Quantum Field Theory

Yury Holubeu *

October 28, 2025

The note is not intended for distribution. QFT is discussed in detail. Links below show contents of solved problems and summary of other topics. Readers who have opened this note for the first time are highly recommended to read the preface.

Contents

Preface, main motivation, main tips for studying **20**

I —— Typical QFT in a Nutshell —— **24**

1 Main Methods and Models of QFT **24**
1.1 Most used methods in a nutshell . . . 24
1.1.1 Path integral formalism for applications in QFT . . . 24
1.1.2 Operator formalism, second quantization . . . 27
1.1.3 Quantization of the fields . . . 28
1.1.4 Wick's theorem, origin of diagrams, averaging . . . 31
1.1.5 Kinematics, cross sections, decay widths, form factors . . . 38
1.1.6 Analysis of diagrams . . . 43
1.1.7 γ-matrices, spinors, density matrices . . . 44
1.2 Integrals for QFT . . . 50
1.3 Fields . . . 53
1.3.1 Scalar Field . . . 53
1.3.2 Dirac Field . . . 56
1.3.3 Vector Field . . . 64
1.4 QED $\mathcal{L}_{\text{int}} = e\bar{\psi}\gamma^{\mu}\hat{A}_{\mu}\psi$ main properties and phenomena . . . 69
1.4.1 Estimations for QED (???!!) . . . 69
1.4.2 1-loop QED . . . 70
1.4.3 Coupling of Light to Matter . . . 75
1.4.4 Electron and Photon Self-Energy . . . 77
1.5 Main QFT processes and experiments . . . 82
1.5.1 Overview of QFT processes and their comparison (???) . . . 82
1.5.2 Typical scatterings, decays in QED . . . 85
1.5.3 Typical motion in external field . . . 92

2 Most Useful Special Methods **92**
2.1 Typical renormalizations . . . 92
2.2 QFT for condensed matter: main methods . . . 97
2.3 QFT for statistical field theory: main methods . . . 97

II —— Specific Quantum Field Theories in a Nutshell —— **98**

*https://yuriholubeu.github.io/, yuri.holubev@gmail.com

3 Details of Fundamental QFT Methods and Properties in a Nutshell **98**
3.1 General important properties of QFT . . . 98
3.1.1 Nature of microworld and what do we mean by QFT? . . . 98
3.1.2 Constants of QFT: α, e, m_e, μ, $\hbar$ . . . 99
3.1.3 Vacuum, Casimir effect . . . 100
3.1.4 On Causality, Locality, (etc) . . . 106
3.1.5 QED: Other conceptual properties . . . 108
3.1.6 Understanding gravity in QFT formalism . . . 108
3.2 Other properties of basic methods 1 . . . 109
3.2.1 Kinematics, cross sections, decay widths, form factors: details . . . 109
3.2.2 Poincare group for QFT . . . 113
3.2.3 Path integral in QFT: details of the formalism . . . 113
3.2.4 Diagrams in QFT: other information about basics . . . 133
3.2.5 Spinors: other properties . . . 134
3.2.6 Vortex function . . . 136
3.2.7 Schwinger-Dyson equation . . . 136
3.2.8 Dyson equation . . . 137
3.2.9 Bethe-Salpeter equation . . . 137
3.2.10 Properties of amplitudes . . . 139
3.2.11 The Optical Theorem . . . 140
3.3 Other properties of basic methods 2 . . . 147
3.3.1 Soft Theorems . . . 147
3.3.2 Spectral Representation . . . 149
3.3.3 The LSZ Reduction Formula . . . 152
3.3.4 Time-Ordered Correlators . . . 155
3.3.5 Ward-Takahashi Identity . . . 157
3.3.6 Feynman Diagrams . . . 160
3.3.7 Scattering Amplitudes . . . 162
3.3.8 Physical Observables . . . 166
3.3.9 1-loop QED: other properties and approaches . . . 170
3.4 Renormalization: other well-known methods . . . 170
3.4.1 Physical Interpretation . . . 170
3.4.2 Power Counting . . . 172
3.4.3 Renormalization of ϕ^4 Theory . . . 175
3.4.4 Renormalization of Quantum Electrodynamics . . . 182
3.4.5 Scalar QED . . . 189
3.4.6 Basics of Regularization . . . 196
3.4.7 Systematics of Renormalization after Peskin & Schroeder . . . 199
3.4.8 Renormalization and Symmetry after Peskin & Schroeder . . . 199
3.4.9 On the Renormalization Group (???) . . . 199
3.4.10 symptotic Freedom and the Renormalization Group . . . 200
3.5 Free quantum fields: other properties . . . 206
3.5.1 Dirac field: other properties . . . 206
3.5.2 Electromagnetic field: other properties . . . 210
3.5.3 Spin-3/2 field . . . 215
3.5.4 Spin-2 field . . . 215
3.5.5 Other about free quantum fields . . . 215
3.6 Other models of interaction of fields . . . 215
3.6.1 ϕ^3 theory . . . 215
3.6.2 ϕ^4 theory . . . 216

3.6.3 Yukawa theory $\mathcal{L}_{\text{Yukawa}}(\phi,\psi) = -g\bar{\psi}\phi\psi$ . . . 216
3.6.4 Standard Model main properties, algebra . . . 219
3.6.5 Other toy illustrative theories . . . 220
3.7 Useful background for QFT . . . 222
3.7.1 Other mathematics for QFT . . . 222
3.7.2 Quantum Mechanics for QFT . . . 223
3.7.3 Classical field theory for QFT . . . 224

4 Other QFT processes **224**
4.1 Overview of other processes . . . 224
4.1.1 Other QED processes . . . 224
4.2 Special Phenomena of Electrons and Photons . . . 225
4.2.1 Electron Scattering, Ionization Losses, Positronium, Interaction of Atoms . . . 225
4.2.2 $\gamma e \to \gamma e,\ ee \to \gamma\gamma,\ ee^+ \to \gamma\gamma\gamma$ . . . 226
4.2.3 Photons in Magnetic Field, in Nucleus, Pairs in the Ultrarelativistic Case . . . 231
4.2.4 Special Effects with Photons . . . 234
4.2.5 Radiative Corrections to the Mass Operator, Scattering in External Field . . . 235
4.2.6 Radiative Level Shifts, Bound States . . . 235
4.2.7 $\gamma\gamma \to$ (?), Photon Splitting . . . 236
4.2.8 Hadrons, Scattering of Electrons on Them, Transformations . . . 238
4.3 Hypothetical processes . . . 239
4.3.1 Examples from the Standard Model and its SUSY extension by Dreiner et.al. . . . 239

5 Other Well-Known Methods of QFT **239**
5.1 On Other Properties of QFT (?) . . . 239
5.1.1 On typical spontaneous symmetry breaking, Higgs boson (???) . . . 239
5.1.2 Wilsonian Renormalization, effective action, RG flow, effective theories (!!!!!) . . . 240
5.1.3 Corrections to Polarization Operator and to Coulomb Law, Form Factors . . . 257
5.1.4 Asymptotic Formulas of QED, High Energies . . . 259
5.1.5 Entanglement in Quantum Fields . . . 260
5.2 On Special Path Integral Methods . . . 260
5.2.1 Effective Quantum Mechanics . . . 260
5.2.2 Quantum Statistical Mechanics . . . 264
5.2.3 Quantum Fields . . . 267
5.2.4 Symmetries of the Path Integral . . . 271

6 Experiments and methods for experiments **278**
6.0.1 Ideas for experimental determining parameters of fields . . . 278
6.0.2 Properties of fundamental particles . . . 278

7 Special Phenomena and Theoretical Extensions of QFT **279**
7.1 Non-Abelian Gauge Theory in a nutshell . . . 279
7.1.1 Classical Yang-Mills, quantization, Faddeev-Popov method . . . 279
7.1.2 BRST Symmetry . . . 290
7.1.3 Perturbative Renormalization, asymptotic freedom . . . 294
7.1.4 QCD: main laws and ideas, quarks, confinement . . . 296
7.1.5 Partons, Deep Inelastic Scattering, Drell–Yan Process . . . 300
7.1.6 On Operator Products and Effective Vertices . . . 302
7.1.7 On the Anomaly of Perturbation Theory . . . 302
7.1.8 On Gauge Theories with Spontaneous Symmetry Breaking . . . 303
7.1.9 On Quantization of Spontaneously Broken Gauge Theories . . . 303

7.2 Radiation Theory in a Nutshell . . . 303
7.2.1 Radiation of the Simplest Atoms and Nuclei, Photoelectric Effect . . . 303
7.2.2 Dipole and Multipole Electromagnetic Radiation . . . 304
7.3 Solitons, kinks, monopoles, vortices, instantons . . . 305
7.3.1 Kinks . . . 305
7.3.2 Vortices, Monopoles, Instantons . . . 312
7.3.3 Anomalies: Pion decay, triangle diagrams, features . . . 341
7.4 Hypothetical particles and their phenomena in a nutshell . . . 355
7.5 Gauge symmetries, theories, lattices . . . 356
7.5.1 Strong Coupling Approximation . . . 356
7.5.2 On non-renormalizable theories . . . 356
7.5.3 Instantons in Abelian Systems (after Polyakov) . . . 357
7.6 Specific properties of QFT (???) . . . 357
7.6.1 On QFT in Real Time (???) . . . 357
7.6.2 On Integrable Quantum Fields . . . 357
7.6.3 On Other Number Fields, Special Algebra for QFT . . . 358
7.7 Condensed matter models . . . 358
7.7.1 Critical Exponents and Scalar Field Theory (after Peskin & Schroeder) . . . 358
7.7.2 Typical Phase Transitions in Matter (!?) . . . 358
7.7.3 Quantum Phase Transitions in Matter (!?) . . . 358
7.7.4 Superconductivity [see note on SC] . . . 358
7.7.5 Disorder in Matter . . . 358
7.8 Other Modifications of QFT in a Nutshell (?) . . . 358
7.8.1 QFT in curved space-time . . . 359
7.8.2 The Euler-Heisenberg Lagrangian . . . 359
7.8.3 Supersymmetry (???) . . . 361
7.8.4 String Theory . . . 361
7.9 Specific applications of QFT in a nutshell . . . 361
7.9.1 On methods of QFT for quantum optics . . . 361
7.9.2 Waveguide QFT: basics ans useful methods . . . 361
7.9.3 Circuit QFT: basics ans useful methods . . . 361
7.9.4 QFT for finances . . . 361

III QFT Fundamentals and Free Quantum Fields 362

8 Formalisms and a general view of QFT 362
8.1 Fundamental Experiments for QFT . . . 362
8.2 Philosophy of QFT: Main Ideas (??) . . . 362
8.2.1 The Idea of the Quantum-Field Approach (????) . . . 362
8.2.2 When in Physics “all is field” and when it is not? . . . 362
8.2.3 Examples for Introducing the Essence of QFT (??) . . . 362
8.2.4 What is a Quantum Field (??????) . . . 371
8.2.5 What Does It Mean to “Quantize” a Field (??????) . . . 372
8.2.6 Causality (?!??!?) . . . 372
8.2.7 Does the Idea of Quantizing Fields Lead to Contradictions? . . . 373
8.2.8 Connection with Quantum Mechanics and Wave Functions (???) . . . 374
8.3 Philosophy of QFT: Other Ideas (??) . . . 374
8.3.1 Locality . . . 374
8.3.2 How Were Particles Created? . . . 374

8.3.3 What is Time and Space? . . . 374
8.4 What is Really a Vacuum? . . . 374
8.4.1 Why is Something in the Quantum World Renormalized? . . . 374
8.4.2 How Rigorous should be Mathematics for QFT? . . . 374
8.4.3 Зи.III.1 Cutting Off Our Ignorance . . . 374
8.4.4 Can a Diagram Be Something More? . . . 382
8.4.5 What Is Life? . . . 382
8.4.6 O, Actually, QFT Is in Condensed Matter . . . 382
8.4.7 Gravity is Not a Quantum Field, Right? . . . 382
8.5 Poincare Group for QFT . . . 382
8.5.1 Mathematical Details of Relativistic Invariance . . . 382
8.5.2 Field Equations from Poincare Group . . . 382
8.6 Field Formalism for QFT . . . 383
8.6.1 Lagrange Field Formalism . . . 383
8.6.2 Conservation Laws for Quantum Fields (after Mandl & Shaw) . . . 383
8.6.3 Idea of Symmetries (after Zi) . . . 389
8.6.4 Hamiltonian Field Formalism . . . 393
8.6.5 Noether Theorem: Basics . . . 395
8.6.6 Noether Theorem: Introduction to Consequences . . . 397
8.7 So, What Is Exactly a Quantum Field? . . . 397
8.7.1 What Do We Mean By "Operator Quantum Field"? . . . 397
8.7.2 The Transition from Classical to Quantum Fields . . . 397
8.7.3 Is a Particle a One Field or Several? . . . 397
8.7.4 Single-quantum Field . . . 397
8.7.5 Two- and Three-Quantum Fields (???) . . . 404
8.7.6 What Is Exactly a Quantum Field? . . . 404
8.7.7 Wave-particle Duality . . . 405
8.7.8 What is Not a Quantum Field? . . . 406
8.7.9 What is QFT, and What Did We Think It Is? (Weinberg, 1996) . . . 406
8.7.10 Connection of Particles and Fields 1 . . . 414
8.7.11 Connection of Particles and Fields 2 . . . 417
8.8 World of Quantum Fields . . . 419
8.8.1 Concept of Mass . . . 419
8.8.2 Forces in Scope of QFT . . . 419
8.8.3 Deriving Coulomb's Law from QFT . . . 419
8.8.4 Deriving Newton's Law from QFT (??) . . . 422
8.8.5 Зи.I.6 Inverse-Square Law and Floating 3-Brane . . . 426
8.8.6 Зи.I. Canonical Quantization and Vacuum Perturbation . . . 428
8.9 Concept of Operators and Second Quantization . . . 433
8.9.1 Origin of Operators . . . 433
8.9.2 Concept of Second Quantization . . . 434
8.10 Concept of Path Integral . . . 434
8.10.1 Idea of Path Integral . . . 434
8.10.2 What is Exactly Meant by Path Integral? . . . 434
8.10.3 Quantization Using of Path Integral . . . 434
8.10.4 Where Path Integral is Also? . . . 434
8.11 Conceptual Properties of Emptiness . . . 434
8.11.1 Vacuum Energy . . . 434
8.11.2 Idea of Casimir Effect . . . 435
8.11.3 Emptiness in Cosmology: Main Ideas . . . 437

8.12 Details of Quantization . . . 437
8.12.1 Quantization of Non-plane Waves: Main Ideas . . . 437
8.12.2 Quantization on a Curved Spacetime: Main Ideas . . . 437
8.12.3 Other Ideas about Quantization of Fields . . . 437
8.12.4 Other Ideas about Quantization . . . 437
8.12.5 What about that Illustrative Picture of "Quants-bullets"? . . . 437
8.13 Deeper Understanding of General QFT Concepts . . . 438
8.13.1 Newtonian Mechanics as a Particular Case of QFT . . . 438
8.13.2 Field Theory as a Particular Case of QFT . . . 438
8.13.3 Quantum Mechanics as a Particular Case of QFT . . . 438
8.13.4 Haag's theorem . . . 438

9 Free Quantum Fields 439
9.1 Scalar Field (bosons) . . . 439
9.1.1 The Klein-Gordon field as a set of harmonic oscillators . . . 439
9.1.2 The Klein-Gordon field in space-time . . . 451
9.1.3 Causality for Scalar Field . . . 453
9.1.4 The Klein-Gordon Propagator . . . 456
9.1.5 Production of particles by a classical source . . . 458
9.1.6 Examples of Typical Transformations of a Scalar Field . . . 459
9.2 Vector Field (photons) . . . 461
9.2.1 Derivation of Vector Field Equations . . . 461
9.2.2 Quantization of a Vector Field: Basics . . . 461
9.2.3 Quantization of a Vector Field: Features . . . 465
9.2.4 The Photon Propagator . . . 467
9.2.5 Covariant Gauges and the Photon Propagator . . . 469
9.2.6 Quantum Vector Field in a Medium . . . 470
9.3 Quantization of the Electromagnetic Field . . . 470
9.3.1 The Continuum Integral for Degenerate Systems . . . 470
9.3.2 Electromagnetic Field as a Dynamic System . . . 473
9.3.3 Covariant Quantization Rules and the Faddeev-Popov Trick . . . 478
9.3.4 Faddeev-Popov Trick: Detailed Overview . . . 480
9.4 Spinor Field (fermions) 1: General Methods . . . 480
9.4.1 Fermion Propagator (after Mandl & Shaw) . . . 480
9.4.2 The Electromagnetic Interaction and Gauge Invariance . . . 482
9.4.3 Зи.II.1 Dirac Equation . . . 484
9.4.4 Зи.II.2 Quantization of the Dirac Field . . . 496
9.4.5 Зи.II.3 Lorentz Group and Weyl Spinors . . . 503
9.4.6 Зи.II.4 Connection of Spin and Statistics . . . 507
9.4.7 Зи.II.5 Grassmann Integrals and Fermion Diagrams . . . 510
9.4.8 Зи.II.6 Electron Scattering and Gauge Invariance . . . 517
9.4.9 Зи.II.7 Diagrammatic Proof of Gauge Invariance . . . 521
9.5 Spinor Field (fermions) 2: Other Properties and Conceptual Questions . . . 527
9.5.1 Lorentz Invariance of Wave Equations . . . 527
9.5.2 Dirac Equation . . . 532
9.5.3 Weyl Spinors . . . 535
9.5.4 Solutions of the Dirac Equation for Free Particles . . . 536
9.5.5 Spin Sums . . . 540
9.5.6 Dirac Matrices and Bilinear Forms . . . 540
9.5.7 Quantization of the Dirac Field . . . 543

9.5.8 Dirac Propagator . . . 553
9.5.9 Discrete Symmetries in Dirac Theory . . . 554
9.5.10 Parity . . . 555
9.5.11 Time Reversal . . . 557
9.5.12 Charge Conjugation . . . 560
9.5.13 Summary of Formulas for C, P, and T Transformations . . . 561
9.5.14 How does the electron know that some state is occupied and not go there by Pauli's principle? . . . 562
9.5.15 Examples of Problems and Solutions . . . 562
9.6 Spinor Field (fermions) 3: Mathematical Details . . . 567
9.6.1 1. Dirac Equation . . . 568
9.6.2 2. Nonrelativistic Limit . . . 571
9.6.3 3. Quantization of the Dirac Field . . . 572
9.6.4 4. Algebra of Dirac Matrices . . . 577
9.6.5 5. Discrete Symmetries of the Dirac Equation . . . 578
9.6.6 6. Weyl Equation . . . 580
9.6.7 7. Exact Solution of the Dirac Equation in a Coulomb Potential . . . 581
9.7 L9-1 Quantization of Fermions Using a Functional Integral . . . 586
9.7.1 1. Fermionic Oscillator . . . 586
9.7.2 2. Representation of Fermionic Amplitudes via Functional Integrals . . . 587
9.7.3 3. Functional Integral in Dirac Theory . . . 592
9.8 Other Quantum Fields (?) . . . 594
9.8.1 Massive Quantum Vector Field (??) . . . 594
9.8.2 Facts of life with γ_5 (by F. Jegerlehner) . . . 594

10 Other Properties of Free Fields and Other Fields **604**
10.0.1 Зи.I.10 Quantum Field Theory in Curved Spacetime . . . 604
10.1 Symmetries (after Polyakov) . . . 612
10.1.1 Global and Local Symmetries: Preliminary Description . . . 613
10.1.2 Discrete Global Symmetries . . . 613
10.1.3 Continuous Abelian Global Symmetries . . . 613
10.1.4 Non-Abelian Global Symmetries . . . 613
10.1.5 Discrete Gauge Symmetries . . . 613
10.1.6 O(2)-Gauge Systems . . . 613
10.1.7 Non-Abelian Gauge Symmetries . . . 613
10.2 Non-Abelian Fields, Ghosts, BRST Invariance (??) . . . 613
10.3 Free Quantum Fields at Finite Temperature . . . 617

IV Practical Methods in QFT **618**

11 Setups for Phenomena **618**
11.1 L9-2 S-Matrix . . . 618
11.1.1 4. General Formula for the S-Matrix in QED and the Simplest Amplitudes . . . 618
11.1.2 Introduction to Mathematical Perturbation Theory . . . 622
11.2 Description of Decays . . . 627
11.2.1 Basics of Decays . . . 627
11.2.2 Other Aspects of Decays (??????) . . . 629
11.3 Description of Scatterings . . . 629
11.3.1 Scattering Cross-Section . . . 630

11.3.2 Particle Reactions (!?!??) . . . 636
11.3.3 Scattering Cross-Sections and the S-Matrix by Peskin & Schroeder . . . 636
11.3.4 Expressing Process Probabilities via Amplitudes . . . 638
11.3.5 Spin Density Matrices . . . 642
11.4 Scattering Matrix by Landau 4 . . . 645
11.4.1 Scattering Amplitude . . . 645
11.4.2 Reactions with Polarized Particles . . . 645
11.4.3 Kinematic Invariants . . . 645
11.4.4 Physical Regions . . . 645
11.4.5 Expansion in Partial Amplitudes . . . 646
11.4.6 Symmetry of Spiral Scattering Amplitudes . . . 646
11.4.7 Invariant Amplitudes . . . 646
11.4.8 Unitarity Condition . . . 646
11.5 Taking Into Account Features of Real Setups . . . 646
11.5.1 Distorted Wave Approximation . . . 646

V Theoretical Methods and Fundamental Effects of QFT 647

12 Operator Formalism 647
12.0.1 Quantization with Operators . . . 647
12.0.2 Quantization with Operators: Detailed Overview . . . 647
12.0.3 Interactions of Fields in the Operator Formalism . . . 647
12.0.4 Other Aspects of the Operator Formalism . . . 647

13 Path Integral Formalism 648
13.0.1 Simplified Mathematics Used in the Path Integral (!?!??) . . . 648
13.0.2 Mathematical Identities for Constructing the Path Integral (!?!??) . . . 648
13.0.3 Path Integral for Particles . . . 648
13.0.4 Path Integral for Fields . . . 651
13.0.5 Path Integral for Fields: Easy Examples . . . 651
13.0.6 Infinite Series Sums and Expansions in QFT (!?!?) . . . 655
13.0.7 Perturbative Expansion – Making Sense of Divergent Series . . . 655
13.0.8 Regularization and Renormalization as Extensions of Distributions . . . 666
13.0.9 On the Strict Formalism (??) . . . 675
13.0.10 On Something Else (??) . . . 675
13.1 Holomorphic Path Integral, S-Matrix, Scalar Field Theory . . . 675
13.1.1 1. Creation and Annihilation Operators . . . 675
13.1.2 2. General Operators . . . 677
13.1.3 3. Functional Integral in the Holomorphic Representation . . . 678
13.1.4 4. Definition of the S-Matrix . . . 680
13.1.5 5. S-Matrix in Scalar Field Theory . . . 681
13.1.6 6. S-Matrix in Interacting Field Theory . . . 686

14 Interacting Fields in Series, Feynman Diagrams 689
14.1 Expansion of Correlation Functions in Perturbation Theory . . . 689
14.2 Basics of Feynman Diagrams . . . 695
14.2.1 Connected Diagrams . . . 695
14.2.2 Loop Expansion (????) . . . 696
14.2.3 One-Particle Irreducible Diagrams (1PI) . . . 697

14.2.4 Reduction Formulas . . . 699
14.2.5 Feynman Rules by Kiselev . . . 700
14.2.6 Coupling Constant Expansion by Vergeles (!!!!) . . . 702
14.2.7 Combinatoric Factors . . . 712
14.2.8 Feynman Rules: Derivation from Weinberg . . . 712
14.2.9 Examples of Feynman Rules in Different Theories . . . 725
14.2.10 Furry's theorem about Fermionic loop . . . 726
14.2.11 Feynman Diagrams by Zi.I.7 1 . . . 726
14.2.12 Feynman Diagrams by Zi.I.7 2 . . . 736
14.2.13 4.3 Wick's Theorem . . . 742
14.2.14 Wick's Theorem by Mandl & Shawl . . . 747
14.3 4.4 Feynman Diagrams . . . 749
14.4 4.5 Cross Sections and the S-Matrix . . . 757
14.5 4.6 Computing S-Matrix Elements from Feynman Diagrams . . . 765
14.6 4.7 Feynman Rules for Fermions . . . 771
14.7 4.8 Feynman Rules for Quantum Electrodynamics . . . 778
14.7.1 5. Feynman Rules for QED . . . 785
14.8 Series Expansion in QFT . . . 787
14.8.1 Mathematics of Series Expansion for QFT and Regions of Convergence (!!!) . . . 787
14.8.2 Quantum Amplitudes and External Fields by Kiselev (!!!!) . . . 787

15 Other Fundamental Methods of QFT **789**
15.1 Some Well-known General Properties . . . 790
15.1.1 Ward–Takahashi–Slavnov–Taylor Identities . . . 790

16.8 L6 Renormalization Group . . . 860
16.8.1 1. Wilsonian Approach to Renormalization Theory . . . 860
16.8.2 2. Callan–Symanzik Equation . . . 866
16.8.3 3. Evolution of the Running Coupling Constant . . . 867
16.9 L5 General Scheme of Renormalizations . . . 869
16.9.1 1. Källén–Lehmann Spectral Representation of the Two-Point Function . . . 869
16.9.2 2. Renormalizations . . . 873
16.9.3 3. Unitarity Condition . . . 877

17 Radiative Corrections: Some Formal Developments 1 **878**
17.1 7.1 Field-Strength Renormalization . . . 879
17.2 7.2 The LSZ Reduction Formula . . . 888
17.3 7.3 The Optical Theorem . . . 895
17.4 7.4 The Ward-Takahashi Identity . . . 902
17.5 7.5 Renormalization of the Electric Charge . . . 907
17.6 Chapter 8 Invitation to Renormalization: Ultraviolet Cutoffs and Critical Fluctuations . 922
17.7 L11 Electron and Photon Propagators at One-Loop . . . 930
17.7.1 1. Mass Operator . . . 930
17.7.2 2. Polarization Operator . . . 934
17.7.3 3. Radiative Corrections to Coulomb's Law . . . 937
17.8 L12 Vertex Operator and Anomalous Magnetic Moment of the Electron . . . 939
17.8.1 1. Electron Form Factors . . . 939
17.8.2 2. Analytical Properties of Form Factors . . . 941
17.8.3 3. Calculation of Imaginary Parts Using the Feynman Integral . . . 943
17.8.4 4. Anomalous Magnetic Moment of the Electron . . . 948
17.9 L13 Infrared Problem. Lamb Shift of Energy Levels . . . 948
17.9.1 1. Massive Vector Field . . . 949
17.9.2 2. Emission of Soft Photons . . . 949
17.9.3 3. Cancellation of Infrared Divergences . . . 955
17.9.4 4. Lamb Shift of Energy Levels . . . 956

18 Radiative Corrections: Some Formal Developments 2 **962**
18.1 Renormalization and Gauge Invariance by Zi . . . 962
18.1.1 Zi.III.2 Renormalizable vs. Nonrenormalizable . . . 962
18.1.2 Zi.III.3 Counterterms and Physical Perturbation Theory . . . 965
18.1.3 Zi.III.4 Gauge Invariance: Photon Knows No Rest . . . 974
18.1.4 Zi.III.5 Field Theory Without Relativistic Invariance . . . 978
18.1.5 Zi.III.6 Magnetic Moment of the Electron . . . 981
18.1.6 Zi.III.7 Polarizing the Vacuum and Renormalizing the Charge . . . 988
18.2 K-l.II: Regularization . . . 995
18.2.1 Euclidean integral and the ultraviolet cutoff . . . 995
18.2.2 Pauli-Villars Regularization . . . 997
18.2.3 Dimensional Regularization . . . 998
18.3 K-l.III: Examples of Calculations. One-loop Integrals . . . 1000
18.3.1 The scalar theory . . . 1000
18.3.2 Quantum electrodynamics . . . 1002

18.3.3 Quantum chromodynamics . . . 1006
18.4 K-l.IV: Renormalization. General Idea . . . 1010
18.4.1 The scalar theory. The one-loop approximation . . . 1010
18.4.2 The scalar theory. The two-loop approximation . . . 1013
18.4.3 The general structure of the R-operation . . . 1016
18.5 K-l.V: Renormalization. Gauge Theories and the Standard Model . . . 1020
18.5.1 Quantum electrodynamics . . . 1020
18.5.2 Quantum chromodynamics . . . 1021
18.5.3 The Standard Model of fundamental interactions . . . 1023
18.6 K-l.VI: Renormalization Group . . . 1028
18.6.1 The group equations and solutions via the method of characteristics . . . 1028
18.6.2 The effective coupling . . . 1031
18.6.3 Dimensional regularization and the $\overline{MS}$ scheme . . . 1032
18.6.4 Λ_{QCD} . . . 1035
18.6.5 The running masses . . . 1037
18.7 K-l.VII: Zero Charge and Asymptotic Freedom . . . 1040
18.7.1 The zero charge . . . 1040
18.7.2 The asymptotic freedom . . . 1042
18.7.3 The screening and anti-screening of the charge . . . 1044
18.7.4 Non-Abelian Gauge Transformations in QFT . . . 1045
18.7.5 Faddeev–Popov Method . . . 1046
18.7.6 BRST Method . . . 1055

19 What If There Is Another Fundamental Effect? 1057
19.0.1 Vacuum in Gravity, Excitation of an Accelerated Detector by Ginzburg, Frolov . . . 1057
19.0.2 Effect on a Lattice or Condensate in Particle Scatterings . . . 1058

20 Other, Useful Methods 1058
20.1 Other ways of Calculation Feynman Diagrams . . . 1058
20.1.1 Scattering Amplitudes For All Masses and Spins . . . 1058
20.2 Other Feynman Rules . . . 1058
20.2.1 Feynman Rules for Non-Abelian Theory and Ghost Fields . . . 1058
20.2.2 Feynman Rules for Non-Abelian Theory with Fermion Fields . . . 1058

VI QFT Processes and Effects 1060

21 Typical Phenomena of Quantum Electrodynamics (?!!!) 1060
21.1 5.1$e^+e^- \to \mu^+\mu^-$: Introduction . . . 1060
21.2 5.2$e^+e^- \to \mu^+\mu^-$:Helicity Structure . . . 1068
21.3 5.3$e^+e^- \to \mu^+\mu^-$: Nonrelativistic Limit . . . 1073
21.4 5.4 Crossing Symmetry . . . 1080
21.5 5.5 Compton Scattering . . . 1085
21.6 Anomalous Magnetic Moment . . . 1099
21.6.1 On higher order terms . . . 1099
21.7 Well-known Vacuum Effects . . . 1099
21.7.1 Casimir Effect by Vergeles . . . 1099
21.7.2 Casimir Effect in Different Configurations 1 . . . 1100
21.7.3 Casimir Effect in Different Configurations 2 . . . 1100
21.7.4 Vacuum polarization по Matthew Schwartz . . . 1101

21.8 Finding Main Fundamental Constants Using QFT . . . 1114
21.8.1 Testing Electron Charge . . . 1114
21.8.2 Testing Fine Structure Constant . . . 1114
21.8.3 Testing Ridberg's Constant . . . 1114
21.9 Finding Some Other Other Constants Using QFT . . . 1114
21.10 Determining Fundamental Quantities of Nature . . . 1114
21.10.1 Determining Proton Radius . . . 1114
21.10.2 Determining Proton Radius: Extra Understanding . . . 1114

22 Radiation and Scattering of Light 1114
22.1 Radiation of Light by Landau 4 . . . 1114
22.1.1 Electromagnetic Interaction Operator . . . 1114
22.1.2 Emission and Absorption . . . 1114
22.1.3 Dipole Radiation . . . 1114
22.1.4 Electric Multipole Radiation . . . 1114
22.1.5 Magnetic Multipole Radiation . . . 1115
22.1.6 Angular Distribution and Polarization of Radiation . . . 1115
22.1.7 Introduction to Quantum Optics (?!??!) . . . 1115
22.2 Fundamentals of Scattering . . . 1115
22.2.1 Scattering Tensor . . . 1115
22.2.2 Scattering by Freely Oriented Systems . . . 1115
22.2.3 Scattering on Molecules . . . 1115
22.2.4 Natural Width of Spectral Lines . . . 1115
22.2.5 Resonance Fluorescence . . . 1115

23 Phenomena in Particle Physics 1115

24 Other Models of Quantum Electrodynamics 1115
24.1 Electron Interaction by Landau (??) . . . 1115
24.2 Electron-Photon Interaction by Landau 1 . . . 1115
24.2.1 86. Photon Scattering by an Electron . . . 1115
24.2.2 87. Photon Scattering by an Electron: Polarization Effects . . . 1117
24.2.3 88. Two-Photon Annihilation of an Electron Pair . . . 1119
24.2.4 89. Positronium Annihilation . . . 1120
24.2.5 90. Synchrotron radiation . . . 1122
24.2.6 91. Pair Production by a Photon in a Magnetic Field . . . 1124
24.2.7 92. Electron-nucleus bremsstrahlung. The non-relativistic case . . . 1125
24.2.8 93. Electron-nucleus bremsstrahlung. The relativistic case . . . 1125
24.2.9 94. Pair Production by a Photon in the Field of a Nucleus . . . 1125
24.3 Electron-Photon Interaction by Landau 2 . . . 1125
24.3.1 95. Exact Theory of Pair Production in the Ultrarelativistic Case . . . 1125
24.3.2 96. Exact Theory of Bremsstrahlung in the Ultrarelativistic Case . . . 1125
24.3.3 97. Electron-electron bremsstrahlung in the ultra-relativistic case . . . 1125
24.3.4 98. Emission of soft photons in collisions . . . 1125
24.3.5 99. The method of equivalent photons . . . 1125
24.3.6 100. Pair production in collisions between particles . . . 1125
24.3.7 101. Photon Emission by an Electron in the Field of an Intense Electromagnetic Wave 1125
24.4 Radiative Corrections in QED by Landau . . . 1125
24.5 Asymptotic Formulas of Quantum Electrodynamics . . . 1126
24.6 Other Effects (????) . . . 1126

24.6.1 Schwinger Effect (!?!?) . . . 1126

25 Other about Quantum Field Phenomena 1126
25.1 Overview of Phenomena in QFT . . . 1126
25.1.1 Comparison of Scattering Cross-Sections for Different Processes in QFT (?) . . . 1126
25.1.2 Comparison of Scattering Cross-Sections in QFT and in Relativistic Mechanics (?) 1126
25.2 Some Phenomena of the Standard Model . . . 1126

VII Problems in QFT 1127

26 Problems about messing with typical QFT formalism 1127
26.1 Problems about fundamentals of QFT . . . 1127
26.1.1 Problems about classical fields and mechanics for preparation to QFT . . . 1127
26.1.2 Problems about free quantum fields 1 . . . 1136
26.1.3 Problems about free quantum fields 2 . . . 1153
26.1.4 Problems about free quantum fields 3 . . . 1171
26.1.5 Problems about free quantum fields 4 . . . 1180
26.1.6 Problems about relativity and Poincare group 1 . . . 1182
26.1.7 Problems about relativity and Poincare group 2 . . . 1187
26.1.8 Problems about spinors and Dirac equation . . . 1202
26.1.9 Problems about spinors and Dirac equation 2 . . . 1210
26.1.10 Problems about spinors and Dirac equation 3 . . . 1221
26.2 Problems about Useful QFT Formalism . . . 1234
26.2.1 Problems about operators in QFT . . . 1234
26.2.2 Problems about propagators in QFT . . . 1234
26.2.3 Problems about path integral formalism in QFT 1 . . . 1234
26.2.4 Problems about path integral formalism in QFT 3 . . . 1253
26.2.5 Problems about path integral formalism in QFT 4 . . . 1259
26.3 Other Problems about Messing with Typical QFT Formalism . . . 1262
26.3.1 Problems about understanding diagrams . . . 1262
26.3.2 Problems about computation of diagrams . . . 1264

27 Problems about physics in QFT 1265
27.1 Problems about decays and scatterings . . . 1265
27.1.1 Problems about typical scatterings in QED . . . 1265
27.1.2 Problems about other, special decays and scatterings . . . 1276
27.2 Problems about Pure QED . . . 1284
27.3 Problems about important methods and relations in QFT . . . 1284
27.3.1 Problems about properties of QED (?!?!) . . . 1284
27.3.2 Basic problems about renormalization . . . 1293

28 Other problems in QFT 1316
28.1 Problems for checking knowledge of QFT . . . 1316
28.1.1 Questions on Understanding the Essence of QFT . . . 1316
28.1.2 Typical Problems for Checking Knowledge of Fundamentals . . . 1316
28.2 Problems about mathematical preparation . . . 1317
28.2.1 Problems about integrals and mathematical features for QFT . . . 1317
28.2.2 Other Problems about γ-Matrices and Other Mathematics for Spinors . . . 1323
28.3 Problems about special quantum theories . . . 1324
28.3.1 Problems about Non-Abelian QED . . . 1324

28.3.2 Problems of Typical Modifications of QFT . . . 1324
28.3.3 Problems about QFT Formalism in Condensed Media . . . 1330
28.4 Other Problems about Messing with Exotic QFT Formalism . . . 1330
28.5 Other, unusual problems . . . 1330
28.5.1 Problems about Deep Understanding of QFT . . . 1330
28.5.2 Problems of Classical Mechanics in QFT Formalism (???) . . . 1331
28.5.3 Problems about Computing Correlations . . . 1331

VIII Other Parts and Topics of QFT 1332

29 Two-component spinor techniques by Dreiner, Haber 1332
29.1 Introduction . . . 1332
29.2 Essential conventions, notations and two-component spinor identities . . . 1335
29.3 Properties of fermion fields . . . 1347
29.3.1 The two-component fermion field and spinor wave functions . . . 1347
29.3.2 Fermion mass diagonalization in a general theory . . . 1353
29.4 Feynman rules with two-component spinors . . . 1359
29.4.1 External fermion and boson rules . . . 1359
29.4.2 Propagators . . . 1360
29.4.3 Fermion interactions with bosons . . . 1363
29.4.4 General structure and rules for Feynman graphs . . . 1369
29.4.5 Basic examples of writing down diagrams and amplitudes . . . 1371
29.4.6 Self-energy functions and pole masses for two-component fermions . . . 1381
29.5 Conventions for fermion and antifermion names and fields . . . 1388
29.6 Practical examples from the Standard Model and its SUSY extension . . . 1392
29.6.1 Top quark decay: $t \to bW^+$ . . . 1392
29.6.2 Z^0 vector boson decay: $Z^0 \to f\bar{f}$ . . . 1394
29.6.3 Bhabha scattering: $e^-e^+ \to e^-e^+$ . . . 1395
29.6.4 Polarized muon decay . . . 1397
29.6.5 Neutral MSSM Higgs boson decays: $\phi^0 \to f\bar{f}$ for $\phi^0 = h^0, H^0, A^0$ . . . 1399
29.6.6 Sneutrino decay: $\widetilde{\nu}_e \to \widetilde{C}_i^+ e^-$ . . . 1401
29.6.7 Chargino decay: $\widetilde{C}_i^+ \to \widetilde{\nu}_e e^+$ . . . 1402
29.6.8 Neutralino decays: $\widetilde{N}_i \to \phi^0 \widetilde{N}_j$ for $\phi^0 = h^0, H^0, A^0$ . . . 1402
29.6.9 $\widetilde{N}_i \to Z^0 \widetilde{N}_j$ . . . 1403
29.6.10 Selectron pair production in electron-electron collisions . . . 1405
29.6.11 $e^-e^+ \to \widetilde{\nu}\widetilde{\nu}^*$ . . . 1409
29.6.12 $e^-e^+ \to \widetilde{N}_i\widetilde{N}_j$ . . . 1411
29.6.13 $\widetilde{N}_1\widetilde{N}_1 \to f\bar{f}$ . . . 1414
29.6.14 $e^-e^+ \to \widetilde{C}_i^-\widetilde{C}_j^+$ . . . 1422
29.6.15 $u\bar{d} \to \widetilde{C}_i^+\widetilde{N}_j$ . . . 1425
29.6.16 $\widetilde{N}_i \to \widetilde{N}_j\widetilde{N}_k\widetilde{N}_\ell$ . . . 1426
29.6.17 Three-body slepton decays: $\widetilde{\ell}_R^- \to \ell^-\tau^\pm\widetilde{\tau}_1^\mp$ for $\ell = e, \mu$ . . . 1428
29.6.18 Neutralino decay to photon and Goldstino: $\widetilde{N}_i \to \gamma\widetilde{G}$ . . . 1431
29.6.19 Gluino pair production from gluon fusion: $gg \to \widetilde{g}\widetilde{g}$ . . . 1433
29.6.20 R-parity violating stau decay: $\widetilde{\tau}_R^+ \to e^+\bar{\nu}_\mu$ . . . 1437
29.6.21 R-parity-violating neutralino decay: $\widetilde{N}_i \to \mu^- u\bar{d}$ . . . 1438
29.6.22 Top-quark condensation from a Nambu-Jona-Lasinio model gap equation . . . 1440
29.6.23 Electroweak vector boson self-energies from fermion loops . . . 1442

29.6.24 Self-energy and pole mass of the top quark . . . 1444
29.6.25 Self-energy and pole mass of the gluino . . . 1451
29.6.26 Triangle anomaly from chiral fermion loops . . . 1453
29.7 Appendixes . . . 1463
29.7.1 Metric and sigma matrix conventions . . . 1463
29.7.2 Sigma matrix identities and Fierz identities . . . 1467
29.7.3 Explicit forms for the two-component spinor wave functions . . . 1473
29.7.4 Matrix decompositions for mass matrix diagonalization . . . 1483
29.7.5 Lie group theoretical techniques for gauge theories . . . 1490
29.7.6 Path integral treatment of two-component fermion propagators . . . 1494
29.7.7 Correspondence to four-component spinor notation 1 . . . 1497
29.7.8 Correspondence to four-component spinor notation 2 . . . 1510
29.7.9 Correspondence to four-component spinor notation 3 . . . 1521
29.7.10 Covariant spin operators and the Bouchiat-Michel formulae . . . 1528
29.7.11 Helicity amplitudes and the spinor helicity method . . . 1536
29.7.12 The Standard Model and its seesaw extension 1 . . . 1549
29.7.13 The Standard Model and its seesaw extension 2 . . . 1556
29.7.14 MSSM fermion interaction vertices . . . 1561
29.7.15 Trilinear R-parity-violating Yukawa interactions . . . 1573

30 Special Topics by Zi **1578**
30.1 Zi.IV Symmetry and Symmetry Breaking . . . 1578
30.1.1 Zi.IV.1 Symmetry Breaking . . . 1578
30.1.2 Zi.IV.2 Pion as a Nambu–Goldstone Boson . . . 1584
30.1.3 Zi.IV.3 Effective Potential . . . 1588
30.1.4 Zi.IV.4 Magnetic Monopole . . . 1595
30.1.5 Zi.IV.5 Non-Abelian Gauge Theory . . . 1601
30.1.6 Zi.IV.6 Anderson-Higgs Mechanism . . . 1610
30.1.7 Zi.IV.7 Chiral Anomaly (????) . . . 1616
30.2 Zi.V Field Theory and Collective Phenomena . . . 1626
30.2.1 Zi.V.1 Superfluid Liquids . . . 1626
30.2.2 Zi.V.2 Euclid, Boltzmann, Hawking, and Field Theory at Finite Temperature . . . 1629
30.2.3 Zi.V.3 Ginzburg–Landau Theory of Critical Phenomena . . . 1633
30.2.4 Zi.V.4 Superconductivity . . . 1635
30.2.5 Zi.V.5 Peierls Instability . . . 1637
30.2.6 Zi.V.6 Solitons . . . 1639
30.2.7 Zi.V.7 Vortices, Monopoles, and Instantons . . . 1642
30.3 Zi.VI Field Theory and Condensed Media . . . 1648
30.3.1 Zi.VI.1 Fractional Statistics, Chern–Simons Term, and Topological Field Theory . . . 1648
30.3.2 Zi.VI.2 Quantum Hall Liquids . . . 1653
30.3.3 Zi.VI.3 Duality . . . 1660
30.3.4 Zi.VI.4 σ-Models as Effective Field Theories . . . 1668
30.3.5 Zi.VI.5 Ferromagnets and Antiferromagnets . . . 1670
30.3.6 Zi.VI.6 Surface Growth and Field Theory . . . 1673
30.3.7 Zi.VI.7 Disorder: Replicas and Grassmann Symmetry . . . 1675
30.3.8 Zi.VI.8 RG Flow as a Natural Concept in High-Energy and Condensed Matter Physics 1680
30.3.9 Nonequilibrium Field Theory in Matter: Introduction . . . 1691
30.4 Zi.VII Grand Unification . . . 1691

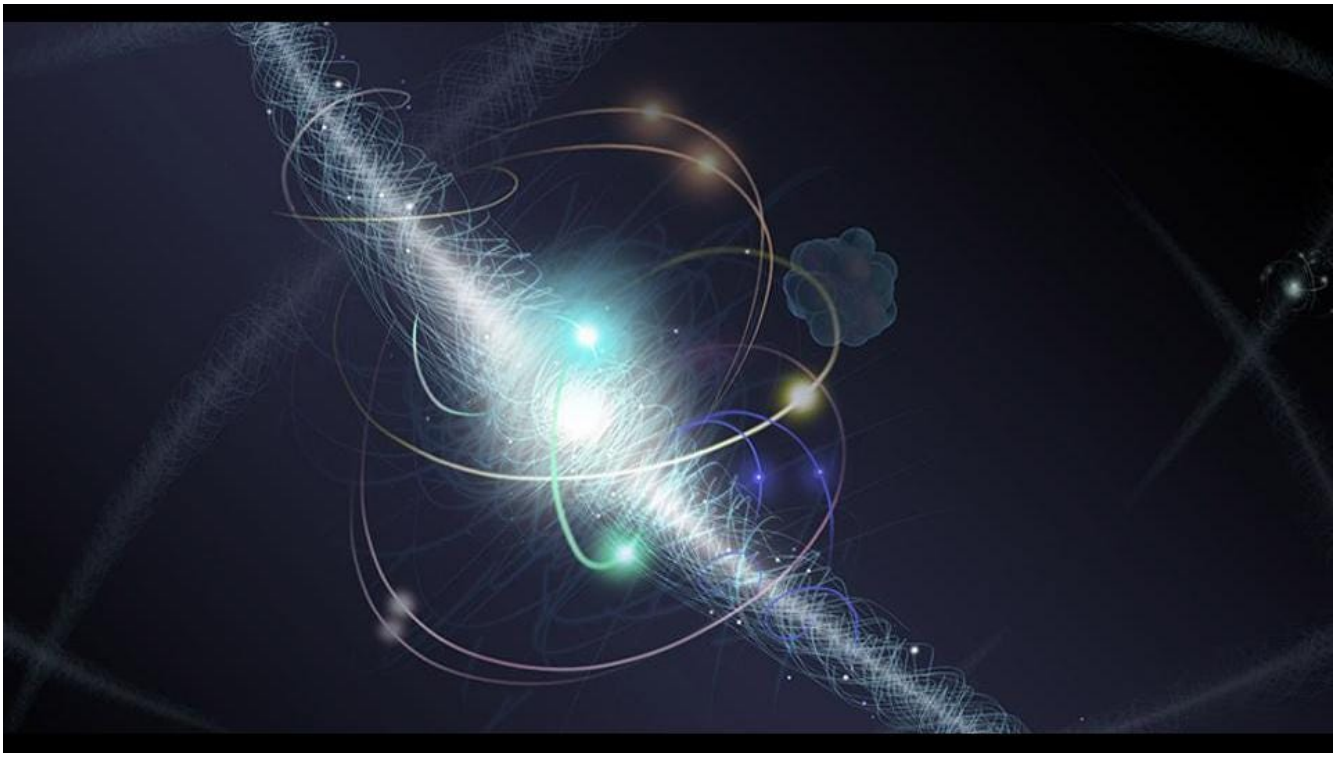
Preface, main motivation, main tips for studying



QFT Fundamentals and Free Quantum Fields

Typical Methods for Interaction of Quantum Fields

Typical QFT Processes

Other Parts and Topics of QFT

Also there are topics from Zi's book, examples of regularizations by Kazakov, good lectures by Vergeles, theory about spinors, Standard Model and SUSY by Dreiner, et al..

I used the following literature.

Let's discuss some minimum knowledge and motivation that would be good to understand for studying the subject.

Idea of the note in a nutshell

(I'll write very shortly the main idea of this approach later)

Основная мотивация

Можно понять лучше фундаментальную природу материи

(раскрою потом эту мысль так, чтобы хотелось это сделать)

Диаграммы очень много в современной физике используются, поэтому поймете формализм КТП - очень вероятно, что он поможет в какой-то теоретической физике

(раскрою потом, что на самом деле, даже если не придется заниматься КТП, уверенность в диаграммных методах - очень стоящий навык)

Лучшие идейные головоломки КТП

(напишу те, на которые ответы есть. философские интересные, но когда понимаешь, что на них нет ответов, то мотивации наоборот мало!)

m-th.1 Об суммах бесконечности и эффекте Казимира (???)

(тут пара абзацев будет, постараюсь компактнее написать, но тем не менее, в пару строчек это не выйдет)

Some instructions

Лучшие технические головоломки КТП

m-te.1 Какой на самом деле закон Кулона? (????)

(там вот поляризация вакуума еще есть, это очень прикольное КТП явление)
Some instructions

m-te.1 Чему равен магнитный момент мюона?

Почему магнитный момент на эксперименте отличен от вычисленного в квантовой механике?

(!! идейно тут укажу, что так вот к нему в квантмехе прийти, такое значение. а на эксперименте чуть другое, что делать? строчка, что так-то решится он. типичная задача КТП, результат Шивнгера. мб вопрос про электрон тут??? крч, там в теории типичное вычисление для этой задачи, тут потом укажу это!)
Some instructions

m-te.1 Как взаимодействуют фотоны?

(там через гравитацию, через ЛЛ4 один из параграфов и еще приколы в кв. оптике. укажу потом ответ на это.)
Some instructions

m-te.1 Как взаимодействуют кварки?

(вообще, идея была в том, что про госты какую-то задачу придумать, но пока не готов я еще и близко к этому.)
Some instructions

Лучшие головоломки формализма

m-f.1 Связь спина со статистикой

(про то, все-таки почему это так? напишу в теории четко!)
Some instructions

Обзор подхода к КТП

В целом, конечно же, предмет берется теми же установками и тем же подходом, как и всегда, это понимание подхода - самое важное, как и всегда.

QFT can never be learned in a hurry

If one don't sit and think about each topic in scope of basic topics of QFT, he/she will never understand QFT even on a basic level.

(I'll write better about it later)

So it is important to slow down, focus on fundamentals and go through all details. Otherwise there will be never solid understanding.

Теория - теорией, а можно решать задачи и обойти ее строной до поры до времени. Так и следует делать.

Рыться в теории тут - растягивается на годы. Это очень были бы неприятные годы, потому что хочется что-то уметь делать. Для этого можно просто сесть и начать думать про явления и задачи, много всего решено, так что можно смотреть не примеры описаний явлений.

Теорию до деталей понимать не обязательно. Кто это не понимает, тот скорее всего застрянет на КТП на долго.

Фундаментальная физика - круто, но у нее свой приоритет, не всегда он большой!

(про Понимание того, что нужно вмеру погружаться в фундаментальные вопросы, особо сильно важно в КТП, где в фундаментальных вопросах можно очень уж надолго зависнуть и ничего не сделать.)

Конечно, заниматься построением КТП, понимать поля тоже полезно, однако лучше это делать лишь небольшую часть времени, а основное время заниматься задачами и полезными методами.

И пробовать делегировать это! Пусть те, кто много времени на это потратили и кто хочет/обязан по своей работе отвечать на фундаментальные вопросы, на них и отвечают. Пусть иногда им и может казаться, что ты задаешь вопросы, на самом деле твои фундаментальные теоретические вопросы будут малой частью твоей работы, большую часть времени ты изучаешь методы и тренируешь их на задачах, которых очень много и которые очень интересные. Самому отдельно много сидеть на этом, пока не освоены методы и задачи - малополезное дело. И это речь про первые полгода.

Собственно, это же верно для любого другого предмета, но в других предметах не настолько много общей теории, только после которой идет ее применение.

Нужны лишь пара разделов КТП и пара основ для исследований и решений задач

Не нужно изучать все. Достаточно ограничится обычным, базовым уровнем. И доработать его, а потом углубляться.

Понять большинство основных разделов - дело нескольких лет, не меньше. Не нужно ставить такую цель. Куда правильнее ограничиться основами, а все остальное - только по потребности, пусть оно и важное вообще-то. Для этого у меня и есть самая 1я часть, где не только основы, но и их минимум. Вторая 1я часть - вот там другие основы указаны. Очень важное это деление, именно для того, чтобы использовать только то, что нужно, а не заниматься много чем.

А там уже когда будет движение - раз в неделю или две можно и в принципе своим пониманием заниматься, вот в таком темпе все и хорошо учится.

Part I
Typical QFT in a Nutshell

1 Main Methods and Models of QFT

1.1 Most used methods in a nutshell

1.1.1 Path integral formalism for applications in QFT

(!! очень много формул и указаний тут будет! пишу упрощенно - а далее точно!!! как и всегда со всеми формулами в 1 части.)

Z производящий функционал

(по сути его раскладываем и все про него делаем, так что он на первом месте)

Основные формулы

$$\tilde{Z}[j] := \frac{Z[j]}{Z[0]} = 1 + \sum_{k=1}^{\infty} \left(\frac{\mathrm{i}}{\hbar}\right)^k \int \mathcal{D}^{(k)}_{1\ldots k}(x_1, \ldots, x_k) \frac{1}{k!} \prod_{k'=1}^{k} j(x_{k'}) \, \mathrm{d}^4 x_{k'}$$
$$= 1 + \sum_{N=1}^{\infty} \sum_{n_k} \left(\prod_{k=1}^{\infty} \frac{1}{(n_k)!} a_k^{n_k} \right) \Bigg|_{\sum n_k = N}$$

где $a_k = \left(\frac{\mathrm{i}}{\hbar}\right)^k \int \mathcal{D}^{c(k)}_{1\ldots k}(x_1, \ldots, x_k) \frac{1}{k!} \prod_{k'=1}^{k} j(x_{k'}) \, \mathrm{d}^4 x_{k'}$, N - число произведений связных вкладов, т. е. число компонент связности в диаграмме, а n_k - количество вкладов с k-точечными связными функциями Грина, которые входят симметрично и, стало быть, допускают $(n_k)!$ перестановок, дающих одинаковые вклады, причем $\sum n_k = N$.

$$\hat{Z}[j] = \int \mathcal{D}\varphi \exp\left\{\frac{\mathrm{i}}{\hbar}\left(S_0[\varphi] + j_{x'}\varphi_{x'}\right) + \frac{\mathrm{i}}{\hbar} S_{\mathrm{int}}[\varphi]\right\} =$$
$$= \exp\left\{\frac{\mathrm{i}}{\hbar} S_{\mathrm{int}}\left(-\mathrm{i}\hbar\frac{\delta}{\delta j}\right)\right\} \int \mathcal{D}\varphi \exp\left\{\frac{\mathrm{i}}{\hbar}\left(S_0[\varphi] + j_{x'}\varphi_{x'}\right)\right\}$$

Производящий функционал от эффективного действия

$$Z_\Gamma[j] = \exp\left\{\frac{\mathrm{i}}{\hbar_\Gamma} G_\Gamma[j]\right\} = \mathcal{N} \int \mathcal{D}\varphi \exp\left\{\frac{\mathrm{i}}{\hbar_\Gamma}\left(\Gamma[\varphi] + \varphi_{x'} j_{x'}\right)\right\}$$

О разложениях по Киселеву

(тут все его методы, лекция 4, просто я мб уже это писал?)

Об обозначениях Киселева (!?!??!?!)

(чтобы в них не запутаться, отдельно напишу! что там значат его цифры и буквы! один малый раздел про это и все.)

О теореме Вика в формализме интеграла по траекториям и переходе к диаграммам

(мб в указания на теорию ниже напишу это, пока тут)
Теорема Вика:

$$\mathcal{D}^{(n)}_{1...n} = \sum_{\substack{\text{все}\\ \text{пары}}} \underbrace{\tilde{\varphi}_k \tilde{\varphi}_{k'}} \cdots \underbrace{\tilde{\varphi}_l \tilde{\varphi}_{l'}},$$

Proof:

$$\mathcal{D}^{(n)}\left(x_1, ..., x_n\right) = \left\langle \text{in} \left| \hat{\mathrm{T}}\left\{\hat{\varphi}\left(x_1\right) ... \hat{\varphi}\left(x_n\right)\right\} \right| \text{ in} \right\rangle,$$

$$Z[j] = \exp\left\{-\frac{\mathrm{i}}{\hbar}\frac{1}{2} j_x \hat{\Gamma}^{-1}_{xy} j_y\right\} = \exp\left\{\frac{\mathrm{i}}{\hbar}\frac{1}{2} j_x \mathcal{G}^{(2)}_{xy} j_y\right\} = \exp\left\{-\frac{1}{\hbar^2}\frac{1}{2} j_x \mathcal{D}^{(2)}_{xy} j_y\right\}$$

$$j(x) = -\mathrm{i}\hbar \frac{\delta}{\delta\tilde{\varphi}(x)} \mathrm{e}^{\frac{\mathrm{i}}{\hbar} j_{x'} \tilde{\varphi}_{x'}}\Big|_{\tilde{\varphi}=0} \Rightarrow F[j] = F\left[-\mathrm{i}\hbar\frac{\delta}{\delta\tilde{\varphi}}\right] \mathrm{e}^{\frac{\mathrm{i}}{\hbar} j_{x'} \tilde{\varphi}_{x'}}\Big|_{\tilde{\varphi}=0}$$

$$\mathcal{D}^{(n)}_{1...n} = (-\mathrm{i}\hbar)^n \frac{\delta^n Z[j]}{\delta j_1 ... \delta j_n}\Big|_{j=0} = \exp\left\{-\frac{\mathrm{i}\hbar}{2}\mathcal{G}^{(2)}_{xy}\frac{\delta^2}{\delta\tilde{\varphi}_x \delta\tilde{\varphi}_y}\right\} \tilde{\varphi}_1 ... \tilde{\varphi}_n\Big|_{\tilde{\varphi}=0} =$$

$$= \exp\left\{\frac{1}{2}\mathcal{D}^{(2)}_{xy}\frac{\delta^2}{\delta\tilde{\varphi}_x \delta\tilde{\varphi}_y}\right\} \tilde{\varphi}_1 ... \tilde{\varphi}_n\Big|_{\tilde{\varphi}=0}$$

$$\underbrace{\tilde{\varphi}_k \tilde{\varphi}_{k'}} := -\mathrm{i}\hbar \mathcal{G}^{(2)}_{kk'} = \mathcal{D}^{(2)}_{kk'}$$

Интеграл по путям в квантовой механике

(пока по по Пескину Шредеру, но это быстро соберется, суть тут не такая большая. в теории большой раздел про это будет.)

Континуальный интеграл для скалярного поля

континуальный интеграл для скалярного поля

$$\langle 0|\hat{\mathrm{T}}\{\hat{\Phi}(x)\hat{\Phi}^\dagger(y)\}|0\rangle = \mathrm{i}\int \frac{\mathrm{d}^4 k}{(2\pi)^4} e^{-\mathrm{i}k(x-y)} \frac{1}{k^2 - m^2 + \mathrm{i}0}$$

$$\langle 0|\hat{\mathrm{T}}\{\hat{\varphi}(x)\hat{\varphi}(y)\}|0\rangle = (-\mathrm{i})^2 \frac{\delta^2 Z(j)}{\delta j(x)\delta j(y)}\Big|_{j=0} = \mathcal{D}^{(2)}(x-y)$$

$$Z(j) = \mathcal{D}^{(0)} + \mathrm{i}\mathcal{D}^{(1)}_1 j_1 + \frac{1}{2!}\mathrm{i}^2 \mathcal{D}^{(2)}_{12} j_1 j_2 + ... = \sum_{n=0}^{\infty} \frac{\mathrm{i}^n}{n!} \mathcal{D}^{(n)}_{1...n} \prod_{k=1}^{n} j_k$$

$\mathcal{D}^{(n)}_{1...n} := (-\mathrm{i})^n \frac{\delta^n Z}{\delta j_1 ... \delta j_n}\Big|_{j=0}$.

свободные поля

Для свободных полей:

$$-i\frac{\delta Z}{\delta j(x)}\bigg|_{j=0} = \mathcal{D}^{(1)}(x) = \langle 0|\hat{\varphi}(x)|0\rangle = \varphi_{\text{vac}} \equiv 0$$

а значит, значение поля в вакууме тождественно равно нулю. (??? подумаю глубже про это!!!)

Вычислим:

$$Z(j) = \mathcal{N}\int \mathcal{D}\varphi e^{\mathrm{i}\int \mathrm{d}^4x \frac{1}{2}\varphi(x)\hat{\Gamma}\varphi(x)+\mathrm{i}j_1\varphi_1}$$

где $\hat{\Gamma} := -(\partial^2 + m^2)$ с заданными вакуумными граничными условиями имеет решения уравнения $\hat{\Gamma}\varphi(x) = 0$ только $\varphi(x) = 0$. Именно это условие позволяет далее провести однозначные манипуляции с интегралом (???).

С учетом индексного обозначения:

$$Z(j) = \mathcal{N}\int \mathcal{D}\varphi e^{\mathrm{i}\left(\frac{1}{2}\varphi_1\hat{\Gamma}\varphi_1+j_1\varphi_1\right)}$$

Сперва сдвигаем $\varphi_1 = \tilde{\varphi}_1 - \hat{\Gamma}^{-1}_{12}j_2$, получим

$$Z(j) = \tilde{\mathcal{N}}\exp\left\{-\mathrm{i}\frac{1}{2}j_1\hat{\Gamma}^{-1}_{12}j_2\right\}$$

где независящий от источников вклад $\tilde{\mathcal{N}} := \mathcal{N}\int \mathcal{D}\tilde{\varphi}e^{\frac{\mathrm{i}}{2}\tilde{\varphi}_1\hat{\Gamma}\tilde{\varphi}_1}$. Введем производящий функционал

$$\hat{Z}(j) = \frac{Z(j)}{Z(0)} = \exp\left\{-\frac{\mathrm{i}}{2}j_1\hat{\Gamma}^{-1}_{12}j_2\right\}.$$

Для него

$$\mathcal{D}^{(1)}_1 = 0$$

а все высшие причинные коррелляторы, $\mathcal{D}^{(n)}_{1\ldots n}|_{n>2}$ построены из комбинаций

$$\mathcal{D}^{(2)}(x-y) = \langle 0|\hat{\mathrm{T}}\hat{\varphi}(x)\hat{\varphi}(y)|0\rangle = \mathrm{i}\hat{\Gamma}^{-1}_{xy}$$

(?? и что?? нужно тут дописать!)

Примеры полезных вычислений интегралом по траекториям

(порешаю - напишу, пока не нарешал)

Интеграл по траекториям:

$$Z(j) = \int_{\varphi_0(x)}^{\varphi_1(x)} D\varphi(x) e^{iS_0(\varphi)+i\int d_4x j(x)\varphi(x)}$$

$$\int D\varphi e^{-\frac{1}{2}\varphi\cdot K\cdot\varphi - V(\varphi)+J\cdot\varphi} = e^{-V(\delta/\delta J)}e^{\frac{1}{2}J\cdot K^{-1}\cdot J}$$

Для $V = 0$:

$$\int D\varphi e^{-\frac{1}{2}\varphi\cdot K\cdot\varphi + J\cdot\varphi} = e^{\frac{1}{2}J\cdot K^{-1}\cdot J}$$

(???) Бывает, что K не имеет обратной матрицы, например, это происходит в действии Максвелла: $S(A) = \int d^4x \left[\frac{1}{2}A_\mu \left(\partial^2 g^{\mu\nu} - \partial^\mu\partial^\nu\right) A_\nu + A_\mu J^\mu\right]$. Тут $K \sim \left(\partial^2 g^{\mu\nu} - \partial^\mu\partial^\nu\right) \equiv Q^{\mu\nu}$, отсутствие обратной - наличие некоторых нулевых собственных значений, т.е. если при ее действии на вектор матрица зануляет этот вектор. Тензор $Q^{\mu\nu}$ зануляет любой вектор вида $\partial_\nu\Lambda(x)$: $Q^{\mu\nu}\partial_\nu\Lambda(x) = 0$. Значит, $Q^{\mu\nu}$ не имеет обратной. В этом явлении нет ничего таинственного; мы уже встречались с ним в классической физике, когда говорили о том, что смысл именно в разности потенциалов, а не их абсолютном выражении (??). На более сложном уровне мы видим, что, решая уравнение Максвелла $\partial_\mu F^{\mu\nu}$ (в виде $Q_{\mu\nu}A^\nu = J_\mu$), мы находим обратную матрицу Q^{-1} (Решение $A^\nu = (Q^{-1})^{\nu\mu}\, J_\mu$). Q^{-1} не существует! Что делать? Мы знаем, что следует наложить дополнительное условие на калибровочный потенциал A^μ, так называемую «фиксацию калибровки». (????? подумаю про это потом еще, как это спасет дело?!!)

1.1.2 Operator formalism, second quantization

Bosonic, fermionic operators

$$\left[a_r, a_s^\dagger\right]_+ = \delta_{rs}, \quad [a_r, a_s]_+ = \left[a_r^\dagger, a_s^\dagger\right]_+ = 0$$
$$(a_r)^2 = \left(a_r^\dagger\right)^2 = 0$$

$$[a_1^*, a_2] = [a_2^*, a_1] = 0, \qquad \text{скалярное поле}$$
$$\{a_1^*, a_1\} = \{a_2^*, a_2\} = 0, \quad \text{спинорное поле}$$

$\mathrm{H_B} = a^* a + a_c a_c^*$, скалярное поле
$\mathrm{H_F} = a^* a - a_c a_c^*$, спинорное поле.

$$\not\delta(\mathbf{p}) = (2\pi)^3\delta(\mathbf{p}) \text{ and } \not\delta(p) = (2\pi)^4\delta(p)$$

(тут может быть про нормировку будут формулы, для непрерывного сперва, потом для дискретногос пектра)

Formalism of confinement and bound states

(answer about how they are fitting into the basic theory)

Propagators main formulas

$$\underbrace{\phi\left(x_1\right)\phi}\left(x_2\right)\phi = \mathrm{i}\Delta_{\mathrm{F}}\left(x_1 - x_2\right)$$

$$\underbrace{\phi\left(x_1\right)\phi^{\dagger}}\left(x_2\right) = \underbrace{\phi^{\dagger}\left(x_2\right)\phi}\left(x_1\right) = \mathrm{i}\Delta_{\mathrm{F}}\left(x_1 - x_2\right)$$

$$\underbrace{\psi_{\alpha}\left(x_1\right)\bar{\psi}_{\beta}}\left(x_2\right) = -\underbrace{\bar{\psi}_{\beta}\left(x_2\right)\psi_{\alpha}}\left(x_1\right) = \mathrm{i}S_{\mathrm{F}\alpha\beta}\left(x_1 - x_2\right)$$

$$\underbrace{A^{\mu}\left(x_1\right)A^{v}}\left(x_2\right) = \mathrm{i}D_{\mathrm{F}}^{\mu v}\left(x_1 - x_2\right).$$

(?? а кстати, почему там у бозонов симметрия, а у фермионов антисимметрия в свертках???? забыл)

$$\Delta_{\mathrm{F}}(x) = \frac{1}{(2\pi)^4}\int \frac{\mathrm{d}^4 k \mathrm{e}^{-\mathrm{i}kx}}{k_0^2 - \left(\frac{\omega_{\mathrm{k}}^c}{c} - \mathrm{i}\eta\right)^2} = \frac{1}{(2\pi)^4}\int \frac{\mathrm{d}^4 k \mathrm{e}^{-\mathrm{i}kx}}{k^2 - \mu^2 + \mathrm{i}\varepsilon},$$

(пара слов про вывод)

$$S_{\mathrm{F}}(x) = \theta(t)S^{+}(x) - \theta(-t)S^{-}(x) = \left(\mathrm{i}\gamma^{\mu}\frac{\partial}{\partial x^{\mu}} + \frac{mc}{\hbar}\right)\Delta_{\mathrm{F}}(x)$$

$$= \frac{\hbar}{(2\pi\hbar)^4}\int \mathrm{d}^4 p \mathrm{e}^{-\mathrm{i}px/\hbar}\frac{\not{p} + mc}{p^2 - m^2c^2 + \mathrm{i}\varepsilon}$$

$$D_{\mathrm{F}}^{\mu v}(x) = \frac{1}{(2\pi)^4}\int \mathrm{d}^4 k D_{\mathrm{F}}^{\mu v}(k)\mathrm{e}^{-\mathrm{i}kx}$$

$$D_{\mathrm{F}}^{\mu v}(k) = \frac{-g^{\mu\nu}}{k^2 + \mathrm{i}\varepsilon} = \frac{1}{k^2 + \mathrm{i}\varepsilon}\sum_r \zeta_r \varepsilon_r^{\mu}(\mathbf{k})\varepsilon_r^{v}(\mathbf{k})$$

In the special frame of reference, where $\varepsilon_0^{\mu}(\mathbf{k}) = n^{\mu} \equiv (1,0,0,0), \varepsilon_r^{\mu}(\mathbf{k}) = (0, \boldsymbol{\varepsilon}_r(\mathbf{k}))\,,\ r = 1,2,3$:

$$D_{\mathrm{F}}^{\mu v}(k) = \frac{1}{k^2 + \mathrm{i}\varepsilon}\left\{\sum_{r=1}^{2}\varepsilon_r^{\mu}(\mathbf{k})\varepsilon_r^{v}(\mathbf{k}) + \frac{\left[k^{\mu} - (kn)n^{\mu}\right]\left[k^{v} - (kn)n^{v}\right]}{(kn)^2 - k^2} + (-1)n^{\mu}n^{v}\right\}$$

(???? додумаю, почему?)

(!?!?!? еще добавлю формулы для самих пропагаторов!!!)

1.1.3 Quantization of the fields

(пока идея написать обзор всего в один раздел, мб удалю его, если это невозможно.)

Canonical Quantization

Q of scalar field

$$[\phi(\mathbf{x}), \pi(\mathbf{y})] = i\delta(\mathbf{x} - \mathbf{y})$$

with all other commutators equal to zero. Pointwise, these operators behave like x and p in quantum mechanics, but the position/momentum is in field space, not physical space.

$\int d\mathbf{x} e^{i\mathbf{p}\cdot\mathbf{x}} = (2\pi)^3\delta(\mathbf{p}), \quad \int d\mathbf{p} e^{i\mathbf{p}\cdot\mathbf{x}} = (2\pi)^3\delta(\mathbf{x})$

$$\tilde{f}(\mathbf{p}) = \int d\mathbf{x} f(\mathbf{x}) e^{-i\mathbf{p}\cdot\mathbf{x}}, \quad f(\mathbf{x}) = \int \tilde{d}\mathbf{p} \tilde{f}(\mathbf{p}) e^{i\mathbf{p}\cdot\mathbf{x}}, \quad \tilde{d}\mathbf{p} = \frac{d\mathbf{p}}{(2\pi)^3}$$

$$\not{\delta}(\mathbf{p}) := (2\pi)^3\delta(\mathbf{p}) \qquad \not{\delta}\phi(p) = (2\pi)^4\delta(p).$$

$$H = \frac{1}{2}\int d\mathbf{x} \left(\dot{\phi}^2 + (\nabla\phi)^2 + m^2\phi^2\right)$$

$\phi(\mathbf{p}) = \phi^\dagger(-\mathbf{p})$, $\pi(\mathbf{p}) = \pi^\dagger(-\mathbf{p})$, which holds because $\phi(\mathbf{x})$ and $\pi(\mathbf{x})$ are self-adjoint, giving

$$H = \frac{1}{2}\int d\mathbf{p} \left(|\pi(\mathbf{p})|^2 + \omega_p^2|\phi(\mathbf{p})|^2\right), \quad \omega_p = \sqrt{p^2 + m^2}$$

where for an operator A, $|A^2| = A^\dagger A$. This describes decoupled harmonic oscillators with frequency ω_p.

For the ordinary oscillator, $H = (1/2)\left(p^2 + \omega^2 q^2\right)$, we defined $q = \frac{a+a^\dagger}{\sqrt{2\omega}}$, $\quad p = -i\sqrt{\frac{\omega}{2}}\left(a - a^\dagger\right)$, so

$$a_\mathbf{p} = \frac{1}{2}\left(\sqrt{2\omega_p}\phi(\mathbf{p}) + i\sqrt{\frac{2}{\omega_p}}\pi(\mathbf{p})\right)$$

$$\phi(\mathbf{p}) = \frac{a_\mathbf{p} + a^\dagger_{-\mathbf{p}}}{\sqrt{2\omega_p}}$$

The calculations are a little more complicated because both $\mathbf{p}$ and $-\mathbf{p}$ terms are present. After working through the algebra (????), we find

$$\phi(\mathbf{x}) = \int \frac{d\mathbf{p}}{\sqrt{2\omega_p}}\left(a_\mathbf{p} e^{i\mathbf{p}\cdot\mathbf{x}} + a^\dagger_\mathbf{p} e^{-i\mathbf{p}\cdot\mathbf{x}}\right), \quad \pi(\mathbf{x}) = \int d\mathbf{p}(-i)\sqrt{\frac{\omega_p}{2}}\left(a_\mathbf{p} e^{i\mathbf{p}\cdot\mathbf{x}} - a^\dagger_\mathbf{p} e^{-i\mathbf{p}\cdot\mathbf{x}}\right).$$

We'll use this form of the field operators almost exclusively.

Some calculation gives the commutation relations

$$\left[a_\mathbf{p}, a^\dagger_\mathbf{q}\right] = \not{\delta}(\mathbf{p} - \mathbf{q})$$

with all other commutators equal to zero. Applying these commutation relations in a slightly long but straightforward calculation gives

$$H = \int d\mathbf{p}\omega_p a^\dagger_\mathbf{p} a_\mathbf{p} + \frac{1}{2}\int d\mathbf{p}\omega_p\delta(\mathbf{0})$$

with a large divergent counterterm.

We find a divergent constant for two reasons. The $\delta(\mathbf{0})$ term is an IR divergence due to the infinite size of our space. Generally, IR divergences signal that we are asking an unphysical question. The integral of $\omega_\mathbf{p}$ also diverges in the UV because the theory must break down at some upper scale. E.g. if we take the continuum limit of a lattice with spacing a, it should break down at energy $\Lambda \sim 1/a$. We will be able to perform calculations at $E \ll \Lambda$ using the machinery of regularization and renormalization.

As an explicit example, we can instead quantize the Lagrangian

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu \phi\right)^2 - \frac{1}{2}m^2\phi^2 - V_0$$

where V_0 is a counterterm, and regularize by introducing a cutoff Λ. We choose $V_0(\Lambda)$ so that the vacuum energy density is a finite constant for every choice of Λ, then take the limit $\Lambda \to \infty$ without issue. The price is that our theory now no longer predicts the value of the vacuum energy density. Generically, we would expect it to be some arbitrary number between zero and M_P^4 (the cutoff for quantum gravity), and to lie somewhere in the middle of the range. But we instead observe a vacuum energy density about 10^{122} times smaller than the maximum value. This is the "old fashioned" way to explain the cosmological constant problem.

As we'll see later, the reasoning here is not quite correct, but in the modern Wilsonian framework the problem remains. Furthermore, we cannot simply ignore the vacuum energy entirely, defining it to always be zero, because we can measure differences in it via the Casimir effect.

• The spatial momentum is

$$P^i = \int d\mathbf{x}\dot{\phi}(\mathbf{x})\partial^i\phi(\mathbf{x}) = \int d\mathbf{p}p^i a^\dagger_{\mathbf{p}}a_{\mathbf{p}} + \frac{1}{2}\int d\mathbf{p}p^i\delta(\mathbf{0})$$

where the constant is zero by "symmetry". (This can also be justified more carefully by regulating the delta function in any way.) Thus in general we define the four-momentum

$$P^\mu = \int d\mathbf{p}p^\mu a^\dagger_{\mathbf{p}}a_{\mathbf{p}}, \quad p^\mu = (\omega_p, \mathbf{p})$$

The four-momentum operator satisfies:

$$\left[P^\mu, a^\dagger_{\mathbf{p}}\right] = p^\mu a^\dagger_{\mathbf{p}}, \quad \left[P^\mu, a_{\mathbf{p}}\right] = -p^\mu a_{\mathbf{p}}$$

$$|\mathbf{p}\rangle = \sqrt{2E_p}a^\dagger_{\mathbf{p}}|0\rangle$$

$$\langle\mathbf{q}|\mathbf{p}\rangle = (2E_p)\,\phi(\mathbf{p}-\mathbf{q})$$

$$1_{\text{one-particle}} = \int \frac{d\mathbf{p}}{2E_p}|\mathbf{p}\rangle\langle\mathbf{p}|$$

$$\int dp\not{\theta}\left(p^2 - m^2\right)\Theta\left(p^0\right) = \int \frac{d\mathbf{p}}{2E_p}.$$

Left-hand side is Lorentz invariant, so $d\mathbf{p}/2E_p$ is as well.

• Similarly, $(2E_p)\,\delta(\mathbf{p}-\mathbf{q})$ is Lorentz-invariant, since it gives one when integrated against the Lorentz invariant measure. Thus the normalization of the one-particle states is Lorentz invariant; when a Lorentz transformation Λ is represented as a unitary operator $U(\Lambda)$, it will satisfy $U(\Lambda)|\mathbf{p}\rangle = |\Lambda\mathbf{p}\rangle$, where $\Lambda\mathbf{p}$ is defined as the spatial part of $\Lambda\left(E_p, \mathbf{p}\right)$.

$|\mathbf{x}\rangle = \phi(\mathbf{x})|0\rangle$.

$$\langle\mathbf{p}|\mathbf{x}\rangle = e^{-i\mathbf{p}\cdot\mathbf{x}}$$

which is similar to how momentum and position eigenstates are related in quantum mechanics. Then $|\mathbf{x}\rangle$ represents a particle localized near $\mathbf{x}$.

• There are no perfectly localized states in relativistic quantum field theory. Using the definition above, $\langle \mathbf{y}|\mathbf{x}\rangle$ is not a delta function, but rather has range on the order of the Compton wavelength $1/m$, which stems from the Lorentz invariant measure factor of $1/2E_p$. Alternatively, one could omit this factor, yielding perfectly localized "Newton-Wigner" states. However, these states don't transform nicely under Lorentz transformations, and in particular, they do not remain localized states in other frames.

• Note that the quantum field has $1/\sqrt{2E_p}$ rather than the Lorentz invariant $1/2E_p$. This is because the creation operators have to be multiplied by $\sqrt{2E_p}$ to give relativistically normalized states, i.e. the expression is really $(d\mathbf{p}/2E_p)\sqrt{2E_p}a^\dagger$.

Example:

$$\mathcal{L} = (\partial_\mu \phi)^\dagger (\partial^\mu \phi) - m^2 \phi^\dagger \phi$$

ϕ and $\phi^\dagger$ as independent fields. $\phi^\dagger$ are $\pi = \dot{\phi}^\dagger$ and $\pi^\dagger = \dot{\phi}$ giving Hamiltonian

$$\mathcal{H} = \pi^\dagger \pi + \nabla \phi^\dagger \cdot \nabla \phi + m^2 \phi^\dagger \phi$$

$$[\phi(\mathbf{x}), \pi(\mathbf{y})] = \left[\phi^\dagger(\mathbf{x}), \pi^\dagger(\mathbf{y})\right] = i\delta(\mathbf{x}-\mathbf{y})$$

other [ ] = 0.

$$\phi(\mathbf{x}) = \int \frac{d\mathbf{p}}{\sqrt{2E_p}} \left(a_\mathbf{p} e^{i\mathbf{p}\cdot\mathbf{x}} + b^\dagger_\mathbf{p} e^{-i\mathbf{p}\cdot\mathbf{x}}\right)$$

$$\left[a_\mathbf{p}, a^\dagger_\mathbf{q}\right] = \left[b_\mathbf{p}, b^\dagger_\mathbf{q}\right] = \not{\delta}(\mathbf{p}-\mathbf{q})$$

$$P^\mu = \int d\mathbf{p} p^\mu \left(a^\dagger_\mathbf{p} a_\mathbf{p} + b^\dagger_\mathbf{p} b_\mathbf{p}\right)$$

$$Q = i\int d\mathbf{x}\,(\pi\phi - \phi^*\pi^*) = \int d\mathbf{p}\left(b^\dagger_\mathbf{p} b_\mathbf{p} - a^\dagger_\mathbf{p} a_\mathbf{p}\right)$$

E.g.:

$$Q^i = i\int d\mathbf{x}\left(\pi_a \sigma^i_{ab} \phi_b - \phi^*_a \sigma^i_{ab} \pi^*_b\right)$$

(абзац про то, в каком смысле можно считать скалярное поле осцилляторами??? пока не очень понял, в теории это подробно опишу. наверняка многие это неверно понимают.)

Типичные тонкости с квантованием полей (???)

Что делать с вакуумной энергией при квантовании? (???)

(пока вопрос, напишу потом. очень важный для теории вопрос.)

Appearance of entanglement in quantum fields

(I'll explain, where does it appear, in 2nd 1 part there there is a special section about it)

1.1.4 Wick's theorem, origin of diagrams, averaging

(тут же ниже будет указание, как разные правила для диаграмм делать. не только фейнмановские.)

О теореме Вика в операторном формализме (!?!?!)

(допишу скоро)

О нормальном упорядочении

Мы операторы с крестами двигаем влево, ну или поля и плюсовыми (+) модами двигаем вправо (? поч - теория).

$$\underbrace{A(x_1)B}(x_2) \equiv \langle 0 |\, \mathrm{T}\left\{A\left(x_1\right) B\left(x_2\right)\right\} |\, 0\rangle$$

$$T[\psi(x)\bar{\psi}(y)] = N[\psi(x)\bar{\psi}(y)] + \overbrace{\psi(x)\bar{\psi}}(y)$$

(????? тут очень важный абзац, зачем это мы делаем??? чтобы причинность спасти??? напишу четко!)

$$N(\overbrace{\bar{\psi}_1\psi_2}\bar{\psi}_3\bar{\psi}_4) = -\overbrace{\bar{\psi}_1\bar{\psi}_3}N\left(\psi_2\bar{\psi}_4\right) = -S_F\left(x_1 - x_3\right) N\left(\psi_2\bar{\psi}_4\right).$$

(!!! додумаю это!!!!)

$$T[\psi(x)\bar{\psi}(y)] = N[\psi(x)\bar{\psi}(y)] + \overbrace{\psi(x)\bar{\psi}(y)}$$

О Т-упорядочении

$$\text{bosons}: \quad \mathrm{T}\{\phi(x)\phi(x')\} := \begin{cases} \phi(x)\phi(x'), & \text{if } t > t' \\ \phi(x')\phi(x), & \text{if } t' > t \end{cases} = \theta\left(t - t'\right)\phi(x)\phi\left(x'\right) + \theta\left(t' - t\right)\phi\left(x'\right)\phi(x).$$

$$\text{fermions}: \quad \mathrm{T}\{\phi(x)\phi(x')\} := \begin{cases} \phi(x)\phi(x'), & \text{if } t > t' \\ -\phi(x')\phi(x), & \text{if } t' > t \end{cases}$$

The idea is to make 'earlier' operators operate 'first'. (???? цвета поменяю, допишу формулу!!!)

Main formulas of expansion (!?!?!?!?)

(напишу их скоро, к ним все понимание КТП и сводится!!!)

$$S = \sum_{n=0}^{\infty} S^{(n)} \equiv \sum_{n=0}^{\infty} \frac{(-\mathrm{i})^n}{n!} \int \ldots \int \mathrm{d}^4x_1 \ldots \mathrm{d}^4x_n \ \mathrm{T}\left\{\mathcal{H}_{\mathrm{I}}\left(x_1\right) \ldots \mathcal{H}_{\mathrm{I}}\left(x_n\right)\right\}.$$

$$\text{QED}: \qquad \begin{aligned} \mathscr{H}_{\mathrm{I}}(x) &= -e\ \mathrm{N}\{\bar{\psi}(x)\boldsymbol{A}(x)\psi(x)\} \\ &= -e\ \mathrm{N}\left\{\left(\bar{\psi}^+ + \bar{\psi}^-\right)\left(\boldsymbol{A}^+ + \boldsymbol{A}^-\right)\left(\psi^+ + \psi^-\right)\right\} \end{aligned}$$

With $\psi^+\left(\bar{\psi}^-\right), \bar{\psi}^+\left(\psi^-\right)$and $A^+\left(A^-\right)$being linear in absorption (creation) operators of electrons, positrons and photons, respectively. It gives rise to 8 basic processes.

(тут еще есть разложение S матрицы до 2го порядка, там много членов от теоремы Вика, пока не пишу их, мб это не нужно)

S-matrix expansion

(четко напишу, что так-то её раскладыаем)

О S-матрице по ПШ (?!?!!)

(!!! скоро додумаю и напишу нормаьлно!!!)

$$\langle \mathbf{p}_1\mathbf{p}_2...|S|\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\rangle = \lim_{T\to\infty}\left\langle \mathbf{p}_1\mathbf{p}_2... \left| e^{-iH(2T)}\right| \mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\right\rangle$$

$$|\Omega\rangle = \lim_{T\to\infty(1-i\varepsilon)} \left(e^{-iE_0T}\langle\Omega|0\rangle\right)^{-1} e^{-iHT}|0\rangle.$$

На этот раз мы хотим найти соотношение вида

$$|\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\rangle \propto \lim_{T\to\infty(1-i\varepsilon)} e^{-iHT}\left|\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\right\rangle_0,$$

$$\lim_{T\to\infty(1-i\varepsilon)}\langle \left\langle \mathbf{p}_1...\mathbf{p}_n \left| e^{-iH(2T)}\right| \mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\right\rangle_0 \propto$$

$$\propto \lim_{T\to\infty(1-i\varepsilon)} \left\langle \mathbf{p}_1...\mathbf{p}_n \left| T\left(\exp\left[-i\int\limits_{-T}^{T} dtH_I(t)\right]\right)\right| \mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\right\rangle_0.$$

$$\langle \mathbf{p}_1...\mathbf{p}_n|iT|\mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\rangle =$$

$$= \lim_{T\to\infty(1-i\varepsilon)} \left({}_0\left\langle \mathbf{p}_1...\mathbf{p}_n \left| T\left(\exp\left[-i\int\limits_{-T}^{T} dtH_I(t)\right]\right)\right| \mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\right\rangle_0\right)_{\substack{\text{амputированная}\\ \text{связная,}}}.$$

Сначала следует понять, как представить матричный элемент из (4.90) в виде суммы диаграмм Фейнмана. Вычислим явно несколько первых слагаемых в ϕ^4-теории для случая двух частиц в конечном состоянии. Первое слагаемое будет равно:

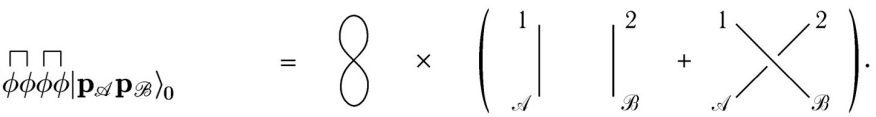
$${}_0\langle \mathbf{p}_1\mathbf{p}_2|\mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\rangle_0 = \sqrt{2E_1 2E_2 2E_{\mathscr{A}} 2E_{\mathscr{B}}}\left\langle 0\left| a_1a_2a^\dagger_{\mathscr{A}}a^\dagger_{\mathscr{B}}\right| 0\right\rangle =$$
$$= 2E_{\mathscr{A}}2E_{\mathscr{B}}(2\pi)^6\left(\delta\left(\mathbf{p}_{\mathscr{A}}-\mathbf{p}_1\right)\delta\left(\mathbf{p}_{\mathscr{B}}-\mathbf{p}_2\right)+\delta\left(\mathbf{p}_{\mathscr{A}}-\mathbf{p}_2\right)\delta\left(\mathbf{p}_{\mathscr{B}}-\mathbf{p}_1\right)\right).$$

(тут две диаграммы, параллельные прямые и крест без пересечения)
Используя теорему Вика, получим следующее слагаемое в $\langle \mathbf{p}_1\mathbf{p}_2|S|\mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\rangle$:

$${}_0\langle \mathbf{p}_1\mathbf{p}_2|\, T\left(-i\frac{\lambda}{4!}\int d^4x\phi_I^4(x)\right)|\mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\rangle_0 =$$
$$= {}_0\langle \mathbf{p}_1\mathbf{p}_2|\, N\left(-i\frac{\lambda}{4!}\int d^4x\phi_I^4(x) + \text{ свертки }\right)|\mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\rangle_0.$$

$$\phi^+{}_I(x)|\mathbf{p}\rangle_0 = \int\frac{d^3k}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{k}}}}a_{\mathbf{k}}e^{-ik\cdot x}\sqrt{2E_{\mathbf{p}}}a^\dagger_{\mathbf{p}}|0\rangle =$$
$$= \int\frac{d^3k}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{k}}}}e^{-ik\cdot x}\sqrt{2E_{\mathbf{p}}}(2\pi)^3\delta(\mathbf{k}-\mathbf{p})|0\rangle =$$
$$= e^{-ip\cdot x}|0\rangle.$$

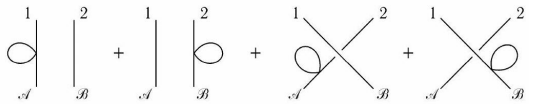
$$-i\frac{\lambda}{4!}\int d^4x\,{}_0\langle \mathbf{p_1}\mathbf{p_2}|\overbrace{\phi\phi\phi\phi}|\mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\rangle_0 =$$



$$\overbrace{\phi_I(x)|\mathbf{p}\rangle} =$$

$$\langle\mathbf{p}|\overbrace{\phi_I(x)} =$$

$\overbrace{\phi\phi\phi\phi}$ Приводит к



(еще чуть текста добавлю!)

Например, для $\phi\phi\phi\phi$. мы должны свернуть 2 операторов ϕ с $|\mathbf{p}_{\mathscr{A}}\mathbf{p}_{\mathscr{B}}\rangle$ и другие два - с $\langle\mathbf{p}_1\mathbf{p}_2|$. Для этого существует 4! способов. Таким образом, получаем диаграмму:

$$\chi^2_{\mathscr{B}} = (4!)\cdot\left(-i\frac{\lambda}{4!}\right)\int d^4x e^{-i(p_{\mathscr{A}}+p_{\mathscr{B}}-p_1-p_2)\cdot x} =$$
$$= -i\lambda(2\pi)^4\delta^{(4)}\left(p_{\mathscr{A}}+p_{\mathscr{B}}-p_1-p_2\right).$$

Это выражение в точности имеет вид $i\mathscr{M}(2\pi)^4\delta^{(4)}\left(p_{\mathscr{A}}+p_{\mathscr{B}}-p_1-p_2\right)$ с $\mathscr{M} = -\lambda$. Прежде чем продолжить обсуждение диаграмм Фейнмана для элементов S-матрицы, применим полученный результат к сечению рассеяния. Для рассеяния в системе центра инерции можно просто подставить $|\mathscr{M}|^2 = \lambda^2$ в (4.85), в результате:

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{СМ}} = \frac{\lambda^2}{64\pi^2 E^2_{\text{ци}}}.$$

Таким образом, мы вычислили наше первое сечение рассеяния в квантовой теории поля. (!!!! все, это раза 3 нужно проработать!!!)

$$\sigma_{\text{total}} = \frac{\lambda^2}{32\pi E^2_{\text{ци}}}.$$

О других разложениях S-матрицы (?!?!!)

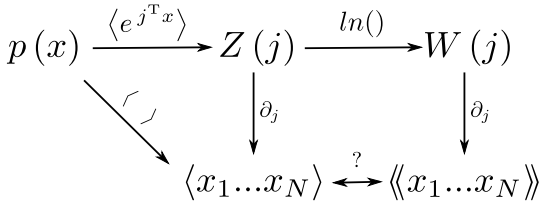
(много что может быть, важное указание)

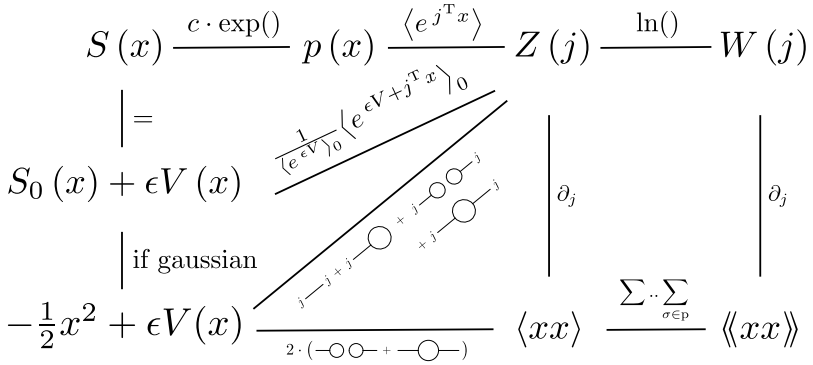
О разложении в квантовой оптике (!??!)

(важное указание, скорее всего только текстом будет, мб пара формул еще, что там важно понимать. слишком тут много особенностей, мб потом во 2й 1й напишу про это.)

О моментах, коммулянтах (????)

(см. статфиз про это, это большие, глубокие темы)





Feynman Rules for QED (in Feynman gauge)

• Each interaction vertex has two fermion legs and one photon leg, and gives the factor $-ie\gamma^\mu$. Here, the spinor indices are contracted along the fermion lines as usual, while the Lorentz indices are contracted along photon lines. Momentum is conserved at each vertex and loop momenta are integrated as usual.

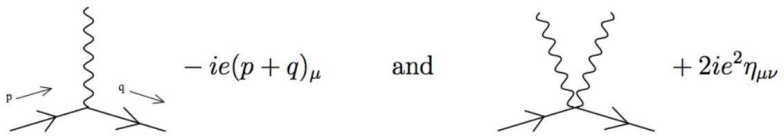
• Internal lines get the Feynman propagators,

$$\text{fermion: } \frac{i(\not{p}+m)}{p^2-m^2+i\epsilon}, \qquad \text{photon: } \frac{-i\eta^{\mu\nu}}{p^2+i\epsilon}$$

• External fermion receive the usual factors, while incoming and outgoing photons of momentum $\mathbf{p}$ receive factors $\epsilon_\mu(\mathbf{p})$ and $\epsilon^*_\mu(\mathbf{p})$, respectively. As with the fermion factors, this can be derived from the LSZ analysis for photon fields or less rigorously in the interaction picture.

• Strictly speaking, both external fermion and photon lines should receive factors of $\sqrt{Z_e}$ and $\sqrt{Z_A}$, respectively. We ignore these issues for now because we are focusing on tree-level QED.

• For charged scalars, we have the Feynman rules



The factor of 2 arises because the $A^\mu A_\mu \phi^\dagger \phi$ term has two identical particles but no compensating factor of 1/2!. Note that for the sign to be right in the first term, the momentum arrows need to be oriented along the particle flow arrows.

Note. If we had quantized in Coulomb gauge, we would have more work to do. In the presence of matter, we no longer have $A_0 = 0$. Instead we find $\nabla^2 A_0 = -ej^0$ and we may eliminate A_0 by substituting

$$A_0(\mathbf{x},t) = e\int d\mathbf{x}' \frac{j^0(\mathbf{x}',t)}{4\pi|\mathbf{x}-\mathbf{x}'|}$$

However, this makes the action nonlocal in j. Thus we have both a non-Lorentz invariant propagator and a nonlocal current-current interaction. With some effort, they can be combined into the Lorentz invariant propagator above.

Symmetries give us some useful identities.

• If we had quantized with a general ξ above, we would have found the propagator

$$-\frac{i}{p^2+i\epsilon}\left(\eta^{\mu\nu}+(\xi-1)\frac{p^\mu p^\nu}{p^2}\right)$$

We will show later that we always get the same quantum theory regardless of the value of ξ.

• For now, we can show that ξ doesn't matter at tree level. For concreteness, consider s-channel electron-positron scattering, with incoming momenta p and q. Then the photon has momentum $p+q$, and the extra term above contributes

$$\bar{v}(p)\gamma^\mu(p_\mu+q_\mu)u(q) = (\bar{v}(p)\not{p})u(q) + \bar{v}(p)(\not{q}u(q)) = (m-m)\bar{v}(p)u(q) = 0$$

where we used the on-shell spinor conditions,

$$(\not{p}-m)u(\mathbf{p}) = \bar{u}(\mathbf{p})(\not{p}-m) = (\not{p}+m)v(\mathbf{p}) = \bar{v}(\mathbf{p})(\not{p}+m) = 0$$

Similar reasoning holds for all tree-level diagrams.

• The Ward identity gives a useful result for polarization sums. Define $\mathcal{M}^\mu$ as above and let $k^\mu \propto (1,0,0,1)$. Then the Ward identity implies

$$k_\mu\mathcal{M}^\mu = 0, \quad \mathcal{M}^0 = \mathcal{M}^3$$

Now, the sum over physical polarizations is

$$\sum_{\lambda=1}^{2}\left|\epsilon_\mu^\lambda\mathcal{M}^\mu\right|^2 = \left|\mathcal{M}^1\right|^2+\left|\mathcal{M}^2\right|^2 = \left|\mathcal{M}^1\right|^2+\left|\mathcal{M}^2\right|^2+\left|\mathcal{M}^3\right|^2-\left|\mathcal{M}^0\right|^2 = -\eta_{\mu\nu}\mathcal{M}^\mu\mathcal{M}^\nu$$

by the Ward identity, so we can replace a sum over physical polarizations with a sum over all polarizations; this will be useful in some QED calculations.

• This result shows why it is possible to ignore the negative-norm states: the amplitudes to produce the unphysical states cancel out. Let P be the projector onto the space of transverse polarizations. Then our result above heuristically says

$$S^\dagger PS = S^\dagger S$$

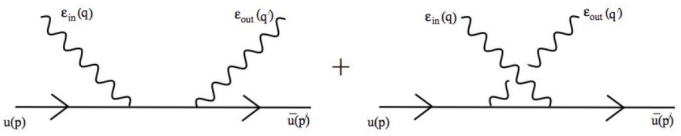
Using the unitarity of the S-matrix on the entire Fock space, we have $(PSP)^\dagger(PSP) = P$. Then the restriction of the S-matrix to the subspace of transverse polarizations is unitary, as desired.

• Note that unphysical polarizations are still produced in intermediate states, as shown by the photon propagator being proportional to $\eta_{\mu\nu}$. We cannot simply ignore these unphysical polarizations entirely, because the transverse polarizations alone are not Lorentz invariant; one can perform a Lorentz transformation on the field to convert a transverse polarization into an

unphysical one. That is, gauges that restrict to transverse polarizations only, such as Coulomb gauge, are necessarily not Lorentz invariant.

• In the case of a massive vector field, there is no gauge symmetry; instead we have three physical polarizations and a single negative-norm polarization with $\epsilon^\mu(k) \propto k^\mu$. In this case, a direct application of the Ward identity $k_\mu \mathcal{M}^\mu = 0$, which still holds, is enough to show the unphysical state decouples.

Example. Compton scattering. Two diagrams contribute to the amplitude $i\mathcal{M}$, as shown below.



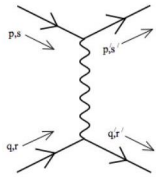
$$= i(-ie)^2 \bar{u}^{r'}(\vec{p}') \left(\frac{\gamma_\mu (\not{p} + \not{q} + m)\gamma_\nu}{(p+q)^2 - m^2} + \frac{\gamma_\nu (\not{p} - \not{q}' + m)\gamma_\mu}{(p-q')^2 - m^2} \right) u^s(\vec{p})\, \epsilon^\nu_{\text{in}}\, \epsilon^\mu_{\text{out}}$$

If we wish to sum over final polarizations and average over initial polarizations, we could use the identity derived above from the Ward identity. Alternatively, we can use this result to check the Ward identity. Setting $\epsilon_{\text{in}} = q$, we get

$$i\mathcal{M} \propto \frac{2p \cdot q}{(p+q)^2 - m^2} + \frac{2p' \cdot q}{(p'-q)^2 - m^2} = 1 - 1 = 0$$

where we used the on-shell spinor equations and $q^2 = \not{q}q = 0$. Note that the Ward identity doesn't hold for each diagram individually; it is a result for amplitudes, not diagrams.

• The same sign flip can be found in scalar QED. E.g. we have:



$$= -i\eta_{\mu\nu}(-ie)^2 \frac{(p+p')^\mu (q+q')_\nu}{(p'-p)^2} \;\to\; -i(-ie)^2 \frac{(2m)^2}{-(\vec{p}-\vec{p}')^2}$$

Then particles with the same charge repel, and again only A_0 contributes. If we flipped the charge of one of the incoming scalars, then we would get a sign flip because the momentum factors are correlated with the charge flow, giving attraction.

Note. More intuition for the sign. We consider coupling to a current j^μ, so that at lowest order the energy of interaction of two currents is

$$E \sim \int dk J^\mu(k)^* D_{\mu\nu}(k) J^\nu(k)$$

We work with a massive photon for simplicity. Naively, since each component of A_μ satisfies the Klein-Gordan equation, we should sum over all four polarizations, giving a numerator of $\eta_{\mu\nu}$. However, since we automatically have $\partial_\mu A^\mu = 0$, the polarizations satisfy $k^\mu \epsilon_\mu = 0$, or equivalently we are missing the "timelike" polarization $\epsilon^\mu \sim k^\mu$, called so because it is $(1,0,0,0)$ in the particle's rest frame. Then in a general frame, we have

$$\sum_\lambda \epsilon^{\mu *}_\lambda(k) \epsilon^\nu_\lambda(k) = -\eta^{\mu\nu} + \frac{k^\mu k^\nu}{m^2}$$

This gives the propagator for a massive vector,

$$D_{\mu\nu}(k) = \frac{-i\eta_{\mu\nu} + ik_\mu k_\nu/m^2}{k^2 - m^2 + i\epsilon}$$

Now we take the mass to zero. For a massless photon, we can only couple to a conserved current, so that $k_\mu J^\mu(k) = 0$ and the singular second term vanishes; then the spacelike components have the usual sign and the timelike component has the opposite sign. This is why parallel currents attract in electromagnetism but like charges repel!

1.1.5 Kinematics, cross sections, decay widths, form factors

О кинематике, переменных Мандельштама, переходах в системы отсчета для распадов и столкновений

(это же в СТО по теорполу, но тут по сути и для типичных задач по КТП)
For $2 \to 2$ scattering:

$$s = (p_1 + p_2)^2 = (p_1' + p_2')^2$$
$$t = (p_1 - p_1')^2 = (p_2 - p_2')^2$$
$$u = (p_1 - p_2')^2 = (p_2 - p_1')^2$$

E.g. for the process $a + b \to c + d$ with Mandelstam variables s, t, and u and scattering amplitude $f(s, t, u)$, crossing symmetry implies that the amplitude for $\bar{c} + b \to \bar{a} + d$, in terms of its Mandelstam variables s', t', u', is $f(u', t', s')$. An equivalent way of saying this is that upon expressing (s', t', u') back in terms of (s, t, u), the amplitude is the exact same analytic function $f(s, t, u)$.

In the center of mass frame, so that the initial two particles have four-momenta

$$p_1 = (E, 0, 0, p) \text{ and } p_2 = (E, 0, 0, -p)$$

The particles then scatter at some angle θ and leave with momenta

$$p_1' = (E, 0, p\sin\theta, p\cos\theta) \text{ and } p_2' = (E, 0, -p\sin\theta, -p\cos\theta)$$

Then from the above definitions, we have that

$$s = 4E^2 \text{ and } t = -2p^2(1 - \cos\theta) \text{ and } u = -2p^2(1 + \cos\theta)$$

О сечениях рассеяния

О том, что такое вообще сечение?

$$\text{Число событий } = \sigma \ell_{\mathscr{A}} \ell_{\mathscr{B}} \int d^2x \rho_{\mathscr{A}}(x) \rho_{\mathscr{B}}(x).$$

Для постоянных плотностей пучков и для эффективной площади A сечения пучков:

$$\text{Число событий } = \frac{\sigma N_{\mathscr{A}} N_{\mathscr{B}}}{A},$$

где $N_{\mathscr{A}}$ и $N_{\mathscr{B}}$ - полное число частиц типа $\mathscr{A}$ и $\mathscr{B}$.

Более простая измеримая величина - это вероятность распада Γ нестабильной частицы $\mathscr{A}$ (которая считается покоящейся) в определенное конечное состояние (из двух или более частиц). Эта вероятность определяется как

$$\Gamma \equiv \frac{\text{Число распадов в единицу времени}}{\text{Число имеющихся частиц типа } \mathscr{A}}.$$

$$\sigma \propto \frac{1}{\left(E - E_0\right)^2 + \Gamma^2/4}$$

для массивных:

$$\frac{1}{p^2 - m^2 + im\Gamma} \approx \frac{1}{2E_{\mathbf{p}}\left(p^0 - E_{\mathbf{p}} + i\left(m/E_{\mathbf{p}}\right)\Gamma/2\right)}$$

Сечения по лекции 5 Киселева (????)

Дифференциальная вероятность процесса в единицу времени вычисляется возведением в квадрат модуля амплитуды и делением его на время наблюдения за системой, а также делением на нормировку состояния мишени, которой мы можем считать, например, античастицу, с последующим домножением на плотность состояний в конечном состоянии

$$\mathrm{d}w = \frac{|\mathcal{M}|^2}{\Delta t}\frac{1}{2E_1' V_{[3]}}\frac{\mathrm{d}^3 k_2}{(2\pi)^3 2E_2}\frac{\mathrm{d}^3 k_2'}{(2\pi)^3 2E_2'},$$

откуда

$$\mathrm{d}w = \frac{\Lambda_!^2 \Lambda_2^2}{\left(s - M^2\right)^2 + M^2\Gamma^2}\frac{1}{2E_1'}(2\pi)^4 \delta\left(k_1 + k_1' - k_2 - k_2'\right)\frac{\mathrm{d}^3 k_2}{(2\pi)^3 2E_2}\frac{\mathrm{d}^3 k_2'}{(2\pi)^3 2E_2'}$$

Важные формулы для сечения в случае скалярных частиц по ПШ (????)

Волновой пакет, представляющий некоторое заданное состояние $|\phi\rangle$, может быть представлен в виде:

$$|\phi\rangle = \int \frac{d^3 k}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{k}}}}\phi(\mathbf{k})|\mathbf{k}\rangle,$$

где $\phi(\mathbf{k})$ - фурье-образ пространственной волновой функции, а $|\mathbf{k}\rangle$ - одночастичное состояние с импульсом $\mathbf{k}$ в теории с взаимодействием. В свободной теории мы имели бы $|\mathbf{k}\rangle = \sqrt{2E_{\mathbf{k}}}a_{\mathbf{k}}^\dagger|0\rangle$. Множитель $\sqrt{2E_{\mathbf{k}}}$ преобразует релятивистскую нормировку $|\mathbf{k}\rangle$ в стандартную:

$$\langle\phi|\phi\rangle = 1, \quad \text{если} \quad \int \frac{d^3 k}{(2\pi)^3}|\phi(\mathbf{k})|^2 = 1$$

(??? про все это еще раз нужно подумать, теор части переписать!!!)

Вероятность, которую мы хотим вычислить, равна:

$$\mathscr{P} = \left|\left\langle \underbrace{\phi_1\phi_2...}_{\text{будущее}} \middle| \underbrace{\phi_{\mathscr{A}}\phi_{\mathscr{B}}}_{\text{прошлое}} \right\rangle\right|^2,$$

где $|\phi_{\mathscr{A}}\phi_{\mathscr{B}}\rangle$ - состояние двух волновых пакетов в далеком прошлом и $\langle\phi_1\phi_2...|$ состояние нескольких волновых пакетов в далеком будущем.

$$|\phi_{\mathscr{A}}\phi_{\mathscr{B}}\rangle_{\text{in}} = \int \frac{d^3k_{\mathscr{A}}}{(2\pi)^3}\int \frac{d^3k_{\mathscr{B}}}{(2\pi)^3}\frac{\phi_{\mathscr{A}}(\mathbf{k}_{\mathscr{A}})\,\phi_{\mathscr{B}}(\mathbf{k}_{\mathscr{B}})\,e^{-i\mathbf{b}\cdot\mathbf{k}_{\mathscr{B}}}}{\sqrt{(2E_{\mathscr{A}})\,(2E_{\mathscr{B}})}}\,|\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\rangle_{\text{in}}\ .$$

$$_{\text{out}}\,\langle\phi_1\phi_2...| = \left(\prod_f \int \frac{d^3p_f}{(2\pi)^3}\frac{\phi_f(\mathbf{p}_f)}{\sqrt{2E_f}}\right)_{\text{out}}\langle\mathbf{p}_1\mathbf{p}_2...|$$

(?????)

$$_{\text{out}}\,\langle\mathbf{p}_1\mathbf{p}_2...|\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\rangle_{\text{in}} = \lim_{T\to\infty}\langle\underbrace{\mathbf{p}_1\mathbf{p}_2...}_{T}|\underbrace{\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}}_{-T}\rangle = \\ = \lim_{T\to\infty}\left\langle\mathbf{p}_1\mathbf{p}_2...\left|e^{-iH(2T)}\right|\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\right\rangle.$$

Определение S-матрицы: (??напишу!)

$$_{\text{out}}\,\langle\mathbf{p}_1\mathbf{p}_2...|\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\rangle_{\text{in}} \equiv \langle\mathbf{p}_1\mathbf{p}_2...|S|\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\rangle$$

Выделяя множитель с T-матрицей, мы определяем инвариантный матричный элемент $\mathscr{M}$:

$$\langle\mathbf{p}_1\mathbf{p}_2...|iT|\mathbf{k}_{\mathscr{A}}\mathbf{k}_{\mathscr{B}}\rangle = (2\pi)^4\delta^{(4)}\left(k_{\mathscr{A}}+k_{\mathscr{B}}-\sum p_f\right)\cdot i\mathscr{M}\left(k_{\mathscr{A}},k_{\mathscr{B}}\to p_f\right).$$

$$\mathscr{P}(\mathscr{A}\mathscr{B}\to 12...n) = \left(\prod_f\frac{d^3p_f}{(2\pi)^3}\frac{1}{2E_f}\right)|\langle\mathbf{p}_1...\mathbf{p}_n|\phi_A\phi_B\rangle|^2$$

$$N = \sum_{\substack{\text{все падающие}\\ \text{частицы } i}}\mathscr{P}_i = \int d^2bn_{\mathscr{B}}\mathscr{P}(\mathbf{b}),$$

$$\sigma = \frac{N}{n_{\mathscr{B}}N_{\mathscr{A}}} = \frac{N}{n_{\mathscr{B}}\cdot 1} = \int d^2b\mathscr{P}(\mathbf{b}).$$

$$\int d\bar{k}^z_{\mathscr{A}}d\bar{k}^z_{\mathscr{B}}\delta\left(\bar{k}^z_{\mathscr{A}}+\bar{k}^z_{\mathscr{B}}-\sum p^z_f\right)\delta\left(\bar{E}_{\mathscr{A}}+\bar{E}_{\mathscr{B}}-\sum E_f\right) = \\ = \int d\bar{k}^z_{\mathscr{A}}\delta\left(\sqrt{\bar{k}^2_{\mathscr{A}}+m^2_{\mathscr{A}}}+\sqrt{\bar{k}^2_{\mathscr{B}}+m^2_{\mathscr{B}}}-\sum E_f\right)\Bigg|_{\bar{k}^z_{\mathscr{B}}=\Sigma p^z_f-\bar{k}^z} = \\ = \frac{1}{\left|\frac{\bar{k}^z_{\mathscr{A}}}{\bar{E}_{\mathscr{A}}}-\frac{\bar{k}^z_{\mathscr{B}}}{\bar{E}_{\mathscr{B}}}\right|} \equiv \frac{1}{|v_{\mathscr{A}}-v_{\mathscr{B}}|}.$$

(???? тут мб очень важная связь с рел механикой, абзац про это напишу!!! чтобы показать, что мы имеем именно обобщение рел механики!!!)

$$d\sigma = \left(\prod_f\frac{d^3p_f}{(2\pi)^3}\frac{1}{2E_f}\right)\frac{|\mathscr{M}(p_{\mathscr{A}},p_{\mathscr{B}}\to\{p_f\})|^2}{2E_{\mathscr{A}}2E_{\mathscr{B}}|v_{\mathscr{A}}-v_{\mathscr{B}}|}\int\frac{d^3k_{\mathscr{A}}}{(2\pi)^3}\int\frac{d^3k_{\mathscr{B}}}{(2\pi)^3}\times \\ \times|\phi_{\mathscr{A}}(\mathbf{k}_{\mathscr{A}})|^2|\phi_{\mathscr{B}}(\mathbf{k}_{\mathscr{B}})|^2(2\pi)^4\delta^{(4)}\left(k_{\mathscr{A}}+k_{\mathscr{B}}-\sum p_f\right).$$

$$d\sigma = \frac{1}{2E_{\mathscr{A}}2E_{\mathscr{B}}|v_{\mathscr{A}}-v_{\mathscr{B}}|}\left(\prod_f\frac{d^3p_f}{(2\pi)^3}\frac{1}{2E_f}\right)|\mathscr{M}(p_{\mathscr{A}},p_{\mathscr{B}}\to\{p_f\})|^2(2\pi)^4\delta^{(4)}\left(p_{\mathscr{A}}+p_{\mathscr{B}}-\sum p_f\right)$$

$$\int d\Pi_n = \left(\prod_f \int \frac{d^3p_f}{(2\pi)^3}\frac{1}{2E_f}\right)(2\pi)^4\delta^{(4)}\left(P - \sum p_f\right),$$

$$\frac{1}{E_{\mathscr{A}}E_{\mathscr{B}}\left|v_{\mathscr{A}} - v_{\mathscr{B}}\right|} = \frac{1}{\left|E_{\mathscr{B}}p^z_{\mathscr{A}} - E_{\mathscr{A}}p^z_{\mathscr{B}}\right|} = \frac{1}{\left|\varepsilon_{\mu x y \nu}p^\mu_{\mathscr{A}}p^\nu_{\mathscr{B}}\right|}$$

$$\int d\Pi_2 = \int \frac{dp_1 p_1^2 d\Omega}{(2\pi)^3 2E_1 2E_2}(2\pi)\delta\left(E_{\text{ци}} - E_1 - E_2\right),$$

$$\int d\Pi_2 = \int d\cos\theta \frac{1}{16\pi}\frac{2\left|\mathbf{p}_1\right|}{E_{\text{ци}}}.$$

Сечение рассеяния для двух частиц в конечном состоянии:

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{СМ}} = \frac{1}{2E_{\mathscr{A}}2E_{\mathscr{B}}\left|v_{\mathscr{A}} - v_{\mathscr{B}}\right|}\frac{\left|\mathbf{p}_1\right|}{(2\pi)^2 4E_{\text{ци}}}\left|\mathscr{M}\left(p_{\mathscr{A}}, p_{\mathscr{B}} \to p_1, p_2\right)\right|^2.$$

В частном случае, когда все четыре частицы имеют одинаковые массы (включая обычно рассматриваемый предел $m \to 0$), последнее выражение сводится к формуле, приведенной в главе 1 ПШ (????):

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{СМ}} = \frac{\left|\mathscr{M}\right|^2}{64\pi^2 E^2_{\text{ци}}} \quad \text{(все четыре массы одинаковы).}$$

$$d\Gamma = \frac{1}{2m_{\mathscr{A}}}\left(\prod_f \frac{d^3p_f}{(2\pi)^3}\frac{1}{2E_f}\right)\left|\mathscr{M}\left(m_{\mathscr{A}} \to \{p_f\}\right)\right|^2(2\pi)^4\delta^{(4)}\left(p_{\mathscr{A}} - \sum p_f\right).$$

(пара общих абзацев о смысле)

Методы быстро оценить зависимость сечения от чего-то или его величину (!!!!!!!???)

(в космологии, кстати, такое с ходу и нужно, так что сделаю заготовку!!! мб у Мигдала Крайнова есть про это ответы?)

Final steps for the cross section

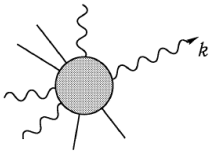
Суммирование по поляризациям фотона (?????)

(пропишу это, все-таки это часто нужно применять. не такой первый параграф, тем не менее, вначале, ибо важный.)

$\Sigma u(p)\bar{u}(p) = \not{p} + m$,

$$\sum_{\text{поляризация}} \varepsilon^*_\mu \varepsilon_\nu \longrightarrow -g_{\mu\nu}$$

Proof: (????)



$= i\mathscr{M}(k) \equiv i\mathscr{M}^\mu(k)\varepsilon^*_\mu(k).$

$$\sigma \sim \sum_{\varepsilon} \left|\varepsilon_\mu^*(k)\mathscr{M}^\mu(k)\right|^2 = \sum_{\varepsilon} \varepsilon_\mu^*\varepsilon_\nu \mathscr{M}^\mu(k)\mathscr{M}^{\nu*}(k)$$

If $k^\mu = (k,0,0,k)$, then $\varepsilon_1^\mu = (0,1,0,0)$; $\quad \varepsilon_2^\mu = (0,0,1,0)$,

$$\sum_{\varepsilon} \left|\varepsilon_\mu^*(k)\mathscr{M}^\mu(k)\right|^2 = \left|\mathscr{M}^1(k)\right|^2 + \left|\mathscr{M}^2(k)\right|^2$$

Внешние фотонные линии возникают от слагаемого с взаимодействием $\int d^4x e j^\mu A_\mu$, $j^\mu = \bar{\psi}\gamma^\mu\psi$.

$$\mathscr{M}^\mu(k) = \int d^4x e^{ik\cdot x} \left\langle f \left| j^\mu(x) \right| i \right\rangle$$

где начальное и конечное состояние включают все частицы, кроме выделенного фотона.

Из классических уравнений движения следует, что ток j^μ сохраняется: $\partial_\mu j^\mu(x) = 0$. Предполагая, что это утверждение справедливо и в квантовой теории, можно умножить (5.78) на k_μ и получить:

$$k_\mu \mathscr{M}^\mu(k) = 0$$

Амплитуда $\mathscr{M}$ обращается в нуль, если заменить вектор поляризации фотона $\varepsilon_\mu(k)$ на k_μ. Это соотношение известно как знаменитое тождество Уорда. Оно является следствием калибровочной симметрии (4.6) КЭД (????).

Полезно непосредственно проверить, что комптоновская амплитуда (5.74) удовлетворяет тождеству Уорда.

Для этого заменим $\varepsilon_\nu(k)$ на k_ν или $\varepsilon_\mu^*(k')$ на k'_μ, а затем вычислим произведения дираковских матриц.

После несложных алгебраических преобразований слагаемые, соответствующие двум разным диаграммам, сократятся, и в итоге получится нуль.

Вернемся к выводу формулы (5.75) для суммы по поляризациям.

Отметим, что если $k^\mu = (k,0,0,k)$, тождество Уорда принимает вид:

$$k\mathscr{M}^0(k) - k\mathscr{M}^3(k) = 0$$

Следовательно, $\mathscr{M}^0 = \mathscr{M}^3$ и

$$\sum_{\varepsilon} \varepsilon_\mu^*\varepsilon_\nu \mathscr{M}^\mu(k)\mathscr{M}^{\nu*}(k) = \left|\mathscr{M}^1\right|^2 + \left|\mathscr{M}^2\right|^2 = \left|\mathscr{M}^1\right|^2 + \left|\mathscr{M}^2\right|^2 + \left|\mathscr{M}^3\right|^2 - \left|\mathscr{M}^0\right|^2 =$$

$$= -g_{\mu\nu}\mathscr{M}^\mu(k)\mathscr{M}^{\nu*}(k)$$

Поэтому в вычислениях КЭД можно выбрасывать нефизические времениподобные и продольные фотоны, так как для любого процесса квадраты амплитуд рождения таких состояний сокращают друг друга. (!??!??) Отрицательная норма состояния времениподобного фотона см(???)(4.134), играет в этом сокращении существенную роль (???).

Form Factors

- Consider the scattering of an electron in the static potential due to an extended charge distribution.

-The potential at $\vec{r}$ from the centre is given by:

$$V(\vec{r}) = \int \frac{Q\rho\left(\vec{r}'\right)}{4\pi\left|\vec{r}-\vec{r}'\right|} d^3\vec{r}' \quad \text{with} \int \rho(\vec{r})\mathrm{d}^3\vec{r} = 1$$

- In first order perturbation theory the matrix element is given by:

$$\begin{aligned} M_{fi} &= \langle\psi_f|V(\vec{r})|\psi_i\rangle = \int e^{-i\vec{p}_3\cdot\vec{r}} V(\vec{r}) e^{i\vec{p}_1\cdot\vec{r}}\, \mathrm{d}^3\vec{r} \\ &= \iint e^{iq\cdot r_r} \frac{Q\rho\left(\vec{r}'\right)}{4\pi\left|\vec{r}-\vec{r}'\right|} \mathrm{d}^3\vec{r}'\mathrm{d}^3\vec{r} = \iint e^{i\dot{r}\cdot(\dot{r}'-r')} e^{iq\cdot r'} \frac{Q\rho\left(\vec{r}'\right)}{4\pi\left|\vec{r}-\vec{r}'\right|} \mathrm{d}^3\vec{r}'\mathrm{d}^3\vec{r} \end{aligned}$$

- Fix $\vec{r}'$ and integrate over $\mathrm{d}^3\vec{r}$ with substitution $\vec{R} = \vec{r} - \vec{r}'$

$$M_{fi} = \int e^{i\vec{q}\cdot\vec{R}} \frac{Q}{4\pi|\vec{R}|} \mathrm{d}^3\vec{R} \int \rho\left(\vec{r}'\right) e^{i\vec{q}\cdot\vec{r}'} \mathrm{d}^3\vec{r}' = \left(M_{fi}\right)_{\text{point}}\ F\left(\vec{q}^2\right)$$

⋆ The resulting matrix element is equivalent to the matrix element for scattering from a point source multiplied by the form factor

$$F\left(\vec{q}^2\right) = \int \rho(\vec{r}) e^{i\vec{q}\cdot\vec{r}}\, \mathrm{d}^3\vec{r}$$

1.1.6 Analysis of diagrams

(очень важный раздел, очень четко напишу!)

Классификация диаграмм (!!!)

(ниже уже написал, сюда тоже добавлю это)

Правила Фейнмана

обзор сильносвязных диаграмм

These symmetry factors can all be found with the following rules:
• 1/2 for every vertex connected to itself.
• $1/k$! for k propagators connecting the same two vertices.
• 1/2 for two interchangeable vertices.

1.1.7 γ-matrices, spinors, density matrices

Contraction Identities

$$\begin{gathered}\gamma_\lambda\gamma^\lambda = 4,\\ \gamma_\lambda\gamma^\alpha\gamma^\lambda = -2\gamma^\alpha\\ \gamma_\lambda\gamma^\alpha\gamma^\beta\gamma^\lambda = 4g^{\alpha\beta},\\ \gamma_\lambda\gamma^\alpha\gamma^\beta\gamma^\gamma\gamma^\lambda = -2\gamma^\gamma\gamma^\beta\gamma^\alpha\\ \gamma_i\gamma^\alpha\gamma^\beta\gamma^\gamma\gamma^\delta\gamma^\lambda = 2\left(\gamma^\delta\gamma^\alpha\gamma^\beta\gamma^\gamma + \gamma^\gamma\gamma^\beta\gamma^\alpha\gamma^\delta\right)\end{gathered} \quad .$$

For 4-vectors $A, B, ...$

$$\begin{gathered}\gamma_\lambda \not{A}\gamma^\lambda = -2\not{A} \qquad\qquad \not{A} := \gamma^\alpha A_\alpha:\\ \gamma_\lambda \not{A}\not{B}\gamma^\lambda = 4\not{A}\not{B},\\ \gamma_\lambda \not{A}\not{B}\not{C}\gamma^\lambda = -2\not{C}\not{B}\not{A}\\ \gamma_\lambda \not{A}\not{B}\not{C}\not{D}\gamma^\lambda = 2(\not{D}\not{A}\not{B}\not{C} + \not{C}\not{B}\not{A}\not{D})\end{gathered}$$

Traces of γ-matrices:

$$\begin{gathered}\mathrm{Tr}(\not{A}\not{B}) = 4(AB)\\ \mathrm{Tr}(\not{A}\not{B}\not{C}\not{D}) = 4\{(AB)(CD) - (AC)(BD) + (AD)(BC)\},\end{gathered}$$

and generally, if $A_1, A_2, ..., A_{2n}$ are four-vectors, then

$$\begin{aligned}\mathrm{Tr}\left(\not{A}_1 A_2 ... A_{2n}\right) = \{&(A_1A_2)\,\mathrm{Tr}\left(\not{A}_3 ... \not{A}_{2n}\right) - (A_1A_3)\,\mathrm{Tr}\left(A_2A_4 ... A_{2n}\right)\\ &+ ... + (A_1A_{2n})\,\mathrm{Tr}\left(A_2A_3 ... A_{2n-1}\right)\}\,.\end{aligned}$$

$$\not{A}\not{B} = AB - \mathrm{i}\sigma^{\alpha\beta}A_\alpha B_\beta = 2AB - \not{B}\not{A}, \qquad \begin{aligned}&\not{A}\not{A} = A^2;\\ &\not{A}\not{B} = -\not{B}\not{A}, \quad \text{if } AB = 0.\end{aligned}$$

(i) For any two $n \times n$ matrices U, V we have: $\mathrm{Tr}(UV) = \mathrm{Tr}(VU)$
(ii) If $\left(\gamma^\alpha\gamma^\beta\cdots\gamma^\mu\gamma^\upsilon\right)$ contains an odd number of γ-matrices: $\mathrm{Tr}\left(\gamma^\alpha\gamma^\beta\cdots\gamma^\mu\gamma^\upsilon\right) = 0$
(iii) For a product of an even number of γ-matrices:

$$\begin{gathered}\mathrm{Tr}\left(\gamma^\alpha\gamma^\beta\right) = 4g^{\alpha\beta}, \quad \mathrm{Tr}\,\sigma^{\alpha\beta} = 0\\ \mathrm{Tr}\left(\gamma^\alpha\gamma^\beta\gamma^\gamma\gamma^\delta\right) = 4\left(g^{\alpha\beta}g^{\gamma\delta} - g^{\alpha\gamma}g^{\beta\delta} + g^{\alpha\delta}g^{\beta\gamma}\right)'\end{gathered}$$

(iv) For any product of γ-matrices

$$\mathrm{Tr}\left(\gamma^{\alpha}\gamma^{\beta}...\gamma^{\mu}\gamma^{v}\right) = \mathrm{Tr}\left(\gamma^{v}\gamma^{\mu}...\gamma^{\beta}\gamma^{\alpha}\right)$$

whence

$$\mathrm{Tr}\left(\not{A}_1 A_2 ... A_{2n}\right) = \mathrm{Tr}\left(\not{A}_{2n} ... \not{A}_2 A_1'\right)$$

$$\left.\begin{array}{c} \mathrm{Tr}\,\gamma^5 = \mathrm{Tr}\left(\gamma^5\gamma^{\alpha}\right) = \mathrm{Tr}\left(\gamma^5\gamma^{\alpha}\gamma^{\beta}\right) = \mathrm{Tr}\left(\gamma^5\gamma^{\alpha}\gamma^{\beta}\gamma^{\gamma}\right) = 0 \\ \mathrm{Tr}\left(\gamma^5\gamma^{\alpha}\gamma^{\beta}\gamma^{\gamma}\gamma^{\delta}\right) = -4\mathrm{i}\varepsilon^{\alpha\beta\gamma\delta} \end{array}\right\}.$$

Other results involving γ^5 are easily obtained from Eqs. (A.15)-(A.21), using Eqs. (A.7) and (A.8) which define γ^5 and state its main properties.

The following comments should suffice to enable the reader to derive Eqs. (A.16)(A.21). We obtain Eq. (A.16) by using $\left(\gamma^5\right)^2 = 1$ and Eq. (A.15), whence

$$\mathrm{Tr}\left(\gamma^{\alpha}...\gamma^{v}\right) = \mathrm{Tr}\left[\left(\gamma^5\right)^2\gamma^{\alpha}...\gamma^{v}\right] = \mathrm{Tr}\left(\gamma^5\gamma^{\alpha}...\gamma^{v}\gamma^5\right)$$

In the last trace, we use $\left[\gamma^{\mu},\gamma^5\right]_+ = 0$ to commute the left-hand γ^5 matrix through to the right-hand side, with the result $-\mathrm{Tr}\left(\gamma^{\alpha}...\gamma^{\nu}\right)$ for an odd number of factors in $\left(\gamma^{\alpha}...\gamma^{\nu}\right)$. Hence Eq. (A.16) follows.

Eqs. (A.17) are derived by repeated use of the anticommutation relations (A.5) of the γ matrices and of the cyclic property (A.15) of traces.

To derive Eq. (A.20a), we introduce the transposed matrices $\gamma^{\alpha\mathrm{T}}$. It follows from Eqs. (A.5) and (A.6) that the matrices $\left(-\gamma^{\alpha\mathrm{T}}\right)$ also satisfy the anticommutation relations (A.5) and the Hermiticity conditions (A.6). Hence by Pauli's fundamental theorem (A.61) there exists a unitary matrix C such that

$$C\gamma^{\alpha}C^{-1} = -\gamma^{\alpha\mathrm{T}}$$

Eq. (A.20a) then follows from

$$\begin{aligned}\mathrm{Tr}\left(\gamma^{\alpha}\gamma^{\beta}...\gamma^{v}\right) &= \mathrm{Tr}\left[\left(-C^{-1}\gamma^{\alpha\mathrm{T}}C\right)\left(-C^{-1}\gamma^{\beta\mathrm{T}}C\right)...\left(-C^{-1}\gamma^{\nu\mathrm{T}}C\right)\right] \\ &= \mathrm{Tr}\left(\gamma^{\alpha\mathrm{T}}\gamma^{\beta\mathrm{T}}\cdots\gamma^{\nu\mathrm{T}}\right) = \mathrm{Tr}\left[\left(\gamma^{\nu}\cdots\gamma^{\beta}\gamma^{\alpha}\right)^{\mathrm{T}}\right]\end{aligned}$$

Основные свойства спиноров

$$\gamma^0 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}, \quad \gamma^1 = \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{pmatrix}, \quad \gamma^2 = \begin{pmatrix} 0 & 0 & 0 & -i \\ 0 & 0 & i & 0 \\ 0 & i & 0 & 0 \\ -i & 0 & 0 & 0 \end{pmatrix},$$

$$\gamma^3 = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ -1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}. \quad I_4 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad \gamma^5 \equiv i\gamma^0\gamma^1\gamma^2\gamma^3 = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}$$

$\left(\gamma^0\right)^{\dagger} = \gamma^0$

$\gamma^0\gamma^\mu\gamma^0 = (\gamma^\mu)^\dagger$,

$$\mathrm{tr}\,(\text{odd N of } \gamma^\mu) = 0, \quad \mathrm{tr}\,\gamma^\mu\gamma^\nu = 4\eta^{\mu\nu}, \quad \mathrm{tr}\,\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma = 4\left(\eta^{\mu\nu}\eta^{\rho\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}\right)$$

For pseudoscalar and pseudovector interactions, we will also need

$$\mathrm{tr}\left(\gamma^5\,(\text{ zero to three } \gamma^\mu)\right) = 0, \quad \mathrm{tr}\,\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma = -4i\epsilon^{\mu\nu\rho\sigma}$$

• These identities can generally be proven by inserting the identity, in terms of $(\gamma^0)^2$ or $(\gamma^5)^2$, and using the anticommutation relations; the γ^5 identities can be shown by noting that the result must be a totally antisymmetric tensor.

A more general technique is to recall that $S[\Lambda]^{-1}\gamma^\mu S[\Lambda] = \Lambda^\mu{}_\nu\gamma^\nu$. The trace remains invariant, but the right-hand side transforms like a Lorentz tensor, or a pseudotensor if γ^5 appears. Thus, the right-hand side must be a Lorentz invariant (pseudo)tensor, which can only be built from $\eta^{\mu\nu}$ and $\epsilon^{\mu\nu\rho\sigma}$. This fixes the answer in all cases above, and is also useful for larger traces.

• We can express antisymmetrized products of gamma matrices as

$$\gamma^5 = -\frac{i}{24}\epsilon_{\mu\nu\rho\sigma}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma, \quad \gamma^{[\nu}\gamma^\rho\gamma^{\sigma]} = i\epsilon^{\mu\nu\rho\sigma}\gamma_\mu\gamma^5$$

In fact, the identity, $\gamma^\mu, \gamma^{[\mu}\gamma^{\nu]}, \gamma^\mu\gamma^5$, and γ^5 form a basis for the space of 4×4 matrices; we used this when analyzing all Dirac bilinears above.

• Finally, we have

$$\gamma^\mu\gamma_\mu = 4, \quad \gamma^\mu\gamma^\nu\gamma_\mu = -2\gamma^\nu, \quad \gamma^\mu\gamma^\nu\gamma^\rho\gamma_\mu = 4\eta^{\nu\rho}, \quad \gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_\mu = -2\gamma^\sigma\gamma^\rho\gamma^\nu$$

To show

$$\mathrm{tr}(\text{ odd num of } \gamma) = 0$$

First note that

$$\mathrm{tr}\,(\gamma^\mu) = 0$$

We'll also use two facts about the fifth gamma matrix γ^5 that says:

$$\left(\gamma^5\right)^2 = I_4, \quad \text{and} \quad \gamma^\mu\gamma^5 = -\gamma^5\gamma^\mu$$

So lets use these two facts to prove this identity for the first non-trivial case: the trace of three gamma matrices. Step one is to put in one pair of γ^5 's in front of the three original γ', and step two is to swap the γ^5 matrix back to the original position, after making use of the cyclicity of the trace.

$$\begin{aligned}
\mathrm{tr}\,(\gamma^\mu\gamma^\nu\gamma^\rho) &= \mathrm{tr}\left(\gamma^5\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\right) \\
&= \mathrm{tr}\left(\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^5\right) \\
&= -\,\mathrm{tr}\left(\gamma^5\gamma^5\gamma^\mu\gamma^\nu\gamma^\rho\right) \text{ (using tr(ABC) = tr(BCA))} \\
&= -\,\mathrm{tr}\,(\gamma^\mu\gamma^\nu\gamma^\rho)
\end{aligned}$$

This can only be fulfilled if

$$\mathrm{tr}\,(\gamma^\mu\gamma^\nu\gamma^\rho) = 0$$

The extension to $2n+1$ (n integer) gamma matrices, is found by placing two gamma- 5 s after (say) the $2n$-th gamma-matrix in the trace, commuting one out to the right (giving a minus sign) and commuting the other gamma- $52n$ steps out to the left [with sign change $(-1)\hat{}2n = 1$]. Then

we use cyclic identity to get the two gamma-5s together, and hence they square to identity, leaving us with the trace equalling minus itself, i.e. 0.

Proof of $\mathrm{tr}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^5\right) = -4i\epsilon^{\mu\nu\rho\sigma}$. For a proof of identity 7, the same trick still works unless $(\mu\nu\rho\sigma)$ is some permutation of (0123), so that all 4 gammas appear. The anticommutation rules imply that interchanging two of the indices changes the sign of the trace, so $\mathrm{tr}\left(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^5\right)$ must be proportional to $\epsilon^{\mu\nu\rho\sigma}$ ($\epsilon^{0123} = \eta^{0\mu}\eta^{1\nu}\eta^{2\rho}\eta^{3\sigma}\epsilon_{\mu\nu\rho\sigma} = \eta^{00}\eta^{11}\eta^{22}\eta^{33}\epsilon_{0123} = -1$). The proportionality constant is $4i$, as can be checked by plugging in $(\mu\nu\rho\sigma) = (0123)$, writing out γ^5, and remembering that the trace of the identity is 4.

Main spinor propertis

The Gordon identity,

$$\bar{u}_r\left(p'\right)\gamma^\mu u_s(p) = \bar{u}_r\left(p'\right)\left(\frac{p'^\mu + p^\mu}{2m} + \frac{i\sigma^{\mu\nu}\left(p'_\nu - p_\nu\right)}{2m}\right)u_s(p)$$

where $\sigma^{\mu\nu} = \frac{i}{2}\left[\gamma^\mu, \gamma^\nu\right]$. ((words about proof!!) This can be done using only the Dirac equation and the defining property of the gamma matrices.)

The completeness relation for the Γ matrices:

$$\delta_{ac}\delta_{db} = \frac{1}{4}\sum_I \tilde{\Gamma}^I_{dc}\Gamma^I_{ab}$$

((words about proof!!) it suffices to show that both sides give the same result when multiplied by a general matrix M_{cd}.)

The Fierz identity:

$$\tilde{\Gamma}^I_{ab}\Gamma^J_{cd} = \frac{1}{16}\sum_{KL}\mathrm{tr}\left[\tilde{\Gamma}^I\tilde{\Gamma}^K\Gamma^J\Gamma^L\right]\tilde{\Gamma}^L_{ad}\Gamma^K_{cb}$$

(words about proof!!)

(maybe I'll add some formulas from the articles about spinors!!!)

A set of relativistic classical fields transforms under a representation of the Lorentz group,

$$\phi_i(x) \to R(\Lambda)_{ij}\phi_j\left(\Lambda^{-1}x\right)$$

We would thus like to classify representations of $SO(1,3)$.

• As we've seen, an infinitesimal Lorentz transformation takes the form

$$\Lambda^\mu_\nu = \delta^\mu{}_\nu + \omega^\mu{}_\nu$$

where $\omega^{\mu\nu} = -\omega^{\nu\mu}$. We may index the six independent Lorentz transformations with two antisymmetric indices,

$$\left(J^{\rho\sigma}\right)^{\mu\nu} = \eta^{\rho\mu}\eta^{\sigma\nu} - \eta^{\sigma\mu}\eta^{\rho\nu}$$

• Then any infinitesimal Lorentz transformation can be written as

$$\omega^\mu_\nu = \frac{1}{2}\Omega_{\rho\sigma}\left(J^{\rho\sigma}\right)^\mu_\nu$$

and finite Lorentz transformations are given by exponentiation,

$$\Lambda^\mu_{\ \nu} = \exp\left(\frac{1}{2}\Omega_{\rho\sigma}\,(J^{\rho\sigma})^\mu_{\ \nu}\right)$$

The factors of $1/2$ are canceled by the antisymmetry of Ω and J. Explicitly, $\Omega_{12} = -\Omega_{21} = \theta$ gives an active θ rotation about $\hat{\mathbf{z}}$, while $\Omega_{0i} = \chi_i$ gives an active boost with rapidity χ.

• Note that while the generators are antisymmetric with indices raised, they aren't with mixed indices, so the $\Lambda^\mu{}_\nu$ are not unitary. Alternatively, Lorentz transformations preserve $\eta_{\mu\nu}V^\mu V^\nu$ and not $\delta_{\mu\nu}V^\mu V^\nu$. In general, there are no finite-dimensional unitary representations of a noncompact Lie group like the Lorentz group.

• Some explicit computation yields the Lorentz algebra $\mathfrak{so}(1,3)$,

$$[J^{\rho\sigma}, J^{\tau\nu}] = \eta^{\sigma\tau}J^{\rho\nu} - \eta^{\rho\tau}J^{\sigma\nu} + \eta^{\rho\nu}J^{\sigma\tau} - \eta^{\sigma\nu}J^{\rho\tau}$$

We seek representations of this algebra. When we exponentiate them, we will generally find a projective representation of the Lorentz group, i.e. a representation of its double cover $\mathrm{Spin}(1,3) \cong SL(2,\mathbb{C})$. This is a bit strange, since classical fields don't have phase ambiguities like quantum states, but acceptable since the spinor field will not be directly measurable.

We construct the Dirac spinor representation starting from the Clifford algebra.

• The Clifford algebra is a set of four matrices γ^μ satisfying

$$\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$$

That is, all of the γ^μ anticommute with each other, and they square as

$$\left(\gamma^0\right)^2 = 1, \quad \left(\gamma^i\right)^2 = -1$$

• The lowest-dimensional representation of the Clifford algebra is four-dimensional. We will use the Weyl/chiral representation,

$$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}$$

We note the useful Pauli matrix identities

$$\sigma^i\sigma^j = \delta^{ij} + i\epsilon^{ijk}\sigma^k, \quad \left\{\sigma^i, \sigma^j\right\} = 2\delta^{ij}, \quad \left[\sigma^i, \sigma^j\right] = 2i\epsilon^{ijk}\sigma^k$$

Other representations can be constructed by replacing γ^μ with $V\gamma^\mu V^{-1}$.

• The commutators of the γ^μ are

$$S^{\rho\sigma} = \frac{1}{4}\left[\gamma^\rho, \gamma^\sigma\right] = \left\{ \begin{array}{ll} 0 & \rho = \sigma \\ (1/2)\gamma^\rho\gamma^\sigma & \rho \neq \sigma \end{array} \right\} = \frac{1}{2}\gamma^\rho\gamma^\sigma - \frac{1}{2}\eta^{\rho\sigma}$$

We claim the $S^{\mu\nu}$ form a representation of the Lorentz algebra. First, note that

$$[S^{\mu\nu}, \gamma^\rho] = \frac{1}{2}\left[\gamma^\mu\gamma^\nu, \gamma^\rho\right] = \frac{1}{2}\gamma^\mu\gamma^\nu\gamma^\rho - \frac{1}{2}\gamma^\rho\gamma^\mu\gamma^\nu = \gamma^\mu\eta^{\nu\rho} - \gamma^\nu\eta^{\rho\mu}$$

where we used anticommutation to cancel the two terms, picking up $\gamma\eta$ terms. Next,

$$[S^{\mu\nu}, S^{\rho\sigma}] = \frac{1}{2}\left[S^{\mu\nu}, \gamma^\rho\gamma^\sigma\right] = \frac{1}{2}\left(\gamma^\mu\gamma^\sigma\eta^{\nu\rho} - \gamma^\nu\gamma^\sigma\eta^{\rho\mu} + \gamma^\rho\gamma^\mu\eta^{\nu\sigma} - \gamma^\rho\gamma^\nu\eta^{\sigma\mu}\right)$$

where we used the commutator product rule and the previous result. Finally, applying $\gamma^\mu\gamma^\nu = 2S^{\mu\nu} + \eta^{\mu\nu}$ gives the result. Note that the γ and S matrices contain complex numbers, so we have a complex representation.

Next, we exponentiate the $S^{\mu\nu}$ to find a projective representation of $SO(1,3)$.

• The $S^{\mu\nu}$ act on a Dirac spinor field, i.e. a field with four complex components $\psi^\alpha(x)$ so that

$$\psi^\alpha(x) \to S[\Lambda]^\alpha_\beta \psi^\beta\left(\Lambda^{-1}x\right), \quad S[\Lambda] = \exp\left(\frac{1}{2}\Omega_{\rho\sigma}S^{\rho\sigma}\right)$$

• To see this is a projective representation, we explicitly work out $S[\Lambda]$ for rotations. For $i \neq j$,

$$S^{ij} = \frac{1}{2}\gamma^i\gamma^j = -\frac{i}{2}\epsilon^{ijk}\begin{pmatrix}\sigma^k & 0\\ 0 & \sigma^k\end{pmatrix}$$

Defining the angle by $\Omega_{ij} = \epsilon_{ijk}\varphi^k$, we have

$$S[\Lambda] = \begin{pmatrix} e^{-i\boldsymbol{\varphi}\cdot\boldsymbol{\sigma}/2} & 0\\ 0 & e^{-i\boldsymbol{\varphi}\cdot\boldsymbol{\sigma}/2}\end{pmatrix}$$

which is -1 for a 2π rotation.

• Similarly, for boosts, we define $\Omega_{0i} = \chi_i$ and

$$S^{0i} = \frac{1}{2}\begin{pmatrix}-\sigma^i & 0\\ 0 & \sigma^i\end{pmatrix}, \quad S[\Lambda] = \begin{pmatrix} e^{-\boldsymbol{\chi}\cdot\boldsymbol{\sigma}/2} & 0\\ 0 & e^{\boldsymbol{\chi}\cdot\boldsymbol{\sigma}/2}\end{pmatrix}$$

We see the Dirac spinor splits into two components which transform identically under rotations but oppositely under boosts.

• Sources may differ on the signs of φ and χ. Here we have taken the active point of view, so χ refers to the amount we actively change the spinor's velocity. But χ can also label the relative velocity of a frame we transform into, which would give an extra minus sign.

• The Dirac spinor representation is not unitary. To see this at the level of the Clifford algebra, note that unitarity requires $S^{\mu\nu}$ to be anti-Hermitian, which works if the γ^μ are all Hermitian or all anti-Hermitian. But since $(\gamma^0)^2 = 1$ and $(\gamma^i)^2 = -1, \gamma^0$ can only be picked to be Hermitian and γ^i can only be picked to be anti-Hermitian. Again, the issue comes from the indefinite signature of η.

Weyl spinors

• To define the Weyl spinors in an invariant way, define

$$\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$$

Then one can show

$$\left\{\gamma^5, \gamma^\mu\right\} = 0, \quad \left(\gamma^5\right)^2 = 1$$

Given this definition, the matrices $(\gamma^\mu, -i\gamma^5)$ form a five-dimensional Clifford algebra. Moreover, choosing γ^0 to be Hermitian and γ^i to be anti-Hermitian as before, $\gamma^5 = \gamma^5$.

$[S_{\mu\nu}, \gamma^5] = 0$, so γ^5 is a 'Lorentz scalar'. Then we have

$$\gamma^5 = \begin{pmatrix}-1 & 0\\ 0 & 1\end{pmatrix}, \quad P_L = \frac{1}{2}\left(1 - \gamma^5\right), \quad P_R = \frac{1}{2}\left(1 + \gamma^5\right)$$

where P_L and P_R project on the left-handed and right-handed Weyl spinors.

the concept and properties of spinors

(добавлю многое, мб это уже написано тут)

1.2 Integrals for QFT

Integrals for QFT

(??)

Gaussian integrals

Example 1:

$$
\begin{aligned}
Z(J) &= \int\limits_{-\infty}^{+\infty} dq e^{-\frac{1}{2}m^2q^2-\frac{\lambda}{4!}q^4+Jq} = \qquad (\lambda \approx 0) \\
&= \int\limits_{-\infty}^{+\infty} dq e^{-\frac{1}{2}m^2q^2+Jq}\left[1-\frac{\lambda}{4!}q^4+\frac{1}{2}\left(\frac{\lambda}{4!}\right)^2 q^8+...\right] \\
&= \left(1-\frac{\lambda}{4!}\left(\frac{d}{dJ}\right)^4+\frac{1}{2}\left(\frac{\lambda}{4!}\right)^2\left(\frac{d}{dJ}\right)^8+...\right)\int\limits_{-\infty}^{+\infty} dq e^{-\frac{1}{2}m^2q^2+Jq} \\
&= e^{-\frac{\lambda}{4!}\left(\frac{d}{dJ}\right)^4 \int\limits_{-\infty}^{+\infty} dq e^{-\frac{1}{2}m^2q^2+Jq}} = \\
&= \left(\frac{2\pi}{m^2}\right)^{1/2} e^{-\frac{\lambda}{4!}\left(\frac{d}{dJ}\right)^4} e^{\frac{1}{2m^2}\cdot d^2}
\end{aligned}
$$

(????)

We use:

$$
\frac{1}{AB} = \int\limits_0^1 \frac{dx}{(xA+(1-x)B)^2},
$$

$$
\frac{1}{A_1...A_n} = \int\limits_0^1 dx_1...dx_n \delta\left(\sum_i x_i - 1\right)\frac{(n-1)!}{(x_1A_1+...+x_nA_n)^n}
$$

$$
\int\limits_0^1 dx_1...dx_n (n-1)!\delta\left(\sum_i x_i - 1\right) = 1
$$

After some simplification and a change of variables (???):

$$
i\Sigma_2(\not{p}) = e^2\int\limits_0^1 dx \int d\ell \frac{\gamma^\mu\left(\not{K}+m_0\right)\gamma_\mu}{\left(\ell^2-\Delta+i\epsilon\right)^2}, \qquad \begin{aligned} &\ell := k - xp, \\ &\Delta := -x(1-x)p^2 + x\mu^2 + (1-x)m_0^2 \end{aligned}
$$

This form is useful because the denominator has a simple dependence on the integration variable. Note that the ℓ term in the numerator vanishes because it is odd in ℓ.

for integer d, we have

$$\int d\Omega_d \equiv \text{Vol}\left(S^{d-1}\right) = \frac{2\pi^{d/2}}{\Gamma(d/2)}$$

where $\Gamma(n) = (n-1)!$ and $\Gamma(z)$ has poles at $z = 0, -1, -2, ...$ This formula may be derived from $\pi^{d/2} = \left(\int dx e^{-x^2}\right)^d$ by evaluating the right-hand side in d-dimensional spherical coordinates. We then define this to hold for all $d \in \mathbb{C}$. Example:

$$\text{Vol}\left(S^1\right) = 2\pi, \quad \text{Vol}\left(S^2\right) = 4\pi, \quad \text{Vol}\left(S^3\right) = 2\pi^2$$

Therefore, the measure in d dimensions with spherical symmetry is

$$d^d p = \text{Vol}\left(S^{d-1}\right) \frac{p^{d-1} dp}{(2\pi)^d} = \frac{\left(p^2\right)^{d/2-1} d\left(p^2\right)}{(4\pi)^{d/2}\Gamma(d/2)}$$

Thus our integral generalized to d dimensions is

$$I_d = \frac{1}{(4\pi)^{d/2}\Gamma(d/2)} \int_0^\infty \frac{u^{d/2-1}}{(u+\Delta)^2} du = \frac{\Delta^{d/2-2}}{(4\pi)^{d/2}\Gamma(d/2)} \int_0^1 dx x^{1-d/2}(1-x)^{d/2-1}$$

where $x := \Delta/(u+\Delta)$, using the beta function, $B(\alpha,\beta) \equiv \int_0^1 dx x^{\alpha-1}(1-x)^{\beta-1} = \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha+\beta)}$.

• More generally, for an arbitrary power of p in the numerator, we have

$$\int d^d p \frac{p^{2a}}{\left(p^2-\Delta\right)^b} = i(-1)^{a-b} \frac{1}{(4\pi)^{d/2}} \frac{1}{\Delta^{b-a-d/2}} \frac{\Gamma\left(a+\frac{d}{2}\right)\Gamma\left(b-a-\frac{d}{2}\right)}{\Gamma(b)\Gamma\left(\frac{d}{2}\right)}$$

by similar logic, where the sign factors come from flipping the negative-definite Euclidean signature.

In particular,

$$\begin{aligned}
\int d^d p \frac{1}{p^2-\Delta} &= \frac{-i}{(4\pi)^{d/2}} \frac{1}{\Delta^{1-d/2}} \Gamma\left(\frac{2-d}{2}\right), \\
\int d^d p \frac{1}{\left(p^2-\Delta\right)^2} &= \frac{i}{(4\pi)^{d/2}} \frac{1}{\Delta^{2-d/2}} \Gamma\left(\frac{4-d}{2}\right), \\
\int d^d p \frac{p^2}{\left(p^2-\Delta\right)^2} &= \frac{d}{2} \frac{-i}{(4\pi)^{d/2}} \frac{1}{\Delta^{1-d/2}} \Gamma\left(\frac{2-d}{2}\right), \\
\int d^d p \frac{p^2}{\left(p^2-\Delta\right)^3} &= \frac{d}{4} \frac{i}{(4\pi)^{d/2}} \frac{1}{\Delta^{2-d/2}} \Gamma\left(\frac{4-d}{2}\right).
\end{aligned}$$

We generally end up with a so-called loop factor $1/(4\pi)^2$, which suppresses the contribution of the loop.

• In Euclidean signature, we have the same result with no i or sign factors,

$$\int d^d k \frac{k^{2a}}{\left(k^2+\Delta\right)^b} = \frac{1}{(4\pi)^{d/2}} \frac{1}{\Delta^{b-a-d/2}} \frac{\Gamma\left(a+\frac{d}{2}\right)\Gamma\left(b-a-\frac{d}{2}\right)}{\Gamma(b)\Gamma\left(\frac{d}{2}\right)}$$

Alternate way - to use Schwinger parametrization:

$$\frac{1}{a^n} \equiv \frac{1}{\Gamma(n)} \int_0^\infty du u^{n-1} e^{-ua}$$

$$\int d^d k \frac{k^{2a}}{(k^2+\Delta)^b} = \frac{1}{\Gamma(b)} \int du u^{b-1} e^{-u\Delta} \int d^d k e^{-uk^2} k^{2a}$$

in Euclidean signature. After doing the angular integral, the inner integral is merely a gamma function after substitution, and so is the outer integral, giving the same result.

• Finally, we need to handle numerators, which involve spinors and the metric. We define

$$g^{\mu\nu} g_{\mu\nu} = d$$

and the Lorentz-invariant phase space as

$$d\Pi_{\text{LIPS}} = \phi^d \left(\sum p_j \right) \prod_j \frac{d^{d-1} p_j}{2E_{p_j}}$$

О гамма матрицах в $d-\varepsilon$-мерном пространстве

Formally, we suppose there are d four-dimensional gamma matrices satisfying $\{\gamma^\mu, \gamma^\nu\} = 2g^{\mu\nu}$, so that the trace of the identity in spinor space is still 4.

$$\gamma^\mu \gamma_\mu = d, \quad \gamma^\mu \gamma^\nu \gamma_\mu = (2-d)\gamma^\nu$$
$$\gamma^\mu \gamma^\nu \gamma^\rho \gamma_\mu = 4\eta^{\nu\rho} + (d-4)\gamma^\nu \gamma^\rho, \quad \gamma^\mu \gamma^\nu \gamma^\rho \gamma^\sigma \gamma_\mu = -2\gamma^\sigma \gamma^\rho \gamma^\nu + (4-d)\gamma^\nu \gamma^\rho \gamma^\sigma$$

We also assume there exists a matrix γ_5 so that $\{\gamma_5, \gamma_\mu\} = 0$, though this runs into some subtleties with anomalies, as we'll see below.

• For the final step, we substitute $d = 4 - \epsilon$ and take the limit $\epsilon \to 0^+$, using

$$\Gamma(\epsilon) = \frac{1}{\epsilon} - \gamma + O(\epsilon), \quad x^\epsilon = 1 + \epsilon \log x + O\left(\epsilon^2\right)$$

$\Gamma(z+1) = z\Gamma(z)$,

$$\Gamma(\epsilon - 1) = -\frac{1}{\epsilon} - 1 + \gamma + O(\epsilon), \quad \Gamma(\epsilon - 2) = \frac{1}{2\epsilon} + \frac{3}{4} - \frac{\gamma}{2} + O(\epsilon)$$

• Note that dimensional regularization is just a formal technique. It is merely a perturbative regularization scheme, and it does not provide a definition of the path integral in $d = 4$.

Note. A proof of our identity for the beta function. Let us define

$$C(\alpha, \beta) = \int_0^1 dx x^{-\alpha-1} (1-x)^{\beta-1}$$

We wish to prove that this coincides with the definition of $B(\alpha, \beta)$ in terms of the gamma function. By integration by parts, it is straightforward to see that

$$C(\alpha - 1, \beta + 1) = \frac{\beta}{\alpha - 1} C(\alpha, \beta)$$

Furthermore, by writing $x = 1 - (1 - x)$, we have

$$C(\alpha + 1, \beta) = C(\alpha, \beta) - C(\alpha, \beta + 1).$$

It is easy to see using the gamma function recursion relation $\Gamma(z+1) = z\Gamma(z)$ that the gamma function obeys the same relations. Since $C(1,1) = B(1,1)$, the above relations imply that B and C agree on integers; using their similar asymptotic behaviors suffices to show they are equal.

We now apply this technique to our divergent integral.

• Applying our results, we find

$$I_d = \frac{\Gamma(2-d/2)}{(4\pi)^{d/2}\Delta^{2-d/2}}$$

Special functions for QFT

1.3 Fields

1.3.1 Scalar Field

Основные свойства комплексного квантового скалярного поля

(I'll add here the same from field theory)

$$\left(\Box + \mu^2\right)\phi(x) = 0,$$

это же $E^2 = m^2c^4 + c^2\mathbf{p}^2$, где $\mathbf{p} = -\mathrm{i}\hbar\nabla, E = \mathrm{i}\hbar\partial/\partial t$. Ему соответствует $L = \frac{1}{2}\left(\phi_{,\alpha}\phi,^{\alpha} - \mu^2\phi^2\right)$, из которого $\pi(x) = \frac{\partial L}{\partial\dot{\phi}} = \frac{1}{c^2}\dot{\phi}(x)$.

(слова потом напишу важные)

$$\left[\phi(\mathbf{x},t), \dot{\phi}\left(\mathbf{x}',t\right)\right] = \mathrm{i}\hbar c^2\delta\left(\mathbf{x}-\mathbf{x}'\right) \qquad \left[\phi(\mathbf{x},t), \phi\left(\mathbf{x}',t\right)\right] = \left[\dot{\phi}(\mathbf{x},t), \dot{\phi}\left(\mathbf{x}',t\right)\right] = 0$$

$$\phi(x) = \phi^+(x) + \phi^-(x)$$

$$\phi^+(x) = \sum_{\mathbf{k}}\left(\frac{\hbar c^2}{2V\omega_{\mathbf{k}}}\right)^{1/2} a(\mathbf{k})\mathrm{e}^{-\mathrm{i}kx}, \qquad \phi^-(x) = \sum_{\mathbf{k}}\left(\frac{\hbar c^2}{2V\omega_{\mathbf{k}}}\right)^{1/2} a^\dagger(\mathbf{k})\mathrm{e}^{\mathrm{i}kx}.$$

(??? проверю по другим книгам, неужели везде такая запутанная нотация???? пока просто по Мандл Шаулу пишу и все.)

$$k^0 = \frac{1}{c}\omega_{\mathbf{k}} = +\left(\mu^2 + \mathbf{k}^2\right)^{1/2}$$

$$E = \hbar\omega_{\mathbf{k}} = +\left[m^2c^4 + c^2(\hbar\mathbf{k})^2\right]^{1/2}$$

$$\left[a(\mathbf{k}), a^\dagger\left(\mathbf{k}'\right)\right] = \delta_{\mathbf{k}\mathbf{k}'}$$
$$\left[a(\mathbf{k}), a\left(\mathbf{k}'\right)\right] = \left[a^\dagger(\mathbf{k}), a^\dagger\left(\mathbf{k}'\right)\right] = 0$$

$$H = \int \mathrm{d}^3\mathbf{x}\frac{1}{2}\left[\frac{1}{c^2}\dot{\phi}^2 + (\boldsymbol{\nabla}\phi)^2 + \mu^2\phi^2\right]$$

$$\mathbf{P} = -\int \mathrm{d}^3\mathbf{x}\frac{1}{c^2}\dot{\phi}\boldsymbol{\nabla}\phi.$$

или после подстановки полей через операторы:

$$H = \sum_{\mathbf{k}} \hbar\omega_{\mathbf{k}} \left(a^\dagger(\mathbf{k}) a(\mathbf{k}) + \frac{1}{2} \right),$$
$$\mathbf{P} = \sum_{\mathbf{k}} \hbar\mathbf{k} \left(a^\dagger(\mathbf{k}) a(\mathbf{k}) + \frac{1}{2} \right),$$

Вакуумное среднее можно отбросить, потому что все равно мы измеряем только разницы энергий, а не саму энергию, да и вообще классический гамильтониан можно переписать как $H = (1/2)(\omega q - ip)(\omega q + ip)$, после квантования $H = \omega a^\dagger a$ и не будет никакого вакуумного среднего. Хотя и есть явления, когда можно измерить вакуумную энергию (???)

У нас теперь пси и пси-крест.

$$\left[\phi(\mathbf{x},t), \dot{\phi}^\dagger(\mathbf{x}',t)\right] = \mathrm{i}\hbar c^2 \delta(\mathbf{x}-\mathbf{x}')$$
$$[\phi(\mathbf{x},t), \phi(\mathbf{x}',t)] = \left[\phi(\mathbf{x},t), \phi^\dagger(\mathbf{x}',t)\right] = \left[\dot{\phi}(\mathbf{x},t), \dot{\phi}(\mathbf{x}',t)\right]$$
$$= \left[\dot{\phi}(\mathbf{x},t), \dot{\phi}^\dagger(\mathbf{x}',t)\right] = \left[\phi(\mathbf{x},t), \dot{\phi}(\mathbf{x}',t)\right] = 0$$

$$\phi(x) = \phi^+(x) + \phi^-(x) = \sum_{\mathbf{k}} \left(\frac{\hbar c^2}{2V\omega_{\mathbf{k}}} \right)^{1/2} \left[a(\mathbf{k}) \mathrm{e}^{-\mathrm{i}kx} + b^\dagger(\mathbf{k}) \mathrm{e}^{\mathrm{i}kx} \right]$$
$$\phi^\dagger(x) = \phi^{\dagger+}(x) + \phi^{\dagger-}(x) = \sum_{\mathbf{k}} \left(\frac{\hbar c^2}{2V\omega_{\mathbf{k}}} \right)^{1/2} \left[b(\mathbf{k}) \mathrm{e}^{-\mathrm{i}kx} + a^\dagger(\mathbf{k}) \mathrm{e}^{\mathrm{i}kx} \right].$$

$$\left[a(\mathbf{k}), a^\dagger(\mathbf{k}')\right] = \left[b(\mathbf{k}), b^\dagger(\mathbf{k}')\right] = \delta_{\mathbf{k}\mathbf{k}'},$$
$$[a(\mathbf{k}), a(\mathbf{k}')] = [b(\mathbf{k}), b(\mathbf{k}')] = [a(\mathbf{k}), b(\mathbf{k}')] = \left[a^\dagger(\mathbf{k}), b(\mathbf{k}')\right] = 0$$

$$Q = \frac{-\mathrm{i}q}{\hbar c^2} \int \mathrm{d}^3\mathbf{x} \mathrm{N} \left[\phi^\dagger(x)\phi(x) - \phi(x)\phi^\dagger(x) \right]$$
$$s^\alpha(x) = (c\rho(x), \mathbf{j}(x)) = \frac{-\mathrm{i}q}{\hbar} \mathrm{N} \left[\frac{\partial\phi^\dagger}{\partial x_\alpha}\phi - \frac{\partial\phi}{\partial x_\alpha}\phi^\dagger \right]$$
$$[\phi(x), \phi(y)] = \mathrm{i}\hbar c \Delta(x-y)$$
$$\Delta(x) \equiv \Delta^+(x) + \Delta^-(x) = \frac{-c}{(2\pi)^3} \int \frac{\mathrm{d}^3\mathbf{k}}{\omega_{\mathbf{k}}} \sin kx.$$

$$\left[\phi^+(x), \phi^-(y)\right] = \mathrm{i}\hbar c \Delta^+(x-y),$$

Since $[\phi^+(x), \phi^-(y)] = \frac{\hbar c^2}{2V} \sum_{\mathbf{k}\mathbf{k}'} \frac{1}{(\omega_{\mathbf{k}}\omega_{\mathbf{k}'})^{1/2}} \left[a(\mathbf{k}), a^\dagger(\mathbf{k}')\right] \mathrm{e}^{-\mathrm{i}kx + \mathrm{i}k'y} = \frac{\hbar c^2}{2(2\pi)^3} \int \frac{\mathrm{d}^3\mathbf{k}}{\omega_{\mathbf{k}}} \mathrm{e}^{-\mathrm{i}k(x-y)}$; $[\phi^-(x), \phi^+(y)] = -\mathrm{i}\hbar c \Delta^+(y-x) \equiv \mathrm{i}\hbar c \Delta^-(x-y)$.

$$\Delta(x) = \frac{-\mathrm{i}}{(2\pi)^3} \int \mathrm{d}^4k \delta\left(k^2 - \mu^2\right) \varepsilon(k_0) \mathrm{e}^{-\mathrm{i}kx}$$

where $\mathrm{d}^4k = \mathrm{d}^3\mathbf{k}\mathrm{d}k_0$, the k_0-integration is over $-\infty < k_0 < \infty$ and $\varepsilon(k_0)$ is defined by

$$\varepsilon(k_0) = \frac{k_0}{|k_0|} = \begin{cases} +1, & \text{if } k_0 > 0 \\ -1, & \text{if } k_0 < 0 \end{cases}$$

Также $\delta(k^2 - \mu^2) = \delta\left[k_0^2 - (\omega_\mathbf{k}/c)^2\right] = \frac{c}{2\omega_\mathbf{k}}\left[\delta\left(k_0 + \frac{\omega_\mathbf{k}}{c}\right) + \delta\left(k_0 - \frac{\omega_\mathbf{k}}{c}\right)\right]$ and performing the k_0-integration.

$$[\phi(\mathbf{x}, t), \phi(\mathbf{y}, t)] = \mathrm{i}\hbar c\Delta(\mathbf{x} - \mathbf{y}, 0) = 0$$

which we had earlier [Eq. (3.6)]. [4] The invariance of $\Delta(x - y)$ implies that

$$[\phi(x), \phi(y)] = \mathrm{i}\hbar c\Delta(x - y) = 0, \quad \text{for } (x - y)^2 < 0,$$

(??? тут еще пара умных мыслей)

$$\Delta^{\pm}(x) = \frac{-1}{(2\pi)^4}\int\limits_{C^{\pm}} \frac{\mathrm{d}^4k\mathrm{e}^{-\mathrm{i}kx}}{k^2 - \mu^2}$$

$$\mathrm{i}\hbar c\Delta_\mathrm{F}(x - x') \equiv \langle 0 |\, \mathrm{T}\{\phi(x)\phi(x')\}|\, 0\rangle .$$

$$\Delta_\mathrm{F}(x) = \theta(t)\Delta^+(x) - \theta(-t)\Delta^-(x).$$
$$\Delta_\mathrm{F}(x) = \pm\Delta^{\pm}(x). \quad \text{if t} \gtrless 0.$$

Получили пропагатор мезона.

$$\Delta_\mathrm{F}(x) = \frac{1}{(2\pi)^4}\int\limits_{C_\mathrm{F}} \frac{\mathrm{d}^4k\mathrm{e}^{-\mathrm{i}kx}}{k^2 - \mu^2}$$

И там контур сперва снизу обходит полюс, потом сверху.

$$\begin{aligned}\Delta_\mathrm{F}(x) &= \frac{1}{(2\pi)^4}\int \frac{\mathrm{d}^4k\mathrm{e}^{-\mathrm{i}kx}}{k_0^2 - \left(\frac{\omega_\mathrm{k}}{c} - \mathrm{i}\eta\right)^2} \\ &= \frac{1}{(2\pi)^4}\int \frac{\mathrm{d}^4k\mathrm{e}^{-\mathrm{i}kx}}{k^2 - \mu^2 + \mathrm{i}\varepsilon},\end{aligned}$$

(?!??!?? я не верю теории Мандала Шава, очень абстрактная, нет примеров, нет конкретики, потом много дополнять её буду!)

Другие свойства квантового скалярного поля

О вещественным полем по Пескину Шредеру (????)

(мб добавлю в теорию выше, пока думаю, что это не такая нужная теория, хотя и многое показывающая)

Волновой пакет, представляющий некоторое заданное состояние $|\phi\rangle$, может быть представлен в виде:

$$|\phi\rangle = \int \frac{d^3k}{(2\pi)^3}\frac{1}{\sqrt{2E_\mathbf{k}}}\phi(\mathbf{k})|\mathbf{k}\rangle,$$

где $\phi(\mathbf{k})$ - фурье-образ пространственной волновой функции, а $|\mathbf{k}\rangle$ - одночастичное состояние с импульсом $\mathbf{k}$ в теории с взаимодействием. В свободной теории мы имели бы $|\mathbf{k}\rangle = \sqrt{2E_{\mathbf{k}}}a^\dagger_{\mathbf{k}}|0\rangle$. Множитель $\sqrt{2E_{\mathbf{k}}}$ преобразует релятивистскую нормировку $|\mathbf{k}\rangle$ в стандартную:

$$\langle\phi|\phi\rangle = 1, \quad \text{если} \quad \int \frac{d^3k}{(2\pi)^3}|\phi(\mathbf{k})|^2 = 1$$

(??? про все это еще раз нужно подумать, теор части переписать!!!)

1.3.2 Dirac Field

Основные свойства

$$\mathrm{i}\hbar\frac{\partial\psi(x)}{\partial t} = \left[c\boldsymbol{\alpha}\cdot(-\mathrm{i}\hbar\nabla) + \beta mc^2\right]\psi(x)$$

$$\mathrm{i}\hbar\gamma^\mu\frac{\partial\psi(x)}{\partial x^\mu} - mc\psi(x) = 0$$

$$\gamma^0 = \beta, \quad \gamma^i = \beta\alpha_i, \quad i = 1,2,3,$$

$$[\gamma^\mu,\gamma^v]_+ = 2g^{\mu v}, \qquad \gamma^{\mu\dagger} = \gamma^0\gamma^\mu\gamma^0$$

$$\bar\psi(x) := \psi^\dagger(x)\gamma^0$$

$$\mathrm{i}\hbar\frac{\partial\bar\psi(x)}{\partial x^\mu}\gamma^\mu + mc\bar\psi(x) = 0$$

$$\mathscr{L} = c\bar\psi(x)\left[\mathrm{i}\hbar\gamma^\mu\frac{\partial}{\partial x^\mu} - mc\right]\psi(x)$$

$$\pi_\alpha(x) = \frac{\partial\mathscr{L}}{\partial\dot\psi_\alpha} = \mathrm{i}\hbar\psi^\dagger_\alpha, \quad \bar\pi_\alpha(x) = \frac{\partial\mathscr{L}}{\partial\dot{\bar\psi}_\alpha} \equiv 0$$

$$H = \int \mathrm{d}^3\mathbf{x}\bar\psi(x)\left[-\mathrm{i}\hbar c\gamma^j\frac{\partial}{\partial x^j} + mc^2\right]\psi(x)$$

$$\mathbf{P} = -\mathrm{i}\hbar\int \mathrm{d}^3\mathbf{x}\psi^\dagger(x)\boldsymbol{\nabla}\psi(x)$$

The angular momentum of the Dirac field follows similarly from Eq. (2.54). The transformation of the field under an inf initesimal Lorentz transformation, i.e. Eq. (2.47), is, in the case of the Dirac field, given by

$$\psi_\alpha(x) \to \psi'_\alpha(x') = \psi_\alpha(x) - \frac{\mathrm{i}}{4}\varepsilon_{\mu\nu}\sigma^{\mu v}_{\alpha\beta}\psi_\beta(x)$$

where summation over $\mu, v = 0, ..., 3$ and $\beta = 1, ..., 4$ is implied, and where $\sigma^{\mu\nu}_{\alpha\beta}$ is the (α,β) matrix element of the 4×4 matrix

$$\sigma^{\mu v} \equiv \frac{\mathrm{i}}{2}[\gamma^\mu,\gamma^v]$$

the angular momentum of the Dirac field:

$$\mathbf{M} = \int \mathrm{d}^3\mathbf{x}\psi^\dagger(x)[\mathbf{x}\wedge(-\mathrm{i}\hbar\boldsymbol{\nabla})]\psi(x) + \int \mathrm{d}^3\mathbf{x}\psi^\dagger(x)\left(\frac{\hbar}{2}\boldsymbol{\sigma}\right)\psi(x),$$

where the 4×4 matrices

$$\boldsymbol{\sigma} = \left(\sigma^{23}, \sigma^{31}, \sigma^{12}\right)$$

are the generalizations for the Dirac theory of the 2×2 Pauli spin matrices. We see that

$$Q = q \int \mathrm{d}^3\mathbf{x}\psi^\dagger(x)\psi(x)$$

$$s^\alpha(x) = (c\rho(x), \mathbf{j}(x)) = cq\bar{\psi}(x)\gamma^\alpha\psi(x)$$

$$\frac{\partial s^\alpha}{\partial x^\alpha} = 0$$

О конструкции майорановских и вейлевских спинорах (????)

(в теории поля подробнее)

$$\psi_{\mathrm{M}}(x) = \sum_{r\mathbf{p}} \left(\frac{mc^2}{VE_{\mathbf{p}}}\right)^{1/2} \left[c_r(\mathbf{p})u_{\mathrm{M}r}(\mathbf{p})\mathrm{e}^{-\mathrm{i}px/\hbar} + d_r^\dagger(\mathbf{p})u_{\mathrm{M}r}^*(\mathbf{p})\mathrm{e}^{\mathrm{i}px/\hbar}\right]$$

$$\psi_{\mathrm{M}}^{\dagger T}(x) = \sum_{r\mathbf{p}} \left(\frac{mc^2}{VE_{\mathbf{p}}}\right)^{1/2} \left[d_r(\mathbf{p})u_{\mathrm{M}r}(\mathbf{p})\mathrm{e}^{-\mathrm{i}px/\hbar} + c_r^\dagger(\mathbf{p})u_{\mathrm{M}r}^*(\mathbf{p})\mathrm{e}^{\mathrm{i}px/\hbar}\right]$$

$$\left[\psi_\alpha(x), \psi_\beta(y)\right]_+ = \left[\bar{\psi}_\alpha(x), \bar{\psi}_\beta(y)\right]_+ = 0$$

$$\left[\psi_\alpha^\pm(x), \bar{\psi}_\beta^\mp(y)\right]_+ = \mathrm{i}\left(\mathrm{i}\gamma^\mu\frac{\partial}{\partial x^\mu} + \frac{mc}{\hbar}\right)_{a\beta}\Delta^\pm(x-y)$$

Omitting suffixes, i.e. considered as a 4×4 matrix equation, we can write Eqs. (4.52b) as

$$\left[\psi^\pm(x), \bar{\psi}^\mp(y)\right]_+ = \mathrm{i}S^\pm(x-y); \qquad S^\pm(x) := \left(\mathrm{i}\gamma^\mu\frac{\partial}{\partial x^\mu} + \frac{mc}{\hbar}\right)\Delta^\pm(x).$$

From the last two equations

$$\left[\psi(x), \bar{\psi}(y)\right]_+ = \mathrm{i}S(x-y)$$

$$S(x) := S^+(x) + S^-(x) = \left(\mathrm{i}\gamma^\mu\frac{\partial}{\partial x^\mu} + \frac{mc}{\hbar}\right)\Delta(x) = \frac{-\hbar}{(2\pi\hbar)^4}\int\limits_{C^\pm}\mathrm{d}^4p\frac{\mathrm{e}^{-\mathrm{i}px/\hbar}}{\not{p} - mc}$$

(???)

$$\psi_{\mathrm{L}}(x) \equiv \frac{1}{2}\left(1-\gamma_5\right)\psi(x), \quad \psi_{\mathrm{R}}(x) \equiv \frac{1}{2}\left(1+\gamma_5\right)\psi(x)$$

in the limit $m = 0$.

$$\mathscr{L}(x) = \mathrm{i}\hbar c\bar{\psi}_{\mathrm{L}}(x)\gamma^\mu\partial_\mu\psi_{\mathrm{L}}(x)$$

$$\sigma^\mu := \left(1, \sigma^i\right), \qquad \bar{\sigma}^\mu := \left(1, -\sigma^i\right)$$

the Dirac Lagrangian in terms of Weyl spinors:

$$\mathcal{L} = iu_-^\dagger\sigma^\mu\partial_\mu u_- + iu_+^\dagger\bar{\sigma}^\mu\partial_\mu u_+ - m\left(u_+^\dagger u_- + u_-^\dagger u_+\right)$$

Therefore the mass term couples the Weyl spinors together. To get a theory with only one Weyl spinor, we must set it to zero. The individual Weyl spinors satisfy the Weyl equations

$$i\bar{\sigma}^\mu \partial_\mu u_+ = 0, \quad i\sigma^\mu \partial_\mu u_- = 0$$

• Suppose a classical field theory has n real degrees of freedom in configuration space at each spatial point. Then it has $2n$ degrees of freedom per point in phase space, which become $2n/2 = n$ particles upon quantization. This yields $n = 1$ for a real scalar field and $n = 2$ for a complex scalar field, as expected.

• Now, the Dirac spinor naively has 16 real degrees of freedom in phase space. However, since the Dirac equation is first-order, $\pi_\psi = i\psi^\dagger$, so the phase space is parametrized by ψ and $\psi^\dagger$. Then the phase space has real dimension 8, giving 4 particles upon quantization, i.e. a spin up/down particle/antiparticle. Similarly the Weyl spinor yields 2 particles.

• Another way of saying this is that physical fermions must have constraints in their phase space; it can be shown that we otherwise inevitably get negative-norm states.

О пространственно-временных и групповых свойствах дираковского поля

(додумаю, мб отдеьлный раздел создам)

Plane Wave Solutions (!!!!!!!)

(!!!! додумаю, как связано с другим видом пл волн???? важный абзац ниже будет)

• We consider a positive frequency plane wave $\psi(x) = u(\mathbf{p})e^{-ipx}$ where $p^0 > 0$. Then the Dirac equation becomes

$$\begin{pmatrix} -m & p\cdot\sigma \\ p\cdot\bar{\sigma} & -m \end{pmatrix} u(\mathbf{p}) = 0$$

Since the individual components satisfy the Klein-Gordan equation, $p^2 = m^2$. Now we have

$$u(\mathbf{p}) = \begin{pmatrix} mu_1 \\ (p\cdot\bar{\sigma})u_1 \end{pmatrix}$$

for some spinor u_1. Defining $mu_1 = \sqrt{p\cdot\sigma}\xi$ and using the identity

$$(p\cdot\sigma)(p\cdot\bar{\sigma}) = p\cdot p = m^2$$

on the bottom spinor, we arrive at the general form

$$u(\mathbf{p}) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar{\sigma}}\xi \end{pmatrix}$$

We will conventionally normalize ξ by $\xi^\dagger\xi = 1$.

• Similarly, there are negative frequency solutions. Letting $\psi(x) = v(\mathbf{p})e^{ipx}$ with $p^0 > 0$,

$$v(\mathbf{p}) = \begin{pmatrix} \sqrt{p\cdot\bar{\sigma}}\eta \\ -\sqrt{p\cdot\bar{\sigma}}\eta \end{pmatrix}$$

where we normalize $\eta^\dagger\eta = 1$. Note these classical field solutions vary in space as if they had four-momentum $-p$. However, we will fix this sign discrepancy after quantization, so that the corresponding particles indeed have four-momentum p.

• As a simple example, consider the positive frequency solution with mass m and $\mathbf{p} = 0$,

$$u(\mathbf{p}) = \sqrt{m} \begin{pmatrix} \xi \\ \xi \end{pmatrix}$$

To interpret ξ, recall that the angular momentum operator is $J^i = \text{diag}\,(\sigma^i/2, \sigma^i/2)$. Then ξ describes the spin, with $\xi = (1, 0)^T$ yielding spin up.

• Next, consider a boost along the x^3 direction, $p^\mu = (E, 0, 0, p)$. Then for spin up,

$$u(\mathbf{p}) = \begin{pmatrix} \sqrt{E - p^3} \begin{pmatrix} 1 \\ 0 \end{pmatrix} \\ \sqrt{E + p^3} \begin{pmatrix} 1 \\ 0 \end{pmatrix} \end{pmatrix}$$

In particular, in the massless case we have $u(\mathbf{p}) = (0, 0, 1, 0)^T$. Similarly, for a massless spin down field we have $u(\mathbf{p}) = (0, 1, 0, 0)^T$.

• Define the helicity as the projection of spin along the direction of momentum,

$$h = \frac{i}{2}\epsilon_{ijk} p^i S^{jk} = \frac{1}{2} \begin{pmatrix} p_i \sigma^i & 0 \\ 0 & p_i \sigma^i \end{pmatrix}$$

Then the spin up solution above has positive/right-handed helicity and the spin down solution has negative/left-handed helicity. In the massless case helicity coincides with chirality. When a mass is added, helicity is no longer Lorentz invariant, and chirality is no longer conserved. However, we're playing a dangerous game here because we're assigning helicity to classical solutions, while it is really a property of quantum states; this will lead to some extra sign flips.

• Now pick orthonormal bases ξ_s and χ_s for the positive and negative frequency solutions. Then $u^{r\dagger}(\mathbf{p})u^s(\mathbf{p}) = 2p_0\delta^{rs}$, $\bar{u}^r(\mathbf{p})u^s(\mathbf{p}) = 2m\delta^{rs}$, $v^{r\dagger}(\mathbf{p})v^s(\mathbf{p}) = 2p_0\delta^{rs}$, $\bar{v}^r(\mathbf{p})v^s(\mathbf{p}) = -2m\delta^{rs}$ by direct expansion, using the identity $(p \cdot \sigma)(p \cdot \bar{\sigma}) = m^2$. Another useful identity is

$$u^{r\dagger}(\mathbf{p})v^s(-\mathbf{p}) = v^{r\dagger}(\mathbf{p})u^s(-\mathbf{p}) = 0$$

• Finally, for outer products we have

$$\sum_s u^s(\mathbf{p})\bar{u}^s(\mathbf{p}) = \not{p} + m, \quad \sum_s v^s(\mathbf{p})\bar{v}^s(\mathbf{p}) = \not{p} - m.$$

These combinations will appear in the numerator of the propagator.

Quantizing the Dirac Field

$\pi := \frac{\partial \mathcal{L}}{\partial \dot{\bar{\psi}}} = i\bar{\psi}\gamma^0 = i\psi^\dagger$, and $\mathcal{H} := \pi\dot{\psi} - \mathcal{L} = \int d\mathbf{x}\bar{\psi}\left(-i\gamma^i\partial_i + m\right)\psi$, as we found earlier when computing $T^{\mu\nu}$ (???).

• Now, we impose the usual canonical commutators

$$\left[\psi_\alpha(\mathbf{x}), \psi^\dagger_\beta(\mathbf{y})\right] = \delta_{\alpha\beta}\delta(\mathbf{x} - \mathbf{y}),$$

all other commutators zero, and perform the mode expansion

$$\psi(\mathbf{x}) = \int \frac{d\mathbf{p}}{\sqrt{2E_p}} \left(b^s_{\mathbf{p}} u^s(\mathbf{p}) e^{i\mathbf{px}} + c^{s\dagger}_{\mathbf{p}} v^s(\mathbf{p}) e^{-i\mathbf{px}}\right)$$

Taking the conjugate gives

$$\psi^\dagger(\mathbf{x}) = \int \frac{d\mathbf{p}}{\sqrt{2E_p}} \left(b^{s\dagger}_{\mathbf{p}} u^s(\mathbf{p})^\dagger e^{-i\mathbf{px}} + c^s_{\mathbf{p}} v^s(\mathbf{p})^\dagger e^{i\mathbf{px}} \right)$$

Here, the spin indices s run from 1 to 2, the spinor indices α and β run from 1 to 4, and the summation convention is used on the spin indices.

• By a similar computation to the scalar field case, we have the commutators

$$\left[b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}} \right] = \delta^{rs} \not{\delta}(\mathbf{p}-\mathbf{q}), \quad \left[c^r_{\mathbf{p}}, c^{s\dagger}_{\mathbf{q}} \right] = -\delta^{rs} \not{\delta}(\mathbf{p}-\mathbf{q}) \qquad \textit{withallotherszero;}$$

On-shell spinor condition:

$$\left(-\gamma^i p_i + m \right) u^s(\mathbf{p}) = \gamma^0 p_0 u^s(\mathbf{p}), \qquad \left(\gamma^i p_i + m \right) v^s(\mathbf{p}) = -\gamma^0 p_0 v^s(\mathbf{p})$$

so we simply have

$$\left(-i\gamma^i \partial_i + m \right) \psi = \int d\mathbf{p} \sqrt{\frac{E_p}{2}} \gamma^0 \left(b^s_{\mathbf{p}} u^s(\mathbf{p}) e^{i\mathbf{px}} - c^{s\dagger}_{\mathbf{p}} v^s(\mathbf{p}) e^{-i\mathbf{px}} \right)$$

Note there is an extra minus sign here because $e^{i\mathbf{px}}$ looks like e^{-ipx}. Applying our spinor inner product identities gives

$$H = \int d\mathbf{p} E_p \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - c^s_{\mathbf{p}} c^{s\dagger}_{\mathbf{p}} \right) = \int d\mathbf{p} E_p \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - c^{s\dagger}_{\mathbf{p}} c^s_{\mathbf{p}} + \phi(\mathbf{0}) \right).$$

• Now, note that $\left[H, c^\dagger(\mathbf{p}) \right] = E_p c^\dagger(\mathbf{p})$ as usual for a creation operator; the extra minus sign in the commutation relations cancels out the minus sign in the Hamiltonian. The problem is that the particles created by $c^\dagger$ have negative norm, as

$$\| c^{r\dagger}_{\mathbf{p}} |0\rangle \|^2 = \left\langle 0 \left| \left[c^r_{\mathbf{p}}, c^{r\dagger}_{\mathbf{p}} \right] \right| 0 \right\rangle < 0$$

which violates unitarity, as we get negative probabilities. We can fix this by interpreting $c^\dagger$ as an annihilation operator and c as a creation operator, but then c creates particles with negative energy, so the spectrum is unbounded below. Either way, the theory is sick.

Note. The problem above can be traced backwards to the fact that the Hamiltonian for a spinor field is linear in time derivatives, while that of a scalar field is quadratic, which can in turn be traced back to the Lagrangian. This generalizes to higher spins. An integer spin field can be represented using a number of vector indices, while a half-integer spin field must additionally have one spinor index. The kinetic term of the Lagrangian must contract the spinor indices by a factor of γ_μ (or more properly, for a Weyl spinor index, a factor of σ_μ), whose Lorentz index must then be contracted with a single derivative ∂_μ. The remaining Lorentz indices simply come in pairs, so half-integer spin fields have equations of motion with an odd number of derivatives.

The problem is fixed by switching to anticommutation relations: (??!!)

$$\left\{ \psi_\alpha(\mathbf{x}), \psi^\dagger_\beta(\mathbf{y}) \right\} \equiv \delta_{\alpha\beta} \delta(\mathbf{x}-\mathbf{y})$$

which are equivalent to the anticommutation relations

$$\left\{ b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}} \right\} = \delta^{rs} \not{\delta}(\mathbf{p}-\mathbf{q}), \quad \left\{ c^r_{\mathbf{p}}, c^{s\dagger}_{\mathbf{q}} \right\} = \delta^{rs} \not{\delta}(\mathbf{p}-\mathbf{q})$$

with all other anticommutators zero.

• All of our manipulations above go through unchanged, except that at the last step,

$$H = \int d\mathbf{p} E_p \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - c^s_{\mathbf{p}} c^{s\dagger}_{\mathbf{p}} \right) = \int d\mathbf{p} E_p \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} + c^{s\dagger}_{\mathbf{p}} c^s_{\mathbf{p}} - \phi(\mathbf{0}) \right)$$

Then both types of particles have positive energy and positive norm. The vacuum energy contribution also comes out negative, canceling part of the boson contribution.

• We can construct the Hilbert space exactly as before, acting with the creation operators on the vacuum. They both raise the energy, as

$$\left[H, b^{s\dagger}_{\mathbf{p}} \right] = E_{\mathbf{p}} b^{s\dagger}_{\mathbf{p}}, \quad \left[H, c^{s\dagger}_{\mathbf{p}} \right] = E_{\mathbf{p}} c^{s\dagger}_{\mathbf{p}}$$

The anticommutation relations imply the Pauli exclusion principle: every mode can have either zero or one particle. The anticommutation makes the multiparticle wavefunction antisymmetric, as postulated in nonrelativistic quantum mechanics.

• As an example, the conserved charge from the internal vector symmetry is

$$Q = \int d\mathbf{p} \left(b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} - c^{s\dagger}_{\mathbf{p}} c^s_{\mathbf{p}} \right)$$

indicating that the c particles have negative charge. We thus interpret them as antimatter.

• One might wonder how the c particles can have positive energy when they are the quantization of a classical mode with negative frequency. Each of these modes can have occupancy either 0 or 1, and it is arbitrary which of these two states is labeled 'unoccupied'. We thus define the vacuum to be the lowest energy state, and for the vacuum to have all modes unoccupied. In this new picture, the excitations created by $c^\dagger$ are 'holes' in the Dirac sea.

• The Dirac sea also explains why the vacuum energy comes out negative for fermionic fields. All the bosonic degrees of freedom get zero-point energy $\hbar\omega/2$, while all the negative frequency fermionic degrees of freedom get Dirac sea energy $-\hbar\omega$.

• Since $c^\dagger$ makes a hole, every quantum number is flipped, so that $c^{s\dagger}_{\mathbf{p}}$ creates a particle with momentum $\mathbf{p}$ and negative charge. It's convenient to define the basis spinors so that $c^{s\dagger}_{\mathbf{p}}$ and $b^{s\dagger}_{\mathbf{p}}$ have the same spin.

Next, we switch to Heisenberg picture, establish causality, and find the fermionic propagator. Field:

$$\psi(\mathbf{x}) = \int \frac{d\mathbf{p}}{\sqrt{2E_p}} \left(b^s_{\mathbf{p}} u^s(\mathbf{p}) e^{-ipx} + c^{s\dagger}_{\mathbf{p}} v^s(\mathbf{p}) e^{ipx} \right)$$

$$\begin{aligned} iS_{\alpha\beta}(x-y) :&= \left\{ \psi_\alpha(x), \bar{\psi}_\beta(y) \right\} = \text{suppressing spinor indices} = \\ &= \int \frac{d\mathbf{p}}{2E_p} \left(u^s(\mathbf{p}) \bar{u}^s(\mathbf{p}) e^{-ip(x-y)} + v^s(\mathbf{p}) \bar{v}^s(\mathbf{p}) e^{ip(x-y)} \right) = \\ &= \int \frac{d\mathbf{p}}{2E_p} \left((\not{p} + m) e^{-ip(x-y)} + (\not{p} - m) e^{ip(x-y)} \right) = \\ &= (i\partial_x + m) \left(D(x-y) - D(y-x) \right) \end{aligned}$$

where $D(x-y) = \langle 0 | \phi(x) \phi(y) | 0 \rangle$ is the propagator for a free scalar field. (??? проделаю потом матем!)

• Since $D(x-y)$ vanishes for spacelike separations, $S(x-y)$ and hence the anticommutator vanishes for spacelike separations. Since all observables are fermion bilinears or combinations thereof, observables commute at spacelike separations. (??????????????????)

Let's look at

$$T(\psi(x)\bar{\psi}(y)) := \begin{cases} \psi(x)\bar{\psi}(y) & x^0 \geq y^0 \\ -\bar{\psi}(y)\psi(x) & y^0 > x^0 \end{cases}$$

To see one reason the minus sign is necessary, note that at spacelike separations we have $\psi(x)\bar{\psi}(y) = -\bar{\psi}(y)\psi(x)$ by the above calculation. In such cases we can perform a boost to change the time ordering of x and y, so the two cases in the time ordering must be equal.

Feynman propagator:

$$\begin{aligned} S_F(x-y) :&= \langle 0|T\psi(x)\bar{\psi}(y)|0\rangle \\ &= \theta\left(x^0-y^0\right)\int \frac{d\mathbf{p}}{2E_p}(\not{p}+m)e^{-ip(x-y)} - \theta\left(y^0-x^0\right)\int \frac{d\mathbf{p}}{2E_p}(\not{p}-m)e^{ip(x-y)} \\ &= \left(i\not{\partial}_x + m\right)D_F(x-y) = i\int dp \frac{\not{p}+m}{p^2-m^2+i\epsilon}e^{-ip(x-y)} \end{aligned}$$

where D_F is the Feynman propagator for a free scalar theory. If we had used commutation relations to quantize the field, we would have found an ugly, non-Lorentz invariant result.

• As expected, S_F is a Green's function for the Dirac equation, since applying $i\not{\partial}_x - m$ gives $(\not{p}-m)(\not{p}+m) = p^2 - m^2$ in the numerator. Because of this identity, the Feynman propagator is sometimes formally written as $S_F(p) = i(\not{p}-m)^{-1}$. Alternatively, we can think of the Feynman propagator as a sum of Feynman propagators for each degree of freedom; in this picture the numerator is a sum over polarizations. We will prove this more generally later.

• Normal ordering for fermionic fields is also defined with an extra minus sign for every interchange. Thus the general method for normal and time ordering is to simply commute or anticommute, neglecting all extra resulting terms. The proof of Wick's theorem goes through as before, with contractions yielding a factor of S_F.

• Contractions now come with signs, so that swapping any two ψ or $\bar{\psi}$ fields in the contraction structure yields a factor of -1. If we draw lines connecting contracted fields, the number of sign flips is the number of intersections of the lines.

• Note that the contraction of ψ with ψ, or of $\bar{\psi}$ with $\bar{\psi}$, is automatically zero. Then n-point functions of spinor fields can only be nonzero if there are an equal number of ψ and $\bar{\psi}$ fields, reflecting charge conservation.

• The proof of the LSZ reduction formula also goes through mostly as before, expect that the poles are projected out by factors of $i\not{\partial} - m$ rather than $\partial^2 + m^2$.

Other properties of Dirac field

Other general properties

$$\psi \to S[\Lambda]\psi, \quad \psi^\dagger \to \psi^\dagger S^\dagger[\Lambda]$$

Therefore, the naive guess $\psi^\dagger\psi$ does not work because the $S[\Lambda]$ are not unitary.

• For concreteness, we use a representation of the Clifford algebra where γ^0 is Hermitian and the γ^i are anti-Hermitian, such as the chiral representation.

• In any specific representation, it is straightforward to show that

$$\gamma^0\gamma^\mu\gamma^0 = (\gamma^\mu)^\dagger$$

which means γ^0 takes the adjoint of gamma matrices when pulled through them. (Since all representations are related by unitary transformations, it suffices to show this result in any representation - but it's not straightforward to do it without ever picking one.) Then

$$(S^{\mu\nu})^\dagger = -\gamma^0 S^{\mu\nu}\gamma^0, \quad S[\Lambda]^\dagger = \gamma^0 S[\Lambda]^{-1}\gamma^0$$

• Defining the Dirac adjoint $\bar{\psi} = \psi^\dagger\gamma^0$, we have

$$\bar{\psi} \to \psi^\dagger S[\Lambda]^\dagger\gamma^0 = \psi^\dagger\gamma^0 S[\Lambda]^{-1} = \bar{\psi}S[\Lambda]^{-1}$$

which implies that $\bar{\psi}\psi$ is a Lorentz scalar.

• Moreover, $\bar{\psi}\gamma^\mu\psi$ is a Lorentz vector. Since we have

$$\bar{\psi}\gamma^\mu\psi \to \bar{\psi}S[\Lambda]^{-1}\gamma^\mu S[\Lambda]\psi$$

we need to show $S[\Lambda]^{-1}\gamma^\mu S[\Lambda] = \Lambda^\mu{}_\nu\gamma^\nu$. For infinitesimal Lorentz transformations, this becomes

$$[-S^{\rho\sigma}, \gamma^\mu] = (J^{\rho\sigma})^\mu_\nu\,\gamma^\nu$$

We can directly verify this is true using computations we've already done.

• Similarly, one can show that $\bar{\psi}\gamma^\mu\gamma^\nu\psi$ transforms as a Lorentz tensor, as does any combination of more gamma matrices. Taking the symmetric part yields $\eta^{\mu\nu}\bar{\psi}\psi$, which is simply a multiple of our Lorentz scalar. The new feature is the antisymmetric part, $\bar{\psi}S^{\mu\nu}\psi$.

• We use our scalar and vector to build the Dirac Lagrangian

$$\mathcal{L} = \bar{\psi}(i\not{\partial} - m)\psi, \quad \not{\partial} = \gamma^\mu\partial_\mu$$

Note that the factor of i is necessary to make $\mathcal{L}$ real, i.e. invariant under conjugation, to cancel out a minus sign from integration by parts. We haven't seen this issue before because our other Lagrangians were second-order, requiring two integrations by parts.

• Using the trick of treating ψ and $\bar{\psi}$ as independent fields, varying with respect to $\bar{\psi}$ gives the Dirac equation

$$(i\not{\partial} - m)\psi = 0$$

Varying with respect to ψ gives the conjugate equation

$$i\not{\partial}_\mu\bar{\psi}\gamma^\mu + m\bar{\psi} = \bar{\psi}(i\overleftarrow{\not{\partial}} + m) = 0$$

where the arrow indicates the derivative acts to the left.

• Each component of the Dirac spinor satisfies the Klein-Gordan equation, as

$$(i\gamma^\nu\partial_\nu + m)\,(i\gamma^\mu\partial_\mu - m)\,\psi = -\left(\gamma^\mu\gamma^\nu\partial_\mu\partial_\nu + m^2\right)\psi = -\left(\partial^2 + m^2\right)\psi = 0$$

Thus the Dirac spinor describes four types of particles of mass m. The left-hand side contains a 'factorization' of the Klein-Gordan operator $\partial^2 + m^2$, so the Dirac equation is sometimes called the 'square root' of the Klein-Gordan equation. Here it's clear that the definition of a Clifford algebra was originally chosen just to make this work out.

Next, we decompose the Dirac spinor into Weyl spinors.

• As we've seen, in the chiral representation of the Clifford algebra, the Lorentz transformations are block-diagonal. Hence the Dirac spinor splits into two irreps, $\psi = (u_+, u_-)$, called Weyl spinors, which transform as

$$u_\pm \to e^{-i\boldsymbol{\varphi}\cdot\boldsymbol{\sigma}/2}u_\pm, \quad u_\pm \to e^{\mp\boldsymbol{\chi}\cdot\boldsymbol{\sigma}/2}u_\pm$$

The Weyl spinors are $(1/2,0)$ and $(0,1/2)$, or left-handed and right-handed respectively, and the Dirac spinor is $(1/2,0)\oplus(0,1/2)$.

Bremsstrahlung

(про это в теорполе пока, потом сюда перепишу суть короче)

1.3.3 Vector Field

(уменьшу скорее всего, пока так пусть будет, с теорией поля свяжу еще)

О векторном поле и фотонах: main formulas

Основные свойства

(???? про это потом буду думать снова, мб что-то тут неверно написано пока будет)
Нам известны уравнения Максвелла и весь формализм классической электродинамики:

$$\partial_v F^{\mu v}(x) = \frac{1}{c}s^\mu(x)$$
$$\partial^\lambda F^{\mu v}(x) + \partial^\mu F^{v\lambda}(x) + \partial^v F^{\lambda\mu}(x) = 0.$$

Тут $F^{\mu\nu}$ is antisymmetric, поэтому заряд сохраняется $\partial_\mu s^\mu(x) = 0$.
Поле описывается лагранжианом:

$$\mathcal{L} = -\frac{1}{2}\partial_v A_\mu(x)\cdot\partial^v A^\mu(x) - \frac{1}{c}s_\mu(x)A^\mu(x).$$

Вообще, можно было бы взять и $\mathscr{L} = -\frac{1}{4}F_{\mu v}(x)F^{\mu v}(x) - \frac{1}{c}s_\mu(x)A^\mu(x)$, но от него $\pi^0 \equiv 0$, что плохо, а оба лагранжиана дают одну и ту же физику. (???? в теории про это подробно подумаю.) Мы подразумеваем тут везде Лоренцеву калибровку: $\partial_\mu A^\mu(x) = 0$, из которой следует еще условие на дополнительные калибровки: если $A'^\mu(x) = A^\mu(x) + \partial^\mu f(x)$, то должно быть $\Box f(x) = 0$.
Решение в параллелепипеде с периодическими гран условиями:

$$A^\mu(x) = A^{\mu+}(x) + A^{\mu-}(x)$$
$$A^{\mu+}(x) = \sum_{r\mathbf{k}}\left(\frac{\hbar c^2}{2\ \mathrm{V}\omega_\mathbf{k}}\right)^{1/2}\varepsilon_r^\mu(\mathbf{k})a_r(\mathbf{k})\mathrm{e}^{-\mathrm{i}kx}, \qquad A^{\mu-}(x) = \sum_{r\mathbf{k}}\left(\frac{\hbar c^2}{2\ \mathrm{V}\omega_\mathbf{k}}\right)^{1/2}\varepsilon_r^\mu(\mathbf{k})a_r^\dagger(\mathbf{k})\mathrm{e}^{\mathrm{i}kx}.$$

Тут $k^0 = \frac{1}{c}\omega_\mathbf{k} = |\mathbf{k}|$, $r \in \{0,3\}$. Вообще, a тут - вообще любые функции, при которых сумма/интеграл сходится (!??!??!?!?!?да???)
У нас сразу выходят условия на вектора поляризации:

$$\varepsilon_r(\mathbf{k})\varepsilon_s(\mathbf{k}) = \varepsilon_{r\mu}(\mathbf{k})\varepsilon_s^\mu(\mathbf{k}) = -\zeta_r\delta_{rs}, \quad r,s = 0,...,3,$$
$$\sum_r \zeta_r\varepsilon_r^\mu(\mathbf{k})\varepsilon_r^v(\mathbf{k}) = -g^{\mu\nu},$$
$$\zeta_0 = -1, \quad \zeta_1 = \zeta_2 = \zeta_3 = 1.$$

(??? в теории еще подумаю, как конкретно такие условия получаются и почему конкретно там минус????)

(???? не, ниже про квантование не могу писать, я ничего не понимаю, нужно К-Г переучивать?!!!!)

Квантуем просто заменой вектор-потенциалов операторами. (??? почитаю еще, какие особенности там с квантованием????) Явно можно увидеть, что коммутаторы:

$$[A^\mu(\mathbf{x},t), A^v(\mathbf{x}',t)] = 0, \quad \left[\dot{A}^\mu(\mathbf{x},t), \dot{A}^v(\mathbf{x}',t)\right] = 0$$
$$\left[A^\mu(\mathbf{x},t), \dot{A}^v(\mathbf{x}',t)\right] = -\mathrm{i}\hbar c^2 g^{\mu v}\delta(\mathbf{x}-\mathbf{x}')$$

Точнее, the full photon propagator. It is corrected by Dyson resummation of the 1PI contribution,

$$\mu \sim \mathrm{PP} \sim\sim v \equiv i\Pi^{\mu\nu}\left(q^2\right)$$

and $\Pi^{\mu\nu}(q^2)$ is called the self-energy of the photon or the vacuum polarization.

О фотонном пропагаторе

О пространственно-временных и групповых свойствах векторного поля

Quantization of a vector field

(I'll summarize all it here, since there are a lot of questions about it)

Features of vector field quantization

(выше уже оно проквантовано, тут другие методы и другие вопросы, этого много еще)

Gauge Symmetry, quantizing the electromagnetic field

(??? все те же вопросы про это остаются, вот тут их и отвечу)

Electromagnetism is described by $\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$, where $F_{\mu\nu} := \partial_\mu A_\nu - \partial_\nu A_\mu$ and satisfies the equations of motion and Bianchi identity $\partial_\mu F^{\mu\nu} = 0, \quad \partial_\lambda F_{\mu\nu} + \partial_\mu F_{\nu\lambda} + \partial_\nu F_{\lambda\mu} = 0$.

These each produce four equations, i.e. two of Maxwell's equations each.

(абзац про то, в чем вообще проблема с квантованием эм поля?)

• Many of the degrees of freedom in A_μ are redundant, as we know the photon has only two polarization states. The first issue is that A_0 has no kinetic term, as the Lagrangian does not depend on $\dot{A}_0$. It is a 'non-dynamical' field, whose value is totally determined by initial conditions for A_i and $\dot{A}_i$.

• Intuitively, a kinetic term $\dot{A}_0^2$ gives the action a 'penalty' for changing A_0, and hence gives the field A_0 some 'inertia'. Without this inertia, action minimization always takes $A_0(t)$ to whatever minimizes the Lagrangian given $A_i(t)$ and $\dot{A}_i(t)$ at every time t.

• More explicitly, we can solve for A_0 (up to gauge symmetry) using its equation of motion,

$$\nabla^2 A_0 + \nabla\cdot\frac{\partial\mathbf{A}}{\partial t} = 0, \quad A_0(\mathbf{x}) = \int d\mathbf{x}' \frac{(\nabla\cdot(\partial\mathbf{A}/\partial t))(\mathbf{x}')}{4\pi|\mathbf{x}-\mathbf{x}'|}$$

Note that this equation of motion is equivalent to the constraint $\nabla\cdot\mathbf{E} = 0$. We could plug this expression for A_0 back into the Lagrangian, eliminating A_0 entirely, but this would be much messier than just keeping A_0 explicit.

• The Lagrangian also has a gauge symmetry

$$A_\mu(x) \to A_\mu(x) + \partial_\mu \alpha(x)$$

where we assume $\alpha(x) \to 0$ as $x \to \infty$, under which the field strength is invariant. Classically, we think of states related by a gauge transformation as the same physical state. The gauge symmetry also takes away one degree of freedom because the gauge parameter α has one value at every point, leaving two.

• Gauge symmetry places powerful constraints on the action. E.g. as we will see in detail for the non-abelian case, the Maxwell action is essentially the only possible kinetic term for a photon which is gauge invariant, not irrelevant, and not a total derivative.

• Since A_0 is non-dynamical its conjugate momentum vanishes,

$$\pi^0 = 0, \quad \pi^i = -F^{0i} = E^i$$

The Hamiltonian can be straightforwardly computed to be

$$H = \int d\mathbf{x} \frac{1}{2}E^2 + \frac{1}{2}B^2 - A_0(\nabla \cdot \mathbf{E})$$

We hence recover the familiar electromagnetic field energy, with A_0 serving as a Lagrange multiplier which enforces Gauss's law. Thus we have first-class constraints $\pi^0 = \nabla \cdot \mathbf{E} = 0$.

We will look at a few different gauges.

• Lorenz gauge is the condition $\partial_\mu A^\mu = 0$. This is always achievable since we can set $\partial^2 \alpha = -\partial_\mu A^\mu$ for any starting A^μ. This is not a complete gauge fixing, because $\partial^2 \alpha = 0$ has nontrivial solutions, but Lorenz gauge is Lorentz invariant.

• Coulomb gauge is the additional restriction $\nabla \cdot \mathbf{A} = 0$, which means A_0 is time-independent in vacuum; it is achievable by the same logic as Lorenz gauge. This is still not a complete gauge fixing, because we may still apply gauge transformations with parameters α so that

$$\ddot{\alpha} = \nabla^2 \alpha = 0.$$

Usually, we further require $A_0 = 0$, which can be achieved by performing a final gauge transformation with $\alpha = A_0 t$. This brings us to Coulomb gauge, which breaks Lorentz invariance, but makes it easy to see the two independent polarizations.

• In Lorenz gauge and hence in Coulomb gauge, the equation of motion is $\partial^2 A_\mu = 0$.

• The counting of degrees of freedom can be a little puzzling. Intuitively, there is only "one degree of freedom" in $\alpha(x)$, which is a function on spacetime. Lorenz gauge is also intuitively "one constraint", so it seems nothing should be left over. The point is that the remaining freedom is of measure zero, as a solution to $\partial^2 \alpha = 0$ can be specified by initial conditions on a hypersurface. Similarly, after fixing Coulomb gauge, we have the freedom to perform gauge transformations with $\dot{\alpha} = \nabla^2 \alpha = 0$, which again is of measure zero relative to what we started with.

• For a fixed four-vector n^μ, the axial gauge is $n^\mu A_\mu = 0$. We will not deal with axial gauge here, but it is useful in Yang-Mills theory because ghost fields are not required.

Quantization in Coulomb Gauge

This gauge is popular in atomic physics, where the breaking of Lorentz invariance is not problematic, since the matter is typically nonrelativistic anyway. However, it is especially difficult to perform renormalization with it. (????)

• Since we have set $A_0 = 0$, the classical plane wave solutions are

$$\mathbf{A}(\mathbf{x}) = \int d\mathbf{p}\boldsymbol{\xi}(\mathbf{p})e^{i\mathbf{p}\cdot\mathbf{x}}, \quad p^2 = 0$$

where $\boldsymbol{\xi}(\mathbf{p})$ is the polarization. The constraint $\nabla \cdot \mathbf{A} = 0$ yields $\boldsymbol{\xi} \cdot \mathbf{p} = 0$.

• For each momentum, there are two independent polarization vectors $\boldsymbol{\epsilon}_r(\mathbf{p})$ satisfying

$$\boldsymbol{\epsilon}_r(\mathbf{p}) \cdot \mathbf{p} = 0, \quad \boldsymbol{\epsilon}_r(\mathbf{p}) \cdot \boldsymbol{\epsilon}_s(\mathbf{p}) = \delta_{rs}$$

Note that it is impossible to choose the polarization vectors continuously by the hairy ball theorem. (??????? в теории про это) However, this topological issue has no impact on scattering calculations.

• Naively, we would impose the canonical commutators

$$[A_i(\mathbf{x}), E_j(\mathbf{y})] = i\delta_{ij}\delta(\mathbf{x} - \mathbf{y})$$

with all other commutators zero, but we must account for the constraints. Before gauge fixing, we had the first-class constraints

$$\pi^0 = 0, \quad \nabla \cdot \mathbf{E} = 0$$

In the process of gauge fixing, we imposed the additional constraints

$$A^0 = 0, \quad \nabla \cdot \mathbf{A} = 0$$

and now $\pi^0 = A^0 = 0$ are automatically satisfied since we have eliminated those variables entirely. The remaining constraints are now second-class. They are not obeyed by the naive commutators, as, for example,

$$[\nabla \cdot \mathbf{A}(\mathbf{x}), \nabla \cdot \mathbf{E}(\mathbf{x})] = i\nabla^2\delta(\mathbf{x} - \mathbf{y}) \neq 0$$

• The fix is to use the Dirac bracket, i.e. the modified bracket

$$[A_i(\mathbf{x}), E_j(\mathbf{y})] = i\left(\delta_{ij} - \frac{\partial_i\partial_j}{\nabla^2}\right)\delta(\mathbf{x} - \mathbf{y})$$

Then in momentum space, we have

$$[A_i(\mathbf{x}), E_j(\mathbf{y})] = i\int d\mathbf{p}\left(\delta_{ij} - \frac{p_i p_j}{|\mathbf{p}|^2}\right)e^{i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}$$

so that $\partial_i A_i$ and $\partial_i E_i$ each have zero bracket with everything else.

• Formally, because our theory has constraints, we would like to define it on a subset of the full phase space. However, explicitly reducing the three degrees of freedom to two would be quite ugly. Thinking geometrically of Poisson brackets $\{f, g\}$ as the rate of change of g under the flow generated by f, the Dirac bracket amounts to adjusting the flows so that they stay on the constraint manifold, giving the same result.

• Now, the usual mode expansion gives

$$\mathbf{A}(\mathbf{x}) = \int \frac{d\mathbf{p}}{\sqrt{2|\mathbf{p}|}}\sum_{r=1}^{2}\boldsymbol{\epsilon}_r(\mathbf{p})\left(a^r_{\mathbf{p}}e^{i\mathbf{p}\cdot\mathbf{x}} + a^{r\dagger}_{\mathbf{p}}e^{-i\mathbf{p}\cdot\mathbf{x}}\right)$$

and

$$\mathbf{E}(\mathbf{x}) = \int d\mathbf{p}(-i)\sqrt{\frac{|\mathbf{p}|}{2}}\sum_{r=1}^{2}\boldsymbol{\epsilon}_r(\mathbf{p})\left(a^r_{\mathbf{p}}e^{i\mathbf{p}\cdot\mathbf{x}} - a^{r\dagger}_{\mathbf{p}}e^{-i\mathbf{p}\cdot\mathbf{x}}\right)$$

The polarizations $\boldsymbol{\epsilon}_r(\mathbf{p})$ remain vectors, not operators, obeying the same constraints as before.

• One can show that the commutation relations above lead to the usual result

$$\left[a^r_{\mathbf{p}}, a^{s\dagger}_{\mathbf{q}}\right] = \delta^{rs}\phi(\mathbf{p}-\mathbf{q})$$

with all others zero. This can be derived using the completeness relation for the polarizations,

$$\sum_{r=1}^{2}\epsilon^i_r(\mathbf{p})\epsilon^j_r(\mathbf{p}) = \delta^{ij} - \frac{p^i p^j}{|\mathbf{p}|^2}$$

• Finally, we substitute our mode expansion back into the Hamiltonian, which gives

$$H = \int d\mathbf{p}|\mathbf{p}|\sum_{r=1}^{2}a^{r\dagger}_{\mathbf{p}}a^r_{\mathbf{p}}$$

which confirms the excitations all have energy p.

• Switching to Heisenberg picture and applying the completeness relation gives the propagator

$$D_{ij}(x-y) = \langle 0\,|TA_i(x)A_j(y)|\,0\rangle = \int dp\frac{i}{p^2+i\epsilon}\left(\delta_{ij} - \frac{p_i p_j}{|\mathbf{p}|^2}\right)e^{-ip(x-y)}$$

Unfortunately, the result is far from Lorentz invariant. Instead we'll redo the quantization procedure keeping Lorentz invariance explicit throughout.

Note. When treating the electromagnetic field, we typically either consider the quantized version, or the classical limit, which arises out of states with many photons. However, it is also valid to consider states with one photon, and see what the quantum theory says about them. For massive fields, the one-particle states would be useful in the nonrelativistic limit, where there isn't enough energy to make more particles. For photons, this doesn't apply, but considering one photon at a time is still interesting since many processes involve only one, or a few photons.

We can write a general state containing one photon as

$$|\psi\rangle = \int d\mathbf{p}\sum_{r=1}^{2}\boldsymbol{\epsilon}_r(\mathbf{p})\psi_r(\mathbf{p})a^{r\dagger}_{\mathbf{p}}|0\rangle$$

Here, we are working with a basis of one-photon states that diagonalizes momentum $\mathbf{p}$ and helicity, so $\psi_r(\mathbf{p})$ is the "wavefunction in momentum/helicity space". It is normalized in the usual way,

$$\int d\mathbf{p}\sum_{r=1}^{2}|\psi_r(\mathbf{p})|^2 = 1$$

Unlike nonrelativistic quantum mechanics, in quantum field theory it is simpler to start in momentum space. We can define a position operator by noting that, by the canonical commutation relations, we should have $\mathbf{x} = -i\nabla$ where the gradient is in momentum space. (This operator is formally called the Newton-Wigner position operator. One can show that this is the unique

candidate for $\mathbf{x}$ which transforms appropriately under the Poincare group.) There is no problem in defining a position space wavefunction, by taking the Fourier transform. Next, we can define the orbital angular momentum $\mathbf{L} = \mathbf{x} \times \mathbf{p}$, which has the same value on one-photon states as the orbital angular momentum derived by Noether's theorem for the fields. The spin $\mathbf{S}$ is already defined, taking values $\pm\hat{\mathbf{p}}$ depending on the polarization, and the helicity is $h = \hat{\mathbf{p}} \cdot \mathbf{S}$.

However, this has a serious problem, which can be seen by defining a vector-valued wavefunction

$$\psi(\mathbf{p}) = \sum_{r=1}^{2} \boldsymbol{\epsilon}_r(\mathbf{p}) \psi_r(\mathbf{p})$$

This wavefunction obeys the transverse constraint, $\mathbf{p} \cdot \boldsymbol{\psi}(\mathbf{p}) = 0$, which means the position space wavefunction obeys $\nabla \cdot \boldsymbol{\psi}(\mathbf{x}) = 0$. But in position space, the position operator just multiplies by $\mathbf{x}$, which does not preserve this property. More formally, Wigner's classification tells us that photons only occupy helicity states $\lambda = \pm 1$, with $\lambda = 0$ forbidden. But $\mathbf{x}$ does not commute with helicity, since it does not commute with $\mathbf{p}$, so it introduces a $\lambda = 0$ component. One can restrict $\mathbf{x}$ to the $\lambda = \pm 1$ subspace, but then it no longer has the right transformation properties. This problem also applies to $\mathbf{L}$ and $\mathbf{S}$. Intuitively, these rotate the field rigidly in space, and the field value itself, and rotating the two independently will turn transverse polarizations into longitudinal ones. More generally, this problem does not occur for massive particles, where one can boost to the rest frame and straightforwardly construct the operators there. For massless particles, the problem only appears for helicities of $|\lambda| \geq 1$, since otherwise there are no missing helicities.

Note that $(\mathbf{p}, h)$ is not the only choice for a complete set of commuting observables for onephoton states. E.g. if one wants to talk about angular momentum, one can diagonalize (p, J^2, J_z, h) or (p, J^2, J_z, P) where P is parity. The position space wavefunctions involve spherical Bessel functions and spherical harmonics, and are known as vector multipole fields.

The obstruction above is usually described by mathematical physicists as saying that "the position of a photon is meaningless", which is probably overenthusiastic. There clearly is no problem with confining a photon in a cavity or a beam.

Note. There are yet more subtleties even when the Newton-Wigner position operator exists. In this case, there exist states that are perfectly localized in a given reference frame, but localization is not Lorentz invariant: the very same state is not perfectly localized upon applying a boost. (However, this might not be relevant in an experimental situation where the detector defines a preferred frame.) Furthermore, the wavefunction spreads out faster than the speed of light, a result known as the Hegerfeldt paradox. The easiest way to see that causality is not actually violated is to return to the field picture. This is one of the reasons modern particle physics sources often avoid the topic of one-photon wavefunctions: they have historically led to much confusion.

1.4 QED $\mathcal{L}_{\text{int}} = e\bar{\psi}\gamma^\mu \hat{A}_\mu \psi$ main properties and phenomena

(!! только на самом деле основное, дополительные свойства - следующая 1я часть!)

1.4.1 Estimations for QED (???!!)

(после квантмеха есть идея написать это тут. По Мигдалу Крайнову и просто по опыту соберу, но позже.)

elastic scattering

$$\frac{d\sigma}{d\Omega} = \underbrace{\frac{\alpha^2}{4E_1^2 \sin^4\theta/2}}_{\text{Rutherford}} \underbrace{\frac{E_3}{E_1}}_{\text{Proton recoil}} \left(\underbrace{\cos^2\frac{\theta}{2}}_{\text{Electric/ Magnetic scattering}} - \underbrace{\frac{q^2}{2M^2}\sin^2\frac{\theta}{2}}_{\text{Magnetic term due to spin}} \right)$$

For elastic scattering of relativistic electrons from an extended proton:

$$\frac{d\sigma}{d\Omega} = \frac{\alpha^2}{4E_1^2 \sin^4\theta/2} \frac{E_3}{E_1} \left(\frac{G_E^2 + \tau G_M^2}{(1+\tau)} \cos^2\frac{\theta}{2} + 2\tau G_M^2 \sin^2\frac{\theta}{2} \right) \qquad \text{(Rosenbluth Formula)}$$

$\star$ Electron elastic scattering from protons demonstrates that the proton is an extended object with rms charge radius of ~ 0.8fm

Elastic Scattering from a Finite Size Proton $\star$ In general the finite size of the proton can be accounted for by introducing two structure functions. One related to the charge distribution in the proton, $G_E(q^2)$ and the other related to the distribution of the magnetic moment of the proton, $G_M(q^2)$ - It can be shown that equation (16) generalizes to the Rosenbluth formula with with the Lorentz Invariant quantity:

$$\tau := -\frac{q^2}{4M^2} > 0$$

- Unlike our previous discussion of form factors, here the form factors are a function of q^2 rather than $\vec{q}^2$ and cannot simply be considered in terms of the FT of the charge and magnetic moment distributions. But $q^2 = (E_1 - E_3)^2 - \vec{q}^2$ and from eq (15) obtain

$$-\vec{q}^2 = q^2 \left[1 - \left(\frac{q}{2M} \right)^2 \right]$$

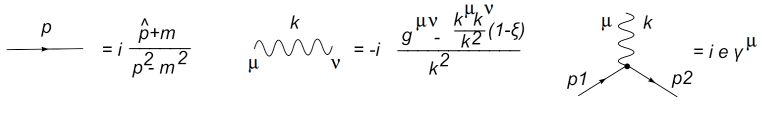
So for $\frac{q^2}{4M^2} \ll 1$ we have $q^2 \approx -\vec{q}^2$ and $G(q^2) \approx G(\vec{q}^2)$

1.4.2 1-loop QED

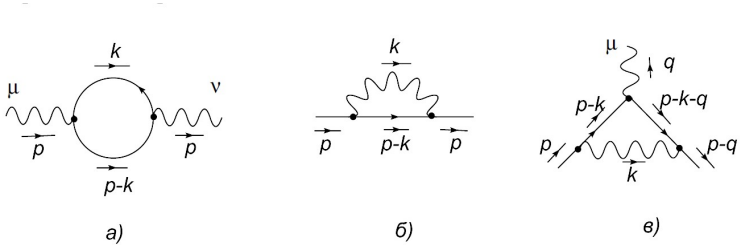
(!!! see Vergeles!)

Основные формулы и особенности

$$\mathcal{L}_{QED} = -\frac{1}{4}F_{\mu\nu}^2 + \bar{\psi}\left(i\gamma^\mu\partial_\mu - m\right)\psi + e\bar{\psi}\gamma^\mu A_\mu\psi - \frac{1}{2\xi}\left(\partial_\mu A_\mu\right)^2$$



Однопетлевые расходящиеся это только:



$$\partial_\nu F^{\nu\mu} = e\bar{\psi}\gamma^\mu\psi$$

Если принять калибровочное условие Лоренца $\partial_\mu A^\mu = 0$, уравнения сводятся к

$$\Box A^\mu = e\bar{\psi}\gamma^\mu\psi$$

$$\mathrm{i}\hbar\frac{\partial}{\partial t} \to \mathrm{i}\hbar\frac{\partial}{\partial t} - q\phi(x), \quad -\mathrm{i}\hbar\boldsymbol{\nabla} \to -\mathrm{i}\hbar\boldsymbol{\nabla} - \frac{q}{c}\mathbf{A}(x)$$

$$\partial_\mu \equiv \frac{\partial}{\partial x^\mu} \to D_\mu = \left[\partial_\mu + \frac{\mathrm{i}q}{\hbar c}A_\mu(x)\right].$$

$$\psi(x) \to \psi'(x) = \psi(x)\mathrm{e}^{\mathrm{i}ef(x)/\hbar c}$$
$$\bar{\psi}(x) \to \bar{\psi}'(x) = \bar{\psi}(x)\mathrm{e}^{-\mathrm{i}ef(x)/\hbar c}$$

$$\mathscr{L}_0 \to \mathscr{L}'_0 = \mathscr{L}_0 - e\bar{\psi}(x)\gamma^\mu\psi(x)\partial_\mu f(x)$$
$$\mathscr{Y}_1 \to \mathscr{Y}'_1 = \mathscr{L}_1 + e\bar{\psi}(x)\gamma^\mu\psi(x)\partial_\mu f(x)$$

О скалярной КЭД

Правила Фейнмана в КЭД

For vertices and internal lines, we write

- Vertex:  $-ie\gamma^\mu$
- Photon Propagator: $-\dfrac{i\eta_{\mu\nu}}{p^2 + i\epsilon}$
- Fermion Propagator:  $\dfrac{i(\not{p} + m)}{p^2 - m^2 + i\epsilon}$

For external lines in the diagram, we attach

- Photons: We add a polarization vector ϵ^μ_{in} /$\epsilon^\mu_{\text{out}}$ for incoming/outgoing photons. In Coulomb gauge, $\epsilon^0 = 0$ and $\vec{\epsilon}\cdot\vec{p} = 0$.

- Fermions: We add a spinor $u^r(\vec{p})/\bar{u}^r(\vec{p})$ for incoming/outgoing fermions. We add a spinor $\vec{v}^r(\vec{p})/v^r(\vec{p})$ for incoming/outgoing anti-fermions.

Массовый оператор по Вергелесу

(диаграмма тут)
аналитическое выражение которой даётся выражением

$$-i\mathcal{M}(p) = (-ie)^2 \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d} \gamma^\mu i S_c(p-k) \gamma^\nu \left(-iD^\alpha_{\mu\nu}(k)\right).$$

Проще всего вычисление проводится в калибровке Фейнмана $\alpha = 1$, в которой

$$-i\mathcal{M}(p) = -4\pi e^2 \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d} \frac{\gamma^\mu[(\not{p}-\not{k})+m]\gamma_\mu}{(p-k)^2-m^2} \frac{1}{k^2-\lambda^2}.$$

(вычисление на пару страниц, которое соберу словами в абзац)

$$\mathcal{M} = \frac{e^2}{2\pi m}(\not{p}-m)^2 \left\{ \frac{1}{2(1-\rho)} \left(1 - \frac{2-3\rho}{1-\rho}\ln\rho\right) - \right.$$
$$\left. -\frac{\not{p}+m}{m\rho} \left[\frac{1}{2(1-\rho)} \left(2-\rho+\frac{\rho^2+4\rho-4}{1-\rho}\ln\rho\right) + 1 + 2\ln\frac{\lambda}{m}\right]\right\}.$$

О поляризационном операторе по Вергелесу

(поизучаю, у него целый раздел про это)

$$\sum_\lambda \int \frac{d^3p_-}{(2\pi)^3 2p_-^0} \frac{d^3p_+}{(2\pi)^3 2p_+^0}$$

причём далее $\sum\limits_\lambda$ означает сумму лишь по поляризациям промежуточных частиц, $p_-^2 = p_+^2 = m^2$ и в сумме по промежуточным состояниям 3 -вектора $\mathbf{p}_-$и $\mathbf{p}_+$считаются независимыми. Имеем:

$$2\,\mathrm{Im}\, M_{ii} = (2\pi)^4 \sum_\lambda \int \frac{\mathrm{d}^3p_-}{(2\pi)^3 2p_-^0} \frac{\mathrm{d}^3p_+}{(2\pi)^3 2p_+^0} \delta^{(4)}\left(k-p_--p_+\right) \left|M_{\lambda i}\right|^2,$$

где амплитуда $M_{\lambda i}$ даётся частью диаграммы на рис. 24 правее крестиков:

$$iM_{\lambda i} = \bar{u}_{p_-}\left(-ie\gamma^\mu\right) u_{-p_+} \sqrt{4\pi} e_\mu.$$

Введём параметр

$$t = k^2 = (p_- + p_+)^2 = 2\left(p_-p_+ + m^2\right).$$

(???? дальше умные преобразования)

$$2e_\mu e_\nu\, \mathrm{Im}\, \mathcal{P}^{\mu\nu} = -\frac{2e^2}{3} e_\mu e_\nu \sqrt{\frac{t-4m^2}{t}} \cdot \frac{t+2m^2}{t} \left(k^2\eta^{\mu\nu} - k^\mu k^\nu\right).$$

Поэтому из (33) получаем асимптотику при больших $|t|$:

$$\mathcal{P}(t) = \begin{cases} \frac{e^2}{3\pi}\ln\frac{|t|}{m^2}, & \text{если } -t \gg 4m^2 \\ \frac{e^2}{3\pi}\left(\ln\frac{t}{m^2} - i\pi\right), & \text{если } t \gg 4m^2. \end{cases}$$

Мнимые части $\mathcal{P}(t)$, полученные при помощи (30) и (38), совпадают. Это подтверждает равенство $\ln\xi = \ln|\xi| + i\pi$ при $-1 < \xi < 0$.

Формфакторы электрона по Вергелесу

(тут диаграммы)
(допишу это, пока не до этого)

$$\delta M_{fi} = \frac{e}{m} g(0) \bar{u}_2 \left(\frac{i}{2} \varepsilon_{ijk} \sigma^{jk} \right) u_1 H^i$$

Такой же вклад в амплитуду даст добавка к гамильтониану

$$\delta \mathcal{H} = \int \mathrm{d}^{(3)} x \bar{\psi} \left[-\frac{e}{m} g(0) \left(\frac{i}{2} \varepsilon_{ijk} \sigma^{jk} \right) H^i \right] \psi \longrightarrow \int \mathrm{d}^{(3)} x \varphi^\dagger \left[-\frac{e}{m} g(0) \mathbf{sH} \right] \varphi$$

$$\mu = \frac{e\hbar}{2mc}(1 + g(0)).$$

Очевидно, что первое слагаемое в (6) не может дать вклад в аномальный магнитный момент. Действительно, при $k \to 0$ для первого слагаемого в (6) имеем $f\left(k^2\right)\left(\bar{u}_2 \gamma^\mu u_1\right) \to 2f(0)p^\mu$, где p^μ - импульс электрона.
(на этот раздел минимум часа 3 уйдет, если захочу разобраться.)

anomalous magnetic moment

$$\mu = \frac{e\hbar}{2mc} \left(1 + \frac{e^2}{2\pi\hbar c} \right)$$

(!!! это вот допишу, очень важные размышления, что вообще происходит, чтобы прийти к формуле!!!)
Ибо по Вергелесу

$$g(0) = \frac{e^2 m^2}{\pi} \int\limits_{4m^2}^{\infty} \frac{\mathrm{d}t}{t\sqrt{t\left(t - 4m^2\right)}} = \frac{e^2}{2\pi}$$

$$\mu = \frac{e\hbar}{2mc}(1 + g(0))$$

• One can show that the F_2 form factor affects the magnetic moment of the electron, by

$$\boldsymbol{\mu} = \frac{ge}{2m}\mathbf{S}, \quad g = 2 + 2F_2(0), \quad F_2(0) = \frac{\alpha}{2\pi}.$$

This is one of the most famous predictions of QED.
(кст, в теории создам раздел про вычисление этого!!!)
(!!! хотя бы одну диагрмму посчитаю по статье Волкова!!! проверю, что на самом деле могу это делать, отличная будет тренировка!)

118. Аномальный магнитный момент электрона по Ландау 4

По Зи (???)

(там мб Зи что-то годное вывел??)

По Мандл Шаулу

(???? общая идея то в чем???)

We saw in Section 9.6.1 that this correction to the magnetic moment stems from the vertex correction, Fig. 9.15(c), given by Eq. (9.48). By dimensional regularization, retaining the infrared cut-off λ, we can rewrite this equation

$$e_0^2\Lambda^\mu\left(p',p\right)=\frac{-\mathrm{i}e_0^2\mu^{4-D}}{(2\pi)^D}\int \mathrm{d}^D k\frac{N^\mu\left(p',p,k\right)}{\left(k^2-\lambda^2+\mathrm{i}\varepsilon\right)\left[\left(p'-k\right)^2-m^2+\mathrm{i}\varepsilon\right]\left[(p-k)^2-m^2+\mathrm{i}\varepsilon\right]},$$

where μ is the mass scale introduced in Section 10.3.1 and

$$N^\mu\left(p',p,k\right)=\gamma^\alpha\left(\not{p}'-\not{k}+m\right)\gamma^\mu(\not{p}-\not{k}+m)\gamma_\alpha$$

(а дальше словами пишу, потому что иначе формулы на страницу. Типа используем параметризацию Фейнмана, делаем замену переменных, дальше хрен знает что происходит, дальше разменую регуляризацию применяем (!??!?!??!?))

In order to derive the anomalous magnetic moment of the electron, we next consider the observable corrections which the vertex modification $e^2\Lambda^\mu\left(p',p\right)$ contributes to the scattering of electrons by an external static electromagnetic field. The Feynman amplitude for this is given by

$$M=\mathrm{i}e_0\bar{u}\left(\mathbf{p}'\right)e_0^2\Lambda^\mu\left(p',p\right)u(\mathbf{p})A_{\mathrm{e}\mu}\left(\mathbf{q}=\mathbf{p}'-\mathbf{p}\right).$$

The most general form for this amplitude, allowing for Lorentz invariance, the Lorentz gauge condition

$$q_\mu A_{\mathrm{e}}^\mu(\mathbf{q})=0$$

and the Gordon identity is

$$M=\mathrm{i}e_0\bar{u}\left(\mathbf{p}'\right)\left[\gamma^\mu F_1\left(q^2\right)+\frac{\mathrm{i}}{2m}\sigma^{\mu v}q_\nu F_2\left(q^2\right)\right]u(\mathbf{p})A_{\mathrm{e}\mu}(\mathbf{q})$$

where F_1 and F_2 are arbitrary functions of q^2. In order to calculate the magnetic moment, we

Получаем

$$F_2(0)=\frac{\alpha}{\pi}\int\limits_0^1 \mathrm{d}y\int\limits_0^{1-y}\mathrm{d}z\frac{1-y-z}{y+z}=\frac{\alpha}{2\pi}$$

which is the second-order correction to the magnetic moment quoted earlier, Eq. (9.72).

Lamb shift

(все указания про него в этом параграфе, должно хватить. порешаю, мб дело часов 3х.)

Радиационные поправки к закону Кулона по Вергелесу

(скоро продумаю)

(??? интеграл 48 Вергелеса какой??)

В частности:

а) $mr\gg 1$.

Интеграл (48) легко оценивается при помощи подстановки $\zeta = 1 + \xi$:

$$\varphi(r) = \frac{e_1}{r}\left[1 + \frac{e^2}{4\sqrt{\pi}} \cdot \frac{e^{-2mr}}{(mr)^{3/2}}\right], \qquad r \gg \frac{1}{m}.$$

б) $mr \ll 1$. Опуская вычисления, приводим ответ (см. ЛЛ.4, §114):

$$\varphi(r) = \frac{e_1}{r}\left[1 + \frac{2e^2}{3\pi}\left(\ln\frac{1}{mr} - C - \frac{5}{6}\right)\right], \qquad r \ll \frac{1}{m},$$

$C \approx 0,577$.

Идея в том, что....

$$\varphi_0(r) \equiv A_0^{(e)}(r) = \frac{e_1}{r}, \quad \mathbf{A}^{(e)} = 0.$$

$$\varphi_0(\mathbf{k}) = \frac{4\pi e_1}{\mathbf{k}^2}.$$

С учётом квантовых поправок:

$$\varphi = A_0^{(e)} + \mathcal{D}_{0\mu}\frac{\mathcal{P}^{\mu\nu}}{4\pi}A_\nu^{(e)}.$$

Получим первую поправку. Для этого поляризационный оператор возьмём в (32) и заменим точный фотонный пропагатор на свободный. С учётом того что $k^0 = 0$ получаем:

$$\varphi(\mathbf{k}) = \varphi_0(\mathbf{k}) + \mathcal{P}\left(-\mathbf{k}^2\right)\varphi_0(\mathbf{k}).$$

Отсюда видно, что возмущение потенциала есть

$$\delta\varphi(\mathbf{k}) = \frac{4\pi e_1}{\mathbf{k}^2}\mathcal{P}\left(-\mathbf{k}^2\right) = \frac{4\pi e_1}{y^2}\mathcal{P}\left(-y^2\right) \equiv \delta\varphi\left(-y^2\right)$$

(дальше преобразование интеграла, которое додумаю потом)

1.4.3 Coupling of Light to Matter

Theory

• While naively we can write down any Lorentz-invariant interaction term involving A_μ, we must be careful to maintain decoupling of the negative-norm and zero-norm states. By the Feynman rules, a scattering amplitude involving an external photon of momentum k and polarization $\zeta_\mu(k)$ has the form

$$\mathcal{M} = \zeta_\mu(k)\mathcal{M}^\mu$$

Note that by the Feynman rules, $\mathcal{M}^\mu$ depends on k but not on ζ.

The Ward identity:

$$k_\mu\mathcal{M}^\mu. = 0$$

It ensures the amplitude to produce a photon with $\zeta_\mu(k) \propto k_\mu$ is zero, which means the zero-norm states decouple as desired. We'll show later that the Ward identity implies that all unphysical polarizations decouple. (?????)

• Suppose the coupling to matter takes the form $A_\mu j^\mu$. The classical equation of motion is

$$\partial_\mu F^{\mu\nu} = j^\nu$$

which implies that $\partial_\mu j^\mu = 0$, so j^μ must be a conserved current. Heuristically, at the quantum level, since j^μ creates photons we have

$$M^\mu(k) \sim \int dx e^{ikx} \langle f | j^\mu(x) | i \rangle$$

so the Ward identity follows from conservation of the current j^μ.

• More generally, it can be shown that j^μ must be the conserved current arising from a global $U(1)$ symmetry of the action. To maintain gauge invariance, this symmetry must be gauged.

We will justify these statements more carefully later; now we turn to some examples. Note that different sources will differ on the sign of e below.

• First, consider coupling to Dirac fermions. We have a global $U(1)$ symmetry from phase rotation $\psi(x) \to e^{-ie\alpha}\psi(x)$, where we have introduced a dimensionless coupling constant e, which yields the conserved current $j^\mu = e\bar{\psi}\gamma^\mu\psi$.

• The interaction term can be written neatly with the covariant derivative,

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \bar{\psi}(i\not{D} - m)\psi, \qquad D_\mu\psi := \partial_\mu\psi + ieA_\mu\psi$$

We gauge the global symmetry to

$$A_\mu \to A_\mu + \partial_\mu\alpha, \quad \psi \to e^{-ie\alpha}\psi$$

where α is a general function of x. Then the action is gauge-invariant because

$$D_\mu\psi \to \partial_\mu\left(e^{-ie\alpha}\psi\right) + ie\left(A_\mu + \partial_\mu\alpha\right)\left(e^{-ie\alpha}\psi\right) = e^{-ie\alpha}D_\mu\psi$$

• Given the coupling $A_\mu j^\mu$, the component j^0 can be interpreted as electric charge. Tracing back to our earlier results, this shows that particles and antiparticles have charge $\pm e$. One can also show that charge conjugation turns e to $-e$, as expected.

• Note that a gauge transformation with constant parameter is just the same as a global transformation, which does not take us to the same physical state; this must be true because we can infer a conservation law from the global symmetry. Only gauge transformations where the parameter goes to zero at infinity are 'true' gauge transformations.

• Next, we turn to scalar fields. A real scalar field has no suitable conserved current, so we focus on a complex scalar field φ, which has a symmetry $\varphi \to e^{-ie\alpha}\varphi$ and conserved current

$$j^\mu = ie\left(\varphi^\dagger\partial^\mu\varphi - \left(\partial^\mu\varphi^\dagger\right)\varphi\right)$$

However, the naive coupling $j^\mu A_\mu$ doesn't work, because j^μ depends on $\partial^\mu\varphi$. Then if we add the term $j^\mu A_\mu$ to the Lagrangian, the conserved quantity associated with the $U(1)$ global symmetry changes, so j^μ is no longer conserved!

• It's possible to fix this by manually adding terms, but a simpler, reliable method is 'minimal coupling', i.e. replacing partial derivatives with covariant derivatives as above. We have

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \left(D_\mu\phi\right)^\dagger D^\mu\phi - m^2\phi^\dagger\phi \qquad D_\mu\phi := \left(\partial_\mu + ieA_\mu\right)\phi,$$

$$\mathcal{L}_{\text{int}} = -\left(ie\left(\phi^\dagger\partial^\mu\phi - \left(\partial^\mu\phi^\dagger\right)\phi\right)A_\mu - e^2A_\mu A^\mu\phi^\dagger\phi\right) \equiv -j'^\mu A_\mu$$

$$\left(D_\mu D^\mu + m^2\right)\phi = 0.$$

$$j^{\prime\mu}_{U(1)\text{gl}} = ie\left(\phi^\dagger D^\mu \phi - \left(D^\mu \phi\right)^\dagger \phi\right)$$

But this final result would have been rather difficult to guess without the benefit of the covariant derivative. Also note that to lowest order in e, the coupling is $-j^\mu A_\mu$. This is a universal result for gauge theories.

1.4.4 Electron and Photon Self-Energy

(?? я хз, или тут об этом или дальше, в разделе про явления и рад. поправки???)

Electron SE

The bare propagator is the tree-level propagator:

$$S_F(x-y) = \int dp e^{-ip(x-y)} \frac{i\left(\not{p} + m_0\right)}{p^2 - m_0^2 + i\epsilon} = \int dp e^{-ip(x-y)} \frac{i}{\not{p} - m_0 + i\epsilon}$$

where m_0 - bare fermion mass, the latter notation is just suggestive, motivated by 'factoring the difference of squares'.

• We define the electron self-energy $\Sigma(\not{p})$ by the sum of 1PI diagrams,

$$A - 1\text{PI} - B \equiv -i\Sigma(p)_{AB}$$

By Dyson resummation, the full propagator is

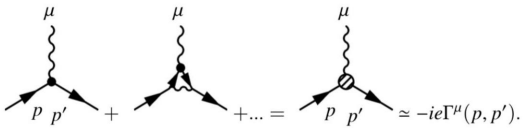
$$\int dp e^{-ip(x-y)} \frac{i}{\not{p} - m_0 - \Sigma(\not{p}) + i\epsilon}$$

and hence we call $\Sigma(\not{p})$ the self-energy of the electron. Note the self-energy has two spinor indices which contract with the spinor indices of the incoming and outgoing electron.

The full photon propagator is corrected by Dyson resummation of the 1PI contribution,

and $\Pi^{\mu\nu}\left(q^2\right)$ is called the self-energy of the photon or the vacuum polarization.

• Finally, the interaction vertex receives radiative corrections, and summing all these corrections gives the effective vertex,



We only count amputated diagrams, which in this case coincide with 1PI diagrams.

• Generally, we will find UV divergences from virtual particles with arbitrarily high momenta; they must be tamed by regularization. There are also IR divergences for loops with photons; these cancel against IR divergences from the radiation of soft photons.

Note. One strange feature of Dyson resummation is that it involves summing over diagrams of all orders, even though we only calculate the 1PI diagrams (and most other things) to a fixed order. For instance, if we calculate the sum of 1PI diagrams up to $O(e^2)$, then the Dyson sum includes additional contributions of $O(e^4)$ and higher. But this extra accuracy seems pointless, because there are also 1PI diagrams of $O(e^4)$ we're neglecting!

The real point is that in processes where the intermediate propagator is nearly on-shell, the higherorder terms in the Dyson sum become important. To see this, note that $\Sigma \sim m_0$ on dimensional grounds, so each term in the Dyson series is suppressed relative to the last by a factor

$$\Sigma\left(p^2\right) D_F^0\left(p^2\right) \sim \frac{e^2 m_0}{\not{p} - m_0} \sim \frac{e^2 m_0^2}{p^2 - m_0^2}$$

This ratio can be large when $p^2 - m_0^2$ is small enough, in which case the entire Dyson series has to be summed to get an accurate answer, even at $O(e^2)$. That is, in some situations we must sum over diagrams of all orders merely to ensure accuracy at a fixed order.

We need to perform Dyson resummation for the photon propagator for a similar reason. For processes with low-energy photons, the full Dyson series needs to be summed to get an accurate result, and the result is the "running coupling" where the effective strength of the electromagnetic interaction varies with energy, as described below. A more obscure example of this phenomenon occurs when two nonrelativistic charged particles scatter. The propagator for photon exchange in the t-channel can be very large, since $1/t \sim 1/v^2$. In this case, all the "ladder" diagrams involving n photon exchanges are comparable in size, and must be summed to get an accurate result. The result is a complex structure with resonant peaks corresponding to the bound states of the particles, which matches what one finds using the nonrelativistic Schrodinger equation. These kinds of calculations are not covered in standard introductory textbooks, but can be found in Quantum Electrodynamics by Berestetskii, Lifshitz, and Pitaevskii.

Calculation of the one-loop electron self-energy.

The one-loop contribution is due to emission and absorption of a virtual photon:

$$-i\Sigma_2(\not{p}) = (-ie)^2 \int dk \frac{\gamma^\mu \left(i\left(\not{K} + m_0\right)\right) \gamma_\mu (-i)}{\left(k^2 - m_0^2 + i\epsilon\right)\left((p-k)^2 - \mu^2 + i\epsilon\right)}$$

Feynman rules, Feynman gauge, μ - small photon mass.

(!!! проверю этот вывод, добавлю тут тоже диаграмму!)

$$i\Sigma_2(\not{p}) = e^2 \int_0^1 dx \int d\ell \frac{\gamma^\mu \left(\not{K} + m_0\right) \gamma_\mu}{\left(\ell^2 - \Delta + i\epsilon\right)^2}, \qquad \begin{array}{l} \ell := k - xp, \\ \Delta := -x(1-x)p^2 + x\mu^2 + (1-x)m_0^2 \end{array}$$

$d\ell^0$ integral above can be viewed as a contour integral, with poles in the second and fourth quadrants. We can rotate the contour to go along the positive imaginary axis.

$\ell^0 = i\ell_E^0$,

$$\int \frac{d\ell}{\left(\ell^2 - \Delta + i\epsilon\right)^m} = i(-1)^m \int \frac{d\ell_E}{\left(\ell_E^2 + \Delta - i\epsilon\right)^m}, \quad \ell_E^2 = \left(\ell_E^0\right)^2 + \boldsymbol{\ell} \cdot \boldsymbol{\ell}$$

where the sign flip occurs because the metric for (ℓ_E^0, ℓ) is negative definite. Finally, we drop the $i\epsilon$ and regard the integral as an integral in real Euclidean space $\mathbb{R}^4$.

• In our case, we would like to evaluate the UV-divergent integral

$$I_4 = \int \frac{d\ell_E}{\left(\ell_E^2 + \Delta\right)^2}$$

The simplest method is a hard UV cutoff at $r = \Lambda$, which gives $I_4 \sim \log\left(\Lambda^2/\Delta\right)$, which is a log-divergence. However, this method breaks gauge invariance, since a gauge transformation can introduce arbitrarily high Fourier modes.

We instead regulate the integral with dimensional regularization (DR), using $d = 4 - \epsilon$ dimensions. For the angular part, note that We now set $d = 4 - \epsilon$ and taking the limit $\epsilon \to 0$. The dimensions of I_d depend on d, so we introduce a compensating mass scale $\widetilde{M}$, giving

$$I_4 = \lim_{\epsilon\to 0} \frac{1}{(4\pi)^2}\left(\frac{2}{\epsilon} + \log\frac{M^2}{\Delta} + O(\epsilon)\right), \quad M^2 = 4\pi e^{-\gamma}\widetilde{M}^2$$

Simplifying the numerator with spinor identities gives

$$\Sigma_2(\not{p}) = \lim_{\epsilon\to 0} \frac{\alpha}{2\pi}\int_0^1 dx\,((2-\epsilon/2)m_0 - (1-\epsilon/2)x\not{p})\left(\frac{2}{\epsilon} + \log\frac{M^2}{\Delta}\right)$$

The same result can be carried out in Pauli-Villars regularization, where we subtract off a loop diagram containing a fictitious massive particle of mass Λ in place of the photon. This is a better approach than the hard-cutoff, and introducing an arbitrary mass scale M gives

$$\Sigma_2(\not{p}) = \lim_{\Lambda\to\infty} \frac{\alpha}{2\pi}\int_0^1 dx\,(2m_0 - x\not{p})\left(\log\frac{x\Lambda^2}{M^2} + \log\frac{M^2}{\Delta}\right)$$

The momentum-dependent terms are the same, while the log-divergence matches with that seen with the hard cutoff, and translates to a $1/\epsilon$ pole in DR.

Spectral representation

To understand the consequences of the self-energy, we recall the spectral representation.

• Applying the spectral representation, we have

$$\frac{i}{\not{p} - m_0 - \Sigma(\not{p})} = \frac{iZ_2}{\not{p} - m} + \text{ terms analytic at } m$$

The physical mass m is the location of the lowest-lying pole, and hence satisfies

$$\not{p} - m_0 - \Sigma(\not{p})\big|_{\not{p}=m} = 0$$

We can extract the residue Z_2 by differentiating with respect to $\not{p}$ here, giving

$$Z_2^{-1} = 1 - \left.\frac{d\Sigma(\not{p})}{d\not{p}}\right|_{\not{p}=m}$$

In both equations above, the equality $\not{p} = m$ looks rather strange, though it's straightforward to use. It is a valid shortcut for a more correct procedure, as justified here.

• Since we are working to lowest order in α, the mass shift is

$$\delta m = m - m_0 = \Sigma_2 \left(\not{p} = m_0\right) + O\left(\alpha^2\right)$$

where we evaluated Σ_2 at m_0 rather than m since the resulting error is second-order.

• We need to interpret the fact that the correction δm is divergent. The parameter m is physical, while m_0 can never be measured directly. Hence we interpret our mass renormalization as a definition of m_0 in terms of m in terms of the regularization parameters (e.g. ϵ and M). As the regularization is removed, m_0 diverges, but this is acceptable since it is not physical. The cost of this interpretation is that m is now an input rather than an output of the theory.

Note. In classical electrodynamics, the UV divergence of the mass is even worse, as

$$\delta m \sim \int d\mathbf{x} E^2 \sim \alpha \int \frac{r^2 dr}{r^4} \sim \alpha\Lambda$$

The reason the divergence is less strong in quantum electrodynamics is that when $m_0 = 0$, the electron separates into two uncoupled Weyl spinors, which must remain massless. Then assuming δm is analytic in m_0, the leading term is linear in m_0, and for that term the dependence on Λ must be logarithmic; indeed, we have $\delta m \sim m_0 \log\left(\Lambda^2/m_0^2\right)$.

Photon Self-Energy

By Lorentz invariance, its tensorial structure can only depend on $\eta^{\mu\nu}$ and $q^\mu q^\nu$. By the Ward identity, the photon self-energy is also transverse, $q^\mu \Pi_{\mu\nu}(q) = 0$. (Note that this does not imply the photon propagator is transverse; instead, this depends on the gauge.) Therefore, the relative magnitude of the two terms is fixed, as

$$i\Pi^{\mu\nu}(q) = \left(\eta^{\mu\nu} - \frac{q^\mu q^\nu}{q^2}\right) f\left(q^2\right)$$

Heuristically, $i\Pi^{\mu\nu}(q)$ is regular at $q^2 = 0$ because poles can only come from single-particle massless intermediate states. (This is a bit too quick; there are subtleties here, but they don't apply to QED in four dimensions.)

• Therefore, we can pull out a q^2 factor from $f\left(q^2\right)$ to give

$$i\Pi^{\mu\nu}(q) = \left(q^2\eta^{\mu\nu} - q^\mu q^\nu\right)\Pi\left(q^2\right)$$

with $\Pi\left(q^2\right)$ also regular at $q^2 = 0$. Note that when we talk about regularity, we always imagine a UV cutoff, since $\Pi^{\mu\nu}(q)$ is UV divergent.

• As a result, when we apply Dyson resummation, only the transverse part of the propagator is affected. In general R_ξ gauge, the exact propagator is

$$\begin{aligned}\Delta_{\mu\nu}(q) &= \Delta^0_{\mu\nu}(q) + \Delta^0_{\mu\rho}(q)\Pi^{\rho\sigma}(q)\Delta^0_{\sigma\nu}(q) + \ldots \\ &= \frac{-i}{q^2\left(1 - \Pi\left(q^2\right)\right)}\left(\eta_{\mu\nu} - \frac{q_\mu q_\nu}{q^2}\right) + \underbrace{\xi\frac{-i}{q^2}\frac{q_\mu q_\nu}{q^2}}_{\approx 0 \text{ Landau gauge} \xi = 0}\end{aligned}$$

We see the photon remains massless, since $\Pi\left(q^2\right)$ is regular at $q = 0$, and

$$Z_3 = \frac{1}{1 - \Pi(0)}$$

• Explicitly, one can show that at one-loop, under DR,

$$\Pi_2\left(q^2\right) = -\frac{2\alpha}{\pi}\lim_{\epsilon\to 0}\int_0^1 dx x(1-x)\left(\frac{2}{\epsilon}+\log\frac{M^2}{\Delta}\right), \quad \Delta = m_0^2 - x(1-x)q^2$$

If we had instead used a hard cutoff, we would have found a correction to $\Pi_2^{\mu\nu}(q)$ proportional to $\eta^{\mu\nu}$, violating the Ward identity. Path integral formulation tells us that such anomalous symmetries occur because the path integral measure is not invariant under the classical symmetry.

Running coupling

The photon field renormalization leads to a running coupling.

• Consider electron-electron scattering by an intermediate photon of momentum q. Then the amplitude is proportional to

$$\frac{\left(-ie_0\right)^2}{1-\Pi\left(q^2\right)}$$

this motivates to define the effective coupling

$$e\left(q^2\right) = \frac{e_0}{\sqrt{1-\Pi\left(q^2\right)}}$$

Note that there are other processes that contribute, e.g. by the exchange of two photons. However, to 'lowest order' this is a good estimate of the total scattering amplitude.

• As with the electron mass, $\Pi\left(q^2\right)$ is divergent, so we define the physical/renormalized coupling

$$e = \frac{e_0}{\sqrt{1-\Pi(0)}} = e_0\sqrt{Z_3}$$

As before, we then flip this around and regard it as an expression for the divergent bare quantity e_0 in terms of the physical quantity e. Therefore, the effective coupling and physical coupling are related at one-loop order by

$$e^2\left(q^2\right) = \frac{1-\Pi_2(0)}{1-\Pi_2\left(q^2\right)}e^2 + O\left(\alpha^2\right) = \frac{e^2}{1-\widehat{\Pi}_2\left(q^2\right)} + O\left(\alpha^2\right)$$

$$\widehat{\Pi}_2\left(q^2\right) := \Pi_2\left(q^2\right) - \Pi_2(0) = -\frac{2\alpha}{\pi}\int_0^1 dx x(1-x)\log\frac{m^2}{m^2 - x(1-x)q^2}$$

where we replaced m_0 with m, which is accurate up to $O\left(\alpha^2\right)$ terms. Physically, this result tells us that the interaction between electrons gets stronger at high energies; note that the unphysical renormalization scale M has dropped out.

• The e that appears in Coulomb's law, which corresponds to the typical quoted value $\alpha \approx 1/137$, applies at very low energies. At energies $q^2 \sim m_W^2$, we instead have $\alpha \approx 1/128$.

Note. Heuristically, the vertex renormalization is really what renormalizes the charge e, if we think of e as the coefficient of the vertex factor. But as we'll see below, this effect is exactly canceled by the renormalization of the electron field Z_2. The effect we've computed above is really a renormalization of the electromagnetic field, but since its effects always appear in tandem with an electron-field interaction, it can be thought of as renormalizing the charge.

Interpreting the running coupling.

In the nonrelativistic limit, the potential is

$$V(\mathbf{q}) = -\frac{e^2}{|\mathbf{q}|^2\left(1-\hat{\Pi}_2\left(-|\mathbf{q}|^2\right)\right)}$$

and the real-space potential is found by Fourier transform. Taking the inverse Fourier transform is tricky, since for high $|\mathbf{q}|$ the $\hat{\Pi}_2$ factor provides a branch cut; doing this yields the Uehling potential.

High and low limit

Alternatively, for low $|\mathbf{q}|$ we can simply expand $\hat{\Pi}_2$ in a Taylor series. The zeroth order term slightly modifies e, while the $|\mathbf{q}|^2$ term contributes a constant to $V(\mathbf{q})$ and hence a delta function to the potential. This slightly lowers the energy of the $2s$ state in hydrogen relative to the $2p$ state, producing the Lamb shift.

In the opposite limit, we consider a high-energy scattering where the photon is in the t-channel or u-channel, so $-q^2 \gg m^2$. Then

$$\alpha_{\text{eff}}\left(q^2\right) = \frac{e^2\left(q^2\right)}{4\pi} \approx \alpha\left(1-\frac{\alpha}{3\pi}\log\frac{-q^2}{\exp(5/3)m^2}\right)^{-1}$$

by straightforward calculation. This diverges for very high energies at the Landau pole of QED.

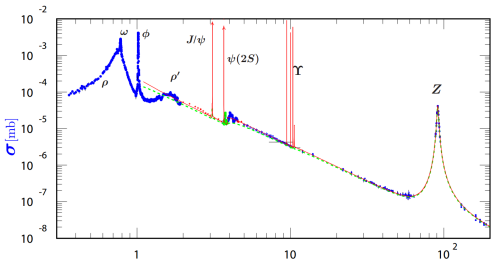
1.5 Main QFT processes and experiments

(по большей части тут КЭД. просто нет такого прямо на него ограничения, ибо часто какая-то частица вне КЭД появялется.)

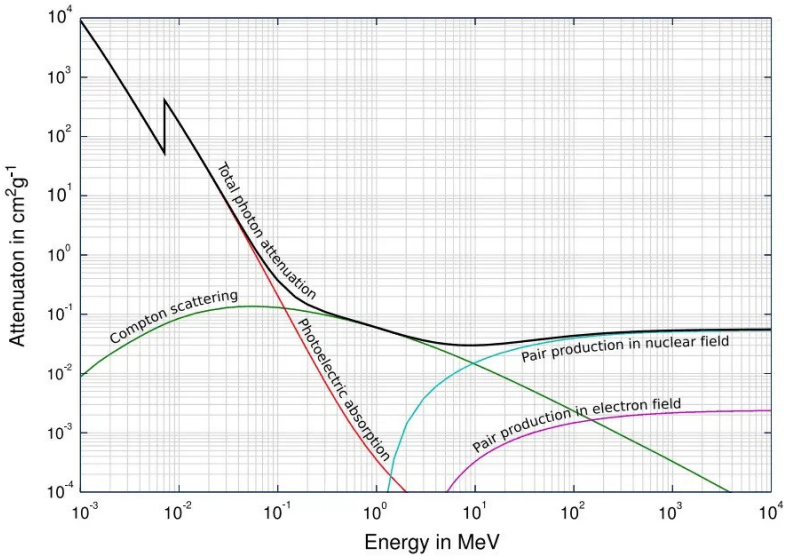
1.5.1 Overview of QFT processes and their comparison (???)

(!!! допишу обзор процессов, которые вообще мы решать будем!!! пока нужно додумать их, что вообще там происходит и какие графики вообще имеются! допишу абзацы с пояснениями каждого графика и словами указаниями про вывод!)

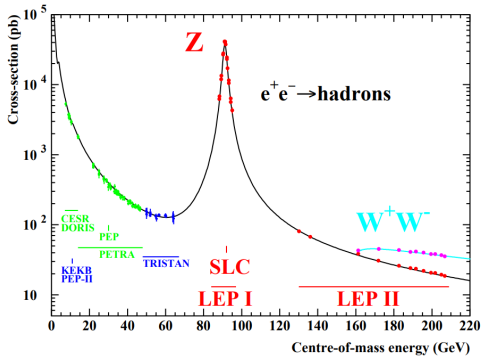
Электрон-позитронное рассеяние имеет сечение:



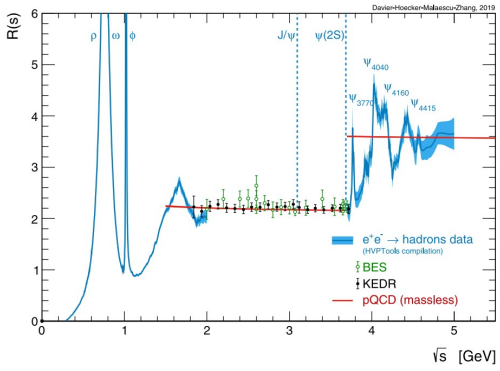
total photon attenuation:

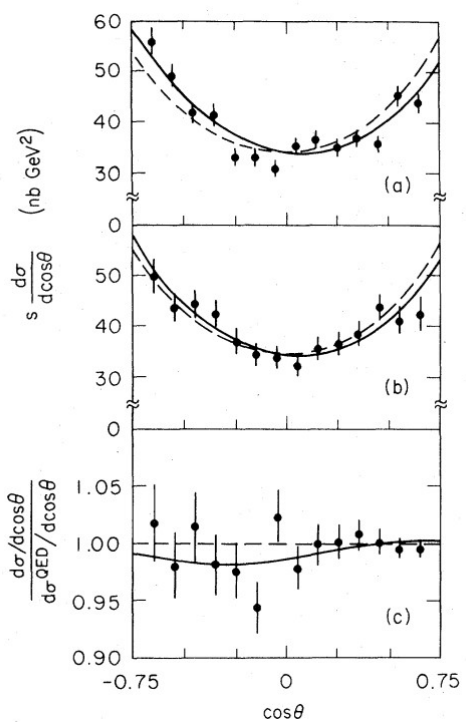


e+e-hadrons



el-el-scatt





The differential cross sections for (a) Reaction (2) and (b) Reaction (3), normalized to the QED prediction. (c) The ratio of the differential cross section for Reaction (1) to the $O(\alpha^3)$ QED prediction. The experimental cross section in (c) is normalized to the electroweak cross section taken from a simultaneous fit to all three reactions. In (a) - (c) the dashed line corresponds to the $O(\alpha^3)$ QED cross section and the solid line to the fitted cross section.

$$e^+e^- \to e^+e^- \qquad (1)$$

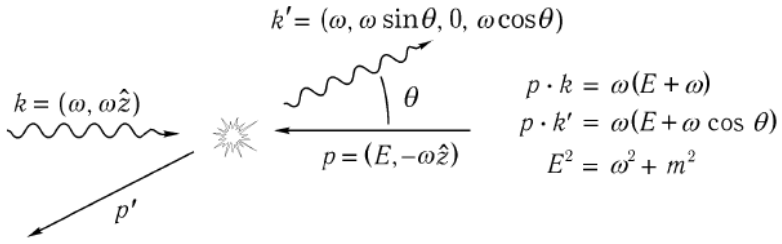
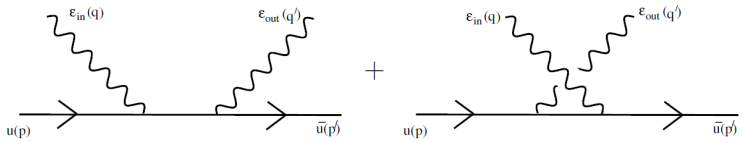
1.5.2 Typical scatterings, decays in QED

Compton Scattering $\gamma e^- \to \gamma e^-$



$$i\mathscr{M} = -ie^2\varepsilon_\mu^*(k')\,\varepsilon_\nu(k)\bar{u}(p')\left[\frac{\gamma^\mu k\gamma^\nu + 2\gamma^\mu p^\nu}{2p\cdot k} + \frac{-\gamma^\nu \not{k}'\gamma^\mu + 2\gamma^\nu p^\mu}{-2p\cdot k'}\right]u(p)$$

где векторы поляризации начального и конечного фотонов $\varepsilon_\nu(k)$ и $\varepsilon_\mu^*(k')$, а также были произведены некоторые преобразования (??? потом допишу).



$$= i(-ie)^2\bar{u}^{r'}(\vec{p}')\left(\frac{\gamma_\mu(\not{p}+\not{q}+m)\gamma_\nu}{(p+q)^2-m^2} + \frac{\gamma_\nu(\not{p}-\not{q}'+m)\gamma_\mu}{(p-q')^2-m^2}\right)u^s(\vec{p})\,\epsilon_{\text{in}}^\nu\,\epsilon_{\text{out}}^\mu$$

(тут связь с простейшим описанием из квантфиза (??))

еще раз прочитаю ЛЛ-86. Рассеяние фотона электроном, там точно ничего нового???

Сохранение 4-импульса при рассеянии фотона свободным электроном (эффект Комптона) выражается равенством

$$p + k = p' + k'$$

где p и k – 4-импульсы электрона и фотона до столкновения, а p' и k' - их 4-импульсы после столкновения.

$$s = (p+k)^2 = (p'+k')^2 = m^2 + 2pk = m^2 + 2p'k',$$
$$t = (p-p')^2 = (k'-k)^2 = 2\left(m^2 - pp'\right) = -2kk',$$
$$u = (p-k')^2 = (p'-k)^2 = m^2 - 2pk' = m^2 - 2p'k,$$
$$s + t + u = 2m^2.$$

Рассматриваемый процесс изображается двумя диаграммами Фейнмана (74, 14), и его амплитуда

$$M_{fl} = -4\pi e^2 e_\mu'^* e_v\left(\bar{u}'Q^{\mu v}u\right),$$

$$Q^{\mu\nu} = \frac{1}{s-m^2}\gamma^\mu(\gamma p + \gamma k + m)\gamma^\nu + \frac{1}{u-m^2}\gamma^\nu\left(\gamma p - \gamma k' + m\right)\gamma^\mu.$$

$$d\sigma = \frac{\pi e^4}{4}\frac{dt}{\left(s-m^2\right)^2}\,\mathrm{Sp}\left\{(\gamma p'+m)\,Q^{\lambda\mu}(\gamma p+m)\bar{Q}_{\lambda\mu}\right\}$$

$$g(s,u) = \frac{2m^2}{(s-m^2)\,(u-m^2)}\left\{4m^2+\left(s-m^2\right)+\left(u-m^2\right)\right\}.$$

$$d\sigma = 8\pi r_e^2\frac{m^2dt}{\left(s-m^2\right)^2}\left\{\left(\frac{m^2}{s-m^2}+\frac{m^2}{u-m^2}\right)^2+\left(\frac{m^2}{s-m^2}+\frac{m^2}{u-m^2}\right)-\frac{1}{4}\left(\frac{s-m^2}{u-m^2}+\frac{u-m^2}{s-m^2}\right)\right\}.$$

где $r_e = e^2/m$.

(вывод потом понимать буду)

$$d\sigma = \frac{r_e^2}{2}\left(\frac{\omega'}{\omega}\right)^2\left(\frac{\omega}{\omega'}+\frac{\omega'}{\omega}-\sin^2\vartheta\right)do'$$

Наибольший член в сечении $(86,6)$

$$d\sigma \approx 8\pi r_e^2\frac{m^2dt}{4\,(s-m^2)\,(m^2-u)},$$

откуда

$$d\sigma = \frac{r_B^2}{2}\frac{do'}{1+(\pi-\theta)^2\omega^2/m^2}.$$

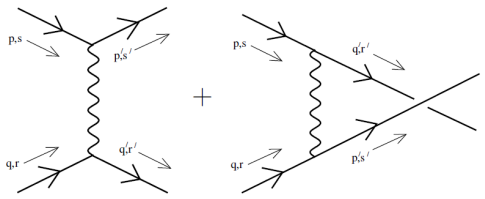
Сечение $d\sigma/do' \sim r_e^2$ в узком конусе $\pi-\theta \leqslant m/\omega$, а вне его уменьшается по порядку величины в ω^2/m^2 раз.

(write that in nonrel limit we get the Thompson cross section, ...)

Electron-electron $e^- + e^- \to e^- + e^-$ scattering (Moller scattering)

Main results

(решу еще раз, потом суть выпишу)



$$= -i(-ie)^2\left(\frac{[\bar{u}^{s'}(\vec{p}')\gamma^\mu u^s(\vec{p})]\,[\bar{u}^{r'}(\vec{q}')\gamma_\mu u^r(\vec{q})]}{(p'-p)^2}-\frac{[\bar{u}^{s'}(\vec{p}')\gamma^\mu u^r(\vec{q})]\,[\bar{u}^{r'}(\vec{q}')\gamma_\mu u^s(\vec{p})]}{(p-q')^2}\right)$$

$$S^{(2)}\left(2e^-\to 2e^-\right) = \frac{-e^2}{2!}\int \mathrm{d}^4x_1\;\mathrm{d}^4x_2\;\mathrm{N}\left[\left(\bar{\psi}^-\gamma^\alpha\psi^+\right)_{x_1}\left(\bar{\psi}^-\gamma^\beta\psi^+\right)_{x_2}\right]\mathrm{i}D_{\mathrm{F}\alpha\beta}\left(x_1-x_2\right).$$

$$|i\rangle = c^\dagger(2)c^\dagger(1)|0\rangle \qquad \to \qquad |f\rangle = c^\dagger\left(2'\right)c^\dagger\left(1'\right)|0\rangle$$

In order to obtain explicit expressions for these two contributions, let

$$\psi_j^+(x) = c(j) f_j(x), \quad \bar{\psi}_j^-(x) = c^\dagger(j) g_j(x)$$

be the parts of the operators $\psi^+(x)$ and $\bar{\psi}^-(x)$ proportional to $\mathrm{c}(j)$ and $\mathrm{c}^\dagger(j)$ respectively. $j = 1, 2, 1', 2'$ labels the electron states involved in the process. The part of the S-matrix operator (7.14) which effects the transition $|i\rangle \to |f\rangle$, Eq. (7.15), is then given by

$$S^{(2)}_{(e^-(1)+e^-(2)\to e^-(1')+e^-(2'))} = S_\mathrm{a} + S_\mathrm{b}$$

$$S_\mathrm{a} = -e^2 \int \mathrm{d}^4x_1\ \mathrm{d}^4x_2\ \mathrm{N}\left[\left(\bar{\psi}^-_{1'}\gamma^\alpha\psi^+_1\right)_{x_1}\left(\bar{\psi}^-_{2'}\gamma^\beta\psi^+_2\right)_{x_2}\right] \mathrm{i}D_{\mathrm{F}\alpha\beta}\left(x_1 - x_2\right)$$

$$S_\mathrm{b} = -e^2 \int \mathrm{d}^4x_1\ \mathrm{d}^4x_2\ \mathrm{N}\left[\left(\bar{\psi}^-_{2'}\gamma^\alpha\psi^+_1\right)_{x_1}\left(\bar{\psi}^-_{1'}\gamma^\beta\psi^+_2\right)_{x_2}\right] \mathrm{i}D_{\mathrm{F}\alpha\beta}\left(x_1 - x_2\right).$$

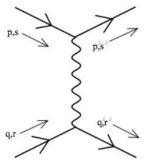
$$\begin{aligned}
p_1 \cdot p_2 = p_1' \cdot p_2' &\approx 2E^2, \\
p_1 \cdot p_2' = p_1' \cdot p_2 &\approx 2E^2 \cos^2(\theta/2), \\
p_1 \cdot p_1' = p_2' \cdot p_2 &\approx 2E^2 \sin^2(\theta/2), \\
\left(p_1' - p_1\right)^2 &\approx -2p_1 \cdot p_1' = -4E^2 \sin^2(\theta/2), \\
\left(p_2' - p_1\right)^2 &\approx -2p_1 \cdot p_2' = -4E^2 \cos^2(\theta/2).
\end{aligned}$$

$$\begin{aligned}
\frac{d\bar{\sigma}}{d\Omega} &= \frac{e^4m^4}{8(2\pi)^2} \int \frac{E^2 dE}{E^4\beta} \left|\mathcal{M}_{fi}\right|^2 \delta\left(E_1' + E_2' - E_1 - E_2\right) \\
&= \frac{\alpha^2}{8E^2}\left[\frac{1+\cos^4(\theta/2)}{\sin^4(\theta/2)} + \frac{2}{\sin^2(\theta/2)\cos^2(\theta/2)} + \frac{1+\sin^4(\theta/2)}{\cos^4(\theta/2)}\right].
\end{aligned}$$

(а дальше я не понял, у Мандл Шаула какой-то текст, а итоговый ответ я так и не вижу, так что потом почитаю это.)

Recovering the Coulomb potential.

• First, consider electron-electron scattering, with the following amplitude.



$$= -i(-ie)^2 \frac{[\bar{u}(\vec{p}')\gamma^\mu u(\vec{p})]\,[\bar{u}(\vec{q}')\gamma_\mu u(\vec{q})]}{(p'-p)^2}$$

• In the nonrelativistic limit, the spinors become $u(p) \to \sqrt{m}(\xi, \xi)^T$. Then the only term in the spinor contractions that contributes is $\mu = 0$ (which means the interaction is mediated by a timelike photon) giving a numerator of $(2m)^2$, canceling the relativistic normalization.

• Working in the center-of-mass frame, the process is elastic, so the denominator gives a factor of $-(\Delta\mathbf{p})^2$ where $\Delta\mathbf{p}$ is the momentum transfer. The nonrelativistic amplitude for scattering is $\mathcal{M} \sim -i\widetilde{U}(\Delta\mathbf{p})$ by the Born approximation, giving

$$U(\mathbf{p}) = \frac{e^2}{p^2}$$

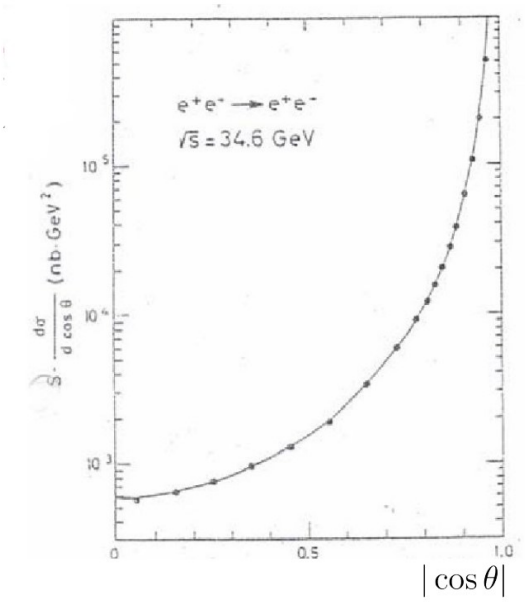
which is a repulsive Coulomb potential.

Electron-Positron $e^- + e^+ \to e^- + e^+$ Scattering (Bhabha Scattering)

Main results

Perfect agreement with QED, first order computation:

$$\frac{d\sigma}{d\Omega} = \frac{\alpha}{2s}\left(\frac{3+\cos^2\theta}{1-\cos\theta}\right)^2$$

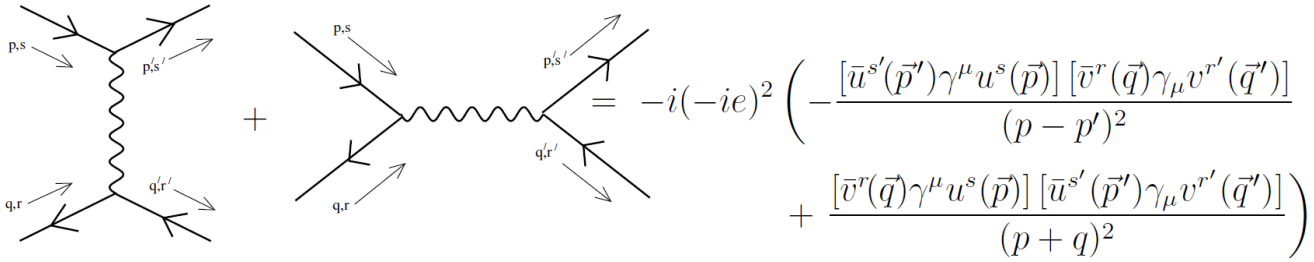


divergent for $\cos\theta \to 1$
Additional „heavy photon“:

$$\frac{1}{q^2} \to \frac{1}{q^2}\left(1 \mp \frac{q^2}{q^2-\Lambda_\pm^2}\right)$$

$\Rightarrow$ Can be described by form factor:

$$F\left(q^2\right) = 1 \mp \frac{q^2}{q^2-\Lambda_\pm^2}$$



(!! если другие продукты реакции - это другое)

О рассеянии электронов и позитронов нв электроне по Ландау 4 (???)

(!!! убеждусь, чтобы тут выше было четкое указание на методы, которые в этом параграфе выписываю!!! пока вроде четких указаний нет)

$$s = (p_1 + p_2)^2 = 2\left(m^2 + p_1 p_2\right),$$
$$t = (p_1 - p_1')^2 = 2\left(m^2 - p_1 p_1'\right),$$
$$u = (p_1 - p_2')^2 = 2\left(m^2 - p_1 p_2'\right),$$
$$s + t + u = 4m^2.$$

Рассматриваемый процесс изображается двумя диаграммами Фейнмана $(73, 13 - 14)$, и его амплитуда

$$M_{fl} = 4\pi e^2 \left\{ \frac{1}{t} \left(\bar{u}_2' \gamma^\mu u_2\right) \left(\bar{u}_1' \gamma_\mu u_1\right) - \frac{1}{u} \left(\bar{u}_1' \gamma^v u_2\right) \left(\bar{u}_2' \gamma_v u_1\right) \right\}.$$

Согласно указанным в ∅65 правилам для состояний начальных и конечных частиц, описывающихся полярнзационными мат рицами плотности $\rho_1, \rho_1', ...$, заменяем

$$|M_{fi}|^2 \to 16\pi^2 e^4 \{ \frac{1}{t^2} \operatorname{Sp}\left(\rho_2' \gamma^\mu \rho_2 \gamma^v\right) \operatorname{Sp}\left(\rho_1' \gamma_\mu \rho_1 \gamma_v\right) +$$
$$+ \frac{1}{u^2} \operatorname{Sp}\left(\rho_1' \gamma^\mu \rho_2 \gamma^v\right) \operatorname{Sp}\left(\rho_2' \gamma_\mu \rho_1 \gamma_v\right) -$$
$$- \frac{1}{tu} \operatorname{Sp}\left(\rho_2' \gamma^\mu \rho_2 \gamma^v \rho_1' \gamma_\mu \rho_1 \gamma_v\right) - \frac{1}{tu} \operatorname{Sp}\left(\rho_1' \gamma^\mu \rho_2 \gamma^v \rho_2' \gamma_\mu \rho_1 \gamma_v\right) \Big\}.$$

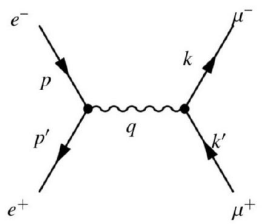
(??? результат????)

Attraction of electron and positron

• Next, we consider electron-positron scattering. In this case, we pick up a sign flip from fermionic statistics, as in Yukawa theory. In Yukawa theory, there was an second sign flip since $\bar{v}v \to -2m$, but here we instead have $\bar{v}\gamma^0 v \to 2m$. Then all the logic above goes through as before, and the result is an attractive Coulomb potential.

• Thus, we have shown that while forces mediated by spin-0 particles are universally attractive, forces mediated by spin-1 particles are not. One might say the sign flip really comes from the negative norm of the timelike photon.

Electron to muon scattering $e^+e^- \to \mu^+\mu^-$



We set the initial spin polarizations to s and s' and the final polarizations to r and r'.

$$i\mathcal{M}\left(s, s', r, r'\right) = \frac{ie^2}{q^2} \left(\bar{v}_{s'}\left(p'\right) \gamma^\mu u_s(p)\right) \left(\bar{u}_r(k) \gamma_\mu v_{r'}\left(k'\right)\right), \quad q = p + p' = k + k'$$

Often, the initial state is unpolarized, and the detector cannot measure the polarization, then

$$|\mathcal{M}|^2_{\text{tot}} = \frac{1}{2}\sum_s \frac{1}{2}\sum_{s',r,r'} |\mathcal{M}(s,s',r,r')|^2$$

Using the identities $(\gamma^0)^\dagger = \gamma^0$ and $\gamma^0\gamma^\mu\gamma^0 = (\gamma^\mu)^\dagger$, we have

$$(\bar{v}_{s'}\gamma^\mu u_s)^* = \bar{u}_s\gamma^\mu v_{s'}$$

A similar rule holds in general: the gamma matrices just reverse in order, and there's an additional sign flip for every factor of γ^5 since $\gamma^0\gamma^5\gamma^0 = -\gamma^5 = (-\gamma^5)^\dagger$. For example, $(\bar{v}_{s'}\gamma^\mu\gamma^\nu\gamma^\rho u_s)^* = \bar{u}_s\gamma^\rho\gamma^\nu\gamma^\mu v_{s'}$.

In our current case, the total squared amplitude has two factors,

$$|\mathcal{M}|^2_{\text{tot}} = \frac{1}{4}\frac{e^4}{q^4}\sum_{ss'rr'} (\bar{u}_s\gamma^\mu v_{s'}\bar{v}_{s'}\gamma^\nu u_s)(\bar{v}_{r'}\gamma_\mu u_r\bar{u}_r\gamma_\nu v_{r'})$$

where we suppress momentum arguments. After the completeness relations $\sum_s u_s(p)\bar{u}_s(p) = \not{p} + m_e$, $\sum_s v_s(p)\bar{v}_s(p) = \not{p} - m_\mu$

$$|\mathcal{M}|^2_{\text{tot}} = \frac{1}{4}\frac{e^4}{q^4}\operatorname{tr}\left((\not{p}+m_e)\gamma^\mu(\not{p}''-m_e)\gamma^\nu\right)\operatorname{tr}\left((\not{k}''-m_\mu)\gamma_\mu(\not{k}+m_\mu)\gamma_\nu\right)$$

More generally, we will have multiple diagrams that contribute, so the squared amplitude will have cross-terms.

• Sometimes it's useful to rearrange things using the Clifford algebra, $\not{p}\not{q} = 2p\cdot q - \not{q}\not{p}$.

Note that the γ^5 identities use the convention $\epsilon^{0123} = 1$, $\epsilon_{0123} = -1$. (??? они такие???)

This is the opposite of the convention in general relativity, where the volume form naturally has lowered indices, so $\epsilon_{0123} = \sqrt{|g|} > 0$.

• Applying these identities to our result and setting m_e to zero gives

$$|\mathcal{M}|^2_{\text{tot}} = \frac{8e^4}{q^4}\left((p\cdot k)(p'\cdot k') + (p'\cdot k)(p\cdot k') + (p\cdot p')m_\mu^2\right)$$

Working in the center of mass frame, let the initial energies of the particles be E, and let the outgoing muon come out at an angle θ from the incoming electron. Then

$$|\mathcal{M}|^2_{\text{tot}} = e^4\left(1 + m_\mu^2/E^2 + \left(1 - m_\mu^2/E^2\right)\cos^2\theta\right).$$

• Finally, we may substitute this into the $2\to 2$ scattering cross section and integrate for

$$\sigma = \frac{4\pi\alpha^2}{3E_{\text{cm}}}\sqrt{1+m_\mu/E}\left(1+m_\mu^2/2E^2\right), \quad \alpha = \frac{e^2}{4\pi}$$

Here, the factor in parentheses is determined by the dynamics of QED, while everything else is determined by the "kinematics", i.e. by dimensional analysis and the volume of available phase space. E.g. for $E_{\text{cm}} \gg m_\mu$ we must have $\sigma \propto 1/E_{\text{cm}}^2$ by dimensional analysis.

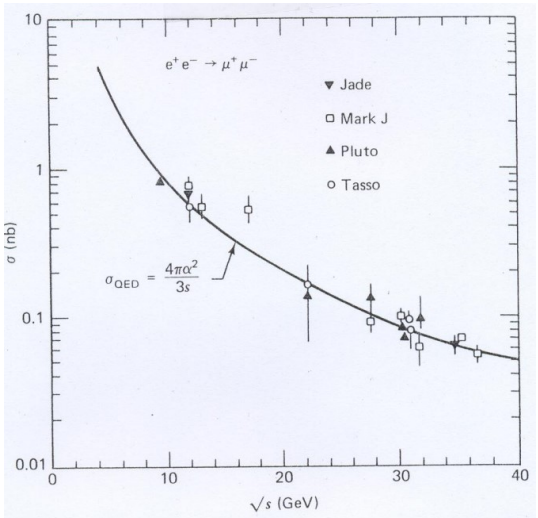


Fig. 6.6 The total cross section for $e^-e^+ \to \mu^-\mu^+$ measured at PETRA versus the center-of-mass energy.

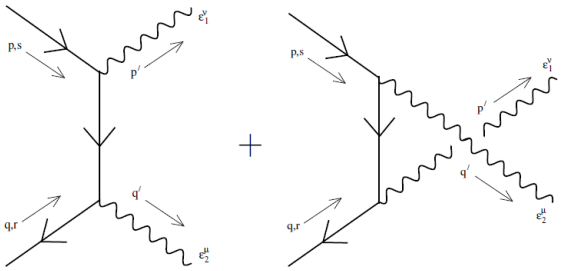
Electron positron annihilation to photons $e + e^+ \to \gamma + \gamma$



$$= i(-ie)^2\,\bar{v}^r(\vec{q})\left(\frac{\gamma_\mu(\not{p} - \not{p}' + m)\gamma_\nu}{(p-p')^2 - m^2} + \frac{\gamma_\nu(\not{p} - \not{q}' + m)\gamma_\mu}{(p-q')^2 - m^2}\right) u^s(\vec{p})\epsilon_1^\nu(\vec{p}')\epsilon_2^\mu(\vec{q}')$$

(тоже дорешаю потом, мб в теор части или задачах?)

Scattering by an External Field

(посмотрю ЛЛ4, этого должно и хватить)

О распаде мюона, (??)

(???)

Electron-positron to hadrons scattering

$$\sigma^{qq}(s) = \sigma^{qq}_{Q\in D}(s)[1 + \underbrace{\frac{\alpha_s(s)}{\pi} + 1.411\cdot\frac{\alpha_s(s)^2}{\pi^2} + ...}_{\sim 7\%}]$$

$$R_{\text{had}} = \frac{\sigma(ee \to \text{ hadrons })}{\sigma(ee \to \mu\mu)} = 3\cdot\sum_i Q_i^2$$

$\sqrt{s}$	Quarks	$R_{\text{nad}} = 3 \cdot \sum_1^1 Q_i^2$
$<\sim$ 3GeV	uds	$3.6/9 = 2.00$
$<\sim$ 10GeV	udsc	$3 \cdot 10/9 = 3.33$
$<\sim$ 350GeV	udscb	$3 \cdot 11/9 = 3.67$
$>\sim$ 350GeV	udscbt	$3.15/9 = 5.00$

Data lies systematically higher than the prediction from Quark Parton Model (QPM) $\rightarrow$ gluon bremsstrhl.

$\star$ In the centre-of-mass frame the $e^+e^- \rightarrow \mu^+\mu^-$differential cross-section is

$$\frac{d\sigma}{d\Omega} = \frac{\alpha^2}{4s}\left(1 + \cos^2\theta\right)$$

NOTE: neglected masses of the muons, i.e. assumed $E \gg m_\mu$

In QED only certain combinations of LEFT- and RIGHT-HANDED CHIRAL states give non-zero matrix elements

$\star$ CHIRAL states defined by chiral projection operators

$$P_R = \frac{1}{2}\left(1 + \gamma^5\right); \quad P_L = \frac{1}{2}\left(1 - \gamma^5\right)$$

$\star$ In limit $E \gg m$ the chiral eigenstates correspond to the HELICITY eigenstates and only certain HELICITY combinations give non-zero matrix elements

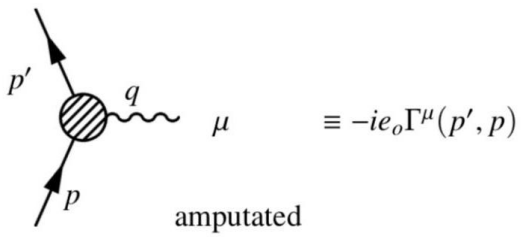
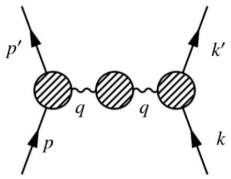
2 Most Useful Special Methods

(???)

2.1 Typical renormalizations

Typical Vertex Renormalization in QED





$$=\sim \bar{u}\left(p'\right)\left(-ie_0 Z_2 \Gamma^{\mu}(p',p)\right) u(p) \frac{-i\left(\eta_{\mu\nu}-q^{\mu}q^{\nu}/q^2\right)}{q^2\left(1-\Pi(q^2)\right)} \bar{u}\left(k'\right)\left(-ie_0 Z_2 \Gamma^{\nu}(k',k)\right) u(k)$$

The most general form possible is

$$\Gamma^{\mu} \equiv A\gamma^{\mu} + B\left(p'^{\mu}+p^{\mu}\right) + C\left(p'^{\mu}-p^{\mu}\right)$$

Since the Γ^{μ} is sandwiched between on-shell spinors, we can replace all factors of $\not{p}$ and $\not{p}''$ with m. Then the coefficients can only depend on q^2. The Ward identity requires the amplitude to vanish when Γ^{μ} is contracted with q_{μ}, setting $C=0$.

By the Gordan identity $\bar{u}\left(p'\right)\gamma^{\mu}u(p) = \bar{u}\left(p'\right)\left(\frac{p'^{\mu}+p^{\mu}}{2m} + \frac{iS^{\mu\nu}q_{\nu}}{2m}\right)u(p), \quad S^{\mu\nu} = \frac{i}{4}\left[\gamma^{\mu},\gamma^{\nu}\right]$ we arrive at the conventional form (???? why??)

$$\Gamma^{\mu}\left(p',p\right) = \gamma^{\mu}F_1\left(q^2\right) + i\frac{S^{\mu\nu}q_{\nu}}{2m_0}F_2\left(q^2\right)$$

where $F_1\left(q^2\right)$ and $F_2\left(q^2\right)$ are called form factors.

• The first form factor δF_1 is both UV and IR divergent. At one loop with PV regularization,

$$\delta F_1\left(q^2\right) = \frac{\alpha}{2\pi}\int_0^1 dxdydz\delta(x+y+z-1)\left(\log\frac{z\Lambda^2}{\Delta} + \frac{(1-x)(1-y)}{\Delta}q^2 + \left(1-4z+z^2\right)m_0^2\right)$$

$$\delta F_2\left(q^2\right) = \frac{\alpha}{2\pi}\int_0^1 dxdydz\delta(x+y+z-1)\frac{2m_0^2 z(1-z)}{\Delta} \qquad \text{(finite)},$$

$\Delta := -xyq^2 + (1-z)^2m_0^2 + \mu^2 z$, and μ is a photon mass that regulates the IR divergence.

• In the limit of small momentum transfer $q\to 0$, only F_1 contributes, so we define the vertex renormalization

$$\lim_{q\to 0}\Gamma^{\mu}(p+q,p) = Z_1^{-1}\gamma^{\mu}$$

The Ward-Takahashi identity can be used to show that $Z_1 = Z_2$, so

$$\lim_{q\to 0} Z_2\Gamma^{\mu}(p+q,p) = \gamma^{\mu}$$

and at each order in perturbation theory,

$$\delta F_1(0) = -\delta Z_2$$

• Comparing this with our scattering amplitude, the physical charge at $q=0$ is $e_0\left(Z_2/Z_1\right)\sqrt{Z_3} = e_0\sqrt{Z_3}$ as found earlier. As a physical application, this means that electrons and muons have the same bare charge if and only if they have the same physical charge.

At this point one could make a metaphysical objection: what does it mean for a "fundamental constant of nature" to be scale-dependent? Isn't the amount of charge on the electron fixed? The point is that there is no such thing as a direct measurement of the charge itself; instead we only measure how strongly the electron interacts in various situations. We've found that the effective interaction strength changes depending on the scale μ of the process, and there's nothing strange, physically or metaphysically, about that. The only reason one might think it was strange is that the dependence happens to be very weak at low μ, where most experiments historically took place. But once we frame it this way, $e(0)$ stops appearing particularly fundamental at all; the truly fundamental constants are defined at high scales.

Scalar field theory example of renormalization by Schwartz (????)

(доучу тоже, наверное, содержательный там пример)

Renormalized Perturbation Theory, loop corrections

• For a systematic treatment of UV divergent diagrams, it suffices to consider amputated, 1PI UV divergent diagrams; all other UV divergent diagrams can be built from them.

It is possible to classify the divergent 1PI diagrams by power counting. At one-loop order we found, in PV,

$$\begin{aligned}
\text{(photon)} \qquad \Pi_2\left(q^2\right) &= c_0^{(1)} \log \frac{\Lambda}{M} && + \text{finite}, \\
\text{(photon)} \qquad -i\Sigma_2(\not{p}) &= a_0^{(1)} m_0 \log \frac{\Lambda}{M} + a_1^{(1)} \not{p} \log \frac{\Lambda}{M} && + \text{finite}, \\
\text{(photon)} \qquad -i\Gamma_2^{\mu}\left(p', p\right) &= b_0^{(1)} \gamma^{\mu} \log \frac{\Lambda}{M} && + \text{finite},
\end{aligned}$$

M is the renormalization scale, Λ is the cutoff.

• Later, we will show that this structure persists to all orders in perturbation theory. Then the UV divergences are completely described by the four divergent constants a_0, a_1, b_0, and c_0, where e.g. $a_0^{(1)}$ is the $O(\alpha)$ term of a_0.

• In bare perturbation theory, we write the Lagrangian in terms of bare parameters m_0 and e_0 and impose a finite cutoff Λ, or in DR, a nonzero ϵ. We then compute the physical electron mass m, the physical coupling e, and the field renormalizations Z_2 and Z_3 in terms of m_0, e_0, and Λ. The renormalization step is to regard m_0 and e_0 as functions of m, e, and Λ, and vary them as $\Lambda \to \infty$ so that m and e remain fixed.

• Finally, we perform the usual perturbation theory, e.g. expanding in powers of e_0 with a cutoff Λ. If the preceding step has been performed correctly, then when the answers are written in terms of m and e, all divergences will cancel out of scattering amplitudes.

• In practice, we only compute $m\left(m_0, e_0, \Lambda\right)$ and $e\left(m_0, e_0, \Lambda\right)$ to some loop order in e_0. Then we must compute the scattering amplitudes to the same order in e_0.

• It might be disturbing that we are expanding in the formally divergent parameter e_0. In fact, this is acceptable because e_0 diverges only logarithmically, and the theory of QED has a reasonable cutoff so that $e_0(\Lambda)$ is still small. However, we will reformulate perturbation theory without e_0 below.

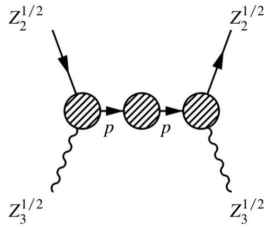
• In general, a theory is renormalizable if there are only a finite number of UV divergent resummed amputated 1PI diagrams. If there are m fields and n such diagrams, then m divergent

constants can be absorbed into field renormalizations, while $n-m$ are absorbed into bare couplings. The $n-m$ bare couplings must then be specified by measurements of physical couplings.

• Philosophically, the UV divergences signal that our theory must break down at some high scale, where some unknown physics takes over. The process of renormalization parametrizes our ignorance about this new physics into $n-m$ observables that must be measured. A renormalizable theory is one where this process only requires a finite number of experimental inputs. A truly fundamental theory must be UV finite, as string theory is believed to be.

• Finally, recall that our regularization schemes introduce an arbitrary mass scale M. The results don't depend on M, but higher-order corrections for a process with energy scale E contain factors of $\log E/M$. Then the perturbation theory converges fastest when $M \sim E$.

