dagger(\vec{\boldsymbol{p}}_1, s_1)\right]\Big\} + (\text{crossed})\,, \tag{29.4.18}$$

and the assignments of momenta and spins are as before.

The computation of the amplitude for the scattering of a charged fermion and a charged vector boson is straightforward and will not be given explicitly here.

Two-body fermion–fermion scattering

Finally, let us work out an example with four external state fermions. Consider the case of elastic scattering of two identical Majorana fermions due to scalar exchange, governed by the interaction of eq. (29.4.1). The diagrams for scattering initial fermions labeled $1, 2$ into final state fermions labeled $3, 4$ are shown in Fig. 29.4.10.

The resulting invariant matrix element is:

$$i\mathcal{M} = (-1)\frac{-i}{s - m_\phi^2}\left\{\lambda^2 (x_1 x_2)(y_3 y_4) + (\lambda^*)^2 (y_1^\dagger y_2^\dagger)(x_3^\dagger x_4^\dagger) + |\lambda|^2 \left[(x_1 x_2)(x_3^\dagger x_4^\dagger) + (y_1^\dagger y_2^\dagger)(y_3 y_4)\right]\right\}$$
$$+ \frac{-i}{t - m_\phi^2}\left\{\lambda^2 (y_3 x_1)(y_4 x_2) + (\lambda^*)^2 (x_3^\dagger y_1^\dagger)(x_4^\dagger y_2^\dagger) + |\lambda|^2 \left[(x_3^\dagger y_1^\dagger)(y_4 x_2) + (y_3 x_1)(x_4^\dagger y_2^\dagger)\right]\right\}$$
$$+ (-1)\frac{-i}{u - m_\phi^2}\left\{\lambda^2 (y_4 x_1)(y_3 x_2) + (\lambda^*)^2 (x_4^\dagger y_1^\dagger)(x_3^\dagger y_2^\dagger)\right.$$
$$\left. + |\lambda|^2 \left[(x_4^\dagger y_1^\dagger)(y_3 x_2) + (y_4 x_1)(x_3^\dagger y_2^\dagger)\right]\right\}\,, \tag{29.4.19}$$

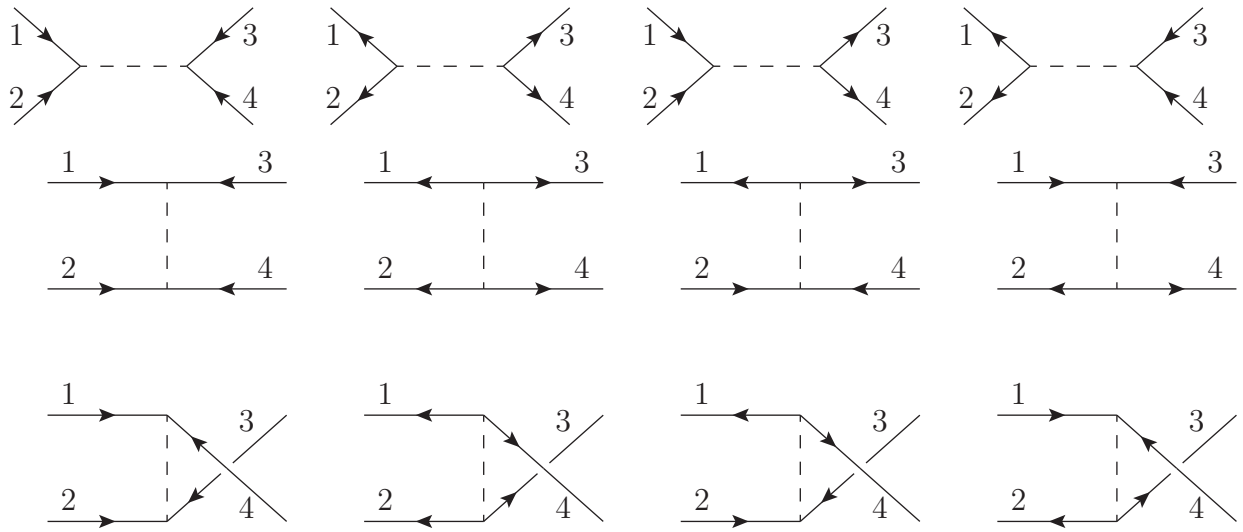

Figure 29.4.10: Tree-level Feynman diagrams contributing to the elastic scattering of identical Majorana fermions via scalar exchange in the s-channel (top row), t-channel (middle row), and u-channel (bottom row).

where $x_i \equiv x(\vec{\boldsymbol{p}}_i, s_i)$, $y_i \equiv y(\vec{\boldsymbol{p}}_i, s_i)$, m_ϕ is the mass of the exchanged scalar, $s = (p_1 + p_2)^2$, $t = (p_1 - p_3)^2$ and $u = (p_1 - p_4)^2$. We have chosen the canonical ordering of external fermions to be 3142 (corresponding to the t-channel contribution). For elastic scattering, this choice of canonical ordering guarantees that if no scattering occurs then the S-matrix is just equal to the unit operator with no extraneous minus sign (cf. footnote 52). The relative minus signs between the t-channel diagram and the s and u-channel diagrams [shown in parentheses in eq. (29.4.19)] are obtained by observing that both 1234 and 4132 are both odd permutations of 3142. Note that we would have obtained the same relative signs for the u-channel diagrams had we crossed the initial state fermion lines instead of the final state fermion lines.

Eq. (29.4.19) can be factorized with respect to the scalar line:

$$i\mathcal{M} = \frac{i}{s - m_\phi^2}(\lambda x_1 x_2 + \lambda^* y_1^\dagger y_2^\dagger)(\lambda y_3 y_4 + \lambda^* x_3^\dagger x_4^\dagger) + \frac{-i}{t - m_\phi^2}(\lambda y_3 x_1 + \lambda^* x_3^\dagger y_1^\dagger)(\lambda y_4 x_2 + \lambda^* x_4^\dagger y_2^\dagger)$$
$$+ \frac{i}{u - m_\phi^2}(\lambda y_4 x_1 + \lambda^* x_4^\dagger y_1^\dagger)(\lambda y_3 x_2 + \lambda^* x_3^\dagger y_2^\dagger)\,. \tag{29.4.20}$$

This is a common feature of Feynman graphs with a virtual boson. This example also illustrates that in contrast to the four-component fermion formalism, the two-component fermion Feynman rules typically yield many more diagrams, but the contribution of each of the diagrams is correspondingly simpler.

Non-relativistic potential due to scalar or pseudoscalar exchange

Consider two distinguishable fermions, and a scalar-fermion-fermion Yukawa interaction given by eq. (29.4.9). We can compute the force law that the fermions experience due to exchange of a spinless boson. That is, we shall derive the Yukawa potential as a function of the separation distance of the two fermions in the static limit.

To carry out this computation, we compute the invariant matrix element for two-body fermion-fermion elastic scattering in the non-relativistic limit. The relevant diagrams are shown in Fig. 29.4.10. As our two fermions are distinguishable, only the t-channel graphs (shown in the

middle row of Fig. 29.4.10) are relevant. As a result, the matrix element for the elastic scattering of two Majorana fermions is given by the t-channel contribution of eq. (29.4.20),

$$i\mathcal{M} = \frac{i}{m_\phi^2 - t}(\lambda y_3 x_1 + \lambda^* x_3^\dagger y_1^\dagger)(\lambda y_4 x_2 + \lambda^* x_4^\dagger y_2^\dagger)\,. \tag{29.4.21}$$

The choice of the overall sign is fixed by the canonical ordering of the external fermions.[55] Although the two fermions are distinguishable, we have assumed for simplicity that their (complex) Yukawa coupling strengths are the same and given by λ. For the scattering of two distinguishable Dirac fermions, the resulting expression for the scattering amplitude is identical to eq. (29.4.21), with λ replaced by the appropriate complex Yukawa coupling κ.

We denote the masses of the distinguishable fermions by m_1 and m_2. In the non-relativistic limit, $p_1 \simeq (m_1\,;\,\vec{\boldsymbol{p}}_{\boldsymbol{1}})$ and $p_3 \simeq (m_1\,;\,\vec{\boldsymbol{p}}_{\boldsymbol{3}})$, so that

$$m_\phi^2 - t \simeq |\vec{\boldsymbol{p}}_{\boldsymbol{1}} - \vec{\boldsymbol{p}}_{\boldsymbol{3}}|^2 + m_\phi^2 \equiv |\vec{\boldsymbol{q}}|^2 + m_\phi^2\,, \tag{29.4.22}$$

where

$$\vec{\boldsymbol{q}} \equiv \vec{\boldsymbol{p}}_{\boldsymbol{3}} - \vec{\boldsymbol{p}}_{\boldsymbol{1}} = \vec{\boldsymbol{p}}_{\boldsymbol{2}} - \vec{\boldsymbol{p}}_{\boldsymbol{4}} \tag{29.4.23}$$

is the momentum-transfer three-vector. Two separate cases will be considered.

In the first case, λ is a real coupling. This corresponds to the exchange of a $J^{PC} = 0^{++}$ scalar. Using the non-relativistic forms of eqs. (C.2.17) and (C.2.23) for the spinor bilinears, it is only necessary to keep the leading term. We then find:

$$i\mathcal{M} = \frac{4i|\lambda|^2 m_1 m_2}{|\vec{\boldsymbol{q}}|^2 + m_\phi^2}\delta_{s_1 s_3}\delta_{s_2 s_4}\,, \tag{29.4.24}$$

in agreement with eq. (4.123) of [115].

In the second case, λ is purely imaginary, and we will write $\lambda = i|\lambda|$ (the overall sign is not significant). This corresponds to the exchange of a $J^{PC} = 0^{-+}$ pseudoscalar. Again, we use the non-relativistic forms of eqs. (C.2.17) and (C.2.23) for the spinor bilinears. However, in this case the leading term cancels and we must retain the $\mathcal{O}(|\vec{\boldsymbol{p}}|/m)$ terms appearing in the non-relativistic limit of the spinor bilinears. In this case, we find

$$i\mathcal{M} = \frac{i|\lambda|^2}{|\vec{\boldsymbol{q}}|^2 + m_\phi^2}(\vec{\boldsymbol{q}}\cdot\hat{\boldsymbol{s}}^{\boldsymbol{a}}\tau^a_{s_3 s_1})\,(\vec{\boldsymbol{q}}\cdot\hat{\boldsymbol{s}}^{\boldsymbol{b}}\tau^b_{s_4 s_2})\,. \tag{29.4.25}$$

We choose the spin quantization axis to lie along the z-direction. That is, according to eq. (C.1.27), we choose

$$(\hat{\boldsymbol{s}}^{\boldsymbol{1}}\,,\,\hat{\boldsymbol{s}}^{\boldsymbol{2}}\,,\,\hat{\boldsymbol{s}}^{\boldsymbol{3}}) = (\hat{\boldsymbol{x}}\,,\,\hat{\boldsymbol{y}}\,,\,\hat{\boldsymbol{z}})\,, \tag{29.4.26}$$

in which case one can rewrite eq. (29.4.25) in the more traditional way,

$$i\mathcal{M} = \frac{i|\lambda|^2}{|\vec{\boldsymbol{q}}|^2 + m_\phi^2}(\vec{\boldsymbol{q}}\cdot\vec{\boldsymbol{\sigma}}_{s_3 s_1})\,(\vec{\boldsymbol{q}}\cdot\vec{\boldsymbol{\sigma}}_{s_4 s_2})\,, \tag{29.4.27}$$

where $\vec{\boldsymbol{\sigma}} \equiv \hat{\boldsymbol{x}}\tau^1 + \hat{\boldsymbol{y}}\tau^2 + \hat{\boldsymbol{z}}\tau^3$ are the usual spin-1/2 Pauli matrices.[56]. Thus, pseudoscalar exchange yields a spin-dependent force law.

The non-relativistic potential that arises from the t-channel scalar or pseudoscalar exchange is obtained by comparing the relativistic scattering amplitude $\mathcal{M}$ with the Born approximation for scattering off a potential $V(\vec{\boldsymbol{x}})$ in non-relativistic quantum mechanics. Taking into account

[55] As noted in Section 29.4.5, the canonical ordering of the external fermions in two-body elastic scattering is determined by the requirement that $\langle f|i\rangle = +1$ for $f = i$ (cf. footnote 52).

