Equation (22.104) can be formally interpreted as the motion of a particle of unit mass in one dimension, described by the coordinate ϕ, with ρ playing the role of time, moving in the potential $-V$ shown in Fig. 22.8, and further subject to a damping force $-\eta(\rho)v$, where $v = d\phi/d\rho$ is the velocity of this fictitious particle and $\eta(\rho) = 3/\rho$ a rather peculiar friction coefficient, depending on "time" ρ. This fictitious particle is subject to the boundary conditions (22.105) and (22.106). This mechanical analogy allows us to understand the qualitative features of the solution. The "particle" must start at "time" $\rho = 0$ with zero velocity [see eq. (22.106)], from some initial position ϕ_i chosen so that, at time $\rho \to \infty$, it reaches the position $\phi = 0$. Because of the friction term, its initial energy must therefore be greater than zero, so the initial position must be in the region $\phi_e < \phi_i < \phi_0$, see Fig. 22.9. Its precise value can be determined by integrating eq. (22.104) numerically, assigning a value of $\phi(\rho = 0)$ in the range $\phi_e < \phi(\rho = 0) < \phi_0$, setting $d\phi/\, d\rho|_{\rho=0} = 0$ and using an under-shooting/over-shooting procedure. If we chose a value of $\phi(\rho = 0)$ smaller than ϕ_i, then, because of the friction term, the solution will not have enough energy to reach $\phi = 0$, and will bounce back and perform oscillations around the minimum of $-V$. If we choose a value of $\phi(\rho = 0)$ such that $\phi_i < \phi(\rho = 0) < \phi_0$, then the solution over-shoots, and reaches the region $\phi < 0$, so eventually $\phi \to -\infty$, as we see from the form of $-V$ in Fig. 22.9 (observe that the friction term goes to zero as $\rho \to +\infty$, so it does not significantly damp the evolution at large values of "time" ρ).

In this way we can determine the solution, $\phi_b(\rho)$, numerically. We still call this solution a bounce since, if we follow its evolution as a
function of Euclidean time τ at $\mathbf{x} = 0$, it corresponds to a solution that for $\tau \to -\infty$ (which means $\rho \to +\infty$) goes to zero, increases to the maximum value ϕ_i, which is reached at $\tau = 0$, and then for positive τ bounces back, reaching $\phi = 0$ again as $\tau \to +\infty$. When we continue back to Minkowski space, the solution $\phi = \phi_b(\rho)$ becomes $\phi = \phi_b\left(\sqrt{-t^2 + r^2}\right)$, where $r = |\mathbf{x}|$. If we look at it as a function of r for fixed t, for example at $t = 0$, we see that at small r it is near the value $\phi = \phi_i$, and thus close to the true vacuum ϕ_0. As r increases, ϕ evolves toward the value $\phi = 0$, corresponding to the false vacuum. It therefore represents a "bubble"

in which the field configuration in the inner region is close to the true vacuum, and the field in the exterior is close to the false vacuum. Since the full dependence of the solution on t and r is through the combination $-t^2 + r^2$, with time this bubble of true vacuum expands into the false vacuum at the speed of light. [17] Actually, the description in terms of a bubble is especially appropriate if the transition between the inner and outer region is sharp. This is the case when the energy difference between the true and the false vacuum is small, which is the situation depicted in Fig. 22.10. In this case we see from Fig. 22.10 that the value ϕ_i must be quite close to the maximum ϕ_i of the function $-V$. From the mechanical analogy we see that in this case, in the Euclidean solution, the "particle" with coordinate ϕ will stay for a long "time" ρ near the value ϕ_i, since here the potential is close to flat, up to a "time" $\rho = R$ when this slow-roll regime terminates and the particle quickly rolls toward the "position" $\phi = 0$. Translated in terms of the Minkowskian solution, at fixed time $t = 0$, this describes a field configuration in which, for $r < R, \phi$ is very close to the value $\phi = \phi_0$ corresponding to the true vacuum; it remains almost constant up to $r = R$, and then it quickly goes to the false vacuum value $\phi = 0$. The transition between the region where $\phi \simeq \phi_0$ and the region where $\phi \simeq 0$ takes place in a layer of width $\delta r \ll R$. This corresponds to the thin-wall solution, in which a bubble of true vacuum is separated by a thin wall from the surrounding false vacuum. Again, because of the dependence on $-t^2 + r^2$, with time this bubble expands into the false vacuum at the speed of light.

We now have all the elements to readily adapt the computation of the transition rate that we performed in the quantum-mechanical case. [18] The result is

$$\frac{\Gamma}{V} = Ae^{-S_b/\hbar} \tag{22.107}$$

where S_b is the Euclidean action (22.103) evaluated on the bounce solution $\phi_b(\rho)$. [19] As in the quantum-mechanical computation, the prefactor A in eq. (22.107) can be computed by keeping track of the normalization factors u_n for the four zero modes [which give a factor $(S_b/2\pi)^{1/2}$ each], as well as of the normalization factor $\mathcal{N}$ in the measure (22.79). This gives [20]

$$A = \left(\frac{S_b}{2\pi}\right)^2 \left|\frac{\det'\left[-\partial_\mu\partial_\mu + V''\left(\phi_b\right)\right]}{\det\left[-\partial_\mu\partial_\mu + V''(0)\right]}\right|^{-1/2} \tag{22.111}$$

[17] Observe, however, that this Minkowskian description in terms of an expanding bubble only holds after the bubble has been nucleated, and therefore only for the expanding branch of the hyperboloid $r^2(t) = R^2 + t^2$. The situation is analogous to the description of barrier penetration by a particle in quantum mechanics, in which the WKB approximation is used to compute the tunneling probability, and only after the particle escapes can it be described as freely propagating.

[18] It can again be proved that the fluctuations around the bounce solution have one and only one negative eigenvalue; see Section 6.5 of Coleman (1977b). 19 Observe that, even if V is negative for some values of the field, it can be shown that $S_b > 0$. Indeed, consider the family of functions $\phi_\lambda(x) = \phi_b(x/\lambda)$. Rescaling the integration variable $x \to \lambda x$ in the action, we get $S\left[\phi_\lambda\right] = \int d^4x \left[\frac{\lambda^2}{2}\left(\partial_\mu\phi_b\right)^2 + \lambda^4 V\left(\phi_b\right)\right]$.

Since ϕ_b is a solution of the equations of motion, it is an extremum in the space of all functions, so in particular within the family of function $\phi_\lambda(x)$. Thus, the action (22.108) must be stationary at $\lambda = 1$. This gives

$\int d^4x V(\phi_b) = -(1/4)\int d^4x \left(\partial_\mu \phi_b\right)^2$,
and therefore

$$S_b = \frac{1}{4}\int d^4x \left(\partial_\mu \phi_b\right)^2 > 0 \tag{22.109}$$

see Section 6.2 of Coleman (1977b). Observe that this is a generalization of the result (22.85), (22.86) valid in the quantum-mechanical case.

[20] See Coleman (1977b), eq. (6.47).

[21] More precisely, at a given T one can have both solutions of the equations of motion with $O(4)$ symmetry and solutions with $O(3)$ symmetry. The solution with the lowest action dominates the path integral. At low T the $O(4)$ symmetric solution will dominate, and will reproduce the result of the previous subsection, while above a critical temperature the $O(3)$-symmetric solution will dominate.

Tunneling in QFT at finite temperature

We can finally generalize this formalism to finite-temperature QFT, which is the situation relevant to a phase transition in the early Universe. A first difference, with respect to the previous computation, is that the potential $V(\phi)$ must now be replaced by the effective potential at finite temperature, $V(\phi, T)$. Furthermore, we should not take the limit $\beta \to \infty$ in eq. (22.67), or in its field-theoretical generalization, since $\beta = 1/T$ is the temperature of the system. Thus, the tunneling rate is now obtained from the finite-temperature path integral

$$\int \mathcal{D}\phi e^{-S_4} \tag{22.112}$$

where

$$S_4[\phi] = \int_0^{1/T} d\tau \int d^3x \left[\frac{1}{2}\partial_\mu \phi \partial_\mu \phi + V(\phi, T)\right] \tag{22.113}$$

The boundary conditions in the path integral are $\phi(0, \mathbf{x}) = \phi(1/T, \mathbf{x})$, and we have finally set $\hbar = 1$. In the limit $T \to 0$ we recover the results of the previous subsection. Here we are rather interested in the opposite limit, in which T is large compared with $1/R$, where R is the typical bubble radius. In this limit the dependence of ϕ on Euclidean time becomes negligible, since the overall range of Euclidean times becomes small, and we can write

$$S_4[\phi] \simeq \frac{1}{T} S_3[\phi] \tag{22.114}$$

where

$$S_3[\phi] = \int d^3x \left[\frac{1}{2}\left(\partial_i \phi\right)^2 + V(\phi, T)\right] \tag{22.115}$$

and $\phi = \phi(\mathbf{x})$. In this limit it is natural to look for a solution of the equation of motion with $O(3)$ symmetry, $\phi = \phi_b(r)$, where $r = |\mathbf{x}|$[21] For an $O(3)$-symmetric solution $\phi(r)$, the action S_3 reduces to

$$S_3 = 4\pi \int_0^\infty dr r^2 \left[\frac{1}{2}\left(\frac{d\phi}{dr}\right)^2 + V(\phi, T)\right] \tag{22.116}$$

and the corresponding equation of motion is

$$\frac{d^2\phi}{dr^2} + \frac{2}{r}\frac{d\phi}{dr} = V'(\phi, T) \tag{22.117}$$

The boundary conditions are now

$$\lim_{r\to\infty} \phi(r) = 0 \tag{22.118}$$

in order to have a finite action, and

$$\left.\frac{d\phi}{dr}\right|_{r=0} = 0 \tag{22.119}$$

in order to ensure regularity at the origin. There are now only three zero modes, corresponding to the invariance under spatial translation, so Γ is proportional to V. The factor $1/\beta = T$ in eq. (22.69) is no longer canceled, but this is not a problem since now T is finite. Furthermore, each of the three zero modes contributes to the prefactor with a factor $[S_4/(2\pi)]^{1/2} = [S_3/(2\pi T)]^{1/2}$, so overall they give a factor $[S_3/(2\pi T)]^{3/2}$. Thus, the tunneling rate Γ is given by

$$\frac{\Gamma}{V} = Ae^{-S_{3,b}(T)/T} \tag{22.120}$$

where $S_{3,b}(T)$ is the action $S_3[\phi, T]$ evaluated on the bounce solution $\phi_b(r)$, and the prefactor A is given by

$$A = T\left(\frac{S_3(T)}{2\pi T}\right)^{3/2} \left|\frac{\det'\left[-\nabla^2 + V''\left(\phi_b\right)\right]}{\det\left[-\nabla^2 + V''(0)\right]}\right|^{-1/2} \tag{22.121}$$

A precise evaluation of the determinants in eq. (22.121) is in general difficult, even numerically. However, for most purposes it is sufficient to observe that (in units $\hbar = c = 1$) A has dimensions of (mass) ^{4}, as is clear from the fact that $\Gamma/V \sim (\text{ mass })^4$.[22] In the high-temperature limit the only relevant mass scale becomes T, so we must have $A = cT^4$, with c a number of order 1. Thus, finally,

$$\frac{\Gamma}{V} \simeq cT^4 e^{-S_{3,b}(T)/T} \tag{22.122}$$

At time t the rate of bubble nucleation in a Hubble volume $H^{-3}(t)$ is $(\Gamma/V) \times H^{-3}(t)$. The time t_* at which the phase transition takes place can then be obtained by requiring that the total number of bubbles nucleated from time $t = 0$ to $t = t_*$ is of order 1,

$$\int_0^{t_*} dt \frac{\Gamma}{VH^3(t)} = O(1) \tag{22.123}$$

We can transform the integral with respect to time into an integral with respect to temperature using $T \propto 1/a$, which gives $dT/T = -Hdt$. For transitions taking place in RD, which is the case of interest, using eq. (17.112) for $H^2\left(t_*\right)$ and setting $c = O(1)$, we find that the temperature T_* at which the phase transition takes place is determined by the condition

$$\int_{T_*}^{\infty} \frac{dT}{T}\left(\frac{45}{4\pi^3 g_*(T)}\right)^2 \left(\frac{M_{\rm Pl}}{T}\right)^4 e^{-S_3(T)/T} = O(1) \tag{22.124}$$

Once T_* has been determined in this way, the parameter α is given by eqs. (22.63) and (22.64). The information on the transition rate is in principle fully contained in eq. (22.122).

However, it can be useful to [22] Equivalently, we can directly observe that, in eq. (22.121), det' differs from det by the omission of three eigenvalues corresponding to the three zero modes, so

$$\frac{\det'\left[-\nabla^2+V''\left(\phi_b\right)\right]}{\det\left[-\nabla^2+V''(0)\right]}$$

has dimensions $1/\lambda^3$, where λ is the dimension of the eigenvalues. The latter is the same as the dimension of the operator ∇^2, i.e. (mass) ^{2}, so

$\left|\frac{\det'\left[-\nabla^2+V''(\phi_b)\right]}{\det[-\nabla^2+V''(0)]}\right|^{-1/2} \sim (\text{ mass })^3$.

[23] It should also be stressed that the whole formalism that we have discussed computes the nucleation rate assuming that quantum fluctuations in the thermal environment are responsible for the bubble nucleation. It is in principle possible that different mechanisms are at work, in which bubbles are nucleated by various forms of impurities and inhomogeneities of non-thermal origin. For instance, cosmic strings could act as nucleation sites, as could inhomogeneities due to some pre-existing turbulence; see Witten (1984). In this case β could be very different, and very difficult to predict.

Taylor-expand this expression around the transition time t_*, expressing T as a function of time, $T = T(t)$, and writing

$$\frac{S_{3,b}(T)}{T} \simeq \left(\frac{S_{3,b}(T)}{T}\right)_{t=t_*} + (t-t_*)\frac{d}{dt}\left(\frac{S_{3,b}(T)}{T}\right)_{t=t_*} \tag{22.125}$$

We then define

$$\beta = -\frac{d}{dt}\left(\frac{S_{3,b}(T)}{T}\right)_{t=t_*} \tag{22.126}$$

so, in a small interval of times near $t = t_*$, eq. (22.122) becomes

$$\Gamma(t) \simeq \Gamma_* e^{\beta(t-t_*)} \tag{22.127}$$

Again using $dT/T = -Hdt$, eq. (22.126) becomes

$$\frac{\beta}{H_*} = T_*\frac{d}{dT}\left(\frac{S_{3,b}(T)}{T}\right)_{T=T_*} \tag{22.128}$$

Notice that, in order to compute α, it is sufficient to know the transition temperature T_* and the potential $V(\phi, T)$, while to compute β one must also know how the action $S_{3,b}(T)$ depends on T in a neighborhood of T_* [23]

Equations (22.124) and (22.128) allows one in principle to perform an accurate numerical computation of T_* and of β. We can, however, also obtain an analytic understanding of typical orders of magnitude that one would obtain for β. The integral in eq. (22.124) will in general be dominated by its value at $T = T_*$, so in a first approximation

$$\left(\frac{45}{4\pi^3 g_*\left(T_*\right)}\right)^2\left(\frac{M_{\rm Pl}}{T_*}\right)^4 e^{-S_3(T_*)/T_*} = O(1) \tag{22.129}$$

Setting $g_*\left(T_*\right)$ to its high-temperature value in the Standard Model, $g_* \simeq 106.75$, this gives

$$\frac{S_3\left(T_*\right)}{T_*} \simeq 4\log\frac{M_{\rm Pl}}{T_*} - 11.4 \tag{22.130}$$

For a transition at the electroweak scale, $T_* = O(100\text{GeV})$ and we get $S_3\left(T_*\right)/T_* \simeq 145$, while, for the QCD scale, $S_3\left(T_*\right)/T_* \simeq 173$. In general, barring fine tuning, we expect that

$T_* d/dT \left[S_3(T)/T\right]_{T_*}$ will be of the same order of magnitude as $S_3\left(T_*\right)/T_*$, so as a rough estimate we expect $\beta/H_* = O(100)$, both at the electroweak scale and at the QCD scale. This estimate is roughly confirmed by the explicit numerical computations. Of course, precise numbers can only obtained with an accurate numerical evaluation of eq. (22.128), given the potential $V(\phi, T)$, and values of β/H_* as low as $O(10)$ or as high as $O\left(10^3\right)$ can be obtained in different models. In general α, β and T_* are correlated and, in typical models, as α increases, so that the energy released in the transition increases, β and T_* decrease.

Finally we observe that, in the thin-wall limit, eq. (22.116) allows us to formalize the physical intuition, discussed at the beginning of this section, that the dynamics of true vacuum bubbles is determined by a competition between the volume energy gained by tunneling to the true vacuum, and the effect of surface tension, which tends to shrink the bubbles to zero. Indeed, in the thin-wall limit the bubble configuration has $\phi \simeq \phi_0$ for $r < R$, and $\phi \simeq 0$ and $V(\phi) \simeq 0$ for $r > R$, with the transition taking place in a small range δr near $r = R$. Then the term proportional to the potential in eq. (22.116) is negative and proportional to the bubble volume,

$$4\pi \int_0^\infty dr r^2 V(\phi, T) \simeq 4\pi \int_0^R dr r^2 V(\phi, T) = -|\bar{V}(T)| \frac{4\pi R^3}{3} \tag{22.131}$$

where $\bar{V}(T) < 0$ is the average of the potential inside the bubble volume, which is of order $V\left(\phi_0(T), T\right)$. The term proportional to $(d\phi/dr)^2$ in eq. (22.116) can instead be simplified by observing that, in the thin-wall limit, $(d\phi/dr)$ is sharply peaked around $r = R$, so

$$\begin{aligned} 4\pi \int_0^\infty dr r^2 \frac{1}{2} \left(\frac{d\phi}{dr}\right)^2 &\simeq 4\pi R^2 \int_0^\infty dr \frac{1}{2} \left(\frac{d\phi}{dr}\right)^2 \\ &\equiv 4\pi R^2 S_1(T) \end{aligned} \tag{22.132}$$

So, this term is positive and proportional to the bubble surface, and we recognize the contribution from the surface tension. Thus, in the thin-wall approximation, on a bubble of radius R,

$$S_3(R) = -|\bar{V}(T)| \frac{4\pi R^3}{3} + 4\pi R^2 S_1(T) \tag{22.133}$$

The bounce solution is an extremum of this action in the whole space of field configurations, so in particular with respect to the parameter R. The bubble radius R in the thin-wall approximation can therefore be determined by minimizing eq. (22.133) with respect to R, which gives

$$R(T) = \frac{2 S_1(T)}{|\bar{V}(T)|} \tag{22.134}$$

16.2.4 22.4.4 Bubble dynamics and GW production

In a first-order phase transition, once these supercritical bubbles have nucleated, their subsequent dynamics depends on their environment. Conceptually, the simplest situation is that of vacuum bubbles, i.e. bubbles that are assumed to expand in the vacuum, neglecting their interaction with the cosmic fluid. In that case, the bubbles expand until their walls move at a speed close to the speed of light. The energy gained in the transition from the metastable state

to the ground state is transferred to the kinetic energy of the bubble wall. As the bubble expands, more and more regions of space convert to the ground state, and the wall becomes more and more energetic. At the same time, it also becomes thinner, and therefore the energy density stored in the wall increases very rapidly. Of course, as long as we have a single spherical bubble, this large energy cannot be converted to GWs. However, when two bubbles collide, spherical symmetry is broken and GW production can take place.

More realistically, in the cosmological setting in which we are eventually interested, the bubbles interact with the cosmic fluid. This interaction can in principle be quite complex, and results in friction over the bubble wall, which slows down and changes the bubble evolution, while at the same time the cosmic fluid is stirred by the expanding bubbles, with the generation of turbulent motions and acoustic waves. Indeed, three main mechanisms for GW production have been identified, namely GWs from bubble collisions, from turbulence and from colliding acoustic waves in the fluid. We examine them in turn.

GWs from bubble collisions

Before discussing the results obtained in the literature from numerical computations, let us first estimate the orders of magnitude involved, for the peak frequency and the amplitude of the stochastic background produced by bubble collisions.

At the time of production, the characteristic frequency scale of the process is given by the parameter β that appears in eq. (22.127); thus the typical frequency f_* at the time of production can be estimated as $2\pi f_* \sim \beta$.[24] Inserting this value into eq. (22.6) and setting $g_* \simeq 106.75$, as is appropriate at the electroweak scale, the frequency of the GWs produced, redshifted to the present epoch, can then be estimated to be peaked at

$$f_{\rm peak} \;\sim\; \text{a few} \;\times 10^{-6} \left(\frac{\beta}{H_*}\right) \left(\frac{T_*}{100\text{GeV}}\right) \text{Hz} \tag{22.135}$$

Thus, if there is a first-order phase transition at the electroweak scale $T_* = O(100)$GeV, for values of β/H_* in the typical range $10 - 10^3$ we find that f_0 is in the range $10^{-4} - 10^{-2}$ Hz, which is just in the frequency band of the LISA space-interferometer.

Similarly, if there is a first-order phase transition in QCD at $T_* \simeq 150$MeV, we get

$$f_{\rm peak} \;\sim\; \text{a few} \;\times 10^{-9} \left(\frac{\beta}{H_*}\right) \left(\frac{T_*}{150\text{MeV}}\right) \text{Hz} \tag{22.136}$$

If β/H_* is not too large, this could potentially be within the frequency window of pulsar timing arrays, as we will see in Chapter 23.

To get a first rough order-of-magnitude estimate of the value of $\Omega_{\rm gw}(f)$ at the peak frequency, we can observe that the typical wavelength λ_* of the radiation, at the time of production, is of the order of the typical radius R_* of the bubbles when they collide. Then, the energy liberated in

[24] Actually, when the bubble velocity v_b is not close to the speed of light, there are two different time- or lengthscales in the problem. One is the typical time-scale of the phase transition, β^{-1}, which can also identified with the duration of the phase transition. The other is the typical size of the bubbles near the end of the phase transition, when most bubble collisions take place, which is rather given by $R_* = v_b\beta^{-1}$. One should then ask which of these two scales is more appropriate for estimating the peak frequency through eq. (22.6). The answer is quite subtle, and depends on the detailed time evolution of the energy-momentum tensor of the source. It turns out that, in a first approximation, β^{-1} is appropriate for GWs from bubble collisions, while $v_b\beta^{-1}$ is appropriate for turbulence; see the Further Reading. A fit to the dependence on v_b for bubble collisions will be given in eqs. (22.144) and (22.145).

GWs in the collision of two bubbles is of order $E_{GW} \sim GM_B^2/\lambda_*$, where $M_B \sim \rho_{\rm vac}\lambda_*^3$ is the energy of a typical bubble and $\rho_{\rm vac}$ is the difference in energy density from the metastable state to the ground state. The fraction of the false-vacuum energy that goes into GWs instead of going into radiation is given by

$$\frac{\Omega_{\rm gw}}{\Omega_R} \sim \frac{E_{\rm GW}}{M_B} \tag{22.137}$$

This is, however, valid only for bubble collisions in vacuum, where the energy gained in the transition to the true vacuum can only go into the kinetic energy of the bubble walls, i.e., at the fundamental level, into the kinetic energy of the scalar field. For bubbles evolving in a primordial plasma, the underlying physics is quite different. Indeed, since the energy gained in the transition grows with the bubble radius as R^3, while the energy stored into the bubble walls only grows as R^2, in the presence of other channels only a tiny fraction of the vacuum energy will go into the scalar field. Most of the energy goes into the primordial fluid, where part of it is dissipated. We must therefore insert an efficiency factor κ, which gives the fraction of the available energy that actually contributes to GW generation, and replace M_B by κM_B. Then

$$E_{GW} \sim \kappa^2 \frac{GM_B^2}{\lambda_*} \tag{22.138}$$

Therefore

$$\frac{E_{\rm GW}}{M_B} \sim \kappa^2 \frac{GM_B}{\lambda_*} \sim \kappa^2 G\rho_{\rm vac}\lambda_*^2 \tag{22.139}$$

Using $G\rho_{\rm vac} \sim H_*^2$, we get, at the time of production

$$\Omega_{\rm gw} \sim \kappa^2 \lambda_*^2 H_*^2 \Omega_R \tag{22.140}$$

For a phase transition with characteristic time-scale β we have $\lambda_* = 1/f_* \sim 1/\beta$, and therefore we can also rewrite it as

$$\Omega_{\rm gw} \sim \kappa^2 \left(\frac{H_*}{\beta}\right)^2 \Omega_R \tag{22.141}$$

Despite the crudeness of the approximation, this relation allows us to get a first feeling for the numbers involved. Equation (22.141) suggests that, even in the most optimistic case $\kappa = 1$ (which, as we will see, is far from being realized in realistic situations), for typical values of β/H_* in the range range $10 - 10^3, \Omega_{\rm gw}$ at the peak ranges from a (very optimistic) $10^{-2}\Omega_R \sim 10^{-7}$ to $10^{-6}\Omega_R \sim 10^{-11}$. As we will see, however, the efficiency factor κ and other effects can significantly lower these estimates. It is also interesting to observe that the dependence on $\epsilon_* = \lambda_* H_*$ in eqs. (22.6) and (22.140) is such that, as ϵ_* decreases, the peak frequency increases as $1/\epsilon_*$ while the amplitude at the peak decreases as ϵ_*^2.

To compute the GW spectrum more quantitatively, one can begin by considering the collision of two vacuum bubbles. This can be simulated

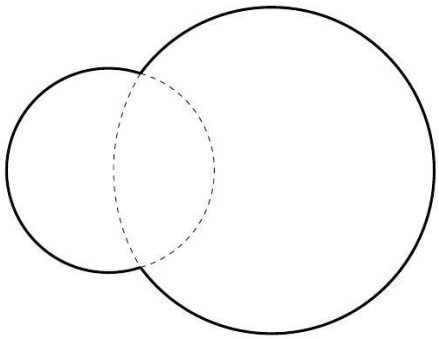

Fig. 22.11 The envelope approximation for bubble collision.

numerically, studying the dynamics of the underlying scalar field and computing the GW production from the time-evolving energy-momentum tensor of the scalar fields. For bubbles evolving in vacuum, it turns out that the numerical results are well reproduced, with an accuracy of about 20%, by the so-called envelope approximation. This is an analytic approximation in which all the energy is assumed to be stored in the bubble walls, assumed to be thin, and, as the two bubbles collide, one uses as a source for GW production the energy-momentum tensor of the uncollided part of the bubble walls, represented by the thick lines in Fig. 22.11, while the complicated overlap region between the colliding bubbles is simply neglected. This approximation can then be used to study the GWs produced by nucleating at random points in space an ensemble of bubbles. The number of bubbles nucleated in a time step δt is drawn from a Poisson distribution whose mean is determined by the bubble nucleation rate $\Gamma(t)$ computed in Section 22.4.3, and the results are then averaged over several realization of the nucleation process. The envelope approximation allows one to compute the cumulative GWs produced by collisions in a system with hundreds of bubbles, which would be unfeasible if one had to evolve numerically the profile of the scalar field of each bubble. With this combination of analytic and numerical techniques, Kamionkowski, Kosowsky and Turner (1994) found that the peak value of $h_0^2\Omega_{\rm gw}$ is well fitted by

$$h_0^2\Omega_{\rm gw}\left(f_{\rm peak}\right) \simeq 1.1\times 10^{-6}\kappa^2\left(\frac{H_*}{\beta}\right)^2\left(\frac{\alpha}{1+\alpha}\right)^2\left(\frac{v_b^3}{0.24+v_b^3}\right)\left(\frac{100}{g_*}\right)^{1/3} \tag{22.142}$$

where α, defined in eq. (22.64), determines the strength of the phase transition, and v_b is the average velocity of the bubble walls at collision. Comparing with eq. (22.141) we see that the crude estimate leading to eq. (22.141) correctly reproduces the dependence on κ and on H_*/β, and even gives the correct order of magnitude of the overall numerical factor, in the limit of strong first-order phase transitions, $\alpha \gg 1$, and relativistic bubble velocities. If α or v_b are small, however, there are further suppression factors. Equation (22.142) has been widely used in the literature. Later, numerical work with increased accuracy [25] has confirmed the basic features of this result and provided a more accurate fitting formula,

$$h_0^2\Omega_{\rm gw}\left(f_{\rm peak}\right) \simeq 1.84\times 10^{-6}\kappa^2\left(\frac{H_*}{\beta}\right)^2\left(\frac{\alpha}{1+\alpha}\right)^2\left(\frac{v_b^3}{0.42+v_b^2}\right)\left(\frac{100}{g_*}\right)^{1/3} \tag{22.143}$$

while the peak frequency is well fitted by

$$f_{\rm peak} \simeq 3.83\times 10^{-6}\ {\rm Hz}\left(\frac{\beta}{H_*}\right)\left(\frac{T}{100{\rm GeV}}\right)\left(\frac{g_*}{106.75}\right)^{1/6} g\left(v_b\right) \tag{22.144}$$

[12525] See Huber and Konstandin (2008a).

where

$$g\left(v_b\right) \simeq \frac{2.7}{1.8 - 0.1 v_b + v_b^2} \tag{22.145}$$

is a function of v_b, which monotonically decreases from $g(0) = 1.5$ to $g(1) = 1$. We see that the approximate estimate (22.135) is consistent with the numerical result (22.144). [26]

For QCD we rather use as a reference value $g_* = 64.75$, which takes into account all degrees of freedom that are relativistic just above the transition (including the strange quark), [27] and setting $T_* = 150\text{MeV}$. Then eq. (22.144) reads

$$f_{\text{peak}} \simeq 5.28 \times 10^{-9}\ \text{Hz} \left(\frac{\beta}{H_*}\right) \left(\frac{T}{150\text{MeV}}\right) \left(\frac{g_*}{64.75}\right)^{1/6} g\left(v_b\right) \tag{22.146}$$

The latter numerical study also allowed determination of the frequency spectrum in the region near the peak. In general, at sufficiently low frequency, such that the corresponding wavelength is well outside the horizon, causality requires that $h_0^2 \Omega_{\text{gw}}(f) \propto f^3$; see eq. (22.3) and the discussion after it. Existing numerical studies of GW production in bubble collisions in the envelope approximation only explore the frequency region not very far from the peak, and do not reach the regime of superhorizon modes. For frequencies lower than the peak, but not yet in the super-horizon regime, the frequency dependence is well fitted by a power $h_0^2 \Omega_{\text{gw}}(f) \propto f^{2.8}$, not far from the f^3 behavior expected for the even lower frequencies corresponding to super-horizon modes. At frequencies higher than the peak, in contrast, the numerical study shows that $h_0^2 \Omega_{\text{gw}}(f)$ decays only as $1/f$. This relatively slow decay can be quite interesting from the observational point of view, since it means that a sizable signal could still be present in the bandwidth of a detectors, such as LISA, even when the peak of the spectrum lies at a lower frequency.

The next step is to compute κ and v_b in terms of the parameters of the phase transition. In the physically relevant case of bubbles evolving in the cosmic fluid this is a complicated problem, and the result depends on the detailed dynamics of the bubbles. In general, there are two possible "combustion" modes in the collision of two bubbles: detonation, which basically takes place when the boundaries propagate faster than the speed of sound, and deflagration, when instead they move slower. Only in the first case can we expect a large production of GWs. In deflagration there will be no large concentration of kinetic energy near the bubble walls, so GW production is suppressed. The bubble velocity has a relatively simple form in the case of Chapman-Jouguet detonation (i.e. when the detonation propagates at a speed such that, in the frame of the shock wave, the fluid velocity is exactly equal to the speed of sound). In this case one can show that v_b is fixed in terms of α by

$$v_b(\alpha) = \frac{\sqrt{1/3} + \sqrt{\alpha^2 + 2\alpha/3}}{1 + \alpha} \tag{22.147}$$

[28] See again Kamionkowski, Kosowsky and Turner (1994)

[29] See Espinosa, Konstandin, No and Servant (2010) for more recent estimates of $\kappa(\alpha)$ in different regimes.

Observe also that, while for bubbles propagating and colliding in vacuum the source of GW production is the energy-momentum tensor of the scalar field, for bubbles propagating in the cosmic fluid by far the dominant contribution is given by the energy-momentum tensor $T_{ij} = (\rho + p) v_i v_j$ of the fluid displaced and stirred by the bubbles. In the envelope approximation one

[25][26] See also Jinno and Takimoto (2017) for related analytic results in the thinwall and envelope approximation.

[27] A listing of the degrees of freedom as a function of mass can be found in Table I of Watanabe and Komatsu (2006). As we saw in eq. (17.99), the contribution of fermions must be multiplied by a factor 7/8.

assumes again that only the fluid at the envelope contributes (an assumption to which we will return later). Assuming Jouguet detonation and the envelope approximation, one can estimate [28] that

$$\kappa(\alpha) = \frac{1}{1+A\alpha}\left(A\alpha + \frac{4}{27}\sqrt{\frac{3\alpha}{2}}\right) \tag{22.148}$$

where $A \simeq 0.715$. Equations (22.147) and (22.148) have been widely used in the literature, because of their relative simplicity. However, to model bubble evolution in a plasma more realistically it is also necessary to include terms representing friction between the bubble walls and the plasma. These have been parametrized phenomenologically by adding to the equation of motion of the scalar field a term proportional to $\eta u^\mu \partial_\mu \phi$, where u^μ is the plasma four-velocity and η a friction coefficient. Then, κ and v_b are also functions of η. In general, only for a limited range of values of the parameters α and η does the solution correspond to detonation, while the most probable outcome is either deflagration or a runaway solution where the walls continuously accelerate. [29]

Finally, the values of α and β should in principle be derived from the fundamental theory under consideration, using the nucleation theory discussed in Section 22.4.3. This has been done for some selected models that could give a first-order phase transition at the electroweak scale, such as non-minimal supersymmetric extensions of the Standard Model; see the Further Reading. It is clear that, in the end, the computation of GW production from bubble collisions suffers from many uncertainties, first of all because at present these extensions of the Standard Model are unavoidably somewhat speculative and, on a more technical side, because of the uncertainties regarding bubble evolution in a realistic thermal environment. In any case, existing predictions at the electroweak scale in general do not exceed $h_0^2\Omega_{\rm gw} \sim 10^{-12}$ at the peak frequency. Figure 22.12 shows the signal obtained for different typical values of the parameters α and β/H_*, comparing the result from the collision of two bubbles (left panel) with the result for the nucleation and collision of an ensemble of bubbles (right panel). The slower decay with frequency in the latter case is due to the cumulative effect from the late nucleation of small bubbles, which is absent in the two-bubble case. Observe that the signal is too small for a space interferometer such as LISA but, thanks to the slow $1/f$ decrease at high frequencies, for some values of the parameters it could be detectable at an advanced space interferometer such as DECIGO or BBO.

It is important to observe that, when the envelope approximation is applied to bubbles evolving in the primordial plasma, rather than in vacuum, we are actually assuming that the main source of GW gener-

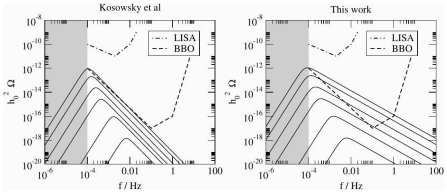

Fig. 22.12 $h_0^2\Omega_{\rm gw}(f)$ for several values of α and β/H_*. Left panel, using the numerical results from the collision of two bubbles studied in Kosowsky, Turner and Watkins (1992a, 1992b). Right panel, using the envelope approximation for an ensemble of bubbles, from the numerical study of Huber and Konstandin (2008b). The curves from top to bottom correspond to values of $(\alpha, \beta/H_*)$ equal to $(0.20, 30), (0.15, 40), (0.10, 60), (0.07, 100), (0.05, 300)$ and $(0.03, 1000)$, respectively. The corresponding transition temperature decreases from 130GeV (top) to 70GeV (bottom). From Huber and Konstandin (2008b). CCSISSA Medialab Srl. Reproduced by permission of IOP Publishing. ation is the energy-momentum tensor of the fluid near the envelope of the colliding bubbles.

This is an assumption that can actually miss a potentially dominant contribution to GW production, as we will discuss later.

GWs from turbulence in the cosmic fluid

Collision of bubbles injects a large amount of energy into the cosmic fluid. At the electroweak epoch this fluid has a very high Reynolds number, of order 10^{13}, and therefore turbulent motion rapidly sets in. Furthermore, even the magnetic Reynolds number is very large, so magnetic fields generated during the phase transition are amplified and full magnetohydrodynamic (MHD) turbulence develops. When the phase transition terminates, so does the energy injection. However, because of the very high Reynolds number, MHD turbulence decays quite slowly, over several Hubble times, and therefore provides a long-lasting source of GWs. The peak frequency $f_{\rm peak}$ turns out to be determined by the size R_* of the bubbles at collisions, $k_{\rm peak} = 2\pi f_{\rm peak} \simeq 1/R_*$; see the discussion in Note 24 on page 676. At low frequencies one has a spectrum $h_0^2\Omega_{\rm gw}(k) \propto k^3$, as required by causality (at least in the limit of superhorizon modes). On the high-frequency side the GW spectrum decays as k^{-n}, but the value of n depends strongly on how turbulence is modeled, in particular on the power spectrum of the turbulent fluid motion and on whether the source is modeled as short-lasting or long-lasting. In the more appropriate case of a long-lasting source analytical estimates suggest $n = 5/3$ if the turbulent fluid motion has a Kolmogorov spectrum,
[30] See Caprini, Durrer and Siemens (2010).

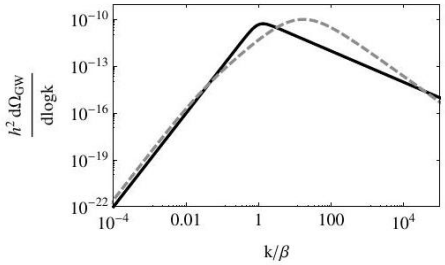

Fig. 22.13 The GW spectra from bubble collisions (solid) and MHD turbulence (dashed) for $v_b = 0.7$, $\kappa\alpha/(1+\alpha) = 0.1, \beta/H_* = 10$ and $T_* = 100$MeV (as appropriate for a phase transition at the QCD scale). From Caprini, Durrer and Siemens (2010).

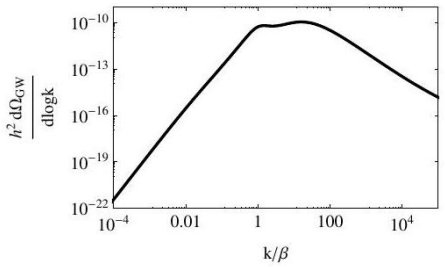

Fig. 22.14 The total GW spectrum resulting from the sum of the two contributions in Fig. 22.13. From Caprini, Durrer and Siemens (2010). and $n = 3/2$ for a Iroshnikov-Kraichnan spectrum. Probably, only full MHD numerical simulations can address the issue precisely. A fit to the numerical results for MHD turbulence is given by [30]

$$h_0^2\Omega_{\rm gw}\left(f_{\rm peak}\right)\big|_{\rm turb} \simeq 3.3\times 10^{-5}\left(\frac{\kappa\alpha}{1+\alpha}\right)^{3/2}\left(\frac{H_*}{\beta}\right)v_b \times \frac{\left(f/f_{\rm peak}\right)^3}{\left(\left[1+\left(f/f_{\rm peak}\right)\right]^{11/3}\left(1+4k_*/H_*\right)\right.} \tag{22.149}$$

where k_* is the physical wavenumber at the time of production, and

$$f_{\rm peak} \simeq 2.7 \times 10^{-5}\ {\rm Hz} \frac{1}{v_b} \left(\frac{\beta}{H_*}\right) \left(\frac{T_*}{100{\rm GeV}}\right) \left(\frac{g_*}{100}\right)^{1/6} \tag{22.150}$$

These formulas include both the contribution to GW production from the turbulent kinetic motion of the fluid, and that due to the magnetic field, which are generated by the turbulent motion itself, and, for simplicity, assumes equipartition, i.e. the same amount of energy density in the turbulent kinetic motion and in magnetic fields.

In general, the GW spectrum produced by turbulence peaks at a higher frequency than that due to bubble collisions, because of the factor $1/v_b$ in eq. (22.150), and the overall amplitude can be somewhat larger. The two contributions are shown separately in Fig. 22.13, and their sum is shown in Fig. 22.14. We see that the lower peak from bubble collisions causes the hump on the left of the true peak of the spectrum, which could be a distinctive feature of this signal.

GWs from sound waves in the cosmic fluid

The picture discussed in the preceding subsections basically assumes that the primordial plasma can be described as an incompressible and turbulent fluid. Recently, it has become possible to test this assumption using fully three-dimensional simulations of bubble nucleation in the coupled system of the scalar field and the fluid, and to compute the resulting GW production. The numerical simulations indicate that sound waves in the fluid, created by the bubble collisions, are important. These are completely missed in the envelope approximation, where the fluid on the colliding part of the bubble walls (the dashed lines in Fig. 22.11) is simply neglected. These sound waves, which describe coherent motions of the fluid, are, however, a potentially important source of GWs. Furthermore, they last for a long time after the phase transition has been completed. This boosts their GW signal by the ratio of their lifetime, which can be of the order of the Hubble time, to the duration of the transition, i.e. by a factor H_*^{-1}/β^{-1}. For a typical value $\beta/H_* \sim 10^2$, the resulting GW signal can then be two orders of magnitudes larger than that due to bubble collisions.

To describe the coupled field-fluid system one starts from the energy-momentum tensor of the total system,

$$T^{\mu\nu}_{\rm tot} = T^{\mu\nu}_{\rm field} + T^{\mu\nu}_{\rm fluid} \tag{22.151}$$

where

$$T^{\mu\nu}_{\rm field} = \partial^\mu\phi\partial^\nu\phi - \frac{1}{2}\eta^{\mu\nu}(\partial\phi)^2 \tag{22.152}$$

and

$$T^{\mu\nu}_{\rm fluid} = (\rho + p)u^\mu u^\nu + \eta^{\mu\nu}p \tag{22.153}$$

where p is the pressure in the rest frame, ρ is the energy density, and u^μ the four-velocity of the fluid; compare with eq. (10.30). Over the relatively short time-scale of the phase transition one can in a first approximation neglect the expansion of the Universe and use the flat-space metric. The fundamental interaction between the field ϕ responsible for the bubble profile and the matter fields composing the primordial plasma results in an effective friction on the bubble. To describe this fieldfluid interaction phenomenologically it is common to split the energymomentum conservation equation $\partial_\mu T^{\mu\nu}_{\rm tot} = 0$ as

$$\partial_\mu T^{\mu\nu}_{\rm field} = \delta^\nu \tag{22.154}$$

$$\partial_\mu T^{\mu\nu}_{\rm fluid} = -\delta^\nu \tag{22.155}$$

where

$$\delta^\nu = \eta u^\mu \partial_\mu \phi \partial^\nu \phi \tag{22.156}$$

and η is an adjustable friction parameter. Of course this splitting, and the precise choice of δ^ν, are somewhat arbitrary, but this latter term, proportional to the fluid four-velocity, is believed to give a good phenomenological description of the friction-induced interaction between the field and the fluid. Starting from a system in the symmetric phase, one models as usual bubble nucleation with the rate given in eq. (22.65), and from this one generates a set of nucleation times and locations, at each of which one inserts a static bubble with a Gaussian profile for the scalar field. One can then evolve the system numerically on a lattice, and compute the time evolution of the energy-momentum tensor, as well as the resulting GW production. In this way one finds [31] that the GW energy $\Omega_{\rm GW}$ from acoustic waves is related to the value $\Omega_{\rm GW}^{\rm ea}$ obtained in the envelope approximation by

$$\frac{\Omega_{\rm GW}}{\Omega_{\rm GW}^{\rm ea}} \gtrsim 60 C_{\rm GW} \left(\frac{\beta}{H_*}\right) \tag{22.157}$$

where $C_{\rm GW}$ is a dimensionless parameter. The numerical simulation gives $C_{\rm GW} \sim 0.04$. Since β/H_* can easily be of order 10^2, this "acoustic" production mechanism can give a signal orders of magnitude larger than the standard estimates based on the envelope approximation. The peak frequency is estimated to be comparable to the value (22.150) obtained from turbulence. One should keep in mind, however, that these results were obtained in simulations with values of $\alpha \lesssim 0.1$ and small fluid velocities. The extrapolation to higher values of α might be nontrivial, with the possible conversion of part of this acoustic signal into the turbulent one discussed earlier. [32] [31] See Hindmarsh, Huber, Rummukainen and Weir (2014, 2015).

[32] See Section 2.1.2 of Caprini et al (2016).

[33] More formally, the existence of this topologically non-trivial configuration is due to the fact that the first homotopy group of the vacuum manifold, $\pi_1(\mathcal{M})$, is non-trivial. The first homotopy group classifies the mappings $S^1 \to \mathcal{M}$ from a circle to the vacuum manifold $\mathcal{M}$, which for a $U(1)$ group is itself a circle S^1.

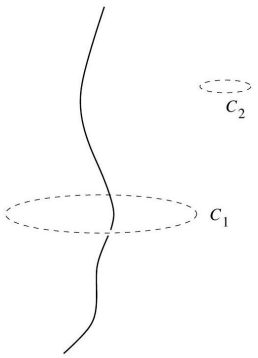

Fig. 22.15 A infinite string caught inside the circle $\mathcal{C}_1$.

16.3 22.5 Cosmic strings

16.3.1 22.5.1 Global and local strings

Cosmic strings are configurations of scalar and/or gauge fields whose energy density is concentrated along a one-dimensional line, either an infinite line or a closed loop. Such objects might have formed in the early Universe during a symmetry-breaking phase transitions (independently of the order of the phase transition) in extensions of the Standard Model. The

prototype example is given by the breaking of a $U(1)$ symmetry, due to a complex scalar field Φ whose potential, in the broken phase, has the standard Mexican hat potential,

$$V(\Phi) = \frac{1}{4}\lambda\left(|\Phi|^2 - \eta^2\right)^2 \tag{22.158}$$

If we write $\Phi = |\Phi|e^{i\psi}$, then at the minimum of the potential we have $|\Phi| = \eta$, but the phase ψ is undefined. Therefore there is not just a single vacuum state, but a whole manifold $\mathcal{M}$ of vacua, which in this case is just a circle, parametrized by an angle ψ, with $0 \leqslant \psi \leqslant 2\pi$. Since Φ is single-valued, as we go around a closed path in physical space, the phase ψ must change by $\Delta\psi = 2\pi n$, where $n = 0, \pm 1, \pm 2, \ldots$ If $n \neq 0$, as we go around the circle in physical space, the phase ψ wraps one or more times around this circle in the field space. We then have a configuration that is topologically non-trivial, and cannot be deformed continuously into the topologically trivial configuration $\psi = 0$.[33] Consider now a circle $\mathcal{C}_1$ in physical space, such that along it $\Delta\psi = 2\pi$, and study what happens if we shrink it to a point or, more precisely, to an infinitesimally small circle $\mathcal{C}_2$ with $\Delta\psi = 0$. In order for n to change discontinuously from $n = 1$ to $n = 0$ it is necessary that, in the process, a singularity be encountered, i.e. we must encounter at least a point where the phase ψ is undefined, which happens when the modulus $|\Phi| = 0$. This means that at least one string of false vacuum must be caught inside a loop with $\Delta\psi = 2\pi$; see Fig. 22.15. Furthermore, the string must either be infinitely long or be a loop that winds around the circle $\mathcal{C}_1$, otherwise we would be able to unwind the circle $\mathcal{C}_1$ from this line of singularities. Of course, in a cosmological setting, an infinite loop should rather be seen as an idealization of a closed loop with size much larger than the horizon. At the string location we have $\Phi = 0$, so we are in the false vacuum, and there is an associated energy density. Thus, we have a concentration of energy density along a string.

To be more quantitative, we have to specify the Lagrangian, and in particular we will see that crucial differences emerge depending on whether the $U(1)$ symmetry that is broken is a global or a local symmetry. The corresponding strings are called global or local strings, respectively. Consider first a theory with a global $U(1)$ symmetry, with just a complex scalar field Φ and Lagrangian density

$$\mathcal{L} = -\partial_\mu\Phi\partial^\mu\Phi^* - V(\Phi) \tag{22.159}$$

with $V(\Phi)$ given by eq. (22.158) (we limit ourselves for the moment to flat space). For $\eta \neq 0$ we can write

$$\Phi(x) = \left(\eta + \frac{\varphi(x)}{\sqrt{2}}\right)e^{i\psi(x)} \tag{22.160}$$

and we get

$$\begin{aligned}\mathcal{L} &= -\frac{1}{2}\partial_\mu\varphi\partial^\mu\varphi - \frac{\lambda}{4}\left(\sqrt{2}\eta\varphi + \frac{1}{2}\varphi^2\right)^2 - \left(\eta + \frac{\varphi}{\sqrt{2}}\right)^2\partial_\mu\psi\partial^\mu\psi \\ &= \mathcal{L}_2 + \mathcal{L}_{\rm int}\end{aligned} \tag{22.161}$$

where the quadratic term is

$$\mathcal{L}_2 = -\frac{1}{2}\partial_\mu\varphi\partial^\mu\varphi - \frac{1}{2}m_s^2\varphi^2 - \eta^2\partial_\mu\psi\partial^\mu\psi \tag{22.162}$$

with $m_s^2 = \lambda\eta^2$, and $\mathcal{L}_{\rm int}$ contains the interaction terms. We therefore have a massless scalar field ψ, which is the Goldstone boson associated with the breaking of the global $U(1)$ symmetry, and a massive scalar field φ with mass m_s.

The equation of motion derived from the Lagangian (22.159) is

$$\Box\Phi = \frac{\lambda}{2}\left(|\Phi|^2 - \eta^2\right)\Phi \tag{22.163}$$

We can look for a static solution representing a string along the z axis, of the form

$$\Phi(\rho,\theta) = \eta f\left(m_s\rho\right)e^{in\theta} \tag{22.164}$$

where (ρ,θ) are polar coordinates in the (x,y) plane, and the integer n is the winding number of the string. Observe that, in terms of the phase ψ of the field Φ, this ansatz means $\psi(\rho,\theta) = n\theta$. Substituting into the equations of motion, one finds that near the origin $f\left(m_s\rho\right) \propto \rho^{|n|}$ while, for $m_s\rho \gg 1$,

$$f\left(m_s\rho\right) \simeq 1 - O\left(\frac{1}{m_s^2\rho^2}\right) \tag{22.165}$$

The energy density of this configuration is

$$\begin{aligned}\mathcal{E} &= \partial_i\Phi\partial_i\Phi^* + V(\Phi)\\ &= \left|\partial_\rho\Phi\right|^2 + \frac{1}{\rho^2}\left|\partial_\theta\Phi\right|^2 + V(\Phi)\end{aligned} \tag{22.166}$$

Using the asymptotic form of $f\left(m_s\rho\right)$ we see that the energy density is peaked around $\rho \sim m_s^{-1}$, and vanishes at large distances as $1/\rho^2$. The $1/\rho^2$ behavior at infinity is due to the $\partial_\theta\Phi$ term in eq. (22.166). Indeed, $\partial_\theta\Phi = in\eta f\left(m_s\rho\right)e^{in\theta}$, so at large distances $|\partial_\theta\Phi| \to n\eta$. Then, as $\rho\to\infty$

$$\mathcal{E}(\rho,\theta) \to \frac{n^2\eta^2}{\rho^2} \tag{22.167}$$

Since the energy density is localized in a region of width $\sim m_s^{-1}$ (which is the Compton wavelength of the massive state described by φ) and
goes to zero as $1/\rho^2$ at infinity, this configuration describes a localized string. However, when we integrate $\mathcal{E}$ over $dxdy = \rho d\rho d\theta$ to get the energy of the configuration per unit length, the $1/\rho^2$ behavior is not integrable, and the energy per unit length diverges logarithmically. The string tension μ, i.e. the energy per unit length, is given by

$$\mu \simeq 2\pi n^2\eta^2\log\left(m_sR\right) \tag{22.168}$$

where R is the infrared cutoff, and we have taken m_s^{-1} as the order of magnitude of the distance where the asymptotic behavior is no longer valid and the behavior $f\left(m_s\rho\right) \propto \rho^{|n|}$ sets in. This infrared divergence is a reflection of the existence in the spectrum of the Goldstone boson θ, which, being massless, induces long-range interactions between different parts of the string. In a condensed matter system the infrared divergence is cut off by the finite volume of the system. Indeed, global strings of this type are observed in condensed matter, in particular as quantized vortex lines in liquid helium. More generally, in a system with several global strings the cutoff will be provided by the average distance between strings, and for a string forming a loop this will the loop size itself.

Consider now a model with spontaneous breaking of a local $U(1)$ symmetry. The prototype example is the Abelian Higgs model, with Lagrangian density

$$\mathcal{L} = -\left|D_\mu\Phi\right|^2 - V(\Phi) - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} \tag{22.169}$$

where again $V(\Phi)$ is given by eq. (22.158) and the covariant derivative is given by $D_\mu\Phi = (\partial_\mu - igA_\mu)\,\Phi$. The particle spectrum now consists of a massive Higgs field with mass $m_s = \lambda^{1/2}\eta$, as before, plus a massive gauge boson with mass $m_v = g\eta$. As usual in the Higgs mechanism, the Goldstone boson ψ that appears in the model with global symmetry breaking has been turned into the longitudinal component of the massive gauge field.

This system again has static string-like solutions, which have the form

$$\Phi(\rho,\theta) = \eta f(\rho) e^{in\theta} \tag{22.170}$$

$$A_A = -\epsilon_{AB} x_B \frac{n}{g\rho^2}\alpha(\rho) \tag{22.171}$$

where $A, B = 1, 2$ correspond to the x and y directions, (ρ, θ) are again the polar coordinates in the (x, y) plane and $f(\rho)$ and $\alpha(\rho)$ are two functions. Now there are two mass scales in the problem, m_s and m_v, so $f(\rho)$ no longer depends on the single combination $m_s\rho$, as in the global case. Inserting this ansatz into the equations of motion one finds that at large distances the field Φ tends asymptotically to the value

$$\Phi \to \eta e^{in\theta} \tag{22.172}$$

as in the global case, while, at the same time,

$$A_\mu \to \frac{n}{g}\partial_\mu\theta \tag{22.173}$$

Observe that this configuration carries a quantized magnetic flux,

$$\int_S d\mathbf{S}\cdot\mathbf{B} = \int_C d\mathbf{l}\cdot\mathbf{A} = \frac{2\pi n}{g} \tag{22.174}$$

where C is a closed curve bounding the surface S. This configuration is called the Nielsen-Olesen vortex and is the prototype example of a local string, i.e. a string-like solution in a theory with a spontaneously broken local symmetry. As $\rho \to \infty$ we have $D_\mu\Phi \to 0$, since the gauge field contribution cancels the scalar field contribution. Thus, the term $\partial_\theta\Phi$, which in the global case goes to a constant, leading to a $1/\rho^2$ behavior in the energy density and to a logarithmic divergence in the string tension, is now replaced by $D_\theta\Phi$, which goes to zero as $\rho \to \infty$. Furthermore, also $F_{\mu\nu} \to 0$ as $\rho \to \infty$. Thus, the energy per unit length of a local string is finite and, on setting $n = 1$, is given by

$$\mu = 2\pi\eta^2 g(\beta) \tag{22.175}$$

where $\beta = (m_s/m_v)^2 = \lambda/g^2$ and $g(\beta)$ is a slowly varying function such that $g(1) = 1$.

Beside the fact that local strings have a finite string tension, while a single straight global string has a logarithmically divergent string tension, the other crucial difference between global and local strings is in the mechanisms by which they can radiate away energy. Both global and local strings can in principle emit gravitational waves. We will discuss in section 22.5.4 the GW emission by loops of cosmic strings, and we will see that the power radiated in GWs is $P_{\rm GW} = \Gamma G\mu^2$, where Γ is a numerical coefficient that depends on the loop shape, with typically $\Gamma \sim 50 - 100$. For a global string there is, however, another channel of massless particles available, i.e. it can emit the Goldstone particles associated with the broken global symmetry. In this case a computation similar to the one that we will discuss for the GW emission gives a power emitted in scalar radiation $P_S = \Gamma_S\eta^2$, where again $\Gamma_S = O(100)$. Apart from the logarithmic enhancement in eq. (22.168), which, as we have discussed, for a loop is actually cut off by the loop size, even for a global string we have $\mu \sim \eta^2$, so $G\mu^2 \sim (\eta/M_{\rm Pl})^2\,\eta^2$, and the

radiation in GWs is suppressed, compared with the radiation in Goldstone bosons, by a factor $(\eta/M_{\rm Pl})^2$, which even for a GUT theory is at least of order 10^{-8}. Thus, a global string loop mainly decays by emission of Goldstone bosons. This channel does not exist for local strings, which rather radiate GWs. In the following, we will therefore restrict ourselves to the study of local strings.

Finally, we observe that for quite some time cosmic strings have been considered as an alternative to inflation as a mechanism for producing the initial density perturbations from which cosmological structure formation evolved. However, as discussed in Section 19.2.1, they would seed isocurvature perturbations and, as the main mechanism for structure formation, they have been ruled out by cosmological observations, in particular those of the CMB. The spectrum of the C_l predicted by cosmic strings has only a single broad peak, covering values of l in the range

[34] See [Planck Collaboration], Ade et al. (2016a), "Planck 2015 results. XIII. Cosmological parameters".

$\sim 150 - 400$, rather than the set of much sharper acoustic peaks beautifully observed by CMB experiments. As we have already mentioned in Section 19.2.1, the present cosmological data are entirely consistent with adiabatic perturbations, and any admixture of CDM isocurvature perturbations in the initial conditions, if present at all, is below a few percent. As we will discuss later, the abundance of strings is fixed by their string tension. Writing

$$G\mu = A \times 10^{-7} \tag{22.176}$$

and requiring that cosmic strings do not spoil the agreement with CMB data, gives a bound on the string tension. The most recent analysis [34] gives (at 95% c.l.) $A < 2.4$ for strings described by the Abelian Higgs model, and $A < 1.3$ for strings modeled with the Nambu-Goto action, which we will describe in the next subsection.

16.3.2 22.5.2 Effective description and Nambu-Goto action

At a fundamental level the dynamics of Nielsen-Olesen vortices, i.e. their motion in flat or curved space as well as their interaction with other vortices, is determined by the dynamics of the underlying scalar and gauge fields. However, if we are only interested in the dynamics on scales much larger than the characteristic thickness of the vortex (which is determined by whichever is the largest between the Compton wavelength of the scalar, m_s^{-1}, and that of the massive vector field, m_v^{-1}), we can use an effective description in which we neglect the internal structure and regard the string as a one-dimensional object in space (defined by the line of zeros of the Higgs field), which spans a twodimensional surface in space-time.

The dynamics of such a string is a generalization of the dynamics of a relativistic point particle, which may be useful to recall here (see also the discussion in Section 20.2). In Newtonian mechanics a point particle moving in three-dimensional space is described by three functions $X^i(t)$ with $i = 1, 2, 3$. This description is not convenient in the relativistic case, since it breaks Lorentz invariance. Rather, it is convenient to introduce a variable τ that parametrizes the world-line swept by the particle, and describe the particle using four functions $X^\mu(\tau)$, with $\mu = 0, \ldots, 3$. Apparently, we have introduced one extra degree of freedom, $X^0(\tau)$. However, the way we decide to parametrize the world-line is arbitrary, so we also impose invariance under reparametrizations: if we transform $\tau \to \tilde{\tau}(\tau)$, the four functions $X^\mu(\tau)$ transform into four new functions $\tilde{X}^\mu(\tilde{\tau})$, such that $\tilde{X}^\mu(\tilde{\tau}) = X^\mu(\tau)$, and we require that the action governing $X^\mu(\tau)$ be invariant under such a transformation. In field-theoretical language, we can view the four functions $X^\mu(\tau)$ as four fields living in a $(0+1)$-dimensional space-time, scalar under reparametrizations of the world-line, i.e. under one-dimensional diffeomorphisms. With respect to the description in terms of $X^i(t)$ we have therefore added one more field, X^0, but we also

have one "gauge" symmetry, so the number of
degrees of freedom is the same. We could for instance chose the gauge $X^0(\tau) = \tau$, and we would be back to the description in terms of $X^i(t)$, with $t \equiv X^0(\tau) = \tau$. However, it is in general more useful to keep the redundant description in terms of $X^\mu(\tau)$, which explicitly preserves Lorentz invariance. The action of a point-like massive particle in a curved space with metric $g_{\mu\nu}$ is given by

$$S_{\rm pp} = -m \int ds \tag{22.177}$$

where $ds^2 = -g_{\mu\nu}(X) dX^\mu(\tau) dX^\nu(\tau)$. This action is explicitly invariant under reparametrizations, since ds is the invariant length. Observe that, for a time-like path, $ds^2 > 0$. Using $dX^\mu(\tau) = \dot{X}^\mu d\tau$, where the dot denotes the derivative with respect to τ, we can rewrite eq. (22.177) as

$$S_{\rm pp} = -m \int d\tau \left(-g_{\mu\nu} \dot{X}^\mu \dot{X}^\nu \right)^{1/2} \tag{22.178}$$

see also eq. (20.18). As we have already discussed [see eqs. (20.21)(20.23)], we can get rid of the square root by introducing an auxiliary field $e(\tau)$ and writing

$$S_{\rm pp} = \frac{1}{2} \int d\tau \left(e^{-1} g_{\mu\nu} \dot{X}^\mu \dot{X}^\nu - e m^2 \right) \tag{22.179}$$

Indeed, the variation with respect to $e(\tau)$ gives

$$e(\tau) = \frac{1}{m} \left(-g_{\mu\nu} \dot{X}^\mu \dot{X}^\nu \right)^{1/2} \tag{22.180}$$

which, inserted into eq. (22.179), gives back eq. (22.178). The action (22.179) is invariant under the reparametrization $\tau \to \tilde{\tau}(\tau)$, with $X^\mu(\tau) \to \tilde{X}^\mu(\tilde{\tau})$ and $e(\tau) \to \tilde{e}(\tilde{\tau})$ such that

$$\begin{aligned} \tilde{X}^\mu(\tilde{\tau}) &= X^\mu(\tau) \\ \tilde{e}(\tilde{\tau}) d\tilde{\tau} &= e(\tau) d\tau \end{aligned} \tag{22.181}$$

Observe also that eq. (22.179) has a well-defined massless limit, which is not the case for the action (22.177).

The generalization to the string dynamics is obtained by parametrizing the world-sheet of the string by a time-like parameter τ (analogous to the parameter τ for the world-line of a point-like particle) and a spacelike parameter σ. The position of the string in space-time (whose coordinates we denote by x^μ) is then described by the four functions $X^\mu(\tau, \sigma)$, so that the position in space-time of the point of the world-sheet labeled by (τ, σ) is given by $x^\mu = X^\mu(\tau, \sigma)$. For cosmic strings we will consider a four-dimensional space-time, while the theory of a fundamental bosonic string requires for consistency $D = 26$ space-time dimensions and superstrings live in 10 dimensions (or, non-perturbatively, in 11 dimensions). The generalization of the point-particle action (22.178) is given by the Nambu - Goto action

$$S_{\rm NG} = -\mu \int d^2\zeta \sqrt{-h} \tag{22.182}$$

[35] See Section 1.2 of Polchinski (1998), which we are following here. where $\zeta^a = (\tau, \sigma)$, the indices a, b take the values 1 and 2 corresponding to τ and σ, and μ is the string tension. We have also introduced $h = \det h_{ab}$, where

$$h_{ab} = g_{\mu\nu}(X) \partial_a X^\mu \partial_b X^\nu \tag{22.183}$$

is the induced metric, i.e. the metric induced on the world-sheet by its embedding into a space-time with metric $g_{\mu\nu}$, through the functions $X^\mu(\tau,\sigma)$. Under diffeomorphisms of the world-sheet, $\zeta \to \tilde{\zeta}(\zeta)$, the four fields X^μ transform as scalars,

$$X^\mu(\zeta) \to \tilde{X}^\mu(\tilde{\zeta}) = X^\mu(\zeta) \tag{22.184}$$

Then h_{ab} transforms as a metric tensor on the world-sheet, and the Nambu-Goto action is invariant. Just as in the point-particle case, we can get rid of the square root by introducing an auxiliary field, which in this case is a tensor γ_{ab}, with Lorentzian signature $(-,+)$. The action (22.182) is in fact equivalent to the Polyakov action

$$S_P = -\frac{\mu}{2}\int d^2\zeta\sqrt{-\gamma}\gamma^{ab}g_{\mu\nu}(X)\partial_a X^\mu \partial_b X^\nu \tag{22.185}$$

where $\gamma = \det\gamma_{ab}$. This can be shown by taking the variation with respect to γ_{ab}, which gives [35] $\gamma_{ab} = \kappa h_{ab}$, where κ is an arbitrary constant. Inserting this back into eq. (22.185), κ cancels between $\sqrt{-\gamma}$ and γ^{ab}, while $h^{ab}g_{\mu\nu}\partial_a X^\mu \partial_b X^\nu = h^{ab}h_{ab} = 2$, and we get back eq. (22.182). In this formulation, the theory is invariant under two-dimensional diffeomorphisms, under which $X^\mu(\zeta)$ transforms as in eq. (22.184), while γ_{ab} transforms as a metric,

$$\gamma_{ab}(\zeta) \to \tilde{\gamma}_{ab}(\tilde{\zeta}) = \gamma_{cd}(\zeta)\frac{\partial\zeta^c}{\partial\tilde{\zeta}^a}\frac{\partial\zeta^d}{\partial\tilde{\zeta}^b} \tag{22.186}$$

In the Polyakov formulation we further have an invariance under Weyl transformation, in which the world-sheet coordinates ζ^a, as well as the fields X^μ, are not changed, while

$$\gamma_{ab} \to e^{2\omega(\zeta)}\gamma_{ab} \tag{22.187}$$

The Nambu-Goto action can indeed be obtained from the NielsenOlesen vortex solution, as follows. The solution (22.170), (22.171) was obtained considering a static string along the z axis. Consider now a more general string solution, in general neither static nor a straight line. The location of the string, identified by the line of points where the Higgs field vanishes, defines a world-sheet in space-time $X^\mu(\zeta)$, so that a point labeled by ζ^a on the world-sheet has space-time coordinates $x^\mu = X^\mu(\zeta)$. At each point on the world-sheet we can define two space-like vectors $n^\mu_A(\zeta), A = 1,2$, which are orthogonal to the world-sheet, i.e.

$$g_{\mu\nu}n^\mu_A(\zeta)\partial_a X^\nu(\zeta) = 0 \tag{22.188}$$

for $a = 1,2$. We also normalize them so that

$$g_{\mu\nu}n^\mu_A n^\nu_B = \delta_{AB} \tag{22.189}$$

Then, at least infinitesimally close to the world-sheet, a generic spacetime point x^μ can be written as

$$x^\mu(\xi) \equiv x^\mu\left(\zeta^a,\rho^A\right) = X^\mu(\zeta) + \rho^A n^\mu_A(\zeta) \tag{22.190}$$

and we can therefore trade the four coordinates x^μ for the four coordinates $\xi \equiv \left(\zeta^a,\rho^A\right)$.[36]

Sufficiently close to the world-sheet (i.e. at spatial distances much smaller than its typical radius of curvature) we can still approximate the solution as a straight line in space, so the Nielsen-Olesen vortex solution at the space-time point $x^\mu(\xi)$ is still given by eqs. (22.170) and (22.171), in which now the transverse plane is the one spanned by the (n^μ_1, n^μ_2) vectors, and the role of the (x,y) coordinates is taken by (ρ_1,ρ_2). Thus, sufficiently close to the world-sheet, Φ is still given by (22.170), where now (ρ,θ) are the polar coordinates corresponding to the Cartesian coordinates (ρ_1,ρ_2), i.e.

$$\Phi[x(\xi)] = \eta f(\rho) e^{in\theta} \tag{22.191}$$

while the gauge field can be written as

$$A^\mu[x(\xi)] = -n^\mu_A(\zeta)\epsilon_{AB}\rho_B \frac{n}{g\rho^2}\alpha(\rho) \tag{22.192}$$

We can now reduce the action of the Abelian Higgs model,

$$S = -\int d^4x\sqrt{-g}\left[|D_\mu\Phi|^2 + V(\Phi) + \frac{1}{4}F_{\mu\nu}F^{\mu\nu}\right] \tag{22.193}$$

to an effective action for the variables $X^\mu(\zeta)$, observing that

$$d^4x\sqrt{-g} = d^4\xi\sqrt{-M} \tag{22.194}$$

where $d^4\xi = d^2\zeta d^2\rho$ and $M = \det M_{\alpha\beta}$, with

$$M_{\alpha\beta} = g_{\mu\nu}\frac{\partial x^\mu}{\partial\xi^\alpha}\frac{\partial x^\nu}{\partial\xi^\beta} \tag{22.195}$$

and α runs over the four values $a = 1, 2$ and $A = 1, 2$. Sufficiently close to the string world-sheet we can use eq. (22.190). Then, for the matrix elements where $\alpha = a$ and $\beta = b$ we get

$$\begin{aligned} M_{ab} &\simeq g_{\mu\nu}\left(\partial_a X^\mu + \rho^A\partial_a n^\mu_A\right)\left(\partial_b X^\nu + \rho^B\partial_b n^\nu_B\right) \\ &= h_{ab} + O(\rho/R) \end{aligned} \tag{22.196}$$

where R is the typical radius of curvature of the string. Similarly,

$$M_{AB} \simeq g_{\mu\nu}n^\mu_A n^\nu_B = \delta_{AB} \tag{22.197}$$

$$M_{Aa} \simeq g_{\mu\nu}n^\mu_A\left(\partial_a X^\nu + \rho^A\partial_a n^\nu_A\right) = O(\rho/R) \tag{22.198}$$

where we have used eqs. (22.188) and (22.189). Therefore, to lowest order in ρ/R, $\det M_{\alpha\beta} \simeq \det h_{ab}$, and the action (22.193) becomes

$$S \simeq -\int d^2\zeta\sqrt{-h}\int d^2\rho\left[|D_\mu\Phi|^2 + V(\Phi) + \frac{1}{4}F_{\mu\nu}F^{\mu\nu}\right](\zeta,\rho) \tag{22.199}$$

[12536] Actually, in a curved space-time with metric $g_{\mu\nu}$, to make the construction generally covariant we must pass to a system of Riemann normal coordinates, as discussed in Section 1.3.2 of Vol. 1, based on the geodesics leaving from the point $X^\mu(\zeta)$ with a given tangent vector n^μ. However, in a sufficiently small region close to the worldsheet, the geodesics in the direction n^μ_A parametrized by a proper-time parameter ρ_A becomes the same as the straight line $\rho^A n^\mu_A$. Furthermore, in the cosmological context in which we are eventually interested, the metric $g_{\mu\nu}$ only changes on a cosmological scale, while the string thickness is a microscopic quantity.

[125]

[37] Observe that the derivation that we have given does not go through for global strings, as signaled by the fact that their energy per unit length diverges. The reason is that in this case the theory also has a Goldstone particle, which, being massless, cannot be integrated out, but must be kept in the low-energy effective theory. The corresponding effective string action in this case is the Kalb-Ramond action, which besides the Nambu-Goto term also involves an antisymmetric tensor field, whose dual is related to the Goldstone boson; see Section 4.4.2 of Vilenkin and Shellard (2000).

The expression in square brackets is evaluated over the fields (22.191) and (22.192). On this static configuration, this expression coincides with the component $-T^0_0$ of the energy-momentum tensor derived from the Lagrangian (22.169), and its integral over $d^2\rho$ is therefore the energy per unit length of the string, i.e. the string tension μ. We have therefore recovered the Nambu-Goto action (22.182). Keeping also higher-order terms in ρ/R gives a further contribution, which depends for instance on the extrinsic curvatures $K^A_{ab} = -g_{\mu\nu}\partial_a n^\mu_A \partial_b X^\nu$ associated with the directions n^μ_A. These terms, in the language of effective actions, are higher-derivative operators, and are suppressed at scales $r \ll R$ with respect to the Nambu-Goto term. Their presence, however, is a signal of the fact that the string description is here only an effective one. A fundamental (bosonic) string, or the bosonic sector of superstring theory, taken as a fundamental theory, has only the Nambu-Goto term. [37]

16.3.3 22.5.3 String dynamics. Cusps and kinks

The use of the Nambu-Goto action allows us to study the dynamics of a local string much more easily, compared with what could be done by studying the dynamics of the vortex solution directly in the Abelian Higgs model. Furthermore, this effective action approach makes it clear that the dynamics on scales much larger than the thickness of the string is independent of the details of the underlying fundamental theory. We consider for simplicity the motion of strings in flat space-time, $g_{\mu\nu} = \eta_{\mu\nu}$, and we use the Polyakov action (22.185). As we have already mentioned, the variation with respect to γ_{ab} gives $\gamma_{ab} = \kappa h_{ab}$, where κ is an arbitrary constant, and h_{ab} is defined in eq. (22.183). Using the Weyl symmetry (22.187) we can always set $\kappa = 1$. Setting $\gamma_{ab} = h_{ab}$, the equation of motion derived by performing the variation of the action (22.185) with respect to X^μ is

$$\partial_a \left(\sqrt{-h} h^{ab} \partial_b X^\mu \right) = 0 \tag{22.200}$$

This is the same as $\Box X^\mu = 0$, where $\Box = (-h)^{-1/2}\partial_a \left(\sqrt{-h}h^{ab}\partial_b\right)$ is the two-dimensional d'Alembertian operator with respect to the metric h^{ab}, and acting on fields, such as X^μ, that are scalars under diffeomorphisms of the world-sheet. Of course, one obtains the same equation of motion by directly taking the variation with respect to X^μ of the Nambu-Goto action (22.182), using $\delta h = h h^{ab}\delta h_{ab}$.

In general, eq. (22.200) has a highly non-linear dependence on X^μ, since h_{ab} is itself a functional of X^μ given by eq. (22.183). However, we can now make use of the two-dimensional diffeomorphism invariance to fix the gauge to simplify this equation. The two-dimensional diffeomorphisms allow us to fix two conditions. It is convenient to require

$$h_{01} = 0 \tag{22.201}$$

and

$$h_{00} + h_{11} = 0 \tag{22.202}$$

so that h_{ab} can be written in the form

$$h_{ab} = e^\phi \eta_{ab} \tag{22.203}$$

i.e. the world-sheet metric becomes conformally flat. [38] This gauge is therefore called the conformal gauge. The advantage of this gauge choice is that $-h = e^{2\phi}$ while $h^{ab} = e^{-\phi}\eta^{ab}$, so in the combination $\sqrt{-h}h^{ab}$ that appears in eq. (22.200) the conformal factor cancels, and we are left with a simple linear equation

$$\left(-\partial_\tau^2 + \partial_\sigma^2\right) X^\mu = 0 \tag{22.204}$$

which is just the Klein-Gordon wave equation in two-dimensional flat space. Furthermore, using eq. (22.183) with $g_{\mu\nu} = \eta_{\mu\nu}$, the gauge conditions (22.201) and (22.202) give, respectively,

$$\eta_{\mu\nu}\partial_\sigma X^\mu \partial_\tau X^\nu = 0 \tag{22.205}$$

$$\eta_{\mu\nu}\left(\partial_\sigma X^\mu \partial_\sigma X^\nu + \partial_\tau X^\mu \partial_\tau X^\nu\right) = 0 \tag{22.206}$$

These two equations do not involve second derivative with respect to τ, and are therefore constraints on the initial values of $\partial_\tau X^\mu$ and $\partial_\sigma X^\mu$, which are preserved by the time evolution.

The dynamics of the string can be further simplified as follows. [39] The conditions (22.201) and (22.202) do not remove the gauge freedom completely. Indeed, consider a diffeomorphism $\zeta^a \to \tilde{\zeta}^a(\zeta)$, i.e. $\tau \to \tilde{\tau}(\tau,\sigma)$ and $\sigma \to \tilde{\sigma}(\tau,\sigma)$. The metric h_{ab} transforms in the same way as γ_{ab} in eq. (22.186). Using eqs. (22.201) and (22.202) and requiring that $\hat{h}_{01} = 0$ gives

$$\partial_\tau\tilde{\tau}\partial_\sigma\tilde{\tau} = \partial_\tau\tilde{\sigma}\partial_\sigma\tilde{\sigma} \tag{22.207}$$

while requiring $\tilde{h}_{00} + \tilde{h}_{11} = 0$ gives

$$\left(\partial_\tau\tilde{\tau}\right)^2 + \left(\partial_\sigma\tilde{\tau}\right)^2 = \left(\partial_\tau\tilde{\sigma}\right)^2 + \left(\partial_\sigma\tilde{\sigma}\right)^2 \tag{22.208}$$

We see by inspection that a solution of eqs. (22.207) and (22.208) is obtained using functions $\tilde{\sigma}(\tau,\sigma)$ and $\tilde{\tau}(\tau,\sigma)$ that satisfy the two conditions

$$\partial_\tau\tilde{\sigma} = \partial_\sigma\tilde{\tau} \tag{22.209}$$

$$\partial_\sigma\tilde{\sigma} = \partial_\tau\tilde{\tau} \tag{22.210}$$

Applying ∂_σ to the first equation, and using the second one, we also get

$$\left(-\partial_\tau^2 + \partial_\sigma^2\right)\tilde{\tau} = 0 \tag{22.211}$$

and similarly $\left(-\partial_\tau^2 + \partial_\sigma^2\right)\tilde{\sigma} = 0$. Having at our disposal a function $\tilde{\tau}$ that satisfies eq. (22.211) but is otherwise arbitrary, we can use it to fix the gauge $X^0(\tau,\sigma) = \tau$, since X^0 also satisfies eq. (22.204). Once $\tilde{\tau}(\tau,\sigma)$ has been fixed in this way, the derivatives of the function $\tilde{\sigma}$ are also fixed, so the gauge fixing is now complete, apart from the irrelevant possibility of shifting σ by a constant. In this gauge, therefore, X^0 drops from the set of dynamical variables and, using the notation $X^0 \equiv t$, we [38] Locally, i.e. in an open neighborhood of a point on the world-sheet, it is always possible to impose these conditions. The same is true globally, if the world-sheet has the topology of a plane or, for closed string loops, of a cylinder. These are the cases of relevance for the effective string that we are discussing here.

[39] We follow Section 6.2 of Vilenkin and Shellard (2000), to which we refer for more details. have $\tau = t$. Thus, the string is now described by a vector $\mathbf{X}(t,\sigma)$, and eqs. (22.204) $-$(22.206) become

$$\ddot{\mathbf{X}} - \mathbf{X}'' = 0 \tag{22.212}$$

$$\dot{\mathbf{X}} \cdot \mathbf{X}' = 0 \tag{22.213}$$

$$\dot{\mathbf{X}}^2 + \mathbf{X}'^2 = 1 \tag{22.214}$$

where the dot denotes the derivative with respect to t and the prime that with respect to σ. The solution of eq. (22.212) is a superposition of generic left-moving and right-moving waves,

$$\mathbf{X}(t,\sigma) = \frac{1}{2}[\mathbf{a}(\sigma - t) + \mathbf{b}(\sigma + t)] \tag{22.215}$$

with $\mathbf{a}$ and $\mathbf{b}$ arbitrary vector functions of one variable. The constraints (22.213) and (22.214) then give

$$\mathbf{a}'^2 = \mathbf{b}'^2 = 1 \tag{22.216}$$

The energy-momentum tensor of the string is obtained from eq. (22.185),

$$\begin{aligned} T^{\mu\nu}(x) &= \frac{2}{\sqrt{-g}} \frac{\delta S}{\delta g_{\mu\nu}(x)} \\ &= -\mu \int d^2\zeta \sqrt{-h} h^{ab} \frac{1}{\sqrt{-g}} \delta^{(4)}(x - X) \partial_a X^\mu \partial_b X^\nu \end{aligned} \tag{22.217}$$

where, after taking the variation with respect to $g_{\mu\nu}$, we have used the equation of motion $\gamma^{ab} = h^{ab}$. In flat space, and using the conformal gauge (22.203), we get

$$T^{\mu\nu}(x) = \mu \int d^2\zeta \delta^{(4)}(x - X) \left[\partial_\tau X^\mu \partial_\tau X^\nu - \partial_\sigma X^\mu \partial_\sigma X^\nu\right] \tag{22.218}$$

If we fix the residual gauge freedom by further imposing $X^0(\tau, \sigma) = \tau$, we finally get for the energy density $\rho(x) = T^{00}$,

$$\begin{aligned} \rho(t, \mathbf{x}) &= \mu \int d\sigma d\tau \delta^{(3)}[\mathbf{x} - \mathbf{X}(\tau, \sigma)] \delta(t - \tau) \\ &= \mu \int d\sigma \delta^{(3)}[\mathbf{x} - \mathbf{X}(t, \sigma)] \end{aligned} \tag{22.219}$$

The total energy is therefore

$$\begin{aligned} E &= \int d^3x \rho(x) \\ &= \mu \int d\sigma \end{aligned} \tag{22.220}$$

Thus, in this gauge σ provides a measure of length on the string, given by $d\sigma = dE/\mu$. Similarly, for the momentum we get

$$\begin{aligned} P^i &= \int d^3x T^{0i} \\ &= \mu \int d\sigma \dot{X}^i \end{aligned} \tag{22.221}$$

Consider now a closed loop. According to eq. (22.220), the parameter σ can be taken to be in the range $0 \leqslant \sigma \leqslant L$, where $L = E/\mu$ is called the invariant length of the loop. For a closed loop we require periodic boundary conditions $\mathbf{X}(t, \sigma + L) = \mathbf{X}(t, \sigma)$. In terms of the functions a and $\mathbf{b}$ introduced in eq. (22.215), this implies

$$\begin{aligned} -\mathbf{a}(\sigma + L - t) + \mathbf{a}(\sigma - t) &= \mathbf{b}(\sigma + L + t) - \mathbf{b}(\sigma + t) \\ &\equiv \boldsymbol{\Delta} \end{aligned} \tag{22.222}$$

and, because of invariance under translations in the world-sheet, the vector $\mathbf{\Delta}$ is independent of σ. From eq. (22.221), the momentum $\mathbf{P}$ is given by

$$\begin{aligned}\mathbf{P} &= \frac{\mu}{2}\int_0^L d\sigma\,[\partial_t\mathbf{a}(\sigma-t)+\partial_t\mathbf{b}(\sigma+t)]\\ &= \frac{\mu}{2}\int_0^L d\sigma\,[-\partial_\sigma\mathbf{a}(\sigma-t)+\partial_\sigma\mathbf{b}(\sigma+t)]\\ &= \frac{\mu}{2}[-\mathbf{a}(L-t)+\mathbf{a}(-t)+\mathbf{b}(L+t)-\mathbf{b}(t)]\\ &= \mu\mathbf{\Delta}\end{aligned} \tag{22.223}$$

In the center-of-mass frame of the string, which is defined by $\mathbf{P}=0$, we therefore have $\mathbf{\Delta}=0$, and eq. (22.222) shows that $\mathbf{a}$ and $\mathbf{b}$ are separately periodic,

$$\mathbf{a}(\sigma+L-t)=\mathbf{a}(\sigma-t) \tag{22.224}$$
$$\mathbf{b}(\sigma+L+t)=\mathbf{b}(\sigma+t) \tag{22.225}$$

With this formalism it is easy to understand the emergence of cusps in the generic motion of a string. Indeed, from eq. (22.215) we have

$$(\partial_t\mathbf{X})^2=\frac{1}{4}\left(-\mathbf{a}'+\mathbf{b}'\right)^2 \tag{22.226}$$

Thus, using eq. (22.216), we see that at a point of the world-sheet where $\mathbf{a}'=-\mathbf{b}'$, the world-sheet moves at the speed of light. Equation (22.216) shows that, as σ runs from zero to L, the functions $\mathbf{a}'(\sigma-t)$ and $\mathbf{b}'(\sigma+t)$ sweep curves on the unit sphere. Because of eqs. (22.224) and (22.225), these are actually closed curves on the sphere. The periodic boundary conditions on these vector functions also imply that

$$\int_0^L d\sigma\mathbf{a}'=\int_0^L d\sigma\mathbf{b}'=0 \tag{22.227}$$

so these curves cannot be confined to a single hemisphere. This means that, as σ runs from zero to L, the curves swept by $\mathbf{a}'(\sigma-t)$ and by $-\mathbf{b}'(\sigma+t)$ will generically intersect, and therefore in a typical motion of the string there will be points on the world-sheet that travel at the speed of light. Since this happens just at the intersection point, the corresponding point of the string travels at the speed of light only at

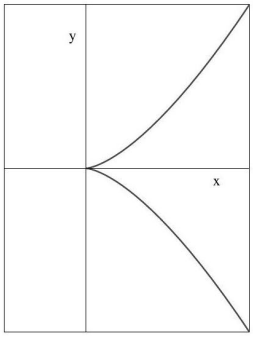

Fig. 22.16 The cusp developed by a cosmic string. some instant of time. When this happens, the spatial configuration of the string takes the form of a cusp. Indeed, let us choose the origin of the world-sheet coordinates so that the point of the world-sheet travelling at the speed of light corresponds to $\tau = \sigma = 0$. We also choose the origin of the spatial coordinates so that, at $\tau = 0$, this point is at $\mathbf{x} = 0$, and $\mathbf{a} = \mathbf{b} = 0$, and we again use the gauge $t = \tau$. Expanding $\mathbf{a}(\sigma_-)$ and $\mathbf{b}(\sigma_+)$in powers of $\sigma_\pm \equiv \sigma \pm t$ near the point $t = \sigma = 0$, i.e. $\sigma_+ = \sigma_- = 0$, we get

$$\mathbf{a}(\sigma_-) = \mathbf{a}_0'\sigma_- + \frac{1}{2}\mathbf{a}_0''\sigma_-^2 + \frac{1}{6}\mathbf{a}_0'''\sigma_-^3 + \dots \tag{22.228}$$

$$\mathbf{b}(\sigma_+) = \mathbf{b}_0'\sigma_+ + \frac{1}{2}\mathbf{b}_0''\sigma_+^2 + \frac{1}{6}\mathbf{b}_0'''\sigma_+^3 + \dots \tag{22.229}$$

so that

$$\mathbf{a}'(\sigma_-) = \mathbf{a}_0' + \mathbf{a}_0''\sigma_- + \dots \tag{22.230}$$

$$\mathbf{b}'(\sigma_+) = \mathbf{b}_0' + \mathbf{b}_0''\sigma_+ + \dots \tag{22.231}$$

The condition that the curves spanned by $\mathbf{a}'(\sigma - t)$ and $-\mathbf{b}'(\sigma + t)$ intersect at $\sigma = t = 0$ gives $\mathbf{a}_0' = -\mathbf{b}_0'$. Thus, from eq. (22.215), at $t = 0$ we have

$$\mathbf{X}(0,\sigma) = \frac{1}{4}\left(\mathbf{a}_0'' + \mathbf{b}_0''\right)\sigma^2 + \frac{1}{6}\left(\mathbf{a}_0''' + \mathbf{b}_0'''\right)\sigma^3 + \dots \tag{22.232}$$

If $(\mathbf{a}_0'' + \mathbf{b}_0'') \neq 0$, we can chose the axes so that $(\mathbf{a}_0'' + \mathbf{b}_0'')$ points, say, along the x axis. Then, in the (x, y) plane, we have

$$X_x(0,\sigma) \simeq c_x\sigma^2 \tag{22.233}$$

$$X_y(0,\sigma) \simeq c_y\sigma^3 \tag{22.234}$$

where $c_x = (1/4)\,|\mathbf{a}_0'' + \mathbf{b}_0''|$ and $c_y = (1/6)\left(\mathbf{a}_0''' + \mathbf{b}_0'''\right)_y$ (assuming that $c_y \neq 0$). This is the parametric description of a cusp, as shown in Fig. 22.16 and, near $\sigma = 0$, the shape of the string is given by $X_x^3(0,\sigma) \propto X_y^2(0,\sigma)$. The velocity of the string at this point is orthogonal to the direction of the cusp. This can be shown by inserting eqs. (22.230) and (22.231) into eq. (22.216) and requiring that it be satisfied order by order in σ, which gives

$$|\mathbf{a}_0'| = |\mathbf{b}_0'| = 1 \tag{22.235}$$

$$\mathbf{a}_0' \cdot \mathbf{a}_0'' = \mathbf{b}_0' \cdot \mathbf{b}_0'' = 0 \tag{22.236}$$

Thus the direction of the cusp, which is given by $(\mathbf{a}_0'' + \mathbf{b}_0'')$, is orthogonal to the direction of the velocity, which is given by $(1/2)\left(-\mathbf{a}_0' + \mathbf{b}_0'\right) = \mathbf{b}_0'$, since $\mathbf{a}_0' = -\mathbf{b}_0'$.