Example: contribution to the amplitude for Compton scattering.



$$M = \left(Z_3^{1/2} i e_0 \Gamma^\mu Z_2\right) \frac{1}{Z_2} \frac{i}{\not p - m_0 - \Sigma(\not p)} \left(Z_3^{1/2} i e_0 \Gamma_\mu Z_2\right)$$

$e = e_0 Z_3^{1/2}$ is the finite physical charge. The factor $\Gamma^\mu Z_2$ is also finite, since

$$\Gamma^\mu(p+q,p) = \gamma^\mu F_1\left(q^2\right) + \text{ finite}\,, \quad F_1\left(q^2\right) = 1 + \delta F_1(0) + \text{ finite}$$

so the divergent part of $\Gamma^\mu Z_2$ is $\delta Z_2 + \delta F_1(0) = 0$ at each order in perturbation theory. Finally, the propagator is

$$\frac{1}{Z_2} \frac{i}{\not p - m_0 - \Sigma(\not p)} = \frac{i}{\not p - m} + \frac{1}{Z_2}(\text{ finite terms analytic in } \not p = m)$$

The extra terms are finite because they come from the second and higher derivatives of $\Sigma(\not p)$, which are finite, as the divergences in $\Sigma(\not p)$ are proportional to m_0 and $\not p$.

We can also use renormalized perturbation theory, which works explicitly with physical parameters. In this formulation, the action depends on the cutoff/renormalization parameters just as before, but we split it into a finite, cutoff-independent "renormalized" piece and an infinite, cutoff-dependent "counterterm" piece.

$$\mathcal{L} = -\frac{1}{4}F^2 + \bar\psi\left(i\not\partial - m_0\right)\psi - e_0\bar\psi\gamma^\mu\psi A_\mu.$$

$$A^\mu = Z_3^{1/2} A_r^\mu, \quad \psi = Z_2^{1/2}\psi_r$$

$$\mathcal{L} = -\frac{1}{4}Z_3 F_r^2 + Z_2\bar\psi_r\left(i\not\partial - m_0\right)\psi_r - Z_2 Z_3^{1/2} e_0\bar\psi_r\gamma^\mu\psi_r A_\mu^r$$

This is simply a change of variables; the Lagrangian itself is unchanged.

The Feynman rules for the renormalized fields have no Z factors, the fermion has mass $m = Z_2 m_0$, and the coupling is $e' = Z_2 Z_3^{1/2} e_0$. Applying these rules yields the same results as the original Feynman rules.

• Next, we split the (bare) Lagrangian into the renormalized Lagrangian and the counterterms. We further define the parameters e and m by

$$e' = Z_1 e, \qquad Z_2 m_0 = m + \delta_m \qquad Z_i = 1 + \delta_i$$

and suppressing the r subscript,

$$\mathcal{L} \equiv \mathcal{L}^{(1)} + \mathcal{L}^{(2)} = \left(-\frac{1}{4}F^2 + \bar{\psi}(i\not{\partial} - m)\psi - e\bar{\psi}\gamma^\mu\psi A_\mu\right) + \left(-\frac{1}{4}\delta_3 F^2 + \bar{\psi}\left(i\delta_2\not{\partial} - \delta_m\right)\psi - e\delta_1\bar{\psi}\gamma^\mu\psi A^\mu\right).$$

The perturbation parameter is now e. The four counterterms $\delta_1, \delta_2, \delta_3$, and δ_m are are defined order by order in $\alpha = e^2/4\pi$. The new arbitrary parameters e and m will be chosen to be more physically meaningful than e_0 and m_0.

• The Feynman rules for $\mathcal{L}^{(1)}$ have no Z factors, mass m, and coupling e. They are UV divergent in the exact same way as before, but with m_0 and e_0 replaced with m and e. The terms in $\mathcal{L}^{(2)}$ lead to additional diagrams, such as

The dependence on the bare parameters is entirely captured by the counterterms.

• The one-loop electron self-energy takes the form

$$\begin{aligned}
&-i\Sigma_r^{(1)}(\not{p}) = -i\Sigma_2^{(1)}(\not{p}) + i\left(\not{p}\delta_2^{(1)} - \delta_m^{(1)}\right) && (\Sigma_2^{(1)} \text{ is due to } \mathcal{L}_r^{(1)})\\
&i\Pi_r^{(1)\mu\nu}(q) = i\left(q^2\eta^{\mu\nu} - q^\mu q^\nu\right)\left(\Pi_2^{(1)}\left(q^2\right) - \delta_3^{(1)}\right). && (\text{Landau gauge})\\
&-ie\Gamma_r^{(1)\mu}(p+q,p) = -ie\Gamma^{(1)\mu}(p+q,p) - ie\gamma^\mu\delta_1^{(1)}
\end{aligned}$$

• Next, we determine the counterterms, which depend on the cutoff, by renormalization conditions. In the on-shell scheme, we let m be the physical mass of the electron and e be the physical charge measured at $q = 0$. By construction, we also require the propagators to have no Z-factors at the physical mass poles. Then we have four conditions,

$$\Sigma_r(\not{p})\big|_{\not{p}=m} = 0, \quad \frac{d}{d\not{p}}\Sigma_r(\not{p})\bigg|_{\not{p}=m} = 0, \quad \Pi_r\left(q^2\right)\big|_{q^2=0} = 0, \quad -ie\Gamma_r^\mu(p,p) = -ie\gamma^\mu$$

which fix the values of the counterterms order by order in α in terms of e, m, and the cutoff. We have removed all dependence on e_0 and m_0, and when the regularization is removed, all amplitudes are finite functions of e and m.

• At two-loop order, we have two-loop diagrams involving renormalized fields and second-order contributions to the counterterms such as $\delta_1^{(2)}$. In addition, one-loop diagrams containing first-order counterterms like $\delta_1^{(1)}$ also contribute.

• We assumed that the counterterms above were sufficient to absorb all UV divergences. As before, we can do this with finitely many counterterms only for a renormalizable theory.

Note. There's a fair deal of historical confusion about renormalization. Many sources phrase the procedure above in terms of "adding counterterms" to "cancel divergences". This is not a good way of thinking about it, because adding terms to a Lagrangian changes the theory. We are simply working with a single Lagrangian the entire time, whose terms may be formally divergent but whose physical predictions are always finite.

However, this naive picture is redeemed in Wilsonian renormalization. As we will see later, the bare Lagrangian is the fundamental Lagrangian, while the renormalized Lagrangian can be thought of as the effective Lagrangian after integrating out high-energy modes. The parameters in the effective Lagrangian are closely related to physically measurable ones, because loop integrals are cut off at a low scale and hence have little effect. The counterterm consists of the terms added to the fundamental Lagrangian as we perform Wilsonian RG flow down to the low scale.

Note. There are a wide variety of ways to set the counterterms, called subtraction schemes. E.g. in minimal subtraction, we use DR regularization and let the counterterms have zero finite part, so they're only series in $1/\epsilon$. This is more computationally efficient, and the standard in modern calculations. Alternatively, in the off-shell scheme, we do the same thing as the on-shell scheme, but let m above be an arbitrary parameter rather than the physical mass. Note that the bare Lagrangian doesn't depend on the subtraction scheme; it only affects the split into $\mathcal{L}_r^{(1)} + \mathcal{L}_r^{(2)}$.

Whenever a subtraction scheme contains a mass parameter, such as the μ parameter in DR, we have a continuum RG flow by changing the parameter. In the on-shell scheme, there is no continuum RG, though we have the Wilsonian RG as always.

Note. The point of these other subtraction schemes is to improve perturbation theory. Generically, a loop integral will give logarithmic factors like $\log(s/\Lambda^2)$, so

$$\mathcal{M}(s) \sim \lambda + \lambda^2 \log \frac{s}{\Lambda^2} + ...$$

We may define the renormalized coupling to be the physical coupling at some arbitrary scale s_0,

$$\lambda_R = \mathcal{M}(s_0)$$

$$\mathcal{M}(s) \sim \lambda_R + \lambda_R^2 \log \frac{s}{s_0} + ...$$

Then if s is very far from s_0, the perturbation series doesn't converge quickly. Thus it's very useful to be able to adjust s_0 as needed. The continuum RG gives a differential equation for $\mathcal{M}(s_0)$ as s_0 is varied, essentially resumming the perturbation series.

2.2 QFT for condensed matter: main methods

(I'll write soon)

2.3 QFT for statistical field theory: main methods

(I'll write soon)

Part II
Specific Quantum Field Theories in a Nutshell

3 Details of Fundamental QFT Methods and Properties in a Nutshell

3.1 General important properties of QFT

3.1.1 Nature of microworld and what do we mean by QFT?

(очень важный раздел для глубокого профессионального понимания КТП. В первые несколько лет изучения можно им вообще не заниматься, потому что все равно для задач мы используем формулы, для которых не так важен их фундаментальный смысл.)

Что такое квантовое поле?

(один из не многих вопросов теории, который тут я и обсуждаю, этот ответ нужно иметь готовым!)

Квантовое поле - это возмущение к большому классическому полю или само большое классическое поле - это большое количество маленьких квантовых полей?

(пока насколько я понял, четко на этот вопрос никто не отвечает, иногда считают одним образом, иногда другим.)

Что вообще из себя представляет материя на микро уровне и почему?

(сперва коротко выводы)
(добавлю какие-то графики, из которых сделано заключение, что все из кварков и т.п. Свяжу ключевыми формулами графики с выводами.)

О связи спина со статистикой (!??!?!??!?)

(!??!? а хрен его знает, я так и не понял эти доказательства, что за бред вообще????? еще раз посмотрю доказательства, в теории подробно их обсужу, потом сюда напишу лучшее)

Почему считают, что элементарных (составных) частиц так много?

(важный теор вопрос, пока не так сильно готов к этому, нужно нормально ответить, а не для галочки, как любой может)

Об экспериментальных фактах в основе КТП (??!!?)

(полезное указание.)

Что по итогу с расходимостями с физической и математической точки зрения?

(это большой вопрос, в курсах вуза проходятся методы в духе "делайте - и будет работать" и все. Может, потом подумаю про это, это важный, большой и фундаментальный вопрос)

О философии и идеи КТП (???)

(хз)

Restoring quantum mechanics from QFT

(I'll write later and detailed discussion of it will be in theory)

Аналогия между квантовой теорией поля и статистической механикой интегралы - 0 размерность, квантмех: 1, КТП: 3+1 (????)

Что за фигня? Но лучше написать, потом когда-то пойму.

Связь квантового поля с волновой функцией (??)

(пока остался вопрос.)

3.1.2 Constants of QFT: α, e, m_e, μ, $\hbar$

(more details about all of them, experiments and calculations)

On fine structure constant (????)

(впишу про нее что узнал очень коротко)

$$\alpha\left(q^2\right)=\frac{\alpha\left(\mu^2\right)}{1-\frac{\alpha(\mu^2)}{3\pi}\log\frac{q^2}{\mu^2}}$$

On magnetic moment (????)

Exact results of a magnetic moment

Note. When one speaks of the physical charge of a particle, one almost always means the charge $e(\mu)$ evaluated at zero momentum, $e(0)^2\approx 1/137$. This is the quantity relevant to all experiments besides those in high energy physics.

$$a_e=0.00115965218059(13)$$

См статью Волкова от 2023, и там куча ссылок.

$$a_e=a_e(\text{QED})+a_e(\text{ hadronic })+a_e(\text{ electroweak }),$$

$$a_e(\text{QED})=\sum_{n\geq 1}\left(\frac{\alpha}{\pi}\right)^n a_e^{2n},$$

$$a_e^{2n}=A_1^{(2n)}+A_2^{(2n)}\left(m_e/m_\mu\right)+A_2^{(2n)}\left(m_e/m_\tau\right)+A_3^{(2n)}\left(m_e/m_\mu,m_e/m_\tau\right),$$

where m_e, m_μ, m_τ are the masses of the electron, muon, and tau-lepton, respectively, α is the fine-structure constant; a similar expression is used for the muon AMM a_μ.

3.1.3 Vacuum, Casimir effect

(!!! доделаю раздел про скалярное поле!!!)

Что такое вакуум? (!?!??!?)

Это пустота.

Которая еще и имеет энергию.

А еще она может себя расталкивать.

(важное про понимание указание, потом додумаю. Большой вопрос, пока просто помню факты и модели)

Что такое энергия вакуума и почему ее иногда можно не рассматривать? (!?!??!?)

For a free scalar field $H = \int \frac{d^3k}{(2\pi)^3}\omega_k \left(a_k^\dagger a_k + \frac{1}{2}\right)$, where $\omega_k = |\vec{k}|$ (??? Шварц что ли безмассовые поля рассматривает???). So the contribution to the vacuum energy of the photon zero modes is zero-point energy:

$$E = \langle 0|H|0\rangle = \int \frac{d^3k}{(2\pi)^3}\frac{\omega_k}{2} = \frac{1}{4\pi^2}\int k^3 dk = \infty,$$

Or from

$$\langle 0|H|0\rangle = \frac{1}{2}\int d^Dx \left\langle 0 \left| \pi^2 + (\vec{\nabla}\varphi)^2 + m^2\varphi^2 \right| 0 \right\rangle,$$

тут третий член:

$$\langle 0|\varphi(\vec{x},t)\varphi(\vec{x},t)|0\rangle = \langle 0|\varphi(\overrightarrow{0},0),\varphi(\overrightarrow{0},0)|0\rangle = \lim_{\vec{x},t\to\overrightarrow{0},0}\langle 0|\varphi(\vec{x},t)\varphi(\overrightarrow{0},0)|0\rangle =$$

$$= \lim_{\vec{x},t\to\overrightarrow{0},0}\int \frac{d^Dk}{(2\pi)^D 2\omega_k} e^{-i\left(\omega_k t - \vec{k}\cdot\vec{x}\right)} = \int \frac{d^Dk}{(2\pi)^D 2\omega_k}.$$

Первое равенство следует из трансляционной инвариантности, которая означает, что мы можем заменить $\int d^Dx$ в $\langle 0|H|0\rangle$ на объем пространства V. Вычисление двух других членов производится во многом аналогично: например, два множителя $\vec{\nabla}$ в $(\vec{\nabla}\varphi)^2$ просто дают множитель $\vec{k}^2$. Таким образом

$$\langle 0|H|0\rangle = V\int \frac{d^Dk}{(2\pi)^D 2\omega_k}\left[\frac{1}{2}\left(\omega_k^2 + \vec{k}^2 + m^2\right)\right] = V\int \frac{d^Dk}{(2\pi)^D}\frac{1}{2}\hbar\omega_k,$$

где мы восстановили $\hbar$.

Following our procedure for the harmonic oscillator, let's define the vacuum $|0\rangle$ by insisting that it is annihilated by all $a_{\vec{p}}$,

$$a_{\vec{p}}|0\rangle = 0 \quad \forall \vec{p}$$

With this definition, the energy E_0 of the ground state comes from the second term in (2.22),

$$H|0\rangle \equiv E_0|0\rangle = \left[\int d^3p \frac{1}{2}\omega_{\vec{p}}\delta^{(3)}(0)\right]|0\rangle = \infty|0\rangle$$

The subject of quantum field theory is rife with infinities. Each tells us something important, usually that we're doing something wrong, or asking the wrong question. Let's take some time to explore where this infinity comes from and how we should deal with it.

In fact there are two different ∞ 's lurking in the expression (2.24). The first arises because space is infinitely large. (Infinities of this type are often referred to as infra-red divergences although in this case the ∞ is so simple that it barely deserves this name). To extract out this infinity, let's consider putting the theory in a box with sides of length L. We impose periodic boundary conditions on the field. Then, taking the limit where $L \to \infty$, we get

$$(2\pi)^3\delta^{(3)}(0) = \lim_{L\to\infty} \int_{-L/2}^{L/2} d^3x \quad e^{i\vec{x}\cdot\vec{p}}\Big|_{\vec{p}=0} = \lim_{L\to\infty} \int_{-L/2}^{L/2} d^3x = V$$

where V is the volume of the box. So the $\delta(0)$ divergence arises because we're computing the total energy, rather than the energy density $\mathcal{E}_0$. To find $\mathcal{E}_0$ we can simply divide by the volume,

$$\mathcal{E}_0 = \frac{E_0}{V} = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2}\omega_{\vec{p}}$$

which is still infinite. We recognize it as the sum of ground state energies for each harmonic oscillator. But $\mathcal{E}_0 \to \infty$ due to the $|\vec{p}| \to \infty$ limit of the integral. This is a high frequency - or short distance - infinity known as an ultra-violet divergence.

(??? додумаю, почему именно для единицы объема все считаем тут??? как-то не думал, что это так, допишу в указания про свойства полей это!)

(?? тут энергию вакуума для других полей тоже допишу)

Так мы всегда делаем, мол энергия отсчитывается от вакуума.

(абзац про то, почему ее нельзя измерить? никак вообще что ли?)

(важное про понимание указание, потом додумаю. пока так вот просто типичная фраза, конечно, она ничего не отвечает.)

Об эффекте Казимира (!??!)

Суть эффекта Казимира

For simple 1D box of size r with scalar field, $H = \int \frac{d^3k}{(2\pi)^3}\omega_k \left(a_k^\dagger a_k + \frac{1}{2}\right)$.

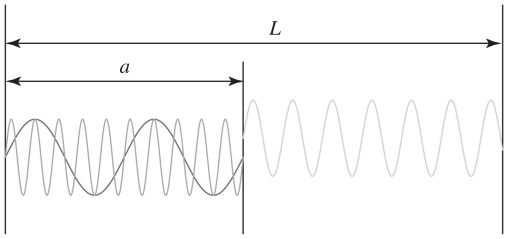
$$E(r) = \langle 0|H|0\rangle = \sum_n \frac{\omega_n}{2}, \qquad \omega_n = \frac{\pi}{r}n \qquad F = -\frac{dE}{da}$$

$$F(a) = -\frac{\pi\hbar c}{24a^2}.$$

Разные ренормировки для вычисления силы Казимира

$$
\begin{aligned}
E(r) &= \tfrac{1}{2}\sum_n \omega_n \theta\left(\pi\Lambda - \omega_n\right) && \text{(hard cutoff)},\\
E(r) &= \tfrac{1}{2}\sum_n \omega_n e^{-\frac{\omega_n}{\pi\Lambda}} && \text{(heat kernel)},\\
E(r) &= \tfrac{1}{2}\sum_n \omega_n e^{-\left(\frac{\omega_n}{\pi\Lambda}\right)^2} && \text{(Gaussian)},\\
E(r) &= \tfrac{1}{2}\sum_n \omega_n \left(\tfrac{\omega_n}{\mu}\right)^{-s} && (\zeta\text{-function}).\\
\tfrac{\pi}{2r}\sum_{n=1}^{\infty} n \quad &\to \quad -\tfrac{\pi}{24r} && 1+2+3+\cdots = -\tfrac{1}{12}
\end{aligned}
$$

All four of these regulators agree.



Casimir force by just summation:

$$E_{\text{tot}}\left(a\right) = E(a) + E(L-a) = \left(\frac{1}{a} + \frac{1}{L-a}\right)\frac{\pi}{2}\sum_{n=1}^{\infty} n = \infty$$

$$F(a) = -\frac{dE_{\text{tot}}}{da} = \left(\frac{1}{a^2} - \frac{1}{(L-a)^2}\right)\frac{\pi}{2}\sum_{n=1}^{\infty} n \overset{L\to\infty}{\longrightarrow} \frac{\pi}{2}\frac{1}{a^2}(1+2+3+\cdots) = \infty.$$

Casimir force by Hard cutoff. Very high frequency can't interact with atoms. We put in a high-frequency cutoff Λ so that $\omega < \pi\Lambda$, Λ in $\frac{1}{\text{atomic size}}$, or some other natural scale that limits the high-frequency light.

$$n_{\max}(r) = \Lambda r.$$

$$E(r) = \frac{1}{r}\frac{\pi}{2}\sum_{n=1}^{n_{\max}} n = \frac{\pi}{2r}\frac{n_{\max}\left(n_{\max}+1\right)}{2} = \frac{\pi}{4r}(\Lambda r)(\Lambda r+1) = \frac{\pi}{4}\left(\Lambda^2 r + \Lambda\right).$$

$$E_{\text{tot}} = E(L-a) + E(a) = \frac{\pi}{4}\left(\Lambda^2 L + 2\Lambda\right)$$

$$F(a) = -\frac{dE_{\text{tot}}}{da} = 0.$$

But $n_{\max}$ can only change by discrete amounts:

$$n_{\max}(r) = \lfloor \Lambda r \rfloor,$$

$$E(r) = \frac{\pi}{4r}\lfloor \Lambda r \rfloor(\lfloor \Lambda r \rfloor + 1)$$

$$E_{\text{tot}}(a) = E(L-a) + E(a) = \quad \text{  }$$

$$E(a) = \frac{\pi}{4}\left[\Lambda^2 a + \Lambda - 2\Lambda x - \frac{x(1-x)}{a}\right] \qquad x := \Lambda a - \lfloor \Lambda a \rfloor \in [0,1),$$

We will also take ΛL to be an integer, which is allowed because L was some arbitrary fixed size that does not change when we move the wall at a. Then $\lfloor \Lambda L - \Lambda a \rfloor = \Lambda L - \lceil \Lambda a \rceil$. For simplicity, let us also assume Λa is not an integer, which lets us use $\lceil \Lambda a \rceil = \lfloor \Lambda a \rfloor + 1$. Then,

$$\begin{aligned} E(L-a) &= \frac{\pi}{4}\left[\frac{(\Lambda L - \lceil \Lambda a \rceil)(\Lambda L - \lceil \Lambda a \rceil + 1)}{L-a}\right] \\ &= \frac{\pi}{4}\left[\Lambda^2(L-a) - \Lambda + 2\Lambda x - \frac{x(1-x)}{L-a}\right] \end{aligned}$$

and

$$E_{\text{tot}}(a) = E(L-a) + E(a) = \frac{\pi}{4}\left[\Lambda^2 L - \frac{x(1-x)}{a} - \frac{x(1-x)}{L-a}\right].$$

The $\Lambda^2 L$ piece is the extrinsic energy of the whole system, which does not contribute to the force, and a part that oscillates as x goes between 0 and 1. Keeping only terms up to order L^0, the total energy is

$$E_{\text{tot}}(a) = \frac{\pi}{4} L\Lambda^2 - \frac{\pi}{4a} x(1-x).$$

The $\frac{\pi}{4} L\Lambda^2$ term is the extrinsic energy, which does not contribute to the force, and a part that oscillates as $0 \le x < 1$.

Since $x = \Lambda a - \lfloor \Lambda a \rfloor$, as $\Lambda \to \infty$ at fixed a, there are more and more oscillations. In the continuum limit ($\Lambda \to \infty$), the plate will only experience the average force. Thus, we can average x between 0 and 1, using $\int x(1-x) = \frac{1}{6}$. So,

$$E_{\text{tot}}(a) \approx \frac{\pi}{4} L\Lambda^2 - \frac{\pi}{24a}.$$

$$F(a) = -\frac{dE_{\text{tot}}}{da} = -\frac{\pi}{24a^2} \longrightarrow -\frac{\pi \hbar c}{24a^2}.$$

Casimir force by Heat-kernel regularization. What if there is some penetration depth of the modes into the walls, with high-frequency modes getting further. This means that the contribution of high-frequency modes to the relevant energy sum is exponentially suppressed (??? why??)

$$E(r) = \frac{1}{2}\sum_n \omega_n e^{-\omega_n/(\pi\Lambda)}. \qquad \omega_n = \frac{\pi}{r} n$$

$$E(r) = \frac{1}{r}\frac{\pi}{2}\sum_{n=1}^{\infty} n e^{-n/(\Lambda r)} = \frac{1}{r}\frac{\pi}{2}\sum_{n=1}^{\infty} n e^{-\varepsilon n}, \quad \varepsilon = \frac{1}{\Lambda r} \ll 1.$$

$$\sum_{n=1}^{\infty} n e^{-\varepsilon n} = -\partial_\varepsilon \sum_{n=1}^{\infty} e^{-\varepsilon n} = -\partial_\varepsilon \frac{1}{1-e^{-\varepsilon}} = \frac{e^{-\varepsilon}}{(1-e^{-\varepsilon})^2} = \frac{1}{\varepsilon^2} - \frac{1}{12} + \frac{\varepsilon^2}{240} + \cdots$$

$$E(r) = \frac{1}{r}\frac{\pi}{2}\left[\Lambda^2 r^2 - \frac{1}{12} + \frac{1}{240 r^2\Lambda^2}\cdots\right] = \frac{\pi}{2} r\Lambda^2 - \frac{\pi}{24 r} + \cdots,$$

$$F(a) = -\frac{d}{da}[E(L-a)+E(a)] = -\frac{d}{da}\left[\frac{\pi}{2}L\Lambda^2 - \frac{\pi}{24}\left(\frac{1}{L-a}+\frac{1}{a}\right)+\cdots\right] = \frac{\pi}{24}\left(\frac{1}{(L-a)^2}-\frac{1}{a^2}\right)+\cdots$$

$$F(a) \overset{L\to\infty}{\longrightarrow} -\frac{\pi\hbar c}{24 a^2},$$

which is the same thing we found with the floor-function cutoff. Note, however, that the extrinsic energy term was $\frac{\pi}{4}L\Lambda^2$ in the previous case and is $\frac{\pi}{2}L\Lambda^2$ in this case.

Casimir force by ζ-function regulator:

$$E(r) = \frac{1}{2}\sum_n \omega_n \left(\frac{\omega_n}{\mu}\right)^{-s}\hbar$$

where we take $s \to 0$ instead of $\omega_{\max} \to \infty$ and have added an arbitrary scale μ to keep the dimensions correct. μ does not have to be large - it should drop out for any μ. Let us work out the ζ-function case. Substituting in for ω_n we get

$$E(r) = \frac{1}{2}\left(\frac{\pi}{r}\right)^{1-s}\mu^s\sum_n n^{1-s} = \frac{1}{r}\frac{\pi}{2}\zeta(s-1) = -\frac{\pi}{24 r}+\cdots, \qquad \sum n^{1-s} = \zeta(s-1) = -\tfrac{1}{12} - 0.165 s + \cdots$$

Casimir force by Regulator-independent derivation (Casimir 1948)

$$E(a) := \frac{\pi}{2}\sum_n \frac{n}{a} f\left(\frac{n}{a\Lambda}\right),$$

$f(x)$ is some function whose properties we will determine shortly.

$$E(L-a) = \frac{\pi}{2}(L-a)\Lambda^2\sum_n \frac{n}{(L-a)^2\Lambda^2} f\left(\frac{n}{(L-a)\Lambda}\right) \quad \overset{L\to\infty}{\longrightarrow}$$

$$\to \frac{\pi}{2}L\Lambda^2\int x dx f(x) - \frac{\pi}{2}a\Lambda^2\int x dx f(x) \qquad\qquad x := \frac{n}{(L-a)\Lambda}$$

The first integral is just the extrinsic vacuum energy, with energy density

$$\rho = \frac{\pi}{2}\Lambda^2\int x dx f(x).$$

The second integral simplifies with the change of variables $x = \frac{n}{a\Lambda}$. Adding the discrete sum, for the a side, with the continuum limit of the $L-a$ side, gives

$$E_{\text{tot}} = E(a)+E(L-a) = \rho L + \frac{\pi}{2a}\left[\sum_n n f\left(\frac{n}{a\Lambda}\right) - \int n dn f\left(\frac{n}{a\Lambda}\right)\right].$$

This contains the difference between an infinite sum and an infinite integral. Such a difference is given by the Euler-Maclaurin series:

$$\sum_{n=1}^{N} F(n) - \int_0^N F(n)dn = \frac{F(0)+F(N)}{2} + \frac{F'(N)-F'(0)}{12} + \cdots + B_j\frac{F^{(j-1)}(N)-F^{(j-1)}(0)}{j!}+\cdots,$$

where $F^{(j)}(N) = \frac{d^j F(N)}{dN^j}$ and B_j are the Bernoulli numbers ($B_2 = \frac{1}{6}$ and B_j for odd $j > 1$ they vanish). In our case, $F(n) = nf\left(\frac{n}{a\Lambda}\right)$. So, assuming that $f(x)$ dies sufficiently fast,

$$\lim_{x\to\infty} xf^{(j)}(x) = 0$$

then

$$E_{\text{tot}} = \rho L - \frac{\pi f(0)}{24a} - \frac{B_4}{4!}\frac{3\pi}{2a^3\Lambda^2}f''(0) + \cdots .$$

E.g.if $f(x) = e^{-x}$, then

$$E_{\text{tot}} = \frac{\pi}{2}\Lambda^2 L - \frac{\pi}{24a} + \mathcal{O}\left(\frac{1}{a^2\Lambda}\right),$$

which gives the correct Casimir force.

In fact, it is now clear that any regulator will give this force as long as

$$\lim_{x\to\infty} xf^{(j)}(x) = 0 \quad \text{and} \quad f(0) = 1.$$

You can see that all four of the regulators in Eq. (15.38) satisfy these requirements. The first requirement, that $f(x)$ die fast enough at high energy, means that UV modes go right through the box. It is this requirement that makes the force finite. The second requirement, that $f(0) = 1$, means that the regulator does not affect the spectrum in the IR. On physical grounds, only modes of size $\frac{1}{a}$ can reach both walls of the box to transmit the force, thus our deformation should not affect those modes.

Об экспериментах и применениях эффекта Казимира

Casimir force, first predicted in 1948 and observed 10 years later (по Зи). (по Шварцу - в 1997, Lamoreaux, S. K. 1997. Demonstration of the Casimir force in the 0.6 to 6 μm range. Phys. Rev. Lett., 78, 5–8. Кто там в итоге впервые это увидел?)

(как проверили это?)

(про то, где он на самом деле используется? проверю все это, потом напишу)

О другом про эффект Казимира

(все это в теории чуть решено, а также в отдельной записи, пока не до этих тем)

(короткий по сути абзац, а что идейно делать, если у нас другая геометрия?)

(короткий по сути абзац, а что идейно делать, если у нас температура ненулевая?)

(короткий по сути абзац, а что идейно делать, если одна из пластин движется?)

О космологической постоянной

(see cosmology for now)

О взаимодействии тел, сил Ван дер Ваальса, методах ЛЛ9

(пока мб в конд средах напишу, тоже не особо до этого мне сейчас.)

О других важных вакуумных эффектах и их применениях

(какие-то основные темы из Гриба Мамая выпишу, остальное - другая 1я часть. слишком тут много всего.)

3.1.4 On Causality, Locality, (etc)

(другие мелкие общие вопросы тоже сюда поставлю.)

Heisenberg Picture, causality (????)

To restore some of the Lorentz invariance, we switch to Heisenberg picture, where $A^H(t) = e^{iH^S t}A^S e^{-iH^S t}$, where we have assumed all Schrodinger operators are time-independent. In particular, the Hamiltonian satisfies $H^S = H^H$, and the time evolution is

$$\frac{d}{dt}A^H(t) = i\left[H, A^H(t)\right]$$

• Switching to Heisenberg picture preserves relations between operators as long as all operators are evaluated at the same time. Then the commutators become equal time commutators,

$$\left[q_i^H(t), p_j^H(t)\right] = i\delta_{ij}$$

• For fields, we will drop the indices. A Schrodinger field will have argument $\mathbf{x}$, while a Heisenberg field will have argument $x = (t, \mathbf{x})$. The equal time commutators are

$$[\phi(t,\mathbf{x}), \pi(t,\mathbf{y})] = i\delta(\mathbf{x}-\mathbf{y}), \quad [\phi(t,\mathbf{x}), \phi(t,\mathbf{y})] = [\pi(t,\mathbf{x}), \pi(t,\mathbf{y})] = 0$$

• The Heisenberg equation of motion for the fields is

$$\dot{\phi}(t,\mathbf{x}) = i[H, \phi(t,\mathbf{x})]$$

Now, H doesn't evolve in time, so we choose to evaluate it at time t, where

$$\mathcal{H}(t,\mathbf{x}) = \frac{1}{2}\pi^2(t,\mathbf{x}) + \frac{1}{2}(\nabla\phi(t,\mathbf{x}))^2 + \frac{1}{2}m^2\phi(t,\mathbf{x})^2$$

so we can apply the equal time commutation relations. We thus find

$$\dot{\phi}(t,\mathbf{x}) = \pi(t,\mathbf{x}), \quad \dot{\pi}(t,\mathbf{x}) = \left(\nabla^2 - m^2\right)\phi(t,\mathbf{x})$$

which correspond to the classical Hamilton's equations. The first equation gives an easy way of recovering the mode expansion for π. The two together show the field ϕ obeys the Klein-Gordon equation.

• The Heisenberg equations also 'covariantize', i.e. we can show that

$$\partial^\mu\phi(x) = i\left[P^\mu, \phi(x)\right], \quad \phi(x+a) = e^{iaP}\phi(x)e^{-iaP}$$

• Finally, we compute the mode expansion in Heisenberg picture; we choose to keep the creation and annihilation operators the same. We get factors like $e^{iHt}a_{\mathbf{p}}e^{-iHt}$ in the field expansion; to handle them note that

$$Ha_{\mathbf{p}} = a_{\mathbf{p}}\left(H - \omega_p\right), \quad f(H)a_{\mathbf{p}} = a_{\mathbf{p}}f\left(H - \omega_p\right)$$

Commuting the creation and annihilation operators in this way gives

$$\phi(x) = \int \frac{d\mathbf{p}}{\sqrt{2\omega_p}}\left(a_{\mathbf{p}}e^{-ipx} + a_{\mathbf{p}}^\dagger e^{ipx}\right)$$

$$a_{\mathbf{p}} = \frac{i}{\sqrt{2\omega_p}} \int d\mathbf{x} e^{iqx} \overleftrightarrow{\partial_0} \phi(x) \qquad f \overleftrightarrow{\partial} g = f\partial g - g\partial f$$

Finally, we return to the question of causality.

• Using the Heisenberg picture, we can think of measurements as taking place at different times; conceptually $O^H(t)$ represents a measurement of O at time t.

• To understand this, suppose that $O_1(t_1)$ and $O_2(t_2)$ commute. Then they have a common eigenbasis $|\psi_i\rangle$ where the $|\psi_i\rangle$ are nonevolving Heisenberg states. In Schrodinger picture,

$$|\psi_i(t_j)\rangle \text{ is an eigenvector of } O_j.$$

Thus, if O_1 is measured at t_1, there is no statistical effect on a measurement of O_2 at time t_2.

• Therefore, we say operators $O_1(x)$ and $O_2(y)$ on spacetime are local if

$$[O_1(x), O_2(y)] = 0 \text{ when } (x-y)^2 < 0.$$

This enforces causality: a measurement of O_1 cannot affect O_2 superluminally.

• Since the elementary observables are the fields ϕ, we compute

$$\Delta(x-y) = [\phi(x), \phi(y)] = \int \frac{d\mathbf{p}}{2\omega_p} \left(e^{-ip(x-y)} - e^{-ip(y-x)}\right)$$

Now, the integration measure and integrand are both Lorentz invariant, so if the separation is spacelike we can switch to a frame where $x^0 = y^0$, giving factor $\left(e^{i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})} - e^{-i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}\right)$, which integrates to zero as desired.

• More generally, the same calculation goes through for commutators of $\partial_\mu\phi$, and all local operators $O(x)$ can be built out of $\phi(x)$ and $\partial_\mu\phi(x)$. Thus quantum fields maintain causality.

• For interacting fields, we cannot use the free mode expansion; the commutator turns out to be an operator rather than a number. Working casually, we could show it also vanishes at spacelike separation, but formally, we would take this as one of our axioms.

Next, we consider propagators and Green's functions.

• Define $|x\rangle = \phi^H(x)|0\rangle$. To interpret $|x\rangle$, switch back to Schrodinger picture for

$$|x\rangle = U(-t)\phi(\mathbf{x})U(t)|0\rangle = U(-t)\phi(\mathbf{x})|0\rangle = U(-t)|\mathbf{x}\rangle$$

Since $|\mathbf{x}\rangle$ is roughly a state with a particle at $\mathbf{x}$, $|x\rangle$ is a state that has a particle at $\mathbf{x}$ after evolution for a time t, so $|x\rangle$ has a particle at x. This particle exists for all times, both before and after t, but is only well-localized at time t.

$$D(x-y) := \langle 0|\phi(x)\phi(y)|0\rangle = \int \frac{d\mathbf{p}}{2\omega_p} e^{-ip(x-y)}$$

(amplitude for a particle to go from y to x).

While the propagator is nonzero for spacelike separations, the commutator $D(x-y) - D(y-x)$ is, because the amplitudes for propagation from x to y and y to x cancel out! Note the interplay between the field intuition for ϕ (in the commutator) and the particle intuition for ϕ (in the propagator).

• When we generalize this to the complex scalar field, we see that the amplitude for a particle to go from x to y is canceled by the amplitude for an antiparticle to go from y to x. (For the real scalar field, the particles are their own antiparticles.) This is generally the reason that a multi-particle picture is necessary to preserve causality in relativistic quantum mechanics.

$$D_F(x-y) := \langle 0|T\phi(x)\phi(y)|0\rangle$$

where time ordering means to order fields "later on left", so that earlier fields are applied to the state first. Then

$$\begin{aligned} D_F(x-y) &= \theta\left(x^0-y^0\right) D(x-y) + \theta\left(y^0-x^0\right) D(y-x) \\ &= \int \frac{d\mathbf{p}}{2\omega_p} e^{i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})} \left(\theta\left(x^0-y^0\right) e^{-i\omega_p\left(x^0-y^0\right)} + \theta\left(y^0-x^0\right) e^{i\omega_p\left(x^0-y^0\right)}\right) \\ &= D_F(x-y) = \int dp \frac{i}{p^2-m^2+i\epsilon} e^{-ip(x-y)} \end{aligned}$$

$$\left(\partial_x^2 + m^2\right) D_F(x-y) = -i\delta(x-y)$$

3.1.5 QED: Other conceptual properties

Low Energy Models from QED

(очень важно для понимания коротко вывести многие физические модели из КТП, пойму - напишу)

Lattice QED

(there are a lot of articles, later I'll write, how exactly it is connected with QFT)

3.1.6 Understanding gravity in QFT formalism

Guessing the propagator for gravity.

In general, the numerator of a propagator is simply the sum of projections onto polarizations. Define the spin 1 numerator as $-G_{\mu\nu}(k)$, we have

$$\sum_a \epsilon_\mu^{(a)}(k)\epsilon_\nu^{(a)}(k) = -G_{\mu\nu}(k)$$

as can be checked by explicit computation in the rest frame. Now for spin 2, there are five matrix polarizations satisfying

$$k^\mu \epsilon_{\mu\nu}^{(a)} = 0, \quad \eta^{\mu\nu}\epsilon_{\mu\nu}^{(a)} = 0$$

which project away the spin 1 and spin 0 components. Applying these constraints to the most general candidate built out of $G_{\mu\nu}$ and k_μ gives

$$D_{\mu\nu,\lambda\sigma}(k) = i\frac{G_{\mu\lambda}G_{\nu\sigma} + G_{\mu\sigma}G_{\nu\lambda} - (2/3)G_{\mu\nu}G_{\lambda\sigma}}{k^2-m^2+i\epsilon}$$

where the overall constant can be found by evaluating in the rest frame. Gravity couples to the stress-energy tensor, and its conservation means we can replace $G_{\mu\nu}$ with $\eta_{\mu\nu}$. It turns out that in proper GR, the massless limit converts the 2/3 to a 1.

The sign of the gravitational force is determined by the sign of $D_{00,00}$, which is indeed positive. (Another way of understanding this is that the sign flip for spin 1 occurs twice; universal attraction

holds for even spins.) Pressure is also attractive by the same amount as energy density, since $D_{ii,ii} = D_{00,00}$, as we know from the notes on General Relativity.

3.2 Other properties of basic methods 1

(like what is in 1 part, but details about it)

3.2.1 Kinematics, cross sections, decay widths, form factors: details

Приложение A from Vergeles Выражение вероятностей процессов через амплитуды

Рассмотрим вопрос о выражении сечений рассеяния и вероятностей распадов частиц через инвариантные амплитуды рассеяния в трёхмерном пространстве.

Сначала проясним вопрос о нормировке r-частичных состояний. Согласно (39 Л2)

$$\langle k|k\rangle = 2\omega_k(2\pi)^3\delta^{(3)}(0) \tag{A1}$$

Так как объём пространства представляется как

$$V = \int \mathrm{d}^{(3)}x e^{i(\mathbf{p}-\mathbf{k})\mathbf{x}}\Big|_{\mathbf{p}=\mathbf{k}} = (2\pi)^3\delta^{(3)}(0)$$

то (A1) означает, что принятая нами лоренц-инвариантная нормировка состояний (38 Л2) такова, что в единице объёма содержится

$$n_{\mathbf{k}} = 2\omega_k = 2\sqrt{m^2+\mathbf{k}^2} \tag{A2}$$

частиц.

Построим r-частичное нормированное состояние. Пусть G - малая область в импульсном пространстве частиц вблизи значений импульсов $(\mathbf{p}_1, ..., \mathbf{p}_r)$, так что объём G равен:

$$G = \int\limits_G \mathrm{d}^{(3)}p_1 ... \mathrm{d}^{(3)}p_r = \prod_{j=1}^{r}\Delta^{(3)}p_j \tag{A3}$$

Состояние $\left(\omega_j \equiv \sqrt{m_j^2+\mathbf{p}_j^2}\right)$

$$|\tilde{f}\rangle = \prod_{j=1}^{r}\int\limits_G \frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]}\,|\mathbf{p}_1, ..., \mathbf{p}_r\rangle$$

имеет норму

$$\langle\tilde{f}|\tilde{f}\rangle = \prod_{j=1}^{r}\int\limits_G \frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]}\int\limits_G \frac{\mathrm{d}^{(3)}p'_j}{\left[(2\pi)^3 2\omega'_j\right]}\,\langle\mathbf{p}'_1, ..., \mathbf{p}'_r|\mathbf{p}_1, ..., \mathbf{p}_r\rangle =$$

$$= \prod_{j=1}^{r}\int\limits_G \frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]}\int\limits_G \mathrm{d}^{(3)}p'_j\delta^{(3)}\left(\mathbf{p}_j-\mathbf{p}'_j\right) = \prod_{j=1}^{r}\frac{\Delta^{(3)}p_j}{[(2\pi)^3 2\omega_j]} \tag{A4}$$

При получении (А4) была использована формула (45 Л2), а также тот факт, что импульсы $\mathbf{p}_j$ и $\mathbf{p}'_j$ почти совпадают при всех j, в то время как импульсы $\mathbf{p}_j$ и $\mathbf{p}'_i$ при $i \neq j$ принадлежат непересекающимся областям Δp_j и Δp_i. Следует заметить, что (А4) есть лоренц-инвариант. Таким образом состояние

$$|f\rangle = \left[\prod_{j=1}^{r} \frac{\Delta^{(3)} p_j}{[(2\pi)^3 2\omega_j]}\right]^{-1/2} |\tilde{f}\rangle \tag{A5}$$

нормировано, причём это свойство лоренц-инвариантно.

Пусть $|i\rangle$ - n-частичное состояние (43 Л2) и $|f\rangle$ - состояние (А5). Тогда для недиагональных матричных элементов (см. (2 ЛЗ)-(4 ЛЗ))

$$\langle f|S|i\rangle = \langle f|iT|i\rangle = \left[\prod_{j=1}^{r} \frac{\Delta^{(3)} p_j}{[(2\pi)^3 2\omega_j]}\right]^{-1/2} \prod_{j=1}^{r} \int\limits_G \frac{\mathrm{d}^{(3)} p_j}{[(2\pi)^3 2\omega_j]} \langle \mathbf{p}_1, ..., \mathbf{p}_r|iT|\mathbf{k}_1, ..., \mathbf{k}_n\rangle \tag{A6}$$

Согласно вышесказанному выражение (А6) лоренц-инвариантно. Перепишем (А6) при помощи амплитуды M_{fi} (см. (4 ЛЗ) и вычислим вероятность перехода из состояния $|i\rangle$ в состояние $|f\rangle$. Так как $|f\rangle$ - нормированное состояние, то согласно общим правилам квантовой механики эта вероятность

$$|\langle f|S|i\rangle|^2 = \prod_{j=1}^{r} \int\limits_G \frac{\mathrm{d}^{(3)} p_j}{[(2\pi)^3 2\omega_j]} \left[(2\pi)^4 \delta^{(4)} (P_f - P_i)\right]^2 |M_{fi}|^2 \tag{A7}$$

При получении последней формулы была учтена малость объёма G, а также равенство

$$\left[\prod_{j=1}^{r} \frac{\Delta^{(3)} p_j}{[(2\pi)^3 2\omega_j]}\right]^{-1} \prod_{j=1}^{r} \int\limits_G \frac{\mathrm{d}^{(3)} p_j}{[(2\pi)^3 2\omega_j]} = 1$$

В(А7)

$$P_i = k_1 + ... + k_n, \quad P_f = p_1 + ... + p_r$$

Положим

$$\left[(2\pi)^4 \delta^{(4)} (P_f - P_i)\right]^2 = VT(2\pi)^4 \delta^{(4)} (P_f - P_i)$$

где V - объём пространства, а T-полный промежуток времени, в течение которого рассматривается процесс. Таким образом, деля выражение (А7) на 4 -объём VT, мы получаем вероятность перехода в единице пространства в единицу времени:

$$\mathrm{d}w_{fi} = (2\pi)^4 \delta^{(4)} (P_f - P_i)\big] |M_{fi}|^2 \prod_{j=1}^{r} \frac{\mathrm{d}^{(3)} p_j}{[(2\pi)^3 2\omega_j]} \tag{A8}$$

В (А8) опущен знак интеграла по импульсам конечных частиц. Поэтому вероятность перехода (А8) является дифференциальной вероятностью перехода в бесконечно малый элемент импульсного пространства конечных состояний.

Ещё раз подчеркнём, что выражение (A8) лоренц-инвариантно и в случае применимости ТВ амплитуда M_{fi} вычисляется при помощи диаграммной техники Фейнмана согласно вышеизложенным правилам.

Теперь рассмотрим частные случаи

1. Процессы распада.

В этом процессе в начальном состоянии имеется одна частица с массой M. Чтобы получить вероятность распада одной частицы, следует разделить (A8) на плотность начальных частиц $n_{\mathbf{k}} = 2\sqrt{M^2 + \mathrm{k}^2} = 2\omega_k$. Таким образом вероятность распада частицы в единицу времени

$$\mathrm{d}\Gamma = \frac{(2\pi)^4}{2\sqrt{M^2 + \mathbf{k}^2}} \delta^{(4)}\left(P_f - k\right) |M_{fi}|^2 \prod_{j=1}^{r} \frac{\mathrm{d}^{(3)} p_j}{[(2\pi)^3 2\omega_j]} \tag{A9}$$

2. Взаимное рассеяние двух частиц

В системе отсчёта, в которой одна из рассеивающихся частиц покоится, вероятность (A8) представляется в виде

$$\mathrm{d}w_{fi} \equiv \mathrm{d}\sigma \cdot v_{\mathrm{OTH}} n_1 n_2 \tag{A10}$$

где n_1 и n_2 - плотности частиц сортов 1 и 2, соответственно, $v_{\text{отн}}$ - относительная скорость частиц и $\mathrm{d}\sigma$ - лоренц-инвариантное дифференциальное сечение рассеяния. Из определения (A10) видно, что сечение имеет размерность площади, если n_1 и n_2 в (A10) нормируются так же как и начальные состояния при вычислении амплитуды рассеяния, т.е. согласно (A2).

Для проведения лоренц-инвариантных вычислений при нахождении сечений введём инвариантную величину, которую можно назвать инвариантной плотностью потока:

$$j = \sqrt{\left(k_1 k_2\right)^2 - m_1^2 m_2^2} \tag{A11}$$

В системе отсчёта, в которой частица 2 покоится

$$j = \frac{m_1 m_2 v_{\mathrm{OTH}}}{\sqrt{1 - v_{\mathrm{OTH}}^2}} = \frac{1}{4} v_{\mathrm{OTH}} n_1 n_2 \tag{A12}$$

где

$$n_1 = \frac{2m_1}{\sqrt{1 - v_{\mathrm{OTH}}^2}}, \quad n_2 = 2m_2$$

Если же налетающая частица 1 является безмассовой, то выражение для j при помощи правой части (A12) остаётся справедливым, если положить $v_{\mathrm{O}} = 1$. Таким образом лоренц-инвариантное дифференциальное сечение рассеяния представляется как

$$\mathrm{d}\sigma = \frac{\mathrm{d}w_{fi}}{4j} \tag{A13}$$

Легко проверить следующую формулу:

$$2j = \sqrt{\left[s - (m_1 + m_2)^2\right]\left[s - (m_1 - m_2)^2\right]}, \quad s = (k_1 + k_2)^2 \tag{A14}$$

В системе центра инерции частиц

$$k_1 = (\omega_1, \mathbf{k}), \quad k_2 = (\omega_2, -\mathbf{k})$$

и плотность потока

$$j = |\mathbf{k}|(\omega_1 + \omega_2) \tag{A15}$$

Рассмотрим подробнее формулу (A13) в системе центра инерции в том случае, когда в конечном состоянии имеется также две частицы с массами m_1' и m_2'. Имеем:

$$p_1 = (\omega_1', \mathbf{p}), \quad p_2 = (\omega_1', -\mathbf{p}), \quad \omega_1'^2 - m_1'^2 = \omega_2'^2 - m_2'^2 = |\mathbf{p}|^2 \tag{A16}$$

Отсюда

$$\omega_1' \mathrm{d}\omega_1' = \omega_2' \mathrm{d}\omega_2' = |\mathbf{p}|\mathrm{d}|\mathbf{p}| \longrightarrow \mathrm{d}(\omega_1' + \omega_2') = (\omega_1' + \omega_2')\frac{|\mathbf{p}|\mathrm{d}|\mathbf{p}|}{\omega_1'\omega_2'} \tag{A17}$$

При помощи обозначений

$$\omega = \omega_1 + \omega_2, \quad \omega' = \omega_1' + \omega_2'$$

формулы (A15) и (A17) переписываются как

$$j = |\mathbf{k}|\omega, \quad |\mathbf{p}|\mathrm{d}|\mathbf{p}| = \frac{\omega_1'\omega_2'}{\omega'}\mathrm{d}\omega' \tag{A18}$$

что позволяет представить сечение (A13) в виде

$$\mathrm{d}\sigma = \frac{|M_{fi}|^2 |\mathbf{p}|\mathrm{d}o'}{64\pi^2 |\mathbf{k}|\omega^2} \tag{A19}$$

Здесь d o' - элемент телесного угла, в котором заключён импульс рассеянной частицы:

$$\mathrm{d}o' = \sin\theta \mathrm{d}\theta \mathrm{d}\phi \tag{A20}$$

так что θ есть угол между векторами $\mathbf{k}$ и $\mathbf{p}$, а угол ϕ является азимутальным углом вектора $\mathbf{p}$ относительно некого фиксированного ортогонального репера, третья ось которого совпадает с $\mathbf{k}$. Таким образом

$$t = (k_1 - p_1)^2 = m_1^2 + m_1'^2 - 2\omega\omega' + 2|\mathbf{k}||\mathbf{p}|\cos\theta$$

Поэтому при фиксированной энергии ω

$$\mathrm{d}t = 2|\mathbf{k}||\mathbf{p}|\mathrm{d}\cos\theta, \quad \mathrm{d}o' = \mathrm{d}\phi\mathrm{d}(-\cos\theta) = \frac{\mathrm{d}\phi\mathrm{d}(-t)}{2|\mathbf{k}||\mathbf{p}|}$$

так что

$$\mathrm{d}\sigma = \frac{|M_{fi}|^2\ \mathrm{d}t}{64\pi|\mathbf{k}|^2\omega^2} \cdot \frac{\mathrm{d}\phi}{2\pi} = \frac{|M_{fi}|^2\ \mathrm{d}t}{64\pi j^2} \cdot \frac{\mathrm{d}\phi}{2\pi} \tag{A21}$$

Так как в физически интересных случаях амплитуда не зависит от угла ϕ, то, интегрируя (A21) по этому углу, находим:

$$\mathrm{d}\sigma = \frac{|M_{fi}|^2 \ \mathrm{d}t}{64\pi j^2} \tag{A22}$$

Поскольку в последнем равенстве инвариантное дифференциальное сечение представлено через инвариантные же величины, то этим равенством можно пользоваться в любой системе отсчёта.

ll4-39. Система волновых функций непрерывного спектра для рассеяния в кулоновом поле

3.2.2 Poincare group for QFT

(это же в теорполе, только тут в контексте КТП и короче пояснения)

Об СТО и группе Пуанкаре для КТП

(уже почти готов написать, но пока об этом в теории поля. потом это же сюда и выпишу, мб с особенностями для КТП)

3.2.3 Path integral in QFT: details of the formalism

Построение интеграла по траекториям разбиением экранами

(типичный вывод, другого и не знаю.)

Path Integrals in Zero Dimensions

Основная физическая идея интеграла по траекториям (???)

(додумаю - напишу, пока не так въехал)

Introduction

$$\mathcal{Z} = \int\limits_{\mathcal{C}} \mathcal{D}\phi \exp\left(-\frac{S[\phi]}{\hbar}\right)$$

$$\left\langle \prod_i \mathcal{O}_i[\phi] \right\rangle = \frac{1}{\mathcal{Z}} \int\limits_{C} \mathcal{D}\phi \exp\left(-\frac{S[\phi]}{\hbar}\right) \prod_i \mathcal{O}_i[\phi]$$

• Often we are interested in local operators, such as $\phi^3(x)\partial^\mu\phi(x)\partial_\mu\phi(x)$ or $e^{\phi(x)}$, but we can also consider nonlocal operators. E.g. the Wilson loop $W_\Gamma[A] = \operatorname{tr} P\exp(-\oint A)$ depends on the value of the gauge field A along the loop Γ. (?? P экспонента это???) Again, correlation functions of such operators don't depend on the fields themselves, only on the theory.

• Formal differentiation of the partition function allows us to recover correlation functions of operators in the action. E.g. if the action has a term

$$\mathcal{O} = \lambda \int_M d^d x \phi^4(x)$$

then differentiating with respect to λ gives

$$\frac{\partial \mathcal{Z}}{\partial \lambda} = -\frac{1}{\hbar} \int_{\mathcal{C}} \mathcal{D}\phi e^{-S[\phi]/\hbar} \int_M d^d x \phi^4 = -\frac{\mathcal{Z}\langle \mathcal{O} \rangle}{\hbar}$$

Thus, correlation functions tell us about the response of the partition function to changes in the parameters of the theory.

• Similarly, suppose we add a source term to the action,

$$S[\phi] \to S[\phi] + \int_M d^d x J_i(x) \mathcal{O}_i(x)$$

Then the sources $J_i(x)$ are fields, and $\mathcal{Z}$ is a functional of it; varying with respect to it gives correlation functions of local operators,

$$-\hbar \frac{\delta \mathcal{Z}\left[J_i\right]}{\delta J_i\left(x_i\right)} = \int_{\mathcal{C}} \mathcal{D}\phi e^{-\left(S[\phi] + \int J_j \mathcal{O}_j\right)/\hbar} \mathcal{O}_i\left(x_i\right) = \mathcal{Z}\left\langle \mathcal{O}_i\left(x_i\right) \right\rangle$$

...

$$\langle \mathcal{O}_1(x_1) ... \mathcal{O}_n(x_n) \rangle = \frac{(-\hbar)^n}{\mathcal{Z}} \frac{\delta^n \mathcal{Z}[J]}{\delta J_1(x_1) ... \delta J_n(x_n)} \bigg|_{J=0}$$

E.g.:

$$\langle \phi(x_1) ... \phi(x_n) \rangle = \frac{(-\hbar)^n}{\mathcal{Z}} \frac{\delta^n \mathcal{Z}[J]}{\delta J(x_1) ... \delta J(x_n)} \bigg|_{J=0}$$

E.g.:

$$\delta S[\phi] = \frac{1}{2} \int_M d^d x \sqrt{g} T_{\mu\nu}(x) \delta g^{\mu\nu}(x)$$

$$-\frac{2\hbar}{\sqrt{g(x)}} \frac{\delta \log \mathcal{Z}}{\delta g^{\mu\nu}(x)} = \langle T_{\mu\nu}(x) \rangle \qquad \text{at } \delta g = 0$$

• Suppose our manifold M has boundaries, $\partial M = \cup_i B_i$. Then to specify the path integral, we must choose boundary conditions on the B_i. For each B_i, the set of boundary conditions forms a Hilbert space $\mathcal{H}_i$, so the path integral defines a map $\mathcal{Z} : \otimes_i \mathcal{H}_i \to \mathbb{C}$ by

$$\mathcal{Z}\left[B_i\right] = \int_{\phi|_{B_i} = \varphi_i} \mathcal{D}\phi e^{-S[\phi]/\hbar}$$

We won't specify an inner product on the $\mathcal{H}_i$, because it's unknown how to define it in general.

• An important special case is $M = N \times I$ where I is an interval of length T with respect to the metric g on M. Then the path integral gives a map

$$U(T) : \mathcal{H} \to \mathcal{H}, \quad \langle \varphi_1 | U(T) | \varphi_0 \rangle = \int_{\phi|_{N\times\{0\}}=\varphi_0}^{\phi|_{N\times\{T\}}=\varphi_1} \mathcal{D}\phi e^{-S[\phi]/\hbar}$$

This is simply the time evolution operator. However, it is difficult to show that this map is unitary; that's one of the advantages of the canonical picture.

• Now we take a detour in classical field theory, i.e. considering only the action and not integrating over the fields. The variation of the action takes the form

$$\delta S[\phi] = (\text{ bulk eom })\delta\phi + \sum_i \int_{B_i} n_i^\mu \frac{\delta \mathcal{L}}{\delta\left(\partial^\mu \phi\right)} \delta\phi \sqrt{g} d^{d-1}x$$

$$\pi_i := \sqrt{g} n_i^\mu \frac{\delta \mathcal{L}}{\delta\left(\partial^\mu \phi\right)}$$

E.g. when ∂M is a constant time slice of flat spacetime, then $\pi(t) = \delta\mathcal{L}/\delta\dot{\phi}(t)$.

• Now, the variation δ maps functions on $\mathcal{H}$ to one-forms, since $\delta S[\phi]$ is a number, so we may extend its definition so it is an exterior derivative on differential forms. Then

$$0 = \delta^2 S[\phi]\big|_{\text{eom}} = \int_{N\times\{T\}} \delta\pi \wedge \delta\phi d^{d-1}x - \int_{N\times\{0\}} \delta\pi \wedge \delta\phi d^{d-1}x$$

This implies that there is a conserved quantity

$$\Omega = \int_N \delta\pi \wedge \delta\phi d^{d-1}$$

which is a symplectic form on the space of fields. The symplectic form defines a Poisson bracket, and its conservation implies Liouville's theorem. This is the structure that we aim to quantize in canonical quantization, replacing brackets with commutators.

• E.g. for the canonical quantization on $(\mathbb{R}^4, \eta)$ of the free real scalar field,

$$\phi(x) = \int \frac{d\mathbf{p}}{\sqrt{2E}} \left(e^{ipx} a(\mathbf{p}) + e^{-ipx} a^\dagger(\mathbf{p})\right), \quad [\phi(\mathbf{x}), \pi(\mathbf{y})] = i\delta(\mathbf{x} - \mathbf{y})$$

The commutation relations are only canonical at equal times, since the symplectic form is defined on timeslices. We defined $\phi(x)$ on all of spacetime, rather than timeslices, but this isn't a big difference since the values of ϕ and π on one timeslice determine it everywhere, so boundary values and full solutions are equivalent.

• Next, we look at the state space. A general state on the boundary Hilbert space is

$$|\Psi\rangle = \int_{\mathcal{C}[B]} [d\varphi] |\varphi\rangle\langle\varphi|\Psi\rangle, \quad \Psi[\varphi] = \langle\varphi|\Psi\rangle$$

where we are vague about the inner product and measure. That is, a general state is a superposition of $|\varphi\rangle$ states, each of which correspond to a function on N, representing a definite field configuration.

• In canonical quantization, we used wavefunctions that were polynomials, with monomials

$$\int\limits_{N\otimes n} d\mathbf{x}_1 ... d\mathbf{x}_n \psi\left(\mathbf{x}_1, ..., \mathbf{x}_n\right) \phi\left(\mathbf{x}_1\right) ... \phi\left(\mathbf{x}_n\right)$$

interpreted as n-particle states. E.g. the monomial $\phi(\mathbf{x})$ corresponds to the state $\widehat{\phi}(\mathbf{x})|0\rangle$, i.e. a single particle at $\mathbf{x}$. This state is a superposition of the states $|\varphi\rangle$, weighting states with larger $\phi(\mathbf{x})$ more.

• Assuming our particles are bosons, n-particle states live in the Fock space

$$\mathcal{H} = \mathcal{C} \oplus V \oplus \mathrm{Sym}^2 V \oplus \mathrm{Sym}^3 V \oplus ...$$

where V is the one-particle Hilbert space. Working in the Fock basis, which is not always available, is analogous to expanding a solution to the quantum harmonic oscillator in terms of Hermite polynomials (times Gaussian weights). The general problem is analogous to working in the position basis in quantum mechanics, which is mathematically much trickier.

• If M is non-compact, there may be a region that is asymptotically far away. Then to define the path integral, we must specify asymptotic values of the fields. The simplest choice is $\phi \to 0$, but another important choice is $\phi \to \phi_i$ in the asymptotic past and $\phi \to \phi_f$ in the asymptotic future, in which case the path integral gives the scattering amplitude $\langle \phi_f | \phi_i \rangle$. These are related to correlation functions by the LSZ reduction formula.

Zero Dimensional Field Theory

• If our spacetime M is zero-dimensional and connected, it must be a single point. There is no metric, and the Lorentz group is trivial, so all of its representations are; all fields are scalars. In the path integral, fields are just maps from the single point to $\mathbb{R}$, so $\mathcal{C} \cong \mathbb{R}$.

• The path integral measure $\mathcal{D}\phi$ becomes the usual measure $d\phi$ on $\mathbb{R}$ and the partition function $\mathcal{Z} = \int\limits_{\mathbb{R}} d\phi e^{-S(\phi)/\hbar}$ is an ordinary real integral.

• The action can't have derivatives, so there are no kinetic terms. We'll usually choose it to be a polynomial, such as $S(\phi) = m^2\phi^2/2 + g\phi^4/4!$, where the highest term must have even degree and positive coefficient for the partition function to converge. We can think of the coupling constants as coordinates on an infinite-dimensional 'space of theories'.

• The partition function is a function of these coupling constants, $\mathcal{Z} = \mathcal{Z}\left(m^2, g, ...\right)$. We denote the free partition function $\mathcal{Z}_0$ to be the partition function where the action is quadratic.

$$\langle f \rangle := \frac{1}{\mathcal{Z}} \int\limits_{\mathbb{R}} d\phi f(\phi) e^{-S(\phi)/\hbar}$$

The only restriction is that f cannot grow so fast the integral diverges; in practice we restrict f to be polynomial. Thinking of $e^{-S(\phi)/\hbar}$ as a probability distribution, $\langle f \rangle$ is simply the expectation value of f.

• Again, we can recover correlation functions from the partition function. For example,

$$\frac{1}{p!} \langle \phi^p \rangle = -\frac{\hbar}{\mathcal{Z}} \frac{\partial}{\partial g_p} \mathcal{Z}\left(m^2, \lambda_i\right)$$

where the action has terms $g_p\phi^p/p!$.

For n fields ϕ^a with action $S(\phi) = \frac{1}{2}M(\phi,\phi) = \frac{1}{2}M_{ab}\phi^a\phi^b$, where M_{ab} is real, positive-definite and symmetric the partition function $\mathcal{Z}_0 = \int\limits_{\mathbb{R}^n} d^n\phi e^{-M(\phi,\phi)/2\hbar}$ is a Gaussian integral.

• We may diagonalize M using an orthogonal transformation, which leaves the measure invariant. Then applying the standard Gaussian integral,

$$\int\limits_{\mathbb{R}} d\chi e^{-m\chi^2/2\hbar} = \sqrt{\frac{2\pi\hbar}{m}}, \quad \mathcal{Z}_0 = \frac{(2\pi\hbar)^{n/2}}{\sqrt{\det M}}$$

• More generally, we can consider a linear source term,

$$S(\phi) = \frac{1}{2}M(\phi,\phi) + J\cdot\phi = \frac{1}{2}M(\tilde{\phi},\tilde{\phi}) - \frac{1}{2}M^{-1}(J,J), \quad \tilde{\phi} \equiv \phi + M^{-1}(J,\cdot)$$

where the shift from ϕ to $\tilde{\phi}$ removes the linear term and leaves the measure invariant. Then

$$\mathcal{Z}(J) = \exp\left(\frac{M^{-1}(J,J)}{2\hbar}\right)\mathcal{Z}_0$$

• Now we consider the correlation function $\langle P(\phi)\rangle$ where P is a polynomial in the n fields. By linearity, it suffices to let P be a monomial. We will treat the case where P is a product of linear factors $\ell(\phi) = \ell\cdot\phi$, so we compute

$$\langle \ell_1(\phi)...\ell_p(\phi)\rangle = \frac{1}{\mathcal{Z}_0}\int\limits_{\mathbb{R}^n} d^n\phi e^{-M(\phi,\phi)/2\hbar}\prod_{i=1}^{p}\ell_i(\phi)$$

$p = 2k$,

$$\begin{aligned}
\langle \ell_1(\phi)...\ell_{2k}(\phi)\rangle &= \frac{1}{\mathcal{Z}_0}\int\limits_{\mathbb{R}^n} d^n\phi\prod_{i=1}^{2k}\ell_i(\phi)e^{-M(\phi,\phi)/2\hbar - J(\phi)/\hbar}\Bigg|_{J=0} \\
&= \frac{(-\hbar)^{2k}}{\mathcal{Z}_0}\int\limits_{\mathbb{R}^n} d^n\phi\prod_{i=1}^{2k}\ell_i\cdot\partial_J e^{-M(\phi,\phi)/2\hbar - J(\phi)/\hbar}\Bigg|_{J=0} \\
&= \prod_{i=1}^{2k}\ell_i\cdot\partial_J\frac{(-\hbar)^{2k}}{\mathcal{Z}_0}\int\limits_{\mathbb{R}^n} d^n\phi e^{-M(\phi,\phi)/2\hbar - J(\phi)/\hbar}\Bigg|_{J=0} \\
&= \hbar^{2k}\prod_{i=1}^{2k}\ell_i\cdot\partial_J\left(e^{M^{-1}(J,J)/2\hbar}\right)\Bigg|_{J=0}
\end{aligned}$$

Every factor of ∂_J pops out a factor of $M^{-1}(\ell_i, J)$. Each of these factors must be differentiated with respect to J, to leave a factor of $M^{-1}(\ell_i,\ell_j)$, since we set $J=0$ at the end.

• E.g. for a two-point function

$$\langle \ell_1(\phi)\ell_2(\phi)\rangle = M^{-1}(\ell_1,\ell_2)$$

and more generally

$$\langle \ell_1(\phi)...\ell_{2k}(\phi)\rangle = \hbar^k\sum_{\text{pairs }(a_i,b_i)}\prod_{i=1}^{k}M^{-1}(\ell_{a_i},\ell_{b_i})$$

where, for example, the four-point function has three terms. We call M^{-1} the (free) propagator; it is simply the inverse of the kinetic term. When all the ℓ_i are the same,

$$\left\langle (\ell \cdot \phi)^{2k} \right\rangle = \frac{(2k)!}{2^k k!} \left(\hbar M^{-1}(\ell, \ell) \right)^k$$

The terms can be represented with free field Feynman diagrams with $2k$ external points.

• The result we've just proven is called Wick's theorem. In the context of probability theory, it's a result about moments of the Gaussian distribution called Isserlis' theorem.

• For fermionic variables that anticommute, $\theta^a \theta^b = -\theta^b \theta^a$, the starting point is

$$\int d^n\theta d^n\bar{\theta} \exp(M(\bar{\theta}, \theta) + \bar{\eta} \cdot \theta + \bar{\theta} \cdot \eta) = e^{M^{-1}(\bar{\eta}, \eta)} \det M$$

and we can use this to derive an analogue of Wick's theorem.

Perturbation Theory

• In general, we can't evaluate the path integral exactly for an interacting theory, even in zero dimensions. We might hope to Taylor expand in the small parameter $\hbar$. However, the radius of convergence is zero, because the integral diverges in the region $\mathrm{Re}(\hbar) < 0$.

• However, it is possible to obtain an asymptotic expansion. Suppose $S(\phi)$ has a global minimum at ϕ_0. Then the method of stationary phase gives

$$\int\limits_{\mathbb{R}^n} d^n\phi f(\phi) e^{-S(\phi)/\hbar} \sim (2\pi\hbar)^{n/2} \frac{f(\phi_0)\, e^{-S(\phi_0)/\hbar}}{\sqrt{\det\left(\partial_a \partial_b S(\phi_0)\right)}} \left(1 + \hbar A_1 + \hbar^2 A_2 + \ldots\right)$$

as $\hbar \to 0^+$, where the first term is the 'semiclassical' term. This is an asymptotic series.

• In general, an asymptotic series $\sum\limits_n a_n \hbar^n$ for $I(\hbar)$ means that $\lim_{\hbar \to 0^+} \frac{1}{\hbar^N} \left| I(\hbar) - \sum\limits_{n=0}^{N} a_n \hbar^n \right| = 0$, so the truncated series is arbitrarily good for fixed N and sufficiently small $\hbar$. But we cannot make the series arbitrarily good for fixed $\hbar$. Instead, for sufficiently high N, the error goes back up; the entire series diverges.

• Consider a single scalar field with action $S(\phi) = m^2\phi^2/2 + \lambda\phi^4/4!$ where we need $\lambda > 0$ for convergence and $m^2 > 0$ to get a unique minimum at $\phi_0 = 0$. The leading term is

$$(2\pi\hbar)^{1/2} \frac{e^{-S(\phi_0)}}{\sqrt{S''(\phi_0)}} = \frac{\sqrt{2\pi\hbar}}{m}$$

Going further, we can construct an asymptotic series by expanding the action,

$$\mathcal{Z}\left(m^2, \lambda\right) = \int\limits_{\mathbb{R}} d\phi e^{-\left(m^2\phi^2/2 + \lambda\phi^4/4!\right)/\hbar} = \int\limits_{\mathbb{R}} d\phi e^{-m^2\phi^2/2\hbar} \sum_{n=0}^{\infty} \frac{1}{n!} \left(\frac{-\lambda}{4!\hbar}\right)^n \phi^{4n}.$$

It is illegitimate to exchange the sum and integral because the integral does not converge when λ is negative. However, we can cut off the sum and then exchange the finite sum, for

$$\mathcal{Z}\left(m^2, \lambda\right) \sim \sum_{n=0}^{N} \frac{1}{n!} \left(\frac{-\lambda}{4!\hbar}\right)^n \int\limits_{\mathbb{R}} d\phi e^{-m^2\phi^2/2} \phi^{4n} = \frac{\sqrt{2\hbar}}{m} \sum_{n=0}^{N} \frac{1}{n!} \left(\frac{-\hbar\lambda}{3! m^4}\right)^n \Gamma(2n + 1/2)$$

where we recognized the integral representation of the gamma function, and the $\sim$ denotes asymptotic equality, i.e. equality in the limit $\hbar \to 0^+$.

• Expanding the gamma function, we have the asymptotic series

$$\mathcal{Z}\left(m^2,\lambda\right) \sim \frac{\sqrt{2\pi\hbar}}{m}\sum_{n=0}^{N}\left(\frac{-\hbar\lambda}{m^4}\right)^n \frac{(4n)!}{(4!)^n n! 4^n (2n)!} = \frac{\sqrt{2\pi\hbar}}{m}\left(1-\frac{\hbar\lambda}{8m^4}+\frac{35}{384}\frac{\hbar^2\lambda^2}{m^8}-\ldots\right)$$

Note that up to the overall factor of $\sqrt{2\pi\hbar}$, the series only depends on the combination $\hbar\lambda$. Thus our series can either be thought of as a semiclassical expansion in $\hbar$, or a weak coupling expansion in λ, and this is generally true for graphs with a fixed number of external lines by some graph theory.

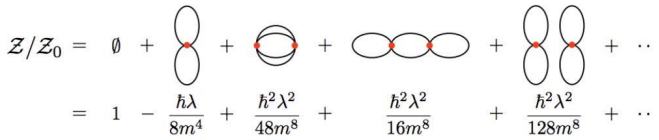
• The series is asymptotic, because $n! \sim e^{n\log n}$, so the numerical factor goes as $e^{n\log n}$. Then eventually it overwhelms the exponential suppression, and the series has zero radius of convergence. However, it is possible to recover $\mathcal{Z}$ from this asymptotic series using Borel summation.

• The theory is well-defined if $m^2 < 0$, but then our asymptotic series is invalid, because we end up integrating a divergent Gaussian. The issue is that we expanded about a maximum instead of a minimum. In physical terminology, we have expanded about an 'unstable vacuum' and found tachyons.

Asymptotic series via Feynman diagrams.

• There are two Feynman rules: a propagator is $\hbar/m^2$ and a four-point vertex is $-\lambda/\hbar$. Note that various factors of i are different since we are in Euclidean signature. Here, since the path integral's integrand is proportional to e^{-S}, every vertex comes with a factor of -1.

• The partition function is the sum of graphs with zero external points. For instance,



The hard part is explaining the numerical factors, which we do below.

• We let a graph be a Feynman diagram where every vertex and edge has a distinguishable label, and let D_n be the set of graphs with n vertices. Adding the labels introduces overcounting; formally the group $G_n = (S_4)^n \rtimes S_n$ performs arbitrary relabelings, and we have overcounted by a factor of $|G_n|$. Then

$$\frac{\mathcal{Z}}{\mathcal{Z}_0} \sim \sum_{n=0}^{\infty}\left(\frac{-\hbar\lambda}{m^4}\right)^n \frac{|D_n|}{|G_n|}, \qquad \mathcal{Z}_0 = \mathcal{Z}\left(m^2,0\right)$$

$$|G_n| = (4!)^n n!,$$

$$|D_n| = (4n-1)(4n-3)\ldots(3)(1) = \frac{(4n)!}{4^n(2n)!}$$

We can find factors $|D_n|\,/\,|G_n|$ by symmetries of the diagram. Note that G_n acts on D_n, partitioning it into orbits O_n. Each orbit $\Gamma \in O_n$ is a 'topological graph', i.e. a graph without labellings. Then the orbit-stabilizer theorem states that

$$\frac{|D_n|}{|G_n|} = \sum_{\Gamma\in O_n}\frac{1}{|\operatorname{Aut}\Gamma|}$$

where Aut Γ is the stabilizer of any element of Γ and $|\mathrm{Aut}\Gamma|$ is also called the symmetry factor. E.g.for the lowest order term, we can flip within each loop and interchange the loops, giving a symmetry factor of 8.

• Finally, we can then express our sum as a sum over orbits,

$$\frac{\mathcal{Z}}{\mathcal{Z}_0} = \sum_{\Gamma} \frac{\hbar^{e(\Gamma)-v(\Gamma)}}{|\operatorname{Aut}\Gamma|} \frac{(-\lambda)^{v(\Gamma)}}{(m^2)^{e(\Gamma)}}$$

This recovers the usual Feynman diagram expansion.

• If we define the free energy or Wilsonian effective action by $\mathcal{W} := -\hbar \log \mathcal{Z}$,

$$\frac{\mathcal{Z}}{\mathcal{Z}_0} \equiv e^{(-\mathcal{W}+\mathcal{W}_0)/\hbar}$$

By the standard combinatoric argument, $\mathcal{W}$ contains only connected diagrams; note that the empty diagram is not connected. Note that because of the sign, $\mathcal{W}$ is really the opposite of the sum of connected diagrams.

Let's see it explicitly. Let $F(\Gamma)$ be the contribution of a Feynman graph without the symmetry factor. We may expand any graph as the product of disconnected pieces,

$$\left|\mathrm{Aut}\left(\Gamma_1^{n_1}...\Gamma_k^{n_k}\right)\right| = \prod_{j=1}^{k} \left(n_j!\right) \left|\mathrm{Aut}\left(\Gamma_j\right)\right|^{n_j}, \qquad F\left(\prod_j \Gamma_j^{n_j}\right) = \prod_j F\left(\Gamma_j\right)^{n_j},$$

therefore we have

$$\frac{\mathcal{Z}}{\mathcal{Z}_0} = \sum_{\Gamma} \frac{F(\Gamma)}{|\operatorname{Aut}(\Gamma)|} = \sum_{\{n_j\}} \frac{F\left(\prod_j \Gamma_j^{n_j}\right)}{\left|\mathrm{Aut}\left(\prod_j \Gamma_j^{n_j}\right)\right|} = \sum_{\{n_j\}} \prod_j \frac{1}{n_j!} \left(\frac{F\left(\Gamma_j\right)}{\left|\mathrm{Aut}\left(\Gamma_j\right)\right|}\right)^{n_j} = \exp\left(\sum_j \frac{F\left(\Gamma_j\right)}{\left|\mathrm{Aut}\left(\Gamma_j\right)\right|}\right)$$

Therefore, $\mathcal{W}$ is the opposite of the sum of connected vacuum graphs,

$$-\mathcal{W} + \mathcal{W}_0 = \hbar \sum_{\text{connected } \Gamma} \frac{F(\Gamma)}{|\operatorname{Aut}(\Gamma)|}$$

In a general quantum field theory, $\mathcal{Z}$ sums over vacuum graphs (measures the "vacuum to vacuum' transition amplitude $e^{-iEt/\hbar}$ where E is the vacuum energy), $\mathcal{W}$ directly measures the vacuum energy.

Note. Counting powers of $\hbar$. Propagators are proportional to $\hbar$ and vertices are inversely proportional to $\hbar$, so a graph contributes $\hbar^{\ell(\Gamma)}$ where $\ell(\Gamma) = e(\Gamma) - v(\Gamma) + 1$ in the expansion for $\mathcal{W}$. For a connected graph, this is the number of loops by Euler's theorem, as loops are just faces of a planar graph, and the 'outside face' doesn't count.

To count powers of $\hbar$ in detail, let there be v_a vertices with a fields. Then for vacuum graphs,

$$2e = \sum_a a v_a$$

where we suppress the Γ argument, so

$$\ell = 1 + e - \sum_a v_a = 1 + \sum_a \left(\frac{a}{2} - 1\right) v_a$$

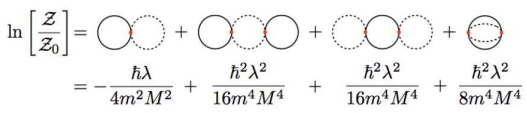
The $\hbar^0$ term is from classical field theory, and corresponds to tree-level diagrams; there are none here because we're focusing on vacuum diagrams. The $\hbar^1$ term comes from one-loop diagrams, and we see above that such diagrams only have quadratic vertices. This makes sense, because the semiclassical contribution comes from integrating over fluctuations in the Gaussian (quadratic) ensemble, and hence only depends on the quadratic part of the action. Finally, all vacuum graphs with an interaction vertex are two-loop or higher. Note that while loops correspond to powers of $\hbar$ in general, the result may be shifted by a constant by field insertions, external states, and external sources.

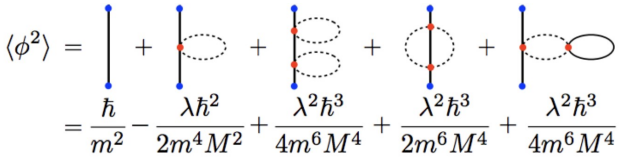
Effective Actions

Zero-dimensional field theory also provides simple examples of effective theories. Consider two real scalar fields with

$$S(\phi,\chi) := \frac{m^2}{2}\phi^2 + \frac{M^2}{2}\chi^2 + \frac{\lambda}{4}\phi^2 chi^2$$

Then we have propagators $\hbar/m^2$ and $\hbar/M^2$, and a vertex $-\lambda/\hbar$.





• Now suppose that we only want to evaluate correlation functions of ϕ. E.g. the mass M of the χ may be very high, so we cannot produce it in an experiment. Then it is useful to "integrate out" the χ, defining the effective action

$$S_{\text{eff}}(\phi) \equiv -\hbar \log\left(\int_{\mathbb{R}} d\chi e^{-S(\phi,\chi)/\hbar}\right)$$

Then correlation functions of ϕ can be evaluated with the weight $e^{-S_{\text{eff}}(\phi)/\hbar}$. Here the action is quadratic in χ, so we can explicitly compute

$$\int_{\mathbb{R}} d\chi e^{-S(\phi,\chi)/\hbar} = e^{-m^2\phi^2/2\hbar}\sqrt{\frac{2\pi\hbar}{M^2+\lambda\phi^2/2}}$$

However, in general we must use perturbation theory. Here we have, exactly,

$$S_{\text{eff}}(\phi) = \frac{m^2}{2}\phi^2 + \frac{\hbar}{2}\log\left(1+\frac{\lambda}{2M^2}\phi^2\right) + \frac{\hbar}{2}\log\frac{M^2}{2\pi\hbar}$$

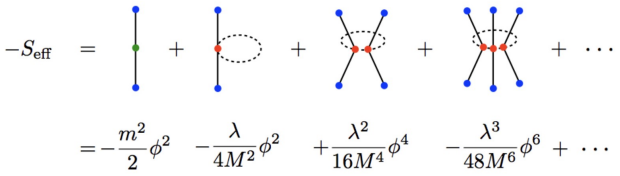
We ignore the final term, which is a constant, but its appearance is a manifestation of the cosmological constant problem.

$$S_{\text{eff}}(\phi) \approx \frac{m_{\text{eff}}^2}{2}\phi^2 + \frac{\lambda_4}{4!}\phi^4 + \frac{\lambda_6}{6!}\phi^6 + ...,$$

$$m_{\text{eff}}^2 = m^2 + \frac{\hbar\lambda}{2M^2}$$

$$\lambda_4 = -\frac{3\hbar}{2}\frac{\lambda^2}{M^4}, \qquad \lambda_6 = 15\hbar\frac{\lambda^3}{M^6}, \qquad \lambda_{2k} = (-1)^{k+1}\hbar\frac{(2k)!}{2^{k+1}k}\frac{\lambda^k}{M^{2k}}$$

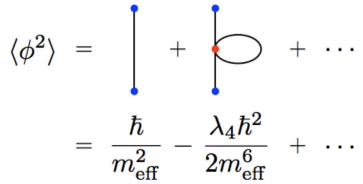
Diagrammatically, it is a polynomial in ϕ, where the contribution to the ϕ^n term comes from diagrams with n external ϕ fields, only connected diagrams are used since we take the logarithm, and only χ propagators appear since the ϕ is not dynamical:



Terms that depend only on ϕ can be simply pulled out of the integral; here we have represented the original mass term using a diagram with a special green vertex. The solid lines aren't ϕ propagators; they're for visual convenience, to separate the ϕ fields from their vertices.

• In this theory, all contributions to $S_{\text{eff}}(\phi)$ have one χ loop, so the corrections to the couplings are $O(\hbar)$. In general, the corrections will each themselves be asymptotic series in $\hbar$. We can imagine the process of integrating out χ as 'zooming out' until we can't see the loop.

• Using the effective action, it is much easier to compute $\langle\phi^2\rangle$ to $O(\lambda^2)$,



In general, we think of the world as a series of nested effective field theories. As a result, every field theory has an infinite amount of terms, i.e. all terms allowed by symmetry, and every computation is actually using an effective action. But at higher energy scale only renormalizable terms in actions are significant.

Note. We've talked about two kinds of effective action, $\mathcal{W}$ and $S_{\text{eff.}}$. These are essentially the same; consider adding an external current, so the action becomes $S[\phi, J]$. Then $\mathcal{W}[J]$ is the effective action for J after integrating out ϕ. Since we've done everything with $J = 0$, only vacuum diagrams appear in the expansion for $\mathcal{W}$, but generally there would be external J points just like in S_{eff}. Both $\mathcal{W}$ and S_{eff} are examples of Wilsonian effective actions.

1PI effective action

• The effective action $\mathcal{W}[J]$ is the effective action for J once the field ϕ has been integrated out; it is analogous to the Helmholtz free energy $F(H)$ for a magnet. However, for an isolated system there is no clear external source.

• In thermodynamics, we deal with this by switching to the Gibbs free energy $G(M)$. By minimizing $G(M)$, we may find the equilibrium magnetization $M = \langle s(\mathbf{x})\rangle$. We can perform a simple minimization because $G(M)$ already accounts for thermal effects, unlike $H(s(\mathbf{x}))$.

• Similarly, in quantum field theory we Legendre transform from the effective action $\mathcal{W}(J)$ to the 1PI effective action $\Gamma(\Phi)$, where the 'classical field' Φ is the VEV in the presence of a source,

$$\Phi = \langle\phi\rangle_J$$

We will see that minimizing $\Gamma(\Phi)$ can tell us about phase transitions, just like $G(M)$.

$$\frac{\partial\mathcal{W}}{\partial J} = -\frac{\hbar}{\mathcal{Z}(J)}\frac{\partial}{\partial J}\int d\phi e^{-(S+J\phi)/\hbar} = \frac{1}{\mathcal{Z}(J)}\int d\phi e^{-(S+J\phi)/\hbar}\phi = \langle\phi\rangle_J$$

$$\Phi = \partial\mathcal{W}/\partial J$$

Quantum effective action $\Gamma(\Phi)$:

$$\Gamma(\Phi) := \mathcal{W}(J) - \Phi J$$

$$J = -\frac{\partial\Gamma}{\partial\Phi}$$

• To understand the meaning of $\Gamma(\Phi)$, note that when $J = 0$, possible values for Φ correspond to extrema of Γ. Then in higher dimensions, the action S yields the classical equations of motion $\delta S/\delta\phi = 0$ while Γ yields the 'quantum' equations of motion for $\delta\Gamma/\delta\Phi = 0$ which account for quantum effects. In zero dimensions these are simply algebraic equations, but in higher dimensions we can have nontrivial spatial dependence, yielding solitons.

• Next, we define a quantum theory by a path integral of Φ, where we let $\Gamma(\Phi)$ play the role of the classical action.

$$e^{-W_\Gamma(J)/g} := \int d\Phi e^{-(\Gamma(\Phi)+J\Phi)/g}$$

$$W_\Gamma(J) = \sum_{\ell=0}^{\infty} g^\ell \mathcal{W}_\Gamma^{(\ell)}(J),$$

$W_\Gamma^{(\ell)}(J)$ is the sum of all ℓ-loop connected Feynman graphs built from $\Gamma(\Phi)$.

In the limit $g \to 0$ only the tree-level connected Feynman graphs contribute;

$$\lim_{g\to 0}\mathcal{W}_\Gamma(J) = W_\Gamma^{(0)}(J) \equiv \Gamma(\Phi) + J\Phi|_{J=-\frac{\partial\Gamma}{\partial\Phi}} = \mathcal{W}(J)$$

Therefore, the connected graphs built from the classical action $S(\phi) + J\phi$ are equal to the tree graphs built from the effective action $\Gamma(\Phi) + J\Phi$, another sense in which Γ includes quantum corrections to S.

• Diagrammatically, every connected diagram is a tree whose vertices are one-particle irreducible (1PI) graphs. Therefore, we can interpret $\Gamma(\Phi)$ as the sum of 1PI graphs built from $S(\phi)$, where a 1PI diagram with n external ϕ fields contributes to the Φ^n term/vertex in $\Gamma(\Phi)$.

• Explicitly, suppose we have fields ϕ^a and sources J_a. Then

$$-\hbar\frac{\partial^2\mathcal{W}}{\partial J_a\partial J_b} = -\hbar\frac{\partial}{\partial J_a}\left(\frac{1}{\mathcal{Z}(J)}\int d^n\phi e^{-(S(\phi^a)+J_a\phi^a)/\hbar}\phi^b\right) = \left\langle\phi^a\phi^b\right\rangle_J - \left\langle\phi^a\right\rangle_J\left\langle\phi^b\right\rangle_J \equiv \left\langle\phi^a\phi^b\right\rangle_J^{\text{conn}}$$

The first term contains both connected and disconnected diagrams, but the disconnected ones are canceled out by the second term, leaving the connected correlation function, also called the exact propagator. It is the quadratic term in $\mathcal{W}[J]$, as expected.

$$\left\langle \phi^a \phi^b \right\rangle_J^{\text{conn}} \equiv -\hbar \frac{\partial^2 \mathcal{W}}{\partial J_a \partial J_b} = -\hbar \frac{\partial \Phi^b}{\partial J_a} = -\hbar \left(\frac{\partial J_a}{\partial \Phi_b} \right)^{-1} = \hbar \left(\frac{\partial^2 \Gamma}{\partial \Phi^b \partial \Phi^a} \right)^{-1}$$

That is, the exact propagator is the inverse of the quadratic term of the 1PI effective action.

• To connect this to diagrams, note that we have the diagrammatic recurrence relation

$$\text{connected} \sim \text{connected} \times \text{1PI} \times \text{connected}$$

which is indeed compatible with what we found.

• For more than two external fields, we can continue differentiating $\mathcal{W}$ with respect to J. The details are messy, but the key identity is

$$\frac{\partial}{\partial \Phi} = \frac{\partial J}{\partial \Phi} \frac{\partial}{\partial J} = \left(\left\langle \phi^2 \right\rangle^{\text{conn}} \right)^{-1} \frac{\partial}{\partial J}$$

That is, adding another external Φ leg to Γ is the same as adding another external J to $\mathcal{W}$ and amputating the resulting leg; this is exactly how 1PI diagrams are produced.

• In general dimension, Γ is extensive and dividing it by the spacetime volume gives the effective potential $V_{\text{eff}}(\Phi)$. As in thermodynamics, the effective potential must be convex; taking the convex hull is the same as the Maxwell construction for the var der Waals gas.

Note. There are various sign flips above, so $\mathcal{W}[J]$ and $\Gamma[\Phi]$ are not really the sum of connected and 1PI diagrams, but rather the sum up to a sign. Explicitly, we have

$$W[J] = \sum_n \frac{(-1)^{n-1}}{n!} J^n \left\langle \phi^n \right\rangle^{\text{conn}}, \quad \Gamma[\Phi] = -\sum_n \frac{1}{n!} \Phi^n \left\langle \phi^n \right\rangle^{\text{1PI}}$$

as can be shown using the identities above. The only exception is the case $n = 2$ for the 1PI effective action. Note that for $n > 2$, the n^{th} order terms in the action contribute directly to $\langle \phi^n \rangle^{\text{1PI}}$, but the quadratic terms don't contribute directly to Π. This is because we treated the quadratic part of the action as 'free' and hence differently from the 'interacting' part when setting per perturbation theory. By summing a geometric series, we hace

$$\left\langle \phi^2 \right\rangle^{\text{conn}} \left(p^2\right) = \frac{1}{p^2 - m_0^2 - \Pi\left(p^2\right)}, \qquad \Pi\left(p^2\right) = \sum \text{1PI diagrams}$$

which implies that the quadratic term of the 1PI effective action is

$$\left\langle \phi^2 \right\rangle^{\text{conn}} \left(p^2\right)^{-1} = p^2 - m^2 - \Pi\left(p^2\right)$$

with an extra inverse bare propagator.

Example. In the case of no external sources, $J = 0$, we have

$$W[0] = \Gamma[\Phi]|_{\partial\Gamma/\partial\Phi = 0}.$$

Thus, by plugging in the equilibrium value of Φ, we get a relationship between the set of connected vacuum bubbles and the set of 1PI diagrams. E.g. in the simple case $\Phi = 0$ we find

$$\sum \text{ connected vacuum bubbles } = \sum \text{1PI vacuum bubbles}$$

which holds because all non-1PI connected vacuum bubbles have tadpoles, which vanish when $\Phi = 0$.

Analogy with statistical mechanics

Consider a magnet with spin field $s(x)$ and energy $E(s)$. Then the partition function is

$$\mathcal{Z} = \int ds e^{-\beta(E(s)-Hs)}$$

where H is an external field. We define the Helmholtz free energy by

$$F(H) = -\frac{1}{\beta}\log \mathcal{Z}$$

where we integrated out the spin field, leaving a function of the external field. We leave the dependence on T implicit, because in quantum field theory its analogue $\hbar$ can't be varied.

• We define the magnetization $M = \langle s\rangle = -\partial F/\partial H$. This is the spin seen on a macroscopic scale, accounting for thermal corrections. We define the Gibbs free energy

$$G(M) = F(H) + MH, \quad \frac{\partial G}{\partial M} = H$$

by Legendre transform so it is directly a function of M.

• To compute the equilibrium value of M, we simply find the minima of G. That is, we don't have to do a path integral over configurations of M, so G 'accounts for thermal corrections'. In particular, it's easy to tell where phase transitions occur.

• E.g.in the ferromagnetic phase transition, the energy is minimized by having the spins aligned, but thermal effects favor disorder; we can tell which wins by looking at $G(T, M)$. In quantum field theory, an analogue is the Coleman-Weinberg potential: a ϕ^4 theory can exhibit spontaneous symmetry breaking because the effective potential has a nonzero minimum.

Fermionic Fields

• A fermionic field is an anticommuting field. In zero dimensions, there is no notion of spin, but in $d = 3 + 1$ fermionic fields have half-integer spin by the spin-statistics theorem.

• The Grassmann algebra is an algebra over the complex numbers, generated by n elements θ^a that anticommute, $\theta^a\theta^b = -\theta^b\theta^a$. Note that scalar multiplication still commutes, $\theta^a\alpha = \alpha\theta^a$ for $\alpha \in \mathbb{C}$. Also, products of an even number of Grassmann numbers commute with everything, so they are 'bosonic'.

• Every Grassmann number squares to zero, so a general element of the algebra is

$$F(\theta) = \alpha + \rho_a\theta^a + \frac{1}{2!}g_{a_1a_2}\theta^{a_1}\theta^{a_2} + ... + \frac{1}{n!}h_{a_1...a_n}\theta^{a_1}...\theta^{a_n}$$

where we can take the coefficients to be totally antisymmetric.

• Next, we define differentiation and integration. The derivative is defined by

$$\frac{\partial\theta^a}{\partial\theta^b} = \delta^a_b, \quad \frac{\partial\alpha}{\partial\theta^a} = 0, \quad \alpha \in \mathbb{C}$$

so it anticommutes with multiplication by a Grassmann number,

$$\frac{\partial}{\partial\theta^a}\theta^b + \theta^b\frac{\partial}{\partial\theta^a} = \delta^b_a$$

where the derivatives act on everything to the right, i.e. on a test function. Then the Grassmann derivative obeys a product rule with an extra minus sign. (Note the spatial derivative of a product of Grassmann fields obeys the product rule, with no extra signs.)

• To define the integral, we consider the case of one Grassmann number, so the most general function is $f(\theta) = \alpha + \rho\theta$. We demand the integral be linear, so

$$\int d\theta(\alpha + \rho\theta) = \alpha \int d\theta + \rho \int d\theta\theta$$

We also demand invariance under a shift of the integration variable by η. For complex η,

$$\int d\theta f(\theta) = \int d\theta f(\theta + \eta) = (\alpha + \rho\eta) \int d\theta + \rho \int d\theta\theta$$

• Using our choice of normalization for the measure, we conclude

$$\int d\theta 1 = 0, \quad \int d\theta\theta = 1$$

More generally, η can be Grassmann valued, which shows that the $d\theta$ integral of anything not linear in θ vanishes; in particular, Grassmann differentiation and integration are equal!

• Using the definition of integration, we find

$$\int d\theta \frac{\partial}{\partial\theta} F(\theta) = 0$$

since the derivative removes the term linear in θ. This allows us to integrate with parts, though there's an extra sign flip.

• If we have n Grassmann variables θ^a, we define $d^n\theta = d\theta^n ... d\theta^1$, so

$$\int d^n\theta\theta^1 ... \theta^n = 1$$

with all lower-order terms integrating to zero, and in general,

$$\int d^n\theta\theta^{a_1} ... \theta^{a_n} = \epsilon^{a_1 ... a_n}$$

• Next, consider a change of variables $\theta'^a = N^a_b \theta^b$. Then by linearity,

$$\int d^n\theta\theta^{a_1} ... \theta'^{a_n} = N^{a_1}_{b_1} ... N^{a_n}_{b_n} \int d^n\theta\theta^{b_1} ... \theta^{b_n} = N^{a_1}_{b_1} ... N^{a_n}_{b_n} \epsilon^{b_1 ... b_n} = (\det N)\epsilon^{a_1 ... a_n}$$

which shows that

$$d^n\theta = (\det N) d^n\theta'$$

This is the exact opposite of the transformation for bosons, e.g. $d\theta = 2d(2\theta)$.

$$\int d\eta \delta(\eta - \theta) f(\eta) = f(\theta) \qquad \text{Grassmann Dirac delta-f.}$$

By considering the general form $f(\eta)$ could take, we see that $\delta(\eta - \theta) = \eta - \theta$.

Note. Concretely, the θ^a can be thought of as one-forms, and the product can be thought of as the wedge product. The Grassmann integral $\int d^n\theta$ can be thought of as integration of a differential form over $\mathbb{R}^n$, where only the integral of a top-dimensional form is nonzero.

A simple calculation in a fermionic free field theory.

• To get a nontrivial theory, we need two fermionic fields, θ^1 and θ^2. The action must be bosonic, so it must be even in the fields, so we must have

$$S(\theta) = \frac{1}{2} A \theta^1 \theta^2$$

$$\mathcal{Z}_0 = \int d^2\theta e^{-S(\theta)/\hbar} \overset{\text{Taylor}}{=} \int d^2\theta \left(1 - \frac{A}{2\hbar}\theta^1\theta^2\right) = -\frac{A}{2\hbar}$$

• More generally, consider $2m$ fermionic fields θ^a with

$$S(\theta) = \frac{1}{2} A_{ab}\theta^a\theta^b$$

where A is $2m \times 2m$ antisymmetric matrix.

$$\mathcal{Z}_0 = \int d^{2m}\theta e^{-A(\theta,\theta)/2\hbar} = \left(-\frac{1}{2\hbar}\right)^m \frac{1}{m!} \int d^{2m}\theta A_{a_1a_2}...A_{a_{2m-1}a_{2m}}\theta^{a_1}...\theta^{a_{2m}}$$

where we used the fact that only the m^{th} order term can contribute.

$$\text{Pfaff } A := \frac{1}{2^m m!}\epsilon^{a_1...a_{2m}} A_{a_1a_2}...A_{a_{2m-1}a_{2m}}$$

$$(\text{Pfaff } A)^2 = \det A$$

$$\mathcal{Z}_0 = \pm\sqrt{\frac{\det A}{\hbar^n}}$$

while for free bosons we had the $\hbar$'s in the numerator and the determinant in the denominator.

• We can also consider sources,

$$S(\theta,\eta) = \frac{1}{2} A_{ab}\theta^a\theta^b + \eta_a\theta^b$$

where the source η must be fermionic.

$$S(\theta,\eta) = \frac{1}{2}\left(\theta^a + \eta_c\left(A^{-1}\right)^{ca}\right) A_{ab}\left(\theta^b + \eta_d\left(A^{-1}\right)^{db}\right) + \frac{1}{2}\eta_a\left(A^{-1}\right)^{ab}\eta_b.$$

Here the two cross-terms are equal because A is antisymmetric and θ and η anticommute.

$$\mathcal{Z}_0(\eta) = \exp\left(-\frac{1}{2\hbar}A^{-1}(\eta,\eta)\right)\mathcal{Z}_0(0)$$

$$\left\langle\theta^a\theta^b\right\rangle = \frac{\hbar^2}{\mathcal{Z}_0(0)}\frac{\partial^2\mathcal{Z}_0(\eta)}{\partial\eta_a\partial\eta_b}\bigg|_{\eta=0} = \hbar\left(A^{-1}\right)^{ab}$$

(???? derive!) where we use Taylor expansion and the fact that derivatives anticommute with Grassmann numbers. This is just the same as the bosonic result: the free propagator is always the inverse of the kinetic term.

• The fact that functions of a finite number of Grassmann variables can always be represented as polynomials means that in $d = 0$, all fermionic path integrals can be evaluated exactly. In higher

dimensions, we use Grassmann-valued fields which contain infinitely many independent Grassmann variables, and turn to perturbation theory with Feynman diagrams.

Note. Strictly speaking, all fermionic fields in relativistic quantum field theory must be Grassmann numbers, even when we are performing canonical quantization. E.g. a Majorana mass term cannot be written down in a classical Lagrangian unless the spinors are anticommuting variables; otherwise the term vanishes identically.

One might worry our classical analysis of the Dirac Lagrangian missed some sign flips. The results are unchanged as long as we define $\pi = \partial\mathcal{L}/\partial\dot{\psi}$ as a derivative to the right of $\mathcal{L}$ acting to the left, and $\mathcal{H} = \pi\dot{\psi} - \mathcal{L}$. Practically speaking, just as there are ambiguities when going from a classical to a quantum theory (which are, e.g. fixed by normal ordering and other prescriptions), there are ambiguities when going from a classical to a semiclassical theory, where the spinors become Grassmann valued. As with normal ordering, we pick the conventions so that the results work.

How supersymmetry makes a path integral much easier to evaluate.

• Consider a theory with one bosonic field ϕ and two fermionic fields ψ_1 and ψ_2, normalizing the measure so that

$$\mathcal{Z} = \int \frac{d\phi d\psi_1 d\psi_2}{\sqrt{2\pi}} e^{-S(\phi,\psi_i)}$$

$$S(\phi,\psi_1,\psi_2) := \frac{1}{2}(\partial h)^2 - \psi_1\psi_2\partial^2 h$$

where $h(\phi)$ is a real-valued polynomial and ∂h is its derivative with respect to ϕ. This action has the most general possible fermionic term, so this just restricts the purely bosonic piece.

0D SUSY:

$$\delta\phi = \epsilon_1\psi_1 + \epsilon_2\psi_2, \qquad \delta\psi_1 = \epsilon_2\partial h, \qquad \delta\psi_2 = -\epsilon_1\partial h \qquad (\epsilon_i \text{ - fermionic})$$

$$\delta S = \partial h\partial^2 h\,(\epsilon_1\psi_1 + \epsilon_2\psi_2) - (\epsilon_2\partial h)\,\psi_2\partial^2 h - \psi_1\,(-\epsilon_1\partial h)\,\partial^2 h = 0$$

S is invariant; one can show the measure is invariant as well. We also have $\delta_1^2 = \delta_2^2 = [\delta_1,\delta_2] = 0$.

$$\forall\mathcal{O}(\phi,\psi_i) \qquad \langle\delta\mathcal{O}\rangle = \frac{1}{\mathcal{Z}_0}\int d\phi d^2\psi e^{-S}\delta\mathcal{O} = \frac{1}{\mathcal{Z}_0}\int d\phi d^2\psi\,\delta\left(e^{-S}\mathcal{O}\right)$$

Now, the quantity in parentheses is at most linear in the ψ_i, so the terms that come from varying ψ_i don't depend on ψ_i and hence integrate to zero. The terms that come from varying ϕ are total derivatives in ϕ. Then $\langle\delta\mathcal{O}\rangle = 0$.

• Now suppose we choose $\mathcal{O} = (\partial g)\psi_1$ for some $g(\phi)$. Setting $\epsilon_1 = -\epsilon_2 = \epsilon$, we have

$$0 = \langle\delta\mathcal{O}\rangle = \epsilon\left\langle\partial g\partial g - \partial^2 g\psi_1\psi_2\right\rangle$$

But this is also the first-order change of the action under the deformation $h \to h + g$. That is, we can replace h in the action with any $h + g$ as long as we don't change the behavior at infinity. In particular, if $g = h$, then we can scale h up. Then the path integral only depends on regions right around extrema of ϕ, a phenomenon known as localization.

• We can explicitly find the partition function. Near an extremum ϕ_*, we have

$$h(\phi) = h(\phi_*) + \frac{c_*}{2}(\phi - \phi_*)^2, \quad S(\phi, \psi_i) \approx \frac{c_*^2}{2}(\phi - \phi_*)^2 + c_*\psi_1\psi_2$$

The contribution to the partition function is

$$\frac{1}{\sqrt{2\pi}} \int d\phi d^2\psi e^{-c_*^2(\phi-\phi_*)^2/2}(1 - c_*\psi_1\psi_2) = \frac{c_*}{\sqrt{2\pi}} \int d\phi e^{-c_*^2(\phi-\phi_*)^2/2} = \frac{c_*}{\sqrt{c_*^2}} = \text{sign}(c_*)$$

• Then the full partition function is

$$\mathcal{Z}[h] = \sum_{\text{extrema } \phi_*} \text{sign}\left(\partial^2 h\big|_{\phi_*}\right)$$

I.e. if h has odd degree, then the partition function is 0, and if h has even degree, the partition function is ± 1.

• Localization is also useful for computing correlation functions of operators $\mathcal{O}_i$. We are interested in supersymmetry-invariant operators, $\delta\mathcal{O} = 0$. On the other hand, if $\mathcal{O} = \delta\mathcal{O}'$ then the correlator is automatically zero. Thus the nontrivial observables in the theory correspond to the cohomology of δ. That is, one can use supersymmetric quantum field theories to compute the cohomologies of interesting spaces.

Quantum Mechanics (1D QFT)

• We recall that we usually consider fields of the form $x : M \to N$ where (N, g) is a Riemannian manifold. In the one-dimensional case, M is either the circle S^1, parametrized by $t \in [0, T)$ with endpoints identified, or the interval I, parametrized by $t \in [0, T]$.

• For every time $t, x(t)$ is a point in N. We let $x^a(t)$ denote its coordinates; specifically this is the pullback to M by x of coordinates on a patch of N. A standard choice of action is

$$S[\phi] = \int_M \frac{1}{2} g_{ab}(x)\dot{x}^a\dot{x}^b + V(x)dt$$

$g_{ab}(x(t))$ is the pullback to M of the Riemannian metric on N, and $V : N \to \mathbb{R}$ is a 'potential' and $V(x(t))$ is its pullback. We've implicitly chosen the metric on M to be the Euclidean metric $\delta_{tt} = 1$.

• Directly varying this action gives the Euler-Lagrange equation

$$\frac{d^2x^a}{dt^2} + \Gamma^a_{bc}\dot{x}^b\dot{x}^c = g^{ab}(x)\frac{dV}{dx^b}, \qquad \text{(geodesic eq.)}$$

$\Gamma^a_{bc} := \frac{1}{2}g^{ad}(\partial_b g_{cd} + \partial_c g_{bd} - \partial_d g_{bc})$. Note that there is no minus sign on the right-hand side because of the Wick rotation $t \to it$. In Euclidean signature, $\mathbf{F} = -m\mathbf{a}$ because a picks up a factor of i^2 in the Wick rotation (????).

• We interpret the target space N as being the space where we live, and $x(t)$ as the trajectory of a quantum particle; we call either M or $x(M) \subset N$ the worldline of the particle. However, note that we usually interpret M as being the space where we live, and N as an abstract space of fields, e.g. a Grassmann algebra for fermion fields. Even within quantum mechanics, with two particles N is no longer space, but a configuration space with twice the dimension.

Path integral picture from standard quantum mechanics.

$$H = \frac{1}{2}\Delta + V, \qquad \Delta := \frac{1}{\sqrt{g}}\frac{\partial}{\partial x^a}\left(\sqrt{g}g^{ab}\frac{\partial}{\partial x^b}\right)$$

$$K_T\left(y_0, y_1\right) := \left\langle y_1 \left| e^{-HT} \right| y_0 \right\rangle = \langle y_1, T | y_0, 0 \rangle$$

$$\frac{\partial}{\partial t}K_t(x,y) + HK_t(x,y) = 0$$

the Schrodinger equation in Euclidean signature, with $\hbar = 1$.

E.g.in $N \cong \mathbb{R}^n$, we have $g_{ab} = \delta_{ab}$, $V = 0$,

$$K_t(x,y) = \frac{1}{(2\pi t)^{n/2}} \exp\left(-\frac{|x-y|^2}{2t}\right)$$

For a general metric:

$$\lim_{\Delta t \to 0} K_{\Delta t}(x,y) \sim \frac{1}{(2\pi\Delta t)^{n/2}} a(x) \exp\left(-\frac{d(x,y)^2}{2\Delta t}\right)$$

where $d(x,y)$ is the geodesic distance from x to y and $a(x)$ is a polynomial in the Riemann curvature tensor.

The heat kernel can be rewritten by inserting copies of the identity:

$$\left\langle y_1 \left| e^{-HT} \right| y_0 \right\rangle := \lim_{N\to\infty} \left(\frac{1}{2\pi\Delta t}\right)^{nN/2} \int \prod_{i=1}^{N-1} d^n x_i a\left(x_i\right) \exp\left[-\frac{\Delta t}{2}\left(\frac{d\left(x_{i+1}, x_i\right)}{\Delta t}\right)^2\right]$$

$$\mathcal{D}x := \lim_{N\to\infty} \left(\frac{1}{2\pi\Delta t}\right)^{nN/2} \int \prod_{i=1}^{N-1} d^n x_i a\left(x_i\right)$$

If the paths are differentiable, then the sum over $\left(d\left(x_{i+1}, x_i\right)/\Delta t\right)^2$ converges to the integral over $g_{ab}\dot{x}^a\dot{x}^b$ and we recover the path integral expression

$$K_T\left(y_0, y_1\right) = \int\limits_{C_T[y_0,y_1]} \mathcal{D}x e^{-S}$$

where S is the action we wrote down earlier with $V = 0$, and $C_T\left[y_0, y_1\right]$ specifies boundary conditions $x(0) = y_0$ and $x(T) = y_1$.

Computation of correlation functions.

• A local operator is one which depends on the field (in this case, $\mathbf{x}$) at only one point of the worldline. E.g. any function $\mathcal{O} : N \to \mathbb{R}$ corresponds to a local operator $\hat{\mathcal{O}}$. Let $|y,t\rangle$ be the Heisenberg state that will be peaked at y at time t. Then in Heisenberg picture,

$$\left\langle y_1, T | \hat{\mathcal{O}}(t) | y_0, 0 \right\rangle = \left\langle y_1, 0 \left| e^{-H(T-t)}\hat{\mathcal{O}}(0)e^{-Ht} \right| y_0, 0 \right\rangle = \left\langle y_1 \left| e^{-H(T-t)}\hat{\mathcal{O}}e^{-Ht} \right| y_0 \right\rangle$$

where the final expression is in Schrodinger picture.

• Inserting a complete set of states, we find this is equal to

$$\int d^n x \mathcal{O}(x) K_{T-t}(y_1, x) K_t(x, y_0) = \int_{C_T[y_1,y_0]} \mathcal{D}x e^{-S} \mathcal{O}(x(t))$$

Therefore, in general correlation functions are computed from the path integral by (??????)

$$\left\langle y_1, T \left| \hat{\mathcal{O}}_n(t_n) ... \hat{\mathcal{O}}_1(t_1) \right| y_0, 0 \right\rangle = \int_{C_T[y_0,y_1]} \mathcal{D}x e^{-S} \prod_{i=1}^{n} \mathcal{O}_i(x(t_i))$$

Note that we don't need to divide by a partition function here, because the normalization is implicitly in the definition of the path integral measure.

• Note that when we insert complete sets of states, we find a path of the form $(y_0, 0) \to (x_1, t_1) \to ... \to (x_n, t_n) \to (y_1, T)$ and integrate out the internal points to get an arbitrary path $(y_0, 0) \to (y_1, T)$. This is only possible if the points are in time order, as otherwise we'd end up with an integral over paths that go forward and backward in time. Then

$$\left\langle y_1, T \left| \mathcal{T} \prod_{i=1}^{n} \hat{\mathcal{O}}_i(t_i) \right| y_0, 0 \right\rangle = \int_{C_T[y_0,y_1]} \mathcal{D}x e^{-S} \prod_{i=1}^{n} \mathcal{O}_i(x(t_i))$$

This is fitting, as we know the $\mathcal{O}_i$ commute, but the $\hat{\mathcal{O}}_i$ do not, and time ordering makes everything inside it effectively commute. Time-ordered products appear ubiquitously when dealing with the path integral, and we will often drop the time-ordering symbol.

• Note that if there are no derivative terms, positions at arbitrarily close times 'decouple', and the path integral splits into individual independent integrals for each time. Then all correlation functions split as

$$\left\langle \hat{\mathcal{O}}_1(t_1) \hat{\mathcal{O}}_2(t_2) \right\rangle = \left\langle \hat{\mathcal{O}}_1(t_1) \right\rangle \left\langle \hat{\mathcal{O}}_2(t_2) \right\rangle$$

so there are no nontrivial correlations. This corresponds to the statement that fields without kinetic terms are nondynamical and do not propagate.

• More generally, we can consider operators that depend on derivatives of $\mathbf{x}$. In particular, the canonical momentum for our action is

$$p_a = \frac{\partial L}{\partial \dot{x}^a} = g_{ab} \dot{x}^b,$$

so we could replace the function $\mathcal{O}(x^a, \dot{x}^a)$ with the operator $\hat{\mathcal{O}} = \mathcal{O}\left(\hat{x}^a, g^{ab}(\hat{x})\hat{p}_b\right)$. However, this is also puzzling because the latter depends on an ordering prescription while the former does not (??? why???). One can simply define $\hat{\mathcal{O}}$ to be normal ordered, but we would like to understand where this comes from in the path integral.

Ordering problems and the continuum limit.

Note. Such ordering problems also occur in canonical quantization. Here, given the Poisson bracket structure $\{f, g\} = h$ we would like to define operators satisfying $[\hat{f}, \hat{g}] = i\hbar\hat{h}$ which act irreducibly on the Hilbert space. However, the Groenewald-van Hove theorem states that this is

impossible in general; in fact, it's even impossible for polynomials in the positions and momenta, once we go beyond quadratics. The idea of quantizing a classical system in general remains ambiguous.

• For a free particle in one dimension, let $0 < t_- < t < t_+ < T$. Then

$$\int\limits_{C_T[y_0,y_1]} \mathcal{D}x e^{-S} x(t)\dot{x}\left(t_-\right) = \left\langle y_1 \left| e^{-H(T-t_+)} \hat{x} e^{-H(t_+-t)} \hat{p} e^{-Ht} \right| y_0 \right\rangle$$

$$\int\limits_{C_T[y_0,y_1]} \mathcal{D}x e^{-S} x(t)\dot{x}\left(t_+\right) = \left\langle y_1 \left| e^{-H(T-t)} \hat{x} e^{-H(t-t_-)} \hat{p} e^{-Ht} \right| y_0 \right\rangle$$

Taking the limits $t_+ \to t$ from above and $t_- \to t$ from below, the difference of the right-hand sides is nonzero, as

$$\left\langle y_1 \left| e^{-H(T-t)} [\hat{x}, \hat{p}] e^{-Ht} \right| y_0 \right\rangle = \left\langle y_1 \left| e^{-HT} \right| y_0 \right\rangle$$

• To take the same limits on the left-hand side, we explicitly restore the discretization Δt. Then the furthest we can take the limit is

$$x(t)\dot{x}\left(t_-\right) - x(t)\dot{x}\left(t_+\right) \to x_t \frac{x_t - x_{t-\Delta t}}{\Delta t} - x_t \frac{x_{t+\Delta t} - x_t}{\Delta t}$$

This is a discretized second derivative times $x_t \Delta t$, which would vanish in the limit $\Delta t \to 0$ if our paths were smooth. However, we integrate over paths that are not even differentiable.

• More explicitly, the part of the path integral that depends on x_t is

$$\int dx_t K_{\Delta t}\left(x_{t+\Delta t}, x_t\right) \left(x_t \frac{x_t - x_{t-\Delta t}}{\Delta t} - x_t \frac{x_{t+\Delta t} - x_t}{\Delta t} \right) K_{\Delta t}\left(x_t, x_{t-\Delta t}\right)$$

but using the known form of the heat kernel, this is equal to

$$-\int dx_t x_t \frac{\partial}{\partial x_t} \left(K_{\Delta t}\left(x_{t+\Delta t}, x_t\right) K_{\Delta t}\left(x_t, x_{t-\Delta t}\right) \right) = K_{2\Delta t}\left(x_{t+\Delta t}, x_{t-\Delta t}\right)$$

by integration by parts. Performing the other integrals gives $\left\langle y_1 \left| e^{-HT} \right| y_0 \right\rangle$ as desired. Similarly, the operator ordering in the Hamiltonian is also determined by the discretization procedure.

• To understand the result more quantitatively, note that

$$K_t(x, y) = \frac{1}{2\pi t} e^{-(x-y)^2/2t}$$

has $\langle (x-y)^2 \rangle = t$, typical for a diffusion process. Then a typical derivative is actually $O(\sqrt{\Delta t})$ instead of $O(1)$, allowing it to contribute in ways it naively should not. E.g. changing a forward derivative to a backward derivative within a single timeslice yields a change of

$$x_{t+\Delta t} \frac{x_{t+\Delta t} - x_t}{\Delta t} - x_t \frac{x_{t+\Delta t} - x_t}{\Delta t} = \Delta t \left(\frac{x_{t+\Delta t} - x_t}{\Delta t} \right)^2 = O(1)$$

Hence the operator ordering is hidden in the discretization procedure.

The issue of the path integral measure.

• Naively, we may take the limit of infinitely many position-space integration measures to yield the path integral measure $\mathcal{D}x$. Alternatively, one might want to do this in Fourier space, taking the limit of arbitrarily high frequencies; in this picture it is clear we only need a countable infinity of integrations. However, both these limits do not exist.

• We say $d\mu$ is a Lebesgue measure on $\mathbb{R}^D$ if it assigns a strictly positive volume

$$\mathrm{vol}(U) \equiv \int_U d\mu$$

to every non-empty open set U, is translationally invariant, and if for every $x \in \mathbb{R}^D$ there is at least one open neighborhood U_x of x with finite volume. A standard choice is $d\mu = d^D x$.

• There is no non-trivial Lebesgue measure on a vector space with countably infinite dimension. Let $C(L)$ denote an open hypercube of side length L. Dividing it gives

$$\mathrm{vol}(C(L)) \geq 2^D \,\mathrm{vol}(C(L/2))$$

Then if $D \to \infty$, the only way for the measure to remain finite is for $\mathrm{vol}(C(L/2))$ to go to zero, so the measure of any hypercube must be zero. Since the dimension is countably infinite any open set can be covered with countably many cubes, so the measure is identically zero.

• For the path integral in one dimension, there is a nontrivial measure,

$$d\mu = \lim_{N\to\infty} \left(\frac{1}{2\pi\Delta t}\right)^{nN/2} \int \prod_{i=1}^{N-1} d^n x_i \exp\left(-\frac{\Delta t}{2}\left(\frac{x_{t_{i+1}} - x_{t_i}}{\Delta t}\right)^2\right)$$

This is called the Wiener measure, and it necessarily involves the $\mathcal{D}x$ and $e^{-S[x]}$ factor together. It evades the above theorem because it is not translationally invariant, i.e. shifting one of the x_i changes the measure.

• In higher dimensions, the naive generalization of the Wiener measure does not generally exist, but it is believed that quantum field theories that are asymptotically free, such as Yang-Mills, do have a continuum limit. However, a continuum limit almost certainly doesn't exist for general relativity or quantum electrodynamics, and probably doesn't exist for the Standard Model. This is acceptable in practice because we can just treat them as effective theories.

(вообще, люди курсы по теории меры проходят, чтобы разобраться с этим, но мне этот вопрос сейчас не интересен.)

О функциональном квантовании векторных полей

О функциональном квантовании спинорных полей

Симметрии в функциональном формализме

On holomorphic path integral (!!!!)

(!!! напишу скоро про это!!! типичная тема, просто что-то опустил ее)

3.2.4 Diagrams in QFT: other information about basics

Examples of diagrams for practice

(I'll collect some of them to have a reference just in case)

Other general questions about diagrams

требования к теории для применения к ней диаграммных методов

(????)

О разных диаграммных техниках

(?? why there are different diagram techniques??)

3.2.5 Spinors: other properties

Спиновые матрицы плотности (from Vergeles)

Спиновые матрицы плотности необходимы при вычислении сечений и вероятностей распадов, т.к. в процессе таких вычислений приходится делать замены выражений, билинейных относительно спиновых волновых функций начальных и конечных частиц, согласно правилу

$$e_{\mathbf{k}\mu}e^*_{\mathbf{k}\nu} \longrightarrow \rho_{\mu\nu}(k), \quad u_{\pm ka}\bar{u}_{\pm kb} \longrightarrow \rho^{(\pm)}_{ab}(k) \tag{Б1}$$

где $\rho_{\mu\nu}(k)$ - спиновая матрица плотности фотона, $\rho^{(+)}_{ab}(k)\left(\rho^{(-)}_{ab}(k)\right)$ - спиновая матрица плотности электрона (позитрона), причём импульс всех этих частиц равен $\mathbf{k}$.

Фотонные спиновые матрицы плотности.

$$\rho_{ij\text{unpol}} = \frac{1}{2}\left(\delta_{ij} - \frac{k_i k_j}{\mathbf{k}^2}\right), \quad \rho_{0i} = \rho_{i0} = \rho_{00} = 0 \tag{Б2}$$

$$\rho^\mu_\mu = -1 \tag{Б3}$$

$$\rho_{\mu\nu}(k) \longrightarrow \rho_{\mu\nu}(k) + (\chi_\mu k_\nu + \chi_\nu k_\mu) \tag{Б4}$$

$$\chi^\mu = \left(-\frac{1}{4\omega}, \frac{\mathbf{k}}{4\omega^2}\right) \qquad \Rightarrow \qquad \rho_{\mu\nu} = -\eta_{\mu\nu}/2 \tag{Б5}$$

В общем случае матрица плотности представляется в виде

$$\rho_{\mu\nu} = \rho^*_{\nu\mu} = \sum_{\alpha,\beta=1}^{2} \rho^{\alpha\beta} e_{\alpha\mu} e^*_{\beta\nu} \tag{Б6}$$

$$\rho^{\alpha\beta} = \rho^{\beta\alpha *} \tag{Б7}$$

В случае неполяризованного фотона

$$\rho^{\alpha\beta} = (1/2)\delta^{\alpha\beta} \tag{Б8}$$

$$\det \rho^{\alpha\beta} = 1/4 \tag{Б9}$$

В случае полностью поляризованного фотона:

$$\rho^{\alpha\beta} = v^{\alpha} v^{\beta *} \tag{Б10}$$

$$\det \rho^{\alpha\beta} = 0 \tag{Б11}$$

В общем случае:

$$\sum_{\alpha=1}^{2} \rho^{\alpha\alpha} = 1 \tag{Б12}$$

$$0 \leq \det \rho^{\alpha\beta} \leq 1/4 \tag{Б13}$$

$$\rho = \frac{1}{2}(1 + \boldsymbol{\xi}\boldsymbol{\sigma}), \quad \boldsymbol{\xi} = (\xi_1, \xi_2, \xi_3) \tag{Б14}$$

$$\det \rho = \frac{1}{4}\left(1 - \xi_1^2 - \xi_2^2 - \xi_3^2\right) \tag{Б15}$$

$$0 \leq \xi_1^2 + \xi_2^2 + \xi_3^2 \equiv \boldsymbol{\xi}^2 \leq 1 \tag{Б16}$$

Поэтому в неполяризованном случае $\xi^2 = 0$, а в полностью поляризованном случае $\xi^2 = 1$.

Спинорные матрицы плотности.

$$\operatorname{tr} \rho^{(\pm)}(k) = \pm 2m \tag{Б19}$$

$$(\not{k} \mp m)\rho^{(\pm)}(k) = \rho^{(\pm)}(k)(\not{k} \mp m) = 0 \tag{Б20}$$

$$\langle \mathbf{s} \rangle = \frac{1}{2\omega_k} \operatorname{tr}\left(\rho^{(\pm)}\gamma^0 \boldsymbol{\Sigma}\right) = \frac{1}{4\omega_k} \operatorname{tr}\left(\rho^{(\pm)}\gamma^5\gamma\right) \tag{Б21}$$

Матрица плотности для неполяризованного состояния получается при помощи $\frac{1}{2}\sum\limits_{s=1,2} u_{\pm ks}\bar{u}_{\pm ks} = k \pm \pm$

$$\rho^{(\pm)}(k) = (1/2)(\not{k} \pm m) \tag{Б22}$$

В общем случае

$$\rho^{(\pm)}(k) = (1/2)(\not{k} \pm m)\left(1 - \gamma^5 \not{a}\right) \tag{Б23}$$

$a^\mu: \quad k_\mu a^\mu = 0 \quad \longleftrightarrow \quad \not{a}\not{k} + \not{k}\not{a} = 0$

$$\pm a^\mu = \frac{1}{2m} \operatorname{tr}\left(\rho^{(\pm)}\gamma^5\gamma^\mu\right) \tag{b25}$$

В системе покоя частицы

$$a^\mu = (0, \pm 2\langle \mathbf{s} \rangle) \tag{Б26}$$

$0 \leq \langle \mathbf{s} \rangle^2 \leq 1/4 \quad \Rightarrow -1 \leq a^2 \leq 0$

Также в сечение рассеяния следует внести дополнительный множитель 2^r, где r - суммарное число электронов, позитронов и фотонов в конечном состоянии. Этот множитель означает учёт обоих состояний спина каждой конечной частицы. (??)

3.2.6 Vortex function

(не знаю, что это вообще. пока пусть повесит)

Формулы по Ландау

(ЛЛ4 пар 106, но вообще много где это должно быть написано тоже.)

$$K^{\mu}_{ik}(x_1, x_2, x_3) = \left\langle 0 \left| \, \mathrm{T} A^{\mu}(x_1) \, \psi_i(x_2) \, \bar{\psi}_k(x_3) \right| 0 \right\rangle$$

с одним 4-векторным и двумя биспинорными индексами; в силу однородности пространства-времени она зависит лишь от разностей аргументов x_1, x_2, x_3. Выраженная через операторы в представлении взаимодействия, функция K имеет вид

$$K^{\mu}_{ik}(x_1, x_2, x_3) = \frac{\left\langle 0 \left| \, \mathrm{T} A^{\mu}_{\mathrm{int}}(x_1) \, \psi^{\mathrm{int}}_i(x_2) \, \bar{\psi}^{\mathrm{int}}_k(x_3) \, s \right| 0 \right\rangle}{\langle 0|S|0\rangle}.$$

Переход к импульсному представлению осуществляется формулой

$$(2\pi)^4 \delta^{(4)}(p_1 + k - p_2) \, K^{\mu}_{ik}(p_2, p_1; k) = \\ = \iiint K^{\mu}_{ik}(x_1, x_2, x_3) \, e^{-ikx_1 + ip_2x_2 - ip_1x_3} d^4x_1 d^4x_2 d^4x_3.$$

В диаграммной технике функциям K^{μ}_{ik} соответствуют блоки (треххвостки) вида

(тут много картинок, скорее всего выгружу ЛЛ4, потом уже скопирую их)

$$\int K_{ik,lm}(x_1, x_2; x_3, x_4) \, e^{i(p_3x_1 + p_4x_2 - p_3x_3 - p_2x_4)} d^4x_1 d^4x_2 d^4x_3 d^4x_4 = \\ = (2\pi)^4 \delta^{(4)}(p_1 + p_2 - p_3 - p_4) \, K_{ik,lm}(p_3, p_4; p_1, p_2),$$

причем

$$K_{lk,lm}(p_3, p_4; p_1, p_2) = \\ = (2\pi)^4 \delta^{(4)}(p_1 - p_3) \, \mathscr{G}_{il}(p_1) \, \mathscr{G}_{km}(p_2) - (2\pi)^4 \delta^{(4)}(p_2 - p_3) \, \mathscr{G}_{im}(p_1) \, \mathscr{G}_{kl}(p_2) + \\ + \mathscr{G}_{ln}(p_3) \, \mathscr{G}_{kr}(p_4) \left[-i\Gamma_{nr,st}(p_3, p_4; p_1, p_2) \right] \mathscr{G}_{sl}(p_1) \, \mathscr{G}_{tm}(p_2).$$

3.2.7 Schwinger-Dyson equation

вкратце формулы и суть

Суть в том, что это квантовое уравнение Эйлера-Лагранжа
(потом допишу, в процессе размышления)
(тут место явного сравнения ЭЛ и ШД)

пример: уравнение Ш-Д для потенциала φ^4

(см википедию английскую, скоро додумаю)

3.2.8 Dyson equation

Формулы (????!!!)

(ЛЛ4 пока что)

$$\mathscr{H}(p) = G^{-1}(p) - \mathscr{G}^{-1}(p) = \\ = -ie^2 \int \gamma^\nu \mathscr{G}(p+k) \cdot \Gamma^\mu(p+k, p; k) \cdot \mathscr{D}_{\mu\nu}(k) \frac{d^4k}{(2\pi)^4}.$$

3.2.9 Bethe-Salpeter equation

(никто не понимает, как это работает и как этим пользоваться, отдельные часа 15 нужно только на эту тему. Так что пока вдали, научусь - мб в 1ю переставлю. Пока не увидел, что на самом деле требуется где-то понимание этого уравнения, хотя, конечно, запросто можно это найти)

Разберу скоро, это мб от Киселева (?????)

Основным методом решения задач со взаимодействием, бесспорно, является теория возмущений, однако это далеко не единственный метод. Существуют, так называемые, непертурбативные методы и один из них ведет к уравнению Бете - Солпитера. Рассматривается система двух связанных фермионов. В свободной теории, как известно, для одночастичной волновой функции ψ_a (где a - спинорный индекс) пропагатор определяется следующим образом:

$$\psi(x_2) = -i \int d\sigma(x_1) S_F(x_2, x_1) \not{n}(x_1) \psi(x_1)$$

Тут используется запись с использованием «перечёркнутых матриц», $n(x_1)$ - 4-х вектор внешней нормали. Интегрирование ведется по поверхности объёма, включающего в себя событие x_2, S_F. - фейнмановский пропагатор. В случае невзаимодействующих частиц он определяется как решение следующего уравнения [2].

$$(i\nabla' - m_0) S_F = \delta^4(x' - x)$$

Аналогично пропагатору для одночастичной волновой функции, можно определить пропагатор для двучастичной волновой функции следующим выражением:

$$\psi_{ab}(x_3, x_4) = \int d\sigma(x_1) d\sigma(x_2) S^{ab}(x_3, x_1 x_4, x_2) \not{x}(x_1) \not{x}(x_2) \psi_{ab}(x_1, x_2)$$

Здесь ψ_{ab} - спинор, обладающий двумя спинорными индексами a, b. В случае невзаимодействующих частиц, двучастичная волновая функция распадается в произведение одночастичных, а пропагатор в произведение пропагаторов:

$$S^{0ab}(x_3, x_4; x_1, x_2) = iS_F^a(x_3, x_1) S_F^b(x_4, x_2)$$

Однако это самый тривиальный случай. Теперь же «включим» электромагнитное взаимодействие между двумя частицами. Если бы мы следовали идеологии теории возмущений, то получили бы, следуя Фейнману, S^{ab} представляется в виде:

$$S^{ab}(x_3, x_4; x_1, x_2) = iS_F^a(x_3, x_1) S_F^b(x_4, x_2) + \Sigma$$

Под Σ понимается сумма всевозможных диаграмм, получаемых из теории возмущения. Основная идея, приводящая к уравнению заключается в том, что всю

сумму диаграмм мы обозначаем, как некоторое ядро K. Мы будем называть диаграмму приводимой, если после удаления двух фермионных линий она становится несвязной. Тогда K можно представить в виде суммы двух вкладов: вклада приводимых диаграмм и вклада неприводимых диаграмм $\bar{K}$. Можно показать [3], что выражение для $S^{ab}(x_3,x_4;x_1,x_2)$ может быть переписано как:

$$S^{ab}(x_3,x_4;x_1,x_2) = iS_F^a(x_3,x_1)\,S_F^b(x_4,x_2) + \int d^4x_5 d^4x_6 d^4x_7 d^4x_8 \cdot iS_F^a(x_3,x_5)\,iS_F^b(x_4,x_6)\,\bar{K}^{ab}(x_5,x_6;x_7,x_8)\,S^{a}$$

Подставляя это выражение в (2) получаем уравнение Бете - Солпитера:

$$\psi_{ab}(x_1,x_2) = \varphi_{ab}(x_1,x_2) + \int d^4x_3 d^4x_4 d^4x_5 d^4x_6 \cdot iS_F^a(x_1,x_5)\,iS_F^b(x_2,x_6)\,\bar{K}^{ab}(x_5,x_6;x_3,x_4)\,\psi_{ab}(x_3,x_4)$$

В этом выражении φ_{ab} - свободная двучастичная волновая функция, то есть волновая функция в отсутствии взаимодействия между частицами. Таким образом, получили интегральное уравнение Фредгольма II рода.

Основные формулы уравнения Бете-Солпитера

(вики)

Подействуем теперь на уравнение Бете-Солпитера операторами $(i\nabla_1 - m_a), (i\nabla_2 - m_b)$, в силу (1) получим следующее выражение:

$$(i\nabla_1 - m_a)(i\nabla_2 - m_b)\,\psi_{ab}(x_1,x_2) = -\int d^4x_3 d^4x_4 \bar{K}^{ab}(x_1,x_2;x_3,x_4)\,\psi_{ab}(x_3,x_4)$$

Соответственно вместо интегрального уравнения типа Фредгольма, мы получаем интегро-дифференциальное уравнение на двухчастичную волновую функцию $\psi_{ab}(x_1,x_2)$. Ещё одной возможной формой записи уравнения Бете-Солпитера, является запись в импульсном пространстве, а именно, определим преобразование Фурье двухчастичной волновой функции $\psi_{ab}(x_1,x_2)$ следующим образом:

$$\chi_{ab}(p_1,p_2) = \frac{1}{(2\pi)^4}\int d^4x_1 d^4x_2 \cdot e^{i(p_1x_1+p_2x_2)}\psi_{ab}(x_1,x_2)$$

Фурье преобразования самого уравнения Бете-Солпитера запишется следующим образом:

$$\frac{1}{(2\pi)^4}\int d^4x_1 d^4x_2 e^{i(p_1x_1+p_2x_2)}(i\nabla_1 - m_a)(i\nabla_2 - m_b)\,\psi_{ab}(x_1,x_2) = -\frac{1}{(2\pi)^4}\int d^4x_1 d^4x_2 d^4x_3 d^4x_4 e^{i(p_1x_1+p_2x_2)}\bar{K}^{ab}$$

В левой части можно перенести градиенты на экспоненту при помощи интегрирования по частям. Также добавим в правую часть две дельта-функции. Получим:

$$\frac{1}{(2\pi)^4}\int d^4x_1 d^4x_2 \left[(i\nabla_1 - m_a)(i\nabla_2 - m_b)\,e^{i(p_1x_1+p_2x_2)}\right]\psi_{ab}(x_1,x_2) =$$
$$= -\frac{1}{(2\pi)^4}\int d^4x_1 d^4x_2 d^4x_3 d^4x_4 d^4x_3' d^4x_4' e^{i(p_1x_1+p_2x_2)}\delta^4(x_3'-x_3)\,\delta^4(x_4'-x_4)\,\bar{K}^{ab}(x_1,x_2;x_3',x_4')\,\psi_{ab}(x_3,x_4)$$

Используя импульсное представление дельта-фрункций со штрихованными переменными мы можем переписать ядро $\bar{K}^{ab}$ в импульсном представлении, а именно:

$$\bar{K}^{ab}\left(p_1,p_2;p_3,p_4\right)=\frac{1}{(2\pi)^8}\int d^4x_1d^4x_2d^4x_3d^4x_4e^{i(p_1x_1+p_2x_2-p_3x_3-p_4x_4)}\bar{K}^{ab}\left(x_1,x_2;x_3,x_4\right)$$

Используя это, мы получаем уравнение Бете-Солпитера в импульсной форме:

$$\left(\not{p}_1-m_a\right)\left(\not{p}_2-m_b\right)\chi_{ab}\left(p_1,p_2\right)=-\int d^4p_1'd^4p_2'\bar{K}^{ab}\left(p_1,p_2;p_1',p_2'\right)\chi_{ab}\left(p_1',p_2'\right)$$

О применениях уравнения Бете-Солпитера (!!!!)

(додумаю - займусь этим.)

3.2.10 Properties of amplitudes

In this section, we consider some of the properties of amplitudes, i.e. the quantities $\mathcal{M}(i\to f)$ simply related to S-matrix elements.

• Amplitudes are constrained by Poincare invariance. Note that

$$\langle f,\ \text{out}\ |i,\ \text{in}\ \rangle=\left\langle f,\ \text{out}\ \left|U^\dagger(\Lambda,a)U(\Lambda,a)\right|i,\ \text{in}\ \right\rangle$$

where $U(\Lambda,a)$ is our representation of the Poincare group. We know how it must act on the in and out states, since these are just combinations of independent single particles, and using this gives us a relation between two amplitudes.

• Specifically, let us label the incoming particles with momenta p_i, little group indices σ_i, and discrete labels n_i for the particle type, and likewise with primes for the outgoing particles. Then

$$S_{\{p_i,\sigma_i,n_i\},\left\{p_i',\sigma_i',n_i'\right\}}=\exp\left(ia_\mu\Lambda^\mu_\nu\left(\Sigma p_i'-\Sigma p_i\right)^\nu\right)\cdot$$
$$\cdot\left(\sum_{\{\bar{\sigma}_i\}}\prod_i D^{(j_i)}_{\bar{\sigma}_i\sigma_i}\left(W\left(\Lambda,p_i\right)\right)\right)\left(\sum_{\left\{\bar{\sigma}_i'\right\}}\prod_i D^{\left(j_i'*\right)}_{\bar{\sigma}_i'\sigma_i'}\left(W\left(\Lambda,p_i'\right)\right)\right)S_{\{\Lambda p_i,\bar{\sigma}_i,n_i\},\left\{\Lambda p_i',\bar{\sigma}_i',n_i'\right\}}$$

In other words, we just pick up the expected transformations for the momenta and little group labels. Here, we've omitted a convention-dependent normalization factor.

• We pick up additional constraints from internal symmetries, which are defined to be those that change the particle type label n_i, without changing the momenta.

• Scattering amplitudes are analytic in the momenta, so we can analytically continue them "offshell". At the perturbative level, we can define this analytic continuation by simply demanding that off-shell amplitudes can be computed using the same Feynman rules as on-shell ones.

• A simple reason this is useful is that diagrammatically, off-shell amplitudes could appear as internal parts of larger, on-shell amplitudes.

• Another reason is that they appear when one has an external source,

$$\mathcal{L}=\mathcal{L}_0+\mathcal{L}_{\text{int}}\ -J(x)\phi(x)$$

In this case, one has a Feynman rule where a particle can appear out of the source, with a factor $iJ(x)$. The diagrams that contribute to the vacuum-to-vacuum transition amplitude $Z[J]$, at n^{th} order in J, have n copies of this vertex.

• Taking the Fourier transform, since $\tilde{J}(k)$ can have support off-shell, the resulting amplitude is just an n-particle off-shell scattering amplitude times factors of $i\tilde{J}(k_i)$. This is important because, as we'll see later, $Z[J]$ is what the path integral naturally computes.

• There is one more direct interpretation of off-shell amplitudes. We recall that the S-matrix in the adiabatic formalism is $S = U_I(\infty, -\infty)$. With the external source,

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_{\text{int}} \ + J(x)\phi(x)$$

Now, suppose we work in interaction picture by treating $\mathcal{H}_0 + \mathcal{H}_{\text{int}}$ as the "free" Hamiltonian. In this case, the interaction picture fields are what we usually call the Heisenberg fields, and the vacuum-to-vacuum amplitude is

$$Z[J] = \langle \Omega | S | \Omega \rangle = \left\langle \Omega \left| T \exp\left(-i \int dx J(x) \phi_H(x) \right) \right| \Omega \right\rangle$$

By Taylor expanding the right-hand side, we see that n-particle off-shell amplitudes are just the Fourier transforms of the VEV of the time-ordered product of n Heisenberg fields.

• This point is important because we usually take for granted that symmetries work for off-shell amplitudes or amplitudes with external currents just as they do for on-shell amplitudes, which is not strictly justified. If we define off-shell amplitudes in terms of Heisenberg fields, then we can establish this rigorously. E.g. this ensures that momentum is conserved in off-shell amplitudes, beyond perturbation theory, where it is clear from the Feynman diagram expansion.

Another useful consequence of analytic continuation is crossing symmetry.

• Crossing symmetry is the statement that

$$\mathcal{M}(\phi(p) + ... \to ...) = \mathcal{M}(... \to ... + \tilde{\phi}(-p))$$

where $\phi(p)$ represents a particle with four-momentum p, and $\tilde{\phi}(-p)$ represents an antiparticle with momentum $-p$. Note that it is impossible for both sides above to be on-shell, so this statement must be understood in terms of analytic continuations.

• For scalars, crossing symmetry can easily be shown perturbatively with the Feynman rules, as for every diagram with ϕ incoming there is a corresponding diagram with $\tilde{\phi}$ outgoing. For spinors and vectors, one picks up factors for the external polarizations, which can lead to extra sign flips; however, these can be removed if one uses appropriate conventions for the off-shell polarization vectors.

• Crossing symmetry can also be shown nonperturbatively using the LSZ reduction formula. This gives an analytic formula for S-matrix elements which only distinguishes between in and out particles by the sign of the energy in the Fourier transform. Analytically continuing a positive energy to a negative one thus yields a crossed S-matrix element.

• Also note that applying crossing symmetry to switch all incoming particles to outgoing ones, and vice versa, just yields the S-matrix element related by CPT.

3.2.11 The Optical Theorem

Об оптической теореме в КТП (???)

$$\left\langle \mathbf{p}_1 \mathbf{p}_2 \left| T^\dagger T \right| \mathbf{k}_1 \mathbf{k}_2 \right\rangle = \sum_n \left(\prod_{i=1}^n \int \frac{d^3 q_i}{(2\pi)^3} \frac{1}{2E_i} \right) \left\langle \mathbf{p}_1 \mathbf{p}_2 \left| T^\dagger \right| \{\mathbf{q}_i\} \right\rangle \left\langle \{\mathbf{q}_i\} \left| T \right| \mathbf{k}_1 \mathbf{k}_2 \right\rangle$$

Оптическая теорема. Мнимая часть амплитуды рассеяния вперед возникает за счет вкладов всех возможных многочастичных промежуточных состояний.

Theory

The unitarity of the S-matrix leads to useful constraints.

• We recall that we have defined

$$S = 1 + iT, \quad T = \mathcal{M}\phi\left(\Sigma p_{\text{in}} - \Sigma p_{\text{out}}\right)$$

The unitarity condition $S^\dagger S = 1$ gives

$$-i\left(T - T^\dagger\right) = T^\dagger T$$

• To make this more explicit, we take matrix elements of both sides, suppressing "in" and "out" labels, and introduce a resolution of the identity on the right-hand side. Canceling a delta function from both sides, and considering a $2 \to 2$ scattering for concreteness, we have

$$\begin{aligned} &- i\left(\mathcal{M}\left(k_1 k_2 \to p_1 p_2\right) - \mathcal{M}^*\left(p_1 p_2 \to k_1 k_2\right)\right) \\ &= \sum_n \left(\prod_{i=1}^n \int \frac{d\mathbf{q}_i}{2E_i}\right) \mathcal{M}^*\left(p_1 p_2 \to \{q_i\}\right) \mathcal{M}\left(k_1 k_2 \to \{q_i\}\right) \not{\delta}\left(k_1 + k_2 - \sum_i q_i\right). \end{aligned}$$

In a more abbreviated notation, this is

$$2\,\mathrm{Im}\,\mathcal{M}(a \to b) = \sum_f \int d\Pi_f \mathcal{M}^*(b \to f)\mathcal{M}(a \to f)$$

This is the optical theorem.

• The optical theorem is most useful when a and b are the same state. For a one-particle state, the right-hand side is just the decay rate, up to some constants, so

$$\mathrm{Im}\,\mathcal{M}(a \to a) = m_A \sum_f \Gamma(a \to f) = m_a \Gamma_a$$

It's not clear if the left-hand side makes sense for an unstable particle, because such particles can't appear in asymptotic states. One needs to do more work to resolve this, but we'll just ignore it. (resolve)

• For a two-particle state, the right-hand side gives the total scattering cross section, up to some constants, and we have

$$\mathrm{Im}\,\mathcal{M}(a \to a) = 2E_{\text{cm}} p_{\text{cm}} \sigma_{\text{tot}}(a \to \text{ anything })$$

where p_{cm} is the momentum of either particle in the center of mass frame.

• These results have precisely the same interpretation as in the notes on Undergraduate Physics. The imaginary part of the forward scattering amplitude is precisely the amount by which the amplitude for remaining in the same state is depleted, so it is sensible that this is related to the probability to end up in a different state.

• The optical theorem is especially useful when we work perturbatively, because it relates contributions from different orders in perturbation theory. E.g. we will see that the leading contribution to $\mathrm{Im}\,\mathcal{M}(a \to a)$ is at loop level, while the right-hand sides have leading contributions

at tree level. Thus, even if we didn't know the full theory, unitarity can still be used to constrain loop level amplitudes given tree level ones. This will be formalized below by "cutting rules".

Next, we give an explicit example of the optical theorem. We focus on a $2 \to 2$ scattering and consider $\mathcal{M}$ as an analytic function of s, defined by the Feynman rules.

• First, it's worth noting that typically, we expect the imaginary part of $\mathcal{M}$, for real s, to vanish. This is a bit confusing because the Feynman rules have many factors of i, but we can trace them as follows.

• Vertices always come with a factor of i, e.g. because they come from expanding $e^{iH_{\text{int}}\,t}$, along with a momentum conserving delta function.

• Edge (i.e. Feynman propagators) always come with a factor of i in the numerator, along with an integral over four-momentum dp.

• Each seemingly real integral over four-momentum is secretly a purely imaginary number, because the integral over p^0 can be thought of as a contour integral, which yields $2\pi i$ times the residues of relevant poles. This might sound unfamiliar but it isn't strange, because this is precisely the reverse of the logic that let us introduce four-momentum integrals in the first place.

• Thus, each edge secretly comes with an extra factor of i, as does every vertex (since delta functions remove these four-momentum integrals).

Since edges and vertices each come with two factors of i, the amplitude is real. Alternatively, if we use the delta functions to do as many four-momentum integrals as possible, then the number of remaining integrals is the number of loops. Then the total number of factors of i is the number of vertices, plus edges, plus faces (loops) mod 2, which is zero by Euler's formula.

• The idea that a loop gives a factor of i is also consistent with our previous treatment of renormalization. All of our renormalization schemes (dimensional regularization, Pauli-Villars, or a Wilsonian cutoff) begin by Wick rotating the integral over p^0, giving a factor of i.

• Another way of thinking about this is that, as a distribution,

$$\operatorname{Im} \frac{1}{p^2 - m^2 \pm i\epsilon} = \mp \pi \delta\left(p^2 - m^2\right)$$

In a typical loop integral, where only one propagator can be on-shell at once, this yields an imaginary number, making the amplitude overall real. But there is a chance for the amplitude to become imaginary if multiple propagators go on-shell at once. And if the intermediate states in a diagram are on-shell, then we can "cut" the diagram in half, giving diagrams contributing to the right-hand side of the optical theorem.

• Now we treat this explicitly. First, we note that at low s, we are "below threshold" to produce on-shell intermediate states, so we have

$$\mathcal{M}(s) = \left(\mathcal{M}\left(s^*\right)\right)^*$$

Both sides are analytic, so by analytic continuation we have, for all real s,

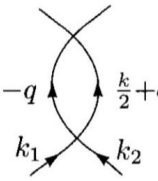
$$\operatorname{Re} \mathcal{M}(s + i\epsilon) = \operatorname{Re} \mathcal{M}(s - i\epsilon), \quad \operatorname{Im} \mathcal{M}(s + i\epsilon) = -\operatorname{Im} \mathcal{M}(s - i\epsilon)$$

At threshold, $\mathcal{M}(s)$ picks up a branch cut along the real axis, across which the imaginary part is discontinuous. The physically measured quantity corresponds to $\mathcal{M}(s + i\epsilon)$, which is related to the discontinuity across the cut by

$$\operatorname{Disc} \mathcal{M}(s) = 2i \operatorname{Im} \mathcal{M}(s + i\epsilon)$$

• As an example, we consider ϕ^4 theory. For $2 \to 2$ scattering, at loop level we have s, t, and u-channel diagrams. The latter two don't give rise to branch cuts, so we focus on the s-channel.

$$i(\delta\mathcal{M}) = \quad \frac{\lambda^2}{2}\int \frac{dq}{((k/2-q)^2-m^2+i\epsilon)\,((k/2+q)^2-m^2+i\epsilon)},$$



where $k = k_1 + k_2$.

Now we consider the (contour) integral over q^0. In the center of mass frame, $k = (k^0, \mathbf{0})$, and defining $E_\mathbf{q} = \sqrt{|\mathbf{q}|^2 + m^2}$ as usual, the integral has poles at

$$q^0 = \frac{1}{2}k^0 \pm (E_\mathbf{q} - i\epsilon)\,, \quad q^0 = -\frac{1}{2}k^0 \pm (E_\mathbf{q} - i\epsilon)$$

To perform the integral, we close the contour downward, picking up the residues of the poles in the lower half-plane. Only the pole at $q^0 = -(1/2)k^0 + E_\mathbf{q}$ will contribute to the discontinuity, and accounting for it is equivalent to replacing

$$\frac{1}{(k/2+q)^2-m^2+i\epsilon} \to -i\phi\left((k/2+q)^2-m^2\right)$$

in the original integral.

• Straightforwardly performing the integral gives

$$i(\delta\mathcal{M}) = -i\frac{\lambda^2}{2}\int \frac{d\mathbf{q}}{2E_\mathbf{q}}\frac{1}{(k^0-E_\mathbf{q})^2-E_\mathbf{q}^2} = -i\frac{\lambda^2}{2}\frac{1}{2\pi^2}\int_m^\infty dE_\mathbf{q}E_\mathbf{q}|\mathbf{q}|\frac{1}{2E_\mathbf{q}}\frac{1}{k^0\,(k^0-2E_\mathbf{q})}$$

The integrand has a pole at $E_\mathbf{q} = k^0/2$, which thus produces a branch cut if the integral goes over it, $k^0 > 2m$. To find the discontinuity across the branch cut, note that

$$\frac{1}{k^0-2E_\mathbf{q}\pm i\epsilon} = P\frac{1}{k^0-2E_\mathbf{q}} \mp i\pi\delta\left(k^0-2E_\mathbf{q}\right)$$

so we may replace this factor with a delta function. This is equivalent to replacing

$$\frac{1}{(k/2-q)^2-m^2+i\epsilon} \to -i\phi\left((k/2-q)^2-m^2\right)$$

in the original integral. (Of course, the original integral is also divergent and must be regularized. We don't need to talk about a specific regulator here, however, because any reasonable regulator must preserve unitarity.)

• Now we return to the original integral, rewriting the loop integral as

$$\int dq = \int dp_1 \int dp_2 \phi\,(p_1+p_2-k)$$

If we make the two replacements above, we simply put the momenta p_i on shell, and integrating the p_i^0 against the delta functions produces the standard factors for Lorentz invariant phase space, giving

$$\text{Disc}\,\mathcal{M}(k) = 2i\,\text{Im}\,\mathcal{M}(k) = \frac{i}{2}\int \frac{d\mathbf{p}_1}{2E_1}\frac{d\mathbf{p}_2}{2E_2}\lambda^2 \not{\phi}\left(p_1 + p_2 - k\right)$$

This is precisely the prediction of the optical theorem, where the $1/2$ in front is the phase space factor for identical final particles, and the λ^2 is the squared matrix element.

• This logic above can be generalized to yield "Cutkosky cutting rules" to compute the discontinuity of any diagram:

• Cut through the diagram, so that it falls apart into two pieces, separating the initial and final particles.

• For each cut, replace $1/\left(p^2 - m^2 + i\epsilon\right) \to -i\not{\phi}\left(p^2 - m^2\right)$.

• Sum over all possible cuts.

This can be used to prove the optical theorem to all orders in perturbation theory.

• Another way to arrive at this is to note that the Feynman propagator and retarded propagator differ only in that the retarded propagator has both poles in the upper half plane, so

$$D_F(p) = D_R(p) + \frac{\pi}{E_{\mathbf{p}}}\delta\left(p^0 - E_{\mathbf{p}}\right)$$

If we apply this formula to all propagators in a loop, then the resulting term consisting of a product of only retarded propagators has zero contour integral, by closing the contour in the lower half plane. By applying the formula in reverse, we recover terms with Feynman propagators, but each term has at least one delta function, thereby reducing a loop amplitude to a tree amplitude.

• We could also treat the example by just evaluating the integral explicitly in, e.g. dimensional regularization, in which case the discontinuity appears through a logarithm.

• Now consider applying the same logic to particles with spin. The right-hand side of the optical theorem will involve spin sums, e.g. for decay into two fermions $\psi\left(p_1\right)\bar{\psi}\left(p_2\right)$ we get $\text{tr}\left(\left(\not{p}_1 + m\right)\left(\not{p}_2 - m\right)\right)$, as shown in the previous section. The optical theorem hence requires that the numerator of a propagator must involve a sum over physical spin states.

• For Dirac fermions this is clearly true, as $\not{p} + m$ indeed appears in the numerator. The result is also clearly true for massive vectors. But for massless vectors, the spin sum is over the two physical polarizations, while the propagator numerator is ξ-dependent! However, as we've seen, we can replace the spin sum with $\eta^{\mu\nu}$ by the Ward identity, and we can freely choose $\xi = 1$ by gauge invariance to make the propagator match.

Next, we apply the optical theorem to unstable particles.

• Recall that we wrote the exact propagator for a scalar particle as

$$D_F\left(p^2\right) = \frac{i}{p^2 - m_0^2 - M^2\left(p^2\right)}$$

where $-iM^2\left(p^2\right)$ was the sum of all 1PI diagrams. On the other hand, these same diagrams can be used to compute $1 \to 1$ forward scattering, and the LSZ reduction formula gives

$$\mathcal{M}(p \to p) = -ZM^2\left(p^2\right)$$

• Suppose that the scalar particle is stable. Then by the optical theorem, $\mathcal{M}(p \to p)$ is real, so the self-energy is real, which implies that the pole of the propagator is simply shifted along the real axis, as we've seen before.

• If the particle can decay, then $M^2\left(p^2\right)$ acquires an imaginary part, shifting the pole off the real axis. In this case, the particle is not an asymptotic state, so we can't assign it an unambiguous

mass; equivalently, we have some freedom over what to call the mass. A reasonable choice for a slowly decaying particle is to let m be the "real pole mass",

$$m^2 - m_0^2 - \operatorname{Re} M^2\left(m^2\right) = 0$$

Then for $p^2 \approx m^2$, the exact propagator is

$$D_F\left(p^2\right) \sim \frac{iZ}{p^2 - m^2 - iZ \operatorname{Im} M^2\left(p^2\right)}$$

For particles such as the bottom quark, which immediately hadronize, the standard choice is to instead use the $\overline{\text{MS}}$ mass.

• If the propagator appears in the s-channel of a Feynman diagram, then the cross section obeys

$$\sigma(s) \propto \left|\frac{1}{s - m^2 - iZ \operatorname{Im} M^2(s)}\right|^2 = \frac{1}{\left(s - m^2\right)^2 + \left(Z \operatorname{Im} M^2(s)\right)^2}$$

which gives a Breit-Wigner resonance peak.

The optical theorem thus tells us that the width of this peak is related to the particle's decay rate,

$$\Gamma = -\frac{Z}{m} \operatorname{Im} M^2\left(m^2\right).$$

Above we have treated $\operatorname{Im} M^2\left(p^2\right)$ as a constant near the peak, so this holds in the case of narrow resonances, $\Gamma \ll m$. For broad resonances, there can be deviations from the Breit-Wigner shape.

• Suppose we are searching for a weakly coupled particle produced in the s-channel of a scattering process. There is naively a paradox here. If we consider just the first half of the Feynman diagram, involving the on-shell production of the new particle, then there is only one vertex, so the cross section scales as g^2. But if we consider the full Feynman diagram, which includes the particle's subsequent decay, then there are two vertices and the cross section scales as g^4.

• The resolution is that in the full diagram, we should perform the integral $\int \sigma(s) ds$ to get the full rate, and the sharp peak of the Breit-Wigner distribution gives a factor of $1/\Gamma \propto 1/\mathrm{g}^2$. Therefore, the two calculations give equivalent results. This enhancement was used by LEP when it ran at the Z-pole.

• The above story does not hold if the kinematics are such that the weakly coupled particle is always far off-shell; in that case the diagram cannot be cut, and the rate scales as g^4. Also, there is a limit to how long in g one can probe, because for sufficiently low g the particle becomes so long-lived that it does not decay before exiting the detector.

• If we trace through the definitions above, the shifted pole in s is below the real axis, while for stable particles, the physical values of s were $i\epsilon$ above the real axis. So if we place the multiparticle branch cut along the real axis, we reach this pole by analytically continuing downward through it, so the pole is really on the "second sheet".

Unitarity bounds

Finally, we discuss unitarity bounds.

• Consider a $2 \to 2$ elastic scattering in the CM frame. The total cross section is

$$\sigma_{\text{el}} = \frac{1}{32\pi E_{\text{cm}}^2} \int d\cos\theta |\mathcal{M}(\theta)|^2$$

where θ is the final angle between the particles. In quantum field theory, the partial wave expansion is simply the decomposition

$$\mathcal{M}(\theta) = 16\pi \sum_{j=0}^{\infty} a_j (2j+1) P_j(\cos\theta)$$

- By logic similar to the nonrelativistic version of the partial wave expansion,

$$\sigma_{\text{el}} = \frac{16\pi}{E_{\text{cm}}^2} \sum_{j=0}^{\infty} (2j+1) \left|a_j\right|^2$$

- The optical theorem gives us the relation

$$\text{Im}\, \mathcal{M}(\theta = 0) = 2E_{\text{cm}} p_{\text{cm}} \sigma_{\text{tot}} \geq 2E_{\text{cm}} p_{\text{cm}} \sigma_{\text{el}}$$

where σ_{tot} is the cross section for scattering into any final state. This yields

$$\sum_{j=0}^{\infty} (2j+1)\, \text{Im}\, a_j \geq \frac{2p_{\text{cm}}}{E_{\text{cm}}} \sum_{j=0}^{\infty} (2j+1) \left|a_j\right|^2$$

In fact, the sum on j can be dropped, by considering scattering of angular momentum eigenstates rather than plane waves.

- For simplicity, consider the ultrarelativistic limit, where $p_{\text{cm}} \approx E_{\text{cm}}/2$. Then

$$\text{Im}\, a_j \geq \left|a_j\right|^2$$

which is the interior of a circle of unit diameter in the complex plane, centered at $i/2$, so

$$|a_j| \leq 1, \quad 0 \leq \text{Im}\, a_j \leq 1, \quad |\text{Re}\, a_j| \leq \frac{1}{2}$$

- The coefficients a_j can be computed order by order in perturbation theory. If the partial wave unitarity bound is violated at some order, we say the theory violates "perturbative unitarity". This doesn't mean that the theory violates unitarity; rather, it means that the results of perturbation theory cannot be trusted, and we must switch to a new description that can be.

- This was one of the main motivations for searching for the Higgs boson. If one calculates the amplitude for $W^+W^- \to W^+W^-$in the Standard Model without including the diagrams with the Higgs boson, the amplitude scales as $\mathcal{M} \sim g^2 E^2/m_W^2$, leading to a breakdown of perturbative unitarity above a few hundred GeV. However, adding the diagrams involving the Higgs precisely cancels this growth.

- Another useful fact is the Froissart bound: the total cross section cannot grow faster than $\log^2(E_{\text{cm}})$ at high energies.

- Finally, recall that the spectral representation writes the exact time-ordered two-point function as a combination of bare Feynman propagators with positive spectral weight. This implies that propagators cannot fall off faster than $1/p^2$ at large p^2.

- E.g. the theory

$$\mathcal{L} \supset -\frac{1}{2}\phi \left(\partial^2 + \frac{\partial^4}{\Lambda^2} + m^2\right) \phi$$

has a propagator that falls off as $1/p^4$ at large p^2. Thus, it is tempting to use this to construct a UV finite quantum field theory, but the point above forbids this. As we'll see later, terms like this do appear in effective theories, but this is acceptable because this behavior only kicks in as we approach the cutoff, at which point infinitely many other terms become important and the naive calculation of the propagator falls apart.

3.3 Other properties of basic methods 2

3.3.1 Soft Theorems

Soft limit and Lorentz invariance can establish strong constraints on how massless particles can interact.

• Consider an arbitrarily complicated amplitude with an incoming particle of momentum p_i, $\mathcal{M}_0(p_i)$. Now suppose a photon of momentum q is emitted off that particle's incoming line, giving the amplitude $\mathcal{M}_i(p_i, q)$.

• For concreteness, we suppose the particle is a scalar with charge e. Using the Feynman rules of scalar QED, and assuming the photon polarization is real to avoid having to write ϵ_μ^* everywhere,

$$\mathcal{M}_i(p_i, q) = (ie)\frac{i\left(p_i^\mu + (p_i^\mu - q^\mu)\right)}{(p_i - q)^2 - m^2}\epsilon_\mu \mathcal{M}_0(p_i - q)$$

Since external particles are on-shell, we have $p_i^2 = m^2$ and $q^2 = 0$. Since the photon polarizations are transverse, $q^\mu \epsilon_\mu = 0$. Thus, we have

$$\mathcal{M}_i(p_i, q) = e\frac{p_i \cdot \epsilon}{p_i \cdot q}\mathcal{M}_0(p_i - q)$$

• Next, we take the soft limit of small q, which strictly speaking means $|q \cdot p_i| \ll |p_j \cdot p_k|$ for all external momenta p_j and p_k. Then we have

$$\mathcal{M}_i(p_i, q) \approx \left(e\frac{p_i \cdot \epsilon}{p_i \cdot q}\right)\mathcal{M}_0(p_i)$$

• Now, consider the total scattering amplitude $\mathcal{M}(q)$ involving all of the original particles in $\mathcal{M}_0$, and an extra outgoing soft photon with momentum q. To compute this, we need to sum over all possible attachment points for the photon. However, the "soft factor" that we pick up is large only when the photon attaches to an on-shell particle. For generic amplitudes, this can only happen on external lines or in loops, but in loops the on-shell part is softened by an integration over momenta, so the contributions of external lines dominate.

• Repeating the reasoning above, we find that when we attach the photon on incoming particles, we get a factor of the charge eQ_i, while attaching the photon on outgoing particles gives the same result with the opposite sign. Thus,

$$\mathcal{M}(q) \approx e\left(\sum_{i \text{ incoming}} Q_i\frac{p_i \cdot \epsilon}{p_i \cdot q} - \sum_{i \text{ outgoing}} Q_i\frac{p_i \cdot \epsilon}{p_i \cdot q}\right)\mathcal{M}_0$$

• Now, the amplitude $\mathcal{M}(q)$ must be Lorentz invariant. Under a Lorentz transformation, the amplitude can only pick up a trivial phase factor due to the little group action on the photon. But we also know that in general, a Lorentz transformation shifts the polarization vector, $\epsilon_\mu \to \epsilon_\mu + q_\mu$, which changes the amplitude by

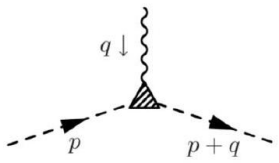
$$e\left(\sum_{i \text{ incoming}} Q_i - \sum_{i \text{ outgoing}} Q_i\right)\mathcal{M}_0$$

Demanding this be zero implies conservation of the charge the photon couples to.

• Note that we have already shown that a photon must couple to a conserved current using the canonical formalism, but this derivation is much more minimal, requiring only Lorentz invariance of the S-matrix and the soft limit.

Next, we generalize this derivation.

• First, it's not clear that the logic above holds for any type of external particle. Let's suppose that the particle is a scalar, but the interaction vertex is arbitrary,



$$= -ie\Gamma_\mu\left(p,q\right).$$

• In general, we can write the vertex in terms of form factors,

$$\Gamma^\mu = 2p^\mu F\left(p^2,q^2,p\cdot q\right) + q^\mu G\left(p^2,q^2,p\cdot q\right)$$

The form factor G is irrelevant because $q^\mu\epsilon_\mu = 0$.

• Since $p^2 = m^2$ and $q^2 = 0$, the dependence of F can be written by dimensional analysis as

$$\Gamma^\mu = 2p^\mu F\left(\frac{p\cdot q}{m^2}\right)$$

In the soft limit, the vertex simplifies further to $2p^\mu F(0)$. Thus everything goes through as before, with $F(0)$ being the definition of the conserved charge, as we've already seen in QED.

• For a minimally coupled Dirac spinor, we would instead pick up the factor

$$\bar{u}^s(\mathbf{p})\gamma^\mu(\not{p}+m) = \sum_{s'}\bar{u}^s(\mathbf{p})\gamma^\mu u^{s'}(\mathbf{p})\bar{u}^s(\mathbf{p})$$

in the numerator. However, we end up getting precisely the same result, by the identity

$$\bar{u}^s(\mathbf{p})\gamma^\mu u^{s'}(\mathbf{p}) = 2p^\mu\delta^{ss'}$$

The analysis proceeds similarly for a non-minimally coupled Dirac spinor.

• Next, we consider a massless spin 2 field. Such a field has two polarizations $\epsilon^i_{\mu\nu}$, satisfying

$$q^\mu\epsilon_{\mu\nu} = 0, \quad \eta^{\mu\nu}\epsilon_{\mu\nu} = 0$$

Under a little group transformation, we have

$$\epsilon_{\mu\nu} \to \epsilon_{\mu\nu} + \Lambda_\mu q_\nu + q_\mu\Lambda_\nu + \Lambda q_\mu q_\nu$$

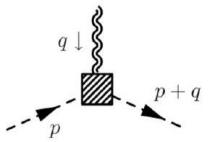
where Λ_μ and Λ depend on the little group transformation in a way we do not write out here.

• Therefore, the Ward identity must be that for any amplitude involving such an external particle, $\mathcal{M} = \epsilon_{\mu\nu}\mathcal{M}^{\mu\nu}$, we must have

$$q_\mu\mathcal{M}^{\mu\nu} = q_\nu\mathcal{M}^{\mu\nu} = 0$$

so that the amplitude is properly Lorentz invariant.

• Now we can repeat our above argument. By similar logic, an arbitrary interaction vertex is



$$= -i\Gamma^{\mu\nu}(p,q) = -2ip^\mu p^\nu \tilde{F}\left(\frac{p\cdot q}{m^2}\right),$$

where the index structure must be $p^\mu p^\nu$, because we cannot use factors of q^μ as the polarizations are transverse, and we cannot use factors of $\eta^{\mu\nu}$ as the polarizations are traceless.

• Therefore, in the soft limit,

$$\mathcal{M}(q) \approx \left(\sum_{i \text{ incoming}} \tilde{F}_i(0) \frac{p_i^\mu \epsilon_{\mu\nu} p_i^\nu}{p_i \cdot q} - \sum_{i \text{ outgoing}} \tilde{F}_i(0) \frac{p_i^\mu \epsilon_{\mu\nu} p_i^\nu}{p_i \cdot q} \right) \mathcal{M}_0$$

By Lorentz invariance, this must vanish if we substitute $\epsilon_{\mu\nu} \to q_\mu \Lambda_\nu$, so

$$\mathcal{M}_0 \Lambda_\nu \left(\sum_{i \text{ incoming}} \tilde{F}_i(0) p_i^\nu - \sum_{i \text{ outgoing}} \tilde{F}_i(0) p_i^\nu \right) = 0$$

However, we already know that the sum of incoming and outgoing momenta must be equal, by momentum conservation. So the quantity above can only vanish in general if the $\tilde{F}_i(0)$ are all equal, which means that massless spin 2 particles must couple with universal strength. This is indeed the case for the only massless spin 2 particle we know of, the graviton.

• For higher spin, the soft limit becomes even more restrictive. For massless spin 3,

$$\sum_{i \text{ incoming}} \tilde{F}_i(0) p_i^\mu p_i^\nu = \sum_{i \text{ outgoing}} \tilde{F}_i(0) p_i^\mu p_i^\nu$$

but when combined with momentum conservation, this only has solutions for general momenta if the $\tilde{F}_i(0)$ are all zero. As a result, higher spin massless particles cannot mediate long-range forces, though they can mediate interactions with a faster falloff.

• By applying this reasoning to two soft particles, one can get further constraints. E.g. it is possible to show that Yang-Mills theory is essentially the unique theory of interacting massless spin 1 particles (e.g. the quartic gauge boson interaction that appears in Yang-Mills is required by the soft limit). Similar reasoning can be used to constrain the graviton self-coupling, in a way that matches what appears in the Einstein-Hilbert action.

3.3.2 Spectral Representation

We now carefully treat interacting scalar fields.

• We consider an interacting Lagrangian

$$\mathcal{L} = \mathcal{L}_0 + \mathcal{L}_{\text{int}}\,, \quad \mathcal{L}_{\text{int}} = -V_{\text{int}}$$

where V_{int} is a power series in ϕ starting at cubic order.

• We still have Poincare symmetry, i.e. we still have unitary operators realizing these symmetries. Thus we can still talk, for example, about the momentum of a state. We also still have the equal-time commutation relations.

• We assume the full Hamiltonian has a unique vacuum $|\Omega\rangle$ with zero four-momentum,

$$P^\mu |\Omega\rangle = 0$$

Hence the vacuum is translation invariant, $e^{ixP}|\Omega\rangle = |\Omega\rangle$.

• Since we still have translation invariance, the Hamiltonian and 3-momentum commute, so we can choose a basis of states with definite four-momentum,

$$H\,|\lambda_{\mathbf{p}}\rangle = E_p(\lambda)\,|\lambda_{\mathbf{p}}\rangle\,, \qquad \mathbf{P}\,|\lambda_{\mathbf{p}}\rangle = \mathbf{p}\,|\lambda_{\mathbf{p}}\rangle$$

One can show that, by applying a Lorentz boost, we get a family of states $|\lambda_{\mathbf{p}}\rangle$ for every λ, whose energies are $E_p = (\mathbf{p}^2 + m_\lambda^2)^{1/2}$.

• The index λ labels irreps of the Poincare group in the interacting Hilbert space. In a weakly interacting theory, the sum includes "dressed" versions of the particles in the free theory, bound states of those particles, and unbound multiparticle states. In the latter case, λ has a continuum of values, as necessary to specify the relative motion of the particles.

• In a strongly interacting theory, there is no sharp distinction between dressed particles and bound states. The only meaningful distinction we can make is between multiparticle states and others, because the continuous values of λ for multiparticle states will have analytic consequences.

• Since the equation of motion is now nonlinear, the mode decomposition of ϕ is no longer useful. Even at the classical level, such a decomposition doesn't work because the interaction mixes the modes. At the quantum level, we could formally expand $\phi(x)$ in terms of ladder operators as in the free field case, but as we'll shortly see, these operators wouldn't have a simple interpretation in terms of creating and annihilating particles.

• The completeness relation, with relativistic normalization, is

$$1 = |\Omega\rangle\langle\Omega| + \sum_\lambda \int \frac{d\mathbf{p}}{2E_p(\lambda)} |\lambda_{\mathbf{p}}\rangle\langle\lambda_{\mathbf{p}}|$$

• Translation operators and Lorentz boost act on the field as

$$\phi(x) = e^{ixP}\phi(0)e^{-ixP}, \quad \phi(x) = U^{-1}(\Lambda)\phi\left(x'\right)U(\Lambda)$$

where $U(\Lambda)$ carries out the Lorentz transformation $x' = \Lambda x$. To check the signs, we can take matrix elements on both sides and act on the states instead.

With this setup, we now compute the Feynman propagator.

• Consider $\langle\Omega|\phi(x)|\Omega\rangle$. Using the translational invariance of the vacuum, we find that $\langle\Omega|\phi(x)|\Omega\rangle = \langle\Omega|\phi(0)|\Omega\rangle$ for all x. We can set the constant to zero by shifting the field, as this preserves the canonical commutators.

• Therefore, inserting the identity in a correlation function,

$$\langle\Omega|\phi(x)\phi(y)|\Omega\rangle = \sum_\lambda \int \frac{d\mathbf{p}}{2E_p(\lambda)} \langle\Omega|\phi(x)|\lambda_{\mathbf{p}}\rangle \langle\lambda_{\mathbf{p}}|\phi(y)|\Omega\rangle$$

where the vacuum term vanishes. Using the fact that the $|\lambda_{\mathbf{p}}\rangle$ have definite momentum,

$$\langle\Omega|\phi(x)|\lambda_{\mathbf{p}}\rangle = \langle\Omega|\phi(0)|\lambda_{\mathbf{p}}\rangle\, e^{-ipx}$$

Next, applying a Lorentz boost such that $|\lambda_{\mathbf{p}}\rangle = U^{-1}\,|\lambda_0\rangle$,

$$\langle\Omega|\phi(0)|\lambda_{\mathbf{p}}\rangle = \left\langle\Omega\left|U^{-1}U\phi(0)U^{-1}U\right|\lambda_{\mathbf{p}}\right\rangle e^{-ipx} = \langle\Omega|\phi(0)|\lambda_0\rangle$$

where we used the Lorentz invariance of the zero vector and the vacuum.

• Putting these results together, we have

$$\langle\Omega|\phi(x)\phi(y)|\Omega\rangle = \sum_\lambda \int \frac{d\mathbf{p}}{2E_p(\lambda)} e^{-ip(x-y)} \left|\langle\Omega|\phi(0)|\lambda_0\rangle\right|^2$$

Doing the exact same manipulations for the time ordered correlator gives

$$\langle\Omega|T\phi(x)\phi(y)|\Omega\rangle = \sum_\lambda \int dp \frac{i}{p^2 - m_\lambda^2 + i\epsilon} e^{-ip(x-y)} \left|\langle\Omega|\phi(0)|\lambda_0\rangle\right|^2$$

We parametrize the result by mass:

$$\langle\Omega|T\phi(x)\phi(y)|\Omega\rangle = \int_0^\infty d\left(M^2\right) \rho\left(M^2\right) D_F^0\left(x-y, M^2\right);$$

$$D_F^0\left(x-y, M^2\right) := \int dp \frac{i}{p^2 - M^2 + i\epsilon} e^{-ip(x-y)},$$

$$\rho\left(M^2\right) := \sum_\lambda \not{\delta}\left(M^2 - m_\lambda^2\right) \left|\langle\Omega|\phi(0)|\lambda_0\rangle\right|^2$$

$\rho\left(M^2\right)$ is called the spectral function, and by its definition, it is real and positive.

• Typically the spectral function will have poles for one-particle states and bound states. Multiparticle states have continuously "smeared out" poles, i.e. branch cuts. Separating out the one-particle contribution,

$$\rho\left(M^2\right) = \not{\delta}\left(M^2 - m^2\right) Z + \text{ higher}, \quad Z = \left|\langle\Omega|\phi(0)|1_0\rangle\right|^2$$

so that

$$\int dx e^{ip(x-y)} \langle\Omega|T\phi(x)\phi(y)|\Omega\rangle = \frac{iZ}{p^2 - m^2 + i\epsilon} + \int_{m^2_{\text{bound}}}^\infty d\left(M^2\right) \rho\left(M^2\right) \frac{i}{p^2 - M^2 + i\epsilon}.$$

The quantity Z is called the wavefunction renormalization, where $Z = 1$ when the theory is free. We see that in an interacting theory, $\phi(x)$ creates not only a one-particle state, but a superposition of many kinds of states. However, as long as $Z \neq 0$, it has at least some amplitude to create the single-particle states that we need to calculate scattering amplitudes.

• Note that this derivation was very general, and never required an expansion into creation and annihilation operators; it works for any field operator, e.g. also for composite operators. However, one can show that for bare fields (i.e. fields that satisfy $[\phi_0(t,\mathbf{x}), \partial_t\phi_0(t,\mathbf{y})] = i\delta(\mathbf{x}-\mathbf{y})$), the spectral function has unit integral, and hence $Z \leq 1$.

• There is also a similar spectral representation for the Dirac field,

$$\int dx e^{ip(x-y)} \langle\Omega|T\psi(x)\bar{\psi}(y)|\Omega\rangle = \frac{iZ_2 \sum_s u^s(p)\bar{u}^s(p)}{p^2 - m^2 + i\epsilon} + ..., \quad \sqrt{Z_2} u^s(p) = \langle\Omega|\psi(0)|p,s\rangle$$

To derive it, we also need to keep track of how the Lorentz boosts above affect the field.

• Interactions could also render one-particle states unstable, e.g. by allowing them to decay to lighter particles. Such states are not energy eigenstates at all. They instead appear in the Fourier transform of the two-point function as poles off the real axis, as we'll discuss later. Another possible subtlety is that in a theory with massless particles, the branch cut extends down to $M^2 = 0$.

Note. A cheap RG analysis. Consider interactions of the form $\lambda_n \phi^n$. Since $[\mathcal{L}] = 4$ and $[\phi] = 1$, we have $[\lambda_n] = 4 - n$. We consider a few examples.

• For the cubic interaction, $[\lambda_3] = 1$, so the effect of the interaction is described by the dimensionless parameter λ_3/E, where E is the energy scale of the process. (This is clearest in the path integral picture, where λ_3/E estimates the action contribution.) Then the interaction is strong at low energies, so it is called relevant.

• For the quartic interaction, $[\lambda_4] = 0$, and we say it is marginal.

• For the quintic interaction, $[\lambda_5] = -1$, so its effect is described by $\lambda_5 E$, which is weak at low energies, so it is called irrelevant.

• Now suppose we have a fundamental theory defined at some high scale Λ. Then the dimensionless coupling constant for ϕ^5 would be $g_5 = \Lambda\lambda_5$, where by naturalness we expect $g_5 = O(1)$. Then the effect of the interaction at scale E is $g_5(E/\Lambda)$.

• If Λ is taken to be the GUT scale or the Planck scale, then E/Λ is extremely small, so it is an excellent approximation to ignore irrelevant terms.

• But there is a subtlety: consider the dimension 2 mass term. If the above argument worked, then we would expect it to scale as $\Lambda^2\phi^2$, which implies a mass of order Λ. But clearly, there exist plenty of particles with masses well below the Planck scale. This violation of naive dimensional analysis can result from approximate symmetries, tuning, or nontrivial dynamics.

Note that this analysis depends on the spatial dimension. In six dimensions, $[\mathcal{L}] = 6, [\phi] = 2$, and it is λ_6 that is marginal.

3.3.3 The LSZ Reduction Formula

Обсудим формулу Лемана-Симанчика-Циммермана (ЛСЦ)
(мб выше потом вставлю, пока тут.)

Основные формулы

$$= \frac{i}{p^2 - m_0^2} + \frac{i}{p^2 - m_0^2}\left(-iM^2\right)\frac{i}{p^2 - m_0^2} + \cdots =$$
$$= \frac{i}{p^2 - m_0^2 - M^2\left(p^2\right)}.$$

Иллюстративные примеры (?!?)

Theory

• We are still working in Heisenberg picture, so all states are "fixed in time". Note that a better way of thinking about Heisenberg picture is that all the states "extend through time", so they may be described by how they look at any given time.

• An in state $|i, \text{ in } \rangle$ is a state which looks like several widely separated, incoming particles as $t \to -\infty$. Similarly, an out state $|f, \text{ out } \rangle$ is a state which has widely separated, outgoing particles as $t \to \infty$. Here, i and f are shorthand for a specification like "two particles, of momenta p^μ and q^μ". The asymptotic vacua are $|$ vac, in $\rangle$ and $|$ vac, out $\rangle$.

• The S matrix maps out states to in states,

$$|i, \text{ in } \rangle = S|i, \text{ out } \rangle$$

In most reasonable physical theories, we have

$$| \text{ vac, in } \rangle = | \text{ vac, out } \rangle = |\Omega\rangle, \quad S|\Omega\rangle = |\Omega\rangle, \quad S^\dagger = S^{-1}$$

We are interested in calculating the transition amplitudes

$$\langle f, \text{ out } | i, \text{ in } \rangle = \langle f, \text{ in } | S | i, \text{ in } \rangle.$$

Hence these transition amplitudes are also called S-matrix elements. Note that all of these states live in the full interacting Hilbert space.

• To formally construct the in states, we define an "in field" ϕ_{in} with the following properties.

• The in field is a free Klein-Gordan field $\phi(x)$ which creates in states from $|vac, \text{in}\rangle$ as $t \to -\infty$. Hence we have the mode expansion

$$\phi_{\text{in}}(x) = \int \frac{d\mathbf{p}}{\sqrt{2\omega_p}} \left(a_{\text{in},\mathbf{p}} e^{-ipx} + a^\dagger_{\text{in},\mathbf{p}} e^{ipx} \right)$$

• Since the in states have mass m, where m is the single-particle mass in the full theory, the in field must have mass m.

• The in field approaches the interacting field as $t \to -\infty$ in the sense that

$$\langle \alpha | \phi(x) | \beta \rangle \to \sqrt{Z} \langle \alpha | \phi_{\text{in}}(x) | \beta \rangle$$

for all states as $t \to -\infty$. The constant $\sqrt{Z}$ is determined by setting $|\beta\rangle = |\Omega\rangle$ and $|\alpha\rangle = |1_{\mathbf{p}}\rangle$ and using the spectral form.

• The out field ϕ_{out} has analogous properties as $t \to \infty$. The two are related by

$$\phi_{\text{in}}(x) = S \phi_{\text{out}}(x) S^{-1}.$$

We now apply our setup to derive the LSZ reduction formula.

• For concreteness, consider the S-matrix element $\langle p_1, p_2, \text{ out } | q_1, q_2, \text{ in } \rangle$. We have

$$\begin{aligned}
\langle p_1, p_2, \text{ out } | q_1, q_2, \text{ in } \rangle &= \sqrt{2\omega_{q_1}} \left\langle p_1, p_2, \text{ out } \left| a^\dagger_{\text{in},\mathbf{q}_1} \right| q_2, \text{ in } \right\rangle \\
&= \frac{1}{i} \int d\mathbf{x} e^{-iq_1 x} \overleftrightarrow{\partial_0} \langle p_1, p_2, \text{ out } | \phi_{\text{in}}(x) | q_2, \text{ in } \rangle \Big|_{x^0 = t} \\
&= \lim_{t \to -\infty} Z^{-1/2} \frac{1}{i} \int d\mathbf{x} e^{-iq_1 x} \overleftrightarrow{\partial_0} \langle p_1, p_2, \text{ out } | \phi(x) | q_2, \text{ in } \rangle
\end{aligned}$$

where we used the expression for $a^\dagger_{\text{in}}$ in terms of ϕ_{in}, which holds for arbitrary t, then took $t \to -\infty$ to match with the interacting field.

• The next step is to act with $\phi(x)$ on the left to get rid of one of the out particles. This is only possible if we have an out field, which requires a limit $t \to +\infty$, so we use

$$\lim_{t \to -\infty} f(t) = \lim_{t \to +\infty} f(t) - \int dt \partial_0 f(t)$$

The first term will give us terms like $\langle p_2, \text{ out } | q_2, \text{ in } \rangle \delta(\mathbf{p}_1 - \mathbf{q}_1)$ with another term with p_1 and p_2 swapped. These represent "disconnected" contributions to the S-matrix, i.e. one where the first particle doesn't scatter at all. We don't care about them here because it can be recursively computed from S-matrix elements with fewer particles.

• The connected term yields an integral over spacetime, and directly carrying out the derivatives and integrating by parts yields

$$iZ^{-1/2}\int dx_1 e^{-iq_1x_1}\left(\Box_1+m^2\right)\langle p_1,p_2,\text{ out }|\phi(x_1)|\,q_2,\text{ in }\rangle$$

There is a sticky point here, which is that the integration by parts is not legal, because e^{-iq_1x} doesn't go to zero at infinity. This occurs because momentum eigenstates unphysically cover all of space. To define our in and out states properly, we should have constructed finite wavepackets and worked with them from the start, but we sweep this under the rug to avoid the complication.

• Next, we would like to repeat this process for all of the other incoming and outgoing particles. The only snag is that when we flip $t\to-\infty$ to $t\to+\infty$ with the identity above, the new fields may be in the "wrong place" and can't be commuted past the others. The fix is to replace the correlation functions with time-ordered correlation functions, which automatically put the in and out fields on the right side.

• Carrying out this procedure and generalizing to $n+r$ particles,

$$\langle p_1,...,p_n,\text{ out }|q_1,...,q_4,\text{ in }\rangle=\sum\text{ disconnected }+$$
$$+\left(iZ^{-1/2}\right)^{n+r}\int dy_1...dx_1...\prod_k e^{ip_ky_k}\left(\Box_{y_k}+m^2\right)\prod_\ell e^{-iq_\ell x_\ell}\left(\Box_{x_\ell}+m^2\right)\langle\Omega\,|T\phi\,(y_1)\,...\phi(x_1)...|\,\Omega\rangle\,.$$

This is the LSZ reduction formula, relating S-matrix elements to time ordered correlation functions. Note that all momenta here are on-shell, since they are the momenta of asymptotic particles, so we can't treat the scattering of unstable particles.

• In momentum space, the connected part becomes

$$\left(iZ^{-1/2}\right)^{n+r}\prod_k\left(-p_k^2+m^2\right)\prod_\ell\left(-q_\ell^2+m^2\right)\langle\Omega\,|T\phi\,(p_1)\,...\phi\,(q_1)\,...|\,\Omega\rangle$$

For the S-matrix element to be nonsingular, the time-ordered correlators must have a corresponding pole structure, with a Feynman propagator factor giving poles for on-shell particles.

• Another useful rewriting is

$$\prod_k\int dy_k e^{ip_ky_k}\prod_\ell\int dx_\ell e^{-iq_lx_l}\langle\Omega|T\phi(y_1)...\phi(x_1)...|\Omega\rangle=$$
$$=\prod_k\frac{i\sqrt{Z}}{p_k^2-m^2}\prod_\ell\frac{i\sqrt{Z}}{q_\ell^2-m^2}\left\langle p_1,...|S|q_1,...\right\rangle\Big|_{\text{connected}}\,.$$

Note. In summary, in free field theory, the fields always create or destroy a particle near a point. Then position-space correlation functions describe amplitudes for particle propagation between those points, and LSZ states that momentum-space correlation functions are essentially equal to S-matrix elements after removing the poles.

In an interacting field theory, $\phi(x)$ still creates some kind of excitation near the point x (as can be seen by its transformation properties) but it is generally a complicated combination of single-particle and multiparticle states, as shown in the spectral representation. The point of the LSZ reduction formula is that we can project out the part we want (i.e. above, single-particle states of mass m) by looking at the residues of the appropriate poles, up to a $\sqrt{Z}$ correction factor.

More generally, the LSZ reduction theorem means that any field can be used to compute S-matrix elements of any kind of particle, as long as that field has nonzero overlap with the particle. E.g.we can compute S-matrix elements using the canonical momentum $\pi(x)$, because it has some amplitude to make single-particle states. For a complex scalar field, we can compute S-matrix elements for bound particle-antiparticle pairs using the field $\psi^\dagger(x)\psi(x)$.

3.3.4 Time-Ordered Correlators

We compute time-ordered correlators in the interaction picture.

• In the interaction picture, we split

$$H = H_0 + H_{\text{int}}$$

and evolve the states with H_{int} and the operators with H_0. In particular, this means the interaction picture field

$$\phi_I(x) = e^{iH_0 t}\phi(0,\mathbf{x})e^{-iH_0 t}$$

act exactly like the free Heisenberg fields which we introduced earlier. They satisfy the KleinGordan equation with the bare mass m_0, not the physical mass m. Moreover, using the free mode expansion to define $a_{I,\mathbf{p}}$, the interacting annihilation operator annihilates the free vacuum $|0\rangle$, not the interacting vacuum $|\Omega\rangle$.

• At general times, the Heisenberg picture operators are related by

$$\phi(t,\mathbf{x}) = U^\dagger(t)\phi_I(t,\mathbf{x})U(t), \qquad U(t) = e^{iH_0 t}e^{-iHt}.$$

Taking matrix elements of both sides shows that states evolve in interaction picture via $U(t)$.

$$i\frac{\partial}{\partial t}U(t) = H_I(t)U(t), \qquad H_I(t) = e^{iH_0 t}H_{\text{int}}e^{-iH_0 t}$$

$$U(t) = T\exp\left(-i\int_0^t dt' H_I(t')\right)$$

$$= 1 - i\int_0^t dt_1 H_I(t_1) + (-i)^2\int_0^t\int_0^t dt_1 dt_2 T H_I(t_1)H_I(t_2) + \ldots \qquad \text{(Dyson's equation)}$$

$$U(t,t_0) = T\exp\left(-i\int_{t_0}^t dt' H_I(t')\right)$$

and the time ordering ensures $U(t_1,t_2)U(t_2,t_3) = U(t_1,t_3)$.

• Next, we relate the interacting and free vacuum. Let $H|n\rangle = E_n|n\rangle$. Then

$$e^{-iHt}|0\rangle = \sum_n e^{iE_n t}|n\rangle\langle n|0\rangle$$

by inserting the energy basis. The vacuum state will have some nonzero energy E_Ω (as we already used up our vacuum energy counterterm to set $E_0 = 0$), but all other states will have higher energy. Thus, sending time to infinity with a small damping,

$$|\Omega\rangle = \lim_{t\to\infty(1-i\epsilon)}\frac{e^{-iHt}|0\rangle}{e^{-iE_\Omega t}\langle\Omega|0\rangle}$$

Note that we must assume $\langle\Omega|0\rangle$ is nonzero, which should be true if H_{int} is 'weak'. This trick also fails if the theory has massless particles, which yield states of arbitrarily low energy.

• Next, note that

$$e^{-iHt}|0\rangle = e^{-iHt}e^{iH_0t}|0\rangle = U(-t)^\dagger|0\rangle = U(t)|0\rangle = U(0,-t)|0\rangle$$

where we used $H_0|0\rangle = 0$. Plugging this into a correlation function,

$$\langle\Omega|\phi(x)\phi(y)|\Omega\rangle = \lim_{t\to\infty(1-i\epsilon)} \left(|\langle 0|\Omega\rangle|^2 e^{-2iE_\Omega t}\right)^{-1} \cdot \\ \cdot \left\langle 0 \left| U(t,0)U\left(x^0,0\right)^\dagger \phi_I(x) U\left(x^0,0\right) U\left(y^0,0\right)^\dagger \phi_I(y) U\left(y^0,0\right) U(0,-t) \right| 0 \right\rangle$$

where we simply switched to interaction picture.

• Using the multiplication rule for $U(t,t')$, we have

$$\langle\Omega|\phi(x)\phi(y)|\Omega\rangle = \lim_{t\to\infty(1-i\epsilon)} \left(|\langle 0|\Omega\rangle|^2 e^{-2iE_\Omega t}\right)^{-1} \cdot \left\langle 0 \left| U\left(t,x^0\right)\phi_I(x) U\left(x^0,y^0\right)\phi_I(y) U\left(y^0,-t\right) \right| 0 \right\rangle$$

We see that as long as the fields were time ordered, everything inside the expectation value is automatically timed ordered!

• To deal with the prefactor, note that

$$1 = \langle\Omega|\Omega\rangle = \lim_{t\to\infty(1-i\epsilon)} \frac{\langle 0|U(t,-t)|0\rangle}{|\langle 0|\Omega\rangle|^2 e^{-2iE_\Omega t}}$$

Combining these results together and generalizing to n fields, we find

$$\langle\Omega\left|T\phi(x_1)...\phi(x_n)\right|\Omega\rangle = \lim_{t\to\infty(1-i\epsilon)} \frac{\langle 0\left|T\phi_I(x_1)...\phi_I(x_n)U(t,-t)\right|0\rangle}{\langle 0|U(t,-t)|0\rangle}$$

We use Wick's theorem to compute these interaction picture correlators. Since we'll be working exclusively with interaction picture fields from now on, we drop the subscript.

• We decompose the interaction picture field into positive and negative free modes,

$$\phi(x) = \phi^+(x) + \phi^-(x) = \int \frac{d\mathbf{p}}{\sqrt{2\omega_p}} a_{\mathbf{p}} e^{-ipx} + \int \frac{d\mathbf{p}}{\sqrt{2\omega_p}} a^\dagger_{\mathbf{p}} e^{ipx}$$

The plus and minus fields are easier to deal with because $\phi^+(x)|0\rangle = \langle 0|\phi^-(x) = 0$.

• Given an operator O define as a string of creation and annihilation operators, its normal ordering $:O:$ is the same string but with all the annihilation operators moved to the right. As long as O does not have a c-number piece cI,

$$\langle 0|:O:|0\rangle = 0.$$

• Note that normal ordering is not a map on operators, but a map on strings of creation and annihilation operators. E.g. $aa^\dagger - a^\dagger a = 1$ is an operator equation, but normal ordering both sides gives $0 = 1$. (??? и что делать с этим???)

• Now, for the product of two fields, we have

$$\phi(x)\phi(y) = \phi^-(x)\phi^+(y) + \phi^-(x)\phi^+(y) + \phi^+(y)\phi^+(y) + \phi^+(x)\phi^-(y).$$

The first three terms are in normal order, but the last is not. Normal ordering both sides (which is legal because we haven't done anything nontrivial like applying commutation relations) gives

$$\phi(x)\phi(y) =: \phi(x)\phi(y) : + \left[\phi^+(x), \phi^-(y)\right]$$

• Applying this to a time-ordered pair of fields, we have

$$T\phi(x)\phi(y) =: \phi(x)\phi(y) : +\theta\left(x^0 - y^0\right)\left[\phi^+(x), \phi^-(y)\right] + \theta\left(y^0 - x^0\right)\left[\phi^+(y), \phi^-(x)\right]$$

The last two terms are c-numbers by the commutation relations. By taking the VEV of both sides, we see they must sum to the VEV of $T\phi(x)\phi(y)$, i.e. the (bare) Feynman propagator, so

$$T\phi(x)\phi(y) =: \phi(x)\phi(y) : +D_F^0(x-y).$$

• More generally, for a string of n fields, we get 2^n terms in total, $(n!)^2$ of which are already normal ordered. For the other terms, we have to do some number of commutations to reach normal ordering, each of which produces a two-point function.

• The full result can be written in terms of contractions, where contracting two fields removes them from the normal ordering and produces a factor of their two-point function. Wick's theorem states that

$$T\left(\phi_1 ... \phi_n\right) =: \phi_1 ... \phi_n : + \text{ all possible contractions}$$

which includes terms with any number of contractions; here we write $\phi_i = \phi\left(x_i\right)$.

• The sum includes terms which are not fully contracted, such as $D_F^0\left(x_1 - x_2\right) : \phi_3\phi_4 :$, which vanish when we take the vev. The fully contracted terms all come from the term that begins anti-normal ordered. We thus conclude

$$\left\langle 0\left|T\phi_1 ... \phi_{2n}\right|0\right\rangle = D_F^0\left(x_1 - x_2\right)\cdots D_F^0\left(x_{2n-1}, x_{2n}\right) + \text{ all other full contractions}$$

while the time-ordered correlator of an odd number of fields vanishes.

3.3.5 Ward-Takahashi Identity

(не нужно будет - во 2ю 1ю переставлю!!!)

Теория

$$\phi(x): \qquad \frac{\delta S}{\delta\phi(x)} = -\left(\partial^2 + m^2\right)\phi(x) = 0.$$

$$\left(\partial_x^2 + m^2\right) i\left\langle 0\left|T\phi(x)\phi(x_1)\right|0\right\rangle = \delta\left(x - x_1\right),$$

where the delta function comes from differentiating a step function, and we use the equal-time commutation relations (???). Домножая это уравнение на ϕ_i и подставляя уравнение движения через действие, we have the Schwinger-Dyson equation

$$\left\langle 0\left|T\frac{\delta S}{\delta\phi(x)}\phi(x_1)...\phi(x_n)\right|0\right\rangle = i\sum_{j=1}^{n}\left\langle 0\left|T\phi(x_1)...\hat{\phi}\left(x_j\right)\delta\left(x - x_j\right)...\phi(x_n)\right|0\right\rangle,$$

hat indicates a missing argument; it is the analog of the classical 'equations of motion' for correlation functions. (??? я вот не понял, там мы то ли еще обкладки берем, то ли изначально как-то в обоих частях они появляются? в теории додумаю!)

The Schwinger-Dyson equation says that correlation functions in classical field theory obey the classical equations of motion, while correlation functions in quantum field theory are corrected by 'contact terms' which correspond to the emission and absorption of virtual particles (????); accordingly, classical field theory Feynman diagrams have no loops.

• Off-shell, the Noether current associated with the symmetry $\delta\phi(x)$ satisfies $\partial_\mu j^\mu = -\frac{\delta S}{\delta\phi(x)}\delta\phi(x)$, so the Schwinger-Dyson equations become the Ward-Takahashi identity:

$$\partial_\mu \langle 0 | T j^\mu(x)\phi(x_1)...\phi(x_n) | 0\rangle + i\sum_{j=1}^{n} \left\langle 0 \left| T\phi(x_1)...\hat{\phi}(x_j)\,\delta\phi(x)\delta(x-x_j)...\phi(x_n)\right| 0\right\rangle = 0$$

it is the analog of classical current conservation for correlation functions. They are generalized in Yang-Mills to the Slavnov-Taylor identities. (??? formulas???)

• We have only justified these results for a free theory, but the same results hold for an interacting theory, where $\delta S/\delta\phi(x)$ simply gets more complicated; we will justify this with the path integral later. One caveat is that correlation functions generally involve divergent loop integrals that must be regulated. If we cannot find a regulator that respects the classical symmetry, then the symmetry is anomalous and does not hold at the quantum level.

Now we see how these results imply the Ward identity.

• By the LSZ reduction formula, a scattering amplitude involving an external photon $|k^\mu, \xi^\mu(k)\rangle$ and n other external particles has the form

$$\langle f|i\rangle \sim \xi^\mu(k)\int dx e^{-ikx}\partial_x^2 ... \langle 0|TA_\mu(x)...|0\rangle$$

• In Feynman gauge, the classical equation of motion for A^μ is $\partial^2 A^\mu = j^\mu$. Then we have

$$\partial_x^2 \langle 0|TA_\mu(x)...|0\rangle = \langle 0|Tj_\mu(x)...|0\rangle + \text{ contact terms}$$

where the contact terms contract our photon with another external photon. This represents a disconnected contribution and hence doesn't contribute to the connected S-matrix.

• Now set $\xi^\mu = k^\mu$. Integrating by parts turns the momentum into a derivative, giving

$$\partial^\mu \langle 0|Tj_\mu(x)...|0\rangle = \text{ contact terms}$$

by the Ward-Takahashi identity. Since j^μ is the conserved current associated with the $U(1)$ symmetry of the electron field, we get a contact term for each external electron. None of these terms contribute to the S-matrix because in each term, the momentum of one external leg will be displaced by $\pm k$ from where it should be; this proves the Ward identity.

• Alternatively, backing up a step and removing the LSZ pole cancellation factors, we have derived an identity between off-shell momentum-space correlation functions, where a correlation function involving an external photon is equal to a sum of correlation functions without it, where the external electron momenta are shifted by $\pm k$. This is the form of the Ward-Takahashi identity presented in Peskin, where it is proven diagrammatically.

Note. More generally, any amplitude $\mathcal{M}^{\mu\nu\cdots}\epsilon_\mu^{(1)}\epsilon_\nu^{(2)}...$ will vanish if any nonzero number of the $\epsilon^{(i)}$ are made longitudinal. However, in non-abelian gauge theory the equations of motion are

more complicated, and the above argument is not applicable. It turns out that the amplitude still vanishes if any one of the $\epsilon^{(i)}$ are made longitudinal, but the rest must be transverse.

This leads to some subtleties. For processes involving off-shell gluons, we cannot naively replace sums over physical polarizations with $\eta_{\mu\nu}$ as we did for QED. However, the extra contribution due to including the extra unphysical polarizations can be cancelled by ghosts. E.g. in the amplitude for $q\bar{q} \to gg$, the extra unphysical contribution can be cancelled by adding the amplitude for $q\bar{q} \to c\bar{c}$. This latter amplitude contributes negatively to the cross section, which is possible because the ghosts have negative norm.

We now explicitly link current conservation and gauge invariance.

• Write the action as $S = S_A[A] + S_{\text{int}}[A, \phi] + S_\phi[\phi]$.

In retrospect, we see that our derivation of the Ward identity only requires S to have a global continuous symmetry with conserved current j^μ that couples to A^μ as

$$\frac{\delta S_{\text{int}}[A, \phi]}{\delta A_\mu} = -j^\mu$$

This is the first step in the derivation, and conservation of j^μ is the second.

• We claim that if A^μ couples to a conserved current in a massless vector theory, the action S must be gauge invariant. To see this, consider the global continuous symmetry $\phi(x) \to \phi(x) + \epsilon\delta\phi(x)$, which leaves S invariant. If we promote ϵ to $\epsilon(x)$, then

$$\delta S = \int dx \tilde{j}^\mu \partial_\mu \epsilon(x) = -\int dx \left(\partial_\mu \tilde{j}^\mu\right) \epsilon(x)$$

where the first step follows by Lorentz invariance, and because δS is zero when $\epsilon(x)$ is constant. Comparing this to our earlier expression shows that $\tilde{j}^\mu = j^\mu$.

• Next, using our original hypothesis we have

$$\int dx \left(\frac{\delta S_{\text{int}}}{\delta A_\mu} + j^\mu\right) \partial_\mu \epsilon(x) = 0$$

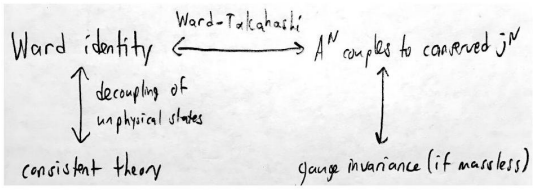
As we've just seen, the second term is the change in the action due to the local transformation $\phi(x) \to \phi(x) + \epsilon(x)\delta\phi(x)$. The first term is the change in the action due to the local transformation $A_\mu \to A_\mu + \partial_\mu \epsilon(x)$, where we used the fact that $S_A[A]$ is gauge invariant. Thus we have shown that the full action has a gauge symmetry.

• The converse of this statement follows from running the steps in reverse. If there is a gauge symmetry, taking ϵ constant gives a global symmetry with conserved current j^μ, and the variation of the action under the gauge transformation is

$$\int dx \left(\frac{\delta S_{\text{int}}}{\delta A_\mu} + j^\mu\right) \partial_\mu \epsilon(x) = 0$$

as before. Since $\partial_\mu \epsilon(x)$ is arbitrary, the term in brackets is zero.

• In the case of a massive vector theory, there is no gauge invariance, but the Ward identity still holds if A^μ couples to a conserved current j^μ. A map of equivalences is given below.



All of these statements are so closely related that the Ward identity is sometimes called a statement of 'current conservation' or 'gauge invariance'.

3.3.6 Feynman Diagrams

We can represent the terms in Wick's theorem diagrammatically.

• For $\langle 0\,|T\phi_1...\phi_n|\,0\rangle$, draw n points, then draw all possible diagrams made by connecting disjoint pairs of points. For an edge from i to j, write down the factor $D_F^0\left(x_i - x_j\right)$.

• Interactions can be expanded order by order, e.g. for a ϕ^4 interaction,

$$\left\langle 0\left|T\phi(x)\phi(y)e^{-i(\lambda/4!)\int dz\phi^4(z)}\right|0\right\rangle = \langle 0|T\phi(x)\phi(y)|0\rangle + \left\langle 0\left|T\phi(x)\phi(y)\int dz\left(\frac{-i\lambda}{4!}\right)\phi^4(z)\right|0\right\rangle + ...$$

The $1/n!$ factor in the Taylor series is always canceled by the permutation symmetry of the vertices. Naively, the $1/4!$ factors are canceled because we have $4\,!$ contractions possible for each factor of $\phi^4(z)$, but this is not true for symmetric diagrams; the overall result is that we must divide by the symmetry factor of the diagram.

• This gives the position-space Feynman rules for $\langle 0\,|T\phi(x_1)...\phi(x_n)U(\infty,-\infty)|\,0\rangle$.

• Draw a point for every 'external' point x_i. These are the original fields in the correlator.

• Draw some internal vertices z_i to account for the interaction. For every vertex, multiply by $-i\lambda$ and integrate over z_i.

• Draw directed lines between points until every external point is connected to one line, and every internal vertex is connected to four.

• For a line from x to y, write down the Feynman propagator

$$D_F^0(x-y) = \int dp \frac{i}{p^2 - m_0^2 + i\epsilon} e^{-ip(x-y)}$$

The orientation of the line doesn't matter, since $D_F^0(x-y) = D_F^0(y-x)$.

• Divide by the symmetry factor of the diagram and sum over all diagrams.

• Note that we can contract fields at a point to other fields at the same point, giving factors of $D_F^0(0)$ which diverges. This is a loop diagram, which must be addressed by renormalization.

• To simplify this, we can perform the position integrals, leaving behind only momentum integrals. If lines with momentum p_1 and p_2 point into a vertex z and lines with momentum p_3 and p_4 point out, the position integral is

$$\int dz e^{ip_1 z} e^{ip_2 z} e^{-ip_3 z} e^{-ip_4 z} = \not{\delta}\left(p_1 + p_2 - p_3 - p_4\right)$$

Therefore, we have the momentum-space Feynman rules shown below.

• Give each line a directed momentum p_i and write down the factor

$$\tilde{D}_F^0(p) = \frac{i}{p^2 - m_0^2 + i\epsilon}$$

• For each vertex, multiply by

$$(-i\lambda)\phi\left(\Sigma_{\text{in}}\, p_i - \Sigma_{\text{out}}\, p_j\right)$$

• For each external point, multiply by e^{-ipx} if momentum p points out of the point, and e^{ipx} if it points in.

• Integrate dp over each internal momentum.

• For each connected component that is a vacuum bubble, multiply by the volume of spacetime VT.

• To explain the last rule, note that for vacuum bubbles, not all of the position integrals can be performed. We are left with integrals parametrizing the location of each bubble,s

$$\int dz = \not{\delta}(0) = VT$$

where VT is the volume of the spacetime. This is generally what $\delta(0)$ means when it appears.

Working with disconnected diagrams.

• The nomenclature is a bit confusing. We say a diagram is connected if every vertex is connected, in the graph theory sense, to an external point, i.e. there are no vacuum bubbles. We say a diagram is fully connected if it has one connected component. Neither condition implies the other. E.g. a diagram with only a vacuum bubble is fully connected but not connected.

• Every diagram can be factorized into the product of a connected diagram and a diagram with no external points (vacuum bubbles):

$$\sum \text{ all diagrams } = \left(\sum \text{ connected diagrams }\right)\left(\sum \text{ vacuum bubbles }\right).$$

• By applying our rules above to the case of zero external points, we have

$$\lim_{t\to\infty(1-i\epsilon)} \langle 0|U(t,-t)|0\rangle = \sum \text{ vacuum bubbles } \equiv Z$$

which tells us that the correlator of Heisenberg fields is

$$\langle \Omega \,|T\phi_1...\phi_n|\, \Omega\rangle = \sum \text{ connected diagrams with } n \text{ external points.}$$

We call the sum of the vacuum bubbles Z the partition function.

• The partition function has further structure. Let $\{V_i\}$ be the set of fully connected vacuum bubbles. Then a vacuum bubble with n_i copies of V_i comes with the additional symmetry factor $\prod_i 1/n_i!$, so

$$Z = \exp\left(\sum \text{ fully-connected vacuum bubbles }\right)$$

• On the other hand, by our previous work we have

$$\lim_{t\to\infty(1-i\epsilon)} \langle 0|U(t,-t)|0\rangle = \lim_{t\to\infty(1-i\epsilon)} |\langle\Omega|0\rangle|^2 e^{-iE_\Omega T}$$

Taking the logarithm, the $|\langle\Omega|0\rangle|^2$ term is finite and vanishes in the limit, giving

$$E_\Omega = \lim_{t\to\infty(1-i\epsilon)} \frac{i}{T}\log Z$$

Thus the sum of fully-connected vacuum bubbles gives the vacuum energy.

• We can divide by V to get the vacuum energy density. On the right-hand side, this combines with T to give the volume of the spacetime, which cancels with the factor of $\phi(0)$ which comes

with every fully-connected vacuum bubble. This removes the IR divergence, though we still have a UV divergence, which must be handled by renormalization.

Next, we introduce 1PI diagrams to compute the propagator.

• In perturbation theory, the exact propagator can be expanded as,

$$D_F(x-y) = \langle\Omega|T\phi(x)\phi(y)|\Omega\rangle = \sum \text{ connected diagrams with 2 external points.}$$

To organize the perturbation series, define a one-particle irreducible (1PI) diagram to be one which cannot be separated into two separate nontrivial diagrams by cutting a single line.

• We define

$$-iM^2\left(p^2\right) = \sum \text{ all non-trivial 1PI diagrams}$$

where the 1PI diagrams have incoming and outgoing momentum p^2, and do not include factors for the incoming/outgoing propagators or external points.

• We define the Fourier transform

$$D_F(x-y) = \int dp e^{-ip(x-y)} D_F\left(p^2\right)$$

Then $D_F\left(p^2\right)$ is computed with the same Feynman rules as $D_F(x-y)$, but there are no factors for external points.

• Therefore by Dyson resummation:

$$D_F\left(p^2\right) = D_F^0\left(p^2\right) + D_F^0\left(p^2\right)\left(-iM^2\left(p^2\right)\right)D_F^0\left(p^2\right) + \ldots = \frac{i}{p^2-m_0^2+i\epsilon}\frac{1}{1-\frac{M^2(p^2)}{p^2-m_0^2+i\epsilon}}$$

$$D_F\left(p^2\right) = \frac{i}{p^2-\left(m_0^2+M^2\left(p^2\right)\right)+i\epsilon}.$$

$M^2\left(p^2\right)$ is the self-energy of the particle.

• Let m^2 be the first analytic pole of $D_F\left(p^2\right)$. Then we may write

$$D_F\left(p^2\right) = \frac{iZ}{p^2-m^2+i\epsilon} + \text{ terms regular at } m^2$$

Comparing this with the spectral representation, Z is the wavefunction renormalization and m is the physical mass. Thus we have found a way to compute Z and m perturbatively.

3.3.7 Scattering Amplitudes

We now use LSZ to relate our correlators back to S-matrix elements.

• We return to our statement of LSZ, with $n+r$ total incoming and outgoing particles,

$$\prod_k \int dy_k e^{ip_k y_k} \prod_\ell \int dx_\ell e^{-iq_l x_l} \langle\Omega|T\phi\left(y_1\right)\ldots\phi(x_1)\ldots|\Omega\rangle$$
$$= \prod_k \frac{i\sqrt{Z}}{p_k^2-m^2} \prod_\ell \frac{i\sqrt{Z}}{q_\ell^2-m^2} \left\langle p_1,\ldots|S|q_1,\ldots\right\rangle\Big|_{\text{connected}}.$$

Above, all momenta are on-shell. The S-matrix element cannot cancel any of the poles, because then it would be proportional to $p_k^2 - m^2$ or $q_\ell^2 - m^2$, and hence vanish entirely. Thus contributions to $S|_{\text{connected}}$ come from correlation functions with $n + r$ poles at m^2.

• The only diagrams which produce such poles are fully connected diagrams. E.g. if one particle was in its own connected component, it would only contribute one factor of $iZ/\left(p^2 - m^2\right)$ from its propagator rather than the two it should. This lines up with our intuition that $S|_{\text{connected}}$ gives scattering amplitudes where all particles participate together.

• Every fully connected diagram can be decomposed as $n + r$ exact propagators attaching to an "amputated" diagram. Specifically, to amputate a leg, we start at some external point and cut off as much as possible so that the diagram splits into two components, one of which contains only that external point. Note that all 1PI diagrams are amputated but not vice versa.

• As we've seen above, each resummed propagator contributes $iZ/\left(p^2 - m^2 + i\epsilon\right)$, plus a regular piece which is not relevant to our calculation; these cancel with the factors on the right-hand side of the LSZ reduction formula. Taking the Fourier transform has the sole effect of removing the exponential factors for the external points.

• Therefore, the Feynman rules for $\langle p_1, ..., p_n|S|q_1, ..., q_r\rangle|_{\text{connected}}$ are

• Add internal points and lines as specified earlier, giving every line a directed momentum.

• For each internal line of momentum p, multiply by

$$\frac{i}{p^2 - m_0^2 + i\epsilon}$$

• For each vertex, multiply by

$$(-i\lambda)\phi\left(\Sigma_{\text{in}}\, p_i - \Sigma_{\text{out}}\, p_j\right)$$

• Integrate dp over each internal momentum and divide by the symmetry factor.

• Sum over fully-connected, amputated diagrams and multiply by $\sqrt{Z}^{n+r}$.

Formally, $\sqrt{Z} = 1 + O(\lambda)$, so we can set $Z = 1$ for a lowest-order computation. We will always get an overall factor of $\phi\left(q_1 + ... + q_r - p_1 + ... - p_n\right)$.

• For the physical computations which follow, we will almost never be interested in vacuum bubbles, i.e. all diagrams will be connected. Hence we will rename "fully connected" to "connected" for the rest of these notes; note that we've already been using this nomenclature to refer to the connected S-matrix.

We will now introduce a naive version of perturbation theory which is easier to handle at tree level.

• Working in Schrodinger picture, we suppose that $H = H_0 + f(t)H_{\text{int}}$, where $f(t)$ is chosen so the interaction adiabatically turns on and off. This makes calculations much easier, though we lose generality. E.g. if H_0 is just taken to be the free part of H, then it is impossible to describe the scattering of bound states, which fall apart when the interaction is turned off; however, it is possible if H_0 is chosen appropriately.

• We define an "in" state $\left|i^{\text{in}}\left(t\right)\right\rangle$ to be a state which approaches a free state for $t \to -\infty$,

$$\left|i^{\text{in}}(-\infty)\right\rangle = |i(-\infty)\rangle$$

where $\left|i^{\text{in}}\right\rangle$ evolves by H and $|i\rangle$ evolves by H_0, and i stands for a state specification like 'two one-particle wavepackets with momenta $\mathbf{p}$ and $\mathbf{q}$ approaching each other'.

• We define the S-matrix by

$$\langle f(0)|S|i(0)\rangle = \left\langle f^{\text{out}}\,(0)|i^{\text{in}}\,(0)\right\rangle .$$

Thus, when the particles in the free state $|i(0)\rangle$ are about to meet and pass through each other, S takes them to a superposition of other free particle states in order to reproduce the dynamics of an interaction. This definition is equivalent to our earlier one, though everything is evaluated at time $t = 0$ on the left rather than at $t \to -\infty$.

• Letting U and U_0 be the full and free time evolution operators,

$$\begin{aligned}\left\langle f^{\text{out}}\,(0)|i^{\text{in}}\,(0)\right\rangle &= \left\langle f^{\text{out}}\,(\infty)|U(\infty,-\infty)|i^{\text{in}}\,(-\infty)\right\rangle \\ &= \langle f(\infty)|U(\infty,-\infty)|i(-\infty)\rangle \\ &= \langle f(0)\,|U_0(\infty,0)U(\infty,-\infty)U_0(-\infty,0)|\,i(0)\rangle \\ &= \left\langle f(0)\,\middle|U_I(\infty,0)U_I^\dagger(-\infty,0)\middle|\,i(0)\right\rangle \\ &= \langle f(0)\,|U_I(\infty,-\infty)|\,i(0)\rangle\end{aligned}$$

which shows that $S = U_I(\infty,-\infty)$. In other words, the point of the adiabatic turn-off is that it allows us to get a simple formal expression for the S-matrix itself. We can also show that $[S, H_0] = 0$, so scattering does not change the free particle energy.

Calculations can also be done with the adiabatic approach introduced above.

Example: scalar Yukawa theory

$$\mathcal{L} = |\partial_\mu\psi|^2 + \frac{1}{2}\left(\partial^\mu\phi\right)^2 - M^2|\psi|^2 - \frac{1}{2}m^2\phi^2 - g\psi^\dagger\psi\phi$$

$$S = U_I(\infty,-\infty) = T\exp\left(-ig\int dx\psi^\dagger\psi\phi\right)$$

where the fields above are interaction picture fields.

• We would like to calculate the amplitudes $\langle f(0)|S|i(0)\rangle$. For convenience, we construct the states in interaction picture, i.e. we view $|i(0)\rangle_S = |i(0)\rangle_I$, so that particles in the initial state are also created by interaction picture operators. Since the interaction picture states don't change at all (as the states are free), we drop the $t = 0$ argument.

• Concretely, we call the real particles mesons and the complex particles nucleons, with

$$\phi \sim a + a^\dagger, \quad \psi \sim b + c^\dagger, \quad \psi^\dagger \sim b^\dagger + c$$

where $b^\dagger$ creates a nucleon and $c^\dagger$ creates an antinucleon. Then for meson decay,

$$|i\rangle = \sqrt{2E_{\mathbf{p}}}a^\dagger_{\mathbf{p}}|0\rangle, \quad |f\rangle = \sqrt{4E_{\mathbf{q}_1}E_{\mathbf{q}_2}}b^\dagger_{\mathbf{q}_1}c^\dagger_{\mathbf{q}_2}|0\rangle.$$

• To lowest order in g, we have

$$\langle f|S-1|i\rangle = -ig\left\langle f\left|\int dx\psi^\dagger(x)\psi(x)\phi(x)\right|i\right\rangle$$

This can be simplified using the commutation relations for free field creation and annihilation operators; only one combination of operators gives a nonzero contribution. We find

$$\langle f|S-1|i\rangle = -ig\phi\left(q_1+q_2-p\right)$$

in accordance with the Feynman rules above. To save space, we define

$$\langle f|S-1|i\rangle = \langle f|iT|i\rangle = i\mathcal{M}\phi(\cdots)$$

since the delta function always appears, so that $i\mathcal{M} = -ig$.

• For more complicated processes, we use Wick's theorem, but slightly differently. Since the initial and final states aren't vacuum, we don't care about full contractions; instead we want enough fields left over to turn the initial and final states to vacuum. In this formalism, contractions correspond to only internal lines in diagrams.

Example: nucleon-nucleon scattering, $\psi\psi \to \psi\psi$

$$|i\rangle = |p_1, p_2\rangle = \sqrt{4E_{\mathbf{p}_1}E_{\mathbf{p}_2}}b^\dagger_{\mathbf{p}_1}b^\dagger_{\mathbf{p}_2}|0\rangle, \quad |f\rangle = |q_1, q_2\rangle = \sqrt{4E_{\mathbf{q}_1}E_{\mathbf{q}_2}}b^\dagger_{\mathbf{q}_1}b^\dagger_{\mathbf{q}_2}|0\rangle$$

and the $O(g^2)$ contribution to the S-matrix element is

$$\frac{(-ig)^2}{2}\left\langle f\left|\int dx_1 dx_2 T\left(\psi^\dagger(x_1)\psi(x_1)\phi(x_1)\psi^\dagger(x_2)\psi(x_2)\phi(x_2)\right)\right|i\right\rangle$$

Then the only contraction which contributes is

$$T\left(\psi^\dagger(x_1)\psi(x_1)\phi(x_1)\psi^\dagger(x_2)\psi(x_2)\phi(x_2)\right) \supset :\psi^\dagger(x_1)\psi(x_1)\psi^\dagger(x_2)\psi(x_2): D_F^0(x_1-x_2)$$

Since all the annihilation operators are moved to the right, we have

$$\left\langle f\left|:\psi^\dagger(x_1)\psi(x_1)\psi^\dagger(x_2)\psi(x_2):\right|i\right\rangle = \left\langle f\left|\psi^\dagger(x_1)\psi^\dagger(x_2)\right|0\right\rangle\langle 0|\psi(x_1)\psi(x_2)|i\rangle$$

Expanding the fields into creation and annihilation operators, each piece has two terms, giving

$$\frac{(-ig)^2}{2}\int dx_1 dx_2\left(e^{i(q_1x_1+q_2x_2)}+e^{i(q_1x_2+q_2x_1)}\right)\left(e^{-i(p_1x_1+p_2x_2)}+e^{-i(p_1x_2+p_2x_1)}\right)\int\frac{dk i e^{ik(x_1-x_2)}}{k^2-m^2+i\epsilon}$$

Doing the position integrals gives momentum-conserving delta functions, giving

$$i\mathcal{M} = (-ig)^2\left(\frac{i}{(p_1-q_1)^2-m^2}+\frac{i}{(p_1-q_2)^2-m^2}\right)$$

We dropped the $i\epsilon$ because the denominator is never zero; to see this, work in the center of mass frame where $|\mathbf{p}_1| = |\mathbf{q}_1|$. Then the timelike component of $p_1 - q_1$ is zero, so $(p_1-q_1)^2 < 0$. There is also an $O(g^0)$ contribution when $|i\rangle = |f\rangle$, which is not included in $S-1$.

We can generalize this calculation into Feynman rules.

• The Feynman rules for computing $i\mathcal{M}$, valid at tree level, are the following.

• Add internal vertices and lines as specified earlier, giving every line a directed momentum, and conserving momentum at every vertex.

• For each internal line of momentum p and mass m, multiply by $i/(p^2-m^2+i\epsilon)$.

• For every vertex, multiply by $-ig$.

• Divide by the symmetry factor, and sum over tree-level diagrams, excluding the totally disconnected diagram.

For complex scalar fields, we draw arrows on the lines to indicate the flow of particle number, but define the direction of the momentum so that p^0 is positive for external legs. There is no fixed convention for internal lines; there we might as well align the two.

- As another example, for $\psi\bar{\psi} \to \psi\bar{\psi}$, we have

$$i\mathcal{M} = (-ig)^2 \left(\frac{i}{(p_1 - q_1)^2 - m^2} + \frac{i}{(p_1 + p_2)^2 - m^2 + i\epsilon} \right)$$

where the $i\epsilon$ cannot be dropped in the second term, as it diverges when the incoming nucleons form an on-shell meson. As we'll describe in more detail later, this appears as a resonance peak in the scattering cross section.

Note. The calculational formalism we have built up in this chapter is very different from the material one learns in ordinary quantum mechanics. It's important to keep in mind that quantum field theory is in principle a special case of quantum mechanics, so the same techniques still work. E.g. one can calculate cross sections using the standard techniques of time-independent perturbation theory, in a procedure particle physicists call "old-fashioned perturbation theory", but which atomic and optical physicists still commonly use. E.g. one gets expressions like

$$\frac{dP}{dt} \sim |\mathcal{M}|^2, \quad \mathcal{M} \sim \sum_k \frac{\langle f | H_i | k \rangle \langle k | H_i | i \rangle}{E_i - E_k}$$

for a process that occurs at second order. Old-fashioned perturbation theory doesn't require learning complex, abstract new tools such as the LSZ reduction theory. However, it relies on the Hamiltonian and hence breaks Lorentz invariance. In particular, single Feynman diagrams break into multiple diagrams in this formalism, one for each possible time ordering of the interaction vertices, making calculations more complicated. (By combining pairs of such diagrams, one combines the energy denominators $1/(E_i - E_k)$ into Lorentz invariant Feynman propagators.)

Note. Above, we have seen that the connected part of the S-matrix contains a single overall momentum conserving delta function, so the connected amplitude $\mathcal{M}$ contains no delta functions. In our treatment, this followed automatically from the structure of the perturbative expansion, in terms of Feynman diagrams.

More generally, this result can be understood as a requirement of the cluster decomposition principle, the notion that distant experiments should give uncorrelated results. To see this, first note that the connected S-matrix can be defined independently of the dynamics; it is simply the part of the S-matrix, for n-particle scattering, that cannot be constructed from combining S-matrix elements for $(n-1)$-particle scattering and lower. Thus, the connected S-matrix tells us about the part of the scattering that involves all n particles together. Now, the S-matrix is unchanged under translating all of the particles, which is equivalent in momentum space to requiring an overall momentum conserving delta function. If there were further delta functions in the connected amplitude, it would imply that the connected S-matrix was invariant under translating a subset of the particles, i.e. that these particles would continue to have an effect on the others if they were translated arbitrarily far away. Hence this is forbidden by the cluster decomposition principle.

Following Weinberg, the fact that this result follows automatically from a local field description is one of the key motivations for introducing quantum fields at all, rather than focusing on just the particle states.

3.3.8 Physical Observables

We now link our scattering amplitudes to physical quantities. We begin with the potential energy $U(r)$ of two nucleons.

• At the classical level, a delta-function source for the meson field yields

$$\phi(\mathbf{x}) = \frac{e^{-mr}}{4\pi r}$$

where m is the meson mass. (?????)

We would like to think of nucleons as such delta-function sources, so that this gives the potential energy of two nucleons.

• To see this picture at the quantum level, we consider the process $\psi\psi \to \psi\psi$ at tree level. We work in the center of mass frame, so $\mathbf{p} = \mathbf{p}_1 = -\mathbf{p}_2$ and $\mathbf{q} = \mathbf{q}_1 = -\mathbf{q}_2$. Then

$$i\mathcal{M} = ig^2 \left(\frac{1}{(\mathbf{p}-\mathbf{q})^2 + m^2} + \frac{1}{(\mathbf{p}+\mathbf{q})^2 - m^2} \right)$$

On the other hand, we know from nonrelativistic quantum mechanics that the amplitude for this scattering is $\widetilde{U}(\mathbf{p}-\mathbf{q}) + \widetilde{U}(\mathbf{p}+\mathbf{q})$ in the first Born approximation, where we took into account the fact that the ψ particles are identical. Then

$$\widetilde{U}(\mathbf{p}-\mathbf{q}) = \frac{-\lambda^2}{(\mathbf{p}-\mathbf{q})^2 + m^2}, \quad U(\mathbf{r}) = -\frac{\lambda^2}{4\pi r} e^{-mr}$$

where $\lambda = g/2M$ and the extra factors of $2M$ are from the relativistic normalization. To get the result for $U(\mathbf{r})$, we have to work in spherical coordinates and perform a contour integral.

• The exact same logic holds for $\psi\bar{\psi} \to \psi\bar{\psi}$. In this case, the s-channel doesn't contribute because it vanishes in the nonrelativistic limit, as long as $M \gg m$, but the t-channel contributes in the same way, giving the exact same potential. Therefore, the force between a nucleon and antinucleon is also attractive. In general, forces mediated by particles of even spin are universally attractive.

• Similarly, in ϕ^4 theory with $H_{\text{int}} = \lambda\phi^4/4!$ the tree-level amplitude is

$$i\mathcal{M} = -i\lambda, \quad \widetilde{U}(\mathbf{p}) \propto \lambda, \quad U(\mathbf{r}) \propto \delta(\mathbf{r})$$

That is, the potential in ϕ^4 theory has zero range.

• In general, the Born approximation is a useful way of relating the scattering amplitudes we know how to compute to "position-space" quantities such as potentials. E.g. we can use it to relate the magnetic moment of the electron to its scattering amplitude off a fixed background vector potential, which can be computed diagrammatically.

• For $2 \to 2$ scattering, the Mandelstam variables

$$s = (p_1 + p_2)^2, \quad t = (p_1 - q_1)^2, \quad u = (p_1 - q_2)^2$$

appear frequently. We say that $\psi\psi \to \psi\psi$ has t-channel and u-channel diagrams at $O(g^2)$, while $\psi\bar{\psi} \to \psi\bar{\psi}$ has s-channel and t-channel diagrams. If the particles have masses m_i,

$$s + t + u = \sum_i m_i^2$$

Suppose two identical particles scatter by an angle θ in the center-of-mass frame. Then

$$s = 4E_{\text{cm}}^2, \quad t = -2p^2(1 - \cos\theta), \quad u = -2p^2(1 + \cos\theta)$$

In this frame, s determines the energy of each particle, while t and u give directional information.

Next, we turn to the calculation of cross sections and decay rates.

• Let V be the spatial volume and T be the total time separating the asymptotic past and future. Then $\phi(0) = VT$ and $\phi(\mathbf{0}) = V$, as we've seen earlier. We'll need these results because we will encounter squared delta functions, which arise from working in an infinite space.

• By definition, the probability to transition from state $|i\rangle$ (with particles of momentum p_i) to $|f\rangle$ (with particles of momentum q_j) is

$$P = \frac{|\langle f|S|i\rangle|^2}{\langle f|f\rangle\langle i|i\rangle}$$

$$\langle f|f\rangle = \prod_j 2E_{\mathbf{q}_i}\phi(\mathbf{0}) = \prod_j 2E_{\mathbf{q}_j}V, \quad \langle i|i\rangle = \prod_i 2E_{\mathbf{p}_i}V$$

$$|\langle f|S|i\rangle|^2 = |\mathcal{M}_{fi}|^2\,\phi\left(p_I - p_F\right)^2 = |\mathcal{M}_{fi}|^2\,\phi\left(p_I - p_F\right)VT$$

$$\frac{1}{V}\sum_{\mathbf{p}} \to \int d\mathbf{p}, \quad V\delta_{\mathbf{p},\mathbf{q}} \to \phi(\mathbf{p}-\mathbf{q})$$

$$P = \left(\prod_i \frac{1}{2E_{\mathbf{p}_i}V}\right)VT\int |\mathcal{M}_{fi}|^2\,d\Pi, \qquad d\Pi := \not{\phi}\left(p_F - p_I\right)\prod_j \frac{d\mathbf{q}_j}{2E_{\mathbf{q}_j}}$$

If some of the particles in the final state are identical, the Lorentz invariant phase space $d\Pi$ should contain $1/N!$ factors to avoid overcounting.

• First, consider the decay rate of a particle with mass m. Taking a rate cancels the T. The result is not Lorentz invariant, because of the factor of $1/E_{\mathbf{p}}$, but this is correct because it accounts for time dilation. Usually we will work in the rest frame, where $E_{\mathbf{p}} = m$, giving

$$\Gamma = \frac{1}{2m}\int |\mathcal{M}_{fi}|^2\,d\Pi$$

If there are multiple decay channels, we must also sum over types of final states.

• Next, consider scattering of two particles with energies E_1 and E_2. Then we wish to calculate the differential cross section

$$d\sigma = \frac{\text{differential probability}}{\text{unit time} \times \text{unit flux}} = \frac{1}{4E_1E_2V}\frac{1}{F}\,|\mathcal{M}_{fi}|^2\,d\Pi.$$

The flux F is the number of incoming particles per area per unit time.

• Working in the center of mass frame, the probability per volume is $1/V$ for each initial particle, and the relative velocity is $|\mathbf{v}_1 - \mathbf{v}_2|$, giving

$$d\sigma = \frac{1}{4E_1E_2\,|\mathbf{v}_1 - \mathbf{v}_2|}\,|\mathcal{M}_{fi}|^2\,d\Pi$$

• The denominator is Lorentz-invariant under boosts along $\mathbf{v}_1 - \mathbf{v}_2$, but not others, since the cross section can length contract. To see this, note that for velocities parallel to $\hat{\mathbf{z}}$,

$$E_1E_2\,|\mathbf{v}_1 - \mathbf{v}_2| = |E_2\mathbf{p}_1 - E_1\mathbf{p}_2| = |\epsilon_{\mu xy\nu}p_1^\mu p_2^\nu|$$

Thus, the inverse of this quantity has precisely the Lorentz transformation quantities of the xy component of an antisymmetric rank 2 tensor, which is precisely the geometrical representation of an area element in the xy plane.

• Some other sources define the cross section in a slightly different, Lorentz invariant way,

$$d\sigma = \frac{1}{4v_{\text{rel}}\left(p_1 \cdot p_2\right)} \left|\mathcal{M}_{fi}\right|^2 d\Pi$$

$$v_{\text{rel}} = \sqrt{1 - \frac{m_1^2 m_2^2}{\left(p_1 \cdot p_2\right)^2}}$$

This matches the definition above in the center of mass frame, so it will make no difference for these notes. On the other hand, in situations where the particles may not have opposite momenta (such as in a thermal average) one has to be careful about which definition is used.

• For scattering with two particles in the final state, we are interested in the quantity $d\sigma/d\Omega$, which can be found by writing $d\Pi = (d\Pi/d\Omega)d\Omega$. One can show, in the CM frame,

$$d\Pi = \frac{|\mathbf{q}_1|}{(2\pi)^2\left(4E_{\text{cm}}\right)} d\Omega$$

where $\mathbf{q}_1$ is the final momentum, which gives

$$\frac{d\sigma}{d\Omega} = \frac{1}{4E_1E_2\left|\mathbf{v}_1 - \mathbf{v}_2\right|} \frac{|\mathbf{q}_1|}{(2\pi)^2\left(4E_{\text{cm}}\right)} \left|\mathcal{M}_{fi}\right|^2$$

• For all equal masses, this reduces to

$$\frac{d\sigma}{d\Omega} = \frac{\left|\mathcal{M}_{fi}\right|^2}{64\pi^2 E_{\text{cm}}^2}$$

E.g. we see that s-wave scattering is isotropic, and $\sigma \propto 1/s$ for ϕ^4 theory. This is a general phenomenon for scattering off pointlike sources.

• The traditional unit for a cross section is the typical cross sectional area of a uranium nucleus,

$$1 \text{ barn } = 10^{-28} \text{ m}^2 = 100\text{fm}^2$$

which corresponds to a scatterer whose radius is a few femtometers. For context, the total cross section for proton-proton scattering is of order 100mb, and the instantaneous luminosity of the LHC is about $10\text{nb}^{-1}\ \text{s}^{-1}$. The total integrated luminosity of the LHC so far is about $200\text{fb}^{-1} = 0.2\text{ab}^{-1}$, while the future HL-LHC will accumulate 3ab^{-1}.

Final state with 3 particles

In the CM frame, the momenta $\mathbf{q}_i$ lie in a common plane, called the event plane.

$$x_i := \frac{2E_i}{E_{\text{cm}}}, \qquad x_1 + x_2 + x_3 = 2$$

In these variables, a laborious calculation shows that the phase space takes a very simple form,

$$d\Pi = \frac{E_{\text{cm}}^2}{128\pi^3} dx_1 dx_2,$$

the right-hand side is implicitly supported only over the kinematically allowed region.

• The result is also simple in terms of the invariant masses of pairs:

$$m_{12}^2 = (p_1 + p_2)^2, \quad m_{23}^2 = (p_2 + p_3)^2$$

$$d\Pi = \frac{1}{128\pi^3 E_{\text{cm}}^2} dm_{12}^2 dm_{23}^2$$

• Again, there are implicit and messy theta functions on the right-hand side to mark the kinematically allowed region. Thus, the utility of this parametrization is really on the experimental side. Plotting events in the (m_{12}^2, m_{23}^2) plane yields a Dalitz plot, and features of the plot can be attributed to the scattering amplitude itself, and hence indicate physically interesting effects.

(??? когда-то буду продумывать, см. литературу в теории поля про это, открывал, но не моя это специализация, не до этого было)

3.4 Renormalization: other well-known methods

3.4.1 Physical Interpretation

We now give some insight into the meaning of renormalization using simple toy models.

• We consider the general problem of fitting a quantum mechanical model to data. We try a candidate class of Hamiltonians $H(\theta)$ with parameters θ, which output predictions $v(\theta)$, such as energy eigenvalues. We then compute the predictions to data to infer θ.

• An important point is that the parameters θ need not have a direct physical meaning. E.g. different models of quarks will have significantly different quark masses in θ, and this is acceptable because quark masses are not physically measurable.

• Parameters that are model-independent and directly measurable by experiment, such as the physical electron mass, are called renormalized or dressed parameters, in contrast to bare parameters. The purpose of renormalization is to reparametrize $H(\theta)$ as H_{ren} (θ_{ren}) so that ideally the θ_{ren} are directly measurable, or at least can be easily inferred from the data.

• As a trivial example, consider a two-state system with

$$H(g, \Lambda) = H_0 + gV_\Lambda, \quad H_0 = \begin{pmatrix} 0 & 0 \\ 0 & \omega \end{pmatrix}, \quad V_\Lambda = \begin{pmatrix} -1 & \Lambda \\ \Lambda & 0 \end{pmatrix}$$

where Λ plays a role like a UV cutoff. The energy eigenvalues are

$$E_\pm = \frac{1}{2}\left(\omega - g \pm \sqrt{(\omega + g)^2 + 4g^2\Lambda^2}\right)$$

If Λ is a very large number, the outputs $E_\pm$are extremely sensitive to changes in g, indicating a poor choice of parametrization.

• To avoid this problem, we could reparametrize in terms of $E_\pm$, but these quantities are somewhat complicated. A simpler option is to use $g_{\text{ren}} = g\Lambda$, giving the renormalized Hamiltonian

$$H_{\text{ren}}\left(g_{\text{ren}}, \Lambda\right) = \begin{pmatrix} -g_{\text{ren}}\Lambda^{-1} & g_{\text{ren}} \\ g_{\text{ren}} & \omega \end{pmatrix}$$

In this case, the energy levels are less sensitive to g_{ren} for large Λ. The reparametrization is so nice that we can even take the limit $\Lambda \to \infty$ and find a finite result.

• Situations of this form typically arise when there is a naturally large parameter, such as a volume or energy cutoff. Note that taking $\Lambda \to \infty$ is not logically necessary; in the Wilsonian picture we never do this because realistic theories will have some finite cutoff. The point is that after a successful renormalization we have removed the extreme sensitivity to Λ, so we could take $\Lambda \to \infty$ if we wanted to; either way it shouldn't affect the experimental outputs.

Next, we turn to perturbation theory.

• Usually, for practical reasons, we expand perturbatively about a reference Hamiltonian $H_0(\mu)$, where $\mu = \mu(\theta)$. E.g. the decomposition $H = H_0 + gV_\Lambda$ expands about $H_0(\omega)$. The energy levels are

$$E_- = -g - \frac{g^2\Lambda^2}{\omega} + O\left(g^3\right), \quad E_+ = \omega + \frac{g^2\Lambda^2}{\omega} + O\left(g^3\right)$$

• We see that g is a bad expansion parameter because for large Λ, we require $g \ll \Lambda^{-1}$ instead of the typical $g \ll 1$. Alternatively, it is impossible to expand in g at all in the limit $\Lambda \to \infty$.

• On the other hand, after renormalization and taking the limit $\Lambda \to \infty$, we have

$$E_- = -\frac{g_{\text{ren}}^2}{\omega} + O\left(g_{\text{ren}}^4\right), \quad E_1 = \omega + \frac{g_{\text{ren}}^2}{\omega} + O\left(g_{\text{ren}}^4\right)$$

which is a perfectly well-behaved series. Thus the quality of the perturbation series depends on the parametrization θ.

• As another example of this phenomenon, consider the Taylor series of the logarithm,

$$\log(1+g) = \sum_{k=1}^{\infty} \frac{(-1)^{k-1}}{k} g^k$$

This only converges for $|g| < 1$. But if we expand in terms of $z = g/(g+2)$, we have

$$\log(1+g) = \log\left(\frac{1+z}{1-z}\right) = \sum_{k=0}^{\infty} \frac{2}{2k+1} z^{2k+1}$$

which converges for $|z| < 1$ and hence for all $\operatorname{Re} g > -1$, much faster than the original series. The singularity at $g = -1$ remains at $z = -1$, but all $\operatorname{Re} g > -1$ are 'sucked into' the region $|z| < 1$.

• The quality of the perturbation series also depends on the choice $H_0(\mu)$ as well as the specific value of μ. Since the total Hamiltonian is always the same, these choices do not affect the exact results, but they can affect the accuracy of a truncated series expansion. One might worry that this reduces predictivity; thus a good choice of μ is one which minimizes the sensitivity of the results to changes in μ.

• As an example, consider finding $x(t)$ for a particle in the potential $V(x) = ax^2 + \epsilon x^4$ at a large time $t = T$, so that T is the large parameter. Then $x(T)$ depends very sensitively upon the bare parameters a and b. Now suppose we attempt a perturbative expansion. Taking $H_0 = p^2/2m$ is clearly a very poor choice; a more reasonable choice is $H_0 = p^2/2m + ax^2$. However, expanding in ϵ gives a bad perturbation series; the terms in the series depend on T and diverges for $T \to \infty$.

• The solution is to work in terms of a renormalized frequency. We set

$$H_0 = \frac{p^2}{2m} + cx^2, \quad c = a + \sum_n c_n \epsilon^n$$

so that H_0 describes a harmonic oscillator with the same period as the anharmonic oscillator. Then if we perform a first-order expansion in ϵ, we can set the 'counterterm' c_1 so that the first-order correction is small for all T. Similarly to perform a second-order expansion we would have to also determine c_2.

• The sensitivity to T has been reduced; changing variables from (a, ϵ) to (c, ϵ'), where c is the renormalized frequency and ϵ describes the amount of anharmonicity. The result $x(T)$ depends sensitively on ϵ, but not on ϵ'.

О нерелятивистском пределе (!?!?!?)

(важный переход туда, укажу тут это! мб в другие переходы тоже тут напишу, нпр в квантовую оптику, пока сам это не понял.)

3.4.2 Power Counting

In this section, we explore the systematics of perturbative renormalization. We begin by estimating the degree of divergence of a Feynman diagram.

• We consider a scalar field theory with a ϕ^n interaction. Consider a connected diagram with V such vertices, I internal propagators, E external lines, and L loops. Euler's formula gives

$$L = I - V + 1$$

while counting the number of edges in two different ways gives

$$nV = 2I + E$$

• The momentum integral will contain Ld^dk integrals and I factors of $1/k^2$, so we define the superficial degree of divergence

$$D = dL - 2I$$

We estimate $\mathcal{M} \sim \Lambda^D$, so diagrams with $D > 0$ are superficially divergent, diagrams with $D = 0$ are superficially log-divergent, and diagrams with $D < 0$ are superficially finite. Note that for particles with half-integer spin, propagators would instead contribute as $1/k$.

• Superficially divergent diagrams can actually be finite due to a symmetry. Moreover, superficially finite diagrams may diverge: the superficial estimate assumes that all of the loop momenta are of the same order Λ, but divergences can come from regions where only some of the loop momenta are large. One can show, rather tediously, that all such divergences come from superficially divergent subdiagrams.

• Rewriting D in terms of V and E, we have

$$D = d - \left(d - n\frac{d-2}{2}\right)V - \frac{d-2}{2}E$$

Note that the quantity in brackets is simply the mass dimension of the ϕ^n coupling, while the coefficient of E is simply the mass dimension of the field. This generalizes straightforwardly to multiply types of vertices and fields.

• We see in general that more external lines decreases D, while more internal vertices increases or decreases D depending on the dimension of V. We say that a theory is (power-counting)

• renormalizable if the number of superficially divergent amplitudes is finite, but superficial divergences appear at every order in perturbation theory,

• superrenormalizable if the number of superficially divergent diagrams is finite,

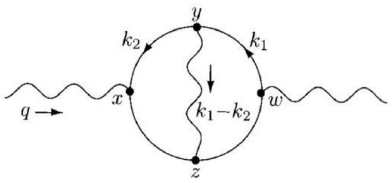
• nonrenormalizable if the number of superficially divergent amplitudes is infinite.

In general, the couplings in a renormalizable or superrenormalizable theory all have nonnegative mass dimensions, while in a superrenormalizable theory the dimensions are all strictly positive. A single coupling with negative mass dimension renders a theory nonrenormalizable.

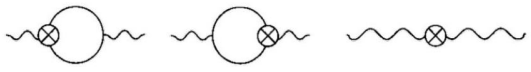
• Ignoring the issue of divergent subdiagrams, if a theory is (power-counting) renormalizable, then at every order in perturbation theory only a finite number of divergent diagrams appear, parametrized by a finite number of divergent constants.

• The BPHZ theorem ensures that divergent subdiagrams cannot change these conclusions; the divergences there are simply canceled by "counterterm subdiagrams", requiring no new counterterms to be introduced. The proof is by giving an explicit algorithm to perform this cancellation, and it is nontrivial because of the possibility of "overlapping divergences", where two divergent subdiagrams overlap, and hence their loop integrals can't be treated separately.

Note. A glimpse of higher-order renormalization. Consider the following two-loop diagram in QED.



This diagram contains two overlapping divergences. It is canceled by the counterterm diagrams shown below.



When k_2 is large, the points x, y, and z are "close together", so the divergence is canceled by the first counterterm diagram. Similarly, the second counterterm diagrams accounts for the divergence where k_1 is large, while the third accounts for the divergence where both k_1 and k_2 are large. In DR, such a divergence appears as a double pole in ϵ.

As an example, we apply power counting to QED.

• In QED, the interaction term is $e\bar{\psi}A\psi$ and the superficial degree of divergence of an amplitude with E_γ external photons and E_e external electrons is

$$D = 4 - E_\gamma - \frac{3}{2}E_e$$

since $[e] = 0$. The theory is hence renormalizable.

• The amplitudes with $D \geq 0$, that don't vanish automatically by Lorentz invariance, are:

• The vacuum energy with $D = 4$.

• The photon tadpole with $D = 3$, and the three-photon amplitude with $D = 1$.

• The four-photon amplitude with $D = 0$.

• The photon propagator with $D = 2$, the electron propagator with $D = 1$, and the renormalized vertex with $D = 0$.

Only the amplitudes in the final group are important, as we'll justify below.

• The vacuum energy is divergent, and we can absorb it with a vacuum energy counterterm. Since it has no observable consequences, we typically ignore it entirely by normal ordering.

• The one-photon and three-photon amplitudes all vanish by symmetry. QED is invariant under charge conjugation, $j^\mu \to -j^\mu$, which requires $A^\mu \to -A^\mu$. Therefore a correlation function of an odd number of photons vanishes, a result known as Furry's theorem. Diagrammatically, each diagram cancels against another with all of the electron loops reversed.

• The four-photon amplitude is finite by the Ward identity. To see this, let the amplitude be $A^{\mu\nu\rho\sigma}$. By the Ward identity, $k_\mu A^{\mu\nu\rho\sigma} = 0$, which implies that the amplitude must be proportional to something like $g^{\mu\nu}k^\sigma - g^{\mu\sigma}k^\nu$.

• To show this more explicitly, the divergent part of one diagram is

$$A^{\mu\nu\rho\sigma} \sim \int dk \frac{\mathrm{tr}\left(k\gamma^\mu \not{k}\gamma^\nu \not{k}\gamma^\rho \not{k}\gamma^\sigma\right)}{k^8}$$

and there are five more diagrams corresponding to the different ways to attach the photons to the electron loop. Using spherical symmetry, we simplify the integral to

$$A^{\mu\nu\rho\sigma} \sim \int dk \frac{\mathrm{tr}\left(\gamma^{\alpha_1}\gamma^\mu\gamma^{\alpha_2}\gamma^\nu\gamma^{\alpha_3}\gamma^\rho\gamma^{\alpha_4}\gamma^\sigma\right)}{k^4}\left(\eta_{\alpha_1\alpha_2}\eta_{\alpha_3\alpha_4} + \text{ perms. }\right)$$

which can be simplified using the standard trace identities. Finally, symmetrizing over $\mu\nu\rho\sigma$ to account for the six diagrams yields zero.

• Pulling this factor out leaves an amplitude with $D = -1$, which is hence finite. One might naively think this means the amplitude is proportional to $1/\Lambda$ and hence vanishes, but the four-photon vertex is nonzero; it mediates light-by-light scattering. The point is that D only gives us the UV dependence of the amplitude on Λ, while the finite contribution comes from the IR part of the loop integral.

• Finally, we arrive at the propagators. In our one-loop analysis of QED we found they were only logarithmically divergent, and this is indeed guaranteed by symmetries as we see below. For the degree of divergence, it suffices to look at the self energies.

• The electron self energy takes the form

$$A_0 + A_1 \not{p} + A_2 p^2 + ...$$

and has mass dimension 1. Then the only place a linear divergence can appear is in the A_0 coefficient. Now, A_0 is an analytic function in the electron mass,

$$A_0 \sim \Lambda + m_e \log(...) + \frac{m_e^2}{\Lambda}\log(...) + ...$$

When $m_e = 0$ the theory has an axial symmetry, by opposite rotations of the left and righthanded Weyl spinors; then a mass term cannot be generated by renormalization. Thus A_0 has no term independent of m_e and the divergence is at most logarithmic in Λ.

• The photon self energy has mass dimension 2 and takes the form

$$\Pi^{\mu\nu} \sim B_0\eta_{\mu\nu} + B_2 q_\mu q_\nu + B_2'\eta_{\mu\nu}q^2 + ...$$

where quadratic divergences can come from B_0. But we saw that the Ward identities required

$$\Pi^{\mu\nu} = \left(\eta^{\mu\nu}q^2 - q^\mu q^\nu\right)\Pi\left(q^2\right)$$

where $\Pi\left(q^2\right)$ is regular in q. Then we must have $B_0 = 0$.

• These results ensure that the divergences of QED can be absorbed by renormalizing terms already present in the Lagrangian. E.g. if B_0 had been nonzero, we would have had a quadratic divergence independent of q in $\Pi^{\mu\nu}$. This could only be absorbed by adding a term $A_\mu A^\mu$ to the Lagrangian, which would break gauge invariance. Similarly, if the four-photon amplitude had been divergent, we would have had to add the term $\left(A_\mu A^\mu\right)^2$. Of course, these terms would appear, and be necessary, in QED with a massive "photon".

• The more general lesson here is that, in order to absorb all divergences, a renormalizable theory must contain all renormalizable terms that are allowed by symmetry, and no more.

Note. The logic above requires that the divergent part of an amplitude be written as a polynomial in external momenta, with divergent coefficients. To see this in general, note that we may simply differentiate any superficially divergent loop integral $D+1$ times with respect to external momenta to get a convergent integral (ignoring the issue of divergent subdiagrams), which has a finite result. Integrating $D+1$ times produces a finite piece plus the advertised divergent polynomial. The finite piece contains all the analytically nontrivial dependence on the external momenta, such as the logarithms.

3.4.3 Renormalization of ϕ^4 Theory

We perform renormalization in ϕ^4 theory with a hard cutoff. We will consider the renormalization of the propagator and the ϕ^4 coupling. Equivalently, we are computing the quadratic and quartic terms in the 1PI effective action.

• We consider the action

$$S_{\Lambda_0}[\phi] = \int dx \frac{1}{2}(\partial\phi)^2 + \frac{1}{2}m^2\phi^2 + \frac{\lambda}{4!}\phi^4$$

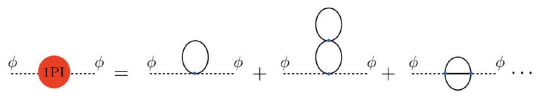
where we are working in four dimensions and Euclidean signature. We work perturbatively, which means we are near the Gaussian fixed point, so λ is marginal.

• The exact propagator/connected two-point function in momentum space is

$$\Delta\left(k^2\right) = \int dx e^{ikx}\langle\phi(x)\phi(0)\rangle_c = \frac{1}{k^2 + m^2 - \Pi\left(k^2\right)}$$

which $\Pi\left(k^2\right)$ is the sum of 1PI diagrams, by the usual geometric series argument.

• The terms in $\Pi\left(k^2\right)$ up to two loops are shown below.



Here, a dotted line denotes an amputated propagator, i.e. they are not associated with $1/\left(p^2+m^2\right)$ factors. At one loop, the contribution is simply

$$\Pi\left(k^2\right) \supset -\frac{\lambda}{2}\int\limits_{|p|\leq\Lambda_0}\frac{dp}{p^2+m^2} = -\lambda\frac{\mathrm{Vol}\left(S^3\right)}{2(2\pi)^4}\int\limits_0^{\Lambda_0}\frac{p^3dp}{p^2+m^2} = -\frac{\lambda}{2}\frac{m^2}{16\pi^2}\int\limits_0^{\Lambda_0^2/m^2}\frac{udu}{1+u}$$

Here, we used $\mathrm{Vol}\left(S^3\right)=2\pi^2$ and let $u=p^2/m^2$. We see the appearance of the generic $1/16\pi^2$ "loop factor" that appears in four dimensions. Explicitly performing the integral gives

$$\Pi\left(k^2\right) \supset -\frac{\lambda}{32\pi^2}\left(\Lambda_0^2 - m^2\log\left(1+\frac{\Lambda_0^2}{m^2}\right)\right)$$

which has a quadratic and a logarithmic divergence.

• To "cancel" these divergences, we "add counterterms" to the action, subject to the same caveats as before. That is, we work with the action

$$S_{\Lambda_0}[\phi] + \hbar S^{\mathrm{CT}}\left[\phi,\Lambda_0\right], \quad S^{\mathrm{CT}}\left[\phi,\Lambda_0\right] = \int dx\frac{1}{2}\delta Z(\partial\phi)^2 + \frac{1}{2}\delta m^2\phi^2 + \frac{1}{4!}\delta\lambda\phi^4$$

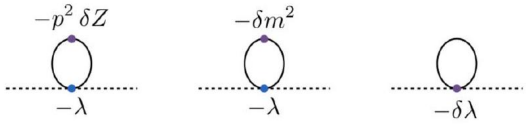
Note that this is rather different from what we did earlier, where we started from the low-energy effective action we wanted and added counterterms to get the high-energy action. At this point, the terms S_{Λ_0} and S^{CT} have no physical meaning individually.

• At $O(\hbar)$, the counterterms contribute two diagrams,

$$\Pi^{1\text{ loop}}\left(k^2\right) = -k^2\delta Z - \delta m^2 - \frac{\lambda}{32\pi^2}\left(\Lambda_0^2 - m^2\log\left(1+\frac{\Lambda_0^2}{m^2}\right)\right)$$

and we must choose δZ and δm^2 so the result is finite.

• At two loops, the corresponding counterterm diagrams have one loop, as shown.



• Since the counterterms guarantee we get finite results, we may take the continuum limit $\Lambda_0 \to \infty$ while fixing our action to match experiment. This is done by requiring the exact propagator have a pole at $p^2=-m_{\mathrm{phys}}^2$ with residue one, where m_{phys} is the physical mass, which is measured by 'weighing' a stable particle, or more generally by looking for peaks in cross sections for processes involving the exchange of the particle.

• Quantitatively, this means we require

$$\Pi\left(-m_{\mathrm{phys}}^2\right) = m^2 - m_{\mathrm{phys}}^2, \quad \left.\frac{\partial\Pi}{\partial k^2}\right|_{k^2=-m_{\mathrm{phys}}^2} = 0$$

Note that these are only constraints on the total action; we are still free to pick how it is split into S_{Λ_0} and S^{CT}. In the on-shell scheme, we choose S_{Λ_0} so that the parameter m is equal to the physical mass, so

$$\Pi\left(-m^2\right) = 0, \quad \left.\frac{\partial \Pi}{\partial k^2}\right|_{k^2=-m^2} = 0$$

Hence, in the on-shell scheme S_{Λ_0} does have a physical meaning, being roughly equivalent to the low-energy effective action encountered in Wilsonian renormalization. However, in other schemes S_{Λ_0} has no direct interpretation.

• In our case, at one loop we have

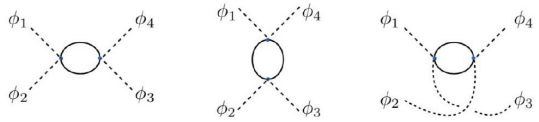
$$\delta Z = 0, \quad \delta m^2 = -\frac{\lambda}{32\pi^2}\left(\Lambda_0^2 - m^2 \log\left(1 + \frac{\Lambda_0^2}{m^2}\right)\right)$$

so that the one loop correction exactly vanishes. This is rather special; the reason it happened is that the loop is a tadpole, which doesn't depend on the external momenta at all. The tadpole only renormalizes the mass, so its effects may be entirely canceled by a counterterm. One can reformulate perturbation theory so that all tadpoles are set to zero from the start, reflecting the fact that they don't affect the physics.

• More generally, a loop will generate an infinite series of terms, such as $\phi^2, (\partial\phi)^2$, and all higher derivatives, though the higher derivative terms will be suppressed by powers of Λ_0 rather than divergent. The on-shell scheme only fixes Π and its derivative at a single point, so loop effects can be seen away from this point, e.g. in virtual particle exchange.

Next, we turn to the renormalization of the quartic coupling, which we take to mean the quartic part of the 1PI effective action.

• The one-loop corrections come from the graphs below.



Letting the external momenta k_i all flow into the diagram, the diagrams sum to

$$\frac{\lambda^2}{2}\int^{\Lambda_0} \frac{dp}{p^2+m^2}\left(\frac{1}{(p+k_1+k_2)^2+m^2} + \frac{1}{(p+k_1+k_4)^2+m^2} + \frac{1}{(p+k_1+k_3)^2+m^2}\right).$$

Since the external momenta also flow through the loop, we generate an infinite series of derivative terms, as anticipated above.

• The contribution to the pure quartic coupling λ comes from the momentum-independent part,

$$\frac{3\lambda^2}{2}\int^{\Lambda_0} \frac{dp}{(p^2+m^2)^2} = \frac{3\lambda^2}{32\pi^2}\left(\log\left(1+\frac{\Lambda_0^2}{m^2}\right) - \frac{\Lambda_0^2}{\Lambda_0^2+m^2}\right)$$

which is logarithmically divergent. One possible choice for the counterterm is

$$\delta\lambda = \frac{3\lambda^2}{32\pi^2}\left(\log\frac{\Lambda_0^2}{m^2} - 1\right)$$

The quartic term in the 1PI effective action is the negative of the sum of 1PI diagrams, so

$$\lambda_{\text{eff}} = \lambda - \frac{3\hbar\lambda^2}{32\pi^2}\left(\log\left(1+\frac{m^2}{\Lambda_0^2}\right) + \frac{m^2}{m^2+\Lambda_0^2}\right)$$

This choice ensures that in the continuum limit, $\lambda_{\text{eff}} = \lambda$, in the spirit of the on-shell scheme.

• The contributions for terms with more derivatives come in a power series in k^2/Λ_0^2, and are hence finite, vanishing in the continuum limit $\Lambda_0 \to \infty$.

• The integrals here are essentially the same as in Wilsonian renormalization. There, we integrated loops over momenta in $[\Lambda, \Lambda_0]$, getting a renormalized coupling constant. Here, we are integrate over momenta in $[0, \Lambda_0]$ in essentially the same expressions. Hence in the limit $\Lambda_0 \to \infty$ the functional dependence is the same. This mean we know, e.g. that a marginal coupling gets logarithmically divergent corrections.

• While the above is true at one loop, matters are complicated at higher loops due to divergent subdiagrams, and we need the BPHZ theorem to ensure the divergences don't get worse than expected. But the Wilsonian intuition makes it clear that the BPHZ procedure must work.

• We now do a full calculation to see the derivative terms explicitly:

$$\frac{1}{(p+k_{12})^2+m^2}\frac{1}{p^2+m^2} \equiv \int_0^1 \frac{dx}{\left[x\left((p+k_{12})^2+m^2\right)+(1-x)\left(p^2+m^2\right)\right]^2}$$

so completing the square gives the loop integral

$$\frac{\lambda^2}{2}\int_0^1 dx \int \frac{d\ell}{\left(\ell^2+M^2\right)^2}, \quad \ell = p - xk_{12}, \quad M^2 = m^2 + x(1-x)k_{12}^2$$

Note that integrating over the region $|p| \leq \Lambda_0$ is the same as integrating over the region $|\ell| \leq \Lambda_0$ up to error terms of order $|k_{12}|/\Lambda$, which vanish in the continuum limit $\Lambda_0 \to \infty$. For simplicity, we discard these terms now.

• Working in spherical coordinates, we get a factor of $\text{Vol}\left(S^3\right)$ for

$$\pi^2 \int_0^1 dx \int_0^{\Lambda_0^2} \frac{\ell^2 d\left(\ell^2\right)}{\left(\ell^2+M^2\right)^2} = \pi^2 \int_0^1 dx \log\frac{\Lambda_0^2+M^2}{M^2} + \frac{M^2}{\Lambda_0^2+M^2} - 1$$

Keeping only terms that survive in the continuum limit, our three loop diagrams yield

$$\frac{\lambda^2}{32\pi^2}\int_0^1 dx \log\frac{\Lambda_0^2}{m^2-x(1-x)s} + \log\frac{\Lambda_0^2}{m^2-x(1-x)t} + \log\frac{\Lambda_0^2}{m^2-x(1-x)u} - 3$$

$$s := -\left(k_1+k_2\right)^2, \qquad t := -\left(k_1+k_4\right)^2, \qquad u := -\left(k_1+k_3\right)^2$$

• Using the same choice of counterterm as in our rough calculation above, the quartic term in the effective action is

$$\mathcal{A}\left(k_i\right) = \lambda + \frac{\hbar\lambda^2}{32\pi^2}\int_0^1 dx \log\left(1-\frac{x(1-x)s}{m^2}\right) + \log\left(1-\frac{x(1-x)t}{m^2}\right) + \log\left(1-\frac{x(1-x)u}{m^2}\right)$$

Since this expression is in momentum space, expanding to get powers of the Mandelstam variables yields derivative terms. As expected, these terms correspond to no UV divergences, since they are irrelevant. But they are nonzero, because they are generated by the ϕ^4 coupling.

• At this point, we can compute everything else using just tree-level diagrams. E.g. the amplitude for ϕ^4 scattering only contains one diagram, the quartic vertex, which is $-\delta^4\Gamma/\delta\phi^4 = \mathcal{A}(k_i)$. Similarly for ϕ^6 scattering we have

so we only need the ϕ^2, ϕ^4, and ϕ^6 terms in $\Gamma[\phi]$.

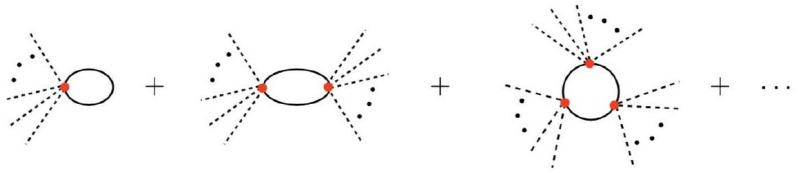
Note. A subtlety with getting a "pure coupling" is that with a hard cutoff, the effective action in momentum space is not analytic! Concretely, if the coupling is $f(k)$, then RG modifies it by an analytic function times step functions in the external momenta. This was not a problem here, but in general, computing $f(0)$ by taking zero external momenta will not give the same result as computing $f(k)$ for nonzero k, expanding in a Taylor series in k, and taking the constant term. The proliferation of step functions is one reason the hard cutoff is not practical.

Another fact we know from the Wilsonian picture is that irrelevant couplings in the high-energy theory should not affect anything at low energies. We can see this explicitly by including irrelevant couplings from the start.

• In this case, we take the action

$$S_{\Lambda_0}[\phi] = \int dx \frac{1}{2}(\partial\phi)^2 + \frac{1}{2}m^2\phi^2 + V(\phi), \quad V(\phi) = \sum_{k\geq 2} g_{2k}\Lambda_0^{4-2k}\phi^{2k}$$

We would like to compute the ϕ^{2m} coupling in the 1PI effective action. At one loop, all such diagrams have the form below.



This is merely the $O(\hbar)$ contribution to the effective action we've seen in the zero-dimensional case; it can also be found by expanding the functional determinant $\det\left(-\nabla^2 + m^2 + V''(\phi)\right)^{-1/2}$.

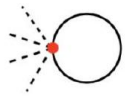
• We already know that the derivative terms are suppressed by powers of k/Λ_0, so we focus on the renormalization of the ϕ^{2m} coupling. A one-loop graph with e propagators contributes

$$\int dp \prod_{j=1}^{e} \frac{1}{(p+K_j)^2 + m^2} \sim \int \frac{dp}{p^{2e}} \sim \begin{cases} \Lambda_0^2 & e = 1 \\ \log\Lambda_0 & e = 2 \\ \text{finite but nonzero} & e > 2 \end{cases}$$

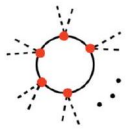
For each vertex ϕ^{2k+2}, we also pick up a factor of $\Lambda_0^{2(1-k)}$.

• Therefore, the only divergent one-loop diagrams are the mass and quartic vertex diagrams,

which we've already considered. Almost all other one-loop diagrams vanish in the continuum limit, but we find finite contributions from



which has no new effect, since we are already setting the ϕ^4 coupling with a counterterm, and



where all of the vertices are ϕ^4. That is, in the continuum limit the effective strength of the irrelevant interactions is totally fixed by the $\lambda\phi^4$ coupling, while the original high-energy irrelevant couplings play no role at all, just as in the Wilsonian picture.

Note. This result is very different from what we got by naive power counting, where we concluded that a single irrelevant coupling made every amplitude diverge. The difference is that there, we fixed the value of the dimensionful coupling. This corresponds to thinking about an effective field theory (e.g. the dimensionful masses should be fixed to match experiment), and indeed one cannot take the continuum limit of an effective field theory, and one should require infinitely many counterterms.

By contrast, here we've been thinking about S_{Λ_0}, the action of a fundamental theory. Then we've been fixing the dimensionless couplings, since they should all be presumably $O(1)$, and there is no issue with irrelevant couplings.

Finally, we repeat our calculations using DR and $\overline{\text{MS}}$.

• First, we consider the mass renormalization. We define the dimensionless coupling $g(\mu)$ by

$$\lambda = \mu^{4-d} g(\mu)$$

where μ is an arbitrary mass scale. Then the one-loop correction to $\Pi\left(k^2\right)$ is

$$\Pi\left(k^2\right) \supset -\frac{1}{2} g(\mu)\mu^{4-d} \int \frac{dp}{p^2+m^2} = -\frac{g(\mu)m^2}{2(4\pi)^{d/2}} \left(\frac{\mu}{m}\right)^{4-d} \Gamma\left(1-\frac{d}{2}\right)$$

by our usual DR formulas, with some extra signs due to the Euclidean signature.

• Setting $d = 4-\epsilon$ and expanding as usual, we find

$$\frac{g(\mu)m^2}{32\pi^2}\left(\frac{2}{\epsilon} - \gamma + \log\left(\frac{4\pi\mu^2}{m^2}\right) - 1\right) + O(\epsilon)$$

as $\epsilon \to 0^+$. In MS we choose the counterterm

$$\delta m^2 = -\frac{g(\mu)m^2}{16\pi^2\epsilon}$$

to remove the divergence only, while in $\overline{\text{MS}}$ we choose

$$\delta m^2 = -\frac{g(\mu)m^2}{32\pi^2}\left(\frac{2}{\epsilon} - \gamma + \log 4\pi\right), \quad \Pi_{1\text{ loop}}\left(k^2\right) = \frac{g(\mu)m^2}{32\pi^2}\left(\log\frac{\mu^2}{m^2} - 1\right)$$

The one-loop mass correction now depends on μ, but this is perfectly acceptable, as μ is part of the specification of the renormalization scheme. If we sum the corrections to all orders, μ must

drop out, since we should just arrive back at the pole mass. Note that the pole mass is no longer equal to m, as we're not using the on-shell scheme.

• Next, we turn to the quartic coupling, where the 1PI diagrams are

$$\frac{g^2\mu^{4-d}}{2}\int\frac{d^dp}{(p^2+m^2)\left((p+k_1+k_2)^2+m^2\right)}+2\text{ other channels.}$$

We set the external momenta k_i to zero to focus on the pure quartic coupling, giving

$$\frac{3g^2}{2(4\pi)^{d/2}}\left(\frac{\mu}{m}\right)^{4-d}\Gamma\left(2-\frac{d}{2}\right)=\frac{3g^2}{32\pi^2}\left(\frac{2}{\epsilon}-\gamma+\log\frac{4\pi\mu^2}{m^2}\right)+O(\epsilon)$$

Then in the $\overline{\text{MS}}$ scheme we have

$$\delta\lambda=\frac{3g^2}{32\pi^2}\left(\frac{2}{\epsilon}-\gamma+\log 4\pi\right),\quad g_{\text{eff}}(\mu)=g(\mu)-\frac{3\hbar g^2(\mu)}{32\pi^2}\log\frac{\mu^2}{m^2}+O\left(\hbar^2\right)$$

where we restored $\hbar$ to emphasize the one-loop effect is quantum.

• If we work to all orders, the dependence of $g_{\text{eff}}(\mu)$ on μ must drop out, because it's just the ϕ^4 coefficient of the effective action. Therefore its derivative is zero,

$$\frac{dg_{\text{eff}}}{d\log\mu}=0$$

This is a "continuum RG" equation, not to be confused with a Wilsonian RG equation.

• Differentiating our result and keeping only the lowest order terms, we have

$$\beta(g)=\frac{dg}{d\log\mu}=\frac{3\hbar g^2}{16\pi^2}+O\left(\hbar^2\right)$$

where the classical term, independent of $\hbar$, vanishes since the ϕ^4 coupling is marginal. Therefore, at one loop the coupling is marginally irrelevant.

• Separating and integrating, we find

$$\frac{1}{g\left(\mu'\right)}=\frac{1}{g(\mu)}+\frac{3\hbar}{16\pi^2}\log\frac{\mu}{\mu'},\quad g(\mu)=\frac{16\pi^2}{3\hbar}\frac{1}{\log\left(\Lambda_{\phi^4}/\mu\right)}$$

at least at one-loop order. The fact that a dimensionless initial condition can be exchanged for a dimensionful scale, Λ_{ϕ^4}, where the coupling diverges, is called dimensional transmutation.

Note. Interpreting the running coupling $g(\mu)$. The amplitude to all orders can't depend on μ, but changing μ modifies each of the terms. Generically, we have a perturbation series in $g(\mu)\log\left(\mu^2/E^2\right)$ where E is the energy scale of the process. Thus we can significantly improve the convergence of the series if we take $\mu\approx E$. In particular, when $\mu\approx E$ the sum of the series g_{eff} is well-approximated by its first term $g(\mu)$. Thus $g(\mu)$ estimates the strength of interactions at energy scale μ.

Previously, we used the on-shell scheme, where the coupling e was fixed. Using this fixed coupling we computed the one-loop amplitude for $e^+e^-\to e^+e^-$by exchange of a photon with momentum q, and found it depended on q^2, yielding a running coupling. While the particulars were different, in both cases the running coupling referred to the fact that the vertices in the 1PI effective action are momentum-dependent.

Note. The energy scale μ is not to be interpreted as a cutoff, but it does have a relationship. Note that DR integral measures take the form $\int d^{4-\epsilon}p\mu^\epsilon$. For positive ϵ, we have more momentum

modes at energies less than μ, and less at energies greater than μ. DR removes a greater and greater fraction of the momentum modes as their energy increases, acting like a smooth cutoff.

Of course, there's more to DR than just that, because DR is defined in more subtle way that preserves symmetries, but this can lead to some useful intuition. Note that the density of momentum modes starts to be significantly changed when $(p/\mu)^\epsilon \sim 1 + \epsilon \log(p/\mu)$ is significantly greater than one, which corresponds to $\epsilon \log(p/\mu) \sim 1$. Treating this momentum scale as a UV cutoff, $p \sim \Lambda$, we have $1/\epsilon \sim \log(\Lambda/\mu)$. This is the reason $1/\epsilon$ poles in DR correspond to logarithmic divergences in cutoff regularization.

3.4.4 Renormalization of Quantum Electrodynamics

We work in Euclidean signature.

$$S[A,\psi] := \int d^d x \frac{1}{4e^2} F^{\mu\nu} F_{\mu\nu} + \bar{\psi}(\not{D} + m)\psi, \quad \not{D} = \not{\partial} + i\not{A}$$

Under these conventions we have

$$[e] = \frac{4-d}{2}, \quad [A] = 1$$

in general dimensions, so the kinetic term is irrelevant when $d < 4$. Then the only relevant and marginal terms are topological ones, such as the Chern-Simons term, and this normalization is convenient for highlighting this fact: irrespective of normalization, the topological terms dominate the kinetic ones.

• However, when we do practical calculations for QED in $d = 4$, we would like the photon field to be canonically normalized. This is done by multiplying it by e^{-1}, giving

$$S[A,\psi] = \int d^d x \frac{1}{4} F^{\mu\nu} F_{\mu\nu} + \bar{\psi}(\not{D} + m)\psi + ie\bar{\psi} A \psi, \quad \not{D} = \not{\partial} + ie\not{A}$$

so that the photon field now has the usual dimension $[A] = (d-2)/2$ and the kinetic term is marginal in all dimensions. There is no contradiction: while being marginal or relevant depends on the normalization, the Chern-Simons term is more relevant in all normalizations. We'll use this convention below and suppress the d dependence.

• The Clifford algebra is modified since the metric is, giving

$$\{\gamma_\mu, \gamma_\nu\} = 2\delta_{\mu\nu}, \quad (\gamma^\mu)^\dagger = -\gamma^\mu, \quad \operatorname{tr} \gamma^\rho \gamma^\sigma = 4\delta^{\rho\sigma}$$

so that γ^0 is no longer distinguished. Then the boost generators

$$S^{\mu\nu} = \frac{i}{4}[\gamma^\mu, \gamma^\nu]$$

are Hermitian, reflecting the fact that $SO(d)$ is compact, and the action is real, and

$$\operatorname{tr}(\gamma^\mu \gamma^\rho \gamma^\nu \gamma^\sigma) = 4(\delta^{\mu\rho}\delta^{\nu\sigma} - \delta^{\mu\nu}\delta^{\rho\sigma} + \delta^{\mu\sigma}\delta^{\nu\rho})$$

• To find the classical photon propagator, we expand the kinetic term in momentum space, for

$$\begin{aligned}\frac{1}{4}\int dx F^{\mu\nu}F_{\mu\nu} &= \frac{1}{4}\int dk(-i)\left(k^\mu \tilde{A}^\nu(-k) - k^\nu \tilde{A}^\mu(-k)\right) i\left(k_\mu \tilde{A}_\nu(k) - k_\nu \tilde{A}_\mu(k)\right) \\ &= \frac{1}{2}\int dk k^2 \left(\delta^{\mu\nu} - \frac{k^\mu k^\nu}{k^2}\right)\tilde{A}_\mu(-k)\tilde{A}_\nu(k).\end{aligned}$$

The propagator is the inverse of the kinetic term, and one possible inverse is

$$\Delta^0_{\mu\nu}(k) = \frac{1}{k^2}\left(\delta_{\mu\nu} - \frac{k_\mu k_\nu}{k^2}\right)$$

The other possibilities are indexed by the ξ parameter in R_ξ gauge. Here we have chosen Landau/Lorenz gauge, $\partial^\mu A_\mu(x) = 0$ or equivalently $k^\mu \Delta^0_{\mu\nu}(k) = 0$.

• Next, we define the exact photon propagator

$$\Delta_{\mu\nu}(k) = \int dx e^{ikx} \langle A_\mu(x) A_\nu(0)\rangle$$

and by the usual argument, denoting the sum of 1PI diagrams as Π^ρ_σ,

$$\Delta_{\mu\nu}(k) = \Delta^0_{\mu\nu}(k) + \Delta^0_{\mu\rho}(k)\Pi^\rho_\sigma(k)\Delta^{0\sigma}{}_\nu + ...$$

• Using the Ward identity, we can show that

$$\Pi_{\mu\nu}(k) = k^2\pi\left(k^2\right)P_{\mu\nu}, \quad P_{\mu\nu} = \left(\eta_{\mu\nu} - \frac{k_\mu k_\nu}{k^2}\right)$$

The quantity in brackets is just an idempotent projection operator, $k^\mu P_{\mu\nu} = 0$, so the series sums to

$$\Delta_{\mu\nu}(k) = \frac{\Delta^0_{\mu\nu}(k)}{1 - \pi\left(k^2\right)}$$

• Since $\Delta_{\mu\nu}(k)$ is the inverse of the quadratic term in the 1PI effective action S_{eff} ,

$$S^{(2)}_{\text{eff}}[\tilde{A}] = \frac{1}{2}\int dk \left(1 - \pi\left(k^2\right)\right) k^2 \left(\delta^{\mu\nu} - \frac{k^\mu k^\nu}{k^2}\right)\tilde{A}_\mu(-k)\tilde{A}_\nu(k)$$

Then in position space, we get a wavefunction renormalization of $1-\pi(0)$, along with an infinite series of derivative interactions suppressed by powers of the electron mass.

Note. Showing that the photon self-energy is transverse. By diagrammatics, we have

$$\langle j^\mu j^\nu\rangle(k) = \Pi^{\mu\nu}(k) + (\Pi\Delta\Pi)^{\mu\nu}(k)$$

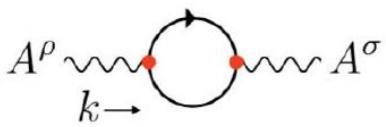
where $j^\mu = \bar{\psi}\gamma^\mu\psi$. Then the Ward identity ensures

$$k_\mu(\Pi + \Pi\Delta\Pi)^{\mu\nu} = 0$$

Expanding order by order and using the fact that Π starts at order e gives $k_\mu\Pi^{\mu\nu} = 0$, as claimed. Note that in both this proof and our earlier proof, we've had to work perturbatively. Indeed, the statement does not hold in general; it fails in the case of spontaneous symmetry breaking.

Now we turn to the one-loop contribution to $\Pi^{\rho\sigma}(k)$.

• We use dimensional regularization, defining the dimensionless coupling g by $e^2 = \mu^{4-d}g^2(\mu)$. The only diagram that contributes is



where there is no symmetry factor, since the electron and positron are distinct.

• Applying the Feynman rules, we have

$$\Pi^{\rho\sigma}_{1\text{ loop}}(k) = -\mu^{4-d}(ig)^2 \int dp \,\mathrm{tr}\left(\frac{1}{i\not{p}+m}\gamma^\rho \frac{1}{i(\not{p}-\not{k})+m}\gamma^\sigma\right)$$

where we picked up a minus sign from the fermion loop. As in the canonical formalism, we can understand this minus sign by going back to the level of contractions. When we apply Wick's theorem, we will always need to perform an odd number of Grassmann anticommutations to get the spinors all 'in order'. Equivalently, the path integral for fermions gives $\det(\not{D}+m)$ in the numerator rather than the denominator, and taking a logarithm gives the sign.

• Simplifying, the loop integral becomes

$$\int dp \frac{\mathrm{tr}\left((-i\not{p}+m)\gamma^\rho(-i(\not{p}-\not{k})+m)\gamma^\sigma\right)}{(p^2+m^2)\left((p-k)^2+m^2\right))}$$

We begin by using the Feynman trick to complete the square, turning the denominator into

$$\int_0^1 \frac{dx}{\left((p^2+m^2)(1-x)+\left((p-k)^2+m^2\right)x\right)^2} = \int_0^1 \frac{dx}{\left((p-kx)^2+m^2+k^2x(1-x)\right)^2}.$$

We then shift $p \to p+kx$, noting that this also changes the numerator.

• Next, we apply the trace identities, giving

$$\Pi^{\rho\sigma}_{1\text{ loop}}(k) = 4\mu^{4-d}g^2 \int dp \int_0^1 dx \frac{\text{numerator}}{\left(p^2+\Delta\right)^2}, \quad \Delta = m^2+k^2x(1-x)$$

$$\text{numerator} = -(p+kx)^\rho(p-k(1-x))^\sigma + (p+kx)\cdot(p-k(1-x))\delta^{\rho\sigma} - (p+kx)^\sigma(p-k(1-x))^\rho + m^2\delta^{\rho\sigma}.$$

• We can dramatically simplify the numerator using symmetry. All terms odd in p must vanish, while since the integral is isotropic we may replace

$$p^\mu p^\nu \to \frac{1}{d}\delta^{\mu\nu}p^2$$

We finally use two of our DR results to find

$$\Pi^{\rho\sigma}_{1\text{ loop}} = \left(k^2\delta^{\rho\sigma}-k^\rho k^\sigma\right)\pi_{1\text{ loop}}\left(k^2\right)$$

as required by the Ward identity, where

$$\pi_{1\text{ loop}}\left(k^2\right) = -\frac{8g^2(\mu)\Gamma(2-d/2)}{(4\pi)^{d/2}}\int_0^1 dx x(1-x)\left(\frac{\mu^2}{\Delta}\right)^{2-d/2}$$

Finally, setting $d = 4-\epsilon$ yields

$$\pi_{1\text{ loop}}\left(k^2\right) = -\frac{g^2(\mu)}{2\pi^2}\int_0^1 dx x(1-x)\left(\frac{2}{\epsilon}-\gamma+\log\frac{4\pi\mu^2}{\Delta}\right)$$

Next, we set the counterterms.

• As argued earlier, we require three counterterms for QED, which are

$$S^{\mathrm{CT}}[A,\psi]=\int dx\delta Z_3\frac{1}{4}F^{\mu\nu}F_{\mu\nu}+\delta Z_2\bar{\psi}\not{D}\psi+\delta m\bar{\psi}\psi$$

Here we've used $Z_1=Z_2$ to combine the electron field strength renormalization and the vertex renormalization into one term. This guarantees the counterterm Lagrangian is gauge invariant, as it must be if our regulator preserved gauge invariance.

• In $\overline{\mathrm{MS}}$ the δZ_3 counterterm contributes

$$\delta Z_3=-\frac{g^2(\mu)}{12\pi^2}\left(\frac{2}{\epsilon}-\gamma+\log 4\pi\right)$$

$$\pi_{1\text{ loop}}\left(k^2\right)=\frac{g^2(\mu)}{2\pi^2}\int_0^1 dxx(1-x)\log\frac{m^2+x(1-x)k^2}{\mu^2}$$

• The logarithm produced here is typical for loop corrections. Moreover, it creates a branch cut for the photon propagator in the region $m^2+x(1-x)k^2\leq 0$. This is inaccessible for real Euclidean momenta, but in Lorentz signature with $k_0=iE$ we have

$$x(1-x)\left(E^2-\mathbf{k}^2\right)\geq m^2$$

so the branch cut starts at $E=2m$, the threshold for creating a real electron-positron pair.

• Now, reverting to our original normalization of the photon field, where the coefficient of the kinetic term is $1/e^2$, we find

$$\frac{1}{g_{\mathrm{eff}}^2}=\frac{1-\pi(0)}{g^2(\mu)}=\frac{1}{g^2(\mu)}+\frac{\hbar}{12\pi^2}\log\frac{\mu^2}{m^2}$$

where we explicitly restore factors of $\hbar$. Note that there is no contribution from the vertex renormalization because, as we've shown, the covariant derivative $D_\mu=\partial_\mu+ieA_\mu$ is renormalized as a 'single piece' (i.e. $Z_1=Z_2$) and hence is absorbed by a field renormalization of ψ alone, without changing e.

• Setting $\partial g_{\mathrm{eff}}/\partial\log\mu$ to zero gives

$$\beta(g)=\frac{\hbar g^3(\mu)}{12\pi^2}+O\left(\hbar^2\right),\quad g^2(\mu)=\frac{6\pi^2}{\hbar}\frac{1}{\log\left(\Lambda_{\mathrm{QED}}/\mu\right)},\quad \Lambda_{\mathrm{QED}}\approx 10^{286}\mathrm{GeV}$$

where we set $\alpha\left(m_e\right)=g^2\left(m_e\right)/4\pi\approx 1/137$. That is, the QED coupling is marginally irrelevant and there is a Landau pole.

Note. How are our results here compatible with our earlier analysis of QED? In this section, we think in terms of the 1PI effective action. For simplicity, we set $m=0$. Then

$$\mathcal{L}=\frac{1}{4}F_0^2+\bar{\psi}_0\not{\partial}\psi_0+ie_0\bar{\psi}_0A_0\psi_0$$

This is gauge invariant because the interactions are built from the covariant derivative $D=\partial+ie_0A_0$. The effective Lagrangian in Fourier space takes the form

$$\mathcal{L}^{\text{eff}} \supset \frac{1}{4} f_3\left(q^2\right)\left|F_0^q\right|^2+\frac{1}{Z_2} f_2\left(q^2\right) \bar{\psi}_0^q \not{\partial} \psi_0^q+i e_0 f_1(q, p) \bar{\psi}_0^{q+p} A_0^q \psi_0^p$$

Here, we're using an abbreviated notation where superscripts stand for momenta; we get this momentum dependence because the effective action has an infinite series of derivative terms. The parameters Z_1, Z_2, and Z_3 are defined by

$$\frac{1}{Z_3}=f_3\left(q^2\right)\big|_{q^2=0}, \quad \frac{1}{Z_2}=f_2\left(q^2\right)\big|_{q^2=m_e^2}, \quad \frac{1}{Z_1}=f_1(q, p)|_{q^2=0}$$

where m_e is the pole mass of the electron, in this case zero. Therefore, at low momenta, we have

$$\mathcal{L}^{\text{eff}} \supset \frac{1}{4} \frac{1}{Z_3} F_0^2+\frac{1}{Z_2} \bar{\psi}_0 \not{\partial} \psi_0+\frac{i e_0}{Z_1} \bar{\psi}_0 A_0 \psi_0$$

We are thus motivated to define the renormalized fields and renormalized/physical coupling

$$A=\frac{A_0}{\sqrt{Z_3}}, \quad \psi=\frac{\psi_0}{\sqrt{Z_2}}, \quad e=\frac{Z_2}{Z_1} \sqrt{Z_3} e_0$$

which gives

$$\mathcal{L}=\frac{1}{4} Z_3 F^2+Z_2 \bar{\psi} \not{\partial} \psi+i Z_1 e \bar{\psi} A \psi, \quad \mathcal{L}^{\text{eff}} \supset \frac{1}{4} F^2+\bar{\psi} \not{\phi} \psi+i e \bar{\psi} A \psi$$

Therefore, e is a direct measure of the all-orders interaction strength at low momentum. In terms of these rescaled fields and couplings, the covariant derivative in $\mathcal{L}$ is $D=\partial+i\left(Z_1 / Z_2\right) e A$. On the other hand, $\mathcal{L}^{\text{eff}}$ is built from $\partial+i e A$. Hence conceptually the result $Z_1=Z_2$ tells us that the effective action is built from covariant derivatives in the same way as the original action.

We are now working solely in terms of physical variables, which is the essential point of renormalization. The last step is to split $\mathcal{L}$ into a finite and "counterterm" part. In renormalized perturbation theory, we set the finite part of $\mathcal{L}$ equal to $\mathcal{L}^{\text{eff}}$ evaluated at on-shell momenta, i.e. low momenta here. The running coupling arises because the coefficient of $\bar{\psi} A \psi$ in $\mathcal{L}^{\text{eff}}$ depends on momentum.

In $\overline{\text{MS}}$, we instead set the counterterm to have a simple form; then the parameters in the finite part of $\mathcal{L}$ are not physical parameters; instead we have an ' $\overline{\text{MS}}$ mass' and ' $\overline{\text{MS}}$ coupling' $e(\mu)$. But as argued earlier, $e(\mu)$ is physically meaningful because it approximates the coefficient of $\bar{\psi} A \psi$ in $\mathcal{L}^{\text{eff}}$ at momentum scale μ.

Note. The $\overline{\text{MS}}$ scheme is a bit strange, since it does not have "decoupling". The coupling continues to run even when we are far below the mass of the electron, even though one would intuitively think the electron should have no effect at these energies. As another example, applying $\overline{\text{MS}}$ to the $SU(5)$ GUT, all three gauge couplings are equal at all energies, since $\overline{\text{MS}}$ knows nothing about the symmetry breaking. This is perfectly consistent, as the full perturbation series in principle sums to the same thing, but not physically transparent.

An alternative scheme that makes the decoupling explicit is to demand that the quantum corrections vanish at an arbitrary scale $k^2=\mu^2$, which is the MOM/momentum space subtraction scheme. That is, we set

$$\delta Z_3=-\frac{\hbar g^2(\mu)}{2 \pi^2} \int_0^1 d x x(1-x)\left(\frac{2}{\epsilon}-\gamma+\log \frac{4 \pi \mu^2}{m^2+x(1-x) \mu^2}\right)$$

so the total one-loop contribution is

$$\pi\left(k^2\right) = \frac{\hbar g^2(\mu)}{2\pi^2}\int_0^1 dx x(1-x)\log\left(\frac{m^2+x(1-x)k^2}{m^2+x(1-x)\mu^2}\right) + O\left(\hbar^2\right)$$

Then the beta function is

$$\beta(\mu) = \frac{g^3(\mu)}{2\pi^2}\int_0^1 dx \frac{x^2(1-x)^2\mu^2}{m^2+x(1-x)\mu^2}$$

which indeed goes to zero when $\mu \ll m$, freezing $\alpha \approx 1/137$. This is an example of the AppelquistCarazzone decoupling theorem. In general, a mass-dependent (or "physical") scheme is one where the beta function depends explicitly on the renormalization scale μ, and hence explicitly on the particle mass m. Decoupling only holds for mass-dependent schemes, which include this scheme and a hard cutoff, where Λ plays the role of the renormalization scale.

The disadvantage of mass-dependent schemes is that perturbation theory is harder; we've seen that for a hard cutoff the loops are not small. Thus in practice, a modified version of $\overline{\text{MS}}$ is used, where the decoupling is put in by hand. We consider two theories, one with an electron, valid for $\mu > m_e$, and one with no electron, valid for $\mu < m_e$. We perform renormalization in both theories with $\overline{\text{MS}}$ or another mass-independent scheme and match physical quantities at $\mu = m_e$, such as S-matrix elements. At leading order, this means that $g(\mu)$ is continuous at $\mu = m_e$, and stops running below m_e. However, at higher orders, or if we choose $\mu \neq m_e$, the coupling jumps discontinuously at the matching. This is a "threshold correction", and must be computed carefully to get, e.g. gauge coupling unification to work out correctly.

This method is called "continuum EFT" in contrast to "Wilsonian EFT", since we never have a momentum cutoff. The idea is so common today that it is often used implicitly. E.g. the QCD beta function is written in terms of n_f, the "number of light quarks". But in $\overline{\text{MS}}$ all of the quarks contribute in the same way to the beta function, regardless of mass. The standard $g(\mu)$ for QCD is actually using successive matchings, integrating out each heavy quark as we pass its mass.

Note. The first two terms of the beta function, corresponding to the one-loop and two-loop contributions, are independent of the subtraction scheme, provided that we maintain canonical normalization. Changing the normalization clearly adds terms to the beta function even at tree level; in this case that corresponds to setting $Z = 1$ at the physical mass pole. We did this for $\overline{\text{MS}}$ but not for our other scheme, which instead sets $Z = 1$ at μ.

Note. In $\overline{\text{MS}}$, the mass is not the same as the pole mass, so what is its physical meaning? One can think of the mass term as like any other renormalized coupling. E.g. the up quark mass provides an extra two-point vertex in QCD scattering problems. The $\overline{\text{MS}}$ mass at scale μ approximates the overall all-order effect of this interaction term at tree level. (Note that there is nothing preventing $\overline{\text{MS}}$ mass terms from being negative!) The PDG gives most quark masses as $\overline{\text{MS}}$ masses (the universal choice for modern theory calculations), since there is no way to define a pole mass for them. But its top quark mass is a "Pythia" mass, meaning it's simply what one gets by fitting to Pythia, which has no direct link to any theoretical calculation. When speaking of the mass of any fundamental particle, we need to specify the scheme in which it's defined.

Finally, we prove that $Z_1 = Z_2$ using the Ward-Takahashi identity.

• Starting from the global $U(1)$ symmetry of QED,

$$\psi \to \psi' = e^{i\alpha\psi}, \quad j^\mu = i\bar{\psi}\gamma^\mu\psi$$

we may apply the Ward-Takahashi identity to find

$$\partial_\mu \left\langle j^\mu(x)\psi(x_1)\bar{\psi}(x_2)\right\rangle = -i\delta\left(x-x_1\right)\left\langle \psi(x_1)\bar{\psi}(x_2)\right\rangle + i\delta\left(x-x_2\right)\left\langle \psi(x_1)\bar{\psi}(x_2)\right\rangle .$$

Note that the presence of gauge fixing terms makes no difference here, because we're only considering global symmetry transformations. However, we will see an alternate derivation below that uses the local symmetry.

• We define the exact electron propagator by Fourier transforming the two-point function,

$$\left\langle \psi\left(k_1\right)\bar{\psi}\left(-k_2\right)\right\rangle \equiv \int dx_1 dx_2 e^{ik_1x_2}e^{-ik_2x_2}\left\langle \psi(x_1)\bar{\psi}(x_2)\right\rangle = \not{\delta}\left(k_1-k_2\right)S(k)$$

where we defined

$$S(k) = \int dx e^{ikx}\langle\psi(x)\bar{\psi}(0)\rangle = \frac{1}{i\not{k}+m-\Sigma(\not{k})}$$

and $\Sigma(\not{k})$ is the sum of 1 PI diagrams.

• We define the exact vertex by

$$\left\langle j_\mu(k)\psi\left(k_1\right)\bar{\psi}\left(-k_2\right)\right\rangle \equiv \phi\left(p+k_1-k_2\right)S\left(k_1\right)\Gamma_\mu\left(k_1,k_2\right)S\left(k_2\right)$$

To understand this expression, consider computing the left-hand side diagrammatically. Here, it can be useful conceptually to draw a 'phantom' photon attached to x, though no such photon field actually appears in the correlator. The lowest-order term is γ_μ, so indeed

$$\Gamma_\mu\left(k_1,k_2\right) = \gamma_\mu + \text{ quantum corrections.}$$

At one-loop order, either the ψ and $\bar{\psi}$ can emit and reabsorb a photon. This has nothing to do with the vertex, and is accordingly absorbed by the $S\left(k_1\right)$ and $S\left(k_2\right)$ factors. Recalling that 1PI and amputated diagrams are equivalent for three external fields, we end up computing the sum of 1PI diagrams with an external photon and two external fermions.

• Finally, taking the Fourier transform of the Ward-Takahashi identity,

$$\left(k_1-k_2\right)_\mu S\left(k_1\right)\Gamma^\mu\left(k_1,k_2\right)S\left(k_2\right) = iS\left(k_1\right) - iS\left(k_2\right)$$

which is equivalent to

$$\left(k_1-k_2\right)\Gamma^\mu\left(k_1,k_2\right) = iS^{-1}\left(k_2\right) - iS^{-1}\left(k_1\right)$$

This result relates the vertex to electron kinetic term in the 1PI effective action.

• To extract the desired result, differentiate with respect to k_1 and then take $k_1, k_2 \to k$ for

$$\Gamma_\mu(k,k) = -i\frac{\partial}{\partial k^\mu}S^{-1}(k) = \gamma_\mu + i\frac{\partial}{\partial k^\mu}\Sigma(\not{k})$$

Thus, at lowest order in k, the effective action looks like

$$S^{\text{eff}} \supset \bar{\psi}\left(\gamma_\mu + i\frac{\partial}{\partial k^\mu}\Sigma(\not{k})\right)D\psi$$

so the covariant derivative $D\psi$ is renormalized as a single piece. Expanding our result in a series in k shows that interactions must come in the form $\bar{\psi}D^p\psi$.