[56] The subscripted spin labels on $\vec{\boldsymbol{\sigma}}$ should be interpreted in the same way as outlined in footnote 102.

the difference between the conventions for the normalization of relativistic and non-relativistic single-particle states, one finds that the static potential is given by [158]

$$V(\vec{\boldsymbol{x}}) = -\frac{1}{4m_1m_2}\int \frac{d^3q}{(2\pi)^3}\,\mathcal{M}(\vec{\boldsymbol{q}})e^{i\vec{\boldsymbol{q}}\cdot\vec{\boldsymbol{x}}}\,, \tag{29.4.28}$$

in a convention where the invariant amplitude is defined as in footnote 52. Inserting the scattering amplitude for scalar (S) exchange, one obtains the well-known attractive spin-independent Yukawa potential

$$V(\vec{\boldsymbol{x}})_{\rm S} = -\frac{|\lambda|^2}{4\pi r}\,e^{-m_\phi r}\,\delta_{s_1s_3}\delta_{s_2s_4}\,, \tag{29.4.29}$$

where $r \equiv |\vec{\boldsymbol{x}}|$. For the case of pseudoscalar (PS) exchange, one can easily evaluate the integral in eq. (29.4.28) by writing $q_jq_ke^{i\vec{\boldsymbol{q}}\cdot\vec{\boldsymbol{x}}} = -\nabla_j\nabla_k e^{i\vec{\boldsymbol{q}}\cdot\vec{\boldsymbol{x}}}$. The end result is [159]:

$$\begin{aligned} V(\vec{\boldsymbol{x}})_{\rm PS} &= \frac{|\lambda|^2}{16\pi m_1m_2}(\vec{\boldsymbol{\sigma}}_{s_3s_1}\cdot\vec{\boldsymbol{\nabla}})(\vec{\boldsymbol{\sigma}}_{s_4s_2}\cdot\vec{\boldsymbol{\nabla}})\,\frac{e^{-m_\phi r}}{r} \\ &= \frac{|\lambda|^2 m_\phi^2}{16\pi m_1m_2}\Bigg\{\left[-\frac{4\pi}{3m_\phi^2}\delta^{(3)}(\vec{\boldsymbol{x}}) + \frac{e^{-m_\phi r}}{r}\right]\vec{\boldsymbol{\sigma}}_{s_3s_1}\cdot\vec{\boldsymbol{\sigma}}_{s_4s_2} \\ &\qquad + \left[\frac{1}{(m_\phi r)^2} + \frac{1}{(m_\phi r)} + \frac{1}{3}\right]\left[\frac{3\,(\vec{\boldsymbol{\sigma}}_{s_3s_1}\cdot\vec{\boldsymbol{x}})(\vec{\boldsymbol{\sigma}}_{s_4s_2}\cdot\vec{\boldsymbol{x}})}{r^2} - \vec{\boldsymbol{\sigma}}_{s_3s_1}\cdot\vec{\boldsymbol{\sigma}}_{s_4s_2}\right]\frac{e^{-m_\phi r}}{r}\Bigg\}\,, \end{aligned} \tag{29.4.30}$$

where we have used [160]:

$$\nabla_i\nabla_j\left(\frac{1}{r}\right) = -\frac{4\pi}{3}\delta_{ij}\,\delta^{(3)}(\vec{\boldsymbol{x}}) + \frac{3x_ix_j - r^2\delta_{ij}}{r^5}\,. \tag{29.4.31}$$

29.4.6 Self-energy functions and pole masses for two-component fermions

In this section, we discuss the self-energy functions for fermions in two-component notation, taking into account the possibilities of loop-induced mixing and absorptive parts corresponding to decays to intermediate states. This formalism is useful in the computation of loop-corrected physical pole masses.

Consider a theory with left-handed fermion degrees of freedom $\hat{\psi}_i$ labeled by an index $i = 1, 2, ..., N$. Associated with each $\hat{\psi}_i$ is a right-handed fermion $\hat{\psi}^{\dagger i}$, where the flavor labels are treated as described below eq. (29.3.2). The theory is assumed to contain arbitrary interactions, which we will not need to refer to explicitly. As discussed in Section 29.3.2, we diagonalize the fermion mass matrix and identify the fermion mass eigenstates ψ_i as indicated in eq. (29.4.5). In general, the mass eigenstates consist of Majorana fermions ξ_k ($k = 1, ...N-2n$) and Dirac fermion pairs χ_ℓ and η_ℓ ($\ell = 1, ..., n$).[57] With respect to this basis, the symmetric $N \times N$ tree-level fermion mass matrix, $\boldsymbol{m}^{ij}$, is made up of diagonal elements m_k and 2×2 blocks $\left(\begin{smallmatrix} 0 & m_\ell \\ m_\ell & 0\end{smallmatrix}\right)$ along the diagonal, where the m_k and m_ℓ are real and non-negative. Since $\boldsymbol{m}^{ij}$ is real, the height of the flavor indices is not significant. Nevertheless, it is useful to define $\overline{\boldsymbol{m}}_{ij} \equiv \boldsymbol{m}^{ij}$ in order to maintain the convention

[57] In order to have a unified description, we shall take the flavor index of all left-handed fields (including η_k) in the lowered position (in contrast to the convention adopted in Sections 29.3.2 and 29.4.3) when considering a collection of two-component fermion fields that contains both Majorana and Dirac fermions.

that two repeated flavor indices are summed when one index is raised and the other is lowered.[58] Note that $\overline{\boldsymbol{m}}_{ik}\boldsymbol{m}^{kj} = \boldsymbol{m}^{ik}\overline{\boldsymbol{m}}_{kj} = m_i^2\delta_i^j$ is a diagonal matrix.

The full, loop-corrected Feynman propagators with four-momentum p^μ are defined by the Fourier transforms of vacuum expectation values of time-ordered products of bilinears of the fully interacting two-component fermion fields [cf. footnote 41]. Following eqs. (29.4.1)–(29.4.4), we define:

$$\langle 0|\, T\psi_{\alpha i}(x)\psi^{\dagger j}_{\dot\beta}(y)\,|0\rangle_{\rm FT} = ip{\cdot}\sigma_{\alpha\dot\beta}\,\boldsymbol{C}_i{}^j(s)\,, \tag{29.4.1}$$

$$\langle 0|\, T\psi^{\dagger\dot\alpha i}(x)\psi^{\beta}_{j}(y)\,|0\rangle_{\rm FT} = ip{\cdot}\overline{\sigma}^{\dot\alpha\beta}\,(\boldsymbol{C}^{\mathsf T})^{i}{}_{j}(s)\,, \tag{29.4.2}$$

$$\langle 0|\, T\psi^{\dagger\dot\alpha i}(x)\psi^{\dagger j}_{\dot\beta}(y)\,|0\rangle_{\rm FT} = i\delta^{\dot\alpha}{}_{\dot\beta}\,\boldsymbol{D}^{ij}(s)\,, \tag{29.4.3}$$

$$\langle 0|\, T\psi_{\alpha i}(x)\psi^{\beta}_{j}(y)\,|0\rangle_{\rm FT} = i\delta_\alpha{}^{\beta}\,\overline{\boldsymbol{D}}_{ij}(s)\,, \tag{29.4.4}$$

where $s \equiv p^2$ and

$$(\boldsymbol{C}^{\mathsf T})^{i}{}_{j} \equiv \boldsymbol{C}_j{}^{i}\,. \tag{29.4.5}$$

One can derive eq. (29.4.2) from eq. (29.4.1) by first writing

$$\psi^{\dagger\dot\alpha i}(x)\psi^{\beta}_{j}(y) = -\epsilon^{\beta\alpha}\,\epsilon^{\dot\alpha\dot\beta}\psi_{\alpha j}(y)\psi^{\dagger i}_{\dot\beta}(x)\,, \tag{29.4.6}$$

where the minus sign arises due to the anticommutativity of the fields, and then using eq. (29.32); the interchange of x and y (after FT) simply changes p^μ to $-p^\mu$.

In general, $\boldsymbol{D}$ and $\overline{\boldsymbol{D}}$ are complex symmetric matrices, and $\overline{\boldsymbol{D}} = \boldsymbol{D}^\star$. The matrix $\boldsymbol{C}$ satisfies the hermiticity condition $[\boldsymbol{C}^{\mathsf T}]^\star = \boldsymbol{C}$. Here, we have introduced the star symbol to mean that a quantity $Q^\star$ is obtained from Q by taking the complex conjugate of all Lagrangian parameters appearing in its calculation, but not taking the complex conjugates of Euclideanized loop integral functions, whose imaginary (absorptive) parts correspond to fermion decay widths to multi-particle intermediate states. That is, the dispersive part of $\boldsymbol{C}$ is hermitian and the absorptive part of $\boldsymbol{C}$ is anti-hermitian.

The diagrammatic representations of the full propagators are displayed in Fig. 29.4.1, where $\boldsymbol{C}_i{}^j$, $\boldsymbol{D}^{ij}$, and $\overline{\boldsymbol{D}}_{ij}$ defined above are each $N\times N$ matrix functions. Note that the second diagram of Fig. 29.4.1, when flipped by 180° about the axis that bisects the diagram, is equivalent to the first diagram of Fig. 29.4.1 (with $p\to -p$, $\alpha\to\beta$, $\dot\beta\to\dot\alpha$ and $i\leftrightarrow j$). In analogy with Fig. 29.4.2, one could replace the first two diagrammatic rules of Fig. 29.4.1 with a single rule shown in Fig. 29.4.2, where we have used eq. (29.4.5) to rewrite the second version of the rule in terms of $\boldsymbol{C}^{\mathsf T}$. Indeed,

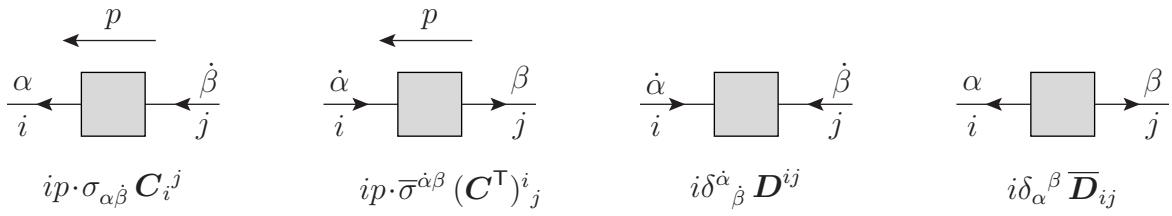

Figure 29.4.1: The full, loop-corrected propagators for two-component fermions are associated with functions $\boldsymbol{C}(p^2)_i{}^j$ [and its matrix transpose], $\boldsymbol{D}(p^2)^{ij}$, and $\overline{\boldsymbol{D}}(p^2)_{ij}$, as shown. The shaded boxes represent the sum of all connected Feynman diagrams, with external legs included. The four-momentum p flows from right to left.

[58] We will soon be suppressing the indices, so it is convenient to employ the bar on $\overline{\boldsymbol{m}}_{ij}$ to indicate its lowered index structure.

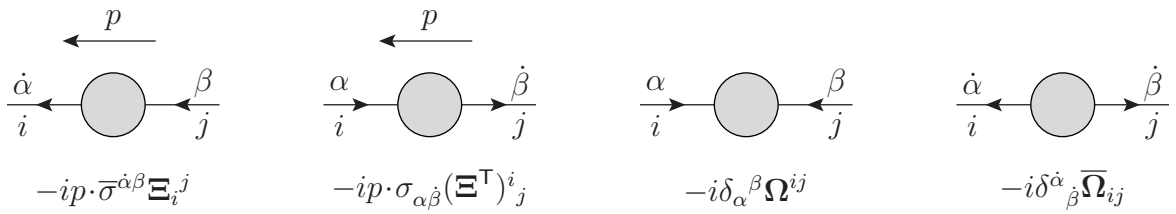

Figure 29.4.3: The self-energy functions for two-component fermions are associated with functions $\Xi(s)_i{}^j$ [and its matrix transpose], $\Omega(s)^{ij}$, and $\overline\Omega(s)_{ij}$, as shown. The shaded circles represent the sum of all one-particle irreducible, connected Feynman diagrams, and the external legs are amputated. The four-momentum p flows from right to left.