Of course, the cusp singularity is an artifact of the zero-thickness approximation implicit in the use of the Nambu-Goto action. For a Nielsen-Olesen vortex the singularity will be smoothed by its inner structure, on the scales m_s^{-1} or m_v^{-1}, whichever is larger, and the velocity at the cusp will be strictly smaller than the speed of light. However, this
smoothing occurs on scales that are much smaller than the horizon-scale length typical of the cosmic strings in which we are interested, and the idealized cusp obtained in the Nambu-Goto approximation is an exceedingly good description of the dynamics. Clearly, the presence of such a singularity where formally the string reaches the speed of light is very interesting for GW production, as we will discuss further in Section 22.5.4.

Another significant structure that can develop on cosmic strings is a kink, i.e. a point where the functions $\mathbf{a}'$ and $\mathbf{b}'$ are discontinuous, so that there is a discontinuity in the vector $\mathbf{X}'$ tangent to the string. While cusps, as we have seen, are a rather generic product of the evolution of a single string, kinks are formed when two strings interact with each other, exchanging parts as in Fig. 22.17, or when a single string self-intersects, as in Fig. 22.18. In the latter case there is both formation of a kink and emission of a smaller string loop. Numerical simulations for the Abelian Higgs model show that such processes, also referred as reconnections, are quite frequent. A kink implies that both $\mathbf{a}'$ and $\mathbf{b}'$ are discontinuous. Since $\mathbf{a}$ is a function of $\sigma - t$ and $\mathbf{b}$ is a function of $\sigma + t$, after the kink has been generated it splits into two kinks, moving in opposite directions along the string, at the speed of light. The argument that we have presented regarding the generic intersection of the curves spanned by $\mathbf{a}'$ and $\mathbf{b}'$ on the unit sphere indicates that cusps are generically expected to appear on smooth strings a few times per oscillation period. However, if a string develops kinks, the corresponding curve on the unit sphere has discontinuities, and in this case there are more chances that the two curves do not intersect. In that case the string has kinks, traveling on it at the speed of light, but does not develop cusps.

16.3.4 22.5.4 Gravitational radiation from cosmic strings

In the Standard Model these is no spontaneously broken local $U(1)$ symmetry that could give rise to cosmic strings. [40] However, cosmic strings could emerge in extensions of the Standard Model based on larger grandunified groups. If cosmic strings exist, they would be very remarkable objects. For $G\mu \simeq 10^{-7}$, which is about the largest value consistent with the CMB [see eq. (22.176)], we have $\mu^{1/2} \simeq 4 \times 10^{15}$GeV, in our units $\hbar = c = 1$. Reinstating c, a mass per unit length μ such that $G\mu/c^2 = 10^{-7}$ has the huge numerical value $\mu \simeq 10^{21}$ g/cm. A cosmic string loop with this tension and a length equal to one astronomical unit (and thus much smaller than the cosmological scale that most cosmic string loops would be expected to have, as we shall see) would already have a mass $\sim 10 M_\odot$. This energy is concentrated in a tube of width $\sim m_s^{-1}$ or $\sim m_v^{-1}$. As we saw in Section 22.5.1, $m_s = \lambda^{1/2}\eta$ and $m_v = g\eta$, so their value is basically determined by the Higgs vacuum expectation value η. For a phase transition at a GUT scale, and any reasonable values of the couplings λ and g, the thickness of the string is much smaller than, say, the proton radius. Thus, we have a huge energy per unit length, concentrated in an extremely narrow tube. Because of their huge tension, these objects oscillate relativistically and we have

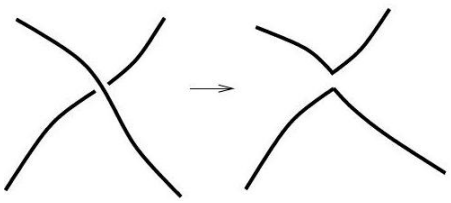

Fig. 22.17 The kinks generated by the reconnection of two cosmic strings.

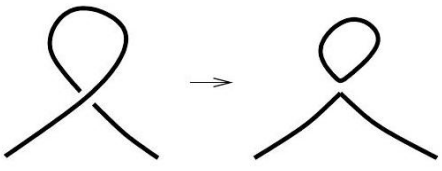

Fig. 22.18 The kink and the closed loop generated by the self intersection of a cosmic string.

even seen that, during their evolutions, cusps are generically formed, where a point of the string instantaneously moves at the speed of light. Cosmic strings are therefore potentially very interesting sources of GWs.

Stochastic GW background from a cosmic string network

To study GW generation by a network of cosmic strings, we must address two questions. First, what is the radiation generated by a cosmic string loop and, second, what are the statistical properties of a cosmic string network. Let us begin with the radiation from a single loop. A first naive estimate can be obtained using the quadrupole formula (3.75). The mass of a string loop of length L is $M \sim \mu L$, so its quadrupole moment is $Q \sim \mu L^3$. The typical oscillation frequency of a loop of length L oscillating relativistically is $\omega \sim 1/L$, so $\dddot{Q} \sim Q\omega^3 \sim \mu$, and eq. (3.75) gives $P_{\rm quad} \sim G\mu^2$. However, the use of the quadrupole formula is obviously inappropriate, given that the loop moves relativistically. One must rather use the formalism discussed in Section 3.1 of Vol. 1, valid for (weak-field) sources with arbitrary velocity. An oscillating string loop of length L emits at a discrete set of frequencies ω_n. Observe that, for a closed loop of length L in its rest frame, the functions $\mathbf{a}$ and $\mathbf{b}$ are periodic with respect to σ period L; see eqs. (22.224) and (22.225). From eq. (22.215) this means that

$$\mathbf{X}\left(\sigma + \frac{L}{2}, t + \frac{L}{2}\right) = \mathbf{X}(\sigma, t) \tag{22.237}$$

so the string configuration is periodic in time with period $L/2$, modulo a shift in the parameter σ. Thus, the oscillation frequencies of a cosmic string loop of length L are $\omega_n = 2\pi f_n$, with $f_n = n/(L/2) = 2n/L$. Adapting to this case eqs. (3.16)-(3.20), which were written for a simply periodic source, we see that the energy radiated per unit solid angle is still given by eq. (3.16), where the Fourier transform of the energymomentum tensor of the source is

$$\tilde{T}_{ij}(\omega, \mathbf{k}) = \sum_n \theta_{ij}\left(\omega_n, \mathbf{k}\right) 2\pi\delta\left(\omega - \omega_n\right) \tag{22.238}$$

and the radiated power is

$$P = \sum_n P_n \tag{22.239}$$

where (in our present units $c = 1$)

$$\frac{dP_n}{d\Omega} = \frac{G\omega_n^2}{\pi}\Lambda_{ij,kl}(\hat{\mathbf{n}})\theta_{ij}\left(\omega_n, \omega_n\hat{\mathbf{n}}\right)\theta^*_{kl}\left(\omega_n, \omega_n\hat{\mathbf{n}}\right) \tag{22.240}$$

One can now consider some explicit exact solutions for the motion of the loop, and compute numerically the power radiated in the various harmonics, and hence the total power. The result is of the form

$$P = \Gamma G\mu^2 \tag{22.241}$$

where the proportionality to $G\mu^2$ is the same as in the quadrupole formula, and is fixed by the facts that eq. (22.240) is proportional to G and that each factor $\theta_{ij}\left(\omega_n, \omega_n\hat{\mathbf{n}}\right)$ is proportional to μ. The numerical factor Γ depends on the shape of the loop, and turns out to be a large number, $\Gamma \sim 50 - 100$, because many harmonics contribute. A value of Γ of this order is obtained for loops with cusps, for loops with kinks, and also for loops with neither cusps nor kinks. However, the dependence of P_n on n is different in these cases. In particular, cusps or

[12540] The spontaneous breaking of the $SU(2) \times U(1)$ gauge symmetry of the Standard Model does not give rise to stable string configurations; see Section 4.2.6 of Vilenkin and Shellard (2000).

kinks correspond to very small-scale structures on the string, and contribute to harmonics with very large n. Thus, for loops with cusps or with kinks, P_n decreases quite slowly with n. For loops with cusps, at large n, one has

$$P_n^{\rm cusps} \sim G\mu^2 n^{-4/3} \tag{22.242}$$

while for loops with kinks

$$P_n^{\rm kinks} \sim G\mu^2 n^{-5/3} \tag{22.243}$$

The energy radiated in GWs is taken from the energy $E = \mu L$ of the loop. Thus, as the loop loses energy, it must shrink and eventually disappear. From eq. (22.241) we get we have

$$\mu \frac{dL}{dt} = -\Gamma G\mu^2 \tag{22.244}$$

Since Γ, to a first approximation, is independent of the loop size, a loop created initially with a length L_0 at time t_0 evolves as

$$L(t) = L_0 - \Gamma G\mu\,(t - t_0) \tag{22.245}$$

Thus, in the absence of interaction with other strings, the loop lifetime is due to GW emission and is given by $T = L_0/(\Gamma G\mu)$. For $G\mu \sim 10^{-7}$ and $\Gamma \sim 10^2$ we have $T \sim 10^5 L_0$. Therefore, the loop is long-lived compared with the natural length-scale given by its size, and performs $O\,(10^5)$ oscillations before disappearing.

The other crucial aspect for computing the GW production from an ensemble of cosmic strings is the distribution of loop sizes. Several analytical and numerical investigations have shown that a cosmic string network evolves toward an attractor solution characterized by a scaling regime, in which the average distance between strings remains a fixed fraction of the Hubble length $H^{-1}(t)$, i.e. it scales linearly with cosmic time t, and the energy density of the network remains a constant fraction of the total energy density of the Universe. If cosmic strings were absolutely stable, the energy of a single cosmic string $E = \mu L$ would scale with the expansion as $a(t)$, since $L \propto a(t)$. A physical volume V scales as a^3, so the energy density of cosmic strings would scale only as $1/a^2$, i.e. much more slowly than radiation, so during RD the ratio of the energy density in cosmic strings to the energy density in radiation would increase as a^2. If this were the case, cosmic strings would quickly reach an unacceptably large density and would be dangerous relics to

[41] See Blanco-Pillado, Olum and Shlaer (2014).

be washed out by an inflationary epoch, just like monopoles or domain walls. However, cosmic strings lose energy by GW emission, and this saves them from becoming dangerous relics. What happens in a cosmic string network is that long strings cross each other and produce smaller loops, as in Fig. 22.18, which then shrink and eventually disappear by emitting GWs. Numerical simulations give, for the number density (per physical volume) of loops of length L, [41]

$$\frac{n(L,t)}{a^3(t)} \simeq \frac{0.18}{t^{3/2}(L + \Gamma G\mu t)^{5/2}} \tag{RD}$$

which is valid for L smaller than a cutoff value $L_{\rm max} \simeq 0.1t$, and

$$\frac{n(L,t)}{a^3(t)} \simeq \frac{0.27 - 0.45(L/t)^{0.31}}{t^2(L + \Gamma G\mu t)^2} \tag{MD}$$

with a cutoff $L_{\rm max} \simeq 0.18t$. This describes a population of loops with a broad range of values of L, from $L = 0$ up to values not much smaller than the horizon radius. Writing $L = \alpha t$, in this distribution there are loops up to $\alpha \sim 0.1$. It is still under debate whether there exists also

a separate population of small loops, with typical values $\alpha \sim \Gamma G\mu$, as was assumed in earlier works. The scaling property of these distributions is reflected in the fact that they have the form $n(L,t)/a^3(t) = t^{-4}N(L/t)$, for some function N.

Given the energy radiated by a loop and the loop distribution, the resulting GW background can be computed as follows. The power radiated by a single loop of length L can be written as in eq. (22.239). It is convenient to extract explicitly the factor $G\mu^2$, writing $P_n = G\mu^2 p_n$, so

$$\begin{aligned}\frac{dE_{\rm GW}}{dt} &= G\mu^2 \sum_n p_n \\ &= G\mu^2 L \int_0^\infty df_e S\left(Lf_e\right)\end{aligned} \tag{22.248}$$

where

$$S(x) \equiv \sum_n p_n \delta\left(x - x_n\right) \tag{22.249}$$

The subscript e in f_e is a reminder that this is the frequency at the time of emission, before any redshifting, $x = Lf_e, x_n = Lf_{e,n}$, and $f_{e,n} = 2n/L$ are the frequencies at which the loop of length L emits. Comparing with eq. (22.241) we have

$$\int_0^\infty dx S(x) = \Gamma \tag{22.250}$$

This continuous notation is useful because is allows us to write the frequency spectrum of the GWs emitted by a single loop, in the interval between the emission time t_e and $t_e + dt_e$, as

$$\frac{dE_{\rm GW}\left(t_e\right)}{df_e} = G\mu^2 LS\left(Lf_e\right) dt_e \tag{22.251}$$

The energy density of the radiation emitted by a network of loops with number density $n(L,t)dL$ in the interval between time t_e and $t_e + dt_e$ is therefore

$$\frac{d\rho_{\rm GW}\left(t_e\right)}{df_e} = G\mu^2 dt_e \int_0^{\alpha t_e} dL n\left(L,t_e\right) LS\left(Lf_e\right) \tag{22.252}$$

where we have taken into account the fact that, at time t_e, the maximum length of the loop is αt_e. We now observe that $\rho_{\rm GW}$ redshifts as $1/a^4$, so $\rho_{\rm GW}\left(t_e\right) = a^{-4}\left(t_e\right)\rho_{\rm GW}\left(t_0\right)$, where t_0 is the present value of cosmic time and we have set $a\left(t_0\right) = 1$. The emission frequency is related to the frequency $f_{\rm obs}$ observed today by $f_e = f_{\rm obs}/a\left(t_e\right)$, so

$$\frac{d\rho_{\rm GW}\left(t_e\right)}{df_e} = \frac{1}{a^3\left(t_e\right)} \frac{d\rho_{\rm GW}\left(t_0\right)}{df_{\rm obs}} \tag{22.253}$$

Integrating over the emission time t_e from the primordial epoch $t_e \simeq t_*$ when cosmic strings first formed to the present time t_0, we get

$$\left(\frac{d\rho_{\rm GW}}{df}\right)_0 = G\mu^2 \int_{t_*}^{t_0} dt a^3(t) \int_0^{\alpha t} dL n(L,t) LS\left(\frac{Lf}{a(t)}\right) \tag{22.254}$$

where we henceforth use simply f to denote $f_{\rm obs}$, and we have denoted the integration variable t_e simply by t. Therefore, using the definition (7.198), $\Omega_{\rm gw}(f) = \rho_c^{-1} f d\rho_{\rm GW}/df$, together with $\rho_c = 3H_0^2/(8\pi G)$, we get

$$h_0^2 \Omega_{\rm gw}(f) = \frac{8\pi}{3} \left(\frac{h_0}{H_0}\right)^2 (G\mu)^2 f \int_{t_*}^{t_0} dt a^3(t) \int_0^{\alpha t} dL n(L,t) L S\left(\frac{Lf}{a(t)}\right) \tag{22.255}$$

Given the function $S(x)$ that models the loop emission and the number density of loops $n(L,t)$, this integral can then be computed numerically. Currently the typical value of the power P_n in a realistic string network is not known. One can, however, study various limiting cases. In particular, as a model for the loop radiation we can use the radiation from loops with cusps, as given in eq. (22.242), or that for loops with kinks, as given in eq. (22.243). For the number density we can use the distribution for large loops given in eqs. (22.246) and (22.247), which is the case favored by the most recent numerical studies. Alternatively, one can study the contribution from a population of small loops, with $\alpha \sim \Gamma G\mu$, which was suggested by earlier analytic and numerical studies that assumed that the loop size is determined by the smallest lengthscale on which gravitational back-reaction washes out inhomogeneities on the string. Actually, more recent studies have suggested that such small-scale structures should be even smaller, with $\alpha \sim (\Gamma G\mu)^n$, with $n = 3/2$ in RD and $n = 5/2$ in MD. It is conventional to parametrize this uncertainty by introducing $\varepsilon \equiv \alpha/(\Gamma G\mu)$, so $\varepsilon = 1$ corresponds to the "old" scenario, while $\varepsilon \ll 1$ in the scenario with $\alpha \sim (\Gamma G\mu)^n$ with $n > 1$; for instance, if $\Gamma = 50, G\mu = 10^{-7}$ and $n = 5/2$ we get $\varepsilon \sim 10^{-8}$.

A final parameter that must be taken into account is the recombination probability p, which measures the probability that two strings

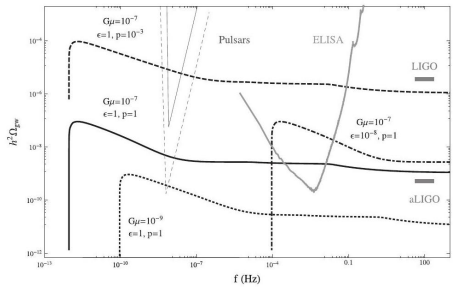

Fig. 22.19 $h_0^2 \Omega_{\rm gw}(f)$ for cosmic strings with cusps, with a small initial loop size $\varepsilon \equiv \alpha/(\Gamma G\mu)$, for different choices of $\varepsilon, G\mu$ and the reconnection probability p, assuming $\Gamma = 50$. From Binetruy, Bohe, Caprini and Dufaux (2012). (C)SISSA Medialab Srl. Reproduced by permission of IOP Publishing. All rights reserved.

crossing each other exchange their segments, as in Fig. 22.17. For the effective Nambu-Goto strings that describe Nielsen-Olesen vortices one basically has $p = 1$. However, it has also been suggested that fundamental superstrings can expand to cosmological scales. For fundamental strings in typical string models, where the string scale is close to the Planck scale, this is quite unlikely, since such strings would be unstable to break-up into smaller Planckian-size strings, and even if they were stable, they would anyhow be removed by inflation. However, in string models with a lower scale, based for example on large extra dimensions, fundamental strings (F-strings) or one-dimensional D-branes (D-strings) of cosmological size could exist, and could be produced after inflation. For such strings the reconnection probability p is suppressed by a factor of order g_s^2, where g_s is the string coupling. Furthermore, strings moving in a higher-dimensional space-time can avoid intersections more easily. As a result, one estimates $10^{-3} \lesssim p \lesssim 1$ for F-strings and $0.1 \lesssim p \lesssim 1$ for D-strings. In turn, this gives a larger number density of long strings, since a small reconnection probability means that processes such as

those in Fig. 22.18 are suppressed, and long strings are much more abundant. Indeed, $n(L,t)$ scales possibly as $1/p$ (although the exact dependence is still debated) and the values in eqs. (22.246) and (22.247) correspond to $p = 1$.

When computing the stochastic background of GWs one must also take into account that, depending on the detector sensitivity, some of the strongest bursts coming from cusps could be detected individually (a point that we will discuss in more detail later), and therefore must be subtracted from the contribution of the stochastic background.

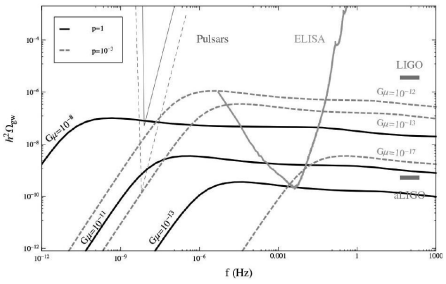

Fig. 22.20 $h_0^2\Omega_{\rm gw}(f)$ for cosmic strings with cusps, with a large initial loop size ($\alpha = 0.1$) and different choices of $G\mu$ and the reconnection probability p, assuming $\Gamma = 50$. From Binetruy, Bohe, Caprini and Dufaux (2012). (C)SISSA Medialab Srl. Reproduced by permission of IOP Publishing. All rights reserved.

Figure 22.19 shows $h_0^2\Omega_{\rm gw}(f)$ generated by strings with cusps, taking for $n(L,t)$ a distribution of small loops with a fixed value $\varepsilon \equiv \alpha/(\Gamma G\mu)$, for different choices of $\varepsilon, G\mu$, and the reconnection probability p, assuming $\Gamma = 50$. The theoretical prediction is compared with the limit set by the LIGO S5 run, with the design sensitivity of advanced LIGO, with the sensitivity expected for LISA and with pulsar timing experiments. Pulsar timing arrays (PTAs) will be discussed in Chapter 23, and provide very interesting limits in the frequency range between 10^{-9} and 10^{-7} Hz. The solid wedge-shaped line corresponds to the current sensitivities, and the dashed line to expected future sensitivities.

Figure 22.20 shows $h_0^2\Omega_{\rm gw}(f)$ generated again by strings with cusps, but taking for $n(L,t)$ a distribution of large loops with $\alpha = 0.1$ and various values of $G\mu$ and p. For large loop size and recombination parameter $p = 1$, pulsar timing arrays impose a very strong bound. The nine-year data set released in 2015 by the pulsar timing array NANOGrav provides a limit

$$G\mu < 3.3 \times 10^{-8} \tag{22.256}$$

at 95% c.l., while the European Pulsar Timing Array (EPTA) currently provides a limit $G\mu < 1.3 \times 10^{-7}$. These bounds are stronger than the CMB limit (22.176), although they are more model-dependent since various parameters, such as Γ and α, enter the computation. The space interferometer LISA is expected to reach values as small as $G\mu \sim 10^{-13}$, for $p = 1$ and large loops.

GW bursts from cusps and kinks

Beside generating a stochastic background, cusps and kinks on strings can also generate GW bursts so strong that, potentially, they could be detectable individually. To compute the burst generated by a cusp one can use the expansion (22.228), (22.229) for the time evolution of the cosmic string near the cusp, and plug it into the energy-momentum tensor of the string, eq. (22.218). The resulting waveform is obtained using the formalism of Section 3.1 of Vol. 1, valid for weak-field sources with arbitrary velocity. This gives the result in the local wave zone, i.e. at distances large compared with the size of the source, but small compared with cosmological scales. One must then evolve the GWs to the present time through a FRW metric.

The computation has been performed in detail in Damour and Vilenkin (2000, 2001). The result is that the amplitude in Fourier space is

$$\tilde{h}(f) \sim \frac{G\mu L}{[(1+z)fL]^{1/3}} \frac{1+z}{t_0 z} \tag{22.257}$$

where t_0 is the present value of cosmic time and z the redshift of the source. The Fourier mode $\tilde{h}(f)$ is focused in a narrow cone in the direction of the cusp velocity, with an opening angle

$$\theta_m \simeq [(1+z)fL/2]^{-1/3} \tag{22.258}$$

Writing the loop length as $L = \alpha t$, and expressing t in terms of the redshift, one finds

$$\tilde{h}(f) \sim G\mu\alpha^{2/3} (ft_0)^{-1/3} \phi_h(z) \tag{22.259}$$

where

$$\phi_h(z) = z^{-1}(1+z)^{-1/3} (1+z/z_{\rm eq})^{-1/3} \tag{22.260}$$

The rate of bursts due to cusps can be estimated assuming that C cusps are formed per oscillation cycle of the string, with $C = O(1)$. A string with length L has on oscillation period $T(L) = L/2$ [see eq. (22.237)], so the number of cusp events per unit space-time volume is

$$\begin{aligned} \nu(t) &\simeq \frac{Cn(L,t)}{T(L)} \\ &= \frac{2Cn(L,t)}{L} \end{aligned} \tag{22.261}$$

Then, the rate of GW bursts in the direction of the observer due to cusps in the redshift interval dz, observed at frequency f, is

$$d\dot{N} \sim \frac{\theta_m^2}{4}(1+z)^{-1}\nu(z)dV(z) \tag{22.262}$$

where the factor $\theta_m^2/4$ is the beaming angle of the burst, the factor $(1+z)^{-1}$ comes from the cosmological time dilatation between the time $t_{\rm obs}$ measured by the observer and the time t of the source, $dt_{\rm obs} =$
$(1+z)dt$, and $dV(z)$ is the proper volume between redshifts z and $z+dz$. In MD

$$dV(z) = 54\pi t_0^3 \left[(1+z)^{1/2} - 1\right]^2 (1+z)^{-11/2} dz \tag{22.263}$$

while in RD

$$dV(z) = 72\pi t_0^3 (1+z_{\rm eq})^{1/2} (1+z)^{-5} dz \tag{22.264}$$

Given the amplitude of a single burst (22.257) and the burst rate (22.262) as a function of redshift, one can compute the typical amplitude of a burst generated by cusps over a period, say, of one year, and compare with the experimental sensitivities. A similar analysis can be done for kinks. Similarly to the stochastic background case discussed earlier, the result depends on the population of loops considered, in particular on whether one considers loops with typical length $L = \alpha t$ with $\alpha \sim \Gamma G\mu$, which was once considered the standard scenario, or whether $\alpha \sim 0.1$, which is favored by the most recent simulations, or even values of $\varepsilon = \alpha/(\Gamma G\mu) \ll 1$, as discussed following eq. (22.255). As we see from eq. (22.259), the signal is not sharply peaked

at a specific frequency, but rather has a smooth power-law behavior, so it can be relevant both for ground-based and for space-borne interferometers.

The result for the scenario with $\varepsilon = 1$ is shown in Fig. 22.21, in the frequency range of LIGO/Virgo, as a function of $\alpha = 50G\mu$. We see that, for some values of the parameters, the signal is potentially detectable.

16.4 22.6 Alternatives to inflation

We have seen in Chapter 21 that inflation provides an elegant solution to the homogeneity and flatness problems of FRW cosmology (as well as diluting unwanted relics such as monopoles that could appear in extensions of the Standard Model and would otherwise dominate over radiation since their density scales slower than $1/a^4$), and furthermore provides the initial adiabatic perturbations that seed structure formation. As such, it is a very successful paradigm. The simplest scenario for obtaining inflation is the single-field slow-roll inflation that we discussed a length in Section 21.1, or relatively simple modifications of it, such as the hybrid inflationary model [see eq. (21.82)]. There have, however, been several attempts at incorporating inflation into a more fundamental theory, such as string theory, that could at the same time address fundamental problems such as the big-bang singularity. Such models have in general distinctive predictions for the stochastic GW background, which differ from that of standard slow-roll inflation computed in Section 21.3. [42] In the following we will briefly discuss some of these models, just to give a flavor of how the prediction of standard slow-roll inflation can be modified in alternative theories of inflation. Of course, all these models suffer from uncertainties due to the difficulty of dealing with the regime of Planckian curvatures, so the results must be taken only as examples of possible scenarios.

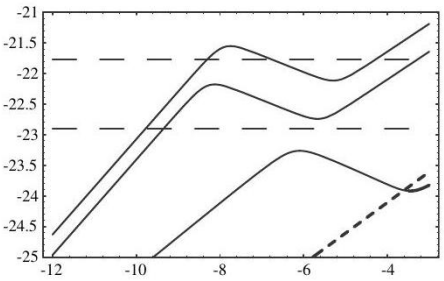

Fig. 22.21 GW amplitude of bursts emitted by cosmic string cusps (upper and middle curves) and kinks (lower curve), in the LIGO/Virgo frequency band, as a function of $\alpha = 50G\mu$, in a base- $10\log - \log$ plot. The upper curve assumes that the average number of cusps per loop oscillation is $C = 1$. The middle curve assumes $C = 0.1$. The lower curve gives the kink signal (assuming only one kink per loop). The horizontal dashed lines indicate the 1-sigma noise levels (after optimal filtering) of initial LIGO and advanced LIGO. The short-dashed line indicates the "confusion" amplitude noise of the stochastic GW background. From Damour and Vilenkin (2001).

As an example of such alternatives to standard inflation, we consider the pre-big-bang model. The starting point is the low-energy effective action from string theory, which, besides

[12542] It should also be observed that in principle these models could also be joined, at sub-Planckian curvature, to standard slow-roll inflation, providing a way of addressing the initial singularity problem while still matching later to standard inflationary cosmology.
[125]

[43] The low-energy effective action of string theory also includes an antisymmetric tensor, whose effect has also been studied in this context. Here, for simplicity, we limit ourselves to the metric-dilaton sector.

the metric, also includes a scalar field, the dilaton ϕ.[43] The effective action in the metric-dilaton sector, to lowest order in the derivatives and in the coupling e^{ϕ}, is given by

$$S_{\rm eff} \sim \int d^D x \sqrt{-g} \left[e^{-\phi} \left(R - \partial_\mu \phi \partial^\mu \phi \right) \right] \tag{22.265}$$

where ϕ is the dilaton field. This action receives two kinds of perturbative corrections: corrections parametrized by e^{ϕ}, which are just higher loops in the field-theory sense, and corrections proportional to α', where $\lambda_s = \sqrt{2\alpha'}$ is the string length. The latter are genuinely string effects, and take into account the finite size of the string. Since α' has dimensions of (length) ^{2}, it is associated with higher-derivative operators such as the square of the Riemann tensor, $R^2_{\mu\nu\rho\sigma}$. Remarkably, there exists a regime in the early Universe evolution of this model where the perturbative approach is well justified, and in a first approximation one can use eq. (22.265), neglecting the corrections. This regime occurs if we take as initial condition a Universe at weak coupling and low curvatures. Then, a generic inhomogeneous string vacuum shows a gravitational instability. Specializing for simplicity to a homogeneous model, the solution of the equations of motion derived from the action (22.265) reads, for generic anisotropic FRW scale factors $a_i(t), i = 1, \ldots, D-1$,

$$\begin{aligned} a_i(t) &= (-t)^{c_i} \\ \phi_i(t) &= \phi_0 + c_0 \log(-t) \end{aligned} \tag{22.266}$$

with

$$\sum_{i=1}^{D-1} c_i^2 = 1, \quad \sum_{i=1}^{D-1} c_i = 1 + c_0 \tag{22.267}$$

This is just a generalization in the presence of the dilaton of the Kasner solution of general relativity. Considering for simplicity an isotropic model, one has in particular a solution with $c_i = -1/\sqrt{D-1}$ and $c_0 = -1 - \sqrt{D-1}$. This corresponds to a super-inflationary evolution: the Hubble parameter $H = \dot{a}/a$ grows until it reaches the string scale $1/\lambda_s$, and eventually formally diverges at a singularity. When $H \sim 1/\lambda_s$, of course, the description based on the lowest-order action is no longer adequate. The inclusion of α' corrections, at least to first order, i.e. terms $O\left(R^2_{\mu\nu\rho\sigma}\right)$, has been shown to turn the unbounded growth of the curvature into a de Sitter phase with a linearly growing dilaton. Of course, in this regime the curvature is anyhow of order one in string units, so a full non-perturbative study would in principle be necessary, but the fact that the $O(\alpha')$ corrections already regularize the big-bang singularity is encouraging.

Since in this new regime the dilaton keeps growing linearly, finally even e^{ϕ} becomes large, even if the evolution started at very weak coupling; at this stage loop corrections are important, and they can trigger the exit from the de Sitter phase. An example of this behavior, using both α' corrections to first order and loop corrections derived from orbifold compactifications of string theory (using modular-invariant loop corrections to the Kähler potential known to all orders, as well as oneloop corrections to the gravitational couplings of the higher-derivative terms), has been studied explicitly, and is shown in Fig. 22.22.

Using this type of evolution as an example of what could be obtained from string theory, the corresponding stochastic GW background can be computed as follows. We consider a model with three phases: first an isotropic superinflationary evolution described by eq. (22.266), with the value of the constants c_i and c_0 determined by eq. (22.267). Then this phase is matched to a de Sitter phase with linearly growing dilaton, which may be considered as representative of a typical solution in the large-curvature regime; the constant values of H and $\dot{\phi}$ in this phase are taken as free parameters, of the order of the string scale. Finally, we match this phase to the

standard RD era. Of course, this model can only be taken as indicative of possible behavior in string cosmology, since what happens in the large-curvature phase is certainly much more complicated, and a full understanding would require a non-perturbative approach. However, we will see that some important characteristics of the GW spectrum depend only on the low-curvature regime, where we can use the lowest-order effective action and which is therefore under good theoretical control.

We specialize for illustration to a isotropic model compactified to four dimensions. Writing the scale factors and the dilaton in terms of conformal time, from eq. (22.266) we find that for $-\infty < \eta < \eta_s$ (with $\eta_s < 0$) we have a dilaton-dominated regime with

$$a(\eta) = -\frac{1}{H_s \eta_s} \left(\frac{\eta - (1-\alpha)\eta_s}{\alpha \eta_s} \right)^{-\alpha} \tag{22.268}$$

$$\phi(\eta) = \phi_s - \gamma \log \frac{\eta - (1-\alpha)\eta_s}{\eta_s} \tag{22.269}$$

and the Kasner conditions eq. (22.267) give $\alpha = 1/(1+\sqrt{3})$ and $\gamma = \sqrt{3}$.

At a value $\eta = \eta_s$ the curvature becomes of the order of the string scale, and there we assume a de Sitter expansion with linearly growing dilaton. In terms of conformal time, this means

$$a(\eta) = -\frac{1}{H_s \eta}, \quad \phi(\eta) = \phi_s - 2\beta \log \frac{\eta}{\eta_s} \tag{22.270}$$

The parameter H_s is of the order of the string scale, while β is a free parameter of the model. Note that $2\beta = \dot{\phi}/H_s$, where $\dot{\phi}$ is the derivative with respect to cosmic time, and in this model $\beta > 0$.

The stringy phase lasts for $\eta_s < \eta < \eta_1$ (again $\eta_1 < 0$), and at η_1 we match this phase to a standard RD era. This gives, for $\eta_1 < \eta < \eta_r$ (with $\eta_r > 0$),

$$a(\eta) = \frac{1}{H_s \eta_1^2} (\eta - 2\eta_1), \quad \phi = \phi_0 \tag{22.271}$$

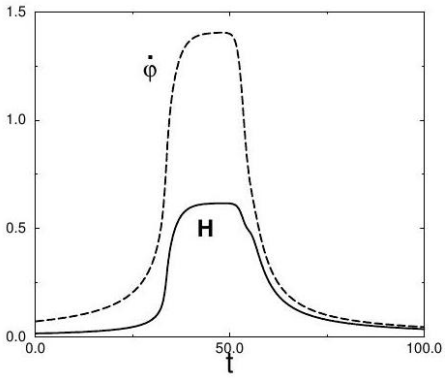

Fig. 22.22 The evolution of the Hubble parameter H and of $\dot{\phi}$ in string cosmology with α' and loop corrections. From Foffa, Maggiore and Sturani (1999).

Then, the standard MD era follows. We have chosen the additive and multiplicative constants in $a(\eta)$ in such a way that $a(\eta)$ and $da/d\eta$ (and therefore also da/dt) are continuous across the transitions. The equation for the tensor perturbations in these three regimes can be solved exactly (see the Further Reading), and matched at the transition points. The matching gives the Bogoliubov coefficients, similarly to the computation in Section 21.3.7. The quantity η_1 can be estimated by observing that, since it marks the end of the de Sitter phase,

$|\eta_1| = 1/\left[H_s a\left(\eta_1\right)\right]$. On the other hand, assuming no intermediate inflationary phase and a direct matching to RD, η_1 also marks the beginning of the RD phase. Therefore, the Friedmann equation (17.117) gives

$$H_s \simeq 0.62 \left(\frac{106.75}{g_*(T)}\right)^{1/6} \frac{H_0 \Omega_R^{1/2}}{a^2\left(\eta_1\right)} \tag{22.272}$$

Then, writing

$$k\left|\eta_1\right| = \frac{2\pi f}{H_s a\left(\eta_1\right)} \tag{22.273}$$

the parameter η_1 can be traded for a parameter f_1 defined by $k\left|\eta_1\right| = f/f_1$. Numerically,

$$f_1 \simeq 2.5 \times 10^{10}\ \text{Hz} \left(\frac{H_s}{0.1 M_{\rm pl}}\right)^{1/2} \left(\frac{106.75}{g_*}\right)^{1/12} \tag{22.274}$$

where we have chosen a reference value H_s of the order of a typical string scale. Similarly, we can introduce a parameter f_s instead of η_s, from $k\left|\eta_s\right| = f/f_s$. However, this parameter depends on the duration of the string phase, and therefore, in contrast to f_1, is totally unknown, even as an order of magnitude. However, since $|\eta_1| < |\eta_s|$, we have $f_s < f_1$.

To summarize, the model has a parameter f_s with dimensions of a frequency, which can have any value in the range $0 < f_s < f_1$, with $f_1 = O(1-10)$GHz, and a dimensionless parameter β. It is useful to further trade the latter for the parameter $\mu = |\beta - (3/2)|$.

Performing the matching between the solutions in the three phases one obtains the Bogoliubov coefficients and then one finally gets the spectrum. The computation can be done fully analytically. From the exact expressions one finds that, in the regime $f \ll f_s$ we have $h_0^2 \Omega_{\rm gw}(f) \propto f^3$, while for $f_s \ll f < f_1$ the slope changes to $h_0^2 \Omega_{\rm gw}(f) \propto f^{3-2\mu}$. Thus, the exact analytic solution obtained from the computation of the Bogoliubov coefficients is well approximated by

$$h_0^2 \Omega_{\rm gw}(f) \simeq h_0^2 \Omega_{\rm gw}\left(f_1\right) \times \begin{cases} \left(\frac{f_1}{f_s}\right)^{2\mu} \left(\frac{f}{f_1}\right)^3 & (f \ll f_s) \\ \left(\frac{f}{f_1}\right)^{3-2\mu} & (f_s \ll f < f_1) \end{cases} \tag{22.275}$$

where the factor $\left(f_1/f_s\right)^{2\mu}$ is determined by continuity in $f = f_s$. The overall normalization is determined by the fact that the value of $h_0^2 \Omega_{\rm gw}(f)$
at the cutoff value f_1 is fixed by the scale H_s reached by the Hubble parameter during the string phase. Writing $H_s = g_1 M_{\rm Pl}$, one finds $h_0^2 \Omega_{\rm gw}\left(f_1\right) \simeq g_1^2 h_0^2 \Omega_R$, where Ω_R is the present fraction of the energy density in radiation. Assuming that $H_s = g_1 M_{\rm Pl}$ is of the order of the string scale, one gets, in typical string models, $g_1 \sim 0.1$. Thus, the value of the peak frequency f_1, as well as that $h_0^2 \Omega_{\rm gw}\left(f_1\right)$, is fixed, at least within some order of magnitude, and assuming typical values for the string mass scale. In contrast, the parameters (μ, f_s) must be taken as free parameters of the model, except for the bounds $\mu \geqslant 0$ and $f_s < f_1$ that follow from their definition. Furthermore we must have $\mu \leqslant 3/2$, otherwise, moving from its value at $f = f_s$ toward lower frequencies, $h_0^2 \Omega_{\rm gw}(f)$ would increase and would eventually violate observational limits, such as the nucleosynthesis bound, that we will discuss in Section 22.7. Depending on the values of the two parameters μ and f_s, a broad range of possibilities for the GW spectrum is possible. If f_s is very close to f_1, or if μ is very close to zero, when moving from its peak at f_1 toward lower frequencies the spectrum decreases as f^3 (just like a black-body spectrum), and is totally unobservable at the frequencies at which ground-based interferometers, space interferometers and pulsar timing array operate. This corresponds to the solid line in Fig. 22.23. In contrast, if $\mu \simeq 3/2$, the spectrum is almost flat in the region $f_s \ll f < f_1$, so, if f_s is

sufficiently small, it can be sizable at the frequencies of interferometers, or even pulsar timing, and in fact possibly even at the very small frequencies probed by the CMB, as shown by the two dashed lines in Fig. 22.23.

The preceding computation only takes into account the matching between the string phase and the RD phase. For waves that enter during RD this is all that is needed. Otherwise, in general, the spectrum is multiplied by the transfer function $T^2\,(f/f_{\rm eq}\,)$, just as we discussed for the slow-roll inflationary spectrum. For $f < f_{\rm eq}$ we then have an extra factor of order $(f_{\rm eq}\,/f)^2$. Thus, just as in slow-roll inflation $h_0^2\Omega_{\rm gw}(f)$ changes from an (almost) flat spectrum at $f \gg f_{\rm eq}$ to a $1/f^2$ behavior at $f < f_{\rm eq}$, in the pre-big-bang scenario $h_0^2\Omega_{\rm gw}(f)$ changes from an f^3 to an f behavior. Of course, this is relevant only if the knee frequency f_s is so low as to be itself comparable to $f_{\rm eq}$, otherwise, at $f < f_{\rm eq}$, $h_0^2\Omega_{\rm gw}(f)$ is anyhow utterly negligible. However, this is the case that would be interesting for detection of this stochastic background from its effect on the CMB. The $\propto f$ behavior of $h_0^2\Omega_{\rm gw}(f)$ at $f \lesssim 10^{-17}$ Hz is visible in the left-most curve of Fig. 22.23.

Despite this wide range of possibilities, the low-frequency behaviors $\propto f$ at $f < f_{\rm eq}$ and $\propto f^3$ at $f_{\rm eq} < f < f_s$ are general properties of this model that depend only on the form of the low-energy effective action, and would therefore be a specific signature of the model. Performing the exact computation one finds that some oscillations are also superimposed on the asymptotic behaviors (22.275), and are visible when the spectrum is plotted on a more narrow range of frequencies; see Fig. 22.24.

The main phenomenological difficulty that must be addressed in this model, to make it a viable competitor with standard slow-roll inflation,

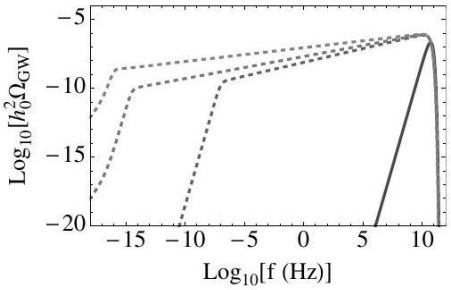

Fig. 22.23 $\Omega_{\rm gw}(f)$ versus f for different values of f_s and μ. From left to right, the curves correspond to $\{f_s = 10^{-16}$ Hz, $\mu = 1.45\}$, $\{f_s = 10^{-14.5}$ Hz, $\mu = 1.42\}$ and $\{f_s = 10^{-7}$ Hz, $\mu = 1.40\}$ (all three dashed), and $f_s = f_1$ (solid line). We set $f_1 = 2.5 \times 10^{10}$ Hz and $h_0^2\Omega_{\rm gw}\,(f_1) = 10^{-6}$.

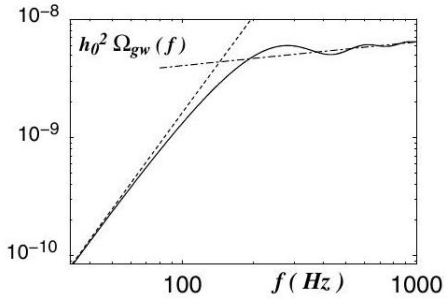

Fig. 22.24$\Omega_{\rm gw}(f)$ versus f for $\mu = 1.4$, $f_s = 100$ Hz and $f_1 = 2.5\times\ 10^{10}$ Hz (solid line). The dashed lines are the the low- and highfrequency limits. From Buonanno, Maggiore and Ungarelli (1997).

[44] There are in principle analogous neutrino asymmetry parameters η_{ν_l}, which, however, have an effect only if they are several orders of magnitude larger than η_B. In standard BBN one assume that this is not the case, for example that η_{ν_l} is of order η_B, in which case they have

a negligible effect, and can be omitted altogether. is the generation of a nearly scale-invariant spectrum of adiabatic perturbations. The simplest mechanism give an unacceptable blue-tilted spectrum of perturbations. However, mechanisms based on the decay of massive axions ("curvaton mechanism") could give a correct spectrum of primordial perturbations; see the Further Reading. In any case, the pre-big-bang model provides an interesting explicit example of how the spectrum of relic GWs can be a signature of alternative early-universe scenarios, as we can appreciate by comparing the pre-big-bang prediction in Fig. 22.23 with the predictions from standard single-field slow-roll inflation in Figs. 21.7 and 21.9.

Several other alternative models addressing the issue of the big-bang singularity have been proposed. Many of them are characterized by an initial contracting phase, leading to Planckian curvatures. At this point the universe bounces back, and the standard phase of expansion follows. Similarly to the pre-big-bang model, the main theoretical problem is the lack of control on the Planckian regime. An example of this family is the ekpyrotic model, which can be described in terms of collision of branes moving in an extra spatial dimension, as well as related cyclic models where the Universe undergoes subsequents phases of contraction, bounce and expansion; see the Further Reading. These models generically predict a strongly blue spectrum, similar to the $f_s = f_1$ case of the pre-big-bang model, shown as a solid line in Fig. 22.23. Once their peak value at high frequency has been normalized so that it does not exceed the nucleosynthesis bound (which we will discuss in Section 22.7), the GW spectrum in these models is therefore completely unobservable at all frequencies at which existing or planned detectors operate.

16.5 22.7 Bounds on primordial GW backgrounds

We next investigate the observational limits on stochastic GW backgrounds of primordial origin that can be obtained from various cosmological observations.

16.5.1 22.7.1 The nucleosynthesis bound

Big-bang nucleosynthesis (BBN) successfully predicts the primordial abundances of deuterium (D), ^{3}He, ^{4}He and ^{7}Li (while heavier elements, up the iron group, are synthesized in stars, and even heavier elements are produced through neutron capture, as we discussed in Section 15.3.4). In the simplest scenario the only cosmological parameter that enters into these predictions is the baryon-to-photon ratio $\eta_B = n_B/n_\gamma$ · [44] The agreement with observation of the prediction for the primordial abundances of these four nuclei (whose abundances span more than nine of orders of magnitude) in terms of a single parameter η_B has long been one of the cornerstones of standard big-bang cosmology. In more recent years, η_B has also been accurately determined by CMB experiments
such as WMAP and Planck, through their determination of the baryon fraction Ω_B. The agreement between the CMB and the BBN determinations of η_B is another remarkable success of the standard cosmological model. In turn, this agreement puts constraints on possible deviations from the standard cosmological model at the BBN epoch. In particular it constraints the existence of extra forms of energy density at the BBN epoch, such as the energy density in GWs or in more exotic components such as primordial black holes, which are not included in the primordial nucleosynthesis computations, and which would spoil the agreement if they were too large.

To physically understand how such a limit comes out, we begin by observing that a crucial quantity in the computations of BBN is the ratio of the number density of neutrons, n_n, to that of protons, n_p. As long as thermal equilibrium is maintained we have (for non-relativistic nucleons, as is appropriate at $T \sim$ MeV, when BBN takes place)

$$\frac{n_n}{n_p} = e^{-Q/T} \tag{22.276}$$

where $Q = m_n - m_p \simeq 1.3\text{MeV}$. Equilibrium is maintained by the process $pe \leftrightarrow n\nu$, as long as its rate $\Gamma_{pe\to n\nu}$ is much larger than the Hubble parameter $H(t)$. When the rate drops below $H(t)$ the process can no longer compete with the expansion of the Universe and the ratio n_n/n_p remains frozen at the value $\exp(-Q/T_\text{f})$, where T_f is the value of the temperature at the time of freeze-out. This number therefore determines the density of neutrons available for nucleosynthesis. Since practically all neutrons available will eventually form ^{4}He, the final primordial abundance of ^{4}He is exponentially sensitive to the freeze-out temperature T_f.

Precise computations of BBN involve detailed numerical studies of the relevant kinetic equations, including a whole series of thermonuclear reactions. However, the main effect of extra contributions to the energy density on T_f can be easily understood analytically by restricting to the process $pe \leftrightarrow n\nu$ and taking for simplicity

$$\Gamma_{pe\to n\nu} \sim G_F^2 T^5 \tag{22.277}$$

(which is really appropriate only in the limit $T \gg Q$). The Hubble parameter is given as usual by the Friedmann equation (17.48), $H^2 = (8\pi/3)G\rho$, where ρ includes all forms of energy density at the time of BBN. BBN takes place deep into the RD phase, but slightly below the MeV scale, when ρ is made up of photons and neutrinos plus any types of extra energy density ρ_extra that might be present, such as, indeed, GWs,

$$\rho = \rho_\gamma + \rho_\nu + \rho_\text{extra} \tag{22.278}$$

The principle of the nucleosynthesis bound is that, since the computation performed with $\rho_\text{extra} = 0$ correctly reproduces the primordial abundances of the light elements, any extra form of energy density present at the time of nucleosynthesis cannot be too large, since otherwise it would
spoil the agreement. To understand the physics involved we must take into account that there are several events that happen at temperatures around an MeV.

First of all, the electron neutrino ν_e decouples from the primordial plasma at $T \simeq 1.9\text{MeV}$ (while ν_μ and ν_τ already decoupled at $T \simeq 3.1\text{MeV}$; see Note 25 on page 383). Subsequently, at $T \simeq 0.3\text{MeV}$, e^+e^-annihilation takes place. As we have discussed in Section 17.5, in a first approximation the entropy of electrons and positrons is transferred uniquely to the photons, whose temperature is thereby raised, compared with the neutrino temperature, by a factor $(11/4)^{1/3}$, as we saw in eq. (17.106). However, neutrino decoupling is not instantaneous, and given that the temperature corresponding to an ideal instantaneous neutrino decoupling is close to the temperature of e^+e^-annihilation, a small fraction of the $e^\pm$entropy actually goes into neutrinos. This, together with a finite-temperature QED effect due to the fact that electromagnetic interactions in the plasma modify the $e^\pm$and γ dispersion relation, actually increases the ratio T_ν/T_γ, compared with the value $(4/11)^{1/3}$. It is customary to take this effect into account by introducing an effective number of neutrino species [see eq. (17.107)], which in the Standard Model with three neutrino families turns out to have the value $N_\text{eff}^{(\nu)} \simeq 3.046$ [see eq. (17.108)].

A third relevant temperature is given by the temperature at which BBN starts. Naively, one would imagine that nucleosynthesis begins, with the formation of deuterium through the process $p + n \to \text{D} + \gamma$, when the temperature drops below the deuterium binding energy, $B_\text{D} \simeq 2.2\text{MeV}$. However, the value of η_B is of order 10^{-9}, so the number density of photons exceeds that of baryons by a factor $\eta_B^{-1} \sim 10^9$. This means that, even at temperatures somewhat below B_D, there are still enough photons in the high-energy tail of the thermal distribution

to destroy the newly formed deuterium nuclei through the inverse process $\mathrm{D} + \gamma \to p + n$. Deuterium production is then delayed (the so-called deuterium bottleneck) until $T \simeq 100\mathrm{keV}$, when the number density of the photons in the energy tail of the thermal distribution has been sufficiently suppressed. Once deuterium begins to form, the whole chain of BBN reactions starts. Thus, because of the deuterium bottleneck, BBN takes place after neutrino decoupling and e^+e^-annihilation, when the neutrino energy density has the form (17.107), with $N_{\rm eff}^{(\nu)} \simeq 3.046$.

To take into account the possible existence of extra energy components, it is convenient to introduce an "effective number of neutrino species" $N_{\rm eff}$, defined so that before e^+e^-annihilation

$$\rho_\nu + \rho_{\rm extra} \equiv \frac{7}{8} N_{\rm eff} \rho_\gamma \tag{22.279}$$

Thus, the addition of an extra component with an energy density equal to that of a massless neutrino would correspond to increasing $N_{\rm eff}$ by one unit, compared with its Standard Model value, but of course in general this is just a way of parametrizing any extra form of energy. To obtain the expression for $\rho_\nu + \rho_{\rm extra}$ just after e^+e^-annihilation we assume
that, similarly to the neutrinos, $\rho_{\rm extra}$ describes a relativistic component, decoupled from the primordial plasma (as would indeed be the case for GWs). Then both ρ_ν and $\rho_{\rm extra}$ scale as $1/a^4$, while the photon temperature evolves according to $g_*^S(T)T^3a^3 = \text{const}$, i.e. constant entropy, so

$$\rho_\gamma \sim T^4 \sim \frac{1}{a^4 \left(g_*^S\right)^{4/3}} \tag{22.280}$$

As we saw in Section 17.5, before e^+e^-annihilation the active degrees of freedoms are the photon (with two helicities), $e^\pm$with two helicities each, and the three neutrinos and three antineutrinos, all with the same temperature. Then, at this epoch, $g_*^S(1\mathrm{MeV}) = 2 + (7/8)(4 + 6) = 43/4$, while, after e^+e^-annihilation, $\left(g_*^S\right)_0 = 43/11$ [see eq. (17.103)], so

$$\frac{\left(g_*^S\right)_0}{g_*^S(1\mathrm{MeV})} = \frac{4}{11} \tag{22.281}$$

Then, just after e^+e^-annihilation (and up to the present epoch, since, neglecting neutrino masses, no other particle becomes non-relativistic in the subsequent evolution),

$$\rho_\nu + \rho_{\rm extra} \equiv N_{\rm eff} \frac{7}{8} \left(\frac{4}{11}\right)^{4/3} \rho_\gamma \tag{22.282}$$

We can then write, after e^+e^-annihilation,

$$\begin{aligned} \rho_{\rm extra} &= \left(N_{\rm eff} - N_{\rm eff}^{(\nu)}\right) \frac{7}{8} \left(\frac{4}{11}\right)^{4/3} \rho_\gamma \\ &\simeq \left(N_{\rm eff} - 3.046\right) \frac{7}{8} \left(\frac{4}{11}\right)^{4/3} \rho_\gamma \end{aligned} \tag{22.283}$$

The Hubble parameter during BBN can be written as

$$\begin{aligned} H^2 &= \frac{8\pi G}{3} \left[1 + N_{\rm eff} \frac{7}{8} \left(\frac{4}{11}\right)^{4/3}\right] \rho_\gamma \\ &= \frac{8\pi G}{3} \left[1 + N_{\rm eff} \frac{7}{8} \left(\frac{4}{11}\right)^{4/3}\right] \frac{\pi^2}{15} T^4 \end{aligned} \tag{22.284}$$

The freeze-out temperature $T_{\rm f}$ is determined by the condition $\Gamma \sim H$, i.e.

$$G_F^2 T_{\rm f}^5 \sim \left(\frac{8\pi^3}{45}\right)^{1/2} \left[1 + N_{\rm eff}\frac{7}{8}\left(\frac{4}{11}\right)^{4/3}\right]^{1/2} \frac{T_{\rm f}^2}{M_{\rm Pl}} \tag{22.285}$$

which gives

$$T_{\rm f} \sim \left(\frac{8\pi^3}{45}\right)^{1/6} \left[1 + N_{\rm eff}\frac{7}{8}\left(\frac{4}{11}\right)^{4/3}\right]^{1/6} \frac{1}{\left(G_F^2 M_{\rm Pl}\right)^{1/3}} \tag{22.286}$$

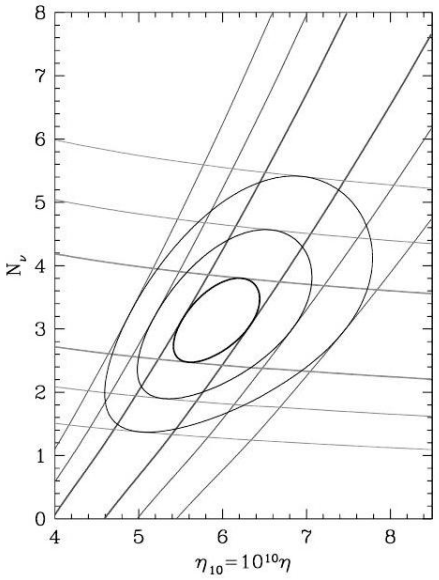

Fig. 22.25 BBN-only constraints on η_B and $N_{\rm eff}$. The nearly vertical curves are the $1\sigma, 2\sigma$ and 3σ limits from D/H, while the nearly horizontal curves are from ^{4}He, and the closed contours combine both. From Cyburt, Fields, Olive and Skillman (2005).

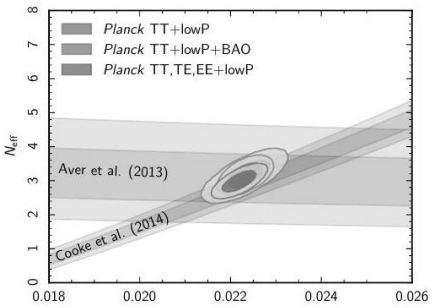

Fig. 22.26 The combined limit in the plane $(N_{\rm eff}\,, \omega_b = h_0^2\Omega_B)$ from Planck+BAO data and BBN. From [Planck Collaboration], Ade et al. (2016a). "Planck 2015 results. XIII. Cosmological parameters". Reproduced with permission (CESO.

We see that any extra form of energy, and in particular an energy density in relic gravitons, results in a larger freeze-out temperature, so more available neutrons and then overproduction of ^{4}He. However, since the density of ^{4}He also increases with the baryon-to-photon ratio η_B, we could compensate for an increase in $N_{\rm eff}$ with a decrease in η_B. Thus, the comparison with ^{4}He alone is not sufficient to put a bound on $N_{\rm eff}$. However, lowering the value of η_B results in an increase in the abundance of D, so this provides a lower limit on η_B. Figure 22.25 shows in particular that the measurements of the abundances of ^{4}He and D/H are nicely complementary for the determination of η_B and $N_{\rm eff}$. Indeed, the ^{4}He fraction has only a very weak (actually,

logarithmic) sensitivity to η_B, but is very sensitive to $N_{\rm eff}$, while for D/H the opposite is the case. Combined together, they already provide a useful bound $N_{\rm eff} < 4.6$ at 95% c.l.

The limit is further improved by adding the value of η_B determined directly by the CMB, as was first done by WMAP and then, with improved accuracy, by Planck. In particular, combining Planck 2015 data from the TT, TE and EE correlators and low-multipole polarization (lowP) data, together with BBN computations of the deuterium abundance, gives

$$N_{\rm eff} = 2.91 \pm 0.37 \tag{22.287}$$

at 95% c.l. (while using helium abundance give a similar value, $N_{\rm eff} = 2.99 \pm 0.39$). The combined contours are shown in Fig. 22.26.

If we use as upper limit the value $N_{\rm eff} = 2.91 + 0.37 = 3.28$, we have $N_{\rm eff} - 3.046 = 0.234$, which we use as the reference value for this quantity. Then, eq. (22.283) reads

$$\rho_{\rm extra}\left(t_{\rm BBN}\right) < 0.053 \left(\frac{N_{\rm eff} - 3.046}{0.234}\right) \rho_\gamma\left(t_{\rm BBN}\right) \tag{22.288}$$

and the energy density in GWs at time of BBN is bounded by $\rho_{\rm gw}\left(t_{\rm BBN}\right) \leqslant \rho_{\rm extra}\left(t_{\rm BBN}\right)$. To obtain a bound on the GW energy density at the present time we observe that, since we have defined $N_{\rm eff}$ in eq. (22.282) in terms of the energy density of neutrinos after e^+e^-annihilation, from this epoch to the present time there is no further change in the effective number of degrees of freedom $g_*(T)$, so the GW energy density scales exactly as the photon energy density. Thus, we get the nucleosynthesis bound at the present time,

$$\frac{\rho_{\rm gw}}{\rho_\gamma} < 0.053 \left(\frac{N_{\rm eff} - 3.046}{0.234}\right) \tag{22.289}$$

Of course this bound holds only for GWs that were already produced at the time of nucleosynthesis, $T \sim 0.1$MeV. It does not apply to stochastic backgrounds produced later, such as backgrounds of astrophysical origin.

Note that this is a bound on the total energy density in GWs, integrated over all frequencies. However, only the frequencies that were inside the horizon at the time of BBN contribute to the expansion of the Universe. The corresponding GW frequency today is obtained from eq. (22.6). We take for definiteness $T \sim 0.1$MeV (corresponding to the onset of BBN after the deuterium bottleneck), so $g_*^S\left(T_*\right) = 43/11$, and we set for definiteness $\epsilon_* = 0.1$, to require that the (reduced) wavelengths are well inside the horizon scale at production. [45] Then this corresponds to GWs that today have a frequency

$$f_{\rm BBN} \simeq 1.5 \times 10^{-11}\ {\rm Hz} \tag{22.290}$$

Writing, as in eq. (7.198) of Vol. 1,

$$\Omega_{\rm gw}(f) = \frac{1}{\rho_c}\frac{d\rho_{\rm gw}}{d\log f} \tag{22.291}$$

and inserting the numerical value $h_0^2\rho_\gamma/\rho_c \simeq 2.473 \times 10^{-5}$ [see eq. (17.110)], eq. (22.289) gives [46]

$$\int_{f=f_{\rm BBN}}^{f=\infty} d(\log f) h_0^2 \Omega_{\rm gw}(f) < 1.3 \times 10^{-6} \left(\frac{N_{\rm eff} - 3.046}{0.234}\right) \tag{22.292}$$

where $\log f$ denotes as usual the natural logarithm, and we have restricted the integral over f to $f > f_{\rm BBN}$. The BBN bound is therefore a bound on the integral of $h_0^2\Omega_{\rm gw}(f)$ for $f > f_{\rm BBN}$, and not directly on $h_0^2\Omega_{\rm gw}(f)$. From the mathematical point of view one could of course imagine

a function $h_0^2\Omega_{\rm gw}(f)$ with a very narrow peak at some frequency f, with a peak value larger than the right-hand side of eq. (22.292), but sufficiently narrow that its contribution to the integral was small enough. However, all cosmological mechanisms that we have discussed rather give a spectrum that, even in the most peaked cases, such as phase transitions, still covers at least one decade in frequency. For such spectra, we can transform the bound in eq. (22.292) into a bound on $h_0^2\Omega_{\rm gw}(f)$, requiring that, if the integral cannot exceed a given value, even its positive-definite integrand $h_0^2\Omega_{\rm gw}(f)$ cannot exceed it over an appreciable interval of frequencies $\Delta \log f \sim 1$, so we can impose

$$h_0^2\Omega_{\rm gw}(f) < 1.3 \times 10^{-6} \left(\frac{N_{\rm eff} - 3.046}{0.234} \right) \quad (\text{ for } f > f_{\rm BBN}) \tag{22.293}$$

This is the meaning of the bound marked as "BBN" in Fig. 22.27 (where we set $N_{\rm eff} - 3.046 = 0.234$). Of course, the precise bound on the spectrum depends on the actual shape of $h_0^2\Omega_{\rm gw}(f)$. For instance if $h_0^2\Omega_{\rm gw}(f)$ has the form

$$h_0^2\Omega_{\rm gw}(f) = \left(h_0^2\Omega_{\rm gw}\right)_* \left(\frac{f}{f_*} \right)^\alpha \tag{22.294}$$

with $\alpha > 0$, for $f_{\rm min} < f < f_{\rm max} \equiv f_*$, and vanishes beyond the cutoff $f_{\rm max}$, then the bound on the peak value $\left(h_0^2\Omega_{\rm gw}\right)_*$ of the spectrum is

$$\begin{aligned} \left(h_0^2\Omega_{\rm gw}\right)_* &< 1.3 \times 10^{-6} \alpha \left[1 - \left(\frac{f_{\rm min}}{f_{\rm max}} \right)^\alpha \right]^{-1} \left(\frac{N_{\rm eff} - 3.046}{0.234} \right) \\ &\simeq 1.3 \times 10^{-6} \alpha \left(\frac{N_{\rm eff} - 3.046}{0.234} \right) \end{aligned} \tag{22.295}$$

[45] There is of course some arbitrariness in the choice $\epsilon_* = 0.1$. In any case ϵ_* must be sufficiently smaller than 1 in order for the bound to apply. Recall in fact from Section 1.4 of Vol. 1 that the energy of GWs is defined only as an average over a volume larger than several wavelengths, so the wavelength must be sufficiently small that the volume used for averaging is at least well inside the Hubble volume. Indeed, we saw in Section 19.5.1 that only when the modes are well inside the horizon can we associate with them an energy density that scales as $1/a^4$.

There is also some arbitrariness in the choice $T \sim 0.1$MeV. BBN is an extended process that lasts from temperatures of a few MeV until temperatures of about 10keV. Certainly GWs that were still outside the horizon at $T = 10$keV, corresponding to $f \simeq 10^{-12}$ Hz, are not bounded by BBN, and those that entered slightly earlier have less of an effect on BBN. So, rather than a sharp cutoff at $f \simeq 10^{-11}$ Hz, one has more precisely a smooth decreases of the effect of GWs, and therefore a less and less stringent bound, as f decreases from $\sim 10^{-10}$ to $\sim 10^{-12}$ Hz.

[46] Observe, from the definition

$$h_0^2\Omega_{\rm gw} = \frac{h_0^2}{\rho_c} \frac{d\rho_{\rm gw}}{d \log f}$$

that $h_0^2\Omega_{\rm gw}$ is independent of h_0, since the explicit factor h_0^2 cancels with the factor h_0^2 that is present in ρ_c. For this reason we prefer to give the bounds in terms of $h_0^2\Omega_{\rm gw}$ rather than $\Omega_{\rm gw}$. This avoids the need to rescale the values of the bounds whenever a more accurate value of h_0 is determined. Furthermore, the determination of h_0 from CMB data assumes the validity of the Λ CDM cosmological model; see Note 16 on page 342. Thus, quoting a result for $\Omega_{\rm gw}(f)$ assuming a value of h_0, such as $h_0 = 0.68$, rather than giving $h_0^2\Omega_{\rm gw}(f)$, introduces a spurious dependence on the cosmological model that, even if numerically small, has nothing to do with the measurement being performed.

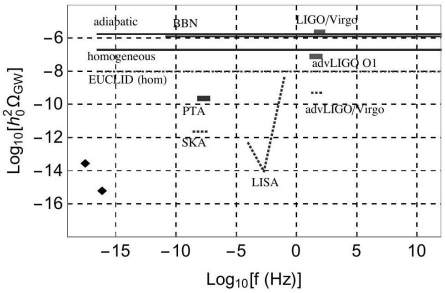

Fig. 22.27 The limits on $h_0^2\Omega_{\rm gw}(f)$ discussed in the text. The solid lines refer to existing (2017) limits, while dashed lines are forecasts for future experiments. The BBN limit is the solid line at $f \gtrsim 1.5 \times 10^{-11}$ Hz. The bound on extra radiation in the CMB from Planck 2015 plus structure formation, for adiabatic initial conditions, is almost superimposed but holds for $f \gtrsim 3 \times 10^{-17}$ Hz, and is labeled "adiabatic". The same bound for homogeneous initial conditions (extrapolated from the bound on adiabatic initial conditions as discussed in Note 47) is labeled "homogeneous". Expectations for EUCLID for homogeneous initial conditions are shown dotted, assuming an improvement by a factor 20 compared with Planck. The CMB limits on r at the pivot scales $k_* = 0.002{\rm Mpc}^{-1}$ and $k_* = 0.05{\rm Mpc}^{-1}$ (corresponding to $f_* = 3.09 \times 10^{-18}$ Hz and 7.73×10^{-17} Hz, respectively) are shown as filled diamonds. The short segments at $f = O(10-100)$Hz show the limit set by initial LIGO/Virgo and the limit set by advanced LIGO in the O1 run. The expectations for the final design of advanced LIGO/Virgo and for LISA are also shown. The present PTA limit (discussed in Section 23.5) is compared with future expectations for the SKA.

where the second equality holds in the limit $(f_{\rm min}/f_{\rm max})^\alpha \ll 1$. Thus the bound on the peak value of the spectrum can be stronger or weaker than eq. (22.293), depending on whether $\alpha < 1$ or $\alpha > 1$, respectively. If $h_0^2\Omega_{\rm gw}(f)$ has a constant value $(h_0^2\Omega_{\rm gw})_*$ between the frequencies $f_{\rm min}$ and $f_{\rm max}$, and is small outside this interval, then eq. (22.292) rather gives

$$\left(h_0^2\Omega_{\rm gw}\right)_* < \frac{1.3\times10^{-6}}{\log\left(f_{\rm max}/f_{\rm min}\right)}\left(\frac{N_{\rm eff}-3.046}{0.234}\right) \tag{22.296}$$

As we have seen in this chapter, the spectrum of some cosmological signals, such as those due to cosmic strings, indeed extends over many decades in frequencies, and in this case the BBN bound is correspondingly more stringent.

16.5.2 22.7.2 Bounds on extra radiation from the CMB

CMB observations provide another sensitive probe of the presence of extra relativistic components, in this case at the time of last scattering. Indeed, extra radiation, such as that due to a fourth relativistic neutrino or to GWs, affects the rate of expansion of the Universe and the epoch of matter-radiation equilibrium, shifting it to a later time, and as a consequence it shifts the position of the acoustic peaks of the CMB. Furthermore, since structure formation can only start in MD, extra radiation delays the start of structure formation. Then, the horizon is larger when structures begin to collapse, and this shifts the peak of the matter power spectrum to larger scales, which can be tested using probes of structure formation, such as galaxy surveys and the Lyman- α forest.

If the GW perturbations are adiabatic, their effect on the CMB is indistinguishable from that of extra neutrinos, and one can therefore immediately apply the bounds on extra massless neutrino families obtained from the CMB. In this case the Planck 2015 data (combining TT, TE, EE and lowP data) together with BAO give $N_{\rm eff} < 3.5$ at 95% c.l. Proceeding as in the derivation of eq. (22.292) we then obtain

$$\int_{f=f_{\rm CMB}}^{f=\infty} d(\log f) h_0^2 \Omega_{\rm gw}(f) < 2.5 \times 10^{-6} \tag{22.297}$$

Combining Planck data with BAO, lensing and the deuterium BBN abundance tightens the bound to

$$\int_{f=f_{\rm CMB}}^{f=\infty} d(\log f) h_0^2 \Omega_{\rm gw}(f) < 1.7 \times 10^{-6} \tag{22.298}$$

which is the value that we plot in Fig. 22.27. The numerical value is therefore of the same order as that from the BBN bound (22.292). However, now the lower limit of the integral is lower, since all modes that were inside the horizon at the epoch of CMB decoupling contribute to the expansion. Putting into eq. (22.6) the value $T_{\rm dec} \simeq 0.26$eV from eq. (17.93) and the corresponding value of g_*, and again setting for definiteness $\epsilon_* = 0.1$, we get

$$f_{\rm CMB} \simeq 3 \times 10^{-17}\ {\rm Hz} \tag{22.299}$$

The bound therefore extends to much lower frequencies, and is shown as the dashed line (marked "adiabatic") in Fig. 22.27. Just as in the case of the BBN bound, it must be recalled that this is actually an integrated bound, and the corresponding bound on $h_0^2 \Omega_{\rm gw}(f)$ becomes stronger for a spectrum that is spread over several decades in frequency, as in eq. (22.296).

As discussed in Section 19.2.1, adiabatic perturbations are defined by the fact that, in the conformal Newtonian gauge, we only have temperature perturbations, so the perturbations in radiation (and therefore, in this case, the perturbations in GWs) are generated by the same temperature fluctuations responsible for matter perturbation. This is not the

[47] See Smith, Pierpaoli and Kamionkowski (2006) and Sendra and Smith (2012). More precisely, using WMAP data the limit is 8.7×10^{-6} for adiabatic perturbations and 1.0×10^{-6} for homogeneous perturbations. With Planck 2015 data the limit on adiabatic perturbations becomes the one in eq. (22.297), while the limit on homogeneous perturbations has not been recomputed. We have drawn the line in Fig. 22.27 assuming that the same factor $\simeq 8.7$ between adiabatic and homogeneous perturbations remains with Planck 2015 data, so this line should only be taken as indicative.

case for any of the GW production mechanism that we have discussed, such as inflation, phase transitions, cosmic strings or pre-big-bang cosmology. For instance, in inflation the initial matter perturbations originate from the decay of the inflaton field at reheating after inflation, while GWs are generated by the amplification of quantum fluctuations during inflation, as discussed in Section 21.3, so the two kind of perturbations are totally unrelated. The same holds for example for the radiation emitted by cosmic string cusps, for which again there is no reason why δ_M should be equal to $(3/4)\delta_{\rm gw}$, or why $\delta_{\rm gw}$ should be equal to δ_γ. As discussed in Section 19.2.1, a second independent type of initial perturbation are isocurvature perturbations, defined by the fact that, in the conformal Newtonian gauge, the total density contrast vanishes. Alternatively, as far as GW perturbations are concerned, we can consider as a second independent component the perturbations whose initial value $(\delta_{\rm gw})_{\rm in} = 0$, i.e. homogeneous initial conditions in the GW field. Because of the source term in eq. (19.39), non-vanishing GW perturbations will anyhow be generated at later times. For such initial conditions the degeneracy with the effect of extra massless neutrinos is broken and, since the CMB is fully consistent with adiabatic initial condition, the resulting bound for homogeneous initial conditions is stronger than that for adiabatic initial conditions, by almost an order of magnitude; see the line labeled "homogeneous" in Fig. 22.27.47 Future CMB experiments, such as EUCLID, could improve these limits by about a factor of 20.

16.5.3 22.7.3 Bounds from the CMB at large angles

We have seen in Chapter 20 that the low- l multipoles of the temperature and polarization anisotropies of the CMB provide an upper bound on the tensor-to-scalar ratio r at a given pivot scale $k_* = 2\pi f_*$. Using eq. (19.290) this translates into an upper bound on $h_0^2\Omega_{\rm gw}(f_*)$. In particular, we saw that CMB experiments typically express their results in terms of an upper bound on $r(k_*)$ at a pivot scale $k_* = 0.05{\rm Mpc}^{-1}$, corresponding to $f_* \simeq 7.73\times 10^{-17}$ Hz; see eq. (21.354). This is slightly larger than $f_{\rm eq} \simeq 3\times 10^{-17}$ Hz [see eq. (19.254)], and we can use the approximation to the transfer function leading to eq. (19.291), apart from a numerical factor close to 1.

At the pivot scale the tensor primordial spectrum (19.281) is simply given by $\mathcal{P}_{T,\,\rm in}(f_*) = A_T(f_*)$, and we write as usual $A_T(f_*) = r(f_*)\,A_{\mathcal{R}}(f_*)$. Then we get

$$h_0^2\Omega_{\rm gw}\left(f = 7.73\times 10^{-17}\ {\rm Hz}\right) \simeq 4\times 10^{-16}\left(\frac{r_{0.05}}{0.1}\right)\left(\frac{A_{\mathcal{R}}(k_{0.05})}{2.14\times 10^{-9}}\right) \tag{22.300}$$

apart from a numerical factor close to 1, which can be obtained from a numerical evaluation of the transfer function. As we saw in eq. (20.332), the current limit on $r_{0.05}$ is $r_{0.05} < 0.12$.

Alternatively, we can use the bound on $r(k_*)$ obtained at the pivot scale $k_* = 0.002{\rm Mpc}^{-1}$, corresponding to $f_* \simeq 3.09\times 10^{-18}$ Hz; see
eq. (21.354). This pivot scale is smaller than $f_{\rm eq}$, so we can use the approximation to the transfer function leading to eq. (19.295), which gives

$$h_0^2\Omega_{\rm gw}(f_*) \simeq 1.87\times 10^{-16}\left(\frac{f_{\rm eq}}{f_*}\right)^2\left(\frac{r(k_*)}{0.1}\right)\left(\frac{A_{\mathcal{R}}(k_*)}{2.14\times 10^{-9}}\right) \tag{22.301}$$

compare with eq. (21.358). In particular, inserting the numerical value $f_* \simeq 3.09\times 10^{-18}$ Hz, we get[48]

$$\begin{aligned} h_0^2\Omega_{\rm gw}\left(f = 3.09\times 10^{-18}\ {\rm Hz}\right) \simeq & 2.4\times 10^{-14}\left(\frac{r_{0.002}}{0.1}\right) \\ & \times\left(\frac{h_0}{0.7}\right)^4\left(\frac{\Omega_M}{0.3}\right)^2\left(\frac{A_{\mathcal{R}}(k_{0.002})}{2.37\times 10^{-9}}\right) \end{aligned} \tag{22.302}$$

The current Planck limit from temperature anisotropies is $r_{0.002} < 0.11$ at 95% c.l. [see eq. (20.331)], while the combined BICEP2/Keck Array/Planck limit from polarization is $r_{0.002} < 0.09$ [see eq. (20.333)].

Observe that the bound on $h_0^2\Omega_{\rm gw}(f)$ at $f = 3.09\times 10^{-18}$ Hz is much weaker than the bound at $f = 7.73\times 10^{-17}$ Hz, despite the fact that the bounds on $r_{0.002}$ and on $r_{0.05}$ are very similar. This is due to the factor $(f_{\rm eq}/f)^2$ that appears in the transfer function at $f \lesssim f_{\rm eq}$. These limits are marked as filled diamonds in Fig. 22.27.

16.5.4 22.7.4 Limits on stochastic backgrounds from interferometers

Correlating the output of different detectors, as discussed in detail in Section 7.8, upper limits on stochastic GW background have been put by the initial LIGO and Virgo interferometers, and have been further improved by advanced LIGO. Assuming a flat spectrum for $\Omega_{\rm gw}(f)$, the limit set in the first advanced LIGO run, in the frequency band $20 - 86$ Hz, is

$$h_0^2\Omega_{\rm gw} < 7.9\times 10^{-8} \quad (95\%\ {\rm c.l}\ ) \tag{22.303}$$

In this frequency range this is better than the bounds from BBN and from the CMB plus structure formation, and also has a different meaning, since it comes from a direct search

for GWs. Thus, it applies not only to stochastic backgrounds that were already present at cosmological epochs, such as those probed by CMB or by BBN, but even to stochastic backgrounds of more recent astrophysical origin, such as those generated by a large number of unresolved BH − BH binaries. Advanced LIGO/Virgo are expected to probe further down to $h_0^2\Omega_{\rm gw} \simeq 5 \times 10^{-9}$ (for a flat spectrum), on a band centered around 30 Hz.

The space-borne interferometer LISA can search for stochastic backgrounds which are not flat in frequency, but rather a broken power-law, such as those due to first-order phase transitions or cosmic strings. For

such spectra, LISA aims at reaching, [49] [48] Recall, from eq. (19.185) and Note 33 on page 624, that $A_{\mathcal{R}} \simeq 2.14 \times 10^{-9}$ is the value measured at the pivot scale $k_* = 0.05{\rm Mpc}^{-1}$. Using the spectral tilt $n_s = 0.9677$ one finds that, at $k_* = 0.002{\rm Mpc}^{-1}$, $A_{\mathcal{R}}(k_*) \simeq 2.37 \times 10^{-9}$. Therefore, in eq. (22.302) we use this as a reference value for $A_{\mathcal{R}}(k_*)$. [49] See the LISA proposal, Audley et al. (2017).

$$h_0^2\Omega_{\rm gw}(f) \simeq 1.3 \times 10^{-11} \left(\frac{10^{-4}\ {\rm Hz}}{f}\right), \quad 0.1{\rm mHz} < f < 20{\rm mHz} \tag{22.304}$$

and

$$h_0^2\Omega_{\rm gw}(f) \simeq 4.5 \times 10^{-12} \left(\frac{f}{10^{-2}\ {\rm Hz}}\right)^3, \quad 20{\rm mHz} < f < 0.2\ {\rm Hz} \tag{22.305}$$

These existing and forecast limits are shown in Fig. 22.27. Finally, we have already mentioned limits on stochastic backgrounds of GWs that can be obtained by pulsar timing arrays (PTAs). We will discuss them in more detail in the next chapter, after having discussed the basic principles of PTAs.

16.6 Further reading

- For reviews of stochastic backgrounds of GWs see Allen (1997) and Maggiore (2000). Reviews of cosmological backgrounds focused on LISA are Binetruy, Bohe, Caprini and Dufaux (2012) and, for cosmological phase transitions, Caprini et al. (2016).

- Parametric resonance and out-of-equilibrium particle production at the end of inflation are discussed by Traschen and Brandenberger (1990), Kofman, Linde and Starobinsky (1994, 1997), Shtanov, Traschen and Brandenberger (1995) and Boyanovsky, de Vega, Holman, Lee and Singh (1995). GW production from preheating in chaotic inflation was first studied by Khlebnikov and Tkachev (1997a, 1997b) and considered again by Easther and Lim (2006). The general formalism for GW production by inhomogeneous random fields and accurate numerical studies of GW production during preheating are presented in Dufaux, Bergman, Felder, Kofman and Uzan (2007), which we have followed in our presentation. Further works include Felder and Kofman (2007) and Easther, Giblin and Lim (2007). Tachyonic preheating in hybrid inflation has been studied in Felder et al. (2001) and Felder, Kofman and Linde (2001). GW production from preheating in hybrid inflation has been studied in Garcia-Bellido and Figueroa (2007), GarciaBellido, Figueroa and Sastre (2008) and Dufaux, Felder, Kofman and Navros (2009), which also contains a useful critical review of earlier literature and a detailed study of parameter space. The pro- duction of GWs from gauge fields at preheating is discussed in Dufaux, Figueroa and Garcia-Bellido (2010).

- The (lack of) electroweak phase transition in the Standard Model for realistic values of the Higgs mass is studied in Kajantie, Laine, Rummukainen and Shaposhnikov (1996a, 1996b). The corresponding crossover temperature is accurately determined, with lattice

simulations, in D'Onofrio and Rummukainen (2016). The addition of a second Higgs doublet or of an extra real scalar singlet can, however, lead to a strong first-order phase transition; see Fromme, Huber and Seniuch (2006) and Barger, Langacker, McCaskey, Ramsey-Musolf and Shaughnessy (2008), respectively. The crossover nature of the QCD phase transition with dynamical quarks (and zero baryon chemical potential) is determined, using lattice QCD, in Aoki, Endrodi, Fodor, Katz and Szabo (2006). The possibility that a large lepton asymmetry could induce a first-order QCD phase transition is discussed in Schwarz and Stuke (2009). The possibility of having a firstorder QCD phase transition thanks to a large preexisting value of μ_B/T, which is later diluted by a short inflationary period at the QCD scale, is discussed in Boeckel and Schaffner-Bielich (2010). Schwaller (2015) discusses the GW production in a first-order phase transition in extensions of the Standard Model with a confining dark sector.