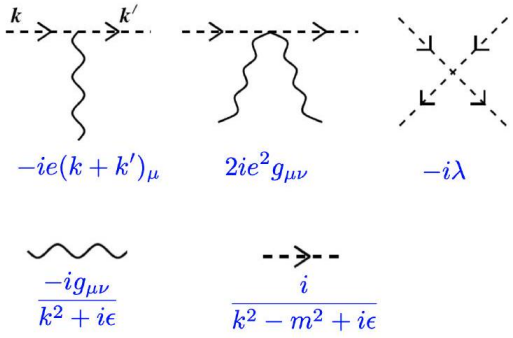
3.4.5 Scalar QED

As a final example, we'll consider the one-loop renormalization of scalar QED in $(+---)$ signature with $\overline{\text{MS}}$. Note that switching from MS to $\overline{\text{MS}}$ is equivalent to using $\mu^2_{\text{MS}} = \mu^2_{\text{MS}} 4\pi e^{-\gamma}$ throughout, so if we define $\mu = \mu_{\overline{\text{MS}}}$, we won't need to add extra "macaroni and pie" to the counterterms. We will use a new technique, to be explained below, that can compute the beta functions from only the divergent parts of the counterterms, hence displaying the simplicity of the $\overline{\text{MS}}$ scheme.

The scalar QED Lagrangian is

$$\mathcal{L} = |\partial_\mu \phi|^2 - m^2|\phi|^2 - \frac{1}{4}F^{\mu\nu}F_{\mu\nu} - \frac{\lambda}{4}|\phi|^4 - ieA_\mu\left(\phi^*\partial^\mu\phi - \phi\partial^\mu\phi^*\right) + e^2 A_\mu A^\mu \phi^*\phi.$$

Here we must include a ϕ^4 interaction because it is consistent with the symmetries, or equivalently because it may be generated by the other interaction terms. The Feynman rules are:



$\epsilon^\mu_{\lambda_i}(k), \epsilon^{\mu*}_{\lambda_i}(k)$ for incoming and outgoing photons respectively

However, for this analysis, we will work in Landau gauge, so the photon propagator comes with a factor of $P_{\mu\nu} = \eta_{\mu\nu} - q_\mu q_\nu/q^2$ rather than just $\eta_{\mu\nu}$. As we'll see, this sets many diagrams to zero, shortening the analysis.

• Relabeling all the fields above as bare fields with 0 subscripts, and defining physical fields as

$$\phi = \frac{\phi_0}{\sqrt{Z_2}}, \quad A = \frac{A_0}{\sqrt{Z_3}}, \quad e = \frac{Z_2}{Z_1}\sqrt{Z_3}e_0$$

we have

$$\mathcal{L} = Z_2\,|\partial_\mu\phi|^2 - Z_m m^2|\phi|^2 - \frac{Z_3}{4}F^{\mu\nu}F_{\mu\nu} - Z_\lambda\frac{\lambda}{4}|\phi|^4 - iZ_1 eA_\mu\left(\phi^*\partial^\mu\phi - \phi\partial^\mu\phi^*\right) + Z_4 e^2 A_\mu A^\mu\phi^*\phi$$

Here we have $Z_4 = Z_1^2/Z_2$, and we should have $Z_1 = Z_2$. In the calculations below we will not assume these results, but rather directly compute the Z_i at one-loop order in DR and $\overline{\text{MS}}$ to demonstrate they hold.

• Defining $Z_i = 1 + \delta_i$, it is convenient to split the Lagrangian as

$$\mathcal{L} = \mathcal{L}_0 + \mathcal{L}_1 + \mathcal{L}_{\text{ct}}$$

where

$$\mathcal{L}_0 = |\partial_\mu\phi|^2 - m^2|\phi|^2 - \frac{1}{4}F^{\mu\nu}F_{\mu\nu}, \quad \mathcal{L}_{\text{ct}} = \delta_2\,|\partial_\mu\phi|^2 - \delta_m m^2|\phi|^2 - \frac{\delta_3}{4}F^{\mu\nu}F_{\mu\nu}$$

and $\mathcal{L}_1$ contains the interactions. Below we will work to order $O\left(e^2\right)$ and $O(\lambda)$ in the Z_i. First, we consider the photon propagator.

• As we've seen before, the exact photon propagator remains transverse in Landau gauge, as

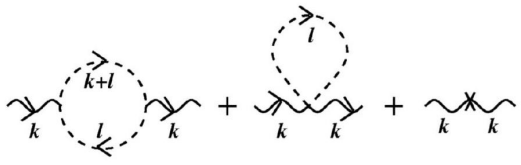
$$\Delta_{\mu\nu}(k) = \frac{\Delta^0_{\mu\nu}(k)}{1-\pi\left(k^2\right)}$$

where $\pi\left(k^2\right)$ is determined by the sum of 1PI diagrams,

$$\Pi_{\mu\nu}\left(k^2\right) = k^2\pi\left(k^2\right)P_{\mu\nu}$$

which is transverse by the Ward identity.

• At order e^2, we have the contributing diagrams:



• Since $Z_i = 1 + O\left(e^2\right)$, we can replace Z_1 and Z_4 in the first two diagrams with just 1, giving

$$i\Pi^{\mu\nu}\left(k^2\right) = (-ie)^2 i^2 \int d\ell \frac{(2\ell+k)^\mu (2\ell+k)^\nu}{(\ell+k)^2-m^2)\left(\ell^2-m^2\right)} + (2i)e^2\eta^{\mu\nu} i\int \frac{d\ell}{\ell^2-m^2} - i\left(Z_3-1\right)\left(k^2\eta^{\mu\nu}-k^\mu k^\nu\right).$$

The first two terms can be combined into

$$e^2\int d\ell \frac{N^{\mu\nu}}{\left((\ell+k)^2-m^2\right)\left(\ell^2-m^2\right)}, \quad N^{\mu\nu} = (2\ell+k)^\mu(2\ell+k)^\nu - 2\left((\ell+k)^2-m^2\right)\eta^{\mu\nu}.$$

• Applying Feynman parameters as usual, this term becomes

$$e^2\int_0^1 dx\int dq \frac{N^{\mu\nu}}{\left(q^2-\Delta\right)^2}, \quad q = \ell + xk, \quad \Delta = -x(1-x)k^2+m^2$$

Replacing ℓ with q in $N^{\mu\nu}$, it simplifies to

$$N^{\mu\nu} \sim 4q^\mu q^\nu + (1-2x)^2 k^\mu k^\nu - 2\left(q^2+(1-x)^2k^2-m^2\right)\eta^{\mu\nu}$$

where we removed terms odd in q as they integrate to zero. We replace $q^\mu q^\nu \to q^2\eta^{\mu\nu}/D$ by isotropy, leaving two standard DR integrals.

• Performing these integrals with the standard formulas and then performing the x integral gives

$$i\Pi^{\mu\nu}\left(k^2\right) = ie^2\mu^\epsilon\left(k^\mu k^\nu - k^2\eta^{\mu\nu}\right)\left(Z_3 - 1 + \frac{1}{3}\frac{1}{(4\pi)^{d/2}}\Gamma\left(\frac{4-d}{2}\right) + \text{ finite }\right)$$

where $\epsilon = 4-d$, with the transverse structure required by the Ward identity. The finite parts are momentum-dependent and can be used to compute the running coupling, as in QED.

• In this section, we'll work with $\overline{\text{MS}}$, and hence can ignore the finite parts. Then we have

$$Z_3 = 1 - \frac{e^2}{24\pi^2}\frac{1}{\epsilon}$$

at one loop. We will use this later to recover the running coupling by another way.

Note. In QED, we used the Ward-Takahashi identity associated with the global $U(1)$ symmetry to derive $Z_1 = Z_2$. For variety, we can do the same here using a somewhat different setup, essentially using the Schwinger-Dyson equation corresponding to a $U(1)$ gauge transformation. In this case, we must account for the gauge fixing term, which in R_ξ gauge is

$$\mathcal{L} \supset \mathcal{L}_{\text{gf}} = -\frac{1}{2\xi}\left(\partial_\mu A^\mu\right)^2$$

The bare photon propagator is now

$$\Delta^0_{\mu\nu}(k) = \frac{1}{k^2}\left(\eta_{\mu\nu} - (1-\xi)\frac{k_\mu k_\nu}{k^2}\right) = \frac{1}{k^2}\left(P_{\mu\nu}(k) + \xi\frac{k_\mu k_\nu}{k^2}\right)$$

Now, the sum of 1PI diagrams remains transverse, so the additional non-transverse piece is unaffected when we sum over 1PI diagrams, giving the exact propagator

$$\Delta_{\mu\nu}(k) = \frac{P_{\mu\nu}}{k^2\left(1-\pi\left(k^2\right)\right)} + \xi\frac{k_\mu k_\nu}{k^2}$$

The strategy we will use to derive our relations is to start with the generating functional with currents. Schematically, consider some local symmetry $\phi \to \phi' = \phi + \epsilon(x)\delta\phi$ under which the path integral measure is invariant. Then we have

$$Z[J] = \int \mathcal{D}\phi e^{i(S[\phi]+\phi J)} = \int \mathcal{D}\phi' e^{i(S[\phi']+\phi' J)} = \int \mathcal{D}\phi e^{i(S[\phi]+\phi J)}\left(1 + i\left(\delta S + \int dx J\delta\phi\right)\right)$$

Therefore, we must have

$$\int \mathcal{D}\phi e^{i(S[\phi]+\phi J)}\left(\delta S + \int dx J\delta\phi\right) = 0$$

Integrating by parts to get an overall factor of $\epsilon(x)$, we can use the fact that $\epsilon(x)$ is arbitrary to peel it off and remove the dx integral, leaving an correlation function identity. Since we are working with the generating functional, we can differentiate with respect to J to yield identities for higher-point functions.

In this context, we will use the gauge transformation

$$\delta\phi(x) = ie\alpha(x)\phi(x), \quad \delta A_\mu(x) = \partial_\mu\alpha(x)$$

In this case δS is solely due to the gauge fixing term $\mathcal{L}_{\text{gf}}$,

$$\delta S = -\int dx \frac{1}{\xi}\alpha(x)\partial^2\partial_\mu A^\mu(x)$$

We also get three terms from the variations of the currents, so we have, suppressing x arguments,

$$\int \mathcal{D}\phi\mathcal{D}\phi^*\mathcal{D}A_\mu e^{i(S[\phi,A_\mu]+\phi J^*+\phi^* J+J^\mu A_\mu)}\int dx\left(-\frac{1}{\xi}\alpha\partial^2\partial_\mu A^\mu\right) + J^*\delta\phi + J\delta\phi^* - iJ^\mu\delta A_\mu = 0.$$

Integrating by parts to get a factor of $\alpha(x)$ and using the fact that $\alpha(x)$ is arbitrary, we have

$$\left\langle -\frac{1}{\xi}\partial^2\partial_\mu A^\mu + ie\phi J^* - ie\phi^* J + i\partial_\mu J^\mu \right\rangle = 0$$

Dividing by $Z\left[J^\mu, J^*, J\right]$ puts this in terms of the connected generating functional $W\left[J^\mu, J^*, J\right]$,

$$\frac{1}{\xi}\partial^2\partial_\mu \frac{\delta W}{\delta J_\mu(x)} - ieJ^*(x)\frac{\delta W}{\delta J^*(x)} + ieJ(x)\frac{\delta W}{\delta J(x)} + \partial_\mu J^\mu(x) = 0$$

Acting with $(\delta/\delta J^*(y))\,(\delta/\delta J(z))$ on both sides and setting the currents to zero,

$$\frac{1}{\xi}\partial^2\partial_\mu \left\langle A_\mu(x)\phi(y)\phi(z)\right\rangle_c + ie\delta(y-x)\left\langle \phi(x)\phi^*(z)\right\rangle_c - ie\delta(z-x)\left\langle \phi^*(x)\phi(y)\right\rangle_c = 0$$

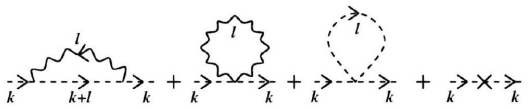
The last two terms are exact scalar propagators, while the first term is the product of the exact photon propagator, two exact scalar propagators, and the exact three-point vertex. However, upon a Fourier transform the derivatives on the photon propagator yield

$$\frac{1}{\xi}k^2 k^\mu \Delta_{\mu\nu}(k) = k^\mu$$

This reduces the identity we have here to the Ward-Takahashi identity we saw earlier for QED, and the proof continues in the same way.

Next, we consider the scalar propagator, where Landau gauge will be somewhat useful.

• The scalar propagator $i\Pi_\phi\left(k^2\right)$ has five contributions:



Here, the final diagram contains both the δ_2 and δ_m counterterms.

• The second diagram is a "scaleless" integral, and using the DR formulas gives an answer of zero. But this is too quick: the DR formulas are not actually valid at all, because there does not exist any value of d for which a scaleless integral converges (i.e. it is always either UV or IR divergent), so there are no values of d to analytically continue from!

• A glib way to justify the result is to say "the DR answer has to depend on μ, but there are no other mass scales in the integral, so what else could it be?" A bit more seriously, the integral can be IR regulated, in which case the DR formulas legitimately give

$$i\Pi_\phi\left(k^2\right) \supset \left(2Z_4 ie^2\eta^{\mu\nu}\right)(-i)\int d\ell \frac{P_{\mu\nu}}{\ell^2 - m_\gamma^2}$$

The resulting integral is proportional to m_γ^2/ϵ in DR, which vanishes in the limit $m_\gamma \to 0$.

• The first diagram contributes

$$i\Pi_\phi\left(k^2\right) \supset \left(-iZ_1 e\right)^2(-i)i\int d\ell \frac{P_{\mu\nu}(\ell)(\ell+2k)^\mu(\ell+2k)^\nu}{\ell^2\left((\ell+k)^2 - m^2\right)}$$

in Landau gauge, and since $\ell_\mu P^{\mu\nu} = 0$ we have

$$i\Pi_\phi\left(k^2\right) \supset -e^2\int d\ell \frac{4\left(\ell^2 k^2 - (k\cdot\ell)^2\right)}{\ell^4\left((\ell+k)^2 - m^2\right)}$$

where we again set $Z_1 = 1$ since we only want the $O(e^2)$ terms.

• The denominator can be simplified using Feynman parameters,

$$\frac{1}{\ell^4\left((\ell+k)^2-m^2\right)} = 2\int_0^1 dx_1 \int_0^{1-x_1} dx_2 \frac{dx_1 dx_2}{\left(\left(1-x_1-x_2\right)\ell^2 + x_2\ell^2 + x_1\left((\ell+k)^2-m^2\right)\right)^3}.$$

The x_2 dependence drops out, so evaluating the x_2 integral and renaming x_1 to x,

$$\frac{1}{\ell^4\left((\ell+k)^2-m^2\right)} = 2\int \frac{(1-x)dx}{\left(\ell^2+2x\ell\cdot k + xk^2 - xm^2\right)^3}.$$

Using the usual shift $q = \ell + xk$ we have

$$i\Pi_\phi\left(k^2\right) \supset -8e^2\int_0^1 dx \int dq \frac{q^2k^2-(q\cdot k)^2}{\left(q^2-\Delta\right)^3}, \quad \Delta = -x(1-x)k^2+m^2.$$

Applying isotropy and a standard DR formula we find

$$i\Pi_\phi\left(k^2\right) \supset -i\frac{3e^2}{8\pi^2}\frac{1}{\epsilon}k^2$$

• Next, for the scalar loop contribution, we have

$$i\Pi_\phi\left(k^2\right) \supset (-i\lambda)(i)\int \frac{d\ell}{\ell^2-m^2} = \frac{i\lambda}{8\pi^2}\frac{1}{\epsilon}m^2$$

by a standard DR formula.

• For comparison, the counterterms contribute

$$i\Pi_\phi\left(k^2\right) \supset i\delta_2 k^2 - i\delta_m m^2$$

from which we conclude

$$Z_2 = 1 + \frac{3e^2}{8\pi^2}\frac{1}{\epsilon}, \quad Z_m = 1 + \frac{\lambda}{8\pi^2}\frac{1}{\epsilon}$$

Note. A bit more about scaleless integrals in DR. The argument above is sketchy, because it requires a separate IR regulator; in principle DR can handle both UV and IR divergences by itself. Within pure DR, the justification for setting the integral to zero is the 't Hooft-Veltman conjecture, which simply states that "no inconsistencies" arise from doing this.

A bit more precisely, a proper treatment of DR would begin with a list of postulates that DR integrals must obey, just as we begin with postulates for Grassmann integration. Changing notation for clarity, these postulates are linearity, shift invariance, and the scaling

$$\int d^d\mathbf{p} f(\lambda\mathbf{p}) = \lambda^{-d}\int d^d\mathbf{p} f(\mathbf{p})$$

It can be shown (e.g. in Collins) that these postulates essentially uniquely determine the DR prescription. The result is equivalent to how we've presented DR earlier: take the measure to be $d^d\mathbf{p} = p^{d-1}\Omega_d dp$, do the integral for the d where it is defined, and analytically continue in d.

Now, using linearity, we can split the scaleless integral as

$$I = \int \frac{d\ell}{\ell^2} = \int d\ell \frac{\ell^2}{\ell^2\left(\ell^2 - m^2\right)} - \int d\ell \frac{m^2}{\ell^2\left(\ell^2 - m^2\right)}$$

where m is an arbitrary scale, thereby converting it into two ordinary DR integrals. Both integrals are convergent in an open region of the complex plane, so they may be analytically continued as usual, and the standard DR formulas apply as $d \to 4$. We find that as long as the ϵ 's and μ 's used in each are the same, the two results cancel, yielding the desired result. Further arguments can be used to show that, due to the DR postulates, $\int d\ell \left(\ell^2\right)^\alpha = 0$ for any α.

Of course, in this view the 't Hooft-Veltman conjecture simply reduces to the conjecture that these postulates do not lead to inconsistencies. (This is by no means guaranteed, as inconsistencies can arise when we try to account for spinors and the associated γ^μ.) The "proof" for our purposes is simply experience. However, it turns out that it will eventually lead to trouble, in the form of "renormalons", i.e. poor convergence at large orders in perturbation theory, which are connected to the fact that the QFT perturbation series is asymptotic.

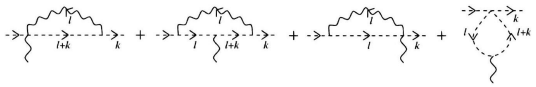
Note. There are more subtleties for integrals which are simultaneously UV and IR divergent, like

$$I = \int \frac{d\ell}{\ell^4}$$

Using the same trick as above, we can split this into a UV divergent and an IR divergent integral, which are each evaluated in DR with $(\epsilon_{\text{UV}}, \mu_{\text{UV}})$ and $(\epsilon_{\text{IR}}, \mu_{\text{IR}})$ respectively. The integrals converge for $\epsilon_{\text{UV}} > 0$ and $\epsilon_{\text{IR}} < 0$ respectively, and the integral is zero when we take $\epsilon_{\text{UV}} = \epsilon_{\text{IR}}$. The subtlety here is that this integral cannot simply be ignored, because the counterterm, being a UV quantity, only can cancel the $1/\epsilon_{\text{UV}}$ pole; something else is required to cancel the $1/\epsilon_{\text{IR}}$ pole. That is, the UV and IR divergences are conceptually distinct. (think more about this)

Now we consider the vertices, where clever choices for the external momenta will greatly simplify the calculation in Landau gauge.

• First, we consider the one-loop corrections to the three-point vertex V_3^μ.



These are renormalized by Z_1. Since we only care about the divergence structure, we are free to choose any external momenta we want, so we choose the incoming ϕ to have zero momentum and the outgoing ϕ to have k. Then in the second and third diagrams, the left vertex yields a factor of ℓ_μ which vanishes when contracted with the $P^{\mu\nu}(\ell)$ from the photon propagator in Landau gauge.

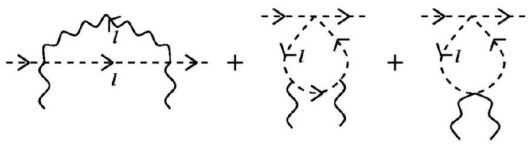
• The remaining terms take the form

$$\begin{aligned} iV_3^\mu(k,0) = ieZ_1 k^\mu + (iZ_1 e)\left(-2iZ_4 e^2 \eta^{\mu\nu}\right)(-i)^2 \int d\ell \frac{P_{\nu\rho}(\ell)(\ell+2k)^\rho}{\ell^2\left((\ell+k)^2+m^2\right)} \\ + (-iZ_\lambda \lambda)(iZ_1 e)(-i)^2 \int d\ell \frac{(2\ell+k)^\mu}{\left(\ell^2+m^2\right)\left((\ell+k)^2+m^2\right)} \end{aligned}$$

Upon Feynman parametrization, shifting the loop momentum, and integrating over x, the final term is proportional to ℓ^μ and hence vanishes by symmetry. Evaluating the remaining integral by the usual methods gives

$$Z_1 = 1 + \frac{3e^2}{8\pi^2}\frac{1}{\epsilon}$$

• Next, consider the four-point, scalar-scalar-photon-photon vertex. In this case, a convenient choice is to set all external momenta to zero, so that only five diagrams survive.



For each of the first two diagrams, there is another diagram which swaps how the photon lines attach. Then we have

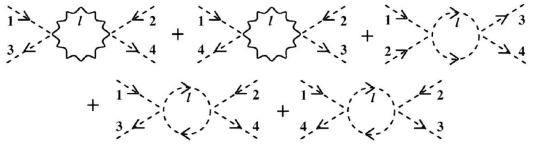
$$\begin{aligned} iV_4^{\mu\nu}(0,0,0) = -2iZ_4e^2\eta^{\mu\nu} &+ \left(-2iZ_4e^2\right)^2(-i)^2\int d\ell \frac{P^{\mu\nu}}{\ell^2\left(\ell^2+m^2\right)} + (\mu \leftrightarrow \nu) \\ &+ (iZ_1e)^2(-iZ_\lambda\lambda)(-i)^3\int d\ell \frac{(2\ell)^\mu(2\ell)^\nu}{\left(\ell^2+m^2\right)^3} + (\mu \leftrightarrow \nu) \\ &+ (-iZ_\lambda\lambda)\left(-2iZ_4e^2\eta^{\mu\nu}\right)(-i)^2\int d\ell \frac{1}{\left(\ell^2+m^2\right)^2}. \end{aligned}$$

All of these may be evaluated in the usual ways to find

$$Z_4 = 1 + \frac{3e^2}{8\pi^2}\frac{1}{\epsilon}$$

We've now shown $Z_1 = Z_2 = Z_4$, as expected and required by general considerations above.

• Finally, consider the four-scalar vertex. Again we may set all external momenta to zero, giving the remaining diagrams below.



Note that the first three have a symmetry factor of 2. The first two and the last three all have the same structure, giving

$$\begin{aligned} iV_4(0,0,0) = -iZ_\lambda\lambda &+ \left(\frac{1}{2}+\frac{1}{2}\right)\left(-2iZ_4e^2\right)^2(-i)^2\int d\ell \frac{P^{\mu\nu}(\ell)P_{\mu\nu}(\ell)}{\left(\ell^2+m_\gamma^2\right)^2} \\ &+ \left(\frac{1}{2}+1+1\right)(-iZ_\lambda\lambda)^2(-i)^2\int d\ell \frac{1}{\left(\ell^2+m^2\right)^2} \end{aligned}$$

which may be evaluated in the usual ways to find

$$Z_\lambda = 1 + \left(\frac{3e^4}{2\pi^2\lambda} + \frac{5\lambda}{16\pi^2}\right)\frac{1}{\epsilon}$$

We now consider the running couplings.

• One of the best features of $\overline{\text{MS}}$ is that we can read off the beta functions directly from the Z_i, without ever having to compute the momentum-dependence of the vertices. We note that

$$e_0 = Z_3^{-1/2}\mu^{\epsilon/2}e, \quad \lambda_0 = Z_2^{-2}Z_\lambda\mu^\epsilon\lambda$$

The Z_i may be expanded in a series in the couplings e^2 and λ, and in $1/\epsilon$.
• The key result is that the e_0 and λ_0 are independent of μ. Now note that

$$\log e_0 = \log\left(Z_3^{-1/2}\right) + \log e + \frac{\epsilon}{2}\log\mu + ... = \frac{e^2}{48\pi^2}\frac{1}{\epsilon} + \log e + \frac{\epsilon}{2}\log\mu + ...$$

Differentiating with respect to $\log\mu$ on both sides and letting $\beta_e = de/d\log\mu$, we have

$$0 = \frac{\epsilon e}{2} + \beta + \frac{e^2}{24\pi^2}\frac{1}{\epsilon}\beta$$

Solving for β and taking the limit $e \to 0$ (crucially, before the limit $\epsilon \to 0$), we get

$$\beta = -\frac{\epsilon e}{2}\left(1 + \frac{e^2}{24\pi^2}\frac{1}{\epsilon}\right)^{-1} + ... = -\frac{\epsilon e}{2}\left(1 - \frac{e^2}{24\pi^2}\frac{1}{\epsilon}\right) + ... = \frac{e^3}{48\pi^2} + ...$$

which is the beta function in scalar QED.
• A slightly more complicated calculation along the same lines gives

$$\beta_\lambda = \frac{1}{16\pi^2}\left(5\lambda^2 - 6\lambda e^2 + 24e^4\right) + ...$$

for the quartic coupling.
• For reference, the analogous factors for QED are

$$Z_1 = Z_2 = 1 - \frac{e^2}{8\pi^2\epsilon}, \quad Z_m = 1 - \frac{\delta_m}{m} = 1 - \frac{e^2}{2\pi^2\epsilon}, \quad Z_3 = 1 - \frac{e^2}{6\pi^2\epsilon}$$

where Z_3 immediately gives the QED beta function

$$\beta = \frac{e^3}{12\pi^2}$$

by the same argument as in scalar QED.

3.4.6 Basics of Regularization

Анализ и индекс расходимости диаграмм

Для произвольной диаграммы введём следующие обозначения:
L_e - число внешних электронных линий;
L_γ - число внешних фотонных линий;
N_e - число внутренних электронных линий;
N_γ - число внутренних фотонных линий;
n - число вершин;
l - число петель.
Тогда индекс расходимости диаграммы

$$\omega = dl - N_e - 2N_\gamma.$$

Для числа петель имеем:

$$l = N_e + N_\gamma - n + 1,$$

так как каждому пропагатору соответствует интегрирование (по своему d-импульсу), но каждая верщина содержит δ-функцию по входящим импульсам, однако одна δ-функция даёт общий закон сохранения. Для числа вершин имеем:

$$n = L_\gamma + 2N_\gamma = \frac{1}{2}\left(L_e + 2N_e\right).$$

(??? как его применять - тут)

О размерной регуляризации

Метрика: $g_4^{\mu\nu} \to g_{4-2\varepsilon}^{\mu\nu}$.
$g^{\mu\nu}g_{\mu\nu} = \delta_\mu^\mu = D = 4 - 2\varepsilon$.
Мера: $d^4q \to (\mu^2)^\varepsilon d^{4-2\varepsilon}q$, где μ есть параметр размерной регуляризации размерности массы.

$$\gamma^\mu\gamma_\mu = D = 4 - 2\epsilon; \quad \operatorname{Tr}\gamma^\mu\gamma^\nu = g^{\mu\nu}\operatorname{Tr}1 = g^{\mu\nu}\begin{cases} 2^{[D/2]} \\ 4 \end{cases}.$$

$$\operatorname{Tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma = \operatorname{Tr}1\left[g^{\mu\nu}g^{\rho\sigma} + g^{\mu\sigma}g^{\nu\rho} - g^{\nu\rho}g^{\mu\sigma}\right],$$
$$\gamma^\mu\gamma^\nu\gamma^\mu = -\gamma^\mu\gamma^\mu\gamma^\nu + 2g^{\mu\nu}\gamma^\mu = -(4-2\epsilon)\gamma^\nu + 2\gamma^\nu = -(2-2\epsilon)\gamma^\nu, \quad \text{и т.д.}$$

$$\frac{1}{p^2 - m^2} \to \frac{1}{p^2 - m^2}.$$

$$\int \frac{d^4p}{p^2}e^{ipx} \sim \frac{1}{x^2} \Rightarrow \int \frac{d^{4-2\epsilon}p}{p^2}e^{ipx} \sim \frac{1}{[x^2]^{1-\epsilon}}.$$

$$\int \frac{d^Dk}{\left[k^2 + M^2\right]^2} = \frac{\Omega_D}{2}\int\limits_0^\infty \frac{(k^2)^{D/2-1}\,dk^2}{\left[k^2 + M^2\right]^2}, \quad M^2 \equiv p^2x(1-x) + m^2$$

$$I\left(p^2\right) = \frac{i}{(2\pi)^D}\frac{\Omega_D}{2}\int\limits_0^1 dx\frac{\Gamma(D/2)\Gamma(2-D/2)}{\left[p^2x(1-x) + m^2\right]^{2-D/2}} =$$

$$= \frac{i(-\pi)^{2-\varepsilon}}{(2\pi)^{4-2\varepsilon}}\Gamma(\varepsilon)\int\limits_0^1 \frac{dx\,(\mu^2)^\varepsilon}{\left[p^2x(1-x) - m^2\right]\varepsilon} =$$

$$= \frac{i}{16\pi^2}\Gamma(1+\varepsilon)\left(\frac{1}{\varepsilon} - \int\limits_0^1 dx\log\left[\frac{p^2x(1-x) - m^2}{-\mu^2}\right] + \log(4\pi)\right)$$

$$\int \frac{d^Dp}{\left[p^2 - 2kp + m^2\right]^\alpha} = i\frac{\Gamma(\alpha - D/2)}{\Gamma(\alpha)}\frac{(-\pi)^{D/2}}{\left[m^2 - k^2\right]^{\alpha - D/2}}$$

или дифференцируя

$$\int \frac{d^{4-2\epsilon}p}{[p^2-2kp+m^2]^2} = i\frac{\Gamma(\epsilon)}{\Gamma(2)}\frac{(-\pi)^{2-\epsilon}}{[m^2-k^2]^\epsilon}, \quad \Gamma(\epsilon)\sim\frac{1}{\epsilon}\to\infty$$
$$\int \frac{d^{4-2\epsilon}pp_\mu}{[p^2-2kp+m^2]^2} = i\frac{\Gamma(\epsilon)}{\Gamma(2)}\frac{(-\pi)^{2-\epsilon}k_\mu}{[m^2-k^2]^\epsilon}$$
$$\int \frac{d^{4-2\epsilon}pp_\mu p_\nu}{[p^2-2kp+m^2]^2} = i(-\pi)^{2-\epsilon}\left[\frac{\Gamma(\epsilon)}{\Gamma(2)}\frac{k_\mu k_\nu}{[m^2-k^2]^\epsilon}+\frac{g^{\mu\nu}}{2}\frac{\Gamma(\epsilon-1)}{\Gamma(2)}\frac{1}{[m^2-k^2]^{\epsilon-1}}\right]$$

$$\int \frac{d^Dk}{(k^2)^\alpha} = 0, \quad \forall\alpha.$$

На самом деле здесь происходит сокращение ультрафиолетовой и инфракрасной расходимостей, которые обе имеют вид полюса по $1/\varepsilon$.

О регуляризации обрезанием на верхнем пределе

(спишу у Казакова, пока не очень готов к этому)

О регуляризации Паули-Вилларса

$$\frac{1}{p^2-m^2}\to\frac{1}{p^2-m^2}-\frac{1}{p^2-M^2},$$

где $M\to\infty$ - масса полей Паули-Вилларса.

Регуляризация Паули-Вилларса является лоренц и калибровочная инвариантность (в абелевом случае), но она весьма сложна при вычислениях, поскольку приходится вычислять диаграммы с массами, в то время как безмассовые интегралы заметно проще.

Иногда используют разновидности регуляризации Паули - Вилларса, когда замену (2.9) производят не для каждого пропагатора, а для петли в целом. Такой способ регуляризации называется регуляризацией по циклам. Этот приём применяется в абелевых калибровочных теориях для петель образованных полями материи. При этом удаётся сохранить калибровочную инвариантность. Однако в неабелевых теориях мы сталкиваемся с трудностью в связи с наличием петель образованных калибровочными полями, которым нельзя придать массу, не нарушая калибровочную инвариантность. Эту проблему часто решают путём введения дополнительной регуляризации для векторных частиц, например, с помощью высших производных.

Основные критические соображения об адекватности регуляризаций (???????)

(??? пока просто их прошел, критически особо не думал про них. Может, каждый способ - бред, не знаю пока.)

Основное о переходе к физически осмысленным значениям (?????)

(очень важный вопрос, как же конкретно к ним приходить, тут раздел про это.)

Анализ возможности регуляризовать теорию

Иллюстрация

$$\begin{aligned}

Асимптотическая свобода по Владимирову

обзор

Изобразим историю борьбы с расходимостями в виде схемы:

$$F(k,g,m) \xrightarrow{\infty} F_{\text{reg}}(k,M,g,m) \overset{M\to\infty}{\longrightarrow} F_{\text{ren}}(k,\mu,g,m) \xrightarrow{\text{РГ}} F_{\text{phys}}(k,\Lambda,m)$$

Здесь k условно обозначает все импульсные аргументы, μ можно понимать как $\sqrt{\mu^2}$????, и т.п.

Смысл этой диаграммы такой.

Изначально можно было ожидать, что некая интересующая нас функция F будет зависеть от внешних импульсов k, константы связи g и массы m.

Но вмешались бесконечности, и нам пришлось ввести регуляризацию (M).

Добавив в лагранжиан сингулярные контрчлены, мы смогли перейти к пределу $M \to \infty$ и получить перенормированную функцию F_{ren}, свободную от бесконечностей.

(заработав, правда, при этом новый параметр μ; такого рода ренормировочный параметр с неизбежностью появляется при любой регуляризации).

Далее мы освободимся и от μ, ибо на самом деле F_{ren} окажется функцией от некоторой комбинации $\Lambda(\mu, g)$, вобравшей в себя всю зависимость от μ и g.

Тем самым, эффективное число аргументов функции F вернется к прежнему значению, только вместо безразмерного заряда g будет фигурировать размерная величина Λ.

Этот оставшийся шаг основан на идеях ренормгруппы и тесно связан с вопросом об однозначности определения функции F_{ren} в процессе перенормировки.

С одной стороны, сингулярные компенсирующие вклады (контрчлены) произвольно менять нельзя, иначе не сократятся расходимости.

Но с другой - никто не мешает, наряду с бесконечными, добавлять к лагранжиану и конечные поправки, тем более что такие действия вполне укладываются в рамки произвола, изначально заложенного в определение T-экспоненты. ?????

С физической же точки зрения, добавление контрчленов (конечных и даже бесконечных) может быть оправдано тем, что истинные значения g, m и других возможных параметров лагранжиана все равно неизвестны, и выясняются только по результатам сравнения предсказаний теории с экспериментом.

?????

Эффективный заряд и β -функция

В основе ренормгруппы лежит следующий фундаментальный принцип ренорм-инвариантности, эквивалентный утверждению о перенормируемости теории: добавление любых конечных (несингулярных) контрчленов в точности компенсируется конечным изменением масс и зарядов.

Под точной компенсацией имеется в виду неизменность любых физических величин, вычисляемых в данной теории (нефизические величины типа n -хвосток могут при этом приобретать дополнительный множитель).

??? пример: изменение значения ренормировочного параметра

Рассмотрим очевидный (хотя и не самый общий) пример введения конечных контрчленов - изменение значения ренормировочного параметра $\mu \to \mu'$.

Отвечающее ему конечное изменение заряда

$$g \to g' = \bar{g}\left(\frac{\mu'}{\mu}, g\right) \quad \Longrightarrow \quad f\left(\frac{k}{\mu}, g\right) = f\left(\frac{k}{\mu'}, g'\right) = f\left(\frac{k}{\mu'}, \bar{g}\left(\frac{\mu'}{\mu}, g\right)\right)$$

подбирается так, чтобы физика (в лице безразмерной функции f) оставалась неизменной.

Функция $\bar{g}\left(\mu'/\mu, g\right)$ - эффективный заряд или бегущая константа связи (running coupling), задает преобразование заряда $g \to g'$ в явном виде.

(Для простоты изложения мы забываем про массы; в общем случае надо еще вводить эффективную массу $\bar{m}$).

Исходно, термин ренормгруппа относился именно к этой однопараметрической группе преобразований $\mu \to \mu', g \to g'$.

По сути, речь идет о функциональной зависимости $g(\mu)$, налагаемой требованием физической инвариантности и реализуемой функцией $\bar{g}$.

Очевидное условие согласования для $\bar{g}$,

$$g'' = \bar{g}\left(\frac{\mu''}{\mu}, g\right) = \bar{g}\left(\frac{\mu''}{\mu'}, g'\right) = \bar{g}\left(\frac{\mu''}{\mu'}, \bar{g}\left(\frac{\mu'}{\mu}, g\right)\right),$$

выражает тот факт, что изменения $\mu \to \mu' \to \mu''$ можно проделать и за один шаг, и за два.

β -функция

$$\beta(g) \doteq \left.\frac{dg}{d\ln\mu}\right|_{\text{физ} = \text{const}} = \left.\frac{dg'}{d\ln\mu'}\right|_{g'=g} = \left.\frac{\partial}{\partial \ln t}\bar{g}(t,g)\right|_{t=1} = \left.\frac{\partial}{\partial t}\bar{g}(t,g)\right|_{t=1}$$

β -функция - скорость изменения заряда g в ответ на изменение μ, иначе говоря -производная функции $\bar{g}$:

С ее помощью ренормгрупповую зависимость $g(\mu)$ можно представить в виде

$$d\ln\mu = \frac{dg}{\beta(g)} \equiv d\psi(g) \quad \Longleftrightarrow \quad d\Lambda = 0, \quad \psi(g) = \int^{g} \frac{du}{\beta(u)}, \quad \Lambda(\mu, g) = \mu e^{-\psi(g)}$$

Точкам на плоскости $\{\mu, g\}$, связанным преобразованиями ренормгруппы, соответствует одна и та же физика, и одно и то же значение $\Lambda(\mu, g)$.

Это и означает, что наблюдаемые величины реально зависят от Λ, а не от μ и g по отдельности.

вычисление β -функций

Несколько слов о методике практического вычисления β -функций.

Если вкратце, то считать нужно (так)???????

Как видно из (256), ренормгрупповую зависимость $g(\mu)$ можно задавать не только в форме (262), но и условием $g_B = \text{const}$.

Значит, определение β -функции можно переписать и так:

$$\beta(g) = \left.\frac{dg}{d\ln\mu}\right|_{g_B=\text{ const}} = -\frac{\partial g_B/\partial \ln\mu}{\partial g_B/\partial g}.$$

Например, в M -регуляризации сингулярный заряд есть формальный ряд вида

$$g_B\left(\ln\frac{M}{\mu}, g\right) = g + a(g)\ln\frac{M}{\mu} + b(g)\ln^2\frac{M}{\mu} + \mathcal{O}\left(\ln^3\frac{M}{\mu}\right)$$

поэтому

$$\beta(g) = \frac{a(g) + 2b(g)\ln(M/\mu) + ...}{1 + a'(g)\ln(M/\mu) + ...} = a(g) + [2b(g) - a(g)a'(g)]\ln\frac{M}{\mu} + \mathcal{O}\left(\ln^2\frac{M}{\mu}\right)$$

??????

Все сингулярности в выражении для $\beta(g)$ обязаны сократиться, так что из правой части мы извлекаем не только ответ для β -функции, но и явные формулы, выражающие через нее функции от коэффициентов???? при любых старших степенях $\ln(M/\mu)$:

$$\beta(g) = a(g), \quad b(g) = \frac{1}{2}a(g)a'(g) = \frac{1}{2}\beta(g)\beta'(g), ...$$

ε-регуляризация

Аналогичное вычисление в ε -регуляризации имеет ту особенность, что в определении (263) надо еще взять предел $\varepsilon \to 0$:

$$g_B = \mu^\varepsilon\left(g + \frac{a(g)}{\varepsilon} + \mathcal{O}\left(\frac{1}{\varepsilon^2}\right)\right), \quad \beta(g) = -\lim_{\varepsilon\to 0}\frac{\partial g_B/\partial\ln\mu}{\partial g_B/\partial g} = \left(g\frac{\partial}{\partial g} - 1\right)a(g)$$

Несмотря на некоторое различие правил нахождения β -функции в этих двух подходах, общий принцип ясен: $\beta(g)$ определяется коэффициентной функцией при самой младшей сингулярности, а коэффициенты при всех старших через нее выражаются.

Уравнения ренормгруппы

Перепишем условия

$$g \to g' = \bar{g}\left(\frac{\mu'}{\mu}, g\right) \quad \Longrightarrow \quad f\left(\frac{k}{\mu}, g\right) = f\left(\frac{k}{\mu'}, g'\right) = f\left(\frac{k}{\mu'}, \bar{g}\left(\frac{\mu'}{\mu}, g\right)\right)$$

и

$$g'' = \bar{g}\left(\frac{\mu''}{\mu}, g\right) = \bar{g}\left(\frac{\mu''}{\mu'}, g'\right) = \bar{g}\left(\frac{\mu''}{\mu'}, \bar{g}\left(\frac{\mu'}{\mu}, g\right)\right),$$

в более удобном виде

$$f(xt,g)=f(x,\bar g(t,g)),\quad \bar g(xt,g)=\bar g(x,\bar g(t,g)),\quad \bar g(1,g)=g$$

Дифференцируя второе из этих равенств по x в точке $x=1$, и привлекая определение β -функции $\beta(g)\doteq\frac{dg}{d\ln\mu}\Big|_{\text{физ}=\text{const}}$, получим ренормгрупповое уравнение для $\bar g(t,g)$:

$$t\frac{\partial}{\partial t}\bar g(t,g)=\beta(\bar g(t,g))$$

Выразить t -зависимость функции $\bar g(t,g)$, считая g просто параметром, можно и в виде следующих соотношений, эквивалентных уравнению ренормгруппы:

$$d\ln t=\frac{d\bar g(t,g)}{\beta(\bar g(t,g))}=d\psi(\bar g(t,g)),\quad \ln t=\psi(\bar g(t,g))-\psi(g)=\int\limits_g^{\bar g(t,g)}\frac{du}{\beta(u)}$$

Аналогично, дифференцируя два первых равенства в условии согласования для $\bar g$ по t при $t=1$, а потом переобозначая x через t, приходим к альтернативной форме уравнений ренормгруппы:

$$\left(t\frac{\partial}{\partial t}-\beta(g)\frac{\partial}{\partial g}\right)\bar g(t,g)=0,\quad \left(t\frac{\partial}{\partial t}-\beta(g)\frac{\partial}{\partial g}\right)f(t,g)=0$$

Ясно, что с учетом начального условия $\bar g(1,g)=g$ эффективный заряд $\bar g(t,g)$ однозначно восстанавливается по функции $\beta(g)$ с помощью любого из уравнений реномгруппы, в этом смысле они эквивалентны.

восстановление всего ряда по коэффициентам

Далее, подставляя формальное разложение $\bar g(t,g)$ по степеням $\ln t$ в первое равенство уравнения реномгруппы, получаем

$$\bar g(t,g)=g+\beta(g)\ln t+b(g)\ln^2 t+...,\quad b(g)=\frac{1}{2}\beta(g)\beta'(g),\quad ...$$

и приходим к следующему выводу: зная коэффициент при первой степени $\ln t$, т.е. функцию $\beta(g)$, мы знаем и весь ряд (271).

Другими словами, ренормгруппа восстанавливает все логарифмические вклады по самому младшему из них.

Особенно важно, что при этом мы иногда имеем возможность улучшать свойства рядов теории возмущений.

Пусть t в $f(xt,g)=f(x,\bar g(t,g))$ имеет смысл большого по величине импульсного аргумента (точнее, большого множителя, равномерно увеличивающего все импульсы, ибо неоднородные асимптотики часто выходят за рамки возможностей ренормгруппы).

??? асимптотическая свобода

Мы видим, что асимптотическая зависимость f от импульса эффективно перешла в заряд, оправдывая название функции $\bar{g}$. ?????

Если же $\bar{g}(t,g)$ при больших t еще и стремится к нулю, то действительно можно говорить об улучшении теории возмущений: вместо исходного заряда g (малым параметром, возможно, не являющегося) мы получаем право использовать асимптотически малую величину $\bar{g}(t,g)$ в качестве нового параметра разложения.

?????

Такая ситуация носит название асимптотической свободы и осуществляется при отрицательном знаке однопетлевого вклада в β -функцию: $\beta(g) = ag^2 + \mathcal{O}(g^3)$, $a < 0$.

логарифмическое убывание заряда

Ограничиваясь этим приближением для $\beta(g)$, получим из ренормгруппового уравнения

$$t\frac{\partial}{\partial t}\bar{g}(t,g) = a\bar{g}^2(t,g) \quad \Longrightarrow \quad \bar{g}(t,g) = \frac{g}{1-ag\ln t} \sim \frac{1}{|a|\ln t}$$

то есть эффективный заряд в этом случае логарифмически убывает при больших t.

По сути, единственным примером асимптотически свободной теории служит КХД, в которой $a \sim \left(-11 + \frac{2}{3}n_f\right)$, где n_f -число сортов кварков.

По современным представлениям $n_f = 6$, благодаря чему a оказывается отрицательным.

Как было отмечено выше, у n -хвосток и им подобных объектов (обозначим их Γ) закон ренормгруппового преобразования отличается от (267) на фактор Z_Γ:

$$\Gamma(xt,g) = Z_\Gamma^{-1}(t,g)\Gamma(x,\bar{g}(t,g)), \quad Z_\Gamma(xt,g) = Z_\Gamma(t,g)Z_\Gamma(x,\bar{g}(t,g)), Z_\Gamma(1,g) = 1$$

Дифференцированием получаем отсюда уравнения ренормгруппы для Z_Γ и Γ:

$$t\frac{\partial}{\partial t}\ln Z_\Gamma(t,g) = \gamma_\Gamma(\bar{g}(t,g)), \quad \left(t\frac{\partial}{\partial t} - \beta(g)\frac{\partial}{\partial g} + \gamma_\Gamma(g)\right)\Gamma(t,g) = 0$$

Введенную здесь функцию

$$\gamma_\Gamma(g) \doteq \frac{\partial}{\partial t}\ln Z_\Gamma(t,g)\Big|_{t=1}$$

называют аномальной размерностьто.

Ее, как и $\beta(g)$, вычисляют по теории возмущений.

Решения уравнений (274) можно, с помощью (269), записать в виде

$$Z_\Gamma(t,g) = \exp\int_1^t \frac{du}{u}\gamma_\Gamma(\bar{g}(u,g)) = \exp\int_g^{\bar{g}(t,g)} \frac{du\gamma_\Gamma(u)}{\beta(u)}$$

$$\Gamma(xt,g) = \Gamma(x,\bar{g}(t,g))\exp\left[-\int_g^{\bar{g}(t,g)} \frac{du\gamma_\Gamma(u)}{\beta(u)}\right]$$

чтобы затем разлагать (в случае асимптотической свободы) по степеням $\bar{g}(t,g)$.

Схемная зависимость

Нам осталось объяснить, как осуществляется переход к аргументу Λ.

Совместим это с изучением проблемы зависимости ренормгрупповых величин от схемы перенормировки.

То, что различные варианты процедуры перенормировки (например, основанные на разных регуляризациях) приводят к различным выражениям для β -функции и многих других объектов, не удивительно.

Однако физические величины не должны, по идее, зависеть от этого.

Снова переписав ключевое соотношение (259), на этот раз в форме

$$f\left(\frac{k}{\mu}, g\right) = f\left(1, \bar{g}\left(\frac{k}{\mu}, g\right)\right) \doteq \Phi\left(\ln\frac{k}{\Lambda}\right)$$

можно ожидать, что схемная зависимость, если она есть в функциях f и $\bar{g}$, должна каким-то образом сократиться.

При этом выяснится, что функция Φ от перенормировочной схемы практически не зависит.

Согласно принципу ренорм-инвариантности, разные способы перенормировки могут отличаться лишь на конечные контрчлены.

Если условиться в обеих схемах обозначать ренормировочный параметр через μ, то всё различие схем должно свестись к переопределению заряда $g \to \tilde{g}(g)$ (массы мы не рассматриваем).

Соответственно, для физических (f) и нефизических (Γ) объектов формулы перехода имеют вид

$$f\left(\frac{k}{\mu}, g\right) = \tilde{f}\left(\frac{k}{\mu}, \tilde{g}(g)\right), \quad \Gamma\left(\frac{k}{\mu}, g\right) = q(g)\tilde{\Gamma}\left(\frac{k}{\mu}, \tilde{g}(g)\right)$$

Далее, прямыми следствиями определений (262) являются равенства

$$\frac{dg}{\beta(g)} = d\psi(g) = d\ln\mu = d\tilde{\psi}(\tilde{g}) = \frac{d\tilde{g}}{\tilde{\beta}(\tilde{g})}$$

которые говорят о том, что весь схемный произвол в $\psi(g)$ сводится к аддитивной, а в Λ -к мультипликативной константе (не зависящей от g):

$$\tilde{\psi}(\tilde{g}(g)) = \psi(g) + \text{ const}, \quad \tilde{\Lambda}(\mu, \tilde{g}(g)) = \mu\exp(-\tilde{\psi}(\tilde{g}(g))) = \Lambda(\mu, g)\cdot \text{ const}.$$

Впрочем, при внимательном рассмотрении формул (262) становится ясно, что именно такие допуски были предусмотрены уже в определениях этих функций.

Приведем также вытекающее из (280) правило пересчета β -функции в другую схему, а заодно и аналогичную формулу для аномальной размерности:

$$\tilde{\beta}(\tilde{g}(g)) = \beta(g)\frac{d\tilde{g}(g)}{dg}, \quad \tilde{\gamma}_\Gamma(\tilde{g}(g)) = \gamma_\Gamma(g) - \beta(g)\frac{d\ln q(g)}{dg}$$

Применяя формулу для β в стандартной ситуации

$$\beta(g) = ag^2 + bg^3 + cg^4 + ..., \quad \tilde{\beta}(g) = \tilde{a}g^2 + \tilde{b}g^3 + \tilde{c}g^4 + ..., \quad \tilde{g}(g) = g + Ag^2 + ...$$

наблюдаем любопытный эффект: два первых коэффициента β -функции не зависят от схемы, зависимость начинается только с третьего, $\tilde{a} = a, \tilde{b} = b, \tilde{c} \neq c$.

Чтобы найти связь между $\bar{g}$ и Λ, а также явный вид Φ, объединим (269) и (278) :

$$\psi\left(\bar{g}\left(\frac{k}{\mu}, g\right)\right) = \psi(g) + \ln\frac{k}{\mu} = \ln\frac{k}{\Lambda} \doteq L, \quad \bar{g} = \psi^{-1}(L), \quad f(1, \bar{g}) = \Phi(L)$$

для перехода к (более физическому) аргументу L надо обратить функцию ψ.

После этого, подстановка результата в f даст Φ.

Применим (279) для выяснения схемной зависимости функции Φ :

$$\Phi(\psi(x)) = f(1, x) = \tilde{f}(1, \tilde{g}(x)) = \tilde{\Phi}(\tilde{\psi}(\tilde{g}(x))) = \tilde{\Phi}(\psi(x) + \text{ const })$$

Она, как видим, исчерпывается возможностью сдвига аргумента на константу, что как раз соответствует мультипликативному произволу в Λ или аддитивному в L.

Явное нахождение $\psi(g)$ потребует разложения подынтегрального выражения из определения (262) в формальный ряд.

Типичный вид ответа таков:

$$\beta(g) = ag^2 + bg^3 + \mathcal{O}\left(g^4\right) \quad \Longrightarrow \quad \psi(g) = -\frac{1}{ag} - \frac{b}{a^2}\ln g + \text{ const } + \mathcal{O}(g)$$

Обратная функция ψ^{-1}, нужная нам для замены $\bar{g}$ на L, тоже ищется в виде формального разложения.

Окончательные результаты обычно выглядят примерно так:

$$\bar{g} = \psi^{-1}(L) = -\tfrac{1}{aL} - \tfrac{b}{a^3}\tfrac{\ln L}{L^2} + \tfrac{c}{L^2} + \mathcal{O}\left(\tfrac{\ln^2 L}{L^3}\right),$$
$$f\left(\tfrac{k}{\mu}, g\right) = f(1, \bar{g}) = \Phi(L) = 1 + \tfrac{A}{L} + \tfrac{B\ln L}{L^2} + \tfrac{C}{L^2} + \mathcal{O}\left(\tfrac{\ln^2 L}{L^3}\right) = \sum_{mn} A_{mn}\tfrac{\ln^m L}{L^n}$$

Преимущество разложений по $1/L$ вида (287) над рядами улучшенной теории возмущений по степеням $\bar{g}$ заключается в их практической независимости от схемы перенормировки.

Точнее говоря, наборы коэффициентов A_{mn} в двух разных схемах могут поначалу различаться, но одна-единственная операция - сдвиг L на надлежащую константу - эту разницу полностью устраняет.

Вильсоновский подход к теории перенормировок по ПШ (?????)

Асимптотическая свобода по Полякову (????????)

(???? тут жесть какая-то, отложил пока что, потом мб посмотрю, как основное будет сделано.)

Главные киральные поля

Модель п-поля

3.5.1 Dirac field: other properties

(пока тут, всякие не такие актуальные свойства, их скорее всего много)

Электронный пропагатор

По Мандл Шалуу

$$\left\langle 0 \left| \ \mathrm{T}\left\{\psi(\mathrm{x})\bar{\psi}\left(x'\right)\right\}\right| 0\right\rangle = \mathrm{i}S_{\mathrm{F}}\left(x-x'\right)$$

$$S_{\mathrm{F}}(x) := \theta(t)S^{+}(x) - \theta(-t)S^{-}(x) = \left(\mathrm{i}\gamma^{\mu}\frac{\partial}{\partial x^{\mu}} + \frac{mc}{\hbar}\right)\Delta_{\mathrm{F}}(x)$$

(??? тут еще текст какой-то, который я вообще не понимаю)

По Ландау (????)

(лл пар 105 хз, что-то очень далеко этот параграф, мб тут и не такое нужное?)
Подобно фотонному, точный электронный пропагатор определяется формулой

$$\mathscr{G}_{ik}\left(x-x'\right) = -i\left\langle 0 \left| \ \mathrm{T}\psi_i(x)\bar{\psi}_k\left(x'\right)\right| 0\right\rangle$$

(i, k - - биспинорные индексы), отличающейся от определения $(75,1)$ пропагатора свободных частиц

$$G_{ik}\left(x-x'\right) = -i\left\langle 0 \left| \ \mathrm{T}\psi_i^{\mathrm{int}}\ (x)\bar{\psi}_k^{\mathrm{int}}\ \left(x'\right)\right| 0\right\rangle$$

заменой ψ-операторов в представлении взаимодействия гейзенберговскими.

Те же рассуждения, что и при выводе $(103,7)$, позволяют преобразовать $\mathscr{G}_{ik}$ к виду

$$\mathscr{G}_{ik}\left(x-x'\right) = -i\frac{\left\langle 0 \left| \ \mathrm{T}\psi_i^{\mathrm{int}}\ (x)\bar{\psi}_k^{\mathrm{int}}\ \left(x'\right)s\right| 0\right\rangle}{\langle 0|S|0\rangle}.$$

(тут картинки типа поляризации вакуума, их сумма, вставлю мб.)

Путем суммирования, в точности аналогичного выводу $(103,13)$, получим

$$\mathscr{G}(p) = G(p) + G(p)\mathscr{M}(p)\mathscr{G}(p)$$

(биспинорные индексы опускаем), или, для обратных матриц,

$$\mathscr{G}^{-1}(p) = G^{-1}(p) - \mathscr{A}(p) = \gamma p - m - \mathscr{M}(p).$$

В результате преобразования $(102,8)$ пропагаторы $\mathscr{D}(103,1)$ и $\mathscr{G}(105,1)$ переходят в

$$\mathscr{D}_{\mu\nu} \to i\left\langle 0 \left| \ \mathrm{T}\left[A_{\mu}(x) - \partial_{\mu}\chi(x)\right]\left[A_{v}\left(x'\right) - \partial'_{v}\chi\left(x'\right)\right]\right| 0\right\rangle,$$

$$\mathscr{G}_{ik} \to -i\left\langle 0 \left| \ \mathrm{T}\psi_i(x)e^{ie\chi(x)}e^{-ie\chi(x')}\bar{\psi}_k\left(x'\right)\right| 0\right\rangle.$$

$$\left\langle 0 \left| \ \mathrm{T}e^{ie\delta\chi(x)}e^{-ie\delta\chi(x')}\right| 0\right\rangle \approx -\frac{1}{2}e^2\left\langle 0 \left|\delta\chi^2(x) + \delta\chi^2\left(x'\right) - 2\ \mathrm{T}\delta\chi(x)\delta\chi\left(x'\right)\right| 0\right\rangle.$$

С учетом определения $(105,12)$ находим, таким образом, следующий закон преобразования электронного пропагатора:

$$\mathscr{G} \to \mathscr{G} + \delta\mathscr{G}, \qquad \delta\mathscr{G} = ie^{2\mathscr{G}}\left(x-x'\right)\left[d^{(l)}(0) - d^{(l)}\left(x-x'\right)\right].$$

В импульсном представлении [1]):

$$\delta\mathscr{G}(p) = ie^2\int d^{(l)}(q)[\mathscr{G}(p) - \mathscr{G}(p-q)]\frac{d^4q}{(2\pi)^4}.$$

При этом функция $d^{(l)}(q)$ связана с изменением функции $\mathscr{D}^{(l)}$ согласно

$$\delta\mathscr{D}^{(l)}(q) == q^2 d^{(l)}(q)$$

Symmetries and Conserved Quantities

• Conjugating a rotation by parity leaves it invariant, but conjugating a boost with parity flips its sign. Thus we want parity to exchange the Weyl spinors,

$$P : \psi_{\pm}(\mathbf{x}, t) \mapsto \psi_{\mp}(-\mathbf{x}, t).$$

Thus, in the chiral representation,

$$P : \psi(\mathbf{x}, t) \mapsto \gamma^0 \psi(-\mathbf{x}, t)$$

The Dirac equation is parity invariant, since if $\psi(\mathbf{x}, t)$ satisfies it, so does $\gamma^0\psi(-\mathbf{x}, t)$.

• Note that $\bar{\psi}\psi$ transforms as a scalar under parity because $(\gamma^0)^2 = 1$. However, for the vector $\bar{\psi}\gamma^\mu\psi$, the spacelike parts flip sign,

$$\bar{\psi}\gamma^i\psi \to \bar{\psi}\gamma^0\gamma^i\gamma^0\psi = -\bar{\psi}\gamma^i\psi$$

which implies that $\bar{\psi}\gamma^\mu\psi$ transforms as a vector under parity.

• Similarly, $\bar{\psi}S^{\mu\nu}\psi$ transforms as a tensor under parity. We also have $\bar{\psi}\gamma^5\psi$, which transforms as a pseudoscalar, and $\bar{\psi}\gamma^5\gamma^\mu\psi$, which transforms as a pseudovector; both of these pick up an extra sign flip due to the γ^5.

• As we've seen above, the Dirac spinor is a certain representation of the Lorentz group and the set of spinor bilinears is that representation's tensor product with itself,

$$((1/2,0)+(0,1/2)) \times ((1/2,0)+(0,1/2)) = (0,0)+(1/2,1/2)+(1,0)+(0,1)+(1/2,1/2)+(0,0)$$

which decompose as $1 + 4 + 3 + 3 + 4 + 1$. The two 3's are packaged together into the rank 2 antisymmetric tensor and correspond to self-dual and anti-self-dual tensors.

• The pseudoscalar and axial vector terms treat the $u_{\pm}$asymmetrically since they are not parity invariant. In general, any theory that treats the $u_{\pm}$asymmetrically is called a chiral theory (vs. a vector-like theory). However, chiral theories can be parity invariant; for example, the term $\phi\bar{\psi}\gamma^5\psi$ respects parity if ϕ is a pseudoscalar.

Note. Sometimes people ask: why don't the gamma matrices transform under Lorentz transformations, like everything else with a four-vector index does? The representation theory above shows the right way to think about this. A gamma matrix is a set of Clebsch-Gordan coefficients which extracts the Lorentz vector representation from the tensor product of two Dirac spinor representations. These coefficients don't change under Lorentz transformations, for exactly the same reason that ordinary Clebsch-Gordan coefficients for spin don't. E.g. for spin we have $1 \subset 1/2 \times 1/2$, and the state $|\ell, m_z\rangle = |1, 0\rangle$ is always of the form $(|1/2, 1/2\rangle|1/2, -1/2\rangle + |1/2, -1/2\rangle|1/2, 1/2\rangle)/\sqrt{2}$. This doesn't depend on how you orient the z-axis, as long as you use the same z-axis to define the m_z states in the 1 and 1/2 representations, which of course we always do.

We now define charge conjugation symmetry and Majorana fermions.

• Naively, we would like to define charge conjugation of a classical field as just the complex conjugate, as is suitable for a complex scalar field. But charge conjugation should commute with Lorentz transformations, so the naive option doesn't work since $S[\Lambda]$ is not real.

• Instead, we define

$$\psi^{(c)} = C\psi^*$$

where C is a 4×4 unitary matrix satisfying

$$C^\dagger \gamma^\mu C = (-\gamma^\mu)^*$$

in a general representation of the Clifford algebra where $(\gamma^0)^\dagger = \gamma^0$ and $(\gamma^i)^\dagger = -\gamma^i$.

• To check the transformation properties, we have

$$\psi^{(c)} \to CS[\Lambda]^*\psi^* = S[\Lambda]C\psi^* = S[\Lambda]\psi^{(c)}$$

as desired. The Dirac equation is also invariant. Complex conjugating it gives

$$(-i\not{\partial}* - m)\,\psi^* = 0$$

Multiplying on the left by C and pulling it through shows that $\psi^{(c)}$ obeys the Dirac equation.

• A Majorana spinor obeys the reality condition $\psi^{(c)} = \psi$. This constraint relates the two Weyl spinors. Majorana spinors can have a mass, but they cannot have charges.

• Finally, we can write C explicitly given a fixed basis for the Clifford algebra. In the chiral basis,

$$C = i\gamma^2$$

because only γ^2 is imaginary. In terms of the Weyl spinors, this implies $u_- = -i\sigma^2 u_+^*$.

• Alternatively, in the Majorana basis,

$$\gamma^0 = \begin{pmatrix} 0 & \sigma^2 \\ \sigma^2 & 0 \end{pmatrix}, \quad \gamma^1 = \begin{pmatrix} i\sigma^3 & 0 \\ 0 & i\sigma^3 \end{pmatrix}, \quad \gamma^2 = \begin{pmatrix} 0 & -\sigma^2 \\ \sigma^2 & 0 \end{pmatrix}, \quad \gamma^3 = \begin{pmatrix} -i\sigma^1 & 0 \\ 0 & -i\sigma^1 \end{pmatrix}$$

Then all of the gamma matrices are pure imaginary, so the $S[\Lambda]$ are real and $C = 1$.

Note. This definition of the C matrix differs from the C matrix appearing in the quantum charge conjugation operation $\widehat{C}$. This is because this C arises from the classical charge conjugation on fields, which in this case acts like $\widehat{C}$ with an additional parity factor γ_0. This is explained further in the notes on the Standard Model.

Note. We check the Lagrangian is invariant under charge conjugation. Consider the mass term,

$$\bar{\psi}\psi = \psi^\dagger\gamma^0\psi \to \psi^T C^\dagger \gamma^0 C\psi^* = -\psi^T \left(\gamma^0\right)^* \psi^*$$

This quantity is, naively, equal to its own transpose. However, we must account for the fact that spinors are inherently anticommuting, and hence the classical fields here are really Grassmann numbers; taking the transpose flips the sign because of the anticommutation. Then we get

$$\bar{\psi}\psi \to \psi^\dagger {\gamma^0}^\dagger \psi = \bar{\psi}\psi$$

as desired. Demanding the invariance of the $\bar{\psi}\not{D}\psi$ term forces

$$A_\mu \to -A_\mu$$

under charge conjugation, which intuitively is because $\partial^2 A_\mu = j_\mu$ and $j_\mu \to -j_\mu$. More generally, for a non-abelian gauge theory, the gauge interaction term $\bar{\psi}_i \mathcal{A}_{ij}\psi_j$ is invariant if

$$A^\mu_{ij} \to -A^\mu_{ji}$$

This is sensible, as it's just the usual rule for conjugating a Lie algebra representation.

Finally, we consider the continuous symmetries and conserved currents of the Dirac action.

• We begin with translational symmetry, treating ψ and $\bar{\psi}$ as independent as usual. Since the Lagrangian does not depend on $\partial\bar{\psi}$, we have

$$T^{\mu\nu} = i\bar{\psi}\gamma^\mu\partial^\nu\psi - \eta^{\mu\nu}\mathcal{L}$$

We can further simplify this using the equations of motion, which state that $\mathcal{L}$ vanishes on shell. The total energy is then

$$E = \int d\mathbf{x}T^{00} = \int d\mathbf{x}i\bar{\psi}\gamma^0\dot{\psi} = \int d\mathbf{x}\psi^\dagger\gamma^0\left(-i\gamma^i\partial_i + m\right)\psi$$

• An infinitesimal Lorentz transformation gives

$$\delta\psi^\alpha = -\omega^\mu_\nu x^\nu\partial_\mu\psi^\alpha + \frac{1}{2}\Omega_{\rho\sigma}\left(S^{\rho\sigma}\right)^\alpha_\beta\psi^\beta$$

Expanding out the definitions yields $\omega^{\mu\nu} = \Omega^{\mu\nu}$. Now, the first term contributes the same thing we saw for the scalar field, while the second term contributes a "spin" term,

$$(\mathcal{J}^\mu)^{\rho\sigma} = x^\rho T^{\mu\sigma} - x^\sigma T^{\mu\rho} - i\bar{\psi}\gamma^\mu S^{\rho\sigma}\psi$$

Upon quantization the latter will yield a spin of $\pm 1/2$ for each particle. A similar spin/orbit decomposition appears for general fields with spin.

• The Dirac action has an internal phase symmetry, $\psi \to e^{-i\alpha}\psi$ which yields

$$j^\mu_V = \bar{\psi}\gamma^\mu\psi \qquad \text{(vector current)}$$

$$Q = \int d\mathbf{x}\bar{\psi}\gamma^0\psi = \int d\mathbf{x}\psi^\dagger\psi$$

which we will see can be interpreted as the total particle number.

• When $m = 0$, the Weyl spinors decouple, so there is an additional independent symmetry given by rotating the Weyl spinors in opposite directions,

$$\psi \to e^{i\alpha\gamma^5}\psi, \quad \bar{\psi} \to \bar{\psi}e^{i\alpha\gamma^5}$$

This gives the 'axial current',

$$j^\mu_A = \bar{\psi}\gamma^\mu\gamma^5\psi$$

which is an axial vector. Later, we will see that the axial symmetry is anomalous. In QED with massless fermions, the Lagrangian has axial symmetry, but the current is not conserved in the quantum theory.

3.5.2 Electromagnetic field: other properties

(пока тут, всякие не такие актуальные свойства, их скорее всего много)

Quantization of a vector field: other ideas

Gupta-Bleuler Quantization

Alternatively, we may impose the constraint at the level of the Hilbert space.

• We instead consider the new, "gauge-fixed" Lagrangian

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2\xi}\left(\partial_\mu A^\mu\right)^2$$

where ξ is a number. Naively, we have changed the theory, and this will be justified below by showing the S-matrix is independent of ξ. But it's more correct to say that the non-gauge-fixed theory isn't defined as a quantum theory at all, and we're really checking that the specific way we gauge fix doesn't matter. We'll derive this again in a more satisfying way with the path integral, where the extra term falls out naturally by restricting the integral to gauge-inequivalent configurations.

• To motivate this choice, note that if ξ were a field, the equations of motion would be

$$\partial^2 A^\mu - (1 - 1/\xi)\partial^\mu\partial^\nu A_\nu = 0, \quad \partial_\mu A^\mu = 0$$

so ξ acts as a Lagrange multiplier that enforces Lorenz gauge.

• However, we don't want the extra auxiliary field ξ, so we instead let ξ be a number. A natural choice is $\xi = 1$, where the equation of motion becomes $\partial^2 A^\mu = 0$ as it is in Lorenz gauge. However, note that the Lorenz gauge condition is not enforced, i.e. we don't have $\partial_\mu A^\mu = 0$.

• Next, we perform canonical quantization. The new term ensures all fields are dynamical,

$$\pi^0 = -\partial_\mu A^\mu, \quad \pi^i = \partial^i A^0 - \dot{A}^i$$

Below, it will be more convenient to integrate by parts, yielding the new canonical momenta,

$$\mathcal{L} = -\frac{1}{2}\partial_\mu A_\nu \partial^\mu A^\nu, \quad \pi^\mu = -\dot{A}^\mu$$

Next, we impose the Lorentz-invariant canonical commutation relations

$$[A_\mu(\mathbf{x}), \pi_\nu(\mathbf{y})] = i\eta_{\mu\nu}\delta(\mathbf{x} - \mathbf{y})$$

with all other commutators zero; note the extra minus sign, because of the minus sign in π^μ. We haven't imposed any constraints, so there are no issues with Dirac brackets.

Next, we perform the usual mode expansion, giving

$$A_\mu(x) = \int \frac{d\mathbf{p}}{\sqrt{2|\mathbf{p}|}} \sum_{\lambda=0}^{3} \epsilon_\mu^\lambda(\mathbf{p}) \left(a_{\mathbf{p}}^\lambda e^{-ipx} + a_{\mathbf{p}}^{\lambda\dagger} e^{ipx}\right)$$

in Heisenberg picture, and

$$\pi_\mu(x) = \int d\mathbf{p}\sqrt{\frac{|\mathbf{p}|}{2}}(+i) \sum_{\lambda=0}^{3} \epsilon_\mu^\lambda(\mathbf{p}) \left(a_{\mathbf{p}}^\lambda e^{-ipx} - a_{\mathbf{p}}^{\lambda\dagger} e^{ipx}\right)$$

where the canonical momentum has a $+i$ rather than a $-i$ because $\pi^\mu = -\dot{A}^\mu$.

• Consider a photon of momentum p^μ and let $n^\mu = (1, 0, 0, 0)$. Then we define

$-\epsilon^0_\mu = n_\mu$ is the timelike polarization

• ϵ^1_μ and ϵ^2_μ are the transverse polarizations, obeying

$$\epsilon^i \cdot n = \epsilon^i \cdot p = 0, \quad \epsilon^i \cdot \epsilon^j = -\delta^{ij}$$

$-\epsilon^3_\mu$ is the longitudinal polarization, defined to be orthogonal to all the others,

$$\epsilon^3_\mu \propto p_\mu - n_\mu (p \cdot n)$$

and normalized to have norm -1.

E.g. when $p^\mu = (E, 0, 0, E)$, these are simply the standard basis for $\mathbb{R}^4$. Using these definitions, we have the orthogonality and completeness relations

$$\epsilon^\lambda \cdot \epsilon^{\lambda'} = \eta^{\lambda\lambda'}, \quad \epsilon^\lambda_\mu \epsilon^{\lambda'}_\nu \eta_{\lambda\lambda'} = \eta_{\mu\nu}.$$

• The resulting commutation relations for the creation/annihilation operators are

$$\left[a^\lambda_{\mathbf{p}}, a^{\lambda'\dagger}_{\mathbf{q}}\right] = -\eta^{\lambda\lambda'} \not{\delta}(\mathbf{p} - \mathbf{q}).$$

Then there is a minus sign for the timelike polarizations, which have negative norm, as we saw for the incorrectly quantized spinors. That is, our naive canonical quantization procedure hasn't given us a Hilbert space at all, because the inner product is not positive definite.

Next, we remove the unphysical degrees of freedom by imposing the Lorenz gauge constraint on the naive Fock space.

• The simplest idea is to set $\partial_\mu A^\mu = 0$ as an operator equation in Heisenberg picture, but this is unacceptable as it sets $\pi^0 = 0$. We can also attempt to identify a set of physical states by

$$\partial_\mu A^\mu |\Psi\rangle = 0$$

However, this is also too restrictive since not even the vacuum is a physical state.

• Finally, consider writing $A_\mu = A^+_\mu + A^-_\mu$where A^+_μhas positive frequency, and hence contains only annihilation operators. Then we define physical states by the Gupta-Bleuler condition

$$\partial^\mu A^+_\mu |\Psi\rangle = 0$$

so that the vacuum is indeed physical. This is equivalent to

$$\langle \Psi' | \partial_\mu A^\mu | \Psi \rangle = 0$$

That is, we demand the operator $\partial_\mu A^\mu$ is zero when restricted to the physical states.

• Explicitly, we define the one-photon states by

$$|\mathbf{p}, \xi\rangle = \sqrt{2|\mathbf{p}|}\alpha_\lambda a^\dagger_\lambda(\mathbf{p})|0\rangle, \quad \xi^\mu = \sum_{\lambda,\lambda'} \alpha_\lambda \eta_{\lambda\lambda'} \epsilon^{\mu\lambda'}$$

where ξ is a polarization vector. Then we have

$$\langle \mathbf{q}, \xi' | \mathbf{p}, \xi \rangle = -2|\mathbf{p}| \phi(\mathbf{p} - \mathbf{q}) (\xi' \cdot \xi).$$

• Using the strange convention above, the Gupta-Bleuler condition is simply

$$p^\mu \xi_\mu = 0$$

This eliminates the negative-norm timelike photons, but we still have the zero-norm states

$$|\mathbf{p}, \xi_S\rangle \propto \left(a_0^\dagger(\mathbf{p}) - a_3^\dagger(\mathbf{p})\right)|0\rangle$$

which are combinations of timelike and longitudinal photons, with $p^\mu \propto \xi^\mu$. We need a relative minus sign between the terms above, even though $p^\mu \propto (1,0,0,1)$, because of the minus sign in the commutation relations for timelike photons.

• More generally, a basis for our Fock space contains elements of the form $|\Psi\rangle = |\psi\rangle|\phi\rangle$ where $|\psi\rangle$ contains transverse photons and $|\phi\rangle$ contains timelike and longitudinal photons. Then the allowed $|\phi\rangle$ states satisfy the Gupta-Bleuler condition

$$\left(a_{\mathbf{p}}^3 - a_{\mathbf{p}}^0\right)|\phi\rangle = 0$$

so that the allowed $|\phi\rangle$ are of the form $|\phi_n\rangle = \left(a_{\mathbf{p}}^{0\dagger} - a_{\mathbf{p}}^{3\,\dagger}\right)^n |0\rangle$, which have zero norm for $n > 0$. The presence of these states reflects the fact that Lorenz gauge is not a complete gauge fixing.

• We claim the zero-norm states decouple, in the sense that they have zero expectation value for all gauge-invariant observables. E.g. the Hamiltonian is

$$H = \int d\mathbf{p}|\mathbf{p}| \left(\sum_{i=1}^{3} a_{\mathbf{p}}^{i\dagger} a_{\mathbf{p}}^i - a_{\mathbf{p}}^{0\dagger} a_{\mathbf{p}}^0\right)$$

However, the Gupta-Bleuler condition implies $\langle\phi\left|a_{\mathbf{p}}^{3\dagger}a_{\mathbf{p}}^3 - a_{\mathbf{p}}^{0\dagger}a_{\mathbf{p}}^0\right|\phi\rangle = 0$, so the $|\phi_n\rangle$ have zero energy. Thus, for a free theory, one can think of the states $|\psi\rangle\,|\phi_n\rangle$ as all being 'gauge equivalent' to $|\psi\rangle\,|\phi_0\rangle$, yielding a Hilbert space where all states have positive norm.

• On the other hand, zero-norm states do affect the expectation value of A_μ, as we have

$$\langle\phi_n\,|A_\mu(x)|\,\phi_n\rangle = \partial_\mu\alpha, \quad \partial^\mu\partial_\mu\alpha = 0$$

This is acceptable since A_μ is not gauge-invariant. Indeed, this is the exact analogue of the remaining classical gauge freedom $A_\mu \to A_\mu + \partial_\mu\alpha$ with $\partial^\mu\partial_\mu\alpha = 0$.

• We cannot ignore the zero-norm states entirely. In an interacting theory, they appear as intermediate states in scattering processes, though we will see that the Ward identity guarantees they decouple from initial and final states. They are also required to maintain Lorentz invariance, because a boost can turn a transverse polarization into a partly longitudinal one.

Finally, we have the Lorentz-invariant propagator

$$\langle 0\,|TA_\mu(x)A_\nu(y)|\,0\rangle = \int dp \frac{i}{p^2 + i\epsilon}\left(-\eta_{\mu\nu} + (1-\xi)\frac{p^\mu p^\nu}{p^2}\right)e^{-ip(x-y)}$$

where above we worked with $\xi = 1$, the numerator comes from the sum of all four polarizations, and the minus sign ensures the right sign for the spacelike polarizations. The choice $\xi = 1$ is called Feynman gauge, while $\xi \to 0$ is called Landau gauge. Landau gauge is the quantum version of Lorenz gauge, as the Lorenz gauge condition is imposed exactly in this limit.

What if we wished to introduce a mass term for the photon field?

(мб потом больший раздел про это сделаю, мб это важный вопрос. мб в самом начале, где обсуждаю вообще суть КТП. пока не до этих вопросов)

The Proca action is

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}m^2 A_\mu A^\mu$$

The second term is not gauge invariant, so the theory does not have a gauge symmetry. The equation of motion is

$$\partial_\mu F^{\mu\nu} + m^2 A^\nu = 0$$

so that, as long as the mass term is nonzero, we automatically have $\partial_\mu A^\mu = 0$. Plugging this back into the equation of motion yields the Klein-Gordan equation,

$$\left(\partial^2 + m^2\right) A^\mu = 0$$

Hence we have three massive degrees of freedom. The quantization of this theory is much more straightforward than the quantization of QED. We have only the second-class constraints $\partial_\mu A^\mu = 0$ and $\pi^0 = 0$, and Dirac brackets get the job done.

Stuckelberg trick

In fact, it is possible to obtain the Proca action from a gauge invariant action by gauge fixing; The Stuckelberg action is

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}\left(mA_\mu - \partial_\mu\phi\right)^2$$

The action has the gauge symmetry

$$\delta A_\mu = \partial_\mu \epsilon, \quad \delta\phi = m\epsilon$$

We recover the Proca action by gauge fixing $\phi = 0$. The benefit of starting from the Stuckelberg action is that the gauge symmetry constrains the divergences that may appear in perturbation theory, allowing one to prove the theory is renormalizable. Since the ϕ field is eaten, the Stuckelberg theory can be thought of as the abelian Higgs model in the limit where the Higgs is very heavy, and decouples. The Stuckelberg trick doesn't work for a non-abelian gauge theory, at least in this form, as in that case δA_μ is more complicated.

Об операторном формализме по Киселеву для ϕ^3

$$\mathcal{D}^{(3)}_{123} = \left\langle 0 \left| \hat{\mathrm{T}} \left\{ \hat{\varphi}_1 \hat{\varphi}_2 \hat{\varphi}_3 \right\} \right| 0 \right\rangle \approx$$
$$\approx \exp\left\{ -\frac{\mathrm{i}\hbar}{2} \mathcal{G}^{(2)}_{xy} \frac{\delta^2}{\delta\tilde{\varphi}_x \delta\tilde{\varphi}_y} \right\} \tilde{\varphi}_1 \tilde{\varphi}_2 \tilde{\varphi}_3 \left(-\frac{\mathrm{i}}{\hbar} \right) \int \mathrm{d}^4 x_4 \frac{\Lambda}{3!} \tilde{\varphi}^3 (x_4) \Big|_{\tilde{\varphi}=0} .$$

Остается третья степень, в системе единиц $\hbar = c = 1$ имеем $\mathcal{G}^{(2)}_{xy} = \mathrm{i}\mathcal{D}^{(2)}_{xy}$ (??), так что

$$\mathcal{D}^{(3)}_{123} \approx -\,\mathrm{i}\frac{\Lambda}{3!} \left(\frac{1}{2} \int \mathrm{d}^4 x \; \mathrm{d}^4 y \mathcal{D}^{(2)}_{xy} \frac{\delta^2}{\delta\tilde{\varphi}_x \delta\tilde{\varphi}_y} \right)^3 \frac{1}{3!} \tilde{\varphi}_1 \tilde{\varphi}_2 \tilde{\varphi}_3 \int \mathrm{d}^4 x_4 \tilde{\varphi}^3 (x_4) \Big|_{\tilde{\varphi}=0}$$

(???? полчаса про это подумаю) Связный вклад $\mathcal{D}^c_{123}$ получается, если каждое их полей $\tilde{\varphi}_{1,2,3}$ спарить с полями $\tilde{\varphi}_4$, причем, в силу симметричности варьирования по $\tilde{\varphi}_x$ и $\tilde{\varphi}_y$ фактор $1/2$ компенсируется перестановкой $x \leftrightarrow y$, а комбинаторика по выборке $\tilde{\varphi}_4$ из $\tilde{\varphi}^3_4$ компенсирует фактор $1/3$! и комбинаторика выбора вариации из $\tilde{\varphi}_1 \tilde{\varphi}_2 \tilde{\varphi}_3$ также компенсирует фактор $1/3$!, так что

$$\mathcal{D}^c_{123} \approx -\mathrm{i}\Lambda \int \mathrm{d}^4 x_4 \mathcal{D}^{(2)}_{14} \mathcal{D}^{(2)}_{24} \mathcal{D}^{(2)}_{34}$$

3.6.2 ϕ^4 theory

Основные формулы и особенности

Правила Фейнмана для $-\frac{\lambda}{4!}\phi^4$.

Вычислим

$$Z(J) = \int D\varphi e^{i\int d^4x\left\{\frac{1}{2}\left[(\partial\varphi)^2 - m^2\varphi^2\right] - \frac{\lambda}{4!}\varphi^4 + J\varphi\right\}}$$

(??????)

О другом

3.6.3 Yukawa theory $\mathcal{L}_{\text{Yukawa}}(\phi,\psi) = -g\bar{\psi}\phi\psi$

Main formulas

$$U(\vec{r}) = \frac{-\lambda^2}{4\pi r}e^{-mr}$$

$$H = H_{\text{Дирак}} + H_{\text{Клейн-Гордон}} + \int d^3x g\bar{\psi}\psi\phi.$$

Главный вклад дает слагаемое H_I^2 в S-матрице:

$${}_0\left\langle \mathbf{p}', \mathbf{k}' \middle| T\left(\frac{1}{2!}(-ig)\int d^4x\bar{\psi}_I\psi_I\phi_I \quad (-ig)\int d^4y\bar{\psi}_I\psi_I\phi_I\right)\middle|\mathbf{p},\mathbf{k}\right\rangle_0.$$

$$\psi_I(x)|\mathbf{p},s\rangle = \int \frac{d^3p'}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}'}}}\sum_{s'} a^{s'}_{\mathbf{p}'}u^{s'}(p')\,e^{-ip'\cdot x}\sqrt{2E_{\mathbf{p}}}a^{s\dagger}_{\mathbf{p}}|0\rangle = e^{-ip\cdot x}u^s(p)|0\rangle.$$

Пример:

$$=$$

$$(-ig)^2\int\frac{d^4q}{(2\pi)^4}\frac{i}{q^2-m_\phi^2}(2\pi)^4\delta(p'-p-q)\,(2\pi)^4\delta(k'-k+q)\,\bar{u}(p')\,u(p)\bar{u}(k')\,u(k)$$

(Мы опустили множитель 1/2!, потому что имеется второе, идентичное слагаемое, которое происходит от перестановки местами x и y в (4.115)). Используя любую дельта-функцию для выполнения интегрирования, находим, что это выражение имеет вид $i\mathscr{M}(2\pi)^4\delta(\Sigma p)$, где

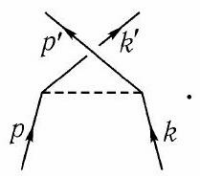
$$i\mathscr{M} = \frac{-ig^2}{q^2-m_\phi^2}\bar{u}(p')\,u(p)\bar{u}(k')\,u(k).$$

При такой записи нельзя забывать накладывать связь $p - p' = q = k' - k$.

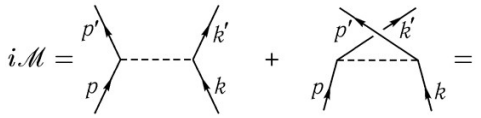
Наконец, обсудим вопрос о фермионных знаках «минус». Вернемся к примеру процесса фермион-фермионного рассеяния. Мы принимаем следующее соглашение о знаках для начальных и конечных состояний:

$$|\mathbf{p},\mathbf{k}\rangle \sim a^{\dagger}_{\mathbf{p}}a^{\dagger}_{\mathbf{k}}|0\rangle, \quad \langle\mathbf{p}',\mathbf{k}'| \sim \langle 0|a_{\mathbf{k}'}a_{\mathbf{p}'},$$

так что $(|p,k\rangle)^{\dagger} = \langle p,k|$. Тогда свертка



Наконец-то ниже важный итог наинисшего порядка!!!



$$= (-i\,g^2)\left(\bar{u}\,(p')\,u\,(p)\frac{1}{(p'-p)^2-m_\phi^2}\,\bar{u}\,(k')\,u\,(k) - \bar{u}\,(p')\,u\,(k)\frac{1}{(p'-k)^2-m_\phi^2}\,\bar{u}\,(k')\,u\,(p)\right).$$

Собирая вместе вклады в эту амплитуду рассеяния, находим:

$$i\mathscr{M} = \frac{ig^2}{|\mathbf{p}'-\mathbf{p}|^2+m_\phi^2}2m\delta^{ss'}2m\delta^{rr'}.$$

Это выражение надо сравнить с борновским приближением для амплитуды рассеяния в нерелятивистской квантовой механике, записанной с помощью потенциала $V(\mathbf{x})$:

$$\langle p'|iT|p\rangle = -i\tilde{V}(\mathbf{q})(2\pi)\delta\left(E_{\mathbf{p}'}-E_{\mathbf{p}}\right), \quad (\mathbf{q}=\mathbf{p}'-\mathbf{p}).$$

Очевидно, для взаимодействия Юкавы

$$\widetilde{V}(\mathbf{q}) = \frac{-g^2}{|\mathbf{q}|^2+m_\phi^2}$$

После обращения фурье и небольшого интегрирования, получаем

$$V(r) = -\frac{g^2}{4\pi}\frac{1}{r}e^{-m_\phi r}.$$

Потенциал взаимодействия!!!

Feynman Rules Illustration

(пока тут, мб тут что-то, что в другую часть вставляется лучше)

The same results can also be found by the same rigorous route followed for the scalar field, starting with the LSZ reduction theorem (??? сделаю это!!!).

For Yukawa theory with

$$\mathcal{L} = \frac{1}{2}(\partial_\mu\phi)^2 - \frac{1}{2}\mu^2\phi^2 + \bar{\psi}(i\not{\partial} - m)\psi - \lambda\phi\bar{\psi}\psi$$

where ϕ is a scalar field. We think of the ψ particles as nucleons and the ϕ particles as mesons (pions).

• We now carefully work out $\psi\psi \to \psi\psi$ scattering, with initial and final states

$$|i\rangle = \sqrt{4E_pE_q}\,b^{s\dagger}_{\mathbf{p}}b^{r\dagger}_{\mathbf{q}}|0\rangle, \quad |f\rangle = \sqrt{4E_{p'}E_{q'}}\,b^{s'\dagger}_{\mathbf{p}'}b^{r'\dagger}_{\mathbf{q}'}|0\rangle.$$

Taking the adjoint to get $\langle f|$ reverses the order of the operators (!!!!!!); we were careless about this before because the operators commuted.

The $O(\lambda^2)$ contribution to $\langle f|S-1|i\rangle$ is

$$\frac{(-i\lambda)^2}{2}\int dx_1dx_2T\left(\bar{\psi}(x_1)\psi(x_1)\phi(x_1)\bar{\psi}(x_2)\psi(x_2)\phi(x_2)\right)$$

where the two ϕ fields must be contracted, just as in scalar Yukawa theory.

• Next, we need to be careful about how the spinor indices are contracted. While we've kept this implicit, there is a contraction between $\bar{\psi}$ and ψ in the interaction term, so explicitly

$$\begin{aligned}&:\bar{\psi}(x_1)\psi(x_1)\bar{\psi}(x_2)\psi(x_2): b^{s\dagger}_{\mathbf{p}}b^{r\dagger}_{\mathbf{q}}|0\rangle = \\ &\quad = -\int\frac{d\mathbf{k}_1d\mathbf{k}_2}{\sqrt{4E_{k_1}E_{k_2}}}\left(\bar{\psi}(x_1)\cdot u^m(\mathbf{k}_1)\right)\left(\bar{\psi}(x_2)\cdot u^n(\mathbf{k}_2)\right)e^{-i(k_1x_2+k_2x_2)}b^m_{\mathbf{k}_1}b^n_{\mathbf{k}_2}b^{s\dagger}_{\mathbf{p}}b^{r\dagger}_{\mathbf{q}}|0\rangle\end{aligned}$$

where the dot indicates spinor contraction, and we picked up a sign from moving $\psi(x_1)$ past $\bar{\psi}(x_2)$. Applying the anticommutation relations gives two terms which differ by a sign.

• Finally, we need to take care of the final state. Each of the two terms above yields two possible contraction structures, canceling the $1/2$ in front of the amplitude. We are left with the position integrations, which yield delta functions, finally giving

$$\mathcal{M} = (-i\lambda)^2\left(\frac{\left(\bar{u}^{s'}(\mathbf{p}')\cdot u^s(\mathbf{p})\right)\left(\bar{u}^{r'}(\mathbf{q}')\cdot u^r(\mathbf{q})\right)}{(p'-p)^2-\mu^2+i\epsilon} - \frac{\left(\bar{u}^{s'}(\mathbf{p}')\cdot u^r(\mathbf{q})\right)\left(\bar{u}^{r'}(\mathbf{q}')\cdot u^s(\mathbf{p})\right)}{(q'-p)^2-\mu^2+i\epsilon}\right)$$

• We can summarize our results with the following Feynman rules.

• For every incoming fermion with momentum p and spin r, write down $u^r(\mathbf{p})$. For outgoing fermions, write $\bar{u}^r(\mathbf{p})$.

• For incoming and outgoing antifermions write $\bar{v}^r(\mathbf{p})$ and $v^r(\mathbf{p})$, respectively,

• Every vertex gives a factor of $-i\lambda$.

• Every internal line gets a Feynman propagator,

$$\text{scalar: } \frac{i}{p^2-\mu^2+i\epsilon}, \qquad \text{fermion: } \frac{i(\not{p}+m)}{p^2-m^2+i\epsilon}.$$

• Conserve momentum at every vertex, and integrate dp over loop momenta.

• For every fermion line, draw an arrow indicating the flow of particle number, and contract spinor indices along these lines. This is independent of the momentum flow arrows, though the two can always be aligned for internal lines.

An easy way to remember the external fermion factors is to note that the matrix multiplications, read left to right, always go opposite the particle flow lines.

• There are also extra minus signs in various places.

• Interchange of identical particles gives a factor of -1. E.g. the t-channel and u-channel diagrams have opposite signs for $\psi\psi \to \psi\psi$, as we saw above.

• Every closed fermion loop has a factor of -1. This is because we will always need an odd number of swaps to 'untangle' all of the contractions. We write 'tr' to indicate the spinor indices are contracted in a loop.

• Unfortunately, there are further signs that are more subtle, for which these two rules don't suffice. The most reliable way is to simply return to the level of contractions and count the anticommutations necessary to form one. An equivalent diagrammatic method is to redraw the diagram so that all fermion lines start on the left (in a standard order) and end on the right; the sign is the sign of the permutation of the lines on the right.

• Finally, we can find the Yukawa potential in the nonrelativistic limit. For $\psi\psi \to \psi\psi$ scattering, note that the spinors become

$$u(\mathbf{p}) \to \sqrt{m}\begin{pmatrix} \xi \\ \xi \end{pmatrix}, \quad v(\mathbf{p}) \to \sqrt{m}\begin{pmatrix} \xi \\ -\xi \end{pmatrix}$$

so the spin-dependence in the terms is just $\delta^{ss'}\delta^{rr'}$ and $\delta^{rs'}\delta^{sr'}$, so the interaction conserves spin and is spin-independent. Besides that, the amplitude is the same as in Yukawa theory, so the potential is attractive.

• Next, consider the process $\psi\bar{\psi} \to \psi\bar{\psi}$. There is a sign flip from fermionic statistics as shown above, but another sign flip from $\bar{v}^{s'} \cdot v^{s} = -2m\delta^{ss'}$, which means nucleons and antinucleons still attract. This is because forces mediated by spin 0 particles are universally attractive.

• More realistically, the pion is a pseudoscalar, so we should considering the coupling

$$\mathcal{L}_{\text{Yuk}} = -\lambda\phi\bar{\psi}\gamma^5\psi$$

which obeys parity. Then the interaction vertex becomes $-i\lambda\gamma^5$. In this case, the calculation becomes significantly more complicated, since taking the naive nonrelativistic limit above just yields zero. The result is a spin-dependent potential which goes as $1/r^3$ for massless pions. For details, see the paper New Macroscopic Forces?

О рассеянии частиц на античастицах по Юквае (?????)

(дальше у ПШ про это)

3.6.4 Standard Model main properties, algebra

(страниц 10 будет самого основного, подробнее - см. пока отдеьлную запись, но может и во 2ю 1ю часть добавлю)

Основные формулы и особенности

(тут абзац про части стандартной модели, типа это КХД и лептоны и они не сильно друг с другом связаны. все общее важное!)

О лептонном и хиггсовском секторе по лекции 13 Киселеву

(когда-то за часа 3 пойму и напишу про это тут что нужно, чисто введение)

$(V-A)$-структура слабого взаимодействия

связь лептнного тока с массивным заряженным W-бозоном и дублет левых лептонов,

группа локальной калибровочной симметрии $U(1)\times SU(2)_L$ и необходимость введения слабых нейтральных токов,

дублет скалярных полей Хиггса и нормировка гиперзаряда,

спонтанное нарушение электрослабой симметрии,

масса W-бозона,

угол Вайнберга,

связь оператора электрического заряда с гиперзарядом и слабым изоспином,

масса Z-бозона,

вершина взаимодействия Z-бозона с нейтральными токами,

вакуумное среднее поля Хиггса и постоянная Ферми в эффективной теории 4-фермионного взаимодействия при низких энергиях,

юкавский сектор и массы заряженных фермионов.

О другом в стандартной модели

3.6.5 Other toy illustrative theories

$\varphi_M\Phi^\dagger\Phi$ theory

Ширина распада (?!)

$$\mathrm{d}\Gamma = \frac{|\mathfrak{M}|^2}{2M} d\mathfrak{p}_f$$

где $\mathrm{d}\mathfrak{p}_f = (2\pi)^4\delta\left(p-\sum\limits_{n=1}^{n_f} k_{(n)}\right)\prod_{n=1}^{n_f}\frac{\mathrm{d}^3k_{(n)}}{2E_{(n)}}$.

Дифференциальное сечением рассеяния частиц с 4-импульсами p и $\tilde{p}$:

$$\mathrm{d}\sigma = \frac{|\mathfrak{M}|^2}{4\sqrt{(p\cdot\tilde{p})^2 - m^2\tilde{m}^2}} d\mathfrak{p}_f$$

$$\mathrm{d}\mathfrak{p}_f := (2\pi)^4\delta\left(p+\tilde{p}-\sum_{n=1}^{n_f} k_{(n)}\right)\prod_{n=1}^{n_f}\frac{\mathrm{d}^3 k_{(n)}}{2E_{(n)}}.$$

Эти правила относятся к случаю, когда одноточечная функция Грина поля равна нулю (??? поч????). Однако, ненулевое вакуумное значение поля $v = \langle 0|\hat{\varphi}(x)|0\rangle$ отвечает просто случаю внешнего поля с нулевым импульсом. Такую внешнюю линию обычно изображают с символом $\otimes$ на конце (???? или такого нет????). При этом вершины взаимодействия внешнего вакуумного поля легко определить, если в исходном лагранжиане произвести замену поля, скажем, $\varphi \mapsto v+\varphi$, так что новое поле уже не имеет вакуумного среднего.

У нас всегда распадаются частицы по Брейту-Вигнеру и там всегда есть параметр - ширина распада.

Ширина для $-\mathcal{L}_{\text{int}} = \Lambda\varphi_M\Phi^\dagger\Phi$ по Киселеву

(мб добавлю формулы Киселева, пока думаю, по ПШ хватит теории.)

$$\begin{aligned}
\mathrm{i}\mathcal{M}^c_{(3)} &= -\mathrm{i}\Lambda\int \mathrm{d}^4x_4\varphi^{\text{cl}}_M(x_4)\,\Phi^\dagger_{\text{cl}}(x_4)\,\Phi_{\text{cl}}(x_4)\\
&= -\mathrm{i}\Lambda(2\pi)^4\delta(p-k_1-k_2)\\
\left|\mathcal{M}^c_{(3)}\right|^2 &= \Lambda^2(2\pi)^4\delta(p-k_1-k_2)\left\{(2\pi)^4\delta(k')\right\}\big|_{k'\to 0}
\end{aligned}$$

Стандартным приемом найдем «сингулярное значение»

$$\left\{(2\pi)^4\delta(k')\right\}\big|_{k'\to 0} = \int\limits_{V_{[4]}} \mathrm{d}^4x \mathrm{e}^{\mathrm{i}k'x}\Big|_{k'\to 0} = V_{[4]} = \Delta t V_{[3]},$$

(тут мб абзац будет про эти бесконечности, что просто нормируем на них и все.)
(словами напишу переходы простые)

$$\Gamma = \frac{\Lambda^2}{2M}\int\delta\left([p-k_2]^2\right)\frac{\mathrm{d}^3k_2}{(2\pi)^2 2E_2}.$$

$$\frac{\mathrm{d}^3k_2}{(2\pi)^2 2E_2} = \frac{4\pi}{4\pi^2}\quad\frac{|\boldsymbol{k}_2|^2\,\mathrm{d}\,|\boldsymbol{k}_2|}{2E_2} = \frac{|\boldsymbol{k}_2|\,\mathrm{d}E_2}{2\pi}.$$

В итоге, релятивистски инвариантный фазовый объем

$$\int\delta\left([p-k_2]^2\right)\frac{\mathrm{d}^3k_2}{(2\pi)^2 2E_2} = \frac{1}{4\pi}\frac{|\boldsymbol{k}_2|}{M} = \frac{1}{8\pi}.$$

Ширина найдена

$$\Gamma = \frac{\Lambda^2}{16\pi M},\quad [\Gamma] = [m].$$

(!!! подумаю про это, очень содержательная формула!)

В теории возмущений необходимо, чтобы

$$\Gamma \ll M \quad\Rightarrow\quad \Lambda \ll M.$$

$$[AB, CD]_\pm = A[B, C]_- D + AC[B, D]_- + [A, C]_- DB + C[A, D]_\pm B$$

$$[[A, B], [C, D]] = \left[[[B, C]_+, A]_+, D\right] - \left[[[B, D]_+, A]_+, C\right] + \left[[[A, D]_+, B]_+, C\right] - \left[[[A, C]_+, B]_+, D\right]$$

$$[A, [B, C]_\pm] + [B, [C, A]_\pm] + [C, [A, B]_\pm] = 0$$

$$[A, BC]_\pm = [A, B]_- C + B[A, C]_\pm = [A, B]_\pm C \mp B[A, C]_-$$

$$[A, BC] = [A, B]_\pm C \mp B[A, C]_\pm$$

Tensors for QFT

Levi-Chivita symbol $\varepsilon^{\alpha\beta\gamma\delta}$:

$$\varepsilon^{\alpha\beta\mu v}\varepsilon_{\alpha\beta\sigma\tau} = -2\left(g^{\mu}_{\sigma}g^{v}_{\tau} - g^{\mu}_{\tau}g^{v}_{\sigma}\right)$$
$$\varepsilon^{\alpha\beta\gamma v}\varepsilon_{\alpha\beta\gamma\tau} = -6g^{v}_{\tau}$$
$$\varepsilon^{\alpha\beta\gamma\delta}\varepsilon_{\alpha\beta\gamma\delta} = -24$$

(мб в др место вставлю)

3.7.2 Quantum Mechanics for QFT

(перегруппирую некоторые отсюда темы потом, вообще поставлю или под начало, где смысл КТП, или под конец, где всякее общее не актуальные соображения)

Attempts at nonrelativistic quantum mechanics

(I'll write in compact form later, or maybe not write it at all. Maybe 1/2 or 1 page will be about it.)

Schrodinger equation from quantum field theory

The Klein-Gordan equation for complex (for probability) scalar field $(\partial^2 + m^2)\,\phi = 0$ and setting $\phi = e^{-imt}\chi/\sqrt{2m}$ yields

$$i\dot{\chi} = \frac{\ddot{\chi} - \nabla^2\chi}{2m}$$

$\ddot{\chi}/m \ll \dot{\chi}$,

$$\mathcal{L} = i\chi^*\dot{\chi} - \frac{1}{2m}\nabla\chi^*\cdot\nabla\chi$$

$$\pi = i\chi^*, \quad \mathcal{H} = \frac{1}{2m}\nabla\chi^*\cdot\nabla\chi, \quad \left[\chi(\mathbf{x}), \chi^\dagger(\mathbf{y})\right] = \delta(\mathbf{x}-\mathbf{y})$$

$$\chi(\mathbf{x}) = \int d\mathbf{p} a_{\mathbf{p}} e^{ipx}, \quad \left[a_{\mathbf{p}}, a^\dagger_{\mathbf{q}}\right] = \not{\delta}(\mathbf{p}-\mathbf{q})$$

$$H = \int d\mathbf{p}\frac{p^2}{2m}a^\dagger_{\mathbf{p}}a_{\mathbf{p}}, \quad \mathbf{P} = \int d\mathbf{p}\mathbf{p}a^\dagger_{\mathbf{p}}a_{\mathbf{p}}$$

which are simply the usual definitions in nonrelativistic quantum field theory.
$|\mathbf{x}\rangle = \chi^\dagger(\mathbf{x})|0\rangle$

$$\mathbf{X} = \int d\mathbf{x}\mathbf{x}\chi^\dagger(\mathbf{x})\chi(\mathbf{x}), \quad \mathbf{X}|\mathbf{x}\rangle = \mathbf{x}|\mathbf{x}\rangle$$

$$|\psi\rangle = \int d\mathbf{x}\psi(\mathbf{x})|x\rangle$$

$$\mathbf{X}|\psi\rangle = \int d\mathbf{x}\mathbf{x}\psi|\mathbf{x}\rangle, \quad \mathbf{P}|\psi\rangle = \int d\mathbf{x}(-i\nabla\psi)|\mathbf{x}\rangle, \quad H|\psi\rangle = \int d\mathbf{x}\left(-\frac{1}{2m}\nabla^2\psi\right)|\mathbf{x}\rangle$$

Основные формулы гармонического осциллятора и его применения в КТП

О когерентных состояниях

О другом про гармонический осциллятор

3.7.3 Classical field theory for QFT

(это же в теорполе, только тут в контексте КТП и короче пояснения)
(Нетер, ТЭИ, параметры, все это тут укажу, чтобы не листать в запись по теории поля)

О Лагранжевом формализме

(суть Мандела Шаула, начала)

4 Other QFT processes

4.1 Overview of other processes

(тоже обзор всяких рассеяний, распадов, т.п., с содежательным графиком, формулой, сутью описания. Не КЭД, КЭД был в 1й части.)

4.1.1 Other QED processes

38. Рассеяние в ультрарелятавистском случае

42. Рассеяние нейтронов в электрическом поле

Уравнение Брейта по Ландау 4 (???)

Позитроний по Ландау 4 (???)

Взаимодействие атомов на далеких расстояниях по Ландау 4 (???)

$$U(r) = \frac{i}{2} \int\limits_{-\infty}^{\infty} \omega^4 \alpha_1(\omega) \alpha_2(\omega) \left[D_{ik}(\omega, \mathbf{r}) \right]^2 \frac{d\omega}{2\pi}$$

Что следует из какого-то замысловатого усреднения S-матрицы (????) Тут

$$D_{ik}(\omega, \mathbf{r}) = -\left(\delta_{ik} + \frac{1}{\omega^2} \frac{\partial^2}{\partial x_i \partial x_k} \right) D(\omega, \mathbf{r})$$

где еще можно чуть преобразовать это. (?? теория пар 76 тут используется, я хз)

В (?? каких-то одних упрощениях) имеем формулу Лондона

$$U(r) = -\frac{2}{3r^6} \sum_{n,n'} \frac{\left|\mathbf{d}_{0n}\right|^2 \left|\mathbf{d}_{0n'}\right|^2}{\hbar \left(\omega_{n0} + \omega_{n'0} \right)}$$

В (??? других??) имеем формулу Казимира-Полдера (1948):

$$U(r) = -\frac{23}{4\pi} \frac{\hbar c \alpha_1(0) \alpha_2(0)}{r^7}$$

(??? пока не понял суть, потом добавлю важные слова сюда!)

О рассеянии электрона во внешнем поле по Ландау 4 (???)

Ионизационные потери быстрых частиц по Ландау 4 (???)

80. Рассеяние электрона во внешнем поле

81. Рассеяние электронов и позитронов на электроне

82. Ионизационные потери быстрых частиц

83. Уравнение Брейта

84. Позитроний

85. Взаимодействие атомов на далеких расстояниях

$$S_{fi} = -i \int \psi_1'^* (\mathbf{r}_1)\, \psi_2'^* (\mathbf{r}_2) U(r) \psi_1 (\mathbf{r}_1)\, \psi_2 (\mathbf{r}_2)\, d^3x_1 d^3x_2 \times \\ \times \int \exp\left\{-i\left(\varepsilon_1 + \varepsilon_2 - \varepsilon_1' - \varepsilon_2'\right) t\right\} dt.$$

$$S_{fi} = \int \psi_1'^* \psi_2'^* \langle S(r)\rangle \psi_1 \psi_2 d^3x_1 d^3x_2$$

Сравнив с $(85, 2)$, мы увидим, что если получить выражение для $\langle S(r)\rangle$ в виде

$$\langle S(r)\rangle = -itU(r),$$

$$\hat{S}^{(4)} = \frac{(-i)^4}{4l} \int dt_1 \ldots \int dt_4 \cdot \mathrm{T}\left\{\hat{V}(t_1)\, \hat{V}(t_2)\, \hat{V}(t_3)\, \hat{V}(t_4)\right\}$$

$$D_{ik}(t, \mathbf{r}) = \int D_{ik}(\omega, \mathbf{r}) e^{-i\omega t} \frac{d\omega}{2\pi}$$

$$D_{lk}^E(t, \mathbf{r}) = -i \int \omega^2 D_{ik}(\omega, \mathbf{r}) e^{-i\omega t} \frac{d\omega}{2\pi}$$

$$\alpha_{ik}(t_1 - t_2) = i \langle \mathrm{T}(d_i(t_1)\, d_k(t_2))\rangle$$

$$\alpha_{ik}(\omega) = \sum_n \left\{ \frac{(d_i)_{0n} (d_k)_{n0}}{\omega_{n0} - \omega - i0} + \frac{(d_k)_{0n} (d_i)_{n0}}{\omega_{n0} + \omega - i0} \right\}$$

Если основное состояние является S-состоянием, то этот тензор сводится к скаляру: $\alpha_{ik} = \alpha\delta_{ik}$, где

$$\dot{\alpha(\omega)} = \frac{1}{3} \sum_n |\mathbf{d}_{0n}|^2 \left(\frac{1}{\omega_{n0} - \omega - i0} + \frac{1}{\omega_{n0} + \omega - i0} \right).$$

$$\langle S(r)\rangle = -itU(r),$$
$$U(r) = \frac{i}{2}\int\limits_{-\infty}^{\infty} \omega^4 \alpha_1(\omega)\alpha_2(\omega)\left[D_{ik}(\omega,\mathbf{r})\right]^2 \frac{d\omega}{2\pi}$$

В предельном же случае больших расстояний, $r \gg \lambda_0$, в интеграле существенны значения $\omega \leqslant c/r \ll \omega_0$; при $\omega \geqslant \omega_0$ интеграл погашается быстро осциллирующим множителем $\exp(2i\omega r)$. Поэтому можно заменить поляризуемости $\alpha_1(\omega)$ и $\alpha_2(\omega)$ их статическими значениями $\alpha_1(0)$ и $\alpha_2(0)$. После этого интегрирование производится элементарно (прнчем для обеспечения сходимости следует заменить в экспоненте $r \to r + i0$). В результате окончательно находим (в обычных единицах):

$$U(r) = -\frac{23}{4\pi}\frac{\hbar c \alpha_1(0)\alpha_2(0)}{r^7}$$

(H.B.G. Casimir, D. Polder, 1948) [1]).

4.2.2 $\gamma e \to \gamma e,\ ee \to \gamma\gamma,\ ee^+ \to \gamma\gamma\gamma$

87. Рассеяние фотона электроном. Поляризационные эффекты

Общие формулы

$$e^{(1)} = \frac{N}{\sqrt{-N^2}}, \quad e^{(2)} = \frac{P}{\sqrt{-P^2}},$$

где

$$P^\lambda = \left(p^\lambda + p'^\lambda\right) - K^\lambda \frac{pK + p'K}{K^2}, \quad N^\lambda = e^{\lambda\mu\nu\rho}P_\mu q_v K_\rho$$
$$K^\lambda = k^\lambda + k'^\lambda, \quad q^\lambda = k'^\lambda - k^\lambda = p^\lambda - p'^\lambda.$$

Непосредственным проецированием тензора $Q_{\mu\nu}$ находим

$$Q_0 = \frac{1}{2}Q^{\mu\nu}\left(e_\mu^{(1)}e_v^{(1)} + e_u^{(2)}e_v^{(2)}\right)$$

и т. д. Для вычисления удобно сначала выразить $Q_{\mu v}$ через взаимно ортогональные 4-векторы P, N, q, K:

$$Q^{\mu\nu} = \gamma^\mu \frac{\gamma P/2 + m}{s - m^2}\gamma^\nu + \gamma^\nu \frac{\gamma P/2 + m}{u - m^2}\gamma^\mu - \frac{1}{t}\left[\gamma^\mu(\gamma K)\gamma^\nu - \gamma^\nu(\gamma K)\gamma^\mu\right].$$

$$\bar u'\left(\gamma p + \gamma p'\right)u = 2m\bar u' u,$$
$$\bar u'\gamma^5(\gamma q)u = \bar u'\left[\gamma^5(\gamma p) + (\gamma p')\,\gamma^5\right]u = 2m\bar u'\gamma^5 u$$

то можно заменить в $Q^{\mu\nu}$ слагаемые

$$\gamma p + \gamma p' \to 2m, \quad \gamma^5(\gamma q) \to 2m\gamma^5$$

Поэтому матрицы плотности начального и конечного фотонов, отнесенные к 4-ортам $e^{(1)}, e^{(2)}$, будут

$$\rho^{(\gamma)} = \tfrac{1}{2}(1 + \xi\sigma), \qquad \xi = (\xi_1, \xi_2, \xi_3)\,;$$
$$\rho^{(\gamma)'} = \tfrac{1}{2}\left(1 + \xi'\sigma\right), \quad \xi' = (-\xi_1', -\xi_2', \xi_3')\,.$$

Теперь тензорный след

$$\rho^{(\nu')}_{\lambda\mu} Q^{\mu\nu} \rho^{(\nu)}_{\nu\rho} \tilde{\tilde{Q}}^{\rho\lambda}$$

Рассеяние на неполяризованных электронах

$$\rho^{(e)} = \frac{1}{2}(\gamma p + m), \quad \rho^{(e)'} = \frac{1}{2}(\gamma p' + m)$$

и удвоить результат, который должен быть подставлен вместо $|M_{fi}|^2$ в формулу для сечения $(64, 22)$

$$d\sigma = \frac{1}{32\pi^2} \frac{dt d\varphi}{(s - m^2)^2} |M_{fi}|^2$$

В лабораторной системе формула $(87, 11)$ принимает вид

$$d\sigma = \frac{r_e^2}{4} \left(\frac{\omega'}{\omega}\right)^2 do' \{F_0 + F_3(\xi_3 + \xi_3') + F_{11}\xi_1\xi_1' + F_{22}\xi_2\xi_2' + F_{33}\xi_3\xi_3'\}$$
$$do' = \sin\theta d\theta d\varphi, \quad (87, 12$$

где

$$F_0 = \frac{\omega}{\omega'} + \frac{\omega'}{\omega} - \sin^2\vartheta, \quad F_3 = \sin^2\vartheta$$
$$F_{11} = 2\cos\vartheta, \quad F_{22} = \left(\frac{\omega}{\omega'} + \frac{\omega'}{\omega}\right)\cos\vartheta, \quad F_{33} = 1 + \cos^2\vartheta$$

(U. Fano, 1949).

Согласно изложенным в §65 правилам величины ξ_i'' равны отношениям коэффициентов при $\xi_i'\dot{\kappa}$ члену, не содержащему ξ':

$$\xi_1^{(f)} = \frac{F_{11}}{F}\xi_1, \quad \xi_2^{(f)} = \frac{F_{22}}{F}\xi_2, \quad \xi_3^{(f)} = \frac{F_3 + F_{33}\xi_3}{F}.$$

В частности, при рассеянии неполяризованного фотона

$$\xi_1^{(f)} = \xi_2^{(f)} = 0, \quad \xi_3^{(f)} = \frac{\sin^2\theta}{\omega/\omega' + \omega'/\omega - \sin^2\theta}$$

$$d\sigma = \frac{r_e^2}{4}\left(\frac{\omega'}{\omega}\right)^2 \left(\frac{\omega}{\omega'} + \frac{\omega'}{\omega} - 2 + 4\cos^2\Theta\right) do',$$

Рассеяние на поляризованных электронах

$$d\sigma = \frac{1}{2} d\sigma(\xi, \xi') +$$
$$+ \frac{r_e^2}{8}\left(\frac{\omega'}{\omega}\right)^2 do' \{\mathbf{f}\xi\xi_2 + \mathbf{f}'\xi_2' + \mathbf{g}\xi'\xi_2 + \mathbf{g}'\xi'\xi_2' + G_{ik}\xi_i\xi_k' + ...\}.$$

фотона поляризованным электроном

$$d\sigma(\xi, \xi) = d\sigma(\xi) + \frac{1}{2} r_e^2 \left(\frac{\omega'}{\omega}\right)^2 \xi_2 \mathrm{f}\xi do'$$

отличается от $d\sigma(\xi)$ только при наличии у фотона круговой поляризации, а у электронов-отличной от нуля проекции среднего спина на плоскость рассеяния. По той же причине электрон отдачи поляризуется только в случае, если фотон обладает круговой поляризацией; вектор же возникающей поляризации электрона лежит при этом в плоскости рассеяния:

$$\xi^{(f)} = \frac{1}{F}\xi_2 \mathbf{g}.$$

Соотношения симметрии

Качественные свойства поляризационных эффектов при рассеянии фотонов на электронах следуют уже из общих требований симметрин.

Параметр ξ_2 циркулярной поляризации - псевдоскаляр (см. §8). Поэтому в силу требования P-инвариантности члены вида $\sim \xi_2$ (или $\propto \xi_2'$) в сечении рассеяния могли бы возникнуть лишь как произведение ξ_2 на какой-либо псевдоскаляр, составленный из имеющихся в нашем распоряжении векторов $\mathbf{k}$ и $\mathbf{k}'$[1]). Но из двух полярных векторов нельзя составить псевдоскаляр. Отсюда и следует, что указанных членов в сечении не может быть.

Параметры линейной поляризации ξ_1 и ξ_3 связаны с компонентами двумерного (в плоскости, перпендикулярной k) симметричного тензора

$$S_{\alpha\beta} = \frac{1}{2}\left(\rho^{(\nu)}_{\alpha\beta} + \rho^{(\nu)}_{\beta\alpha}\right) = \frac{1}{2}\begin{pmatrix} 1+\xi_3 & \xi_1 \\ \xi_1 & 1-\xi_3 \end{pmatrix}.$$

88. Двухфотонная аннигиляция электронной пары

Они отличаются от диаграмм рассеяния фотона на электроне заменой

$$p \to p_-, \quad p' \to -p_+, \quad k \to -k_1, \quad k' \to k_2.$$

Оба процесса - два перекрестных канала одной и той же (обобщенной) реакции. После замены $(88,2)$ кинематические инварианты $(86,2)$ приобретают следующий смысл:

$$\begin{aligned} s &= (p_- - k_1)^2, \\ t &= (p_- + p_+)^2 = (k_1 + k_2)^2, \\ u &= (p_- - k_2)^2. \end{aligned}$$

Если рассеяние фотона было s-каналом, то аннигиляция есть t-канал.

Физическая область аниигиляционного канала есть область II на рис. 7 (см. с. 300). При заданном t (заданной знергии в системе центра инерцин) интервал изменения s определяется уравнением границы $su = m^4$. Вместе с соотношением $s + t + u = 2m^2$ это дает $-\frac{t}{2} - \frac{1}{2}\sqrt{t\,(t-4m^2)} \leqslant s - m^2 \leqslant -\frac{t}{2} + \frac{1}{2}\sqrt{t\,(t-4m^2)}$. Интегрирование выражения $(88,4)$ элементарно; результат надо еше разделить на 2, учитывая тождественность двух конечных частиц (фотонов). Таким образом, получим

$$\sigma = \frac{\pi r_e^2}{2\tau^2(\tau-1)}\left[\left(\tau^2+\tau-\frac{1}{2}\right)\ln\frac{\sqrt{\tau}+\sqrt{\tau-1}}{\sqrt{\tau}-\sqrt{\tau-1}} - (\tau+1)\sqrt{\tau(\tau-1)}\right],$$

$(88,6)$ где $\tau = t/4m^2$ (P. A. M. Dirac, 1930).

В нерелятивистском пределе ($\tau \to 1$) находим отсюда

$$\sigma = \frac{\pi r_e^2}{2\sqrt{\tau - 1}} \text{ (н. р.)}.$$

В системе центра инерции электрон, позитрон и оба фотона имеют одинаковые энергии $\varepsilon = \omega$. Инварианты:

$$m^2 - s = 2\varepsilon(\varepsilon - |\mathbf{p}|\cos\theta), \quad m^2 - u = 2\varepsilon(\varepsilon + |\mathbf{p}|\cos\theta),$$
$$t = 4\varepsilon^2,$$

где θ - угол между импульсами электрона и одного из фотонов. Подставив $(88, 12)$ в $(88, 4)$, получим угловое распределение аннигиляционных фотонов

$$d\sigma = \frac{r_e^2 m^2}{4\varepsilon|\mathrm{p}|}\left[\frac{\varepsilon^2 + \mathrm{p}^2\left(1 + \sin^2\theta\right)}{\varepsilon^2 - \mathrm{p}^2\cos^2\theta} - \frac{2\mathrm{p}^4\sin^4\theta}{\left(\varepsilon^2 - \mathrm{p}^2\cos^2\theta\right)^2}\right] do.$$

В ультрарелятивистском случае оно имеет симметричные максимумы в направлениях $\theta = 0$ и $\theta = \pi$. Вблизи $\theta = 0$

$$d\sigma \approx \frac{r_e^2 m^2 do}{2\varepsilon^2\left(\theta^2 + m^2/\varepsilon^2\right)} \text{ (у. р.)}.$$

Подставив $(88, 12)$ в $(88, 4)$, получй угловое распределение аннигиляционных фотонов

$$d\sigma = \frac{r_e^2 m^2}{4\varepsilon|\mathrm{p}|}\left[\frac{\varepsilon^2 + \mathrm{p}^2\left(1 + \sin^2\theta\right)}{\varepsilon^2 - \mathrm{p}^2\cos^2\theta} - \frac{2\mathrm{p}^4\sin^4\theta}{\left(\varepsilon^2 - \mathrm{p}^2\cos^2\theta\right)^2}\right] do.$$

В ультрарелятивистском случае оно имеет симметричные максимумы в направлениях $\theta = 0$ и $\theta = \pi$. Вблизи $\theta = 0$

$$d\sigma \approx \frac{r_e^2 m^2 do}{2\varepsilon^2\left(\theta^2 + m^2/\varepsilon^2\right)} \text{ (у. р.)}.$$

Полное сечение получается из $(88, 6)$:

$$\sigma = \pi r_e^2 \frac{1 - v^2}{4v}\left[\frac{3 - v^4}{v}\ln\frac{1 + v}{1 - v} - 2\left(2 - v^2\right)\right],$$

где $v = |\mathbf{p}|/\varepsilon = \sqrt{\varepsilon^2 - m^2}/\varepsilon$ - скорость сталкивающихся частин.

89. Аннигиляция позитрония

В нерелятивистском пределе согласно $(88, 11)$[1])

$$\overrightarrow{\sigma}_{2\gamma} = \pi\left(\frac{e^2}{mc^2}\right)^2 \frac{c}{v},$$

где v-относительная скорость частиц. Мы получим вероятность аннигиляции $\overline{\boldsymbol{\omega}}_{2\gamma}$, умножив $\bar{\sigma}_{2\gamma}$ на плотность потока, равную $v|\psi(0)|^2$. Здесь $\psi(r)$ - нормированная на 1 волновая функция основного состояния позитрония:

$$\psi(r) = \frac{1}{\sqrt{\pi a^3}} e^{-r/a}, \quad a = \frac{2\hbar^2}{me^2}$$

(боровский радиус позитрония a в два раза больше радиуса атома водорода из-за вдвое меньшей приведенной массы). Эта

Аналогичным образом найдем, что вероятность распада ортопозитрония связана с усредненным по спинам сечением трехфотонной аннигиляции свободной пары соотношением

$$w_1 = \frac{4}{3}\bar{w}_{3\gamma} = \frac{4}{3}|\psi(0)|^2 \left(v\bar{\sigma}_{3\gamma}\right)_{0\to 0}$$

(3/4 - относительный статистический вес состояния со спином 1). Забегая вперед, укажем, что

$$\bar{\sigma}_{3\nu} = \frac{4\left(\pi^2-9\right)c}{3v}\alpha\left(\frac{e^2}{mc^2}\right)^2.$$

Поэтому продолжительность жизни ортопозитрония

$$\tau_1 = \frac{9\pi}{2\left(\pi^2-9\right)}\frac{\hbar}{mc^2\alpha^5} = 1,4\cdot 10^{-7}\text{с}.$$

Неравенство $\Gamma_1 \ll |E_{\text{осн}}|$ в этом случае, разумеется, выполняется еще в большей степени, чем для парапозитрония.

Вычислим сечение трехфотонной аннигиляции свободной пары (A. Ore, J. L. Powell, 1949).

Соответствующую амплитуду запишем в виде

$$M_{fi} = (4\pi)^{s/2} e_\lambda^{(3)^*} e_\mu^{(2)^*} e_v^{(1^{**})} \bar{u}\left(-p_+\right) Q^{\lambda\mu v} u\left(p_-\right),$$

где

$$Q^{\lambda\mu\nu} = \sum_{\text{пер}} \gamma^\lambda G\left(k_3 - p_+\right)\gamma^\mu G\left(p_- - k_1\right)\gamma^\nu,$$

причем сумма берется по всем перестановкам номеров фотонов $1,2,3$ вместе с одновременными такими же перестановками соответствующих тензорных индексов $\lambda\mu v$.

Квадрат модуля амплитуды, усредненный по поляризациям электрона и позитрона и просуммированный по поляризациям фотонов:

$$\frac{1}{4}\sum_{\text{поляр}} |M_{fi}|^2 = (4\pi)^3 \,\text{Sp}\left\{\rho_+ Q^{\lambda\mu\nu}\rho_- \bar{Q}_{\lambda\mu\nu}\right\},$$

где

$$\rho_- = \frac{1}{2}\left(\gamma p_- + m\right), \quad \rho_+ = \frac{1}{2}\left(\gamma p_+ - m\right).$$

В результате все же довольно длинного вычисления пояучается

$$\frac{1}{4}\sum_{\text{поляр}} |M_{fi}|^2 = (4\pi)^3 e^6 \cdot 16\left[\left(\frac{m-\omega_1}{\omega_2\omega_3}\right)^2 + \left(\frac{m-\omega_2}{\omega_1\omega_3}\right)^2 + \left(\frac{m-\omega_3}{\omega_1\omega_2}\right)^2\right].$$

Подставив это выражение в $(89,8)$, найдем дифференциальное сечение трехфотонной аннигиляции:

$$d\tilde{\sigma}_{3\gamma} = \frac{e^6}{\pi^2 m^2 v}\left[\left(\frac{m-\omega_1}{\omega_2\omega_3}\right)^2 + \left(\frac{m-\omega_2}{\omega_1\omega_3}\right)^2 + \left(\frac{m-\omega_3}{\omega_1\omega_2}\right)^2\right]\times$$
$$\times\,\delta\left(\mathbf{k}_1+\mathbf{k}_2+\mathbf{k}_3\right)\delta\left(\omega_1+\omega_2+\omega_3-2m\right)\frac{d^3k_1 d^3k_2 d^3k_3}{\omega_1\omega_2\omega_3}.$$

Здесь надо еще исключить δ-функции. Первая нз них устраняется интегрированием по d^3k_3, после чего заменяем остальные дифференциалы:

$$d^3k_1 d^3k_2 \to 4\pi\omega_1^2 d\omega_1 \cdot 2\pi\omega_2^2 d\left(\cos\theta_{12}\right) d\omega_2$$

где θ_{12} - угол между $\mathbf{k}_1$ и $\mathbf{k}_2$; подразумевается, что уже произведено интегрирование по направлениям $\mathbf{k}_1$ и азимуту $\mathbf{k}_2$ относительно k_1. Дифференцируя равенство

$$\omega_3 = \sqrt{\omega_1^2 + \omega_2^2 + 2\omega_1\omega_2\cos\theta_{12}},$$

находим

$$d\cos\theta_{12} = \frac{\omega_3}{\omega_1\omega_2} d\omega_3$$

Полнсе сечение аннигиляции получается интегрированием $(89,14)$ по обеим частотам:

$$\bar{\sigma}_{3y} = \frac{4\varepsilon^6}{3vm^2} 3 \int_0^m \int_{m-\omega_1}^m \frac{\left(\omega_1+\omega_2-m\right)^2}{\omega_1^2\omega_2^2} d\omega_1 d\omega_2.$$

Стояший здесь двойной интеграл равен $\left(\pi^2-9\right)/3$, и мы приходим к приведенной выше формуле $(89,6)$.

4.2.3 Photons in Magnetic Field, in Nucleus, Pairs in the Ultrarelativistic Case

90. Магнитотормозное излучение

квантовая отдача при испускании фотона. Последняя определяется отношением $\hbar\omega/\varepsilon$, и условие применимости классической теории требует его малостн. В этой связи удобно ввести параметр

$$\chi = \frac{H}{H_0}\frac{|p|}{m} \approx \frac{H\varepsilon}{H_0 m} \approx \frac{\hbar\omega_0}{\varepsilon}\left(\frac{\varepsilon}{m}\right)^3,$$

где $H_0 = m^2/|e|\hbar\,(= m^2c^3/|e|\hbar) = 4,4\cdot 10^{13}\Gamma$ с. В классической области $\chi \sim \hbar\omega/\varepsilon \ll 1$. В случае $\chi \geqslant 1$ энергия излученного фотона $\hbar\omega \sim \varepsilon$, причем при $\chi \gg 1$ (как мы увидим в дальнейшем) существенная область спектра простирается до частот, при которых энергия электрона после испускания

$$\varepsilon' \sim m\frac{H_0}{H} \ll \varepsilon.$$

Для того чтобы электрон оставался ультрарелятивистским, поле должно удовлетворять условию

$$\frac{H}{H_0} \ll 1$$

символическом виде

$$\psi = (2\hat{H})^{-1/2} u(\hat{p}) \exp\left(-\frac{i}{\hbar}\hat{H}t\right)\varphi(\mathbf{r}),$$

где $\varphi(\mathbf{r}) \sim \exp(iS/\hbar)$ - квазиклассические волновые функцин бесспиновой частицы ($S(\mathbf{r})$ - ее классическое действие); $u(\hat{p})$ - операторный биспинор

$$u(\hat{p}) = \begin{pmatrix} (\hat{H}+m)^{1/2} w \\ (\hat{H}+m)^{-1/2}(\sigma\hat{p})\omega \end{pmatrix},$$

получающийся из биспинорной амплитуды плоской волны $u(p)$ $(23,9)$ заменой $\mathbf{p}$ и ε операторами [2])

$$\hat{\mathbf{p}} = \hat{\mathbf{p}} - e\mathbf{A} = -i\hbar\nabla - e\mathbf{A}, \quad \hat{H} = \left(\hat{\mathbf{p}}^2 + m^2\right)^{1/2},$$

$$V_{fi}(t) = e\sqrt{\frac{2\pi}{\hbar\omega}}\langle f|Q(t)|i\rangle e^{i\omega t},$$

где $\hat{Q}(t)$ обозначает гейзенберговский оператор

$$\widehat{Q}(t) = \frac{u_f^+(\hat{p})}{(2\hat{H})^{1/2}}\,(\alpha \mathrm{e}^*)\,e^{-i\hat{\mathrm{k}}(t)}\frac{u_i(\hat{p})}{(2\hat{H})^{1/2}},$$

$$dI = \frac{e^2}{4\pi^2}d^3k\int e^{-i\omega\tau}\left\langle i\left|Q^+\left(t+\frac{\tau}{2}\right)Q\left(t-\frac{\tau}{2}\right)\right|i\right\rangle d\tau.$$

$$\hat{\mathbf{p}}\exp(-i\mathbf{k}\hat{\mathbf{r}}) = \exp(-i\mathbf{k}\hat{\mathbf{r}})(\hat{\mathbf{p}} - \hbar\mathbf{k})$$
$$H(\hat{\mathbf{p}})\exp(-i\mathbf{k}\hat{\mathbf{r}}) = \exp(-i\mathbf{k}\hat{\mathbf{r}})H(\hat{\mathbf{p}} - \hbar\mathbf{k})$$

сдвига в импульсном пространстве. С помощью $(90,11)$. выносим в $(90,8)$ оператор $\exp(-i\mathrm{k}\hat{\mathbf{r}}(t))$ налево и записываем $\widehat{Q}(t)$ в виде

$$\hat{Q}(t) = \exp[-i\mathbf{k}\hat{\mathbf{r}}(t)]\hat{R}(t), \quad \hat{R}(t) = \frac{u_f^+\left(\hat{p}'\right)}{\left(2\widehat{H}'\right)^{1/2}}\,(\alpha \mathrm{e}^*)\,\frac{u_i(\hat{p})}{(2\widehat{H})^{1/2}},$$

где $\hat{H}' = \hat{H} - \hbar\omega, \hat{\mathbf{p}}' = \hat{\mathbf{p}} - \hbar\mathbf{k}$. Теперь

$$\hat{Q}_2^+\hat{Q}_1 = \hat{R}_2\exp\left(i\mathbf{k}\hat{\mathbf{r}}_2\right)\exp\left(-i\mathbf{k}\hat{\mathbf{r}}_1\right)\hat{R}_1$$

$$L(\tau) = \exp\left\{i\frac{\boldsymbol{\varepsilon}}{\boldsymbol{\varepsilon}'}\left(\mathbf{k}\mathbf{r}_2 - \mathbf{k}\mathbf{r}_1 - \omega\tau\right)\right\}$$

До сих пор мы не использовали конкретного вида траектории электрона. Выразим теперь $\boldsymbol{r}_2 - \mathbf{r}_1$ в $(90,18)$ через $\mathbf{p}_1$ с помощью уравнения движения электрона в плоскости, перпендикулярной полю H (см. II, §21):

$$\mathbf{r}_2 - \mathbf{r}_1 = \frac{\mathbf{p}_1}{e\ddot{H}}\sin\frac{eH\tau}{\varepsilon} + \frac{[\mathbf{p}_1\mathbf{H}]}{eH^2}\left(1 - \cos\frac{eH\tau}{\varepsilon}\right).$$

Разлагая по степеням τ, имеем отсюда

$$\mathbf{k}\left(\mathbf{r}_2 - \mathbf{r}_1\right) - \omega\tau \approx \omega\tau\left\{\left(\mathbf{v}_1\mathbf{n} - 1\right) + \tau\frac{e\mathbf{n}\left[\mathbf{p}_1\mathbf{H}\right]}{2\varepsilon^2} - \tau^2\frac{e^2H^2}{6\varepsilon^2}\right\}$$

Таким образом, окончательно имеем

$$\exp(-i\omega t)\left\langle i\left|Q_2^+Q_1\right|i\right\rangle = R_2^*R_1L(\tau)$$
$$R_2^*R_1 = \mathrm{Sp}\,\frac{1+\xi_i\boldsymbol{\sigma}}{2}\left(\left(\mathrm{A}_2 - i\left[\mathbf{B}_2\boldsymbol{\sigma}\right]\right)\mathrm{e}\right)\frac{1+\xi_i\boldsymbol{\sigma}}{2}\left(\left(\mathbf{A}_1 + i\left[\mathbf{B}_1\boldsymbol{\sigma}\right]\right)\mathrm{e}^*\right).$$

Множители $(1+\xi\sigma)/2$ - двухрядные поляризационные матрицы плотности начального и конечного электронов.

$$\frac{dI}{d\omega}=\frac{ie^2\omega}{2\pi}\int\limits_{-\infty}^{\infty}\left(\frac{m^2}{\varepsilon^2\tau}+\frac{\varepsilon^2+\varepsilon'^2}{4\varepsilon\varepsilon'}\omega_0^2\tau\right)\exp\left\{-\frac{i\omega\tau\varepsilon}{\boldsymbol{\varepsilon}'}\left(1-v+\frac{\tau^2}{24}\omega_0^2\right)\right\}d\tau,$$

причем контур интегрирования выбирается указанным выше способом. Используя интегральное представление, функции Эйри Φ (см. III § b), нетрудно показать, что первый член сводится к интегралу от функции Эйри, а второй-к производной от нее. Окончательно находим

$$\frac{dI}{d\omega}=-\frac{e^2m^2\omega}{\sqrt{\pi}\varepsilon^2}\left\{\int\limits_x^{\infty}\Phi(\xi)d\xi+\left(\frac{2}{x}+\frac{\hbar\omega}{\varepsilon}\chi x^{1/2}\right)\tilde{\Phi}'(x)\right\},$$

$$x=\left(\frac{\hbar\omega}{\varepsilon'\chi}\right)^{2/3}=\frac{m\iota^2}{\varepsilon^2}\left(\frac{\varepsilon\omega}{\varepsilon'\omega_0}\right)^{2/s}$$

(А. И. Никишов, В. И. Ритус, 1967).

Магнитотормозное излучение ириводит к возникновению поляризации движущихся электронов (А. А. Соколов, И. М. Тернов, 1963). Для рассмотрения этого вопроса надо найти всроятность радиационного перехода с обращением направления спина. Положнв в $(90,21)\xi_i=-\xi_f\equiv\xi,|\zeta|=1$, получим

$$R_2^*R_1=(\mathbf{B}_1\mathbf{B}_2)-(\mathrm{e}^*\mathbf{B}_1)(\mathbf{e}_2)-(\mathbf{e}^*[\mathbf{B}_1\zeta])(\mathbf{e}[\mathbf{B}_2\zeta])-i(\zeta\mathrm{e}^*)(\mathbf{e}[\mathbf{B}_1\mathbf{B}_2]).$$

окончательно полную вероятность радиационного перехода с обращением спина:

$$w=\frac{5\sqrt{3}\alpha}{16}\frac{\hbar^2}{m^2}\left(\frac{\varepsilon}{m}\right)^5\omega_0^3\left(1-\frac{2}{9}\zeta_\parallel^2-\frac{8\sqrt{3}}{15}\frac{e}{|e|}\zeta_\perp\right),$$

где $\zeta_\parallel=\zeta\mathbf{v},\zeta_\perp=\zeta\mathbf{H}/H$. Эта формула пригодна как для электронов $(e<0)$, так и для позитронов $(e>0)$.

Вероятность $(90,30)$ не зависит от знака продольной поляризации $\zeta_\parallel$, но зависит от знака $\zeta_\perp$.

91. Образование пар фотоном в магнитном поле

Образование электрон-позитронной пары фотоном в магнитном поле и магнитотормозное излучение - два перекрестных канала одной и той же реакции. Поэтому амплитуда M_{fi} процесса образования пары получается из амплитуды тормозного излучения просто путем замены

$$\varepsilon,p\to-\varepsilon_+,-p_+;\quad\varepsilon',p'\to\varepsilon_-,p_-;\quad\omega,k\to-\omega,-k\quad(91,1)$$

(здесь ε_-,p_-и ε_+,p_+−энергии и импульсы электрона и пози трона в паре; $\boldsymbol{\varepsilon},\mathbf{p}$ и $\boldsymbol{\varepsilon}',\mathbf{p}'$ - начальные и конечные энергии и импульсы электрона при тормозном излучении). В терминах углов и абсолютных значений преобразование импульсов есть

$$|\mathbf{p}|\to|\mathbf{p}_+|,|\mathbf{p}'|\to|\mathbf{p}_-|,\theta\to\pi-\theta_+,\theta'\to\theta_-,\varphi\to\varphi-\pi,$$

где $\theta_\pm$−углы между $\mathbf{p}_\pm$и $\mathbf{k},\varphi$-угол между плоскостями $\mathbf{k},\mathbf{p}_+$и $\mathbf{k},\mathbf{p}_-$.

В случае же образования пары фотоном сечение выражается через амплитуду согласно

$$d\sigma = |M_{fi}|^2 \frac{1}{8\omega\varepsilon_-\varepsilon_+}\delta\left(\omega - \varepsilon_+ - \varepsilon_-\right)\frac{d^3p_+ d^3p_-}{(2\pi)^5}$$

или, после исключения δ-функции:

$$d\sigma = |M_{fi}|^2 \frac{|\mathrm{p}_+|\,|\mathbf{p}_-|}{8(2\pi)^5\omega} do_+ do_- d\varepsilon_+.$$

$$dw = \frac{m^2e^2}{\sqrt{\pi}}\frac{d\varepsilon_+}{\omega^2}\left\{\int_x^\infty \Phi(\xi)d\xi + \left(\frac{2}{x} - xx^{1/2}\right)\Phi'(x)\right\}.$$

где теперь

$$x = \left(\frac{m^3\omega}{|e|H{\varepsilon_+}^2-}\right)^{2/3}, \quad x = \frac{|e|H\omega}{m^3}\left(= \frac{\hbar^2|e|H\omega}{m^3c^5}\right).$$

Полная вероятность рождения пары в единицу времени получается интегрированием $(91,8)$ по ε_+(причем, ввиду очевидной симметрии по отношению к ε_+и $\varepsilon_- = \omega - \varepsilon_+$, достаточно интегрировать от 0 до $\omega/2$ и затем удвонть результат). Производя замену переменной интегрирования ε_+на x и интегрируя первый член в $(91,8)$ дважды по частям, получаем

$$w = -\frac{|e|^3H}{mx\sqrt{\pi}}\int_{(4/x)^{2/6}}^\infty \frac{2\left(x^{3/2}+1/x\right)\Phi'(x)}{x^{1/4}\left(x^{3/2}-4/x\right)^{1/2}}dx$$

(А. И. Никищов, В. И. Ритус, 1967).

97. Тормозное излучение электрона на электроне в ультрарелятивистском случае

98. Излучение мягких фотонов при столкновениях

99. Метод эквивалентных фотонов

100. Образование пар при столкновениях частиц

101. Излучение фотона электроном в поле интенсивной электромагнитной волны

(мб в другой разедл перенесу, пока тут)

4.2.5 Radiative Corrections to the Mass Operator, Scattering in External Field

119. Вычисление массового оператора по Ландау 4

120. Испускание мягких фотонов с ненулевой массой по Ландау 4

121. Рассеяние электрона во внешнем поле во втором борновском приближении по Ландау 4

122. Радиационные поправки к рассеянию электрона во внешнем поле по Ландау 4

4.2.6 Radiative Level Shifts, Bound States

123. Радиационное смещение атомных уровней по Ландау 4

124. Радиационное смещение уровней мезоатомов по Ландау 4

125. Релятивистское уравнение для связанных состояний по Ландау 4

(тут нужно много диаграмм, так что потом выгружу ЛЛ4, их и вставлю.)

$$\Gamma_{ik,lm} = -e^2\gamma^\mu_{il}\gamma^v_{km}D_{\mu\nu}\left(p_- - p'_-\right) + e^2\gamma^\mu_{im}\gamma^v_{kl}D_{\mu\nu}\left(p_- + p_+\right)$$

Будем рассматривать все величины в системе «центра инерции». Поскольку, однако, 4-импульсы внешних концов диаграмм не предполагаются физическими (т. е. $p^2 \neq m^2$), то хотя в этой системе $\mathbf{p}_+ = -p_-$, но $\varepsilon_+ \neq \varepsilon_-$. Таким образом, 4-импульсы концОВ

$$\begin{gathered} p_- = (\varepsilon_-, \mathbf{p}), \quad p_+ = (\varepsilon_+, -\mathbf{p}), \\ p'_- = \left(\varepsilon'_-, \mathbf{p}'\right), \quad p'_+ = \left(\varepsilon'_+, -\mathbf{p}'\right), \\ \varepsilon_- + \varepsilon_+ = \varepsilon'_- + \varepsilon'_+. \end{gathered}$$

Энергия связи электрона и позитрона в позитронии $\sim m\alpha^2$. Поэтому в интересующей нас окрестности полюсов амплитуды рассеяния

$$\begin{gathered} |\mathbf{p}| \sim |\mathbf{p}'| \sim m\alpha \ll m, \\ |\varepsilon_- - m| \sim |\boldsymbol{\varepsilon}_+ - m| \sim \mathbf{p}^2/m \sim m\alpha^2, \ldots \end{gathered}$$

Вклад в вершинную часть от диаграммы $(125, 4, a)$

$$\Gamma^{(4a)}_{ik,lm} = -ie^4 \int \left(\gamma^\lambda G(q)\gamma^\mu\right)_{il} \left(\gamma^v G\left(q - p_- - p_+\right)\gamma^0\right)_{km} \times \\ \times D_{\lambda\rho}\left(q - p'_-\right) D_{\mu v}\left(p_- - q\right) \tfrac{d^4q}{(2\pi)^4}.$$

$$\Gamma^{(4a)} \sim e^4 \int \frac{d^3q}{\cdot \left(q - p'_-\right)^2 \left(p_- - q\right)^2 \left(2m - \varepsilon_- - \varepsilon_+ + q^2/m\right)}$$

и отсюда, с учетом $(125, 6)$, оценку

$$\Gamma^{(4\alpha)} \sim \alpha^2 \frac{(m\alpha)^3}{(m\alpha)^4 m\alpha^2} = \frac{1}{m^2\alpha}.$$

4.2.7 $\gamma\gamma \to (?)$, Photon Splitting

126. Двойное дисперсионное соотношение по Ландау 4

(диаграммы и умные рассуждения)

Каждую из инвариантных амплитуд (которые мы обозначим здесь той же буквой M) можно представить интегралом вида

$$M = \int \frac{iBd^4q}{\left[q^2-m^2\right]\left[(q-k_4)^2-m^2\right]\left[(q-k_1-k_2)^2-m^2\right]\left[(q-k_2)^2-m^2\right]},$$

где B - некоторая функция всех 4-импульсов; множители в знаменателе происходят от пропагаторов четырех виртуальных электронов.

Как и для всякой диаграммы вида

(???? тут два кружка с входящими 4-мя линиями и соединенные двумя линиями??)

$A_{1s}(s,t)$ вычисляется по правилу $(115,9)$ заменой в интеграле $(126,4)$ соответствующих полюсных множителей δ-функциями: $2iA_{1s}(s,t) = (2\pi i)^2 \int \frac{iB\delta\left(q^2-m^2\right)\delta\left\lfloor(q-k_1-k_2)^2-m^2\right\rfloor}{\left[(q-k_4)^2-m^2\right]\left[(q-k_2)^2-m^2\right]}d^4q$, причем интегрирование производится по половине q-пространства, в которой $q^0>0$.

$$M(s,0) = \frac{s}{\pi}\int \frac{f(s')\,ds'}{(s'-s)\,s'}$$

с однократным дисперсионным соотношением $(126,5)$, написанным «с вычитанием», отвечающим условию $(126,20)$:

$$M(s,t) = \frac{s}{\pi}\int \frac{A_{1s}(s',t)}{(s'-s)\,s'}ds'.$$

Таким образом, окончательное двойное дисперсионное соотношение «с вычитанием»:

$$M(s,t) = \frac{st}{\pi^2}\int\int \frac{A_2(s',t')}{(s'-s)(t'-t)\,s't'}ds'dt' + \\ + \frac{s}{\pi}\int \frac{A_{1s}(s',0)}{(s'-s)\,s'}ds' + \frac{t}{\pi}\int \frac{A_{1t}(0,t')}{(t'-t)\,t'}dt'.$$

127. Рассеяние фотона на фотоне по Ландау 4

$$M_{fi} = 2\left(M^{(a)} + M^{(\sigma)} + M^{(\theta)}\right),$$

где $M^{(a)}, M^{(\sigma)}, M^{(\theta)}$ - вклады диаграмм $a),\,),\,)$. Согласно $(64,19)$ сечение рассеяния

$$d\sigma = \frac{1}{64\pi^2}\left|M_{fi}\right|^2\frac{do'}{(2\omega)^2},$$

где do' - элемент телесных углов для направления $\mathbf{k}'$ в системе центра инерции. Угол рассеяния в этой системе обозначим θ. Инвариантные амплитудь Выделив поляризационные множители четырех фотонов, представим M_{fi} в виде

$$M_{fi} = e_1^{\lambda}e_2^{\mu}e_3^{\upsilon^*}e_4^{\rho^*}M_{\lambda\mu\nu\rho};$$

$$M_{\lambda_1\lambda_2\lambda_:\lambda_4}(s,t,u) = M_{\lambda_1\lambda_4\lambda_1\lambda_2}(s,t,u).$$

Наконец, еще одно соотношение является следствием инвариантности амплитуды M_{fi} относительно перестановки двух начальных или двух конечных фотонов. Если произвести сразу обе перестановки $(k_1 \leftrightarrow k_2, k_3 \leftrightarrow k_4)$, то переменные s,t,u ие изменятся, а перестановка в поляризационных индексах приведет к соотношению

$$M_{\lambda_1\lambda_2\lambda_3\lambda_4}(s,t,u) = M_{\lambda_2\lambda_1\lambda_1\lambda_3}(s,t,u).$$

Легко убедиться, что в силу свойств симметрии $(127,10-12)$ цисло независимых инвариантных амплитуд сводится к пяти; в качестве них можно, например, выбрать

$$M_{++++}, M_{++--}, M_{+++-}, M_{+-++}, M_{+++-}$$

(индексы «+", «-" означают спиральности +1 и -1). Если подставить в $(127,3)$ вместо M_{fi} одну из амплитуд $M_{\lambda_1\lambda_2\lambda_5\lambda_4}$, то мы получим сечение рассеяния с заданными поляризациями начальных и конечных фотонов. Сечение же, просуммированное по конечным и усредненное по начальным поляризациям, получится заменой

$$|M_{fi}|^2 \to 1/4\left\{2\left|M_{++++}\right|^2 + 2\left|M_{++--}\right|^2 + 2\left|M_{+-+-}\right|^2 + \right.$$
$$\left. + 2\left|M_{+-++}\right|^2 + 8\left|M_{+++-}\right|^2\right\}.$$

Вычисление амплитуд Интеграл $M_{fi}^{(a)}$, отвечающий диаграмме $(127,1,a)$, имеет вид $(126,4)$, причем

$$B^{(a)} = \frac{e^4}{\pi^2}\,\mathrm{Sp}\left\{(\gamma e_1)(\gamma q - \gamma k_2 + m)(\gamma e_2)(\gamma q + m)\times\right.$$
$$\left.\times(\gamma e_4^*)(\gamma q - \gamma k_4 + m)(\gamma e_3^*)(\gamma q - \gamma k_1 - \gamma k_2 + m)\right\}.$$

(тут большие формулы, нет смысла писать их)

128. Когерентное рассеяние фотона в поле ядра по Ландау 4

Другими (наряду с рассеянием фотона на фотоне) нелинейными эффектами, описывающимися квадратными диаграммами вида $(127,1)$, являются распад одного фотона во внешнем поле на два фотона (и обратный процесс «слияния» двух фотонов в один) и рассеяние фотона во внешнем поле. Первому процессу отвечают диаграммы, в которых один из четырех внешних фотонных концов заменен линией внешнего поля. Второму же процессу отвечают диаграммы с двумя внешними линиями реальных и двумя - виртуальных фотонов.

К последней категории относится, в частности, когерентное (упругое) рассеяние фотона в постоянном электрическом поле неподвижного ядра. В общем случае вычисления приводят к очень громоздким формулам (содержащим кратные квадратуры))[1]. Мы ограничимся здесь лишь некоторыми оценками. В силу требований калибровочной инвариантности амплитуда рассеяния при $\omega \to 0$ должна содержать произведения компонент 4-импульса начального (k) и конечного (k') фотонов (подобно тому как разложение амплитуды рассеяния фотона на фотоне начинается с четверных произведений компонент 4-импульсов всех фотонов). Другими словами, амплитуда рассеяния фотона

малой частоты пропорциональна ω^2. Учитывая также, что эта амплитуда содержит внешнее поле (поле ядра с зарядом Ze) во втором порядке, заключаем, что сечение рассеяния

$$d\sigma \sim Z^4\alpha^4 r_e^2 \left(\frac{\omega}{m}\right)^4 do, \quad \omega \ll m.$$

Зависимость от частоты находится, разумеется, в соответствии с общнми заключениями §59.

Коэффициент в (128, 1) нельзя вычислить с помощью функции Лагранжа однородного электромагнитного поля (как это можно было сделать для рассеяния света на свете). Причина заключается в том, что в данном процессе существенны расстояния от ядра $r \sim 1/m$, на которых поле ядра нельзя рассматривать как однородное. Приведем результат точного расчета:

$$d\sigma_{++} = d\sigma_{--} = 1,004 \cdot 10^{-3}(Z\alpha)^4 r_e^2 \left(\frac{\omega}{m}\right)^4 \cos^4\frac{\theta}{2} do,$$
$$d\sigma_{+-} = d\sigma_{-+} = 3,81 \cdot 10^{-4}(Z\alpha)^4 r_e^2 \left(\frac{\omega}{m}\right)^4 \sin^4\frac{\theta}{2} do.$$

139. Рассеяние электронов адронами по Ландау 4

140. Низкоэнергетическая теорема для тормозного излучения по Ландау 4

В §98 был исследован процесс испускания фотона при столкновении частиц в пределе, когда частота фотона стремится k нулю. Оказалюсь, что амплитуда процесса обратно пропорциональна ω и простым образом выражается через амплитуду того же столкновения без испускания мягкого фотона (об этой носледней мы будем снова говорить условно как об амплитуде щем по ю приближении будет

$$M_{fi} = M_{fi}^{(-1)} + M_{fi}^{(0)},$$

где к главному члену (ω^{-1}) добавляется не зависящий от ω ($\infty\omega^0$) лоправочный член. Мы увидим, что и этот поправочный (как и главный) член может быть выражен через $M_{fi}^{(y)}$, причем независимо от деталей электромагнитной структуры адрона. Это утверждение называют низкоэнергетической теоремой для тормозного излучения (F. E. Low, 1958).

Спонтанное нарушение симметрии в классической теории

Теорема Голдстоуна

Эффективное действие

Эффект Хиггса в абелевой теории по Киселеву

Пусть

$$S = \int \mathrm{d}^4x \left\{ (\nabla_\mu \Phi)^* \nabla_\mu \Phi - \frac{\lambda}{4}\left(\Phi^*\Phi - \frac{v^2}{2}\right)^2 - \frac{1}{4}F_{\mu\nu}^2 \right\},$$

где $\nabla_\mu = \partial_\mu + \mathrm{i}e\mathcal{A}_\mu(x)$. Калибровочную свободу зафиксируем с помощью $\mathfrak{Im}\Phi \equiv 0$.

$$\Phi = \frac{1}{\sqrt{2}}\{v + \chi(x)\}.$$

$$(\nabla_\mu \Phi)^* \nabla^\mu \Phi = \frac{1}{2}\left\{(\partial_\mu \chi)^2 + e^2(v+\chi(x))^2 \mathcal{A}_\mu^2\right\}.$$

$$S_0 = \int \mathrm{d}^4x \left\{ \frac{1}{2} \left(\partial_\mu \chi\right)^2 - \frac{1}{2} m_\chi^2 \chi^2 - \frac{1}{4} F_{\mu\nu}^2 + \frac{1}{2} m_{\mathcal{A}}^2 \mathcal{A}_\mu^2 \right\}, \qquad \begin{aligned} m_{\mathcal{A}}^2 &= e^2 v^2, \\ m_\chi^2 &= \frac{1}{2} \lambda v^2, \end{aligned}$$

$$S_{\text{int}} = \int \mathrm{d}^4x \left\{ -\frac{\lambda}{4} \left(v\chi^3 + \frac{\chi^4}{4} \right) + \frac{e^2}{2} \left(2v\chi + \chi^2 \right) \mathcal{A}_\mu^2 \right\}$$

$$\frac{1}{2} \mathcal{A}^\mu \hat{\Gamma}_{\mu\nu} \mathcal{A}^\nu, \quad \hat{\Gamma}_{\mu\nu} = -g_{\mu\nu} \left(p^2 - m_A^2 \right) + p_\mu p_\nu.$$

$$\mathcal{D}_{\mu\nu}(p) = \mathrm{i} \Gamma_{\mu\nu}^{-1},$$

$$\mathcal{D}_{\mu\nu}(p) = \frac{\mathrm{i}}{p^2 - m_A^2 + \mathrm{i}0} \left(-g_{\mu\nu} + \frac{p_\mu p_\nu}{m_A^2} \right).$$

$$\mathcal{L}_\varphi = \frac{1}{2} \left(\partial_\mu \varphi\right)^2 - \lambda_\varphi \varphi^2 \Phi^* \Phi,$$

$\lambda_\varphi > 0$. Тогда при спонтанном нарушении симметрии это поле приобретает массу за счет взаимодействия с вакуумным средним бозона Хиггса:

$$m_\varphi^2 = \lambda_\psi v^2$$

(!!! как сделаю основные темы - додумаю этот типичный тоже эффект!!!)

5.1.2 Wilsonian Renormalization, effective action, RG flow, effective theories (!!!!!)

(окажется, что нужно пару разделов нужно - сделаю)

Effective Actions

In QFT we no longer have to sit at a minimum of the action, quantum fluctuations appear which involve degrees of freedom at arbitrarily high energies, e.g. in loop integrals. The content of renormalization is that it is still possible to calculate at low energies without knowing what those high-energy degrees of freedom are. (???? отслежу потом, как конкретно то, что действие не минимальное проявляется???)

• We consider a scalar field theory with action

$$S_{\Lambda_0}[\varphi] = \int d^dx \frac{1}{2} \partial^\mu \varphi \partial_\mu \varphi + \sum_i \Lambda_0^{d-d_i} g_{i0} \mathcal{O}_i(x)$$

The subscript Λ_0 refers to the UV cutoff, which must be included to define the path integral. The $\mathcal{O}_i(x)$ are arbitrary local operators with dimensions $d_i > 0$, where the dimensions are found with ordinary dimensional analysis, and the g_{i0} are defined so they are dimensionless.

• The partition function is

$$\mathcal{Z}_{\Lambda_0}\left(g_{i0}\right) = \int\limits_{C^\infty(M)_{\leq \Lambda_0}} \mathcal{D}\varphi e^{-S_{\Lambda_0}[\varphi]/\hbar}$$

where $C^\infty(M)_{\leq\Lambda_0}$ is the space of smooth functions on M with momenta bounded by Λ_0. There are also IR divergences, which we can regulate by putting the system in a box.

• Since $C^\infty(M)_{\leq\Lambda_0}$ is a vector space, we may split the modes as

$$\varphi(x) = \phi(x) + \chi(x), \quad \phi \in C^\infty(M)_{\leq\Lambda}, \quad \chi \in C^\infty(M)_{(\Lambda,\Lambda_0]}, \quad \mathcal{D}\varphi = \mathcal{D}\phi\mathcal{D}\chi$$

Integrating over the high-energy modes χ gives the effective action

$$S_\Lambda^{\text{eff}}[\phi] = -\hbar \log \int\limits_{C^\infty(M)_{(\Lambda,\Lambda_0]}} \mathcal{D}\chi \exp\left(-S_{\Lambda_0}[\phi+\chi]/\hbar\right)$$

We can iterate this process, yielding a semigroup called the renormalization group. Note that the effective action $\mathcal{W}[J]$ is just a Wilsonian effective action with $\Lambda = 0$.

• Setting $\hbar = 1$, we may separate out the kinetic terms of the action as

$$S_{\Lambda_0}[\phi+\chi] = S^0[\phi] + S^0[\chi] + S^{\text{int}}_{\Lambda_0}[\phi,\chi]$$

where there are no $\phi\chi$ mixing terms by momentum conservation. Therefore the interaction terms, which include mass terms, obey

$$S_\Lambda^{\text{int}}[\phi] = -\log \int\limits_{C^\infty(M)_{(\Lambda,\Lambda_0]}} \mathcal{D}\chi \exp\left(-S^0[\chi] - S^{\text{int}}_{\Lambda_0}[\phi,\chi]\right)$$

which yields effective couplings $g_i(\Lambda)$. Note that if we expand the right-hand side in powers of $S^{\text{int}}_{\Lambda_0}$, the even-power terms contribute with an extra minus sign, and the logarithm ensures we only sum over connected diagrams.

• By definition, we must have

$$\mathcal{Z}_\Lambda\left(g_i(\Lambda)\right) = \mathcal{Z}_{\Lambda_0}\left(g_{i0}\right)$$

because both sides are the same integral; the left-hand side depends on Λ through both the cutoff and the couplings. We can also include external currents to have partition functions $\mathcal{Z}[J]$. Then we have $\mathcal{Z}_\Lambda[J] = \mathcal{Z}_{\Lambda_0}[J]$ as long as J has no Fourier components in $(\Lambda, \Lambda_0]$.

• Therefore, the total derivative with respect to $\log\Lambda$ is zero,

$$\frac{d\mathcal{Z}_\Lambda(g)}{d\log\Lambda} = \left(\left.\frac{\partial}{\partial\log\Lambda}\right|_{g_i} + \frac{\partial g_i(\Lambda)}{\partial\log\Lambda}\left.\frac{\partial}{\partial g_i}\right|_\Lambda\right)\mathcal{Z}_\Lambda(g) = 0$$

This is an example of an RG equation, which we'll generically call a Callan-Symanzik equation.

• It will be useful to adjust our definitions to maintain canonical normalization of the kinetic term. With a generic initial action, the effective action will have the form

$$S_\Lambda^{\text{eff}}[\phi] = \int d^dx \frac{Z_\Lambda}{2}\partial^\mu\phi\partial_\mu\phi + \sum_i \Lambda^{d-d_i} Z_\Lambda^{n_i/2} g_i(\Lambda)\mathcal{O}_i(x)$$

where n_i is the number of factors of ϕ in $\mathcal{O}_i(x)$, and we have redefined $g_i(\Lambda)$ to pull out factors of Z_Λ. We then define the renormalized field

$$\varphi = Z_\Lambda^{1/2}\phi$$

so that $S_\Lambda^{\text{eff}}[\varphi]$ has a canonically normalized kinetic term and dimensionless couplings $g_i(\Lambda)$.

• For convenience, we define the beta function

$$\beta_i\left(g_j(\Lambda)\right) = \frac{\partial g_i}{\partial \log \Lambda} = \left(d_i - d\right) g_i(\Lambda) + b_i^q\left(g_j\right)$$

where the first term is just from the variation of the explicit power of Λ, and the second represents the inherently quantum effect of integrating out high-energy modes. This term generically depends on all of the couplings; for example a ϕ^6 vertex can renormalize a ϕ^4 vertex by contracting two of the legs. It also depends on the field renormalization.

• We define the anomalous dimension γ_ϕ of the field ϕ by

$$\gamma_\phi = -\frac{1}{2}\frac{\partial \log Z_\Lambda}{\partial \log \Lambda}$$

This is essentially what the beta function for the kinetic term would be, if we weren't fixing its normalization, and it appears in the RG flow of correlation functions. More generally, for multiple fields we would have a matrix of wavefunction renormalization factors, since the fields may mix as modes are integrated out. In practice, this matrix can be computed perturbatively, as we saw in the notes on Statistical Field Theory.

We now use our setup to compute correlation functions.

• We define the n-point correlator

$$\langle \phi(x_1)...\phi(x_n)\rangle = \frac{1}{\mathcal{Z}} \int\limits_{C^\infty(M)_{\leq\Lambda}} \mathcal{D}\phi e^{-S_\Lambda^{\text{eff}}} \phi(x_1)...\phi_n(x_n)$$

In terms of the canonically normalized field, this is

$$\langle \phi(x_1)...\phi(x_n)\rangle = Z_\Lambda^{-n/2}\langle \varphi(x_1)...\varphi(x_n)\rangle \equiv Z_\Lambda^{-n/2}\Gamma_\Lambda^{(n)}\left(x_1,...,x_n; g_i(\Lambda)\right)$$

where all other factors cancel out due to division by $\mathcal{Z}$.

• As long as the ϕ insertions involve modes with energy less than Λ, we can compute the ϕ correlator in either the original theory or the effective theory. Therefore we have

$$Z_{s\Lambda}^{-n/2}\Gamma_{s\Lambda}^{(n)}\left(x_1,...,x_n; g_i(s\Lambda)\right) = Z_\Lambda^{-n/2}\Gamma_\Lambda^{(n)}\left(x_1,...,x_n; g_i(\Lambda)\right)$$

for $s < 1$. Taking the differential gives the Callan-Symanzik equation

$$\frac{d}{d\log\Lambda}\Gamma_\Lambda^{(n)}\left(x_1,...,x_n; g_i(\Lambda)\right) = \left(\frac{\partial}{\partial\log\Lambda} + \beta_i\frac{\partial}{\partial g_i} + n\gamma_\phi\right)\Gamma_\Lambda^{(n)}\left(x_1,...,x_n; g_i(\Lambda)\right) = 0$$

• It is also useful to consider an "autonomous" RG transformation, where the cutoff Λ remains the same. To do this, we perform the change of variables

$$x' = sx, \quad \phi'\left(x'\right) = s^{(2-d)/2}\phi(x)$$

where the new field ϕ is chosen so that the kinetic term is invariant,

$$\int d^dx(\partial\phi(x))^2 = \int d^dx\left(\partial\phi'(x)\right)^2 = \int d^dx'\left(\partial'\phi'\left(x'\right)\right)^2$$

If $\phi(x)$ has UV cutoff $k = s\Lambda$, then $\phi'(x')$ has UV cutoff $k' = \Lambda$ where k' is formally the Fourier conjugate to x'. Note that all of the dimensionless couplings are left invariant by this transformation. (Equivalently, everything dimensionful transforms with its engineering dimension.)

• At this point, the physical UV cutoff scale has not actually been changed; we have merely performed a change of coordinates. We next perform an active rescaling of the metric so that physical distances shrink by a factor of s. Then the new primed metric coordinates match the old unprimed metric coordinates.

• The composition of these steps (integrating out, changing to primed coordinates, actively rescaling the metric, renaming primed coordinates to unprimed) leaves Λ and the metric invariant, but changes the dimensionless couplings from $g_i(\Lambda)$ to $g_i(s\Lambda)$. It is hence an autonomous RG transformation.

• It can be a bit puzzling to physically interpret the rescaling. In the nonrelativistic context, one might imagine pointing a camera at a physical sample. Then scaling the metric corresponds to "zooming out" the camera. In high energy physics, we would not include the scaling at all: we should not physically rescale the UV cutoff because it represents the scale of new physics. The calculational issues that would arise in the absence of rescaling are moot, because we do not use Wilsonian RG in practice for high energy physics anyway; we instead use "continuum RG". However, for the remainder of this section we will include the rescaling.

• Integrating out by a factor of s and then rescaling by a factor of s gives

$$\begin{aligned}\Gamma_{\Lambda}^{(n)}\left(x_1, ..., x_n; g_i(\Lambda)\right) &= \left(\frac{Z_\Lambda}{Z_{s\Lambda}}\right)^{n/2} \Gamma_{s\Lambda}^{(n)}\left(x_1, ..., x_n; g_i(s\Lambda)\right) \\ &= \left(s^{2-d}\frac{Z_\Lambda}{Z_{s\Lambda}}\right)^{n/2} \Gamma_{\Lambda}^{(n)}\left(sx_1, ..., sx_n; g_i(s\Lambda)\right)\end{aligned}$$

Finally, replacing x_i with x_i/s gives

$$\Gamma_{\Lambda}^{(n)}\left(x_1/s, ..., x_n/s; g_i(\Lambda)\right) = \left(s^{2-d}\frac{Z_\Lambda}{Z_{s\Lambda}}\right)^{n/2} \Gamma_{\Lambda}^{(n)}\left(x_1, ..., x_n; g_i(s\Lambda)\right)$$

For $s \to 0$, this says we can study the long-distance behavior of our theory by consider correlation functions at fixed separation, but using the couplings in the low-energy effective theory, which is intuitive.

• Taking the differential, every factor of the field scales as if the field had mass dimension

$$\Delta_\phi = (d-2)/2 + \gamma_\phi$$

so the anomalous dimension is the difference between the scaling dimension and the naive classical dimension. Note that we pick up a minus sign here since mass dimension is inverse to length dimension.

RG Flow

• A critical point is a point where all of the beta functions vanish, so the couplings are scale independent. A simple example is the Gaussian critical point, where $g_i^* = 0$. At a nontrivial fixed point, quantum effects exactly cancel the classical scaling; this usually requires strong coupling, since the classical terms are always $O(1)$.

• Now, the anomalous dimension γ_ϕ is only a function of the couplings, so at a critical point it is scale-invariant as well, $\gamma_\phi\left(g_i^*\right) = \gamma_\phi^*$. Then we have

$$\frac{\partial \Gamma_\Lambda^{(2)}(x,y)}{\partial \log \Lambda} = -2\gamma_\phi^* \Gamma_\Lambda^{(2)}(x,y)$$

so that $\Gamma^{(2)} \propto \Lambda^{-2\gamma_\phi^*}$. By Lorentz invariance, correlation functions only depend on $|x-y|$. By classical dimensional analysis,

$$\langle \phi(x)\phi(y)\rangle = \Lambda^{d-2} G\left(\Lambda|x-y|, g_i^*\right)$$

Combining these results together, we have

$$\Gamma_\Lambda^{(2)}\left(x,y;g_i^*\right) = \frac{\Lambda^{d-2}}{\Lambda^{2\Delta_\phi}} \frac{c\left(g_i^*\right)}{|x-y|^{2\Delta_\phi}}$$

This power-law behavior of correlation functions is typical at critical points; this is just a special case of our more general result above.

• Performing an RG step at a critical point leaves the partition function invariant, since it leaves the couplings invariant. On the other hand, an RG step is composed of (1) integrating out degrees of freedom, (2) changing to primed coordinates, and (3) rescaling the metric. The first two never change the partition function by definition. Hence at a critical point, the partition function is invariant under rescaling the metric alone, $g^{\mu\nu} \to e^{2\Omega} g^{\mu\nu}$. Now we have

$$0 = \delta g^{\mu\nu}(x) \frac{\delta \log \mathcal{Z}}{\delta g^{\mu\nu}(x)} = -\delta g^{\mu\nu}(x) \left\langle \frac{\delta S}{\delta g^{\mu\nu}(x)} \right\rangle \propto \delta g^{\mu\nu}(x) \langle T_{\mu\nu}(x)\rangle$$

so at an RG critical point, the spacetime integral of $\langle T^\mu{}_\mu \rangle$ is zero.

• All known examples of Lorentz invariant, unitary QFTs that are scale invariant are actually invariant under conformal transformations $g^{\mu\nu} \to e^{2\Omega(x)} g^{\mu\nu}$. It is believed this is true in general; it has been proven in $d = 2$ and is an open question in high dimensions. Assuming this holds, at RG critical points $\left\langle T_\mu^\mu(x)\right\rangle = 0$.

We now linearize about a critical point.

• Near a critical point, at $g_i^* + \delta g_i$, the beta functions are

$$\beta_i = B_{ij}\delta g_j + O\left(\delta g^2\right)$$

Let σ_i be an eigenvector of B_{ij} and let its eigenvalue be $\Delta_i - d$, so the coupling scales as

$$\sigma_i(\Lambda) = \left(\frac{\Lambda}{\Lambda_0}\right)^{\Delta_i - d} \sigma_i\left(\Lambda_0\right)$$

The definition of Δ_i is slightly different from that of Δ_ϕ because we are taking the couplings to be dimensionless but the field to be dimensionful.

• Classically, we would have $\Delta_i = d_i$, but more generally σ_i has an anomalous dimension

$$\gamma_i = \Delta_i - d_i$$

which is defined analogously to the anomalous dimension for ϕ. For the Gaussian fixed point, all anomalous dimensions are zero, as we'll show below.

• It is a bit of an approximation to assign σ_i a classical dimension, because in general the σ_i will be complicated linear combinations of all the operators. However, when the corrections are 'weak' the off-diagonal elements of B_{ij} are small compared to the classical diagonal terms, and the eigenvectors are close to the classical ones.

• Now imagine starting near a critical point and turning on the coupling to any operator with $\Delta_i > d$. Then the coupling becomes smaller as the scale Λ is lowered, so we say the corresponding operator is irrelevant, as it does not affect long-distance physics; we just flow back to the critical point.

• More generally, the critical surface $\mathcal{C}$ is the set of points that flow back to the critical point under RG flow; then the irrelevant operators provide coordinates for $\mathcal{C}$ in the neighborhood of the critical point.

• Couplings with $\Delta_i < d$ instead grow as the scale is lowered, and are called relevant; RG flow instead drives us away from the critical surface. This flow may eventually terminate at a different critical point, or in exotic cases perform a limit cycle. Since each new field or derivative increases Δ_i classically, there are finitely many relevant operators for fixed d.

• In the classical approximation, and the convention where couplings have dimensions, irrelevant operators have couplings with negative mass dimension, and relevant operators have couplings with positive mass dimension. Then it is clear that a mass term is relevant.

• A marginal coupling is an RG eigenvector with $\Delta_i = d$, or equivalently about the Gaussian fixed point, $d_i = d$. In this case, we need to expand to second order about the fixed point, yielding a weak, logarithmic dependence on Λ. Depending on the sign of the next term, the coupling is marginally irrelevant or marginally relevant. Note that the kinetic term is exactly marginal by definition.

Note. Consider calculating the beta function to first order about the Gaussian fixed point. This is equivalent to considering diagrams with only one vertex, so renormalization only goes one way. For example, ϕ^6 can renormalize ϕ^4 but not vice versa. The matrix B_{ij} is thus upper-triangular with the classical values on the diagonal, so all anomalous dimensions are zero. The only effect is that the eigenvectors are slightly tilted.

We must go to second order to figure out what classically marginal operators do. Note that in most practical computations in particle physics, we are implicitly expanding about the Gaussian fixed point. Also note that while the dimensionless couplings change, the dimensionful couplings are approximately constant.

Note. Given a term $\lambda_i \mathcal{O}_i$ in a weakly coupled field theory, its contribution to the action for a field configuration of energy $E \ll \Lambda$ is $\lambda_i E^{\Delta_i - d}$ by dimensional analysis. We don't use Λ here because the field configuration can't know what Λ is. To show this more quantitatively, consider a field configuration with lengthscale $L \sim 1/k$ and dimensionless amplitude $\hat{\phi} = \phi/k$. Then

$$\int dx(\partial\phi)^2 \sim \hat{\phi}^2, \quad \int dx m^2 \phi^2 \sim \frac{m^2}{k^2}\hat{\phi}^2, \quad \int dx(\partial\phi)^p \phi^q \sim k^{2p+q-4}\hat{\phi}^{p+q}$$

Assuming the kinetic term dominates, when we perform the path integral, configurations with $\hat{\phi} \sim 1$ dominate. Then the contribution of a term depends on k just as our dimensional analysis suggests.

Then a dimensionless coupling g_i has effect

$$\Delta S_i \sim g_i \left(\frac{E}{\Lambda}\right)^{\Delta_i - d}$$

where the kinetic term has $\Delta S \sim 1$. This measures the effect of the term on observable quantities derived from the action, such as cross sections. The tree-level RG evolution of g_i simply states that ΔS_i is independent of Λ. Because loops are sensitive to Λ, anomalous dimensions appear at loop-level.

Relevant terms such as masses are more important at $E \ll \Lambda$, while all irrelevant terms become important as E approaches Λ. For marginal terms, which are the majority of couplings we consider, the value of g_i itself is a good estimate of its effect, so perturbation theory really does break down when g_i is $O(1)$.

Example. For a scalar field $d = 4$ with $\mathbb{Z}_2$ symmetry near the gaussian fixed point, we have

$$\text{relevant: } 1, \phi^2, \quad \text{marginal: } \phi^4, (\partial\phi)^2$$

and everything else is irrelevant. The physical mass is independent of the cutoff, as one would expect. In $d = 3$, ϕ^4 becomes relevant while ϕ^6 becomes marginal. In $d = 2$, the field is dimensionless, so

$$\text{relevant: } 1, \phi^2, \phi^4, ..., \quad \text{marginal: } (\partial\phi)^2, \phi^2(\partial\phi)^2, ...$$

That is, we get an infinite series of relevant terms, which is quite rare.

Note. The origin of universality. The theory space is generically infinite-dimensional. Now consider the finite-dimensional set of theories obtained by starting from an RG fixed point, turning on a relevant operator, and performing RG flow, creating a 'renormalized trajectory'. By the discussion above, every initial condition will approach a renormalized trajectory, so theories in the IR are described by a finite number of parameters.

If we continue RG flowing into the deep IR, we often end up at a trivial fixed point, like the "infinite temperature" fixed point in statistical field theory, since we integrate out all massive particles. Alternatively, we may end up at a nontrivial fixed point/CFT, such as the Wilson-Fisher fixed point, where the particles are massless; renormalization exactly cancels the tree-level mass.

We now consider a converse question, more relevant to particle physics: is it possible to fix a low-energy theory at scale Λ while sending the cutoff Λ_0 to infinity?

• The simplest case is when S_{Λ_0} is on the critical surface $\mathcal{C}$. Then taking $\Lambda_0 \to \infty$ gives S_Λ^{eff} exactly at the critical point. Since $\mathcal{C}$ has finite codimension, we have to tune a finite number of parameters to do this, e.g. the temperature in a statistical field theory.

• Theories such as QCD and Yang-Mills are not CFTs, but instead have relevant and marginally relevant terms in their actions. In this case, to fix the low-energy theory we must modify the high-energy theory as Λ_0 varies, which is done perturbatively by adding counterterms. For example, we could parametrize the high-energy theory as

$$S_{\Lambda_0}[\varphi] = S_\Lambda^{\text{eff}}[\varphi] + \hbar S_{\text{CT}}[\varphi, \Lambda_0]$$

so that the counterterms vanish when $\Lambda = \Lambda_0$. The counterterms are tuned so that the limit

$$e^{-S_\Lambda^{\text{eff}}[\phi]/\hbar} = \lim_{\Lambda_0 \to \infty} \int_{C^\infty(M)_{(\Lambda,\Lambda_0]}} \mathcal{D}\chi \exp\left(-\frac{S_\Lambda^{\text{eff}}[\phi+\chi]}{\hbar} - S_{\text{CT}}[\phi+\chi, \Lambda_0]\right)$$

exists. We separate out the counterterms explicitly to organize perturbation theory. In perturbation theory, we work order by order in $\hbar$, canceling the (regularized) divergences produced by the bare action S_Λ^{eff} by counterterms. The extra factor of $\hbar$ is because the one-loop divergences are canceled by tree-level counterterm diagrams, and so on.

• We need our low-energy theory to lie on a renormalized trajectory. Then the counterterms are chosen so that, as Λ_0 is increased, S_{Λ_0} gets closer and closer to the critical point along the renormalized trajectory. Then there's one counterterm for each relevant operator, as we've seen perturbatively, and the continuum limit is the critical point.

• The existence of relevant operators leads to a fine-tuning problem. Suppose we have a very high, fixed cutoff $\Lambda_0 = \Lambda_{\text{Planck}}$. Then if the dimensionless coupling at scale Λ is not extremely large, the dimensionless coupling at scale Λ_0 must be extremely small. This is 'unnatural', because we expect a fundamental theory, where the couplings can be calculated, to have $O(1)$ dimensionless couplings. Note there's no problem with having very large or very small dimensionless couplings in an effective theory.

• Marginally relevant operators aren't nearly as problematic as $\log(\Lambda_{\text{Planck}}/1\text{TeV}) \approx 40$ isn't huge, where 1TeV is about the minimum possible cutoff Λ for the Standard Model.

• In the case of a mass term, the only way to avoid unnaturalness would be to have $m \sim \Lambda_0$, i.e. we need particles so heavy we can't even produce them at Λ in the first place.

• More generally, we could include finite coefficients for irrelevant operators in S_{Λ_0}. This affects the required tuning for the relevant operators, since the two will renormalize each other. However, the effects of the irrelevant operators will disappear exactly in the limit $\Lambda_0 \to \infty$. The point is that we only need one fine tuning for each relevant parameter.

• Note that generically, we should always think of every operator as being present. Even the points on a renormalized trajectory don't only have the relevant couplings turned on; instead these relevant couplings immediately turn on all others, so in general every coupling is nonzero, though the irrelevant operators remain small because they decay away as they're produced.

• As a result, the true coefficient of an irrelevant operator in the IR isn't nearly as small as naive scaling suggests. The real meaning of "irrelevant" is that the value of the coupling in the UV is irrelevant to the value in the IR, since the quick initial decay washes it out; irrelevant operators are still present in S_Λ^{eff} even when $\Lambda_0 \to \infty$, but with small coefficients.

Now suppose that our low-energy effective theory contains an irrelevant operator with a large coefficient, which is often required to match experimental results.

• In this case, there is no hope of our theory lying on a renormalized trajectory. Since there are infinitely many irrelevant operators, which generically all renormalize each other, we now need an infinite number of counterterms and an infinite number of renormalization conditions.

• Moreover, the counterterm coefficients apparently diverge in the limit $\Lambda_0 \to \infty$, so we cannot take the continuum limit. Instead, we say the theory comes with a cutoff $\Lambda_{\text{cutoff.}}$.

• Specifically, Λ_{cutoff} is the scale where the dimensionless irrelevant couplings are $O(1)$. Now, the theory is perfectly predictive at energies $E \ll \Lambda_{\text{cutoff}}$, because the effects of more irrelevant terms are suppressed by more powers of $E/\Lambda_{\text{cutoff}}$, so we can truncate the Lagrangian after a few terms. On the other hand, perturbation theory breaks down as E approaches $\Lambda_{\text{cutoff.}}$. All of the terms become important at once, and we cannot determine all of the couplings with finite data, so the theory is not predictive.

• Generally, what must happen is that new physics takes over. This means that we switch to a new set of degrees of freedom (i.e. new fields, or even non-fields, such as in the Ising model) where the theory is either renormalizable or effective with a higher cutoff, at which point we can truncate the Lagrangian and do calculations again.

• Another possibility is a Landau pole, where a coupling diverges at finite energy, such as the marginally irrelevant coupling in QED. In practice this just means that new physics must take over before then. If it doesn't, then the theory is 'quantum trivial', meaning that the only way for it to have a continuum limit is for the coupling to be exactly zero.

• The usual exposition of the Landau pole uses a perturbatively computed beta function. This isn't valid since perturbation theory breaks down; instead we must establish a Landau pole nonperturbatively, through lattice simulations. Simulations of ϕ^4 theory indicate a Landau pole indeed exists, so the theory is quantum trivial. On the other hand, simulations of QED indicate

that we don't hit the Landau pole; instead chiral symmetry breaking occurs.

• The Standard Model is also suspected to be quantum trivial, through the marginally irrelevant quartic Higgs interaction. Of course, this isn't the main reason we suspect the Standard Model to be incomplete, or even a minor reason. A more compelling reason is the hierarchy problem: the Higgs mass is relevant, so as the usual logic goes, the Standard Model must be extended at the TeV scale to preserve naturalness. A critical evaluation of this argument is given here.

• A final possibility is that we simply flow to some unknown UV fixed point. This is the hypothesis of the asymptotically safe approach to quantum gravity. In this case, new physics need not take over, and our description can be valid up to arbitrarily high energies.

• All of these issues also occur in reverse for relevant couplings, such as in QCD, where the coupling would naively hit a Landau pole at $\Lambda_{\text{QCD}} \sim 1\text{GeV}$. In this case, confinement and chiral symmetry breaking occur; we must describe the dynamics in terms of hadrons rather than quarks and gluons.

Note. Relating our results to the old picture of perturbative renormalization.

• In the old picture, the counterterms are divergent order by order in $\hbar$. Here, they are perfectly finite. This is simply because limits don't commute with sums; for instance,

$$\lim_{x\to\infty} e^{-x} = 0$$

but all the individual terms in the Taylor series for e^{-x} diverge as $x \to \infty$. If we always maintain a finite cutoff and do the path integral exactly, there are never any divergences.

• Before, we thought of the regularization scale Λ_0 as an unphysical scale that had to be sent to infinity at the end of the calculation. Now, we think of it as a physical cutoff, beyond which might lie new physics. Taking Λ_0 to infinity is not essential, and not physical.

• Before, in renormalized perturbation theory, we thought of a bare Lagrangian as composed of a renormalized Lagrangian plus counterterms. Now, we identify the bare Lagrangian with the fundamental theory, at scale Λ_0, and the renormalized Lagrangian with the effective theory, at scale Λ.

• Before, we thought of irrelevant (nonrenormalizable) operators as dangerous and relevant (superrenormalizable) operators as benign. Now, we see that turning on an irrelevant operator changes nothing in the IR, while relevant operators present fine-tuning problems.

• Before, we identified a renormalizable theory as one that required only a finite number of counterterms to absorb the infinities. Now, we think of a renormalizable theory as one that admits a sensible continuum limit.

Note. Conventions differ between SFT and high energy QFT, for physical reasons. In SFT, we typically know the UV theory and want to find the IR behavior, so we keep Λ the same by rescaling; the only thing that matters about the atomic cutoff is that it's very far away. In high energy physics, we know the IR behavior and are trying to find the UV behavior, so we keep the variation of Λ explicit; this is what we've done above.

There is also another convention, which is whether to work with dimensionless couplings by pulling out factors of Λ, or to work with dimensionful couplings. For concreteness, consider $\mathcal{L} \supset m^2\phi^2$. In a free theory, integrating out UV degrees of freedom keeps the dimensionful coupling m^2 the same. However, one could also consider the dimensionless coupling $g = m^2/\Lambda^2$ (common in QFT), or stick with dimensionful couplings but keep Λ the same by rescaling (common in SFT). These are essentially the same idea phrased in different ways. In both cases, the coupling will grow.

Philosophically, in SFT, the slogan is to "find something relevant". This is because we're interested in macroscopic behavior, and the atomic scale is so small that all effects of irrelevant operators are completely undetectable. The fact that relevant operators require fine tuning is acceptable because there is fine tuning in the lab, e.g. by tuning the temperature to a phase transition. In QFT, we already know the low-energy physics, and irrelevant operators are useful as a window into higher-energy physics. Relevant operators are a larger problem because there is nothing outside the universe that does the tuning.

Note. Before, we've argued that contributions to the action from various operators go as $g_i(E/\Lambda)^{\Delta_i - d}$. However, naive power counting can break down because of loops. For instance, in scalar field theory with a hard cutoff, a ϕ^6 loop renormalizes the ϕ^4 coupling at one-loop as

$$\delta g_4 \sim \frac{g_6}{\Lambda^2} \int^{\Lambda} \frac{dk}{k^2 - m^2} \sim g_6$$

which is too large. This occurs because only the external legs are fixed at energy E, while particles in the loop can go up to Λ. But if we regulate with a mass-independent scheme such as DR, we get a result compatible with power counting,

$$\delta g_4 \sim \frac{g_6 \mu^{2\epsilon}}{\Lambda^2} \int \frac{d^{4-\epsilon}k}{k^2 - m^2} \sim \frac{g_6}{\epsilon}\frac{m^2}{\Lambda^2} + g_6 \frac{m^2}{\Lambda^2} \log \frac{m^2}{\mu^2} = O\left(m^2/\Lambda^2\right)$$

That is, DR removes the Λ^2 power divergence entirely; intuitively DR "only sees logarithmic divergences", which show up as $1/\epsilon$ terms that are subtracted out. Thus, if we don't use something like DR, it is difficult to self-consistently truncate the Lagrangian in an EFT. It is still possible, but one has to carefully keep track of counterterms, which can remove the contributions that violate naive power counting. (In this sense, it's the same as using a regulator that violates a symmetry: it's perfectly legal, but requires counterterms to be added with care.) For this reason, $\overline{\text{MS}}$ is used almost universally in practical EFT calculations.

Note. It is tempting to say that if a dimension- 6 operator is measured with coefficient $1/\Lambda^2$, then new physics appears at scale Λ. This is deceptive, because operators come with UV couplings. What we really can conclude is that if nothing UV completes the theory, then the theory becomes strongly coupled at scale Λ. It is perfectly possible for new particles to appear at a lower scale. Indeed, there are many very small couplings in the SM, such as the electron Yukawa coupling, to which this reasoning applies.

Calculating RG Evolution

Next, we present an explicit, though somewhat impractical method for computing RG evolution.

• Concretely, we would like to evaluate

$$S^{\text{int}}_{\Lambda}[\phi] = -\log \int_{C^\infty(M)_{(\Lambda,\Lambda_0]}} \mathcal{D}\chi \exp\left(-S^0[\chi] - S^{\text{int}}_{\Lambda_0}[\phi + \chi]\right)$$

but this is hard in general, as the right-hand side is a general interacting path integral. The general approach is to expand $e^{-S^{\text{int}}_{\Lambda_0}[\phi+\chi]}$ as a series in χ,

$e^{-S^{\text{int}}_{\Lambda_0}[\phi+\chi]} = e^{-S^{\text{int}}_{\Lambda_0}[\phi]} + \int dx \chi(x) \frac{\delta}{\delta\phi(x)} e^{-S^{\text{int}}_{\Lambda_0}[\phi]} + \frac{1}{2}\int dx dy \chi(x)\chi(y) \frac{\delta}{\delta\phi(x)}\frac{\delta}{\delta\phi(y)} e^{-S^{\text{int}}_{\Lambda_0}[\phi]} + \ldots$

then perform the χ path integral. Note that we're Taylor expanding in position space, since eventually we want an action in position space.

• When we perform the χ path integral, we get factors of the position space propagator,

$$D_\Lambda(x,y) = \int\limits_{\Lambda<|p|\leq\Lambda_0} dp \frac{e^{ip(x-y)}}{p^2+m^2}$$

Now the trick is to consider an infinitesimal RG step, $\Lambda = \Lambda_0 - \delta\Lambda$, so that

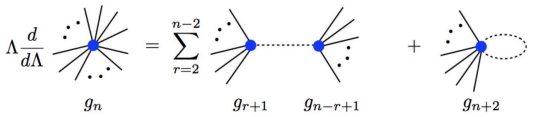
$$D_\Lambda(x,y) = \frac{1}{(2\pi)^d}\frac{\Lambda^{d-1}\delta\Lambda}{\Lambda^2+m^2}\int\limits_{S^{d-1}} d\Omega e^{i\Lambda\hat{p}(x-y)}$$

This is an enormous improvement, because we only need keep track of terms linear in $\delta\Lambda$, which means we only want diagrams with a single χ propagator.

• Therefore, only the zeroth and second order terms in the Taylor expansion matter, and an explicit calculation yields Polchinski's equation,

$$-\frac{\partial S_\Lambda^{\text{int}}[\phi]}{\partial \log\Lambda} = \int dxdy \frac{\delta S_\Lambda^{\text{int}}}{\delta\phi(x)} D_\Lambda(x,y) \frac{\delta S_\Lambda^{\text{int}}}{\delta\phi(y)} - D_\Lambda(x,y)\frac{\delta^2 S_\Lambda^{\text{int}}}{\delta\phi(x)\delta\phi(y)}$$

More concretely, let g_n be the coefficient of ϕ^n. Then schematically we have



which corresponds with the intuition of zooming out, shrinking χ propagators to points.

• Note that since the action is local, we must have $x = y$ in the second term to get a nonzero result. On the other hand, we can have $x \neq y$ in the first term, leading to non-local contributions, as the χ propagator falls off as $e^{-\sqrt{\Lambda^2+m^2}r}/r^{d-3}$. As usual, we simply Taylor expand to get a series of local terms with derivatives.

• Note that the variation of the action is

$$\frac{\delta S}{\delta\phi(x)} \equiv \frac{\partial\mathcal{L}}{\partial\phi} - \partial_\mu\frac{\partial\mathcal{L}}{\partial\left(\partial_\mu\phi\right)} + ...$$

so Polchinski's equation indeed accounts for the derivative terms.

• It's convenient to rewrite Polchinski's equation as

$$\frac{\partial}{\partial t}e^{-S^{\text{int}}[\phi]} = -\int dxdy D_\Lambda(x,y)\frac{\delta^2}{\delta\phi(x)\delta\phi(y)}e^{-S^{\text{int}}[\phi]}, \quad t = \log\Lambda$$

which has the general form of a heat equation, with the 'Laplacian'

$$\Delta = \int dxdy D_\Lambda(x,y)\frac{\delta^2}{\delta\phi(x)\delta\phi(y)}$$

The eigenfunctions of the Laplacian grow or decay exponentially under RG flow; they are simply the *RG* eigenvectors we've seen earlier.

Next, we use the local potential approximation to explicitly compute RG evolution.

• We work in $d > 2$ near the Gaussian fixed point. Then besides the kinetic term, all operators involving derivatives are irrelevant, so we restrict attention to actions of the form

$$S_\Lambda^{\text{eff}}[\phi] = \int d^dx \frac{1}{2}\partial^\mu\phi\partial_\mu\phi + V(\phi), \quad V(\phi) = \sum_k \Lambda^{d-k(d-2)}\frac{g_{2k}}{(2k)!}\phi^{2k}$$

where for simplicity we've imposed $\mathbb{Z}_2$ symmetry. Neglecting the derivative interactions is called the local potential approximation, and works for slowly varying fields.

• Next, we set up our approximation somewhat differently. Before, we expanded $e^{-S_\Lambda^{\text{int}}[\phi+\chi]}$, yielding a Gaussian path integral for χ. Now we instead write

$$S_\Lambda^{\text{eff}}[\phi+\chi] = S_\Lambda^{\text{eff}} + \int dx \frac{1}{2}(\partial\chi)^2 + \frac{1}{2}\chi^2 V''(\phi) + ...$$

so that we maintain a nontrivial action for χ.

• We now consider an infinitesimal RG step $\delta\Lambda$ and work in momentum space. Then the momentum-space propagators are not small, but every loop picks up a factor of $\delta\Lambda$, so we only consider one-loop graphs. Note that there are no tree level graphs at all since the action is even in χ, though we could also relax this assumption.

• We claim that one-loop graphs can only contain the χ^2 vertex. To prove this rigorously, let there be v_i copies of the χ^i vertex. Then Euler's identity gives

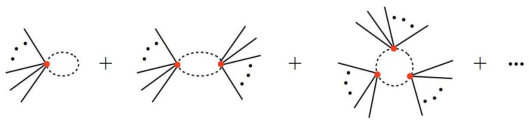
$$e - \sum_i v_i = \ell - 1$$

where ℓ is the number of loops. Since there are no external lines,

$$2e = \sum_i iv_i, \quad \ell = 1 + \sum_i \frac{i-2}{2}v_i$$

Therefore only v_2 can be nonzero, and we recover a quadratic action for χ, which is tractable.

• The types of diagrams that contribute are shown below.



Now, suppressing the position-dependence of ϕ, the action for χ becomes

$$\begin{aligned} S^{(2)}[\chi,\phi] &= \int\limits_{\Lambda-\delta\Lambda<|p|\leq\Lambda} dp\tilde{\chi}(p)\left(\frac{1}{2}p^2 + \frac{1}{2}V''(\phi)\right)\tilde{\chi}(-p) \\ &= \frac{1}{2}\frac{\Lambda^{d-1}\delta\Lambda}{(2\pi)^d}\left(\Lambda^2 + V''(\phi)\right)\int\limits_{S^{d-1}} d\Omega\tilde{\chi}(\Lambda\hat{p})\tilde{\chi}(-\Lambda\hat{p}) \end{aligned}$$

• Performing the Gaussian integration, we find

$$e^{-\delta\Lambda S^{\text{eff}}[\phi]} = \int \mathcal{D}\chi e^{-S^{(2)}[\chi,\phi]} = C\left(\frac{\pi}{\Lambda^2 + V''(\phi)}\right)^{N/2}$$

where N is the number of momentum modes. To regularize this, we put the theory in a box of side length L and use periodic boundary conditions, giving

$$N = \frac{\text{vol}\left(S^{d-1}\right)}{(2\pi)^d}\Lambda^{d-1}\delta\Lambda L^d$$

We can thus rewrite our result as

$$\delta_\Lambda S^{\text{eff}}[\phi] = a\Lambda^{d-1}\delta\Lambda \int dx \log\left(\Lambda^2 + V''(\phi(x))\right)$$

where we restored the position-dependence of ϕ, turning a factor of L^d into an integral over x.

• Finally, expanding the logarithm gives an infinite series of corrections,

$$\frac{dg_{2k}}{d\log\Lambda} = (k(d-2)-2)g_{2k} - a\Lambda^{k(d-2)}\frac{\partial^{2k}}{\partial\phi^{2k}}\log\left(\Lambda^2 + V''(\phi)\right)\Big|_{\phi=0}$$

where the first term is from the classical scaling. For example, the first two terms are

$$\frac{dg_2}{d\log\Lambda} = -2g_2 - \frac{ag_4}{1+g_2}, \quad \frac{dg_4}{d\log\Lambda} = (d-4)g_4 - \frac{ag_6}{a+g_2} + \frac{3ag_4^2}{(1+g_2)^2}$$

For example, we see that in $d = 4$, g_4 is marginally irrelevant.

• Looking back, we've traded one kind of complexity for another. In the local potential approximation, the beta functions are exact at one loop, but can contain arbitrarily high powers of the couplings. In Polchinski's equation, the beta functions are also exact at one loop, and are linear in the couplings, but we need to account for all derivative terms. One can think of the local potential approximation as solving for the derivative term couplings in terms of the non-derivative ones, and plugging them back into the beta functions to eliminate them.

Using our result, we can explicitly look at some simple RG flows.

• First, we consider the Gaussian fixed point. Linearizing the beta function about it gives

$$\beta_{2k} = (k(d-2)-d)g_{2k} - ag_{2k+2}$$

Thus as anticipated, there are no anomalous dimensions since the matrix B in $\beta_i = B_{ij}g_j$ is upper-triangular, though the eigenvectors are mixed a bit.

• In $d = 4$, we see that the mass term is relevant, while ϕ^6 and higher couplings are irrelevant, as expected. To understand g_4, we expand to quadratic order for

$$\beta_4 = \frac{3}{16\pi^2}g_4^2$$

so that the quartic interaction is marginally irrelevant; explicitly,

$$g_4(\Lambda) = \frac{16\pi^2}{3\log\left(\Lambda_0/\Lambda\right)}$$

where Λ_0 is an integration constant, we need $\Lambda_0 > \Lambda$ for $g_4 > 0$, ensuring stability, and the theory has a Landau pole at $\Lambda_0 = \Lambda$.

• The fact that a dimensionless coupling implies an energy scale is known as dimensional transmutation. We've already seen this for irrelevant couplings, which give a natural cutoff for the effective field theory; marginal couplings have the scale appear in a logarithm. There's nothing puzzling about this, since all theories come with a natural energy scale, the cutoff Λ.

• We can find another critical point in $d = 4 - \epsilon$, the Wilson-Fisher fixed point, where

$$g_2 = -\frac{1}{6}\epsilon + O\left(\epsilon^2\right), \quad g_4 = \frac{1}{3a}\epsilon + O\left(\epsilon^2\right), \quad g_{2k} = O\left(\epsilon^2\right) \text{ for } k > 2$$

Staying near $d = 4$, where g_4 is marginal, allows us to find a nontrivial fixed point without requiring strong coupling.

• Linearizing about the fixed point gives

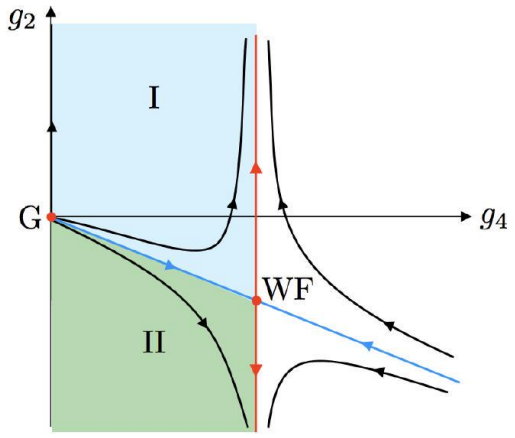
$$\frac{d}{d\log\Lambda}\begin{pmatrix}\delta g_2\\ \delta g_4\end{pmatrix} = \begin{pmatrix}\epsilon/3-2 & -a(1+\epsilon/6)\\ 0 & \epsilon\end{pmatrix}\begin{pmatrix}\delta g_2\\ \delta g_4\end{pmatrix}$$

which has eigenvalues $\epsilon/3 - 2$ and ϵ, so only one direction is relevant. Explicitly, we have

$$a = \frac{1}{(4\pi)^{d/2}}\frac{1}{\Gamma(d/2)}\bigg|_{d=4-\epsilon} = \frac{1}{16\pi^2} + \frac{\epsilon}{32\pi^2}(1-\gamma+\log 4\pi) + O\left(\epsilon^2\right)$$

More sophisticated techniques can be used to show that the Wilson-Fisher fixed point indeed exists in $d = 3$ and $d = 2$.

• The RG flows in three dimensions are shown below.



Theories in region I flow to an interacting massive theory in the IR, and have the Gaussian theory as the continuum limit. Theories in region II are similar, but exhibit spontaneous symmetry breaking since $g_2 < 0$. Theories on the red line have the Wilson-Fisher fixed point as their continuum limit, while all others have no continuum limit at all.

• The situation in two dimensions in more complicated, as all of the operators ϕ^{2n} are marginal. It turns out there are infinitely many fixed points, where the n^{th} fixed point can be reached from the Gaussian fixed point by turning on $\phi^{2(n+1)}$. The n^{th} fixed point has n relevant operators, which are essentially $\phi^2, \phi^4, ..., \phi^{2n}$. This result can be derived by conformal field theory.

Effective Field Theories

In this section, we give an array of examples of effective field theories, illustrating the general way of thinking about theories in the Wilsonian picture.

Example. In some cases, we can pick up extra symmetries just from the requirement of renormalizability; such symmetries are called "accidental" or "emergent". A familiar example is the emergence of rotational symmetry for a lattice spin system. As another example, consider electromagnetism with several fermions, where the most general renormalizable Lagrangian is

$$\mathcal{L} = \frac{1}{4e^2} Z_3 F^{\mu\nu} F_{\mu\nu} + (Z_L)_{ij}\, \bar{\psi}_{L_j} \not{D} \psi_{L_i} + (Z_R)_{ij}\, \bar{\psi}_{R_j} \not{D} \psi_{R_i} + M_{ij} \bar{\psi}_{L_i} \psi_{R_j} + \bar{M}_{ij} \bar{\psi}_{R_i} \psi_{L_j}.$$

Here, $Z_{L/R/3}$ are general wavefunction renormalizations. To have a real Lagrangian, we require $Z_{L/R}$ to be Hermitian. Note that we have no Majorana masses since the fields are charged.

We can dramatically simplify the Lagrangian by defining

$$\psi_L = S_L \psi'_L, \quad \psi_R = S_R \psi'_R$$

so the Lagrangian for the primed fields has

$$Z'_L = S_L^\dagger Z_L S_L, \quad Z'_R = S_R^\dagger Z_R S_R, \quad M' = S_L^\dagger M S_R$$

Then it is possible to choose S_L so that Z'_L is the identity, and similarly choose S_R so that Z'_R is the identity, giving the usual kinetic terms. We can still redefine $S_{L/R}$ by unitaries, which we can use to make M diagonal. Dropping the primes,

$$\mathcal{L} = \frac{1}{4e^2} Z_3 F^{\mu\nu} F_{\mu\nu} + \sum_i \bar{\psi}_i \left(\not{D} + m_i \right) \psi_i$$

Then the number of ψ_i particles is conserved, but this is an accidental symmetry; it could be broken by a nonrenormalizable term such as $Y_{ijkl} \bar{\psi}_i \gamma^\mu \psi_j \bar{\psi}_k \gamma_\mu \psi_\ell$. In the Standard Model, this is the origin of baryon and lepton number symmetry.

Note. More generally, it is believed that there are no continuous global symmetries in a quantum theory of gravity. Then from this perspective, all continuous symmetries we've found in particle physics are accidental! One piece of evidence in favor of this picture is Hawking radiation. The formation and evaporation of a black hole does not conserve baryon or lepton number, but it does conserve gauge quantum numbers, such as electric charge, since they may be measured by flux integrals at infinity. In string theory, it is a folk theorem that all exact symmetries, even discrete symmetries, are gauge symmetries.

Example. The Schrodinger field has kinetic term $\nabla^2 \psi / 2m$. Since the coefficient $1/2m$ has negative mass dimension, the operator is irrelevant. Hence upon renormalization, the Hamiltonian should have all terms allowed by symmetry, giving

$$H \sim \frac{p^2}{2m} \left(1 + a_1 \frac{p^2}{m^2} + a_2 \frac{p^4}{m^4} + ... \right) + V(r)$$

where the factors of m are put in by dimensional analysis. Note that here we are thinking of the renormalized theory which has no cutoff, $\Lambda \to \infty$, so the only mass scale is m.

This theory is perfectly predictive at energies where $p^2 \ll m^2$, despite the infinitely many unknown parameters a_i. But when $p^2 \sim m^2$, perturbation theory breaks down and all of the a_i are important. The Schrodinger field can be UV-completed to either the Klein-Gordan or Dirac field, both of which are renormalizable.

Example. The classic example of an effective field theory is the 4-Fermi theory for β decay,

$$\mathcal{L} \sim G_F \bar{\psi}_p \psi_n \bar{\psi}_e \psi_\nu$$

where we suppress gamma matrices and spinor indices. Similar operators can be used to describe the decay of the muon; this is used to determine

$$G_F = \left(\frac{1}{292.9\text{GeV}}\right)^2$$

which indicates the energy where the theory breaks down; higher-dimension terms contribute in a series in $p^2 G_F$. The specific values of these terms may be found by UV completing the 4-Fermi theory to the electroweak theory.

Sticking with only the dimension 6 term, the 4-Fermi theory is quite predictive. It can compute relations between decay rates, and angular distributions of decays. One can also include loops to get genuinely quantum predictions, which appear in cross sections as logarithmic dependence on the external momenta.

Example. Light scattering; or, why the sky is blue. We consider Rayleigh scattering of visible light off a nitrogen molecule, where the wavelength of the light is much larger than the size of the atom. We assume the photon energy is too weak to excite the molecule, so we can ignore its internal degrees of freedom and model it as a complex scalar field ϕ. The molecule remains at rest since it is heavy, so we break Lorentz invariance, allowing us to use the four-velocity $u^\mu = (1, 0, 0, 0)$ in our

Lagrangian. Finally, the nitrogen molecule is electrically neutral, so the minimal coupling vanishes, $D_\mu \phi = \partial_\mu \phi$.

Given this setup, the kinetic term is $\pi^\dagger i v^\mu \partial_\mu \phi$, which shows that ϕ has mass dimension $3/2$. Here, we can use relativistic dimensional analysis because the photon is relativistic, and the nitrogen is static. The effective interactions are

$$S^{\text{int}}\left[A, \phi\right] = \int dx \frac{g_1}{8\Lambda^3}\phi^2 F^2 + \frac{g_2}{8\Lambda^3}\phi^2 (u \cdot F)^2 + ...$$

where the g_i are dimensionless and the higher terms are suppressed by more powers of Λ. Now consider the tree-level contribution to $\phi + \gamma \to \phi + \gamma$ scattering. Since the field F contains a derivative, the amplitude is proportional to ω^2 and hence the cross section is proportional to ω^4,

$$\sigma \sim g_2^2 \frac{\omega^4}{\Lambda^6}$$

Thus we get the frequency dependence of Rayleigh scattering almost for free! Note that when the scatterer is comparable in size to the wavelength, our effective field theory breaks down and we enter the regime of Mie scattering. It also breaks down once the light can excite the atom, which creates a Lorentzian scattering peak.

Example. Light propagation in an insulator. In vacuum, the unique gauge, Lorentz, and parity invariant action we can write for the photon is

$$S[A] = \frac{1}{4}\int dx \epsilon_0 E^2 - \frac{1}{\mu_0} B^2$$

Now we suppose the light propagates in a medium, whose degrees of freedom are modeled with additional fields Φ. The Euler-Lagrange equations become

$$\partial^\mu F_{\mu\nu} = \mu_0 J_\nu, \quad J_\mu(x) = \frac{\delta S^{\text{int}}}{\delta A^\nu(x)}$$

For example, in a conductor, we might ignore higher energy bands for the electrons, so Λ would be the band gap. Then in an insulator, Λ has the same interpretation, but since the Fermi surface lies in a band gap there are no relevant degrees of freedom at all! Then it would appear that S^{int}

must contain only irrelevant terms. But the insulator also picks out a preferred frame of reference, so we can write down non-Lorentz invariant terms,

$$S_\Lambda^{\text{int}}\left[A,\Phi\right]=\int dx\frac{1}{2}\left(\chi_e E^2-\chi_m B^2+...\right)$$

where the dimensionless couplings $\chi_e(\Lambda)$ and $\chi_m(\Lambda)$ are the susceptibilities. Then light can travel at a different speed, and this is the leading effect an insulator has. More generally, a crystalline insulator breaks rotational symmetry, so we can have

$$S_\Lambda^{\text{int}}[A,\Phi]=\int dx\frac{1}{2}\left(\left(\chi_e\right)_{ij}E_iE_j-\left(\chi_m\right)_{ij}B_iB_j+...\right)$$

which leads to birefringence. At higher orders, we will find nonlinear terms such as E^4/Λ^2, yielding nonlinear optical effects.

Note. Quantum gravity may also be treated as an effective field theory. The action is

$$S[g]=\int dx\sqrt{-g}\left(\lambda+\frac{R}{16\pi G}\right)$$

where the dimensions are

$$[\lambda]=4,\quad [g_{\mu\nu}]=0,\quad [R]=[\partial\partial g]=2,\quad [G]=-2$$

In particular, one can see the metric is dimensionless because in flat spacetime its elements are simply δ. Perturbing about the flat metric,

$$g=\delta+\sqrt{G}h$$

where h is scaled to have canonically normalized kinetic terms. Higher-order terms in h come with positive powers of G and hence negative powers of M_{pl}, so they are all irrelevant. Their form can be obtained from taking the most general diffeomorphism invariant action,

$$S_\Lambda^{\text{eff}}[g]=\int dx\sqrt{-g}\left(c_0\Lambda^4+c_1\Lambda^2R+c_2R^2+c_3R^{\mu\nu}R_{\mu\nu}+c_4R^{\mu\nu\rho\sigma}R_{\mu\nu\rho\sigma}+...\right)$$

where the c_i are dimensionless, and ordinary GR only uses c_0 and c_1. In the UV, either new degrees of freedom appear, such as strings, or the theory flows to a fixed point, a proposal known as asymptotic safety. (Note that "asymptotic freedom" as used above is just the case where this fixed point is the Gaussian fixed point.)

Of course, even though the interaction of gravity with matter is "irrelevant", it is very relevant to everyday life! This is because the gravitational interactions between the particles in macroscopic objects add up coherently, a fact which is not captured in our simple analysis above.

Note. Multiple kinds of renormalizability. So far we've been talking about Wilsonian renormalizability, which, near the Gaussian fixed point, simply corresponds to having no couplings with negative mass dimension. However, historically renormalizability was defined by demanding that all the divergences in a theory could be absorbed by redefinitions of the couplings already in the Lagrangian, which in turn must have a finite number of terms; we will call this counterterm renormalizability. In our picture, this means the Lagrangian must include all renormalizable terms consistent with symmetries; for instance, massless ϕ^4 theory is not permitted. (Thus counterterm renormalizability is obliquely related to naturalness.) The main point is that it directly demands that all predictions up to arbitrary energy can be made given a finite number of parameters.

By contrast, in an effective field theory one requires more and more parameters to get an accurate prediction as one goes to higher energies. In practice, one fixes a desired precision, and then computes up to the order in $1/\Lambda$ required (or more generally, to the required order in the power counting parameter), neglecting all effects associated with higher-order terms. Then it is useful to say an EFT is renormalizable if it is renormalizable in the historic sense, at each order of the power counting expansion. (That is, divergences can appear associated with higher-order terms, but they can be simply neglected.) For example, ϕ^6 theory is renormalizable at this sense, even though it induces a ϕ^8 coupling, because the ϕ^8 coupling is order $1/\Lambda^4$, while the ϕ^6 coupling is only order $1/\Lambda^2$. EFTs are discussed further in the notes on the Standard Model.

Note. Counterterm renormalizability can be much more difficult to show than Wilsonian renormalizability, though the two are related.

• Consider the linear sigma model, a case with spontaneously broken global symmetry. Naively, there are more divergences than there are free parameters, so it looks like the theory is not renormalizable. But the divergences are still constrained by the broken $SO(n)$ symmetry, which is still present but nonlinearly realized, so "secret symmetry yields secret renormalizability".

• Consider a gauge theory. The gauge symmetry constrains the terms in the Lagrangian, but it does not manifestly constrain the divergences, because we need to gauge fix before quantization; that is, the divergences never "see" the gauge symmetry. Thus renormalizability is nontrivial, but can be proven using Ward identities. Using BRST symmetry, one can also prove Yang-Mills is indeed renormalizable.

• Now consider Yang-Mills with an explicit mass term $m^2 A^\mu A_\mu$. This makes the analysis of renormalizability even more difficult because the propagator no longer falls off at high momenta, so superficial degrees of divergence get worse. However, it turns out that it is renormalizable if and only if the gauge group is abelian.

• The Standard Model is more complicated, as it is a gauge theory with spontaneous symmetry breaking. 't Hooft proved its renormalizability in 1971 and we can perform this proof explicitly by working in R_ξ gauge, introduced in the notes on the Standard Model.

These nontrivial facts should not be confused with Wilsonian renormalizability, which is easy to see in all these cases. Sometimes, counterterm and Wilsonian renormalizability are called perturbative and nonperturbative renormalizability. However, Wilsonian renormalizability does not imply counterterm renormalizability, e.g. in the case of quantum gravity if it were asymptotically safe. Here perturbative renormalizability fails because it expands about the Gaussian fixed point, while the nonperturbatively the theory is determined by a different fixed point in the UV.

5.1.3 Corrections to Polarization Operator and to Coulomb Law, Form Factors

113. Вычисление поляризационного оператора по Ландау 4

114. Радиационные поправки к закону Кулона по Ландау 4

115. Вычисление мнимой части поляризационного оператора по интегралу Фейнмана по Ландау 4

При прямом вычислении по диаграмме (петля на диаграмме $(113, 1)$) поляризационный оператор в первом приближении теории возмущений давался бы интегралом

$$\frac{i\mathscr{F}^{\mu\nu}}{4\pi} \to -e^2 \int \mathrm{Sp}\,\gamma^\mu G(p)\gamma^\nu G(p-k)\frac{d^4p}{(2\pi)^4}.$$

Однако этот интеграл, взятый по всему четырехмерному p-пространству, квадратично расходится и для получения конечного результата должен быть регуляризован по описанным в 112 правилам.

Мы не будем воспроизводить здесь полностью такой вывод, но покажем, каким образом можно вычислить по интегралу $(115,1)$ мнимую часть поляризационного оператора (которая была определена нами в \$113 с помощью условия унитарности); этот вывод содержит в себе ряд поучительных моментов.

Мнимая часть интеграла $(115,1)$ не содержит расходимости и не требует поэтому регуляризации. Для скалярной функции $\operatorname{Im}\mathscr{P} = 1/3\operatorname{Im}\mathscr{P}^{\mu}_{\mu}$ имеем

$$\operatorname{Im}\mathscr{P} = \operatorname{Im}\left\{ i\frac{4\pi e^2}{3(2\pi)^4}\int \frac{\operatorname{Sp}\gamma^{\mu}(\gamma p+m)\gamma_{\mu}\left(\gamma p+\gamma^{k}+m\right)}{(p^2-m^2+i0)\left[(p-k)^2-m^2+i0\right]}d^4p \right\}.$$

$$\operatorname{Im}\mathscr{P}\left(k^2\right) = \operatorname{Im}\int d^3p \int\limits_{-\infty}^{\infty} dp_0 \frac{i\varphi\left(p_0,\mathbf{p}\right)}{\left(p_0^2-\varepsilon^2+i0\right)\left[\left(p_0-k_0\right)^2-\varepsilon^2+i0\right]}$$

$$\varphi\left(p_0,\mathbf{p}\right) = \frac{2e^2}{3\pi^3}\left(m^2+\varepsilon^2+p_0k_0-p_0^2\right).$$

Подынтегральное выражение имеет четыре полюса по переменной p_0: а) $p_0=\varepsilon-i0,\ a')\, p_0=-\varepsilon+i0$, b) $p_0=k_0-\varepsilon+i0,\ b')\, p_0=k_0+\varepsilon-i0$.

После этого находим окончательно

$$\Delta\mathscr{P}\left(k^2\right) = i(2\pi i)^2\int\limits_{p_0>0} d^4p\cdot\varphi(p)\delta\left(p^2-m^2\right)\delta\left[(p-k)^2-m^2\right].$$

Ввиду наличия δ-функций интегрирование производится факти чески лишь в области пересечения гиперповерхностей

$$p^2=m^2,\quad (p-k)^2=m^2.$$

Поскольку в этой области все 4-векторы p времениподобны, то условие интегрирования по $p_0>0$ имеет инвариантный характер (верхняя полость конуса $p^2=m^2$).

Сравним (115,7) с исходной формулой $(115,2)$. Мы видим, что скачок функции $\mathscr{P}(t)$ на разрезе в плоскости t можно получить, если в исходном фейнмановском интеграле произвести замену

$$\frac{1}{p^2-m^2+i0}\to -2\pi i\delta\left(p^2-m^2\right)$$

в пропагаторах, отвечающих пересеченным на диаграмме $(113,1)$. линиям петли (S. Mandelstam, 1958, R. Cutkosky, 1960).

116. Электромагнитные формфакторы электрона по Ландау 4

117. Вычисление формфакторов электрона по Ландау 4

129. Радиационные поправки к уравнениям электромагнитного поля по Ландау 4

(поставил выше, потому что это скорее теория)

5.1.4 Asymptotic Formulas of QED, High Energies

(!! скоро допройду!)

132. Асимптотическое поведение фотонного пропагатора при больших импульсах

133. Связь между «затравочным» и истинным зарядами

134. Асимптотическое поведение амплитуд рассеяния при высоких энергиях

135. Выделение дважды логарифмических членов в вершинном операторе

(большой на самом деле параграф такой)

Поправки вида $(\alpha L)^n (L$ - большой логарифм) могут стать существенными, как уже было отмечено в конце §133, лишь при фантастически высоких энергиях и потому имеют только теоретическое значение. Но в амплитудах реальных процессов рассеяния возникают также и гораздо бОльшие поправки - вида $(\alpha L^2)^n$. Такие члены, содержащие по квадрату логарифма на каждую степень α, называют дважды логарифмическими.

Характерным параметром разложения в дважды логарифмических поправках является величина

$$\frac{a}{\pi} \ln^2 \frac{\varepsilon^2}{m^2},$$

где ε-фигурирующие в задаче энергии (скажем, суммарная энергия сталкивающихся частиц в системе их центра инерции). Условие применимости теории возмущений требует малости этой величнны; оно нарушается при энергиях

$$\varepsilon \sim m \exp\left(\frac{1}{2}\sqrt{\frac{\pi}{\alpha}}\right) \sim 3 \cdot 10^4 m$$

Случай виртуальных электронных линий Пусть импульсы p_1, p_2 отвечают виртуальным электронам, причем

$$\left|p_1^2\right|, \left|p_2^2\right| \gg m^2$$

Мы увидим, что основной областью интегрирования, приводящей к дважды логарифмическому выражению, является в этом случае область, определяемая неравенствами $0 < \rho \ll |tu|, |tv|; \left|\frac{p_1^2}{t}\right| \ll |v| \ll 1; \left|\frac{p_2^2}{t}\right| \ll |u| \ll 1$. Соответственно этому в знаменателе подынтегрального выражения в $(135,9)$ можно пренебречь m^2, p_1^2, p_2^2, f^2 по сравнению с $(p_1 f)$ или $(p_2 f)$, так что

$$I_1 = \int \frac{d^4 f}{2\,(p_2 f) \cdot 2\,(p_1 f)\,(f^2 + i0)}.$$

Случай физических электронных концов Пусть теперь импульсы p_1, p_2 отвечают реальным электронам, так что

$$p_1^2 = p_2^2 = m^2.$$

В этом случае существенна область интегрирования

$$0 < \rho \ll |tu|, |tv|; \quad 0 < |v|, |u| \ll 1.$$

136. Дважды логарифмическая асимптотика вершинного оператора

137. Дважды логарифмическая асимптотика амплитуды рассеяния электрона на мюоне

5.1.5 Entanglement in Quantum Fields

(!????????!?!?!?!?!?!?!!!!! an important topic in current physics)

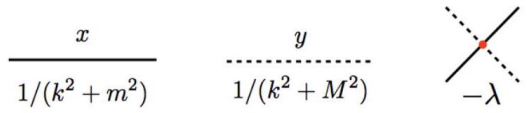
5.2 On Special Path Integral Methods

5.2.1 Effective Quantum Mechanics

- First, we consider a circular worldline with two fields x and y, with action

$$S[x,y]=\int_{S^1}\frac{1}{2}\dot{x}^2+\frac{1}{2}\dot{y}^2+V(x,y)dt,\qquad V(x,y):=\frac{1}{2}\left(m^2x^2+M^2y^2\right)+\frac{\lambda}{4}x^2y^2$$

As a quantum mechanical system, it's two coupled harmonic oscillators in periodic time T. In quantum field theory language, it's a theory of two interacting fields with masses m and M.



where k is the worldline momentum, which is quantized in units $2\pi/T$.

- Alternatively, we can integrate out the y field, giving

$$\int\mathcal{D}y\exp\left(-\frac{1}{2}\int_0^T dty\left(-\frac{d^2}{dt^2}+M^2+\frac{\lambda}{2}x^2\right)y\right)\sim\det\left(-\frac{d^2}{dt^2}+M^2+\frac{\lambda}{2}x^2\right)^{-1/2}$$

(we integrated by parts, boundary terms cancel by periodicity, and performed a formal Gaussian integral.)

$$S_{\text{eff}}[x]=\int_0^T dt\left(\frac{1}{2}\dot{x}^2+\frac{m^2}{2}x^2\right)+\frac{1}{2}\log\det\left(-\frac{d^2}{dt^2}+M^2+\frac{\lambda}{2}x^2\right)$$

$\log\det(AB)=\log\det A+\log\det B$, so $\log\det(AB)=\operatorname{tr}\log A+\operatorname{tr}\log B$.

$$G(t,t'):\qquad\left(\frac{d^2}{dt^2}-M^2\right)G(t,t')=\delta(t-t')$$

$$G(t,t')=\frac{1}{2M}\sum_{n\in\mathbb{Z}}e^{-M|t-t'+nT|}$$

With this:

$$\operatorname{tr}\log\left(-\frac{d^2}{dt^2}+M^2+\frac{\lambda}{2}x^2\right)=\operatorname{tr}\log\left(-\frac{d^2}{dt^2}+M^2\right)+\operatorname{tr}\log\left(1-\lambda\left(\frac{d^2}{dt^2}-M^2\right)^{-1}\frac{x^2}{2}\right)$$

The first term is a divergent constant, while the next term can be expanded in a series. The inverse is simply the Green's function, and the trace is over time, giving

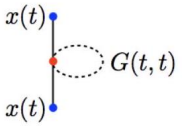
$$-\frac{\lambda}{2}\int_{S^1} dtG(t,t)x^2(t) - \frac{\lambda^2}{8}\int_{S^1\times S^1} dtdt'G\left(t',t\right)x^2(t)G\left(t,t'\right)x^2\left(t'\right) + ...$$

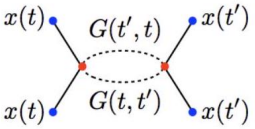
The general term here is

$$-\sum_{n=1}^{\infty}\frac{\lambda^n}{2^n n}\int_{(S^1)^n} dt_1...dt_nG\left(t_n,t_1\right)x^2\left(t_1\right)G\left(t_1,t_2\right)x^2\left(t_2\right)...G\left(t_{n-1},t_n\right)x^2\left(t_n\right)$$

and we generate an infinite series of new interactions as usual.

• The striking new feature is that the new interactions are non-local in time. To understand this, we consider the Feynman diagrams for the first two terms,





Since the y field is dynamical, it has its own propagator which allows it to move around on the worldline, so integrating it out gives a nonlocal interaction.

• To estimate the size of the nonlocal interactions, we Taylor expand in $t-t'$ for

$$\int dtdt'G\left(t,t'\right)^2x^2(t)x^2\left(t'\right) = \int dtdt'G\left(t,t'\right)^2x^t(t)\left(x^2(t)+2x(t)\dot{x}(t)\left(t-t'\right)+...\right).$$

Note that $G\left(t,t'\right)$ only depends on $t-t'$ through the combination $M\left(t-t'\right)$. Then we can integrate over $t-t'$, giving a power of $1/M$ for every time derivative. The terms look like

$$\int dt\frac{x^4(t)}{M} + \frac{\text{two derivatives}}{M^3} + \frac{\text{four derivatives}}{M^5} + ...$$

where we've suppressed numerical factors, and all terms are quartic in x. Therefore, as long as the derivatives are small in units of M^{-1}, we can truncate the series and get a local action.

• Note that we have a double expansion in λ and M. The former is relatively innocuous, but the latter breaks down for energies on the scale of M, where all terms are important; if we continue to try to use only a few terms, we'll find violations of unitarity, signaling that perturbation theory is breaking down. To fix it in a tractable way, we must 'un-integrate out' the y field.

• This same scenario was important in the discovery of the W boson. Fermi's theory of weak decay was an effective theory that had integrated out the W boson, but which led to a violation of unitarity at high energies.

Note. Perturbative unitarity violation is a typical feature of nonrenormalizable theories. For example, consider the innocuous case of massless ϕ^6 theory in $d=4$, with interaction term $\lambda\phi^6/M^2$. The coupling constant gives a mass scale M where perturbation theory must break down. Specifically, the lowest-order contribution to $2\phi\to 4\phi$ scattering is

$$\mathcal{M}\sim\frac{\lambda}{M^2},\quad |\mathcal{M}|^2\sim\frac{\lambda^2}{M^4},\quad \sigma\sim\frac{\lambda^2}{M^4}p^2$$

where we included the p^2 factor by dimensional analysis. Then for $p \gtrsim M$ the cross section violates unitarity bounds. The full nonperturbative result could still be unitary, but in reality the most common case is that some new physics takes over. This situation looks a bit different from the infinite tower of terms found above, but it's really the same, since these terms will be generated by renormalization.

The worldline approach to perturbative quantum field theory.

In this approach, we think about the particles of a quantum field theory in terms of ordinary quantum mechanics.

• The simplest way to describe a relativistic particle is to consider maps $x : [0, T] \to \mathbb{R}^n$ with

$$S[x] = \int_0^T dt \sqrt{G_{ab}(x)\dot{x}^a\dot{x}^b}$$

where G is the metric on $\mathbb{R}^n$ and t is interpreted as a parameter; this is just the standard path length action, and it is invariant under diffeomorphisms of the worldline.

• We claim that this is equivalent to the action

$$S[g, x] = \int_M dt\sqrt{g}\left(\frac{1}{2}G_{ab}(x)g^{tt}(t)\dot{x}^a\dot{x}^b + \frac{1}{2}V(x)\right)$$

where we vary with respect to both the worldline metric g on M and the fields x. Without the square root, this naively looks like the nonrelativistic action. The difference is that now we're dealing with a one-dimensional quantum gravity theory, since g is varied too.

• The metric g is specified by a single function $\sqrt{g} = |e|$ with $g^{tt} = e^{-2}$. The Riemann tensor vanishes, so the Einstein-Hilbert term vanishes. The Einstein equation is simply

$$T_{tt} = \frac{2}{\sqrt{g}}\frac{\delta(\sqrt{g}\mathcal{L})}{\delta g^{tt}} \propto \frac{1}{|e|}\left(G_{ab}(x)\dot{x}^a\dot{x}^b - e^2(t)V(x)\right) = 0$$

which yields

$$g_{tt}(t) = e^2(t) = \frac{1}{V(x)}G_{ab}(x)\dot{x}^a\dot{x}^b$$

We see the metric is non-dynamical; it is simply determined by a constraint.

• Plugging this into our action $S[g, x]$ in the case $V(x) = V_0$ gives

$$S[x] = \sqrt{V_0}\int_M dt\sqrt{G_{ab}(x)\dot{x}^a\dot{x}^b}$$

which is the geometrically natural action we encountered earlier.

• To see this another way, the momentum conjugate to the field x^a is

$$p_a = \frac{\partial\mathcal{L}}{\partial\dot{x}^a} = \frac{1}{|e|}G_{ab}(x)\dot{x}^b$$

so the Einstein equation gives the constraint

$$G^{ab}(x)p_a p_b + V(x) = 0$$

which becomes the Klein-Gordan equation, where $m^2 = V_0$. The Hamiltonian is

$$H = p_a \dot{x}^a - \mathcal{L} = p^2 + m^2$$

which vanishes on shell; this occurs generically for reparametrization-invariant theories. (typos here?)

• To see this a third way, we can perform the path integral explicitly in the case where G is the Minkowski metric. In one dimension, diffeomorphisms of the worldline, which are gauge transformations, let us set $g_{tt} = 1$. Then integrating over all possible metrics is equivalent to integrating over T, which is called a Schwinger parameter. In formal language, we are integrating over the moduli space of Riemannian metrics.

• With fixed T, the propagator is

$$\left\langle y \left| e^{-HT} \right| x \right\rangle = \int dpdq \langle y|p\rangle \left\langle p \left| e^{-HT} \right| q \right\rangle \langle q|x\rangle = \int dp e^{ip(x-y)} e^{-T\left(p^2+m^2\right)}$$

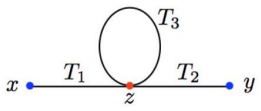
Integrating over T, we indeed find the propagator for a free scalar field in the target space,

$$\int_0^\infty dT \int_{C_I[x,y]} \mathcal{D}x e^{-S} = \int_0^\infty dT \left\langle y \left| e^{-HT} \right| x \right\rangle = \int dp \frac{e^{ip(x-y)}}{p^2+m^2}$$

• We would like to use one-dimensional quantum gravity to describe interacting scalar fields. We can do this by summing over possible topologies of M, replacing the worldline I with a worldgraph Γ. More elaborate setups allow us to include spin.

• Specifically, to compute an r-point correlation function, we sum over all graphs with r endpoints, where, e.g. for ϕ^4 theory all vertices have four edges. Each edge e has a Schwinger parameter T_e integrated over $(0, \infty)$. Each vertex has a position, which is also integrated over, producing momentum-conserving delta functions, and an appropriate factor involving the coupling constant. As usual, we also divide by the symmetry factor.

• Explicitly, in ϕ^4 theory one contribution to the propagator is



$$=$$

$$-\frac{\lambda}{4}\int_0^\infty dT_1 \int_{C_{T_1}[x,z]} \mathcal{D}x e^{-S} \int_0^\infty dT_2 \int_{C_{T_2}[y,z]} \mathcal{D}x e^{-S} \int dz \int_0^\infty dT_3 \int_{C_{T_3}[z,z]} \mathcal{D}x e^{-S}$$

$$=$$

$$-\frac{\lambda}{4}\int dz dp dq d\ell \frac{e^{ip(x-z)}}{p^2+m^2}\frac{e^{iq(y-z)}}{q^2+m^2}\frac{e^{i\ell(z-z)}}{\ell^2+m^2} = -\frac{\lambda}{4}\int dp d\ell \frac{e^{ip(x-y)}}{\left(p^2+m^2\right)^2\left(\ell^2+m^2\right)}$$

• The formalism we've used here is called the worldline approach to quantum field theory, a predecessor to the modern path integral formulation using fields. (The quantum gravity interpretation came much later.) It is explicitly perturbative, since it directly deals with particles and Feynman diagrams.

• In $d = 2$ and $d = 3$, we have a Riemann tensor but no Weyl tensor, so gravitational degrees of freedom do not propagate and the path integral for quantum gravity can be performed. The standard approach to string theory is just the case $d = 2$, where the graph becomes a Riemann surface, and we sum over the topologies of this surface. This approach is thus a perturbative picture of "string field theory", a mysterious subject about which little is known.

5.2.2 Quantum Statistical Mechanics

Our results above are also useful for thermal/statistical field theory (SFT).

Analogies between SFT and QFT

• Consider a QFT with fields $\phi : M \to N$ where $\dim M = D$, so

$$Z_{\text{QFT}} = \int \mathcal{D}\phi e^{iS/\hbar}$$

Wick rotation flips the sign the relative signs of the potential and kinetic terms, giving

$$Z_{\text{QFT}} = \int \mathcal{D}\phi e^{-S_E/\hbar}, \quad \beta = \frac{1}{\hbar}$$

That is, we have

QFT in D spacetime dimensions $\sim$ classical SFT in D spatial dimensions in the sense that their partition functions are simply related. For example, for $D = 1$ we have quantum mechanics $\sim$ classical SFT in 1 spatial dimension.

We've been making this correspondence implicitly above.

• A different correspondence starts with a quantum SFT defined on D spatial dimensions. Partition functions in SFT have the form of a path integral, but with a periodic imaginary "time",

$$Z_{\text{SFT}} = \operatorname{tr} e^{-\beta H} = \sum_n \left\langle n \left| e^{-\beta H} \right| n \right\rangle = \sum_n \int\limits_{C_t[n,n]} \mathcal{D}\phi e^{-S_E/\hbar} = \int\limits_{\mathcal{C}[M\times S^1]} \mathcal{D}\phi e^{-S_E/\hbar}$$

Here S_E is the Euclidean action in $D + 1$ spatial dimensions. Hence we have

quantum SFT in D spatial dimensions $\sim$ classical SFT in $D + 1$ spatial dimensions

where one dimension in the classical SFT has period $t = \hbar\beta$.

• To compute an amplitude in such a theory, integrals $\int dk$ are replaced with sums over discrete frequencies in the periodic time direction. In the high temperature limit $\beta \to 0$, only the zero frequency matters, so we recover classical SFT in D dimensions. Hence the high temperature limit of a quantum SFT in D dimensions is a classical SFT in D dimensions, as expected.

• As we saw in the notes on Undergraduate Physics, amplitudes in quantum mechanics are related to matrix elements of the thermal density matrix $\rho = e^{-\beta H}$ in quantum statistical mechanics, if the time evolution is taken to be imaginary. The diagonal elements of ρ are of course the occupancies, but the off-diagonal elements are harder to interpret.

• Conceptually, the reason that Z_{QFT} doesn't have boundary conditions but Z_{SFT} does is because the time direction in a QFT is infinite, and the $i\epsilon$ damping automatically projects out the vacuum at temporal infinity. By contrast, Z_{SFT} doesn't have a dynamical time at all.

How to perform computations in quantum statistical mechanics.

• In quantum statistical mechanics, our goal is to compute thermal expectation values. Quantum statistical mechanics takes place in zero spatial dimensions and periodic time, so

$$\left\langle \prod_i \hat{O}_i \right\rangle = \frac{\int\limits_{\mathcal{C}[S^1]} \mathcal{D}\phi \prod_i \hat{O}_i e^{-S_E/\hbar}}{\int\limits_{\mathcal{C}[S^1]} \mathcal{D}\phi e^{-S_E/\hbar}}$$

• More explicitly, in the case of a one-dimensional harmonic oscillator,

$$\langle x^n \rangle = \frac{\int dx x^n \int\limits_{C_t[x,x]} \mathcal{D}\phi e^{-S_E/\hbar}}{\int dx \int\limits_{C_t[x,x]} \mathcal{D}\phi e^{-S_E/\hbar}}$$

$$t = \hbar\beta,$$

$$-\frac{1}{\hbar}S_E[x(\tau)] = -\frac{1}{\hbar}\int_0^{\hbar\beta} d\tau \frac{m}{2}\left(\frac{dx}{d\tau}\right)^2 + \frac{k}{2}x^2 = -\frac{1}{2}\int_0^{\hbar\beta} d\tau x(\tau)\hat{D}x(\tau), \quad \hat{D} = -\frac{m}{\hbar}\frac{d^2}{d\tau^2} + \frac{\kappa}{\hbar}$$

Here we pulled the x^n out of the functional integral, because it doesn't depend on τ. However, we can formally consider τ-dependent operators, which behave just as in quantum mechanics. In particular, we get τ-ordered correlators on the left-hand side.

• As before, we may define a generating functional

$$Z[J] = \int \mathcal{D}x(\tau) \exp\left(\int_0^{\hbar\beta} d\tau - \frac{1}{2}x(\tau)\hat{D}x(\tau) + J(\tau)x(\tau)\right)$$

Then $\langle x^n \rangle$ may be obtained by differentiating with respect to $J(0)$ and then setting $J(\tau) = 0$.

• By the same logic as in the zero-dimensional theory, for a free theory $Z[J]$ may be written in terms of the imaginary time Green's function,

$$Z[J] = Z[0]\exp\left(\frac{1}{2}\int d\tau d\tau' J(\tau)G(\tau-\tau')J(\tau')\right), \quad \hat{D}_\tau G(\tau-\tau') = \delta(\tau-\tau'), \quad G(0) = G(\beta\hbar).$$

• Since the Green's function takes place in periodic time, we take a Fourier series,

$$G(\tau) = \frac{1}{\sqrt{\beta\hbar}}\sum_n g_n e^{i\omega_n\tau}, \quad \omega_n = \frac{2\pi n}{\beta\hbar}, \quad n \in \mathbb{Z}$$

where the ω_n are the Matsubara frequencies. Plugging this into the defining equation,

$$G(\tau) = \frac{1}{\beta\kappa}\sum_n \frac{\omega^2}{\omega^2+\omega_n^2}e^{i\omega_n\tau}, \quad \omega = \sqrt{\frac{\kappa}{m}}$$

This is equivalent to

$$G(\tau) = \frac{\hbar\omega}{2\kappa}\left(\frac{e^{\omega|\tau|}}{e^{\hbar\beta\omega}-1} + \frac{e^{-\omega|\tau|}}{1-e^{-\hbar\beta\omega}}\right)$$

as can be shown by contour integrating the latter.

Now we give some explicit examples of computations.

• Correlators may be expanded by Wick's theorem. For example, we have

$$\left\langle \hat{x}^{2n+1} \right\rangle = 0, \quad \left\langle \hat{x}^2 \right\rangle = G(0).$$

To extend to an arbitrary imaginary time, we define the "Heisenberg" operators

$$\bar{x}(\tau) = e^{H\tau/\hbar} \hat{x} e^{-H\tau/\hbar}.$$

One must take some care, since $\bar{x}(\tau)$ is not Hermitian. Now we have

$$\langle T\bar{x}(\tau_1)\,\bar{x}(\tau_2)\rangle = G(\tau_1 - \tau_2)$$

while higher correlators are also decomposed by Wick's theorem.

• Using the form of the Green's function, we have

$$\left\langle \hat{x}^2 \right\rangle = \frac{\hbar\omega}{\kappa}\left(\frac{1}{e^{-\beta\hbar\omega}-1} + \frac{1}{2}\right)$$

Using $\langle H\rangle = 2\langle V\rangle = \kappa G(0)$ and $\hat{H} = \hbar\omega(\hat{n} + 1/2)$, we find the Bose-Einstein distribution.

• We can compute the position probability distribution by using our knowledge of the moments. Alternatively, we can perform the computation in one step, as the probability distribution is

$$\langle \delta(\hat{x} - x_0)\rangle \equiv \int dk \left\langle e^{ik(\hat{x}-x_0)} \right\rangle = \int dk e^{-ikx_0} \frac{Z[ik\delta(\tau)]}{Z[0]} = \int dk e^{-ikx_0} e^{-k^2 G(0)/2}$$

where we used the explicit form of $Z[J]$. Thus, we conclude

$$\langle \delta(\hat{x} - x_0)\rangle = \frac{e^{-x_0^2/2G(0)}}{\sqrt{2\pi G(0)}}$$

In the low temperature limit this gives the ground state probability distribution, while in the high temperature limit this gives the Boltzmann distribution.

• For the harmonic oscillator, the computations done above can also be done in the "Heisenberg" picture. Starting with the usual creation and annihilation operators, define

$$\bar{a}(\tau) = e^{H\tau/\hbar} a e^{-H\tau/\hbar}, \quad \bar{a}^\dagger = e^{H\tau/\hbar} a^\dagger e^{-H\tau/\hbar}$$

Again we must be careful, as $\bar{a}^\dagger(\tau) \neq (\bar{a}(\tau))^\dagger$. Integrating the Heisenberg equation of motion,

$$\bar{a}(\tau) = e^{-\omega\tau} a, \quad \bar{a}^\dagger(\tau) = e^{\omega\tau} a^\dagger$$

• Now we may straightforwardly compute imaginary time-dependent thermal averages,

$$\left\langle \bar{a}(\tau)\bar{a}^\dagger(0) \right\rangle = \frac{1}{Z(\beta)} \operatorname{tr} e^{-\beta H} \bar{a}(\tau)\bar{a}^\dagger(0) = \frac{e^{-\omega\tau}}{1 - e^{-\beta\hbar\omega}}$$

Using the relationship between $\hat{x}$ and $\hat{a}^\dagger$ and $\hat{a}$, which continues to hold with τ-dependence, we may compute $\langle \bar{x}(\tau)\bar{x}(0)\rangle$, which agrees with the Green's function computed above.

• We can set up perturbation theory with Feynman diagrams just as we did earlier. For example, for the anharmonic oscillator with a $\lambda\hat{x}^4/4!$ term, we have

$$Z_\lambda[J] = \int \mathcal{D}x(\tau) \exp\left(-\frac{S_E}{\hbar} + \int_0^{\hbar\beta} d\tau Jx - \frac{\lambda}{4!\hbar}x^4\right) = \exp\left(-\frac{\lambda}{4!\hbar}\int_0^{\hbar\beta} d\tau \frac{\delta^4}{\delta J(\tau)^4}\right) Z_0[J]$$

where S_E is the Euclidean action for the harmonic oscillator. We can then expand the exponential in a series, using our simple expression for $Z_0[J]$, and simplify each term by Wick's theorem. Each set of contractions yields a Feynman diagram.

- Hence we have the following Feynman rules for computing the partition function $Z_\lambda[0]$.
- Draw n internal points at times τ_i.
- For every point, multiply by $-\lambda/\hbar$ and integrate over τ_i.
- Contract the $4n$ edges pairwise. For each edge, write $G(\tau_i - \tau_j)$.
- Multiply by $Z_0[0]$ and sum over all contractions.

Summing over contractions, we get equivalence classes of diagrams, where we must divide by the symmetry factor as usual. We can evaluate correlators similarly, though now there are external points.

5.2.3 Quantum Fields

Finally, we generalize to quantum fields, returning to Lorentzian signature, and tie up some loose ends from the previous sections.

- For a scalar field, we may define field eigenstates by

$$\hat{\phi}(x)|\phi(x)\rangle = \phi(x)|\phi(x)\rangle$$

and similarly field momentum eigenstates $|\pi(x)\rangle$, and use them to construct a path integral as before using the formal completeness relation

$$\int \mathcal{D}\phi(\mathbf{x})|\phi(\mathbf{x})\rangle \left\langle \phi(\mathbf{x}) \right| = \int \mathcal{D}\pi(\mathbf{x}) \left| \pi(\mathbf{x}) \right\rangle \langle \pi(\mathbf{x})| = 1$$

The path integral then yields the transition amplitude between two states $|\phi_a\rangle$ and $|\phi_b\rangle$.

- In relativistic quantum field theory, we are usually interested in vacuum expectation values, since they appear in the LSZ reduction formula. If we let the vacuum be $|\Omega\rangle$, then we can isolate it from arbitrary boundary conditions, as long as they have some overlap with the vacuum state, by taking the time to infinity in a slightly imaginary direction. The result is

$$\left\langle \Omega \left| \mathcal{T} \prod_{i=1}^{n} \hat{\mathcal{O}}_i(x_i) \right| \Omega \right\rangle = \lim_{T\to\infty(1-i\epsilon)} \frac{\int \mathcal{D}\phi(x) e^{iS} \prod_{i=1}^{n} \mathcal{O}_i(x_i)}{\int \mathcal{D}\phi(x) e^{iS}}$$

where the paths on the right-hand side run from $-T$ to T, and the denominator cancels out the phase and overlap factors, so that $\langle\Omega|\Omega\rangle = 1$. We will keep this implicit below.

- Taking the time to infinity this way effectively provides an infinitesimal damping which makes the path integral converge. It is always necessary in the definition of the path integral, even in Lorentzian signature, and it is what makes the transition to Euclidean signature natural. It is equivalent to add an $i\epsilon$ term in the action like

$$\mathcal{L} \supset \left(m^2 - i\epsilon\right)\phi^2$$

This manifestly yields the expected $i\epsilon$ in the Feynman propagator. In all cases, whenever we write m^2, we really mean $m^2 - i\epsilon$.

• A general state of the quantum field is a superposition of the field eigenstates, so it is a wavefunctional of the classical field configurations. For example, the vacuum wavefunctional can be computed from the path integral as

$$\langle \phi(x)|\Omega\rangle = \lim_{t_i \to -\infty(1-i\epsilon)} \int \mathcal{D}\phi(\mathbf{x}) e^{iS}$$

where the final boundary condition is $\phi(x)$ and the initial boundary condition is arbitrary.

• The partition function can be interpreted as the vacuum to vacuum amplitude,

$$\left\langle \Omega \left| e^{-iHT} \right| \Omega \right\rangle = \int\limits_{\text{time } T} \mathcal{D}\phi(x) e^{iS} = \mathcal{Z}[0] = \text{ sum of vacuum diagrams}$$

which implies that it is equal to e^{-iET} where E is the vacuum energy, which is generally divergent. Thus dividing by $\mathcal{Z}[0]$ to compute expectation values is equivalent to renormalizing the vacuum energy to zero. Then $\mathcal{W}[0]$ is simply the vacuum energy times T.

Since Dirac fields are complex, we'll also have to deal with complex Grassmann numbers.

• We can construct complex Grassmann numbers from real Grassmann numbers, e.g.

$$\theta = \frac{1}{\sqrt{2}}\left(\eta_1 + i\eta_2\right), \quad \theta^* = \frac{1}{\sqrt{2}}\left(\eta_1 - i\eta_2\right)$$

Using the change of variables formula derived earlier,

$$\int d\theta^* d\theta \theta\theta^* = (-i)(i) \int d\eta_2 d\eta_1 \eta_1 \eta_2 = 1$$

For multiple Grassmann variables we define $d^n\theta d^n\theta^* = d\theta_n d\theta_n^* ... d\theta_1 d\theta_1^*$. Note that $d\theta_i d\theta_i^*$ is Grassmann-even.

• By convention, we take complex conjugation to reverse the order of products, $(\theta\eta)^* = \eta^*\theta^*$.

• A complex Gaussian integral takes the form

$$\int d^n\theta d^n\theta^* e^{-\theta_i^* M_{ij} \theta_j} = \int d^n\theta d^n\theta^* e^{-\sum\limits_i \theta_i^* m_i \theta_i} = \prod_i m_i = \det M$$

where the m_i are the eigenvalues of M. Note that the derivation of this formula does not require θ^* to be the conjugate of θ, and that the final result has no square root.

• The partition function with anticommuting sources χ and χ^* is

$$Z(\chi) = \int d^n\theta d^n\theta^* e^{-\theta_i^* M_{ij} \theta_j + \chi_i^* \theta_i + \theta_i^* \chi_i}$$

and performing the shift $\theta \to \theta + M^{-1}\chi$ yields

$$Z(\chi) = (\det M) e^{\chi_i^* \left(M^{-1}\right)_{ij} \chi_j}$$

Note that M must be antisymmetric. When n is odd, M has a zero eigenvalue and hence M^{-1} does not exist, so the above formula does not apply.

• In the case of a Dirac field, there is an independent Grassmann algebra at every point in spacetime, and we write

$$\psi(x) = \sum_i \psi_i \phi_i(x)$$

where the $\phi_i(x)$ are a basis of four-component spinors, and the ψ_i form a basis of the Grassmann algebra at x. In particular, this is how one should think of relativistic spinors even on the classical level; otherwise, the anticommutativity must be put in 'by hand' upon quantization.

• As an example, in $d = 4$, every interaction of the form $(\bar{\psi}\psi)^5$ is trivial, because there are only eight independent Grassmann variables at every point. This is physically sensible, because interactions are contact interactions, and we cannot put five Dirac fermions at the same point.

Next, we explicitly construct the fermionic path integral using coherent states.

• We consider a single fermionic degree of freedom, e.g. a single mode that could be occupied by one kind of fermion. We construct the path integral using coherent states,

$$\hat{\psi}|\psi\rangle = \psi|\psi\rangle$$

where ψ is a complex Grassmann number and $\hat{\psi}$ is an annihilation operator. The operators $\hat{\psi}$ and $\hat{\psi}^\dagger$ obey

$$\left\{\hat{\psi}, \hat{\psi}^\dagger\right\} = 1$$

with all other anticommutators zero. Note that we are allowing 'scalar multiplication' with Grassmann numbers in our Hilbert space, though our final answers will be ordinary numbers.

• We postulate a unique ground state $|0\rangle$ so that $\hat{\psi}|0\rangle = 0$ and define $\hat{\psi}^\dagger|0\rangle = |1\rangle$. Then there are no other states. The desired coherent state is

$$|\psi\rangle = |0\rangle - \psi|1\rangle.$$

To show this very explicitly, note that

$$\hat{\psi}|\psi\rangle = -\hat{\psi}\psi|1\rangle = \psi\hat{\psi}|1\rangle = \psi\hat{\psi}\hat{\psi}^\dagger|0\rangle = \psi|0\rangle = \psi|\psi\rangle$$

It is easy to make a mistake, as everything can have Grassmann parity. The matrix elements of $\hat{\psi}$ are Grassmann numbers, and the state $|\psi\rangle$ itself has Grassmann coefficients.

• To make the analogy clearer, note that

$$|\psi\rangle = e^{-\psi\hat{\psi}^\dagger}|0\rangle$$

In the bosonic case, coherent states are defined as

$$a|\mu\rangle = \mu|\mu\rangle, \quad |\mu\rangle = e^{\mu a^\dagger}|0\rangle.$$

The latter expression is identical up to a sign.

• The complex conjugate state $\langle\psi|$ is defined by

$$\langle\psi|\hat{\psi}^\dagger = \langle\psi|\psi^*, \quad \langle\psi| = \langle 0| - \langle 1|\psi^* = \langle 0|e^{-\hat{\psi}\psi^*}$$

The inner product of two coherent states is

$$\langle\psi|\psi'\rangle = \langle 0|0\rangle + \langle 1\,|\psi^*\psi'|\,1\rangle = 1 + \psi^*\psi' = e^{\psi^*\psi'}.$$

• Finally, the completeness relation is

$$\int d\psi^* d\psi |\psi\rangle e^{-\psi^*\psi} \langle\psi| = 1$$

This result holds because the left-hand side is equal to $|0\rangle\langle 0| + |1\rangle\langle 1|$.

We now use this setup to compute transition amplitudes.

• We compute the transition amplitude

$$\left\langle \psi_f \left| e^{-i\hat{H}\left(t_f - t_i\right)} \right| \psi_i \right\rangle, \quad \hat{H} = \hat{\psi}^\dagger M \hat{\psi}$$

for a quadratic Hamiltonian. As in the bosonic path integral, we split the time interval by inserting copies of the identity.

• Each copy comes with a factor of

$$\int d\psi_j^* d\psi_j \left\langle \psi_{j+1} \left| e^{-i\hat{H}\delta t} \right| \psi_j \right\rangle e^{-\psi_j^*\psi_j} \left\langle \psi_j \right|$$

Expanding the exponential, we find

$$\left\langle \psi_{j+1} \left| e^{-i\hat{H}\delta t} \right| \psi_j \right\rangle = \left(1 - i\psi_{j+1}^* M \psi_j \delta t\right) \langle \psi_{j+1} | \psi_j \rangle = e^{\psi_{j+1}^*\psi_j} e^{-i\psi_{j+1}^* M \psi_j \delta t}.$$

Then some of the phase factors telescope, and we find

$$\begin{aligned} \langle \psi_f, t_f | \psi_i, t_i \rangle &= \lim_{N\to\infty} \int \prod_{j=1}^{N} d\psi_j^* d\psi_j \exp\left(\sum_{j=0}^{N} -\psi_{j+1}^* \left(\psi_{j+1} - \psi_j\right) - i\delta t H\left(\psi_{j+1}^*, \psi_j\right) \right) \\ &= \int \mathcal{D}\psi^* \mathcal{D}\psi e^{i\int_{t_i}^{t_f} dt \left(\psi^* i\frac{\partial\psi}{\partial t} - H\right)} \end{aligned}$$

and in the usual case the quantity in parentheses is the Lagrangian.

• Now, the Dirac field is a relativistic field, so the field operator necessarily contains both creation and annihilation operators. Hence the interpretation is somewhat different from above, but the same manipulations work. In this case we integrate $\mathcal{D}\bar{\psi}\mathcal{D}\psi$ and define the generating functional

$$Z[\eta, \bar{\eta}] = \int \mathcal{D}\bar{\psi}\mathcal{D}\psi e^{iS[\psi,\bar{\psi}] + i\bar{\eta}\psi + i\bar{\psi}\eta}$$

and by the same manipulations in the bosonic case, we have

$$\left\langle \Omega \left| T\psi(x_1)\bar{\psi}(x_2) \right| \Omega \right\rangle = \frac{1}{Z[0,0]} \frac{\delta}{i\delta\bar{\eta}(x_1)} \frac{-\delta}{i\delta\eta(x_2)} Z[\eta, \bar{\eta}] \Big|_{\eta=\bar{\eta}=0}$$

where we pick up an extra minus sign by anticommutation.

• By our earlier result for a Gaussian integral with linear sources, the Feynman propagator is again the inverse of the kinetic term $-i(i\not{\partial} - m)$, recovering the usual result in Fourier space.

Note. As mentioned earlier, spinors should be Grassmann-valued in classical field theory, leading to tricky signs. We defined the complex conjugate so that $(\theta_1\theta_2)^* = \theta_2^*\theta_1^*$, and define the transpose of a single Grassmann number to do nothing. Then for spinor fields ψ_i,

$$\left(\bar{\psi}_1\psi_2\right)^T = -\psi_2^T\psi_1$$

because the terms in the sum have the order of the Grassmann variables flipped. But more nicely,

$$\left(\bar{\psi}_1\psi_2\right)^\dagger = -\left(\psi_2^T\bar{\psi}_1^T\right)^* = \psi_2^\dagger\bar{\psi}_1^\dagger$$

so the adjoint simply applies to everything in flipped order.

5.2.4 Symmetries of the Path Integral

In this section, we derive the Ward-Takahashi identities. They are exact, nonperturbative relations between correlation functions that result from symmetries of the path integral. We begin by reviewing Noether's theorem.

• We work in curved spacetime using the language of differential forms, restating every result in coordinates. Consider the infinitesimal transformation

$$\delta_\epsilon\phi(x) = \epsilon f\left(\phi, \partial_\mu\phi\right)$$

The transformation is local if f depends only on the fields and their derivatives at x, in which case it is generated by the vector

$$V_f = \int\limits_M d^dx\sqrt{g}f(\phi,\partial\phi)\frac{\delta}{\delta\phi(x)}$$

acting on the space of fields.

• This transformation is a symmetry if it leaves the action invariant. Now, we introduce the so-called "Noether trick", promoting ϵ to be spacetime-dependent. Since we have a symmetry for constant ϵ, the variation of the action should depend only on derivatives of ϵ, so we can always find some j so that

$$\delta_\epsilon S[\phi] = -\int\limits_M *j\wedge d\epsilon = -\int\limits_M d^dx\sqrt{g}g^{\mu\nu}j_\mu(x)\partial_\nu\epsilon(x)$$

One can check j is just the conserved current found in the usual proof of Noether's theorem.

• When the equations of motion hold, the action is invariant under any infinitesimal change in the fields, $\delta_\epsilon S[\phi] = 0$. Integrating by parts and choosing $\epsilon(x)$ to have compact support,

$$d*j = \partial_\mu\left(\sqrt{g}g^{\mu\nu}j_\nu\right) = 0$$

• We define the charge Q on a hypersurface N of codimension one by

$$Q[N] = \int\limits_N *j = \int\limits_N d^{d-1}x\sqrt{g_N}j_\mu n^\mu$$

where g_N is the metric pulled back to N and n^μ is a unit normal.

• Now consider two such hypersurfaces N_0 and N_1 bounding a region M'. Then

$$Q\left[N_1\right] - Q\left[N_0\right] = \int\limits_{\partial M'} *j = \int\limits_{M'} d*j = 0$$

That is, the charge depends on N only through its homology class. In the simple case where the N_i are constant time-slices of Minkowski space, this means Q is conserved in time.

Example. For the complex scalar field we have

$$S[\phi] = \int_M d\bar{\phi} \wedge *d\phi + *V\left(|\phi|^2\right)$$

where we write conjugation with a bar to avoid confusion with the Hodge star. Then by direct computation, the current is $j = i(\phi d\bar{\phi} - \bar{\phi} d\phi)$ and for a time-slice,

$$Q[N] = i \int_N *(\phi d\bar{\phi} - \bar{\phi} d\phi) = i \int d\mathbf{x} \phi \partial_0 \bar{\phi} - \bar{\phi} \partial_0 \phi$$

The canonical momenta are

$$\pi = \frac{\partial \mathcal{L}}{\partial\left(\partial_0 \phi\right)} = \partial_0 \bar{\phi}, \quad \bar{\pi} = \frac{\partial \mathcal{L}}{\partial\left(\partial_0 \bar{\phi}\right)} = \partial_0 \phi$$

so the charge is

$$Q = i \int d\mathbf{x} (\phi \pi - \bar{\phi} \bar{\pi})$$

which indeed generates the transformations by Poisson brackets.

Note. Dynamical symmetries are symmetries of the equations of motion that are not symmetries of the Lagrangian; they are associated with integrable systems. For example, for a free particle, the Lagrangian has an $O(n)$ symmetry, while the equation of motion has a $\mathrm{GL}_n(\mathbb{R})$ symmetry because it only requires the particle to move uniformly on a line.

Next, we turn to symmetries in the quantum theory.

• In the quantum theory, the local field transformation $\phi \to \phi'(\phi)$ must leave the product of the path integral weight and measure invariant to be a symmetry,

$$\mathcal{D}\phi e^{-S[\phi]} = \mathcal{D}\phi' e^{-S[\phi']}$$

This is necessary and sufficient, but since we have more experience with symmetries of the action from classical field theory, we often use those and hope the measure is invariant as well.

• For example, suppose $S[\phi]$ only depends on the derivatives of ϕ. Then classically we have the shift symmetry $\phi(x) \to \phi(x) + \phi_0$. It would appear that the measure would obviously be invariant, but the measure is not defined without regularization, and the regularized measure might not be invariant.

• If $M = T^d$, we might expand $\phi(x)$ in a Fourier series, then cut off the sum. Since the constant translation only affects the lowest Fourier mode, and the regularized measure integrates over all values of this coefficient, the measure is indeed invariant.

• As another example, consider rotational symmetry in Euclidean space. The action is $SO(d)$ invariant if it is a scalar under rotation. We can regularize the path integral by integrating over all Fourier modes where the $SO(d)$ invariant quantity $p^\mu p_\mu$ is less than some cutoff; this is slightly more subtle for $SO(d-1,1)$ in Minkowski space. Alternatively, we can regularize by replacing space with a lattice, but this breaks $SO(d)$ down to the lattice's point group.

• Sometimes we may run into tradeoffs, where only some symmetries can be preserved, and we may intentionally choose which to lose. A worse situation is when there doesn't exist any regulator that preserves a symmetry, in which case the symmetry is said to be anomalous; it is said to be incompatible with quantum mechanics itself.

• For example, QED in four dimensions with a massless fermion is conformally invariant, but there is a conformal anomaly; indeed, the beta functions are nonzero in DR, with a hard cutoff, and on a lattice. It's possible to prove that a symmetry is anomalous by considering the geometry and topology of the space of fields, using sophisticated mathematics such as the Atiyah-Singer index theorem.

• The Standard Model contains a number of anomalies, such as the global symmetry of baryon number. In general, it's acceptable for global symmetries to be anomalous, but not gauge symmetries, since we lose the Ward identity and hence unitarity. The hypercharges in the Standard Model are fixed by requiring gauge anomalies to vanish.

• Consider operators whose only variation under a symmetry transformation is through the transformation of the field, e.g. scalar operators for rotations. Then $\mathcal{O}(\phi) \to \mathcal{O}(\phi')$, and on a compact manifold M we have

$$\int \mathcal{D}\phi e^{-S[\phi]} \prod_i \mathcal{O}_i(\phi(x_i)) = \int \mathcal{D}\phi' e^{-S[\phi']} \prod_i \mathcal{O}_i(\phi'(x_i)) = \int \mathcal{D}\phi e^{-S[\phi]} \prod_i \mathcal{O}_i(\phi'(x_i))$$

where we simply renamed the dummy variable in the first step, then defined ϕ' in terms of ϕ and used the definition of a symmetry in the second.

• Therefore, we conclude (leaving the time ordering implicit)

$$\langle \mathcal{O}_1(\phi(x_1)) ... \mathcal{O}_n(\phi(x_n)) \rangle = \langle \mathcal{O}_1(\phi'(x_1)) ... \mathcal{O}_n(\phi'(x_n)) \rangle$$

In general, we will call any identity between correlation functions derived from a symmetry a Ward or Ward-Takahashi identity. This is an example of a 'global' Ward-Takahashi identity.

Example. Consider the $U(1)$ symmetry of a complex scalar field,

$$\phi \to \phi' = e^{i\alpha}\phi, \quad \bar{\phi} \to \bar{\phi}' = e^{-i\alpha}\bar{\phi}.$$

The path integral measure is invariant under this symmetry as long as we integrate over as many modes of $\bar{\phi}$ as we do of ϕ. Therefore for $\mathcal{O}_i = \phi^{r_i}\bar{\phi}^{s_i}$, we have

$$\langle \mathcal{O}_1(x_1) ... \mathcal{O}_n(x_n) \rangle = e^{i\alpha \sum_i (r_i - s_i)} \langle \mathcal{O}_1(x_1) ... \mathcal{O}_n(x_n) \rangle$$

Then correlators vanish unless they contain the same number of ϕ and $\bar{\phi}$ fields.

Example. If the action and path integral measure are translationally invariant, and the operators $\mathcal{O}_i$ depend on x only through their dependence on $\phi(x)$, then

$$\langle \mathcal{O}_1(x_1) ... \mathcal{O}_n(x_n) \rangle = \langle \mathcal{O}_1(x_1 - a) ... \mathcal{O}_n(x_n - a) \rangle$$

so correlators only depend on position differences. Similarly, Lorentz invariance ensures that correlators can only depend on the invariant interval between the insertion points.

Note. Formally, the path integral measure picks up a Jacobian factor,

$$\mathcal{D}\phi' = \det\left(\frac{\delta\phi'(x)}{\delta\phi(y)}\right)\mathcal{D}\phi$$

In the case of the transformation described above, we have

$$\frac{\delta}{\delta\phi(y)}(\phi(x) + \epsilon f(x)) = \delta(x - y) + \epsilon\frac{\partial f(\phi(x))}{\partial\phi(y)}$$

and hence the Jacobian is

$$\det\left(\frac{\delta\phi'(x)}{\delta\phi(y)}\right) = 1 + \mathrm{tr}\left(\epsilon\frac{\delta f(\phi(x))}{\delta\phi(y)}\right)$$

Then classical symmetries linear in the fields should remain symmetries in the quantum theory, because the argument of the determinant is field-independent, so the Jacobian is just a constant that cancels out. However, this formal argument is deceptive, because we are working with an undefined, "ideal" path integral measure. Instead we must check invariance directly.

These results roughly correspond to charge conservation, but we can derive more powerful identities that correspond to current conservation, usually called the Ward-Takahashi identities. To warm up, we derive the Schwinger-Dyson and Ward-Takahashi identities in standard notation.

• We consider the partition function of a generic theory $Z[J]$ and a transformation

$$\phi(x) \to \phi'(x) = \phi(x) + \epsilon\Delta\phi(x)$$

not necessarily a symmetry, which leaves the measure invariant. Then infinitesimally

$$Z[J] = \int \mathcal{D}\phi e^{i(S[\phi]+\phi\cdot J)} = \int \mathcal{D}\phi' e^{i(S[\phi']+\phi'\cdot J)} = \int \mathcal{D}\phi e^{i(S[\phi]+\phi\cdot J)}\left(1 + i\left(\frac{\delta S}{\delta\phi} + J\right)\epsilon\Delta\phi\right)$$

which shows that

$$\int \mathcal{D}\phi e^{i(S[\phi]+\phi\cdot J)} \int dy \left(\frac{\delta S}{\delta\phi(y)} + J(y)\right)\Delta\phi(y) = 0.$$

• Next, we consider the specific transformation that shifts the field at one point,

$$\Delta\phi(y) = \delta(y - x)$$

which should leave a reasonable measure invariant; this shift-invariance was the motivation behind our definition of Grassmann integration. Then we find

$$\int \mathcal{D}\phi \left(\frac{\delta S}{\delta\phi(x)} + J(x)\right) e^{i(S[\phi]+J\cdot\phi)} = 0$$

which states that the classical equations of motion hold in vacuum expectation.

• To get relationships between correlation functions, we act by n field derivatives $\delta/i\delta J(x_i)$. This yields one term with n factors of ϕ, and n terms with $n-1$ factors of ϕ, where one of the derivatives hits the $J(x)$ factor. Setting $J = 0$ gives

$$\left\langle \frac{\delta S}{\delta\phi(x)} \prod_{i=1}^{n} \phi(x_i) \right\rangle = i \sum_{i=1}^{n} \left\langle \phi(x_1)...\widehat{\phi}(x_i)\,\delta(x - x_i)\,...\phi(x_n) \right\rangle$$

where the hat denotes a missing argument. This is the Schwinger-Dyson equation, as we derived earlier. Letting X stand for all the fields, it can be concisely written as

$$\left\langle \frac{\delta S}{\delta\phi(x)} X \right\rangle = i \left\langle \frac{\delta X}{\delta\phi(x)} \right\rangle$$

Indeed, here X can be any function of the fields.

• The classical equivalent of a time-ordered correlator is just a product of numbers,

$$\langle \phi(x_1)...\phi(x_n)\rangle \to \phi(x_1)...\phi(x_n)$$

so in the classical limit, the left-hand side is zero as $\delta S/\delta\phi(x) = 0$. Thus the contact terms on the right encode the difference between classical products and quantum correlation functions.

• As an example, consider a free scalar field. Then the Schwinger-Dyson equation for $n = 1$ reduces to the statement that the Feynman propagator is a Green's function for the Klein-Gordan operator; the contact term supplies the required delta function. For an interacting theory, we would instead find a relationship between the two-point correlator and higher correlators, which we can use to organize a perturbative expansion.

• To derive the Ward-Takahashi identities, we do the same procedure, but for a classical global symmetry associated with a field change $\delta\phi$. Here we have

$$\Delta\phi(y) = \delta(y-x)\delta\phi(x), \quad \frac{\delta S}{\delta\phi(x)}\delta\phi(x) = -\partial_\mu j^\mu(x)$$

Assuming this transformation leaves the measure invariant as well, we have

$$\int \mathcal{D}\phi e^{i(S[\phi]+\phi\cdot J)}\left(-\partial_\mu j^\mu(x) + J(x)\delta\phi(x)\right) = 0$$

Taking derivatives as before gives the Ward-Takahashi identity

$$\partial_\mu \left\langle j^\mu(x)\prod_{i=1}^n \phi(x_i)\right\rangle = -i\sum_{i=1}^n \left\langle \phi(x_1)...\widehat{\phi}(x_i)\,\delta\phi(x)\delta(x-x_i)...\phi(x_n)\right\rangle$$

where the derivative acts on x. In the case $n = 0$, we see the current j^μ is conserved in expectation, $\partial_\mu\langle j^\mu\rangle = 0$.

Note. It is conventional in theoretical physics to write the Schwinger-Dyson equation as, e.g.

$$\frac{\delta S}{\delta\phi(x)}\phi(y) = i\delta(x-y)$$

and call this an "operator equation", even though the two sides are not equal as operators on the Hilbert space. The sociological reason behind this is that statements about operators are difficult to make, since they are fraught with short-distance singularities. In the mathematical physics community, these difficulties are addressed in a formalism which replaces operators with operator-valued distributions. In the theoretical physics community, these issues are avoided by simply redefining the phrase "operator equation" to mean something weaker. The operator equation $\mathcal{O}_1 = \mathcal{O}_2$ means that

$$\langle \mathcal{O}_1 X\rangle = \langle \mathcal{O}_2 X\rangle$$

for any product of operators in X involving fields evaluated at times different from those of $\mathcal{O}_1$ and $\mathcal{O}_2$. (If the times matched, we would pick up extra contact terms.)

Ward-Takahashi in curved spacetime, using symmetries of the path integral

• We consider an infinitesimal symmetry of the path integral, $\phi \to \phi' = \phi + \epsilon\delta\phi$, where ϵ is constant. Then if we allow ϵ to vary in space, falling off at infinity to avoid boundary terms,

$$\mathcal{Z} = \int \mathcal{D}\phi' e^{-S[\phi']} = \int \mathcal{D}\phi e^{-S[\phi]}\left(1 - \int_M *j\wedge d\epsilon\right)$$

as we saw classically, but the variation of the measure may also contribute to j. Then

$$0 = -\int_M *\langle j(x)\rangle \wedge d\epsilon = \int_M \epsilon(x) d * \langle j(x)\rangle$$

which implies that $j^\mu(x)$ is a conserved current in expectation, $\partial_\mu \langle j^\mu(x)\rangle = 0$.

• Now, as before, we introduce local operators which transform as

$$\mathcal{O} \to \mathcal{O}' = \mathcal{O} + \epsilon\delta\mathcal{O}$$

Accounting for both the change in the action and measure, and the operators, we find

$$\int_M \epsilon(x) \wedge d * \left\langle j(x) \prod_{i=1}^n \mathcal{O}_i(x_i) \right\rangle = -\sum_{i=1}^n \left\langle \epsilon(x_i)\, \delta\mathcal{O}_i(x_i) \prod_{j\neq i} \mathcal{O}_j(x_j) \right\rangle$$

Note that the exterior derivative d acts on x, and the correlators are time-ordered as usual.

• To finish up, we would like to strip off the parameter $\epsilon(x)$. Note that

$$\epsilon(x_i)\, \delta\mathcal{O}_i(x) = \int_M *\delta(x - x_i)\, \epsilon(x) \delta\mathcal{O}_i(x_i) = \int_M \delta(x - x_i)\, \epsilon(x) \delta\mathcal{O}_i(x_i) \sqrt{g} dx$$

Having expressed both sides as integrals, we simply have

$$d * \left\langle j(x) \prod_{i=1}^n \mathcal{O}_i(x_i) \right\rangle = - * \sum_{i=1}^n \delta(x - x_i) \left\langle \delta\mathcal{O}_i(x_i) \prod_{j\neq i} \mathcal{O}_j(x_j) \right\rangle$$

This is the Ward-Takahashi identity in a curved spacetime. In more pedestrian notation, in flat spacetime, this reduces to

$$\partial_\mu \left\langle j^\mu(x) \prod_{i=1}^n \mathcal{O}_i(x_i) \right\rangle = -\sum_{i=1}^n \delta(x - x_i) \left\langle \delta\mathcal{O}_i(x_i) \prod_{j\neq i} \mathcal{O}_j(x_j) \right\rangle$$

• Next, we integrate over x to investigate charge conservation. Consider integrating over some region $M' \subset M$ with $\delta M' = N_1 - N_0$, as we studied classically, where M' contains all the points x_i. Then

$$\left\langle Q[N_1] \prod_i \mathcal{O}_i(x_i) \right\rangle - \left\langle Q[N_0] \prod_i \mathcal{O}_i(x_i) \right\rangle = -\sum_{i=1}^n \left\langle \delta\mathcal{O}_i(x_i) \prod_{j\neq i} \mathcal{O}_j(x_j) \right\rangle$$

If M is compact without boundary and $M' = M$, the left-hand side vanishes, and

$$\sum_{i=1}^n \left\langle \delta\mathcal{O}_i(x_i) \prod_{j\neq i} \mathcal{O}_j(x_j) \right\rangle = 0$$

which is just the infinitesimal form of the global Ward-Takahashi identity under the symmetry generated by Q.

• If M has a boundary, we pick up extra terms. For example, we saw earlier that correlation functions of ϕ vanish if they have nonzero $U(1)$ charge. In this more general context, they vanish unless their charge is equal to the difference of the initial and final $U(1)$ charges.

• A more subtle example is when M is non-compact. In this case we must impose boundary conditions at infinity, e.g. that the field approaches a constant that is a minimum of the effective potential. This can result in spontaneous symmetry breaking.

Note. We may use the Ward-Takahashi identity to show that the conserved charge generates the symmetry transformation. We integrate over a spacetime region bounded by $t = t_-$and $t = t_+$, where the time interval contains x_1^0 but none of the other x_i^0. Then

$$\langle Q\left(t_+\right)\mathcal{O}_1(x_1)Y\rangle - \langle Q\left(t_-\right)\mathcal{O}_1(x_1)Y\rangle = -\langle \delta\mathcal{O}_1(x_1)Y\rangle\,, \quad Y = \prod_{i=2}^{n}\mathcal{O}_i\left(x_i\right)$$

Taking the limits $t_- \to x_1^0$ and $t_+ \to x_1^0$, the left-hand side becomes a commutator because the correlators are time-ordered. Since Y is arbitrary, we conclude

$$[Q, \mathcal{O}] = -\delta\mathcal{O}$$

as an operator equation in the Hilbert space.

Relation of quantum symmetries and symmetries of the 1PI effective action.

• Under the infinitesimal symmetry $\phi \to \phi' = \phi + \epsilon f(\phi, \partial\phi)$ we have

$$\begin{aligned}
\mathcal{Z}[J] &= \int \mathcal{D}\phi' \exp\left(-\frac{1}{\hbar}\left(S\left[\phi'\right] + \int_M dx J(x)\phi'(x)\right)\right) \\
&= \int \mathcal{D}\phi \exp\left(-\frac{1}{\hbar}\left(S[\phi] + \int_M dx J(x)\phi'(x)\right)\right) \\
&= \mathcal{Z}[J]\left(1 - \frac{\epsilon}{\hbar}\int_M dx J(x)\langle f(\phi, \partial\phi)\rangle_J\right)
\end{aligned}$$

where the expectation value is taken in the presence of the source J. Then we have

$$\int_M dx J(x)\langle f(\phi, \partial\phi)\rangle_J = 0$$

• Next, we evaluate the current at

$$J_\Phi(y) = -\frac{\delta\Gamma[\Phi]}{\delta\Phi(y)}, \quad \langle\phi\rangle_{J_\Phi} = \Phi$$

to give

$$\int_M dx \frac{\delta\Gamma[\Phi]}{\delta\Phi(x)}\langle f(\phi, \partial\phi)\rangle_{J_\Phi} = 0$$

Therefore, the effective action is invariant under the transformation

$$\Phi \to \Phi' = \Phi + \epsilon\langle f(\phi, \partial\phi)\rangle_{J_\Phi}$$

which involves expectation values of the transformations, which can be rather complicated. This result is called a Slavnov-Taylor identity.

• When the symmetry is linear, i.e. f is linear in the fields, we have

$$\langle f(\phi, \partial\phi)\rangle_{J_\Phi} = f(\Phi, \partial\Phi)$$

so the effective action is invariant under the transformation

$$\Phi \to \Phi' = \Phi + \epsilon f(\Phi, \partial\Phi)$$

Therefore, all symmetries of the classical action linear in the fields, under which the path integral measure is invariant, become symmetries of the quantum 1PI action. For example, this result ensures that a ϕ^3 coupling cannot be generated in ϕ^4 theory by $\mathbb{Z}_2$ symmetry, that $O(n)$ symmetry is preserved in the $O(n)$ model, and that Lorentz invariance is preserved.

6 Experiments and methods for experiments

6.0.1 Ideas for experimental determining parameters of fields

(связь с экспериментом, вообще, тоже очень важный вопрос)

Как определяли массу лептонов?

(важный теор вопрос, пока не готов к этому)

6.0.2 Properties of fundamental particles

(не уверен пока, что тут, но по идее суть физики элементарных части, с позиции экспериментов и итоговых свойств. в 1й части же просто модели не нужно будет - удалю)

Overview of particles

(общие свойства и сравнения)

Particle	Mass
Neutrinos	$\sim 10^{-2}$eV
Electron	0.5MeV
Muon	100MeV
Pions	140MeV
Proton, Neutron	1GeV
Tau	2GeV
W,Z Bosons	$80 - 90$GeV
Higgs Boson	125GeV

Properties of electron and photon

(разные физические свойства соберу, мб полезно будет. не полезно - удалю раздел.)

Properties of typical nuclei

(по идее тоже много можно важных графиков вставить, изучу мб)

Which particles can also be?

(что гипотетическое и исследуется - то тут)

On other particles

On dark photon (?)

In 2023 there are many experiments searching for the dark photon, a hypothetical particle whose motivation is described in the notes on Cosmology. The dark photon acts like the regular photon, but it has a mass $m_{A'}$ and couplings ϵe to fermions, where ϵ is the kinetic mixing parameter. Accelerator experiments attempt to produce the dark photon and detect its decay. The dominant production channel depends on the experiment, such as whether it uses lepton or hadron beams, but some important production channels are:

• Electron-positron annihilation, $e^+e^- \to \gamma A'$. At high energies, the rate for this is ϵ^2 smaller than the rate for $e^+e^- \to \gamma\gamma$.

• A' Bremsstrahlung. Most processes can also produce an A' by attaching it to a fermion line.

• Meson decay. For example, pions can decay as $\pi^0 \to \gamma\gamma$, though we won't be able to calculate this rate for some time. However, it is simply related to the rate for $\pi^0 \to \gamma A'$.

The A' can then decay, e.g. through $A' \to e^+e^-$, which is trivial to calculate given what we already know, or through $A' \to \pi^+\pi^-$, which is somewhat more tricky. The way we detect this decay depends on the lifetime of the A', which generally scales as $\tau \sim 1/\Gamma \sim 1/\alpha\epsilon^2 m_{A'}$. The dark photon will travel a distance $\gamma c\tau$, but the opening angle of the decay products is $\sim 1/\gamma$, so the quantity that determines experimental resolution turns out to be

$$\ell \sim c\tau \sim \left(10^{-6}\text{ m}\right)\left(\frac{10^{-3}}{\epsilon}\right)^2 \frac{10\text{MeV}}{m_{A'}}$$

For $\ell \lesssim 10\mu$m, the decay is "prompt", i.e. it happens at the same point as production, up to the detector resolution. In this case, individual dark photon events look like background events, but they can be found by computing the invariant mass of the decay products and looking for a statistically significant bump at $m_{A'}$. For larger ℓ, we enter the "displaced" regime, where the decay products can be measured to be coming from a point away from the interaction point. Here the signal rate tends to be lower, but measuring a displaced decay dramatically cuts down on backgrounds.

7 Special Phenomena and Theoretical Extensions of QFT

(тут же разные калибровочные важные теории!)

7.1 Non-Abelian Gauge Theory in a nutshell

7.1.1 Classical Yang-Mills, quantization, Faddeev-Popov method

(см. также лекции Киселева, там в конце про это есть.)

Classical Yang-Mills

• We consider a Lie group H with Lie algebra $\mathfrak{h}$, so every $h \in H$ can be written as

$$h = e^{ig\alpha}, \quad \alpha = \alpha_a T^a, \quad T^a \in \mathfrak{h}.$$

Here the generators T^a satisfy

$$\left[T^a, T^b\right] = i f_c^{ab} T^c$$

Note that conventions differ here, as one can flip the sign of g, α, or A_μ. In our current convention, also used by Peskin and Schroeder, the covariant derivative comes with a minus sign, $D \sim \partial - igA$, and gauge transformations come with plus signs.

• The Lie algebra contains a symmetric bilinear form called the Killing form,

$$\kappa^{ab} \equiv T^a \circ T^b$$

which is invariant under the adjoint action,

$$hT^a h^{-1} \circ hT^b h^{-1} = T^a \circ T^b.$$

Note that when we focus on the Lie algebra alone, we usually take the infinitesimal version of this equation by setting $h \approx 1 - ig\alpha$, for

$$[T^a, T^c] \circ T^b + T^a \circ \left[T^c, T^b\right] = 0$$

as defined earlier.

• For an abstract Lie algebra, the Killing form is defined as we've seen earlier,

$$\kappa^{ab} = \operatorname{tr}\left[T^a, \left[T^b, \cdot\right]\right]$$

On the other hand, for a matrix Lie group where the generators are traceless we have

$$T^a \circ T^b = \operatorname{tr} T^a T^b$$

We will normalize generators in the fundamental representation as

$$T^a \circ T^b = \frac{1}{2}\delta^{ab}$$

and think of all generators below as being in the fundamental representation. There's no reason to do this at this point, but when we introduce physical matter, it will be in the fundamental representation, so we'll only need one set of generators.

• Under a gauge transformation $U(x) = e^{ig\alpha(x)}$ the gauge potential/connection transforms as

$$A_\mu \to U A_\mu U^{-1} - \frac{i}{g}\left(\partial_\mu U\right) U^{-1}$$

where infinitesimally we have

$$A_\mu \to A_\mu + D_\mu \alpha, \quad D_\mu \alpha \equiv \partial_\mu \alpha - ig\left[A_\mu, \alpha\right]$$

where we have defined the covariant derivative acting on a $\mathfrak{h}$-valued field. Note that A_μ doesn't transform in a representation of H, but the difference of two A_μ 's transforms in the adjoint.

• It will be useful to write the above in components,

$$D_\mu \alpha^a = \partial_\mu \alpha^a + g A^b_\mu \alpha^c f^{abc}.$$

The same applies to any other quantity transforming in the adjoint.
• We define the curvature/field strength as

$$F_{\mu\nu} = \frac{i}{g}\left[D_\mu, D_\nu\right] = \partial_\mu A_\nu - \partial_\nu A_\mu - ig\left[A_\mu, A_\nu\right]$$

as can be shown by acting with both sides on a "test object".
• The field strength transforms in the adjoint representation, so that

$$F_{\mu\nu} \to U F_{\mu\nu} U^{-1} = F_{\mu\nu} + ig\left[\alpha, F_{\mu\nu}\right] + O\left(\alpha^2\right)$$

Since the covariant derivative obeys the Jacobi identity, we have the Bianchi identity,

$$D_\mu F_{\alpha\beta} + D_\beta F_{\mu\alpha} + D_\alpha F_{\beta\mu} = 0$$

• The pure Yang-Mills Lagrangian is

$$\mathcal{L} = -\frac{1}{2}\operatorname{tr} F_{\mu\nu} F^{\mu\nu} = -\frac{1}{4} F^a_{\mu\nu} F^{\mu\nu a}$$

Note that this automatically contains terms cubic and quartic in A.
• To derive the equation of motion, it is useful to note that

$$\delta F_{\mu\nu} = D_\mu \delta A_\nu - D_\nu \delta A_\mu$$

Then the variation of the action is proportional to

$$\operatorname{tr}\left(F_{\mu\nu}\left(\partial^\mu \delta A^\nu + ig\left[A^\mu, \delta A^\nu\right]\right)\right) = -\operatorname{tr}\left(\delta A^\nu D^\mu F_{\mu\nu}\right)$$

using the fact that δA^μ is in the adjoint, the cyclic property of the trace, and integration by parts. Since δA^μ is arbitrary, and the Killing form is nondegenerate, we have the equation of motion

$$D_\mu F^{\mu\nu} = \partial_\mu F^{\mu\nu} - ig\left[A_\mu, F^{\mu\nu}\right] = 0.$$

• Matter fields in a representation R will be introduced through the Lagrangian

$$\mathcal{L} \supset \bar{\psi}(i\not{D} - m)\psi, \quad (i\not{D} - m)\psi = 0, \quad \psi \to e^{ig\alpha}\psi = \left(1 + ig\alpha^a T^a_R\right)\psi + O\left(\alpha^2\right)$$

The covariant derivative acts on ψ in whatever representation it transforms in,

$$D_\mu \psi_i = \partial_\mu \psi_i - ig A^a_\mu \left(T^a_R\right)_{ij} \psi_j$$

which leads to the interaction term

$$\mathcal{L} \supset g\bar{\psi}_i \gamma^\mu A^a_\mu \left(T^a_R\right)_{ij} \psi_j$$

• The matter provides a current for the gauge fields, so that the equation of motion is

$$D_\mu F^{\mu\nu} = J^\nu, \quad J^{\mu a} = -g\bar{\psi}\gamma^\mu T^a_R \psi$$

By the transformation properties of $D_\mu F^{\mu\nu}$, we see that J^ν transforms in the adjoint. Acting with D_ν on both sides and using symmetry, we have $D_\mu J^\mu = 0$, so the current is "covariantly conserved" rather than conserved; this can also be shown with the equation of motion for ψ.

• In fact, there is no gauge-invariant conserved current in this theory. This result is a special case of the Weinberg-Witten theorem, which states that any theory with a global non-abelian symmetry under which massless spin 1 particles are charged does not admit a gauge-invariant conserved current.

• The second part of the Weinberg-Witten theorem implies that any theory with a conserved, Lorentz-covariant energy-momentum tensor cannot contain a massless particle of spin 2. This rules out scenarios where the graviton is a composite particle and space is fundamentally flat.

Note. The reason the classical Yang-Mills equations are not relevant to everyday life is best seen in the "theoretical" normalization, where the Yang-Mills action has a prefactor $1/g^2\hbar$. Then the classical limit is the weak coupling limit. However, in everyday life we're looking at the low energy limit, and since Yang-Mills is asymptotically free, this is precisely where the coupling is strong!

Note. The statements made above are straightforward to prove by expanding in components, but one can show them using differential forms, in a clean index-free notation. We define

$$A' = -igA$$

and hereafter work with A', dropping the prime. We regard A as as one-form and suppress explicit wedge products. Then the transformation of A is

$$A \to UAU^{-1} - (dU)U^{-1} = UAU^{-1} + UdU^{-1}$$

Taking the exterior derivative of both sides,

$$dA \to (dU)AU^{-1} + U(dA)U^{-1} - UAdU^{-1} + (dU)\left(dU^{-1}\right)$$

where we picked up a minus sign from anticommuting d and A. Similarly, we have

$$A^2 \to UA^2U^{-1} + UA\left(dU^{-1}\right) + U\left(dU^{-1}\right)UAU^{-1} + U\left(dU^{-1}\right)U\left(dU^{-1}\right)$$

This may be simplified by noting that $0 = d\left(UU^{-1}\right) = U\left(dU^{-1}\right) + (dU)U^{-1}$, giving

$$A^2 \to UA^2U^{-1} + UA\left(dU^{-1}\right) - (dU)AU^{-1} - (dU)\left(dU^{-1}\right)$$

Adding these expressions, we see that

$$F \to UFU^{-1}, \quad F = dA + A^2$$

In this notation, the covariant derivative is

$$D = d + A, \quad F = D^2$$

Furthermore, the Bianchi identity is simply $DF = 0$. To prove this, note that the A in D acts on F by commutator, so

$$DF = dF + AF - FA = d\left(A^2\right) + AdA + A^3 - (dA)A - A^3 = 0$$

where we expanded $d\left(A^2\right) = (dA)A - AdA$. In this notation, the usual kinetic term is $\mathrm{tr}(F \star F)$, and the theta term is $\mathrm{tr}\, F^2$. Expanding the theta term, we have

$$\operatorname{tr} F^2 = \operatorname{tr}\left((dA)(dA) + A^2 dA + (dA)A^2 + A^4\right)$$

Due to the trace, the final term vanishes while the second and third term are in fact equal. This is easiest to see by expanding explicitly in components. For instance,

$$\operatorname{tr} A^4 = A^a_\mu A^b_\nu A^c_\rho A^d_\sigma \operatorname{tr}\left(T^a T^b T^c T^d\right) dx^\mu dx^\nu dx^\rho dx^\sigma$$

which vanishes because the trace is symmetric under cyclic permutations while the wedge product on the right is antisymmetric. In fact, we have

$$\operatorname{tr} F^2 = d \operatorname{tr}\left(AdA + \frac{2}{3}A^3\right)$$

where the quantity differentiated is the Chern-Simons current. This result will play a role in the theory of anomalies below.

Faddeev-Popov Quantization

First, we discuss some of the challenges associated with quantizing the theory.

• In canonical quantization, we again find that

$$\Pi^0 = \frac{\partial \mathcal{L}}{\partial \dot{A}_0} = 0$$

as in QED, so it is a non-dynamical field which enforces the constraint

$$D_i F^{0i} = 0$$

which is the non-abelian generalization of Gauss's law.

• As in QED, we can enforce the constraints using Dirac brackets, as we did in Coulomb gauge. Alternatively, we can quantize naively and then restrict our Hilbert space to a 'physical' Hilbert space, as we did in the Gupta-Bleuler method. However, these methods are more involved for non-abelian gauge theory because the constraints are more complicated.

• Again as in QED, we still have a gauge symmetry. The gauge symmetry must always be fixed to define the quantum theory in the first place; for instance, with a gauge symmetry the propagator is not defined since the kinetic term is not invertible.

• Unlike for QED, we will first quantize using the path integral, which is much easier. To handle first-class constraints/gauge redundancies, we restrict the path integral to integrate over only one point in each gauge orbit. Note that in Yang-Mills, there are no second-class constraints, so we don't have to worry about them.

Next, we formally introduce the Faddeev-Popov method.

• Let $\mathcal{A}$ be the space of all gauge fields $A_\mu(x)$, and let H be the space of gauge transformations. The physically inequivalent gauge field configurations live in the quotient space $\mathcal{A}/H$, where we identify

$$A_\mu \sim A^h_\mu, \quad A^h_\mu = h A_\mu h^{-1} + \frac{i}{g}\left(\partial_\mu h\right) h^{-1}$$

Thus we want to define the path integral partition function as

$$\mathcal{Z} = \int\limits_{\mathcal{A}/H} d\mu[A] e^{iS[A]}$$

but this is computationally inconvenient, since $\mathcal{A}/H$ is complicated. In the Faddeev-Popov method, we cleverly insert the identity to equate this path integral with another path integral over all of $\mathcal{A}$.

• Specifically, note that the naive path integral measure $\mathcal{D}A$ over $\mathcal{A}$ factors as

$$\int\limits_{\mathcal{A}} \mathcal{D}A = \int\limits_{H} d\mu[h] \int\limits_{\mathcal{A}/H} d\mu[A]$$

Here, we will take $\mu[h]$ to be the Haar measure over H, which is shift-invariant,

$$\mu[g(x)h(x)] = \mu[h(x)]$$

• Now consider a Lie-algebra valued gauge fixing function F, such as $F(A) = \partial_\mu A^\mu$, so that $F(A) = 0$ once on every gauge orbit, say $F\left(A^{h_0}\right) = 0$. Then we have

$$1 = \int\limits_{H} d\mu[H] \delta\left[F\left(A^h\right)\right] M\left(A^h\right), \quad M\left(A^h\right) = \det \frac{\partial F\left(A^h\right)}{\partial h}$$

which holds in analogy with the delta function identity

$$1 = \int dx \delta[f(x)] \left|\frac{\partial f}{\partial x}\right|$$

• Inserting the identity, we have

$$\int\limits_{\mathcal{A}} \mathcal{D}A = \int\limits_{H} d\mu[h] \int\limits_{\mathcal{A}} \mathcal{D}A \delta\left[F\left(A^h\right)\right] M\left(A^h\right)$$

Next, we make the nontrivial assumption that we can find a measure $\mathcal{D}A$ so that

$$\mathcal{D}A = \mathcal{D}A^h$$

which means the gauge symmetry is not anomalous. Upon relabeling, we thus have

$$\int\limits_{\mathcal{A}} \mathcal{D}A = \left(\int\limits_{H} d\mu[h]\right) \int\limits_{\mathcal{A}} \mathcal{D}A \delta[F(A)] M(A)$$

• Equating this to our other expression for $\int\limits_{\mathcal{A}} \mathcal{D}A$ and canceling a factor of the volume of H, we find that the partition function is

$$\mathcal{Z} = \int\limits_{\mathcal{A}} \mathcal{D}A \delta[F(A)] M(A) e^{iS[A]}$$

where we used the fact that the action was gauge-invariant.

• Next, we find a more explicit expression for M. Using the shift-invariance of the Haar measure we can bring the delta function peak to the identity,

$$1 = \int\limits_H d\mu[h]\delta\left[F\left(\tilde{A}^h\right)\right] M\left(\tilde{A}^h\right), \quad \tilde{A} = A^{h_0}$$

so that the peak is at $h(x) = e$. Expanding $h = e^{i\alpha}$, we get

$$1 = \int\limits_{\mathfrak{h}} d\alpha\delta\left[F\left(\tilde{A}^\alpha\right)\right] M\left(\tilde{A}^\alpha\right), \quad M\left(\tilde{A}^\alpha\right) = \det\frac{\partial F\left(\tilde{A}^\alpha\right)}{\partial\alpha}$$

for a suitably normalized Lie algebra measure $d\alpha$. Using the chain rule,

$$\frac{\partial F\left(\tilde{A}^\alpha\right)}{\partial\alpha} = \frac{\partial F\left(\tilde{A}^\alpha\right)}{\partial\tilde{A}^\alpha}\frac{\partial\tilde{A}^\alpha}{\partial\alpha} = \frac{\partial F\left(\tilde{A}^\alpha\right)}{\partial\tilde{A}^\alpha_\mu}D_\mu$$

• Finally, using the gauge invariance of $\mathcal{D}A$ and $S[A]$, we have the partition function

$$\mathcal{Z} = \int\limits_{\mathcal{A}} \mathcal{D}A\delta[F(A)]\det\Delta_{\mathrm{FP}}e^{iS[A]}, \quad \Delta_{\mathrm{FP}} = \frac{\partial F(A)}{\partial A_\mu}D_\mu$$

Note that the covariant D_μ acts on the Lie algebra, in the adjoint representation. Similarly, we may define expectation values of gauge invariant operators.

Note. In the absence of matter, the measure is, formally, automatically invariant under gauge transformations. Infinitesimally we have

$$A'^a_\mu = A^a_\mu + \partial_\mu\alpha^a + igf^{ade}A^d_\mu\alpha^e.$$

The Jacobian factor is

$$\det\frac{\partial A'^a_\mu}{\partial A^b_\nu} = \det\left(\delta^\mu_\nu\delta^a_b + ig\delta^\mu_\nu f^{abc}\alpha^c\right)$$

where the determinant is over both color and Lorentz indices. Using $\det(1+A) = 1 + \mathrm{tr}(A) + O\left(A^2\right)$,

$$\det\frac{\partial A'^a_\mu}{\partial A^b_\nu} = 1 + igf^{aac}\alpha^c = 1$$

by the antisymmetry of the structure constants, so we pick up no Jacobian at all.

Note. In more mathematical language, we begin with a principal G-bundle $P \to M$ and pick a 'base-point' connection A_0. Then any connection can be written as

$$A = A_0 + \delta A, \quad \delta A \in \mathcal{A}$$

The space $\mathcal{A}$ is an affine space, i.e. a vector space without an origin, and there is a natural inner product on it, obtained by integration over the manifold along with contraction by the Killing form, giving a natural path integral measure.

We want to integrate over connections on the bundle, but note that $\mathcal{A}$ counts a connection and the very same connection with a different local trivialization as distinct. Hence we want to integrate over $\mathcal{A}/\mathcal{G}$ where $\mathcal{G}$ is the space of all gauge transformations; note this is much larger than

G. The space $\mathcal{A}/\mathcal{G}$ is much more complicated than $\mathcal{A}$, and it is unclear how to define a measure on it.

The purpose of the Faddeev-Popov procedure is to write the desired path integral over $\mathcal{A}/\mathcal{G}$ in terms of a path integral over all of $\mathcal{A}$ but with a delta function, which is easier to handle. Many sources describe this procedure essentially in reverse, starting with a naive path integral over all of $\mathcal{A}$ and then "factoring out the volume of $\mathcal{G}$ ".

Note. Gauge fixing is more complicated in the non-abelian case. It's difficult to show that Lorenz gauge can even be attained. A worse problem is the Gribov ambiguity: generically gauge orbits intersect the gauge slice more than once. To see this, note that $\mathcal{A}$ is a principal bundle over $\mathcal{A}/\mathcal{G}$ with structure group $\mathcal{G}$, and a gauge slice is equivalent to a global section. Thus we require the bundle to be trivial,

$$\mathcal{A} \cong \mathcal{B} \times \mathcal{G}$$

Since $\mathcal{A}$ is a vector space, it has trivial homotopy groups. However, it can be shown that $\mathcal{G}$ doesn't, giving the result. We won't worry about the 'Gribov copies' since we'll only work perturbatively.

At this point, we have a path integral with a $\mathcal{D}A$ measure, but it contains inconvenient extra factors. We now perform a few more tricks to absorb these terms into the action.