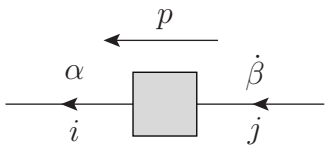
by using the $\overline\sigma$-version of the rule shown in Fig. 29.4.2 and flipping the corresponding diagram by 180° as described above, one reproduces the rule of the second diagram of Fig. 29.4.1.



$$ip\cdot\sigma_{\alpha\dot\beta}\,\boldsymbol{C}_i{}^j \quad \underline{\text{or}} \quad -ip\cdot\overline\sigma^{\dot\beta\alpha}\,(\boldsymbol{C}^{\mathsf T})^j{}_i$$

Figure 29.4.2: The first two diagrammatic rules of Fig. 29.4.1 can be summarized by a single diagram. Here, the choice of the σ or $\overline\sigma$ version of the rule is uniquely determined by the height of the spinor indices on the vertex to which the full loop-corrected propagator is connected (cf. Fig. 29.4.2 and the accompanying text).

In what follows, we prefer to keep the first two rules of Fig. 29.4.1 as separate entities. This will permit us to conveniently assemble the four diagrams of Fig. 29.4.1 into a 2×2 block matrix of two-component propagators [cf. eq. (G.5.2)]. In addition, by choosing the momentum flow in the two-component propagators from right to left, the left-to-right orderings of the spinor labels of the diagrams coincide with the ordering of spinor indices that appear in the corresponding algebraic representations. Thus, we can multiply diagrams together and interpret them as the product of the respective algebraic quantities taken from left to right in the normal fashion.

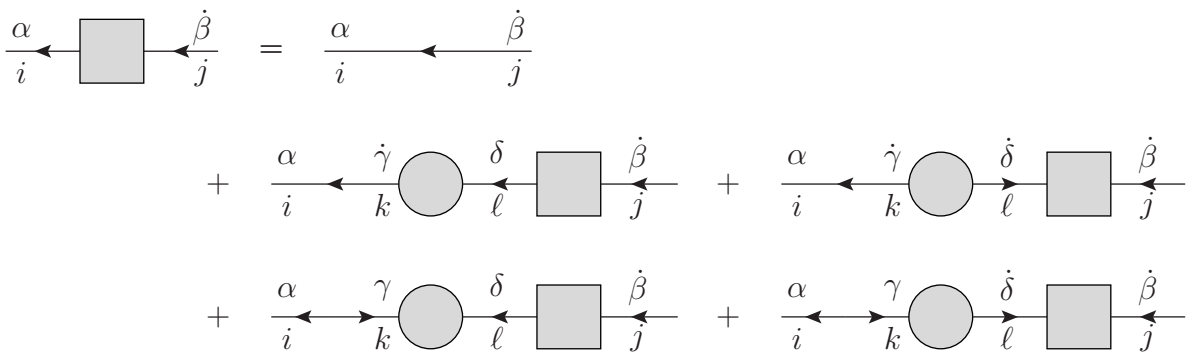
Given the tree-level propagators of Fig. 29.4.1, the full propagator functions are given by:

$$\boldsymbol{C}_i{}^j = \delta_i{}^j/(s-m_i^2)+\ldots \tag{29.4.7}$$
$$\boldsymbol{D}^{ij} = \boldsymbol{m}^{ij}/(s-m_i^2)+\ldots \tag{29.4.8}$$
$$\overline{\boldsymbol{D}}_{ij} = \overline{\boldsymbol{m}}_{ij}/(s-m_i^2)+\ldots, \tag{29.4.9}$$

with no sum on i in each case. They are functions of the external momentum invariant s and the masses and couplings of the theory. Inserting the leading terms [eqs. (29.4.7)–(29.4.9)] into Fig. 29.4.1 and organizing the result in a 2×2 block matrix of two-component propagators reproduces the usual four-component fermion tree-level propagator given in eq. (G.5.2).

The computation of the full propagators can be organized, as usual in quantum field theory, in terms of one-particle irreducible (1PI) self-energy functions. These are formally defined to be the sum of Feynman diagrams to all orders in perturbation theory (with the corresponding tree-level graph *excluded*) that contribute to the 1PI two-point Green function. Diagrammatically, the 1PI self-energy functions are defined in Fig. 29.4.3. As in the case of the full loop-corrected propagators, $\boldsymbol{\Omega}$ and $\overline{\boldsymbol{\Omega}}$ are complex symmetric matrices and the self-energy function satisfy hermiticity conditions, $[\boldsymbol{\Xi}^{\mathsf T}]^\star=\boldsymbol{\Xi}$ and $\overline{\boldsymbol{\Omega}}=\boldsymbol{\Omega}^\star$, where the star symbol was defined in the paragraph following eq. (29.4.6) and $(\boldsymbol{\Xi}^{\mathsf T})^i{}_j\equiv\boldsymbol{\Xi}_j{}^i$.

We illustrate the computation of the full propagator by considering first the following diagrammatic identity (with momentum p flowing from right to left):

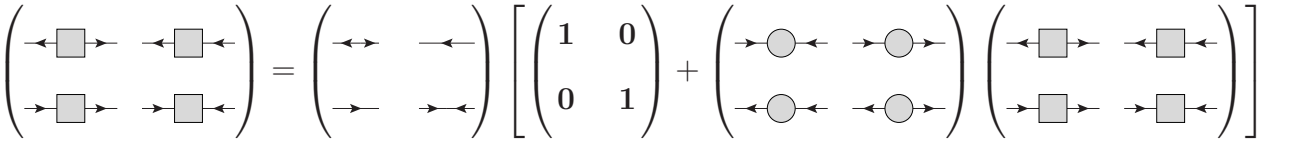


(29.4.10)

Similar diagrammatic identities can be constructed for the three other full loop-corrected propagators of Fig. 29.4.1. The resulting four equations can be neatly summarized by:

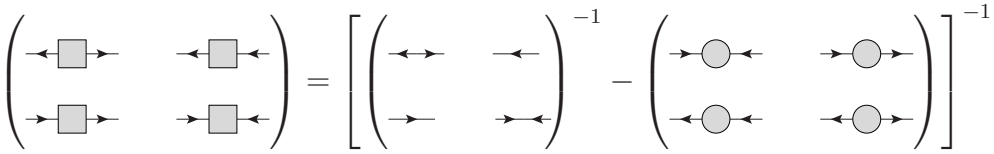
$$F = T + TSF\,, \tag{29.4.11}$$

where F is the matrix of full loop-corrected propagators, T is the matrix of tree-level propagators and S is the matrix of self-energy functions. Expressing eq. (29.4.11) in terms of diagrams,



(29.4.12)

which, when expanded out, yields eq. (29.4.10) and the corresponding identities for the three other full loop-corrected propagators of Fig. 29.4.1. Note that we have chosen the labeling and momentum flow in Figs. 29.4.1 and 29.4.3 such that the spinor and flavor labels of the diagrams appear in the appropriate left-to-right order to permit the interpretation of eq. (29.4.12) as a matrix equation. To solve for F,[59] we multiply eq. (29.4.11) on the left by T^{-1} and on the right by F^{-1} to obtain $T^{-1} = F^{-1} + S$. Thus, $F = [T^{-1} - S]^{-1}$. In pictures:



(29.4.14)

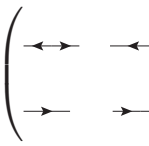
We evaluate the tree-level propagator matrix and its inverse using eqs. (29.4.7)–(29.4.9), keeping

[59] Alternatively, one can solve eq. (29.4.12) by iteration and summing the resulting geometric series. This yields:

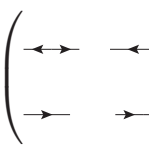
$$\begin{aligned} F &= T + TS(T + TS(T + TS(\cdots))) = T + TST + TSTST + \ldots \\ &= T[1 + ST + (ST)^2 + \ldots] \\ &= T[1 - ST]^{-1} = (T^{-1})^{-1}[1 - ST]^{-1} = [(1 - ST)T^{-1}]^{-1} = [T^{-1} - S]^{-1}\,, \end{aligned} \tag{29.4.13}$$

which is equivalent to eq. (29.4.14).

in mind that the direction of momentum flow is from right to left:



$$= \frac{1}{s - m_i^2} \begin{pmatrix} i\,\overline{\boldsymbol{m}}_{ij}\,\delta_\alpha{}^\beta & ip\cdot\sigma_{\alpha\dot\beta}\,\delta_i{}^j \\ ip\cdot\overline{\sigma}^{\dot\alpha\beta}\,\delta^i{}_j & i\,\boldsymbol{m}^{ij}\,\delta^{\dot\alpha}{}_{\dot\beta} \end{pmatrix}, \tag{29.4.15}$$



$$= \begin{pmatrix} i\,\boldsymbol{m}^{ij}\,\delta_\alpha{}^\beta & -ip\cdot\sigma_{\alpha\dot\beta}\,\delta^i{}_j \\ -ip\cdot\overline{\sigma}^{\dot\alpha\beta}\,\delta_i{}^j & i\,\overline{\boldsymbol{m}}_{ij}\,\delta^{\dot\alpha}{}_{\dot\beta} \end{pmatrix}, \tag{29.4.16}$$

where we follow the index structure defined in Figs. 29.4.1 and 29.4.3. Inserting eq. (29.4.16) into eq. (29.4.14), one obtains a $4N \times 4N$ matrix equation for the full propagator functions:

$$\begin{pmatrix} i\overline{\boldsymbol{D}} & ip\cdot\sigma\,\boldsymbol{C} \\ ip\cdot\overline{\sigma}\,\boldsymbol{C}^{\mathsf{T}} & i\boldsymbol{D} \end{pmatrix} = \begin{pmatrix} i(\boldsymbol{m}+\boldsymbol{\Omega}) & -ip\cdot\sigma\,(\boldsymbol{1}-\boldsymbol{\Xi}^{\mathsf{T}}) \\ -ip\cdot\overline{\sigma}\,(\boldsymbol{1}-\boldsymbol{\Xi}) & i(\overline{\boldsymbol{m}}+\overline{\boldsymbol{\Omega}}) \end{pmatrix}^{-1}, \tag{29.4.17}$$

where $\boldsymbol{1}$ is the $N \times N$ identity matrix. The right hand side of eq. (29.4.17) can be evaluated by employing the following identity for the inverse of a block-partitioned matrix [161]:

$$\begin{pmatrix} P & Q \\ R & S \end{pmatrix}^{-1} = \begin{pmatrix} (P - QS^{-1}R)^{-1} & (R - SQ^{-1}P)^{-1} \\ (Q - PR^{-1}S)^{-1} & (S - RP^{-1}Q)^{-1} \end{pmatrix}, \tag{29.4.18}$$

under the assumption that all inverses appearing in eq. (29.4.18) exist. Applying this result to eq. (29.4.17), we obtain

$$\boldsymbol{C}^{-1} = s(\boldsymbol{1}-\boldsymbol{\Xi}) - (\overline{\boldsymbol{m}}+\overline{\boldsymbol{\Omega}})(\boldsymbol{1}-\boldsymbol{\Xi}^{\mathsf{T}})^{-1}(\boldsymbol{m}+\boldsymbol{\Omega}), \tag{29.4.19}$$

$$\boldsymbol{D}^{-1} = s(\boldsymbol{1}-\boldsymbol{\Xi})(\boldsymbol{m}+\boldsymbol{\Omega})^{-1}(\boldsymbol{1}-\boldsymbol{\Xi}^{\mathsf{T}}) - (\overline{\boldsymbol{m}}+\overline{\boldsymbol{\Omega}}), \tag{29.4.20}$$

$$\overline{\boldsymbol{D}}^{-1} = s(\boldsymbol{1}-\boldsymbol{\Xi}^{\mathsf{T}})(\overline{\boldsymbol{m}}+\overline{\boldsymbol{\Omega}})^{-1}(\boldsymbol{1}-\boldsymbol{\Xi}) - (\boldsymbol{m}+\boldsymbol{\Omega}). \tag{29.4.21}$$

Note that eq. (29.4.21) is consistent with eq. (29.4.20) as $\boldsymbol{\Xi}^\star = \boldsymbol{\Xi}^{\mathsf{T}}$.