- The theory of decay of false vacuum at finite temperature was developed in classic papers by Cole-
man (1977a) and Callan and Coleman (1977), elaborating on previous work by Voloshin, Kobzarev and Okun (1974), and is reviewed in Coleman (1977b). Instantons and bounces are also discussed in detail in the textbook by Zinn-Justin (2002) and in the review by Vandoren and van Nieuwenhuizen (2008). The extension to finite temperature and the cosmological consequences are studied in particular by Linde (1977, 1981, 1983b). The theory of relativistic bubble combustions is developed in Steinhardt (1982). Bubble nucleation in first-order cosmological phase transitions is studied in Hogan (1983), Turner, Weinberg and Widrow (1992), Anderson and Hall (1992), Enqvist, Ignatius, Kajantie and Rummukainen (1992) and Ignatius, Kajantie, Kurki-Suonio and Laine (1994), and is reviewed in Quiros (1999).

- The fact that a first-order cosmological phase transition can be a powerful source of GWs was first pointed out by Witten (1984) in the context of the QCD phase transition, and was further investigated by Hogan (1986), while Turner and Wilczek (1990) estimated GW production in cosmological bubble collisions in the context of inflation.

The theory of GWs production from bubble collisions in a first-order phase transition was developed in a series of papers by Kosowsky, Turner and Watkins (1992a, 1992b), Kosowsky and Turner (1993) and Kamionkowski, Kosowsky and Turner (1994), using a combination of analytic and numerical techniques. In particular the envelope approximation was proposed in Kosowsky and Turner (1993). The numerical results in the envelope approximation were subsequently refined by Huber and Konstandin (2008b), who also determined the shape of the spectrum near the peak. Jinno and Takimoto (2017) show how to obtain analytic results in the envelope approximation by computing the two-point correlator of the energy-momentum tensor, using the formalism that we have discussed in Section 22.2. Different regimes of bubble evolution are studied in Espinosa, Konstandin, No and Servant (2010). The determination of the parameters α and β in supersymmetric extensions of the Standard Model that could give a first-order phase transition is discussed in Apreda, Maggiore, Nicolis and Riotto (2002) and Huber and Konstandin (2008a, 2008b). The dependence of the peak frequency on the bubble velocity v_b is discussed in Caprini, Durrer, Konstandin and Servant (2009), where it is also pointed out that causality implies $h_0^2\Omega_{\rm gw}(f) \propto f^3$ for super-horizon modes.
In Caprini, Durrer and Servant (2009) it is found that the relevant time-scale is β^{-1} for bubble collisions and $v_b\beta^{-1}$ for turbulence. GW production from bubble collisions and MHD turbulence at the QCD phase transition has been studied in Caprini, Durrer and Siemens (2010). Detailed reviews of the literature are given in Binetruy, Bohe, Caprini and Dufaux (2012), Caprini et al. (2016) and Weir (2017).

- GW production from turbulence was discussed in Kamionkowski, Kosowsky and Turner (1994) and subsequently studied in Kosowsky, Mack and Kahniashvili (2002), Dolgov, Grasso and Nicolis (2002), Caprini and Durrer (2006), Caprini, Durrer and Servant (2009) and Caprini, Durrer and Siemens (2010). GW production from sound waves generated in first-order phase transitions is studied in Hindmarsh, Huber, Rummukainen and Weir (2014, 2015) and Giblin and Mertens (2014).

- Cosmic strings are reviewed in Vilenkin (1985), Hindmarsh and Kibble (1995) and the textbook by Vilenkin and Shellard (2000). The relation of topological defects (such as domain walls and strings) to the topology of the vacuum manifold was discussed in a classic paper by Kibble (1976). The idea that cosmic strings could seed structure formation was proposed by Zeldovich (1980) and Vilenkin (1981a). Our discussion of the string dynamics and NambuGoto action follows Polchinski (1998) and Vilenkin and Shellard (2000). The development of cusps is discussed in Turok (1984). The fact that oscillating loops emit GWs efficiently was first pointed out by Vilenkin (1981b), and has been much studied in the literature; see for example Hogan and Rees (1984), Vachaspati and Vilenkin (1985), Bennett and Bouchet (1988), Caldwell and Allen (1992) and Caldwell, Battye and Shellard (1996). Early work on GWs from cosmic strings is reviewed in Allen (1997). A detailed review of the stochastic GW background from cosmic strings is given in Binetruy, Bohe, Caprini and Dufaux (2012). Numerical simulations of the cosmic string network are discussed in Blanco-Pillado, Olum and Shlaer (2014), where it is found that the network is dominated by large loops with $\alpha \sim 0.1$. The emission of GW bursts from cosmic string cusps was suggested in Berezinsky, Hnatyk and Vilenkin (2000) and studied in detail by Damour and Vilenkin (2000, 2001, 2005). For comparison with experimental sensitivities and existing bounds see also Siemens, Mandic and Creighton (2007) and Olmez, Mandic and Siemens (2010).

- The possibility of production of fundamental strings and D-strings of cosmological size during brane inflation is discussed in Majumdar and Christine-Davis (2002), Jones, Stoica and Tye (2002, 2003), Sarangi and Tye (2002) and Dvali and Vilenkin (2004). Interactions and reconnections between such cosmological-size F- and D-strings is studied in Jackson, Jones and Polchinski (2005).

- The pre-big-bang model was developed in Veneziano (1991), Gasperini and Veneziano (1993a, 1993b, 1994) and Brustein and Veneziano (1994) and is reviewed in Gasperini and Veneziano (2003) and Gasperini (2007). The possibility of obtaining a smooth evolution from the pre-big-bang phase to the post-big-bang era using the α' correction of string theory as well as the string loop corrections is discussed in Gasperini, Maggiore and Veneziano (1997), Brustein and Madden (1998) and Foffa, Maggiore and Sturani (1999). The generation of adiabatic density perturbations in this model can take place through the decay of massive axions, leading to the "curvaton" mechanism, as discussed in Enqvist and Sloth (2002), Lyth and Wands (2002) and Lyth, Ungarelli and Wands (2003); see also Mollerach (1990) and Copeland, Easther and Wands (1997). The spectrum of GWs is computed in Brustein, Gasperini, Giovannini and Veneziano (1995), Brustein, Gasperini and Veneziano (1997) and Buonanno, Maggiore and Ungarelli (1997). Our discussion of the computation of the GW background closely follows Maggiore (2000).

- The ekpyrotic model was proposed in Khoury, Ovrut, Steinhardt and Turok (2001) and Khoury, Ovrut, Seiberg, Steinhardt and Turok (2002). Its cycic extension is discussed in Steinhardt and Turok (2002). The GW spectrum is computed in Khoury, Ovrut, Steinhardt and Turok (2001) and in Boyle, Steinhardt and Turok (2004). For reviews see

Lehners (2008) and Appendix B of Baumann et al. [CMBPol Study Team Collaboration] (2009).

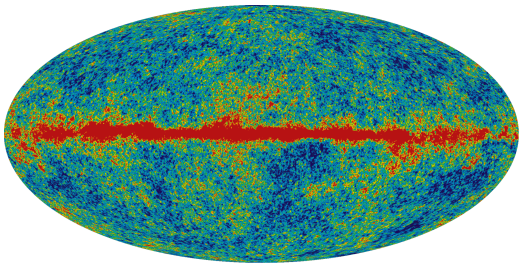
- For reviews of nucleosynthesis and discussions of the BBN bound see Sarkar (1996), Mangano, Miele, Pastor and Peloso (2002), Cyburt, Fields, Olive and Skillman (2005) and Iocco, Mangano, Miele, Pisanti and Serpico (2009). The bound on N_{eff} from Planck is given in Ade et al., [Planck Collaboration] (2016a). The limit of N_{eff} from the effect of extra radiation on the CMB was proposed in Smith, Pierpaoli and Kamionkowski (2006) and updated in Sendra and Smith (2012) and Pagano, Salvati and Melchiorri (2016).
- Limits on stochastic GW backgrounds from the initial LIGO/Virgo interferometers are presented in Aasi et al. [LIGO Scientific and VIRGO Collaborations] (2014). The limit from the O1 run of advanced LIGO is presented in [LIGO Scientific Collaboration and Virgo Collaboration], Abbott et al. (2017a).
- For reviews of stochastic GW background of astrophysical origin see Section 11 of Maggiore (2000) and references therein and, for a more recent discussion, Rosado (2011).

17 Special Models of Cosmology

(пока все остальное тут, потом посмотрим.)

17.1 Cosmic Web

(пока тут, потом мб подниму в приоритете)
(Мб Зельдовича почитаю потом, он вроде про это начал думать.)
(!!!! очень важное применение теории катастроф, кстати, не сложно дожать его!!!)



Cosmic web by Feldbrugge

(мб добавлю его потом статью)
(пока хз, насколько это полезно знать, просто прикольные картинки)

Суть (???)

17.2 Special Models of Cosmology from Landau's Field Theory (??)

(??? I'll add them later, they are not very important)

17.3 Other Special Models

17.3.1 Press–Schechter formalism (???)

пока из Wikipedia, потом подумаю, интересная очень тема, не до нее просто

The Press–Schechter formalism is a mathematical model for predicting the number of objects (such as galaxies, galaxy clusters or dark matter halos[1]) of a certain mass within a given volume of the Universe. It was described in an academic paper by William H. Press and Paul Schechter in 1974.[2]

Background In the context of cold dark matter cosmological models, perturbations on all scales are imprinted on the universe at very early times, for example by quantum fluctuations during an inflationary era. Later, as radiation redshifts away, these become mass perturbations, and they start to grow linearly. Only long after that, starting with small mass scales and advancing over time to larger mass scales, do the perturbations actually collapse to form (for example) galaxies or clusters of galaxies, in so-called hierarchical structure formation (see Physical cosmology).

Press and Schechter observed that the fraction of mass in collapsed objects more massive than some mass M is related to the fraction of volume samples in which the smoothed initial density fluctuations are above some density threshold. This yields a formula for the mass function (distribution of masses) of objects at any given time.

17.3.2 Lyman-alpha forest (???)

In astronomical spectroscopy, the Lyman-alpha forest is a series of absorption lines in the spectra of distant galaxies and quasars arising from the Lyman-alpha electron transition of the neutral hydrogen atom. As the light travels through multiple gas clouds with different redshifts, multiple absorption lines are formed.

The Lyman-alpha forest was first discovered in 1970 by astronomer Roger Lynds in an observation of the quasar 4C 05.34.[1] Quasar 4C 05.34 was the farthest object observed to that date, and Lynds noted an unusually large number of absorption lines in its spectrum and suggested that most of the absorption lines were all due to the same Lyman-alpha transition.[2] Follow-up observations by John Bahcall and Samuel Goldsmith confirmed the presence of the unusual absorption lines, though they were less conclusive about the origin of the lines.[3] Subsequently, the spectra of many other high-redshift quasars were observed to have the same system of narrow absorption lines. Lynds was the first to describe them as the "Lyman-alpha forest".[4] Jan Oort argued that the absorption features are due not to any physical interactions within the quasars themselves, but to absorption inside clouds of intergalactic gas in superclusters.[5]

18 Dark Matter Candidates

(all discussion of this question)

19 Primordial Gravitational Waves

(a special section for them)

20 Black Holes in Cosmology

(a special section for them)

21 Quantum Cosmology: Basics

(see a special note on quantum cosmology for now, there are a lot of theories. I'll write later most basic topics here also)

22 Cosmology from Philosophical Point of View

(general abstract ideas will be here. also, I'll write about ideas which were long time ago about space and Universe)

22.0.1 Other, Exotic Questions

Что на краю Вселенной?

Никто не знает.

Даже можно сказать, что там Чебурашка, потому что никто не сможет это опровергнуть.

23.2 Astrology (???)

(??? I'll discuss, how much sense is in it?)

23.3 What Could be in the Universe if Something Was Different?

(I'll think about some of them, maybe)

24 Cosmological constant by Jérôme Martin

Abstract

This article aims at discussing the cosmological constant problem at a pedagogical but fully technical level. We review how the vacuum energy can be regularized in flat and curved space-time and how it can be understood in terms of Feynman bubble diagrams. In particular, we show that the properly renormalized value of the zero-point energy density today (for a free theory) is in fact far from being 122 orders of magnitude larger than the critical energy density, as often quoted in the literature. We mainly consider the case of scalar fields but also treat the cases of fermions and gauge bosons which allows us to discuss the question of vacuum energy in super-symmetry. Then, we discuss how the cosmological constant can be measured in cosmology and constrained with experiments such as measurements of planet orbits in our solar system or atomic spectra. We also review why the Lamb shift and the Casimir effect seem to indicate that the quantum zero-point fluctuations are not an artifact of the quantum field theory formalism. We investigate how experiments on the universality of free fall can constrain the gravitational properties of vacuum energy and we discuss the status of the weak equivalence principle in quantum mechanics, in particular the Collela, Overhausser and Werner experiment and the quantum Galileo experiment performed with a Salecker-Wigner-Peres clock. Finally, we briefly conclude with a discussion on the solutions to the cosmological constant problem that have been proposed so far.

Everything You Always Wanted To Know About The Cosmological Constant Problem (But Were Afraid To Ask)

24.1 Introduction

This review article aims at discussing the cosmological constant problem [1819, 451, 3, 4, 5, 6, 449, 8, 1393, 10, 11, 12, 508, 14, 15]. This question is central in modern physics because its resolution would certainly mean a very important step forward in our attempts to understand physics beyond the current standard model.

The history of the cosmological constant problem is a long and rich one [5]. Its premises were in fact already present immediately after the birth of quantum field theory. Indeed, from the Heisenberg uncertainty principle, we know that the ground state energy of the quantum mechanical oscillator cannot be zero because the potential and the kinetic energies cannot

vanish at the same time. Since a (free) quantum field can be viewed as an infinite collection of harmonic oscillators, it immediately comes that its ground state energy must be infinite. Of course, this is not yet the cosmological constant problem because gravity does not enter the stage. But, clearly, potentially, a very severe problem is already present.

The infinity mentioned above is the first infinity that one encounters in quantum field theory [16, 17, 18, 19, 20, 21, 22]. However, the presence of this infinity did not prevent the founding fathers of quantum field theory to develop the theory since, in absence of gravity (a working assumption of quantum field theory justified by the weakness of gravity), only differences in energies are observable. Therefore, in this context, this infinity can be merely ignored and the rest of the formalism can be worked out without any problem. As is well-known, other types of infinities appear and, this time, there is no way to get around them. Treating and taming them is the goal of renormalization. The very impressive agreement between high precision measurements in accelerators and the predictions of quantum field theory in presence of radiative corrections is the proof that renormalization is able to correctly regulate these infinities.

Therefore, we see that these two types of infinities are treated very differently. The problem of the zero-point energy is just avoided while the problem of the radiative corrections is directly and explicitly addressed. Clearly, one cannot help thinking that the first problem is in fact swept under the carpet. And, indeed, as soon as gravity is turned on, it badly strikes back.

At this point, it is worth noticing the following. One should not get the impression that the zero-point energy cannot be renormalized. As a matter of fact, as will be discussed in this review, it can be made perfectly finite. However, this finite, renormalized, value of the zero-point energy seems to be too large to be compatible with the observations. Again, this is very different from the usual case of quantum field theory where the finite part extracted from a divergent expression always leads to a good agreement with the experiments. At first sight, the cosmological constant problem is therefore neither the presence of a new infinity nor our inability to regularize it but rather the apparent failure of the renormalization scheme to produce, at the quantitative level, a finite vacuum energy compatible with the observational data.

In fact, a failure of renormalization is not the only logical possibility. The vacuum fluctuations could also be a mathematical artifact of the quantum field theory framework and/or their gravitational properties could be abnormal. However, when one tries to test (theoretically or experimentally) these ideas, it seems that one never encounters a problem of the kind mentioned above. This fact must also be considered as a part of the cosmological constant problem which, therefore, appears to have many different ramifications. We see that this problem is in fact a very deep problem which lies at the cross roads between different branches of physics (gravitational physics, quantum field theory, cosmology etc ...). In brief, it has to do with the gravitational properties of the quantum vacuum.

The importance of this question has recently been reinforced by the discovery that the expansion of our Universe is accelerated [1445, 1524]. According to the standard lore, this could be the first observational evidence that the quantum vacuum is able to curve space-time. On the other hand, the effect of a cosmological constant is visible only on large scales and, therefore, it seems to be problematic to check this result elsewhere than in cosmology. But, if true, the cosmological constant problem represents a unique situation where some aspects of quantum gravity are at play and where, at the same time, corresponding observational signatures are not hopelessly beyond our technical capabilities. This makes it a valuable opportunity to go beyond our current understanding of theoretical physics. The only other situation where the three above mentioned aspects (quantum mechanics, gravity and the possibility to detect sizable observational effects) are mixed is the theory of cosmological inflation [260, 119, 205, 170, 206, 261, 121, 130, 15, 171] (for a review, see Refs. [35, 36, 37]) where the Cosmic Microwave

Background (CMB) anisotropies, first detected by the COBE (COsmic Background Explorer) satellite [38], are supposed to originate from the quantum fluctuations of the inflation and gravitational fields (for the observational status of inflation, see Ref. [39]).

In this review article, we go through all the issues mentioned before. Our prejudice is to present the question at the technical level, in full details, in order for the paper to be reasonably self-contained. The price to pay for this approach is that, sometimes, we are led to consider problems that are well treated in standard textbooks and/or are not, strictly speaking, directly concerned with the cosmological constant problem. On the other hand, this is also an opportunity to review many different subjects belonging to different types of physics.

The outline of the article is the following one. In Sec. 24.2, we discuss how the cosmological constant Λ is introduced in the Einstein field equations and we explain why the vacuum energy also participates in the value of Λ. In Sec. 24.3, we treat the classical cosmological constant problem, *i.e.* we show that, in the presence of gravity, it is no longer true that only differences of energy are observable. We illustrate this discussion by means of the electro-weak phase transition. In Sec. 24.4, we demonstrate that, even if the classical ground state is tuned to zero, the quantum vacuum fluctuations still give a contribution to the cosmological constant. We discuss how the corresponding quantum vacuum energy can be calculated and argue that the method often used in the literature and which consists in introducing a cut-off, is not appropriate. We also investigate how the quantum vacuum energy can be expressed in terms of Feynman diagrams (bubble diagrams) and investigate the case where interactions are present. In Sec. 24.5, we focus on the so-called bubble diagrams. We discuss them in the context of quantum field theory but also in ordinary quantum mechanics. We then show that they have very different properties than the other loop diagrams. In Sec. 24.6, we use the Gaussian effective potential approach to calculate the vacuum energy in a situation where non perturbative effects are present. Since all the calculations are carried out in the case of a scalar field, we treat in Sec. 24.7 the case of other types of fields (spinor and vector fields). This also gives us the opportunity to discuss the idea of super-symmetry. In Sec. 24.8, we present the cosmological constant problem in a more rigorous way. In particular, we show that a flat space-time calculation is a good approximation although a fully consistent approach should be formulated in curved space-time. One concludes the first part of this review article with Sec. 24.9 where we estimate the vacuum energy and find a value very far from the often quoted "122 orders of magnitude". In Sec. 24.10, we explain, from a theoretical point of view, how the value of the cosmological constant was recently measured in cosmology. In particular, we discuss the hypothesis that are implicitly assumed in order to obtain this result. In Sec. 24.11, we discuss whether the cosmological constant can be measured elsewhere than in cosmology and argue that no other experimental context can compete with cosmology. However, we also show that other experiments can put constraints on the vacuum energy that are interesting from the point of view of the cosmological constant problem. In Sec. 24.12, we review the experiments (Lamb shift, Casimir effect) that seem to prove the existence of the vacuum fluctuations. In Sec. 24.13, we investigate whether there are observations that can probe their gravitational properties. In Sec. 24.14, we discuss whether the weak equivalence principle still holds in quantum mechanics since this has obvious implications for the question of the vacuum weight. Finally, in Sec. 28.11, we present our conclusions and very briefly review the solutions to the cosmological constant problem that have been proposed so far. Let us mention that this article is part of a more general review on the dark energy question, see Refs. [40, 41, 42, 43].

Before concluding this introduction, we would like to make the following remark. This article aims at discussing what the cosmological constant problem is. This article does not aim at discussing what solutions to this problem have been proposed even if, as already mentioned, in Sec. 28.11, we say a few words on this topic (and choose, in a totally arbitrary way which only reflects the author prejudices, to focus more on some of them). The justification for the

above mentioned choice is that the question of the gravitational properties of vacuum zero-point fluctuations is already a highly non-trivial one as the variety of the subjects listed above demonstrate. Therefore, it seems to us better to deeply understand what is at play before trying to propose a way out. Of course, it is because this problem is very difficult and has many different ramifications in many different branches of physics that it is so interesting.

24.2 The Cosmological Constant

In this first section, we introduce the cosmological constant as a free parameter in the classical action of the gravitational field. This action, together with the action describing matter, can be expressed as

$$S = \frac{1}{2\kappa}\int \mathrm{d}^4x\sqrt{-g}\,(R-2\Lambda_{\mathrm{B}}) + S_{\mathrm{matter}}\left[g_{\mu\nu},\Psi\right], \tag{297}$$

where $\kappa \equiv 8\pi G/c^4 \equiv 8\pi/m_{\mathrm{Pl}}^2 \equiv 1/M_{\mathrm{pl}}^2$, m_{Pl} and M_{pl} being the Planck mass and the reduced Planck mass respectively. The first term is the standard Einstein-Hilbert action and represents the gravitational part of the total action given by Eq. (297). The cosmological constant appears in the second term of the above expression. As announced, at this level, it is merely a new parameter of the total action and for this reason we write it as Λ_{B} for "bare cosmological constant". It has the dimension of the inverse of a square length. It is compatible with general covariance and is of course compatible with a conserved energy momentum tensor since $\nabla^\mu g_{\mu\nu} = 0$. Therefore, this term appears to be totally natural from the relativistic point of view and there is a priori no reason to discard it. Since, according to the standard lore of field theory, everything which is not forbidden should be considered, the cosmological constant should clearly be included in our description of the gravitational field. Finally, the third term in the above equation denotes the matter action where Ψ represents a generic matter field that we do not need to specify at this stage. Variation of the total action with respect to the metric tensor leads to the Einstein equations of motion which read

$$R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} + \Lambda_{\mathrm{B}}g_{\mu\nu} = \kappa T_{\mu\nu}\,, \tag{298}$$

where the stress-energy tensor is defined by

$$T_{\mu\nu} = -\frac{2}{\sqrt{-g}}\frac{\delta S_{\mathrm{matter}}}{\delta g^{\mu\nu}}\,. \tag{299}$$

As already mentioned, Λ_{B} appears to be just a parameter of the model. At this level, the only thing that can be done is to try to constrain it using various observations. But, clearly, in the present framework, there is no way to calculate its value from more fundamental considerations.

However, as originally shown by Sakharov [1563], the nature of the discussion is crucially changed when one takes into account quantum field theory. The point is that the stress energy tensor of a field placed in the vacuum state must be given by

$$\langle 0|T_{\mu\nu}|0\rangle = -\rho_{\mathrm{vac}}g_{\mu\nu}, \tag{300}$$

where ρ_{vac} is the constant energy density of the vacuum. This equation is valid for all the fields present in the Universe, as will be shown below. There are several ways to prove the above result. Firstly, one can use the fact that, in flat space-time (in Minkowski space-time), the only invariant tensor is $\eta_{\mu\nu}$. Since the vacuum state must be the same for all observers, one necessarily has $\langle T_{\mu\nu}\rangle \propto \eta_{\mu\nu}$. In curved space-time, this means that

$$\langle T_{\mu\nu}\rangle = -\rho_{\mathrm{vac}}(t,\mathbf{x})g_{\mu\nu}, \tag{301}$$

and from the fact that the stress-energy tensor must be conserved, we reach the conclusion that ρ_{vac} must be a constant. Therefore, one obtains the formula shown above.

Another way to obtain the same result is to consider a specific example, for instance a scalar field Φ. The corresponding action reads

$$S_{\Phi} = -\int \mathrm{d}^4x\sqrt{-g}\left[\frac{1}{2}g^{\mu\nu}\partial_\mu\Phi\partial_\nu\Phi + V(\Phi)\right]. \tag{302}$$

where $V(\Phi)$ is the potential. Using the definition (299), the corresponding stress-energy tensor can be written explicitly as

$$T_{\mu\nu} = \partial_\mu\Phi\partial_\nu\Phi - g_{\mu\nu}\left[\frac{1}{2}g^{\alpha\beta}\partial_\alpha\Phi\partial_\beta\Phi + V(\Phi)\right]. \tag{303}$$

From this expression, one sees that the scalar field is in fact a perfect fluid. Now, the vacuum state is the minimum energy state. Clearly, in order to minimize the energy we have to consider a situation where the kinetic energy vanishes and where the field sits at the minimum of its potential. In this case, the stress energy tensor reduces to

$$\langle T_{\mu\nu}\rangle = -V(\Phi_{\text{min}})g_{\mu\nu}, \tag{304}$$

which has exactly the expected form with $\rho_{\text{vac}} = V(\Phi_{\text{min}})$.

In fact what was shown before is that there are at least two sources for the vacuum energy. There is a "classical" contribution given by Eq. (304) which originates from the value of the potential at its minimum. The corresponding vacuum energy will be calculated in Sec. 24.3. There is also a "quantum-mechanical" source given by Eq. (301) which originates from the zero point fluctuations of the ground state. This problem will be treated in Sec. 24.4.

Having established the form of the stress energy momentum tensor in the vacuum, one can now proceed with the Sakharov argument. The next step consists in assuming that the equivalence principle applies to the zero-point fluctuations (here, and from now on, we mean to the "classical" and "quantum-mechanical" contributions as discussed in the last paragraph), that is to say that the zero-point fluctuations gravitate. Clearly, this is not a trivial step but, after all, the vacuum fluctuations are just a specific type of energy and, in general relativity, all forms of energy gravitate. Therefore, a consistent way of writing the Einstein equations when quantum field theory is taken into account seems to be

$$R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} + \Lambda_{\text{B}}g_{\mu\nu} = \kappa T^{\text{matter}}_{\mu\nu} + \kappa\langle T_{\mu\nu}\rangle\,, \tag{305}$$

where on the right hand side the first contribution comes from ordinary matter while the second one represents the contribution originating from the vacuum (of course, it is to be understood that we sum up the contributions coming form all the fields present in the universe). Using the form of $\langle T_{\mu\nu}\rangle$ established before, one arrives at

$$R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} + \Lambda_{\text{eff}}g_{\mu\nu} = \kappa T^{\text{matter}}_{\mu\nu}\,, \tag{306}$$

where

$$\Lambda_{\text{eff}} = \Lambda_{\text{B}} + \kappa\rho_{\text{vac}}. \tag{307}$$

Therefore, we conclude that the effective cosmological constant is the sum of the bare cosmological constant and of a contribution originating from the vacuum fluctuations. The effective cosmological constant Λ_{eff} is the quantity that one can observe and constrain when tests of the Einstein equations are carried out.

As we now discuss, the problem is that $\kappa\rho_{\text{vac}}$ is made of several terms which are all huge in comparison with the observed value of Λ_{eff}.

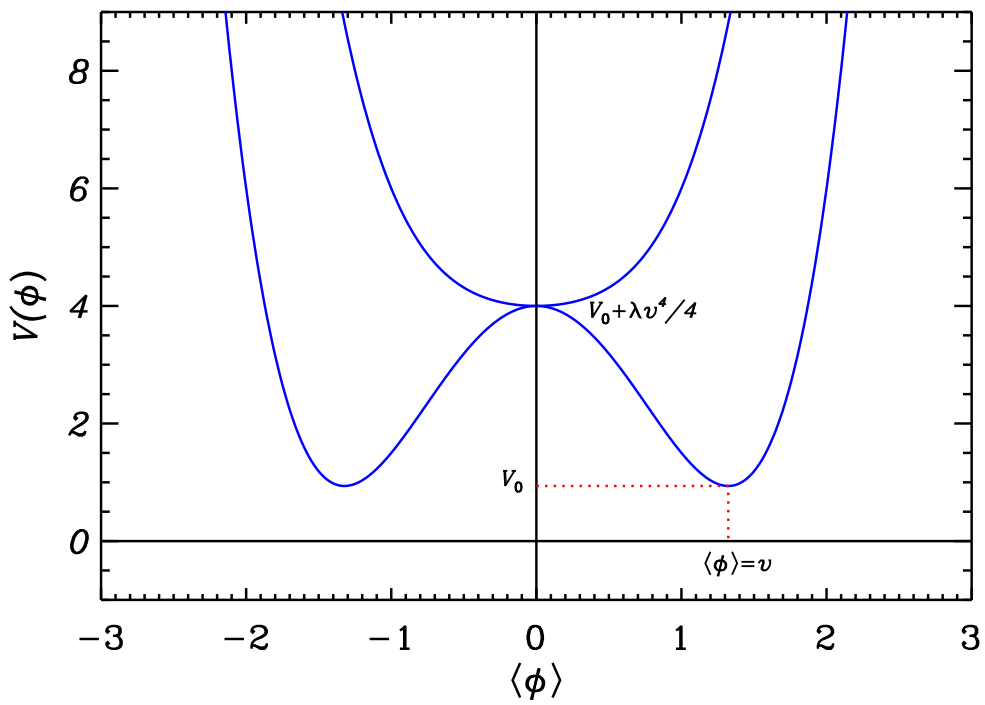

Figure 153: The effective potential given by Eq. (310). Before the transition, for $T > T_{\rm cri}$, the minimum of the potential is located at the origin and the vacuum energy is given by $V_0 + \lambda v^4/4$. After the transition, for $T < T_{\rm cri}$, the minimum is located at $\Phi = v$ and the corresponding vacuum energy has changed and now equals V_0. It is clear that V_0 can always be chosen such that the vacuum energy vanishes either before or after the transition. It is equally clear that one cannot choose the parameters of the potential such that $\rho_{\rm vac}$ is zero before and after the phase transition.

24.3 The Classical Cosmological Constant Problem

The cosmological constant problem is in fact a multi facets question as the quantity $\Lambda_{\rm eff}$ receives contributions from different origins. As was demonstrated in the last section on the example of a scalar field, a classical contribution to $\Lambda_{\rm eff}$ comes from the value of the potential at its minimum. If this is not zero, then it affects the value of the effective cosmological constant. This point is discussed in this section and is exemplified with the electroweak transition. Another contribution comes from the quantum zero point fluctuations but this will be discussed in the next sections.

24.3.1 Phase Transition

It is possible to study the dynamics of a phase transition with the help of the following simple model. Let us consider a scalar field Φ in interaction with another scalar field Ψ such that

$$V(\Phi,\Psi) = V(\Phi) + \frac{\bar{g}}{2}\Phi^2\Psi^2, \tag{308}$$

where $\bar{g}$ is a dimensionless coupling constant and where the self-interacting potential is given by

$$V(\Phi) = V_0 + \frac{\lambda}{4}\left(\Phi^2 - v^2\right)^2, \tag{309}$$

λ being a coupling constant describing the self-interaction and v the value of the scalar field at the minimum of its potential in absence of an interaction with Ψ. The quantity V_0 denotes the classical off-set. If the field Ψ is in thermal equilibrium, then one is entitled to replace Ψ^2 with $\langle\Psi^2\rangle_T$ where the average is taken in a thermal state with temperature T. Since $\langle\Psi^2\rangle_T \propto T^2$ [45], the effective potential becomes

$$V_{\rm eff}(\Phi) = V_0 + \frac{\lambda}{4}\left(\Phi^2 - v^2\right)^2 + \frac{\bar{g}}{2}T^2\Phi^2, \tag{310}$$

where we have slightly redefined the coupling constant $\bar{g}$ in order to take into account the proportionality constant between the thermal average and the temperature. This potential can also be expressed as

$$V_{\rm eff}(\Phi) = V_0 + \frac{\lambda v^4}{4} + \frac{\lambda v^2}{2}\left(\frac{T^2}{T_{\rm cri}^2} - 1\right)\Phi^2 + \frac{\lambda}{4}\Phi^4, \tag{311}$$

where we have defined $T_{\rm cri} = v\sqrt{\lambda/\bar{g}}$. One sees on the above equation that the interaction with the field Ψ gives a temperature dependence to the effective mass of the Φ field, namely

$$m_{\rm eff}^2(T) \equiv \lambda v^2\left(\frac{T^2}{T_{\rm cri}^2} - 1\right). \tag{312}$$

As a consequence, when $T > T_{\rm cri}$, that is to say before the transition, the square of the effective mass is positive while, after the transition, when $T < T_{\rm cri}$, it becomes negative. In the first situation, the minimum is located at $\Phi = 0$ and the corresponding value of the vacuum energy is $V_0 + \lambda v^4/4$, see Fig. 153. In the second situation, the minimum is located at $\Phi = v$ and the off-set is simply given by V_0, see Fig. 153. We now clearly see the problem. If we require the vacuum energy to vanish before the transition, we must choose $V_0 = -\lambda v^4/4$. But, then, after the transition, the vacuum energy is no longer zero and is given by the negative value $\rho_{\rm vac} = -\lambda v^4/4$. On the other hand, one can choose $\rho_{\rm vac}$ to vanish after the transition. In this case, one must choose $V_0 = 0$. But this means that it was not zero before the transition, $\rho_{\rm vac} = \lambda v^4/4$. This last option can maybe viewed as the preferred solution since we do not have direct observational constraints on the matter content of the universe prior to Big Bang Nucleosynthesis (BBN). Anyhow, we see that the choice of a parameter in the potential allows us to change the vacuum energy at the classical level, hence the name "classical cosmological constant problem". But, clearly, the off-set cannot be zero before and after the transition. Of course, in order to really establish that there is a problem, the question remains to estimate this vacuum energy for realistic phase transition and to compare it with the observational constraints. In the next subsection, we turn to the first issue and consider the case of the electroweak phase transition.

24.3.2 The Electro-weak Phase Transition

In this section, we calculate the vacuum energy "induced" by the electroweak phase transition. In order to achieve this goal, we first must recall some basics facts about the standard model of particle physics, see Refs. [16, 17, 18, 19, 20, 21, 22].

The Higgs field is a doublet of complex scalar fields. It is charged under the group $\mathrm{U(1)_Y} \times \mathrm{SU(2)_L}$ characterized by two coupling constant g' and g. The Higgs field Lagrangian reads

$$\mathcal{L}_{\rm Higgs} = -\left(D_\mu\Sigma\right)^\dagger D^\mu\Sigma - V\left(\Sigma, \Sigma^\dagger\right), \tag{313}$$

where the covariant derivative can be expressed as

$$D_\mu\Sigma = \partial_\mu\Sigma + i\frac{g'}{2}Y_{\rm H}B_\mu\Sigma + igT_aW_\mu^a\Sigma, \tag{314}$$

where a runs from one to three. The quantities B_μ and W_μ^a are the gauge bosons, Y_{H} is the Higgs weak hyper-charge and T_a are the generators of the SU(2) group (see below for more details about these quantities). The potential is chosen to be

$$V\left(\Sigma,\Sigma^\dagger\right)=\frac{m^2}{2}\Sigma^\dagger\Sigma+\frac{\lambda}{4}\left(\Sigma^\dagger\Sigma\right)^2, \tag{315}$$

and clearly resembles Eqs. (310) and (311) for $T<T_{\text{cri}}$. Indeed, in this expression, the quantity m^2 is negative (as explained before, m^2 is in fact the square of the effective mass). This also means that the minimum of the potential is not located at $\langle\Sigma\rangle=0$ but at

$$\langle\Sigma\rangle=v=\sqrt{-\frac{m^2}{\lambda}}, \tag{316}$$

obtained from the condition $\partial V/\partial\left(\Sigma^\dagger\Sigma\right)=0$. The quantity v is in fact the new vacuum expectation value of the Higgs after spontaneous symmetry breaking. In particle physics, one studies the theory after the transition, when the Higgs field has stabilized at its new minimum. But, in reality, as explained before, we must consider that the transition is a dynamical process. Before the transition we had $m^2>0$ and the minimum was located at $\langle\Sigma\rangle=0$ and after the transition, m^2 has become negative and, consequently, the new vacuum is given by v. Returning to the minimum after the transition, it is easy to show that the value of the potential at $\langle\Sigma\rangle=v$ is given by

$$V\left(\langle\Sigma\rangle=v\right)=-\frac{m^4}{4\lambda}, \tag{317}$$

and is negative. Clearly, this is because we have chosen $V_0=0$ in Eq. (315). As already explained in Sec. 24.3.1, this means that the vacuum energy vanishes before the transition and becomes negative after, see also Fig. 153. This means that we have considered the situation corresponding to the left panel in Fig. 154. Of course, this is arbitrary and we could also have considered the situation corresponding to the right panel in Fig. 154. Again, as explained in the previous subsection, in this case, the vacuum energy would vanish after the transition but not before.

The numerical value of the vacuum energy given by Eq. (317) is fixed by the electroweak physics in particular by the parameters m and λ. Therefore, in order to compute ρ_{vac} explicitly, we must explain how m and λ are evaluated. For this purpose, we now briefly recall the main features of the standard model of particle physics. Let us come back to the Higgs Lagrangian given at the beginning of this section, see Eq. (313). In the expression of $\mathcal{L}_{\text{Higgs}}$, the quantities T_a are the generator of $\text{SU}(2)_{\text{L}}$ and are given by $T_a=\sigma_a/2$ where σ_a are the Pauli matrices

$$\sigma_1=\begin{pmatrix}0&1\\1&0\end{pmatrix},\quad \sigma_2=\begin{pmatrix}0&-i\\i&0\end{pmatrix},\quad \sigma_3=\begin{pmatrix}1&0\\0&-1\end{pmatrix}. \tag{318}$$

Using the gauge invariance, one can always rewrite the complex doublet as

$$\Sigma=\left(v+\frac{H}{\sqrt{2}}\right)\begin{pmatrix}0\\1\end{pmatrix}, \tag{319}$$

where H is a real scalar field, the "Higgs boson". Therefore, the covariant derivative (314) can be expressed as

$$D_\mu\Sigma=\begin{pmatrix}i\dfrac{g}{2}\left(v+\dfrac{H}{\sqrt{2}}\right)\left(W_\mu^1-iW_\mu^2\right)\\[2ex]\dfrac{1}{\sqrt{2}}\partial_\mu H+i\left(v+\dfrac{H}{\sqrt{2}}\right)\left(\dfrac{g'}{2}Y_{\text{H}}B_\mu-\dfrac{g}{2}W_\mu^3\right)\end{pmatrix}, \tag{320}$$

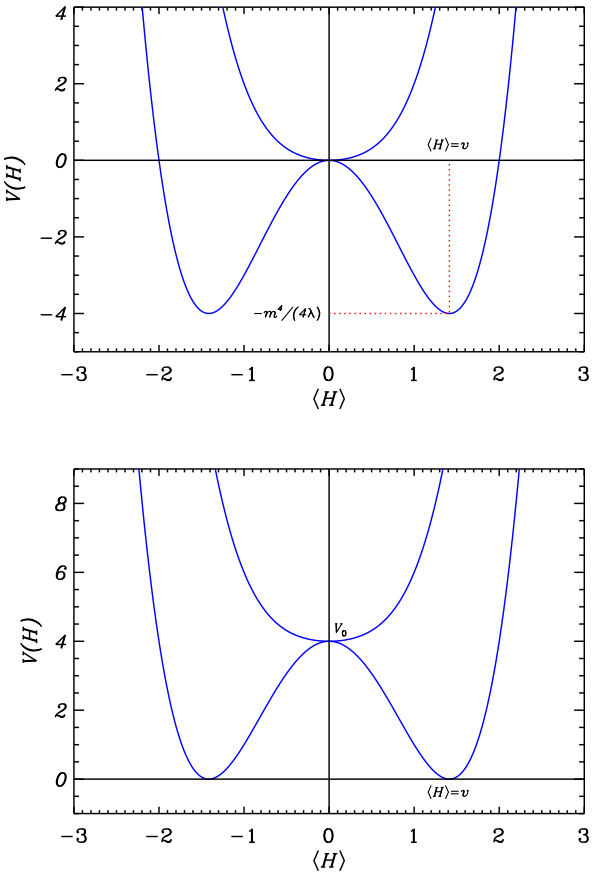

Figure 154: Effective potential of the Higgs boson before and after the electroweak phase transition. The left panel corresponds to a situation where the vacuum energy vanishes at high temperature. As a consequence $\rho_{\rm vac}$ is negative at temperature smaller than the critical temperature. This is the situation treated in the text where the quantity $-m^4/(4\lambda)$ is explicitly calculated. On the right panel, the off-set parameter V_0 is chosen such that the vacuum energy is zero after the transition. As a consequence, it does not vanish at high temperatures.

and the Higgs Lagrangian (313) becomes

$$\begin{aligned}\mathcal{L}_{\text{Higgs}} &= -\frac{1}{2}\partial_\mu H\partial^\mu H - V\left(\Sigma,\Sigma^\dagger\right) - \left(v^2+\sqrt{2}vH+\frac{1}{2}H^2\right)\left(\frac{g^2}{4}W^1_\mu W^{1\mu}+\frac{g^2}{4}W^2_\mu W^{2\mu}+\frac{g^2}{4}W^3_\mu W^{3\mu}\right.\\ &\left.+\frac{g'^2}{4}Y_{\text{H}}^2 B_\mu B^\mu - \frac{gg'}{2}Y_{\text{H}} B_\mu W^{3\mu}\right),\end{aligned} \tag{321}$$

where the scalar potential can be written as

$$V\left(\Sigma,\Sigma^\dagger\right) = -\frac{\lambda v^4}{4}+\frac{1}{2}\lambda v^2 H^2+\frac{\lambda}{2}\frac{v}{\sqrt{2}}H^3+\frac{\lambda}{16}H^4. \tag{322}$$

We now introduce the physical gauge bosons. As is well-known, they are defined by

$$B_\mu = -\sin\theta Z_\mu+\cos\theta A_\mu\,,\quad W^3_\mu = \cos\theta Z_\mu+\sin\theta A_\mu\,,\quad W^2_\mu = \frac{W^+_\mu - W^-_\mu}{i\sqrt{2}}\,,\quad W^1_\mu = \frac{W^+_\mu+W^-_\mu}{\sqrt{2}}\,, \tag{323}$$

where θ is the Weinberg angle, A_μ represents the photon and Z_μ, $W^\pm_\mu$ the massive gauge bosons. Expressing the Higgs Lagrangian (321) in terms of these new fields, one obtains the following expression

$$\begin{aligned}\mathcal{L}_{\text{Higgs}} &= -\frac{1}{2}\partial_\mu H\partial^\mu H - V\left(\Sigma,\Sigma^\dagger\right) - \left(v^2+\sqrt{2}vH+\frac{1}{2}H^2\right)\left[\frac{g^2}{4}W^+_\mu W^{-\mu}+\frac{g^2}{4}W^-_\mu W^{+\mu}\right.\\ &+Z_\mu Z^\mu\left(\frac{g^2}{4}\cos^2\theta+\frac{g'^2}{4}Y_{\text{H}}^2\sin^2\theta+\frac{gg'}{2}Y_{\text{H}}\sin\theta\cos\theta\right)+A_\mu A^\mu\left(\frac{g^2}{4}\sin^2\theta+\frac{g'^2}{4}Y_{\text{H}}^2\cos^2\theta-\frac{gg'}{2}Y_{\text{H}}\sin\theta\cos\theta\right)\\ &\left.+Z_\mu A^\mu\left(\frac{g^2}{2}\cos\theta\sin\theta-\frac{g'^2}{2}Y_{\text{H}}^2\cos\theta\sin\theta-\frac{gg'}{2}Y_{\text{H}}\cos^2\theta+\frac{gg'}{2}Y_{\text{H}}\sin^2\theta\right)\right].\end{aligned} \tag{324}$$

Of course $\mathcal{L}_{\text{Higgs}}$ is not the only term in the standard model Lagrangian. There are also the terms describing the kinetic terms of the gauge fields

$$\mathcal{L}_{\text{K-Gauge}} = -\frac{1}{4}B_{\mu\nu}B^{\mu\nu}-\frac{1}{4}W_{a\mu\nu}W^{a\mu\nu} = -\frac{1}{4}A_{\mu\nu}A^{\mu\nu}-\frac{1}{4}Z_{\mu\nu}Z^{\mu\nu}-\frac{1}{4}W_{+\mu\nu}W^{+\mu\nu}-\frac{1}{4}W_{-\mu\nu}W^{-\mu\nu}+\cdots\,, \tag{325}$$

where $B_{\mu\nu}$ is the B field strength, namely $B_{\mu\nu}\equiv\partial_\mu B_\nu-\partial_\nu B_\mu$ and where a similar definition applies to the other gauge fields.

Finally, one must also specify how leptons are described. In the standard model of particle physics, a fermion is represented by a four-component Dirac spinor Ψ, see also Sec. 24.7.1 where the zero-point fluctuations of spinors are calculated. Let us now recall what chirality is. For this purpose, we introduce the matrix γ^5 such that $\left(\gamma^5\right)^2=\mathbb{I}$ and $\left(\gamma^5\right)^\dagger=\gamma^5$. This allows us to define two chiral projectors by

$$P_{\text{R}}\equiv\frac{\mathbb{I}_4+\gamma_5}{2},\quad P_{\text{L}}=\frac{\mathbb{I}_4-\gamma_5}{2}, \tag{326}$$

where $\mathbb{I}_4$ denotes the identity four by four matrix. We now define the Dirac matrices, see Sec. 24.7.1 for a more general approach. In the chiral representation, they are given by

$$\begin{aligned}\gamma^0 &= \begin{pmatrix}0 & -\mathbb{I}_2\\ -\mathbb{I}_2 & 0\end{pmatrix},\quad \gamma^i=\begin{pmatrix}0 & \sigma^i\\ -\sigma^i & 0\end{pmatrix},\\ \gamma^5 &= \begin{pmatrix}\mathbb{I}_2 & 0\\ 0 & -\mathbb{I}_2\end{pmatrix},\end{aligned} \tag{327}$$

and the two projectors can be written as

$$P_{\text{R}} = \begin{pmatrix}\mathbb{I}_2 & 0\\ 0 & 0\end{pmatrix},\quad P_{\text{L}}=\begin{pmatrix}0 & 0\\ 0 & \mathbb{I}_2\end{pmatrix}. \tag{328}$$

Given a Dirac spinor Ψ (we denote the four-component spinors by a capital Greek letter and the two-component spinors by an ordinary Greek letter)

$$\Psi=\begin{pmatrix}\psi_{\text{R}}\\ \psi_{\text{L}}\end{pmatrix}, \tag{329}$$

one can thus define the two states of chirality (right and left handed) by means of the two following expressions

$$\Psi_{\rm R} \equiv P_{\rm R}\Psi = \begin{pmatrix}\psi_{\rm R}\\ 0\end{pmatrix}, \quad \Psi_{\rm L} \equiv P_{\rm L}\Psi \begin{pmatrix}0\\ \psi_{\rm L}\end{pmatrix}. \tag{330}$$

The quantities $\psi_{\rm R,L}$ are two-component spinors known as Weyl spinors. They play a very important role in super-symmetry, see Sec. 24.7.4. Notice that we also have $\overline{\Psi} \equiv \Psi^\dagger\gamma^0 = -\left(\psi_{\rm L}^\dagger, \psi_{\rm R}^\dagger\right)$. This implies that the (mass-less) Dirac Lagrangian can be expressed as

$$\mathcal{L}_{\rm Dirac} = -i\overline{\Psi}\gamma^\mu\partial_\mu\Psi = -i\psi_{\rm L}^\dagger\overline{\sigma}^\mu\partial_\mu\psi_{\rm L} - i\psi_{\rm R}^\dagger\sigma^\mu\partial_\mu\psi_{\rm R}, \tag{331}$$

where we have defined the covariant Pauli matrices $\sigma^\mu = (\mathbb{I}_2, \sigma^i)$ and $\overline{\sigma}^\mu = (\mathbb{I}_2, -\sigma^i)$.

After these brief reminders, we now consider the first family of the standard model leptons (the other two families can be treated in the same fashion and the quarks must be considered separately), *i.e.* the electron and the neutrino. Following the usual convention, we denote by $e_{\rm R}$ the right-handed electron Weyl spinor and by $e_{\rm L}$ the left-handed one. With regards to the neutrino, only the left-handed particle is present in the standard model and will be denoted as $\nu_{\rm L}$. Then, we have the following properties. The particles $e_{\rm L}$ and $\nu_{\rm L}$ are charged under $\mathrm{U}(1)_{\rm Y}$ but also under $\mathrm{SU}(2)_{\rm L}$, *i.e.* they are considered as a complex doublet of two-component spinors

$$L_e = \begin{pmatrix}\nu_{\rm L}\\ e_{\rm L}\end{pmatrix}, \tag{332}$$

On the other hand, $e_{\rm R}$ is charged under $\mathrm{U}(1)_{\rm Y}$ but is postulated to be a $\mathrm{SU}(2)_{\rm L}$ singlet. Therefore, concretely, the Lagrangian can be written as

$$\begin{aligned}\mathcal{L}_{\rm Leptons} &= -iL_e^\dagger\overline{\sigma}^\mu\left(\partial_\mu + i\frac{g'}{2}Y_{\rm L}B_\mu + igT_aW_\mu^a\right)L_e\\ &\quad -ie_{\rm R}^\dagger\bar{\sigma}^\mu\left(\partial_\mu + i\frac{g'}{2}Y_{\rm R}B_\mu\right)e_{\rm R},\end{aligned} \tag{333}$$

where $L_e^\dagger$ means $\left(\nu_{\rm L}^\dagger, e_{\rm L}^\dagger\right)$. Notice the factor $1/2$ in front of the gauge boson B_μ which is the usual convention [this factor was already present in Eq. (314)]. The quantities $Y_{\rm L}$ and $Y_{\rm R}$ are the leptonic weak hyper-charges. Let us focus on the first term in the above expression. The term between the parenthesis is a two by two matrix that can be written in terms of the physical gauge bosons, using the definitions (323). Similarly, the second term can be expressed in terms of the fields A_μ and Z_μ. Then, the Lagrangian for the leptons can be rewritten as

$$\begin{aligned}\mathcal{L}_{\rm Leptons} &= -i\nu_{\rm L}^\dagger\overline{\sigma}_\mu\left[\partial_\mu - i\left(\frac{g'}{2}Y_{\rm L}\sin\theta - \frac{g}{2}\cos\theta\right)Z_\mu + i\left(\frac{g'}{2}Y_{\rm L}\cos\theta + \frac{g}{2}\sin\theta\right)A_\mu\right]\nu_{\rm L}\\ &\quad -ie_{\rm L}^\dagger\overline{\sigma}_\mu\left[\partial_\mu - i\left(\frac{g'}{2}Y_{\rm L}\sin\theta + \frac{g}{2}\cos\theta\right)Z_\mu + i\left(\frac{g'}{2}Y_{\rm L}\cos\theta - \frac{g}{2}\sin\theta\right)A_\mu\right]e_{\rm L}\\ &\quad +\frac{g}{\sqrt{2}}\nu_{\rm L}^\dagger\overline{\sigma}^\mu W_\mu^- e_{\rm L} + \frac{g}{\sqrt{2}}e_{\rm L}^\dagger\overline{\sigma}^\mu W_\mu^+\nu_{\rm L} - ie_{\rm R}^\dagger\overline{\sigma}^\mu\left(\partial_\mu - i\frac{g'}{2}Y_{\rm R}\sin\theta Z_\mu + i\frac{g'}{2}Y_{\rm R}\cos\theta A_\mu\right)e_{\rm R}.\end{aligned} \tag{334}$$

Therefore, the total Lagrangian is now given by $\mathcal{L} = \mathcal{L}_{\rm Higgs} + \mathcal{L}_{\rm K-Gauge} + \mathcal{L}_{\rm Leptons}$. This Lagrangian depends on various free parameters that we now discuss and choose. Firstly, the neutrino is not electromagnetically charged and from Eq. (334) one has that

$$g'Y_{\rm L}\cos\theta + g\sin\theta = 0. \tag{335}$$

Secondly, the electron carries the charge e. This means that one must recover the following Lagrangian,

$$\mathcal{L}_{\rm EM} = -i\overline{\Psi}\gamma^\mu\left(\partial_\mu + iQA_\mu\right)\Psi, \tag{336}$$

where Q is the electromagnetic charge, $Q = e$ in our case. Working out the interaction part of the above Lagrangian, one obtains

$$\mathcal{L}_{\rm EM}^{\rm int} = -Qe_{\rm L}^\dagger\overline{\sigma}_\mu A_\mu e_{\rm L} - Qe_{\rm R}^\dagger\sigma_\mu A_\mu e_{\rm R}, \tag{337}$$

and, looking at Eq. (334), one deduces that

$$\frac{g'}{2}Y_{\rm L}\cos\theta - \frac{g}{2}\sin\theta \;=\; \frac{g'}{2}Y_{\rm R}\cos\theta = e. \tag{338}$$

As a consequence, comparing Eq. (335) and (338), one can establish that $2Y_{\rm L} = Y_{\rm R}$. It is conventional to choose $Y_{\rm L} = -1$ and therefore $Y_{\rm R} = -2$. Then, Eq. (335) leads to $g' = g\tan\theta$, from which one can write $\cos\theta = g/\sqrt{g^2+g'^2}$ and $\sin\theta = g'/\sqrt{g^2+g'^2}$. Finally, Eq. (338) implies that $g\sin\theta = e$. Everything can be summarized by the Gell-Mann formula

$$Q = e\left(I_3 + \frac{Y}{2}\right), \tag{339}$$

if the leptonic isospin doublet is assigned a "weak isospin" $I = 1/2$ such that the neutrino has a third component $I_3 = 1/2$ while the electron is such that $I_3 = -1/2$. Of course the right handed particles are such that $I = 0$. Returning to Eq. (324) and using the above equations, we see that the photons remains mass-less if $Y_{\rm H} = 1$. This also allows us to determine the mass of the gauge bosons and one arrives at

$$m^2_{W^\pm} \;=\; \frac{g^2v^2}{2}, \tag{340}$$

$$m^2_Z \;=\; 2v^2\left(\frac{g}{2}\cos\theta + \frac{g'}{2}\sin\theta\right)^2 = \frac{m^2_{W^\pm}}{\cos^2\theta}. \tag{341}$$

One also easily proves that the coefficient of the cross-term $Z_\mu A^\mu$ vanishes. Finally, looking at Eq. (322), one establishes that the Higgs mass is given by

$$m^2_{\rm H} = \lambda v^2, \tag{342}$$

and, from the expression of the potential (322), one finds the expression of its value at the minimum

$$V(\langle\Sigma\rangle = v) = -\lambda\frac{v^4}{4} = -\frac{m^4_{\rm H}}{4\lambda}, \tag{343}$$

in agreement with what we had before. Using the expression of the Higgs mass, one can re-write this expression as

$$\rho_{\rm vac} = V(\langle\Sigma\rangle = v) = -\frac{1}{4}m^2_{\rm H}v^2. \tag{344}$$

We see that in order to calculate the vacuum energy, we need to know v and the Higgs mass. Let us first discuss how the vacuum expectation value of the Higgs can be obtained. For this purpose, we focus on the term in the electroweak Lagrangian describing the interaction between leptons and charged gauge bosons (the so-called charged currents). From the above considerations, see Eq. (334), they are given by

$$\mathcal{L}_{\rm intL-W} = \frac{g}{\sqrt{2}}\nu^\dagger_{\rm L}\overline{\sigma}^\mu W^-_\mu e_{\rm L} + \frac{g}{\sqrt{2}}e^\dagger_{\rm L}\overline{\sigma}^\mu W^+_\mu \nu_{\rm L}. \tag{345}$$

It is easy to verify by an explicit calculation that it can be re-expressed in terms of Dirac spinors[126] as

$$\begin{aligned}\mathcal{L}_{\rm intL-W} \;&=\; \frac{g}{\sqrt{2}}\overline{\Psi}_\nu\gamma^\mu\frac{1-\gamma_5}{2}W^-_\mu\Psi_e \\ &+\; \frac{g}{\sqrt{2}}\overline{\Psi}_e\gamma^\mu\frac{1-\gamma_5}{2}W^+_\mu\Psi_\nu,\end{aligned} \tag{347}$$

[126] Let us recall that they are defined by the following expression

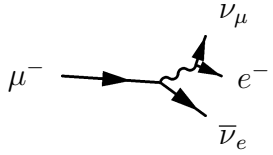
$$\Psi_e = \begin{pmatrix} e_{\rm L} \\ e_{\rm R}\end{pmatrix}, \tag{346}$$

and a similar expression for Ψ_ν.

which is similar to the Fermi theory for the weak interaction described by the following Lagrangian

$$\mathcal{L}_{\text{Fermi}} = \frac{G_{\text{F}}}{\sqrt{2}} J_\lambda J^{\lambda\dagger}, \tag{348}$$

with $J_\lambda = J_\lambda^{(e)} + J_\lambda^{(\mu)}$ (*i.e.* an electronic and a muonic part) where the current is given by $J_\lambda^{(e)} = \overline{\Psi}_e \gamma_\lambda (1-\gamma_5)\Psi_{\nu_e}$ and a similar definition for $J_\lambda^{(\nu)}$. If, for instance we consider the decay of muon into an electron, a muonic neutrino and an anti electronic neutrino, described by the graph



(349)

the two theories will lead to the same leading contribution at small energies if the following identification is made

$$\frac{g^2}{8m_W^2} = \frac{G_{\text{F}}}{\sqrt{2}}. \tag{350}$$

Indeed, the appearance of the gauge boson mass comes from the propagators of W_μ. At small momenta compared to the mass, only m_W remains and the above graph is in fact equivalent to the graph corresponding to the Fermi theory. Then, using the expression of the W-bosons mass established before, $m_W^2 = g^2 v^2/2$, one arrives at

$$v^2 = \frac{\sqrt{2}}{4G_{\text{F}}^2}. \tag{351}$$

Notice that there is a factor $\sqrt{2}$ difference with respect to the textbook [20] because we have defined the Higgs as $v + H/\sqrt{2}$ instead of $(v+H)/\sqrt{2}$. The Fermi constant is given by $G_{\text{F}} \simeq 1.16 \times 10^{-5}\ (\text{GeV})^{-2}$. Therefore,

$$v \simeq 175\,\text{GeV}. \tag{352}$$

or $\sqrt{2}v \simeq 246\,\text{GeV}$. We see that we have been able to calculate the Higgs vacuum expectation value v. As a consequence, Eq. (344) reads

$$\rho_{\text{vac}} = -\frac{\sqrt{2}}{16}\frac{m_{\text{H}}^2}{G_{\text{F}}^2}. \tag{353}$$

The mass of the Higgs boson is not known although, at the time of writing, there are reasons to believe that $m_{\text{H}} < 129\,\text{GeV}$ at 95% CL [46] (there are even reasons to believe that $m_{\text{H}} \simeq 125\,\text{GeV}$ but this is not yet established at a sufficient statistical level at the time of writing). Therefore, we find that

$$\rho_{\text{vac}}^{\text{EW}} \simeq -1.2 \times 10^8\,\text{GeV}^4 \simeq -10^{55}\rho_{\text{cri}}, \tag{354}$$

where $\rho_{\text{cri}} \simeq 10^{-47}\,\text{GeV}^4$ is the critical energy density today. As will be discussed in the following, this result is in fact in contradiction with various observations.

To conclude this section, let us recall that one can always adjust the vacuum energy today to zero by tuning the parameter V_0. This is clearly not a very satisfactory method and this implies that the vacuum energy density was huge prior to the electroweak phase transition. It is also worth noticing that this problem is not specific to the electroweak transition. Exactly the same discussion could be presented for the Quantum Chromo Dynamics (QCD) transition [3, 8] (for instance) and would lead to the same problem since

$$\rho_{\text{vac}}^{\text{QCD}} \simeq 10^{-2}\,\text{GeV}^4 \simeq 10^{45}\rho_{\text{cri}}. \tag{355}$$

Moreover, as we are now going to discuss in detail, even if we "solve" the classical cosmological constant by tuning the vacuum energy to zero, see Eq. (304), the problem reappears at the quantum level. Indeed, we have seen that the zero-point quantum fluctuations also give a contribution to the cosmological constant, see Eq. (301). The goal of the next section is to estimate the corresponding energy density.

24.4 The Quantum-Mechanical Cosmological Constant Problem

We have seen that, even if we solve the classical cosmological constant problem and find a convincing reason to put the minimum of the potential to zero, $\rho_{\rm vac}$ is a quantity which also receives contributions from the zero-point fluctuations of all the quantum fields present in the Universe. We now discuss this "quantum-mechanical" cosmological constant problem. In principle, the corresponding vacuum energy density can be estimated from first principles. The goal of this section (and of Sec. 24.6) is to carry out this task. We will first discuss how the Lorentz invariance affects the calculation of the vacuum energy, see the next subsection 24.4.1. Then, in sub-Sec. 24.4.2, we will show how this question can be formulated in terms of Feynman diagrams. In sub-Sec. 24.4.3, we will also evaluate the vacuum energy not only for a free theory as usually done but also in the more realistic case where interactions are present. Finally, in order to understand better the origin of the vacuum energy density, in sub-Secs. 24.5.1 and 24.5.2, we will address the same question but in the context of ordinary quantum mechanics. This will allow us in sub-Sec. 24.5.3 and 24.5.4 to discuss in more detail the properties of the so-called bubble diagrams from which the cosmological constant originates. As mentioned above, all the fields present in the universe participate in the vacuum energy. Therefore, we need to do the calculation for scalar, fermion and vector fields. Here, in a first step, we carry out the calculation for a real scalar field. The other types will be treated later on in Sec. 24.7. For simplicity, we will also consider that the metric is flat and that the fields live in Minkowski space-time. A sloppy justification is that the main contribution to the vacuum energy density comes from modes with very high momenta, corresponding to scales at which the curvature of space-time is negligible. In fact, we will come back to this very important question in more detail in what follows and will try to discuss this point in a more rigorous way, see Sec. 24.8.

24.4.1 The Zero-Point Energy Density

Let us consider a simple real free scalar field with the potential $V(\Phi) = m^2\Phi^2/2$ where m is the mass of the scalar particle. In flat space-time, the equation of motion is nothing but the Klein-Gordon equation, namely

$$-\ddot{\Phi} + \delta^{ij}\partial_i\partial_j\Phi - m^2\Phi = 0. \tag{356}$$

Since the scalar field is free, the equation of motion is linear and, as a consequence, one can Fourier expand $\Phi(t, \boldsymbol{x})$ as

$$\begin{aligned}\Phi\left(t, \boldsymbol{x}\right) &= \frac{1}{\left(2\pi\right)^{3/2}} \int \frac{\mathrm{d}^3\boldsymbol{k}}{\sqrt{2\omega(k)}} \Big(c_{\boldsymbol{k}} \mathrm{e}^{-i\omega t + i\boldsymbol{k}\cdot\boldsymbol{x}} \\ &\quad + c^\dagger_{\boldsymbol{k}} \mathrm{e}^{i\omega t - i\boldsymbol{k}\cdot\boldsymbol{x}} \Big),\end{aligned} \tag{357}$$

with

$$\omega(k) \equiv \sqrt{k^2 + m^2}. \tag{358}$$

The four-dimensional momentum has been written as $k^\mu = (k^0, \boldsymbol{k})$ and the integration is performed over its spatial part only. We have used the notation $|\boldsymbol{k}| = k$. Its time component is given by $k^0 = \omega$. As usual, the field has been quantized by considering $c_{\boldsymbol{k}}$ and $c^\dagger_{\boldsymbol{k}}$ (the so-called annihilation and creation operators) as quantum operators satisfying the following commutation relation

$$\left[c_{\boldsymbol{k}}, c^\dagger_{\boldsymbol{k}'}\right] = \delta^{(3)}\left(\boldsymbol{k} - \boldsymbol{k}'\right). \tag{359}$$

This equation is in fact equivalent to the standard commutation rule between the field operator and its conjugate momentum.

We are now in a position where one can compute $\langle 0|T_{\mu\nu}|0\rangle$. From Eq. (303), we see that we must first evaluate the mean values of various quantities depending on the field operator and

its derivatives. Straightforward calculations lead to

$$\langle 0|\dot{\Phi}^2|0\rangle = \frac{1}{(2\pi)^3}\int \frac{\mathrm{d}^3\boldsymbol{k}}{2\omega(k)}\,\omega^2(k), \tag{360}$$

$$\langle 0|\delta^{ij}\partial_i\Phi\partial_j\Phi|0\rangle = \frac{1}{(2\pi)^3}\int \frac{\mathrm{d}^3\boldsymbol{k}}{2\omega(k)}\,\boldsymbol{k}^2, \tag{361}$$

$$\langle 0|\Phi^2|0\rangle = \frac{1}{(2\pi)^3}\int \frac{\mathrm{d}^3\boldsymbol{k}}{2\omega(k)}. \tag{362}$$

These equations can then be used to determine the energy density and pressure of the vacuum. From the above expression (303) of the stress-energy tensor, one has

$$T_{00} = \mathcal{H} = \frac{1}{2}\dot{\Phi}^2 + \frac{1}{2}\delta^{ij}\partial_i\Phi\partial_j\Phi + \frac{1}{2}m^2\Phi^2, \tag{363}$$

where $\mathcal{H}$ denotes the Hamiltonian density. This leads to the following expression for the energy density $\rho = u^\mu u^\nu T_{\mu\nu}$ measured by a fundamental observer characterized by its four-velocity vector $u^\mu = (1, \boldsymbol{0})$

$$\langle\rho\rangle = \langle 0|u^0u^0T_{00}|0\rangle = \frac{1}{(2\pi)^3}\frac{1}{2}\int \mathrm{d}^3\boldsymbol{k}\,\omega(k). \tag{364}$$

In the same manner, one can easily estimate the pressure. One obtains

$$\begin{aligned}\langle p\rangle &= \left\langle 0\left|\frac{1}{3}\perp^{\mu\nu}T_{\mu\nu}\right|0\right\rangle \\ &= \left\langle 0\left|\frac{1}{2}\dot{\Phi}^2 - \frac{1}{6}\delta^{ij}\partial_i\Phi\partial_j\Phi - \frac{1}{2}m^2\Phi^2\right|0\right\rangle,\end{aligned} \tag{365}$$

where $\perp^{\mu\nu}\equiv g^{\mu\nu} + u^\mu u^\nu$ is a projector. Upon using the expressions (360), (361) and (362), one arrives at the following expression

$$\langle p\rangle = \frac{1}{(2\pi)^3}\frac{1}{6}\int \mathrm{d}^3\boldsymbol{k}\,\frac{k^2}{\omega(k)}. \tag{366}$$

Notice that we also have

$$\langle 0|T_{0i}|0\rangle = -\frac{1}{(2\pi)^3}\frac{1}{2}\int \mathrm{d}^3\boldsymbol{k}\,k_i = 0, \tag{367}$$

and, hence, we do not need to consider to off-diagonal elements. This completes our calculation of the vacuum stress-energy tensor.

From the above considerations, using Eq. (307), we deduce that

$$\Lambda_{\mathrm{eff}} = \Lambda_{\mathrm{B}} + \frac{\kappa}{(2\pi)^3}\int \mathrm{d}^3\boldsymbol{k}\,\frac{1}{2}\omega(k). \tag{368}$$

The obvious problem with the previous calculation is that the integrals expressing the energy density $\langle\rho\rangle$ and the pressure $\langle p\rangle$ blow up in the ultra-violet regime (and, therefore, strictly speaking, the effective cosmological constant is in fact infinite). This is of course a well-known problem in quantum field theory. Usually, this type of divergences is ignored (or sometimes removed by mean of the normal ordering product) because, in absence of gravity, only differences of energy can be detected [16, 17]. However, in the present context, this is clearly no longer the case since the absolute value of the vacuum energy weighs and, therefore, can be measured. This is why regularizing these infinities becomes a crucial issue that we now discuss in some details.

The common method found in the literature is to introduce a cut-off at $k = M$, where the physical interpretation of M is that this is the scale at which the effective theory used before breaks down [451, 4, 5, 449, 1393]. The quantity M is not known: it could be the Planck scale,

the string scale or even the super-symmetric breaking scale. As we will see later on, this is in fact not important because the cosmological constant problem is present regardless of the precise value of the cut-off. In this approach, the energy density becomes

$$\langle\rho\rangle = \frac{1}{4\pi^2}\int_0^M \mathrm{d}k k^2\sqrt{k^2+m^2} \tag{369}$$

$$= \frac{M^4}{16\pi^2}\left[\sqrt{1+\frac{m^2}{M^2}}\left(1+\frac{1}{2}\frac{m^2}{M^2}\right) - \frac{1}{2}\frac{m^4}{M^4}\ln\left(\frac{M}{m}+\frac{M}{m}\sqrt{1+\frac{m^2}{M^2}}\right)\right] \tag{370}$$

$$= \frac{M^4}{16\pi^2}\left(1+\frac{m^2}{M^2}+\cdots\right), \tag{371}$$

where, in the last expression, we have expanded the exact expression in terms of the small parameter m/M. We see that the divergence is quartic in the cut-off scale. Let us now perform the same calculation for the pressure. Using Eq. (366), one obtains

$$\langle p\rangle = \frac{1}{3}\frac{1}{4\pi^2}\int_0^M \mathrm{d}k \frac{k^4}{\sqrt{k^2+m^2}} \tag{372}$$

$$= \frac{1}{3}\frac{M^4}{16\pi^2}\left[\sqrt{1+\frac{m^2}{M^2}}\left(1-\frac{3}{2}\frac{m^2}{M^2}\right) + \frac{3}{2}\frac{m^4}{M^4}\ln\left(\frac{M}{m}+\frac{M}{m}\sqrt{1+\frac{m^2}{M^2}}\right)\right] \tag{373}$$

$$= \frac{1}{3}\frac{M^4}{16\pi^2}\left(1-\frac{m^2}{M^2}+\cdots\right). \tag{374}$$

It is clear from the previous expressions that $\langle p\rangle/\langle\rho\rangle \neq -1$ which indicates that the stress energy tensor is not of the form $\propto -\rho g_{\mu\nu}$. In the limit $m \to 0$, as can be easily shown from Eqs. (371) and (374), the equation of state is in fact $\langle p\rangle/\langle\rho\rangle = 1/3$. This would mean that the zero point fluctuations do not behave like a cosmological constant but rather like radiation. On the other hand, this result seems to be strange since we know from fundamental considerations that the stress-energy tensor of a system in its ground state must be proportional to the metric tensor. Clearly, something has gone wrong is our calculation.

Interestingly enough, let us also note in passing that if one only focuses on the logarithmic terms, namely

$$\langle\rho\rangle^{\log} = -\frac{m^4}{32\pi^2}\ln\left(\frac{M}{m}+\frac{M}{m}\sqrt{1+\frac{m^2}{M^2}}\right), \tag{375}$$

$$\langle p\rangle^{\log} = \frac{m^4}{32\pi^2}\ln\left(\frac{M}{m}+\frac{M}{m}\sqrt{1+\frac{m^2}{M^2}}\right), \tag{376}$$

then the equation of state of the vacuum is correctly reproduced (even if the energy density can be negative). In fact, as we explain below, this is not a coincidence [47].

It is easy to check that the previous considerations are not an artifact of the fact that we have introduced a sharp cut-off. Indeed, if rather than a sharp cut-off in the upper limit of the integrals, one introduces a smooth exponential cut-off, one obtains (for simplicity, one only

considers the case $m = 0$),

$$\langle\rho\rangle = \frac{1}{4\pi^2}\int_0^\infty \mathrm{d}k\, k^3\, \mathrm{e}^{-\alpha k} = \frac{1}{4\pi^2}\frac{\Gamma(4)}{\alpha^4} \tag{377}$$

$$= \frac{1}{4\pi^2} 6M^4, \tag{378}$$

where we have written $\alpha = 1/M$ and where $\Gamma(z)$ is the Euler's integral of the second kind [48, 49]. One recovers our familiar quartic divergence. Doing the same manipulation for the pressure, one obtains again that $\langle p\rangle/\langle\rho\rangle = 1/3$.

In fact, what has gone wrong is that we have used schemes of regularization that do not respect the symmetry of our underlying theory [47, 50, 51]. Indeed, the Lorentz invariance is broken when we impose a cut-off on the spatial momentum only. As exemplified by Eq. (378), it is easy to show that this is a feature of any regularization scheme breaking Lorentz invariance and not a specific property of the particular cut-off scheme used above (and usually used in the literature). In fact, this property is well-known in the context of gauge theories. If one regulates divergent graphs with a method that is not gauge invariant, then one obtains incorrect results [52]. Here, the situation is very similar.

Therefore, in order to meaningfully evaluate the zero-point energy density, one must use a regularization scheme that does not break Lorentz invariance [47, 50, 51]. An obvious choice is dimensional regularization and we now explore this route. In order to use this method, we first reformulate our problem in a d dimensional Minkowski space-time. Obviously, the Klein-Gordon equation (356) remains unchanged except that the indices of the Krönecker symbol now run from 0 to $d-1$. The Fourier expansion of the field becomes [compare with Eq. (357)]

$$\Phi(t,\boldsymbol{x}) = \frac{1}{(2\pi)^{(d-1)/2}}\int \frac{\mathrm{d}^{d-1}\boldsymbol{k}}{\sqrt{2\omega(k)}}\Big(c_{\boldsymbol{k}}\mathrm{e}^{-i\omega t+i\boldsymbol{k}\cdot\boldsymbol{x}} + c^\dagger_{\boldsymbol{k}}\mathrm{e}^{i\omega t-i\boldsymbol{k}\cdot\boldsymbol{x}}\Big), \tag{379}$$

and, as a consequence, the energy density can be expressed as

$$\langle\rho\rangle = \frac{\mu^{4-d}}{(2\pi)^{(d-1)}}\frac{1}{2}\int \mathrm{d}^{d-1}\boldsymbol{k}\,\omega(k) \tag{380}$$

$$= \frac{\mu^{4-d}}{(2\pi)^{(d-1)}}\frac{1}{2}\int_0^\infty \mathrm{d}k k^{d-2}\mathrm{d}^{d-2}\Omega\,\omega(k), \tag{381}$$

where we have introduced a scale μ in order for the equation to be dimensionally correct. This equation should be compared with Eq. (364). Then, using the fact that the angular integrals can be easily performed, namely $\int \mathrm{d}^{d-2}\Omega = 2\pi^{(d-1)/2}/\Gamma(d/2-1/2)$, where, again, $\Gamma(z)$ is the Euler's integral of the second kind [48, 49], one obtains

$$\langle\rho\rangle = \frac{\mu^4}{2\,(4\pi)^{(d-1)/2}}\frac{\Gamma(-d/2)}{\Gamma(-1/2)}\left(\frac{m}{\mu}\right)^d. \tag{382}$$

Performing the same calculation for the pressure, one arrives at a similar expression

$$\langle p\rangle = \frac{\mu^{4-d}}{(2\pi)^{(d-1)}}\frac{1}{2(d-1)}\int \mathrm{d}^{d-1}\boldsymbol{k}\,\frac{k^2}{\omega(k)} \tag{383}$$

$$= \frac{\mu^4}{4\,(4\pi)^{(d-1)/2}}\frac{\Gamma(-d/2)}{\Gamma(1/2)}\left(\frac{m}{\mu}\right)^d. \tag{384}$$

But $\Gamma(-1/2) = -2\Gamma(1/2)$ and, as a consequence,

$$\langle p\rangle = -\langle\rho\rangle. \tag{385}$$

This time, as expected, we have obtained the equation of state of the vacuum. The fact that the regularization method used satisfies the Lorentz symmetry has led us to the correct result.

The consistency of the above result can be checked in a different manner [47]. Using Eqs. (380) and (383) for the energy density and the pressure, one sees that they satisfy the following differential equation

$$\langle\rho\rangle - 2m^2\frac{\mathrm{d}\langle\rho\rangle}{\mathrm{d}m^2} = (d-1)\langle p\rangle. \tag{386}$$

Using the fact that $\langle p\rangle = -\langle\rho\rangle$ one obtains

$$m^2\frac{\mathrm{d}\langle\rho\rangle}{\mathrm{d}m^2} = \frac{d}{2}\langle\rho\rangle, \tag{387}$$

which can be integrated to give $\langle\rho\rangle \propto m^d$ in full agreement with Eq. (382). Therefore, we conclude that the above considerations are all consistent.

Let us now analyze in more details the structure of the divergences. For this purpose one writes $d = 4-\epsilon$, where ϵ is supposed to be a small parameter, and we expand $\langle\rho\rangle$ in terms of ϵ. The Euler function is such that

$$\Gamma\left(-2+\frac{\epsilon}{2}\right) = \frac{1}{-2+\epsilon/2}\frac{1}{-1+\epsilon/2}\frac{1}{\epsilon/2}\Gamma\left(1+\frac{\epsilon}{2}\right), \tag{388}$$

with $\Gamma(1+\epsilon/2) \simeq \Gamma(1)+\epsilon\Gamma'(1)/2$, $\Gamma'(1) = \Psi(1)\Gamma(1)$ where Ψ is the Polygamma function [48, 49] and $\Psi(1) = -\gamma \simeq 0.57772$ the Euler-Mascheroni constant [48, 49]. If, in addition, we use the two following expansions

$$(4\pi)^{-3/2+\epsilon/2} \simeq \frac{1}{(4\pi)^{3/2}}\left[1+\frac{\epsilon}{2}\ln(4\pi)\right], \tag{389}$$

$$\left(\frac{m}{\mu}\right)^{4-\epsilon} \simeq \left(\frac{m}{\mu}\right)^4\left(1-\epsilon\frac{m}{\mu}\right), \tag{390}$$

then one arrives at the following expression for the energy density of the vacuum

$$\langle\rho\rangle \simeq -\frac{m^4}{64\pi^2}\left[\frac{2}{\epsilon}+\frac{3}{2}-\gamma-\ln\left(\frac{m^2}{4\pi\mu^2}\right)\right]+\cdots. \tag{391}$$

Using a $\overline{\mathrm{MS}}$ renormalization scheme convention [$\overline{\mathrm{MS}}$ means "modified minimal subtraction" and simply consists in subtracting the pole $\sim 1/\epsilon$ together with the accompanying terms γ and $\ln(4\pi)$, see chapter 11 of Ref. [16]; in fact, here, we slightly modify the convention such that the term 3/2 is subtracted as well], the regularized, finite, energy density of the vacuum now reads

$$\langle\rho\rangle = \frac{m^4}{64\pi^2}\ln\left(\frac{m^2}{\mu^2}\right). \tag{392}$$

This result is very different from the result obtained by imposing a sharp cut-off. In fact, one recovers the structures of the logarithm terms found in Eqs. (375) and (376) since it is well-known that the dimensional regularization scheme removes the power law terms. As discussed around Eqs. (375) and (376), this is the reason why those terms lead to the correct vacuum equation of state. We see that the result is not proportional to the cut-off scale to the power four, as usually claimed on dimensional grounds, but to the mass of the particle to the power four, which is also dimensionally correct. Physically, for instance, this means that the photon does not contribute to the vacuum energy density contrary to what a sharp cut-off calculation would predict. Therefore, the order of magnitude of the final result can a priori be very different. We also notice that the sign of $\langle\rho\rangle$ can change according to $m > \mu$ or $m < \mu$. Of course, it remains to be seen whether this could solve the cosmological constant problem and we will argue below that, unfortunately, the answer to this question is no. It should also be kept in mind that the above calculation is valid for free fields. It is clear that a more realistic version should take into account the interactions and we will also consider this issue in the following. However, before addressing these various points and in order to gain further physical insights, we would like to investigate again the above issues, this time from the Feynman diagrams point of view. We turn to this question in the next sub-section.

24.4.2 The Vacuum and the Feynman Diagrams

We have seen in the last sub-section that the vacuum contribution to the cosmological constant is given in terms of divergent integrals. A priori, there is no reason to be surprised since divergent integrals are routinely found in quantum field theory. We have the method of renormalization at our disposal to get rid of these infinities and the so accurate predictions of particle physics are here to remind us that this is a very convincing way of taming these divergences. However, we will see that the divergent integrals that we encounter when we calculate the vacuum energy are in fact of a different nature than the divergent integrals met when we calculate, say, a cross section. In order to discuss this point in more detail and to understand better the structure of these divergences, we now briefly return to some textbook considerations [16, 17, 18, 19, 20, 21, 22].

In quantum field theory, the basic object is the generating functional defined by the following path integral (we still restrict our considerations to a simple scalar field)

$$Z\left[J\right]=\mathcal{N}\int\mathcal{D}\Phi\exp\left\{i\int\mathrm{d}^{4}x\left[\mathcal{L}+J(x)\Phi(x)\right]\right\}, \tag{393}$$

where $\mathcal{N}$ is a number chosen such that $Z[J=0]=1$. The quantity $\mathcal{L}$ is the Lagrangian density while J represents a source coupled to the scalar field. From the generating functional, one can compute the various correlation functions

$$\begin{aligned} G^{(n)}(x_1\cdots x_n) &= \left\langle\Omega\left|T\left[\Phi(x_1)\cdots\Phi(x_n)\right]\right|\Omega\right\rangle & (394)\\ &= \left(\frac{1}{i}\right)^{n}\frac{\delta^{n}Z\left[J\right]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0}, & (395)\end{aligned}$$

where $|\Omega\rangle$ denotes the vacuum state of the theory. We distinguish it from $|0\rangle$ which denotes the vacuum state of the theory without interaction. In this last case, the generating functional can be computed exactly. It reads (notice that we have $Z_0[0]=1$ and that the "0" subscript indicates that we refer to the free theory)

$$Z_0[J]=\exp\left[-\frac{1}{2}\int\mathrm{d}^{4}x\mathrm{d}^{4}yJ(x)D_{\mathrm{F}}(x-y)J(y)\right], \tag{396}$$

where D_{F} is the Feynman propagator defined by the following expression

$$D_{\mathrm{F}}\left(x_1-x_2\right)=\left\langle\Omega\left|T\left[\Phi(x_1)\Phi(x_2)\right]\right|\Omega\right\rangle, \tag{397}$$

T denoting the time ordered product. As is well-known, the propagator can be conveniently expressed in Fourier space as

$$D_{\mathrm{F}}\left(x_1-x_2\right)=\frac{i}{(2\pi)^{4}}\int\frac{\mathrm{d}^{4}k}{k^{2}+m^{2}}\mathrm{e}^{ik_{\mu}\cdot\left(x_1^{\mu}-x_2^{\mu}\right)}. \tag{398}$$

In presence of interactions, one can write $\mathcal{L}=\mathcal{L}_0+\mathcal{L}_{\mathrm{int}}$ where $\mathcal{L}_{\mathrm{int}}$ represents the self-interacting part of the Lagrangian density. In this case the generating functional can be written as

$$Z[J]=\mathcal{N}\exp\left\{i\int\mathrm{d}^{4}x\,\mathcal{L}_{\mathrm{int}}\left[\frac{1}{i}\frac{\delta}{\delta J(x)}\right]\right\}Z_0[J], \tag{399}$$

where, in order to have the correct normalization, the factor $\mathcal{N}$ must be given by

$$\mathcal{N}^{-1}\equiv\exp\left\{i\int\mathrm{d}^{4}x\,\mathcal{L}_{\mathrm{int}}\left[\frac{1}{i}\frac{\delta}{\delta J(x)}\right]\right\}Z_0[J]\bigg|_{J=0}. \tag{400}$$

As explained in the standard quantum field theory textbooks, the above expressions (399) and (400) are particularly well suited for a perturbative expansion. For instance, if we want to

calculate the generating functional for the case of a quartic theory $\mathcal{L}_{\rm int} = \lambda\Phi^4/4!$, where λ is the coupling constant, we are led to the following expansion in λ

$$Z[J] = \mathcal{N}\left[1 - i\frac{\lambda}{4!}\int \mathrm{d}^4x \frac{1}{i^4}\frac{\delta^4 Z_0[J]}{\delta J(x)^4} + \cdots\right]. \tag{401}$$

As usual, the various terms that appear in this expansion can be graphically represented by Feynman diagrams. The Feynman rules of the theory in real space are given by

$$D(x_1 - x_2) \equiv x_1 \bullet\!\!-\!\!-\!\!\bullet\ x_2, \tag{402}$$

$$-i\lambda\int \mathrm{d}^4x \equiv \quad , \tag{403}$$

$$i\int \mathrm{d}^4x J(x) \equiv \circ\!\!-\!\!-\ , \tag{404}$$

and a loop for a propagator evaluated at the same point in space-time. This completes our quick reminder of the basics of field theory that we need in the following.