• First, we rewrite the delta function as an action contribution by introducing a new field, called the Nakanishi-Lautrup field. The simplest way to do this is

$$\delta[F(A)] = \int \mathcal{D}B^a(x) e^{i\int dx B^a(x)F^a(A)}$$

Since $F(A)$ is Lie-algebra valued, $B(x) = B^a(x)T^a$ is as well and hence transforms in the adjoint; it is a bosonic scalar. The auxiliary field just acts like a Lagrange multiplier. Note that B^aF^a is not gauge-invariant and we shouldn't expect it to be, because we are using the delta function to do gauge fixing.

• Next, we can simplify the determinant using the general formula

$$\int d\theta^* d\theta e^{\theta_i^* M_{ij}\theta_j} = \det M$$

Since the Faddeev-Popov matrix acts on the Lie algebra, we have

$$\det \Delta_{\mathrm{FP}} = \int \mathcal{D}\bar{c}\mathcal{D}c e^{-i\int dx \bar{c}^a(x)(\Delta_{\mathrm{FP}}c(x))^a}$$

where c and $\bar{c}$ are $\mathfrak{h}$-valued Grassmann fields, called Faddeev-Popov ghosts and anti-ghosts, which transform in the adjoint. Note that we have added a factor of $-i$ to Δ_{FP}. This is allowed since it merely multiplies $Z[J]$ by a phase and will ensure a canonical kinetic term for the ghosts in the gauge we'll use below.

• The ghosts are fermionic scalars, violating the spin-statistics theorem; this is allowed because the theorem assumes a positive-definite norm, but the ghost states do not have one. Their role is to cancel the unphysical polarizations of the Yang-Mills field: if the A_μ field has 4 polarizations, the ghosts heuristically have -2 because of their fermionic statistics, which cause them to contribute oppositely in loops.

• Now, the partition function is

$$\mathcal{Z} = \int \mathcal{D}[A, B, \bar{c}, c] e^{iS[A,B,\bar{c},c]}, \quad S = \int dx \left(-\frac{1}{4} \left(F^a_{\mu\nu} \right)^2 + B^a F^a(A) + \bar{c}^a \left(\Delta_{\text{FP}} c \right)^a \right)$$

which is the desired form. However, we can make it even more convenient.

• Our gauge fixing condition was $F(A) = 0$, but we could also have required $F(A(x)) = f(x)$ for any $\mathfrak{h}$-valued function $f(x)$. We may also integrate over f with a Gaussian weight,

$$\delta[F(A)] \to \int \mathcal{D}f \delta[F(A) - f] e^{-\frac{i}{2\xi} \int dx f^a(x) f^a(x)}$$

The point of this manipulation is that we do not need an auxiliary field; we may simply perform the integral over f, using the delta function, to get a contribution to the action quadratic in F,

$$\mathcal{Z} = \int \mathcal{D}[A, \bar{c}, c] e^{iS[A,\bar{c},c]}, \quad S = \int dx \left(-\frac{1}{4} \left(F^a_{\mu\nu} \right)^2 - \frac{1}{2\xi} F^a F^a + \bar{c}^a \left(\Delta_{\text{FP}} c \right)^a \right)$$

• Alternatively, we can express the delta function using the auxiliary field as before, then integrate over f. This gives

$$\mathcal{Z} = \int \mathcal{D}[A, B, \bar{c}, c] e^{iS[A,B,\bar{c},c]}, \quad S = \int dx \left(-\frac{1}{4} \left(F^a_{\mu\nu} \right)^2 + B^a F^a + \frac{\xi}{2} B^a B^a + \bar{c}^a \left(\Delta_{\text{FP}} c \right)^a \right)$$

Both of these results are commonly used, and integrating out B in the latter gives the former.

• Specializing to $F(A) = \partial_\mu A^\mu$, we have

$$\Delta_{\text{FP}} = \partial^\mu D_\mu$$

so the former action becomes

$$\mathcal{Z} = \int \mathcal{D}[A, \bar{c}, c] e^{iS[A,\bar{c},c]}, \quad S = \int dx \left(-\frac{1}{4} \left(F^a_{\mu\nu} \right)^2 - \frac{1}{2\xi} F^a F^a + \bar{c}^a \left(-\partial^\mu D_\mu c \right)^a \right)$$

This is known as R_ξ gauge.

• We now revisit QED. In R_ξ gauge, we recover the gauge-fixed QED action we had postulated earlier. The covariant derivative D_μ in the adjoint representation is simply ∂_μ, giving a determinant factor of $\det(-\partial^2)$. This is independent of the gauge field, so we factor it out as a constant; this is why we didn't see ghosts in QED. However, we can encounter ghosts in QED if we use other gauges.

• The choice $\xi = 0$ is called Landau gauge, while $\xi = 1$ is called Feynman gauge; we often use it by default. In the path integral, it's conceptually clear the results do not depend on ξ, since ξ just parametrizes how we do the gauge fixing.

Example. The axial gauge, $F(A) = n^\mu A_\mu$. In this case we have

$$\Delta_{\text{FP}} = \frac{\partial F(A)}{\partial A_\mu} D_\mu = n^\mu D_\mu$$

The ghosts automatically decouple, because when we use the delta function, the dependence on Δ_{FP} on A_μ via $n^\mu A_\mu$ vanishes. Then $\det \Delta_{\text{FP}}$ is simply a constant which can be ignored. The downside is that the gauge explicitly breaks Lorentz invariance.

Alternatively, we can perform the same integration over f as above, giving

$$\mathcal{L} = -\frac{1}{4}\left(F^a_{\mu\nu}\right)^2 - \frac{1}{2\xi}\left(n^\mu A_\mu\right)^2 - \bar{c}n^\mu D_\mu c$$

In this case it is straightforward, if a bit tedious, to invert the quadratic part of the Lagrangian to find the propagator for A_μ, which gives

$$i\Delta^{\mu\nu}_{ab}(k) = \frac{i\delta_{ab}}{k^2 + i\epsilon}\left(\eta^{\mu\nu} - \frac{k^\mu n^\nu + n^\mu k^\nu}{k\cdot n} - \frac{\xi k^2 - n^2}{(k\cdot n)^2}k^\mu k^\nu\right)$$

Note that the interaction vertex between the ghosts and gauge boson contains the factor $n_\mu A^\mu$, and hence is proportional to

$$n_\mu \Delta^{\mu\nu}_{ab}(k) = -\frac{\xi}{k\cdot n}\delta_{ab}k^\nu$$

Hence in the limit $\xi \to 0$ where the gauge condition is exactly imposed, all diagrams where a ghost attaches to a gluon vanish, so the ghosts decouple as we'd expect. A useful special case of this gauge is light cone gauge, the limit $\xi \to 0$ with $n^2 = 0$, giving

$$i\Delta^{\mu\nu}_{ab}(k) = \frac{i\delta_{ab}}{k^2 + i\epsilon}\left(\eta^{\mu\nu} - \frac{k^\mu n^\nu + n^\mu k^\nu}{k\cdot n}\right)$$

Canonical Quantization of Yang-Mills theory

• Motivated by the path integral treatment above, we take the gauge-fixed Lagrangian

$$\mathcal{L} = -\frac{1}{4}\left(F^a_{\mu\nu}\right)^2 - \partial^\mu B^a A^a_\mu + \frac{\xi}{2}B^a B^a + \partial^\mu \bar{c}^a D_\mu c^a$$

where the derivatives only act on the field immediately to their right.

• The field momenta are

$$\Pi^{a\mu}_A = \frac{\partial\mathcal{L}}{\partial\dot{A}^a_\mu} = F^{a\mu 0}, \quad \Pi^a_c = \frac{\partial\mathcal{L}}{\partial\dot{c}^a} = -\dot{\bar{c}}^a, \quad \Pi^a_B = \frac{\partial\mathcal{L}}{\partial\dot{B}^a} = -A^a_0, \quad \Pi^a_{\bar{c}} = \frac{\partial\mathcal{L}}{\partial\dot{\bar{c}}^a} = \dot{c}^a - gf^{abc}A^b_0 c^c$$

The conjugate momentum of A^0 still vanishes, but this is just because we have the auxiliary field B. We can eliminate B by plugging in its equations of motion.

• Next, we perform canonical quantization, imposing the usual commutation relations

$$[A_\mu(t,\mathbf{x}), \Pi_{\nu A}(t,\mathbf{y})] = i\eta_{\mu\nu}\delta(\mathbf{x}-\mathbf{y})$$

Then by direct computation, we find for spacelike j and k,

$$\left[A^a_j(t,\mathbf{x}), \dot{A}^b_k(t,\mathbf{y})\right] = i\delta^{ab}\delta_{kj}\delta(\mathbf{x}-\mathbf{y})$$

Meanwhile, we have

$$\left[A^a_0(t,\mathbf{x}), B^b(t,\mathbf{y})\right] = i\delta^{ab}\delta(\mathbf{x}-\mathbf{y})$$

• Since the ghosts were Grassmann variables, we impose the anti-commutation relations

$$\left\{c^a(t,\mathbf{x}), \Pi^b_c(t,\mathbf{y})\right\} = \left\{\bar{c}^a(t,\mathbf{x}), \Pi^b_{\bar{c}}(t,\mathbf{y})\right\} = i\delta^{ab}\delta(\mathbf{x}-\mathbf{y})$$

We also define

$$c^{a\dagger} = c^a, \quad (\bar{c}^a)^\dagger = -\bar{c}^a$$

which ensures that $\mathcal{L} = \mathcal{L}^\dagger$, yielding a unitary S-matrix.

• At this point we would usually construct the Fock space, but Yang-Mills is an intrinsically interacting theory. Thus the spectrum will contain complicated bound states, e.g. hadrons and glueballs. On the other hand, to compute S-matrix elements it suffices to define 'in' and 'out' states via the LSZ reduction formula. These asymptotic states are free fields, which are fully renormalized but have gauge coupling $g = 0$.

• Therefore, we instead consider the free Lagrangian

$$\mathcal{L}_0 = -\frac{1}{4}\left(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu\right)^2 - \partial^\mu B^a A^a_\mu + \frac{\xi}{2} B^a B^a + \partial^\mu \bar{c}^a \partial_\mu c^a$$

We set $\xi = 1$ and integrate out B^a using the equation of motion $B^a = -\partial^\mu A^a_\mu$, giving

$$\left[A^a_\mu(t,\mathbf{x}), \dot{A}^b_\nu(t,\mathbf{y})\right] = -i\delta^{ab}\eta_{\mu\nu}\delta(\mathbf{x}-\mathbf{y})$$

just as we had in QED.

• The gauge field and ghost field have free mode expansions,

$$A^a_\mu(x) = \int \frac{d\mathbf{k}}{\sqrt{2E_k}} \sum_\lambda \epsilon^a_\mu(\mathbf{k},\lambda)\left(a^a_\lambda(\mathbf{k})e^{-ikx} + a^{a\dagger}_\lambda(\mathbf{k})e^{ikx}\right), \quad \epsilon(\mathbf{k},\lambda)\cdot\epsilon\left(\mathbf{k},\lambda'\right) = \eta_{\lambda\lambda'}$$

and

$$c^a(x) = \int \frac{d\mathbf{p}}{\sqrt{2E_p}} c^a(\mathbf{p})e^{-ipx} + c^{a\dagger}(\mathbf{p})e^{ipx}$$

with the commutation relations

$$\left[a^{a\dagger}_\lambda(\mathbf{k}), a^b_{\lambda'}\left(\mathbf{k}'\right)\right] = \delta^{ab}\eta_{\lambda\lambda'}\phi\left(\mathbf{k}-\mathbf{k}'\right), \quad \left\{c^a(\mathbf{p}), \bar{c}^{b\dagger}\left(\mathbf{p}'\right)\right\} \propto \left\{\bar{c}^a(\mathbf{p}), c^{b\dagger}\left(\mathbf{p}'\right)\right\} \propto \delta^{ab}\delta\left(\mathbf{p}-\mathbf{p}'\right)$$

Thus we have negative norm and zero norm gluon states, as well as zero norm ghost states.

• The physical Hilbert space H_{phys} must have a positive-definite norm. In addition, the S-matrix must be unitary when restricted to H_{phys} , i.e. the unphysical states must decouple. This is much more difficult to guarantee, but it follows if we define H_{phys} using a symmetry of the full interacting theory, as in this case the S-matrix respects this symmetry by assumption.

• We cannot use gauge symmetry for this purpose, because we had to fix the gauge to quantize at all. In QED, we used the $U(1)$ global symmetry, which gave the Ward-Takahashi identities. But in a non-abelian gauge theory, this is complicated by the ghost and auxiliary fields. Instead, we will use the more subtle BRST symmetry.

SU(3) **калибровки по Мандлу Шаулу**

We next generalize the SU(3) transformations (11.22) from global to local phase transformations. The development will be very similar to that for QED in Section 11.1. In order to retain

invariance under local phase transformations, we shall have to introduce gauge fields, and this will automatically generate the interactions.

The first step is to replace the global SU(3) transformations (11.21) by the local phase transformations

$$\left.\begin{array}{l}\Psi f(x) \to \Psi^f(x) = \exp\left[\mathrm{i}g_s\lambda_j\omega_j(x)/2\right]\Psi^f(x) \\ \bar{\Psi}^f(x) \to \bar{\Psi}^{f\prime}(x) = \bar{\Psi}^f(x)\exp\left[-\mathrm{i}g_s\lambda_j\omega_j(x)/2\right]\end{array}\right\}.$$

Here $\omega_j(x)(j = 1, 2, ..., 8)$ are arbitrary real differentiable functions and g_s is a real constant which will later be identified with a coupling constant.

The free-field Lagrangian density (11.20) is not invariant under the transformation (11.26), but transforms as

$$\mathscr{L}_0 \to \mathscr{L}_0' = \mathscr{L}_0 - \frac{1}{2}g_s\bar{\Psi}^f(x)\lambda_j\not{\partial}\omega_j(x)\Psi^f(x)$$

for infinitesimal $\omega_j(x)$. As we shall see, an invariant Lagrangian density can be obtained if, in analogy with Eqs. (11.7) and (11.8) in QED, we replace $\partial^\mu\Psi^f(x)$ in Eq. (11.20) by the covariant derivative

$$D^\mu\Psi f(x) = \left[\partial^\mu + \mathrm{i}g_s\lambda_j A_j^\mu(x)/2\right]\Psi^f(x)$$

so that $\mathscr{L}_0$ goes over to

$$\mathscr{L}_q(x) = \bar{\Psi}^f(x)\left[\mathrm{i}\not{D} - m_f\right]\Psi^f(x) = \mathscr{L}_0 + \mathscr{L}_\mathrm{I}$$

where

$$\mathscr{L}_\mathrm{I} = -\frac{1}{2}g_s\bar{\Psi}^f(x)\gamma_\mu\lambda_j\Psi^f(x)A_j^\mu(x)$$

7.1.2 BRST Symmetry

BRST symmetry is a fermionic global symmetry of the interacting, gauge-fixed Yang-Mills Lagrangian, which roughly corresponds to gauge symmetry when applied to the gauge field alone. It is theoretically useful because it allows us to recover some of the consequences of gauge symmetry, even though the Lagrangian is gauge-fixed.

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}^a F^{\mu\nu a} + \frac{\xi}{2}B^a B^a + B^a\partial_\mu A_\mu^a + \bar{c}^a\left(-\partial^\mu D_\mu c\right)^a$$

We define a Grassmann odd operator S:

$$SA_\mu = -D_\mu c = -\left(\partial_\mu c + ig\left[A_\mu, c\right]\right), \quad Sc = \frac{i}{2}gf^{abc}c^b c^c t^a \equiv \frac{g}{2}[c,c], \quad S\bar{c} = -B, \quad SB = 0$$

$Sc \neq 0$, since c is Grassmann odd. Sc is not just the conjugate of $S\bar{c}$. We regard c and $\bar{c}$ as independent real Grassmann fields, not conjugates of each other.

• Note that S obeys a graded Leibniz rule: if c is Grassmann odd,

$$S(cA) = (Sc)A - c(SA)$$

We now show that $S^2\Phi = 0 \forall \Phi \in \{A, c, \bar{c}, B\}$. This is obvious for B and $\bar{c}$, and we have

$$S^2 c \propto t^a f^{abc}f^{bde}c^c c^d c^e \propto t^a\left(\sum_{\mathrm{cde}}^{\mathrm{cyclic}} f^{abc}f^{bde}\right)c^c c^d c^e = 0$$

by the Jacobi identity. The proof that $S^2 A_\mu = 0$ is similar, but more complicated.

• Now, for a product of any two fields, we have

$$S^2(\Phi_1\Phi_2) = S(S\Phi_1\Phi_2 \pm \Phi_1 S\Phi_2) = \mp S\Phi_1 S\Phi_2 \pm S\Phi_1 S\Phi_2 = 0$$

where we used $S^2\Phi_i = 0$ and the fact that S flips the Grassmann parity. Similar logic applies for any product of fields, which implies S is nilpotent, $S^2 = 0$.

From direct expansion:

$$\mathcal{L} = -\frac{1}{4}F^a_{\mu\nu}F^{\mu\nu a} - S\left(\bar{c}^a\partial^\mu A^a_\mu + \frac{\xi}{2}\bar{c}^a B^a\right)$$

$$S\mathcal{L} = 0,$$

where the first term vanishes by gauge invariance and the second by nilpotence.

We define the BRST symmetry by

$$\delta_\epsilon\Phi = \epsilon S\Phi$$

where ϵ is a constant independent Grassmann number, so $\delta_\epsilon\mathcal{L} = 0$. The BRST transformation preserves the Grassmann parity, and obeys the Leibniz rule without grading.

$$J^\mu = \sum_I \frac{\partial\mathcal{L}}{\partial(\partial_\mu\Phi_I)}\delta_\epsilon\Phi_I, \qquad \partial_\mu J^\mu = 0, \qquad Q = \int d\mathbf{x}J^0, \qquad \dot{Q} = 0$$

• Upon canonical quantization, one can show that we find a BRST charge operator $\hat{Q}^\dagger = \hat{Q}$ which generates the BRST transformation, by

$$[\hat{Q}, \hat{X}] = iS\hat{X}$$

where the bracket is a commutator or anticommutator depending on whether $\hat{X}$ is bosonic or fermionic. The conservation of $\hat{Q}$ is expressed as $[\hat{H}, \hat{Q}] = 0$, and the nilpotency of the BRST transformation implies

$$\hat{Q}^2 = 0$$

• The continuous symmetries of the Yang-Mills Lagrangian are Lorentz invariance, global gauge invariance, BRST invariance, ghost number (a $U(1)$ assigning $+1$ charge to c^a and -1 to $\bar{c}^a$), and anti-ghost translation invariance $\bar{c} \to \bar{c} + \chi$. In fact, the Lagrangian already contains all terms consistent with these symmetries whose coefficients have nonnegative mass dimension. Upon renormalization, BRST symmetry will ensure that the separate appearances of g renormalize in the same way, providing identities analogous to $Z_1 = Z_2$ in QED.

• There are some minor variations we can consider. We can easily include matter fields, which, like the gauge field, transform as under a gauge transformation with gauge parameter $\alpha = -\epsilon c$,

$$\delta\psi_i = -ig\epsilon c^a t^a_{ij}\psi_j$$

It is straightforward to show that $S^2\psi_i$ as well.

• We could also integrate out the B field, in which case the only change is

$$S\bar{c} = \frac{1}{\xi}F^a = \frac{1}{\xi}\partial_\mu A^\mu$$

in R_ξ gauge. However, to show that $S^2\bar{c} = 0$, we have to use the equation of motion for the ghost field. This is a general phenomenon: if we eliminate auxiliary fields, then often symmetries that held off-shell will only hold on-shell, reducing their power.

We now use the BRST operator to define a cohomology and physical Hilbert space.

• Since $\hat{Q}^2 = 0$, it defines a cohomology.

• An element $|\psi\rangle \in \ker \hat{Q}$ is called $\hat{Q}$-closed.

• An element $|\psi\rangle \in \operatorname{im} \hat{Q}$ is called $\hat{Q}$-exact. All exact states are closed.

• For $|\psi\rangle$ exact, note that

$$\langle\psi|\psi\rangle = \left\langle \chi \left| \hat{Q}^\dagger \hat{Q} \right| \chi \right\rangle = \left\langle \chi \left| \hat{Q}^2 \right| \chi \right\rangle = 0$$

Then all exact states are null. More generally, all exact states are orthogonal to all closed states, and any two closed states differing by an exact state have the same norm. Physically, an exact state is gauge-equivalent to vacuum.

• We define the $\hat{Q}$-cohomology by

$$\operatorname{cohom}(\hat{Q}) = \frac{\ker(\hat{Q})}{\operatorname{im}(\hat{Q})}$$

Then there is a well-defined inner product on $\operatorname{cohom}(\hat{Q})$.

• Consider the variation of the time evolution operator

$$\hat{U} = \exp\left(i \int \Pi \dot{\phi} - \mathcal{L} dt \right), \quad \mathcal{L} = -\frac{1}{4} F^a_{\mu\nu} F^{\mu\nu a} - S\psi$$

under a change in the gauge fixing condition $F(A) = 0$. Only S depends on F, so

$$\delta_F \langle\alpha|\hat{U}|\beta\rangle = \langle\alpha\,|i\delta_F S\psi|\,\beta\rangle = \langle\alpha\,|iS\delta_F\psi|\,\beta\rangle = \left\langle \alpha \left| \hat{Q}\delta_F\psi - \delta_F\psi\hat{Q} \right| \beta \right\rangle$$

For this to vanish for all $\delta_F\psi$, we require $\hat{Q}|\beta\rangle = 0$. Since the time-evolution of physical states should not depend on the gauge choice, the physical Hilbert space must be BRST closed.

• Within this space, the BRST exact states have zero overlap with all other states and hence can never be measured. Thus we identify $H_{\text{phys}} = \operatorname{cohom}(\hat{Q})$.

• We can explicitly find the physical Hilbert space for the free in/out states. The states are

$$\left|A^a_\mu(\mathbf{k})\right\rangle = \sum_\lambda \epsilon^a_\mu(\mathbf{k},\lambda) a^{a\dagger}_\lambda(\mathbf{k})|0\rangle, \quad |c^a(\mathbf{k})\rangle = c^{a\dagger}(\mathbf{k})|0\rangle, \quad |\bar{c}^a(\mathbf{k})\rangle = \bar{c}^{a\dagger}(\mathbf{k})|0\rangle$$

and we don't have separate B states since $B \sim \partial A$. The BRST transformation is

$$SA_\mu = -\partial_\mu c, \quad Sc = 0, \quad S\bar{c} = -B = -\partial A, \quad SB = 0$$

where we work in Feynman gauge.

• Therefore, the BRST charge acts as

$$\hat{Q}\,|A^{\mu a}(\mathbf{k})\rangle = \alpha k^\mu\,|c^a(\mathbf{k})\rangle\,, \quad \hat{Q}\,|c^a(\mathbf{k})\rangle = 0, \quad \hat{Q}\,|\bar{c}^a(\mathbf{k})\rangle = \beta k^\mu \left|A^a_\mu(\mathbf{k})\right\rangle$$

where $\alpha, \beta \neq 0$. Since $\hat{Q}^2 = 0$, we have $k^2 = 0$. We now drop the a index.

• The states that are BRST closed must have no $\bar{c}$ excitations, and moreover

$$|\xi\rangle = \xi_\mu\,|A^\mu(\mathbf{k})\rangle$$

is only closed if $\xi^\mu k_\mu = 0$, removing one of the unphysical polarizations.

• Note that c excitations are BRST exact, as is $k^\mu |A_\mu(\mathbf{k})\rangle$. Therefore, the physical one-particle Hilbert space consists of states

$$|\psi\rangle = \xi^\mu |A_\mu(\mathbf{k})\rangle , \quad k^2 = 0, \quad \xi^\mu k_\mu = 0$$

where $\xi^\mu \sim \xi^\mu + k^\mu$. These are indeed the two degrees of freedom we want.

• Next, we check unitarity of the S-matrix. Since $\mathcal{L}^\dagger = \mathcal{L}$, the S-matrix is unitary on the entire Fock space. Letting $|\gamma\rangle$ be a basis,

$$\sum_\gamma \left\langle \alpha \left| S^\dagger \right| \gamma \right\rangle \langle \gamma | S | \beta \rangle = \langle \alpha | \beta \rangle$$

The nontrivial thing to check is that it is unitary on H_{phys} ,

$$\sum_{\chi_T} \left\langle \phi_T \left| S^\dagger \right| \chi_T \right\rangle \langle \chi_T | S | \psi_T \rangle = \langle \phi_T | \psi_T \rangle , \quad |\phi_T\rangle , |\psi_T\rangle \in H_{\text{phys}}$$

where $|\chi_T\rangle$ is a basis for H_{phys} .

• Since $\hat{Q}$ commutes with $\hat{H}$, it commutes with S, so

$$\hat{Q} S |\psi_T\rangle = S \hat{Q} |\psi_T\rangle = 0$$

Therefore, S maps $\ker \hat{Q}$ to itself. However, it can and does produce BRST exact states. These don't spoil unitarity because such states are orthogonal to BRST closed states. Explicitly,

$$\langle \phi_T | \psi_T \rangle = \sum_\gamma \left\langle \phi_T \left| S^\dagger \right| \gamma \right\rangle \langle \gamma | S | \psi_T \rangle = \sum_{\chi_T} \left\langle \phi_T \left| S^\dagger \right| \chi_T \right\rangle \langle \chi_T | S | \psi_T \rangle$$

as desired. Here, γ ranges over physical states, BRST exact states, and states that are not BRST closed, and the latter two don't contribute by the arguments above.

• In the special case of QED in Lorenz gauge, the ghosts automatically decouple, and the constraints above reduce to the Gupta-Bleuler condition $\partial A^+ |\psi\rangle = 0$. The difference in the non-abelian case is that such a constraint is not preserved by time evolution, as we can create BRST exact states.

• Accordingly, the Ward identity $k_\mu \mathcal{M}^\mu = 0$ does not hold in the non-abelian case, and this is related to the nonexistence of a conserved current. Instead, we use the BRST current to construct Slavnov-Taylor identities, which can be used to prove decoupling just like the Ward identities. The Slavnov-Taylor identities also ensure the gluon remains massless, as the Ward identities did for the photon.

• To see the role of the ghosts, note that the optical theorem relates a loop amplitude to a production amplitude squared, where the latter sums over physical external particles. Only two gauge boson polarizations are physical, but all four run around the loop. To maintain the optical theorem and hence unitarity, the ghosts also run around the loop with an extra factor of -1, canceling the unphysical polarizations. In the abelian case, the ghosts aren't necessary because the unphysical polarizations contribute nothing to loop amplitudes.

7.1.3 Perturbative Renormalization, asymptotic freedom

Next, we show the non-abelian gauge theories are asymptotically free. We continue to follow the Peskin and Schroeder conventions.

• By the same reasoning as in QED, the gauge boson propagator is

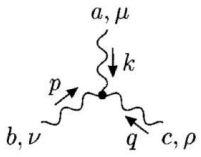
$$D_F^{\mu\nu ab}(p) = \frac{-i\delta^{ab}}{p^2 + i\epsilon}\left(\eta^{\mu\nu} - (1-\xi)\frac{p^\mu p^\nu}{p^2}\right)$$

The propagator is diagonal in color space. Incoming gauge bosons get $\epsilon_\mu^a(\mathbf{k}, \lambda)$ and outgoing gauge bosons get $\epsilon_\mu^{*a}(\mathbf{k}, \lambda)$.

• Next, in our convention the gauge boson interaction terms are

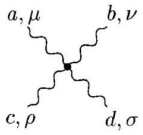
$$\mathcal{L} \supset g f^{abc}\eta^{\nu\rho}\partial^\mu A_\nu^a A_\mu^b A_\rho^c - \frac{g^2}{4} f^{abc} f^{ade}\eta^{\mu\rho}\eta^{\nu\sigma} A_\mu^b A_\nu^c A_\rho^d A_\sigma^e$$

For the cubic Feynman rule, note that every interaction comes with an automatic factor of i, while the derivative contributes $-ip^\mu$ for incoming momentum p. There are six distinct contractions, yielding:



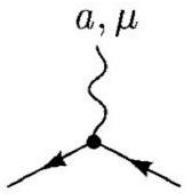
$$= gf^{abc}\big[g^{\mu\nu}(k-p)^\rho + g^{\nu\rho}(p-q)^\mu + g^{\rho\mu}(q-k)^\nu\big]$$

• As for the quartic interaction, there are 4 ! ways to perform the contractions. It turns out that they come in identical groups of 4, canceling the 1/4 factor and giving six terms:



$$= -ig^2\big[f^{abe}f^{cde}(g^{\mu\rho}g^{\nu\sigma} - g^{\mu\sigma}g^{\nu\rho}) + f^{ace}f^{bde}(g^{\mu\nu}g^{\rho\sigma} - g^{\mu\sigma}g^{\nu\rho}) + f^{ade}f^{bce}(g^{\mu\nu}g^{\rho\sigma} - g^{\mu\rho}g^{\nu\sigma})\big]$$

• Next, when we include matter fields in a representation t^a, they have the interaction



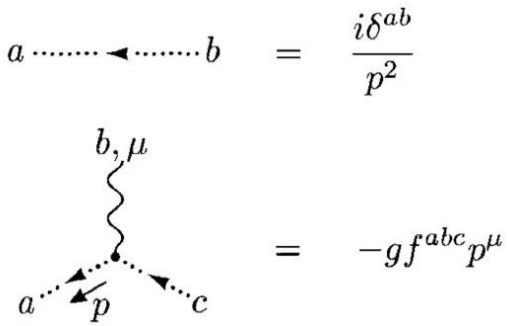
$$= ig\gamma^\mu t^a$$

where again our convention's sign is flipped. The propagator is the same as usual, with an extra δ_{ij} in flavor space.

• Finally, we consider the ghost fields, where

$$\mathcal{L} \supset \bar{c}^a\left(-\partial^\mu D_\mu c\right)^a = \bar{c}^a\left(-\partial^2\delta^{ab}\right)c^b + g f^{abc}\bar{c}^a\partial^\mu\left(A_\mu^b c^c\right)$$

The resulting Feynman rules are shown below.



The propagator is just the usual one, but it has a direction because the ghosts are fermionic; also note that a ghost loop contributes a factor of -1. To get the ghost vertex, we integrate by parts to put the derivative on $\bar{c}^a$. Also note that here, p is outgoing rather than incoming.

Next, we briefly discuss the "group theory" factors that appear in amplitudes.

• In QED, we saw that the spinor-related parts of amplitudes could be constructed by following every fermion line, then writing the entries right-to-left. Similarly, in QCD, we get color factors by following the quark lines, with a generator t^a every time a gluon attaches. The ordering is the same: reading matrix indices along the fermion line will give them ordered right-to-left.

• We also get color factors from gluons, since they themselves are colored. These yield products of structure factors, which are essentially matrix products in the adjoint representation, since $(t_A^a)^{bc} = if^{abc}$.

• We define the Dynkin index and quadratic Casimir as

$$\mathrm{tr}\left(t_R^a t_R^b\right) = T(R)\delta^{ab}, \quad t_R^a t_R^a = C(R)$$

with implicit summation over repeated indices and an identity in the second result. Conventionally, we normalize the generators so that

$$T(F) = \frac{1}{2}$$

which implies that

$$C(F) = \frac{N^2-1}{2N} = \frac{4}{3}, \quad T(A) = C(A) = N = 3$$

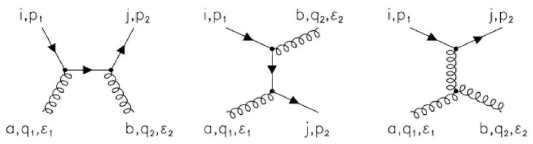
Here F stands for the fundamental representation.

• We also often get factors of the dimensions of these representations,

$$d(F) = N = 3, \quad d(A) = N^2 - 1 = 8$$

Further rules for computing these constants are given in the lecture notes on Group Theory, but these will suffice for our purposes.

Example. The process $qg \to qg$ at tree level. There are three diagrams:



which are in the s-channel, u-channel, and t-channel respectively. We'll focus on the color factors, since the kinematics are quite complicated. Setting the quark mass to zero for simplicity, we have

$$\mathcal{M}_s = g^2 \bar{u}_{s'}(p_2) \not{\epsilon}_2^* \frac{i(\not{p}_1 + \not{p}_2)}{s} \not{\epsilon}_1 u_s(p_1) t^b_{jk} t^a_{ki}$$

and

$$\mathcal{M}_u = g^2 \bar{u}_{s'}(p_2) \not{\epsilon}_1 \frac{i(\not{p}_1 - \not{q}_2)}{u} \not{\epsilon}_2^* u_s(p_1) t^a_{jk} t^b_{ki}$$

and

$$\mathcal{M}_t = g^2 \bar{u}_{s'}(p_2) \gamma^\mu u_s(p_1) \left(\frac{-i}{t}\right) f^{abc} t^c_{ji} \epsilon_2^{*\rho} \epsilon_1^\nu \left(\eta^{\nu\rho}(q_1+q_2)^\mu + \eta^{\rho\mu}(q_1-2q_2)^\nu + \eta^{\mu\nu}(q_2-2q_1)^\rho\right)$$

where repeated color indices are not summed. Upon squaring, and summing over final spins and averaging over initial spins, we get complicated expressions involving traces of up to eight gamma matrices, which can be simplified using the Clifford algebra. Ignoring this, we get, for example,

$$|\mathcal{M}_s|^2 \sim \left(t^b t^a\right)_{ji} \left(t^b t^a\right)^*_{ji} = \left(t^b t^a\right)_{ji} \left(t^b t^a\right)^\dagger_{ij} = \left(t^b t^a\right)_{ji} \left(t^a t^b\right)_{ij}$$

Summing over final colors and averaging over initial colors, and keeping only the color factor,

$$|\mathcal{M}_s|^2 \sim \frac{1}{3}\frac{1}{8} \operatorname{tr}\left(t^b t^a t^a t^b\right) = \frac{1}{24} d(F) C(F)^2 = \frac{2}{9}$$

As another example, we have

$$|\mathcal{M}_t|^2 \sim \frac{1}{24} f^{abc} f^{abd} \operatorname{tr}\left(t^c t^c\right) = \frac{1}{24} T(F) f^{abc} f^{abc} = \frac{1}{24} T(F) C(A) d(A) = \frac{1}{2}$$

As a final example,

$$\mathcal{M}_t \mathcal{M}_s^* \sim \frac{1}{24} f^{abc} \operatorname{tr}\left(t^a t^b t^c\right) = \frac{1}{48} f^{abc} \operatorname{tr}\left(t^a \left[t^b, t^c\right]\right) = \frac{i}{48} f^{abc} f^{bcd} \operatorname{tr}\left(t^a t^d\right) = \frac{i}{48} C(A) d(A) T(F) = \frac{i}{4}$$

Now we proceed to computing the beta function of Yang-Mills.

7.1.4 QCD: main laws and ideas, quarks, confinement

Основные формулы и особенности КХД

$$\mathcal{L}_{\text{QCCD}} = -\frac{1}{4}\left(F^a_{\mu\nu}\right)^2 + \bar{\psi}\left(i\gamma^\mu \partial_\mu - m\right)\psi + g\bar{\psi}\gamma^\mu A^a_\mu T^a \psi - \frac{1}{2\xi}\left(\partial_\mu A^a_\mu\right)^2 + \partial_\mu \bar{c}^a \partial_\mu c^2 + g f^{abc} \partial_\mu \bar{c}^a A^b_\mu c^c$$

Асимптотическая свобода: метод фонового поля

Асимптотическая свобода: качественное объяснение

От кварков к КХД

Quantum chromodynamics is the theory defined by the Lagrangian density

$$\mathscr{L} = \bar{\Psi}^f(x)\left[\not{D} - m_f\right]\Psi^f(x) - \frac{1}{4}G_{i\mu v}(x)G_i^{\mu v}(x)$$

obtained by combining Eqs. (11.28) and (11.34) for the quark and gluon terms, respectively. It incorporates the minimal interactions needed to make the free quark Lagrangian (11.20) gauge invariant. As in QED, it is easy to add more complicated gauge-invariant terms to the Lagrangian, for example,

$$\mathrm{i}'_s\bar{\Psi}^f(x)\Psi^f(x)G_{i\mu v}(x)G_i^{\mu v}(x).$$

However, such terms are excluded by the criterion of renormalizability, as we shall show in Section 11.3.

In contrast to QED, QCD describes a strong interaction and lowest-order perturbation theory is not, in general, a good approximation. We will defer further discussion of this until later.

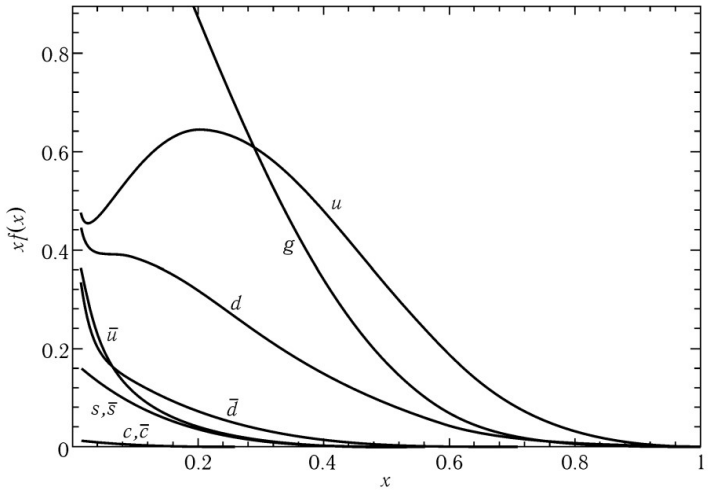
For the moment, we will summarize some important physical properties of QCD which can be inferred directly from the Lagrangian density (11.35). We start by considering the gluons. On substituting Eq. (11.33) in Eq. (11.34) one obtains

$$\begin{aligned}\mathscr{L}_G = &-\frac{1}{4}F_{i\mu v}(x)F_i^{\mu v}(x) + g_s f_{ijk}A_{i\mu}(x)A_{jv}(x)\partial^\mu A_k^v(x)\\ &-\frac{1}{4}g_s^2 f_{ijk}f_{ilm}A_j^\mu(x)A_k^v(x)A_{l\mu}(x)A_{mv}(x)\end{aligned}$$

for the purely gluonic contribution to the Lagrangian density.

О протоне (uud)

(у ПШ есть формулы про это, я пока тупой.)



$$\int_0^1 dx x \left[f_u(x) + f_d(x) + f_{\bar{u}}(x) + f_{\bar{d}}(x) + f_g(x) \right] = 1$$

Функции распределения кварков и антикварков, извлеченные из данных по глубоконеупругим рассеяниям, дают только половину значения этого интеграла. Остальные импульсы должны уносить глюоны.

(??? абзац про то, откуда вообще $SO(3)$???? хз)

are three-dimensional analogs of the Pauli matrices (A.62). [3] The operators $\hat{F}_i (i = 1, 2, ..., 8)$ are called colour charges and satisfy commutation relations of the form

$$\left[\hat{F}_i, \hat{F}_j \right] = \mathrm{i} f_{ijk} \hat{F}_k$$

where a sum over repeated colour indices $k = 1, 2, ..., 8$ is understood here and in what follows. The structure constants f_{ijk} are numbers which are easily determined using Eq. (11.11). They are totally antisymmetric

$$f_{ijk} = -f_{jik} = f_{jki} = -f_{kji} = f_{kij} = -f_{ikj}$$

(потом выгружу, пока лень)

О конфайнменте (!??!?!?)

(важный вопрос, напишу потом)

Качественно, обзорно и упрощенно о процессах КХД (!?!??!?!?)

7.1.5 Partons, Deep Inelastic Scattering, Drell–Yan Process

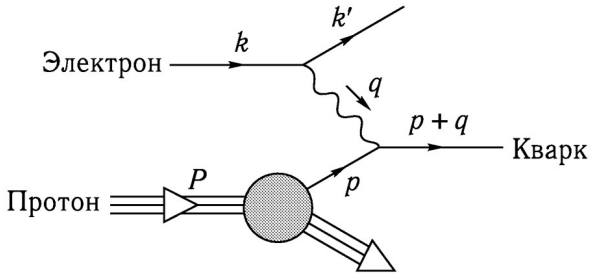
Аннигиляция e^+e^- в адроны

Об испускании глюонов (??)

$$\frac{d\sigma_{(e^+e^-\to q\bar{q}g)}}{dx_1dx_2} = \sigma_0 \cdot \left(3\sum_f Q_f^2\right) \cdot \frac{2\alpha_s}{3\pi}\frac{x_1^2+x_2^2}{(1-x_1)(1-x_2)}$$

Глубоконеупругое рассеяние

О глубоконеупругом рассеянии электрона (рассеянии электрона на протоне)



$f_f(\xi)$ - партонная функция распределения:

$$\left(\begin{array}{c}\text{вероятность найти партон } f\\ \text{с продольной долей } \xi\end{array}\right) = f_f(\xi)d\xi.$$

и вообще тут партонная модель. (????)

$$\frac{d\sigma}{d\widehat{t}}\left(e^-q\to e^-q\right) = \frac{2\pi\alpha^2Q_f^2}{\widehat{s}^2}\left[\frac{\widehat{s}^2+\widehat{u}^2}{\widehat{t}^2}\right]$$

Кинематика (????)

$$\widehat{s}+\widehat{t}+\widehat{u}=0.$$
$$\widehat{t}=-Q^2$$
$$\widehat{s}=2p\cdot k=2\xi P\cdot k=\xi s.$$

В итоге:

$$\frac{d\sigma}{dQ^2} = \int\limits_0^1 d\xi\sum_f f_f(\xi)Q_f^2\frac{2\pi\alpha^2}{Q^4}\left[1+\left(1-\frac{Q^2}{\xi s}\right)^2\right]\theta\left(\xi s-Q^2\right)$$

(вводим новые параметры про которые долго писать) через них

$$\frac{d^2\sigma}{dxdy}\left(e^-p\to e^-X\right) = \left(\sum_f xf_f(x)Q_f^2\right)\frac{2\pi\alpha^2s}{Q^4}\left[1+(1-y)^2\right]$$

тут имеем соотношение Каллана-Гросса (??????)

(в ПШ много глубоких мыслей)

О глубоконеупругом рассеянии нейтрино (рассеянии нейтрино на протоне)

(?????? тут слабое взаимодействие, для него все еще нет заготовок, плохо)

$$\Delta\mathscr{L} = \frac{g^2}{2}\frac{1}{m_W^2}\left[\bar{\ell}\gamma^\mu\left(\frac{1-\gamma^5}{2}\right)\nu\right]\left[\bar{u}\gamma_\mu\left(\frac{1-\gamma^5}{2}\right)d\right] + \text{ э.с.}$$

где ℓ, ν, d, u - фермионные поля, связанные с заряженным лептоном, нейтрино, и u-кварками, а g - константа слабого взаимодействия. Множитель $1/m_W^2$ возникв ет из-за пропагатора W-бозона, рассматриваемого в пределе $q^2 \ll m_W^2$.

$$\frac{G_F}{\sqrt{2}} = \frac{g^2}{8m_W^2}$$

$$\frac{d\sigma}{d\widehat{t}}\left(\nu d \to \mu^- u\right) = \frac{\pi g^4}{2(4\pi)^2\widehat{s}^2}\left[\frac{\widehat{s}^2}{m_W^4}\right] = \frac{G_F^2}{\pi}.$$

(проверю ее потом)

$$\frac{d\sigma}{d\widehat{t}}\left(\bar{\nu}u \to \mu^+ d\right) = \frac{\pi g^4}{2(4\pi)^2\widehat{s}^2}\left[\frac{\widehat{u}^2}{m_W^4}\right] = \frac{G_F^2}{\pi}(1-y)^2$$

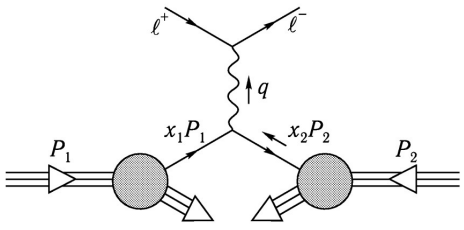
$$\frac{d^2\sigma}{dxdy}\left(\nu p \to \mu^- X\right) = \frac{G_F^2 s}{\pi}\left[x f_d(x) + x f_{\bar{u}}(x)\cdot(1-y)^2\right],$$

$$\frac{d^2\sigma}{dxdy}\left(\bar{\nu} p \to \mu^+ X\right) = \frac{G_F^2 s}{\pi}\left[x f_u(x)\cdot(1-y)^2 + x f_{\bar{d}}(x)\right].$$

Процессы жесткого рассеяния при столкновениях адронов

$$\sigma\left(p\left(P_1\right) + p\left(P_2\right) \to Y + X\right) = \int\limits_0^1 dx_1 \int\limits_0^1 dx_2 \sum_f f_f\left(x_1\right) f_{\bar{f}}\left(x_2\right)\cdot\sigma\left(q_f\left(x_1 P\right) + \bar{q}_f\left(x_2 P\right) \to Y\right),$$

Процесс Дрелла-Яна: $pp \to \ell^+\ell^-$+что-то еще. (!??!?!?!?!??)



(based on 17.4 (?????))

$$\sigma\left(q_f\bar{q}_f \to \ell^+\ell^-\right) = \frac{1}{3}Q_f^2\cdot\frac{4\pi\alpha^2}{3\widehat{s}}.$$

$$\frac{d^2\sigma}{dM^2dY}\left(pp \to e^+e^- + X\right) = \sum_f x_1 f_f\left(x_1\right) x_2 f_{\bar{f}}\left(x_2\right) \cdot \frac{1}{3} Q_f^2 \cdot \frac{4\pi\alpha^2}{3M^4}$$

$$q = x_1 P_1 + x_2 P_2 = \left(\left(x_1 + x_2\right) E, 0, 0, \left(x_1 - x_2\right) E\right)$$

$$M^2 = x_1 x_2 s$$

$$x_1 = \frac{M}{\sqrt{s}} e^Y, \quad x_2 = \frac{M}{\sqrt{s}} e^{-Y}.$$

$$\frac{d^3\sigma}{dx_1 dx_2 d\widehat{t}}(pp \to 3 + 4 + X) = f_1\left(x_1\right) f_2\left(x_2\right) \frac{d\sigma}{d\widehat{t}}(1 + 2 \to 3 + 4).$$

О другом про жесткое рассеяние по ПШ (?????)

(просто сил на это нет, мне основы ктп бы изучить сперва!!! тут еще много всего, но уже сюда хз, что буду вписывать, актуального вряд ли много будет.)

О фотоэффекте

(тут абзац с основными формулами, до которых дойду потом, пока не до них.)

Фотоэффект по Киселеву (!??!?)

(да тут простые формулы, просто собрать в задачу то, к чему уже полно заготовок нужно и все)

$$|\mathrm{i}\rangle = |\boldsymbol{k}_\mathrm{i}, \lambda_\mathrm{i}\rangle\, |\psi_{1\ \mathrm{s}}\rangle$$

$$\langle \boldsymbol{r}|\psi_{1\ \mathrm{s}}\rangle = \frac{1}{\sqrt{\pi a^3}}\mathrm{e}^{-r/a}.$$

$$\hat{V}(t) = -\boldsymbol{d} \cdot \hat{\mathcal{E}} = -e\boldsymbol{r} \cdot \hat{\mathcal{E}}(\boldsymbol{r}, t),$$

$$|\mathfrak{f}\rangle = |\,\mathrm{vac}\rangle\, |\boldsymbol{k}_\mathfrak{f}\rangle\,.$$

$$\mathrm{d}w_{\mathfrak{f}\mathfrak{i}} = \frac{2\pi}{\hbar^2}\delta\left(\omega_\mathrm{i} + \omega_\mathrm{at} - \omega_\mathfrak{f}\right) |V_{\mathrm{f}\mathrm{i}}(0)|^2 \;\mathrm{d}\nu_\mathfrak{f},$$

$$\mathrm{d}\nu_\mathrm{f} = \frac{\mathrm{d}^3 k_\mathrm{f}}{(2\pi)^3},$$

$$\frac{E_\mathrm{at}}{\hbar\omega_\mathrm{i}} \ll 1 \Rightarrow \frac{\hbar^2}{2ma^2}\left(\frac{\hbar^2 k_\mathrm{f}^2}{2m}\right)^{-1} = \frac{1}{\left(k_\mathfrak{f} a\right)^2} \ll 1.$$

(???? а дальше словами нужно писать, тут прямо очень много преобразований, формулами на страницу минимум выйдет.)

$$\frac{1}{2}\sum_{\lambda_\mathrm{i}} |V_{\mathrm{f}\mathrm{i}}(0)|^2 = 2^9\pi^2\frac{\hbar^5 c}{m^2}\alpha_\mathrm{em}\frac{a}{\left(k_\mathrm{f} a\right)^6}\left(1 - \cos^2\theta\right).$$

В итоге, сечение фотоэффекта на основном состоянии атома водорода выражается через боровский радиус, постоянную тонкой структуры и отношение энергии ионизации к энергии фотона и равно

$$\sigma = \frac{8}{3}\pi a^2 \alpha_\mathrm{em}\left(\frac{4E_\mathrm{at}}{\hbar\omega_\mathrm{i}}\right)^{7/2}$$

(??? отлично, а на не атоме водорода мы абсолютно ничего не можем сказать, потому что мы и близко к этому не готовы.)

7.3 Solitons, kinks, monopoles, vortices, instantons

(также у Зи хорошо написано, поизучаю потом мб, в этой записи это уже написано.)

7.3.1 Kinks

Introduction

• Solitons are stable, spatially localized smooth solutions of classical PDEs. We will focus on their description in classical field theory. Often, we will find that they "connect distinct vacua", giving them topological stability. The solitons have a topological charge that makes them distinct from the vacuum.

• To have soliton solutions, we need nonlinear equations, which can be achieved by nontrivial interactions between fields, or by self-interaction, as in ϕ^4 theory.

• Solitons can be quantized, at which point we can interpret them as particles. For example, solitons carry energy and momentum. By Lorentz invariance, a stationary soliton with energy E_0 can be boosted to yield moving solitons, obeying

$$E^2 = p^2 + m^2$$

where the mass of the soliton is $m = E_0$. Solitons can also interact with each other like particles.

• However, solitons cannot be seen by perturbing about a vacuum state. Instead, we fix a soliton solution and treat it as a background for quantization. This is difficult, as we typically can't write down exact soliton solutions; we won't consider this subject too closely.

• Another feature that distinguishes solitons is that ordinary quantum particles have masses proportional to $\hbar$, since $E = \hbar\omega$, while the masses of solitons are independent of $\hbar$.

• We will focus on a few types of solitons, all in relativistic field theory.

• In one spatial dimension, we have kink solutions.

• In two spatial dimension, we have vortices. We will also investigate solitons in nonlinear σ models.

• In three spatial dimensions, we have Skyrmions.

Overview of Skyrmions, domain walls, solitons in cosmology

Nonrelativistic solitons include domain walls in ferromagnets and two-dimensional "baby" Skyrmions in exotic magnets. Solitons also appear in cosmology, where we can have domain walls, cosmic strings, and monopoles.

• Skyrmions are solitons in an effective field theory of interacting pions, representing the (fermionic) nucleons. They were pioneered by Skyrme, who had the strong philosophical opinion that all fermionic fields had to be emergent in this way. Though the skyrmion approach is not particularly accurate in real QCD, it was famously shown by Witten to be a good description in the large N_c limit.

• Finally, we comment on quantization. Typically, for a field whose particles have mass m and coupling g, solitons classically have energy and size

$$E \sim \frac{m}{g}, \quad \ell \sim \frac{1}{m}$$

in natural units; this will hold for our examples below.

• Then the Compton wavelength of a soliton is

$$\lambda \sim \frac{1}{E} \sim g\ell$$

Therefore, we don't expect quantization to significantly affect the soliton when the coupling is weak; we simply find perturbative corrections to E. The fact that E diverges as $g \to 0$ also indicates the solitons cannot be seen in perturbation theory.

• We can also have some insight in the strong coupling regime. For example, the sine-Gordan theory and massive Thirring model are dual, with strong coupling in one mapping to weak coupling in the other, and solitons exchanging with elementary particles. Hence there is no intrinsic difference between an elementary particle and a soliton; all that matters is which viewpoint is more convenient for calculation in a particular regime.

Next, we introduce the basic kink solution.

• We work in $1+1$ dimensions with metric $\mathrm{diag}(1,-1)$. The action is

$$S = \int d^2x \left(\frac{1}{2} \partial_\mu \phi \partial^\mu \phi - U(\phi) \right)$$

The equation of motion is

$$\partial_\mu \partial^\mu \phi + \frac{dU}{d\phi} = 0$$

which is called a nonlinear Klein-Gordan equation.

• For explicit calculations, it will be useful to work 'nonrelativistically'. We define $\dot{\phi} = \partial\phi/\partial t$ and $\phi' = \partial\phi/\partial x$ with

$$L = T - V, \quad T = \int \frac{1}{2}\dot{\phi}^2 dx, \quad V = \int \frac{1}{2}\phi^2 + U(\phi) dx$$

• We are interested in static solutions, which obey $\phi'' = dU/d\phi$. We choose the potential

$$U(\phi) = \frac{1}{2}\left(1 - \phi^2\right)^2$$

so two static solutions to the field equations are the vacua $\phi(x) = \pm 1$. There are soliton solutions that connect these vacua.

• There are plenty of other choices, such as

$$U(\phi) = 1 - \cos\phi$$

which is called the sine-Gordan theory since the field equation contains $\sin\phi$. This theory is integrable, which means that we can find explicit exact solutions involving interacting solitons.

• Sticking with our original choice, the field equation is

$$\phi'' = -2\left(1-\phi^2\right)\phi$$

This is a nonlinear second order differential equation, so instead we think in terms of energy. By Noether's theorem, we have a conserved energy

$$E = \int \frac{1}{2}\dot{\phi}^2 + \frac{1}{2}\phi^2 + U(\phi)dx$$

which is simply V for a static solution. For static solutions, the action is proportional to V and is also extremized, which means that E is minimized.

• We shift $U(\phi)$ so that it is nonnegative, and its minimum value is zero. Then finite energy solutions have fixed boundary conditions $U(\pm\infty)$. Now, we define the function W by

$$U(\phi) = \frac{1}{2}\left(\frac{dW}{d\phi}\right)^2$$

Now the energy is quadratic, so we may complete the square for

$$\begin{aligned} E &= \frac{1}{2}\int \phi'^2 + \left(\frac{dW}{d\phi}\right)^2 dx \\ &= \frac{1}{2}\int \left(\phi' \mp \frac{dW}{d\phi}\right)^2 dx \pm \int \frac{dW}{d\phi}\frac{d\phi}{dx}dx \\ &= \frac{1}{2}\int \left(\phi' \mp \frac{dW}{d\phi}\right)^2 dx \pm (W(\phi(\infty)) - W(\phi(-\infty))). \end{aligned}$$

• Since the second term is fixed, the energy is minimized if the first term vanishes, so

$$\phi' = \pm\frac{dW}{d\phi}$$

while the energy of the solution is

$$E = \pm(W(\phi(\infty)) - W(-\infty))$$

where we take the positive solution. Moreover, any soliton will have at least this energy; this is an example of a so-called Bogomolny bound.

• Note that the equation $\phi'' = dU/d\phi$ for static solutions is equivalent to that of a particle of unit mass and position $x(t)$ in the potential $-U$. This is just like the situation for instantons, and provides some intuition.

• In the case of the ϕ^4 kink, we have

$$W = \phi - \frac{1}{3}\phi^3$$

Fixing the boundary conditions $\phi(\infty) = 1$ and $\phi(-\infty) = -1$, we have $E = \pm 4/3$. Since the energy is positive, we take the plus sign, so $M = 4/3$ and

$$\phi' = \frac{dW}{d\phi} = 1 - \phi^2, \quad \phi(x) = \tanh(x-a)$$

where a is a constant of integration, the position of the soliton. We thus call a a modulus (or collective coordinate) of the solution, and the set of possible moduli is the moduli space; in this case it is $\mathbb{R}$.

• We can also have moving kink solutions, by simply performing a Lorentz transformation,

$$\phi(x,t) = \tanh\gamma(x-vt)$$

It is useful to focus on slowly moving solitons. Then

$$\phi(x,t) \approx \tanh(x-a(t)), \quad a(t) = vt$$

which looks like a static solution with a time-dependent modulus.

• We can write the action in terms of the time-varying modulus in this 'adiabatic' approximation. We have $\dot{\phi} = -\dot{a}\phi'$, so

$$T = \int \frac{1}{2}\dot{\phi}^2 dx = \frac{1}{2}\dot{a}^2 \int \phi'^2 dx = \frac{1}{2}M\dot{a}^2$$

where the final result can be simply written down using Lorentz invariance or computed by an ugly integral. Alternatively, the Bogomolny equation shows that the two terms in the E integral above contribute equally, which means that the integral of ϕ^2 is just M.

• Meanwhile, V doesn't depend on $\dot{a}$, so it is simply $4/3$, and we have the particle Lagrangian

$$L = \frac{1}{2}M\dot{a}^2 - \frac{4}{3}$$

This is an 'effective field theory' style approach; we are restricting our variational problem in field space to a 'valley' given by static solutions, parametrized by $a(t)$.

• The soliton Lagrangian has the equation of motion

$$M\ddot{a} = 0, \quad a(t) = vt + a_0$$

which is exactly what we found above. Geometrically, we can think of the equation of motion as the geodesic equation on the moduli space $\mathbb{R}$, where M specifies the metric. This is trivial here, but generalizes to higher-dimensional systems and multi-soliton dynamics.

• In general, zero modes arise whenever a soliton breaks a symmetry in the Lagrangian; in this case the soliton breaks translational symmetry. Later we'll see more complex examples where a soliton breaks an internal symmetry, i.e. it carries a conserved charge.

Dynamics of Kinks

Next, we consider interactions of kinks.

• In our current theory, there aren't multi-kink solutions. However, we can ask how a solution consisting of a kink and anti-kink behaves.

• First, it's useful to look at conserved quantities. We have

$$T^\mu_\nu = \partial^\mu\phi\partial_\nu\phi - \delta^\mu_\nu\mathcal{L}$$

The energy is the integral of T^0_0, giving the same result we found earlier. The momentum is

$$P = -\int T^0_1 dx = -\int \dot{\phi}\phi' dx$$

For our moving kink solution $\phi = \tanh(x - a(t))$ we have, by the same tricks as above,

$$P = M\dot{a}$$

which is what we would expect for a particle of mass M.

• Next, we would like to compute the interaction force between a widely separated kink and antikink, as only this regime is analytically tractable. Let the kink and antikink be located at $\pm a$, and let b be a point in between them far away from each of them; we'll show the result doesn't depend sensitively on b. We define the momentum of the kink as

$$P = -\int_{-\infty}^{b} \dot{\phi}\phi' dx$$

By conservation of energy-momentum we have

$$\partial_t T_1^0 + \partial_x T_1^1 = 0$$

• The force on the kink is defined as

$$F = \dot{P} = -\int_{-\infty}^{b} \partial_t T_1^0 dx = \int_{-\infty}^{b} \partial_x T_1^1 dx = T_1^1(b) = \left(-\frac{1}{2}\dot{\phi}^2 - \frac{1}{2}\phi'^2 + U\right)_{x=b}$$

• To make further progress, we need to explicitly write down ϕ. An approximate solution is

$$\phi(x) = \tanh(x + a) - \tanh(x - a) - 1 \equiv \phi_1 + \phi_2 - 1$$

as long as $a \gg 1$. We will assume that the kinks are initially at rest, $\dot{\phi} = 0$, though they will begin moving as they exert a force on each other.

• Next, at the point $b, \phi_2 - 1$ and hence ϕ_2' are small, so we expand to first order in them,

$$F = \left(-\frac{1}{2}\phi_1^2 + U(\phi_1) - \phi_1'\phi_2' + (\phi_2 - 1)\frac{dU}{d\phi}(\phi_1)\right)_{x=b}$$

The first two terms cancel out by the Bogomolny equation; physically they must cancel because a kink cannot exert a force on itself.

• Next, the field equation gives $(dU/d\phi)(\phi_1) = \phi_1''$, so we have

$$F = \left(-\phi_1'\phi_2' + (\phi_2 - 1)\phi_1''\right)_{x=b}$$

This is as far as we can go without using the explicit solution.

• To keep the calculations manageable we use the asymptotic form of tanh,

$$\phi_1(x) \sim 1 - 2e^{-2(x+a)}, \quad \phi_2 \sim 1 - 2e^{2(x-a)}$$

which is valid when x is far from both $\pm a$. The factors of 2 here are called the 'amplitude of the tail'. Plugging this in and simplifying,

$$F = 32e^{-4a}$$

where the value of b drops out.

• To understand this solution better, we restore parameters to find

$$F = 2m^2 A^2 e^{-ms}$$

where $s = 2a$ is the separation, A is the amplitude of the tail, and m is the mass of the quanta in the theory. But this looks just like the result from tree-level exchange of quanta of mass m. Physically, applying perturbation theory makes sense because the interaction happens at b, where the field is close to vacuum.

• Evidently, the kink and antikink attract, eventually colliding. We have to resort to numerics to find what happens. Generally, if the kinks are moving slowly, they annihilate into 'meson radiation'. If they are moving very quickly, they can bounce off each other.

Next, we turn to kinks in sine-Gordan theory.

• In this case, the potential has minima at multiples of 2π,

$$U(\phi) = 1 - \cos\phi, \quad \frac{dW}{d\phi} = 2\sin\frac{\phi}{2}$$

The Bogomolny equation is

$$\frac{d\phi}{dx} = 2\sin\frac{\phi}{2}, \quad \phi(x) = 4\tan^{-1}\left(e^{x-a}\right)$$

which describes a kink that interpolates between 0 and 2π, with $M = 8$.

• However, there is no solution to the Bogomolny equations which interpolates between 0 and 4π. The reason is that sine-Gordan kinks repel each other (since we know a kink and antikink attract), no matter how far apart they are. Thus the energy can be continually lowered by bringing the kinks further apart; there are no static multi-kink solutions.

• We can describe dynamical multi-kink solutions. One explicit example is

$$\phi(x,t) = 4\tan^{-1}\frac{v\sinh\gamma x}{\cosh\gamma vt}$$

Physically, the kinks move towards each other until $t = 0$, then bounce off each other, so evidently they repel. There is also a "breather" solution consisting of a kink and antikink bound together and oscillating.

• We might expect that a system of many kinks and antikinks, all with different velocities, will behave in a complicated way. Numerical simulations indicate that the result is simple; there is no energy loss due to "radiation". This is because the sine-Gordan theory is integrable.

• Since everything is periodic modulo 2π, we can choose to physically identify $\phi \sim \phi + 2\pi$. Then we have $\phi : \mathbb{R} \to S^1$ and the boundary condition is $\phi(x) = 0$ at infinity.

• For a topological approach to classifying solitons, we can compactify $\mathbb{R}$ to get $\phi : S^1 \to S^1$, and solitons are classified by their winding number, i.e. their homotopy class in $\pi_1(S^1)$. We call this winding number the topological charge Q.

• We can also take a "physics" style approach. Define the topological current

$$j^\mu = \frac{1}{2\pi}\epsilon^{\mu\nu}\partial_\nu\phi = \frac{1}{2\pi}\left(\partial_x\phi, -\partial_t\phi\right), \quad \epsilon^{01} = 1$$

This current is conserved by the symmetry of mixed partial derivatives. This is remarkable because it is completely independent of the field equations, making its conservation topological rather than dynamical.

• The conserved charge associated with the current is

$$Q = \int j^0 dx = \frac{1}{2\pi} \int \partial_x \phi dx$$

which is simply the topological charge Q as defined earlier.

• Finally, we can define Q geometrically. The target space S^1 has a normalized volume form

$$\int_{S^1} \omega = 1$$

where one example is $\omega = d\phi/2\pi$.

• Given a mapping $\phi : \mathbb{R} \to S^1$ we can pullback the volume form,

$$\phi^* \omega = \frac{1}{2\pi} \frac{d\phi}{dx} dx$$

and we define the degree of the map to be

$$Q = \int_{\mathbb{R}} \phi^* \omega = \frac{1}{2\pi} \int \frac{d\phi}{dx} dx$$

which agrees with the previous expressions.

Next, we briefly discuss quantization of the kink.

• At the simplest level, we can use the moduli space approximation,

$$L = \frac{1}{2} M \dot{a}^2, \quad H = \frac{P^2}{2M}$$

and hence upon canonical quantization we get the ordinary Schrodinger equation for a free particle of mass M. Stationary states take the plane wave form

$$\psi(a) = e^{ika}, \quad P = \hbar k, \quad E = \frac{\hbar^2 k^2}{2M}$$

Note that the wavefunction is on the moduli space.

• More properly, we would quantize the field about a kink solution; this is similar to quantizing a field in a curved spacetime, in that we just generalize the usual plane-wave mode expansion. For example, one can form wavepackets far from the kink that don't feel it at all, while there are also modes that are "bound to the kink", and look like the kink's shape wobbling.

• The zero-point energies of these modes provide an infinite renormalization of the kink mass. This is acceptable, since we get a finite result when we subtract it against the zero-point energy of the vacuum solution. The remainder is a finite shift to the kink mass, which is indeed small when the coupling is weak.

• This computation will be complicated by the presence of zero-frequency modes. These correspond to moduli, and we can't ignore them; they remain important even when the coupling goes all the way to zero. Accounting for the moduli alone and ignoring all other terms in the Lagrangian is exactly what we did above.

• Another way to see the weak coupling requirement is to say that the soliton is essentially unchanged by quantization if there is a length scale L, much smaller than the kink size, where the size of the quantum fluctuations is small; this is the same requirement to treat the electromagnetic field classically. One can show explicitly this is equivalent to weak coupling.

• In the case of strong coupling, the soliton typically survives in the quantum theory, but it doesn't behave anything like the classical soliton.

7.3.2 Vortices, Monopoles, Instantons

Vortices in a complex scalar field in $2+1$

$$\mathcal{L} = \frac{1}{2}\left(\partial_\mu \phi\right)^* \left(\partial^\mu \phi\right) - \frac{\lambda}{4}\left(|\phi|^2 - \frac{\mu^2}{\lambda}\right)^2,$$

the potential is minimized for $|\phi| = v = \sqrt{\mu^2/\lambda}$.

• We expect solitons on topological grounds. Letting $\phi = \rho e^{i\alpha}$ and defining the winding number

$$N = \frac{1}{2\pi}\int_C d\ell \cdot \nabla\alpha$$

we find that N takes integer values. On the other hand, it appears that N must be zero if ϕ is non-singular since we can shrink the loop to zero. Thus for N to be nonzero, there must be at least one point where ϕ vanishes. The solutions with nonzero $N = n$ are topologically stable with vorticity $n \in \mathbb{Z}$.

• To make further progress we must solve the field equations

$$\nabla^2\phi - \lambda\left(|\phi|^2 - v^2\right)\phi = 0$$

We will try the rotationally symmetric ansatz $\phi(\mathbf{x}) = f(r)e^{i\theta}$. Also, if we demand symmetry by a reflection about the x-axis followed by complex conjugation, $f(r)$ must be real.

• There is a general reason the ansatz will work. Naively, taking an ansatz makes the equations of motion overdetermined, so we generically have no solutions at all. But suppose the action is invariant under a group of transformations G, and the ansatz has the most general possible form invariant under G. A variation of the ansatz can be decomposed into a part that is G-invariant and a part that is not, where the second part averages to zero upon integration. Thus the only nontrivial equations of motion come from G-invariant variations, so the ansatz has enough parameters to generically yield a solution. A similar principle in quantum mechanics is that energy eigenstates have the symmetries of the Hamiltonian.

• However, we do need to look at variations that are not G-invariant to determine whether G invariant solutions are stable, since physically there will be external influences that slightly break the symmetry.

• Now, plugging into the equations of motion gives a single equation for the single function f,

$$\frac{d^2 f}{dr^2} + \frac{1}{r}\frac{df}{dr} - \frac{f}{r^2} + \lambda\left(v^2 - f^2\right)f = 0$$

so we indeed get a solution, by the general reasoning above, with $f(0) = 0$ and $f(\infty) = v$.

• However, the solution has infinite energy, because

$$E \supset \int d^2x \frac{1}{2}|\phi|^2(\nabla\theta)^2 \sim \int \frac{dr}{r}$$

which diverges logarithmically. Such configurations could be physically relevant, i.e. we would have a finite energy per vortex if we had a finite density of vortices, but a single vortex is not physically meaningful.

It's possible to understand this result using general scaling reasoning.

• The energy of a finite-energy, static solution $\bar{\phi}$ can be written as $E = I_K + I_V$ where the gradient energy/"kinetic energy" I_K is bilinear in the first derivatives of ϕ and the potential energy I_V is an integral of $V(\phi)$.

• Now consider the scaled field $\phi(\mathbf{x}) = \bar{\phi}(\lambda\mathbf{x})$. In D spatial dimensions,

$$E(\lambda) = \lambda^{2-D} I_K + \lambda^{-D} I_V$$

Since $\bar{\phi}$ is a static solution, it locally minimizes the energy, so $dE/d\lambda = 0$ at $\lambda = 1$, giving

$$0 = (D-2) I_K + D I_V$$

This places strong restrictions on solitons.

• For $D = 1$, we get $I_K = I_V$, which is a generalization of a result we found earlier.

• For $D = 2$, we require $I_V = 0$. This rules out non-singular solitons in our model above, since ϕ must vanish at some point, so we cannot have $|\phi| = v$ everywhere. Solitons can exist in more complicated models, such as the $O(3)$ sigma model. However, then $E(\lambda) = \lambda^{2-D} I_K$ is independent of λ, so the soliton is neutrally stable against expansion and contraction.

• For $D \geq 3$, we require $I_K = I_V = 0$, so the only solution is the constant vacuum solution.

This result is a version of Derrick's theorem, and forbids simple solitons in $D > 1$.

• Solitons can evade Derrick's theorem in several ways. They can have infinite energy (as for our vortices), they can necessarily vary in time (which we won't consider), or they can be unstable or neutrally stable against compression, as we saw for $D = 2$. In this last case, however, this means we don't actually have stable solitons at all: when the soliton size shrinks close to the lattice cutoff, the topological obstruction fades away and the soliton can vanish entirely.

• Thus, in order to have stable finite-energy static solitons, we must add more structure to the theory. One example is an abelian Higgs model, where the energy is now

$$E = I_F + I_K + I_V, \quad I_F = \frac{1}{2}\int d^D x \, \mathrm{tr}\, F_{ij}^2, \quad I_K = \frac{1}{2}\int d^D x \, (D_j\phi)^* \, (D_j\phi)$$

The new term I_F transforms differently under scaling.

• We now consider the scaled fields

$$\phi(x) = \bar{\phi}(\lambda x), \quad A(x) = \lambda \bar{A}(\lambda x)$$

where the factor of λ is necessary to maintain the functional form of I_K. Then

$$E(\lambda) = \lambda^{4-D} I_F + \lambda^{2-D} I_K + \lambda^{-D} I_V$$

which is stationary at $\lambda = 1$ if

$$(D-4) I_F + (D-2) I_K + D I_V = 0$$

which allows soliton solutions in $D = 2$ and $D = 3$.

• Note that in pure Yang-Mills, we have only I_F, in which case a neutrally stable soliton exists only when $D = 4$. These solitons are just Yang-Mills instantons in spacetime dimension $d = 4$, after a Wick rotation to $D = 4$. The neutral stability indicates that instantons have any size.

We will next investigate vortices in the abelian Higgs model in $2 + 1$ dimensions.

• We have a complex scalar field ϕ and a $U(1)$ gauge potential a_μ with

$$\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}\left(D_\mu\phi\right)^*\left(D^\mu\phi\right) - \frac{\lambda}{4}\left(|\phi|^2 - \frac{\mu^2}{\lambda}\right)^2, \quad D_\mu\phi = \partial_\mu\phi + ieA_\mu\phi$$

The gauge transformations take the form

$$\phi(x) \to e^{ie\Lambda(x)}\phi(x), \quad A_\mu(x) \to A_\mu(x) - \partial_\mu\Lambda(x)$$

Under such a gauge transformation, the winding number transforms as

$$N \to N + \frac{e}{2\pi}\int_C d\boldsymbol{\ell}\cdot\nabla\Lambda = N$$

as long as Λ is nonsingular and single-valued, so our topological argument still works.

• Taking spatial components with $\phi = \rho e^{i\alpha}$, we find

$$\mathbf{D}\phi = e^{i\alpha}(\nabla\rho + i\rho(\nabla\alpha - e\mathbf{A}))$$

which means the gradient energy is zero at large distances if

$$\mathbf{A} = \frac{1}{e}\nabla\alpha$$

Hence the energy does not diverge as it did above.

• Evaluating the winding number by a loop at large r, for a solution with vorticity n,

$$n = \frac{1}{2\pi}\int_C d\boldsymbol{\ell}\cdot\nabla\alpha = \frac{e}{2\pi}\int_C d\boldsymbol{\ell}\cdot\mathbf{A} = \frac{e}{2\pi}\int d^2x B, \quad \Phi = \frac{2\pi n}{e}$$

so we find a quantized magnetic flux. Since the field is pure gauge at large r, the flux is localized at small r.

• We now consider a static vortex solution with $n = 1$. We work in the gauge $A_0 = 0$ and take the ansatz

$$\phi(\mathbf{x}) = ve^{i\theta}f(evr), \quad A_j(\mathbf{x}) = \epsilon_{jk}\hat{x}^k\frac{a(evr)}{er}$$

where f and a are real. This is the most general ansatz with the same symmetries we used for the global vortex case. The boundary conditions are

$$f(0) = a(0) = 0, \quad f(\infty) = a(\infty) = 1$$

which ensure the vortex is nonsingular at the origin, and has finite energy.

• There is no closed-form analytic solution, but the form of the solution is intuitive. When $|\phi| \neq 0$, the gauge field acquires a mass, so it is energetically costly to have a magnetic field. Hence it is localized near the origin, where $|\phi|$ is small. Since the magnetic energy depends on B^2, it favors a larger vortex core, but the potential for ϕ favors a smaller vortex core. The relative strength of these two effects is determined by the ratio λ/e^2.

• Also note that the same vortex solution can be written in other gauges, though it will no longer appear rotationally symmetric.

Next, we consider multiple vortices.

• We may also consider the interaction of vortices. Two vortices will interact through both the ϕ field and the A_μ field. Since the former is spin zero, it mediates a universally attractive

force, while the latter makes like-charged vortices repel. Hence at large distances, the interaction is determined by the field with the slower falloff; the vortices attract if and only if $m_\phi < m_A$, or equivalently $\lambda/e^2 < 1/2$.

• It's harder to say what will happen at smaller distances, since the problem becomes nonlinear, but numerical simulations indicate that the sign of the force only depends on whether m_ϕ/m_A is greater or less than one. When they are equal, vortices don't interact at all, and there are static solutions with multiple vortices.

• Otherwise, such static solutions don't exist, but we can still find a static solution consisting of a single vortex with $n > 1$. However, when the force between vortices is repulsive, such a vortex is not energetically stable.

• This result is important for superconductivity, which is described by the same theory, but in three dimensions; our vortices are replaced with vortex lines. Consider forcing a magnetic flux through a superconductor by applying a field; it will then be energetically favorable to form vortices.

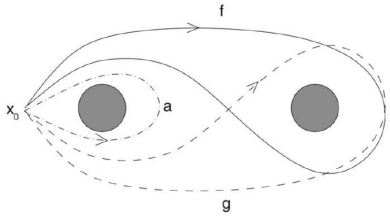
• In a type I superconductor, the superconductivity is lost at a relatively low external field, while a type II superconductor can persist up to a much higher field in a mixed state where the flux is confined to separated vortex lines. Physically, type I superconductors have $\lambda/e^2 < 1/2$, so the vortex lines attract, combining into extended regions where the superconductor breaks down. In a type II superconductor they repel, forming a lattice.

Vortices and Homotopy

• We consider a theory with symmetry group G broken down to H, so the vacuum manifold is $\mathcal{M} = G/H$. In two spatial dimensions, we consider a loop at spatial infinity (or at least well-separated from the vortex cores), which yields a loop in field space. Then naively, if this loop is not homotopic to the trivial loop, it must contain a soliton.

• However, there is a subtlety in this standard argument. When we consider homotopy of loops, we deform the loop while fixing a base point. However, when we consider the stability of solitons, we allow arbitrary variations of the field; there is no point on the loop where the field value is fixed. We are considering loops up to "free homotopy".

• As a specific example, consider the setup shown below.



The loops f and g are not homotopic, but they are related by $g \sim afa^{-1}$. Hence they are freely homotopic. More generally, the set of loops up to free homotopy is the set of conjugacy classes of $\pi_1(\mathcal{M})$.

• Note that the set of conjugacy classes is not a group! Given multiple vortices, there are multiple paths that go around all of them, whose corresponding loops lie in different conjugacy classes.

• We must also account for gauge invariance. One can show that the freedom due to gauge transformations keeps loops within the same free homotopy class, so we don't have to further modify our conclusions.

• Below, we will focus on the abelian case, where these subtleties do not appear, as all conjugacy classes have one element. In this case, the quantum numbers of vortices simply add.

Example. In the models above, the symmetry group was $U(1)$ and completely broken, so $\mathcal{M} = U(1)$, and $\pi_1(\mathcal{M})$ indexes the vortices.

Example. Consider $SO(n)$ broken to $SO(n-1)$, which occurs when a scalar field transforming in the vector representation of $SO(n)$ acquires a vev. Then $\mathcal{M} = S^{n-1}$ and for $N \geq 3, \pi_1(\mathcal{M}) = 0$, so there are no topologically stable vortices.

Example. Consider an $SO(3)$ gauge theory with two scalar fields transforming in the vector representation, with the potential

$$V(\boldsymbol{\phi}, \boldsymbol{\chi}) = \frac{\lambda_\phi}{4}\left(\phi^2 - v_\phi^2\right)^2 + \frac{\lambda_\chi}{4}\left(\chi^2 - v_\chi^2\right)^2 + g(\phi \cdot \chi)^2$$

If g is negative, the vevs are parallel, and the symmetry is broken to $U(1)$. If g is positive they must be orthogonal, so the $SO(3)$ symmetry is completely broken, so $\mathcal{M} = SO(3)$ and $\pi_1(\mathcal{M}) = \mathbb{Z}_2$. Hence we have $\mathbb{Z}_2$ vortices, where a combination of two is topologically trivial. A simple ansatz is

$$\phi = v_\phi(0,0,1), \quad \chi = v_\chi f(r)(\cos\theta, \sin\theta, 0), \quad \mathbf{A}_j = \epsilon_{jk}\hat{x}^k \frac{a(r)}{r}(0,0,1)$$

where the latter two are just an embedding of the $U(1)$ gauged vortex.

Note. Consider the case $v_\phi \gg v_\chi$ above. Then if we integrate out the ϕ field, we are left with a $U(1)$ gauge theory, and a combination of two vortices is topologically stable, even though it isn't in the original $SO(3)$ gauge theory. This is due to energetics. The deformation that takes two $\mathbb{Z}_2$ vortices to the untwisted configuration must involve a non-constant ϕ field at intermediate stages, but if $v_\phi \gg v_\chi$ this has a very large energy cost. The lesson here is that topological stability is not absolute; it can be 'effective' like everything else in field theory.

Note. There is some freedom in the gauge groups. In the previous example, we could have taken gauge group $SU(2)$, in which case a $\mathbb{Z}_2$ symmetry would remain when $g > 0$. We get the same vacuum manifold, as $\mathcal{M} = SU(2)/\mathbb{Z}_2 = SO(3)$.

Example. The electroweak sector of the Standard Model has

$$G = SU(2) \times U(1), \quad H = U(1), \quad \mathcal{M} = S^3$$

because the Higgs VEV can take any value with the same norm. Since $\pi_1\left(S^3\right) = 0$, there are no topological vortices. On the other hand, consider a theory with a local $U(1)$ symmetry but only a global $SU(2)$ symmetry. Then a vortex configuration with

$$\phi = \begin{pmatrix} 0 \\ f(r)e^{i\theta} \end{pmatrix}$$

is indeed topologically stable, as unwinding it would cost an infinite amount of $SU(2)$ gradient energy. Such a vortex is called a semilocal vortex. As before, we must have $f(0) = 0$ to avoid a singularity.

However, the semilocal vortex has a different source of instability. Recall that we can use a local $SU(2)$ symmetry to set the upper component of ϕ to zero everywhere, without loss of generality. With a global $SU(2)$ symmetry, we must consider the more general possibility

$$\phi = \begin{pmatrix} g(r) \\ f(r)e^{i\theta} \end{pmatrix}$$

The scalar potential is minimized if $f^2 + g^2 = v^2$, so a vortex may be unstable to the formation of larger and larger regions where $f(r) = 0$, as long as $g(r) = v$. By the topological arguments, the vorticity must still remain at spatial infinity, but it will become unobservable at any finite radius. This instability occurs when the $U(1)$ gauge coupling is small compared to the scalar self-coupling.

Example. Alice strings. Consider an $SO(3)$ gauge theory with a Higgs field in the 5, i.e. an traceless symmetric 3×3 matrix transforming as

$$\phi \to R\phi R^T$$

Also suppose that $V(\phi)$ is minimized when two of its eigenvalues are equal, so

$$\phi = R\,\mathrm{diag}(a, a, -2a)R^T = a\left(1 - 3\mathbf{e}\mathbf{e}^T\right), \quad \mathbf{e} = R\mathbf{e}_0$$

Then the vacuum manifold is $S^2/\mathbb{Z}_2$ with fundamental group $\mathbb{Z}_2$. To find the unbroken gauge group, note that the vacuum remains invariant under rotations about the e axis, but it is also invariant under a π rotation about the $\mathbf{e}'$ axis, where $\mathbf{e}'$ is an arbitrary vector perpendicular to $\mathbf{e}$. These operations do not commute; instead the group is

$$U(1) \rtimes \mathbb{Z}_2 = \mathrm{Pin}(2)$$

Of course, these results are consistent with the general principle $\mathcal{M} = G/H$.

Now consider a vortex solution described by $\mathbf{e}(\theta) = R(\theta)\mathbf{e}_0$ at large distances. If $R(\theta)$ traverses a nontrivial path through $S^2/\mathbb{Z}_2$, then the vortex is topologically stable. If it is present, it is not possible to define the charge of a particle under the unbroken $U(1)$ subgroup unambiguously, because it is generated by rotations about $\mathbf{e}$, and following $\mathbf{e}$ around a circle flips the sign. In order to remove the ambiguity, one may perform a gauge transformation so that $\mathbf{e}$ is constant everywhere, except for a "branch cut" running out to infinity, across which it flips. Then we may say the sign of the charge flips upon crossing the branch cut. In three dimensions, the vortices become strings, and the branch cuts become surfaces. The location of the surface is not gauge invariant, but its existence is, leading to the term "Alice strings".

Now consider two charges and an Alice string that closes on itself to make a circular loop. We consider two particles with the same charge starting next to each other; this is a physical statement, as it means that, e.g. they cannot annihilate. If we transport one of them in a circle that goes through the loop, it will come back with the opposite charge, and hence the two particles can annihilate; hence this ambiguity in the charge has a real physical effect. We can define the total charge of the system of the two charges and string at all times by a flux integral at infinity, and this must be conserved, so charge must have been transferred to the string. But since the surface associated with the string is arbitrary, it is meaningless to ask when the transfer occurred; hence we have a system where the total charge is defined but cannot be unambiguously localized!

Example. A non-abelian fundamental group. Consider the same theory as above, with a potential that is minimized when the eigenvalues of ϕ are all distinct,

$$\phi = R\,\mathrm{diag}\,(a_1, a_2, a_3)\,R^T, \quad a_1 \neq a_2 \neq a_3$$

This vacuum is invariant under only the identity and rotations by π about the x, y, and z axes, which form the Klein four group. To find $\pi(\mathcal{M})$, it is more convenient to use the universal cover $G = SU(2)$. The unbroken group H has eight elements, $\{\pm I, \pm\sigma_x, \pm\sigma_y, \pm\sigma_z\}$ forming the quaternion group. Since G is simply connected,

$$\pi_1(G/H) = \pi_0(H)$$

so the fundamental group is non-abelian.

Review of topological defects in general, in the SM and GUT theories.

• For a theory with vacuum manifold $\mathcal{M} = G/H$, the topological defects are classified by $\pi_0(\mathcal{M})$ (domain walls), $\pi_1(\mathcal{M})$ (vortices/strings), $\pi_2(\mathcal{M})$ (monopoles), and $\pi_3(\mathcal{M})$ (textures).

• The behavior of these objects changes dramatically if there is gauge symmetry, as in the SM. We call these defects with gauge symmetry "local", in contrast to "global" textures.

• Only local strings and monopoles are interesting as cosmological defects, because global strings and monopoles have infinite energy. However, collections of global strings or monopoles can have finite energy and play a role in other contexts, such as the Kosterlitz-Thouless transition.

• The global/local distinction is not relevant for domain walls; one could add a discrete gauge symmetry, but this doesn't do much because it doesn't produce a gauge field. Local textures are a bit trivial because the field lies in the vacuum manifold at all points, so the energy vanishes. Textures are instead interpreted as other vacuum states. (right? anything else?)

• In the SM, the relevant groups are $G = SU(2)_L \times U(1)_Y$ and $H = U(1)_A$, and $\mathcal{M} \cong S^3$. (This is easier to see by considering the possible states of the Higgs doublet, which takes values in $\mathbb{C}^2$.) As a result, the only possible defects are local textures, which are not interesting.

• Using results from the notes on Geometry and Topology, for the $SU(5)$ GUT, G is connected and simply connected and $H = SU(3)_C \times U(1)_A$, so

$$\pi_1(G/H) = \pi_0(H) = 0, \quad \pi_2(G/H) = \pi_1(H) = \mathbb{Z}$$

This yields monopoles, but not other topological defects. But for more complex GUTs, symmetry breaking generally occurs in multiple stages, and generically produces cosmic strings.

• Cosmologically, there are strong constraints on domain walls and (local) monopoles coming from high-scale physics; both generically contain far too much energy and must be inflated away if they appear. Cosmic (local) strings are acceptable, but CMB measurements show they cannot play a dominant role in structure formation. Global textures were once hypothesized to play a role in structure formation, but this has also been ruled out.

Instantons in Quantum Mechanics

An instanton is a classical solution of the equations of motion with finite, non-zero action. They can be used to describe transitions between vacuum states in a semiclassical approximation.

• First, consider ϕ^4 theory,

$$\mathcal{L} = \frac{1}{2}\partial_\mu\phi\partial^\mu\phi - \frac{1}{2}m^2\phi^2 - g^2\phi^4$$

In the classical case, we are free to scale the Lagrangian. Letting $\phi' = g\phi$, we have

$$\mathcal{L} = \frac{1}{g^2}\left(\frac{1}{2}\partial_\mu\phi'\partial^\mu\phi' - \frac{1}{2}m^2\phi^2 - \phi'^4\right)$$

which means that g is not a physical parameter.

• In the quantum case, the scale of the Lagrangian is set by $\hbar$, so g is important; the physically relevant quantity is

$$\frac{\mathcal{L}}{\hbar} = \frac{1}{g^2\hbar}\left(\frac{1}{2}\partial_\mu\phi'\partial^\mu\phi' + ...\right)$$

Then the relevant dimensionless parameter is $g^2\hbar$, and an expansion in $\hbar$ is the same as an expansion in g, as we've seen before.

• Our approximations will be semiclassical and hence require weak coupling. However, they will extract nonperturbative information essentially by the WKB approximation, which says that the probability of barrier penetration for a particle of unit mass is

$$|T(E)| = \exp\left(-\frac{1}{\hbar}\int_{x_1}^{x_2} dx\sqrt{2(V-E)}\right)(1+O(\hbar))$$

which is zero to all orders in $\hbar$.

• We can't imagine barrier penetration as a classical process, because the velocity would be imaginary in the classically forbidden region. But this is exactly what we would expect if we worked in Euclidean (imaginary) time. This motivates us to consider Euclidean solutions.

• Specifically, Euclidean solutions are precisely those which maximize the WKB probability of barrier penetration. To see this, consider the system

$$L = \int \frac{1}{2}\dot{q}^2 - V(\mathbf{q})$$

and consider a tunneling path $\mathbf{q}(s)$ between minima, where $ds^2 = d\mathbf{q}^2, \mathbf{q}(0) = \mathbf{q}_0, \mathbf{q}(s_f) = \mathbf{q}_f$. The tunneling amplitude is approximately $e^{-B/2}$ where

$$B = 2\int_0^{s_f} ds\sqrt{2(V(\mathbf{q}(s)) - E)}$$

• In the case where the motion is between maxima, and hence classically allowed, Jacobi's principle tells us these paths correspond to stationary points of the action. By similar reasoning, for tunneling between minima, the paths minimize the Euclidean action

$$S_E = \int_{\tau_0}^{\tau_f} d\tau\left(\frac{1}{2}\left(\frac{d\mathbf{q}}{d\tau}\right)^2 + V(\mathbf{q})\right)$$

which has the potential negated.

• The equation of motion is

$$\frac{d^2q_i}{d\tau^2} = \frac{\partial V}{\partial q_i}$$

and the particle is at rest at the start and end of the path $\overline{\mathbf{q}}(\tau)$, so

$$\frac{1}{2}\left(\frac{d\overline{\mathbf{q}}}{d\tau}\right)^2 = V(\overline{\mathbf{q}}) - E, \quad E = V(\overline{\mathbf{q}}_0)$$

• Explicitly, the Euclidean action of the path is

$$S_E[\overline{\mathbf{q}}] = \int_{\tau_0}^{\tau_f} d\tau 2\left(V(\overline{\mathbf{q}}) - V\left(\mathbf{q}_0\right)\right) + \int_{\tau_0}^{\tau_f} d\tau V\left(\mathbf{q}_0\right)$$

and the first term is simply $B/2$ upon a change of variables, so

$$\frac{B}{2} = S_E(\overline{\mathbf{q}}) - S_E\left(\mathbf{q}_0\right)$$

where $\mathbf{q}_0$ is the trivial path $\mathbf{q}_0(\tau) = \mathbf{q}_0$.

• Such a Euclidean solution is called an 'instanton' because it is centered around some point of Euclidean time. However, this is not physically related to real time; at this point it's simply some parameter related to s. Originally, instantons were called pseudoparticles.

• We may also consider tunneling out of a metastable minimum. In this case, the WKB amplitude goes across the potential barrier, but the Euclidean solution goes out and 'bounces' back in, doubling the action. Hence we have

$$B = S_E(\overline{\mathbf{q}}) - S_E\left(\mathbf{q}_0\right)$$

Physically, the amplitude for a particle in the minimum $\mathbf{q}_0$ to stay there falls exponentially in time, with the exponent being proportional to $e^{-B/2}$. Alternatively, one can say the state peaked in $\mathbf{q}_0$ has complex energy. This could be made more precise by starting with a system where $\mathbf{q}_0$ is a true minimum and analytically continuing to the system considered here.

• It is clear here that there are many possible escape paths, and we've just found the most probable one. The other reasonably likely escape paths are simply perturbed about the most probable one, and their effect on B can be found perturbatively.

Next, we'll turn to the path integral, which is better at calculating the subleading corrections.

• Setting $m = \hbar = 1$ and restricting to one dimension,

$$\left\langle x_f \left| e^{-HT} \right| x_i \right\rangle = \int_{x(-T/2)=x_i}^{x(T/2)=x_f} \mathcal{D}x e^{-S_E}, \quad H = \frac{p^2}{2} + V(x)$$

where S_E is the Euclidean action as above. Expanding in energy eigenstates, $H|n\rangle = E_n|n\rangle$,

$$\left\langle x_f \left| e^{-HT} \right| x_i \right\rangle = \sum_n e^{-E_n T} \left\langle x_f | n \right\rangle \left\langle n | x_i \right\rangle$$

so for large T, we may compute the energy and wavefunction of the lowest energy states by evaluating the path integral.

• To define the measure, we choose a set of orthonormal functions $x_n(\tau)$ vanishing at the boundaries and choose $\bar{x}$ obeying the boundary conditions; this is equivalent to the usual $\mathcal{D}x$ measure up to a constant Jacobian. Then we define the measure by

$$x(\tau) = \bar{x}(\tau) + \sum_n c_n x_n(\tau), \quad \mathcal{D}x \equiv N \prod_n \frac{dc_n}{\sqrt{2\pi}}$$

where N is a divergent normalization factor.

• In the semiclassical limit, we expand around stationary points of S. Suppose $\bar{x}$ is the only one; it obeys the classical equations of motion in the potential $-V(x)$. We let the basis functions $x_n(t)$ be eigenfunctions of the second variational derivative of S at $\bar{x}$,

$$-\frac{d^2x_n}{dt^2} + V''(\bar{x})x_n = \lambda_n x_n$$

Expanding about the stationary point, the path integral is a Gaussian, so

$$\left\langle x_f \left| e^{-HT} \right| x_i \right\rangle = Ne^{-S(\bar{x})} \prod_n \lambda_n^{-1/2}(1 + O(\hbar)) \approx Ne^{-S(\bar{x})} \det\left(-\partial_\tau^2 + V''(\bar{x})\right)^{-1/2}$$

Higher order terms here come from the higher-order variation of the action with respect to c_n.

• This result is a generalization of the usual functional determinants seen in field theory. In that case, we usually only explicitly perform path integrals when the action is quadratic, in which case the functional determinant $\det \delta^2 S|_{\bar{x}}$ is independent of $\bar{x}$ and diagonalized by plane waves.

Example. A trivial example. Let $x_i = x_f = 0$ and consider a potential with a minimum at $x = 0$ and $V(0) = 0$. Then the only solution for $\bar{x}$ is the constant $\bar{x} = 0$, where $S = 0$, so

$$\left\langle 0 \left| e^{-HT} \right| 0 \right\rangle = N \det\left(-\partial_t^2 + \omega^2\right)^{-1/2} (1 + O(\hbar)), \quad \omega = V''(0)$$

To evaluate the functional determinant, note the eigenvalues are

$$\lambda_n = \frac{\pi n^2}{T^2} + \omega^2$$

so we have

$$N \det\left(-\partial_\tau^2 + \omega^2\right)^{-1/2} = N \prod_n \left(\frac{\pi^2}{n^2} T^2\right)^{-1/2} \prod_n \left(1 + \frac{\omega^2 T^2}{\pi^2 n^2}\right)^{1/2}$$

The constant N is fixed by matching with the result for the free particle, $\omega = 0$, giving

$$N \det\left(-\partial_\tau^2 + \omega^2\right)^{-1/2} = \frac{1}{\sqrt{2\pi T}} \prod_n \left(1 + \frac{\omega^2 T^2}{\pi^2 n^2}\right)^{1/2} = \frac{1}{\sqrt{2\pi T}} \left(\frac{\sinh(\omega T)}{\omega T}\right)^{-1/2}$$

Taking the limit $T \to \infty$ and neglecting exponentially small terms, and restoring $\hbar$,

$$N \det\left(-\partial_\tau^2 + \omega^2\right)^{-1/2} = \sqrt{\frac{\omega}{\pi\hbar}} e^{-\omega T/2}$$

which implies that the ground state energy is $\hbar\omega/2 + O(\hbar^2)$, and

$$|\langle x = 0 | n = 0 \rangle|^2 = \sqrt{\frac{\omega}{\pi\hbar}}(1 + O(\hbar))$$

These are indeed the correct semiclassical results.

Next, we consider the extended example of the double well.

• Consider an even potential with minima at $\pm a$ with $V(a) = 0$ and $V''(a) = \omega^2$. We will compute $\left\langle a \left| e^{-HT} \right| a \right\rangle$ and $\left\langle a \left| e^{-HT} \right| -a \right\rangle$ semiclassically. As before, we have classical solutions that stay motionless at $\pm a$, but we also have the 'instanton' solution that moves from $-a$ to a, and the 'anti-instanton' that moves from a to $-a$.

• Since we'll take T to infinity anyway, we take this limit now. Then the instanton solutions have zero energy, and

$$\frac{dx}{d\tau} = \sqrt{2V}, \quad \tau = \tau_1 + \int_0^x \frac{dx'}{\sqrt{2V}}$$

Such a solution is called an instanton centered at τ_1. They are like solitons, but localized in Euclidean time rather than space. The action of an instanton is

$$S_0 = \int dt \frac{1}{2}(dx/dt)^2 + V = \int dt (dx/dt)^2 = \int_{-a}^{a} dx \sqrt{2V}$$

• For large times, when x approaches a, the equation of motion is

$$\frac{dx}{dt} = \omega(a - x)$$

which is exponential decay, so instantons have size on the order of $1/\omega$. Then in the $T \to \infty$ limit, we must account for multi-instanton solutions, where the instanton separation is $O(T)$, since they are approximate solutions to the equation of motion.

• Consider a solution with n widely separated instantons, centered at $t_1, ..., t_n$, with

$$T/2 > t_1 > ... > t_N > -T/2$$

The action of this solution is nS_0. The functional determinant is

$$N \det\left(-\partial_t^2 + V''(\bar{x})\right)^{-1/2} = \sqrt{\frac{\omega}{\pi}} e^{-\omega T/2} K^n$$

where the factor K accounts for how each instanton modifies the functional determinant. We may multiply by K^n because the effect of each instanton on the spectrum of fluctuations is localized about each one, and they are widely separated.

• Integrating over the instanton locations gives a factor of $T^n/n!$, so we have

$$\left\langle a \left| e^{-HT} \right| a \right\rangle = \sqrt{\frac{\omega}{\pi}} e^{-\omega T/2} \sum_{n \text{ even}} \frac{\left(K e^{-S_0} T\right)^n}{n!}$$

and carrying out the sums gives

$$\left\langle \pm a \left| e^{-HT} \right| a \right\rangle = \sqrt{\frac{\omega}{\pi}} e^{-\omega T/2} \frac{\exp\left(K e^{-S_0} T\right) \mp \exp\left(-K e^{-S_0} T\right)}{2}.$$

• Thus, we have two low-lying energy eigenstates, with energies

$$E_\pm = \frac{1}{2}\omega \pm K e^{-S_0}$$

These are the two expected energy eigenstates, consisting of even and odd combinations of the ground states of the two wells; the degeneracy is broken by barrier tunneling. Unlike the WKB approximation, the path integral allows us to calculate the preexponential factor K, and if we worked to more accuracy, we could find higher-order corrections.

• Above, we have assumed we were working with an 'instanton gas', i.e. that the instantons were too widely separated to affect each other. To check self-consistency, note that the largest term in the series $\sum_n x^n/n!$ comes when $x \sim n$, so

$$n \sim KTe^{-S_0}$$

If the instanton has characteristic size $\delta\tau$, we require

$$(\delta\tau)Ke^{-S_0} \ll 1$$

On dimensional grounds $K \sim 1/\delta\tau$, so we just need $S_0 \gg \hbar$, which we've already assumed.

• To compute the value of K more carefully, formally we would have

$$K = \left| \frac{\det\left(-\partial_\tau^2 + \omega^2\right)}{\det\left(-\partial_\tau^2 + V''(\bar{x})\right)} \right|^{1/2}$$

However, this is not well-defined because the functional determinant in the denominator has a zero eigenvalue. This zero mode results because the instanton breaks time translation invariance. Explicitly, it is $x_1 = S_0^{-1/2} d\bar{x}/dt$.

• Making the zero mode into a collective coordinate and evaluating its contribution explicitly,

$$K = \left(\frac{S_0}{2\pi}\right)^{1/2} \left| \frac{\det\left(-\partial_\tau^2 + \omega^2\right)}{\det'\left(-\partial_\tau^2 + V''(\bar{x})\right)} \right|^{1/2}$$

where the prime denotes exclusion of the zero mode. The remaining determinants can be computed using standard methods.

Example. Consider a periodic potential with minima at the integers. By similar reasoning,

$$\left\langle j_+ \left| e^{-HT} \right| j_- \right\rangle = \left(\frac{\omega}{\pi}\right)^{1/2} e^{-\omega T/2} \sum_{n,\bar{n}} \frac{1}{n!\bar{n}!} \left(Ke^{-S_0}T\right)^{n+\bar{n}} \delta_{n-\bar{n}-j_++j_-}$$

where n is the number of instantons and n' is the number of anti-instantons. Using the identity $\delta_{ab} = \int_0^{2\pi} d\theta \frac{e^{i\theta(a-b)}}{2\pi}$ we have

$$\left\langle j_+ \left| e^{-HT} \right| j_- \right\rangle = \left(\frac{\omega}{\pi}\right)^{1/2} e^{-\omega T/2} \int_0^{2\pi} \frac{d\theta}{2\pi} e^{i(j_- - j_+)\theta} \exp\left(2KT\cos\theta e^{-S_0}\right)$$

Then the Hamiltonian is diagonalized by states of the form $|\theta\rangle$ where

$$\langle\theta|j\rangle = e^{ij\theta}, \quad E(\theta) = \frac{1}{2}\omega + 2Ke^{-S_0}\cos\theta$$

These $|\theta\rangle$ states are analogous to the " θ-vacua" we will encounter in gauge theories.

Example. Decay from a metastable vacuum. We consider a local minimum at $x = a$ with $V(a) = 0$ and wish to compute the rate of decay. Naively, the instanton solutions $\bar{x}(\tau)$ are bounces, and we can sum over any number of bounces, giving the answer

$$\left\langle a \left| e^{-HT} \right| b \right\rangle = \sqrt{\frac{\omega}{\pi}} e^{-\omega T/2} \sum_n \frac{\left(Ke^{-S_0}T\right)^n}{n!} = \sqrt{\frac{\omega}{\pi}} e^{-\omega T/2} \exp\left(Ke^{-S_0}T\right)$$

where as before,

$$K = \left(\frac{S_0}{2\pi}\right)^{1/2} \left| \frac{\det\left(-\partial_\tau^2 + \omega^2\right)}{\det'\left(-\partial_\tau^2 + V''(\bar{x})\right)} \right|^{1/2}$$

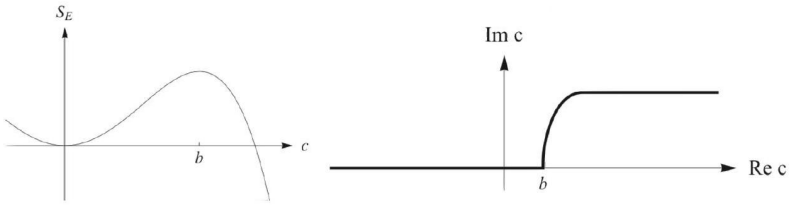
We expect the amplitude to decay exponentially, or equivalently for the state in the well to have a complex energy. Hence taking the logarithm, at large times we have

$$E_0 = \frac{1}{2}\omega - Ke^{-S_0}$$

We get the desired imaginary part because there is a mode with a negative eigenvalue, which renders K imaginary. To see this, note that the equation for the eigenfunctions x_n has the form of the Schrodinger equation, and hence the mode with lowest eigenvalue should have no nodes. However, since the instanton solution bounces, the zero mode has one node, and hence there is one lower mode. This implies that the instanton solution is merely a saddle, not a minimum, of the potential.

To understand this, suppose the 'bounce' occurs at $x = b$, and consider the family of solutions that bounce at $x = c$. Then $S_E(c)$ has a local minimum at $c = 0$, corresponding to the trivial solution, and an extremum at $c = b$ corresponding to the instanton; hence it must be a maximum.

The reason that the bounce can be a local minimum of the barrier penetration integral B but not a local minimum of S_E is that they have different boundary conditions. In our earlier calculations, both were restricted over paths that went from one minimum to the other. But in this case, we're just going from one minimum back to itself, and B has the additional constraint that the paths must bounce at $x = c$. (However, note that we must always consider minima of B, since otherwise our approximation will give a completely wrong result.)



To integrate over this mode, we must essentially perform the integral

$$J = \int_{-\infty}^{\infty} \frac{dc}{\sqrt{2\pi}} e^{-S(c)}$$

This integral seems to diverge. To get a sensible result, we deform the contour as shown above, which gives a finite result. In the semiclassical limit, the only contribution to the integral comes from the vertical region near $c = b$, where we may apply the steepest descent approximation to get

$$\operatorname{Im} J = \frac{1}{2} e^{-S(b)} \left|S''(b)\right|^{-1/2}$$

where the factor of $1/2$ is because we only have half of the Gaussian peak; this is the factor of $1/2$ we anticipated on intuitive grounds earlier. Hence

$$K = \frac{i}{2}\left(\frac{S_0}{2\pi}\right)^{1/2} \left|\frac{\det\left(-\partial_\tau^2 + \omega^2\right)}{\det'\left(-\partial_\tau^2 + V''(\bar{x})\right)}\right|^{1/2}$$

and the decay rate is

$$\Gamma = -2\operatorname{Im} E_0 = \left(\frac{S_0}{2\pi}\right) \left|\frac{\det\left(-\partial_\tau^2 + \omega^2\right)}{\det'\left(-\partial_\tau^2 + V''(\bar{x})\right)}\right|^{1/2} e^{-S_0}$$

Note. The ideas above generalize directly to field theory. For the instantons to have finite B, the deviation of the fields from their initial value must be localized in space as well as time, resulting in additional zero modes; integrating over them gives a factor of the volume of the space. There will also be additional UV divergences that must be renormalized.

It's subtle why tunneling should be permitted in field theory at all. Naively, there are infinitely many degrees of freedom that all have to tunnel at once, giving an infinite suppression; this is exactly why spontaneous symmetry breaking is possible in quantum field theory but not in quantum mechanics. The first caveat is that in $d = 1+1$, the tunneling can occur by the formation and separation of domain walls, which incurs a finite cost; this corresponds to the Mermin-Wagner theorem. The second is gauge symmetry, which allows instantons to tunnel between vacua while being locally gauge-equivalent to zero on almost all of space, avoiding an infinite energy cost.

Note. The above formalism, based on analytic continuation to a Euclidean potential, is almost universally used in quantum field theory, but physically opaque. The instanton trajectories we sum over in Euclidean time bear no resemblance to the tunneling events occurring in physical time. (As they say, "you can't eat an instanton".) For a more physical approach based on the Minkowski path integral, see this paper and this paper.

Yang-Mills Vacua

We will work primarily in $A_0 = 0$ gauge, and begin with some classical subtleties.

• We use conventions where

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu - ie\left[A_\mu, A_\nu\right], \quad D_\mu = \partial_\mu - ieA_\mu$$

and normalize generators so that $\operatorname{tr}\left(T^a T^b\right) = \delta^{ab}/2$.

• In the gauge $A_0 = 0$, the Lagrangian is

$$\mathcal{L} = \operatorname{tr} \dot{A}_j^2 - \frac{1}{2}\operatorname{tr} F_{ij}^2, \quad F_{0i} = \dot{A}_i$$

The dynamical variables are the A_i, and the conjugate momenta are

$$\Pi^j = F^{j0}.$$

Note that we are working in the non-abelian case, but we suppress group indices.

• The classical equations of motion are

$$D_\mu F^{\mu j} = 0.$$

By comparison, if we had not fixed the gauge, it would have been $D_\mu F^{\mu\nu} = 0$. Hence we are missing the Gauss's law constraint

$$C(\mathbf{x}) = D_\mu F^{\mu 0}(\mathbf{x}) = D_j \Pi^j(\mathbf{x}) = 0$$

However, the equations of motion do imply $\dot{C}(\mathbf{x}) = 0$.

• Physically, we have the freedom to make time-independent gauge transformations. If we view them as genuine symmetries, then they yield conserved charges, which correspond to the conservation of $C(\mathbf{x})$. Specifically, for a gauge transformation generated by $\Lambda(\mathbf{x})$ which vanishes at spatial infinity, the Noether charge is

$$C_\Lambda = 2\int d\mathbf{x} \operatorname{tr} D_j \Lambda(\mathbf{x}) \Pi^j(\mathbf{x}) = -2\int d\mathbf{x} \operatorname{tr} \Lambda(\mathbf{x}) D_j \Pi^j(\mathbf{x}) = -2\int d\mathbf{x} \operatorname{tr} \Lambda(\mathbf{x}) C(\mathbf{x})$$

By Noether's theorem, C_Λ is conserved for any $\Lambda(\mathbf{x})$, so $C(\mathbf{x})$ is. Hence we can just restrict to configurations where $C(\mathbf{x}) = 0$.

• The Lagrangian is in the standard $T - V$ form with quadratic kinetic energy, so going to Euclidean signature is straightforward, with

$$\mathcal{L}_E = \operatorname{tr}(\partial_4 A_j)^2 + \frac{1}{2}\operatorname{tr} F_{ij}^2, \quad x_4 = \tau$$

Conventionally, we take $\epsilon^{0123} = \epsilon^{123} = \epsilon^{1234} = 1$.

• Finally, we may include a field $A_4(x)$ which acts as a Lagrange multiplier that enforces Gauss's Law, in which case the Euclidean Lagrangian becomes

$$\mathcal{L}_E = \frac{1}{2}\operatorname{tr} F_{rs}^2, \quad r, s \in \{1, 2, 3, 4\}$$

along with the boundary conditions $F_{j4} = 0$ on the temporal boundaries. This procedure, of first eliminating A_0, then rotating to Euclidean spacetime, then introducing A_4, is a bit longer than the naive approach but avoids some subtleties.

In $A_0 = 0$ gauge, there are topologically distinct vacua.

• Vacuum configurations have $F_{\mu\nu} = 0$, which implies in our gauge that

$$A_j = \frac{i}{g} G^{-1} \partial_j G$$

where $G(\mathbf{x})$ is an element of the gauge group, which we take to be $SU(2)$.

• We assume that G tends to a constant G_∞ as $r \to \infty$, to be justified later, giving a map $S^3 \to SU(2)$. The homotopy classes of such maps are classified by $\pi_3(SU(2)) = \mathbb{Z}$.

• To see why homotopy classes are relevant, we need to distinguish between 'large' and 'small' gauge transformations. Gauge transformations map $G(\mathbf{x})$ to $\Lambda(\mathbf{x})G(\mathbf{x})$. A small gauge transformation is one that can be built from a series of infinitesimal gauge transformations, with gauge functions $\Lambda(\mathbf{x})$ that vanish at spatial infinity. Large gauge transformations instead connect vacua in different homotopy classes.

• Physically, small gauge transformations must be 'do nothing' transformations, but it is ambiguous whether large gauge transformations are; this is a choice that affects the theory. For our purposes, it won't matter; we'll choose them to not be 'do nothing' transformations for clarity.

• We can explicitly compute the homotopy class by the integral

$$N[G] = \frac{1}{24\pi^2}\epsilon^{ijk}\int d\mathbf{x} \operatorname{tr} G^{-1}\partial_i G G^{-1}\partial_j G G^{-1}\partial_k G$$

which is normalized so that if G is taken to be in the fundamental representation of $SU(2)$, with $T_a = \sigma_a/2$, then $N[G]$ is the usual winding number. In the case of gauge group $SU(2)$ only, it is also the Brouwer degree of the mapping G.

• To see this, note that near a point where G is equal to G_0,

$$G(\mathbf{x}) = G_0 \exp(i\sigma_a \Lambda_a(\mathbf{x})) \approx G_0 (I + i\sigma_a \Lambda_a(\mathbf{x}))$$

Plugging this in, we find the spatial integral of

$$-\frac{i}{24\pi^2}\epsilon^{ijk}\operatorname{tr}(\sigma_a\sigma_b\sigma_c)\,\partial_i\Lambda_a\partial_j\Lambda_b\partial_k\Lambda_c = \frac{1}{12\pi^2}\epsilon^{ijk}\epsilon^{abc}\partial_i\Lambda_a\partial_j\Lambda_b\partial_k\Lambda_c = \frac{1}{2\pi^2}\epsilon^{ijk}\partial_i\Lambda_1\partial_j\Lambda_2\partial_k\Lambda_3$$

However, this is precisely the Jacobian factor for the transformation from the spatial coordinates x_j to the group coordinates Λ_a, and $2\pi^2$ is simply the area of S^3.

• An example of a configuration with unit winding number is

$$g_1(x) = \exp\left(i\hat{r}_a\sigma_a f(r)\right)$$

where $f(r)$ is any monotonic function with $f(0) = -\pi$ and $f(\infty) = 0$.

• Next, we have the useful identity

$$N\left[G_1G_2\right] = N\left[G_1\right] + N\left[G_2\right]$$

Here the error term is

$$\frac{1}{8\pi^2}\epsilon^{ijk}\int d\mathbf{x}\,\mathrm{tr}\left(G_1^{-1}\partial_i G_1\partial_j G_2 G_2^{-2}\partial_k G_2 G_2^{-1} + \partial_i G_2 G_2^{-1}G_1^{-1}\partial_j G_1 G_1^{-1}\partial_k G_1\right)$$

and it can be shown to vanish using the product rule, the antisymmetry of ϵ^{ijk}, and the fact that the G_i tend to a constant at infinity.

• Also note that for an infinitesimal gauge transformation, the winding number is the integral of

$$\frac{1}{2\pi^2}\epsilon^{ijk}\partial_i\Lambda_1\partial_j\Lambda_2\partial_k\Lambda_3 = \frac{1}{2\pi^2}\epsilon^{ijk}\partial_i\left(\Lambda_1\partial_j\Lambda_2\partial_k\Lambda_3\right)$$

which is a total derivative, so the winding number is zero. Hence $N[G]$ is invariant under continuous deformations/small gauge transformations.

• Next, we define the current

$$j_A^\mu = \frac{g^2}{8\pi^2}\epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}\left(A_\nu\partial_\rho A_\sigma - \frac{2ig}{3}A_\nu A_\rho A_\sigma\right) = \frac{g^2}{16\pi^2}\epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}\left(A_\nu F_{\rho\sigma} + \frac{2ig}{3}A_\nu A_\rho A_\sigma\right).$$

The current is not gauge invariant, but it has a gauge-invariant divergence,

$$\partial_\mu j_A^\mu = \frac{g^2}{16\pi^2}\,\mathrm{tr}\,F_{\mu\nu}\tilde{F}^{\mu\nu}, \quad \tilde{F}^{\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}$$

To verify this equation, note that the term quartic in A_μ on the right-hand side drops out by contraction with the Levi-Civita symbol.

• The charge associated with this current is

$$Q_A = \int d\mathbf{x} j_A^0 = \frac{g^2}{16\pi^2}\int d\mathbf{x}\epsilon^{ijk}\,\mathrm{tr}\left(A_iF_{jk} + \frac{2ig}{3}A_iA_jA_k\right)$$

Therefore, for a vacuum configuration we have

$$Q_A = N[G]$$

Next, we consider tunneling between these vacua.

• Consider a sequence of finite energy configurations $A_\mu(\mathbf{x}, t)$ interpolating between two vacuum configurations with winding numbers N_1 and N_2. We have

$$\int dx\partial_\mu j_A^\mu = \int dx\left(\partial_0 j_A^0 + \partial_i j_A^i\right)$$

which can be reduced to integrals over the bounding surface, conventionally depicted as a cylinder. The first term yields $N_2 - N_1$, while the second is a surface integral over $r = \infty$, whose only contribution in $A_0 = 0$ gauge is from the $A_j F_{0k}$ term. However, for finite energy configurations F_{0k} must fall off faster than $1/r^{3/2}$, so A_j must fall off faster than $1/r^{1/2}$, and hence this term vanishes in the limit $r \to \infty$. Thus,

$$\Delta N = \frac{g^2}{16\pi^2} \int dx \, \mathrm{tr} \, F_{\mu\nu} \tilde{F}^{\mu\nu}$$

• Note that our derivation above is agnostic over whether t is real or Euclidean time. In the context of Euclidean time, the most important vacuum tunneling solutions will be instantons. They connect vacua with N differing by 1, and hence obey

$$\int dx \, \mathrm{tr} \, F_{\mu\nu} \tilde{F}^{\mu\nu} = \frac{16\pi^2}{g^2}$$

• In the quantum theory, the state can be regarded as a wavefunctional of classical field configurations. The C_Λ generate small gauge transformations, and the Gauss's law constraint means $C_\Lambda = 0$. Hence the wavefunctional must be constant on classical vacua related by small gauge transformations, in the same way that a wavefunction with $L_z = 0$ is independent of θ. From this point on we ignore these states.

• Next, we have vacua $|n\rangle$ related by large gauge transformations, indexed by an integer n. These are not energy eigenstates, as tunneling between the vacua can occur.

• We define an operator T by

$$T|n\rangle = |n+1\rangle$$

and note that by gauge invariant, T commutes with the Hamiltonian. Then the energy eigenstates diagonalize T. They are the θ-vacua,

$$|\theta\rangle = \sum_n e^{-in\theta} |n\rangle$$

The θ-vacua cannot evolve into each other, and this property extends to Fock spaces built upon these vacua. Hence we could simply regard θ as a constant of nature.

• When we perform the path integral, we must sum over gauge field configurations with all possible winding numbers. The net effect is that living in $|\theta\rangle$ is equivalent to ignoring such configurations, at the cost of adding the term

$$\Delta \mathcal{L} = \frac{\theta g^2}{16\pi^2} \, \mathrm{tr} \, F_{\mu\nu} \tilde{F}^{\mu\nu}$$

to the Lagrangian. This is a total derivative, but has nonperturbative effects.

Note. The conclusions above depend on the gauge we're choosing. For example, in the axial gauge

$$A_3 = 0, \quad A_2(x, y, 0, t) = 0, \quad A_1(x, 0, 0, t) = 0, \quad A_0(0, 0, 0, t) = 0$$

the gauge fixing is complete; there is a one-to-one relationship between $F_{\mu\nu}$ and A_μ and hence one classical vacuum, where $A_\mu = 0$. Intuitively, this is because the first condition leaves only z-independent gauge transformations; the second condition fixes z and leaves only z-independent and y-independent gauge transformations, and so on, leaving only global gauge transformations.

In this gauge, the winding number of the vacuum is always zero. Instanton configurations still exist, connecting this vacuum to itself. However, in the surface integral of $n_\mu j^\mu_A$ considered above, only the sides of the cylinder contribute rather than the caps; the 'charge' created by an instanton flows out to spatial infinity. In this picture, the θ term is not a consequence of the θ-vacuum, but simply a parameter in the Lagrangian. (This viewpoint also holds in $A_0 = 0$ gauge, so the theta term would be the sum of a bare, Lagrangian term and the effective term from living in a θ vacuum.) The fundamental difference between this gauge and the previous one is that this one counts the large gauge transformations as 'do nothing' transformations. However, the θ term has the same consequences in both pictures.

A simple analogy is given by the Lagrangian

$$L = \frac{1}{2}B\dot{\alpha}^2 - K(1 - \cos\alpha)$$

For $\alpha \in \mathbb{R}$, it describes a particle of mass B moving in a periodic potential, and the energy eigenstates are the analogues of the θ-vacua. However, we can also regard α as an angle, in which case the Lagrangian describes a pendulum with moment of inertia B. The analogue of the θ term is

$$\Delta L = \frac{\theta}{2\pi}\dot{\alpha}$$

and appears in either case.

Yang-Mills Instantons

Next, we take a closer look at the instanton solutions. First, we take a detour into topology.

• We compactify Euclidean spacetime to S^4 and consider G-bundles over S^4. We may cover S^4 with two patches, which overlap on the "equator" S^3. Here the gauge fields are related by

$$A_p^{\mathbf{II}} = U A_p^{\mathbf{I}} U^{-1} - \frac{i}{g}\left(\partial_p U\right) U^{-1}$$

We would like to classify all topologically distinct bundles.

• First, we consider the simpler situation of a $U(1)$-bundle over S^2, where

$$A_p^{\mathbf{II}} - A_p^{\mathbf{I}} = -\partial_p \Lambda$$

on the overlap region. We define

$$I_1 = \frac{1}{4\pi}\int d^2x \epsilon^{pq} F_{pq}$$

where the x^p are coordinates on S^2. This quantity is manifestly gauge invariant.

• Next, we claim I_1 is a topological invariant, i.e. it does not change under a smooth deformation

$$A_p^{\mathbf{I}} \to A_p^{\mathbf{I}} + \delta A_p^{\mathbf{I}}, \quad A_p^{\mathbf{II}} \to A_p^{\mathbf{II}} + \delta A_p^{\mathbf{II}}$$

In particular, it is continuous from one patch to the next, i.e. on the overlap region

$$\delta A_p^{\mathbf{II}} = \delta A_p^{\mathbf{I}}$$

Now the integrand is a total derivative, and

$$\delta I_1 = \frac{1}{4\pi}\int d^2x\epsilon^{pq}\delta F_{pq} = \frac{1}{2\pi}\int d^2x\partial_p\left(\epsilon^{pq}\delta A_q\right) = 0$$

since S^2 has no boundary.

• Similarly, the value of I_1 itself is

$$I_1 = \frac{1}{2\pi}\int d^2x\partial_p\left(\epsilon^{pq}A_q\right) \equiv \int d^2x\partial_p j^p$$

However, it is incorrect to simply set this to zero, because the current varies from patch to patch; it is not gauge invariant. Instead, we split it into integrals over the two hemispheres, yielding two integrals over the equator Σ,

$$I_1 = \frac{1}{2\pi}\int\limits_{\Sigma} d\ell_p\epsilon^{pq}\left(A_q^{\mathbf{I}} - A_q^{\mathbf{II}}\right) = \frac{1}{2\pi}\int\limits_{\Sigma} d\ell_p\epsilon^{pq}\partial_q\Lambda$$

which is simply the winding number of the map $\Lambda : \Sigma \to U(1)$. Hence we have related I_1 to the winding number, a topological invariant of the fibre bundle. The integrand of I_1 is called the first Chern class/form and I_1 itself is called the first Chern number; the Chern class/form is only locally the derivative of the Chern-Simons 1-form.

• In four dimensions, we have the second Chern number

$$I_2 = \frac{g^2}{32\pi^2}\int d^4x\epsilon^{pqrs}\,\mathrm{tr}\,F_{pq}F_{rs}$$

Again, this is a topological invariant, but now we have

$$\delta A_p^{\mathbf{II}} = U\delta A_p^{\mathbf{I}}U^{-1}$$

Under a deformation we have

$$\delta I_2 = \frac{g^2}{16\pi^2}\int d^4\epsilon^{pqrs}\,\mathrm{tr}\,F_{pq}\delta F_{rs} = \frac{g^2}{8\pi^2}\int d^4x\epsilon^{pqrs}\,\mathrm{tr}\,F_{pq}D_r\delta A_s$$

where the covariant derivative is taken with respect to the unperturbed potential. Now

$$\epsilon^{pqrs}\,\mathrm{tr}\,F_{pq}D_r\delta A_s = \epsilon^{pqrs}\partial_r\left(\mathrm{tr}\,F_{pq}\delta A_s\right) - \epsilon^{pqrs}\,\mathrm{tr}\left(D_rF_{pq}\right)\delta A_s$$

and the second term vanishes by the Bianchi identity. The first term is gauge invariant, so by the same argument as before $\delta I_2 = 0$ since S^4 has no boundary.

• Next, to relate I_2 to the topology of the bundle, we have shown above that

$$\frac{g^2}{32\pi^2}\epsilon^{pqrs}\,\mathrm{tr}\,F_{pq}F_{rs} = \partial_p j_A^p$$

The current j_A^p is the Chern-Simons 3-form, and is not gauge invariant. Hence by the same argument as above, we have

$$I_2 = \int\limits_{\Sigma} dS_p\left(j_A^{\mathbf{I}p} - j_A^{\mathbf{II}p}\right)$$

where Σ is the 'equator' with topology S^3.

• An explicit computation shows that

$$j_A^{\mathbf{I}p} - j_A^{\mathbf{II}p} = \frac{1}{24\pi^2}\epsilon^{pqrs}\,\mathrm{tr}\,U^{-1}\partial_q U U^{-1}\partial_r U U^{-1}\partial_s U - \frac{ig}{8\pi^2}\epsilon^{pqrs}\partial_q\left(\mathrm{tr}\,U^{-1}\partial_q U A_s\right)$$

The second term, while not gauge invariant, is non-singular everywhere on S^3. That is, it can be computed using only the gauge field on a single patch. Then since S^3 has no boundary, the integral of this term vanishes, leaving

$$I_2 = \frac{1}{24\pi^2}\epsilon^{pqrs}\int_\Sigma dS_p\,\mathrm{tr}\,U^{-1}\partial_q U U^{-1}\partial_r U U^{-1}\partial_s U$$

As shown above, for $G = SU(2)$ is is simply the winding number that counts the number of times $SU(2)$ is covered as one goes over Σ. Hence the bundles are classified by $\pi_3\left(S^3\right)$.

• More generally, they are classified by $\pi_3(G)$. Bott's theorem states that any continuous mapping from S^3 into a simple Lie group G can be continuously deformed into a mapping into an $SU(2)$ subgroup of G. Hence our analysis holds unchanged for more general gauge groups. For a general compact Lie group, the $U(1)$ factors don't matter, while each other factor gives an independent winding number.

Finally, we return to the tricky business of justifying the boundary conditions.

• Mathematically, a gauge transformation is a fiber-preserving automorphism $P \to P$, and a large gauge transformation is one which is not connected to the identity. In particular, all gauge transformations preserve transition functions and hence the instanton number. They simply are basis changes for the fibers, which change the description of the connection.

• The transition functions between two patches are sometimes called gauge transformations, but they are completely different objects; they characterize the structure of the bundle itself and are fixed prior to the introduction of the connection.

• Now, the vacua and instantons were classified in different ways. The vacua are invariant under spatial gauge transformations; whether or not they are invariant under large spatial gauge transformations depends on the convention. The instantons, counted by the Chern number, are invariant under arbitrary continuous deformations of the gauge field, which include gauge transformations as a subset, as well as under large gauge transformations because the Chern form is gauge invariant. While instantons correspond to nontrivial fiber bundles over S^4, vacua are all trivial fiber bundles over S^3.

• In the case of instantons, one can shrink one of the patches to a very small region, which makes the transition functions singular. Naively, without the machinery of bundles, this looks like a singularity in the gauge field; one example is the Dirac string for the magnetic monopole.

• As we'll see below, we can write down instanton gauge fields on $\mathbb{R}^4$, but they will always be singular in at least one point. If this is the point at infinity, the instanton can described as the 'winding of the gauge field at long distances', allowing a sensible description without bundles. Alternatively, in the bundle language, the winding number of instanton is encoded in the transition function between this gauge field and a trivial gauge field in a topologically trivial patch containing the point at infinity.

• A more common approach in practice, which we will use below, is to take the gauge field to be constant at $x \to \infty$ but singular at $x = 0$. This is equally valid, and in the bundle language the winding would be encoded in the transition function between the gauge field in an infinitesimal patch containing the origin, and a patch containing everything else.

• The compactification to S^4 is a mathematical tool rather than a physical requirement. The physical content of an instanton is that it is a local minimum of the Euclidean action. Compactification of S^4 is only necessary to get topologically nontrivial fibre bundles, where the instanton

number is additionally invariant under all continuous deformations, but this requirement has nothing to do with the physical business of computing tunneling rates: since instantons have finite sizes, modifying boundary conditions at infinity doesn't affect the Euclidean action.

• Note that there are two definitions of 'topological' going on here. Both the Chern and ChernSimons forms are topological terms in the sense that they don't depend on the metric, but only the Chern form is invariant under arbitrary deformations of the gauge field. These two types of terms yield topological information about the spacetime manifold and bundles over it, respectively. In the special case where the bundle is the tangent bundle, we can use it to get topological information about the manifold; the Gauss-Bonnet theorem is one example.

• Instantons are sometimes mistakenly called "vacua". The confusion arises from the fact that one may take an instanton background and perturb around it to compute subleading corrections, just like one does for a vacuum.

• It is simple to justify the condition $A_\mu(\mathbf{x}) \to \text{const}$ in the physical gauge, since this is required by the uniqueness of the vacuum $A_\mu(\mathbf{x}) = 0$.

• The situation is more subtle in $A_0 = 0$ gauge. If we do not take this condition, the quantity $N[G]$ will not be an integer, intuitively because there is a singular winding 'near the point at infinity'. On the other hand, the difference of $N[G]$ for two vacua will always be an integer, because it's simply the instanton number. Hence by performing a large gauge transformation we can always set $N[G]$ to an integer, and instantons will preserve this. Hence we can really just take $A_\mu(\mathbf{x})$ to be constant without loss of generality.

We now find explicit instanton solutions on $\mathbb{R}^4$ using the 't Hooft symbols.

• The trick is to use the relation between $\mathfrak{so}(4)$ and $\mathfrak{su}(2) \oplus \mathfrak{su}(2)$. Define the matrices

$$e_p = \begin{cases} i\tau_p & p = 1,2,3 \\ I & p = 4 \end{cases}, \quad e_p^\dagger = \begin{cases} -i\tau_p & p = 1,2,3 \\ I & p = 4 \end{cases}$$

where the τ_p are the usual Pauli matrices. Then for an $SO(4)$ vector V_p, define

$$V = e_p^\dagger V_p = \begin{pmatrix} V_4 - iV_3 & -V_2 - iV_1 \\ V_2 - iV_1 & V_4 + iV_3 \end{pmatrix}, \quad \det V = V_p V_p$$

Then V is a unitary matrix times a multiple of the identity. We map the other way by

$$V_p = \frac{1}{2} \operatorname{tr} V e_p$$

• Rotations of V_p can be implemented on V by

$$V \to U_L^{-1} V U_R, \quad U_L, U_R \in SU(2)$$

where we need U_L/U_R to be unitary to preserve the form of V and special unitary to preserve the determinant. Since the transformation $U_L = U_R = -I$ does nothing, we conclude

$$SO(4) = (SU(2) \times SU(2))/\mathbb{Z}_2.$$

• To compute the effect of an infinitesimal transformation, let

$$U_L = e^{-i\boldsymbol{\omega}_L \cdot \boldsymbol{\tau}}, \quad U_R = e^{-i\boldsymbol{\omega}_R \cdot \boldsymbol{\tau}}.$$

Then infinitesimally we have

$$\delta V = i\left(\boldsymbol{\omega}_L \cdot \boldsymbol{\tau}\right) V - iV\left(\boldsymbol{\omega}_R \cdot \boldsymbol{\tau}\right)$$

• By some messy but direct calculation, we can show this implies

$$\delta V_p = \left(\omega_L^j \bar{\eta}_{pq}^j + \omega_R^j \eta_{pq}^j\right) V_q$$

and the numbers η_{pq}^j are best written in terms of the matrices

$$\eta_{pq} = \eta_{pq}^j \tau_j = -i\left(e_p e_q^\dagger - \delta_{pq} I\right), \quad \bar{\eta}_{pq} = \bar{\eta}_{pq}^j \tau_j = -i\left(e_p^\dagger e_q - \delta_{pq} I\right)$$

• These matrices are antisymmetric, with the nonzero η_{pq}^j and $\bar{\eta}_{pq}^j$ fixed by

$$\eta_{ij}^k = \bar{\eta}_{ij}^k = \epsilon_{ijk}, \quad \eta_{i4}^k = -\bar{\eta}_{i4}^k = \delta_{ik}$$

This implies that η_{pq} is self-dual and $\bar{\eta}_{pq}$ is anti-self-dual,

$$\eta_{pq} = \frac{1}{2}\epsilon_{pqrs}\eta_{rs}, \quad \bar{\eta}_{pq} = -\frac{1}{2}\epsilon_{pqrs}\bar{\eta}_{rs}$$

Above, we have seen that $\bar{\eta}_{pq}$ determines the effect of U_L while η_{pq} determines the effect of U_R. This is because an antisymmetric rank two $SO(4)$ tensor transforms as $(1,0) \oplus (0,1)$ under $SU(2) \times SU(2)$. These two terms each transform trivially under one of the $SU(2)$ factors, and are self-dual and anti-self-dual.

• Finally, we will use the identities

$$\eta_{pq}\eta_{qr} = -2i\eta_{pr} - 3\delta_{pr} I, \quad \bar{\eta}_{pq}\bar{\eta}_{qr} = -2i\bar{\eta}_{pr} - 3\delta_{pr} I$$

Next, we explicitly construct the unit instanton. It is convenient to proceed without gauge fixing.

• We can bound the action by noting that $F_{rs}^2 = \tilde{F}_{rs}^2$, so

$$\int d^4x \frac{1}{2} \operatorname{tr} F_{rs}^2 = \int d^4x \frac{1}{4} \operatorname{tr}\left(F_{rs}^2 + \tilde{F}_{rs}^2\right) = \int d^4x \frac{1}{4} \operatorname{tr}\left(F_{rs} - \tilde{F}_{rs}\right)^2 + \int d^4x \frac{1}{2} \operatorname{tr} F_{rs}\tilde{F}_{rs} \geq \frac{8\pi^2}{g^2} k$$

where k is the instanton number. The unit instanton has $k = 1$ and locally minimizes the action, which means its action is $8\pi^2/g^2$ and the field strength is self-dual. In the case of $k < 0$, we may flip a sign above to conclude that anti-instantons have anti-self-dual field strength.

• The result above is a Bogomolny bound, and it is useful because imposing self-duality requires solving only a first-order differential equation, while naively we would have to solve a secondorder differential equation.

• We take the ansatz

$$A_p = \eta_{pq} x_q f\left(x^2\right)$$

with the corresponding field strength

$$F_{pq} = 2\eta_{qp} f + 2\left(\eta_{qr} x_r x_p - \eta_{pr} x_r x_q\right) f' - ig\left[\eta_{pr}\eta_{qs}\right] x_r x_s f^2, \quad f' = \frac{df}{d\left(x^2\right)}$$

Requiring self-duality imposes constraints on $f\left(x^2\right)$.

• By rotational invariance, it suffices to examine the fields along the positive x_4 axis, where

$$F_{ij} = -2\eta_{ij} f - ig\left[\eta_{i4}, \eta_{j4}\right] x^2 f^2, \quad F_{k4} = -2\eta_{k4} f - 2\eta_{k4} x^2 f'$$

and the self-equality condition $F_{ij} = \epsilon_{ijk} F_{k4}$ reduces to

$$f' = -gf^2, \quad f = \frac{1}{g}\frac{1}{x^2 + \lambda^2}$$

• Therefore, the unit instanton solution, also called the BPST instanton, is

$$A_p = \frac{1}{g}\frac{\eta_{pq} x_q}{x^2 + \lambda^2}, \quad A_p^j = \frac{2}{g}\frac{\eta_{pq}^j x_q}{x^2 + \lambda^2}$$

The parameter λ gives the characteristic size of the instanton; all values of λ are allowed by the scale invariance of classical Yang-Mills. The anti-self-dual anti-instanton has the same form, with η_{pq} replaced with $\bar{\eta}_{pq}$. The field strength is

$$F_{pq} = -\frac{2}{g}\frac{\eta_{pq}\lambda^2}{\left(x^2 + \lambda^2\right)^2}$$

Note that this falls off as $1/x^4$ even though A_p falls off as $1/x$. This is because the leading large-distance component of A_p is pure gauge.

• Alternatively, by taking a gauge transformations, we have

$$A_p' = \frac{1}{g}\frac{\bar{\eta}_{pq} x_q \lambda^2}{x^2\left(x^2 + \lambda^2\right)}$$

In terms of bundles over S^4, the original gauge field is singular at the point at infinity, while this gauge field is singular at the origin. Such a singularity is necessary, since the fiber bundle is nontrivial.

• Yet another way to write the unit instanton is to let

$$G = \frac{x_4 + i\mathbf{x}\cdot\boldsymbol{\tau}}{|x|}, \quad A_p = \frac{x^2}{x^2 + \lambda^2}\left(-\frac{i}{g}\right)\left(\partial_p G\right) G^{-1}$$

This works because G wraps around $SU(2)$ once in an S^3 slice at constant $|x|$. Multiple instantons can be found by taking powers of G. Finally, one can explicitly transform this to $A_0 = 0$ gauge, giving explicit tunneling between vacua with different winding.

Physical Consequences

Finally, we investigate the physical consequence of instantons. First we connect them to anomalies.

• Consider a theory of N_f massless fermions. The $U(1)_A$ symmetry is anomalous by

$$\partial_\mu j_5^\mu = \frac{N_f g^2}{8\pi^2}\,\mathrm{tr}\, F_{\mu\nu}\tilde{F}^{\mu\nu}$$

We can form a divergenceless current

$$J_5^\mu = j_5^\mu - 2N_f j_A^\mu$$

where j_A^μ is as defined above; this current is not gauge invariant.

• In the $A_0 = 0$ gauge, the instanton corresponds to tunneling between vacua of different winding number; moreover this current vanishes at spatial infinity. Hence we have a conserved charge

$$Q_5 = n_R - n_L - 2N_f n$$

where n is the winding number of the gauge field. Hence a change in winding number must be accompanied by a change in fermion chirality,

$$\Delta\left(n_R - n_L\right) = 2N_f \Delta n$$

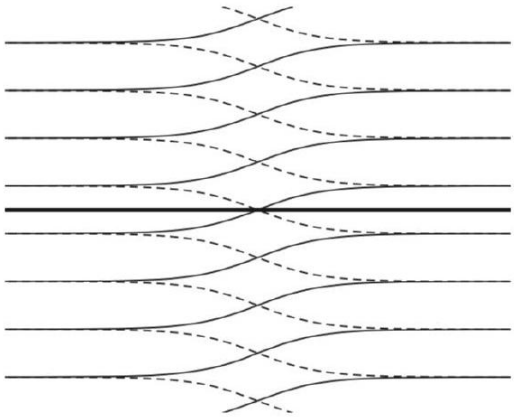
• To understand exactly how this happens, we consider the Dirac equation. The Hamiltonian for a single particle is

$$H = -i\alpha^j D_j, \quad \alpha^j = \gamma^0\gamma^j = \begin{pmatrix} \sigma^j & 0 \\ 0 & -\sigma^j \end{pmatrix}$$

in a particular representation of the γ^μ matrices. The four-component fermions naturally split into a pair of two-component Weyl fermions, where

$$H_R = -i\sigma^j D_j, \quad H_L = i\sigma^j D_j = -H_R$$

• Now we work in the Dirac sea picture. Both H_L and H_R have both positive and negative energy eigenstates, and we suppose all the negative energy states are filled. During the tunneling process, A_μ is not in a vacuum state, so the fermion spectrum changes; however it must be the same in both the initial and final states. However, the spectrum can 'flow' as shown below.



Here the heavy line is the zero of energy. If the change is slow, the adiabatic theorem holds, so that the initial Dirac sea turns into a Dirac sea plus a right-chiral particle and a left-chiral negative energy hole, corresponding to a right-chiral positive energy antiparticle.

• Even if the adiabatic theorem does not hold, the Hamiltonian only couples fermion fields of the same chirality, so any transitions between states do not affect the change in net chirality. Similarly, the initial state need not be the vacuum state.

• The fact that the instanton number is generally equal to the number of energy levels that cross zero can be proven with an index theorem, which we won't go into here.

• Now consider the physical gauge. In this case, the vacua have been gauge transformed to all have the same winding number. However the effect of the instanton of course cannot be gauged

away; the spectral flow occurs as before. Then the charge Q_5 is not conserved, which appears paradoxical. The resolution is that, as we've seen already, the current j^μ_A does not vanish at spatial infinity in this gauge; instead it yields a finite surface integral.

• The chirality-violating processes associated with instantons can be represented by a nonlocal effective Lagrangian density,

$$\mathcal{L}_{\text{eff}} = Ce^{-8\pi^2/g^2(\lambda)} \prod_{s=1}^{N_f} \left(\bar{\psi}^s_R \omega\right) \left(\bar{\omega} \psi^s_L\right)$$

where we must integrate over the positions of the fermion fields, ω is a fixed Dirac spinor transforming under the fundamental representation of the gauge group which depends on the gauge orientation of the instanton, and C is obtained from the one-loop corrections to the instanton. The Hermitian conjugate of this term accounts for the anti-instanton, and one must also integrate over instanton positions and scales. One may also integrate over gauge orientations of ω to get a gauge-invariant result.

• To solve the $U(1)$ problem of QCD, note that if we define

$$\mathcal{M}_{rs} = \left(\bar{q}_{Rr} \omega\right) \left(\bar{\omega} q_{Ls}\right)$$

then the anticommutativity of the fermion fields implies

$$\prod_{s=1}^{N_f} \left(\bar{q}_{Rs} \omega\right) \left(\bar{\omega} q_{Ls}\right) = \frac{1}{N_f!} \det \mathcal{M}$$

The chiral transformations of the quark fields are

$$q_L \to U_L q_L, \quad q_R \to U_R q_R, \quad \mathcal{M} \to U_R^\dagger \mathcal{M} U_L$$

under which $\det \mathcal{M}$ is not invariant for a $U(1)_A$ transformation. Hence $U(1)_A$ is explicitly broken when one accounts for instanton effects, and so is not a spontaneously broken symmetry.

• Computing the coefficient C amounts to evaluating functional determinants as we did for quantum mechanical tunneling, to find how the action varies as the instanton solution is deformed. We must also integrate over collective coordinates. The troublesome coordinate is the instanton size; we find a divergence due to large instantons, where the gauge coupling is strong. Hence unless we have a natural cutoff on the instanton size, it is difficult to estimate C. We only know that in QCD, instanton effects are significant.

Note. However, the $U(1)_A$ problem is a bit more confusing when one thinks in terms of θ-vacua instead of Lagrangian terms. The charge associated with $U(1)_A$ generates θ translations. Hence it appears the $U(1)_A$ symmetry is spontaneously broken by the choice of a θ vacuum, and hence should yield a PNBG.

Formally, any explicitly broken symmetry can be thought of as a spontaneously broken symmetry by enlarging the Hilbert space (i.e. treating the symmetry breaking parameter as a spurion), but it will not correspond to a physical excitation. The key property that distinguishes $U(1)_A$ breaking from the genuine spontaneous rotational symmetry breaking of a ferromagnet is that the magnetization $\mathbf{M}(x)$ is a local field which can have local excitations, while θ is a global property of the state, so it doesn't make sense to promote it to $\theta(x)$. We dwell on this point because often the introduction of the axion is oversimplified to saying that "axions result from promoting θ to a field". As shown in the notes on the Standard Model, one has to work a bit harder than that!

Note. A very similar phenomenon occurs in the simpler context of QED with a massless fermion in $d = 2$, where we can do the calculations simply and explicitly. In this case, the particles are either right-movers or left-movers, with the numbers n_R and n_L separately conserved. The axial charge, proportional to $n_R - n_L$, is violated by the anomaly,

$$\Delta\left(n_R - n_L\right) = \int d^2x \frac{e}{2\pi}\epsilon^{\mu\nu}F_{\mu\nu}$$

To relate this to spectral flow, suppose we adiabatically turn on a constant A^1 field, and for simplicity compactify space to length L. The Hamiltonian for a Weyl field is

$$H = \int dx\psi^\dagger\left(-i\alpha^1 D_a\right)\psi, \quad \alpha = \gamma^0\gamma^1 = \gamma^5$$

Splitting this into right-moving and left-moving components,

$$H = \int dx\left(-i\psi_+^\dagger\left(\partial_1 - ieA^1\right)\psi_+ + i\psi_-^\dagger\left(\partial_1 - ieA^1\right)\psi_-\right)$$

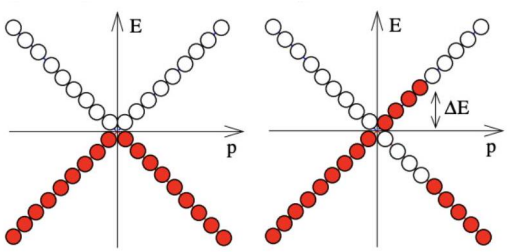
The eigenfunctions of the covariant derivative the form $e^{ik_n x}$ with $k = 2\pi n/L$, which implies the corresponding single-particle eigenstates of H have the energies

$$E_n^+ = k_n - eA^1, \quad E_n = -\left(k_n - eA^1\right)$$

Suppose we shift A^1 by $\Delta A^1 = 2\pi/eL$. Then spectral flow occurs in exactly the same manner as we saw above for $d = 4$, changing $n_R - n_L$ by -2. Correspondingly, we have

$$\int d^2x \frac{e}{2\pi}\epsilon^{\mu\nu}F_{\mu\nu} = \int dtdx\frac{e}{\pi}\partial_0 A_1 = -2$$

as expected. We can understand the spectral flow in a very concrete way: turning on the A_1 field corresponds to giving an equal impulse $e\Delta A^1$ to each particle. This affects the Dirac sea as follows:



The impulse creates right-moving particles and left-moving antiparticles, violating axial charge conservation.

This derivation didn't need instantons: we just postulated a background field configuration, nonzero over all space. Instantons are necessary to get a nontrivial result if we also require the fields to vanish quickly at infinity, i.e. they are the only contributions that matter in the infinite volume limit, where constant field configurations like this one would have infinite action.

Note. As with all anomaly effects, the result depends on the UV regularization. This is because the spectral flow affects energy levels all the way to positive and negative infinity. For example, if we had a hard cutoff, then spectral flow would never change the charges; in the above example, for example, the creation of low-energy right-moving particles would be compensated by the creation

of high-energy right-moving antiparticles. But we cannot just use this regulator because, as we've seen before, it would ultimately lead to an anomaly in the vector current, rendering the theory inconsistent.

Next, we investigate baryon number violation.

• In the $SU(2) \times U(1)$ electroweak theory there are also instantons. The Higgs acquires its usual VEV at infinity but vanishes at the center of the instanton. The Higgs VEV hence breaks the classical scale invariance, by favoring a smaller instanton size. As a result the integration over instanton size is finite, peaking around $\lambda \sim 1/\langle\phi\rangle$.

• Each electroweak instanton leads to a violation of baryon and lepton number by

$$\Delta B = \Delta L = 3$$

where the factor of 3 is from the three generations. The effective Lagrangian is nonlocal at the electroweak scale and hence, at longer distances, one can approximate the terms as local. For example, an instanton could mediate the scattering process $p + n \to \bar{p} + e^+ + e^+ + \bar{\nu}_e$.

• The rate of the associated processes is suppressed by

$$\left(e^{-8\pi^2/g^2}\right)^2 = e^{-16\pi^2 \sin^2\theta_W/e^2} \sim 10^{-161}$$

where we evaluated e at the Z mass, since the typical instanton size is set by the electroweak scale. The universe contains about 10^{78} protons and has an age of about 10^{10} years, or 10^{40} times a typical strong interaction time of 10^{-23} seconds. Hence baryon number violation by instantons appears to be completely negligible.

• However, one can also travel between different vacua by thermal fluctuations, rather than quantum tunneling. For every path connecting two vacua in spacetime, there is a point of highest energy; the minimum of all such maxima determines the thermal fluctuation rate. Such a solution is called a sphaleron, and it heuristically looks like the "midpoint" of the unit instanton solution. In particular, it has half-integer winding number. Sphalerons shouldn't be confused with instantons: instantons are spacetime configurations that are minima of the Euclidean action, while sphalerons are spatial configurations that are saddle points of the energy.

• Since a sphaleron is a critical point of the potential, it corresponds to a static solution (in $A_0 = 0$ gauge) of the field equations. Since it is a saddle point, it is unstable, leading to its name; sphaleron is etymologically related to "slippery".

• The size of the sphaleron is set by the Higgs vev, leading to the estimate

$$E_{\text{sph}} \sim \frac{4\pi v}{g} \sim 10\text{GeV}$$

where g is the $SU(2)$ gauge coupling. We then estimate $\Gamma \sim e^{-E_{\text{sph}}/T}$, though a more accurate calculation would give $\Gamma \sim e^{-F_{\text{sph}}/T}$ where the free energy F_{sph} accounts for finite temperature corrections to the effective potential, which change the expectation value of the Higgs field.

• More quantitatively, the rate per spacetime volume goes as

$$\Gamma \sim \begin{cases} T^4 e^{-F_{\text{sph}}/T} & T \lesssim F_{\text{sph}} \\ T^4 \alpha_w^4 & T \gtrsim F_{\text{sph}} \end{cases}$$

where the T^4 is by dimensional analysis, and the casework occurs because electroweak symmetry is unbroken for $T \gtrsim F_{\text{sph}}$.

• In any case, it is clear that at temperatures near or above that of the electroweak phase transition, baryon number violation can be significant. Depending on the model, this can be an obstacle to baryogenesis, diluting existing baryon number asymmetry, or the reason for baryogenesis itself.

Next, we discuss the QCD θ term.

• As we've motivated above, the Yang-Mills Lagrangian contains the θ term

$$\Delta\mathcal{L} = \frac{\theta g^2}{16\pi^2}\,\mathrm{tr}\,F_{\mu\nu}\tilde{F}^{\mu\nu} = \frac{\theta g^2}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}\,F_{\mu\nu}F_{\rho\sigma}$$

Such a term does not contribute classically but can in quantum mechanics.

• As a simple analogue, consider a particle on a ring, at angular coordinate α, and

$$L = \frac{1}{2}B\dot{\alpha}^2 + \frac{\theta}{2\pi}\dot{\alpha}$$

The conjugate momentum to α is

$$J = B\dot{\alpha} + \frac{\theta}{2\pi}$$

is quantized and takes on integer values, so for $J = n$,

$$E_n = \frac{1}{2B}\left(n - \frac{\theta}{2\pi}\right)^2$$

Hence a total derivative term affects the spectrum, though θ only matters up to multiples of 2π. For example, when $\theta = 0$ or $\theta = \pi$, the energy levels are doubly degenerate; in both cases this is a consequence of time reversal symmetry.

• Now add a potential energy $K(1 - \cos\alpha)$ where $K \gg 1/B$, so we may think of the particle as a rigid pendulum. In this case, the θ dependence only comes from tunneling processes, so the θ-dependence of the energy levels is exponentially suppressed.

• As for the physical consequences of the θ term, we cannot consider the θ-dependence of the vacuum energy, since θ is fixed. (However, such dependence is important when there is an axion.) The θ term also cannot explain observed CP violating processes, such as kaon decay, because neutron EDM requirements mean θ must be extremely small. In fact, no effects of the θ term have ever been observed. This is the strong CP problem.

Finally, we describe the Witten effect.

• The Witten effect links the θ term to the electric charge of magnetic monopoles. Here we must distinguish between two senses of the electric charge: the quantity that is coupled to electric fields which can be measured by their Coulomb tail, and the conserved Noether charge Q_n associated with phase rotations.

• Now consider a global $U(1)$ transformation composed with a gauge transformation,

$$\delta\mathbf{A}_\mu = \frac{1}{e}\mathbf{D}_\mu(\phi/|\phi|), \quad \delta\phi = 0$$

in a theory with gauge coupling e where $SU(2)$ is broken to $U(1)$ by a triplet, and the bold refers to $SU(2)$ indices.

• The Noether charge is

$$Q_n = \int d\mathbf{x}\delta\mathbf{A}_j \cdot \mathbf{\Pi}^j$$

where the conjugate momentum $\mathbf{\Pi}^j$ is

$$\mathbf{\Pi}_j = \frac{\partial \mathcal{L}}{\partial \left(\partial_0 \mathbf{A}_j\right)} = \mathbf{F}^{j0}$$

which implies that when $\theta = 0$,

$$eQ_n = \int d\mathbf{x} \mathbf{D}_j \hat{\boldsymbol{\phi}} \cdot \mathbf{F}^{j0} = \int d\mathbf{x} \left(\partial_j \left(\hat{\boldsymbol{\phi}} \cdot \mathbf{F}^{j0} \right) - \hat{\boldsymbol{\phi}} \cdot \mathbf{D}_j \mathbf{F}^{j0} \right)$$

The field equation $\mathbf{D}_j \mathbf{F}^{j0} = \boldsymbol{\phi} \times \mathbf{D}^0 \boldsymbol{\phi}$ shows the second term vanishes, so

$$eQ_n = \int d^2 S_j \hat{\boldsymbol{\phi}} \cdot \mathbf{F}^{j0} = Q_E$$

where electric charge is defined by the unbroken $U(1))$ subgroup. Since the Noether charge Q_n is conjugate to a periodic value, it is an integer, so the charge is quantized.

• Adding the θ term changes the conjugate momenta to

$$\mathbf{\Pi}^j = \mathbf{F}^{j0} - \frac{\theta e^2}{16\pi^2} \epsilon^{jkl} \mathbf{F}_{kl}$$

and repeating the steps above, using the Bianchi identity $\epsilon^{jkl} \mathbf{D}_j \mathbf{F}_{kl} = 0$ gives

$$eQ_n = \int d^2 S_j \hat{\boldsymbol{\phi}} \cdot \mathbf{F}^{j0} - \frac{\theta e^2}{16\pi^2} \epsilon^{jkl} \hat{\boldsymbol{\phi}} \cdot \mathbf{F}_{kl} = Q_E - \frac{e\theta}{2\pi} \left(\frac{eQ_M}{4\pi} \right)$$

• However, the Noether charge remains quantized to integer values. Thus, a monopole with magnetic charge $Q_M = 4\pi/e$ must have electric charge

$$Q_E = ne + \frac{e\theta}{2\pi}$$

for some integer n. Note that the result is periodic in θ as required.

• This can be understood by looking at the monopole from a distance, where it looks like a point charge. The Lagrangian is that of ordinary electromagnetism with the additional term

$$\Delta \mathcal{L} = -\frac{\theta e^2}{8\pi^2} \mathbf{E} \cdot \mathbf{B}$$

so that the abelian Gauss's law becomes

$$\nabla \cdot \mathbf{E} - \frac{\theta e^2}{8\pi^2} \nabla \cdot \mathbf{B} = \rho$$

where ρ is a purely electric source, which vanishes for a monopole. Hence magnetic charge must be accompanied by electric charge.

• This doesn't contradict the fact that the θ term does not affect the equations of motion, because for trivial gauge bundles $\nabla \cdot \mathbf{B}$ vanishes identically. It can only be nonzero if the bundle is nontrivial, in which case the θ term, which is still a total derivative, cannot be converted to a vanishing surface integral at infinity; instead we get a contribution at the overlap of the patches.

• Note that the Witten effect is totally independent of instantons; it only relies on there being a θ term in the Lagrangian. This term is thought of as "caused" by instantons for historical reasons.

7.3.3 Anomalies: Pion decay, triangle diagrams, features

(см. также последние лекции Вергелеса)

Pion Decay

We begin with an overview of anomalies.

• A anomaly is a symmetry of a classical theory that is not present in the quantum theory. Specifically, anomalies mean the Ward-Takahashi identities will no longer hold. They arise because the theory cannot be regularized without breaking the symmetry, or equivalently because the path integral measure cannot be chosen to be invariant.

• Anomalies can apply to either gauge or global symmetries. A gauge anomaly is dangerous because it destroys the Ward identities, and hence prevents the decoupling of unphysical states, leading to violation of unitarity. Thus we must arrange our theories so that all gauge anomalies cancel. Such a theory is called 'anomaly free'.

• Global anomalies are not dangerous, and are instead ubiquitous. For example, the $U(1)_B$ baryon number symmetry is anomalous, and this allows for nonconservation of baryon number, which is required for baryogenesis.

• We will see that anomalies are infrared effects, resulting from massless particles in the spectrum. This leads to the idea of anomaly matching, which relates the spectrum of massless particles above and below a phase transition. In renormalizable gauge theories, anomalies arise exclusively from chiral fermions.

• More specifically, consider a theory with gauge group G and global symmetry group $\tilde{G}$, with currents j^μ and $\tilde{j}^\mu$. It will turn out that anomalies can be computed by considering correlators of three currents, each of which may be from G or $\tilde{G}$, at one-loop order with a massless particle in the loop.

• For reasons that will become clear later, we will write, e.g. the anomaly resulting from three j^μ 's as $\mathrm{tr}(GGG)$. As a result, there are four important cases.

– $\mathrm{tr}(GGG)$ corresponds to an anomalous gauge symmetry, which is dangerous for the reasons explained above. The Ward-Takahashi identities correspond roughly to $\partial_\mu j^\mu \sim F\tilde{F}$.

– $\mathrm{tr}(GG\tilde{G})$ and $\mathrm{tr}(G\tilde{G}\tilde{G})$ may correspond to either an anomalous gauge symmetry or an anomalous global symmetry, depending on how we regularize the theory; for consistency we always choose the latter. This results in a non-conserved global current, $\partial_\mu \tilde{j}^\mu \sim F\tilde{F}$. For historical reasons, this is called a chiral anomaly.

• Note that many anomalies of this mixed form automatically vanish, because $\mathrm{tr}\,(T_a) = 0$ for any generator of a semi-simple Lie group.

– $\mathrm{tr}(\tilde{G}\tilde{G}\tilde{G})$ corresponds to a 't Hooft anomaly. These do not cause nonconservation of the current, $\partial_\mu \tilde{j}^\mu \sim 0$, but they are an obstruction to gauging $\tilde{G}$. It is these anomalies that are used in anomaly matching.

• There are also linear/mixed/gravitational anomalies of the form $\mathrm{tr}\,(G\,\mathrm{grav}^2)$ or $\mathrm{tr}\left(\tilde{G}\,\mathrm{grav}^2\right)$ where two of the external legs are gravitons. These cause nonconservation of a current in the presence of spacetime curvature. This can be understood in terms of the previous anomalies by working with a vierbein, in which case coupling to gravity is like coupling to an $SO(3,1)$ gauge field.

• Since $F\tilde{F}$ is a total derivative term, one might think that an anomalous global symmetry still has a conserved charge. However, this is not true if we account for instantons, the subject of the

next chapter, which can occur in non-abelian gauge theories. For gravitational anomalies, there are also corresponding gravitational instantons.

• Finally, quantum field theories generically break scale invariance. In this case the anomaly is called the trace anomaly, since scale invariance makes the energy-momentum tensor traceless, and it is proportional to the β-function. Conformal field theories are trace anomaly free.

• Historically, anomalies were first encountered in the computation of the decay rate for $\pi^0 \to \gamma\gamma$, where the chiral anomaly has an effect. In this context, it is also called an ABJ anomaly or the axial anomaly.

• The anomalies we have described above are sometimes called "perturbative" anomalies, in the sense that they can be computed using perturbative techniques. There are also more subtle anomalies, such as Witten's global $SU(2)$ anomaly (not to be confused with the anomalies of global symmetries we've considered above), which states that an $SU(2)$ gauge theory with an odd number of fermions in the fundamental representation is inconsistent.

First, we consider the decay $\pi^0 \to \gamma\gamma$ in the context of QCD with the up and down quark.

• An overview of the symmetries of the theory is given in the notes on the Standard Model. As a quick summary, the symmetry group is

$$\tilde{G} = U(1)_L \times U(1)_R \times SU(2)_L \times SU(2)_R$$

This is spontaneously broken to

$$\tilde{G} = U(1)_V \times SU(2)_V$$

by the formation of the quark condensate. The $U(1)_V$ symmetry is the total quark number, while the symmetry $U(1)_{\text{EM}} \subseteq SU(2)_V$ is gauged. The spontaneously broken symmetries $U(1)_A$ and $SU(2)_A$ correspond to the η' and the pions, respectively.

• However, we should also account for the quark masses. Equal masses for the up and down quark break the symmetry group explicitly to

$$\tilde{G} = U(1)_V \times SU(2)_V$$

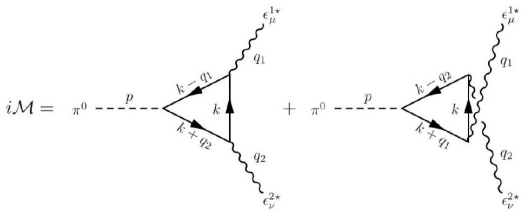
independent of the quark condensate. In this context $SU(2)_V$ is known as isospin. It is broken by the up-down quark mass difference, which we neglect.

• Now, suppose the π^0 couples to the proton ψ by the interaction

$$\mathcal{L}_{\text{int}} = i\lambda\pi\bar{\psi}\gamma^5\psi$$

and it decays to photons by a proton loop, where the proton has mass m.

• The two contributing diagrams are shown below.



The diagrams may be computed in the usual way. The amplitude is superficially divergent, of the form $\int d^4k/k^3$, but the combination of the two terms turns out to be finite, with

$$\mathcal{M} = \frac{\lambda e^2}{4\pi^2 m}\epsilon^{\mu\nu\rho\sigma}\epsilon_\mu^{1*}\epsilon_\nu^{2*}q_1^\rho q_2^\sigma, \quad \Gamma = \frac{\alpha^2}{64\pi^3}\frac{\lambda^2 m_\pi^3}{m^2}$$

• To make the result more quantitative, we need to find the value of λ. In the context of chiral perturbation theory, this coupling is related at tree level to the nucleon mass by $\lambda = m/f_\pi$, so

$$\Gamma = \frac{\alpha^2}{64\pi^3}\frac{m_\pi^3}{F_\pi^2}$$

• Alternatively, the computation can be done by current algebra. The key fact is that the neutral pion is a Goldstone boson associated with the spontaneous breaking of $SU(2)_A$. The three pions satisfy

$$\left\langle \Omega \left| j_\mu^{5a}(x) \right| \pi^a(p) \right\rangle = ie^{ipx}F_\pi p_\mu, \quad j_\mu^{5a} = \bar{\Psi}\tau^a\gamma_\mu\gamma^5\Psi$$

where Ψ can be taken to be either (p, n) or (u, d). The neutral pion corresponds to $a = 3$.

• Now, if we had used $\Psi = (u, d)$ instead, there would be contributions from both up quark loops and down quark loops, of which there are N colors, giving an overall factor of

$$N\left((2/3)^2 - (1/3)^2\right) = \frac{N}{3}$$

in the amplitude, where the minus sign comes from the negative isospin of the down quark, and we get q^2 factors from the two photon vertices. Hence the pion decay rate was an early test that $N = 3$ in QCD.

• One might complain that higher-order effects in QCD should be significant. The above result is only accurate because the chiral anomaly is exact at one loop, as we'll see below.

• The fact that the spinor ψ in the loop has a mass means that it violates $U(1)_A$ axial symmetry,

$$j^{\mu 5} = \bar{\psi}\gamma^\mu\gamma^5\psi, \quad \partial_\mu j^{\mu 5} = 2im\bar{\psi}\gamma^5\psi$$

This basic fact holds whether we think of the loop as containing nucleons or quarks.

• Now, the calculation we did above essentially says that

$$\left\langle A \left| \bar{\psi}\gamma^5\psi \right| A \right\rangle = i\frac{e^2}{32\pi^2}\frac{1}{m}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$$

where $F_{\mu\nu}$ is a background electromagnetic field. But then we have

$$\left\langle A \left| \partial_\mu j^{\mu 5} \right| A \right\rangle = -\frac{e^2}{16\pi^2}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$$

which means that the axial current is not conserved in a background electromagnetic field, even when we take the mass m to zero! Hence our simple calculation shows us something strange is going on with the axial symmetry - an anomaly is present.

• The reason the chiral anomaly is important here is that, if one reasoned from chiral symmetry alone, the decay rate should be much smaller. Naively we could have a term in the effective Lagrangian of the form

$$\mathcal{L}_{\text{eff}} = \frac{e^2}{8\pi^2 f_\pi}\pi^0\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$$

where the f_π is by dimensional analysis, and the extra $1/4\pi^2$ is because we are dealing with a loop effect. This yields the same result that we found above.

• This is surprising since the pion is a Goldstone boson of $SU(2)_A$, and hence should not have a non-derivative coupling. We know that $SU(2)_A$ is not an exact symmetry, so such a coupling may arise due to the breaking of $SU(2)_A$ by the quark masses. But it must be proportional to $m_u + m_d \propto m_\pi^2$, and hence smaller by a factor of m_π^2/f_π^2, giving a result that is too small.

• The resolution comes from the chiral anomaly, which in this case shows that there is a violation of $SU(2)_A$ symmetry independent of the quark masses. We know that under an $SU(2)_A$ transformation with $a = 3$, the π^0 field shifts, $\delta\pi^0 = \theta F_\pi$. When the quarks are integrated out,

$$\mathcal{L}_{\text{eff}} \supset -\frac{e^2}{16\pi^2 f_\pi}\pi^0 \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}$$

almost exactly as expected by the naive argument. This is the vertex in the effective theory that replaces the triangle diagrams.

• In the language we used above, the π^0 decay rate is due to an $SU(2)_A U(1)_{\text{EM}}^2$ anomaly. There is also a $U(1)_A U(1)_{\text{EM}}^2$ anomaly. However, what distinguishes $U(1)_A$ is that it is anomalous even in pure QCD, by a $U(1)_A SU(3)_C^2$ anomaly. This has a large effect on the mass of the η' because QCD is strongly coupled, resolving the $U(1)_A$ problem.

Triangle Diagrams

Let's compute the anomaly directly, starting with a massless Dirac fermion. In this case we have the global symmetry $U(1)_A \times U(1)_V$.

• We consider the correlation function $\langle j^{\alpha 5}(x) j^\mu(y) j^\nu(z)\rangle$. Under an axial transformation we have $\delta j^\mu = 0$, so the Ward-Takahashi identity is simply

$$\partial_\alpha \left\langle j^{\alpha 5}(x) j^\mu(y) j^\nu(z)\right\rangle = 0$$

This correlator is closely related to the pion decay amplitude, but without the external lines or the coupling constants. • Defining

$$iM_5^{\alpha\mu\nu}(p, q_1, q_2)\not{\delta}(p - q_1 - q_2) := \int dx dy dz e^{ipx} e^{iq_1 y} e^{iq_2 z} \left\langle j^{\alpha 5}(x) j^\mu(y) j^\nu(z)\right\rangle .$$

Feynman rules at one loop give:

$$M_5^{\alpha\mu\nu} = \int dk \,\mathrm{tr}\left(\gamma^\mu \frac{1}{\not{k}} \gamma^\nu \frac{1}{\not{k} + q/2} \gamma^\alpha \gamma^5 \frac{i}{\not{k} - q/1} + \begin{pmatrix} \mu \leftrightarrow \nu \\ 1 \leftrightarrow 2 \end{pmatrix}\right)$$

• Using standard identities, we may show

$$p_\alpha M_5^{\alpha\mu\nu} = 4i\epsilon^{\mu\nu\rho\sigma} \int dk \left(\frac{k^\rho q_2^\sigma}{k^2 (k + q_2)^2} + \frac{k^\rho q_1^\sigma}{k^2 (k - q_1)^2}\right) + \begin{pmatrix} \mu \leftrightarrow \nu \\ 1 \leftrightarrow 2 \end{pmatrix} .$$

By Lorentz invariance the integrals must be proportional to $q_1^\rho q_1^\sigma$ and $q_2^\rho q_2^\sigma$ respectively, and hence vanish when contracted with the Levi-Civita symbol. So naively it looks like the WardTakahashi identity is obeyed.

• Similarly, by contracting with q_μ^1, we find

$$q_\mu^1 M_5^{\alpha\mu\nu} = -4i\epsilon^{\mu\nu\rho\sigma}\int dk\left(\frac{(k-q_1)^\rho(k+q_2)^\sigma}{(k-q_1)^2(k+q_2)^2}-\frac{(k-q_2)^\rho(k+q_1)^\sigma}{(k-q_2)^2(k+q_1)^2}\right)$$

If we shift $k\to k+q_1$ in the first term and $k\to k+q_2$ in the second, the integral vanishes identically, so naively it looks like the vector current is conserved as well.

• However, this calculations are deceptive. If an integral is regularized, the integration variable can always be shifted, but we haven't done any regularization here. In fact, our standard regulators don't work, because DR has trouble with γ^5 and PV explicitly breaks chiral symmetry by introducing a massive fermion. One can still make sense of linearly divergent integrals, but their value changes upon a shift.

• To see this, consider the integral

$$\Delta(a)=\int dx f(x+a)-f(x)$$

where the integration bounds are $\pm\infty$, and $f(x)$ goes to a constant at infinity. Naively the integral is zero by shifting the first term, but by Taylor expanding we have

$$\Delta(a)=\int dx a f'(x)+\text{ higher derivatives }=a(f(\infty)-f(-\infty))$$

where the higher derivatives don't contribute since f goes to a constant at infinity. This result holds regardless of whether or how we regulate $f(x)$ at infinity.

• By similar reasoning, one can show that for the linearly divergent integral

$$\Delta^\alpha(a^\mu)=\int dk\left(F^\alpha(k+a)-F^\alpha(k)\right),\quad \lim_{k_E\to\infty}F^\alpha(k_E)=A\frac{k_E^\alpha}{k_E^4}$$

where k_E is a Euclidean momentum, we have

$$\Delta^\alpha(a^\mu)=\frac{i}{32\pi^2}Aa^\alpha$$

where the factor of i comes from Wick rotation.

• Returning to the vector current calculation above, the quadratic divergences cancel, while for the linear divergence gives

$$q_\mu^1 M_5^{\alpha\mu\nu}=\frac{1}{4\pi^2}\epsilon^{\alpha\nu\rho\sigma}q_1^\rho q_2^\sigma$$

Hence it appears the vector current is not conserved. The resolution is that the definitions of the loop momenta k are independent between the two contributing diagrams. In other words, by choosing the k 's we did above, we had implicitly fixed a regularization scheme for the correlator.

• We may choose the vector current to be conserved by shifting $k\to k+q_1$ in the first diagram, which fixes $k\to k+q_2$ in the second by Bose symmetry. Then the linear divergences cancel exactly, but one can show that

$$p_\alpha M_5^{\alpha\mu\nu}=\frac{1}{4\pi^2}\epsilon^{\mu\nu\rho\sigma}q_1^\rho q_2^\sigma$$

Taking the most general possible shift $k\to k+b_1q_1+b_2q_2$ it can be shown that it is impossible to preserve both the vector and axial symmetry; we choose to preserve the former.

• To compare with what we found earlier, we can relate correlation functions to matrix elements by LSZ reduction. The form of the LSZ reduction formula for photons is

$$\langle f|i\rangle = i\epsilon^\mu \int dx e^{-ikx} \left(-\partial^2\right) ... \langle A_\mu(x)...\rangle$$

By the Schwinger-Dyson equation associated with the classical equation of motion $-\partial^2 A_\mu = j_\mu$,

$$\langle f|i\rangle = i\epsilon^\mu \int dx e^{-ikx} ... \langle j_\mu(x)...\rangle + \text{ contact terms}$$

where the latter do not contribute to S-matrix elements and hence don't matter here.

• Applying the LSZ reduction formula, we have

$$\left\langle q_1, q_2 \left| j^{\alpha 5}(p) \right| 0 \right\rangle = (ig)^2 \epsilon_\mu \epsilon'_\nu \left(iM^{\alpha\mu\nu}\left(p, q_1, q_2\right) \not{\delta}\left(p - q_1 - q_2\right)\right).$$

Contracting both sides with p_α, we have

$$\left\langle q_1, q_2 \left| \partial_\alpha j^{\alpha 5}(x) \right| 0 \right\rangle = -\frac{g^2}{2\pi^2} \epsilon^{\mu\nu\rho\sigma} q_{1\rho} q_{2\sigma} \epsilon_\mu \epsilon'_\nu e^{-i(q_1+q_2)z} + O\left(g^4\right)$$

where the higher-order terms vanish by the one-loop exactness of the anomaly. This is consistent with the operator equation

$$\partial_\mu j^{\mu 5} = -\frac{g^2}{16\pi^2} \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}$$

Note. We haven't proven the above operator equation, only that a certain matrix element of both sides matches. Later, we will use the path integral to give a more general proof, which establishes that the two sides are equal when placed inside arbitrary time-ordered correlation functions.

The reason we hesitate to work with the actual operators is because they are difficult to define: quantum fields are operator-valued distributions and hence two fields at the same point can't be multiplied, but $j^{\mu 5}$ contains products of this form. In this case, we can "regularize" by point-splitting, separating the two ψ fields in $j^{\mu 5}$ and connecting them with a Wilson line,

$$j^{\mu 5} = \lim_{\epsilon \to 0} \bar{\psi}(x + \epsilon/2) \gamma^\mu \gamma^5 \exp\left(-ie \int_{x-\epsilon/2}^{x+\epsilon/2} dz^\mu A_\mu(z) \right) \psi(x - \epsilon/2)$$

Taking the limit carefully proves the desired operator equation. This somewhat old-fashioned approach is given in detail in chapter 19 of Peskin and Schroeder. In modern high-energy theory, many simply circumvent this issue by working exclusively with the path integral. In this language, an "operator" is just defined as any expression that can go under a path integral, and an "operator equation" is defined to be any statement that holds underneath a path integral up to contact terms.

Note. As stated above, dimensional regularization has problems with γ^5. So far, we've mostly treated dimensional regularization as a series of ad hoc rules. That is, we assume that the trace obeys the usual properties (linearity, cyclicity), and further assume that

$$\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}, \quad \{\gamma_5, \gamma^\mu\} = 0, \quad \gamma_5^2 = 1$$

These properties can be used to derive others; for instance,

$$d \operatorname{tr} \gamma_5 = \operatorname{tr} (\gamma_5 \gamma^\mu \gamma_\mu) = -\operatorname{tr} (\gamma_5 \gamma_\mu \gamma^\mu) = -d \operatorname{tr} \gamma_5$$

which implies that $\operatorname{tr} \gamma_5 = 0$ for all $d \neq 0$. If $\operatorname{tr} \gamma_5$ is to be meromorphic in d, then $\operatorname{tr} \gamma_5 = 0$ for all d.

If γ^5 really could satisfy all these properties simultaneously, the axial anomaly would vanish. However, other results would come out incorrect. For instance, it can be shown that

$$(4 - d) \operatorname{tr} (\gamma_5 \gamma_\mu \gamma_\nu \gamma_\rho \gamma_\sigma) = 0$$

which this trace to be zero for all d, including $d = 4$, making many amplitudes vanish identically, and giving completely wrong physical results.

To avoid problems of this sort, we need to give a more constructive definition of dimensional regularization. For example, Collins defines integrals in non-integer dimensions axiomatically in chapter 4. One consistent way to define γ_5 is to take $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$ in all dimensions. This formally means that γ^5 anticommutes with 4 of the gamma matrices, and commutes with $d - 4$ of them, breaking Lorentz invariance. Practically, this means that to evaluate loop integrals, we must split the loop momentum as $\ell = \ell_\parallel + \ell_\perp$, where the two pieces have 4 and $d - 4$ components, respectively, and treat the latter piece like a typical dimensional regularization integral in $d - 4$ dimensions. This is used to derive the axial anomaly in chapter 19 of Peskin and Schroeder.

There are other methods for defining γ_5, which are described in article by F. Jegerlehner. For instance, one can proceed naively if one only is interested in amplitudes with an even number of γ_5 's. This is used in chapter 21 of Peskin and Schroeder to handle one-loop computations in the Standard Model.

Comments about results

• We see that we may choose which symmetry to preserve; we could also choose to preserve neither. If we give the Dirac fermion a charge, we must choose the vector symmetry to be preserved to avoid a gauge anomaly. If we give the fermion a mass, then axial symmetry is automatically broken and we may regulate with PV, so none of the subtleties above apply.

• The reason we considered this correlator was that taking more currents would yield divergences weaker than a linear one. Also, we needed one or three axial currents, because we need an odd number of γ^5 matrices (otherwise they can cancel out and we can use DR) and at least one vector current to check vector current conservation. However, we could also derive the axial anomaly by considering a correlator of three axial currents.

• In general, anomalies in four dimensions are studied with triangle diagrams, while anomalies in $2n$ dimensions are studied with $(n + 1)$-gons. Moreover, we don't need to look at higher-loop diagrams since the chiral anomaly is one-loop exact. (why not 2 currents?)

• In general, for QED with any number of Dirac fermions, the gauge anomaly can be made to vanish by similar manipulations. However, for a single left-chiral Weyl fermion, this is not the case. The photon couples to the current

$$j_L^\mu = \bar{\psi} \gamma^\mu P_L \psi$$

The factors of P_L can be manipulated to show that

$$\langle j_L^\alpha j_L^\mu j_L^\nu \rangle = \frac{1}{2} \left(\langle j^\alpha j^\mu j^\nu \rangle - \langle j_5^\alpha j^\mu j^\nu \rangle \right)$$

The former vanishes when contracted with any of the momenta, as we may use DR there. Now we can have $p_\alpha \langle j_5^\alpha j^\mu j^\nu \rangle = 0$ or $q_{1\mu} \langle J_5^\alpha j^\mu j^\nu \rangle = 0$, but not both. Then the Ward-Takahashi identity for j_L^μ cannot be satisfied, and QED with a single Weyl fermion is inconsistent.

• Now suppose we have a left-chiral and right-chiral Weyl fermion with different charges. In this case the gauge boson A_μ couples to

$$j_{LR}^\mu = Q_L \bar{\psi} \gamma^\mu P_L \psi + Q_R \bar{\psi} \gamma^\mu P_R \psi$$

Since the mass is zero, there is no mixing between left-chiral and right-chiral fermions, so the contributions just add, giving

$$\langle j_{LR}^\alpha j_{LR}^\mu j_{LR}^\nu \rangle = Q_L^3 \langle j_L^\alpha j_L^\mu j_L^\nu \rangle + Q_R^3 \langle j_R^\alpha j_R^\mu j_R^\nu \rangle \supset \frac{1}{2} \left(Q_R^3 - Q_L^3 \right) M_5^{\alpha\mu\nu}$$

Hence the theory is consistent if $Q_L = Q_R$.

• Another way to understand the relative minus sign is to convert the right-chiral Weyl fermions to left-chiral Weyl fermions, which flips their charge; then the total anomaly is just proportional to $\sum_i Q_i^3$. In the case of a non-chiral gauge theory, every Q_i is paired with another of the opposite sign, which guarantees the sum is zero.

• In general, we only need to worry about vector symmetries being anomalous if the gauge theory is chiral. And chiral fermions in four dimensions must be massless, so we only need the lowenergy spectrum; the chiral anomaly is an infrared effect. This allows us to check gauge anomaly cancellation in the Standard Model below. (However, we shouldn't forget that axial symmetries can be anomalous even in non-chiral theories, as we saw in π^0 decay.)

• By generalizing the computation of the triangle diagram to a non-abelian gauge symmetry, for a massless Dirac fermion in a representation R, we have

$$\partial_\mu j^{\mu 5} = -\frac{g^2}{16\pi^2} T(R) \epsilon^{\mu\nu\rho\sigma} \left(\partial_\mu A_\nu^a - \partial_\nu A_\mu^a \right) \left(\partial_\rho A_\sigma^a - \partial_\sigma A_\rho^a \right) + O\left(g^3\right)$$

which suggests the result

$$\partial_\mu j^{\mu 5} = -\frac{g^2}{16\pi^2} T(R) \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu}^a F_{\rho\sigma}^a = -\frac{g^2}{16\pi^2} \epsilon^{\mu\nu\rho\sigma} \operatorname{tr} F_{\mu\nu} F_{\rho\sigma}$$

by gauge invariance; it can properly be derived by computing square and pentagon diagrams.

• By the LSZ logic above, this anomaly will also affect Ward-Takahashi identities for correlation functions of the form $\langle j^5 jjj \rangle$ and $\langle j^5 jjjj \rangle$, since the term $F\tilde{F}$ can also annihilate three or four gauge bosons.

• Massive fermions don't contribute to the chiral anomaly, because there we can simply use PV regularization. Hence the chiral anomaly is an infrared effect. Note that the (historically prior) calculation we presented above can obscure this, since it makes it look like anomalies are due to loop divergences.

Anomalies from the Path Integral

Next, we see how anomalies can arise from the path integral.

• We consider the quantity

$$Z(A) = \int \mathcal{D}\Psi \mathcal{D}\bar{\Psi} e^{iS(A)}, \quad S(A) = \int dx \bar{\Psi} (i \not{D}) \Psi, \quad D_\mu = \partial_\mu - igA_\mu$$

for a fixed background gauge field A, under which the Dirac fermion Ψ transforms in a representation R. Formally, we have

$$Z(A) = \det(i\not{D})$$

but this expression must be regularized.

• Now consider a spacetime-dependent axial $U(1)$ transformation,

$$\Psi'(x) = e^{-i\alpha(x)\gamma_5}\psi(x), \quad \bar{\Psi}'(x) = \bar{\psi}(x)e^{-i\alpha(x)\gamma_5}.$$

If the measure were invariant, we would have

$$Z(A) = \int \mathcal{D}\Psi'\mathcal{D}\overline{\Psi'} \exp\left(i\int dx\overline{\Psi'(i\not{D})\Psi'}\right) = \int \mathcal{D}\Psi\mathcal{D}\bar{\Psi} \exp\left(i\int dx\bar{\Psi}(i\not{D})\Psi + j_A^\mu(x)\partial_\mu\alpha(x)\right)$$

where we used invariance of the measure in the second step. Integrating by parts and setting this equal to $Z(A)$, we have $\langle\partial_\mu j_A^\mu\rangle = 0$. If we had other operators present, we would have this result up to contact terms, which is precisely the Ward-Takahashi identity.

• Now we consider the Jacobian of the transformation more closely. We have

$$J(x,y) = \delta(x-y)e^{-i\alpha(x)\gamma_5}, \quad \mathcal{D}\Psi'\mathcal{D}\overline{\Psi'} = (\det J)^{-2}\mathcal{D}\Psi\mathcal{D}\bar{\Psi}$$

where the negative power is due to Grassmann variables, and

$$(\det J)^{-2} = \exp(-2\,\mathrm{tr}\log J) = \exp\left(2i\int dx\alpha(x)\,\mathrm{tr}\,(\delta(x-x)\gamma_5)\right)$$

where the trace is over spin and group indices.

• Again, this result is meaningless without regularization, as the delta function is infinite and the trace vanishes. Since we need to regularize $Z(A)$ in any case, we should use $\not{D}$, so we replace

$$\delta(x-y) \to e^{-\left(i\not{D}_x\right)^2/M^2}\delta(x-y) = \int dk e^{-\left(i\not{D}_x\right)^2/M^2}e^{ik(x-y)}$$

for a mass M that will be taken to infinity. This replaces the delta function with a Gaussian in a gauge-invariant way, as we'll see below. Other cutoff functions would also work.

• If one is unsatisfied, one can also define the path integral more explicitly, using the same method we use for instantons below. That is, we expand Ψ in a basis of suitably orthonormalized eigenfunctions of $\not{D}$,

$$\psi(x) = \sum_n a_n\phi_n(x), \quad i\not{D}\phi_n = \lambda_n\phi_n$$

and define the measure by $\mathcal{D}\Psi = \prod_n da_n$, with a similar definition for $\mathcal{D}\bar{\Psi}$. One can then derive the Jacobian above more carefully, getting

$$\mathrm{tr}\,(\delta(x-x)\gamma_5) \to \sum_n \bar{\phi}_n(x)\gamma^5\phi_n(x)$$

which is equally divergent without regularization, but less manifestly nonsensical. One can then regulate the sum by adding a factor of $e^{-\lambda_n^2/M^2}$, then switch to a plane wave basis, recovering the expression above.

• Next, moving the derivative through the exponential with the identity

$$f(\partial)e^{ikx} = e^{ikx}f(\partial + ik)$$

we have

$$\delta(x-y) \to \int dk e^{ik(x-y)} e^{-(i\not{D}-\not{k})^2/M^2}$$

Expanding the exponential, we have

$$-(i\not{D}-\not{k})^2 = -\not{k}^2 + i\{\not{k},\not{D}\} + \not{D}^2 = -k^2 + 2ik\cdot D + D^2 + \frac{1}{2}\left[\gamma^\mu,\gamma^\nu\right] D_\mu D_\nu$$

where we used standard gamma matrix identities and $\gamma^\mu\gamma^\nu = \left(\{\gamma^\mu,\gamma^\nu\} + [\gamma^\mu,\gamma^\nu]\right)/2$. Finally, we replace $D_\mu D_\nu$ with $[D_\mu, D_\nu]/2 = igF_{\mu\nu}/2$.

• Finally, rescaling k by M, we have

$$\delta(x-y) \to M^4 \int dk e^{iMk(x-y)} e^{-k^2} e^{2ik\cdot D/M + D^2/M^2 + igF_{\mu\nu}[\gamma^\mu,\gamma^\nu]/4M^2}$$

Therefore, we have

$$\operatorname{tr}\delta(x-x)\gamma_5 \to M^4 \int dk e^{-k^2} \operatorname{tr} e^{2ik\cdot D/M + D^2/M^2 + igF_{\mu\nu}[\gamma^\mu,\gamma^\nu]/4M^2}\gamma_5$$

• We now expand the exponential in powers of $1/M$, where only terms up to M^{-4} survive the $M\to\infty$ limit. The only way to get a nonzero trace is to have four gamma matrices, so we get
$\operatorname{tr}\delta(x-x)\gamma_5 \to \int dk e^{-k^2} \frac{1}{2}\left(\frac{ig}{4M^2}\right)^2 \operatorname{tr} F_{\mu\nu}F_{\rho\sigma}\left[\gamma^\mu,\gamma^\nu\right]\left[\gamma^\rho,\gamma^\sigma\right]\gamma_5 = \frac{ig^2}{2}\epsilon^{\mu\nu\rho\sigma}\operatorname{tr}\left(F_{\mu\nu}F_{\rho\sigma}\right)\int dk e^{-k^2}$
using standard identities, where the remaining trace is over the group. The Gaussian integral is

$$\int dk e^{-k^2} = \frac{i}{(4\pi)^2}$$

where the factor of i is from Wick rotation, and the denominator is the usual loop factor.

• Putting everything together, we have

$$(\det J)^{-2} = \exp\left(-\frac{ig^2}{16\pi^2}\int dx\alpha(x)\epsilon^{\mu\nu\rho\sigma}\operatorname{tr} F_{\mu\nu}F_{\rho\sigma}\right)$$

Thus, the invariance of $Z(A)$ implies that

$$\left\langle \partial_\mu j_A^\mu + \frac{g^2}{16\pi^2}\epsilon^{\mu\nu\rho\sigma}\operatorname{tr} F_{\mu\nu}F_{\rho\sigma}\right\rangle = 0$$

with the same holding up to contact terms in correlators, as desired.

Now we reflect on the result.

• Taking $\alpha(x)$ to be constant, we have additionally shown that a chiral redefinition of a fermion field can induce extra terms in the Lagrangian, which is important for understanding the strong CP problem.

• The Adler-Bardeen theorem states that the anomaly is one-loop exact. It can be proven by a careful study of Feynman diagrams, or by noting that we never expanded in g above. (right?)

• By direct computation, we see the divergence of the current is a total derivative,

$$\epsilon^{\mu\nu\rho\sigma} \operatorname{tr} F_{\mu\nu} F_{\rho\sigma} = \partial_\mu \left(4\epsilon^{\mu\nu\rho\sigma} \operatorname{tr} \left(A_\nu \partial_\rho A_\sigma - \frac{2}{3} i g A_\nu A_\rho A_\sigma \right) \right)$$

where the quantity in brackets is called a Chern-Simons current. In particular, given an anomalous symmetry, we can construct an alternative current that is conserved. However, note that this current is not gauge-invariant.

• Note that the total value of the axial charge cannot change for topologically trivial configurations. Such changes must be mediated via instantons, but instantons don't exist for $U(1)$ gauge fields, so the axial charge is conserved even if the current locally isn't.

• A better proof for the one-loop exactness of the anomaly uses topology. Imagine higher-order corrections to the anomaly. The most general answer has the form

$$\partial_\mu j_A^\mu = f(g) g^2 \epsilon^{\mu\nu\rho\sigma} \operatorname{tr} F_{\mu\nu} F_{\rho\sigma}$$

by dimensional analysis and parity invariance. Integrating over spacetime,

$$\Delta Q_A = f(g) \int dx g^2 \epsilon^{\mu\nu\rho\sigma} \operatorname{tr} F_{\mu\nu} F_{\rho\sigma}$$

Assuming the gauge group is non-abelian, both the integral and the left-hand side are integers, so $f(g)$ cannot depend on g, and hence is one-loop exact. (This proof doesn't work in the abelian case because both sides vanish identically.)

• A similar derivation can be used for any even dimension $d = 2n$, giving

$$\partial_\mu j^{\mu 5} = (-1)^{n+1} \frac{2g^n}{n!(4\pi)^n} \epsilon^{\mu_1 \cdots \mu_{2n}} F_{\mu_1\mu_2} \cdots F_{\mu_{2n-1}\mu_{2n}}$$

Note that in $d = 2$, anomalies only arise from abelian gauge groups, as otherwise $\operatorname{tr} F_{\mu\nu} = 0$.

Note. The meaning of an anomaly for a global symmetry can be described directly in terms of the path integral as follows. Suppose j^μ is the current for a global symmetry. We can formally couple the symmetry to a background gauge field, which in the simplest case can be done by adding $j^\mu A_\mu$ to the Lagrangian for a background field A_μ, giving a partition function $Z[A]$. The symmetry can be gauged if we add in the Yang-Mills action for A_μ and integrate $Z[A]$ over gauge-inequivalent A_μ. This cannot be done if the global symmetry is anomalous, which occurs precisely when $Z[A]$ is not gauge-invariant.

Anomalies in the Standard Model

Next, we show gauge anomaly cancellation in the SM, introducing non-abelian anomalies.

• In the SM, we have the three currents j_μ^C, j_μ^L and j_μ^Y, which couple to $SU(3)_C, SU(2)_L$ and $U(1)_Y$ respectively. (For brevity, we'll drop the subscripts.) Gauge anomaly cancellation requires

$$\partial_\mu \left\langle j_\mu^i j_\nu^j j_\rho^k \right\rangle = 0$$

for all combinations of i, j, and k.

• In the case where all of the currents are j_μ^Y, we have the $U(1)^3$ anomaly

$$\partial_\mu j_Y^\mu = \left(\sum_{\text{left}} Y_i^3 - \sum_{\text{right}} Y_i^3 \right) \frac{g^2}{32\pi^2} \epsilon^{\mu\nu\rho\sigma} B_{\mu\nu} B_{\rho\sigma}$$

where $B_{\mu\nu}$ is the $U(1)$ field strength and g is the associated coupling.

• For the anomaly to vanish, we need

$$0 = \left(2Y_L^3 - Y_e^3 - Y_\nu^3\right) + 3\left(2Y_Q^3 - Y_u^3 - Y_d^3\right)$$

where the 3 accounts for color charge, the 2 accounts for the two members in a doublet, and we've added a right-handed neutrino for later.

• Plugging in the numbers

$$Y_L = -\frac{1}{2}, \quad Y_e = -1, \quad Y_\nu = 0, \quad Y_Q = \frac{1}{6}, \quad Y_u = \frac{2}{3}, \quad Y_d = -\frac{1}{3}$$

we find the anomaly vanishes for each generation, but not for the quarks or leptons individually.

• Next, consider triangle diagrams with three of the same non-abelian current. Here a fermion ψ in a representation R contributes to the current as

$$j_\mu^a = \bar{\psi}_i \left(T_R^a\right)_{ij} \gamma^\mu T_j$$

Therefore, the two diagrams pick up factors of $\operatorname{tr}\left(T_R^a T_R^b T_R^c\right)$ and $\operatorname{tr}\left(T_R^a T_R^c T_R^b\right)$ respectively.

• By substituting $T_R^a T_R^b = \left(\left[T_R^a, T_R^b\right] + \left\{T_R^a, T_R^b\right\}\right)/2$, we have

$$\operatorname{tr}\left(T_R^a T_R^b T_R^c\right) = \frac{i}{2} T_R f^{abc} + \frac{1}{4} d_R^{abc}, \quad d_R^{abc} = 2\operatorname{tr}\left(T_R^a \left\{T_R^b, T_R^c\right\}\right)$$

The quantity d_R^{abc} is a totally symmetric rank 3 tensor. In the case of $SU(n)$, there is only one such tensor, so we have

$$d_{abc}^R = A(R) d_{abc}$$

where d_{abc} is defined with the generators in the fundamental representation, and $A(R)$ is called the anomaly coefficient of the representation R.

• The term proportional to f^{abc} contributes through the difference of the diagrams and is UV divergent. However, it does not contribute to the anomaly; instead it merely renormalizes the three gauge boson vertex.

• The term proportional to d_{abc}^R contributes to the anomaly by

$$\partial_\mu j^{\mu a}(x) = \left(\sum_{\text{left}} A\left(R_i\right) - \sum_{\text{right}} A\left(R_i\right)\right) \frac{g^2}{128\pi^2} d^{abc} \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu}^b F_{\rho\sigma}^b$$

where $F_{\mu\nu}$ is the associated gauge field strength and g is the coupling. The overall factor is fixed by $U(1)$, where we have $T^a = 1$ and hence $d^{abc} = 4$.

• Since $T_{\bar{R}}^a = -\left(T_R^a\right)^T$, the anomaly coefficient obeys

$$A(R) = -A(\bar{R})$$

Since the representations of $SU(2)$ are all pseudoreal, there is no $SU(2)^3$ anomaly because the anomaly coefficients all vanish. Moreover, there is no $SU(3)^3$ anomaly because QCD is non-chiral. The anomaly coefficient obeys the useful identities

$$A\left(R_1 \oplus R_2\right) = A\left(R_1\right) + A\left(R_2\right), \quad A\left(R_1 \otimes R_2\right) = A\left(R_1\right) d\left(R_2\right) + d\left(R_1\right) A\left(R_2\right)$$

so we can compute anomaly coefficients by building up from the fundamental.

Now we consider the mixed anomalies involving different currents. In this case, the trace is taken over matrices which are tensor products of the matrices associated with each group factor.

• An $SU(n)U(1)^2$ anomaly would be proportional to $\operatorname{tr}(T_R^a\{1,1\}) \propto \operatorname{tr} T_R^a = 0$, so they automatically vanish. Similarly, any anomaly with exactly one factor of $SU(2)$ or $SU(3)$ vanishes. Therefore, the only cases to check are $SU(3)^2U(1)$ and $SU(2)^2U(1)$.

• One has to be careful when applying this point: not all $SU(n)U(1)^2$ anomalies vanish, only those where $SU(n)\times U(1)$ is a symmetry. For example, the $SU(2)_A U(1)^2$ anomaly does not vanish, and this is precisely what accounts for the decay $\pi^0 \to \gamma\gamma$.

• The $SU(3)^2U(1)$ anomaly only receives contributions from quarks, of the form

$$Y \operatorname{tr}\left(\left\{T^a, T^b\right\}\right) \propto \delta^{ab}$$

which means the overall contribution is

$$\delta^{ab}\left(6Y_Q - 3Y_u - 3Y_d\right) = 0$$

where the right-handed quarks contribute negatively as usual.

• The $SU(2)^2U(1)$ anomaly receives contributions from left-handed fields only, giving

$$\delta^{ab}\left(2Y_L + 6Y_Q\right) = 0$$

• The final constraint is from the gravitational anomaly, which comes from diagrams with two external gravitons and one external gauge boson. We find

$$\partial^\mu j_\mu^a \propto \operatorname{tr}(T_R^a)\,\epsilon^{\mu\nu\rho\sigma} R_{\mu\nu\alpha\beta} R_{\rho\sigma}^{\alpha\beta}$$

Since the generators of $SU(n)$ are traceless, the only constraint is from $\text{grav}^2\, U(1)$, which gives

$$\sum_{\text{left}} Y_i - \sum_{\text{right}} Y_i = 0$$

• In summary, we have four constraints on six hypercharges. There are two two-parameter families of allowed hypercharges, one of which is ruled out by demanding $Y_Q \neq 0$. The other is

$$Y_L = -\frac{a}{2} - b, \quad Y_e = -a - b, \quad Y_\nu = -b, \quad Y_Q = \frac{a}{6} + \frac{b}{3}, \quad Y_u = \frac{2a}{3} + \frac{b}{3}, \quad Y_d = -\frac{a}{3} + \frac{b}{3}$$

Note that we may also swap Y_d and Y_u, and Y_e and Y_ν, since the constraints don't distinguish between them; there is also an arbitrary hypercharge normalization we've neglected. The coupling a corresponds to hypercharge as it is in the SM, while b corresponds to $B - L$.

• No matter what the values of a and b are, we must have $Y_L + 3Y_Q = 0$ exactly, indicating that the electron and proton have exactly opposite electric charges. However, for general $b \neq 0$, the neutron is not electrically neutral, and charge is not quantized.

• If there is no right-handed neutrino, or if it is Majorana, then we must have $Y_\nu = 0$, implying $b = 0$ and therefore fixing the SM hypercharges up to scaling. On the other hand, if the opposite is true, then it is possible to extend the Standard Model by gauging both $U(1)_Y$ as in the usual Standard Model, and $U(1)_{B-L}$.

For more about anomaly coefficients, see the notes on Group Theory. Next, we consider global anomalies in the Standard Model.

• Recall the $U(1)_A$ axial symmetry considered earlier. We cannot compute an anomaly from a $U(1)_A^3$ triangle diagram, because there is nothing $\partial_\mu j_A^\mu$ can be equal to. Instead the anomaly is due to $U(1)_A U(1)_V^2$, since the latter is associated with the electromagnetic gauge group.

• By similar reasoning, all anomalies for a global symmetry G come from GH^2 triangle diagrams, where H is one of the gauge groups of the SM. We must use H^2 since the trace of a single factor is zero.

• Two important global symmetries are baryon number and lepton number. Now, we have anomalies due to $SU(2)^2U(1)_B$ and $SU(2)^2U(1)_L$, giving

$$\partial_\mu j^{\mu B} = \partial_\mu j^{\mu L} \supset n_g \frac{g^2}{32\pi^2} \epsilon^{\mu\nu\rho\sigma} W^a_{\mu\nu} W^a_{\rho\sigma}$$

where $n_g = 3$ is the number of generations. But if there is a sterile neutrino, $U(1)_{B-L}$ is nonanomalous, as we saw earlier, so it can be gauged. Such gauge bosons are common in grand unified theories and cause baryon number violation. Note that in neutral atoms, such a gauge boson would couple to neutron number. If gauged $U(1)_{B-L}$ is unbroken, it would need an exceptionally small coupling. If it is broken, the gauge boson mass is at least 3.5TeV.

• The right-hand side is a total derivative, which means that baryon and lepton number are conserved perturbatively. However, there are $SU(2)$ instantons for which the right-hand side integrates to a nonzero value over spacetime; these mediate violation of baryon and lepton number. The rate for this process is extremely small, but at high temperatures, it can be much higher because the transitions are caused by thermal fluctuations rather than quantum effects. In this case, we say the process is mediated by sphalerons.

• There are also anomalies due to $U(1)_Y^2 U(1)_B$ and $U(1)_Y^2 U(1)_L$. However, since there are no $U(1)$ instantons, such anomalies cannot lead to global nonconservation of baryon or lepton number, so they are less important.

• Next, we consider theta terms. The theta term of $U(1)_Y$ has no physical effects, because there are no $U(1)$ instantons. The theta term of $SU(2)$ may be rotated away by the $SU(2)^2U(1)_B$ anomaly. There is also an $SU(2)^2U(1)_L$ anomaly, which matches the $U(1)_B$ anomaly so that $U(1)_{B-L}$ is nonanomalous.

• However, the theta term of $SU(3)$ cannot be removed. The reason that we could easily remove the theta term of $SU(2)$ was because of the chiral structure of the weak force; rotating all quarks contributes to the anomaly because $SU(2)$ only couples to left-handed quarks.

• For $SU(3)$, we may try $SU(3)^2U(1)_A$ since $U(1)_A$ is chiral, but $U(1)_A$ is not a symmetry of the SM because of the quark masses. Instead, such an axial transformation changes the phases of the quark Yukawa couplings, and the invariant quantity is

$$\bar{\theta} = \theta - \arg\det M$$

where M is the quark mass matrix. The fact that $\bar{\theta}$ is observed to be zero within experimental error is the strong CP problem, as explained further in the notes on the Standard Model.

Note. A bit more about baryon and lepton number violation. In order to see what an $SU(2)_L$ instanton does, we note there are $12 SU(2)_L$ doublets in the SM (3 families of left-handed leptons, and 3×3 families and colors of left-handed quarks). The number of corresponding particles changes by 1 in each, so for a unit instanton we have

$$\Delta L_e = \Delta L_\mu = \Delta L_\tau = 1, \quad \Delta B = 3$$

Of course such a process must still conserve energy, electric charge, and color charge. Also note that instantons can't make isolated protons decay, because baryon number is violated in multiples of 3.

Finally, we describe the technique of anomaly matching.

• As an example, consider pure QCD with three massless quark flavors, where the global symmetry is $G = SU(3)_L \times SU(3)_R \times U(1)_V$. There are no $SU(3)^2 G$ anomalies, which ensures G remains a symmetry in a background gauge field, though there are G^3 anomalies.

• We now imagine gauging the symmetry G with an arbitrarily weak coupling. The G^3 anomalies now render the theory inconsistent, but they can be removed by adding spectator fermions. They are only coupled to the existing particles through the gauge field, and can be effectively decoupled by taking the gauge coupling arbitrarily small.

• Now consider the low-energy theory where quarks are confined. Since anomalies are infrared effects, gauge anomaly cancellation must still hold. This must be due to massless particles in the spectrum, which could be either Goldstone bosons or massless hadrons.

• Suppose the latter occurs, so $SU(3)_L \times SU(3)_R$ is not spontaneously broken, and consider the $SU(3)_L^3$ anomalies. In the deconfined phase, the left-handed quarks each contribute A (fund) = 1, and there are three colors, so the spectator fermions contribute an anomaly coefficient of -3.

• Now, for the anomalies to be canceled in the confined phase, color singlet fermions constructed from quarks must provide a total anomaly coefficient of 3. We have

$$3 \times 3 \times 3 = 10 + 8 + 8 + 1$$

and the 8 cannot contribute since it is a real representation. To evaluate $A(10)$, note

$$A(6) = A(3 \times 3) = A(\overline{3}) = 3A(3) + 3A(3) - A(\overline{3}) = 7$$

and

$$A(10) = A(6 \times 3) - A(8) = 3A(6) + 6A(3) - A(8) = 27.$$

Hence a 10 of baryons can only contribute in multiples of 27. Thus, for consistency, pure QCD with three flavors must have spontaneous chiral symmetry breaking!

• In real QCD, chiral symmetry breaking indeed occurs, and the anomalies are transferred over to the Goldstone bosons. For example, anomaly matching allows us to conclude there must be a $U(1)_{\pi^0} U(1)_V^2$ anomaly, where $U(1)_{\pi^0} \subseteq SU(2)_A$ is associated with the π^0. Indeed, this was our original motivating example.

7.4 Hypothetical particles and their phenomena in a nutshell

(тоже всякое можно предполагать, вот сюда и напишу коротко осоновные предположения)

On dark photon

Intro to dark photon by Zhou (??)

Currently, there are many experiments searching for the dark photon, a hypothetical particle whose motivation is described in the notes on Cosmology. The dark photon acts like the regular photon, but it has a mass $m_{A'}$ and couplings ϵe to fermions, where ϵ is the kinetic mixing parameter. Accelerator experiments attempt to produce the dark photon and detect its decay. The dominant

production channel depends on the experiment, such as whether it uses lepton or hadron beams, but some important production channels are:

- Electron-positron annihilation, $e^+e^- \to \gamma A'$. At high energies, the rate for this is ϵ^2 smaller than the rate for $e^+e^- \to \gamma\gamma$.

- A' Bremsstrahlung. Most processes can also produce an A' by attaching it to a fermion line.

- Meson decay. For example, pions can decay as $\pi^0 \to \gamma\gamma$, though we won't be able to calculate this rate for some time. However, it is simply related to the rate for $\pi^0 \to \gamma A'$.

The A' can then decay, e.g. through $A' \to e^+e^-$, which is trivial to calculate given what we already know, or through $A' \to \pi^+\pi^-$, which is somewhat more tricky. The way we detect this decay depends on the lifetime of the A', which generally scales as $\tau \sim 1/\Gamma \sim 1/\alpha\epsilon^2 m_{A'}$. The dark photon will travel a distance $\gamma c\tau$, but the opening angle of the decay products is $\sim 1/\gamma$, so the quantity that determines experimental resolution turns out to be

$$\ell \sim c\tau \sim \left(10^{-6}\text{ m}\right)\left(\frac{10^{-3}}{\epsilon}\right)^2 \frac{10\text{MeV}}{m_{A'}}.$$

For $\ell \lesssim 10\mu$m, the decay is "prompt", i.e. it happens at the same point as production, up to the detector resolution. In this case, individual dark photon events look like background events, but they can be found by computing the invariant mass of the decay products and looking for a statistically significant bump at $m_{A'}$. For larger ℓ, we enter the "displaced" regime, where the decay products can be measured to be coming from a point away from the interaction point. Here the signal rate tends to be lower, but measuring a displaced decay dramatically cuts down on backgrounds. Finally, if ℓ is larger than the detector, we enter the "long-lived" regime, where the dark photon flies out undetected. These can be detected by looking for "missing energy/momentum", but this procedure introduces its own backgrounds and uncertainties. Alternatively, one can search for the dark photon's decay inside a shielded secondary detector, far downstream of the main detector. These events would be very rare, but backgrounds are very low. Furthermore, in this case the dark photon doesn't need to be traced back to the event that produced it, so we can enhance the luminosity by using a "beam dump", crashing a beam into a wall rather than colliding it with another beam. Every one of these options is being considered by several completed, ongoing and proposed experiments around the world, including BaBar, Belle II, APEX, MAMI, MESA, DarkLight, HPS, DarkQuest, NA48, and NA42 (for prompt and displaced decays) and GAZELLE, CODEXb, FASER, MATHUSLA, E137, E141, E774, NA64, CHARM, NuCal, and NA62 (for long-lived particles).

7.5.2 On non-renormalizable theories

(У Шварца почитаю, пока не думал про это особо, ну есть такие и есть)

Summary of non-renormalizable theories

We have looked at four important non-renormalizable theories:

- The Schrödinger equation is perturbative for $E < m_e$. Its UV completion is the Dirac equation and QED, which is perturbative up to its Landau pole, $E \sim 10^{286}$GeV.

- The Fermi theory of weak interactions is perturbative for $E < G_F^{-1/2} \sim 300$GeV. Its UV completion is the electroweak theory with massive vector bosons W and Z. The electroweak theory is also non-renormalizable. Its UV completion contains a Higgs boson.

- The Chiral Lagrangian is the low-energy theory of pions. It is perturbative and very predictive for $E < 4\pi F_\pi \sim 1200$MeV. Its UV completion is QCD. QCD is predictive at high energies. The fields in QCD, quarks and gluons, are related to pions and other hadrons (quark and gluon bound states) in a complicated, non-perturbative way. Thus, to study hadrons in QCD, we need non-perturbative methods, such as the lattice. In contrast, at low energy the Chiral Lagrangian is perturbative and therefore more useful than QCD for answering certain questions.

- General relativity is the low-energy theory of gravity. It is perturbative for $E < M_{\rm Pl} \sim 10^{19}$GeV. It is extremely predictive at low energies, including predictive quantum corrections. One possible UV completion is string theory. Gravitational physics at distances larger than the Planck length, 10^{-33} cm, is independent of the UV completion, which explains why string theory (as a quantum theory of gravity) is so hard to test.

These four examples correspond to the four forces of nature: the electromagnetic force, the weak force, the strong force, and gravity. Notice that the UV completions are all qualitatively very different. In some cases, certainly for many physical applications, the non-renormalizable theory is more useful than the renormalizable one. Renormalizable just means there are a finite number of counterterms; it does not mean that you can calculate every observable perturbatively.

(???)

7.8.2 The Euler-Heisenberg Lagrangian

Finally, we sketch the derivation of the Euler-Heisenberg Lagrangian, which results from integrating out the electron.

• We expect we should be able to integrate out the electron because it appears quadratically in the QED action,

$$S[A,\psi] = \int dx \frac{1}{4} F^{\mu\nu} F_{\mu\nu} + \bar{\psi}(\not{D} + m)\psi$$

Since the electron is fermionic, we get a functional determinant in the numerator,

$$\Gamma_{\text{eff}}[A] = \frac{1}{4}\int dx F^{\mu\nu} F_{\mu\nu} - \hbar \log\det(\not{D} + m)$$

Here, the determinants are in both spinor space and functional space.

• To understand the functional determinant better, note that we can expand

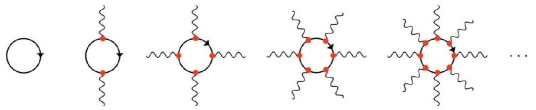
$$\log\det(\not{D} + m) = \log\det(\not{\partial} + m) + \operatorname{tr}\log\left(1 + ie(\not{\partial} + m)^{-1}\not{A}\right)$$

where we used $\log\det M = \operatorname{tr}\log M$. The first term comes from an electron loop vacuum bubble. The other term gives an infinite series in powers of A,

$$\operatorname{tr}\log\left(1 + ie(\not{\partial} + m)^{-1}\mathcal{A}\right) = -\sum_{n=1}^{\infty}\frac{(-ie)^n}{n}\int\prod_{i=1}^{n} dx_i \operatorname{tr}\left(S\left(x_n, s_1\right)\mathcal{A}(x_1)...S\left(x_{n-1}, x_n\right)\mathcal{A}(x_n)\right)$$

where the trace on the right is just a Dirac trace, and the functional trace is handled by the integration. All terms odd in A vanish by Furry's theorem, and $S\left(x_i, x_{i+1}\right)$ is the Dirac propagator, i.e. the inverse of the kinetic term.

• Thus the diagrams that contribute are



so the effective action has interaction terms for any even number of photons. To make the calculation tractable, we will assume the electromagnetic field is constant while taking the trace, which is equivalent to neglecting derivative terms; from an effective field theory standpoint this is valid if we consider light with frequency much less than the electron mass.

• As a result, the first diagram contributes only to vacuum energy, the second renormalizes the photon field, and all the others produce new interactions, which mediate light-by-light scattering. Thus the Euler-Heisenberg Lagrangian is useful when considering high-intensity, low-frequency light.

• We now turn to the explicit evaluation of $\log\det(\not{D} + m)$.

Since the trace of an odd number of gamma matrices vanishes, we must have

$$\operatorname{tr}\log(\not{D} + m) = \operatorname{tr}\log(-\not{D} + m)$$

which gives

$$\operatorname{tr}\log(\not{D}+m)=\frac{1}{2}(\log\det(\not{D}+m)+\log\det(-\not{D}+m))=\frac{1}{2}\log\det\left(-\not{D}^2+m^2\right).$$

• Next we can simplify $\not{D}^2$ as

$$\not{D}^2=\gamma^\mu\gamma^\nu D_\mu D_\nu=\left(\frac{1}{2}\{\gamma^\mu,\gamma^\nu\}+\frac{1}{2}[\gamma^\mu,\gamma^\nu]\right)D_\mu D_\nu=D^\mu D_\mu-eS^{\mu\nu}F_{\mu\nu}$$

The same manipulations yield the electron's magnetic moment in the Dirac equation.

• Therefore, we want to evaluate the functional

$$\begin{aligned}\frac{1}{2}\operatorname{tr}\log\left(-D^2+eS^{\mu\nu}F_{\mu\nu}+m^2\right)&\\ =\frac{1}{2}\operatorname{tr}\log\left(-\left((\partial+ieA)^2+m^2\right)\begin{pmatrix}1&0\\0&1\end{pmatrix}+e\begin{pmatrix}(\mathbf{B}+i\mathbf{E})\cdot\boldsymbol{\sigma}&0\\0&(\mathbf{B}-i\mathbf{E})\cdot\boldsymbol{\sigma}\end{pmatrix}\right)&\end{aligned}$$

where the $\boldsymbol{\sigma}$ are the usual Pauli matrices and the electromagnetic field is constant.

• Suppressing the spinor indices temporarily, we can perform the functional trace in position space, giving

$$\Gamma_{\text{eff}}[A]=\int dx\frac{1}{4}F^{\mu\nu}F_{\mu\nu}+\frac{1}{2}\langle x|\log\left(-D^2+eS^{\mu\nu}F_{\mu\nu}+m^2|x\right\rangle$$

To remove the logarithm, we use the asymptotic relation

$$\lim_{s_0\to0^+}\int_{s_0}^{\infty}e^{-sX}\frac{ds}{s}=-\log(s_0X)+\text{ finite}$$

to find

$$\frac{1}{2}\left\langle x\left|\log\left(-D^2+eS^{\mu\nu}F_{\mu\nu}+m^2\right)\right|x\right\rangle=\lim_{s_0\to0^+}\frac{1}{2}\int_{s_0}^{\infty}\frac{ds}{s}e^{-sm^2/2}\left\langle x\left|e^{-s\left(-D^2+eS^{\mu\nu}F_{\mu\nu}\right)}\right|x\right\rangle.$$

Thus the problem has been reduced to nonrelativistic quantum mechanics; we essentially have to find the energy eigenstates of the Pauli equation in position space. For example, in the case of a constant magnetic field, the solutions are Landau levels.

• A complicated calculation yields the effective Lagrangian

$$\frac{1}{4}F^{\mu\nu}F_{\mu\nu}-\lim_{s_0\to0^+}\frac{e^2}{64\pi^2}\int_{s_0}^{\infty}\frac{ds}{s}e^{-sm^2}\frac{\operatorname{Re}\cosh(esX)}{\operatorname{Im}\cosh(esX)}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma},\quad X=\sqrt{\mathbf{E}^2-\mathbf{B}^2+\mathbf{E}\cdot\mathbf{B}}.$$

Finally, we need to handle the UV divergences, which occur for small s. Expanding the integrand as a series in es, we find

$$\frac{\operatorname{Re}\cosh(esX)}{\operatorname{Im}\cosh(esX)}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} = \frac{4}{e^2s^2} + \frac{2}{3}F^{\mu\nu}F_{\mu\nu} - \frac{e^2s^2}{45}\left((F^{\mu\nu}F_{\mu\nu})^2 + \frac{7}{4}\left(\widetilde{F}^{\mu\nu}F_{\mu\nu}\right)^2\right) + O\left(e^4\right)$$

and the first two terms are a vacuum energy and photon field renormalization, which we remove by minimal subtraction, and all other terms are finite. This yields the Euler-Heisenberg Lagrangian. It is fully nonperturbative in e, since the real expansion parameter is E/m_e.

Note. One might wonder what the most general terms in the series above look like. In particular, is it true that every term is built out of $F^2 \sim E^2 - B^2$ and $F\tilde{F} \sim \mathbf{E}\cdot\mathbf{B}$? One slick way to prove this is to consider the complex vector $\mathbf{E} + i\mathbf{B}$. Boosts correspond to imaginary rotations of this vector, so rotations and boosts together cover all possible rotations. But the only invariant of a vector with respect to rotation is its square, and

$$(\mathbf{E} + i\mathbf{B})\cdot(\mathbf{E} + i\mathbf{B}) = \left(E^2 - B^2\right) + 2i(\mathbf{E}\cdot\mathbf{B}).$$

Note that this proof only works in $d = 4$.

8.2.1 The Idea of the Quantum-Field Approach (????)

Обсудим подробно, зачем конкретно нам вообще КТП?

Почему мы описываем микромир полями?

Для чего мы должны изучать квантование полей? (ПШ,????)

8.2.2 When in Physics "all is field" and when it is not?

На макро уровне это, конечно, бред, однако на микро уровне это начинает иметь смысл. Вот и напишу, чтобы лишний раз про это не думать.

8.2.3 Examples for Introducing the Essence of QFT (??)

(такое очень полезно иметь под рукой)

Рождение пар e^+e^- как введение в КТП по Пескину Шредеру

Главная цель части I этой книги заключается в развитии основного вычислительного метода квантовой теории поля - формализма диаграмм Фейнмана. Затем мы применим этот формализм для вычислений в квантовой электродинамике - квантовой теории электронов и фотонов.

Квантовая электродинамика (КЭД) - вероятно, наилучшая из имеющихся фундаментальных теорий. Она формулируется как набор простых уравнений (Максвелла и Дирака), вид которых определяется, по существу, релятивистской инвариантностью. Квантово-механические решения этих уравнений дают детальные предсказания

электромагнитных явлений в масштабах от макроскопических расстояний вплоть до расстояний, в несколько сотен раз меньших размера протона.

Фейнмановские диаграммы обеспечивают соответствующую элегантную вычислительную схему для этой элегантной теории. Достаточно представить процесс, который может происходить между электронами и фотонами, нарисовать его диаграмму, а затем с помощью диаграммы записать математическое выражение для квантово-механической амплитуды этого процесса.

В этой части книги мы развиваем как теорию КЭД, таю и метод фейнмановских диаграмм, исходя из основных принципов квантовой механики и теории относительности. В конце концов мы приходим к состоянию, которое позволит рассчитывать наблюдаемые величины, представляющие большой интерес при изучении элементарных частиц. Однако чтобы достичь цели и развить простой вычислительный метод, нам, к сожалению, придется сначала серьезно погрузиться в формализм теории. Три главы, следующие за этой, почти полностью формальны, и при их изучении читатель в какой-то момент может задаться вопросом, а куда мы, собственно, движемся? Мы хотели бы хоть частично заранее ответить на этот вопрос, обсудив в этой главе физику особенно простого процесса КЭД, многие свойства которого следуют непосредственно из физической интуиции. Конечно, такой интуитивный приземленный подход содержит много прорех. В гл. 5 мы вернемся к рассмотрению этого процесса, вооруженные всей мощью формализма фейнмановских диаграмм. Спускаясь вниз с горных высот, мы увидим, как ликвидируются все трудности интуитивного подхода.

Простейшая ситуация

Так как большинство экспериментов в физике частиц включает рассеяние, наиболее часто вычисляемыми в квантовой теории поля величинами являются сечения рассеяния. Мы хотим вычислить сечение простейшего, из возможных, процесса КЭД: рождение пары более тяжелых лептонов (например, мюонов) при аннигиляции электрона с его античастицей - позитроном. Существование античастиц, на самом деле, предсказывает квантовая теория поля, и мы будем обсуждать это предсказание в гл. 2

и 3. Сейчас примем его на веру.

Опыт по измерению вероятности такой аннигиляции заключается в наблюдении столкновения пучка электронов с пучком позитронов. Измеряемой при этом величиной является сечение реакции $e^+e^- \to \mu^+\mu^-$как функция энергии в системе центра инерции и относительного угла θ между направлениями полета начальных электронов и конечных мюонов. Процесс показан на рис. 1.1. Для простоты будем работать в системе центра инерции (с. ц. и.), где импульсы частиц удовлетворяют условию $\mathbf{p}' = -\mathbf{p}$ и $\mathbf{k}' = -\mathbf{k}$. Предположим также, что энергия пучков E много больше как массы электрона, так и массы мюона, так что $|\mathbf{p}| = |\mathbf{p}'| = |\mathbf{k}| = |\mathbf{k}'| = E \equiv E_{\text{ци}}/2$. (Мы используем полужирный шрифт для обозначения 3-векторов и обычный курсивный шрифт для обозначения 4-векторов.)

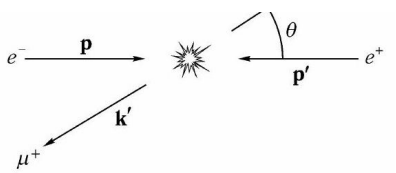

Рис. 1.1. Реакция аннигиляции $e^+e^- \to \mu^+\mu^-$, показанная в системе центра инерции.

Так каю и электрон, и мюон имеют спин 1/2, то нужно задать ориентации их спинов. Удобно выбрать ось, определяющую квантование спина каждой частицы, в направлении ее движения. Тогда спин каждой частицы может быть направлен либо параллельно, либо антипараллельно этой оси. На практике пучки электронов и позитронов часто не поляризованы, а мюонные детекторы не регистрируют поляризацию мюонов. Поэтому нам следует усреднить сечение по ориентациям спина электрона и позитрона и просуммировать его по ориентациям спина мюонов. Для любой заданной ориентации спинов всех частиц принято записывать дифференциальное сечение этого процесса с вылетом μ^+в заданный элемент телесного угла $d\Omega$ как

$$\frac{d\sigma}{d\Omega} = \frac{1}{64\pi^2 E_{\text{ци}}^2}|\mathscr{M}|^2$$

Множитель $E_{\text{ци}}^2$ обеспечивает правильную размерность сечения, так как в выбранной системе единиц (энергия $)^{-2} \sim$ длина $)^{2}$[2]. Следовательно, величина $\mathscr{M}$ безразмерна. Она представляет квантово-механическую амплитуду рассматриваемого процесса (аналогичную амплитуде f в нерелятивистской квантовой механике). Главный вопрос заключается в том, как вычислить эту амплитуду, исходя из фундаментальных принципов теории. Другие множители в (1.1) являются исключительно результатом соглашения. Формула (1.1) представляет, на самом деле, частный случай более общей формулы, справедливой для рассеяния в с. ц. и., когда конечное состояние содержит две безмассовые частицы. Общую формулу нельзя получить на основании размерных соображений, и мы выведем ее в разделе 4.5.

Теперь наступает время плохих и хороших новостей.

Плохая новость заключается в том, что даже для простейшего из процессов КЭД точное выражение для $\mathscr{M}$ неизвестно. Это не должно удивлять, так как даже в не- релятивистской квантовой механике задача рассеяния редко имеет точное решение. Лучшее, что можно сделать, это получить формальное выражение для $\mathscr{M}$ в виде ряда теории возмущений по константе электромагнитного взаимодействия и вычислить несколько первых членов этого ряда.

Хорошая новость состоит в том, что Фейнман разработал красивый способ упорядочить и сделать наглядным ряд теории возмущений, получивший название метода фейнмановских диаграмм. Грубо говоря, диаграммы изображают потоки электронов и фотонов в процессе рассеяния. В нашем частном случае слагаемое низшего порядка в ряде теории возмущений можно представить единственной диаграммой рис. 1.2. В этой диаграмме имеются элементы трех типов: внешние линии (представляющие четыре начальные и конечные частицы), внутренние линии (представляющие «виртуальные» частицы; в нашем случае - один виртуальный фотон) и вершины. Принято изображать фермионы сплошными линиями, а фотоны - волнистыми. Стрелки на сплошных линиях указывают не направление импульса, а направление потока отрицательного заряда. Каждой внешней линии приписывается определенный 4-вектор импульса, как показано на рисунке. Импульс q внутренней линии на этой диаграмме определяется законом сохранения импульса в каждой из вершин: $q = p + p' = k + k'$. Кроме того, каждому внешнему фермиону следует сопоставить определенное спиновое состояние (либо «вверх»,

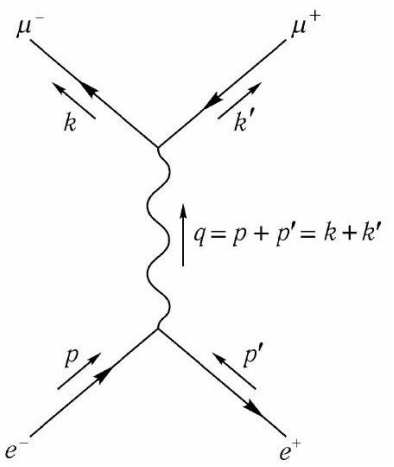

Рис. 1.2. Фейнмановская диаграмма низшего порядка для сечения рассеяния $e^+e^- \to \mu^+\mu^-$. В этом порядке единственным возможным промежуточным состоянием является фотон (γ). либо "Вниз»).

Согласно фейнмановским правилам каждой диаграмме соответствует совершенно определенный вклад в $\mathscr{M}$. Правила приписывают каждому элементу диаграммы компактный алгебраический множитель, так что произведение этих множителей дает значение соответствующего слагаемого в ряде теории возмущений. Однако приведение результирующего выражения для $\mathscr{M}$ к пригодному для использования виду может оказаться нетривиальной задачей. В последующих главах мы разработаем полезную технологию подобных вычислений. Но поскольку сейчас мы ею не владеем, воспользуемся для нахождения ответа для нашей конкретной задачи не точными фейнмановскими правилами, а некоторыми эвристическими аргументами.

Напомним, что в квантово-механической теории возмущений амплитуда перехода в первом порядке может быть записана в виде

$$\langle \text{ конечное состояние } |H_I| \text{ начальное состояние } \rangle ,$$

где H_I - часть гамильтониана, отвечающая за «взаимодействие». В нашем случае начальным является состояние $|e^+e^-\rangle$, а конечным - состояние $\langle\mu^+\mu^-|$. Но гамильтониан взаимодействия связывает электроны с мюонами не напрямую, а только через электромагнитное поле (т. е. фотоны). Поэтому выражение амплитуды первого порядка (1.2) обращается в нуль, и мы должны перейти к рассмотрению вклада второго порядка

$$\mathscr{M} \sim \left\langle \mu^+\mu^- \left|H_I\right| \gamma \right\rangle^{\mu} \left\langle \gamma \left|H_I\right| e^+e^- \right\rangle_{\mu} .$$

В этом и заключается эвристический способ записи $\mathscr{M}$ по диаграмме рис. 1.2. Внешним электронным линиям соответствует множитель $|e^+e^-\rangle$, внешним мюонным линиям - множитель $\langle\mu^+\mu^-|$. Вершинам соответствуют H_I, а внутренней фотонной линии - оператор $|\gamma\rangle\langle\gamma|$. Мы добавили векторные индексы μ, так как фотон является векторной частицей с четырьмя компонентами. Имеются четыре возможных промежуточных состояния, по одному на каждую компоненту. Согласно правилам теории возмущений следует просуммировать по промежуточным состояниям. Заметим, что поскольку сумма в (1.3) имеет вид скалярного произведения 4-векторов, амплитуда $\mathscr{M}$ является лоренц-инвариантным скаляром, если только каждый множитель в (1.3) есть 4-вектор.

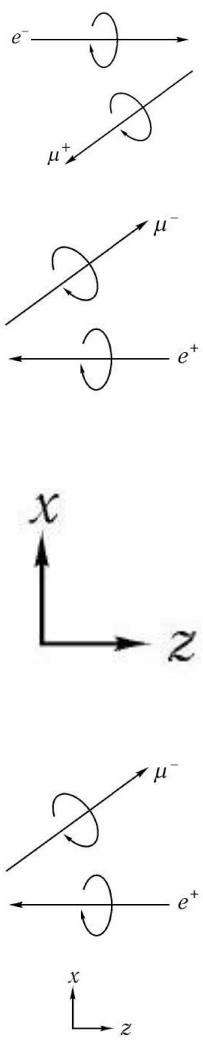

Рис. 1.3. Один возможный набор спиновых ориентаций. Электрон и отрицательный мюон «правые», тогда как позитрон и положительный мюон - «левые».

Попробуем угадать форму вектора $\langle \gamma \left| H_I \right| e^+ e^- \rangle_\mu$. Так как H_I связывает электроны с фотонами с константой e (заряд электрона), матричный элемент должен быть пропорционален e. Рассмотрим конкретный набор начальных и конечных спиновых ориентаций, показанных на рис. 1.3. Спины электрона и мюона параллельны своим направлениям движения: говорят, что эти частицы «правые». Аналогично, античастицы «левые». Спины электрона и позитрона складываются в единицу углового момента в направлении $+z$. Так как H_I должен сохранять угловой момент, фотон, с которым связаны эти частицы, должен обладать правильным вектором поляризации, отвечающим тому же угловому моменту: $\varepsilon^\mu = (0, 1, i, 0)$. Следовательно,

$$\left\langle \gamma \left| H_I \right| e^+ e^- \right\rangle_\mu \propto e(0, 1, i, 0)$$

Аналогично, мюонный матричный элемент должен иметь поляризацию, соответствующую единице углового момента вдоль направления импульса отрицательно заряженного мюона. Чтобы получить правильный вектор, повернем (1.4) на угол θ в плоскости xz:

$$\left\langle \gamma \left| H^I \right| \mu^+ \mu^- \right\rangle^\mu \propto e(0, \cos\theta, i, -\sin\theta)$$

Для вычисления амплитуды $\mathscr{M}$ комплексно сопрягаем этот вектор и скалярно умножаем его на (1.4). Тогда для заданной ориентации спинов получим

$$\mathscr{M}(RL \to RL) = -e^2(1+\cos\theta)$$

Конечно, таким способом невозможно установить общий множитель, но по случайности оказывается, что в (1.6) он правилен благодаря тем соглашениям, которые приняты в (1.1). Заметим, что при $\theta = 180^\circ$ амплитуда обращается в нуль. Этого следовало ожидать: состояние с угловым моментом в направления $+z$ не переходит в состояние с угловым моментом в направлении $-z$. Рассмотрим теперь случай, когда и электрон, и позитрон правополяризованы. Их полный спиновый момент равен нулю. В этом случае нужны более тонкие рассуждения. Можно ожидать, что мы получим продольно поляризованный фотон, причем появится коэффициент Клебша-Гордана $\frac{1}{\sqrt{2}}$, по аналогии со случаем сложения трехмерных угловых моментов: $|\uparrow\downarrow\rangle = (1/\sqrt{2})(|j=1, m=0\rangle + |j=0, m=0\rangle)$. Но на самом деле мы складываем угловые моменты в рамках четырехмерной группы Лоренца, поэтому следует принимать во внимание не только спин (свойства преобразования состояний при вращениях), но и преобразования состояний при бустах. Оказывается (мы покажем это в гл. 3), что коэффициент Клебша-Гордана, связывающий 4-вектор с состоянием $\left|e_R^- e_R^+\right\rangle$безмассовых фермионов, равен нулю. (Суть в том, что такое состояние есть суперпозиция скаляра и антисимметричного тензора.) Следовательно, амплитуда $M(RR \to RL)$ равна нулю, как и одиннадцать других амплитуд, в которых либо начальное, либо конечное состояние имеет полный нулевой угловой момент.

Остающиеся ненулевые амплитуды можно найти тем же способом, как и первую. Имеем:

$$\mathscr{M}(RL \to LR) = e^2(1-\cos\theta)$$
$$\mathscr{M}(LR \to RL) = e^2(1-\cos\theta)$$
$$\mathscr{M}(LR \to LR) = e^2(1+\cos\theta)$$

Подставляя эти выражения в (1.1), усредняя по четырем начальным и суммируя по четырем конечным спиновым ориентациям, находим

$$\frac{d\Sigma}{d\Omega} = \frac{\alpha^2}{4E_{\text{ци}}^2}\left(1+\cos^2\theta\right),$$

где $\alpha = e^2/4\pi \simeq 1/137$. Интегрируя по углам θ и ϕ, получаем полное сечение

$$\sigma_{\text{полн}} = \frac{4\pi\alpha^2}{3E_{\text{ци}}^2}.$$

Результаты (1.8) и (1.9) согласуются с экспериментом с точностью порядка 10%. Почти все расхождение обязано вкладу следующего слагаемого ряда теории возмущений, отвечающего диаграммам рис. 1.4. Качественные особенности полученных выражений - угловая зависимость и резкое уменьшение сечения с энергией - явно подтверждаются данными эксперимента. (Подробнее свойства полученных результатов обсуждаются в разделе 5.1.)

Уточнения и вопросы

Угловое распределение в реакции $e^+e^- \to \mu^+\mu^-$, предсказываемое квантовой электродинамикой, было получено с помощью аргументов, связанных с сохранением

углового момента, без обращения к формализму, лежащему в основании теории. Однако мы существенно использовали упрощения, связанные с пределом высоких энергий и выбором системы центра инерции. Если отказаться от любого из упрощающих предположений, то проделанный нами анализ разрушится. Как же нужно проводить вычисления в КЭД в общем случае? Чтобы ответить на этот вопрос, следует вернуться к фейнмановским правилам.

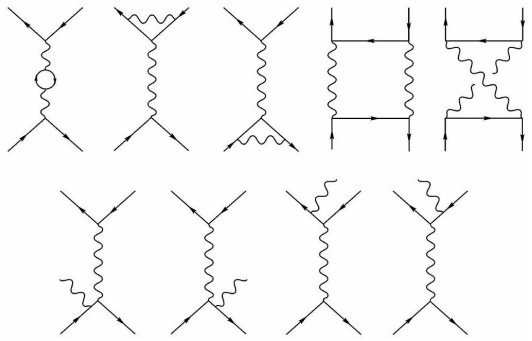

Рис. 1.4. Фейнмановские диаграммы, которые дают вклад α^3 в сечение рассеяния $e^+e^- \to \mu^+\mu^-$.

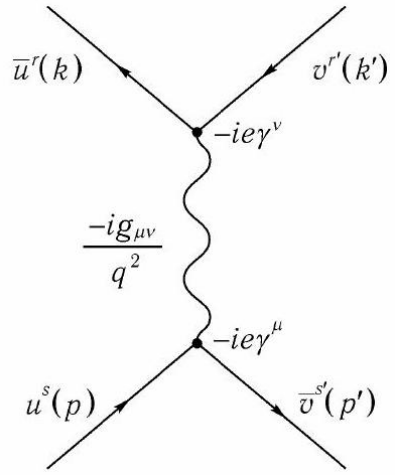

Рис. 1.5. Диаграмма из рис. 1.2, где указаны выражения, соответствующие вершинам, внутренним и внешним линиям.

Выше упоминалось, что эти правила предписывают нам нарисовать диаграмму (диаграммы) рассматриваемого процесса и сопоставить каждому элементу диаграммы определенный алгебраический множитель. На рис. 1.5 приведена диаграмма нашей реакции $e^+e^- \to \mu^+\mu^-$, где показаны предписываемые правилами множители.

Для внутренней фотонной линии пишем множитель $-ig_{\mu\nu}/q^2$, где $g_{\mu\nu}$ - обычный метрический тензор в пространстве Минковского, а q – 4-импульс виртуального фотона. Этот множитель соответствует оператору $|\gamma\rangle\langle\gamma|$ в нашем эвристическом выражении (1.3).

Каждой вершине сопоставляется множитель $-ie\gamma^\mu$, что соответствует H_I в (1.3). Величины γ^μ представляют набор постоянных 4×4-матриц. Именно они осуществляют «сложение угловых моментов», связывая состояния двух частиц со спином $\frac{1}{2}$ с векторной частицей.

Внешним линиям соответствуют выражения для четырехкомпонентных столбцов-спиноров u, v, или строк-спиноров $\bar{u}, \bar{v}$. Они, по существу, являются волновыми функциями начальных и конечных частиц в импульсном пространстве и соответствуют $|e^+e^-\rangle$и $\langle\mu^+\mu^-|$в (1.3). Индексы s, s', r и r' отмечают одно из двух возможных спиновых состояний.

Теперь можно выписать выражение для $\mathscr{M}$, считывая множители непосредственно с диаграммы:

$$\mathscr{M} = \bar{v}^{s'}(p')\,(-ie\gamma^\mu)\,u^s(p)\left(\frac{-ig_{\mu\nu}}{q^2}\right)\bar{u}^r(k)\,(-ie\gamma^\nu)\,v^{r'}(k') =$$
$$= \frac{ie^2}{q^2}\left(\bar{v}^{s'}(p')\,\gamma^\mu u^s(p)\right)\left(\bar{u}^r(k)\gamma^\nu v^{r'}(k')\right)$$

Полезно детально сравнить это выражение с (1.3). Чтобы получить сечение (1.8) из (1.10), можно было бы вернуться к аргументам, связанным с угловым моментом, дополнив их некоторыми конкретными сведениями о γ-матрицах и дираковских спинорах. Подобные вычисления будут проведены в разделе 5.2. Однако существует множество полезных трюков, используемых при манипуляциях с выражениями типа (1.10), особенно в тех случаях, когда нас интересует вычисление сечения для неполяризованных частиц. Используя эту фейнмановскую "технологию следов» (название происходит от того, что приходится вычислять следы от произведения γ-матриц), даже не обязательно знать явный вид этих матриц и дираковских спиноров. Вычисления становятся почти бездумными, и ответ (1.8) получается после алгебраических преобразований, занимающих меньше страницы. Однако поскольку фейнмановские правила и технология следов столь мощны, то можно отказаться и от некоторых упрощающих предположений. В завершение этого раздела обсудим те ситуации, при которых вычисления станут более трудными.

Простейшее ограничение, от которого можно отказаться, - это равенство нулю массы мюона. Если энергия пучков не намного больше массы мюона, то все наши предсказания будут зависеть от отношения $\frac{m_\mu}{E_{\text{ци}}}$. (Поскольку электрон примерно в 200 раз легче мюона, его можно рассматривать безмассовым во всех случаях, когда энергия пучка достаточна для рождения мюонов.) Используя фейнмановскую технологию следов, чрезвычайно просто учесть в вычислениях массу мюона. Объем необходимых алгебраических вычислений возрастает процентов на 50; кроме того, немного меняется выражение (1.1) для связи амплитуды и сечения, но ответ оправдывает затраченные усилия. Мы проделаем эти вычисления в разделе 5.1.

Столь же просто рассмотреть вычисления в другой системе отсчета. Единственное место, которое подвергнется модификации - это связь (1.1) между амплитудой и сечением. Впрочем, можно просто совершить преобразование Лоренца в формуле в с. ц. и., перейдя к другой системе отсчета.

Когда известны спиновые состояния начальных и/или конечных частиц и мы хотим учесть массу мюона, то вычисления становятся более громоздкими, хотя, в принципе, остаются несложными. Технология следов обобщается на такой случай, но часто легче вычислить выражение (1.10) непосредственно, используя выражения для спиноров u и v.

Далее, можно рассчитать сечения разных процессов.

Процесс $e^+e^- \to e^+e^-$, называемый рассеянием Баба, более сложен, так как существует вторая диаграмма (см. рис. 1.6). Сначала следует сложить амплитуды, отвечающие этим диаграммам, а затем возвести результат в квадрат.

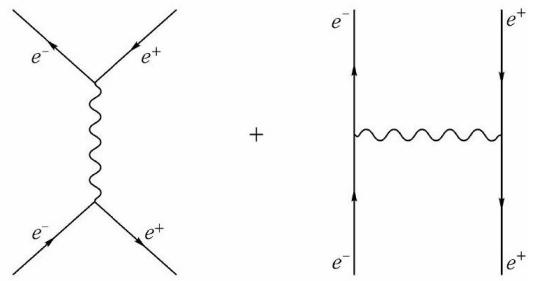

Рис. 1.6. Две диаграммы низшего порядка для рассеяния Баба $e^+e^- \to e^+e^-$.

Другие процессы содержат фотоны в начальном и/или конечном состояниях. Классическим примером является комптоновское рассеяние, две диаграммы низшего порядка для которого показаны на рис. 1.7. Фейнмановские правила для внешних фотонных и внутренних электронных линий не сложнее тех, которые уже рассмотрены. Детальный анализ комптоновского рассеяния проведен в разделе 5.5.

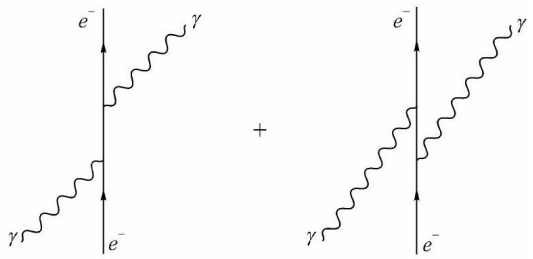

Рис. 1.7. Две диаграммы низшего порядка для комптоновского рассеяния.

Наконец, можно вычислить вклады слагаемых более высокого порядка в ряде теории возмущений. Благодаря Фейнману, по крайней мере, нетрудно нарисовать необходимые диаграммы. На рис. 1.4 были показаны те диаграммы, которые дают вклад в следующий порядок теории возмущений для сечения процесса $e^+e^- \to \mu^+\mu^-$. Весьма примечательно, что алгоритм, приписывающий алгебраические множители отдельным элементам диаграммы, верен для всех вкладов более высоких порядков и позволяет вычислить их непосредственно, хотя такие расчеты очень громоздки. Расчет полного вклада всех девяти диаграмм - серьезная работа на уровне научной статьи.

В этой книге, начиная с гл. 6, мы достаточно подробно проанализируем ту физику, которая возникает при учете фейнмановских диаграмм более высокого порядка типа, показанных на рис. 1.4. Мы увидим, что последние четыре из них, содержащие дополнительный фотон в конечном состоянии, необходимо учитывать потому, что ни один детектор не способен регистрировать фотоны необычайно малых энергий. Поэтому конечное состояние с такими фотонами неотличимо от интересующего нас состояния, где есть только мюонная пара.

Другие пять диаграмм на рис. 1.4 содержат не один виртуальный фотон, а промежуточные состояния нескольких виртуальных частиц. В каждой из этих диаграмм имеется хотя бы одна виртуальная частица, импульс которой не определяется законом сохранения импульсов в вершинах. Поскольку теория возмущений требует взять сумму по всем возможным промежуточным состояниям, мы должны проинтегрировать по всем возможным значениям этого импульса. Однако на этом этапе возникает новая трудность. В первых трех диаграммах при наивном подходе интегралы по импульсу в петле оказываются бесконечными. В конце части I мы сформулируем рецепт решения этой проблемы с тем,

чтобы получить конечные результаты. Однако вопрос о физической природе таких расходимостей просто не решается. Это будет главной темой части II книги.

Мы обсуждали фейнмановские правила как алгоритм для проведения вычислений. В последующих главах мы проиллюстрируем мощь этого метода. Но после того как мы рассмотрим все больше применений диаграмм, мы убедимся, что они начнут жить своей собственной жизнью. Диаграммы укажут на неожиданные связи между различными физическими процессами и позволят сформулировать интуитивные аргументы, которые потом можно будет проверить с помощью вычислений. Мы надеемся, что наша книга поможет читателю научиться этому методу и найти ему новые многообещающие применения.

Квантовые поля в иллюстративных примерах

Поле одного кванта

Поле двух квантов (!?!??!?!?!?!??)

(завис вопрос, подумаю потом.)

Поле одного кванта спинорного поля

(пропишу позже скоро.)

8.2.4 What is a Quantum Field (??????)

Идея квантовых полей (???)

Основная формула квантового поля (????)

(тут решение ур К-Г и Максвелла и рассуждение по поводу того, в чем их смысл? очень важный параграф.)

Если поля фундаментальны, то что делать с ядрами атомов? (????)

(приехали. пока не знаю внятного ответа на этот вопрос)

На каких масштабах квантовая механика неверна и необходима КТП? (????)

Можно ли на нано масштабах использовать квантовую механику?

Ее внаглую используют и все, и ничего не поделать.

Примеры, когда квантовая механика неверна и необходима КТП? (????)

Что такое квант поля

(подробно про это)

Что такое квазичастица? (????)

(подробно про это)

8.2.5 What Does It Mean to “Quantize” a Field (??????)

(четко с примерами напишу)

8.2.6 Causality (?!??!?)

(подробно об этом!! мб даже еще один раздел про это создам!)

Почему нельзя проквантовать релятивистские частицы так же, как мы квантуем нерелятивистские? (ПШ, ????)

Ответ можно дать несколькими способами. Вероятно, лучше всего выписать одночастичное релятивистское волновое уравнение (например, уравнений Клейна-Гордона или Дирака) и убедиться, что оно приводит к состояниям с отрицательной энергией и другим несообразностям. Так как это рассмотрение обычно проводится в конце продвинутого курса нерелятивистской квантовой механики, мы не будем здесь его повторять. Тем не менее нетрудно понять, почему не работает одночастичный подход. Мы не имеем права предполагать, что какой-либо релятивистский процесс можно объяснить на языке отдельной частицы, так как соотношение Эйнштейна $E = mc^2$ допускает образование пар частица-античастица.

Даже в случае, когда для рождения пары не хватает энергии, многочастичные состояния возникают, например, как промежуточные состояния во втором порядке теории возмущений.

В соответствии с соотношением неопределенностей $\Delta E \cdot \Delta t = \hbar$ можно считать, что эти состояния существуют только в течение очень короткого времени и в более высоких порядках теории возмущений возможно рождение произвольного числа таких «виртуальных» частиц.

Менее очевидно, что необходимость многочастичной теории вытекает из требования причинности.

Рассмотрим амплитуду распространения свободной частицы из точки $\mathbf{x}_0$ в точку $\mathbf{x}$:

$$U(t) = \left\langle \mathbf{x} \left| e^{-iHt} \right| \mathbf{x}_0 \right\rangle$$

В нерелятивистской квантовой механике имеем $E = \mathbf{p}^2/2m$, так что

$$\begin{aligned} U(t) = \left\langle \mathbf{x} \left| e^{-i\left(\mathbf{p}^2/2m\right)t} \right| \mathbf{x}_0 \right\rangle = \int \frac{d^3p}{(2\pi)^3} \left\langle \mathbf{x} \left| e^{-i\left(\mathbf{p}^2/2m\right)t} \right| \mathbf{p} \right\rangle \langle \mathbf{p} | \mathbf{x}_0 \rangle = \\ = \frac{1}{(2\pi)^3} \int d^3p e^{-i\left(\mathbf{p}^2/2m\right)t} \cdot e^{i\mathbf{p}\cdot(\mathbf{x}-\mathbf{x}_0)} = \left(\frac{m}{2\pi i t}\right)^{3/2} e^{im(\mathbf{x}-\mathbf{x}_0)^2/2t} \end{aligned}$$

Это выражение отлично от нуля для всех x и t, указывая на то, что частица может распространяться между любыми двумя точками за произвольно короткое время. В релятивистской теории это говорило бы о нарушении причинности. Можно ожидать, что положение исправит использование релятивистского соотношения $E = \sqrt{p^2 + m^2}$, но оказывается, что это не так. По аналогии с нерелятивистским случаем, находим:

$$\begin{aligned} U(t) = \left\langle \mathbf{x} \left| e^{-it\sqrt{\mathbf{p}^2+m^2}} \right| \mathbf{x}_0 \right\rangle = \frac{1}{(2\pi)^3} \int d^3p e^{-it\sqrt{\mathbf{p}^2+m^2}} \cdot e^{i\mathbf{p}\cdot(\mathbf{x}-\mathbf{x}_0)} = \\ = \frac{1}{2\pi^2 \left|\mathbf{x}-\mathbf{x}_0\right|} \int_0^\infty dp p \sin\left(p\left|\mathbf{x}-\mathbf{x}_0\right|\right) e^{-it\sqrt{p^2+m^2}}. \end{aligned}$$

Этот интеграл можно вычислить явно через функции Бесселя*. Мы ограничимся рассмотрением асимптотического поведения этого интеграла при $x^2 \gg t^2$ (достаточно далеко от светового конуса), используя метод стационарной фазы. Фаза $px - t\sqrt{p^2+m^2}$ имеет стационарную точку при $p = imx/\sqrt{x^2-t^2}$. Можно свободно замкнуть контур интегрирования в верхней полуплоскости так, чтобы он прошел через эту точку. Подставляя данное значение p, находим, что с точностью до рациональной функции от x и t,

$$U(t) \sim e^{-m\sqrt{x^2-t^2}}.$$

Таким образом, вне светового конуса амплитуда распространения хотя и мала, но отлична от нуля, и причинность по-прежнему нарушается.

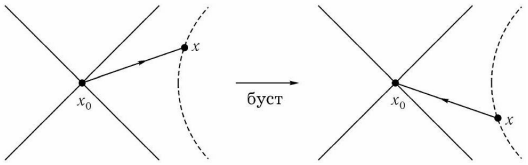

Рис. 2.1. Распространение из точки x_0 в точку x в одной системе отсчета выглядит как распространение из точки x в точку x_0 в другой системе отсчета.

Квантовая теория поля разрешает проблему причинности чудесным способом, который мы обсудим в разделе 2.4. Мы увидим, что в многочастичной теории поля распространение частицы на пространственноподобное расстояние не отличается от распространения античастицы в противоположном направлении (рис. 2.1). Когда мы спрашиваем, может ли наблюдение, сделанное в точке x_0 повлиять на наблюдение, сделанное в точке x, мы находим, что амплитуды распространения для частицы и античастицы в точности сокращаются, так что причинность не нарушается.

*См. Градштейн и Рыжик (1980), #3.914. Квантовая теория поля естественным образом способна описывать не только многочастичные состояния, но и переходы между состояниями с разным числом частиц. Она решает проблему причинности путем введения античастиц и затем позволяет объяснить связь между спином и статистикой. Но самое главное то, что квантовая теория поля дает в руки исследователей инструменты, необходимые для расчета бесчисленного количества сечений процессов рассеяния. Экспериментальное подтверждение этих предсказаний, часто имеющих беспрецедентную точность, и есть главная причина изучения квантовой теории поля.

Допустим, мы не знаем никаких экспериментов, из каких соображений вообще мы начнем именно в квантами поля работать?

(это проблема классической теории поля, потому что там так нас обучают, что нет вообще этих соображений. вот, продумаю, напишу.)

8.2.7 Does the Idea of Quantizing Fields Lead to Contradictions?

(подробно про это)

Допустим мы проквантовали электромагнитное поле вблизи заряда, которые его создает. Далеко вдали от него неужели наши детекторы квантов будут случайным образом щелкать: долетел ли квант до них или не долетел? (????)

(давний вопрос, пока не думал про это, но мб ответ в том, что кванты все-таки квазичастицы, которые не реальные, а реально именно поле или волна. И дальше уже она может проявлять свои квантовые свойства.)

8.2.8 Connection with Quantum Mechanics and Wave Functions (???)

(пропишу потом, как они связаны?)

8.3 Philosophy of QFT: Other Ideas (??)

8.3.1 Locality

(discuss, what it is? how could it be otherwise???)

8.3.2 How Were Particles Created?

Обсудим в двух словах, как создаются частицы

Идейно, почему инфляция рождает частицы

(???)

8.3.3 What is Time and Space?

(this is answered in field theory, but it is important to also write about it here)

8.4 What is Really a Vacuum?

(intro to casimir effect, article by В. Л. Гинзбург, В. П. Фролов. a very deep question)

8.4.1 Why is Something in the Quantum World Renormalized?

(general intro to renormalizations)

(?? big question)

8.4.3 Зи.III.1 Cutting Off Our Ignorance

Следите за руками

Первых исследователей квантовой теории поля приводили в сильнейшее затруднение расходящиеся интегралы, которые часто встречались по ходу расчетов, так что в 1930-1940-е гг. ученые много времени тратили на борьбу с бесконечностями.

Многочисленные неудачи, следующие за, казалось бы, уже сделанными открытиями, все больше подталкивали к тому, чтобы отказаться от квантовой теории поля. Наконец ученые разработали так называемую процедуру перенормировки, которая позволила решить проблему бесконечных интегралов и получить конечные физические результаты. Однако, еще долгие годы, вплоть до конца 1960-х и начала 1970-х гг., многие физики скептически относились к теории перенормировки, считая ее простой ловкостью рук. Шутили, что в квантовой теории поля бесконечность приравнивается к нулю или что под ковром в кабинете физиков запрятано много бесконечностей.

Наконец благодаря усилиям Кена Вильсона и многих других ученых в начале 1970-х гг. появилось новое понимание квантовой теории поля. Постепенно теоретики пришли к выводу, что в квантовой теории поля вовсе не существует проблемы расходимости. Сейчас мы рассматриваем квантовую теорию поля как эффективную низкоэнергетическую теорию. Я кратко затрону этот вопрос здесь и подробнее в главе VIII.3.

Теория поля рушится

Мы должны увидеть саму бесконечность, прежде чем говорить о том, как работать с бесконечностями. В главе I.7 мы уже сталкивались с одним из них. Вспомним, что поправка к амплитуде мезон-мезонного рассеяния порядка λ^2 (выражение I.7.23) расходится. При $K \equiv k_1 + k_2$ имеем:

$$\mathcal{M} = \frac{1}{2}(-i\lambda)^2 i^2 \int \frac{d^4k}{(2\pi)^4} \frac{1}{k^2 - m^2 + i\varepsilon} \frac{1}{(K-k)^2 - m^2 + i\varepsilon}$$

Как говорилось в главе I.7, даже не проводя никаких расчетов, мы можем увидеть проблему, которая ставила в тупик пионеров квантовой теории поля. Для больших значений k подынтегральное выражение равно $1/k^4$, т. е. интеграл будет логарифмически расходиться как $\int [d^4k/(2\pi)^4]\,(1/k^4)$. (Обычный интеграл $\int^{\infty} dr r^n$ линейно расходится при $n = 0$, квадратично расходится при $n = 1$ и т. д., а интеграл $\int^{\infty} \frac{dr}{r}$ расходится логарифмически.) Поскольку эта расходимость связана с большими значениями k, ее называют ультрафиолетовой расходимостью.

Чтобы узнать, как работать с возникшей бесконечностью, мы должны четко представлять разницу между концептуально отличными между собой сюжетами, названными по историческим причинам пугающими терминами «регуляризация» и «перенормировка».

Параметризация неведения

Предположим, вместо искусственной φ^4-теории мы изучаем квантовую электродинамику. Было бы чрезвычайно неразумно утверждать, что теория взаимодействия электрона с фотоном работает до произвольно высокой энергии. По крайней мере с увеличением энергии появятся другие частицы и окажется, что электродинамика станет просто частью большей электрослабой теории. Для увеличения энергии необходимо как минимум участие других частиц, так что электродинамика является лишь частью более обширной теории электрослабых взаимодействий. Действительно, с современной точки зрения при переходе к все более высоким энергиям вся «конструкция» квантовой теории поля с необходимостью оказывается приближением к неизвестной пока нам теории. По мнению некоторых физиков, такой теорией является теория струн.

Современный взгляд состоит в том, что сегодня квантовая теория поля должна рассматриваться как эффективная низкоэнергетическая теория, справедливой до некоторого масштаба энергии (или, в лоренцинвариантной теории, до некоторого масштаба импульса) Λ. Представьте себе, что мы живем во Вселенной, описываемой игрушечной φ^4-теорией. По мере того как физики в этой Вселенной будут изучать физику все более высоких энергий, они придут к выводу, что их Вселенная является матрацем, состоящим из материальных точек и пружин, а масштаб Λ примерно равен обратному размеру решетки.

Когда я преподаю квантовую теорию поля, то, чтобы подчеркнуть свои слова, пишу на доске: «Не стыдитесь своего неведения». Любая физическая теория должна иметь свою область применимости, за пределами которой мы ничего не знаем о соответствующей физике. В противном случае не был бы возможен прогресс знаний в облаcти физики. Хорошо, что Фейнман, Швингер, Томонага и другие исследователи квантовой электродинамики не имели представления о кварках, например.

Подчеркну, что масштаб Λ следует рассматривать не как математический, а как физический элемент, параметризующий порог нашего неведения [1]. Действительно, в физически осмысленных квантовых теориях поля всегда должна появляться неявно заданная величина Λ. Если кто-то вздумает «впариты» вам теорию поля, которая якобы справедлива для произвольно высоких энергий, вам следует проверить, не торговал ли раньше этот человек подержанными автомобилями. (Когда я писал эти строки, мой коллега - редактор Phsical Review Letters - рассказал, что во время каникул в средней школе он подрабатывал сборщиком мусора, и шутя добавил, что такая практика хорошо подготовила его к нынешней профессии.)

[1] В главе I.8 мы видели яркий тому пример. Определив проводящую пластинку как поверхность, на которой перестает существовать тангенциальное поле. мы не учли физику электрона, движение которого противодействует любому наложенному полю. При крайне высоких частотах электроны не могут двигаться достаточно быстро, значит, здесь действуют другие законы физики, согласно которым высокочастотные моды не видят пластинки. При расчете силы Казимира мы параметризуем свое незнание величиной $a \sim \Lambda^{-1}$.

Таким образом, вычисляя интеграл $\int d^4k/(2\pi)^4$ в (1), мы должны интегрировать лишь до значения Λ, называемого параметром обрезания. Мы буквально обрезаем интегрирование по импульсу (рис. III.1.1)2. Говорят, что тем самым «регулиризовали» интеграл.

В этой книге я стремлюсь подчеркнуть скорее концептуальные, нежели вычислительные аспекты, поэтому я не стану сейчас явно вычислять интеграл, но скажу, что он равен $2iC\log(\Lambda^2/K^2)$, где C - некоторая численная константа, которую вы можете вычислить сами (см. приложение 1 к этой главе). Пусть для простоты $m^2 \ll K^2$, тогда величиной m^2 в подынтегральном выражении можно пренебречь. Удобно ввести кинематические переменные $s \equiv K^2 = (k_1+k_2)^2, t \equiv (k_1-k_3)^2$ и $u \equiv (k_1-k_4)^2$. (Записав явным образом параметры k_j в системе центра масс, увидим, что переменные s,t и u соответствуют довольно обычным величинам: энергии центра масс и углу рассеяния). С учетом всего вышеизложенного амплитуда мезон-мезонного рассеяния будет равна:

$$\mathcal{M} = -i\lambda + iC\lambda^2\left[\log\left(\frac{\Lambda^2}{s}\right)+\log\left(\frac{\Lambda^2}{t}\right)+\log\left(\frac{\Lambda^2}{u}\right)\right]+O\left(\lambda^3\right).$$

Это довольно легко понять. После регуляризации мы говорим о величинах, зависящих от обрезания, а не о расходящихся величинах. Параметры расходимости будем называть параметрами, зависимыми от обрезания; $\mathcal{M}$ зависит от обрезания логарифмически.

Что мы в действительности измеряем

Давайте теперь после регуляризации перейдем к перенормировке. Этот термин неудачен, ведь он предполагает, что мы что-то нормируем повторно, когда на самом деле это не так.

Ключевым моментом здесь является то, как бы мы описали экспериментатору процесс измерения мезон-мезонного рассеяния. Мы говорим ей (или ему, если вы настаиваете), что нам необходимо задать обрезание Λ, а он не проявляет ни капли беспокойства; тот факт, что любая заданная теория имеет конечную область применимости, для экспериментатора очевиден.

Мы, вероятно, скажем ему, как рассеяние будет зависеть от энергии в системе центра масс и угла рассеяния. Затем продемонстрируем ей выражение (2). Она укажет на параметр λ и воскликнет: «Что это такое?»

Мы ответим: «Константа связи», на что она воскликнет: «Какая такая константа связи, если это всего-навсего греческая буква!»

Смущенный студент, пусть будет Конфузио, слышавший разговор, в этом случае ответил бы: «В чем дело? Я изучал физику много лет, преподаватели познакомили нас со множеством уравнений, в которых фигурируют латинские и греческие буквы, к примеру, с законом Гука $F = -kx$, и никто не утверждал при этом, что k - всего лишь латинская буква».

Сообразительный экспериментатор скажет: «Но это потому, что я смогу пойти и измерить значение k, если вы дадите мне пружину. В этом все дело! Пускай мистер Заумный Теоретик скажет мне, как я могу измерить эту вашу λ.

Да, вот это действительно хороший экспериментатор! Теперь нам следует более тщательно продумать, что в действительности означает константа связи. Вспомним про константу связи в квантовой электродинамике, α. Ну, это коэффициент при $1/r$ в законе Кулона. Отлично, месье Кулон измерил его с помощью металлических шаров или чего-то вроде этого. Но современный экспериментатор тоже мог бы измерить α, рассеивая электрон при той или иной энергии и под тем или иным углом на протоне. Итак, мы объясним все это нашему другу-экспериментатору.

Он, кивая, согласится: «Да, конечно. Не так давно мои коллеги измеряли константу связи в мезон-мезонном взаимодействии путем рассеяния одного мезона на другом при той или иной энергии и том или ином угле рассеяния. Эти параметры соответствуют вашим переменным s, t и u и имеют значения s_0, t_0 и u_0. Но что общего между той константой связи, которую измеряли мои коллеги (назовем ее λ_P, где индекс P означает «физический»)[3]), с вашей теоретической λ, которая, насколько мне известно, является всего лишь греческой буквой в том, что вы называете лагранжианом!»

Конфузио скажет: «Эй, если вы беспокоитесь по поводу малого лямбда, тогда я начну беспокоиться по поводу большого лямбда. Откуда я знаю, насколько велика область применимости?»

СЭ заметит: «Вы не настолько глупы, как кажетесь! Мистер Заумный Теоретик, если я решу воспользоваться формулой (2), какое конкретно зна-

[3] От англ. «physical». - Прим. пер. чение Λ я должен в нее подставить? Зависит ли выбор исключительно от вашего настроения, мистер Заумный Теоретик? Если вы проснетесь с оптимистическим настроем, примените ли вы значение 2Λ, вместо Λ? А если вас бросит подружка, воспользуетесь ли вы значением $\frac{1}{2}\Lambda$?»

Мы усмехнемся: «Ха! Мы можем ответить на ваш вопрос. Взгляните на формулу (2): считается, что $\mathcal{M}$ является настоящей амплитудой рассеяния и не зависит от Λ. Если кто-то захочет изменить значение Λ, можно просто сдвинуть λ таким образом, чтобы величина $\mathcal{M}$

не изменилась. Пара строчек выкладок, и мы можем точно сказать, каким должно быть значение $d\lambda/d\Lambda$ (см. упражнение III.1.3)».

Экспериментатор: «Хорошо. Значит, λ есть скрытая функция от Λ. Ваше обозначение ничего не стоит».

Мы согласимся: «Это правда. Неудачное обозначение вводило в заблуждение не одно поколение физиков».

Экспериментатор: «Я так и не услышал от вас, каким образом параметр λ_P, который измеряли мои коллеги, связан с вашим λ.

Мы скажем: «Это просто. Посмотрите на уравнение (2), которое мы еще раз приведем здесь для наглядности:

$$\mathcal{M} = -i\lambda + iC\lambda^2 \left[\log\left(\frac{\Lambda^2}{s}\right) + \log\left(\frac{\Lambda^2}{t}\right) + \log\left(\frac{\Lambda^2}{u}\right)\right] + O\left(\lambda^3\right)$$

Согласно нашей теории, параметр λ_P равен:

$$-i\lambda_P = -i\lambda + iC\lambda^2 \left[\log\left(\frac{\Lambda^2}{s_0}\right) + \log\left(\frac{\Lambda^2}{t_0}\right) + \log\left(\frac{\Lambda^2}{u_0}\right)\right] + O\left(\lambda^3\right).$$

Обозначим сумму логарифмов в квадратных скобках в выражениях (3) и (4) как L и L_0 соответственно. Перепишем данные выражения в более компактной форме:

$$\mathcal{M} = -i\lambda + iC\lambda^2 L + O\left(\lambda^3\right)$$

и

$$-i\lambda_P = -i\lambda + iC\lambda^2 L_0 + O\left(\lambda^3\right)$$

Вот так связаны параметры λ_P и λ.

Экспериментатор скажет: «Если вы выразите амплитуду рассеяния через физическую константу связи λ_P, то это будет полезно для меня, но никак не для λ. Я понимаю смысл λ_P, но не могу понять смысла λ.

На это мы ответим: «Хорошо, нам ничего не стоит исключить из формулы параметр λ, вместо λ_P. Большое дело! Разрешив уравнение (6) относительно λ, получим:

$$-i\lambda = -i\lambda_P - iC\lambda^2 L_0 + O\left(\lambda^3\right) = -i\lambda_P - iC\lambda_P^2 L_0 + O\left(\lambda_P^3\right).$$

Второе равенство верно с указанной точностью. Теперь подставим его в (5):

$$\mathcal{M} = -i\lambda + iC\lambda^2 L + O\left(\lambda^3\right) = -i\lambda_P - iC\lambda_P^2 L_0 + iC\lambda_P^2 L + O\left(\lambda_P^3\right)$$

Проверьте пожалуйста, что все выкладки верны с указанной точностью».

«Чудо»

И вдруг! Вот оно, чудо перенормировки!

Теперь в амплитуду рассеяния $\mathcal{M}$ входит комбинация $L - L_0 = [\log(s_0/s) + \log(t_0/t) + \log(u_0/u)]$. Другими словами, амплитуда рассеяния сводится к виду:

$$\mathcal{M} = -i\lambda_P + iC\lambda_P^2 \left[\log\left(\frac{s_0}{s}\right) + \log\left(\frac{t_0}{t}\right) + \log\left(\frac{u_0}{u}\right)\right] + O\left(\lambda_P^3\right)$$

С триумфальным чувством мы объявляем нашему другу-экспериментатору, что в случае представления амплитуды рассеяния через зависимость от физической константы связи λ_P, как ей и хотелось, обрезание Λ полностью исчезает!

Ответ всегда должен быть выражен через физически измеримые величины

Урок в том, что физические величины всегда следует выражать не через «фиктивные» теоретические параметры, такие как λ, а через физически измеримые параметры, такие как λ_P.

Кстати, в литературе параметр λ_P часто обозначают как λ_R и по историческим причинам называют «перенормированной константой связи». Я считаю, что физический смысл «перенормировки» становится более понятным, если употреблять термин «физическая константа связи» и, следовательно, подстрочный индекс «р». К тому же, у нас никогда не было «нормированной константы связи».

Неожиданно Конфузио появляется опять; мы про него почти забыли: «Вы начали работу с выражением для $\mathcal{M}$, в котором фигурировали две нефизические величины λ и Λ, а в конечном итоге их «нефизическая природа» нейтрализовала друг друга». Экспериментатор соглашается: «Да, это и отличает хороших теоретиков от плохих. Хорошие теоретики всегда допускают четное число ошибок в знаках, тогда как плохие - всегда делают нечетное число».

Интегрирование лишь по медленным модам

В формулировке интеграла по траекториям амплитуда рассеяния $\mathcal{M}$ получается вычислением интеграла (глава I.7):

$$\int D\varphi\varphi\left(x_1\right)\varphi\left(x_2\right)\varphi\left(x_3\right)\varphi\left(x_4\right)e^{i\int d^dx\left\{\frac{1}{2}\left[(\partial\varphi)^2-m^2\varphi^2\right]+\frac{\lambda}{4!}\varphi^4\right\}}.$$

Используемая здесь регуляризация соответствует, грубо говоря, тому, что мы интегрируем при вычислении интеграла $\int D\varphi$, лишь по тем модам поля $\varphi(x)$, фурье-преобразование которых равно нулю при $k \gtrsim \Lambda$. Иначе говоря, поли, соответствующие внутренним линиям на фейнмановских диаграммах (рис. I.7.10), не могут флуктуировать со слишком большой энергией. Позже мы вернемся к этой формулировке интеграла по траекториям, когда будем рассматривать ренорм-группу.

Альтернативные пути

Возможно, следует упомянуть некоторые альтернативные способы регуляризации фейнмановских диаграмм, каждый из которых имеет свои преимущества и недостатки, что делает их удобными в одних случаях, а в других - нет. Регуляризация, о которой мы говорили в настоящей главе, известна под названием регуляризации Паули-Вилларса. Ее преимуществом считается прозрачность с точки зрения физики. Другой часто используемой регуляризацией является размерная регуляризация. Предположим, наши расчеты производятся в d-мерном пространстве-времени. После приведения интеграла Фейнмана к удобной для нас форме, мы прибегаем к методу аналитического продолжения по d и в конце концов кладем $d = 4$. Зависимость различных интегралов от обрезания характеризуется теперь полюсами ($d \to 4$). Аналогично тому, как после представления амплитуды рассеяния в виде зависимости от физической константы связи λ_P исчезает масштаб обрезания λ, в размерной регуляризации амплитуда рассеяния, выраженная в виде

зависимости от λ_P, не содержит полюсов. Во многих случаях применение размерной регуляризации оказывается предпочтительнее, как я покажу в следующих главах, хотя, по сравнению с регуляризаци- ей Паули-Вилларса, она носит более абстрактный и формальный характер. Когда дело доходит до регуляризации, делайте выбор по своему вкусу.

Поскольку основное внимание в книге уделяется концептуальным, а не вычислительным моментам квантовой теории поля, я не буду описывать другие схемы регуляризации, но вкратце покажу, как работают регуляризация Паули-Вилларса и размерная регуляризация в двух приложениях к этой главе.

Приложение 1. Регуляризация Паули-Вилларса

Важным моментом настоящей главы является концептуальное утверждение, согласно которому выражение физических амплитуд в терминах физических констант связи приводит к исчезновению зависимости от обрезания. Фактическое вычисление интеграла Фейнмана не имеет для нас значения. Однако на всякий случай я продемонстрирую вам процесс его вычисления, ведь в будущем это может вам понадобиться.

Начнем со сходящегося интеграла

$$\int \frac{d^4k}{(2\pi)^4} \frac{1}{\left(k^2 - c^2 + i\varepsilon\right)^3} = \frac{-i}{32\pi^2 c^2}$$

Зависимость от c^2 следует из анализа размерностей. Общий множитель вычисляется в приложении D.

Применяя тождество (D.15)

$$\frac{1}{xy} = \int_0^1 d\alpha \frac{1}{[\alpha x + (1-\alpha)y]^2}$$

к (1), получаем

$$\mathcal{M} = \frac{1}{2}(-i\lambda)^2 i^2 \int \frac{d^4k}{(2\pi)^4} \int_0^1 d\alpha \frac{1}{D^2}$$

где

$D = \alpha(K-k)^2 + (1-\alpha)k^2 - m^2 + i\varepsilon = (k - \alpha K)^2 + \alpha(1-\alpha)K^2 - m^2 + i\varepsilon.$

Сдвинем переменную интегрирования $k \to k + \alpha K$ и получим интеграл $\int [d^4k/(2\pi)^4] \left[1/\left(k^2 - c^2 + i\varepsilon\right)^2\right]$, где $c^2 = m^2 - \alpha(1-\alpha)K^2$. Паули и Вилларс предложили заменять его интегралом

$$\int \frac{d^4k}{(2\pi)^4} \left[\frac{1}{\left(k^2 - c^2 + i\varepsilon\right)^2} - \frac{1}{\left(k^2 - \Lambda^2 + i\varepsilon\right)^2}\right].$$

Если k намного меньше Λ, дополнительный второй член в подынтегральной функции имеет порядок Λ^{-4} и, следовательно, ничтожно малое значение, по сравнению со значением первого члена, поскольку априори считается, что Λ намного больше c. Если k существенно превышает Λ, оба члена взаимно сокращаются и подынтегральное выражение быстро стремится к нулю с ростом значения k, что эффективно обрезает интеграл.

Дифференцируя интеграл (12) по c^2 и используя (10), мы получаем, что интеграл (12) равен $(i/16\pi^2)\log(\Lambda^2/c^2)$. Таким образом, интеграл

$$\int^{\Lambda} \frac{d^4k}{(2\pi)^4} \frac{1}{\left(k^2 - c^2 + i\varepsilon\right)^2} = \frac{i}{16\pi^2} \log\left(\frac{\Lambda^2}{c^2}\right)$$

действительно логарифмически зависит от масштаба обрезания, как и утверждалось в тексте.

Итак, получаем

$$\mathcal{M} = \frac{i\lambda^2}{32\pi^2} \int_0^1 d\alpha \log\left(\frac{\Lambda^2}{m^2 - \alpha(1-\alpha)K^2 - i\varepsilon}\right)$$

Приложение 2. Размерная регуляризация

В основе размерной регуляризации лежит очень простая идея. Когда мы приходим к интегралу $I = \int [d^4k/(2\pi)^4] \left[1/\left(k^2 - c^2 + i\varepsilon\right)^2\right]$, мы делаем поворот в евклидово пространство и обобщаем его до d измерений (см. приложение D):

$$I(d) = i \int \frac{d_E^d k}{(2\pi)^d} \frac{1}{\left(k^2 + c^2\right)^2} = i \left[\frac{2\pi^{d/2}}{\Gamma(d/2)}\right] \frac{1}{(2\pi)^d} \int_0^\infty dk k^{d-1} \frac{1}{\left(k^2 + c^2\right)^2}$$

Как я уже говорил, мне бы не хотелось пускаться в длинные вычисления, но приходится делать то, что делать необходимо. Заменим переменную интегрирования $k^2 + c^2 = c^2/x$ и получим выражение:

$$\int_0^\infty dk k^{d-1} \frac{1}{\left(k^2 + c^2\right)^2} = \frac{1}{2} c^{d-4} \int_0^1 dx (1-x)^{d/2-1} x^{1-d/2}$$

которое оказывается интегральным представлением бета-функции. После некоторых манипуляций получаем:

$$i \int \frac{d_E^d k}{(2\pi)^d} \frac{1}{\left(k^2 + c^2\right)^2} = i \frac{1}{(4\pi)^{d/2}} \Gamma\left(\frac{4-d}{2}\right) c^{d-4}$$

При $d \to 4$ правая часть уравнения равна:

$$i \frac{1}{(4\pi)^2} \left[\frac{2}{4-d} - \log c^2 + \log(4\pi) - \gamma + O(d-4)\right],$$

где $\gamma = 0,577....$.сть постоянная Эйлера-Маскерони.

Сравнивая полученное выражение с (13), видим, что в регуляризации Паули-Вилларса логарифм $\log \Lambda^2$ эффективно заменяется полюсом $2/(4-d)$. Как говорилось в тексте, представление физических величин в виде зависимости от физических констант связи приводит к сокращению всех полюсов.

Зи-у.

III.1.1. Проделайте выкладки, приводящие к (9), не пользуясь текстом.

Зи-у.

III.1.2. Поработайте с выражением (1) как с аналитической функцией от K^2. Покажите, что она имеет разрез от $4m^2$ до бесконечности.

[Указание: если вы не можете получить этот ответ прямо из (1), посмотрите на (14).]

Зи-у.

III.1.3. Замените Λ на $e^{\varepsilon}\Lambda$. Покажите, что, чтобы в указанном порядке $\mathcal{M}$ не изменился, λ изменится на $\delta\lambda = 6\varepsilon C\lambda^2 + O\left(\lambda^3\right)$, так что:

$$\Lambda\frac{d\lambda}{d\Lambda} = 6C\lambda^2 + O\left(\lambda^3\right)$$

8.4.4 Can a Diagram Be Something More?

(string theory tells that yes, it can be, there are surfaces. but why? I'll write this later here, it is a conceptually important question?)

8.4.5 What Is Life?

(I'll write the best answer I can think about it here)

8.4.6 O, Actually, QFT Is in Condensed Matter

(write that for some reason, the same concepts are in absolutely different part of physics. a good intro to it)

Why QFT Is Applicable in Condensed Matter?

(????? I can say something now, but I want a really good answer about it)

8.4.7 Gravity is Not a Quantum Field, Right?

(intro to discussion about quantization of gravity. just main ideas, details will be in the end of the note)

8.5 Poincare Group for QFT

(тут суть, подробно в классической теории поля. тут глубокие мысли, потом подумаю про них)

8.5.1 Mathematical Details of Relativistic Invariance

(see field theory about it for now)

8.5.2 Field Equations from Poincare Group

(see field theory about it for now)

8.6 Field Formalism for QFT

(все это в теории поля я подробно писал, так что тут очень коротко и в контексте ктп)

8.6.1 Lagrange Field Formalism

Фундаментальная величина классической механики - действие S, являющееся интегралом по времени от лагранжиана L.

В локальной теории поля лагранжиан может быть записан как пространственный интеграл от плотности лагранжиана, обозначаемой $\mathscr{L}$, которая является функцией одного или более полей $\phi(x)$ и их производных $\partial_\mu \phi$. Таким образом,

$$S = \int L dt = \int \mathscr{L}\left(\phi, \partial_\mu \phi\right) d^4 x$$

Так как это книга по теории поля, далее мы называем $\mathscr{L}$ просто лагранжианом.

Принцип наименьшего действия утверждает, что когда система эволюционирует от одной заданной конфигурации к другой за промежуток времени от t_1 до t_2, то ее «путь» в конфигурационном пространстве таков, что действие S имеет экстремум (обычно минимум). Мы можем записать это условие в виде:

$$\begin{aligned} 0 = \delta S &= \int d^4 x \left\{ \frac{\partial \mathscr{L}}{\partial \phi} \delta\phi + \frac{\partial \mathscr{L}}{\partial\left(\partial_\mu \phi\right)} \delta\left(\partial_\mu \phi\right) \right\} = \\ &= \int d^4 x \left\{ \frac{\partial \mathscr{L}}{\partial \phi} \delta\phi - \partial_\mu \left(\frac{\partial \mathscr{L}}{\partial\left(\partial_\mu \phi\right)} \right) \delta\phi + \partial_\mu \left(\frac{\partial \mathscr{L}}{\partial\left(\partial_\mu \phi\right)} \delta\phi \right) \right\}. \end{aligned}$$

Последнее слагаемое можно превратить в поверхностный интеграл по границе четырехмерной пространственно-временной области интегрирования. Так как начальная и конечная полевые конфигурации считаются заданными, то $\delta\phi$ равно нулю в начальный и конечный моменты времени на этой области. Если мы также ограничимся рассмотрением вариаций $\delta\phi$, исчезающих на пространственной границе области, то поверхностный интеграл равен нулю. Вынося $\delta\phi$ как множитель из первых двух слагаемых и замечая, что интеграл должен исчезать для любой вариации $\delta\phi$, делаем вывод, что множитель при $\delta\phi$ должен исчезать во всех точках. Таким образом, мы приходим к уравнениям движения Эйлера-Лагранжа для поля:

$$\partial_\mu \left(\frac{\partial \mathscr{L}}{\partial\left(\partial_\mu \phi\right)} \right) - \frac{\partial \mathscr{L}}{\partial \phi} = 0$$

Если лагранжиан содержит более одного поля, то имеется по одному такому уравнению для каждого из них.

8.6.2 Conservation Laws for Quantum Fields (after Mandl & Shaw)

Теория

It follows from the Heisenberg equation of motion of an operator $O(t)$

$$\mathrm{i}\hbar \frac{\mathrm{d}O(t)}{\mathrm{d}t} = [O(t), H]$$

(we are not considering operators with explicit time dependence) that O is a constant of the motion provided

$$[O, H] = 0.$$

Constants of the motion generally stem from invariance properties of systems under groups of transformations, e.g. translational and rotational invariance lead to conservation of linear and angular momentum, respectively. Such transformations lead to equivalent descriptions of the system; for example, referred to two frames of reference related by a Lorentz transformation. Quantum-mechanically, two such descriptions must be related by a unitary transformation U under which states and operators transform according to

$$|\Psi\rangle \to |\Psi'\rangle = U|\Psi\rangle, \quad O \to O' = UOU^\dagger$$

The unitarity of the transformation ensures two things. Firstly, operator equations are covariant, i.e. have the same form whether expressed in terms of the original or the transformed operators. In particular, this will be true of the commutation relations of the fields and of the equations of motion, e.g. Maxwell's equations will be covariant with respect to Lorentz transformations. Secondly, under a unitary transformation, amplitudes, and hence observable predictions, are invariant.

If one deals with continuous transformations, the unitary operator U can be written

$$U = \mathrm{e}^{\mathrm{i}\alpha T}$$

where $T = T^\dagger$ and α is a real continuously variable parameter. For $\alpha = 0, U$ goes over into the unit operator. For an infinitesimal transformation

$$U \approx 1 + \mathrm{i}\delta\alpha T$$

and Eq. (2.33) becomes

$$O' = O + \delta O = (1 + \mathrm{i}\delta\alpha T)O(1 - \mathrm{i}\delta\alpha T)$$

i.e.

$$\delta O = \mathrm{i}\delta\alpha[T, O].$$

If the theory is invariant under this transformation, the Hamiltonian H will be invariant, $\delta H = 0$, and taking $O = H$ in Eq. (2.35) we obtain $[T, H] = 0$, i.e. T is a constant of the motion. For a field theory derived from a Lagrangian density $\mathscr{L}$, one can construct conserved quantities from the invariance of $\mathscr{L}$ under symmetry transformations. We shall show that for such a theory, the invariance of $\mathscr{L}$ leads to equations of the form

$$\frac{\delta f^\alpha}{\delta x^\alpha} = 0$$

where the f^α are functions of the field operators and their derivatives. If we define

$$F^\alpha(t) = \int \mathrm{d}^3\mathbf{x} f^\alpha(\mathbf{x}, t),$$

where integration is over all space, then the continuity equation (2.36) gives

$$\frac{1}{c}\frac{\mathrm{d}F^0(t)}{\mathrm{d}t} = -\int \mathrm{d}^3\mathbf{x} \sum_{j=1}^{3} \frac{\partial}{\partial x^j} f^j(\mathbf{x}, t) = 0$$

where the last step follows by transforming the integral into a surface integral by means of Gauss's divergence theorem and assuming (as always) that the fields, and hence the f^j, tend to zero sufficiently fast at infinity. [3] Hence

$$F^0 = \int \mathrm{d}^3\mathbf{x} f^0(\mathbf{x}, t)$$

is a conserved quantity. With $T = F^0$, the corresponding unitary operator is then given by Eq. (2.34).

The interpretation of the four-vector f^α follows from Eqs. (2.36)-(138). f^0/c and f^j are the three-dimensional volume and current densities of the conserved quantity F^0/c. Eq. (2.36a), applied to a finite three-dimensional volume V bounded by a surface S, then states that the rate of decrease of F^0/c within V equals the current of F^0/c flowing out through S. Correspondingly, the four-vector $f^\alpha(x)$, satisf ying the conservation equation (2.36), is called a conserved current. (Strictly speaking, one should call it a four-current

density.) The result, that the invariance of the Lagrangian density $\mathscr{L}$ under a continuous one-parameter set of transformations implies a conserved quantity, is known as Noether's theorem. We apply these ideas to the transformation

$$\phi_r(x) \to \phi'_r(x) = \phi_r(x) + \delta\phi_r(x)$$

of the fields. The change induced in $\mathscr{L}$ is given by

$$\delta\mathscr{L} = \frac{\partial\mathscr{L}}{\partial\phi_r}\delta\phi_r + \frac{\partial\mathscr{L}}{\partial\phi_{r,\alpha}}\delta\phi_{r,\alpha} = \frac{\partial}{\partial x^\alpha}\left(\frac{\partial\mathscr{L}}{\partial\phi_{r,\alpha}}\delta\phi_r\right),$$

where the last step follows since $\phi_r(x)$ satisfies the field equations (2.16), and summations over repeated indices r and α are implied as previously. If $\mathscr{L}$ is invariant under the transformation (2.39) so that $\delta\mathscr{L} = 0$, the last equation reduces to the continuity equation (2.36) with

$$f^\alpha = \frac{\partial L}{\partial\phi_{r,\alpha}}\delta\phi_r$$

and the constant of the motion, from Eqs. (2.38) and (2.22), is

$$F^0 = c\int \mathrm{d}^3\mathbf{x}\pi_r(x)\delta\phi_r(x).$$

An important particular case of the above arises for complex fields ϕ_r, i.e. nonHermitian operators in the quantized theory. ϕ_r and $\phi_r^\dagger$ are then treated as independent fields, as discussed earlier. Suppose $\mathscr{L}$ is invariant under the transformation

$$\left.\begin{array}{l}\phi_r \to \phi'_r = \mathrm{e}^{\mathrm{i}\varepsilon}\phi_r \approx (1+\mathrm{i}\varepsilon)\phi_r \\ \phi_r^\dagger \to \phi_r^{\dagger\prime} = \mathrm{e}^{-\mathrm{i}\varepsilon}\phi_r^\dagger \approx (1-\mathrm{i}\varepsilon)\phi_r^\dagger\end{array}\right\}$$

where ε is a real parameter, and the right-hand expressions result for very small ε. From Eqs. (2.41)

$$\delta\phi_r = \mathrm{i}\varepsilon\phi_r, \quad \delta\phi_r^\dagger = -\mathrm{i}\varepsilon\phi_r^\dagger,$$

and Eq. (2.40) becomes

$$F^0 = \mathrm{i}\varepsilon c\int \mathrm{d}^3\mathbf{x}\left[\pi_r(x)\phi_r(x) - \pi_r^\dagger(x)\phi_r^\dagger(x)\right].$$

Since F^0 multiplied by any constant is also conserved, we shall, instead of F^0, consider

$$Q = -\frac{\mathrm{i}q}{\hbar}\int \mathrm{d}^3\mathbf{x}\left[\pi_r(x)\phi_r(x) - \pi_r^\dagger(x)\phi_r^\dagger(x)\right]$$

where q is a constant to be determined later. The reason for this change is that $\pm q$ will turn out to be the electric charges of the particles represented by the fields.

We evaluate the commutator $[Q, \phi_r(x)]$. Since ϕ_r and $\phi_r^\dagger$ are independent fields, ϕ_r commutes with all fields except π_r [see Eq. (2.31)]. Hence taking $(x')^0 = x^0 = ct$,

$$[Q, \phi_r(x)] = -\frac{\mathrm{i}q}{\hbar}\int \mathrm{d}^3\mathbf{x}' \left[\pi_s\left(x'\right), \phi_r(x)\right]\phi_s\left(x'\right)$$

and using the commutation relations (2.31) one obtains

$$[Q, \phi_r(x)] = -q\phi_r(x)$$

From this relation one easily verifies that if $|Q'\rangle$ is an eigenstate of Q with the eigenvalue Q', then $\phi_r(x)\,|Q'\rangle$ is also an eigenstate of Q belonging to the eigenvalue $(Q' - q)$, and correspondingly $\phi_r^\dagger(x)$ | $(Q'\rangle$ belongs to $(Q' + q)$. In the next chapter we shall see that, consistent with these results, ϕ_r and $\phi_r^\dagger$ are linear in creation and absorption operators, with ϕ_r absorbing particles of charge $(+q)$ or creating particles of charge $(-q)$, while $\phi_r^\dagger$ absorbs particles of charge $(-q)$ or creates particles of charge $(+q)$. Hence, we interpret the operator Q, Eq. (2.42), as the charge operator. We have therefore shown that charge is conserved $(\mathrm{d}Q/\mathrm{d}t = 0, [Q, H] = 0)$, provided the Lagrangian density $\mathscr{L}$ is invariant with respect to the transformation (2.41), which is known as a global phase transformation [corresponding to the fact that the phase ε in Eq. (2.41) is independent of x] or as a gauge transformation of the first kind. We see from Eq. (2.42) that we require complex, i.e. nonHermitian, fields to represent particles with charge. Real, i.e. Hermitian, fields represent uncharged particles. Interpreting Eq. (2.42) as an operator involves the usual ambiguity as to the order of factors. We shall have to choose these so that for the vacuum state | $(0\rangle$, in which no particles are present, Q | $(0) = 0$. We shall return to this point in the next chapter.

The unitary transformation corresponding to the phase transformation (2.41) can, from Eq. (2.34), be written

$$U = \mathrm{e}^{\mathrm{i}\alpha Q}.$$

Hence for infinitesimally small α, we obtain from Eq. (2.33)

$$\begin{aligned}\phi_r' &= \mathrm{e}^{\mathrm{i}\alpha Q}\phi_r\mathrm{e}^{-\mathrm{i}\alpha Q}\\ &= \phi_r + \mathrm{i}\alpha\,[Q, \phi_r] = (1 - \mathrm{i}\alpha q)\phi_r\end{aligned}$$

where the last line follows from Eq. (2.43). Comparing Eqs. (2.45) and (2.41), we see that they are consistent if we take $\varepsilon = -\alpha\mathrm{q}$.

Although we have talked of electric charge, with which one is familiar, this analysis applies equally to other types of charge, such as hypercharge.

Conservation of energy and momentum and of angular momentum follows from the invariance of the Lagrangian density $\mathscr{L}$ under translations and rotations. Since these transformations form a continuous group we need only consider infinitesimal transformations. Any finite transformation can be built up through repeated infinitesimal transformations. In four dimensions these are given by

$$x_\alpha \to x'_\alpha \equiv x_\alpha + \delta x_\alpha = x_\alpha + \varepsilon_{\alpha\beta}x^\beta + \delta_\alpha$$

where δ_α is an infinitesimal displacement and $\varepsilon_{\alpha\beta}$ is an infinitesimal antisymmetric tensor, $\varepsilon_{\alpha\beta} = -\varepsilon_{\beta\alpha}$, to ensure the invariance of $x_\alpha x^\alpha$ under homogeneous Lorentz transformations ($\delta_\alpha = 0$).

The transformation (2.46) will induce a transformation in the fields which we assume to be

$$\phi_r(x) \to \phi'_r(x') = \phi_r(x) + \frac{1}{2}\varepsilon_{\alpha\beta} S^{\alpha\beta}_{rs} \phi_s(x).$$

In this section, summation over repeated indices r, s, labelling fields, as well as over Lorentz indices α, β, is implied. Here x and x' label the same point in space-time referred to the two frames of reference, and ϕ_r and ϕ'_r are the field components referred to these two coordinate systems. The coefficients $S^{\alpha\beta}_{rs}$ in Eq. (2.47) are antisymmetric in α and β, like $\varepsilon_{\alpha\beta}$, and are determined by the transformation properties of the fields. For example, for the vector potential $A_\alpha(x)$, Eq. (2.47) reduces to the transformation law of a vector. Invariance under the transformations (2.46) and (2.47) means that the Lagrangian density expressed in terms of the new coordinates and fields has the same functional form as when expressed in the original coordinates and fields:

$$\mathscr{L}\left(\phi_r(x), \phi_{r,\alpha}(x)\right) = \mathscr{L}\left(\phi'_r(x'), \phi'_{r,\alpha}(x')\right).$$

(Here $\phi_{r,\alpha}(x') \equiv \partial\phi'_r(x')/\partial x'^\alpha$.) From Eq. (2.48) the covariance of the field equations, etc. follows; i.e. they will have the same form expressed in terms of either the original or the transformed coordinates and fields.

The conservation laws follow by expressing the right-hand side of Eq. (2.48) in terms of the original coordinates and fields by means of Eqs. (2.46) and (2.47). We shall first state and discuss these results, postponing their derivation to the end of this section. For a translation (i.e. $\varepsilon_{\alpha\beta} = 0$), one obtains the four continuity equations

$$\frac{\partial \mathscr{T}^{\alpha\beta}}{\partial x^\alpha} = 0,$$

where

$$\mathscr{J}^{-\alpha\beta} \equiv \frac{\partial \mathscr{L}}{\partial \phi_{r,\alpha}} \frac{\partial \phi_r}{\partial x_\beta} - \mathscr{L} g^{\alpha\beta},$$

and the four conserved quantities are

$$cP^\alpha \equiv \int \mathrm{d}^3\mathbf{x} \mathscr{T}^{-\alpha\alpha} = \int \mathrm{d}^3\mathbf{x} \left\{ c\pi_r(x) \frac{\partial \phi_r(x)}{\partial x_\alpha} - \mathscr{L} g^{0\alpha} \right\}.$$

P^α is the energy-momentum four-vector, with

$$\left.\begin{aligned} cP^0 &= \int \mathrm{d}^3\mathbf{x} \left\{ \pi_r(x)\dot{\phi}_r(x) - \mathscr{L}\left(\phi_r, \phi_{r,\alpha}\right) \right\} \\ &= \int \mathrm{d}^3\mathbf{x} \mathscr{H} = H \end{aligned}\right\}$$

being the Hamiltonian, Eqs. (2.24) and (2.25), and

$$P^j = \int \mathrm{d}^3\mathbf{x} \pi_r(x) \frac{\partial \phi_r(x)}{\partial x_j}$$

being the momentum components of the fields. This interpretation will be confirmed when we come to express these operators in the number representation. Correspondingly $\mathscr{F}^{\alpha\beta}$ is called

the energy-momentum tensor. For a rotation (i.e. $\delta_\alpha = 0$) Eqs. (2.46)-(2.48) give the continuity equations

$$\frac{\partial \|^{\alpha\beta\gamma}}{\partial x^\alpha} = 0,$$

where

$$\|^{\alpha\beta\gamma} \equiv \frac{\partial,}{\partial \phi_{r,\alpha}} S_{rs}^{\beta\gamma} \phi_s(x) + \left[x^\beta, -\alpha\gamma - x^\gamma, -\alpha\beta\right],$$

and the six conserved quantities (note that $\|^{\alpha\beta\gamma} = -\mathbb{1}^{\alpha\gamma\beta}$) are

$$\begin{aligned} cM^{\alpha\beta} &= \int \mathrm{d}^3\mathbf{x} \|^{0\alpha\beta} \\ &= \int \mathrm{d}^3\mathbf{x} \left\{ \left[x^\alpha \mathscr{F}^{-0\beta} - x^\beta \mathcal{J}^{0\alpha} \right] + c\pi_r(x) S_{rs}^{\alpha\beta} \phi_s(x) \right\}. \end{aligned}$$

For two space-like indices ($i, j = 1, 2, 3$), M^{ij} is the angular momentum operator of the field (M^{12} being the z-component, etc.). Remembering that $\mathscr{F}^{oi}/c$ is the momentum density of the field [see Eqs. (2.51)], we interpret the term in square brackets in Eq. (2.54)

as the orbital angular momentum and the last term as the intrinsic spin angular momentum.

We return to the derivation of the continuity equations (2.49) and (2.52).[4] The variation of a function ϕ_r(x) with the argument unchanged was defined in Eq. (2.39) as

$$\delta\phi_r(x) \equiv \phi'_r(x) - \phi_r(x).$$

In addition, we now define the variation

$$\delta_{\mathrm{T}}\phi(x) \equiv \phi'_r(x\prime) - \phi_r(x).$$

which results from changes of both the form and the argument of the function. We can then write

$$\begin{aligned} \delta_{\mathrm{T}}\phi_r(x) &= \left[\phi'_r\left(x'\right) - \phi_r\left(x'\right)\right] + \left[\phi_r\left(x'\right) - \phi_r(x)\right] \\ &= \delta\phi_r\left(x'\right) + \frac{\partial \phi_r}{\partial x_\beta} \delta x_\beta, \end{aligned}$$

where δx_β is given by Eq. (2.46). To first order in small quantities this can be written

$$\delta_{\mathrm{T}}\phi_r(x) = \delta\phi_r(x) + \frac{\partial \phi_r}{\partial x_\beta} \delta x_\beta.$$

We can similarly write Eq. (2.48) as

$$\begin{aligned} 0 &= \mathscr{L}\left(\phi'_r\left(x'\right), \phi_{r,\alpha}\left(x'\right)\right) - \mathscr{L}\left(\phi_r(x), \phi_{r,\alpha}(x)\right) \\ &= \delta y + \frac{\partial \mathscr{L}}{\partial x^\alpha} \delta x^\alpha \end{aligned}$$

For $\delta\mathscr{L}$ we obtain, since $\phi_r(x)$ satisfies the field equations (2.16),

$$\begin{aligned} \delta\mathscr{L} &= \frac{\partial \mathscr{L}}{\partial \phi_r} \delta\phi_r + \frac{\partial L}{\partial \phi_{r,\alpha}} \delta\phi_{r,\alpha} \\ &= \frac{\partial}{\partial x^\alpha} \left\{ \frac{\partial y}{\partial \phi_{r,\alpha}} \delta\phi_r \right\} = \frac{\partial}{\partial x^\alpha} \left\{ \frac{\partial y}{\partial \phi_{r,\alpha}} \left[\delta_{\mathrm{T}}\phi_r - \frac{\partial \phi_r}{\partial x_\beta} \delta x_\beta \right] \right\}. \end{aligned}$$

We combine Eqs. (2.58) and (2.59) to obtain the continuity equations

$$\frac{\partial f^\alpha}{\partial x^\alpha} = 0,$$

where

$$f^\alpha \equiv \frac{\partial \mathscr{L}}{\partial \phi_{r,\alpha}} \delta_{\mathrm{T}} \phi_r - \mathcal{T}^{\alpha\beta} \delta x_\beta$$

with $\mathcal{I}^{\alpha\beta}$ given by Eq. (2.50). We first consider translations, i.e. $\varepsilon_{\alpha\beta} = 0$, so that from Eqs. (2.46) and (2.47) $\delta x_\beta = \delta_\beta$ and $\delta_{\mathrm{T}} \phi_r = 0$. Eq. (2.61) reduces to $f^\alpha = -\mathcal{J}^{\alpha\beta} \delta x_\beta$, and, since the four displacements δ_β are independent of each other, Eq. (2.60) reduces to the four continuity equations (2.49) for energy and momentum conservation.