The pole mass can be found most easily by considering the rest frame of the (off-shell) fermion, in which the space components of p^μ vanish. This reduces the spinor index dependence to a triviality. Setting $p^\mu = (\sqrt{s}\,;\,\boldsymbol{0})$, we search for values of s where the inverse of the full propagator has a zero eigenvalue. This is equivalent to setting the determinant of the inverse of the full propagator to zero. Here we shall use the well-known formula for the determinant of a block-partitioned matrix [161]:

$$\det \begin{pmatrix} P & Q \\ R & S \end{pmatrix} = \det P \, \det\,(S - RP^{-1}Q). \tag{29.4.22}$$

The end result is that the poles of the full propagator (which are in general complex),

$$s_{\text{pole},j} \equiv M_j^2 - i\Gamma_j M_j, \tag{29.4.23}$$

are formally the solutions to the non-linear equation[60]

$$\det\,\left[s\boldsymbol{1} - (\boldsymbol{1}-\boldsymbol{\Xi}^{\mathsf{T}})^{-1}(\boldsymbol{m}+\boldsymbol{\Omega})(\boldsymbol{1}-\boldsymbol{\Xi})^{-1}(\overline{\boldsymbol{m}}+\overline{\boldsymbol{\Omega}})\right] = 0. \tag{29.4.24}$$

[60]The determinant of the inverse of the full propagator [the inverse of eq. (29.4.17)] is equal to eq. (29.4.24) multiplied by $\det\,[-(\boldsymbol{1}-\boldsymbol{\Xi})(\boldsymbol{1}-\boldsymbol{\Xi}^{\mathsf{T}})]$. We assume that the latter does not vanish. This must be true perturbatively since the eigenvalues of $\boldsymbol{\Xi}$ are one-loop (or higher) quantities, which one assumes cannot be as large as 1.

Some care is required in using eq. (29.4.24), since the pole squared mass always has a *non-positive* imaginary part, while the loop integrals used to find the self-energy functions are complex functions of a real variable s that is given an infinitesimal *positive* imaginary part. Therefore, eq. (29.4.24) should be solved iteratively by first expanding the self-energy function matrices $\boldsymbol{\Xi}$, $\boldsymbol{\Omega}$ and $\overline{\boldsymbol{\Omega}}$ in a series in s about either $m_j^2 + i\epsilon$ or $M_j^2 + i\epsilon$. The complex quantities $s_{\text{pole},j}$, which can be identified as the complex pole squared masses, are renormalization group and gauge invariant physical observables. Examples are given in Sections 29.6.24 and 29.6.25.

The results of this section can be applied to an arbitrary collection of fermions (both Majorana or Dirac). However, it is convenient to treat separately the case where all fermions are Dirac fermions (consisting of pairs of two-component fields χ_i and η^i). As discussed in Section 29.3.2, the Dirac fermion mass eigenstates are defined in eq. (29.3.31) and are determined by the singular value decomposition of the Dirac fermion mass matrix. With respect to the mass basis, we denote the diagonal Dirac fermion mass matrix by $\boldsymbol{M}^{ij}$. The elements of this matrix are real and non-negative. Nevertheless, it will be convenient as before to define $\overline{\boldsymbol{M}}_{ij} \equiv \boldsymbol{M}^{ij}$ to maintain covariance when manipulating tensors with flavor indices.

At tree level, there are four propagators for each pair of χ and η fields as shown in Fig. 29.4.4. The corresponding full, loop-corrected propagators are shown in Fig. 29.4.4. The naming and sign

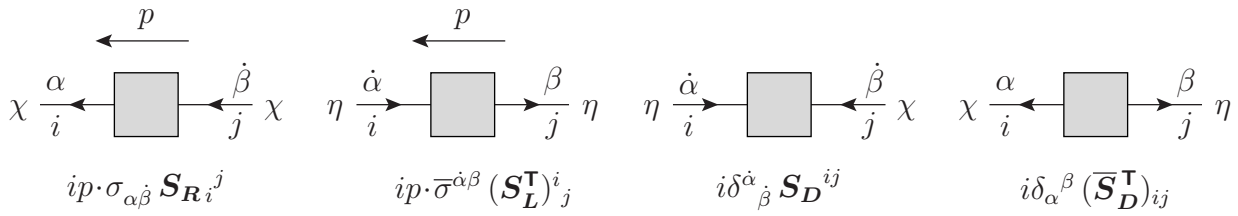


Figure 29.4.4: The full, loop-corrected propagators for Dirac fermions, represented by pairs of two-component (oppositely charged) fermion fields χ_i and η_i, are associated with functions $\boldsymbol{S_R}(s)_i{}^j$, $\boldsymbol{S_L^\mathsf{T}}(s)^i{}_j$, $\boldsymbol{S_D}(s)^{ij}$, and $\overline{\boldsymbol{S}}_{\boldsymbol{D}}^{\mathsf{T}}(s)_{ij}$, as shown. The shaded boxes represent the sum of all connected Feynman diagrams, with external legs included. The four-momentum p and the charge of χ flow from right to left.

conventions employed for the full, loop-corrected Dirac fermion propagator functions in Fig. 29.4.4 derives from the corresponding functions used in the more traditional four-component treatment presented in Appendix G [cf. eq. (G.7.2)].

In general, the complex matrices $\boldsymbol{S_R}$ and $\boldsymbol{S_L}$ satisfy hermiticity conditions $[\boldsymbol{S_R^\mathsf{T}}]^\star = \boldsymbol{S_R}$ and $[\boldsymbol{S_L^\mathsf{T}}]^\star = \boldsymbol{S_L}$, whereas the complex matrices $\boldsymbol{S_D}$ and $\overline{\boldsymbol{S}}_{\boldsymbol{D}}$ are related by $\overline{\boldsymbol{S}}_{\boldsymbol{D}} = \boldsymbol{S_D^\star}$, where the star symbol is defined in the paragraph below eq. (29.4.6). In contrast to the general case of an arbitrary collection of fermions treated earlier, $\boldsymbol{S_R}$ and $\boldsymbol{S_L}$ are unrelated and $\boldsymbol{S}_D$ is a complex matrix (not necessarily symmetric).

Instead of working in a χ–η basis for the two-component Dirac fermion fields, one can Takagi-diagonalize the fermion mass matrix. In the new ψ-basis, the loop-corrected propagators of Fig. 29.4.1 are applicable. It is easy to check that the number of independent functions is the same in both methods for treating Dirac fermions. In particular, the loop-corrected propagator functions in the ψ-basis are given in terms of the corresponding functions in the χ–η basis by:[61]

$$\boldsymbol{C} = \begin{pmatrix} \boldsymbol{S}_R & 0 \\ 0 & \boldsymbol{S}_L \end{pmatrix}, \qquad \boldsymbol{D} = \begin{pmatrix} 0 & \boldsymbol{S}_D^\mathsf{T} \\ \boldsymbol{S}_D & 0 \end{pmatrix}, \qquad \overline{\boldsymbol{D}} = \begin{pmatrix} 0 & \overline{\boldsymbol{S}}_{\boldsymbol{D}}^{\mathsf{T}} \\ \overline{\boldsymbol{S}}_{\boldsymbol{D}} & 0 \end{pmatrix}. \tag{29.4.25}$$

We similarly introduce the 1PI self-energy matrix functions for the Dirac fermions in the χ–η basis, where the corresponding self-energy functions are defined in Fig. 29.4.5. As before, the naming and sign conventions employed for the Dirac fermion self-energy functions above derives from

[61] The simple forms of $\boldsymbol{C}$ in eq. (29.4.25) and $\boldsymbol{\Xi}$ in eq. (29.4.26) motivate our definitions of $\boldsymbol{S_L}$ and $\boldsymbol{\Sigma_R}$ with the transpose as indicated in Figs. 29.4.4 and 29.4.5, respectively.

the corresponding functions used in the more traditional four-component treatment of Appendix G [cf. eq. (G.7.3)].

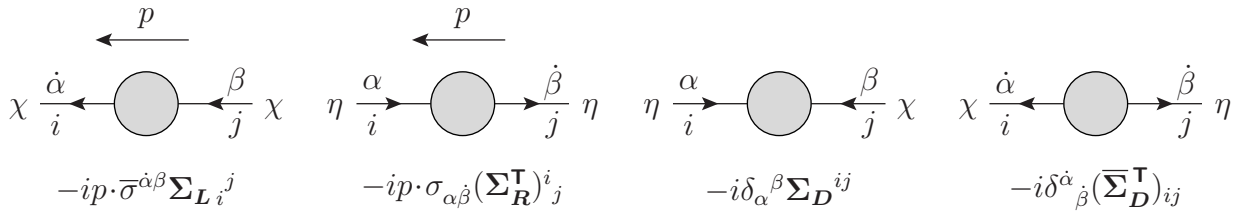

Figure 29.4.5: The self-energy functions for two-component Dirac fermions, represented by pairs of two-component (oppositely charged) fermion fields χ_i and η_i, are associated with functions $\boldsymbol{\Sigma_L}(s)_i{}^j$, $\boldsymbol{\Sigma_R^\mathsf{T}}(s)^i{}_j$, $\boldsymbol{\Sigma_D}(s)^{ij}$, and $\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}^{\mathsf{T}}(s)_{ij}$, as shown. The shaded circles represent the sum of all one-particle irreducible, connected Feynman diagrams, and the external legs are amputated. The four-momentum p flows from right to left.

Once again, the complex matrices $\boldsymbol{\Sigma_L}$ and $\boldsymbol{\Sigma_R}$ satisfy hermiticity conditions $[\boldsymbol{\Sigma_L^\mathsf{T}}]^\star = \boldsymbol{\Sigma_L}$ and $[\boldsymbol{\Sigma_R^\mathsf{T}}]^\star = \boldsymbol{\Sigma_R}$, whereas the complex matrices $\boldsymbol{\Sigma_D}$ and $\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}$ are related by $\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}} = \boldsymbol{\Sigma_D^\star}$, where the star symbol is defined in the paragraph below eq. (29.4.6). Likewise, $\boldsymbol{\Sigma_L}$ and $\boldsymbol{\Sigma_R}$ are unrelated and $\boldsymbol{\Sigma_D}$ is a complex matrix (not necessarily symmetric). The self-energy functions in the ψ-basis are given in terms of the corresponding functions in the χ–η basis by:[61]

$$\boldsymbol{\Xi} = \begin{pmatrix} \boldsymbol{\Sigma}_L & 0 \\ 0 & \boldsymbol{\Sigma}_R \end{pmatrix}, \qquad \boldsymbol{\Omega} = \begin{pmatrix} 0 & \boldsymbol{\Sigma}_D^\mathsf{T} \\ \boldsymbol{\Sigma}_D & 0 \end{pmatrix}, \qquad \overline{\boldsymbol{\Omega}} = \begin{pmatrix} 0 & \overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}^{\mathsf{T}} \\ \overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}} & 0 \end{pmatrix}. \tag{29.4.26}$$

In the case of Dirac fermions fields, eq. (29.4.14) still holds in the χ–η basis, which yields:

$$\begin{pmatrix} i\overline{\boldsymbol{S}}_{\boldsymbol{D}}^{\mathsf{T}} & ip\cdot\sigma\,\boldsymbol{S}_R \\ ip\cdot\overline{\sigma}\,\boldsymbol{S_L^\mathsf{T}} & i\boldsymbol{S}_D \end{pmatrix} = \begin{pmatrix} i(\boldsymbol{M}+\boldsymbol{\Sigma}_D) & -ip\cdot\sigma\,(\mathbf{1}-\boldsymbol{\Sigma}_R^\mathsf{T}) \\ -ip\cdot\overline{\sigma}\,(\mathbf{1}-\boldsymbol{\Sigma}_L) & i(\overline{\boldsymbol{M}}+\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}^{\mathsf{T}}) \end{pmatrix}^{-1}. \tag{29.4.27}$$

Using eq. (29.4.18), it follows that:

$$\boldsymbol{S_L}^{-1} = s(\mathbf{1}-\boldsymbol{\Sigma_R}) - (\overline{\boldsymbol{M}}+\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}})(\mathbf{1}-\boldsymbol{\Sigma_L^\mathsf{T}})^{-1}(\boldsymbol{M}+\boldsymbol{\Sigma_D^\mathsf{T}}), \tag{29.4.28}$$

$$\boldsymbol{S_R}^{-1} = s(\mathbf{1}-\boldsymbol{\Sigma_L}) - (\overline{\boldsymbol{M}}+\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}^{\mathsf{T}})(\mathbf{1}-\boldsymbol{\Sigma_R^\mathsf{T}})^{-1}(\boldsymbol{M}+\boldsymbol{\Sigma_D}), \tag{29.4.29}$$

$$\boldsymbol{S_D}^{-1} = s(\mathbf{1}-\boldsymbol{\Sigma_L})(\boldsymbol{M}+\boldsymbol{\Sigma_D})^{-1}(\mathbf{1}-\boldsymbol{\Sigma_R^\mathsf{T}}) - (\overline{\boldsymbol{M}}+\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}^{\mathsf{T}}), \tag{29.4.30}$$

$$\overline{\boldsymbol{S}}_{\boldsymbol{D}}{}^{-1} = s(\mathbf{1}-\boldsymbol{\Sigma_L^\mathsf{T}})(\overline{\boldsymbol{M}}+\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}})^{-1}(\mathbf{1}-\boldsymbol{\Sigma_R}) - (\boldsymbol{M}+\boldsymbol{\Sigma_D^\mathsf{T}}). \tag{29.4.31}$$

Note that eq. (29.4.31) is consistent with eq. (29.4.30) as $\boldsymbol{\Sigma_{L,R}^\star} = \boldsymbol{\Sigma_{L,R}^\mathsf{T}}$.