Now, we compute the energy density of a free scalar field (the interacting case is treated in the next subsection) using the tools that we have just presented. In fact, it is interesting to calculate the trace of the stress-energy tensor. Upon using Eq. (303), one obtains

$$\langle T\rangle = \langle \eta^{\mu\nu}T_{\mu\nu}\rangle = -\langle\rho\rangle + (d-1)\langle p\rangle. \tag{405}$$

Then, since the energy density and the pressure are given by Eqs. (380) and (383), the above relation can be re-expressed as

$$\langle T\rangle = -\mu^{4-d}\int \frac{\mathrm{d}^{d-1}\boldsymbol{k}}{(2\pi)^{d-1}}\frac{m^2}{2\omega(k)} \tag{406}$$

But, from Eqs. (397) and (398), and now specifying to the case $d = 4$, one has

$$D_{\rm F}(0) = \frac{i}{(2\pi)^4}\int \frac{\mathrm{d}^4k}{k^2+m^2} = \frac{i}{(2\pi)^4}\int \frac{\mathrm{d}k^0\mathrm{d}^3\boldsymbol{k}}{-(k^0)^2+\omega^2}, \tag{407}$$

where we have distinguished the integration over the time and space components of the momentum. Using the identity $\int \mathrm{d}k^0/[-(k^0)^2+\omega^2] = -\pi/(i\omega)$, see also Eq. (451), this leads to

$$D_{\rm F}(0) = -\int \frac{\mathrm{d}^3\boldsymbol{k}}{(2\pi)^3 2\omega}. \tag{408}$$

or, in other words,

$$\langle T\rangle = m^2 D_{\rm F}(0). \tag{409}$$

But, if we now use the fact that $\langle p\rangle = -\langle\rho\rangle$, Eq. (405) can also be written as $\langle T\rangle = -d\langle\rho\rangle$. As a consequence, Eq. (409) implies that

$$\langle\rho\rangle = -\frac{m^2}{4}D_{\rm F}(0). \tag{410}$$

This equation can also be obtained by a direct calculation. Indeed one has

$$D_{\rm F}(0) = \frac{i\mu^{4-d}}{(2\pi)^d}\int \frac{\mathrm{d}k^0\mathrm{d}^{d-1}\boldsymbol{k}}{-(k^0)^2+\omega^2} \tag{411}$$

$$= -\frac{d}{m^2}\frac{\mu^4}{2\,(4\pi)^{(d-1)/2}}\frac{\Gamma(-d/2)}{\Gamma(-1/2)}\left(\frac{m}{\mu}\right)^d \tag{412}$$

$$= -\frac{d}{m^2}\langle\rho\rangle, \tag{413}$$

where, in the second step of the calculation, we have used dimensional regularization. Now, using Eq. (307) and the Feynman rule stipulating that a propagator evaluated at the same point is represented by a loop, one can re-write the cosmological constant as

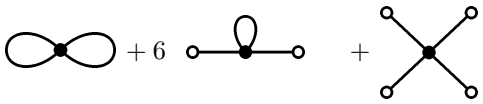
$$\Lambda_{\rm eff} = \Lambda_{\rm B} - \kappa \frac{m^2}{4} \quad . \tag{414}$$

In other words, the cosmological constant is given by a "bubble diagram", *i.e.* a diagram that has no external leg.

We have just established that the vacuum energy density, or equivalently the cosmological constant, can be expressed in term of a bubble diagram. This type of diagram plays a special role in quantum field theory and we will discuss this point in more detail in the following next sub-sections. In order to develop our intuition, let us first calculate explicitly the generating function in the case of a self-interacting scalar field. The calculation is straightforward and upon using Eq. (396), this leads to

$$\begin{aligned} -i\frac{\lambda}{4!}\int \mathrm{d}^4x \frac{1}{i^4}\frac{\delta^4 Z_0[J]}{\delta J(x)^4} &= -i\frac{\lambda}{4!}\Bigg\{3\int \mathrm{d}^4x D^2(0) - 6\int \mathrm{d}^4x D(0)\left[\int \mathrm{d}^4y D(x-y)J(y)\right]^2 \\ &\quad + \int \mathrm{d}^4x \left[\int \mathrm{d}^4y D(x-y)J(y)\right]^4\Bigg\} Z_0[J] + \cdots \end{aligned} \tag{415}$$

$$= \frac{1}{4!}\Bigg(3 \quad + 6 \quad + \quad + \cdots \Bigg) Z_0[J]. \tag{416}$$

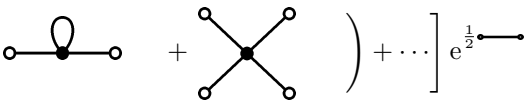


One notices the appearance of a "bubble diagram" (the first one), similar (*i.e.* with no external leg) but not identical to the one encountered in the calculation of the cosmological constant. We also have a diagram with a loop (the second one) but with external legs and a diagram with no loop (the last one). All the diagram with loops (that is to say the two first ones) are divergent in quantum field theory. Nevertheless, the bubble diagram and the loop diagram play in fact a very different role as we are going to see. Let us now calculate the normalization $\mathcal{N}$, see Eq. (400). It uses the same expression as before but with $J = 0$ which means that all the diagram containing a source disappear. As a consequence, we have

$$\mathcal{N}^{-1} = 1 + \frac{3}{4!} \tag{417}$$

We can now gather everything and compute the generating functional. Upon using the expression (401) and the results (416) and (417), one arrives at

$$Z[J] = \Bigg[1 + \frac{1}{4!}\Bigg(6 \quad + \quad \Bigg) + \cdots\Bigg] \mathrm{e}^{\frac{1}{2}} \quad . \tag{418}$$



We see that the bubble diagram has canceled in the final expression. Since all the predictions (cross-sections etc...) follow from the calculation of the generating functional, we see that the bubble diagrams never contribute, in absence of gravity, to any observables. On the contrary, when the gravitational field is turned on, the bubble diagrams become important and can affect the predictions of the theory. In summary, the cosmological constant problem can be viewed as the appearance of a new type of divergent graphs. As demonstrated with Eq. (392), these graphs can be regularized but, as will be discussed below, the regularized value seems to be incompatible with some astrophysical observations.

24.4.3 The Vacuum in Presence of Interactions

So far we have calculated the vacuum energy density for a free field. It is natural to ask what happens when one considers interaction [50] since we know that a realistic model necessarily contains such terms. For this purpose, let us therefore consider again a simple self-interacting

scalar field with $\mathcal{L}_{\rm int} = \lambda\Phi^4/4!$. As a consequence, this adds the following contribution to the energy density of the vacuum

$$\Delta\rho = \frac{\lambda}{4!}\left\langle\Phi^4\right\rangle = \frac{3\lambda}{4!}\left\langle\Phi^2\right\rangle^2 = \frac{\lambda}{8}D_{\rm F}^2(0) \tag{419}$$

$$= \frac{i}{8\int \mathrm{d}^4x} \quad \text{ } \tag{420}$$

where, on the first line in the above expression, we have used the fact that the vacuum wave-functional is a Gaussian. As expected, this new term is also given by a bubble diagram. However, one should not forget that, when interaction is present, one must also renormalize the mass. As is well-known, at one loop, the renormalization of the mass comes from the tadpole diagram. More precisely, one has to calculate the correction to the propagator. It is given by the following expression

$$\langle\Omega\,|T\left[\Phi(x_1)\Phi(x_2)\right]|\,\Omega\rangle = \quad \text{  } \tag{421}$$

or, in terms of explicit expressions [see Eq. (398)]

$$\langle\Omega\,|T\left[\Phi(x_1)\Phi(x_2)\right]|\,\Omega\rangle = D_{\rm F}(x_1-x_2) - \frac{i\lambda}{2}\int \mathrm{d}^4x D_{\rm F}(x_1-x)D_{\rm F}(0)D_{\rm F}(x-x_2) + \cdots \tag{422}$$

$$= \frac{i}{(2\pi)^4}\int\frac{\mathrm{d}^4p}{p^2+m^2}\mathrm{e}^{ip_\mu\cdot\left(x_1^\mu-x_2^\mu\right)} + \frac{i\lambda}{2}D_{\rm F}(0)\frac{1}{(2\pi)^4}\int\mathrm{d}^4p\frac{\mathrm{e}^{ip_\mu\cdot\left(x_1^\mu-x_2^\mu\right)}}{(p^2+m^2)^2} + \cdots \tag{423}$$

$$= \frac{i}{(2\pi)^4}\int\frac{\mathrm{d}^4p}{p^2+m^2}\mathrm{e}^{ip_\mu\cdot\left(x_1^\mu-x_2^\mu\right)}\left[1+\frac{\lambda}{2}D_{\rm F}(0)\frac{1}{p^2+m^2}\right] + \cdots \tag{424}$$

$$= \frac{i}{(2\pi)^4}\int\frac{\mathrm{d}^4p}{p^2+m^2-\lambda D_{\rm F}(0)/2}\mathrm{e}^{ip_\mu\cdot\left(x_1^\mu-x_2^\mu\right)} + \cdots, \tag{425}$$

where the last equation is equivalent to the previous one at leading order in the coupling constant. We see that this implies the following redefinition (or renormalization) of the mass

$$m_{\rm ren}^2 = m^2 - \frac{\lambda}{2}D_{\rm F}(0) \tag{426}$$

As a consequence, the vacuum energy which is now the sum of the free contribution (410) and of the contribution (419), which originates from the self-interaction of the field, can be re-expressed as

$$\begin{aligned}\langle\rho\rangle &= -\frac{m^2}{4}D_{\rm F}(0) + \frac{\lambda}{8}D_{\rm F}^2(0)\\ &= -\frac{m_{\rm ren}^2}{4}D_{\rm F}(0) - \frac{1}{4}\left[\frac{\lambda}{2}D_{\rm F}(0)\right]D_{\rm F}(0) + \frac{\lambda}{8}D_{\rm F}^2(0)\\ &= -\frac{m_{\rm ren}^2}{4}D_{\rm F}(0),\end{aligned} \tag{427}$$

where, in the second line, we have used Eq. (426). The extra contribution coming from the interacting term is exactly canceled by the renormalization of the mass [53, 50]. In other words, one sees that the presence of the interaction has not modified the expression of the vacuum energy density (410), at least at one loop, provided the final result is expressed in terms of the renormalized mass rather than the bare one.

24.5 The Bubble Diagrams

The previous sections have shown the central role played by the bubble diagrams in the vacuum energy problem. These diagrams do not affect the physical predictions when the gravitational field is turned off and this is why, in standard quantum field theory, there are usually ignored. In this section, we wish to discuss in more detail this type of diagram. For this purpose, we will analyze them in ordinary quantum mechanics where the technical aspects are less complicated and where the interpretation is easier [54, 55, 56].

24.5.1 Quantum Mechanics as a Field Theory

Let us start with the simplest quantum-mechanical system, namely the one-dimensional harmonic oscillator. Let us denote by $x(t)$ the position of the particle evolving into a parabolic potential. Then, the corresponding Lagrangian is given by

$$L(\dot{x}, x) = \frac{1}{2}m\dot{x}^2 - \frac{1}{2}m\omega^2 x^2 \,, \tag{428}$$

where m is the mass of the particle and ω is the effective frequency. Then, let us define the "scalar field" $\Phi(t)$ by

$$\Phi(t) \equiv \sqrt{m}x(t) \,, \tag{429}$$

which implies that Φ has dimension $-1/2$. As a consequence, the Lagrangian now reads

$$L = \frac{\dot{\Phi}^2}{2} - \frac{\omega^2}{2}\Phi^2 \,. \tag{430}$$

This Lagrangian is similar to the one one encounters in field theory for a free scalar field. This means that all the techniques of quantum field theory can in fact be used in ordinary quantum mechanics. Of course, this does not lead to genuine new results since both approaches are equivalent but this can shed a new light of some physical results. This is the strategy that we use here applied to the vacuum energy problem. We now quickly remind how the formalism of quantum field theory can be implemented in quantum mechanics. We will also compare this approach to the standard approach of quantum mechanics. The first step is to define the conjugate momentum. It is given by

$$\Pi(t) = \frac{\partial L}{\partial \dot{\Phi}} = \dot{\Phi}(t) \,. \tag{431}$$

and this leads to the following Hamiltonian

$$H = \frac{\Pi^2}{2} + \frac{\omega^2}{2}\Phi^2 \,. \tag{432}$$

The next step is to introduce the creation and annihilation $c^\dagger$ and c operators. They are defined by the expressions

$$\Phi = \frac{1}{\sqrt{2\omega}}\left(c^\dagger + c\right) \,, \tag{433}$$

$$\Pi = i\sqrt{\frac{\omega}{2}}\left(c^\dagger - c\right) \,. \tag{434}$$

As usual one can check that $[\Phi, \Pi] = i$ implies $\left[c, c^\dagger\right] = 1$. As it is standard in field theory, we now work in the Heisenberg picture where the operators are time dependent. A straightforward calculation shows that the Hamiltonian can be expressed as

$$H = \frac{\omega}{2}\left(cc^\dagger + c^\dagger c\right) \,. \tag{435}$$

This allows us to calculate the time evolution of the operator c. Indeed, the Heisenberg equation reads

$$i\frac{\mathrm{d}c}{\mathrm{d}t} = [c, H] = \omega c \,, \tag{436}$$

from which we deduce that

$$c(t) = c(0)\mathrm{e}^{-i\omega t} = c_0\mathrm{e}^{-i\omega t} \,. \tag{437}$$

As a consequence, the field operator can be written in terms of the creation and annihilation operators in a way which is very similar to Eq. (357), namely

$$\Phi(t) = \frac{1}{\sqrt{2\omega}}\left(c_0\mathrm{e}^{-i\omega t} + c_0^\dagger\mathrm{e}^{i\omega t}\right) \,. \tag{438}$$

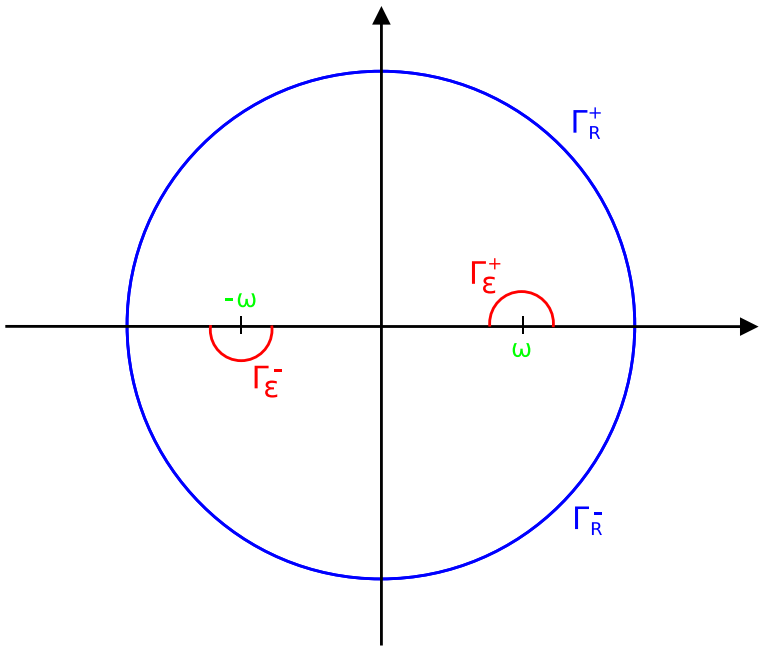


Figure 155: Contours in the complex time plane used to calculate the Feynman propagators of the one-dimensional harmonic oscillator. As usual, there are two poles on the real axis that can be avoided by going along the two small red circles. The final contour is closed by a large blue circle of radius R.

Of course we do not have an integral over the Fourier modes because, in quantum mechanics, we deal with a single harmonic oscillator as opposed to an infinite collection of harmonic oscillators in field theory.

At this level, the theory is known exactly. It is clear that the most interesting part is in fact the treatment of the interactions which, in field theory, is based on the calculation of the Feynman diagrams. Since this calculation is itself based on the calculation of the propagator, one must now evaluate it for our simple system. It is defined by an equation similar to Eq. (397), namely

$$D(t_1,t_2) \equiv \langle 0|T\left[\Phi(t_1)\Phi(t_2)\right]|0\rangle\,, \tag{439}$$

where we recall that the time ordered product is defined by

$$T\left[\Phi(t_1)\Phi(t_2)\right] = \begin{cases}\Phi(t_1)\Phi(t_2), & t_1 > t_2\\ \Phi(t_2)\Phi(t_1), & t_2 > t_1.\end{cases}$$

Then, the calculation proceeds straightforwardly and one obtains for $t_1 > t_2$

$$\begin{aligned} D(t_1,t_2) &= \left\langle 0\left|\frac{1}{\sqrt{2\omega}}\left(c_0 e^{-i\omega t_1} + c_0^\dagger e^{i\omega t_1}\right)\right.\right. \\ &\quad \left.\left.\frac{1}{\sqrt{2\omega}}\left(c_0 e^{-i\omega t_2} + c_0^\dagger e^{i\omega t_2}\right)\right|0\right\rangle \qquad (440)\\ &= \frac{1}{2\omega}e^{-i\omega(t_1-t_2)}\,, \qquad (441)\end{aligned}$$

and, in a similar way if $t_2 > t_1$,

$$\begin{aligned} D(t_1,t_2) &= \left\langle 0\left|\frac{1}{\sqrt{2\omega}}\left(c_0 e^{-i\omega t_2} + c_0^\dagger e^{i\omega t_2}\right)\right.\right. \\ &\quad \left.\left.\frac{1}{\sqrt{2\omega}}\left(c_0 e^{-i\omega t_1} + c_0^\dagger e^{i\omega t_1}\right)\right|0\right\rangle \qquad (442)\\ &= \frac{1}{2\omega}e^{i\omega(t_1-t_2)}\,. \qquad (443)\end{aligned}$$

The two previous equations can be summarized into a single one

$$D(t_1,t_2)=\frac{1}{2\omega}\mathrm{e}^{-i\omega|t_2-t_1|}\,. \tag{444}$$

We see that the system is so simple that we obtain an explicit expression of the propagator in real space (in fact, in field theory, there is also an expression of the propagator in real space but it is not so often used because of its complexity – it is given in terms of ordinary and modified Bessel functions –). Nevertheless, in order to compare with the standard approach and Eq. (398), it is interesting to obtain the expression of the propagator in Fourier space. The Fourier transform of a function $f(t)$ is defined by

$$f(t)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{+\infty}f(E)\,\mathrm{e}^{iEt}\,\mathrm{d}E. \tag{445}$$

The calculation is easy and well-known. Here, for convenience, we quickly remind how it proceeds. For that purpose, let us consider the function

$$f(z)\equiv\frac{\mathrm{e}^{-izt}}{z^2-\omega^2}\,. \tag{446}$$

It has two poles at $z=\pm\omega$ on the real axis, see Fig. 155. We assume that $t>0$ and consider the following contour: along the real axis with two small circles $\Gamma_\epsilon^\pm$ around the two poles (the circle around $z=-\omega$ goes into the lower part of the complex plane while the circle around $z=+\omega$ goes into the upper part); and we complete by a big circle Γ_R^- going into the lower part of the complex plane. In this case, only the pole $z=+\omega$ is inside the contour $\Gamma=\mathbb{R}\cup\Gamma_\epsilon^\pm\cup\Gamma_R^-$, see Fig. 155. We have

$$\lim_{|z|\to\infty}|zf(z)|=\lim_{|z|\to\infty}\frac{|z|\mathrm{e}^{\Im(z)t}}{z^2-\omega^2}=0\,, \tag{447}$$

since $\Im(z)<0$ in the lower part of the complex plan. According to the first Jordan lemma, this means that the integral on the big circle vanishes. In the same way, we have $\lim_{z\to0}|zf(z)|=0$ and the second Jordan lemma tells that the integral on $\Gamma_\epsilon^\pm$ is also zero. Then, using the fact that $f(z)\equiv P(z)/Q(z)$ and that, in this case, the residue can be written as $\mathrm{Res}(f,z)=P(z)/Q'(z)$, one obtains

$$\mathrm{Res}(f,z=+\omega)=\frac{\mathrm{e}^{-i\omega t}}{2\omega}. \tag{448}$$

As a consequence

$$\begin{aligned}\lim_{R\to+\infty}\left[\frac{i}{2\pi}\int_\Gamma f(z)\mathrm{d}z\right] &= \frac{i}{2\pi}\int_{-\infty}^{\infty}f(z)\mathrm{d}z\\ &= \frac{i}{2\pi}\times-2i\pi\mathrm{Res}(f,z=+\omega)\\ &= \frac{\mathrm{e}^{-i\omega t}}{2\omega},\end{aligned} \tag{449}$$

where the minus sign in the second line comes from the fact that the contour is clockwise (*i.e.* opposite to the direct direction).

Now if $t<0$, then the big circle is taken in the upper plane. As a consequence, the pole inside the contour is now the one located at $z=-\omega$. Therefore,

$$\begin{aligned}\frac{i}{2\pi}\int_\Gamma f(z)\mathrm{d}z &= \frac{i}{2\pi}\int_{-\infty}^{\infty}f(z)\mathrm{d}z\\ &= \frac{i}{2\pi}\times+2i\pi\mathrm{Res}(f,z=-\omega)\\ &= \frac{\mathrm{e}^{i\omega t}}{2\omega}.\end{aligned} \tag{450}$$

The previous considerations allow us to conclude that

$$\frac{i}{2\pi}\int_{-\infty}^{+\infty}\frac{\mathrm{e}^{-iEt}}{E^2-\omega^2}\mathrm{d}E=\frac{\mathrm{e}^{-i\omega|t|}}{2\omega}=D(t), \tag{451}$$

that is to say we have established the Fourier transform of the propagator. It should be obvious that the above equation is the counterpart of Eq. (398). As in field theory, we will show that it can be used to develop a perturbative method which allows us to take into account interactions.

24.5.2 Perturbations Theory in Quantum Mechanics

Before discussing our main subject, we need to explain how the Feynman diagrams can be used in quantum mechanics [55, 56]. Usually, in quantum mechanics, the perturbation theory is not based on the Feynman diagrams [57]. This gives the impression that the techniques of field theory are very different. In fact, as we now demonstrate, these techniques can also be utilized in ordinary quantum mechanics [54] and, obviously (as could have been guessed from the very beginning), they lead to the same physical predictions. In the following, we will discuss this question and compare the two approaches in some details. We believe that this can improve our physical understanding of the vacuum energy problem.

In order to achieve the above mentioned task, we need to recall how interactions are treated in quantum mechanics. For this purpose, let us consider a system obeying the following Schrödinger equation

$$i\frac{\mathrm{d}|\Psi(t)\rangle_{\mathrm{S}}}{\mathrm{d}t}=H(p_{\mathrm{S}},x_{\mathrm{S}})|\Psi(t)\rangle_{\mathrm{S}}, \tag{452}$$

where $H(p_{\mathrm{S}},x_{\mathrm{S}})$ is the Hamiltonian operator. The above equation is written in the Schrödinger representation, hence the subscript "S". Then, one can define the evolution operator $U(t,t_{\mathrm{i}})$ which relates the state vector at the time t to the state vector at some initial time $t_{\mathrm{i}}<t$ by the following expression

$$|\Psi(t)\rangle_{\mathrm{S}}=U(t,t_{\mathrm{i}})|\Psi(t_{\mathrm{i}})\rangle_{\mathrm{S}}. \tag{453}$$

This operator obeys

$$i\frac{\partial U(t,t_{\mathrm{i}})}{\partial t}=HU(t,t_{\mathrm{i}})\,, \tag{454}$$

and, provided the Hamiltonian is not explicitly time dependent, it can also be written as

$$U(t,t_{\mathrm{i}})=\mathrm{e}^{-iH(t-t_{\mathrm{i}})}. \tag{455}$$

Of course, in this representation, the operator p_{S} and x_{S} are time independent since only the state can change with time.

One the contrary, in the Heisenberg representation, the state vector does not evolve and can be expressed in terms of the Schrödinger state vector evaluated at some reference time $t=t_0$,

$$|\Psi\rangle_{\mathrm{H}}\equiv|\Psi(t_0)\rangle_{\mathrm{S}}. \tag{456}$$

Notice that the reference time is arbitrary and is not necessarily t_{i}. In this picture, the operators are time-dependent and, for instance, $x_{\mathrm{H}}(t)$ is given by

$$x_{\mathrm{H}}(t)\equiv U^{\dagger}(t,t_0)x_{\mathrm{S}}U(t,t_0), \tag{457}$$

such that $x_{\mathrm{H}}(t_0)=x_{\mathrm{S}}$. In this picture, the time evolution of the operators is computed from the Heisenberg equation which reads

$$i\frac{\mathrm{d}x_{\mathrm{H}}}{\mathrm{d}t} = i\frac{\partial U^{\dagger}(t,t_0)}{\partial t}x_{\mathrm{S}}U(t,t_0)+iU^{\dagger}(t,t_0)x_{\mathrm{S}}\frac{\partial U(t,t_0)}{\partial t} \tag{458}$$

$$= -U^{\dagger}Hx_{\mathrm{S}}U+U^{\dagger}x_{\mathrm{S}}HU \tag{459}$$

$$= [x_{\mathrm{S}},H]\,, \tag{460}$$

where in the second line we have used that $-i\partial U^\dagger/\partial t = U^\dagger H$.

Let us now consider the case where interactions are explicitly present. We assume that the corresponding Hamiltonian can be split into two parts, one corresponding to the free theory and one corresponding to the interactions

$$H = H_0 + H_{\rm int}. \tag{461}$$

We also assume that $H_{\rm int}$ is a small perturbation. The free evolution, due to the free Hamiltonian H_0, is described by the evolution operator U_0. This operator is of course different from U which describes the full evolution with the interactions taken into account. Clearly, U_0 can be expressed as

$$U_0(t,t_{\rm i}) = {\rm e}^{-iH_0(t-t_{\rm i})}\,. \tag{462}$$

Then the idea is to factor out the free evolution (which is supposed to be known) and to focus on the time evolution due to the perturbation on top of the free evolution. For this purpose, we define the interaction representation by (again, the representations are supposed to coincide when $t = t_0$)

$$\begin{aligned} x_{\rm I}(t) &= U_0^\dagger(t,t_0)x_{\rm S}U_0(t,t_0) &(463)\\ &= {\rm e}^{iH_0(t-t_0)}x_{\rm S}{\rm e}^{-iH_0(t-t_0)}. &(464)\end{aligned}$$

Clearly $x_{\rm I}(t)$ is different from $x_{\rm H}(t)$ because its time evolution is "generated" only by the free Hamiltonian and not by the total one. Let us now calculate the equation of motion of $x_{\rm I}(t)$. One has

$$\begin{aligned} \frac{{\rm d}x_{\rm I}}{{\rm d}t} &= iH_0x_{\rm I} + {\rm e}^{iH_0(t-t_0)}x_{\rm S}\times -iH_0{\rm e}^{-iH_0(t-t_0)} &(465)\\ &= i\left[H_0, x_{\rm I}\right]. &(466)\end{aligned}$$

Therefore, the time evolution of $x_{\rm I}(t)$ is controlled by the free Hamiltonian. This evolution is supposed to be known. In the same manner, we define the state vector in the interaction picture by

$$|\Psi(t)\rangle_{\rm I} = U_0^\dagger(t,t_0)|\Psi(t)\rangle_{\rm S}. \tag{467}$$

As a consequence, in the interaction picture, both the state vectors and the operators are time dependent. The equation obeyed by the state vector is given by

$$\begin{aligned} i\frac{{\rm d}|\Psi\rangle_{\rm I}}{{\rm d}t} &= -H_0|\Psi\rangle_{\rm I} + {\rm e}^{iH_0(t-t_0)}i\frac{{\rm d}|\Psi\rangle_{\rm S}}{{\rm d}t} &(468)\\ &= -H_0{\rm e}^{iH_0(t-t_0)}|\Psi\rangle_{\rm S}\\ &\quad +{\rm e}^{iH_0(t-t_0)}(H_0+H_{\rm int})|\Psi\rangle_{\rm S} &(469)\\ &= {\rm e}^{iH_0(t-t_0)}H_{\rm int}|\Psi\rangle_{\rm S} &(470)\\ &= {\rm e}^{iH_0(t-t_0)}H_{\rm int}{\rm e}^{-iH_0(t-t_0)}|\Psi\rangle_{\rm I} &(471)\\ &= H_{\rm I}|\Psi\rangle_{\rm I}, &(472)\end{aligned}$$

where $H_{\rm I} = U_0^\dagger(t,t_0)H_{\rm int}U_0(t,t_0)$ in agreement with the definition (463). The time evolution of $|\Psi\rangle_{\rm I}$ is therefore generated only by the interacting Hamiltonian. Then, it is natural to define the evolution operator in the interaction picture. This operator is associated with the Schrödinger equation (472). Its definition reads

$$|\Psi(t)\rangle_{\rm I} = U_{\rm I}(t,t_{\rm i})|\Psi(t_{\rm i})\rangle_{\rm I}. \tag{473}$$

Of course $U_{\rm I}$ is different from U_0 (and from U). A straightforward calculation shows that it can also be expressed as

$$U_{\rm I}(t,t_{\rm i}) = {\rm T}\exp\left[-i\int_{t_{\rm i}}^{t}{\rm d}\tau H_{\rm I}(\tau)\right]. \tag{474}$$

Another expression for $U_{\rm I}$ is based on the following considerations. From Eqs. (473) and (467), we have

$$\begin{aligned} |\Psi(t)\rangle_{\rm I} &= U_{\rm I}(t,t_{\rm i})|\Psi(t_{\rm i})\rangle_{\rm I} && (475)\\ &= U_{\rm I}(t,t_{\rm i})U_0^\dagger(t_{\rm i},t_0)|\Psi(t_{\rm i})\rangle_{\rm S} && (476)\\ &= U_0^\dagger(t,t_0)|\Psi(t)\rangle_{\rm S}. && (477)\end{aligned}$$

Therefore, one obtains

$$\begin{aligned} |\Psi(t)\rangle_{\rm S} &= U_0(t,t_0)U_{\rm I}(t,t_{\rm i})U_0^\dagger(t_{\rm i},t_0)|\Psi(t_{\rm i})\rangle_{\rm S} && (478)\\ &= U(t,t_{\rm i})|\Psi(t_{\rm i})\rangle_{\rm S}, && (479)\end{aligned}$$

from which we deduce that

$$U(t,t_{\rm i}) = U_0(t,t_0)U_{\rm I}(t,t_{\rm i})U_0^\dagger(t_{\rm i},t_0), \tag{480}$$

or

$$\begin{aligned} U_{\rm I}(t,t_{\rm i}) &= U_0^\dagger(t,t_0)U(t,t_{\rm i})U_0^\dagger(t_{\rm i},t_0), && (481)\\ &= {\rm e}^{iH_0(t-t_0)}{\rm e}^{-iH(t-t_{\rm i})}{\rm e}^{-iH_0(t_{\rm i}-t_0)}. && (482)\end{aligned}$$

This expression is very natural since it expresses nothing but the fact that the full evolution of the system is just the combination of the free evolution and of the evolution due to the interacting term. Let us also remark that one can write

$$\begin{aligned} x_{\rm I}(t) &= U_0^\dagger(t,t_0)x_{\rm S}U_0(t,t_0) && (483)\\ &= U_0^\dagger(t,t_0)U(t,t_0)x_{\rm H}U^\dagger(t,t_0)U_0(t,t_0) && (484)\\ &= {\rm e}^{iH_0(t-t_0)}{\rm e}^{-iH(t-t_0)}x_{\rm H}(t){\rm e}^{iH(t-t_0)}{\rm e}^{-iH_0(t-t_0)} && (485)\\ &= U_{\rm I}(t,t_0)x_{\rm H}(t)U_{\rm I}^\dagger(t,t_0). && (486)\end{aligned}$$

Again, this result is very intuitive and expresses the fact that, in the interacting picture, the free evolution of the operators is factorized out.

After these preliminaries, one can now derive the Gell-Man Law equation which is at the heart of the perturbative treatment presented in what follows. Let $|n_{\rm I}\rangle$ be the energy eigenstates of the full Hamiltonian, *i.e.* the free Hamiltonian plus the Hamiltonian describing the interactions. We denote the true vacuum state by $|0_{\rm I}\rangle \equiv |\Omega\rangle$, in agreement with the conventions adopted in the previous subsections. Then, one can always expand the vacuum state of the free theory according to

$$\begin{aligned} |0\rangle &= \sum_{n=0}^{\infty}|n_{\rm I}\rangle\langle n_{\rm I}|0\rangle, && (487)\\ &= |\Omega\rangle\langle\Omega|0\rangle + \sum_{n\neq 0}^{\infty}|n_{\rm I}\rangle\langle n_{\rm I}|0\rangle. && (488)\end{aligned}$$

As a consequence, applying the operator ${\rm e}^{-iH(t+t_0)}$ to the above relation, one obtains

$$\begin{aligned} {\rm e}^{-iH(t+t_0)}|0\rangle &= {\rm e}^{-iE_0(t+t_0)}|\Omega\rangle\langle\Omega|0\rangle \\ &+ \sum_{n\neq 0}^{\infty}{\rm e}^{-iE_n(t+t_0)}|n_{\rm I}\rangle\langle n_{\rm I}|0\rangle. && (489)\end{aligned}$$

Then, we take the limit $t \to \infty(1-i\epsilon)$. This kills all the terms on the right hand side but the first one. Indeed, we have $E_n > E_0$ $(n \neq 0)$ and this means that ${\rm e}^{-iE_0 t}$ goes to zero

less rapidly than all the other exponential terms. Therefore, in this limit, Eq. (489) reads $\mathrm{e}^{-iH(t+t_0)}|0\rangle \simeq \mathrm{e}^{-iE_0(t+t_0)}|\Omega\rangle\langle\Omega|0\rangle$ and, by inverting this formula, this allows us to express the interacting vacuum as

$$|\Omega\rangle = \lim_{t\to\infty(1-i\epsilon)} \frac{\mathrm{e}^{iE_0(t+t_0)}}{\langle\Omega|0\rangle}\mathrm{e}^{-iH(t+t_0)}|0\rangle \tag{490}$$

$$= \lim_{t\to\infty(1-i\epsilon)} \frac{\mathrm{e}^{iE_0(t+t_0)}}{\langle\Omega|0\rangle}\mathrm{e}^{-iH(t+t_0)}\mathrm{e}^{iH_0(t+t_0)}|0\rangle$$

$$= \lim_{t\to\infty(1-i\epsilon)} \frac{\mathrm{e}^{iE_0(t+t_0)}}{\langle\Omega|0\rangle}U_{\mathrm{I}}(t_0,-t)|0\rangle. \tag{491}$$

In the second line, we have used the fact that $H_0|0\rangle = 0$ since we can always define the ground state as the state associated to the zero of energy. This means that $\mathrm{e}^{iH_0(t+t_0)}|0\rangle = |0\rangle$ and explains the appearance of the new factor $\mathrm{e}^{iH_0(t+t_0)}$. In the same fashion, using $\mathrm{e}^{iH(t-t_0)}|\Omega\rangle = \mathrm{e}^{iE_0(t-t_0)}|\Omega\rangle$, one has

$$\langle 0|\mathrm{e}^{-iH(t-t_0)} = \lim_{t\to\infty(1-i\epsilon)} \langle 0|\Omega\rangle\langle\Omega|\mathrm{e}^{-iE_0(t-t_0)}, \tag{492}$$

from which one deduces that

$$\langle\Omega| = \lim_{t\to\infty(1-i\epsilon)} \frac{\mathrm{e}^{iE_0(t-t_0)}}{\langle 0|\Omega\rangle}\langle 0|\mathrm{e}^{-iH(t-t_0)} \tag{493}$$

$$= \lim_{t\to\infty(1-i\epsilon)} \frac{\mathrm{e}^{iE_0(t-t_0)}}{\langle 0|\Omega\rangle}\langle 0|\mathrm{e}^{iH_0(t-t_0)}\mathrm{e}^{-iH(t-t_0)}$$

$$= \lim_{t\to\infty(1-i\epsilon)} \frac{\mathrm{e}^{iE_0(t-t_0)}}{\langle 0|\Omega\rangle}\langle 0|U_{\mathrm{I}}(t,t_0). \tag{494}$$

Therefore, the norm of the vacuum state is given by

$$\langle\Omega|\Omega\rangle = \lim_{t\to\infty(1-i\epsilon)} \frac{\mathrm{e}^{2iE_0t}}{|\langle 0|\Omega\rangle|^2}\langle 0|U_{\mathrm{I}}(t,t_0)U_{\mathrm{I}}(t_0,-t)|0\rangle. \tag{495}$$

In the following, we take $\langle\Omega|\Omega\rangle = 1$ although this choice is not mandatory (but, then, when we compute a correlation function, it would be necessary to divide the corresponding expression by $\langle\Omega|\Omega\rangle$).

We are now in a position where one can calculate the two-point correlation function of the field operator [recall that $x(t)$ is directly proportional to the field operator, see Eq. (429)]. Using the previous results, one obtains

$$\langle\Omega|x_{\mathrm{H}}(t_2)x_{\mathrm{H}}(t_1)|\Omega\rangle = \lim_{t\to\infty(1-i\epsilon)} \frac{\mathrm{e}^{2iE_0t}}{|\langle 0|\Omega\rangle|^2}\langle 0|U_{\mathrm{I}}(t,t_0)U_{\mathrm{I}}^{\dagger}(t_2,t_0)x_{\mathrm{I}}(t_2)U_{\mathrm{I}}(t_2,t_0)U_{\mathrm{I}}^{\dagger}(t_1,t_0)x_{\mathrm{I}}(t_1)U_{\mathrm{I}}(t_1,t_0)U_{\mathrm{I}}(t_0,-t)|0\rangle \tag{496}$$

$$= \lim_{t\to\infty(1-i\epsilon)} \frac{\langle 0|U_{\mathrm{I}}(t,t_0)U_{\mathrm{I}}(t_0,t_2)x_{\mathrm{I}}(t_2)U_{\mathrm{I}}(t_2,t_0)U_{\mathrm{I}}(t_0,t_1)x_{\mathrm{I}}(t_1)U_{\mathrm{I}}(t_1,t_0)U_{\mathrm{I}}(t_0,-t)|0\rangle}{\langle 0|U_{\mathrm{I}}(t,t_0)U_{\mathrm{I}}(t_0,-t)|0\rangle} \tag{497}$$

$$= \lim_{t\to\infty(1-i\epsilon)} \frac{\langle 0|U_{\mathrm{I}}(t,t_2)x_{\mathrm{I}}(t_2)U_{\mathrm{I}}(t_2,t_1)x_{\mathrm{I}}(t_1)U_{\mathrm{I}}(t_1,-t)|0\rangle}{\langle 0|U_{\mathrm{I}}(t,-t)|0\rangle} \tag{498}$$

$$= \lim_{t\to\infty(1-i\epsilon)} \frac{\langle 0|\mathrm{T}\left[x_{\mathrm{I}}(t_2)x_{\mathrm{I}}(t_1)U_{\mathrm{I}}(t,-t)\right]|0\rangle}{\langle 0|U_{\mathrm{I}}(t,-t)|0\rangle} \tag{499}$$

$$= \lim_{t\to\infty(1-i\epsilon)} \frac{\langle 0|\mathrm{T}\left[x_{\mathrm{I}}(t_2)x_{\mathrm{I}}(t_1)\exp\left(-i\int_{-t}^{t}\mathrm{d}\tau H_{\mathrm{I}}\right)\right]|0\rangle}{\langle 0|\exp\left(-i\int_{-t}^{t}\mathrm{d}\tau H_{\mathrm{I}}\right)|0\rangle}, \tag{500}$$

where, in order to go from the first to the second line, we have used Eq. (495) and the normalization $\langle\Omega|\Omega\rangle = 1$ to express the term $|\langle 0|\Omega\rangle|^2$. Eq. (500) is the Gell-Mann Law equation [16]. It will be the basis for our perturbative treatment of quantum mechanics. It plays the same role as Eq. (394) since it allows us to perturbatively evaluate the various correlation functions in terms of Feynman diagrams (the Gell-Mann Law equation can be generalized to higher correlation function if needed).

24.5.3 Quantum Mechanics and Bubble Diagrams

In order to mimic the self-interacting field theory studied before, we now consider a quartic oscillator in quantum mechanics [55, 56], *i.e.* a system where the potential is given by $V(x) \sim x^2 + x^4$. More precisely, this means that the interacting Hamiltonian can be expressed as

$$H_{\rm int} = \frac{\lambda}{4!}\Phi^4, \tag{501}$$

where we recall that Φ is given by Eq. (429). Let us then compute the two-point correlation function. For this purpose, as explained before, we use the Gell-Mann Law equation. The numerator reads

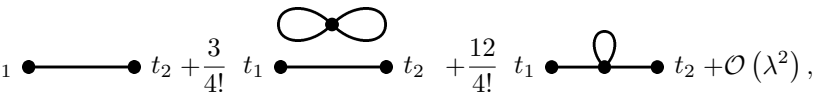
$$\left\langle 0 \left| \mathrm{T}\left[\Phi(t_2)\Phi(t_1)\exp\left(-i\int \mathrm{d}\tau H_{\rm I}\right)\right]\right| 0\right\rangle, \tag{502}$$

where, for simplicity, we do not write the limits (but there will be reestablished when needed). It is also important to remember that the field are written in the interacting picture (and, again for simplicity we do not write the subscript "I", they can be considered as free fields). Obviously, one cannot calculate exactly this quantity so we do it perturbatively by expanding the exponential. At first order in the coupling constant λ, we obtain

$$\begin{aligned}\left\langle 0 \left| \mathrm{T}\left\{\Phi(t_2)\Phi(t_1)\left[1 - i\frac{\lambda}{4!}\int \mathrm{d}\tau\Phi^4(\tau) + \cdots\right]\right\}\right| 0\right\rangle &= \langle 0|\mathrm{T}\left[\Phi(t_2)\Phi(t_1)\right]|0\rangle \\ &\quad -i\frac{\lambda}{4!}\int \mathrm{d}\tau \left\langle 0 \left| \mathrm{T}\left[\Phi(t_2)\Phi(t_1)\Phi^4(\tau)\right]\right| 0\right\rangle + \cdots, \qquad (503)\\ &= D(t_1,t_2) - i\frac{\lambda}{4!}\int \mathrm{d}\tau \left\langle 0 \left| \mathrm{T}\left[\Phi(t_2)\Phi(t_1)\Phi^4(\tau)\right]\right| 0\right\rangle + \cdots. \qquad (504)\end{aligned}$$

It should now be clear that the same expression can also be written in terms on Feynman diagrams. One arrives at the following expression

$$\left\langle 0 \left| \mathrm{T}\left[\Phi(t_2)\Phi(t_1)\exp\left(-i\int \mathrm{d}\tau H_{\rm I}\right)\right]\right| 0\right\rangle =$$



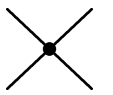
(505)

where we have defined the following Feynman rules [55, 56]

$$D(t_1,t_2) \equiv$$

(506)

$$-i\lambda\int \mathrm{d}\tau \equiv$$

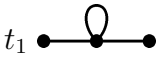


. (507)

Clearly, these Feynman rules are nothing but the one-dimensional version of the standard Feynman rules (402) and (403) of quantum field theory. The only difference is that four dimensional space-time integrations are simply replaced with one-dimensional time integration. In fact, in terms of diagrams, the expressions in field theory or in quantum mechanics are exactly similar. In particular, we see the appearance of diagrams with loops and external legs (the tadpole) and also of diagrams with loops but no external legs, our bubble diagrams. The advantage of our approach now becomes clear. We are in a position where not only one can compute these diagrams in quantum mechanics but we can also investigate their deep meaning by comparing

the result with the standard perturbative theory of quantum mechanics where everything is well under control.

Let us start with the tadpole diagram. Using Eqs. (506) and (507), the corresponding expression can be written as



$$= -i\lambda \int \mathrm{d}\tau D(t_1,\tau)D(\tau,\tau)D(\tau,t_2) \tag{508}$$

$$= -\frac{i\lambda}{8\omega^3}\int \mathrm{d}\tau \mathrm{e}^{-i\omega|t_1-\tau|-i\omega|\tau-t_2|} \tag{509}$$

$$= -\frac{i\lambda}{4\omega^2}D(t_2,t_1)\left(|t_2-t_1|-\frac{i}{\omega}\right). \tag{510}$$

The most striking difference with the case of quantum field theory is that the tadpole diagram is now finite. In some sense, this is the signal that ordinary quantum mechanics does not need renormalization: the perturbative approach leads to finite result. Technically, this is due to the fact that we deal with one-dimensional integrals that have better convergence properties. Physically, this is due to the fact that a single quantum-mechanical oscillator leads to finite predictions while an infinite collections of such systems apparently lead to infinite physical quantities.

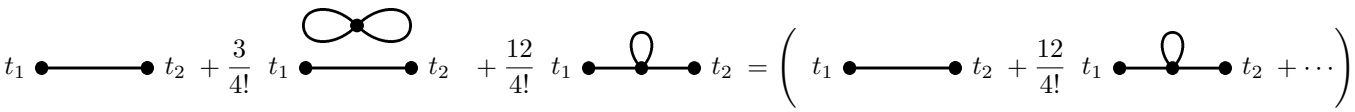
Now let us calculate the "bubble diagram" present in the second term of the above expansion (505). Having established that the tadpole diagram is now finite, it is particularly interesting to see what happens for this type of diagram. Using again the Feynman rules (506) and (507), it is straightforward to establish that

$$= -i\lambda \int D^2(\tau,\tau)\mathrm{d}\tau \tag{511}$$

$$= -i\frac{\lambda}{4\omega^2}\int \mathrm{d}\tau = \infty. \tag{512}$$

Therefore, even in quantum mechanics, the bubble diagram remains divergent. This shows that the divergent nature of the loop and bubble diagrams is, in some sense, different. They are both divergent in quantum field theory but one (loop diagrams with external legs) becomes finite in the limit of quantum mechanics while the other (bubble diagram) remains infinite.

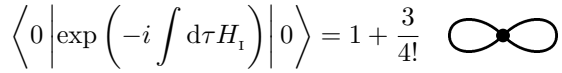
But this now leads to the following question. We know from the standard perturbation theory of quantum mechanics that all the physical predictions are finite, even without renormalization. However, using the other approach based on the Feynman diagrams, we have just seen that it leads to terms that can be divergent. How these two facts can be consistent with each other? The answer is of course that, as in field theory, the bubble diagrams exactly cancel out in the calculation of the correlation functions. This can easily be seen if one notices that



(513)

(514)

and that



(515)

Therefore (as expected) the infinities of the bubble diagram never play a role in ordinary quantum mechanics. As a consequence, the two-point correlation function is given by

$$\langle\Omega|\Phi(t_2)\Phi(t_1)|\Omega\rangle = \quad t_1 \bullet\!\!-\!\!-\!\!\bullet\ t_2 \ + \frac{12}{4!}\ t_1 \bullet\!\!-\!\!\bigcirc\!\!-\!\!\bullet\ t_2 \ + \mathcal{O}\left(\lambda^2\right), \tag{516}$$

which is perfectly finite. Again, in terms of Feynman diagrams the above equation is strictly equivalent to the corresponding one in quantum field theory, see Eq. (421).

24.5.4 Quantum Mechanics and Vacuum Energy

Let us now discuss how the vacuum energy is evaluated in ordinary quantum mechanics. The calculation is straightforward when there is no interaction and, from Eq. (435), one obtains

$$\langle H\rangle = \frac{\omega}{2}. \tag{517}$$

This is of course nothing but the ground state energy of an harmonic oscillator. It cannot be zero because, due the Heisenberg uncertainty principle, the kinetic and potential energy cannot vanish at the same time. It can also be rewritten as

$$\langle H\rangle = \omega^2 D(0), \tag{518}$$

where we have used Eq. (444). This exactly corresponds to Eq. (410) with $m = \omega$ and $4 \to 1$ (since we now work in one dimension rather than in four), except that there is a sign difference which comes from the fact that, in field theory, we have used the signature (- + + +). Of course, the big difference is that $D(0)$ is a finite quantity in quantum mechanics. In some sense, the vacuum energy problem appears to be very simple, almost trivial. The ground state of a quantum-mechanical oscillator is finite but a quantum field is a system which can be described by an infinite collection of harmonic oscillators and, as a consequence, its ground state energy is infinite.

Let us now consider a case where an interaction is present as we did in Sec. 24.4.3. For simplicity, we consider again the case of a quartic oscillator with $V_{\rm int} = \lambda\Phi^4/4!$. Upon using the standard perturbation theory in quantum mechanics, one can calculate the displacement of the energy levels. They are given by the standard formula [57]

$$E_n = E_n^0 + \langle n|V_{\rm int}|n\rangle, \tag{519}$$

where $|n\rangle$ are the unperturbed eigenvectors. It is easy to show that they can be expressed as

$$\Delta E_n \equiv E_n - E_n^0 = \frac{\lambda}{32\omega^2}\left(2n^2+2n+1\right), \tag{520}$$

which means that, for the first two levels, the shift in energy is given by

$$\Delta E_0 \ = \ \frac{\lambda}{32\omega^2}, \quad \Delta E_1 = \frac{5\lambda}{32\omega^2}. \tag{521}$$

We can now use the other method, based on the Feynman diagrams. It is easy to obtain that

$$\begin{aligned}\Delta E_0 \ &= \ \frac{\lambda}{4!}\left\langle\Phi^4\right\rangle = \frac{3\lambda}{4!}\left\langle\Phi^2\right\rangle^2 = \frac{\lambda}{8}D^2(0)\\ &= \ \frac{i}{8\int \mathrm{d}t}\end{aligned} \quad \bigcirc\!\!-\!\!\bullet\!\!-\!\!\bigcirc \tag{522}$$

Clearly, we have just obtained the strict equivalent of Eq. (420), the term $\int \mathrm{d}^4x$ being replaced by $\int \mathrm{d}t$ as could have been guessed in the context of quantum mechanics. Then, using the fact that $D(0) = 1/(2\omega)$, one obtains that

$$\Delta E_0 = \frac{\lambda}{32\omega^2}, \tag{523}$$

that is to say we recover the result established before, see Eq. (521). Therefore, we have shown explicitly that the two approaches lead to the same result. It is also interesting to notice that ΔE_0 is given by a bubble diagram but that this divergent graph is canceled by the infinite term $\int \mathrm{d}t$ so that a finite quantity is left.

The previous considerations also lead to the following question: before we had to deal with the renormalization of the mass. How does this aspect appear in the present context? In this case, we deal with the same diagrams, namely

$$\langle \Omega \,|T\left[\Phi(t_1)\Phi(t_2)\right]|\,\Omega\rangle \quad = \quad x_1 \bullet\!\!-\!\!-\!\!\bullet\, x_2 + \frac{1}{2}\; x_1 \bullet\!\!-\!\!\bigcirc\!\!-\!\!\bullet\, x_2 + \cdots\,, \tag{524}$$

or, in terms of explicit expressions [compare with Eqs. (421) and (422)]

$$\begin{aligned}\langle \Omega \,|T\left[\phi(t_1)\phi(t_2)\right]|\,\Omega\rangle &= D_{\mathrm{F}}(t_1-t_2) - \frac{i\lambda}{2}\int \mathrm{d}\tau D(t_1-\tau)D_{\mathrm{F}}(0)D_{\mathrm{F}}(\tau-t_2) &(525)\\ &= D_{\mathrm{F}}(t_1-t_2) + \frac{i\lambda}{2}D_{\mathrm{F}}(0)\frac{1}{2\pi}\int \mathrm{d}E \frac{\mathrm{e}^{-iE(t_1-t_2)}}{(E^2-\omega^2)^2}, &(526)\end{aligned}$$

and this leads to

$$\omega_{\mathrm{ren}}^2 = \omega^2 + \frac{\lambda}{2}D(0), \tag{527}$$

which is exactly Eq. (426) (again, there is a sign difference which originates from the sign difference in the propagator, see above). In quantum mechanics, the propagator is finite and therefore

$$\omega_{\mathrm{ren}}^2 = \omega^2 + \frac{\lambda}{4\omega}, \tag{528}$$

or

$$\omega_{\mathrm{ren}} = \omega + \frac{\lambda}{8\omega^2}. \tag{529}$$

Then, one can express the spectrum in terms of the renormalized "mass" ω_{ren} as we have done in quantum field theory although this is not necessary here since the result is anyway finite. Straightforward calculations lead to

$$E_n = \omega_{\mathrm{ren}}\left(n+\frac{1}{2}\right) - \frac{\lambda}{32\omega_{\mathrm{ren}}^2}\left(2n^2-2n-1\right). \tag{530}$$

It does not come as a surprised that, as a function of the renormalized mass, the spectrum is a different function of n, see Eq. (520). However, from the above expression one also obtains

$$E_1 - E_0 = \omega_{\mathrm{ren}}. \tag{531}$$

In presence of an interaction, the difference between the first excited state and the fundamental level has been "modified" (or, rather, is expressed differently). But, observationally, we define or measure the spectrum with respect to $E_1 - E_0$. In other words what we define as ω is in fact $E_1 - E_0$. Therefore, renormalizing ω consists in preserving this definition even in presence of an interaction. Obviously, $E_1 - E_0$ is not the bare ω (the one which appears in the Lagrangian) when the an-harmonic term is present. What we do here is to define ω as the observed one, namely as $E_1 - E_0$, and then calculate the spectrum in terms of that observational quantity. What is done in quantum field theory is clearly exactly similar to the above described procedure except of course that the bare quantities are in fact infinite because $D_{\mathrm{F}}(0)$ is infinite. Therefore, this exercise illustrates nicely the deep meaning of renormalization.

This concludes our discussion of the vacuum energy density in terms of Feynman diagrams. We have shown that the cosmological constant is in fact given in terms of very peculiar graphs, the so-called bubble diagrams. These diagrams are, in a sense, more divergent than the usual loop diagrams because they remain infinite even in the limit of quantum mechanics contrary to the last ones. In non gravitational physics, this is not a problem because the bubble diagrams always cancel out in the equations describing observable quantities. When the gravitational field is turned on, we face the tasks of renormalizing these diagrams which is more difficult than in the standard situation because of their bad behavior mentioned before. Given that

astrophysical observations seem to indicate that the vacuum energy is non vanishing (see below), the details of the renormalizing procedure become a crucial issue. Not only we have to extract a finite quantity from a divergent graph but this finite quantity must be in agreement with the observations. As argued before, the technique which consists in imposing a spatial cut-off is certainly not consistent (and, as well-known, gives a very large contribution to the vacuum energy). A more reasonable approach seems to be dimensional regularization since this satisfies Lorentz invariance and is therefore consistent with the vacuum equation of state. As shown before, this typically leads to Eq. (392). In the next section, we present a new argument, based on the Gaussian effective potential, which seems to support this conclusion.

24.6 The Gaussian Effective Potential

The Gaussian effective potential is a non perturbative approach to quantum field theory [58, 59, 60, 61, 62, 63, 64, 65, 66]. Originally developed in the context of quantum mechanics, it is has been generalized to field theory. Much less known is the fact that the Gaussian effective potential method has something to say about the vacuum energy problem and the aim of this section is to present these considerations [59]. In the next subsection, we quickly recall the main idea and how this approach can be applied to ordinary quantum mechanics. Then, we explain how it can be implemented in quantum field theory and, finally, we discuss its implication for the cosmological constant problem.

24.6.1 The Gaussian Effective Potential in Quantum Mechanics

The main idea underlying the Gaussian effective potential approach is the following one [58]. At the classical level, a system is described by a potential. Once this one is specified, one can compute the evolution of the system. When quantum effects are taken into account, the behavior of the system will be modified and, by means of the formalism of quantum mechanics, one can work out the corresponding physical predictions. The idea of the Gaussian effective potential is to find an effective potential which, at the same time, can be used as if it were a "classical" potential (that is to say can be used in the framework of Newtonian dynamics) and takes into account the quantum effects. At first sight, this approach seems equivalent to what is known in the literature as the effective potential [67, 68]. In this method, one requires the wave-function mean value to be centered at a fixed point Φ_0. Then, the effective potential gives the exact ground state energy of the system in presence of quantum corrections. However, in some situation, the result can be quite artificial. Consider for instance a situation where the wave-function possesses two large peaks on each side of Φ_0. In such a case, the effective potential does not necessarily lead to a correct description of what happens in the vicinity of Φ_0 because its shape could just be determined by some average procedure between the two distant peaks. Typically, one would obtain a convex potential centered at Φ_0 while our physical intuition rather indicates that the effective potential should be a double-well potential, the two wells corresponding to the two peaks of the wave-function. Another problem is that the standard effective potential is usually computed perturbatively in $\hbar$. Clearly, when the quantum corrections become important, this approach breaks down. Since the Gaussian effective potential does not suffer from the two above mentioned drawbacks, we will use it in this review. When possible, we will discuss the difference between the two approaches in order to stress their differences and similarities [69].

We now turn to the precise definition of the Gaussian effective potential. This definition is based on a variational principle. Here we consider a one-dimensional system as we have already done in Sec. 24.5.1. In particular, this means that the scalar field is given by Eq. (429). Then, the Gaussian effective potential is defined by [58]

$$V_{\mathrm{G}}\left(\Phi_0\right) = \min_{\Omega} \left\langle \Psi \left| H \right| \Psi \right\rangle , \tag{532}$$

where H is the Hamiltonian of the system and where the wave-function is taken to be a simple Gaussian (hence the name Gaussian effective potential)

$$\Psi\left(\Phi\right) = \left(\frac{\Omega}{\hbar\pi}\right)^{1/4} \mathrm{e}^{-\Omega(\Phi-\Phi_0)^2/(2\hbar)}. \tag{533}$$

The parameter Ω is related to the width of the wave-function. Here the idea is to find the value of Ω which minimizes the energy of the system. In practice, the mean value of the Hamiltonian that appears in Eq. (532) can be expressed as

$$\langle H\rangle = \int_{-\infty}^{\infty} \mathrm{d}\Phi \Psi^{*}(\Phi)\left[-\frac{\hbar^2}{2}\frac{\mathrm{d}^2}{\mathrm{d}\Phi^2} + V(\Phi)\right]\Psi(\Phi). \tag{534}$$

To illustrate how the calculation of the Gaussian effective potential works on a concrete example, we choose the following potential

$$V(\Phi) = \frac{1}{2}m^2\Phi^2 + \lambda\Phi^4, \tag{535}$$

that is to say the potential of an an-harmonic oscillator. Another motivation for this choice is that the comparison with field theory is easy since the prototypical model possesses the same potential. Upon using Eq. (533) in Eq. (534), one arrives at

$$\begin{aligned}\langle H\rangle(\Phi_0,\Omega) &= \frac{\hbar\Omega}{4} + \frac{1}{2}m^2\left(\Phi_0^2 + \frac{\hbar}{2\Omega}\right) \\ &\quad +\lambda\left[\Phi_0^4 + 6\Phi_0^2\frac{\hbar}{2\Omega} + \frac{3\hbar^2}{(2\Omega)^2}\right].\end{aligned} \tag{536}$$

We must now determine the optimal Ω. As explained above, this is achieved by requiring $\partial\langle H\rangle/\partial\Omega = 0$, which leads to the equation

$$\Omega^3 - \left(m^2 + 12\lambda\Phi_0^2\right)\Omega - 6\hbar\lambda = 0. \tag{537}$$

This equation allows us to determine Ω in terms of Φ_0. In the following, we write this result as $\Omega_0 \equiv \Omega(\Phi_0)$. Upon using the above relation in the expression of $\langle H\rangle$, one obtains the following expression for the Gaussian effective potential

$$V_{\mathrm{G}}(\Phi_0) = \frac{1}{2}m^2\Phi_0^2 + \lambda\Phi_0^4 + \frac{\hbar\Omega_0}{2} - \frac{3\hbar^2\lambda}{4\Omega_0}. \tag{538}$$

Of course, as already emphasized before, one should not forget that Ω_0 is a function of Φ_0.

A complete study of the above potential has been provided in Ref. [58] and we will not repeat this analysis. Here, we just want to illustrate that the Gaussian effective potential is an accurate method to estimate the ground state of a system (even in the strong coupling limit) since this is directly relevant for the cosmological constant problem. Let us consider the case where $m^2 > 0$ (the case of the double-well potential, reminiscent of symmetry breaking in field theory has been studied in Ref. [58]). The ground state of the an-harmonic oscillator is given by Eq. (538)

$$V_{\mathrm{G}}(\Phi_0 = 0) = \frac{\hbar\Omega_0}{2}\left(1 - \frac{3}{2}\frac{\hbar\lambda}{\Omega_0^3}\right), \tag{539}$$

where Ω_0 is solution of

$$\Omega^3 - m^2\Omega - 6\hbar\lambda = 0. \tag{540}$$

The discriminant of this cubic equation can be expressed as

$$\Delta(\Phi_0 = 0) = 4m^6\left(1 - \frac{972}{16}\frac{1}{\xi^6}\right), \tag{541}$$

where the quantity ξ in the above relation is given by

$$\xi^2 \equiv \frac{m^2}{(2\lambda)^{2/3}}. \tag{542}$$

The awkward coefficient 972/16 in Eq. (541) originates from our will to work with the definition of ξ used in Ref. [58]. The cubic equation (540) can be explicitly solved. We deal with different branches according to the sign of the discriminant. This sign is determined by $\xi_{\text{lim}} = (972/16)^{1/6} \simeq 1.9827$. If $\xi < \xi_{\text{lim}}$ ($\xi = 0$ represent the quartic oscillator) we are in the strong coupling regime which is of particular interest in order to demonstrate the usefulness of the Gaussian effective potential. Therefore, let us focus on this situation. In this case, the exact solution of Eq. (540) can be written as

$$\begin{aligned}\Omega_0 &= m\left[\frac{3}{2\xi^3} - \frac{1}{27}\sqrt{27\left(\frac{972}{16}\frac{1}{\xi^6} - 1\right)}\right]^{1/3} \\ &\quad + m\left[\frac{3}{2\xi^3} + \frac{1}{27}\sqrt{27\left(\frac{972}{16}\frac{1}{\xi^6} - 1\right)}\right]^{1/3}. \end{aligned} \tag{543}$$

Together with Eq. (539), the above equation gives an excellent approximation for the ground state. For instance, if $m = 1$ and $\lambda = 10$, then $\xi^2 \simeq (1/20)^{2/3} \simeq 0.1357$ and $\Omega_0 = 4$. As a consequence, this gives $V_{\text{G}}(\Phi_0 = 0) \simeq 1.53$, a result that is accurate at $\simeq 1.75\%$ according to Ref. [58].

This simple example has shown that the Gaussian effective potential can be an efficient tool to calculate the ground state of a quantum system even in a non perturbative regime. Therefore, it appears as an interesting approach for the vacuum energy problem. However, before turning to the calculation of the Gaussian effective potential in field theory, it is interesting to compare it with the standard effective potential in more detail. This is the purpose of the next subsection.

24.6.2 Comparison with the One Loop Effective Potential

In order to explain how the effective potential is obtained, we need to quickly return to the basics of quantum field theory. In Eq. (393), we have defined the generating functional $Z[J]$. Let us now define another generating functional $W[J]$ by [16, 17]

$$Z[J] = \mathrm{e}^{iW[J]}. \tag{544}$$

Following the procedure in Eq. (394), one can define new correlation functions $G_{\text{c}}^{(n)}$ according to

$$G_{\text{c}}^{(n)} = \left(\frac{1}{i}\right)^{n-1} \frac{\delta^n W[J]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0}. \tag{545}$$

As is well-known, these functions represent in fact the connected n-points functions. Then, one introduces the classical field Φ_{c}

$$\Phi_{\text{c}} \equiv \frac{\delta W[J]}{\delta J(x)}\bigg|_{J=0}, \tag{546}$$

where we remind that $J(x)$ is a source. This definition can be easily justified. Indeed, from Eqs. (393) and (544), one sees that

$$\Phi_{\text{c}} = \frac{1}{iZ[J]}\frac{\delta Z[J]}{\delta J(x)} \tag{547}$$

$$= \frac{\mathcal{N}\int \mathcal{D}\Phi \exp\left\{i\int \mathrm{d}^4x\left[\mathcal{L} + J(x)\Phi(x)\right]\right\}\Phi(x)}{\mathcal{N}\int \mathcal{D}\Phi \exp\left\{i\int \mathrm{d}^4x\left[\mathcal{L} + J(x)\Phi(x)\right]\right\}}$$

$$= \frac{\langle\Omega\,|\Phi(x)|\,\Omega\rangle}{\langle\Omega|\Omega\rangle}. \tag{548}$$

Therefore, we see that the classical field is in fact the vacuum expectation value of the field operator in the vacuum state of the theory. When the source vanishes, the classical field does not necessarily goes to zero, a typical and well-known example being of course symmetry breaking.

The next step consists in introducing a new generating function, the so-called effective action, defined by

$$\Gamma[\Phi_c] = W[J] - \int \mathrm{d}^4x J(x)\Phi_c(x). \tag{549}$$

Clearly, $\Gamma[\Phi_c]$ does not depend on the source since $\delta\Gamma/\delta J = 0$. Let us now calculate the functional derivative of Γ with respect with the classical field. This gives

$$\begin{aligned}\frac{\delta\Gamma[\Phi_c]}{\delta\Phi_c(x)} &= \frac{\delta W}{\delta\Phi_c(x)} - \int \mathrm{d}^4y \frac{\delta J(y)}{\delta\Phi_c(x)}\Phi_c(y) \\ &\quad - \int \mathrm{d}^4y J(y)\frac{\delta\Phi_c(y)}{\delta\Phi_c(x)} \qquad (550)\\ &= \int \mathrm{d}^4y \frac{\delta W}{\delta J(y)}\frac{\delta J(y)}{\delta\Phi_c(x)} - \int \mathrm{d}^4y \frac{\delta J(y)}{\delta\Phi_c(x)}\Phi_c(y) \\ &\quad - J(x) = -J(x). \qquad (551)\end{aligned}$$

In order to interpret these equations and to better understand their meaning, it is interesting to apply them to the case of a free theory where all the calculations can be carried out explicitly. From Eq. (396), we immediately see that (the subscript zero indicates that the calculation is performed for the free theory)

$$iW_0[J] = -\frac{1}{2}\int \mathrm{d}^4x\,\mathrm{d}^4y J(x)D_{\mathrm{F}}(x-y)J(y). \tag{552}$$

Upon using Eq. (546), one obtains

$$\Phi_c(z) = -\frac{1}{i}\int \mathrm{d}^4x\, D_{\mathrm{F}}(z-x)J(x). \tag{553}$$

But iD_{F} is the Green function of the Klein-Gordon operator. As a consequence, the above equation implies that

$$\left(\eta^{\mu\nu}\partial_\mu\partial_\nu - m^2\right)\Phi_c(x) = J(x), \tag{554}$$

i.e. the classical field obeys the classical equation of motion (hence its name). Then, using Eqs. (552) and (553) into the definition (549), the effective action can be expressed as

$$\Gamma_0[\Phi_c] = \frac{1}{2i}\int \mathrm{d}^4x\mathrm{d}^4y J(x)D_{\mathrm{F}}(x-y)J(y). \tag{555}$$

The next step is to use the equation of motion of the classical field (554) to rewrite the effective action as

$$\begin{aligned}\Gamma_0[\Phi_c] &= \frac{1}{2i}\int \mathrm{d}^4x\,\mathrm{d}^4y D_{\mathrm{F}}(x-y)\left(\eta^{\mu\nu}\partial^x_\mu\partial^x_\nu - m^2\right)\Phi_c(x) \\ &\quad \times\left(\eta^{\mu\nu}\partial^y_\mu\partial^y_\nu - m^2\right)\Phi_c(y), \qquad (556)\end{aligned}$$

where $\partial^{x,y}_\mu$ means a partial derivative with respect to the coordinates at point x and y. Then, integrating by part the x dependent terms in the above integral leads to

$$\begin{aligned}\Gamma_0[\Phi_c] &= \frac{1}{2i}\int \mathrm{d}^4x\mathrm{d}^4y\Phi_c(x)\left(\eta^{\mu\nu}\partial^x_\mu\partial^x_\nu - m^2\right)D_{\mathrm{F}}(x-y) \\ &\quad \times\left(\eta^{\mu\nu}\partial^y_\mu\partial^y_\nu - m^2\right)\Phi_c(y). \qquad (557)\end{aligned}$$

Finally, using the fact that D_{F}/i is the Green function satisfying $-\eta^{\mu\nu}\partial_\mu\partial_\nu D_{\mathrm{F}} + m^2 D_{\mathrm{F}} = \delta$, one obtains

$$\begin{aligned}\Gamma_0[\Phi_c] &= \frac{1}{2}\int \mathrm{d}^4x\Phi_c(x)\left(\eta^{\mu\nu}\partial_\mu\partial_\nu - m^2\right)\Phi_c(x) \\ &= -\frac{1}{2}\int \mathrm{d}^4x\left(\eta^{\mu\nu}\partial_\mu\Phi_c\partial_\nu\Phi_c + m^2\Phi_c\right), \qquad (558)\end{aligned}$$

and one recovers the action of a free scalar field theory. In presence of interactions, $\Gamma[\Phi_c]$ will no longer agree with the classical action. The quantum corrections will transform it into a complicated non local functional. In this situation, one typically expects an expression that can be written as

$$\begin{aligned}\Gamma[\Phi_c] &= -\int \mathrm{d}^4x \Big[\frac{1}{2}A(\Phi_c)\eta^{\mu\nu}\partial_\mu\Phi_c\partial_\nu\Phi_c \\ &+ V_{\text{eff}}(\Phi_c) + B(\Phi_c)\left(\eta^{\mu\nu}\partial_\mu\Phi_c\partial_\nu\Phi_c\right)^4 + \cdots\Big],\end{aligned} \tag{559}$$

where $A(\Phi_c)$ and $B(\Phi_c)$ are functions (not functionals) of Φ_c and the dots represent higher derivative terms. Clearly, the previous considerations justify the name "effective action" for $\Gamma[\Phi_c]$.

Another interesting aspect is that the effective action is also the generating functional of the irreducible correlation functions $\Gamma^{(n)}$ (also known as proper vertices). In other words, one has

$$\Gamma^{(n)}(x_1,\cdots,x_n) = \left.\frac{\delta^n\Gamma[\Phi_c]}{\delta\Phi_c(x_1)\cdots\delta\Phi_c(x_n)}\right|_{\Phi_c=0}. \tag{560}$$

Equivalently, one can express the effective action as a Volterra expansion, namely

$$\begin{aligned}\Gamma[\Phi_c] &= \sum_{n=0}^{\infty}\frac{1}{n!}\int \mathrm{d}^4x_1\cdots\mathrm{d}^4x_n\Gamma^{(n)}(x_1,\cdots,x_n) \\ &\times\Phi_c(x_1)\cdots\Phi_c(x_n),\end{aligned} \tag{561}$$

which is nothing but another way to write the functional (559).

Now, suppose that we are interested in determining the effective action concretely. It is clear that this is a complicated calculation. As a first step, it is worth calculating the effective potential in Eq. (559). It is true that it does not represent all the information contained in the effective action but this would allow us to determine the location of the minimum of the system in presence of quantum corrections. Therefore, this is an interesting quantity. For this purpose, it is sufficient to consider a case where Φ_c is constant. Indeed, in this situation, the effective action reduces to $\Gamma = -VV_{\text{eff}}(\Phi_c)$, where V is the space-time volume. On the other hand, the Volterra expansion can be re-expressed as

$$\Gamma[\Phi_c] = \sum_{n=0}^{\infty}\frac{1}{n!}\int \mathrm{d}^4x_1\cdots\mathrm{d}^4x_n\Gamma^{(n)}(x_1,\cdots,x_n)\Phi_c^n. \tag{562}$$

This expression can be further simplified if one takes the Fourier transform of the proper vertex,

$$\begin{aligned}\Gamma^{(n)}(x_1,\cdots,x_n) &= \int\frac{\mathrm{d}^4k_1}{(2\pi)^4}\cdots\frac{\mathrm{d}^4k_n}{(2\pi)^4}\Gamma^{(n)}(k_1,\cdots,k_n) \\ &\times\mathrm{e}^{-ik_1\cdot x_1}\cdots\mathrm{e}^{-ik_n\cdot x_n}.\end{aligned} \tag{563}$$

In fact, for convenience, we introduce the coefficients $\overline{\Gamma}^{(n)}(k_1,\cdots,k_n)$ that are easier to manipulate. They are defined by the following expression

$$\Gamma^{(n)}(k_1,\cdots,k_n) \equiv (2\pi)^4\delta(k_1+\cdots k_n)\,\overline{\Gamma}^{(n)}(k_1,\cdots k_n), \tag{564}$$

Then, we insert the Fourier expansion (563) into the expression (562) of the effective action. The integrals over space of the exponentials lead to Dirac functions in momentum. As a consequence, one arrives at the following expression

$$\Gamma[\Phi_c] = V\sum_{n=0}^{\infty}\frac{1}{n!}\overline{\Gamma}^{(n)}(\boldsymbol{k}_i=0)\Phi_c^n, \tag{565}$$

where, as already mentioned, $V = (2\pi)^4\delta(0)$ is the space-time volume. One finally reaches the result that

$$V_{\rm eff}(\phi_{\rm c}) = -\sum_{n=0}^{\infty}\frac{1}{n!}\overline{\Gamma}^{(n)}(\boldsymbol{k}_i = 0)\Phi_{\rm c}^n. \tag{566}$$

Therefore, in order to calculate the effective potential, one just has to evaluate the proper vertices with vanishing momenta. At one loop, this gives rise to the following sum

$V_{\rm eff} =$ $+\cdots$. (567)

It turns out that this series can be summed up as we are now going to show.

In order to see how it works, let us calculate the second diagram in the above expansion. For this purpose, we start with the following diagram

$\mathcal{D} =$ 
(568)

According to the Feynman rules (402) and (403), this diagram is equivalent to the expression

$$\begin{aligned}\mathcal{D} &= (-i\lambda)^2\int {\rm d}u{\rm d}v D(t_1-u)D(t_2-u)D^2(u-v)\\ &\quad\times D(v-t_3)D(v-t_4),\end{aligned} \tag{569}$$

where u and v denotes the two internal vertices. Upon using Eq. (451), this expression takes the form [here, we use the quantum-mechanical theory introduced in Sec. 24.5.1 where the "mass" is denoted ω]

$$\begin{aligned}\mathcal{D} &= (-i\lambda)^2\int {\rm d}u{\rm d}v\int\frac{{\rm d}E_1}{2\pi}\frac{{\rm d}E_2}{2\pi}\frac{{\rm d}E_3}{2\pi}\frac{{\rm d}E_4}{2\pi}\frac{{\rm d}E}{2\pi}\frac{{\rm d}\tilde{E}}{2\pi}\frac{i{\rm e}^{-iE_1(t_1-u)}}{E_1^2-\omega^2}\frac{i{\rm e}^{-iE_2(t_2-u)}}{E_2^2-\omega^2}\frac{i{\rm e}^{-iE_3(v-t_3)}}{E_3^2-\omega^2}\\ &\quad\times\frac{i{\rm e}^{-iE_4(v-t_4)}}{E_4^2-\omega^2}\frac{i{\rm e}^{-iE(u-v)}}{E^2-\omega^2}\frac{i{\rm e}^{-i\tilde{E}(u-v)}}{\tilde{E}^2-\omega^2}.\end{aligned} \tag{570}$$

The integrals over u and v are easily performed and leads to two Dirac functions. Then, a further integration over $\tilde{E}$ can be performed and we are left with the expression

$$\begin{aligned}\mathcal{D} &= (-i\lambda)^2(2\pi)^2\delta(E_1+E_2-E_3-E_4)\int\frac{{\rm d}E_1}{2\pi}\frac{{\rm d}E_2}{2\pi}\frac{{\rm d}E_3}{2\pi}\frac{{\rm d}E_4}{2\pi}\frac{{\rm d}E}{2\pi}\frac{i{\rm e}^{-iE_1t_1}}{E_1^2-\omega^2}\frac{i{\rm e}^{-iE_2t_2}}{E_2^2-\omega^2}\frac{i{\rm e}^{-iE_3t_3}}{E_3^2-\omega^2}\frac{i{\rm e}^{-iE_4t_4}}{E_4^2-\omega^2}\\ &\quad\times\frac{i}{E^2-\omega^2}\frac{i}{(E_3+E_4-E)^2-\omega^2}.\end{aligned} \tag{571}$$

In order to compute the expression (567) (or rather the contribution of the second diagram to this expression), we have seen that we must amputate the diagram by appending the external leg propagators. This amounts to ignore the factors $i/(E_i^2-\omega^2)$ in the above expression. Moreover, since the graph is given by the Fourier transform of $\mathcal{D}$, this means that only the expression inside the above quadruple integrals over E_i should be considered. Finally, the "momentum" (in the present context the energy) of the external legs should be put to zero (*i.e.* we require all the E_i's left in the expression of $\mathcal{D}$ to vanish) and we must factorize out a Dirac function expressing energy conservation [times $(2\pi)^2$ since we are considering a $0+1$ theory]. This means that Eq. (571) takes the following form

 $= (-i\lambda)^2\int\frac{{\rm d}E}{2\pi}\frac{i}{E^2-\omega^2}\frac{i}{E^2-\omega^2}$. (572)

The fact that the propagator appears squared is of course not fortuitous. It comes from the fact that we have two "double legs" attached to the loop. For n "double legs", it is clear that we would have the propagator to the power n and an overall factor $(-i\lambda)^n$. As a consequence, at one loop, Eq. (566) can be expressed as

$$V_{\rm eff}\left(\Phi_{\rm c}\right) = -\sum_{p=1}^{\infty}\frac{\Phi_{\rm c}^{2p}}{2p}\left(\frac{\lambda 4!}{2}\right)^p\int\frac{{\rm d}E}{2\pi}\frac{1}{(E^2-\omega^2)^p}, \tag{573}$$

where we have taken into account a symmetry factor and where we have noted $n = 2p$, p being the number of external points. The sum can now be performed and we obtain

$$V_{\text{eff}}(\Phi_c) = -\frac{1}{2}\int_{-\infty}^{\infty}\frac{dE}{2\pi}\ln\left(1+\frac{12\lambda\Phi_c^2}{E^2-\omega^2}\right) \tag{574}$$

$$= \frac{1}{2}\left(\omega-\sqrt{12\lambda\Phi_c^2-\omega^2}\right) \tag{575}$$

$$= \frac{\hbar}{2}\left(-m+\sqrt{m^2+12\lambda\Phi_c^2}\right), \tag{576}$$

where we have re-established $\hbar$ and where we have taken into account the sign difference for ω (or m) due to the fact that we work with a $(-+++)$ signature, see the remark after Eq. (518). This expression should be compared to Eq. (538). In fact the first term just comes from the fact that the method of the effective potential assumes that $V_{\text{eff}}(0) = 0$. Therefore, in order to compare with the Gaussian effective potential, one must ignore this rescaling. As a consequence, the total potential (including the leading order in $\hbar^0$) reads

$$V_{\text{eff}}(\Phi_c) = \frac{1}{2}m^2\Phi_c^2 + \frac{\hbar}{2}\sqrt{m^2+12\lambda\Phi_c^2}. \tag{577}$$

One sees that the vacuum energy is predicted to be $V_{\text{eff}}(0) = \hbar m/2$ a result which is not realistic in the non perturbative regime.

In fact the comparison can be made in an even more explicit manner if one remembers that the one loop Gaussian effective potential consists in retaining the dominant term is a systematic expansion in $\hbar$. As a consequence, one should ignore the $\hbar^2$ term in Eq. (536) and the $\hbar$ term in Eq. (537). In particular, this last approximation leads to the following explicit solution for the gap equation

$$\overline{\Omega}^2 = m^2 + 12\lambda\Phi_0^2 = \frac{d^2V}{d\Phi_0^2}. \tag{578}$$

If we then use Eq. (538) and neglects the $\hbar^2$ term in that equation, one obtains

$$V_{\text{G}}(\Phi_0) = V(\Phi_0) + \frac{\hbar}{2}\sqrt{\frac{d^2V}{d\Phi_0^2}} + \mathcal{O}(\hbar^2) \tag{579}$$

$$= \frac{1}{2}m^2\Phi_0^2 + \frac{\hbar}{2}\sqrt{m^2+12\lambda\Phi_0^2} + \cdots, \tag{580}$$

that is to say exactly Eq. (577). We conclude that the effective potential is in fact contained in the Gaussian effective potential approach. It just consists in neglecting higher power of $\hbar$ since this is a one loop approach. As a consequence, the effective potential cannot be reliable in the non perturbative regime where the quantum effects are strong.

Having demonstrated that the Gaussian effective potential approach is an efficient tool, we now need to study how it works in quantum field theory. Then, we will able to use it in order to calculate the energy density of the vacuum state.

24.6.3 The Gaussian Effective Potential in Field Theory and the Vacuum Energy

We now turn to the main question of this section, namely the calculation of the Gaussian effective potential in quantum field theory [59, 60, 63, 65]. For this purpose, we now consider a model similar to the one considered in the previous subsections, namely a free model plus a quartic self interaction

$$\mathcal{H} = \frac{1}{2}\dot{\Phi}^2 + \frac{1}{2}\delta^{ij}\partial_i\Phi\partial_j\Phi + \frac{1}{2}m_{\text{B}}^2\Phi^2 + \lambda_{\text{B}}\Phi^4, \tag{581}$$

where $m_{\rm B}$ and $\lambda_{\rm B}$ are the bare mass and coupling constant, respectively. Then, we write the field operator as (we work in d space-time dimensions)

$$\begin{aligned}\Phi\left(t,\boldsymbol{x}\right) &= \Phi_0+\frac{1}{\left(2\pi\right)^{(d-1)/2}}\int\frac{\mathrm{d}^{d-1}\boldsymbol{k}}{\sqrt{2\omega_\Omega(k)}}\Big(c_{\boldsymbol{k}}\mathrm{e}^{-i\omega t+i\boldsymbol{k}\cdot\boldsymbol{x}}\\ &\quad +c^\dagger_{\boldsymbol{k}}\mathrm{e}^{i\omega t-i\boldsymbol{k}\cdot\mathbf{x}}\Big),\end{aligned}\tag{582}$$

with

$$\omega_\Omega(k)\equiv\sqrt{k^2+\Omega^2}.\tag{583}$$

The quantity Φ_0 represents a classical and constant field. The parameter Ω denotes the mass of the excitations around this classical value. The idea at the basis of the calculation is the same as before, namely minimizing the energy with respect to the parameter Ω. Using the properties of the creation and annihilation operators, it is straightforward to calculate the mean value of the Hamiltonian in the vacuum state. We find

$$\begin{aligned}\langle\mathcal{H}\rangle\left(\Omega,\Phi_0\right) &= I_1(\Omega)+\frac{1}{2}\left(m_{\rm B}^2-\Omega^2\right)I_0(\Omega)+\frac{1}{2}m_{\rm B}^2\Phi_0^2\\ &+ \lambda_{\rm B}\Phi_0^4+6\lambda_{\rm B}\Phi_0^2I_0(\Omega)+3\lambda_{\rm B}I_0^2(\Omega),\end{aligned}\tag{584}$$

where we have defined the integrals $I_p(\Omega)$ by

$$I_p(\Omega)=\frac{1}{\left(2\pi\right)^{d-1}}\int\frac{\mathrm{d}^{d-1}\boldsymbol{k}}{2\omega_\Omega(k)}\omega_\Omega^{2p}(k).\tag{585}$$

Of course, the integrals $I_p(\Omega)$ can be divergent and this signals, as usual in field theory, the need for renormalization. In fact, these integrals can be performed exactly and one is led to

$$I_p(\Omega)=\frac{1}{2(4\pi)^{(d-1)/2}}\frac{\Gamma[(2-d-2p)/2]}{\Gamma[(1-2p)/2]}\Omega^{d+2p-2}.\tag{586}$$

It is clear that, for some values of d and p, the above expression does not exist and is only formal.

As already mentioned, in order to calculate the Gaussian effective potential, one must vary $\langle\mathcal{H}\rangle$ with respect to Ω. Upon using Eq. (584) and $\mathrm{d}I_p/\mathrm{d}\Omega=(2p-1)\Omega I_{p-1}$, one arrives at the following "gap" equation, the field theory counterpart of Eq. (537)

$$\Omega^2=m_{\rm B}^2+12\lambda_{\rm B}\left[\Phi_0^2+I_0\left(\Omega\right)\right].\tag{587}$$

This is an algebraic equation for Ω. Its solution can be written as $\overline{\Omega}=\overline{\Omega}\left(\Phi_0;m_{\rm B},\lambda_{\rm B}\right)$, that is to say it depends on Φ_0 and on the bare parameters (in the following we no longer write the dependence on the bare parameters). Then, the Gaussian effective potential is defined by inserting this solution into Eq. (584). This leads to

$$V_{\rm G}(\Phi_0)\equiv\langle\mathcal{H}\rangle\left[\overline{\Omega}(\Phi_0),\Phi_0\right].\tag{588}$$

Upon using the gap equation, one can also find a more compact expression, namely

$$\begin{aligned}V_{\rm G}(\Phi_0) &= I_1\left[\overline{\Omega}\left(\Phi_0\right)\right]-3\lambda_{\rm B}I_0^2\left[\overline{\Omega}\left(\Phi_0\right)\right]+\frac{1}{2}m_{\rm B}^2\Phi_0^2\\ &+\lambda_{\rm B}\Phi_0^4.\end{aligned}\tag{589}$$

At this level, this expression is in fact still formal because of the divergences of the integrals I_p. Therefore, we must first tame those divergences. This is done by means of a renormalization of the parameters appearing in the Lagrangian of the model.