Finally, we consider rotations, i.e. $\delta_\alpha = 0$. From Eqs. (2.46) and (2.47) for δx_β and $\delta_{\mathrm{T}} \phi_r$, and the antisymmetry of $\varepsilon_{\alpha\beta}$, Eq. (2.61) becomes

$$f^\alpha = \frac{1}{2} \varepsilon_{\beta\gamma} \| ^{\alpha\beta\gamma}$$

where $\| ^{\alpha\beta\gamma}$ is the tensor defined in Eq. (2.53). Since the rotations $\varepsilon_{\beta\gamma}$ are independent of each other, Eq. (2.60) reduces to the continuity equations (2.52).

8.6.3 Idea of Symmetries (after Zi)

Симметрия, преобразование и инвариантность

Важность симметрии для современной физики трудно переоценить 1. Когда физический закон не меняется при некотором преобразовании, говорят, что он обладает симметрией.

Я уже использовал лоренц-инвариантность для ограничения формы действия. Конечно, лоренц-инвариантность является симметрией пространства-времени, но поля могут также преобразовываться в так называемом внутреннем пространстве. На самом деле мы уже видели тому пример. В главе I.3 я бегло упомянул, что в теории скалярного поля мы могли бы потребовать инвариантность действия относительно преобразования $\varphi \to -\varphi$ и таким образом исключить из действия члены нечетной степени по φ, например, φ^3.

Если член φ^3 присутствует, два мезона могут рассеяться и перейти в три мезона, как показано для примера на рис. I.9.1.

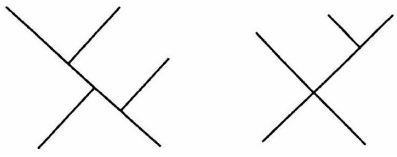

Рис. I.9.1

Но в отсутствие этого члена такой процесс запрещен, и вы легко можете убедиться в этом. Нельзя нарисовать диаграмму Фейнмана с нечетным числом внешних линий. (Подумайте о модификации интеграла из нашей младенческой задачи

[1] A. Zee, Fearful Symmetry. в главе I.7 до вида $\int_{-\infty}^{+\infty} dq e^{-\frac{1}{2}m^2q^2 - gq^3 - \lambda q^4 + Jq}$.) Таким образом, простая симметрия относительно отражений $\varphi \to -\varphi$ подразумевает, что в любом процессе рассеяния число мезонов сохраняется по модулю 2.

После того как мы рассмотрели случай одного скалярного поля, обратимся к теории с двумя скалярными полями φ_1 и φ_2, удовлетворяющими симметрии относительно отражений $\varphi_a \to -\varphi_a (a = 1, 2)$:

$$\mathcal{L} = \frac{1}{2}(\partial\varphi_1)^2 - \frac{1}{2}m_1^2\varphi_1^2 - \frac{\lambda_1}{4}\varphi_1^4 + \frac{1}{2}(\partial\varphi_2)^2 - \frac{1}{2}m_2^2\varphi_2^2 - \frac{\lambda_2}{4}\varphi_2^4 - \frac{\rho}{2}\varphi_2^2\varphi_2^2$$

Имеем две скалярные частицы, назовем их 1 и 2, с массами m_1 и m_2. В низшем порядке они могут рассеиваться следующим образом: $1+1 \to 1+ +1, 2+2 \to 2+2, 1+2 \to 1+2, 1+1 \to 2+2$ и $2+2 \to 1+1$ (убедитесь в этом самостоятельно). Если пять параметров $m_1, m_2, \lambda_1, \lambda_2$ и ρ абсолютно произвольны, между частицами нет никакой взаимосвязи.

Точка зрения, которую среди прочих активно поддерживал Эйнштейн и согласно которой фундаментальные законы должны быть упорядоченными и простыми, а не произвольными и сложными, является почти символом веры среди физиков-теоретиков.

Такая упорядоченность находит свое отражение в симметрии действия.

Предположим, что $m_1 = m_2$ и $\lambda_1 = \lambda_2$. Тогда две частицы будут иметь одинаковые массы и одинаково взаимодействовать как с собой, так и друг с другом. Лагранжиан $\mathcal{L}$ оказывается инвариантным относительно симметрии перестановки $\varphi_1 \leftrightarrow \varphi_2$.

Предположим, далее, что мы налагаем условие $\rho = \lambda_1 = \lambda_2$, так что лагранжиан становится равным

$$\mathcal{L} = \frac{1}{2}\left[(\partial\varphi_1)^2 + (\partial\varphi_2)^2\right] - \frac{1}{2}m^2\left(\varphi_1^2 + \varphi_2^2\right) - \frac{\lambda}{4!}\left(\varphi_1^2 + \varphi_2^2\right)^2$$

и инвариантным относительно двумерных вращений

$\{\varphi_1(x) \to \cos\theta\varphi_1(x) + \ +\sin\theta\varphi_2(x), \varphi_2(x) \to -\sin\theta\varphi_1(x) + \cos\theta\varphi_2(x)\}$

с произвольным углом θ. Говорят, что теория обладает «внутренней» $SO(2)$-симметрией, внутренней в том смысле, что преобразование не имеет ничего общего с пространством-временем. В отличие от симметрии перестановки $\varphi_1 \leftrightarrow \varphi_2$, это преобразование зависит от непрерывного параметра θ, а соответствующая симметрия называется непрерывной.

Из этого простого примера мы видим, что существуют иерархии симметрий.

Непрерывные симметрии

Если мы будем достаточно долго смотреть на уравнения движения $(\partial^2 + m^2)\varphi_a + \lambda\vec{\varphi}^2\varphi_a = 0$, то увидим, что если определить $J^\mu \equiv i(\varphi_1\partial^\mu\varphi_2 - \ -\varphi_2\partial^\mu\varphi_1)$, то $\partial_\mu J^\mu = i(\varphi_1\partial^2\varphi_2 - \varphi_2\partial^2\varphi_1) = 0$, то есть J^μ является сохраняющимся током. Соответствующий заряд $Q = \int d^D x J^0$, подобно электрическому заряду, сохраняется.

Обратимся к истории. Когда Гейзенберг заметил, что масса только что открытого нейтрона почти совпадает с массой протона, он высказал предположение, что если бы электромагнитное взаимодействие можно было бы каким-то образом выключить, то существовала бы внутренняя симметрия, переводящая протон в нейтрон.

Внутренняя симметрия точно так же накладывает ограничения на форму теории, как и лоренц-инвариантность. В качестве обобщения нашего простого примера предположим, что мы хотим построить теорию поля, содержащую N скалярных полей $\varphi_a, a = 1, ..., N$, так, чтобы она была инвариантна относительно преобразований $\varphi_a \to R_{ab}\varphi_b$ (с суммированием по повторяющимся индексам), где матрица R есть элемент группы вращений $SO(N)$ (см. краткое изложение теории групп в приложении В). Поля φ_a преобразуются как вектор $\vec{\varphi} = (\varphi_1, ..., \varphi_N)$. Мы можем составить только один инвариант, а именно скалярное произведение

$\vec{\varphi}\cdot\vec{\varphi} = \varphi_a\varphi_b = \vec{\varphi}^2$ (как обычно, по повторяющимся индексам, если не оговорено особо, производится суммирование). Лагранжиан, таким образом, ограничивается формой

$$\mathcal{L} = \frac{1}{2}\left[(\partial\vec{\varphi})^2 - m^2\vec{\varphi}^2\right] - \frac{\lambda}{4}\left(\vec{\varphi}^2\right)^2.$$

Правила Фейнмана приведены на рис. 1.9.2. Когда мы рисуем диаграммы Фейнмана, каждая линия, помимо импульса, несет на себе внутренний индекс.

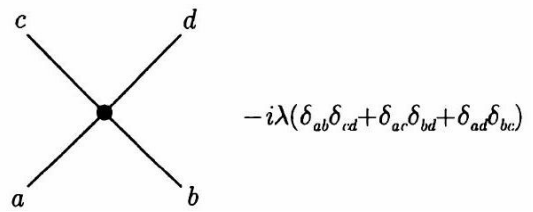

Рис. I.9.2

Симметрия проявляется в физических амплитудах. Представим, например, что мы вычисляем пропагатор $iD_{ab}(x) = \int D\vec{\varphi}e^{iS}\varphi_a(x)\varphi_b(0)$. Предпо- ложим, что мера $D\vec{\varphi}$ инвариантна относительно $SO(N)$. Рассуждая о том, как $D_{ab}(x)$ преобразуется под действием группы симметрии $SO(N)$, вы легко придете к выводу (см. упражнение I.9.2), что он должен быть пропорционален δ_{ab}. Можно проверить справедливость полученного вывода, нарисовав несколько диаграмм Фейнмана или рассмотрев обыкновенный интеграл $\int d\vec{q}e^{-S(q)}q_aq_b$. Независимо от того, насколько сложна нарисованная вами диаграмма (например, рис. I.9.3), вы всегда получите этот множитель δ_{ab}. Аналогично амплитуды рассеяния также должны обладать симметрией.

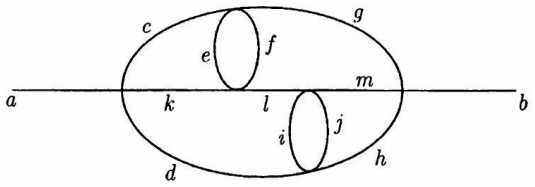

Рис. I.9.3

В отсутствие $SO(N)$-симметрии, в (3) могли бы присутствовать и другие члены (например, $\varphi_a\varphi_b\varphi_c\varphi_d$ с произвольно выбранными a, b, c и d).

Можно записать $R = e^{\theta\cdot T}$, где $\theta\cdot T = \sum_A \theta^A T^A$ есть вещественная антисимметричная матрица. Группа $SO(N)$ имеет $N(N-1)/2$ генераторов, обозначаемых как T^A. [Рассмотрите более знакомый вам случай $SO(3)$.] При инфинитезимальном преобразовании (с суммированием по повторяющимся индексам) $\varphi_a \to R_{ab}\varphi_b \simeq \left(1+\theta^A T^A\right)_{ab}\varphi_b$, то есть, другими словами, имеем бесконечно малое изменение $\delta\varphi_a = \theta^A {T^A}_{ab}\varphi_b$.

Теорема Нётер

Мы подошли к одному из самых принципиальных открытий теоретической физики - теореме Нётер, которая гласит, что каждому генератору группы непрерывной симметрии соответствует сохраняющийся ток. Появление сохраняющегося тока в (2) не было случайным.

Как это часто бывает с особо важными теоремами, доказательство теоремы Нётер удивительно просто. Обозначим поля нашей теории как φ_a. Поскольку симметрия является

непрерывной, можно рассмотреть бесконечно малое изменение $\delta\varphi_a$. Так как $\mathcal{L}$ при этом не меняется, получаем

$$0 = \delta\mathcal{L} = \frac{\delta\mathcal{L}}{\delta\varphi_a}\delta\varphi_a + \frac{\delta\mathcal{L}}{\delta\partial_\mu\varphi_a}\delta\partial_\mu\varphi_a = \frac{\delta\mathcal{L}}{\delta\varphi_a}\delta\varphi_a + \frac{\delta\mathcal{L}}{\delta\partial_\mu\varphi_a}\partial_\mu\delta\varphi_a$$

На этом месте мы придем в тупик, если не воспользоваться уравнениями движения $\delta\mathcal{L}/\delta\varphi_a = \partial_\mu\left(\delta\mathcal{L}/\delta\partial_\mu\varphi_a\right)$ и не объединить два члена, получив

$$0 = \partial_\mu\left(\frac{\delta\mathcal{L}}{\delta\partial_\mu\varphi_a}\delta\varphi_a\right)$$

Если определить

$$J^\mu \equiv \frac{\delta\mathcal{L}}{\delta\partial_\mu\varphi_a}\delta\varphi_a$$

то (5) будет означать, что $\partial_\mu J^\mu = 0$. Мы нашли сохраняющийся ток! [Из наших действий очевидно, что в (6) производится суммирование по повторяющемуся индексу a.

Теперь немедленно проиллюстрируем это на примере простой теории скалярного поля (3). Подставляя $\delta\varphi_a = \theta^A\left(T^A\right)_{ab}\varphi_b$ в (6) и замечая, что θ^A является произвольным, получаем $N(N-1)/2$ сохраняющихся токов $J^A_\mu = \partial_\mu\varphi_a\left(T^A\right)_{ab}\varphi_b$, по одному на каждый генератор группы симметрии $SO(N)$

В частном случае $N = 2$ можно определить комплексное поле $\varphi \equiv (\varphi_1 + i\varphi_2)/\sqrt{2}$. Лагранжиан (3) перепишем в виде

$$\mathcal{L} = \partial\varphi^\dagger\partial\varphi - m^2\varphi^\dagger\varphi - \lambda\left(\varphi^\dagger\varphi\right)^2$$

Видим, что он инвариантен относительно $\varphi \to e^{i\theta}\varphi$ и $\varphi^\dagger \to e^{-i\theta}\varphi^\dagger$. Из (6) находим $J_\mu = i\left(\varphi^\dagger\partial_\mu\varphi - \partial_\mu\varphi^\dagger\varphi\right)$ - это ток, использованный нами в упражнении I.8.4. Математически это объясняется изоморфизмом групп $SO(2)$ и $U(1)$ (см. приложение B).

Пример скалярного поля, преобразующегося как вектор под действием группы $SO(N)$, я рассмотрел из педагогических соображений. Очевидно, что все рассмотренное выше остается справедливым и для случая произвольной группы G с полями φ, преобразующимися в условиях произвольного представления $\mathcal{R}$ группы G. Сохраняющиеся токи также будут определяться выражениями $J^A_\mu = \partial_\mu\varphi_a\left(T^A\right)_{ab}\varphi_b$ с генераторами T^A, вычисленными в представлении $\mathcal{R}$. Например, если φ преобразуется как пятимерное представление группы $SO(3)$, то T^A является 5×5-матрицей.

Для того чтобы физика была инвариантна относительно группы преобразований, нужно лишь, чтобы инвариантным было действие. При этом плотность лагранжиана может измениться на полную производную: $\delta\mathcal{L} = \partial_\mu K^\mu$ при условии, что соответствующий граничный член можно опустить. Тогда из (5) будет следовать, что для вывода формулы для сохраняющегося тока необходимо будет лишь модифицировать (6) до вида $J^\mu \equiv \delta\mathcal{L}/\delta\partial_\mu\varphi_a\delta\varphi_a - K^\mu$. Как мы увидим в главе VIII.4, многие суперсимметричные теории поля принадлежат к этому типу.

Заряд как генераторы

Используя канонический формализм из главы I.8, мы можем получить изящное выражение для заряда, связанного с сохраняющимся током

$$Q \equiv \int d^3x J^0 = \int d^3x \frac{\delta \mathcal{L}}{\delta \partial_0 \varphi_a} \delta \varphi_a.$$

Если узнать в $\delta\mathcal{L}/\delta\partial_0\varphi_a$ канонический импульс, сопряженный полю φ_a, получим

$$i\,[Q, \varphi_a] = \delta\varphi_a.$$

Оператор заряда генерирует соответствующее преобразование полей. Рассмотренный нами частный случай для комплексного поля φ в $SO(2) \simeq U(1)$-теории является важным; здесь $[Q, \varphi] = \varphi$ и $e^{i\theta Q}\varphi e^{-i\theta Q} = e^{i\theta}\varphi$.

Упражнения

I.9.1. Некоторые авторы предпочитают более детальную формулировку теоремы Нётер. Предположим, что действие не меняется под действием инфинитезимального преобразования $\delta\varphi_a(x) = \theta^A V_a^A$ [здесь θ^A - параметры, маркируемые индексом A, а V_a^A - функция от полей φ_b и, возможно, их первых производных по x]. Следует подчеркнуть, что, когда мы говорим о неизменности действия S, мы не используем уравнения движения. В конце концов, уравнения движения Эйлера - Лагранжа следуют из условия $\delta S = 0$ для произвольного изменения $\delta\varphi_a$, удовлетворяющего определенным граничным условиям. Рассмотренный нами пример теории скалярного поля прекрасно иллюстрирует этот момент, который в некоторых книгах может приводить читателей к замешательству: $\delta S = 0$ просто потому, что S построено с помощью скалярного произведения $O(N)$ векторов.

А теперь проделаем нечто, что на первый взгляд выглядит несколько странным. Рассмотрим написанное выше инфинитезимальное изменение, но с параметрами θ^A, зависящими от x. Другими словами, рассмотрим $\delta\varphi_a(x) = \theta^A(x)V_a^A$. В этом случае никак не объяснить факт сокращения δS, но, с другой стороны, мы знаем, что раз δS сводится к нулю при постоянном θ^A, то выражение для δS должно иметь вид $\delta S = \int d^4x J^\mu(x)\partial_\mu\theta^A(x)$. На практике это позволяет нам легко получить ток $J^\mu(x)$; он представляет собой всего лишь коэффициент при $\partial_\mu\theta^A(x)$ в δS.

Покажите, как все это работает для лагранжиана (3). I.9.2. Покажите, что $D_{ab}(x)$ должно быть пропорционально δ_{ab}, как утверждается в тексте.

I.9.3. Напишите лагранжиан $SO(3)$-инвариантной теории для скалярного (относительно преобразований Лоренца) поля φ, преобразующегося по пятимерному представлению, до членов четвертого порядка по полю. [Указание: удобно представить φ симметричной 3×3-матрицей с нулевым следом.]

I.9.4. Добавьте к лагранжиану из упражнения I.9.3 скалярное (относительно преобразований Лоренца) поле η, преобразующееся как вектор под действием $SO(3)$, сохраняя при этом $SO(3)$-инвариантность. Получите нётеровские токи этой теории. Используя уравнения движения, проверьте сохранение токов.

8.6.4 Hamiltonian Field Formalism

Лагранжева формулировка теории поля особенно подходит для релятивистской динамики, потому что все выражения в ней явно лоренц-инвариантны. Тем не менее, в первой части этой книги мы будем использовать гамильтонову формулировку, так как с ее помощью легче осуществить переход к квантовой механике.

Напомним, что в дискретной системе для каждой динамической переменной q можно определить канонически сопряженный импульс $p \equiv \partial L/\partial\dot{q}($ где $\dot{q} = \partial q/\partial t)$. Тогда гамильтониан $H \equiv \sum p\dot{q} - L$. Обобщение на непрерывную систему легче всего понять, если представлять точки пространства $\mathbf{x}$ расположенными дискретно. Мы можем определить

$$p(\mathbf{x}) \equiv \frac{\partial L}{\dot{\phi}(\mathbf{x})} = \frac{\partial}{\partial\dot{\phi}(\mathbf{x})}\int \mathscr{L}(\phi(\mathbf{y}),\dot{\phi}(\mathbf{y}))d^3y \sim \frac{\partial}{\partial\dot{\phi}(\mathbf{x})}\sum_{\mathbf{y}} \mathscr{L}(\phi(\mathbf{y}),\dot{\phi}(\mathbf{y}))d^3y = \pi(\mathbf{x})d^3x,$$

где

$$\pi(\mathbf{x}) \equiv \frac{\partial\mathscr{L}}{\partial\dot{\phi}(\mathbf{x})}$$

называется плотностью импульса, сопряженного к $\phi(\mathbf{x})$. Таким образом, гамильтониан может быть записан в виде

$$H = \sum_{\mathbf{x}} p(\mathbf{x})\dot{\phi}(\mathbf{x}) - L$$

Переходя к континууму, имеем

$$H = \int d^3x[\pi(\mathbf{x})\dot{\phi}(\mathbf{x}) - \mathscr{L}] \equiv \int d^3x\mathscr{H}$$

В конце этого раздела, используя другой метод, мы заново получим это же выражение для плотности гамильтониана $\mathscr{H}$.

В качестве простого примера рассмотрим теорию одного поля $\phi(x)$, лагранжиан которого равен

$$\mathscr{L} = \frac{1}{2}\dot{\phi}^2 - \frac{1}{2}(\nabla\phi)^2 - \frac{1}{2}m^2\phi^2 = \frac{1}{2}\left(\partial_\mu\phi\right)^2 - \frac{1}{2}m^2\phi^2.$$

Пока будем считать ϕ вещественным полем. В разделе 2.3 величина m будет интерпретирована как масса, но пока будем рассматривать ее как некий параметр. Исходя из этого лагранжиана, с помощью обычной процедуры получаем уравнение движения:

$$\left(\frac{\partial^2}{\partial t^2} - \nabla^2 + m^2\right)\phi = 0 \quad \text{или} \quad \left(\partial^\mu\partial_\mu + m^2\right)\phi = 0$$

которое является известным уравнением Клейна-Гордона. (В этом контексте это классическое полевое уравнение, аналогичное уравнениям Максвелла, а не квантово-механическое волновое уравнение.) Замечая, что канонически сопряженная к $\phi(x)$ плотность импульса есть $\pi(x) = \dot{\phi}(x)$, можно также построить гамильтониан

$$H = \int d^3x\mathscr{H} = \int d^3x\left[\frac{1}{2}\pi^2 + \frac{1}{2}(\nabla\phi)^2 + \frac{1}{2}m^2\phi^2\right]$$

Три слагаемых в правой части можно рассматривать, соответственно, как энергию «перемещения» во времени, энергию «сдвига» в пространстве и энергию, связанную с наличием самого поля. Мы исследуем этот гамильтониан более детально в разделах 2.3 и 2.4.

8.6.5 Noether Theorem: Basics

Обсудим теперь связь между симметриями и законами сохранения в классической теории поля, устанавливаемую теоремой Нетер. В этой теореме рассматриваются непрерывные преобразования полей ϕ, которые в инфинитезимальной форме могут быть записаны в виде

$$\phi(x) \to \phi'(x) = \phi(x) + \alpha\Delta\phi(x),$$

где α - инфинитезимальный параметр и $\Delta\phi$ - некоторая деформация конфигурации поля. Мы называем это преобразование симметрией, если оно оставляет инвариантными уравнения движения. Это заведомо имеет место, если действие инвариантно по отношению к преобразованию (2.9). В более общем случае можно допустить, чтобы добавка к действию имела вид поверхностного слагаемого, так как наличие такого слагаемого не влияет на вывод уравнений движения Эйлера-Лагранжа (2.3). Поэтому лагранжиан должен быть инвариантен относительно (2.9) с точностью до 4-дивергенции от некоторого вектора $\mathscr{J}^\mu$:

$$\mathscr{L}(x) \to \mathscr{L}(x) + \alpha\partial_\mu \mathscr{J}^\mu(x),$$

Сравним ожидаемое выражение для $\Delta\mathscr{L}$ с результатом, полученным при вариации полей:

$$\begin{aligned}\alpha\Delta\mathscr{L} &= \frac{\partial\mathscr{L}}{\partial\phi}(\alpha\Delta\phi) + \left(\frac{\partial\mathscr{L}}{\partial\left(\partial_\mu\phi\right)}\right)\partial_\mu(\alpha\Delta\phi) = \\ &= \alpha\partial_\mu\left(\frac{\partial\mathscr{L}}{\partial\left(\partial_\mu\phi\right)}\Delta\phi\right) + \alpha\left[\frac{\partial\mathscr{L}}{\partial\phi} - \partial_\mu\left(\frac{\partial\mathscr{L}}{\partial\left(\partial_\mu\phi\right)}\right)\right]\Delta\phi\end{aligned}$$

В силу уравнения Эйлера-Лагранжа (2.3) второе слагаемое обращается в нуль. Полагая левую часть этого уравнения равной $\alpha\partial_\mu\mathscr{J}^\mu$, находим:

$$\partial_\mu j^\mu(x) = 0, \quad \text{для \%} \quad \%j^\mu(x) = \frac{\partial\mathscr{L}}{\partial\left(\partial_\mu\phi\right)}\Delta\phi - \mathscr{J}^\mu.$$

(Если симметрия включает больше одного поля, то первое слагаемое в этом выражении для $j^\mu(x)$ должно быть заменено суммой таких слагаемых по одному для каждого поля.) Этот результат означает, что ток $j^\mu(x)$ сохраняется. Каждой непрерывной симметрии $\mathscr{L}$ соответствует такой закон сохранения.

Закон сохранения может быть также сформулирован как сохранение заряда

$$Q \equiv \int\limits_{\text{все пространство}} j^0 d^3x$$

во времени. Заметим, однако, что формулировка теории поля в терминах локальной плотности лагранжиана непосредственно приводит к локальной форме закона сохранения (2.12).

Самый простой пример такого закона возникает в теории с лагранжианом, содержавшим лишь кинетическое слагаемое: $\mathscr{L} = \frac{1}{2}\left(\partial_\mu\phi\right)^2$. Преобразование $\phi \to \phi + \alpha$, где α - константа, оставляет $\mathscr{L}$ неизменным, и мы заключаем, что ток $j^\mu = \partial^\mu\phi$ сохраняется. В качестве менее тривиального примера рассмотрим лагранжиан

$$\mathscr{L} = |\partial_\mu\phi|^2 - m^2|\phi|^2$$

где теперь ϕ - комплексное поле. Можно легко показать, что уравнение движения для этого лагранжиана вновь является уравнением Клейна-Гордона (2.7). Этот лагранжиан инвариантен относительно преобразования $\phi \to e^{i\alpha}\phi$; для бесконечно малого преобразования имеем:

$$\alpha\Delta\phi = i\alpha\phi; \quad \alpha\Delta\phi^* = -i\alpha\phi^*$$

(Мы рассматриваем ϕ и ϕ^* как независимые поля. Альтернативно можно было бы работать с вещественной и мнимой частями поля ϕ.) Теперь несложно показать, что сохраняющийся нетеровский ток равен

$$j^\mu = i\left[\left(\partial^\mu\phi^*\right)\phi - \phi^*\left(\partial^\mu\phi\right)\right].$$

(Общий множитель был выбран произвольно.) Используя уравнение Клейна-Гордона, можно непосредственно проверить, что дивергенция этого тока равна нулю. Ниже мы добавим к этому лагранжиану слагаемые, которые связывают ϕ с электромагнитным полем. Тогда j^μ можно будет рассматривать как плотность электромагнитного тока комплексного скалярного поля, а пространственный интеграл j^0 - как электрический заряд.

Теорему Нетер можно также применить к пространственно-временным преобразованиям типа трансляций и вращений. Бесконечно малая трансляция

$$x^\mu \to x^\mu - a^\mu$$

может быть альтернативно описана как преобразование поля:

$$\phi(x) \to \phi(x+a) = \phi(x) + a^\mu\partial_\mu\phi(x).$$

Лагранжиан также является скаляром, поэтому он должен преобразовываться аналогично:

$$\mathscr{L} \to \mathscr{L} + a^\mu\partial_\mu\mathscr{L} = \mathscr{L} + a^\nu\partial_\mu\left(\delta^\mu{}_\nu\mathscr{L}\right).$$

Сравнивая это уравнение с (2.10), видим, что теперь имеется ненулевой ток $\mathscr{J}^\mu$. Учитывая это, можно применить теорему Нетер, чтобы получить четыре отдельно сохраняющихся тока

$$T^\mu_\nu \equiv \frac{\partial\mathscr{L}}{\partial\left(\partial_\mu\phi\right)}\partial_\nu\phi - \mathscr{L}\delta^\mu_\nu$$

Это - в точности тензор энергии-натяжения, называемый также тензором энергиц-импульса поля ϕ. Сохраняющийся заряд, связанный с временными трансляциями, есть гамильтониан

$$H = \int T^{00}d^3x = \int \mathscr{H}d^3x$$

Вычисляя эту величину для поля Клейна-Гордона, можно еще раз получить результат (2.8). Связанные с пространственными трансляциями сохраняющиеся заряды имеЮт вид:

$$P^i = \int T^{0i}d^3x = -\int \pi\partial_i\phi d^3x$$

Мы интерпретируем их как (физический) импульс, переносимый полем (не путать с каноническим импульсом).

8.6.6 Noether Theorem: Introduction to Consequences

(there are a lot of them in QFT)

8.7 So, What Is Exactly a Quantum Field?

8.7.1 What Do We Mean By "Operator Quantum Field"?

(write this in detail)

8.7.2 The Transition from Classical to Quantum Fields

(отдельно прорабатываю это, типичная первая тема.)

8.7.3 Is a Particle a One Field or Several?

(???? It is a fundamental question. I'll write some answer which I have)

8.7.4 Single-quantum Field

(??????????????)

общие соображения о локальных полях

Свободные поля эквивалентны частицам, поэтому их можно описывать в виде операторов рождения и уничтожения элементарных квантов в фоковском пространстве.

Однако поле является первичной сущностью, а его кванты производной от поля сущностью, потому что не всякое квантованное поле представимо как набор квантов.

Например, при наличии потенциала скалярного поля с минимумом потенциала, который достигается при не равном нулю поле, это вакуумное поле вовсе не соответствует каким-либо квантам, оно является самостоятельной сущностью.

Другой пример - поле, которое в силу внешних условий зависит только от времени, также вполне самостоятельная физическая сущность, более общая, чем кванты.

(что?)

условия, про которых квант поля это частица

Мы сформулируем условия, при которых понятие кванта локального поля сводится к точечной частице, которая обладает всеми измеримыми параметрами поля в форме дискретных порций этих параметров, таких как энергия, импульс, заряд и проч.

Мы будем рассуждать в терминах свободного поля, а значит, все наши построения останутся справедливыми в областях физической системы, где становится обоснованным приближение пренебрежимо малого взаимодействия полей.

Эти области называются асимптотически свободными.

Тогда в асимптотически свободных областях физической системы можно ввести понятие фоковского пространства и вакуума - состояния с минимальной энергией без квантов.

итоговые методы

(сперва простая теория)
Вводится причинный коррелятор, который также обозначается как

$$\mathcal{D}^{(2)}(x-y) \equiv \langle 0|\hat{\mathrm{T}}\{\hat{\varphi}(x)\hat{\varphi}(y)\}|0\rangle$$

поле с одним квантом

Рассмотрим релятивистское поле, когда оператор гамильтониана поля после нормального упорядочивания равен

$$\hat{H} = \int \frac{\mathrm{d}^3k}{(2\pi)^3 2\hbar\omega(\boldsymbol{k})}\hbar\omega(\boldsymbol{k})\hat{\mathfrak{a}}^\dagger(\boldsymbol{k})\hat{\mathfrak{a}}(\boldsymbol{k})$$

Изучим характеристики состояния с одним квантом

$$|k\rangle = \hat{\mathfrak{a}}^\dagger(k)|0\rangle.$$

Действие гамильтониана поля на состояние с одним квантом дает

$$\hat{H}|k\rangle = \int \frac{\mathrm{d}^3k'}{(2\pi)^3 2\hbar\omega(k)}\hbar\omega(k)\hat{\mathfrak{a}}^\dagger\left(k'\right)\hat{\mathfrak{a}}\left(k'\right)\hat{\mathfrak{a}}^\dagger(k)|0\rangle$$

преобразуем это выражение. Перестановка операторов рождения и уничтожения приводит к

$$\hat{\mathfrak{a}}\left(\boldsymbol{k}'\right)\hat{\mathfrak{a}}^\dagger(\boldsymbol{k}) = \hat{\mathfrak{a}}^\dagger(\boldsymbol{k})\hat{\mathfrak{a}}\left(\boldsymbol{k}'\right) + (2\pi)^3\delta\left(\boldsymbol{k}-\boldsymbol{k}'\right)2\hbar\omega(\boldsymbol{k}),$$

поэтому интеграл преобразуется:

$$\hat{H}|k\rangle = \hbar\omega(k)|k\rangle + \int \frac{\mathrm{d}^3k'}{(2\pi)^3 2\hbar\omega(k)}\hbar\omega(k)\hat{\mathfrak{a}}^\dagger\left(k'\right)\hat{a}^\dagger(k)\hat{a}\left(k'\right)|0\rangle = \hbar\omega(k)|k\rangle,$$

поскольку действие опрератора уничтожения кванта на вакуум дает нуль $\hat{\mathfrak{a}}\left(k'\right)|0\rangle = 0$.

Получается, что состояние с одним квантом $|k\rangle$ - это собственное состояние гамильтониана поля с квантом энергии $\hbar\omega(k)$.

Конкретно, в чем выражается локальность?

(пропишу, важный вопрос!)

импульс поля с одним квантом

Изучим поле с одним квантом.
Посмотрим на импульс поля
Импульс поля, который задается через плотность импульса

$$p^\alpha = \int \mathrm{d}^3x T_0^\alpha = -\frac{1}{c}\int \mathrm{d}^3x \nabla_\alpha\varphi\partial_t\varphi$$

на уравнениях движения имеет вид (??? мы что ли подставили сюда решение?)

$$\begin{aligned} p = \tfrac{1}{c}\int \tfrac{c^2d^3k}{4\omega^2(2\pi)^3}\big\{&k\omega e^{-2\mathrm{i}\omega t}\alpha(\omega,k)\alpha(\omega,-k) - \\ &-k\omega e^{2\mathrm{i}\omega t}\alpha^*(\omega,k)\alpha^*(\omega,-k) + \\ &+k\omega\left[\alpha(\omega,k)\alpha^*(\omega,k)+\alpha^*(\omega,k)\alpha(\omega,k)\right]\big\} \end{aligned}$$

Преобразуем. В этом выражении две первых строчки справа от знака равенства тождественно равны нулю,

поскольку, глядя на явный вид подынтегральных функций,

при замене переменной интегрирования $k \mapsto -k$ интегралы переходят сами в себя со знаком минус! (???) В итоге импульс поля на уравнениях движения

$$p = \int \frac{\mathrm{d}^3 k}{(2\pi)^3 2\hbar\omega(k)} \hbar k |\alpha(\omega, k)|^2$$

после квантования и применения операции нормального упорядочивания переходит в оператор

$$\hat{p} = \int \frac{\mathrm{d}^3 k}{(2\pi)^3 2\hbar\omega(k)} \hbar k \hat{\mathrm{a}}^\dagger(k) \hat{\mathrm{a}}(k)$$

Вспомним, что оператор энергии поля имеет с точностью до константы такой же вид, так верно:

$$\hat{p}|k\rangle = \hbar k |k\rangle$$

а значит, состояние с одним квантом $|k\rangle$ является собственным для оператора импульса поля,

и этот квант несет импульс поля $\hbar k$.

квант - точечная частица

Покажем теперь, что состояние с одним квантом поля $|k\rangle$ - это точечная частица.

Делается это за счет (?????)

Для этого сначала рассмотрим матричный элемент

$$\langle 0|\hat{\varphi}(x)|k\rangle$$

Физический смысл этого матричного элемента следующий: на состояние поля с одним квантом импульса $\hbar k$ и энергии $\hbar\omega(k)$ в момент времени t в точке x подействовал оператор квантованного поля $\hat{\varphi}(x)$, а в конечном состоянии мы рассматриваем состояние вакуума, а значит, рассматриваем ситуацию, когда данный квант поля исчез в точке x!

С учетом выражения для квантованного поля (2.46),

$$\hat{\varphi}(x) = \int \frac{c d^3 k}{2\omega(2\pi)^3} \left\{ e^{\mathrm{i}kx} \hat{\mathfrak{a}}^\dagger(\boldsymbol{k}) + e^{-\mathrm{i}kx} \hat{\mathfrak{a}}(\boldsymbol{k}) \right\}$$

мысленно повторим упражнения с перестановкой операторов рождения и уничтожения, после чего легко найдем, что искомый матричный элемент равен

$$\langle 0|\hat{\varphi}(x)|\boldsymbol{k}\rangle = e^{-\mathrm{i}kx} \hbar c$$

Таким образом, амплитуда перехода состояния поля с одним квантом в вакуум при действии локального поля отлична от нуля. Более того, с точностью до фактора $\hbar c$ амплитуда (3.2) есть просто положительно частотная мода поля. Подчеркнем, что амплитуда исчезновения частицы с заданным импульсом в

начальном состоянии отвечает именно положительно частотной моде. Ясно, что аналогичный матричный элемент

$$\langle \boldsymbol{k}|\hat{\varphi}(x)|0\rangle = (\langle 0|\hat{\varphi}(x)|\boldsymbol{k}\rangle)^\dagger = e^{\mathrm{i}kx} \hbar c$$

отвечает появлению частицы в конечном состоянии из вакуума, и он описывается, подчеркнем, отрицательно частотной модой.

Логическая трактовка этого матричного элемента возможна только,

если полагать, что сам квант является точечным объектом, т. е. частицей!

квант локального поля является точечной частицей, которая несет вполне определенную порцию энергии и импульса поля.

Если у поля, в добавок к энергии и импульсу, есть другие характеристики, например, заряд, то, как мы покажем, частица также будет обладать этими характеристиками, в частности, квантом заряда.

причинный коррелятор

Вывод (??) можно сделать еще более убедительным, если рассмотреть матричный элемент

$$\langle 0|\hat{\varphi}(x)\hat{\varphi}(y)|0\rangle \text{ при } x_0 > y_0$$

Физический смысл квантованного поля нам известен: квантованное скалярное определенными значениями энергии и импульса.

Действие этого поля на вакуум дает

$$\hat{\varphi}(y)|0\rangle = \int \frac{cd^3k}{2\omega(2\pi)^3} e^{\mathrm{i}ky}\hat{\mathfrak{a}}^\dagger(\boldsymbol{k})|0\rangle = \int \frac{cd^3k}{2\omega(2\pi)^3} e^{\mathrm{i}ky}|\boldsymbol{k}\rangle$$

Как локальное поле действует на состояние одним квантом мы уже выяснили, так что

$$\langle 0|\hat{\varphi}(x)\hat{\varphi}(y)|0\rangle = \hbar c \int \frac{cd^3k}{2\omega(2\pi)^3} e^{-\mathrm{i}k(x-y)} \quad \text{при } x_0 > y_0$$

Физический смысл этого матричного элемента следующий: в момент времени $t_0 = y_0/c$ в точке y действие локального поля породило суперпозицию квантов поля с определенными квантами энергии и импульса, каждый из этих квантов затем при $t_0' = x_0/c > t_0$ исчез в точке x, так что резонно считать, что эти кванты локального поля - точечные частицы.

Построенный матричный элемент с упорядочиванием аргументов по времени можно записать в более общем виде, если воспользоваться T-произведением, которое для бозонных полей определяется как

$$\hat{\mathrm{T}}\{\hat{\varphi}(x)\hat{\varphi}(y)\} = \vartheta(x_0 - y_0)\,\hat{\varphi}(x)\hat{\varphi}(y) + \vartheta(y_0 - x_0)\,\hat{\varphi}(y)\hat{\varphi}(x)$$

где бозонная природа отвечает знаку плюс при перестановке полей.

Тогда

$$\langle 0|\hat{\mathrm{T}}\{\hat{\varphi}(x)\hat{\varphi}(y)\}|0\rangle = \vartheta(x_0 - y_0)\,\hbar c \int \frac{cd^3k}{2\omega(2\pi)^3} e^{-\mathrm{i}k(x-y)} + \vartheta(y_0 - x_0)\,\hbar c \int \frac{cd^3k}{2\omega(2\pi)^3} e^{-\mathrm{i}k(y-x)}$$

Отметим, что при собственных ортохорнных преобразованиях группы Лоренца данное выражение является инвариантным: мера интегрирования явно инвариантна, а аргумент экспоненты - скаляр.

Этот матричный элемент можно переписать более компактно, если воспользоваться интегрированием в плоскости комплексной переменной k_0.

В самом деле, интегрирование вдоль вещественной оси выражения

$$\frac{1}{2\omega/c}\left(\frac{1}{k_0-\omega/c+\mathrm{i}0}-\frac{1}{k_0+\omega/c-\mathrm{i}0}\right)e^{-\mathrm{i}k_0(x_0-y_0)}$$

может быть проведено с помощью теоремы Коши для вычетов.

(????)

При $x_0>y_0$ к контуру интегрирования можно добавить полуокружность на бесконечности с $\operatorname{Im}k_0\to-\infty$, поскольку вклад такой полуокружности подавлен экспонентой.

Поэтому внутри замкнутого контура, ориентированного по часовой стрелке, останется только один полюс при $k_0=\omega/c-\mathrm{i}0$, и в итоге получится вклад

$$-2\pi\mathrm{i}\frac{1}{2\omega/c}e^{-\mathrm{i}\omega(x_0-y_0)/c}$$

где знак минус, конечно, относится к обходу замкнутого контура по часовой стрелке.

И аналогично, при $x_0<y_0$ к контуру интегрирования можно добавить полуокружность на бесконечности с $\operatorname{Im}k_0\to+\infty$, так что внутри замкнутого контура, ориентированного против часовой стрелке, останется только один полюс при $k_0=-\omega/c+\mathrm{i}0$, так получится вклад

$$2\pi\mathrm{i}\frac{1}{2\omega/c}(-1)e^{+\mathrm{i}\omega(x_0-y_0)/c}$$

Значит, матричный элемент можно записать теперь в единообразном виде

$$\langle 0|\hat{\mathrm{T}}\{\hat\varphi(x)\hat\varphi(y)\}|0\rangle=\mathrm{i}\hbar c\int\frac{\mathrm{d}^4k}{(2\pi)^4}e^{-\mathrm{i}k(x-y)}\frac{1}{2\omega/c}\left(\frac{1}{k_0-\omega/c+\mathrm{i}0}-\frac{1}{k_0+\omega/c-\mathrm{i}0}\right)$$

а элементарное преобразование с дробями при учете $\left(\frac{\omega}{c}-\mathrm{i}0\right)^2=\boldsymbol{k}^2+m^2c^2/\hbar^2-\mathrm{i}0$ дает

$$\langle 0|\hat{\mathrm{T}}\{\hat\varphi(x)\hat\varphi(y)\}|0\rangle=\mathrm{i}\hbar c\int\frac{\mathrm{d}^4k}{(2\pi)^4}e^{-\mathrm{i}k(x-y)}\frac{1}{k^2-m^2c^2/\hbar^2+\mathrm{i}0}$$

Подчеркнем, что в силу однородности пространства-времени Минковского и того факта, что вакуум сохраняет эту однородность,

двухточечный коррелятор $\langle 0|\hat{\mathrm{T}}\{\hat\varphi(x)\hat\varphi(y)\}|0\rangle$ является инвариантным относительно трансляций,

и поэтому он зависит лишь от разности координат $x-y$, что конечно связано с сохранением импульса: кванты поля, рожденные с импульсом $\hbar k$ в точке x,

распространяются с тем же импульсом до точки y и уничтожаются в этой точке оператором $\hat{\mathfrak{a}}(k)$ с тем же импульсом.

Причинный коррелятор (3.4) мы также будем обозначать как

$$\langle 0|\hat{\mathrm{T}}\{\hat\varphi(x)\hat\varphi(y)\}|0\rangle\equiv\mathcal{D}^{(2)}(x-y)$$

В естественной системе единиц имеем

$$\langle 0|\hat{\mathrm{T}}\{\hat\varphi(x)\hat\varphi(y)\}|0\rangle=\mathrm{i}\int\frac{\mathrm{d}^4k}{(2\pi)^4}e^{-\mathrm{i}k(x-y)}\frac{1}{k^2-m^2+\mathrm{i}0}$$

сразу видно, что масса и импульс имеют одну размерность, так что в этой формуле применена система единиц $\hbar=c=1$.

система единиц

Для полноты представлений об этой системе единиц укажем в явном виде, чему равны размерности действия и т.п. в единицах массы:

$$[S] = [1], \quad \left[\mathrm{d}^4x\right] = \frac{1}{[m]^4}, \quad [\mathcal{L}] = [m]^4, \quad [\varphi] = [m], \quad [\partial_\mu] = [m]$$

или, как говорят, действие безразмерно, лагранжиан имеет размерность 4, скалярное поле - размерность 1 и проч.

Для дальнейшего изложения и вычислений нам достаточно будет знать значение, как говорят, причинного двухточечного коррелятора (3.4) именно в импульсном представлении.

Как мы увидим, с точностью до постоянных речь идет также о пропагаторе скалярного поля, т.е. функции распространения поля или частиц поля, которую также называют фейнмановским пропагатором или причинной функцией Грина.

В координатах пространствавремени Минковского этот коррелятор после стандартных преобразований переменных интегрирования сводится к вкладу от дельта-функции Дирака на световом конусе, который не зависит от массы, и вкладам от спецфункций Бесселя, Неймана и Ганкеля, которые также зависят от интервала $(x-y)^2$ и обращаются в нуль при $m \to 0$.

Вместе с тем, необходимо знать, что вне светового конуса коррелятор экспоненциально затухает при увеличении пространственно подобного интервала, а внутри светового конуса коррелятор имеет осциллирующее поведение.

согласие с СТО

Как такое поведение согласуется с принципом причинности в специальной теории относительности, который гласит, что события могут быть причинно связаны, только если их разделяют времениподобные интералы?

Наша интерпретация коррелятора, как амплитуды рождения частиц в одной точке с последующим исчезновением этих частиц в другой точке, казалось бы, должна приводить к заключению, что эта амплитуда отлична от нуля только внутри светового конуса будущего и обращаться в нуль вне светового конуса.

Это утверждение было бы совершенно корректным для классических частиц, у которых траектории не имеют неопределенностей даже при точно заданных значениях импульса.

У квантовых частиц, как мы знаем, в силу соотношения неопределенностей координата-импульс, траектории для частиц с заданными импульсами с необходимостью должны флуктуировать и могут проникать в область, которая выглядит запрещенной для классических частиц.

Именно поэтому коррелятор экспоненциально мал при пространственно подобных интервалах.

Однако это объяснение о характере поведения причинного двухточечного коррелятора не снимает с повестки вопрос о принципе причинности в специальной теории относительности для квантованных полей.

У нас есть необходимый аппарат для ответа на этот вопрос в квантовой теории: два эрмитово самосопряженных оператора, которые описывают наблюдаемые величины, могут быть независимо измерены, только если их коммутатор обращается в нуль.

Следовательно, операторы наблюдаемых локальных полей являются независимыми в области координат, разделенных пространственно подобным интервалом, только если коммутатор полей в этой области тождественно обращается в нуль.

функция Паули-Йордона $D(x-y)$

В случае свободного вещественного скалярного поля коммутатор является функцией, так что можно рассмотреть матричный элемент этого коммутатора по вакууму

$$\langle 0|[\hat{\varphi}(x),\hat{\varphi}(y)]|0\rangle = -\mathrm{i}D(x-y)$$

где $D(x-y)$ называют функцией Паули-Йордана.

При расчете этой функции у нас уже нет нужды следить за временными компонентами координат, как мы это делали при рассмотрении T- произведения полей (для определенности при интерпретации амплитуд).

Это значит, что зависимость в виде функций Хевисайда от временных аргументов не возникнет, но, при этом, останется в силе утверждение, что функция является скаляром, и в этом случае она зависит только от интервала $(x-y)^2$.

Тогда расчеты можно существенно упростить и, скажем, при пространственно подобных интервалах $(x-y)^2<0$ проводить рассмотрение в системе отсчета, где $x_0-y_0=0$, а $(x-y)^2\neq 0$. Подстановка этих условий в формулы для амплитуд, которые мы получили выше, дает

$$\langle 0|[\hat{\varphi}(x),\hat{\varphi}(y)]|0\rangle = \hbar c\int\frac{cd^3k}{2\omega(2\pi)^3}e^{\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{x}-\boldsymbol{y})} - \hbar c\int\frac{cd^3k}{2\omega(2\pi)^3}e^{\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{y}-\boldsymbol{x})}\equiv 0$$

поскольку оба интеграла совпадают, как легко увидеть, если в одном из них произвести замену переменной интегрирования $k\mapsto -k$.

функция Паули-Йордана действительно обращается в нуль вне светового конуса, поэтому квантование поля согласовано с принципом причинности в специальной теории относительности.

Эта же функция возникает и при квантовании полей с не равным нулю спином.

Бозонные и фермионные поля

(?? так в чем их отличие?? переформулирую от киселева теорию!)

При этом стоит отметить, что наше рассмотрение опиралось на построение для локальных полей, амплитуды которых для положительно и отрицательно частотных мод в классическом случае являются комплексными числами. Это справедливо для бозонных полей.

В случае с фермионными полями, для которых амплитуды положительно и отрицательно частотных мод являются грассмановыми переменными, необходимо сделать специальное замечание.

Именно, умножение грассмановой амплитуды θ_λ, где λ нумерует моду, на грассманово число χ_λ дает комплексное число $\chi_\lambda\theta_\lambda$ в смысле его перестановочности с другими грассмановыми числами.

А произведение соответствующего фермионного оператора $\hat{\theta}_\lambda$ на грассманово число χ_λ дает бозонный оператор $\chi_\lambda\hat{\theta}_\lambda$ в голоморфном представлении, для которого наши стандартные рассуждения имеют силу.

Так что вычисление коммутатора для двух таких бозонньх операторов сводится в вычислению антикоммутатора для фермионных операторов, поскольку грассмановы числа антиперестановочны.

Для иллюстрации и упрощения записи опустим символы, нумерующие моды, и запишем равенство для коммутатора составных операторов уже бозонного типа, соблюдая правила перестановок грассмановых чисел и операторов в голоморфном представлении

$$\begin{aligned}\left[\chi^{(1)}\hat{\theta}^{(1)}, \chi^{(2)}\hat{\theta}^{(2)}\right] =& \chi^{(1)}\hat{\theta}^{(1)}\chi^{(2)}\hat{\theta}^{(2)} - \chi^{(2)}\hat{\theta}^{(2)}\chi^{(1)}\hat{\theta}^{(1)} = \\ =& -\chi^{(1)}\chi^{(2)}\left(\hat{\theta}^{(1)}\hat{\theta}^{(2)} + \hat{\theta}^{(2)}\hat{\theta}^{(1)}\right) = \\ =& -\chi^{(1)}\chi^{(2)}\left[\hat{\theta}^{(1)}, \hat{\theta}^{(2)}\right]\end{aligned}$$

То есть требование равенства нулю коммутатора локальных бозонных полей, разделенных пространственно подобным интервалом, приводит к требованию равенства нулю антикоммутатора локальных фермионных полей, разделенных пространственно подобным интервалом.

Повторимся, что рассматриваемые нами далее примеры для спинорных и векторных полей в явном виде убедят нас, что для этих полей та же функция Паули-Йордана будет обеспечивать выполнение релятивистского принципа причинности. (?? где??)

Пример выполнения и невыполнения принципа причиннсти (??)

8.7.5 Two- and Three-Quantum Fields (???)

(?? однокв дир поле??? двуквантовое поле??? все про это напишу!)

8.7.6 What Is Exactly a Quantum Field?

(мб во введение потом перенесу, а мб и тут оставлю, посмотрим.)

волновая функция поля и ее связь с функцией поля

подумаем, как ее ввести, какой точно ее смысл?
мб даже приведу примеры ее нахождения.
(?)

эквивалентность лагранжева и гамильтонова формализма

я говорю, что они эквивалентны, но это еще не проверено.
тут обсуждение, всегда ли это так?

Может ли быть скорость полей больше, чем скорость света, раз у нас в оптике фазовая скорость бывает более скорости света?

Типа чтобы групповая скорость была меньше. Говорят в оптике, что это и нормально.
(?? в ктп почему такого нету?)

Примеры квантованных полей

(соберу, такой вопрос может возникнуть)

отличие квантовых полей от классических

можно сказать, что отличие в том, что в классическом случае мы работаем с функцией поля,
а в квантовом - с операторами,
тем не менее, это не то, что хочется услышать.
сравним тут их природу нормально.

граница квантовых полей

я правильно понимаю, что реальное поле спадает к границе?

смысл перехода от частицы к полю

говорят, какая-то частица ударяется с другой.
где тут ктп?

Что фундаментальнее, свободное поле из группы Пунанкаре или квантмех, где всё квантуертся?

я пока не знаю, но это и отражается в последовательности глав в этой записи. мы же склеиваем квантмех и теорию поля, неплохо бы знать, что более фундаментальное? и почему вообще такие два соврешенно разных подхода должны так вот склеиваться совершенно сложно?

принципиальные моменты происходящего КТП

что такое родить частицу?

подействовать оператором рождения.
на а что это на самом деле значит?
обсудим тут подробно.

что такое вообще квантовое поле?

тут подробно ответим, ибо короткие ответы ничего не говорят.

Иллюстрация работы в КТП “на пальцах”

Вывод диаграмм Фейнамана из основ формализма (?????)

(пока я так и не понимаю, откуда конкретно бурутся диаграммы Фейнмана???? чет так и не увидел, лучше нужно пройти эти части еще.)

8.7.7 Wave-particle Duality

(see QM about more details, here will be a very similar discussion)

что значит, что частица эквивалентна волне?

Как поле дирака, в то же время электрон в классической электростатике?

никогда нормально не понимал.

один оператор может рождать несколько частиц

8.7.8 What is Not a Quantum Field?

(discuss some wrong statements)

8.7.9 What is QFT, and What Did We Think It Is? (Weinberg, 1996)

(a good article, which I'll read in free time)

Quantum field theory was originally thought to be simply the quantum theory of fields. That is, when quantum mechanics was developed physicists already knew about various classical fields, notably the electromagnetic field, so what else would they do but quantize the electromagnetic field in the same way that they quantized the theory of single particles? In 1926, in one of the very first papers on quantum mechanics,[1] Born, Heisenberg and Jordan presented the quantum theory of the electromagnetic field. For simplicity they left out the polarization of the photon, and took spacetime to have one space and one time dimension, but that didn't affect the main results. (*Response to comment from audience*: Yes, they were really doing string theory, so in this sense string theory is earlier than quantum field theory.) Born et al. gave a formula for the electromagnetic field as a Fourier transform and used the canonical commutation relations to identify the coefficients in this Fourier transform as operators that destroy and create photons, so that when quantized this field theory became a theory of photons. Photons, of course, had been around (though not under that name) since Einstein's work on the photoelectric effect two decades earlier, but this paper showed that photons are an inevitable consequence of quantum mechanics as applied to electromagnetism.

The quantum theory of particles like electrons was being developed at the same time, and made relativistic by Dirac[2] in 1928–1930. For quite a long time many physicists thought that the world consisted of both fields and particles: the electron is a particle, described by a relativistically invariant version of the Schrödinger wave equation, and the electromagnetic field is a field, even though it also behaves like particles. Dirac I think never really changed his mind about this, and I believe that this was Feynman's understanding when he first developed the path integral and worked out his rules for calculating in quantum electrodynamics. When I first learned about the path-integral formalism, it was in terms of electron trajectories (as it is also presented in the book by Feynman and Hibbs[3]). I already thought that wasn't the best way to look at electrons, so this gave me an distaste for the path integral formalism, which although unreasonable lasted until I learned of 't Hooft's work[4] in 1971. I feel it's all right to mention autobiographical details like that as long as the story shows how the speaker was wrong.

In fact, it was quite soon after the Born–Heisenberg–Jordan paper of 1926 that the idea came along that in fact one could use quantum field theory for everything, not just for electromagnetism. This was the work of many theorists during the period 1928–1934, including Jordan, Wigner, Heisenberg, Pauli, Weisskopf, Furry, and Oppenheimer. Although this is often talked about as second quantization, I would like to urge that this description should be banned from physics, because a quantum field is not a quantized wave function. Certainly the Maxwell field is not

the wave function of the photon, and for reasons that Dirac himself pointed out, the Klein–Gordon fields that we use for pions and Higgs bosons could not be the wave functions of the bosons. In its mature form, the idea of quantum field theory is that quantum fields are the basic ingredients of the universe, and particles are just bundles of energy and momentum of the fields. In a relativistic theory the wave function is a functional of these fields, not a function of particle coordinates. Quantum field theory hence led to a more unified view of nature than the old dualistic interpretation in terms of both fields and particles.

There is an irony in this. (I'll point out several ironies as I go along — this whole subject is filled with delicious ironies.) It is that although the battle is over, and the old dualism that treated photons in an entirely different way from electrons is I think safely dead and will never return, some calculations are actually easier in the old particle framework. When Euler, Heisenberg and Kockel[5] in the mid-thirties calculated the effective action (often called the Euler–Heisenberg action) of a constant external electromagnetic field, they calculated to all orders in the field, although their result is usually presented only to fourth order. This calculation would probably have been impossible with the old fashioned perturbation theory techniques of the time, if they had not done it by first solving the Dirac equation in a constant external electromagnetic field and using those Dirac wave functions to figure out the effective action. These techniques of using particle trajectories rather than field histories in calculations have been revived in recent years. Under the stimulus of string theory, Bern and Kosower,[6] in particular, have developed a useful formalism for doing calculations by following particle world lines rather than by thinking of fields evolving in time. Although this approach was stimulated by string theory, it has been reformulated entirely within the scope of ordinary quantum field theory, and simply represents a more efficient way of doing certain calculations.

One of the key elements in the triumph of quantum field theory was the development of renormalization theory. I'm sure this has been discussed often here, and so I won't dwell on it. The version of renormalization theory that had been developed in the late 1940s remained somewhat in the shade for a long time for two reasons: (1) for the weak interactions it did not seem possible to develop a renormalizable theory, and (2) for the strong interactions it was easy to write down renormalizable theories, but since perturbation theory was inapplicable it did not seem that there was anything that could be done with these theories. Finally all these problems were resolved through the development of the standard model, which was triumphantly verified by experiments during the mid-1970s, and today the weak, electromagnetic and strong interactions are happily all described by a renormalizable quantum field theory. If you had asked me in the mid-1970s about the shape of future fundamental physical theories, I would have guessed that they would take the form of better, more all-embracing, less arbitrary, renormalizable quantum field theories. I gave a talk at the Harvard Science Center at around this time, called "The Renaissance of Quantum Field Theory," which shows you the mood I was in.

There were two things that especially attracted me to the ideas of renormalization and quantum field theory. One of them was that the requirement that a physical theory be renormalizable is a precise and rational criterion of simplicity. In a sense, this requirement had been used long before the advent of renormalization theory. When Dirac wrote down the Dirac equation in 1928 he could have added an extra 'Pauli' term[7] which would have given the electron an arbitrary anomalous magnetic moment. Dirac could (and perhaps did) say 'I won't add this term because it's ugly and complicated and there's no need for it.' I think that in physics this approach generally makes good strategies but bad rationales. It's often a good strategy to study simple theories before you study complicated theories because it's easier to see how they work, but the purpose of physics is to find out why nature is the way it is, and simplicity by itself is I think never the answer. But

renormalizability was a condition of simplicity which was being imposed for what seemed after Dyson's 1949 papers[8] like a rational reason, and it explained not only why the electron has the magnetic moment it has, but also (together with gauge symmetries) all the detailed features of the standard model of weak, electromagnetic, and strong, interactions, aside from some numerical parameters.

The other thing I liked about quantum field theory during this period of tremendous optimism was that it offered a clear answer to the ancient question of what we mean by an elementary particle: it is simply a particle whose field appears in the Lagrangian. It doesn't matter if it's stable, unstable, heavy, light — if its field appears in the Lagrangian then it's elementary, otherwise it's composite.[***]

Now my point of view has changed. It has changed partly because of my experience in teaching quantum field theory. When you teach any branch of physics you must motivate the formalism — it isn't any good just to present the formalism and say that it agrees with experiment — you have to explain to the students why this the way the world is. After all, this is our aim in physics, not just to describe nature, but to explain nature. In the course of teaching quantum field theory, I developed a rationale for it, which very briefly is that it is the only way of satisfying the principles of Lorentz invariance plus quantum mechanics plus one other principle.

Let me run through this argument very rapidly. The first point is to start with Wigner's definition of physical multi-particle states as representations of the inhomogeneous Lorentz group.[9] You then define annihilation and creation operators $a(\vec{p},\sigma,n)$ and $a^\dagger(\vec{p},\sigma,n)$ that act on these states (where $\vec{p}$ is the three-momentum, σ is the spin z-component, and n is a species label). There's no physics in introducing such operators, for it is easy to see that any operator whatever can be expressed as a functional of them. The existence of a Hamiltonian follows from time-translation invariance, and much of physics is described by the S-matrix, which is given by the well known Feynman–Dyson series of integrals over time of time-ordered products of the interaction Hamiltonian $H_I(t)$ in the interaction picture;

$$\begin{aligned} S &= \sum_{n=0}^{\infty} \frac{(-i)^n}{n!} \int_{-\infty}^{\infty} dt_1 \int_{-\infty}^{\infty} dt_2 \cdots \int_{-\infty}^{\infty} dt_n \\ &\quad \times T\{H_I(t_1)H_I(t_2)\cdots H_I(t_n)\} \,. \end{aligned} \tag{8.1}$$

This should all be familiar. The other principle that has to be added is the cluster decomposition principle, which requires that distant experiments give uncorrelated results.[10] In order to have cluster decomposition, the Hamiltonian is written not just as any functional of creation and annihilation operators, but as a power series in these operators with coefficients that (aside from a *single* momentum-conservation delta function) are sufficiently smooth functions of the momenta carried by the operators. This condition is satisfied for an interaction Hamiltonian of the form

$$H_I(t) = \int d^3x \; \mathcal{H}(\vec{x},t) \tag{8.2}$$

where $\mathcal{H}(x)$ is a power series (usually a polynomial) with terms that are local in annihilation fields, which are Fourier transforms of the annihilation operators:

$$\psi_\ell^{(+)}(x) = \int d^3p \; \sum_{\sigma,n} e^{ip\cdot x} u_\ell(\vec{p},\sigma,n)\, a(\vec{p},\sigma,n) \tag{8.3}$$

[***] We should not really give quantum field theory too much credit for clarifying the distinction between elementary and composite particles, because some quantum field theories exhibit the phenomenon of bosonization: At least in two dimensions there are theories of elementary scalars that are equivalent to theories with elementary fermions.

together of course with their adjoints, the creation fields.

So far this all applies to nonrelativistic as well as relativistic theories.[†] Now if you also want Lorentz invariance, then you have to face the fact that the time-ordering in the Feynman–Dyson series (1) for the S-matrix doesn't look very Lorentz invariant. The obvious way to make the S-matrix Lorentz invariant is to take the interaction Hamiltonian density $\mathcal{H}(x)$ to be a scalar, and also to require that these Hamiltonian densities commute at spacelike separations

$$[\mathcal{H}(x), \mathcal{H}(y)] = 0 \quad \text{for spacelike} \quad x - y \ , \tag{8.4}$$

in order to exploit the fact that time ordering *is* Lorentz invariant when the separation between spacetime points is timelike. In order to satisfy the requirement that the Hamiltonian density commute with itself at spacelike separations, it is constructed out of fields which satisfy the same requirement. These are given by sums of fields that annihilate particles plus fields that create the corresponding antiparticles

$$\begin{aligned} \psi_\ell(x) \ &= \ \sum_{\sigma,n} \int d^3p \left[e^{ip\cdot x}\, u_\ell(\vec{p},\sigma,n)\, a(\vec{p},\sigma,n) \right. \\ &\qquad \left. + e^{-ip\cdot x}\, v_\ell(\vec{p},\sigma,n)\, a^\dagger(\vec{p},\sigma,\bar{n}) \right] , \end{aligned} \tag{8.5}$$

where $\bar{n}$ denotes the antiparticle of the particle of species n. For a field ψ_ℓ that transforms according to an irreducible representation of the homogeneous Lorentz group, the form of the coefficients u_ℓ and v_ℓ is completely determined (up to a single over-all constant factor) by the Lorentz transformation properties of the fields and one-particle states, and by the condition that the fields commute at spacelike separations. Thus the whole formalism of fields, particles, and antiparticles seems to be an inevitable consequence of Lorentz invariance, quantum mechanics, and cluster decomposition, without any ancillary assumptions about locality or causality.

This discussion has been extremely sketchy, and is subject to all sorts of qualifications. One of them is that for massless particles, the range of possible theories is slightly larger than I have indicated here. For example, in quantum electrodynamics, in a physical gauge like Coulomb gauge, the Hamiltonian is not of the form (2) — there is an additional term, the Coulomb potential, which is bilocal and serves to cancel a non-covariant term in the propagator. But relativistically invariant quantum theories always (with some qualifications I'll come to later) do turn out to be quantum field theories, more or less as I have described them here.

One can go further, and ask why we should formulate our quantum field theories in terms of Lagrangians. Well, of course creation and annihilation operators by themselves yield pairs of canonically conjugate variables; from the as and $a^\dagger$s, it is easy to construct qs and ps. The time-dependence of these operators is dictated in terms of the Hamiltonian, the generator of time translations, so the Hamiltonian formalism is trivially always with us. But why the Lagrangian formalism? Why do we enumerate possible theories by giving their Lagrangians rather than by writing down Hamiltonians? I think the reason for this is that it is only in the Lagrangian formalism (or more generally the action formalism) that symmetries imply the existence of Lie algebras of suitable quantum operators, and you need these Lie algebras to make sensible quantum theories. In

[†]By the way, the reason that quantum field theory is useful even in nonrelativistic statistical mechanics, where there is often a selection rule that makes the actual creation or annihilation of particles impossible, is that in statistical mechanics you have to impose a cluster decomposition principle, and quantum field theory is the natural way to do so.

particular, the S-matrix will be Lorentz invariant if there is a set of 10 sufficiently smooth operators satisfying the commutation relations of the inhomogeneous Lorentz group. It's not trivial to write down a Hamiltonian that will give you a Lorentz invariant S-matrix — it's not so easy to think of the Coulomb potential just on the basis of Lorentz invariance — but if you start with a Lorentz invariant Lagrangian density then because of Noether's theorem the Lorentz invariance of the S-matrix is automatic.

Finally, what is the motivation for the special gauge invariant Lagrangians that we use in the standard model and general relativity? One possible answer is that quantum theories of mass zero, spin one particles violate Lorentz invariance unless the fields are coupled in a gauge invariant way, while quantum theories of mass zero, spin two particles violate Lorentz invariance unless the fields are coupled in a way that satisfies the equivalence principle.

This has been an outline of the way I've been teaching quantum field theory these many years. Recently I've put this all together into a book,[11] now being sold for a negligible price. The bottom line is that quantum mechanics plus Lorentz invariance plus cluster decomposition implies quantum field theory. But there are caveats that have to be attached to this, and I can see David Gross in the front row anxious to take me by the throat over various gaps in what I have said, so I had better list these caveats quickly to save myself.

First of all, the argument I have presented is obviously based on perturbation theory. Second, even in perturbation theory, I haven't stated a clear theorem, much less proved one. As I mentioned there are complications when you have things like mass zero, spin one particles for example; in this case you don't really have a fully Lorentz invariant Hamiltonian density, or even one that is completely local. Because of these complications, I don't know how even to state a general theorem, let alone prove it, even in perturbation theory. But I don't think that these are insuperable obstacles.

A much more serious objection to this not-yet-formulated theorem is that there's already a counter example to it: string theory. When you first learn string theory it seems in an almost miraculous way to give Lorentz invariant, unitary S-matrix elements without being a field theory in the sense that I've been using it. (Of course it is a field theory in a different sense — it's a two dimensional conformally invariant field theory, but not a quantum field theory in four spacetime dimensions.) So before even being formulated precisely, this theorem suffers from at least one counter example.

Another fundamental problem is that the S-matrix isn't everything. Spacetime could be radically curved, not just have little ripples on it. Also, at finite temperature there's no S-matrix because particles cannot get out to infinite distances from a collision without bumping into things. Also, it seems quite possible that at very short distances the description of events in four-dimensional flat spacetime becomes inappropriate.

Now, all of these caveats really work only against the idea that the final theory of nature is a quantum field theory. They leave open the view, which is in fact the point of view of my book, that although you can not argue that relativity plus quantum mechanics plus cluster decomposition necessarily leads only to quantum field theory, it is very likely that any quantum theory that at sufficiently low energy and large distances looks Lorentz invariant and satisfies the cluster decomposition principle will also at sufficiently low energy *look* like a quantum field theory. Picking up a phrase from Arthur Wightman, I'll call this a folk theorem. At any rate, this folk theorem is satisfied by string theory, and we don't know of any counterexamples.

This leads us to the idea of effective field theories. When you use quantum field theory to study low-energy phenomena, then according to the folk theorem you're not really making any assumption that could be wrong, unless of course Lorentz invariance or quantum mechanics or

cluster decomposition is wrong, provided you don't say specifically what the Lagrangian is. As long as you let it be the most general possible Lagrangian consistent with the symmetries of the theory, you're simply writing down the most general theory you could possibly write down. This point of view has been used in the last fifteen years or so to justify the use of effective field theories, not just in the tree approximation where they had been used for some time earlier, but also including loop diagrams. Effective field theory was first used in this way to calculate processes involving soft π mesons,[12] that is, π mesons with energy less than about $2\pi F_\pi \approx 1200$ MeV. The use of effective quantum field theories has been extended more recently to nuclear physics,[13] where although nucleons are not soft they never get far from their mass shell, and for that reason can be also treated by similar methods as the soft pions. Nuclear physicists have adopted this point of view, and I gather that they are happy about using this new language because it allows one to show in a fairly convincing way that what they've been doing all along (using two-body potentials only, including one-pion exchange and a hard core) is the correct first step in a consistent approximation scheme. The effective field theory approach has been applied more recently to superconductivity. Shankar, I believe, in a contribution to this conference is talking about this. The present educated view of the standard model, and of general relativity,[14] is again that these are the leading terms in effective field theories.

The essential point in using an effective field theory is you're not allowed to make any assumption of simplicity about the Lagrangian. Certainly you're not allowed to assume renormalizability. Such assumptions might be appropriate if you were dealing with a fundamental theory, but not for an effective field theory, where you must include all possible terms that are consistent with the symmetry. The thing that makes this procedure useful is that although the more complicated terms are not excluded because they're non-renormalizable, their effect is suppressed by factors of the ratio of the energy to some fundamental energy scale of the theory. Of course, as you go to higher and higher energies, you have more and more of these suppressed terms that you have to worry about.

On this basis, I don't see any reason why anyone today would take Einstein's general theory of relativity seriously as the foundation of a quantum theory of gravitation, if by Einstein's theory is meant the theory with a Lagrangian density given by just the term $\sqrt{g}R/16\pi G$. It seems to me there's no reason in the world to suppose that the Lagrangian does not contain all the higher terms with more factors of the curvature and/or more derivatives, all of which are suppressed by inverse powers of the Planck mass, and of course don't show up at any energy far below the Planck mass, much less in astronomy or particle physics. Why would anyone suppose that these higher terms are absent?

Likewise, since now we know that without new fields there's no way that the renormalizable terms in the standard model could violate baryon conservation or lepton conservation, we now understand in a rational way why baryon number and lepton number are as well conserved as they are, without having to assume that they are exactly conserved.[††] Unless someone has some *a priori* reason for exact baryon and lepton conservation of which I haven't heard, I would bet very strong odds that baryon number and lepton number conservation are in fact violated by suppressed non-renormalizable corrections to the standard model.

These effective field theories are non-renormalizable in the old Dyson power-counting sense. That is, although to achieve a given accuracy at any given energy, you need only take account of a finite number of terms in the action, as you increase the accuracy or the energy you need to include more and more terms, and so you have to know more and more. On the other hand, effective field

[††]The extra fields required by low-energy supersymmetry may invalidate this argument.

theories still must be renormalizable theories in what I call the modern sense: the symmetries that govern the action also have to govern the infinities, for otherwise there will be infinities that can't be eliminated by absorbing them into counter terms to the parameters in the action. This requirement is automatically satisfied for unbroken global symmetries, such as Lorentz invariance and isotopic spin invariance and so on. Where it's not trivial is for gauge symmetries. We generally deal with gauge theories by choosing a gauge before quantizing the theory, which of course breaks the gauge invariance, so it's not obvious how gauge invariance constrains the infinities. (There is a symmetry called BRST invariance[15] that survives gauge fixing, but that's non-linearly realized, and non-linearly realized symmetries of the action are not symmetries of the Feynman amplitudes.) This raises a question, whether gauge theories that are not renormalizable in the power counting sense are renormalizable in the modern sense. The theorem that says that infinities are governed by the same gauge symmetries as the terms in the Lagrangian was originally proved back in the old days by 't Hooft and Veltman[16] and Lee and Zinn-Justin[17] only for theories that are renormalizable in the old power-counting sense, but this theorem has only recently been extended to theories of the Yang–Mills[18] or Einstein type with arbitrary numbers of complicated interactions that are not renormalizable in the power-counting sense.[‡] You'll be reassured to know that these theories are renormalizable in the modern sense, but there's no proof that this will be true of all quantum field theories with local symmetries.

I promised you a few ironies today. The second one takes me back to the early 1960s when S-matrix theory was very popular at Berkeley and elsewhere. The hope of S-matrix theory was that, by using the principles of unitarity, analyticity, Lorentz invariance and other symmetries, it would be possible to calculate the S-matrix, and you would never have to think about a quantum field. In a way, this hope reflected a kind of positivistic puritanism: we can't measure the field of a pion or a nucleon, so we shouldn't talk about it, while we do measure S-matrix elements, so this is what we should stick to as ingredients of our theories. But more important than any philosophical hang-ups was the fact that quantum field theory didn't seem to be going anywhere in accounting for the strong and weak interactions.

One problem with the S-matrix program was in formulating what is meant by the analyticity of the S-matrix. What precisely are the analytic properties of a multi-particle S-matrix element? I don't think anyone ever knew. I certainly didn't know, so even though I was at Berkeley I never got too enthusiastic about the details of this program, although I thought it was a lovely idea in principle. Eventually the S-matrix program had to retreat, as described by Kaiser in a contribution to this conference, to a sort of mix of field theory and S-matrix theory. Feynman rules were used to find the singularities in the S-matrix, and then they were thrown away, and the analytic structure of the S-matrix with these singularities, together with unitarity and Lorentz invariance, was used to do calculations.

Unfortunately to use these assumptions it was necessary to make uncontrolled approximations, such as the strip approximation, whose mention will bring tears to the eyes of those of us who are old enough to remember it. By the mid-1960's it was clear that S-matrix theory had failed in dealing with the one problem it had tried hardest to solve, that of pion–pion scattering. The strip approximation rested on the assumption that double dispersion relations are dominated by regions of the Mandelstam diagram near the fringes of the physical region, which would only make sense if π–π scattering is strong at low energy, and these calculations predicted that π–π scattering is indeed strong at low energy, which was at least consistent, but it was then discovered that π–π

[‡]I refer here to work of myself and Joaquim Gomis,[19] relying on recent theorems about the cohomology of the Batalin–Vilkovisky operator by Barnich, Brandt, and Henneaux.[20] Earlier work along these lines but with different motivation was done by Voronov, Tyutin, and Lavrov;[21] Anselmi;[22] and Harada, Kugo, and Yamawaki.[23]

scattering is *not* strong at low energy. Current algebra came along at just that time, and was used to predict not only that low energy π-π scattering is not strong, but also successfully predicted the values of the π–π scattering lengths.[24] From a practical point of view, this was the greatest defeat of S-matrix theory. The irony here is that the S-matrix philosophy is not that far from the modern philosophy of effective field theories, that what you should do is just write down the most general S-matrix that satisfies basic principles. But the practical way to implement S-matrix theory is to use an effective quantum field theory — instead of deriving analyticity properties from Feynman diagrams, we use the Feynman diagrams themselves. So here's another answer to the question of what quantum field theory is: it is S-matrix theory, made practical.

By the way, I think that the emphasis in S-matrix theory on analyticity as a fundamental principle was misguided, not only because no one could ever state the detailed analyticity properties of general S-matrix elements, but also because Lorentz invariance requires causality (because as I argued earlier otherwise you're not going to get a Lorentz invariant S-matrix), and in quantum field theory causality allows you to derive analyticity properties. So I would include Lorentz invariance, quantum mechanics and cluster decomposition as fundamental principles, but not analyticity.

As I have said, quantum field theories provide an expansion in powers of the energy of a process divided by some characteristic energy; for soft pions this characteristic energy is about a GeV; for superconductivity it's the Debye frequency or temperature; for the standard model it's 10^{15} to 10^{16} GeV; and for gravitation it's about 10^{18} GeV. Any effective field theory loses its predictive power when the energy of the processes in question approaches the characteristic energy. So what happen to the effective field theories of electroweak, strong, and gravitational interactions at energies of order 10^{15}–10^{18} GeV? I know of only two plausible alternatives.

One possibility is that the theory remains a quantum field theory, but one in which the finite or infinite number of renormalized couplings do not run off to infinity with increasing energy, but hit a fixed point of the renormalization group equations. One way that can happen is provided by asymptotic freedom in a renormalizable theory,[25] where the fixed point is at zero coupling, but it's possible to have more general fixed points with infinite numbers of non-zero nonrenormalizable couplings. Now, we don't know how to calculate these non-zero fixed points very well, but one thing we know with fair certainty is that the trajectories that run into a fixed point in the ultraviolet limit form a finite dimensional subspace of the infinite dimensional space of all coupling constants. (If anyone wants to know how we know that, I'll explain this later.) That means that the condition, that the trajectories hit a fixed point, is just as restrictive in a nice way as renormalizability used to be: It reduces the number of free coupling parameters to a finite number. We don't yet know how to do calculations for fixed points that are not near zero coupling. Some time ago I proposed[26] that these calculations could be done in the theory of gravitation by working in $2+\epsilon$ dimensions and expanding in powers of $\epsilon = 2$, in analogy with the way that Wilson and Fisher[27] had calculated critical exponents by working in $4-\epsilon$ dimensions and expanding in powers of $\epsilon = 1$, but this program doesn't seem to be working very well.

The other possibility, which I have to admit is *a priori* more likely, is that at very high energy we will run into really new physics, not describable in terms of a quantum field theory. I think that by far the most likely possibility is that this will be something like a string theory.

Before I leave the renormalization group, I did want to say another word about it because there's going to be an interesting discussion on this subject here tomorrow morning, and for reasons I've already explained I can't be here. I've read a lot of argument about the Wilson approach[28] vs. the Gell-Mann–Low approach,[29] which seems to me to call for reconciliation. There have been two fundamental insights in the development of the renormalization group. One, due to Gell-Mann and Low, is that logarithms of energy that violate naive scaling and invalidate perturbation theory arise

because of the way that renormalized coupling constants are defined, and that these logarithms can be avoided by renormalizing at a sliding energy scale. The second fundamental insight, due to Wilson, is that it's very important in dealing with phenomena at a certain energy scale to integrate out the physics at much higher energy scales. It seems to me these are the same insight, because when you adopt the Gell-Mann–Low approach and define a renormalized coupling at a sliding scale and use renormalization theory to eliminate the infinities rather than an explicit cutoff, you are in effect integrating out the higher energy degrees of freedom — the integrals converge because after renormalization the integrand begins to fall off rapidly at the energy scale at which the coupling constant is defined. (This is true whether or not the theory is renormalizable in the power-counting sense.) So in other words instead of a sharp cutoff *a la* Wilson, you have a soft cutoff, but it's a cutoff nonetheless and it serves the same purpose of integrating out the short distance degrees of freedom. There are practical differences between the Gell-Mann–Low and Wilson approaches, and there are some problems for which one is better and other problems for which the other is better. In statistical mechanics it isn't important to maintain Lorentz invariance, so you might as well have a cutoff. In quantum field theories, Lorentz invariance is necessary, so it's nice to renormalize *a la* Gell-Mann–Low. On the other hand, in supersymmetry theories there are some non-renormalization theorems that are simpler if you use a Wilsonian cutoff than a Gell-Mann–Low cutoff.[30] These are all practical differences, which we have to take into account, but I don't find any fundamental philosophical difference between these two approaches.

On the plane coming here I read a comment by Michael Redhead, in a paper submitted to this conference: 'To subscribe to the new effective field theory programme is to give up on this endeavor' [the endeavor of finding really fundamental laws of nature], 'and retreat to a position that is somehow less intellectually exciting.' It seems to me that this is analogous to saying that to balance your checkbook is to give up dreams of wealth and have a life that is intrinsically less exciting. In a sense that's true, but nevertheless it's still something that you had better do every once in a while. I think that in regarding the standard model and general relativity as effective field theories we're simply balancing our checkbook and realizing that we perhaps didn't know as much as we thought we did, but this is the way the world is and now we're going to go on the next step and try to find an ultraviolet fixed point, or (much more likely) find entirely new physics. I have said that I thought that this new physics takes the form of string theory, but of course, we don't know if that's the final answer. Nielsen and Oleson[31] showed long ago that relativistic quantum field theories can have string-like solutions. It's conceivable, although I admit not entirely likely, that something like modern string theory arises from a quantum field theory. And that would be the final irony.

8.7.10 Connection of Particles and Fields 1

От поля к частице

В предыдущей главе для свободной теории мы получили выражение

$$W(J) = -\frac{1}{2}\iint d^4x d^4y J(x) D(x-y) J(y)$$

которое мы сейчас запишем через преобразование Фурье $J(k) \equiv \int d^4x e^{-ikx} J(x)$

$$W(J) = -\frac{1}{2}\int \frac{d^4k}{(2\pi)^4} J(k)^* \frac{1}{k^2 - m^2 + i\varepsilon} J(k).$$

(Заметим, что $J(k)^* = J(-k)$ для вещественного $J(x)$.)

Мы можем как угодно прыгать на матраце вверх-вниз. Иными словами, мы можем выбирать любой $J(x)$ и, используя эту свободу выбора, получать большое количество физической информации.

Рассмотрим $J(x) = J_1(x) + J_2(x)$, где $J_1(x)$ и $J_2(x)$ сосредоточены в двух локальных областях 1 и 2 пространства-времени (рис. I.4.1). Тогда $W(J)$ содержит четыре члена вида $J_1^* J_1$, $J_2^* J_2$, $J_1^* J_2$ и $J_2^* J_1$. Рассмотрим два последних членах, один из которых имеет следующую форму:

$$W(J) = -\frac{1}{2}\int \frac{d^4k}{(\pi)^4} J_2(k)^* \frac{1}{k^2 - m^2 + i\varepsilon} J_1(k).$$

Мы видим, что $W(J)$ является большим только тогда, когда фурье-компоненты $J_1(x)$ и $J_2(x)$ значительно перекрываются и когда в области перекрытия в импульсном пространстве член $k^2 - m^2$ близок к нулю. В точке $k^2 = m^2$ существует пик «резонансного типа», при этом выполняется соотношение энергии и импульса для частицы массой m. (Мы будем пользоваться языком, принятым в теории относительности, и писать «импульсное пространство», вместо «пространство энергии-импульса», переходя на нерелятивистский язык только тогда, когда того требует контекст, как, например, в случае словосочетания «соотношение энергии-импульса».)

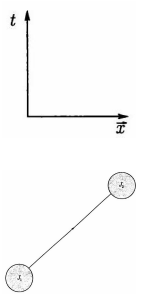

Рис. I.4.1

Итак, мы интерпретируем физические свойства, содержащиеся в нашей простой теории поля, следующим образом: источник в области 1 пространства-времени создает «возмущение поля», которое позднее поглощается стоком в области 2 пространства-времени. Экспериментаторы предпочитают называть это возмущением поля частицей с массой m. Наше предположение, основанное на уравнении движения, о том, что теория содержит частицу массой m, нашло свое подтверждение.

Немного жаргона: при $k^2 = m^2$ говорят, что k находится на массовой поверхности. Заметьте, однако, что в (3) мы интегрировали по всем k, включая k, удаленные от массовой оболочки. Для произвольного k удобно говорить о «виртуальной частице» с импульсом k, распространяющейся от источника к стоку.

От частицы к силе

Продолжим исследовать другие возможности для $J(x)$ (которые мы обобщенно будем называть источниками), например, $J(x) = J_1(x) + J_2(x)$, где $J_a(x) = \delta^{(3)}(\vec{x} - \vec{x}_a)$. Иначе говоря, $J(x)$ есть сумма источников, яв- ляющихся стационарными бесконечно острыми пиками, расположенными в $\vec{x}_1$ и $\vec{x}_2$ в пространстве. (Если вам нужна большая математическая точность, чем предлагается здесь, замените дельта-функцию функциями с

пиками в $\vec{x}_a$. Правда, этим вы лишь загромоздите формулы, не добившись ничего существенного.) Образно выражаясь, мы описываем два массивных сгустка, расположенных на матраце в $\vec{x}_1$ и являющихся абсолютно неподвижными [в $J(x)$ нет временной зависимости].

Что квантовые флуктуации поля φ, то есть вибрации матраца, делают с двумя массами, находящимися на матраце? Если вы считаете, что между этим массами существует взаимное притяжение, то вы совершенно правы.

Как и прежде, $W(J)$ содержит четыре члена. Мы пренебрежем членом «самодействия» $J_1 J_1$, так как он присутствовал бы в W вне зависимости от присутствия J_2. Нас интересует взаимодействие между двумя «массивными сгустками», представленными посредством J_1 и J_2. Аналогично мы пренебрегаем членом $J_2 J_2$.

Подставляя в (1) и вычисляя интеграл по d^3x и d^3y, мы немедленно получаем

$$W(J) = -\iint dx^0 dy^0 \int \frac{dk^0}{2\pi} e^{ik^0(x-y)^0} \int \frac{d^3k}{(2\pi)^3} \frac{e^{i\vec{k}} \cdot (\vec{x}_1 - \vec{x}_2)}{k^2 - m^2 + i\varepsilon}$$

(Множитель 2 обусловлен двумя членами $J_2 J_1$ и $J_1 J_2$.) Интегрируя по y^0, получаем дельта-функцию, которая обнуляет k^0 (так что, если говорить на жаргонном языке, k определенно не находится на массовой поверхности). Итак, мы остаемся с

$$W(J) = \left(\int dx^0 \right) \int \frac{d^3k}{(2\pi)^3} \frac{e^{i\vec{k}\cdot(\vec{x}_1 - \vec{x}_2)}}{\vec{k}^2 + m^2}$$

Обратите внимание, что бесконечно малое $i\varepsilon$ можно опустить, поскольку знаменатель $\vec{k}^2 + m^2$ всегда положителен.

Множитель $\left(\int dx^0 \right)$ может вселить в нас ужас и тревогу: интеграл по времени кажется бесконечным. Не бойтесь! Вспомним, что в формализме интеграла по траекториям $Z = \mathcal{C} e^{iW(J)}$ представляет собой $\left\langle 0 \left| e^{-iHT} \right| 0 \right\rangle = e^{-iET}$, где E - энергия, обусловленная двумя источниками, воздействующими друг на друга. Множитель $\left(\int dx^0 \right)$ дает в точности временной интервал T. Все в порядке. Подставляя $iW = -iET$, из (5) получаем

$$E = -\int \frac{d^3k}{(2\pi)^3} \frac{e^{i\vec{k}\cdot(\vec{x}_1 - \vec{x}_2)}}{\vec{k}^2 + m^2}$$

Эта энергия отрицательна! Наличие двух дельта-функциональных источников в $\vec{x}_1$ и $\vec{x}_2$ уменьшило энергию. Иными словами, два источника притягивают друг друга в силу их взаимодействия с полем φ. Мы добились первого физического результата в квантовой теории поля!

Величина E отождествляется с потенциальной энергией между двумя статическими источниками. Даже без вычисления интеграла видно, что с увеличением расстояния $\vec{x}_1 - \vec{x}_2$ между источниками осциллирующая экспонента обрезает интеграл. Характерное расстояние является обратным характерному значению k, равному m. Итак, можно ожидать, что взаимодействие между двумя источниками быстро убывает до нуля на расстоянии $1/m$.

Радиус действия силы притяжения, порождаемой полем φ, определяется обратной массой m частицы, описываемой полем. Это понятно?

Интеграл вычисляется в приложении к этой главе, в итоге получаем

$$E = -\frac{1}{4\pi r} e^{-mr}$$

Результат вполне ожидаемый: потенциал убывает экспоненциально на масштабе расстояний $1/m$. Очевидно, $dE/dr > 0$: две расположенные на матраце массы могут уменьшить энергию, приближаясь друг к другу.

Вывод, к которому мы пришли, явился одним из наиболее выдающихся результатов в физике двадцатого века. Юкава предположил, что взаимодействие между нуклонами в атомном ядре обусловлено взаимодействием с полем, подобным вышеописанному полю φ. Известный радиус действия ядерных сил позволил ему не только предсказать существование частицы, ассоциированной с этим полем и называемой ныне π-мезоном [1] или пионом, но также определить ее массу. Как вам, вероятно, известно, в итоге было установлено, что пион наделен свойствами, в значительной степени совпадающими с предсказанными Юкавой.

Происхождение силы

Тот факт, что обмен частицей порождает силу, явился одним из наиболее значительных концептуальных достижений в физике. Сейчас мы ассоциируем частицу с каждой из известных нам сил: например, фотон с электромагнитной силой, а гравитон с гравитационной силой; первое утверждеиис однозначно подтверждается экспериментально, второе - пока никто не

1r) тимология этого слова довольно интересна. (A. Zee. Fearful Symmetry: читайте стр. 169 II 335, чтобы узнать, наряду с другими вещами, о возражении французов и связи между мезопом и иллюзией.) подтвердил опытным путем, но вряд ли кто-то сомневается в его истинности. Фотон и гравитон мы рассмотрим в следующей главе, но уже сейчас мы может ответить на вопрос, который очень любят задавать сообразительные школьники: почему гравитационная сила Ньютона и электрическая сила Кулона подчиняются закону $1/r^2$.

Из (7) видно, что если масса m промежуточной частицы равна нулю, возникающая сила будет подчиняться закону $1/r^2$. Прослеживая обратно наш вывод, видим, что это следует из того факта, что плотность лагранжиана для простейшей теории поля содержит пространственно-временную производную ∂ второй степени (так как любой член, включающий одну производную, не является лоренц-инвариантным). В самом деле, степенная зависимость потенциала следует из анализа размерностей: $\int d^3k \left(e^{i\vec{k}\cdot\vec{x}}/k^2\right) \sim 1/r$

8.7.11 Connection of Particles and Fields 2

(two sections, since it is a conceptually important question, so there will be a lot to write)

Связанные против несвязанных

В заключение сделаем несколько формальных замечаний, которые будут важны для нас только в главе I.7. Во-первых, обратите внимание, что мы могли нарисовать небольшой рисунок (рис. I.4.2) для иллюстрации подынтегрального выражения $J(x)D(x - -y)J(y)$ в $W(J)$: возмущение распространяется из точки x в точку y (или наоборот).

Рис. I.4.2

В действительности это начало фейнмановских диаграмм! Во-вторых, вспомним, что

$$Z(J) = Z(J=0)\sum_{n=0}^{\infty}\frac{[(iW(J))^n]}{n!}$$

Например, член с $n=2$ в $Z(J)/Z(J=0)$ определяется выражением

$$\frac{1}{2!}\left(-\frac{i}{2}\right)^2 \iiint\int d^4x_1 d^4x_2 d^4x_3 d^4x_4 D\left(x_1-x_2\right)\times$$
$$\times D\left(x_3-x_4\right) J\left(x_1\right) J\left(x_2\right) J\left(x_3\right) J\left(x_4\right).$$

Подынтегральное выражение графически представлено на рисунке I.4.3. Этот процесс называется несвязанным: распространение из x_1 в x_2 и из x_3 в x_4 происходит независимо. Мы вернемся к вопросу о разнице между связанными и несвязанными диаграммами в главе I.7.

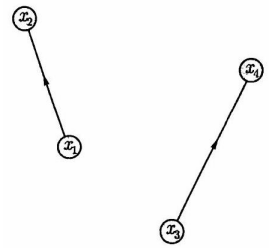

Рис. I.4.3

Приложение

С учетом того, что $\vec{x} \equiv (\vec{x}_1 - \vec{x}_2)$ и $u \equiv \cos\theta$, где θ - угол между $\vec{k}$ и $\vec{x}$, вычисляем интеграл в (6) в сферических координатах (с $k = |\vec{k}|$ и $r = |\vec{x}|$) и получаем

$$I \equiv \frac{1}{(2\pi)^2}\int_0^{\infty} dk k^2 \int_{-1}^{+1} du \frac{e^{ikru}}{k^2+m^2} = \frac{2i}{(2\pi)^2 ir}\int_0^{\infty} dk k \frac{\sin kr}{k^2+m^2}$$

Так как подынтегральное выражение четно, можно расширить область интегрирования и записать

$$\frac{1}{2}\int_{-\infty}^{\infty} dk k \frac{\sin kr}{k^2+m^2} = \frac{1}{2i}\int_{-\infty}^{\infty} dk k \frac{1}{k^2+m^2} e^{ikr}$$

Поскольку r положительно, можно замкнуть контур в верхней полуплоскости, чтобы включить полюс в $+im$, получая тем самым $(1/2i)(2\pi i)(im/2im)e^{-mr} = (\pi/2)e^{-mr}$. Итак, $I = (1/4\pi r)e^{-mr}$.

Упражнение

I.4.1. Вычислите аналог закона обратных квадратов в $(2+1)$-мерной Вселенной и в более общем случае в $(D+1)$-мерной Вселенной.

8.8 World of Quantum Fields

8.8.1 Concept of Mass

(??? discussion what is mass?)

8.8.2 Forces in Scope of QFT

(discuss, what is it in general???)

Обход понятия силы в квантовой теории поля (!??!?)

Чем мы заменяем понятие “сила”?

8.8.3 Deriving Coulomb’s Law from QFT

What is a force at all?

(this argument that it is a field, so on... (???? is it a really good argument??))

Почему одноименные заряды отталкиваются

Мы предположили, что квантовая теория поля дает естественное объяснение как гравитационной силе Ньютона, так и электрической силе Кулона. Между подобными объектами ньютоновская сила является притягивающей, а кулоновская - отталкивающей. Является ли квантовая теория поля «достаточно умной», чтобы объяснить этот наблюдаемый факт - один из основополагающих в нашем понимании физической Вселенной? Делайте ставки!

Вначале мы рассмотрим квантовую теорию электромагнитного поля, известную как квантовая электродинамика, или сокращенно КЭД. Чтобы на этом этапе избежать сложностей, связанных с калибровочной инвариантностью (подробнее о ней позже), рассмотрим теорию массивного мезона со спином 1, или векторного мезона. В конце концов, все, что нам известно экспериментально, - это верхняя граница массы фотона, которая, хотя и маленькая, не является нулем с математической точки зрения. Можно встать на прагматическую позицию: проводить вычисления с массой фотона m, в конце положить $m = 0$ и, если результат окажется разумным, считать, что все ОК[1].

Вспомним максвелловский лагранжиан для электромагнетизма $\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$, где $F_{\mu\nu} \equiv \partial_\mu A_\nu - \partial_\nu A_\mu$ с векторным потенциалом $A_\mu(x)$. Причину появления важного общего знака «минус» в лагранжиане можно понять, если посмотреть на коэффициент при $(\partial_0 A_i)^2$, который должен быть положительным, как и коэффициент при $(\partial_0\varphi)^2$ в лагранжиане для

скалярного поля. Это просто означает, что вариация по времени приводит к положительному изменению действия.

'Когда. будучи студентом, я слушал курс квантовой теории поля Сиднея Коулмена. он трактовал КЭД именно таким образом. чтобы избегать обсуждения калибровочной инвариантности. Сейчас наделим фотон небольшой массой, изменив лагранжиан на $\mathcal{L} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}m^2A_\mu A^\mu + A_\mu J^\mu$. (Массовый член мы записали по аналогии с массовым членом $m^2\varphi^2$ в лагранжиане скалярного поля; впоследствии станет очевидным, что это на самом деле масса фотона.) Я также добавил источник $J^\mu(x)$, который в этом случае более известен как ток. Будем предполагать, что ток сохраняется, то есть $\partial_\mu J^\mu = 0$.

Итак, вы знаете, что теория поля нашего векторного мезона определяется интегралом по траекториям $Z = \int DAe^{iS(A)} \equiv e^{iW(J)}$ с действием

$$S(A) = \int d^4x\mathcal{L} = \int d^4x \left\{A_\mu \left[\left(\partial^2 + m^2\right) g^{\mu\nu} - \partial^\mu\partial^\nu\right] A_\nu + A_\mu J^\mu\right\}$$

Ко второму равенству приходим путем интегрирования по частям [сравните с (I.3.15)].

Надо просто применить уравнение (I.3.16). Для этого всего лишь нужно обратить дифференциальный оператор в квадратных скобках; другими словами, необходимо решить уравнение

$$\left[\left(\partial^2 + m^2\right) g^{\mu\nu} - \partial^\mu\partial^\nu\right] D_{\nu\lambda}(x) = \delta^\mu_\lambda\delta^{(4)}(x)$$

Как и раньше [сравните с (I.3.17)], переходим в импульсное пространство, определяя

$$D_{\nu\lambda}(x) = \int \frac{d^4k}{(2\pi)^4} D_{\nu\lambda}(k)e^{ikx}$$

Подставим последнее выражение в (2) и получим $\left[-\left(k^2 - m^2\right) g^{\mu\nu} + \ + k^\mu k^\nu\right] D_{\nu\lambda}(k) = \delta^\mu_\lambda$, в итоге найдем

$$D_{\nu\lambda}(k) = \frac{-g_{\nu\lambda} + k_\nu k_\lambda/m^2}{k^2 - m^2}$$

Это и есть пропагатор фотона или, точнее, массивного векторного мезона. Таким образом

$$W(J) = -\frac{1}{2}\int \frac{d^4k}{(2\pi)^4} J^\mu(k)^* \frac{-g_{\mu\nu} + k_\mu k_\nu/m^2}{k^2 - m^2 + i\varepsilon} J^\nu(k)$$

Так как закон сохранения тока $\partial_\mu J^\mu(x) = 0$, сформулированный для импульсного пространства, имеет вид $k_\mu J^\mu(k) = 0$, мы можем опустить член $k_\mu k_\nu$ в фотонном пропагаторе. Эффективное действие при этом упрощается до

$$W(J) = \frac{1}{2}\int \frac{d^4k}{(2\pi)^4} J^\mu(k)^* \frac{1}{k^2 - m^2 + i\varepsilon} J_\mu(k).$$

Никаких вычислений больше не требуется для получения фундаментального результата. Просто сравним его с (I.4.2). Теория поля привела к дополнительному знаку «минус». Потенциальная энергия между двумя сгустками с плотностью заряда $J^0(x)$ положительна. Электромагнитная сила между одноименными зарядами является отталкивающей.

В силу закону сохранения тока мы можем теперь спокойно положить массу фотона m равной 0. [Обратите внимание, что мы не могли этого сделать в (3).] В самом деле,

обратившись к (I.4.7) мы видим, что потенциальная энергия между одноименными зарядами равна

$$E = \frac{1}{4\pi r} e^{-mr} \to \frac{1}{4\pi r}.$$

Чтобы включить положительные и отрицательные заряды, можно просто записать $J_p^\mu - J_n^\mu$. Мы видим, что сгусток с плотностью заряда J_p^0 притягивается к сгустку с плотностью заряда J_n^0.

Идем в обход Максвелла

Покончив с электромагнетизмом за две минуты, перейду теперь к гравитации. Обратимся к массивному мезонному полю со спином 2. При анализе массивного мезонного поля со спином 1 я двигался кратчайшим путем. Предположил, что вы знакомы с максвелловским лагранжианом, просто добавил к нему массовый член и начал вычисления. Однако я сомневаюсь, что вы столь же хорошо знакомы с соответствующим лагранжианом для массивного поля со спином 2. (Так называемый линеаризованный эйнштейновский лагранжиан, речь о котором пойдет в следующей главе.) Поэтому сейчас я прибегну к другой стратегии.

Давайте, рассуждая физически, вместе получим пропагатор массивного поля со спином 2. Для начала рассмотрим массивное поле со спином 1. Фактически мы начнем с нечто еще более простого: с пропагатора $D(k) = 1/(k^2 - m^2)$ массивного поля со спином 0. Он соответствует ситуации, когда амплитуда распространения возмущения со спином 0 устремляется к бесконечности, когда возмущение - почти реальная частица. Вычет в полюсе определяется свойствами частицы. Пропагатор для поля со спином $1 D_{\nu\lambda}$ имеет пару лоренцевых индексов, и мы действительно можем получить его форму из выражения (3):

$$D_{\nu\lambda}(k) = \frac{-G_{\nu\lambda}}{k^2 - m^2}$$

где для дальнейшего удобства введено обозначение

$$G_{\nu\lambda}(k) \equiv g_{\nu\lambda} - \frac{k_\nu k_\lambda}{m^2}$$

Теперь попробуем объяснить физику, скрывающуюся за $G_{\nu\lambda}$. Я надеюсь, вы помните понятие поляризации из курса электромагнетизма. Массивная частица со спином 1 имеет три степени поляризации по той простой причине, что в собственной системе покоя вектор ее спина может быть направлен по трем разным направлениям. Эти три вектора поляризации $\varepsilon_\mu^{(a)}$ являются просто тремя единичными векторами, направленными вдоль осей x, y и z соответственно, $(a = 1, 2, 3) : \varepsilon_\mu^{(1)} = (0, 1, 0, 0), \varepsilon_\mu^{(2)} = (0, 0, 1, 0), \varepsilon_\mu^{(3)} = (0, 0, 0, 1)$. В системе покоя $k^\mu = (m, 0, 0, 0)$, и поэтому

$$k^\mu \varepsilon_\mu^{(a)} = 0$$

Поскольку мы пришли к лоренц-инвариантному уравнению, оно также верно для движущейся частицы со спином 1. Действительно, вместе с подходящим условием нормировки оно фиксирует три вектора поляризации $\varepsilon_\mu^{(a)}(k)$ для частицы с импульсом k.

Амплитуда рождения источником частицы с импульсом k и поляризацией a пропорциональна $\varepsilon_\lambda^{(a)}(k)$, а амплитуда поглощения ее в стоке пропорциональна $\varepsilon_\nu^{(a)}(k)$.

Чтобы получить амплитуду распространения частицы от источника до стока, необходимо перемножить эти амплитуды и затем просуммировать по трем возможным поляризациям. Становится понятным смысл вычета в полюсе пропагатора частицы со спином $1 D_{\nu\lambda}$: он представляет собой $\sum_a \varepsilon_\nu^{(a)}(k)\varepsilon_\lambda^{(a)}(k)$. Чтобы вычислить эту величину, заметим, что в силу лоренц-инвариантности она может выражаться лишь линейной комбинацией $g_{\nu\lambda}$ и $k_\nu k_\lambda$. Условие $k^\mu \varepsilon_\mu^{(a)} = 0$ фиксирует эту комбинацию как $g_{\nu\lambda} - k_\nu k_\lambda / m^2$. Вычислив левую часть выражения для k, находящегося в состоянии покоя, при, скажем, $\nu = \lambda = 1$, мы придем к общему знаку -1, который имеет принципиальное значение. Таким образом:

$$\sum_a \varepsilon_\nu^{(a)}(k)\varepsilon_\lambda^{(a)}(k) = -G_{\nu\lambda}(k) \equiv -\left(g_{\nu\lambda} - \frac{k_\nu k_\lambda}{m^2}\right)$$

Итак, мы построили пропагатор частицы со спином 1, двигаясь в обход Максвелла. А теперь перейдем к спину 2 ! Попробуем аналогичным образом пойти в обход Эйнштейна.

Все механические силы имеют только электромагнитную природу

(????????????? why????)

Появление силы трения из КТП (???)

(вряд ли скоро отвечу на этот вопрос)

Other about derivation of Coulomb's Law from QFT

How can we understand other interactions if we don't have force in our equations?

(?? is there a generalization of a force??? for QCD, for week interactions??)

Is force a fundamental concept?

(?? I'll think later??)

8.8.4 Deriving Newton's Law from QFT (??)

Идем в обход Эйнштейна

Массивная частица со спином 2 имеет $5 (2 \cdot 2 + 1 = 5$, помните?) степеней поляризации, характеризуемых пятью тензорами поляризации $\varepsilon_{\mu\nu}^{(a)}$ $(a = 1, 2, ..., 5)$, симметричными относительно индексов μ и ν и удовлетворяющими

$$k^\mu \varepsilon_{\mu\nu}^{(a)} = 0$$

а также условию нулевого следа

$$g^{\mu\nu} \varepsilon_{\mu\nu}^{(a)} = 0$$

Проверим выполнимость условий. Симметричный лоренцевский тензор имеет $4 \cdot 5/2 = 10$ компонент. Четыре условия (11) и одно условие (12) сокращают число компонент до

$10-4-1=5$, а нам только этого и надо. (И еще немного жаргона: помните ли вы, как построить неприводимое представление группы? Если нет, читайте приложение B.) Мы фиксируем нормировку $\varepsilon_{\mu\nu}$, полагая, что положительная величина $\sum\limits_a \varepsilon_{12}^{(a)}(k)\varepsilon_{12}^{(a)}(k)=1$.

Итак, по аналогии со случаем частицы спина 1, определим $\sum\limits_a \varepsilon_{\mu\nu}^{(a)}(k)\varepsilon_{\lambda\sigma}^{(a)}(k)$. Для этого необходимо выразить этот объект через $g_{\mu\nu}$ и k_μ, или, что эквивалентно, через $G_{\mu\nu}$ и k_μ. Объект должен представлять собой линейную комбинацию $G_{\mu\nu}G_{\lambda\sigma}, G_{\mu\nu}k_\lambda k_\sigma$, и т. д. Используя (11) и (12) (упр. I.5.1), вы легко придете к выражению

$$\sum_a \varepsilon_{\mu\nu}^{(a)}(k)\varepsilon_{\lambda\sigma}^{(a)}(k)=(G_{\mu\lambda}G_{\nu\sigma}+G_{\mu\sigma}G_{\nu\lambda})-\frac{2}{3}G_{\mu\nu}G_{\lambda\sigma}$$

Общий знак и коэффициент пропорциональности определяются из вычисления обеих частей данного равенства при, например, $\mu=\lambda=1$ и $\nu=\sigma=2$. Таким образом, мы нашли пропагатор массивной частицы со спином 2

$$D_{\mu\nu,\lambda\sigma}(k)=\frac{(G_{\mu\lambda}G_{\nu\sigma}+G_{\mu\sigma}G_{\nu\lambda})-\frac{2}{3}G_{\mu\nu}G_{\lambda\sigma}}{k^2-m^2}$$

Почему мь падаем?

Мы уже в состоянии объяснить одну из фундаментальных тайн Вселенной: почему массы притягиваются.

Вспомним из курсов электродинамики и специальной теории относительности, что плотность энергии или массы является частью тензора энергии импульса $T^{\mu\nu}$. Для наших целей вам фактически нужно помнить лишь то, что это симметричный тензор и что его компонента T^{00} является плотностью энергии.

Для взаимодействия с тензором энергии импульса необходимо тензорное поле $\varphi_{\mu\nu}$, симметричное по своим индексам. Другими словами, лагранжиан Вселенной должен содержать член вида $\varphi_{\mu\nu}T^{\mu\nu}$. Фактически это и означает, что гравитон - частица, ответственная за гравитацию, имеет спин 2, точно так же, как фотон - частица, ответственная за электромагнетизм и взаимодействующая с током J^μ, - имеет спин 1. В теории Эйнштейна, которую мы будем обсуждать позднее, $\varphi_{\mu\nu}$ является, конечно же, частью метрического тензора.

Подобно тому как мы наделяли фотон маленькой массой для того, чтобы избежать обсуждения калибровочной инвариантности, мы предположим, что гравитон имеет малую массу, уклоняясь тем самым от обсуждения общей координатной инвариантности [2]. Ага, мы только что получили пропагатор массивной частицы со спином 2. Посмотрим, как он работает. По аналогии с выражением (4)

$$W(J)=-\frac{1}{2}\int\frac{d^4k}{(2\pi)^4}J^\mu(k)^*\frac{-g_{\mu\nu}+k_\mu k_\nu/m^2}{k^2-m^2+i\varepsilon}J^\nu(k)$$

описывающим взаимодействие двух электромагнитных токов, взаимодействие между двумя сгустками энергии импульса описывается формулой

$$W(T)=-\frac{1}{2}\int\frac{d^4k}{(2\pi)^4}T^{\mu\nu}(k)^*\frac{(G_{\mu\lambda}+G_{\mu\sigma}G_{\nu\lambda})-\frac{2}{3}G_{\mu\nu}G_{\lambda\sigma}}{k^2-m^2+i\varepsilon}T^{\lambda\sigma}(k).$$

[2] В настоящий момент я прошу вас пренебречь нюансами и просто предположить, что для осмысления гравитации стоит положить $m \to 0$. Подробнее я остановлюсь на теории гравитации Эйнштейна в главе VIII.1. Закон сохранения энергии-импульса $\partial_\mu T^{\mu\nu}(x) = 0$ и, следовательно, $k_\mu T^{\mu\nu}(k) = 0$ позволяет заменить $G_{\mu\nu}$ в (16) на $g_{\mu\nu}$.

Наступает момент истины. Взглянем на взаимодействие двух сгустков плотности энергии T^{00}. Из (16) следует

$$W(T) = -\frac{1}{2}\int \frac{d^4k}{(2\pi)^4} T^{00}(k)^* \frac{1+1-\frac{2}{3}}{k^2 - m^2 + i\varepsilon} T^{00}(k).$$

Сравнивая с (5) и учитывая хорошо известный факт, что $1 + 1 - 2/3 > 0$, мы видим, что в то время как одноименные заряды отталкиваются, массы притягиваются. Аплодисменты, пожалуйста!

Вселенная

Трудно переоценить важность (не говоря о красоте) того, что мы только что узнали: обмен частицей со спином 0 порождает притягивающую силу, со спином 1 - отталкивающую силу, а со спином 2 - притягивающую силу. Упомянутые силы реализуются в сильном взаимодействии адронов, электромагнитном взаимодействии и гравитационном взаимодействии соответственно. Универсальное гравитационное притяжение порождает нестабильности, приводящие к образованию структур в ранней Вселенной 3. Плотные области становятся еще плотнее. Притягивающая ядерная сила, обусловленная частицей со спином 0, в конечном итоге зажигает звезды. Более того, притягивающая сила между протонами и нейтронами, порождаемая обменом частицей со спином 0, способна преодолеть отталкивающую электрическую силу между протонами, порождаемую обменом частицей со спином 1, что приводит к образованию огромного разнообразия ядер, без которого мир определенно был бы довольно скучным.

Отталкивание между одноименными и, следовательно, притяжение между противоположными зарядами, вызываемое частицей со спином 1, приводит к образованию электрически нейтральных атомов.

Наш мир является результатом хрупкого равновесия между спинами 0, 1 и 2.

В нашем кратком обзоре Вселенной мы не упомянули слабое взаимодействие. В действительности слабое взаимодействие играет решающую роль в поддержании постоянной скорости горения звезд, подобных нашему Солнцу.

[3] О гравитационной неустойчивости и образовании структур во Вселенной читайте в книге A. Zee Einstein's Universe (ранее известной под названием An Old Man's Toy').

Степени свободы

Пора немножко остыть: с логической и математической точек зрения физика частицы с массой $m \neq 0$ может отличаться от физики частицы с массой $m = 0$. В самом деле, как известно из классической электродинамики, электромагнитная волна имеет 2 поляризации, то есть 2 степени свободы. Для массивной частицы со спином 1 мы можем перейти в ее собственную систему покоя, после чего группа вращений даст нам $2 \cdot 1 + 1 = 3$ степени свободы. Ключевым с точки зрения физики здесь является то, что безмассовый фотон нельзя привести в его собственную систему покоя. Математически группа вращений $SO(3)$ вырождается в группу вращений $SO(2)$, т. е. группу двумерных вращений вокруг направления импульса фотона.

В главе II.7 мы увидим, что в пределе нулевой массы продольная степень свободы массивного мезона со спином 1 отщепляется. Поэтому рассмотренное здесь взаимодействие между зарядами (6) следует признать корректным. Однако в главе VIII.1 вы узнаете, что в случае с гравитацией коэффициент $\frac{2}{3}$ в (17) заменяется на 1 в эйнштейновской теории. К счастью, знак взаимодействия в (17) не меняется. Приглушите немного аплодисменты.

Приложение

Давайте представим, что мы никогда не слышали о лагранжиане Максвелла. Нам надо написать релятивистский лагранжиан для массивного мезонного поля со спином 1. Общими усилиями мы придем к теории Максвелла. Спин 1 означает, что поле преобразуется как вектор под действием трехмерной группы вращений. Простейшим лоренцевским объектом, содержащим трехмерный вектор, является, очевидно, четырехмерный вектор. Поэтому начнем с векторного поля $A_\mu(x)$.

То, что векторное поле имеет массу m, означает, что оно удовлетворяет полевому уравнению

$$\left(\partial^2 + m^2\right) A_\mu = 0$$

Частица со спином 1 имеет три степени свободы [на научном языке: представление j группы вращений имеет размерность $(2j+1)$; здесь $j=1$. С другой стороны, поле $A_\mu(x)$ содержит 4 компоненты. Таким образом, необходимо наложить условие, которое сократило бы число степеней свободы с 4 до 3. Единственной лоренц-ковариантной возможностью (линейной по A_μ) является условие

$$\partial_\mu A^\mu = 0$$

Полезно проанализировать выражения (18) и (19), которые для импульсного пространства имеют вид $(k^2 - m^2)\, A_\mu(k) = 0$ и $k_\mu A^\mu(k) = 0$. Первое уравнение говорит о том, что $k^2 = m^2$, а из второго следует, что при переходе в собственную систему покоя, где $k^\mu = (m, \overrightarrow{0}), A^0$ сводится к 0, при этом остаются три ненулевые компоненты A^i с $i = 1, 2, 3$.

Обратите особое внимание на то, что (18) и (19) можно объединить в одно уравнение

$$\left(g^{\mu\nu}\partial^2 - \partial^\mu\partial^\nu\right) A_\nu + m^2 A^\mu = 0.$$

Проверим, что (20) содержит как (18), так и (19). Подействуем с помощью ∂_μ на (20). Получим $m^2\partial_\mu A^\mu = 0$, что предполагает $\partial_\mu A^\mu = 0$. (На этом этапе критично, что $m \neq 0$, то есть мы не рассматриваем фотон с массой, строго равной 0.) Таким образом, получаем (19); используя (19) в (20), мы приходим к (18).

Теперь можно построить лагранжиан, умножая левую часть (20) на $\frac{1}{2}A_\mu$ (где $\frac{1}{2}$ есть результат соглашения, а общий знак «+» обусловлен физикой, а именно условием положительности кинетической энергии); то есть

$$\mathcal{L} = \frac{1}{2} A_\mu \left[\left(\partial^2 + m^2\right) g^{\mu\nu} - \partial^m\partial^\nu\right] A_\nu$$

Интегрируя по частям, приходим к версии лагранжиана Максвелла с ненулевой массой. В пределе $m \to 0$ получаем вариант Максвелла.

Несколько слов о терминологии. Некоторые настаивают на том, чтобы называть полем только $F_{\mu\nu}$, а A_μ - потенциалом. Но в соответствии с общепринятым обозначением мы не

будем делать этих тонких различий. Для нас любая динамическая функция в пространстве-времени является полем.

Упражнения

I.5.1. Используя свойства симметрии, запишите наиболее общую форму для $\sum_a \varepsilon^{(a)}_{\mu\nu}(k)\varepsilon^{(a)}_{\lambda\sigma}(k)$. Например, она должна быть инвариантна относительно перестановки $\{\mu\nu \leftrightarrow \lambda\sigma\}$. Вы должны получить нечто типа

$$AG_{\mu\nu}G_{\lambda\sigma} + B\left(G_{\mu\lambda}G_{\nu\sigma} + G_{\mu\sigma}G_{\nu\lambda}\right) + C\left(G_{\mu\nu}k_\lambda k_\sigma + k_\mu k_\nu G_{\lambda\sigma}\right) + \\ + D\left(k_\mu k_\lambda G_{\nu\sigma} + k_\mu k_\sigma G_{\nu\lambda} + k_\nu k_\sigma G_{\mu\lambda} + k_\nu k_\lambda G_{\mu\sigma}\right) + Ek_\mu k_\nu k_\lambda k_\sigma$$

с неизвестными $A, ..., E$. Примените $k^\mu \sum_a \varepsilon^{(a)}_{\mu\nu}\varepsilon^{(a)}_{\lambda\sigma} = 0$ и выясните, что это условие означает для констант. Действуя таким образом, получите (13).

8.8.5 Зи.I.6 Inverse-Square Law and Floating 3-Brane

Почему обратный квадрат?

При первом знакомстве с физикой не задавались ли вы вопросом, почему сила действует по закону обратных квадратов, а, скажем, не по закону обратных кубов? Сейчас у вас есть исчерпывающий ответ. Когда две частицы обмениваются безмассовой частицей, потенциальная энергия между ними равна

$$V(r) \propto \int d^3k e^{i\vec{k}\cdot\vec{x}} \frac{1}{\vec{k}^2} \propto \frac{1}{r}$$

Спин обмениваемой частицы определяет общий знак, но $1/r$, как я отмечал ранее, следует из анализа размерностей. На самом деле $V(r)$ - преобразование Фурье пропагатора. Член $\vec{k}^2$ в пропагаторе обусловлен членом $(\partial_i\varphi \cdot \partial_i\varphi)$ в выражении для действия, где φ обозначает поле, ассоциированное с обмениваемой безмассовой частицей, а форма $(\partial_i\varphi \cdot \partial_i\varphi)$ объясняется инвариантностью относительно вращений. Поэтому в (1) не может фигурировать ни $\vec{k}$, ни $\vec{k}^3; \vec{k}^2$ есть простейшая возможность. То есть можно сказать, что закон обратных квадратов в некотором смысле проистекает из инвариантности относительно врашений!

С физической точки зрения закон обратных квадратов восходит к модели потока Фарадея. Рассмотрим сферу радиуса r, окружающую заряд. Электрический поток на единицу площади, протекающий сквозь сферу, изменяется по закону $1/4\pi r^2$. Этот геометрический факт отражается множителем d^3k в (1).

Мир бран

Удивительно, но тех минимальных знаний по квантовой теории поля, которые я вам успел преподать, достаточно, чтобы вывести вас на передовой край современных исследований, современных, разумеется, на момент написания книги. В теории струн наш $(3+1)$-мерный мир может быть вложен в большую Вселенную, подобно тому как $(2+1)$-мерный лист бумаги вкладывается в наш привычный $(3+1)$-мерный мир. Считается, что мы живем на 3-бране.

Предположим, существуют n дополнительных измерений с координатами $x^4, x^5, ..., x^{n+3}$. Пусть характеристическими масштабами, ассоциированными с дополнительными

координатами, будет R. Я не могу вдаваться в подробности, касающиеся различных сценариев, описывающих суть R. Я также не могу объяснить, почему мы привязаны к 3-бране. Однако могу сказать, что гравитация по своей сути связана со структурой пространства-времени и поэтому пронизывает всю $(n+3+1)$-мерную Вселенную.

Хорошо, какому же закону подчиняется гравитационная сила между двумя частицами? Конечно не закону гравитации, известному еще вашим дедам: используя преобразование Фурье

$$V(r) \propto \int d^{3+n}k e^{i\vec{k}\cdot\vec{x}} \frac{1}{\vec{k}^2} \propto \frac{1}{r^{1+n}},$$

мы получаем закон $1/r^{1+n}$.

Не противоречит ли он наблюдениям?

На самом деле нет, поскольку закон Ньютона остается справедливым для $r \gg R$. В этом пределе дополнительные координаты эффективно зануляются, по сравнению с рассматриваемым нами характеристическим масштабом длины r. Поток не может распространиться далеко в направлении n дополнительных координат. Представьте себе поток, вынужденно распространяющийся лишь по трем известным нам направлениям подобно тому, как электромагнитное поле в волноводе вынуждено распространяться только вдоль трубы. Мы эффективно возвращаемся в $(3+1)$-мерное пространство-время, а $V(r)$ возвращается к зависимости $1/r$.

Новый закон гравитации (2) справедлив только в противоположном пределе $r \ll R$. Эвристически, когда R много больше расстояния между двумя частицами, поток не знает о том, что дополнительные координаты конечны, и считает, что он живет в $(n+3+1)$-мерной Вселенной.

В силу слабости гравитации, закон Ньютона не был проверен с достаточной точностью на лабораторных масштабах расстояний, поэтому теоретикам есть чем спекулировать: R легко может существенно превышать масштаб элементарных частиц, но все же быть много меньше масштаба явлений повседневной жизни. Невероятно, но Вселенная может иметь «большие дополнительные измерения»! (Слово «большие» означает большие в масштабах физики элементарных частиц.)

Масса Планка

Обратимся к расчетам и определим массу Планка $M_{\rm Pl}$, записав закон Ньютона в более удобной форме $v(r) = G_N m_1 m_2 (1/r) = (m_1 m_2 / M_{\rm Pl}^2)\,(1/r)$. Численно $M_{\rm PI} \simeq 10^{19}$ ГэВ. Очевидно, что такое огромное значение отражает слабость гравитации.

В фундаментальных единицах, в которых $\hbar$ и c берутся равными единице, гравитация определяет собственный масштаб массы или энергии, который много больше любого экспериментально исследованного масштаба. Действительно, одна из фундаментальных загадок современной физики элементарных частиц как раз и заключается в том, почему этот массовый масштаб столь велик, по сравнению со всеми остальными известными нам масштабами. Когда придет время, я вернусь к этой так называемой проблеме иерархии. А сейчас зададимся вопросом, может ли эта новая модель гравитации - новая на рубеже последнего столетия - облегчить решение проблемы иерархии за счет уменьшения собственного гравитационного массового масштаба?

Пусть $M_{{\rm Pl}(n+3+1)}$ обозначает характеристический масштаб массы для гравитации в $(n+3+1)$-мерной Вселенной, так что гравитационный потенциал между двумя объектами с массами

m_1 и m_2, находящимися на расстоянии $r \ll R$ друг от друга, равен

$$V(r) = \frac{m_1 m_2}{\left[M_{\mathrm{Pl}(n+3+1)}\right]^{2+n}} \frac{1}{r^{1+n}}$$

Заметим, что зависимость от $M_{\mathrm{Pl}(n+3+1)}$ непосредственно следует из анализа размерностей: две степени нужны, чтобы сократить $m_1 m_2$, и n степеней - чтобы согласовать с n дополнительными степенями $1/r$. Для случая $r \gg R$, как уже говорилось ранее, геометрическая протяженность гравитационного потока ограничивается значением R так, что потенциал становится равным

$$V(r) = \frac{m_1 m_2}{\left[M_{\mathrm{Pl}(n+3+1)}\right]^{2+n}} \frac{1}{R^n} \frac{1}{r}$$

Сравнивая с экспериментально наблюдаемым законом $V(r) = (m_1 m_2 / M_{\mathrm{Pl}}^2) \times \times (1/r)$, получаем

$$M_{\mathrm{Pl}(n+3+1)}^2 = \frac{M_{\mathrm{Pl}}^2}{\left[M_{\mathrm{Pl}(n+3+1)} R\right]^n}$$

Если величина $M_{\mathrm{Pl}(n+3+1)} R$ может быть достаточно большой, то появляется интригующая возможность того, что фундаментальный масштаб гравитации $M_{\mathrm{P}(n+3+1)}$ много меньше, чем мы всегда думали.

Таким образом, величина R ограничена, с одной стороны, нашим желанием уменьшить фундаментальный гравитационный масштаб и, с другой стороны, результатами экспериментов.

Упражнения

I.6.1. Подставив числа, покажите, что случай $n = 1$ уже исключен. Для справки см. S. Nussinov and R. Schrock, Phys. Rev. D59: 105002, 1999.

8.8.6 Зи.I. Canonical Quantization and Vacuum Perturbation

Взаимодополняющие формализмы

Я рассматриваю формализм интеграла по траекториям как наиболее быстрый путь построения квантовой теории поля. Но я также должен обсудить канонический формализм не только в силу того, что исторически именно этим путем развивалась квантовая теория поля, но и потому, что он сохраняет актуальность и поныне. Интересно заметить, что канонический формализм и формализм интеграла по траекториям часто являются взаимодополняющими в том смысле, что результаты, которые трудно получить в одном, легко получаются в другом.

При обсуждении канонического формализма я буду довольно краток, отчасти из-за того, что он является стандартным подходом и потому детально излагается в большинстве книг по квантовой теории поля.

Гейзенберг и Дирак

Начнем с краткого обзора гейзенберговского подхода к квантовой механике. Для заданного классического лагранжиана одной частицы $L = \frac{1}{2}\dot{q}^2$ - - $V(q)$ (мы положили массу равной 1) канонический импульс определяется как $p \equiv \delta L/\delta\dot{q} = \dot{q}$. После этого, гамильтониан системы записывается в виде $H = p\dot{q} - L = p^2/2 + V(q)$. Гейзенберг заменяет положение $q(t)$ и импульс $p(t)$ на операторы, накладывая каноническое коммутационное соотношение

$$[p, q] = -i$$

Операторы эволюционируют во времени по закону

$$\frac{dp}{dt} = i[H, p] = -V'(q)$$

к

$$\frac{dq}{dt} = i[H, q] = p$$

Другими словами, операторы, составленные из p и q, эволюционируют как $O(t) = e^{iHt}O(0)e^{-iHt}$. В формуле (1) p и q рассматриваются в один и тот же момент времени. Объединяя (2) и (3), мы получаем операторное уравнение движения $\ddot{q} = -V'(q)$.

Следуя Дираку, рассмотрим в некоторый момент времени оператор $a \equiv (1/\sqrt{2\omega})(\omega q + ip)$ с некоторым параметром ω. Из (1) получаем

$$\left[a, a^\dagger\right] = 1$$

Оператор $a(t)$ эволюционирует по закону

$$\frac{da}{dt} = i\left[H, \frac{1}{\sqrt{2\omega}}(\omega q + ip)\right] = -i\sqrt{\frac{\omega}{2}}\left(ip + \frac{1}{\omega}V'(q)\right)$$

который можно переписать в терминах a и $a^\dagger$. Основное состояние $|0\rangle$ определяется как состояние, такое что $a|0\rangle = 0$.

В частном случае $V'(q) = \omega^2 q$ получаем особенно простой результат $\frac{da}{dt} = -i\omega a$. Он представляет собой гармонический осциллятор $L = \frac{1}{2}\dot{q}^2$ - $-\frac{1}{2}\omega^2 q^2$ и $H = \omega\left(a^\dagger a + \frac{1}{2}\right)$

Обобщение на случай многих частиц следует немедленно. Начиная с

$$L = \sum_a \frac{1}{2}\dot{q}_a^2 - V\left(q_1, q_2, ..., q_N\right)$$

получаем $p_a = \delta L/\delta\dot{q}_a$ и

$$[p_a(t), q_b(t)] = -i\delta_{ab}$$

Обобщение до теории поля следует почти немедленно. Фактически мы просто используем нашу таблицу подстановок (I.3.6) и видим, что в D-мерном пространстве L обобщается до

$$L = \int d^D x \left\{\frac{1}{2}\left(\dot{\varphi}^2 - (\vec{\nabla}\varphi)^2 - m^2\varphi^2\right) - u(\varphi)\right\}$$

где ангармоничный член (член взаимодействия в квантовой теории поля) обозначается через $u(\varphi)$. Плотность канонического импульса, сопряженного полю $\varphi(\vec{x}, t)$, при этом равна

$$\pi(\vec{x},t)=\frac{\delta L}{\delta\dot{\varphi}(\vec{x},t)}=\partial_0\varphi(\vec{x},t)$$

так что каноническое коммутационное соотношение для равных моментов времени теперь имеет вид

$$[\pi(\vec{x},t),\varphi(\vec{x}',t)]=[\partial_0\varphi(\vec{x},t),\varphi(\vec{x}',t)]=-i\delta^{(D)}(\vec{x}-\vec{x}')$$

(и, конечно, $[\pi(\vec{x},t),\pi(\vec{x}',t)]=0$ и $[\varphi(\vec{x},t),\varphi(\vec{x}',t)]=0$). Заметьте, что δ_{ab}, из (5) становится в (8) в $\delta^{(D)}(\vec{x}-\vec{x}')$. Проверьте, что (8) имеет правильную размерность. Проворачивая рукоятку канонического формализма, находим гамильтониан

$$\begin{aligned}H&=\int d^Dx\left[\pi(\vec{x},t)\partial_0\varphi(\vec{x},t)-\mathcal{L}\right]\\&=\\&=\int d^Dx\left\{\frac{1}{2}\left[\pi^2+(\vec{\nabla}\varphi)^2+m^2\varphi^2\right]+u(\varphi)\right\}\end{aligned}$$

Для случая $u=0$, соответствующего гармоническому осциллятору, приходим к теории свободного скалярного поля и можем продвинуться существенно дальше. Полевое уравнение имеет вид

$$\left(\partial^2+m^2\right)\varphi=0$$

Раскладывая в интеграл Фурье, получаем

$$\varphi(\vec{x},t)=\int\frac{d^Dk}{\sqrt{(2\pi)^D2\omega_k}}\left[a(\vec{k})e^{-i\left(\omega_kt-\vec{k}\cdot\vec{x}\right)}+a^\dagger(\vec{k})e^{i\left(\omega_kt-\vec{k}\cdot\vec{x}\right)}\right]$$

где $\omega_k=+\sqrt{\vec{k}^2+m^2}$, так что удовлетворяется полевое уравнение (10). Странный на вид множитель $(2\omega_k)^{-1/2}$ выбирается с тем, чтобы каноническое соотношение

$$\left[a(\vec{k}),a^\dagger\left(\vec{k}'\right)\right]=\delta^{(D)}\left(\vec{k}-\vec{k}'\right)$$

для операторов рождения и уничтожения приводило к каноническому коммутированию $[\partial_0\varphi(\vec{x},t),\varphi(\vec{x}',t)]=-i\delta^{(D)}(\vec{x}-\vec{x}')$ в (8). Лучше вам это проверить, хотя необходимость в множителе $(2\omega_k)^{-1/2}$ можно увидеть еще и потому, что в $\partial_0\varphi$ множитель ω_k спускается из показателя экспоненты.

Как и в квантовой механике, вакуумное, или основное, состояние $|0\rangle$ определяется условием $a(\vec{k})|0\rangle=0$ для всех $\vec{k}$. Вычислим $\langle0|\varphi(\vec{x},t)\varphi(\overrightarrow{0},0)|0\rangle$ для $t>0$. Из четырех членов $a^\dagger a^\dagger,a^\dagger a,aa^\dagger$ и aa, фигурирующих в произведении двух полей, остается вычислить только член $aa^\dagger$. Таким образом, используя (12), получаем $\int\left[d^Dk/(2\pi)^D2\omega_k\right]e^{-i\left(\omega_kt-\vec{k}\cdot\vec{x}\right)}$. Другими словами, если мы определим упорядоченное по времени произведение

$$T[\varphi(x)\varphi(y)]=\theta\left(x^0-y^0\right)\varphi(x)\varphi(y)+\theta\left(y^0-x^0\right)\varphi(y)\varphi(x),$$

то

$$\langle0|T[\varphi(\vec{x},t),\varphi(\overrightarrow{0},0)]|0\rangle=\int\frac{d^Dk}{(2\pi)^D2\omega_k}\left[\theta(t)e^{-i\left(\omega_kt-\vec{k}\cdot\vec{x}\right)}+\theta(-t)e^{+i\left(\omega_kt-\vec{k}\cdot\vec{x}\right)}\right].$$

Вернемся назад к (I.3.23). Находим, что $\langle 0|T[\varphi(x)\varphi(0)]|0\rangle = iD(x)$ есть пропагатор частицы, распространяющейся из 0 в x, полученный нами в формализме интеграла по траекториям. Полученный результат также подтверждает обоснованность i прескрипции в (I.3.22). Физический смысл состоит в том, что мы всегда рождаем, перед тем как уничтожить, а не наоборот. Это одна из форм причинности.

Обратите внимание на то, что условие эрмитовости позволяет выразить второй член в квадратных скобках в (11) через первый член. Если бы $\varphi \neq \varphi^\dagger$ (как вы увидите в главе I.9), то два члена должны были быть разными. Этот важный случай рассматривается в упражнении I.8.3, которое следует выполнить, так как его результаты понадобятся нам в дальнейшем.

Никто не совершенен

В каноническом формализме время рассматривается не так, как пространство, в силу чего у читателя может возникнуть вопрос о лоренц-инвариантности получившейся теории. В стандартном подходе, используемом во многих учебниках, начиная с этого момента мы должны были бы использовать гамильтониан для описания динамики, развивая теорию возмущений по взаимодействию $u(\varphi)$. После ряда формальных шагов мы получили бы правила Фейнмана, которые явно задавали бы лоренц-инвариантную теорию.

Был период, когда люди считали, что квантовая теория поля определяется набором правил Фейнмана, которые дают конкретный алгоритм расчета наблюдаемых величин, таких как сечения рассеяния. В своем крайнем проявлении такая точка зрения рассматривала поля лишь как математические объекты, помогающие нам добраться до правил Фейнмана, и которые после этого надо просто выбросить.

Начиная с 1970-х годов, такая точка зрения оказалась несостоятельной, так как стало понятно, что квантовая теория поля представляет собой нечто большее, чем просто набор диаграмм Фейнмана. Теория поля содержит в себе непертурбативные эффекты, которые по определению не ухватываются диаграммами Фейнмана. Многие из этих эффектов, которые мы рассмотрим в свое время, наиболее легко формулируются в формализме интеграла по траекториям.

Как я отмечал, канонический формализм и формализм интеграла по траекториям часто дополняют друг друга, поэтому я воздержусь от дискуссии на тему, который из них является более эффективным. В своей книге я принимаю прагматическую точку зрения и использую тот из них, который наилучшим образом подходит для обсуждаемой проблемы.

Тем не менее позвольте мне отметить некоторые особенности обоих формализмов, вызывающие особые затруднения. В каноническом формализме поля являются квантовыми операторами, содержащими бесконечное число степеней свободы. Были времена, когда ученые обсуждали такие тонкие вопросы, как, например, определение произведения полей. С другой стороны, в формализме интеграла по траекториям многие грехи можно замести под ковер, в качестве которого выступает мера интегрирования (см. главу IV.7).

Приложение

Вас может озадачить тот факт, что пропагатор в каноническом формализме должен определяться с упорядочиванием по времени, тогда как в формализме интеграла по траекториям в нем нет необходимости. Для разрешения этой кажущейся загадки достаточно посмотреть на квантовую механику.

Пусть $A\left[q\left(t_1\right)\right]$ - функция от q, определенная в момент времени t_1. Что представляет собой интеграл по траекториям $\int Dq(t)A\left[q\left(t_1\right)\right]e^{i\int_0^T dtL(\dot{q},q)}$ на операторном языке? Вернемся назад к (I.2.3) и вставим $A\left[q\left(t_1\right)\right]$ в подходящий множитель $\left\langle q_{j+1}\left|e^{-iH\delta t}\right|q_j\right\rangle$. Слово «подходящий» означает, что момент времени t_1 располагается между моментами времени $j\delta t$ и $(j+1)\delta t$ для этого j. В $\left\langle q_{j+1}\left|e^{-iH\delta t}A\left[q\left(t_1\right)\right]\right|q_j\right\rangle$ мы заменяем c-число $A\left[q\left(t_1\right)\right]$ оператором $A\left[\widehat{q}\left(t_1\right)\right]$. Таким образом, интеграл представляет собой выражение $\left\langle q_F\right|e^{-iH(T-t_1)}\times\ \times A\left[\widehat{q}\left(t_1\right)\right]e^{-iHt_1}\left|q_I\right\rangle$

Теперь мы готовы ответить на более сложный вопрос: что представляет собой интеграл по траекториям

$$\int Dq(t)A\left[q\left(t_1\right)\right]B\left[q\left(t_2\right)\right]e^{i\int_0^T dtL(\dot{q},q)}$$

на операторном языке? Здесь $B\left[q\left(t_2\right)\right]$ означает некоторую другую функцию от q, определенную в момент времени t_2. Мы также подставляем $B\left[q\left(t_2\right)\right]$ в соответствующий множитель в (I.2.3) и заменяем $B\left[q\left(t_2\right)\right]$ на $B\left[\widehat{q}\left(t_2\right)\right]$. Видим, что нам необходимо следить за тем, какой из двух моментов времени t_1 и t_2 наступает раньше. Если сначала наступает t_2, то оператор $A\left[\widehat{q}\left(t_1\right)\right]$ должен стоять слева от оператора $B\left[\widehat{q}\left(t_2\right)\right]$, и наоборот, если сначала наступает t_1. Итак, если t_2 раньше t_1, мы получаем следующую последовательность:

$$e^{-iH(T-t_1)}A\left[\widehat{q}\left(t_1\right)\right]e^{-iH(t_1-t_2)}B\left[\widehat{q}\left(t_2\right)\right]e^{-iHt_2}$$

Таким образом, определяется упорядоченное по времени произведение

$$T\left\{A\left[\widehat{q}\left(t_1\right)\right]B\left[\widehat{q}\left(t_2\right)\right]\right\}\equiv\theta\left(t_1-t_2\right)A\left[\widehat{q}\left(t_1\right)\right]B\left[\widehat{q}\left(t_2\right)\right]+\theta\left(t_2-t_1\right)B\left[\widehat{q}\left(t_2\right)\right]A\left[\widehat{q}\left(t_1\right)\right].$$

Имеем

$$\left\langle q_F\left|T\left\{A\left[\widehat{q}\left(t_1\right)\right]B\left[\widehat{q}\left(t_2\right)\right]e^{-iHT}\right\}\right|q_I\right\rangle=\int Dq(t)A\left[q\left(t_1\right)\right]B\left(q\left(t_2\right)\right]e^{i\int_0^T dtL(\dot{q},q)}$$

Упорядочение по времени не появляется в правой части, но играет важную роль в левой.

Зи-I.8.1.

Некоторые авторы предпочитают определять $a(\vec{k})$ и $a^\dagger(\vec{k})$ без квадратного корня. Покажите, что для произвольной функции f

$$\int d^4k\delta\left(k^2-m^2\right)\theta\left(k^0\right)f\left(k^0,\vec{k}\right)=\int\frac{d^3k}{2\omega_k}f\left(\omega_k,\vec{k}\right)$$

Обоснуйте, что $d^3k/2\omega_k$ есть лоренц-инвариантная мера. [Указание: преобразования Лоренца не изменяют знак k^0.] Значит, определенные этими авторами операторы рождения и уничтожения являются лоренц-ковариантными. Получите их коммутационные соотношения.

Зи-I.8.2.

Вычислите $\left\langle\vec{k}'|H|\vec{k}\right\rangle$, где $|\vec{k}\rangle=a^\dagger(\vec{k})|0\rangle$.

Зи-I.8.3.

Мы рассмотрели эрмитово (или вещественное, как говорят при несколько вольном употреблении терминологии) скалярное поле. Рассмотрим теперь комплексное скалярное поле, определяемое лагранжианом $\mathcal{L} = \partial\varphi^\dagger\partial\varphi$ - $-m^2\varphi^\dagger\varphi$. Считая φ и $\varphi^\dagger$ независимыми переменными, получите уравнения движения Эйлера -Лагранжа. Неэрмитовость φ означает, что (11) должно быть заменено на

$$\varphi(\vec{x},t) = \int \frac{d^Dk}{\sqrt{(2\pi)^D 2\omega_k}} \left[a(\vec{k})e^{-i\left(\omega_k t - \vec{k}\cdot\vec{x}\right)} + b^\dagger(\vec{k})e^{i\left(\omega_k t - \vec{k}\cdot\vec{x}\right)}\right.$$

Докажите, что канонические коммутационные соотношения предполагают, что $\left(a, a^\dagger\right)$ и $\left(b, b^\dagger\right)$ формируют два независимых множества операторов рождения и уничтожения. Вычислите $\left\langle 0 \left| T\left[\varphi(x)\varphi^\dagger(0)\right] \right| 0 \right\rangle$. [Указание: ∂_φ сопряжено с $\varphi^\dagger$, а не с φ.]

Зи-I.8.4.

Используя уравнения движения, проверьте, что ток $J_\mu = i\left(\varphi^\dagger\partial_\mu\varphi - -\partial_\mu\varphi^\dagger\varphi\right)$ сохраняется, а соответствующий заряд равен $Q = \int d^Dx J_0(x) = \int d^Dk \left[a^\dagger(\vec{k})a(\vec{k}) - b^\dagger(\vec{k})b(\vec{k})\right]$. Мы видим, что частица, порожденная $a^\dagger$ (назовем ее «частица»), и частица, порожденная $b^\dagger$ (назовем ее «античастица»), несут противоположные заряды. Таким образом, $\varphi^\dagger$ рождает частицу и уничтожает античастицу, то есть создает единицу заряда. Поле φ делает обратное. Покажите, что $[Q, \varphi(x)] = -\varphi(x)$.

Зи-I.8.5.

Для поля A покажите, что при $q^0 > 0$ имеет место выражение

$$\mathrm{Im}\left\{ i\int d^4x e^{iqx}\langle 0|T[A(x)A(0)]|0\rangle \right\} = \frac{1}{2}\int d^4x e^{iqx}\langle 0|[A(x), A(0)]|0\rangle$$

Для этого вставьте $1 = \sum\limits_n |n\rangle\langle n|$($|n\rangle$ - полный набор состояний) между $A(x)$ и $A(0)$ в левой части равенства. [Указание: используйте интегральные представления $\theta(t) = -i\int(d\omega/2\pi)e^{i\omega t}/(\omega - i\varepsilon)$ и $\theta(-t) = = i\int(d\omega/2\pi)e^{i\omega t}/(\omega + i\varepsilon)$.]

Зи-I.8.6.

Продемонстрируйте свое умение вычислять интегралы на примере расчета силы Казимира в $(3+1)$-мерном пространстве-времени. В помощь см. M. Kardar and R. Golestanian, Rev. Mod. Phys. 71: 1233, (1999); J. Feinberg, A. Mann, and M. Revzen, Ann. Phys. 288: 103, (2001).

8.11 Conceptual Properties of Emptiness

Обсудим подробно вакуум.
(мб статью Гинзбурга сюда вставлю, пока она вдали. (????))

8.11.1 Vacuum Energy

Энергия вакуума

В качестве содержательного упражнения вычислим для теории свободного скалярного поля среднее

$$\langle 0|H|0\rangle = \frac{1}{2}\int d^D x \left\langle 0 \left| \pi^2 + (\vec{\nabla}\varphi)^2 + m^2\varphi^2 \right| 0 \right\rangle$$

которое мы условно назовем «энергией вакуума». Все, что нам нужно, это объединить вместе (7), (11) и (12). Сфокусируемся на третьем члене в $\langle 0|H|0\rangle$, который мы уже фактически вычислили, так как

$$\langle 0|\varphi(\vec{x},t)\varphi(\vec{x},t)|0\rangle = \langle 0|\varphi(\overrightarrow{0},0),\varphi(\overrightarrow{0},0)|0\rangle = \lim_{\vec{x},t\to 0,0}\langle 0|\varphi(\vec{x},t)\varphi(\overrightarrow{0},0)|0\rangle =$$

$$= \lim_{\vec{x},t\to 0,0}\int \frac{d^Dk}{(2\pi)^D 2\omega_k} e^{-i\left(\omega_k t-\vec{k}\cdot\vec{x}\right)} = \int \frac{d^Dk}{(2\pi)^D 2\omega_k}.$$

Первое равенство следует из трансляционной инвариантности, которая означает, что мы можем заменить $\int d^Dx$ в $\langle 0|H|0\rangle$ на объем пространства V. Вычисление двух других членов производится во многом аналогично: например, два множителя $\vec{\nabla}$ в $(\vec{\nabla}\varphi)^2$ просто дают множитель $\vec{k}^2$. Таким образом

$$\langle 0|H|0\rangle = V\int \frac{d^Dk}{(2\pi)^D 2\omega_k}\left[\frac{1}{2}\left(\omega_k^2+\vec{k}^2+m^2\right)\right] = V\int \frac{d^Dk}{(2\pi)^D}\frac{1}{2}\hbar\omega_k,$$

где мы восстановили $\hbar$.

Полученный результат должен вызвать у вас чувство удовлетворения и тревоги одновременно: удовлетворения потому, что мы узнаем в нем энергию нулевых колебаний гармонического осциллятора, проинтегрированную по всем импульсным модам, а тревоги из-за того, что интеграл по $\vec{k}$ явно расходится. Нам, однако, не следует тревожиться: энергия любой физической конфигурации, например масса частицы, должна измеряться относительно «энергии вакуума». Нас интересует разница между энергией мира с частицей и энергией мира без частицы. Другими словами, мы могли бы просто определить правильный гамильтониан как $H-\langle 0|H|0\rangle$. К некоторым из обсуждавшихся здесь вопросов мы вернемся в главах II.5, III.1 и VIII.2.

8.11.2 Idea of Casimir Effect

Эффект Казимира

А что случится, если мы возмутим вакуум?

Разумеется, не только скалярное поле вносит вклад в энергию вакуума. Электромагнитное поле, например, также испытывает квантовые флуктуации и добавляет к плотности энергии вакуума ε что-то типа $2\int[d^3k/(2\pi)^3]\,\frac{1}{2}\hbar\omega_k$. В 1948 году Казимир сделал блестящее предположение, что вызванное нами возмущение вакуума может привести к сдвигу $\Delta\varepsilon$. Хотя ε является экспериментально ненаблюдаемой величиной, сдвиг $\Delta\varepsilon$ должен поддаваться измерению, поскольку мы можем контролировать процесс возмущения нами вакуума. В частности, Казимир рассматривал ситуацию со внесением в вакуум двух параллельных «идеально» проводящих пластин (которые формально имеют бесконечную протяженность и нулевую толщину). Изменение $\Delta\varepsilon$ в зависимости от расстояния d между пластинами приводило к возникновению силы между ними, известной как сила Казимира.

Назовем направление, перпендикулярное пластинам, осью x. В силу граничных условий, которым должно удовлетворять электромагнитное поле на пластинах, волновой вектор может принимать лишь значения $(\pi n/d, k_y, k_z)$ с целым n. Таким образом, энергия между пластинами в расчете на единицу площади изменяется на величину

$$\frac{1}{2}\sum_n \int \frac{dk_y dk_z}{(2\pi)^2}\sqrt{\left(\frac{\pi n}{d}\right)^2 + k_y^2 + k_z^2}.$$

Для вычисления силы мы изменяем d, но при этом должны учитывать, как изменяется плотность энергии снаружи двух пластин. Существует, однако, хитрый прием, позволяющий этого избежать: надо вставить третью пластину, как показано на рис. I.8.1! Расстояние L между двумя внешними пластинами можно выбрать произвольно большим.

В соответствии с общей атмосферой книги (и моей философией), я стараюсь избегать, насколько это возможно, утомительных вычислений, поэтому предлагаю ввести два упрощения: (1) провести вычисления для безмассового скалярного, а не электромагнитного поля, чтобы не беспокоиться о поляризации и тому подобном, и (2) перейти в $(1+1)$-мерное пространство-время, чтобы не интегрировать по k_y и k_z. Как вы увидите, вычисления окажутся очень поучительными, они позволят ощутить прелесть выделения конечных физических результатов из явно расходящихся выражений. Это называется перенормировкой, мы рассмотрим ее в главах III. 1-3.

При такой формальной постановке энергия равна $E = f(d) + f(L-d)$, где

$$f(d) = \frac{\pi}{2d}\sum_{n=1}^{\infty} n$$

поскольку моды задаются выражением $\sin(n\pi x/d)(n = 1, ..., \infty)$, а соответствующая энергия равна $\omega_n = n\pi/d$.

Ой! А что нам делать с $\sum\limits_{n=1}^{\infty} n$? Никто из древних греков, начиная с Зенона, нам не подскажет.

Им следовало бы нам ответить, что мы решаем физическую, а не математическую задачу. Физические пластины не могут препятствовать прохождению волн произвольно большой частоты. Чтобы учесть это крайне важное физическое свойство, нам следует ввести множитель $e^{-a\omega_n}$, с тем чтобы исключить вклад мод с $\omega_n \gg a^{-1}$: этим модам не видны пластины. Таким образом, получаем

$$f(d) = \frac{\pi}{2d}\sum_{n=1}^{\infty} n e^{-an\pi/d} = -\frac{1}{2}\frac{\partial}{\partial a}\sum_{n=1}^{\infty} e^{-an\pi/d} = -\frac{1}{2}\frac{\partial}{\partial a}\frac{1}{1-e^{-a\pi/d}} = \frac{\pi}{2d}\frac{e^{a\pi/d}}{\left(e^{a\pi/d}-1\right)^2}$$

Так как мы хотим, чтобы a^{-1} было большим, рассмотрим предел малого a, когда

$$f(d) = \frac{d}{2\pi a^2} - \frac{\pi}{24d} + O\left(a^2\right).$$

Заметим, что $f(d)$ устремляется к бесконечности при $a \to 0$, как и должно быть, иначе мы бы возвратились к (17). Но сила между двумя проводящими пластинами не должна устремляться к бесконечности. Экспериментаторы это бы точно заметили!

Итак, сила дается выражением

$$\frac{\partial E}{\partial d} = f'(d) - f'(L-d) = \left(\frac{1}{2\pi a^2} + \frac{\pi}{24d^2} + ...\right) - (d \to L-d) \underset{a\to 0}{\longrightarrow}$$
$$\underset{a\to 0}{\longrightarrow} \frac{\pi}{24}\left(\frac{1}{d^2} - \frac{1}{(L-d)^2}\right)_L \widetilde{\gg} d\frac{\pi\hbar c}{24d^2}, \quad (20)$$

взятым с обратным знаком. Расходимость $1/a^2$ сократилась.

Видите, наша любимая физика приводит к разумному результату. Мы восстановили $\hbar$, чтобы подчеркнуть квантовую природу силы. Так как $\partial E/\partial d > 0$, сила Казимира между двумя пластинами является притягивающей. Чтобы измерить эту крошечную силу, потребовались довольно сложные эксперименты.

Об экспериментальных подтверждениях (???)

Другое про эффект Казимира

О модификациях и эффекте Казимира (????)

8.11.3 Emptiness in Cosmology: Main Ideas

(this is the most important topic there, there is a dark matter, so on, so it is written in cosmology, here I'll make an intro to that important question)

What Is a Quantum Field If There Is No Plane Wave?

(???? actually, there are no plane waves, so this is a fundamental question)

8.12.3 Other Ideas about Quantization of Fields

(read Maslov's book and write his ideas)
(and also from QM, there are many things known about it, but why they are not in QFT?)

8.12.4 Other Ideas about Quantization

Квантование вселенной через квазиклассику

(???? is it a physical idea at all???)

8.12.5 What about that Illustrative Picture of "Quants-bullets"?

(??? is it valid or not???)

8.13 Deeper Understanding of General QFT Concepts

(reminder: there is a section below "Philosophy of QFT: Other Ideas ", where I discuss some general questions, here I assume that there are no general questions and deal with some particular)

8.13.1 Newtonian Mechanics as a Particular Case of QFT

(!??!??!?!??!)

(очень важный раздел, где очень многое выведу, что уже известно нам в клас. физике, но из общих формул, которые тут развиваем.)

переход из КТП в классическую механику

можно заметить, что легко видеть классический предел...

как мы помним, переход в классику происходит изменением масштаба, то есть $\hbar \to 0$, так что в фазе

$$\delta S = 0, \quad \delta x = \delta y = 0$$

$$\mathcal{G}_{\text{ret}}\left(x, y, t > 0\right) \approx \mathcal{A} e^{\frac{1}{\hbar} S_0}$$

и тут еще пару нюансов про него можно сказать

8.13.2 Field Theory as a Particular Case of QFT

(!??!??!?!??!)

переход из КТП в теорию поля (???)

8.13.3 Quantum Mechanics as a Particular Case of QFT

(!??!??!?!??!)

переход из КТП в квантовую механику (??)

8.13.4 Haag's theorem

While working on the mathematical physics of an interacting, relativistic, quantum field theory, Rudolf Haag developed an argument[1] against the existence of the interaction picture, a result now commonly known as Haag's theorem. Haag's original proof relied on the specific form of then-common field theories, but subsequently generalized by a number of authors, notably Dick Hall and Arthur Wightman, who concluded that no single, universal Hilbert space representation can describe both free and interacting fields.[2] A generalization due to Michael C. Reed and Barry Simon shows that applies to free neutral scalar fields of different masses,[3] which implies that the interaction picture is always inconsistent, even in the case of a free field.

(?????? I have no idea how it works)

9 Free Quantum Fields

(for a detailed discussion without focus on quantum properties see my note on field theory)

9.1 Scalar Field (bosons)

9.1.1 The Klein-Gordon field as a set of harmonic oscillators

Теория

Начнем обсуждение квантовой теории поля с довольно формального рассмотрения простейшего типа поля - вещественного поля Клейна-Гордона. Идея состоит в том, чтобы начать с классической теории поля (теории классического скалярного поля, описываемого лагранжианом (2.6)) и затем «проквантовать» ее, то есть реинтерпретировать динамические переменные как операторы, которые подчиняются каноническим коммутационным соотношениям*. Далее мы «решаем» теорию, находя собственные значения и собственные состояния гамильтониана, в качестве аналогии используя гармонический осциллятор.

Классическая теория вещественного поля Клейна-Гордона была кратко (но достаточно) обсуждена в предыдущем разделе; соответствующие выражения даны в формулах (2.6), (2.7) и (2.8). При квантовании теории мы следуем тем же путем, что и для любой другой динамической системы: полагаем ϕ и π операторами и накладываем на них подходящие коммутационные соотношения. Напомним, что для дискретной системы одной или более частиц коммутационные соотношения имеют вид:

$$[q_i, p_j] = i\delta_{ij}$$
$$[q_i, q_j] = [p_i, p_j] = 0.$$

Обобщение для непрерывной системы вполне естественно: так как $\pi(\mathbf{x})$ является плотностью импульса, то вместо символа Кронекера мы берем дельта-функцию Дирака:

$$[\phi(\mathbf{x}), \pi(\mathbf{y})] = i\delta^{(3)}(\mathbf{x} - \mathbf{y})$$
$$[\phi(\mathbf{x}), \phi(\mathbf{y})] = [\pi(\mathbf{x}), \pi(\mathbf{y})] = 0.$$

(До сих пор мы используем представление Шредингера, в котором ϕ и π не зависят от времени. В следующем разделе мы перейдем к представлению Гейзенберга и эти «одновременные»коммутационные соотношения будут по-прежнему верны при условии, что оба оператора рассматриваются в один и тот же момент времени.)

Так как гамильтониан является функцией ϕ и π, то он также становится оператором. Следующая задача состоит в том, чтобы, зная гамильтониан, найти его спектр. Так как нет очевидного способа сделать это, попробуем записать уравнение КлейнаГордона в фурье-пространстве. Если разложить классическое поле Клейна-Гордона

$$\phi(\mathbf{x}, t) = \int \frac{d^3p}{(2\pi)^3} e^{i\mathbf{p}\cdot\mathbf{x}} \phi(\mathbf{p}, t)$$

(где $\phi^*(\mathbf{p}) = \phi(-\mathbf{p})$, так что $\phi(\mathbf{x})$ вещественно), то уравнение (2.7) принимает вид:

$$\left[\frac{\partial^2}{\partial t^2} + \left(|\mathbf{p}|^2 + m^2\right)\right] \phi(\mathbf{p}, t) = 0.$$

Это - уравнение движения для простого гармонического осциллятора с частотой

$$\omega_{\mathbf{p}} = \sqrt{|\mathbf{p}|^2 + m^2}.$$

- Эта процедура иногда называется вторичным квантованием, чтобы отличать возникающее в результате уравнение Клейна - Гордона (в котором ϕ является оператором) от старого одночастичного уравнения Клейна - Гордона (в котором ϕ было волновой функцией). В этой книге мы никогда не обращаемся ко второй точке зрения; мы стартуем с классического уравнения (в котором ϕ является классическим полем) и квантуем его только один раз. Мы знаем, как найти спектр простого гармонического осциллятора (ПГО). Коротко напомним, как это делается. Запишем гамильтониан в виде:

$$H_{\text{Пго}} = \frac{1}{2}p^2 + \frac{1}{2}\omega^2\phi^2.$$

Чтобы найти собственные значения $H_{\text{П}}$, запишем ϕ и p через лестничные операторы:

$$\phi = \frac{1}{\sqrt{2\omega}}\left(a + a^\dagger\right); \quad p = -i\sqrt{\frac{\omega}{2}}\left(a - a^\dagger\right).$$

Каноническое коммутационное соотношение $[\phi, p] = i$ эквивалентно соотношению

$$\left[a, a^\dagger\right] = 1.$$

Гамильтониан можно теперь переписать в виде:

$$H_{\text{Пго}} = \omega\left(a^\dagger a + \frac{1}{2}\right).$$

Состояние $|0\rangle$, такое, что $a|0\rangle = 0$, является собственным состоянием H с собственным значением $\frac{1}{2}\omega$, равным энергии нулевых колебаний. Далее, с помощью коммутаторов

$$\left[H_{\text{Пго}}\,, a^\dagger\right] = \omega a^\dagger, \quad \left[H_{\text{Пго}}\,, a\right] = -\omega a$$

легко проверить, что состояния

$$|n\rangle \equiv \left(a^\dagger\right)^n |0\rangle$$

являются собственными состояниями $H_{\text{ПГО}}$ с собственными значениями $\left(n+\frac{1}{2}\right)\omega$. Этими состояниями исчерпывается спектр.

Спектр гамильтониана Клейна-Гордона можем найти, используя тот же прием, но теперь каждая мода Фурье поля рассматривается как независимый осциллятор со своими собственными a и $a^\dagger$. По аналогии с (2.23) мы пишем:

$$\phi(\mathbf{x}) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2\omega_{\mathbf{p}}}}\left(a_{\mathbf{p}}e^{i\mathbf{p}\cdot\mathbf{x}} + a^\dagger_{\mathbf{p}}e^{-i\mathbf{p}\cdot\mathbf{x}}\right)$$

$$\pi(\mathbf{x}) = \int \frac{d^3p}{(2\pi)^3}(-i)\sqrt{\frac{\omega_{\mathbf{p}}}{2}}\left(a_{\mathbf{p}}e^{i\mathbf{p}\cdot\mathbf{x}} - a^\dagger_{\mathbf{p}}e^{-i\mathbf{p}\cdot\mathbf{x}}\right)$$

Обратные выражения для $a_{\mathbf{p}}$ и $a_{\mathbf{p}}^{\dagger}$ через ϕ и π легко выводятся, но они редко используются. Для дальнейших вычислений полезно переписать (2.25) и (2.26) следующим образом:

$$\phi(\mathbf{x}) = \int \frac{d^3p}{(2\pi)^3} \frac{1}{\sqrt{2\omega_{\mathbf{p}}}} \left(a_{\mathbf{p}} + a_{-\mathbf{p}}^{\dagger}\right) e^{i\mathbf{p}\cdot\mathbf{x}}$$
$$\pi(\mathbf{x}) = \int \frac{d^3p}{(2\pi)^3} (-i) \sqrt{\frac{\omega_{\mathbf{p}}}{2}} \left(a_{\mathbf{p}} - a_{-\mathbf{p}}^{\dagger}\right) e^{i\mathbf{p}\cdot\mathbf{x}}.$$

Коммутационное соотношение (2.24) принимает вид:

$$\left[a_{\mathbf{p}}, a_{\mathbf{p}'}^{\dagger}\right] = (2\pi)^3 \delta^{(3)}\left(\mathbf{p} - \mathbf{p}'\right),$$

при помощи которого вычисляется коммутатор ϕ и π:

$$[\phi(\mathbf{x}), \pi\left(\mathbf{x}'\right)] = \int \frac{d^3p d^3p'}{(2\pi)^6} \frac{-i}{2} \sqrt{\frac{\omega_{\mathbf{p}'}}{\omega_{\mathbf{p}}}} \left(\left[a_{-\mathbf{p}}^{\dagger}, a_{\mathbf{p}'}\right] - \left[a_{\mathbf{p}}, a_{-\mathbf{p}'}^{\dagger}\right]\right) e^{i(\mathbf{p}\cdot\mathbf{x} + \mathbf{p}'\cdot\mathbf{x}')} =$$
$$= i\delta^{(3)}\left(\mathbf{x} - \mathbf{x}'\right).$$

Этот коммутатор имеет правильный вид. (Если вычисления такого типа незнакомы читателю, то мы рекомендуем тщательно их проделать; после небольшой практики они становятся совершенно простыми, но имеют фундаментальное значение для формализма, рассматриваемого в следующих двух главах.)

Теперь можно выразить гамильтониан через повышающие и понижающие операторы. Начиная с выражения (2.8) через ϕ и π, получаем:

$$H = \int d^3x \int \frac{d^3p d^3p'}{(2\pi)^6} e^{i(\mathbf{p}+\mathbf{p}')\cdot\mathbf{x}} \left\{ -\frac{\sqrt{\omega_{\mathbf{p}}\omega_{\mathbf{p}'}}}{4} \left(a_{\mathbf{p}} - a_{-\mathbf{p}}^{\dagger}\right) \left(a_{\mathbf{p}'} - a_{-\mathbf{p}'}^{\dagger}\right) + \right.$$
$$\left. + \frac{-\mathbf{p}\cdot\mathbf{p}' + m^2}{4\sqrt{\omega_{\mathbf{p}}\omega_{\mathbf{p}'}}} \left(a_{\mathbf{p}} + a_{-\mathbf{p}}^{\dagger}\right) \left(a_{\mathbf{p}'} + a_{-\mathbf{p}'}^{\dagger}\right) \right\} =$$
$$= \int \frac{d^3p}{(2\pi)^3} \omega_{\mathbf{p}} \left(a_{\mathbf{p}}^{\dagger} a_{\mathbf{p}} + \frac{1}{2}\left[a_{\mathbf{p}}, a_{\mathbf{p}}^{\dagger}\right]\right)$$

Второе слагаемое пропорционально бесконечному с-числу $\delta(0)$. Это есть просто сумма по всем модам энергий нулевых колебаний $\omega_{\mathbf{p}}/2$. Наличие этого слагаемого следовало ожидать, но оно вызывает беспокойство. К счастью, этот бесконечный сдвиг энергии не может быть обнаружен экспериментально, так как эксперименты измеряют только разность между данной энергией и энергией основного состояния H. Поэтому мы игнорируем это бесконечное постоянное слагаемое во всех вычислениях. Возможно, что этот сдвиг энергии основного состояния может создавать проблему на более глубоком уровне теории; мы обсудим этот вопрос в Эпилоге.

Используя выражение для гамильтониана через $a_{\mathbf{p}}$ и $a_{\mathbf{p}}^{\dagger}$, нетрудно найти коммутаторы:

$$\left[H, a_{\mathbf{p}}^{\dagger}\right] = \omega_{\mathbf{p}} a_{\mathbf{p}}^{\dagger}; \quad [H, a_{\mathbf{p}}] = -\omega_{\mathbf{p}} a_{\mathbf{p}}$$

Теперь можно выписать спектр теории так же, как и для гармонического осциллятора. Состояние $|0\rangle$, такое, что $a_{\mathbf{p}}|0\rangle = 0$ для всех $\mathbf{p}$, является основным состоянием, или вакуумом, причем его энергия $E = 0$ после отбрасывания бесконечной константы в (2.31). Все другие собственные состояния энергии могут быть построены путем действия операторами рождения

на $|0\rangle$. Состояние $a^\dagger_{\mathbf{p}}a^\dagger_{\mathbf{q}}\cdots|0\rangle$ является собственным состоянием гамильтониана H с энергией $\omega_{\mathbf{p}}+\omega_{\mathbf{q}}+\cdots$. Эти состояния исчерпывают спектр.

Найдя спектр гамильтониана, попробуем дать интерпретацию его собственных состояний. При помощи (2.19) и вычислений, подобных (2.31), можно записать оператор полного импульса

$$\mathbf{P}=-\int d^3x\pi(\mathbf{x})\nabla\phi(\mathbf{x})=\int\frac{d^3p}{(2\pi)^3}\mathbf{p}a^\dagger_{\mathbf{p}}a_{\mathbf{p}}$$

Таким образом, оператор $a^\dagger_{\mathbf{p}}$ рождает состояние с импульсом $\mathbf{p}$ и энергией $\omega_{\mathbf{p}}=\sqrt{|\mathbf{p}|^2+m^2}$. Аналогично, состояние $a^\dagger_{\mathbf{p}}a^\dagger_{\mathbf{q}}\cdots|0\rangle$ имеет импульс $\mathbf{p}+\mathbf{q}+....$ Естественно называть эти возбуждения частицами, так как они являются дискретными объектами, Удовлетворяющими правильному релятивистскому соотношению между импульсом и энергией. (Под частицей мы не подразумеваем нечто такое, что должно быть локализовано в пространстве; $a^\dagger_{\mathbf{p}}$ рождает частицы как собственные состояния импульса). С этого момента мы обозначаем $\omega_{\mathbf{p}}$ через $E_{\mathbf{p}}$ (или просто E), так как это действительно есть энергия частицы. Обратим внимание, что энергия всегда положительна: $E_{\mathbf{p}}=+\sqrt{|\mathbf{p}|^2+m^2}$

Обсуждаемый формализм позволяет также определить статистику наших частиц. Рассмотрим двухчастичное состояние $a^\dagger_{\mathbf{p}}a^\dagger_{\mathbf{q}}|0\rangle$. Так как $a^\dagger_{\mathbf{p}}$ и $a^\dagger_{\mathbf{q}}$ коммутируют, то это состояние тождественно состоянию $a^\dagger_{\mathbf{q}}a^\dagger_{\mathbf{p}}|0\rangle$, в котором две частицы переставлены местами. Более того, одна мода $\mathbf{p}$ может содержать произвольное количество частиц (точно так же, как простой гармонический осциллятор может быть возбужден до произвольно высокого уровня). Отсюда можно заключить, что частицы Клейна-Гордона подчиняются статистике Бозе-Эйнштейна.

Вакуумное состояние естественно считать нормированным условием $\langle0|0\rangle=1$. Одночастичные состояния $|\mathbf{p}\rangle\propto a^\dagger_{\mathbf{p}}|0\rangle$ также достаточно часто встречаются в теории, поэтому необходимо принять соглашение об их нормировке. Простейшая нормировка $\langle\mathbf{p}|\mathbf{q}\rangle=(2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})$ (используемая во многих книгах) не является лоренц-инвариантной, что можно показать, рассматривая действие буста в направлении оси z. В результате такого буста имеем $p'_3=\gamma\left(p_3+\beta E\right),E'=\gamma\left(E+\beta p_3\right)$. Используя тождество для дельта-функции

$$\delta\left(f(x)-f\left(x_0\right)\right)=\frac{1}{\left|f'\left(x_0\right)\right|}\delta\left(x-x_0\right),$$

можно записать:

$$\begin{aligned}\delta^{(3)}(\mathbf{p}-\mathbf{q})&=\delta^{(3)}\left(\mathbf{p}'-\mathbf{q}'\right)\cdot\frac{dp'_3}{dp_3}=\\&=\delta^{(3)}\left(\mathbf{p}'-\mathbf{q}'\right)\gamma\left(1+\beta\frac{dE}{dp_3}\right)=\\&=\delta^{(3)}\left(\mathbf{p}'-\mathbf{q}'\right)\frac{\gamma}{E}\left(E+\beta p_3\right)=\\&=\delta^{(3)}\left(\mathbf{p}'-\mathbf{q}'\right)\frac{E'}{E}\end{aligned}$$

Проблема состоит в том, что объемы не инвариантны по отношению к бустам; ящик объемом V в собственной системе покоя имеет объем V/γ в движущейся системе в силу лоренцевского сокращения. Но из приведенного вычисления видно, что величина $E_{\mathbf{p}}\delta^{(3)}(\mathbf{p}-\mathbf{q})$ лоренц-инвариантна. Поэтому мы определяем

$$|\mathbf{p}\rangle = \sqrt{2E_{\mathbf{p}}}a^\dagger_{\mathbf{p}}|0\rangle,$$

так что

$$\langle\mathbf{p}|\mathbf{q}\rangle = 2E_{\mathbf{p}}(2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})$$

(Множитель 2 не является необходимым, но он удобен из-за множителя 2 в (2.25).)

В гильбертовом пространстве квантовых состояний преобразование Лоренца Λ действует как унитарный оператор $U(\Lambda)$. Из условия нормировки (2.35) вытекает, что

$$U(\Lambda)|\mathbf{p}\rangle = |\Lambda\mathbf{p}\rangle.$$

Если рассматривать это преобразование действующим на оператор $a^\dagger_{\mathbf{p}}$, то можно записать

$$U(\Lambda)a^\dagger_{\mathbf{p}}U^{-1}(\Lambda) = \sqrt{\frac{E_{\Lambda\mathbf{p}}}{E_{\mathbf{p}}}}a^\dagger_{\Lambda\mathbf{p}}$$

При выбранной нормировке следует в других местах разделить некоторые выражения на $2E_{\mathbf{p}}$. Например, соотношение полноты для одночастичных состояний примет вид:

$$(\mathbf{1})_{\text{одночастичные}} = \int \frac{d^3p}{(2\pi)^3}|\mathbf{p}\rangle\frac{1}{2E_{\mathbf{p}}}\langle\mathbf{p}|,$$

где оператор слева тождествен единичному на подпространстве одночастичных состояний и равен нулю на остальной части гильбертова пространства состояний. Интегралы такого вида будут встречаться достаточно часто; действительно, интеграл

$$\int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}} = \int \frac{d^4p}{(2\pi)^4}(2\pi)\delta\left(p^2-m^2\right)\Big|_{p^0>0}$$

является лоренц-инвариантным интегралом по пространству 3-импульсов, в том смысле, что если $f(p)$ лоренц-инвариантна, то и выражение $\int \frac{d^3pf(p)}{(2E_{\mathbf{p}})}$ лоренц-инвариантно. Предполагается, что интегрирование идет по ветви $p^0 > 0$ гиперболоида $p^2 = m^2$ в пространстве 4-импульсов (рис. 2.2).

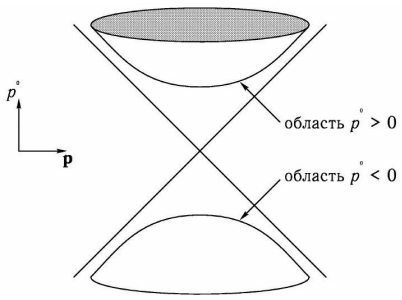

Рис. 2.2. Лоренц-инвариантный интеграл по пространству 3-импульсов берется по верхней ветви гиперболоида $p^2 = m^2$.

В заключение рассмотрим интерпретацию состояния $\phi(\mathbf{x})|0\rangle$. Из разложения (2.25) видно, что

$$\phi(\mathbf{x})|0\rangle = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}e^{-i\mathbf{p}\cdot\mathbf{x}}|\mathbf{p}\rangle$$

является линейной суперпозицией одночастичных состояний, имеющих хорошо определенный импульс. Если бы не множитель $1/2E_{\mathbf{p}}$, то это выражение совпало бы с известным нерелятивистским выражением для собственного состояния оператора координаты $|\mathbf{x}\rangle$; на самом деле дополнительный множитель почти постоянен для малых (нерелятивистских) $\mathbf{p}$. Поэтому мы придерживаемся такой же интерпретации и считаем, что оператор $\phi(\mathbf{x})$, действующий на вакуум, рождает частицу в точке x. Эта интерпретация подтверждается следующими вычислениями:

$$\langle 0|\phi(\mathbf{x})|\mathbf{p}\rangle = \left\langle 0 \left| \int \frac{d^3p'}{(2\pi)^3} \frac{1}{\sqrt{2E_{\mathbf{p}'}}} \left(a_{\mathbf{p}'} e^{i\mathbf{p}'\cdot\mathbf{x}} + a^\dagger_{\mathbf{p}'} e^{-i\mathbf{p}'\cdot\mathbf{x}} \right) \sqrt{2E_{\mathbf{p}}} a^\dagger_{\mathbf{p}} \right| 0 \right\rangle = e^{i\mathbf{p}\cdot\mathbf{x}}$$

Мы можем интерпретировать этот результат как координатное представление одночастичной волновой функции состояния $|\mathbf{p}\rangle$, точно так же, как в нерелятивистской квантовой механике $\langle \mathbf{x}|\mathbf{p}\rangle \propto e^{i\mathbf{p}\cdot\mathbf{x}}$ является волновой функцией состояния $|\mathbf{p}\rangle$ в координатном представлении.

свойства настоящего скалярного поля

(здесь по итогу останутся только свойства, пока что это не так)

Квантованное поле в релятивистской нормировке имеет вид оператора

$$\hat{\varphi}(x) = \int \frac{c d^3k}{2\omega(2\pi)^3} \left\{ e^{\mathrm{i}kx} \hat{\mathfrak{a}}^\dagger(k) + e^{-\mathrm{i}kx} \hat{\mathfrak{a}}(k) \right\}$$

Подчеркнем, что классическое поле не имеет смысла амплитуды вероятности,

т. е. волновой функции.

Оно является средним значением оператора квантованного поля по когерентным состояниям.

Согласно принципу соответствия, при большом количестве квантов $|\alpha(k)|^2 \gg 1$ флуктуациями их количества можно пренебречь, и мы имеем наблюдаемое классическое поле.

По построению гамильтониан квантованного поля получается из гамильтониана классического поля подстановкой квантованного поля и взятием нормального символа:

$$\hat{\mathcal{H}} = \frac{1}{2} \int \mathrm{d}^3\boldsymbol{x} : \left\{ \frac{1}{c^2} (\dot{\hat{\varphi}}(x))^2 + (\boldsymbol{\nabla}\hat{\varphi}(x))^2 + \frac{m^2c^2}{\hbar^2} \hat{\varphi}^2(x) \right\}$$

определение объектов

Комплексное скалярное поле с массой m определяется как суперпозиция двух вещественных полей φ_1, φ_2 с той же массой,

$$\Phi(x) = \frac{1}{\sqrt{2}} \left\{ \varphi_1(x) + \mathrm{i}\varphi_2(x) \right\}$$

так что сумму действий для вещественных компонент можно представить в виде

$$S = \frac{1}{c\hbar^2} \int \mathrm{d}^4x \Phi^\dagger(x) \left(p^2 - m^2c^2 \right) \Phi(x)$$

основные свойства

(соберем тут их)

Выделение в комплексном поле пары динамических вещественных полей допускает введение произвольной глобальной комплексной фазы u:

$$\Phi_u(x) = e^{-\mathrm{i}ue/(\hbar c)}\Phi(x)$$

что, как говорят, определяет калибровочные преобразования поля, оставляющие инвариантным действие.

Мы ввели в определение фазы фактор $\frac{e}{\hbar c}$ в том же виде, что и при определении калибровочных преобразований нерелятивистской волновой функции.

введение операторов

Мы хотим

На уравнениях движения можно ввести положительно и отрицательно частотные решения с амплитудами,

которые выражаются через амплитуды исходных вещественных полей

$$\alpha(k) = \frac{1}{\sqrt{2}}\left\{\alpha_1(k) + \mathrm{i}\alpha_2(k)\right\}, \quad \alpha_c^*(k) = \frac{1}{\sqrt{2}}\left\{\alpha_1^*(k) + \mathrm{i}\alpha_2^*(k)\right\}$$

Тогда элементарные подстановки, как в случае с вещественным полем, дают энергию

$$H = \int \frac{\mathrm{d}^3k}{2\hbar\omega(2\pi)^3}\hbar\omega\left\{\alpha^*(k)\alpha(k) + \alpha_c^*(k)\alpha_c(k)\right\}$$

и заряд $Q = \int d^3x j_0 = \mathrm{i}\frac{e}{c\hbar}\left\{\Phi^\dagger\partial_0\Phi - (\partial_0\Phi)^\dagger\Phi\right\}$ равен

$$Q = e\int \frac{\mathrm{d}^3k}{2\hbar\omega(2\pi)^3}\hbar\omega\left\{\alpha^*(k)\alpha(k) - \alpha_c^*(k)\alpha_c(k)\right\}$$

Введем для комплексного квантованного поля операторы, составленные из операторов рождения и уничтожения вещественных полей,

$$\hat{\mathfrak{a}}(\boldsymbol{k}) = \frac{1}{\sqrt{2}}\left\{\hat{\mathfrak{a}}_1(\boldsymbol{k}) + \mathrm{i}\hat{\mathfrak{a}}_2(\boldsymbol{k})\right\}, \quad \hat{\mathfrak{a}}_c^\dagger(\boldsymbol{k}) = \frac{1}{\sqrt{2}}\left\{\hat{\mathfrak{a}}_1^\dagger(\boldsymbol{k}) + \mathrm{i}\hat{\mathfrak{a}}_2^\dagger(\boldsymbol{k})\right\}$$

Для этих операторов справедливы следующие коммутационные соотношения:

$$\left[\hat{\mathfrak{a}}(k), \hat{\mathfrak{a}}^\dagger(k')\right] = \left[\hat{\mathfrak{a}}_c(k), \hat{\mathfrak{a}}_c^\dagger(k')\right] = 2\hbar\omega(2\pi)^3\delta(k-k')$$
$$\left[\hat{\mathfrak{a}}(k), \hat{\mathfrak{a}}_c(k')\right] = \left[\hat{\mathfrak{a}}(k), \hat{\mathfrak{a}}_c^\dagger(k')\right] = 0$$

И теперь квантованное поле запишется через эти операторы в виде

$$\hat{\Phi}(x) = \int \frac{cd^3k}{2\omega(2\pi)^3}\left\{e^{\mathrm{i}kx}\hat{\mathfrak{a}}_c^\dagger(k) + e^{-\mathrm{i}kx}\hat{\mathfrak{a}}(k)\right\}$$

Энергия поля задается гамильтонианом

$$\hat{\mathcal{H}} = \int \frac{\mathrm{d}^3k}{2\hbar\omega(2\pi)^3}\hbar\omega\left\{\hat{\mathfrak{a}}^\dagger(\boldsymbol{k})\hat{\mathfrak{a}}(\boldsymbol{k}) + \hat{\mathfrak{a}}_c^\dagger(\boldsymbol{k})\hat{\mathfrak{a}}_c(\boldsymbol{k})\right\}$$

В то же время квантованный заряд - это нормальный символ

$$\hat{Q} = \int \mathrm{d}^3x : j_0(x)$$

который равен

$$\hat{Q} = e \int \frac{\mathrm{d}^3k}{2\hbar\omega(2\pi)^3} \left\{ \hat{\mathfrak{a}}^\dagger(\boldsymbol{k})\hat{\mathfrak{a}}(\boldsymbol{k}) - \hat{\mathfrak{a}}_c^\dagger(\boldsymbol{k})\hat{\mathfrak{a}}_c(\boldsymbol{k}) \right\}$$

где осциллирующие со временем вклады сократились.

Полученные выражения для полной энергии и заряда квантованного поля говорят о том, что в пространстве волнового вектора

$$n_+(\boldsymbol{k}) = \frac{1}{2\hbar\omega}\hat{\mathfrak{a}}^\dagger(\boldsymbol{k})\hat{\mathfrak{a}}(\boldsymbol{k}), \quad n_-(\boldsymbol{k}) = \frac{1}{2\hbar\omega}\hat{\mathfrak{a}}_c^\dagger(\boldsymbol{k})\hat{\mathfrak{a}}_c(\boldsymbol{k})$$

- это плотности квантов с зарядом e и $-e$ соответственно.

То есть в релятивистской нормировке $\hat{a}^\dagger(k)$ - оператор рождения кванта с зарядом e,

а $\hat{\mathfrak{a}}_c^\dagger(k)$ - оператор рождения античастицы с зарядом $-$.

зарядовое сопряжение

Посмотрим, какие свойства комплексного поля можно увидеть, производя над ним зарядовое сопряжение.

Если взять комплексное сопряжение классического поля

$$\Phi(x) = \int \frac{cd^3k}{2\omega(2\pi)^3} \left\{ e^{\mathrm{i}kx}\alpha_c^*(\boldsymbol{k}) + e^{-\mathrm{i}kx}\alpha(\boldsymbol{k}) \right\}$$

в явном виде

$$\Phi^*(x) = \int \frac{cd^3k}{2\omega(2\pi)^3} \left\{ e^{-\mathrm{i}kx}\alpha_c(k) + e^{\mathrm{i}kx}\alpha^*(k) \right\}$$

то это соответствует перестановке амплитуд $\alpha \leftrightarrow \alpha_c$, а значит, вспоминая явные формулы, мы понимаем,

что для комплексно сопряженного поля сохраняется выражение для энергии H, но меняется знак заряда Q.

В этом случае это то же, что и зарядовое сопряжение.

Для обобщения этой операции на квантованные поля построим антилинейный оператор зарядового сопряжения,

который оставляет инвариантным вакуум $\mathbb{C}|0\rangle = |0\rangle$ и переводит состояние частицы в состояние античастицы, сохраняя нормировку:

$$\mathbb{C}|\boldsymbol{k}\rangle = \eta\left(Q_\Phi\right)|\boldsymbol{k}_c\rangle, \quad |\eta| = 1$$

где $Q_\Phi = 1$, - знак заряда поля, и $|\boldsymbol{k}\rangle = \hat{\mathfrak{a}}^\dagger(\boldsymbol{k})|0\rangle$, $\quad |\boldsymbol{k}_c\rangle = \hat{\mathfrak{a}}_c^\dagger(\boldsymbol{k})|0\rangle$ и

$$\eta\left(Q_\Phi\right) = e^{\mathrm{i}\gamma Q_\Phi} \equiv \eta, \quad \gamma \in \mathbb{R}, \quad \mathbb{C}Q_\Phi\mathbb{C}^{-1} = -Q_\Phi$$

Поэтому (???)

$$\mathbb{C}\eta\mathbb{C}^{-1} = \eta, \quad \mathbb{C}\hat{\mathfrak{a}}^\dagger(\boldsymbol{k})\mathbb{C}^{-1}\mathbb{C}|0\rangle = \eta\hat{\mathfrak{a}}_c^\dagger(\boldsymbol{k})|0\rangle$$

и наконец, деиствие зарядового сопряжения на оператор рож

$$\mathbb{C}\hat{\mathfrak{a}}^\dagger(\boldsymbol{k})\mathbb{C}^{-1} = \eta\hat{\mathfrak{a}}_c^\dagger(\boldsymbol{k})$$

Поскольку двукратное применение зарядового сопряжения возвращает состояние в исходное с точностью до фазы,

$$\mathbb{C}^2 = \xi, |\xi| = 1 \to \mathbb{C}^{-2} = \xi^*$$

Тогда из ($\overline{3.19}$) следует, что

$$\eta\mathbb{C}\hat{\mathfrak{a}}_c^\dagger(\boldsymbol{k})\mathbb{C}^{-1} = \hat{\mathfrak{a}}^\dagger(\boldsymbol{k}) \leftrightarrow \mathbb{C}\hat{\mathfrak{a}}_c^\dagger(\boldsymbol{k})\mathbb{C}^{-1} = \eta^*\hat{\mathfrak{a}}^\dagger(\boldsymbol{k})$$

Совершенно аналогично из инвариантности вакуума получаем

$$\mathbb{C}\hat{\mathfrak{a}}(\boldsymbol{k})\mathbb{C}^{-1}\mathbb{C}|\boldsymbol{k}\rangle = \mathbb{C}\hat{\mathfrak{a}}(\boldsymbol{k})\mathbb{C}^{-1}\eta\,|\boldsymbol{k}_c\rangle$$

Поstomy

$$\mathbb{C}\hat{\mathfrak{a}}(\boldsymbol{k})\mathbb{C}^{-1} = \eta^*\hat{\mathfrak{a}}_c(\boldsymbol{k})$$

и, как следствие,

$$\mathbb{C}\hat{\mathfrak{a}}_c(\boldsymbol{k})\mathbb{C}^{-1} = \eta\hat{\mathfrak{a}}(\boldsymbol{k})$$

В итоге, очевидно, что зарядовое сопряжение меняет знак заряда $\hat{Q}$: $\mathbb{C}Q\mathbb{C}^{-1} = -Q$, оставляя инвариантным гамильтониан. Кроме того, легко заметить, что действие зарядового сопряжения на квантованное поле практически сводится к его эрмитовому сопряжению:

$$\mathbb{C}\hat{\Phi}(x)\mathbb{C}^{-1} = \eta^*\hat{\Phi}^\dagger(x)$$

При получении данного равенства необходимо было учесть, что в определение положительно и отрицательно частотных мод формально нужно ввести символ Q_Φ, который позволяет отличать, какой заряд рождается или уничтожается:

$$\hat{\Phi}(x) = \int \frac{cd^3k}{2\omega(2\pi)^3}\left\{e^{\mathrm{i}kxQ_\Phi}\hat{\mathfrak{a}}_c^\dagger(k) + e^{-\mathrm{i}kxQ_\Phi}\hat{\mathfrak{a}}(k)\right\}$$

Тогда квантовый вариант зарядового сопряжения с антилинейным оператором C дает тот же результат, что и классический вариант комплексного сопряжения поля. При этом, конечно, квантованное действие остается инвариантным.

и что???????

нахрена нам оно?

Инверсия времени

(пока что не актуально)

Как мы уже установили, оператору инверсии стрелы времени $t \xrightarrow{\mathrm{T}} t_\mathrm{T} = -t$ отвечает операция с комплексным сопряжением. (?????) Для классического поля преобразование

$$\Phi(t,\boldsymbol{x}) \mapsto \Phi_\mathrm{T}(t_\mathbb{T},\boldsymbol{x}) = \Phi^*(t,\boldsymbol{x}) \quad \to \quad \Phi_\mathrm{T}(t_\mathrm{T},\boldsymbol{x}) = \Phi^*(-t_\mathbb{T},\boldsymbol{x})$$

или, что то же, подстановка

$$\Phi(t,\boldsymbol{x}) \mapsto \Phi^*(-t,\boldsymbol{x})$$

не изменяет действие, а поле

$$\Phi^*(-t,\boldsymbol{x}) = \int \frac{cd^3k}{2\omega(2\pi)^3}\left\{e^{\mathrm{i}\omega t+\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}\alpha_c(\boldsymbol{k}) + e^{-\mathrm{i}\omega t-\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}}\alpha^*(\boldsymbol{k})\right\}$$

после замены переменной интегрирования $k \mapsto -k$ сводится к

$$\Phi^*(-t,\boldsymbol{x}) = \int \frac{cd^3k}{2\omega(2\pi)^3}\left\{e^{\mathrm{i}kx}\alpha_c(-k) + e^{-\mathrm{i}kx}\alpha^*(-k)\right\}$$

которое, конечно, удовлетворяет уравнениям движения, и мы можем говорить об инвариантном преобразовании с инверсией стрелы времени. При этом, имеют место подстановки $\alpha(k) \mapsto \alpha^*(-k)$ и $\alpha_c^*(k) \mapsto \alpha_c(-k)$, что, конечно, оставляет инвариантными энергию и заряд, но, скажем, ток j меняет знак, поскольку вектор движения меняет направление на противоположное.

Точно такие же выводы и аналог (3.25) теперь нужно получить в квантовом случае, что должно соответствовать действию оператора

$$t \xrightarrow{\mathrm{T}} t_{\mathrm{T}} = -t$$

на поле

$$\mathbb{T}\hat{\Phi}(t,\boldsymbol{x})\mathbb{T}^{-1} \equiv \hat{\Phi}_{\mathbb{T}}\left(t_{\mathbb{T}},\boldsymbol{x}\right) = \zeta^*\hat{\Phi}^\dagger(t,\boldsymbol{x}) = \zeta^*\hat{\Phi}^\dagger\left(-t_{\mathbb{T}},\boldsymbol{x}\right)$$

Для полноты изложения отметим, что сохраняющий нормировку состояния антилинейный оператор называется антиунитарным. Действие такого оператора обладает следующими свойствами:

$$\mathbb{T}\left(c_1\left|\psi_1\right\rangle + c_2\left|\psi_2\right\rangle\right) = c_1^*\left|\mathbb{T}\psi_1\right\rangle + c_2^*\left|\mathbb{T}\psi_2\right\rangle$$

и

$$\langle\mathbb{T}\Phi|\mathbb{T}\Psi\rangle = \langle\Psi|\Phi\rangle = \langle\Phi|\Psi\rangle^*$$

Эрмитово сопряженный оператор для антилинейного определяется соотношением

$$\langle\Phi|\mathbb{T}\Psi\rangle = \left\langle\Psi|\mathbb{T}^\dagger\Phi\right\rangle$$

Движение вспять по времени нетривиально формулируется в терминах операторов рождени и уничтожения квантов. В самом деле, если оператор $\mathfrak{a}^\dagger(k)$ рождает квант с волновым вектором k в момент времени t, то рассмотрение этого же процесса в обратном направлении означает, что в момент времени $t_{\mathbb{T}} = -t$ происходит уничтожение кванта, который двигался с волновым вектором $-k$, оператором $\mathfrak{a}(-k)$. Эти взаимосвязи соответствуют операторной записи

$$\mathbb{T}e^{\mathrm{i}\omega t}\hat{\mathfrak{a}}^\dagger(k)\mathbb{T}^{-1} = \zeta e^{-\mathrm{i}\omega t_{\mathrm{T}}}\hat{\mathfrak{a}}(-k), \quad |\zeta| = 1$$

С учетом действия антилинейного оператора

$$\mathbb{T}e^{\mathrm{i}\omega t}\ \mathrm{T}^{-1} = e^{-\mathrm{i}\omega t_{\mathrm{T}}}$$

устанавливаем, что

$$\mathbb{T}\hat{\mathfrak{a}}^\dagger(k)\mathbb{T}^{-1} = \zeta\hat{\mathfrak{a}}(-k)$$

В этом тождестве двукратное действие операторами T дает

$$\hat{\mathfrak{a}}^\dagger(\boldsymbol{k}) = \mathbb{T}\zeta\hat{\mathfrak{a}}(-\boldsymbol{k})\mathbb{T}^{-1} = \mathbb{T}\zeta\mathbb{T}^{-1}\mathbb{T}\hat{\mathfrak{a}}(-\boldsymbol{k})\mathbb{T}^{-1}$$

Теперь необходимо установить, как преобразуется фазовый множитель ζ, и мы положим

$$\mathbb{T}\zeta\mathbb{T}^{-1} = \zeta$$

что возможно только, если по аналогии с зарядовым сопряжением, где мы вводили оператор знака заряда, ввести знак стрелы времени $\lambda_{\mathbb{T}} = 1$, чтобы

$$\mathbb{T}\lambda_{\mathbb{T}}\mathbb{T}^{-1} = -\lambda_{\mathbb{T}}$$

и

$$\zeta = e^{\mathrm{i}\gamma'\lambda_{\mathrm{T}}}, \quad \gamma' \in \mathbb{R}$$

При такой прескрипции, как мы увидим, эрмитов оператор числа квантов переходит в эрмитов оператор числа квантов, которые движутся в противоположном направлении.

Подытоживая выкладки, находим для антилинейного оператора инверсии времени

$$\begin{aligned}
\mathbb{T}\hat{\mathfrak{a}}(k)\mathbb{T}^{-1} &= \zeta^*\hat{\mathfrak{a}}^\dagger(-k) \\
\mathbb{T}\hat{\mathfrak{a}}_c^\dagger(k)\mathbb{T}^{-1} &= \zeta_c\hat{\mathfrak{a}}_c(-k) \\
\mathbb{T}\hat{\mathfrak{a}}_c(k)\mathbb{T}^{-1} &= \zeta_c^*\hat{a}_c^\dagger(-k)
\end{aligned}$$

где мы ввели аналогичный фазовый фактор ζ_c и для античастиц. Тогда в силу

$$\begin{aligned}
\mathbb{T}\hat{\mathfrak{a}}^\dagger(k)\hat{\mathfrak{a}}(k)\mathbb{T}^{-1} &= \hat{\mathfrak{a}}(-k)\hat{\mathfrak{a}}^\dagger(-k) \\
\mathbb{T}\hat{\mathfrak{a}}_c^\dagger(k)\hat{\mathfrak{a}}_c(k)\mathbb{T}^{-1} &= \hat{\mathfrak{a}}_c(-k)\hat{\mathfrak{a}}_c^\dagger(-k)
\end{aligned}$$

применение к этим эрмитово самосопряженным выражениям операции нормального упорядочивания позволяет установить, что гамильтониан $\hat{\mathcal{H}}$ и заряд поля $\hat{Q}$ останутся инвариантными при обрашении стрелы времени, как этого и следовало ожидать.

Действие оператора инверсии времени на квантовое поле при $t \mapsto t_{\mathrm{T}} = -t$ будет соответствовать классическим операциям, если в явном виде ввести соответствие положительно и отрицательно частотнъх мод и знака стрелы времени:

$$e^{\mp\mathrm{i}kx} \mapsto e^{\mp\mathrm{i}kx\lambda_{\mathrm{T}}}$$

а значит, с учетом $\mathbb{T}\left(\mathrm{i}\lambda_{\mathbb{T}}\right)\mathrm{T}^{-1} = \mathrm{i}\lambda_{\mathbb{T}}$ найдем после замены переменной интегрирования во втором из следующих равенств $k \mapsto -k$

$$\begin{aligned}
\mathbb{T}\hat{\Phi}(t,\boldsymbol{x})\mathbb{T}^{-1} = \int \frac{cd^3k}{2\omega(2\pi)^3}\left\{e^{\mathrm{i}(\omega t_{\mathrm{T}}-\boldsymbol{k}\cdot\boldsymbol{x})}\zeta_c\hat{\mathfrak{a}}_c(-\boldsymbol{k}) + e^{-\mathrm{i}(\omega t_{\mathrm{T}}-\boldsymbol{k}\cdot\boldsymbol{x})}\zeta^*\hat{\mathfrak{a}}^\dagger(-\boldsymbol{k})\right\} = \\
= \int \frac{cd^3k}{2\omega(2\pi)^3}\left\{e^{-\mathrm{i}(-\omega t_{\mathrm{T}}-\boldsymbol{k}\cdot\boldsymbol{x})}\zeta_c\hat{\mathfrak{a}}_c(\boldsymbol{k}) + e^{\mathrm{i}(-\omega t_{\mathrm{T}}-\boldsymbol{k}\cdot\boldsymbol{x})}\zeta^*\hat{\mathfrak{a}}^\dagger(\boldsymbol{k})\right\} \quad (9.1)
\end{aligned}$$

что, конечно, сводится к

$$\mathbb{T}\hat{\Phi}(t,\boldsymbol{x})\mathbb{T}^{-1} \equiv \hat{\Phi}_{\mathbb{T}}\left(t_{\mathbb{T}},\boldsymbol{x}\right) = \zeta^*\hat{\Phi}^\dagger\left(-t_{\mathbb{T}},\boldsymbol{x}\right)$$

ТОлько если

$$\zeta^* = \zeta_c$$

С учетом (3.33) квантовое действие свободного комплексного скалярного поля останется инвариантным относительно инверсии времени.

Инверсия пространства

(пока что не актуально)
Зеркальное отражение пространства

$$\boldsymbol{x} \xrightarrow{\mathbb{P}} \boldsymbol{x}_{\mathbb{P}} = -\boldsymbol{x}$$

в квантовой механике свободной релятивистской скалярной частицы соответствует линейному оператору, сохраняющему вакуум

$$\mathbb{P}|0\rangle = |0\rangle$$

и преобразующему, например, одночастичное состояние, сохраняя его норму:

$$\mathbb{P}|k\rangle = \xi|-k\rangle, \quad |\xi| = 1$$

и аналогично для античастицы.

Тогда та же схема рассуждений, что и в двух предыдущих разделах, приводит к следующим соотношениям:

$$\begin{array}{ll} \mathbb{P}\hat{\mathfrak{a}}^\dagger(k)\mathbb{P}^{-1} = \xi\hat{\mathfrak{a}}^\dagger(-k), & \mathbb{P}\hat{\mathfrak{a}}(k)\mathbb{P}^{-1} = \xi^*\hat{\mathfrak{a}}(-k) \\ \mathbb{P}\hat{\mathfrak{a}}_c^\dagger(k)\mathbb{P}^{-1} = \xi_c\hat{\mathfrak{a}}_c^\dagger(-k), & \mathbb{P}\hat{\mathfrak{a}}_c(k)\mathbb{P}^{-1} = \xi_c^*\hat{\mathfrak{a}}_c(-k) \end{array}$$

Если учесть элементарные соотношения типа

$$\mathbb{P}e^{\mathrm{i}\boldsymbol{x}\cdot\boldsymbol{k}}\mathbb{P}^{-1} = e^{\mathrm{i}\boldsymbol{x}_{\mathrm{P}}\cdot\boldsymbol{k}} = e^{-\mathrm{i}\boldsymbol{x}\cdot\boldsymbol{k}}$$

и в разложении поля по модам сделать очевидную замену переменных $k \mapsto -k$, то поле преобразуется согласно

$$\mathbb{P}\hat{\Phi}(t,\boldsymbol{x})\mathbb{P}^{-1} = \hat{\Phi}_{\mathbb{P}}(t,\boldsymbol{x}_{\mathbb{P}}) = \xi^*\hat{\Phi}(t,\boldsymbol{x})$$

если $\xi^* = \xi_c$, что дает также инвариантность действия. В итоге, преобразованное поле -

$$\hat{\Phi}_{\mathbb{P}}(t,\boldsymbol{x}) = \xi^*\hat{\Phi}(t,-\boldsymbol{x})$$

3.2.4.

Моды и пропагатор

Для квантованного комплексного скалярного поля

$$\hat{\Phi}(x) = \int \frac{\mathrm{d}^3k}{2\omega(2\pi)^3}\left\{e^{\mathrm{i}kx}\hat{\mathfrak{a}}_c^\dagger(k) + e^{-\mathrm{i}kx}\hat{\mathfrak{a}}(k)\right\}$$

необходимо подчеркнуть связь положительно и отрицательно частотных мод с пропагатором. В самом деле, для частиц положительно частотная мода получается при действии на состояние кванта оператора поля,

$$\langle 0|\hat{\Phi}(x)|k\rangle = e^{-\mathrm{i}kx}$$

а для античастиц положительно частотная мода получается при действии на состояние кванта оператора эрмитово сопряженного поля,

$$\left\langle 0\left|\hat{\Phi}^\dagger(x)\right|k_c\right\rangle = e^{-\mathrm{i}kx}$$

Аналогично для отрицательно частотных мод

$$\left\langle \boldsymbol{k} \left| \hat{\Phi}^\dagger(x) \right| 0 \right\rangle = e^{\mathrm{i}kx}, \quad \left\langle \boldsymbol{k}_c | \hat{\Phi}(x) | 0 \right\rangle = e^{\mathrm{i}kx}$$

Поэтому причинная функция Грина отвечает следующему матричному элементу

$$\left\langle 0 \left| \, \mathrm{T} \left\{ \hat{\Phi}(x) \hat{\Phi}^\dagger(y) \right\} \right| 0 \right\rangle = \mathrm{i} \int \frac{\mathrm{d}^4 k}{(2\pi)^4} e^{-\mathrm{i}k(x-y)} \frac{1}{k^2 - m^2 + \mathrm{i}0}$$

Это значит, что при графическом изображении пропагатора заряженной частицы необходимо указывать стрелкой направление распространения заряда: частица распространяется, если $x_0 > y_0$, а если $y_0 > x_0$, то распространяется античастица.

Что касается коммутатора полей, который необходимо рассмотреть для выяснения зависимости операторов вне светового конуса, то необходимо напомнить, что комплексное поле построено из двух независимых вещественных полей $\Phi = \frac{1}{\sqrt{2}} (\varphi_1 + \mathrm{i}\varphi_2)$, так что

$$\left[\hat{\Phi}(x), \hat{\Phi}^\dagger(y) \right] = \frac{1}{2} \left[\hat{\varphi}_1(x), \hat{\varphi}_1(y) \right] + \frac{1}{2} \left[\hat{\varphi}_2(x), \hat{\varphi}_2(y) \right]$$

а значит, мы имеем дело всё с той же функцией Паули-Йордана, которая обращается в нуль вне светового конуса, и, стало быть, принцип релятивистской причинности, конечно, выполняется.

9.1.2 The Klein-Gordon field in space-time

Теория

В предыдущем разделе мы проквантовали поле Клейна-Гордона в представлении Шредингера и дали интерпретацию возникающей в результате теории в терминах релятивистских частиц. В этом разделе рассмотрим представление Гейзенберга, в котором будет легче обсуждать зависимость величин от времени и вопросы причинности. После вводных формул мы вернемся к вопросу о причинном распространении, поднятому в разделе 2.1. Мы также получим выражение для пропагатора Клейна-Гордона, играющего ключевую роль в разрабатываемых в гл. 4 правилах Фейнмана.

В представлении Гейзенберга операторы ϕ и π зависят от времени обычным обра30М:

$$\phi(x) = \phi(\mathbf{x}, t) = e^{iHt} \phi(\mathbf{x}) e^{-iHt}$$

и аналогично для $\pi(x) = \pi(\mathbf{x}, t)$. Уравнения движения Гейзенберга

$$i \frac{\partial}{\partial t} \mathscr{O} = [\mathscr{O}, H]$$

позволяют найти зависимость ϕ и π от времени:

$$
\begin{aligned}
i\frac{\partial}{\partial t}\phi(\mathbf{x},t) &= \left[\phi(\mathbf{x},t), \int d^3x' \left\{\frac{1}{2}\pi^2\left(\mathbf{x}',t\right) + \frac{1}{2}\left(\nabla\phi\left(\mathbf{x}',t\right)\right)^2 + \frac{1}{2}m^2\phi^2\left(\mathbf{x}',t\right)\right\}\right] = \\
&= \int d^3x' \left(i\delta^{(3)}\left(\mathbf{x}-\mathbf{x}'\right)\pi\left(\mathbf{x}',t\right)\right) = \\
&= i\pi(\mathbf{x},t); \\
i\frac{\partial}{\partial t}\pi(\mathbf{x},t) &= \left[\pi(\mathbf{x},t), \int d^3x' \left\{\frac{1}{2}\pi^2\left(\mathbf{x}',t\right) + \frac{1}{2}\phi\left(\mathbf{x}',t\right)\left(-\nabla^2+m^2\right)\phi\left(\mathbf{x}',t\right)\right\}\right] = \\
&= \int d^3x' \left(-i\delta^{(3)}\left(\mathbf{x}-\mathbf{x}'\right)\left(-\nabla^2+m^2\right)\phi\left(\mathbf{x}',t\right)\right) = \\
&= -i\left(-\nabla^2+m^2\right)\phi(\mathbf{x},t).
\end{aligned}
$$

Объединяя результаты, находим:

$$\frac{\partial^2}{\partial t^2}\phi = \left(\nabla^2 - m^2\right)\phi$$

т. е. получаем уравнение Клейна-Гордона. Мы можем лучше понять зависимость от времени $\phi(x)$ и $\pi(x)$, записывая их через операторы рождения и уничтожения. Сначала заметим, что

$$Ha_{\mathbf{p}} = a_{\mathbf{p}}\left(H - E_{\mathbf{p}}\right)$$

и, следовательно,

$$H^n a_{\mathbf{p}} = a_{\mathbf{p}}\left(H - E_{\mathbf{p}}\right)^n$$

для любого n. Подобное соотношение (с $-$, замененным на $+$) имеет место для $a^\dagger_{\mathbf{p}}$. Таким образом, мы получаем тождества

$$e^{iHt}a_{\mathbf{p}}e^{-iHt} = a_{\mathbf{p}}e^{-iE_{\mathbf{p}}t}, \quad e^{iHt}a^\dagger_{\mathbf{p}}e^{-iHt} = a^\dagger_{\mathbf{p}}e^{iE_{\mathbf{p}}t}$$

которые можно использовать в выражении (2.25) для $\phi(\mathbf{x})$, чтобы согласно (2.43) найти искомое выражение для гейзенберговского оператора $\phi(x)$. (Для обозначения независящих от времени повышающих и понижающих операторов в представлении Шредингера мы всегда будем использовать символы $a_{\mathbf{p}}$ и $a^\dagger_{\mathbf{p}}$.) Результат имеет вид

$$
\begin{aligned}
\phi(\mathbf{x},t) &= \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\left(a_{\mathbf{p}}e^{-ip\cdot x} + a^\dagger_{\mathbf{p}}e^{ip\cdot x}\right)\Big|_{p^0=E_{\mathbf{p}}} \\
\pi(\mathbf{x},t) &= \frac{\partial}{\partial t}\phi(\mathbf{x},t)
\end{aligned}
$$

Стоит заметить, что такие же манипуляции можно выполнить с $\mathbf{P}$ вместо H, чтобы связать $\phi(\mathbf{x})$ и $\phi(0)$. По аналогии с (2.46) можно показать, что

$$e^{-i\mathbf{P}\cdot\mathbf{x}}a_{\mathbf{p}}e^{i\mathbf{P}\cdot\mathbf{x}} = a_{\mathbf{p}}e^{i\mathbf{p}\cdot\mathbf{x}}, \quad e^{-i\mathbf{P}\cdot\mathbf{x}}a^\dagger_{\mathbf{p}}e^{i\mathbf{P}\cdot\mathbf{x}} = a^\dagger_{\mathbf{p}}e^{-i\mathbf{p}\cdot\mathbf{x}},$$

и, следовательно,

$$\phi(x) = e^{i(Ht-\mathbf{P}\cdot\mathbf{x})}\phi(0)e^{-i(Ht-\mathbf{P}\cdot\mathbf{x})} = e^{iP\cdot x}\phi(0)e^{-iP\cdot x},$$

где $P^\mu = (H, \mathbf{P})$. (Обозначения здесь могут запутать, но они стандартны. Напомним, что $\mathbf{P}$ - оператор импульса, собственное значение которого является полным импульсом системы. С другой стороны, p - импульс одной фурье-моды поля, который мы интерпретируем как импульс частицы в этой моде. Для одночастичного состояния с определенным импульсом величина $\mathbf{p}$ является собственным значением оператора P.)

Уравнение (2.47) указывает на корпускулярно-волновой дуализм в интерпретации квантованного поля $\phi(x)$. С одной стороны, поле $\phi(x)$ представлено как оператор в гильбертовом пространстве, который рождает и уничтожает частицы, являющиеся квантами возбуждения этого поля. С другой стороны, поле $\phi(x)$ записывается как линейная комбинация решений ($e^{ip\cdot x}$ и $e^{-ip\cdot x}$) уравнения Клейна-Гордона. В экспоненте появляются оба знака для временнОй зависимости: присутствуют как $e^{-ip^0 t}$, так и $e^{+ip^0 t}$, причем p^0 всегда положителен. Для одночастичных волновых функций это соответствовало бы состояниям с положительной и отрицательной энергиями; далее будем называть эти состояния положительно- и отрицательно-частотными модами. Такая связь между операторами рождения частиц и видом рассматриваемых волновых функций всегда имеет место для свободных квантовых полей: положительно-частотное решение уравнения поля имеет в качестве коэффициента оператор уничтожения частицы в состоянии с соответствующей одночастичной волновой функцией. Отрицательно-частотное решение уравнения поля, являющееся эрмитово сопряженным к положительно-частотному решению, имеет коэффициентом оператор рождения частицы в состоянии с соответствующей одночастичной волновой функцией с положительной энергией. Таким образом, тот факт, что релятивистские волновые уравнения имеют и положительно-, и отрицательно-частотные решения, согласуется с требованием, чтобы разумная квантовая теория содержала только положительные энергии возбуждения.

9.1.3 Causality for Scalar Field

Обсудим подробно причинность.
(это очень подробно нужно написать!!!!)

Теория

Теперь вернемся к вопросу о причинности, поднятому в начале этой главы. В рамках рассматриваемого формализма и в представлении Гейзенберга амплитуда распространения частицы от точки y до точки x равна $\langle 0|\phi(x)\phi(y)|0\rangle$. Обозначим эту величину $D(x-y)$. Каждый оператор ϕ есть сумма операторов уничтожения a и рождения $a^\dagger$, но в выражении для этой амплитуды выживает только слагаемое $\left\langle 0 \left| a_{\mathbf{p}} a_q^\dagger \right| 0 \right\rangle = (2\pi)^3 \delta^{(3)}(\mathbf{p}-\mathbf{q})$. Легко проверить, что

$$D(x-y) = \langle 0|\phi(x)\phi(y)|0\rangle = \int \frac{d^3p}{(2\pi)^3} \frac{1}{2E_{\mathbf{p}}} e^{-ip\cdot(x-y)}$$

Мы уже показали в (2.40), что интегралы такого вида лоренц-инвариантны. Теперь вычислим этот интеграл для конкретных значений $x-y$.

Сначала рассмотрим случай, когда отлична от нуля только временная компонента разности $x-y : x^0 - y^0 = t, \mathbf{x}-\mathbf{y} = 0$. (Если интервал от y до x времениподобен, то всегда найдется система отсчета, в которой он чисто временной.) Тогда имеем:

$$D(x-y) = \frac{4\pi}{(2\pi)^3}\int\limits_0^\infty dp \frac{p^2}{2\sqrt{p^2+m^2}} e^{-i\sqrt{p^2+m^2}t} =$$
$$= \frac{1}{4\pi^2}\int\limits_m^\infty dE\sqrt{E^2-m^2}e^{-iEt} \underset{t\to\infty}{\sim} e^{-imt}$$

Далее рассмотрим случай, когда разность $x-y$ является чисто пространственной: $x^0-y^0 = 0, \mathbf{x}-\mathbf{y} = \mathbf{r}$. Амплитуда тогда имеет вид:

$$D(x-y) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}} e^{i\mathbf{p}\cdot\mathbf{r}} =$$
$$= \frac{2\pi}{(2\pi)^3}\int\limits_0^\infty dp \frac{p^2}{2E_{\mathbf{p}}}\frac{e^{ipr}-e^{-ipr}}{ipr} =$$
$$= \frac{-i}{2(2\pi)^2 r}\int\limits_{-\infty}^\infty dp \frac{pe^{ipr}}{\sqrt{p^2+m^2}}$$

Подынтегральное выражение, рассматриваемое как функция комплексной переменной p, имеет разрезы вдоль мнимой оси, начинающиеся в точках $\pm im$ (рис. 2.3). Для вычисления интеграла деформируем контур интегрирования в верхнюю полуплоскость так, чтобы он обошел верхний разрез. Полагая $\rho = -ip$, получаем

$$\frac{1}{4\pi^2 r}\int\limits_m^\infty d\rho \frac{\rho e^{-\rho r}}{\sqrt{\rho^2-m^2}} \underset{r\to\infty}{\sim} e^{-mr}.$$

Таким образом, оказывается, что вне светового конуса амплитуда распространения экспоненциально убывает, тем не менее, она остается отличной от нуля.

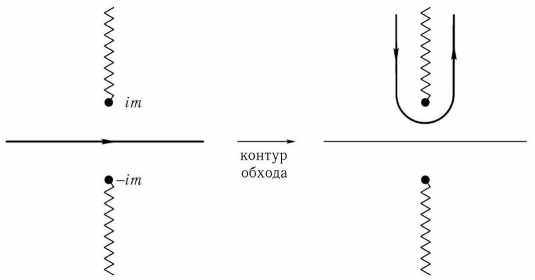

Рис. 2.3. Контур для вычисления амплитуды распространения $D(x-y)$ по пространственноподобному интервалу.

Однако для действительного понимания принципа причинности следует рассмотреть не столько вопрос о том, могут ли распространяться частицы на пространственноподобные расстояния, сколько вопрос о возможности воздействия измерения, проведенного в одной точке, на измерение, проводимое в другой точке, если эти точки разделены пространственноподобным интервалом. Простейшее, что можно попытаться измерить, - это поле $\phi(x)$. Для этого следует вычислить коммутатор $[\phi(x), \phi(y)]$; если этот коммутатор равен нулю, то одно измерение не может повлиять на другое. На самом деле, если

коммутатор равен нулю для $(x-y)^2 < 0$, то принцип причинности имеет место в общем случае, так как коммутаторы от любых функций $\phi(x)$, включая $\pi(x) = \partial\phi/\partial t$, также будут нулевыми. Из выражения (2.20) мы знаем, что этот коммутатор равен нулю при $x^0 = y^0$; теперь проведем более общее вычисление:

$$[\phi(x), \phi(y)] = \int \frac{d^3p}{(2\pi)^3} \frac{1}{\sqrt{2E_{\mathbf{p}}}} \int \frac{d^3q}{(2\pi)^3} \frac{1}{\sqrt{2E_{\mathbf{q}}}} \left[\left(a_{\mathbf{p}} e^{-ip\cdot x} + a^\dagger_{\mathbf{p}} e^{ip\cdot x} \right), \left(a_{\mathbf{q}} e^{-iq\cdot y} + a^\dagger_{\mathbf{q}} e^{iq\cdot y} \right) \right] =$$
$$= \int \frac{d^3p}{(2\pi)^3} \frac{1}{2E_{\mathbf{p}}} \left(e^{-ip\cdot(x-y)} - e^{ip\cdot(x-y)} \right) = D(x-y) - D(y-x).$$

Если $(x-y)^2 < 0$, то можно совершить преобразование Лоренца над вторым слагаемым (так как каждый член в отдельности лоренц-инвариантен), переводящее $(x-y) \to -(x-y)$ (рис. 2.4).

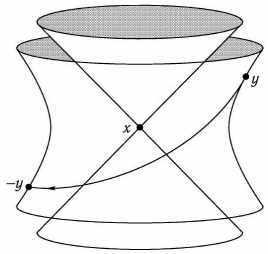

Рис. 2.4. Когда разность $x-y$ пространственноподобна, существует непрерывное преобразование Лоренца, переводящее $(x-y)$ в $-(x-y)$. (????? да почему????)

Таким образом, два слагаемых оказываются равными и сокращаются. Тем самым причинность сохраняется. Обратим внимание, что, если $(x-y)^2 > 0$, то не существует непрерывного преобразования Лоренца, которое переводит $(x-y) \to -(x-y)$. В этом случае согласно (2.51) амплитуда (к счастью) отлична от нуля, в частности, когда $\mathbf{x}-\mathbf{y}=0$, она ведет себя как $(e^{-imt} - e^{imt})$. Таким образом, мы заключаем, что никакое измерение в теории Клейна-Гордона не может повлиять на другое измерение вне светового конуса.

Как мы и предполагали в конце раздела 2.1, в теории Клейна-Гордона причинность имеет место. Чтобы лучше понять этот механизм, следует расширить рамки нашего обсуждения, включив в рассмотрение комплексное поле Клейна-Гордона, имеющее различающиеся возбуждения, отвечающие частицам и античастицам. Как было упомянуто при обсуждении (2.15), если поле $\phi(x)$ является не вещественным, а комплексным, в теории Клейна-Гордона существует сохраняющийся заряд. При квантовании комплексной скалярной теории поля (см. задачу 2.2) поле $\phi(x)$ рождает положительно заряженные и уничтожает отрицательно заряженные частицы, в то время как $\phi^\dagger(x)$ производит противоположные операции. Тогда коммутатор $\left[\phi(x), \phi^\dagger(y)\right]$ будет иметь отличные от нуля составляющие, которые для сохранения причинности должны точно сокращаться вне светового конуса. Два вклада с приписанными зарядами отвечают двум слагаемым в (2.53). Первое слагаемое представляет амплитуду распространения отрицательно заряженной частицы из точки y в точку x. Второе слагаемое представляет амплитуду распространения положительно заряженной частицы из точки x в точку y. Для того чтобы оба упомянутых процесса имели место и их амплитуды взаимно сокращались, обе эти частицы должны существовать в теории и иметь одинаковые массы. Таким образом, принцип причинности в квантовой теории поля требует, чтобы каждая частица имела соответствующую античастицу той же самой массы и с противоположными квантовыми числами (в данном

случае - электрическим зарядом). Для вещественного поля Клейна-Гордона частица является своей собственной античастицей.

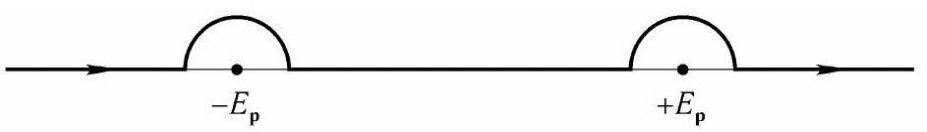
9.1.4 The Klein-Gordon Propagator

Теория

Изучим коммутатор $[\phi(x), \phi(y])$. Так как он является с-числом, можно записать: $[\phi(x), \phi(y)] = \langle 0|[\phi(x), \phi(y)]|0\rangle$. Предполагая, что $x^0 > y^0$, можно переписать это выражение в виде четырехмерного интеграла:

$$\begin{aligned}\langle 0|[\phi(x), \phi(y)]|0\rangle &= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}\left(e^{-ip\cdot(x-y)} - e^{ip\cdot(x-y)}\right) = \\ &= \int \frac{d^3p}{(2\pi)^3}\left\{\frac{1}{2E_{\mathbf{p}}}e^{-ip\cdot(x-y)}\Big|_{p^0=E_{\mathbf{p}}} + \frac{1}{-2E_{\mathbf{p}}}e^{-ip\cdot(x-y)}\Big|_{p^0=-E_{\mathbf{p}}}\right\} x^0 > y^0 \\ &= {}_{x^0>y^0}\int \frac{d^3p}{(2\pi)^3}\int \frac{dp^0}{2\pi i}\frac{-1}{p^2-m^2}e^{-ip\cdot(x-y)}.\end{aligned}$$

В последнем интеграле интегрирование по p^0 выполняется вдоль контура:



Для $x^0 > y^0$ можно замкнуть контур в нижней полуплоскости, обходя оба полюса сверху, в результате чего получим предпоследнюю строку в формуле (2.54). Для $x^0 < y^0$ мы можем замкнуть контур в верхней полуплоскости, получив нуль. Таким образом, интеграл в последней строке (2.54) вместе с правилом обхода полюсов является чис- ленным выражением величины

$$D_R(x-y) \equiv \theta\left(x^0 - y^0\right)\langle 0|[\phi(x), \phi(y)]|0\rangle.$$

Чтобы лучше понять смысл этой величины, проделаем еще одно вычисление:

$$\begin{aligned}\left(\partial^2 + m^2\right)D_R(x-y) = &\left(\partial^2\theta\left(x^0-y^0\right)\right)\langle 0|[\phi(x),\phi(y)]|0\rangle + \\ &+ 2\left(\partial_\mu\theta\left(x^0-y^0\right)\right)\left(\partial^\mu\langle 0|[\phi(x),\phi(y)]|0\rangle\right) + \\ &+ \theta\left(x^0-y^0\right)\left(\partial^2+m^2\right)\langle 0|[\phi(x),\phi(y)]|0\rangle = \\ =&\delta\left(x^0-y^0\right)\langle 0|[\pi(x),\phi(y)]|0\rangle + \\ &+ 2\delta\left(x^0-y^0\right)\langle 0|[\pi(x),\phi(y)]|0\rangle + 0 = \\ =&-i\delta^{(4)}(x-y).\end{aligned}$$

Отсюда следует, что $D_R(x-y)$ является функцией Грина оператора Клейна-Гордона. Так как эта функция обращается в нуль для $x^0 < y^0$, то это запаздывающая функция Грина.

Если бы мы еще не получили выражение (2.54), его можно было бы получить с помощью преобразования Фурье. Записывая

$$D_R(x-y) = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot(x-y)} \widetilde{D}_R(p),$$

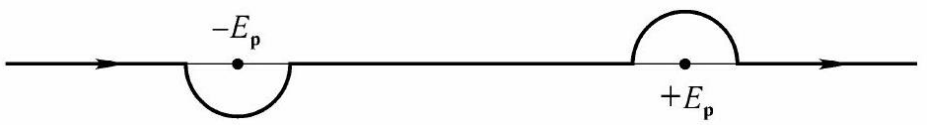
мы получаем алгебраическое выражение для $\widetilde{D}_R(p)$:

$$\left(-p^2 + m^2\right) \widetilde{D}_R(p) = -i.$$

Таким образом, сразу приходим к следующему результату:

$$D_R(x-y) = \int \frac{d^4p}{(2\pi)^4} \frac{i}{p^2 - m^2} e^{-ip\cdot(x-y)}$$

Интеграл по p^0 в (2.58) может быть вычислен по четырем различным контурам, из которых в (2.54) использовался только один. В гл. 4 мы найдем, что чрезвычайно полезным является другое правило обхода полюсов:



Это правило называется правилом Фейнмана. Чтобы запомнить его, удобно записать интеграл для функции Грина в виде:

$$D_F(x-y) \equiv \int \frac{d^4p}{(2\pi)^4} \frac{i}{p^2 - m^2 + i\varepsilon} e^{-ip\cdot(x-y)}$$

так как полюса теперь находятся в точках $p^0 = \pm\left(E_{\mathbf{p}} - i\varepsilon\right)$, смещенных соответственно ниже и выше вещественной оси. Когда $x^0 > y^0$, можно брать интеграл по p^0, замыкая контур интегрирования вниз, в результате получая в точности амплитуду распространения $D(x-y)$(2.50). Если $x^0 < y^0$, то контур интегрирования замыкается вверху, и в результате получается то же самое выражение, но с переставленными x и y. Таким образом,

$$\begin{aligned} D_F(x-y) &= \begin{cases} D(x-y) & \text{для } x^0 > y^0 \\ D(y-x) & \text{для } x^0 < y^0 \end{cases} \\ &= \theta\left(x^0 - y^0\right) \langle 0|\phi(x)\phi(y)|0\rangle + \theta\left(y^0 - x^0\right) \langle 0|\phi(y)\phi(x)|0\rangle \equiv \\ &\equiv \langle 0|T\phi(x)\phi(y)|0\rangle. \end{aligned}$$

Последняя строка определяет символ «хронологического упорядочивания» T, который указывает на то, что операторы, зависящие от более поздних моментов времени, располагаются левее тех, которые зависят от более ранних моментов времени. Применяя к последней строке оператор $(\partial^2 + m^2)$, можно непосредственно проверить, что D_F есть функция Грина оператора Клейна-Гордона.

С практической точки зрения выражения (2.59) и (2.60) являются наиболее важными результатами этой главы. Функция Грина $D_F(x-y)$ называется пропагатором Фейнмана для частицы Клейна-Гордона, так как она в конечном счете является амплитудой распространения. Действительно, фейнмановский пропагатор входит в правила Фейнмана: $D_F(x-y)$ (или $\widetilde{D}_F(p)\Big)$ является тем выражением, которое приписывается внутренним линиям диаграмм Фейнмана, представляя распространение виртуальных частиц.

Однако нам предстоит еще длинный путь, прежде чем мы сможем произвести какие-либо реальные вычисления, так как до сих пор мы работали только со свободной теорией Клейна-Гордона, в которой уравнение поля является линейным и взаимодействие отсутствует. Отдельные частицы живут в своих изолированных модах, не замечая существования друг друга и любых других сортов частиц. В рамках такой теории невозможно проделать какие-либо наблюдения при помощи рассеяния или любыми другими средствами. С другой стороны, разработанный формализм чрезвычайно важен, так как свободная теория формирует основу для выполнения вычислений по теории возмущений в теории с взаимодействием.

9.1.5 Production of particles by a classical source

Теория

Имеется один тип взаимодействия, к рассмотрению которого мы уже готовы. Рассмотрим поле Клейна-Гордона, связанное с внешним классическим полем-источником $j(x)$. Иными словами, рассмотрим уравнение поля:

$$\left(\partial^2 + m^2\right)\phi(x) = j(x),$$

где $j(x)$ - некоторая фиксированная известная функция пространственно-временных координат, которая отлична от нуля лишь на конечном временнОм интервале. Если в далеком прошлом система находится в вакуумном состоянии, что мы будем иметь после того, как поле $j(x)$ включается и затем вновь отключается?

Уравнение поля (2.61) вытекает из лагранжиана

$$\mathscr{L} = \frac{1}{2}\left(\partial_\mu\phi\right)^2 - \frac{1}{2}m^2\phi^2 + j(x)\phi(x).$$

Но если $j(x)$ включается только на конечное время, то проще всего решить поставленную задачу, непосредственно используя полевое уравнение. До того, как источник $j(x)$ включен, поле $\phi(x)$ имеет вид

$$\phi_0(x) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\left(a_{\mathbf{p}}e^{-ip\cdot x} + a^\dagger_{\mathbf{p}}e^{ip\cdot x}\right)$$

При отсутствии источника это поле было бы решением для всех моментов времени. При наличии источника решение уравнения движения может быть построено с помощью запаздывающей функции Грина:

$$\begin{aligned}\phi(x) &= \phi_0(x) + i\int d^4y D_R(x-y)j(y) = \\ &= \phi_0(x) + i\int d^4y \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}\theta\left(x^0-y^0\right)\left(e^{-ip\cdot(x-y)} - e^{ip\cdot(x-y)}\right)j(y)\end{aligned}$$

Если для наблюдателя моменты включения и выключения поля j находятся в прошлом, то тета-функция равняется единице во всей области интегрирования. Тогда поле $\phi(x)$ содержит лишь фурье-компоненты поля j:

$$\tilde{j}(p) = \int d^4y e^{ip\cdot y}j(y)$$

вычисленные при таких 4-импульсах p, что $p^2 = m^2$. Естественно сгруппировать положительно-частотные слагаемые вместе с $a_{\mathbf{p}}$ и отрицательно-частотные слагаемые вместе с $a_{\mathbf{p}}^\dagger$; в результате получим выражение:

$$\phi(x) = \int \frac{d^3p}{(2\pi)^3} \frac{1}{\sqrt{2E_{\mathbf{p}}}} \left\{ \left(a_{\mathbf{p}} + \frac{i}{\sqrt{2E_{\mathbf{p}}}} \tilde{\jmath}(p) \right) e^{-ip\cdot x} + \text{ э.с.} \right\}$$

Теперь можно догадаться (или вычислить), какую форму будет иметь гамильтониан после действия $j(x)$. Чтобы получить ответ, остается лишь сделать замену $a_{\mathbf{p}}$ на $\left(a_{\mathbf{p}} + i\tilde{\jmath}(p)/\sqrt{2E_{\mathbf{p}}}\right)$:

$$H = \int \frac{d^3p}{(2\pi)^3} E_{\mathbf{p}} \left(a_{\mathbf{p}}^\dagger - \frac{i}{\sqrt{2E_{\mathbf{p}}}} \tilde{\jmath}^*(p) \right) \left(a_{\mathbf{p}} + \frac{i}{\sqrt{2E_{\mathbf{p}}}} \tilde{\jmath}(p) \right)$$

Энергия системы после выключения источника равна

$$\langle 0|H|0\rangle = \int \frac{d^3p}{(2\pi)^3} \frac{1}{2} |\tilde{\jmath}(p)|^2$$

где $|0\rangle$ по-прежнему обозначает основное состояние свободной теории. Мы можем интерпретировать эти результаты в терминах частиц, рассматривая $|\tilde{\jmath}(p)|^2/2E_{\mathbf{p}}$ как плотность вероятности рождения частицы в моде p. Тогда общее число рожденных частиц равно

$$\int dN = \int \frac{d^3p}{(2\pi)^3} \frac{1}{2E_{\mathbf{p}}} |\tilde{\jmath}(p)|^2$$

При рождении частиц существенны лишь те фурье-компоненты источника $j(x)$, которые находятся в резонансе с волнами Клейна-Гордона на «массовой поверхности» (т. е. $p^2 = m^2$).

Мы вернемся к этому вопросу в задаче 4.1. В гл. 6 будет рассмотрена аналогичная задача о рождении фотонов ускоренным электроном (тормозное излучение).

9.1.6 Examples of Typical Transformations of a Scalar Field

ПШ-2.1. Об электродинамике

Классическая теория электромагнетизма (без источников) следует из выражения для действия

$$S = \int d^4x \left(-\frac{1}{4} F_{\mu\nu} F^{\mu\nu} \right), \quad \text{где \%} \quad \%F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$$

(a) Получите уравнения Максвелла как уравнения Эйлера-Лагранжа для этого действия, трактуя компоненты $A_\mu(x)$ как динамические переменные. Запишите уравнения в стандартной форме, отождествляя $E^i = -F^{0i}$ и $\varepsilon^{ijk} B^k = -F^{ij}$.

(b) Постройте тензор энергии-импульса в этой теории. Обратите внимание, что обычная процедура приводит к несимметричному тензору. Чтобы исправить это, можно добавить к $T^{\mu\nu}$ слагаемое вида $\partial_\lambda K^{\lambda\mu\nu}$, где $K^{\lambda\mu\nu}$ антисимметричен по первым двум индексам. Такая добавка автоматически имеет нулевую дивергенцию, так что тензор

$$\widehat{T}^{\mu\nu} = T^{\mu\nu} + \partial_\lambda K^{\lambda\mu\nu}$$

равносилен исходному тензору энергии-импульса с теми же самыми полными сохраняющимися энергией и импульсом. Покажите, что такое построение, где

$$K^{\lambda\mu\nu} = F^{\mu\lambda}A^{\nu},$$

приводит к симметричному тензору энергии-импульса $\widehat{T}$ и стандартным формулам для плотностей электромагнитной энергии и импульса:

$$\mathscr{E} = \frac{1}{2}\left(E^2 + B^2\right); \quad \mathbf{S} = \mathbf{E} \times \mathbf{B}.$$

ПШ-2.2. Комплексное скалярное поле.

Рассмотрите теорию комплексного скалярного поля, удовлетворяющего уравнению Клейна-Гордона. Действие этой теории имеет вид

$$S = \int d^4x \left(\partial_\mu \phi^* \partial^\mu \phi - m^2 \phi^* \phi\right).$$

Проще изучать эту теорию, рассматривая в качестве базисных динамических переменных $\phi(x)$ и $\phi^*(x)$, а не вещественную и мнимую части поля $\phi(x)$.

(a) Найдите сопряженные импульсы к $\phi(x)$ и $\phi^*(x)$ и канонические коммутационные соотношения. Покажите, что гамильтониан равен

$$H = \int d^3x \left(\pi^*\pi + \nabla\phi^* \cdot \nabla\phi + m^2\phi^*\phi\right).$$

Запишите гейзенберговское уравнение движения для $\phi(x)$ и покажите, что оно совпадает с уравнением Клейна-Гордона.

(b) Диагонализируйте гамильтониан H, вводя операторы рождения и уничтожения. Покажите, что теория содержит два типа частиц с массой m.

(c) Перепишите сохраняющийся заряд

$$Q = \int d^3x \frac{i}{2}\left(\phi^*\pi^* - \pi\phi\right)$$

в терминах операторов рождения и уничтожения и вычислите заряд частиц каждого типа. (d) Рассмотрите случай двух комплексных полей Клейна-Гордона с одинаковой массой. Обозначьте поля как $\phi_a(x)$, где $a = 1, 2$. Покажите, что теперь имеются четыре сохраняющихся заряда: один, задаваемый путем обобщения заряда, рассмотренного в (c), и три других, задаваемых формулами

$$Q^i = \int d^3x \frac{i}{2}\left(\phi_a^* \left(\sigma^i\right)_{ab} \pi_b^* - \pi_a \left(\sigma^i\right)_{ab} \phi_b\right)$$

где σ^i - матрицы Паули. Покажите, что последние три заряда имеют коммутационные соотношения, совпадающие с коммутаторами для углового момента ($SU(2)$). Обобщите эти результаты на случай n одинаковых комплексных скалярных полей.

ПШ-2.3.

Вычислите явно через функции Бесселя функцию

$$\langle 0|\phi(x)\phi(y)|0\rangle = D(x-y) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}e^{-ip\cdot(x-y)}$$

для случая пространственноподобной разности $(x-y)$, причем $(x-y)^2 = -r^2$.

9.2 Vector Field (photons)

9.2.1 Derivation of Vector Field Equations

9.2.2 Quantization of a Vector Field: Basics

Теория

We now apply the canonical formalism of Chapter 2 to quantize the free electromagnetic field, using the Lagrangian density (5.10) with $s_\mu(x) = 0$ and, in the first place, ignoring the Lorentz condition (5.13). With the fields $\pi^\mu(x)$ conjugate to $A_\mu(x)$ given by Eqs. (5.11), the equal-time commutation relations (2.31) become

$$\begin{aligned}
&\left[A^\mu(\mathbf{x},t), A^v(\mathbf{x}',t)\right] = 0,\\
&\left[\dot{A}^\mu(\mathbf{x},t), \dot{A}^v(\mathbf{x}',t)\right] = 0\\
&\left[A^\mu(\mathbf{x},t), \dot{A}^v(\mathbf{x}',t)\right] = -\mathrm{i}\hbar c^2 g^{\mu v}\delta(\mathbf{x}-\mathbf{x}')
\end{aligned}$$

Apart from the factor $(-g^{\mu\nu})$, these equations are identical with the commutation relations (3.6) of four independent Klein-Gordon fields, and each component $A^\mu(x)$ satisfies the wave equation (5.16) which is the limit of the Klein-Gordon equation (3.3) for particles of mass zero. [Both these points can be appreciated by comparing the Lagrangian densities (5.10) and (3.4).] This similarity enables us to take over earlier mathematical results, although their physical interpretation will have to be re-examined, taking into account the factor $(-g^{\mu\nu})$.

In Section 3.3, we derived the covariant commutation relations (3.42) for the Klein-Gordon field. From these we can at once write down the covariant commutation relations for the $A^\mu(x)$:

$$\left[A^\mu(x), A^v(x')\right] = \mathrm{i}\hbar c D^{\mu v}(x-x')$$

where

$$D^{\mu v}(x) = \lim_{m\to 0}\left[-g^{\mu v}\Delta(x)\right],$$

and $\Delta(x)$ is the invariant Δ-function (3.43). The Feynman photon propagator is similarly given by

$$\langle 0\,|\mathbf{T}\left\{A^\mu(x)A^v(x')\right\}|\,0\rangle = \mathrm{i}\hbar c D_{\mathrm{F}}^{\mu v}(x-x'),$$

where

$$D_{\mathrm{F}}^{\mu v}(x) = \lim_{m\to 0}\left[-g^{\mu v}\Delta_{\mathrm{F}}(x)\right] = \frac{-g^{\mu v}}{(2\pi)^4}\int \frac{\mathrm{d}^4k\mathrm{e}^{-\mathrm{i}kx}}{k^2+i\varepsilon},$$

as is seen from Eqs. (3.55) and (3.58). The photon propagator will be discussed fully in the next section.

To gain the photon interpretation of the quantized fields, we substitute the field expansions (5.16) in the commutation relations (5.23), with the result

$$\left.\begin{array}{c}\left[a_r(\mathbf{k}), a_s^\dagger(\mathbf{k}')\right] = \zeta_r \delta_{rs}\delta_{\mathbf{k}\mathbf{k}'} \\ \left[a_r(\mathbf{k}), a_s(\mathbf{k}')\right] = \left[a_r^\dagger(\mathbf{k}), a_s^\dagger(\mathbf{k}')\right] = 0\end{array}\right\}.$$

From Eq. (5.20) $\zeta_r = 1$ for $r = 1, 2, 3$ so that for these values of r, Eqs. (5.28) are the standard boson commutation relations (3.9) leading to the usual number representation for transverse photons ($r = 1, 2$) and longitudinal photons ($r = 3$). For $r = 0$ (scalar photons) $\zeta_0 = -1$, and it consequently looks as though the usual roles of absorption and creation operators must be interchanged for $a_0(\mathbf{k})$ and $a_0^\dagger(\mathbf{k})$. However, effecting only this change results in other difficulties, and the standard formalism must be modified more radically. Of the several procedures available, we shall follow that due to Gupta and to Bleuler. In the Gupta-Bleuler theory, the operators $a_r(\mathbf{k}), \mathrm{r} = 1, 2, 3$ and 0, are interpreted as absorption operators, $a_r^\dagger(\mathbf{k}), r = 1, 2, 3$ and 0, as creation operators for transverse, longitudinal and scalar photons. The vacuum state $|0\rangle$ is defined as the state in which there are no photons of any kind present, i.e.

$$a_r(\mathbf{k})|0\rangle = 0, \quad \text{all } \mathbf{k}, \quad r = 0..., 3,$$

 or, equivalently,

$$A^{\mu+}(x)|0\rangle = 0, \quad \text{all } x, \quad \mu = 0, ..., 3.$$

The operators $a_r^\dagger(\mathbf{k})$ operating on the vacuum state $|0\rangle$ create the one-photon states

$$|1_{\mathbf{k}r}\rangle = a_r^\dagger(\mathbf{k})|0\rangle$$

in which one transverse ($r = 1, 2$), longitudinal ($r = 3$) or scalar ($r = 0$) photon of momentum $\mathbf{k}$ is present.

To justify this interpretation of the operators a_r and $a_r^\dagger$, we consider the Hamiltonian operator of the field. From Eq. (2.51a) this is given by

$$H = \int \mathrm{d}^3\mathbf{x}\mathbf{N}\left[\pi^\mu(x)\dot{A}_\mu(x) - \mathscr{L}(x)\right],$$

which, as usual, is to be taken as a normal product. On substituting the free Lagrangian density corresponding to Eq. (5.10), Eq, (5.11) for $\pi^\mu(x)$ and the expansions (5.16) for the fields, Eq. (5.31) becomes

$$H = \sum_{r\mathbf{k}} \hbar\omega_{\mathbf{k}}\zeta_r a_r^\dagger(\mathbf{k})a_r(\mathbf{k}).$$

Despite the minus sign ($\zeta_0 = -1$) associated with the scalar photons in Eq. (5.32), this energy is positive definite. For example, for the one-photon states (5.30) one easily obtains, using the commutation relations (5.28),

$$\begin{aligned} H\,|1_{\mathbf{k}r}\rangle &= \sum_{\mathbf{q}s} \hbar\omega_{\mathbf{q}}\zeta_s a_s^\dagger(\mathbf{q})a_s(\mathbf{q})a_r^\dagger(\mathbf{k})|0\rangle \\ &= \hbar\omega_{\mathbf{k}} a_r^\dagger(\mathbf{k})|0\rangle, \quad r = 0, ..., 3, \end{aligned}$$

i.e. the energy has the positive value $\hbar\omega_{\mathbf{k}}$ for transverse, longitudinal and scalar photons. Correspondingly, we must define the number operators by

$$N_r(\mathbf{k}) = \zeta_r a_r^\dagger(\mathbf{k})a_r(\mathbf{k}),$$

and these definitions, together with the commutation relations (5.28), lead to consistent number representations for all types of photons.

Although the formalism, as far as we have developed it, seems satisfactory, there are some difficulties which show up if we calculate the normalization of photon states. For example, the norm of the state (5.30) is

$$\langle 1_{\mathrm{k}r}|1_{\mathrm{k}r}\rangle = \left\langle 0 \left| a_r(\mathbf{k})a_r^\dagger(\mathbf{k}) \right| 0 \right\rangle = \zeta_r\langle 0|0\rangle = \zeta_r$$

(if we normalize $|0\rangle$ to $\langle 0|0\rangle = 1$), and for a scalar photon this norm is negative. More generally, one can show that for any state containing an odd number of scalar photons the norm is negative. At first sight this looks like a serious difficulty, since the probability interpretation of quantum mechanics depends on states having positive norms. However, no scalar or longitudinal photons have ever been observed. Both these points are related to the fact that so far we have ignored the Lorentz condition (5.13), so that our theory is not yet equivalent to Maxwell's equations. We must now try and impose the Lorentz condition. 80 Quantum Field Theory Unfortunately, we cannot simply take the Lorentz condition (5.13) as an operator identity. Eq. (5.13) is incompatible with the commutation relations (5.24), since

$$[\partial_\mu A^\mu(x), A^v\,(x')] = \mathrm{i}\hbar c\partial_\mu D^{\mu v}\,(x - x')$$

and this is not identically zero. This problem was resolved by Gupta and Bleuler by replacing the Lorentz condition (5.13) by the weaker condition

$$\partial_\mu A^{\mu+}(x)|\Psi\rangle = 0,$$

involving absorption operators only. Eq. (5.34) is a restriction on the states which are allowed by the theory. From Eq. (5.34) and its adjoint

$$\langle\Psi|\partial_\mu A^{\mu-}(x) = 0$$

it follows that the Lorentz condition holds for expectation values:

$$\langle\Psi\,|\partial_\mu A^\mu(x)|\,\Psi\rangle = \left\langle\Psi\left|\partial_\mu A^{\mu+}(x) + \partial_\mu A^{\mu-}(x)\right|\,\Psi\right\rangle = 0.$$

This ensures that the Lorentz condition and hence Maxwell's equations hold as the classical limit of this theory.

In order to understand the meaning of the subsidiary condition (5.34), we express it in momentum space. On substituting Eqs. (5.16b) and (5.21), (5.22) for $A_\mu^+(x)$ and $\varepsilon_r^\mu(\mathbf{k})$, we obtain the conditions

$$[a_3(\mathbf{k}) - a_0(\mathbf{k})]\,|\Psi\rangle = 0, \qquad \text{all } \mathbf{k}.$$

This is a constraint on the linear combinations of longitudinal and scalar photons, for each value of $\mathbf{k}$, that may be present in a state. It places no restriction on the transverse photons that may be present.

The effect of the subsidiary condition (5.36) becomes apparent if we calculate the expectation value of the energy of an allowed state $|\Psi\rangle$. Since from Eq. (5.36) and its adjoint we have

$$\left\langle\Psi\left|a_3^\dagger(\mathbf{k})a_3(\mathbf{k}) - a_0^\dagger(\mathbf{k})a_0(\mathbf{k})\right|\,\Psi\right\rangle = \left\langle\Psi\left|a_3^\dagger(\mathbf{k})\,[a_3(\mathbf{k}) - a_0(\mathbf{k})]\right|\,\Psi\right\rangle = 0,$$

it follows from Eq. (5.32) that

$$\langle\Psi|H|\Psi\rangle = \left\langle \Psi \left| \sum_{\mathbf{k}} \sum_{r=1}^{2} \hbar\omega_k a_r^\dagger(\mathbf{k}) a_r(\mathbf{k}) \right| \Psi \right\rangle$$

i.e. only the transverse photons contribute to the expectation value of the energy as a consequence of the subsidiary condition. The same is true for all other observables.

Thus, as a result of the subsidiary condition, in free space, observable quantities will involve transverse photons only. This explains our earlier assertion that longitudinal and scalar photons are not observed as free particles. Only transverse photons are so observed, corresponding to the two degrees of freedom (for each $\mathbf{k}$) of the radiation field, which we found in the non-covariant formalism of Chapter 1 where we worked in the Coulomb gauge. In the covariant treatment, although they don't show up as free particles, the presence of longitudinal and scalar photons is not ruled out Photons: Covariant Theory 81 altogether. Of the resulting additional two degrees of freedom (for each $\mathbf{k}$), one is removed by the subsidiary condition (5.36). The other can be shown to correspond to the arbitrariness in choice of Lorentz gauge. More specifically, one can show that altering the allowed admixtures of longitudinal and scalar photons is equivalent to a gauge transformation between two potentials, both of which are in Lorentz gauges. (See Problems 5.2 and 5.3.)

For free fields (i.e. no charges present), it is then simplest to work in a gauge such that the vacuum is represented by the state $|0\rangle$ in which no photons of any kind are present [see Eq. (5.29a)]. But the vacuum could also be described by any state containing no transverse and only allowed admixtures of scalar and longitudinal photons. This description would merely correspond to a different choice of Lorentz gauge. The situation is entirely analogous for states containing transverse photons.

For the electromagnetic field in the presence of charges, the situation is more complicated. We can no longer ignore the longitudinal and scalar photons. When discussing the photon propagator in the next section, we shall see that longitudinal and scalar photons play an important role as virtual particles in intermediate states and provide a covariant description of the instantaneous Coulomb interaction of Chapter 1. However, in this case too, one need consider only transverse photons in initial and final states of scattering processes. This corresponds to a particular choice of gauge and the fact that one can consider particles initially and finally, when they are far apart, as free. In Section 6.2 we shall return to this idea of switching the interaction between colliding particles on and off adiabatically as they approach and as they move apart.

We have developed the Gupta-Bleuler formalism only to the limited extent to which it is needed in applications. It is possible to develop a more complete systematic formalism in which states with negative norm do not appear as a blemish in Hilbert space, but occur in a self-consistent manner in a function space with an indefinite metric. For most purposes, this complete formalism is not required.

Другое о квантовании векторного поля

> **Вот допустим у меня другое поле, искрилвенное, например, поле бублика, проквантуйте мне его! (!??!?!??!?)**

(и все, усели мы!!! я хз, напишу четко этот вопрос, перекину умным людям, я хз, что тут ответить вообще.)

9.2.3 Quantization of a Vector Field: Features

Первое, что приходит в голову после познания метода квантования, это идея проквантовать хорошо знакомое нам электроамгнитное поле.

итоговые методы

обзор квантования и сложностей

подготовимся

Квантование электромагнитного поля по Тонгу

In the following we shall quantize free Maxwell theory twice: once in Coulomb gauge, and again in Lorentz gauge. We'll ultimately get the same answers and, along the way, see that each method comes with its own subtleties.

The first of these subtleties is common to both methods and comes when computing the momentum π^μ conjugate to A_μ

$$\pi^0 = \frac{\partial \mathcal{L}}{\partial \dot{A}_0} = 0$$
$$\pi^i = \frac{\partial \mathcal{L}}{\partial \dot{A}_i} = -F^{0i} \equiv E^i$$

so the momentum π^0 conjugate to A_0 vanishes. This is the mathematical consequence of the statement we made above: A_0 is not a dynamical field. Meanwhile, the momentum conjugate to A_i is our old friend, the electric field. We can compute the Hamiltonian,

$$H = \int d^3x \pi^i \dot{A}_i - \mathcal{L} \quad = \int d^3x \frac{1}{2}\vec{E}\cdot\vec{E} + \frac{1}{2}\vec{B}\cdot\vec{B} - A_0(\nabla\cdot\vec{E})$$

So A_0 acts as a Lagrange multiplier which imposes Gauss' law

$$\nabla\cdot\vec{E} = 0$$

which is now a constraint on the system in which $\vec{A}$ are the physical degrees of freedom. Let's now see how to treat this system using different gauge fixing conditions.

6.2.1 Coulomb Gauge In Coulomb gauge, the equation of motion for $\vec{A}$ is

$$\partial_\mu\partial^\mu\vec{A} = 0$$

which we can solve in the usual way,

$$\vec{A} = \int \frac{d^3p}{(2\pi)^3}\vec{\xi}(\vec{p})e^{ip-x}$$

with $p_0^2 = |\vec{p}|^2$. The constraint $\nabla\cdot\vec{A} = 0$ tells us that $\vec{\xi}$ must satisfy

$$\vec{\xi}\cdot\vec{p} = 0$$

which means that $\vec{\xi}$ is perpendicular to the direction of motion $\vec{p}$. We can pick $\vec{\xi}(\vec{p})$ to be a linear combination of two orthonormal vectors $\vec{\epsilon}_r, r = 1, 2$, each of which satisfies $\vec{\epsilon}_r(\vec{p})\cdot\vec{p} = 0$ and

$$\vec{\epsilon}_r(\vec{p})\cdot\vec{\epsilon}_s(\vec{p}) = \delta_{rs}\% \quad \%r, s = 1, 2$$

These two vectors correspond to the two polarization states of the photon. It's worth pointing out that you can't consistently pick a continuous basis of polarization vectors for every value of $\vec{p}$ because you can't comb the hair on a sphere. But this topological fact doesn't cause any complications in computing QED scattering processes.

To quantize we turn the Poisson brackets into commutators. Naively we would write

$$[A_i(\vec{x}), A_j(\vec{y})] = [E^i(\vec{x}), E^j(\vec{y})] = 0 [A_i(\vec{x}), E^j(\vec{y})] = i\delta_i^j \delta^{(3)}(\vec{x} - \vec{y})$$

But this can't quite be right, because it's not consistent with the constraints. We still want to have $\nabla \cdot \vec{A} = \nabla \cdot \vec{E} = 0$, now imposed on the operators. But from the commutator relations above, we see

$$[\nabla \cdot \vec{A}(\vec{x}), \nabla \cdot \vec{E}(\vec{y})] = i\nabla^2 \delta^{(3)}(\vec{x} - \vec{y}) \neq 0$$

What's going on? In imposing the commutator relations (6.23) we haven't correctly taken into account the constraints. In fact, this is a problem already in the classical theory, where the Poisson bracket structure is already altered [4]. The correct Poisson bracket structure leads to an alteration of the last commutation relation,

$$[A_i(\vec{x}), E_j(\vec{y})] = i \left(\delta_{ij} - \frac{\partial_i \partial_j}{\nabla^2} \right) \delta^{(3)}(\vec{x} - \vec{y})$$

To see that this is now consistent with the constraints, we can rewrite the right-hand side of the commutator in momentum space,

$$[A_i(\vec{x}), E_j(\vec{y})] = i \int \frac{d^3p}{(2\pi)^3} \left(\delta_{ij} - \frac{p_i p_j}{|\vec{p}|^2} \right) e^{i\vec{p}\cdot(\vec{x}-\vec{y})}$$

which is now consistent with the constraints, for example

$$[\partial_i A_i(\vec{x}), E_j(\vec{y})] = i \int \frac{d^3p}{(2\pi)^3} \left(\delta_{ij} - \frac{p_i p_j}{|\vec{p}|^2} \right) i p_i e^{i\vec{p}\cdot(\vec{x}-\vec{y})} = 0$$

We now write $\vec{A}$ in the usual mode expansion,

$$\vec{A}(\vec{x}) = \int \tfrac{d^3p}{(2\pi)^3} \tfrac{1}{\sqrt{2|\vec{p}|}} \sum_{r=1}^{2} \vec{\epsilon}_r(\vec{p}) \left[a^r_{\vec{p}} e^{i\vec{p}\cdot\vec{x}} + a^{r\dagger}_{\vec{p}} e^{-i\vec{p}\cdot\vec{x}} \right]$$
$$\vec{E}(\vec{x}) = \int \tfrac{d^3p}{(2\pi)^3} (-i) \sqrt{\tfrac{|\vec{p}|}{2}} \sum_{r=1}^{2} \vec{\epsilon}_r(\vec{p}) \left[a_{\vec{p}} e^r e^{i\vec{p}\cdot\vec{x}} - a^{r\dagger}_{\vec{p}} e^{-i\vec{p}\cdot\vec{x}} \right]$$

where, as before, the polarization vectors satisfy

$$\vec{\epsilon}_r(\vec{p}) \cdot \vec{p} = 0 \quad \text{and} \quad \%\%\vec{\epsilon}_r(\vec{p}) \cdot \vec{\epsilon}_s(\vec{p}) = \delta_{rs}$$

It is not hard to show that the commutation relations (6.25) are equivalent to the usual commutation relations for the creation and annihilation operators,

$$\left[a^r_{\vec{p}}, a^s_{\vec{q}}\right] = \left[a^{r\dagger}_{\vec{p}}, a^{s\dagger}_{\vec{q}}\right] = 0$$
$$\left[a^r_{\vec{p}}, a^s_{\vec{q}}\right] = (2\pi)^3 \delta^{rs} \delta^{(3)}(\vec{p} - \vec{q})$$

where, in deriving this, we need the completeness relation for the polarization vectors,

$$\sum_{r=1}^{2} \epsilon^i_r(\vec{p}) \epsilon^j_r(\vec{p}) = \delta^{ij} - \frac{p^i p^j}{|\vec{p}|^2}$$

You can easily check that this equation is true by acting on both sides with a basis of vectors $(\vec{\epsilon}_1(\vec{p}), \vec{\epsilon}_2(\vec{p}), \vec{p})$ We derive the Hamiltonian by substituting (6.28) into (6.17). The last term vanishes in Coulomb gauge. After normal ordering, and playing around with $\vec{\epsilon}_r$ polarization vectors, we get the simple expression

$$H = \int \frac{d^3p}{(2\pi)^3} |\vec{p}| \sum_{r=1}^{2} a_{\vec{p}}^{r\dagger} a_{\vec{p}}^{r}$$

The Coulomb gauge has the advantage that the physical degrees of freedom are manifest.

However, we've lost all semblance of Lorentz invariance.

One place where this manifests itself is in the propagator for the fields $A_i(x)$ (in the Heisenberg picture). In Coulomb gauge the propagator reads

$$D_{ij}^{\rm tr}(x-y) \equiv \langle 0 \left| T A_i(x) A_j(y) \right| 0 \rangle = \int \frac{d^4p}{(2\pi)^4} \frac{i}{p^2 + i\epsilon} \left(\delta_{ij} - \frac{p_i p_j}{|\vec{p}|^2} \right) e^{-ip\cdot(x-y)}$$

The *tr* superscript on the propagator refers to the "transverse" part of the photon. When we turn to the interacting theory, we will have to fight to massage this propagator into something a little nicer.

9.2.4 The Photon Propagator

The Photon Propagator by Mandl Shawl

In Section 3.4 we interpreted the Klein-Gordon propagator (3.56) as the exchange of a virtual meson in an intermediate state. We now expect a similar interpretation for the photon propagator (5.26) but, corresponding to the four-vector nature of the field $A^\mu(x)$ and the resulting four independent polarization states, we expect the exchange of four kinds of photons, two corresponding to transverse polarization and one each to longitudinal and scalar polarization. This description differs markedly from that of Chapter 1, where only transverse radiation occurred, but no longitudinal or scalar radiation. Instead we had the instantaneous Coulomb interaction between charges. We shall see that these two descriptions are indeed equivalent.

To establish this interpretation in terms of photon exchange we consider the momentum space propagator $D_{\rm F}^{\mu\nu}(k)$, related to the configuration space propagator $D_{\rm F}^{\mu\nu}(x)$ Eq. (5.27), by

$$D_{\rm F}^{\mu\nu}(x) = \frac{1}{(2\pi)^4} \int {\rm d}^4k D_{\rm F}^{\mu\nu}(k) {\rm e}^{-{\rm i}kx}.$$

From Eqs. (5.27) and (5.19) we obtain

$$D_{\rm F}^{\mu\nu}(k) = \frac{-g^{\mu\nu}}{k^2 + {\rm i}\varepsilon} = \frac{1}{k^2 + {\rm i}\varepsilon} \sum_r \zeta_r \varepsilon_r^\mu(\mathbf{k}) \varepsilon_r^v(\mathbf{k}).$$

In order to interpret this expression, we use the special frame of reference in which the polarization vectors $\varepsilon_r^\mu(\mathbf{k})$ are given by Eqs. (5.21) and (5.22). The last equation then becomes:

$$D_{\mathrm{F}}^{\mu\nu}(k) = \frac{1}{k^2 + \mathrm{i}\varepsilon}\left\{\sum_{r=1}^{2}\varepsilon_r^\mu(\mathbf{k})\varepsilon_r^v(\mathbf{k}) + \frac{\left[k^\mu - (kn)n^\mu\right]\left[k^\nu - (kn)n^\nu\right]}{(kn)^2 - k^2} + (-1)n^\mu n^\nu\right\}.$$

This equation exhibits the contributions to the photon propagator from transverse, longitudinal and scalar photons. By analogy with the meson case, we interpret the first term in Eq. (5.40),

$${}_{\mathrm{T}}D_{\mathrm{F}}^{\mu v}(k) \equiv \frac{1}{k^2 + \mathrm{i}\varepsilon}\sum_{r=1}^{2}\varepsilon_r^\mu(\mathbf{k})\varepsilon_r^\nu(\mathbf{k})$$

as the exchange of transverse photons. In the language of Chapter 1, it corresponds to the interaction of charges via the transverse radiation field.

The interpretation of the remaining two terms in Eq. (5.40) follows not from considering longitudinal and scalar photons separately, but from combining them into a term proportional to $n^\mu n^\nu$ plus the remainder. Eq. (5.40) then becomes

$$D_{\mathrm{F}}^{\mu\mathrm{v}}(k) = {}_{\mathrm{T}}D_{\mathrm{F}}^{\mu\mathrm{v}}(k) + {}_{\mathrm{C}}D_{\mathrm{F}}^{\mu\mathrm{v}}(k) + {}_{\mathrm{R}}D_{\mathrm{F}}^{\mu\mathrm{v}}(k),$$

where

$${}_{c}D_{\mathrm{F}}^{\mu\mathrm{v}}(k) \equiv \frac{n^\mu n^\nu}{(kn)^2 - k^2},$$

$${}_{\mathrm{R}}D_{\mathrm{F}}^{\mu\mathrm{v}}(k) \equiv \frac{1}{k^2 + \mathrm{i}\varepsilon}\left[\frac{k^\mu k^\nu - (kn)\left(k^\mu n^\nu + k^v n^\mu\right)}{(kn)^2 - k^2}\right],$$

and it is these linear combinations, both of which involve longitudinal and scalar photons, which allow a simple interpretation.

We first consider Eq. (5.41b) in configuration space. From Eqs. (5.38) and (5.21a) we obtain

$$\begin{aligned}{}_{c}D_{\mathrm{F}}^{\mu v}(x) &= \frac{g^{\mu 0}g^{v0}}{(2\pi)^4}\int\frac{\mathrm{d}^3\mathbf{k}\mathrm{e}^{\mathrm{ik}\cdot\mathrm{x}}}{|\mathbf{k}|^2}\int\mathrm{d}k^0\mathrm{e}^{-\mathrm{i}k^0x^0}\\ &= g^{\mu 0}g^{\mathrm{v}0}\frac{1}{4\pi|\mathbf{x}|}\delta\left(x^0\right).\end{aligned}$$

This expression has the time dependence $[\delta(x^0)]$ and the space dependence $[1/|\mathbf{x}|]$ characteristic of an instantaneous Coulomb potential. Thus we see that the exchange of longitudinal and scalar photons, represented by the term (5.43), corresponds to the instantaneous Coulomb interaction between charges. In Chapter 1, we quantized the transverse radiation field only and treated the instantaneous Coulomb interaction as a classical potential, corresponding to the fact that the instantaneous Coulomb field does not represent independent dynamical degrees of freedom, but is fully determined by the charges. In the present treatment, the longitudinal and scalar field components are also quantized and the instantaneous Coulomb interaction emerges as an exchange of longitudinal and scalar photons.

Finally, we must discuss the remainder term (5.41c). In Chapter 1, the complete electromagnetic interaction between charges was represented in terms of the interactions via the transverse radiation field and the instantaneous Coulomb fields. Both these have been accounted for in the present treatment, and for the two treatments to be equivalent, the contribution of the remainder

term (5.41c) to all observable quantities must vanish. This is indeed the case, the basic reason being that the electromagnetic field only interacts with the conserved charge-current density $s^\mu(x)$, Eqs. (5.2) and (5.4). We shall illustrate this for a simple example.

We shall see in Section 7.1, Eq. (7.14), that the scattering of charges by each other is, in lowest order of perturbation theory, given by the matrix element of the operator

$$\int \mathrm{d}^4x \int \mathrm{d}^4y s_1^\mu(x) D_{\mathrm{F}\mu v}(x-y) s_2^v(y).$$

Here $s_1^\mu(x)$ and $s_2^\nu(y)$ are the two interacting charge-current densities. It is clear from Eq. (5.43) that the contribution of $\mathrm{C_C}D_{\mathrm{F}\nu}(x-y)$ to (5.44) corresponds to the instantaneous Coulomb interaction between the charge densities $\rho_1(\mathbf{x}, x^0) = s_1^0(\mathbf{x}, x^0)/c$ and $\rho_2(\mathbf{y}, x^0) = s_2^0(\mathbf{y}, x^0)/c$. Similarly, the transverse propagator ${}_{\mathrm{T}}D_{\mathrm{F}\mu\nu}(x-y)$ accounts for the electromagnetic interaction between the current densities $\mathbf{j}_1(x) = \mathbf{s}_1(x)$ and $\mathbf{j}_2(y) = \mathbf{s}_2(y)$. The contribution to (5.44) of the remainder term ${}_{\mathrm{R}}D_{\mathrm{F}\mu\nu}(x-y)$ is easily shown to vanish, on account of current conservation. Transforming this contribution to expression (5.44) into momentum space, one obtains

$$\frac{1}{(2\pi)^4} \int \mathrm{d}^4k s_1^\mu(-k) {}_{\mathrm{R}}D_{\mathrm{F}\mu v}(k) s_2^v(k)$$

where the momentum transforms $s_r^\mu(k), r = 1, 2$, are defined, analogously to Eq. (5.38), by

$$s_r^\mu(x) = \frac{1}{(2\pi)^4} \int \mathrm{d}^4k s_r^\mu(k) \mathrm{e}^{-\mathrm{i}kx}, \quad r = 1, 2.$$

The current conservation equations, $\partial_\mu s_r^\mu(x) = 0$, translated into momentum space, become

$$k_\mu s_r^\mu(k) = 0, \quad r = 1, 2.$$

We see from the explicit form (5.41c) that each term in ${}_{\mathrm{R}}D_{\mathrm{F}\mu\nu}(k)$ is proportional to either k_μ or k_ν or both. Hence it follows from Eq. (5.47) that the expression (5.45) vanishes. This completes our discussion of the equivalence of the two formulations of quantum electrodynamics. In doing this, we employed a special frame of reference leading to a division of the fields into transverse, longitudinal and scalar parts. In general, such a division is not required, and we shall work with manif estly covariant expressions involving summations over all four polarization states. In particular, the photon propagator, Eqs. (5.38) and (5.39), which will be very important in the development of quantum electrodynamics, has this property.

9.2.5 Covariant Gauges and the Photon Propagator

(мб в КЭД перенесу)

Theory

В электродинамике калибровочное условие Лоренца

$$X(\mathcal{A}) = \partial_\mu \mathcal{A}^\mu$$

приводит к лагранжиану, квадратичному по полю,

$$\mathcal{L}_F = -\frac{1}{4} F_{\mu\nu}^2 - \frac{1}{2\xi} (\partial_\mu \mathcal{A}^\mu)^2$$

В импульсном представлении дифференциальный оператор

$$\hat{\Gamma}_{\mu\nu} = k^2 \left(-g_{\mu\nu} + \frac{k_\mu k_\nu}{k^2} \right) - \frac{1}{\xi} k_\mu k_\nu$$

который определяет

$$\mathcal{L}_F = \frac{1}{2} \mathcal{A}^\mu(k) \hat{\Gamma}_{\mu\nu} \mathcal{A}^{*\nu}(k)$$

(что это такое???:))

может быть обращен, чтобы получить причинный пропагатор фотона

$$\mathcal{D}^{(2)}_{\mu\nu} = \frac{\mathrm{i}}{k^2 + \mathrm{i}0} \left(-g_{\mu\nu} + (1 - \xi) \frac{k_\mu k_\nu}{k^2} \right)$$

Значение $\xi = 1$ отвечает калибровке Фейнмана, а $\xi = 0$ - поперечной калибровке Ландау.

При этом, конечно, амплитуда квантового перехода для асимптотических поперечных состояний никак не зависит от выбора ξ.

Подчеркнем, что вклад отдельных диаграмм может зависеть от калибровочного параметра и от выбора калибровочного условия.

Этим пользуются, чтобы выделять доминирующие диаграммы.

Однако суммирование диаграмм для заданной амплитуды никак не зависит от выбора калибровки и ее параметров.

Отметим, наконец, что калибровка Лоренца означает, что при калибровочном преобразовании $\partial_\mu \mathcal{A}^\mu \mapsto \partial_\mu \mathcal{A}^\mu - \partial^2 u$ матрица (как например она выглядит?????)

$$\frac{\partial X}{\partial u} = -\partial^2$$

совсем не зависит от поля.

Поэтому фактор

$$\mathrm{Det}\left(\mathcal{M}_X(\mathcal{A})\right)|_{X(\mathcal{A})=0} = -\mathcal{D}et\partial^2$$

можно вынести из под знака континуального интеграла и считать его несущественным нормировочным множителем,

который, конечно, сократится в $\hat{Z}(j) = Z(j)/Z(0)$. В этом смысле калибровка Лоренца весьма практична.

Вместе с тем, часто используют калибровки, в которых от детерминанта избавится невозможно, но это мы рассмотрим чуть позже в случае неабелевых теорий.

9.2.6 Quantum Vector Field in a Medium

9.3 Quantization of the Electromagnetic Field

9.3.1 The Continuum Integral for Degenerate Systems

Рассмотрим многомерную динамическую систему, гамильтониан которой зависит от n пар канонически сопряжённых переменных $\{p_\alpha, q^\alpha\}$ и в которой имеется $m < n$ связей первого рода $\varphi_i(p, q)$, а связи второго рода отсутствуют. Связи первого рода - это такие связи между динамическими переменными

$$\varphi_i(p, q) = 0, \quad i = 1, ..., m \tag{1}$$

что

$$[\varphi_i, \varphi_j] = c_{ij}^k \varphi_k, \quad [\varphi_i, \mathcal{H}] = 0 \tag{2}$$

В этом пункте $[..., ...]$ обозначает классическую скобку Пуассона (СП), а $\mathcal{H}$, как и везде гамильтониан. При вычислении всех СП связи игнорируются. В рассматриваемом случае полный гамильтониан системы $\mathcal{H}_T = \mathcal{H} + \sum_{i=1}^{m} v_i \varphi_i$ зависит от m произвольных функций времени v_i. Действительно, уравнения Гамильтона для связей

$$\frac{\mathrm{d}\varphi_i}{\mathrm{d}t} = \left[\ \varphi_i, \mathcal{H}_T\right] = 0 \pmod{\varphi_j}$$

показывают, что при любых значениях множителей Лагранжа $\{v_i\}$ равенства (1) совместны с динамикой системы. Обозначим через Γ^{2n} фазовое $2n$-мерное пространство с координатами $\{p_\alpha, q^\alpha\}$.

На классическом уровне рассматриваемая обобщённая гамильтонова система эквивалентна обычной гамильтоновой системе с $(n-m)$ степенями свободы. Фазовое пространство $\Gamma^{*2(n-m)}$ последней системы реализуем следующим образом. Рассмотрим m дополнительных условий

$$\chi^j(p, q) = 0 \tag{3}$$

фиксирующих калибровку, для которых выполняются требования

$$\det \left\| \left[\varphi_i, \chi^j\right] \right\| \neq 0, \quad \left[\chi^i, \chi^j\right] = 0 \tag{4}$$

Фиксация калибровки означает определённый выбор набора функций $\{v_i\}$ (см. ниже (11)). Подпространство в Γ^{2n}, определяемое равенствами

$$\chi^i(p, q) = 0, \quad \varphi_i(p, q) = 0, \quad i = 1, ..., m \tag{5}$$

является пространством $\Gamma^{*2(n-m)}$. Вследствие (4) можно выбрать в Γ^{2n} канонические переменные так, чтобы первые m координатных переменных $q^1, ..., q^m$ совпали с величинами $\chi^1, ..., \chi^m$:

$$q = \left\{\chi^1, ..., \chi^m, q^*\right\} \tag{6}$$

Здесь q^* - остальные $(n-m)$ координатных переменных. Записывая лагранжиан в переменных (6), находим соответствующие канонически сопряжённые импульсные переменные. Обозначим их через

$$p = \{p_1, ..., p_m, p^*\} \tag{7}$$

В новых переменных условия (4) принимают вид

$$\det \left\| \frac{\partial \varphi_i}{\partial p_j} \right\| \neq 0 \tag{8}$$

Отсюода следует, что уравнения связей (1) можно разрешить относительно p_i с $i = 1, ..., m$. Эти решения обозначим $p_i\,(p^*, q^*)$. В результате подпространство $\Gamma^{*2(n-m)}$ задаётся уравнениями

$$\chi^i \equiv q^i = 0, \quad p_i = p_i\left(p^*, q^*\right), \quad i = 1, ..., m \tag{9}$$

Переменные $\{p^*, q^*\}$ являются каноническими, и гамильтонианом системы является функция

$$\mathcal{H}^*\left(p^*, q^*\right) \equiv \mathcal{H}(p, q)|_{\varphi=0, \chi=0} \tag{10}$$

Обозначим исходную систему с гамильтонианом $\mathcal{H}_T$ и фазовым пространством Γ^{2n} и новую систему с гамильтонианом $\mathcal{H}^*$ и фазовым пространством $\Gamma^{*2(n-m)}$ через Γ и Γ^*, соответственно.

Системы Γ и Γ^* эквивалентны и эквивалентность означает следующее.

Выберем в $\mathcal{H}_T$ лагранжевы множители v_i так, чтобы выполнялись равенства

$$\dot{q}^j = \left[\chi^j, \mathcal{H}_T\right] = \frac{\partial \mathcal{H}}{\partial p_j} + \sum_i v_i \frac{\partial \varphi_i}{\partial p_j} = 0, \quad j = 1, ..., m \tag{11}$$

Вследствие (4) эта задача имеет однозначное решение. При этом уравнения Гамильтона $\dot{g} = [g, \mathcal{H}_T]$ и связей (1), (9) совпадают с уравнениями Гамильтона для системы Γ^*.

Докажем этот факт в координатах (6). При помощи равенств (11) получаем следующие соотношения:

$$\begin{aligned}
&\sum_{i=1}^{m}\left(v_i \frac{\partial \varphi_i}{\partial q^*} - \frac{\partial \mathcal{H}}{\partial p_i}\frac{\partial p_i}{\partial q^*}\right) = \sum_{i=1}^{m} v_i\left(\frac{\partial \varphi_i}{\partial q^*} + \sum_{j=1}^{m}\frac{\partial \varphi_i}{\partial p_j}\frac{\partial p_j}{\partial q^*}\right) = 0 \\
&\sum_{i=1}^{m}\left(v_i \frac{\partial \varphi_i}{\partial p^*} - \frac{\partial \mathcal{H}}{\partial p_i}\frac{\partial p_i}{\partial p^*}\right) = \sum_{i=1}^{m} v_i\left(\frac{\partial \varphi_i}{\partial p^*} + \sum_{j=1}^{m}\frac{\partial \varphi_i}{\partial p_j}\frac{\partial p_j}{\partial p^*}\right) = 0
\end{aligned} \tag{12}$$

Последние равенства в (12) вытекают из того, что имеются тождества

$$\varphi_i\left(p\left(p^*, q^*\right), p^*, q^*\right) \equiv 0, \quad i = 1, ..., m$$

Из (12) следует, что уравнения

$$\dot{p}^* = -\left(\frac{\partial \mathcal{H}}{\partial q^*} + v_i \frac{\partial \varphi_i}{\partial q^*}\right)$$

и

$$\dot{p}^* = -\frac{\partial \mathcal{H}^*}{\partial q^*} = -\left(\frac{\partial \mathcal{H}}{\partial q^*} + \frac{\partial \mathcal{H}}{\partial p_i}\frac{\partial p_i}{\partial q^*}\right)$$

совпадают (соответствующие уравнения для переменных q^* не выписываются). Таким образом утверждение об эквивалентности систем Γ и Γ^* доказано.

Система Γ может быть проквантована в переменных $\{p^*, q^*\}$, в которых она является невырожденной. В этих переменных квантовый оператор эволюции задаётся континуальным интегралом (см. (12 Л1))

$$\left\langle q^{*\prime\prime}\left|U^*\left(t'', t'\right)\right|q^{*\prime}\right\rangle = \int \exp\left\{i\int_{t'}^{t''}\left(p^*\dot{q}^* - \mathcal{H}^*\left(p^*, q^*\right)\right)\mathrm{d}t\right\}\prod_t \frac{\mathrm{d}p^*(t)\mathrm{d}q^*(t)}{2\pi} \tag{13}$$

Чаще всего (как в электродинамике и многих других калибровочных теориях) нецелесообразно разрешать связи явно. Напротив, оператор эволюции полезно представить непосредственно в терминах переменных обобщённой системы Г. Покажем, что континуальный интеграл

$$\int \exp\left\{ i \int_{t'}^{t''} \left[p\dot{q} - \left(\mathcal{H}(p,q) + v_i \varphi_i(p,q) \right) \right] \mathrm{d}t \right\} \prod_t \prod_i \delta\left(\chi^i\right) \det \left\| \left[\varphi_k, \chi^j \right] \right\| \prod_\alpha \frac{\mathrm{d}p_\alpha(t) \mathrm{d}q^\alpha(t)}{2\pi} \frac{\mathrm{d}v_i(t)}{2\pi} \tag{14}$$

совпадает с интегралом (13). Для этого проинтегрируем (14) по лагранжеву множителю v, в результате чего он принимает вид

$$\int \exp\left\{ i \int_{t'}^{t''} \left[p\dot{q} - \mathcal{H}(p,q) \right] \mathrm{d}t \right\} \prod_t \prod_i \delta\left(\chi^i\right) \delta\left(\varphi_i\right) \det \left\| \left[\varphi_k, \chi^j \right] \right\| \prod_\alpha \frac{\mathrm{d}p_\alpha(t) \mathrm{d}q^\alpha(t)}{2\pi} \tag{15}$$

Мера в интеграле (15) инвариантна относительно канонических преобразований переменных интегрирования. Будем считать, что он вычисляется в переменных (6), (7), в которых

$$\prod_t \prod_i \delta\left(\chi^i\right) \delta\left(\varphi_i\right) \det \left\| \left[\varphi_k, \chi^j \right] \right\| = \prod_t \prod_i \delta\left(q^i\right) \delta\left(\varphi_i\right) \det \left\| \frac{\partial \varphi_k}{\partial p_j} \right\| = \prod_t \prod_i \delta\left(q^i\right) \delta\left[p_i - p_i\left(p^*, q^*\right) \right]$$

Теперь очевидно, что после интегрирования по переменным $\{p_i, q^i\}$ с $i = 1, ..., m$ интеграл (15) сводится к (13).

Заметим, что выражение в круглой скобке в экспоненте в (14) является полным гамильтонианом $\mathcal{H}_T$.

9.3.2 Electromagnetic Field as a Dynamic System

Свободное электромагнитное поле описывается действием

$$\mathcal{S} = -\frac{1}{16\pi} \int \mathrm{d}^{(4)}x F_{\mu\nu} F^{\mu\nu}, \quad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu \tag{16}$$

Электрическое и магнитное поля равны соответственно

$$E^i = F^{i0} = -\partial_i A^0 - \dot{A}^i, \quad H^i = -\frac{1}{2} \varepsilon_{ijk} F^{jk} \tag{17}$$

Выпишем лагранжиан системы:

$$\mathcal{L} = \frac{1}{8\pi} \int \mathrm{d}^{(3)}x \left(F^{io}\right)^2 - \frac{1}{16\pi} \int \mathrm{d}^{(3)}x F_{ij}^2 \tag{18}$$

Проварьируем лагранжиан (18) относительно $\dot{A}^\mu$:

$$\delta_{\dot{A}} \mathcal{L} = -\frac{1}{4\pi} \int \mathrm{d}^{(3)}x F^{io} \delta\dot{A}^i = -\frac{1}{4\pi} \int \mathrm{d}^{(3)}x E^i \delta\dot{A}^i \tag{19}$$

Отсюда видно, что если поле A^μ рассматривается как совокупность координатных переменных, то соответствующие импульсные переменные π_μ равны

$$\pi_i(x) = -\frac{1}{4\pi}E^i(x) \tag{20}$$

$$\pi_0(x) = 0 \tag{21}$$

При помощи формул (17)-(21) находим гамильтониан:

$$\mathcal{H}_T \equiv \int \mathrm{d}^{(3)}x\pi_i\dot{A}^i - \mathcal{L} = \int \mathrm{d}^{(3)}x \left\{ \frac{\mathbf{E}^2 + \mathbf{H}^2}{8\pi} - \frac{1}{4\pi}A^0\nabla\mathbf{E} \right\} \tag{22}$$

Канонические одновременные СП имеют вид (выписаны лишь ненулевые СП):

$$\left[E^i(\mathbf{x}), A^j(\mathbf{y})\right] = 4\pi\delta^{ij}\delta^{(3)}(\mathbf{x}-\mathbf{y}), \quad \left[\pi^0(\mathbf{x}), A^0(\mathbf{y})\right] = -\delta^{(3)}(\mathbf{x}-\mathbf{y}) \tag{23}$$

Мы имеем множество первичных связей (21). Вычислим их СП с гамильтонианом:

$$\left[\pi^0(\mathbf{x}), \mathcal{H}\right] = \frac{1}{4\pi}\nabla\mathbf{E}(\mathbf{x}) \tag{24}$$

Чтобы связи (21) сохранялись, необходимо наложить множество новых связей:

$$\varphi(\mathbf{x}) \equiv \nabla\mathbf{E}(\mathbf{x}) = 0 \tag{25}$$

При помощи (23) находим:

$$\left[A^i(\mathbf{x}), \frac{1}{4\pi}\int \mathrm{d}^3y A^0(\mathbf{y})\nabla\mathbf{E}(\mathbf{y})\right] = \partial_i A^0(\mathbf{x}) \tag{26}$$

Таким образом, связи (25) генерируют калибровочные преобразования. Нетрудно проверить, что положительная часть гамильтониана

$$\mathcal{H} = \int \mathrm{d}^{(3)}x \frac{\mathbf{E}^2 + \mathbf{H}^2}{8\pi} \tag{27}$$

калибровочно инвариантен:

$$[\nabla\mathbf{E}(\mathbf{x}), \mathcal{H}] = 0 \tag{28}$$

Кроме того, все взаимные СП связей (21), (25) обращаются в ноль. Поэтому все связи - первого рода и поле A^0 играет роль лагранжевого множителя, принимающего произвольные значения и гамильтониан (22) является полным гамильтонианом.

Равенство (26) показывает, что естественными дополнительными условиями, аналогичными (3), в рассматриваемом случае являются условия, фиксирующие калибровку:

$$\chi(x) \equiv \nabla\mathbf{A}(x) = 0 \tag{29}$$

Вычислим одновременные СП связей (25) и (29). При помощи СП (23) находим:

$$[\varphi(\mathbf{x}), \chi(\mathbf{y})] = [\nabla\mathbf{E}(\mathbf{x}), \nabla\mathbf{A}(\mathbf{y})] = -4\pi\nabla^2\delta^{(3)}(\mathbf{x}-\mathbf{y}) \tag{30}$$

Таким образом, $\det \|[\varphi(\mathbf{x}), \chi(\mathbf{y})]\| = \mathrm{const}$, то есть этот определитель является величиной, не зависящей от динамических переменных, которая включается в общий нормировочный

множитель. (В более сложных калибровочных теориях, как теория Янга-Миллса, аналог оператора (30) зависит от полей и соответствующий определитель должен быть явно учтён.)

Обозначим через $\mathbf{A}^{\perp}(x)$ поперечное векторнозначное поле, удовлетворяющее условию

$$\nabla \mathbf{A}^{\perp} = 0 \tag{31}$$

В нашем случае система Γ описывается переменными $\{\mathbf{E}, \pi^0, A^\mu\}$, а система Γ* - переменными $\left\{\mathbf{E}^{\perp}, \mathbf{A}^{\perp}\right\}$. Однако удобнее взять в качестве исходной системы Γ несколько сокращённую систему с фазовым пространством, точками которого являются поля $\{\mathbf{E}, \mathbf{A}\}$, связями (25) и условиями (29), фиксирующими калибровку. При таком подходе роль лагранжевых множителей $\{v_i\}$ из предыдущего пункта берёт на себя поле, обозначаемое A^0.

При квантовании переменные системы Γ* удовлетворяют следующим одновременным КС (сравни с (23)):

$$\left[E^{\perp i}(\mathbf{x}), A^{\perp j}(\mathbf{y})\right] = 4\pi i \int \frac{d^{(3)}k}{(2\pi)^3}\left(\delta^{ij} - \frac{k^i k^j}{k^2}\right) e^{i\mathbf{k}(\mathbf{x}-\mathbf{y})} \tag{32}$$

Последние КС реализуются, если полевые переменные разлагаются согласно (сравни с (34 Л2))

$$\begin{aligned}
&\mathbf{A}^{\perp}(x) = \sum_{\alpha=1,2}\int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\sqrt{\frac{2\pi}{|\mathbf{k}|}}\left(c_{\mathbf{k}\alpha}\mathbf{e}^{\perp}_{\mathbf{k}\alpha}e^{i\mathbf{k}\mathbf{x}} + c^{\dagger}_{\mathbf{k}\alpha}\mathbf{e}^{\perp}_{\mathbf{k}\alpha} * e^{-i\mathbf{k}\mathbf{x}}\right)\\
&\mathbf{E}^{\perp}(x) = i\sum_{\alpha=1,2}\int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\sqrt{2\pi|\mathbf{k}|}\left(c_{\mathbf{k}\alpha}\mathbf{e}^{\perp}_{\mathbf{k}\alpha}e^{i\mathbf{k}\mathbf{x}} - c^{\dagger}_{\mathbf{k}\alpha}\mathbf{e}^{\perp}_{\mathbf{k}\alpha}e^{-i\mathbf{k}\mathbf{x}}\right)\\
&\left[c_{\mathbf{k}\alpha}, c^{\dagger}_{\mathbf{p}\beta}\right] = (2\pi)^3\delta_{\alpha\beta}\delta^{(3)}(\mathbf{k}-\mathbf{p}), \quad \alpha,\beta = 1,2\\
&\mathbf{k}\cdot\mathbf{e}^{\perp}_{\mathbf{k}\alpha} = 0, \quad \mathbf{e}^{\perp *}_{\mathbf{k}\alpha}\cdot\mathbf{e}^{\perp}_{\mathbf{k}\beta} = \delta_{\alpha\beta}, \quad \sum_{\alpha=1,2} e^{\perp i}_{\mathbf{k}\alpha}e^{\perp *j}_{\mathbf{k}\alpha} = \left(\delta^{ij} - \frac{k^i k^j}{\mathbf{k}^2}\right)
\end{aligned} \tag{33}$$

Если в (27) подставить переменные (33), то мы получим гамильтониан Γ*-системы:

$$\mathcal{H}^*_0 = \frac{1}{2}\sum_{\alpha=1,2}\int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}|\mathbf{k}|\left(c^{\dagger}_{\mathbf{k}\alpha}c_{\mathbf{k}\alpha} + c_{\mathbf{k}\alpha}c^{\dagger}_{\mathbf{k}\alpha}\right) \tag{34}$$

Фотонный вакуум определяется условиями

$$c_{\mathbf{k}\alpha}|0\rangle = 0 \tag{35}$$

Однофотонное состояние с импульсом $\mathbf{k}$ и поляризацией α в релятивистской нормировке представляется как (сравни с (38 Л2))

$$|\mathbf{k},\alpha\rangle = \sqrt{2|\mathbf{k}|}c^{\dagger}_{\mathbf{k}\alpha}|0\rangle \tag{36}$$

Двух- и т.д. фотонные состояния строятся из вакуумного очевидным образом при помощи операторов рождения $c^{\dagger}_{\mathbf{k}\alpha}$. Приведём гамильтониан (34) к нормальному виду (далее индекс *, отмечающую принадлежность к Γ*-системе, не выписываем):

$$\mathcal{H}_0 = \sum_{\alpha=1,2} \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} |\mathbf{k}| c^\dagger_{\mathbf{k}\alpha} c_{\mathbf{k}\alpha} + \mathcal{E}_0 \tag{37}$$

$$\mathcal{E}_0 = V \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} |\mathbf{k}| \tag{38}$$

Здесь V - объём пространства. Величина (38) является энергией нулевых колебаний или энергией вакуума. Также как и в скалярной теории, в электродинамике она положительна и её плотность бесконечна. Существуют экспериментальные методы "тестирования"энергии вакуума (эффект Казимира, см. задачу к этой лекции).

Как известно, плотность импульса электромагнитного поля равна $(1/4\pi)[\mathbf{E}, \mathbf{H}]$. Поэтому оператор импульса электромагнитного поля (сравни с (42 Л2))

$$\mathcal{P} = \frac{1}{4\pi} \int \mathrm{d}^{(3)}x [\mathbf{E}, \mathbf{H}] = \sum_{\alpha=1,2} \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \mathbf{k} c^\dagger_{\mathbf{k}\alpha} c_{\mathbf{k}\alpha}$$

Из данных определений следует, что (энергия вакуума вычеркнута из гамильтониана)

$$\mathcal{H}|0\rangle = \mathcal{P}|0\rangle = 0, \quad \mathcal{H}|\mathbf{k}, \alpha\rangle = |\mathbf{k}||\mathbf{k}, \alpha\rangle, \quad \mathcal{P}|\mathbf{k}, \alpha\rangle = \mathbf{k}|\mathbf{k}, \alpha\rangle$$

Таким образом, фотон является безмассовой частицей, распространяющейся со скоростью света.

Теперь при помощи формул из предыдущего пункта и лекции 2 мы можем, минуя детальные вычисления, выписать нормальный символ S-матрицы в фотодинамике в терминах переменных исходной Г-системы (сравни с (52 Л2)):

$$S(c^*, c) = \frac{1}{N} \int \exp\left\{ i \int \mathrm{d}^{(4)}x \left[-\frac{1}{4\pi} \left(\mathbf{E}\dot{\mathbf{A}} - A^0 \nabla \mathbf{E} \right) - \frac{\mathbf{E}^2 + \mathbf{H}^2}{8\pi} \right] \right\} \times$$
$$\times \prod_x \prod_{i=1}^{3} \delta(\nabla \mathbf{A}(x)) \mathrm{d}E^i(x) \mathrm{d}A^i(x) \mathrm{d}A^0(x) \tag{39}$$

Граничные условия в интеграле (39) таковы:

$$\mathbf{A}^\perp(x) \underset{t\to\pm\infty}{\longrightarrow} \mathbf{A}^\perp_{\substack{\text{out} \\ \text{in}}}(x) \qquad \mathbf{A}^\perp_{\text{in}}(x) = \sum_{\alpha=1,2} \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \sqrt{\frac{2\pi}{|\mathbf{k}|}} \left(c_{\mathbf{k}\alpha \ \substack{\text{out} \\ \text{in}}} \mathbf{e}^\perp_{\mathbf{k}\alpha} e^{-ikx} + c^*_{\mathbf{k}\alpha \ \substack{\text{out} \\ \text{in}}} \mathbf{e}^{\perp *}_{\mathbf{k}\alpha} e^{ikx} \right),$$

$$c_{\mathbf{k}\alpha \text{ in}} = c_{\mathbf{k}\alpha}, \quad c^*_{\mathbf{k}\alpha \text{ out}} = c^*_{\mathbf{k}\alpha}, \quad kx = k^0 x^0 - \mathbf{k}\mathbf{x}, \quad k^0 = |\mathbf{k}| \tag{40}$$

Обратим внимание на то, что граничные условия (40) имеют место лишь для физических степеней свободы, описываемых поперечной частью поля $\mathbf{A}^\perp(x)$ (31). Проинтегрируем в (39) по импульсным переменным $\mathbf{E}(x)$ и введём в теорию внешний источник. Это интегрирование проводится однозначно при помощи правила вычисления гауссовых интегралов, поскольку проблема граничных условий при этом интегрировании отсутствует. С учётом (16)-(18) получаем:

$$S_J\left(c^*,c\right)=\frac{1}{N}\int\exp\left\{i\int \mathrm{d}^{(4)}x\left[-\frac{1}{16\pi}F_{\mu\nu}F^{\mu\nu}+J^\mu A_\mu\right]\right\}\prod_x\delta\left(\partial_i A^i(x)\right)DA_\mu$$
$$DA_\mu\equiv\prod_x\prod_\mu \mathrm{d}A_\mu(x) \tag{41}$$

Интеграл (41) вычисляется с граничными условиями (40).

Из континуального интеграла (41) видно, что интегрирование идёт не по всем полям, а лишь по поперечным физическим полям $\mathbf{A}^\perp$.

Для вычисления пропагатора электромагнитного поля преобразуем интеграл (41) следующим образом:

$$S_J\left(c^*,c\right)=\frac{1}{N}\int\exp\left\{i\int \mathrm{d}^{(4)}x\left[-\frac{1}{16\pi}\left(\partial_\mu A_\nu-\partial_\nu A_\mu\right)^2+J^\mu A_\mu+\lambda\partial_i A_i\right]\right\}\prod_x\,\mathrm{d}\lambda(x)DA_\mu \tag{42}$$

Для вычисления гауссового интеграла следует найти экстремум показателя экспоненты в (42) относительно переменных $\{\lambda,A_\mu\}$. Этот экстремум находится при помощи системы уравнений

$$\partial_i A_i=0,\quad \Delta A^0=4\pi J^0,\quad \partial_\mu\partial^\mu A^i+\partial_i\dot{A}_0=4\pi\left(\partial_i\lambda-J^i\right) \tag{43}$$

Естественно считать, что источник удовлетворяет условию поперечности:

$$\partial_i J^i=0 \tag{44}$$

Вычисляя дивергенцию последнего из уравнений (43) и учитывая первые два, находим:

$$\Delta\lambda=\partial_0 J^0 \tag{45}$$

В результате система уравнений (43)-(44) сводится к уравнению (45), а также уравнениям

$$\Delta A^0=4\pi J^0,\quad \partial_\mu\partial^\mu\mathbf{A}^\perp=-4\pi\mathbf{J}^\perp \tag{46}$$

Теперь аналогично (53 Л2) мы можем представить электромагнитное поле, для которого действие в (42) экстремально:

$$A^\mu(x)=A_0^\mu(x)+\int \mathrm{d}^{(4)}y D_C^{\mu\nu}(x-y)J_\nu(y)$$
$$A_0^0=0,\quad \mathbf{A}_0(x)=\sum_{\alpha=1,2}\int\frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\sqrt{\frac{2\pi}{|\mathbf{k}|}}\left(c_{\mathbf{k}\alpha}\mathbf{e}^\perp_{\mathbf{k}\alpha}e^{-ikx}+c^*_{\mathbf{k}\alpha}\mathbf{e}^\perp_{\mathbf{k}\alpha}e^{ikx}\right),\quad k^0=|\mathbf{k}| \tag{47}$$
$$D_C^{ij}(x)=-4\pi\int\frac{d^{(4)}k}{(2\pi)^4}\frac{e^{-ikx}}{k^2+i\varepsilon}\left(\delta^{ij}-\frac{k^ik^j}{\mathbf{k}^2}\right),\quad D_C^{0i}=0,\quad D_C^{00}(x)=-4\pi\int\frac{d^{(4)}k}{(2\pi)^4}\frac{e^{-ikx}}{\mathbf{k}^2} \tag{48}$$

Явное выражение для $D_C^{\mu\nu}(x)$ показывает, что распространяются во времени только трёхмерно поперечные составляющие поля A_μ.

Недостатком диаграммной техники, развитой при помощи пропагатора (48), является отсутствие явной релятивистской инвариантности.

9.3.3 Covariant Quantization Rules and the Faddeev-Popov Trick

Чтобы восстановить явную релятивистскую инвариантность, поступим следующим образом. Обозначим через $a(x)$ некое скалярное поле и через A_μ^ω - калибровочно преобразованное электромагнитное поле:

$$A_\mu^\omega = A_\mu + \partial_\mu \omega \tag{49}$$

Определим величину Δ_L при помощи равенства

$$\Delta_L \int \prod_x \delta\left[\partial^\mu A_\mu^\omega - a(x)\right] \mathrm{d}\omega(x) = 1 \tag{50}$$

Очевидно, Δ_L не зависит от полей A_μ и $a(x)$: $\Delta_L = \det \partial^2$. Теперь вставим левую часть (50) в интеграл (41), что не изменит его значения:

$$S_J(c^*, c) = \frac{1}{N} \int \exp\left\{ i \int \mathrm{d}^{(4)}x \left[-\frac{1}{16\pi} F_{\mu\nu} F^{\mu\nu} + J^\mu A_\mu \right] \right\} \times$$
$$\times \prod_x \delta\left(\partial_i A^i(x)\right) \Delta_L \delta\left[\partial^\mu A_\mu^\omega - a(x)\right] \mathrm{d}\omega(x) DA_\mu \tag{51}$$

Теперь в интеграле (51) сделаем калибровочное преобразование, обратное к (49), и учтём, что мера DA_μ и плотность действия $F_{\mu\nu}^2$ при этом не изменяются, являясь калибровочными инвариантами. Поэтому после соответствующего переобозначения внешнего тока интеграл (51) принимает вид

$$S_J(c^*, c) = \frac{1}{N} \int \exp\left\{ i \int \mathrm{d}^{(4)}x \left[-\frac{1}{16\pi} F_{\mu\nu} F^{\mu\nu} + J^\mu A_\mu - J^\mu \partial_\mu \omega \right] \right\} \times$$
$$\times \prod_x \delta\left(\partial_i A_i^{\omega^{-1}}(x)\right) \Delta_L \delta\left[\partial^\mu A_\mu - a(x)\right] \mathrm{d}\omega(x) DA_\mu$$

За слагаемым вида $J^\mu \partial_\mu \omega$ в экспоненте нет смысла следить потому что асимптотическое поле (47) определено с точностью до слагаемого $\partial_\mu \omega$, где поле ω, так же как и в рассматриваемых функциональных интегралах - произвольное, удовлетворяющее уравнению д'Аламбера (см. ниже ур. (57)). Так как интеграл

$$\int \prod_x \delta\left[\partial_i A_i^{\omega^{-1}}(x)\right] \mathrm{d}\omega(x) = \det \Delta^{-1}$$

также не зависит от от вектор-потенциала, то его можно выбросить. Таким образом

$$S_J(c^*, c) = \frac{1}{N} \int \exp\left\{ i \int \mathrm{d}^{(4)}x \left[-\frac{1}{16\pi} F_{\mu\nu} F^{\mu\nu} + J^\mu A_\mu \right] \right\} \prod_x \delta\left[\partial^\mu A_\mu - a(x)\right] DA_\mu$$

Поскольку здесь левая часть не зависит от поля $a(x)$, мы можем проинтегрировать последнее выражение с весом

$$\exp\left\{ -\frac{i}{8\pi\alpha} \int a^2(x) \mathrm{d}^{(4)}x \right\}$$

что влияет лишь на нормировочный множитель:

$$S_J(c^*,c) = \frac{1}{N}\int \exp\left\{ i\int \mathrm{d}^{(4)}x \left[-\frac{1}{16\pi}F_{\mu\nu}F^{\mu\nu} - \frac{1}{8\pi\alpha}a^2(x) + J^\mu A_\mu \right] \right\} \times$$
$$\times \prod_x \delta\left[\partial^\mu A_\mu - a(x)\right] \mathrm{d}a(x) DA_\mu =$$
$$= \frac{1}{N}\int \exp\left\{ i\int \mathrm{d}^{(4)}x \left[-\frac{1}{16\pi}F_{\mu\nu}F^{\mu\nu} - \frac{1}{8\pi\alpha}\left(\partial_\mu A^\mu\right)^2 + J^\mu A_\mu \right] \right\} DA_\mu \tag{52}$$

Находя пропагатор таким же образом, как это было сделано выше, находим, что континуальный интеграл (52) приводит к ковариантному пропагатору

$$D^\alpha_{\mu\nu}(x) = 4\pi \int \frac{\mathrm{d}^{(4)}k}{(2\pi)^4}\frac{e^{-ikx}}{k^2+i\varepsilon}\left[\eta_{\mu\nu} - \frac{(1-\alpha)k_\mu k_\nu}{k^2+i\varepsilon}\right], \quad \eta_{\mu\nu} = \mathrm{diag}(1,-1,-1,-1) \tag{53}$$

Калибровка, в которой пропагатор имеет вид (53), называется α-калибровкой. Частный случай этой калибровки $\alpha = 1$ называется калибровкой Фейнмана, а частный случай $\alpha = 0$ - калибровкой Ландау.