The pole mass is now easily computed using the technique previously outlined. In particular, eq. (29.4.24) becomes:

$$\det\left[s\mathbf{1} - (\mathbf{1}-\boldsymbol{\Sigma}_R^\mathsf{T})^{-1}(\boldsymbol{M}+\boldsymbol{\Sigma}_D)(\mathbf{1}-\boldsymbol{\Sigma}_L)^{-1}(\overline{\boldsymbol{M}}+\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}^{\mathsf{T}})\right] = 0, \tag{29.4.32}$$

which determines the complex pole squared masses, s_{pole}, of the corresponding Dirac fermions. Again, the self-energy functions should be expanded in a series in s about a point with an infinitesimal positive imaginary part.

Finally, we examine the special case of a parity-conserving vectorlike theory of Dirac fermions (such as QED or QCD). In this case, the following relations hold among the loop-corrected propagator functions and self-energy functions, respectively:[62]

$$\boldsymbol{S_{R}}_{i}{}^{j} = (\boldsymbol{S_{L}^{\mathsf{T}}})^{i}{}_{j}\,, \qquad \boldsymbol{S_{D}}^{ij} = (\overline{\boldsymbol{S}}_{\boldsymbol{D}}^{\mathsf{T}})_{ij}\,, \tag{29.4.33}$$

$$\boldsymbol{\Sigma_{L}}_{i}{}^{j} = (\boldsymbol{\Sigma_{R}^{\mathsf{T}}})^{i}{}_{j}\,, \qquad \boldsymbol{\Sigma_{D}}^{ij} = (\overline{\boldsymbol{\Sigma}}_{\boldsymbol{D}}^{\mathsf{T}})_{ij}\,. \tag{29.4.34}$$

By imposing eq. (29.4.34) on eqs. (29.4.28)–(29.4.31) and recalling that $\overline{\boldsymbol{M}}_{ij} = \boldsymbol{M}^{ij}$, it is straightforward to verify that eq. (29.4.33) is satisfied.

29.5 Conventions for fermion and antifermion names and fields

In this section, we establish conventions for labeling Feynman diagrams that contain two-component fermion fields of the Standard Model (SM) and its minimal supersymmetric extension (MSSM). In the case of Majorana fermions, there is a one-to-one correspondence between the particle names and the undaggered $(\frac{1}{2},0)$ [left-handed] fields. In contrast, for Dirac fermions there are always two distinct two-component fields that correspond to each particle name. For a quark or lepton generically denoted by f, we employ the two-component undaggered $(\frac{1}{2},0)$ [left-handed] fields f and $\bar{f}$ (where the bar is part of the field name and does *not* refer to complex conjugation of any kind). This is illustrated in Table 29.1, which lists the SM and MSSM fermion particle names together with the corresponding two-component fields. For each particle, we list the two-component field with the same quantum numbers, i.e., the field that contains the annihilation operator for that one-particle state (which creates the one-particle state when acting to the *left* on the vacuum $\langle 0|$).

There is an option of labeling fermion lines in Feynman diagrams by particle names or by field names; each choice has advantages and disadvantages.[63] In all of the examples that follow, we have chosen to eliminate the possibility of ambiguity as follows. We always label fermion lines with two-component fields (rather than particle names), and adopt the following conventions:

- In the Feynman rules for interaction vertices, the external lines are always labeled by the undaggered $(\frac{1}{2},0)$ [left-handed] field, regardless of whether the corresponding arrow is pointed in or out of the vertex. Two-component fermion lines with arrows pointing away from the vertex correspond to dotted indices, and two-component fermion lines with arrows pointing toward the vertex always correspond to undotted indices. This also applies to Feynman diagrams where the roles of the initial state and the final state are ambiguous (such as self-energy diagrams).
- Internal fermion lines in Feynman diagrams are also always labeled by the undaggered $(\frac{1}{2},0)$ [left-handed] field(s). Internal fermion lines containing a propagator with opposing arrows can carry two labels (e.g., see Fig. 29.4.7).
- Initial state external fermion lines (which always have physical three-momenta pointing into the vertex) in Feynman diagrams for complete processes are labeled by the corresponding undaggered $(\frac{1}{2},0)$ [left-handed] field if the arrow is into the vertex, and by the daggered $(0,\frac{1}{2})$ [right-handed] field if the arrow is away from the vertex.
- Final state external fermion lines (which always have physical three-momenta pointing out of the vertex) in Feynman diagrams for complete processes are labeled by the corresponding daggered $(0,\frac{1}{2})$ [right-handed] field if the arrow is into the vertex, and by the undaggered $(\frac{1}{2},0)$ [left-handed] field if the arrow is away from the vertex.

The rules for labeling external Dirac fermions are summarized in Fig. 29.1. These labeling conventions differ slightly from the ones employed in Section 29.4.5, where *all* internal and external

[62] These relations are derived using four-component spinor methods in Appendix G [cf. eqs. (G.7.10) and (G.7.11)].

[63] Unfortunately, the notation for fermion names can be ambiguous because some of the symbols used also appear as names for one of the two-component fermion fields. In practice, it should be clear from the context which set of names are being employed.

Table 29.1: Fermion and antifermion names and two-component fields in the Standard Model and the MSSM. In the listing of two-component fields, the first is an undaggered $(\frac{1}{2},0)$ [left-handed] field and the second is a daggered $(0,\frac{1}{2})$ [right-handed] field. The bars on the two-component (antifermion) fields are part of their names, and do not denote some form of complex conjugation. (In this table, neutrinos are considered to be exactly massless and the left-handed antineutrino $\bar{\nu}$ is absent from the spectrum.)

Fermion name	Two-component fields
ℓ^- (lepton)	$\ell\,,\ \bar{\ell}^\dagger$
ℓ^+ (antilepton)	$\bar{\ell}\,,\ell^\dagger$
ν (neutrino)	$\nu\,,\ -$
$\bar{\nu}$ (antineutrino)	$-\,,\ \nu^\dagger$
q (quark)	$q\,,\ \bar{q}^\dagger$
$\bar{q}$ (antiquark)	$\bar{q}\,,\ q^\dagger$
f (quark or lepton)	$f\,,\ \bar{f}^\dagger$
$\bar{f}$ (antiquark or antilepton)	$\bar{f}\,,\ f^\dagger$
$\widetilde{N}_i$ (neutralino)	$\chi_i^0\,,\ \chi_i^{0\dagger}$
$\widetilde{C}_i^+$ (chargino)	$\chi_i^+\,,\ \chi_i^{-\dagger}$
$\widetilde{C}_i^-$ (anti-chargino)	$\chi_i^-\,,\ \chi_i^{+\dagger}$
$\widetilde{g}$ (gluino)	$\widetilde{g}\,,\ \widetilde{g}^\dagger$

initial state and final state fermion lines were labeled by the corresponding *undaggered* $(\frac{1}{2},0)$ left-handed fields. In this latter convention, the conserved quantities (charges, lepton numbers, baryon numbers, etc.) of the labeled fields follow the direction of the arrow that adorns the corresponding fermion line in the diagram. In contrast, in the convention of Fig. 29.1, the field labels used for external fermion lines always correspond to the physical particle, and the corresponding conserved quantities of the labeled fields follow the direction of the particle three-momentum. As an example, for either initial or final states, the two-component fields e and $\bar{e}^\dagger$ both represent a negatively charged electron, conventionally denoted by e^-, whereas both $\bar{e}$ and $e^\dagger$ represent a positively charged positron, conventionally denoted by e^+ (cf. Table 29.1).

The application of our labeling conventions to processes involving Majorana fermions is completely straightforward. For example, the conventions for employing the neutralino states as external particles are summarized in Fig. 29.2.

As a simple example, consider Bhabha scattering ($e^-e^+ \to e^-e^+$) [162]. We require the two-component Feynman rules for the QED coupling of electrons and positrons to the photon, which are exhibited in Fig. 29.3. Consider the s-channel tree-level Feynman diagrams that contribute to the invariant amplitude for $e^-e^+ \to e^-e^+$. If we were to label the external fermion lines according to the corresponding particle names (which does *not* conform to the conventions introduced above), the result is shown in Fig. 29.4. One can find the identity of the external two-component fermion fields by carefully observing the direction of the arrow of each fermion line. For contrast, the same

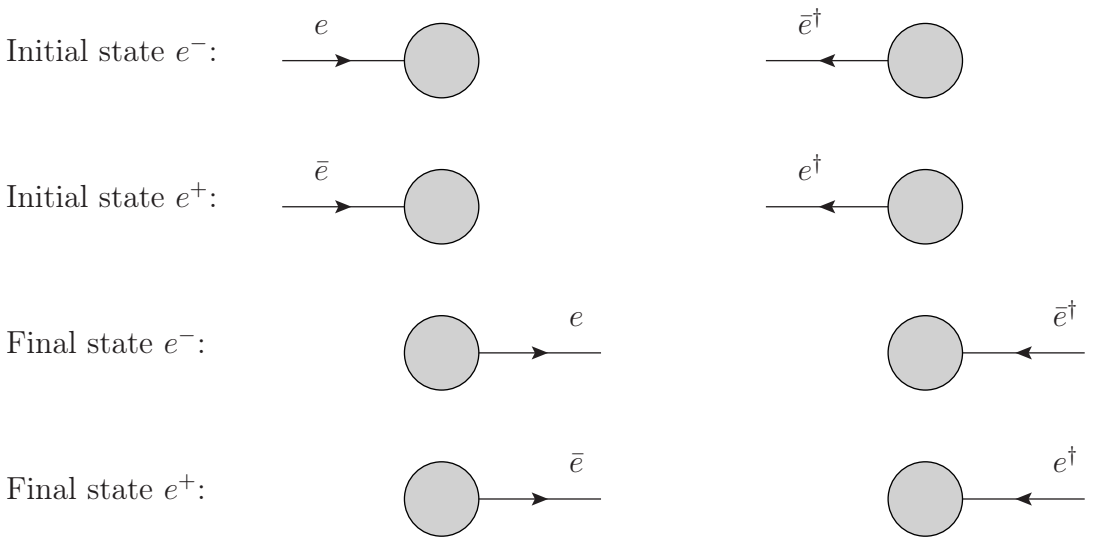

Figure 29.1: The two-component field labeling conventions for external Dirac fermion lines in a Feynman diagram for a physical process. The top row corresponds to an initial state electron, the second row to an initial state positron, the third row to a final state electron, and the fourth row to a final state positron. The labels above each line are the two-component field names. The corresponding conventions for a massless neutrino are obtained by deleting the diagrams with $\bar{e}$ or $\bar{e}^\dagger$, and changing e and $e^\dagger$ to ν and $\nu^\dagger$, respectively.