Renormalization consists in parametrizing the physical quantities in terms of new, observable parameters, different from the bare parameters that appear in the Lagrangian. We now define the renormalized mass by

$$m_{\rm R}^2 = \left.\frac{{\rm d}^2 V_{\rm G}}{{\rm d}\Phi_0^2}\right|_{\Phi_0=0}. \tag{590}$$

Upon using Eq. (589) and the following relation [which comes from differentiating Eq. (587)]

$$\frac{{\rm d}\overline{\Omega}}{{\rm d}\Phi_0} = \frac{\Phi_0}{\overline{\Omega}}\frac{12\lambda_{\rm B}}{1+6\lambda_{\rm B} I_{-1}(\overline{\Omega})}, \tag{591}$$

one finds that

$$\begin{aligned}\frac{{\rm d}^2 V_{\rm G}}{{\rm d}\Phi_0^2} &= m_{\rm B}^2 + 12\lambda_{\rm B}\left[\Phi_0^2 + I_0(\overline{\Omega})\right] \\ &\quad -\frac{(12\lambda_{\rm B}\Phi_0)^2 I_{-1}(\overline{\Omega})}{1+6\lambda_{\rm B} I_{-1}(\overline{\Omega})}.\end{aligned} \tag{592}$$

As a consequence, putting $\Phi_0 = 0$ in the above equation, the renormalized mass can be expressed as

$$m_{\rm R}^2 = m_{\rm B}^2 + 12\lambda_{\rm B} I_0(\overline{\Omega}_0), \tag{593}$$

where $\overline{\Omega}_0$ denotes the solution of the gap equation (587) when $\Phi_0 = 0$, *i.e.* $\Omega^2 = m_{\rm B}^2 + 12\lambda_{\rm B} I_0(\Omega)$. It is obvious that $\overline{\Omega}_0$ is not a function of Φ_0 but depends only on $m_{\rm B}$ and $\lambda_{\rm B}$. In fact, this can also been seen from Eq. (587) since it tells us that $m_{\rm R}^2 = \overline{\Omega}_0^2$. As a consequence, the above equation can be re-written as

$$m_{\rm B}^2 = m_{\rm R}^2 - 12\lambda_{\rm B} I_0(m_{\rm R}). \tag{594}$$

We are now in a position where we can calculate the Gaussian effective potential in terms of the renormalized mass. For this purpose, we restart from Eq. (588) and substitute the expression (594). One obtains

$$\begin{aligned}V_{\rm G}(\Phi_0) &= I_1(\overline{\Omega}) + \frac{1}{2}\left(m_{\rm R}^2 - \overline{\Omega}^2\right) I_0(\overline{\Omega}) + \frac{1}{2} m_{\rm R}^2 \Phi_0^2 \\ &\quad +\lambda_{\rm B}\Phi_0^4 + 6\lambda_{\rm B}\left[I_0(\overline{\Omega}) - I_0(m_{\rm R})\right]\Phi_0^2 \\ &\quad +3\lambda_{\rm B} I_0^2(\overline{\Omega}) - 6\lambda_{\rm B} I_0(\overline{\Omega})\, I_0(m_{\rm R}).\end{aligned} \tag{595}$$

However, at this stage, the expression of the Gaussian effective potential is not yet a function of the renormalized mass only as one still needs to express $I_0(\overline{\Omega})$ and $I_1(\overline{\Omega})$ in terms of $I_0(m_{\rm R})$ and $I_1(m_{\rm R})$. There are several ways to do it, see Ref. [59]. Here we choose to use a method where a cut-off is temporarily introduced. We work in $d = 4$ dimensions to simplify the calculations. Let us exemplify the method with I_0. We have

$$I_0(\Omega) = \frac{1}{2(2\pi)^3}\int {\rm d}^3\boldsymbol{k}\,\omega_\Omega^{-1} \tag{596}$$

$$= \frac{1}{4\pi^2}\int_0^M {\rm d}k k^2\left(k^2+\Omega^2\right)^{-1/2}, \tag{597}$$

where we have performed the angular integrals and where we have introduced a cut-off M to regulate the otherwise divergent integral. This gives

$$\begin{aligned}I_0(\Omega) &= \frac{1}{4\pi^2}\left[\frac{M}{2}\sqrt{\Omega^2+M^2}\right. \\ &\quad \left. -\frac{\Omega^2}{2}\ln\left(M+\sqrt{\Omega^2+M^2}\right) + \frac{\Omega^2}{2}\ln\Omega\right].\end{aligned} \tag{598}$$

As a consequence, one can write

$$I_0(\Omega) - I_0(m) = \frac{1}{2}\left(m^2-\Omega^2\right) I_{-1}(m) + \frac{1}{4\pi^2}\left[\frac{M}{2}\sqrt{\Omega^2+M^2} - \frac{M}{2}\sqrt{m^2+M^2} + \frac{\Omega^2}{2}\ln\left(\frac{M+\sqrt{m^2+M^2}}{M+\sqrt{\Omega^2+M^2}}\right) + \frac{\Omega^2}{2}\ln\Omega - \frac{m^2}{2}\ln m + \frac{1}{2}\left(m^2-\Omega^2\right)\left(\frac{M}{\sqrt{m^2+M^2}} + \ln m\right)\right], \tag{599}$$

where we have used

$$I_{-1}(\Omega) = \frac{1}{4\pi^2}\left[\frac{-M}{\sqrt{\Omega^2+M^2}} + \ln\left(M+\sqrt{\Omega^2+M^2}\right) - \ln\Omega\right], \tag{600}$$

an expression which can be obtained with the same method as described above. Then we take the limit $M \to +\infty$ and Eq. (599) becomes

$$I_0(\Omega) - I_0(m) = -\frac{1}{2}\left(\Omega^2-m^2\right) I_{-1}(m) + \frac{m^2}{16\pi^2}\left[x\ln x - (x-1)\right], \tag{601}$$

where $x \equiv \Omega^2/m^2$. Notice that, at this stage of the calculation, there is no need to write x in terms of $\overline{\Omega}$ and/or $m_{\rm R}$. The above expression is valid for any Ω and m. Following Ref. [59], we call the function between the square brackets in the above equation $L_2(x)$. Exactly in the same manner, one can also show that

$$I_1(\Omega) - I_1(m) = \frac{1}{2}\left(\Omega^2-m^2\right) I_0(m) - \frac{1}{8}\left(\Omega^2-m^2\right)^2 I_{-1}(m) + \frac{m^4}{32\pi^2}L_3(x), \tag{602}$$

with $L_3(x) = [2x^2\ln x - 2(x-1) - 3(x-1)^2]/4$. Then, upon using Eqs. (601) and (602) in Eq. (595), one obtains

$$V_{\rm G}(\Phi_0) = I_1\left(m_{\rm R}\right) - 3\lambda_{\rm B} I_0^2\left(m_{\rm R}\right) + \frac{1}{2}m_{\rm R}^2\Phi_0^2 + \lambda_{\rm B}\Phi_0^4 + \frac{m_{\rm R}^4}{32\pi^2}L_3(\overline{x}) + \frac{3}{4}\lambda_{\rm B} m_{\rm R}^4\left(\overline{x}-1\right)^2 I_{-1}^2\left(m_{\rm R}\right) + \frac{1}{8}I_{-1}\left(m_{\rm R}\right) m_{\rm R}^4(\overline{x}-1)\left\{(\overline{x}-1) - \frac{3\lambda_{\rm B}}{2\pi^2}\left[L_2(\overline{x}) + \frac{16\pi^2}{m_{\rm R}^2}\Phi_0^2\right]\right\} - \frac{m_{\rm R}^4}{32\pi^2}L_2(\overline{x})\left\{(\overline{x}-1) - \frac{3\lambda_{\rm B}}{8\pi^2}\left[L_2(\overline{x}) + 32\pi^2\frac{\Phi_0^2}{m_{\rm R}^2}\right]\right\}, \tag{603}$$

with $\overline{x} \equiv \overline{\Omega}^2/m_{\rm R}^2$. Finally, the gap equation (587) can also be re-written in terms of the renormalized mass. The corresponding expression reads

$$(\overline{x}-1)\left[1 + 6\lambda_{\rm B} I_{-1}\left(m_{\rm R}\right)\right] = \frac{3\lambda_{\rm B}}{4\pi^2}\left[L_2(\overline{x}) + 16\pi^2\frac{\Phi_0^2}{m_{\rm R}^2}\right]. \tag{604}$$

We see that the dependence on Φ_0 of the Gaussian effective potential is quite complicated. Indeed, solving the gap equation provides us with $\overline{x} = \overline{x}(\Phi_0)$ that we must then insert in Eq. (603).

We shall now discuss the renormalization of the coupling constant $\lambda_{\rm B}$. It is defined by

$$\lambda_{\rm R} = \frac{1}{4!}\frac{{\rm d}^4 V_{\rm G}}{{\rm d}\Phi_0^4}\bigg|_{\Phi_0=0}. \tag{605}$$

Proceeding in the same manner as before, one obtains the following equation for the quantity $\lambda_{\rm R}$

$$\lambda_{\rm R} = \lambda_{\rm B}\frac{1-12\lambda_{\rm B}I_{-1}(m_{\rm R})}{1+6\lambda_{\rm B}I_{-1}(m_{\rm R})}. \tag{606}$$

The renormalization of the coupling constant has been discussed at length in Refs. [59, 63] and we will not repeat all the details since, here, our main concern is the vacuum energy. In fact we will focus on the case named "precarious" in Ref. [59]. Let us return to Eq. (606); one can invert this expression and express the bare coupling constant in terms of the renormalized one. One obtains

$$\begin{aligned}\lambda_{\rm B} &= \frac{1-6\lambda_{\rm R}I_{-1}(m_{\rm R})}{24I_{-1}(m_{\rm R})} \\ &\times\left\{1\pm\sqrt{1-\frac{48\lambda_{\rm R}I_{-1}(m_{\rm R})}{[1-6\lambda_{\rm R}I_{-1}(m_{\rm R})]^2}}\right\}.\end{aligned} \tag{607}$$

Then, from Eq. (600), we see that $I_{-1}(m_{\rm R})$ is in fact a logarithmically divergent quantity when the cut-off M is sent to infinity. Therefore, we must treat $I_{-1}(m_{\rm R})$ as an arbitrarily large quantity. In this limit, if one chooses the plus sign in Eq. (607), one obtains

$$\lambda_{\rm B} = -\frac{1}{2}\lambda_{\rm R} + \mathcal{O}\left[\frac{1}{I_{-1}(m_{\rm R})}\right]. \tag{608}$$

As shown in Ref. [59], this case is not viable. Intuitively, it is clear that a large negative coupling constant leads to a potential which is not bounded from below. Therefore, we are left with the minus sign for which one finds that

$$\begin{aligned}\lambda_{\rm B} &= -\frac{1}{6I_{-1}(m_{\rm R})}\left\{1+\frac{1}{2\lambda_{\rm R}I_{-1}(m_{\rm R})}\right. \\ &\left.+\mathcal{O}\left[\frac{1}{I_{-1}^2(m_{\rm R})}\right]\right\}.\end{aligned} \tag{609}$$

In passing, it is worth signaling that this equation can be re-expressed in a different manner as follows. Let us first introduce the new characteristic scale $M_{\rm C}$ (not to be confused with the cut-off M discussed before) defined by

$$\frac{1}{\lambda_{\rm R}} \equiv -\frac{1}{4\pi^2}\ln\left(\frac{m_{\rm R}^2}{M_{\rm C}^2}\right). \tag{610}$$

Then, if we use the fact that

$$I_{-1}(M_{\rm C}) - I_{-1}(m_{\rm R}) = -\frac{1}{8\pi^2}L_1(x), \tag{611}$$

where $L_1(x) = \ln x$ [an expression which can be derived with the same method that has led to Eqs. (599) and (602)], the bare coupling constant can be re-written as

$$\lambda_{\rm B} = -\frac{1}{6I_{-1}(M_{\rm C})}. \tag{612}$$

Therefore, it has a negative but infinitesimal value which implies that the stability properties of the corresponding scenario are much better compared to the case (608). As argued in Ref. [59], besides simplifying the expression of the renormalized coupling constant, the scale $M_{_C}$ plays an important role in a complete study of the precarious case (even if, in the present context, this is not apparent since we focus on the vacuum energy only). Inserting the expression (609) [or Eq. (612)] into Eq. (603), one can re-write the effective potential as

$$\begin{aligned} V_{_G}(\Phi_0) &= I_1\left(m_{_R}\right) - 3\lambda_{_B} I_0^2\left(m_{_R}\right) + \frac{1}{2} m_{_R}^2 \overline{x} \Phi_0^2 \\ &+ \frac{m_{_R}^4}{32\pi^2} L_3(\overline{x}) - \frac{m_{_R}^4}{16\lambda_{_R}} \left(\overline{x}-1\right)^2 \\ &+ \mathcal{O}\left[\frac{1}{I_{-1}(m_{_R})}\right], \end{aligned} \tag{613}$$

while the gap equation (604) becomes

$$\overline{x} - 1 = \frac{\lambda_{_R}}{4\pi^2}\left[L_2\left(\overline{x}\right) + 16\pi^2 \frac{\Phi_0^2}{m_{_R}^2}\right]. \tag{614}$$

Let us notice that, in Eq. (613), we have left the quantity $\lambda_{_B}$ into the field independent term $I_1\left(m_{_R}\right) - 3\lambda_{_B} I_0^2\left(m_{_R}\right)$ since it represents the zero point energy that will be treated in detail in the next sub-section 24.6.4. Finally, if one uses the explicit form of the functions L_2 and L_3, then the Gaussian effective potential takes the form

$$\begin{aligned} V_{_G}(\Phi_0) &= I_1\left(m_{_R}\right) - 3\lambda_{_B} I_0^2\left(m_{_R}\right) + \frac{1}{2} m_{_R}^2 \overline{x} \Phi_0^2 \\ &+ \frac{m_{_R}^4}{128\pi^2}\Bigg[2\overline{x}^2 \ln \overline{x} - 2(\overline{x}-1) - 3(\overline{x}-1)^2 \\ &- 2\frac{4\pi^2}{\lambda_{_R}}(\overline{x}-1)^2\Bigg], \end{aligned} \tag{615}$$

and the gap equation can be re-expressed as

$$(\overline{x}-1)\left(1 + \frac{4\pi^2}{\lambda_{_R}}\right) - 16\pi^2 \frac{\Phi_0^2}{m_{_R}^2} = \overline{x} \ln \overline{x}. \tag{616}$$

The two equations (615) and (616) give a complete expression of the Gaussian effective potential for the renormalized precarious "$\lambda\Phi^4$" theory [59, 63].

As we have done for the quantum mechanics case, it is interesting to compare the above result to the standard effective potential approach. We know that this potential can be obtained from the Gaussian effective potential method by neglecting the terms proportional to $\hbar^2$. Therefore, we restart from Eq. (584) and neglect the term $3\lambda_{_B} I_0^2$ since this corresponds to the standard one loop method (*i.e.* it is of order $\hbar^2$). One obtains

$$\begin{aligned} \langle \mathcal{H} \rangle (\Omega, \Phi_0) &= I_1(\Omega) + \frac{1}{2}\left(m_{_B}^2 - \Omega^2\right) I_0(\Omega) + \frac{1}{2} m_{_B}^2 \Phi_0^2 \\ &+ \lambda_{_B} \Phi_0^4 + 6\lambda_{_B} \Phi_0^2 I_0(\Omega) + \mathcal{O}(\hbar^2). \end{aligned} \tag{617}$$

As a consequence, this leads to the new following gap equation

$$\Omega^2 = m_{_B}^2 + 12\lambda_{_B} \Phi_0^2. \tag{618}$$

Clearly, this relation is the exact counter-part of Eq. (578). Then, one has to calculate the renormalized mass and coupling constant. one arrives at

$$m_{_R}^2 = m_{_B}^2 + 12\lambda_{_B} I_0(m_{_B}), \tag{619}$$

$$\lambda_{_R} = \lambda_{_B}\left[1 - 18\lambda_{_B} I_{-1}(m_{_B})\right]. \tag{620}$$

These equations should be compared to Eqs. (594) and (606). We notice that it is now $m_{\rm B}$ that appears in the argument of the integrals rather than $m_{\rm R}$ as in Eqs. (594) and (606). This is because Eq. (618) implies that $\overline{\Omega}(\Phi_0 = 0) = m_{\rm B}$ and not $\overline{\Omega}(\Phi_0 = 0) = m_{\rm R}$ as before. The final step consists in using the two previous equation in Eq. (617). One obtains

$$V_{\rm G}(\Phi_0) = I_1(m_{\rm B}) + \frac{1}{2}m_{\rm R}^2\Phi_0^2 + \lambda_{\rm R}\Phi_0^4 + \frac{m_{\rm B}^4}{64\pi^2}\left[\left(1+12\lambda_{\rm B}\frac{\Phi_0^2}{m_{\rm B}^2}\right)^2 \ln\left(1+12\lambda_{\rm B}\frac{\Phi_0^2}{m_{\rm B}^2}\right) - 12\lambda_{\rm B}\frac{\Phi_0^2}{m_{\rm B}^2} - 216\lambda_{\rm B}^2\frac{\Phi_0^4}{m_{\rm B}^4}\right] + \cdots, \tag{621}$$

the dots corresponding to the higher order terms in $\hbar$. If one neglects those terms, then $V_{\rm G}$ reduces to $V_{\rm eff}$. The corresponding expression is nothing but the Coleman-Weinberg potential. The previous analysis confirms that the effective potential is indeed a particular case of the Gaussian effective potential approach. An even more detailed comparisons of the two methods can be found in Refs. [59, 63]. Here, we do not pursue this issue and now come to the question of the vacuum energy problem.

24.6.4 Vacuum Energy and Gaussian Effective Potential

We are now in a position where the main problem of this section can be addressed. From Eqs. (603) and (613), we see that the vacuum energy density predicted by the Gaussian effective potential method (*i.e.* the term left after having taken $\Phi_0 = 0$ in those expressions) can be expressed as

$$\rho_{\rm vac} = I_1(m_{\rm R}) - 3\lambda_{\rm B} I_0(m_{\rm R}). \tag{622}$$

As we have already stressed many times, it is important to remember that this result is a priori non perturbative. Using the expression of the precarious coupling constant (609), one obtains

$$\rho_{\rm vac} = I_1(m_{\rm R}) + \frac{1}{2}\frac{I_0(m_{\rm R})}{I_{-1}(m_{\rm R})}\left[1+\frac{1}{2\lambda I_{-1}(m_{\rm R})}\right] I_0(m_{\rm R}). \tag{623}$$

The expressions of the integrals I_p have been given in Eqs. (585) and (586). The three integrals that appear in the above expression are all divergent. Nevertheless, the ratio I_0/I_{-1} is finite and reads

$$\frac{I_0(m_{\rm R})}{I_{-1}(m_{\rm R})} = \frac{m_{\rm R}^2}{2-d}. \tag{624}$$

Nevertheless, even after having inserted the above ratio into Eq. (623), this expression still contains singular terms. Explicitly, one has

$$\rho_{\rm vac} = \frac{m_{\rm R}^4}{4(2-d)}\left[-m_{\rm R}^{d-4}\frac{4-d}{2\sqrt{\pi}(4\pi)^{(d-1)/2}}\Gamma\left(-\frac{d}{2}\right) + \frac{1}{\lambda_{\rm R}(2-d)}\right]. \tag{625}$$

However, writing this expression for $d = 4+\epsilon$ and taking the limit $\epsilon \to 0$, we have the remarkable result that a second cancellation occurs and that the final expression is in fact finite. It can be expressed as

$$\rho_{\rm vac} = \frac{m_{\rm R}^4}{128\pi^2}\left[1 - 2\ln\left(\frac{m_{\rm R}^2}{M_{\rm C}^2}\right)\right], \tag{626}$$

where we have used Eq. (612). Even more remarkable is that the above equation is very similar to Eq. (392). In particular, the vacuum energy is proportional to fourth power, not of the cut-off, but of the mass of the corresponding particle and the scale $M_{\rm C}$ is present as a logarithmic

correction. Therefore, we conclude that our analysis based on the Gaussian effective potential has totally confirmed the results presented in the previous sections. We end this section by noticing that the vacuum energy predicted by the Coleman Weinberg potential is, see Eq. (621), $\rho_{\text{vac}} = I_1(m_{\text{B}})$ and is therefore different from the one obtained before, see Eq. (626). Moreover, it seems that this expression remains divergent.

24.7 Contribution from Other Fields

So far, for simplicity, we have only treated the case of a scalar field. However, in order to be more realistic, it is clear that one must also evaluate the vacuum energy for other type of fields. This question is the purpose of the present section. As we will see, the corresponding calculations are in fact very similar. In fact, the important question is the dependence of the overall coefficient which multiplies ρ_{vac} with the spin of the particle. As is well-known, this is at the origin of a remarkable cancellation which leads to the concept of super-symmetry. Therefore, in the following, we will pay special attention to this issue.

24.7.1 Fermion Fields

We start with the case of a Dirac spinor field describing a spin 1/2 particle [16, 17, 18, 19, 20, 21, 22]. For convenience, we quickly remind basics fact about the quantum field theory of a spin 1/2 field. Then, we turn to the calculation of ρ_{vac}.

The Lagrangian of the free model is [we treated the mass-less case in Eq. (331)]

$$\mathcal{L}_{\text{Dirac}} = -\overline{\Psi}\left(i\gamma^{\mu}\partial_{\mu} - m\right)\Psi, \tag{627}$$

where γ^{μ} are matrices satisfying

$$\{\gamma^{\mu}, \gamma^{\nu}\} = -2g^{\mu\nu}. \tag{628}$$

The above equation is in fact valid for any metric tensor. Here, we just consider the flat space-time case and, therefore, we will always consider that $g_{\mu\nu} = \eta_{\mu\nu}$. The quantity $\Psi(t, \boldsymbol{x})$ represents a four components Dirac spinor and $\overline{\Psi} \equiv \Psi^{\dagger}\gamma^0$ [this definition was already mentioned just after Eq. (329)]. Here, we use the Dirac representation which means that the γ^{μ} matrices can be taken to be equal to [recall that, in Eq. (327), we used the chiral representation]

$$\begin{aligned} \gamma^0 &= \begin{pmatrix} \mathbb{I}_2 & 0 \\ 0 & -\mathbb{I}_2 \end{pmatrix}, \quad \gamma^i = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix}, \\ \gamma^5 &= \begin{pmatrix} 0 & \mathbb{I}_2 \\ \mathbb{I}_2 & 0 \end{pmatrix}, \end{aligned} \tag{629}$$

where σ^i are the standard two-dimensional Pauli matrices. The equation of motion for the spinor Ψ is easily obtained from Eq. (627). Varying the Dirac Lagrangian, it is straightforward to show that

$$\left(i\gamma^{\mu}\partial_{\mu} - m\right)\Psi = 0, \tag{630}$$

which is of course nothing but the Dirac equation. Then, as we have done for the scalar field case, we now expand the Ψ operator in Fourier modes according to

$$\begin{aligned} \Psi(t, \boldsymbol{x}) = \frac{1}{(2\pi)^{3/2}} \int \frac{\mathrm{d}\boldsymbol{k}}{\sqrt{2\omega(k)}} \sum_{r=1}^{2} \Big[& b_{\boldsymbol{k}}^{r} u(\boldsymbol{k}, r) \mathrm{e}^{-i\omega t + i\boldsymbol{k}\cdot\boldsymbol{x}} \\ & + \left(d_{\boldsymbol{k}}^{r}\right)^{\dagger} v(\boldsymbol{k}, r) \mathrm{e}^{i\omega t - i\boldsymbol{k}\cdot\boldsymbol{x}} \Big]. \end{aligned} \tag{631}$$

As appropriate for a spinor field, the operators $b_{\boldsymbol{k}}^{r}$ and $d_{\boldsymbol{k}}^{r}$ satisfy anti-commutation rules. The index r represents the two polarization states. Inserting the expansion (631) into the Dirac equation (630) leads to two equations, namely

$$\left(\gamma^0\omega - \gamma^i k_i - m\right) u(\boldsymbol{k}, r) = 0, \tag{632}$$

$$\left(\gamma^0\omega - \gamma^i k_i + m\right) v(\boldsymbol{k}, r) = 0. \tag{633}$$

Upon using the explicit form (629), the first equation can be re-written as

$$\begin{pmatrix} (m-\omega)\,\mathbb{I}_2 & \sigma^i k_i \\ -\sigma^i k_i & (m+\omega)\,\mathbb{I}_2 \end{pmatrix} u(\boldsymbol{k}, r) = 0. \tag{634}$$

In order to have a non-trivial solution, the determinant of this matrix should vanish and this leads to

$$w(k) = \sqrt{k^2 + m^2}, \tag{635}$$

where we have used the following properties of the Pauli matrices, $\sigma^i k_i \sigma^j k_j = k^2$. On the other hand, Eq. (634) also implies that

$$u(\boldsymbol{k}, r) = \begin{pmatrix} \psi \\ \dfrac{\sigma^i k_i}{m+\omega}\psi \end{pmatrix}, \tag{636}$$

where ψ is an arbitrary two components spinor. Choosing the solution to be an eigenstate of the spin operator along the z-direction (in the rest frame of the particle), the two components of $u(\boldsymbol{k}, r)$ can be expressed as

$$u(\boldsymbol{k}, 1) = \sqrt{m+\omega}\begin{pmatrix} \begin{pmatrix} 1 \\ 0 \end{pmatrix} \\ \dfrac{\sigma^i k_i}{m+\omega}\begin{pmatrix} 1 \\ 0 \end{pmatrix} \end{pmatrix}, \tag{637}$$

and

$$u(\boldsymbol{k}, 2) = \sqrt{m+\omega}\begin{pmatrix} \begin{pmatrix} 0 \\ 1 \end{pmatrix} \\ \dfrac{\sigma^i k_i}{m+\omega}\begin{pmatrix} 0 \\ 1 \end{pmatrix} \end{pmatrix}. \tag{638}$$

It is easy to check that this spinor is normalized according to

$$\overline{u}(\boldsymbol{k}, r) u(\boldsymbol{k}, s) = 2m\delta_{sr}. \tag{639}$$

In the same manner, the solution $v(\boldsymbol{k}, r)$, corresponding to the other branch of the Fourier expansion, can be written as

$$v(\boldsymbol{k}, 1) = \sqrt{m+\omega}\begin{pmatrix} \dfrac{\sigma^i k_i}{m+\omega}\begin{pmatrix} 1 \\ 0 \end{pmatrix} \\ \begin{pmatrix} 1 \\ 0 \end{pmatrix} \end{pmatrix}, \tag{640}$$

and

$$v(\boldsymbol{k}, 2) = \sqrt{m+\omega}\begin{pmatrix} \dfrac{\sigma^i k_i}{m+\omega}\begin{pmatrix} 0 \\ 1 \end{pmatrix} \\ \begin{pmatrix} 0 \\ 1 \end{pmatrix} \end{pmatrix}. \tag{641}$$

The normalization of this spinor satisfies a relation almost identical to that of $u(\boldsymbol{k}, r)$ except for the presence of a minus sign

$$\overline{v}(\boldsymbol{k}, r) v(\boldsymbol{k}, s) = -2m\delta_{sr}. \tag{642}$$

Finally, we also have

$$\overline{u}(\boldsymbol{k}, r) v(\boldsymbol{k}, s) = 0, \tag{643}$$

which can easily be obtained from the above expressions.

All the previous considerations are standard textbooks calculations. We now turn to our main goal, namely the calculation of the vacuum energy. Therefore, the next step consists in calculating the energy momentum tensor. Either using the Noether procedure or a variation of the action with respect to vierbeins lead to the equation

$$T_{\mu\nu} = -\frac{i}{4}\left(\overline{\Psi}\gamma_\mu\partial_\nu\Psi + \overline{\Psi}\gamma_\nu\partial_\mu\Psi - \partial_\mu\overline{\Psi}\gamma_\nu\Psi - \partial_\nu\overline{\Psi}\gamma_\mu\Psi\right). \tag{644}$$

Of course, this expression is symmetric in μ and ν as it should. Endowed with this formula, one can now evaluate the various components of the stress energy tensor in the vacuum state. Let us first calculate the energy density. One has

$$\langle\rho\rangle = -\frac{i}{4}\langle 0\,\big|\left(-2\Psi^\dagger\partial_0\Psi + 2\partial_0\Psi^\dagger\Psi\right)\big|\,0\rangle, \tag{645}$$

since $\gamma^0 = -\gamma_0$ and $(\gamma^0)^2 = \mathbb{I}_4$. Inserting the Fourier expansion (631) into the above expression, one arrives at

$$\langle\rho\rangle = -\frac{1}{(2\pi)^3}\frac{1}{2}\int \mathrm{d}\boldsymbol{k}\sum_{s=1}^{2} v^\dagger(\boldsymbol{k},s)v(\boldsymbol{k},s). \tag{646}$$

This equation can be further simplified. Upon using the explicit form of the spinors given above, one can show that

$$\sum_{s=1}^{2} v^\dagger(\boldsymbol{k},s)v(\boldsymbol{k},s) = 4\omega(k), \tag{647}$$

and, therefore, we obtain the following expression for the vacuum energy

$$\langle\rho\rangle = -\frac{1}{(2\pi)^3}\frac{4}{2}\int \mathrm{d}\boldsymbol{k}\,\omega(k). \tag{648}$$

Several comments are in order at this point. From the above expression, we see that we find minus four times the corresponding result for a scalar field, see Eq. (364). We have a factor four because we have two particles (the particle and its anti-particle) with two polarization state each. Of course, the most striking aspect of the above equation is that $\langle\rho\rangle$ is negative. It is therefore interesting to understand the origin of the minus sign in more details. For this purpose, let us calculate the Hamiltonian operator associated to the Dirac field

$$H = \int \mathrm{d}^3\boldsymbol{x}\, T_{00}. \tag{649}$$

Inserting the Fourier expansion (631) of the spinor Ψ into the above equation, it is straightforward to arrive at [127]

$$H = \int \mathrm{d}\boldsymbol{k}\sum_{s=1}^{2}\omega(k)\left[(b^s_{\boldsymbol{k}})^\dagger\, b^s_{\boldsymbol{k}} - d^s_{\boldsymbol{k}}\,(d^s_{\boldsymbol{k}})^\dagger\right]. \tag{653}$$

However, as we have already recalled, a spinor field is a quantity which anti-commutes and, therefore, one has $\left\{d^s_{\boldsymbol{k}}, \left(d^r_{\boldsymbol{p}}\right)^\dagger\right\} = \delta\left(\boldsymbol{k}-\boldsymbol{p}\right)\delta_{rs}$. As a consequence, the Hamiltonian (653) can be re-written as

$$H = \int \mathrm{d}\boldsymbol{k}\sum_{s=1}^{2}\omega(k)\left[N_b + N_d - \delta(0)\right], \tag{654}$$

[127] For convenience, let us notice that the following relationships are useful for this calculation

$$u^\dagger(\boldsymbol{k},s)u(\boldsymbol{k},r) = 2\omega\delta_{rs}, \tag{650}$$
$$v^\dagger(\boldsymbol{k},s)v(\boldsymbol{k},r) = 2\omega\delta_{rs}, \tag{651}$$
$$v^\dagger(\boldsymbol{k},s)v(-\boldsymbol{k},r) = 0. \tag{652}$$

These three equations are responsible for the fact that only the quantity $\omega(k)$ appears into the expression of the Hamiltonian (653).

where $N_b \equiv (b^s_{\boldsymbol{k}})^\dagger\, b^s_{\boldsymbol{k}}$ and $N_d \equiv (d^s_{\boldsymbol{k}})^\dagger\, d^s_{\boldsymbol{k}}$ are the particle and anti-particle number operators respectively. Of course, their mean value vanishes in the vacuum state which contains no particle. The zero point energy is thus given by the formally infinite term $\delta(0)$. Since this term appears with a minus sign in the Hamiltonian, the corresponding energy density is indeed negative. The origin of this minus sign is the anti-commuting properties of the creation and annihilation operators. We conclude that the vacuum energy density is negative because we deal with fermions which are anti-commuting objects.

Let us now turn to the calculation of the pressure. Upon using Eq. (644), one has

$$\begin{aligned}
\langle p\rangle &= \frac{1}{3}\perp^{\mu\nu} T_{\mu\nu} && (655)\\
&= -\frac{i}{6}g^{00}\big(\overline{\Psi}\gamma_0\partial_0\Psi - \partial_0\overline{\Psi}\gamma_0\Psi\big) - \frac{i}{6}g^{ij}\big(\overline{\Psi}\gamma_i\partial_j\Psi \\
&- 2\partial_i\overline{\Psi}\gamma_j\Psi\big) - \frac{i}{6}u^0u^0\big(\overline{\Psi}\gamma_0\partial_0\Psi - \partial_0\overline{\Psi}\gamma_0\Psi\big) && (656)\\
&= -\frac{i}{6}\delta^{ij}\left(\overline{\Psi}\gamma_i\partial_j\Psi - 2\partial_i\overline{\Psi}\gamma_j\Psi\right). && (657)
\end{aligned}$$

From the above expression, we see that we have two terms to calculate. Using the definition of $\overline{\Psi}$, the first one reads

$$\begin{aligned}
\langle 0\left|\Psi^\dagger\gamma^0\gamma^i\partial_i\Psi\right|0\rangle &= -\frac{i}{(2\pi)^3}\int\frac{\mathrm{d}\boldsymbol{k}}{\sqrt{2\omega(k)}}k_i \\
&\times \sum_{s=1}^{2} v^\dagger(\boldsymbol{k},s)\gamma^0\gamma^i v(\boldsymbol{k},s), && (658)
\end{aligned}$$

while the second one takes the form

$$\langle 0\left|\Psi^\dagger\gamma^0\gamma^i\partial_i\Psi\right|0\rangle = -\langle 0\left|\partial_i\Psi^\dagger\gamma^0\gamma^i\Psi\right|0\rangle. \quad (659)$$

As a consequence, one finds that the vacuum pressure is given by the following expression

$$\begin{aligned}
\langle p\rangle &= -\frac{1}{3}\frac{1}{(2\pi)^3}\int\frac{\mathrm{d}\boldsymbol{k}}{\sqrt{2\omega(k)}} \\
&\times \sum_{s=1}^{2} v^\dagger(\boldsymbol{k},s)\gamma^0\gamma^i k_i v(\boldsymbol{k},s). && (660)
\end{aligned}$$

One must now evaluate the sum present in the above integral. We have seen that the spinors v obeys the Dirac equation $(\gamma^0\omega - \gamma^i k_i + m)\, v(\boldsymbol{k},s) = 0$. Using this last equation, one deduces that

$$\begin{aligned}
v^\dagger(\boldsymbol{k},s)\gamma^0\gamma^i k_i v(\boldsymbol{k},s) &= \omega v^\dagger(\boldsymbol{k},s)v(\boldsymbol{k},s) \\
&+ v^\dagger(\boldsymbol{k},s)\gamma^0 m v(\boldsymbol{k},s). && (661)
\end{aligned}$$

Then, one can sum over the polarization and use the normalization of the spinors established before, see for instance Eqs. (639), (642) and (643), to obtain that

$$\begin{aligned}
&\sum_{s=1}^{2} v^\dagger(\boldsymbol{k},s)\gamma^0\gamma^i k_i v(\boldsymbol{k},s) = 4\omega^2 \\
&+\sum_{s=1}^{2} v^\dagger(\boldsymbol{k},s)\gamma^0 m v(\boldsymbol{k},s). && (662)
\end{aligned}$$

On the other hand, with the explicit expressions (640) and (641), it is easy to directly check that $\sum_{s=1}^{2} v^{\dagger}(\mathbf{k},s)\gamma^0 m v(\mathbf{k},s) = -4m^2$ from which one can establish that

$$\sum_{s=1}^{2} v^{\dagger}(\boldsymbol{k},s)\gamma^0\gamma^i k_i v(\boldsymbol{k},s) = 4\omega^2 - 4m^2 = 4k^2, \tag{663}$$

which is exactly the sum needed to evaluate the pressure. Therefore, our final expression for $\langle p\rangle$ can be written as

$$\langle p\rangle \;=\; -\frac{1}{(2\pi)^3}\frac{4}{6}\int \mathrm{d}\boldsymbol{k}\frac{k^2}{\omega(k)}. \tag{664}$$

We see that, again, we recover exactly the same result as for the scalar field but with the additional multiplicative factor -4, see Eq. (366). This means that all the previous considerations discussed in the scalar field case also apply to the fermion case. In particular, the regularization of the above divergent integrals would proceed in the same way. Introducing a cut-off would break Lorentz invariance and would lead to an incorrect equation of state. On the other hand, using, say, dimensional regularization produces the correct vacuum equation of state and leads to a regularized vacuum energy which is minus four times the regularized scalar field vacuum energy. We do not need to repeat all these calculations here and we now move to the case of a vector field.

24.7.2 Proca Fields

Having treated the case of a spin 1/2 field in the previous sub-section, we now turn to the case of a Proca field [16, 17, 18, 19, 20, 21, 22]. A Proca field $A_\mu(t,\boldsymbol{x})$ is a massive vector, spin 1, field. The corresponding action can be written as

$$S[A_\mu] \equiv -\int \mathrm{d}^4x\sqrt{-g}\left(\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}m^2 A_\mu A^\mu\right), \tag{665}$$

where $F_{\mu\nu} \equiv \partial_\mu A_\nu - \partial_\nu A_\mu$ and m is the mass of the particle. Again, we will restrict our considerations to flat space-time and, therefore, we will take for the metric determinant $g = \eta = 1$.

Before turning to the calculation of the vacuum stress energy momentum, we quickly remind some basics fact about the quantization of this type of fields. Varying with respect to A_μ, one obtains the equation of motion

$$\partial_\mu F^{\mu\nu} - m^2 A^\nu = 0. \tag{666}$$

Taking the derivative of this expressions and noting that $\partial_\nu\partial_\mu F^{\mu\nu} = 0$ (since this is the contraction of a symmetric expression with an anti-symmetric one), one arrives at

$$\partial_\nu A^\nu = 0, \tag{667}$$

provided that $m \neq 0$, which we assume in this section. As a consequence, the equation of motion of the vector field is given by

$$\partial_\nu\partial^\nu A_\mu - m^2 A_\mu = 0, \tag{668}$$

which is nothing but a Klein-Gordon equation for each component of A_μ. As usual, we Fourier expand the field in terms of creation and annihilation operators. This leads to the following expression

$$\begin{aligned} A_\mu(t,\boldsymbol{x}) \;=\; & \frac{1}{(2\pi)^{3/2}}\int\frac{\mathrm{d}\boldsymbol{k}}{\sqrt{2\omega(k)}}\sum_{\alpha=0}^{4}\epsilon_\mu^\alpha(\boldsymbol{k})\Big[a_{\boldsymbol{k}}^\alpha \mathrm{e}^{-i\omega t + i\boldsymbol{k}\cdot\boldsymbol{x}} \\ & + (a_{\boldsymbol{k}}^\alpha)^\dagger\,\mathrm{e}^{i\omega t - i\boldsymbol{k}\cdot\boldsymbol{x}}\Big], \end{aligned} \tag{669}$$

where, as usual, one has $\omega(k) = \sqrt{k^2 + m^2}$. Of course, the operators $a^\alpha_{\boldsymbol{k}}$ satisfy commutation rules since a vector field is a bosonic field. The sum over α is a sum over four vectors that span space-time and form a basis. At this point, A_μ satisfies the equation of motion but not yet the constraint $\partial_\nu A^\nu = 0$. Working out this constraint, it is easy to show that this amounts to $\epsilon^\alpha_\mu k^\mu a^\alpha_{\boldsymbol{k}} = 0$. If we now choose a frame where the wave-vector is aligned along the z-direction, then the basis can be taken to be

$$\epsilon^0_\mu = \begin{pmatrix} -\omega/m \\ 0 \\ 0 \\ k/m \end{pmatrix}, \quad \epsilon^1_\mu = \begin{pmatrix} 0 \\ \hat{\epsilon}^1_x \\ \hat{\epsilon}^1_y \\ 0 \end{pmatrix}, \tag{670}$$

$$\epsilon^2_\mu = \begin{pmatrix} 0 \\ \hat{\epsilon}^2_x \\ \hat{\epsilon}^2_y \\ 0 \end{pmatrix}, \quad \epsilon^3_\mu = \begin{pmatrix} -k/m \\ 0 \\ 0 \\ \omega/m \end{pmatrix}, \tag{671}$$

where $\hat{\epsilon}^{1,2}$ are vectors perpendicular to the wave-vector (the time components of ϵ^0 and ϵ^3 carry a minus sign because we show here the covariant vectors). But we have $\epsilon^0_\mu k^\mu \neq 0$ despite the fact that this is the only choice such that $\epsilon^0_\mu \epsilon^{\mu 3} = 0$. Therefore, the only possibility left in order to satisfy the constraint is to take $a^0_{\boldsymbol{k}} = 0$. As a consequence, the Fourier expansion of the vector potential is now given by

$$A_\mu(t, \boldsymbol{x}) = \frac{1}{(2\pi)^{3/2}} \int \frac{\mathrm{d}\boldsymbol{k}}{\sqrt{2\omega(k)}} \sum_{\alpha=1}^{3} \epsilon^\alpha_\mu(\boldsymbol{k}) \Big[a^\alpha_{\boldsymbol{k}} \mathrm{e}^{-i\omega t + i\boldsymbol{k}\cdot\boldsymbol{x}} + (a^\alpha_{\boldsymbol{k}})^\dagger \mathrm{e}^{i\omega t - i\boldsymbol{k}\cdot\boldsymbol{x}} \Big], \tag{672}$$

where the three vectors appearing in this decomposition are still given in Eqs. (670) and (671).

Let us now come to our main subject and calculate the stress-energy tensor. There are several ways to carry out this calculation. Here, we choose to return to Eq. (665) and to vary this action with respect to the space-time metric tensor. Then, in order to work with the stress energy tensor in flat space-time, we will take $g_{\mu\nu} = \eta_{\mu\nu}$ but, of course, only after having performed the variation. Straightforward manipulations lead to the following expression

$$T_{\mu\nu} \equiv -\frac{2}{\sqrt{-g}} \frac{\delta S[A_\mu]}{\delta g^{\mu\nu}} \tag{673}$$

$$= -g_{\mu\nu} \left(\frac{1}{4} g^{\lambda\alpha} g^{\kappa\beta} F_{\lambda\kappa} F_{\alpha\beta} + \frac{1}{2} m^2 g^{\alpha\beta} A_\alpha A_\beta \right) + g^{\alpha\beta} F_{\mu\alpha} F_{\nu\beta} + m^2 A_\mu A_\nu. \tag{674}$$

We are now in a position where we can compute the various components of $T_{\mu\nu}$. Let us start with the energy density. From the above expression, one deduces that

$$T_{00} = \frac{1}{2}\delta^{ij} F_{0i} F_{0j} + \frac{1}{4}\delta^{ij}\delta^{kl} F_{ik} F_{jl} + \frac{1}{2} m^2 A_0^2 + \frac{1}{2} m^2 \delta^{ij} A_i A_j. \tag{675}$$

Then, in order to evaluate the above equation, we have to separately calculate the four terms that appear in this expression. Let us first give the relevant results needed to calculate the first

term. Upon using Eq. (672), it is easy to establish that

$$\begin{aligned}\delta^{ij}\langle 0|\partial_0 A_i \partial_0 A_j|0\rangle &= \frac{1}{(2\pi)^3}\int \frac{\mathrm{d}\boldsymbol{k}}{2\omega(k)}\delta^{ij} \\ &\times \sum_{\alpha=1}^{3}\epsilon_i^\alpha \epsilon_j^\alpha \omega^2, \end{aligned} \tag{676}$$

$$\begin{aligned}\delta^{ij}\langle 0|\partial_0 A_i \partial_j A_0|0\rangle &= -\frac{1}{(2\pi)^3}\int \frac{\mathrm{d}\boldsymbol{k}}{2\omega(k)}\delta^{ij} \\ &\times \sum_{\alpha=1}^{3}\epsilon_i^\alpha \epsilon_0^\alpha \omega k_j, \end{aligned} \tag{677}$$

and,

$$\begin{aligned}\delta^{ij}\langle 0|\partial_i A_0 \partial_j A_0|0\rangle &= \frac{1}{(2\pi)^3}\int \frac{\mathrm{d}\boldsymbol{k}}{2\omega(k)}\delta^{ij} \\ &\times \sum_{\alpha=1}^{3}\epsilon_0^\alpha \epsilon_0^\alpha k_i k_j. \end{aligned} \tag{678}$$

In the same manner, the second term, containing the space space component of the field strength, can be expressed as

$$\begin{aligned}\delta^{ij}\delta^{kl}\langle 0|F_{ik}F_{jl}|0\rangle &= \frac{2}{(2\pi)^3}\int \frac{\mathrm{d}\boldsymbol{k}}{2\omega(k)}\delta^{ij}\delta^{kl} \\ &\times \sum_{\alpha=1}^{3}\left(\epsilon_k^\alpha \epsilon_l^\alpha k_i k_j - \epsilon_k^\alpha \epsilon_j^\alpha k_i k_l\right). \end{aligned} \tag{679}$$

The third term can be written as

$$\langle 0|A_0^2|0\rangle = \frac{1}{(2\pi)^3}\int \frac{\mathrm{d}\boldsymbol{k}}{2\omega(k)}\sum_{\alpha=1}^{3}\epsilon_0^\alpha \epsilon_0^\alpha, \tag{680}$$

and, finally, the fourth and last term takes the form

$$\delta^{ij}\langle 0|A_i A_j|0\rangle = \frac{1}{(2\pi)^3}\int \frac{\mathrm{d}\boldsymbol{k}}{2\omega(k)}\sum_{\alpha=1}^{3}\delta^{ij}\epsilon_i^\alpha \epsilon_j^\alpha. \tag{681}$$

Having calculated the four terms appearing in the expression of T_{00}, one must now combine them. Using the relationships satisfied by the vectors basis[128], one obtains the following ex-

[128]For convenience, let us give the two equations needed to complete the calculation. It involves simple combination of the polarization vectors. Using the explicit representation given by Eqs. (670) and (671), one arrives at

$$\delta^{ij}\sum_{\alpha=1}^{3}\epsilon_i^\alpha \epsilon_j^\alpha = 2 + \frac{\omega^2}{m^2}, \tag{682}$$

$$\sum_{\alpha=1}^{3}\epsilon_0^\alpha \epsilon_0^\alpha = \frac{k^2}{m^2}. \tag{683}$$

Then, these two expressions can be combined to lead to the following relation which is what is needed in order to simplify the expression of the vacuum energy density

$$\begin{aligned}\sum_{\alpha=1}^{3}\left(\epsilon_k^\alpha \epsilon_l^\alpha k_i k_j - \epsilon_k^\alpha \epsilon_j^\alpha k_i k_l\right) &= k^2\left(2 + \frac{\omega^2}{m^2}\right) - \frac{k^2\omega^2}{m^2} \\ &= 2. \end{aligned} \tag{684}$$

pression for the vacuum energy density

$$\langle \rho \rangle = \frac{1}{(2\pi)^3} \frac{3}{2} \int \mathrm{d}\boldsymbol{k}\, \omega(k). \tag{685}$$

Based on our experience with the calculation of the vacuum energy of a spin 1/2 field, this expression is totally expected. As before, it is equal to the scalar field energy density times a multiplicative factor which takes into account the spin of the particle. Here, for a massive vector field, there are three polarization states and, as a consequence, the multiplicative factor is three.

In order to be exhaustive, let us now evaluate the pressure. The calculation proceeds exactly as before and it is easy to show that

$$\perp^{\mu\nu} T_{\mu\nu} = T_{00} + m^2 A_0^2 - m^2 \delta^{ij} A_i A_j, \tag{686}$$

from which, using the relations already established before, we immediately deduce that

$$\langle p \rangle = \frac{1}{(2\pi)^3} \frac{3}{6} \int \mathrm{d}\boldsymbol{k}\, \frac{k^2}{\omega(k)}. \tag{687}$$

Of course, this is again the expected formula, namely the scalar field pressure times a multiplicative factor equals to three. Clearly, there is no need to repeat the discussion about the regularization of the above divergent integrals. It proceeds exactly as explained before.

24.7.3 Mass-less Vector Field

Finally, we consider the case where the vector field is mass-less, $m = 0$ [16, 17, 18, 19, 20, 21, 22]. This is of course necessary if we want to realistically evaluate the vacuum energy density since we know that this type of field exist in Nature. If the mass vanishes, this means that the dispersion relation is now given by

$$\omega(k) = k, \tag{688}$$

as appropriate for photons. In that case, contrary to the massive case, we can no longer establish that $\partial_\nu A^\nu = 0$. Therefore, the equation of motion takes the form

$$\partial_\mu \partial^\mu A^\nu - \partial^\nu \left(\partial_\mu A^\mu \right) = 0. \tag{689}$$

At this stage, we need to fix a gauge. As is well-known, it is convenient to work in the Coulomb gauge defined by the following conditions

$$A_0 = 0, \quad \partial_i A^i = 0. \tag{690}$$

In particular, the last condition implies that $A_i(t, \boldsymbol{x})$ is a transverse field. As a consequence, its Fourier expansion can be written as

$$\begin{aligned} A_i\left(t, \boldsymbol{x}\right) &= \frac{1}{(2\pi)^{3/2}} \int \frac{\mathrm{d}\boldsymbol{k}}{\sqrt{2\omega(k)}} \sum_{\alpha=1}^{2} \epsilon_i^\alpha(\boldsymbol{k}) \Big[a_{\boldsymbol{k}}^\alpha \mathrm{e}^{-i\omega t + i\boldsymbol{k}\cdot\boldsymbol{x}} \\ &\quad + \left(a_{\boldsymbol{k}}^\alpha\right)^\dagger \mathrm{e}^{i\omega t - i\boldsymbol{k}\cdot\boldsymbol{x}} \Big]. \end{aligned} \tag{691}$$

The two three-vectors ϵ^1 and ϵ^2 are perpendicular to the wave-vectors $\boldsymbol{k}$. In the mass-less case, only two degrees of freedom remain.

The calculation of the stress-energy tensor is now straightforward. Using the calculation of the previous section, in particular the expression of the time-time component of the stress-energy tensor (675), one finds that

$$T_{00} = \frac{1}{2} \delta^{ij} \partial_0 A_i \partial_0 A_j + \frac{1}{4} \delta^{ij} \delta^{kl} F_{ik} F_{jl}, \tag{692}$$

and, since we now have,

$$\delta^{ij}\sum_{\alpha=1}^{2}\epsilon_i^\alpha\epsilon_j^\alpha = 2, \tag{693}$$

$$\sum_{\alpha=1}^{2}\left(\epsilon_k^\alpha\epsilon_l^\alpha k_i k_j - \epsilon_k^\alpha\epsilon_j^\alpha k_i k_l\right) = 2k^2, \tag{694}$$

one finally arrives at the following expression for the vacuum energy density

$$\langle\rho\rangle = \frac{1}{(2\pi)^3}\frac{2}{2}\int \mathrm{d}\boldsymbol{k}\,\omega(k), \tag{695}$$

that is to say the scalar field energy density times two, as expected since there are two polarization states. For the pressure, using the same approach, one immediately obtains

$$\langle p\rangle = \frac{1}{(2\pi)^3}\frac{2}{6}\int \mathrm{d}\boldsymbol{k}\,\frac{k^2}{\omega(k)}, \tag{696}$$

where, as usual, the factor two in front of the whole expression originates from the the two polarization states of a mass-less vector particle.

We conclude by stating the main result established in this section. For any type of fields, the vacuum energy density can be written as

$$\langle\rho\rangle = \frac{1}{(2\pi)^3}\frac{s}{2}\int \mathrm{d}\boldsymbol{k}\,\omega(k), \tag{697}$$

where s represents the number of polarization states ($s = 1$ for a scalar field, $s = 4$ for a spinor field, $s = 3$ for a massive vector field and $s = 2$ for a mass-less vector field). The pressure is given by a similar expression. When these divergent integrals are regularized, one can show that, again for any type of field, this leads to the Lorentz invariant form of the vacuum equation of state, namely $\langle p\rangle = -\langle\rho\rangle$. In principle, the results of this section makes the accurate evaluation of the vacuum energy density in the standard model of particle physics possible. However, before discussing this point, we need to say something about the fact that ρ_{vac} is positive for bosons and negative for fermions.

24.7.4 Application: Super-Symmetry

Motivation

The fact that the sign of the zero-point energy density is different for fermions and bosons, see Eqs. (364) and (648), suggests a very simple way of solving the cosmological constant problem. It is clear that one can design a theory where the two contributions are equal in absolute value such that the final result is exactly zero. Let us see how it works in practice. For this purpose, let us consider again the Lagrangian of a massive real scalar field, see also Eq. (302)

$$\mathcal{L}_\phi = -\frac{\alpha}{2}\eta^{\mu\nu}\partial_\mu\Phi\partial_\nu\Phi - \frac{1}{2}m^2\Phi^2, \tag{698}$$

where we have introduced a constant α in front of the kinetic term. Before we took $\alpha = 1$ and it is interesting to discuss why we made this choice (after all, how do we know that $\alpha = 1$?). As usual, see Eq. (357), one Fourier expands the scalar field as

$$\Phi(t,\boldsymbol{x}) = \frac{1}{(2\pi)^{3/2}}\int\frac{\mathrm{d}\boldsymbol{k}}{\sqrt{2\omega(k,\alpha)}}\Big(c_{\boldsymbol{k}}\mathrm{e}^{-i\omega t+i\boldsymbol{k}\cdot\boldsymbol{x}} + c_{\boldsymbol{k}}^\dagger\mathrm{e}^{i\omega t-i\boldsymbol{k}\cdot\boldsymbol{x}}\Big), \tag{699}$$

with a new expression for the quantity ω, compare to Eq. (358), namely

$$\omega(k,\alpha) = \sqrt{k^2 + \frac{m^2}{\alpha^2}}, \tag{700}$$

since this is the condition for Eq. (699) to be a solution of the "new" equation of motion [see also Eq. (356)]

$$-\alpha\ddot{\phi} + \alpha\delta^{ij}\partial_i\phi\partial_j\phi - m^2\phi = 0. \tag{701}$$

The new dispersion relation can easily be understood. We see that the quantity α simply renormalizes the value of the mass m. This makes sense since, if $m = 0$, we clearly see that the relativistic relation $\omega = k$ is not affected by the presence of the constant α.

The next step is to derive the commutation relations for the creation and annihilation operators. Let us assume for the moment that we have the standard relation (359)

$$\left[c_{\boldsymbol{k}}, c^\dagger_{\boldsymbol{p}}\right] = \delta\left(\boldsymbol{k} - \boldsymbol{p}\right). \tag{702}$$

Then, from the expression of the Lagrangian, one can calculate the conjugate momentum. It reads $\Pi(t,\boldsymbol{x}) = -\alpha\dot{\Phi}(t,\boldsymbol{x})$. This implies that the commutation relation between the field and its conjugate momentum now reads

$$[\phi(t,\boldsymbol{x}), \pi(t,\boldsymbol{y})] = i\alpha\delta(\boldsymbol{x} - \boldsymbol{y}), \tag{703}$$

an expression which reduces to the standard commutation relation only if $\alpha = 1$. Therefore, if one wants to have $[\Phi, \Pi] = i\delta(\boldsymbol{x}-\boldsymbol{y})$ and, at the same time, $[c_{\boldsymbol{k}}, c^\dagger_{\boldsymbol{p}}] = \delta\left(\boldsymbol{k} - \boldsymbol{p}\right)$ there is no other choice that taking $\alpha = 1$. It is worth noticing that working with the two previous commutation relations (702), (703) and $\alpha \neq 1$ would lead to a different prediction for the energy density of the vacuum. Indeed, the stress-energy tensor is now given by

$$T_{\mu\nu} = \alpha\partial_\mu\Phi\partial_\nu\Phi - g_{\mu\nu}\left(\frac{\alpha}{2}g^{\alpha\beta}\partial_\alpha\Phi\partial_\beta\Phi + \frac{1}{2}m^2\Phi^2\right), \tag{704}$$

which implies that

$$T_{00} = \frac{\alpha}{2}\dot{\Phi}^2 + \frac{\alpha}{2}\delta^{ij}\partial_i\Phi\partial_j\Phi + \frac{1}{2}m^2\Phi^2. \tag{705}$$

From this expression, it is easy to show that

$$\langle\rho\rangle = \frac{\alpha}{(2\pi)^3}\frac{1}{2}\int \mathrm{d}\boldsymbol{k}\,\omega(k,\alpha), \tag{706}$$

an expression that should be compared to Eq. (364).

Of course, one can also demonstrate that the consistency can be re-establish if the commutation relations for the creation and annihilation operators are taken to be $[c_{\boldsymbol{k}}, c^\dagger_{\boldsymbol{p}}] = \delta\left(\boldsymbol{k} - \boldsymbol{p}\right)/\alpha$. In this case the commutation relation of the field and its conjugate momentum have the correct form. Moreover, one has

$$\langle 0|\dot{\Phi}^2|0\rangle = \frac{1}{(2\pi)^3}\int\frac{\mathrm{d}\boldsymbol{k}}{2\omega(k,\alpha)}\frac{\omega^2(k,\alpha)}{\alpha}, \tag{707}$$

$$\langle 0|\delta^{ij}\partial_i\Phi\partial_j\Phi|0\rangle = \frac{1}{(2\pi)^3}\int\frac{\mathrm{d}\boldsymbol{k}}{2\omega(k,\alpha)}\frac{k^2}{\alpha}, \tag{708}$$

$$\langle 0|\Phi^2|0\rangle = \frac{1}{(2\pi)^3}\int\frac{\mathrm{d}\boldsymbol{k}}{2\omega(k,\alpha)}\frac{1}{\alpha}, \tag{709}$$

[these formulas should be compared to Eqs. (360), (361) and (362), which implies that

$$\langle\rho\rangle = \frac{1}{(2\pi)^3}\frac{1}{2}\int \mathrm{d}\boldsymbol{k}\,\omega(k,\alpha), \tag{710}$$

that is to say the "standard" result.

Therefore, in conclusion, the "1/2" coefficient in the expression of the vacuum energy density is only obtained if the commutation relations and the normalization of the field are properly and consistently chosen. In particular, if one chooses to work with a coefficient "1/2" in front of the kinetic term (canonical normalization), then there is no other choice than working with $[c_{\boldsymbol{k}}, c^{\dagger}_{\boldsymbol{p}}] = \delta(\boldsymbol{k} - \boldsymbol{p})$. Or, in other words, the previous commutation relation implies that a "1/2" in front of the kinetic term must be present.

We now apply the previous discussion to the cases of a complex scalar field and to a Majorana spinor. The Lagrangian for a complex scalar field should be written as

$$\mathcal{L} = -g^{\mu\nu}\partial_\mu\Phi^*\partial_\nu\Phi - m^2\Phi^*\Phi, \tag{711}$$

with, this time, no "1/2" in front of the whole expression. Indeed, if one writes that

$$\phi = \frac{1}{\sqrt{2}}(A_1 + iA_2), \tag{712}$$

then the Lagrangian takes the form of the sum of two Lagrangian for the two real canonically normalized fields A_1 and A_2.

The previous discussion has also important implications for the Lagrangian of a Majorana spinor. A Majorana spinor is a spinor satisfying

$$\Psi^{\rm c}_{\rm M} = \Psi_{\rm M}, \tag{713}$$

where the charge conjugate spinor $\Psi^{\rm c}$ is defined by

$$\Psi^{\rm c} \equiv C\overline{\Psi}^{\rm T}. \tag{714}$$

In this expression the symbol "T" denotes the transpose matrix. The matrix C is the charge conjugation operator that can be represented by $i\gamma^2\gamma^0$ and satisfies $C\gamma^{\rm T}_\mu C^{-1} = -\gamma_\mu$. We have of course $(\Psi^{\rm c})^{\rm c} = \Psi$. From a Dirac spinor Ψ one can always write two Majorana spinors

$$\Psi_{\rm M1} = \frac{1}{\sqrt{2}}(\Psi + \Psi^{\rm c}), \tag{715}$$

$$\Psi_{\rm M2} = \frac{1}{i\sqrt{2}}(\Psi - \Psi^{\rm c}). \tag{716}$$

Of course, the above expressions can always be inverted and re-written as

$$\Psi = \frac{1}{\sqrt{2}}(\Psi_{\rm M1} + i\Psi_{\rm M2}), \tag{717}$$

$$\Psi^{\rm c} = \frac{1}{\sqrt{2}}(\Psi_{\rm M1} - i\Psi_{\rm M2}). \tag{718}$$

The two previous expression can be inserted in the Dirac Lagrangian (627) (taking $m = 0$). This leads to the following expression

$$\begin{aligned}\mathcal{L}_{\rm Dirac} &= -\frac{1}{\sqrt{2}}\left(\overline{\Psi}_{\rm M1} - i\overline{\Psi}_{\rm M2}\right) i\gamma^\mu\partial_\mu\frac{1}{\sqrt{2}}\left(\overline{\Psi}_{\rm M1} + i\overline{\Psi}_{\rm M2}\right)\\ &= -\frac{i}{2}\overline{\Psi}_{\rm M1}\gamma^\mu\partial_\mu\Psi_{\rm M1} - \frac{i}{2}\overline{\Psi}_{\rm M2}\gamma^\mu\partial_\mu\Psi_{\rm M2}\\ &\quad -\frac{i}{2}\left(-i\overline{\Psi}_{\rm M2}\gamma^\mu\partial_\mu\Psi_{\rm M1} + i\overline{\Psi}_{\rm M1}\gamma^\mu\partial_\mu\Psi_{\rm M2}\right).\end{aligned} \tag{719}$$

But, using partial integrations, one easily shows that

$$\overline{\Psi}_{\rm M2}\gamma^\mu\partial_\mu\Psi_{\rm M1} = -\left(\partial_\mu\overline{\Psi}_{\rm M2}\right)\gamma^\mu\Psi_{\rm M1} = +\overline{\Psi}_{\rm M1}\gamma^\mu\partial_\mu\Psi_{\rm M2}, \tag{720}$$

so that the last term vanishes. Therefore, one conclude that the Lagrangian for a Majorana spinor is given by

$$\mathcal{L}_{\text{Majorana}} = -\frac{1}{2}\overline{\Psi}_{\text{M}}\left(i\gamma^{\mu}\partial_{\mu} - m\right)\Psi_{\text{M}}, \tag{721}$$

and that the expansion of a Majorana spinor operator in Fourier can be expressed as, see also Eq. (631)

$$\begin{aligned}\Psi_{\text{M}}(t,\boldsymbol{x}) &= \frac{1}{(2\pi)^{3/2}}\int\frac{\mathrm{d}\boldsymbol{k}}{\sqrt{2\omega(k)}}\sum_{r=1}^{2}\Big[b^{r}_{\boldsymbol{k}}u(\boldsymbol{k},r)\mathrm{e}^{-i\omega t+i\boldsymbol{k}\cdot\boldsymbol{x}}\\ &\quad + (b^{r}_{\boldsymbol{k}})^{\dagger}v(\boldsymbol{k},r)\mathrm{e}^{i\omega t-i\boldsymbol{k}\cdot\boldsymbol{x}}\Big],\end{aligned} \tag{722}$$

where we notice that only the operators $b^{r}_{\boldsymbol{k}}$ are present which reflects the fact that, for a Majorana spinor, the particle and the anti-particle are the same. But the most important aspect is the coefficient "1/2" in Eq. (721). Clearly, it means that if we perform the calculation of $\langle\rho\rangle$ again, we are going to find

$$\langle\rho\rangle = -\frac{1}{(2\pi)^{3}}\frac{2}{2}\int\mathrm{d}\boldsymbol{k}\,\omega(k), \tag{723}$$

that is to say an expression with an overall factor 2 instead of 4 for a Dirac fermion, see Eq. (648).

We are now in a position to address the main point of this section. Let us consider the following model described by a complex scalar field and a Marojana spinor

$$\mathcal{L} = -g^{\mu\nu}\partial_{\mu}\Phi^{*}\partial_{\nu}\Phi - m^{2}_{\text{B}}\phi^{*}\phi - \frac{1}{2}\overline{\Psi}_{\text{M}}\left(i\gamma^{\mu}\partial_{\mu} - m_{\text{F}}\right)\Psi_{\text{M}}, \tag{724}$$

where m_{B} is the mass of the bosonic field and m_{F} is the mass of the fermionic field. From the above considerations, it is obvious to calculate the vacuum energy density. It reads

$$\begin{aligned}\langle\rho\rangle &= \frac{1}{(2\pi)^{3}}\frac{2}{2}\int\mathrm{d}\boldsymbol{k}\,\sqrt{k^{2}+m^{2}_{\text{B}}}\\ &\quad -\frac{1}{(2\pi)^{3}}\frac{2}{2}\int\mathrm{d}\boldsymbol{k}\,\sqrt{k^{2}+m^{2}_{\text{F}}}.\end{aligned} \tag{725}$$

We have a factor two for the complex scalar field since we have seen that a complex scalar field is equivalent to two real scalar fields and a factor -2 for the Marojana spinor as shown before. In general, the quantity $\langle\rho\rangle$ is not zero because $m_{\text{B}} \neq m_{\text{F}}$. But if we now assume that

$$m_{\text{B}} = m_{\text{F}}, \tag{726}$$

then the zero-point energy density exactly cancels out and we have solved the cosmological constant problem. The above model is in fact nothing but the simplest super-symmetric model, the so-called Wess-Zumino model [70, 71, 72, 73, 19, 74].

The Vacuum Energy in Super-Symmetry

Having motivated the idea of super-symmetry, we now study in more detail its implications. In particular, we would like to check that the type of cancellation studied before is generic in super-symmetry. In order to simplify the discussion, we start with considering the Lagrangian (724) with $m_{\text{B}} = m_{\text{F}} = 0$. We will now use the standard super-symmetric notation with the dotted two-components Weyl spinors [19, 74]. In this formalism, the Majorana spinor can be written as

$$\Psi_{\text{M}} = \begin{pmatrix}\Psi_{\alpha}\\ \overline{\Psi}^{\dot{\alpha}}\end{pmatrix}. \tag{727}$$

Then, using that the Dirac matrices can be expressed as

$$\gamma^\mu = \begin{pmatrix} 0 & (\sigma^\mu)_{\alpha\dot{\alpha}} \\ (\overline{\sigma}^\mu)^{\dot{\alpha}\alpha} & 0 \end{pmatrix}, \tag{728}$$

we find that the Lagrangian (721) can be re-written as

$$\mathcal{L}_{\text{Majorana}} = -\frac{i}{2}\overline{\Psi}_{\dot{\alpha}} (\overline{\sigma}^\mu)^{\dot{\alpha}\alpha} \partial_\mu \Psi_\alpha - \frac{i}{2}\Psi^\alpha (\sigma^\mu)_{\alpha\dot{\alpha}} \partial_\mu \overline{\Psi}^{\dot{\alpha}}, \tag{729}$$

where we used that (by definition) $\overline{\Psi}_{\dot{\alpha}} = (\Psi_\alpha)^*$ and $\Psi^\alpha = (\overline{\Psi}^{\dot{\alpha}})^*$. The next step consists in using the relation $\Psi^\alpha (\sigma^\mu)_{\alpha\dot{\alpha}} \partial_\mu \overline{\Psi}^{\dot{\alpha}} = -\partial_\mu \overline{\Psi}_{\dot{\alpha}} (\overline{\sigma}^\mu)^{\dot{\alpha}\alpha} \Psi_\alpha$ (the spinor components are Grassmann variables and, therefore, anti-commute, see below) and, then, to transform the resulting expression by integration by part. In this way, one shows that the Lagrangian (729) is in fact twice the first term. As a consequence, the Wess-Zumino model is described by

$$\mathcal{L}_{\text{W-Z}} = -\eta^{\mu\nu}\partial_\mu \Phi^\dagger \partial_\nu \Phi - i\overline{\Psi}_{\dot{\alpha}} (\overline{\sigma}^\mu)^{\dot{\alpha}\alpha} \partial_\mu \Psi_\alpha. \tag{730}$$

Let us now consider a super-symmetric transformation. In order to understand what it really means, let us use the analogy with a gauge transformation [19, 74]. For definiteness, we consider a SU(2) transformation. Let v be a SU(2) doublet of spinor fields. After an infinitesimal transformation, this doublet v becomes a new doublet v' such that

$$v' = \mathrm{e}^{i\epsilon^j \sigma_j/2} v \simeq \left(\mathbb{I}_2 + i\epsilon^j \frac{\sigma_j}{2}\right) v, \tag{731}$$

or

$$\delta v = i\epsilon^j \frac{\sigma_j}{2} v, \tag{732}$$

where σ_j are the Pauli matrices, the generators of the group. The quantity ϵ^j is a vector (or a collection of three parameters) specifying the transformation. In super-symmetry, the transformation is characterized by a Weyl spinor ξ^α which, therefore, plays the role of the quantity ϵ^j. A super-symmetric transformation transforms a boson into a fermion and vice-versa. As a consequence, one can write

$$\delta\Phi = \sqrt{2}\xi^\alpha \Psi_\alpha, \tag{733}$$

$$\delta\Psi_\alpha = -i\sqrt{2} (\sigma^\mu)_{\alpha\dot{\beta}} \overline{\xi}^{\dot{\beta}} \partial_\mu \Phi, \tag{734}$$

where the factors i or $\sqrt{2}$ are introduced for future convenience. Before showing that the Wess-Zumino Lagrangian is indeed invariant under a super-symmetric transformation, one needs to introduce a last result. We would like the Lagrangian to be invariant without using the equation of motion (in other words, we would like the Lagrangian to be invariant "off-shell"). In this case, one needs to add a term such that the new Lagrangian reads

$$\mathcal{L}_{\text{W-Z}} = -\eta^{\mu\nu}\partial_\mu \Phi^\dagger \partial_\nu \Phi - i\overline{\Psi}_{\dot{\alpha}} (\overline{\sigma}^\mu)^{\dot{\alpha}\alpha} \partial_\mu \Psi_\alpha - F^\dagger F, \tag{735}$$

where F is a complex scalar field. It is easy to see that this term is harmless since the corresponding equation of motion is just $F = 0$. But this term is necessary if one wants to match the bosonic and fermionic degrees of freedom. A Weyl spinor has two-complex components and we now have two complex scalar fields. Obviously, we also need to modify our super-symmetric transformation and they now take the form

$$\delta\Phi = \sqrt{2}\xi^\alpha \Psi_\alpha, \tag{736}$$

$$\delta\Psi_\alpha = \sqrt{2}\xi_\alpha F - i\sqrt{2} (\sigma^\mu)_{\alpha\dot{\beta}} \overline{\xi}^{\dot{\beta}} \partial_\mu \Phi, \tag{737}$$

$$\delta F = i\sqrt{2} (\partial_\mu \Psi^\alpha) (\sigma^\mu)_{\alpha\dot{\beta}} \overline{\xi}^{\dot{\beta}}. \tag{738}$$

Our goal is now to show that the Lagrangian (735) is indeed invariant under the three transformations (736), (737) and (738).

In fact, the key to show that the Lagrangian is invariant is to be able to evaluate the above transformations for the complex conjugate quantities. We have

$$\begin{aligned}\delta\Phi^\dagger &= \sqrt{2}\,(\xi^\alpha\Psi_\alpha)^\dagger = \sqrt{2}\,(\Psi_\alpha)^\dagger\,(\xi^\alpha)^\dagger \\ &= \sqrt{2}\,(\Psi_\alpha)^*\,(\xi^\alpha)^* = \sqrt{2}\,\overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\alpha} \\ &= \sqrt{2}\,\overline{\xi}_{\dot\alpha}\overline{\Psi}^{\dot\alpha} = -\sqrt{2}\,\overline{\xi}^{\dot\alpha}\overline{\Psi}_{\dot\alpha}. \end{aligned} \tag{739}$$

We cannot review here the complete dotted spinors formalism in detail, see Ref. [74], but in order to make the calculations reasonably self-consistent, it is nevertheless interesting to recall a few things. The first point to discuss is the definition of the dagger symbol for Grassmann variables. In fact, a very clear discussion can be found in p. 35 of Ref. [74] and there is no need here to entirely repeat it. In brief, one needs to remember that we deal with quantum fields. Usually, the dagger symbols means complex conjugation and transposition. For a scalar field, it simply amounts to take the complex conjugate of the mode function and put (or remove) a dagger to the creation and annihilation operators. For the spinor component Ψ_α, this is the same (here it is important to remember that one discusses one component only and not the spinor viewed as a column and, therefore, we "cannot" take the transpose of the matrix -there is no matrix- !) and one defines $\Psi^\dagger_{\dot\alpha}$ as the complex conjugate of the corresponding spinor component times the creation and annihilation operators with or without the dagger symbol. However, the question arises as how to evaluate the Hermitian conjugate of a product of Grassmann variables. Here, Ref. [74] shows that the most convenient way is to define $(\xi^\alpha\Psi_\alpha)^\dagger = \Psi^\dagger_\alpha\xi^{\alpha\dagger}$, that is to say something similar to what we are used to in the case of two matrices even if, again, we do not deal with matrices here but with components of Weyl spinors. This definition justifies the first step in the previous equation.

Then, it is also interesting to discuss how the two last equations are obtained. Let us write $\overline{\Psi}_{\dot 1} = a$, $\overline{\Psi}_{\dot 2} = b$ and $\overline{\xi}^{\dot 1} = c$, $\overline{\xi}^{\dot 2} = d$, where a, b, c and d are (complex) Grassman variables. As a consequence, one has $\overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\alpha} = ac + bd$. On the other hand, $\overline{\xi}_{\dot\alpha} \equiv \epsilon_{\dot\alpha\dot\beta}\overline{\xi}^{\dot\beta}$, where

$$\epsilon_{\dot\alpha\dot\beta} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \tag{740}$$

from which we deduce that $\overline{\xi}_{\dot 1} = d$ and $\overline{\xi}_{\dot 2} = -c$. In the same manner, one has $\overline{\Psi}^{\dot\alpha} = \epsilon^{\dot\alpha\dot\beta}\overline{\Psi}_{\dot\beta}$ with

$$\epsilon^{\dot\alpha\dot\beta} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \tag{741}$$

from which one obtains $\overline{\psi}^{\dot 1} = -b$ and $\overline{\psi}^{\dot 2} = a$. Using these results, one has $\overline{\xi}_{\dot\alpha}\overline{\Psi}^{\dot\alpha} = -db - ca = ac + bd = \overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\alpha}$, which is the wanted result. But, using again the expressions of the components obtained above, one also notices that $\overline{\xi}_{\dot\alpha}\overline{\Psi}^{\dot\alpha} = -\overline{\xi}^{\dot\alpha}\overline{\Psi}_{\dot\alpha}$ which is the last result used to establish the expression (739) of $\delta\Phi^\dagger$. In a more compact notation, one has

$$\begin{aligned}\overline{\xi}_{\dot\alpha}\overline{\Psi}^{\dot\alpha} &= \epsilon_{\dot\alpha\dot\beta}\overline{\xi}^{\dot\beta}\overline{\Psi}^{\dot\alpha} = \overline{\xi}^{\dot\beta}\epsilon_{\dot\alpha\dot\beta}\overline{\Psi}^{\dot\alpha} = -\overline{\xi}^{\dot\beta}\epsilon_{\dot\beta\dot\alpha}\overline{\Psi}^{\dot\alpha} \\ &= -\overline{\xi}^{\dot\beta}\overline{\Psi}_{\dot\beta}, \end{aligned} \tag{742}$$

the key point being the fact that the matrix $\epsilon_{\dot\alpha\dot\beta}$ is antisymmetric.

We now need the transformation of $(\delta\Psi_\alpha)^* = \delta\overline{\Psi}_{\dot\alpha}$. one has

$$\delta\overline{\Psi}_{\dot\alpha} = \sqrt{2}\,\overline{\xi}_{\dot\alpha}F^\dagger + i\sqrt{2}\left[(\sigma^\mu)_{\alpha\dot\beta}\right]^*\xi^\beta\partial_\mu\phi^\dagger, \tag{743}$$

$$= \sqrt{2}\,\overline{\xi}_{\dot\alpha}F^\dagger + i\sqrt{2}\,(\sigma^\mu)_{\beta\dot\alpha}\,\xi^\beta\partial_\mu\Phi^\dagger. \tag{744}$$

Finally, following the same lines, the transformation of $\delta F^\dagger$ can be expressed as

$$\begin{aligned}\delta F^\dagger &= -i\sqrt{2}(\overline{\xi}^{\dot\beta})^\dagger\left(\partial_\mu\Psi^\alpha\right)^\dagger\left[\left(\sigma^\mu\right)_{\alpha\dot\beta}\right]^* &(745)\\ &= -i\sqrt{2}\xi^\beta\left(\partial_\mu\overline{\Psi}^{\dot\alpha}\right)\left(\sigma^\mu\right)_{\beta\dot\alpha}. &(746)\end{aligned}$$

We are now in a position where one can compute the variation of the super-symmetric Lagrangian. Collecting the above results, one obtains

$$\begin{aligned}\delta\mathcal{L}_{\rm w-z} &= -\eta^{\mu\nu}\partial_\mu\delta\Phi^\dagger\partial_\nu\Phi-\eta^{\mu\nu}\partial_\mu\Phi^\dagger\partial_\nu\delta\Phi-i\delta\overline{\Psi}_{\dot\alpha}\left(\overline{\sigma}^\mu\right)^{\dot\alpha\alpha}\partial_\mu\Psi_\alpha-i\overline{\Psi}_{\dot\alpha}\left(\overline{\sigma}^\mu\right)^{\dot\alpha\alpha}\partial_\mu\delta\Psi_\alpha-\delta F^\dagger F-F^\dagger\delta F &(747)\\ &= -i\sqrt{2}F^\dagger\overline{\xi}_{\dot\alpha}\left(\overline{\sigma}^\mu\right)^{\dot\alpha\alpha}\partial_\mu\Psi_\alpha-i\sqrt{2}F^\dagger\left(\partial_\mu\Psi^\alpha\right)\left(\sigma^\mu\right)_{\dot\alpha\beta}\overline{\xi}^{\dot\beta}-i\sqrt{2}\,\overline{\Psi}_{\dot\alpha}\left(\overline{\sigma}^\mu\right)^{\dot\alpha\alpha}\xi_\alpha\partial_\mu F\\ &\quad+i\sqrt{2}\xi^\beta\left(\sigma^\mu\right)_{\beta\dot\alpha}\left(\partial_\mu\overline{\Psi}^{\dot\alpha}\right)F+\sqrt{2}\eta^{\mu\nu}\overline{\xi}^{\dot\alpha}\partial_\mu\overline{\Psi}_{\dot\alpha}\partial_\nu\Phi-\sqrt{2}\left(\overline{\sigma}^\mu\right)^{\dot\alpha\alpha}\left(\sigma^\nu\right)_{\alpha\dot\beta}\overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\beta}\partial_\mu\partial_\nu\Phi-\sqrt{2}\eta^{\mu\nu}\xi^\alpha\partial_\nu\Psi_\alpha\partial_\mu\Phi^\dagger\\ &\quad+\sqrt{2}\left(\sigma^\nu\right)_{\beta\dot\alpha}\left(\overline{\sigma}^\mu\right)^{\dot\alpha\alpha}\xi^\beta\partial_\mu\Psi_\alpha\partial_\nu\Phi^\dagger. &(748)\end{aligned}$$

Each term in this expression needs to be studied in detail. The first term is also equal to $i\sqrt{2}F^\dagger\partial_\mu\Psi^\alpha\left(\sigma^\mu\right)_{\alpha\dot\alpha}\overline{\xi}^{\dot\alpha}$ and, therefore, exactly cancels the second one. The third one is, after integration by parts, $i\sqrt{2}\left(\partial_\mu\overline{\Psi}_{\dot\alpha}\right)\left(\overline{\sigma}\right)^{\dot\alpha\alpha}\xi_\alpha F$, which is also equal to $-i\sqrt{2}\xi^\alpha\left(\sigma^\mu\right)_{\alpha\dot\alpha}\left(\partial_\mu\overline{\Psi}^{\dot\alpha}\right)F$. This cancels exactly the fourth term. As a consequence, all the term involving the field F give a total derivative contribution only. It remains the four terms involving the scalar field Φ and $\Phi^\dagger$. We first focus on the terms involving Φ only. For this purpose, we use the following relation [19, 74]

$$\left(\overline{\sigma}^\mu\right)^{\dot\alpha\alpha}\left(\sigma^\nu\right)_{\alpha\dot\beta}=\eta^{\mu\nu}\delta^{\dot\alpha}{}_{\dot\beta}+2\left(\overline{\sigma}^{\mu\nu}\right)^{\dot\alpha}{}_{\dot\beta}, \tag{749}$$

where

$$\overline{\sigma}^{\mu\nu}\equiv\frac{1}{4}\left(\overline{\sigma}^\mu\sigma^\nu-\overline{\sigma}^\nu\sigma^\mu\right)=-\overline{\sigma}^{\nu\mu}. \tag{750}$$

Therefore, the second term involving Φ [*i.e.* the sixth term in the above formula (748)] can be re-written as

$$\begin{aligned}&-\sqrt{2}\left(\overline{\sigma}^\mu\right)^{\dot\alpha\alpha}\left(\sigma^\nu\right)_{\alpha\dot\beta}\overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\beta}\partial_\mu\partial_\nu\Phi\\ =\;&-\sqrt{2}\left[\eta^{\mu\nu}\delta^{\dot\alpha}{}_{\dot\beta}+2\left(\overline{\sigma}^{\mu\nu}\right)^{\dot\alpha}{}_{\dot\beta}\right]\overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\beta}\partial_\mu\partial_\nu\Phi\\ =\;&-\sqrt{2}\eta^{\mu\nu}\overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\alpha}\partial_\mu\partial_\nu\Phi, &(751)\end{aligned}$$

the second term in this equation leading to a vanishing contribution since $\overline{\sigma}^{\mu\nu}$ is anti-symmetric. The next manipulation is to integrate by part. This gives

$$\begin{aligned}&-\sqrt{2}\left(\overline{\sigma}^\mu\right)^{\dot\alpha\alpha}\left(\sigma^\nu\right)_{\alpha\dot\beta}\overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\beta}\partial_\mu\partial_\nu\Phi\\ =\;&-\sqrt{2}\eta^{\mu\nu}\overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\alpha}\partial_\mu\partial_\nu\Phi=\sqrt{2}\eta^{\mu\nu}\partial_\mu\overline{\Psi}_{\dot\alpha}\overline{\xi}^{\dot\alpha}\partial_\nu\Phi\\ =\;&\sqrt{2}\eta^{\mu\nu}\overline{\xi}_{\dot\alpha}\partial_\mu\overline{\Psi}^{\dot\alpha}\partial_\nu\Phi=-\sqrt{2}\eta^{\mu\nu}\overline{\xi}^{\dot\alpha}\partial_\mu\overline{\Psi}_{\dot\alpha}\partial_\nu\Phi.\end{aligned} \tag{752}$$

Therefore, this term exactly cancels the first term involving Φ [or the fifth term in the formula (748)]. Clearly, this also works for the two terms involving $\Phi^\dagger$. We have thus shown, without using the equation of motion, that the variation of the Wess-Zumino Lagrangian (735) is a total derivative. As a consequence, the Wess-Zumino model is indeed super-symmetric, that is to say invariant under the super-symmetric transformations (736), (737) and (738).

We have seen before that the constant spinor ξ^α was the equivalent of the vector ϵ^j in the case of the SU(2) transformation considered at the beginning of this section. But what is the equivalent of the generator $\sigma_j/2$ for a super-symmetric transformation? Moreover, we know that the generators obey the formula $[\sigma_i/2,\sigma_j/2]=i\epsilon_{ijk}\sigma_k/2$. What is the corresponding equation satisfied by the super-symmetric generators? We now turn to these questions.

Using again the analogy with the SU(2) transformation, we expect that an infinitesimal super-symmetric transformation to have the form

$$\delta_\xi \Phi \simeq i \left(\xi^\alpha Q_\alpha + \overline{\xi}_{\dot{\alpha}} \overline{Q}^{\dot{\alpha}} \right) \Phi. \tag{753}$$

Here Q_α is the super-symmetric generator, the equivalent of $\sigma_j/2$. Clearly, since $\xi^\alpha Q_\alpha$ must be a scalar, Q_α is a Weyl spinor as the notation indicates.