Правильность задания обхода полюсов в (53) легче всего устанавливается следующим образом. Пропагатор (48), конечно, как пропагатор, описывающий распространение реальных частиц в рамках теории S-матрицы, позволяет сделать поворот Вика в евклидово пространство. Иными словами, при вычислении S-матрицы можно использовать интеграл вида (41) в евклидовом пространстве, и лишь после вывода правил Фейнмана перейти в пространство Минковского. В евклидовом пространстве можно перейти к α-калибровке (52) при помощи описанного трюка Фаддеева-Попова и получить соответствующий евклидовский пропагатор. После этого обратный поворот Вика в пространство Минковского приводит к пропагатору (53) с указанным обходом полюсов.

Теперь мы можем выписать нормальный символ S-матрицы для свободного электромагнитного поля при наличии внешнего источника (сравни с (51 Л2). Значение экстремального значения электромагнитного поля задаётся формулой (см. (47))

$$A^\mu(x) = A^\mu_0(x) + \int \mathrm{d}^{(4)}y D^{\alpha\mu\nu}(x-y)J_\nu(y)$$

а нормальный символ S-матрицы имеет вид

$$S_J(c^*,c) = \frac{1}{N}\exp\left\{ i\int \mathrm{d}^{(4)}x J^\mu A_{0\mu} + \frac{i}{2}\iint \mathrm{d}^{(4)}x\ \mathrm{d}^{(4)}y J^\mu(x) D^\alpha_{\mu\nu}(x-y) J^\nu(y) \right\} \tag{54}$$

Последнее замечание касается вопроса об однозначности определения векторов поляризации фотонов $\mathbf{e}^\perp_{\mathbf{k}\alpha}$. Введём 4 -вектор поляризации фотона $e^\mu_{\mathbf{k}\alpha} = \left(0, \mathbf{e}^\perp_{\mathbf{k}\alpha}\right)$. Если $k^\mu = (|\mathbf{k}|, \mathbf{k}) - 4$ импульс фотона, то согласно (33)

$$k_\mu e^\mu_{\mathbf{k}\alpha} = 0, \quad \eta_{\mu\nu} e^\mu_{\mathbf{k}\alpha} e^{\nu *}_{\mathbf{k}\beta} = -\delta_{\alpha\beta} \tag{55}$$

Очевидно, что оба свойства (55) сохраняются, если сделать преобразование вектора поляризации согласно правилу

$$e^\mu_{\mathbf{k}\alpha} \to e^\mu_{\mathbf{k}\alpha} + f(\mathbf{k})k^\mu \tag{56}$$

где $f(\mathbf{k})$ - любая функция. Поэтому вектор поляризации фотона определён неоднозначно с точностью до преобразования (56), изменяющего четырёхмерно продольную часть фотона. Поэтому и асимптотическое поле (47) определено с точностью до произвольного калибровочного преобразования вида

$$A_{0\mu} \longrightarrow A_{0\mu} + \partial_\mu \omega, \quad \partial_\mu \partial^\mu \omega = 0 \tag{57}$$

В то же время, как мы увидим ниже, все физические величины инвариантны относительно преобразований (56). Эта инвариантность является следствием калибровочной инвариантности теории.

Задачи

1. Трёхмерный эффект Казимира.

а) В трёхмерном пространстве на расстоянии l друг от друга расположены две бесконечные плоские параллельные металлические пластины. Считая, что на пластинах обращаются в ноль тангенциальные компоненты электрического поля $\mathbf{E}$ и разность потенциалов между пластинами равна нулю, проквантовать фотонное поле и выразить его гамильтониан через лестничные операторы.

б) Вычислить силу на единицу площади пластин, с которой взаимодействуют эти пластины вследствие искажений нулевых колебаний фотонного поля и сдвига энергии вакуума.

Указание. При регуляризации интеграла типа (38), формально задающего энергию вакуума, использовать формулу размерностной регуляризации (3 Л4), а при регуляризации расходящихся сумм степеней целых чисел использовать аналитическое продолжение ζ-функции Римана.

2. Вычислить явно в координатном представлении в четырёхмерном пространстве фотонный пропагатор в α-калибровке.

9.3.4 Faddeev-Popov Trick: Detailed Overview

(??? discussion about is it important to know it, and what exactly happened and what is the idea????)

9.4 Spinor Field (fermions) 1: General Methods

(this shuold be rewritten, now structure does not match the title, I should go through this theory to find out what to delete and what to move????)

9.4.1 Fermion Propagator (after Mandl & Shaw)

Теория

In Section 3.4 we introduced the meson propagator. Corresponding to Eq. (3.55), we now define the Feynman fermion propagator as

$$\left\langle 0 \left| \mathbf{T} \left\{ \psi(x) \bar{\psi}\left(x'\right) \right\} \right| 0 \right\rangle$$

where spinor indices have again been suppressed. For fermion fields, the time-ordered product is defined by

$$T\left\{\psi(x)\bar{\psi}\left(x'\right)\right\} = \theta\left(t-t'\right)\psi(x)\bar{\psi}\left(x'\right) - \theta\left(t'-t\right)\bar{\psi}\left(x'\right)\psi(x)$$
$$= \left\{ \begin{array}{ll} \psi(x)\bar{\psi}\left(x'\right), & \text{if } t > t' \\ -\bar{\psi}\left(x'\right)\psi(x), & \text{if } t' > t \end{array} \right\}$$

The Dirac Field 67 (where $t = x^0/c$, etc.). This definition differs by a factor (-1) in the $t' > t$ term from the corresponding boson definition, Eqs. (3.52) and (3.54). This change in sign reflects the anticommutation property of fermion fields. (A similar difference occurred in the definition of the normal products of boson and fermion fields.) In order to calculate the fermion propagator (4.58), using Eq. (4.59), we note that

$$\left\langle 0\left|\psi(x)\bar{\psi}\left(x'\right)\right|0\right\rangle = \left\langle 0\left|\psi^{+}(x)\bar{\psi}^{-}\left(x'\right)\right|0\right\rangle$$
$$= \left\langle 0\left|\left[\psi^{+}(x),\bar{\psi}^{-}\left(x'\right)\right]_{+}\right|0\right\rangle = \mathrm{i}S^{+}\left(x-x'\right),$$

where we used Eq. (4.53a); similarly

$$\left\langle 0\left|\bar{\psi}\left(x'\right)\psi(x)\right|0\right\rangle = \mathrm{i}S^{-}\left(x-x'\right).$$

Combining Eqs. (4.58)-(4.60), we obtain the fermion propagator:

$$\left\langle 0\left|\ \mathrm{T}\left\{\psi(\mathrm{x})\bar{\psi}\left(x'\right)\right\}\right|0\right\rangle = \mathrm{i}S_{\mathrm{F}}\left(x-x'\right)$$

where $\mathrm{S_F}(x)$ is defined, analogously to Eqs. (3.56) and (4.54), by

$$S_{\mathrm{F}}(x) = \theta(t)S^{+}(x) - \theta(-t)S^{-}(x) = \left(\mathrm{i}\gamma^{\mu}\frac{\partial}{\partial x^{\mu}} + \frac{mc}{\hbar}\right)\Delta_{\mathrm{F}}(x).$$

Corresponding to the integral representation (3.58) for $\Delta_{\mathrm{F}}(x), S_{\mathrm{F}}(x)$ can be written

$$S_{\mathrm{F}}(x) = \frac{\hbar}{(2\pi\hbar)^4}\int \mathrm{d}^4p\mathrm{e}^{-\mathrm{i}px/\hbar}\frac{\not{p}+mc}{p^2-m^2c^2+\mathrm{i}\varepsilon},$$

where the integration in the complex p_0-plane is along the whole real axis: $-\infty < p_0 < \infty$. (Compare Fig. 3.6.)

As for the meson propagator, it is useful to visualize the fermion propagator in terms of Feynman diagrams. (As mentioned before, one must not take this interpretation too literally.)

For $t' < t$, the contribution to the fermion propagator (4.61) stems from the term (4.60a) and thus leads to the interpretation of (4.61) as creation of an electron at x', its propagation to x and its annihilation at x. On the other hand, for $t < t'$, the contribution to (4.61) comes from (4.60b) and is pictured as the emission of a positron at x, and its propagation to x' where it is annihilated. The two cases are illustrated in Fig. 4.1. Note that in both diagrams the arrow on the fermion line points from the vertex associated with the $\bar{\psi}$-field (x') to the vertex associated with the ψ-field (x), i.e. the arrow runs in the same direction as time for electrons, in the opposite direction for positrons.

These ideas are illustrated in Fig. 4.2, which shows two of the leading contributions, in lowest order of perturbation theory, to Compton scattering by electrons. Fig. 4.2(a) represents an electron propagating in the direction of the arrow on the fermion line, emitting the final photon at the vertex x' and absorbing the initial photon at x. Fig. 4.2(b) represents the corresponding process for $t < t'$.

The initial photon is annihilated at x, creating an electron-positron pair, i.e. the final electron and a positron which propagates to x, where it annihilates with the initial electron to produce the final-state photon. Note that the arrow is always in the same sense along a fermion line, and in both diagrams is from the x'-vertex (associated with the $\bar{\psi}$ operator) to the x-vertex (associated with ψ) on the internal fermion line. Thus the two diagrams are topologically equivalent, i.e. they can be continuously deformed into each other.

The fermion propagator (4.61) includes both the contributions from Figs. 4.2(a) and (b), and we represent it by the single Feynman diagram in Fig. 4.3, in which no time ordering of the vertices x and x' is implied, and consequently no time direction is attached to the internal fermion line joining x' and x. The orientation of the line $x'x$ is of no significance in this diagram. However, we shall continue to interpret external lines (i.e. lines entering or leaving a diagram from outside) in the same way for Feynman graphs as for time-ordered graphs. A line entering a diagram from the left-hand side will be interpreted as a particle present initially, one leaving a diagram on the right-hand side as one present finally. With these conventions, Figs. 4.4(a) and (b) represent Compton scattering by electrons and positrons, without further labelling being necessary. The arrows on the fermion lines are required to distinguish electrons (arrows on external lines from left to right) from positrons (arrows on external lines from right to left). Although no arrows are required on the photon lines, we shall at times use arrows on external photon lines to emphasize initially and finally present quanta. In the following we shall frequently use such Feynman diagrams.

9.4.2 The Electromagnetic Interaction and Gauge Invariance

Теория

We shall now consider the interaction of relativistic electrons with an electromagnetic field, specified by the scalar and vector potentials $\phi(x)$ and $\mathrm{A}(x)$. For this purpose we shall take over the procedure which is successful in non-relativistic quantum mechanics. In the latter case, making the substitution

$$\mathrm{i}\hbar\frac{\partial}{\partial t} \to \mathrm{i}\hbar\frac{\partial}{\partial t} - q\phi(x), \quad -\mathrm{i}\hbar\nabla \to -\mathrm{i}\hbar\boldsymbol{\nabla} - \frac{q}{c}\mathbf{A}(x),$$

in the free-particle Schrödinger equation leads to the correct wave equation for a particle of charge q in this field. [The corresponding classical result is contained in Eq. (1.59).] The substitution (4.64a) is usually referred to as the 'minimal substitution'. In terms of the four-vector potential $A^\mu(x) = (\phi, \mathrm{A})$, the minimal substitution takes the explicitly covariant form

$$\partial_\mu \equiv \frac{\partial}{\partial x^\mu} \to D_\mu = \left[\partial_\mu + \frac{\mathrm{i}q}{\hbar c}A_\mu(x)\right].$$

We shall assume that this substitution also correctly introduces the electromagnetic interaction into the Dirac equation. With the replacement (4.64b), and $q = -e$ for electrons, the Dirac equation (4.14) and the Lagrangian density (4.20) become

$$(\mathrm{i}\hbar\gamma^\mu\partial_\mu - mc)\,\psi(x) = -\frac{e}{c}\gamma^\mu A_\mu(x)\psi(x)$$

and

$$\left.\begin{aligned}\mathscr{L} &= c\bar{\psi}(x)\,(\mathrm{i}\hbar\gamma^\mu D_\mu - mc)\,\psi(x)\\ &= \mathscr{L}_0 + \mathscr{G}_\mathrm{I}\end{aligned}\right\}$$

where $\mathscr{L}_0$ is the Lagrangian density of the free Dirac field, i.e.

$$\mathscr{L}_0 = c\bar{\psi}(x)\,(\mathrm{i}\hbar\gamma^\mu\partial_\mu - mc)\,\psi(x),$$

and $\mathscr{L}_{\mathrm{I}}$ is the interaction Lagrangian density

$$y' = e\bar{\psi}(x)\gamma^{\mu}\psi(x)A_{\mu}(x),$$

which couples the conserved current $s^{\mu}(x) = c(-e)\bar{\psi}\gamma^{\mu}\psi$, Eq. (4.28), to the electromagnetic field.

To obtain the complete Lagrangian density for electrodynamics, we must add to Eq. (4.66) the Lagrangian density $\mathscr{L}_{\mathrm{rad}}$ of the radiation field, i.e. of the electromagnetic field in the absence of charges. This division is analogous to that of the Hamiltonian in Chapter 1, Eqs. (1.61)-(1.63). $\mathscr{L}_{\mathrm{rad}}$ depends on the potential $A_{\mu}(x)$ only, and we shall study it in the next chapter.

We know that it is only the electromagnetic fields E and **B** which have physical significance, not the potential A_{μ} itself, i.e. the theory must be invariant under the gauge transformations of the potentials, Eqs. (1.3). The latter can be written in the covariant form

$$A_{\mu}(x) \to A'_{\mu}(x) = A_{\mu}(x) + \partial_{\mu}f(x)$$

where $f(x)$ is an arbitrary function. The invariance of the theory under gauge transformations follows from that of the Lagrangian density. $\mathscr{L}_{\mathrm{rad}}$ has this invariance property, as we shall see in the next chapter. However, applying (4.69a) to Eq. (4.66), we obtain

$$\to\to y' = y + e\bar{\psi}(x)\gamma^{\mu}\psi(x)\partial_{\mu}f(x)$$

i.e. $\mathscr{L}$ is not gauge invariant with respect to (4.69a). We can restore gauge invariance by demanding that coupled with the gauge transformation (4.69a) of the electromagnetic potentials, the Dirac fields transform according to

$$\left.\begin{array}{ll} \psi(x) \to \psi'(x) & = \psi(x)\mathrm{e}^{\mathrm{i}ef(x)/\hbar c} \\ \bar{\psi}(x) \to \bar{\psi}'(x) & = \bar{\psi}(x)\mathrm{e}^{-\mathrm{i}ef(x)/\hbar c} \end{array}\right\}.$$

Under the coupled transformations (4.69a) and (4.69b), the Lagrangian densities (4.67) and (4.68) transform according to

$$\begin{aligned} \mathscr{L}_0 \to \mathscr{L}'_0 &= \mathscr{L}_0 - e\bar{\psi}(x)\gamma^{\mu}\psi(x)\partial_{\mu}f(x) \\ \mathscr{L}_1 \to \mathscr{L}'_1 &= \mathscr{L}_1 + e\bar{\psi}(x)\gamma^{\mu}\psi(x)\partial_{\mu}f(x). \end{aligned}$$

Consequently, $\mathscr{G} = \mathscr{Z}_0 + \mathscr{Y}_1$ remains invariant under the coupled transformations. Eqs. (4.69b) are called a local phase transformation, since the phase factors depend on x. In the special case that $f(x) = \text{const.}$, Eqs. (4.69b) reduce to a global phase transformation, considered in Section 2.4, where we saw that invariance under a global phase transformation leads to a conserved charge. We have now seen that gauge invariance of the theory requires invariance when simultaneously transforming the electromagnetic potentials according to the gauge transformation (4.69a) and the Dirac fields according to the local phase transformation (4.69b), and we shall in future refer to these coupled transformations as gauge transformations. It can be shown that the application of Noether's theorem to the invariance with respect to these (coupled) gauge transformations does not lead to a new conservation law, but only reproduces the conservation of charge.

In what follows we shall assume that Eq. (4.68) gives the correct interaction of quantum electrodynamics. One could try and add other gauge-invariant and Lorentzinvariant local interaction terms, but these can be excluded if we impose another restriction - renomalizability of the theory - as shown in Section 11.3.2. The ultimate justif ication for taking Eq. (4.68) as the correct interaction lies, of course, in the complete agreement between some of physics' most precise experiments and theoretical predictions based on this interaction.

9.4.3 Зи.II.1 Dirac Equation

Смотря на огонь

Согласно физической легенде, по-видимому, соответствующей действительности, в один из вечеров 1928 года Дирак смотрел на огонь и вдруг осознал, что, по причинам, теперь не имеющим никакого значения, ему необходимо релятивистское волновое уравнение первого порядка по пространственно-временным производным $\partial_\mu \equiv \partial/\partial x^\mu$. Уже в то время хорошо было известно уравнение Клейна-Гордона $(\partial^2 + m^2)\,\varphi = 0$, которое описывает свободную частицу массой m и является квадратичным по пространственно-временным производным. Оно фактически является уравнением движения в теории скалярного поля, изученной нами ранее.

На первый взгляд желание Дирака не имеет смысла. Предположительно уравнение должно иметь форму «некая линейная комбинации ∂_μ, действующая на некое поле ψ, равна некоторой константе, умноженной на поле». Обозначим линейную комбинацию через $c^\mu\partial_\mu$. Если c^μ есть четыре обычных числа, то 4-вектор c^μ определяет некоторое направление и потому уравнение не может быть лоренц-инвариантным.

Тем не менее, следуя Дираку, запишем (воспользовавшись современными обозначениям):

$$(i\gamma^\mu\partial_\mu - m)\,\psi = 0.$$

На данном этапе четыре величины $i\gamma^\mu$ являются просто коэффициентами при ∂_μ, а m - просто константой. Мы уже знаем, что в качестве γ^μ не могут выступать просто четыре числа. Итак, давайте выясним, что должны представлять из себя эти четыре объекта, чтобы обозначенное уравнение правильно описывало физику.

Действуя на (1) выражением $(i\gamma^\mu\partial_\mu + m)$, Дирак получил $-\left(\gamma^\mu\gamma^\nu\partial_\mu\partial_\nu + \ + m^2\right)\psi = 0$. По традиции, определим в дополнение к коммутатору $[A, B] = AB - BA$, известному нам из квантовой механики, антикоммутатор $\{A, B\} = AB + BA$. Поскольку производные коммутируют друг с другом, $\gamma^\mu\gamma^\nu\partial_\mu\partial_\nu = \frac{1}{2}\{\gamma^\mu, \gamma^\nu\}\,\partial_\mu\partial_\nu$, получаем $\left(\frac{1}{2}\{\gamma^\mu, \gamma^\nu\}\,\partial_\mu\partial_\nu + m^2\right)\psi = 0$. В момент озарения Дирак осознал, что если бы

$$\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu},$$

где $\eta^{\mu\nu}$ является метрикой Минковского, то он пришел бы к выражению $(\partial^2 + m^2)\,\psi = 0$, которое описывает частицу массой m, и, стало быть, (1) также описывало бы частицу массой m.

Так как $\eta^{\mu\nu}$ есть диагональная матрица с диагональными элементами $\eta^{00} = 1$ и $\eta^{jj} = -1$, формула (2) гласит, что $(\gamma^0)^2 = 1, (\gamma^j)^2 = -1$ и $\gamma^\mu\gamma^\nu = -\gamma^\nu\gamma^\mu$ при $\mu \neq \nu$. В этой ситуации коэффициенты γ^μ антикоммутируют друг с другом, а это означает, что они и в самом деле не могут выражаться обычными числами. Рассуждения Дирака будут иметь смысл, если мы сможем найти четыре таких объекта.

Алгебра Клиффорда

Говорят, что множество объектов γ^μ (очевидно, что d из них в d-мерном пространстве-времени), удовлетворяющих соотношению (2), образует алгебру Клиффорда. Я изложу математику алгебры Клиффорда чуть позднее. А сейчас достаточно будет проверить, что следующие матрицы 4×4 удовлетворяют условию (2):

$$\gamma^0 = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix} = I \otimes \tau_3,$$
$$\gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix} = \sigma^i \otimes i\tau_2.$$

Здесь σ и τ обозначают стандартные матрицы Паули. По историческим причинам четыре матрицы γ^μ называют гамма-матрицами - не слишком образное название! (Согласно принятому соглашению, нам совершенно неважно, верхний или нижний индекс имеет матрица Паули. С другой стороны, мы определяем $\gamma_\mu \equiv \eta_{\mu\nu}\gamma^\nu$, и теперь нам не все равно, сверху или снизу стоит у гамма-матрицы индекс; его необходимо рассматривать подобно индексу любого лоренцевского вектора. Такое соглашение удобно, поскольку оно позволяет записать $\gamma^\mu\partial_\mu = \gamma_\mu\partial^\mu$.)

При расчетах удобным оказывается обозначение с использованием прямого произведения: например, $\gamma^i\gamma^j = (\sigma^i \otimes i\tau_2)(\sigma^j \otimes i\tau_2) = (\sigma^i\sigma^j \otimes\ i^2\tau_2\tau_2) = -(\sigma^i\sigma^j \otimes I)$, и поэтому $\{\gamma^i, \gamma^j\} = -\{\sigma^i, \sigma^j\} \otimes I = -2\delta^{ij}$, как и должно быть.

Можете убедиться в том, что размерность матриц γ^μ не может быть меньше, чем 4×4. С математической точки зрения спинор Дирака ψ должен иметь четыре компоненты! Физическое содержание уравнения Дирака (1) становится более понятным, если перейти в импульсное пространство: подставляем $\psi(x) = \int [d^4p/(2\pi)^4]\, e^{-ipx}\psi(p)$ в (1) и получаем

$$(\gamma^\mu p_\mu - m)\,\psi(p) = 0$$

В силу лоренц-инвариантности выражения (5), которую мы докажем позднее, его физическое содержание можно исследовать в любой системе координат. В частности, мы можем рассмотреть его в системе покоя $p^\mu = (m, \overrightarrow{0})$, где уравнение сводится к виду

$$\left(\gamma^0 - 1\right)\psi = 0$$

Так как $(\gamma^0 - 1)^2 = -2(\gamma^0 - 1)$, мы узнаем в $(\gamma^0 - 1)$ проектор с точностью до тривиальной нормировки. В самом деле, записав (3) в явной форме, мы видим, что в уравнении Дирака нет ничсго таинственного: в явном виде формула (6) равна

$$\begin{pmatrix} 0 & 0 \\ 0 & I \end{pmatrix}\psi = 0,$$

то есть две из четырех компонент в ψ равны нулю.

Это вполне осмысленеенное утверждение, поскольку известно, что электрон имеет 2 физические степени свободы, а не 4. В этом свете загадочное уравнение Дирака является ни больше ни меньше чем проекцией, избавляющей нас от нежелательных степеней свободы. Сравним полученный результат с уравнением движения массивной частицы со спином 1 (глава I.5). Для него мы также отбрасывали одну из четырех компонент A^μ. Действительно, уравнение Клейна-Гордона $(\partial^2 + m^2)\,\varphi(x) = 0$ выкидывает те фурье-компоненты $\varphi(k)$, которые не удовлетворяют условию массовой поверхности $k^2 = m^2$. Из наших рассуждений вытекает единый взгляд на уравнения движения в релятивистской физике: эти уравнения просто отбрасывают нефизические составляющие.

Удобное обозначение, введенное Фейнманом: $\not{a} \equiv \gamma^\mu a_\mu$ для произвольного 4-вектора a_μ, сейчас стало стандартным. Уравнение Дирака при этом имеет вид $(i\ \not{\partial} - m)\psi = 0$.

Родственники гамма-матриц

При преобразовании Лоренца $x'^{\nu} = \Lambda^{\nu}_{\mu} x^{\mu}$ четыре компоненты векторного поля A_{μ} преобразуются как вектор. А как преобразуются 4 компоненты ψ? Конечно же, не так, как A_{μ}, ведь даже при вращении поля ψ и A_{μ} преобразуются неодинаково: одно - как спин 1/2, а другое - как спин 1. Запишем $\psi(x) \to \psi'(x') \equiv S(\Lambda)\psi(x)$ и попытаемся определить 4×4-матрицу $S(\Lambda)$.

Для начала было бы неплохо выбрать (и обозначить) 16 линейно независимых матриц размерностью 4×4. Пять из них мы уже знаем: единичная матрица и четыре матрицы γ^{μ}. Стратегия заключается в простом умножении γ^{μ} друг на друга, в результате чего образуется больше 4×4-матриц. Перемножаем таким образом до тех пор, пока не получим все 16 матриц. Поскольку квадрат гамма-матрицы γ^{μ} равен \pm 1, а γ^{μ} антикоммутируют друг с другом, достаточно рассмотреть только $\gamma^{\mu}\gamma^{\nu}, \gamma^{\mu}\gamma^{\nu}\gamma^{\lambda}$ и $\gamma^{\mu}\gamma^{\nu}\gamma^{\lambda}\gamma^{\rho}$ с отличными друг от друга μ, ν, λ и ρ. Таким образом, единственным произведением четырех гамма-матриц, которое мы должны рассмотреть, является

$$\gamma^5 \equiv i\gamma^0\gamma^1\gamma^2\gamma^3$$

Эта комбинация настолько важна, что она имеет свое собственное имя! (Происхождение сего странного имени связано с тем, что в некоторых старомодных обозначениях временная координата называлась x^4 с соответствующей γ^4.) Имеем

$$\gamma^5 = i\left(I \otimes \tau_3\right)\left(\sigma^1 \otimes i\tau_2\right)\left(\sigma^2 \otimes i\tau_2\right)\left(\sigma^3 \otimes i\tau_2\right) = i^4\left(I \otimes \tau_3\right)\left(\sigma^1\sigma^2\sigma^3 \otimes \tau_2\right)$$

и поэтому

$$\gamma^5 = I \otimes \tau_1 = \begin{pmatrix} 0 & I \\ I & 0 \end{pmatrix}$$

Восстановив множитель i, видим, что матрица γ^5 явно является эрмитовой. Ее важной особенностью является то, что γ^5 антикоммутирует со всеми γ^{μ}:

$$\left\{\gamma^5, \gamma^{\mu}\right\} = 0$$

Далее, видим, что произведение трех различных гамма-матриц может быть записано как $\gamma^{\mu}\gamma^5$ (например, $\gamma^1\gamma^2\gamma^3 = -i\gamma^0\gamma^5$). Наконец, используя (2), можно записать произведение двух гамма-матриц как $\gamma^{\mu}\gamma^{\nu} = \eta^{\mu\nu}$ - $-i\sigma^{\mu\nu}$, где

$$\sigma^{\mu\nu} \equiv \frac{i}{2}\left[\gamma^{\mu}, \gamma^{\nu}\right]$$

Всего имеется $4 \cdot 3/2 = 6$ таких $\sigma^{\mu\nu}$-матриц.

Подсчитаем их все и получим число 16. Множество 16 матриц $\{1, \gamma^{\mu}, \sigma^{\mu\nu}, \gamma^{\mu}\gamma^5, \gamma^5\}$ образует полный базис в пространстве всех 4×4-матриц, то есть любую 4×4-матрицу можно записать в виде линейной комбинации этих 16 матриц. Полезно записать $\sigma^{\mu\nu}$ в явном виде, используя представления (3) и (4):

$$\sigma^{0i} = i\begin{pmatrix} 0 & \sigma^i \\ \sigma^i & 0 \end{pmatrix}$$
$$\sigma^{ij} = \varepsilon^{ijk}\begin{pmatrix} \sigma^k & 0 \\ 0 & \sigma^k \end{pmatrix}.$$

Видим, что σ^{ij} являются просто удвоенными матрицами Паули, например,

$$\sigma^{12} = \begin{pmatrix} \sigma^3 & 0 \\ 0 & \sigma^3 \end{pmatrix}$$

Преобразование Лоренца

Вспомним из курса квантовой механики, что произвольное вращение может быть записано в форме $e^{i\vec{\theta}\vec{J}}$, где $\vec{J}$ - три генератора вращения, а $\vec{\theta}$ - три параметра вращения. Вспомним также, что группа Лоренца содержит, помимо вращений, еще и собственные преобразования Лоренца (бусты) с тремя соответствующими генераторами $\vec{K}$. Из курса электромагнетизма вспомним, что 6 генераторов $\{\vec{J}, \vec{K}\}$ преобразуются под действием группы Лоренца как компоненты антисимметричного тензора, подобно электромагнитному полю $F_{\mu\nu}$, и поэтому могут быть обозначены как $J_{\mu\nu}$. Более подробно обсудим это в главе II.3. В настоящий момент достаточно запомнить, что, используя такое обозначение, мы можем записать преобразование Лоренца в виде $\Lambda = e^{-\frac{i}{2}\omega_{\mu\nu}J^{\mu\nu}}$, где J^{ij} порождают вращения, J^{0i} порождают бусты, а антисимметричный тензор равен $\omega_{\mu\nu} = -\omega_{\nu\mu}$, шесть составляющих которого ($6 = 4 \cdot 3/2$) соответствуют трем вращениям и трем бустам.

Опираясь на предыдущие рассуждения и тот факт, что у нас есть шесть матриц $\sigma^{\mu\nu}$, можно ожидать, что с точностью до общего численного множителя матрицы $\sigma^{\mu\nu}$ должны представлять собой 6 генераторов $J_{\mu\nu}$ группы Лоренца, действующей на спинор. Действительно, это предположение подтверждается анализом того, как действует вращение $e^{-\frac{1}{2}i\omega_{ij}J^{ij}}$. Возвращаясь к (12), видим, что если бы J^{ij} были равны $\frac{1}{2}\sigma^{ij}$, то это в точности соответствовало бы тому, как частица со спином 1/2 преобразуется в квантовой механике. Более точно, разобьем четыре компоненты дираковского спинора на две группы по две компоненты:

$$\psi = \begin{pmatrix} \phi \\ \chi \end{pmatrix}$$

Из (12) следует, что при вращении вокруг третьей оси $\phi \to e^{-i\omega_{12}\frac{1}{2}\sigma^3}\phi$ и $\chi \to e^{-i\omega_{12}\frac{1}{2}\sigma^3}\chi$. Приятно видеть, что ϕ и χ преобразуются как 2-компонентные спиноры Паули.

Таким образом, мы пришли к выводу, что преобразование Лоренца Λ, действующее на ψ, представляется в виде $S(\Lambda) = e^{-(i/4)\omega_{\mu\nu}\sigma^{\mu\nu}}$, и поэтому, действуя на ψ, генераторы $J^{\mu\nu}$ в самом деле равны $\frac{1}{2}\sigma^{\mu\nu}$. Следовательно, можно ожидать, что если $\psi(x)$ удовлетворяет уравнению Дирака (1), то $\psi'(x') \equiv S(\Lambda)\psi(x)$ будет удовлетворять уравнению Дирака в штрихованной системе отсчета

$$\left(i\gamma^\mu\partial'_\mu - m\right)\psi'(x') = 0$$

где $\partial'_\mu \equiv \partial/\partial x'^\mu$. Чтобы это доказать, вычислим $\left[\sigma^{\mu\nu}, \gamma^\lambda\right] = 2i\left(\gamma^\mu\eta^{\nu\lambda} - \ -\gamma^\nu\eta^{\mu\lambda}\right]$ и, следовательно, для бесконечно малого ω получим $S\gamma^\lambda S^{-1} = \gamma^\mu - (i/4)\omega_{\mu\nu}\left[\sigma^{\mu\nu}, \gamma^\lambda\right] = \gamma^\lambda + \gamma^\mu\omega^\lambda_\mu$. Строя конечное преобразование Лоренца из комбинации бесконечно малых преобразований (так же, как при обсуждении группы вращений в квантовой механике), получаем $S\gamma^\lambda S^{-1} = \Lambda^\lambda_\mu\gamma^\mu$

Билинейные комбинации дираковских полей

Алгебра Клиффорда говорит нам, что $(\gamma^0)^2 = +1$ и $(\gamma^i)^2 = -1$, и, таким образом, указывает на необходимость i в (4). Одним из следствий такой необходимости в i является то, что γ^0 оказывается эрмитовой, в то время как γ^i являются антиэрмитовыми. Этот факт удобно выразить следующим образом:

$$(\gamma^\mu)^\dagger = \gamma^0\gamma^\mu\gamma^0$$

Таким образом, билинейная комбинация $\psi^\dagger\gamma^\mu\psi$ не является эрмитовой, как вы могли подумать; эрмитовой же является $\bar{\psi}\gamma^\mu\psi \text{c}\bar{\psi} \equiv \psi^\dagger\gamma^0$. Необходимость введения в релятивисткой физике параметра $\bar{\psi}$, помимо $\psi^\dagger$, обуславливается $(+,-,-,-)$-сигнатурой метрики Минковского.

Оказывается, $(\sigma^{\mu\nu})^\dagger = \gamma^0\sigma^{\mu\nu}\gamma^0$. Следовательно, $S(\Lambda)^\dagger = \gamma^0 e^{(i/4)\omega_{\mu\nu}\sigma^{\mu\nu}}\gamma^0$ (что, кстати, явно указывает на то, что S не является унитарным - этот факт нам известен из условия неэрмитовости σ_{0i}), и поэтому

$$\bar{\psi}'(x') = \psi(x)^\dagger S(\Lambda)^\dagger\gamma^0 = \bar{\psi}(x)e^{+(i/4)\omega_{\mu\nu}\sigma^{\mu\nu}}$$

Имеем

$$\bar{\psi}'(x')\,\psi'(x') = \bar{\psi}(x)e^{+(i/4)\omega_{\mu\nu}\sigma^{\mu\nu}}e^{-(i/4)\omega_{\mu\nu}\sigma^{\mu\nu}}\psi(x) = \bar{\psi}(x)\psi(x)$$

Вы, вероятно, привыкли писать $\psi^\dagger\psi$ в нерелятивистской физике. В релятивистской физике вы должны привыкнуть писать $\bar{\psi}\psi$. Именно $\bar{\psi}\psi$, а не $\psi^\dagger\psi$, преобразуется как лоренцевский скаляр.

Очевидно, что существует 16 билинейных комбинаций дираковских полей $\bar{\psi}\Gamma\psi$, соответствующих 16 линейно независимым Γ. Теперь можете рассмотреть, как преобразуются различные фермионные билинейные комбинации (упражнение II.1.1). Используемое обозначение очень удачно: различные объекты преобразуются так, как им и следовало бы. Мы просто смотрим на их лоренцевские индексы. Таким образом, $\bar{\psi}(x)\gamma^\mu\psi(x)$ преобразуется как лоренцевский вектор.

Четность

Важной дискретной симметрией в физике является четность, или зер-

кальное отражение [1]

$$x^\mu \to x^\mu = \left(x^0, -\vec{x}\right)$$

Умножим уравнение Дирака (1) на γ^0 : $\gamma^0\left(i\gamma^\mu\partial_\mu - m\right)\psi(x) = 0 = \left(i\gamma^\mu\partial'_\mu - -m\right)\gamma^0\psi(x)$, где $\partial'_\mu \equiv \partial/\partial x'^\mu$. Таким образом

$$\psi'(x') \equiv \eta\gamma^0\psi(x)$$

удовлетворяет уравнению Дирака в пространственно-отраженном мире (где η является произвольной фазой, которую можно положить равной 1).

Обратите внимание, что, например, $\bar{\psi}'(x')\,\psi'(x') = \bar{\psi}(x)\psi(x)$, но $\bar{\psi}'(x')\,\gamma^5\psi'(x') = \bar{\psi}(x)\gamma^0\gamma^5\gamma^0\psi(x) = -\bar{\psi}(x)\gamma^5\psi(x)$. При преобразовании

[1] Вращение состоит из всех линейных [2] преобразований $x^i \to R^{ij}x^j$, таких что $\det R = +1$. Преобразования с $\det R = -1$ состоят из отражения с последующим вращением. В

(3 + 1)-мерном пространстве-времени отражение можно определить как изменение знака одной из пространственных координат или всех трех пространственных координат. Эти 'Іве операции связаны вращением. Заметьте. что зеркальное отражение в нечетномерном пространстве-времени не эквивалентно инверсии пространства. при котором меняется знак всех пространственных координат (см. упражнение II.1.11).

[2] Точнее ортогональных. - Прим. ped. Лоренца $\bar{\psi}(x)\gamma^5\psi(x)$ и $\bar{\psi}(x)\psi(x)$ преобразуются одинаковым образом, но при пространственном отражении они преобразуются прямо противоположно друг другу; иными словами, в то время как $\bar{\psi}(x)\psi(x)$ преобразуется как скаляр, $\bar{\psi}(x)\gamma^5\psi(x)$ преобразуется как псевдоскаляр.

Теперь вы уже в состоянии выполнить крайне важные упражнения к этой главе.

Дираковский лагранжиан

Интересный вопрос: какой лагранжиан приводит к уравнению Дирака? Ответ таков:

$$\mathcal{L} = \bar{\psi}(i\not{\partial} - m)\psi.$$

Поскольку ψ - комплексное поле, для вывода уравнения движения Эйлера - Лагранжа можно варьировать ψ и $\bar{\psi}$ независимо друг от друга. Таким образом, $\partial_\mu\left(\partial\mathcal{L}/\delta\partial_\mu\psi\right) - \delta\mathcal{L}/\delta\psi = 0$ дает $\partial_\mu\left(i\bar{\psi}\gamma^\mu\right) + m\bar{\psi} = 0$, что в условиях эрмитова сопряжения и умножения на γ^0 приводит к уравнению Дирака (1). Другое вариационное уравнение $\partial_\mu\left(\delta\mathcal{L}/\delta\partial_\mu\bar{\psi}\right) - \delta\mathcal{L}/\partial\bar{\psi} = 0$ дает нам уравнение Дирака еще более непосредственно. (Если вам не нравится несимметричное рассмотрение ψ и $\bar{\psi}$, вы всегда можете проинтегрировать в действии по частям так, что ∂_μ в лагранжиане будет действовать на $\bar{\psi}$, а затем взять среднее от этих двух форм лагранжиана. В действие $S = \int d^4x\mathcal{L}$ поля ψ и $\bar{\psi}$ входят симметрично.)

Медленные и быстрые электроны

Для данного набора гамма-матриц легко решить уравнение Дирака

$$(\not{p} - m)\psi(p) = 0$$

относительно $\psi(p)$: оно представляет собой простое матричное уравнение (см. упражнение II.1.3).

Заметьте, что если кто-то использует гамма-матрицы γ^μ, вы вправе вместо этого использовать $\gamma'^\mu = W^{-1}\gamma^\mu W$ с произвольной обратимой 4×4-матрицей W. Очевидно, что γ'^μ также удовлетворяют алгебре Клиффорда. Такая свобода выбора соответствует простому изменению базиса. Физика не зависит от выбора базиса, зато выбор наиболее удобного базиса зависит от физики.

Например, предположим, что мы исследуем медленно движущиеся электроны. Используем для этого базис, определенный в (3) и (4), и двухкомпонентное разбиение ψ (13). Из (6) следует, что для покоящегося элек- трона $\chi(p) = 0$, поэтому можно ожидать, что для медленно движущегося электрона $\chi(p)$ будет много меньше, чем $\phi(p)$.

В противоположность этому, для импульсов, намного превышающих массу, можно приближенно записать (20) как $p\psi(p) = 0$. Умножая слева на γ^5, видим, что если $\psi(p)$ является решением, то $\gamma^5\psi(p)$ также является решением, поскольку γ^5 антикоммутирует с γ^μ. В силу того, что $\left(\gamma^5\right)^2 = 1$, мы можем построить два проекционных оператора $P_L \equiv \frac{1}{2}(1 - \gamma^5)$ и $P_R \equiv \frac{1}{2}(1+\gamma^5)$, удовлетворяющих условиям $P_L^2 = P_L, P_R^2 = P_R$ и $P_LP_R = 0$. Чрезвычайно полезно ввести две комбинации $\psi_L = \frac{1}{2}(1-\gamma^5)\psi$ и $\psi_R = \frac{1}{2}(1+\gamma^5)\psi$.

Обратите внимание, что $\gamma^5\psi_L = -\psi_L$ и $\gamma^5\psi_R = +\psi_R$. Говоря физически, релятивистский электрон имеет две степени свободы: он может вращаться либо по, либо против часовой стрелки вокруг направления движения. В качестве упражнения докажите, что ψ_L и ψ_R соответствуют именно этим двум возможностям. Индексы L и R указывают на то, левой или правой является частица. Таким образом, для быстро движущегося электрона более удобным оказывается базис, известный как базис Вейля, в котором диагональной оказывается матрица γ^5, а не γ^0. Вместо (3) выбираем

$$\gamma^0 = \begin{pmatrix} 0 & I \\ I & 0 \end{pmatrix} = I \otimes \tau_1$$

γ^i остаются теми же самыми, что в (4). Так определяется базис Вейля. Вычислим теперь матрицу

$$\gamma^5 \equiv i\gamma^0\gamma^1\gamma^2\gamma^3 = i\left(I \otimes \tau_1\right)\left(\sigma^1\sigma^2\sigma^3 \otimes i^3\tau_2\right) = -\left(I \otimes \tau_3\right) = \begin{pmatrix} -I & 0 \\ 0 & I \end{pmatrix},$$

которая в самом деле оказывается диагональной, как мы того и хотели. Разложение на левые и правые поля, естественно, не зависит от нашего выбора базиса. Однако в базисе Вейля у нас есть одно хорошее свойство: ψ_L имеет две верхние компоненты, а ψ_R - две нижние. Спиноры ψ_L и ψ_R называются спинорами Вейля.

Обратите внимание, что при переходе от базиса Дирака к базису Вейля γ^0 и γ^5 меняются местами (с точностью до знака):

Дирак: γ^0 диагональна, Вейль: γ^5 диагональна.

Каким базисом пользоваться, зависит от физики: когда мы имеем дело с медленными частицами со спином $1/2$, то предпочтительнее иметь диа- гональной матрицу γ^0, в то время как для быстро движущихся частиц со спином $1/2$ удобнее иметь диагональной γ^5.

Замечу мимоходом, что если мы определим $\sigma^\mu \equiv (I, \vec{\sigma})$ и $\bar{\sigma}^\mu \equiv (I, -\vec{\sigma})$, то в базисе Вейля можно записать

$$\gamma^\mu = \begin{pmatrix} 0 & \sigma^\mu \\ \bar{\sigma}^\mu & 0 \end{pmatrix}$$

в более компактной форме. (Более подробно данный вопрос обсуждается в приложении E.)

Киральность

Вне зависимости от того, является ли дираковское поле $\psi(x)$ массивным или безмассовым, чрезвычайно полезно разбить ψ на левое и правое поля $\psi(x) = \psi_L(x) + \psi_R(x) \equiv \frac{1}{2}\left(1-\gamma^5\right)\psi(x) + \frac{1}{2}\left(1+\gamma^5\right)\psi(x)$. В качестве упражнения покажите, что лагранжиан Дирака можно записать в виде

$$\mathcal{L} = \bar{\psi}(i\not{\partial} - m)\psi = \bar{\psi}_L i\not{\partial}\psi_L + \bar{\psi}_R i\not{\partial}\psi_R - m\left(\bar{\psi}_L\psi_R + \bar{\psi}_R\psi_L\right)$$

Кинетическая энергия связывает левое поле с левым, а правое поле с правым, тогда как массовый член связывает левое поле с правым, а правое поле с левым.

Преобразование $\psi \to e^{i\theta}\psi$ оставляет лагранжиан $\mathcal{L}$ инвариантным. Применяя теорему Нётер, получаем связанный с этой симметрией сохраняющийся ток $J^\mu = \bar{\psi}\gamma^\mu\psi$. Проецируя на левые и правые поля, видим, что они преобразуются одинаково: $\psi_L \to e^{i\theta}\psi_L$ и $\psi_R \to e^{i\theta}\psi_R$.

Если $m = 0$, то $\mathcal{L}$ обладает дополнительной симметрией, известной как киральная симметрия, относительно которой $\psi \to e^{i\phi\gamma^5}\psi$. Теорема Нётер гласит, что киральный ток $J^{5\mu} \equiv \bar{\psi}\gamma^\mu\gamma^5\psi$ сохраняется. Левые и правые поля преобразуются противоположным образом: $\psi_L \to e^{-i\phi}\psi_L$ и $\psi_R \to e^{i\phi}\psi_R$. Все вышесказанное становится особенно очевидным, если выразить $\mathcal{L}$ через ψ_L и ψ_R, как в (24).

В 1956 году Ли и Янг выдвинули предположение, согласно которому слабое взаимодействие не сохраняет четность. Со временем стало понятно (мне пришлось опустить замечательную главу, в которой бы рассказывалось о развитии физики элементарных частиц, но я настоятельно советую вам прочитать об этом!), что лагранжиан слабого взаимодействия в общей форме записывается как

$$\mathcal{L} = G\bar{\psi}_{1L}\gamma^\mu\psi_{2L}\bar{\psi}_{3L}\gamma_\mu\psi_{4L}$$

где $\psi_{1,2,3,4}$ обозначают четыре дираковских поля, а G - константу связи Ферми. Очевидно, что лагранжиан нарушает четность: при пространственном отражении левые поля преобразуются в правые поля и наоборот.

Впредь, когда я буду говорить, что лагранжиан имеет определенную форму, я буду включать в лагранжиан только один или несколько значимых членов, как в (25). Остальные члены в лагранжиане, такие как $\bar{\psi}_1(i\partial\!\!\!/ - m_1)\,\psi_1$, будут только подразумеваться. Если член не является эрмитовым, то подразумевается, что мы также добавляем в лагранжиан эрмитово сопряженный.

Взаимодействия

Как мы видели в (25), что с помощью билинейных комбинаций по спинорному полю, классификацию которых вы получили в упражнении, легко ввести взаимодействия. В качестве другого примера можно связать скалярное поле φ с полем Дирака, добавив член $g\varphi\bar{\psi}\psi$ (с произвольной константой связи g) в лагранжиан $\mathcal{L} = \bar{\psi}(i\partial\!\!\!/ - m)\psi($ и, конечно же, добавив лагранжиан для φ). Аналогичным образом можно связать векторное поле A_μ, добавив член $eA_\mu\bar{\psi}\gamma^\mu\psi$. Обратите внимание, что в этом случае мы можем определить ковариантную производную $D_\mu = \partial_\mu - ieA_\mu$ и записать $\mathcal{L} = \bar{\psi}(i\partial\!\!\!/ - m)\psi + eA_\mu\bar{\psi}\gamma^\mu\psi = \bar{\psi}\left(i\gamma^\mu D_\mu - m\right)\psi$. Таким образом, лагранжиан дираковского поля, взаимодействующего с векторным полем массой μ, имеет вид

$$\mathcal{L} = \bar{\psi}\left(i\gamma^\mu D_\mu - m\right)\psi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2}\mu^2 A_\mu A^\mu$$

Если масса μ равна нулю, имеем лагранжиан квантовой электродинамики. Варьируя по $\bar{\psi}$, получаем уравнение Дирака в присутствии электромагнитного поля:

$$\left[i\gamma^\mu\left(\partial_\mu - ieA_\mu\right) - m\right]\psi = 0$$

Зарядовое сопряжение и антиматерия

Взаимодействие с электромагнитным полем связано с понятием заряда и, следовательно, зарядового сопряжения. Попробуем изменить знак заряда e. Возьмем комплексное

сопряжение от (27): $[-i\gamma^{\mu *}(\partial_\mu + ieA_\mu) - m]\psi^* = 0$. Комплексно сопрягая (2), мы видим, что $-\gamma^{\mu *}$ также удовлетворяют алгебре Клиффорда и, стало быть, должны выражаться матрицами γ^μ, записанными в другом базисе, то есть существует такая матрица $C\gamma^0$ (обозначение с явным множителем γ^0 является стандартным; см. ниже), что $-\gamma^{\mu *} = (C\gamma^0)^{-1}\gamma^\mu(C\gamma^0)$. Подставляя, получаем

$$[i\gamma^\mu(\partial_\mu + ieA_\mu) - m]\psi_c = 0,$$

где мы определили $\psi_c \equiv C\gamma^0\psi^*$. Таким образом, если ψ является полем электрона, то ψ_c является полем частицы с зарядом, противоположным заряду электрона, но с такой же, как у электрона, массой, то есть полем позитрона.

Открытие антиматерии было одним из самых значимых в физике двадцатого столетия. Более подробно об антиматерии мы поговорим в следующей главе.

Может оказаться полезным посмотреть на конкретную форму матрицы зарядового сопряжения C. Определяющее уравнение для C можно записать в виде $C\gamma^0\gamma^{\mu *}\gamma^0 C^{-1} = -\gamma^\mu$. Комплексно сопрягая уравнение $(\gamma^\mu)^\dagger = \gamma^0\gamma^\mu\gamma^0$, получаем $(\gamma^\mu)^T = \gamma^0\gamma^{\mu *}\gamma^0$, если γ^0 - вещественная матрица. Таким образом,

$$(\gamma^\mu)^T = -C^{-1}\gamma^\mu C$$

что объясняет, почему C необходимо задавать с добавлением γ^0.

В обоих базисах Дирака и Вейля γ^2 является единственной мнимой гамма-матрицей. Значит, определяющее уравнение для C свидетельствует о том, что $C\gamma^0$ коммутирует с γ^2, но антикоммутирует с тремя другими γ-матрицами. Отсюда очевидно, что $C = \gamma^2\gamma^0$ [с точностью до произвольной фазы, которая не фиксируется уравнением (29)] и действительно $\gamma^2\gamma^{\mu *}\gamma^2 = \gamma^\mu$. Заметьте, что имеет место простое (и удовлетворяющееся) соотношение

$$\psi_c = \gamma^2\psi^*.$$

Вы можете легко убедиться в том (упражнение 8), что зарядовое сопряжение левого поля является правым и наоборот. Этот факт, как мы увидим позднее, оказывается ключевым при построении теории великого объединения. Экспериментально установлено, что нейтрино является левым полем. Таким образом, уже сейчас можно предсказать, что антинейтрино - это правое поле.

Более того, ψ_c преобразуется как спинор. Давайте проверим: при преобразовании Лоренца $\psi \to e^{-(i/4)\omega_{\mu\nu}\sigma^{\mu\nu}}\psi$ с учетом комплексного сопряжения имеем $\psi^* \to e^{+(i/4)\omega_{\mu\nu}(\sigma^{\mu\nu})^*}\psi^*$; следовательно, $\psi_c \to \gamma^2 e^{+(i/4)\omega_{\mu\nu}(\sigma^{\mu\nu})^*}\psi^* = e^{-(i/4)\omega_{\mu\nu}\sigma^{\mu\nu}}\psi_c$. [Вспомните из (10), что в определении $\sigma^{\mu\nu}$ явно присутствует i.] Обратите внимание, что в обоих базисах Дирака и Вейля $C^T = \gamma^0\gamma^2 = -C$.

Майорановское нейтрино

Поскольку ψ_c преобразуется как спинор, Майорана [3] заметил, что лоренц-инвариантность допускает не только уравнение Дирака $i\not{\partial}\psi = m\psi$, но и уравнение Майораны

$$i\not{\partial}\psi = m\psi_c.$$

Комплексно сопрягая это уравнение и умножая на γ^2, мы получаем $-\gamma^2 i\gamma^{\mu *}\partial_\mu\psi^* = \gamma^2 m(-\gamma^2)\psi$, то есть $i\not{\partial}\psi_c = m\psi$. Таким образом,

$-\partial^2\psi = i\not{\partial}(i\not{\partial}) = i\not{\partial}\psi_c = m^2\psi$. Как мы и предполагали, m в самом деле является массой, называемой майорановской массой, частицы, связанной с полем ψ.

Уравнение Майораны (31) можно получить из лагранжиана [4]

$$\mathcal{L} = \bar{\psi} i\not{\partial}\psi - \frac{1}{2}m\left(\psi^T C\psi + \bar{\psi}C\bar{\psi}^T\right)$$

варьируя по $\bar{\psi}$.

Так как ψ и ψ_c несут противоположный заряд, уравнение Майораны, в отличие от уравнения Дирака, может применяться только к электрически нейтральным полям. Однако раз ψ_c является правым при условии, что ψ - левое поле, то уравнение Майораны, опять же в отличие от уравнения Дирака, сохраняет спиральность. Уравнение Майораны, таким образом, практически идеально подходит для описания нейтрино.

По замыслу нейтрино предполагалось безмассовым, но несколько лет назад экспериментаторы обнаружили, что оно имеет очень малую, но не нулевую массу. На момент написания этой книги остается неизвестным, является ли масса нейтрино дираковской или майорановской. В главе VII.7 мы увидим, что майорановская масса для нейтрино естественно возникает в $SO(10)$-теории великого объединения.

И наконец, может быть, что $\psi = \psi_c$, в этом случае ψ называется майорановским спинором.

[3] Карьера Этторе Майорана была блестящей, но трагически короткой. В возрасте 32 лет он пропал без вести около побережья Сицилии во время лодочной прогулки. Истинная причина его смерти остается загадкой.

[4] Вспоминая, что C является антисимметричной, можно предположить, что $\psi^T C\psi = C_{\alpha\beta}\psi_\alpha\psi_\beta$ обращается в нуль. В последующих главах мы узнаем, что ψ необходимо рассматривать как антикоммутирующие «грассмановы переменные».

Обращение времени

Наконец мы добрались до обращения времени [5], которое, как вы, вероятно, знаете, гораздо труднее понять, чем четность или зарядовое сопряжение. В знаменитой статье 1932 года Вигнер показал, что обращению времени соответствует антиунитарный оператор. Так как эта особенность появляется уже в нерелятивистской квантовой физике, то, в некотором смысле, книга по релятивистской теории поля не обязана разъяснять, почему обращение времени соответствует антиунитарному оператору. Тем не менее я постараюсь как можно более доступно это объяснить. Воспользуюсь для этого подходом: «пусть физика, а точнее, уравнения направляют нас».

Рассмотрим уравнение Шредингера $i(\partial/\partial t)\Psi(t) = H\Psi(t)$ (пусть, для определенности, $H = -(1/2m)\nabla^2 + V(\vec{x})$ описывает всего лишь простую одночастичную нерелятивистскую квантовую механику). Опускаем зависимость Ψ от $\vec{x}$. Рассмотрим преобразование $t \to t' = -t$. Необходимо найти такую $\Psi'(t')$, что $i\left(\partial/\partial t'\right)\Psi'(t') = H\Psi'(t')$. Запишем $\Psi'(t') = T\Psi(t)$, где T - некоторый оператор, подлежащий определению (с точностью до некоторого фазового множителя η). Подставляя, получаем $i[\partial/\partial(-t)]T\Psi(t) = HT\Psi(t)$. Умножая на T^{-1}, получаем $T^{-1}(-i)T(\partial/\partial t)\Psi(t) = T^{-1}HT\Psi(t)$. Так как H ни в каком виде не содержит t, мы хотим, чтобы $T^{-1}H = HT^{-1}$. Тогда $T^{-1}(-i)T(\partial/\partial t)\Psi(t) = H\Psi(t)$. Как и Вигнер, мы вынуждены сделать заключение, согласно которому

$$T^{-1}(-i)T = i$$

Проще говоря, в квантовой физике время появляется вместе с i, и поэтому, изменение знака времени также означает изменение знака i.

Пусть $T = UK$, где K комплексно сопрягает все, что стоит от него справа. Тогда $T^{-1} = KU^{-1}$ и (33) остается справедливым, если $U^{-1}iU = i$, то есть если U^{-1} является обычным (унитарным) оператором, который ничего не делает с i. В дальнейшем мы определим U. Присутствие K делает T «антиунитарным».

Проверим, что все это работает для бесспиновой частицы в состоянии плоской волны $\Psi(t) = e^{i(\vec{k}\cdot\vec{x}-Et)}$. Подставляя, получаем $\Psi'(t') = T\Psi(t) = UK\Psi(t) = U\Psi^*(t) = Ue^{-i(\vec{k}\cdot\vec{x}-Et)}$; так как Ψ состоит только

[5] Кстати, я не думаю, что мы до конца осознаем все следствия инвариантности относительно обращения времени. См. A. Zee. «Night thoughts on consciousness and time reversal» in: Art and Symmetry in Experimental Physics, pp. 246-249. из одной компоненты, U есть простой фазовый множитель [6]η, который мы можем выбрать равным 1. Переписывая, получаем $\Psi'(t) = e^{-i(\vec{k}\cdot\vec{x}+Et)} = e^{i(-\vec{k}\cdot\vec{x}-Et)}$. В самом деле, Ψ' описывает плоскую волну, распространяющуюся в противоположном направлении. Очень важно, что $\Psi'(t) \propto e^{-iEt}$ и, следовательно, имеет положительную энергию, как и должно быть. Обратите внимание, что при действии на бесспиновые частицы $T^2 = UKUK = UU^*K^2 = +1$

Далее рассмотрим нерелятивистский электрон со спином $1/2$. Действуя T на состояние $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$ со спином, направленным вверх, мы хотим получить состояние со спином, направленным вниз, $\begin{pmatrix} 0 \\ 1 \end{pmatrix}$. Таким образом, нам нужна нетривиальная матрица $U = \eta\sigma_2$, изменяющая направление спина:

$$T\begin{pmatrix} 1 \\ 0 \end{pmatrix} = U\begin{pmatrix} 1 \\ 0 \end{pmatrix} = i\eta\begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

Аналогично при воздействии T на состояние со спином, направленным вниз, появляется состояние со спином, направленным вверх. Обратите внимание, что при действии на частицу со спином $1/2$

$$T^2 = \eta\sigma_2 K\eta\sigma_2 K = \eta\sigma_2\eta^*\sigma_2^* KK = -1$$

Этим объясняется вырождение Крамера: в системе с нечетным числом электронов в электрическом поле, неважно насколько сложным, каждый энергетический уровень является двукратно вырожденным. Доказательство очень простое: так как система инвариантна относительно обращения времени, Ψ и $T\Psi$ имеют одинаковую энергию. Предположим, что они фактически представляют одно и то же состояние. Тогда $T\Psi = e^{i\alpha}\Psi$, но при этом $T^2\Psi = T(T\Psi) = Te^{i\alpha}\Psi = e^{-i\alpha}T\Psi = \Psi \neq -\Psi$. Поэтому Ψ и $T\Psi$ должны представлять два различных состояния.

Все эти удивительные вещи вы, как я уже заметил, могли и должны были выучить из курса квантовой механики. Моя же обязанность здесь состоит в том, чтобы показать вам, как все это работает для уравнения Дирака. Умножая (1) слева на γ^0, имеем $i(\partial/\partial t)\psi(t) = H\psi(t)$ с $H = -i\gamma^0\gamma^i\partial_i + +\gamma^0 m$. Еще раз подчеркну, что мы хотим получить $i\left(\partial/\partial t'\right)\psi'\left(t'\right) = H\psi'\left(t'\right)$ с $\psi'\left(t'\right) = T\psi(t)$ и некоторым оператором T, который и предстоит определить. Предыдущие рассуждения остаются в силе, если $T^{-1}HT = H$, то

[6] Это именно фазовый множитель, а не произвольное комплексное число, потому что мы накладываем условие $|\Psi'|^2 = |\Psi|^2$. есть $KU^{-1}HUK = H$. Таким образом, мы требуем

$KU^{-1}\gamma^0 UK = \gamma^0$ и $KU^{-1}\left(i\gamma^0\gamma^i\right)UK = i\gamma^0\gamma^i$. Умножая на K слева и справа, мы видим, что необходимо найти такое U, для которого $U^{-1}\gamma^0 U = \gamma^{0*}$ и $U^{-1}\gamma^i U = -\gamma^{i*}$. Теперь ограничимся рассмотрением базисов Дирака и Вейля, в каждом из которых мнимым объектом является γ^2. Итак, что изменяет знак γ^1 и γ^3, но не изменяет знак γ^0 и γ^2? Ну, хорошо, подойдет $U = \eta\gamma^1\gamma^3$ (с произвольным фазовым множителем η):

$$\psi'(t') = \eta\gamma^1\gamma^3 K\psi(t)$$

Так как γ^i одинаковы в обоих базисах Дирака и Вейля, для каждого из них из (4) получаем

$$U = \eta\left(\sigma^1\otimes i\tau_2\right)\left(\sigma^3\otimes i\tau_2\right) = \eta i\sigma^2\otimes 1.$$

Как мы и предполагали, при действии на двухкомпонентные спиноры, содержащиеся в ψ, оператор обращения времени T умножает их на $i\sigma^2$. Заметьте также, что, как и в нерелятивистском случае, $T^2\psi = -\psi$.

От вашего внимания, вероятно, не ускользнуло то, что γ^0 присутствует в операторе четности (18), γ^2 в зарядовом сопряжении (30), а $\gamma^1\gamma^3$ в обращении времени (34). Если заменить дираковскую частицу на ее античастицу и обратить пространство-время, то появится γ^5.

CPT-теорема

Существует основополагающая теорема, утверждающая, что любая локальная лоренц-инвариантная теория поля должна быть инвариантна относительно [7]$\mathcal{CPT}$ - совместного действия зарядового сопряжения, четности и обращения времени. Наивное доказательство сводится к проверке того, что любое локальное лоренц-инвариантное взаимодействие, какое бы вы ни написали (к примеру, (25)), даже если оно нарушает зарядовое сопряжение, четность или обращение времени по отдельности, обязательно будет сохранять $\mathcal{CPT}$. Для более строго доказательства необходим гораздо более сложный формализм, который я не буду здесь развивать. Советую вам почитать о феноменологическом исследовании зарядового сопряжения, четности, обращении времени и $\mathcal{CPT}$, - несомненно одной из захватывающих глав истории физики.

[7] Довольно педантичный вопрос, но, возможно, неясный для некоторых студентов: я четко провожу различия между действием зарядового сопряжения $\mathcal{C}$ и матрицей C :: зарядовое сопряжение состоит в комплексном сопряжении ψ с последующим перемешиванием ее компонент с помощью $C\gamma^0$. Аналогично я различаю оператор обращения времени $\mathcal{T}$ и матрицу T.

Упражнения

II.1.1. Покажите, что следующие билинейные комбинации спинорного поля $\bar\psi\psi$, $\bar\psi\gamma^\mu\psi, \bar\psi\sigma^{\mu\nu}\psi, \bar\psi\gamma^\mu\gamma^5\psi$ и $\bar\psi\gamma^5\psi$ преобразуются под действием группы Лоренца и четности соответственно как скаляр, вектор, тензор, псевдоили аксиальный вектор и псевдоскаляр. [Указание: например, при бесконечно малом преобразовании Лоренца имеет место $\bar\psi\gamma^\mu\gamma^5\psi \to \bar\psi[1+ +(i/4)\omega\sigma]\gamma^\mu\gamma^5[1-(i/4)\omega\sigma]\psi$, а при четности $\to \bar\psi\gamma^0\gamma^\mu\gamma^5\gamma^0\psi$. Получите эти законы преобразования и покажите, что они определяют аксиальный вектор.]

II.1.2. Выразите все билинейные комбинации из предыдущего упражнения через ψ_L и ψ_R.

II.1.3. Решите явно $(\not{p}-m)\psi(p) = 0$ (в силу вращательной инвариантности достаточно решить это уравнение для $\vec{p}$ вдоль, например, третьей оси). Проверьте, что для медленно движущегося электрона χ действительно много меньше ϕ. Что происходит для быстро движущегося электрона?

II.1.4. Используя тот факт, что для медленно движущегося электрона χ много меньше ϕ, получите приближенное уравнение, которому удовлетворяет ϕ.

[9] C. N. Yang. Lectures at the Schwinger Memorial Session of the American Physical Society Meeting in Washington D.C., 1995. II.1.5. Выполните поворот вокруг оси z для релятивистского электрона, движущегося вдоль оси z. Другими словами, исследуйте действие $e^{-(i/4)\omega\sigma^{12}}$ на $\psi(p)$ и проверьте сделанное в тексте утверждение о ψ_L и ψ_R.

II.1.6. Явно покажите, что (25) нарушает четность.

II.1.7. Очевидно, что определяющее уравнение для C фиксирует C лишь с точностью до общей константы. Покажите, что значение константы определяется условием $(\psi_c)_c = \psi$.

II. 1.8. Покажите, что зарядовое сопряжение левого поля есть правое поле и наоборот.

II.1.9. Покажите, что $\psi C\psi$ есть лоренцевский скаляр.

II.1.10. Получите уравнение Дирака в $(1+1)$-мерном пространстве-времени.

II.1.11. Получите уравнение Дирака в $(2+1)$-мерном пространстве-времени. Покажите, что кажущийся безобидным массовый член нарушает четность и обращение времени. [Указание: три матрицы γ^μ являются просто тремя матрицами Паули с соответствующими множителями i.]

9.4.4 Зи.II.2 Quantization of the Dirac Field

Антикоммутирование

Для квантования дираковского поля воспользуемся каноническим формализмом из главы I.8.

Длительное и тщательное исследование атомной спектроскопии показало, что волновая функция двух электронов должна быть антисимметричной по отношению к перестановке их квантовых чисел. Отсюда следует, что мы не можем поместить два электрона на один и тот же энергетический уровень так, чтобы они имели одинаковые квантовые числа. В 1928 году Йордан и Вигнер продемонстрировали, как можно формализовать данное требование антисимметричности волновой функции с помощью операторов рождения и уничтожения электронов, удовлетворяющих антикоммутационным соотношениям, а не коммутационным соотношениям, как в (I.8.12).

Начнем с рассмотрения состояния без электронов $|0\rangle$ и обозначим через $b^\dagger_\alpha$ оператор рождения электрона с квантовыми числами α. Другими словами, состояние $b^\dagger_\alpha|0\rangle$ является состоянием с одним электроном, имеющим квантовые числа α. Предположим теперь, что мы хотим иметь другой электрон с квантовыми числами β, и поэтому образуем состояние $b^\dagger_\beta b^\dagger_\alpha|0\rangle$. Для того чтобы оно было антисимметрично относительно перестановки α и β, мы должны иметь

$$\left\{b^\dagger_\alpha, b^\dagger_\beta\right\} \equiv b^\dagger_\alpha b^\dagger_\beta + b^\dagger_\beta b^\dagger_\alpha = 0.$$

Эрмитово сопрягая, получаем $\{b_\alpha, b_\beta\} = 0$. В частности, $b^\dagger_\alpha b^\dagger_\alpha = 0$, так что мы не можем породить два электрона с одинаковыми квантовыми числами.

К полученному антикоммутационному соотношению добавим

$$\left\{b_\alpha, b_\beta^\dagger\right\} = \delta_{\alpha\beta}$$

Одним из аргументов в пользу этого является наше желание иметь оператор числа частиц, равный $N = \sum\limits_\alpha b_\alpha^\dagger b_\alpha$, как и в бозонном случае. По- кажите в одну строку, что $[AB, C] = A[B, C] + [A, C]B$ или $[AB, C] = A\{B, C\} - \{A, C\}B$. (Тот факт, что в антикоммутирующем случае стоит знак минус, можно запомнить эвристически: чтобы антикоммутировать C и A, мы должны протащить C через B.) Для того чтобы желаемый оператор числа частиц работал как положено, необходимо выполнение условия $\left[\sum\limits_\alpha b_\alpha^\dagger b_\alpha, b_\beta^\dagger\right] = +b_\beta^\dagger$ (так что, как и обычно, $N|0\rangle = 0$ и $Nb_\beta^\dagger|0\rangle = b_\beta^\dagger|0\rangle$), в результате чего приходим к (2).

Поле Дирака

Обратимся теперь к свободному лагранжиану Дирака

$$\mathcal{L} = \bar\psi(i\not\partial - m)\psi$$

Импульс, сопряженный с ψ, есть $\pi_\alpha = \delta\mathcal{L}/\delta\partial_t\psi_\alpha = i\psi_\alpha^\dagger$. Можно предвидеть, что корректная каноническая процедура требует наложения антикоммутационного соотношения:

$$\left\{\psi_\alpha(\vec x, t), \psi_\beta^\dagger(\overrightarrow{0}, t)\right\} = \delta^{(3)}(\vec x)\delta_{\alpha\beta}$$

Выведем его ниже.

Поле Дирака удовлетворяет условию

$$(i\not\partial - m)\psi = 0.$$

Подставляя плоские волны $u(p,s)e^{-ipx}$ и $v(p,s)e^{ipx}$ вместо ψ, получаем

$$(\not p - m)u(p,s) = 0$$

и

$$(\not p + m)v(p,s) = 0.$$

Индекс $s = \pm 1$ указывает на то, что каждое из двух уравнений имеет два решения: со спином, направленным вверх, и спином, направленным вниз. Очевидно, что при преобразовании Лоренца два спинора u и v преобразуются так же, как ψ. Таким образом, если определить $\bar u \equiv u^\dagger\gamma^0$ и $\bar v \equiv v^\dagger\gamma^0$, то $\bar u u$ и $\bar v v$ будут лоренцевскими скалярами.

Для этого сюжета характерно частое появление «особых» знаков, поэтому я буду действовать очень осторожно и раскрою вам смысл каждого из них. Во-первых, так как (6) и (7) линейны, мы должны зафиксировать нормировку u и v. В силу того что $\bar u(p,x)u(p,s)$ и $\bar v(p,s)v(p,s)$ являются лоренцевскими скалярами, условие нормировки, которое мы налагаем на них в системе покоя, будет справедливо в любой системе отсчета.

Наша стратегия состоит в том, чтобы, используя особый базис, проделать все в собственной системе покоя, а затем применить условие лоренц-инвариантности и независимости от базиса. В покоящейся системе координат (6) и (7) сводятся к

$(\gamma^0 - 1)\, u = 0$ и $(\gamma^0 + 1)\, v = 0$. В частности, в базисе Дирака $\gamma^0 = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}$, и поэтому два независимых спинора u (со спином $s = \pm 1$) имеют вид

$$\begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix} \quad \text{и \%} \quad \% \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}$$

а два независимых спинора v - вид

$$\begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix} \text{ и \% } \% \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}.$$

Тогда условиями нормировки, неявно выбранными нами, будут $\bar{u}(p,s)\times\ \times u(p,s) = 1$ и $\bar{v}(p,s)v(p,s) = -1$. Обратите внимание на знак «минус». Очевидно, что мы также имеем условие ортогональности $\bar{u}v = 0$ и $\bar{v}u = 0$. Лоренц-инвариантность и независимость от базиса обеспечивают справедливость этих четырех соотношений и в общем случае.

Далее, в покоящейся системе координат

$$\sum_s u_\alpha(p,s)\bar{u}_\beta(p,s) = \begin{pmatrix} I & 0 \\ 0 & 0 \end{pmatrix}_{\alpha\beta} = \frac{1}{2}\left(\gamma^0 + 1\right)_{\alpha\beta}$$

И

$$\sum_s v_\alpha(p,s)\bar{v}_\beta(p,s) = \begin{pmatrix} 0 & 0 \\ 0 & -I \end{pmatrix}_{\alpha\beta} = \frac{1}{2}\left(\gamma^0 - 1\right)_{\alpha\beta}.$$

Таким образом, в общем случае

$$\sum_s u_\alpha(p,s)\bar{u}_\beta(p,s) = \left(\frac{\not{p} + m}{2m}\right)_{\alpha\beta}$$

И

$$\sum_s v_\alpha(p,s)\bar{v}_\beta(p,s) = \left(\frac{p - m}{2m}\right)_{\alpha\beta}$$

Есть и другой способ получить (8). Для этого необходимо заметить, что левая часть формулы есть 4×4-матрица (подобная вектор-столбцу, умноженному справа на вектор-строку) и поэтому должна быть линейной комбинацией шестнадцати матриц размерностью 4×4, перечисленных в главе II.1. Докажите, что γ^5 и $\gamma^\mu\gamma^5$ не могут быть среди них в силу четности, а $\sigma^{\mu\nu}$ - в силу лоренц-инвариантности и того факта, что в распоряжении имеется только один лоренцевский вектор, а именно p^μ. Следовательно, правая часть формулы должна быть линейной комбинацией p и m. Зафиксируем относительный коэффициент действием $p - m$ слева. Нормировка фиксируется условием $\alpha = \beta$ и суммированием по α. Аналогично и для (9). В частности, положив $\alpha = \beta$ и суммируя по α, мы восстанавливаем $\bar{v}(p,s)v(p,s) = -1$.

Теперь мы готовы преобразовать $\psi(x)$ в оператор. По аналогии с (I.8.11) разложим поле на плоские волны [1]

$$\psi(x) = \\ = \int \frac{d^3p}{(2\pi)^{3/2}\left(E_p/m\right)^{1/2}} \sum_s \left[b(p,s)u(p,s)e^{-ipx} + d^\dagger(p,s)v(p,s)e^{ipx}\right]$$

(Здесь $E_p = p_0 = +\sqrt{\vec{p}^2 + m^2}$ и $px = p_\mu x^\mu$.) Нормировочный множитель $(E_p/m)^{1/2}$ несколько отличен от нормировочного множителя в (I.8.11) по причинам, которые станут понятны вам ниже. Во всем остальном аргументация в пользу (10) аналогична той, что имеет место для (I.8.11). Мы интегрируем по импульсу $\vec{p}$, суммируем по спину s, разлагаем по плоским волнам и даем имена коэффициентам этого разложения. В силу того что ψ комплексно, имеем оператор b и оператор $d^\dagger$, как и в упражнении I.8.3, но в отличие от (I.8.11).

Как и в упражнении I.8.3, операторы b и $d^\dagger$ должны нести одинаковый заряд. Таким образом, если b уничтожает электрон с зарядом $e = -|e|$, оператор $d^\dagger$ должен уносить заряд e, то есть рождать позитрон с зарядом $-e = |e|$

Несколько слов об обозначениях: $b(p,s), d^\dagger(p,s), u(p,s)$ и $v(p,s)$ в (10) записаны как функции от 4-импульса p, но, строго говоря, они зависят только от $\vec{p}$, а p^0 всегда подразумевается равным $+\sqrt{\vec{p}^2 + m^2}$.

'Обозначение стандартно. См., например. J. A. Bjorken and S. D. Drell. Relativistic Quantum Mechanics (Д. А. Бьеркен и С. Д. Дрелл, Релятивистская квантовая механика). Итак, пусть $b^\dagger(p,s)$ и $b(p,s)$ являются операторами рождения и уничтожения электрона с импульсом p и спином s. Из наших предварительных рассуждений следует, что мы должны наложить условия

$$\left\{b(p,s), b^\dagger\left(p',s'\right)\right\} = \delta^{(3)}\left(\vec{p} - \vec{p}'\right)\delta_{ss'},$$
$$\left\{b(p,s), b\left(p',s'\right)\right\} = 0,$$
$$\left\{b^\dagger(p,s), b^\dagger\left(p',s'\right)\right\} = 0.$$

Для операторов рождения и уничтожения позитрона $d^\dagger(p,s)$ и $d(p,s)$ существует соответствующий набор соотношений, например:

$$\left\{d(p,s), d^\dagger\left(p',s'\right)\right\} = \delta^{(3)}\left(\vec{p} - \vec{p}'\right)\delta_{ss'}.$$

Теперь необходимо доказать, что мы в самом деле получаем (4). Запишем

$$\bar{\psi}(0) = \int \frac{d^3p'}{(2\pi)^{3/2}\left(E_{p'}/m\right)^{1/2}} \sum_{s'} \left[b^\dagger\left(p',s'\right)\bar{u}\left(p',s'\right) + d\left(p',s'\right)\bar{v}\left(p',s'\right)\right].$$

Ничего другого не остается, как двигаться вперед:

$$\{\psi(\vec{x},0), \bar{\psi}(0)\} = \\ = \int \frac{d^3p}{(2\pi)^3\left(E_p/m\right)} \sum_s \left[u(p,s)\bar{u}(p,s)e^{-i\vec{p}\cdot\vec{x}} + v(p,s)\bar{v}(p,s)e^{i\vec{p}\cdot\vec{x}}\right],$$

если ввести b и $b\dagger$, антикоммутирующие с d и $d^\dagger$. Используя (8) и (9), получаем

$$\{\psi(\vec{x},0),\bar{\psi}(0)\} = \int \frac{d^3p}{(2\pi)^3\,(2E_p)}\left[(p+m)e^{-i\vec{p}\cdot\vec{x}} + (\not{p}-m)e^{i\vec{p}\cdot\vec{x}}\right] =$$
$$= \int \frac{d^3p}{(2\pi)^3\,(eE_p)} 2p^0\gamma^0 e^{-i\vec{p}\cdot\vec{x}} = \gamma^0\delta^{(3)}(\vec{x}),$$

которое является слегка замаскированным соотношением (4).

Аналогично, записывая схематично, имеем $\{\psi,\psi\} = 0$ и $\left\{\psi^\dagger,\psi^\dagger\right\} = 0$. Несомненно, нормировочный множитель $(E_p/m)^{1/2}$ в (10) можно модифицировать путем включения соответствующих множителей в u и v. Порой сообразительные студенты спрашивают, что произойдет в случае безмассовой частицы со спином 1/2. Мы могли бы использовать нормировочный множитель $(2E_p)^{1/2}$ [подобный нормировочному множителю в (I.8.11)] и одновременно заменить (8) и (9) на $\sum\limits_s u\bar{u} = \not{p}$ и $\sum\limits_s v\bar{v} = \not{p}$.

Энергия вакуума

На данном этапе важно выполнить упражнение, заключающееся в вычислении гамильтониана, начиная с выражения для гамильтоновой плотности

$$\mathcal{H} = \pi\frac{\partial\psi}{\partial t} - \mathcal{L} = \bar{\psi}(i\vec{\gamma}\cdot\vec{\partial} + m)\psi$$

Подставляя в него (10) и интегрируя, получаем

$$H = \int d^3x\mathcal{H} = \int d^3x\bar{\psi}(i\vec{\gamma}\cdot\vec{\partial} + m)\psi = \int d^3x\bar{\psi}i\gamma^0\frac{\partial\psi}{\partial t}$$

что преобразуется к виду

$$H = \int d^3p\sum_s E_p\left[b^\dagger(p,s)b(p,s) - d(p,s)d^\dagger(p,s)\right]$$

Рассмотрим схематично появление в (17) важного знака минус: $\bar{\psi}$ в (16) дает множитель $\sim \left(b^\dagger + d\right)$, в то время как $\partial/\partial t$, действуя на ψ, привносит относительный знак минус, давая $\sim \left(b - d^\dagger\right)$, а все вместе дает нам $\sim \left(b^\dagger + d\right)\left(b - d^\dagger\right) \sim b^\dagger b - dd^\dagger$ (ортогональность между спинорами $\bar{v}u = 0$ сокращает перекрестные члены).

Чтобы переписать второй член в (17) в правильном порядке, антикоммутируем $-d(p,s)d^\dagger(p,s) = d^\dagger(p,s)d(p,s) - \delta^{(3)}(\overrightarrow{0})$ так, чтобы

$$H = \int d^3p\sum_s E_p\left[b^\dagger(p,s)b(p,s) + d^\dagger(p,s)d(p,s)\right] = -\delta^{(3)}(\overrightarrow{0})\int d^3p\sum_s E_p$$

Первые два члена указывают на то, что все электроны и все позитроны с импульсом p и спином s имеют одинаковую энергию E_p, как и должно быть. Но как насчет последнего члена? Эта $\delta^{(3)}(\overrightarrow{0})$ может вызывать опасения.

Все, однако, в порядке: замечая, что $\delta^{(3)}(\vec{p}) = [1/(2\pi)^3]\int d^3x e^{i\vec{p}\vec{x}}$, мы видим, что $\delta^{(3)}(\overrightarrow{0}) = [1/(2\pi)^3]\int d^3x$ (аналогичный маневр используется в упражнении I.8.2) и поэтому вклад последнего члена в H равен

$$E_0 = -\frac{1}{h^3}\int d^3x \int d^3p \sum_s 2\left(\frac{1}{2}E_p\right)$$

(поскольку в естественных единицах $\hbar = 1$ и, следовательно, $h = 2\pi$). Мы получили энергию $-\frac{1}{2}E_p$, приходящуюся на каждую элементарную ячейку фазового пространства $(1/h^3)\,d^3x d^3p$, с точки зрения статистической механики: на каждый спин и на каждый электрон и позитрон по отдельности (отсюда множитель 2). Этот бесконечный аддитивный член E_0 есть аналог энергии нулевых колебаний $\frac{1}{2}\hbar\omega$ гармонического осциллятора, известной вам из курса квантовой механики. Однако эта энергия появляется здесь со знаком минус, что кажется странным и непривычным!

Каждая мода дираковского поля дает вклад $-\frac{1}{2}\hbar\omega$ в энергию вакуума. В противоположность этому каждая мода скалярного поля, как мы видели в главе I.8, дает вклад $\frac{1}{2}\hbar\omega$. Этот факт имеет решающее значение для развития суперсимметрии, речь о которой пойдет в главе VIII.4.

Фермион, распространяющийся в пространстве-времени

По аналогии с (I.8.14), пропагатор для электрона определяется выражением $iS_{\alpha\beta}(x) \equiv \left\langle 0\left|T\psi_\alpha(x)\bar\psi_\beta(0)\right|0\right\rangle$, где аргумент функции $\bar\psi$ положен равным 0 в силу трансляционной инвариантности. Позднее мы увидим, что из-за антикоммутационного характера ψ мы должны определять упорядоченное по времени произведение со знаком минус, то есть

$$T\psi(x)\bar\psi(0) \equiv \theta\left(x^0\right)\psi(x)\bar\psi(0) - \theta\left(-x^0\right)\bar\psi(0)\psi(x)$$

Принимая во внимание (10), для $x^0 > 0$ получаем

$$iS(x) = \langle 0|\psi(x)\bar\psi(0)|0\rangle = \int \frac{d^3p}{(2\pi)^3\,(E_p/m)}\sum_s u(p,s)\bar u(p,s)e^{-ipx} = \\ = \int \frac{d^3p}{(2\pi)^3\,(E_p/m)}\frac{\not p + m}{2m}e^{-ipx}.$$

В случае $x^0 < 0$ мы должны быть более осторожными со спинорными индексами:

$$iS_{\alpha\beta}(x) = -\left\langle 0\left|\bar\psi_\beta(0)\psi_a(x)\right|0\right\rangle = \\ = -\int \frac{d^3p}{(2\pi)^3\,(E_p/m)}\sum_s \bar v_\beta(p,s)v_\alpha(p,s)e^{-ipx} = \\ = -\int \frac{d^3p}{(2\pi)^3\,(E_p/m)}\left(\frac{\not p - m}{2m}\right)_{\alpha\beta}e^{-ipx},$$

где используется тождество (9). Объединяя, получаем

$$iS(x) = \int \frac{d^3p}{(2\pi)^3\,(E_p/m)}\left[\theta\left(x^0\right)\frac{\not p + m}{2m}e^{-ipx} - \theta\left(-x^0\right)\frac{p - m}{2m}e^{+ipx}\right]$$

Теперь покажем, как можно этот фермионный пропагатор более изящно записать в виде 4-мерного интеграла:

$$iS(x) = i\int \frac{d^4p}{(2\pi)^4} e^{ip\cdot x} \frac{\not p + m}{p^2 - m^2 + i\varepsilon} = \int \frac{d^4p}{(2\pi)^4} e^{-ip\cdot x} \frac{i}{\not p - m + i\varepsilon}.$$

Чтобы увидеть, что (22) на самом деле эквивалентно (21), проделаем, в сущности, те же шаги, что и после получения (I.8.14). В комплексной p^0-плоскости подынтегральное выражение имеет полюсы в точках $p^0 = \pm\sqrt{\vec{p}^2 + m^2 - i\varepsilon} \simeq (E_p - i\varepsilon)$. При $x^0 > 0$ множитель $e^{-ip^0x^0}$ указывает на необходимость замыкания контура интегрирования в нижней полуплоскости. Мы обходим по часовой стрелке полюс в $+(E_p - i\varepsilon)$ и получаем

$$iS(x) = (-i)i\int \frac{d^3p}{(2\pi)^3} e^{-ip\cdot x} \frac{\not p + m}{2E_p}$$

что дает первый член в (21). При $x^0 < 0$ мы замыкаем контур в верхней полуплоскости и, таким образом, обходим полюс в $-(E_p - i\varepsilon)$ против часовой стрелки. Получаем

$$iS(x) = i^2\int \frac{d^3p}{(2\pi)^3} e^{+iE_px^0 + i\vec{p}\cdot\vec{x}} \frac{1}{-2E_p}\left(-E_p\gamma^0 - \vec{p}\vec{\gamma} + m\right)$$

и, обращая знак $\vec{p}$, приходим к выводу, что
$iS(x) = -\int \frac{d^3p}{(2\pi)^3} e^{ip\cdot x} \frac{1}{2E_p}\left(E_p\gamma^0 - \vec{p}\vec{\gamma} - m\right) = -\int \frac{d^3p}{(2\pi)^3} e^{ip\cdot x} \frac{1}{2E_p}(\not p - m)$
есть в точности второй член в (21) со знаком минус. Таким образом, мы обязаны определять упорядоченное по времени произведение со знаком минус, как в (20).

После всех этих вычислений заключаем, что фермионный пропагатор в импульсном пространстве имеет изящную форму

$$iS(p) = \frac{i}{\not p - m + i\varepsilon}$$

Она вполне логична: $S(p)$ соответствует обратному оператору Дирака $\not p - m$, так же как пропагатор скалярного бозона $D(k) = 1/\left(k^2 - m^2 - i\varepsilon\right)$ соответствует обратному оператору Клейна - Гордона $k^2 - m^2$.

Поэтические, но сбивающие с толку метафоры

В заключение этой главы позвольте мне задать риторический вопрос. Рассказывал ли я об электроне, распространяющемся назад во времени? Упоминал ли я море электронов с отрицательной энергией? Такой метафорический язык, будучи использованным блестящими умами, такими как Дирак и Фейнман, был легко запоминающимся и вдохновляющим, но, к сожалению, запутал не одно поколение студентов-физиков и самих физиков. Приведенное в книге изложение отвечает современному духу, при котором мы стремимся избежать этих потенциально приводящих к недоразумениям метафор.

Упражнения

- II.2.1. Используйте теорему Нётер для вывода сохраняющегося тока $J^\mu = \bar\psi\gamma^\mu\psi$. Вычислите $[Q, \psi]$, показав таким образом, что b и $d^\dagger$ несут одинаковый заряд.

- II.2.2. Проквантуйте дираковское поле в ящике объема V и покажите, что энергия вакуума E_0 действительно пропорциональна V. [Указание: интеграл по импульсам $\int d^3p$ необходимо заменить суммой по дискретным значениям импульса.]

9.4.5 Зи.II.3 Lorentz Group and Weyl Spinors

Алгебра Лоренца

В главе II.1 мы следовали оригинальным идеям Дирака при выводе его уравнения. Здесь мы более последовательно развиваем математическую теорию дираковского спинора. Более глубокое понимание дираковского спинора не только порождает чувство удовлетворения, но и является необходимым, как мы увидим далее, при изучении суперсимметрии - одной из фундаментальных концепций теории суперструн. И конечно, большинство фундаментальных частиц, таких как электрон и кварки, несут спин $1/2$ и описываются спинорными полями.

Для начала вспомним, как действует группа вращений. Три генератора $J_i (i = 1, 2, 3$ или $x, y, z)$ группы вращений удовлетворяют коммутационным соотношениям.

$$[J_i, J_j] = i\epsilon_{ijk} J_k$$

При действии на пространственно-временные координаты, записанные как вектор-столбец

$$\begin{pmatrix} x^0 \\ x^1 \\ x^2 \\ x^3 \end{pmatrix}$$

генераторы вращения задаются эрмитовыми матрицами

$$J_1 = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -i \\ 0 & 0 & i & 0 \end{pmatrix}$$

а J_2 и J_3 находятся путем соответствующих перестановок. Вы можете проверить справедливость (1), старательно перемножая эти три матрицы. Обратите внимание, что знаки J_i фиксируются коммутационным соотношениеМ (1). Добавим теперь лоренцевский буст. Буст в направлении $x \equiv x^1$ преобразует пространственно-временные координаты следующим образом:

$$t' = (\operatorname{ch}\varphi)t + (\operatorname{sh}\varphi)x; \quad x' = (\operatorname{sh}\varphi)t + (\operatorname{ch}\varphi)x$$

или, для бесконечно малого φ,

$$t' = t + \varphi x; \quad x' = x + \varphi t.$$

Иными словами, бесконечно малый лоренцевский буст в направлении x задается эрмитовой матрицей (как обычно $x^0 \equiv t$)

$$iK_1 = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

Аналогично

$$iK_2 = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

Запишите K_3 самостоятельно.

Проверьте, что $[J_i, K_j] = i\epsilon_{ijk}K_k$. Данное условие означает, что генераторы бустов K_i преобразуются при вращении как 3-векторы, как и следовало ожидать.

Вы сейчас готовы проделать один из самых важных вычислений в истории физики двадцатого столетия. Получите прямым вычислением $[K_1, K_2]$. Вы обнаружите, что он равен $-iJ_3$. Два лоренцевых буста генерируют вращение! (Из курса электромагнетизма вспомним, что полученный математический факт ответственен за томасовскую прецессию.)

Математически генераторы группы Лоренца удовлетворяют следующей алгебре [известной знатокам как $SO(3,1)$]:

$$\begin{aligned} [J_i, J_j] &= i\epsilon_{ijk}J_k, \\ [J_i, K_j] &= i\epsilon_{ijk}K_k, \\ [K_i, K_j] &= -i\epsilon_{ijk}J_k. \end{aligned}$$

Обратите внимание на крайне важный знак минус.

Как нам изучать эту алгебру? Решающим наблюдением является то, что при образовании комбинаций $J_{\pm i} \equiv \frac{1}{2}(J_i \pm iK_i)$ алгебра разбивается на две части. Убедитесь, что

$$\begin{aligned} [J_{+i}, J_{+j}] &= i\epsilon_{ijk}J_{+k} \\ [J_{-i}, J_{-j}] &= i\epsilon_{ijk}J_{-k} \end{aligned}$$

и, что более важно,

$$[J_{+i}, J_{-j}] = 0.$$

Последнее коммутационное соотношение означает, что J_+и J_-образуют две независимые алгебры $SU(2)$. Иначе говоря, алгебра $SO(3,1)$ изоморфна $SU(2) \otimes SU(2)$.

От алгебры к представлению

Отсюда следует, что мы можем использовать наши знания о представлениях $SU(2)$ для построения представлений $SO(3,1)$. Как вы знаете, представления $SU(2)$ характеризуются $j = 0, \frac{1}{2}, 1\frac{3}{2}, \ldots$ Каждое представление можно рассматривать как набор $(2j+1)$ объектов ψ_m с $m = -j, -j+ +1, \ldots, j-1, j$, которые преобразуются друг в друга под действием $SU(2)$. Отсюда немедленно следует, что представления $SO(3,1)$ характеризуются (j^+, j^-), где j^+и j^-принимают значения $0, \frac{1}{2}, 1\frac{3}{2}, \ldots$ Каждое представление состоит из $(2j^+ + 1)(2j^- + 1)$ объектов $\psi_{m^+m^-}$с $m^+ = -j^+, -j^+ + +1, \ldots, j^+ - 1, j^+$и $m^- = -j^-, -j^- + 1, \ldots, j^- - 1, j^-$.

Таким образом, представлениями $SO(3,1)$ являются $(0,0)$, $\left(\frac{1}{2}, 0\right)$, $\left(0, \frac{1}{2}\right)$, $(1,0)$, $(0,1)$, $\left(\frac{1}{2}, \frac{1}{2}\right)$ и так далее в порядке возрастания размерности. Ясно, что одномерное представление $(0,0)$ тривиально, т. е. соответствует лоренцевскому скаляру. Из размерных соображений можно ожидать, что 4-мерное представление $\left(\frac{1}{2}, \frac{1}{2}\right)$ соответствует лоренцевскому вектору, т. е. представлению наименьшей размерности группы Лоренца (см. упражнение II.3.1).

Спинорные представления

Что можно сказать о представлении $\left(\frac{1}{2},0\right)$? Запишем эти два объекта как ψ_α с $\alpha = 1,2$. Итак, что означает обозначение $\left(\frac{1}{2},0\right)$? Оно указывает на то, что $J_{+i} = \frac{1}{2}(J_i + iK)$ при действии на ψ_α соответствует $\frac{1}{2}\sigma_i$, тогда как $J_{-i} = \frac{1}{2}(J_i - iK_i)$ при действии на ψ_α соответствует 0. Складывая и вычитая, находим

$$J_i = \frac{1}{2}\sigma_i$$

и

$$iK_i = \frac{1}{2}\sigma_i$$

В этом контексте знак равенства означает «представляется как». (По традиции, мы не будем делать различий между верхними и нижними индексами 3-мерных величин J_i, K_i и σ_i.)

Аналогично обозначим два объекта в $\left(0,\frac{1}{2}\right)$ особенным символом $\bar{\chi}^{\dot{\alpha}}$. Обращаю ваше внимание на тривиальный, но порой сбивающий с толку факт: в отличие от фигурировавшей в главе II.1 черты, черта над $\bar{\chi}^{\dot{\alpha}}$ являстся типографическим элементом. По желанию можете рассматривать $\bar{\chi}$ как букву в хеттском алфавите. Точно так же символ $\dot{\alpha}$ не имеет никакого отношения к α: нельзя получить $\dot{\alpha}$ из α. Такое довольно странное обозначение, неформально называемое «пунктирным и непунктирным», а более формально - обозначением Ван дер Вардена, является для наших скромных целей несколько чрезмерным, но я ввел его потому, что именно такое обозначение используется в суперсимметричной физике и теории суперструн. (Между прочим, Дирак якобы жалел, что это не он придумал систему пунктирных обозначений.) Повторяя предыдущие шаги, вы обнаружите, что для представления $\left(0,\frac{1}{2}\right)$ имеет место $J_i = \frac{1}{2}\sigma_i$ и $iK_i = -\frac{1}{2}\sigma_i$. Знак минус критичен.

Двухкомпонентные спиноры ψ_α и $\bar{\chi}^{\dot{\alpha}}$ называются вейлевскими спинорами и образуют полноценные представления группы Лоренца. Почему же тогда дираковский спинор имеет 4 компоненты?

Причина в четности. При отражении имеем $\vec{x} \to -\vec{x}$ и $\vec{p} \to -\vec{p}$ и, следовательно, $\vec{J} \to \vec{J}$ и $\vec{K} \to -\vec{K}$, так что $\vec{J}_+ \leftrightarrow \vec{J}_-$. Другими словами, при отражении представления переходят друг в друга $\left(\frac{1}{2},0\right) \leftrightarrow \left(0,\frac{1}{2}\right)$. Таким образом, для описания электрона мы должны использовать оба этих двумерных представления или, в математических обозначениях, 4-мерное приводимое представление $\left(\frac{1}{2},0\right) \oplus \left(0,\frac{1}{2}\right)$.

Итак, из двух спиноров Вейля получаем спинор Дирака

$$\Psi = \begin{pmatrix} \psi_\alpha \\ \bar{\chi}^{\dot{\alpha}} \end{pmatrix}$$

Конечно, спинор $\Psi(p)$ является функцией от 4-импульса p [и косвенно от $\psi_\alpha(p)$ и $\bar{\chi}^{\dot{\alpha}}(p)$], но мы будем опускать зависимость от p. Возвращаясь к (13) и (14), видим, что действующие на Ψ генераторы вращений задаются следующим образом:

$$\vec{J} = \begin{pmatrix} \frac{1}{2}\vec{\sigma} & 0 \\ 0 & \frac{1}{2}\vec{\sigma} \end{pmatrix},$$

где равенство опять-таки означает «представляется как», а генераторы бустов задаются как

$$i\vec{K} = \begin{pmatrix} \frac{1}{2}\vec{\sigma} & 0 \\ 0 & -\frac{1}{2}\vec{\sigma} \end{pmatrix}.$$

Снова обращаю ваше внимание на крайне важный знак минус.

В силу четности мы должны рассматривать 4-мерный спинор, но, с другой стороны, мы знаем, что электрон имеет только две физические степени свободы. Перейдем в покоящуюся систему координат. Мы должны избавиться от двух компонент, содержащихся в $\Psi(p_r)$ с импульсом покоя $p_r \equiv (m, \overrightarrow{0})$. Используя прошлый опыт, запишем проекционный оператор как $\mathcal{P} = \frac{1}{2}(1 - \gamma^0)$. Глядя на обозначения, вы, вероятно, уже догадались, что γ^0 оказывается одной из гамма-матриц, но на данном этапе логично предположить, что это всего лишь некоторая 4×4-матрица. Из условия $\mathcal{P}^2 = \mathcal{P}$ следует, что $(\gamma^0)^2 = 1$, так что собственные значения γ^0 равны \pm 1. Так как при отражении $\psi_\alpha \leftrightarrow \bar{\chi}^{\dot{\alpha}}$, естественно предположить, что ψ_α и $\bar{\chi}^{\dot{\alpha}}$ соответствуют левом и правым полям из главы II.1. Мы не можем просто использовать проекцию и положить, например, $\bar{\chi}^{\dot{\alpha}}$ равным 0. Четность подразумевает, что мы должны рассматривать ψ_α и $\bar{\chi}^{\dot{\alpha}}$ на равном основании. Выбираем

$$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

или, в более явном виде,

$$\begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}.$$

(Разный выбор γ^0 соответствует разному выбору базиса, обсуждавшемуся в главе II.1.) Другими словами, в покоящейся системе координат $\psi_\alpha - \bar{\chi}^{\dot{\alpha}} = 0$. Проекция на две степени свободы может быть записана как

$$\left(\gamma^0 - 1\right)\Psi(p_r) = 0$$

В самом деле, узнаем в полученном базис Вейля, речь о котором шла в глаВе II.1.

Уравнение Дирака

Мы только что вывели уравнение Дирака, правда в слегка завуалированной форме!

Поскольку наш вывод основан на поэтапном изучении спинорного представления группы Лоренца, мы знаем, как получить уравнение, которому удовлетворяет $\Psi(p)$ при любом p: необходимо совершить буст. Записывая $\Psi(p) = e^{-i\vec{\varphi}\vec{K}}\Psi(p_r)$, имеем $\left(e^{-i\vec{\varphi}\vec{K}}\gamma^0 e^{i\vec{\varphi}\vec{K}} - 1\right)\Psi(p) = 0$. Вводя обозначение $\gamma^\mu p_\mu/m \equiv e^{-i\vec{\varphi}\vec{K}}\gamma^0 e^{i\vec{\varphi}\vec{K}}$, получаем уравнение Дирака

$$(\gamma^\mu p_\mu - m)\Psi(p) = 0$$

Проделайте все детали этого вычисления в качестве упражнения.

Приведенный здесь вывод представляет собой глубокий теоретикогрупповой подход к уравнению Дирака: он заключается в проекции, преобразованной к произвольной системе отсчета.

Заметьте, что этот пример демонстрирует всю мощь симметрии, которой пропитана современная физика и эта книга: наше знание того, как поле электрона преобразуется под действием группы вращений, а именно то, что он имеет спин 1/2, позволяет нам определить, как оно преобразуется под действием группы Лоренца. Симметрия правит миром!

В приложении Е более подробно излагается пунктирная система обозначений, поскольку она понадобится нам при изучении главы, посвященной суперсимметрии.

Для более глубокого теоретико-группового понимания материала нелишним будет перечитать главу II.1 и сравнить ее с настоящей главой.

Упражнения

II.3.1. Прямым вычислением покажите, что $\left(\frac{1}{2},\frac{1}{2}\right)$ действительно является лоренцевым вектором. II.3.2. Установите, как преобразуются шесть объектов, содержащихся в $(1,0)$ и $(0,1)$, под действием группы Лоренца. Вспомните из курса по электродинамике, как преобразуются электрическое и магнитное поля $\vec{E}$ и $\vec{B}$. Покажите, что электромагнитное поле действительно преобразуется как $(1,0)\oplus(0,1)$. Покажите, что именно четность вынуждает нас использовать приводимое представление.

II.3.3. Покажите, что

$$e^{-i\vec{\varphi}\vec{K}}\gamma^0 e^{i\vec{\varphi}\vec{K}} = \begin{pmatrix} 0 & e^{-\vec{\varphi}\vec{\sigma}} \\ e^{\vec{\varphi}\vec{\sigma}} & 0 \end{pmatrix}$$

и

$$e^{\vec{\varphi}\vec{\sigma}} = \operatorname{ch}\varphi + \vec{\sigma}\cdot\widehat{\varphi}\operatorname{sh}\varphi$$

где $\vec{\varphi}\equiv\vec{\varphi}/\varphi$ - единичный вектор. Полагая $\vec{p} = m\widehat{\varphi}\operatorname{sh}\varphi$, выведите уравнение Дирака. Покажите, что

$$\gamma^i = \begin{pmatrix} 0 & \sigma_i \\ -\sigma_i & 0 \end{pmatrix}$$

II.3.4. Покажите, как можно частицу со спином 3/2 описать вектор-спинором $\Psi_{\alpha\mu}$, то есть спинором Дирака, несущим лоренцевский индекс. Найдите соответствующее уравнение движения, известное как уравнение Рариты-Швингера. [Указание: объект $\Psi_{\alpha\mu}$ имеет 16 компонент, которые надо свести к количеству $2\cdot\frac{3}{2}+1=4$.]

9.4.6 Зи.II.4 Connection of Spin and Statistics

Степени интеллектуальной неполноты

Из курса нерелятивистской квантовой механики вы знаете о принципе Паули и его последующем обобщении, утверждающем, что частицы с полуцелыми спинами, такие как электроны, подчиняются статистике Ферми-Дирака и предпочитают находиться подальше друг от друга, а частицы с целыми спинами, такие как фотоны, или пары электронов, подчиняются статистике Бозе-Эйнштейна и любят собираться вместе. Все ослепительное богатство физических явлений, от микроскопической структуры атомов до макроскопической структуры нейтронных звезд, нельзя объяснить без правила спин-статистики. Многие элементы физики конденсированных сред, к примеру зонная

структура, теория ферми-жидкости, сверхтекучесть, сверхпроводимость, квантовый эффект Холла и т.д. и т.п., являются следствиями этого правила.

Квантовая статистика - одна из наиболее хрупких физических концепций - основывается на том факте, что в квантовом мире все элементарные частицы и, следовательно, все атомы абсолютно идентичны и потому неотличимы друг от друга [3]. То, что квантовая теория поля способна легко и естественно объяснить полную идентичность и неразличимость частиц, следует рассматривать как ее триумф. Каждый электрон во Вселенной есть возбуждение одного и того же электронного поля ψ. В противном случае можно было бы представить, что электроны, о которых мы знаем в настоящий момент, были выпущены сборочным конвейером где-то в ранней Вселенной и могли бы несколько отличаться друг от друга из-за некоторой халатности в процессе производства.

Несмотря на то что правило спин-статистики оказывает такое существенное влияние на квантовую механику, для его объяснения пришлось ждать формулировки релятивистской квантовой теории поля. Представьте себе цивилизацию, которая в силу каких-то причин сформулировала квантовую механику, но все еще ожидает открытия специальной теории относительности. Физики этой цивилизации со временем осознали бы, что им необходимо придумать некоторое правило для объяснения упомянутых выше явлений, ни одно из которых не связано с движением, скорость которого превышает скорость света. Физика была бы интеллектуально неудовлетворительной и неполной.

Интересным критерием сравнения различных областей физики является степень их интеллектуальной неполноты.

Несомненно, в физике мы часто принимаем правило, которое невозможно объяснить до тех пор, пока мы не перейдем на следующий уровень знаний. Например, в большинстве разделов физики мы воспринимаем как данное, что заряды протона и электрона в точности одинаковы по абсолютной величине и противоположны по знаку. Квантовая электродинамика сама по себе не в состоянии объяснить сей поразительный факт. Как мы увидим в главе VII.6, явление квантования заряда можно объяснить только путем рассмотрения квантовой электродинамики в рамках более общей структуры, такой как теория великого объединения. (В главе IV.4 мы узнаем, что существование магнитных монополей предполагает квантование заряда, но монополи не существуют в чистой квантовой электродинамике.)

Таким образом, обьяснение связи спина со статистикой (Фирцем и Паули в конце 1930-х, Людерсом и Зумино, а также Бергойном в конце 1950-х) расценивается как один из величайших триумфов релятивистской квантовой теории поля. Объем моей книти не позволяет привести тому общее и строгос доказательство 4. Опишу в общих чертах, какие серьезныс нарушения произойдут, если нарушить связь спина со статистикой.

Цена упрямства

Основной квантовый принцип утверждает, что если две наблюдаемые величины коммутируют, то их можно одновременно диагонализовать и, следовательно, наблюдать. Основной релятивистский принцип утверждает, что, если две пространственно-временные точки являются пространственно подобными по отношению друг к другу, то никакой сигнал не может распространиться между ними и, следовательно, измерение наблюдаемой величины в одной из точек не может влиять на измерение другой наблюдаемой величины во второй точке.

Рассмотрим плотность заряда $J_0 = i\left(\varphi^\dagger \partial_0 \varphi - \partial_0 \varphi^\dagger \varphi\right)$ в теории заряженного скалярного

поля. В соответствии с двумя только что провозглашенными фундаментальными принципами, $J_0(\vec{x}, t = 0)$ и $J_0(\vec{y}, t = 0)$ должны коммутировать при $\vec{x} \neq \vec{y}$. Вычисляя коммутатор $J_0(\vec{x}, t = 0)$ с $J_0(\vec{y}, t = 0)$, мы используем тот факт, что $\varphi(\vec{x}, t = 0)$ и $\partial_0\varphi(\vec{x}, t = 0)$ коммутируют с $\varphi(\vec{y}, t = 0)$ и $\partial_0\varphi(\vec{y}, t = 0)$, так что можно просто поменять местами поля в $\vec{x}$ и $\vec{y}$. Коммутатор обращается в нуль практически тривиально.

Теперь предположим, что мы упрямимся и квантуем операторы рождения и уничтожения в разложении (I.8.11)

$$\varphi(\vec{x}, t = 0) = \int \frac{d^D k}{\sqrt{(2\pi)^D 2\omega_k}} \left[a(\vec{k}) e^{i\vec{k}\cdot\vec{x}} + a^\dagger(\vec{k}) e^{-i\vec{k}\cdot\vec{x}} \right]$$

в соответствии с антикоммутационными соотношениями

$$\left\{ a(\vec{k}), a^\dagger(\vec{q}) \right\} = \delta^{(D)}(\vec{k} - \vec{q})$$

И

$$\{a(\vec{k}), a(\vec{q})\} = 0 = \left\{ a^\dagger(\vec{k}), a^\dagger(\vec{q}) \right\}$$

а не правильными коммутационными соотношениями.

Какова цена упрямства?

Теперь, когда мы пытаемся пронести $J_0(\vec{y}, t = 0)$ через $J_0(\vec{x}, t = 0)$, необходимо пронести поле в $\vec{y}$ через поле в $\vec{x}$, используя антикоммутатор

$$\begin{aligned}
\{\varphi(\vec{x}, t = 0), \varphi(\vec{y}, t = 0)\} &= \iint \frac{d^D k}{\sqrt{(2\pi)^D 2\omega_k}} \frac{d^D q}{\sqrt{(2\pi)^D 2\omega_q}} \times \\
&\times \left\{ \left[a(\vec{k}) e^{i\vec{k}\cdot\vec{x}} + a^\dagger(\vec{k}) e^{-i\vec{k}\cdot\vec{x}} \right], \left[a(\vec{q}) e^{i\vec{q}\cdot\vec{y}} + a^\dagger(\vec{q}) e^{-i\vec{q}\cdot\vec{y}} \right] \right\} = \\
&= \int \frac{d^D k}{\sqrt{(2\pi)^D 2\omega_k}} \left(e^{i\vec{k}\cdot(\vec{x}-\vec{y})} + e^{-i\vec{k}\cdot(\vec{x}-\vec{y})} \right)
\end{aligned}$$

Вы видите, в чем состоит проблема? В обычной теории скалярного поля, удовлетворяющего связи спина со статистикой, мы вычислили бы коммутатор, и тогда в последнем выражении в (2) получили бы $\left(e^{i\vec{k}\cdot(\vec{x}-\vec{y})} - \quad - e^{-i\vec{k}\cdot(\vec{x}-\vec{y})} \right)$, вместо $\left(e^{i\vec{k}\cdot(\vec{x}-\vec{y})} + e^{-i\vec{k}\cdot(\vec{x}-\vec{y})} \right)$. Интеграл

$$\int \frac{d^D k}{\sqrt{(2\pi)^D 2\omega_k}} \left(e^{i\vec{k}\cdot(\vec{x}-\vec{y})} - e^{-i\vec{k}\cdot(\vec{x}-\vec{y})} \right)$$

очевидно обращался бы в ноль, что очевидно, и все было бы хорошо. Со знаком плюс мы получаем в (2) не равную нулю часть. Катастрофа, если мы квантуем скалярное поле как антикоммутирующее! Поле со спином 0 должно быть коммутирующим. Таким образом, теория относительности и квантовая физика объединяют свои усилия и обуславливают связь спина со статистикой.

Иногда говорят, что благодаря электромагнетизму вы не проваливаетесь сквозь пол, а благодаря гравитации - не воспаряете к потолку. К тому же, если бы не было слабого взаимодействия, регулирующего горение звезд, то вы бы проваливались или воспаряли в полной темноте. Без связи спина со статистикой электрон не подчинялся бы принципу Паули. Материя просто коллапсировала бы.

Упражнения

Зи-у.

II.4.1. Покажите появление аналогичной проблемы для случая, если квантовать поле Дирака с коммутаторами вместо антикоммутаторов. Вычислите $[J^0(\vec{x},0), J^0(0)]$

[5] Доказательство устойчивости материи. данное Дайсоном и Ленардом, существенно опирается на принцип Паули.

9.4.7 Зи.II.5 Grassmann Integrals and Fermion Diagrams

Фермионы таинственны

Я построил квантовую теорию скалярного поля $\varphi(x)$ сначала в формализме интеграла по траекториям, а затем в каноническом формализме. Квантовую же теорию свободного поля $\psi(x)$ со спином 1/2 я построил только в каноническом формализме. Мы узнали, что связь спина со статистикой вынуждает полевой оператор $\psi(x)$ удовлетворять антикоммутационным соотношениям. Из этого немедленно следует несколько странная запись интеграла по траекториям для спинорного поля ψ. В формализме интеграла по траекториям $\psi(x)$ является не оператором, а просто переменной интегрирования. Как отобразить тот факт, что операторный аналог в каноническом формализме антикоммутирует?

По-видимому, мы не сможем представить ψ как коммутирующую переменную, как в отношении с φ. В самом деле, мы обнаружим, что в формализме интеграла по траекториям ψ должно рассматриваться не как обыкновенное комплексное число, а как новое математическое понятие, известное под именем грассманова числа.

Если задуматься над этим, то, вероятно, придем к выводу, что здесь необходима новая математическая структура. В главе I.3 мы обобщили координаты точечной частицы $q_i(t)$ в квантовой механике до понятия скалярного поля $\varphi(\vec{x},t)$. Однако из квантовой механики известно, что частица со спином 1/2 имеет одно особое свойство: ее волновая функция меняет знак при повороте на 2π. В отличие от координат частицы, полуцелый спин не является интуитивным понятием.

Энергия вакуума

Чтобы мотивировать введение грассмановых полей, рассмотрим понятие энергии вакуума. Причина, по которой я выбрал эту на первый взгляд странную стратегию, вскоре будет понятна.

Квантовая теория поля вначале была построена для описания рассеяния фотонов и электронов, и позднее для рассеяния частиц. Вспомним, что в главе I.7 при рассмотрении рассеяния частиц мы строили диаграммы, описывающие вакуумные флуктуации, которыми мы просто пренебрегали (см. рис. I.7.12). Совершенно естественно, что специалисты в области физики элементарных частиц не придают этим флуктуациям особого значения. Экспериментально мы рассеиваем частицы друг на друге. Кого интересуют флуктуации где-то там в вакууме? И лишь в начале 1970-х физики в полной мере оценили значимость вакуумных флуктуаций. К вопросу о важности вакуума вернемся позже [1].

В главах I.8 и II.2 мы вычислили энергию вакуума свободного скалярного поля и свободного спинорного поля в каноническом формализме. Чтобы мотивировать использование грассмановых чисел при формулировке интеграла по траекториям для

спинорного поля, я прибегну к следующей стратегии. Сначала я воспользуюсь формализмом интеграла по траекториям и получу результат для свободного скалярного поля, найденный нами с помощью канонического формализма. Далее мы узнаем, что для получения уже известного нам результата для свободного спинорного поля мы должны модифицировать интеграл по траекториям.

По определению, вакуумные флуктуации происходят даже при отсутствии источников, способных создать частицы. Поэтому рассмотрим производящий функционал теории свободного скалярного поля при отсутствии источников [2]:

$$Z = \int D\varphi e^{i\int d^4x \frac{1}{2}\left[(\partial\varphi)^2 - m^2\varphi^2\right]} = C\left(\frac{1}{\det[\partial^2+m^2]}\right)^{1/2} = Ce^{-\frac{1}{2}\operatorname{Tr}\log\left(\partial^2+m^2\right)}$$

[1] На самом деле мы уже упоминали один из способов наблюдения за эффектами вакуумных флуктуаций в главе I.8.

[2] Строго говоря, чтобы приведенное здесь выражение являлось однозначно определенным. мы должны, как обсуждалось ранее, заменить m^2 на $m^2 - i\varepsilon$. Для первого равенства мы воспользовались выражением (I.2.15), в котором включили несущественные множители в константу C. Во втором равенстве мы воспользовались важным тождеством

$$\det M = e^{\operatorname{Tr}\log M}$$

с которым вы встречались в упражнении I.10.2.

Вспомним, что $Z = \left\langle 0\left|e^{-iHT}\right|0\right\rangle$ (где подразумевается $T \to \infty$, так что в (1) идет интегрирование по всему пространству-времени), в нашем случае равен e^{-iET}, где E - энергия вакуума. Вычисляя след в (1)

$$\operatorname{Tr}\mathcal{O} = \int d^4x\langle x|\mathcal{O}|x\rangle = \int d^4x \int \frac{d^4k}{(2\pi)^4}\int \frac{d^4q}{(2\pi)^4}\langle x|k\rangle\langle k\mathcal{O}|q\rangle\langle q|x\rangle$$

получаем

$$iET = \frac{1}{2}VT\int \frac{d^4k}{(2\pi)^4}\log\left(k^2 - m^2 + i\varepsilon\right) + A$$

где A - бесконечная константа, соответствующая множителю C в (1). Вспомним, что при выводе интеграла по траекториям у нас было много расходящихся множителей; все они собираются именно в множитель A. Польза от A выражается в том, что она позволяет решить проблему, которую вы, должно быть, уже заметили: аргумент логарифма не является безразмерным. Определим m', записав

$$A = -\frac{1}{2}VT\int \frac{d^4k}{(2\pi)^4}\log\left(k^2 - m'^2 + i\varepsilon\right)$$

Другими словами, мы вычисляем не энергию вакуума саму по себе, а только разницу между ней и энергией вакуума, которую мы имели бы, если бы частицы имели массу m', вместо m. Произвольно большое время T сокращается и, как и следовало ожидать, E оказывается пропорциональной объему пространства V. Таким образом, плотность энергии вакуума (точнее, разность плотностей энергии вакуума) равна

$$\begin{aligned}\frac{E}{V} &= -\frac{i}{2}\int \frac{d^4k}{(2\pi)^4}\log\left[\frac{k^2 - m^2 + i\varepsilon}{k^2 - m'^2 + i\varepsilon}\right] = \\ &= -\frac{i}{2}\int \frac{d^3k}{(2\pi)^3}\int \frac{d\omega}{2\pi}\log\left[\frac{\omega^2 - \omega_k^2 + i\varepsilon}{\omega^2 - \omega_k'^2 + i\varepsilon}\right]\end{aligned}$$

где $\omega'_k \equiv +\sqrt{\vec{k}^2 + m'^2}$. Мы вычисляем (сходящийся) интеграл по ω путем интегрирования по частям:

$$\int \frac{d\omega}{2\pi} \int \frac{d\omega}{d\omega} \log\left[\frac{\omega^2 - \omega_k^2 + i\varepsilon}{\omega^2 - \omega_k'^2 + i\varepsilon}\right] =$$
$$= -2\int \frac{d\omega}{2\pi}\omega \left[\frac{\omega}{\omega^2 - \omega_k^2 + i\varepsilon} - (\omega_k \to \omega'_k)\right] =$$
$$= -i2\omega_k^2\left(\frac{1}{-2\omega_k}\right) - (\omega_k \to \omega'_k) = +i\left(\omega_k - \omega'_k\right).$$

Восстанавливая $\hbar$, мы действительно приходим к желаемому результату:

$$\frac{E}{V} = \int \frac{d^3k}{(2\pi)^3}\left(\frac{1}{2}\hbar\omega_k - \frac{1}{2}\hbar\omega'_k\right)$$

Чтобы получить этот результат, нам пришлось проделать несколько выкладок, но важным моментом здесь является то, что, используя формализм интеграла по траекториям, мы смогли получить результат, ранее полученный в каноническом формализме.

Особый знак для фермионов

Наша задача - записать интеграл по траекториям для спинорного поля. Вспомним из главы II.2, что вакуумная энергия спинорного поля появляется со знаком, противоположным знаку вакуумной энергии скалярного поля, и этот знак определенно находится в «верхней десятке» самых значимых знаков теоретической физики. Как его получить с помощью интеграла по траекториям?

Как говорилось в главе I.3, выражение (1) строится на основе простой формулы для гауссова интеграла

$$\int_{-\infty}^{+\infty} dx e^{-\frac{1}{2}ax^2} = \sqrt{\frac{2\pi}{a}} = \sqrt{2\pi}e^{-\frac{1}{2}\log a}.$$

Грубо говоря, мы должны найти такой новый интеграл, чтобы аналогом гауссова интеграла было выражение типа $e^{+\frac{1}{2}\log a}$.

Грассманова математика

Оказывается, что необходимая для этих целей математика была изобретена Грассманом давным-давно. Введем новый тип числа, называемого грассмановым или антикоммутирующим числом, такой, что если η и ξ - грассмановы числа, то $\eta\xi = -\xi\eta$. В частности, $\eta^2 = 0$. Эвристически это отражает антикоммутационное соотношение, которому удовлетворяет спинорное поле. Грассман предположил, что любая функция от η может быть разложена в ряд Тейлора. Так как $\eta^2 = 0$, то наиболее общей функцией η является $f(\eta) = a + b\eta$.

Как нам определить интегрирование по η? Грассман заметил, что важным свойством обыкновенного интеграла является возможность сдвига фиктивной переменной интегрирования: $\int\limits_{-\infty}^{+\infty} dx f(x+c) = \int\limits_{-\infty}^{+\infty} dx f(x)$. Таким образом, мы должны требовать, чтобы

грассманов интеграл также удовлетворял правилу $\int d\eta f(\eta + \xi) = \int d\eta f(\eta)$, где ξ - произвольное грассманово число. Подставляя наиболее общую функцию, приведенную выше, находим, что $\int d\eta b\xi = 0$. Так как ξ произвольно, полученное выражение может выполняться только тогда, когда мы определяем $\int d\eta b = 0$ для любого обычного числа b, в частности, $\int d\eta \equiv \int d\eta 1 = 0$.

Поскольку для трех грассмановых чисел χ, η и ξ имеет место $\chi(\eta\xi) = (\eta\xi)\chi$, то есть произведение $(\eta\xi)$ коммутирует с любым грассмановым числом χ, приходим к заключению, что произведение двух антикоммутирующих чисел должно выражаться обычным числом. Таким образом, значение интеграла $\int d\eta\eta$ есть просто обычное число, которое можно положить равным 1: при этом фиксируется нормировка $d\eta$. Итак, грассманово интегрирование необычайно просто, оно определяется двумя правилами:

$$\int d\eta = 0$$

К

$$\int d\eta\eta = 1$$

Используя эти правила, можно проинтегрировать любую функцию от η:

$$\int d\eta f(\eta) = \int d\eta(a + b\eta) = b$$

если b - обычное число, то есть $f(\eta)$ является грассмановым, и

$$\int d\eta f(\eta) = \int d\eta(a + b\eta) = -b$$

если b - грассманово, то есть $f(\eta)$ - обычное число. Обратите внимание, что для грассманова интегрирования не существует понятия пределов интегрирования. Грассманово интегрирование гораздо легче освоить, чем обычное!

Пусть η и $\bar{\eta}$ - два независимых грассмановых числа, а a - произвольное обычное число. Тогда грассмановый аналог гауссова интеграла равен

$$\int d\eta \int d\bar{\eta} e^{\bar{\eta}a\eta} = \int d\eta \int d\bar{\eta}(1 + \bar{\eta}a\eta) = \int d\eta a\eta = a = e^{+\log a}.$$

В точности то, что нам и нужно!

Можно немедленно получить обобщение. Пусть $\eta = (\eta_1, \eta_2, ..., \eta_N)$ - N грассмановых чисел, и аналогично для $\bar{\eta}$; тогда имеем

$$\int d\eta \int d\bar{\eta} e^{\bar{\eta}A\eta} = \det A$$

для антисимметричной $N \times N$-матрицы $A = \{A_{ij}\}$. (Заметьте, что, в отличие от бозонного случая, матрицы, обратной матрице A, может и не существовать.) Можно построить дальнейшее обобщение до функционального интеграла.

Как мы вскоре увидим, у нас есть вся необходимая математика.

Грассманов интеграл по траекториям

По аналогии с производящим функционалом для скалярного поля

$$Z = \int D\varphi e^{iS(\varphi)} = \int D\varphi e^{i\int d^4x \frac{1}{2}\left[(\partial\varphi)^2 - \left(m^2 - i\varepsilon\right)\varphi^2\right]}$$

производящий функционал для спинорного поля естественно записать в виде:

$$Z = \int D\psi D\bar{\psi} e^{iS(\psi,\bar{\psi})} = \int D\psi \int D\bar{\psi} e^{i\int d^4x \bar{\psi}(i\not{\partial} - m + ie)\psi}.$$

Считая переменные интегрирования ψ и $\bar{\psi}$ дираковскими спинорами, значения которых выражаются грассмановыми числами, получаем:

$$\begin{aligned} Z &= \int D\psi \int D\bar{\psi} e^{i\int d^4x \bar{\psi}(i\not{\partial} + m + i\varepsilon)\psi} = C' \det(i\not{\partial} - m + i\varepsilon) = \\ &= C' e^{\operatorname{tr}\log(i\not{\partial} + m + i\varepsilon)}, \end{aligned}$$

где C' - некоторая мультипликативная константа. С учетом свойства цикличности следа видим, что (m берется равной $m - i\varepsilon$):

$$\begin{aligned} \operatorname{tr}\log(i\not{\partial} - m) &= \operatorname{tr}\log\gamma^5(i\not{\partial} - m)\gamma^5 = \operatorname{tr}\log(-i\not{\partial} - m) = \\ &= \frac{1}{2}[\operatorname{tr}\log(i\not{\partial} - m) + \operatorname{tr}\log(-i\not{\partial} - m)] = \\ &= \frac{1}{2}\operatorname{tr}\log\left(\partial^2 + m^2\right). \end{aligned}$$

То есть $Z = C' e^{\frac{1}{2}\operatorname{tr}\log\left(\partial^2 + m^2 - i\varepsilon\right)}$ [сравните с выражением (1)!].

Мы увидим, что получили ту же энергию вакуума, что и в главе II.2, с использованием канонического формализма, если вспомним, что здесь операция взятия следа содержит множитель 4 по сравнению с операцией взятия следа в уравнении (1), ведь $(i\not{\partial} - m)$ есть матрица 4×4.

Эвристически вы можете теперь видеть необходимость использования грассмановых переменных. Если бы мы рассматривали параметры ψ и $\bar{\psi}$ в уравнении (12) как комплексные числа, то получили бы что-то вроде $(1/\det[i\not{\partial} - m]) = e^{-\operatorname{tr}\log(i\not{\partial} - m}$ и получили бы энергию вакуума с неправильным знаком. Мы хотим, чтобы детерминант появлялся в числителс, а не в знаменателе.

Пропагатор Дирака

Мы знаем, что дираковское поле должно квантоваться грассмановым интегралом по траекториям, поэтому введем грассмановы спинорные источники η и $\bar{\eta}$:

$$Z(\eta,\bar{\eta}) = \int D\psi D\bar{\psi} e^{i\int d^4x[\bar{\psi}(i\not{\partial} - m)\psi + \bar{\eta}\psi + \bar{\psi}\eta]}$$

и будем действовать, как и раньше. Дополняя до полного квадрата, как в случае скалярного поля, получаем:

$$\bar{\psi}K\psi + \bar{\eta}\psi + \bar{\psi}\eta = \left(\bar{\psi} + \bar{\eta}K^{-1}\right)K\left(\psi + K^{-1}\eta\right) - \bar{\eta}K^{-1}\eta$$

и, следовательно,

$$Z(\eta,\bar{\eta}) = C'' e^{-i\bar{\eta}(i\not{\partial}-m)^{-1}\eta}$$

Пропагатор $S(x)$ для дираковского поля соответствует обратному оператору $(i\not{\partial} - m)$. Другими словами, $S(x)$ определяется уравнением:

$$(i\not{\partial} - m)S(x) = \delta^{(4)}(x).$$

Как вы можете проверить, решение будет иметь вид:

$$iS(x) = \int \frac{d^4p}{(2\pi)^4} \frac{ie^{-ipx}}{p - m + i\varepsilon}$$

в согласии с (II.2.22).

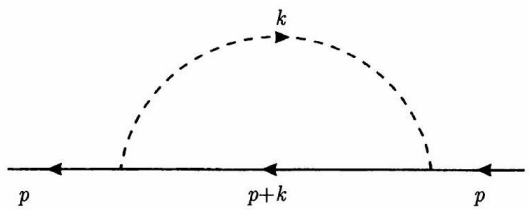

Рис. II.5.1

Правила Фейнмана для фермионов

Теперь получим правила Фейнмана для фермионов таким же образом, как и правила Фейнмана для скалярного поля. К примеру, воспользуемся теорией взаимодействия скалярного и дираковского полей

$$\mathcal{L} = \bar{\psi}\left(i\gamma^\mu\partial_\mu - m\right)\psi + \frac{1}{2}\left[(\partial\varphi)^2 - \mu^2\varphi^2\right] - \lambda\varphi^4 + f\varphi\bar{\psi}\psi$$

Производящий функционал

$$Z(\eta,\bar{\eta},J) = \int D\psi D\bar{\psi} D\varphi e^{iS(\psi,\bar{\psi},\varphi)+i\int d^4x(J\varphi+\bar{\eta}\psi+\bar{\psi}\eta)}$$

можно вычислить как двойной ряд по константам связи λ и f. Правила Фейнмана (исключая правила для чисто бозонного случая) формулируются следующим образом:

1. Нарисуйте диаграмму, используя сплошные линии для фермиона и пунктирные линии для бозона, и припишите каждой линии импульс, как, например, на рис. II.5.1.

2. Сопоставьте каждой фермионной линии пропагатор

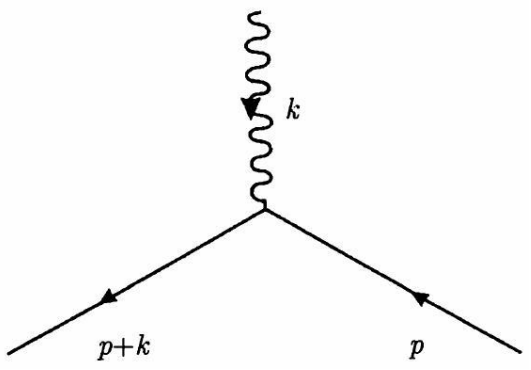
$$\frac{i}{p - m + i\varepsilon} = i\frac{\not{p} + m}{p^2 - m^2 + i\varepsilon}.$$

3. Сопоставьте каждую вершину взаимодействия с константой связи if и коэффициентом $(2\pi)^4\delta^{(4)}\left(\sum\limits_{\text{вх.}} p - \sum\limits_{\text{вых.}} p\right)$, выражающим закон сохранения импульса (суммируются входящие и выходящие импульсы соответственно).

4. По связанным с внутренними линиями импульсам проинтегрируйте с мерой $\int [d^4p/(2\pi)^4]$.

5. Внешние линии ампутируются. Для входящей фермионной линии пишем $u(p,s)$, а для выходящей фермионной линии $-\bar{u}(p',s')$. Источники и стоки должны различать спиновую поляризацию рожденных и поглощенных фермиона. [Для антифермионов имеем $v(p,s)$ и $\bar{v}(p',s')$].

6. Сопоставьте каждой замкнутой фермионной линии фактор (-1).



$ie\gamma^\mu$

Рис. II.5.2

Обратите внимание, что правило 6 справедливо только для фермионов, и в начале главы мы уже говорили об этом. Фейнмановская диаграмма, соответствующая вакуумным флуктуациям, не содержит внешних линий. Более подробно читайте в главе IV.3.

Для теории взаимодействия массивного векторного поля с дираковским полем, описываемой в главе II.1,

$$S(\psi,\bar{\psi},A)=\bar{\psi}\left[i\gamma^\mu\left(\partial_\mu-ieA_\mu\right)-m\right]\psi-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}-\frac{1}{2}\mu^2A_\mu A^\mu,$$

правила отличаются в следующем. Пропагатор векторного бозона равен:

$$\frac{i}{k^2-\mu^2}\left(\frac{k_\mu k_\nu}{\mu^2}-g_{\mu\nu}\right),$$

так что каждая векторная бозонная линия помечается не только импульсом, но и индексами μ и ν. Вершине (рис. II.5.2) соответствует $ie\gamma^\mu$.

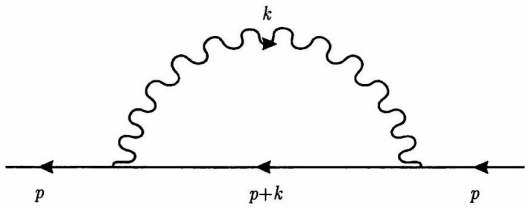


Рис. II.5.3

Упражнения

Зи-у.

II.5.1. Запишите фейнмановскую амплитуду для диаграммы на рис.

Зи-у.

II.5.1 для скалярной теории (уравнение (19)). Правильный ответ приведен в главе III.3.

Зи-у.

II.5.2. Применяя правила Фейнмана для векторной теории (22), покажите, что амплитуда для диаграммы на рис.

Зи-у.

II.5.3 будет иметь вид:

$$(ie)^2 i^2 \int \frac{d^4k}{(2\pi)^4} \frac{1}{k^2-\mu^2}\left(\frac{k_\mu k_\nu}{\mu^2}-g_{\mu\nu}\right)$$
$$\bar{u}(p)\gamma^\nu \frac{\not{p}+\not{k}+m}{(p+k)^2-m^2}\gamma^\nu u(p).$$

9.4.8 Зи.II.6 Electron Scattering and Gauge Invariance

Рассеяние электронов

Наконец, рассчитаем физический процесс, который можно провести и измерить экспериментальным путем. Рассмотрим два электрона, рассеивающихся друг на друге. На рис. II.6.1a,b приведены соответствующие фейнмановские диаграммы, в которых два электрона обмениваются фотоном.

Подождите, из главы I.5 мы знаем только пропагатор $iD_{\mu\nu} = [i/(k^2-\mu^2)](k_\mu k_\nu/\mu^2-\eta_{\mu\nu})$ для гипотетического массивного фотона. (Проведем очевидную замену: массу фотона будем обозначать μ, поскольку буквой m принято обозначать массу электрона.) В главе I.5 я изложил свою стратегию, согласно которой в последующих расчетах буду использовать ненулевое значение μ и надеяться на то, что в конце концов мы сможем положить μ равной нулю. Действительно, при вычислении потенциальной энергии между двумя внешними зарядами можно без проблем положить $\mu \to 0$ [см. уравнение (I.5.6)]. В этой и следующей главе мы проверим, всегда ли справедливо данное условие.

Применяя правила Фейнмана, находим амплитуду для диаграммы на рис. II.6.1a (передачу импульса при рассеянии берем равной $k = P_1 - p_1$):

$$A(P_1,P_2) =$$
$$= (-ie)^2 \frac{i}{(P_1-p_1)^2-\mu^2}\left(\frac{k_\mu k_\nu}{\mu^2}-\eta_{\mu\nu}\right)\bar{u}(P_1)\gamma^\mu u(p_1)\,\bar{u}(P_2)\gamma^\nu u(p_2) =$$
$$= (-ie)^2 \frac{(-i)}{(P_1-p_1)^2-\mu^2}\bar{u}(P_1)\gamma^\mu u(p_1)\,\bar{u}(P_2)\gamma_\mu u(p_2).$$

Мы пользовались тем, что $\bar{u}(P_1)$ и $u(p_1)$ удовлетворяют уравнениям движения, поэтому:

$$k_\mu \bar{u}\left(P_1\right)\gamma^\mu u\left(p_1\right) = \left(P_1 - p_1\right)_\mu \bar{u}\left(P_1\right)\gamma^\mu u\left(p_1\right) = \bar{u}\left(P_1\right)\left(\not{P}_1 - \not{p}_1\right) u\left(p_1\right) =$$
$$= \bar{u}\left(P_1\right)(m-m)u\left(p_1\right) = 0.$$

Это важное наблюдение означает, что член $k_\mu k_\nu/\mu^2$ в фотонном пропагаторе не дает вклада, следовательно, можно безболезненно положить массу фотона μ равной нулю. То есть

$$A\left(P_1, P_2\right) = \frac{ie^2}{\left(P_1 - p_1\right)^2}\bar{u}\left(P_1\right)\gamma^\mu u\left(p_1\right)\bar{u}\left(P_2\right)\gamma_\mu u\left(p_2\right)$$

Обратите внимание на то, что тождество, позволяющее нам положить μ равным нулю, является разновидностью условия сохранения электромагнитного тока в импульсном пространстве $\partial_\mu J^\mu = 0$, где $J^\mu = \bar{\psi}\gamma^\mu\psi$. Заметим, что это вычисление тесно связано с вычислением, которое мы провели, переходя от (I.5.4) к (I.5.5), только сейчас роль $J^\mu(k)$ играет $\bar{u}\left(P_1\right)\gamma^\mu u\left(p_1\right)$. Мы обозначили зависимость A исключительно от конечных импульсов. Согласно статистике Ферми, амплитуда для диаграммы на рис. II.6.1b будет равна $-A\left(P_2, P_1\right)$. Следовательно, амплитуда двух электронов, имеющих начальные импульсы p_1 и p_2 и рассеивающихся в два электрона с импульсами P_1 и P_2, равна

$$\mathcal{M} = A\left(P_1, P_2\right) - A\left(P_2, P_1\right)$$

Чтобы найти сечение, мы должны возвести в квадрат амплитуду:

$$\left|\mathcal{M}\right|^2 = \left[\left|A\left(P_1, P_2\right)\right|^2 + \left(P_1 \leftrightarrow P_2\right)\right] - 2\,\mathrm{Re}\,A\left(P_2, P_1\right)^* A\left(P_1, P_2\right)$$

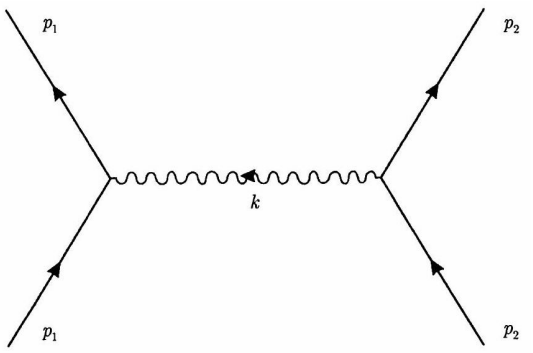
Теперь нам необходимо совершить довольно много выкладок, которые, однако, нельзя назвать сложными. Во-первых, член

$$\left|A\left(P_1, P_2\right)\right|^2 = \frac{e^4}{\left(P_1 - p_1\right)^4}\times$$
$$\times\left[\bar{u}\left(P_1\right)\gamma^\mu u\left(p_1\right)\bar{u}\left(p_1\right)\gamma^\nu u\left(P_1\right)\right]\left[\bar{u}\left(P_2\right)\gamma^\mu u\left(p_2\right)\bar{u}\left(p_2\right)\gamma^\nu u\left(P_2\right)\right]$$

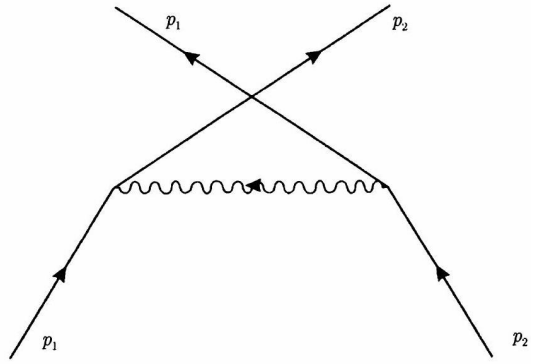
представляется в виде двух сомножителей так, что один из них содержит спиноры, несущие импульс с индексом 1, а другой - спиноры, несущие импульс с индексом 2. Напротив, интерференционный член $A\left(P_2, P_1\right)^* A\left(P_1, P_2\right)$ не факторизуется.

В простейших экспериментах начальные электроны не поляризованы и поляризация вылетающих электронов также не измеряется. Следовательно, можно провести усреднение по начальным спинам и суммирование по конечным спинам, используя соотношение (II.2.8):

$$\sum_s u(p,s)\bar{u}(p,s) = \frac{\not{p} + m}{2m}$$



(a)



(b)

Рис. II.6.1 Таким образом, усредняя и суммируя по спинам $|A(P_1,P_2)|^2$ приходим к выражению (спиновые значки выписаны явно):

$$\tau^{\mu\nu}(P_1,p_1)\equiv\sum_s\sum_S\bar{u}(P_1,S)\gamma^\mu u(p_1,s)\,\bar{u}(p_1,s)\gamma^\nu u(P_1,S)=$$
$$=\frac{1}{(2m)^2}\operatorname{tr}\left(\not{P}_1+m\right)\gamma^\mu\left(\not{p}_1+m\right)\gamma^\nu,$$

которое следует умножить на $\tau_{\mu\nu}(P_2,p_2)$. Аналогичным образом путем усреднения и суммирования $A(P_2,P_1)^*A(P_1,P_2)$ приходим к более сложному выражению

$$\varkappa\equiv\sum\sum\sum$$
$$\bar{u}(P_1)\gamma^\mu u(p_1)\,\bar{u}(P_2)\gamma_\mu u(p_2)\,\bar{u}(p_1)\gamma^\nu u(P_2)\,\bar{u}(p_2)\gamma_\nu u(P_1)$$

где для наглядности опущены спиновые значки. С учетом соотношения (6) можно записать $\varkappa$ в виде следа.

Теперь мы, точнее, вы должны научиться вычислять след произведения гамма-матриц. Ключевое наблюдение состоит в том, что квадрат гамма-матрицы равен либо +1, либо -1, а разные гамма-матрицы антикоммутируют. Отсюда очевидно, что след произведения нечетного количества гамма-матриц равен нулю. Таким образом,

$$\tau^{\mu\nu}(P_1,p_1)=\frac{1}{(2m)^2}\left[\operatorname{tr}\left(\not{P}_1\gamma^\mu\not{p}_1\gamma^\nu\right)+m^2\operatorname{tr}\left(\gamma^\mu\gamma^\nu\right)\right]$$

Если учесть, что

$$\mathrm{tr}\left(\not{P}_1\gamma^\mu\not{p}_1\gamma^\nu\right) = P_{1\rho}p_{1\lambda}\,\mathrm{tr}\left(\gamma^\rho\gamma^\mu\gamma^\lambda\gamma^\nu\right)$$

а также выражение для расчета следа произведения четного количества гамма-матриц, приведенное в приложении D, получим:

$$\tau^{\mu\nu}\left(P_1,p_1\right) = \frac{4}{(2m)^2}\left(P_1^\mu p_1^\nu - \eta^{\mu\nu}P_1\cdot p_1 + P_1^\nu p_1^\mu + m^2\eta^{\mu\nu}\right)$$

Более того, поскольку существуют лишь четыре различные гамма-матрицы, след произведения шести гамма-матриц всегда можно свести к следу произведения четырех гамма-матриц, ведь среди данных шести матриц всегда будут пары одинаковых матриц, которые можно поставить рядом антикоммутированием. Это справедливо и для следа произведения большего числа гамма-матриц. Расчет $\varkappa$ достаточно трудоемок, поскольку включает в себя вычисление следов произведения до восьми гамма-матриц. Мы ограничимся вычислением $\varkappa$ в релятивистском пределе, где m пренебрежимо мала по сравнению с импульсами:

$$\varkappa = \frac{1}{(2m)^4}\,\mathrm{tr}\left(\not{P}_1\gamma^\mu\not{p}_1\gamma^\nu\ \not{P}_2\gamma_\mu\not{p}_2\gamma_\nu\right)$$

Применяя к выражению (10) тождества, которые приведены в приложении D, получим:
$\mathrm{tr}\left(\not{P}_1\gamma^\mu\not{p}_1\gamma^\nu P_2\gamma_\mu\not{p}_2\gamma_\nu\right) = -2\,\mathrm{tr}\left(P_1\gamma^\mu\not{p}_1\not{p}_2\gamma_\mu\not{P}_2\right) = -32p_1\cdot p_2 P_1\cdot P_2$
В этом же пределе имеем

$$\tau^{\mu\nu}\left(P_1,p_1\right) = \frac{4}{(2m)^2}\left(P_1^\mu p_1^\nu + P_1^\nu p_1^\mu - \eta^{\mu\nu}P_1\cdot p_1\right)$$

и, следовательно,

$$\begin{aligned}
&\tau^{\mu\nu}\left(P_1,p_1\right)\tau_{\mu\nu}\left(P_2,p_2\right) = \\
&\quad = \frac{16}{(2m)^4}\left(P_1^\mu p_1^\nu + P_1^\nu p_1^\mu - \eta^{\mu\nu}P_1\cdot p_1\right)\left(2P_2^\mu p_2^\nu - \eta^{\mu\nu}P_2\cdot p_2\right) = \\
&\quad = \frac{16\cdot 2}{(2m)^4}\left(p_1\cdot p_2 P_1\cdot P_2 + p_1\cdot P_2 p_2\cdot P_1\right)
\end{aligned}$$

Хотя у меня нет цели обучить вас релятивистской кинематике и вычислснию сечений, чрезвычайно полезным иногда оказывается довести расчеты до логического завершения. В системе центра масс в релятивистском пределе: $p_1 = E(1,0,0,1), p_2 = E(1,0,0,-1), P_1 = E(1,\sin\theta,0,\cos\theta)$ и $P_2 = E(1,-\sin\theta,0,-\cos\theta)$. Следовательно, $p_1\cdot p_2 = P_1\cdot P_2 = -2E^2, p_1\cdot P_1 = p_2\cdot P_2 = 2E^2\sin^2(\theta/2)$ и $p_1\cdot P_2 = p_2\cdot P_1 = 2E^2\cos^2(\theta/2)$. Также в этом пределе выполняется условие $(P_1-p_1)^4 = \text{-}\ (-2p_1\cdot P_1)^2 = 16E^4\sin^4(\theta/2)$. Объединяя их вместе, приходим к выражснию $\frac{1}{2}\sum\limits_s\sum\limits_S|\mathcal{M}|^2 = (e^4/4m^4)\,f(\theta)$, в котором

$$f(\theta) = \frac{1+\cos^4(\theta/2)}{\sin^4(\theta/2)} + \frac{2}{\sin^2(\theta/2)\cos^2(\theta/2)} + \frac{1+\sin^4(\theta/2)}{\cos^4(\theta/2)}.$$

()изический смысл каждого из членов очевиден. Первый член характеризуст рассеяние, обусловленное фотонным пропагатором $\sim 1/k^2$. Третий член обусловлен неразличимостью двух вылетающих электронов: при $\theta\to\pi-\theta$ рассеяние должно быть симметрично, поскольку экспериментатор не в состоянии определить, какой из нелетающих электронов рассеивается вперед, а какой - в обратном направлении. Второй член представляет наибольший интерес:

он обусловлен квантовой интерференцией. Если ошибочно принять электроны за бозоны и учесть (3) со знаком плюс, второй член в выражении для $f(\theta)$ окажется со знаком минус. Разница огромна: например, $f(\pi/2)$ будет равна $5-8+5=2$, вместо $5+8+5=18$.

В связи с тем, что переход от квадрата амплитуды вероятности к эффективному сечению идейно аналогичен тому, как это делается в рамках нерелятивистской квантовой механики (делением на падающий поток и т. д.), я сошлюсь на соответствующую формулу в приложении С. В качестве упражнения попробуйте самостоятельно сделать последние шаги и вычислить дифференциальное сечение рассеяния:

$$\frac{d\sigma}{d\Omega}=\left(\frac{e^2}{4\pi}\right)^2\frac{1}{8E^2}f(\theta)$$

Эта удивительная физика

Если задуматься, теоретическая физика покажется удивительным занятием. Подготовив необходимое оборудование и осуществив процесс рассеяния электронов высокой энергии друг на друге, экспериментаторы действительно смогут определить дифференциальное сечение рассеяния, задаваемое формулой (12). В этом есть что-то почти магическое.

Зи-у.II.6.1. Проверьте утверждения из текста.

(??? напишу нормально вопрос тут.)

Зи-у.

II.6.2.
Вычислите сечение, приведенное в (12).

9.4.9 Зи.II.7 Diagrammatic Proof of Gauge Invariance

Калибровочная инвариантность

С концептуальной точки зрения нам важнее не вычислять сечения, а доказать тот факт, что мы действительно можем положить массу фотона μ равной нулю при вычислении любого физического процесса. При $\mu=0$ лагранжиан, который приведен в главе II.1, сводится к лагранжиану для квантовой электродинамики:

$$\mathcal{L}=\bar{\psi}\left[i\gamma^{\mu}\left(\partial_{\mu}-ieA_{\mu}\right)-m\right]\psi-\frac{1}{4}F_{\mu\nu}F^{\mu\nu}$$

Мы теперь готовы к одному из важнейших наблюдений в истории теоретической физики. Смотрите, лагранжиан левоинвариантен относительно калибровочного преобразования:

$$\psi(x)\to e^{i\Lambda(x)}\psi(x)$$

и

$$A_{\mu}(x)\to A_{\mu}(x)+\frac{1}{ie}e^{-i\Lambda(x)}\partial_{\mu}e^{i\Lambda(x)}=A_{\mu}(x)+\frac{1}{e}\partial_{\mu}\Lambda(x)$$

что означает

$$F_{\mu\nu}(x) \to F_{\mu\nu}(x)$$

Вы, конечно, уже знакомы с (3) и с инвариантностью $F_{\mu\nu}$ из классической электродинамики.

В современной теоретической физике калибровочная инвариантность [1] относится к числу фундаментальных и имеющих крайне важное значение, как мы увидим ниже. С современной точки зрения принято рассматривать лагранжиан (1) как следствие (2) и (3). Если мы хотим построить калибровочно-инвариантную релятивистскую теорию поля для полей со спинами $\frac{1}{2}$ и 1, мы с необходимостью придем к квантовой электродинамике.

Вы должны заметить, что в (3) я привел две эквивалентные формы. В большинстве учебных пособий пользуются второй формой, более простой, но не стоит забывать и про первую форму. Обратите внимание, что $\Lambda(x)$ и $\Lambda(x) + 2\pi$ приводят в точности к одинаковым преобразованиям. На математическом языке величины $e^{i\Lambda(x)}$ и $\partial_\mu \Lambda(x)$ хорошо определены, тогда как величина $\Lambda(x)$ - нет.

С учетом этих формальных, но физически важных замечаний мы можем приступить к работе над доказательством. Я оставляю вам самим дать общее доказательство, но покажу вам как это сделать, разобрав несколько характерных примеров.

Вспомним, что пропагатор гипотетического массивного фотона равен $iD_{\mu\nu} = i\left(k_\mu k_\nu/\mu^2 - g_{\mu\nu}\right)/\left(k^2 - \mu^2\right).\mu^2$ в знаменателе можно положить равной нулю, тогда выражение для фотонного пропагатора будет иметь вид $iD_{\mu\nu} = i\left(k_\mu k_\nu/\mu^2 - g_{\mu\nu}\right)/k^2$. Опасным является член $k_\mu k_\nu/\mu^2$. Мы хотим показать, что он выпадает.

Конкретный пример

Сначала рассмотрим электрон-электронное рассеяние с точностью до e^4. Среди всех возможных диаграмм сосредоточимся на двух, приведенных на рис. II.7.1a. Фейнмановская амплитуда равна:

$$\bar{u}\left(p'\right)\left(\gamma^\lambda \frac{1}{\not p + \not k - m}\gamma^\mu + \gamma^\mu \frac{1}{\not p' - \not k - m}\gamma^\lambda\right) u(p) \frac{i}{k^2}\left(\frac{k_\mu k_\nu}{\mu^2}\right)\Gamma^\nu_\lambda$$

где Γ^ν_λ - некоторый фактор, точная структура которого нас не интересует. Однако для конкретного случая, изображенного на рис. II.7.1a, мы, конечно, могли бы получить явное выражение для Γ^ν_λ. Обратите внимание на знак плюс, который обусловлен обменом двумя фотонами, подчиняющимися Бозе-статистике.

Обратимся к опасному члену. Сворачивая $\bar{u}\left(p'\right)(...)u(p)$ из (5) с k_μ, получаем

$$\bar{u}\left(p'\right)\left(\gamma^\lambda \frac{1}{\not p + \not k - m}\not k + \not k \frac{1}{\not p' - \not k - m}\gamma^\lambda\right) u(p)$$

Хитрость состоит в том, чтобы представить k в числителе первой дроби как $(\not p + k - m) - (\not p - m)$, а в числителе второй дроби как $(\not p - m) - (\not p$ - $-\not k - m)$. Поскольку $(\not p - m)u(p) = 0$ и $\bar{u}\left(p'\right)(\not p - m) = 0$, выражение (6) обращается в нуль, что доказывает теорему в этом простом случае. В связи с тем что в нашем доказательстве не фигурирует Γ^ν_λ в явном виде, оно будет справедливым даже в случае замены диаграммы на рис. II.7.1a более общей диаграммой на рис. II. 7.1b, в заштрихованной области которой могут протекать произвольно сложные процессы.

Можно обобщить доказательство на случай рис. II.7.1c. Помимо фотона, несущего импульс k, уже есть n фотонов на линии электрона. В доказательстве теоремы эти n фотонов

выступают в качестве «зрителей», точно так же, как фотон с импульсом k' на рис. II.7.1a не участвует в доказательстве утверждения о том, что (6) сокращается. Фотон с импульсом k может прицепляться к линии электрона в $n+1$ разных точках. Теперь в качестве упражнения попробуйте расширить доказательство на этот случай.

Попадание фотона на внутреннюю линию

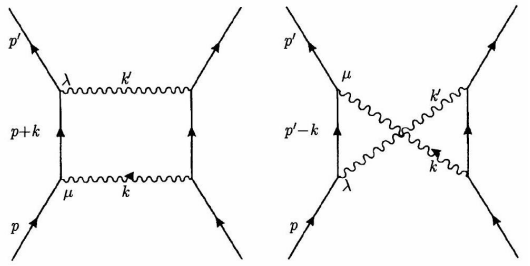
В только что рассмотренном нами примере фотонная линия оканчивается на внешней электронной линии. Ключевым моментом в доказательстве является тот факт, что линия «ограничена с двух концов» $\bar{u}(p')$ и $u(p)$. А что, если фотонная линия оканчивается на внутренней линии электрона?

На рис. II.7.2 изображен пример, соответствующий электрон-электронному рассеянию порядка e^8. Рисунок содержит три разные диаграммы. Электрон «слева» испускает три фотона, которые присоединяются ко внутренней электронной петле. Электрон «справа» испускает фотон с импульсом k, который может присоединиться к петле тремя разными способами.

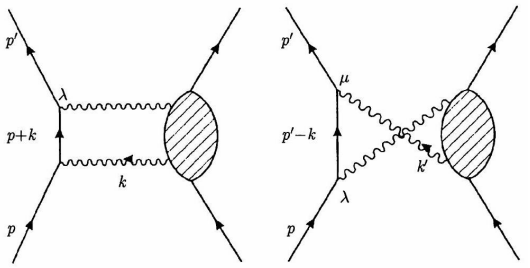
Поскольку нас интересует, исчезнет или нет член $k_\mu k_\rho/\mu^2$ из выражения для фотонного пропагатора $i\left(k_\mu k_\rho/\mu^2 - g_{\mu\rho}\right)/k^2$, заменим фотонный пропагатор на k_μ. Для удобства записи введем обозначения $p_1 = p+q_1$ и $p_2 = p_1+q_2$ (смотрите обозначения импульсов на рис. II.7.2). Рассмотрим лишь интересующие нас части трех диаграмм, обозначенных как A, B и C:

$$A = \int \frac{d^4p}{(2\pi)^4}\,\mathrm{tr}\left(\gamma^\nu \frac{1}{\not p_2 + k - m}\gamma^\sigma \frac{1}{\not p_1 + k - m}\gamma^\lambda \frac{1}{\not p + \not K - m}\not K \frac{1}{\not p - m}\right)$$

$$B = \int \frac{d^4p}{(2\pi)^4}\,\mathrm{tr}\left(\gamma^\nu \frac{1}{p_2 + \not K - m}\gamma^\sigma \frac{1}{\not p_1 + \not K - m}\not K \frac{1}{\not p_1 - m}\gamma^\lambda \frac{1}{\not p - m}\right)$$



(a)



(b)

Рис. II.7.1

И

$$C = \int \frac{d^4p}{(2\pi)^4}\,\mathrm{tr}\left(\gamma^\nu \frac{1}{\not p_2 + \not K - m}\not K \frac{1}{\not p_2 - m}\gamma^\sigma \frac{1}{\not p_1 - m}\gamma^\lambda \frac{1}{\not p - m}\right)$$

Создается впечатление, что с приведенными выражениями больше ничего нельзя сделать, однако это не так. Прибегнем к известному нам трюку

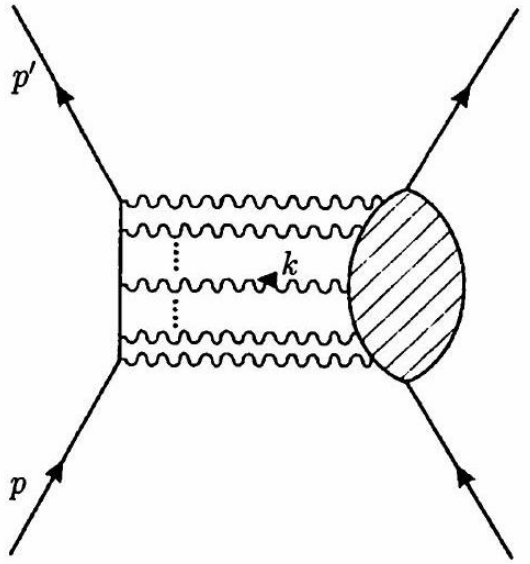


Рис. II.7.1. (Продолжение)

и представим $\not{k}$ в выражении для C как $\not{k} = (\not{p}_2 + \not{k} - m) - (\not{p}_2 - m)$ и получим:

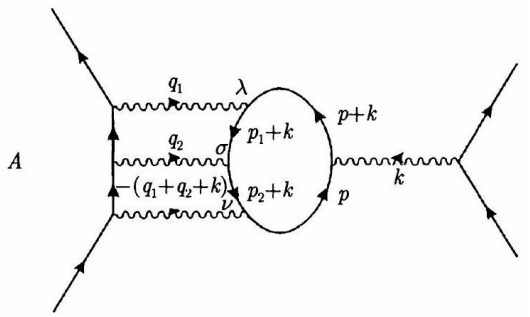
$$C = \int \frac{d^4p}{(2\pi)^4} \left[\mathrm{tr} \left(\gamma^\nu \frac{1}{p_2 - m} \gamma^\sigma \frac{1}{p_1 - m} \gamma^\lambda \frac{1}{\not{p}' - m} \right) - \right.$$
$$\left. - \mathrm{tr} \left(\gamma^\nu \frac{1}{p_2 + k - m} \gamma^\sigma \frac{1}{p_1 - m} \gamma^\lambda \frac{1}{p' - m} \right) \right].$$

В выражении для B запишем $k\prime = (p_1' + k\prime - m) - (p_1' - m)$, так что получим:

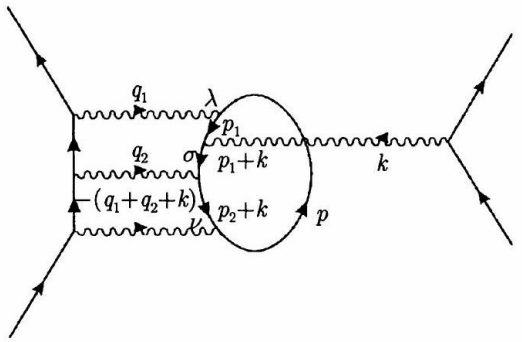
$$C = \int \frac{d^4p}{(2\pi)^4} \left[\mathrm{tr} \left(\gamma^\nu \frac{1}{p_2 + k - m} \gamma^\sigma \frac{1}{p_1 - m} \gamma^\lambda \frac{1}{p' - m} \right) - \right.$$
$$\left. - \mathrm{tr} \left(\gamma^\nu \frac{1}{p_2 + \not{l} - m} \gamma^\sigma \frac{1}{p_1 + k\prime - m} \gamma^\lambda \frac{1}{p' - m} \right) \right].$$

Наконец, в выражении для A запишем $\not{k} = (\not{p} + \not{k} - m) - (\not{p} - m)$, так что получим:

$$A = \int \frac{d^4p}{(2\pi)^4} \left[\mathrm{tr} \left(\gamma^\nu \frac{1}{p_2 + k - m} \gamma^\sigma \frac{1}{p_1 + k/ - m} \gamma^\lambda \frac{1}{p' - m} \right) - \right.$$
$$\left. - \mathrm{tr} \left(\gamma^\nu \frac{1}{p_2 + kb' - m} \gamma^\sigma \frac{1}{p_1 + k\prime - m} \gamma^\lambda \frac{1}{\not{l} + \not{l}' - m} \right) \right].$$



B



C

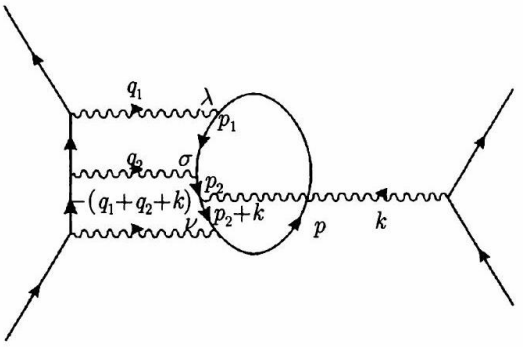


Рис. II.7.2 Теперь посмотрим, к чему это приведет. Если объединить все три диаграммы, члены попарно сократятся:

$$A+B+C=\int\frac{d^4p}{(2\pi)^4}\left[\mathrm{tr}\left(\gamma^\nu\frac{1}{\not p_2-m}\gamma^\sigma\frac{1}{\not p_1-m}\gamma^\lambda\frac{1}{\not p-m}\right)-\right.$$
$$\left.-\,\mathrm{tr}\left(\gamma^\nu\frac{1}{\not p_2+\not k-m}\gamma^\sigma\frac{1}{\not p_1+\not k-m}\gamma^\lambda\frac{1}{\not p+\not k-m}\right)\right]$$

Если сдвинуть (см. упражнение II.7.2) во втором члене переменную интегрирования $p\to p-k$, два члена взаимно сократятся. Действительно, в фотонном пропагаторе член $k_\mu k_\rho/\mu^2$ исчезает, так что можно положить $\mu=0$

Я оставляю вам найти общее доказательство. Мы получили его для одного конкретного процесса. Попробуте сами проделать то же самое для других процессов. Вы увидите, как оно работает.

Тождество Уорда-Такахаши

Подведем итоги. Если известна физическая амплитуда $T^{\mu\cdots}(k,...)$ со внешними электронами на массовой поверхности (т. е. все необходимые множители $u(p)$ и $\bar u(p)$ включены в $T^{\mu\cdots}(k,...)$), описывающая процесс испускания или поглощения фотона с импульсом k вершиной, обозначенной лоренцевым индексом μ, то выполняется условие:

$$k_\mu T^{\mu\cdots}(k,...)=0$$

Его иногда называют тождеством Уорда-Такахаши.

Решающим моментом служит представление фотонного пропагатора в виде $iD_{\mu\nu} = -ig^{\mu\nu}/k^2$. Раз мы можем исключить член $k_\mu k_\nu/\mu^2$ из фотонного пропагатора $i\left(k_\mu k_\nu/\mu^2 - g_{\mu\nu}\right)/k^2$, с тем же успехом мы можем добавить в него член $k_\mu k_\nu/k^2$ с произвольным коэффициентом. В результате получим фотонный пропагатор вида:

$$iD_{\mu\nu} = \frac{i}{k^2}\left[(1-\xi)\frac{k_\mu k_\nu}{k^2} - g_{\mu\nu}\right]$$

где для упрощения вычислений число ξ можно выбрать произвольным образом. Очевидно, что выбор значения ξ связан с выбором калибровки для электромагнитного поля. В частности, случай $\xi = 1$ известен под названием фейнмановской калибровки, а случай $\xi = 0$ - под названием калибровки Ландау. Если вы особенно удачно подберете иное значение ξ, можете назвать соответствующую калибровку в свою честь! Для простых вычислений разумно использовать произвольное значение ξ. Независимость конечного результата от ξ является полезной проверкой выкладок.

Итак, мы завершили вывод правил Фейнмана для квантовой электродинамики: они аналогичны правилам для теории массивного векторного бозона, которые даны в главе II.5, за исключением выражения (15) для фотонного пропагатора.

Таково диаграммное доказательство калибровочной инвариантности квантовой электродинамики. Впоследствии (в главе IV.7) мы увидим, что в некоторых случаях нельзя сдвигать, как при нашем доказательстве, импульс интегрирования.

Продольная мода

Вернемся к тому, что вызывало у нас беспокойство в главе I.5. Рассмотрим массивный мезон со спином 1, двигающийся в направлении z. Три вектора поляризации зафиксированы условием $k^\lambda\varepsilon_\lambda = 0$, где $k^\lambda = (\omega, 0, 0, k)$ (см. главу I.5), и нормировкой $\varepsilon^\lambda\varepsilon_\lambda = -1$, так что $\varepsilon_\lambda^{(1)} = (0,1,0,0), \varepsilon_\lambda^{(2)} = (0,0,1,0), \varepsilon_\lambda^{(3)} = (-k,0,0,\omega)/\mu$. Обратите внимание, что при $\mu \to 0$ вектор продольной поляризации $\varepsilon_\lambda^{(3)}$ пропорционален $k_\lambda = (\omega, 0, 0, -k)$. Амплитуда испускания мезона с продольной поляризацией в процессе, описываемом уравнением (14), равна $\varepsilon_\lambda^{(3)}T^{\lambda\cdots} = (-kT^{0\cdots} + +\omega T^{3\cdots})/\mu = \left(-kT^{0\cdots} + \sqrt{k^2+\mu^2}T^{3\cdots}\right)/\mu \simeq \left(-kT^{0\cdots} + \left(k + \frac{\mu^2}{2k}\right)T^{3\cdots}\right)/\mu$ (для $\mu \ll l$), т. е. $-k_\lambda T^{\lambda\cdots}/\mu + \frac{\mu}{2k}T^{3\cdots}$, где $k_\lambda = (k, 0, 0, -k)$. С учетом условия (14) приходим к тому, что при $\mu \to 0$ амплитуда $\frac{\mu}{2k}T^{3\cdots} \to 0$.

Продольная мода фотона не существует, так как она отщепляется во всех физических процессах.

Есть такой парадокс. Мистер Больцман утверждает, что при тепловом равновесии каждая степень свободы связана с $\frac{1}{2}T$. Значит, путем измерения некоторого теплового свойства (например, теплоемкости) ящика с фотонным газом с точностью 2/3 экспериментатор скорее подтвердит, что фотон действительно безмассов, чем скажет, что его масса равна одной миллиардной электрон-вольта.

Объяснение парадокса состоит в том, что по мере исчезновения продольной моды при $\mu \to 0$, время, необходимое продольной моде для уста- новления теплового равновесия, стремится к бесконечности. Экспериментатор из описанной парадоксальной ситуации должен в этом случае быть чрезвычайно терпеливым.

Упражнения

Зи-у.

II.7.1. Обобщите доказательство на случай, изображенный на рис. II.7.1c.
[Указание: обратите внимание на то, что рис. II.7.1b соответствует случаю $n = 1$.]

Зи-у.

II.7.2. Вы, наверное, хотели бы знать, когда можно сдвигать переменную интегрирования, а когда нельзя. Упрощая знаменатель в первом интеграле, в (13),

$$\int \frac{d^4p}{(2\pi)^4} \operatorname{tr}\left(\gamma^\nu \frac{1}{\not p_2 - m}\gamma^\sigma \frac{1}{\not p_1 - m}\gamma^\lambda \frac{1}{\not p - m}\right),$$

и вычислив след, вы можете убедиться, что этот интеграл расходится только логарифмически и, значит, сдвиг возможен. К этому вопросу мы еще раз вернемся в главе IV.7.

9.5 Spinor Field (fermions) 2: Other Properties and Conceptual Questions

(this shuold be rewritten, now structure does not match the title, I should go through this theory to find out what to delete and what to move????)

9.5.1 Lorentz Invariance of Wave Equations

(see field theory, there, there should be the same section)

Теория

В первую очередь мы должны поставить вопрос, к которому подошли в главе 2: что имеется в виду, когда говорят, что уравнение «релятивистски инвариантно»? Подходящим определением является следующее. Если ϕ - поле или совокупность полей и $\mathscr{D}$ - некоторый дифференциальный оператор, то утверждение, что уравнение $\mathscr{D}\phi = 0$ релятивистски инвариантно, означает, что если $\phi(x)$ удовлетворяет этому уравнению и мы совершаем преобразование Лоренца перехода к другой системе отсчета, то преобразованное поле в новой системе отсчета удовлетворяет тому же самому уравнению. Эквивалентно, можно применить одно и то же преобразование Лоренца ко всем частицам или полям, тогда уравнение $\mathscr{D}\phi = 0$ должно остаться справедливым и после преобразования. Далее мы будем придерживаться этой «активной» точки зрения на преобразования.

Лагранжева формулировка теории поля существенно облегчает вопрос о лоренц-инвариантности. Уравнение движения автоматически будет лоренц- инвариантным по данному выше определению, если это уравнение следует из лагранжиана, который является лоренцевым скаляром. Это - непосредственное следствие принципа наименьшего действия. Если преобразования Лоренца оставляют лагранжиан неизменным, то преобразованный экстремум действия будет снова экстремумом.

В качестве примера рассмотрим теорию Клейна-Гордона. Мы можем записать произвольное преобразование Лоренца как

$$x^\mu \to x'^\mu = \Lambda^\mu_\nu x^\nu$$

с какой-то 4×4-матрицей Λ. Что произойдет с полем Клейна-Гордона $\phi(x)$ при этом преобразовании? Представим себе поле ϕ как локальную меру некоторой величины, распределенной в пространстве. Если эта величина скапливается в точке $x = x_0$, тогда $\phi(x)$ будет иметь максимум в точке x_0. Если теперь подвергнуть первоначальное распределение преобразованию Лоренца, новое распределение будет иметь максимум в точке $x = \Lambda x_0$.

Это показано на рис. 3.1(a).

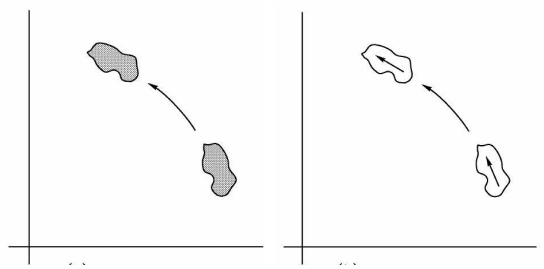

Рис. 3.1.

(a) скалярное поле (b) векторное поле

При вращении векторного поля изменяется ориентация вектора, а также расположение области локализации этого поля.

Соответствующее преобразование поля имеет вид:

$$\phi(x) \to \phi'(x) = \phi\left(\Lambda^{-1}x\right)$$

Иными словами, преобразованное поле, вычисленное в преобразованной точке, дает то же самое значение, что и первоначальное поле, вычисленное в исходной точке. Следует проверить, что это преобразование оставляет неизменной форму лагранжиана КлейнаГордона. Согласно (3.2) массовое слагаемое $\frac{1}{2}m^2\phi^2(x)$ просто смещается в точку $(\Lambda^{-1}x)$. Преобразование $\partial_\mu\phi(x)$ описывается формулой

$$\partial_\mu\phi(x) \to \partial_\mu\left(\phi\left(\Lambda^{-1}x\right)\right) = \left(\Lambda^{-1}\right)^\nu{}_\mu\left(\partial_\nu\phi\right)\left(\Lambda^{-1}x\right)$$

Так как метрический тензор $g^{\mu\nu}$ лоренц-инвариантен, матрицы Λ^{-1} удовлетворяют тождеству:

$$\left(\Lambda^{-1}\right)^\rho{}_\mu\left(\Lambda^{-1}\right)^\sigma{}_\nu g^{\mu\nu} = g^{\rho\sigma}.$$

Используя это соотношение, можно вычислить закон преобразования кинетического слагаемого в лагранжиане Клейна-Гордона:

$$\begin{aligned}\left(\partial_\mu\phi(x)\right)^2 &\to g^{\mu\nu}\left(\partial_\mu\phi'(x)\right)\left(\partial_\nu\phi'(x)\right) = \\ &= g^{\mu\nu}\left[\left(\Lambda^{-1}\right)^\rho{}_\mu\partial_\rho\phi\right]\left[\left(\Lambda^{-1}\right)^\sigma{}_\nu\partial_\sigma\phi\right]\left(\Lambda^{-1}x\right) = \\ &= g^{\rho\sigma}\left(\partial_\rho\phi\right)\left(\partial_\sigma\phi\right)\left(\Lambda^{-1}x\right) = \\ &= \left(\partial_\mu\phi\right)^2\left(\Lambda^{-1}x\right).\end{aligned}$$

Таким образом, весь лагранжиан преобразуется просто как скаляр:

$$\mathscr{L}(x) \to \mathscr{L}\left(\Lambda^{-1}x\right)$$

Действие S, полученное интегрированием $\mathscr{L}$ по пространству-времени, лоренц-инвариантно. Аналогичное вычисление показывает, что уравнение движения также лоренц-инвариантно:

$$\begin{aligned}\left(\partial^2 + m^2\right)\phi'(x) &= \left[\left(\Lambda^{-1}\right)_{\mu}^{\ \nu}\partial_\nu\left(\Lambda^{-1}\right)^{\sigma\mu}\partial_\sigma + m^2\right]\phi\left(\Lambda^{-1}x\right) = \\ &= \left(g^{\nu\sigma}\partial_\nu\partial_\sigma + m^2\right)\phi\left(\Lambda^{-1}x\right) = 0.\end{aligned}$$

Закон преобразования (3.2), использованный для поля ϕ, является простейшим из всех возможных законов преобразования полей. Для поля, имеющего одну компоненту, этот закон является единственно возможным. Но нам известны примеры многокомпонентных полей, которые преобразуются более сложным образом. Наиболее знакомый случай - векторное поле, например, плотность 4-тока $j^\mu(x)$ или вектор-потенциал $A^\mu(x)$. В этом случае величина, распределенная в пространстве-времени, имеет ориентацию, которая должна быть также преобразована. Как показано на рис. 3.1(б), ориентация должна вращаться в направлении перемещения точки, в которой вычисляется поле:

$$\begin{gathered}\text{при трехмерных вращениях } V^i(x) \to R^{ij}V^j\left(R^{-1}x\right); \\ \text{при преобразованиях Лоренца } V^\mu(x) \to \Lambda^\mu{}_\nu V^\nu\left(\Lambda^{-1}x\right).\end{gathered}$$

Тензоры произвольного ранга могут быть построены из векторов путем добавления большего количества индексов, и соответственно большего количества множителей Λ в законе преобразования. Используя такие векторные и тензорные поля, можно записать множество лоренц-инвариантных уравнений, например, уравнения Максвелла

$$\partial^\mu F_{\mu\nu} = 0 \quad \text{или \%} \quad \%\partial^2 A_\nu - \partial_\nu\partial^\mu A_\mu = 0,$$

которые следуют из лагранжиана

$$\mathscr{L}_{\text{Максвелл}} = -\frac{1}{4}\left(F_{\mu\nu}\right)^2 = -\frac{1}{4}\left(\partial_\mu A_\nu - \partial_\nu A_\mu\right)^2.$$

Вообще, любое уравнение, каждый член которого имеет одинаковое число не просуммированных (висячих) лоренцевых индексов, будет инвариантным по отношению к преобразованиям Лоренца. Такой метод тензорных обозначений позволяет построить большой класс лоренц-инвариантных уравнений, но оказывается, что таких уравнений намного больше. Как их искать? Можно было бы попробовать систематически найти все возможные законы преобразований поля. Тогда было бы нетрудно выписать инвариантные лагранжианы. Для простоты ограничимся линейными преобразованиями, так что, если Φ_a является n-компонентным мультиплетом, закон лоренцевского преобразования определяется $n \times n$ матрицей $M(\Lambda)$:

$$\Phi_a(x) \to M_{ab}(\Lambda)\Phi_b\left(\Lambda^{-1}x\right).$$

Можно показать, что наиболее общие нелинейные законы преобразований могут быть построены из этих линейных преобразований, поэтому нет смысла рассматривать преобразования, более общие, чем (3.8). В последующих рассуждениях мы будем опускать изменение аргумента поля и записывать преобразование (3.8) в виде:

$$\Phi \to M(\Lambda)\Phi.$$

Каков допустимый вид матриц $M(\Lambda)$? Основное ограничение на $M(\Lambda)$ можно найти, рассматривая два последовательных преобразования Λ и Λ'. Результат должен быть снова преобразованием Лоренца Λ'', т. е. преобразования Лоренца образуют группу. Это дает условие согласованности, которому должны удовлетворять матрицы $M(\Lambda)$. При последовательном действии двух преобразований

$$\Phi \to M\left(\Lambda'\right) M(\Lambda)\Phi = M\left(\Lambda''\right)\Phi$$

где $\Lambda'' = \Lambda'\Lambda$. Таким образом, соответствие между матрицами M и преобразованиями Λ должно сохраняться при умножении. На математическом языке мы говорим, что матрицы M должны образовывать n-мерное представление группы Лоренца. Таким образом, на математическом языке наш вопрос перефразируется следующим образом: каковы (конечномерные) матричные представления группы Лоренца?

Прежде чем ответить на этот вопрос для группы Лоренца, рассмотрим более простую группу трехмерных вращений. Эта группа имеет представления любой размерности n, известные в квантовой механике как матрицы, которые вращают n-компонентные волновые функции частиц различных спинов. Размерность связана со спиновым квантовым числом s формулой $n = 2s + 1$. Наиболее важное нетривиальное представление - двумерное представление, соответствующее спину $1/2$. Матрицы этого представления - 2×2 унитарные матрицы с детерминантом, равным 1, которые могут быть представлены как

$$U = e^{-i\theta^i\sigma^i/2},$$

где θ^i - три произвольных параметра и σ^i - сигма-матрицы Паули.

Для любой непрерывной группы преобразования, бесконечно близкие к тождественному, определяют векторное пространство, называемое алгеброй Ли этой группы. Базисные векторы этого векторного пространства называются генераторами алгебры или группы Ли. Для группы вращений генераторы - это операторы углового момента J^i, которые удовлетворяют коммутационным соотношениям

$$\left[J^i, J^j\right] = i\varepsilon^{ijk}J^k.$$

Конечные преобразования вращения получаются экспоненцированием этих генераторов или операторов. В квантовой механике оператор

$$R = \exp\left[-i\theta^i J^i\right]$$

определяет вращение на угол $|\theta|$ вокруг оси $\hat{\theta}$. Коммутационные соотношения операторов J^i определяют законы умножения этих преобразований вращения. Таким образом, набор матриц, удовлетворяющих коммутационным соотношениям (3.12), дает при помощи экспоненцирования, как в (3.13), представление группы вращений. В примере из предыдущего раздела представление операторов углового момента

$$J^i \to \frac{\sigma^i}{2}$$

дает представление группы вращений (3.11). Имеет место общее утверждение: матричные представления непрерывной группы можно получить, зная матричные представления генераторов этой группы (которые должны удовлетворять соответствующим

коммутационным соотношениям) с последующим экспоненцированием этих бесконечно малых преобразований.

Для решения рассматриваемой задачи необходимо знать коммутационные соотношения генераторов преобразований группы Лоренца. Для группы вращений можно найти коммутационные соотношения, записывая генераторы, как дифференциальные операторы. Из выражения

$$\mathbf{J} = \mathbf{x} \times \mathbf{p} = \mathbf{x} \times (-i\nabla)$$

непосредственно следуют коммутационные соотношения (3.12) для углового момента. Использование векторного произведения в (3.15) характерно для трехмерного пространства. Однако можно также записать эти операторы в виде антисимметричных тензоров:

$$J^{ij} = -i\left(x^i\nabla^j - x^j\nabla^i\right)$$

так что $J^3 = J^{12}$ и так далее. Обобщение на четырехмерные преобразования Лоренца теперь очевидно:

$$J^{\mu\nu} = i\left(x^\mu\partial^\nu - x^\nu\partial^\mu\right).$$

Вскоре мы увидим, что эти шесть операторов группы Лоренца генерируют три собственно лоренцевых преобразования и три преобразования пространственных вращений.

Чтобы определить коммутационные соотношения в алгебре Лоренца, можно просто вычислить коммутаторы дифференциальных операторов (3.16). В результате

$$[J^{\mu\nu}, J^{\rho\sigma}] = i\left(g^{\nu\rho}J^{\mu\sigma} - g^{\mu\rho}J^{\nu\sigma} - g^{\nu\sigma}J^{\mu\rho} + g^{\mu\sigma}J^{\nu\rho}\right)$$

Любые матрицы, которые представляют эту алгебру, должны удовлетворять таким же коммутационным соотношениям.

Чтобы увидеть, что мы получили, рассмотрим одно конкретное представление. Возьмем 4×4 матрицы

$$\left(\mathscr{J}^{\mu\nu}\right)_{\alpha\beta} = i\left(\delta^\mu_\alpha\delta_{\beta\beta} - \delta^\mu_\beta\delta^\nu_\alpha\right).$$

(Здесь μ и ν нумеруют каждую из шести матриц, в то время как α и β нумеруют матричные элементы.) Можно легко проверить, что эти матрицы удовлетворяют коммутационным соотношениям (3.17). Действительно, они являются ничем иным, как матрицами, действующими на обычные лоренцевы 4-векторы. Чтобы увидеть это, параметризуем бесконечно малые преобразования следующим образом:

$$V^\alpha \to \left(\delta^\alpha\beta - \frac{i}{2}\omega_{\mu\nu}\left(\mathscr{J}^{\mu\nu}\right)^\alpha{}_\beta\right)V^\beta,$$

где V – 4-вектор и $\omega_{\mu\nu}$ - антисимметричный тензор, задающий бесконечно малые углы. Например, рассмотрим случай, когда $\omega_{12} = -\omega_{21} = \theta$, а все остальные компоненты ω равны нулю. Тогда (3.19) дает

$$V \to \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & -\theta & 0 \\ 0 & \theta & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} V$$

что представляет бесконечно малое вращение в плоскости xy. Можно также проверить, что, полагая $\omega_{01} = -\omega_{10} = \beta$, получим

$$V \to \begin{pmatrix} 1 & \beta & 0 & 0 \\ \beta & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} V$$

и это является бесконечно малым бустом в направлении оси x. Другие компоненты ω генерируют оставшиеся бусты и вращения.

9.5.2 Dirac Equation

Теория

Теперь, когда мы нашли одно конечномерное представление группы Лоренца, следующим логическим шагом является разработка формализма для нахождения всех других представлений. Хотя это не очень трудно сделать (см. задачу 3.1), это едва ли необходимо для наших целей, так как нас главным образом интересуют представления, соответствующие спину 1/2. Мы можем найти такое представление, используя прием Дирака. Предположим, что мы имеем набор из четырех $n \times n$ матриц γ^μ, удовлетворяющих антикоммутационным соотношениям:

$$\{\gamma^\mu, \gamma^\nu\} \equiv \gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2g^{\mu\nu} \times \mathbf{1}_{n\times n}\% \quad \% \text{ (алгебра Дирака)}$$

Тогда можно немедленно записать n-мерное представление алгебры Лоренца. Оно имеет вид:

$$S^{\mu\nu} = \frac{i}{4}[\gamma^\mu, \gamma^\nu]$$

Повторно используя (3.22), легко проверить, что эти матрицы удовлетворяют коммутационным соотношениям (3.17).

Это вычисление можно выполнить в пространстве любой размерности с лоренцевой или евклидовой метрикой. В частности, оно должно быть верным в трехмерном евклидовом пространстве. Действительно, можно просто взять

$$\begin{aligned} &\gamma^j \equiv i\sigma^j\% \quad \% \text{ (сигма-матрицы Паули)}, \\ \text{так что} \quad &\{\gamma^i, \gamma^j\} = -2\delta^{ij}. \end{aligned}$$

Множитель i в первой строке и знак «минус» во второй строке полностью условны. Тогда матрицы, представляющие алгебру Лоренца, имеют вид:

$$S^{ij} = \frac{1}{2}\varepsilon^{ijk}\sigma^k,$$

и мы узнаем известное двумерное представление группы вращений.

Теперь найдем матрицы Дирака γ^μ для четырехмерного пространства Минковского. Оказывается, что они должны быть по крайней мере матрицами 4×4.(Не существует четвертой 2×2 матрицы, которая антикоммутирует с тремя сигма-матрицами Паули.) Далее, все 4×4 представления алгебры Дирака унитарно эквивалентны * Таким образом,

нужно выписать только одну явную реализацию алгебры Дирака. Одно представление в форме 2×2 блоков имеет вид:

$$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}; \quad \gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}.$$

Это представление называется представлением Вейля или киральным представлением. Мы увидим, что это представление наиболее удобно, и будем использовать именно его на протяжении всей книги. (Однако будьте внимательными, так как многие учебники по теории поля выбирают другое представление, в котором γ^0 является диагональной. Кроме того, в книгах, использующих киральные представления, часто выбирают другие соглашения о знаках.)

В нашем представлении генераторы буста имеют вид:

$$S^{0i} = \frac{i}{4}\left[\gamma^0, \gamma^i\right] = -\frac{i}{2}\begin{pmatrix} \sigma^i & 0 \\ 0 & -\sigma^i \end{pmatrix},$$

а генераторы пространственных вращений равны

$$S^{ij} = \frac{i}{4}\left[\gamma^i, \gamma^j\right] = \frac{1}{2}\varepsilon^{ijk}\begin{pmatrix} \sigma^k & 0 \\ 0 & \sigma^k \end{pmatrix} \equiv \frac{1}{2}\varepsilon^{ijk}\Sigma^k.$$

*Это и предшествующее утверждения следуют из общей теории представлений группы Лоренца, изложенной в задаче 3.1. Четырехкомпонентное поле ψ, преобразующееся при бустах и вращениях согласно (3.26) и (3.27), называется дираковским спинором. Заметим, что генератор вращений S^{ij} представляет собой в точности трехмерную спинорную матрицу преобразования (3.24), взятую дважды. Генераторы бустов S^{0i} не являются эрмитовыми и, таким образом, наша реализация бустов неунитарна (это было верно и для векторного представления (3.18)). Действительно, так как группа Лоренца некомпактна, она не имеет однозначных конечномерных унитарных представлений. Но для нас это не имеет значения, поскольку ψ является не волновой функцией, а классическим полем.

Теперь, когда известен закон преобразования для ψ, следует найти соответствующее полевое уравнение. Одна из возможностей - просто взять уравнение КлейнаГордона:

$$\left(\partial^2 + m^2\right)\psi = 0.$$

Это уравнение годится, поскольку спинорные матрицы преобразования (3.26) и (3.27) действуют только во «внутреннем» пространстве; они коммутируют с дифференциальным оператором. Но можно написать более сильное уравнение первого порядка, содержащее дополнительную информацию и включающее (3.28). Для этого понадобится еще одно свойство γ-матриц. При помощи несложных вычислений можно проверить, что

$$[\gamma^\mu, S^{\rho\sigma}] = (\mathscr{J}^{\rho\sigma})^\mu_\nu \gamma^\nu,$$

или эквивалентно,

$$\left(1 + \frac{i}{2}\omega_{\rho\sigma}S^{\rho\sigma}\right)\gamma^\mu\left(1 - \frac{i}{2}\omega_{\rho\sigma}S^{\rho\sigma}\right) = \left(1 - \frac{i}{2}\omega_{\rho\sigma}\mathscr{J}^{\rho\sigma}\right)^\mu\gamma^\nu$$

Это уравнение есть инфинитизимальная форма соотношения

$$\Lambda^{-1}_{\frac{1}{2}}\gamma^\mu\Lambda_{\frac{1}{2}} = \Lambda^\mu_\nu\gamma^\nu$$

где

$$\Lambda_{\frac{1}{2}} = \exp\left(-\frac{i}{2}\omega_{\mu\nu}S^{\mu\nu}\right)$$

является спинорным представлением преобразования Лоренца Λ (сравни с (3.19)). Уравнение (3.29) показывает, что γ-матрицы инвариантны относительно одновременного вращения по векторным и спинорным индексам (точно так же как σ^i инвариантны при пространственных вращениях). Другими словами, можно воспринимать векторный индекс μ в γ^μ всерьез и сворачивать γ^μ с ∂_μ, чтобы образовать лоренц-инвариантный дифференциальный оператор.

Теперь мы готовы записать уравнение Дирака. Оно имеет вид:

$$\left(i\gamma^\mu\partial_\mu - m\right)\psi(x) = 0$$

Чтобы показать, что это уравнение лоренц-инвариантно, подвергнем лоренцевскому преобразованию его левую часть и проведем соответствующие вычисления:

$$\begin{aligned}
\left[i\gamma^\mu\partial_\mu - m\right]\psi(x) \to \left[i\gamma^\mu \left(\Lambda^{-1}\right)^\nu{}_\mu\partial_\nu - m\right]\Lambda_{\frac{1}{2}}\psi\left(\Lambda^{-1}x\right) = \\
= \Lambda_{\frac{1}{2}}\Lambda^{-1}_{\frac{1}{2}}\left[i\gamma^\mu \left(\Lambda^{-1}\right)^\nu{}_\mu\partial_\nu - m\right]\Lambda_{\frac{1}{2}}\psi\left(\Lambda^{-1}x\right) = \\
= \Lambda_{\frac{1}{2}}\left[i\Lambda^{-1}_{\frac{1}{2}}\gamma^\mu\Lambda_{\frac{1}{2}}\left(\Lambda^{-1}\right)^\nu{}_\mu\partial_\nu - m\right]\psi\left(\Lambda^{-1}x\right) = \\
= \Lambda_{\frac{1}{2}}\left[i\Lambda^\mu_\sigma\gamma^\sigma\left(\Lambda^{-1}\right)^\nu_\mu\partial_\nu - m\right]\psi\left(\Lambda^{-1}x\right) = \\
= \Lambda_{\frac{1}{2}}\left[i\gamma^\nu\partial_\nu - m\right]\psi\left(\Lambda^{-1}x\right) = 0.
\end{aligned}$$

Чтобы увидеть, что из уравнения Дирака вытекает уравнение Клейна-Гордона, подействуем слева оператором $(-i\gamma^\mu\partial_\mu - m)$:

$$\begin{aligned}
0 = \left(-i\gamma^\mu\partial_\mu - m\right)\left(i\gamma^\nu\partial_\nu - m\right)\psi = \left(\gamma^\mu\gamma^\nu\partial_\mu\partial_\nu + m^2\right)\psi = \\
= \left(\frac{1}{2}\left\{\gamma^\mu,\gamma^\nu\right\}\partial_\mu\partial_\nu + m^2\right)\psi = \left(\partial^2 + m^2\right)\psi
\end{aligned}$$

Чтобы записать лагранжиан для теории Дирака, нужно установить, как умножать два дираковских спинора, чтобы получить лоренцевский скаляр. Простейшее предположение $\psi^\dagger\psi$ не проходит. При лоренцевском преобразовании получаем $\psi^\dagger\Lambda^\dagger_{\frac{1}{2}}\Lambda_{\frac{1}{2}}\psi$; если бы матрица буста была унитарна, мы бы имели $\Lambda^\dagger_{\frac{1}{2}} = \Lambda^{-1}_{\frac{1}{2}}$, и все было бы прекрасно. Но матрица $\Lambda_{\frac{1}{2}}$ неунитарна, потому что генераторы (3.26) неэрмитовы.

Решение заключается в том, чтобы определить

$$\bar{\psi} \equiv \psi^\dagger\gamma^0$$

При бесконечно малом преобразовании Лоренца, параметризованном величинами $\omega_{\mu\nu}$, $\bar{\psi} \to \psi^\dagger\left(1 + \frac{i}{2}\omega_{\mu\nu}\left(S^{\mu\nu}\right)^\dagger\right)\gamma^0$. Сумма по μ и ν имеет шесть различных отличных от нуля слагаемых. Во вращательных слагаемых, где μ и ν оба отличны от нуля, $\left(S^{\mu\nu}\right)^\dagger = S^{\mu\nu}$ и $S^{\mu\nu}$ коммутирует с γ^0. В слагаемых, отвечающих бусту, где индекс μ или ν равен 0, $\left(S^{\mu\nu}\right)^\dagger = -\left(S^{\mu\nu}\right)$, но при этом $S^{\mu\nu}$ антикоммутирует с γ^0. Поэтому перенос γ^0 налево снимает знак эрмитова сопряжения у $S^{\mu\nu}$, и в результате приходим к закону преобразования:

$$\bar{\psi} \to \bar{\psi}\Lambda^{-1}_{\frac{1}{2}}$$

Таким образом, величина $\bar{\psi}\psi$ есть лоренцевский скаляр. Аналогично можно показать при помощи (3.29), что $\bar{\psi}\gamma^\mu\psi$ является лоренцевским вектором.

Поэтому лоренц-инвариантный дираковский лагранжиан имеет вид:

$$\mathscr{L}_{\text{Dirac}} = \bar{\psi}\left(i\gamma^\mu\partial_\mu - m\right)\psi.$$

Уравнение Эйлера-Лагранжа для $\bar{\psi}$ (или $\psi^\dagger$) немедленно приводит к уравнению Дирака в форме (3.31); уравнение Эйлера-Лагранжа для ψ дает то же самое уравнение для эрмитово-сопряженной формы:

$$-i\partial_\mu\bar{\psi}\gamma^\mu - m\bar{\psi} = 0$$

9.5.3 Weyl Spinors

Теория

Из блочно-диагонального вида генераторов (3.26) и (3.27) видно, что представление Дирака группы Лоренца приводимо*. Мы можем образовать два 2-мерных представления, рассматривая каждый блок отдельно и записав

$$\psi = \begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix}$$

Кстати, при использовании другого представления гамма-матриц приводимость не столь явная; это, по существу, и является причиной использования кирального представления.

Двухкомпонентные объекты ψ_L и ψ_R называются левым и правым вейлевскими спинорами, соответственно. Можно легко проверить, что их законы преобразования при бесконечно малых вращениях $\boldsymbol{\theta}$ и бустах $\boldsymbol{\beta}$ имеют вид:

$$\psi_L \to \left(1 - i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} - \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_L$$
$$\psi_R \to \left(1 - i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} + \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)\psi_R$$

Эти законы преобразования связаны комплексным сопряжением. Используя тождество

$$\sigma^2\sigma^* = -\sigma\sigma^2,$$

нетрудно показать, что величина $\sigma^2\psi_L^*$ преобразуется подобно правому спинору.

С помощью ψ_L и ψ_R уравнение Дирака записывается в виде:

$$\left(i\gamma^\mu\partial_\mu - m\right)\psi = \begin{pmatrix} -m & i\left(\partial_0 + \boldsymbol{\sigma}\cdot\boldsymbol{\nabla}\right) \\ i\left(\partial_0 - \sigma\cdot\nabla\right. & \end{pmatrix}\begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix} = 0$$

В уравнении Дирака два представления группы Лоренца ψ_L и ψ_R перемешиваются за счет массового слагаемого. Но если положить $m = 0$, то уравнения для ψ_L и ψ_R расцепляются:

$$i\left(\partial_0 - \sigma\cdot\nabla\right)\psi_L = 0$$
$$i\left(\partial_0 + \sigma\cdot\nabla\right)\psi_R = 0$$

Они называются уравнениями Вейля. Эти уравнения особенно важны при рассмотрении нейтрино и теории слабых взаимодействий.

Возможно некоторое усовершенствование введенных обозначений. Определим

$$\sigma^\mu \equiv (1, \sigma), \quad \bar{\sigma}^\mu \equiv (1, -\sigma),$$

так что

$$\gamma^\mu = \begin{pmatrix} 0 & \sigma^\mu \\ \bar{\sigma}^\mu & 0 \end{pmatrix}$$

(Черта в $\bar{\sigma}$ не имеет никакого отношения к черте в $\bar{\psi}$.) Тогда уравнение Дирака может быть записано в виде

$$\begin{pmatrix} -m & i\sigma \cdot \partial \\ i\bar{\sigma} \cdot \partial & -m \end{pmatrix} \begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix} = 0$$

а уравнения Вейля примут вид:

$$i\bar{\sigma} \cdot \partial \psi_L = 0; \quad i\sigma \cdot \partial \psi_R = 0.$$

9.5.4 Solutions of the Dirac Equation for Free Particles

Теория

Чтобы ощутить физический смысл уравнения Дирака, обсудим его решения в виде плоских волн. Так как поле Дирака ψ удовлетворяет уравнению Клейна-Гордона, мы немедленно делаем вывод, что оно может быть записано как линейная комбинация плоских волн:

$$\psi(x) = u(p)e^{-ip\cdot x}, \quad \text{где } p^2 = m^2$$

На время сосредоточим внимание на решениях с положительной частотой, т. е. при $p^0 > 0$. Вектор-столбец $u(p)$ должен удовлетворять дополнительному ограничению, которое находится путем подстановки (3.45) в уравнение Дирака:

$$(\gamma^\mu p_\mu - m)\, u(p) = 0$$

Проще всего проанализировать это уравнение в системе покоя частицы, где $p = p_0 = (m, \mathbf{0})$. Решение для произвольного p может быть затем найдено при помощи буста с $\Lambda_{\frac{1}{2}}$. В системе покоя (3.46) принимает вид:

$$\left(m\gamma^0 - m\right) u\left(p_0\right) = m \begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix} u\left(p_0\right) = 0$$

Его решения имеют вид

$$u\left(p_0\right) = \sqrt{m} \begin{pmatrix} \xi \\ \xi \end{pmatrix}$$

для любого числового двухкомпонентного спинора ξ. Мы, как обычно, нормируем ξ так, что $\xi^\dagger \xi = 1$; множитель $\sqrt{m}$ вставлен из соображений удобства. Спинор ξ можно

интерпретировать, рассматривая генератор вращения (3.27). Величина ξ преобразуется при вращениях как обычный двухкомпонентный спинор группы вращения и, следовательно, обычным образом определяет ориентацию спина частицы, описываемой этим дираковским решением. Например, когда $\xi = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$, спин частицы ориентирован вверх вдоль третьей оси.

Заметим, что после использования уравнения Дирака можно произвольно выбрать только две из четырех компонент поля $u(p)$. Это как раз то, что нужно, так как частица со спином $1/2$ имеет только два физических состояния со спином вверх и вниз. (Конечно, здесь несколько преждевременно говорить о частицах и спине. Мы докажем в разделе 3.5 после квантования поля Дирака, что спиновый угловой момент дираковской частицы равен $\hbar/2$. Пока только обратим внимание, что для любого импульса p имеются два возможных решения $u(p)$.

Теперь, когда известен общий вид решения $u(p)$ в системе покоя, можно получить $u(p)$ в любой другой системе путем применения буста. Рассмотрим буст вдоль третьей оси. Сначала мы должны вспомнить, как буст действует на 4-вектор. В инфинитезимальной форме

$$\begin{pmatrix} E \\ p^3 \end{pmatrix} = \left[1 + \eta \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\right] \begin{pmatrix} m \\ 0 \end{pmatrix}$$

где η - бесконечно малый параметр. Для конечного η следует написать:

$$\begin{aligned} \begin{pmatrix} E \\ p^3 \end{pmatrix} &= \exp\left[\eta \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\right] \begin{pmatrix} m \\ 0 \end{pmatrix} = \\ &= \left[\operatorname{ch}\eta \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \operatorname{sh}\eta \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}\right] \begin{pmatrix} m \\ 0 \end{pmatrix} = \begin{pmatrix} m \operatorname{ch}\eta \\ m \operatorname{sh}\eta \end{pmatrix} \end{aligned}$$

Параметр η называется быстротой. Эта величина является аддитивной при последовательных бустах. Теперь применим то же самое преобразование к $u(p)$. Соглас- но (3.26) и (3.30),

$$\begin{aligned} u(p) &= \exp\left[-\frac{1}{2}\eta \begin{pmatrix} \sigma^3 & 0 \\ 0 & -\sigma^3 \end{pmatrix}\right] \sqrt{m} \begin{pmatrix} \xi \\ \xi \end{pmatrix} = \\ &= \left[\operatorname{ch}\left(\frac{1}{2}\eta\right) \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} - \operatorname{sh}\left(\frac{1}{2}\eta\right) \begin{pmatrix} \sigma^3 & 0 \\ 0 & -\sigma^3 \end{pmatrix}\right] \sqrt{m} \begin{pmatrix} \xi \\ \xi \end{pmatrix} = \\ &= \begin{pmatrix} e^{\eta/2}\left(\frac{1-\sigma^3}{2}\right) + e^{-\eta/2}\left(\frac{1+\sigma^3}{2}\right) & 0 \\ 0 & e^{\eta/2}\left(\frac{1+\sigma^3}{2}\right) + e^{-\eta/2}\left(\frac{1-\sigma^3}{2}\right) \end{pmatrix} \sqrt{m} \begin{pmatrix} \xi \\ \xi \end{pmatrix} = \\ &= \begin{pmatrix} \left[\sqrt{E+p^3}\left(\frac{1-\sigma^3}{2}\right) + \sqrt{E-p^3}\left(\frac{1+\sigma^3}{2}\right)\right]\xi \\ \left[\sqrt{E+p^3}\left(\frac{1+\sigma^3}{2}\right) + \sqrt{E-p^3}\left(\frac{1-\sigma^3}{2}\right)\right]\xi \end{pmatrix}. \end{aligned}$$

Последняя строка может быть упрощена, так что

$$u(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar{\sigma}}\xi \end{pmatrix},$$

где предполагается, что при взятии квадратного корня из матрицы мы извлекаем положительный корень из каждого собственного значения. Это выражение для $u(p)$ не

только более компактно, но и сохраняет силу для произвольного направления p. При работе с выражениями такого вида полезно знать тождество

$$(p \cdot \sigma)(p \cdot \bar{\sigma}) = p^2 = m^2.$$

Теперь можно непосредственно проверить, что (3.50) есть решение уравнения Дирака в форме (3.43).

На практике часто удобно работать со специальными спинорами ξ. Полезным был бы выбор собственных состояний σ^3. Например, если $\xi = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ (спин вверх вдоль третьей оси), имеем:

$$u(p) = \begin{pmatrix} \sqrt{E-p^3}\begin{pmatrix} 1 \\ 0 \end{pmatrix} \\ \sqrt{E+p^3}\begin{pmatrix} 1 \\ 0 \end{pmatrix} \end{pmatrix} \xrightarrow[\text{большой буст}]{} \sqrt{2E}\begin{pmatrix} 0 \\ \begin{pmatrix} 1 \\ 0 \end{pmatrix} \end{pmatrix},$$

в то время как для $\xi = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$ (спин вниз вдоль третьей оси)

$$\boldsymbol{u(p) = \begin{pmatrix} \sqrt{E+p^3}\begin{pmatrix} 0 \\ 1 \end{pmatrix} \\ \sqrt{E-p^3}\begin{pmatrix} 0 \\ 1 \end{pmatrix} \end{pmatrix} \xrightarrow[\text{большой буст}]{} \sqrt{2E}\begin{pmatrix} \begin{pmatrix} 0 \\ 1 \end{pmatrix} \\ 0 \end{pmatrix}.}$$

В пределе $\eta \to \infty$ состояния вырождаются в два двухкомпонентных спинора для безмассовой частицы. (Теперь видна причина введения множителя $\sqrt{m}$ в (3.47) - он сохраняет конечность выражений для спиноров в безмассовом пределе.)

Решения (3.52) и (3.53) являются собственными состояними оператора спиральности

$$h \equiv \hat{p} \cdot \mathbf{S} = \frac{1}{2}\hat{p}_i \begin{pmatrix} \sigma^i & 0 \\ 0 & \sigma^i \end{pmatrix}$$

Частица с $h = +1/2$ называется правополяризованной, в то время как частица с $h = -1/2$ - левополяризованной. Спиральность массивной частицы зависит от системы отсчета, так как всегда можно перейти к системе отсчета, в которой импульс частицы противоположно направлен (но ее спин неизменен). Для безмассовой частицы, которая движется со скоростью света, такое преобразование выполнить нельзя.

Чрезвычайно простая форма $u(p)$ для безмассовой частицы в состоянии с определенной спиральностью делает понятным поведение такой частицы. В гл. 1 это дало возможность установить форму сечения рассеяния для процесса $e^+e^- \to \mu^+\mu^-$в безмассовом пределе. В последующих главах мы будем часто сначала проводить на первый взгляд бессмысленные вычисления, а затем рассматривать собственные состояния спиральности в пределе высоких энергий, чтобы понять, что было сделано.

Наконец, мы готовы понять происхождение обозначений ψ_L и ψ_R для вейлевских спиноров. Решения уравнений Вейля - это состояния с определенной спиральностью, отвечающие лево- и правополяризованным частицам, соответственно. Лоренц-инвариантность спиральности (для безмассовой частицы) явно видна в записи вейлевских спиноров, так как ψ_L и ψ_R относятся к разным представлениям группы Лоренца.

Условие нормировки для $u(p)$ удобно записывать в лоренц-инвариантном виде. Мы видели выше, что выражение $\psi^\dagger\psi$ не лоренц-инвариантно. Аналогично,

$$u^\dagger u = \left(\xi^\dagger\sqrt{p\cdot\sigma}, \xi^\dagger\sqrt{p\cdot\bar{\sigma}}\right)\cdot\begin{pmatrix}\sqrt{p\cdot\sigma}\xi\\ \sqrt{p\cdot\bar{\sigma}}\xi\end{pmatrix} = 2E_{\mathbf{p}}\xi^\dagger\xi$$

Чтобы получить лоренцевский скаляр, определим

$$\bar{u}(p) = u^\dagger(p)\gamma^0.$$

Затем при помощи почти такого же вычисления находим:

$$\bar{u}u = 2m\xi^\dagger\xi.$$

Это будет наше условие нормировки, причем мы также требуем, чтобы двухкомпонентный спинор ξ был нормирован как обычно: $\xi^\dagger\xi = 1$. Удобно также выбрать взаимно ортогональные базисные спиноры ξ^1 и ξ^2 (типа $\begin{pmatrix}1\\0\end{pmatrix}$ и $\begin{pmatrix}0\\1\end{pmatrix}$). Для безмассовой частицы выражение (3.57) тривиально, так что следует пользоваться условием нормировки в форме (3.55).

Подведем промежуточный итог. Общее решение уравнения Дирака может быть записано как линейная комбинация плоских волн. Волны с положительной частотой имеют вид:

$$\psi(x) = u(p)e^{-ip\cdot x}, \quad p^2 = m^2, \quad p^0 > 0.$$

Существуют два линейно независимых решения для $u(p)$:

$$u^s(p) = \begin{pmatrix}\sqrt{p\cdot\sigma}\xi^s\\ \sqrt{p\cdot\bar{\sigma}}\xi^s\end{pmatrix}, \quad s = 1, 2$$

которые нормированы условиями:

$$\bar{u}^r(p)u^s(p) = 2m\delta^{rs}\% \quad \% \text{ или } \% \quad \%u^{r\dagger}(p)u^s(p) = 2E_{\mathbf{p}}\delta^{rs}.$$

Точно так же можно найти отрицательно-частотные решения:

$$\psi(x) = v(p)e^{+ip\cdot x}, \quad p^2 = m^2, \quad p^0 > 0.$$

(Обратим внимание, что мы предпочли изменить знак в экспоненте, но не писать $p^0 < 0$). Имеются два линейно независимых решения для $v(p)$:

$$v^s(p) = \begin{pmatrix}\sqrt{p\cdot\sigma}\eta^s\\ -\sqrt{p\cdot\bar{\sigma}}\eta^s\end{pmatrix}, \quad s = 1, 2$$

где η^s - другой базис двухкомпонентных спиноров. Эти решения нормированы согласно

$$\bar{v}^r(p)v^s(p) = -2m\delta^{rs}\% \quad \% \text{ или } \% \quad \%v^{r\dagger}(p)v^s(p) = +2E_{\mathbf{p}}\delta^{rs}.$$

Столбцы u и v также взаимно ортогональны:

$$\bar{u}^r(p)v^s(p) = \bar{v}^r(p)u^s(p) = 0.$$

Следует быть внимательными, так как $u^{r\dagger}(p)v^s(p) \neq 0$ и $v^{r\dagger}(p)u^s(p) \neq 0$. Однако заметим, что

$$u^{r\dagger}(\mathbf{p})v^s(-\mathbf{p}) = v^{r\dagger}(-\mathbf{p})u^s(\mathbf{p}) = 0,$$

где мы изменили знак 3-импульса в одном из сомножителей в каждом из спинорных произведений.

9.5.5 Spin Sums

Теория

При вычислении вкладов диаграмм Фейнмана часто будет необходимо производить суммирование по поляризациям фермионных состояний. С помощи простых вычислений можно вывести необходимые соотношения полноты:

$$\sum_{s=1,2} u^s(p)\bar{u}^s(p) = \sum_s \begin{pmatrix} \sqrt{p\cdot\sigma}\xi^s \\ \sqrt{p\cdot\bar{\sigma}}\xi^s \end{pmatrix} \left(\xi^{s\dagger}\sqrt{p\cdot\bar{\sigma}}, \xi^{s\dagger}\sqrt{p\cdot\sigma}\right) =$$
$$= \begin{pmatrix} \sqrt{p\cdot\sigma}\sqrt{p\cdot\bar{\sigma}} & \sqrt{p\cdot\sigma}\sqrt{p\cdot\sigma} \\ \sqrt{p\cdot\bar{\sigma}}\sqrt{p\cdot\bar{\sigma}} & \sqrt{p\cdot\bar{\sigma}}\sqrt{p\cdot\sigma} \end{pmatrix} = \begin{pmatrix} m & p\cdot\sigma \\ p\cdot\bar{\sigma} & m \end{pmatrix}.$$

Во второй строке мы использовали формулу

$$\sum_{s=1,2} \xi^s\xi^{s\dagger} = \mathbf{1} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

Таким образом, приходим к желаемой формуле:

$$\sum_s u^s(p)\bar{u}^s(p) = \gamma\cdot p + m$$

Аналогично,

$$\sum_s v^s(p)\bar{v}^s(p) = \gamma\cdot p - m$$

Комбинация $\gamma\cdot p$ встречается настолько часто, что Фейнман ввел обозначение: $\not{p} \equiv \gamma^\mu p_\mu$. С этого момента мы будем часто использовать эту запись.

9.5.6 Dirac Matrices and Bilinear Forms

Теория

Мы видели в разделе 3.2, что величина $\bar{\psi}\psi$ есть лоренцевский скаляр. Легко показать, что $\bar{\psi}\gamma^\mu\psi$ является 4-вектором; мы использовали этот факт для записи дираковского лагранжиана (3.34). Зададим более общий вопрос. Рассмотрим выражение $\bar{\psi}\Gamma\psi$, где Γ - произвольная 4×4 постоянная матрица. Можем ли мы разложить это выражение на слагаемые, имеющие определенные трансформационные свойства по отношению к преобразованиям группы Лоренца? Ответ положителен, если представить матрицу Γ разложеной по базису, состоящему из шестнадцати 4×4 матриц, определенных как антисимметричные комбинации γ-матриц:

1	1 матрица
γ^μ	4 матрицы
$\gamma^{\mu\nu} = \frac{1}{2}\left[\gamma^\mu, \gamma^\nu\right] \equiv \gamma^{[\mu}\gamma^{\nu]} \equiv -i\sigma^{\mu\nu}$	6 матриц
$\gamma^{\mu\nu\rho} = \gamma^{[\mu}\gamma^\nu\gamma^{\rho]}$	4 матрицы
$\gamma^{\mu\nu\rho\sigma} = \gamma^{[\mu}\gamma^\nu\gamma^\rho\gamma^{\sigma]}$	1 матрица
	Всего 16 матриц

Легко установить свойства этих матриц относительно преобразований Лоренца. Например,

$$\bar{\psi}\gamma^{\mu\nu}\psi \to \left(\bar{\psi}\Lambda^{-1}_{\frac{1}{2}}\right)\left(\frac{1}{2}\left[\gamma^\mu, \gamma^\nu\right]\right)\left(\Lambda_{\frac{1}{2}}\psi\right) =$$
$$= \frac{1}{2}\bar{\psi}\left(\Lambda^{-1}_{\frac{1}{2}}\gamma^\mu\Lambda_{\frac{1}{2}}\Lambda^{-1}_{\frac{1}{2}}\gamma^\nu\Lambda_{\frac{1}{2}} - \Lambda^{-1}_{\frac{1}{2}}\gamma^\nu\Lambda_{\frac{1}{2}}\Lambda^{-1}_{\frac{1}{2}}\gamma^\mu\Lambda_{\frac{1}{2}}\right)\psi = \Lambda^\mu_\alpha\Lambda^\nu_\beta\bar{\psi}\gamma^{\alpha\beta}\psi$$

Каждый набор матриц преобразуется каю антисимметричный тензор последовательно возрастающего ранга. Последние два набора матриц можно упростить, вводя дополнительную гамма-матрицу

$$\gamma^5 \equiv i\gamma^0\gamma^1\gamma^2\gamma^3 = -\frac{i}{4!}\varepsilon^{\mu\nu\rho\sigma}\gamma_\mu\gamma_\nu\gamma_\rho\gamma_\sigma$$

Тогда $\gamma^{\mu\nu\rho\sigma} = -i\varepsilon^{\mu\nu\rho\sigma}\gamma^5$ и $\gamma^{\mu\nu\rho} = -i\varepsilon^{\mu\nu\rho\sigma}\gamma_\sigma\gamma^5$. Матрица γ^5 имеет следующие свойства, которые могут быть проверены при помощи (3.68) и антикоммутационных соотношений (3.22):

$$\left(\gamma^5\right)^\dagger = \gamma^5$$
$$\left(\gamma^5\right)^2 = 1$$
$$\left\{\gamma^5, \gamma^\mu\right\} = 0$$

Из последнего свойства следует, что $[\gamma^5, S^{\mu\nu}] = 0$. Таким образом, представление Дирака должно быть приводимо, так как собственные векторы матрицы γ^5, чьи собственные значения различны, преобразуются не смешиваясь (этот критерий приводимости известен как лемма Шура). В нашем базисе матрица

$$\gamma^5 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix},$$

т. е. является блочно-диагональной. Таким образом, дираковский спинор только с левой (правой) компонентой является собственным состоянием γ^5 с собственным значением $-1(+1)$. Эти спиноры, действительно, преобразуются без смешивания, как мы явно показали в разделе 3.2.

Теперь перепишем таблицу из 4×4 матриц, введя стандартную терминологию:

1	скаляр	1
γ^μ	вектор	4
$\sigma^{\mu\nu}\left[\gamma^\mu, \gamma^\nu\right]$	тензор	6
$\gamma^\mu\gamma^5$	псевдовектор	4
γ^5	псевдоскаляр	1

Термины псевдовектор и псевдоскаляр применяются к величинам, которые при непрерывных преобразованиях Лоренца преобразуются как вектор и скаляр, соответственно, но с дополнительным изменением знака при преобразованиях четности (как мы покажем в разделе 3.6).

Из векторных и псевдовекторных матриц можно построить два тока, билинейных относительно дираковских полей:

$$j^{\mu}(x) = \bar{\psi}(x)\gamma^{\mu}\psi(x); \quad j^{\mu 5}(x) = \bar{\psi}(x)\gamma^{\mu}\gamma^{5}\psi(x)$$

Вычислим дивергенции этих токов, предполагая, что ψ удовлетворяет уравнению Дирака:

$$\partial_{\mu}j^{\mu} = \left(\partial_{\mu}\bar{\psi}\right)\gamma^{\mu}\psi + \bar{\psi}\gamma^{\mu}\partial_{\mu}\psi = (im\bar{\psi})\psi + \bar{\psi}(-im\psi) = 0.$$

Таким образом, j^{μ} всегда сохраняется, если $\psi(x)$ удовлетворяет уравнению Дирака. Когда мы связываем поле Дирака с электромагнитным полем, ток j^{μ} приобретает смысл плотности электрического тока. Аналогичным образом можно вычислить

$$\partial_{\mu}j^{\mu 5} = 2im\bar{\psi}\gamma^{5}\psi$$

Если $m = 0$, этот ток (часто называемый аксиальным векторным током) также сохраняется. В этом случае полезно образовать следующие линейные комбинации:

$$j^{\mu}_{L} = \bar{\psi}\gamma^{\mu}\left(\frac{1-\gamma^{5}}{2}\right)\psi, \quad j^{\mu}_{R} = \bar{\psi}\gamma^{\mu}\left(\frac{1+\gamma^{5}}{2}\right)\psi$$

Когда $m = 0$, эти токи являются плотностями электрических токов левых и правых частиц, соответственно, и сохраняются по отдельности.

Два тока $j^{\mu}(x)$ и $j^{\mu 5}(x)$ являются нетеровскими токами, соответствующими двум преобразованиям

$$\psi(x) \to e^{i\alpha}\psi(x) \quad \text{и \%} \quad \%\psi(x) \to e^{i\alpha\gamma^{5}}\psi(x).$$

Первое из них представляет собой симметрию дираковского лагранжиана (3.34). Второе, называемое киральным преобразованием, является симметрией кинетического слагаемого в $\mathscr{L}$, но не массового слагаемого. Таким образом, теорема Нетер подтверждает, что аксиальный векторный ток сохраняется лишь в случае $m = 0$. Произведения дираковских билинейных форм подчиняются соотношениям, известным как тождества Фириа. Мы обсудим лишь простейшее из них, которое будет несколько раз использоваться в дальнейшем. Это простейшее тождество легче всего записывается через двухкомпонентные вейлевские спиноры, введенные в (3.36).

Суть этого соотношения - тождество для 2×2 матриц σ^{μ}, определенных в (3.41):

$$(\sigma^{\mu})_{\alpha\beta}(\sigma_{\mu})_{\gamma\delta} = 2\varepsilon_{\alpha\gamma}\varepsilon_{\beta\delta}.$$

(Здесь α, β и т. д. - спинорные индексы и ε - антисимметричный символ.) Чтобы понять это соотношение, заметим, что индексы α, γ преобразуются по лоренцевскому представлению ψ_L, в то время как β, δ преобразуются по отдельному представлению ψ_R, при этом полная величина должна быть лоренц-инвариантной. Альтернативно, можно непосредственно проверить путем перебора все 16 компонент (3.77).

Заключая тождество (3.77) в обкладки из правых частей (то есть нижних половин) дираковских спиноров u_1, u_2, u_3, u_4, находим тождество

$$\begin{aligned}(\bar{u}_{1R}\sigma^{\mu}u_{2R})\,(\bar{u}_{3R}\sigma_{\mu}u_{4R}) &= 2\varepsilon_{\alpha\gamma}\bar{u}_{1R\alpha}\bar{u}_{3R\gamma}\varepsilon_{\beta\delta}u_{2R\beta}u_{4R\delta} = \\ &= -\,(\bar{u}_{1R}\sigma^{\mu}u_{4R})\,(\bar{u}_{3R}\sigma_{\mu}u_{2R})\end{aligned}$$

Это нетривиальное соотношение показывает, что произведение билинейных комбинаций в (3.78) антисимметрично относительно перестановок компонент с индексами 2 и 4, и также компонент с индексами 1 и 3. Тождество (3.77) имеет место также для $\bar{\sigma}^{\mu}$, таким образом, находим:

$$(\bar{u}_{1L}\bar{\sigma}^{\mu}u_{2L})\,(\bar{u}_{3L}\bar{\sigma}_{\mu}u_{4L}) = -\,(\bar{u}_{1L}\bar{\sigma}^{\mu}u_{4L})\,(\bar{u}_{3L}\bar{\sigma}_{\mu}u_{2L})$$

Иногда полезно объединить тождество Фирца (3.78) с тождеством, связывающим σ^{μ} и $\bar{\sigma}^{\mu}$:

$$\varepsilon_{\alpha\beta}\,(\sigma^{\mu})_{\beta\gamma} = \left(\bar{\sigma}^{\mu T}\right)_{\alpha\beta}\varepsilon_{\beta\gamma}.$$

Последнее соотношение также проверяется непосредственно. Используя (3.80), (3.79) и соотношение

$$\bar{\sigma}^{\mu}\sigma_{\mu} = 4,$$

мы можем упростить, например, громоздкие произведения билинейных комбинаций типа

$$\begin{aligned}\left(\bar{u}_{1L}\bar{\sigma}^{\mu}\sigma^{\nu}\bar{\sigma}^{\lambda}u_{2L}\right)(\bar{u}_{3L}\bar{\sigma}_{\mu}\sigma_{\nu}\bar{\sigma}_{\lambda}u_{4L}) &= 2\varepsilon_{\alpha\gamma}\bar{u}_{1L\alpha}\bar{u}_{3L\gamma}\varepsilon_{\beta\delta}\left(\sigma^{\nu}\bar{\sigma}^{\lambda}u_{2L}\right)_{\beta}(\sigma_{\nu}\bar{\sigma}_{\lambda}u_{4L})_{\delta} = \\ &= 2\varepsilon_{\alpha\gamma}\bar{u}_{1L\alpha}\bar{u}_{3L\gamma}\varepsilon_{\beta\delta}u_{2L\beta}\left(\sigma^{\lambda}\bar{\sigma}^{\nu}\sigma_{\nu}\bar{\sigma}_{\lambda}u_{4L}\right)_{\delta} = \\ &= 2\cdot(4)^2\cdot\varepsilon_{\alpha\gamma}\bar{u}_{1L\alpha}\bar{u}_{3L\gamma}\varepsilon_{\beta\delta}u_{2L\beta}u_{4L\delta} = \\ &= 16\,(\bar{u}_{1L}\bar{\sigma}^{\mu}u_{2L})\,(\bar{u}_{3L}\bar{\sigma}_{\mu}u_{4L})\,.\end{aligned}$$

Имеются также тождества Фирца для перестановок 4-компонентных дираковских спиноров и 4×4 матриц Дирака. Однако для их вывода полезно применить более систематический подход. В задаче 3.6 рассмотрен общий метод и некоторые примеры его применения.

9.5.7 Quantization of the Dirac Field

Теория

Мы теперь готовы построить квантовую теорию свободного дираковского поля. Из лагранжиана

$$\mathscr{L} = \bar{\psi}(i\partial\!\!\!/ - m)\psi = \bar{\psi}\,(i\gamma^{\mu}\partial_{\mu} - m)\,\psi$$

видим, что импульс, канонически сопряженный к ψ есть $i\psi^{\dagger}$, и, таким образом, гамильтониан имеет вид:

$$H = \int d^3x\bar{\psi}(-i\gamma\cdot\nabla + m)\psi = \int d^3x\psi^{\dagger}\left[-i\gamma^0\gamma\cdot\nabla + m\gamma^0\right]\psi$$

Если определить $\alpha = \gamma^0\gamma, \beta = \gamma^0$, то величину в скобках можно рассматривать как гамильтониан Дирака в одночастичной квантовой механике:

$$h_D = -i\boldsymbol{\alpha}\cdot\boldsymbol{\nabla} + m\beta$$

Как нельзя квантовать дираковское поле: урок по связи спина и статистики

Чтобы проквантовать дираковское поле по аналогии с полем Клейна-Гордона, следует потребовать выполнения канонических коммутационных соотношений

$$\left[\psi_a(\mathbf{x}), \psi_b^\dagger(\mathbf{y})\right] = \delta^{(3)}(\mathbf{x}-\mathbf{y})\delta_{ab}, \qquad \text{(времена одинаковые)}$$

где a и b обозначают компоненты спинора ψ. Это выглядит довольно странно: если $\psi(x)$ было бы вещественным, то левая сторона была бы антисимметричной при замене $\mathbf{x} \longleftrightarrow \mathbf{y}$, в то время как правая сторона - симметричной. Но так как спинор ψ комплексный, пока еще противоречия нет. На самом деле мы скоро увидим, что при наложении коммутационных соотношений на дираковское поле возникают более серьезные проблемы. Но, чтобы лучше понять связь между спином и статистикой, полезно посмотреть, как далеко мы можем продвинуться в этом направлении. Так что продолжим; но не забудьте, что рассуждения на нескольких следующих страницах приведут в тупик.

Первая задача - найти представление коммутационных соотношений через операторы рождения и уничтожения, которое диагонализует H. Из формы гамильтониана (3.84) ясно, что полезно разложить поле $\psi(x)$ по базису собственных функций h_D. Мы уже знаем эти собственные функции из вычислений в разделе 3.3. Там было обнаружено, что

$$\left[i\gamma^0\partial_0 + i\gamma\cdot\nabla - m\right] u^s(p)e^{-ip\cdot x} = 0$$

так что $u^s(\mathbf{p})e^{i\mathbf{p}\cdot\mathbf{x}}$ являются собственными функциями h_D с собственными значениями $E_\mathbf{p}$. Аналогично, функции $v^s(\mathbf{p})e^{-i\mathbf{p}\cdot\mathbf{x}}$ (или эквивалентно, $v^s(-\mathbf{p})e^{+i\mathbf{p}\cdot\mathbf{x}}$) - собственные функции h_D с собственными значениями $-E_\mathbf{p}$. Они образуют полный набор собственных функций, так как для любого $\mathbf{p}$ имеются два спинора u и два спинора v, дающих четыре собственных вектора 4×4 матрицы h_D.

Раскладывая ψ по этому базису, получаем:

$$\psi(\mathbf{x}) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_\mathbf{p}}}e^{i\mathbf{p}\cdot\mathbf{x}}\sum_{s=1,2}\left(a^s_\mathbf{p}u^s(\mathbf{p}) + b^s_{-\mathbf{p}}v^s(-\mathbf{p})\right)$$

где $a^s_\mathbf{p}$ и $b^s_\mathbf{p}$ - операторные коэффициенты. (Пока что мы используем представление Шредингера, где ψ не зависит от времени.) Постулируем следующие коммутационные соотношения:

$$\left[a^r_\mathbf{p}, a^{s\dagger}_\mathbf{q}\right] = \left[b^r_\mathbf{p}, b^{s\dagger}_\mathbf{q}\right] = (2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})\delta^{rs}.$$

Тогда нетрудно проверить, что коммутационные соотношения (3.86) для ψ и $\psi^\dagger$ имеют вид:

$$\begin{aligned}
\left[\psi(\mathbf{x}), \psi^\dagger(\mathbf{y})\right] &= \int \frac{d^3pd^3q}{(2\pi)^6}\frac{1}{\sqrt{2E_\mathbf{p}2E_\mathbf{q}}}e^{i(\mathbf{p}\cdot\mathbf{x}-\mathbf{q}\cdot\mathbf{y})}\times \\
&\quad\times\sum_{r,s}\left(\left[a^r_\mathbf{p}, a^{s\dagger}_\mathbf{q}\right]u^r(\mathbf{p})\bar{u}^s(\mathbf{q}) + \left[b^r_{-\mathbf{p}}, b^{s\dagger}_{-\mathbf{q}}\right]v^r(-\mathbf{p})\bar{v}^s(-\mathbf{q})\right)\gamma^0 = \\
&= \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_\mathbf{p}}e^{i\mathbf{p}\cdot(\mathbf{x}-\mathbf{y})}\left[\left(\gamma^0E_\mathbf{p} - \gamma\cdot\mathbf{p} + m\right) + \left(\gamma^0E_\mathbf{p} + \gamma\cdot\mathbf{p} - m\right)\right]\gamma^0 = \\
&= \delta^{(3)}(\mathbf{x}-\mathbf{y})\times\mathbf{1}_{4\times4}.
\end{aligned}$$

На втором шаге мы использовали условия полноты (3.66) и (3.67) для сумм по спиновым состояниям. Теперь мы готовы написать H через операторы a и b. После еще одного небольшого вычисления (использующего соотношение ортогональности (3.60), (3.63) и (3.65)) находим:

$$H = \int \frac{d^3p}{(2\pi)^3} \sum_s \left(E_{\mathbf{p}} a^{s\dagger}_{\mathbf{p}} a^s_{\mathbf{p}} - E_{\mathbf{p}} b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} \right)$$

Во втором слагаемом таится какая-то ужасная ошибка: рождая все новые и новые частицы при помощи $b^\dagger$, мы можем уменьшать энергию до бесконечности. (Замена $b \longleftrightarrow b^\dagger$ не помогла бы, так как это разрушило бы коммутационные соотношения (3.89).)

Похоже, мы столкнулись с серьезной трудностью, но попытаемся еще продвинуться вперед и исследуем причинность в этой теории. Для этого нам нужно вычислить $\left[\psi(x), \psi^\dagger(y)\right)$ (или удобнее, $\left[\psi(x), \bar\psi(y)\right])$ в разные моменты времени, в надежде получить нуль вне светового конуса. Сначала следует перейти к представлению Гейзенберга и восстановить зависимость от времени ψ и $\bar\psi$. Используя соотношения

$$e^{iHt} a^s_{\mathbf{p}} e^{-iHt} = a^s_{\mathbf{p}} e^{-iE_{\mathbf{p}}t}, \quad e^{iHt} b^s_{\mathbf{p}} e^{-iHt} = b^s_{\mathbf{p}} e^{+iE_{\mathbf{p}}t}$$

немедленно получаем

$$\psi(x) = \int \frac{d^3p}{(2\pi)^3} \frac{1}{\sqrt{2E_{\mathbf{p}}}} \sum_s \left(a^s_{\mathbf{p}} u^s(p) e^{-ip\cdot x} + b^s_{\mathbf{p}} v^s(p) e^{ip\cdot x} \right)$$

$$\bar\psi(x) = \int \frac{d^3p}{(2\pi)^3} \frac{1}{\sqrt{2E_{\mathbf{p}}}} \sum_s \left(a^{s\dagger}_{\mathbf{p}} \bar u^s(p) e^{ip\cdot x} + b^{s\dagger}_{\mathbf{p}} \bar v^s(p) e^{-ip\cdot x} \right)$$

Теперь можно вычислить общий коммутатор:

$$\begin{aligned}
\left[\psi_a(x), \bar\psi_b(y)\right] &= \int \frac{d^3p}{(2\pi)^3} \frac{1}{2E_{\mathbf{p}}} \sum_s \left(u^s_a(p) \bar u^s_b(p) e^{-ip\cdot(x-y)} + v^s_a(p) \bar v^s_b(p) e^{ip\cdot(x-y)} \right) = \\
&= \int \frac{d^3p}{(2\pi)^3} \frac{1}{2E_{\mathbf{p}}} \left((\not p + m)_{ab} e^{-ip\cdot(x-y)} + (\not p - m)_{ab} e^{ip\cdot(x-y)} \right) = \\
&= (i\partial_x + m)_{ab} \int \frac{d^3p}{(2\pi)^3} \frac{1}{2E_{\mathbf{p}}} \left(e^{-ip\cdot(x-y)} - e^{ip\cdot(x-y)} \right) = \\
&= (i\partial_x + m)_{ab} \left[\phi(x), \phi(y)\right].
\end{aligned}$$

Так как коммутатор вещественного поля Клейна-Гордона $[\phi(x), \phi(y)]$ равен нулю вне светового конуса, эта величина также равна нулю.

Однако в этом решении проблемы причинности имеется что-то странное. Пусть $|0\rangle$ - состояние, которое уничтожается всеми операторами $a^s_{\mathbf{p}}$ и $b^s_{\mathbf{p}}$: $a^s_{\mathbf{p}}|0\rangle = b^s_{\mathbf{p}}|0\rangle = 0$. Тогда

$$\left[\psi_a(x), \bar\psi_b(y)\right] = \left\langle 0 \left| \left[\psi_a(x), \bar\psi_b(y)\right] \right| 0 \right\rangle = \left\langle 0 \left| \psi_a(x) \bar\psi_b(y) \right| 0 \right\rangle - \left\langle 0 \left| \bar\psi_b(y) \psi_a(x) \right| 0 \right\rangle$$

так же, как для поля Клейна-Гордона. Но в случае поля Клейна-Гордона в коммутатор давали вклады каждая из этих двух частей: вне светового конуса распространение частицы от y до x сокращалось с распространением античастицы от x до y. Здесь же оба вклада исходят от первой части $\langle 0|\psi(x)\bar\psi(y)|0\rangle$, так как вторая часть нулевая. Сокращение происходит между частицами с положительной энергией и частицами с отрицательной энергией, причем обе распространяются от y к x.

Это наблюдение может привести нас к разрешению проблемы отрицательной энергии. Одно из предположений, сделанных при квантовании теории Дирака, должно быть неправильным. Таким образом, забудем постулированные коммутационные соотношения (3.86) и (3.88) и посмотрим, можем ли мы найти способ обоснования распространения частиц с положительной энергией в обоих направлениях. Мы будем также вынуждены отбросить наше определение вакуума $|0\rangle$ как состояния, которое уничтожается всеми $a^s_{\mathbf{p}}$ и $b^s_{\mathbf{p}}$. Однако мы сохраним выражения (3.92) для $\psi(x)$ и $\bar\psi(x)$ как операторов Гейзенберга, так как, если $\psi(x)$ и $\bar\psi(x)$ являются решениями уравнения Дирака, то они должны разлагаться по таким плоско-волновым решениям.

Сначала рассмотрим амплитуду распространения $\langle 0|\psi(x)\bar\psi(y)|0\rangle$, которая должна представлять частицу с положительной энергией, распространяющуюся от y к x. В этом случае мы хотели бы, чтобы гейзенберговское состояние $\bar\psi(y)|0\rangle$ было линейной комбинацией состояний только с положительной или только с отрицательной энергией (так как гейзенберговское состояние равно $\Psi_H = e^{+iHt}\Psi_S$). Таким образом, вклад могут давать только слагаемые с $a^{s\dagger}_{\mathbf{p}}$ из $\bar\psi(y)$, что означает, что $b^{s\dagger}_{\mathbf{p}}$ должны при действии на вакуум давать нуль. Аналогично, $\langle 0|\psi(x)$ может содержать только положительночастотные компоненты. Таким образом, имеем:

$$\langle 0|\psi(x)\bar\psi(y)|0\rangle = \langle 0|\int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\sum_r a^r_{\mathbf{p}}u^r(p)e^{-ipx}\times \\ \times\int\frac{d^3q}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{q}}}}\sum_s a^{s\dagger}_{\mathbf{q}}\bar u^s(q)e^{iqy}|0\rangle.$$

Можно кое-что сказать о матричных элементах $\left\langle 0\left|a^r_{\mathbf{p}}a^{s\dagger}_{\mathbf{q}}\right|0\right\rangle$, даже не зная перестановочных соотношений $a^r_{\mathbf{p}}$ и $a^{s\dagger}_{\mathbf{q}}$, а просто используя трансляционную и вращательную инвариантности. Если основное состояние $|0\rangle$ инвариантно относительно трансляций, то $|0\rangle = e^{i\mathbf{P}\cdot\mathbf{x}}|\mathbf{0}\rangle$. Далее, так как $a^{s\dagger}_{\mathbf{q}}$ порождает импульс $\mathbf{q}$, мы можем для вычисления использовать (2.48):

$$\left\langle 0\left|a^r_{\mathbf{p}}a^{s\dagger}_{\mathbf{q}}\right|0\right\rangle = \left\langle 0\left|a^r_{\mathbf{p}}a^{s\dagger}_{\mathbf{q}}e^{i\mathbf{P}\cdot\mathbf{x}}\right|0\right\rangle = e^{i(\mathbf{p}-\mathbf{q})\cdot\mathbf{x}}\left\langle 0\left|e^{i\mathbf{P}\cdot\mathbf{x}}a^r_{\mathbf{p}}a^{s\dagger}_{\mathbf{q}}\right|0\right\rangle = e^{i(\mathbf{p}-\mathbf{q})\cdot\mathbf{x}}\left\langle 0\left|a^r_{\mathbf{p}}a^{s\dagger}_{\mathbf{q}}\right|0\right\rangle.$$

Отсюда видно, что, если $\left\langle 0\left|a^r_{\mathbf{p}}a^{s\dagger}_{\mathbf{q}}\right|0\right\rangle$ отличнен от нуля, то $\mathbf{p}$ должен равняться $\mathbf{q}$. Аналогично можно показать, что из вращательной инвариантности $|0\rangle$ вытекает, что $r = s$. (Это должно быть интуитивно понятно и может быть проверено после изучения оператора углового момента далее в этом разделе.) Из этих рассуждений заключаем, что матричный элемент имеет вид:

$$\left\langle 0\left|a^r_{\mathbf{p}}a^{s\dagger}_{\mathbf{q}}\right|0\right\rangle = (2\pi)^3\delta^{(3)}(\mathbf{p}-\mathbf{q})\delta^{rs}\cdot A(\mathbf{p}),$$

где $A(\mathbf{p})$ пока неопределено. Обратим внимание, что, если норма состояния всегда положительна (что должно выполняться в любом приемлемом гильбертовом пространстве), то $A(\mathbf{p})$ должно быть больше нуля. Теперь можно вернуться к (3.93) и записать:

$$\langle 0|\psi(x)\bar\psi(y)|0\rangle = \int\frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}\sum_s u^s(p)\bar u^s(p)A(\mathbf{p})e^{-ip(x-y)} = \\ = \int\frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}(\not p + m)A(\mathbf{p})e^{-ip(x-y)}$$

Это выражение явно инвариантно относительно бустов только тогда, когда $A(\mathbf{p})$ - лоренцевский скаляр, то есть $A(\mathbf{p}) = A(p^2)$. Так как $p^2 = m^2$, то A должно быть константой. В конечном итоге получаем:

$$\left\langle 0 \left| \psi_a(x)\bar{\psi}_b(y) \right| 0 \right\rangle = (i\partial_x + m)_{ab} \int \frac{d^3p}{(2\pi)^3} \frac{1}{2E_{\mathbf{p}}} e^{-ip(x-y)} \cdot A$$

Аналогично, в амплитуде $\langle 0|\bar{\psi}(y)\psi(x)|0\rangle$ мы хотели бы оставить только вклады от положительно-частотных слагаемых в $\psi(y)$ и отрицательно-частотных слагаемых в $\psi(x)$. Таким образом, $a^s_{\mathbf{p}}$ все еще уничтожает вакуум, но $b^s_{\mathbf{p}}$ - нет. Согласно аргументам, аналогичным приведенным выше, имеем:

$$\left\langle 0 \left| \bar{\psi}_b(y)\psi_a(x) \right| 0 \right\rangle = -(i\not{\partial}_x + m)_{ab} \int \frac{d^3p}{(2\pi)^3} \frac{1}{2E_{\mathbf{p}}} e^{ip(x-y)} \cdot B$$

где B - другая положительная константа. Знак «минус» важен; он происходит из соотношения полноты (3.67) для $\sum v\bar{v}$ и знака при x в экспоненте. Отсюда следует, что мы не можем иметь $\langle 0|[\psi(x), \bar{\psi}(y)]|0\rangle = 0$ вне светового конуса. Два слагаемых (3.94) и (3.95) действительно сократились бы в случае $A = -B$, но это невозможно, так как A и B должны быть оба положительными. Теперь мы близки к решению. Полагая $A = B = 1$, нетрудно получить (вне светового конуса):

$$\left\langle 0 \left| \psi_a(x)\bar{\psi}_b(y) \right| 0 \right\rangle = -\left\langle 0 \left| \bar{\psi}_b(y)\psi_a(x) \right| 0 \right\rangle .$$

Иными словами, спинорные поля антикоммутируют в точках, разделенных пространственноподобным интервалом. Этого достаточно, чтобы сохранить причинность, так как любые мыслимые наблюдаемые (такие, как энергия, заряд и число частиц) построены из четного числа спинорных полей; для любых наблюдаемых такого типа $\mathscr{O}_1$ и $\mathscr{O}_2$ все еще выполнено равенство $[\mathscr{O}_1(x), \mathscr{O}_2(y)] = 0$ для $(x-y)^2 < 0$. Примечательно, что постулируя антикоммутационные соотношения для дираковского поля, мы одновременно решаем проблему отрицательной энергии. ОдновременнЫе антикоммутационные соотношения примут вид:

$$\left\{ \psi_a(\mathbf{x}), \psi^\dagger_b(\mathbf{y}) \right\} = \delta^{(3)}(\mathbf{x}-\mathbf{y})\delta_{ab}$$
$$\{\psi_a(\mathbf{x}), \psi_b(\mathbf{y})\} = \left\{ \psi^\dagger_a(\mathbf{x}), \psi^\dagger_b(\mathbf{y}) \right\} = 0$$

Мы можем разложить $\psi(\mathbf{x})$ по $a^s_{\mathbf{p}}$ и $b^{s\dagger}_{\mathbf{p}}$, как и прежде (см. (3.87)). Операторы рождения и уничтожения должны теперь удовлетворять соотношениям

$$\left\{ a^r_{\mathbf{p}}, a^{s\dagger}_{\mathbf{q}} \right\} = \left\{ b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}} \right\} = (2\pi)^3 \delta^{(3)}(\mathbf{p}-\mathbf{q})\delta^{rs}$$

(все остальные антикоммутаторы равны нулю), чтобы удовлетворялись соотношения (3.96). Другое вычисление приводит к прежнему гамильтониану:

$$H = \int \frac{d^3p}{(2\pi)^3} \sum_s \left(E_{\mathbf{p}} a^{s\dagger}_{\mathbf{p}} a^s_{\mathbf{p}} - E_{\mathbf{p}} b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} \right)$$

При этом $b^{s\dagger}_{\mathbf{p}}$ все еще рождает состояния с отрицательной энергией. Однако соотношение $\left\{ b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}} \right\} = (2\pi)^3 \delta^{(3)}(\mathbf{p}-\mathbf{q})\delta^{rs}$ является симметричным относительно $b^r_{\mathbf{p}}$ и $b^{s\dagger}_{\mathbf{q}}$. Поэтому просто переопределим:

$$\tilde{b}^s_{\mathbf{p}} \equiv b^{s\dagger}_{\mathbf{p}}; \quad \tilde{b}^{s\dagger}_{\mathbf{p}} \equiv b^s_{\mathbf{p}}.$$

Новые операторы удовлетворяют тем же антикоммутационным соотношениям, но теперь второе слагаемое в гамильтониане равно:

$$-E_{\mathbf{p}} b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} = +E_{\mathbf{p}} \tilde{b}^{\dagger\dagger}_{\mathbf{p}} \tilde{b}^s_{\mathbf{p}} - (\text{ const }).$$

Если определить $|0\rangle$ как состояние, которое уничтожается операторами $a^s_{\mathbf{p}}$ и $\tilde{b}^s_{\mathbf{p}}$, то все возбуждения над $|0\rangle$ имеют положительную энергию.

Что же случилось? Чтобы лучше понять этот прием, на время откажемся от теории поля и рассмотрим теорию с единственной парой операторов b и $b^\dagger$, удовлетворяющих соотношениям $\left\{b, b^\dagger\right\} = 1$ и $\{b, b\} = \left\{b^\dagger, b^\dagger\right\} = 0$. Выберем состояние $|0\rangle$ таким, что $b|0\rangle = 0$. Тогда $b^\dagger|0\rangle$ - новое состояние; обозначим его $|1\rangle$. Это состояние удовлетворяет условиям $b|1\rangle = |0\rangle$ и $b^\dagger|1\rangle = 0$. Таким образом, b и $b^\dagger$ действуют в гильбертовом пространстве из двух состояний $|0\rangle$ и $|1\rangle$. Мы могли бы сказать, что $|0\rangle$ представляет «пустое» состояние и что $b^\dagger$ «аполняет» это состояние. Но с таким же успехом можно было бы назвать $|1\rangle$ пустым состоянием и сказать, что $b = \tilde{b}^\dagger$ заполняет его. Два описания полностью эквивалентны, пока не определена некоторая наблюдаемая, которая позволяет нам физически различать эти состояния. В нашем случае правильным является такой выбор, когда состояние с более низкой энергией пусто. В результате оператором рождения объявляется тот оператор, который повышает энергию. Именно это и было сделано.

Заметим, между прочим, что так как $\left(\tilde{b}^\dagger\right)^2 = 0$, состояние не может быть заполнено дважды. Более общо, из антикоммутационных соотношений вытекает, что любое многочастичное состояние антисимметрично при перестановке двух частиц: $a^\dagger_{\mathbf{p}} a^\dagger_{\mathbf{q}}|0\rangle = -a^\dagger_{\mathbf{q}} a^\dagger_{\mathbf{p}}|0\rangle$. Таким образом, мы заключаем, что если лестничные операторы подчиняются антикоммутационным соотношениям, то соответствующие частицы удовлетворяют статистике Ферми-Дирака. Мы только что показали, что для того, чтобы быть уверенными, что обеспечено наличие только возбуждений с положительными энергиями, следует проквантовать дираковское поле с антикоммутационными соотношениями; при этих условиях частицы, связанные с дираковским полем, подчиняются статистике Ферми - Дирака. Этот вывод является частью более общего результата, впервые полученного Паули*: из совместного требования лоренц-инвариантности, положительности энергии, положительности нормы и причинности вытекает то, что частицы с целочисленным спином подчиняются статистике Бозе-Эйнштейна, в то время как частицы с полуцелыми спинами подчиняются статистике Ферми-Дирака.

Квантованное дираковское поле

Теперь систематизируем результаты квантования теории Дирака. Чтобы очистить записи от ненужной шелухи, следует улучшить обозначения. С этого места будем записывать $\tilde{b}_{\mathbf{p}}$ (оператор, понижающий энергию состояния) просто как $b_{\mathbf{p}}$, и $\tilde{b}^\dagger_{\mathbf{p}}$ как $b^\dagger_{\mathbf{p}}$. Все выражения, которые понадобятся в дальнейшем, выписаны ниже; соответствующие выражения, приведенные выше, должны быть забыты, если они отличаются от новых. Сначала выпишем полевые операторы:

$$\psi(x) = \int \frac{d^3p}{(2\pi)^3} \frac{1}{\sqrt{2E_{\mathbf{p}}}} \sum_s \left(a^s_{\mathbf{p}} u^s(p) e^{-ip\cdot x} + b^{s\dagger}_{\mathbf{p}} v^s(p) e^{ip\cdot x} \right)$$
$$\bar{\psi}(x) = \int \frac{d^3p}{(2\pi)^3} \frac{1}{\sqrt{2E_{\mathbf{p}}}} \sum_s \left(b^s_{\mathbf{p}} \bar{v}^s(p) e^{-ip\cdot x} + a^{s\dagger}_{\mathbf{p}} \bar{u}^s(p) e^{ip\cdot x} \right)$$

Операторы рождения и уничтожения удовлетворяют антикоммутационным правилам:

$$\left\{ a^r_{\mathbf{p}}, a^{s\dagger}_{\mathbf{q}} \right\} = \left\{ b^r_{\mathbf{p}}, b^{s\dagger}_{\mathbf{q}} \right\} = (2\pi)^3 \delta^{(3)}(\mathbf{p} - \mathbf{q}) \delta^{rs},$$

причем все остальные антикоммутаторы равны нулю. Тогда одновременные антикоммутационные соотношения для ψ и $\psi^\dagger$ имеют вид:

$$\left\{ \psi_a(\mathbf{x}), \psi^\dagger_b(\mathbf{y}) \right\} = \delta^{(3)}(\mathbf{x} - \mathbf{y}) \delta_{ab}$$
$$\{ \psi_a(\mathbf{x}), \psi_b(\mathbf{y}) \} = \left\{ \psi^\dagger_a(\mathbf{x}), \psi^\dagger_b(\mathbf{y}) \right\} = 0$$

Вакуум $|0\rangle$ определяется как такое состояние, что

$$a^s_{\mathbf{p}} |0\rangle = b^s_{\mathbf{p}} |0\rangle = 0.$$

Гамильтониан может быть записан в виде:

$$H = \int \frac{d^3p}{(2\pi)^3} \sum_s E_{\mathbf{p}} \left(a^{s\dagger}_{\mathbf{p}} a^s_{\mathbf{p}} + b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} \right)$$

где отброшено бесконечное постоянное слагаемое, возникающее от антикоммутирования $b^s_{\mathbf{p}}$ и $b^{s\dagger}_{\mathbf{p}}$. Отсюда видно, что вакуум является состоянием с наинизшей энергией, как мы того и хотели. Оператор импульса равен

$$\mathbf{P} = \int d^3x \psi^\dagger (-i\boldsymbol{\nabla}) \psi = \int \frac{d^3p}{(2\pi)^3} \sum_s \mathbf{p} \left(a^{s\dagger}_{\mathbf{p}} a^s_{\mathbf{p}} + b^{s\dagger}_{\mathbf{p}} b^s_{\mathbf{p}} \right)$$

* W. Pauli, Phys. Rev. 58, 716 (1940), перепечатано в Schwinger (1958). Строгое рассмотрение дано в книге: R. F. Streater and A.S. Wightman, PCT, Spin and Statistics, and All That (Benjamin/Cummings, Reading, Mass., 1964). Таким образом, как $a^{s\dagger}_{\mathbf{p}}$, так и $b^{s\dagger}_{\mathbf{p}}$ рождают частицы с энергией $+E_{\mathbf{p}}$ и импульсом $\mathbf{p}$. Мы будем называть частицы, рожденные операторами $a^{s\dagger}_{\mathbf{p}}$, Фермионами, а рожденные операторами $b^{s\dagger}_{\mathbf{p}}$ - антифермионами.

Одночастичные состояния

$$|\mathbf{p}, s\rangle \equiv \sqrt{2E_{\mathbf{p}}} a^{s\dagger}_{\mathbf{p}} |0\rangle$$

определены так, что их скалярное произведение

$$\langle \mathbf{p}, r | \mathbf{q}, s \rangle = 2E_{\mathbf{p}} (2\pi)^3 \delta^{(3)}(\mathbf{p} - \mathbf{q}) \delta^{rs}$$

является лоренц-инвариантным. Отсюда следует, что оператор $U(\Lambda)$, осуществляющий преобразования Лоренца на состояниях гильбертова пространства, унитарен, хотя бусты $\Lambda_{\frac{1}{2}}$ не унитарны.

Для надежности удостоверимся, что $U(\Lambda)$ осуществляет правильное преобразование поля $\psi(x)$. Для этого вычислим

$$U\psi(x)U^{-1} = U\int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\sum_s \left(a^s_{\mathbf{p}}u^s(p)e^{-ipx} + b^{s\dagger}_{\mathbf{p}}v^s(p)e^{ipx}\right)U^{-1}$$

Рассмотрим первое слагаемое; второе рассматривается полностью аналогично. Из уравнения (3.106) следует, что $a^s_{\mathbf{p}}$ преобразуется согласно правилу:

$$U(\Lambda)a^s_{\mathbf{p}}U^{-1}(\Lambda) = \sqrt{\frac{E_{\Lambda p}}{E_p}}a^s_{\Lambda p},$$

если принять, что ось квантования спина параллельна направлению буста или оси вращения. Для того, чтобы использовать это соотношение для вычисления (3.108), перепишем интеграл в виде:

$$\int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}a^s_{\mathbf{p}} = \int \frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}\cdot\sqrt{2E_{\mathbf{p}}}a^s_{\mathbf{p}}$$

Второй множитель просто преобразуется под действием U, а первый является лоренц-инвариантным интегралом. Таким образом, если мы применим (3.109) и сделаем замену $\tilde{p} = \Lambda p$, то (3.108) принимает вид:

$$U(\Lambda)\psi(x)U^{-1}(\Lambda) = \int \frac{d^3\tilde{p}}{(2\pi)^3}\frac{1}{2E_{\tilde{p}}}\sum_s u^s\left(\Lambda^{-1}\tilde{p}\right)\sqrt{2E_{\tilde{p}}}a^s_{\tilde{p}}e^{-i\tilde{p}\cdot\Lambda x} + \cdots$$

Но $u^s\left(\Lambda^{-1}\tilde{p}\right) = \Lambda^{-1}_{\frac{1}{2}}u^s(\tilde{p})$, поэтому действительно мы имеем:

$$U(\Lambda)\psi(x)U^{-1}(\Lambda) = \int \frac{d^3\tilde{p}}{(2\pi)^3}\frac{1}{\sqrt{2E_{\tilde{p}}}}\sum_s \Lambda^{-1}_{\frac{1}{2}}u^s(\tilde{p})a^s_{\tilde{p}}e^{-i\tilde{p}\cdot\Lambda x} + \cdots = \Lambda^{-1}_{\frac{1}{2}}\psi(\Lambda x)$$

Этот результат говорит о том, что преобразованное поле рождает и уничтожает частицы в точке Λx, как и должно быть. Однако обратим внимание, что это преобразование осуществляется в обратном направлении по сравнению с (3.2), где преобразованное поле ϕ было вычислено в точке $\Lambda^{-1}x$. Различие в том, что в разделе 3.1 мы считали, что преобразуется ранее существовавшее распределение поля, которое измерялось величиной $\phi(x)$. Здесь мы преобразовываем действие поля $\phi(x)$ при рождении или уничтожении частиц. Эти два пути выполнения преобразования Лоренца работают в противоположных направлениях. Тем не менее, отметим, что матрицы, действующие на ψ и преобразующие координаты x, имеют правильную относительную ориентацию, согласованную с (3.8).

Обсудим вопрос о спине дираковской частицы. Мы ожидаем, что дираковские фермионы будут иметь спин 1/2. Теперь можно вывести это свойство из нашего формализма. Мы уже показали, что частицы, рожденные операторами $a^{s\dagger}_{\mathbf{p}}$ и $b^{s\dagger}_{\mathbf{p}}$, имеют два "спиновых» состояния: $s = 1, 2$. Но мы все же не доказали, что этот «спин» имеет какое-либо отношение к угловому моменту. Чтобы сделать это, следует выписать оператор углового момента.

Напомним, что оператор обычного импульса в разделе 2.2 связан с трансляционной инвариантностью. Оператор момента импульса может быть найден аналогично, как следствие инвариантности относительно вращений. При вращении (или любом преобразовании Лоренца) дираковское поле ψ преобразуется (согласно исходному определению) как

$$\psi(x) \to \psi'(x) = \Lambda_{\frac{1}{2}}\psi\left(\Lambda^{-1}x\right).$$

Чтобы применить теорему Нетер, следует вычислить изменение поля в фиксированной точке, то есть

$$\delta\psi = \psi'(x) - \psi(x) = \Lambda_{\frac{1}{2}}\psi\left(\Lambda^{-1}x\right) - \psi(x).$$

Рассмотрим для определенности бесконечно малое вращение координат на угол θ вокруг оси z. Параметризация этого преобразования дана сразу после формулы (3.19): $\omega_{12} = -\omega_{21} = \theta$. Используя те же параметры, что и в (3.30), находим

$$\Lambda_{\frac{1}{2}} \approx 1 - \frac{i}{2}\omega_{\mu\nu}S^{\mu\nu} = 1 - \frac{i}{2}\theta\Sigma^3.$$

Теперь можно вычислить

$$\begin{aligned}\delta\psi(x) &= \left(1 - \frac{i}{2}\theta\Sigma^3\right)\psi(t, x+\theta y, y-\theta x, z) - \psi(x) = \\ &= -\theta\left(x\partial_y - y\partial_x + \frac{i}{2}\Sigma^3\right)\psi(x) \equiv \theta\Delta\psi\end{aligned}$$

ВременнАя компонента сохраняющегося нетеровского тока будет равна

$$j^0 = \frac{\partial\mathscr{L}}{\partial\left(\partial_0\psi\right)}\Delta\psi = -i\bar{\psi}\gamma^0\left(x\partial_y - y\partial_x + \frac{i}{2}\Sigma^3\right)\psi$$

Аналогичные выражения имеют место для вращений вокруг осей x и y. Таким образом, оператор углового момента имеет вид:

$$\mathbf{J} = \int d^3x\psi^\dagger\left(\mathbf{x}\times(-i\boldsymbol{\nabla}) + \frac{1}{2}\boldsymbol{\Sigma}\right)\psi$$

Для нерелятивистских фермионов первое слагаемое в (3.111) дает орбитальный угловой момент. Следовательно, второе слагаемое отвечает спиновому угловому моменту. К сожалению, для релятивистских фермионов разделение (3.111) на спиновую и орбитальную части не столь непосредственно очевидно, поэтому не так-то просто написать общее выражение для этой величины в терминах лестничных операторов.

Чтобы доказать, что дираковская частица имеет спин 1/2, достаточно рассмотреть покоящиеся частицы. В этом случае орбитальное слагаемое в (3.111) не дает вклада, и можно легко записать спиновое слагаемое через лестничные операторы. Проще всего использовать шредингеровское представление (3.87) для $\psi(\mathbf{x})$:

$$\begin{aligned}J_z = \int d^3x \int \frac{d^3pd^3p'}{(2\pi)^6}\frac{1}{\sqrt{2E_{\mathbf{p}}2E_{\mathbf{p}'}}}e^{-i\mathbf{p}'\cdot\mathbf{x}}e^{i\mathbf{p}\cdot\mathbf{x}}\times \\ \times\sum_{r,r'}\left(a^{r'\dagger}_{\mathbf{p}'}u^{r'\dagger}(\mathbf{p}') + b^{r'}_{-\mathbf{p}'}v^{r'\dagger}(-\mathbf{p}')\right)\frac{\Sigma^3}{2}\left(a^r_{\mathbf{p}}u^r(\mathbf{p}) + b^{r\dagger}_{-\mathbf{p}}v^r(-\mathbf{p})\right).\end{aligned}$$

Мы хотели бы применить этот оператор к одночастичному состоянию с нулевым импульсом $a_0^{s\dagger}|0\rangle$. Это легче всего выполнить, используя следующий прием. Так как J_z уничтожает вакуум, то $J_z a_0^{s\dagger}|0\rangle = \left[J_z, a_0^{s\dagger}\right]|0\rangle$. Единственное отличное от нуля слагаемое в последней величине имеет структуру $\left[a^{r\dagger}_{\mathbf{p}}a^{r'}_{\mathbf{p}}, a_0^{s\dagger}\right] = (2\pi)^3\delta^{(3)}(\mathbf{p})a_0^{r\dagger}\delta^{r's}$; другие три слагаемых в коммутаторе или исчезают, или уничтожают вакуум. Таким образом,

$$J_z a_0^{s\dagger}|0\rangle = \frac{1}{2m}\sum_r \left(u^{r\dagger}(0)\frac{\Sigma^3}{2}u^s(0)\right) a_0^{r\dagger}|0\rangle = \sum_r \left(\xi^{r\dagger}\frac{\sigma^3}{2}\xi^s\right) a_0^{r\dagger}|0\rangle$$

Чтобы получить последнее выражение, здесь использована явная форма (3.47) для $u(0)$. Сумма по r проще всего берется, если выбрать спиноры ξ^r как собственные состояния σ^3. Тогда находим, что для $\xi^s = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$ одночастичное состояние есть собственное состояние J_z с собственным значением $+1/2$, в то время как для $\xi^s = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$ оно является собственным состоянием J_z с собственным значением $-1/2$. Этот результат как раз совпадает с нашими ожиданиями для электронов.

Аналогичное вычисление определяет спин антифермиона с нулевым импульсом. Но в этом случае, так как порядок b и $b^\dagger$ в J_z обращен, при вычислении $\left[b_{\mathbf{p}}b_{\mathbf{p}}^\dagger, b_0^\dagger\right] = \left[-b_{\mathbf{p}}^\dagger b_{\mathbf{p}}, b_0^\dagger\right]$ получаем дополнительный знак "минус». Таким образом, для позитронов связь между спинорами ξ^s и спиновым угловым моментом противоположная: $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$ соответствует спину $-1/2$, в то время как $\begin{pmatrix} 0 \\ 1 \end{pmatrix}$ соответствует спину $+1/2$. Это обращение знака согласуется с предсказаниями дираковской теории дырок. С этой точки зрения позитрон есть отсутствие электрона с отрицательной энергией. Если пропавший электрон имел положительную проекцию J_z, то его отсутствие приводит к отрицательной проекции $-J_z$.

Итак, угловой момент фермионов с нулевым импульсом определяется равенствами:

$$J_z a_0^{s\dagger}|0\rangle = \pm\frac{1}{2}a_0^{s\dagger}|0\rangle, \quad J_z b_0^{s\dagger}|0\rangle = \mp\frac{1}{2}b_0^{s\dagger}|0\rangle,$$

где верхний знак берется для $\xi^s = \begin{pmatrix} 1 \\ 0 \end{pmatrix}$, а нижний знак - для $\xi^s = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$.

В теории Дирака имеется еще одна важная сохраняющаяся величина. В разделе 3.4 мы видели, что ток $j^\mu = \bar{\psi}\gamma^\mu\psi$ сохраняется. Заряд, связанный с этим током, есть

$$Q = \int d^3x\psi^\dagger(x)\psi(x) = \int \frac{d^3p}{(2\pi)^3}\sum_s \left(a_{\mathbf{p}}^{s\dagger}a_{\mathbf{p}}^s + b_{-\mathbf{p}}^s b_{-\mathbf{p}}^{s\dagger}\right)$$

или, если мы отбрасываем еще одну бесконечную константу,

$$Q = \int \frac{d^3p}{(2\pi)^3}\sum_s \left(a_{\mathbf{p}}^{s\dagger}a_{\mathbf{p}}^s - b_{\mathbf{p}}^{s\dagger}b_{\mathbf{p}}^s\right)$$

Таким образом, операторы $a_{\mathbf{p}}^{s\dagger}$ рождают фермионы с зарядом $+1$, в то время как операторы $b_{\mathbf{p}}^{s\dagger}$ рождают антифермионы с зарядом -1. Когда мы связываем дираковское поле с электромагнитным, мы видим, что Q есть не что иное, как электрический заряд (с точностью до постоянного множителя, который зависит от того, какого типа частицы мы хотим описать; например, для электронов электрический заряд равен Qe).

В квантовой электродинамике спинорное поле ψ используется для описания электронов и позитронов. Частицы, рождаемые операторами $a_{\mathbf{p}}^{s\dagger}$, - электроны; они имеют энергию $E_{\mathbf{p}}$, импульс $\mathbf{p}$, спин 1/2 с поляризацией, соответствующей ξ^s, и заряд $+1$ (в единицах e). Частицы, рождаемые операторами $b_{\mathbf{p}}^{s\dagger}$, - позитроны; они имеют энергию $E_{\mathbf{p}}$, импульс

$\mathbf{p}$, спин 1/2 с поляризацией, обратной поляризации ξ^s, и заряд -1. Состояние $\psi_\alpha(x)|0\rangle$ содержит позитрон в точке x, чья поляризация соответствует выбранной компоненте спинора. Аналогично, $\bar\psi_\alpha(x)|0\rangle$ является состоянием одного электрона в точке x.

9.5.8 Dirac Propagator

Теория

Теперь вычисление амплитуд распространения для дираковского поля становится простым упражнением:

$$\begin{aligned}\left\langle 0\left|\psi_a(x)\bar\psi_b(y)\right|0\right\rangle &= \int\frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}\sum_s u_a^s(p)\bar u_b^s(p)e^{-ip\cdot(x-y)} = \\ &= (i\not\partial_x + m)_{ab}\int\frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}e^{-ip\cdot(x-y)} \\ \left\langle 0\left|\bar\psi_b(y)\psi_a(x)\right|0\right\rangle &= \int\frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}\sum_s v_a^s(p)\bar v_b^s(p)e^{-ip\cdot(y-x)} = \\ &= -(i\not\partial_x + m)_{ab}\int\frac{d^3p}{(2\pi)^3}\frac{1}{2E_{\mathbf{p}}}e^{-ip\cdot(y-x)}.\end{aligned}$$

Так же, как для уравнения Клейна-Гордона, можно построить для уравнения Дирака функции Грина, удовлетворяющие различным граничным условиям. Например, запаздывающая функция Грина

$$S_R^{ab}(x-y)\equiv\theta\left(x^0-y^0\right)\left\langle 0\left|\left\{\psi_a(x),\bar\psi_b(y)\right\}\right|0\right\rangle.$$

Нетрудно проверить, что

$$S_R(x-y) = (i\not\partial_x + m)\,D_R(x-y)$$

так как в правой части слагаемое, включающее $\partial_0\theta\left(x^0-y^0\right)$, исчезает. Используя (3.117)

и то, что $\not\partial\not\partial = \partial^2$, получаем, что S_R — функция Грина оператора Дирака:

$$(i\not\partial_x - m)\,S_R(x-y) = i\delta^{(4)}(x-y)\cdot\mathbf{1}_{4\times4}.$$

Функция Грина оператора Дирака может также быть найдена при помощи преобразования Фурье. Раскладывая $S_R(x-y)$ в интеграл Фурье и действуя с обеих сторон оператором $(i\partial_x - m)$, находим:

$$i\delta^{(4)}(x-y) = \int\frac{d^4p}{(2\pi)^4}(\not p - m)e^{-ip\cdot(x-y)}\widetilde S_R(p)$$

следовательно,

$$\widetilde S_R(p) = \frac{i}{\not p - m} = \frac{i(\not p + m)}{p^2-m^2}.$$

Чтобы получить запаздывающую функцию Грина, следует вычислить интеграл по p^0 в (3.120) по контуру, показанному после формулы (2.54). Для $x^0 > y^0$ замыкаем контур внизу,

огибая оба полюса, получая в результате сумму (3.115) и (3.114). Для $x^0 < y^0$ замыкаем контур вверху и получаем ноль.

Функция Грина с граничными условиями Фейнмана определяется контуром, показанным после формулы (2.58):

$$S_F(x-y) = \int \frac{d^4p}{(2\pi)^4} \frac{i(\not{p}+m)}{p^2-m^2+i\varepsilon} e^{-ip\cdot(x-y)} =$$
$$= \begin{cases} \langle 0|\psi(x)\bar{\psi}(y)|0\rangle & \text{для \% \%} x^0 > y^0 \text{ (контур замыкается внизу)} \\ -\langle 0|\bar{\psi}(y)\psi(x)|0\rangle & \text{для \% \%} x^0 < y^0 \text{ (контур замыкается вверху)} \end{cases} \equiv$$
$$\equiv \langle 0|T\psi(x)\bar{\psi}(y)|0\rangle.$$

Здесь мы определили хронологическое произведение спинорных полей с дополнительным изменением знака при перестановке операторов. Это изменение знака чрезвычайно важно в квантовой теории поля фермионов; мы снова встретимся с этим фактом в разделе 4.7.

Как и в теории Клейна-Гордона, выражение (3.121) для фейнмановского пропагатора - наиболее полезный результат этой главы. Когда мы проводим вычисления по теории возмущений с помощью диаграмм Фейнмана, мы сопоставляем множитель $\widetilde{S}_F(p)$ каждой внутренней линии фермиона.

9.5.9 Discrete Symmetries in Dirac Theory

Теория

В последнем разделе обсуждалась реализация непрерывных преобразований Лоренца на гильбертовом пространстве в теории Дирака. Мы нашли, что для каждого преобразования Λ имеется унитарный оператор $U(\Lambda)$, который производит правильное преобразование полей:

$$U(\Lambda)\psi(x)U^{-1}(\Lambda) = \Lambda^{-1}_{\frac{1}{2}}\psi(\Lambda x)$$

В этом разделе мы рассмотрим аналогичные операторы, которые реализуют различные дискретные симметрии на дираковском поле.

В дополнение к непрерывным преобразованиям Лоренца имеются две других пространственно-временных операции, которые являются потенциальными симметриями лагранжиана: четность и обращение времени. Четность, обозначаемая P, преобразует $(t,\mathbf{x}) \to (t,-\mathbf{x})$, обращая ориентацию пространства. Обращение времени, обозначаемое T, преобразует $(t,\mathbf{x}) \to (-t,\mathbf{x})$, меняя местами будущий и прошлый световые конусы. Ни одна из этих операций не может быть получена при помощи непрерывных преобразований Лоренца. Обе, однако, сохраняют интервал Минковского $x^2 = t^2 - \mathbf{x}^2$. Согласно стандартной терминологии множество непрерывных преобразований Лоренца называется собственной ортохронной группой Лоренца и обозначается $\mathbf{L}^{\uparrow}_{+}$. Полная группа Лоренца разбивается на четыре несвязные компоненты:

$$\begin{array}{ccccc} \mathbf{L}^{\uparrow}_{+} & \overset{P}{\longleftrightarrow} & \mathbf{L}^{\uparrow}_{-} = P\mathbf{L}^{\uparrow}_{+} & & \text{«ортохронная»} \\ T\updownarrow & & \updownarrow T & & \\ \mathbf{L}^{\downarrow}_{+} = T\mathbf{L}^{\uparrow}_{+} & \overset{P}{\longleftrightarrow} & \mathbf{L}^{\downarrow}_{-} = PT\mathbf{L}^{\uparrow}_{+} & & \text{«неортохронная»} \\ \text{«собственная»} & & \text{«несобственная»} & & \end{array}$$

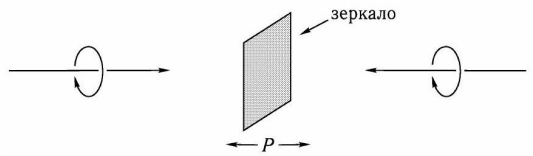
Одновременно с обсуждением симметрий P и T, удобно рассмотреть третью (не относящуюся к пространственно-временным) дискретную операцию - зарядовое сопряжение, обозначаемое C. Эта операция меняет местами частицы и античастицы.

Хотя любая релятивистская теория поля должна быть инвариантна относительно $\mathbf{L}_+^\uparrow$, она не обязана быть инвариантной относительно преобразований P, T или C. Каков статус этих операций симметрии в реальном мире? Из эксперимента известно, что три из сил природы - гравитационные, электромагнитные и сильные взаимодействия - симметричны относительно преобразований P, C и T. Слабые взаимодействия нарушают симметрии C и P по отдельности, но сохраняют CP и T. Одако некоторые редкие процессы (все до сих пор наблюдавшиеся включают нейтральные K-мезоны) также нарушают CP и T. Все наблюдения показывают, что комбинация CPT является точной симметрией природы.

Принятая в настоящее время теоретическая модель слабых взаимодействий - калибровочная теория Глэшоу-Вайнберга-Салама, описанная в гл. 20. В этой теории C и P нарушаются максимально. То, что C и P оказываются весьма хорошими симметриями в большинстве легко наблюдаемых процессов, неожиданно (хотя и не случайно). С другой стороны, никому неизвестна по-настоящему красивая теория, которая нарушает CP-симметрию. В существующей теории, где имеются три (или более) поколения фермионов, определен параметр, вызывающий CP-нарушение в случае, когда он отличен от нуля. Но величина этого параметра понята не лучше, чем величина массы электрона. Физическое происхождение CP-нарушения остается тайной. Мы обсудим этот вопрос далее в разделе 20.3.

9.5.10 Parity

После этого краткого вступления обсудим действие P-, T - и C-преобразований на дираковские частицы и поля. Сначала рассмотрим четность. Оператор P должен менять направление импульса частицы без изменения ее спина:



На математическом языке это означает, что операция P должна быть реализована унитарным оператором (правильнее обозначать его $U(P)$, но мы будем писать просто P), который преобразует, например, состояние $a^s_{\mathbf{p}}|0\rangle$ в $a^s_{-\mathbf{p}}|0\rangle$. Другими словами, мы хотим иметь следующий закон преобразования:

$$Pa^s_{\mathbf{p}}P = \eta_a a^s_{-\mathbf{p}}\% \quad \% \text{ и } \% \quad \%Pb^s_{\mathbf{p}}P = \eta_b b^s_{-\mathbf{p}}$$

где η_a и η_b - возможные фазы. Эти фазы ограничены условием, что двукратное применение оператора четности должно возвращать наблюдаемые к их первоначальным значениям. Так как наблюдаемые построены из четного числа фермионных операторов, то $\eta_a^2, \eta_b^2 = \pm 1$

Так же, как непрерывное преобразование Лоренца реализуется на дираковском поле как 4×4 постоянная матрица $\Lambda_{\frac{1}{2}}$, так и преобразование четности должно представляться 4×4 постоянной матрицей. Чтобы найти эту матрицу и определить η_a и η_b, вычислим действие P на $\psi(x)$. Используя (3.123), находим:

$$P\psi(x)P = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\sum_s \left(\eta_a a^s_{-\mathbf{p}}u^s(p)e^{-ipx} + \eta_b^* b^{s\dagger}_{-\mathbf{p}}v^s(p)e^{ipx}\right)$$

Теперь сделаем замену переменных на $\tilde{p} = (p^0, -\mathbf{p})$. Заметим, что $p\cdot x = \tilde{p}\cdot(t,-\mathbf{x})$. Также $\tilde{p}\cdot\sigma = p\cdot\bar{\sigma}$ и $\tilde{p}\cdot\bar{\sigma} = p\cdot\sigma$. Это позволяет записать:

$$u(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar{\sigma}}\xi \end{pmatrix} = \begin{pmatrix} \sqrt{\tilde{p}\cdot\bar{\sigma}}\xi \\ \sqrt{\tilde{p}\cdot\sigma}\xi \end{pmatrix} = \gamma^0 u(\tilde{p})$$
$$v(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ -\sqrt{p\cdot\bar{\sigma}}\xi \end{pmatrix} = \begin{pmatrix} \sqrt{\tilde{p}\cdot\bar{\sigma}}\xi \\ -\sqrt{\tilde{p}\cdot\sigma}\xi \end{pmatrix} = -\gamma^0 v(\tilde{p}).$$

Поэтому (3.124) будет иметь вид:

$$P\psi(x)P = \int \frac{d^3\tilde{p}}{(2\pi)^3}\frac{1}{\sqrt{2E_{\tilde{p}}}}\sum_s \left(\eta_a a^s_{\tilde{p}}\gamma^0 u^s(\tilde{p})e^{-i\tilde{p}(t,-\mathbf{x})} - \eta_b^* b^{s\dagger}_{\tilde{p}}\gamma^0 v^s(\tilde{p})e^{i\tilde{p}(t,-\mathbf{x})}\right)$$

Это выражение должно равняться некоторой постоянной матрице, умноженной на $\psi(t,-\mathbf{x})$, и это действительно выполняется, если положить $\eta_b^* = -\eta_a$. Отсюда следует, чТо

$$\eta_a\eta_b = -\eta_a\eta_a^* = -1$$

Таким образом, преобразование четности поля $\psi(x)$ в окончательной форме имеет вид:

$$P\psi(t,\mathbf{x})P = \eta_a\gamma^0\psi(t,-\mathbf{x}).$$

Нам важно знать (например, при построении лагранжианов), как преобразуются разные дираковские билинейные формы полей под действием преобразования четности. Имеется пять таких билинейных форм:

$$\bar{\psi}\psi, \quad \bar{\psi}\gamma^\mu\psi, \quad i\bar{\psi}\left[\gamma^\mu,\gamma^\nu\right]\psi, \quad \bar{\psi}\gamma^\mu\gamma^5\psi, \quad i\bar{\psi}\gamma^5\psi$$

Множитель i в некоторых из них присутствует для того, чтобы все эти величины были эрмитовыми, что легко проверяется. (Любое новое слагаемое, дающее вклад в лагранжиан, должно быть вещественным.) Сначала следует вычислить

$$P\bar{\psi}(t,\mathbf{x})P = P\psi^\dagger(t,\mathbf{x})P\gamma^0 = (P\psi(t,\mathbf{x})P)^\dagger\gamma^0 = \eta_a^*\bar{\psi}(t,-\mathbf{x})\gamma^0$$

Тогда скалярная билинейная форма преобразуется как

$$\boldsymbol{P}\bar{\psi}\psi\boldsymbol{P} = |\eta_a|^2\,\bar{\psi}(t,-\mathbf{x})\gamma^0\gamma^0\psi(t,-\mathbf{x}) = +\bar{\psi}\psi(t,-\mathbf{x}),$$

в то время как для векторной формы получаем:

$$P\bar{\psi}\gamma^\mu\psi\boldsymbol{P} = \bar{\psi}\gamma^0\gamma^\mu\gamma^0\psi(t,-\mathbf{x}) = \begin{cases} +\bar{\psi}\gamma^\mu\psi(t,-\mathbf{x}) & \text{для } \mu = 0, \\ -\bar{\psi}\gamma^\mu\psi(t,-\mathbf{x}) & \text{для } \mu = 1,2,3. \end{cases}$$

Обратим внимание, что вектор приобретает тот же самый знак «минус» при пространственных компонентах, как и вектор x^μ. Аналогично, найдем преобразования псевдоскаляра и псевдовектора:

$$\boldsymbol{P}\boldsymbol{i}\bar{\psi}\gamma^5\psi\boldsymbol{P} = i\bar{\psi}\gamma^0\gamma^5\gamma^0\psi(t,-\mathbf{x}) = -i\bar{\psi}\gamma^5\psi(t,-\mathbf{x})$$

$$P\bar{\psi}\gamma^\mu\gamma^5\psi P = \bar{\psi}\gamma^0\gamma^\mu\gamma^5\gamma^0\psi(t,-\mathbf{x}) = \begin{cases} -\bar{\psi}\gamma^\mu\gamma^5\psi & \text{для } \mu = 0 \\ +\bar{\psi}\gamma^\mu\gamma^5\psi & \text{для } \mu = 1,2,3. \end{cases}$$

Как мы и предупреждали в разделе 3.4, приставка "псевдо» означает дополнительный знак «минус» при преобразовании четности. (Свойства преобразования $i\bar{\psi}\left[\gamma^\mu,\gamma^\nu\right]\psi = 2\bar{\psi}\sigma^{\mu\nu}\psi$ разбираются в задаче 3.7.) Заметим, что свойства преобразования фермионных билинейных форм не зависят от η_a, поэтому без потери общности можно положить с самого начала $\eta_a = -\eta_b = 1$.

Однако относительный знак «минус»в (3.125) в преобразованиях четности фермиона и антифермиона имеет важные следствия. Рассмотрим фермион-антифермионное состояние $a^{s\dagger}_{\mathbf{p}}b^{s'\dagger}_{\mathbf{q}}|0\rangle$. Примененяя P, мы находим $P\left(a^{s\dagger}_{\mathbf{p}}b^{s'\dagger}_{\mathbf{q}}|0\rangle\right) = -\left(a^{s\dagger}_{-\mathbf{p}}b^{s'\dagger}_{-\mathbf{q}}|0\rangle\right)$. Таким образом, состояние, содержащее фермионно-антифермионную пару, приобретает знак (-1) при преобразовании четности. Эта информация наиболее полезна при изучении связанных состояний, в которых импульсы фермиона и антифермиона интегрируются со шредингеровской волновой функцией, образуя систему, локализованную в пространстве. Мы подробно рассматриваем такие состояния в разделе 5.3, здесь же следует заметить, что если пространственная волновая функция симметрична при замене $x \to -x$, то состояние имеет отрицательную четность, в то время как если эта функция антисимметрична при замене $x \to -x$, то состояние имеет положительную четность. Например, связанное состояние с $L = 0$ имеет отрицательную четность; состояния с $J = 0$ преобразуется как псевдоскаляр, в то время как три состояния с $J = 1$ преобразуются как пространственные компоненты вектора. Эти свойства обнаруживаются в правилах отбора для распадов позитрония и системы кварк-антикварк (см. задачу 3.8).

9.5.11 Time Reversal

Теперь обратимся к реализации обращения времени. Мы хотели бы трактовать T как унитарный оператор, переводящий $a_{\mathbf{p}}$ в $a_{-\mathbf{p}}$ (и аналогично для $b_{\mathbf{p}}$) и $\psi(t,\mathbf{x})$ в $\psi(-t,\mathbf{x})$ (с точностью до постоянной матрицы). Однако удовлетворить этим требованиям чрезвычайно трудно, так как мы видели, что преобразование, переводящее $a_{\mathbf{p}}$ в $a_{-\mathbf{p}}$, эквивалентно преобразованию, переводящему $(T,\mathbf{x})$ в $(T,-\mathbf{x})$ в разложении ψ. Трудность еще более очевидна, когда мы требуем, чтобы операция обращения времени являлась симметрией в свободной теории Дирака, $[T,H]=0$. Тогда

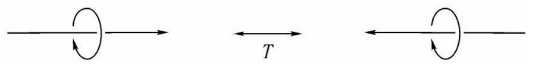
$$\psi(t,\mathbf{x}) = e^{iHt}\psi(\mathbf{x})e^{-iHt} \Rightarrow$$
$$\Rightarrow T\psi(t,\mathbf{x})T = e^{iHt}[T\psi(\mathbf{x})T]e^{-iHt} \Rightarrow$$
$$\Rightarrow T\psi(t,\mathbf{x})T|0\rangle = e^{iHt}[T\psi(\mathbf{x})T]|0\rangle,$$

в предположении, что $H|0\rangle = 0$. Здесь правая часть есть сумма лишь отрицательночастотных слагаемых. Но, если T обращает временную зависимость поля $\psi(t,\mathbf{x})$, тогда левая часть равна (с точностью до постоянной матрицы) $\psi(-t,\mathbf{x})|0\rangle = e^{-iHt}\psi(\mathbf{x})|0\rangle$, что является суммой положительно-частотных слагаемых. Таким образом, мы доказали, что T не может действовать как линейный унитарный оператор. Что можно сделать? Выход был бы в сохрании условия унитарности $T^\dagger = T^{-1}$, но при этом T должен действовать как на с-числа, так и на операторы по правилу:

$$T(\text{ с-число }) = (\text{ с-число })^* T.$$

Тогда, даже если $[T, H] = 0$, зависимость от времени всех множителей в показателе экспоненты обращается: $Te^{+iHt} = e^{-iHt}T$. Так как вся эволюция во времени в квантовой механике выполняется при помощи таких экспоненциальных множителей, это фактически изменяет знак t. Заметим, что операция комплексного сопряжения нелинейна, поэтому T называется антилинейным или антиунитарным оператором.

Кроме изменения импульса частицы, T также должен переворачивать спин:



Чтобы формально описать это, следует найти математическую операцию, которая переворачивает спинор ξ.

В предыдущих частях этой главы мы обозначали спиновое состояние фермиона индексом $s = 1, 2$. В оставшейся части этого раздела, мы свяжем s с физической проекцией спина фермиона на определенную ось. Если эта ось имеет полярные координаты θ, ϕ, то двухкомпонентные спиноры со спином вверх и вниз вдоль этой оси имеют вид:

$$\xi(\uparrow) = \begin{pmatrix} \cos\frac{\theta}{2} \\ e^{i\phi}\sin\frac{\theta}{2} \end{pmatrix}, \quad \xi(\downarrow) = \begin{pmatrix} -e^{-i\phi}\sin\frac{\theta}{2} \\ \cos\frac{\theta}{2} \end{pmatrix}.$$

Пусть $\xi^s = (\xi(\uparrow), \xi(\downarrow))$ для $s = 1, 2$. Определим также

$$\xi^{-s} = -i\sigma^2 (\xi^s)^* .$$

Эта величина есть перевернутый спинор; из явных формул находим:

$$\xi^{-s} = (\xi(\downarrow), -\xi(\uparrow)).$$

Вид формулы для обращения спина в более общем случае следует из тождества $\boldsymbol{\sigma}\sigma^2 = \sigma^2(-\sigma^*)$. Из него следует, что если ξ удовлетворяет $\mathbf{n}\cdot\boldsymbol{\sigma}\xi = +\xi$ для некоторой оси $\mathbf{n}$, то

$$(\mathbf{n}\cdot\sigma)\left(-i\sigma^2\xi^*\right) = -i\sigma^2(-\mathbf{n}\cdot\sigma)^*\xi^* = i\sigma^2(\xi^*) = -\left(-i\sigma^2\xi^*\right)$$

Обратим внимание, что, приняв такое определение переворота спина, находим, что два последовательных переворота приводят к умножению первоначального спинового состояния на (-1).

Теперь сопоставим различные фермионные спиновые состояния выписанным спинорам. Электронный оператор уничтожения $a^s_{\mathbf{p}}$ уничтожает электрон, описываемый спинором $u^s(p)$, содержащим ξ^s. Оператор уничтожения позитрона $b^s_{\mathbf{p}}$ уничтожает позитрон, чей спинор $v^s(p)$ содержит ξ^{-s}:

$$v^s(p) = \begin{pmatrix} \sqrt{p\cdot\sigma}\xi^{-s} \\ -\sqrt{p\cdot\bar{\sigma}}\xi^{-s} \end{pmatrix}$$

Как и в (3.135), определяем:

$$a^{-s}_{\mathbf{p}} = \left(a^2_{\mathbf{p}}, -a^1_{\mathbf{p}}\right), \quad b^{-s}_{\mathbf{p}} = \left(b^2_{\mathbf{p}}, -b^1_{\mathbf{p}}\right).$$

Теперь можно вывести соотношение между дираковскими спинорами u и v и их обращениями во времени. Определим $\tilde{p} = (p^0, -\mathbf{p})$. Этот вектор удовлетворяет тождеству $\sqrt{\tilde{p}\cdot\sigma}\sigma^2 = \sigma^2\sqrt{p\cdot\sigma^*}$. Для доказательства разложим квадратный корень как в (3.49). При некотором выборе спина и импульса, связанных с дираковским спинором $u^s(p)$, пусть $u^{-s}(\tilde{p})$ обозначает спинор с обращенным импульсом и перевернутым спином. Эти величины связаны соотношением:

$$u^{-s}(\tilde{p}) = \begin{pmatrix} \sqrt{\tilde{p}\cdot\sigma}\,(-i\sigma^2\xi^{s*}) \\ \sqrt{\tilde{p}\cdot\bar{\sigma}}\,(-i\sigma^2\xi^{s*}) \end{pmatrix} = \begin{pmatrix} -i\sigma^2\sqrt{p\cdot\sigma^*}\xi^{s*} \\ -i\sigma^2\sqrt{p\cdot\bar{\sigma}^*}\xi^{s*} \end{pmatrix} =$$
$$= -i\begin{pmatrix} \sigma^2 & 0 \\ 0 & \sigma^2 \end{pmatrix}[u^s(p)]^* = -\gamma^1\gamma^3\,[u^s(p)]^*$$

Аналогично для $v^s(p)$,

$$v^{-s}(\tilde{p}) = -\gamma^1\gamma^3\,[v^s(p)]^*$$

в этом соотношении v^{-s} содержит $\xi^{-(-s)} = -\xi^s$.

Используя (3.137), определим преобразование обращения времени фермионных операторов уничтожения следующим образом:

$$Ta^s_{\mathbf{p}}T = a^{-s}_{-\mathbf{p}}, \quad Tb^s_{\mathbf{p}}T = b^{-s}_{-\mathbf{p}}.$$

(Дополнительная общая фаза не имеет никакого влияния на дальнейшее изложение и для простоты опускается.) Соотношения (3.138) позволяют вычислить действие T на фермионное поле $\psi(x)$:

$$T\psi(t,\mathbf{x})T = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\sum_s T\left(a^s_{\mathbf{p}}u^s(p)e^{-ipx} + b^{s\dagger}_{\mathbf{p}}v^s(p)e^{ipx}\right)T =$$
$$= \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\sum_s \left(a^{-s}_{-\mathbf{p}}\,[u^s(p)]^*\,e^{ipx} + b^{-s\dagger}_{-\mathbf{p}}\,[v^s(p)]^*\,e^{-ipx}\right) =$$
$$= \left(-\gamma^1\gamma^3\right)\int \frac{d^3\tilde{p}}{(2\pi)^3}\frac{1}{\sqrt{2E_{\tilde{p}}}}\sum_s \left(a^{-s}_{\tilde{p}}u^{-s}(\tilde{p})e^{i\tilde{p}(t,-\mathbf{x})} + b^{-s\dagger}_{\tilde{p}}v^{-s}(\tilde{p})e^{-i\tilde{p}(t,-\mathbf{x})}\right) =$$
$$= \left(-\gamma^1\gamma^3\right)\psi(-t,\mathbf{x}).$$

На последнем шаге мы использовали $\tilde{p}\cdot(t,-\mathbf{x}) = -\tilde{p}\cdot(-t,\mathbf{x})$. Как и для четности, мы получили простой закон преобразования для фермионного поля $\psi(x)$. Относительный знак «минус»в законах преобразования для частицы и античастицы неявно присутствует и здесь, в дважды перевернутом спиноре в v^{-s}.

Теперь можно установить результат действия T на различные билинейные формы. Нам потребуется формула:

$$T\bar{\psi}T = (T\psi T)^\dagger\left(\gamma^0\right)^* = \psi^\dagger(-t,\mathbf{x})\left[-\gamma^1\gamma^3\right]^\dagger\gamma^0 = \bar{\psi}(-t,\mathbf{x})\left[\gamma^1\gamma^3\right]$$

Тогда для преобразования скалярной билинейной формы имеем:

$$T\bar{\psi}\psi(t,\mathbf{x})T = \bar{\psi}\left(\gamma^1\gamma^3\right)\left(-\gamma^1\gamma^3\right)\psi(-t,\mathbf{x}) = +\bar{\psi}\psi(-t,\mathbf{x})$$

При протаскивании T через i, псевдоскаляр приобретает дополнительный знак «минус»:

$$Ti\bar{\psi}\gamma^5\psi T = -i\bar{\psi}\left(\gamma^1\gamma^3\right)\gamma^5\left(-\gamma^1\gamma^3\right)\psi = -i\bar{\psi}\gamma^5\psi(-t,\mathbf{x})$$

Для вектора нужно провести вычисления отдельно для каждого из четырех случаев $\mu = 0,1,2,3$. После небольшой работы находим:

$$T\bar{\psi}\gamma^\mu\psi T = \bar{\psi}\left(\gamma^1\gamma^3\right)\left(\gamma^\mu\right)^*\left(-\gamma^1\gamma^3\right)\psi = \begin{cases} +\bar{\psi}\gamma^\mu\psi(-t,\mathbf{x}) & \text{для } \mu = 0 \\ -\bar{\psi}\gamma^\mu\psi(-t,\mathbf{x}) & \text{для } \mu = 1,2,3 \end{cases}$$

Это как раз то свойство преобразования, которое нужно для таких векторов, как плотность тока. Можно проверить, что при обращении времени псевдовектор преобразуется таким же образом.

9.5.12 Charge Conjugation

Последняя из трех дискретных симметрий - это симметрия относительного зарядового сопряжения C, меняющая местами частицы и античастицы. Без труда можно реализавать C как унитарный линейный оператор. Зарядовое сопряжение обычно определяется как преобразование фермиона с заданной ориентацией спина в антифермион с той же спиновой ориентацией. Таким образом, удобным выбором для преобразования фермионных операторов уничтожения будет

$$Ca^s_{\mathbf{p}}C = b^s_{\mathbf{p}}; \quad Cb^s_{\mathbf{p}}C = a^s_{\mathbf{p}}.$$

Снова для простоты мы игнорируем возможные дополнительные фазы.

Далее мы хотим выяснить результат действия C на поле $\psi(x)$. Прежде всего нам понадобится соотношение между $v^s(p)$ и $u^s(p)$. Используя (3.136) и (3.134), находим:

$$\left(v^s(p)\right)^* = \begin{pmatrix} \sqrt{p\cdot\sigma}\left(-i\sigma^2\xi^*\right) \\ -\sqrt{p\cdot\bar{\sigma}}\left(-i\sigma^2\xi^*\right) \end{pmatrix}^* = \begin{pmatrix} -i\sigma^2\sqrt{p\cdot\bar{\sigma}^*}\xi^* \\ i\sigma^2\sqrt{p\cdot\sigma^*}\xi^* \end{pmatrix}^* = \begin{pmatrix} 0 & -i\sigma^2 \\ i\sigma^2 & 0 \end{pmatrix}\begin{pmatrix} \sqrt{p\cdot\sigma}\xi \\ \sqrt{p\cdot\bar{\sigma}}\xi \end{pmatrix},$$

где ξ стоит за ξ^s. Это означает, что

$$u^s(p) = -i\gamma^2\left(v^s(p)\right)^*, \quad v^s(p) = -i\gamma^2\left(u^s(p)\right)^*.$$

Если подставить (3.144) в выражение для оператора фермионного поля и затем преобразовать этот оператор при помощи C, то

$$C\psi(x)C = \int\frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\sum_s\left(-i\gamma^2 b^s_{\mathbf{p}}\left(v^s(p)\right)^* e^{-ipx} - i\gamma^2 a^{s\dagger}_{\mathbf{p}}\left(u^s(p)\right)^* e^{ipx}\right) =$$
$$= -i\gamma^2\psi^*(x) = -i\gamma^2\left(\psi^\dagger\right)^T = -i\left(\bar{\psi}\gamma^0\gamma^2\right)^T$$

Обратим внимание, что C является линейным унитарным оператором, несмотря на то, что он переводит $\psi \to \psi^*$.

Снова мы хотели бы знать, как C действует на фермионные билинейные формы. Во-первых, нам понадобится формула:

$$C\bar{\psi}(x)C = C\psi^\dagger C\gamma^0 = \left(-i\gamma^2\psi\right)^T\gamma^0 = \left(-i\gamma^0\gamma^2\psi\right)^T$$

Вывод преобразований для билинейных форм несколько сложнее. Удобнее всего явно выписывать спинорные индексы. Для скаляра

$$C\bar{\psi}\psi C = \left(-i\gamma^0\gamma^2\psi\right)^T \left(-i\bar{\psi}\gamma^0\gamma^2\right)^T = -\gamma^0_{ab}\gamma^2_{bc}\psi_c\bar{\psi}_d\gamma^0_{de}\gamma^2_{ea} = \\ = +\bar{\psi}_d\gamma^0_{de}\gamma^2_{ea}\gamma^0_{ab}\gamma^2_{bc}\psi_c = -\bar{\psi}\gamma^2\gamma^0\gamma^0\gamma^2\psi = +\bar{\psi}\psi$$

(Знак "минус» на третьем шаге вытекает из антикоммутативности фермионов.) Для псевдоскаляра вывод не более сложен:

$$Ci\bar{\psi}\gamma^5\psi C = i\left(-i\gamma^0\gamma^2\psi\right)^T\gamma^5\left(-i\bar{\psi}\gamma^0\gamma^2\right)^T = i\bar{\psi}\gamma^5\psi$$

Преобразование для каждой компоненты вектора и псевдовектора следует делать отдельно. Учитывая, что γ^0 и γ^2 являются симметричными матрицами, в то время как γ^1 и γ^3 - антисимметричны, находим:

$$C\bar{\psi}\gamma^\mu\psi C = -\bar{\psi}\gamma^\mu\psi$$
$$C\bar{\psi}\gamma^\mu\gamma^5\psi C = +\bar{\psi}\gamma^\mu\gamma^5\psi$$

Хотя оператор C меняет местами ψ и $\bar{\psi}$, он реально не меняет порядка операторов уничтожения и рождения. Таким образом, если $\bar{\psi}\gamma^0\psi$ определена так, что в ней вычтена бесконечная константа, упомянутая перед (3.113), то эта константа не появляется вновь в результате зарядового сопряжения.

9.5.13 Summary of Formulas for C, P, and T Transformations

Свойства преобразования различных фермионных билинейных форм под действием преобразований $C, P,$ и T сведены вместе в приведенной ниже таблице. Здесь мы используем сокращения $(-1)^\mu \equiv 1$ для $\mu = 0$ и $(-1)^\mu \equiv -1$ для $\mu = 1, 2, 3$.

	$\bar{\psi}\psi$	$i\bar{\psi}\gamma^5\psi$	$\bar{\psi}\gamma^\mu\psi$	$\bar{\psi}\gamma^\mu\gamma^5\psi$	$\bar{\psi}\sigma^{\mu\nu}\psi$	∂_μ
P	$+1$	-1	$(-1)^\mu$	$-(-1)^\mu$	$(-1)^\mu(-1)^\nu$	$(-1)^\mu$
T	$+1$	-1	$(-1)^\mu$	$(-1)^\mu$	$-(-1)^\mu(-1)^\nu$	$-(-1)^\mu$
C	$+1$	$+1$	-1	$+1$	-1	$+1$
CPT	$+1$	$+1$	-1	-1	$+1$	-1

Мы включили сюда свойства преобразования тензорной билинейной формы (см. задачу 3.7), а также оператора производной.