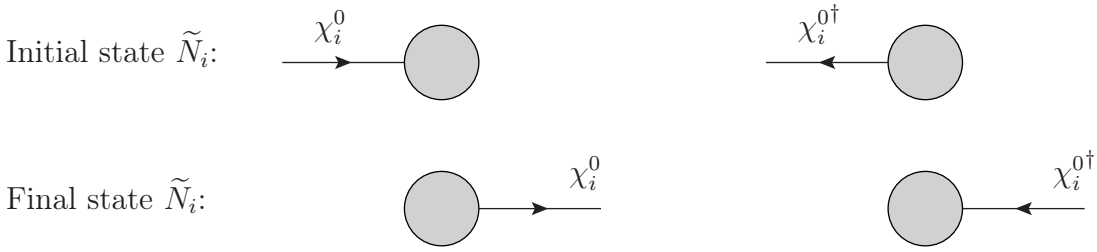

Figure 29.2: The two-component field labeling conventions for external Majorana fermion lines in a Feynman diagram for a physical process. The top row corresponds to an initial state neutralino, and the second row to a final state neutralino. The labels above each line are the two-component field names. (The neutralino is its own antiparticle.)

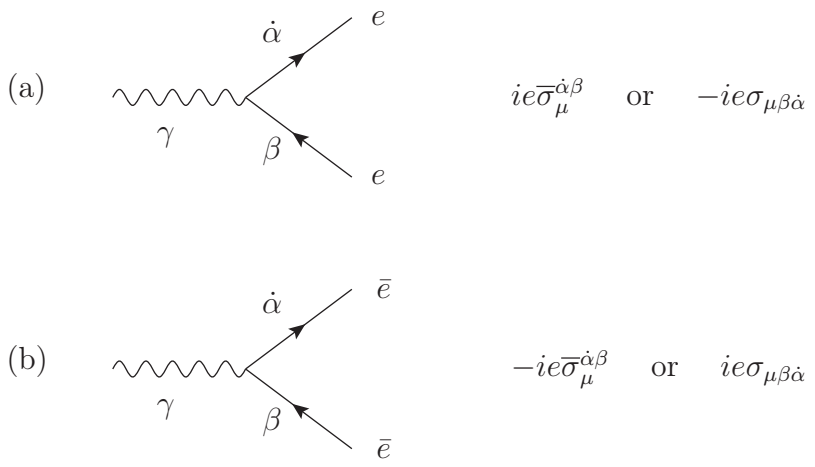

Figure 29.3: The two-component Feynman rules for the QED vertex. Following the conventions outlined in Section 29.5, we label these rules with the $(\frac{1}{2}, 0)$ [left-handed] fields e and $\bar{e}$, which comprise the Dirac electron. Note that $Q_e = -1$, and the electromagnetic coupling constant e (not to be confused with the two-component electron field that is denoted by the same letter) is conventionally defined such that $e > 0$ [cf. Fig. J.1.2].

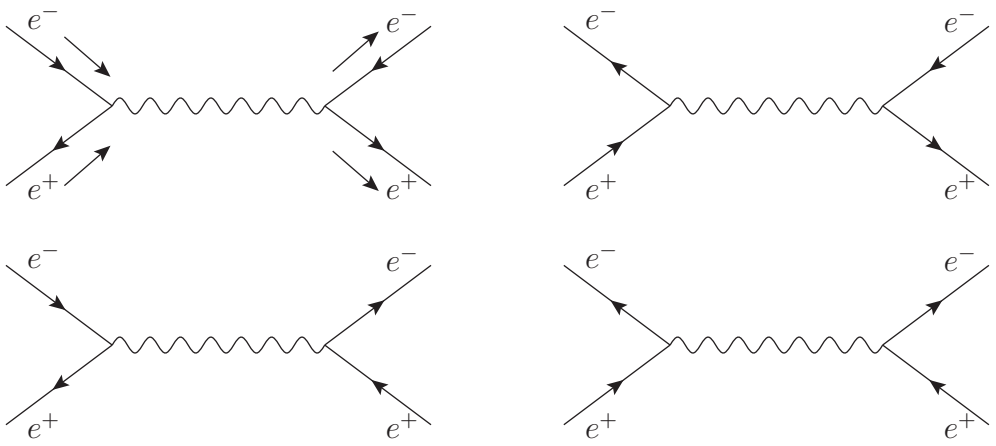

Figure 29.4: Tree-level s-channel Feynman diagrams for $e^-e^+ \to e^-e^+$, with the external lines labeled according to the particle names. The initial state is on the left, and the final state is on the right. Thus, the physical momentum flow of the external particles, as well as the flow of the labeled charges, are indicated by the arrows adjacent to the corresponding fermion lines in the upper left diagram.

diagrams, relabeled with two-component fields following the conventions established in this section (cf. Fig. 29.1), are shown in Fig. 29.5. An explicit computation of the invariant amplitude is given in Section 29.6.3.

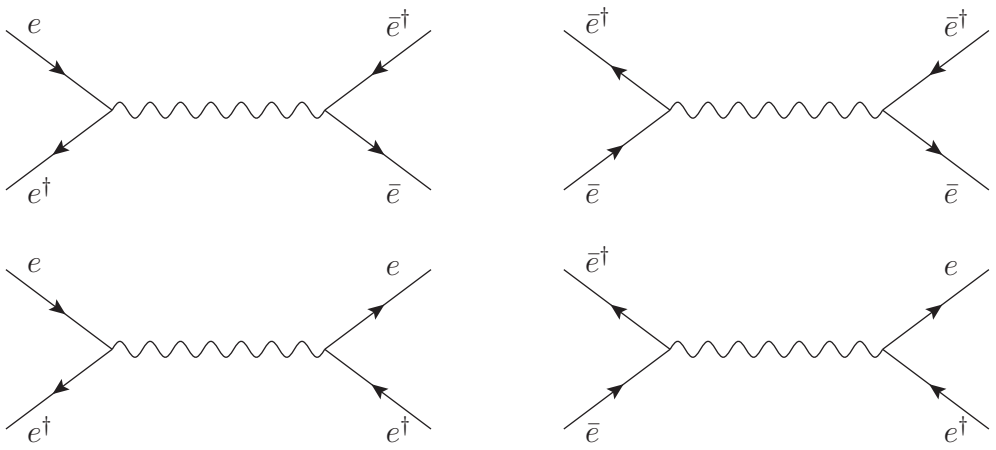

Figure 29.5: Tree-level s-channel Feynman diagrams for $e^+e^- \to e^+e^-$. These diagrams are the same as in Fig. 29.4, but with the external lines relabeled by the two-component fermion fields according to the conventions of Fig. 29.1.

29.6 Practical examples from the Standard Model and its SUSY extension

In this section we will present some examples to illustrate the use of the rules presented in this paper. These examples are chosen from the Standard Model [163] and its supersymmetric (SUSY) extension [6, 7, 8, 9, 10], in order to provide an unambiguous point of reference. In all cases, the fermion lines in Feynman diagrams are labeled by two-component field names, rather than the particle names, as explained in Section 29.5.

29.6.1 Top quark decay: $t \to bW^+$

We begin by calculating the decay width of a top quark into a bottom quark and W^+ vector boson. For simplicity, we treat this as a one-generation problem and ignore Cabibbo-Kobayashi-Maskawa (CKM) [164] mixing among the three quark generations [see eq. (J.1.16) and the surrounding text]. Let the four-momenta and helicities of these particle be (p_t, λ_t), (k_b, λ_b) and (k_W, λ_W), respectively. Then $p_t^2 = m_t^2$, $k_b^2 = m_b^2$ and $k_W^2 = m_W^2$ and

$$2p_t{\cdot}k_W = m_t^2 - m_b^2 + m_W^2\,, \tag{29.6.1}$$
$$2p_t{\cdot}k_b = m_t^2 + m_b^2 - m_W^2\,, \tag{29.6.2}$$
$$2k_W{\cdot}k_b = m_t^2 - m_b^2 - m_W^2\,. \tag{29.6.3}$$

Because only left-handed top quarks couple to the W boson, the only Feynman diagram for $t \to bW^+$ is the one shown in Fig. 29.6.1. The corresponding amplitude can be read off of the Feynman rule of Fig. J.1.2 in Appendix J . Here the initial state top quark is a two-component field t going into the vertex and the final state bottom quark is created by a two-component field $b^\dagger$. Therefore the amplitude is given by:

$$i\mathcal{M} = -i\frac{g}{\sqrt{2}}\varepsilon_\mu^* x_b^\dagger \overline{\sigma}^\mu x_t\,, \tag{29.6.4}$$

where $\varepsilon_\mu^* \equiv \varepsilon_\mu(k_W, \lambda_W)^*$ is the polarization vector of the W^+, and $x_b^\dagger \equiv x^\dagger(\vec{\boldsymbol{k}}_b, \lambda_b)$ and $x_t \equiv x(\vec{\boldsymbol{p}}_t, \lambda_t)$ are the external state wave function factors for the bottom and top quark. Squaring this amplitude using eq. (29.46) yields:

$$|\mathcal{M}|^2 = \frac{g^2}{2}\varepsilon_\mu^*\varepsilon_\nu (x_b^\dagger \overline{\sigma}^\mu x_t)\,(x_t^\dagger \overline{\sigma}^\nu x_b)\,. \tag{29.6.5}$$

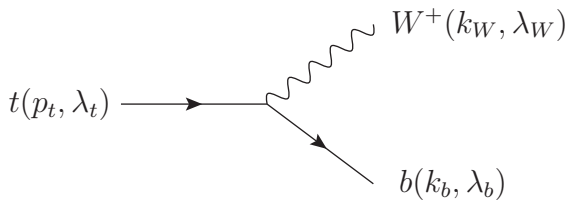

Figure 29.6.1: The Feynman diagram for $t \to bW^+$ at tree level.

Next, we can average over the top quark spin polarizations using eq. (29.3.57):

$$\frac{1}{2}\sum_{\lambda_t} |\mathcal{M}|^2 = \frac{g^2}{4}\varepsilon_\mu^* \varepsilon_\nu x_b^\dagger \overline{\sigma}^\mu \, p_t \cdot \sigma \, \overline{\sigma}^\nu x_b \, . \tag{29.6.6}$$

Summing over the bottom quark spin polarizations in the same way yields a trace over spinor indices:

$$\begin{aligned}\frac{1}{2}\sum_{\lambda_t,\lambda_b} |\mathcal{M}|^2 &= \frac{g^2}{4}\varepsilon_\mu^* \varepsilon_\nu \, \mathrm{Tr}[\overline{\sigma}^\mu p_t \cdot \sigma \, \overline{\sigma}^\nu k_b \cdot \sigma] \\ &= \frac{g^2}{2}\varepsilon_\mu^* \varepsilon_\nu \left(p_t^\mu k_b^\nu + k_b^\mu p_t^\nu - g^{\mu\nu} p_t \cdot k_b - i\epsilon^{\mu\rho\nu\kappa} p_{t\rho} k_{b\kappa}\right) ,\end{aligned} \tag{29.6.7}$$

where we have used eq. (29.58). Finally we can sum over the W^+ polarizations according to:

$$\sum_{\lambda_W} \varepsilon_\mu^* \varepsilon_\nu = -g_{\mu\nu} + (k_W)_\mu (k_W)_\nu / m_W^2 \, . \tag{29.6.8}$$

The end result is:

$$\frac{1}{2}\sum_{\text{spins}} |\mathcal{M}|^2 = \frac{g^2}{2}\left[p_t \cdot k_b + 2(p_t \cdot k_W)(k_b \cdot k_W)/m_W^2\right] . \tag{29.6.9}$$

After performing the phase space integration, one obtains:

$$\begin{aligned}\Gamma(t \to bW^+) &= \frac{1}{16\pi m_t^3}\lambda^{1/2}(m_t^2, m_W^2, m_b^2)\left(\frac{1}{2}\sum_{\text{spins}} |\mathcal{M}|^2\right) \\ &= \frac{g^2}{64\pi m_W^2 m_t^3}\lambda^{1/2}(m_t^2, m_W^2, m_b^2)\left[(m_t^2 + 2m_W^2)(m_t^2 - m_W^2) + m_b^2(m_W^2 - 2m_t^2) + m_b^4\right] ,\end{aligned} \tag{29.6.10}$$

where the kinematical triangle function $\lambda^{1/2}$ is defined by [165]:

$$\lambda(x, y, z) \equiv x^2 + y^2 + z^2 - 2xy - 2xz - 2yz. \tag{29.6.11}$$

In the approximation $m_b \ll m_W, m_t$, one ends up with the well-known result [166]

$$\Gamma(t \to bW^+) = \frac{g^2 m_t}{64\pi}\left(2 + \frac{m_t^2}{m_W^2}\right)\left(1 - \frac{m_W^2}{m_t^2}\right)^2 , \tag{29.6.12}$$

which exhibits the Nambu-Goldstone enhancement factor (m_t^2/m_W^2) for the longitudinal W contribution compared to the two transverse W contributions [166].