In order to find the super-symmetric algebra, we first compute the quantity $(\delta_\eta \delta_\xi - \delta_\xi \delta_\eta)\,\Phi$ using Eqs. (736), (737) and (738). It is straightforward to show that

$$\begin{aligned}
&(\delta_\eta \delta_\xi - \delta_\xi \delta_\eta)\,\Phi = 2\xi^\alpha \eta_\alpha F - 2i\xi^\alpha \left(\sigma^\mu\right)_{\alpha\dot{\beta}} \overline{\eta}^{\dot{\beta}} \partial_\mu \Phi \\
&-2\eta^\alpha \xi_\alpha F + 2i\eta^\alpha \left(\sigma^\mu\right)_{\alpha\dot{\beta}} \overline{\xi}^{\dot{\beta}} \partial_\mu \Phi \qquad (754) \\
&= -2i\xi^\alpha \left(\sigma^\mu\right)_{\alpha\dot{\beta}} \overline{\eta}^{\dot{\beta}} \partial_\mu \Phi + 2i\eta^\alpha \left(\sigma^\mu\right)_{\alpha\dot{\beta}} \overline{\xi}^{\dot{\beta}} \partial_\mu \Phi, \qquad (755)
\end{aligned}$$

since $\xi^\alpha \eta_\alpha = \eta^\alpha \xi_\alpha$. But, of course, we can evaluate the same commutator using the expression (753) for the infinitesimal super-symmetric transformation. This leads to

$$\begin{aligned}
&(\delta_\eta \delta_\xi - \delta_\xi \delta_\eta)\,\Phi = -\left(\eta^\alpha Q_\alpha + \overline{\eta}_{\dot{\alpha}} \overline{Q}^{\dot{\alpha}} \right) \\
&\times \left(\xi^\beta Q_\beta + \overline{\xi}_{\dot{\beta}} \overline{Q}^{\dot{\beta}} \right) \Phi + \left(\xi^\alpha Q_\alpha + \overline{\xi}_{\dot{\alpha}} \overline{Q}^{\dot{\alpha}} \right) \\
&\times \left(\eta^\beta Q_\beta + \overline{\eta}_{\dot{\beta}} \overline{Q}^{\dot{\beta}} \right) \Phi. \qquad (756)
\end{aligned}$$

Then, expanding this expression (carefully taking into account the fact that the spinor components are Grassmann variables), we arrive at

$$\begin{aligned}
(\delta_\eta \delta_\xi - \delta_\xi \delta_\eta)\,\Phi \;&=\; \eta^\alpha \left(Q_\alpha Q_\beta + Q_\beta Q_\alpha \right) \xi^\beta \Phi \\
&+\; \overline{\eta}_{\dot{\alpha}} \left(\overline{Q}^{\dot{\alpha}} \overline{Q}^{\dot{\beta}} + \overline{Q}^{\dot{\beta}} \overline{Q}^{\dot{\alpha}} \right) \overline{\xi}_{\dot{\beta}} \Phi \\
&+\; \eta^\alpha \left(Q_\alpha \overline{Q}^{\dot{\beta}} + \overline{Q}^{\dot{\beta}} Q_\alpha \right) \overline{\xi}_{\dot{\beta}} \Phi \\
&-\; \xi^\alpha \left(Q_\alpha \overline{Q}^{\dot{\beta}} + \overline{Q}^{\dot{\beta}} Q_\alpha \right) \overline{\eta}_{\dot{\beta}} \Phi. \qquad (757)
\end{aligned}$$

One must now compare Eq. (755) with Eq. (757). First of all, we notice that, in Eq. (755), there is no term with two undotted or two dotted spinors ξ and η. This implies that

$$\left\{ Q_\alpha, Q_\beta \right\} = \left\{ Q^{\dot{\alpha}}, Q^{\dot{\beta}} \right\} = 0. \tag{758}$$

Then, a comparison of the first "cross-terms" leads to

$$\left\{ Q_\alpha, \overline{Q}_{\dot{\beta}} \right\} \Phi = -2i \left(\sigma^\mu\right)_{\alpha\dot{\beta}} \partial_\mu \Phi, \tag{759}$$

and a similar relation for the second cross-term. Remembering that $P_\mu = -i\partial_\mu$ (the minus sign is in fact just a convention; the problem with super-symmetry is that the literature contains many different conventions (A nice treatment of this question can be found in the first problem of Ref. [75], Appendix C), one arrives at

$$\left\{ Q_\alpha, \overline{Q}_{\dot{\beta}} \right\} = 2 \left(\sigma^\mu\right)_{\alpha\dot{\beta}} P_\mu. \tag{760}$$

This equation shows that two successive super-symmetric transformations are in fact equivalent to a space-time translation. As we will see, this has far-reaching consequences. However, for

the subject discussed here, the above formula has also very important implications. Indeed, working it out explicitly, one has

$$Q_1\overline{Q}_{\dot{1}} + \overline{Q}_{\dot{1}}Q_1 = 2P_3 + 2P_0, \tag{761}$$
$$Q_2\overline{Q}_{\dot{2}} + \overline{Q}_{\dot{2}}Q_2 = -2P_3 + 2P_0, \tag{762}$$

from which we deduce

$$4P_0 = Q_1\overline{Q}_{\dot{1}} + \overline{Q}_{\dot{1}}Q_1 + Q_2\overline{Q}_{\dot{2}} + \overline{Q}_{\dot{2}}Q_2. \tag{763}$$

Therefore, since the Hamiltonian is nothing but the time translation generator P_0, this implies that

$$\langle 0\,|H|\,0\rangle = \frac{1}{4}\left\langle 0\left|Q_1\overline{Q}_{\dot{1}} + \overline{Q}_{\dot{1}}Q_1 + Q_2\overline{Q}_{\dot{2}} + \overline{Q}_{\dot{2}}Q_2\right|0\right\rangle \geq 0. \tag{764}$$

We have learned two things: firstly, if the vacuum state is not super-symmetric, *i.e.* if super-symmetry is spontaneously broken (the underlying theory is super-symmetric but the solution or the state in which the system is placed is not), then the vacuum energy is necessarily positive. Secondly, another remarkable consequence of the above results is that, when the vacuum state is super-symmetric, that is to say when

$$Q_\alpha|0\rangle = 0, \tag{765}$$

one has $\langle 0\,|H|\,0\rangle = 0$, *i.e.* the vacuum energy is automatically zero. We have thus proven that the cancellation discussed at the beginning of this section is in fact not a coincidence. Moreover, we have identified under which conditions it is valid: it is always true for a super-symmetric system. This is the reason why super-symmetry has the potential to solve the cosmological constant problem. It gives a concrete example of a symmetry which forces the vacuum energy to vanish.

Unfortunately, we know that super-symmetry must be broken in the real world. This comes from the fact that each boson (fermion) of the standard model is not observed to have a super-symmetric partner of the same mass. This means that vacuum energy is now given by Eq. (725). Let us evaluate it with our "incorrect" method which consists in regularizing the divergent integrals with a cut-off M, see Eq. (371). We find

$$\begin{aligned}\langle\rho\rangle_{\text{SUSY}} &= \frac{M^4}{8\pi^2}\left(1 + \frac{m_{\text{B}}^2}{M^2} + \cdots\right) \\ &\quad -\frac{M^4}{8\pi^2}\left(1 + \frac{m_{\text{F}}^2}{M^2} + \cdots\right) \qquad (766)\\ &= \frac{M^2}{8\pi^2}\left(m_{\text{B}}^2 - m_{\text{F}}^2\right). \qquad (767)\end{aligned}$$

We see that, even if super-symmetry is broken, the most divergent part $\propto M^4$ of the energy density cancel out. If we now properly estimate the energy density by means of dimensional regularization (392), one obtains that

$$\langle\rho\rangle_{\text{SUSY}} = \frac{m_{\text{B}}^4}{32\pi^2}\ln\left(\frac{m_{\text{B}}^4}{\mu^2}\right) - \frac{m_{\text{F}}^4}{32\pi^2}\ln\left(\frac{m_{\text{F}}^4}{\mu^2}\right). \tag{768}$$

Therefore, roughly speaking, one can estimate that vacuum energy is now given by $\simeq M_{\text{SUSY}}^4$ where M_{SUSY} is the typical difference between the mass of the super-partners, which is also the super-symmetric breaking mass.

A last remark is in order. In this section we have considered super-symmetry in flat space-time while the cosmological constant problem is formulated in curved space-time. In order to be consistent, we should therefore treat super-symmetry in this last context. As is well-known, this leads to super-gravity [19, 75]. Regarding the vacuum energy question, super-gravity presents important differences compared to super-symmetry. In particular, one loses the result that vacuum energy is always positive. But, this also shows that discussing the zero-point energy density issue in curved space-time can bring new aspects to the problem. This is the reason why, in the next section, we address this question.

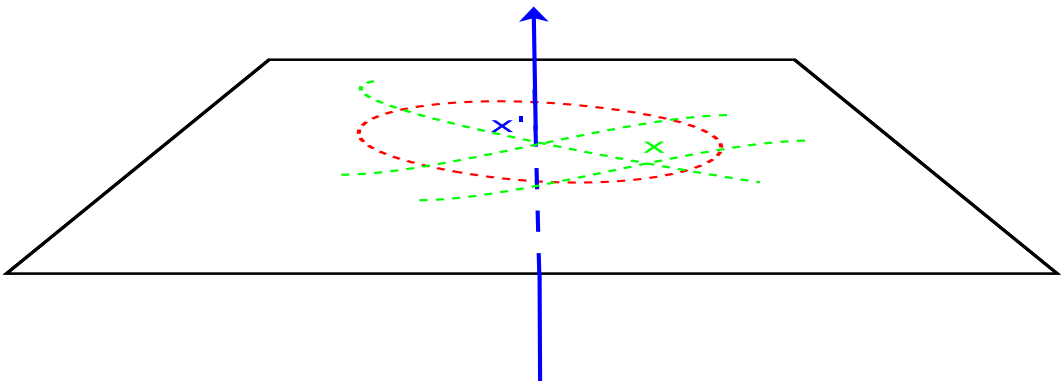


Figure 156: Sketch of the Riemann coordinates used in order to derive an approximate expression for the Green function, see Eq. (799). The plot aims at illustrating the fact that the Riemann coordinates are a local concept. Since it is sufficient to establish the Green function locally (and not in the entire curved manifold), one can always endow the neighborhood of a point x' (denoted here by the region surrounded by the closed dotted line) with special coordinates x^μ such that the calculation is simplified. It is important to notice that this does not restrict the generality of the obtained results.

24.8 The Vacuum Energy Density in Curved Space-time

In the previous sections, we have computed the vacuum energy density in flat space-time. This may seem inappropriate since we have argued that the problem occurs only in curved space-time. Here we show how to justify the previous approach. Intuitively, this is justified because we deal with ultra-violet divergences for which the large scale structure of the curved manifold should not play a too important role. In other words, in the ultra-violet regime, one only probes the local properties of space-time and, locally, one cannot distinguish a curved manifold from the Minkowski space-time. However, we need to put this intuitive reasoning on solid grounds. For this purpose, let us consider our toy model again where matter is simply represented by a scalar field. The only difference with the previous sections is that, now, this quantum field lives in a curved space-time. Therefore, in order to have meaningful Einstein equations, one must assume that the quantum average of the stress energy tensor sources the Einstein equations. In other words, we start from [53]

$$R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu} + \Lambda_{\rm B} g_{\mu\nu} = \kappa \langle T_{\mu\nu} \rangle \,, \tag{769}$$

Then, by analogy with Eq. (299), we define the effective action W to be

$$\langle T_{\mu\nu} \rangle = -\frac{2}{\sqrt{-g}} \frac{\delta W}{\delta g^{\mu\nu}}. \tag{770}$$

The effective action can be written in term of the sourceless generating functional $Z[0]$, namely

$$W = -i \ln Z[0], \tag{771}$$

where we recall that the explicit expression of $Z[0]$ is given by, see also Eq. (393),

$$Z[0] = \int \mathcal{D}\phi \, {\rm e}^{iS_{\rm matter}[\phi]}, \tag{772}$$

the quantity $S_{\rm matter}$ being the action of the scalar field. The above result can be proven in the following way. Varying $Z[0]$, one obtains

$$\delta Z[0] = \int \mathcal{D}\phi \, i\delta S_{\rm matter} \, {\rm e}^{iS_{\rm matter}[\phi]} \tag{773}$$

$$= \langle 0 \, | i\delta S_{\rm matter} | \, 0 \rangle \,. \tag{774}$$

As a consequence,

$$-\frac{2}{\sqrt{-g}}\frac{\delta W}{\delta g^{\mu\nu}} = -\frac{2}{\sqrt{-g}}\frac{-i}{Z[0]}\frac{\delta Z[0]}{\delta g^{\mu\nu}} \tag{775}$$

$$= \frac{1}{Z[0]}\left\langle 0\left|-\frac{2}{\sqrt{-g}}\frac{\delta S_{\text{matter}}}{\delta g^{\mu\nu}}\right|0\right\rangle \tag{776}$$

$$= \frac{1}{Z[0]}\langle 0\,|T_{\mu\nu}|\,0\rangle = \langle T_{\mu\nu}\rangle\,, \tag{777}$$

since the mean value is defined by $\langle\cdots\rangle \equiv \langle 0|\cdots|0\rangle/\langle 0|0\rangle$.

The next step is to calculate W explicitly in our case, *i.e.* for a scalar field. We now show that the effective action can be expressed in terms of the Green function. The Green function is defined by the following expression [53]

$$\left(-g^{\mu\nu}\nabla_\mu\nabla_\nu + m^2\right) G_{\text{F}}(x,y) = \frac{1}{\sqrt{-g}}\delta(x-y). \tag{778}$$

It is easy to show that $G_{\text{F}}(x,y) = iD_{\text{F}}(x-y)$, where the propagator has been defined in Eq. (397). Integrating by part the action of the scalar field $\Phi(x)$, the generating function can be written as

$$Z[J] = \int \mathcal{D}\Phi \exp\left[-\frac{i}{2}\int \mathrm{d}^d x\sqrt{-g}\Phi(x)\left(-g^{\mu\nu}\nabla_\mu\nabla_\nu + m^2\right)\Phi(x) + i\int \mathrm{d}^d x\sqrt{-g}J(x)\Phi(x)\right], \tag{779}$$

where we have considered the d-dimensional case for future convenience. This path integral is a Gaussian integral and, therefore, can be evaluated using the standard techniques. For $J = 0$ one has

$$Z[0] = (2\pi)^{\infty/2}\left(\det K\right)^{-1/2} \tag{780}$$

$$= (2\pi)^{\infty/2}\mathrm{e}^{\frac{1}{2}\mathrm{tr}\left(\ln K^{-1}\right)}, \tag{781}$$

where K is the following operator, appearing in Eq. (779),

$$K(x,y) \equiv i\sqrt{-g}\left(-g^{\mu\nu}\nabla_\mu\nabla_\nu + m^2\right)\delta^d(x-y). \tag{782}$$

But the inverse of the operator K is in fact the propagator $D_{\text{F}}(x,y)$. A pedagogical, but simplistic, demonstration of this fact is the following one. The generating functional can be written as

$$Z[0] = \int \Pi_x \mathrm{d}\Phi_i \mathrm{e}^{-\frac{1}{2}\sum\limits_{x,y}\Phi_x K_{xy}\Phi_y}, \tag{783}$$

where, in order to reproduce Eq. (782) (or, rather, to mimic this formula), the matrix K_{xy} is taken to be $K_{xy} = K\delta_{xy}$ and the "number K is defined" by $K \equiv i\sqrt{-g}\left(-g^{\mu\nu}\nabla_\mu\nabla_\nu + m^2\right)$. Then, the inverse of the matrix K must obey

$$\sum_z K_{xz}K^{-1}_{zy} = \delta_{xy}, \tag{784}$$

that is to say, using the definition of K_{xy},

$$KK^{-1}_{xy} = \delta_{xy}. \tag{785}$$

But this equation is nothing but Eq. (778). This shows that, as announced, $K^{-1}_{xy} = \left(D_{\text{F}}\right)_{xy}$. As a consequence, one can write

$$Z[0] = (2\pi)^{\infty/2}\mathrm{e}^{\frac{1}{2}\mathrm{tr}\left(\ln D_{\text{F}}\right)}, \tag{786}$$

or,

$$W = -\frac{i}{2}\mathrm{tr}\left(\ln D_{\mathrm{F}}\right) - i\ln\left[(2\pi)^{\infty/2}\right]. \tag{787}$$

We have reduced the evaluation of the effective action to the evaluation of the Green function (or the propagator) in curved space-time. We now turn to this question.

For this purpose, we introduce the Riemann normal coordinates x^μ with origin at the point x', see Fig. 156 and Refs. [76, 77, 78]. As it will become gradually clear, the motivation for such a choice is as follows. Since we want to see how the Einstein equations are modified, one only needs to evaluate the Green function locally. In this case, one can introduce coordinates that drastically simplify the problem, *i.e.* the calculation. This is exactly the role played by the Riemann normal coordinates. In these coordinates, the metric can be written as [76, 77]

$$g_{\mu\nu} = \eta_{\mu\nu} - \frac{1}{3}R_{\mu\alpha\nu\beta}x^\alpha x^\beta - \frac{1}{6}R_{\mu\alpha\nu\beta;\gamma}x^\alpha x^\beta x^\gamma + \left(-\frac{1}{20}R_{\mu\alpha\nu\beta;\gamma\delta} + \frac{2}{45}R_{\alpha\mu\beta\lambda}R^\lambda{}_{\gamma\nu\delta}\right)x^\alpha x^\beta x^\gamma x^\delta + \cdots \tag{788}$$

Then, we insert this metric into the Green function equation (778) and retain terms with coefficients involving four derivatives of the metric or fewer. A lengthy calculation leads to

$$\begin{aligned}
&\eta^{\mu\nu}\partial_\mu\partial_\nu\overline{G} - \left(m^2 - \frac{1}{6}\right)\overline{G} - \frac{1}{3}R_\alpha{}^\nu\partial_\nu\overline{G} + \frac{1}{3}R^\mu{}_\alpha{}^\nu{}_\beta x^\alpha x^\beta\partial_\mu\partial_\nu\overline{G} + \frac{1}{6}R_{;\alpha}x^\alpha\overline{G} + \left(-\frac{1}{3}R_\alpha{}^\nu{}_{;\beta} + \frac{1}{6}R_{\alpha\beta}{}^{;\nu}\right)x^\alpha x^\beta\partial_\nu\overline{G} \\
+ &\frac{1}{6}R^\mu{}_\alpha{}^\nu{}_{\beta;\gamma}x^\alpha x^\beta x^\gamma\partial_\mu\partial_\nu\overline{G} + \frac{1}{12}R_{;\alpha\beta}x^\alpha x^\beta\overline{G} + \left(-\frac{1}{30}R_\alpha{}^\lambda R_{\lambda\beta} + \frac{1}{60}R^\kappa{}_\alpha{}^\lambda{}_\beta R_{\kappa\lambda} + \frac{1}{60}R^{\lambda\mu\kappa}{}_\alpha R_{\lambda\mu\kappa\beta} - \frac{1}{120}R_{;\alpha\beta}\right. \\
+ &\left.\frac{1}{40}\eta^{\mu\nu}\partial_\mu\partial_\nu R_{\alpha\beta}\right)x^\alpha x^\beta\overline{G} + \left(-\frac{3}{20}R^\nu{}_{\alpha;\beta\gamma} + \frac{1}{10}R_{\alpha\beta}{}^{;\nu}{}_\gamma - \frac{1}{60}R^\kappa{}_\alpha{}^\nu{}_\beta R_{\kappa\lambda} + \frac{1}{15}R^\kappa{}_{\alpha\lambda\beta}R_\kappa{}^\nu{}_\gamma{}^\lambda\right)x^\alpha x^\beta x^\gamma\partial_\nu\overline{G} \\
+ &\left(\frac{1}{20}R^\mu{}_\alpha{}^\nu{}_{\beta;\gamma\delta} + \frac{1}{15}R^\mu{}_{\alpha\lambda\beta}R^\lambda{}_\gamma{}^\nu{}_\delta\right)x^\alpha x^\beta x^\gamma x^\delta\partial_\mu\partial_\nu\overline{G} = -\delta^d(x),
\end{aligned} \tag{789}$$

where all the indices are raised or lowered by the Minkowski metric and where we have defined a rescaled Green function according to $G_{\mathrm{F}}(x,y) \equiv g^{-1/4}\overline{G}(x,y)$. The next step is to Fourier transform the above equation. In this way the local expansion which, in real space, looks like an expansion in the coordinates x^μ is transformed, in momentum space, as an expansion in terms of the inverse of k^μ, as appropriate for a local expansion. More precisely, defining

$$\overline{G}(x,x') = \frac{1}{(2\pi)^d}\int \mathrm{d}^d k\, \mathrm{e}^{i\eta^{\alpha\beta}k_\alpha x_\beta}\overline{G}(k), \tag{790}$$

we can expand the Green function as $\overline{G}(k) = \overline{G}_0(k) + \overline{G}_1(k) + \cdots$ where $\overline{G}_i(k)$ is the quantity appearing in front of a coefficient involving the i-th derivatives of the metric tensor [76, 77]. Let us notice that the Green function is a function of x' in the sense that x^μ represents the coordinates of a point x defined such x' is at the origin. Another remark is that we define the Fourier transform of the Green function with an overall factor $(2\pi)^{-d}$ such that the coefficient of the Dirac function in the right hand side of Eq. (789) is minus one and does not contain factors of π, thanks to the formula $\delta^d(x) = 1/(2\pi)^d\int \mathrm{d}^d k\, \mathrm{e}^{ikx}$.

Introducing this expansion into Eq. (789) and consistently identifying the terms of a given order leads to the desired result. This iterative procedure gives

$$\begin{aligned}
\overline{G}(k) &= \frac{1}{k^2+m^2} + \frac{R}{6}\frac{1}{(k^2+m^2)^2} + \frac{i}{6}R_{;\alpha}\frac{1}{k^2+m^2}\frac{\partial}{\partial k_\alpha}\left[\left(k^2+m^2\right)^{-1}\right] + \frac{R^2}{36}\frac{1}{(k^2+m^2)^3} \\
&\quad + a_{\alpha\beta}\frac{1}{k^2+m^2}\frac{\partial^2}{\partial k_\alpha\partial k_\beta}\left[\left(k^2+m^2\right)^{-1}\right] + \cdots, \qquad (791) \\
&= \frac{1}{k^2+m^2} + \frac{R}{6}\frac{1}{(k^2+m^2)^2} + \frac{i}{12}R_{;\alpha}\frac{\partial}{\partial k_\alpha}\left[\left(k^2+m^2\right)^{-2}\right] + \frac{1}{3}a_{\alpha\beta}\partial^\alpha\partial^\beta\left[\left(k^2+m^2\right)^{-2}\right] \\
&\quad + \left(\frac{R^2}{36} - \frac{2}{3}a^\lambda{}_\lambda\right)\frac{1}{(k^2+m^2)^3} + \cdots, \qquad (792)
\end{aligned}$$

where the coefficient $a_{\alpha\beta}$ can be expressed as

$$a_{\alpha\beta} = -\frac{3}{40}R_{;\alpha\beta} - \frac{1}{40}\eta^{\mu\nu}\partial_\mu\partial_\nu R_{\alpha\beta} + \frac{1}{30}R_\alpha{}^\lambda R_{\lambda\beta} - \frac{1}{60}R^\kappa{}_\alpha{}^\lambda{}_\beta R_{\kappa\lambda} + \frac{1}{60}R^{\lambda\mu\kappa}{}_\alpha R_{\lambda\mu\kappa\beta}. \tag{793}$$

Inserting this last expression into Eq. (790) leads to

$$\overline{G}(x,x') = \frac{1}{(2\pi)^d}\int \mathrm{d}^n k\, \mathrm{e}^{i\eta^{\alpha\beta}k_\alpha x_\beta}\left[1 + f_1(x,x')\left(-\frac{\partial}{\partial m^2}\right) + f_2(x,x')\left(-\frac{\partial}{\partial m^2}\right)^2 + \cdots\right]\frac{1}{k^2+m^2}, \tag{794}$$

with

$$f_1(x,x') = \frac{R}{6} + \frac{1}{12}R_{;\alpha}x^\alpha - \frac{1}{3}a_{\alpha\beta}x^{\alpha\beta}, \tag{795}$$

$$f_2(x,x') = \frac{R^2}{72} - \frac{1}{3}a^\lambda{}_\lambda \tag{796}$$

The final step of the calculation consists in expressing the Green function in the so-called proper time formalism [76, 77]. Firstly, we replace the quantity $(k^2+m^2)^{-1}$ with

$$\frac{1}{k^2+m^2} = \int_0^\infty i\mathrm{d}s \mathrm{e}^{-is\left(k^2+m^2\right)}, \tag{797}$$

and, secondly, we make use of the result

$$\begin{aligned}&\frac{1}{(2\pi)^d}\int \mathrm{d}^n k\, \mathrm{e}^{i\eta^{\alpha\beta}k_\alpha x_\beta - is\left(k^2+m^2\right)} \\ &= \frac{i}{(4\pi)^{d/2}}\,(is)^{-d/2}\,\mathrm{e}^{-ism^2+i\sigma/(2s)},\end{aligned} \tag{798}$$

where $\sigma = \eta^{\alpha\beta}x_\alpha x_\beta/2$. This leads to our final expression for the Green function, namely

$$\begin{aligned}\overline{G}(x,x') &= \frac{i}{(4\pi)^{d/2}}\int_0^\infty \frac{i\mathrm{d}s}{(is)^{d/2}}\mathrm{e}^{-im^2s-\sigma/(2is)} \\ &\quad\times\left[1+isf_1+(is)^2 f_2+\cdots\right].\end{aligned} \tag{799}$$

Of course, one could always push the expansion to higher orders in inverse of the momenta in order to obtain higher orders in s. But, in the present context, this will not be necessary.

We now have all the tools to evaluate the effective action (787). We now seek an explicit expression for the quantity $\ln(D_{\mathrm{F}})$. As already mentioned, D_{F} can be viewed as the inverse of the "continuous matrix" K which means that, formally, one can write

$$D_{\mathrm{F}} = \int_0^\infty \mathrm{e}^{-iKs} i\mathrm{d}s, \tag{800}$$

where we have used again Eq. (797). This expression allows us to express the matrix element of e^{-iKs}. Indeed, given that $D_{\mathrm{F}} = -ig^{-1/4}\overline{G}$, a direct comparison of Eq. (799) with the previous relation leads to

$$\begin{aligned}\left(\mathrm{e}^{-iKs}\right)_{xx'} &= \frac{g^{-1/4}}{(4\pi)^{d/2}}\frac{\mathrm{e}^{-im^2s-\sigma/(2is)}}{(is)^{d/2}} \\ &\times \left[1+isf_1+(is)^2 f_2+\cdots\right].\end{aligned} \tag{801}$$

Now, let us consider the following integral

$$\begin{aligned}\int_\lambda^\infty \mathrm{e}^{-iKs}\frac{i\mathrm{d}s}{is} &= -\int_{i\lambda K}^\infty \frac{\mathrm{e}^{-t}}{t}\mathrm{d}t \\ &= -\gamma - \ln(i\lambda K) - \sum_{k=1}^\infty \frac{(-1)^{k+1}(i\lambda K)^k}{kk!}.\end{aligned} \tag{802}$$

In the limit $\lambda \to 0$, up to an infinite constant that can be ignored, only the logarithm survives. Therefore, we can define the logarithm of the operator K as

$$-\ln K = \ln D_{\rm F} = \int_0^\infty {\rm e}^{-iKs} \frac{i{\rm d}s}{is}. \tag{803}$$

Then, using Eq. (801), one obtains

$$\begin{aligned} \left(\ln D_{\rm F}\right)_{xx'} &= \frac{g^{-1/4}(x)}{(4\pi)^{d/2}} \int_0^\infty \frac{{\rm e}^{-im^2 s - \sigma(x,x')/(2is)}}{(is)^{d/2}} \\ &\times \left[1 + is f_1(x,x') \right. \\ &\left. + (is)^2 f_2(x,x') + \cdots \right] \frac{i{\rm d}s}{is}. \end{aligned} \tag{804}$$

As a consequence, we have now an explicit expression for the effective action, namely

$$W = -\frac{i}{2} \int {\rm d}^d x \sqrt{-g} \lim_{x' \to x} \left(\ln D_{\rm F}\right)_{xx'}, \tag{805}$$

or

$$\begin{aligned} W &= \int {\rm d}^d x \sqrt{-g} \left\{ -\frac{i}{2} \frac{1}{(4\pi)^{d/2}} \int_0^\infty \frac{{\rm e}^{-im^2 s}}{(is)^{d/2}} \right. \\ &\left. \times \left[1 + is f_1 + (is)^2 f_2 + \cdots \right] \frac{i{\rm d}s}{is} \right\}. \end{aligned} \tag{806}$$

In the coincident limit $x' \to x$, the determinant of the metric tensor has been taken to one since it is calculated in x', that is to say for $x = 0$. For the same reason, we also have considered that $\sigma = 0$. The above expression can be evaluated explicitly in terms of Euler function and one obtains

$$\begin{aligned} W &= \int {\rm d}^d x \sqrt{-g} \left\{ -\frac{i}{2} \frac{1}{(4\pi)^{d/2}} \left(\frac{m}{\mu}\right)^{d-4} \right. \\ &\times \left[m^4 \Gamma\left(-\frac{d}{2}\right) + m^2 f_1 \Gamma\left(1 - \frac{d}{2}\right) \right. \\ &\left. \left. + f_2 \Gamma\left(2 - \frac{d}{2}\right) + \cdots \right] \right\}, \end{aligned} \tag{807}$$

where we have introduced the scale μ in order to maintain the correct dimension of the effective action. The above expression can be analyzed in a dimensional regularization scheme. In this case, one is led to the following expression

$$\begin{aligned} iW &= \int {\rm d}^d x \sqrt{-g} \left\{ \left[\frac{2}{\epsilon} - \gamma - \ln\left(\frac{m^2}{4\pi\mu^2}\right) \right] \right. \\ &\left. \times \left(\frac{m^4}{64\pi^2} - \frac{m^2 f_1}{32\pi^2} + \frac{f_2}{32\pi^2} \right) + \cdots \right\}, \end{aligned} \tag{808}$$

which is our final result. The i factor can be absorbed into a constant shift so we do not need to worry about it. If we compare the effective action with the original Lagrangian (297), we see that the first divergent term in the above expression can be absorbed into a redefinition of the cosmological constant (the second term can be viewed as a redefinition of the Newton constant and the third term leads to the appearance of new terms in the action, see Ref. [53]). Explicitly, one has

$$\Lambda_{\text{eff}} = \Lambda_{\text{B}} + \kappa \frac{m^4}{64\pi^2} \left[\frac{2}{\epsilon} - \gamma - \ln\left(\frac{m^2}{4\pi\mu^2} \right) \right], \tag{809}$$

that is to say exactly the same expression as before (except an unimportant factor 3/2), see for instance Eq. (391). As a consequence in a $\overline{\text{MS}}$ scheme [16], we can remove the divergence and obtain exactly the same expression derived before, see Eq. (392), namely

$$\Lambda_{\text{eff}} = \Lambda_{\text{B}} + \kappa \frac{m^4}{64\pi^2} \ln\left(\frac{m^2}{\mu^2} \right). \tag{810}$$

The calculations of this section justify our previous approach in flat space-time. Indeed, we have just proven that all the results derived before in flat space-time are in fact valid in the more rigorous approach where the curvature of space-time is properly taken into account. This confirms that the vacuum energy does not scale as the cut-off to the power four, see Eqs. (371) and (374) but is in fact proportional to the mass of the particle to the power four times a logarithmic factor depending on the renormalization scale. In some sense, the calculation in flat space-time can be considered as a computational trick: it is sufficient to calculate the vacuum energy in this simple framework since, from the previous considerations, we know that this is also the result that consistently emerges from an approach where the curvature of space-time is properly included. Of course, physically, the reason for this success is not so surprising and was already mentioned before. Since we deal with the ultraviolet behavior of the theory, a local analysis should necessarily lead to a correct and consistent result.

It is also worth mentioning that Eqs. (392) and (810) recently attracted lot of attention, see Refs. [47, 51]. In particular, as we discussed at length in Sec. 24.4.1 and as was emphasized in these articles, these equations are the consequence of the fact that the regularization scheme used to tame the divergence of the vacuum energy must respect Lorentz invariance. In fact, these equations have been known for a long time, see in particular Eq. (6.50) of the standard textbook [53]. Therefore, the fact that the cosmological constant is proportional to the mass of the particle to the power four, and not to the cut-off to the power four as usually claimed, see again Eqs. (371) and (374), is in fact not a new result. Of course, it modifies a lot our estimate of vacuum energy. For instance, the correct result gives zero for the photons while, for the same situation, the result based on the wrong regularization scheme gives infinity. Clearly, this means that the correct regularization scheme leads to a cosmological constant much smaller than the one obtained from the wrong approach. As a consequence, one could hope that the cosmological constant problem is in fact just an artifact due to the use of an incorrect regularization method. We turn to this question in the next section but, unfortunately, we will see that this is not the case.

24.9 The Value of the Cosmological Constant

We are now in a position to conclude the first part of this review. The considerations of the previous sections lead to the following expression for the vacuum energy [51]

$$\rho_{\text{vac}} = \sum_i n_i \frac{m_i^4}{64\pi^2} \ln\left(\frac{m_i^2}{\mu^2} \right) + \rho_{\text{B}} + \rho_{\text{vac}}^{\text{EW}} + \rho_{\text{vac}}^{\text{QCD}} + \cdots, \tag{811}$$

where ρ_{B} indicates the contribution coming from the bared cosmological constant and where the dots means that other phase transition could contribute. Let us now evaluate the first term more precisely for the standard model of particles physics [51]. In this case, one has one scalar field, the Higgs boson with $n_{\text{H}} = 1$, $m_{\text{H}} \simeq 125$ GeV, the six quarks (fermions) for which $n_{\text{quarks}} = -4$ and $m_{\text{t}} \simeq 171.2\text{GeV}$, $m_{\text{b}} \simeq 4.2\text{GeV}$, $m_{\text{c}} \simeq 1.27\text{GeV}$, $m_{\text{s}} \simeq 0.104\text{GeV}$, $m_{\text{u}} \simeq 0.24\text{GeV}$ and $m_{\text{d}} \simeq 0.48\text{GeV}$, the leptons (fermions) with $n_{\text{leptons}} = 4$ and $m_{\text{e}} \simeq 0.511\text{MeV}$,

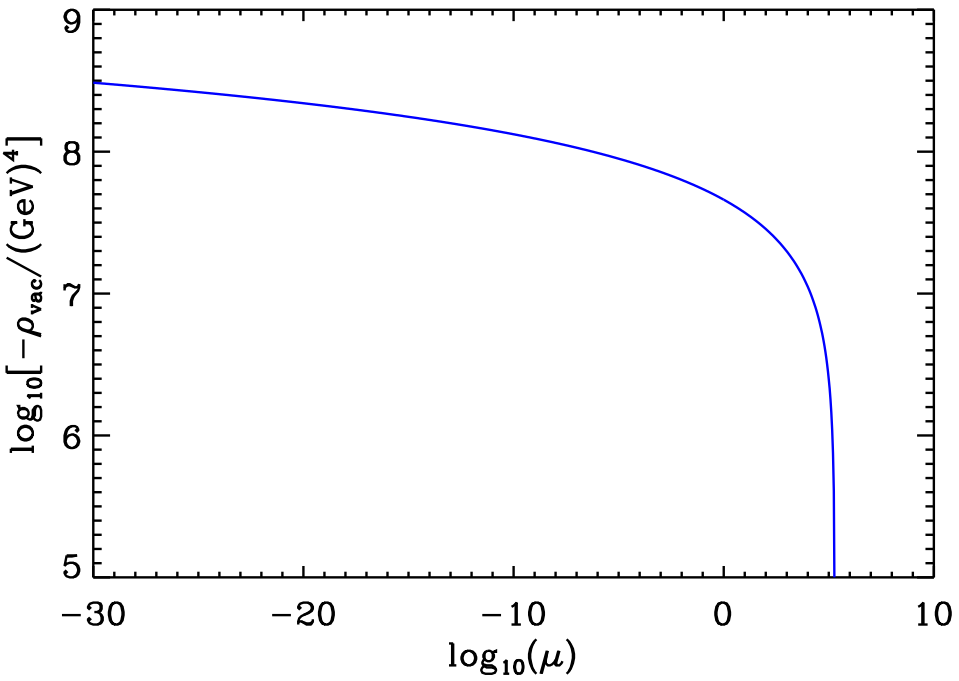

Figure 157: Evolution of the vacuum energy density [more precisely the first term in Eq. (811) versus the renormalization scale μ. In the range considered here, the vacuum energy density is negative. The "divergence" observed around $\log_{10}\mu \simeq 5$ does not correspond to a new physical effect but just signal that $\rho_{\rm vac}$ becomes positive.

$m_\mu \simeq 105$MeV, $m_\tau \simeq 1.77$MeV, the neutrinos (fermions) the mass of which is so small that we can ignore them and, finally, the gauge bosons (massive vector fields), $n_{\rm Z} = 3$, $m_{\rm Z} \simeq 91$GeV and $n_{\rm W^\pm} = 3$, $m_{\rm W^\pm} \simeq 80$GeV. Of course, we also have the photon but since $m_\gamma = 0$, as already mentioned before, it does not contribute to the vacuum energy. The only piece missing in order to calculate $\rho_{\rm vac}$ in Eq. (811) is the renormalization scale μ. It was argued in Ref. [51] that, because we use the photons coming from the supernovae to determine the cosmological constant and because these photons couple to the metric the expansion rate of which is characterized by the Hubble constant, one should take $\mu \sim \sqrt{E_\gamma E_{\rm grav}}$ with $E_{\rm grav} \simeq H_0 \simeq 3.7 \times 10^{-41}\,{\rm GeV}$ and with the energy of the photons corresponding to the wavelength $\lambda \simeq 500\,{\rm nm}$. This leads to $\mu \simeq 3 \times 10^{-25}\,{\rm GeV}$ and implies that Eq. (811) reads

$$\rho_{\rm vac} \simeq -2 \times 10^8\,{\rm GeV}^4 + \rho_{\rm B} + \rho_{\rm vac}^{\rm EW} + \rho_{\rm vac}^{\rm QCD} + \cdots . \tag{812}$$

If one does not want to estimate μ, one can simply plot $\rho_{\rm vac}$ as a function of μ as done in Fig. 157. Clearly, regardless of the precise value of μ, we are very far from $\rho_{\rm vac} \simeq 10^{72}\,{\rm GeV}^4$ always mentioned in the literature.

At this stage, Eq. (812) can be seen as the "prediction" of the standard model for the vacuum energy. At first sight, the calculation is straightforward and, in order to obtain the number in Eq. (812), we have used techniques of regularization that are known to work in similar contexts (*i.e.* when one computes a cross-section in particle physics) and to lead to a very good agreement with experiments. Therefore, we now turn to the question of what is known experimentally about the vacuum energy.

24.10 Measuring the Cosmological Constant in Cosmology

Having discussed how the vacuum energy can be calculated, we now address the question of how it is determined and/or constrained experimentally/observationally. Here, we should

distinguish the case of cosmology, treated in this section, and the other experiments, treated in the following sections. The difference is that, in cosmology, one claims a detection of Λ while, as we will see, the other experiments can only put an upper limit on its value. Moreover, in cosmology, there are in fact many different and independent observables that can be used to measure the cosmological constant [1445, 1524, 79, 80, 1677, 82]. All these techniques are reviewed in other articles [40, 41] and, therefore, it is not our purpose here to discuss this question in details. However, for completeness and also because this has some impact on the theoretical status of the cosmological constant problem, we now discuss how Λ can be determined. We will do so from a theoretical perspective leaving, as mentioned before, the technical aspects to other articles [40, 41].

24.10.1 The Accelerating Universe

As is well-known, the claim that vacuum energy has been measured (and not only constrained) was first established from the discovery that the expansion of the universe is accelerated (although one can find many claims about the value of the cosmological constant in the history of cosmology) [1445, 1524]. Since the above mentioned claim has clearly very important consequences for physics, one needs to be very precise at this stage and this is why, in what follows, we will review the exact origin of this result.

In order to construct a cosmological model we apply general relativity to the Universe as a whole [83]. The cosmological principle implies that the Universe is, on large scales, homogeneous and isotropic. As a consequence, the metric is given by the following expression

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + a^2(t)\gamma^{(3)}_{ij}\mathrm{d}x^i\mathrm{d}x^j\,, \tag{813}$$

where $\gamma^{(3)}_{ij}$ is the metric of the three-dimensional space-like sections and where $a(t)$ is the scale factor. The expansion is characterized by the Hubble parameter, $H = \dot{a}/a$ where a dot means a derivative with respect to cosmic time. In the standard model of cosmology, matter is assumed to be a collection of N perfect fluids (at least in the simplest version) and, as a consequence, its stress-energy tensor is given by the following expression

$$T_{\mu\nu} = \sum_{i=1}^{N} T^{(i)}_{\mu\nu} = (\rho_{\scriptscriptstyle\mathrm{T}} + p_{\scriptscriptstyle\mathrm{T}})u_\mu u_\nu + p_{\scriptscriptstyle\mathrm{T}} g_{\mu\nu}\,, \tag{814}$$

where $\rho_{\scriptscriptstyle\mathrm{T}}$ is the (total) energy density and $p_{\scriptscriptstyle\mathrm{T}}$ the (total) pressure. These two quantities are related by the equation of state

$$p_{\scriptscriptstyle\mathrm{T}} = w(\rho_{\scriptscriptstyle\mathrm{T}}), \tag{815}$$

[in general, there is an equation of state per fluid considered *i.e.* $p_i = w_i(\rho_i)$]. The vector u_μ is the four velocity and satisfies the relation $u_\mu u^\mu = -1$. In terms of cosmic time this means that $u^\mu = (1, \mathbf{0})$. The fact that the stress-energy tensor is conserved, $\nabla^\alpha T_{\alpha\mu} = 0$, amounts to

$$\dot{\rho}_{\scriptscriptstyle\mathrm{T}} + 3\frac{\dot{a}}{a}(\rho_{\scriptscriptstyle\mathrm{T}} + p_{\scriptscriptstyle\mathrm{T}}) = 0,. \tag{816}$$

This expression is obtained when one takes $\mu = 0$. The case $\mu = i$ does not lead to an interesting equation for the background. Moreover, if we assume that the fluids are separately conserved, then the above relation is in fact true for each fluid, *i.e.* $\dot{\rho}_i + 3H(\rho_i + p_i) = 0$.

We are now in a position to write down the Einstein equations (306) for the Universe. We arrive at the following non-linear, second order, differential equations

$$\frac{\dot{a}^2}{a^2} + \frac{k}{a^2} = \frac{\kappa}{3}\sum_{i=1}^{N}\rho_i + \frac{\Lambda_{\scriptscriptstyle\mathrm{eff}}}{3}\,, \tag{817}$$

$$-\left(2\frac{\ddot{a}}{a} + \frac{\dot{a}^2}{a^2} + \frac{k}{a^2}\right) = \kappa\sum_{i=1}^{N} p_i - \Lambda_{\scriptscriptstyle\mathrm{eff}}\,, \tag{818}$$

From the previous formulas, as already signaled in Eq. (307), we see that we can also define ρ_{Λ_B} by $\rho_{\Lambda_B} = \Lambda_B/\kappa$ and p_{Λ_B} by $p_{\Lambda_B} = -\rho_{\Lambda_B} = -\Lambda_B/\kappa$. In this case, the cosmological constant is described as fluid with a constant energy density and pressure and with an equation of state $p_{\Lambda_B} + \rho_{\Lambda_B} = 0$, i.e.

$$w_{\rm vac} \equiv \frac{p_{\Lambda_B}}{\rho_{\Lambda_B}} = -1\,. \tag{819}$$

This is of course consistent with Eq. (301). It is worth noticing that the vacuum energy is described by a fluid with a negative effective pressure.

Combining the two Einstein equations, one gets an equation which permits to calculate the acceleration of the scale factor

$$\frac{\ddot{a}}{a} = -\frac{\kappa}{6}\sum_{i=1}^{N}(\rho_i + 3p_i) + \frac{2}{3}\Lambda_{\rm eff}\,. \tag{820}$$

Let us notice that, in order to obtain the above formula, we have not assumed anything about the curvature k. This equation is especially interesting because it gives the condition leading to an accelerated expansion, namely

$$\rho_T + 3p_T < 0\,. \tag{821}$$

Since the energy density of matter must be positive, we see that the above condition requires a negative pressure, *i.e.* some exotic form of matter. But, this is of course exactly what happens when the vacuum energy is the dominant fluid in the universe. Then, Eq. (820) can be written as $\ddot{a}/a \simeq 2\Lambda_{\rm eff}/3$ which is positive for a positive effective cosmological constant. Therefore, in the framework of the standard model described before, the discovery that $\ddot{a} > 0$ means that a fluid with a negative pressure is driving the expansion.

24.10.2 The Hubble Diagram

In this section, we explain how the measurement of the Hubble diagram can be used to infer the value of the cosmological constant.

Let us first consider a source in flat space-time whose absolute luminosity is given by L (energy emitted per unit of time). This quantity can be written as

$$L = \frac{n_E \hbar\nu}{\Delta t}\,, \tag{822}$$

where n_E is the number of photons emitted during the time interval Δt. Suppose that we observe the source from a distance d_L using a telescope, the surface of the mirror being ΔS. The number of photons received is given by

$$n_R = n_E\left(\frac{\Delta S}{4\pi d_L^2}\right). \tag{823}$$

On the other hand, the flux of photons (or apparent luminosity *i.e.* energy per unit of time and surface) through the telescope is, by definition,

$$\Phi_R = \frac{n_R \hbar\nu}{\Delta S \Delta t}\,, \tag{824}$$

from which we deduce that

$$\Phi_R = \frac{L}{4\pi d_L^2}\,. \tag{825}$$

We have just recovered the well-known fact that the apparent luminosity of a source decreases as the inverse squared of the distance. On the other hand, we can use this relation as an operational definition of the distance, namely $d_L = \sqrt{L/(4\pi\Phi_R)}$.

The previous considerations can be used as a definition of distance in cosmology. For this purpose, let us now consider the same situation but in a curved space-time with the following metric [a form more explicit than the one given in Eq. (813)]

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + a^2(t)(\mathrm{d}r^2 + r^2\mathrm{d}\Omega_2^2)\,. \tag{826}$$

We assume that the source is located at the co-moving coordinate r_1 while the observer is located at the origin of the coordinates. In order to reproduce the above flat space-time calculation in this new situation, we first need to calculate the surface of the sphere $t = t_{\mathrm{R}}$ =const., $r = r_1$ =const. surrounding the source. The surface is just given by the integral of the covariant volume element, namely

$$S = \int \sqrt{g}\,\mathrm{d}^2x = \int_0^{\pi}\int_0^{2\pi} \sqrt{a_{\mathrm{R}}^4 r_1^4}\,\sin\theta \mathrm{d}\theta\mathrm{d}\varphi = 4\pi a_{\mathrm{R}}^2 r_1^2\,. \tag{827}$$

This means that the number of photons received in the telescope can now be expressed as

$$n_{\mathrm{R}} = n_{\mathrm{E}}\left(\frac{\Delta S}{4\pi a_{\mathrm{R}}^2 r_1^2}\right). \tag{828}$$

But we have also to take into account the two following phenomena. Firstly, the energy of the photons has changed during the propagation from the source to the observer. If λ is the wavelength, we have $\lambda = (2\pi/k)a(t) \propto \nu^{-1}$, from which we deduce that $E_{\mathrm{R}}/E_{\mathrm{E}} = \nu_{\mathrm{R}}/\nu_{\mathrm{E}} = a_{\mathrm{E}}/a_{\mathrm{R}}$, that is to say we have the redshift due to the expansion. Secondly, if the photons are emitted as a burst of duration Δt_{E}, they will be received as burst of duration $\Delta t_{\mathrm{R}} = \Delta t_{\mathrm{E}} a_{\mathrm{R}}/a_{\mathrm{E}}$. We are now in a position where we can calculate the apparent luminosity. We obtain

$$\Phi_{\mathrm{R}} = \frac{L}{4\pi a_{\mathrm{R}}^2 r_1^2}\left(\frac{a_{\mathrm{E}}}{a_{\mathrm{R}}}\right)^2 = \frac{L}{4\pi a_{\mathrm{R}}^2 r_1^2}\frac{1}{(1+z)^2}\,, \tag{829}$$

where z is the redshift of the source. Now if we use the operational definition of the luminosity distance (825), we find

$$d_{\mathrm{L}}(z) = a_{\mathrm{R}} r_1 (1+z) = a_{\mathrm{R}}(1+z)\int_{t_{\mathrm{E}}}^{t_{\mathrm{R}}} \frac{c\mathrm{d}\tau}{a(\tau)}\,. \tag{830}$$

We see from the last expression that the distance of a source depends on the behavior of the scale factor between the time of emission and the time of reception. On the contrary, if we measure the luminosity distance versus the redshift, we can learn about this behavior. Measuring the apparent luminosity is quite easy and, clearly, the difficulty lies in estimating the absolute luminosity of the source. It is also convenient to work in terms of the distance modulus, $m - M$, since the data are often presented in this way. The quantity m (or sometimes m_{bol}) is the apparent bolometric magnitude. It is related to the apparent bolometric luminosity ℓ by

$$\ell = 10^{-2m/5} \times 2.52 \times 10^{-5}\,\mathrm{erg/cm^2} \times \mathrm{sec}\,. \tag{831}$$

For instance the sun has an apparent bolometic magnitude of -26.85. On the other hand, the absolute bolometric magnitude M is the apparent bolometric magnitude that the source would have at a distance of 10 pc and is given by

$$L = 10^{-2M/5} \times 3.02 \times 10^{35}\,\mathrm{erg/sec}\,. \tag{832}$$

For instance, the absolute bolometric magnitude of the sun is 4.72. As a consequence, using these two definitions, the distance modulus is defined by

$$d_{\mathrm{L}}(z) \equiv \frac{c}{H_0}\bar{d}_{\mathrm{L}}(z) \equiv 10^{1+(m-M)/5} \times 10^{-6}\mathrm{Mpc}\,, \tag{833}$$

such that $\bar{d}_{\rm L}$ is dimensionless and $c/H_0 = 3000\,h^{-1}$Mpc is of course nothing but the Hubble length (we have re-established the speed of light for convenience). From the above expression, one immediately deduces that

$$\mu(z) \equiv m - M = 5\log_{10}\bar{d}_{\rm L}(z) + 25 + 5\log_{10}\left(\frac{c}{H_0}\right)\,, \tag{834}$$

where c is expressed in km $\times$ s^{-1}, H_0 in km$\times$s^{-1} $\times$ Mpc^{-1} and $d_{\rm L}$ in Mpc.

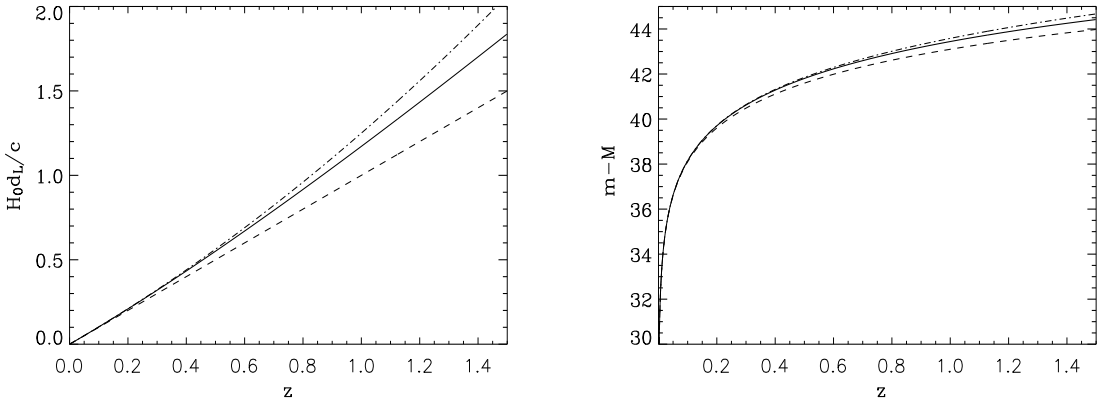

Figure 158: Luminosity distance $d_{\rm L}(z)$ (left panel) and distance modulus $\mu(z)$ (right panel) in a matter dominated Universe. The solid line corresponds to the exact result. The dashed line is the linear law $d_{\rm L} \simeq cz/H_0$ and the dotted dashed line represents the approximated result at second order, see Eq. (840). We have used $h = 0.72$.

In practice we only have access to $d_{\rm L}$ over a limited range of redshifts. Therefore, one can derive a general expression by Taylor expanding the scale factor. For small redshifts, we have

$$a(t) = a(t_{\rm R}) + \dot{a}(t_{\rm R})(t-t_{\rm R}) + \frac{1}{2}\ddot{a}(t_{\rm R})(t-t_{\rm R})^2 + \cdots = a(t_{\rm R})\left[1 + H_{\rm R}(t-t_{\rm R}) - \frac{1}{2}H_{\rm R}^2 q_{\rm R}(t-t_{\rm R})^2 + \cdots\right], \tag{835}$$

where $q \equiv -a\ddot{a}/(\dot{a})^2$ is the acceleration parameter. A positive acceleration parameter corresponds to a decelerating universe whether a negative one corresponds to an accelerating universe. Using the previous expression, the luminosity distance becomes

$$\begin{aligned} d_{\rm L}(z) &= c(1+z)\int_{t_{\rm E}}^{t_{\rm R}} {\rm d}\tau\left[1 - H_{\rm R}(\tau - t_{\rm R}) + \frac{1}{2}H_{\rm R}^2 q_{\rm R}(\tau - t_{\rm R})^2 + H_{\rm R}^2 q_{\rm R}(\tau - t_{\rm R})^2 + \cdots\right] &(836)\\ &= c(1+z)\left[-(t_{\rm E} - t_{\rm R}) + \frac{1}{2}H_{\rm R}(t_{\rm E} - t_{\rm R})^2 - \frac{1}{6}H_{\rm R}^2 q_{\rm R}(t_{\rm E} - t_{\rm R})^3 - \frac{1}{3}H_{\rm R}^2 q_{\rm R}(t_{\rm E} - t_{\rm R})^3 + \cdots\right]. &(837)\end{aligned}$$

As expected the result only depends on the time of flight $t_{\rm E} - t_{\rm R}$. In order to obtain our final result, we must express this time of flight in terms of the redshift. The redshift of the source is defined by $z = a(t_{\rm R})/a(t_{\rm E}) - 1$. Using the Taylor expansion of the scale factor, we end up with

$$z = -H_{\rm R}(t_{\rm E} - t_{\rm R}) + H_{\rm R}^2\left(1 + \frac{1}{2}q_{\rm R}\right)(t_{\rm E} - t_{\rm R})^2 + \cdots\,, \tag{838}$$

which can be easily inverted to give the expression of the time of flight, namely

$$t_{\rm E} - t_{\rm R} = -\frac{z}{H_{\rm R}} + \frac{1}{H_{\rm R}}\left(1 + \frac{1}{2}q_{\rm R}\right)z^2 + \cdots\,. \tag{839}$$

The last step is to replace the above expression into the Eq. (837). This gives

$$d_{\rm L}(z) = \frac{c}{H_0}\left[z + \frac{1}{2}(1-q_0)z^2 + \cdots\right], \tag{840}$$

where we have taken into account that the time of reception is the present time (denoted with the subscript "0"). We see that the measurement of the luminosity distance versus the redshift allows us to determine the Hubble parameter today. If one goes sufficiently far in redshifts, one can determine whether the universe is accelerating or not via the accelerating parameter q_0. It is worth noticing that this last conclusion is independent of the underlying gravity theory (provided this is a metric theory). The typical behavior of the luminosity distance and of the modulus is illustrated in Fig. 158 for a matter dominated universe. Let us also notice that the method that we have just presented for pedagogical reasons is of course not used in practice because we have now measured up to redshifts of $z \simeq 1.4$ for which the Taylor expansion is not valid (and, of course, in the real world the analysis is always more complicated that the simplified version discussed above). In this case, one must use an exact expression, that is to say one must compute the integral in Eq. (830) exactly.

If we now use general relativity (*i.e.* a specific theory for gravity), one can go further and relates the value of the acceleration parameter to the matter content of the Universe. The critical energy density $\rho_{\rm cri}$, defined by $\rho_{\rm cri} \equiv 3H^2/\kappa$, is used to evaluate the contribution of each species through the parameter $\Omega_i \equiv \rho_i/\rho_{\rm cri}$ where ρ_i is the energy density of the species i at present time. Then, the Friedman equation can be re-written as

$$\sum_{i=1}^{N} \Omega_i = 1 + \frac{k}{a^2 H^2} \,, \tag{841}$$

and the acceleration parameter can be re-expressed according to

$$q_0 = \frac{1}{2} \sum_{i=1}^{N} \Omega_i \left(1 + 3w_i\right) \,. \tag{842}$$

The universe contains pressure-less gas (cold dark matter and ordinary baryonic matter) for which $w = 0$ but also radiation ($w = 1/3$) and, finally, vacuum energy ($w = -1$). In this case, one obtains

$$q_0 = \frac{1}{2}\Omega_{\rm m} + \Omega_\gamma - \Omega_{\rm vac} \,. \tag{843}$$

Today, the contribution of radiation is negligible since we know from the measurement of the CMB that $\Omega_\gamma h^2 \simeq 2.48 \times 10^{-5}$ [1677]. Therefore, the acceleration parameter is in fact given by $q_0 \simeq \Omega_{\rm m}/2 - \Omega_{\rm vac}$. On the other, we also know that the universe is spatially flat which means that $\Omega_{\rm m} + \Omega_{\rm vac} \simeq 1$ [1677]. As a consequence, from the measurement of $q_0 \simeq -0.67 \pm 0.25$ [1445, 1524], one can deduce the two quantities $\Omega_{\rm m}$ and $\Omega_{\rm vac}$. On finds that $\Omega_{\rm m} \simeq 0.3$ and $\Omega_{\rm vac} \simeq 0.7$. This is how one reaches the conclusion that our universe is accelerating and that vacuum energy dominates the present energy content. Remarkably, as announced at the beginning of this section, it is a detection and a measurement of $\rho_{\rm vac}$. One finds

$$\rho_{\rm vac} \simeq \Omega_{\rm vac} \rho_{\rm cri} \simeq 10^{-47}\,{\rm GeV}^4, \tag{844}$$

a number that should be compared with Eq. (812).

At this stage, several remarks are in order. Firstly, we notice the large mismatch between the theoretical expectation (812) and the above, observationally determined, number (844), something like 54 orders of magnitude (but much less than the 122 orders of magnitude often quoted in the literature). This is of course nothing but the cosmological constant problem although we will be more accurate with regards to its definition in the subsequent sections. Something is clearly wrong but, as will be discussed, it is difficult to identify where the mistake is. Secondly, it is clear that the above conclusion rests on many assumptions. For instance, we have assumed that the universe is homogeneous and isotropic [42] and that gravity is well described by general relativity. This means that, a priori, the cosmological constant problem is present in this context only. Thirdly, we have also implicitly assumed that the reason for the accelerated expansion is vacuum energy. This is clearly a natural idea since there is a term in our theory that must be present since it satisfies all the required properties (covariance, energy conservation) and that precisely leads to the observed phenomenon. A priori, nothing more can be asked to a new theoretical framework. But, given the mismatch discussed before, one can also doubt the identification of the source of the accelerated expansion with vacuum energy. As a

matter of fact, it is possible to construct models where the universe accelerates because of some new source of matter (often named "dark energy"). This is for instance the case of quintessence and/or galileons [43] models where a scalar field is responsible for the acceleration. In this case, one can no longer claim that we have detected the vacuum energy and that its value is given by Eq. (844). However, this does not solve the cosmological constant problem because, even if the source of the acceleration is another fluid, we still have the constraint $\rho_{\rm vac} < \rho_{\rm cri}$. Clearly, the number (812) does not satisfy this inequality which means that the problem is still present. In this sense, the constraint deduced from cosmology is very important: even if dark energy is not the cosmological constant, the observation that the energy density today is the critical energy density severely limits the value of $\Lambda_{\rm eff}$. Fourthly, in principle, it is possible to check experimentally whether the reason for the accelerated expansion is vacuum energy or something else like quintessence [1497, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 448, 97, 98, 99] (more recently, in Ref. [100], the current acceleration was also explained by a scalar field experiencing quantum fluctuations during inflation). Measuring the equation of state parameter w is the clue since, if this is a constant equals to -1, then one can be sure that the source of the acceleration is the cosmological constant. Unfortunately, this measurement is difficult [101].

One more general grounds, it is clear that it would be better to have constraints, or even a measurement, of vacuum energy in an experimental context which is is not cosmology where, as reminded before, measurements are difficult and always subject to many biases and systematic errors. In the next sections, we explore whether this is possible.

24.11 Measuring the Cosmological Constant Elsewhere Than In Cosmology?

In the previous section, we have written the Einstein equation in an homogeneous and isotropic universe. Here, we investigate the influence of the cosmological term in a spherically symmetric situation. This will allow us to study how the presence of $\Lambda_{\rm eff}$ affects the motion of the planets in our solar system and how it modifies the energy levels of the Hydrogen atom.

24.11.1 The Static and Spherically Symmetric Gravitational Field in Presence of a Cosmological Constant

Let us analyze the influence of the cosmological constant in a static and spherically symmetric situation [102]. This means that, in spherical coordinates, one can write the metric tensor as [102]

$$\mathrm{d}s^2 = -B(r)\mathrm{d}t^2 + A(r)\mathrm{d}r^2 + r^2\left(\mathrm{d}\theta^2 + \sin^2\theta\mathrm{d}\varphi^2\right), \tag{845}$$

where $A(r)$ and $B(r)$ are two free functions. We seek solutions of the Einstein equations (306) with a vanishing stress energy tensor. It is easy to show that these equations can be expressed as

$$R_{\mu\nu} - \Lambda_{\rm eff} g_{\mu\nu} = 0. \tag{846}$$

The next step is to calculate the components of the Ricci tensor for the metric tensor given by Eq. (845). Straightforward calculations lead to the following expressions

$$R_{tt} = \frac{B}{A}\left(\frac{1}{2}\frac{B''}{B} - \frac{1}{4}\frac{B'^2}{B^2} - \frac{1}{4}\frac{A'B'}{AB} + \frac{1}{r}\frac{B'}{B}\right), \tag{847}$$

$$R_{rr} = -\frac{1}{2}\frac{B''}{B} + \frac{1}{4}\frac{B'^2}{B^2} + \frac{1}{4}\frac{A'B'}{AB} + \frac{1}{r}\frac{B'}{B}, \tag{848}$$

$$R_{\theta\theta} = \frac{1}{A}\left(\frac{r}{2}\frac{A'}{A} - \frac{r}{2}\frac{B'}{B} - 1\right) + 1, \tag{849}$$

$$R_{\varphi\varphi} = R_{\theta\theta}\sin^2\theta, \tag{850}$$

the other components being zero. In the above equations, a prime denotes a derivative with respect to the radial coordinate r.

We are now in a position where one can determine the solution of the field equations. If we take the combination $R_{tt}/B + R_{rr}/A = -\Lambda_{\text{eff}}B/B + \Lambda_{\text{eff}}A/A = 0$ [from the Einstein equations (846)], one obtains

$$\frac{1}{rA}\left(\frac{B'}{B} + \frac{A'}{A}\right) = 0, \tag{851}$$

which implies that $B(r) = C/A(r)$, where C is a constant. Using this expression, one can re-express $R_{\theta\theta}$ as

$$R_{\theta\theta} = \frac{B(r)}{C}\left(-r\frac{B'}{B} - 1\right) + 1, \tag{852}$$

and, as a consequence, the corresponding Einstein equation now reads

$$rB'(r) + B(r) = C - C\Lambda_{\text{eff}}r^2. \tag{853}$$

This equation can easily be integrated and one obtains

$$B(r) = D + \frac{C}{r} - D\Lambda_{\text{eff}}\frac{r^2}{3}, \tag{854}$$

where D is another integration constant. The constants C and D are fixed in such a way that, in absence of a cosmological constant, one recovers the standard Schwarschild solution. This amounts to take $D = 1$ and $C = 2GM$, where M is the mass of the central body and G the Newton constant. This completes our calculation since the two functions $A(r)$ and $B(r)$ are now completely specified, namely

$$A(r) = \frac{1}{B(r)}, \quad B(r) = 1 - \frac{2GM}{r} - \frac{\Lambda_{\text{eff}}r^2}{3}. \tag{855}$$

We can now compare this solution to the standard Schwarschild solution. The fact that the time-time component of the metric tensor is inversely proportional to the r-r component is still true but the radial dependence of the function $B(r)$ is modified by the presence of a cosmological constant. In the Newtonian limit, we have $g_{tt} \simeq 1 + 2V(r)$, where $V(r)$ is the Newtonian potential. In the present context, this implies that

$$V(r) \simeq -\frac{GM}{r} - \frac{\Lambda_{\text{eff}}r^2}{6}. \tag{856}$$

Therefore, we obtain the usual gravitational potential corrected by a term proportional to the cosmological constant. This term looks like an inverted harmonic oscillator. This corresponds to a force felt by a test body of mass m given by

$$\boldsymbol{F} = \frac{GMm}{r^2}\boldsymbol{u} - \frac{m\Lambda_{\text{eff}}r}{3}\boldsymbol{u}, \tag{857}$$

where $\boldsymbol{u}$ is a vector directed towards the central body of mass M. The cosmological constant force is directed in the other direction and can therefore be viewed as a kind of "anti-gravity force". We also notice that it is proportional to r which means that its effect will be more important on large scales. This last property is the clue to understand why measuring the cosmological constant is more efficient on large scales (the best example being of course cosmology). This means that the modification of the planet orbits and/or the energy levels of the atoms will certainly be a small effect. On the other hand, we know that measurements in, say, atomic physics are extremely accurate and, a priori, there is the hope that this accuracy could compensate the smallness of the effect. Unfortunately, as we are now going to study, this will not be the case.

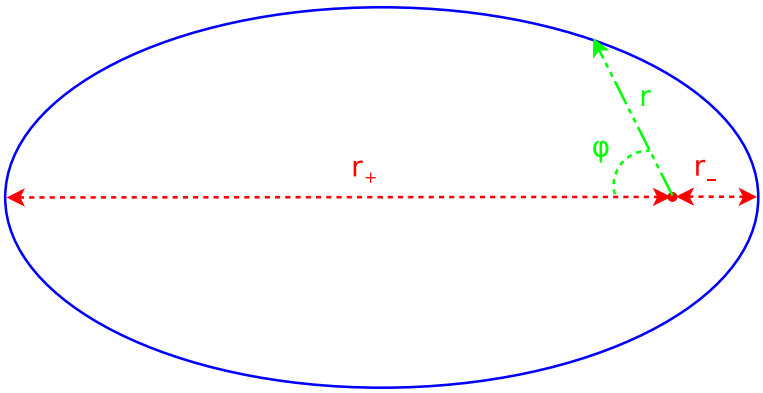

Figure 159: Sketch of the elliptic planet orbit with the aphelion and perihelion. The orbit is planar and the position of the planet can be characterized by the coordinates (r, φ).

24.11.2 Planets Orbits

Our goal in this section is to study how the planet orbits are modified by the presence of vacuum energy [103, 104, 105]. We will follow the treatment of Ref. [103]. We assume that the gravitational field created by the sun and the cosmological constant is given by Eqs. (845) and (855) with $M = M_\odot$. The motion of a planet is represented by the motion of a test body in this background gravitational field. The corresponding geodesic equation can be written as

$$\frac{\mathrm{d}^2 x^\mu}{\mathrm{d}\tau^2} + \Gamma^\mu_{\nu\lambda}\frac{\mathrm{d}x^\nu}{\mathrm{d}\tau}\frac{\mathrm{d}x^\lambda}{\mathrm{d}\tau} = 0, \tag{858}$$

where τ is an affine parameter (not necessarily the proper time). Then, after having evaluated the Christoffel symbols for the metric (845), one can express these equations explicitly. One obtains

$$\frac{\mathrm{d}^2 t}{\mathrm{d}\tau^2} + \frac{B'}{B}\frac{\mathrm{d}t}{\mathrm{d}\tau}\frac{\mathrm{d}r}{\mathrm{d}\tau} = 0, \tag{859}$$

$$\frac{\mathrm{d}^2 r}{\mathrm{d}\tau^2} + \frac{B'}{2A}\left(\frac{\mathrm{d}t}{\mathrm{d}\tau}\right)^2 + \frac{A'}{2A}\left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2 - \frac{r}{A}\left(\frac{\mathrm{d}\theta}{\mathrm{d}\tau}\right)^2 - \frac{r\sin^2\theta}{A}\left(\frac{\mathrm{d}\varphi}{\mathrm{d}\tau}\right)^2 = 0, \tag{860}$$

$$\frac{\mathrm{d}^2\theta}{\mathrm{d}\tau^2} + \frac{2}{r}\frac{\mathrm{d}r}{\mathrm{d}\tau}\frac{\mathrm{d}\theta}{\mathrm{d}\tau} - \cos\theta\sin\theta\left(\frac{\mathrm{d}\varphi}{\mathrm{d}\tau}\right)^2 = 0, \tag{861}$$

$$\frac{\mathrm{d}^2\varphi}{\mathrm{d}\tau^2} + \frac{2}{r}\frac{\mathrm{d}r}{\mathrm{d}\tau}\frac{\mathrm{d}\varphi}{\mathrm{d}\tau} + 2\frac{\cos\theta}{\sin\theta}\frac{\mathrm{d}\theta}{\mathrm{d}\tau}\frac{\mathrm{d}\varphi}{\mathrm{d}\tau} = 0, \tag{862}$$

Let us now solve these equations. Firstly, we can assume that the orbit stays in the $\theta = \pi/2$ plane. This automatically solves Eq. (861). Then, if we divide Eq. (859) by $\mathrm{d}t/\mathrm{d}\tau$ and Eq. (862) by $\mathrm{d}\varphi/\mathrm{d}\tau$, we obtain two new equations, namely

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\left[\ln\left(\frac{\mathrm{d}t}{\mathrm{d}\tau}\right) + \ln B\right] = 0, \tag{863}$$

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\left[\ln\left(\frac{\mathrm{d}\varphi}{\mathrm{d}\tau}\right) + \ln r^2\right] = 0. \tag{864}$$

The first equation can be used to define the affine parameter. We choose it such that it satisfies $\mathrm{d}t/\mathrm{d}\tau = 1/B$. Then, the second equation tells us that

$$r^2\frac{\mathrm{d}\varphi}{\mathrm{d}\tau} = J, \tag{865}$$

where J is a constant. Finally, Eq. (860) can be re-written as

$$\frac{\mathrm{d}^2 r}{\mathrm{d}\tau^2} + \frac{A'}{2A}\left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2 - \frac{J^2}{Ar^3} + \frac{B'}{2AB^2} = 0. \tag{866}$$

If we multiply this last equation by $2A\mathrm{d}r/\mathrm{d}\tau$, one arrives at

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\left[A\left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2+\frac{J^2}{r^2}-\frac{1}{B}\right]=0. \tag{867}$$

This means that the quantity inside the square brackets is a constant. Let us call this constant $-E$. Then, this gives an equation expressing how the radial coordinate r varies with the angle φ,

$$\left(\frac{\mathrm{d}r}{\mathrm{d}\varphi}\right)^2=\frac{r^4}{A(r)}\left[\frac{1}{J^2B(r)}-\frac{1}{r^2}-\frac{E}{J^2}\right]. \tag{868}$$

It is easy to express the constants E and J in terms of the aphelion and perihelion r_+ and r_-, which are the two points on the orbit such that $\mathrm{d}r/\mathrm{d}\varphi=0$, see Fig. 159 (where the elements of the orbits are represented). This gives

$$\frac{1}{J^2} = \frac{r_+^{-2}-r_-^{-2}}{B_+^{-1}-B_-^{-1}}, \tag{869}$$

$$E = \frac{r_+^2/B_+-r_-^2/B_-}{r_+^2-r_-^2}, \tag{870}$$

with $B_\pm$ defined by $B_\pm\equiv B(r_\pm)$.

So far, we have been very general and we have never specified the function $B(r)$. From now on, we are going to use the explicit form of this function, see Eq. (855). Let us notice in particular that, in absence of a cosmological constant and in the limit where $GM/r\ll 1$, the two above expressions reduce to

$$\frac{E-1}{2}\simeq\frac{GM}{r_++r_-},\quad J^2\simeq 2GMD, \tag{871}$$

where $D\equiv r_+r_-/(r_++r_-)$ (of course, not to be confused with the integration constant introduced in the previous sub-section). As is shown in the following footnote, these are exactly the relations obtained in the Newtonian case. More generally, Eq. (868) takes the form

$$\left(\frac{\mathrm{d}r}{\mathrm{d}\varphi}\right)^2 = \frac{1-E}{J^2}r^4+\frac{2GME}{J^2}r^3-r^2+2GMr \\ +\frac{\Lambda_{\rm eff}r^4}{3}+\frac{E\Lambda_{\rm eff}r^6}{3J^2}. \tag{872}$$

Performing the standard change of variable, $u\equiv 1/r$ and differentiating with respect to φ, we obtain [129]

$$\frac{\mathrm{d}^2u}{\mathrm{d}\varphi^2}+u=\frac{E}{J^2}GM+3GMu^2-\frac{E}{J^2}\frac{\Lambda_{\rm eff}}{3u^3}. \tag{881}$$

[129] It is interesting to compare this result with the Newtonian analysis. In this case, the Lagrangian is given by

$$L=\frac{m}{2}\left(\dot r^2+r^2\dot\varphi^2\right)+\frac{GMm}{r}, \tag{873}$$

where a dot denotes a derivative with respect to time. Again we have chosen the orbit to be in the plane $\theta=\pi/2$. This leads to the following equations of motion

$$m\ddot r-mr\dot\varphi^2+\frac{GMm}{r^2} = 0, \tag{874}$$

$$mr^2\ddot\varphi+2mr\dot r\dot\varphi = 0. \tag{875}$$

The second equation gives $\dot\varphi=J/r^2$ while the first one can be re-written as

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\dot r^2}{2}+\frac{J^2}{2r^2}-\frac{GM}{r}\right)=0 \tag{876}$$

This is the differential equation that needs to be solved in order to find the trajectory of the planet. It should be compared with its Newtonian counterpart, see Eq. (879). One can check that, in this regime (without a cosmological constant), the two equations are indeed identical since according to Eq. (871), $E \to 1$, $\Lambda_{\text{eff}} = 0$ and the term $3GMu^2$ can be neglected. The relativistic term $3GMu^2$ is responsible for the precession of the perihelion and the last term represents the correction due to the cosmological constant.

We now turn to the solution of Eq. (881). Let us first review how one calculates the precession of the perihelion without a cosmological constant [102]. The idea is to restart from Eq. (872). For $\Lambda_{\text{eff}} = 0$, the polynomial on the right hand side can be written as

$$\frac{1-E}{J^2} r(r-r_+)(r-r_-)(r-\epsilon) \tag{882}$$

since we know it has to vanish at $r = r_\pm$. The only quantity that remains to be determined in this expression is ϵ. Comparing the above relation with Eq. (872), we deduce that

$$\frac{1-E}{J^2} r_+ r_- \epsilon = 2GM. \tag{883}$$

Using the expressions derived before, it is easy to show that $\epsilon = 2GM/(1-2GM/D)$. As a consequence, one can write

$$\begin{aligned} \varphi_+ - \varphi_- &= \frac{J}{\sqrt{1-E}} \int_{r_-}^{r_+} \frac{1}{\sqrt{(r-r_+)(r-r_-)}} \\ &\quad \times \frac{1}{\sqrt{1-\epsilon/r}} \frac{\mathrm{d}r}{r}. \end{aligned} \tag{884}$$

There are several methods to evaluate this integral. As a matter of fact, it can be integrated exactly in terms of Elliptic functions [48, 49]. But, being given that ϵ is a small quantity, it is better to expand the result in this parameter. This leads to easier calculations that are, moreover, more explicit. In addition, the method can be generalized to the case of a non-vanishing cosmological constant, which is of course our main goal. In fact, if we restart from Eq. (868) and use that $B^{-1} \simeq 1 + 2GM/r + \cdots$, we see that the term in the squared bracket in Eq. (868) is a quadratic function of $1/r$ which vanishes at $r = r_\pm$. This means that one necessarily has

$$\frac{1}{J^2 B(r)} - \frac{E}{J^2} - \frac{1}{r^2} \simeq C \left(\frac{1}{r} - \frac{1}{r_-}\right)\left(\frac{1}{r} - \frac{1}{r_+}\right). \tag{885}$$

The quantity between the parenthesis is a constant and we call it $-E$. Then, this equation can be re-expressed as

$$\left(\frac{\mathrm{d}r}{\mathrm{d}\varphi}\right)^2 = -\frac{2E}{J^2} r^4 + \frac{2GM}{J^2} r^3 - r^2. \tag{877}$$

From this equation one can deduce an expression for E and J in terms of the aphelion and the perihelion. One gets

$$E = \frac{GM}{r_+ + r_-}, \quad J^2 = 2GMD. \tag{878}$$

Introducing the variable $u = 1/r$ and differentiating once more with respect to φ, one arrives at

$$\frac{\mathrm{d}^2 u}{\mathrm{d}\varphi^2} + u = \frac{GM}{J^2}. \tag{879}$$

This equation can easily be integrated. The solution reads

$$u(\varphi) = F\cos(\varphi - \varphi_0) + \frac{GM}{J^2} = \frac{GM}{J^2}(1 - e\cos\varphi), \tag{880}$$

where F and φ_0 are two arbitrary constants. Clearly, one can always take $\varphi_0 = 0$. The above trajectory represents, as is well-known, an ellipse with eccentricity e.

Then, writing Eq. (868) in terms of u rather than r, one arrives at

$$\left(\frac{\mathrm{d}u}{\mathrm{d}\varphi}\right)^2 \simeq \frac{C}{A(r)}\left(u-u_-\right)\left(u-u_+\right). \tag{886}$$

Now, when $\Lambda_{\text{eff}} \neq 0$, as is clear from Eq. (872), the term in the square bracket of Eq. (868) is no longer a quadratic function of $1/r$ even if the expansion of the function $B^{-1}(r)$ is used. However, this term still vanishes at $r = r_\pm$ and the integral will be dominated by the contributions coming from the vicinity of these points, see also Eq. (884). The idea is then to continue to work with Eq. (885) and to take into account the cosmological constant in the definition of C [103]. This should provide a reasonable approximation of $\varphi_+ - \varphi_-$. Using Eqs. (869) and (870), one can write

$$\begin{aligned}
&\frac{1}{J^2 B(r)} - \frac{E}{J^2} - \frac{1}{r^2} \\
= \;& \frac{r_-^2\left[B^{-1}(r) - B_-^{-1}\right] - r_+^2\left[B^{-1}(r) - B_+^{-1}\right]}{r_+^2 r_-^2\left(B_+^{-1} - B_-^{-1}\right)} - \frac{1}{r^2} \\
\simeq \;& C\left(\frac{1}{r} - \frac{1}{r_-}\right)\left(\frac{1}{r} - \frac{1}{r_+}\right).
\end{aligned} \tag{887}$$

Then, if we differentiate both sides twice with respect to u, this gives

$$C = \frac{\left(u_+ - u_-\right)\left(u_+ - u_-\right)A''(u)}{2\left(u_+ - u_-\right)A'(u)} - 1, \tag{888}$$

$$\simeq -1 + \left.\frac{uA''}{A'}\right|_{u=L^{-1}}, \tag{889}$$

where $L \equiv 2D$ is the semilatus rectum. In the above expression, we have used $A_+ - A_- \simeq \left(u_+ - u_-\right)A'\left(L^{-1}\right)$. So far, the method is completely general provided that $A^{-1} = B$. We now use the explicit form of A^{-1}. Expanding everything in GMu and in Λ_{eff}, one obtains [103]

$$C \simeq -1 + \frac{4GM}{L} + \frac{\Lambda_{\text{eff}} L^3}{GM} + \frac{4\Lambda_{\text{eff}} L^3}{3} + \cdots. \tag{890}$$

The final step consists in using the above expression in Eq. (886). One finds [103]

$$\begin{aligned}
\varphi_+ - \varphi_- &\simeq \int_{u_-}^{u_+} \frac{A^{1/2}(u)\mathrm{d}u}{\left[C\left(u-u_+\right)\left(u-u_-\right)\right]^{1/2}} \\
&= \pi\left(1 + \frac{3}{2}\frac{2GM}{L} + \frac{\Lambda_{\text{eff}} L^3}{2GM} + \cdots\right),
\end{aligned} \tag{891}$$

where we have expanded $A^{1/2}C^{-1/2}$ and where we have used the fact that $\int_{u_-}^{u_+} \mathrm{d}u/[(u-u_+)(u-u_-)]^{1/2} = \ln(u_+ - u_-) - \ln(u_+ - u_-) + 2i\pi/2$, the complex i being exactly cancel by the i coming from the fact that C, which appears in a square root, is negative [its expansion starts with -1, see Eq. (890)]. As a consequence, we obtain

$$\Delta\varphi \equiv 2\left(\varphi_+ - \varphi_-\right) - 2\pi \simeq 6\pi\frac{GM}{L} + \Delta\varphi_\Lambda, \tag{892}$$

where the first term is the standard relativistic perihelion precession while [103]

$$\Delta\varphi_\Lambda \simeq \frac{\pi\Lambda_{\text{eff}} L^3}{GM}, \tag{893}$$

is the contribution due to the cosmological constant. The above equation is the main result of this sub-section. It gives the perihelion precession due to the presence of vacuum energy. Let us notice that the scaling $\Delta\varphi_{\Lambda} \propto L^3$ indicates that the precession is larger for planets that are far from the Sun. It is of course totally consistent with the fact that the effect of the cosmological constant is more important on large scales.

We now use the above result to constrain the amount of vacuum energy present in our universe. For this purpose, let us now calculate this perihelion shift for, say, Mercury (as mentioned before, the effect is larger for other planets but this does not modify the conclusions obtained below; estimates for Venus, Earth and Mars can be found in Ref.[105]). In this case, we have $r_+ \simeq 68.8 \times 10^6$km and $r_- \simeq 46 \times 10^6$km. This implies that $D \simeq 27.7 \times 10^6$km. We also have $GM \simeq 2.95$km. Finally, it is interesting to calculate in terms of the vacuum energy density observed in cosmology, see Eq. (844). For the cosmological constant, this leads to the following number $\Lambda_{\text{obs}} \simeq 8.81\, h^2 \times 10^{-48}\text{km}^{-2}$. This leads to the following expression

$$\Delta\varphi_{\Lambda} \simeq 1.6h^2 \times 10^{-24} \left(\frac{\Lambda}{\Lambda_{\text{obs}}}\right) \quad \text{rad/revolution}, \tag{894}$$

or, since Mercury completes 415 revolutions each century and there are $360 \times 60 \times 60/(2\pi)$ arc-seconds per radian,

$$\Delta\varphi_{\Lambda} \simeq 2.7h^2 \times 10^{-16} \left(\frac{\Lambda}{\Lambda_{\text{obs}}}\right) \quad \text{arc-second/century}, \tag{895}$$

which is, of course, completely unobservable. The reason for such a result has already been mentioned. The solar system has a characteristic scale (say a few astronomical units) which is too small for the cosmological constant to leave a sizable imprint. However, even if one cannot measure the vacuum energy density with this method, it can nevertheless be used to constrain its value. Indeed, the uncertainty in the precession of the perihelion of Mercury is about $0.1''$ par century, which means that

$$\Delta\varphi_{\Lambda} \simeq 2.7h^2 \times 10^{-16} \left(\frac{\rho_{\Lambda}}{\rho_{\text{cri}}}\right) < 0.1, \tag{896}$$

implying that

$$\rho_{\text{vac}} \lesssim 10^{15}\rho_{\text{cri}} \simeq 3 \times 10^{-32}\,\text{GeV}^4. \tag{897}$$

Of course, this limit is not competitive with what one has obtained in cosmology. However, when compared to Eq. (812), it leads to an interesting piece of information which allows us to define what the cosmological constant problem is more accurately. Indeed, we see that there is a contradiction between the theoretical expectation (812) and the observations of the planet trajectories in our solar system. In other words, the predictions of Eq. (812), if true, would lead to orbits drastically different from what we observe. Therefore, even without the cosmological observations and only from the motion of the planets in the solar system, one sees that our calculation of vacuum energy must be incorrect. Put it differently, it would be incorrect to say that the cosmological constant problem originates only from the recent astrophysical observations. In some sense, the problem is much worse. Only by observing the planets in the solar system, a class of observations which seems to be much more straightforward than the cosmological observations, we know that our regularization method of the vacuum energy must be flawed.