Во-первых, заметим, что свободный дираковский лагранжиан $\mathscr{L}_0 = \bar{\psi}\left(i\gamma^\mu\partial_\mu - m\right)\psi$ инвариантен относительно преобразований C, P и T по отдельности. Можно построить более общие квантовые системы, которые нарушают любые из этих симметрий, добавляя к $\mathscr{L}_0$ некоторые возмущения $\delta\mathscr{L}$. Но $\delta\mathscr{L}$ должен быть лоренцевым скаляром, и последняя строка таблицы показывает, что все комбинации $\bar{\psi}$ и ψ, являющиеся лоренцевыми скалярами, инвариантны относительно комбинированной симметрии CPT. На самом деле в общем случае справедливо утверждение, что невозможно построить лоренц-инвариантную квантовую теорию поля с эрмитовым гамильтонианом, в которой нарушается CPT симметрия*.

9.5.14 How does the electron know that some state is occupied and not go there by Pauli's principle?

(вопрос о том, как передается об этом информация? у нас же скорость света конечная. фотон что ли какой-то летит из таких занятых состояний? Или как-то волновая функция размыта и он чувствует, что там всё занято? это похоже на большой вопрос, вообще не знаю, как ответить на него???)

9.5.15 Examples of Problems and Solutions

ПШ-3.1. Группа Лоренца.

Напомним вытекающие из (3.17) коммутационные соотношения для генераторов группы Лоренца:

$$[J^{\mu\nu}, J^{\rho\sigma}] = i\left(g^{\nu\rho}J^{\mu\sigma} - g^{\mu\rho}J^{\nu\sigma} - g^{\nu\sigma}J^{\mu\rho} + g^{\mu\sigma}J^{\nu\rho}\right)$$

(a) Определим генераторы вращений и собственно лоренцевых преобразований (бустов) как

$$L^i = \frac{1}{2}\varepsilon^{ijk}J^{jk}, \quad K^i = J^{0i}$$

где $i, j, k = 1, 2, 3$. Тогда бесконечно малое преобразование Лоренца можно записать в виде

$$\Phi \to (1 - i\boldsymbol{\theta}\cdot\mathbf{L} - i\boldsymbol{\beta}\cdot\mathbf{K})\Phi$$

Выпишите явно коммутационные соотношения для этих векторных операторов. (Например, $[L^i, L^j] = i\varepsilon^{ijk}L^k$.) Покажите, что комбинации

$$\mathbf{J}_+ = \frac{1}{2}(\mathbf{L} + i\mathbf{K}) \quad \text{и} \quad \%\quad \%\mathbf{J}_- = \frac{1}{2}(\mathbf{L} - i\mathbf{K})$$

коммутируют друг с другом и по отдельности удовлетворяют коммутационным соотношениям углового момента.

(b) Конечномерные представления группы вращений в точности соответствуют допустимым значениям углового момента, который может быть целым или полуцелым числом. Из результата части (a) следует, что все конечномерные представления группы Лоренца соответствуют парам целых или полуцелых чисел (j_+, j_-), соответствующих парам представлений группы вращений. Используя тот факт, что $J = \sigma/2$ в представлении углового момента со спином $1/2$, выпишите явно законы преобразования для двухкомпонентных объектов, преобразующихся по представлениям группы Лоренца, соответствующим парам $\left(\frac{1}{2}, 0\right)$ и $\left(0, \frac{1}{2}\right)$. Покажите, что они в точности соответствуют преобразованиям ψ_L и ψ_R, заданным в (3.37).

(c) Тождество $\sigma^T = -\sigma^2\sigma\sigma^2$ позволяет переписать преобразование для ψ_L в унитарно эквивалентной форме

$$\psi' \to \psi'\left(1 + i\boldsymbol{\theta}\cdot\frac{\boldsymbol{\sigma}}{2} + \boldsymbol{\beta}\cdot\frac{\boldsymbol{\sigma}}{2}\right)$$

где $\psi' = \psi_L^T\sigma^2$. Применяя этот закон, можно представить объект, преобразующийся по представлению $\left(\frac{1}{2}, \frac{1}{2}\right)$ в виде 2×2 матрицы, которая включает левый закон преобразования

для ψ_R вместе с правым законом преобразования для транспонированного ψ_L. Параметризуем эту матрицу как

$$\begin{pmatrix} V^0+V^3 & V^1-iV^2 \\ V^1+iV^2 & V^0-V^3 \end{pmatrix}$$

Покажите, что объект V^μ преобразуется как 4-вектор.

ПШ-3.2. Тождество Гордона

Получите тождество Гордона

$$\bar{u}\left(p'\right)\gamma^\mu u(p)=\bar{u}\left(p'\right)\left[\frac{p'^\mu+p^\mu}{2m}+\frac{i\sigma^{\mu\nu}q_\nu}{2m}\right]u(p)$$

где $q=(p'-p)$. Мы будем использовать эту формулу в гл. 6.

ПШ-3.3. Произведения спиноров.

(Эта задача, вместе с задачами 5.3 и 5.6, дает эффективный вычислительный метод для процессов, включающих безмассовые частицы.) Пусть k_0^μ, k_1^μ - фиксированные 4-векторы, удовлетворяющие условиям $k_0^2=0,\ k_1^2=-1, k_0\cdot k_1=0$. Определим базисные спиноры следующим способом. Пусть u_{L0} - левополяризованный спинор для фермиона с импульсом k_0. Пусть $u_{R0}=\not{k}_1 u_{L0}$. Тогда для любого изотропного (светоподобного) $(p^2=0)$ 4-импульса p определим

$$u_L(p)=\frac{1}{\sqrt{2p\cdot k_0}}\not{p}u_{R0}\%\quad \%\text{ и }\%\quad \%u_R(p)=\frac{1}{\sqrt{2p\cdot k_0}}\not{p}u_{L0}$$

Этот набор условий однозначно определяет фазы спиноров (за исключением того случая, когда p параллелен k_0).

(a) Покажите, что $\not{k}_0 u_{R0}=0$. Покажите, что для любого изотропного $p\quad \not{p}u_L(p)=\not{p}u_R(p)=0$.

(b) Для случаев $k_0=(E,0,0,-E), k_1=(0,1,0,0)$, постройте явно $u_{L0}, u_{R0}, u_L(p)$ и $u_R(p)$.

(c) Определим произведение спиноров $s\left(p_1,p_2\right)$ и $t\left(p_1,p_2\right)$ для изотропных p_1,p_2 согласно формуле

$$s\left(p_1,p_2\right)=\bar{u}_R\left(p_1\right)u_L\left(p_2\right),\quad t\left(p_1,p_2\right)=\bar{u}_L\left(p_1\right)u_R\left(p_2\right)$$

Используя явный вид u_λ, заданный в (b), вычислите явно произведения спиноров и покажите, что $t\left(p_1,p_2\right)=\left(s\left(p_2,p_1\right)\right)^*$ и $s\left(p_1,p_2\right)=-s\left(p_2,p_1\right)$. Кроме того, покажите, что

$$\left|s\left(p_1,p_2\right)\right|^2=2p_1\cdot p_2.$$

Таким образом, произведение спиноров является квадратным корнем из скалярного произведения 4-векторов.

ПШ-3.4. Майорановские фермионы.

Напомним, что при помощи (3.40) можно написать релятивистское уравнение для безмассового 2-компонентного фермионного поля, преобразующегося как две верхних компоненты дираковского спинора (ψ_L). Обозначим такое двухкомпонентное поле $\chi_a(x), a = 1, 2$.

(a) Покажите, что уравнение для $\chi(x)$ можно записать как уравнение для массивного поля:

$$i\bar{\sigma} \cdot \partial\chi - im\sigma^2\chi^* = 0$$

Иначе говоря, во-первых, покажите, что это уравнение является релятивистски инвариантным и, во-вторых, что из него следует уравнение Клейна-Гордона $(\partial^2 + m^2)\,\chi = 0$. Этот вид массового слагаемого для фермиона назван майорановским массовым слагаемым.

(b) Следует ли уравнение Майорана из лагранжиана? Казалось бы, массовое слагаемое, получается варьированием выражения $(\sigma^2)_{ab}\,\chi_a^*\chi_b^*$; Однако, так как σ^2 - антисимметричная матрица, это выражение обратилось бы в нуль, если бы $\chi(x)$ было обычным с-числовым полем. Известно, что при переходе к квантовой теории поля $\chi(x)$ становится антикоммутирующим квантовым полем. Следовательно, имеет смысл развивать классическую теорию этого поля, рассматривая $\chi(x)$ как классическое антикоммутирующее поле, то есть как поле, которое принимает значения в грассмановых числах, удовлетворяющих условиям:

$$\alpha\beta = -\beta\alpha \quad \text{для любых } \alpha, \beta.$$

Заметим, что из этих соотношений следует, что $\alpha^2 = 0$. Грассманово поле $\xi(x)$ может быть разложено по базису функций как

$$\xi(x) = \sum_n \alpha_n \phi_n(x),$$

где $\phi_n(x)$ - ортогональные с-числовые функции и α_n - набор независимых грассмановых чисел. Определим комплексное сопряжение произведения грассмановых чисел как обращающее их порядок:

$$(\alpha\beta)^* \equiv \beta^*\alpha^* = -\alpha^*\beta^*.$$

Это правило по форме совпадает с эрмитовым сопряжением квантовых полей. Покажите, что классическое действие

$$S = \int d^4x \left[\chi^\dagger i\bar{\sigma} \cdot \partial\chi + \frac{im}{2}\left(\chi^T\sigma^2\chi - \chi^\dagger\sigma^2\chi^*\right)\right]$$

(где $\chi^\dagger = (\chi^*)^T$) является вещественным ($S^* = S$) и варьирование S относительно χ и χ^* приводит к уравнению Майорана.

(c) Запишем 4-компонентное дираковское поле как

$$\psi(x) = \begin{pmatrix} \psi_L \\ \psi_R \end{pmatrix}$$

и напомним, что нижняя компонента ψ преобразуется по представлению, унитарно эквивалентному комплексно-сопряженному представлению ψ_L. Таким образом, можно переписать 4-компонентное дираковское поле в терминах двух 2-компонентных спиноров:

$$\psi_L(x) = \chi_1(x), \quad \psi_R(x) = i\sigma^2\chi_2^*(x).$$

Перепишите лагранжиан Дирака в терминах χ_1 и χ_2 и обратите внимание на форму массового слагаемого.

(d) Покажите, что действие пункта (c) имеет глобальную симметрию. Вычислите дивергенции токов

$$J^\mu = \chi^\dagger\bar\sigma^\mu\chi, \quad J^\mu = \chi_1^\dagger\bar\sigma^\mu\chi_1 - \chi_2^\dagger\bar\sigma^\mu\chi_2,$$

для теорий пунктов (b) и (c), соответственно, и свяжите результаты с симметриями этих теорий. Постройте теорию из N свободных массивных 2-компонентных фермионных полей с $O(N)$ симметрией (то есть с вращательной симметрией в N-мерном пространстве).

(e) Проквантуйте теорию Майорана пунктов (a) и (b). Иными словами, рассмотрите $\chi(x)$ как квантовое поле, удовлетворяющее каноническому антикоммутационному соотношению

$$\left\{\chi_a(\mathbf{x}), \chi_b^\dagger(\mathbf{y})\right\} = \delta_{ab}\delta^{(3)}(\mathbf{x}-\mathbf{y})$$

Постройте эрмитовый гамильтониан и найдите представление канонических коммутационных соотношений, которое диагонализует гамильтониан в терминах набора операторов рождения и уничтожения. (Указание: сравните поле $\chi(x)$ с двумя верхними компонентами проквантованного дираковского поля.)

ПШ-3.5. Суперсимметрия.

Можно написать теории поля с непрерывными симметриями, смешивающими фермионы и бозоны. Соответствующие преобразования названы суперсимметриями.

(a) Простейший пример суперсимметричной теории поля - теория свободных комплексного бозонного и фермионного вейлевского полей с лагранжианом

$$\mathscr{L} = \partial_\mu\phi^*\partial^\mu\phi + \chi^\dagger i\bar\sigma\cdot\partial\chi + F^*F.$$

Здесь F является дополнительным комплексным скалярным полем с уравнением движения $F = 0$. Покажите, что этот лагранжиан является инвариантным (с точностью до полной производной) относительно бесконечно малых преобразований вида

$$\begin{aligned}\delta\phi &= -i\varepsilon^T\sigma^2\chi,\\ \delta\chi &= \varepsilon F + \sigma\cdot\partial\phi\sigma^2\varepsilon^*,\\ \delta F &= -i\varepsilon^\dagger\bar\sigma\cdot\partial\chi,\end{aligned}$$

где параметр ε_a есть 2-компонентный грассмановский спинор.

(b) Покажите, что слагаемое

$$\Delta\mathscr{L} = \left[m\phi F + \frac{1}{2}im\chi^T\sigma^2\chi\right] + (\text{ комплексно-сопряженное })$$

является также лево-инвариантным под действием преобразования, заданного в части (a). Устраните F из полного лагранжиана $\mathscr{L}+\Delta\mathscr{L}$, решая его уравнение движения, и покажите, что бозонное и фермионное поля ϕ и χ имеют одинаковые массы.

(c) Можно написать суперсимметричные нелинейные уравнения поля, добавляя к лагранжиану слагаемые кубического и более высокого порядков. Покажите, что следующая, достаточно общая теория поля, содержащая поля $(\phi_i,\chi_i)\,, i=1,...,n$, является суперсимметричной:

$$\mathscr{L}=\partial_\mu\phi_i^*\partial^\mu\phi_i+\chi_i^\dagger i\bar\sigma\cdot\partial\chi_i+F_i^*F_i+\left(F_i\frac{\partial W[\phi]}{\partial\phi_i}+\frac{i}{2}\frac{\partial^2W[\phi]}{\partial\phi_i\partial\phi_j}\chi_i^T\sigma^2\chi_j+\text{ к.с. }\right)$$

где $W[\phi]$ - произвольная функция поля ϕ_i, называемая суперпотенциалом. Для простого случая $n=1$ и $W=g\phi^3/3$ выпишите уравнения движения для полей ϕ и χ (после устранения F).

ПШ-3.6. Преобразования Фирца.

Пусть $u_i, i=1,...,4$ - четыре 4-компонентных дираковских спинора. В тексте мы доказали формулы перестановки Фирца (3.78) и (3.79). Первая из этих формул может быть записана в 4-компонентных обозначениях как

$$\bar u_1\gamma^\mu\left(\frac{1+\gamma^5}{2}\right)u_2\bar u_3\gamma_\mu\left(\frac{1+\gamma^5}{2}\right)u_4=-\bar u_1\gamma^\mu\left(\frac{1+\gamma^5}{2}\right)u_4\bar u_3\gamma_\mu\left(\frac{1+\gamma^5}{2}\right)u_2.$$

На самом деле подобные формулы перестановки имеют место для любого произведения

$$\left(\bar u_1\Gamma^Au_2\right)\left(\bar u_3\Gamma^Bu_4\right),$$

где Γ^A,Γ^B - любая из 16 комбинаций матриц Дирака, перечисленных в разделе 3.4. (a) Для начала нормируем эти 16 матриц Γ^A по правилу

$$\text{tr}\left[\Gamma^A\Gamma^B\right]=4\delta^{AB}.$$

Это дает $\Gamma^A=\{1,\gamma^0,i\gamma^j,...\}$. Выпишите все 16 элементов этого набора.

(b) Выпишите главное тождество Фирца как уравнение

$$\left(\bar u_1\Gamma^Au_2\right)\left(\bar u_3\Gamma^Bu_4\right)=\sum_{C,D}C_{CD}^{AB}\left(\bar u_1\Gamma^Cu_4\right)\left(\bar u_3\Gamma^Du_2\right)$$

с неизвестными коэффициентами $C^{AB}{}_{CD}$. Используя условие полноты для шестнадцати матриц Γ^A, покажите, что

$$C_{CD}^{AB}=\frac{1}{16}\,\text{tr}\left[\Gamma^C\Gamma^A\Gamma^D\Gamma^B\right].$$

(c) Найдите явно законы преобразования Фирца для произведений $(\bar u_1u_2)\,(\bar u_3u_4)$ и $(\bar u_1\gamma^\mu u_2)\,(\bar u_3\gamma_\mu u_4)$

ПШ-3.7. О дискретных симметриях P, C, и T.

(a) Найдите свойства преобразования под действием P, C, и T преобразований антисимметричной тензорной фермионной билинейной формы $\bar{\psi}\sigma^{\mu\nu}\psi$, где $\sigma^{\mu\nu} = \frac{i}{2}[\gamma^\mu, \gamma^\nu]$. Это завершает таблицу свойств преобразования билинейных форм, приведенную в конце главы.

(b) Пусть $\phi(x)$ - комплексное поле Клейна-Гордона, которое было рассмотрено в задаче 2.2. Найдите унитарные операторы P, C и антиунитарный оператор T (определенные в терминах их действия на операторы уничтожения a_p и b_p для частиц и античастиц Клейна-Гордона), которые дают следующие преобразования поля Клейна-Гордона:

$$P\phi(t,\mathbf{x})P = \phi(t,-\mathbf{x})$$
$$T\phi(t,\mathbf{x})T = \phi(-t,\mathbf{x})$$
$$C\phi(t,\mathbf{x})C = \phi^*(t,\mathbf{x})$$

Найдите свойства преобразования компонент тока

$$J^\mu = i\left(\phi^*\partial^\mu\phi - \partial^\mu\phi^*\phi\right)$$

при преобразованиях P, C и T.

(c) Покажите, что любой эрмитовый скалярный по отношению к преобразованиям Лоренца локальный оператор, построенный из полей $\psi(x), \phi(x)$ и их сопряженных, имеет $CPT = +1$.

ПШ-3.8. Связанные состояния.

Две частицы со спином 1/2 могут объединяться в состояние с полным спином, равным либо 0, либо 1. Волновые функции этих состояний при перестановке их спинов будут, соответственно, нечетные или четные.

(a) Используйте эту информацию, чтобы вычислить квантовые числа P - и C-четностей всех связанных состояний электрона и позитрона с S, P или D волновыми функциями. (b) Так как электрон-фотонное взаимодействие задается гамильтонианом

$$\Delta H = \int d^3x e A_\mu j^\mu$$

где j^μ - электрический ток, то электродинамика инвариантна относительно преобразований P и C, если компоненты векторного потенциала имеют такие же P - и C-четности, как и соответствующие компоненты j^μ. Покажите, что отсюда вытекает следующий удивительный факт: основное состояние позитрония со спином 0 может распадаться на 2 фотона, но основное состояние со спином 1 должно распадаться на 3 фотона. Найдите правила отбора для аннигиляции высших состояний позитрония, а также для однофотонных переходов между уровнями позитрония.

9.6 Spinor Field (fermions) 3: Mathematical Details

(this shuold be rewritten, now structure does not match the title, I should go through this theory to find out what to delete and what to move????)

9.6.1 1. Dirac Equation

В этой лекции рассмотрение идёт в четырёхмерном пространстве Минковского, $\mu, \nu, ... = 0, 1, 2, 3, \quad i, j, ... = 1, 2, 3.$

Рассмотрим операторы

$$J^i = -i\varepsilon_{ijk} x^j \partial_k + \frac{1}{2}\sigma^i \tag{1}$$

где

$$\sigma^1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma^2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma^3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \tag{2}$$

• сигма-матрицы Паули. Легко проверить, что

$$\left[J^i, J^j\right] = i\varepsilon_{ijk} J^k \tag{3}$$

Таким образом, оператор $\mathbf{J}$ является оператором полного момента импульса, включая спин частицы, который в рассмотренном случае равен (1/2). Как известно, операторы полного момента J являются генераторами вращений в 3 -мерном пространстве, что выражается формулами

$$\begin{gathered}(1 + i\boldsymbol{\omega}\mathbf{J})\mathbf{x}(1 - i\boldsymbol{\omega}\mathbf{J}) = \mathbf{x} + [\boldsymbol{\omega}, \mathbf{x}], \quad (1 + i\boldsymbol{\omega}\mathbf{J})\boldsymbol{\sigma}(1 - i\boldsymbol{\omega}\mathbf{J}) = \boldsymbol{\sigma} + [\boldsymbol{\omega}, \boldsymbol{\sigma}] \\ (1 + i\boldsymbol{\omega}\mathbf{J})\boldsymbol{\partial}(1 - i\boldsymbol{\omega}\mathbf{J}) = \boldsymbol{\partial} + [\boldsymbol{\omega}, \boldsymbol{\partial}], \quad (1 + i\boldsymbol{\omega}\mathbf{J})\boldsymbol{\sigma}\boldsymbol{\partial}(1 - i\boldsymbol{\omega}\mathbf{J}) = \boldsymbol{\sigma}\boldsymbol{\partial}\end{gathered} \tag{4}$$

где $\boldsymbol{\omega}$ - бесконечно малый вектор угла поворота и $\boldsymbol{\sigma} = (\sigma^1, \sigma^2, \sigma^3)$.

Задача заключается в обобщении формул (1)-(4) на случай четырёхмерного пространства Минковского. На этом пути строится релятивистская теория частиц со спином (1/2).

Введём четыре комплексные матрицы γ^μ четвёртого порядка со следующими свойствами (сравни с соотношениями $\sigma^i\sigma^j + \sigma^j\sigma^i = 2\delta^{ij}$):

$$\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2\eta^{\mu\nu} \tag{5}$$

Чаще всего используются

а) спинорное представление ($\gamma^\mu = (\gamma^0, \gamma^i)$):

$$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \gamma^i = \begin{pmatrix} 0 & -\sigma^i \\ \sigma^i & 0 \end{pmatrix} \tag{6}$$

б) стандартное представление:

$$\gamma^0 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad \gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix} \tag{7}$$

Из (5)-(7) вытекает, что

$$\left(\gamma^0\right)^\dagger = \gamma^0, \quad \left(\gamma^i\right)^\dagger = -\gamma^i, \quad \gamma^0\left(\gamma^i\right)^\dagger\gamma^0 = \gamma^i \tag{8}$$

Последние соотношения имеют место в любом представлении, поскольку γ-матрицы в разных представлениях различаются унитарным преобразованием.

Введенные матрицы (5) называются γ-матрицами Дирака.
Пусть $\gamma^5 \equiv -i\gamma^0\gamma^1\gamma^2\gamma^3$. Из этого определения имеем:

$$\left(\gamma^5\right)^\dagger = \gamma^5, \quad \gamma^5\gamma^\mu + \gamma^\mu\gamma^5 = 0, \quad \left(\gamma^5\right)^2 = 1 \tag{9}$$

$$\gamma^5 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} - - - \text{ спинорное представление;}$$

$$\gamma^5 = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix} - - - \text{ стандаотное представление.}$$

Введём набор из шести матриц:

$$\sigma^{\mu\nu} \equiv \frac{1}{4}\left[\gamma^\mu, \gamma^\nu\right] = -\sigma^{\nu\mu} \tag{10}$$

Вследствие (8)

$$\gamma^0 \left(\sigma^{\mu\nu}\right)^\dagger \gamma^0 = -\sigma^{\mu\nu} \tag{11}$$

Используя лишь алгебру (5), находим:

$$\left[\sigma^{\mu\nu}, \gamma^\lambda\right] = \eta^{\nu\lambda}\gamma^\mu - \eta^{\mu\lambda}\gamma^\nu, \quad \left[\sigma^{\mu\nu}, \sigma^{\lambda\rho}\right] = \eta^{\mu\rho}\sigma^{\nu\lambda} - \eta^{\nu\rho}\sigma^{\mu\lambda} - \eta^{\mu\lambda}\sigma^{\nu\rho} + \eta^{\nu\lambda}\sigma^{\mu\rho} \tag{12}$$

Генераторы четырёхмерных вращений $l_{\mu\nu} = x_\mu\partial_\nu - x_\nu\partial_\mu$ удовлетворяют тем же перестановочным соотношениям, что и матрицы $\sigma^{\mu\nu}$. Поэтому для $J_{\mu\nu} = l_{\mu\nu} + \sigma_{\mu\nu}$ имеем:

$$[J_{\mu\nu}, J_{\lambda\rho}] = \eta_{\mu\rho}J_{\nu\lambda} - \eta_{\nu\rho}J_{\mu\lambda} - \eta_{\mu\lambda}J_{\nu\rho} + \eta_{\nu\lambda}J_{\mu\rho} \tag{13}$$

Мы видим, что матрицы $\sigma^{\mu\nu}$ являются обобщением нерелятивистских спиновых матриц $(1/2)\ \sigma^i$ на релятивистский случай.

Пусть поле

$$\psi(x) = \begin{pmatrix} \psi_1(x) \\ \psi_2(x) \\ \psi_3(x) \\ \psi_4(x) \end{pmatrix} = \begin{pmatrix} \varphi(x) \\ \chi(x) \end{pmatrix} \tag{14}$$

является матрицей-столбцом, состоящим из четырёх комплексных полей $\psi_a, a = 1, 2, 3, 4$ и

$$\bar{\psi}(x) = \psi^\dagger(x)\gamma^0 \tag{15}$$

- матрица-строка. Поля φ и χ в (14) являются двухрядными матрицами-столбцами, задающими верхнюю и нижнюю половины поля (14), соответственно. Поля ψ и $\bar{\psi}$ в (14) и (15) взаимно сопряжены (в смысле Дирака).

Уравнение Дирака во внешнем электромагнитном поле имеет вид

$$\left(i\hbar\gamma^\mu\nabla_\mu - mc\right)\psi(x) = 0, \quad \nabla_\mu = \frac{\partial}{\partial x^\mu} + i\frac{e}{\hbar c}A_\mu(x) \tag{16}$$

Далее, как обычно, полагаем $\hbar = c = 1$.

Прежде всего установим факт лоренц-инвариантности уравнения Дирака. Пуст $\omega_{\mu\nu} = -\omega_{\nu\mu}$ - шесть вещественных параметров преобразования Лоренца и

$$(\Omega_\omega)^\mu_\nu = \delta^\mu_\nu + \omega^\mu_\nu + \frac{1}{2!}\omega^\mu_\lambda\omega^\lambda_\nu + ..., \quad \Lambda_\omega = \exp\left[\frac{1}{2}\omega_{\mu\nu}J^{\mu\nu}\right] \tag{17}$$

Путём прямого вычисления находим:

$$\tilde{x}^\mu = \Lambda_\omega^{-1}x^\mu\Lambda_\omega = (\Omega_\omega)^\mu{}_\nu x^\nu \tag{18a}$$

$$\Lambda_\omega\frac{\partial}{\partial x^\mu}\Lambda_\omega^{-1} = (\Omega_\omega)^\nu{}_\mu\frac{\partial}{\partial x^\nu} \tag{18b}$$

$$\Lambda_\omega^{-1}\gamma^\mu\Lambda_\omega = (\Omega_\omega)^\mu{}_\nu \tag{18c}$$

Равенство (18 a) коротко можно записать в виде $\tilde{x} = \Omega_\omega x$. Из (18 b) и (18 c) следует, что

$$\Lambda_\omega\gamma^\mu\partial_\mu\Lambda_\omega^{-1} = \gamma^\mu\partial_\mu \tag{19}$$

Определим лоренц-преобразованное дираковское поле как

$$\tilde{\psi}(x) \equiv \Lambda_\omega\psi(x) = \left(\exp\frac{1}{2}\omega_{\mu\nu}\sigma^{\mu\nu}\right)\psi\left(\Omega_\omega^{-1}x\right) \tag{20}$$

Здесь второе равенство получено при помощи (18 a). Комбинируя (19) и (20), находим:

$$i\gamma^\mu\partial_\mu\psi(x) = i\Lambda_\omega^{-1}\left(\Lambda_\omega\gamma^\mu\partial_\mu\Lambda_\omega^{-1}\right)\left(\Lambda_\omega\psi(x)\right) = \Lambda_\omega^{-1}\left[i\gamma^\mu\partial_\mu\tilde{\psi}(x)\right] \tag{21}$$

Поэтому

$$\left(i\gamma^\mu\partial_\mu - m\right)\psi(x) = \Lambda_\omega^{-1}\left[\left(i\gamma^\mu\partial_\mu - m\right)\tilde{\psi}(x)\right] \tag{22}$$

откуда следует лоренц-инвариантность свободного уравнения Дирака. Уравнение Дирака во внешнем калибровочном поле также лоренц-инвариантно, поскольку наряду с (19) имеет место равенство

$$\Lambda_\omega\gamma^\mu\nabla_\mu\Lambda_\omega^{-1} = \gamma^\mu\tilde{\nabla}_\mu = \gamma^\mu\left(\partial_\mu + ie\tilde{A}_\mu\right) \tag{23}$$

если оператор лоренц-преобразования Λ_ω преобразует электромагнитное поле согласно формуле (18*b*), так что $\tilde{A}_\mu(x) = (\Omega_\omega)^\nu{}_\mu A_\nu\left(\Omega_\omega^{-1}x\right)$.

Умножим тождество (20) на оператор Λ_ω^{-1} и сделаем затем дираково сопряжение:

$$\bar{\psi}(x) = \tilde{\psi}^\dagger(x)\gamma^0\left(\gamma^0\Lambda_\omega^{-1\dagger}\gamma^0\right) \tag{24}$$

Поскольку вследствие (11)

$$\gamma^0\Lambda_\omega^{-1\dagger}\gamma^0 = \Lambda_\omega \tag{25}$$

то (24) означает, что

$$\bar{\psi}(x) = \bar{\tilde{\psi}}(x)\Lambda_\omega \tag{26}$$

Уравнение Дирака (16) может быть получено путём вариации фермионного действия

$$\mathcal{S}_\psi = \int \mathrm{d}^{(4)}x\bar{\psi}\left(i\gamma^\mu\nabla_\mu - m\right)\psi \tag{27}$$

в котором комплексные поля $\bar{\psi}, \psi$ следует рассматривать как независимые динамические переменные. При помощи формул (22) и (26) устанавливается, что действие (27) лоренц-инвариантно. Вещественность действия (27) устанавливается при помощи равенств (8) и (15).

По определению, вариация действия материи относительно электромагнитного поля даёт электромагнитный ток материи J^μ. В нашем случае имеем:

$$\delta_A\mathcal{S}_\psi \equiv -e\int \mathrm{d}^{(4)}xJ^\mu\delta A_\mu, \quad J^\mu = \bar{\psi}\gamma^\mu\psi$$

9.6.2 2. Nonrelativistic Limit

Перейдём к нерелятивистскому пределу в уравнении Дирака (16). Для этого подействуем на уравнение (16) оператором $(i\gamma^\mu\nabla_\mu + m)$ и учтём, что согласно уравнениям (5) и (10) $\gamma^\mu\gamma^\nu = \eta^{\mu\nu} + 2\sigma^{\mu\nu}$. Таким образом получим:

$$\left\{\nabla_\mu\nabla^\mu + \sigma^{\mu\nu}\left[\nabla_\mu, \nabla_\nu\right] + m^2\right\}\psi = 0$$

Но $[\nabla_\mu, \nabla_\nu] = ieF_{\mu\nu}$. При переходе к нерелятивистскому пределу следует сделать замену

$$\psi \to e^{-imt}\psi, \quad \nabla_0 = \frac{\partial}{\partial t} + ieA_0 \to \frac{\partial}{\partial t} + ieA_0 - im, \quad (\nabla_0)^2 \to -m^2 - 2im\left(\frac{\partial}{\partial t} + ieA_0\right)$$

Членами, не содержащими m (точнее $-mc^2$), мы вправе пренебречь в нерелятивистском пределе. С учётом этого последнее уравнение для дираковского поля принимает вид

$$i\dot{\psi} = \left\{-\frac{1}{2m}\nabla_i^2 + \frac{ie}{2m}\sigma^{\mu\nu}F_{\mu\nu} + eA_0\right\}\psi = \left\{-\frac{1}{2m}\nabla_i^2 - \frac{e}{m}\left(\frac{i}{2}\varepsilon_{ijk}\sigma^{jk}\right)H^i + \frac{ie}{m}\sigma^{0i}E^i + eA_0\right\}\psi \tag{28}$$

Здесь учтено, что согласно определению электрическое $\mathbf{E}$ и магнитное $\mathbf{H}$ поля связаны с тензором электромагнитного поля следующими формулами: $E^i = F^{io}, F_{ij} = -\varepsilon_{ijk}H^k$. Далее работаем в стандартном представлении (7), в котором

$$\sigma^{ij} = -\frac{i}{2}\varepsilon_{ijk}\begin{pmatrix}\sigma^k & 0\\ 0 & \sigma^k\end{pmatrix}, \quad \sigma^{0i} = \frac{1}{2}\begin{pmatrix}0 & \sigma^i\\ \sigma^i & 0\end{pmatrix} \tag{29}$$

Рассмотрим плоскую волну

$$\psi_k = e^{-imt-ikx}u_k, \quad u_k = \text{ const}$$

Для покоящейся частицы ($k^\mu = 0$) свободное уравнение Дирака принимает вид

$$\left(\gamma^0 - 1\right)u = 0$$

то есть $\chi = 0$ (см. (14)). Нетрудно проследить, что при малых k вследствие уравнения Дирака имеет место оценка $\chi_k \sim (|\mathbf{k}|/m)\varphi_k$, и потому в нерелятивистском пределе χ следует

положить равным нулю. Поэтому из (28) для верхней компоненты φ следует уравнение Паули:

$$i\frac{\partial}{\partial t}\varphi = \left\{-\frac{1}{2m}\nabla_i^2 - \frac{e}{m}\left(\frac{\boldsymbol{\sigma}}{2}\right)\mathbf{H} + eA_0\right\}\varphi \tag{30}$$

Так как оператор спина электрона $\mathbf{s} = (1/2)\boldsymbol{\sigma}$ (см. задачу 2. в)), то уравнение Паули показывает, что в рассмотренном приближении магнитный момент электрона

$$\boldsymbol{\mu} = \frac{e}{m}\mathbf{s} \tag{31}$$

9.6.3 3. Quantization of the Dirac Field

Пусть $\dot{\psi} = (\partial/\partial t)\psi$. Определим стандартным образом обобщённый импульс дираковского поля:

$$\delta_{\dot{\psi}}\mathcal{S}_\psi = \int \mathrm{d}t \int \mathrm{d}^{(3)}x\pi_\psi\delta\dot{\psi}$$

Отсюда и из (27) имеем:

$$\pi_\psi = i\bar{\psi}\gamma^0 = i\psi^\dagger \tag{32}$$

Дираковский гамильтониан имеет вид

$$\mathcal{H}_\psi = \int \mathrm{d}^{(3)}x\pi_\psi\dot{\psi} - \mathcal{L} = \int \mathrm{d}^{(3)}x\psi^\dagger\left(-i\alpha^i\nabla_i + m\gamma^0 + eA_0\right)\psi, \quad \alpha^i \equiv \gamma^0\gamma^i, \quad \left(\alpha^i\right)^\dagger = \alpha^i \tag{33}$$

Оператор в круглых скобках в (33) - эрмитовский. Поэтому имеет смысл задача о собственных функциях этого оператора. Рассмотрим эту задачу для случая свободного дираковского поля, когда $A_\mu = 0$, что предполагается до конца этого пункта.

Уравнение для собственных функций оператора Гамильтона-Дирака в свободной теории имеет вид

$$\left(-i\alpha^i\partial_i + m\gamma^0\right)\psi_{\mathbf{k}} = \epsilon_{\mathbf{k}}\psi_{\mathbf{k}} \tag{34}$$

Решение этого уравнения ищется в виде бегущих волн $\psi_{\mathbf{k}}(x) = u_{\mathbf{k}}e^{i\mathbf{kx}}$, амплитуды которых удовлетворяют уравнениям

$$\left(\boldsymbol{\alpha}\mathbf{k} + m\gamma^0 - \epsilon_{\mathbf{k}}\right)u_{\mathbf{k}} = 0 \tag{35}$$

Умножая последнее уравнение на $(\boldsymbol{\alpha}\mathbf{k} + m\gamma^0 + \epsilon_{\mathbf{k}})$ и учитывая, что

$$\gamma^0\boldsymbol{\alpha} + \boldsymbol{\alpha}\gamma^0 = 0, \quad \alpha^i\alpha^j + \alpha^j\alpha^i = 2\delta^{ij} \tag{36}$$

получаем

$$\left(\epsilon_{\mathbf{k}}^2 - m^2 - \mathbf{k}^2\right)u_{\mathbf{k}} = 0$$

Отсюда видно, что при $\epsilon_{\mathbf{k}} = \pm\sqrt{m^2 + \mathbf{k}^2}$ уравнение (35) имеет решение. Если $u_{\mathbf{k}}$ удовлетворяет уравнению (35), то $\tilde{u}_{\mathbf{k}} = \gamma^0\gamma^5 u_{\mathbf{k}}$ удовлетворяет уравнению

$$\left(\boldsymbol{\alpha}\mathbf{k} + m\gamma^0 + \epsilon_{\mathbf{k}}\right)\tilde{u}_{\mathbf{k}} = 0 \tag{37}$$

Поэтому имеется два независимых решения уравнения (35) с $\epsilon_{\mathbf{k}} = \sqrt{m^2 + \mathbf{k}^2} = \omega_k$ и два независимых решения с $\epsilon_{\mathbf{k}} = -\sqrt{m^2 + \mathbf{k}^2} = -\omega_k$. Эти решения называются положительно и отрицательно
частотными. Далее положительно частотные решения с амплитудой u_{k} обозначается u_k, а отрицательно частотные решения с амплитудой $u_{(-\mathbf{k})}$ обозначается u_{-k}. Для любого 4 -вектора p^μ введём обозначение $\gamma^\mu p_\mu \equiv \not{p}$. Тогда уравнение (35) для положительно и отрицательно частотных мод записывается как

$$(\not{k} - m)u_k = 0 \tag{38a}$$

$$(\not{k} + m)u_{-k} = 0 \tag{38b}$$

где $k^\mu = (\omega_k, \mathbf{k})$. Заметим, что если ψ_1 и ψ_2 - дираковские спиноры, то $\bar{\psi}_1\psi_2$ есть лоренцинвариант, а $\bar{\psi}_1\gamma^\mu\psi_2$ – 4-вектор. Поэтому мы примем лоренц-инвариантные условия нормировки:

$$\bar{u}_k u_k = 2m, \quad \bar{u}_{-k}u_{-k} = -2m \tag{39}$$

При этом предполагается, что спиноры $u_{\pm k}$ получаются (с точностью до фазового множителя) из спиноров в системе покоя частицы при помощи соответствующего преобразования Лоренца. Равенства (39) согласованы с равенствами

$$\bar{u}_k\gamma^\mu u_k = \bar{u}_{-k}\gamma^\mu u_{-k} = 2k^\mu \tag{40}$$

Для проверки равенств (39)-(40) заметим, что в системе покоя частицы, где $k^\mu = (m, \mathbf{0})$, уравнения (38) принимают вид $\gamma^0 u_{\pm k} = \pm u_{\pm k}$, из которых непосредственно вытекают следующие соотношения:

$$u^\dagger_{\pm k} = \pm\bar{u}_{\pm k}, \quad \gamma^0\gamma u_{\pm k} = \mp\gamma u_{\pm k}$$

Умножая скалярно соответственно левые и правые части последних уравнений, получаем:

$$\bar{u}_{\pm k}\gamma u_{\pm k} = -\bar{u}_{\pm k}\gamma u_{\pm k} = 0$$

Таким образом в системе покоя частицы

$$\bar{u}_{\pm k}\gamma^\mu u_{\pm k} = \left(u^\dagger_{\pm k}u_{\pm k}, 0, 0, 0\right)$$

Так как $u^\dagger_{\pm k}u_{\pm k} > 0$, то примем нормировку $u^\dagger_{\pm k}u_{\pm k} = 2m$. Тогда равенства (40) в любой системе отсчёта получаются путём преобразования Лоренца. Теперь умножим равенства (38) на $\bar{u}_{\pm k}$ соответственно и учтём (40):

$$m\bar{u}_{\pm k}u_{\pm k} = \pm\bar{u}_{\pm k}\gamma^\mu u_{\pm k}k_\mu = \pm 2m^2$$

Полученные равенства равносильны равенствам (39).

При помощи явных вычислений легко найти, что в стандартном представлении (7) решения уравнений (38) имеют вид

$$u_k = \begin{pmatrix} \sqrt{\omega_k + m}w \\ \sqrt{\omega_k - m}(\mathbf{n}\boldsymbol{\sigma})w \end{pmatrix}, \quad u_{-k} = \begin{pmatrix} \sqrt{\omega_k - m}(\mathbf{n}\boldsymbol{\sigma})w' \\ \sqrt{\omega_k + m}w' \end{pmatrix}$$
$$\mathbf{n} = \frac{\mathbf{k}}{|\mathbf{k}|}, \quad w^\dagger w = 1, \quad w'^\dagger w' = 1 \tag{41}$$

В системе покоя ($\omega_k = m$) имеем:

$$u_k = \sqrt{2m}\begin{pmatrix} w \\ 0 \end{pmatrix}, \quad u_{-k} = \sqrt{2m}\begin{pmatrix} 0 \\ w' \end{pmatrix} \tag{42}$$

то есть $w\,(w')$ представляет собой тот двухкомпонентный спинор в трёхмерном пространстве, к которому сводится в нерелятивистском пределе амплитуда волны. Сопрягая (41), получаем:

$$\bar{u}_k = \left(\sqrt{\omega_k + m}w^\dagger, -\sqrt{\omega_k - m}w^\dagger(\mathbf{n}\boldsymbol{\sigma})\right), \quad \bar{u}_{-k} = \left(\sqrt{\omega_k - m}w'^\dagger(\mathbf{n}\boldsymbol{\sigma}), -\sqrt{\omega_k + m}w'^\dagger\right) \tag{43}$$

При помощи формул (41) и (43) равенства (39) и (40) получаются непосредственно. Ортонормированный базис в спинорном пространстве $\{w\}\,(\{w'\})$ состоит из двух элементов, которые выбираются ортонормированными:

$$w^\alpha = \sum_{s=1,2} a_s w^\alpha_{(s)}, \quad \alpha = 1,2, \quad \sum_{\alpha=1,2} w^{\alpha *}_{(s)} w^\alpha_{(s')} = \delta_{ss'}, \quad \sum_{s=1,2} w^\alpha_{(s)} w^{\beta *}_{(s)} = \delta_{\alpha\beta} \tag{44}$$

Везде $\alpha, \beta, \ldots$ - спинорные индексы, а индексы $s, s', \ldots$ нумеруют спиноры. Аналогичные формулы имеют место для штрихованных спиноров. Обозначим через $u_{\pm k}s, s = 1,2$ дираковские спиноры (41), в которых сделаны подстановки $w \to w_{(s)}, w' \to w'_{(s)}$. Тогда при помощи (40) и (41) получаем:

$$u^\dagger_{ks} u_{ks'} = 2\omega_k \delta_{ss'}, \quad u^\dagger_{-ks} u_{-ks'} = 2\omega_k \delta_{ss'}, \quad u^\dagger_{ks} u_{-ps'} = 0 \tag{45}$$

Последнее равенство в (45) является следствием того, что $u^\dagger_{ks}$ и $u_{-ps'}$ являются собственными векторами эрмитовой матрицы (35) с разными собственными значениями.

Теперь мы можем выписать квантованное дираковское поле:

$$\psi(x) = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \frac{1}{\sqrt{2\omega_k}} \sum_{s=1,2} \left[a_{\mathbf{k}s} u_{ks} e^{i\mathbf{kx}} + b^\dagger_{\mathbf{k}s} u_{-ks} e^{-i\mathbf{kx}} \right]$$
$$\bar{\psi}(x) = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \frac{1}{\sqrt{2\omega_k}} \sum_{s=1,2} \left[b_{\mathbf{k}s} \bar{u}_{-ks} e^{i\mathbf{kx}} + a^\dagger_{\mathbf{k}s} \bar{u}_{ks} e^{-i\mathbf{kx}} \right] \tag{46}$$

Далее показывается, что множество величин $\left\{a_{\mathbf{k}s}, b_{\mathbf{k}s}, a^\dagger_{\mathbf{k}s}, b^\dagger_{\mathbf{k}s}\right\}$ являются фермиевскими операторами уничтожения и рождения. При помощи соотношений (38) и (45) вычисляем значение свободного гамильтониана (33) на полях (46):

$$\mathcal{H}_{0\psi} = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \omega_k \sum_{s=1,2} \left(a^\dagger_{\mathbf{k}s} a_{\mathbf{k}s} - b_{\mathbf{k}s} b^\dagger_{\mathbf{k}s} \right) \tag{47}$$

Находим также оператор электрического заряда:

$$Q = e\int \mathrm{d}^{(3)}xJ^0 = e\int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\sum_{s=1,2}\left(a^\dagger_{\mathbf{k}s}a_{\mathbf{k}s} + b_{\mathbf{k}s}b^\dagger_{\mathbf{k}s}\right) \tag{48}$$

Обратим внимание на то, что условия квантования, определяющие фермионный вакуум, должны иметь вид

$$a_{\mathbf{k}s}|0\rangle = 0, \quad b_{\mathbf{k}s}|0\rangle = 0 \tag{49}$$

Действительно, пусть $x^0 > y^0$ и рассмотрим величину

$$\langle 0|\psi(x)\bar{\psi}(y)|0\rangle \tag{50}$$

где $\psi(x)$ и $\bar{\psi}(y)$ - дираковские поля в представлении Гейзенберга. Гейзенберговские поля представляются согласно (46) с той лишь поправкой, что в (46) производятся замены $\exp(\pm i\mathbf{kx}) \to \exp(\mp ikx)$, где $kx = \omega_k x^0 - \mathbf{kx}$. Действительно, вследствие (38) в результате этой замены экспонент поля (46) удовлетворяют свободному уравнению Дирака. Поэтому величина (50) равна, как и в скалярной теории, амплитуде распространения частицы, рождённой в точке y и распространяющейся в точку x. Вследствие условий (49) эта амплитуда является суперпозицией амплитуд с импульсом $\mathbf{k}$, содержащих множитель $\exp\left[-i\omega_k\left(x^0 - y^0\right)\right]$, то есть суперпозицией положительночастотных волн. Такая зависимость от времени означает, что распространяется частица с положительной энергией. Амплитуда распространения скалярной частицы из точки y в точку x (см. лекцию 2) $\langle 0|\phi(x)\phi(y)|0\rangle$ содержит такую же зависимость от времени. Условия квантования, отличные от (49), нарушили бы эту закономерность. Проведенное рассмотрение подтверждает правильность условий квантования (49).

Так как $\pi_\psi = i\psi^\dagger$, то одновременные перестановочные соотношения дираковских полей должны иметь вид либо

$$\left[\psi_a(x), \psi^\dagger_b(y)\right] = \delta_{ab}\delta^{(3)}(\mathbf{x}-\mathbf{y}) \tag{51}$$

либо

$$\left\{\psi_a(x), \psi^\dagger_b(y)\right\} \equiv \psi_a(x)\psi^\dagger_b(y) + \psi^\dagger_b(y)\psi_a(x) = \delta_{ab}\delta^{(3)}(\mathbf{x}-\mathbf{y}) \tag{52}$$

Вариант (51) реализуется, если (выписываются лишь ненулевые (анти)коммутаторы)

$$\left[a_{\mathbf{k}s}, a^\dagger_{\mathbf{p}s'}\right] = \left[b^\dagger_{\mathbf{k}s}, b_{\mathbf{p}s'}\right] = (2\pi)^3\delta_{ss'}\delta^{(3)}(\mathbf{k}-\mathbf{p}) \tag{53}$$

а вариант (52) - если

$$\left\{a_{\mathbf{k}s}, a^\dagger_{\mathbf{p}s'}\right\} = \left\{b_{\mathbf{k}s}, b^\dagger_{\mathbf{p}s'}\right\} = (2\pi)^3\delta_{ss'}\delta^{(3)}(\mathbf{k}-\mathbf{p}) \tag{54}$$

Действительно, для (51) при помощи (53) и для (52) при помощи (54) получаем:

$$\int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\frac{1}{2\omega_k}\sum_{s=1,2}\left[e^{i\mathbf{k}(\mathbf{x}-\mathbf{y})}u_{ks}\bar{u}_{ks} + e^{-i\mathbf{k}(\mathbf{x}-\mathbf{y})}u_{-ks}\bar{u}_{-ks}\right]\gamma^0 \tag{55}$$

Теперь учтём, что

$$\sum_{s=1,2} u_{\pm ks}\bar{u}_{\pm ks} = \not{k} \pm m \tag{56}$$

Соотношения (56) следуют из равенств

$$\bar{u}_{\pm ks}u_{\pm ks'} = \pm 2m\delta_{ss'}, \quad \bar{u}_{ks}u_{-ks'} = 0 \tag{57}$$

уточняющих условия нормировки (39), и уравнений (38): при помощи (38) и (57) немедленно устанавливается, что все матричные элементы вида $\bar{u}_{\pm ks'}...u_{\pm ks''}4\times 4$ матриц в левых и правых частях равенств (56) совпадают. При помощи (56) выражение (55) преобразуется к виду

$$\int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\frac{1}{2\omega_k}\sum_{s=1,2}\left[e^{i\mathbf{k}(\mathbf{x}-\mathbf{y})}\left(\omega_k\gamma^0 - \gamma\mathbf{k} + m\right) + e^{-i\mathbf{k}(\mathbf{x}-\mathbf{y})}\left(\omega_k\gamma^0 - \gamma\mathbf{k} - m\right)\right]\gamma^0 = \delta^{(3)}(\mathbf{x}-\mathbf{y})$$

что и требовалось.

Теперь покажем, что коммутационные соотношения (53) неприемлемы с физической точки зрения. Действительно, с учётом условий квантования (49) КС (53) приводят к индефинитной метрике в пространстве состояний. Например, если $|\mathbf{k}s\rangle = b^\dagger_{\mathbf{k}s}|0\rangle$, то $\langle\mathbf{k}s|\mathbf{k}s\rangle < 0$. Поэтому остаётся единственная возможность (52), (54). Выпишем дополняющие (52), (54) одновременные антикоммутационные соотношения:

$$\begin{gathered}\{\psi_a(x),\psi_b(y)\} = \left\{\bar{\psi}_a(x),\bar{\psi}_b(y)\right\} = 0\\ \{a_{\mathbf{k}s},a_{\mathbf{p}s'}\} = \{b_{\mathbf{k}s},b_{\mathbf{p}s'}\} = \left\{a^\dagger_{\mathbf{k}s},a^\dagger_{\mathbf{p}s'}\right\} = \left\{b^\dagger_{\mathbf{k}s},b^\dagger_{\mathbf{p}s'}\right\} = \{a_{\mathbf{k}s},b_{\mathbf{p}s'}\} = \left\{a_{\mathbf{k}s},b^\dagger_{\mathbf{p}s'}\right\} = 0\end{gathered} \tag{58}$$

Приведём оператор Гамильтона-Дирака (47) к нормальному виду при помощи (54) (сравни с (38 7)) :

$$\mathcal{H}_{0\psi} = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\omega_k\sum_{s=1,2}\left(a^\dagger_{\mathbf{k}s}a_{\mathbf{k}s} + b^\dagger_{\mathbf{k}s}b_{\mathbf{k}s}\right) + \mathcal{E}_{0D}, \quad \mathcal{E}_{0D} = -2V\int\frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\omega_k \tag{59}$$

где V - объём пространства. Аналогично для электрического заряда (48) получаем:

$$Q = e\int\frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\sum_{s=1,2}\left(a^\dagger_{\mathbf{k}s}a_{\mathbf{k}s} - b^\dagger_{\mathbf{k}s}b_{\mathbf{k}s}\right) + Q_{0D}, \quad Q_{0D} = 2eV\int\frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \tag{60}$$

Из (59) и (60) мы видим, что плотность энергии и заряда в теории Дирака равны $(-\infty)$ (поскольку $e<0$). Если эти постоянные значения $\mathcal{E}_{0D}$ и Q_{0D} вычеркнуть, то энергия любого фермионного состояния (за исключением вакуумного с нулевой энергией) положительна, а заряд равен $e\times$ (число частиц - число античастиц). Считается, что частицы порождаются операторами $a^\dagger$, а античастицы - операторами $b^\dagger$. Первые называются электронами, а вторые - позитронами. Например, одноэлектронное состояние

$$|\mathbf{p}s\rangle = \sqrt{2\omega_p}a^\dagger_{\mathbf{p}s}|0\rangle, \quad \langle\mathbf{q}s'|\mathbf{p}s\rangle = (2\pi)^3 2\omega_p\delta_{ss'}\delta^{(3)}(\mathbf{p}-\mathbf{q})$$

а однопозитронное состояние

$$|(+)\mathbf{p}s\rangle = \sqrt{2\omega_p} b^\dagger_{\mathbf{p}s}|0\rangle$$

Оператор импульса дираковского поля (сравни с (42 Л2))

$$\mathcal{P}_{0\psi} = -i\int \mathrm{d}^{(3)}x\psi^\dagger\nabla\psi = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\mathbf{k}\sum_{s=1,2}\left(a^\dagger_{\mathbf{k}s}a_{\mathbf{k}s} + b^\dagger_{\mathbf{k}s}b_{\mathbf{k}s}\right)$$

Имеем:

$$\begin{aligned}
&\mathcal{H}_{0\psi}|0\rangle = \mathcal{P}_{0\psi}|0\rangle = 0\\
&\mathcal{H}_{0\psi}|\mathbf{p}s\rangle = \omega_p|\mathbf{p}s\rangle, \quad \mathcal{H}_{0\psi}|(+)\mathbf{p}s\rangle = \omega_p|(+)\mathbf{p}s\rangle\\
&\mathcal{P}_{0\psi}|\mathbf{p}s\rangle = \mathbf{p}|\mathbf{p}s\rangle, \quad \mathcal{P}_{0\psi}|(+)\mathbf{p}s\rangle = \mathbf{p}|(+)\mathbf{p}s\rangle
\end{aligned}$$

Таким образом, операторы рождения порождают состояния с теми импульсами, которые содержатся в обозначениях этих операторов. Из (58) следует, что $(a_{\mathbf{k}s})^2 = (b_{\mathbf{k}s})^2 = 0$. Последние равенства означают, что в фермионной системе в одном состоянии не может находиться более одной частицы. Таким образом, имеется фундаментальное различие между бозонными и фермионными системами.

Описанная ситуация в теории Дирака интерпретируется следующим образом. В теории имеется равное число состояний с положительной и отрицательной энергией. Вакуумное состояние - это такое состояние, в котором все состояния с отрицательной энергией заполнены, а все состояния с положительной энергией - пустые. Электронные состояния получаются путём заполнения положительноэнергетических уровней, а позитронные - путём освобождения (создания дырок) некоторых заселённых отрицательночастотных состояний. При этом энергия и заряд относительно основного состояния возрастают (помните, что $e < 0$). Поэтому энергия и заряд позитронов положительны. Заметим, что антикоммутационные соотношения симметричны относительно перестановок операторов рождения и уничтожения. Поэтому ответ на вопрос, какие операторы являются операторами рождения, а какие - операторами уничтожения, а также как заполняется вакуум, определяется общим знаком перед гамильтонианом.

Обозначим через $|f;0\rangle$ ложный вакуум, то есть такое состояние, в котором и положительно- и отрицательночастотные состояния не заполнены. Такое состояние удовлетворяет условиям $a_{\mathbf{k}s}|f;0\rangle = 0, b^\dagger_{\mathbf{k}s}|f;0\rangle = 0$. Это - действительно не заполненное состояние, поскольку оно обращает в нуль операторы Гамильтона (47) и заряда (48). Кроме того, $\psi|f;0\rangle = 0$. В теории с таким вакуумом следовало бы сделать переобозначение $b^\dagger_{\mathbf{k}s} \longleftrightarrow b_{\mathbf{k}s}$. Мы видим, что с физической точки зрения такая теория неудовлетворительна, поскольку в ней существуют и распространяются во времени состояния с отрицательной энергией.

9.6.4 4. Algebra of Dirac Matrices

Из соотношений (5) вытекает ряд соотношений между γ-матрицами, необходимыми при конкретных вычислениях. Напрмер,

$$\eta_{\mu\nu}\gamma^\mu\gamma^\nu \equiv \gamma_\mu\gamma^\mu = 4 \tag{61}$$

где $\gamma_\mu = \eta_{\mu\nu}\gamma^\nu$. Далее:

$$\gamma_\mu\gamma^\nu\gamma^\mu = -2\gamma^\nu, \quad \gamma_\mu\gamma^\lambda\gamma^\nu\gamma^\mu = 4\eta^{\lambda\nu}, \quad \gamma_\mu\gamma^\lambda\gamma^\nu\gamma^\rho\gamma^\mu = -2\gamma^\rho\gamma^\nu\gamma^\lambda$$
$$\gamma_\mu\gamma^\lambda\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^\mu = 2\left(\gamma^\sigma\gamma^\lambda\gamma^\nu\gamma^\rho + \gamma^\rho\gamma^\nu\gamma^\lambda\gamma^\sigma\right) \tag{62}$$

Введём обозначение

$$T^{\mu_1\mu_2\cdots\mu_n} = \frac{1}{4}\operatorname{tr}\left(\gamma^{\mu_1}\gamma^{\mu_2}...\gamma^{\mu_n}\right) \tag{63}$$

Очевидно

$$4T^\mu = \operatorname{tr}\gamma^\mu = 0 \tag{64}$$

так как из (18c) следует, что $\operatorname{tr}\gamma^\mu = (\Omega_\omega)^\mu{}_\nu \operatorname{tr}\gamma^\nu$. Из (5) находим, что

$$T^{\mu\nu} = \eta^{\mu\nu} \tag{65}$$

(след единичной 4×4-матрицы равен 4). Протаскивая в $T^{\lambda\mu\nu\rho}$ матрицу γ^λ под знаком следа слева направо и пользуясь при этом (5) и (65), получаем

$$T^{\lambda\mu\nu\rho} = \eta^{\lambda\mu}\eta^{\nu\rho} - \eta^{\lambda\nu}\eta^{\mu\rho} + \eta^{\lambda\rho}\eta^{\mu\nu} \tag{66}$$

Отсюда следует, что

$$\operatorname{tr}\gamma^5 = 0 \tag{67}$$

Имеем также:

$$\frac{1}{4}\operatorname{tr}\gamma^5\gamma^\lambda\gamma^\mu\gamma^\nu\gamma^\rho = i\varepsilon^{\lambda\mu\nu\rho} \tag{68}$$

Отметим, что след от любого нечётного числа γ-матриц равен нулю.

9.6.5 5. Discrete Symmetries of the Dirac Equation

A. Пространственная инверсия (-чётностъ).

В результате этой инверсии пространственные компоненты 4-векторов изменяют знак, а временные компоненты остаются неизменными. Пусть штрих сверху отмечает преобразованные величины. Тогда

$$x'^0 = x^0, \quad \mathbf{x}' = -\mathbf{x}, \quad J'^0\left(x^0,\mathbf{x}\right) = J^0\left(x^0,-\mathbf{x}\right), \quad \mathbf{J}'\left(x^0,\mathbf{x}\right) = -\mathbf{J}\left(x^0,-\mathbf{x}\right) \tag{69}$$

Кроме того мы потребуем, чтобы преобразованное дираковское поле так же, как и исходное поле, удовлетворяло уравнению Дирака.

Легко проверить, что если

$$\psi'\left(x^0,\mathbf{x}\right) \equiv \psi_P\left(x^0,\mathbf{x}\right) = \gamma^0\psi\left(x^0,-\mathbf{x}\right) \tag{70}$$

то все перечисленные требования удовлетворяются.

Действительно, для $J'^\mu(x) = \bar\psi'(x)\gamma^\mu\psi'(x)$ имеем соотношения (69) вследствие свойств γ матриц (5) и (8). Кроме того, из уравнения Дирака вытекает уравнение

$$\left(i\gamma^{\mu}\nabla'_{\mu} - m\right)\psi_P\left(x^0, \mathbf{x}\right) = 0 \tag{71}$$

где $\nabla'_0 = \nabla_0, \nabla'_i = -\nabla_i$. Наоборот, из последнего уравнения следует уравнение Дирака для поля $\psi(x)$. Аналогично показывается, что

$$(\bar{\psi}\psi)'\left(x^0, \mathbf{x}\right) = (\bar{\psi}\psi)\left(x^0, -\mathbf{x}\right)$$

то есть величина $(\bar{\psi}\psi)$ является скалярной относительно преобразования чётности.

Повторное применение преобразования чётности приводит к тождественному преобразованию.

Б. Обращение времени (Т-чётностъ).

При обращении времени имеем:

$$\begin{gathered} x'^0 = -x^0, \quad \mathbf{x}' = \mathbf{x}, \quad J'^0\left(x^0, \mathbf{x}\right) = J^0\left(-x^0, \mathbf{x}\right), \quad \mathbf{J}'\left(x^0, \mathbf{x}\right) = -\mathbf{J}\left(-x^0, \mathbf{x}\right) \\ A'^0\left(x^0, \mathbf{x}\right) = A^0\left(-x^0, \mathbf{x}\right), \quad \mathbf{A}'\left(x^0, \mathbf{x}\right) = -\mathbf{A}\left(-x^0, \mathbf{x}\right) \end{gathered} \tag{72}$$

Уравнение Дирака может сохранять свой вид лишь если дираковское поле сопрягается комплексно, что следует из уравнения Паули, в которое переходит уравнение Дирака в нерелятивистском пределе. О необходимости в данном случае эрмитовского сопряжения состояний и операторов говорит также тот факт, что при обращении времени начальное и конечное состояния меняются местами, но в амплитуды перехода первые входят в бра-представлении, а вторые - в кет-представлении.

Всем этим требованиям удовлетворяет преобразование дираковского поля вида

$$\psi'\left(x^0, \mathbf{x}\right) \equiv \psi_T\left(x^0, \mathbf{x}\right) = U_T\bar{\psi}^t\left(-x^0, \mathbf{x}\right), \quad \bar{\psi}_T\left(x^0, \mathbf{x}\right) = -\psi^t\left(-x^0, \mathbf{x}\right)U_T \tag{73}$$

где в спинорном и стандартном представлениях

$$U_T = \gamma^3\gamma^1\gamma^0, \quad U_T^2 = -1 \tag{74}$$

Имеем

$$U_T\gamma^{0t} = \gamma^0 U_T, \quad U_T\gamma^t = -\gamma U_T \tag{75}$$

Поскольку при обращении времени переставляются начальное и конечное состояния, то формулы преобразования (72)-(75) должны быть дополнены правилом, согласно которому всякое произведение операторов преобразуется в произведение преобразованных операторов в обратном порядке. При помощи формул (73)-(75) устанавливаем, что поле ψ_T удовлетворяет уравнению Дирака, если поле $\bar{\psi}$ удовлетворяет сопряжённому уравнению Дирака, и наоборот. Кроме того, согласно (73)-(75) и указанному правилу

$$\left(\bar{\psi}\gamma^{\mu}\psi\right)_T\left(x^0, \mathbf{x}\right) = -\left(\psi^t U_T\gamma^{\mu}U_T\bar{\psi}^t\right)^t\left(-x^0, \mathbf{x}\right) = \eta_{\mu\mu}\left(\psi^t\gamma^{\mu t}\bar{\psi}^t\right)^t\left(-x^0, \mathbf{x}\right) = \eta_{\mu\mu}\left(\bar{\psi}\gamma^{\mu}\psi\right)\left(-x^0, \mathbf{x}\right) \tag{76}$$

Здесь отсутствует суммирование по индексу μ.

В. Зарядовое сопряэнение (С-чётностъ).

Из (46) и (49) видно, что поля ψ и $\bar{\psi}$ уничтожают частицу и античастицу, соответственно, которые имеют взаимно противоположные заряды. Поэтому операция

зарядового сопряжения должна сопровождаться операцией дираковского сопряжения полей. При этом векторный ток должен менять знак:

$$J'^{\mu}(x) \equiv J_C(x) = -J^{\mu}(x) \tag{77}$$

Следует также считать, что при зарядовом сопряжении изменяет знак либо электрический заряд, либо 4-потенциал. Кроме того, исходные и зарядово-сопряжённые поля должны одновременно удовлетворять уравнению Дирака.

Все указанные требования выполнены, если

$$\psi'(x) \equiv \psi_C(x) = U_C\bar{\psi}^t(x), \quad \bar{\psi}_C = -\psi^t(x)U_C^{-1} \tag{78}$$

причём в спинорном и стандартном представлениях

$$U_C = i\gamma^2\gamma^0, \quad U_C^{-1}\gamma^{\mu}U_C = -\gamma^{\mu t}, \quad U_C^{-1}\gamma^5 U_C = \gamma^{5t}, \quad U_C^{-1}\sigma^{\mu\nu}U_C = -\sigma^{\mu\nu t} \tag{79}$$

При помощи (79) легко проверить, что после преобразования (78) и изменения знака 4 -потенциала уравнение Дирака переходит в уравнение Дирака для зарядово сопряжённого поля. Кроме того,

$$J'^{\mu} = -\psi^t U_C^{-1}\gamma^{\mu}U_C\bar{\psi}^t = \psi^t\gamma^{\mu t}\bar{\psi}^t$$

Отсюда и из свойства антикоммутативности (52) следует равенство (77).

Повторное применение операции зарядового сопряжения приводят к тождественному преобразованию.

Сформулируем понятие "вещественности"дираковского поля. "Вещественное"дираковское поле называется майорановским полем.

Определение. Дираковское поле называется майорановским, если операция зарядового сопряжения (78) не изменяет это поле, то есть если

$$\psi(x) = U_C\bar{\psi}^t(x) = i\gamma^2\psi^{\dagger t}(x) \tag{80}$$

Формула (80) имеет смысл в спинорном и стандартном представлениях.

Так как уравнение Дирака инвариантно относительно зарядового сопряжения, то майорановское поле может быть решением уравнения Дирака: если поле ψ удовлетворяет уравнению Дирака, то и поле $U_C\bar{\psi}^t$ также удовлетворяет уравнению Дирака. Поэтому и майорановское поле $\left(\psi + U_C\bar{\psi}^t\right)$ удовлетворяет уравнению Дирака.

9.6.6 6. Weyl Equation

Пусть поле ψ удовлетворяет уравнению Дирака с нулевой массой ($m = 0$). Тогда этому же уравнению удовлетворяет и поле $\gamma^5\psi$, а также поля

$$\psi_{\pm} = \frac{1}{2}\left(1 \mp \gamma^5\right)\psi \tag{81}$$

Два поля (81) называются правым и левым вейлевскими полями, соответственно.

В спинорном представлении (6)

$$\psi_+ = \begin{pmatrix}\varphi\\0\end{pmatrix}, \quad \psi_- = \begin{pmatrix}0\\\chi\end{pmatrix} \tag{82}$$

и уравнения Дирака для вейлевских полей имеют вид

$$i\left(\partial_0+\sigma^i\partial_i\right)\varphi=0,\quad i\left(\partial_0-\sigma^i\partial_i\right)\chi=0 \tag{83}$$

Уравнения (83) называются уравнениями Вейля.

Так как генераторы преобразования Лоренца $\sigma^{\mu\nu}$ (10) коммутируют с проекционными операторами $(1/2)\,(1\pm\gamma^5)$, то уравнения Вейля Лоренц-инвариантны.

9.6.7 7. Exact Solution of the Dirac Equation in a Coulomb Potential

Рассмотрим стационарное уравнение Гамильтона-Дирака в кулоновом потенциале (см. (33), (34)):

$$\left(-i\boldsymbol{\alpha}\boldsymbol{\partial}+m\gamma^0-\frac{Z\alpha}{r}\right)\psi=\epsilon\psi,\quad \alpha=\frac{e^2}{\hbar c} \tag{84}$$

Безразмерная величина α называется постоянной тонкой структуры.

Для решения уравнения Дирака (84) в центрально симметричном поле следует пользоваться нерелятивистскими двухкомпонентными спинорными состояниями Ω_{jl}, имеющими определённые значения квадрата орбитального момента $l_i=-i\varepsilon_{ijk}x^j\partial_k$, квадрата полного момента (1) и его проекции M, Из нерелятивистской квантовой механики известно, что

$$\Omega_{l+1/2,l,M}=\begin{pmatrix}\sqrt{\frac{j+M}{2j}}Y_{l,M-1/2}\\ \sqrt{\frac{j-M}{2j}}Y_{l,M+1/2}\end{pmatrix},\quad \Omega_{l-1/2,l,M}=\begin{pmatrix}\sqrt{\frac{j+1-M}{2j+2}}Y_{l,M-1/2}\\ -\sqrt{\frac{j+1+M}{2j+2}}Y_{l,M+1/2}\end{pmatrix}$$

$$\int\Omega^\dagger_{jlM'}\Omega_{j'l'M'}\mathrm{d}o=\delta_{jj'}\delta_{ll'}\delta_{MM'} \tag{85}$$

Так как

$$[\mathbf{j},(\boldsymbol{\sigma}\boldsymbol{\partial})]=[\mathbf{j},(\boldsymbol{\sigma}\mathbf{n})]=0,\quad \mathbf{n}=\mathbf{x}/r \tag{86}$$

то спиноры

$$(\boldsymbol{\sigma}\partial)\Omega_{jlM},\quad (\boldsymbol{\sigma}\mathbf{n})\Omega_{jlM} \tag{87}$$

имеют прежние значения чисел j и M. Однако числа орбитальных моментов спиноров (87) изменяются, поскольку чётности спинора Ω_{jl} и спиноров (87) относительно преобразования $\mathbf{x}\to-\mathbf{x}$ противоположны. Так как при заданном значении j для l имеется всего две возможности $l=j\pm(1/2)$, то ясно, что спиноры (87) пропорциональны друг другу:

$$(\boldsymbol{\sigma}\partial)\Omega_{jlM}=-\left[j(j+1)-l(l+1)-\frac{3}{4}\right]\frac{1}{r}(\boldsymbol{\sigma}\mathbf{n})\Omega_{jlM} \tag{88}$$

Коэффициент в равенстве (88) проверяется путём умножения этого равенства слева на $(\boldsymbol{\sigma}\mathbf{n})$.

Будем решать уравнение (84) в стандартном представлении (7) при помощи подстановки

$$\psi=\begin{pmatrix}f(r)\Omega_{jlM}(\theta,\phi)\\ -ig(r)(\boldsymbol{\sigma}\mathbf{n})\Omega_{jlM}(\theta,\phi)\end{pmatrix} \tag{89}$$

Спинор (89) имеет определённую чётность относительно операции пространственного сопряжения: согласно (7), (69) и (70) имеем для спинора (89) $\psi_P = (-1)^l\psi$. Так как оператор Дирака-Гамильтона в левой части уравнения (84) коммутирует с оператором P-чётности (см. (70)), то диагонализовать следует одновременно эти два оператора. Подставляя (89) в уравнение (84), пользуясь равенством (88), в результате несложных преобразований приходим к следующей системе уравнений:

$$\begin{cases} f' + \frac{1+\varkappa}{r} f - \left(m + \epsilon + \frac{Z\alpha}{r}\right) g = 0, \\ g' + \frac{1-\varkappa}{r} g - \left(m - \epsilon - \frac{Z\alpha}{r}\right) f = 0, \end{cases} \tag{90}$$

$$\varkappa = \begin{cases} -(j+1/2) = -(l+1), & \text{если } j = l + 1/2 \\ (j+1/2) = l, & \text{если } j = l - 1/2 \end{cases}. \tag{91}$$

Штрих сверху означает производную по r.

Исследуем поведение решений системы уравнений (90) при $r \to 0$ и $r \to \infty$.

При $r \to 0$ система (90) переходит в систему

$$\begin{cases} rf' + (1+\varkappa) f - Z\alpha g = 0 \\ rg' + (1-\varkappa) g + Z\alpha f = 0 \end{cases} \tag{92}$$

решение которой ищется в виде $f = a_0 r^\gamma, \quad g = b_0 r^\gamma$. Подстановка такого вида f и g в (92) приводит к уравнению

$$\begin{pmatrix} \gamma + 1 + \varkappa & -Z\alpha \\ Z\alpha & \gamma + 1 - \varkappa \end{pmatrix} \begin{pmatrix} a_0 \\ b_0 \end{pmatrix} = 0 \tag{93}$$

Для существования ненулевого и нормируемого решения уравнения (93) необходимо и достаточно, чтобы

$$\gamma = -1 + \sqrt{\varkappa^2 - (Z\alpha)^2} \tag{94}$$

Соответствующее ненулевое решение с точностью до общего множителя имеет вид

$$a_0 = Z\alpha, \quad b_0 = \left(\varkappa + \sqrt{\varkappa^2 - (Z\alpha)^2}\right) \tag{95}$$

При $r \to \infty$ система (90) переходит в систему

$$\begin{cases} f' - (m+\epsilon) g = 0 \\ g' - (m-\epsilon) f = 0 \end{cases} \tag{96}$$

Мы будем интересоваться лишь дискретными уровнями, для которых $m^2 - \epsilon^2 > 0$. Тогда система уравнений (96) приводит к следующему поведению f и g нормируемых состояний при $r \to \infty$:

$$f \sim e^{-\lambda r}, \quad g \sim e^{-\lambda r}, \quad \lambda = \sqrt{m^2 - \epsilon^2} \tag{97}$$

Из проведенного рассмотрения видно, что решение системы уравнений (90) в случае дискретных уровней энергии следует искать в виде

$$f = e^{-\lambda r} \sum_{s=0}^{\infty} a_s r^{\gamma+s}, \quad g = e^{-\lambda r} \sum_{s=0}^{\infty} b_s r^{\gamma+s} \tag{98}$$

В (98) константы γ и λ задаются согласно (94) и (97) соответственно, а коэффициенты a_0 и b_0 - согласно (95).

Подставим анзац (98) в систему (90) и приравняем нулю по отдельности коэффициенты при одинаковых степенях r. Таким образом получается следующая система рекурсионных уравнений:

$$A_s u_{s+1} = B u_s, \quad s = 0, 1, ..., \quad u_s = \begin{pmatrix} a_s \\ b_s \end{pmatrix} \quad u_0 = \begin{pmatrix} Z\alpha \\ \varkappa + \sqrt{\varkappa^2 - (Z\alpha)^2} \end{pmatrix} \tag{99}$$

$$A_s = \begin{pmatrix} 1 + \sqrt{\varkappa^2 - (Z\alpha)^2} + s + \varkappa & -Z\alpha \\ Z\alpha & 1 + \sqrt{\varkappa^2 - (Z\alpha)^2} + s - \varkappa \end{pmatrix}, \quad B = \begin{pmatrix} \lambda & m + \epsilon \\ m - \epsilon & \lambda \end{pmatrix}$$

Заметим, что самое первое соотношение при степени r^{-1}, связывающее лишь значения a_0 и b_0 между собой, удовлетворяется автоматически вследствие специального выбора u_0 в соответствии с (95).

Так как

$$\det A_s = (1 + s)\left(1 + s + 2\sqrt{\varkappa^2 - (Z\alpha)^2}\right) \neq 0 \tag{100}$$

то уравнение (99) переписывается в виде

$$u_{s+1} = A_s^{-1} \cdot B \cdot u_s, \quad A_s^{-1} = (\det A_s)^{-1} \begin{pmatrix} 1 + \sqrt{\varkappa^2 - (Z\alpha)^2} + s - \varkappa & Z\alpha \\ -Z\alpha & 1 + \sqrt{\varkappa^2 - (Z\alpha)^2} + s + \varkappa \end{pmatrix}.$$

Собственные значения матрицы B равны нулю и 2λ и пусть v_1 и v_2 обозначают соответствующие собственные векторы:

$$Bv_1 = 0, \quad v_1 = \begin{pmatrix} \sqrt{m + \epsilon} \\ -\sqrt{m - \epsilon} \end{pmatrix}, \quad Bv_2 = 2\lambda v_2, \quad v_2 = \begin{pmatrix} \sqrt{m + \epsilon} \\ \sqrt{m - \epsilon} \end{pmatrix} \tag{102}$$

Согласно (100) и (101) при $s \to \infty$

$$A_s^{-1} \to \frac{1}{s} \tag{103}$$

Поэтому, если при достаточно больших s

$$u_s = pv_1 + qv_2, \quad q \neq 0 \tag{104}$$

где p и q - некие числа, то согласно (98), (102) и (103) при $r \to \infty$ функции f и g ведут себя как $e^{\lambda r}$. Волновые функции с таким поведением ненормируемы и потому неприемлемы. Чтобы избежать этой ситуации, для некого s мы должны иметь

$$A_s^{-1} v_2 = t v_1 \tag{105}$$

Здесь t - некое число. Действительно, для вектора общего вида (104) $Bu_s = 2\lambda q v_2$. Если имеет место равенство (105) для некого числа t, то вследствие (102) $u_{s+2} = 0$, рекурсионная цепочка обрывается и волновая функция оказывается нормируемой. При помощи (102) уравнение (105) переписывается как

$$B \cdot A_s^{-1} \cdot v_2 = 0, \quad s = 0, 1, ... \tag{106}$$

Ещё одна возможность обрыва рекурсионной цепочки (101), не учтённая в (106), реализуется при $\varkappa < 0$ в случае $u_0 = tv_1$ для некого числа t. Действительно, при $\varkappa < 0$ компоненты вектора u_0 разного знака (при $\varkappa > 0$ - одного знака) и уравнение $u_0 = tv_1$ может быть реализовано соответствующим подбором параметров ϵ и t. Следовательно, уравнение

$$Bu_0 = 0 \quad \text{при} \quad \varkappa < 0 \tag{107}$$

также является условием квантования энергии. Поскольку B - вырожденная матрица 2×2, то каждое из уравнений (106) и (107) содержит лишь одно независимое алгебраическое уравнение, решение совокупности которых приводит к следующим значениям уровней энергии связанных состояний:

$$\epsilon = mc^2 \left[1 + \frac{(Z\alpha)^2}{\left(n_r + \sqrt{(j+1/2)^2 - (Z\alpha)^2} \right)^2} \right]^{-1/2}, \qquad n_r = \begin{cases} 0, 1, 2, ..., \text{ если } j = l + 1/2 \\ 1, 2, ..., \text{ если } j = l - 1/2 \end{cases} \tag{108}$$

При получении формулы (108) было использовано соотношение (91). Энергия основного состояния получается из формулы (108), если в ней положить $l = 0, j = 1/2, n_r = 0$:

$$\epsilon_0 = mc^2 \sqrt{1 - (Z\alpha)^2} \tag{109}$$

Формулы (108), (109) являются точными и они остаются справедливыми при всех значениях заряда ядра, удовлетворяющих условию $(Z\alpha) < 1$. Поскольку $|\varkappa| = j + 1/2$, то согласно (108) имеет место двукратное вырождение (не считая вырождения относительно прекции полного момента M) уровней: энергии при $l = j \pm 1/2$ совпадают, что является точным результатом.

При малых зарядах ядра, когда $(Z\alpha) \ll 1$, представляет интерес разложение формулы (108) относительно $(Z\alpha)$. Поскольку $\alpha = e^2/\hbar c$, то это разложение можно трактовать как учёт релятивистских поправок. Имеем:

$$\epsilon = mc^2 - \frac{(Z\alpha)^2 mc^2}{2n^2} \left\{ 1 + \frac{(Z\alpha)^2}{n} \left[\frac{1}{j+1/2} - \frac{3}{4n} \right] \right\} + O\left((Z\alpha)^6 \right), \quad n = n_r + j + \frac{1}{2} = 1, 2, ... \tag{110}$$

Учёт поправок порядка $O\left((Z\alpha)^6\right)$ не имеет смысла, поскольку они перекрываются радиационными поправками, имеющими порядок $O\left(\alpha(Z\alpha)^4\right)$ (см. лекцию 13). Формула (110) может быть также получена при помощи ТВ в рамках нерелятивистской квантовой механики, когда спин-орбитальное взаимодействие и релятивистская поправка к кинетической энергии электрона воспринимаются как возмущение (см. задачу (5)).

Задачи

1. Выписать уравнение Дирака для сопряжённого поля $\bar{\psi}$.

2. а) Показать, что векторный ток $J^\mu = \bar{\psi}\gamma^\mu\psi$ сохраняется в силу уравнения Дирака (во внешнем электромагнитном поле), то есть $\partial_\mu J^\mu = 0$.

б) Доказать, что аксиально-векторный ток $J^{5\mu} \equiv \bar{\psi}\gamma^\mu\gamma^5\psi$ веществен и в силу уравнения Дирака

$$\partial_\mu J^{5\mu} = 2im\bar{\psi}\gamma^5\psi$$

Это означает, что в безмассовой теории сохраняется также и аксиально-векторный ток (в классической теории).

в) Показать, что полный 4 -момент

$$M^{\mu\nu} = \int \mathrm{d}^{(3)}x\psi^\dagger iJ^{\mu\nu}\psi$$

сохраняется, если поле ψ удовлетворяет свободному уравнению Дирака. Проверить, что в стандартном представлении

$$\frac{1}{2}\varepsilon_{ijk}M^{jk} = \int \mathrm{d}^{(3)}x\psi^\dagger J^i\psi$$

где J^i совпадает с оператором полного 3 -момента (1), если в (1) сделать замену

$$\frac{1}{2}\sigma^i \longrightarrow \Sigma^i \equiv \frac{1}{2}\begin{pmatrix} \sigma^i & 0 \\ 0 & \sigma^i \end{pmatrix} = -\frac{1}{2}\alpha^i\gamma^5 \tag{111}$$

Таким образом, в нерелятивистском пределе оператор $\mathbf{s} = (1/2)\boldsymbol{\sigma}$ является оператором спина электрона.

3. Используя закон преобразования дираковских полей при Лоренц-преобразованиях показать, что векторный и аксиально-векторный токи являются 4 -векторами.

4. Показать, что уравнение Дирака инвариантно относительно калибровочных преобразований:

$$\psi(x) \to e^{ie\alpha(x)}\psi(x), \quad A_\mu(x) \to A_\mu(x) - \partial_\mu\alpha(x)$$

где $\alpha(x)$ - произвольная вещественная функция.

5. Продолжить разложение уравнения Дирака до членов $\sim 1/c^2$ и получить соответствующий гамильтониан для шредингеровской двухкомпонентной волновой функции. Считать, что имеется только электрическое центрально-симметричное внешнее поле ($\mathbf{A} = 0, eA_0 = \Phi(r)$). Получить выражение для спин-орбитальной связи в случае атома водорода.

Ответ:

$$H = \left(\frac{\mathbf{p}^2}{2m} + \Phi(r)\right) + \left\{-\frac{\mathbf{p}^4}{8m^3c^2} + \frac{\hbar^2}{8m^2c^2}(\Delta\Phi) + \frac{\hbar^2}{2m^2c^2r}\frac{\mathrm{d}\Phi}{\mathrm{d}r}(\mathbf{ls})\right\}$$

6. а) Доказать, что при преобразовании P-чётности

$$J'^{5\mu}\left(x^0, \mathbf{x}\right) = -\eta_{\mu\mu}J'^{5\mu}\left(x^0, -\mathbf{x}\right), \quad \left(\bar{\psi}\gamma^5\psi\right)'\left(x^0, \mathbf{x}\right) = -\left(\bar{\psi}\gamma^5\psi\right)'\left(x^0, -\mathbf{x}\right)$$

Здесь нет суммирования по индексу μ.

б) Показать, что при T - и C-преобразованиях уравнение Дирака сохраняет свой вид.

в) Пусть ψ_{CPT} обозначает поле, возникающее из дираковского поля ψ при последовательном проведении операций обращения времени, затем пространственной инверсии и, наконец, зарядового сопряжения. Выразить ψ_{CPT} через ψ.

г) Показать, что векторный ток майорановского поля тождественно равен нулю.

7. Показать, что уравнения Вейля инвариантны относительно обращения времени и комбинированного CP-преобразования. Существуют ли вейлевско-майорановские (т.е. одновременно вейлевские и майорановские) поля?

Лекция 9

9.7 L9-1 Quantization of Fermions Using a Functional Integral

9.7.1 1. Fermionic Oscillator

Рассмотрим гармонический фермионный осциллятор, динамика которого описывается гамильтонианом

$$\mathcal{H} = \omega a^\dagger a \tag{1}$$

где $a^\dagger$ и a - взаимно сопряжённые фермионные операторы рождения и уничтожения:

$$\left\{a, a^\dagger\right\} = 1, \quad a^2 = 0, \quad \left(a^\dagger\right)^2 = 0 \tag{2}$$

Основное состояние $|0\rangle$ определяется условиями

$$a|0\rangle = 0, \quad \langle 0|0\rangle = 1 \tag{3}$$

Очевидно, что в теории имеется ещё лишь одно состояние, ортогональное к основному:

$$|1\rangle = a^\dagger|0\rangle, \quad \langle 1|0\rangle = \langle 0|a|0\rangle = 0, \quad \langle 1|1\rangle = \left\langle 0\left|aa^\dagger\right|0\right\rangle = \langle 0|0\rangle = 1 \tag{4}$$

Кроме того, в силу (1)-(3)

$$\mathcal{H}|0\rangle = 0, \quad \mathcal{H}|1\rangle = \omega|1\rangle \tag{5}$$

Простейшая фермионная система (1)-(5) интересна тем, что дираковская система (59 Л8) является суммой простейших ферми-систем.

Обратим внимание на следующий факт. Если бы гамильтониан был равен $\mathcal{H} = -\omega\alpha^\dagger\alpha$, где фермионные операторы $\alpha^\dagger$ и α удовлетворяют соотношениям (2), а основное состояние $|f;0\rangle$ удовлетворяет условию $\alpha|f;0\rangle = 0$ и $|f;1\rangle = \alpha^\dagger|f;0\rangle$, то $\mathcal{H}|f;0\rangle = 0, \mathcal{H}|f;1\rangle = -\omega|f;1\rangle$.

В этом случае энергия возбуждённого состояния меньше энергии основного. Однако путём переопределения $a = \alpha^\dagger, a^\dagger = \alpha, |0\rangle = |f;1\rangle, |1\rangle = |f;0\rangle$ мы приходим к ситуации, описанной формулами (1)-(5) с той лишь разницей, что $\mathcal{H} = \omega a^\dagger a - \omega$.

Здесь последнее слагаемое в гамильтониане соответствует энергии вакуума $\mathcal{E}_0$ (59 Л8). Таким образом, после переопределения новое основное состояние совпадает с исходным возбуждённым или заполненным состоянием. Описанная процедура переопределения называется операцией заполнения состояний с отрицательной энергией. В результате, хотя основное состояние имеет отрицательную энергию, все возбуждённые состояния имеют энергию большую, чем энергия основного состояния. Мы видели, что в квантовой теории Дирака все состояния с отрицательной энергией заполнены. На рис. 12 изображено основное состояние в теории Дирака. Заштрихованная область спектра с энергиями меньше $(-m)$ полностью заполнена.

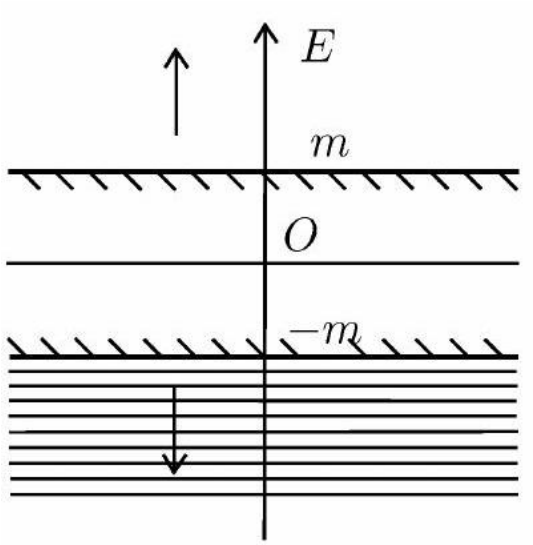


Рис. 12

9.7.2 2. Representation of Fermionic Amplitudes via Functional Integrals

Для решения этой задачи необходимо использование основ математического анализа над грассмановой алгеброй.

Пусть $\{a_\alpha, a_\alpha^*\}$ - образующие алгебры Грассмана над комплексными числами, $\alpha = 1, 2, ..., n$, причём

$$(a_\alpha)^* = a_\alpha^*, \quad (a_\alpha^*)^* = a_\alpha \tag{6}$$

По определению

$$a_\alpha a_\beta + a_\beta a_\alpha = a_\alpha^* a_\beta^* + a_\beta^* a_\alpha^* = a_\alpha a_\beta^* + a_\beta^* a_\alpha = 0, \quad c a_\alpha = a_\alpha c, \quad c a_\alpha^* = a_\alpha^* c \tag{7}$$

где c - комплексное число. Других соотношений, кроме (7), между образующими грассмановой алгебры нет. Из (7) следует, что

$$a_1^2 = a_2^2 = ... = a_n^2 = (a_1^*)^2 = (a_2^*)^2 = ... = (a_n^*)^2 = 0 \tag{8}$$

Отсюда видно, что общий элемент грассмановой алгебры представляется в виде

$$\begin{aligned} f(a, a^*) = f = & f_{0|0} + \sum_{\alpha_1} f_{\alpha_1|0} a_{\alpha_1} + \sum_{\alpha_1} f_{0|\alpha_1} a_{\alpha_1}^* + \sum_{\alpha_1 \alpha_2} f_{\alpha_1|\alpha_2} a_{\alpha_1} a_{\alpha_2}^* + ... + \\ & + f_{12...n|n(n-1)...1} a_1 a_2 ... a_n a_n^* a_{n-1}^* ... a_1^* \end{aligned} \tag{9}$$

где коэффициенты $f_{0|0}, f_{\alpha_1|0}$ и т. д. - комплексные числа. Определим производные на грассмановой алгебре при помощи следующих формул:

$$\begin{aligned} & \frac{\partial}{\partial a_\alpha} a_\beta = \delta_{\alpha\beta}, && \frac{\partial}{\partial a_\alpha^*} a_\beta^* = \delta_{\alpha\beta} \\ & \frac{\partial}{\partial a_\alpha} a_\beta^* = 0, && \frac{\partial}{\partial a_\alpha^*} a_\beta = 0. \end{aligned} \tag{10}$$

Представим элемент (9) в двух следующих видах:

$$f = f_0 + a_\alpha f_\alpha = \bar{f}_0 + a^*_\alpha \bar{f}_\alpha \tag{11}$$

где f_0 и f_α не зависят от a_α, а $\bar{f}_0$ и $\bar{f}_\alpha$ не зависят от a^*_α. (В (11) нет суммирования по α.) Вследствие (7) коэффициенты $f_0, f_\alpha, \bar{f}_0, \bar{f}_\alpha$ определены однозначно элементом (9). Согласно определению (10)

$$\frac{\partial}{\partial a_\alpha} f = f_\alpha, \quad \frac{\partial}{\partial a^*_\alpha} f = \bar{f}_\alpha \tag{12}$$

Из сказанного следует, что

$$\frac{\partial}{\partial a_\alpha}\frac{\partial}{\partial a_\beta} = -\frac{\partial}{\partial a_\beta}\frac{\partial}{\partial a_\alpha}, \quad \frac{\partial}{\partial a^*_\alpha}\frac{\partial}{\partial a^*_\beta} = -\frac{\partial}{\partial a^*_\beta}\frac{\partial}{\partial a^*_\alpha}, \quad \frac{\partial}{\partial a_\alpha}\frac{\partial}{\partial a^*_\beta} = -\frac{\partial}{\partial a^*_\beta}\frac{\partial}{\partial a_\alpha} \tag{13}$$

Интегрирование на алгебре Грассмана определяется с помощью правил

$$\int \mathrm{d}a_\alpha f = f_\alpha, \quad \int \mathrm{d}a^*_\alpha f = \bar{f}_\alpha \tag{14}$$

Кратный интеграл понимается как повторный. Например,

$$\int \mathrm{d}a^*_\alpha \, \mathrm{d}a_\beta f \equiv \int \mathrm{d}a^*_\alpha \left(\int \mathrm{d}a_\beta f \right) = \int \mathrm{d}a^*_\alpha f_\beta \tag{15}$$

Введенное правило интегрирования оправдывается тем, что интеграл от полной производной равен нулю:

$$\int \mathrm{d}a_\alpha \left(\frac{\partial}{\partial a_\alpha} f \right) = 0, \quad \int \mathrm{d}a^*_\alpha \left(\frac{\partial}{\partial a^*_\alpha} f \right) = 0 \tag{16}$$

Из данных определений видно, что дифференциалы грассмановых образующих антиперестановочны:

$$\mathrm{d}a_\alpha \mathrm{d}a_\beta = -\mathrm{d}a_\beta \mathrm{d}a_\alpha, \quad \mathrm{d}a^*_\alpha \, \mathrm{d}a^*_\beta = -\mathrm{d}a^*_\beta \, \mathrm{d}a^*_\alpha, \quad \mathrm{d}a_\alpha \mathrm{d}a^*_\beta = -\mathrm{d}a^*_\beta \, \mathrm{d}a_\alpha \tag{17}$$

Обозначим через

$$\mathrm{d}a^* \, \mathrm{d}a \equiv \mathrm{d}a^*_1 \, \mathrm{d}a^*_2 ... \mathrm{d}a^*_n \, \mathrm{d}a_n \, \mathrm{d}a_{n-1} ... \mathrm{d}a_1 \tag{18}$$

Имеем:

$$\int \mathrm{d}a^* \, \mathrm{d}a f\,(a, a^*) = f_{12...n|n(n-1)...1} \tag{19}$$

Пусть полное множество образующих грассмановой алгебры состоит из двух множеств $\{a_\alpha, a^*_\alpha\}$ и $\{\eta_\alpha, \eta^*_\alpha\}$. Будем называть чётными (нечётными) элементами грассмановой алгебры те элементы, которые разлагаются по чётным (нечётным) суммарным степеням образующих грассмановой
алгебры. Суммарная степень (или просто степень) произведения образующих алгебры Грассмана называется чётной (нечётной), если произведение составлено из чётного (нечётного) числа образующих. Таким образом, все образующие грассмановой алгебры являются нечётными элементами.

Пусть

$$\tilde{a}_\alpha = a_\alpha + q_\alpha, \quad \tilde{a}^*_\alpha = a^*_\alpha + p^*_\alpha \tag{20}$$

где q_α, p^*_α - нечётные элементы, разлагающиеся лишь по образующим $\{\eta_\alpha, \eta^*_\alpha\}$. Согласно данным определениям (сравни с (19))

$$\int \mathrm{d}a^* \ \mathrm{d}a f\left(\tilde{a}, \tilde{a}^*\right) = f_{12\ldots n|n(n-1)\ldots 1} = \int \mathrm{d}a^* \ \mathrm{d}a f\left(a, a^*\right) \tag{21}$$

то есть сдвиг переменных интегрирования согласно равенствам (20) не изменяет значения интеграла.

Сделаем линейную однородную замену образующих грассмановой алгебры:

$$a_\alpha = U_{\alpha\beta} b_\beta, \quad a^*_\alpha = U^*_{\alpha\beta} b^*_\beta, \tag{22}$$

или, сокращённо

$$a = Ub, \quad a^{*t} = b^{*t} U^\dagger$$

Для интеграла (19) имеем:

$$f_{12\ldots n|n(n-1)\ldots 1} = \int \mathrm{d}a^* \ \mathrm{d}a f\left(a, a^*\right) = \int \mathrm{d}a^* \ \mathrm{d}a f\left(Ub, b^{*t} U^\dagger\right) =$$

$$= \int \mathrm{d}a^* \ \mathrm{d}a f_{12\ldots n|n(n-1)\ldots 1} \left(U_{1\alpha_1} b_{\alpha_1}\right) \ldots \left(U_{n\alpha_n} b_{\alpha_n}\right) \left(U^*_{n\beta_n} b^*_{\beta_n}\right) \ldots \left(U^*_{1\beta_1} b^*_{\beta_1}\right) =$$

$$= f_{12\ldots n|n(n-1)\ldots 1} |\det U|^2 \int \mathrm{d}a^* \ \mathrm{d}a b_1 \ldots b_n b^*_n \ldots b^*_1$$

то есть

$$\int |\det U|^2 \ \mathrm{d}a^* \ \mathrm{d}a b_1 \ldots b_n b^*_n \ldots b^*_1 = 1$$

Отсюда следует заключение, что (!)

$$|\det U|^2 \ \mathrm{d}a^* \ \mathrm{d}a = \mathrm{d}b^* \ \mathrm{d}b. \tag{23}$$

Подчеркнём, что при замене переменных (22) в случае коммутирующих переменных мы имели бы $\mathrm{d}a^* \ \mathrm{d}a = |\det U|^2 \ \mathrm{d}b^* \ \mathrm{d}b$.

Рассмотрим гауссов интграл

$$I = \int \mathrm{d}a^* \ \mathrm{d}a \exp\left(a^*_\alpha A_{\alpha\beta} a_\beta\right) \tag{24}$$

Будем считать, что все элементы $A_{\alpha\beta}$ - чётные. Имеем:

$$\exp\left(a^*_\alpha A_{\alpha\beta} a_\beta\right) = 1 + \ldots + \frac{1}{n!} \left(a^*_\alpha A_{\alpha\beta} a_\beta\right)^n$$

Нас интересует лишь последнее слагаемое, которое равно

$$\left(a^*_{\alpha_1} A_{\alpha_1\beta_1} a_{\beta_1}\right) \ldots \left(a^*_{\alpha_n} A_{\alpha_n\beta_n} a_{\beta_n}\right) = n!(\det A) a^*_1 \ldots a^*_n a_n \ldots a_1 = (-1)^n n!(\det A) a_1 \ldots a_n a^*_n \ldots a^*_1 \tag{25}$$

Поэтому в соответствии с (19) (общий знак здесь нас не интересует)

$$I = (\det A) \tag{26}$$

Рассмотрим теперь интеграл

$$I(\eta, \eta^*) = \int \mathrm{d}a^* \; \mathrm{d}a \exp\left(a^*_\alpha A_{\alpha\beta} a_\beta + i\eta^*_\alpha a_\alpha + i a^*_\alpha \eta_\alpha\right) \tag{27}$$

где $\{\eta_\alpha, \eta^*_\alpha\}$ - образующие алгебры Грассмана, независимые от образующих $\{a_\alpha, a^*_\alpha\}$. Если сдвинуть переменные интегрирования в (27) согласно (20) с $q_\alpha = -iA^{-1}_{\alpha\beta}\eta_\beta, p^*_\alpha = -i\eta^*_\beta A^{-1}_{\beta\alpha}$, то интеграл (27) переписывается как

$$I(\eta, \eta^*) = \int \mathrm{d}a^* \; \mathrm{d}a \exp\left(a^*_\alpha A_{\alpha\beta} a_\beta\right) \exp\left(\eta^*_\alpha A^{-1}_{\alpha\beta}\eta_\beta\right)$$

С учётом (26) окончательно получаем:

$$I(\eta, \eta^*) = \int \mathrm{d}a^* \; \mathrm{d}a \exp\left(a^*_\alpha A_{\alpha\beta} a_\beta + i\eta^*_\alpha a_\alpha + i a^*_\alpha \eta_\alpha\right) = (\det A) \exp\left(\eta^*_\alpha A^{-1}_{\alpha\beta}\eta_\beta\right) \tag{28}$$

Далее мы будем использовать тот факт, что показатель экспоненты в правой части (28) равен экстремуму показателя экспоненты в левой части (28) относительно переменных интегрирования $\{a_\alpha, a^*_\alpha\}$, рассматриваемых как независимые переменные. Действительно, дифференцируя показатель экспоненты в левой части (28) и приравнивая результат нулю, находим экстремальные значения переменных:

$$a^{(cl)}_\alpha = -iA^{-1}_{\alpha\beta}\eta_\beta, \quad a^{*(cl)}_\alpha = -i\eta^*_\beta A^{-1}_{\beta\alpha} \tag{29}$$

Подставляя значения (29) в показатель экспоненты в левой части (28) мы получаем показатель экспоненты в правой части (28). В этом отношении фермионные гауссовы интегралы аналогичны бозонным.

Теперь разработаем аппарат для фермионных операторов и фермионных фоковских пространств в голоморфном представлении. Для простоты ограничимся одной степенью свободы. Обобщение на многомерный случай очевидно.

Голоморфными функциями назовём элементы грассмановой алгебры, зависящие только от a^*:

$$f(a^*) = f_0 + f_1 a^* \tag{30}$$

Множество таких функций образует двумерное пространство, и мы используем их для представления векторов состояний системы (1)-(5). Скалярное произведение в пространстве голоморфных функций определяется формулой

$$\langle f_1 | f_2 \rangle = \int \mathrm{d}a^* \; \mathrm{d}a \left(f_1(a^*)\right)^* f_2(a^*) e^{-a^* a}, \quad \left(f(a^*)\right)^* = f^*_0 + f^*_1 a \tag{31}$$

Скалярное произведение (31) положительно определено. Для этого покажем, что базис из двух одночленов $\{\psi_0 = 1, \psi_1 = a^*\}$ ортонормирован. Имеем:

$$\langle\psi_0|\psi_0\rangle = \int \mathrm{d}a^*\ \mathrm{d}a e^{-a^*a} = \int \mathrm{d}a^*\ \mathrm{d}a\,(1-a^*a) = 1$$
$$\langle\psi_0|\psi_1\rangle = \int \mathrm{d}a^*\ \mathrm{d}a a^* e^{-a^*a} = 0, \quad \langle\psi_1|\psi_1\rangle = \int \mathrm{d}a^*\ \mathrm{d}a a a^* e^{-a^*a} = 1 \tag{32}$$

Операторы $a^\dagger$ и a действуют в пространстве (30) следующим образом:

$$a^\dagger f(a^*) = a^* f(a^*), \quad a f(a^*) = \frac{\mathrm{d}}{\mathrm{d}a^*} f(a^*) \tag{33}$$

Если введенный базис представить базисными векторами в двумерном эрмитовом пространстве как

$$\psi_0 = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad \psi_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \tag{34}$$

то операторы $a^\dagger$ и a в этом базисе представляются матрицами

$$a^\dagger = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad a = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \tag{35}$$

откуда очевидна их взаимная сопряжённость, а также правила антикоммутации (2).

Опишем способы задания операторов в голоморфном представлении. Запишем оператор общего вида:

$$A = K_{00} + K_{10}a^\dagger + K_{01}a + K_{11}a^\dagger a \tag{36}$$

Оператору (36) сопоставим его нормальный символ

$$K(a^*, a) = K_{00} + K_{10}a^* + K_{01}a + K_{11}a^*a \tag{37}$$

и ядро

$$A(a^*, a) = A_{00} + A_{10}a^* + A_{01}a + A_{11}a^*a \tag{37}$$

По определению действие оператора (36) задаётся в гломорфном представлении согласно правилу (сравни с (10 Л2))

$$(Af)(a^*) \equiv \int A(a^*, \alpha) f(\alpha^*) e^{-\alpha^*\alpha} \mathrm{d}\alpha^*\ \mathrm{d}\alpha \tag{39}$$

Отсюда находим:

$$A\psi_0 = A_{00}\psi_0 + A_{10}\psi_1, \quad A\psi_1 = A_{01}\psi_0 + A_{11}\psi_1$$

откуда видно, что матрица ядра и матрица оператора

$$A_{mn} = \langle m|A|n\rangle, \quad m, n = 0, 1 \tag{40}$$

совпадают (сравни с (11 Л2) и (12 Л2)). Произведение операторов в голоморфном представлении задаётся формулой

$$(A_1A_2)(a^*,a)=\int A_1(a^*,\alpha)\,A_2(\alpha^*,a)\,e^{-\alpha^*\alpha}\mathrm{d}\alpha^*\;\mathrm{d}\alpha \tag{41}$$

Для записи (39) и (41) необходимо было ввести две новые образующие грассмановой алгебры (α^*,α), которые и далее будут вводиться по мере необходимости.

Подставляя оператор (36) в (40), находим:

$$A_{00}=K_{00},\quad A_{10}=K_{10},\quad A_{01}=K_{01},\quad A_{11}=K_{00}+K_{11}$$

Отсюда видно, что связь между ядром оператора и его нормальным символом такова (сравни с (13 Л2)):

$$A(a^*,a)=e^{a^*a}K(a^*,a) \tag{42}$$

Поскольку ядро S-матрицы для одномерного бозонного осциллятора (28 Л2) было получено при помощи лишь двух формул (12 Л2) и (13 Л2), аналоги которых в фермионном случае (41) и (42) имеют точно такой же вид, то выражение для S-матрицы фермионного гармонического осциллятора с внешним антикоммутирующим источником η и гамильтонианом

$$h=\omega a^*a-\frac{1}{\sqrt{2\omega}}(\eta^*a+a^*\eta) \tag{43}$$

может быть выписано при помощи справедливых также и в фермионном случае формул (15 Л2) и (26 Л2). Однако в фермионном случае следует учитывать антикоммутативность образующих грассмановой алгебры и правило вычисления гауссовых функциональных интегралов (28). В результате в фермионном случае мы получим следующее выражение для оператора S-матрицы:

$$S_\eta\left(a^\dagger,a\right)=\frac{1}{N}:\exp\left\{\frac{i}{\sqrt{2\omega}}\int \mathrm{d}t\left[\eta^*(t)ae^{-i\omega t}+a^\dagger\eta(t)e^{i\omega t}\right]+i\iint_{s<t}\mathrm{d}t\;\mathrm{d}s\eta^*(t)\frac{ie^{-i\omega(t-s)}}{2\omega}\eta(s)\right\} \tag{44}$$

Выражение (44) формально совпадает с оператором S-матрицы, следующим из формулы (27 Л2).

9.7.3 3. Functional Integral in Dirac Theory

В теории Дирака аналогом одночастичного гамильтониана (43) является гамильтониан (см. (33 Л8))

$$\mathcal{H}_\psi=\int \mathrm{d}^{(3)}x\left\{\bar\psi\left(-i\gamma^i\partial_i+m\right)\psi-(\bar\psi\eta+\bar\eta\psi)\right\} \tag{45}$$

в котором дираковские поля представляются согласно (46 Л8) и фермиевские операторы рождения и уничтожения удовлетворяют антикоммутационным соотношениям (54 Л8), (58 Л8), поля $\eta(x)$ $\bar\eta(x)$ - антикоммутирующие. Согласно (59 Л8) выражение (45) переписывается в виде

$$\mathcal{H}_\psi = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\left\{\omega_k \sum_{s=1,2}\left(a^\dagger_{\mathbf{k}s}a_{\mathbf{k}s} + b^\dagger_{\mathbf{k}s}b_{\mathbf{k}s}\right) - \frac{1}{\sqrt{2\omega_k}}\left[\gamma_{ks}a_{\mathbf{k}s} + a^\dagger_{\mathbf{k}s}\delta_{ks} - \delta_{-ks}b_{\mathbf{k}s} - b^\dagger_{\mathbf{k}s}\gamma_{-ks}\right]\right\}$$

$$\gamma_{\pm ks}(t) = \tilde{\bar{\eta}}_{\pm\mathbf{k}}(t)u_{\pm ks}, \quad \delta_{\pm ks}(t) = \bar{u}_{\pm ks}\tilde{\eta}_{\pm\mathbf{k}}(t)$$

$$\tilde{\eta}_{\mathbf{k}}(t) = \int \mathrm{d}^{(3)}x\eta(x)e^{-i\mathbf{kx}}, \quad \tilde{\bar{\eta}}_{\mathbf{k}}(t) = \int \mathrm{d}^{(3)}x\bar{\eta}(x)e^{i\mathbf{kx}} \tag{46}$$

Представление (46) показывает, что дираковский гамильтониан (45) распадается на сумму одночастичных гамильтонианов вида (43). Поэтому оператор S-матрицы равен

$$S_\eta\left(a^\dagger, a\right) = \frac{1}{N} : \exp\left\{i\int \mathrm{d}^{(4)}x\left(\bar{\eta}\psi_0 + \bar{\psi}_0\eta\right) + \right.$$

$$\left. + i\iint_{s<t} \mathrm{d}t\ \mathrm{d}s \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\frac{ie^{-i\omega_k(t-s)}}{2\omega_k}\sum_{s=1,2}\left[\gamma_{ks}(t)\delta_{ks}(s) - \gamma_{-ks}(s)\delta_{-ks}(t)\right]\right\} : \tag{47}$$

При помощи формул (56 Л8) преобразуем суммы в экспоненте следующим образом:

$$\sum_{s=1,2}\gamma_{ks}(t)\delta_{ks}(s) = \tilde{\bar{\eta}}_{\mathbf{k}}(t)(\not{k} + m)\tilde{\eta}_{\mathbf{k}}(s), \quad -\sum_{s=1,2}\gamma_{-ks}(s)\delta_{-ks}(t) = \tilde{\bar{\eta}}_{-\mathbf{k}}(s)(-\not{k} + m)\tilde{\eta}_{-\mathbf{k}}(t)$$

где $k = (\omega_k, \mathbf{k})$. Последние равенства позволяют преобразовать второе слагаемое в экспоненте в (47) сначала к виду

$$i\iint \mathrm{d}x^0\ \mathrm{d}y^0 \int \frac{\mathrm{d}^{(4)}k}{(2\pi)^4}\frac{e^{-ik^0\left(x^0-y^0\right)}}{-k^2+m^2-i\varepsilon}\tilde{\bar{\eta}}_{\mathbf{k}}\left(x^0\right)(\not{k}+m)\tilde{\eta}_{\mathbf{k}}\left(y^0\right)$$

и затем к

$$i\int \mathrm{d}^{(4)}x\ \mathrm{d}^{(4)}y\bar{\eta}(x)\left(i\gamma^\mu\partial_\mu + m\right)D_c(x-y)\eta(y) \tag{48}$$

где $D_c(x-y)$ определена согласно (49 Л2). Определим дираковский пропагатор как

$$S_c(x-y) = -\left(i\gamma^\mu\partial_\mu + m\right)D_c(x-y) = \int \frac{\mathrm{d}^{(4)}k}{(2\pi)^4}\frac{\not{k}+m}{k^2-m^2+i\varepsilon}e^{-ik(x-y)} = \int \frac{\mathrm{d}^{(4)}k}{(2\pi)^4}S_c(k)e^{-ik(x-y)}$$

$$S_c(k) = \frac{\not{k}+m}{k^2-m^2+i\varepsilon} = (\not{k}-m+i\varepsilon)^{-1}, \quad \left(i\gamma^\mu\partial_\mu - m\right)S_c(x-y) = \delta^{(4)}(x-y) \tag{49}$$

Таким образом

$$S_\eta\left(a^\dagger, b^\dagger, a, b\right) = \frac{1}{N} : \exp\left\{i\int \mathrm{d}^{(4)}x\left(\bar{\eta}\psi_0 + \bar{\psi}_0\eta\right) - i\int \mathrm{d}^{(4)}x\ \mathrm{d}^{(4)}y\bar{\eta}(x)S_c(x-y)\eta(y)\right\} :$$

$$\psi_0(x) = \psi_0^{(+)}(x) + \psi_0^{(-)}(x), \quad \bar{\psi}_0(x) = \bar{\psi}_0^{(+)}(x) + \bar{\psi}_0^{(-)}(x)$$

$$\psi_0^{(+)}(x) = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\frac{1}{\sqrt{2\omega_k}}\sum_{s=1,2}a_{\mathbf{k}s}u_{ks}e^{-ikx}, \quad \psi_0^{(-)}(x) = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\frac{1}{\sqrt{2\omega_k}}\sum_{s=1,2}b^\dagger_{\mathbf{k}s}u_{-ks}e^{ikx}$$

$$\bar{\psi}_0^{(+)}(x) = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\frac{1}{\sqrt{2\omega_k}}\sum_{s=1,2}b_{\mathbf{k}s}\bar{u}_{-ks}e^{-ikx}, \quad \bar{\psi}_0^{(-)}(x) = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3}\frac{1}{\sqrt{2\omega_k}}\sum_{s=1,2}a^\dagger_{\mathbf{k}s}\bar{u}_{ks}e^{ikx} \tag{50}$$

где $k = (\omega_k, \mathbf{k})$.

Укажем, что правая часть уравнения (50) может быть получена также при помощи формулы (28) путём прямого вычисления фермионного функционального интеграла (сравни с (44 Л7))

$$\int D\psi D\bar{\psi} \exp\left\{ i \int \mathrm{d}^{(4)}x \left[\bar{\psi} \left(i\gamma^\mu \partial_\mu - m \right) \psi + \bar{\eta}\psi + \bar{\psi}\eta \right] \right\} \tag{51}$$

с граничными условиями, фиксирующими при $t \to -\infty$ положительночастотные составляющие полей $\psi_0^{(+)}(x)$ и $\bar{\psi}_0^{(+)}(x)$ и при $t \to +\infty$ - отрицательночастотные составляющие полей $\psi_0^{(-)}(x)$ и $\bar{\psi}_0^{(-)}(x)$ согласно (50). В (51) дираковская функциональная мера

$$D\psi D\bar{\psi} \equiv \prod_x \prod_a \mathrm{d}\bar{\psi}_a(x) \mathrm{d}\psi_a(x) = \text{ const } \cdot \prod_t \prod_{\mathbf{k}} \prod_s \mathrm{d}a^*_{\mathbf{k}s}(t) \mathrm{d}a_{\mathbf{k}s}(t) \mathrm{d}b^*_{\mathbf{k}s}(t) \mathrm{d}b_{\mathbf{k}s}(t) \tag{52}$$

Это утверждение легко проверяется, если учесть, что экстремальное значение показателя экспоненты в (51) при указанных граничных условиях достигается на полях (сравни с (53 Л2))

$$\psi_{(cl)}(x) = \psi_0(x) - \int \mathrm{d}^{(4)}y S_c(x-y)\eta(y), \quad \bar{\psi}_{(cl)}(x) = \bar{\psi}_0(x) - \int \mathrm{d}^{(4)}y \bar{\eta}(y) S_c(y-x) \tag{53}$$

Подстановка полей (53) в экспоненту в (51) опять приводит к (50).

Второе равенство в (52) легко получается из соотношения для интегралов от квадратичных форм дифференциалов фермионных переменных:

$$\int \mathrm{d}^{(3)}x \ \mathrm{d}\bar{\psi}(x) \mathrm{d}\psi(x) = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \sum_{s=1,2} \frac{m}{\omega_k} \left(\ \mathrm{d}a^*_{\mathbf{k}s} \ \mathrm{d}a_{\mathbf{k}s} + \mathrm{d}b^*_{\mathbf{k}s} \ \mathrm{d}b_{\mathbf{k}s} \right) \tag{54}$$

При выводе (54) фермионные операторы $\left\{ a_{\mathbf{k}s}, b_{\mathbf{k}s}, a^\dagger_{\mathbf{k}s}, b^\dagger_{\mathbf{k}s} \right\}$ в выражениях для дираковских полей (46 Л8) заменяются на соответствующие грассмановы переменные и используются формулы (57 Л8).

9.8 Other Quantum Fields (?)

9.8.1 Massive Quantum Vector Field (??)

(пока не встречал это)

9.8.2 Facts of life with γ_5 (by F. Jegerlehner)

(в другое место перенесу скорее всего)

Abstract

The increasing precision of many experiments in elementary particle physics leads to continuing interest in perturbative higher order calculations in the electroweak Standard Model or extensions of it. Such calculations are of increasing complexity because more loops and/or more legs are considered. Correspondingly efficient computational methods are mandatory

for many calculations. One problem which affects the feasibility of higher order calculations is the problem with γ_5 in dimensional regularization. Since the subject thirty years after its invention is still controversial I advocate here some ideas which seem not to be common knowledge but might shed some new light on the problem. I present arguments in favor of utilizing an anticommuting γ_5 and a simple 4–dimensional treatment of the hard anomalies.

Introduction

The electroweak Standard Model (SM) [1] has been extremely successful in the interpretation of LEP/SLC data and higher order effects typically amount to 10 σ deviations if not taken into account [2]. These precise predictions are only possible due to the renormalizability [3] of the SM and the by now very precise knowledge of the relevant input parameters. Last but not least the relevant coupling constants are small enough such that perturbation theory mostly works very well.

The formal proofs of renormalizability of the SM [4] often relied on the assumption that a gauge invariant regularization exists. The question whether such a regularization exists is non–trivial because of the chiral structure of the fermions involved. At present the only regularization, which makes elaborate computations of radiative corrections feasible, is the dimensional regularization (DR) scheme [5, 6] which is well-defined for field theories with vectorial gauge symmetries only. However, in theories exhibiting chiral fermions, like the electroweak SM, problems with the continuation of the Dirac matrix γ_5 to dimensions $D \neq 4$ remain open within this context and several modifications of the 't Hooft–Veltman DR have been proposed [7, 8, 9, 10, 11, 12, 13, 14, 15]. It turns out that starting from the standard SM-Lagrangian and using a γ_5, which does not anticommute with the other Dirac matrices γ^μ, leads to "spurious anomalies" which violate chiral symmetry and hence gauge invariance. These anomalies would spoil renormalizability if we would not get rid of them by imposing "by hand" the relevant Ward-Takahashi (WT) [16] and Slavnov-Taylor (ST) [17, 18] identities order by order in perturbation theory [13, 19, 20, 21, 22]. At first sight this might not look to be a serious problem, however, violating the symmetries of the SM makes practical calculations much more difficult and tedious than they are anyway.

The problems of course are related to the existence of the Adler–Bell–Jackiw (ABJ) anomaly [23], which must cancel in the SM in order not to spoil its renormalizability [24].

Surprisingly, the prescriptions proposed and/or used by many authors continue to be controversial [9, 11, 13, 15, 20, 25, 26, 27, 28, 29, 30, 31, 32], and hence it seems to be necessary to reconsider the problem once again. We shall emphasize, in particular, the advantage of working with chiral fields. The consequences of working as closely as possible with chiral fields, it seems to me, has not been stressed sufficiently in the literature so far.

As a matter of principle it is important to mention two other approaches which both work in $D = 4$ dimensions. i) In quantum field theories on the lattice a recent breakthrough was the discovery of exact chiral invariance on the lattice [33] which circumvents the Nielsen–Ninomiya no–go theorem [34]. A well defined regularization which preserves simultaneously chiral–and gauge–symmetries is thus known and could be applied to the SM. ii) The algebraic renormalization of the electroweak SM to all orders [35] within the Bogoliubov-Parasiuk-Hepp-Zimmermann (BPHZ) framework is a mathematically well defined scheme, which is much more involved because it breaks the symmetries at intermediate stages and hence leads to much longer expressions which are extremely tedious to handle in practice. In cases of doubt this is the only known scheme which is free of ambiguities and works directly in 4–dimensional continuum field theory.

For perturbative calculations in the continuum we have to stick as much as possible to the

more practical route of dimensional regularization. In the following tensor quantities in $D = 4$ dimensions are supposed to be defined by interpolation of $D = 2n$ ($n \geq 2$, integer) dimensions to dimensions below $D = 4$. It is well known that the γ–algebra, the so called "naive dimensional regularization" (NDR) [5]

$$\{\gamma^\mu, \gamma^\nu\} = 2g_{\mu\nu} \cdot \mathbf{1} \ , \quad g^\mu{}_\mu = D \ , \quad \mathrm{AC}(\mu) \equiv \{\gamma^\mu, \gamma_5\} = 0 \tag{9.2}$$

for dimensions of space–time $D = 4 - 2\epsilon$, $\epsilon \neq 0$ is inconsistent with

$$\mathrm{Tr}(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_5) \neq 0 \ . \tag{9.3}$$

The latter condition is often considered to be necessary, however, for an acceptable regularization since at $D = 4$ we must find

$$\mathrm{Tr}(\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma_5) = 4\mathrm{i}\varepsilon^{\mu\nu\rho\sigma} \ . \tag{9.4}$$

Generally, for γ_5 odd traces one obtains trace conditions from the cyclic property of traces. They are not fulfilled automatically, as we shall see, and hence the algebra is ill-defined in general. Considering $\mathrm{Tr}(\prod_{j=0}^{4} \gamma^{\mu_j}\gamma_5\gamma^\alpha)$ cyclicity requires

$$\mathrm{Tr}(\prod_{j=0}^{4} \gamma^{\mu_j}\mathrm{AC}(\alpha)) - 2\sum_{i=0}^{4}(-1)^i g^{\alpha\mu_i}\mathrm{Tr}(\prod_{j=0,\, j\neq i}^{4} \gamma^{\mu_j}\gamma_5) = 0 \ . \tag{9.5}$$

Contraction with the metric tensor $g_{\alpha\mu_0}$ yields

$$2\,(g^\alpha{}_\alpha - 4)\,\mathrm{Tr}(\prod_{j=1}^{4} \gamma^{\mu_j}\gamma_5) + \mathrm{Tr}(\prod_{j=1}^{4} \gamma^{\mu_j}\mathrm{AC}(\gamma)) = 0 \tag{9.6}$$

with $\mathrm{AC}(\gamma) \equiv \gamma_\alpha\mathrm{AC}(\alpha)$. Thus $g^\alpha{}_\alpha = D \neq 4$ together with (9.3) implies $\mathrm{AC}(\mu) \neq 0$. However, non-anti-commutativity of γ_5 is in conflict with the chiral structure and hence with gauge invariance of the SM, in general. It is the purpose of this note to study the possibility of restoring gauge invariance by employing chiral fields systematically.

Formally gauge invariant Feynman rules

Obviously only terms involving γ^μ in the standard SM Lagrangian can be affected by a non–anticommuting γ_5. As an example we consider the leptonic part, given by

$$\begin{aligned} \mathcal{L}_\ell &= \bar{\ell}_\mathrm{R} i\gamma^\mu\,(\partial_\mu + ig'B_\mu)\ell_\mathrm{R} + \bar{\nu}_{\ell\mathrm{R}} i\gamma^\mu\partial_\mu\nu_{\ell\mathrm{R}} \\ &+ \bar{L}_\ell i\gamma^\mu\,(\partial_\mu + i\frac{g'}{2}B_\mu - ig\frac{\tau_a}{2}W_{\mu a})\,L_\ell \end{aligned} \tag{9.7}$$

using standard notation. As usual the chiral fields

$$\ell_\mathrm{R} = \Pi_+\ell \ , \quad \nu_{\ell\mathrm{R}} = \Pi_+\nu_\ell \ , \quad L_\ell = \begin{pmatrix} \nu \\ \ell \end{pmatrix}_\mathrm{L} = \Pi_- \begin{pmatrix} \nu \\ \ell \end{pmatrix} \tag{9.8}$$

[5] I read it as "normal dimensional regularization"

may be represented in terms of the lepton fields $\ell(x)$ and the neutrino field $\nu_\ell(x)$ with the help of the chiral projectors

$$\Pi_\pm \equiv \frac{1}{2}\left(\mathbf{1} \pm \gamma_5\right) . \tag{9.9}$$

In order that $\Pi_\pm$ are Hermitean projection operators γ_5 must have the properties

$$\gamma_5^2 = \mathbf{1} \ , \quad \gamma_5^+ = \gamma_5 \ . \tag{9.10}$$

Furthermore, we demand $\Pi_\pm$ to be chiral projectors also for the adjoint $\bar{\psi} = \psi^+\gamma^0$ of a Dirac field ψ. This implies

$$\{\gamma^0, \gamma_5\} = 0 \ . \tag{9.11}$$

By Lorentz covariance in the 4–dimensional physical subspace the latter condition extends to

$$\{\gamma^\mu, \gamma_5\} = 0 \ \text{ for } \ \mu = 0, 1, 2, 3 \ . \tag{9.12}$$

It is easy to verify that $\mathcal{L}_\ell$ is invariant under local $SU(2)_{\rm L} \otimes U(1)_{\rm Y}$ gauge transformations, irrespective of $\mathrm{AC}(\mu) \neq 0$. Since the chiral fields have the simple transformation properties

$$\begin{aligned} L_\ell &\rightarrow \exp\{-i/2\,(g'\beta - g\tau_a\omega_a)\,\Pi_-\}L_\ell = \exp\{-i/2\,(g'\beta - g\tau_a\omega_a)\}L_\ell \\ \ell_{\rm R} &\rightarrow \exp\{-ig'\beta\Pi_+\}\ell_{\rm R} = \exp\{-ig'\beta\}\ell_{\rm R} \\ \nu_{\rm R} &\rightarrow \nu_{\rm R} \ , \end{aligned} \tag{9.13}$$

the invariance of $\mathcal{L}_\ell$ follows immediately from the properties of $\Pi_\pm$ alone.

We notice that in utilizing chiral fields there seems to be no conflict with the non–anticommutativity of γ_5 and the formal validity of the ST–identities.

Usually, one prefers to write Feynman rules in terms of the Dirac fields ℓ and ν_ℓ. The standard Feynman rules are obtained using the relations

$$\bar{\psi}\Pi_\mp\gamma^\mu\Pi_\pm\psi = \bar{\psi}\gamma^\mu\Pi_\pm\psi \ , \tag{9.14}$$

which are valid only, provided $\mathrm{AC}(\mu) = 0$.

If $\mathrm{AC}(\mu) \neq 0$ in $D \neq 4$ dimensional space–time, the above relations no longer hold and hence the standard Feynman rules manifestly violate gauge invariance. The correct relations, replacing (9.14), read

$$\bar{\psi}\Pi_\mp\gamma^\mu\Pi_\pm\psi = \frac{1}{2}\bar{\psi}\ \left(\Gamma^\mu \pm \Gamma_5^\mu\right)\ \psi \ , \tag{9.15}$$

with

$$\Gamma^\mu \equiv \gamma^\mu - \frac{1}{2}\mathrm{AC}(\mu)\gamma_5 = \frac{1}{2}\left(\gamma^\mu - \gamma_5\gamma^\mu\gamma_5\right) \tag{9.16}$$

and

$$\Gamma_5^\mu = \frac{1}{2}[\gamma^\mu, \gamma_5] = \Gamma^\mu\gamma_5 \ . \tag{9.17}$$

We notice that by definition all Γ's are anticommuting with γ_5

$$\{\Gamma^\mu, \gamma_5\} \equiv 0 \ . \tag{9.18}$$

According to (9.15) the proper expressions for the vector current and for the axial–vector current read

$$V^\mu(x) = \bar{\psi}\Gamma^\mu\psi = \bar{\psi}\gamma^\mu\psi - \frac{1}{2}\bar{\psi}\mathrm{AC}(\mu)\gamma_5\psi \tag{9.19}$$

and

$$A^\mu(x) = \bar\psi\Gamma^\mu\gamma_5\psi = \bar\psi\gamma^\mu\gamma_5\psi - \frac{1}{2}\bar\psi \mathrm{AC}(\mu)\psi \ , \tag{9.20}$$

respectively. It might be worthwhile to point out that the standard form of the axial current $\bar\psi\gamma^\mu\gamma_5\psi$ is not Hermitean when $\mathrm{AC}(\mu) \neq 0$. The above consideration also shows how anomalies may come about in the vector current when $\gamma_5\gamma^\mu\gamma_5 \neq -\gamma^\mu$.

The fermion kinetic term changes to

$$\bar\psi i\Gamma^\mu\partial_\mu\psi = \bar\psi i\gamma^\mu\partial_\mu\psi - \frac{1}{2}\bar\psi i\mathrm{AC}(\mu)\gamma_5\partial_\mu\psi \ . \tag{9.21}$$

Correspondingly, the free massless fermion fields must satisfy the field equation

$$\left(\gamma^\mu - \frac{1}{2}\mathrm{AC}(\mu)\gamma_5\right)\partial_\mu\psi = 0 \ . \tag{9.22}$$

This formally implies that the conserved canonical Noether currents are precisely the ones given above.

By the field equation the fermion spinors satisfy

$$\begin{aligned}\left(\not k - \frac{1}{2}\mathrm{AC}(k)\gamma_5 - m\right)\, u(k,s) &= 0\\ \left(\not k - \frac{1}{2}\mathrm{AC}(k)\gamma_5 + m\right)\, v(k,s) &= 0\end{aligned} \tag{9.23}$$

and the free fermion propagator reads ($\mathrm{AC}(k) \equiv k_\mu\mathrm{AC}(\mu)$)

$$S_F(k) = \frac{1}{\not k - \frac{1}{2}\mathrm{AC}(k)\gamma_5 - m + i0} = \frac{\not k - \frac{1}{2}\mathrm{AC}(k)\gamma_5 + m}{K^2 - m^2 + i0} \tag{9.24}$$

with

$$K^2 \equiv k^2 - \frac{1}{4}\mathrm{AC}(k)\mathrm{AC}(k) \ . \tag{9.25}$$

Formally, we have obtained chiral and gauge invariant Feynman rules for non-anticommuting γ_5. Eqs. (9.19), (9.20) and (9.24) replace the standard expressions valid for $\mathrm{AC}(\mu) = 0$.

Non-existence of a chirally invariant DR

The gauge invariant Feynman rules presented in the preceding section do not permit a regularization by continuation in the dimension D when $\mathrm{AC}(\mu)$ is chosen compatible with the trace condition (9.3). This can be proven as follows. First we consider the Dirac algebra extended to $D = 2n$ ($n \geq 2$, integer). In this case 2^n–dimensional representations of the γ–algebra are well known [8]. A basis for the algebra is given by the set of matrices $\mathbf{1}$, γ_5 and the antisymmetrized products $\gamma^{[\mu_1\cdots\mu_p]}$ associated with p–dimensional subspaces of M_D. We will split the $SO(1, D-1)$ vectors (tensors) into 4–dimensional vectors $p^\mu_\parallel = \hat p^\mu$ ($\mu = 0, 1, 2, 3$), in the physical subspace M_4, and their orthogonal complements $p^\mu_\perp = \bar p^\mu$ ($\mu = 4, ..., D-1$). If we impose the trace condition (9.3) in the physical subspace (see Eq. (9.12) above) we obtain the 't Hooft–Veltman algebra [5]:

$$\mathrm{AC}(\mu) = \begin{cases} 0 & ;\ \mu = 0, 1, 2, 3 \\ 2\bar\gamma^\mu\gamma_5 & ;\ \mu = 4, ..., D-1 \end{cases} \tag{9.26}$$

with $\gamma_5 = \frac{i}{4!}\varepsilon_{\mu\nu\rho\sigma}\hat{\gamma}^\mu\hat{\gamma}^\nu\hat{\gamma}^\rho\hat{\gamma}^\sigma$. Here, it is important to notice that $\mathrm{AC}(\mu)$ is a matrix of rank $\bar{\epsilon} \equiv D-4$. The matrix–elements themselves are of order $O(1)$. As a consequence higher products of AC-terms are not of higher order in $\bar{\epsilon}$ for $D \to 4$. This is the reason why the extra terms needed to restore the Ward-Takahashi identitiescannot be considered as perturbations. They affect the free part of the Lagrangian! and hence the form of the fermion propagators, as shown above. The symmetry at the end can only be there if the free and the interacting parts of the Lagrangian match appropriately.

We are now ready to reconsider the fermion propagator (9.24). Using (9.26), we get for the scalar product (32.63)

$$K^2 = k^2 - \bar{k}^2 = \hat{k}^2 \tag{9.27}$$

and thus

$$S_F(k) = \frac{\hat{\not{k}} + m}{\hat{k}^2 - m^2 + i0} \tag{9.28}$$

takes its 4–dimensional form, independent of D! It is then impossible to regularize fermion-loop integrals by continuation in D. The crucial point is that the consistency with the trace condition requires that in (32.63) the extra term proportional to $\mathrm{AC}(k)^2$ like AC is a matrix of rank $\bar{\epsilon} \equiv D-4$ and not a correction of order $O(\epsilon^2)$ in the ϵ–expansion!

The problem may be reconsidered in terms of the Γ–algebra defined by (9.16), which may be associated to any γ–algebra:

$$\{\Gamma^\mu, \Gamma^\nu\} = 2g^{\mu\nu} \cdot \mathbf{1} - \frac{1}{4}\{\mathrm{AC}(\mu), \mathrm{AC}(\nu)\}\ , \quad \{\Gamma^\mu, \gamma_5\} = 0\ . \tag{9.29}$$

For any Γ–algebra in order to be closed, we must require

$$\{\Gamma^\mu, \Gamma^\nu\} \quad = \quad 2G^{\mu\nu} \cdot \mathbf{1} \tag{9.30}$$

for some symmetric $D \times D$–matrix G, which satisfies

$$g^\mu{}_\nu G^{\nu\rho} = G^{\mu\rho}\ . \tag{9.31}$$

The trace condition (9.5) must hold with the replacements

$$(\gamma^\mu,\ g^{\mu\nu},\ \mathrm{AC}(\mu) \neq 0) \to (\Gamma^\mu,\ G^{\mu\nu},\ \mathrm{AC}(\mu) = 0) \tag{9.32}$$

which implies

$$g_{\mu\nu}G^{\mu\nu} = G^\mu{}_\mu = 4\ . \tag{9.33}$$

Assuming G to have block–diagonal form

$$G = \left(\begin{array}{c|c} \hat{g} & 0 \\ \hline 0 & \bar{g} \end{array}\right) \tag{9.34}$$

the condition (9.3) can be satisfied with a singular metric G only:

$$\bar{g} = 0\ , \quad G = \hat{g} \tag{9.35}$$

where $\hat{g}$ must be the Minkowski metric. Thus, starting from the 't Hooft–Veltman scheme, we are lead to a dimensional reduction (DRED) scheme [10] by adding just some terms in the Feynman rules which vanish in $D = 4$.

As a result, the Γ–form of the 't Hooft–Veltman algebra is identical to the 4–dimensional Dirac algebra. In other words, using the 't Hooft–Veltman algebra (in its D–dimensional form) together with the chiral fields, which are adapted to the gauge symmetry, "non-regularization" of fermion–loops is implied. Again, a regularization can only be obtained by giving up either the trace condition (9.3) or gauge invariance.

This last statement, of course, is not terribly new. What we have shown is that the Dirac algebra assuming anticommuting γ_5 on the one hand and the 't Hooft–Veltman algebra on the other hand are not really different, since the latter can always be rewritten in the anticommuting Γ–form by means of the relations (9.16) and (9.17). In any case, for theories involving γ_5, "dimensional regularization" compatible with (9.5), does not provide well–defined integrals for loops involving fermion lines. This has been noticed by 't Hooft and Veltman in their original paper [5] where they state: "the usual ambiguity of choice of integration variables is replaced in our formalism by the ambiguity of location of γ_5 in the trace". Statements to the contrary, frequently found in the literature, are misleading. Usually, extra "prescriptions" about where to put the γ_5 in a particular calculation are proposed. These prescriptions, however, do not resolve the problem of mathematical inconsistencies, i.e., they still require an explicit check and the restoration of the Ward-Takahashi identities.

The use of chiral fields provides an unambiguous rule for the proper location of the γ_5–matrices before generalization to $D \neq 4$. Unfortunately, this has lead to the "non-regularization" by dimensional continuation when the $D \neq 4$ trace condition (9.3) is imposed, which in turn essentially implies the 't Hooft–Veltman scheme.

If we violate gauge invariance by the naive application of the 't Hooft–Veltman prescription, we have to restore the symmetry by imposing the relevant Ward–Takahashi identities and fixing appropriate counter terms. But this precisely amounts to including the extra $\mathrm{AC}(\mu)$ terms given in Eqs. (9.19) and (9.20). Which in turn is nothing but another way of utilizing the naive anticommuting γ_5.

Conclusion for the practitioner

According to our considerations above we are left with two possible strategies:

i) $\mathrm{AC}(\mu) \neq 0$: the chirally improved 't Hooft–Veltman scheme

If we insist on the trace condition (9.3) the gauge invariance must be manifestly broken in order to obtain the "pseudo regularization" by dimensional continuation. Again we start at the level of the chiral fields but must avoid the non–regularization by treating the AC–terms in the free part of the Lagrangian as interaction terms, i.e., we use the standard D–dimensional Fermi propagator

$$S_F(k) = \frac{\not{k} + m}{k^2 - m^2 + i0} \tag{9.36}$$

together with the chiral currents (9.19, 9.20) as our "chiral Feynman rules". Since $\mathrm{AC}(\mu) \neq 0$, the choice of the Fermi propagator (9.36) amounts to adding the symmetry breaking term

$$\Delta\mathcal{L}_{\mathrm{SB}} = \frac{1}{2}\bar{\psi} i \mathrm{AC}(\mu)\gamma_5 \partial_\mu \psi = \bar{\psi} i \bar{\gamma}^\mu \partial_\mu \psi \tag{9.37}$$

to the Lagrangian. Besides the fact that this operator has no 4–dimensional representation, it is not a higher order term for $D \neq 4$ as it would be necessary for treating it as a counter-term

(perturbation). Expanding $\Delta\mathcal{L}_{\rm SB}$ perturbatively amounts to the assumption that $\mathrm{AC}(\mu) = O(\epsilon)$ in the sense of matrix elements, which conflicts with (9.3). As we have mentioned earlier, (9.3) requires $\mathrm{AC}(\mu)$ to be a matrix of rank $\bar{\epsilon} = D - 4$ with matrix elements of order $O(1)$. A mathematically satisfactory way out of the dilemma within the framework of DR is not possible as a result of the existence of the ABJ–anomaly.

Our considerations show that "quasi gauge invariant" Feynman rules may be obtained for non-anticommuting γ_5 provided $\mathrm{AC}(\mu)$ is treated as a perturbation i.e. $\mathrm{AC}(\mu) = O(\epsilon)$. Examples are briefly considered in the Appendix. Results turn out to be AC–independent in this case. AC–invariance may be used as a helpful tool for checking the gauge invariance of fermionic loop contributions to amplitudes. Usually such checks are possible only by explicit consideration of WT- and/or ST-identities. We stress, once again, that any approach which treats the AC–term as a perturbation conflicts with the trace condition (9.3) at some point. Ignoring this point leads to "standard" confusions, frequently appearing in the literature. While working with the 't Hooft–Veltman prescription in the standard form requires the subsequent check of the Ward-Takahashi identities,after utilizing the chiral version of the Feynman rules we may restrict ourselves to check the hard anomaly diagrams.

Since amplitudes exhibiting spurious anomalies only may be chiralized either by our chirally improved Feynman rules or by imposing the Ward-Takahashi identitieswhich makes them AC–invariant we obviously may directly choose the scheme $\mathrm{AC}(\mu) = 0$, which is our second and preferred option:

ii) $\mathrm{AC}(\mu) = 0$**: the quasi self-chiral scheme**

From a practical point of view an acceptable computational scheme should avoid spurious anomalies in the first place. This is possible only if the trace condition (9.3) is given up. Gauge invariance can be preserved then by using an anticommuting γ_5. This has been noticed in [7] (see also [25, 26, 28, 38]).

We observe that taking chiral fields seriously on a formal level, the only consistent way to avoid the above non-regularization is the simple one: use anticommuting γ_5 from the very beginning, i.e., choose the NDR algebra (9.2). Since $\Gamma^\mu \equiv \gamma^\mu$ in this case we do not get the non-regularization of the fermion propagators. The ABJ–anomaly must be considered separately as we are going to discuss now [6].

In the gauge invariant approach, closed fermion loops exhibiting γ_5 odd traces and hard anomalies, cannot be obtained by dimensional continuation, merely, γ_5 odd traces are to be considered as intrinsically 4-dimensional quantities. Since charge conjugation properties and the related Bose symmetry are not automatically satisfied one has to account left- and right-circulation of the fermions in closed loops separately. In any case Adler's approach [39] can be utilized to resolve the remaining ambiguities. For this purpose, let us briefly consider the ABJ–anomaly [23] exhibited by the current correlator $< 0|T\{V^\mu(x_1)V^\nu(x_2)A^\lambda(y)\}|0 >$ of two vector currents and an axial–vector current. The one–loop diagrams are shown in Fig. 9.1.

In $D = 4$, working as usual in momentum space, we may perform a covariant decomposition of

[6] The terminology introduced in [9, 13] which calls a scheme "consistent" if it respects the trace condition (9.3) and "inconsistent" otherwise is definitely misleading by the considerations presented in this paper. Since we cannot satisfy the Ward-Takahashi identitiesand the trace condition simultaneously we have the choice which one we want to consider more fundamental. Something has to be restored at the end by hand in any case. To put into place the model independent ABJ–anomalies, is by far simpler, than restoring the chiral symmetry which is broken by non–NDR schemes.

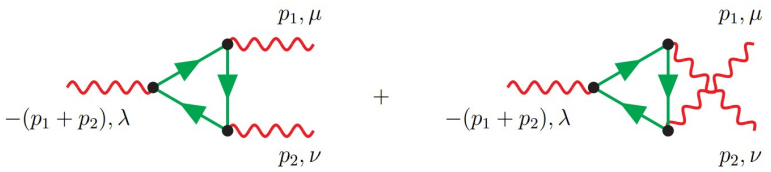

Figure 9.1: The VVA triangle diagrams.

the third rank pseudotensor which depends on the two independent momenta p_1 and p_2:

$$\begin{aligned} A^{\mu\nu\lambda}(p_1,p_2) &= \varepsilon^{\mu\nu\lambda\alpha}\ (p_{1\alpha}\, A_1 + p_{2\alpha}\, A_2) \\ &+ \varepsilon^{\mu\lambda\alpha\beta}\, p_{1\alpha}p_{2\beta}\ (p_1^\nu\, A_3 + p_2^\nu\, A_4) \\ &+ \varepsilon^{\nu\lambda\alpha\beta}\, p_{1\alpha}p_{2\beta}\ (p_1^\mu\, A_5 + p_2^\mu\, A_6) \\ &+ \varepsilon^{\mu\nu\alpha\beta}\, p_{1\alpha}p_{2\beta}\ \left(p_1^\lambda\, A_7 + p_2^\lambda\, A_8\right) \end{aligned} \tag{9.38}$$

where the amplitudes A_i are Lorentz scalars. We now impose

- Bose symmetry (i.e. consider the sum of the two diagrams of Fig. 9.1):

$$A^{\mu\nu\lambda}(p_1,p_2) = A^{\nu\mu\lambda}(p_2,p_1)$$

which implies

$$\begin{aligned} A_1(p_1,p_2) &= -A_2(p_2,p_1), \quad A_3(p_1,p_2) = -A_6(p_2,p_1), \\ A_4(p_1,p_2) &= -A_5(p_2,p_1), \quad A_7(p_1,p_2) = +A_8(p_2,p_1). \end{aligned} \tag{9.39}$$

- Vector current conservation:

$$p_{1\mu}A^{\mu\nu\lambda} = p_{2\nu}A^{\mu\nu\lambda} = 0$$

which implies

$$\begin{aligned} A_1 &= -\left(p_2^2\, A_4 + p_1p_2\, A_3\right) \\ A_2 &= -\left(p_1^2\, A_5 + p_1p_2\, A_6\right)\ . \end{aligned} \tag{9.40}$$

We thus find that the amplitudes A_1 and A_2 are determined uniquely in terms of the A_i, $i = 3, ..., 6$. The crucial observation, made by Adler long time ago [39], is that the amplitudes A_i, $i = 3, ..., 8$, have dimension $d_{\rm eff} = 1 - 3 = -2$ and hence are represented by convergent integrals. In contrast, A_i, $i = 1, 2$, have dimension $d_{\rm eff} = 1 - 1 = 0$ (logarithmically divergent) and thus require regularization and renormalization. However, imposing Bose symmetry and vector current conservation uniquely determines the two regularization/renormalization dependent amplitudes in terms of the other convergent and hence unambiguous ones, i.e., the result is unique without need to refer to a specific renormalization scheme. The divergence of the axial–vector current takes the form

$$-(p_1+p_2)_\lambda A^{\mu\nu\lambda} = 2mR^{\mu\nu} + 8\pi^2 p_{1\alpha}p_{2\beta}\varepsilon^{\alpha\beta\mu\nu} \neq 0$$

where the first term on the r.h.s. is the normal term which vanishes for vanishing fermion mass m while the second term is the mass independent anomaly. Formal axial–vector current conservation in the limit of vanishing fermion mass would require

$$A_1 - A_2 - (p_1^2 + p_1p_2)\, A_7 - (p_2^2 + p_1p_2)\, A_8 = 0\,?$$

with A_1 and A_2 fixed already by vector current conservation, this expression as we know does not vanish but yields the famous axial–vector current anomaly. All true anomalies, i.e.,quantum effects like the triangle anomaly which cannot be removed by adding a corresponding counter term to the Lagrangian, are well known to be related to the triangle diagram. Besides the triangle diagram itself they appear by tensor reduction from one–loop box and pentagon diagrams and diagrams which contain the one–loop anomalous graphs as subgraphs.

The Adler–Bardeen non-renormalization theorem [36] of the one–loop anomalies implies that matters are under control provided Bose symmetry and vector current conservation are imposed, if necessary by hand. In DR it has been reconsidered in [37, 38]. Last but not least we must have the anomaly cancelation, possible by virtue of the quark lepton duality, in order to have the SM renormalizable [24].

Summary: we have shown that different γ_5–schemes may be related by adding suitable terms in the D–dimensional Lagrangian which vanish at $D = 4$. In any scheme we can mimic chiral fields by the appropriate choice of the Feynman rules. We consider this to be crucial since the physical SM derives via a Higgs mechanism from a symmetric phase which exhibits chiral fermions only. The corresponding "chiral completion" (see (9.19,9.20)) of the Feynman rules cannot make a consistent scheme inconsistent or vice versa. Avoidable (often called "spurious") anomalies are then absent. Our arguments strongly support the application of the NDR scheme (9.2), i.e., the D–dimensional γ–algebra together with a strictly anticommuting γ_5, together with the simple 4–dimensional treatment of the hard anomalies discussed above. The NDR is easily implemented into computer codes and is by far the most convenient and efficient approach in calculations of radiative corrections. Removable anomalies are avoided and hence a tedious procedure of restoration of WT- and ST-identities is not needed.

The rules advocated here have been utilized successfully in the last twenty years by many authors at the one– and the two–loop level and beyond. Most SM calculations of higher order effects adopted the NDR scheme without encountering any inconsistencies. Of course, the NDR scheme has been advocated by several authors [7, 11, 25, 26, 28, 38] (see also [30]) in the past. I hope the present paper contributes to clarify part of the ongoing controversy.

Appendix: Calculations with $\mathrm{AC}(\mu) \neq 0$ in the SM: Two examples.

We [40] have verified explicitly that all spurious anomalies disappear from fermion propagators and fermion form factors at one-loop order for the case where we use Feynman rules as proposed in Sec. 9.8.2 in case $\mathrm{AC}(\mu) \neq 0$. As explained earlier, in order to avoid the "non-regularization" of fermion lines, we must treat AC as a perturbation $\mathrm{AC}(\mu) = O(\epsilon)$ and work to linear order in AC. All calculations have been performed in the 't Hooft gauge with an arbitrary gauge parameter ξ, which makes possible direct analytical checks of gauge invariance. We only summarize the structure of the results.

The irreducible self-energy $\Sigma(k)$ we obtained has the following form

$$\Sigma(k) = \left(\not{k} - m - \frac{1}{2}\mathrm{AC}(k)\gamma_5\right) A + \frac{1}{2}[\not{k}, \gamma_5]\, B + mC\,. \tag{9.41}$$

This implies that the mass- and wave-function renormalization are completely AC–independent:

$$\delta m = -mc_0\,, \quad \sqrt{Z_2} = 1 - \frac{1}{2}a_0 - \frac{1}{2}b_0\gamma_5\,. \tag{9.42}$$

Here the wave-function renormalization constant is given by the matrix

$$\sqrt{Z_2} = \sqrt{Z_R}\,\Pi_+ \;+\; \sqrt{Z_L}\,\Pi_- \tag{9.43}$$

where $\sqrt{Z_R}$ and $\sqrt{Z_L}$ are the independent wave–function renormalizations of the right–handed and left–handed fields, respectively. Thus the renormalized self–energy reads

$$\Sigma_r(k) = \left(\not{k} - m - \frac{1}{2}\mathrm{AC}(k)\gamma_5 \right) (A - a_0) + \frac{1}{2}[\not{k}, \gamma_5] (B - b_0) + m (C - c_0) \tag{9.44}$$

with $A - a_0$, $B - b_0$ and $C - c_0$ finite, and hence

$$\Sigma_r(k) = (\not{k} - m) (A - a_0) + \not{k}\gamma_5 (B - b_0) + m (C - c_0) + O(\epsilon) \tag{9.45}$$

By contrast, using standard Feynman rules, we obtain

$$\begin{aligned} \Sigma(k) &= (\not{k} - m) A + \frac{1}{2}[\not{k}, \gamma_5] B + mC \\ &+ \mathrm{AC}(k)\gamma_5 D + [\not{k}, \mathrm{AC}(\gamma)] E + [\not{k}, \mathrm{AC}(\gamma)] \gamma_5 F \end{aligned} \tag{9.46}$$

for the bare self-energy. In this case it is not possible to perform the renormalization in the standard way without imposing the Ward-Takahashi identitiesfirst, which must lead to the form (9.41).

Similar results can be found for form-factors. The following applies to the $\bar{\ell}\ell\gamma$ and $\bar{\ell}\ell Z$ vertices. The general form of the irreducible vertices reads

$$\Pi^\mu(p_1, p_2) = \left(\gamma^\mu - m - \frac{1}{2}\mathrm{AC}(\mu)\gamma_5 \right) F_1 + \frac{1}{2}[\gamma^\mu, \gamma_5] F_2 + p_1^\mu F_3 + p_2^\mu F_4 \,. \tag{9.47}$$

We notice that the only surviving AC–term is $\mathrm{AC}(\mu)\gamma_5$ which appears in the canonical from (9.16) as in the Born term. Thus the vertex renormalization can be performed in an AC–independent way, i.e., the renormalized vertex is given by

$$\Pi_r^\mu(p_1, p_2) = \left(\gamma^\mu - m - \frac{1}{2}\mathrm{AC}(\mu)\gamma_5 \right) (F_1 - c_1) + \frac{1}{2}[\gamma^\mu, \gamma_5] (F_2 - c_2) + p_1^\mu F_3 + p_2^\mu F_4 \tag{9.48}$$

with $F_1 - c_1$, $F_2 - c_2$, F_3 and F_4 finite. Hence, we have

$$\Pi_r^\mu(p_1, p_2) = \gamma^\mu (F_1 - c_1) + \gamma^\mu\gamma_5 (F_2 - c_2) + p_1^\mu F_3 + p_2^\mu F_4 + O(\epsilon) \tag{9.49}$$

independent of any AC–term. In contrast, by applying standard Feynman rules, we find additional terms of the form $\mathrm{AC}(\mu)\gamma_5$, $[\gamma^\mu, \mathrm{AC}(\gamma)]$ and $\{\gamma^\mu, \mathrm{AC}(\gamma)\}\gamma_5$ which cannot be removed by renormalization, unless we impose the Ward-Takahashi identitiesfirst. In the chiral scheme we obtain gauge invariant form factors directly without imposing Ward-Takahashi identitiesby hand. Calculations in this "chiral" scheme in fact look very similar to the ones performed with anticommuting γ_5.

As a result of these findings we decided to work with an anti-commuting γ_5 henceforth, first at the one–loop level [41, 42], later at the two–loop level [43, 44, 45]. In most of these calculations we worked in the 't Hooft gauge with a free gauge parameter which allowed us to check explicitly the gauge invariance of on-shell matrix elements.

10 Other Properties of Free Fields and Other Fields

10.0.1 Зи.I.10 Quantum Field Theory in Curved Spacetime

Общее преобразование координат

В теории гравитации Эйнштейна инвариантный пространственно-временной интервал Минковского $ds^2 = \eta_{\mu\nu}dx^\mu dx^\nu = (dt)^2 - (d\vec{x})^2$ заменяется на $ds^2 = g_{\mu\nu}dx^\mu dx^\nu$, где

метрический тензор $g_{\mu\nu}(x)$ является функцией пространственно-временных координат x. Основополагающий принцип, известный как принцип общей ковариантности, гласит, что заключенная в действии S физика должна быть инвариантна относительно произвольного преобразования координат $x \to x'(x)$. Точнее, принцип [1] гласит, что с соответствующими ограничениями эффект гравитационного поля эквивалентен эффекту преобразования координат.

Так как

$$ds^2 = g'_{\lambda\sigma} dx'^{\lambda} dx'^{\sigma} = g'_{\lambda\sigma} \frac{\partial x'^{\lambda}}{\partial x^{\mu}} \frac{\partial x'^{\sigma}}{\partial x^{\nu}} dx^{\mu} dx^{\nu} = g_{\mu\nu} dx^{\mu} dx^{\nu}$$

метрика преобразуется как

$$g'_{\lambda\sigma}\left(x'\right) \frac{\partial x'^{\lambda}}{\partial x^{\mu}} \frac{\partial x'^{\sigma}}{\partial x^{\nu}} = g_{\mu\nu}(x)$$

Обратная метрика $g^{\mu\nu}$ определяется выражением $g^{\mu\nu} g_{\nu\rho} = \delta^{\mu}_{\rho}$.

Скалярное поле, в соответствии со своим названием, не преобразуется: $\varphi(x) = \varphi'\left(x'\right)$. Градиент скалярного поля преобразуется как

$$\partial_{\mu}\varphi(x) = \frac{\partial x'^{\lambda}}{\partial x^{\mu}} \frac{\partial \varphi'\left(x'\right)}{\partial x'^{\lambda}} = \frac{\partial x^{\lambda}}{\partial x^{\mu}} \partial'_{\lambda} \varphi'\left(x'\right)$$

[1] Точную формулировку принципа общей ковариантности смотрите в книге С. Вейнберга, Гравитачия и космология. с. 92. По определению (ковариантное) векторное поле преобразуется согласно

$$A_{\mu}(x) = \frac{\partial x'^{\lambda}}{\partial x^{\mu}} A'_{\lambda}\left(x'\right)$$

так что $\partial_{\mu}\varphi(x)$ является векторным полем. Если известны два векторных поля $A_{\mu}(x)$ и $B_{\nu}(x)$, можно свернуть их с $g^{\mu\nu}(x)$ в форму $g^{\mu\nu}(x) A_{\mu}(x) B_{\nu}(x)$, которая, как вы можете непосредственно проверить, является скаляром. В частности, $g^{\mu\nu}(x)\partial_{\mu}\varphi(x)\partial_{\nu}\varphi(x)$ является скаляром. Таким образом, если в лагранжиане $\mathcal{L} = \frac{1}{2}\left[(\partial\varphi)^2 - m^2\varphi^2\right] = \frac{1}{2}\left(\eta^{\mu\nu}\partial_{\mu}\varphi\partial_{\nu}\varphi - \right.$ $\left. -m^2\varphi^2\right)$ заменить метрику Минковского $\eta^{\mu\nu}$ на метрику Эйнштейна $g^{\mu\nu}$, то он станет координатно-инвариантным.

Действие находится интегрированием лагранжиана по пространствувремени. При координатном преобразовании имеет место $d^4x' = d^4x \times \ \times \det\left(\partial x'/\partial x\right)$. Вычисляя детерминант выражения (1), получаем

$$g \equiv \det g_{\mu\nu} = \det g'_{\lambda\sigma} \frac{\partial x'^{\lambda}}{\partial x^{\mu}} \frac{\partial x'^{\sigma}}{\partial x^{\nu}} = g' \left[\det\left(\frac{\partial x'}{\partial x}\right)\right]^2$$

Видим, что комбинация $d^4x\sqrt{-g} = d^4x'\sqrt{-g'}$ является координатно-инвариантной.

Таким образом, для произвольной квантовой теории поля можно немедленно записать соответствующую теорию в искривленном пространстве-времени. Все, что для этого требуется, - это заменить в нашем лагранжиане метрику Минковского $\eta^{\mu\nu}$ на метрику Эйнштейна $g^{\mu\nu}$ и включить множитель $\sqrt{-g}$ в меру интегрирования по пространству-времени [2]. При этом действие будет инвариантным относительно произвольных преобразований координат. Например, действие S для скалярного поля в искривленном пространстве-времени просто равно

$$S = \int d^4x\sqrt{-g}\frac{1}{2}\left(g^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi - m^2\varphi^2\right)$$

(Для поля со спином 1/2 имеется некоторая тонкость, о которой мы поговорим в части II. Со временем мы вернемся к этому в главе VIII.1.)

В квантовании скалярного поля в искривленном пространстве-времени нет никакой принципиальной трудности. Мы просто оперируем метрикой $g_{\mu\nu}$ как заданной [например, это может быть метрика Шварцшильда

[2] Мы также должны заменить обычные производные ∂_μ на ковариантные D_μ из теории относительности, но при действии на скалярное поле φ ковариантная производная совпадает с обычной $D_\mu\varphi = \partial_\mu\varphi$. в сферических координатах: $g_{00} = (1-2GM/r), g_{rr} = -(1-2GM/r)^{-1}$, $g_{\theta\theta} = -r^2$ и $g_{\phi\phi} = -r^2\sin\theta$] и изучаем интеграл по траекториям $\int D\varphi e^{iS}$, который по-прежнему является гауссовым и потому вычислимым. Можно получить пропагатор $D(x,y)$ скалярного поля и так далее, и тому подобное. (См. упражнение I.10.1.)

На данном этапе метрика $g_{\mu\nu}$ выглядит в точности как поле, если не считать того факта, что $G_{\mu\nu}(x)$ несет на себе лоренцевы индексы, а $\varphi(x)$ - нет, и на самом деле является классическим полем. Запишем действие мира $S = S_g + S_M$ в виде суммы двух членов: S_g, описывающего динамику гравитационного поля $g_{\mu\nu}$ (которое мы обсудим в главе VIII.1), и S_M, описывающего динамику всех остальных полей в мире [«материальных полей», как, например, φ в нашем простом примере с S_M, вычисляемым по (3)]. Мы могли бы проквантовать гравитацию, проинтегрировав также по $G_{\mu\nu}$, обобщая тем самым интеграл по траекториям до $\int DgD\varphi e^{iS}$.

Легчс сказать, чем сделать! Я уверен, вы слышали, что все попытки проинтегрировать по $g_{\mu\nu}(x)$ завершились непреодолимыми трудностями, так что в конечном итоге теоретикам пришлось искать утешение в теории струн. Когда придет время, я объясню, почему теорию Эйнштейна называют «неперенормируемой».

На что реагирует гравитон

Одним из наиболее глубоких результатов теории гравитации Эйнштейна является фундаментальное определение энергии и импульса. Чем же в точности являются энергия и импульс? Энергия и импульс - это то, на что реагирует гравитон. (Гравитон, конечно, есть частица, отвечающая полю $g_{\mu\nu}$)

Тензор энергии импульса $T^{\mu\nu}$ определяется как вариационная производная действия материи S по метрике $g_{\mu\nu}$ (при фиксированных координатах x^μ)

$$T^{\mu\nu}(x) = -\frac{2}{\sqrt{-g}}\frac{\delta S_M}{\delta g_{\mu\nu}(x)}.$$

Энергия, по определению, равна $E = P^0 = \int d^3x\sqrt{-g}T^{00}(x)$, а импульс $P^i = \int d^3x\sqrt{-g}T^{0i}(x)$

Даже если нас не интересует само по себе искривленное пространство-время, выражение (4) по-прежнему дает нам простой (и фундаментальный) способ определения тензора энергии импульса для теории поля в плоском пространстве-времени. Мы просто варьируем метрику Минковского $\eta_{\mu\nu}$, записывая $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$, и разлагаем S_M до первого порядка по h. Согласно (4) получаем [3]

$$S_M(h) = S_M(h=0) - \int d^4x \left[\frac{1}{2} h_{\mu\nu} T^{\mu\nu} + O\left(h^2\right)\right]$$

Симметричное тензорное поле $h_{\mu\nu}(x)$ является фактически полем гравитона (см. главы I.5 и VIII.1). Тензор энергии импульса $T^{\mu\nu}(x)$ - это то, с чем взаимодействует гравитон, точно так же, как электромагнитный ток $J^\mu(x)$ - это то, с чем взаимодействует фотон.

Рассмотрим общее выражение $S_M = \int d^4x\sqrt{-g}\left(A + g^{\mu\nu}B_{\mu\nu} + \ + g^{\mu\nu}g^{\lambda\rho}C_{\mu\nu\lambda\rho} + ...\right)$. Так как $-g = 1 + \eta^{\mu\nu}h_{\mu\nu} + O\left(h^2\right)$ и $g^{\mu\nu} = \eta^{\mu\nu}$ - $-h^{\mu\nu} + O\left(h^2\right)$, то в плоском пространстве-времени получаем

$$T_{\mu\nu} = 2\left(B_{\mu\nu} + 2C_{\mu\nu\lambda\rho}\eta^{\lambda\rho} + ...\right) - \eta_{\mu\nu}\mathcal{L}.$$

Заметим, что

$$T \equiv \eta^{\mu\nu}T_{\mu\nu} = -\left(4A + 2\eta^{\mu\nu}B_{\mu\nu} + 0\cdot\eta^{\mu\nu}\eta^{\lambda\rho}C_{\mu\nu\lambda\rho} + ...\right)$$

где специально подчеркивается тот факт, что $C_{\mu\nu\lambda\rho}$ не вносит вклада в след тензора энергии импульса.

Теперь продемонстрируем всю мощь подобного определения $T_{\mu\nu}$, получив давно известный результат для электромагнитного поля. Обобщая лагранжиан массивного поля со спином 1 до случая с искривленным пространством-временем, находим [4] $\mathcal{L} = \left(-\frac{1}{4}g^{\mu\nu}g^{\lambda\rho}F_{\mu\lambda}F_{\nu\rho} + \frac{1}{2}m^2 g^{\mu\nu}A_\mu A_\nu\right)$ и, следовательно [5], $T_{\mu\nu} = -F_{\mu\nu}F^\lambda_\nu + m^2 A_\mu A_\nu - \eta_{\mu\nu}\mathcal{L}$.

Для электромагнитного поля полагаем $m = 0$. Во-первых, $\mathcal{L} = -\frac{1}{4}\times$ $\times F_{\mu\nu}F^{\mu\nu} = -\frac{1}{4}\left(-2F_{0i}^2 + F_{ij}^2\right) = \frac{1}{2}\left(\vec{E}^2 - \vec{B}^2\right)$. Таким образом, $T_{00} = -F_{0\lambda}\times$ $\times F_0^\lambda - \frac{1}{2}\left(\vec{E}^2 - \vec{B}^2\right) = \frac{1}{2}\left(\vec{E}^2 + \vec{B}^2\right)$. Успокаивает то, что мы получили

[3] Я использую обычное соглашение, согласно которому суммирование по индексам производится без учета какой-либо возможной симметрии; другими словами, $\frac{1}{2}h_{\mu\nu}T^{\mu\nu} = \frac{1}{2}\left(h_{01}T^{01} + h_{10}T^{10} + ...\right) = h_{01}T^{01} + ...$

[4] Здесь используется тот факт, что ковариантный ротор равен обычному ротору $D_\mu A_\nu$ - $-D_\nu A_\mu = \partial_\mu A_\nu - \partial_\nu A_\mu$, и поэтому $F_{\mu\nu}$ не включает в себя метрику.

[5] То. что координаты x^μ остаются фиксированными. означает, что фиксированным остается ∂_μ и, следовательно, A_μ. [Поскольку a_μ и ∂_μ связаны калибровочной инвариантностью здесь мы немного торопим события (см. главу II.7). но вы уже наверняка слышали о калибровочной инвариантности в нерелятивистском контексте.] известный «с детства» результат. Между прочим, становится ясно, что $\vec{E}^2$ можно рассматривать как кинетическую энергию, а $\vec{B}^2$ как потенциальную энергию. Далее, $T_{0i} = -F_{0\lambda}F_i^\lambda = F_{0j}F_{ij} = \varepsilon_{ijk}E_jB_k = (\vec{E}\times\vec{B})_i$ - это и есть вектор Пойнтинга.

Так как лагранжиан Максвелла $\mathcal{L} = -\frac{1}{4}g^{\mu\nu}g^{\lambda\rho}F_{\mu\lambda}F_{\nu\rho}$ включает в себя лишь C-член с $C_{\mu\nu\lambda\rho} = -\frac{1}{4}F_{\mu\nu}F_{\lambda\rho}$, из (7) следует, что тензор энергии импульса электромагнитного поля имеет нулевой след - это важный факт, который нам понадобится в главе VIII.1. Можно также непосредственно проверить, что $T = 0$ (упражнение I.10.4) [6].

Приложение: искривленное пространство-время - краткое введение

Общая теория относительности часто излагается более трудно и загадочно, чем следовало бы. Для дальнейшего использования я приведу здесь краткий обзор ее основных элементов.

Обозначим через X^μ пространственно-временные координаты точечной частицы. Для того чтобы построить для нее действие, заметим, что единственной координатно-инвариантной величиной является «длина» [7] мировой линии, вдоль которой движется частица (рис. I.10.1), а именно $\int ds = \int \sqrt{g_{\mu\nu} dX^\mu dX^\nu}$, где $G_{\mu\nu}$ вычисляется в точке нахождения частицы. Таким образом, действие для точечной частицы должно быть пропорционально

$$\int ds = \int \sqrt{g_{\mu\nu} dX^\mu dX^\nu} = \int \sqrt{g_{\mu\nu}[X(\zeta)] \frac{dX^\mu}{d\zeta} \frac{dX^\nu}{d\zeta}} d\zeta$$

где ζ - произвольный параметр, монотонно изменяющийся вдоль мировой линии. Длина, будучи геометрической величиной, явно является инвариантной относительно изменения параметризации, то есть не зависит от нашего выбора ζ, если он корректен. Это один из «более чем очевидных» фактов, так как $\int \sqrt{g_{\mu\nu} dX^\mu dX^\nu}$ явно не зависит от ζ. Если хотите, мы можем проверить параметризационную инвариантность $\int ds$.

[6] Мы видим, что условие бесследовости связано с тем. что электромагнитное поле не имеет масштаба. Как говорят, чистый электромагнетизм является масштабно-, или дилатационно-, инвариантным. Подробнее о дилатационной инвариантности можно узнать из работы Коулмена, Аспекты сияиметрии (S. Coleman. Aspects of Symmetry, p. 67).

[7] Мы употребили слово «длина» в кавычках потому, что если бы $g_{\mu\nu}$ имела евклидову сигнатуру, то величина $\int ds$ действительно соответствовала бы длине, и, минимизируя $\int ds$. мы бы получили кратчайшую траекторию (геодезическую) между конечными точками. но в нашем случае $g_{\mu\nu}$ имеет сигнатуру Минковского.

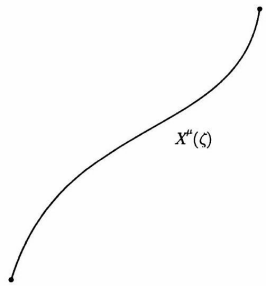

Рис. I.10.1

Очевидно, что степени $d\zeta$ согласуются. То есть если записать $\zeta = \zeta(\eta)$, то $dX^\mu/d\zeta = (d\eta/d\zeta)\,(dX^\mu/d\eta)$, то $d\zeta = (d\zeta/d\eta)d\eta$.

Для облегчения записи определим

$$K \equiv g_{\mu\nu}[X(\zeta)] \frac{dX^\mu}{d\zeta} \frac{dX^\nu}{d\zeta}$$

Считая изменение $\int d\zeta \sqrt{K}$ равным нулю, получаем выражение

$$\int d\zeta \frac{1}{\sqrt{K}} \left(2 g_{\mu\nu} \frac{dX^\mu}{d\zeta} \frac{d\delta X^\nu}{d\zeta} + \partial_\lambda g_{\mu\nu} \frac{dX^\mu}{d\zeta} \frac{dX^\nu}{d\zeta} \delta X^\lambda \right) = 0$$

которое после интегрирования по частям (при стандартном условии $\delta X^\lambda = 0$ на концах) приводит к уравнению движения

$$\sqrt{K}\frac{d}{d\zeta}\left(\frac{1}{\sqrt{K}}2g_{\mu\lambda}\frac{dX^\mu}{d\zeta}\right)-\partial_\lambda g_{\mu\nu}\frac{dX^\mu}{d\zeta}\frac{dX^\nu}{d\zeta}=0$$

Для упрощения (8) воспользуемся нашей свободой выбора ζ и положим $d\zeta = ds$ так, что $K = 1$. Получим

$$2g_{\mu\lambda}\frac{d^2X^\mu}{ds^2}+2\partial_\sigma g_{\mu\lambda}\frac{dX^\sigma}{ds}\frac{dX^\mu}{ds}-\partial_\lambda g_{\mu\nu}\frac{dX^\mu}{ds}\frac{dX^\nu}{ds}=0$$

Умножив на $g^{\rho\lambda}$, приходим к выражению

$$\frac{d^2X^\rho}{ds^2}+\frac{1}{2}g^{\rho\lambda}\left(2\partial_\nu g_{\mu\lambda}-\partial_\lambda g_{\mu\nu}\right)\frac{dX^\mu}{ds}\frac{dX^\nu}{ds}=0$$

То есть

$$\frac{d^2X^\rho}{ds^2}+\Gamma^\rho_{\mu\nu}[X(s)]\frac{dX^\mu}{ds}\frac{dX^\nu}{ds}=0$$

где мы определили символ Римана - Кристоффеля

$$\Gamma^\rho_{\mu\nu}\equiv\frac{1}{2}g^{\rho\lambda}\left(\partial_\mu g_{\nu\lambda}+\partial_\nu g_{\mu\lambda}-\partial_\lambda g_{\mu\nu}\right)$$

При заданном начальном положении $X^\mu(s_0)$ и скорости $(dX^\mu/ds)(s_0)$ имеем четыре дифференциальных уравнения второго порядка (9), определяющих геодезическую траекторию, по которой частица движется в искривленном пространстве-времени. Обратите внимание, что вопреки впечатлению, которое остается после прочтения некоторых книг, уравнение (9), в отличие от (8), не является репараметризационно инвариантным.

Для перехода к ньютоновской гравитации необходимо выполнение трех условий: (1) частицы двигаются медленно $dX^i/ds \ll dX^0/ds$; (2) гравитационное поле слабое, так что метрика близка к метрике Минковского $g_{\mu\nu} \simeq \eta_{\mu\nu} + h_{\mu\nu}$; и (3) гравитационное поле не зависит от времени. Условие (1) означает, что $d^2X^\rho/ds^2 + +\Gamma^\rho_{00}\left(dX^0/ds\right)^2 \simeq 0$, а (2) и (3) подразумевают, что $\Gamma^\rho_{00} \simeq -\frac{1}{2}\eta^{\rho\lambda}\partial_\lambda h_{00}$. Таким образом, (9) упрощается до вида $d^2X^0/ds^0 \simeq 0$ (и, как следствие, значение dX^0/ds остается неизменным) и $d^2X^i/ds^2 + \frac{1}{2}\partial_i h_{00}\left(dX^0/ds\right)^2 \simeq 0$, что, учитывая пропорциональность X^0 и s, сводится к виду $d^2X^i/dt^2 \simeq -\frac{1}{2}\partial_i h_{00}$. Таким образом, получаем уравнение Ньютона $\frac{d^2\vec{X}}{dt^2} \simeq -\vec{\nabla}\phi$, если определить гравитационный потенциал ϕ как $h_{00} = 2\phi$:

$$g_{00}\simeq 1+2\phi$$

С учетом метрики Шварцшильда приходим к выводу, что на больших расстояниях от массивного тела имеет место $\phi = -GM/r$, как мы и предполагали. (Заметьте, что процесс получения результата не зависит ни от h_{ij}, ни от h_{0j} до тех пор, пока они не зависят от времени.)

Таким образом, действие для точечной частицы равно

$$S=-m\int\sqrt{g_{\mu\nu}dX^\mu dX^\nu}=-m\int\sqrt{g_{\mu\nu}[X(\zeta)]\frac{dX^\mu}{d\zeta}\frac{dX^\nu}{d\zeta}}d\zeta$$

Множитель m следует из соображелий размерностей.

Быстрый способ найти S (в рамках которого мы, к тому же, получаем знак минус) состоит в том, чтобы начать с нерелятивистского действия для частицы в гравитационном потенциале ϕ, то есть с выражения $S = \int Ldt = \int \left(\frac{1}{2}mv^2 - \ -m - m\phi\right)dt$. Обратите внимание, что масса m входит со знаком минус, так как является частью потенциальной энергии в нерелятивистской физике. А теперь представим S в релятивистской форме: для малых v и ϕ

$$S = -m\int\left(1 - \frac{1}{2}v^2 + \phi\right)dt \simeq -m\int\sqrt{1 - v^2 + 2\phi}dt =$$
$$= -m\int\sqrt{(1+2\phi)(dt)^2 - (d\vec{x})^2}.$$

Видим [8], что происхождение 2 в (11) обуславливается квадратным корнем в множителе Лоренца-Фитцжеральда $\sqrt{1-v^2}$.

Теперь, зная S, с помощью (4) можно вычислить тензор энергии импульса точечной частицы:

$$T^{\mu\nu}(x) = \frac{m}{\sqrt{-g}}\int d\zeta K^{-1/2}\delta^{(4)}[x - X(\zeta)]\frac{dX^\mu}{d\zeta}\frac{dX^\nu}{d\zeta}$$

Полагая ζ равной s (которую в этом случае можно назвать собственным временем τ), получаем

$$T^{\mu\nu}(x) = \frac{m}{\sqrt{-g}}\int d\tau\delta^{(4)}[x - X(\tau)]\frac{dX^\mu}{d\tau}\frac{dX^\nu}{d\tau}$$

В частности, как мы и ожидали, 4-импульс частицы равен

$$P^\nu = \int d^3x\sqrt{-g}T^{0\nu} = m\int d\tau\delta\left[x^0 - X^0(\tau)\right]\frac{dX^0}{d\tau}\frac{dX^\nu}{d\tau} = m\frac{dX^\nu}{d\tau}$$

Приведенное здесь действие (12) имеет два недостатка: (1) трудно работать с интегралом по траекториям $\int DXe^{-im\int d\zeta\sqrt{(dX^\mu/d\zeta)(dX_\mu/d\zeta)}}$, содержащим квадратный корень, и (2) S не имеет смысла для безмассовой частицы.

Для устранения указанных недостатков заметим, что в классическом случае S эквивалентно

$$S_{\text{imp}} = -\frac{1}{2}\int d\zeta\left(\frac{1}{\gamma}\frac{dX^\mu}{d\zeta}\frac{dX_\mu}{d\zeta} + \gamma m^2\right)$$

[8] Отсюда не следует, что $g_{ij} = \delta_{ij}$. Важно то, что в главном порядке по v/c наша частица чувствительна только к g_{00}. В самом деле, восстанавливая c в метрике Шварцшильда. получаем

$$ds^2 = \left(1 - \tfrac{2GM}{c^2r}\right)c^2dt^2 - \left(1 - \tfrac{2GM}{c^2r}\right)^{-1} \quad dr^2 - -r^2d\theta^2 - r^2\sin^2\theta d\phi^2 \to$$
$$\to c^2dt^2 - \vec{x}^2 - \tfrac{2GM}{r}dt^2 + O\left(1/c^2\right)$$

где $\left(dX^\mu/d\zeta\right)\left(dX_\mu/d\zeta\right) = g_{\mu\nu}(X)\left(dX^\mu/d\zeta\right)\left(dX^\nu/d\zeta\right)$. Варьируя по $\gamma(\zeta)$, получаем $m^2\gamma^2 = \left(dX^\mu/d\zeta\right)\left(dX_\mu/d\zeta\right)$. Исключая γ из S_{imp} , мы восстанавливаем S.

Интеграл по траекториям $\int DXe^{iS_{\text{imp}}}$ имеет стандартную квадратичную форму9. Квантовая механика релятивистской точечной частицы наиболее удобным образом формулируется в терминах $S_{\text{imp},}$, н не S. Более того, для случая $m = 0$ выражение

$S_{\rm imp} = -\frac{1}{2}\int d\zeta\left[\gamma^{-1}\left(dX^\mu/d\zeta\right)\left(dX_\mu/d\zeta\right)\right]$ совершенно осмысленно. Заметьте, что варьирование по γ приводит к хорошо известному факту, что для безмассовой частицы $g_{\mu\nu}(X)dX^\mu dX^\nu = 0$.

Действие $S_{\rm imp}$ послужит нам отправной точкой при обсуждении теории струн в главе VIII.5.

Упражнения

I.10.1. Проинтегрировав по частям, получите действие для скалярного поля

$$S = -\int d^4x\sqrt{-g}\frac{1}{2}\varphi\left(\frac{1}{\sqrt{-g}}\partial_\mu\sqrt{-g}g^{\mu\nu}\partial_\nu + m^2\right)\varphi$$

и выведите уравнение движения для φ в искривленном пространстве-времени. Обсудите пропагатор скалярного поля $D(x,y)$ (который, конечно, уже не является трансляционно инвариантным, то есть не является больше функцией от $x-y$).

I.10.2. Используя (4), найдите E для скалярного поля в плоском пространстве-времени. Покажите, что результат совпадает с тем, который вы бы получили при использовании канонического формализма из главы I.8.

I.10.3. Покажите, что в плоском пространстве-времени величина P^μ, полученная нами из тензора энергии импульса $T^{\mu\nu}$, будучи интерпретированной как оператор в каноническом формализме, удовлетворяет условию $[P^\mu, \varphi(x)] = -i\partial^\mu\varphi(x)$, то есть выполняют ту самую роль, которую мы ожидаем от операторов энергии и импульса, а именно является сопряженной со временем и пространством и, следовательно, имеет вид $-i\partial^\mu$.

I.10.4. Покажите, что для максвелловского поля $T_{ij} = -\left(E_iE_j + B_iB_j\right) + \frac{1}{2}\delta_{ij}\left(\vec{E}^2 + \ + \vec{B}^2\right)$ и, следовательно, $T = 0$.

[9] Техническая трудность, которую мы рассмотрим в главе III.4, состоит в том, что в интеграле по $X(\zeta)$ кажущиеся различными функции $X(\zeta)$ могут на самом деле быть физически тождественными, связанными друг с другом репараметризацией.

Зи.I. 11 Резюме теории поля

Что вы узнали?

Теперь, когда мы подошли к концу первой части, оценим критически то, что вы узнали. Квантовая теория поля вовсе не трудна; она сводится к вычислению одного-единственного, но большущего интеграла

$$Z(J) = \int D\varphi e^{i\int d^{D+1}x\left[\frac{1}{2}(\partial\varphi)^2 - \frac{1}{2}m^2\varphi^2 - \lambda\varphi^4 + J\varphi\right]}.$$

Многократным функциональным дифференцированием $Z(J)$ и последующим наложением условия $J = 0$ получаем

$$\int D\varphi\varphi\left(x_1\right)\varphi\left(x_2\right)...\varphi\left(x_n\right)e^{i\int d^{n+1}x\left[\frac{1}{2}(\partial\varphi)^2 - \frac{1}{2}m^2\varphi^2 - \lambda\varphi^4\right]},$$

что соответствует амплитуде для n частиц, ассоциированных с полем φ, которые возникают и исчезают в пространственно-временных точках $x_1, x_2, ..., x_n$, взаимодействуя друг с другом в интервалах между ними. Это есть рождение, смерть и, в некотором смысле, жизнь между ними.

Ах, если бы мы только могли вычислить интеграл (1)! Но мы не можем. Один из способов выйти из положения состоит в разложении этого интеграла в ряд по λ:

$$\sum_{k=0}^{\infty} \frac{(-i\lambda)^k}{k!} \int D\varphi\varphi\left(x_1\right)\varphi\left(x_2\right)...\varphi\left(x_n\right)\left[\int d^{D+1}y\varphi(y)^4\right]^k e^{i\int d^{D+1}x\left[\frac{1}{2}(\partial\varphi)^2-\frac{1}{2}m^2\varphi^2\right]}.$$

Для отслеживания членов полученного ряда мы рисуем маленькие диаграммы. Теоретики, занимающиеся квантовой теорией поля, пытаются придумать способы вычисления (1), но, не добившись успеха, изобретают разные трюки и методы, чтобы правдами или неправдами извлечь нужные физические результаты без явных вычислений (1).

Для того чтобы понять, что квантовая теория поля является непосредственным обобщением квантовой механики, посмотрим, как соответствующим образом упрощается (1). Мы записали теорию в $(D+1)$-мерном пространстве-времени, то есть в D пространственных измерениях и одном временном измерении. Рассмотрим (1) в $(0+1)$-мерном пространстве-времени, то есть в отсутствие пространства; получим

$$Z(J) = \int D\varphi e^{i\int dt\left[\frac{1}{2}\left(\frac{d\varphi}{dt}\right)^2-\frac{1}{2}m^2\varphi^2-\lambda\varphi^4+J\varphi\right]}$$

где мы теперь обозначаем пространственно-временную координату x просто временем t. Мы узнаем в полученном выражении квантовую механику ангармонического осциллятора, с обозначенным φ положением прикрепленной к пружине массы и внешней силой J, действующей на осциллятор.

Каждый член в действии квантовой теории поля (1) имеет физический смысл: первые два члена обобщают гармонический осциллятор до случая пространственных колебаний, третий член соответствует антармоничности, а последний член соответствует внешнему пробнику. Вы можете рассматривать квантовую теорию поля как бесконечный набор гармонических осцилляторов, по одному на каждую точку пространства.

Здесь у нас было скалярное поле φ. В предыдущих и последующих главах понятие поля было и будет несколько обобщено: поле может преобразовываться в соответствии с нетривиальным представлением группы Лоренца. Мы уже встречали поля, преобразующиеся как вектор и как тензор, а впоследствии встретим поле, преобразующееся как спинор. Лоренц-инвариантность или какие-либо другие имеющиеся симметрии накладывают ограничения на форму действия. Интеграл будет выглядеть более сложно, но подход к его вычислению останется в точности таким же.

Вот, собственно, и вся квантовая теория поля.

10.2 Non-Abelian Fields, Ghosts, BRST Invariance (??)

(мб перекину в главу с методами описания полей, почему нет? больше это как теория..)

введение

В абелевой теории калибровочного поля, в лоренцевой калибровке детерминант калибровочного условия факторизовался как нормировочный множитель и был несущественнен для правил Фейнмана, потому что он не зависел от полей.

В неабелевой теории бесконечно малое калибровочное преобразование поля

$$\mathcal{A}_\mu \mapsto \mathcal{A}_\mu - \partial_\mu u + \mathrm{i}e\,[u, \mathcal{A}_\mu] = \mathcal{A}_\mu - [\nabla_\mu, u]$$

приводит (как????) к оператору $\mathcal{M}_L$ лоренцевского калибровочного условия $\partial^\mu \mathcal{A}_\mu = 0$ в виде

$$(\mathcal{M}_L(\mathcal{A}))^a_b|_{u\to 0} = \frac{\delta}{\delta u^b}\partial^\mu \left(-\partial_\mu u^a - e f^{ab'c} u^{b'} \mathcal{A}^c_\mu\right)\Big|_{u\to 0} = -\delta^{ab}\partial^2 - e f^{abc}\mathcal{A}^c_\mu \partial^\mu$$

Здесь в последнем равенстве мы учли, что $\partial^\mu \mathcal{A}_\mu = \mathcal{A}_\mu \partial^\mu + (\partial^\mu \mathcal{A}_\mu) = \mathcal{A}_\mu \partial^\mu$.

Детерминант этого оператора, явно зависящего от калибровочного поля, уже не удастся вынести из-под знака интеграла.

духи Фаддеева-Попова

Вспоминая свойства интегрирования по грассмановым полям???, мы можем переписать функциональный детерминант в виде функционального интеграла по вспомогательным грассмановым полям $\mathfrak{c}^b, \bar{\mathfrak{c}}_a$, которых называют духами Фаддева-Попова,

$$\mathrm{Det}\,(\mathcal{M}_L) = \int \mathcal{D}\bar{\mathfrak{c}}\mathcal{D}\mathfrak{c}\,\exp\left(\mathrm{i}\int \mathrm{d}^4x \bar{\mathfrak{c}}_a(x)(\mathcal{M}_L)^a_b \mathfrak{c}^b(x)\right)$$

Наименование «духи» становится более понятным, если, во-первых, обратить внимание на свободную кинетическую часть лагранжиана для полей $\mathfrak{c}(x)$ без калибровочного поля:

$$\bar{\mathfrak{c}}_a(x)\delta^a_b\left(-\partial^2\right)\mathfrak{c}^b(x)$$

который в точности воспроизводит лагранжиан скалярного бозонного поля, но мы вынуждены приписать этому полю статистику Ферми-Дирака.

А это означает, как мы знаем, что каждая петля духов добавляет в амплитуду фактор (-1), что весьма нетривиально.

Во-вторых, вспомогательные поля $\mathfrak{c}(x)$ не имеют никакого отношения к асимптотическим состояниям: внешние поля обусловлены только физическими модами полей исходного лагранжиана.

Стало быть, при построении амплитуд квантовых переходов необходимо рассматривать только диаграммы, в которых нет внешних линий с духами.

отличие методов для неабелевых теорий от абелевых

Необходимость особых мер в квантовой теории неабелевых калибровочных полей была показана Фейнманом.

Он установил, что из-за нелинейности теории по калибровочным полям, у этих полей возникает самодействие, причем вычисление петлевой поправки к пропагатору калибровочного поля странным образом приводит к противоречию:

при использовании правил Фейнмана с самодействием полей возникает одно выражение, а вычисление унитарным методом, когда в петле учитываются только физические моды поля, к другому выражению.

противоречие и его устранение (????)

(киселев чет сказал, ну и ладно)

Противоречие полностью исчезает, если учитываются правила Фейнмана при наличии духов, которые дают петлевой вклад, обеспечивающий согласование с унитарным методом.

тут нормально пороюсь, в чем же противоречие.

лагранжиан духов

в лоренцевской калибровке к действию необходимо вклад от лагранжиана духов

$$\mathcal{L}_{\mathrm{gh}} = -\delta^a_b \bar{\mathfrak{c}}_a \partial^2 \mathfrak{c}^b - e f^{abc} \bar{\mathfrak{c}}_a \mathcal{A}^c_\mu \partial^\mu \mathfrak{c}^b,$$

(???) После интегрирования по частям с учетом 4-мерной поперечности калибровочного поля дает эквивалентную запись

$$\mathcal{L}_{\text{gh}} = \delta^a_b \left(\partial_\mu \bar{\mathfrak{c}}_a\right) \partial^\mu \mathfrak{c}^b - e f^{abc} \mathcal{A}^c_\mu \frac{1}{2} \left(\bar{\mathfrak{c}}_a \partial^\mu \mathfrak{c}^b - \left(\partial^\mu \bar{\mathfrak{c}}_a\right) \mathfrak{c}^b\right)$$

(????) К этому лагранжиану можно, конечно, добавить источники для духов $\bar{\zeta}$ и антидухов ζ, а затем повторить стандартную технику построения диаграмм в теории возмущений.

правила Фейнмана для вклада духов

Отсюда сразу следуют правила Фейнмана для вклада духов.
(????? я тут полностью хз)
На внутренних линиях пропагатор духа

$$\mathrm{i}\frac{\delta^a_b}{p^2 + \mathrm{i}0}$$

Вершина духов с калибровочным полем легко вычисляется, если учесть, что стандартный фактор перед лагранжианом i при умножении на ∂_μ дает 4 -импульс p_μ, так что

$$-e f^{abc} \frac{1}{2} \left(p_{\mathfrak{c}} - p_{\bar{c}}\right)^\mu$$

(тут диаграммка)

примеры диаграмм для духов

пока ни один не могу привести.

аксиальная калибровка

Для справок укажем калибровочное условие, которое не требует введения духов: аксиальная калибровка

$$X_N = n^\mu \mathcal{A}_\mu(x) = 0$$

где 4-вектор n^μ не зависит от координат.

Тогда оператор

$$\mathcal{M}_N = -\delta^a_b n^\mu \partial_\mu$$

не зависит от поля, и его можно вынести из-под знака континуального интеграла по полям, как это было в случае лоренцевской калибровки в абелевой теории.

В аксиальной калибровке при добавлении в лагранжиан члена

$$\mathcal{L}_{\text{g.fix.}} = -\frac{\xi}{2}(n \cdot \mathcal{A})^2$$

пропагатор калибровочного поля принимает вид

пропагатор калибровочного поля принимает вид

$$\mathrm{i}\frac{\delta^a_b}{k^2 + \mathrm{i}0} \left(-g_{\mu\nu} + \frac{k_\mu n_\nu + k_\nu n_\mu}{k \cdot n} - \frac{k_\mu k_\nu}{(k \cdot n)^2} \frac{k^2 + \xi n^2}{\xi}\right)$$

Но поскольку физические результаты не зависят от ξ, часто проводят вычисления, полагая $\xi \to \infty$ при $n^2 \neq 0$, что, конечно, несколько упрощает вид пропагатора.

лагранжианы фиксации калибровки и гостов

Формально вклады в лагранжиан от члена, фиксирующего калибровку, и от духов Фаддеева-Попова

$$\begin{aligned}\mathcal{L}_{\text{g.fix.}}+\mathcal{L}_{\text{gh}} &= -\frac{1}{2\xi}\left(\partial_\mu \mathcal{A}^\mu\right)^2+\delta^a_b\left(\partial_\mu \bar{\mathfrak{c}}_a\right)\partial^\mu \mathfrak{c}^b - ef^{abc}\mathcal{A}^c_\mu\frac{1}{2}\left(\bar{\mathfrak{c}}_a\partial^\mu\mathfrak{c}^b-\mathfrak{c}^b\partial^\mu\bar{\mathfrak{c}}_a\right)\cong\\ &\cong -\frac{1}{2\xi}\left(\partial_\mu\mathcal{A}^\mu\right)^2+\bar{\mathfrak{c}}\left(\mathcal{M}_L(\mathcal{A})\mathfrak{c}\right)\cong\\ &\cong -\frac{1}{2\xi}\left(\partial_\mu\mathcal{A}^\mu\right)^2+\left(\partial_\mu\bar{\mathfrak{c}}\right)\left[\nabla^\mu,\mathfrak{c}\right]\end{aligned}$$

не обладают инвариантностью относительно калибровочной группы.
и что делать с ними?

бесконечно малые преобразования

бесконечно малые преобразования калибровочного поля и духа равны

$$\begin{aligned}\delta\mathcal{A}_\mu &= \varepsilon\left(-\partial_\mu\mathfrak{c}+\mathrm{i}e\left[\mathfrak{c},\mathcal{A}_\mu\right]\right)=-\varepsilon\left[\nabla_\mu,\mathfrak{c}\right]\\ \delta\mathfrak{c} &= Y_{\mathrm{c}}\varepsilon\mathrm{i}e[\mathfrak{c},\mathfrak{c}]\equiv Y_{\mathrm{c}}\varepsilon\mathrm{i}\mathfrak{c}^a\mathfrak{c}^b\left[t_a,t_b\right]\end{aligned}$$

где $Y_{\mathfrak{c}}$ - заряд духа
(????) потому что что если записать параметр локального калибровочного преобразования в виде произведения грассмановых переменных

$$u^a(x)=\varepsilon\mathfrak{c}^a(x)$$

с глобальным параметром ε и локальным духом $\mathfrak{c}(x)$.
Заряд нужно найти, поскольку

$$\mathfrak{c}\mapsto e^{\mathrm{i}eY_{\mathrm{c}}\varepsilon\mathfrak{c}}\mathfrak{c}e^{-\mathrm{i}eY_{\mathrm{c}}\varepsilon\mathfrak{c}}$$

а коммутаторы вычисляются в матричной форме, так что, например,

$$[\mathfrak{c},\mathfrak{c}]=\mathfrak{c}^a\mathfrak{c}^b\left[t_a,t_b\right]=\mathrm{i}f_{abc}t_c\mathfrak{c}^a\mathfrak{c}^b$$

причем для грассмановых переменных конструкция $\mathfrak{c}^a\mathfrak{c}^b$ антисимметрична по перестановке индексов $a\leftrightarrow b$, так что за счет полной антисимметрии структурных констант группы f_{abc} коммутатор отличен от нуля.

вариация полного калибровочного лагранжиана

Тогда вариация калибровочно инвариантных вкладов, конечно, равна нулю, а

$$\delta\left(\mathcal{L}_{\text{g.fix.}}+\mathcal{L}_{\text{gh}}\right)=-\frac{1}{\xi}(\partial_\mu\mathcal{A}^\mu)\varepsilon\left(\mathcal{M}_L(\mathcal{A})\mathfrak{c}\right)+\left(\delta\bar{\mathfrak{c}}\right)\left(\mathcal{M}_L(\mathcal{A})\mathfrak{c}\right)+\left(\partial^\mu\bar{\mathfrak{c}}\right)\delta\left[\nabla_\mu,\mathfrak{c}\right]$$

Покажем, что вариация $\delta\left[\nabla_\mu,\mathfrak{c}\right]\equiv 0$ при действии (9.24).
В общем выражении

$$\delta\left[\nabla_\mu,\mathfrak{c}\right]=\partial_\mu\delta\mathfrak{c}-\mathrm{i}e\left[\delta\mathfrak{c},\mathcal{A}_\mu\right]-\mathrm{i}e\left[\mathfrak{c},\delta\mathcal{A}_\mu\right]$$

первый член равен

$$\mathrm{i}e\varepsilon\, Y_{\mathfrak{c}}\partial_\mu[\mathfrak{c},\mathfrak{c}] = \mathrm{i}\, e\varepsilon 2Y_{\mathfrak{c}}\,[\partial_\mu\mathfrak{c},\mathfrak{c}]$$

второй -

$$-(\mathrm{i}e)^2\varepsilon Y_{\mathrm{c}}\,[[\mathfrak{c},\mathfrak{c}],\mathcal{A}_\mu]$$

третий -

$$-\mathrm{i}\, e\varepsilon\,[\mathfrak{c},-[\nabla_\mu,\mathfrak{c}]] = \mathrm{i}e\varepsilon\,[\mathfrak{c},\partial_\mu\mathfrak{c}] - (\mathrm{i}e)^2\varepsilon\,[\mathfrak{c},[\mathfrak{c},\mathcal{A}_\mu]]$$

Как видим, при $Y_{\mathfrak{c}} = -\frac{1}{2}$ сокращаются вклады с производной поля духов $\partial_\mu\mathfrak{c}$. Что же касается, членов с двойными коммутаторами, то

$$-\frac{1}{2}\Big[[\mathfrak{c},\mathfrak{c}] + [\mathfrak{c},[\mathfrak{c},\mathcal{A}_\mu]] = -\frac{1}{2}\mathfrak{c}^a\mathfrak{c}^b\mathcal{A}^c_\mu\left([[t_a,t_b]\,,t_c] - 2\,[t_a,[t_b,t_c]]\right)$$

Но в силу антисимметрии грассманова фактора

$$\mathfrak{c}^a\mathfrak{c}^b 2\,[t_a,[t_b,t_c]] = \mathfrak{c}^a\mathfrak{c}^b\left([t_a,[t_b,t_c]] - [t_b,[t_a,t_c]]\right.$$

так что, в итоге, используя антисимметрию коммутатора $[A,B] = -[B,F]$, находим выражение

$$\frac{1}{2}\mathfrak{c}^a\mathfrak{c}^b\mathcal{A}^c_\mu\left([t_c,[t_a,t_b]] + [t_a,[t_b,t_c]] + [t_b,[t_c,t_a]]\right) \equiv 0$$

в силу тождества Якоби для коммутатора.

BRST-суперпреобразования

Таким образом, действие, которое включает в себя также вклад от фиксирующего калибровку члена и поля духов Фаддеева-Попова локально инвариантно относительно преобразований

$$\begin{aligned}\delta\mathcal{A}_\mu &= \varepsilon\left(-\partial_\mu\mathfrak{c} + \mathrm{i}e\,[\mathfrak{c},\mathcal{A}_\mu]\right) = -\varepsilon\,[\nabla_\mu,\mathfrak{c}]\\ \delta\mathfrak{c} &= -\frac{1}{2}\varepsilon\mathrm{i}e[\mathfrak{c},\mathrm{c}]\\ \delta\overline{\mathfrak{c}} &= \frac{1}{\xi}\left(\partial_\mu\mathcal{A}^\mu\right)\varepsilon\end{aligned}$$

которые называют BRST-суперпреобразованиями по именам четырех авторов Becchi-Rouet-Stora-Tyutin. Суперсимметричность преобразований обусловлена грассмановой переменной ε, а так как эта переменна не зависит от координат, симметрия является глобальной.

примеры BRST-инвариантности

свойства интегрирования по грассмановым полям

хз, но там где-то они были нужны.

10.3 Free Quantum Fields at Finite Temperature

(this is also a fundamental properties of fields, so I'll add theory about it here. se cond matter for now. I haven't heard that it is used in particles physics and somewhere except phase transitions, condensed matter...)

Part IV
Practical Methods in QFT

11 Setups for Phenomena

(пока тут этот раздел, в 1 части очень четкое указание на важные тут формулы будет!!!!)

11.1 L9-2 S-Matrix

11.1.1 4. General Formula for the S-Matrix in QED and the Simplest Amplitudes

Мы можем, наконец, собрать все формулы вместе и выписать общее выражение для S-матрицы в КЭД при помощи континуального интеграла по бозонным и фермионным полям:

$$S_{J,\eta,\bar{\eta}} = \frac{1}{N}\int \exp\left\{ i\int \mathrm{d}^{(d)}x \left[-\frac{1}{16\pi}F_{\mu\nu}^2 - \frac{1}{8\pi\alpha}\left(\partial_\mu A^\mu\right)^2 + \right.\right.$$
$$\left.\left. +\bar{\psi}\left(i\gamma^\mu\nabla_\mu - m\right)\psi + J^\mu A_\mu + \bar{\eta}\psi + \bar{\psi}\eta \right] \right\} DA_\mu D\bar{\psi}D\psi \tag{55}$$

Граничные условия для полей при $|t|\to\infty$ указаны в лекции 7 и предыдущем пункте. Как обычно, для развития ТВ действие в экспоненте в (55) разбивается на квадратичную (линейную) и нелинейную части. Последняя описывает взаимодействие:

$$S = S_0\{A,\bar{\psi},\psi;J,\bar{\eta},\eta\} + S_{int}, \quad iS_{int} = -ie\int \mathrm{d}^{(d)}x A_\mu \bar{\psi}_a \gamma^\mu_{ab}\psi_b \tag{56}$$

Представим S_{int} в виде дифференциального оператора

$$i\hat{S}_{int} = -e\int \mathrm{d}^{(d)}x \frac{\delta}{\delta J^\mu}\frac{\delta}{\delta\eta_a}\gamma^\mu_{ab}\frac{\delta}{\delta\bar{\eta}_b} \tag{57}$$

который может находиться как под знаком функционального интеграла, так и вне его. Это позволяет переписать выражение (55) в виде

$$S = \frac{1}{N}\exp\left\{ -e\int \mathrm{d}^{(4)}x \frac{\delta}{\delta J^\mu(x)}\frac{\delta}{\delta\eta_a(x)}\gamma^\mu_{ab}\frac{\delta}{\delta\bar{\eta}_b(x)} \right\} : \exp\left\{ i\int \mathrm{d}^{(4)}x \left(-\mathbf{J}\mathbf{A}_0 + \bar{\eta}\psi_0 + \bar{\psi}_0\eta\right) + \right.$$
$$\left. +i\int \mathrm{d}^{(4)}x\, \mathrm{d}^{(4)}y \left[\frac{1}{2}J^\mu(x)D^\alpha_{\mu\nu}(x-y)J^\nu(y) - \bar{\eta}(x)S_c(x-y)\eta(y) \right] \right\} : |_{J,\bar{\eta},\eta=0} \tag{58}$$

где пропагаторы $D^\alpha_{\mu\nu}$ и S_c задаются формулами (53 Л7) и (49), соответственно. Асимптотические поля $\mathbf{A}_0,\bar{\psi}_0,\psi_0$ разлагаются согласно (см. (47 Л7) и (46 Л8))

$$\mathbf{A}_0(x) = \sum_{\alpha=1,2} \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \sqrt{\frac{2\pi}{|\mathbf{k}|}} \left(c_{\mathbf{k}\alpha} \mathbf{e}_{\mathbf{k}\alpha} e^{-ikx} + c^\dagger_{\mathbf{k}\alpha} \mathbf{e}^*_{\mathbf{k}\alpha} e^{ikx} \right)$$

$$\psi_0(x) = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \frac{1}{\sqrt{2\omega_k}} \sum_{s=1,2} \left(a_{\mathbf{k}s} u_{ks} e^{-ikx} + b^\dagger_{ks} u_{-ks} e^{ikx} \right)$$

$$\bar\psi_0(x) = \int \frac{\mathrm{d}^{(3)}k}{(2\pi)^3} \frac{1}{\sqrt{2\omega_k}} \sum_{s=1,2} \left(b_{\mathbf{k}s} \bar u_{-ks} e^{-ikx} + a^\dagger_{ks} \bar u_{ks} e^{ikx} \right) \tag{59}$$

Здесь вектора поляризации фотонов $\mathbf{e}_{\mathbf{k}}\alpha$ удовлетворяют условиям (55 J 7), а спиноры u_{ks}, u_{-ks} - уравнениям (38 Л8) и условиям (57 Л8). Коммутационные или антикоммутационные соотношения операторов рождения и уничтожения имеют вид (33 Л7) и (54 Л8), (58 Л8). Вакуумное состояние определяется условиями

$$a_{\mathbf{k}s}|0\rangle = b_{\mathbf{k}s}|0\rangle = c_{\mathbf{k}\alpha}|0\rangle = 0$$

a, например, состояние электрона с импульсом $\mathbf{p}$ и спином s и позитрона с импульсом $\mathbf{q}$ и спином s' и фотона с импульсом $\mathbf{k}$ и поляризацией α имеет вид

$$|\mathbf{p}s, \mathbf{q}s', \mathbf{k}\alpha\rangle = \sqrt{2\omega_p 2\omega_q 2|\mathbf{k}|} a^\dagger_{\mathbf{p}s} b^\dagger_{\mathbf{q}s'} c^\dagger_{\mathbf{k}\alpha}|0\rangle$$

и т.д.

Из выражения (58) получаем также амплитуду перехода из вакуума в вакуум в присутствии внешних источников:

$$Z(J,\eta,\bar\eta) = \frac{1}{N} \exp\left\{ -e \int \mathrm{d}^{(4)}x \frac{\delta}{\delta J^\mu} \frac{\delta}{\delta \eta_a} \gamma^\mu_{ab} \frac{\delta}{\delta \bar\eta_b} \right\}$$
$$\cdot \exp\left\{ i \int \mathrm{d}^{(4)}x \; \mathrm{d}^{(4)}y \left[\frac{1}{2} J^\mu(x) D^\alpha_{\mu\nu}(x-y) J^\nu(y) - \bar\eta(x) S_c(x-y) \eta(y) \right] \right\} \tag{60}$$

Укажем здесь, что при комплексном значении параметра размерности пространства d базовое соотношение для матриц Дирака (5 Л8) остаётся в силе, в то время как ряд других принимают следующий вид:

$$g_{\mu\nu} g^{\mu\nu} = d, \quad \gamma_\mu \gamma^\mu = d, \quad \mathrm{tr}\, \gamma^\mu \gamma^\nu = 2^{d/2} \eta^{\mu\nu} \tag{61}$$

Поэтому если в (63 Л8) определить

$$2^{d/2} T^{\mu_1 \mu_2 \ldots \mu_n} = \mathrm{tr}\,(\gamma^{\mu_1} \gamma^{\mu_2} \ldots \gamma^{\mu_n})$$

то все формулы для этой величины, полученные в лекции 8, сохраняются. Парадоксы возникают при комплексном d лишь при работе с γ^5-матрицей, однако с этим парадоксом нам придётся столкнуться лишь в лекции, посвящённой аксиальной аномалии.

При комплексном значении размерности пространства d выражения для S-матрицы (58) и производящего функционала (60) регуляризованы. При этом сохранена калибровочная инвариантность теории, поскольку эта симметрия имеет место при любом d.

Рассмотрим простейший процесс рассеяния двух электронов в два электрона. Для этого следует выражение для оператора S-матрицы (58) поместить в обкладки между

бра-состоянием $\langle 0|a_{\mathbf{p}_1' s_1'} a_{\mathbf{p}_2' s_2'}$ и кет-состоянием $a^\dagger_{\mathbf{p}_2 s_2} a^\dagger_{\mathbf{p}_1 s_1}|0\rangle$. Здесь $\mathbf{p}_i, s_i \quad$ и $p_i', s_i', \quad i = 1, 2$ - импульсы и спины начальных и конечных электронов. Чтобы сократить запись формул, мы будем писать u_1 вместо $u_{p_1 s_1}$ и $\bar{u}_2'$ вместо $\bar{u}_{\mathrm{p}_2' s_2'}, u_{-1}$ вместо $u_{-p_1 s_1}$, и т.д. Наинизший порядок, в котором амплитуда этого процесса отличается от нуля, получается при разложении первой экспоненты в (58) до второго порядка, что даёт вклад в S-матрицу

$$\frac{ie^2}{2!} : \int \mathrm{d}^{(4)}x \; \mathrm{d}^{(4)}y \left[\bar{\psi}_0(x)\gamma^\mu \psi_0(x)\right] \left[\bar{\psi}_0(y)\gamma^\nu \psi_0(y)\right] : D^\alpha_{\mu\nu}(x-y) \tag{62}$$

Поскольку поле ψ_0 удовлетворяет уравнению Дирака, то $\partial_\mu \left[\bar{\psi}_0(x)\gamma^\mu \psi_0(x)\right] = 0$, и потому продольная часть фотонного пропагатора в (62) выпадает, в качестве фотонного пропагатора можно взять $D^1_{\mu\nu} \sim \eta_{\mu\nu}$. Мы видим, что физические величины не зависят от калибровки. Это утверждение имеет место во всех порядках теории возмущений. Помещая выражение (62) в указанные выше обкладки, в результате простых вычислений получаем для амплитуды iM:

$$iM = 4\pi i e^2 \left\{ \frac{1}{t} \left(\bar{u}_2' \gamma^\mu u_2\right) \left(\bar{u}_1' \gamma_\mu u_1\right) - \frac{1}{u} \left(\bar{u}_2' \gamma^\mu u_1\right) \left(\bar{u}_1' \gamma_\mu u_2\right) \right\} \tag{63}$$

где используются введенные согласно (27 Л4) инварианты

$$\begin{gathered} s = (p_1 + p_2)^2, \quad t = (p_1 - p_1')^2, \quad u = (p_1 - p_2')^2 \\ p_1^\mu + p_2^\mu = p_1'^\mu + p_2'^\mu \end{gathered} \tag{64}$$

Формула для сечения рассеяния σ двух частиц в две частицы в системе центра инерции содержится в Приложении (см. (А19)). Пусть $\varepsilon = p_1^0 + p_2^0$ - полная энергия, $\mathbf{p}_1 = -\mathbf{p}_2 \equiv \mathbf{p}$ и $\mathbf{p}_1' = -\mathbf{p}_2' \equiv \mathbf{p}'$ - начальный и конечный импульсы. Тогда в нашем случае

$$\mathrm{d}\sigma = \frac{|M|^2}{64\pi^2 \varepsilon^2} \, \mathrm{d}o' \tag{65}$$

где $\mathrm{d}o'$ - дифференциал телесного угла конечного импульса $\mathbf{p}'$. В системе центра инерции

$$t = -(\mathbf{p}_1 - \mathbf{p}_1')^2 = -4\mathbf{p}^2 \sin^2 \frac{\theta}{2}, \quad u = -4\mathbf{p}^2 \cos^2 \frac{\theta}{2}, \quad -\mathrm{d}t = 2\mathbf{p}^2 |\, \mathrm{d}\cos\theta| = \frac{\mathbf{p}^2}{\pi} \mathrm{d}o' \tag{66}$$

где θ - угол рассеяния.

Рассмотрим это сечение в нерелятивистском пределе, когда согласно (42 Л8)

$$\bar{u}' \gamma^\mu u = 2m w'^\dagger w \delta_0^\mu \tag{67}$$

Подставим (63) с учётом (67) в (65) и усредним по начальным спинам электронов (то есть заменим везде $w_\alpha w_\beta^* \to \frac{1}{2}\delta_{\alpha\beta}$ для начальных частиц):

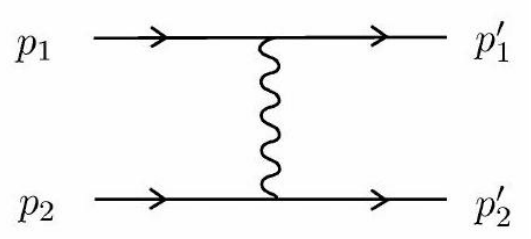
$$\mathrm{d}\sigma = e^4 m^2 \left\{ \frac{1}{4t^2} + \frac{1}{4u^2} - 2\frac{\left(u_1'^\dagger u_2\right)^2}{4tu} \right\} \mathrm{d}o' \tag{68}$$

Теперь просуммируем независимо по спинам конечных частиц. В результате получим:

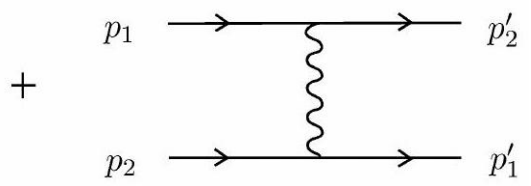
$$\mathrm{d}\sigma = e^4 m^2 \left(\frac{1}{t^2} + \frac{1}{u^2} - \frac{1}{tu}\right) \mathrm{d}o' = \left(\frac{e^2}{mv^2}\right)^2 \left(\frac{1}{\sin^4\frac{\theta}{2}} + \frac{1}{\cos^4\frac{\theta}{2}} - \frac{1}{\sin^2\frac{\theta}{2}\cos^2\frac{\theta}{2}}\right) \mathrm{d}o' \qquad (69)$$

где $\mathbf{v} = 2\mathbf{p}/m$ - относительная скорость электронов. Сечение (69) совпадает с известным результатом в нерелятивистской теории.

Графически амплитуда (63) представляется в виде суммы двух следующих диаграмм Фейнмана:



(a)



(b)

Рис. 13

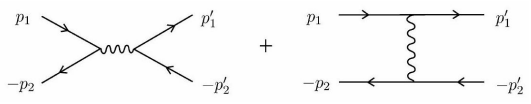
Укажем, что в используемой системе единиц

$$\frac{e^2}{\hbar c} = \frac{1}{137,04} \qquad (70)$$

Вычислим теперь в наинизшем порядке упругую амплитуду рассеяния электрона на позитроне. Для этого следует вычислить выражение (62) в обкладках $\langle 0|a_{\mathbf{p}_1' s_1'} b_{\mathbf{p}_2' s_2'}$ и $b^\dagger_{\mathbf{p}_2 s_2} a^\dagger_{\mathbf{p}_1 s_1}|0\rangle$:

$$iM = 4\pi i e^2 \left\{ \frac{1}{s} \left(\bar{u}_1' \gamma^\mu u_{-2}'\right) \left(\bar{u}_{-2} \gamma_\mu u_1\right) - \frac{1}{t} \left(\bar{u}_{-2} \gamma^\mu u_{-2}'\right) \left(\bar{u}_1' \gamma_\mu u_1\right) \right\} \qquad (71)$$

где s, t и u задаются согласно (64). Амплитуда (71) представляется двумя диаграммами:



(a)

(b)

Рис. 14

Легко увидеть, что амплитуда (71) получается из амплитуды (63) (и наоборот) путём замены $p_2 \to -p_2', p_2' \to -p_2$, При этом происходят замены $t \leftrightarrow t, u \leftrightarrow s$, диаграмма (a) на рис. 13 переходит в диаграмму (b) на рис. 14, диаграмма (b) на рис. 13 переходит в диаграмму (a) на рис. 14.

11.1.2 Introduction to Mathematical Perturbation Theory

Теория

Мы достаточно подробно обсудили квантование двух свободных теорий поля, приближенно описывающих многие из найденных в природе свободных частиц. Однако до сих пор состояния свободных частиц были собственными состояниями гамильтониана. У нас не было ни взаимодействия, ни рассеяния. Чтобы получить описание, более близкое к реальности, следует включить в гамильтониан (или лагранжиан) новые, нелинейные слагаемые, связывающие друг с другом различные фурье-моды (и частицы, которые их населяют). Для сохранения причинности потребуем, чтобы новые слагаемые содержали произведения полей только в одной и той же точке пространства-времени. Так, выражение $[\phi(x)]^4$ прекрасно подходит, а выражение $\phi(x)\phi(y)$ не годится. Таким образом, слагаемые, описывающие взаимодействия, будут иметь вид:

$$H_{\text{int}} = \int d^3x \mathscr{H}_{\text{int}}[\phi(x)] = -\int d^3x \mathscr{L}_{\text{int}}[\phi(x)].$$

Пока ограничимся рассмотрением теорий, в которых $\mathscr{H}_{\text{int}}$ $(= -\mathscr{L}_{\text{int}})$ является функцией только самих полей, но не их производных.

В этой главе мы обсудим три важных примера взаимодействующих теорий поля. Первый из них - это теория ϕ^4:

$$\mathscr{L} = \frac{1}{2}\left(\partial_\mu \phi\right)^2 - \frac{1}{2}m^2\phi^2 - \frac{\lambda}{4!}\phi^4,$$

где λ - безразмерная константа связи. (Взаимодействие ϕ^3 было бы немного проще, но в этом случае энергия не будет положительно определена, до тех пор, пока не добавить более высокую четную степень ф.) Хотя мы рассматриваем эту теорию в чисто педагогических целях (так как она - самая простая из всех квантовых теорий с взаимодействием), модели реального мира содержат взаимодействия ϕ^4. Наиболее важный пример такого взаимодействия в физике частиц - самодействие хиггсовского поля в стандартной электрослабой теории. В части II мы увидим, что теория ϕ^4 возникает также в статистической механике. Уравнение движения для теории ϕ^4 имеет вид

$$\left(\partial^2 + m^2\right)\phi = -\frac{\lambda}{3!}\phi^3.$$

Оно не может быть решено с помощью фурье-разложения по примеру свободного уравнения Клейна-Гордона. В квантовой теории мы налагаем одновременные коммутационные соотношения

$$[\phi(\mathbf{x}), \pi(\mathbf{y})] = i\delta^{(3)}(\mathbf{x}-\mathbf{y}),$$

на которые не влияет $\mathscr{L}_{\text{int.}}$. (Заметим, однако, что если бы в $\mathscr{L}_{\text{int}}$ содержалось $\partial_\mu\phi$, то определение $\pi(\mathbf{x})$ было бы иным.) Нетрудно записать гамильтониан этой теории и найти гейзенберговские уравнения движения для оператора $\phi(x)$. Так же, как это было в свободной теории, результат совпадает с классическим уравнением движения (4.2).

Нашим вторым примером взаимодействующей теории поля будет квантовая электродинамика:

$$\begin{aligned}\mathscr{L}_{\text{КЭд}} &= \mathscr{L}_{\text{Дирак}} + \mathscr{L}_{\text{Максвелл}} + \mathscr{L}_{\text{int}} = \\ &= \bar{\psi}(i\not{\partial} - m)\psi - \frac{1}{4}\left(F_{\mu\nu}\right)^2 - e\bar{\psi}\gamma^\mu\psi A_\mu,\end{aligned}$$

где A_μ - электромагнитный векторный потенциал, $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ - тензор электромагнитного поля и $e = -|e|$ - электрический заряд. (Чтобы описать фермион с зарядом Q, заменим e на Q. Если мы хотим рассмотреть сразу несколько разновидностей заряженных частиц, мы просто продублируем $\mathscr{L}_{\text{Дирак и}}\,\mathscr{L}_{\text{int}}$ для каждой отдельной разновидности.) Удивительно, что этот простой лагранжиан описывает почти все наблюдаемые явления от макроскопических масштабов до масштабов 10^{-13}cm. На самом деле лагранжиан в КЭД может быть записан еще проще:

$$\mathscr{L}_{\text{КЭд}} = \bar{\psi}(i\not{D} - m)\psi - \frac{1}{4}\left(F_{\mu\nu}\right)^2,$$

где D_μ - калибровочно-ковариантная производная,

$$D_\mu \equiv \partial_\mu + ieA_\mu(x).$$

Определяющее свойство лагранжиана КЭД состоит в том, что он инвариантен относительно калибровочного преобразования

$$\psi(x) \to e^{i\alpha(x)}\psi(x), \quad A_\mu \to A_\mu - \frac{1}{e}\partial_\mu\alpha(x)$$

которое действует на дираковское поле как локальное фазовое вращение. Эта инвариантность при локальных фазовых вращениях имеет фундаментальное геометрическое значение, которое мотивирует появление ковариантной производной. Однако для наших целей достаточно того факта, что преобразование (4.6) является симметрией теории.

Уравнения движения получаются из (4.3) при помощи канонической процедуры. Уравнение Эйлера-Лагранжа для ψ имеет вид:

$$(i\not{\partial} - m)\psi(x) = 0$$

Это уравнение является уравнением Дирака, связанным с электромагнитным полем по рецепту минимальной связи, отвечающей замене $\partial \to D$. Уравнение Эйлера-Лагранжа для поля A_ν имеет вид:

$$\partial_\mu F^{\mu\nu} = e\bar{\psi}\gamma^\nu\psi = ej^\nu.$$

Это неоднородные уравнения Максвелла с плотностью тока $j^\nu = \bar{\psi}\gamma^\nu\psi$, определяемой сохраняющимся дираковским векторным током (3.73). Так же, как и в теории ϕ^4, уравнения движения могут быть получены как гейзенберговские уравнения для операторов $\psi(x)$ и $A_\mu(x)$. Это нетрудно проверить для поля $\psi(x)$, но мы до сих пор не провели квантование электромагнитного поля.

На самом деле мы вообще не будем обсуждать в этой книге каноническое квантование электромагнитного поля. Это весьма запутанный вопрос, главным образом из-за калибровочной инвариантности. Заметим, что, так как $\dot{A}^0$ не содержится в лагранжиане (4.3), то импульс, сопряженный к A^0, тождественно равен нулю. Это противоречит каноническому коммутационному соотношению $[A^0(\mathbf{x}), \pi^0(\mathbf{y})] = i\delta(\mathbf{x} - \mathbf{y})$. Одно из решений

состоит в квантовании в кулоновской калибровке, когда $\nabla \cdot \mathbf{A} = 0$ и компонента A^0 является не динамической переменной, а подчиняется некой связи. Но в этом случае неочевидна явная лоренц-инвариантность. С другой стороны, можно квантовать поле в лоренцевской калибровке $\partial_\mu A^\mu = 0$. Тогда можно модифицировать лагранжиан, добавляя слагаемое с $\dot{A}^0$. При таком подходе возникают коммутационные соотношения $\left[A^\mu(\mathbf{x}), \dot{A}^\nu(\mathbf{y})\right] = -ig^{\mu\nu}\delta(\mathbf{x}-\mathbf{y})$, по существу совпадающие с аналогичными соотношениями для четырех полей Клейна-Гордона. Но дополнительный знак «минус» в коммутаторе $\left[A^0, \dot{A}^0\right]$ приводит к другой (преодолимой) трудности: состояния, рожденные оператором $a_p^0\dagger$, имеют отрицательную норму*

Правила Фейнмана для вычисления амплитуд рассеяния, включающих фотоны, легче получаются в рамках формулировки теории поля на языке функционального интегрирования, излагаемом в главе 9. Как мы увидим в части III, этот метод имеет дополнительное преимущество обобщения на случай неабелевых калибровочных полей. В данной главе мы просто попытаемся угадать правила Фейнмана для фотонов. Сделать это будет совсем нетрудно после того, как мы получим правила Фейнмана для аналогичной, но более простой теории - теории Юкавы:

$$\mathscr{L}_{\text{Юкава}} = \mathscr{L}_{\text{Дирак}} + \mathscr{L}_{\text{Клейн - Гордон}} - g\bar{\psi}\psi\phi.$$

Это будет нашим третьим примером. Теория Юкавы подобна КЭД, но в ней фотон заменен скалярной частицей ϕ. Слагаемое с взаимодействием содержит безразмерную константу связи g, аналогичную электрическому заряду e. Вначале Юкава предложил эту теорию для описания взаимодействия нуклонов (ψ) и пионов (ϕ). В современной теории частиц стандартная модель содержит слагаемое с взаимодействием Юкавы, связывающий скалярное поле Хиггса с кварками и лептонами; большинство свободных параметров в стандартной модели - это юкавские константы связи.

Выписав три основополагающих взаимодействия, сделаем паузу и обсудим, какие другие взаимодействия можно найти в природе. Сначала может показаться, что список будет бесконечен; даже для скалярной теории можно было бы записать взаимодействия вида ϕ^n при любом n. Однако одна простая и убедительная аксиома устраняет почти все из возможных взаимодействий, кроме нескольких. Эта аксиома заключается в том, что теория должна быть перенормируемой, и возникает следующим образом. Как упоминалось в главе 1, слагаемые более высокого порядка в теории возмущений включают интегралы по 4-импульсам промежуточных («виртуальных») частиц. Эти интегралы часто формально расходятся, поэтому в общем случае необходимо применять некоторую процедуру обрезания. Простейший метод заключается в обрезании интегралов при некотором большом, но конечном импульсе Λ. В конце вычисления переходят к пределу $\Lambda \to \infty$, ожидая, что физические величины окажутся независящими от Λ. Если это действительно имеет место, то теория называется перенормируемой. Предположим, однако, что теория включает взаимодействия с константами связи, имеющими размерность массы в некоторой отрицательной степени. Тогда, для получения безразмерной амплитуды рассеяния, эта константа связи должна быть умножена на некоторую величину положительной массовой размерности. Эта обезразмеривающая величина оказывается ни чем иным, как параметром обрезания Λ. Такое слагаемое расходится при $\Lambda \to \infty$, так что теория оказывается неперенормируемой.

*Легко найти превосходное изложение обеих процедур квантования. Так, для квантования в кулоновской калибровке см. Bjorken, Drell (1965), глава 14; для квантования

в лоренцевой калибровке см. Mandl и Shaw (1984), глава 5. Мы обсудим эти вопросы подробно в главе 10. Пока что просто обратим внимание на то, что любая теория, содержащая константу связи с отрицательной массовой размерностью, неперенормируема. Размерный анализ позволяет легко отвергнуть почти всех кандидатов на взаимодействие. Так как действие $S = \int \mathscr{L} d^4x$ безразмерно, то лагранжиан $\mathscr{L}$ должен иметь размерность (масса) ^{4} (или просто размерность 4). Из вида кинетических слагаемых различных свободных лагранжианов следует, что скалярное и векторное поля ϕ и A^μ имеют размерность 1, в то время как спинорное поле ψ имеет размерность 3/2. Теперь можно свести в таблицу все допустимые перенормируемые взаимодействия. Для теорий, включающих только скаляры, допустимые слагаемые, описывающие взаимодействия, имеют вид

$$\mu\phi^3 \quad \text{и} \quad \lambda\phi^4.$$

Константа связи μ имеет размерность 1, в то время как λ безразмерна. Члены вида ϕ^n для $n > 4$ не подходят, так как их константы связи имели бы размерность $4 - n$. Конечно, более интересные теории могут быть получены включением нескольких вещественных или комплексных скалярных полей (см. задачу 4.3).

Теперь добавим спинорные поля. Спинорные самодействия не допускаются, так как ψ^3 (не говоря уже о нарушении лоренцевской инвариантности) имеет размерность 9/2. Таким образом, единственное новое допустимое взаимодействие имеет вид взаимодействия Юкавы

$$g\bar{\psi}\psi\phi$$

Правда, подобные взаимодействия могут быть построены также из вейлевских и майорановских спиноров.

Много новых взаимодействий можно получить, добавляя векторные поля. Наиболее знакомое из них - это векторно-спинорное взаимодействие в КЭД:

$$e\bar{\psi}\gamma^\mu\psi A_\mu$$

И вновь нетрудно построить аналогичные слагаемые с помощью вейлевских и майорановских спиноров. Менее важной теорией является скалярная КЭД с лагранжианом

$$\mathscr{L} = |D_\mu\phi|^2 - m^2|\phi|^2,$$

который содержит слагаемые

$$eA^\mu\phi\partial_\mu\phi^*, \quad e^2|\phi|^2A^2.$$

Это - наш первый пример взаимодействия с производными; квантование такой теории будет намного проще в формализме функционального интегрирования, поэтому мы откладываем ее рассмотрение до главы 9. Другие возможные лоренц-инвариантные слагаемые, включающие векторные поля, имеют вид

$$A^2\left(\partial_\mu A^\mu\right) \quad \text{и} \quad A^4.$$

Хотя это далеко не очевидно, выписанные слагаемые приводят к противоречиям, если только их константы связи не выбраны на основе специального типа симметрии, которая должна включать несколько векторных полей. Эта симметрия лежит в основе неабелевых

калибровочных теорий, которые будут основным предметом изучения в части III. Массовое слагаемое $\frac{1}{2}m^2A^2$ для векторных полей также приводит к противоречию за исключением отдельного случая, когда оно добавляется к КЭД; в любом случае оно нарушает (абелеву или неабелеву) калибровочную инвариантность. Сказанное выше исчерпывает список возможных лагранжианов, включающих скалярные, спинорные и векторные частицы. Интересно отметить, что принятые в настоящее время модели сильного, слабого и электромагнитного взаимодействий включают все перечисленные выше типы взаимодействий. Три типа взаимодействий, которые будут изучаться в этой главе, покрывают почти половину всех возможностей. Другие взаимодействия мы подробно рассмотрим далее в этой книге.

Предположение, что реалистичные теории должны быть перенормируемыми, конечно, удобно, так как неперенормируемая теория имела бы минимальную предсказательную силу. Однако возникает вопрос, почему природа так добра, что использует только перенормируемые взаимодействия. Можно было бы ожидать, что истинная теория природы является квантовой теорией гораздо более общего вида. Однако можно показать, что какой бы сложной не была фундаментальная теория при очень высоких энергиях, низкоэнергетическое приближение к этой теории, наблюдаемое в экспериментах, должно быть перенормируемой квантовой теорией поля. Мы покажем это в разделе 12.1.

На более практическом уровне предыдущий анализ высвечивает большую методологическую разницу в построении нерелятивистской квантовой механики и релятивистской квантовой теории поля. Так как потенциал $V(\mathbf{r})$, появляющийся в уравнении Шредингера, абсолютно произволен, нерелятивистская квантовая механика не накладывает ограничений на вид взаимодействий в реальном мире. Но мы только что видели, что квантовая теория поля налагает очень жесткие ограничения на природу (или наоборот). Образно говоря, из нашего обсуждения вытекает, что единственная оставшаяся задача в физике частиц состоит в перечислении существующих элементарных частиц, измерении их масс и констант связи. Может быть, эта точка зрения несколько радикальна, но тот факт, что она существует, по-видимому, означает, что физика частиц находится на верном пути к фундаментальной теории.

Имея данный набор частиц и взаимодействий, нужно еще получить экспериментальные следствия. Как мы должны анализировать квантовую механику взаимодействующей теории поля? Было бы хорошо, если бы мы могли явно решить по крайней мере несколько примеров (то есть точно найти собственные значения и собственные векторы, как мы это делали в свободных теориях), чтобы получить представление о свойствах взаимодействующих теорий. К сожалению, это проще сказать, чем сделать. Точно решаемые (интегрируемые) взаимодействующие теории поля в пространстве-времени с размерностью, больше двух, не известны. Даже интегрируемые модели, содержащие специальные симметрии, чрезвычайно сложны*. Рассмотрение этих теорий было бы интересно, но едва ли стоит усилий на этом уровне изучения. Вместо этого мы вернемся к более простому и применимому в большинстве случаев подходу. Будем рассматривать гамильтониан взаимодействия H_{int} как возмущение и вычислим производимые им эффекты с помощью теории возмущений, предполагая, что константа связи достаточно мала для того, чтобы получалось разумное приближение к точному ответу. На самом деле ряд теории возмущений, который мы получим, окажется очень простым по своей структуре. Эффекты взаимодействий в произвольно высоком порядке удастся, по крайней мере, сделать наглядными с помощью диаграмм Фейнмана.

Такое упрощение ряда теории возмущений для релятивистских теорий поля было

огромным достижением Томонаги, Швингера и Фейнмана. Чтобы достичь этого упрощения, каждый независимо нашел способ, как переформулировать квантовую механику, устранив выделенную роль времени, и затем применил новую точку зрения, чтобы представить каждый член ряда теории возмущений как пространственно-временной процесс. В главе 9 мы разовьем квантовую теорию поля с пространственно-времен-

*Краткий обзор интегрируемых квантовых теорий поля дан в Эпилоге. ной точки зрения, используя метод функционального интегрирования Фейнмана. В данной главе мы следуем путем, более пригодным для новичка и впервые разработанным Дайсоном, чтобы получить пространственно-временную картину теории возмущений с помощью обычной техники квантовой механики †.

11.2 Description of Decays

11.2.1 Basics of Decays

параметры распада

Посмотрим, какие вообще есть параметры и что они означают?
Есть ширина распада.

алгоритм расчета параметров

я пока хз, как их считать....

Ширина распада по Киселеву

постановка задачи

Рассмотрим для примера взаимодействие массивного поля φ_M с комплексным безмассовым полем Φ,

$$V_{\text{int}} = -\mathcal{L}_{\text{int}} = \Lambda \varphi_M \Phi^\dagger \Phi$$

То есть распад нейтральной массивной частицы на 2 безмассовых заряженных частицы.

Считаем, что исчезновению нейтральной частице в прошлом (поле φ_M) сопоставить положительно частотную моду $e^{-\mathrm{i}px}$, и появлению заряженной частицы в будущем (поле $\Phi^\dagger$) сопоставить отрицательно частотную моду $e^{\mathrm{i}k_1 x}$, и появлению античастицы в будущем (поле Φ) - отрицательно частотную моду $e^{\mathrm{i}k_2 x}$

амплитуда распада

В этой модели считаем амплитуду распада
(?????)

$$\mathrm{i}\mathcal{M}^c_{(3)} = -\mathrm{i}\Lambda(2\pi)^4 \delta\left(p - k_1 - k_2\right)$$

где p - 4-импульс распадающейся частицы, а $k_{1,2}$ - 4-импульсы частицы и античастицы, соответственно, как это графически показано ниже

Возведение модуля амплитуды в квадрат дает

$$\left|\mathcal{M}^c_{(3)}\right|^2 = \Lambda^2(2\pi)^4\delta\left(p-k_1-k_2\right)\left\{(2\pi)^4\delta\left(k'\right)\right\}\Big|_{k'\to 0}$$

(????)

Стандартным приемом найдем «сингулярное значение»

$$\left\{(2\pi)^4\delta\left(k'\right)\right\}\Big|_{k'\to 0} = \int \mathrm{d}^4x e^{\mathrm{i}k'x}\Big|_{k'\to 0} = \delta t V_{[3]}$$

где интервал времени наблюдения за системой δt и объем 3 -мерной области пространства $V_{[3]}$ мы считаем стремящимися к бесконечности.

Подчеркнем, что релятивистски инвариантное выражение для потенциала приводит к релятивистски инвариантной амплитуде с учетом,

что мы следуем релятивистски инвариантной нормировке квантовых состояний и мод поля.

Напомним, что состояния нормированы на величину $2EV_{[3].}$

вероятность распада

Поэтому для расчета вероятности квантового распада в единицу времени необходимо модуль квадрата инвариантной амплитуду поделить на нормировку начального состояния и умножить на плотность состояний частиц в конечном состоянии в непрерывном спектре,

$$\mathrm{d}\Gamma = \frac{\left|\mathcal{M}^c_{(3)}\right|^2}{\delta t}\frac{1}{2EV_{[3]}}\frac{\mathrm{d}^3k_1}{(2\pi)^3 2E_1}\frac{\mathrm{d}^3k_2}{(2\pi)^3 2E_2}$$

где временные компоненты 4-импульсов $E = p^0, E_1 = k_1^0, E_2 = k_2^0$. Интегрирование дифференциальной вероятности распада в единицу времени дает ширину распада, которую мы вычислим в системе покоя исходной частицы, $E = M$

$$\Gamma = \int \frac{\Lambda^2}{2M}(2\pi)^4\delta\left(p-k_1-k_2\right)\frac{\mathrm{d}^3k_1}{(2\pi)^3 2E_1}\frac{\mathrm{d}^3k_2}{(2\pi)^3 2E_2}$$

Преобразуем с помощью уравнения массовой поверхности для частицы в конечном состоянии,

$$\int (2\pi)^4\delta\left(p-k_1-k_2\right)\frac{\mathrm{d}^3k_1}{(2\pi)^3 2E_1} = \int (2\pi)^4\delta\left(p-k_1-k_2\right)2\pi\delta\left(k_1^2\right)\frac{\mathrm{d}^4k_1}{(2\pi)^4}\Big|_{E_1>0}$$

так что интеграл по 4-импульсу снимается законом сохранения 4-импульса, и

$$\Gamma = \frac{\Lambda^2}{2M}\int \delta\left(\left[p-k_2\right]^2\right)\frac{\mathrm{d}^3k_2}{(2\pi)^2 2E_2}$$

В системе покоя распадающейся частицы $\left(p-k_2\right)^2 = M^2 - 2ME_2$,

так что

$$\delta\left(\left[p-k_2\right]^2\right) = \frac{1}{2M}\delta\left(E_2 - \frac{M}{2}\right)$$

и с учетом $|k_2|\,\mathrm{d}\,|k_2| = E_2 dE_2$ и независимости квадрата амплитуды от углов

$$\frac{\mathrm{d}^3 k_2}{(2\pi)^2 2E_2} = \frac{4\pi}{4\pi^2}\frac{|k_2|^2\, d\,|k_2|}{2E_2} = \frac{|k_2|\,\mathrm{d}E_2}{2\pi}$$

В итоге, релятивистски инвариантный фазовый объем

$$\int \delta\left([p-k_2]^2\right)\frac{\mathrm{d}^3 k_2}{(2\pi)^2 2E_2} = \frac{1}{4\pi}\frac{|k_2|}{M} = \frac{1}{8\pi}$$

Ширина найдена

$$\Gamma = \frac{\Lambda^2}{16\pi M}, \quad [\Gamma] = [m]$$

(!!!!????????)

В теории возмущений необходимо, чтобы

$$\Gamma \ll M \quad \to \quad \Lambda \ll M$$

(???)

Важно подчеркнуть, что «вспомогательные» величины: время и объем области, в которых велись наблюдения, конечно, не вошли в ответ, так что их можно было не записывать в явном виде.

Они потребовались только для того,

чтобы согласовать рассуждения с нормировками.

Поэтому можно использовать правила,

согласно которым матричный элемент процесса $\mathcal{M}$ выражается через редуцированный матричный элемент $\mathfrak{M}$ на поверхности закона сохранения 4-имспульса

$$\mathcal{M} = (2\pi)^4\delta\left(k_{(0)} - \sum_{n=1}^{n_f} k_{(n)}\right)\mathfrak{M}$$

так что дифференциальная ширина распада частицы с массой M и импульсом $k_{(0)}$

$$\mathrm{d}\Gamma = \frac{|\mathfrak{M}|^2}{2M} d\mathfrak{p}_f$$

где релятивистски инвариантный фазовый объем частиц в конечном состоянии

$$\mathrm{d}\mathfrak{p}_f = (2\pi)^4\delta\left(k_{(0)} - \sum_{n=1}^{n_f} k_{(n)}\right)\prod_{n=1}^{n_f}\frac{\mathrm{d}^3 k_{(n)}}{2E_{(n)}}$$

(место итогов и выводов?)

11.2.2 Other Aspects of Decays (??????)

(много вопросов будет, все это тут будет)

11.3 Description of Scatterings

соберем всю теорию, которую будем использовать для рассеяний.

11.3.1 Scattering Cross-Section

простейшая модель рассеяния

Для описания расчета сечения рассеяния в квантовой теории поля определим похожую модель,

что и при распаде, но с двумя типами безмассового заряженного скалярного поля

$$\mathcal{L}_{\text{int}} = -\Lambda_1 \varphi_M \Phi_1^\dagger \Phi_1 - \Lambda_2 \varphi_M \Phi_2^\dagger \Phi_2$$

Рассмотрим аннигиляцию частицы с зарядом e_1 и 4-импульсом k_1 и ее античастицы с 4-импульсом k_1' в частицу с зарядом e_2 и 4-импульсом k_2 и ее античастицу с 4-импульсом k_2' в ведущем приближении по $\Lambda_{1,2.}$

Ясно, что в этом случае экспонента от S_{int} сведется к

$$e^{\mathrm{i}S_{\text{int}}} \approx -\mathrm{i}\int \mathrm{d}^4x \Lambda_1 \varphi_M \Phi_1^\dagger \Phi_1 \times (-\mathrm{i})\int \mathrm{d}^4y \Lambda_2 \varphi_M \Phi_2^\dagger \Phi_2$$

где заряженные поля в теории возмущений перейдут в заданные внешние поля, а массивное нейтральное поле необходимо спарить, т. е. заменить пропагатором.

Более детально.

При вычислении трехточечных функций Грина сначала введем действие с внешними источниками для всех квантовых полей в исходном действии,

$$\begin{aligned} S_{\text{ext}}\left(\varphi_M, \Phi_1, \Phi_1^\dagger, \Phi_2, \Phi_2^\dagger\right) = \int \mathrm{d}^4x \Big(& j^M(x)\varphi_M(x) \\ & + J_1^\dagger(x)\Phi_1(x) + \Phi_1(x)J_1^\dagger(x) + \\ & + J_2^\dagger(x)\Phi_2(x) + \Phi_1(x)J_2^\dagger(x)\Big) \end{aligned}$$

Теперь в первом порядке по $\Lambda_{1,2}$ для амплитуды квантовых переходов запишем

$$\begin{aligned} Z \approx & \exp\left\{-\frac{1}{2}\hat{j}_{x'}^M \mathcal{D}_{x'y'}^M \hat{j}_{y'}^M - \hat{J}_1^\dagger(x_1')\,\mathcal{D}_{x_1'y_1'}^{[1]}\hat{J}_1(y_1') - \hat{J}_2^\dagger(x_2')\,\mathcal{D}_{x_2'y_2'}^{[1]}\hat{J}_2(y_2')\right\} \times \\ & \times \left(-\mathrm{i}\Lambda_1 \int \mathrm{d}^4x \tilde{\varphi}_M \tilde{\Phi}_1^\dagger \tilde{\Phi}_1 - \mathrm{i}\Lambda_2 \int \mathrm{d}^4y \tilde{\varphi}_M \tilde{\Phi}_2^\dagger \tilde{\Phi}_2\right) \times \\ & \times \exp\left\{\mathrm{i}S_{\text{ext}}\left(\tilde{\varphi}_M, \tilde{\Phi}_1, \tilde{\Phi}_1^\dagger, \tilde{\Phi}_2, \tilde{\Phi}_2^\dagger\right)\right\}\Big|_{\tilde{\varphi}_M = \ldots = 0} \end{aligned}$$

где внешние токи со шляпками - это операторы вариационного дифференцирования по полям с тильдой

$$\hat{j}_x^M = \frac{\delta}{\delta\tilde{\varphi}_M(x)}, \quad \hat{J}_{1,2}(x) = \frac{\delta}{\delta\tilde{\Phi}_{1,2}^\dagger(x)} \quad \hat{J}_{1,2}^\dagger(x) = \frac{\delta}{\delta\tilde{\Phi}_{1,2}(x)}$$

при эти вариационные производные действуют только на последний фактор $\exp\{\mathrm{i}S_{\text{ext}}\}$, который только и зависит от полей с тильдой.

А спаривания определяются в следующем виде: для заряженных безмассовых полей -

$$\mathcal{D}_{1x}^{[1]} = \mathcal{D}_{1x}^{[2]} = \int \frac{\mathrm{d}^4k}{(2\pi)^4}\frac{\mathrm{i}}{k^2 + \mathrm{i}0}e^{-\mathrm{i}k(x_1 - x)}$$

для массивного вещественного поля -

$$\mathcal{D}^{M}_{xy} = \int \frac{\mathrm{d}^4 k}{(2\pi)^4} \frac{\mathrm{i}}{k^2 - M^2 + \mathrm{i}0} e^{-\mathrm{i}k(x-y)}$$

Легко сообразить, что в такой записи тильду у полей вполне можно опустить (?????), при этом опять-таки подчеркивая, что внешние токи содержатся только в действии S_{ext}

Тогда трехточечная функция Грина для взаимодействия вещественного поля с заряженным полем типа 1 (??????) в первом порядке теории возмущений сведется с одной стороны к Т-произведению полей,

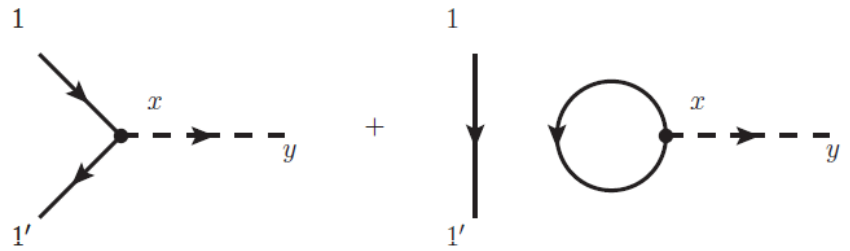
$$\mathcal{D}^{[1]}_{11'y} = (-\mathrm{i})^3 \frac{\delta^3 Z}{\delta j^M(y) \delta J_1(x_1) \delta J_1^{\dagger}(x_1')} = \langle 0| \ \mathrm{T} \left\{ \hat{\varphi}_M(y) \hat{\Phi}_1^{\dagger}(x_1) \hat{\Phi}_1(x_1') \right\} |0\rangle$$

а с другой стороны, к спариваниям в выражении (???)

$$\mathcal{D}^{[1]}_{11'y} = \sum_{\text{спар.}} -\mathrm{i}\Lambda_1 \int \mathrm{d}^4 x \varphi_M(x) \Phi_1^{\dagger}(x) \Phi_1(x) \varphi_M(y) \Phi_1^{\dagger}(x_1) \Phi_1(x_1')$$

Для вещественного поля есть только один вариант спаривания, что дает фактор $\mathcal{D}^{M}_{xy}$, а для заряженного поля - 2 варианта: $\mathcal{D}^{[1]}_{xx}\mathcal{D}^{[1]}_{11'}$ и $\mathcal{D}^{[1]}_{x1}\mathcal{D}^{[1]}_{1'x}$.

Первый вариант отвечает петле заряженного поля с вершиной в точке x и свободному распространению заряженного поля от внешний точки 1 к внешней точке $1'$, а второй вариант - вершине, в которой сходятся все линии, как это показано на рис.



Связный и не связный вклад с 3-точечную функцию $\mathcal{D}^{[1]}_{11'y}$.

(???? что происходит?????)

мы получим следующие выражения для связной 3 -точечной функции в координатном представлении для взаимодействия вещественного поля с безмассовыми заряженными частицами первого сорта

$$\mathcal{D}^{[1c]}_{11'y} = -\mathrm{i}\Lambda_1 \mathcal{D}^{[1]}_{1x} \mathcal{D}^{[1]}_{xx'} \mathcal{D}^{M}_{xy}$$

Ясно, что ровно такие же рассуждения приведут к связной функции Грина для взаимодействия вещественного поля с заряженным полем второго сорта $\mathcal{D}^{[2c]}_{11'y}$.

(???? что за сорт частиц кстати?)

Если теперь поставить вопрос о связной 4-точечной функции для перехода частицы и античастицы сорта 1 в частицу и античастицу сорта 2

$$\mathcal{D}_{11'22'} = (-\mathrm{i})^4 \frac{\delta^4 Z}{\delta J_1(x_1) \delta J_1^{\dagger}(x_1') \delta J_2(x_2) \delta J_2^{\dagger}(x_2')} = \\ = \langle 0| \ \mathrm{T} \left\{ \hat{\Phi}_1^{\dagger}(x_1) \hat{\Phi}_1(x_1') \hat{\Phi}_2^{\dagger}(x_2) \hat{\Phi}_2(x_2') \right\} |0\rangle$$

то в ведущем порядке теории возмущений по константам связи отличный от нуля вклад возникает для произведения $\Lambda_1\Lambda_2$, а значит, мы рассмотрим спаривания в выражении

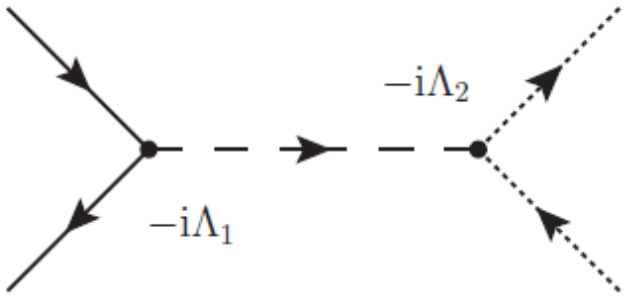
$$\mathcal{D}_{11'22'} = \sum_{\text{спар.}} (-\mathrm{i}\Lambda_1) \int \mathrm{d}^4x \varphi_M(x) \Phi_1^\dagger(x) \Phi_1(x) \Phi_1^\dagger(x_1)\, \Phi_1(x_1') \times$$
$$\times (-\mathrm{i}\Lambda_2) \int \mathrm{d}^4y \varphi_M(y) \Phi_2^\dagger(y) \Phi_2(y) \Phi_2^\dagger(x_2)\, \Phi_2(x_2')$$

где спаривание вещественного поля даст фактор $\mathcal{D}^M_{xy}$, а связный вклад для заряженных полей приведет к выражению

$$\mathcal{D}^c_{11'22'} = (-\mathrm{i}\Lambda_1)(-\mathrm{i}\Lambda_2)\, \mathcal{D}^{[1]}_{1x} \mathcal{D}^{[1]}_{x1'} \mathcal{D}^M_{xy} \mathcal{D}^{[2]}_{y2} \mathcal{D}^{[1]}_{2'y}$$

где, конечно ведется интегрирование по повторяющимся координатным индексам. В теории возмущений получается диаграмма рассеяния на рис.

(?????)



Эта 4-точечная функция задает связный вклад в вариационный ряд для амплитуды квантовых переходов в заданном порядке теории возмущений в виде

$$Z = \mathrm{i}^4 \int \mathrm{d}^4x_1 d^4x_1' \mathrm{d}^4x_2 d^4x_2' \mathcal{D}^c_{11'22'} J_1(x_1)\, J_1^\dagger(x_1')\, J_2(x_2)\, J_2^\dagger(x_2') + \ldots$$

Для расчета амплитуды квантовых переходов в асимптотически свободной области необходимо перейти от Z к $\mathcal{S}$ -матрице $S = \mathbb{1} + \mathrm{i}T$ и от внешних токов к внешним полям, когда

$$\mathrm{i} \int \mathrm{d}^4x_1 J_1(x_1)\, \mathcal{D}^{[1]}_{1x} = \Phi_1^{\mathrm{cl}}(x), \quad \mathrm{i} \int \mathrm{d}^4x_2 J_2(x_2)\, \mathcal{D}^{[2]}_{2y} = \Phi_2^{\mathrm{cl}}(y)$$

а также

$$\mathrm{i} \int \mathrm{d}^4x_1' J_1^\dagger(x_1')\, \mathcal{D}^{[1]}_{x1'} = \left(\Phi_1^{\mathrm{cl}}(x)\right)^\dagger, \quad \mathrm{i} \int \mathrm{d}^4x_2' J_2^\dagger(x_2')\, \mathcal{D}^{[2]}_{y2'} = \left(\Phi_2^{\mathrm{cl}}(y)\right)^\dagger$$

Но это означает, что в выражении для амплитуды в асимптотически свободной области $\mathcal{D}^c_{11'22'}$ все двухточечные функции при интегрировании с внешними токами заменяются на классические внешние поля, и остается только пропагатор виртуального вещественного поля

$$\mathrm{i}\mathcal{M} = (-\mathrm{i}\Lambda_1)(-\mathrm{i}\Lambda_2) \int \mathrm{d}^4x d^4y \mathcal{D}^M_{xy} \Phi_1^{\mathrm{cl}}(x) \left(\Phi_1^{\mathrm{cl}}(x)\right)^\dagger \Phi_2^{\mathrm{cl}}(y) \left(\Phi_2^{\mathrm{cl}}(y)\right)^\dagger$$

В задаче аннигиляции частицы сорта 1 со своей античастицей начальным состояниям внешних полей отвечают положительно частотные моды полей $\Phi_1^{\rm cl}(x)$ и $\left(\Phi_1^{\rm cl}(x)\right)^\dagger$, соответственно, поскольку в точке x эти частица античастица исчезают, так что

$$\Phi_1^{\rm cl}(x) \mapsto e^{-{\rm i}k_1 x}, \quad \left(\Phi_1^{\rm cl}(x)\right)^\dagger \mapsto e^{-{\rm i}k_1' x}$$

где мы присвоили внешним полям в начальном состоянии вполне определенные 4-импульсы k_1 для частицы и k_1' для античастицы.

Аналогично, внешним полям в конечном состоянии соответствуют отрицательно частотные моды полей второго сорта $\Phi_2^{\rm cl}(y)$ и $\left(\Phi_2^{\rm cl}(y)\right)^\dagger$, соответственно поскольку в точке эти частица и античастица рождаются, так что

$$\Phi_2^{\rm cl}(y) \mapsto e^{{\rm i}k_2' y}, \quad \left(\Phi_2^{\rm cl}(2)\right)^\dagger \mapsto e^{{\rm i}k_2 y}$$

где мы присвоили внешним полям в конечном состоянии вполне определенные 4-импульсы k_2 для частицы и k_2' для античастицы.

Наконец, подстановка пропагатора виртуальной частицы в виде интеграла по импульсу дает

$${\rm i}\mathcal{M} = (-{\rm i}\Lambda_1)\,(-{\rm i}\Lambda_2) \int {\rm d}^4x d^4y \frac{{\rm d}^4p}{(2\pi)^4} \mathcal{D}^M(p) e^{{\rm i}x\left(k_1+k_1'-p\right)+{\rm i}y\left(p-k_1-k_2'\right)}$$

Как видим, в каждой вершине имеет место закон сохранения 4-импульса.

При этом отметим, что в качестве внешнего поля в начальном и конечном состоянии можно рассматривать и волновые пакеты,

в прямом соответствии с тем, как ставится экспериментальная задача.

В итоге, матричный элемент процесса в импульсном представлении примет вид

$${\rm i}\mathcal{M} = (2\pi)^4 \delta\left(k_1 + k_1' - k_2 - k_2'\right) (-{\rm i}\Lambda_1)\,(-{\rm i}\Lambda_2)\, \mathcal{D}^M\left(k_1 + k_1'\right)$$

(?????)

где мы учли, что 4-импульс массивной частицы по закону сохранения равен сумме 4-импульсов частиц в начальном состоянии, так что

$$\mathcal{D}^M\left(k_1 + k_1'\right) = \frac{\rm i}{\left(k_1 + k_1'\right)^2 - M^2 + {\rm i}0} = \frac{\rm i}{s - M^2 + {\rm i}0}$$

где мы ввели стандартную характеристику для столкновения двух частиц квадрат инвариантной массы системы s. В реальности, как мы уже знаем,

массивная частица может иметь ненулевую ширину распада Γ за счет того же взаимодействия, как минимум.

Это значит, что вместо массы следует использовать величину $M \to M - {\rm i}\Gamma/2$, так что в силу $\Gamma \ll M$ пропагатор принимает вид

$$\mathcal{D}^M\left(k_1 + k_1'\right) = \frac{\rm i}{s - M^2 + {\rm i}\Gamma M}$$

Дифференциальная вероятность процесса в единицу времени вычисляется возведением в квадрат модуля амплитуды и делением его на время наблюдения за системой,

а также делением на нормировку состояния мишени,

которой мы можем считать, например, античастицу,

с последующим домножением на плотность состояний в конечном состоянии,
то есть:

$$\mathrm{d}w = \frac{|\mathcal{M}|^2}{\delta t}\frac{1}{2E_1' V_{[3]}}\frac{\mathrm{d}^3 k_2}{(2\pi)^3 2E_2}\frac{\mathrm{d}^3 k_2'}{(2\pi)^3 2E_2'}$$

откуда

$$\mathrm{d}w = \frac{\Lambda_1^2\Lambda_2^2}{\left(s-M^2\right)^2+M^2\Gamma^2}\frac{1}{2E_1'}(2\pi)^4\delta\left(k_1+k_1'-k_2-k_2'\right)\frac{\mathrm{d}^3 k_2}{(2\pi)^3 2E_2}\frac{\mathrm{d}^3 k_2'}{(2\pi)^3 2E_2'}$$

Число событий определяется потоком частиц, которые падают на античастицу.

Этот поток мы вычисляли для неподвижной мишени.

(и что там было?)

Его обобщение очевидно, так как наблюдаемый объем увеличивается для наблюдателя за счет того,

что сама мишень движется навстречу пучку, и в нашем случае

$$j = 2E_1\left(v_1+v_1'\right)$$

Поэтому дифференциальное сечение

$$\mathrm{d}\sigma = \frac{\mathrm{d}w}{j}$$

и в него войдет величина

$$2E_1' 2E_1\left(v_1+v_1'\right)$$

которая является релятивистским инвариантом.

В самом деле, покажем это в самом общем случае,

и для краткости дальнейших выкладок по этому вопросу будем рассматривать столкновение частиц с массой m и $\tilde{m}$:

$$2E2\tilde{E}(v+\tilde{v})$$

Элементарные преобразования квадрата суммы скоростей дает

$$(v+\tilde{v})^2 = v^2+2v\tilde{v}+\tilde{v}^2 = 1+2v\tilde{v}+v^2\tilde{v}^2-\left(1-v^2\right)\left(1-\tilde{v}^2\right)$$

а, стало быть, умножение на квадраты энергий приводит к формуле

$$E^2\tilde{E}^2(v+\tilde{v})^2 = (E\tilde{E}+E\tilde{E}v\tilde{v})^2-E^2\left(1-v^2\right)\tilde{E}^2\left(1-\tilde{v}^2\right) = (p\cdot\tilde{p})^2-m^2\tilde{m}^2$$

где $p\cdot\tilde{p}$ - произведение 4-импульсов частиц, которые движутся навстречу друг другу.

В итоге,

$$2E2\tilde{E}(v+\tilde{v}) = 4\sqrt{(p\cdot\tilde{p})^2-m^2\tilde{m}^2}$$

В нашей задаче массы сталкивающихся частиц равны нулю, так что

$$2E_1' 2E_1\left(v_1+v_1'\right) = 8E_1'E_1 = 4\sqrt{\left(\left(k_1+k_1'\right)^2/2\right)^2} = 2s$$

Таким образом,

$$\mathrm{d}\sigma = \frac{\Lambda_1^2\Lambda_2^2}{\left(s-M^2\right)^2+M^2\Gamma^2}\frac{1}{2s}(2\pi)^4\delta\left(k_1+k_1'-k_2-k_2'\right)\frac{\mathrm{d}^3 k_2}{(2\pi)^3 2E_2}\frac{\mathrm{d}^3 k_2'}{(2\pi)^3 2E_2'}$$

Вычисление инвариантного фазового объема для безмассовых частиц при фиксированной инвариантной массе мы уже проводили (??????)

$$\int (2\pi)^4 \delta\left(k_1 + k_1' - k_2 - k_2'\right) \frac{\mathrm{d}^3 k_2}{(2\pi)^3 2E_2} \frac{\mathrm{d}^3 k_2'}{(2\pi)^3 2E_2'} = \frac{1}{8\pi}$$

Полное сечение аннигилляции

$$\sigma = \frac{1}{16\pi s} \frac{\Lambda_1^2 \Lambda_2^2}{\left(s - M^2\right)^2 + M^2\Gamma^2}, \quad [\sigma] = \frac{1}{[m]^2}$$

и оно в данном случае имеет резонансный пик Брейта-Вигнера при инвариантной массе, равной массе промежуточной частицы.

Отметим также, что матричный элемент процесса при скалярном обмене не зависит от углов, т. е. это рассеяние изотропно.

Резюмируя,

стоит записать общее выражение для дифференциального сечения в терминах редуцированного матричного элемента $\mathfrak{M}$ так же, как мы это сделали для дифференциальной ширины распада,

$$\mathrm{d}\sigma = \frac{|\mathfrak{M}|^2}{4\sqrt{(p\cdot\tilde{p})^2 - m^2\tilde{m}^2}} d\mathfrak{p}_f$$

где фазовый объем в конечном состоянии по аналогии с (5.2)

$$\mathrm{d}\mathfrak{p}_f = (2\pi)^4 \delta\left(p + \tilde{p} - \sum_{n=1}^{n_f} k_{(n)}\right) \prod_{n=1}^{n_f} \frac{\mathrm{d}^3 k_{(n)}}{2E_{(n)}}$$

а $p, \tilde{p}$ - 4-импульсы сталкивающихся частиц.

Приведенные нами примеры показывает, что связный вклад определяет матричный элемент процесса распада или рассеяния, и в теории возмущений он находится элементарно с помощью диаграмм.

Поэтому стоит систематизировать общие утверждения о получении всех связных диаграмм и вне теории возмущений.

Ширина распада

И наконец, повторим, как связана амплитуда с дифференциальной шириной распада частицы массой M с 4 -импульсм p

$$\mathrm{d}\Gamma = \frac{|\mathfrak{M}|^2}{2M} d\mathfrak{p}_f$$

где релятивистски инвариантный фазовый объем частиц в конечном состоя- нии

$$\mathrm{d}\mathfrak{p}_f = (2\pi)^4 \delta\left(p - \sum_{n=1}^{n_f} k_{(n)}\right) \prod_{n=1}^{n_f} \frac{\mathrm{d}^3 k_{(n)}}{2E_{(n)}}$$

и дифференциальным сечением рассеяния частиц с 4-импульсами p и $\tilde{p}$

$$\mathrm{d}\sigma = \frac{|\mathfrak{M}|^2}{4\sqrt{(p\cdot\tilde{p})^2 - m^2\tilde{m}^2}} d\mathfrak{p}_f$$

где фазовый объем в конечном состоянии

$$\mathrm{d}\mathfrak{p}_f = (2\pi)^4 \delta\left(p + \tilde{p} - \sum_{n=1}^{n_f} k_{(n)}\right) \prod_{n=1}^{n_f} \frac{\mathrm{d}^3 k_{(n)}}{2E_{(n)}}$$

Отметим, что эти правила относятся к случаю, когда одноточечная функция Грина поля равна нулю. Однако, легко сообразить, что ненулевое

вакуумное значение поля $v = \langle 0|\hat{\varphi}(x)|0\rangle$ отвечает просто случаю внешнего поля с нулевым импульсом. Такую внешнюю линию обычно изображают с символом $\otimes$ на конце. При этом вершины взаимодействия внешнего вакуумного поля легко определить, если в исходном лагранжиане произвести замену поля, скажем, $\varphi \mapsto v + \varphi$, так что новое поле уже не имеет вакуумного среднего.

11.3.2 Particle Reactions (!?!??)

я вообще хз, как описывать их с помощью КТП, но буду изучать.

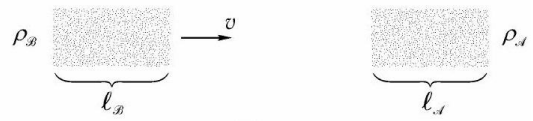
11.3.3 Scattering Cross-Sections and the S-Matrix by Peskin & Schroeder

Теперь в нашем распоряжении чрезвычайно красивая формула (4.57) для вычисления совершенно абстрактной величины - n-точечной корреляционной функции. Следующая задача - найти в равной степени красивые пути вычисления величин, которые могут быть фактически измерены, - сечений рассеяния и вероятностей распада. В этом разделе после краткого обзора определений этих величин мы свяжем их (без излишней строгости, но вполне аккуратным образом) с более примитивной величиной S-матрицей. В следующем разделе мы узнаем, как вычислять элементы S-матрицы, используя диаграммы Фейнмана.

Сечение рассеяния по Пескину Шредеру

Эксперименты, которые исследуют поведение элементарных частиц, особенно в релятивистском режиме, являются экспериментами по рассеянию. Сталкивают два пучка частиц с известными импульсами и наблюдают за тем, что происходит. Вероятность обнаружения любого отдельного конечного состояния может быть выражена через *се* - чение рассеяния - величину, которая характеризует внутренние свойства сталкивающихся частиц и, следовательно, позволяет провести сравнение двух различных экспериментов с пучками разных размеров и интенсивностей.

Сечение рассеяния определяется следующим образом. Рассмотрим покоящуюся мишень, состоящую из частиц типа $\mathscr{A}$ с плотностью $\rho_{\mathscr{A}}$ (число частиц на единицу объема). Направим на эту мишень пучок частиц типа $\mathscr{B}$ с плотностью числа частиц $\rho_{\mathscr{B}}$ и скоростью v:



Пусть $\ell_{\mathscr{A}}$ и $\ell_{\mathscr{B}}$ - длины пучков частиц. Тогда мы ожидаем, что полное число событий рассеяния (или событий рассеяния любого заданного типа) должно быть пропорционально

$\rho_{\mathscr{A}}, \rho_{\mathscr{B}}, \ell_{\mathscr{A}}, \ell_{\mathscr{B}}$ и площади пересечения пучков рассеяния A, общей для двух пучков. Сечение рассеяния, обозначаемое σ, равно общему числу событий (любого заданного типа), деленному на произведение всех этих величин:

$$\sigma \equiv \frac{\text{Число событий рассеяния}}{\rho_{\mathscr{A}}\ell_{\mathscr{A}}\rho_{\mathscr{B}}\ell_{\mathscr{B}}A}.$$

Данное определение симметрично относительно $\mathscr{A}$ и $\mathscr{B}$, поэтому можно было бы считать покоящимися частицы типа $\mathscr{B}$ или проводить рассмотрение в любой другой системе отсчета. Сечение рассеяния имеет размерность площади. Действительно, это есть эффективная площадь куска, выбиваемого из одного пучка каждой частицей другого пучка и впоследствии переходящего в интересующее нас конечное состояние.

В реальных пучках $\rho_{\mathscr{A}}$ и $\rho_{\mathscr{B}}$ не постоянны - плотность частиц в центре пучка обычно больше, чем на краях. Однако мы будем полагать, что как радиус взаимодействия частиц, так и ширина отдельных волновых пакетов частиц малы по сравнению с диаметром пучка. Поэтому в дальнейшем можно считать $\rho_{\mathscr{A}}$ и $\rho_{\mathscr{B}}$ постоянными, не забывая при этом, что для вычисления вероятности событий в реальном ускорителе нужно проинтегрировать по сечению пучка:

$$\text{Число событий } = \sigma\ell_{\mathscr{A}}\ell_{\mathscr{B}}\int d^2x\rho_{\mathscr{A}}(x)\rho_{\mathscr{B}}(x).$$

Если плотности постоянны или если мы используем эту формулу для вычисления эффективной площади A сечения пучков, то

$$\text{Число событий } = \frac{\sigma N_{\mathscr{A}}N_{\mathscr{B}}}{A},$$

где $N_{\mathscr{A}}$ и $N_{\mathscr{B}}$ - полное число частиц типа $\mathscr{A}$ и $\mathscr{B}$.

Сечения многих различных процессов могут быть получены в одном эксперименте рассеяния. Например, в столкновениях e^+e^-можно измерять сечения рождения $\mu^+\mu^-$, $\tau^+\tau^-, \mu^+\mu^-\gamma, \mu^+\mu^-\gamma\gamma$ и т. д. и бесчисленных процессов, включающих рождение адронов, не говоря уже о простом e^+e^-рассеянии. Обычно мы хотим определить не только тип частиц в конечном состоянии, но также и их импульсы. Определение (4.59) сечения σ все еще применимо и в этом случае, но если мы выделяем точные значения импульсов, то σ будет бесконечно малым. Решение состоит в том, чтобы определить дифференциальное сечение рассеяния $d\sigma/\left(d^3p_1...d^3p_n\right)$. Это величина, которая в результате интегрирования по любому малому объему $d^3p_1...d^3p_n$ определяет сечение рассеяния в этот объем импульсов конечного состояния. Импульсы в конечном состоянии не являются независимыми. Четыре компоненты будут всегда связаны условием сохранения 4-импульса. В самом простом случае, когда имеется только две частицы в конечном состоянии, это условие оставляет только две независимых компоненты импульса, в качестве которых обычно выбираются углы θ и ϕ импульса одной из частиц. Интегрирование $d\sigma/\left(d^3p_1d^3p_2\right)$ по четырем ограниченным законом сохранения компонентам импульса приводит к обычному дифференциальному сечению рассеяния $d\sigma/d\Omega$.

Более простая измеримая величина - это вероятность распада нестабильной частицы $\mathscr{A}$ (которая считается покоящейся) в определенное конечное состояние (из двух или более частиц). Эта вероятность определяется как

$$\Gamma \equiv \frac{\text{Число распадов в единицу времени}}{\text{Число имеющихся частиц типа } \mathscr{A}}.$$

Тогда время жизни τ частицы является обратным сумме ее вероятностей распадов во все возможные конечные состояния. (Время полураспада частицы $-\tau \cdot \ln 2$.)

В нерелятивистской квантовой механике нестабильное атомное состояние проявляет себя в экспериментах по рассеянию как резонанс. Вблизи резонансной энергии E_0 амплитуда рассеяния определяется формулой Брейта-Вигнера:

$$f(E) \propto \frac{1}{E - E_0 + i\Gamma/2}$$

Следовательно, сечение рассеяния имеет пик вида

$$\sigma \propto \frac{1}{(E - E_0)^2 + \Gamma^2/4}$$

Ширина пика резонанса равна вероятности распада нестабильного состояния.

Формула Брейта-Вигнера (4.63) имеет место также и в релятивистской квантовой механике. В частности, она определяет амплитуду рассеяния для процессов, в которых начальные частицы образуют составную частицу, которая затем распадается. Нестабильная частица, рассматриваемая как возбужденное состояние вакуума, является прямым аналогом нестабильного нерелятивистского атомного состояния. Если задать 4-импульс p нестабильной частицы массой m, то можно получить релятивистски инвариантное обобщение формулы (4.63):

$$\frac{1}{p^2 - m^2 + im\Gamma} \approx \frac{1}{2E_{\mathbf{p}}\left(p^0 - E_{\mathbf{p}} + i\left(m/E_{\mathbf{p}}\right)\Gamma/2\right)}.$$

Вероятность распада нестабильной частицы в произвольной системе отсчета равна $(m/E_{\mathbf{p}})\,\Gamma$, что согласуется с релятивистским растяжением времени. Хотя обе части равенства в (4.64) равны в окрестности резонанса, запись слева, которая является явно лоренц-инвариантной, намного удобнее.

11.3.4 Expressing Process Probabilities via Amplitudes

Рассмотрим вопрос о выражении сечений рассеяния и вероятностей распадов частиц через инвариантные амплитуды рассеяния в трёхмерном пространстве.

Сначала проясним вопрос о нормировке r-частичных состояний. Согласно (39 Л2)

$$\langle k|k\rangle = 2\omega_k(2\pi)^3\delta^{(3)}(0) \tag{A1}$$

Так как объём пространства представляется как

$$V = \int \mathrm{d}^{(3)}x e^{i(\mathbf{p}-\mathbf{k})\mathbf{x}}\Big|_{\mathbf{p}=\mathbf{k}} = (2\pi)^3\delta^{(3)}(0)$$

то (A1) означает, что принятая нами лоренц-инвариантная нормировка состояний (38 Л2) такова, что в единице объёма содержится

$$n_{\mathbf{k}} = 2\omega_k = 2\sqrt{m^2 + \mathbf{k}^2} \tag{A2}$$

частиц.

Построим r-частичное нормированное состояние. Пусть G - малая область в импульсном пространстве частиц вблизи значений импульсов $(\mathbf{p}_1, ..., \mathbf{p}_r)$, так что объём G равен:

$$G = \int\limits_G \mathrm{d}^{(3)}p_1 ... \mathrm{d}^{(3)}p_r = \prod_{j=1}^{r} \Delta^{(3)} p_j \tag{A3}$$

Состояние $\left(\omega_j \equiv \sqrt{m_j^2 + \mathbf{p}_j^2}\right)$

$$|\tilde{f}\rangle = \prod_{j=1}^{r} \int\limits_G \frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]} \, |\mathbf{p}_1, ..., \mathbf{p}_r\rangle$$

имеет норму

$$\begin{aligned} \langle \tilde{f}|\tilde{f}\rangle &= \prod_{j=1}^{r} \int\limits_G \frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]} \int\limits_G \frac{\mathrm{d}^{(3)}p'_j}{\left[(2\pi)^3 2\omega'_j\right]} \, \langle \mathbf{p}'_1, ..., \mathbf{p}'_r | \mathbf{p}_1, ..., \mathbf{p}_r\rangle = \\ &= \prod_{j=1}^{r} \int\limits_G \frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]} \int\limits_G \mathrm{d}^{(3)}p'_j \delta^{(3)}\left(\mathbf{p}_j - \mathbf{p}'_j\right) = \prod_{j=1}^{r} \frac{\Delta^{(3)} p_j}{[(2\pi)^3 2\omega_j]} \end{aligned} \tag{A4}$$

При получении (А4) была использована формула (45 Л2), а также тот факт, что импульсы $\mathbf{p}_j$ и $\mathbf{p}'_j$ почти совпадают при всех j, в то время как импульсы $\mathbf{p}_j$ и $\mathbf{p}'_i$ при $i \neq j$ принадлежат непересекающимся областям Δp_j и Δp_i. Следует заметить, что (А4) есть лоренц-инвариант. Таким образом состояние

$$|f\rangle = \left[\prod_{j=1}^{r} \frac{\Delta^{(3)} p_j}{[(2\pi)^3 2\omega_j]}\right]^{-1/2} |\tilde{f}\rangle \tag{A5}$$

нормировано, причём это свойство лоренц-инвариантно.

Пусть $|i\rangle$ - n-частичное состояние (43 Л2) и $|f\rangle$ - состояние (А5). Тогда для недиагональных матричных элементов (см. (2 ЛЗ)-(4 ЛЗ))

$$\langle f|S|i\rangle = \langle f|iT|i\rangle = \left[\prod_{j=1}^{r} \frac{\Delta^{(3)} p_j}{[(2\pi)^3 2\omega_j]}\right]^{-1/2} \prod_{j=1}^{r} \int\limits_G \frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]} \, \langle \mathbf{p}_1, ..., \mathbf{p}_r | iT | \mathbf{k}_1, ..., \mathbf{k}_n\rangle \tag{A6}$$

Согласно вышесказанному выражение (А6) лоренц-инвариантно. Перепишем (А6) при помощи амплитуды M_{fi} (см. (4 ЛЗ) и вычислим вероятность перехода из состояния $|i\rangle$ в состояние $|f\rangle$. Так как $|f\rangle$ - нормированное состояние, то согласно общим правилам квантовой механики эта вероятность

$$|\langle f|S|i\rangle|^2 = \prod_{j=1}^{r} \int\limits_G \frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]} \left[(2\pi)^4 \delta^{(4)}\left(P_f - P_i\right)\right]^2 |M_{fi}|^2 \tag{A7}$$

При получении последней формулы была учтена малость объёма G, а также равенство

$$\left[\prod_{j=1}^{r} \frac{\Delta^{(3)} p_j}{[(2\pi)^3 2\omega_j]}\right]^{-1} \prod_{j=1}^{r} \int\limits_G \frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]} = 1$$

В(А7)

$$P_i = k_1 + ... + k_n, \quad P_f = p_1 + ... + p_r$$

Положим

$$\left[(2\pi)^4\delta^{(4)}\left(P_f - P_i\right)\right]^2 = VT(2\pi)^4\delta^{(4)}\left(P_f - P_i\right)$$

где V - объём пространства, а T-полный промежуток времени, в течение которого рассматривается процесс. Таким образом, деля выражение (А7) на 4 -объём VT, мы получаем вероятность перехода в единице пространства в единицу времени:

$$\mathrm{d}w_{fi} = (2\pi)^4\delta^{(4)}\left(P_f - P_i\right)\left]\,|M_{fi}|^2\prod_{j=1}^{r}\frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]}\right. \tag{А8}$$

В (А8) опущен знак интеграла по импульсам конечных частиц. Поэтому вероятность перехода (А8) является дифференциальной вероятностью перехода в бесконечно малый элемент импульсного пространства конечных состояний.

Ещё раз подчеркнём, что выражение (А8) лоренц-инвариантно и в случае применимости ТВ амплитуда M_{fi} вычисляется при помощи диаграммной техники Фейнмана согласно вышеизложенным правилам.

Теперь рассмотрим частные случаи

1. Процессы распада.

В этом процессе в начальном состоянии имеется одна частица с массой M. Чтобы получить вероятность распада одной частицы, следует разделить (А8) на плотность начальных частиц $n_{\mathbf{k}} = 2\sqrt{M^2 + \mathrm{k}^2} = 2\omega_k$. Таким образом вероятность распада частицы в единицу времени

$$\mathrm{d}\Gamma = \frac{(2\pi)^4}{2\sqrt{M^2 + \mathbf{k}^2}}\delta^{(4)}\left(P_f - k\right)|M_{fi}|^2\prod_{j=1}^{r}\frac{\mathrm{d}^{(3)}p_j}{[(2\pi)^3 2\omega_j]} \tag{А9}$$

2. Взаимное рассеяние двух частиц

В системе отсчёта, в которой одна из рассеивающихся частиц покоится, вероятность (А8) представляется в виде

$$\mathrm{d}w_{fi} \equiv \mathrm{d}\sigma \cdot v_{\text{ОТН}} n_1 n_2 \tag{А10}$$

где n_1 и n_2 - плотности частиц сортов 1 и 2, соответственно, $v_{\text{отн}}$ - относительная скорость частиц и $\mathrm{d}\sigma$ - лоренц-инвариантное дифференциальное сечение рассеяния. Из определения (А10) видно, что сечение имеет размерность площади, если n_1 и n_2 в (А10) нормируются так же как и начальные состояния при вычислении амплитуды рассеяния, т.е. согласно (А2).

Для проведения лоренц-инвариантных вычислений при нахождении сечений введём инвариантную величину, которую можно назвать инвариантной плотностью потока:

$$j = \sqrt{(k_1 k_2)^2 - m_1^2 m_2^2} \tag{А11}$$

В системе отсчёта, в которой частица 2 покоится

$$j = \frac{m_1 m_2 v_{\text{OTH}}}{\sqrt{1 - v_{\text{OTH}}^2}} = \frac{1}{4} v_{\text{OTH}} n_1 n_2 \tag{A12}$$

где

$$n_1 = \frac{2m_1}{\sqrt{1 - v_{\text{OTH}}^2}}, \quad n_2 = 2m_2$$

Если же налетающая частица 1 является безмассовой, то выражение для j при помощи правой части (A12) остаётся справедливым, если положить $v_{\text{O}} = 1$. Таким образом лоренц-инвариантное дифференциальное сечение рассеяния представляется как

$$\mathrm{d}\sigma = \frac{\mathrm{d}w_{fi}}{4j} \tag{A13}$$

Легко проверить следующую формулу:

$$2j = \sqrt{\left[s - (m_1 + m_2)^2\right]\left[s - (m_1 - m_2)^2\right]}, \quad s = (k_1 + k_2)^2 \tag{A14}$$

В системе центра инерции частиц

$$k_1 = (\omega_1, \mathbf{k}), \quad k_2 = (\omega_2, -\mathbf{k})$$

и плотность потока

$$j = |\mathbf{k}| (\omega_1 + \omega_2) \tag{A15}$$

Рассмотрим подробнее формулу (A13) в системе центра инерции в том случае, когда в конечном состоянии имеется также две частицы с массами m_1' и m_2'. Имеем:

$$p_1 = (\omega_1', \mathbf{p}), \quad p_2 = (\omega_1', -\mathbf{p}), \quad \omega_1'^2 - m_1'^2 = \omega_2'^2 - m_2'^2 = |\mathbf{p}|^2 \tag{A16}$$

Отсюда

$$\omega_1' \mathrm{d}\omega_1' = \omega_2' \mathrm{d}\omega_2' = |\mathbf{p}| \mathrm{d}|\mathbf{p}| \longrightarrow \mathrm{d}(\omega_1' + \omega_2') = (\omega_1' + \omega_2') \frac{|\mathbf{p}| \mathrm{d}|\mathbf{p}|}{\omega_1' \omega_2'} \tag{A17}$$

При помощи обозначений

$$\omega = \omega_1 + \omega_2, \quad \omega' = \omega_1' + \omega_2'$$

формулы (A15) и (A17) переписываются как

$$j = |\mathbf{k}| \omega, \quad |\mathbf{p}| \mathrm{d}|\mathbf{p}| = \frac{\omega_1' \omega_2'}{\omega'} \mathrm{d}\omega' \tag{A18}$$

что позволяет представить сечение (A13) в виде

$$\mathrm{d}\sigma = \frac{|M_{fi}|^2 |\mathbf{p}| \mathrm{d}o'}{64\pi^2 |\mathbf{k}| \omega^2} \tag{A19}$$

Здесь d o' - элемент телесного угла, в котором заключён импульс рассеянной частицы:

$$\mathrm{d}o' = \sin\theta \mathrm{d}\theta \mathrm{d}\phi \tag{A20}$$

так что θ есть угол между векторами $\mathbf{k}$ и $\mathbf{p}$, а угол ϕ является азимутальным углом вектора $\mathbf{p}$ относительно некого фиксированного ортогонального репера, третья ось которого совпадает с $\mathbf{k}$. Таким образом

$$t = (k_1 - p_1)^2 = m_1^2 + m_1'^2 - 2\omega\omega' + 2|\mathbf{k}||\mathbf{p}|\cos\theta$$

Поэтому при фиксированной энергии ω

$$\mathrm{d}t = 2|\mathbf{k}||\mathbf{p}|\mathrm{d}\cos\theta, \quad \mathrm{d}o' = \mathrm{d}\phi\mathrm{d}(-\cos\theta) = \frac{\mathrm{d}\phi\mathrm{d}(-t)}{2|\mathbf{k}||\mathbf{p}|}$$

так что

$$\mathrm{d}\sigma = \frac{|M_{fi}|^2 \ \mathrm{d}t}{64\pi|\mathbf{k}|^2|\omega^2} \cdot \frac{\mathrm{d}\phi}{2\pi} = \frac{|M_{fi}|^2 \ \mathrm{d}t}{64\pi j^2} \cdot \frac{\mathrm{d}\phi}{2\pi} \tag{A21}$$

Так как в физически интересных случаях амплитуда не зависит от угла ϕ, то, интегрируя (A21) по этому углу, находим:

$$\mathrm{d}\sigma = \frac{|M_{fi}|^2 \ \mathrm{d}t}{64\pi j^2} \tag{A22}$$

Поскольку в последнем равенстве инвариантное дифференциальное сечение представлено через инвариантные же величины, то этим равенством можно пользоваться в любой системе отсчёта.

11.3.5 Spin Density Matrices

Выпишем некоторые формулы, относящиеся к спиновым матрицам плотности. Спиновые матрицы плотности необходимы при вычислении сечений и вероятностей распадов, т.к. в процессе таких вычислений приходится делать замены выражений, билинейных относительно спиновых волновых функций начальных и конечных частиц, согласно правилу

$$e_{\mathbf{k}\mu}e^*_{\mathbf{k}\nu} \longrightarrow \rho_{\mu\nu}(k), \quad u_{\pm ka}\bar{u}_{\pm kb} \longrightarrow \rho^{(\pm)}_{ab}(k) \tag{Б1}$$

где $\rho_{\mu\nu}(k)$ - спиновая матрица плотности фотона, $\rho^{(+)}_{ab}(k)$ $\left(\rho^{(-)}_{ab}(k)\right)$ - спиновая матрица плотности электрона (позитрона), причём импульс всех этих частиц равен $\mathbf{k}$.

1. Photon Spin Density Matrices

Для неполяризованного фотона в трёхмерно-поперечной калибровке (см. (33 ЛП7))

$$\rho_{ij} = \frac{1}{2}\left(\delta_{ij} - \frac{k_i k_j}{\mathbf{k}^2}\right), \quad \rho_{0i} = \rho_{i0} = \rho_{00} = 0 \tag{Б2}$$

Структура матрицы плотности неполяризованного фотона (Б2) очевидна, а общий коэффициент определяется требованием того, что сумма вероятностей нахождения спина фотона во всех состояниях равна единице:

$$\rho^\mu_\mu = -1 \tag{Б3}$$

Преобразуем выражение (Б2) к более удобному для использования виду, воспользовавшись свойством калибровочной инвариантности теории. В отношении фотонной матрицы плотности последнее свойство означает, что с физической точки зрения матрица плотности не изменяется при замене (сравни с (56Ω7))

$$\rho_{\mu\nu}(k) \longrightarrow \rho_{\mu\nu}(k) + (\chi_\mu k_\nu + \chi_\nu k_\mu) \tag{Б4}$$

где $\chi_\mu(k)$ - произвольный 4 -вектор. Действительно, каждый из векторов k^μ в круглых скобках в (Б4) сворачивается по векторному индексу с хронологическими корреляторами токов, из которых строятся все амплитуды. При этом импульс фотона k^μ есть входящий (или выходящий) импульс в соответствующую вершину. Вследствие равенств (17 Л10) описанные слагаемые обращаются в нуль и потому слагаемое в круглых скобках в (Б4) несущественно. При помощи преобразования (Б4) матрица плотности (Б2)приводится к виду

$$\rho_{\mu\nu} = -\eta_{\mu\nu}/2 \tag{Б5}$$

если

$$\chi^\mu = \left(-\frac{1}{4\omega}, \frac{\mathbf{k}}{4\omega^2}\right)$$

В общем случае матрица плотности представляется в виде

$$\rho_{\mu\nu} = \rho^*_{\nu\mu} = \sum_{\alpha,\beta=1}^{2} \rho^{\alpha\beta} e_{\alpha\mu} e^*_{\beta\nu} \tag{Б6}$$

Здесь $(e_{1\mu}, e_{2\mu})$ - базис векторов поляризации фотона. Эрмитовость матрицы (Б6) обеспечивается эрмитовостью матрицы $\rho^{\alpha\beta}$:

$$\rho^{\alpha\beta} = \rho^{\beta\alpha *} \tag{Б7}$$

Очевидно, в рассмотренном случае неполяризованного фотона

$$\rho^{\alpha\beta} = (1/2)\delta^{\alpha\beta} \tag{Б8}$$

Из (Б8) находим, что

$$\det \rho^{\alpha\beta} = 1/4 \tag{Б9}$$

В случае полностью поляризованного фотона матрица (Б6) должна представляться как тензорное произведение двух взаимно сопряжённых 4 -векторов. Это возможно лишь в том случае когда

$$\rho^{\alpha\beta} = v^\alpha v^{\beta *} \tag{В10}$$

Очевидно, что в этом случае

$$\det \rho^{\alpha\beta} = 0 \tag{Б11}$$

В общем случае матрица $\rho^{\alpha\beta}$ подчиняется условию (Б7), условию

$$\sum_{\alpha=1}^{2} \rho^{\alpha\alpha} = 1 \tag{Б12}$$

вытекающему из (Б3), а также условию

$$0 \leq \det \rho^{\alpha\beta} \leq 1/4 \tag{Б13}$$

Общий вид матрицы ранга 2, удовлетворяющий условиям (Б7) и (Б12), таков:

$$\rho = \frac{1}{2}(1 + \boldsymbol{\xi}\boldsymbol{\sigma}), \quad \boldsymbol{\xi} = (\xi_1, \xi_2, \xi_3) \tag{Б14}$$

Здесь $\boldsymbol{\sigma} = (\sigma^1, \sigma^2, \sigma^3)$ - матрицы Паули. Имеем:

$$\det \rho = \frac{1}{4}\left(1 - \xi_1^2 - \xi_2^2 - \xi_3^2\right) \tag{Б15}$$

Из условия (Б13) следует, что

$$0 \leq \xi_1^2 + \xi_2^2 + \xi_3^2 \equiv \boldsymbol{\xi}^2 \leq 1 \tag{Б16}$$

Из сказанного выше вытекает, что в неполяризованном случае

$$\xi^2 = 0 \tag{Б17}$$

а в полностью поляризованном случае

$$\xi^2 = 1 \tag{Б18}$$

2. Spinor Density Matrices

Из определения (Б1) и (39 Л8) вытекает, что

$$\operatorname{tr} \rho^{(\pm)}(k) = \pm 2m \tag{Б19}$$

Спинорные матрицы плотности удовлетворяют уравнениям (ср. с (38 Л8))

$$(\not{k} \mp m)\rho^{(\pm)}(k) = \rho^{(\pm)}(k)(\not{k} \mp m) = 0 \tag{Б20}$$

При заданной матрице плотности среднее значение спина вычисляется при помощи формулы (определение спинового оператора $\boldsymbol{\Sigma}$ см. в (111 Л8))

$$\langle \mathbf{s} \rangle = \frac{1}{2\omega_k} \operatorname{tr}\left(\rho^{(\pm)}\gamma^0\boldsymbol{\Sigma}\right) = \frac{1}{4\omega_k} \operatorname{tr}\left(\rho^{(\pm)}\gamma^5\gamma\right) \tag{Б21}$$

Матрица плотности для неполяризованного состояния получается при помощи суммы (56 Л8), делённой на 2. Действительно, в неполяризованном состоянии обе проекции спина имеют одинаковую вероятность (1/2). Таким образом в неполяризованном состоянии

$$\rho^{(\pm)}(k) = (1/2)(\not{k} \pm m) \tag{Б22}$$

Матрица плотности (Б22) удовлетворяет условиям (Б19) и (Б20).

В общем случае спинорные матрицы плотности представляются в виде

$$\rho^{(\pm)}(k) = (1/2)(\not{k} \pm m)\left(1 - \gamma^5 \not{a}\right) \tag{Б23}$$

где a^μ есть 4-вектор, характеризующий поляризацию и удовлетворяющий условию

$$k_\mu a^\mu = 0 \longleftrightarrow \not{a}\not{k} + \not{k}\not{a} = 0 \tag{Б24}$$

Непосредственно проверяется, что при условии выполнения равенств (Б24) матрица (Б23) также удовлетворяет условиям (Б19) и (Б20). Имеем также:

$$\pm a^\mu = \frac{1}{2m}\,\mathrm{tr}\left(\rho^{(\pm)}\gamma^5\gamma^\mu\right) \tag{b25}$$

Сравнение формулы (Б21), (Б24) и (Б25) показывает, что в системе покоя частицы

$$a^\mu = (0, \pm 2\langle \mathbf{s}\rangle) \tag{Б26}$$

Поскольку

$$0 \le \langle \mathbf{s}\rangle^2 \le 1/4$$

то 4-вектор a^μ удовлетворяет ограничению

$$-1 \le a^2 \le 0 \tag{Б27}$$

Напоследок укажем, что в случае рассеяния неполяризованных частиц без фиксации поляризации рассеянных частиц каждой начальной и конечной частице в сечении рассеяния соответствуют матрицы (Б5) либо (Б22) (в зависимости от сорта частиц), причём в сечение рассеяния следует внести дополнительный множитель 2^r, где r - суммарное число электронов, позитронов и фотонов в конечном состоянии. Этот множитель означает учёт обоих состояний спина каждой конечной частицы.

11.4 Scattering Matrix by Landau 4

11.4.1 Scattering Amplitude

(?? I'll check what was here in the book and move it to the previous part most likely)

13.0.3 Path Integral for Particles

(nearly the same is in QM)

9.1 Path Integrals in Quantum Mechanics

Feynman once said that* "every theoretical physicist who is any good knows six or seven different theoretical representations for exactly the same physics." Following his advice, we introduce in this chapter an alternative method of deriving the Fcynman rules for an interacting quantum field theory: the method of functional integration.

Aside from Feynman's general principle, we have several specific reasons for introducing this formalism. It will provide us with a relatively easy derivation of our expression for the photon propagator, completing the proof of the Feynman rules for QED given in Section 4.8. The functional method generalizes more readily to other interacting theories, such as scalar QED (Problem 9.1), and especially the non-Abelian gauge theories (Part III). Since it uses the Lagrangian, rather than the Hamiltonian, as its fundamental quantity, the functional formalism explicitly preserves all symmetries of a theory. Finally, the functional approach reveals the close analogy between quantum field theory and statistical mechanics. Exploiting this analogy, we will turn Feynman's advice upside down and apply the same theoretical representation to two completely different areas of physics.

We begin by applying the functional integral (or path integral) method to the simplest imaginable system: a nonrelativistic quantum-mechanical particle moving in one dimension. The Hamiltonian for this system is

$$H = \frac{p^2}{2m} + V(x)$$

Suppose that we wish to compute the amplitude for this particle to travel from one point (x_a) to another (x_b) in a given time (T). We will call this amplitude $U(x_a, x_b; T)$; it is the position representation of the Schrdinger time-evolution operator. In the canonical Hamiltonian formalism, U is given by

$$U(x_a, x_b; T) = \langle x_b | e^{-iHT/h} | x_a \rangle \tag{9.1}$$

(For the next few pages we will display all factors of $\hbar$ explicitly.)
In the path-integral formalism, U is given by a very different-looking expression. We will first try to motivate that expression, then prove that it is equivalent to (9.1).

Recall that in quantum mechanics there is a superposition principle: When a process can take place in more than one way, its total amplitude is the coherent sum of the amplitudes for each way. A simple but nontrivial example is the famous double-slit experiment, shown in Fig. 9.1. The total amplitude for an electron to arrive at the detector is the sum of the amplitudes for the two paths shown. Since the paths differ in length, these two amplitudes generally differ, causing interference.

For a general system, we might therefore write the total amplitude for traveling from x_a to x_b as

$$U\left(x_a, x_b; T\right) = \sum_{\text{all paths}} e^{i\cdot(\text{ phase })} = \int \mathcal{D}x(t) e^{i\cdot(\text{ phase })} \tag{9.2}$$

To be democratic, we have written the amplitude for each particular path as a pure phase, so that no path is inherently more important than any other. The symbol $\int \mathcal{D}x(t)$ is simply another way of writing "sum over all paths"; since there is one path for every function $x(t)$ that begins at x_a and ends at x_b, the sum is actually an integral over this continuous space of functions.

We can define this integral as part of a natural generalization of the calculus to spaces of functions. A function that maps functions to numbers is called a functional. The integrand in (9.2) is a functional, since it associates a complex amplitude with any function $x(t)$. The argument of a functional $F[x(t)]$ is conventionally written in square brackets rather than parentheses. Just as an ordinary function $y(x)$ can be integrated over a set of points x, a functional $F[x(t)]$ can be integrated over a set of functions $x(t)$; the measure of such a functional integral is conventionally written with a script capital $\mathcal{D}$, as in (9.2). A functional can also be differentiated with respect to its argument (a function), and this functional derivative is denoted by $\delta F/\delta x(t)$. We will develop more precise definitions of this new integral and derivative in the course of this section and the next.

What should we use for the "phase" in Eq. (9.2)? In the classical limit, we should find that only one path, the classical path, contributes to the total amplitude. We might therefore hope to evaluate the integral in (9.2) by the method of stationary phase, identifying the classical path $x_{\text{cl}}(t)$ by the stationary condition,

$$\frac{\delta}{\delta x(t)}(\text{phase}[x(t)])\bigg|_{x_{\text{cl}}} = 0$$

But the classical path is the one that satisfies the principle of least action,

$$\frac{\delta}{\delta x(t)}(S[x(t)])\bigg|_{x_{\text{cl}}} = 0$$

[6]*The Character of Physical Law (MIT Press, 1965), p. 168.

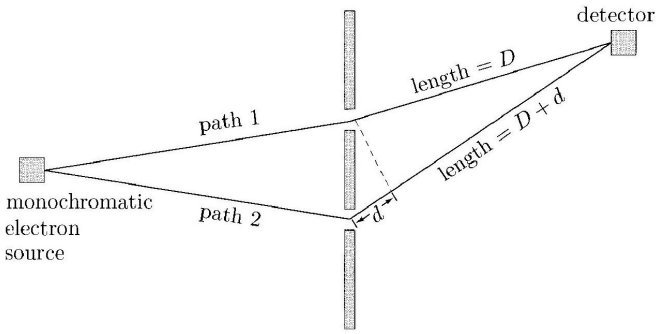

Figure 9.1. The double-slit experiment. Path 2 is longer than path 1 by an amount d, and therefore has a phase that is larger by $2\pi d/\lambda$, where $\lambda = 2\pi\hbar/p$ is the particle's de Broglie wavelength. Constructive interference occurs when $d = 0, \lambda, ...$, while destructive interference occurs when $d = \lambda/2, 3\lambda/2, ...$

where $S = \int L dt$ is the classical action. It is tempting, therefore, to identify the phase with S, up to a constant. Since the stationary-phase approximation should be valid in the classical limit-that is, when $S \gg \hbar$-we will use $S/\hbar$ for the phase. Our final formula for the propagation amplitude is thus

$$\langle x_b | \, e^{-iHT/\hbar} \, | x_a \rangle = U\left(x_a, x_b; T\right) = \int \mathcal{D}x(t) e^{iS[x(t)]/\hbar} \tag{9.3}$$

We can easily verify that this formula gives the correct interference pattern in the double-slit experiment. The action for either path shown in Fig. 9.1 is just $(1/2)mv^2t$, the kinetic energy times the time. For path 1 the velocity is $v_1 = D/t$, so the phase is $mD^2/2\hbar t$. For path 2 we have $v_2 = (D+d)/t$, so the phase is $m(D+d)^2/2\hbar t$. We must assume that $d \ll D$, so that $v_1 \approx v_2$ (i.e., the electrons have a well-defined velocity). The excess phase for path 2 is then $mDd/\hbar t \approx pd/\hbar$, where p is the momentum. This is exactly what we would expect from the de Broglie relation $p = h/\lambda$, so we must be doing something right.

To evaluate the functional integral more generally, we must define the symbol $\int \mathcal{D}x(t)$ in the case where the number of paths $x(t)$ is more than two (and, in fact, continuously infinite). We will use a brute-force definition, by discretization. Break up the time interval from 0 to T into many small pieces of duration ϵ, as shown in Fig. 9.2. Approximate a path $x(t)$ as a sequence of straight lines, one in each time slice. The action for this discretized path is

$$S = \int_0^T dt \left(\frac{m}{2}\dot{x}^2 - V(x) \right) \longrightarrow \sum_k \left[\frac{m}{2} \frac{\left(x_{k+1} - x_k\right)^2}{\epsilon} - \epsilon V\left(\frac{x_{k+1} + x_k}{2} \right) \right].$$

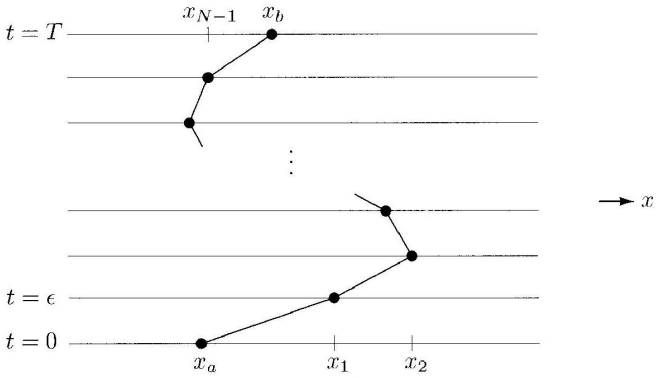

Figure 9.2. We define the path integral by dividing the time interval into small slices of duration ϵ, then integrating over the coordinate x_k of each slice.