29.6.2 Z^0 vector boson decay: $Z^0 \to f\bar{f}$

Consider the partial decay width of the Z^0 boson into a Standard Model fermion-antifermion pair. As in the generic example of Fig. 29.4.4, there are two contributing Feynman diagrams, shown in Fig. 29.6.1. In diagram (a), the fermion particle f in the final state is created by a two-component field f in the Feynman rule, and the antifermion particle $\bar{f}$ by a two-component field $f^\dagger$. In diagram (b), the fermion particle f in the final state is created by a two-component field $\bar{f}$, and the antifermion particle $\bar{f}$ by a two-component field $\bar{f}^\dagger$. Denote the initial Z^0 four-momentum and helicity $(p,\, \lambda_Z)$ and the final state fermion (f) and antifermion $(\bar{f})$ momentum and helicities (k_f, λ_f) and $(k_{\bar{f}}, \lambda_{\bar{f}})$, respectively. Then, $k_f^2 = k_{\bar{f}}^2 = m_f^2$ and $p^2 = m_Z^2$, and

$$k_f \cdot k_{\bar{f}} = \frac{1}{2} m_Z^2 - m_f^2 \,, \tag{29.6.1}$$

$$p \cdot k_f = p \cdot k_{\bar{f}} = \tfrac{1}{2} m_Z^2 \,. \tag{29.6.2}$$

According to the rules of Fig. J.1.2, the matrix elements for the two Feynman graphs are:

$$i\mathcal{M}_a \;=\; -i \frac{g}{c_W} (T_3^f - s_W^2 Q_f)\, \varepsilon_\mu x_f^\dagger \overline{\sigma}^\mu y_{\bar{f}} \,, \tag{29.6.3}$$

$$i\mathcal{M}_b \;=\; ig \frac{s_W^2}{c_W} Q_f\, \varepsilon_\mu y_f \sigma^\mu x_{\bar{f}}^\dagger \,, \tag{29.6.4}$$

where $x_i \equiv x(\vec{\boldsymbol{k}}_i, \lambda_i)$ and $y_i \equiv y(\vec{\boldsymbol{k}}_i, \lambda_i)$, for $i = f, \bar{f}$, and $\varepsilon_\mu \equiv \varepsilon_\mu(p, \lambda_Z)$.

Using the Bouchiat-Michel formulae developed in Appendix H.3 , one can explicitly evaluate $\mathcal{M}_a$ and $\mathcal{M}_b$ as a function of the final state fermion helicities. The result of this computation is given in eqs. (H.3.40) and (H.3.41). If the final state helicities are not measured, then it is simpler to square the amplitude and sum over the final state spins.

It is convenient to define:

$$a_f \equiv T_3^f - Q_f s_W^2 \,, \qquad\qquad b_f \equiv -Q_f s_W^2 \,. \tag{29.6.5}$$

Then the squared matrix element for the decay is, using eqs. (29.45) and (29.46),

$$|\mathcal{M}|^2 = \frac{g^2}{c_W^2} \varepsilon_\mu \varepsilon_\nu^* \left(a_f x_f^\dagger \overline{\sigma}^\mu y_{\bar{f}} + b_f y_f \sigma^\mu x_{\bar{f}}^\dagger \right) \left(a_f y_{\bar{f}}^\dagger \overline{\sigma}^\nu x_f + b_f x_{\bar{f}} \sigma^\nu y_f^\dagger \right) . \tag{29.6.6}$$

Summing over the antifermion helicity using eqs. (29.3.57)–(29.3.60) gives:

$$\sum_{\lambda_{\bar{f}}} |\mathcal{M}|^2 = \frac{g^2}{c_W^2} \varepsilon_\mu \varepsilon_\nu^* \Big(a_f^2 x_f^\dagger \overline{\sigma}^\mu k_{\bar{f}} \cdot \sigma \overline{\sigma}^\nu x_f + b_f^2 y_f \sigma^\mu k_{\bar{f}} \cdot \overline{\sigma} \sigma^\nu y_f^\dagger$$

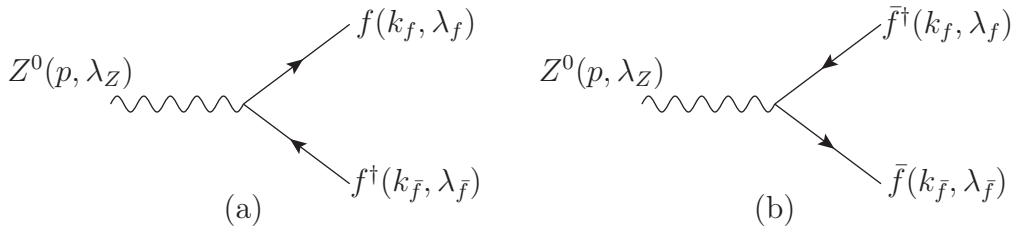

Figure 29.6.1: The Feynman diagrams for Z^0 decay into a fermion-antifermion pair. Fermion lines are labeled according to the two-component fermion field labeling convention established in Section 29.5.

$$-m_f a_f b_f x_f^\dagger \overline{\sigma}^\mu \sigma^\nu y_f^\dagger - m_f a_f b_f y_f \sigma^\mu \overline{\sigma}^\nu x_f \Big) \,. \tag{29.6.7}$$

Next, we sum over the fermion helicity:

$$\sum_{\lambda_f,\lambda_{\bar f}} |\mathcal{M}|^2 = \frac{g^2}{c_W^2} \varepsilon_\mu \varepsilon_\nu^* \Big(a_f^2 \mathrm{Tr}[\overline{\sigma}^\mu k_{\bar f}\cdot\sigma \overline{\sigma}^\nu k_f\cdot\sigma] + b_f^2 \mathrm{Tr}[\sigma^\mu k_{\bar f}\cdot\overline{\sigma} \sigma^\nu k_f\cdot\overline{\sigma}]$$
$$- m_f^2 a_f b_f \mathrm{Tr}[\overline{\sigma}^\mu \sigma^\nu] - m_f^2 a_f b_f \mathrm{Tr}[\sigma^\mu \overline{\sigma}^\nu] \Big) \,. \tag{29.6.8}$$

Averaging over the Z^0 polarization using

$$\frac{1}{3} \sum_{\lambda_Z} \varepsilon_\mu \varepsilon_\nu^* = \frac{1}{3} \left(-g_{\mu\nu} + \frac{p_\mu p_\nu}{m_Z^2} \right) \,, \tag{29.6.9}$$

and applying eqs. (29.56)–(29.58), one gets:

$$\frac{1}{3} \sum_{\text{spins}} |\mathcal{M}|^2 = \frac{g^2}{3c_W^2} \left[(a_f^2 + b_f^2) \left(2k_f\cdot k_{\bar f} + 4\, k_f\cdot p\, k_{\bar f}\cdot p/m_Z^2 \right) + 12 a_f b_f m_f^2 \right]$$
$$= \frac{2g^2}{3c_W^2} \left[(a_f^2 + b_f^2)(m_Z^2 - m_f^2) + 6 a_f b_f m_f^2 \right] \,, \tag{29.6.10}$$

where we have used eqs. (29.6.1) and (29.6.2). After the standard phase space integration, we obtain the well-known result for the partial width of the Z^0:

$$\Gamma(Z^0 \to f\bar f) = \frac{N_c^f}{16\pi m_Z} \left(1 - \frac{4m_f^2}{m_Z^2} \right)^{1/2} \left(\frac{1}{3} \sum_{\text{spins}} |\mathcal{M}|^2 \right)$$
$$= \frac{N_c^f g^2 m_Z}{24\pi c_W^2} \left(1 - \frac{4m_f^2}{m_Z^2} \right)^{1/2} \left[(a_f^2 + b_f^2) \left(1 - \frac{m_f^2}{m_Z^2} \right) + 6 a_f b_f \frac{m_f^2}{m_Z^2} \right] \,. \tag{29.6.11}$$

Here we have also included a factor of N_c^f (equal to 1 for leptons and 3 for quarks) for the sum over colors. Since the Z^0 is a color singlet, the color factor is simply equal to the dimension of the color representation of the outgoing fermions.

29.6.3 Bhabha scattering: $e^-e^+ \to e^-e^+$

In our next example, we consider the computation of Bhabha scattering in QED (that is, we consider photon exchange but neglect Z^0-exchange) [162]. Bhabha scattering has also been computed using two-component spinors in [105]. We denote the initial state electron and positron momenta and helicities by (p_1, λ_1) and (p_2, λ_2) and the final state electron and positron momenta and helicities by (p_3, λ_3) and (p_4, λ_4), respectively. Neglecting the electron mass, we have in terms of the usual Mandelstam variables s, t, u:

$$p_1\cdot p_2 = p_3\cdot p_4 \equiv \tfrac{1}{2} s \,, \tag{29.6.1}$$
$$p_1\cdot p_3 = p_2\cdot p_4 \equiv -\tfrac{1}{2} t \,, \tag{29.6.2}$$
$$p_1\cdot p_4 = p_2\cdot p_3 \equiv -\tfrac{1}{2} u \,, \tag{29.6.3}$$

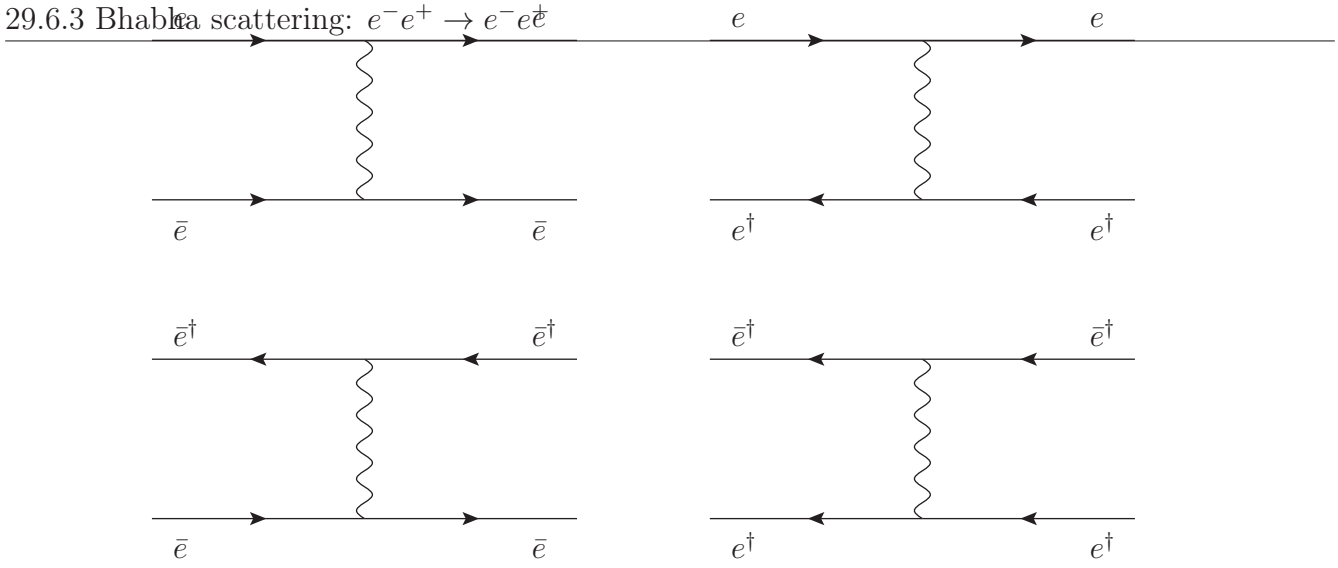

Figure 29.6.1: Tree-level t-channel Feynman diagrams for $e^-e^+ \to e^-e^+$, with the external lines labeled according to the two-component field names. The momentum flow of the external particles is from left to right.