24.11.3 Modifications of the Atomic Levels

We have just seen that observing the motion of planets in our solar system can tell us something about the value of the vacuum energy. A priori, another possibility to observe the influence of the cosmological constant is through the modification of the atomic energy levels that its presence would cause. In this section, we investigate this question in the case of the Hydrogen atom since this is technically simple [106, 107, 108, 109, 110, 111]. We will follow the treatment of Ref. [106]. In particular, since the problem is still spherically symmetric, one can use the metric tensor (845) obtained before.

The motion of an electron around the nucleus, living in a static and spherically symmetric manifold, is described by the following Dirac equation

$$\left(\Gamma^{\mu} D_{\mu} + m\right) \Psi = 0, \tag{898}$$

where Ψ is a Dirac spinor, see Sec. 24.7.1 and m the mass of the electron. In the above equation, Γ_{μ} are the Dirac matrices satisfying the relation

$$\{\Gamma^{\mu}, \Gamma^{\nu}\} = 2g^{\mu\nu}. \tag{899}$$

Let us notice that we have already presented this formula, see Eq. (628). Here, we slightly change the notation and now denote the Dirac matrices in curved space-time by Γ^{μ} (notice that we have also included a factor i in the definition of Γ^{μ}). The matrices Γ^{μ} are related to the Dirac matrices in flat space-time, γ^{μ}, by $\Gamma_{\mu} = e^{\alpha}{}_{\mu}\gamma_{\alpha}$, where $e^{\alpha}{}_{\mu}$ are the vierbein fields such that $g_{\mu\nu} = e^{\alpha}{}_{\mu} e^{\beta}{}_{\nu} \eta_{\alpha\beta}$. The symbol D_{μ} denotes the covariant derivative acting on the spinor, namely

$$D_{\mu}\Psi = \left(\partial_{\mu} - \omega_{\mu}\right)\Psi, \tag{900}$$

where the spinorial connection can be expressed as

$$\omega_{\mu} \equiv -\frac{1}{4}\gamma_{\alpha}\gamma_{\beta} e^{\alpha}{}_{\nu} g^{\nu\lambda} \left(\nabla_{\mu} e^{\beta}{}_{\lambda}\right) + iqA_{\mu}, \tag{901}$$

with $\nabla_{\mu} e^{\beta}{}_{\lambda} \equiv \partial_{\mu} e^{\beta}{}_{\lambda} - \Gamma^{\sigma}_{\mu\lambda} e^{\beta}{}_{\sigma}$ and A_{μ} is the vector field describing the electromagnetic field acting on the electron (q is the charge). The Dirac equation can also be re-written as

$$i\partial_0 \Psi = H\Psi, \tag{902}$$

where the effective Hamiltonian is given by

$$\begin{aligned} H &= -i\left(g^{00}\right)^{-1} \Gamma^0 \Gamma^i \left(\partial_i \Psi - \omega_i \Psi\right) + i\Gamma_0 \Psi \\ &\quad -i\left(g^{00}\right)^{-1} \Gamma^0 m \Psi. \end{aligned} \tag{903}$$

In this case, the Dirac equation looks like an effective Schrödinger equation.

It is clear that the typical dimension of an atom is very small in comparison to the typical curvature scale of the manifold. Therefore, as was done for the calculation of the Green function in Sec. 24.8, one can perform a local analysis. For this purpose, we now use the Fermi normal coordinates [78]. In these coordinates, the metric tensor takes the form

$$g_{00} = -1 - R_{0\ell 0m} x^{\ell} x^{m} + \cdots, \tag{904}$$

$$g_{0i} = -\frac{2}{3} R_{0\ell im} x^{\ell} x^{m} + \cdots, \tag{905}$$

$$g_{ij} = \delta_{ij} - \frac{1}{3} R_{i\ell jm} x^{\ell} x^{m} + \cdots, \tag{906}$$

where the dots indicate higher order terms. This implies that the veirbein fields can be expressed as

$$e^{\alpha}{}_{0} = \delta^{\alpha}{}_{0} - \frac{1}{2} R^{\alpha}{}_{\ell 0m} x^{\ell} x^{m}, \tag{907}$$

$$e^{\alpha}{}_{i} = \delta^{\alpha}{}_{i} - \frac{1}{2} R^{\alpha}{}_{\ell im} x^{\ell} x^{m}, \tag{908}$$

and the Christoffel symbols can be written as

$$\Gamma^{0}_{ij} = \frac{1}{3}\left(R_{0ijm} + R_{0jim}\right) x^{m}, \tag{909}$$

$$\Gamma^{0}_{0i} = R_{0iom} x^{m}, \tag{910}$$

$$\Gamma^{i}_{jk} = \frac{1}{3}\left(R_{jikm} + R_{kijm}\right) x^{m}, \quad \Gamma^{0}_{00} = 0, \tag{911}$$

$$\Gamma^{i}_{0j} = R_{0mji} x^{m}, \quad \Gamma^{i}_{00} = R_{0i0m} x^{m}. \tag{912}$$

Using the above results, this finally leads to the following expression for the spinorial connection [106]

$$\begin{aligned}\omega_0 &= \frac{1}{2}\gamma_0\gamma_j R^j{}_{00m}x^m + \frac{1}{4}\gamma_k\gamma_j R^{kj}{}_{0m}x^m \\ &\quad +iqA_0, \qquad (913)\\ \omega_i &= \frac{1}{4}\gamma_0\gamma_j R^{0j}{}_{im}x^m + \frac{1}{8}\gamma_k\gamma_j R^{kj}{}_{im}x^m \\ &\quad +iqA_i. \qquad (914)\end{aligned}$$

The above formulas will allow us to calculate the effective Hamiltonian (903) explicitly. But before reaching this stage, we must also determine vector field A_μ. The Lagrangian of the corresponding gauge field is given by, see also Eq. (665)

$$S = -\int \mathrm{d}^4x\sqrt{-g}\left(\frac{1}{4}g^{\alpha\beta}g^{\mu\nu}F_{\mu\alpha}F_{\nu\beta} - j^\mu A_\mu\right), \qquad (915)$$

from which we deduce that the equations of motion read

$$g^{\mu\nu}\nabla_\mu\nabla_\nu A_\gamma - R^\sigma{}_\gamma A_\sigma = -j_\gamma. \qquad (916)$$

At first order in the curvature, these equations can be expressed as [106]

$$\delta^{ij}\partial_i\partial_j A_0 + \frac{1}{3}R_{i\ell jm}x^\ell x^m\partial^i\partial^j A_0 + \frac{5}{3}R_{i00m}x^m\partial^i A_0 + 2R^k{}_{i0m}x^m\partial^i A_k - \frac{2}{3}R_{im}x^m\partial^i A_0 = -j_0 \qquad (917)$$

$$\begin{aligned}&\delta^{ij}\partial_i\partial_j A_k + \frac{1}{3}R_{i\ell jm}x^\ell x^m\partial^i\partial^j A_k + \frac{2}{3}\delta^{ij}\left(R^\alpha{}_{kim} + R^\alpha{}_{ikm}\right)x^m\partial_j A_\alpha - \frac{2}{3}R^\sigma{}_k A_\sigma - \frac{1}{3}R^p{}_{00k}A_p \\ &-\frac{1}{3}R_{i00m}x^m\partial^i A_k - \frac{2}{3}R_{pm}x^m\partial^p A_k = j_k. \qquad (918)\end{aligned}$$

For a one electron atom with a nucleus of charge Ze, one can take

$$j^0 = -Ze\,\delta(\boldsymbol{r}), \quad j^k = 0. \qquad (919)$$

In what follows, we determine the vector perturbatively in the curvature. At zeroth order, in flat space-time, the equation for the time component reduces to

$$\delta^{ij}\partial_i\partial_j A_0 = Ze\,\delta(\boldsymbol{r}), \qquad (920)$$

whose solution is of course

$$A_0^{(0)} = -\frac{Ze}{4\pi}\frac{1}{r}. \qquad (921)$$

Then, we write $A_0 = A_0^{(0)} + \delta A_0$, where δA_0 is first order in the curvature. By inserting this expression into the full equation (917) and using the zeroth order solution (921), one arrives at [106]

$$\delta^{ij}\partial_i\partial_j\delta A_0 + \frac{1}{3}\frac{Ze}{4\pi r^3}\left(3R^0{}_{\ell 0m} - R_{\ell m}\right)x^\ell x^m = 0. \qquad (922)$$

The solution of the above equation reads [106]

$$\begin{aligned}\delta A_0 &= \frac{1}{12}\frac{Ze}{4\pi}\left(R + 4R_{00}\right)r \\ &\quad +\frac{1}{12}\frac{Ze}{4\pi}\left(3R^0{}_{\ell 0m} - R_{\ell m}\right)\frac{x^\ell x^m}{r}. \qquad (923)\end{aligned}$$

In the same manner, one can determine the space component. Obviously, at zeroth order, one has $A_k^{(0)} = 0$. The first order perturbation δA_k obeys the equation [106]

$$\delta^{ij}\partial_i\partial_j\delta A_k + \frac{2}{3}\frac{Ze}{4\pi}R^0{}_k\frac{1}{r} + \frac{2}{3}\frac{Ze}{4\pi}R^0{}_{ikm}\frac{x^i x^m}{r^3} = 0, \qquad (924)$$

whose solution can be written as [106]

$$\delta A_k = \frac{1}{2}\frac{Ze}{4\pi}R_{0k}r + \frac{1}{6}\frac{Ze}{4\pi}R^0{}_{lkm}\frac{x^\ell x^m}{r}. \tag{925}$$

This completes our calculation of the electromagnetic field.

Having determined the vierbeins fields (*i.e.* the quantities describing the gravitational force) and the gauge field (*i.e.* the quantity describing the electromagnetic force), we are now in a position where we can calculate the Hamiltonian (903). In order to make contact with the usual treatment of the Hydrogen atom, it is more convenient to introduce the standard Dirac matrices α_i and β related to the flat space-time Dirac matrices by

$$\gamma_0 = i\beta, \quad \gamma_i = -i\beta\alpha_i. \tag{926}$$

As is well-known, they satisfy

$$\alpha_i\alpha_j + \alpha_j\alpha_i = 2\delta_{ij}, \tag{927}$$

$$\alpha_i\beta + \beta\alpha_i = 0, \quad \beta^2 = 1. \tag{928}$$

Then, we use the expressions of the spinorial connections (913), of the gauge field (921), (925) and of the Dirac matrices in the equation (903) of the Hamiltonian. This leads to the following expression

$$\begin{aligned} H &= -i\alpha^i\partial_i + m\beta - \frac{\zeta}{r} - \frac{i}{2}R_{0\ell 0m}x^\ell x^m\alpha_i\partial^i - \frac{i}{6}R_{i\ell jm}x^\ell x^m\alpha^j\partial^i - \frac{i}{6}R_{0\ell jm}x^\ell x^m\alpha^j\alpha^i\partial_i - \frac{i}{2}R_{0\ell im}x^\ell x^m\partial^i \\ &+\frac{i}{8}\alpha^i\alpha^j\alpha^k R_{jkim}x^m + \frac{i}{4}\alpha^i\alpha^j R_{0jmi}x^m + \frac{i}{4}\alpha^i\alpha^j R_{0mij}x^m - \frac{i}{2}\alpha^j R_{0j0m}x^m + \frac{1}{6}\zeta R_{0\ell mi}x^\ell x^m\frac{\alpha^i}{r} + \frac{1}{2}\zeta R_{0i}\alpha^i r \\ &+\frac{1}{12}\zeta\left(R + 4R_{00}\right)r - \frac{1}{12}\zeta\left(R_{\ell m} + 3R_{0\ell 0m}\right)\frac{x^\ell x^m}{r} - \frac{m}{6}R_{i\ell 0m}x^\ell x^m\beta\alpha^i + \frac{m}{2}R_{0\ell 0m}x^\ell x^m\beta. \end{aligned} \tag{929}$$

In this expression we have defined $\zeta \equiv Ze^2/(4\pi)$ and we have taken $q = -e$. The three first terms are the usual Dirac Hamiltonian. The other terms represent the correction due to space-time curvature. Since the above expression is quite complicated, it is interesting to estimate the order of magnitude of each term. The curvature is given by D^{-2} where D is a typical distance. Each x^i is typically of the order of the Bohr radius, *i.e.* $x^i \simeq a_0 \simeq m^{-1}e^{-2} \simeq m^{-1}\zeta^{-1}$. As a consequence, ∂_i is of order $m\zeta$. This also means that the typical velocity is given by $m\zeta/m \simeq \zeta$. Of course the matrices α^i and β are dimensionless but, in the non relativistic limit $\alpha^i\partial_i$ must reduce to $\simeq mv^2$ which implies that $\alpha^i \simeq v \simeq \zeta$. In the following we consider that $\zeta = Z\alpha$ where α is the fine structure constant is a small number. Then, the dominant term in the above expression is the last one, which means that the Hamiltonian can be approximated as

$$\begin{aligned} H &= H_0 + H_{\rm int} \simeq \boldsymbol{\alpha}\cdot\boldsymbol{p} + m\beta - \frac{\zeta}{r} \\ &+\frac{1}{2}mR_{0\ell 0m}x^\ell x^m\beta, \end{aligned} \tag{930}$$

where we have used $p_i = -i\partial_i$. If we use the following representation for the Dirac matrices

$$\alpha^i = \begin{pmatrix} 0 & \sigma^i \\ \sigma^i & 0 \end{pmatrix}, \quad \beta = \begin{pmatrix} \mathbb{I}_2 & 0 \\ 0 & -\mathbb{I}_2, \end{pmatrix} \tag{931}$$

and write the Dirac spinor as

$$\Psi = \mathrm{e}^{iEx^0}\begin{pmatrix}\phi \\ \chi\end{pmatrix}, \tag{932}$$

then the Dirac equation reduces to two equations that can be expressed as

$$\boldsymbol{\alpha}\cdot\boldsymbol{p}\,\chi + \left(m - \frac{\zeta}{r} + \frac{1}{2}mR_{0\ell 0m}x^\ell x^m\right)\phi = E\phi, \tag{933}$$

$$\boldsymbol{\alpha}\cdot\boldsymbol{p}\,\phi - \left(m + \frac{\zeta}{r} + \frac{1}{2}mR_{0\ell 0m}x^\ell x^m\right)\chi = E\chi. \tag{934}$$

From the second relation we can express χ in terms of $\boldsymbol{\alpha}\cdot\boldsymbol{p}\,\phi$ and then we can insert this expression into the first equation. This leads to

$$\left(E+m+\frac{\zeta}{r}+\frac{1}{2}mR_{0\ell 0m}x^\ell x^m\right)^{-1}(\boldsymbol{\alpha}\cdot\boldsymbol{p})^2\,\phi+\left(m-\frac{\zeta}{r}+\frac{1}{2}mR_{0\ell 0m}x^\ell x^m\right)\phi \;=\; E\phi \tag{935}$$

or, using $\boldsymbol{\alpha}\cdot\boldsymbol{p}\,\phi=p^2\,\phi$ and expanding the denominator of the first term in the above equation

$$\left[1-\frac{1}{E+m}\frac{\zeta}{r}-\frac{m}{2(E+m)}R_{0\ell 0m}x^\ell x^m\right]\frac{p^2}{E+m}\phi-\left(\frac{\zeta}{r}-\frac{1}{2}mR_{0\ell 0m}x^\ell x^m\right)\phi \;=\; (E-m)\phi. \tag{936}$$

But, if we now perform an additional expansion assuming non-relativistic velocities for the electron (which, in practice, is a good approximation), one arrives at the following expression for the term $p^2/(E+m)$

$$\frac{p^2}{E+m}=\frac{p}{m+m+p^2/(2m)+\cdots}\simeq\frac{p^2}{2m}+\cdots \tag{937}$$

As a consequence, we conclude that the non relativistic limit is given by

$$H_{\rm NR}\phi=(E-m)\phi, \tag{938}$$

where the non-relativistic Hamiltonian can be written as [106]

$$\begin{aligned}H_{\rm NR} &= H_0+H_{\rm int}=\frac{p^2}{2m}-\frac{\zeta}{r}\\ &\quad+\frac{1}{2}mR_{0\ell 0m}x^\ell x^m\beta.\end{aligned} \tag{939}$$

This is our final result. Endowed with this equation, one can calculate, by means of perturbations theory, the modification of the ground state due to the presence of a cosmological constant. This leads to (the arguments of E indicates the value of the quantum numbers n and ℓ)

$$\Delta E(1,0) \;=\; \frac{1}{2}mR_{0\ell 0m}\left\langle 1s\left|x^\ell x^m\right|1s\right\rangle \tag{940}$$

$$\;=\; \frac{1}{2}mR_{0\ell 0m}\frac{1}{3}\delta^{\ell m}\left\langle 1s\left|r^2\right|1s\right\rangle \tag{941}$$

$$\;=\; \frac{1}{6}mR_{00}\left\langle 1s\left|r^2\right|1s\right\rangle \tag{942}$$

The ground state wave function is given by (at this order of perturbations theory, there is no need to take into account the modification on the wave-function; one can use the standard one)

$$|1s\rangle=\frac{1}{\sqrt{\pi a_0^3}}\mathrm{e}^{-r/a_0}, \tag{943}$$

where we recall that a_0 is the Bohr radius. This implies that

$$\left\langle 1s\left|r^2\right|1s\right\rangle=\frac{4\pi}{\pi a_0^3}\int_0^\infty r^4\mathrm{e}^{-r/a_0}\mathrm{d}r=\frac{4\pi}{\pi a_0^3}\frac{3a_0^5}{4}=3a_0^2. \tag{944}$$

The vacuum Einstein equations are, see Eq. (846), $R_{\mu\nu}=\Lambda_{\rm eff}g_{\mu\nu}$ and, therefore, at first order in the cosmological constant one $R_{00}=-\Lambda_{\rm eff}$ (here, of course, we only compute the corrections due to the cosmological constant and not those originating from the Earth gravitational field). This means that

$$\Delta E(1,0) \;=\; -\frac{1}{2}mc^2\Lambda_{\rm eff}a_0^2, \tag{945}$$

where we have re-established the speed of light for convenience. In fact, this result could have been anticipated from the Newtonian approach. Indeed, we have seen that the Newtonian potential, in presence of a cosmological constant, is given by $-\Lambda_{\text{eff}}mc^2r^2/6$, see Eqs. (856) and (857). Using the perturbation theory with this potential exactly leads Eq. (945). Let us now evaluate the correction. Using that the reduced mass of the atom is essentially the electron mass, $m \simeq 9.1 \times 10^{-31}\,\text{kg}$ and that the Bohr radius is $a_0 = 0.52 \times 10^{-10}\,\text{m}$, one obtains

$$\Delta E(1,0) = -6 \times 10^{-69} h^2 \left(\frac{\Lambda}{\Lambda_{\text{obs}}}\right) \text{eV}, \tag{946}$$

a quantity completely unobservable, probably for ever. For comparison the Lamb shift is of the order $10^{-6}\,\text{eV}$. At this stage this does not come as a surprise. As discussed in the case of planet orbits, the size of the system is so small that the influence of the cosmological constant is negligible. However, requiring that the shift due to the cosmological constant be smaller than the Lamb shift leads to

$$\rho_{\text{vac}} \lesssim 1.6 \times 10^{62} \rho_{\text{cri}} \simeq 1.3 \times 10^{16} \text{GeV}^4. \tag{947}$$

This result is less good than the one obtained from planet motion by about 50 orders of magnitude. Moreover, the theoretical expectation (812) satisfies this inequality. Let us notice in passing that the result based on the wrong regularization scheme, $\rho_{\text{vac}} \simeq M_{\text{Pl}}^4$ does not satisfy the previous bound.

We now have a clearer view of what the cosmological constant problem is. On one hand, one can calculate the vacuum energy density by means of, apparently, well known techniques of regularization. These techniques usually lead very robust results, fully consistent with the observations. For instance, the radiative corrections to the calculation of cross-sections have proven in very good agreement with various high energy physics experiments. One the other hand, various observational results (and not only in cosmology) indicate that the previous calculation is not correct. The theoretical expectation value for the vacuum energy density is so large that it should have already be seen by many experiences. Moreover, in cosmology, under a certain number of hypothesis, one even measures ρ_{vac} which is found to be many orders of magnitude smaller than the number derived from the theory. Since, as mentioned before, the theoretical framework seems to be robust (let us recall again that it involves calculations that can be found in the first pages of any textbook on quantum field theory) and since the observations seem to be convincing, we are facing a genuine mystery. However, before accepting this conclusion, it is worth checking that no loophole is present in the previous reasoning. This will be the goal of the next sections. A first question that can be asked is whether the zero-point fluctuations that are at the origin of the problem are a real physical phenomenon or just an artifact of the formalism of quantum field theory. We turn to this issue in the next section.

24.12 Do the Vacuum Fluctuations Really Exist?

We have seen in the previous sections that the zero-point fluctuations manifest themselves as the vacuum energy. Since this leads to conclusions that seem to be in contradiction with observations, it is legitimate to ask whether these fluctuations really exist in Nature. In particular, we want to investigate whether the zero-point fluctuations could manifest themselves in other physical phenomena. The answer to this question is usually positive and one experiment which is considered as a proof that the vacuum fluctuations are real is the measurement of the Lamb shift [112, 18]. In the next sub-section, we discuss this phenomenon.

24.12.1 The Lamb Shift

Let us consider the "motion" of an electron in an atom. Its "location" is described by the vector $\boldsymbol{r}$. The vector $\boldsymbol{r}$ is going to fluctuate because of the interaction between the electron and the zero-point fluctuations of the electromagnetic field. This interaction will slightly modify the position of the atomic levels leading to the Lamb shift. Let us study in details how this effect can be derived. Let $V(\boldsymbol{r})$ be the Coulomb potential which determines the properties of the atom. At the point $\boldsymbol{r} + \delta\boldsymbol{r}$, the potential can be Taylor expanded according to

$$V(\boldsymbol{r} + \delta\boldsymbol{r}) = V(\boldsymbol{r}) + \frac{\partial V}{\partial x_i}\delta x_i + \frac{1}{2}\frac{\partial^2 V}{\partial x_i \partial x_j}\delta x_i \delta x_j + \cdots. \tag{948}$$

Then, if we time average the previous expression, one obtains

$$\langle V(\boldsymbol{r}+\delta\boldsymbol{r})\rangle \simeq V(\boldsymbol{r}) + \frac{\partial V}{\partial x_i}\langle \delta x_i\rangle + \frac{1}{2}\frac{\partial^2 V}{\partial x_i \partial x_j}\langle \delta x_i \delta x_j\rangle + \cdots, \tag{949}$$

and, because the problem is spherically symmetric, we have $\langle \delta x_i\rangle = 0$ and $\langle \delta x_i \delta x_j\rangle = \langle \delta r^2\rangle \delta_{ij}/3$. The first term in Eq. (949) is the unperturbed Coulomb potential and the last one (since the second one vanishes) can be viewed as a small perturbation of the Hamiltonian, namely

$$\Delta H = \frac{1}{6}\frac{\partial^2 V}{\partial x_i \partial x_j}\left\langle \delta r^2\right\rangle \delta_{ij}. \tag{950}$$

In an atom with atomic number Z, the Coulomb potential is given by

$$V = -\frac{Z\alpha}{r}, \tag{951}$$

where $\alpha \simeq 1/137$ is the fine structure constant. This means that $\delta_{ij}\partial^2 V/(\partial x_i \partial x_j) = 4\pi Z\alpha\delta(\boldsymbol{r})$.

Let now us assume that the atom is placed in the quantum state $|\ell, m\rangle$. As we have already discussed in Sec. 24.11.3, at first order, the time-independent perturbations theory tells us that the correction to the energy of the level (ℓ, m) is given by [57]

$$\Delta E(n,\ell) = \langle \ell, m|\Delta H|\ell, m\rangle. \tag{952}$$

Using Eq. (950), one obtains the following expression for the energy displacement

$$\Delta E(n,\ell) = \frac{2\pi}{3} Z\alpha \left|\Psi_{n\ell}(0)\right|^2 \left\langle \delta r^2\right\rangle, \tag{953}$$

where $\Psi_{n\ell}$ is the wave-function in the corresponding quantum state. Since the wave-function at the origin can be expressed as [57]

$$|\Psi_{n\ell}(0)| = \frac{1}{\pi^{1/2}}\left(\frac{mZ\alpha}{n}\right)^{3/2}\delta_{\ell 0}, \tag{954}$$

where m is the electron mass ($m \simeq 0.511\,\mathrm{MeV}$) one finally arrives at [18]

$$\Delta E(n,\ell) = \frac{(2mZ\alpha)^3}{12}\frac{Z\alpha}{n^3}\left\langle \delta r^2\right\rangle \delta_{\ell 0}. \tag{955}$$

Therefore, we have reduced the problem to the calculation of the quantity $\langle \delta r^2\rangle$. In order to evaluate this quantity, we must now evaluate the displacement of the electron. The electron "moves" under the influence of the electric field within the atom and, as a consequence, δr_i obeys the following equation

$$m\frac{\mathrm{d}^2}{\mathrm{d}t^2}\delta r_i = eE_i, \tag{956}$$

where $E_\mu \equiv u^\nu F_{\mu\nu} = -\dot{A}_i$ is the electric field (or, rather, its vacuum fluctuating component). Using the usual expansion of the vector potential in terms of creation and annihilation operators, see Eq. (691), one can write

$$\begin{aligned} E_i(t,\boldsymbol{x}) &= \frac{-1}{(2\pi)^{3/2}}\int \frac{\mathrm{d}\boldsymbol{k}}{\sqrt{2\omega(k)}}\sum_{\alpha=1}^{2}\epsilon_i^\alpha(\boldsymbol{k}) \\ &\times \left[-i\omega a_{\boldsymbol{k}}^\alpha \mathrm{e}^{-i\omega t + i\boldsymbol{k}\cdot\boldsymbol{x}} + i\omega\left(a_{\boldsymbol{k}}^\alpha\right)^\dagger \mathrm{e}^{i\omega t - i\boldsymbol{k}\cdot\boldsymbol{x}}\right], \end{aligned} \tag{957}$$

In the same manner, one has to Fourier expand δr_i which is considered as an operator in this context. One obtains

$$\begin{aligned}\delta r_i\,(t,\boldsymbol{x}) &= \frac{1}{(2\pi)^{3/2}}\int \mathrm{d}\boldsymbol{k}\sum_{\alpha=1}^{2}\epsilon_i^{\alpha}(\boldsymbol{k})\Big[\delta r(\boldsymbol{k},t)a_{\boldsymbol{k}}^{\alpha}\mathrm{e}^{i\boldsymbol{k}\cdot\boldsymbol{x}}\\ &\quad +\delta r^{*}(\boldsymbol{k},t)\,(a_{\boldsymbol{k}}^{\alpha})^{\dagger}\,\mathrm{e}^{-i\boldsymbol{k}\cdot\boldsymbol{x}}\Big].\end{aligned} \tag{958}$$

The Fourier amplitude of the displacement operator can be calculated from the equation of motion (956). This leads to the following expression

$$\delta r(\boldsymbol{k},t)=\frac{e}{m}\frac{1}{\sqrt{2\omega^3}}\mathrm{e}^{-i\omega t}. \tag{959}$$

From this expression, one can now evaluate the quantity $\langle\delta r^2\rangle$. One finds

$$\begin{aligned}\left\langle\delta r^2\right\rangle &= \left\langle 0\left|\delta^{ij}\delta r_i\delta r_j\right|0\right\rangle\\ &= \frac{1}{(2\pi)^3}\int \mathrm{d}\boldsymbol{k}\sum_{\alpha=1}^{2}\delta^{ij}\epsilon_i^{\alpha}\epsilon_j^{\alpha}\delta r(\boldsymbol{k},t)\delta r^{*}(\boldsymbol{k},t)\end{aligned} \tag{960}$$

$$= \frac{2\alpha}{m^2\pi}\int_0^{\infty}\frac{\mathrm{d}\omega}{\omega}, \tag{961}$$

where we have used $\alpha=e^2/(4\pi)$. Therefore, inserting the above formula into Eq. (955), one obtains the following equation for the energy shift [18]

$$\Delta E(n,\ell)=\frac{4mZ^4\alpha^5}{3\pi n^3}\int_0^{\infty}\frac{\mathrm{d}\omega}{\omega}\delta_{\ell 0}. \tag{962}$$

This equation is the main result of this section. It gives the energy levels displacement due to the presence of the electromagnetic zero-point fluctuations.

As usual this expression is divergent and needs to be regularized. In a simplified treatment, one simply assumes, see Ref. [18], that the wavelengths in the above sum must be larger than the Compton wavelength of the electron, which implies $\omega<\omega_{\max}\simeq m$ and that $\omega>\omega_{\min}\simeq 1/a_0\simeq 1/[1/(\alpha m)]\simeq m\alpha$, where a_0 is the Bohr radius. In this case, the previous results reduces to

$$\Delta E(n,\ell)\simeq\frac{4mZ^4\alpha^5}{3\pi n^3}\ln\left(\frac{1}{\alpha}\right)\delta_{\ell 0}. \tag{963}$$

Let us now evaluate this quantity for the Hydrogen atom. Clearly, there is no effect for $n=1$. But for $n=2$ and $\ell=0$, one has

$$\Delta E(2,0)\simeq\frac{4m\alpha^5}{3\pi 8}\ln\left(\frac{1}{\alpha}\right)\delta_{\ell 0}\simeq 668\,\mathrm{MHz}, \tag{964}$$

where we have used $m\simeq 0.511\mathrm{MeV}=h\nu$ with $h=4.135\times 10^{-15}\mathrm{eV}\times\mathrm{s}$.

This shift has been experimentally observed and is usually taken as a proof that the zero point fluctuations are real since they lead to an observed physical phenomenon. Based on this result, it now seems difficult to argue that the zero-point fluctuations are just an artifact of the formalism of quantum field theory. Moreover, there exists another experiment, the Casimir effect, where the effects of the vacuum fluctuations can be observed. In the next section, we investigate this case.

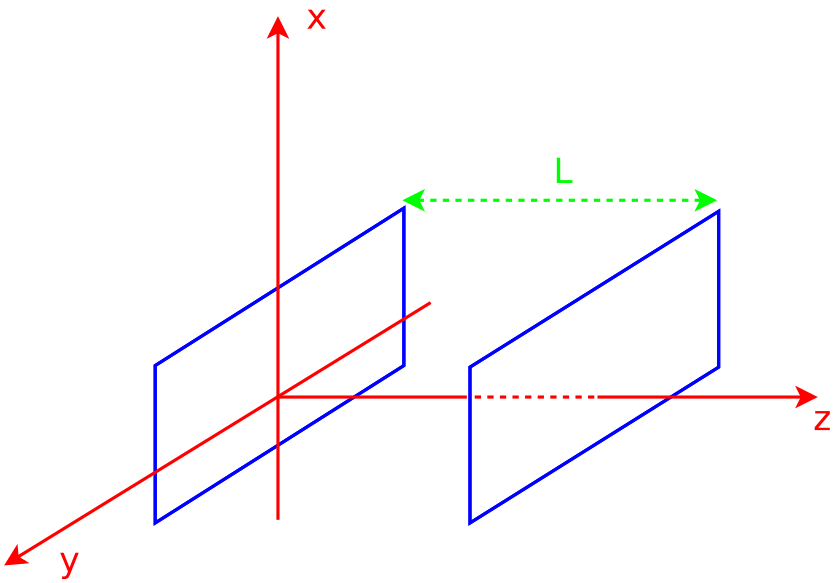

Figure 160: Sketch of a Casimir cavity of width L.

24.12.2 The Casimir Effect

In this section, we study the Casimir effect [113, 114, 115, 116, 117, 118, 119]. Since its discovery, this effect has been studied in great details and it is clear that, here, one cannot review all the literature. We will give a description of this phenomenon in a simplified context only and will refer to Refs. [113, 114, 115] for readers interested in learning more about this interesting subject.

The Casimir Force

Let us consider an experimental situation where we have two conducting plates in the (x, y) plane separated by a distance L long the z direction, see Fig. 160. For simplicity, instead of considering the electromagnetic field in the cavity (which is the case in the real world, especially when measurements are performed), we will just treat the case of a real massive scalar field $\Phi(t, \boldsymbol{x})$. This field obeys the Klein-Gordon equation already studied and solved before, see Eq. (356), except that now the boundary conditions are modified by the presence of the two plates. Let us write $\Phi(t, \boldsymbol{x}) = X(x)Y(y)Z(z)T(t)$. Then, inserting this anzatz into the Klein-Gordon equation, one obtains

$$-\frac{\ddot{T}}{T} + \frac{1}{X}\frac{\mathrm{d}^2X}{\mathrm{d}x^2} + \frac{1}{Y}\frac{\mathrm{d}^2Y}{\mathrm{d}y^2} + \frac{1}{Z}\frac{\mathrm{d}^2Z}{\mathrm{d}z^2} - m^2 = 0, \tag{965}$$

where m is the mass of the scalar particle. Clearly, one can separate the variables and, as a consequence, the above equation can be split into four differential equations, namely

$$-\frac{\ddot{T}}{T} - m^2 = C^2 \tag{966}$$

$$\frac{1}{X}\frac{\mathrm{d}^2X}{\mathrm{d}x^2} = k_x^2 \tag{967}$$

$$\frac{1}{Y}\frac{\mathrm{d}^2Y}{\mathrm{d}y^2} = k_y^2 \tag{968}$$

$$\frac{1}{Z}\frac{\mathrm{d}^2Z}{\mathrm{d}z^2} = k_z^2, \tag{969}$$

where the constants C, k_x, k_y and k_z are related by

$$C - k_x^2 - k_y^2 - k_z^2 = 0. \tag{970}$$

The solution in the x and y direction can be expressed in terms of standard plane waves, $X(x) = A_x \mathrm{e}^{ik_x x} + B_x \mathrm{e}^{-ik_x x}$ and $Y(y) = A_y \mathrm{e}^{ik_y y} + B_y \mathrm{e}^{-ik_y y}$. The quantities $A_{x,y}$ and $B_{x,y}$ are just integration constants. Of particular interest is of course the solution along the z-axis. It can also be written as

$$Z(z) = A_z \mathrm{e}^{ik_z z} + B_z \mathrm{e}^{-ik_z z}, \tag{971}$$

where A_z and B_z are two integration constants. But the difference with the case of a free field is that the boundary conditions "feel" the presence of the two plates. These boundary conditions are given by $Z(0) = 0$ and $Z(L) = 0$. The first one implies that $A_z = -B_z$ while the second one gives

$$2i \sin\left(k_z L\right) = 0, \tag{972}$$

or, equivalently,

$$k_z = n\frac{\pi}{L}, \tag{973}$$

where n is an integer. Finally, the equation for the function $T(t)$ can also be easily solved and the solution reads

$$T(t) = A_t \mathrm{e}^{i\omega t} + B_t \mathrm{e}^{-i\omega t}, \tag{974}$$

where $\omega^2 = C^2 + m^2$. Therefore, upon using Eq. (970), the frequency ω takes the form

$$\omega = \sqrt{k_x^2 + k_y^2 + n^2\frac{\pi^2}{L^2} + m^2}. \tag{975}$$

In this expression, k_x and k_y take continuous values.

Based on the previous considerations, one can now write the field operator as an expansion in terms of creation and annihilation operators. But this expansion encodes the fact that, along the z-axis, the wave-number is discrete. Concretely, we have

$$\Phi(t,\boldsymbol{x}) = \int \frac{\mathrm{d}k_x}{(2\pi)^{1/2}} \int \frac{\mathrm{d}k_y}{(2\pi)^{1/2}} \sum_{n=1}^{\infty} \sqrt{\frac{2}{L}} \frac{1}{\sqrt{2\omega}} \sin\left(n\frac{\pi}{L}z\right) \left(c_{k_x,k_y,n} \mathrm{e}^{-i\omega t + ik_x x + ik_y y} + c^{\dagger}_{k_x,k_y,n} \mathrm{e}^{i\omega t - ik_x x - ik_y y}\right). \tag{976}$$

The operators $c_{k_x,k_y,n}$ and $c^{\dagger}_{k_x,k_y,n}$ obey the usual commutation relations for bosons. It is interesting to check that the above expansion is indeed consistent with the commutation relations between the field and its conjugate momentum. For this purpose, let us compute the following quantity

$$\begin{aligned}\int \mathrm{d}x \int \mathrm{d}y \int_0^L \mathrm{d}z\, \Phi\, \mathrm{e}^{-ip_x x - ip_y y} \sin\left(m\frac{\pi}{L}z\right) &= \int \frac{\mathrm{d}k_x}{(2\pi)^{1/2}} \int \frac{\mathrm{d}k_y}{(2\pi)^{1/2}} \sum_{n=1}^{\infty} \int \mathrm{d}x \int \mathrm{d}y \sqrt{\frac{2}{L}} \frac{1}{\sqrt{2\omega}} \Big(c_{k_x,k_y,n} \mathrm{e}^{-i\omega t + ik_x x + ik_y y} \\ &\quad + c^{\dagger}_{k_x,k_y,n} \mathrm{e}^{i\omega t - ik_x x - ik_y y}\Big) \mathrm{e}^{-ip_x x - p_y y} \int_0^L \mathrm{d}z \sin\left(m\frac{\pi}{L}z\right) \sin\left(n\frac{\pi}{L}z\right). \end{aligned} \tag{977}$$

Using the fact that $\int_0^L \mathrm{d}z \sin(n\pi z/L)\sin(m\pi z/L) = (L/2)\delta_{mn}$ (as can be checked directly) and $\int \mathrm{d}x \mathrm{e}^{i(k_x - p_x)x} = (2\pi)\delta(k_x - p_x)$ one arrives at

$$\int \mathrm{d}x \int \mathrm{d}y \int_0^L \mathrm{d}z\, \Phi(t,\boldsymbol{x})\, \mathrm{e}^{-ip_x x - ip_y y} \sin\left(m\frac{\pi}{L}z\right) = \frac{2\pi}{2}\sqrt{\frac{L}{\omega}} \Big(c_{p_x,p_y,m} \mathrm{e}^{-i\omega t} + c^{\dagger}_{-p_x,-p_y,m} \mathrm{e}^{i\omega t}\Big). \tag{978}$$

In the same manner, one can also evaluate the following integral involving the conjugate momentum $\Pi(t,\boldsymbol{x}) = \dot{\Phi}(t,\boldsymbol{x})$ (a dot means a derivative with respect to time)

$$\int \mathrm{d}x \int \mathrm{d}y \int_0^L \mathrm{d}z\, \Pi(t,\boldsymbol{x})\, \mathrm{e}^{-ip_x x - ip_y y} \sin\left(m\frac{\pi}{L}z\right) = \frac{2\pi}{2} i\omega \sqrt{\frac{L}{\omega}} \Big(-c_{p_x,p_y,m} \mathrm{e}^{-i\omega t} + c^{\dagger}_{-p_x,-p_y,m} \mathrm{e}^{i\omega t}\Big) \tag{979}$$

From the two above expression, one can deduce a formula expressing the creation and the annihilation operators in terms of the field operator and its conjugate momentum. One obtains

$$c_{p_x,p_y,m} = \sqrt{\frac{\omega}{L}}\frac{\mathrm{e}^{i\omega t}}{2\pi}\left[\int \mathrm{d}x\mathrm{d}y \int_0^L \mathrm{d}z\, \Phi\, \mathrm{e}^{-ip_x x - ip_y y}\sin\left(m\frac{\pi}{L}z\right) + \frac{i}{\omega}\int \mathrm{d}x\mathrm{d}y \int_0^L \mathrm{d}z\, \Pi\, \mathrm{e}^{-ip_x x - ip_y y}\sin\left(m\frac{\pi}{L}z\right)\right],$$

$$c^\dagger_{p_x,p_y,m} = \sqrt{\frac{\omega}{L}}\frac{\mathrm{e}^{-i\omega t}}{2\pi}\left[\int \mathrm{d}x\mathrm{d}y \int_0^L \mathrm{d}z\, \Phi\, \mathrm{e}^{ip_x x + ip_y y}\sin\left(m\frac{\pi}{L}z\right) - \frac{i}{\omega}\int \mathrm{d}x\mathrm{d}y \int_0^L \mathrm{d}z\, \Pi\, \mathrm{e}^{ip_x x + ip_y y}\sin\left(m\frac{\pi}{L}z\right)\right].$$

We are now in a position where we can compute the commutator of a creation and an annihilation operators. It can be written as

$$\begin{aligned}\left[c_{p_x,p_y,n}, c^\dagger_{q_x,q_y,m}\right] = \frac{\mathrm{e}^{i(\omega_p-\omega_q)t}}{(2\pi)^2}\frac{\sqrt{\omega_p\omega_q}}{L}\int \mathrm{d}x\mathrm{d}y \int_0^L \mathrm{d}z \int \mathrm{d}\overline{x}\mathrm{d}\overline{y} \int_0^L \mathrm{d}\overline{z}\Bigg[&\Phi(t,\boldsymbol{x})\,\mathrm{e}^{-ip_x x - ip_y y}\sin\left(n\frac{\pi}{L}z\right)\\ &+\frac{i}{\omega_p}\Pi(t,\boldsymbol{x})\,\mathrm{e}^{-ip_x x - ip_y y}\sin\left(n\frac{\pi}{L}z\right), \Phi(t,\overline{\boldsymbol{x}})\,\mathrm{e}^{iq_x\overline{x}+iq_y\overline{y}}\sin\left(m\frac{\pi}{L}\overline{z}\right)\\ &-\frac{i}{\omega_q}\Pi(t,\overline{\boldsymbol{x}})\,\mathrm{e}^{iq_x\overline{x}+iq_y\overline{y}}\sin\left(m\frac{\pi}{L}\overline{z}\right)\Bigg].\end{aligned} \tag{980}$$

Then, we make use of the canonical relation $[\Phi(t,\boldsymbol{x}),\Pi(t,\boldsymbol{y})] = i\delta^3(\boldsymbol{x}-\boldsymbol{y})$ in the previous formula. This leads to the following complicated expression

$$\begin{aligned}\left[c_{p_x,p_y,n}, c^\dagger_{q_x,q_y,m}\right] &= \frac{\mathrm{e}^{i(\omega_p-\omega_q)t}}{(2\pi)^2}\frac{\sqrt{\omega_p\omega_q}}{L}\int \mathrm{d}x\mathrm{d}y \int_0^L \mathrm{d}z \int \mathrm{d}\overline{x}\mathrm{d}\overline{y} \int_0^L \mathrm{d}\overline{z}\Bigg\{-\frac{i}{\omega_q}\mathrm{e}^{-ip_x x - ip_y y + iq_x\overline{x}+iq_y\overline{y}}\sin\left(n\frac{\pi}{L}z\right)\\ &\times\sin\left(m\frac{\pi}{L}\overline{z}\right)[\Phi(t,\boldsymbol{x}),\Pi(t,\bar{\boldsymbol{x}})] + \frac{i}{\omega_p}\mathrm{e}^{-ip_x x - ip_y y + iq_x\overline{x}+iq_y\overline{y}}\sin\left(n\frac{\pi}{L}z\right)\sin\left(m\frac{\pi}{L}\overline{z}\right)\\ &\times[\Pi(t,\boldsymbol{x}),\Phi(t,\overline{\boldsymbol{x}})]\Bigg\}\end{aligned} \tag{981}$$

$$\begin{aligned}&= \frac{\mathrm{e}^{i(\omega_p-\omega_q)t}}{(2\pi)^2}\frac{\sqrt{\omega_p\omega_q}}{L}\left(\frac{1}{\omega_q}+\frac{1}{\omega_p}\right)\int \mathrm{d}x\mathrm{d}y \int_0^L \mathrm{d}z\mathrm{e}^{-i(p_x-q_x)x - i(p_y-q_y)y}\sin\left(n\frac{\pi}{L}z\right)\sin\left(m\frac{\pi}{L}z\right)\\ &= \frac{\omega}{L}\frac{2}{\omega}\delta(p_x-q_x)\delta(p_y-q_y)\frac{L}{2}\delta_{mn} = \delta(p_x-q_x)\delta(p_y-q_y)\delta_{mn}.\end{aligned} \tag{982}$$

We have thus reached our goal, namely we have shown that the canonical commutation relation between the field and its conjugate momentum implies the usual commutation relation between the creation and the annihilation operator.

We are now in a position where we can evaluate the energy density of the field in the Casimir cavity. It is of course given by the same expression as in the free case, see Eq. (363). This means that one should first calculate the three terms that participate in the expression of T_{00}, see Eqs. (360), (361) and (362). Let us start with $\langle 0|\dot{\Phi}^2|0\rangle$. Using the Fourier expansion of the field and the commutation relations established above, one obtains

$$\begin{aligned}\langle 0|\dot{\Phi}^2|0\rangle &= \int\frac{\mathrm{d}k_x}{2\pi}\int\frac{\mathrm{d}k_y}{2\pi}\sum_{n=1}^{\infty}\frac{2}{L}\frac{\omega^2}{2\omega}\\ &\times\sin^2\left(n\frac{\pi}{L}z\right),\end{aligned} \tag{983}$$

and, if we integrate over the cavity volume

$$\int_{\text{Cavity}} \mathrm{d}\boldsymbol{x}\,\langle 0|\dot{\Phi}^2|0\rangle = \frac{D^2}{2}\int\frac{\mathrm{d}k_x}{2\pi}\int\frac{\mathrm{d}k_y}{2\pi}\sum_{n=1}^{\infty}\omega, \tag{984}$$

where D^2 is the area of the plates (of course, the two parallel plates have the same surface). In the same manner, one finds

$$\int\limits_{\text{Cavity}} \mathrm{d}\boldsymbol{x}\, \langle 0|\delta^{ij}\partial_i\Phi\partial_j\Phi|0\rangle = \frac{D^2}{2}\int\frac{\mathrm{d}k_x}{2\pi}\int\frac{\mathrm{d}k_y}{2\pi} \times \sum_{n=1}^{\infty}\frac{1}{2\omega}\left(k_x^2+k_y^2+n^2\frac{\pi^2}{L^2}\right). \tag{985}$$

Finally, the last relevant term reads

$$\int\limits_{\text{Cavity}} \mathrm{d}\boldsymbol{x}\, \langle 0|\Phi^2|0\rangle = \frac{D^2}{2}\int\frac{\mathrm{d}k_x}{2\pi}\int\frac{\mathrm{d}k_y}{2\pi}\sum_{n=1}^{\infty}\frac{1}{2\omega}. \tag{986}$$

Putting everything together and using the definition (363), the expression of the energy of the field within the empty cavity takes the form

$$\int\limits_{\text{Cavity}} \mathrm{d}\boldsymbol{x}\, \langle 0|T_{00}|0\rangle \tag{987}$$

$$= \left(\frac{D}{2\pi}\right)^2\int\mathrm{d}k_x\int\mathrm{d}k_y\sum_{n=1}^{\infty}\frac{\omega}{2} \tag{988}$$

$$= \left(\frac{D}{2\pi}\right)^2\int\mathrm{d}k_x\int\mathrm{d}k_y\sum_{n=1}^{\infty}\frac{1}{2}\sqrt{k_x^2+k_y^2+n^2\frac{\pi^2}{L^2}+m^2}. \tag{989}$$

Of course, this expression has exactly the expected form. Roughly speaking it can be written as "$\sum\frac{1}{2}\omega$", see Eq. (975), the only difference being that, along the z-axis, the sum takes into account the fact that the momentum is discrete. Another common point with our previous considerations is that the above number is actually divergent and must be regularized. In the following, we assume $m=0$ for simplicity and use dimensional regularization. Therefore, the expression of the energy can now be written as

$$E = \left(\frac{D}{2\pi}\right)^d\int\mathrm{d}^d\boldsymbol{k}_\perp\sum_{n=1}^{\infty}\frac{1}{2}\sqrt{k_\perp^2+n^2\frac{\pi^2}{L^2}} \tag{990}$$

$$= \left(\frac{D}{2\pi}\right)^d\int\mathrm{d}k_\perp k_\perp^{d-1}\mathrm{d}^{d-1}\Omega\sum_{n=1}^{\infty}\frac{1}{2}\sqrt{k_\perp^2+n^2\frac{\pi^2}{L^2}} = \left(\frac{D}{2\pi}\right)^d\frac{2\pi^{d/2}}{\Gamma(d/2)}\int\mathrm{d}k_\perp k_\perp^{d-1}\sum_{n=1}^{\infty}\frac{1}{2}\sqrt{k_\perp^2+n^2\frac{\pi^2}{L^2}} \tag{991}$$

where d is the "dimension" of the plates (*i.e.* $d=2$ in the real world) and $k_\perp$ denotes the wave-vector living in the sub-manifold defined by the plates. Then using the change of variables $y=Lk_\perp/(n\pi)$ and the following definition [48, 49] of the Euler's integral of first kind

$$B(x,y) = 2\int_0^{\infty}\frac{t^{2x-1}}{(1+t^2)^{x+y}}\mathrm{d}t = \frac{\Gamma(x)\Gamma(y)}{\Gamma(x+y)}, \tag{992}$$

the energy can be re-expressed as

$$E = \left(\frac{D}{2\pi}\right)^d\frac{\pi^{d/2}}{2}\left(\frac{\pi}{L}\right)^{d+1}\frac{\Gamma(-d/2-1/2)}{\Gamma(-1/2)}\sum_{n=1}^{\infty}n^{d+1}. \tag{993}$$

The above formula can be expressed in term of the Riemann zeta function defined by the following expression

$$\zeta(s) \equiv \sum_{n=1}^{\infty} n^{-s}. \tag{994}$$

Moreover, upon using the two following equations

$$\zeta(-1-d) = 2^{-1-d}\pi^{-2-d}\sin\left[\frac{\pi}{2}(-1-d)\right] \times\Gamma(2+d)\zeta(2+d), \tag{995}$$

$$\Gamma\left(-\frac{d}{2}-\frac{1}{2}\right)\sin\left[\frac{\pi}{2}(-1-d)\right] = \frac{\pi}{\Gamma(d/2+3/2)}, \tag{996}$$

one can re-write the energy as

$$\frac{E}{D^d} = -\frac{1}{L^{d+1}}\frac{\Gamma(1+d/2)}{2^{d+2}\pi^{d/2+1}}\zeta(2+d). \tag{997}$$

The Casimir force arises because of a shift in the vacuum energy when the plates are present compared to the situation where they are absent. So the relevant quantity is in fact $\Delta E/D^d \equiv (E-E_0)/D^d$ where E_0/D^d is the above quantity in the limit $L \to +\infty$. As a consequence, for $d=2$, one arrives at

$$\frac{\Delta E}{D^2} = -\frac{\pi^2}{1440L^3}, \tag{998}$$

where we have used $\zeta(4) = \pi^4/90$. Therefore, the corresponding force is given by [113, 114, 115, 116]

$$F = -\frac{\partial}{\partial L}\left(\frac{\Delta E}{D^2}\right) = -\frac{\pi^2}{480L^4}, \tag{999}$$

which is one half the result obtained in the case of the electromagnetic field since we have only one state of polarization instead of two. We notice that the force is attractive (this could change in the case of more complicated geometries).

It is also interesting to check that the final result is independent from the regularization scheme used to obtain it. In order to test this idea in the simplest situation (*i.e.* where the calculations are easy), let us consider again the energy of a Casimir cavity but, this time, with $d=0$. In this case, our zeta-function regularized result reads

$$\frac{E}{D^0} = -\frac{1}{L}\frac{\Gamma(1)\zeta(2)}{4\pi} = -\frac{\pi}{24L}, \tag{1000}$$

since $\Gamma(1)=1$ and $\zeta(2)=\pi^2/6$. One the other hand, we can return to the expression of E in Eq. (993). In the case $d=0$, the energy density $\rho(L) = E/L$ reads

$$\rho(L) = \frac{\pi}{2L^2}\sum_{n=1}^{\infty} n. \tag{1001}$$

In order to regularize this divergent quantity, we now proceed differently and introduce an exponential cut-off such that (previously, we argued that introducing a cut-off was not a good method because this breaks Lorentz invariance. Here, of course, this objection is no longer valid as the presence of the two plates along the z-axis obviously breaks translation invariance; as a consequence working with a cut-off seems legitimate in the present context)

$$\rho(L,\alpha) = \frac{\pi}{2L^2}\sum_{n=1}^{\infty} n\,\mathrm{e}^{-n\alpha/L}. \tag{1002}$$

The sum is easy to perform and one obtains

$$\rho(L,\alpha) = \frac{\pi}{8L^2}\sinh^{-2}\left(\frac{\alpha}{2L}\right) \quad (1003)$$

$$\simeq \frac{\pi}{2\alpha^2} - \frac{\pi}{24L^2} + \cdots \quad (1004)$$

Now, the regularized Casimir energy is the shift energy in the vacuum after having sent the cut-off to zero; in other words

$$E = L\lim_{\alpha\to 0}\left[\rho(L,\alpha) - \lim_{L\to\infty}\rho(L,\alpha)\right] \quad (1005)$$

$$= -\frac{\pi}{24L}, \quad (1006)$$

that is to say exactly the same expression obtained with another regularization scheme. It is reassuring to notice that the final result is independent of the regularization method used.

The Casimir Stress-Energy Tensor

In this section, we aim at calculating the stress energy tensor of a scalar field in a Casimir cavity [119, 113, 114, 115, 116]. Our goal is of course to compare this tensor with the vacuum stress-energy tensor $T_{\mu\nu} = -\rho_{\text{vac}} g_{\mu\nu}$. Here, we use a method based on the calculations of the Green function. This is yet another method of calculation of the Casimir effect, different from the two ones exposed before and, therefore, it will be interesting to compare this approach with the treatments used previously.

Let us start with the calculation of the Green function. It obeys the following equation

$$-\eta^{\mu\nu}\partial_\mu\partial_\nu G(x,\overline{x}) = \delta^{(4)}(x^\mu - \overline{x}^\mu). \quad (1007)$$

It is interesting to compare the above formula with Eq. (778). It is clear that this is the same equation but with $g_{\mu\nu} = \eta_{\mu\nu}$ (flat space-time) and $m = 0$ (mass-less field). In order to solve this equation, it is convenient to Fourier transform $G(x,\overline{x})$ in frequency and transverse momentum. Explicitly, one writes

$$G(x,\overline{x}) = \int \frac{\mathrm{d}\omega}{2\pi}\frac{\mathrm{d}\boldsymbol{k}_\perp}{(2\pi)^2}\mathrm{e}^{-i\omega\left(t-\overline{t}\right)+ik_x(x-\overline{x})+ik_y(y-\overline{y})} \times g(z,\overline{z};\omega,k_x,k_y). \quad (1008)$$

Inserting this expression into the Green equation (1007), one obtains

$$-\left(\frac{\mathrm{d}^2}{\mathrm{d}z^2} + \lambda^2\right) g(z,\overline{z}) = \delta(z-\overline{z}), \quad (1009)$$

where we have defined

$$\lambda^2 \equiv \omega^2 - k_\perp^2 = \omega^2 - k_x^2 - k_y^2. \quad (1010)$$

Our goal is now to determine explicitly the Green function. Let us start with the solution within the plates, *i.e.* $0 < z, \overline{z} < L$. When $z \neq \overline{z}$, the solution can be written

$$g(z,\overline{z}) = A(\overline{z})\cos(\lambda z) + B(\overline{z})\sin(\lambda z), \quad (1011)$$

where $A(\overline{z})$ and $B(\overline{z})$ are two unknown function of $\overline{z}$. We must now take into account the boundary conditions. If $z < \overline{z}$, the condition $g(z=0,\overline{z}) = 0$ implies that $A = 0$ and therefore $g = B\sin(\lambda z)$ (for $z < \overline{z}$). On the other hand, if $z > \overline{z}$, the condition $g(z=L,\overline{z}) = 0$ means that

$$g = A\cos(\lambda z) - A\frac{\cos(\lambda L)}{\sin(\lambda L)}\sin(\lambda z), \quad z > \overline{z}. \quad (1012)$$

We have two unknown quantities and, therefore, we need two equations. One is provided by writing the continuity of the Green function when $z = \overline{z}$. The other is obtained by integrating Eq. (1009) from $\overline{z} - \epsilon$ to $\overline{z} + \epsilon$. This gives

$$-\int_{\overline{z}-\epsilon}^{\overline{z}+\epsilon} \frac{\mathrm{d}^2 g}{\mathrm{d}z^2}\mathrm{d}z - \lambda^2 \int_{\overline{z}-\epsilon}^{\overline{z}+\epsilon} g\mathrm{d}z = \int_{\overline{z}-\epsilon}^{\overline{z}+\epsilon} \delta(z-\overline{z})\mathrm{d}z, \tag{1013}$$

which leads to

$$-\left[\frac{\mathrm{d}g}{\mathrm{d}z}(\overline{z}+\epsilon) - \frac{\mathrm{d}g}{\mathrm{d}z}(\overline{z}-\epsilon)\right] = 1. \tag{1014}$$

Therefore, taking the limit $\epsilon \to 0$, the solutions of these two equations (*i.e.* the one expressing the continuity of the Green function and the one we have just derived) read

$$A(\overline{z}) = \frac{1}{\lambda}\sin(\lambda\overline{z}), \tag{1015}$$

$$B(\overline{z}) = \frac{1}{\lambda}\cos(\lambda\overline{z}) - \frac{\cos(\lambda L)}{\sin(\lambda L)}A(\overline{z}). \tag{1016}$$

As a consequence, the Green function between the plates can be expressed as [116]

$$g(z,\overline{z}) = \begin{cases} \dfrac{\sin(\lambda z)\sin(\lambda L - \lambda\overline{z})}{\lambda\sin(\lambda L)}, & z < \overline{z}, \\ \dfrac{\sin(\lambda\overline{z})\sin(\lambda L - \lambda z)}{\lambda\sin(\lambda L)}, & z > \overline{z}. \end{cases} \tag{1017}$$

The same method can be used to determine the Green function outside the cavity. Let us apply it for z and $\overline{z}$ larger than L, *i.e.* on the right hand side of the cavity. In this case, it is more convenient to re-write the general solution (1011) as

$$g(z,\overline{z}) = C(\overline{z})\mathrm{e}^{i\lambda z} + D(\overline{z})\mathrm{e}^{-i\lambda z}. \tag{1018}$$

When $z > \overline{z}$, we require only one branch to be present which amounts to take $D = 0$. For $z < \overline{z}$, the boundary condition is still $g(L,\overline{z}) = 0$. Then, straightforward manipulations lead to [116]

$$g(z,\overline{z}) = \begin{cases} \dfrac{1}{\lambda}\mathrm{e}^{i\lambda(\overline{z}-L)}\sin(\lambda z - \lambda L), & z < \overline{z}, \\ \dfrac{1}{\lambda}\mathrm{e}^{i\lambda(z-L)}\sin(\lambda\overline{z} - \lambda L), & z > \overline{z}, \end{cases} \tag{1019}$$

which completes our determination of the Green function. The calculation of the Green function outside the cavity, but on the left hand side, proceeds exactly in the same way. The corresponding expression is obtained from the one above with $L = 0$, reflecting the fact that the boundary condition is now $g(0,\overline{z}) = 0$.

Endowed with the Green function of the problem, one can now turn to our main goal, namely the calculation of the stress-energy tensor. We have already seen that, see also Eq. (397),

$$G(\boldsymbol{r},\overline{\boldsymbol{r}}) = i\left\langle 0\left|T\left[\Phi(\boldsymbol{r})\Phi(\overline{\boldsymbol{r}})\right]\right|0\right\rangle. \tag{1020}$$

But we know that the T_{00} component of the stress energy tensor can be expressed as, see Eq. (303),

$$T_{00} = \frac{1}{2}\left[(\partial_0\Phi)^2 + (\partial_x\Phi)^2 + (\partial_y\Phi)^2 + (\partial_z\Phi)^2\right]. \tag{1021}$$

Therefore, if we apply the following operator to the Green function in Eq. (1020)

$$\frac{1}{2}\left[\partial_0\partial_{\overline{0}} + \partial_x\partial_{\overline{x}} + \partial_y\partial_{\overline{y}} + \partial_z\partial_{\overline{z}}\right], \tag{1022}$$

where $\partial_{\overline{\mu}}$ means a derivative with respect to $\overline{x}^{\mu}$, to $G(\boldsymbol{r},\overline{\boldsymbol{r}})$ and, then, take the space-time points to be the same $\boldsymbol{r}=\overline{\boldsymbol{r}}$, one should obtain an expression for $\langle T_{00}\rangle$. Using Eqs. (1008) and (1010), the result reads

$$\begin{aligned}\langle T_{00}\rangle &= \frac{1}{2i}\int\frac{\mathrm{d}\omega}{2\pi}\frac{\mathrm{d}k_x\mathrm{d}k_y}{(2\pi)^2}\left(\omega^2+k_x^2+k_y^2+\partial_z\partial_{\overline{z}}\right)\\ &\quad\times g(z,\overline{z})\Big|_{z=\overline{z}}.\end{aligned}\tag{1023}$$

Then, we use the expression of the Green function inside the plates (1017) and one arrives at

$$\begin{aligned}\langle T_{00}\rangle &= \frac{1}{2i}\int\frac{\mathrm{d}\omega}{2\pi}\frac{\mathrm{d}k_x\mathrm{d}k_y}{(2\pi)^2}\frac{1}{\lambda\sin(\lambda L)}\Big[(\omega^2+k_x^2+k_y^2)\sin(\lambda z)\sin(\lambda L-\lambda L)-\lambda^2\cos(\lambda z)\cos(\lambda L-\lambda L)\Big] &(1024)\\ &= -\frac{1}{2i}\int\frac{\mathrm{d}\omega}{2\pi}\frac{\mathrm{d}k_x\mathrm{d}k_y}{(2\pi)^2}\frac{1}{\lambda\sin(\lambda L)}\left[\omega^2\cos(\lambda L)-k^2\cos(2\lambda z-\lambda L)\right]. &(1025)\end{aligned}$$

In order to evaluate this integral, we perform the two Wick rotations $\omega\to i\zeta$ and $\lambda\to i\kappa$. This leads to

$$\langle T_{00}\rangle=-\frac{1}{2}\int_0^{\infty}\frac{\mathrm{d}\zeta}{2\pi}\int\frac{\mathrm{d}k_x\mathrm{d}k_y}{(2\pi)^2}\frac{1}{\kappa\sinh(\kappa L)}\left[\zeta^2\cosh(\kappa L)+k^2\cosh(2\kappa z-\kappa L)\right].\tag{1026}$$

Then, we introduce polar coordinates in the plane (ζ,k), *i.e.* $\zeta=\kappa\cos\theta$ and $k=\kappa\sin\theta$. This gives

$$\begin{aligned}\langle T_{00}\rangle &= -\frac{1}{4\pi^2}\int_0^{\infty}\mathrm{d}\kappa\kappa\int_0^{\pi/2}\mathrm{d}\theta\kappa^2\frac{\sin\theta}{\sinh(\kappa L)}\left[\cos^2\theta\cosh(\kappa L)+\sin^2\theta\cosh(2\kappa z-\kappa L)\right] &(1027)\\ &= -\frac{1}{12\pi^2}\int_0^{\infty}\mathrm{d}\kappa\kappa^3\left[\frac{\cosh(\kappa L)}{\sinh(\kappa L)}+2\frac{\cosh(2\kappa z-\kappa L)}{\sinh(\kappa L)}\right]. &(1028)\end{aligned}$$

Finally, writing that

$$\frac{\cosh(\kappa L)}{\sinh(\kappa L)}=1+\frac{2}{\mathrm{e}^{2\kappa L}-1},\tag{1029}$$

the expression of $\langle T_{00}\rangle$ can be re-expressed as

$$\begin{aligned}\langle T_{00}\rangle &= -\frac{1}{6\pi^2}\int_0^{\infty}\mathrm{d}\kappa\kappa^3\left[\frac{1}{\mathrm{e}^{2\kappa L}-1}+\frac{1}{2}\right.\\ &\quad\left.+\frac{\mathrm{e}^{2\kappa z}+\mathrm{e}^{2\kappa(L-z)}}{\mathrm{e}^{2\kappa L}-1}\right].\end{aligned}\tag{1030}$$

The last step of the calculation consists in evaluating the last term [we call it $g(z)$ in what follows; not to be confused with the Green function] of the above equation. One has

$$\begin{aligned}g(z) &= -\frac{1}{6\pi^2}\frac{1}{16L^4}\int_0^{\infty}\mathrm{d}y\,y^3\frac{\mathrm{e}^{y/L}+\mathrm{e}^{y(1-z/L)}}{\mathrm{e}^{y}-1} &(1031)\\ &= -\frac{1}{6\pi^2}\frac{1}{16L^4}\sum_{n=1}^{\infty}\int_0^{\infty}\mathrm{d}y\,y^3\left[\mathrm{e}^{y(z/L-n)}\right.\\ &\quad\left.+\mathrm{e}^{y(1-n-z/L)}\right], &(1032)\end{aligned}$$

where we have expanded the denominator in a geometric series. The two above integrals can be expressed in terms of the Hurwitz zeta function defined by [48, 49]

$$\zeta(s,a) \equiv \sum_{m=0}^{\infty} \frac{1}{(m+a)^s}, \tag{1033}$$

and this leads to

$$g(z) = -\frac{1}{16\pi^2 L^4}\left[\zeta\left(4,\frac{z}{L}\right)+\zeta\left(4,1-\frac{z}{L}\right)\right]. \tag{1034}$$

If we use the fact that $\int_0^{+\infty} \kappa^3/(\mathrm{e}^{2\kappa L}-1)\mathrm{d}\kappa = \pi^4/(240L^4)$, one arrives at our final expression for the time-time component of the stress energy tensor, namely

$$\langle T_{00}\rangle = -\frac{\pi^2}{1440L^4} - \frac{1}{6\pi^2}\int_0^{\infty}\mathrm{d}\kappa\frac{\kappa^3}{2} + g(z). \tag{1035}$$

Of course we notice that the first term in the above equation is similar to Eq. (998).

Let us now evaluate $\langle T_{00}\rangle$ outside the cavity. The calculation proceeds along the same lines but we now need to use the Green function given by Eq. (1019). Straightforward manipulations lead to

$$\langle T_{00}\rangle = -\frac{1}{6\pi^2}\int_0^{\infty}\mathrm{d}\kappa\frac{\kappa^3}{2} - \frac{1}{16\pi^2}\frac{1}{(z-L)^4}. \tag{1036}$$

We obtain the same structure as inside the cavity, namely a divergent term and a surface divergence term, *i.e.* a term which is divergent only on the plate. As explained in Ref. [116], this type of terms can be removed by restoring conformal invariance.

Let us now calculate the quantity $\langle T_{zz}\rangle$ inside the cavity. Clearly, following the previous considerations, it can be written as

$$\begin{aligned}\langle T_{zz}\rangle &= \frac{1}{2i}\int\frac{\mathrm{d}\omega}{2\pi}\frac{\mathrm{d}k_x\mathrm{d}k_y}{(2\pi)^2}\left(\partial_t\partial_{\overline{t}} - \partial_x\partial_{\overline{x}} - \partial_y\partial_{\overline{y}} + \partial_z\partial_{\overline{z}}\right)\\ &\quad\times g(z,\overline{z})\Big|_{z=\overline{z}}.\end{aligned} \tag{1037}$$

Following exactly the same procedure as before, we arrive at

$$\langle T_{zz}\rangle = -3\frac{\pi^2}{1440L^4} - \frac{3}{6\pi^2}\int_0^{\infty}\mathrm{d}\kappa\frac{\kappa^3}{2}. \tag{1038}$$

Let us now calculate $\langle T_{zz}\rangle$ outside the plates. As we did for the time time component, we must now use the Green function (1019). This gives

$$\begin{aligned}\langle T_{zz}\rangle &= \frac{1}{2i}\int\frac{\mathrm{d}\omega}{2\pi}\frac{k_x\mathrm{d}k_y}{(2\pi)^2}\frac{\mathrm{e}^{i\lambda(z-L)}}{\lambda}\lambda^2\Big[\sin\left(\lambda z-\lambda L\right)\\ &\quad + i\cos\left(\lambda z-\lambda L\right)\Big]\end{aligned} \tag{1039}$$

$$= -\frac{3}{6\pi^2}\int_0^{\infty}\frac{\kappa^3}{2}\mathrm{d}\kappa. \tag{1040}$$

Of course, this quantity is divergent.

Finally, in order to complete the determination of the stress-energy tensor, one must calculate $\langle T_{xx}\rangle = \langle T_{yy}\rangle$. It can be expressed as

$$\begin{aligned}\langle T_{xx}\rangle &= \frac{1}{2i}\int\frac{\mathrm{d}\omega}{2\pi}\frac{\mathrm{d}k_x\mathrm{d}k_y}{(2\pi)^2}\left(\partial_t\partial_{\overline{t}}+\partial_x\partial_{\overline{x}}-\partial_y\partial_{\overline{y}}-\partial_z\partial_{\overline{z}}\right)\\ &\quad\times g(z,\overline{z})\Big|_{z=\overline{z}} \qquad (1041)\\ &= \frac{1}{2i}\int\frac{\mathrm{d}\omega}{2\pi}\frac{\mathrm{d}k_x\mathrm{d}k_y}{(2\pi)^2}\frac{1}{\lambda\sin(\lambda L)}\Big[\left(\omega^2+k_x^2-k_y^2\right)\\ &\quad\times\sin(\lambda z)\sin(\lambda L-\lambda z)\\ &\quad+\lambda^2\cos(\lambda z)\cos(\lambda L-\lambda z)\Big]. \qquad (1042)\end{aligned}$$

A first step consists in dealing with the terms proportional to $k_x^2-k_y^2$. In fact these terms are of the form $\int \mathrm{d}\boldsymbol{k}_\perp(k_x^2-k_y^2)\mathcal{F}(k_\perp)$, where $\mathcal{F}(k_\perp)$ represents the other terms in the integral which are function of $k_x^2+k_y^2$ only. Therefore, one can evaluate them by going to polar coordinates in the plane (k_x,k_y). This leads to an expression of the form $\int \mathrm{d}k_\perp\mathrm{d}\psi k_\perp^2(\cos^2\psi-\sin^2\psi)\mathcal{F}(k_\perp)=0$, which shows that the corresponding contribution vanishes. Then, following the same steps as before, one reduces the above expression to

$$\begin{aligned}\langle T_{xx}\rangle &= \frac{1}{12\pi^2}\int_0^\infty\mathrm{d}\kappa\frac{\kappa^3}{\sinh(\kappa L)}\Big[\cosh(2\kappa z-\kappa L)+\\ &\quad+2\cosh(\kappa z)\cosh(\kappa L-\kappa z)\Big]=-\langle T_{00}\rangle, \qquad (1043)\end{aligned}$$

where we have used that $2\cosh(\kappa z)\cosh(\kappa L-\kappa z)=\cosh(\kappa L)+\cosh(2\kappa z-\kappa L)$. Of course, as already mentioned, this also shows that $\langle T_{yy}\rangle=-\langle T_{00}\rangle$. All the other components being zero, this completes our calculation of the stress energy in the cavity. Only the calculations of $\langle T_{xx}\rangle=\langle T_{yy}\rangle$ outside the plates remains to be done and we now turn to this question. Considering again Eq. (1041), we have

$$\begin{aligned}\langle T_{xx}\rangle &= \frac{1}{2i}\int\frac{\mathrm{d}\omega}{2\pi}\frac{\mathrm{d}k_x\mathrm{d}k_y}{(2\pi)^2}\frac{\mathrm{e}^{i\lambda(z-L)}}{\lambda}\Big[\omega^2\sin(\lambda z-\lambda L)\\ &\quad-i\lambda^2\cos(\lambda z-\lambda L)\Big]=-\langle T_{00}\rangle. \qquad (1044)\end{aligned}$$

We are now in a position where we can write the full stress energy tensor. Inside the cavity, it takes the form

$$\begin{aligned}\langle T_{\mu\nu}\rangle_{\text{inside}} &= (\rho_{\text{vac}}+\rho_{\text{Casimir}})\begin{pmatrix}1&0&0&0\\0&-1&0&0\\0&0&-1&0\\0&0&0&3\end{pmatrix}\\ &\quad+g(z)\begin{pmatrix}1&0&0&0\\0&-1&0&0\\0&0&-1&0\\0&0&0&0\end{pmatrix}, \qquad (1045)\end{aligned}$$

where we have defined the two quantities ρ_{vac} and ρ_{Casimir} by

$$\rho_{\text{vac}}=-\frac{1}{6\pi^2}\int_0^\infty\mathrm{d}\kappa\frac{\kappa^3}{2},\quad \rho_{\text{Casimir}}=-\frac{\pi^2}{1440L^4}. \qquad (1046)$$

Outside the cavity (more precisely on the right hand side), the results derived above imply that

$$\langle T_{\mu\nu}\rangle_{\text{outside}} = \rho_{\text{vac}} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 3 \end{pmatrix} - \frac{1}{16\pi^2(z-L)^4} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \tag{1047}$$

As discussed in Ref. [116], the terms proportional to $g(z)$ and $(z-L)^{-4}$ are surface divergent terms. They can be removed in the case where conformal invariance is re-established and, for that reason, are not present in electromagnetism, *i.e.* when one considers an electric field inside the cavity rather than a scalar field. In this case, we see that the difference between the stress-energy tensors inside and outside the cavity reads

$$\Delta\langle T_{\mu\nu}\rangle = \rho_{\text{Casimir}} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 3 \end{pmatrix}, \tag{1048}$$

which is a finite result. The infinite part has been removed by subtraction. Finally, the stress energy tensor can be written in a covariant form, namely [119]

$$\Delta\langle T_{\mu\nu}\rangle = \rho_{\text{Casimir}} \left(4\hat{z}^\mu \hat{z}^\nu - g^{\mu\nu}\right), \tag{1049}$$

where $\hat{z}^\mu$ in the unit vector in the z direction.

At this point, several comments are in order. Firstly, we notice in Eqs. (1048) and (1049) that the energy density (*i.e.* the time-time component) is similar to the expressions already derived in Sec. 24.12.2 by other methods. This confirms that this calculation is independent of the regularization scheme used to obtain the result. Secondly, it is clear that the stress-energy tensor (1049) is not similar to the cosmological constant stress-energy tensor $T_{\mu\nu} = -\rho_{\text{vac}} g_{\mu\nu}$. This illustrates the difference between the Casimir case and the cosmological constant case. In the latter case, one measures the absolute value of the vacuum energy while, in the former case, one is only sensitive to the difference of vacuum energy from one side of the plates to the other.

Thirdly, the Casimir Force has been observed in the laboratory and this is usually taken as another evidence in favor of the existence of the zero-point fluctuations. After all, since we observe the Casimir force and since this force is due to a change in the structure of the vacuum that is perturbed by the presence of the plates, the fact is that the vacuum must exist as a real physical phenomenon and is not an artifact of the quantum field theory formalism. In addition, this also validates the methods of regularization used to calculate ρ_{vac}. In the context of the Casimir effect, these methods seem to work very well and to lead to predictions that are in agreement with the experiments. Therefore, why would the very same techniques, used in a similar context, fail to regularize the cosmological constant?

Fourthly, the claim that the calculation and the observation of the Casimir force are evidences in favor of the reality of vacuum fluctuations has been challenged in Refs. [120, 121]. It is indeed possible to derive the expression of the Casimir force without referring at all to zero point fluctuations, by means of the "source theory" approach to quantum field theory. However, to our knowledge, there is no attempt to do the same for the Lamb shift (but this would certainly be an interesting exercise). Therefore, it seems that zero-points fluctuations are nevertheless necessary to quantum field theory even if the above remark should lead us to tone down the claim that they have been seen in the laboratory. Let us also notice that, very recently, another situation where the vacuum fluctuations can lead to an observable effect has been studied in Ref. [122]. This article investigates whether the quantum zero point fluctuations could cause the rotation of a small nano device. This "rotational vacuum effect" has in fact a similar origin than the Casimir effect.

Finally, it should be clear that, if the Lamb shift and the Casimir effect seem to indicate that the vacuum fluctuations are real, they do not say anything with regards to their gravitational properties. In other words, they do not say how the vacuum fluctuations weigh (it

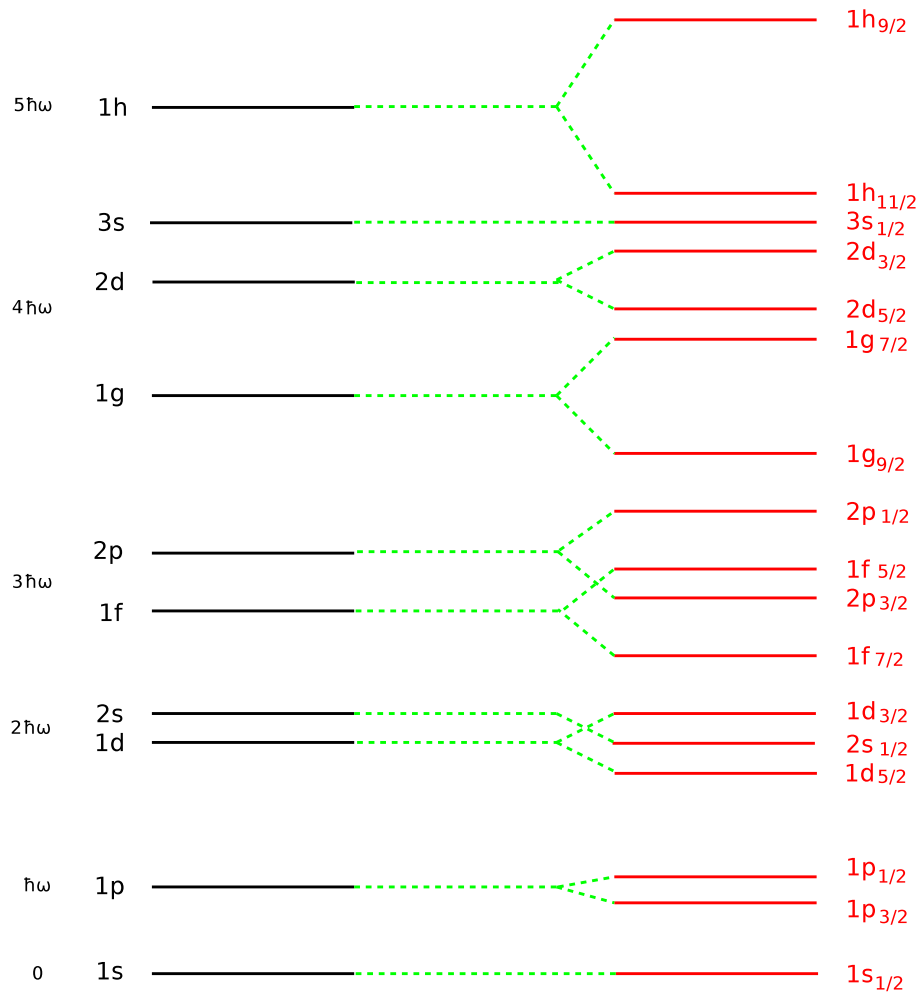

Figure 161: Energy levels of the nucleus. On the left-hand side are represented the levels in the approximation where the Woods-Saxon potential is approximated by a parabola. In this case, each level (which includes a series of sub-levels) is separated by the energy $\hbar\omega$. On the right hand side are represented the levels where the spin orbit interaction (1051) is taken into account. This breaks the degeneracy of the sub-levels and reproduces the magic numbers.

is worth noticing here that the gravitational properties of a Casimir cavity have been studied in Refs. [123, 124, 125, 126, 127, 128, 129]). It is clear that there exists the possibility that the zero-point fluctuations do exist but have non-standard gravitational properties, *i.e.* that they abnormally weigh. It is therefore interesting to investigate if there is an experiment which measures whether this is true or not. In the next section, we turn to this question.

24.13 Do the Quantum Fluctuations Gravitate?

In this section, we study the gravitational property of the Lamb shift [12, 130]. We will follow the treatment of Ref. [130]. In Sec. 24.12.1, we showed that the interaction of the electron with the "vacuum electric field" inside the atom leads to a shift of the atomic levels. In some sense, this means that the zero-point fluctuations affect the mass (energy) of the atom. Therefore, by studying how the atom falls down, one can put constraints on the gravitational properties of the vacuum fluctuations. This is the idea that we pursue in this section. However, since the corresponding effect is small for an atom and is larger for a nucleus (of course, the Lamb shift also exists in this case), it is better to study the latter case. For this reason, we start with recalling some basics facts about nuclear models.

The main idea is that the interaction between a given nucleon and the other $A-1$ nucleons

can be mimicked by a Woods-Saxon potential given by

$$V_{\rm ws}(r) = -V_0 \left[1 - \exp\left(\frac{r-R}{a}\right)\right], \tag{1050}$$

where a describes how abrupt the potential is while R is the radius of the nucleus. As is well-known one can take $R = r_0 A^{1/3}$ where $r_0 \simeq 1.3 \times 10^{-15}\,{\rm m} = 1.3\,{\rm fm}$. The quantity V_0 represents the depth of the potential and can be taken to be $V_0 \simeq 45\,{\rm MeV}$. In fact, in order to have a reasonable model, one must add to the Woods-Saxon potential a spin orbit interaction term which can be expressed as

$$V_{\rm L,s} = -f(r)\boldsymbol{L}\cdot\boldsymbol{s}, \tag{1051}$$

where $\boldsymbol{L}$ is the angular momentum of the nucleon and $\boldsymbol{s}$ its spin. With a good approximation, one can write $f(r) \simeq 24 A^{-2/3}\,{\rm MeV}$. Then, the Hamiltonian of the nucleus can be written as

$$H = \sum_{j=1}^{A}\left[\frac{p_j^2}{2m_j} + V_{\rm ws}(r_j) - f(r_j)\boldsymbol{L}_j\cdot\boldsymbol{s}_j\right]. \tag{1052}$$

The total wave-function can be taken as the product of the individual wave functions (in fact, more precisely, one should consider a Slater determinant in order to take into account the fact that the total wave function must be anti-symmetrized), that is to say

$$\Psi\left(\boldsymbol{r}_1, \cdots, \boldsymbol{r}_A\right) = \prod_{j=1}^{A}\Psi_j\left(\boldsymbol{r}_j\right). \tag{1053}$$

Each individual wave-function can be obtained from a Schrödinger equation given by (for the moment, one ignores the spin orbit term since it can be treated as a perturbation)

$$\left[-\frac{\hbar^2}{2\mu}\nabla^2 + V_{\rm ws}(r_j)\right]\Psi_j(r_j) = E_j\Psi_j(r_j), \tag{1054}$$

where μ is the reduced mass,

$$\frac{1}{\mu} \equiv \frac{1}{m_{\rm p}} + \frac{1}{(A-1)m_{\rm p}}, \tag{1055}$$

or $\mu \simeq m_{\rm p}(A-1)/A \simeq m_{\rm p} \simeq 1.6 \times 10^{-27}\,{\rm kg}$, $m_{\rm p}$ being the proton mass. Unfortunately, the Schrödinger equation cannot be solved analytically for the Woods-Saxon potential and, therefore, we are forced to make approximations. The simplest one is just to describe the Woods-Saxon potential with a parabola, *i.e.*

$$V_{\rm ws}(r) \simeq -V_0\left(1 - \frac{r^2}{R^2}\right) = -V_0 + \frac{1}{2}\mu\omega_0^2 r^2, \tag{1056}$$

with $\omega_0 \equiv \sqrt{2V_0/(\mu R^2)}$. In this case, the question becomes solvable. We can use the spherical symmetry of the problem and write the wave function as

$$\Psi_j(\boldsymbol{r_j}) = \frac{u_{n,\ell}(r_j)}{r_j} Y_{\ell m}\left(\theta_j, \varphi_j\right), \tag{1057}$$

where $Y_{\ell m}$ is a spherical harmonics [48, 49]. The radial function $u_{n\ell}$ is controlled by the equation

$$\left[-\frac{\hbar^2}{2\mu}\frac{{\rm d}^2}{{\rm d}r_j^2} + \frac{\ell(\ell+1)}{2\mu r_j^2} + \frac{1}{2}\mu\omega_0^2 r^2\right]u_{n,\ell} = (E_j + V_0)u_{n,\ell}, \tag{1058}$$

which can be solved in terms of Laguerre polynomials L_n^α [48, 49]. Explicitly, one has

$$\Psi(r_j) = C r_j^\ell \mathrm{e}^{-\mu\omega_0 r_j^2/(2\hbar)} L_{n-1}^{\ell+1/2}\left(\frac{\mu\omega_0}{\hbar} r^2\right) Y_{\ell m}\left(\theta_j, \varphi_j\right), \tag{1059}$$

where C is a normalization constant to be determined. In the above expression, one has $n \geq 1$ and $\ell \geq 0$. The energy levels are given by the expression

$$E(n,\ell) = -V_0 + \hbar\omega_0\left[2(n-1) + \ell + \frac{3}{2}\right]. \tag{1060}$$

The factor $3/2 = 3 \times 1/2$ originates from the fact that we have a three-dimensional harmonic oscillator. The quantum numbers have been chosen so that the ground state is $n = 1$, $\ell = 0$ which allows the spectroscopic notation "$1s$", see Fig. 161.