We then define the path integral by

$$\int \mathcal{D}x(t) \equiv \frac{1}{C(\epsilon)} \int \frac{dx_1}{C(\epsilon)} \int \frac{dx_2}{C(\epsilon)} \cdots \int \frac{dx_{N-1}}{C(\epsilon)} = \frac{1}{C(\epsilon)} \prod_k \int_{-\infty}^{\infty} \frac{dx_k}{C(\epsilon)} \tag{9.4}$$

where $C(\epsilon)$ is a constant, to be determined later. (We have included one factor of $C(\epsilon)$ for each of the N time slices, for reasons that will be clear below.) At the end of the calculation we take the limit $\epsilon \to 0$. (As in Sections 4.5 and 6.2, the $\prod$ symbol is an instruction to write what follows once for each k.)

Using (9.4) as the definition of the right-hand side of (9.3), we will now demonstrate the validity of (9.3) for a general one-particle potential problem. To do this, we will show that the left- and right-hand sides of (9.3) are obtained by integrating the same differential cquation, with the same initial condition. In the process, we will determine the constant $C(\epsilon)$.

To derive the differential equation satisfied by (9.4), consider the addition of the very last time slice in Fig. 9.2. According to (9.3) and the definition (9.4), we should have

$$U(x_a, x_b; T) = \int_{-\infty}^{\infty} \frac{dx'}{C(\epsilon)} \exp\left[\frac{i}{\hbar} \frac{m(x_b - x')^2}{2\epsilon} - \frac{i}{\hbar} \epsilon V\left(\frac{x_b + x'}{2}\right)\right] U(x_a, x'; T - \epsilon)$$

The integral over x' is just the contribution to $\int \mathcal{D}x$ from the last time slice, while the exponential factor is the contribution to $e^{iS/\hbar}$ from that slice. All contributions from previous slices are contained in $U(x_a, x'; T - \epsilon)$.

As we send $\epsilon \to 0$, the rapid oscillation of the first term in the exponential constrains x' to be very close to x_b. We can therefore expand the above

13.0.4 Path Integral for Fields

(a place for main theory)

13.0.5 Path Integral for Fields: Easy Examples

(??? I'll write later good ones)

описание векторного мезона

Теория поля векторного мезона определяется интегралом по траекториям:

$$Z = \int DA e^{iS(A)} \equiv e^{iW(J)}$$

И действие:

$$S(A) = \int d^4x \mathcal{L} = \int d^4x \{A_\mu[(\partial^2 + m^2)g^{\mu\nu} - \partial^\mu \partial^\nu]A_\nu + A_\mu J^\mu\}$$

какая-то теория Киселева

пока не использую это.

При введении в действие полиномиального взаимодействия по полям степени выше 2

$$S_{\rm int}(\varphi) = -\int {\rm d}^4 x V(\varphi)$$

та же методика спаривания полей трансформирует амплитуду вероятности квантовых переходов при наличии источников

$$Z(j) = \exp\left\{\frac{\rm i}{\hbar} S_{\rm int}\left(-{\rm i}\hbar\frac{\delta}{\delta j}\right)\right\} \exp\left\{\frac{\rm i}{\hbar}\frac{1}{2} j_x \mathcal{G}^{(2)}_{xy} j_y\right\}$$

в выражение

$$Z(j) = \exp\left\{-\frac{{\rm i}\hbar}{2}\mathcal{G}^{(2)}_{xy}\frac{\delta^2}{\delta\tilde\varphi_x\delta\tilde\varphi_y}\right\} e^{\frac{\rm i}{\hbar}\{S_{\rm int}(\tilde\varphi)+j_{x'}\tilde\varphi_{x'}\}}\Big|_{\tilde\varphi=0}$$

Значит, для многоточечной амплитуды находим

$$\mathcal{D}^{(n)}_{1\ldots n} = \exp\left\{-\frac{{\rm i}\hbar}{2}\mathcal{G}^{(2)}_{xy}\frac{\delta^2}{\delta\tilde\varphi_x\delta\tilde\varphi_y}\right\} e^{\frac{\rm i}{\hbar}S_{\rm int}(\tilde\varphi)}\tilde\varphi_1\ldots\tilde\varphi_n\Big|_{\tilde\varphi=0}$$

В этом выражении нужно учитывать все спаривания полей, включая поля в $S_{\rm int}$.

Формула (4.53) представляет собой основу для построения теории возмущений,

поскольку все многоточечные функции выражаются через спаривания «свободных» полей,

часть из которых возникает при разложении экспоненты с действием взаимодействия.

В свою очередь, действие взаимодействия обычно включает в себя полиномы по полям с коэффициентами - константами взаимодействия.

Подчеркнем, что в рассмотренном нами простом случае, когда нет вакуумных полей, т. е. $\mathcal{G}^{(1)} \equiv 0$, вклад вакуумных амплитуд

$$\mathcal{D}^{(0)} = \exp\left\{-\frac{{\rm i}\hbar}{2}\mathcal{G}^{(2)}_{xy}\frac{\delta^2}{\delta\tilde\varphi_x\delta\tilde\varphi_y}\right\} e^{\frac{\rm i}{\hbar}S_{\rm int}(\tilde\varphi)}\Big|_{\tilde\varphi=0}$$

очевидно, факторизуется для всех многоточечных функций в виде суммы всех диаграмм без внешних концов.

Теория возмущений для потенциала ϕ^3 (??)

(??? суть еще не понял??)

Рассмотрим теперь взаимодействие с модельным потенциалом

$$V = \frac{\Lambda}{3!}\varphi^3,$$

где $[\Lambda] = [m]$.

Вычислим трехточечный причинный коррелятор в ведущем приближении по константе взаимодействия Λ,

$$\begin{aligned}\mathcal{D}^{(3)}_{123} &= \left\langle 0\left|\hat{\rm T}\left\{\varphi_1\varphi_2\varphi_3\right\}\right|0\right\rangle \approx \\ &\approx \exp\left\{-\frac{{\rm i}\hbar}{2}\mathcal{G}^{(2)}_{xy}\frac{\delta^2}{\delta\tilde\varphi_x\delta\tilde\varphi_y}\right\}\tilde\varphi_1\tilde\varphi_2\tilde\varphi_3\left(-\frac{\rm i}{\hbar}\right)\int {\rm d}^4x_4\frac{\Lambda}{3!}\tilde\varphi^3(x_4)\Big|_{\tilde\varphi=0}\end{aligned}$$

В этом выражении отличный от нуля вклад получается, если имеет место спаривание всех шести полей, а стало быть, экспоненту необходимо разложить до третьей степени ($\exp x \mapsto x^3/3!$)

$$\mathcal{D}^{(3)}_{123} \approx \hbar^2 \frac{\Lambda}{3!} \left(\frac{1}{2} \int \mathrm{d}^4x d^4y \mathcal{G}^{(2)}_{xy} \frac{\delta^2}{\delta\tilde{\varphi}_x \delta\tilde{\varphi}_y} \right)^3 \frac{1}{3!} \tilde{\varphi}_1 \tilde{\varphi}_2 \tilde{\varphi}_3 \int \mathrm{d}^4x_4 \tilde{\varphi}^3 (x_4) \Bigg|_{\tilde{\varphi}=0}$$

В системе единиц $\hbar = c = 1$, как мы знаем, $\mathcal{G}^{(2)}_{xy} = \mathrm{i}\mathcal{D}^{(2)}_{xy}$, так что

$$\mathcal{D}^{(3)}_{123} \approx -\,\mathrm{i}\frac{\Lambda}{3!} \left(\frac{1}{2} \int \mathrm{d}^4x d^4y \mathcal{D}^{(2)}_{xy} \frac{\delta^2}{\delta\tilde{\varphi}_x \delta\tilde{\varphi}_y} \right)^3 \frac{1}{3!} \tilde{\varphi}_1 \tilde{\varphi}_2 \tilde{\varphi}_3 \int \mathrm{d}^4x_4 \tilde{\varphi}^3 (x_4) \Bigg|_{\tilde{\varphi}=0}$$

Связный вклад $\mathcal{D}^c_{123}$ получается, если каждое их полей $\tilde{\varphi}_{1,2,3}$ спарить с полями $\tilde{\varphi}_4$, причем, в силу симметричности варьирования по $\tilde{\varphi}_x$ и $\tilde{\varphi}_y$ фактор $1/2$ компенсируется перестановкой $x \leftrightarrow y$, а комбинаторика по выборке $\tilde{\varphi}_4$ из $\tilde{\varphi}^3_4$ компенсирует фактор $1/3!$ и комбинаторика выбора вариации из $\tilde{\varphi}_1\tilde{\varphi}_2\tilde{\varphi}_3$ также компенсирует фактор $1/3!$, так что

$$\mathcal{D}^c_{123} \approx -\mathrm{i}\Lambda \int \mathrm{d}^4x_4 \mathcal{D}^{(2)}_{14} \mathcal{D}^{(2)}_{24} \mathcal{D}^{(2)}_{34}$$

На этой диаграмме мы показали также несвязный вклад с одной петлей. Он получается, если, например, произвести спаривание полей в точках 1 и 2, а спаривание других точек дает вклад, который за счет комбинаторики повторяется трижды, так что

$$\mathcal{D}^{nc}_{123} \approx -\mathrm{i}\frac{\Lambda}{2} \mathcal{D}^{(2)}_{12} \int \mathrm{d}^4x_4 \mathcal{D}^{(2)}_{34} \mathcal{D}^{(2)}_{44}$$

Многоточие на диаграмме означает аналогичные вклады с перестановкой точек 1,2,3

внутренние линии

На диаграмме многоточечной функции Грина встречаются внешние линии,

когда одна из точек пропагатора относится ко множеству точек-аргументов самой функции Грина,

а также внутренние линии, когда обе точки пропагатора не принадлежат множеству аргументов функции Грина.

При этом, по координатам внутренних линий проводится интегрирование.

Среди внутренних линий встречаются и петли, когда конец одной из внутренних линий совпадает с началом другой или,

как в примере, той же внутренней линии.

Говорят, что частицы на внутренних линиях диаграммы являются виртуальными:

квантовые флуктуации приводят к тому, что квадрат 4-импульса виртуально частицы отличается от квадрата массы, т.е. виртуальная частицы находится вне массовой поверхности.

Виртуальные частицы появляются только при наличии взаимодействий: как мы видели, согласно теореме Вика для свободных частиц внутренние линии не возникают, а стало быть, не возникают и условия схода частиц с массовой поверхности.

Если внутренняя линия, тем не менее, при каких-то определенных условиях попадает на массовую поверхность,

то говорят, что возникают сингулярности Ландау.

В этой части курса квантовой теории поля мы не рассматриваем ни петли, ни сингулярности Ландау.

Рассмотрим, какой вклад в амплитуду $\hat{Z}(j)$ дает связная диаграмма,

$$Z^c_{(3)} = \frac{1}{3!}\mathrm{i}^3\mathcal{D}^c_{123}j_1j_2j_3$$

Учтем, что в асимптотической области внешние токи связаны с внешними классическими полями,

например,

$$\mathrm{i}\mathcal{D}^{(2)}_{xy}j_y = \varphi_{\mathrm{cl}}(x) \to j_y = -\mathrm{i}\left(\mathcal{D}^{(2)}_{xy}\right)^{-1}\varphi_{\mathrm{cl}}(x)$$

$\mathcal{T}$-матрица

При рассмотрении амплитуды квантовых переходов в асимптотической области для Z вводят специальное обозначение $\mathcal{S}$-матрицы, а для отличия $\mathcal{S}$-матрицы от единицы:

$$\mathcal{S} = \mathbb{1} + \mathrm{i}\mathcal{T}.$$

Матричные элементы $\mathcal{T}$ -матрицы для конкретных процессов обычно обозначают либо символом $\mathcal{M}$, либо $\mathcal{A}$.

Тогда в выражении для связного вклада в 3 -точку

(4.54)

подстановка внешних токов через внешние поля в асимптотически свободной области

(4.55)

в точности приводит к сокращению двухточечных пропагаторов, и

$$\mathrm{i}\mathcal{M}^c_{(3)} = \frac{1}{3!}(-\mathrm{i}\Lambda)\int \mathrm{d}^4x_4\varphi^3_{\mathrm{cl}}(x_4)$$

что, конечно, в точности совпадает с выражением для затравочного действия взаимодействия, как и должно быть в теории возмущений.

(???)

В это выражение мы теперь можем подставить вполне определенные моды внешнего классического поля,

которые соответствуют поставленной задаче.

Например, если речь идет о переходе одной частицы в две: $\varphi_{\mathrm{cl}}(x_n) \mapsto e^{\mp\mathrm{i}k_nx_n}$ в зависимости от того, какие моды распространяются в будущее, а какие в прошлое,

интегрирование по координате дает амплитуду в импульсном представлении

$$\mathrm{i}\mathcal{M}^c_{(3)} = \frac{1}{3!}(-\mathrm{i}\Lambda)(2\pi)^4\delta(k_1-k_2-k_3)\,3!\frac{1}{\sqrt{2!}}$$

где мы ввели комбинаторный фактор 3! по счету вариантов прескрипции импульсов для квантов поля φ_{cl} в силу их тождественности и фактор $1/\sqrt{2!}$ для нормировки амплитуды по перестановке тождественных частиц в конечном состоянии.

Этот пример в данном случае тривиален, поскольку сохранение 4-импульса с учетом того,

что все эти 4-импульсы находятся на массовой поверхности, приводит при $m \neq 0$ к нулевому результату,

так как под аргументом дельта-функции стоит ненулевая величина, т. е. переход запрещен при $m \neq 0$.

В месте с тем, отметим следующее: при вычислении амплитуды квантового перехода пропагаторы от внешних точек функции Грина к внутренним вершинам сокращаются, когда мы выражаем внешние токи через внешние поля в асимптотически свободной области наблюдений! Такая операция называется редукцией или усечением (ампутацией) внешних ног диаграммы, а получающиеся диаграммы называются усеченными. При этом обычно внешние линии перечеркивают, обозначая тем самым, что процедура усечения произведена.

редукция внешних ног диаграммы

Вместе с тем, отметим следующее: при вычислении амплитуды квантового перехода пропагаторы от внешних точек функции Грина к внутренним вершинам сокращаются,

когда мы выражаем внешние токи через внешние поля в асимптотически свободной области наблюдений!

Такая операция называется редукцией или усечением (ампутанией) внешних ног диаграммы, а получающиеся диаграммы называются усеченными.

При этом обычно внешние линии перечеркивают, обозначая тем самым, что процедура усечения произведена.

13.0.6 Infinite Series Sums and Expansions in QFT (!?!?)

(тут про тот гениальный ход, что так берем и вариационную производную выводим через экспоненту. кто бы мог подумать, что так можно вообще делать???? про это тут подробно.)

(??? maybe it will be written later, in special section)

13.0.7 Perturbative Expansion – Making Sense of Divergent Series

By How I Learned to Stop Worrying and Love QFT 2011 Robert C. Helling

Before we take a look at divergent series, we will first give a brief review of how perturbative expansion is used in quantum field theory.

Brief overview on path integrals

A quantum field theory in Minkowski spacetime is described by a Lagrangian density

$\mathcal{L}(\phi, \partial\phi)$ and a generating functional of correlation functions[1]

$$\mathcal{Z}[J] = \int \mathcal{D}\phi e^{i\int \mathrm{d}^4x(\mathcal{L}+J\phi)}$$

The correlation functions can be obtained by functional derivatives of (1) with respect to J

$\langle \phi(x_1)\,\phi(x_2)\,...\phi(x_n)\rangle = \frac{1}{\mathcal{Z}[0]}\left(-i\frac{\delta}{\delta J(x_1)}\right)\left(-i\frac{\delta}{\delta J(x_2)}\right)...\left(-i\frac{\delta}{\delta J(x_n)}\right)\mathcal{Z}[J]\Big|_{J=0}$

In this lecture we will use Euclidean signature for the metric instead of Minkowski. The change between the metrics can be performed as rotation of the time axis in the complex plane $t \to -i\tau$ if all expressions are analytic. In Euclidean metric, the exponent in the generating functional is real and falls of at large field values. This gives the path integral a chance to have a mathematical definition in terms of Wiener measures but that will not concern us in these notes.

$$\mathcal{Z}[J] = \int \mathcal{D}\phi e^{\int \mathrm{d}^4x(\mathcal{L}+J\phi)}$$

In general, the integral (3) cannot be computed exactly. For a scalar quantum field theory in Euclidean space the Lagrangian has the form

$$\mathcal{L} = \frac{1}{2}\phi\left(\Box - m^2\right)\phi - V(\phi)$$

with $\Box \equiv (\partial_\tau)^2 + (\nabla)^2$

If the potential $V(\phi)$ vanishes, equation (3) can be formally computed as it becomes an integral of Gaussian type. One therefore arbitrarily splits the Lagrangian into its "kinetic part" $\frac{1}{2}\phi\left(\Box - m^2\right)\phi$ and its "interaction part" $-V(\phi)$.

$$\begin{aligned}\mathcal{Z}[J] &= \int \mathcal{D}\phi e^{\frac{1}{2}\int \mathrm{d}^4x\phi\left(\Box-m^2\right)\phi} e^{-\int \mathrm{d}^4xV(\phi)} e^{-\int \mathrm{d}^4xJ\phi} \\ &= e^{-\int \mathrm{d}^4xV\left(\frac{\delta}{\delta J}\right)} \int \mathcal{D}\phi e^{\int \mathrm{d}^4x\frac{1}{2}\phi\left(\Box-m^2\right)\phi - J\phi}\end{aligned}$$

To obtain the Gaussian integral one has to complete the square in the exponent. This is achieved by shifting the field ϕ:

$$\phi' = \phi + \left(\Box - m^2\right)^{-1} J$$

[1] This subsection displays some standard expressions to set the context. For many more details see for example [1. The inverse of $\Box - m^2$, called "Green's function" $G(x-y)$, is a distribution defined by

$$\left(\Box - m^2\right) G(x-y) = \delta(x-y)$$

Changing variables in the functional integral (5) leads to

$$\mathcal{Z}[J] = e^{-\int \mathrm{d}^4xV\left(\frac{\delta}{\delta J}\right)} \int \mathcal{D}\phi' e^{\int \mathrm{d}^4x\frac{1}{2}\phi'\left(\Box-m^2\right)\phi'} e^{-\int \mathrm{d}^4x\int \mathrm{d}^4y\frac{1}{2}J(x)G(x-y)J(y)}$$

The complicated expression in the middle of equation (8) does not depend on J and will in fact cancel out in equation (2) for the correlation function, so we will just denote it C and forget about it:

$$\mathcal{Z}[J] = Ce^{-\int \mathrm{d}^4xV\left(\frac{\delta}{\delta J}\right)} e^{-\int \mathrm{d}^4x\int \mathrm{d}^4y\frac{1}{2}J(x)G(x-y)J(y)}$$

Now let us take a look on a specific example for a quantum field theory by choosing a potential for the scalar field. We will consider our favorite ϕ^4 theory given by the potential

$$V(\phi) = \lambda\phi^4$$

The next step is to insert this potential in equation (8) and write the exponential as a power series in the coupling strength λ.

$$\mathcal{Z}[J] = C\sum_{k=0}^{\infty}\frac{(-\lambda)^k}{k!}\int \mathrm{d}^4x_1\frac{\delta^4}{\delta J\left(x_1\right)^4}\cdots\int \mathrm{d}^4x_k\frac{\delta^4}{\delta J\left(x_k\right)^4}e^{-\int \mathrm{d}^4x\int \mathrm{d}^4y\frac{1}{2}J(x)G(x-y)J(y)}$$

We now found an expression for any general correlation function in terms of an power series expansion in the coupling strength.

$$\begin{aligned}\left\langle\phi\left(y_1\right)...\phi\left(y_n\right)\right\rangle =& \frac{\delta}{\delta J\left(y_1\right)}\cdots\frac{\delta}{\delta J\left(y_1\right)}\sum_{k=0}^{\infty}\frac{(-\lambda)^k}{k!}\int \mathrm{d}^4x_1\frac{\delta^4}{\delta J\left(x_1\right)^4}\cdots\int \mathrm{d}^4x_k\frac{\delta^4}{\delta J\left(x_k\right)^4}\times\\ & e^{-\int \mathrm{d}^4x\int \mathrm{d}^4y\frac{1}{2}J(x)G(x-y)J(y)}\Big|_{J=0}\end{aligned}$$

The combinatorics of the occurring expressions in terms of integrals over interaction points x_i, Green's functions and external fields can be summarized in terms of Feynman diagrams each standing for a single term in the power series in the coupling constant λ^2 In the following, we want to study the convergence behavior of this power series.

Radius of convergence of correlation functions

Let us briefly review the definition of the radius of convergence for a power series from introductory analyis. It is useful to think of a power series to be defined in the complex plane:

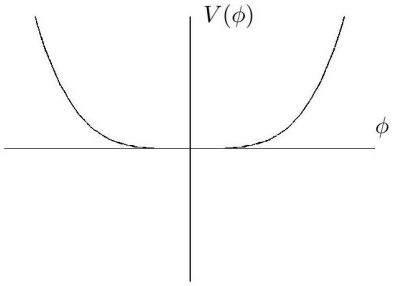
$$\sum_k^{\infty}\lambda^k(...)\quad \lambda\in\mathbb{C}$$

[2] The careful reader wishing to avoid ill-defined expressions using path-integrals, can use this formula as the definition of the terms in the perturbative series. (If one does not like the idea of a complex coupling strength in a quantum field theory, just restrict to the special $\lambda\in\mathbb{C}$ that happen to be real.). Every power series has a radius of convergence $R\in[0,\infty]$ such that

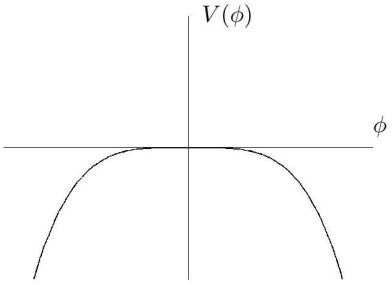
$$\sum_k^{\infty}\lambda^k(...)\begin{cases}\text{converges} & \forall|\lambda|<R\\ \text{diverges} & \forall|\lambda|>R\end{cases}$$

Now we want to find out the radius of convergence for the correlation functions (11) in a quantum field theory. A physicist's argument was given by Freeman Dyson in 1952 22]. Let us take a look on the potential, for example in our ϕ^4 theory as shown in figure 1 For positive coupling strength λ the potential is bounded from below and large values of ϕ are strongly disfavored. This behavior, however, gets radically different in case of a negative λ. The potential becomes unbounded from below and the field ϕ will want to run off to $\phi=\pm\infty$. Obviously, such a behavior is highly unphysical, since ever increasing values of ϕ would lead to an infinite energy gain. It is thus clear that such a theory cannot lead to healthy correlation functions, in other words for any negative λ the power series (12 will diverg]][3] From this we can conclude the radius of convergence being $R=0$!

$$\sum_k^{\infty}\lambda^k(...)\quad \text{diverges } \forall\lambda>0$$



(a) $\lambda > 0$



(b) $\lambda < 0$

Figure 1: Potentials of ϕ^4 theory

For readers not satisfied by this argument using physics of unstable potentials for determining the radius of convergence, let us mention an alternative line of argument. Again, consider equation (11), this time, however, we will focus on the Feynman diagrams. At any order k in the perturbation expansion there is a sum of different Feynman diagrams expressing the integrals in (11), where k counts the number of vertices. The combinatorics of all Feynman diagrams shows that the

[3] We expect at least a phase transition when λ is changed from positive to negative values.

number of Feynman diagrams grows like k !. The power series, therefore, will behave like

$$\sum_k^\infty \lambda^k k!(...)$$

Assuming that (...) is not surprisingly suppressed for large k, the coefficients of λ^k grow faster than any power, we again find the radius of convergence $R = 0$.

In the following, we want to give an example, how one can nevertheless make sense of (some) divergent power series.

Non-perturbative corrections

In order to get a feeling for the problem of divergent power series, we will consider a one dimensional toy problem (rather than the infinite dimensional problem of a path integral):

$$\mathcal{Z}(\lambda) = \int_{-\infty}^{\infty} \mathrm{d}x e^{-x^2-\lambda x^4}$$

We take $\lambda \geq 0$, so this integral yields some finite, positive number. For $\lambda = 0$ the solution is well known

$$\mathcal{Z}(0) = \sqrt{\pi}$$

In general, equation (16) can be expressed in terms of special functions, e.g. Mathematica gives the solution

$$\mathcal{Z}(\lambda) = \frac{e^{\frac{1}{8\lambda}} K_{1/4}(1/8\lambda)}{2\sqrt{\lambda}}$$

with $K_n(x)$ being the modified Bessel function of the second kind. We call solution (18) the "full, non-perturbative answer". Now we will do the same as in quantum field theory and split the integral into a "kinetic" and an "interaction" part, respectively.

Treating the toy model perturbatively

Following the same procedure, we will again expand the "interaction part" $-\lambda x^4$ in a power series:

$$\mathcal{Z}(\lambda) = \int_{-\infty}^{\infty} \mathrm{d}x e^{-x^2-\lambda x^4} = \int_{-\infty}^{\infty} \mathrm{d}x e^{-x^2} \sum_{k=0}^{\infty} \frac{\left(-\lambda x^4\right)^k}{k!}$$

Now comes the crucial step and "root of all evil". Following precisely the same steps leading towards equation (11) for correlation functions in quantum field theory, we will change the order of integration and summation, leading to the interpretation of a power series of Feynman diagrams:

$$\mathcal{Z}(\lambda)" = " \sum_{k=0}^{\infty} \frac{(-\lambda)^k}{k!} \int_{-\infty}^{\infty} \mathrm{d}x x^{4k} e^{-x^2}$$

From this step, as we will see later, the problems arise. Although this step is forbidden (as roughly speaking, we are changing the behavior of the integrand at $x = \pm\infty$), we are interested in to what extent a "perturbative solution" obtained from equation (20) will agree with the full, non-perturbative solution (18). Carrying on, we observe that the integral in (20) is now of the type "polynomial times Gaussian" and can be computed with standard methods. We smuggle an addtional factor a into the exponent allowing us to write the integrand as derivatives of e^{-ax^2} with respect to a at the point $a = 1$.

$$\mathcal{Z}(\lambda) = \sum_{k=0}^{\infty} \frac{(-\lambda)^k}{k!} \int_{-\infty}^{\infty} \mathrm{d}x \frac{\partial^{2k}}{\partial a^{2k}} e^{-ax^2} \bigg|_{a=1} = \sum_{k=0}^{\infty} \frac{(-\lambda)^k}{k!} \frac{\partial^{2k}}{\partial a^{2k}} \sqrt{\frac{\pi}{a}} \bigg|_{a=1}$$

Of course we can easily evaluate the derivatives:

$$\frac{\partial^{2k}}{\partial a^{2k}} a^{-\frac{1}{2}} \bigg|_{a=1} = \underbrace{\frac{1}{2}\frac{3}{2} \cdot \frac{5}{2}\frac{7}{2} \cdot \frac{9}{2}\frac{11}{2} \cdots}_{\text{total of } 2k \text{ factors}}$$

In order to find an explicit expression for (22) one can insert factors of 1 between all factors, such that the nominator becomes $(4k)!$:

$$\left.\frac{\partial^{2k}}{\partial a^{2k}} a^{-\frac{1}{2}}\right|_{a=1} = \underbrace{\frac{1}{2}\frac{2}{2}\frac{3}{2}\frac{4}{4}\frac{5}{2}\frac{6}{6}\frac{7}{2}\frac{8}{8}\frac{9}{2}\frac{10}{10}\frac{11}{2}\frac{12}{12}\cdots}_{\text{total of } 4k \text{ factors}} = \frac{(4k)!}{2^{2k}} \underbrace{\frac{1}{2}\frac{1}{4}\frac{1}{6}\frac{1}{8}\frac{1}{10}\frac{1}{12}\cdots}_{\text{total of } 2k \text{ factors}}$$
$$= \frac{(4k)!}{2^{2k}} \frac{1}{2^{2k}(2k)!} = \frac{(4k)!}{2^{4k}(2k)!}$$

Thus we obtain the "perturbative solution" of problem 16p

$$\mathcal{Z}(\lambda) = \sum_{k=0}^{\infty} \sqrt{\pi} \frac{(-\lambda)^k (4k)!}{2^{4k}(2k)!k!}$$

Let us take a closer look at this expression. By observing that the denominator of the summand eventually contains smaller factors than the nominator for all k larger than a critical integer, we can realize that the series is divergent. More carefully we can apply Stirling's formula $n! \approx \sqrt{2\pi n}\left(\frac{n}{e}\right)^n$ for large values of k:

$$\frac{(4k)!}{2^{4k}(2k)!k!} \approx \frac{4^k}{\sqrt{\pi k}} \left(\frac{k}{e}\right)^k \approx \frac{1}{\sqrt{2}\pi} 4^k k!$$

We already know that the sum

$$\sum_{k=0}^{\infty} (-4\lambda)^k k!$$

will diverge. This shows that the power series (24) is divergent and in particular it is not the finite number that we are looking for as an expression for (16).

The perturbative and the full solution compared

Even though the perturbative series will diverge, we want to study its numerical usefulness at finite order. After all, one usually computes only a finite number of Feynman diagrams to obtain only the first few summands of the perturbative expansion. Is there a way to approximate the full, non-perturbative solution 18p from 24. ? Let us choose one value for λ, e.g. $\frac{1}{50}$, and evaluate 18 numerically:

$$\mathcal{Z}\left(\frac{1}{50}\right) = 1.7478812...$$

For the same value of λ the evaluation of the first few terms of the infinite sum 24

$$\mathcal{Z}_N(\lambda) = \sum_{k=0}^{N} \sqrt{\pi} \frac{(-\lambda)^k (4k)!}{2^{4k}(2k)!k!}$$

gives

$$\mathcal{Z}_5 = 1.7478728...$$
$$\mathcal{Z}_{10} = 1.7478818...$$

The first terms of the perturbative solution agree up to six digits! We can use conveniently a figure for plotting higher orders of the perturbative series. Figure 2 shows that the perturbative

solution gets in a certain regime very close to the result of the full solution, before the series starts to diverge. We can use a figure as well

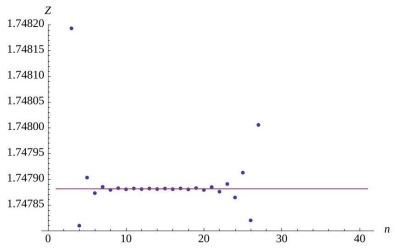


Figure 2: Values of the perturbative series 24 evaluated to order N

to compare the solutions for variable λ. Figure 3 shows nicely the non-perturbative solution and compares it to the perturbative solution for orders of one to twelve. We can see that at some point all approximations given by the perturbative solution will disagree strongly from the full solution!

The question that arises is, how long does the perturbative solution become better before it starts to diverge? Obviously, the fact that it approximates the non-perturbative solution to high precision leads to the great success of quantum field theory, even if for higher orders the series diverges! As we will see now, the perturbative solution 24 is a good approximation as long as we only consider terms up to order $N = O\left(\frac{1}{\lambda}\right)$. Remembering the dimensionless coupling strength of Quantum Electrodynamics being the Sommerfeld finestructure constant $\alpha \approx \frac{1}{137}$ we can be ensured that perturbation theory will lead to great precision given that the most elaborate QED calculations for $(g-2)$ are to order $N = 7$!

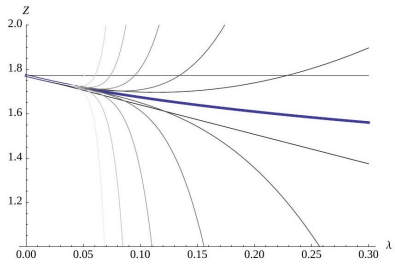

Figure 3: $\mathcal{Z}(\lambda)$ obtained from the full solution (thick) and first approximations from the perturbative series

The method of steepest descend

But what is the origin of the eventual divergence and complete loss of numerical accuracy? It turns out that there are "non-perturbative" terms that do not show up in a Taylor expansion but that become dominant when the perturbative expansion breaks down. To see this, let us substitute $x^2 \equiv \frac{u^2}{\lambda}$ in equation 16:

$$\mathcal{Z}(\lambda) = \frac{1}{\sqrt{\lambda}} \int \mathrm{d}u e^{-\frac{u^2+u^4}{\lambda}}$$

The exponent is strictly negative and its absolute value becomes very large in the limit of small λ. This allows to perform the method of steepest descent: The main contribution to the integral, as $\lambda \to 0$ comes from the extrema of the integrand

$$u^2 + u^4$$

In general the method works as follow: For $\Lambda \to \infty$ we want to solve an integral of the general form

$$\int \mathrm{d}x A(x) e^{(i)\phi(x)\Lambda}$$

One expands now around its extrema $\overset{4}{\frown} \phi'(x_0) = 0$ and obtains again an integral of "Gaussian times polynomial" typt 5^5

$$\begin{aligned} &= \sum_{x_0:\phi'(x_0)=0} \int \mathrm{d}x \left(A(x_0) + (x - x_0) A'(x_0) ...\right) e^{\Lambda\left(\phi(x_0)+(x-x_0)^2\phi''(x_0)+...\right)} \\ &= \sum_{x_0:\phi'(x_0)=0} A(x_0) e^{\Lambda\phi(x_0)} \sqrt{\frac{2\pi}{\phi''(x_0)\Lambda}} \left(1 + O\left(\frac{1}{\Lambda}\right)\right). \end{aligned}$$

[4] Notice that in field theory $\phi'(x) = 0$ is the equation of motion

[5] Corrections from $(x - x_0) A'(x_0)$ can be obtained by doing again the trick of smuggling an a into the exponent and write the term as derivative with respect of a evaluated at $a = 1$. In our case, the extrema of 31 are $u = 0$ and $u = \pm i/\sqrt{2}$. Expansion around the first yields the perturbative expansion of above. The other two yield contributions like $e^{\frac{1}{4\lambda}}$ that are invisible to a Taylor expansion around $\lambda = 0$, as all derivative vanish here. We have found an example of a "non-perturbative contribution".

The perturbative solution, however, gives meaningful results, as long as its terms are bigger than to the non-perturbative contributions. This allows an estimate, to what order in the perturbative series the expansion around $\lambda = 0$ dominates. This happens also to be the order at which the divergence from the exat solution starts as we are missing the non-perturbative terms:

$$\begin{aligned} e^{-\frac{1}{4\lambda}} &\approx \lambda^k \\ -\frac{1}{4\lambda} &\approx k \cdot \ln(\lambda) \\ k &\approx \frac{1}{\lambda} \end{aligned}$$

We have seen that the perturbative analysis of 30 requires as well expansions around the other extrema, besides $\lambda = 0$! Combining all power series together, the resulting perturbative solution has a chance to converge. Before we continue to the mathematical discussion of the problem how finite results can be obtained from divergent series, we will take a look on examples of non-perturbative contributions in physics.

Instantons

"Field configurations" contributing $e^{-\frac{1}{\sim\lambda}}$ are called "instantons". Usually these contributions are hard to calculate, in some situations, however, one can find the result. Consider for example a gauge theory [6]

$$S = \int \mathcal{L} = \int \frac{1}{g^2} \mathrm{tr}(F \wedge *F)$$

The stationary point we use for the expansion is given by the equations of motion

$$\mathrm{d}F = 0$$
$$\mathrm{d} * F = 0$$

The first equation (36a) is automatically fulfilled once we express the field-strength in terms of a vector potential $F = \mathrm{d}A$. The second 36 b is automatically solved if it happens that

$$F = *F.$$

One calls solutions to (37) instantons. In terms of the vector potential A (37) is a first order partial differential equation as compared to 336 b which is second order. One can easily see that there exist no solution in Lorentzian metric as the Hodge star squares to -1 on 2 -forms.

$$F = *F = * * F = -F.$$

In Euclidean metric, however, such solutions exist because of $* * F = F$. As it turns out (as one can for example argue using the Atiya-Singer index theorem), for

[6] Hodge $*$ operator: $*F^{\mu\nu} \equiv \epsilon^{\mu\nu\sigma\tau} F_{\sigma\tau}$. More details can be found in chapters 1.10 and 10.5 of 3]. a compact manifold M, the action in the instanton case yields an integer (up to a pre-factor):

$$\int_M \mathrm{tr}(F \wedge F) \in 8\pi^2 \mathbb{Z}$$

This leads to

$$e^{\frac{1}{g^2}\int \mathrm{tr}(F \wedge *F)} = e^{\frac{1}{g^2}\int \mathrm{tr}(F \wedge F)} = e^{-\frac{1}{g^2} 8\pi^2 N}$$

Dual theories

Sometimes a quantum field theory with coupling constant λ can be rewritten in terms of another (or possibly the same) quantum field theory with coupling $\tilde{\lambda} = 1/\lambda$. One calls such a relation between two theories a "duality". In many examples, such theories arise from string theory constructions, where the coupling λ can be given a geometric meaning. Imagine for example a problem of a quantum field theory on a torus. A torus can be viewed as $\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z})$ with $\tau \in \mathbb{C}\backslash\mathbb{R}$. The torus has a basis of two non-contractible circles, one that goes along the real axis from 0 to 1 and one that goes from 0 to τ. This choice of basis, however, is not unique: For example, swapping these cycles corresponds to a substitution $\tau \to -1/\tau$. If the torus parameter τ is identified with the coupling strength a duality has been found since both τ and $-1/\tau$ describe geometricaly the same torus! To make contact with our discussion above, we should identify λ with the imaginary part of τ. The duality allows for a Taylor expansion of the non-perturbative contributions via

$$e^{-\frac{1}{4\lambda}} = e^{-\frac{\tilde{\lambda}}{4}} = \sum_k^\infty \frac{(-\tilde{\lambda})^k}{k! 4^k}$$

Troublesome terms in one theory are therefore perfectly defined in the dual theory. The caveat however is the difficulty of actually proving that $\lambda \to 1/\lambda$ is a symmetry of the quantum field theory at hand.

Asymptotic series and Borel summation

In the following, we take a look on the mathematical situation of asymptotic series. This discussion is based on chapter XII of 4].

Definition 1 Let $f : \mathbb{R}_{\geq 0} \to \mathbb{C}$. The series $\sum_n^\infty a_n z^n$ is called asymptotic to f as $z \searrow 0$ iff

$$\forall N \in \mathbb{N} : \lim_{z \searrow 0} \frac{f(z) - \sum_n^N a_n z^n}{z^n} = 0$$

For $z \in \mathbb{C}$ a analog definition is possible.

Obviously, every function can have at most one asymptotic expansion. This can be seen by assuming two asymptotic expansions a_n and $\tilde{a}_n$.42 requires that $a_n = \tilde{a}_n$. Otherwise, let n be the smallest index for which $a_n \neq \tilde{a}_n$ and

$$\lim_{z \searrow 0} \frac{\sum_k (a_k - \tilde{a}_k) z^k}{z^n} = a_n - \tilde{a}_n \stackrel{!}{=} 0.$$

The other way around is not true, as can be seen by $f(z) = e^{-\frac{1}{z}}$ and $\tilde{f}(z) = 0$ having both the asymptotic series $\sum_k^\infty 0 \cdot z^k$. This means that knowing the asymptotic series of a function tells us nothing about $f(z)$ for a non vanishing z, we only know how $f(z)$ approaches $f(0)$ as $z \searrow 0$.

We try to find a stronger definition of an asymptotic series, allowing us to uniquely recover one function. The following theorem helps us to find the necessary conditon:

Theorem 2 (Carleman's theorem) Let g be an analytic function in the interior of $S = \left\{z \in \mathbb{C} || z| \leq B, |\arg z| \leq \frac{\pi}{2}\right\}$ and continous on S. If for all $n \in \mathbb{N}$ and $z \in S$ we have $|g(z)| \leq b_n |z|^n$ and $\sum_n^\infty b_n^{-\frac{1}{n}} = \infty$, then g is identically zero.

A simpler special case of the theorem is found by considering g an analytic function in the interior of $S_\epsilon = \left\{z \in \mathbb{C} || z| \leq R,\ |\arg z| \leq \frac{\pi}{2} + \epsilon\right\}$ for some $\epsilon > 0$ and continous on S_ϵ. If there exist C and B so that $|g(z)| < CB^n n! |z|^n \forall z \in S$ and $\forall n$, then g is identically zero.

In order to find a unique function for an asymptotic series, we use Carleman's theorem to define "strong asymptotic series".

Definition 3 Let f be an analytic function on the interior of $S_\epsilon = \left\{z \in \mathbb{C} || z| \leq R, |\arg z| \leq \frac{\pi}{2} + \epsilon\right\} \to \mathbb{R}$. The series $\sum_n^\infty a_n z^n$ is a strong asymptotic series if there exist C, σ so that $\forall N \in \mathbb{N}, z \in S_\epsilon$ the strong asymptotic condition

$$\left| f(z) - \sum_n^N a_n z^n \right| \leq C \sigma^{N+1} (N+1)! |z|^{N+1}$$

is fulfilled.

This means, if we are given a strong asymptotic series, we can recover by theorem 2 the function! Assume for example $\sum_n^\infty a_n z^n$ is a strong asymptotic series for two functions f and g, respectively. Then

$$|f(z) - g(z)| \leq 2C\sigma^{N+1}(N+1)!|z|^{N+1} \Rightarrow f = g$$

The strong asymptotic condition (44) implies $|a_n| \leq C\sigma^n n\,!$. This is precisely the growth behavior of 24 we found in our toy example, where $C = \frac{1}{\sqrt{2\pi}}$ and $\sigma = 4$. The necessary conditions, therefore, are fulfilled in our toy model (assuming analyticity away from 0 of course).

By now, we learned that a strong asymptotic series (in particular the type we obtain in quantum field theory) although not converging has the chance to be a unique approximation to one function. The final question is, how one can obtain this function f from its strong asymptotic series. In the last theorem we introduce the method of "Borel summation" to obtain a final result. We can define a convergent series by taking out a factor of $n\,!$ from the coefficients:

Theorem 4 (Watson's theorem) If $f : S_\epsilon \to \mathbb{R}$ has a strong asymptotic series $\sum_n^\infty a_n z^n$, we define the Borel transform

$$g(z) = \sum_n^\infty \frac{a_n}{n!} z^n$$

The Borel transform converges for $|z| < \frac{1}{|\sigma|}$. We obtained a convergent power series with finite radius of convergence, which, as it turns out, can be analytically continued to all complex $z \in \mathbb{C}$ with $|\arg z| < \epsilon$. Then the function f is given by the Laplace transform

$$f(z) = \int_0^\infty \mathrm{d}b g(bz) e^{-b}.$$

This Laplace transform is called "inverse Borel transform" and the method outlined here is known as "Borel summability method". It describes how to obtain a finite answer from divergent series, that is formally a sum for the series.

Let us make a sanity check. Using $\int_0^\infty \mathrm{d}x x^k e^{-x} = k\,!$ we can plug the definition of the Borel transform into 47), formally interchange the sum and the integration and obtain

$$f(z) = \int_0^\infty \mathrm{d}b g(bz) e^{-b} = \int_0^\infty \mathrm{d}b \sum_n \frac{a_n}{n!} b^n z^n e^{-b} \text{"} = \text{"} \sum_n a_n z^n.$$

So at least for analytic functions we do recover the original function.

Summary

We have learned why for $N < \mathcal{O}\left(\frac{1}{\lambda}\right)$ the sum of the first N terms of the perturbation expansion is numerically good, even when the original series $\sum_n a_n z^n = \infty$ diverges. This way we approximate the true function up to instantonic terms of the order of $e^{1/\lambda}$ which a Taylor expansion cannot resolve. Given that the coefficients a_n obey the strong asymptotic condition $|a_n| \leq C\sigma^n n\,!$, which is usually the case when using Feynman diagrams, the Borel transform exists and one can compute the Borel summation. Unfortunately this is more a theoretical assurance that perturbation theory can be given a mathematical meaning even though it does not converge, since in order to really compute the integral (47) one has to know the analytic continuation of g which requires knowledge of all coefficients a_n and not just the first N.

13.0.8 Regularization and Renormalization as Extensions of Distributions

from "How I Learned to Stop Worrying and Love QFT" 2011 by Robert C. Helling

In the previous section, we learned how to make sense of (some) divergent series of the form $\sum_{k=0}^{\infty} a_k = \infty$, but in QFT the factors a_k are typically complicated mathematical expressions described by Feynman diagramms, and generically, these expressions diverge themselves, creating a need for renormalization techniques.

A typical example of a divergent diagramm (in 4 dimensions) is shown in Figure 4

The term described by this diagramm reads (without unimportant factors):

$$\int d^4k \frac{1}{k^2+m^2} \frac{1}{(p_1+p_2+k)^2+m^2} \overset{k\gg p,m}{\longrightarrow} \int \frac{k^3 dk}{k^4} = \infty$$

where m denotes the mass of the scalar particles we are scattering. This integral obviously diverges logarithmically for $k \to \infty$ as shown above. The most straightforward approach to this problem is to introduce a cut-off energy-scale Λ, such that the divergence at the upper boundary becomes

$$\int^{\Lambda} \frac{k^3 dk}{k^4} \sim \log(\Lambda)$$

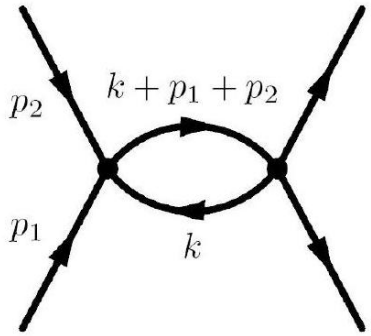

Figure 4: Divergent 1-loop diagramm

Usually, such blunt cut-off regularization is incompatible with the symmetries of the theory at hand and is thus only useful to estimate "how divergent" a diagram is (a notion we will below formalize as the "singular degree") and has to be replaced by more sophisticated methods like dimensional or Pauli-Villars regularization in more practical applications.

In these notes, instead of momentum representation, we will work in position space where instead of loop momenta one integrates over the position of the interaction vertices.

What was $1/(k^2+m^2)$, is now the propagator G defined by the equation

$$\left(\Box + m^2\right) G(x) = \delta(x)$$

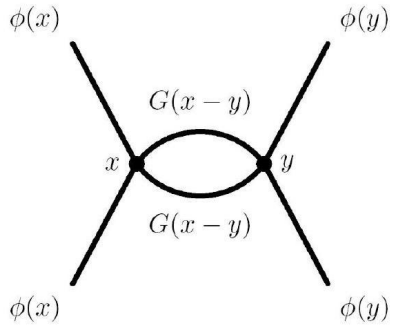

Figure 5: Divergent 1-loop diagramm in position-space language

we can compute the same diagramm in position space language, which then reads (see Figure 5):

$$\int d^4x \int d^4y \phi_0^2(x) G^2(x-y) \phi_0^2(y) = \int d^4x \int d^4u \phi_0^2(x) G^2(u) \phi_0^2(x-u)$$

The approach of "causal perturbation theory" or "Epstein-Glaser regularization" is to take seriously the fact that the propagator is really a distribution and in the above expression, we are trying to multiply distributions which in general is undefined. This approach is advocated in the book by Scharf [5]. Here, we will follow (a simplified, flat space version) of [6] and in particular [7.

Specifically, in the defining equation δ is not a function but a distribution (physicists writing $\delta(x)$ are trying to imply that this is the kernel of the distribution δ, i.e. that δ arises by muliplying the testfunction by a function $\delta(x)$ and then integrating over x, which of course does not exist). Thus, we should interpret $G(x)$ as a distribution as well (a priori it is only a weak solution of the differential equation (49)). But as it is in general not possible to multiply distributions, as we will see later, we do not have a naive way to obtain " G^2 " as a distribution. In this chapter, our goal will be to understand renormalization techniques in terms of distributions. Our route will be led by the question how to define the product of two distributions that are almost everywhere functions (which can be multiplied). We will first, therefore, recapitulate what distributions actually are. Then, we will see in which cases it is possible to multiply distributions and in which it is not. This will lead us to the renormalization techniques we are searching for.

Recapitulation of distributions

Distributions are generalized functions. Like in many other cases of generalizations this is done via dualization: Starting from an ordinatry function f (in our case locally integrable, that is $f : \mathbb{R}^n \to \mathbb{C}$ with $\int\limits_K |f| < \infty$ for each compact $K \subset \mathbb{R}^n$, so that "divergence of the integral $\int |f|$ at infinity" is tolerated) one can view it as a linear functional T_f (called a "regular distribution") on the functions of compact support via

$$T_f : \phi \mapsto \int f\phi$$

As the map $f \mapsto T_f$ is injective we can use the T_f 's to distinguish the different f 's and view T_f in place of f. This suggests to generalize the construction to all linear functionals $T : \phi \mapsto T(\phi)$ called distributions of which the regular ones arising from functions f as above are a subset.

Specifically, distributions are defined to be linear and continuous functionals on the space of test functions $D(\mathbb{R}^n) = \mathcal{C}_0^\infty(\mathbb{R}^n)$ (the subscript 0 meaning compact support) equipped with an

appropriate topology that will not concern us here. So formally, we can denote the distributions to be elements of a space:

$$D'(\mathbb{R}^n) = \{T : D(\mathbb{R}^n) \to \mathbb{C} | T \text{ is linear and continuous } \}$$

Besides the regular distibutions T_f encountered above (of which the function f is called the kernel) the typical example of a singular distribution is the δ-distribution: if we take a given test function $\phi(x) \in D$, then the δ-distribution is defined to be the functional $\delta[\phi] = \phi(0)$. This distribution is not regular even though physicists pretend it to be with a kernel $\delta(x)$ that is so singular at $x = 0$ that $\int \delta(x) = 1$ even though it vanishes for all $x \neq 0$.

Later, we will make use of the fact that distributions can be differentiated. Using integration by parts in the integral representation of a regular distribution, we easily obtain $T_{f'}[\phi] = -T_f[\phi']$ which enables us to define the derivative of a distribution to be $T'[\phi] \equiv -T[\phi']$. Thus we can take the derivative of a regular distribution T_f even if the kernel f is not differentiable.

The only operation defined on functions that does not directly carry over to distributions is (pointwise) multiplication $(f \cdot g)(x) = f(x)g(x)$. Already L^1_{loc} is not closed under multiplication (recall that in order for a function to be in L^1_{loc} it must not have singularities that go like $1/x^\alpha$ with $\alpha \geq 1$, a property not stable under multiplication) and in general the product of distributions is not defined. Of course, as long as with f and g also $f \cdot g \in L^1_{\text{loc}}$ we still have the regular distribution $T_{f \cdot g}$ and, from a technical perspective, in this sections, we will deal with the problem to extend a distribution that can be written as $T_{f \cdot g}$ for a subset of test functions (those that vanish where $f \cdot g$ is too singular to be in L^1_{loc}) to all test functions.

To this end, for any distribution $T \in D'$ we define the singular support of T (singsupp(T)) as the smallest closed set in $\mathbb{R}^n$ such that there exists a function $f \in L^1_{\text{loc}}$ with $T[\phi] = T_f[\phi]$ for all $\phi \in D$ with $\operatorname{supp}\phi \cap \text{singsupp}(T) = \emptyset$. For example singsupp$(\delta) = \{0\}$, and the corresponding function $f \in L^1_{\text{loc}}$ is simply $f(x) = 0$. So the idea behind this definition is that every distribution can be written as regular distributions as long as it is only applied to test functions which vanish in a neighbourhood of the distribution's singular support, which enables us to multiply distributions if we manage to take care of the singular support.

Definition of G^2 in $D'(\mathbb{R}^4 \backslash \{0\})$

Coming back to our concrete field-theoretic problem for a moment, we now have to answer one important question: what is the singular support of G? Here, we can utilize the fact that $\Box + m^2$ is an elliptic operator $\Box$[7] and it can be shown that if two distributions T and S are related by $\sigma T = S$ with an elliptic operator σ, then singsupp$(T) \subset$ singsupp(S), so we immediately see singsupp$(G) \subset \{0\}$.

It is clear that the singularity of $G(x)$ at $x = 0$ corresponds to the divergence of the momentum-integral at high energies $\Lambda \to \infty$, because in order to probe small distances, short wavelengths which correspond to high momenta are needed, therefore we speak of UV-divergencies. In this regime, we can set $m^2 \approx 0$, and so (49) simplifies to $\Box G(x) = \delta(x) \Rightarrow G(x) \sim \frac{1}{x^2}$ for small $x\Box$[8]

Using this, we see that the position-space integral $\int\limits_{|x| > \frac{1}{\Lambda}} d^4x G^2(x)$ again diverges as $\log(\Lambda)$. Because of this divergence $G^2(x) \notin L^1_{\text{loc}}(\mathbb{R}^4)$, so G^2 is still not defined as distribution in $D'(\mathbf{R}^4)$. Nevertheless, we can use $G^2(x)$ as kernel of a distribution in $D'(\mathbf{R}^4 \backslash \{0\}) = \{T : D(\mathbb{R}^4 \backslash \{0\}) \to \mathbb{C} \mid$ linear and continuous $\}$ where $D(\mathbb{R}^4 \backslash \{0\})$ is the set of test functions with $\{0\} \notin \operatorname{supp}\phi$.

We now managed to define a distribution G^2, but we still have to extend it from $D(\mathbb{R}^4 \backslash \{0\})$ to $D(\mathbb{R}^4)$. Formally, as a linear map, we have to say what values the extension takes on

$D(\mathbb{R}^4)/D(\mathbb{R}^4\backslash\{0\})$ which is still an infinite dimensional vector space. To control this infinity, we will use the scaling degree.

The scaling degree and extensions of distributions

Consider a scaling-map Λ acting on test functions:

$$\begin{aligned}\mathbb{R}_{>0}\times D(\mathbb{R}^n)&\to D(\mathbb{R}^n)\\(\lambda,\phi)&\mapsto \phi_\lambda(x)\equiv\lambda^{-n}\phi\left(\lambda^{-1}x\right)\end{aligned}$$

[7] Explaining it without going into details, a differential operator which is defined as polynomial of $\vec{\partial}$ (with possible coordinate dependent coefficients) is elliptic if it is non-zero if we replace $\vec{\partial}$ with any non-zero vector $\vec{y}$. In our euclidian examples, $\Box=\sum_{i=1}^{4}\partial_i^2\to|\vec{y}|^2>0$ foy any non-zero $\vec{y}$

[8] The relation $\delta(\vec{x})=-\frac{1}{4\pi}\Box\frac{1}{|\vec{x}|}$ is well known to hold in 3 dimensions. In general, $\Box|x|^{2-n}\propto\delta$ in n dimensions The pullback of this map to the space distributions reads

$$(\Lambda^*T)[\phi]=T[\phi_\lambda]\equiv T_\lambda[\phi]$$

which for regular distributions gives

$$T_{f,\lambda}[\phi]=\int\frac{d^nx}{\lambda^n}f(x)\phi\left(\frac{x}{\lambda}\right)=\int d^nxf(\lambda x)\phi(x),$$

so power of λ in the scaling map acting on test functions is chosen such that the kernel f transforms in a simple manner without prefactor. We now define the scaling degree (sd) of $T\in D'(M\subset\mathbb{R}^n)$

$$sd(T)=\inf\left\{\omega\in\mathbb{R}|\lim_{\lambda\searrow0}\lambda^\omega T_\lambda=0\right\}$$

To understand this definition, we have to note several properties:

- $sd(T)\in[-\infty,\infty[$
- For regular distributions $sd(T_f)\leq0$
- $sd(\delta)=n$
- $sd(\partial^\alpha T)\leq\mathrm{sd}(T)+|\alpha|$ with some multi-index α
- $sd(x^\alpha T)\leq sd(T)-|\alpha|$ with some multi-index a[9]
- $sd(T_1+T_2)=\max\{sd(T_1),sd(T_2)\}$

This leads us to the following important theorem:

Theorem 5 If $T_0\in D'(\mathbb{R}^n\backslash\{0\})$ is a distribution with $\mathrm{dd}(T_0)<n$, then there is a unique distribution $T\in D'(\mathbb{R}^n)$ with $sd(T)=\mathrm{sd}(T_0)$ extending T_0.

The proof of uniqueness is quite easy: We do it by assuming the existence of two solutions T and $\tilde{T}$ extending T_0, and showing a contradiction. Obviously supp(T - $\tilde{T}$) = $\{0\}$ and from this it follows that $T-\tilde{T}=P(\partial)\delta$ with some polynomial P. As can be seen from the above notes, $sd(P(\partial)\delta)\geq n$ and this would be a contradiction to $sd(T)=sd(\tilde{T})=sd(T_0)<n$. Existence is

shown constructively using a smooth cut-off function $c_\epsilon(x)$ that is 1 outside a ball of radius 2ϵ and and vanishes in a ball of radius ϵ. Then we can define

$$T[\phi] = \lim_{\epsilon \searrow 0} T_0 \left[c_\epsilon \phi\right]$$

where one still has to show that the above limit exists in the sense of distributions.

The theorem above now enables us to uniquely extend distributions of low scaling degree to the full space $D'\left(\mathbb{R}^n\right)$, but what about distributions with scaling degree $\geq n$? We will solve this problem in the next section, and afterwards we will be able to return to our field-theoretic problem of understanding the nature of G^2.

But first we have to determine what the scaling degree of the massive propagator G, defined by $\delta = (\Box + m^2)\, G$. We know that $\mathrm{sd}(\delta) = n$, and therefore $\mathrm{sd}((\Box + m^2)\, G) = n$ too. If we denote $\mathrm{sd}(G)$ by w, from the above items it follows that $sd(\Box G) = w + 2, sd\left(m^2 G\right) = w$ and therefore $sd\left((\Box + m^2)\, G\right) = w + 2$. From this it follows that $w = n - 2$ even for the massive propagator.

[9] Remember that distributions do not depend on coordinates, only their kernels. Here we used the definition $\left(x^\alpha T\right)[\phi] \equiv T\left[x^\alpha \phi\right]$

Case of distributions with high scaling degree

Considering now a distribution $T_0 \in D'\left(\mathbb{R}^n \backslash \{0\}\right)$ with $sd\left(T_0\right) \geq n$, uniqueness as in the above theorem does not hold anymore. But if we take a test function $\phi \in D(\mathbb{R})$ which vanishes of order $\omega \equiv sd\left(T_0\right) - n$ ("singular order") at $x = 0$, i.e. which can be written as $\phi(x) = \sum_{|\alpha| = \lfloor \omega \rfloor + 1} x^\alpha \phi_\alpha(x)$ where $\phi_\alpha(0)$ is finite and $\lfloor \omega \rfloor$ denotes the largest integer not bigger than ω, we can define $T[\phi] \equiv \sum_{|\alpha| = [\omega] + 1} \left(x^\alpha T_0\right)[\phi_\alpha]$. Then the distribution $x^\alpha T_0$ has scaling degree less than n and can thus be uniquely extended.

A general test function can of course be written as a sum of a function vanishing of order ω and a polynomial of degree at most ω by subtracting and adding the order ω Taylor polynomial at $x = 0$:

$$\phi_s(x) \equiv \phi(x) - \sum_{|\alpha| \leq \omega} \frac{x^\alpha}{|\alpha|!} \partial^\alpha \phi(0)$$

This procedure of subtracting the terms leading to divergencies is the regularization in this framework. Since the extended distribution T beeing applied to ϕ_s is unique, by linearity, we still have to define T only on the monomials in x of maximal degree ω. There is no further restriction on doing this and this ambiguity in the extension T is what one would have expected: Changing the value of T on a monomial x^α correspond to adding a multiple of $\partial^\alpha \delta$ to T.

Note well that the arbitratry values of $T\left[x^\alpha\right]$ are exactly those where $T_0\left[x^\alpha\right]$ was undefined (divergent in physicists' parlance) and selecting a certain value corresponds to picking a counter term. procedure known as renormalization, as formally infinite values are replaced by finte ones (that have to be fixed by further physical input like the measurement of the "physical mass" or the physical "coupling constant"). In the following small sections, we will try out this method in a few easy, concrete examples.

Example in $n = 1$

In order to let our steps so far become clearer, we are going to apply them to a simple example in $n = 1$. In fact, this example shows already the full regularization and renormalization procedure.

As can be easily checked, the function $f(x) = \frac{1}{|x|}$ is not an element of $L^1_{loc}(\mathbb{R})$ because of its pole at $x = 0$ is not integrable (it is of course log-divergent), so we can not a priori use it as kernel of a distribution $T_f \in D'(\mathbb{R})$ as we have seen in section 3.1. But $f(x) \in L^1_{loc}(\mathbb{R}\backslash\{0\})$ and $sd\,(T_f) = 1 = n$, therefore $\omega = 0$. This means that for a test function $\phi(x)$ with $\phi(0) = 0$ we can define $T_f[\phi] \equiv \int dx \frac{\phi(x)}{|x|}$ which gives a finite result: Using l'Hôpital's rule, we see $\lim_{x\to\pm 0} \frac{\phi(x)}{|x|} = \lim_{x\to\pm 0} \frac{\phi'(x)}{\mathrm{sign}(x)} =$ finite and thus the integrand is finite everywhere. This is similar to what we have done in sections 3.2 and 3.3. For other test functions, we can again (as in this section above) define $\phi_s(x) \equiv \phi(x) - \phi(0)$. Afterwards, we write the general extension for a distribution acting on ϕ as $T_f[\phi] \equiv T_f\,[\phi_s] + c\phi(0)$ with one arbitrary constant c of our choice.

The careful reader will have realised that there is still a problem as ϕ_s fails to have compact support when $\phi(0) \neq 0$ and thus the integration now diverges at the boundary $x \to \pm\infty$. We will deal with this problem below but the important observation is that the divergence in the ultraviolet, that is at small x is cured.

Example in $n = 4$

In our field theoretic problem 50 from above, we have $G^2 \sim \frac{1}{x^4}$ in $\mathbb{R}^4$ which is quite similar to the previous example, as it is the kernel of a distribution $T_{G^2} = T_{\frac{1}{x^4}} \in D'\left(\mathbb{R}^4\backslash\{0\}\right)$. Again, we are looking for an extension. Once more, we have $sd\,(G^2) = 4 = n$. Regularization and renormalization are as in the example above and yield

$$T^r_{\frac{1}{x^4}}[\phi] = \int d^4x \frac{\phi(x) - \phi(0)}{x^4} + c\delta[\phi]$$

with $T^r_{\frac{1}{x^4}} \in D'\left(\mathbb{R}^4\right)$ and arbitrary c. Again, we successfully got rid of the problems at $x = 0$ (at the cost of introducing one constant c).

This concludes our calculation of the fish diagram Fig. 4 that computes a contribution of the form $\phi(x)^2\phi(y)^2$ to the effective action of the theory. Since the ambiguous term we found is $c\delta(x-y)$, the ambiguity in the effective action is indeed $\phi(x)^4\delta(x-y)$. We see, that it corresponds to the counter term Fig. 6 and renormalizes the coupling constant (the coefficient of the ϕ^4-term in the action).

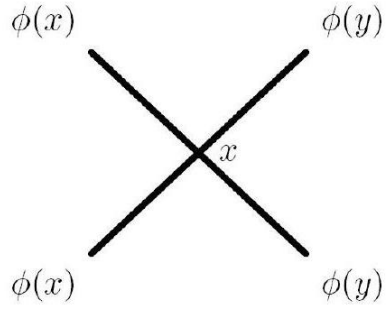

Figure 6: Counter-term diagramm.

Example with $sd(T) > n$ and preservation of symmetry

In the two examples above, we had both times distributions T with $sd(T) = n$ which led us to the introduction of one arbitrary constant c. This amount of ambiguity increases with $sd(T)$, but not all possible polynomials $P(\partial)\delta$ allowed by the counting can arise physically. In particular, we require that our theory is still Lorentz invariant after renormalization and if it has a local gauge symmetry before that needs to be maintained as well (otherwise one has an anomaly that renders the theory illdefined at the quantum level since the number of degrees of freedom changes upon renormalization).

Let us consider one example where SO(4) invariance (the euclidian version of the Lorentz group SO(3, 1)) selects a subset of the possible counter terms.

In a theory with potential $\propto \phi^4$ (quartic interaction), there cannot only be diagramms like Figure 4 but also such ones like Figure 7 known as the setting sun diagram.

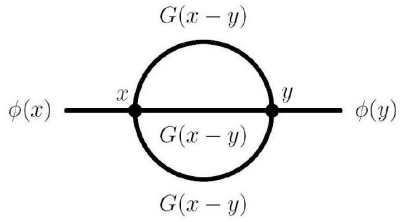

Figure 7: Setting sun diagramm in quartic interaction

The term encoded by this diagramm obviously contains $G^3 \sim \frac{1}{x^6}$, which has $sd\left(G^3\right) = 6 > n = 4$. By performing the same steps as above, in this case we a priori get an ambiguity $c_1\delta + c_2^i\partial_i\delta + c_3^{ij}\partial_i\partial_j\delta$ with in total $1 + 4 + \frac{4(4+1)}{2} = 15$ arbitrary constants, but upon imposing SO(4)-invariance this reduces to $c_1\delta + c_3\Delta\delta$ with only 2 arbitrary constants.

In the effective action, as above, they contribute to the quadratic terms (as the diagram Fig. 7 has two external lines) $\phi(x)\left(c_1\delta(x-y) + c_3\Delta\delta(x-y)\right)\phi(y) = \phi(x)\left(c_3\Delta + c_1\right)\phi(x)\delta(x-y)$. We recognize that c_3 is a wave function renormalization while c_1 renormalizes the mass-term $m^2\phi^2$.

The fact that ϕ^4-theory is renormalizable in $n = 4$ means that these two counter terms and the one in the previous subsection are the only ambiguities that arise when any Feynman diagram of the theory is renormalized, a proof of being well beyond the scope of these notes.

Regaining compact support and RG flow

In the above calculations, we ignored an important problem: $\phi_s(x) = \phi(x) - \phi(0)$ is not necessarily a test function, as it obviously has $\lim_{x\to\infty} = -\phi(0)$, therefore for example the integral $\int dx \frac{\phi(x)-\phi(0)}{|x|}$ that we encountered in section 3.4.1 may diverge at infinity. We can solve this by introducing a function $w(x) \in D\left(\mathbb{R}^n\right)$ with (without loss of generality) $w(0) = 1$. We then change the regularized part (i.e. the part without arbitrary constants) of the integral in (54) to

$$T_{\frac{1}{|x|}}[\phi] \equiv \int dx \frac{\phi(x) - w(x)\frac{\phi(0)}{w(0)}}{|x|}.$$

This is a special case of the general formula

$$\phi_s(x) \equiv \phi(x) - \sum_{|\alpha|\leq\omega} \frac{x^\alpha w(x)}{|\alpha|!}\left(\partial^\alpha \frac{\phi(x)}{w(x)}\right)\Bigg|_{x=0}$$

which replaces equation (53). Starting from (55) we can now write

$$T_{\frac{1}{|x|}}[\phi] = \int dx \frac{w(x)(\phi(x)-\phi(0))}{|x|} + \underbrace{\int dx \frac{(1-w(x))\phi(x)}{|x|}}_{=T_{\frac{1-w(x)}{|x|}}[\phi]}.$$

The second term already is a perfectly fine distribution, the first term can be manipulated in the following way:

$$\int dx \frac{w(x)(\phi(x)-\phi(0))}{|x|} = \int dx \frac{w(x)}{|x|} \int_0^x du \phi'(u)$$

Now, in the inner integral we can substitute $u = tx$ and afterwards interchange the integrals:

$$\int dx \frac{w(x)}{|x|} \int_0^1 dt x \phi'(tx) = \int_0^1 dt \int dx \, \mathrm{sign}(x) w(x) \phi'(tx)$$

After this, we can substitute $y = tx$ in the inner integral, giving us

$$\begin{aligned}
&\int_0^1 dt \int \frac{dy}{t} w\left(\frac{y}{t}\right) \mathrm{sign}\left(\frac{y}{t}\right) \phi'(y) \\
&= \int dy \underbrace{\int_0^1 \frac{dt}{t} w\left(\frac{y}{t}\right) \mathrm{sign}(y)}_{\equiv f(y)} \phi'(y) \\
&= T_f[\partial\phi] = -\left(\partial T_f\right)[\phi].
\end{aligned}$$

So also the first term is a good distribution. The function $f(y)$ defined above as function of y is well behaved, as $w(x)$ which enters its definition is a test function, and therefore extremely well behaved, in particular vanishes for large arguments, so taking $t \to 0$ does not introduce problems.

As an example, let us now set $w(x) = \theta(1 - M|x|)$ (or actually a smoothed out version of this non-continuous function)

$$\begin{aligned}
f(y) &= \int_0^1 \frac{dt}{t} \theta\left(1 - M\frac{|y|}{t}\right) \mathrm{sign}(y) \\
&= \int_{M|y|}^1 \frac{dt}{t} \theta(1 - M|y|) \, \mathrm{sign}(y) \\
&= -\ln(M|y|)\theta(1 - M|y|) \, \mathrm{sign}(y)
\end{aligned}$$

Morally, we regularized our distribution with non-integrable kernel $\propto \frac{1}{|x|}$ by substituting the derivative of a distribution with kernel $\propto \log(|y|)$, which is integrable.

In the above calculations, we introduced a mass/energy-scale M. It is now an important question to ask how the distribution changes under transformations of this scale, i.e. renormalization

group (RG) transformations generated by $M\frac{\partial}{\partial M}$, so called RG flows. We will now show that it is only the part const $\delta(x)$, i.e. the part that is fixed by arbitrary renormalization constants that will change.

First of all, using $\partial_x \operatorname{sign}(x) = 2\delta(x)$, we see:

$$f'(x) = \frac{-1}{x}\theta(1 - M|x|)\operatorname{sign}(x) - \log(M|x|)\theta(1 - M|x|)2\delta(x)$$

Then, we start with:

$$M\frac{\partial}{\partial M}T_{\frac{1}{|x|}}[\phi] = M\frac{\partial}{\partial M}\left(\int dx\frac{(1 - w(x))\phi(x)}{|x|} + T_{-\partial f}[\phi]\right)$$

Because of $\frac{1-w(x)}{|x|} = \frac{\theta(M|x|-1)}{|x|}$ in our example, the first term becomes a distribution with kernel

$$M\frac{\partial}{\partial M}\frac{\theta(M|x| - 1)}{|x|} = M\delta(M|x| - 1).$$

The second term in contrast becomes a distribution with kernel

$$M\frac{\partial}{\partial M}\left(-f'(x)\right) = -M\delta(M|x| - 1) + M\frac{\partial}{\partial M}[2\log(M|x|)\theta(1 - M|x|)\delta(x)]$$

The first term of this expression obviously cancels with the contribution from (56), so $M\frac{\partial}{\partial M}T_{\frac{1}{|x|}}$ turns out to be a distribution with kernel:

$$\begin{aligned}
&M\frac{\partial}{\partial M}[2\log(M|x|)\theta(1 - M|x|)\delta(x)] \\
&= 2\delta(x)[\theta(1 - M|x|) - \log(M|x|)M\delta(1 - M|x|)|x|] \\
&= 2\delta(x)
\end{aligned}$$

In the last step, we used the presence of the factor $\delta(x)$ (under an integral!) to set $\log(M|x|)|x| = 0$ and $\theta(1 - M|x|) = 1$. So, under a renormalization group transformation, the distribution changes by $\delta T \propto \text{const} \cdot\delta(x)$, that means that a change of energy-scale corresponds to a change of the (at the beginning) arbitrarily selected renormalization coefficients.

What we have achieved in this section

We have seen a way to recast what looks like divergent Feynman diagrams as to what looks like distributions for non-integrable functions. We could then turn these into proper distributions by first restricting the space of test-functions and then extend them to a full distribution, possibly at the price of a finite number of undetermined numerical constants. Those have to be determined by a finite number of measurements.

In order for the number of introduced parameters for all Feynman diagrams of the theory to be finite, the scaling degrees of all appearing distributions in all diagramms have to be below some maximum, otherwise the theory is not renormalizable.

Summary

The material in these notes will not be useful for any concrete calculation in quantum field theory that a physicist might be interested in. But they might give him or her some confidence that the calculation envisaged has a chance to be meaningful.

We tried to present material that is in no sense original but still is probably not covered in most introductions to quantum field theory. Hopefully, it helps to refute some of the prejudices against (perturbative) quantum field theory that mathematically minded people may have and helps others to better understand how far the hand waving arguments that we use in our daily work can carry.

In particular, we put our emphasis on two points: Even if the perturbative expansion is divergent as a power series it can serve two purposes: The first terms do provide a numerically good approximation to the true, non-perturbative result and all terms taken together can indeed recover the full result but only in terms of Borel resummation rather than as a power series. Second, unphysical in

nite momentum integrals in the computation of Feynman diagrams can be avoided when properly expressed in terms of distributions. The renormalization of coupling constants is then expressed as the problem to extend a distribution from a subspace to all test functions. The language of distribution theory allows one to avoid mathematically ill-de

ned divergent expressions altogether.

13.0.9 On the Strict Formalism (??)

(тут суть всякой теории меры напишу, пока не до нее)

Пример, когда знать строгий формализм важно (!??!)

(хз, важный вопрос для определения, стоит ли этим заниматься?)

13.0.10 On Something Else (??)

(много дополнений будет, пока не до них)

13.1 Holomorphic Path Integral, S-Matrix, Scalar Field Theory

13.1.1 1. Creation and Annihilation Operators

Далее полагаем $\hbar = c = 1$.

Действие осциллятора (19 Л1) в случае нулевого источника приводит к следующему гамильтониану:

$$\mathcal{H}(p,q) = \frac{1}{2}p^2 + \frac{\omega^2}{2}q^2 \tag{1}$$

Введём комплексные взаимно сопряжённые переменные a, a^*:

$$q = \sqrt{\frac{1}{2\omega}}\,(a + a^*)\,, \quad p = -i\sqrt{\frac{\omega}{2}}\,(a - a^*) \tag{2}$$

В квантовой теории формулы (2) сохраняются для операторов и коммутационные соотношения

$$[q,q] = [p,p] = 0, \quad [q,p] = i \tag{3}$$

и

$$[a,a]=\left[a^{\dagger},a^{\dagger}\right]=0,\quad \left[a,a^{\dagger}\right]=1 \tag{4}$$

эквивалентны.

Перестановочные соотношения (4) имеют представление в пространстве аналитических и, более того, голоморфных функций $f\left(a^{*}\right)$ со скалярным произведением

$$\langle f_1|f_2\rangle=\int\left(f_1\left(a^{*}\right)\right)^{*}f_2\left(a^{*}\right)e^{-a^{*}a}\frac{\mathrm{d}a^{*}\ \mathrm{d}a}{2\pi i} \tag{5}$$

Пояснение. Можно считать, что

$$a=x+iy,\quad (a)^{*}=a^{*}=x-iy,\quad a^{*}a=x^{2}+y^{2}$$

Тогда

$$\left|\begin{array}{cc}\frac{\partial a^{*}}{\partial x} & \frac{\partial a^{*}}{\partial y}\\ \frac{\partial a}{\partial x} & \frac{\partial a}{\partial y}\end{array}\right|=\left|\begin{array}{cc}1 & -i\\ 1 & i\end{array}\right|=2i$$

Поэтому

$$\frac{\mathrm{d}a^{*}\ \mathrm{d}a}{2\pi i}=\frac{\mathrm{d}x\ \mathrm{d}y}{\pi}=\frac{\rho\mathrm{d}\rho\mathrm{d}\varphi}{\pi} \tag{6}$$

где (ρ,φ) - полярные координаты в плоскости (x,y)

Произведение (5) положительно определено. Действительно, произвольная голоморфная функция $f\left(a^{*}\right)$ является линейной комбинацией одночленов $\psi_n\left(a^{*}\right)=\left(a^{*}\right)^{n}/\sqrt{n!},n\geq 0$. Имеем:

$$\langle\psi_n|\psi_m\rangle=\frac{1}{\sqrt{n!m!}}\int a^{n}\left(a^{*}\right)^{m}e^{-a^{*}a}\frac{\mathrm{d}a^{*}\ \mathrm{d}a}{2\pi i}=\frac{1}{\sqrt{n!m!}}\int\limits_{0}^{\infty}\rho^{m+n+1}e^{-\rho^{2}}\ \mathrm{d}\rho\int\limits_{0}^{2\pi}e^{i(n-m)\varphi}\frac{\mathrm{d}\varphi}{\pi}=$$

$$=\frac{\delta_{n,m}}{n!}\int\limits_{0}^{\infty}\left(\rho^{2}\right)^{n}e^{-\rho^{2}}2\rho\mathrm{d}\rho=\delta_{n,m} \tag{7}$$

Поэтому множество функций $\left\{\psi_n\right\},n=0,1,...$ образует полный ортонормированный базис (ОНБ).

По определению, операторы $a^{\dagger}$ и a действуют согласно правилу

$$a^{\dagger}f\left(a^{*}\right)=a^{*}f\left(a^{*}\right),\quad af\left(a^{*}\right)=\frac{\mathrm{d}}{\mathrm{d}a^{*}}f\left(a^{*}\right) \tag{8}$$

Заметим, что

$$\frac{\mathrm{d}}{\mathrm{d}a^{*}}=\frac{1}{2}\left(\frac{\partial}{\partial x}+i\frac{\partial}{\partial y}\right),\quad \frac{\mathrm{d}}{\mathrm{d}a}=\frac{1}{2}\left(\frac{\partial}{\partial x}-i\frac{\partial}{\partial y}\right),\quad\longrightarrow\quad \frac{\mathrm{d}}{\mathrm{d}a^{*}}a^{*}=1,\quad \frac{\mathrm{d}}{\mathrm{d}a^{*}}a=0 \tag{9}$$

Согласно определениям скалярного произведения (5) и операторов $a^{\dagger},a$ (8) эти операторы взаимно сопряжены. Действительно,

$$a^{*}e^{-a^{*}a}=-\frac{\mathrm{d}}{\mathrm{d}a}e^{-a^{*}a},\quad \frac{\mathrm{d}}{\mathrm{d}a}f\left(a^{*}\right)=0$$

и потому

$$\left\langle f_1|a^\dagger f_2\right\rangle = \int \left(f_1\left(a^*\right)\right)^* a^* f_2\left(a^*\right) e^{-a^*a}\frac{\mathrm{d}a^*\ \mathrm{d}a}{2\pi i} = -\int \left(f_1\left(a^*\right)\right)^* f_2\left(a^*\right)\left(\frac{\mathrm{d}}{\mathrm{d}a}e^{-a^*a}\right)\frac{\mathrm{d}a^*\ \mathrm{d}a}{2\pi i} =$$
$$= \int \left[\frac{\mathrm{d}}{\mathrm{d}a}\left(f_1\left(a^*\right)\right)^* f_2\left(a^*\right)\right] e^{-a^*a}\frac{\mathrm{d}a^*\ \mathrm{d}a}{2\pi i} = \int \left[\frac{\mathrm{d}}{\mathrm{d}a^*}f_1\left(a^*\right)\right]^* f_2\left(a^*\right) e^{-a^*a}\frac{\mathrm{d}a^*\ \mathrm{d}a}{2\pi i} =$$
$$= \int \left[af_1\left(a^*\right)\right]^* f_2\left(a^*\right) e^{-a^*a}\frac{\mathrm{d}a^*\ \mathrm{d}a}{2\pi i} = \left\langle af_1|f_2\right\rangle$$

13.1.2 2. General Operators

В голоморфном представлении операторы общего вида описываются при помощи ядра. Пусть A - некий оператор и

$$A_{mn} = \langle\psi_m|A|\psi_n\rangle \tag{10}$$

- матрица этого оператора относительно введенного выше ОНБ. Ядром оператора A называется следующая функция:

$$A\left(a^*, a\right) = \sum_{n,m} A_{nm}\frac{\left(a^*\right)^n}{\sqrt{n!}}\frac{a^m}{\sqrt{m!}} \equiv \sum_{n,m} A_{nm}\left|\psi_n\right\rangle\left\langle\psi_m\right| \tag{11}$$

Основываясь на условии полноты $\sum\limits_n \left|\psi_n\right\rangle\left\langle\psi_n\right| = 1$, получаем следующие очевидные формулы:

$$\left(Af\right)\left(a^*\right) = \int A\left(a^*, \alpha\right) f\left(\alpha^*\right) e^{-\alpha^*\alpha}\frac{\mathrm{d}\alpha^*\ \mathrm{d}\alpha}{2\pi i}$$
$$\left(A_1A_2\right)\left(a^*, a\right) = \int A_1\left(a^*, \alpha\right) A_2\left(\alpha^*, a\right) e^{-\alpha^*\alpha}\frac{\mathrm{d}\alpha^*\ \mathrm{d}\alpha}{2\pi i}. \tag{12}$$

Теперь представим оператор A в виде нормально упорядоченного ряда относительно операторов рождения и уничтожения: $A = \sum\limits_{n,m} K_{n,m}\left(a^\dagger\right)^n a^m$. Функция операторов рождения и уничтожения называется нормально упорядоченной, если в этой функции все операторы рождения расположены левее всех операторов уничтожения. Сопоставим оператору A функцию

$$K\left(a^*, a\right) = \sum_{n,m} K_{nm}\left(a^*\right)^n\left(a\right)^m$$

которая называется нормальным символом этого оператора.

Докажем, что

$$A\left(a^*, a\right) = e^{a^*a}K\left(a^*, a\right) \tag{13}$$

Достаточно проверить (13) в частном случае $A = \left(a^\dagger\right)^k a^l$. Имеем:

$$A_{nm} = \frac{1}{\sqrt{n!m!}} \left\langle 0 \left| a^n \left(a^\dagger\right)^k a^l \left(a^\dagger\right)^m \right| 0 \right\rangle$$

Это выражение отлично от нуля лишь при $m \geq l$ и $n \geq k$ и $m - l = n - k$. Обозначим

$$\theta(m \geq l) = \begin{cases} 1, & \text{если } m \geq l \\ 0, & \text{если } m < l \end{cases}$$

При $m \geq l$

$$a^l \left(a^\dagger\right)^m |0\rangle = m(m-1)...(m-l+1) \left(a^\dagger\right)^{m-l} |0\rangle$$

Поэтому

$$A_{nm} = \delta_{m-l,n-k}\theta(m \geq l)\theta(n \geq k)\frac{\sqrt{m \cdot (m-1)...(m-l+1) \cdot n \cdot (n-1)...(n-k+1)}}{\sqrt{(m-l)!(n-k)!}} \times$$
$$= \sqrt{m \cdot (m-1)...(m-l+1)} \cdot \sqrt{n \cdot (n-1)...(n-k+1)} \cdot \theta(m \geq l)\theta(n \geq k) \cdot \delta_{m-l,n-k}$$

Теперь имеем:

$$A\left(a^*, a\right) = \sum_{m,n \geq 0} A_{mn} \frac{\left(a^*\right)^n}{\sqrt{n!}} \cdot \frac{a^m}{\sqrt{m!}} = \sum_{m \geq l} \sum_{n \geq k} \delta_{m-l,n-k} \frac{\left(a^*\right)^n a^m}{\sqrt{(n-k)!(m-l)!}} =$$
$$= \sum_{n \geq 0} \frac{1}{n!} \left(a^*\right)^{k+n} a^{l+n} = \left(a^*\right)^k a^l e^{a^* a} = e^{a^* a} K\left(a^*, a\right)$$

Тем самым формула (13) доказана.

13.1.3 3. Functional Integral in the Holomorphic Representation

Пусть функция $h\left(a^*, a\right)$ является нормальным символом оператора Гамильтона $\mathcal{H}\left(a^\dagger, a\right)$. Тогда ядро оператора эволюции

$$U = \exp(-i\Delta t \mathcal{H}), \quad \Delta t \to 0$$

согласно сказанному выше представляется как

$$U\left(a^*, a; \Delta t\right) = \exp\left\{a^* a - i h\left(a^*, a\right) \Delta t\right\} \tag{14}$$

Для произвольного интервала времени $t'' - t' = N\Delta t$:

$$U\left(a^*, a; t'', t'\right) = \int \exp\left\{\left[a_N^* a_{N-1} - a_{N-1}^* a_{N-1} + ... - a_1^* a_1 + a_1^* a_0\right] - \right.$$
$$\left. - i\Delta t \left[h\left(a_N^*, a_{N-1}\right) + ... + h\left(a_1^*, a_0\right)\right]\right\} \prod_{k=1}^{N-1} \frac{\mathrm{d}a_k^* \, \mathrm{d}a_k}{2\pi i}$$

Мы обозначили $a_0 = a, a_N^* = a^*$.
Теперь перейдём к пределу $N \to \infty, \Delta t \to 0$:

$$U\left(a^*,a;t'',t'\right)=\int e^{a^*(t'')a(t'')}\exp\left\{\int\limits_{t'}^{t''}\mathrm{d}t\left[-a^*\dot{a}-ih\left(a^*,a\right)\right]\right\}\prod_t\frac{\mathrm{d}a^*\ \mathrm{d}a}{2\pi i} \tag{15}$$

Граничные условия таковы:

$$a^*\left(t''\right)=a^*,\quad a\left(t'\right)=a \tag{16}$$

причём по переменным $a\left(t''\right)$ и $a^*\left(t'\right)$ идёт интегрирование. С учётом того что

$$-\frac{1}{2}\int\limits_{t'}^{t''}\mathrm{d}ta^*\dot{a}=\frac{1}{2}\int\limits_{t'}^{t''}\mathrm{d}t\dot{a}^*a-\frac{1}{2}a^*\left(t''\right)a\left(t''\right)+\frac{1}{2}a^*\left(t'\right)a\left(t'\right)$$

имеем для ядра оператора эволюции:

$$U\left(a^*,a;t'',t'\right)=\int\exp\left\{\frac{1}{2}\left[a^*\left(t''\right)a\left(t''\right)+a^*\left(t'\right)a\left(t'\right)\right]\right\}\times$$

$$\times\exp\left\{i\int\limits_{t'}^{t''}\mathrm{d}t\left[\frac{1}{2i}\left(\dot{a}^*a-a^*\dot{a}\right)-h\left(a^*,a\right)\right]\right\}\prod_t\frac{\mathrm{d}a^*\ \mathrm{d}a}{2\pi i}$$

Обратим внимание на то, что здесь интеграл по времени во второй экспоненте есть действие системы.

В случае гармонического осциллятора интеграл (15) как гауссов интеграл легко вычисляется. Так как

$$\eta q=\frac{\eta}{\sqrt{2\omega}}\left(a+a^*\right)$$

то гамильтониан гармонического осциллятора при наличии источника

$$h\left(a^*,a\right)=\omega\left(a^*a+1/2\right)-\frac{\eta}{\sqrt{2\omega}}\left(a+a^*\right) \tag{17}$$

Из (16) имеем:

$$\delta a^*\left(t''\right)=\delta a\left(t'\right)=0 \tag{18}$$

Поэтому для вариации показателя экспоненты в континуальном интеграле (15) находим:

$$\delta\left\{a^*\left(t''\right)a\left(t''\right)+\int\limits_{t'}^{t''}\mathrm{d}t\left[-a^*\dot{a}-i\omega a^*a+\frac{i\eta}{\sqrt{2\omega}}\left(a+a^*\right)\right]\right\}=$$

$$=a^*\left(t''\right)\delta a\left(t''\right)+\int\limits_{t'}^{t''}\mathrm{d}t\left[-a^*\delta\dot{a}+\delta a\left(-i\omega a^*+\frac{i\eta}{\sqrt{2\omega}}\right)-\delta a^*\left(\dot{a}+i\omega a-\frac{i\eta}{\sqrt{2\omega}}\right)\right]=$$

$$=\int\limits_{t'}^{t''}\mathrm{d}t\left[\delta a\left(\dot{a}^*-i\omega a^*+\frac{i\eta}{\sqrt{2\omega}}\right)-\delta a^*\left(\dot{a}+i\omega a-\frac{i\eta}{\sqrt{2\omega}}\right)\right]$$

Отсюда следует, что точка экстремума показателя экспоненты, которая в теории поля называется массовой поверхностью, есть решение уравнений движения:

$$\dot{a} = -i\omega a + \frac{i\eta}{\sqrt{2\omega}}, \quad \dot{a}^* = i\omega a^* - \frac{i\eta^*}{\sqrt{2\omega}} \tag{19}$$

(Здесь для дальнейшего удобства сделана замена $(\eta/\sqrt{2\omega})(a + a^*) \to (1/\sqrt{2\omega})(\eta^* a + \eta a^*)$, хотя в рассматриваемом случае $\eta^* = \eta$.)

Рассмотрим случай $\eta = 0$, когда уравнения (19) с граничными условиями (16) тривиально решаются:

$$a(t) = e^{-i\omega(t-t')} a(t'), \quad a^*(t) = e^{i\omega(t-t'')} a^*(t'') \tag{20}$$

Далее вместо $a(t')$ и $a^*(t'')$ пишем a и a^*, соответственно. Находим экстремальное значение показателя экспоненты в интеграле (15): $a^* a \exp(-i\omega(t'' - t'))$. Таким образом

$$U_0(a^*, a; t'' - t') = \exp\left\{a^* a e^{-i\omega(t''-t')}\right\} \tag{21}$$

Вследствие унитарности оператора (21) нормировочный множитель $1/N$ равен единице. Если $f(a^*)$ - произвольная функция, то

$$(U_0 f)(a^*) = \int \exp\left\{a^* \alpha e^{-i\omega t}\right\} f(\alpha^*) e^{-\alpha^* \alpha} \frac{\mathrm{d}\alpha^* \, \mathrm{d}\alpha}{2\pi i} = f\left(a^* e^{-i\omega t}\right) \tag{22}$$

(Проверить эту формулу для $f(a^*) = (a^*)^n$.)

Функция (21) является ядром оператора $e^{-it\mathcal{H}_0}$, где $\mathcal{H}_0$ - гамильтониан свободного осциллятора.

Замечание. Здесь мы выбросили "нулевую"энергию из гамильтониана. В противном случае имели бы

$$U_0(a^*, a; t) = \exp\left\{a^* a e^{-i\omega t} - \frac{i}{2}\omega t\right\}$$

Пусть A - оператор с ядром $A(a^*, a)$. Нам понадобится обобщение формулы (22), то есть ядро оператора $e^{it''\mathcal{H}_0} A e^{-it'\mathcal{H}_0}$:

$$[U_0(-t'') A U_0(t')](a^*, a) = A\left(a^* e^{i\omega t''}, a e^{-i\omega t'}\right) \tag{23}$$

13.1.4 4. Definition of the S-Matrix

Пусть $\mathcal{H}$ - гамильтониан теории, $\mathcal{H}_0$ - свободный гамильтониан и $U(t'', t')$ - оператор эволюции взаимодействующей теории. S-матрица определяется при помощи следующей формулы:

$$S = \lim e^{it''\mathcal{H}_0} U(t'', t') e^{-it'\mathcal{H}_0}, \quad t'' \to +\infty, \quad t' \to -\infty \tag{24}$$

Обкладки $e^{it''\mathcal{H}_0} ... e^{-it'\mathcal{H}_0}$ в (24) приводят к исключению свободного движения, которое не представляет интереса. Действительно, если $\mathcal{H} = \mathcal{H}_0$, то S-матрица (24) равна единичному оператору.

Вычислим S-матрицу гармонического осциллятора при наличии внешнего источника. Согласно определению (24) и формуле (23) теперь граничные условия (16) должны быть заменены на следующие:

$$a^*\left(t''\right) = a^* e^{i\omega t''}, \quad a\left(t'\right) = a e^{-i\omega t'} \tag{25}$$

Легко находим решения уравнений (19) с граничными условиями (25):

$$a^*(t) = e^{i\omega t}\left[a^* + i\int\limits_t^{t''} \mathrm{d}s \frac{e^{-i\omega s}\eta^*(s)}{\sqrt{2\omega}}\right], \quad a(t) = e^{-i\omega t}\left[a + i\int\limits_{t'}^{t} \mathrm{d}s \frac{e^{i\omega s}\eta(s)}{\sqrt{2\omega}}\right] \tag{26}$$

Подставим решение (26) в показатель экспоненты в (15) и раздвинем пределы интегрирования ($t' \to -\infty, t'' \to +\infty$). Таким образом мы получим ядро S-матрицы для гармонического осциллятора в присутствии внешнего источника:

$$S_\eta\left(a^*, a\right) = \frac{1}{N}\exp\left\{a^* a + \frac{i}{\sqrt{2\omega}}\int\limits_{-\infty}^{+\infty} \mathrm{d}t\left[\eta^*(t) a e^{-i\omega t} + a^* e^{i\omega t}\eta(t)\right] + \right.$$
$$\left. + i\int\limits_{-\infty}^{+\infty} \mathrm{d}t \int\limits_{-\infty}^{t} \mathrm{d}s \eta^*(t) i \frac{e^{-i\omega(t-s)}}{2\omega}\eta(s)\right\} \tag{27}$$

При помощи (23 Л1) выражение (27) переписывается как

$$S_\eta\left(a^*, a\right) = \frac{1}{N}\exp\left\{a^* a + \frac{i}{\sqrt{2\omega}}\int\limits_{-\infty}^{+\infty} \mathrm{d}t\left[\eta^*(t) a e^{-i\omega t} + a^* e^{i\omega t}\eta(t)\right] + \right.$$
$$\left. + \frac{i}{2}\int\limits_{-\infty}^{+\infty+\infty} \int\limits_{-\infty} \mathrm{d}t\ \mathrm{d}s \eta^*(t) D_c(t-s)\eta(s)\right\} \tag{28}$$

Подчеркнём, что в (28) используется именно причинная гриновская функция, так как уже в определении S-матрицы (24) сделано предположение, что при $|t| \to \infty$ взаимодействие выключается адиабатически и система описывается свободным гамильтонианом $\mathcal{H}_0$.

В дальнейшем нам понадобится формула (26), записанная в несколько изменённом виде:

$$q(t) \equiv \frac{1}{\sqrt{2\omega}}\left[a(t) + a^*(t)\right] = \frac{1}{\sqrt{2\omega}}\left[a e^{-i\omega t} + a^* e^{i\omega t}\right] + \int\limits_{t'}^{t''} \mathrm{d}s D_c(t-s)\eta(s)$$

13.1.5 5. S-Matrix in Scalar Field Theory

Рассмотрим скалярную теорию поля в d-мерном пространстве-времени. В свободном случае в присутствии внешнего источника действие такой теории имеет вид

$$\mathcal{S} = \int \mathrm{d}^{(d)}x \left\{\frac{1}{2}\left(\partial_\mu \phi\right)^2 - \frac{1}{2}m^2\phi^2 + \eta\phi\right\} \tag{29}$$

Отсюда получаем лагранжиан:

$$\mathcal{L} = \int \mathrm{d}^{(d-1)}x \left\{ \frac{1}{2}\dot{\phi}^2 - \frac{1}{2}(\nabla\phi)^2 - \frac{1}{2}m^2\phi^2 + \eta\phi \right\} \tag{30}$$

где $\dot{\phi} = \partial\phi(t,\mathbf{x})/\partial t$. Варьируя лагранжиан (30) относительно поля $\dot{\phi}$ находим обобщённый импульс поля ϕ:

$$\delta_{\dot{\phi}}\mathcal{L} = \int \mathrm{d}^{(d-1)}x\pi\delta\dot{\phi} \quad \longrightarrow \quad \pi = \dot{\phi} \tag{31}$$

Теперь путём канонической процедуры получаем гамильтониан теории:

$$\mathcal{H} = \int \mathrm{d}^{(d-1)}x\pi\dot{\phi} - \mathcal{L} \longrightarrow \mathcal{H} = \int \mathrm{d}^{(d-1)}x \left\{ \frac{1}{2}\pi^2 + \frac{1}{2}(\nabla\phi)^2 + \frac{1}{2}m^2\phi^2 - \eta\phi \right\} \tag{32}$$

Выпишем лишь ненулевые одновременные коммутационные соотношения (КС):

$$[\phi(t,\mathbf{x}), \pi(t,\mathbf{y})] = i\delta^{(d-1)}(\mathbf{x}-\mathbf{y}) \tag{33}$$

Как правило, реализация КС(33) осуществляется согласно следующей схеме:

$$\begin{gathered}
\phi(t,\mathbf{x}) = \int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}} \frac{1}{\sqrt{2\omega_k}} \left(a_{\mathbf{k}}(t)e^{i\mathbf{kx}} + a^\dagger_{\mathbf{k}}(t)e^{-i\mathbf{kx}} \right) \\
\pi(t,\mathbf{x}) = -i \int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}} \sqrt{\frac{\omega_k}{2}} \left(a_{\mathbf{k}}(t)e^{i\mathbf{kx}} - a^\dagger_{\mathbf{k}}(t)e^{-i\mathbf{kx}} \right) \\
[a_{\mathbf{k}}(t), a_{\mathbf{p}}(t)] = \left[a^\dagger_{\mathbf{k}}(t), a^\dagger_{\mathbf{p}}(t) \right] = 0, \quad \left[a_{\mathbf{k}}(t), a^\dagger_{\mathbf{p}}(t) \right] = (2\pi)^{d-1}\delta^{(d-1)}(\mathbf{k}-\mathbf{p})
\end{gathered} \tag{34}$$

Разложение (34) является естественным в случае свободной теории. Действительно, если

$$\omega_k = \sqrt{\mathbf{k}^2 + m^2} \tag{35}$$

то гамильтониан (32) распадается на сумму гамильтонианов гармонических осцилляторов (мы здесь полагаем $\eta = 0$):

$$\mathcal{H}_0 = \frac{1}{2}\int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\omega_k \left(a^\dagger_{\mathbf{k}}a_{\mathbf{k}} + a_{\mathbf{k}}a^\dagger_{\mathbf{k}} \right) = \int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\omega_k a^\dagger_{\mathbf{k}}a_{\mathbf{k}} + \delta^{(d-1)}(0)\int \mathrm{d}^{(d-1)}k\frac{\omega_k}{2}$$

где $(2\pi)^{d-1}\delta^{(d-1)}(0) = \int \mathrm{d}^{(d-1)}x = V$ - объём пространства. Второе слагаемое в правой части последнего равенства является энергией нулевых колебаний осцилляторов. Хотя плотность этой энергии бесконечна, она как правило не играет роли и потому в обычной квантовой теории поля вычёркивается. Энергия нулевых колебаний (или энергия вакуума) является серьёзной проблемой в квантовой теории гравитации, однако эта тема лежит за рамками нашего курса лекций. Отметим лишь, что рассматриваемый далее эффект Казимира существует вследствие реальности энергии вакуума.

Сделаем замечание о нормировке, используемой в этих лекциях. Везде интегрирование в координатном пространстве осуществляется по правилу $\int \mathrm{d}^{(d)}x$, в то время как интегрирование в импульсном пространстве - по правилу $\int \mathrm{d}^{(d)}k/(2\pi)^d$. Это правило согласовано с правилами коммутации (33) и (34). Иными словами, единичный оператор в

линейном пространстве функций в координатном представлении есть $\delta^{(d)}(x-y)$, а в импульсном представлении - $(2\pi)^d\delta^{(d)}(k-p)$.

Основное состояние или вакуум в теории (32)-(35) обозначается $|0\rangle$ и определяется условиями

$$a_{\mathbf{k}}|0\rangle = 0, \quad \langle 0|0\rangle = 1 \tag{36}$$

Очевидно,

$$\mathcal{H}_0|0\rangle = 0 \tag{37}$$

Возбуждённые состояния строятся при помощи операторов рождения $a^\dagger_{\mathbf{k}}$. Например, одночастичное состояние имеет вид

$$|\mathbf{k}\rangle = \sqrt{2\omega_k}a^\dagger_{\mathbf{k}}|0\rangle \tag{38}$$

Вследствие (34) и (36) скалярное произведение двух одночастичных состояний

$$\langle \mathbf{k}|\mathbf{p}\rangle = 2\omega_k(2\pi)^{d-1}\delta^{(d-1)}(\mathbf{k}-\mathbf{p}) \tag{39}$$

Можно показать (см. задачи), что правая часть (39) лоренц-инвариантна. Нормировка состояний (38) оправдывается именно лоренц-инвариантностью скалярных произведений одночастичных состояний. Заметим также, что лоренц-инвариантная мера в пространстве одночастичных состояний равна

$$\frac{\mathrm{d}^{(d-1)}k}{2\omega_k(2\pi)^{d-1}} \tag{40}$$

Мера (40) согласована со скалярным произведением (39), то есть

$$\int \frac{\mathrm{d}^{(d-1)}k}{2\omega_k(2\pi)^{d-1}}|\mathbf{k}\rangle\langle\mathbf{k}| = 1 \tag{41}$$

где единица в правой части равенства (40) обозначает единичный оператор в пространстве одночастичных состояний.

Энергия состояния (38) легко вычисляется при помощи равенства (37) и КС(34):

$$\mathcal{H}_0|\mathbf{k}\rangle = \omega_k|\mathbf{k}\rangle$$

Оператор импульса в скалярной теории поля имеет вид

$$\mathcal{P} = -\int \mathrm{d}^{(d-1)}x\pi(x)\nabla\phi(x) \tag{42}$$

что оправдывается значениями следующих коммутаторов:

$$[\phi(x),\mathcal{P}] = -i\nabla\phi(x), \quad [\pi(x),\mathcal{P}] = -i\nabla\pi(x)$$

и так далее. Подставляя разложение (34) в (42), получаем:

$$\mathcal{P} = \int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\mathbf{k}a^\dagger_{\mathbf{k}}a_{\mathbf{k}}$$

Легко найти, что

$$\mathcal{P}|0\rangle = 0, \quad \mathcal{P}|\mathbf{k}\rangle = \mathbf{k}|\mathbf{k}\rangle$$

Таким образом, состояние $|\mathbf{k}\rangle$ имеет определённый импульс $\mathbf{k}$.

Пусть $\{\mathbf{k}_i\}, i = 1, ..., n$ - такой набор импульсов, что попарно $\mathbf{k}_i \neq \mathbf{k}_j$. Тогда многочастичное состояние представляется в виде

$$|\mathbf{k}_1, \mathbf{k}_2, ..., \mathbf{k}_n\rangle = \prod_{i=1}^{n} \left(\sqrt{2\omega_{k_i}} a^\dagger_{\mathbf{k}_i}\right)|0\rangle \tag{43}$$

Имеем:

$$\begin{aligned}\mathcal{H}_0 |\mathbf{k}_1, \mathbf{k}_2, ..., \mathbf{k}_n\rangle &= \left(\sum_{i=1}^{n} \omega_{k_2}\right) |\mathbf{k}_1, \mathbf{k}_2, ..., \mathbf{k}_n\rangle \\ \mathcal{P} |\mathbf{k}_1, \mathbf{k}_2, ..., \mathbf{k}_n\rangle &= \left(\sum_{i=1}^{n} \mathbf{k}_i\right) |\mathbf{k}_1, \mathbf{k}_2, ..., \mathbf{k}_n\rangle\end{aligned} \tag{44}$$

а также

$$\begin{aligned}\langle \mathbf{p}_1, \mathbf{p}_2, ..., \mathbf{p}_n | \mathbf{k}_1, \mathbf{k}_2, ..., \mathbf{k}_n\rangle = \prod_{i=1}^{n} \left[2\omega_{k_i}(2\pi)^{d-1}\right] \\ \sum_{\text{все перестановки } p_i} \delta^{(d-1)}(\mathbf{k}_1 - \mathbf{p}_{i_1}) ... \delta^{(d-1)}(\mathbf{k}_n - \mathbf{p}_{i_n})\end{aligned} \tag{45}$$

Естественно, существуют также состояния вида $\left(a^\dagger_{\mathbf{k}}\right)^n |0\rangle$ (n частиц в одном состоянии), однако в теории S-матрицы эти состояния интереса не представляют.

Пространство состояний, построенное описанным способом, называется фоковским пространством состояний.

Пусть

$$\eta_{\mathbf{k}}(t) = \int \mathrm{d}^{(d-1)} x \eta(t, \mathbf{x}) e^{-i\mathbf{k}\mathbf{x}} = \eta^*_{-\mathbf{k}} \tag{46}$$

Тогда для гамильтониана (32) имеем:

$$\mathcal{H} = \int \frac{\mathrm{d}^{(d-1)} k}{(2\pi)^{d-1}} \left\{\omega_k a^\dagger_{\mathbf{k}}(t) a_{\mathbf{k}}(t) - \frac{1}{\sqrt{2\omega_k}} \left(\eta^*_{\mathbf{k}}(t) a_{\mathbf{k}}(t) + \eta_{\mathbf{k}}(t) a^\dagger_{\mathbf{k}}(t)\right)\right\} \tag{47}$$

Отсюда видно, что в данном случае гамильтониан является суммой гамильтонианов вида (17) и потому ядро S-матрицы системы (29) получается непосредственно из ядра S-матрицы (27). Первое слагаемое в экспоненте в (27) переходит в

$$\int \frac{\mathrm{d}^{(d-1)} k}{(2\pi)^{d-1}} a^*_{\mathbf{k}} a_{\mathbf{k}}$$

Второе - в

$$i\int \mathrm{d}^{(d)}x\eta(x)\phi_0(x),\quad \phi_0(x)=\int\frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\frac{1}{\sqrt{2\omega_k}}\left(a^*_{\mathbf{k}}e^{ikx}+a_{\mathbf{k}}e^{-ikx}\right)$$
$$kx=k^0x^0-\mathbf{kx},\quad k^0=\omega_k \tag{48}$$

а третье - в

$$i\int\limits_{-\infty}^{+\infty}\mathrm{d}t\int\limits_{-\infty}^{t}\mathrm{d}s\int\frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\eta^*_{\mathbf{k}}(t)\left[i\frac{e^{-i\omega_k(t-s)}}{2\omega_k}\right]\eta_{\mathbf{k}}(s)=\frac{i}{2}\iint\mathrm{d}^{(d)}x\ \mathrm{d}^{(d)}y\eta(x)D_c(x-y)\eta(y)$$

где

$$D_c(x)=i\int\frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\frac{e^{i\mathbf{kx}-i\omega_k\left|x^0\right|}}{2\omega_k}=\int\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}\frac{e^{-ikx}}{-k^2+m^2-i\varepsilon}$$
$$\left(\partial_\mu\partial^\mu+m^2\right)D_c(x)=\delta^{(d)}(x) \tag{49}$$

Из правой части равенства (49) очевидны лоренц-инвариантность причинной гриновской функции $D_c(x)$ и то, что везде $\mathrm{Im}\,\omega_k=-\varepsilon,\varepsilon\to+0$. Для ядра S-матрицы имеем:

$$S\left(a^*,a\right)=\frac{1}{N}\exp\left\{\int\frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}a^*_{\mathbf{k}}a_{\mathbf{k}}+i\int\mathrm{d}^{(d)}x\eta(x)\phi_0(x)+\right.$$
$$\left.+\frac{i}{2}\iint\mathrm{d}^{(d)}x\ \mathrm{d}^{(d)}y\eta(x)D_c(x-y)\eta(y)\right\} \tag{50}$$

Теперь перейдём от ядра к нормальному символу S-матрицы:

$$S\left(a^*,a\right)=\frac{1}{N}\exp\left\{i\int\mathrm{d}^{(d)}x\eta(x)\phi_0(x)+\frac{i}{2}\iint\mathrm{d}^{(d)}x\ \mathrm{d}^{(d)}y\eta(x)D_c(x-y)\eta(y)\right\}\equiv S_0\left(\phi_0;\eta\right) \tag{51}$$

Поле (48) удовлетворяет свободному уравнению

$$\left(\partial_\mu\partial^\mu+m^2\right)\phi_0=0$$

которое называется уравнением Клейна-Гордона-Фока.

Укажем, что нормальный символ S-матрицы представляется также как функциональный интеграл

$$S\left(a^*,a\right)=\frac{1}{N'}\int\exp\left\{i\int\mathrm{d}t\left[\ \mathrm{d}^{(d-1)}x\pi\dot{\phi}-\mathcal{H}\right]\right\}D\pi D\phi=\frac{1}{N}\int\exp(i\mathcal{S})D\phi$$
$$D\pi\equiv\prod_x\ \mathrm{d}\pi(x),\quad D\phi\equiv\prod_x\ \mathrm{d}\phi(x)$$

$$\phi(x)\overrightarrow{}_{t\to\pm\infty}\phi_{\mathbf{k}\ \substack{\mathrm{out}\\ \mathrm{in}}}(x)\qquad \phi_{\mathbf{k}\ \substack{\mathrm{out}\\ \mathrm{in}}}(x)=\int\frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\frac{1}{\sqrt{2\omega_k}}\left(a_{\mathbf{k}\ \substack{\mathrm{out}\\ \mathrm{in}}}e^{-ikx}+a^*_{\mathbf{k}\ \substack{\mathrm{out}\\ \mathrm{in}}}e^{ikx}\right),$$

$$a_{\mathbf{k}\ \mathrm{in}} = a_{\mathbf{k}}, \quad a^*_{\mathbf{k}\ \mathrm{out}} = a^*_{\mathbf{k}}, \quad kx = k^0x^0 - \mathbf{kx}, \quad k^0 = \omega_k \tag{52}$$

Действие $\mathcal{S}$ в (52) может быть как свободным действием (29), так и включающим взаимодействие (см. ниже (54)).

В справедливости представления (52) нетрудно убедиться следующим образом. В случае свободной теории с внешним источником, описывающейся действием (29), интеграл (52) как гауссов вычисляется точно. В этом случае действие в экспоненте функционального интеграла экстремально при условии $(\partial_\mu\partial^\mu + m^2)\,\phi = \eta$. Решение последнего уравнения с необходимыми граничными условиями типа (25) есть (сравни с одномерным случаем (26′))

$$\phi(x) = \phi_0(x) + \int \mathrm{d}^{(d)}y D_c(x-y)\eta(y) \tag{53}$$

Подстановка (53) в экспоненту функционального интеграла приводит к выражению (51). Очевидно, полученный результат не случаен, поскольку, согласно лекции 1, амплитуда перехода вообще, и S-матрица в частности, представляется в виде функционального интеграла (52). Поэтому единственный остающийся вопрос при вычислении нормального символа S-матрицы - это вопрос о граничных условиях динамического поля при $|t| \to \infty$. Важность голоморфного представления функционального интеграла заключается именно в том, что это представление даёт ответ на вопрос, каковы должны быть граничные условия при вычислении нормального символа S-матрицы: положительно частотные волны в ϕ_{in} и отрицательно частотные волны в ϕ_{out} совпадают с соответствующими волнами в ϕ_0 (48). Здесь уместно ещё раз подчеркнуть, что такие граничные условия и сама теория S-матрицы существуют лишь при справедливости предположения об адиабатическом выключении взаимодействия при $|t| \to \infty$.

13.1.6 6. S-Matrix in Interacting Field Theory

Рассмотрим теорию скалярного поля с самодействием, описывающуюся действием

$$\mathcal{S} = \int \mathrm{d}^{(d)}x \left\{ \frac{1}{2}\left(\partial_\mu\phi\right)^2 - \frac{1}{2}m_0^2\phi^2 - V(\phi) + \eta\phi \right\} \tag{54}$$

Наибольший интерес для нас представляет случай

$$V(\phi) = \frac{1}{4!}\lambda_0\phi^4 \tag{55}$$

Размерность полей и констант определяется исходя из того, что действие имеет размерность постоянной Планка, а в случае $\hbar = 1$ - безразмерно. Например, из безразмерности действия (54) имеем:

$$[m] = \mathrm{cm}^{-1}, \quad [\phi] = \mathrm{cm}^{(1-d/2)}, \quad [\lambda] = \mathrm{cm}^{d-4}$$

Теперь континуальный интеграл не может быть вычислен точно, но существует вычислительная техника, основанная на теории возмущений (ТВ). Идея заключается в разложении S-матрицы по потенциалу взаимодействия $\left(\int \mathrm{d}^{(d)}xV(\phi)\right)$. Тогда в нулевом приближении мы имеем точный результат (51), а при разложении по $\left(\int \mathrm{d}^{(d)}xV(\phi)\right)$ возникают интегралы от гауссовых средних вида $\langle 0\,|T\phi_1...\phi_n|\,0\rangle$, где $\phi_i = \phi\,(x_i)$.

Замечание. Рассмотрим интеграл

$$I(\lambda) = \int\limits_{-\infty}^{+\infty} \mathrm{d}x \exp\left(-\frac{1}{2}x^2 - \lambda x^4\right)$$

который точно не вычисляется. Очевидно также, что функция $I(\lambda)$ при $\lambda = 0$ не аналитична, она имеет особенность. Тем не менее при $\lambda \ll 1$ имеет смысл разложение

$$I(\lambda) = \sqrt{2\pi} - \lambda \int \mathrm{d}x x^4 e^{-(1/2)x^2} + \ldots \tag{56}$$

Это разложение имеет смысл лишь до тех пор пока следующий член разложения меньше предыдущего. Интегралы вида

$$I_n = \int \mathrm{d}x x^n e^{-(1/2)x^2} \tag{57}$$

вычисляются при помощи формул

$$x^n e^{-(1/2)x^2} = \left.\frac{\mathrm{d}^n}{\mathrm{d}\eta^n} e^{-(1/2)x^2+\eta x}\right|_{\eta=0} \tag{58}$$

$$\int \mathrm{d}x e^{-(1/2)x^2+\eta x} = \sqrt{2\pi} e^{(1/2)\eta^2} \tag{59}$$

$$I_n = \left[\int \mathrm{d}x \frac{\mathrm{d}^n}{\mathrm{d}\eta^n} e^{-(1/2)x^2+\eta x}\right]\Bigg|_{\eta=0} = \left[\frac{\mathrm{d}^n}{\mathrm{d}\eta^n}\int \mathrm{d}x e^{-(1/2)x^2+\eta x}\right]\Bigg|_{\eta=0} =$$
$$= \sqrt{2\pi}\left[\frac{\mathrm{d}^n}{\mathrm{d}\eta^n} e^{(1/2)\eta^2}\right]\Bigg|_{\eta=0}$$

так что

$$I(\lambda) = \sqrt{2\pi}(1 - 3\lambda + \ldots)$$

Если $\Phi(x)$ - произвольная функция, то

$$\Phi(x) = \left[\Phi\left(\frac{1}{i}\frac{\mathrm{d}}{\mathrm{d}\eta}\right) e^{i\eta x}\right]\Bigg|_{\eta=0}$$

Это равенство позволяет свести вычисление негауссова интеграла к следующей формуле:

$$\int \mathrm{d}x \exp\left\{i\left(\frac{1}{2}x^2 - V(x)\right)\right\} =$$
$$= \left[\exp\left\{-iV\left(\frac{1}{i}\frac{\mathrm{d}}{\mathrm{d}\eta}\right)\right\}\int \mathrm{d}x \exp\left\{i\left(\frac{1}{2}x^2 + \eta x\right)\right\}\right]\Bigg|_{\eta=0} \tag{60}$$

Интеграл в правой части (60) гауссов и потому легко вычисляется. После этого мы можем развить ТВ, разлагая правую часть (60) относительно V и пользуясь теоремой Вика.

В теории поля действуем аналогично. Имеем:

$$\phi\left(x_1\right)...\phi\left(x_n\right)=\frac{1}{i}\frac{\delta}{\delta\eta\left(x_1\right)}\cdots\frac{1}{i}\frac{\delta}{\delta\eta\left(x_n\right)}\exp\left\{i\int\phi(x)\eta(x)\mathrm{d}x\right\}\Bigg|_{\eta=0}$$

Для любого функционала $\Phi\{\phi(x)\}$

$$\Phi\{\phi(x)\}=\Phi\left\{\frac{1}{i}\frac{\delta}{\delta\eta(x)}\right\}\exp\left\{i\int\phi(x)\eta(x)\mathrm{d}x\right\}\Bigg|_{\eta=0} \tag{61}$$

и, в частности,

$$\exp\left\{-i\int V(\phi)\mathrm{d}x\right\}=\exp\left\{-i\int V\left(\frac{1}{i}\frac{\delta}{\delta\eta(x)}\right)\mathrm{d}x\right\}\exp\left\{i\int\phi(x)\eta(x)\mathrm{d}x\right\}\Bigg|_{\eta=0} \tag{62}$$

Теперь, прямолинейно обобщая одномерную формулу (60) на случай теории поля и пользуясь формулой (51) для значения гауссова интеграла в задаче об S-матрице, выпишем нормальный символ S-матрицы в скалярной теории поля со взаимодействием:

$$\begin{aligned}S\left(a^*,a\right)=S\left(\phi_0\right)=\frac{1}{N}\exp\left\{-i\int V\left(\frac{1}{i}\frac{\delta}{\delta\eta(x)}\right)\mathrm{d}x\right\}\times\\ \times\exp\left\{i\int\mathrm{d}x\eta(x)\phi_0(x)+\frac{i}{2}\iint\mathrm{d}x\ \mathrm{d}y\eta(x)D_c(x-y)\eta(y)\right\}\Bigg|_{\eta=0}\end{aligned} \tag{63}$$

Здесь и далее $D_c(x)$ задаётся согласно (49),

Разложим функционал (63) по ϕ_0 и перейдём от нормального символа оператора S-матрицы к самому оператору S-матрицы:

$$\begin{aligned}S\left(\phi_0\right)&=\sum_n\frac{1}{n!}\int S_n\left(x_1,...,x_n\right):\phi_0\left(x_1\right)...\phi_0\left(x_n\right):\mathrm{d}x_1...\mathrm{d}x_n\\ \phi_0(x)&=\int\frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}}\frac{1}{\sqrt{2\omega_k}}\left(a_{\mathbf{k}}e^{-ikx}+a_{\mathbf{k}}^{\dagger}e^{ikx}\right),\quad k^0=\omega_k\end{aligned} \tag{64}$$

Функции $S_n\left(x_1,...,x_n\right)$ являются коэффициентами при степенях поля $\phi_0(x)$ в разложении функционала (63) по степеням этого поля и они называются коэффициентными функциями S матрицы, а $S\left(\phi_0\right)$ - производящим функционалом для функций S_n. Поле ϕ_0 в (64) является свободным квантованным полем в представлении Гейзенберга. Согласно определению, размещение любого оператора, являющегося функцией операторов рождения и уничтожения, между двумя двоеточиями означает приведение оператора к нормальному виду, причём в процессе этого приведения все операторы рождения и уничтожения считаются коммутативными. Например, $:a^{\dagger}a:=a^{\dagger}a,:aa^{\dagger}:=a^{\dagger}a,:a^m\left(a^{\dagger}\right)^n:=\left(a^{\dagger}\right)^n a^m,:aa^{\dagger}a:=a^{\dagger}a^2$, и т.д.

Задачи

1. Проверить в скалярной теории поля, что уравнения Гейзенберга $i\dot{\mathcal{O}}=[\mathcal{O},\mathcal{H}]$ совпадают по форме с лагранжевыми уравнениями.

2. Рассмотрите теорию комплексного скалярного поля с действием

$$S = \int \mathrm{d}^4x \left(\partial_\mu \phi^* \partial^\mu \phi - m^2 \phi^* \phi\right)$$

Изучите эту теорию, рассматривая в качестве базисных динамических переменных $\phi(x)$ и $\phi^*(x)$, а не вещественную и мнимую части поля $\phi(x)$.

а) Выписать канонически сопряжённые импульсы к $\phi(x)$ и $\phi^*(x)$ и канонические коммутационные соотношения. Показать, что гамильтониан

$$\mathcal{H} = \int \mathrm{d}x \left(\pi^* \pi + \nabla \phi^* \nabla \phi + m^2 \phi^* \phi\right)$$

Выписать уравнение Гейзенберга для $\phi(x)$ и показать, что оно совпадает с уравнением КлейнаГордона-Фока.

б) Диагонализуйте гамильтониан, вводя операторы рождения и уничтожения. Покажите, что теория содержит два типа частиц с массой m.

в) Докажите, что заряд

$$Q = \int \mathrm{d}^3x \frac{i}{2} \left(\phi^* \pi^* - \pi \phi\right)$$

сохраняется и перепишите его в терминах операторов рождения и уничтожения и вычислите заряд частиц каждого типа.

3. а) Доказать, что величина

$$\sqrt{m^2 + \mathbf{k}^2} \delta^{(d-1)}(\mathbf{k} - \mathbf{p})$$

лоренц-инвариантна.

б) Доказать, что мера

$$\frac{\mathrm{d}^{(d-1)}k}{\sqrt{m^2 + \mathbf{k}^2}}$$

лоренц-инвариантна.

14 Interacting Fields in Series, Feynman Diagrams

14.1 Expansion of Correlation Functions in Perturbation Theory

Теория

Начнем изучение теории возмущений для взаимодействующих полей с построения формализма, который позволит сделать наглядными ряды теории возмущений как пространственно-временные процессы. Хотя нам не потребуется переформулировать всю квантовую механику, мы вновь построим зависящую от времени теорию возмущений в форме, удобной для наших целей. Ясно, что в конечном счете мы хотим вычислить вероятности распадов и сечения рассеяния. Поставим пока менее амбициозную задачу вычислить простейшую (но более абстрактную) величину - двухточечную корреляционную функцию или двухточечную функцию Грина

$$\langle\Omega|T\phi(x)\phi(y)|\Omega\rangle,$$

в теории ϕ^4. Символом $|\Omega\rangle$ мы обозначим основное состояние взаимодействующей теории, которое в общем случае отличается от основного состояния свободной теории $|0\rangle$. Символ хронологического упорядочения T введен для дальнейшего удобства. Корреляционную функцию можно физически интерпретировать как амплитуду распространения частицы или возбуждения между точками y и x.В свободной теории - это фейнмановский пропагатор:

$$\langle 0|T\phi(x)\phi(y)|0\rangle_{\text{free}} = D_F(x-y) = \int \frac{d^4p}{(2\pi)^4}\frac{ie^{-ip\cdot(x-y)}}{p^2-m^2+i\varepsilon}.$$

Мы хотели бы знать, как это выражение изменяется во взаимодействующей теории. Как только мы проанализируем двухточечную корреляционную функцию, будет легко обобщить результаты на корреляционные функции более высокого порядка, в которых содержится более двух полевых операторов. В разделах 4.3 и 4.4 мы продолжим анализ корреляционных функций и разработаем в конце концов формализм фейнмановских диаграмм для вычисления этих функций по теории возмущений. Затем в разделах 4.5 и 4.6 мы научимся с помощью этой же техники вычислять сечения рассеяния и вероятности распадов.

Чтобы приступить к задаче, запишем гамильтониан теории ϕ^4 в виде:

$$H = H_0 + H_{\text{int}} = H_{\text{Клейн-Гордон}} + \int d^3x \frac{\lambda}{4!}\phi^4(\mathbf{x}).$$

Мы хотим получить выражение для двухточечной корреляционной функции (4.10) в виде ряда по степеням константы λ. Гамильтониан взаимодействия H_{int} встречается в (4.10) в двух местах: во-первых, в определении гейзенберговского поля

$$\phi(x) = e^{iHt}\phi(\mathbf{x})e^{-iHt},$$

и, во-вторых, в определении основного состояния $|\Omega\rangle$. Мы должны выразить как $\phi(x)$, так и $|\Omega\rangle$ через величины, с которыми мы знаем, как обращаться, а именно, через операторы свободного поля и вакуум в свободной теории $|0\rangle$.

† Историческую справку о вкладах Томонаги, Швингера, Фейнмана и Дайсона см. в Schweber (1994). Проще начать с $\phi(x)$. В любой фиксированный момент времени t_0 мы можем, как и прежде, разложить ϕ по лестничным операторам:

$$\phi(t_0,\mathbf{x}) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\left(a_{\mathbf{p}}e^{i\mathbf{p}\cdot\mathbf{x}} + a^\dagger_{\mathbf{p}}e^{-i\mathbf{p}\cdot\mathbf{x}}\right)$$

Тогда, чтобы получить $\phi(t,\mathbf{x})$ при $t \neq t_0$, мы, как обычно, переходим в гейзенберговское представление:

$$\phi(t,\mathbf{x}) = e^{iH(t-t_0)}\phi(t_0,\mathbf{x})\,e^{-iH(t-t_0)}.$$

При $\lambda = 0$ гамильтониан H совпадает с H_0, и последняя формула сводится к

$$\phi(t,\mathbf{x})|_{\lambda=0} = e^{iH_0(t-t_0)}\phi(t_0,\mathbf{x})\,e^{-iH_0(t-t_0)} \equiv \phi_I(t,\mathbf{x}).$$

Если λ мало, то это выражение будет все еще определять самую важную часть временной зависимости поля $\phi(x)$, поэтому удобно присвоить этой величине название: поле в представлении взаимодействия $\phi_I(t,\mathbf{x})$. Так как мы можем диагонализовать H_0, легко выписать ϕ_I явно:

$$\phi_I(t,\mathbf{x}) = \int \frac{d^3p}{(2\pi)^3}\frac{1}{\sqrt{2E_{\mathbf{p}}}}\left(a_{\mathbf{p}}e^{-ip\cdot x} + a^\dagger_{\mathbf{p}}e^{ip\cdot x}\right)\Bigg|_{x^0=t-t_0}$$

Это знакомое выражение для свободного поля из гл. 2.

Задача теперь состоит в том, чтобы выразить полное гейзенберговское поле ϕ в терминах ϕ_I. Формально

$$\begin{aligned}\phi(t,\mathbf{x}) &= e^{iH(t-t_0)}e^{-iH_0(t-t_0)}\phi_I(t,\mathbf{x})e^{iH_0(t-t_0)}e^{-iH(t-t_0)} \equiv \\ &\equiv U^\dagger(t,t_0)\,\phi_I(t,\mathbf{x})U(t,t_0)\end{aligned}$$

где мы определили унитарный оператор

$$U(t,t_0) = e^{iH_0(t-t_0)}e^{-iH(t-t_0)},$$

известный как пропагатор в представлении взаимодействия или оператор временной эволюции. Мы хотели бы выразить $U(t,t_0)$ полностью через поле ϕ_I, для которого существует явное выражение через лестничные операторы. Чтобы сделать это, заметим, что $U(t,t_0)$ - единственное решение с начальным условием $U(t_0,t_0) = 1$ обыкновенного дифференциального уравнения (уравнения Шредингера):

$$\begin{aligned}i\frac{\partial}{\partial t}U(t,t_0) &= e^{iH_0(t-t_0)}(H-H_0)\,e^{-iH(t-t_0)} = \\ &= e^{iH_0(t-t_0)}(H_{\text{int}})\,e^{-iH(t-t_0)} = \\ &= e^{iH_0(t-t_0)}(H_{\text{int}})\,e^{-iH_0(t-t_0)}e^{iH_0(t-t_0)}e^{-iH(t-t_0)} = \\ &= H_I(t)U(t,t_0),\end{aligned}$$

где

$$H_I(t) = e^{iH_0(t-t_0)}(H_{\text{int}})\,e^{-iH_0(t-t_0)} = \int d^3x\frac{\lambda}{4!}\phi_I^4$$

является гамильтонианом взаимодействия, записанным в представлении взаимодействия. Решение этого дифференциального уравнения для $U(t,t_0)$ должно иметь вид, похожий на выражение $U\sim\exp(-iH_It)$; это было бы искомой формулой для U через ϕ_I. Более аккуратно покажем, что настоящее решение является следующим степенным рядом по λ:

$$\begin{aligned}U(t,t_0) = 1 + (-i)\int_{t_0}^{t}dt_1H_I(t_1) + (-i)^2\int_{t_0}^{t}dt_1\int_{t_0}^{t_1}dt_2H_I(t_1)\,H_I(t_2) + \\ +(-i)^3\int_{t_0}^{t}dt_1\int_{t_0}^{t_1}dt_2\int_{t_0}^{t_2}dt_3H_I(t_1)\,H_I(t_2)\,H_I(t_3) + \ldots\end{aligned}$$

Чтобы проверить это, вычислим производную по времени. При этом каждый член ряда дает предыдущий член, умноженный на $-iH_I(t)$. Очевидно, что начальное условие $U(t,t_0) = 1$ для $t = t_0$ Удовлетворено.

Обратим внимание, что различные множители H_I в (4.20) расположены в хронологическом порядке, т. е. отвечающий более позднему времени расположен всегда левее. Это позволяет существенно упростить выражение, используя символ хронологического упорядочения T. Например, слагаемое порядка H_I^2 записывается в виде

$$\int_{t_0}^{t} dt_1 \int_{t_0}^{t_1} dt_2 H_I(t_1) H_I(t_2) = \frac{1}{2} \int_{t_0}^{t} dt_1 \int_{t_0}^{t} dt_2 T\{H_I(t_1) H_I(t_2)\}$$

Двойной интеграл справа учитывает все дважды, так как в $t_1 t_2$-плоскости подынтегральное выражение $T\{H_I(t_1) H_I(t_2)\}$ симметрично относительно прямой $t_1 = t_2$ (см. рис. 4.1).

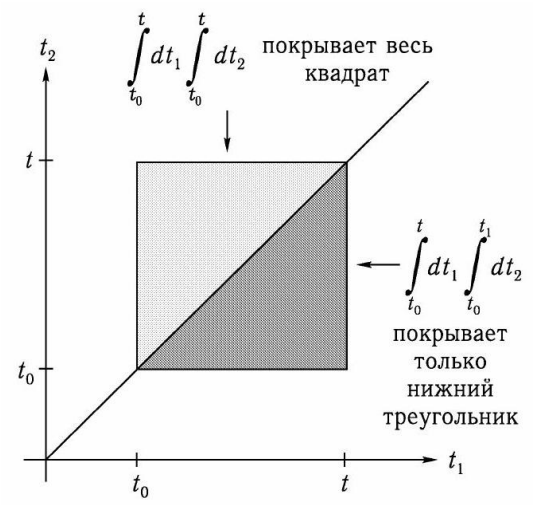

Рис. 4.1. Геометрическая интерпретация формулы (4.21).

Аналогичное тождество имеет место для высших слагаемых:

$$\int_{t_0}^{t} dt_1 \int_{t_0}^{t_1} dt_2 \ldots \int_{t_0}^{t_{n-1}} dt_n H_I(t_1) \ldots H_I(t_n) = \frac{1}{n!} \int_{t_0}^{t} dt_1 \ldots dt_n T\{H_I(t_1) \ldots H_I(t_n)\}$$

Хотя этот случай несколько труднее изобразить наглядно, но нетрудно убедиться, что формула верна. С помощью последнего тождества можно записать $U(t, t_0)$ в чрезвычайно компактной форме:

$$U(t, t_0) = 1 + (-i) \int_{t_0}^{t} dt_1 H_I(t_1) + \frac{(-i)^2}{2!} \int_{t_0}^{t} dt_1 dt_2 T\{H_I(t_1) H_I(t_2)\} + \ldots \equiv$$

$$\equiv T\left\{\exp\left[-i \int_{t_0}^{t} dt' H_I(t')\right]\right\},$$

где хронологически упорядоченная экспонента определяется как ряд Тейлора, в котором каждый член хронологически упорядочен. В реальных вычислениях мы оставляем лишь несколько первых членов этого ряда; хронологически упорядоченная экспонента является лишь компактным способом записи и запоминания нужного выражения.

Теперь мы контролируем поле $\phi(t, \mathbf{x})$ в следующем смысле: мы записали его, как и хотели, полностью через поля ϕ_I. Прежде чем перейти к рассмотрению $|\Omega\rangle$, удобно обобщить определение оператора U, допуская, что его второй аргумент может принимать значения, отличающиеся от нашей «точки отсчета» t_0. Правильное определение вполне естественно:

$$U(t, t') \equiv T\left\{\exp\left[-i\int_{t'}^{t} dt'' H_I(t'')\right]\right\} \quad (t \geqslant t').$$

Проверим несколько свойств, непосредственно следующих из этого определения. Во-первых, $U(t, t')$ удовлетворяет тому же самому дифференциальному уравнению (4.18):

$$i\frac{\partial}{\partial t}U(t, t') = H_I(t)U(t, t'),$$

но теперь с начальным условием $U = 1$ для $t = t'$. Из этого уравнения следует:

$$U(t, t') = e^{iH_0(t-t_0)}e^{-iH(t-t')}e^{-iH_0(t'-t_0)},$$

что доказывает унитарность оператора U. Наконец, $U(t, t')$ удовлетворяет следующим тождествам (для $t_1 \geqslant t_2 \geqslant t_3$):

$$U(t_1, t_2)\,U(t_2, t_3) = U(t_1, t_3)\,; U(t_1, t_3)\,[U(t_2, t_3)]^{\dagger} = U(t_1, t_2).$$

Теперь мы можем перейти к обсуждению состояния $|\Omega\rangle$. Так как $|\Omega\rangle$ - основное состояние гамильтониана H, можно выделить его при помощи следующей процедуры. Допустим, что мы начинаем с $|0\rangle$, являющегося основным состоянием H_0, и рассматриваем его эволюцию во времени, определяющуюся полным гамильтонианом H:

$$e^{-iHT}|0\rangle = \sum_n e^{-iE_nT}|n\rangle\langle n|0\rangle,$$

где E_n - собственные значения H. Мы должны предположить, что $|\Omega\rangle$ перекрывается с $|0\rangle$, то есть $\langle\Omega|0\rangle \neq 0$ (если это не так, то H_I ни в каком смысле не может считаться малым возмущением). Тогда выписанный выше ряд содержит $|\Omega\rangle$, и мы можем записать:

$$e^{-iHT}|0\rangle = e^{-iE_0T}|\Omega\rangle\langle\Omega|0\rangle + \sum_{n\neq 0} e^{-iE_nT}|n\rangle\langle n|0\rangle,$$

где $E_0 \equiv \langle\Omega|H|\Omega\rangle$. (Нулевая энергия определяется как $H_0|0\rangle = 0$.) Так как $E_n > E_0$ для всех $n \neq 0$, можно избавиться от всех слагаемых в разложении с $n \neq 0$, устремляя T к ∞ в направлении с малой мнимой добавкой в комплексной плоскости: $T \to \infty(1 - i\varepsilon)$. Тогда экспоненциальный множитель e^{-iE_nT} вымирает медленнее всего для $n = 0$:

$$|\Omega\rangle = \lim_{T\to\infty(1-i\varepsilon)} \left(e^{-iE_0T}\langle\Omega|0\rangle\right)^{-1} e^{-iHT}|0\rangle.$$

Так как теперь T очень велико, можно сдвинуть его на малую константу:

$$\begin{aligned}
|\Omega\rangle &= \lim_{T\to\infty(1-i\varepsilon)} \left(e^{-iE_0(T+t_0)}\langle\Omega|0\rangle\right)^{-1} e^{-iH(T+t_0)}|0\rangle = \\
&= \lim_{T\to\infty(1-i\varepsilon)} \left(e^{-iE_0(t_0-(-T))}\langle\Omega|0\rangle\right)^{-1} e^{-iH(t_0-(-T))}e^{-iH_0(-T-t_0)}|0\rangle = \\
&= \lim_{T\to\infty(1-i\varepsilon)} \left(e^{-iE_0(t_0-(-T))}\langle\Omega|0\rangle\right)^{-1} U(t_0, -T)\,|0\rangle.
\end{aligned}$$

Во второй строке мы использовали равенство $H_0|0\rangle = 0$. Если отбросить с-числовой множитель, видим, что состояние $|\Omega\rangle$ может быть получено простой эволюцией состояния $|0\rangle$ во времени от $-T$ до t_0 при помощи оператора U. Точно так же можно представить состояние $\langle\Omega|$ как

$$\langle\Omega| = \lim_{T\to\infty(1-i\varepsilon)} \langle 0|U\left(T,t_0\right)\left(e^{-iE_0(T-t_0)}\langle 0|\Omega\rangle\right)^{-1}.$$

Соберем вместе отдельные слагаемые двухточечной корреляционной функции. На время предположим, что $x^0 > y^0 > t_0$. Тогда

$$\begin{aligned}\langle\Omega|\phi(x)\phi(y)|\Omega\rangle = &\lim_{T\to\infty(1-i\varepsilon)} \left(e^{-iE_0(T-t_0)}\langle 0|\Omega\rangle\right)^{-1}\langle 0|U\left(T,t_0\right)\times\\ &\times\left[U\left(x^0,t_0\right)\right]^\dagger\phi_I(x)U\left(x^0,t_0\right)\left[U\left(y^0,t_0\right)\right]^\dagger\phi_I(y)U\left(y^0,t_0\right)\times\\ &\times U\left(t_0,-T\right)|0\rangle\left(e^{-iE_0(t_0-(-T))}\langle\Omega|0\rangle\right)^{-1} =\\ =&\lim_{T\to\infty(1-i\varepsilon)}\left(|\langle 0|\Omega\rangle|^2 e^{-iE_0(2T)}\right)^{-1}\times\\ &\times\left\langle 0\left|U\left(T,x^0\right)\phi_I(x)U\left(x^0,y^0\right)\phi_I(y)U\left(y^0,-T\right)\right|0\right\rangle.\end{aligned}$$

Это выражение выглядело бы простым, если бы не громоздкий множитель впереди. Чтобы избавиться от него, разделим это выражение на 1, представленную в виде

$$1 = \langle\Omega|\Omega\rangle = \left(|\langle 0|\Omega\rangle|^2 e^{-iE_0(2T)}\right)^{-1}\langle 0\left|U\left(T,t_0\right)U\left(t_0,-T\right)\right|0\rangle.$$

Тогда наша формула все еще для $x^0 > y^0$ принимает вид:

$$\langle\Omega|\phi(x)\phi(y)|\Omega\rangle = \lim_{T\to\infty(1-i\varepsilon)}\frac{\langle 0\left|U\left(T,x^0\right)\phi_I(x)U\left(x^0,y^0\right)\phi_I(y)U\left(y^0,-T\right)\right|0\rangle}{\langle 0|U(T,-T)|0\rangle}$$

Теперь обратим внимание на то, что все поля в обеих частях этого выражения упорядочены по времени. Это сохраняет силу и для случая $y^0 > x^0$. Таким образом, получаем окончательное выражение, справедливое теперь для любых x^0 и y^0:

$$\langle\Omega|T\{\phi(x)\phi(y)\}|\Omega\rangle = \lim_{T\to\infty(1-i\varepsilon)1-i}\frac{\left\langle 0\left|T\left\{\phi_I(x)\phi_I(y)\exp\left[-i\int\limits_{-T}^{T}dtH_I(t)\right]\right\}\right|0\right\rangle}{\left\langle 0\left|T\left\{\exp\left[-i\int\limits_{-T}^{T}dtH_I(t)\right]\right\}\right|0\right\rangle}$$

Преимущество рассмотрения хронологически упорядоченного произведения состоит в следующем. Это позволяет вставлять что угодно под знак общего оператора T-упорядочения. Подобная формула имеет место и для корреляционных функций более высокой степени от произвольного числа полей: для каждого дополнительного множителя ϕ слева поместим дополнительный множитель ϕ_I справа. Пока что полученное выражение остается точным. Но теперь оно идеально подходит для выполнения вычислений по теории возмущений. Нужно только сохранить столько членов, сколько требуется, в ряде Тейлора для экспоненты.

14.2 Basics of Feynman Diagrams

14.2.1 Connected Diagrams

Связной компонентой диаграммы мы назовем непрерывную цепочку внутренних линий. Если у диаграммы нет внутренних линий, то это также предельный случай связной компоненты с нулем внутренних линий. Если у диаграммы только одна связная компонента, то диаграмма называется связной.

Разложение в ряд по источникам для амплитуды $\tilde{Z}(j) = Z(j)/Z(0)$ начинается с единицы:

$$\tilde{Z}(j) = 1 + \sum_{k=1}^{\infty} \left(\frac{i}{\hbar}\right)^k \int \mathcal{D}^{(k)}_{1\ldots k}(x_1, \ldots, x_k) \frac{1}{k!} \prod_{k'=1}^{k} j(x_{k'}) \, \mathrm{d}^4 x_{k'}$$

В функциях Грина $\mathcal{D}$, как мы видели, есть несвязные вклады, что соответствует произведениям связных функций $\mathcal{D}^c[c = \text{connected}]$, которые уже не распадаются на произведения других связных функций. Для краткости обозначений запишем k -точечные связные вклады в виде

$$a_k = \left(\frac{\mathrm{i}}{\hbar}\right)^k \int \mathcal{D}^{c(k)}_{1\ldots k}(x_1, \ldots, x_k) \frac{1}{k!} \prod_{k'=1}^{k} j(x_{k'}) \, \mathrm{d}^4 x_{k'}$$

Тогда

$$\tilde{Z}(j) = 1 + \sum_{N=1}^{\infty} \prod_{k=1}^{\infty} \frac{1}{(n_k)!} a_k^{n_k} \Bigg|_{\sum n_k = N}$$

где N - число произведений связных вкладов, а n_k - количество вкладов с k -точечными связными функциями Грина, которые входят симметрично и, стало быть, допускают $(n_k)!$ перестановок, дающих одинаковые вклады, причем $\sum n_k = N$ Заметим теперь, что разложение экспоненты в ряд

$$\exp a_1 = 1 + \sum_{N=1}^{\infty} \prod_{k=1}^{1} \frac{1}{(n_1)!} a_1^{n_1} \Bigg|_{n_1 = N}$$

для двух слагаемых принимает вид

$$\exp\{a_1 + a_2\} = 1 + \sum_{N=1}^{\infty} \prod_{k=1}^{2} \frac{1}{(n_k)!} a_k^{n_k} \Bigg|_{\sum n_k = N}$$

и, как нетрудно сообразить,

$$\exp\left\{\sum_{k=1}^{\infty} a_k\right\} = 1 + \sum_{N=1}^{\infty} \prod_{k=1}^{\infty} \frac{1}{(n_k)!} a_k^{n_k} \Bigg|_{\sum n_k = N}$$

Таким образом, мы показали, что факторизация несвязных амплитуд в произведение связных действительно приводит к экспоненциированию связных амплитуд, и подстановка $Z(j) = \exp\{\mathrm{i}G(j)/\hbar\}$ - это переход к производящему функционалу связных функций Грина $G(j)$. Этот вывод справедлив и при наличии ненулевых вакуумных полей, поскольку вклад вакуума факторизован в $Z(0)$

14.2.2 Loop Expansion (????)

Теория по Киселеву (???)

Амплитуду квантовых переходов при наличии взаимодействий

$$\hat{Z}(j) = \int \mathcal{D}\varphi \exp\left\{\frac{\mathrm{i}}{\hbar}\left(S_0(\varphi) + j_{x'}\varphi_{x'}\right) + \frac{\mathrm{i}}{\hbar}S_{\mathrm{int}}(\varphi)\right\}$$

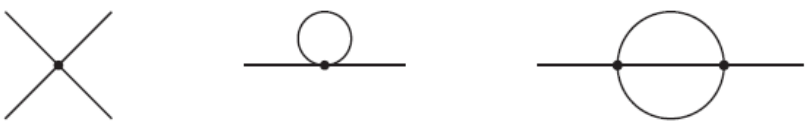
можно выразить с помощью действия оператора поля на функционал, построенный для свободных полей,

$$\hat{Z}(j) = \exp\left\{\frac{\mathrm{i}}{\hbar}S_{\mathrm{int}}\left(-\mathrm{i}\hbar\frac{\delta}{\delta j}\right)\right\}\int \mathcal{D}\varphi \exp\left\{\frac{\mathrm{i}}{\hbar}\left(S_0(\varphi) + j_{x'}\varphi_{x'}\right)\right\}$$

Этот функционал позволяет найти общее соотношение для числа петель,
степени возмущения и числа внутренних линий в связной диаграмме.
Действительно, если N_V - степень вклада возмущения в функцию Грина,
и значит, N_V - это число внутренних вершин в диаграмме,
то вклад вершин в число интегрирований по координатам равен N_V (vertex, number of vertecies).
Если в диаграмме есть внутренняя линия, то она соединяет 2 точки, т. е.
каждой внутренней линии отвечает одно интегрирование по координатам на конце внутренней линии,
так что при наличии N_I внутренних линий (internal lines) N_I интегрирований относятся именно к этим линиям,
и нужно добавить еще одну начальную точку, так что при последовательном счете,
если рассматривать связную цепочку внутренних линий,
имеется $N_I + 1$ число интегрирований в цепочке.
При этом, поскольку внутренняя линия соединяет именно вершины,
по сути мы полагаем, что в диаграмме столько же и вершин.
Однако если диаграмма связная, то некоторые начальные и конечные точки в цепочке внутренних линий могут совпасть.
Каждое такое совпадение означает наличие замкнутой петли.
Число петель N_L (loop, number of loops) определяет число точек посчитанных дважды, так что общее число интегрирований по внутренним вершинам или просто число вершин в действительности равно

$$N_V = N_I + 1 - N_L, \quad N_L = N_I + 1 - N_V$$

В справедливости данной формулы читатель может наглядно убедиться на примере четырех- и двухточечной функции Грина в теории «фи-в-четвертой», как это показано на рис.



Заметим теперь, что связные функции Грина $\mathrm{i}G(j)/\hbar$ с фиксированным числом петель получаются суммированием диаграмм с N_V степенями возмущения и N_I внутренними линиями, причем каждое возмущение дает фактор $1/\hbar$, а каждая внутренняя линия отвечает обратному оператору на квадратичном по траектории свободном действии,

т. е. вносит фактор $\hbar$(cm. связь связной двухточечной функции Грина со связной частью двухточечной функции Грина для амплитуды вероятности $Z(j)$).

В итоге связные функции Грина с петлями имеют следующий масштаб по $\hbar$:

$$\frac{1}{\hbar}G^{(L)} \sim \sum_{N_V,N_I} \left(\frac{1}{\hbar}\right)^{N_V} \hbar^{N_I}\Bigg|_{N_L \text{ fixed}} \sim \hbar^{N_L-1}$$

Таким образом, разложение связных функций Грина по петлям совпадает с разложением по степеням $\hbar$! Это означает, что в классическом пределе $\hbar \to 0$ среди связных диаграмм остаются только диаграммы без петель или, как говорят, древесные диаграммы.

Подчеркнем также, что полученные выше закономерности, связанные с числом петель, никак не зависят от того, как устроено возмущение (кубическое по полям или высшей степени по полям) и сколько внешних линий имеют связные функции Грина.

14.2.3 One-Particle Irreducible Diagrams (1PI)

Теория по Киселеву (???)

Эффективное действие $\Gamma(\varphi_{\mathrm{cl}})$, которое получается из производящего функционала связных функций Грина $G(j)$ посредством преобразования Лежандра, является производящим функционалом сильно связных (proper) функций Грина или, как говорят, вершин (vertex).

Под термином «сильно связный» понимают одночастичную неприводимость (one-particle irreducible): диаграмма остается связной даже после разрезания (усечения, удаления, ампутации) любой одной внутренней линии в этой диаграмме. Для доказательства этого утверждения воспользуемся методом Сиднея Коулмена и Стивена Вайнберга: построим производяший функционал функций Грина не с исходным действием S, а с эффективным действием Γ,

$$Z_\Gamma(j) = \exp\left\{\frac{\mathrm{i}}{\hbar_\Gamma}G_\Gamma(j)\right\} = \mathcal{N}\int \mathcal{D}\varphi \exp\left\{\frac{\mathrm{i}}{\hbar_\Gamma}\left(\Gamma(\varphi) + \varphi_{x'}j_{x'}\right)\right\}$$

где мы также провели формальную замену $\hbar \to \hbar_\Gamma$. Тогда $G_\Gamma(j)$ - это производящий функционал связных функций Грина с действием Γ. При этом, как мы установили, в пределе при $\hbar_\Gamma \to 0$ величина $G_\Gamma(j) \to G^{(0)}_\Gamma(j)$ не будет содержать петель, т. е. будет представлять собой, как говорят, лишь набор связных древесных диаграмм. Но в этом же пределе функциональный интеграл сводится к своему значению в стационарной точке:

$$\begin{aligned}\exp\left\{\frac{\mathrm{i}}{\hbar_\Gamma}G^{(0)}_\Gamma(j)\right\} &= \lim_{\hbar_\Gamma\to 0}\int \mathcal{D}\varphi \exp\left\{\frac{\mathrm{i}}{\hbar_\Gamma}\left(\Gamma(\varphi) + \varphi_{x'}j_{x'}\right)\right\} = \\ &= \exp\left\{\frac{\mathrm{i}}{\hbar_\Gamma}\left(\Gamma + \int \mathrm{d}^4x'\varphi\left(x'\right)j\left(x'\right)\right)\right\}\Bigg|_{\delta[\Gamma(\varphi)+\varphi_{x'}j_{x'}]/\delta\varphi(x)=0}\end{aligned}$$

Условие стационарности означает, что

$$\frac{\delta\Gamma}{\delta\varphi(x)} = -j(x), \quad G^{(0)}_\Gamma = \Gamma(\varphi) + \varphi_{x'}j_{x'}$$

т. е. предел производящего функционала в точности совпадает с производящим функционалом связных функций Грина в исходной теории:

$$G_{\Gamma}^{(0)} = G(j)$$

Таким образом, производящий функционал связных функций Грина соответствует связным древесным диаграммам с пропагаторами и вершинами, которые задаются эффективным действием Γ.

Остается справедливым соотношение

$$\Gamma_{13}^{(2)}\mathcal{G}_{32}^{(2)} = -\delta_{12}$$

так что связная двухточечная функция Грина $\mathcal{G}^{(2)}$ представляет собой двухточечную вершину $\Gamma^{(2)}$ с внешними линиями:

$$\mathrm{i}\ \mathcal{G}_{12}^{(2)} = \mathrm{i}\mathcal{G}_{13}^{(2)}\mathrm{i}\Gamma_{33'}^{(2)}\mathrm{i}\mathcal{G}_{3'2}^{(2)}$$

Более того, многократное повторение (вставка) блоков $\mathrm{i}\Gamma_{33'}^{(2)}\mathrm{i}\mathcal{G}_{3'2}^{(2)}$ в эту диаграмму сводится к единичному оператору, т. е. все цепочки с многократной вставкой двухточечной вершины идентичны древесной диаграмме с одной двухточечной вершинной функцией!

связные функции Грина в $G(j)$ для исходной теории с затравочным действием S являются в то же время диаграммами, построенными в древесном приближении в теории, где затравочным является уже эффективное действие Γ. Это значит, во-первых, что все такие древесные диаграммы, построенные по вершинам с эффективным действием, являются одночастично приводимыми: удаление любой внутренней линии делает диаграмму несвязной. Во-вторых, быть представлена как древесная, поскольку разложение такой вершины на сумму одночастично приводимых вкладов и одночастично неприводимый вклад означал бы, что вклад суммы одночастично приводимых диаграмм уже учтен прежде в виде такого же древесного вклада (см. илллюстрацию этого утверждения на примере 4-точки на рис.). Таким образом, по построению, если учтены все древесные вклады с одночастично неприводимыми вершинами низшего порядка, то вершины более высокого порядка уже не содержат одночастично приводимых вкладов. Отсюда следует, что все вершинные функции должны быть одночастично неприводимыми.

Покажем теперь, что вершинные функции - это усеченные сильносвязные функции Грина (одночастично неприводимые функции Грина с «ампутированными ногами»). В самом деле, поскольку

$$G(j) = \Gamma\left(\varphi_{\mathrm{cl}}\right) - \int \mathrm{d}^4x\varphi_{\mathrm{cl}}(x)\frac{\delta\Gamma}{\delta\varphi_{\mathrm{cl}}(x)}$$

мы видим, что первый член справа - эффективное действие Γ - задает все многоточечные одночастично неприводимые связные функции Грина, а во втором члене уже содержатся одночастично приводимые связные диаграммы. Особый случай - двухточечная связная функция Грина, поскольку это всего одна линия. Значит, для n -точечных функций

$$\Gamma_{1\ldots n}^{(n)}\varphi_{\mathrm{cl}}^{(1)}\cdots\varphi_{\mathrm{cl}}^{(n)} \cong \mathcal{G}_{1\ldots n}^{p(n)}j_1\ldots j_n, \qquad \text{высшие вершины } n > 2$$

где справа уже содержатся только сильно связные диаграммы (proper), за исключением двухточечной связной функции Грина, которая, с точностью до знака, является обратной к двухточечной вершине. Тогда вариационное дифференцирование источников по φ_{cl} при нулевых значениях этих внешних

полей справа дает

$$\Gamma^{(n)}_{1\ldots n} = \frac{\delta^n G^p}{\delta j_{1'}\ldots j_{n'}} \frac{\delta j_{1'}}{\delta\varphi_{\rm cl}(1)}\ldots\frac{\delta j_{n'}}{\delta\varphi_{\rm cl}(n)}, \quad n>2$$

Но вариационные производные при нулевых внешних классических полях

$$\frac{\delta j_{k'}}{\delta\varphi_{\rm cl}(k)} = -\frac{\delta^2\Gamma}{\delta\varphi_{\rm cl}(k)\delta\varphi_{\rm cl}\,(k')} = \left(\mathcal{G}^{(2)}_{kk'}\right)^{-1}$$

так что

$$\Gamma^{(n)}_{1\ldots n} = \frac{\delta^n G^{1-p}}{\delta j_{1'}\ldots j_{n'}} \prod_{k=1}^{n}\left(\mathcal{G}^{(2)}_{kk'}\right)^{-1}, \quad n>2$$

Это и означает, что вершины представляют собой связные одночастично неприводимые диаграммы, в которых внешние линии ампутированы, т. е. пропагаторы этих линий удалены за счет домножения на обратный двухточечный связный пропагатор.

В принципе, эта процедура срабатывает и с двухточечным эффективным действием: нужно взять двухточечную связную функции Грина и домножить ее дважы, по числу внешних точек, на обратную функцию, но добавить еще и множитель, равный -1. Об этом приходится помнить!

Если вариационные производные $Z(j)$ мы условились изображать в виде линий, исходящих из овала, а овал можно затем представить в виде сумм диаграмм в теории возмущений с распространением частиц вдоль тех же линий, то в той же логике можно условиться изображать вариационные производные $G(j)$ в виде линий, исходяших из круга, где круг можно затем представить

в виде сумм связных диаграмм с вершинами в теории возмущений и с распространением частиц вдоль линий, пересекающихся в вершинах. Тогда принято изображать вариационные производные эффективного действия Γ в виде круга с исходящими из него перечеркнутыми линиями, которые

символизируют усеченные внешние пропагаторы)амплитудные ноги)

как это показано на рис.

(рисунки снова)

14.2.4 Reduction Formulas

Теория по Киселеву (???)

Для того, чтобы получить из производящего функционала $\angle(j)$ S-матрицу

необходимо выразить внешние токи j через внешние поля в асимптотической области.

Но в силу

$$j(x) = -\frac{\delta\Gamma}{\delta\varphi_{\rm cl}(x)}, \quad \left.\frac{\delta\Gamma}{\delta\varphi_{\rm cl}(x)}\right|_{\varphi_{\rm cl}=0} = 0$$

в самом общем случае можно записать, что разложение тока j в вариационный ряд начинается со второго члена,

$$j(x) = -\int \frac{\delta^2\Gamma}{\delta\varphi_{\rm cl}(x)\delta\varphi_{\rm cl}(y)}\varphi_{\rm cl}(y)\mathrm{d}^4y + \ldots = \left(\mathcal{G}^{(2)}_{xy}\right)^{-1}\varphi^y_{\rm cl} + \ldots$$

Но в асимптотической области внешние поля стремятся к полям, которые, как мы помним, не содержат флуктуаций, т. е. удовлетворяют классическим уравнениям, а значит, все высшие вклады в (5.9) пренебрежимо малы, и

$$j(x) \mapsto \left(\mathcal{G}^{(2)}_{xy}\right)^{-1} \varphi^{y}_{\mathrm{cl}}$$

а вариаационный ряд для $Z(j)$ преобразуется в вариационный ряд $\mathcal{S}$ -матрицы:

$$\mathcal{D}^{(n)}_{1\ldots n} j_1 \ldots j_n \mapsto \mathcal{D}^{(n)}_{1\ldots n} \prod_{k=1}^{n} \left(\mathcal{G}^{(2)}_{kk'}\right)^{-1} \varphi^{(k')}_{\mathrm{cl}}$$

где асимптотически свободные поля. Эти поля были сгенерированы источниками в обобщенном смысле этого слова: источником можно считать как устройство, которое производит начальное состояние поля, так и детектор, который производит отсчет попавших в него частиц вместе с характеристиками этих частиц, т. е. регистрирует конечное состояние.

Вариационные n -точечные функции $\mathcal{S}$ -матрицы связаны с n -точечными причинными корреляторами редукционными формулами:

$$\mathcal{S}^{(n)}_{1'\ldots n'} = \mathcal{D}^{(n)}_{1\ldots n} \prod_{k=1}^{n} \left(\mathcal{G}^{(2)}_{kk'}\right)^{-1}$$

и мы опять имеем дело с усеченными диаграммами. Для расчета амплитуды вероятности квантового перехода с заданными асимптотическими внешними полями необходимо вычислить величину

$$\frac{1}{n!}\left(\frac{\mathrm{i}}{\hbar}\right)^{n} \mathcal{D}^{(n)}_{1\ldots n} \prod_{k=1}^{n} \left(\mathcal{G}^{(2)}_{kk'}\right)^{-1} \varphi^{(k')}_{\mathrm{cl}}$$

с учетом возможных перестановок тождественных частиц в начальном и конечном состояниях.

Примеры таких расчетов с переходом в импульсное представление мы уже приводили выше, например, для распада скаляра на частицу и античастицу и для аннигиляции скалярных безмассовых частиц в частицу и античастицу другого сорта.

14.2.5 Feynman Rules by Kiselev

Теория по Киселеву (???)

Резюмируя проведенное нами рассмотрение, мы можем теперь сформулировать правила Фейнмана для вычисления амплитуд квантовых переходов

в теории со скалярными полями при заданных начальных и конечных состояниях. Эти правила зависят, конечно, от исходного (bare) лагранжиана, что подразумевает определение состава полей и их взаимодействий. Поэтому опишем типовую модель с нейтральным (вещественным) полем φ и заряженным (комплексным) полем Φ, так что лагранжиан свободных полей имеет стандартный вид

$$\mathcal{L}_0 = \frac{1}{2}\left(\partial_\mu\varphi\partial^\mu\varphi - M^2\varphi^2\right) + \partial_\mu\Phi^\dagger\partial^\mu\Phi - m^2\Phi^\dagger\Phi$$

где M -масса нейтрального поля, а m - масса заряженного поля, а взаимодействия включают в себя

$$\mathcal{L}_{\text{int}} = -\Lambda\varphi\Phi^\dagger\Phi - \frac{\lambda}{4}\left(\Phi^\dagger\Phi\right)^2$$

так что Λ - размерная постоянная юкавского взаимодействия полей, а λ константа самодействия заряженного поля.

В импульсном представлении амплитуда квантового перехода строится по диаграмме с учетом закона сохранения 4-импульса, которые приписываются всем линиям,

$$\mathrm{i}\mathcal{M} = (2\pi)^4\delta\left(\sum p\right)\mathrm{i}\mathfrak{M}$$

причем в $\mathfrak{M}$ внутренним линиям отвечают следующие пропагаторы: вещественное поля φ - штриховая линия -

(вот тут хороший список правил Фейнмана!!!!)

$$\frac{\mathrm{i}}{k^2 - M^2 + \mathrm{i}0}, \quad - - - - -$$

комплексное поле Φ - сплошная линия со стрелкой по направлению движения заряда -

$$\frac{\mathrm{i}}{k^2 - m^2 + \mathrm{i}0},$$

Вершина Юкавского взаимодействия:

....

вершина самодействия заряженного поля

...

Вершина, как мы убедились, получаются из затравочного действия путем дифференцирования лагранжиана $\mathcal{L}_{\text{int}}$ по полям и домножением на мнимую единицу. Внешним линиям в конечном состоянии отвечают следующие моды:

заряженная частица - отрицательно частотная мода поля $\hat{\Phi}^\dagger$,

заряженная античастица - отрицательно частотная мода поля $\hat{\Phi}$,

нейтральная частица - отрицательно частотная мода поля $\hat{\varphi}$.

Внешним линиям в начальном состоянии отвечают следующие моды: заряженная античастица - положительно частотная мода поля $\hat{\Phi}^\dagger$, заряженная частица - положительно частотная мода поля $\hat{\Phi}$, нейтральная частица - положительно частотная мода поля $\hat{\varphi}$. Для скалярных частиц в принятой релятивистски ковариантной нормировке состояний все эти моды в координатном представлении отвечают волнам де Бройля с соответствующей прескрипцией для импульсов и энергий в начальных и конечных состояниях, чтобы выполнялся закон сохранения 4 импульса. В импульсном же представлении эти моды оказываются равными 1. Однако понимание того, как они были получены, упростит нам задачу в случае полей с ненулевым спином, когда моды - это многокомпонентные строки или столбцы, а не единицы.

При наличии в диаграмме петель закон сохранения 4-импульса приводит к дополнительному интегрированию по 4-импульсу, который может принимать произвольные значения,

$$\int \frac{\mathrm{d}^4 p}{(2\pi)^4}$$

для каждой петли. Подчеркнем, что при наличии тождественных полей необходимо учесть симметрийный фактор: для внешних полей провести симметризацию по тождественным

частицам и сосчитать варианты прескрипции 4-импульсов этим полям, для внутренних линий сосчитать число графических вариантов возникновения одних и тех же диаграмм по заданному набору линий и вершин. Пример расчета симметрийного фактора мы видели в теории кубического самодействия нейтрального поля.

14.2.6 Coupling Constant Expansion by Vergeles (!!!!)

(вроде у него круто это написано!)
(!!!! в 1ю часть перенесу многое!!!)

Теория

Рассмотрим случай потенциала самодействия вида $V(\phi) = \frac{1}{4!}\lambda_0\phi^4$ и разложим первую экспоненту в выражении

$$S(a^*, a) = S(\phi_0) = \frac{1}{N}\exp\left\{-i\int V\left(\frac{1}{i}\frac{\delta}{\delta\eta(x)}\right)\mathrm{d}x\right\}\times \\ \times\exp\left\{i\int \mathrm{d}x\eta(x)\phi_0(x) + \frac{i}{2}\iint \mathrm{d}x\ \mathrm{d}y\eta(x)D_c(x-y)\eta(y)\right\}\Bigg|_{\eta=0}.$$

в ряд по потенциалу V.

Члены этого ряда содержат произведения четырёхкратных дифференцирований по $\eta(x_i)$ с последующим интегрированием по x_i. Кратное применение операторов $\delta/\delta\eta(x_i)$ к $S_0(\phi_0;\eta)$ и последующее обращение в нуль поля η приводит к появлению в S-матрице множителей $\phi_0(x_i)$ и $D_c(x_i - x_j)$, причём последняя функция соответствует дифференциальному оператору второго порядка $(-i)\delta^2/\delta\eta(x_i)\,\delta\eta(x_j)$.

(?? выше не совсем еще понимаю.)

Изобразим графически каждый член этого разложения. Эти графики называются диаграммами Фейнмана.

Члену разложения n-ого порядка, содержащему дифференциальный оператор

$$\frac{(-i)^n}{n!}\int \mathrm{d}x_1...\mathrm{d}x_n V\left(\frac{1}{i}\frac{\delta}{\delta\eta(x_1)}\right)...V\left(\frac{1}{i}\frac{\delta}{\delta\eta(x_n)}\right),$$

сопоставляется диаграмма, состоящая из n вершин в точках $x_i, i = 1, ..., n$, находящихся под n-кратным интегралом по пространству-времени.

В рассматриваемом случае $V(\phi) = \frac{1}{4!}\lambda_0\phi^4$ из каждой вершины выходит 4 линии (в теории с потенциалом $\lambda\phi^s$ из каждой вершины выходит s линий). Эти линии могут либо замыкаться, соединяя пару вершин (такие линии называются внутренними), либо выходить из диаграммы, соответствуя полю $\phi_0(x_i)$ (такие линии - внешние).

Каждой внутренней линии, соединяющей точки x_i и x_j, сопоставляется функция $D_c(x_i - x_j)$.

Каждой внешней линии, выходящей из точки x_i, сопоставляется поле $\phi_0(x_i)$.

По всем точкам $\{x_i\}$ производится пространственно-временное интегрирование.

Полное выражение для $S(\phi_0)$ получается суммированием по всем диаграммам.

Приступим к конкретным вычислениям. Представим S-матрицу в виде

$$S = 1 + iT.$$

Пусть начальное и конечное состояния имеют вид

$$|\mathbf{k}_1, \mathbf{k}_2, ..., \mathbf{k}_n\rangle = \prod_{i=1}^{n} \left(\sqrt{2\omega_{k_i}} a^\dagger_{\mathbf{k}_i}\right)|0\rangle$$

обозначим через $|i\rangle$ и $|f\rangle$ начальное и конечное состояния, соответственно:

$$|i\rangle = |\mathbf{k}_1, \mathbf{k}_2, ...\rangle\,, \quad |f\rangle = |\mathbf{p}_1, \mathbf{p}_2, ...\rangle\,.$$

Вследствие общей трансляционной инвариантности теории справедлива формула

$$iT_{fi} \equiv \langle \mathbf{p}_1, \mathbf{p}_2, ...|iT|\mathbf{k}_1, \mathbf{k}_2, ...\rangle = (2\pi)^d \delta^{(d)}\left(P_f - P_i\right) iM_{fi}$$

Здесь $P_i = k_1 + k_2 + ...$ - суммарный начальный и $P_f = p_1 + p_2 + ...$ - суммарный конечный 4-импульсы. Введенная выше величина M_{fi} называется амплитудой рассеяния. Информация о взаимодействии содержится в T-матрице и в амплитуде M_{fi}, через которую выражаются сечения рассеяния, вероятности распадов частиц, и т.п. (в зависимости от постановки задачи). Из общих принципов квантовой механики следует, что эти величины квадратичны по M_{fi}.

Вычислим S-матрицу

$$S\left(\phi_0\right) = \sum_n \frac{1}{n!} \int S_n\left(x_1, ..., x_n\right) : \phi_0\left(x_1\right) ... \phi_0\left(x_n\right) : \mathrm{d}x_1 ... \mathrm{d}x_n$$

$$\phi_0(x) = \int \frac{\mathrm{d}^{(d-1)}k}{(2\pi)^{d-1}} \frac{1}{\sqrt{2\omega_k}} \left(a_{\mathbf{k}} e^{-ikx} + a^\dagger_{\mathbf{k}} e^{ikx}\right), \quad k^0 = \omega_k$$

с точностью до второго порядка по λ_0 и четвёртого по ϕ_0. Будем пользоваться формулами

$$S\left(a^*, a\right) = \frac{1}{N} \exp\left\{i \int \mathrm{d}^{(d)}x \eta(x)\phi_0(x) + \frac{i}{2} \iint \mathrm{d}^{(d)}x\ \mathrm{d}^{(d)}y \eta(x) D_c(x-y)\eta(y)\right\} \equiv S_0\left(\phi_0; \eta\right).$$

и

$$\frac{1}{i}\frac{\delta}{\delta\eta\left(x_i\right)} S_0\left(\phi_0; \eta\right) =: \left[\phi_0\left(x_i\right) + \int \mathrm{d}y D_c\left(x_i - y\right)\eta(y)\right] S_0\left(\phi_0; \eta\right) :\equiv: \left[x_i\right] S_0\left(\phi_0; \eta\right) :$$

$$\frac{1}{i}\frac{\delta}{\delta\eta\left(x_j\right)}\left[x_i\right] = -iD_c\left(x_i - x_j\right).$$

В первом порядке по λ_0 находим (нормировочную константу $1/N$ можно опускать, так как она всегда сокращается в окончательном результате):

$$-i\frac{\lambda_0}{4!} \int \mathrm{d}x : \left(\frac{1}{i}\frac{\delta}{\delta\eta(x)}\right)^4 S_0\left(\phi_0; \eta\right) : |_{\eta=0} = -i\frac{\lambda_0}{4!} \int \mathrm{d}x : \left\{-3D_c^2(0) - 6iD_c(0)\phi_0^2(x) + \phi_0^4(x)\right\} :$$

Во втором порядке следует вычислить величину

$$-\frac{1}{2}\left(\frac{\lambda_0}{4!}\right)^2 \int \mathrm{d}x_1\ \mathrm{d}x_2 : \left(\frac{1}{i}\frac{\delta}{\delta\eta\left(x_2\right)}\right)^4 \left(\frac{1}{i}\frac{\delta}{\delta\eta\left(x_1\right)}\right)^4 S_0\left(\phi_0; \eta\right) : |_{\eta=0} =$$

$$= -\frac{1}{2}\left(\frac{\lambda_0}{4!}\right)^2 \int \mathrm{d}x_1\ \mathrm{d}x_2 \left(\frac{1}{i}\frac{\delta}{\delta\eta\left(x_2\right)}\right)^4 : \left\{-3D_c^2(0) - 6iD_c(0)\left[x_1\right]^2 + \left[x_1\right]^4\right\} S_0\left(\phi_0; \eta\right) : |_{\eta=0}.$$

Далее целесообразно использовать формулу кратного дифференцирования

$$(fg)'''' = f''''g + 4f'''g' + 6f''g'' + 4f'g''' + fg''''$$

подразумевая под f - фигурную скобку в последнем равенстве, а под g - оператор $S_0(\phi_0;\eta)$. Таким образом находим искомую величину:

$$\frac{1}{2}\left(\frac{\lambda_0}{4!}\right)^2 \int \mathrm{d}x_1\ \mathrm{d}x_2 : \Big\{ -\left[9D_c^4(0) + 72D_c^2(0)D_c^2(x_1-x_2) + 24D_c^4(x_1-x_2)\right] -$$
$$-iD_c(x_1-x_2)\left[96D_c^2(x_1-x_2) + 144D_c^2(0)\right]\phi_0(x_1)\,\phi_0(x_2) -$$
$$-iD_c(0)\left[72D_c^2(x_1-x_2) + 18D_c^2(0)\right]\left(\phi_0^2(x_1)+\phi_0^2(x_2)\right) + \left[72D_c^2(x_1-x_2) + 36D_c^2(0)\right]\phi_0^2(x_1)\,\phi_0^2(x_2) +$$
$$+48D_c(0)D_c(x_1-x_2)\left[\phi_0(x_1)\,\phi_0^3(x_2) + \phi_0^3(x_1)\,\phi_0(x_2)\right] + 3D_c^2(0)\left[\phi_0^4(x_1)+\phi_0^4(x_2)\right]\Big\} :$$

При помощи теоремы Вика, а также разложения для ϕ_0 и определения векторов состояния находим следующие значения для элементов S-матрицы в случае перехода одночастичного состояния $|\mathbf{k}\rangle$ в одночастичное состояние $|\mathbf{p}\rangle$ (заметим, что все частоты $\omega_{\mathbf{k}}$, содержащиеся в формулах, определяющих вектора-состояния, и в лоренц-инвариантной мере, взаимно сокращаются):

(?? про это потом подумаю, пока что не вижу это.)

В нулевом приближении по λ_0:

$$\langle \mathbf{p}|S|\mathbf{k}\rangle = 2\omega_k(2\pi)^{d-1}\delta^{(d-1)}(\mathbf{k}-\mathbf{p})$$

(нет взаимодействия).

В первом порядке по λ_0:

$$2\omega_k(2\pi)^{d-1}\delta^{(d-1)}(\mathbf{k}-\mathbf{p})\int \mathrm{d}^{(d)}x\left[\frac{i\lambda_0}{8}D_c^2(0)\right] + (2\pi)^d\delta^{(d)}(k-p)\left[-\frac{\lambda_0}{2}D_c(0)\right].$$

Во втором порядке по λ_0:

$$2\omega_k(2\pi)^{d-1}\delta^{(d-1)}(\mathbf{k}-\mathbf{p})\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2\left[-\frac{\lambda_0^2}{2^7}D_c^4(0) - \frac{\lambda_0^2}{2^4}D_c^2(0)D_c^2(x_1-x_2) - \frac{\lambda_0^2}{2^4\cdot 3}D_c^4(x_1-x_2)\right] -$$
$$-i\frac{\lambda_0^2}{6}\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2 D_c^3(x_1-x_2)\,e^{ipx_1-ikx_2} - i\frac{\lambda_0^2}{4}\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2 D_c^2(0)D_c(x_1-x_2)\,e^{ipx_1-ikx_2} -$$
$$-i\frac{\lambda_0^2}{4}\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2 D_c(0)D_c^2(x_1-x_2)\,e^{i(p-k)x_1} - i\frac{\lambda_0^2}{16}\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2 D_c^3(0)e^{i(p-k)x_1}.$$

Согласно $(\partial_\mu\partial^\mu + m^2)\,D_c(x) = \delta^{(d)}(x)$,

$$D_c(x) = \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d}D_c(k)e^{-ikx}, \quad D_c(k) = \frac{1}{-k^2+m_0^2-i\varepsilon}, \quad \varepsilon\to+0.$$

В частности, $D_c(0) = \int \frac{\mathrm{d}^{(d)}k}{(2\pi)^d}D_c(k)$.

Преобразуем некоторые интегралы при помощи этого:

$$\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2 D_c^2\left(x_1-x_2\right)=\int \mathrm{d}^{(d)}x\int\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}D_c^2(k),$$

$$\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2 D_c^4\left(x_1-x_2\right)=\int \mathrm{d}^{(d)}x\int\frac{\mathrm{d}^{(d)}k_1}{(2\pi)^d}\frac{\mathrm{d}^{(d)}k_2}{(2\pi)^d}\frac{\mathrm{d}^{(d)}k_3}{(2\pi)^d}D_c\left(k_1\right)D_c\left(k_2\right)D_c\left(k_3\right)D_c\left(k_1+k_2+k_3\right),$$

$$\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2 D_c^3\left(x_1-x_2\right)e^{ipx_1-ikx_2}=(2\pi)^d\delta^{(d)}(k-p)\int\frac{\mathrm{d}^{(d)}k_1\mathrm{d}^{(d)}k_2}{(2\pi)^{2d}}D_c\left(k_1\right)D_c\left(k_2\right)D_c\left(k-k_1-k_2\right),$$

$$\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2 D_c\left(x_1-x_2\right)e^{ipx_1-ikx_2}=(2\pi)^d\delta^{(d)}(k-p)D_c(k),$$

$$\int \mathrm{d}^{(d)}x_1\ \mathrm{d}^{(d)}x_2 e^{i(p-k)x_1}D_c^2\left(x_1-x_2\right)=(2\pi)^d\delta^{(d)}(k-p)\int\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}D_c(k)D_c(-k),$$

Теперь при помощи выписанных формул вычислим вклад в амплитуду перехода $|\mathbf{k}\rangle\to|\mathbf{p}\rangle$, содержащийся в сумме членов (8)-(10), с точностью $O\left(\lambda_0^2\right)$:

$$2\omega_k(2\pi)^{d-1}\delta^{(d-1)}(\mathbf{k}-\mathbf{p})\left\{1+\frac{i\lambda_0}{8}\left(\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)\right)^2\int\mathrm{d}^dx-\right.$$

$$-\lambda_0^2\left[\frac{1}{2^7}\left(\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)\right)^4\int\mathrm{d}^{(d)}x_1\int\mathrm{d}^{(d)}x_2+\frac{1}{2^4}\int\mathrm{d}^{(d)}x\left(\int\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}D_c(k)\right)^2\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)D_c(-q)+\right.$$

$$\left.\left.+\frac{1}{2^43}\int\mathrm{d}^{(d)}x\int\frac{\mathrm{d}^{(d)}k_1}{(2\pi)^d}\frac{\mathrm{d}^{(d)}k_2}{(2\pi)^d}\frac{\mathrm{d}^{(d)}k_3}{(2\pi)^d}D_c\left(k_1\right)D_c\left(k_2\right)D_c\left(k_3\right)D_c\left(k_1+k_2+k_3\right)\right]\right\}+$$

$$+(2\pi)^d\delta^{(d)}(k-p)\left\{-\frac{\lambda_0}{2}\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)-i\lambda_0^2\left[\frac{1}{6}\int\frac{\mathrm{d}^{(d)}q_1}{(2\pi)^d}\frac{\mathrm{d}^{(d)}q_2}{(2\pi)^d}D_c\left(q_1\right)D_c\left(q_2\right)D_c\left(k-q_1-q_2\right)+\right.\right.$$

$$\left.\left.+\frac{1}{16}\int\mathrm{d}x\left(\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)\right)^3\right]\right\}$$

2. Диаграммы Фейнмана и правила Фейнмана

Аналитическому выражению

$$2\omega_k(2\pi)^{d-1}\delta^{(d-1)}(\mathbf{k}-\mathbf{p})\left\{1+\frac{i\lambda_0}{8}\left(\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)\right)^2\int\mathrm{d}^dx-\right.$$

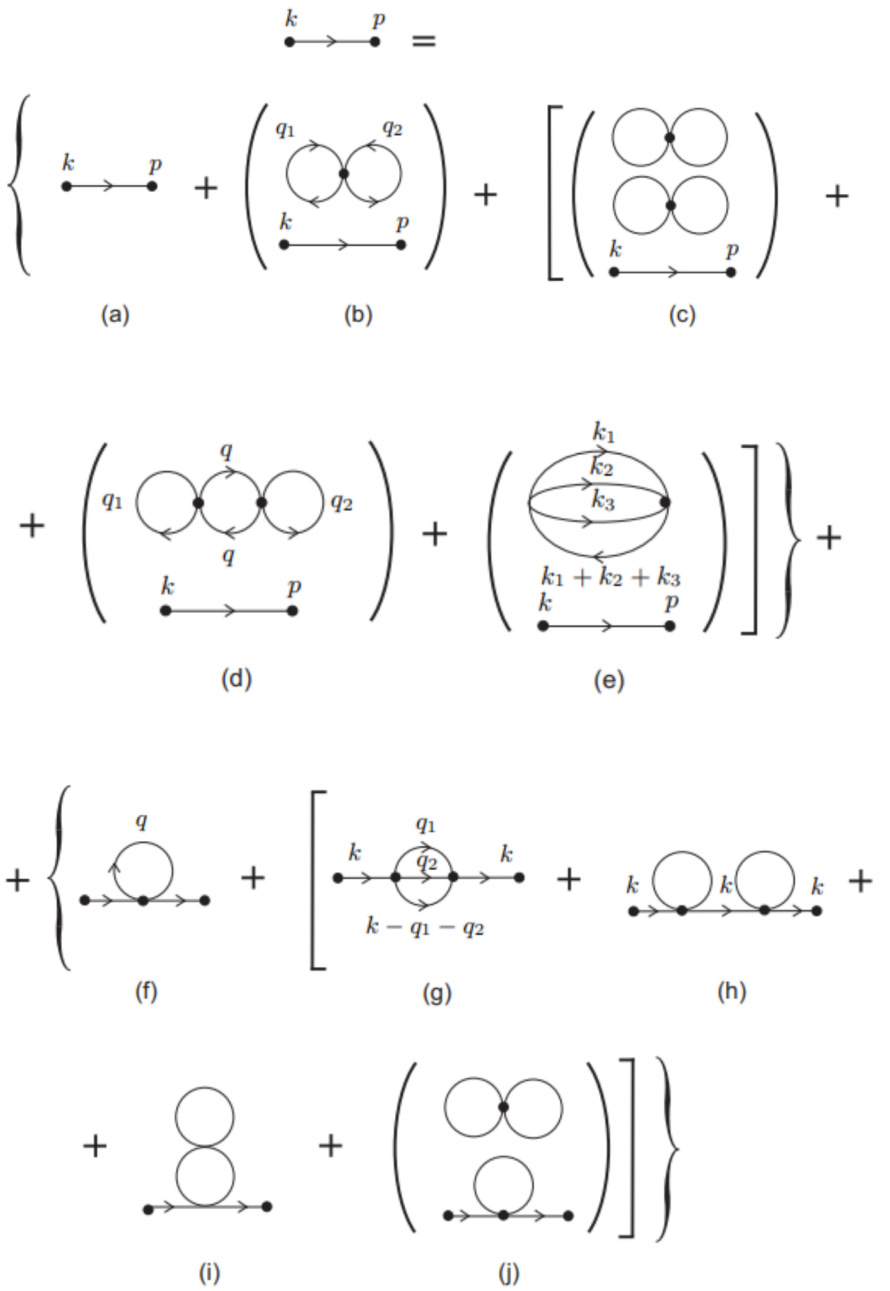
$$-\lambda_0^2\left[\frac{1}{2^7}\left(\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)\right)^4\int\mathrm{d}^{(d)}x_1\int\mathrm{d}^{(d)}x_2+\frac{1}{2^4}\int\mathrm{d}^{(d)}x\left(\int\frac{\mathrm{d}^{(d)}k}{(2\pi)^d}D_c(k)\right)^2\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)D_c(-q)+\right.$$

$$\left.\left.+\frac{1}{2^43}\int\mathrm{d}^{(d)}x\int\frac{\mathrm{d}^{(d)}k_1}{(2\pi)^d}\frac{\mathrm{d}^{(d)}k_2}{(2\pi)^d}\frac{\mathrm{d}^{(d)}k_3}{(2\pi)^d}D_c\left(k_1\right)D_c\left(k_2\right)D_c\left(k_3\right)D_c\left(k_1+k_2+k_3\right)\right]\right\}+$$

$$+(2\pi)^d\delta^{(d)}(k-p)\left\{-\frac{\lambda_0}{2}\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)-i\lambda_0^2\left[\frac{1}{6}\int\frac{\mathrm{d}^{(d)}q_1}{(2\pi)^d}\frac{\mathrm{d}^{(d)}q_2}{(2\pi)^d}D_c\left(q_1\right)D_c\left(q_2\right)D_c\left(k-q_1-q_2\right)+\right.\right.$$

$$\left.\left.+\frac{1}{16}\int\mathrm{d}x\left(\int\frac{\mathrm{d}^{(d)}q}{(2\pi)^d}D_c(q)\right)^3\right]\right\}$$

соответствует следующая сумма диаграмм Фейнмана на рисунке ниже в том же порядке:



Сформулируем правила Фейнмана применительно к рассматриваемой модели.

Внутренним и внешним линиям приписывается D-импульс, а свободным линиям - два D-импульса (по одному каждому концу), причём изменение направления линий влечёт изменение знака соответствующих D-импульсов. Внутренние линии называются пропагаторами.

Сформулируем правила Фейнмана для вычисления амплитуды перехода iM, сопоставляющие диаграммам аналитические выражения:

0. каждому свободному отрезку (см. рис. a)

(отрезок)

$$= (2\pi)^{d-1}\delta^{(d-1)}(\mathbf{k}-\mathbf{p}),\ \text{где } k \text{ и } p - d\text{-импульсы концов отрезка;}$$

1. каждому пропагатору (тупо линия) $\longrightarrow \vec{k} = -iD_c(k)$, где $k - d$-импульс пропагатора;

2. каждой вершине
точка $= -i\lambda$
3. каждой внешней линии
$\longrightarrow \quad = 1$
4. потребовать выполнения закона сохранения d-импульса в каждой вершине;
5. проинтегрировать по каждому не зафиксированному законом сохранения импульсу: $\int \frac{\mathrm{d}^{(d)}p}{(2\pi)^d}$;
6. разделить на множитель D_n - порядок группы симметрии диаграммы;
7. каждый связный вакуумный пузырёк (как "восьмёрка"на рис. 3b) содержит множитель $\left(\int \mathrm{d}^{(d)}x\right)$.

Все интегрирования интерпретируются как следствие принципа суперпозиции, согласно которому амплитуды суммируются.

Правило 0 имеет значение лишь для тривиальной части амплитуды рассеяния. Важная для физики частиц амплитуда M (см. (4)) содержится во второй фигурной скобке в (13), а также во второй фигурной скобке на на рис. 3. Правило 7 имеет значение, как мы увидим, лишь для амплитуды перехода из вакуума в вакуум.

Укажем порядки групп симметрии D_n диаграмм на рис. 3:

(b) $D_n = 8$ - по две перестановки каждого из концов двух пропагаторов и две перестановки самих пропагаторов $(2 \cdot 2 \cdot 2 = 8)$;

(c) $D_n = 2 \cdot 8 \cdot 8 = 2^7$;

(d) $D_n = 2 \cdot 2 \cdot 2 \cdot 2 = 2^4$;

(e) $D_n = 2 \cdot 4!$ - две перестановки вершин и 4 ! перестановки пропагаторов вакуумного пузырька;

(f) $D_n = 2$ - перестановка концов пропагатора;

(g) $D_n = 3$! - число перестановок пропагаторов;

(h) $D_n = 2 \cdot 2 = 4$;

(i) $D_n = 2 \cdot 2 = 4$ - две перестановки пропагаторов в нижней петле и две перестановки концов пропагатора в верхней петле;

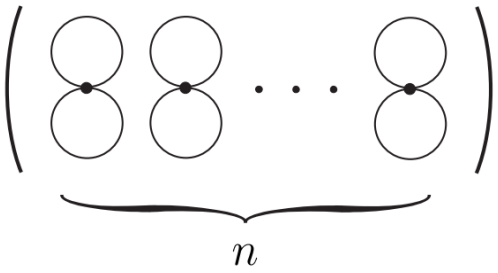
(j) $D_n = 8 \cdot 2 = D'_n \cdot 2 = 16 - D'_n = 8$ для вакуумного пузырька и две перестановки концов пропагатора.

В случае сомнения при вычислении D_n следует непосредственно вычислить коэффициент при диаграмме.

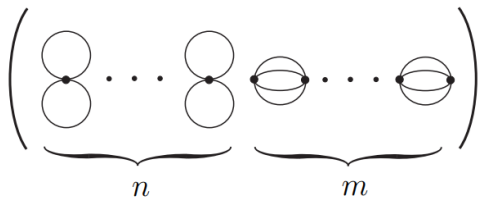
Нетрудно понять происхождение правил Фейнмана. Действительно, каждой вершине сопоставляется множитель $\int \mathrm{d}^{(d)}x(-i\lambda/4!)$ и в случае n-вершинной диаграммы имеется общий множитель $(1/n!)$ из ряда Тейлора. Но множитель $1/n$! всегда сокращается множителем $n!$ от перестановок вершин. Кроме того, каждая вершина имеет 4 линии, приходящие из четырёх различных мест. Перестановки относительно этих мест (что делается автоматически при вычислении $(\delta/i\delta\eta(x))^4$), дают множитель 4 !, сокращающий знаменатель в $(-i\lambda/4!)$. Поэтому каждой вершине сопоставляется множитель $\int \mathrm{d}^{(d)}x(-i\lambda)$. Если же мы имеем, например, вакуумный пузырёк с двумя вершинами такой, как на рис. 3e, то из двух исходных множителей $1/4!$ один остаётся. Не сокращается также общий множитель $(1/2)$. Но в данном случае как раз $D_n = 2 \cdot 4!$. Действительно, при действии дифференциального оператора $[(\delta/i\delta\eta(x))^4]\,[(\delta/i\delta\eta(y))^4]$ на величину $S_0\left(\phi_0;\eta\right)$ та квадратная скобка, которая действует первая, не даёт множителя 4!.

Для подсчета комбинаторного коэффициента диаграммы удобно представлять вычисление так, как будто все операторы $[-i\delta/\delta\eta(x)]$ либо "спариваются"попарно, либо "спариваются"с полем ϕ_0. В первом случае каждой "спарке" $[-i\delta/\delta\eta\left(x_i\right)]$ и $[-i\delta/\delta\eta\left(x_j\right)]$

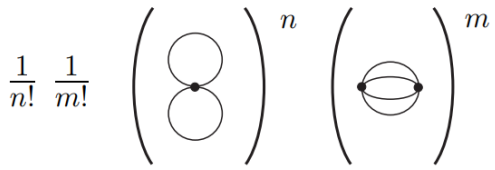
соответствует множитель $[-iD_c(x_i - x_j)]$, а во втором случае - $\phi_0(x)$. Это правило является одним из вариантов теоремы Вика. Легко сообразить, что, например, при вычислении диаграммы на рис.



множитель $(1/n!)$ в дифференциальном операторе (1) не сокращается: каждый множитель $\left[\frac{1}{4!}\int \mathrm{d}x_i \left(\frac{1}{i}\frac{\delta}{\delta\eta(x_i)}\right)^4\right]$ даёт в амплитуде множитель, соответствующий одной диаграмме-восьмёрке. Таким образом, в случае диаграммы на рис. 4 порядок группы симметрии $D_n = n!(8)^n$. Аналогично, если мы имеем несвязную вакуумную диаграмму вида



то она равна



Из сказанного видно, что любая диаграмма, не содержащая несвязных вакуумных компонент, умноЖается на ряд

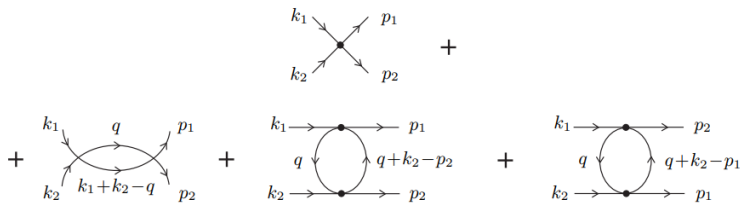
$$\sum_{\{n_i\}} \left(\prod_i \frac{1}{n_i!} V_i^{n_i} \right) = \exp\left(\sum_i V_i \right).$$

Таким образом, сумма всех диаграмм с заданным числом внешних линий равна сумме всех связных диаграмм с этими же внешними линиями, умноженной на экспоненту от суммы всех разных несвязных диаграмм без внешних линий (вакуумных пузырьков). Эта экспонента интерпретируется как фаза, набегающая при переходе вакуума в вакуум за бесконечное время. Заметим, что каждая диаграмма V_i содержит множитель $\left(\int \mathrm{d}^{(d)}x\right)$. Эта вакуумная фаза не представляет интереса, поскольку сокращается в физических величинах. Поэтому её не учитывают.

Во второй фигурной скобке на рис. 3 диаграммы $(f),(g),(h),(i)$ дают поправки к амплитуде распространения одной частицы в вакууме. Все эти поправки могут лишь привести к изменению (перенормировке) тех параметров частицы, которые могут изменяться непрерывно. Например, это может быть масса. Эти поправки далее рассматриваются в меру необходимости. Здесь лишь заметим, что буквальный учёт диаграмм типа рис. $3(f)-(i)$ затруднителен, поскольку, например, диаграммы (f) и (g) квадратично расходятся, диаграмма (h) содержит множитель

$$D_c(k)=\frac{1}{-k^2+m_0^2-i\varepsilon}.$$

Однако $k^2=m_0^2$, и потому $D_c(k)=\frac{1}{0}=\infty$. Мы видим, что поправки к внешним линиям, 4-импульсы которых k_i удовлетворяют условию $k_i^2=m^2$, где m - наблюдаемая (или физическая) масса, требуют отдельного рассмотрения. Такое рассмотрение далее проводится в более изящной теории поля квантовой электродинамике. В скалярной теории поля квантовые поправки к внешним линиям здесь не изучаются. (Говорят, что если импульс частицы удовлетворяет условию $k_i^2=m^2$, то её импульс находится на массовой поверхности; в этой ситуации говорят также, что частица находится на массовой поверхности.) Таким образом, из двух диаграмм левая будет учитываться, а правая - нет.



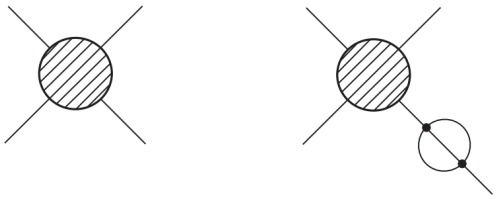
Будем говорить, что у диаграммы ноги на массовой поверхности ампутированы, если её нельзя рассечь на две несвязных диаграммы, разрезая одну внутреннюю линию, и при этом одна из двух диаграмм имеет две внешних линии на массовой поверхности.

Таким образом, при проведении вычислений по ТВ следует нарисовать все диаграммы процесса, имеющие физический смысл, с заданным числом вершим, определяемым степенью необходимой точности вычисления, сопоставить диаграммам аналитические выражения согласно правилам Фейнмана и вычислить их.

(???? все, забили что ли, итоговый ответ не нашли???????)

взаимное рассеяние двух начальных частиц

Например, рассмотрим взаимное рассеяние двух начальных частиц с импульсами $\mathbf{k}_1$ и $\mathbf{k}_2$, в результате чего при $t\to\infty$ имеем две частицы с импульсами $\mathbf{p}_1$ и $\mathbf{p}_2$. Этот процесс с точностью $O\left(\lambda_0^2\right)$ описывается следующими диаграммами:



Аналитическое выражение этих диаграмм таково:

$$iM = -i\lambda_0 + \left\{ \frac{1}{2}\lambda_0^2 \int \frac{\mathrm{d}^{(d)}q}{(2\pi)^d} D_c(q) \left[D_c\left(k_1 + k_2 - q\right) + D_c\left(k_2 - p_2 + q\right) + D_c\left(k_2 - p_1 + q\right) \right] \right\}.$$

Амплитуду (15) легко также получить непосредственно при помощи выражений (6) и (7).

3. Производящий функционал гриновских функций $Z(\eta)$

Если в

$$S\left(a^*, a\right) = S\left(\phi_0\right) = \frac{1}{N} \exp\left\{ -i \int V\left(\frac{1}{i} \frac{\delta}{\delta\eta(x)} \right) \mathrm{d}x \right\} \times$$
$$\times \exp\left\{ i \int \mathrm{d}x \eta(x)\phi_0(x) + \frac{i}{2} \iint \mathrm{d}x\ \mathrm{d}y \eta(x) D_c(x-y)\eta(y) \right\} \Bigg|_{\eta=0}. \quad (14.1)$$

не полагать $\eta = 0$, то полученный функционал обозначим $S\left(\phi_0; \eta\right)$; он является нормальным символом S-матрицы для рассеяния взаимодействующих частиц в присутствии источника $\eta(x)$. Рассмотрим также функционал

$$Z(\eta) = \exp\left\{ -i \int V\left(\frac{1}{i} \frac{\delta}{\delta\eta(z)} \right) \mathrm{d}z \right\} \cdot \exp\left\{ \frac{i}{2} \int \eta(x) D_c(x-y)\eta(y) \mathrm{d}x\ \mathrm{d}y \right\},$$

имеющий смысл амплитуды перехода из вакуума в вакуум в присутствии внешнего источника. Коэффициентные функции $G_n\left(x_1, ..., x_n\right)$ в разложении функционала $Z(\eta)$ в ряд по $\eta(x)$

$$Z(\eta) = \sum_n \frac{1}{n!} \int G_n\left(x_1, ..., x_n\right) \eta\left(x_1\right) ... \eta\left(x_n\right) \mathrm{d}x_1 ... \mathrm{d}x_n$$

определяют функции Грина, то есть вакуумные средние от хронологических произведений гейзенберговых операторов поля (см. конец лекции 1). Поэтому функционал $Z(\eta)$ называется производящим функционалом.

Функционал $Z(\eta)$ содержит в себе больше информации, чем функционал $S\left(\phi_0\right)$ (63 Л2): зная $Z(\eta)$, можно восстановить $S\left(\phi_0\right)$. Чтобы получить явные формулы, введём расширенный функционал $S(\phi)$, заменив в (63 Л2) поле $\phi_0(x)$ произвольной функцией четырёх переменных $\phi(x)$. Коэффициентные расширенные функции $\tilde{S}_n$ суть вариационные производные (под расширенными функциями мы понимаем коэффициентные функции для $S(\phi)$):

$$\tilde{S}_n\left(x_1, ..., x_n\right) = \left(\frac{1}{i} \frac{\delta}{\delta\phi\left(x_1\right)} \right) \cdots \left(\frac{1}{i} \frac{\delta}{\delta\phi\left(x_n\right)} \right) S(\phi) \Big|_{\phi=0} =$$
$$= \exp\left\{ -i \int V\left(\frac{1}{i} \frac{\delta}{\delta\eta(z)} \right) \mathrm{d}z \right\} \eta\left(x_1\right) ... \eta\left(x_n\right) \cdot \exp\left\{ \frac{i}{2} \int \eta(x) D_c(x-y)\eta(y) \mathrm{d}x\ \mathrm{d}y \right\}.$$

Пусть

$$\tilde{\eta}(x) = \int \mathrm{d}y D_c(x-y)\eta(y) \to \eta(x) = (\partial_\mu \partial^\mu +$$
$$\frac{\delta}{\delta\tilde{\eta}(x)} = \left(\partial_\mu \partial^\mu + m^2\right)_x \frac{\delta}{\delta\eta(x)}$$

Очевидно

$$\left(\frac{1}{i}\frac{\delta}{\delta\tilde{\eta}(x)}\right)Z(\eta)=\exp\left\{-i\int V\left(\frac{1}{i}\frac{\delta}{\delta\eta(z)}\right)\mathrm{d}z\right\}\eta(x)\exp\left\{\frac{i}{2}\int\eta(y)D(y-z)\eta(z)\mathrm{d}y\ \mathrm{d}z\right\},$$

$$\left(\frac{1}{i}\frac{\delta}{\delta\tilde{\eta}\left(x_1\right)}\right)\left(\frac{1}{i}\frac{\delta}{\delta\tilde{\eta}\left(x_2\right)}\right)Z(\eta)=\exp\left\{-i\int V\left(\frac{1}{i}\frac{\delta}{\delta\eta(z)}\right)\mathrm{d}z\right\}\cdot$$

$$\cdot\left(\frac{1}{i}\frac{\delta}{\delta\tilde{\eta}\left(x_1\right)}\right)\left(\frac{1}{i}\frac{\delta}{\delta\tilde{\eta}\left(x_2\right)}\right)Z(\eta)=\exp\left\{-i\int V\left(\frac{1}{i}\frac{\delta}{\delta\eta(z)}\right)\mathrm{d}z\right\}$$

$$\left[\eta\left(x_1\right)\eta\left(x_2\right)+\frac{1}{i}\left(\partial_\mu\partial^\mu+m^2\right)_{x_2}\delta^{(d)}\left(x_2-x_1\right)\right]\exp\left\{\frac{i}{2}\int\eta(y)D_c(y-z)\eta(z)\mathrm{d}y\ \mathrm{d}z\right\},$$

и т.д. Очевидно, применение оператора

$$\left(\frac{1}{i}\frac{\delta}{\delta\tilde{\eta}\left(x_1\right)}\right)...\left(\frac{1}{i}\frac{\delta}{\delta\tilde{\eta}\left(x_n\right)}\right)$$

к функционалу (16) даёт функционал того же вида, что в правой части (20), где квадратная скобка заменяется на величину

$$\left[\eta\left(x_1\right)...\eta\left(x_n\right)+\varkappa\left(x_1,...,x_n\right)\right],$$

причём

$$\int\phi_0\left(x_1\right)...\phi_0\left(x_n\right)\varkappa\left(x_1,...,x_n\right)\mathrm{d}x_1...\mathrm{d}x_n=0.$$

Теперь при помощи (18)-(21) находим:

$$\int\mathrm{d}x_1...\mathrm{d}x_n\phi_0\left(x_1\right)...\phi_0\left(x_n\right)\left\{\left(\frac{1}{i}\frac{\delta}{\delta\phi\left(x_1\right)}\right)\cdots\left(\frac{1}{i}\frac{\delta}{\delta\phi\left(x_n\right)}\right)S(\phi)\Big|_{\phi=0}-\right.$$

$$\left.-\left(\frac{1}{i}\frac{\delta}{\delta\tilde{\eta}\left(x_1\right)}\right)\cdots\left(\frac{1}{i}\frac{\delta}{\delta\tilde{\eta}\left(x_n\right)}\right)Z(\eta)\right\}=0$$

Таким образом, для вычисления нормального символа S-матрицы нужно вычислить вариационные производные

$$\left(\frac{1}{i}\frac{\delta}{\delta\eta\left(x_1\right)}\right)\cdots\left(\frac{1}{i}\frac{\delta}{\delta\eta\left(x_n\right)}\right)Z(\eta)\Big|_{\eta=0},$$

т.е. функции Грина $G_n\left(x_1,...,x_n\right)$, подействовать на эти функции дифференциальным оператором

$$\prod_{i=1}^{n}\left(\partial_\mu\partial_{x_i}^\mu+m^2\right)$$

умножить результат на произведение

$$\frac{1}{n!}\prod_i\phi_0\left(x_i\right),$$

проинтегрировать по всем x_i и просуммировать по n.

14.2.7 Combinatoric Factors

(??? discussion of how to obtain it with examples?)

14.2.8 Feynman Rules: Derivation from Weinberg

(??? когда-то выгружу то, что было до этого, пока так.)

Теория

Мы начнем с формулы для S -матрицы, полученной из разложения Дайсона (3.5.10) и выражения (4.2.2) для свободных полей:

$$S_{\mathbf{p}'_1\sigma'_1n'_1;\mathbf{p}'_2\sigma'_2n'_2;...,\mathbf{p}'_1\sigma_1n_1;\mathbf{p}_2\sigma_2n_2;...} =$$

$$= \sum_{N=0}^{\infty} \frac{(-i)^N}{N!} \int d^4x_1 ... d^4x_N \left(\Phi_0, ... a\left(\mathbf{p}'_2\sigma'_2n'_2\right) a\left(\mathbf{p}'_1\sigma'_1n'_1\right) \times \right.$$

$$\left. \times T\left\{\mathscr{H}\left(x_1\right) ... \mathscr{H}\left(x_N\right)\right\} a^{\dagger}\left(\mathbf{p}_1\sigma_1n_1\right) a^{\dagger}\left(\mathbf{p}_2\sigma_2n_2\right) ... \Phi_0\right)$$

Напомним, что $\mathbf{p}, \sigma$ и n обозначают импульс, спин и сорт частиц; штрихи обозначают конечные состояния частиц; Φ_0 - вакуум свободных частиц; $a, a^{\dagger}$ - операторы уничтожения, рождения; T - знак хронологического упорядочивания, который располагает множители $\mathscr{H}(x)$ в таком порядке, что аргументы x^0 уменьшаются слева направо; наконец, $\mathscr{H}(x)$ - гамильтониан (плотность функции Гамильтона) взаимодействия, который считается полиномом от полей и сопряженных полей

$$\mathscr{H}(x) = \sum_i g_i \mathscr{H}_i(x)$$

а каждое слагаемое $\mathscr{H}_i$ является произведением определенного числа полей и сопряженных им величин каждого типа. Поле каждой частицы сорта n, преобразуещееся по определенному представлению однородной группы Лоренца (с пространственными инверсиями или без них), дается формулой

$$\psi_l(x) = \sum_{\sigma} (2\pi)^{-3/2} \int d^3p \left[u_l(\mathbf{p}, \sigma, n) a(\mathbf{p}, \sigma, n) e^{ip\cdot x} + + v_l(\mathbf{p}, \sigma, n) a^{\dagger}\left(\mathbf{p}, \sigma, n^c\right) e^{-ip\cdot x}\right]$$

Здесь n^c обозначает античастицу сорта n, а в экспоненте $e^{\pm ip\cdot x}$ энергия p^0 равна $\sqrt{\mathrm{p}^2 + m_n^2}$. Функции-коэффициенты u_l, v_l зависят от лоренц-трансформационных свойств поля и спина частицы, которую это поле описывает; они были вычислены в гл. 5. (Например, в случае скалярного поля для частицы с энергией E функция u_l есть просто множитель $(2E)^{-1/2}$, а для дираковского поля u_l, v_l являются нормированными дираковскими спинорами, введенными в \$5.5). Индекс l у полей означает не только сорт частицы, но и представление группы Лоренца, по которому преобразуется поле, а также обозначает все "бегушие" индексы многокомпонентного поля в этом представлении. Нет необходимости отдельно рассматривать взаимодействия с производными от полей, поскольку в нашей записи производная от поля (6.1.3) снова является полем того же вида, но с другими u_l, v_l. Мы будем отличать некие произвольные частицы, например электроны, протоны и т.п., от их античастиц, таких, как позитроны и антипротоны. Операторы поля,

которые уничтожают частицы и создают античастицы, у нас называются просто "поля"; сопряженные им операторы, уничтожающие античастицы и создающие частицы, называются "сопряженные поля". Разумеется, некоторые частицы могут совпадать с их античастицами, например фотон γ и нейтральный пи-мезон π^0; для таких полей сопряженные поля пропорциональны самим полям.

Теперь переставим в формуле (6.1.1) все операторы уничтожения направо, применяя нужное число раз (анти)коммутационные соотношения:

$$
\begin{aligned}
&a(\mathbf{p}\sigma n)a^{\dagger}\left(\mathbf{p}'\sigma' n'\right) = \pm a^{\dagger}\left(\mathbf{p}'\sigma' n'\right) a(\mathbf{p}\sigma n) + \delta^3\left(p'-p\right)\delta_{\sigma'\sigma}\delta_{n'n} \\
&a(\mathbf{p}\sigma n)a\left(\mathbf{p}'\sigma' n'\right) = \pm a\left(\mathbf{p}'\sigma' n'\right) a(\mathbf{p}\sigma n) \\
&a^{\dagger}(\mathbf{p}\sigma n)a^{\dagger}\left(\mathbf{p}'\sigma' n'\right) = \pm a^{\dagger}\left(\mathbf{p}'\sigma' n'\right) a^{\dagger}(\mathbf{p}\sigma n)
\end{aligned}
$$

и аналогично для античастиц, причем знак " $\pm$ " равен " - ", если обе частицы n, n' - фермионы, и равен " + ",

если одна или обе частицы - бозоны. Как только оператор уничтожения оказывается крайним справа (или оператор рождения крайним слева), соответствующий вклад в (6.1.1) пропадает, поскольку эти операторы аннулируют вакуумное состояние:

$$
\begin{aligned}
a(\mathbf{p}\sigma n)\Phi_0 &= 0 \\
\Phi_0^{\dagger}a^{\dagger}(\mathbf{p}\sigma n) &= 0
\end{aligned}
$$

В уравнении (6.1.1) остается только вклад от δ -функционных слагаемых (6.1.4), остающихся при каждой перестановке оператора уничтожения с оператором рождения из начального или конечного состояния или гамильтониана взаимодействия, которые, таким образом, должны присутствовать парами.

вклад заданного порядка в (6.1.1) в каждое из слагаемых $\mathscr{H}_i$ полинома $\mathscr{H}\left(\psi(x), \psi^{\dagger}(x)\right)$ дается суммой (по всем способам спаривания операторов рождения и уничтожения [2]) интегралов от произведений множителей, согласно следующим правилам:

а) Спаривание частицы в конечном состоянии с квантовыми числами $\mathbf{p}', \sigma', n'$ с сопряженным полем $\psi_l^{\dagger}(x)$ в $\mathscr{H}_i(x)$ дает множитель

$$
\left[a\left(\mathbf{p}'\sigma' n'\right), \psi_l^{\dagger}(x)\right]_{\mp} = (2\pi)^{-3/2} e^{-ip'\cdot x} u_l^{*}\left(\mathbf{p}'\sigma' n'\right)
$$

б) Спаривание античастицы в конечном состоянии с квантовыми числами $\mathbf{p}', \sigma', n'^c$ с полем $\psi_l(x)$ в $\mathscr{H}_i(x)$ дает множитель

$$
\left[a\left(\mathbf{p}'\sigma' n'^c\right), \psi_l(x)\right]_{\mp} = (2\pi)^{-3/2} e^{-ip'\cdot x} v_l\left(\mathbf{p}'\sigma' n'\right)
$$

в) Спаривание частицы в начальном состоянии с квантовыми числами $\mathbf{p}, \sigma, n$ с полем $\psi_l(x)$ в $\mathscr{H}_i(x)$ дает множитель

$$
\left[\psi_l(x), a^{\dagger}(\mathbf{p}\sigma n)\right]_{\mp} = (2\pi)^{-3/2} e^{ip\cdot x} u_l^{*}(\mathbf{p}\sigma n)
$$

г) Спаривание античастицы в начальном состоянии с квантовыми числами $\mathbf{p}, \sigma, n^c$ с сопряженным полем $\psi_l^{\dagger}(x)$ в $\mathscr{H}_i(x)$ дает множитель

$$
\left[\psi_l^{\dagger}(x), a^{\dagger}\left(\mathbf{p}\sigma n^c\right)\right]_{\mp} = (2\pi)^{-3/2} e^{ip\cdot x} v_l^{*}(\mathbf{p}\sigma n)
$$

д) Спаривание (анти)частицы в конечном состоянии с квантовыми числами $\mathbf{p}', \sigma', n'$ с полем (анти)частицы в начальном состоянии с квантовыми числами $\mathbf{p}, \sigma, n$ дает множитель

$$\left[a\left(\mathbf{p}'\sigma'n'\right), a(\mathbf{p}\sigma n)\right]_{\mp} = \delta^3\left(\mathbf{p}' - \mathbf{p}\right)\delta_{\sigma'\sigma}\delta_{n'n}$$

е) Спаривание поля $\psi_l(x)$ в $\mathscr{H}_i(x)$ с сопряженным полем $\psi_m^{\dagger}(x)$ в $\mathscr{H}_j(y)$ дает множитель)

$$\theta(x-y)\left[\psi_l^{+}(x), \left[\psi_m^{+\dagger}(y)\right]_{\mp} \pm \theta(y-x)\left[\psi_m^{-\dagger}(y), \left[\psi_l^{-}(x)\right]_{\mp} \equiv \right.\right. \\ \equiv -i\delta_{lm}(x,y)$$

где ψ^{+} и ψ^{-} - слагаемые в ψ, которые соответственно уничтожают частицы и создают античастицы:

$$\psi_l^{+}(x) = (2\pi)^{-3/2}\int d^3p \sum_{\sigma} u_l(\mathbf{p}\sigma n)e^{ip\cdot x}a(\mathbf{p}\sigma n)$$
$$\psi_l^{-}(x) = (2\pi)^{-3/2}\int d^3p \sum_{\sigma} v_l(\mathbf{p}\sigma n)e^{-ip\cdot x}a^{\dagger}\left(\mathbf{p}\sigma n^c\right)$$

Напомним, что $\theta(x-y)$ - функция Хевисайда ("ступенька"), равная $+1$ при $x^0 > y^0$ и нулю при $x^0 < y^0$. Эти функции возникают в (6.1.14) из-за хронологизации в (6.1.1); спаривание оператора уничтожения $\psi^{+}(x)$ из $\mathscr{H}(x)$ с оператором рождения $\psi^{+\dagger}(y)$ из $\mathscr{H}(y)$ может произойти, только если множитель $\mathscr{H}(x)$ изначально располагался слева от $\mathscr{H}(y)$ в уравнении (6.1.1), т.е., если $x^0 > y^0$; аналогично, спаривание оператора уничтожения $\psi^{-\dagger}(y)$ из $\mathscr{H}(y)$ с оператором рождения $\psi^{-}(x)$ из $\mathscr{H}(x)$ может произойти, только если из $\mathscr{H}(y)$ изначально располагался слева от $\mathscr{H}(x)$ в уравнении (6.1.1), т.е., если $y^0 > x^0$. Знак $\pm$ во втором слагаемом в (6.1.14) будет объяснен чуть позже. Величина (6.1.14) известна под названием пропагатор.

Она S -матрица получается в результате перемножения всех этих множителей, наряду с дополнительными числовыми множителями, которые мы обсудим далее, интегрирования по $x_1, ..., x_N$, суммирования по всем спариваниям, а затем по всем видам взаимодействий. Прежде чем мы уточним все детали, полезно описать диаграммный формализм, который позволяет отслеживать все возможные спаривания.

Правила вычисления S -матрицы удобно сформулировать в терминах фейнмановских диаграмм (см. рис. 6.1).

Диаграммы состоят из точек, называемых вериинами, каждая из которых представляет один их членов $\mathscr{H}_i(x)$, и линий, которые соответствуют спариванию операторов уничтожения и рождения. Более точно, а) Спаривание частицы в конечном состоянии с сопряженным полем из некоторого $\mathscr{H}(x)$ представляется линией, идущей из вер-

(и тут у Вайнберга Диаграммы, которые мб когда-нибудь перерисую)

шины, отвечаюшей этому $\mathscr{H}(x)$, вверх из диаграммы, со стрелкой вверх.

б) Спаривание античастицы в конечном состоянии с полем из некоторого $\mathscr{H}(x)$ также представляется линией, идущей из верши- ны, отвечаюшей этому $\mathscr{H}(x)$, вверх из диаграммы, но со стрелкой вниз. Для истинно нейтральных (самосопряженных) полей, например фотонов, стрелки опускаются.

в) Спаривание частицы в начальном состоянии с полем из некото- рого $\mathscr{H}(x)$ представляется линией, идущей в вершину, отвечающую этому $\mathscr{H}(x)$, внутрь диаграммы, со стрелкой вверх.

г) Спаривание античастицы в начальном состоянии с полем из некоторого $\mathscr{H}(x)$ представляется линией, идушей в вершину, отвечаЮшую этому $\mathscr{H}(x)$, внутрь диаграммы, со стрелкой вниз.

д) Спаривание конечной (анти)частицы с начальной (анти)частицей представляется линией, идущей через диаграмму снизу вверх, не входяшую ни в какие вершины, со стрелкой вверх или вниз для частицы и античастицы соответственно.

е) Спаривание поля в $\mathscr{H}(x)$ с сопряженным полем из $\mathscr{H}(y)$ представляется линией, соединяюшей вершины, отвечающие этим $\mathscr{H}(x)$ и $\mathscr{H}(y)$, со стрелкой, направленной от y к x.

Заметим, что стрелка направлена в сторону движения частицы и против движения античастицы (как уже было сказано, стрелки для истинно нейтральных частиц следует опускать). Направление стрелки по правилу е) согласуется с этой условностью, потому что сопряженное поле из $\mathscr{H}_j(y)$ может или создать частицу, уничтоженную полем из $\mathscr{H}_i(x)$, или уничтожить античастицу, созданную полем из $\mathscr{H}_i(x)$. Отметим также, что, поскольку каждое (сопряженное) поле должно спариваться с другим полем, полное число линий в вершине типа i, отвечающей члену $\mathscr{H}_i(x)$ в (6.1.2), равно полному числу множителей (полей и сопряженных полей) в $\mathscr{H}_i(x)$.

Число линий со стрелкой внутрь вершины или наружу равно соответственно числу полей или сопряженных полей в соответствуюшем члене взаимодействия.

Чтобы вычислить вклад данного процесса в S -матрицу для данного порядка N_i по каждому из взаимодействий $\mathscr{H}_i(x)$в уравнении (6.1.2), нужно проделать следующие шаги:

(i) Нарисовать все диаграммы Фейнмана, которые содержат N_i вершин каждого типа i, входяшие снизу линии (анти)частиц в начальном состоянии, выходящие сверху линии (анти)частиц в конечном состоянии, а также любое число внутренних линий, соединяющих вершины, так, чтобы в каждую вершину входило нужное число линий. На линиях указываются стрелки вверх или вниз по вышеописанным правилам. Каждая вершина помечается типом взаимодействия и 4-координатой x^μ. Каждая внутренняя или внешняя линия помечается индексом поля l на том конце, где она входит в вершину (что отвечает полю $\psi_l(x)$ или $\psi_l^\dagger(x)$, которое создает или уничтожает (анти)частицу в этой вершине). Каждая внешняя линия помечается квантовыми числами $\mathbf{p}, \sigma, n$ или $\mathbf{p}', \sigma', n'$ начального или конечного состояния (анти)частицы. (ii) Для каждой вершины типа i нужно добавить множитель $-i$, который происходит от множителя $(-i)^N$ в формуле (6.1.1), а также множитель g_i - константу связи для данного взаимодействия $\mathscr{H}_i(x)$. Для каждой выходяшей вверх линии дополнительно вводится множитель (6.1.9) или (6.1.10), в зависимости от направления стрелки (вверх или вниз). Для каждой входяшей снизу линии добавляется множи-

тель (6.1.11), если стрелка указывает вверх, или (6.1.12) - в противном случае. Для каждой линии, проходящей насквозь диаграммы, добавляется множитель (6.1.13). Для каждой внутренней линии, соединяющей вершины, вводится множитель (6.1.14). (iii) Проинтегрировать полученное произведение по всем координатам $x_1, x_2, ...$ каждой вершины. (iv) Сложить результаты для всех диаграмм Фейнмана. Полный ряд теории возмущений для S -матрицы получается сложением вкладов каждого порядка по каждому взаимодействию.

Обратим внимание, что в перечисленных правилах не учитывается множитель 1/N! из формулы (6.1.1), поскольку хронологически упорядоченное произведение есть сумма по $N!$ перестановкам координат $x_1, ..., x_N$, а каждая перестановка дает одинаковый вклад в окончательный результат. Другими словами, каждая диаграмма Фейнмана с N вершинами - это одна из $N!$ идентичных диаграмм, отличающихся лишь перестановками обозначений вершин, что дает множитель $N!$, сокращающий 1/N! в формуле (6.1.1). (Из этого правила есть исключения, о которых см. ниже.) По этой причине мы не учитываем диаграммы

Фейнмана, отличающиеся лишь переобозначением вершин.

В некоторых случаях возникают дополнительные комбинаторные множители или знаки, которые необходимо включить во вклад отдельных диаграмм: (v) Предположим, что взаимодействие $\mathscr{H}_i(x)$ содержит M мно-

жителей одного и того жсе поля. Допустим, каждое из них спарено с сопряженным полем из другого взаимодействия или из начального (конечного) состояния. Первое из этих сопряженных полей может быть спарено с любым из M идентичных полей в $\mathscr{H}_i(x)$, второе только с любым из оставшегося $M-1$ поля, и т.д., что дает дополнительный множитель $M!$ Для его компенсации константы связи g_i обычно определяют так, чтобы множитель 1/M! явным образом появился в гамильтониане $\mathscr{H}_i(x)$, который содержит M идентичных полей (или сопряженных полей). Например, самодействие скалярного поля M -го порядка следует представлять в виде $g\phi^M/M!$ Вообще, множитель 1/M! часто выделяют в случаях, когда взаимодействие содержит сумму M произведений из одного мультиплета группы симметрии или когда по этой или иной причине набор констант взаимодействия полностью симметричен или антисимметричен при перестановках M бозонных или фермионных полей. Однако сокращение множителей $M!$ может быть неполным. Например, рассмотрим фейнмановскую диаграмму, в которой M идентичных полей в одном взаимодействии $\mathscr{H}_i(x)$ спариваются с M соответствующими сопряженными полями в другом взаимодействии $\mathscr{H}_j(y)$(cm. рис. 6.2). Рассуждая аналогично, находим $M!$ различных спариваний, так что сокрашается лишь один из множителей 1/M!

двух различных взаимодействий. Следовательно, нужно добавить множитель 1/M! для этой диаграммы Фейнмана. Другие комбинаторные множители возникают, когда некоторые перестановки вершин не меняют диаграмму Фейнмана. Мы уже об- судили сокращение множителя $1/N!$ в разложении (6.1.1) за счет суммы по идентичным диаграммам, отличающимся лишь переобо- значением N вершин. О днако это сокращение будет неполным, если перестановка вершин не меняет диаграмму. Обычно это наблюдается при вычислении вакуум-вакуумных матричных элементов S -матрицы

в теории с квадратичным взаимодействием $\mathscr{H} = \psi_1^\dagger M_{ll'}\psi_{l'}$, где M может зависеть от внешних полей. (Физический смысл таких вакуумных флуктуаций подробно обсуждается в т. II.) Диаграмма Фейнмана N -го порядка по $\mathscr{H}$ представляет собой кольцо с N вершинами (см. рис. 6.3). Имеется лишь $(N-1)!$ различных диаграмм этого вида, поскольку перестановка значков со сдвигом в соседние вершины

по кругу дает ту же диаграмму. Значит, этой диаграмме отвечает дополнительный множитель

$$\frac{(N-1)!}{N!} = \frac{1}{N}$$

(vi) В теориях с фермионными полями применение формул (6.1.4) - (6.1.6) для перемешения операторов уничтожения и рождения вправо или влево дает дополнительные знаки минус в различных спариваниях. Более точно, знак минус получается, когда для того, чтобы поставить спаренные операторы друг рядом с другом (так, чтобы слева в паре стоял оператор уничтожения), в формуле (6.1.1) нужно сделать нечетное число перестановок местами фермионных операторов. Это можно объяснить так: для вычисления вклада от данного спаривания нужно расположить все операторы уничтожения в формуле (6.1.1) слева от спаренных с каждым из них оператором рождения, игнорируя все (анти)коммутаторы неспаренных операторов, а затем заменить каждую пару спаренных полей на их (анти)коммутатор. Отсюда немедленно следует, что относительный знак двух слагаемых в (6.1.14) для фермионных полей является минусом. Какая бы перестановка ни

помешала уничтожающую часть $\psi^{+}(x)$ поля в $\mathscr{H}(x)$ слева от рождающей части $\psi^{+\dagger}(y)$ сопряженного поля в $\mathscr{H}(y)$, при перестановке уничтожающей части $\psi^{-\dagger}(y)$ сопряженного поля налево от рождающей части $\psi^{-}(x)$ поля происходит одна дополнительная замена местами фермионных операторов, что дает знак " - " для фермионов во втором слагаемом левой части уравнения (6.1.14).

Помимо этого, диаграмма Фейнмана может приобрести дополнительный знак " - ". В качестве примера рассмотрим теорию с единственным взаимодействием фермионов вида

$$\mathscr{H}(x) = \sum_{lmk} g_{lmk} \psi_l^{\dagger}(x) \psi_m(x) \phi_k(x)$$

где $g_{lmk} - 1$ нты общего вида, $\psi_l(x)$ - набор комплексных фермионных полей, а $\phi_m(x)$ - набор вещественных бозонных (необязательно скалярных) полей. Заметим, что не только электродинамика, но и вся стандартная модель слабых, электромагнитных и сильных взаимодействий соответствует взаимодействиям такого вида. Для начала рассмотрим процесс рассеяния фермиона на фермионе, $12 \to 1'2'$, с точностью до второго порядка по $\mathscr{H}$. Фермионные операторы во вкладе второго порядка в формуле (6.1.1) оказываются расположенными в порядке (с очевидными сокращениями обозначений)

$$a\left(2'\right) a\left(1'\right) \psi^{\dagger}(x) \psi(x) \psi^{\dagger}(y) \psi(y) a^{\dagger}(1) a^{\dagger}(2)$$

Имеются две связные диаграммы этого порядка, отвечающие спариваниям

$$\left[a\left(2'\right) \psi^{\dagger}(x)\right] \left[a\left(1'\right) \psi^{\dagger}(y)\right] \left[\psi(y) a^{\dagger}(1)\right] \left[\psi(x) a^{\dagger}(2)\right]$$

и

$$\left[a\left(1'\right) \psi^{\dagger}(x)\right] \left[a\left(2'\right) \psi^{\dagger}(y)\right] \left[\psi(y) a^{\dagger}(1)\right] \left[\psi(x) a^{\dagger}(2)\right]$$

(см. рис. 6.4). Переход от (6.1.19) к (6.1.20) требует четной перестановки фермионных операторов. Например, можно переместить $\psi(x)$

через три оператора направо, а затем переместить $a\left(1'\right)$ через один оператор направо. Поэтому дополнительного минуса не возникает во вкладе от спаривания (6.1.20). Само по себе это было бы неважно, поскольку общий знак матричного элемента не влияет на скорость реакции, и в любом случае зависит от соглашений о знаке начального и конечного состояний. Но вклады спариваний (6.1.20) и (6.1.21) имеют разный знак, что легко заметить, поскольку разница между этими спариваниями компенсируется одной перестановкой местами фермионных операторов: $a\left(1'\right) \leftrightarrow a\left(2'\right)$. На самом деле, относительный знак минус требуется правилами статистики Ферми: амплитуда рассеяния должна быть антисимметрична относительно перестановки одинаковых фермионов ($1', 2'$ или $1, 2$).

Однако не всегда знаковые факторы можно обосновать таким простым образом, даже в наинизшем порядке теории возмущений. Чтобы убедиться в этом, рассмотрим рассеяние фермиона на антифермионе, $12^{c} \to 1'2'^{c}$, во втором порядке по тому же взаимодействию (6.1.18). Фермионные операторы во вкладе второго порядка оказываЮтся в следующем порядке:

$$a\left(2'^{c}\right) a\left(1'\right) \psi^{\dagger}(x) \psi(x) \psi^{\dagger}(y) \psi(y) a^{\dagger}(1) a^{\dagger}\left(2^{c}\right)$$

Здесь снова возникают две диаграммы Фейнмана, отвечающие спари- ваниям

$$\left[a\left(2'^{c}\right) \psi(x)\right] \left[a\left(1'\right) \psi^{\dagger}(x)\right] \left[\psi(y) a^{\dagger}(1)\right] \left[\psi^{\dagger}(y) a^{\dagger}\left(2^{c}\right)\right]$$

И

$$\left[a\left(2'^{c}\right)\psi(x)\right]\left[a\left(1'\right)\psi^{\dagger}(y)\right]\left[\psi(y)a^{\dagger}(1)\right]\left[\psi^{\dagger}(x)a^{\dagger}\left(2^{c}\right)\right]$$

(см. рис. 6.5). Переход от (6.1.22) к (6.1.23) требует четной перестановки фермионных операторов (например, можно переместить $\psi(x)$ через

два оператора налево, а затем переместить $\psi^{\dagger}(y)$ через два оператора направо), поэтому дополнительного минуса не возникает во вкладе от спаривания (6.1.23). С другой стороны, для перехода от (6.1.22) к (6.1.24) требуется нечетная перестановка фермионных операторов (то же, что для (6.1.23), плюс одна перестановка $\psi^{\dagger}(x) \leftrightarrow \psi^{\dagger}(y)\big)$,

поэтому вклад этого спаривания получает дополнительный минус [2]). Дополнительные знаки могут появиться во вкладах высших порядков. В теориях, подобных рассмотренным здесь, со взаимодействием фермионов вида (6.1.18), фермионные линии в диаграммах общего вида образуют либо цепочки, проходящие через диаграмму с произвольным числом взаимодействий с бозонами, как на рис. 6.6, либо фермионные петли, как на рис. 6.7. Рассмотрим вклад фермионной

петли с M вершинами в любой процесс. Она отвечает спариванию операторов

$$\left[\psi\left(x_1\right)\bar{\psi}\left(x_2\right)\right]\left[\psi\left(x_2\right)\bar{\psi}\left(x_3\right)\right]...\left[\psi\left(x_M\right)\bar{\psi}\left(x_1\right)\right]$$

С другой стороны, эти операторы входят в (6.1.1) в следующем порядке:

$$\bar{\psi}\left(x_1\right)\psi\left(x_1\right)\bar{\psi}\left(x_2\right)\psi\left(x_2\right)...\bar{\psi}\left(x_M\right)\psi\left(x_M\right)$$

Для перехода от (6.1.26) к (6.1.25) требуется нечетная перестановка фермионных операторов (перемещение $\bar{\psi}\left(x_1\right)$ направо через $2M-1$ оператор), так что вклад каждой такой петли сопровождается знаком МиНус.

Эти правила позволяют вычислить полную S -матрицу, включая вклады от процессов, в которых различные группы частиц взаимодействуют в удаленных по времени и пространству областях. В гл. 4 уже говорилось, что следует брать лишь связные диаграммы Фейнмана, чтобы исключить вклады от таких групповых взаимодействий.

В частности, это исключает диаграммы с линиями, идушими напрямую без взаимодействия, которые дали бы множители (6.1.13).

Чтобы прояснить правила Фейнмана, вычислим вклад низшего порядка в S -матрицу для рассеяния частиц в двух различных теориях.

теория с фермионами и зарядово-самосопряженными (нейтральными) бозонами, со взаимодействием

Рассмотрим теорию с фермионами и зарядово-самосопряженными (нейтральными) бозонами, со взаимодействием (6.1.18). Связные диаграммы наинизшего порядка фермион-бозонного рассеяния изображены на рис.

6.6. Согласно правилам, приведенным на рис. 6.1, соответствующий матричный элемент равен

$$S_{\mathbf{p}_1'\sigma_1'n_1'\mathbf{p}_2'\sigma_2'n_2',\mathbf{p}_1\sigma_1n_1\mathbf{p}_2\sigma_2n_2} =$$

$$= (2\pi)^{-6}\sum_{k'l'm'klm}(-i)^2 g_{l'm'k'}g_{mlk}u_{l'}^{*}\left(\mathbf{p}_1'\sigma_1'n_1'\right)u_l\left(\mathbf{p}_1\sigma_1n_1\right)\times$$

$$\times \int d^4x \int d^4y \left(-i\delta_{m'm}(y-x)\right) e^{-ip_1'\cdot y} e^{ip_1\cdot x} \times$$

$$\times \Big[e^{-ip_2'\cdot y} u_{k'}^* \left(\mathbf{p}_2'\sigma_2'n_2'\right) e^{ip_2\cdot x} u_k \left(\mathbf{p}_2\sigma_2 n_2\right) +$$

$$+ e^{-ip_2'\cdot x} u_k^* \left(\mathbf{p}_2'\sigma_2'n_2'\right) e^{ip_2\cdot y} u_{k'} \left(\mathbf{p}_2\sigma_2 n_2\right) \Big]$$

Индексы 1 и 2 обозначают здесь соответственно фермионы и бозоны. Для фермион-фермионного рассеяния имеются две диаграммы второго порядка, представленные на рис. 6.4. Они дают S -матричный элемент

$$S_{\mathbf{p}_1'\sigma_1'n_1'\mathbf{p}_2'\sigma_2'n_2',\mathbf{p}_1\sigma_1 n_1\mathbf{p}_2\sigma_2 n_2} = (2\pi)^{-6} \sum_{k'l'm'klm} (-i)^2 g_{m'mk'} g_{l'lk} \times$$

$$\times u_{m'}^* \left(\mathbf{p}_2'\sigma_2'n_2'\right) u_{l'}^* \left(\mathbf{p}_1'\sigma_1'n_1'\right) u_m \left(\mathbf{p}_2\sigma_2 n_2\right) u_l \left(\mathbf{p}_1\sigma_1 n_1\right) \times$$

$$\times \int d^4x \int d^4y e^{-ip_2'\cdot x} e^{-ip_1'\cdot y} e^{ip_2\cdot x} e^{ip_1\cdot y} (-i)\delta_{k'k}(x-y) -$$

$$- \left[1' \rightleftharpoons 2'\right]$$

где последнее слагаемое сокращенно обозначает предыдущее слагаемое, в котором переставлены частицы $1', 2'$ (или, что то же самое, частицы 1,2). Во втором порядке нет диаграмм бозон-бозонного рассеяния; наинизший порядок, в котором они появляются, равен 4 (см. рис. 6.7). Более конкретные примеры формул типа (6.1.27), (6.1.28) будут приведены в \$6.3, после попытки вычисления пропагатора и перехода в импульсное пространство.

Во взаимодействии (6.1.18) все три сомножителя - различные поля. Было бы поучительно рассмотреть трилинейное взаимодействие, в котором все три поля одинаковы или входят во взаимодействие симметрично.

теория 2

Теперь рассмотрим в качестве плотности гамильтониана трилинейную форму

$$\mathscr{H}(x) = \frac{1}{3!} \sum_{lmn} g_{lmn} \phi_l(x) \phi_m(x) \phi_n(x)$$

где $\phi_l(x)$ - вещественные бозонные поля, а g_{lmn} - полностью симметричный набор констант связи. Допустим, мы хотим рассмотреть процесс рассеяния $12 \to 1'2'$ с точностью до второго порядка по этим константам связи. В каждую из двух вершин должны входить две из четырех внешних линий. (Единственная альтернатива - когда одна из внешних линий входит в одну вершину, а три других - в другую, но тогда получается несвязная диаграмма, поскольку у второй вершины не останется места для внутренней, соединяющей линии.)

Остающаяся у каждой вершины линия должна соединять их между собой. Возможны три рисунка такого вида, отличающиеся лишь тем, какие пары внешних линий входят в вершины (см. рис. 6.8). По правилам Фейнмана, приведенным выше, получаем вклад в S -матрицу ОТ ЭТих трех диаграмм:

$$S_{\mathbf{p}_1'\sigma_1'n_1'\mathbf{p}_2'\sigma_2'n_2',\mathbf{p}_1\sigma_1 n_1\mathbf{p}_2\sigma_2 n_2} =$$

$$= (-i)^2(2\pi)^{-6} \sum_{u'l''mm'm''} g_{ll'l''}g_{mm'm''} \int d^4x \int d^4y \left(-i\delta_{l''m''}(x,y)\right) \times$$

$$\times \Big[u_l^* \left(\mathbf{p}_1'\sigma_1'n_1'\right) e^{-ip_1'\cdot x} u_{l'}^* \left(\mathbf{p}_2'\sigma_2'n_2'\right) e^{-ip_2^2\cdot x} \times$$

$$\times u_m \left(\mathbf{p}_1\sigma_1 n_1\right) e^{ip_1\cdot y} u_{m'} \left(\mathbf{p}_2\sigma_2 n_2\right) e^{ip_2\cdot y} +$$

$$+ u_{l'}^* \left(\mathbf{p}_1'\sigma_1'n_1'\right) e^{-ip_1'\cdot x} u_l \left(\mathbf{p}_1\sigma_1 n_1\right) e^{ip_1\cdot x} \times$$

$$\times u_{m'}^* \left(\mathbf{p}_2'\sigma_2'n_2'\right) e^{-ip_2'\cdot y} u_m \left(\mathbf{p}_2\sigma_2 n_2\right) e^{ip_2\cdot y} +$$

$$+ u_{l'}^* \left(\mathbf{p}_2'\sigma_2'n_2'\right) e^{-ip_2'\cdot x} u_l \left(\mathbf{p}_1\sigma_1 n_1\right) e^{ip_1\cdot x} \times$$

$$\times u_{m'}^* \left(p_1'\sigma_1'n_1'\right) e^{-ip_1'\cdot y} u_m \left(p_2\sigma_2 n_2\right) e^{ip_2\cdot y} \Big]$$

В еще более частном случае, когда бозоны являются бесспиновыми частицами одного сорта,

взаимодействие (6.1.29) принимает простой вид

$$\mathscr{H} = g\phi^3/3!$$

а матричный элемент для скаляр-скалярного рассеяния равен

$$S_{\mathbf{p}_1'\mathbf{p}_2',\mathbf{p}_1\mathbf{p}_2} = \frac{ig^2}{(2\pi)^6\sqrt{16E_1'E_2'E_1E_2}} \int d^4x \int d^4y \delta_F(x-y) \times$$

$$\times \left[\exp\left(-i\left(p_1'+p_2'\right)\cdot x\right)\exp\left(i\left(p_1+p_2\right)\cdot y\right) +\right.$$

$$+ \exp\left(i\left(p_1-p_1'\right)\cdot x\right)\exp\left(i\left(p_2-p_2'\right)\cdot y\right) +$$

$$\left. + \exp\left(i\left(p_1-p_2'\right)\cdot x\right)\exp\left(i\left(p_2-p_1'\right)\cdot y\right)\right]$$

где $\delta_F(x-y)$ - пропагатор скалярного поля, который мы вычислим в следующем параграфе. В этой теории отсутствуют диаграммы третьего, и вообще нечетного, порядка.

Вычисление пропагатора

Теперь мы перейдем к вычислению пропагатора (6.1.14),

важного компонента правил Фейнмана,

который возникает от спаривания поля $\psi_l(x)$ с сопряженным полем $\psi_m^\dagger(y)$.

Подставляя формулы (6.1.15) и (6.1.16) в уравнение (6.1.14) и применяя (анти)коммутационные соотношения для операторов рождения-уничтожения,

немедленно получаем:

$$-\delta_{lm}(x,y) = \theta(x-y)(2\pi)^{-3} \int d^3p \sum_\sigma u_l(\mathbf{p}\sigma n) u_m^*(\mathbf{p}\sigma n) e^{ip\cdot(x-y)} \pm$$

$$\pm\theta(y-x)(2\pi)^{-3}\int d^3p\sum_\sigma v_m^*(\mathbf{p}\sigma n)v_l^*(\mathbf{p}\sigma n)e^{ip\cdot(y-x)}$$

При вычислении (анти)коммутаторов в гл. 5 было показано, что

$$\sum_\sigma u_l(\mathbf{p}\sigma n)u_m^*(\mathbf{p}\sigma n)=\left(2\sqrt{\mathbf{p}^2+m_n^2}\right)^{-1}P_{lm}\left(\mathbf{p},\sqrt{\mathbf{p}^2+m_n^2}\right)$$
$$\sum_\sigma v_l(\mathbf{p}\sigma n)v_m^*(\mathbf{p}\sigma n)=\pm\left(2\sqrt{\mathbf{p}^2+m_n^2}\right)^{-1}P_{lm}\left(-\mathbf{p},-\sqrt{\mathbf{p}^2+m_n^2}\right)$$

где $P_{lm}(\mathbf{p},\omega)$ - полином по $\mathbf{p}$ и ω. Здесь, как и в формуле (6.2.1), верхний и нижний знаки отвечают соответственно бозонным и фермионным полям. Например, если $\psi_l(x)$ и $\psi_m(y)$ суть скалярные поля (частицы со спином 0) $\phi(x),\phi(y)$, то получается просто

$$P(p)=1$$

Если $\psi_l(x)$ и $\psi_m(y)$ - дираковские поля (частицы спина 1/2), то

$$P_{lm}(p)=\left[(-i\gamma_\mu p^\mu+m)\,\beta\right]_{lm}$$

где l,m обозначают индексы дираковских 4-компонентных спиноров. (Матрица β здесь появилась, поскольку мы рассматриваем спаривание $\psi_l(x)$ с $\psi_m^\dagger(y)$.) Ее не будет в спаривании $\psi_l(x)$ и $\bar\psi_m(y)\equiv\psi_m^\dagger(y)\beta$.) Если $\psi_l(x)$ - векторные поля (частицы спина 1), то

$$P_{\mu\nu}(p)=\eta_{\mu\nu}+m^{-2}p_\mu p_\nu$$

В общем случае, если $\psi_l(x)$ и $\psi_m(y)$ - компоненты полей $\psi_{ab}(x)$ и $\psi_{\tilde a\tilde b}(y)$ частицы со спином j в неприводимых представлениях (A,B) и $(\widetilde A,\widetilde B)$ однородной группы Лоренца, то

$$P_{ab,\tilde a\tilde b}(p)=\sum_{a'b'}\sum_{\tilde a'\tilde b'}\sum_\sigma C_{AB}\left(j\sigma,a'b'\right)C_{\tilde A\tilde B}\left(j\sigma,\widetilde a'\widetilde b'\right)\times$$
$$\times\left[\exp\left(-\theta\hat p\cdot\mathbf{J}^{(A)}\right)\right]_{aa'}\left[\exp\left(+\theta\hat p\cdot\mathbf{J}^{(B)}\right)\right]_{bb'}\times$$
$$\times\left[\exp\left(-\theta\widehat p\cdot\mathbf{J}^{(\tilde A)}\right)\right]_{\tilde a\tilde a'}\left[\exp\left(+\theta\hat p\cdot\mathbf{J}^{(\tilde B)}\right)\right]_{bb'}$$

где $\operatorname{sh}\theta=|\mathbf{p}|/m$, а индексы $a,b,\tilde a,\tilde b$ пробегают с шагом 1 значения от $-A$ до A, от $-B$ до B, от $-\widetilde A$ до $\widetilde A$, от $-\widetilde B$ до $\widetilde B$ соответственно и аналогично для индексов со штрихами. Подстановка (6.2.2) и (6.2.3) в уравнение (6.2.1) дает

$$-i\delta_{lm}(x,y)=\theta(x-y)P_{lm}\left(-i\tfrac{\partial}{\partial x}\right)\delta_+(x-y)+$$
$$+\theta(y-x)P_{lm}\left(-i\tfrac{\partial}{\partial x}\right)\delta_+(y-x)$$

где $\delta_+(x)$ - функция, введенная в гл. 5:

$$\delta_+(x)=(2\pi)^{-3}\int d^3p\left(2p^0\right)^{-1}e^{ip\cdot x}$$

где $p^0=+\sqrt{\mathbf{p}^2+m^2}$ Перед тем как продолжить вычисления, следует пояснить, как можно обобщить определение полинома $P(p)$. Уравнения (6.2.2) и (6.2.3) определяют его только

на так называемой массовой оболочке, т.е. при $p^0 = \pm\sqrt{\mathbf{p}^2 + m^2}$. Любой многочлен от 4-импульса на массо-

вой оболочке можно считать линейным по p^0, поскольку любая степень $(p^0)^{2\nu}$ или $(p^0)^{2\nu+1}$ может быть записана в виде $(\mathbf{p}^2 + m^2)^{2\nu}$ или $p^0 (\mathbf{p}^2 + m^2)^{2\nu}$ соответственно. Поэтому мы зададим полином $P^{(L)}(q)$ следующими условиями:

$$P^{(L)}(p) = P(p) \quad \left(\text{где } p^0 = \sqrt{\mathbf{p}^2 + m^2} \right)$$
$$P^{(L)}(q) = P^{(0)}(\mathbf{q}) + q^0 P^{(1)}(\mathbf{q}) \quad (\text{ для произвольного } q^\mu)$$

где $P^{(0,1)}$ - полиномы, зависяшие только от q. Используем теперь соотношения

$$\frac{\partial}{\partial x^0}\theta\left(x^0 - y^0\right) = -\frac{\partial}{\partial x^0}\theta\left(y^0 - x^0\right) = \delta\left(x^0 - y^0\right)$$

(вспомнив, что функция $\theta(x)$ имеет скачок на единицу в x^0 и постоянна в других местах), чтобы переместить операторы дифференцирования налево от θ -функций в формуле (6.2.8)

$$\begin{aligned}\delta_{lm}(x,y) =& P^{(L)}_{lm}\left(-i\frac{\partial}{\partial x}\right)\delta_F(x-y) + \\ &+ \delta\left(x^0 - y^0\right) P^{(1)}_{lm}(-i\nabla)\left[\delta_+(x-y) - \delta_+(y-x)\right]\end{aligned}$$

где δ_F - "фейнмановский пропагатор"

$$-i\delta_F(x) \equiv \theta(x)\delta_+(x) + \theta(-x)\delta_+(-x)$$

Однако при $x^0 = 0$ функция $\delta_+(x)$ четна по x, поскольку замену

$\mathbf{x} \to -\mathbf{x}$ в (6.2.9) можно компенсировать заменой $\mathbf{p} \to -\mathbf{p}$ переменной интегрирования. По этой причине можно опустить второе слагаемое в (6.2.12) и получить простое выражение

$$\delta_{lm}(x,y) = P^{(L)}_{lm}\left(-i\frac{\partial}{\partial x}\right)\delta_F(x-y)$$

Для дальнейших вычислений нам понадобится фурье-представление фейнмановского пропагатора. Функции-ступеньки в (6.2.13) записываются в виде интеграла Фурье)

$$\theta(t) = \frac{-1}{2\pi i}\int\limits_{-\infty}^{+\infty}\frac{\exp(-ist)}{s + i\epsilon}ds$$

Это можно объединить с интегралом Фурье (6.2.9) для функции $\delta_+(x)$. Введем новые переменные интегрирования, $\mathbf{q} = \mathbf{p}, q^0 = p^0 = s$ в первом слагаемом уравнения (6.2.13), что дает

$$-i\delta_F(x) = -\frac{1}{2\pi i}\int d^3q \int dq^0 \frac{\exp\left(i\mathbf{q}\cdot\mathbf{x} - iq^0x^0\right)}{(2\pi)^3 2\sqrt{\mathbf{q}^2 + m^2}} \times$$
$$\times\left[\left(q^0 - \sqrt{\mathbf{q}^2 + m^2} + i\epsilon\right)^{-1} + \left(-q^0 - \sqrt{\mathbf{q}^2 + m^2} + i\epsilon\right)^{-1}\right]$$

Приводя подынтегральное выражение к обшему знаменателю и используя 4-мерные обозначения, элементарно получаем

$$\delta_F(x) = (2\pi)^{-4}\int d^4q \frac{\exp(iq\cdot x)}{q^2 + m^2 - i\epsilon}$$

где $q^2 \equiv \mathbf{q}^2 - (q^0)^2$. В знаменателе мы заменили $2\epsilon\sqrt{\mathbf{q}^2+m^2}$ на ϵ, поскольку важно лишь то, что это положительная бесконечно малая величина. Отсюда видно, что δ_F - функция Грина оператора КлейнаГордона, в том смысле, что

$$\left(\Box - m^2\right)\delta_F(x) = -\delta^4(x)$$

а граничные условия определяются добавкой - $i\epsilon$ в знаменателе: как видно из формулы (6.2.13), при $x^0 \to \infty$ или $x^0 \to -\infty$ функция $\delta_F(x)$ содержит только положительные или отрицательные частоты, соответственно $\exp\left(-ix^0\sqrt{\mathbf{p}^2+m^2}\right)$ или $\exp\left(-ix^0\sqrt{\mathbf{p}^2+m^2}\right)$ В результате подстановки (6.2.16) в (6.1.14) получаем пропагатор

в виде

$$\delta_{lm}(x,y) = (2\pi)^{-4}\int d^4q \frac{P^{(L)}_{lm}(q)e^{iq\cdot(x-y)}}{q^2+m^2-i\epsilon}$$

Здесь возникает следующая проблема. Многочлен $P(p)$ лоренц-ковариантен, если p лежит на массовой оболочке, т.е. $p^2 = -m^2$, но в уравнении (6.2.18) производится интегрирование по всем q^μ, а не только по массовой оболочке. Для произвольных q^μ многочлен $P^{(L)}(q)$ по определению линеен по q^0, что явно нарушает лоренц-ковариантность, если многочлен не является линейным по каждой пространственной компоненте q^i. Вместо такого обобщения многочлена $P(p)$ можно ввести его лоренц-ковариантное обобщение на произвольные q^μ (которое мы обозначим просто $P(q)$), в том смысле, что

$$P_{lm}(\Lambda q) = D_{ll'}(\Lambda)D^*_{mm'}(\Lambda)P_{l'm'}(q)$$

где Λ^μ_ν - преобразование Лоренца общего вида, а $D(\Lambda)$ - некоторое представление группы Лоренца. К примеру, в случае скалярных, дираковских и векторных полей такое ковариантное обобщение получается простой заменой импульса p^μ на импульс общего вида q^μ в формулах (6.2.4), (6.2.5) и (6.2.6). В случае скалярных и дираковских

полей пропагатор и так линеен по q^0, а потому нет разницы меж-

ду $P^{(L)}(q)$ и $P(q)$:

$$P^{(L)}_{lm}(q) = P_{lm}(q) \qquad \text{(скалярное поле, дираковское поле)}$$

С другой стороны, в случае векторного (спин-1) поля 00-компонента ковариантного полинома $P_{\mu\nu}(q) \equiv \eta_{\mu\nu} + m^{-2}q_\mu q_\nu$ квадратична по q^0, так что здесь есть разница между $P^{(L)}(q)$ и $P(q)$:

$$\begin{aligned} P^{(L)}_{\mu\nu}(q) = \eta_{\mu\nu} + m^{-2}\left[q_\mu q_\nu - \delta^0_\mu\delta^0_\nu\left(q_0^2 - \mathbf{q} - m^2\right)\right] = \\ = P_{\mu\nu}(q) + m^{-2}\left(q^2+m^2\right)\delta^0_\mu\delta^0_\nu \end{aligned}$$

Дополнительное слагаемое здесь фиксировано двумя условиями - оно должно сокращать слагаемое $(q^0)^2$ в $P_{00}(q)$, и должно зануляться на массовой оболочке. Подстановка этого выражения в формулу (6.2.18) дает пропагатор векторного поля

$$\delta_{\mu\nu}(x,y) = (2\pi)^{-4}\int d^4q \frac{P_{\mu\nu}(q)e^{iq\cdot(x-y)}}{q^2+m^2-i\epsilon} + m^{-2}\delta^{-4}(x-y)\delta^0_\mu\delta^0_\nu$$

Первое слагаемое, очевидно, ковариантно, а второе - не ковариантно, но является локальным, так что его можно сократить путем добавления локального нековариантного члена в гамильтониан. Конкретно, если $V_\mu(x)$ взаимодействует с другими полями

посредством члена $V_\mu(x)J^\mu(x)$ в гамильтониане, то вклад добавочного слагаемого в (6.2.21) равносилен добавлению взаимодействия

$$\mathscr{H}_{NC}(x) = -\mathscr{H}_{eff}(x) = \frac{1}{2m^2}\left[J^0(x)\right]^2$$

Именно сингулярность (при нулевом расстоянии) одновременных коммутаторов векторных полей вынуждает нас использовать более широкий класс взаимодействий, чем просто скалярную плотность гамильтониана. Подробное непертурбативное доказательство лоренцинвариантности S -матрицы в этой теории будет представлено в следующей главе.

Не стоит думать, что это явление специфично для полей спина $j \geqslant 1$. Например, рассмотрим векторное поле, построенное из скалярного поля, равное (см. гл. 5) его производной $\partial_\lambda\phi(x)$. В случае

спаривания этого поля со скалярным полем, $\phi^\dagger(y)$, полином $P(p)$ на массовой оболочке равен

$$P_\lambda(p) = ip_\lambda$$

а спаривание того же поля с $\partial_\eta\phi^\dagger(y)$ дает многочлен

$$P_{\lambda,\eta} = p_\lambda p_\eta$$

Ковариантные многочлены для импульса q^μ вне массовой оболочки опять получаются заменой q^μ на p^μ в формулах (6.2.13) и (6.2.24). Из формулы (6.2.23) мы видим, что $P_\lambda(q)$ линеен по q_0, значит, полиномы $P_\lambda(q)$ и $P^{(L)}_\lambda(q)$ совпадают. Но в случае формулы (6.2.24) разница между ними есть:

$$P^{(L)}_{\lambda,\eta}(q) = q_\lambda q_\eta - \left(q_0^2 - \mathbf{q}^2 - m^2\right)\delta^0_\lambda\delta^0_\eta = \\ = P_{\lambda,\eta}(q) + \left(q^2 + m^2\right)\delta^0_\lambda\delta^0_\eta$$

так что пропагатор равен

$$\delta_{\lambda,\eta}(x,y) = (2\pi)^{-4}\int d^4q \frac{q_\lambda q_\eta e^{iq\cdot x}}{q^2 + m^2 - i\epsilon} + \delta^0_\lambda\delta^0_\eta\delta^4(x-y)$$

Так же как и в предыдущем примере, нековариантный вклад второго слагаемого можно убрать, добавив в гамильтониан нековариантное взаимодействие

$$\mathscr{H}_{NC}(x) = \frac{1}{2}\left[J^{(0)}(x)\right]^2$$

где $J^\mu(x)$ - это ток, на который умножается градиент $\partial_\mu\phi(x)$ в ковариантной части $\mathscr{H}(x)$.

Теперь должно стать понятно, что, по крайней мере для массивных частиц, вклады от нековариантных слагаемых в пропагаторе всегда можно уничтожить путем добавления в гамильтониан нековариантных локальных членов. Это объясняется тем, что числитель $P^{(L)}_{lm}(q)$ в пропагаторе должен быть равен ковариантному полиному $P'_{lm}(q)$, когда q^μ лежит на массовой оболочке, так что разность между ними должна содержать множитель $q^2 + m^2$. Этот множитель сокращается со знаменателем $(q^2 + m^2 - i\epsilon)$ во вкладе этой разности в формулу (6.2.18), следовательно, уравнение (6.2.18) всегда состоит из ковариантного члена и слагаемого, пропорционального дельта-функции $\delta^4(x-y)$ или ее производным. Вклад последнего слагаемого можно убрать, добавив в гамильтониан взаимодействия член, квадратичный по току, с которым взаимодействуют спаренные поля, или по производным

этих полей. В дальнейшем мы будем неявно предполагать, что такое слагаемое уже введено в гамильтониан, а потому будем использовать ковариантный полином $P_{lm}(q)$ в пропагаторе (6.2.18), и будем опускать индекс L.

Может показаться, что такая процедура несколько искусственна. К счастью, в каноническом формализме, который мы рассмотрим в следующей главе, нековариантное слагаемое, нужное для сокрашения нековариантных членов в пропагаторе, появляется автоматически. Это, в частности, может служить мотивацией для развития канонического формализма.

* * *

Прежде чем закончить этот параграф, следует упомянуть некоторые другие часто встречающиеся в литературе определения пропагатора, эквивалентные уравнению (6.2.1). Во-первых, взятие вакуумного среднего от обеих частей уравнения (6.1.14) дает

$$-\delta_{lm}(x,y) = \theta(x-y)\left\langle \left[\psi_l^+(x), \psi_m^{+\dagger}(y)\right]_{\mp}\right\rangle_0 \pm \\ \pm\theta(y-x)\left\langle \left[\psi_m^{-\dagger}(y), \psi_l^-(x)\right]_{\mp}\right\rangle_0$$

Здесь $\langle AB...\rangle_0$ обозначает вакуумное среднее $(\Phi_0, AB...\Phi_0)$. Оба оператора $\psi_l^+(x)$ и $\psi_m^{-\dagger}(y)$ уничтожают вакуум, значит, остается только одно слагаемое в каждом (анти)коммутаторе в уравнении (6.2.28), даюшее вклад в пропагатор:

$$-i\delta_{lm}(x,y) = \theta(x-y)\left\langle \psi_l^+(x)\psi_m^{+\dagger}(y)\right\rangle_0 \pm \theta(y-x)\left\langle \psi_m^{-\dagger}(y)\psi_l^-(x)\right\rangle_0$$

Кроме того, $\psi^{-\dagger}$ и ψ^+ уничтожают вакуумное состояние справа, аψ^- и $\psi^{+\dagger}$ - слева, поэтому ψ^+ и ψ^- повсюду в уравнении (6.2.29)

можно заменить на полное поле $\psi = \psi^+ + \psi^-$:

$$-i\delta_{lm}(x,y) = \theta(x-y)\left\langle \psi_l(x)\psi_m^{\dagger}(y)\right\rangle_0 \pm \theta(y-x)\left\langle \psi_m^{\dagger}(y)\phi_l(x)\right\rangle_0$$

Последнюю формулу можно переписать в виде

$$-i\delta_{lm}(x,y) = \left\langle T\left\{\psi_l(x)\psi_m^{\dagger}(y)\right\}\right\rangle_0$$

где T - хролологическое упорядочение (или символ хронологизации), обобщенное теперь [2]) для любых полей, со знаком минус для любой нечетной перестановки фермионных операторов.

14.2.9 Examples of Feynman Rules in Different Theories

(in cond matter, in QFT, there are many of its)

Feynman Rules in QED

(see Peskin Shroder for now)

14.2.10 Furry's theorem about Fermionic loop

теорема Фари о зануленииfермионной петли с нечетным числом вершин

Если в диаграмме есть фермионная петля с нечетным числом фотонных вершин, то вклад этой петли равен нулю.

В самом деле, поскольку электродинамика инвариантна относительно зарядового сопряжения,

а указанная петля содержит в качестве внешних к ней линий только фотонные, можно вычислить вклад этой петли в зарядово симметричной теории, т. е. просто заменив в вершинах заряд e на $-$.

Тогда петля в точности совпадет сама с собой, но с обратным знаком, а значит, вклад тождественно равен нулю.

Это можно наглядно интерпретировать графически: весь вклад пели соответствует графику с определенным направлением стрелки, отвечающему направлению движения заряда, и графику с противоположным направлением стрелки, а их сумма тождественно обращается в нуль в силу зарядовой инвариантности электродинамики и нечетного числа k произведения факторов $(-1)^k$ для второго графика с обратным направлением стрелки.

(пример применения теоремы Фари нужен)

14.2.11 Feynman Diagrams by Zi.I.7 1

Ангармоничность в теории поля

Для теории свободного поля, которую мы рассматривали в последних главах, найти решение легко, поскольку определяющий интеграл по траекториям (I.3.14) является гауссовым, так что можно просто применить (I.2.15). (Это соответствует решению задачи о гармоническом осцилляторе в квантовой механике.) Как говорилось в главе I.3, в рамках гармонического приближения колебательные моды на матраце можно линейно складывать, и таким образом они просто проходят друг сквозь друга. Частицы, представленные волновыми пакетами, составленными из этих мод, не взаимодействуют [1]: отсюда и название «теория свободного поля». Для того чтобы моды начали рассеиваться друг на друге, мы должны включить в лагранжиан ангармонические члены так, чтобы уравнения движения перестали быть линейными. Для простоты добавим к нашей свободной теории только один ангармонический член $-\frac{\lambda}{4!}\varphi^4$ и с учетом (I.3.11) попробуем вычислить

$$Z(J) = \int D\varphi e^{i\int d^4x\left\{\frac{1}{2}\left[(\partial\varphi)^2 - m^2\varphi^2\right] - \frac{\lambda}{4!}\varphi^4 + J\varphi\right\}}$$

(Мы опустили зависимость Z от λ.)

Решать квантовую теорию поля совсем нетрудно, скажете вы, для этого надо всего лишь вычислить функциональный интеграл (1). Но интеграл-то не из легких! Если бы вы смогли его вычислить, это была бы сенсация.

[1] Потенциальный источник путаницы. Вследствие распространения φ, источники. связанные с φ, как мы видели в главе I.4, взаимодействуют, но частицы, ассоциированные с полем φ, не взаимодействуют друг с другом. Такая ситуация аналогична утверждению, что заряженные частицы. связанные с фотоном, взаимодействуют. но фотоны (в главном приближении) не взаимодействуют друг с другом.

Диаграммы Фейнмана облегчают задачу

Будучи студентом, я слышал об этих таинственных маленьких картинках, называемых диаграммами Фейнмана, и очень хотел о них узнать. Я уверен, что и вы интересуетесь этими забавными диаграммами. Итак, я покажу вам, что в диаграммах Фейнмана нет ничего такого: на самом деле мы уже рисовали маленькие пространственно-временные картинки в главах I.3 и I.4), демонстрирующие, как частицы появляются, распространяются и исчезают.

Для того, кто впервые изучает квантовую теорию поля, диаграммы Фейнмана кажутся несколько сложными. Для их вывода в стандартных учебниках используется канонический формализм (который я введу в следующей главе), вместо формализма интеграла по траекториям, используемого здесь. Впоследствии мы увидим, что в каноническом формализме поля являются квантовыми операторами. Для вывода диаграмм Фейнмана мы должны были бы решить уравнения движения для полевых операторов с применением теории возмущений относительно λ. Для этого требуется развить довольно сложную технику.

По мнению тех, кто предпочитает формализм интеграла по траекториям, построение диаграмм в нем значительно проще (и это естественно!). Тем не менее вывод диаграмм может быть довольно сложным, и студент легко может потерять нить. Так или иначе, придется потрудиться.

Я постараюсь максимально облегчить вам задачу, применив один замечательный педагогический прием, состоящий в том, чтобы дать вам возможность самим открыть диаграммы Фейнмана. Буду придерживаться следующей стратегии: дам вам решить две задачи на возрастающую сложность, которые я называю задачей для младенца и задачей для ребенка соответственно. После того как вы их одолеете, вычисление (1) покажется вам намного проще.

Задача для младенца

Задача для младенца состоит в вычислении обычного интеграла

$$Z(J)=\int\limits_{-\infty}^{+\infty}dqe^{-\frac{1}{2}m^2q^2-\frac{\lambda}{4!}q^4+Jq}$$

который, очевидно, является более простой версией (1). Сначала сделаю тривиальное замечание: мы всегда можем заменить $q\to q/m$ так, чтобы $Z=m^{-1}\mathcal{F}\left(\frac{\lambda}{m^4},\frac{J}{m}\right)$, но делать этого не будем.

Для $\lambda=0$ получаем всего лишь один из гауссовых интегралов, описываемых в приложении к главе I.2. Вы скажете, что $Z(J)$ достаточно просто вычислить как ряд по λ: разложив

$$Z(J)=\int\limits_{-\infty}^{+\infty}dqe^{-\frac{1}{2}m^2q^2+Jq}\left[1-\frac{\lambda}{4!}+\frac{1}{2}\left(\frac{\lambda}{4!}\right)^2q^8+...\right]$$

и почленно проинтегрировав. Вы, возможно, даже знаете один из нескольких приемов вычисления $\int\limits_{-\infty}^{+\infty}dqe^{-\frac{1}{2}m^2q^2+Jq}q^{4n}$: можно записать интеюрал в виде $\left(\frac{d}{dJ}\right)\int\limits_{-\infty}^{+\infty}dqe^{-\frac{1}{2}m^2q^2+Jq}$ и применить (I.2.11). Итак:

$$Z(J)=\left(1-\frac{\lambda}{4!}\left(\frac{d}{dJ}\right)^4+\frac{1}{2}\left(\frac{\lambda}{4!}\right)^2\left(\frac{d}{dJ}\right)^8+...\right)\int\limits_{-\infty}^{+\infty}dqe^{-\frac{1}{2}m^2q^2+.I!}$$

$$=e^{-\frac{\lambda}{4!}\left(\frac{d}{dJ}\right)^4}\int\limits_{-\infty}^{+\infty}dqe^{-\frac{1}{2}m^2q^2+Jq}=\left(\frac{2\pi}{m^2}\right)^{1/2}e^{-\frac{\lambda}{4!}\left(\frac{d}{dJ}\right)^4}e^{\frac{1}{2mm^2},'}$$

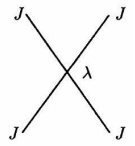
(Есть и другие способы, например, многократное дифферснцировап $\int\limits_{-\infty}^{+\infty}dqe^{-\frac{1}{2}m^2q^2+Jq}$ по m^2, но я хочу использовать трюк, который также ра ботает и в теории поля.)

Разложим обе экспоненты и получим любой члс двойного степенного разложения $Z(J)$ по λ и J. [Часто общий множитл. $(2\pi/m^2)^{1/2}=Z(J=0,\lambda=0)\equiv Z(0,0)$ опускается, поскольку он одынаков для всех членов ряда. Когда нам захочется точности, мы опредслим $\widetilde{Z}=Z(J)/Z(0,0)\cdot$

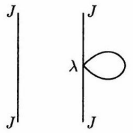
Предположим, например, что нам нужен член в $\widetilde{Z}$ порядка λ и J^4. Выделим член порядка J^8 в $e^{J^2/2m^2}$, то есть $\left[1/4!\left(2m^2\right)^4\right]J^8$, замсиим $e^{-(\lambda/4!)(d/dJ)^4}$ на $-(\lambda/4!)(d/dJ)^4$ и продифференцируем, чтобы получить $\left[8(-\lambda)/(4!)^3\left(2m^2\right)^4\right]J^4$.

Другой пример: член порядка λ^2 и J^6 разен $\frac{1}{2}(\lambda/4!)^2(d/dJ)^8\left[1/7!\left(2m^2\right)^7\right]J^{14}=\left[14!(-\lambda)^2/(4!)^2 6!7!2\left(2m^2\right)^7\right]J^6$. Третий пример: член порядка λ^2 и J^4 имеет вид $\left[12!(-\lambda)^2/(4!)^3 2(6!)\left(2m^2\right)^6\right]J^4$.

И наконец, для члена порядка λ и J^0 получаем $\left[1/2\left(2m^2\right)^2\right](-\lambda)$.



(a)



(b)

$$\left(\frac{1}{m^2}\right)^4\lambda J^4$$

(c)

Рис. I.7.1

Вы можете делать это не хуже меня! Получите еще несколько членов ряда, и вы быстро поймете их структуру. Со временем вы узнаете, что можно отождествлять члены ряда с диаграммами и формулировать для них правила. Рассмотренные нами четыре примера приводятся в соответствие диаграммам, изображенным на рисунках I.7.1-I.7.4. Можно видеть, что по некоторой причине, которую вы потом поймете, каждый член сопоставляется с несколькими диаграммами. В качестве упражнения постарайтесь точно сформулировать соответствующие правила, чтобы получить правильные численные коэффициенты (но поверьте мне, «будущее демократии» от них не зависит.) Правила должны звучать примерно так: (1) диаграммы строятся из линий и вершин, в которых встречаются четыре линии; (2) каждой вершине соответствует множитель $(-\lambda)$; (3) каждой линии соответствует $1/m^2$; и (4) каждому внешнему концу соответствует J (например, рис. I.7.2 имеет семь линий, две вершины и шесть внешних концов, что дает $\sim \left[(-\lambda)^2/\left(m^2\right)^7\right] J^6$). (Вы заметили, что удвоенное число линий равно числу вершин, помноженному на 4, плюс число внешних концов? Соотношения подобного рода встретятся нам в главе III.2.)

По очевидным причинам некоторые диаграммы (например, рис. I.7.1 a, I.7.2a) называются древесными [2], а другие (например, рис. I.7.1b и I.7.3a) петлевыми.

[2] Китайский иероглиф, обозначающий дерево (A. Zi, Swallowing Clouds). показан на рис. I.7.5. В качестве упражнения подумайте, почему эта диаграмма не появляется в разложении $Z(J)$ (?????)

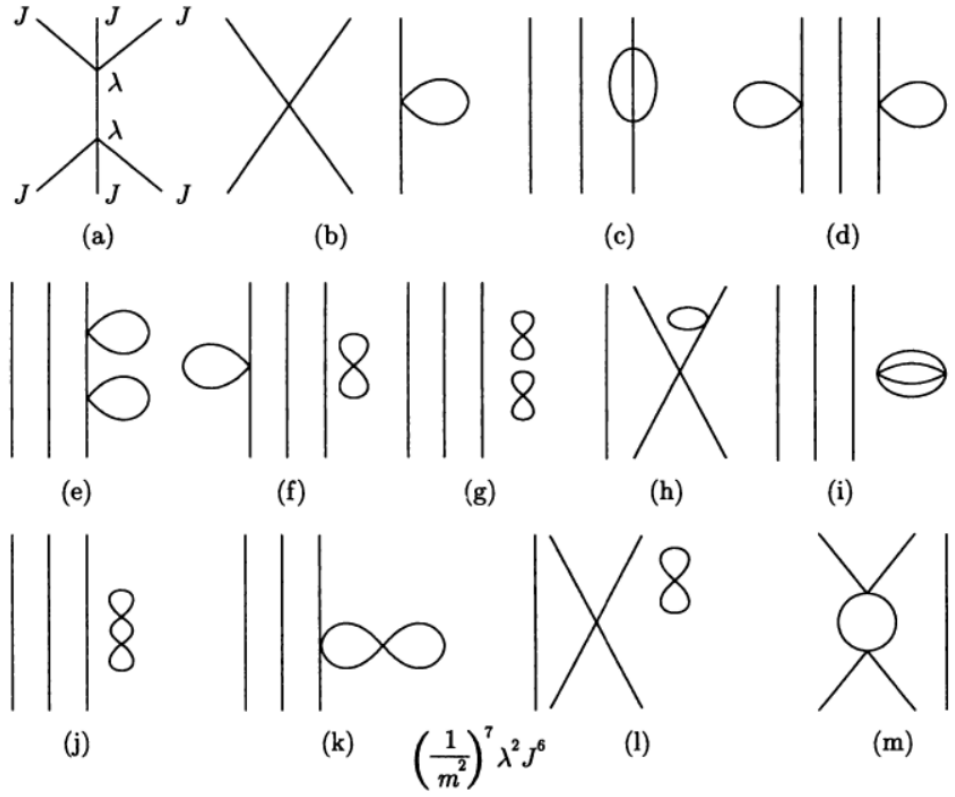


Рис. I.7.2

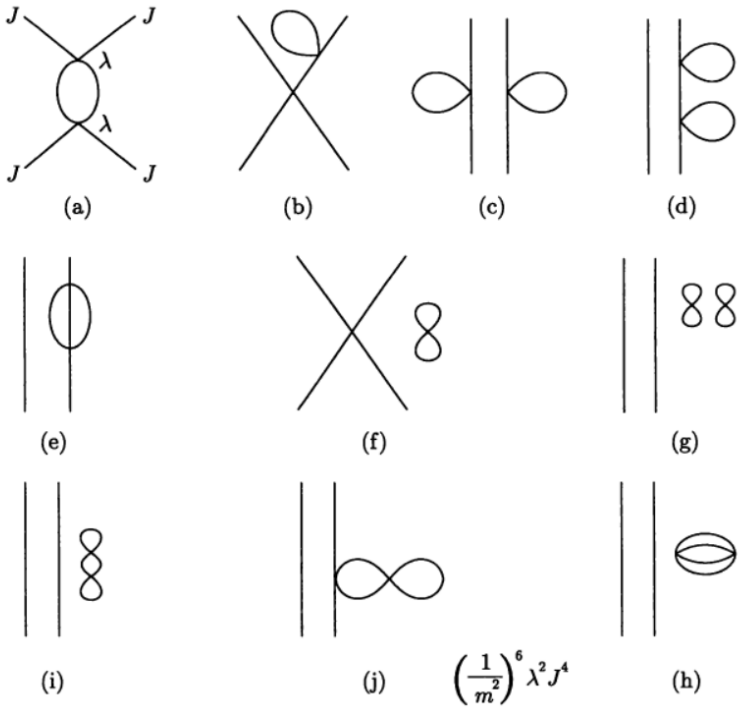
Рассмотрите столько примеров, сколь вам нужно, чтобы добиться должного понимания происходящего, так как мы будем делать в точности то же самое в квантовой теории поля.

Там это будет выглядеть более запутанным, но лишь на первый взгляд. Прежде чем двигаться дальше, удостоверьтесь, что вы понимаете, как использовать диаграммы для представления двойного степенного разложения Z(J). Из своей преподавательской практики я знаю, что у студентов, основательно не разобравшихся с разложением $\widetilde{Z}(J)$, нет шансов понять то, что мы собираемся делать в контексте теории поля.



(??? не уверен, что это тут лучше ставить, но пусть пока тут побудут.)

Виковская свертка

Совершенно очевидно, что $Z(J)$ можно при желании разложить в ряд по степеням J, а не λ. Далее вы увидите, что специалисты в области физики элементарных частиц предпочитают классификацию по степеням J. В рамках нашей задачи для младенца можно записать

$$Z(J) = \sum_{s=0}^{\infty} \frac{1}{s!} J^s \int_{-\infty}^{+\infty} dq e^{-\frac{1}{2}m^2q^2 - \frac{\lambda}{4!}q^4} q^s \equiv Z(0,0) \sum_{s=0}^{\infty} \frac{1}{s!} J^s G^{(s)}$$

Коэффициент $G^{(s)}$, аналоги которого в квантовой теории поля называются функциями Грина, можно вычислить как ряд по λ, каждый член которого определяется виковской сверткой (I.2.10). Например, член $O(\lambda)$ в $G^{(4)}$ имеет вид

$$\frac{-\lambda}{4!Z(0,0)} \int_{-\infty}^{+\infty} dq e^{-\frac{1}{2}m^2q^2} q^8 = \frac{-7!!\lambda}{4!m^8}$$

и который, конечно, равен [3] значению, полученному нами ранее для члена λJ^4 в $\widetilde{Z}$. Таким образом, существует два способа вычисления Z: с разложением сначала по λ или по J.

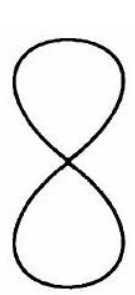


Рис. I.7.4

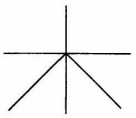

Рис. I.7.5

Связанные против несвязанных

Вы, должно быть, заметили, что некоторые диаграммы Фейнмана являются связанными, а другие - нет. Так, диаграмма на рис. I.7.2a связанная, а на рис. I.7.2b нет. Я предсказывал это в конце главы I.4 и на рис. I.4.2 и I.4.3. Запишем

$$Z(J,\lambda) = Z(J=0,\lambda)e^{W(J,\lambda)} = Z(J=0,\lambda)\sum_{N=0}^{\infty}\frac{1}{N!}[W(J,\lambda)]^N.$$

По определению, $Z(J=0,\lambda)$ состоит из диаграмм без внешнего источника J, таких как диаграмма на рис. I.7.4. Мы утверждаем, что W является суммой связанных диаграмм, тогда как Z содержит как связанные, так и несвязанные диаграммы. Таким образом, рисунок I.7.2b состоит из двух несвязанных частей и определяется членом $(1/2!)[W(J,\lambda)]^2$ в (6); множитель 2 ! указывает на то, что нам абсолютно не важно, какую из двух частей мы помещаем «слева или справа». Аналогично рис. I.7.2c определяется членом $(1/3!)[W(J,\lambda)]^3$. Значит, необходимо вычислять W, а не Z. Если вам хорошо преподавали статистическую механику, вы должны признать, что за всеми этими рассуждениями о связных и несвязных графах лежит то, что служит основой связи между свободной энергией и статистическкой суммой.

Распространение: отсюда туда

Все эти особенности задачи для младенца по своей структуре совершенно аналогичны особенностям теории поля, и мы можем немедленно

[3] В качестве проверки законов арифметики удостоверимся, что действительно $7!!/(4!)^2 = 8!/(4!)^3 2^4$. обратиться к нашим рассуждениям. Однако, прежде чем переходить к теории поля, рассмотрим так называемую задачу для ребенка, т. е. задачу на кратные (а не обычные) интегралы:

$$Z(J) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\cdots\int_{-\infty}^{+\infty} dq_1 dq_2 ... dq_N e^{-\frac{1}{2}q\cdot A\cdot q - \frac{\lambda}{4!}q^4 + J\cdot q}$$

где $q^4 \equiv \sum_i q_i^4$. Обобщая последовательность действий, приведших нас к (3), получаем

$$Z(J)=\left[\frac{(2\pi)^N}{\det A}\right]^{1/2} e^{-\frac{\lambda}{4!}\sum_i(\partial/\partial J_i)^4} e^{\frac{1}{2}J\cdot A^{-1}\cdot J}$$

В качестве альтернативы мы могли бы, как в (5), разложить по степеням J

$$Z(J)=\sum_{s=0}^{\infty}\frac{1}{s!}J_{i_1}...J_{i_s}\int\limits_{-\infty}^{+\infty}\left(\prod_l dq_l\right)e^{-\frac{1}{2}q\cdot A\cdot q-\frac{\lambda}{4!}q^4}q_{i_1}...q_{i_s}=$$
$$=Z(0,0)\sum_{s=0}^{\infty}\frac{1}{s!}J_{i_1}...J_{i_s}G^{(s)}_{i_1}...i_2$$

затем разложить по степеням λ и вычислить виковские свертки.

Одна из особенностей задачи для ребенка, которая отсутствует в задаче для младенца, состоит в распространении «отсюда туда». Вспомним обсуждение пропагатора в главе I.3. Как и в (I.3.16), мы можем рассматривать индекс i как метку узла решетки. В самом деле, в (I.3.16) мы, по сути, вычислили «двухточечную функцию Грина» $G^{(2)}_{ij}$ в нулевом порядке по λ (дважды продифференцируйте (I.3.16) по J):

$$G^{(2)}_{ij}(\lambda=0)=\left[\int\limits_{-\infty}^{+\infty}\left(\prod_l dq_l\right)e^{-\frac{1}{2}q\cdot A\cdot q}q_iq_j\right]/Z(0,0)=\left(A^{-1}\right)_{ij}$$

(см. также приложение к главе I.2). Матричный элемент $\left(A^{-1}\right)_{ij}$ описывает распространение из i в j. В задаче для младенца каждый член в разложении $Z(J)$ можно ассоциировать с несколькими диаграммами, но при наличии распространения этого сделать нельзя. Теперь вычислим «четырехточечную функцию Грина» $G^{(4)}_{ijkl}$ в первом порядке по λ:

$$G^{(4)}_{ijkl}=\int\limits_{-\infty}^{+\infty}\left(\prod_m dq_m\right)e^{-\frac{1}{2}q\cdot A\cdot q}q_iq_jq_kq_l\left[1-\frac{\lambda}{4!}\sum_n q_n^4+O\left(\lambda^2\right)\right]/Z(0,0)=$$
$$=\left(A^{-1}\right)_{ij}\left(A^{-1}\right)_{kl}+\left(A^{-1}\right)_{ik}\left(A^{-1}\right)_{jl}+\left(A^{-1}\right)_{il}\left(A^{-1}\right)_{jk}-$$
$$-\lambda\sum_n\left(A^{-1}\right)_{in}\left(A^{-1}\right)_{jn}\left(A^{-1}\right)_{kn}\left(A^{-1}\right)_{ln}+O\left(\lambda^2\right). \quad (10)$$

Первые три члена описывают распространение одного возбуждения из i в j, а другого - из k в l, плюс две возможные перестановки этой «истории». Наличие члена, порядок которого равен λ, указывает на то, что четыре возбуждения, распространяющиеся из i в n, из j в n, из k в n и из l в n, встречаются в n и взаимодействуют с амплитудой пропорциональной λ, где n может находиться где угодно на решетке или матраце. Между прочим, видно, почему удобно определять взаимодействие $(\lambda/4!)\varphi^4$c1/4! : q_i имеет на выбор четыре q_n для свертывания, q_j - три q_n и так далее, что дает множитель 4 !, который сокращается с (1/4!).

Пертурбативная теория поля

Теперь вы должны быть готовы перейти к теории поля!

В самом деле, функциональный интеграл в (1) (который я здесь снова привожу)

$$Z(J)=\int D\varphi e^{i\int d^4x\left\{\frac{1}{2}\left[(\partial\varphi)^2-m^2\varphi^2\right]-(\lambda/4!)\varphi^4+J\varphi\right\}}$$

имеет такую же форму, что и обыкновенный интеграл в (2) и кратный интеграл в (7). Имеется одна незначительная разница: в (2) и (7) отсутствует i, но, как говорилось в главе I.2, мы можем совершить над (11) виковский поворот и избавиться от i, но делать этого не будем. Существенное отличие состоит в том, что J и φ в (11) являются функциями от непрерывной переменной x, в то время как J и q в (2) ни от чего не зависят, а в (7) они зависят от дискретной переменной. Если не считать этого, все остальное совсршснно идснтично.

Как в (3) и (8) имеем

$$Z(J)=e^{-\frac{i}{4!}\lambda\int d^4w[\delta/i\delta J(w)]^4}\int D\varphi e^{i\int d^4x\left\{\frac{1}{2}\left[(\partial\varphi)^2-m^2\varphi^2\right]+J\varphi\right\}}=$$

$$=Z(0,0)e^{-\frac{i}{4!}\lambda\int d^4w[\delta/i\delta J(w)]^4}e^{-\frac{i}{2}\iint d^4xd^4yJ(x)D(x-y)J(y)}$$

Полное структурное подобие!

Роль $1/m^2$ в (3) и A^{-1} в (8) теперь играет пропагатор

$$D(x-y)=\int\frac{d^4k}{(2\pi)^4}\frac{e^{ik\cdot(x-y)}}{k^2-m^2+i\varepsilon}$$

Кстати, если вернуться к главе I.3, то можно увидеть, что в d-мерном пространстве-времени выражение для $D(x-y)$ имеет такую же форму, но с заменой $d^4k/(2\pi)^4$ на $d^dk/(2\pi)^d$. Обыкновенный интеграл (2) подобен теории поля в 0 -мерном пространстве-времени: если положить $d=0$, то распространение будет отсутствовать и выражение для $D(x-y)$ сведется к виду $-1/m^2$. Согласитесь, что все это вполне логично.

Мы тажже знаем, что $J(x)$ соответствует источнику или стоку. Таким образом, если бы мы разложили $Z(J)$ по J, то степени J отвечали бы числу частиц, вовлеченных в процесс. (Обратите внимание, что в используемой системе обозначений процесс рассеяния $\varphi+\varphi\to\varphi+\varphi$ рассматривается как 4-частичный процесс: мы подсчитываем общее число входящих и выходящих частиц.) Поэтому в теории поля часто разумнее определять степень J. Аналогично тому, как это делалось в младенческой и детской задачах, можно начать с разложения по J:

$$Z(J)=Z(0,0)\sum_{s=0}^{\infty}\frac{1}{s!}\int d^4x_1...d^4x_sJ\left(x_1\right)...J\left(x_s\right)G^{(s)}\left(x_1,...,x_s\right)=$$

$$=\sum_{s=0}^{\infty}\frac{1}{s!}\int d^4x_1...d^4x_sJ\left(x_1\right)...J\left(x_s\right)\times$$

$$\times\int D\varphi e^{i\int d^4x\left\{\frac{1}{2}\left[(\partial\varphi)^2-m^2\varphi^2\right]-\frac{\lambda}{4!}\varphi^4\right\}}\varphi\left(x_1\right)...\varphi\left(x_s\right)$$

В частности, имеем двухточечную функцию Грина:

$$G\left(x_1,x_2\right)\equiv\frac{1}{Z(0,0)}\int D\varphi e^{i\int d^4x\left\{\frac{1}{2}\left[(\partial\varphi)^2-m^2\varphi^2\right]-\frac{\lambda}{4!}\varphi^4\right\}}\varphi\left(x_1\right)\varphi\left(x_2\right)$$

четырехточечную функцию Грина:

$$G\left(x_1,x_2x_3x_4\right)\equiv\frac{1}{Z(0,0)}\int D\varphi e^{i\int d^4x\left\{\frac{1}{2}\left[(\partial\varphi)^2-m^2\varphi^2\right]-\frac{\lambda}{4!}\varphi^4\right\}}\varphi\left(x_1\right)\varphi\left(x_2\right)\varphi\left(x_3\right)\varphi\left(x_4\right)$$

и так далее.

[Иногда $Z(J)$ называют производящим функционалом, так как он порождает функции Грина.]

Очевидно, что в силу трансляционной инвариантности $G(x_1, x_2)$ зависит лишь от $x_1 - x_2$, а не от x_1 и x_2 по отдельности. Аналогично, $G(x_1, x_2, x_3, x_4)$ зависит только от $x_1 - x_4$, $x_2 - x_4$ и $x_3 - x_4$. При $\lambda = 0$ выражение для $G(x_1, x_2)$ сводится к виду $iD(x_1 - x_2)$, т. е. к пропагатору из главы I.3. В то время как $D(x_1 - x_2)$ описывает распространение частицы между x_1 и x_2 в отсутствие взаимодействия, пропагатор $G(x_1 - x_2)$ отвечает за распространение частицы между x_1 и x_2 в присутствии взаимодействия. Если вы поняли, как строится $G^{(4)}_{ijkl}$, то должны знать, что $G(x_1, x_2, x_3, x_4)$ описывает рассеяние частиц.

В некотором смысле существует два способа построения теории поля, которые я мог бы назвать способом Швингера (12) и способом Вика (13).

Подведем итог: с помощью диаграмм Фейнмана очень удобно представлять члены двойного степенного разложения $Z(J)$ по λ и J.

Как говорилось в предисловии, я не стремлюсь сделать из вас специалистов по вычислению фейнмановских диаграмм. В любом случае это может прийти только с опытом. К тому же, существует много прекрасных книг, посвященных вычислению диаграмм. Я постарался дать вам максимально ясное представление о концепции, скрывающейся за этим выдающимся изобретением Фейнмана, которое, как довольно едко заметил Швингер, позволило практически каждому стать теоретиком-полевиком. А пока не думайте слишком много о множителях 4 ! и 2 !.

Столкновения между частицами

Как я уже отмечал, в главе I.4 описывается стратегия введения источников и стоков с целью наблюдения за распространением частицы (которую я буду называть мезоном), связанной с полем φ. Давайте введем два источника и два стока для наблюдения за рассеянием двух мезонов друг на друге (рис. I.7.6). Оба источника, локализованных в областях 1 и 2, порождают по одному мезону, и эти два мезона со временем исчезают в стоках, локализованных в областях 3 и 4. В этом случае достаточно найти в Z член, содержащий $J(x_1) J(x_2) J(x_3) J(x_4)$. Но он в точности совпадает с $G(x_1, x_2, x_3, x_4)$.

Ограничимся вычислением в первом порядке по λ. Следуя Вику, мы должны вычислить

$$\frac{1}{Z(0,0)} \left(-\frac{i\lambda}{4!}\right) \int d^4w \int D\varphi e^{i\int d^4x \left\{\frac{1}{2}\left[(\partial\varphi)^2 - m^2\varphi^2\right]\right\}}{}_{\times}$$
$$\times \varphi(x_1)\varphi(x_2)\varphi(x_3)\varphi(x_4)\varphi(w)^4.$$

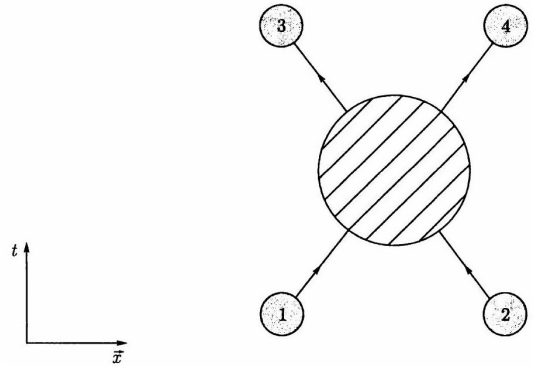

Рис. I.7.6

Как и в (10), мы образуем виковские свертки и получаем

$$(-i\lambda)\int d^4w D\left(x_1-w\right)D\left(x_2-w\right)D\left(x_3-w\right)D\left(x_4-w\right)$$

В качестве проверки получим это выражение способом Швингера. Заменим $e^{-(i/4!)\lambda\int d^4w(\delta/\delta J(w))^4}$% % на $-(i/4!)\lambda\int d^4w(\delta/\delta J(w))^4$% % и $e^{-(i/2)\iint d^4d^4yJ(x)D(x-y)J(y)}$ на

$$\frac{i^4}{4!2^4}\left[\iint d^4d^4yJ(x)D(x-y)J(y)\right]^4$$

Для сокращения записи благоразумным будет обозначать $J\left(x_a\right)$ как J_a, $\int d^4x_a$ как $\int\limits_a$, а $D\left(x_a-x_b\right)$ как D_{ab}. Опуская общие численные коэффициенты, которые я предлагаю вам вписать самостоятельно, получаем

$$\sim i\lambda\int\limits_w\left(\frac{\delta}{\delta J_w}\right)^4\int\cdots\int D_{ae}D_{bf}D_{cg}D_{dh}J_aJ_bJ_cJ_dJ_eJ_fJ_gJ_h$$

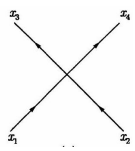
Четыре $(\delta/\delta J_w)$ действуют на восемь J всеми возможными способами, порождая при этом много членов, которые я снова предлагаю вам получить самостоятельно. Связный член равен

$$\sim i\lambda\iiint\iint D_{aw}D_{bw}D_{cw}D_{dw}J_aJ_bJ_cJ_d$$

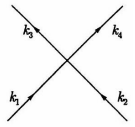
Очевидно, что это выражение является результатом действия четырех $(\delta/\delta J_w)$ на J_e,J_f,J_g и J_h, при котором x_e,x_f,x_g и x_h становятся равными w. Сравните (19) с $\left[8!(-\lambda)/(4!)^3\left(2m^2\right)^4\right]J^4$ из задачи для младенца.

Вспомним, что мы принялись за вычисления с целью породить два мезона источниками, локализованными в областях 1 и 2, пронаблюдать за их рассеянием друг на друге и уничтожить их в стоках, локализованных в областях 3 и 4. Другими словами, мы задаем функцию источника $J(x)$ равной сумме дельта-функций, имеющих пики в точках x_1, x_2,x_3 и x_4. Из (19) немедленно следует, что амплитуда рассеяния равна $-i\lambda\int\limits_w D_{1w}D_{2w}D_{3w}D_{4w}$, что в точности совпадает с (17).

Полученный результат очень легко объяснить (см. рис. I.7.7a). Два мезона распространяются с амплитудой $D\left(x_1-w\right)D\left(x_2-w\right)$ из мест рождения x_1 и x_2 до пространственно-временной точки w, рассеиваются с амплитудой $-i\lambda$ и затем распространяются с амплитудой $D\left(w-x_3\right)D\left(w-x_4\right)$ до своих мест поглощения в x_3 и x_4 [заметим, что $D(x)=D(-x)$]. Интегрирование по w означает, что точка взаимодействия может находиться где угодно. Все как в задаче для ребенка.



(a)



(b)

Рис. I.7.7

Все действительно довольно просто, если понимать, что происходит. Все еще путаетесь? Тогда может оказаться полезным представить $e^{-(i/4!)\lambda\int d^4w[\delta/\delta J(w)]^4}$ как некую машину, действующую на

$$Z(J,\lambda=0)=e^{-(i/2)\iint d^4xd^4yJ(x)D(x-y)J(y)}$$

Будучи разложенной в ряд, $Z(J,\lambda=0)$ представляет собой несколько J, разбросанных в пространстве-времени, а каждая пара J связана посредством D. Вообразите пучок струн, концы которых соответствуют J. Что делает «машина»? Машина состоит из суммы членов, например, члена

$$\sim\lambda^2\int d^4w_1\int d^4w_2\left[\frac{\delta}{\delta J\left(w_1\right)}\right]^4\left[\frac{\delta}{\delta J\left(w_2\right)}\right]^4.$$

Когда этот член действует на какой-либо член в $Z(J,\lambda=0)$, он хватает четыре струнных конца и склеивает их вместе в точке w_2; затем другие четыре струнных конца и склеивает их вместе в точке w_1. Затем по положениям w_1 и w_2 проводит интегрирование. Два примера показаны на рис. I.7.8. В эту игру можно играть даже с ребенком. Эта детская игра, заключающаяся в склеивании четырех струнных концов, генерирует все диаграммы Фейнмана в нашей теории скалярного поля.

14.2.12 Feynman Diagrams by Zi.I.7 2

Сделай это раз и навсегда

А теперь появляется Фейнман и говорит, что глупо каждый раз повторять эту утомительную болтовню. Надо просто понять правила раз и навсегда.

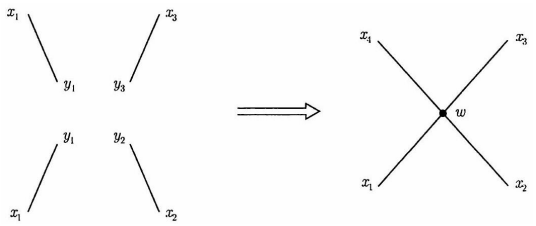
Например, для диаграммы на рис. I.7.7a сопоставим рассеянию множитель $-i\lambda$, распространению из x_1 в w множитель $D\left(x_1-w\right)$ и так далее - что с концептуальной точки зрения аналогично нашей младенческой задаче. Смотрите, вы сами могли бы изобрести диаграммы Фейнмана. (Ну, хорошо, может и могли бы, а может и нет.)

Точно так же, как при переходе от (I.4.1) к (I.4.2), легче работать в импульсном пространстве. И действительно, эксперименты так и проводят. Мезон с импульсом k_1 и мезон с импульсом k_2 сталкиваются и после рассеяния разлетаются с импульсами k_3 и k_4 (см. рис. I.7.7b). Каждый пропагатор пространства-времени дает нам

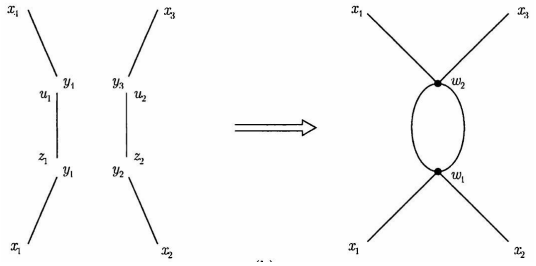
$$D\left(x_a-w\right)=\int\frac{d^4k_a}{(2\pi)^4}\frac{e^{\pm ik_a(x_a-w)}}{k_a^2-m^2+i\varepsilon}.$$

Обратите внимание, что мы свободны выбирать знак (либо плюс, либо минус) фиктивной переменной интегрирования в экспоненте. После интегрирования в (17) по w получаем

$$\int d^4we^{-i(k_1+k_2-k_3-k_4)w}=(2\pi)^4\delta^{(4)}\left(k_1+k_2-k_3-k_4\right).$$



(a)



(b)

Рис. I.7.8

Тот факт, что взаимодействие могло произойти в любой точке пространства-времени, отражается законом сохранения импульса $k_1 + k_2 = k_3 + k_4$. (Мы включили соответствующие знаки минус в два пропагатора D, с тем чтобы рассматривать k_3 и k_4 как выходящие импульсы.)

Итак, существуют диаграммы Фейнмана как в реальном пространстве-времени, так и импульсном пространстве. Пространственно-временные диаграммы Фейнмана буквальным образом представляют картину того, что происходит. (Тривиальное замечание: ориентация диаграмм Фейнмана зависит от личного выбора человека. Кто-то рисует их так, что время изменяется в вертикальном направлении, а кто-то - так, что в горизонтальном.)

Правила

Итак, мы вывели знаменитые правила Фейнмана в импульсном пространстве для нашей теории скалярного поля, которые формулируются следующим образом:

1. Нарисовать диаграмму Фейнмана процесса (рис. I.7.7b для только что рассмотренного процесса).

2. Обозначить каждую линию импульсом k и сопоставить с ней пропагатор $i/\left(k^2 - m^2 + i\varepsilon\right)$.

3. Сопоставить каждой вершине взаимодействия константу связи $-i\lambda$ и $(2\pi)^4\delta^{(4)}\left(\sum_i k_i - \sum_j k_j\right)$, в результате чего сумма входящих в вершину импульсов $\sum_i k_i$ окажется равной сумме выходящих из нее импульсов $\sum_j k_j$.

4. Проинтегрировать по импульсам внутренних линий с мерой $\frac{d^4k}{(2\pi)^4}$. Данное действие соответствует суммированию по промежуточным состояниям в обычной теории возмущений.

5. Наконец, существует правило для вычисления «противных» симметрийных множителей. Они являются аналогами численных коэффициентов в рассмотренной нами младенческой задаче. Как следствие, некоторые диаграммы необходимо умножить на симметрийный множитель, такой как $\frac{1}{2}$. Эти множители обуславливаются различными комбинационными множителями, которые учитывают различные варианты воздействия $(\delta/\delta J)$ на J в выражениях типа (18). Пример вычисления симметрийного множителя вы найдете в упражнении I.7.2.

Проиллюстрируем на примерах, что означают эти правила (а заодно и понятие внутренней линии).

В качестве первого примера рассмотрим вычисленную нами диаграмму (рис. I.7.7b). Применяя правила, получаем

$$-i\lambda(2\pi)^4\delta^{(4)}\left(k_1+k_2-k_3-k_4\right)\prod_{a=1}^{4}\left(\frac{i}{k_a^2-m^2+i\varepsilon}\right).$$