and $p_i^2 = 0$ for $i = 1, ..., 4$. There are eight distinct Feynman diagrams. First, there are four s-channel diagrams, as shown in Fig. 29.5 with amplitudes that follow from the Feynman rules of Fig. 29.3 (more generally, see Fig. J.1.2 in Appendix J):

$$i\mathcal{M}_s = \left(\frac{-ig^{\mu\nu}}{s}\right)\Big[(-ie\,x_1\sigma_\mu y_2^\dagger)(ie\,y_3\sigma_\nu x_4^\dagger) + (-ie\,y_1^\dagger\overline{\sigma}_\mu x_2)(ie\,y_3\sigma_\nu x_4^\dagger) \\ +(-ie\,x_1\sigma_\mu y_2^\dagger)(ie\,x_3^\dagger\overline{\sigma}_\nu y_4) + (-ie\,y_1^\dagger\overline{\sigma}_\mu x_2)(ie\,x_3^\dagger\overline{\sigma}_\nu y_4)\Big]\,, \tag{29.6.4}$$

where $x_i \equiv x(\vec{\boldsymbol{p}}_{\boldsymbol{i}}, \lambda_i)$ and $y_i \equiv y(\vec{\boldsymbol{p}}_{\boldsymbol{i}}, \lambda_i)$, for $i = 1, 4$. The photon propagator in Feynman gauge is $-ig^{\mu\nu}/(p_1 + p_2)^2 = -ig^{\mu\nu}/s$. Here, we have chosen to write the external fermion spinors in the order $1, 2, 3, 4$. This dictates in each term the use of either the $\overline{\sigma}$ or σ forms of the Feynman rules of Fig. 29.3. One can group the terms of eq. (29.6.4) together more compactly:

$$i\mathcal{M}_s = e^2\left(\frac{-ig^{\mu\nu}}{s}\right)\left(x_1\sigma_\mu y_2^\dagger + y_1^\dagger\overline{\sigma}_\mu x_2\right)\left(y_3\sigma_\nu x_4^\dagger + x_3^\dagger\overline{\sigma}_\nu y_4\right). \tag{29.6.5}$$

There are also four t-channel diagrams, as shown in Fig. 29.6.1. The corresponding amplitudes for these four diagrams can be written:

$$i\mathcal{M}_t = (-1)e^2\left(\frac{-ig^{\mu\nu}}{t}\right)\left(x_1\sigma_\mu x_3^\dagger + y_1^\dagger\overline{\sigma}_\mu y_3\right)\left(x_2\sigma_\nu x_4^\dagger + y_2^\dagger\overline{\sigma}_\nu y_4\right). \tag{29.6.6}$$

Here, the overall factor of (-1) comes from Fermi-Dirac statistics, since the external fermion wave functions are written in an odd permutation $(1, 3, 2, 4)$ of the original order $(1, 2, 3, 4)$ established by the first term in eq. (29.6.4).

Fierzing each term using eqs. (29.68)–(29.70), and using eqs. (29.60) and (29.61), the total amplitude can be written as:

$$\mathcal{M} = \mathcal{M}_s + \mathcal{M}_t = 2e^2\Big[\frac{1}{s}(x_1y_3)(y_2^\dagger x_4^\dagger) + \frac{1}{s}(y_1^\dagger x_3^\dagger)(x_2y_4) + \left(\frac{1}{s}+\frac{1}{t}\right)(y_1^\dagger x_4^\dagger)(x_2y_3) \\ + \left(\frac{1}{s}+\frac{1}{t}\right)(x_1y_4)(y_2^\dagger x_3^\dagger) - \frac{1}{t}(x_1x_2)(x_3^\dagger x_4^\dagger) - \frac{1}{t}(y_1^\dagger y_2^\dagger)(y_3y_4)\Big]. \tag{29.6.7}$$

Squaring this amplitude and summing over spins, all of the cross terms will vanish in the $m_e \to 0$ limit. This is because each cross term will have an x or an $x^\dagger$ for some electron or positron combined with a y or a $y^\dagger$ for the same particle, and the corresponding spin sum is proportional to m_e [see eqs. (29.3.59) and (29.3.60)]. Hence, summing over final state spins and averaging over initial state spins, the end result contains only the sum of the squares of the six terms in eq. (29.6.7):

$$\begin{aligned}\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 = e^4 \sum_{\lambda_1,\lambda_2,\lambda_3,\lambda_4} \Bigg\{ &\frac{1}{s^2}\Big[(x_1y_3)(y_3^\dagger x_1^\dagger)(y_2^\dagger x_4^\dagger)(x_4y_2) + (y_1^\dagger x_3^\dagger)(x_3y_1)(x_2y_4)(y_4^\dagger x_2^\dagger)\Big] \\ &+\left(\frac{1}{s}+\frac{1}{t}\right)^2\Big[(y_1^\dagger x_4^\dagger)(x_4y_1)(x_2y_3)(y_3^\dagger x_2^\dagger) + (x_1y_4)(y_4^\dagger x_1^\dagger)(y_2^\dagger x_3^\dagger)(x_3y_2)\Big] \\ &+\frac{1}{t^2}\Big[(x_1x_2)(x_2^\dagger x_1^\dagger)(x_3^\dagger x_4^\dagger)(x_4x_3) + (y_1^\dagger y_2^\dagger)(y_2y_1)(y_3y_4)(y_4^\dagger y_3^\dagger)\Big]\Bigg\}. \end{aligned} \tag{29.6.8}$$

Here we have used eq. (29.44) to get the complex square of the fermion bilinears. Performing these spin sums using eqs. (29.3.57) and (29.3.58) and using the trace identities eq. (B.2.5):

$$\begin{aligned}\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2 &= 8e^4\left[\frac{p_2\cdot p_4\, p_1\cdot p_3}{s^2} + \frac{p_1\cdot p_2\, p_3\cdot p_4}{t^2} + \left(\frac{1}{s}+\frac{1}{t}\right)^2 p_1\cdot p_4\, p_2\cdot p_3\right] \\ &= 2e^4\left[\frac{t^2}{s^2}+\frac{s^2}{t^2}+\left(\frac{u}{s}+\frac{u}{t}\right)^2\right]. \end{aligned} \tag{29.6.9}$$

Thus, the differential cross-section for Bhabha scattering is given by:

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}\left(\frac{1}{4}\sum_{\text{spins}}|\mathcal{M}|^2\right) = \frac{2\pi\alpha^2}{s^2}\left[\frac{t^2}{s^2}+\frac{s^2}{t^2}+\left(\frac{u}{s}+\frac{u}{t}\right)^2\right]. \tag{29.6.10}$$

This agrees with the result given in problem 5.2 of ref. [115].

29.6.4 Polarized muon decay

So far we have only treated cases where the initial state fermion spins are averaged and the final state spins are summed. In the case of the polarized decay of a particle or polarized scattering we must project out the appropriate polarization of the particles in the spin sums. This is achieved by replacing the spin sums given in eqs. (29.3.57)–(29.3.60) by the relevant polarized spin projections exhibited in eqs. (29.3.45)–(29.3.56). As an example, we consider the decay of a polarized muon. Polarized muon decay has also been computed using two-component spinors in [105], however with an effective four-fermion interaction.[64] The leading order Feynman diagram for muon decay is shown in Fig. 29.6.1 (and the relevant four-momenta are indicated).

In our computation, the mass of the muon is denoted by m_μ and the electron mass is neglected. The spin of the muon is measured in its rest frame with respect to a fixed z-axis. Assume that the muon at rest is polarized such that its spin component along the $\hat{\boldsymbol{z}}$-direction is $s = +\frac{1}{2}$. Then, the decay amplitude is given by[65]

$$i\mathcal{M} = \left(\frac{-ig}{\sqrt{2}}\right)^2 \left(x_{\nu_\mu}^\dagger \overline{\sigma}_\rho x_\mu\right)\left(x_e^\dagger \overline{\sigma}_\tau y_{\bar{\nu}_e}\right)\left(\frac{-ig^{\rho\tau}}{D_W}\right), \tag{29.6.1}$$

[64] In a related calculation given in [167], two component spinor techniques are applied to the computation of matrix element for $\nu + n \to p + e^-$ using an effective four-fermion $V-A$ interaction.

[65] Throughout this subsection μ and ν are particle labels. Hence, we employ ρ and τ as Lorentz vector indices.

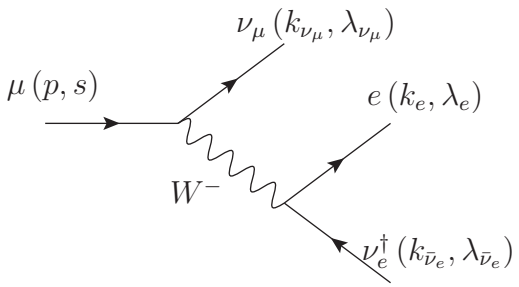

Figure 29.6.1: Feynman diagram for electroweak muon decay.

where $D_W = (p - k_{\nu_\mu})^2 - m_W^2$ is the denominator of the W-boson propagator. In eq. (29.6.1), $x_\mu \equiv x(\vec{\boldsymbol{p}}, s = \frac{1}{2})$ for the spin-polarized initial state muon, and $x^\dagger_{\nu_\mu} \equiv x(\vec{\boldsymbol{k}}_{\nu_\mu}, \lambda_{\nu_\mu})$, $x_e^\dagger \equiv x^\dagger(\vec{\boldsymbol{k}}_e, \lambda_e)$, and $y_{\bar\nu_e} \equiv y(\vec{\boldsymbol{k}}_{\bar\nu_e}, \lambda_{\bar\nu_e})$. Squaring the amplitude using eq. (29.46), we obtain

$$|\mathcal{M}|^2 = \frac{g^4}{4D_W^2}\left(x^\dagger_{\nu_\mu}\overline{\sigma}^\rho x_\mu\right)\left(x^\dagger_\mu\overline{\sigma}^\tau x_{\nu_\mu}\right)\left(x^\dagger_e\overline{\sigma}_\rho y_{\bar\nu_e}\right)\left(y^\dagger_{\bar\nu_e}\overline{\sigma}_\tau x_e\right). \tag{29.6.2}$$

Summing over the neutrino and electron spins using eqs. (29.3.57)–(29.3.58), and using eq. (29.3.45) for the muon spin (with $s = \frac{1}{2}$) yields:

$$\begin{aligned}\sum_{\lambda_{\nu_\mu}\lambda_e\lambda_{\bar\nu_e}} |\mathcal{M}|^2 &= \frac{g^4}{8D_W^2}\mathrm{Tr}[k_{\nu_\mu}\cdot\sigma\,\overline{\sigma}^\rho(p\cdot\sigma - m_\mu S\cdot\sigma)\,\overline{\sigma}^\tau]\,\mathrm{Tr}[k_e\cdot\sigma\,\overline{\sigma}_\rho k_{\bar\nu_e}\cdot\sigma\,\overline{\sigma}_\tau] \\ &= \frac{2g^4}{D_W^2}\,k_e\cdot k_{\nu_\mu}\,k_{\bar\nu_e}\cdot(p - m_\mu S)\,,\end{aligned} \tag{29.6.3}$$

where S^μ in an arbitrary frame is given by eq. (29.3.15) [with $\hat{\boldsymbol{s}} = \hat{\boldsymbol{z}}$]. To obtain the second line we have used the trace identity eq. (29.57) twice; note that the resulting terms linear in the antisymmetric tensor do not contribute, but the term quadratic in the antisymmetric tensor does.

The differential decay amplitude is now given by

$$d\Gamma = \frac{1}{2m_\mu}|\mathcal{M}|^2\frac{d^3\vec{\boldsymbol{k}}_e}{(2\pi)^3 2E_e}\frac{d^3\vec{\boldsymbol{k}}_{\bar\nu_e}}{(2\pi)^3 2E_{\bar\nu_e}}\frac{d^3\vec{\boldsymbol{k}}_{\nu_\mu}}{(2\pi)^3 2E_{\nu_\mu}}(2\pi)^4\delta^4(p - k_e - k_{\bar\nu_e} - k_{\nu_\mu})\,, \tag{29.6.4}$$