The only thing which remains to be done is to determine the constant C. Obviously, this is done by normalizing the wave-function, *i.e.*

$$|C|^2 \int_0^\infty \mathrm{d}r_j r_j^2 \frac{|u_{n,\ell}|^2}{r_j^2} \int \mathrm{d}\Omega_j Y_{\ell m} = 1, \tag{1061}$$

Using the solution obtained above and performing the change of variable $\rho = (\mu\omega_0/\hbar)r^2$, the previous condition reduces to

$$\frac{|C|^2}{2}\left(\frac{\mu\omega_0}{\hbar}\right)^{-\ell-3/2} \times \int_0^\infty \rho^{\ell+1/2}\mathrm{e}^{-\rho} L_{n-1}^{\ell+1/2}(\rho) L_{n-1}^{\ell+1/2}(\rho) = 1. \tag{1062}$$

Then, using Eq. (7.414.3) of Ref. [49], one obtains

$$|C|^2 = 2(n-1)!\left(\frac{\mu\omega_0}{\hbar}\right)^{\ell+3/2}\Gamma^{-1}\left(n+\ell+\frac{1}{2}\right). \tag{1063}$$

We are now in a position where we can compute the value of the wave-function at $r_j = 0$ for $\ell = 0$. This gives

$$|\Psi(0)|^2 = |C|^2\left[L_{n-1}^{1/2}(0)\right]^2 \frac{1}{4\pi}. \tag{1064}$$

Using the fact that $L_{n-1}^{1/2}(0) = \binom{n-1/2}{n-1} = \Gamma(n+1/2)/[\sqrt{\pi}(n-1)!/2]$, one obtains

$$|\Psi_{n,\ell=0}(0)|^2 = \frac{2}{\pi^2}\frac{\Gamma(n+1/2)}{(n-1)!}\left(\frac{\mu\omega_0}{\hbar}\right)^{3/2}. \tag{1065}$$

This completes the first part of the calculation.

We have established on very general grounds that the shift in energy due to the interaction of a charged particle (in Sec. 24.12.1, the electron in the atom, here the proton in the nucleus) is given by Eq. (953). The means value of the square of the displacement has been calculated in Eq. (961). Applying these formulas to the case of the protons in the nucleus, one obtains [130]

$$\Delta E(n,0) \simeq \frac{4\alpha^2}{3m_{\mathrm{p}}^2}\sum_i Z^{(i)}\left|\Psi^{(i)}_{n,\ell=0}(0)\right|^2 \int_0^\infty \frac{\mathrm{d}\omega}{\omega}. \tag{1066}$$

As usual, this infinite integral must be regularized and usually leads to logarithmic corrections, see for instance Eq. (963). We will ignore this factor in what follows since this does not affect

too much the final result. As explained in Ref. [130], the sum over "(i)" runs only over s-wave since this is the only way to get $\Psi_{n,\ell}(0) \neq 0$. Moreover, still following Ref. [130], it is reasonable to approximate the field experienced by a proton by a field produced by the other protons in inner shells. This is why $Z^{(i)}$ represents the total number of protons present in shells inner than the proton "(i)" under consideration.

Our goal is now to test how the vacuum fluctuations weigh. For this purpose, we write the gravitational mass of a given nucleus as [130]

$$m_{\rm g} = m_{\rm i} - \eta \Delta E, \tag{1067}$$

where $m_{\rm i}$ is the inertial mass. The parameter η is a priori a free parameter which controls to which extent the weak equivalence principle would be violated. If $\eta = 0$, there is no violation of the universality of free fall. A convenient measure of potential violations of the weak equivalence principle is given by the Eötvös ratio

$$\eta(1,2) \equiv \frac{m_{\rm g}(1)}{m_{\rm i}(1)} - \frac{m_{\rm g}(2)}{m_{\rm i}(2)}, \tag{1068}$$

for two bodies 1 and 2. Using the previous calculations, this ratio can be expressed as

$$\begin{aligned} \eta(1,2) &= \eta \frac{4\alpha^2}{3m_{\rm p}^3} \left[\frac{1}{A_1} \sum_i Z_1^{(i)} \left| \Psi_{n,\ell=0}^{(1,i)}(0) \right|^2 \right. \\ &\left. - \frac{1}{A_2} \sum_i Z_2^{(i)} \left| \Psi_{n,\ell=0}^{(2,i)}(0) \right|^2 \right], \end{aligned} \tag{1069}$$

where we have used $m_{\rm i} \sim A m_{\rm p}$, a relation valid since we work at first order in the parameter η. Then, we use the fact that

$$(\mu\omega_0)^{3/2} = \left(\frac{2m_{\rm p}V_0}{r_0^2} \right)^{3/4} \frac{1}{A^{1/2}} \tag{1070}$$

to express the Eötvös ratio as [130]

$$\begin{aligned} \eta(1,2) &= \eta \frac{4\alpha^2}{3} \left(\frac{2V_0}{m_{\rm p}^3 r_0^2} \right)^{3/4} \frac{2}{\pi^2} \\ &\times \left[\frac{1}{A_1^{3/2}} \sum_i Z_1^{(i)} \frac{\Gamma(n+1/2)}{(n-1)!} \right. \\ &\left. - \frac{1}{A_2^{3/2}} \sum_i Z_2^{(i)} \frac{\Gamma(n+1/2)}{(n-1)!} \right]. \end{aligned} \tag{1071}$$

Let us evaluate this number for aluminum ($Z = 13$, $A = 27$) and Platinum ($Z = 78$, $A = 195$). In the case of aluminum, since we only have 13 protons, the only s-shell protons are on the $1\,s_{1/2}$ level (in fact, we have two protons in $1\,s_{1/2}$, four protons in $1\,p_{3/2}$, two protons in $1\,p_{1/2}$ and five protons in $1\,d_{5/2}$, see Fig. 161). As a consequence, there is no inner protons for those protons (since, obviously, there is no inner level than the ground state $1\,s_{1/2}$) and the corresponding contribution in the Eötvös ratio vanishes. In the case of Platinum, all the levels are filled up until the level $1\,h_{11/2}$ which contains height protons, see Fig. 161. Therefore, we have two protons on $1\,s_{1/2}$, two protons on $2\,s_{1/2}$ and two on $3\,s_{1/2}$, see again Fig. 161. This means that the $3\,s_{1/2}$ protons see four inner protons and the $2\,s_{1/2}$ protons see two inner protons. As a consequence, one can write

$$\begin{aligned} \eta({\rm Al},{\rm Pt}) &\simeq -\eta \frac{4\alpha^2}{3} \left(\frac{2V_0}{m_{\rm p}^3 r_0^2} \right)^{3/4} \frac{2}{\pi^2} \frac{1}{A_{\rm Pt}^{3/2}} \\ &\times \left[\frac{2}{(2-1)!} \Gamma\left(2+\frac{1}{2}\right) + \frac{4}{(3-1)!} \Gamma\left(3+\frac{1}{2}\right) \right] \end{aligned} \tag{1072}$$

Using the values of V_0 and r_0 chosen previously this leads to

$$\eta(\mathrm{Al}, \mathrm{Pt}) \simeq -5.6 \times 10^{-10}\, \eta \tag{1073}$$

Given the fact that $|\eta(\mathrm{Al}, \mathrm{Pt})| \lesssim 10^{-12}$ [131, 132], we reach the conclusion that

$$\eta \lesssim 1.7 \times 10^{-3}. \tag{1074}$$

Therefore, the vacuum fluctuations seem to have standard gravitational properties to a very good accuracy.

The conclusion of this section is that it seems difficult to argue that the zero-point fluctuations do not gravitate. Clearly, this makes the cosmological constant problem more acute. However, the results obtained here are by no means a final proof. For instance, it seems reasonable to assume that the stress energy tensor of the Lamb shift is not of the cosmological constant type. Therefore, the fact that a nucleus falls down normally does not necessarily imply that the cosmological constant weighs according to the Einstein equations. Nevertheless, no sign of inconsistency appears in the above situation and one is obviously tempted to assume that zero-point fluctuations couple to gravity as any other type of matter. Again, this makes the cosmological constant problem more mysterious.

24.14 The Weak Equivalence Principle in Quantum Mechanics

In the previous sections, we have argued that the zero-point fluctuations seem to be real and seem to gravitate normally. Therefore, these two reasons cannot be invoked to avoid the cosmological constant problem. However, there is another (but related) issue that it is interesting to investigate. When we consider the vacuum stress energy tensor in the Einstein equations, we implicitly assume that the zero-point fluctuations obey the weak equivalence principle, *i.e.* that they "fall" in a gravitational field as any other type of matter. Clearly the zero point fluctuations are of quantum-mechanical origin. The weak equivalence principle is well established (and tested) in classical physics and general relativity is based on this principle. But what is the status of this principle in quantum mechanics? If it is not valid in quantum mechanics, maybe we do not have the right to couple the quantum zero point fluctuations in the standard way in the Einstein equations? Could it be a way to avoid the problem? In order to discuss this issue, we will consider two situations, the Collela, Overhausser and Werner experiment (COW) and the quantum Galileo experiment.

24.14.1 The Collela, Overhausser and Werner (COW) Experiment

The COW experiment [133, 134, 135] consists in sending neutrons in an interferometer placed in a weak gravitational field, see Fig. 162. The presence of the gravitational field affects the wave-function of the neutrons and changes the relative phases between the two beams. When the interferometer is rotated, the gravitational phase shift is modified because the height difference between the two arms is changed. This effect can then be detected (and was detected) in the interference pattern. The COW experiment is conceptually very important. This was the first experiment to measure the effect of the gravitational field on the wave-function. In fact, it shows that the gravitation is just an ordinary force as far as the Schrödinger equation is concerned.

Let us now describe the experiment in more detail. The neutron interferometer is represented in Fig. 162. Let us assume that, along one of the two paths, a phase shift $\Delta\varphi$ is introduced. Our first goal is to evaluate the intensity seen by the detectors O_2 and O_3. After diffraction, the wave function of the neutron takes the form

$$\Psi(\boldsymbol{r}) = \Phi T(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot\boldsymbol{r}} + \Phi D(\theta) \mathrm{e}^{-i\boldsymbol{k}_\mathrm{G}\cdot\boldsymbol{r}}, \tag{1075}$$

where $\boldsymbol{k}_0$ is the incident wave-number and $\boldsymbol{k}_\mathrm{G}$ the wave number after Bragg diffraction (which, therefore, must satisfy the Bragg condition). The quantity Φ is the amplitude of the incident wave and $T = T(\theta)$ (for "transmitted") and $D = D(\theta)$ (for "diffracted") are two coefficients describing the amplitude of the two branches of the wave-function after the neutron has emerged

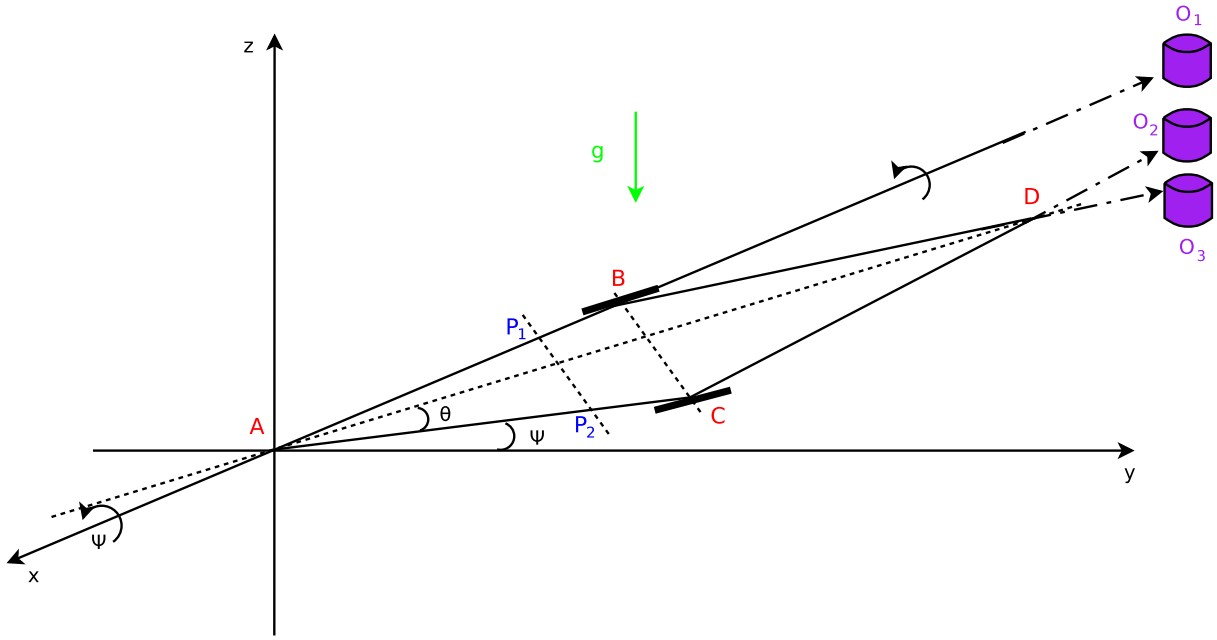

Figure 162: Representation of the Collela, Overhausser and Werner (COW) interferometer. The interferometer is placed in a vertical gravitational field (represented by the green arrow) and is rotated around the axis AB.

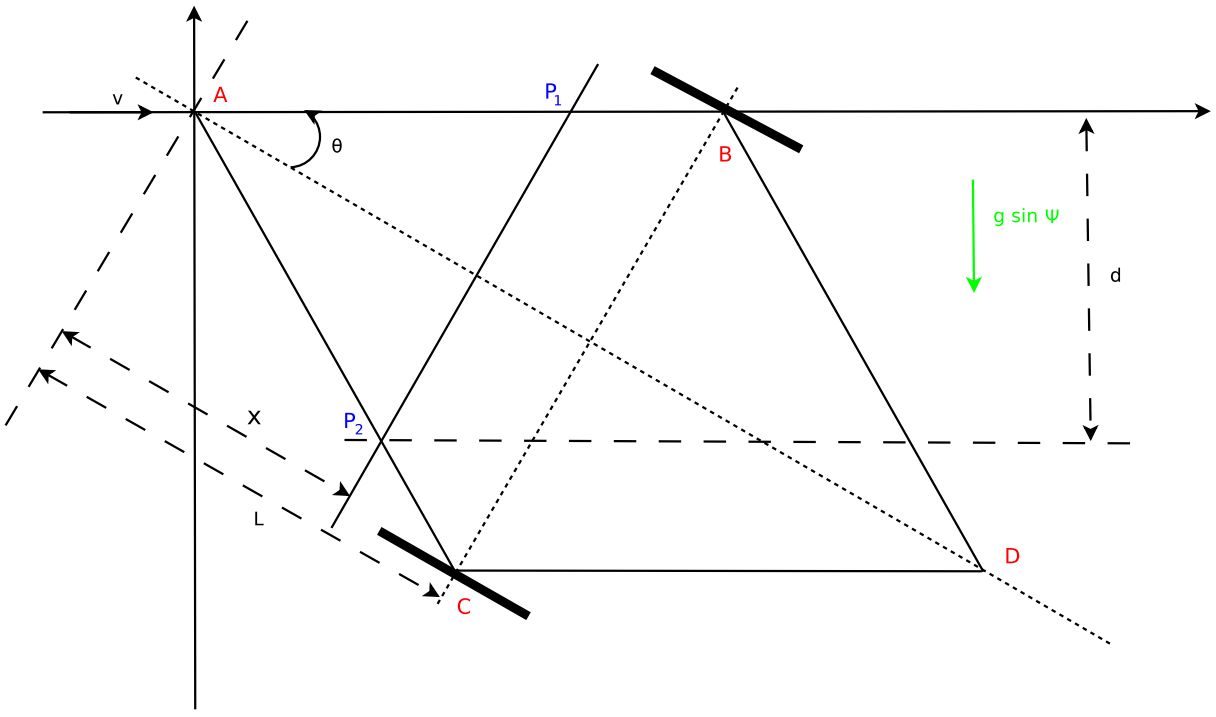

Figure 163: Representation of the COW interferometer in the plane of the two beams.

from the crystal. Let us now consider the the path $ABDO_3$. At point B, the wave function is given by (the origin of the coordinates is chosen to be at point A)

$$\Psi(AB) = \Phi T(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot\boldsymbol{r}_\mathrm{B}}, \tag{1076}$$

since the wave was just transmitted. Then, at point B, we have a diffraction and, therefore, the wave-function at point D reads

$$\Psi(ABD) = \Phi T(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot\boldsymbol{r}_\mathrm{B}} D(\theta) \mathrm{e}^{i\boldsymbol{k}_\mathrm{G}\cdot(\boldsymbol{r}_\mathrm{D}-\boldsymbol{r}_\mathrm{B})}. \tag{1077}$$

Finally, at point D, we have another diffraction but this time with opposite angle. The leads to

$$\begin{aligned}\Psi(ABDO_3) &= \Phi T(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot\boldsymbol{r}_\mathrm{B}} D(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot(\boldsymbol{r}_\mathrm{D}-\boldsymbol{r}_\mathrm{B})} \\ &\quad \times D(-\theta) \mathrm{e}^{i\boldsymbol{k}_\mathrm{G}\cdot(\boldsymbol{r}-\boldsymbol{r}_\mathrm{D})}.\end{aligned} \tag{1078}$$

We also assume that, along that path, there is a phase shift $\Delta\varphi$ that we do not specify for the moment. As a consequence, the total wave function can be written as

$$\begin{aligned}\Psi(ABDO_3) &= \Phi T(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot\boldsymbol{r}_\mathrm{B}} D(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot(\boldsymbol{r}_\mathrm{D}-\boldsymbol{r}_\mathrm{B})} \\ &\quad \times D(-\theta) \mathrm{e}^{i\Delta\varphi} \mathrm{e}^{i\boldsymbol{k}_0\cdot(\boldsymbol{r}-\boldsymbol{r}_\mathrm{D})},\end{aligned} \tag{1079}$$

where we have introduced the factor $\mathrm{e}^{i\Delta\varphi}$.

It is straightforward to follow the same procedure and to establish the expression for $\Psi(ACDO_3)$. This gives the expression of the wave function at detector O_3, namely $\Psi(O_3) = \Psi(ABDO_3) + \Psi(ACDO_3)$,

$$\Psi(O_3) = \Phi \left[T(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot\boldsymbol{r}_\mathrm{B}} D(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot(\boldsymbol{r}_\mathrm{D}-\boldsymbol{r}_\mathrm{B})} D(-\theta) \mathrm{e}^{i\Delta\varphi} + D(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot\boldsymbol{r}_\mathrm{C}} D(-\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot(\boldsymbol{r}_\mathrm{D}-\boldsymbol{r}_\mathrm{C})} T(\theta) \right] \mathrm{e}^{i\boldsymbol{k}_0\cdot(\boldsymbol{r}-\boldsymbol{r}_\mathrm{D})}. \tag{1080}$$

Using this expression, one can calculate the expected intensity. Straightforward manipulations leads to the following expression

$$I(O_3) = |\Psi(O_3)|^2 = \alpha\left(1 + \cos\Delta\varphi\right), \tag{1081}$$

where α is a constant that can be determined from the above expression and which depends on the incident flux and the crystal structure. Then, one can repeat the same analysis and determine the wave function at detector O_2. It reads

$$\Psi(O_2) = \Phi \left[T(\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot\boldsymbol{r}_\mathrm{B}} D(\theta) \mathrm{e}^{i\boldsymbol{k}_\mathrm{G}\cdot(\boldsymbol{r}_\mathrm{D}-\boldsymbol{r}_\mathrm{B})} T(-\theta) \mathrm{e}^{i\Delta\varphi} + D(\theta) \mathrm{e}^{i\boldsymbol{k}_\mathrm{G}\cdot\boldsymbol{r}_\mathrm{C}} D(-\theta) \mathrm{e}^{i\boldsymbol{k}_0\cdot(\boldsymbol{r}_\mathrm{D}-\boldsymbol{r}_\mathrm{C})} D(\theta) \right] \mathrm{e}^{i\boldsymbol{k}_\mathrm{G}\cdot(\boldsymbol{r}-\boldsymbol{r}_\mathrm{D})}. \tag{1082}$$

The intensity at detector O_2 can be computed along the same lines and one is led to

$$I(O_2) = \beta - \alpha\cos\Delta\varphi, \tag{1083}$$

where α and β are just constants that do not play an important role in what follows [of course, the constant α is the same as in Eq. (1081)].

Having estimated the form of the signal expected for any phase shift $\Delta\varphi$, we now turn to its calculation in the case of the COW experiment. For this purpose, we return to the Schrödinger equation which can be written as

$$\nabla^2\Psi + \omega^2\Psi = 0, \tag{1084}$$

with

$$\omega^2 = \frac{2m}{\hbar^2}\left(E - V\right). \tag{1085}$$

Now, let us assume that the potential is given by

$$V = V_0 + \Delta V(\boldsymbol{r}), \tag{1086}$$

where V_0 is a constant and ΔV a small space-dependent small perturbation, *i.e.* $\Delta V \ll V_0$. If the perturbation does not change abruptly, the Wentzel-Kramers-Brillouin (WKB) wave-function

$$\Psi \propto \exp\left[i \int \omega(\boldsymbol{r}) \mathrm{d}\boldsymbol{r} \right], \tag{1087}$$

is a very good approximation to the actual solution. Introducing the notation $k_0 = 2m(E - V_0)/\hbar^2$ and using that $p = mv = \hbar k_0$, an expansion of the phase in $\Delta V/V_0$ leads to the following expression

$$\Psi \propto \exp\left(i\boldsymbol{k}_0 \cdot \boldsymbol{r} - \frac{1}{\hbar}\int\limits_{\mathcal{P}} \Delta V \mathrm{d}t \right), \tag{1088}$$

where the subscript "$\mathcal{P}$" indicates that one integrates along the non perturbed path. From the above equation, we conclude that

$$\Delta\varphi = -\frac{1}{\hbar}\int\limits_{\mathcal{P}} \Delta V \mathrm{d}t. \tag{1089}$$

The same result can also be expressed differently. Using energy conservation, on can write

$$\frac{p^2}{2m} + V_0 + \Delta V = E, \tag{1090}$$

and, since $\boldsymbol{p} = \boldsymbol{p}_0 + \delta\boldsymbol{p}$, one obtains

$$\frac{p_0^2}{2m} + \frac{\boldsymbol{p}_0}{m} \cdot \delta\boldsymbol{p} + V_0 + \Delta V = E, \tag{1091}$$

or,

$$\boldsymbol{v}_0 \cdot \delta\boldsymbol{p} = -\Delta V. \tag{1092}$$

As a consequence, the phase shift can be re-written as the following expression

$$\Delta\varphi = \frac{1}{\hbar}\int\limits_{\mathcal{P}} \delta\boldsymbol{p} \cdot \mathrm{d}\boldsymbol{r}, \tag{1093}$$

where the integral should again be calculated along the path of the neutron.

Let us now determine the phase shift for the COW experiment. Let us consider two point P_1 and P_2 that correspond to one beam transmitted and one beam diffracted in the interferometer, see Fig. 163. The potential difference between those two points is given by

$$V(P_2) - V(P_1) = mgd\sin\psi, \tag{1094}$$

where d can be expressed as $d = AP_1\cos(\pi/2 - 2\theta)$. Given that the quantity x in Fig. 163 can be written as $x = AP_1\cos\theta$, one deduces that $d = 2x\sin\theta$. As a consequence,

$$V(P_2) - V(P_1) = 2m_{\mathrm{grav}}gx\sin\theta\sin\psi, \tag{1095}$$

where we have now carefully written that the mass which appeared in the above expression is the gravitational mass (since this is the "coupling constant" to the gravitational field). This implies that the phase shift can be written as

$$\Delta\varphi = -\frac{2}{\hbar}\int\limits_{0}^{L} 2m_{\mathrm{g}}g_0 x\sin\theta\sin\psi\frac{\mathrm{d}x}{\cos\theta}, \tag{1096}$$

where we have taken into account the fact that the line P_1P_2 is "moving" with a speed $v\cos\theta$. The factor two in front of the whole expression comes from the fact that the phase shift accumulates and is, along the total path, twice its value in the fist part of the interferometer. The integration over the variable x is easily done and we obtain

$$\Delta\varphi = -2\frac{m_{\mathrm{g}}g_0}{\hbar v}L^2\tan\theta\sin\psi. \tag{1097}$$

Finally, noticing that the total area of the interferometer is nothing but $\mathcal{A} \equiv 2L^2 \tan\theta$ and that the de Broglie relation is $v = h/(m_{\rm in}\lambda)$, where $m_{\rm in}$ is the inertial mass and λ the wavelength of the incident beam, we arrive at [133, 134, 135]

$$\Delta\varphi = -\frac{2\pi}{h^2} m_{\rm grav} m_{\rm in} g_0 \mathcal{A}\lambda \sin\psi. \tag{1098}$$

This expression is quite remarkable as it involves the gravitational and the inertial mass together with the Planck constant. Moreover, we deal with an observable quantity which does not depend on the ratio of the gravitational mass to the inertial mass, as is usually the case, but on the product of these quantities. We also see that the intensity of the signal at detectors O_2 and/or O_3 depend on the orientation of the interferometer ψ.

However, in practice, one must deal with two other effects [133, 134, 135]. The first one is the Sagnac effect due to the rotation of Earth. Classically, the Hamiltonian of a neutron is given by

$$H = \frac{p^2}{2m_{\rm in}} + m_{\rm grav}\boldsymbol{g}\cdot\boldsymbol{r} - \boldsymbol{\omega}\cdot\boldsymbol{L}, \tag{1099}$$

where $\boldsymbol{L} = \boldsymbol{r}\times\boldsymbol{p}$ is the angular momentum of the neutron and $\boldsymbol{\omega}$ the angular velocity of Earth. Upon using the Hamilton equations, this implies that

$$\boldsymbol{p} = m_{\rm in}\,\dot{\boldsymbol{r}} + m_{\rm in}\,\boldsymbol{\omega}\times\boldsymbol{r}. \tag{1100}$$

Therefore, one obtains a Sagnac phase shift which can be expressed as

$$\Delta\varphi_{\rm Sagnac} = \frac{m_{\rm in}}{\hbar}\oint(\boldsymbol{\omega}\times\boldsymbol{r})\cdot{\rm d}\boldsymbol{r}, \tag{1101}$$

where we have used Eq. (1093). Using Stokes theorem, this can also be written as

$$\Delta\varphi_{\rm Sagnac} = \frac{4\pi m_{\rm in}}{h}\boldsymbol{\omega}\cdot\boldsymbol{\mathcal{A}}, \tag{1102}$$

where $\boldsymbol{\mathcal{A}}$ is the vector associated to the interferometer area. If Γ is the incident neutron beam west of due south and δ the co-latitude, the Sagnac phase shift takes the form

$$\Delta\varphi_{\rm Sagnac} = \frac{4\pi m_{\rm in}}{h}\omega\mathcal{A}\left(\cos\psi\cos\delta + \sin\psi\sin\Gamma\sin\delta\right). \tag{1103}$$

The COW experiment is such that the incident beam is directed due south which implies that $\Gamma = 0$. In the case, one obtains

$$\Delta\varphi_{\rm Sagnac} = \frac{4\pi m_{\rm i}}{h}\omega\mathcal{A}\cos\delta\cos\psi, \tag{1104}$$

a dependence in ψ which is different from the gravitational phase shift, see Eq. (1098).

Finally, there is a shift due to the fact that the interferometer bends and/or warps under its own weight. The COW experiment claim that this effect can be described by the following equation

$$\Delta\varphi_{\rm bend} = -q_{\rm bend}\sin\psi. \tag{1105}$$

This expression can be justified by noticing that the bending effect depends on the rotation angle. Clearly, this effect is difficult to estimate from first principles.

Therefore, the total phase shift expected in the COW experiment is the sum of the three contributions discussed before, namely the gravity, Sagnac and bending shifts. This leads to the following expression

$$\Delta\varphi = -q_{\rm grav}\sin\psi + q_{\rm Sagnac}\cos\psi - q_{\rm bend}\sin\psi, \tag{1106}$$

where, in order to take into account Eqs. (1098) and (1104), we have defined $q_{\rm grav} \equiv -2\pi m_{\rm grav} m_{\rm in} g_0 \mathcal{A}\lambda/h^2$ and $q_{\rm Sagnac} = 4\pi m_{\rm in}\omega\mathcal{A}\cos\delta/h$. The above expression can be re-written as

$$\Delta\varphi = q\sin\left(\psi - \psi_0\right), \tag{1107}$$

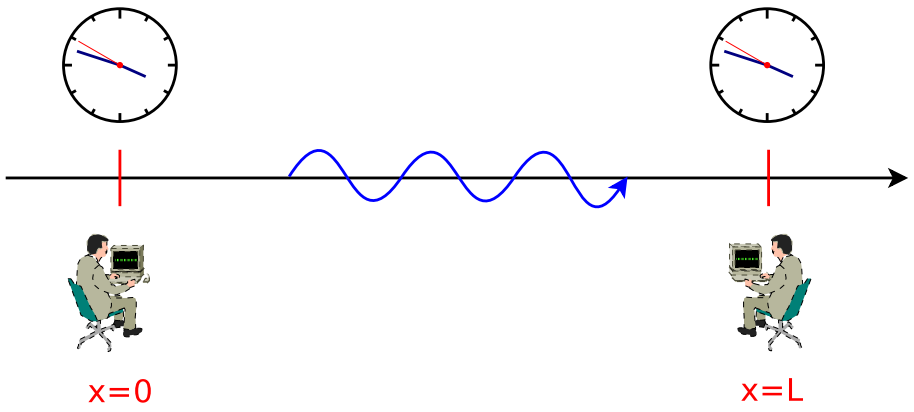

Figure 164: Sketch of a quantum "Peres" clock. The clock is coupled to the particle traveling from the point $x = 0$ to the point $x = L$. When the particle crosses $x = 0$, the clock changes its state and starts running. When the particle reaches $x = L$, the clock stops and a comparison of the two clock states permits a measurement of the time of flight of the particle.

where $q^2 = \left(q_{\rm grav} + q_{\rm bend}\right)^2 + q_{\rm Sagnac}^2$ and $\tan\psi_0 = q_{\rm Sagnac}/\left(q_{\rm grav} + q_{\rm bend}\right)$. In practice, the Sagnac effect is only 2.5% of the gravitational effect but we see it leads to a global shift of the oscillatory pattern.

Let us now describe the result of the experiment. According to the previous considerations, the intensity observed at detector O_3 is

$$I(O_3) = \alpha\left\{1 + \cos\left[q\sin\left(\psi - \psi_0\right)\right]\right\}. \tag{1108}$$

By Fourier transforming this signal, one can extract the frequency $q_{\rm grav}$ of this oscillations. If one repeat this procedure for different wavelengths, one can fit the dependence of $q_{\rm grav}$ with λ which allows us to determine the product $m_{\rm grav}m_{\rm in}$. Let us recall that the neutron mass is usually obtained by mass spectroscopy on the deuteron which leads to the following value

$$m_{\rm n} = m_{\rm D} - m_{\rm p} + \frac{E_\gamma}{c^2} = 1.6747\times10^{-24}{\rm g}, \tag{1109}$$

where E_γ is deuteron binding energy. On the other hand, the COW experiment has found [133]

$$\left(m_{\rm grav}m_{\rm in}\right)^{1/2} = (1.675\pm0.003)\times10^{-24}\,{\rm g}. \tag{1110}$$

This shows that the weak equivalence principle seems to be satisfied even in a purely quantum mechanical situation. This also shows that gravity can be "coupled" to the Schrödinger equation in a standard way. The COW experiment is therefore very important since this was the first time that this was demonstrated. Moreover, if we consider that $m_{\rm n} = m_{\rm in}$ then the two previous equations shows that the COW experiment proves that $m_{\rm in} = m_{\rm grav}$ even in the quantum domain.

24.14.2 The Quantum Galileo Experiment

It is well-known that, classically, the motion of a body in a constant gravitational field only depends on the ratio $m_{\rm grav}/m_{\rm in}$ (which is measured to be unity). However, if one writes the Schrödinger equation for the same situation, namely

$$i\hbar\frac{\partial\Psi(t,z)}{\partial t} = -\frac{\hbar^2}{2m_{\rm in}}\frac{\partial^2\Psi(t,z)}{\partial z^2} + m_{\rm grav}gz\Psi(t,z), \tag{1111}$$

it is apparent that $m_{\rm in}$ and $m_{\rm grav}$ no longer cancel out. Therefore, it is interesting to study how the universality of the free fall is recovered in quantum mechanics. We investigate this point in the following sections.

The Salecker-Wigner-Peres Clock

In this section, we present a simple model of a quantum clock, the so-called "Salecker-Wigner-Peres clock" [136, 137, 138, 139, 140]. We introduce this system because we want to study how a quantum particle falls down in a constant gravitational field. One way to to do that is to measure the time of flight of the particle and to compare it with its classical analogue. Hence the question of how to define the time of flight becomes important. As is well-known, the measurement of time (or, to be more accurate, of time of arrival) is problematic in quantum mechanics [141, 142, 143, 144, 145]. In particular, there is no time operator because time is not a dynamical variable. One way out is to introduce a quantum system, the "clock", that is coupled to the particle and changes its state when the particle crosses the starting and the ending points along its "trajectory", see Fig. 164. Reading these two states then gives information about the time of flight. We now study how this general idea works in practice.

We assume that the clock has an odd number $N = 2j + 1$ of states. The Hamiltonian of the clock is given by

$$H_{\text{clock}} = \omega J = -i\hbar\omega \frac{\partial}{\partial\theta}, \tag{1112}$$

where the quantity θ can be viewed as describing the position of the clock's hand. The corresponding states of the clock are represented by the following wave-function

$$u_n(\theta) = \frac{1}{\sqrt{2\pi}} \mathrm{e}^{in\theta}, \tag{1113}$$

that are eigenfunction of H_{clock} since $H_{\text{clock}} u_n(\theta) = n\hbar\omega u_n(\theta)$. It is also easy to show that

$$\mathrm{e}^{-iH_{\text{clock}}t/\hbar} u_n(\theta) = u_n(\theta - \omega t), \tag{1114}$$

which gives the time evolution of the system.

It is also convenient to introduce another basis $v_s(\theta)$ defined by $(s = 0, \cdots, N-1)$

$$v_s(\theta) = \frac{1}{\sqrt{N}} \sum_{n=-j}^{n=j} \mathrm{e}^{-\frac{2i\pi sn}{N}} u_n(\theta) \tag{1115}$$

$$= \frac{1}{\sqrt{2\pi N}} \frac{\sin\left[N\left(\theta - 2\pi s/N\right)/2\right]}{\sin\left[\left(\theta - 2\pi s/N\right)/2\right]}. \tag{1116}$$

If N is large enough, these functions peak at $\theta = 2\pi s/N$ and this corresponds to the hand of the clock pointing to the s-th hour with an angle uncertainty of $\pm\pi/N$ (hence, as expected, if N is large, the accuracy is good). Moreover, using Eq. (1114), we have

$$\mathrm{e}^{-iH_{\text{clock}}t/\hbar} v_s(\theta) = v_s(\theta - \omega t). \tag{1117}$$

This means that if we evaluate the above equation for a time τ such that $\omega\tau = 2\pi/N$, then one obtains

$$\mathrm{e}^{-iH_{\text{clock}}\tau/\hbar} v_s(\theta) = v_{s+1\,(\mathrm{mod}\,N)}(\theta), \tag{1118}$$

which confirms the interpretation given before.

Let us now consider a free particle traveling along the x-axis. We want to measure the time of flight between $x = 0$ and $x = L$, see Fig. 164. In order for the clock to record this time, we must of course couple it to the particle. Following Ref. [137], we assume that the Hamiltonian of the total system "particle+clock" can be written as

$$H = \frac{p^2}{2m} + \mathcal{P}(x) H_{\text{clock}}, \tag{1119}$$

where $\mathcal{P}(x)$ is the projector operator which is one if $0 < x < L$ and zero otherwise and m is the mass of the particle. We write the eigen wave-functions of the system as

$$\Psi(t, x, \theta) = \psi(x, \theta)\, \mathrm{e}^{-iEt/\hbar}$$

$$= \frac{1}{\sqrt{N}} \sum_{n=-j}^{n=j} \psi_n(x) u_n(\theta) \mathrm{e}^{-iEt/\hbar}, \tag{1120}$$

and inserting this form into the Schrödinger equation, one obtains

$$\sum_{n=-j}^{n=j}\left[-\frac{\hbar^2}{2m}\frac{\mathrm{d}^2\psi_n}{\mathrm{d}x^2}+n\hbar\omega\mathcal{P}(x)\psi_n(x)\right.$$
$$\left.-E\psi_n(x)\right]u_n(\theta)=0. \tag{1121}$$

Therefore, we just have to solve the time-independent Schrödinger equation in presence of a rectangular barrier. Of course, this exercise is solved in any textbooks on quantum mechanics, see for instance Ref. [57]. It is straightforward to show that

$$\psi_n(x)=\begin{cases}A\mathrm{e}^{ikx}+B\mathrm{e}^{-ikx}, & x<0,\\ C\mathrm{e}^{ipx}+D\mathrm{e}^{-ipx}, & 0<x<L,\\ E\mathrm{e}^{ikx}, & x>L,\end{cases} \tag{1122}$$

where we have defined

$$k = \frac{\sqrt{2mE}}{\hbar}, \tag{1123}$$
$$p = \frac{\sqrt{2m(E-n\hbar\omega)}}{\hbar}=k\sqrt{1-\epsilon}, \tag{1124}$$

with $\epsilon\equiv n\hbar\omega/E$, a quantity which measures how the clock perturbs the particle. The quantities A, B, C, D and E are integration constants that are fixed by requiring the wave-function and its derivative to be continuous at the barrier. Notice that, after the barrier there is only one branch; this is of course because we assume that the particle is coming from the left, see Fig. 164. Matching ψ_n and $\mathrm{d}\psi_n/\mathrm{d}x$ at $x=0$ and $x=L$, one obtains

$$A = \frac{1}{4p}\left[(k+p)\mathrm{e}^{i(k-p)L}-(k-p)\mathrm{e}^{i(k+p)L}\right]E+\frac{1}{4k}\left[(k+p)\mathrm{e}^{i(k-p)L}+(k-p)\mathrm{e}^{i(k+p)L}\right]E, \tag{1125}$$
$$B = \frac{1}{4p}\left[(k+p)\mathrm{e}^{i(k-p)L}-(k-p)\mathrm{e}^{i(k+p)L}\right]E-\frac{1}{4k}\left[(k+p)\mathrm{e}^{i(k-p)L}+(k-p)\mathrm{e}^{i(k+p)L}\right]E. \tag{1126}$$

Then, we assume that the clock does not perturb the particle too much and, as a consequence, that $\epsilon\ll 1$. In this case, $B\simeq 0$ and $A\simeq \mathrm{e}^{i(k-p)L}E$. Indeed, we have $p=k\sqrt{1-\epsilon}$ which, at leading order, simply gives $k\simeq p$ (but, of course, one should use the next to leading order when one estimates the argument of the exponentials, see below). Then, initially, this means that the wave-function can be written as, see Eq. (1120)

$$\psi(x,\theta)=\frac{1}{\sqrt{N}}\sum_{n=-j}^{n=j}A\mathrm{e}^{ikx}u_n(\theta)=A\mathrm{e}^{ikx}v_0(\theta),\quad x\ll 0, \tag{1127}$$

because k does not depend on n, see Eq. (1123). We see that, initially, the clock points to zeroth hour, as expected. After the barrier, using the previous considerations, the expression of the wave-function can be written as, see Eq. (1120)

$$\psi(x,\theta)\simeq\frac{A}{\sqrt{N}}\mathrm{e}^{ikx}\sum_{n=-j}^{n=j}\mathrm{e}^{-i(k-p)L}u_n(\theta),\quad x\gg L, \tag{1128}$$

where we have used Eq. (1115). But we have

$$p\simeq k\left(1-\frac{\epsilon}{2}\right)\simeq k-\frac{n\omega}{(2E/m)^{1/2}}, \tag{1129}$$

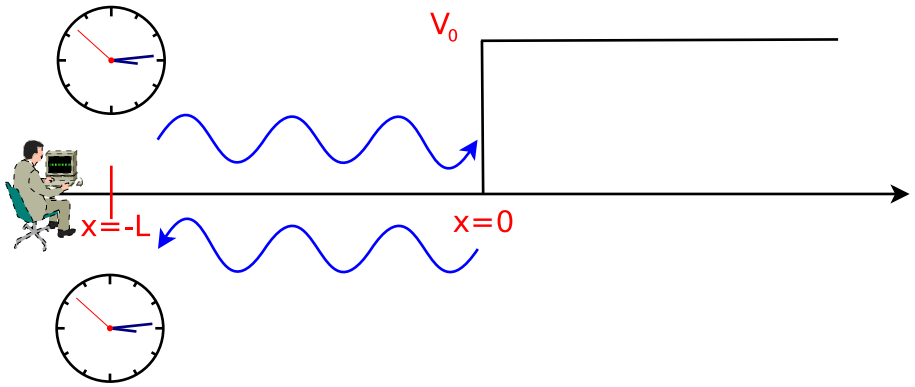

Figure 165: Measurement of an out-and-back time of flight. An observer, located at $x = -L$ sends a particle towards a square potential step located at $x = 0$. The physicist turns on the clock when the particle leaves and turn it off when the reflected wave (*i.e.* the reflected particle) comes back and reaches $x = -L$.

which implies that (for $x \gg L$)

$$\psi(x,\theta) = \frac{A}{\sqrt{2\pi N}} \mathrm{e}^{ikx} \sum_{n=-j}^{n=j} \mathrm{e}^{in\theta - in\omega L/(2E/m)^{1/2}} \tag{1130}$$

$$= A\mathrm{e}^{ikx} v_0 \left(\theta - \frac{\omega L}{\sqrt{2E/m}}\right). \tag{1131}$$

This means, see Eq. (1117), that the clock now indicates the time

$$t = \frac{L}{(2E/m)^{1/2}} = \frac{L}{v_{\rm clas}}, \tag{1132}$$

where $v_{\rm clas} \equiv (2E/m)^{1/2}$ is the classical velocity. Therefore, the clock has measured a time of flight which is nothing but the classical time of flight $L/v_{\rm clas}$ [137].

We now consider the situation represented in Fig. 165, see Ref. [140]. An observer, located at $x = -L$, sends a particle towards a reflecting barrier of height V_0 located at $x = 0$. When the particle leaves the Peres clock is turned on. Then the particle bounces back and when it comes back at the observer position, the Peres clock is turned off. With this experimental set up, one can measure the out-and-back time of flight. Following the same approach as before, the wave-function can be written as

$$\psi_n(x) = \begin{cases} A\mathrm{e}^{ikx} + B\mathrm{e}^{-ikx}, & x < 0, \\ C\mathrm{e}^{-px}, & x > 0, \end{cases} \tag{1133}$$

where we now have

$$k = \frac{\sqrt{2m(E - n\hbar\omega)}}{\hbar} = \frac{\sqrt{2mE}}{\hbar}\sqrt{1-\epsilon} \tag{1134}$$

$$p = \frac{\sqrt{2m(V_0 + n\hbar\omega - E)}}{\hbar}$$

$$= \frac{\sqrt{2m(V_0 - E)}}{\hbar}\left(1 + \frac{E}{V_0 - E}\epsilon\right)^{1/2}. \tag{1135}$$

Then, we have to match the wave-function and its derivative at $x = 0$. This gives

$$B = \frac{k - ip}{k + ip} A \equiv RA, \tag{1136}$$

$$C = \frac{2k}{k + ip} A. \tag{1137}$$

As before, we assume that, initially, the clock was is a given state, here $v_0(\theta)$. Therefore, the wave-function in the region $x < 0$ can be expressed as, see Eq. (1120)

$$\psi(x, \theta) = \frac{A}{\sqrt{N}} \sum_{n=-j}^{n=j} \left(\mathrm{e}^{ikx} + R\mathrm{e}^{-ikx} \right) u_n(\theta). \tag{1138}$$

But $|R| = 1$ and its phase is given by $-2 \arctan(p/k)$. As a consequence, one has

$$\begin{aligned} \psi(x = -L, \theta) &= \frac{A}{\sqrt{N}} \sum_{n=-j}^{n=j} \Big[\mathrm{e}^{-ikL} \\ &+ \mathrm{e}^{-2i \arctan(p/k)} \mathrm{e}^{ikL} \Big] u_n(\theta). \end{aligned} \tag{1139}$$

The next step is similar to the case of a free particle, namely we expand the phases of the two wave-function branches in terms of the parameter ϵ. This gives

$$\begin{aligned} \psi(x = -L, \theta) &= \frac{A}{\sqrt{2\pi N}} \sum_{n=-j}^{n=j} \exp\left[-\frac{iL}{\hbar}\sqrt{2mE} + in\left(\theta + \frac{\omega L}{v_{\mathrm{clas}}}\right)\right] + \exp\left[-2i \arctan\left(\sqrt{\frac{V_0 - E}{E}}\right) + \frac{iL}{\hbar}\sqrt{2mE} \right. \\ &+ \left. in\left(\theta - \frac{\omega L}{v_{\mathrm{clas}}} - \frac{\hbar\omega}{\sqrt{E(V_0 - E)}}\right)\right] \end{aligned} \tag{1140}$$

$$\begin{aligned} &= \frac{A}{\sqrt{N}} \exp\left(-\frac{iL}{\hbar}\sqrt{2mE}\right) v_0\left(\theta + \frac{\omega L}{v_{\mathrm{clas}}}\right) + \frac{A}{\sqrt{N}} \exp\left[-2i \arctan\left(\sqrt{\frac{V_0 - E}{E}}\right) + \frac{iL}{\hbar}\sqrt{2mE}\right] \\ &\times v_0\left(\theta - \frac{\omega L}{v_{\mathrm{clas}}} - \frac{\hbar\omega}{\sqrt{E(V_0 - E)}}\right), \end{aligned} \tag{1141}$$

and this allows us to directly read the time indicated by the clock. For the first branch, it is $-L/v_{\mathrm{clas}}$ while for the second one, it is given by $L/v_{\mathrm{clas}} + \hbar/\sqrt{E(V_0 - E)}$. As a consequence, the time of flight of the particle can be expressed as

$$\Delta t = \frac{2L}{v_{\mathrm{clas}}} + \frac{\hbar}{\sqrt{E(V_0 - E)}}. \tag{1142}$$

Therefore, the time of flight is the classical one, $2L/v_{\mathrm{clas}}$, but, this time, there is an additional contribution. This one can be understood as follows. The quantity Δt can be re-written as [140]

$$\Delta t = \frac{2(L + d)}{v_{\mathrm{clas}}}, \tag{1143}$$

where $d = 1/p$, see Eq. (1135) (evaluated at $\epsilon = 0$) is the penetration depth into the potential step. This means that there is an additional delay due to the tunnel effect and the fact that the particle has a non vanishing probability to be below the barrier [140]. In this regime, the "velocity" is nevertheless given by its classical value v_{clas} [140].

This concludes this section on the Peres clock. We have seen that this is a useful device to measure times of flight. We now use it to study the motion of a quantum particle in an uniform gravitational field.

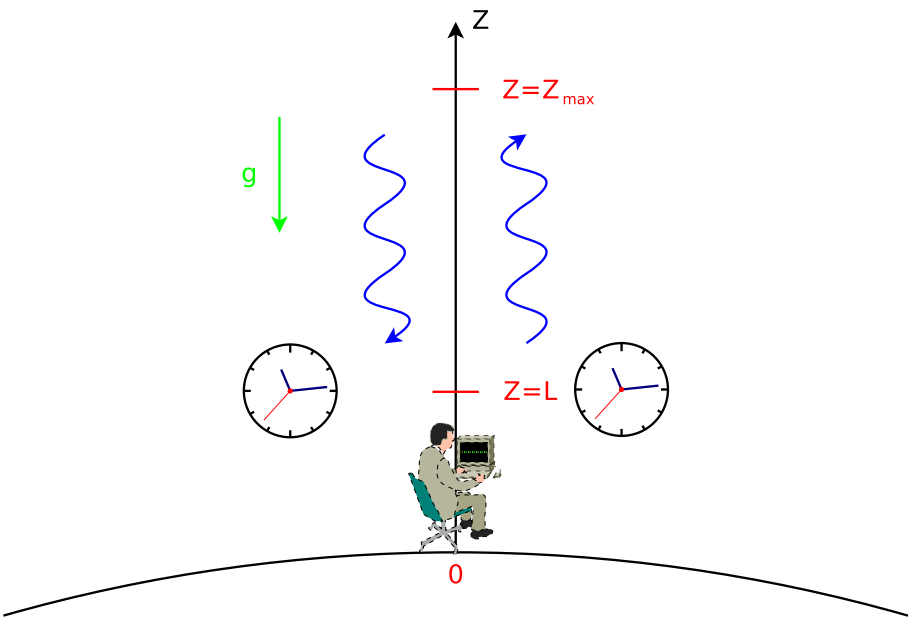

Figure 166: Sketch of a quantum particle in an uniform gravitational field. The particle is sent upward, the initial time being recorded by a quantum Peres clock. The particle reaches a maximum altitude and then falls back to the detector at $z = L$ where the Peres clock measures this return time.

The Gravitational Case

In this section, we study the status of the weak equivalence principle and of the universality of the free fall in quantum mechanics [146, 140, 139, 147, 148, 149, 150].

Following Ref. [140], let us consider the situation where a particle is sent upwards in a uniform gravitational field, see Fig. 166. If z denotes the vertical coordinate, the corresponding classical situation is described by the following Lagrangian

$$L(\dot{z}, z) = \frac{m_{\rm in}}{2}\dot{z}^2 - m_{\rm grav} g z, \tag{1144}$$

where g is the gravitational field and where we have made the difference between the inertial mass $m_{\rm in}$ and the gravitational mass (the "gravitational charge") $m_{\rm g}$. The solution to the classical equation of motion reads

$$z(t) = -\frac{1}{2}\frac{m_{\rm grav}}{m_{\rm in}} g t^2 + v_{\rm ini} t + L, \tag{1145}$$

where $z = L$ is the initial altitude (at $t = 0$) and $v_{\rm ini}$ is the initial velocity, related to the energy E of the particle by the following expression

$$v_{\rm ini} = \sqrt{2g\frac{m_{\rm grav}}{m_{\rm in}}}\left(\frac{E}{m_{\rm grav} g} - L\right)^{1/2}. \tag{1146}$$

Of course, the motion of the particle only depends on the ratio $m_{\rm grav}/m_{\rm in}$. The maximum altitude, $z_{\rm max}$, reached by the particle, see Fig. 166, is given by

$$z_{\rm max} = \frac{E}{m_{\rm grav} g}, \tag{1147}$$

which means that, from its initial position to $z_{\rm max}$, the particle can rise a distance of $E/(m_{\rm grav} g) - L$. After having reached $z_{\rm max}$, the particle falls back and the up-to-down classical time of flight reads

$$\Delta t = 2\sqrt{\frac{2}{g}}\left(\frac{m_{\rm in}}{m_{\rm g}}\right)^{1/2}\left(\frac{E}{m_{\rm grav} g} - L\right)^{1/2}. \tag{1148}$$

If $m_{\rm grav} = m_{\rm in}$, this equation can also be written as $\Delta t = 2v_{\rm ini}/g$.

Then, we would like to consider the same situation but from a quantum-mechanical point of view [140]. In particular, we would like to measure the quantum time of flight. Given the discussion of the previous section, it is clear that we must couple the quantum particle to a Peres clock located at $z = L$. Then, the next step is, of course, to solve the Schrödinger equation. Following the previous considerations, we just have to consider the equivalent of Eq. (1121), but for the case of an uniform gravitational field. It reads

$$\frac{{\rm d}^2\psi_n}{{\rm d}z^2} + \left[\frac{2m_{\rm in}\left(E - n\hbar\omega\right)}{\hbar^2} - \frac{2m_{\rm in}m_{\rm grav}g}{\hbar^2}z\right]\psi_n = 0. \tag{1149}$$

It is straightforward to obtain that the solution can be expressed in terms of Airy functions [48, 49] ${\rm Ai}(z)$ and ${\rm Bi}(z)$. If we retain only the branch that leads to a bounded wave-function, the result is given by

$$\psi(z,\theta) = \frac{A}{\sqrt{N}}\sum_{n=-j}^{n=j}{\rm Ai}\left(\frac{z-b}{a}\right)u_n(\theta), \tag{1150}$$

where A is constant fixed by the normalization of the wave-function and a and b are defined by

$$a = \left(\frac{\hbar^2}{2m_{\rm in}m_{\rm grav}g}\right)^{1/3}, \tag{1151}$$

$$b = \frac{E - n\hbar\omega}{m_{\rm grav}g}. \tag{1152}$$

The next step consists in evaluating the wave-function at $x = L$, with the assumption that the return point is located far from the maximum altitude. This means that $L - b$ is a negative quantity and that $|L-b|$ is large [more precisely, one has $L-b = L-E/(m_{\rm grav}g)+E\epsilon/(m_{\rm grav}g)$ and the quantity $L - E/(m_{\rm grav}g)$ is minus the distance the particle can rise, see the remark after Eq. (1147). Therefore, $L - b < 0$ and, if this distance is large, $|L - b|$ is indeed a large quantity]. In this limit, one has

$$\psi(L,\theta) \simeq \frac{A}{2i\sqrt{\pi N}}\sum_{n=-j}^{n=j}\left(\frac{z-b}{a}\right)^{-1/4} \times\left({\rm e}^{i\xi+i\pi/4} - {\rm e}^{-i\xi-i\pi/4}\right)u_n(\theta), \tag{1153}$$

where $\xi \equiv (2/3)[(b - L)/a]^{3/2}$. Explicitly, this quantity can be expressed as

$$\xi = \frac{2}{3a^{3/2}}\left[\frac{E}{m_{\rm grav}g}(1-\epsilon) - L\right]^{3/2} \tag{1154}$$

$$\simeq \frac{2}{3a^{3/2}}\left(\frac{E}{m_{\rm grav}g} - L\right)^{3/2} - \frac{1}{a^{3/2}}\left(\frac{E}{m_{\rm grav}g} - L\right)^{1/2}\frac{n\hbar\omega}{m_{\rm grav}g}. \tag{1155}$$

In order to calculate the difference between the two times indicated by the clock and corresponding to the two branches of the wave-function, it is in fact sufficient to estimate the part of the phase shift that depends on n. Therefore, it is clear that the phase shift $\pm\pi/4$ in the expression (1153) will not contribute because it is n-independent. Moreover, the term $[(z - b)/a]^{-1/4}$ is n-dependent but is common to the two branches of the wave-functions. As a consequence, it will cancel out when the phase shift is determined (but would participate to the "absolute" time

indicated by the clock when the particle leaves $z = L$ and returns to $z = L$). Summarizing, the up-and down time of flight is given by

$$\Delta t = \frac{2}{a^{3/2}}\left(\frac{E}{m_{\rm grav}g} - L\right)^{1/2}\frac{\hbar}{m_{\rm grav}g} \tag{1156}$$

$$= 2\sqrt{\frac{2}{g}}\left(\frac{m_{\rm in}}{m_{\rm grav}}\right)^{1/2}\left(\frac{E}{m_{\rm grav}g} - L\right)^{1/2}, \tag{1157}$$

that is to say exactly Eq. (1148), see Ref. [140]. Several remarks are in order here. Firstly, although it is of quantum-mechanical origin, the above equation does not contain $\hbar$ that cancels out. Secondly, this result seems to indicate that the weak equivalence principle holds at the quantum level. Thirdly, it may appear surprising that the quantum Δt is not corrected by a term corresponding to the penetration depth, see Sec. 24.14.2, in particular Eq. (1143), as it is the case for a square potential. The interpretation given in Ref. [140] is that there is a finite probability that the particle tunnels below the barrier but there is also a finite probability that the particle is scattered back before the classical turning point. If these two probabilities cancel then one obtains the classical prediction. Fourthly, the above result is valid only if the return time is measured far from the maximum altitude. What happens if, on the contrary, the particle starts from a position which is close to the turning point? To investigate this case, we re-start from Eq. (1150) and write the solution as

$$\psi(z,\theta) = \frac{A}{\sqrt{N}}\sum_{n=-j}^{n=j}\frac{\sqrt{y}}{3}\left\{\left[{\rm e}^{i\pi/3}J_{1/3}\left(\zeta\right) + {\rm e}^{-i\pi/3}J_{-1/3}\left(\zeta\right)\right] + \left[\left(1-{\rm e}^{i\pi/3}\right)J_{1/3}\left(\zeta\right) + \left(1-{\rm e}^{-i\pi/3}\right)J_{-1/3}\left(\zeta\right)\right]\right\}u_n(\theta), \tag{1158}$$

where $y \equiv (b-z)/a > 0$ and $\zeta \equiv 2y^{3/2}/3$. In this way, we have identified the incident (first term in the squared bracket) and the reflected wave (second term in the square bracket). Indeed, using the asymptotic behavior of the Bessel functions at infinity, one can check that each branches give precisely ${\rm e}^{\pm(i\xi+i\pi/4)}$ if $z = L$, see Eq. (1153). If we now consider the limit $y \ll 1$, then one arrives at

$$\psi(z,\theta) = \frac{A}{\sqrt{N}}\sum_{n=-j}^{n=j}\left\{\left[\frac{3^{-2/3}}{2\Gamma(2/3)} + \frac{3^{-4/3}}{2\Gamma(4/3)}y\right] + i\sqrt{3}\left[-\frac{3^{-2/3}}{2\Gamma(2/3)} + \frac{3^{-4/3}}{2\Gamma(4/3)}y\right] + \left[\frac{3^{-2/3}}{2\Gamma(2/3)} + \frac{3^{-4/3}}{2\Gamma(4/3)}y\right]\right.$$
$$\left. -i\sqrt{3}\left[-\frac{3^{-2/3}}{2\Gamma(2/3)} + \frac{3^{-4/3}}{2\Gamma(4/3)}y\right] + \cdots\right\}u_n(\theta), \tag{1159}$$

the two first terms corresponding to the incident wave and the two last ones to the reflected wave. The two branches are of course complex conjugate to each other. Therefore, if we denotes by $\aleph$ the complex number corresponding to the two first terms in the above equation, then the wave-function takes the form

$$\psi(z,\theta) \simeq \frac{A}{\sqrt{N}}\sum_{n=-j}^{n=j}|\aleph|\left({\rm e}^{i\arg\aleph} + {\rm e}^{-i\arg\aleph}\right)u_n(\theta), \tag{1160}$$

where

$$\arg\aleph = \arctan\left[\sqrt{3}\frac{3^{2/3}\Gamma(2/3)y - 3^{4/3}\Gamma(4/3)}{3^{2/3}\Gamma(2/3)y + 3^{4/3}\Gamma(4/3)}\right]. \tag{1161}$$

The rest of the calculation proceeds as before. We first expand the phase in ϵ and, then, take the limit $E/(m_{\rm g}g) - L \to 0$. This leads to

$$\arg\aleph \simeq -\frac{\pi}{3} - \frac{3^{5/6}}{6}\frac{\Gamma(2/3)}{\Gamma(4/3)}\frac{\hbar}{m_{\rm grav}ga}n\omega. \tag{1162}$$

As a consequence, one finds that the time of flight is given by

$$\Delta t \simeq 2\frac{3^{5/6}}{6}\frac{\Gamma(2/3)}{\Gamma(4/3)}2^{1/3}\left(\frac{m_{\rm in}}{m_{\rm grav}}\right)^{1/3}\left(\frac{\hbar}{m_{\rm grav}g^2}\right)^{1/3} \tag{1163}$$

$$\simeq 1.59\times\left(\frac{m_{\rm in}}{m_{\rm grav}}\right)^{1/3}\left(\frac{\hbar}{m_{\rm grav}g^2}\right)^{1/3}, \tag{1164}$$

in rough agreement with Ref. [140]. This time, we notice that $\hbar$ has not canceled in the final expression and that the time of flight is different from its classical counterpart (1148). This also means, as already mentioned, that the cancellation which leads to a quantum time of flight equals to the classical one is in fact valid only if the particle starts far from the turning point.

We conclude that the weak equivalence principle (or the universality of the free fall) can be extended to the quantum regime. The linear potential seems to possess precisely the shape which leads to identical times of flight. It is important to realize that this property depends on the shape of the potential and would not be obtained with another shape, see Ref. [140]. Moreover, this seems to be true only far from the turning point. If one identifies the wave-vector to $k = (2m_{\rm in}m_{\rm grav}g/\hbar^2)^{1/3}$, see Ref. [151], the de Broglie relation $v \simeq \hbar k/m$ allows us to estimate a velocity. Then, from the quantum time of flight, see Eq. (1164), we can construct a length $\simeq [\hbar^2/(m^2 g)]^{1/3}$ which typically controls the validity of the approximation just mentioned.

Atom Trampoline

In this section, we want to briefly mention the case of the "atom trampoline" [150, 151]. Let us consider again the experimental set up of the previous section but let us now assume that a reflecting wall has been installed on the ground, at $z = 0$. Then, the boundary condition $\psi_n(0) = 0$ leads to $\mathrm{Ai}(-b/a) = 0$. If z_n denotes the zero of the Airy function, this means that we now have a discrete spectrum of energy levels given by

$$E_n = -z_n \left(\frac{\hbar^2 m_{\rm grav}^2 g^2}{2m_{\rm in}}\right)^{1/3}. \tag{1165}$$

It is interesting to notice that this result depends on the ratio $m_{\rm grav}^2/m_{\rm in}$ and not on $m_{\rm grav}/m_{\rm in}$. Moreover, this spectrum has been observed (with ultra-cold neutrons which leads to E_n of the order of $\sim 10^{-12}\,$eV) in the gravitational field of the Earth [152, 153]. Therefore, this result confirms the discussion about the COW experiment described in Sec. 24.14.1. It experimentally establishes that the gravitational force "couples" to the Schrödinger equation in a standard way.

Schrödinger Equation in an Accelerated Frame

It is also frequent to refer to the weak equivalence principle as the property stating that, locally, the effect of a constant gravitational field can be mimicked by an accelerating frame. Therefore, it is interesting to study whether this claim holds in quantum mechanics. This question has been studied in Refs. [146, 150, 151]. Here, we follow the treatment of Ref. [146].

Let us consider the free Schröndinger equation (in one dimension to simplify the problem). It reads

$$i\hbar\frac{\partial\Psi(t,z)}{\partial t} = -\frac{\hbar^2}{2m}\frac{\partial^2\Psi(t,z)}{\partial z^2}. \tag{1166}$$

Then, let us consider the following coordinate transformation

$$z' = z - vt - \frac{1}{2}gt^2 \tag{1167}$$

$$t' = t. \tag{1168}$$

It is straightforward to show that the function $\varphi(t',z')$ defined according to

$$\begin{aligned}\Psi(t,z) &= \varphi\left[t'(t), z'(t,z)\right] \\ &\quad \times \exp\left[\frac{imv}{\hbar}\left(z' + \frac{vt'}{2}\right)\right. \\ &\quad \left. + \frac{imgt'}{\hbar}\left(z' + \frac{vt'}{2} + \frac{gt'^2}{6}\right)\right],\end{aligned} \tag{1169}$$

satisfies the equation [146]

$$i\hbar\frac{\partial\varphi(t',z')}{\partial t'} = -\frac{\hbar^2}{2m}\frac{\partial^2\varphi(t',z')}{\partial z'^2} + mgz'\varphi(t',z'). \tag{1170}$$

The potential in the above equation is precisely of the form describing a constant gravitational field. In this sense, we find that the equivalence between a constant gravitational field and an accelerated frame propagates to quantum mechanics.

Falling Composite Quantum Objects

In the previous sections, we have studied how a quantum particle falls in a uniform gravitational field. For instance, we have investigated under which circumstances one can say that the weak equivalence principle holds in quantum mechanics. Here, we would like to study the same question but in the case of a composite quantum object. In particular, it is interesting to ask whether the motion of the composite system (the atom) can depend on its internal state.

Let us start by recalling the Ehrenfest theorem [57] for a quantum particle. It states that the time derivatives of the mean position and momentum are given by (for simplicity, we consider the case of a one-dimensional system since we have in mind a particle falling down along the z-axis)

$$\frac{\mathrm{d}\langle z\rangle}{\mathrm{d}t} = \frac{\langle p_z\rangle}{m_{\mathrm{in}}}, \tag{1171}$$

$$\frac{\mathrm{d}\langle p_z\rangle}{\mathrm{d}t} = -\left\langle\frac{\partial V}{\partial z}\right\rangle. \tag{1172}$$

In the case of a linear potential, $V(z) = m_{\mathrm{grav}}gz$, the two previous equations expressing the Ehrenfest theorem can be combined in such a way that we arrive at

$$\frac{\mathrm{d}^2\langle z\rangle}{\mathrm{d}t^2} = -\frac{m_{\mathrm{grav}}}{m_{\mathrm{in}}}g. \tag{1173}$$

This means that the average position $\langle z\rangle(t)$ evolves exactly as the classical z given in Eq. (1145). However, let us also notice that the variance of the position is not a function of the ratio $m_{\mathrm{grav}}/m_{\mathrm{in}}$ only, see in particular Refs. [146, 147, 148].

After this short reminder, let us consider a bound system of two particles interacting through a potential V which only depends on the distance between them. We also assume that this system is embedded in a region where there is an exterior field described by the potential $U(\boldsymbol{r})$. The corresponding Lagrangian reads

$$\begin{aligned} L\left(\dot{\boldsymbol{r}}_1,\dot{\boldsymbol{r}}_2,\boldsymbol{r}_1,\boldsymbol{r}_2\right) &= \frac{m_{\mathrm{in},1}}{2}\dot{\boldsymbol{r}}_1^2+\frac{m_{\mathrm{in},2}}{2}\dot{\boldsymbol{r}}_2^2-V\left(\boldsymbol{r}_1-\boldsymbol{r}_2\right)\\ &\quad -U\left(\boldsymbol{r}_1\right)-U\left(\boldsymbol{r}_2\right), \end{aligned} \tag{1174}$$

where $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$ are the positions of the two particles and $m_{\mathrm{in},1}$, $m_{\mathrm{in},2}$ their mass. If we now introduce the center of mass position vector,

$$\boldsymbol{r}_{\mathrm{G}} = \frac{m_{\mathrm{in},1}}{m_{\mathrm{in},1}+m_{\mathrm{in},2}}\boldsymbol{r}_1+\frac{m_{\mathrm{in},2}}{m_{\mathrm{in},1}+m_{\mathrm{in},2}}\boldsymbol{r}_2, \tag{1175}$$

and the relative position vector,

$$\boldsymbol{r} = \boldsymbol{r}_1-\boldsymbol{r}_2, \tag{1176}$$

then Eq. (1174) takes the form

$$\begin{aligned} L\left(\dot{\boldsymbol{r}}_{\mathrm{G}},\dot{\boldsymbol{r}},\boldsymbol{r}_{\mathrm{G}},\boldsymbol{r}\right) &= \frac{M}{2}\dot{\boldsymbol{r}}_{\mathrm{G}}^2+\frac{\mu}{2}\boldsymbol{r}^2-V(\boldsymbol{r})\\ &\quad -U(\boldsymbol{r}_1)-U(\boldsymbol{r}_2), \end{aligned} \tag{1177}$$

where $M\equiv m_{\mathrm{in},1}+m_{\mathrm{in},2}$ is the total mass and $\mu\equiv m_{\mathrm{in},1}m_{\mathrm{in},2}/(m_{\mathrm{in},1}+m_{\mathrm{in},2})$ is the reduced one. Of course, in the above expression $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$ must be viewed as function of $\boldsymbol{r}_{\mathrm{G}}$ and $\boldsymbol{r}$[130].

[130]The relation between these quantities is given by

$$\boldsymbol{r}_1 = \boldsymbol{r}_{\mathrm{G}}+\frac{m_{\mathrm{in},2}}{M}\boldsymbol{r}, \tag{1178}$$

$$\boldsymbol{r}_2 = \boldsymbol{r}_{\mathrm{G}}-\frac{m_{\mathrm{in},1}}{M}\boldsymbol{r}. \tag{1179}$$

From the above considerations, it is straightforward to obtain the Hamiltonian of the system. We arrive at the following expression

$$H = \frac{\boldsymbol{p}_{\mathrm{G}}^2}{2M} + \frac{\boldsymbol{p}^2}{2\mu} + V(\boldsymbol{r}) + U(\boldsymbol{r}_1) + U(\boldsymbol{r}_2), \tag{1180}$$

where $\boldsymbol{p}_{\mathrm{G}} \equiv \boldsymbol{p}_1 + \boldsymbol{p}_2$ and $\boldsymbol{p} = (\mu/m_{\mathrm{in},1})\boldsymbol{p}_1 - (\mu/m_{\mathrm{in},2})\boldsymbol{p}_2$. If we now assume that the external field is a uniform gravitational field (directed along the z-axis), then it is easy to show that

$$\begin{aligned} U(\boldsymbol{r}_1) + U(\boldsymbol{r}_2) &= (m_{\mathrm{grav},1} + m_{\mathrm{grav},2})\, g z_{\mathrm{G}} \\ &\quad + \frac{1}{M}\left(m_{\mathrm{grav},1} m_{\mathrm{in},2} - m_{\mathrm{grav},2} m_{\mathrm{in},1}\right) g z \qquad (1181) \\ &\equiv \overline{U}(z_{\mathrm{G}}) + \tilde{U}(z), \qquad (1182) \end{aligned}$$

where, according to Eq. (1176), $z \equiv z_1 - z_2$. As a consequence, the Hamiltonian (1180) takes the form

$$H = H_{\mathrm{G}} + H_{\mathrm{rel}}, \tag{1183}$$

where the center of mass and relative Hamiltonians can be expressed as

$$H_{\mathrm{G}} = \frac{\boldsymbol{p}_{\mathrm{G}}^2}{2M} + \overline{U}(z_{\mathrm{G}}) \tag{1184}$$

$$H_{\mathrm{rel}} = \frac{\boldsymbol{p}^2}{2\mu} + V(\boldsymbol{r}) + \tilde{U}(z). \tag{1185}$$

The physical interpretation of these equations is clear. The center of mass behaves as a free particle embedded in a uniform gravitational field. On the other hand, the internal states of the composite system are determined by the potential $V(\boldsymbol{r})$ but are also affected by the gravitational field through the term $\tilde{U}(z)$. In practice, one expects that $\tilde{U}(z) \ll V(\boldsymbol{r})$ and, therefore, the perturbations of the energy levels will be either very small or even totally negligible. Moreover, because $[z, p_{\mathrm{G},z}] = [z_{\mathrm{G}}, p_z] = 0$, the two above Hamiltonians commute

$$[H_{\mathrm{G}}, H_{\mathrm{rel}}] = 0, \tag{1186}$$

which implies that the total state space is in fact the tensorial product of the center of mass state space and of the relative state space.

Let us now study the behavior of $\langle z_{\mathrm{G}} \rangle$. One has

$$\begin{aligned} \frac{\mathrm{d}\langle z_{\mathrm{G}} \rangle}{\mathrm{d}t} &= \frac{1}{i\hbar}\langle [z_{\mathrm{G}}, H_{\mathrm{G}} + H_{\mathrm{rel}}] \rangle = \frac{1}{i\hbar}\langle [z_{\mathrm{G}}, H_{\mathrm{G}}] \rangle \\ &= \frac{\langle p_{\mathrm{G},z} \rangle}{M}. \qquad (1187) \end{aligned}$$

In the same manner, one can now calculate the evolution of $\langle p_{\mathrm{G},z} \rangle$. One obtains

$$\begin{aligned} \frac{\mathrm{d}\langle p_{\mathrm{G},z} \rangle}{\mathrm{d}t} &= \frac{1}{i\hbar}\langle [p_{\mathrm{G},z}, H_{\mathrm{G}} + H_{\mathrm{rel}}] \rangle = \frac{1}{i\hbar}\langle [p_{\mathrm{G},z}, H_{\mathrm{G}}] \rangle \\ &= \frac{1}{i\hbar}\left\langle \left[p_{\mathrm{G},z}, \overline{U}(z_{\mathrm{G}})\right] \right\rangle \\ &= -\left(m_{\mathrm{grav},1} + m_{\mathrm{grav},2}\right) g. \qquad (1188) \end{aligned}$$

Therefore, combining Eqs. (1187) and (1188), we arrive at the following expression

$$\frac{\mathrm{d}^2\langle z_{\mathrm{G}} \rangle}{\mathrm{d}t^2} = -\frac{m_{\mathrm{grav},1} + m_{\mathrm{grav},2}}{m_{\mathrm{in},1} + m_{\mathrm{in},2}} g. \tag{1189}$$

Of course, this equation is similar to Eq. (1173) and this implies that the center of mass mean value of the quantum composite system will follow the classical trajectory. In particular, this

means that $\langle z_{\rm G}\rangle$ does not depend in which internal energy state the system is placed. Therefore, if, for instance, we consider a falling Hydrogen atom, the behavior of the position mean value of the atom will not depend of whether the atom is in the state, say, $1s$ or $2p$. We also notice that the coefficient in front of g in Eq. (1189) is the ratio of the total gravitational mass to the total inertial mass. In this sense, the weak equivalence principle is also satisfied by the composite quantum systems.

Finally, it is also interesting to repeat the gedanken experiment in Fig. 166 but with a composite system. It seems reasonable to couple the Peres clock to the center of mass of the system which means that the Hamiltonian of the system is still given by

$$H = H_{\rm G} + H_{\rm rel}, \tag{1190}$$

where, now, the center of mass and relative Hamiltonians can be expressed as

$$H_{\rm G} = \frac{\boldsymbol{p}_{\rm G}^2}{2M} + \overline{U}(z_{\rm G}) + \mathcal{P}(z_{\rm G})H_{\rm clock} \tag{1191}$$

$$H_{\rm rel} = \frac{\boldsymbol{p}^2}{2\mu} + V(\boldsymbol{r}) + \tilde{U}(z). \tag{1192}$$

Then, following Eq. (1120), we write the wave-function of the system as

$$\Psi\left(t, \boldsymbol{r}_{\rm G}, \boldsymbol{r}, \theta\right) = \frac{1}{\sqrt{N}} \sum_{n=-j}^{n=j} \psi_n(\boldsymbol{r}_{\rm G})\chi_n(\boldsymbol{r})u_n(\theta)\mathrm{e}^{-iEt/\hbar}. \tag{1193}$$

The next step consists in inserting this wave-function in the Schrödinger equation in order to obtain the equivalent of Eq. (1121). The result can be written as

$$\sum_{n=-j}^{n=j}\Bigg\{\chi_n(\boldsymbol{r})\left[-\frac{\hbar^2}{2M}\Delta_{\rm G}\psi_n(\boldsymbol{r}_{\rm G}) + \overline{U}(z_{\rm G})\psi_n(\boldsymbol{r}_{\rm G}) + n\hbar\omega\mathcal{P}(z_{\rm G})\psi_n(\boldsymbol{r}_{\rm G}) - E_{\rm G}\psi_n(\boldsymbol{r}_{\rm G})\right] + \psi_n(\boldsymbol{r}_{\rm G})\left[-\frac{\hbar^2}{2m}\Delta\chi_n(\boldsymbol{r}) + \tilde{U}(z)\chi_n(\boldsymbol{r}) - E_{\rm rel}\chi_n(\boldsymbol{r})\right]\Bigg\}u_n(\theta) = 0, \tag{1194}$$

where $E = E_{\rm G} + E_{\rm rel}$. This implies that only the center of mass part, $\psi_n(\boldsymbol{r}_{\rm G})$, of the total wave-function will depend on n. As a consequence, the internal part should in fact be written as $\chi(\boldsymbol{r})$ instead of $\chi_n(\boldsymbol{r})$. This means that $\chi(\boldsymbol{r})$ cannot cause a rotation of the Peres clock. Therefore, the time indicated by the clock will not depend on the internal state of the composite system. We conclude that the time of flight of an atom, defined and calculated in terms of the Peres clock, does not depend in which quantum state this atom is placed.

This concludes the section on the weak equivalence principle in quantum mechanics. The result is mixed. We have shown that, very often, it is satisfied in the framework of quantum mechanics. But, on the other hand, it seems sometimes to be modified by quantum effects, see in particular Eq. (1164). Maybe this indicates that its application to the more complicated case of quantum vacuum fluctuations of a field is rather suspicious?

24.15 Conclusions

We are now in a position where we can really formulate the cosmological constant problem. Vacuum fluctuations seem to exist in Nature and to have normal gravitational properties. Therefore, it seems natural to postulate that they participate in the value of the cosmological constant. However, when one tries to use well controlled techniques of quantum field theory to compute their energy density, one obtains a number which seems to be in contradiction with the measurement of Λ that one obtains in cosmology and with the constraints that one deduces from (for instance) the motion of the planets in our solar system. The difficulty of the problem stems from the fact that, in order to remove the above contradiction, one necessarily has to abandon something that is considered as robust, *i.e.* renormalization in quantum field theory, weak equivalence principle, high accuracy measurements of the expansion of the universe, etc ....

Even if this is not the purpose of this article, let us conclude this review with a few words about the solutions that have been proposed to solve the cosmological constant problem, for a complete overview of the subject, see for instance Ref. [154]. Of course, the most obvious solution is super-symmetry [19, 74, 75]. However, as we have discussed in Sec. 24.7.4, super-symmetry has to be broken and this destroys the "miraculous" cancellation of the various terms participating the vacuum energy. In fact, the only common point between these various contributions is gravity. Therefore, this suggests that the mechanism that cancels the cosmological constant makes use of gravity. This idea has been explored in the so-called adjustment mechanisms [155, 728, 157]. These models work reasonably well but, unfortunately, they suffer from a severe disease. Indeed, in these scenarios, the Newton constant is time-dependent and it turns out that the variation of the gravitational coupling is too strong to be compatible with the known constraints on $|\dot{G}/G|$. Therefore, although the idea is very attractive at first sight, it seems that it does not yet exist a realistic realization of it. It is also worth signaling that back-reaction mechanisms have also been studied in Refs. [158, 159]. Here, the idea is that the long wavelength (super-Hubble) cosmological perturbations are described by a stress-energy tensor that exactly cancels the cosmological constant.

Another class of solution is based on quantum gravity and quantum cosmology [160, 161, 162]. It is argued that the no-boundary Hartle-Hawking wave-function is such that it peaks at $\Lambda = 0$. However, this approach suffers from various limitations among which is the fact that the path integral is not properly defined and that probabilities are not positive definite (this comes from the fact that the Wheeler-De Witt equation is in fact similar to a Klein-Gordon equation. The positivity of probabilities in quantum cosmology can be only be restored in the WKB approximation).

Recently, following the pioneered work of Ref. [163], there have been many attempts to solve the cosmological constant problem in the framework of extra dimensions, see chapter seven of Ref. [154] or Ref. [164]. Another popular solution, also based on high-energy physics considerations, is the landscape approach [12] in string theory [165]. This approach assumes that all the pocket universes of the landscape are populated during eternal inflation. Combining this fact with the anthropic principle [1818], it is argued that the most probable value of Λ is approximately the value observed today. This solution suffers from the difficulty of defining a measure on the landscape [167] and the use of the anthropic principle in this context has been criticized in Refs. [168, 169].

Finally, another possibility that has recently been investigated is to modify the Einstein equations such that they become blind to a stress energy tensor of the form $T_{\mu\nu} \propto g_{\mu\nu}$, see Refs. [170, 171, 172].

In order to be complete, let us mention that models of analogue gravity have also been developed to study the vacuum energy problem [173, 174, 175]. In these models, one can calculate the equivalent of the cosmological constant and study precisely its origin since the physics controlling the microscopic constituents is explicitly known. These models are based on many different types of analogue physical systems such as condensed matter systems [176], super-fluid Helium [177], Fermi liquid [178], Bose-Einstein condensates [179, 180] etc ... Then, one can show that a simple calculation of the ground state may lead to an incorrect result, the only possibility in order to reach the correct answer being to fully take into account the microscopic theory. This would indicate that a correct calculation of the cosmological constant must necessarily be based on the fine structure of space-time, *i.e.* probably on a consistent theory of quantum gravity.

As the variety of the subjects studied is this review shows, the cosmological constant problem is a very rich one. Given its difficulty, it is probable that it will have to wait for a new theory beyond the current standard model to find its resolution. This theory will have to describe the gravitational properties of the vacuum fluctuations and to regulate the ultra-violet infinities that appear in the calculation of vacuum energy density. This list of requirements almost constitutes an identity card for a theory of quantum gravity. But the most interesting aspect maybe goes the other way round. Given the fact that cosmology has enabled us to grasp observational signatures related to the vacuum energy, maybe these experimental results will help us to deduce and to establish a convincing theory of quantum gravity? This is the reason why the cosmological constant problem appears to be so important and so interesting.

26 Some Mathematical Methods for Analysis of Experiments

26.1 Analysis

Increasingly, theorists and even busy experimentalists are turning their attention to the fundamental question of how best to analyze a set of data. The main reason for this focus is that the quality and quantity of data have improved dramatically over the past decade. There is every reason to believe that this trend will continue. Anisotropies in the temperature of the CMB have been measured by dozens of experiments already. The satellites MAP and Planck will take these measurements to the next stage, but there is no reason to think this will be the last stage. There are still polarization and very small scale anisotropies to be measured. The power spectrum of matter is probed in a variety of ways; activity here, too, shows no sign of letting up. After the completion of the Sloan Digital Sky Survey and 2DF, the two largest redshift surveys to date, surveyors have begun planning large weak lensing missions and even deeper galaxy surveys. These larger data sets create new challenges in analysis.

A wonderful/disturbing example of these challenges was given recently by Julian Borrill. He used scaling arguments to show that a brute-force algorithm for making a map from the raw data of the Boomerang CMB anisotropy experiment would take 12 years to run on current computers! Already, data sets are far too large for brute-force calculations. And things are rapidly getting more dire. Since typically the number of arithmetic operations scales as the number of pixels cubed, and since MAP and Planck will have of order 10 to 100 times more data than Boomerang, the situation cries out for creative solutions.

Another reason for the recent focus on analysis is one I hope to convey in this chapter: analysis is exciting. The techniques that have been proposed to deal with the complexity of forthcoming data sets are beautiful. The elegance of these techniques is of course enhanced by their importance. But the elegance is there; for this reason alone, it is well worth working through some of these recent advances.

26.1.1 the Likelihood Function

The basic building block of contemporary analysis is the likelihood function. This is defined as the probability that a given experiment would get the data it did given a theory. This seemingly simple definition is exceedingly powerful. Once we have the likelihood function, with a caveat or two, we can determine the parameters of the theory (best estimate is the place in parameter space where the likelihood function is largest) along with errors (determined by the width of the likelihood function). We start with a simple example and move on to the likelihood function for the CMB and then a galaxy survey.

Simple Example

Suppose you want to weigh somebody. Since you are a scientist, you know that, in addition to the measurement, you should also report an uncertainty. So you set up 100 different scales and record the person's weight on each of these different scales. Given these 100 numbers, what value should you report for the weight and the uncertainty in the weight? We all know the answer to this question, so let's introduce the formalism of the likelihood function in this simple context.

The likelihood function is the probability of getting the hundred numbers given a theory. Our theory will be that each measurement is the sum of a constant signal (the person's weight) w and noise, with the noise drawn from a Gaussian distribution with mean zero and variance σ_w^2. Thus our "theory" has two free parameters, w and σ_w. If only one data point d was taken, the probability of getting d given the theory would be

$$P\left[d|w,\sigma_w\right] := \mathcal{L}\left(d;w,\sigma_w\right) = \frac{1}{\sqrt{2\pi\sigma_w^2}}\exp\left\{-\frac{(d-w)^2}{2\sigma_w^2}\right\}$$

Here and throughout, $P[x|y]$ denotes the probability of x given y. Equation (11.1) simply restates the assumptions that $d-w$ is equal to noise and that the noise is drawn from a Gaussian distribution with standard deviation σ_w. In the limit that σ_w becomes very small, this function becomes sharply peaked at $d = w$. Since we are making $N_{\rm m} = 100$ independent measurements, the likelihood function is the product of all the individual likelihood functions. That is,

$$\mathcal{L} = \frac{1}{\left(2\pi\sigma_w^2\right)^{N_m/2}}\exp\left\{-\frac{\sum_{i=1}^{N_{\rm wi}}\left(d_i-w\right)^2}{2\sigma_w^2}\right\}$$

Notice that, although the data are distributed as a Gaussian, the likelihood function is not Gaussian in all the theoretical parameters (it is in w but is not in σ_w).

We are interested in the value of the theoretical parameters w and σ_w. Thus, we don't want $P\left[\{d_i\}\,|w,\sigma_u\right]$. which is the likelihood function we have computed. Rather, we want $P\left[u:\sigma_{w'}\mid\{d_i\}\right]$. To obtain the latter from the former we can use a simple relation from elementary probability theory,

$$P[B\cap A] = P[B|A]P[A]$$

$$= P[A|B]P[B].$$

In this context $A = \{d_i\}$ and $B = \{w,\sigma_w\}$, so the equality between the two lines of Eq. (11.3) means that

$$P\left[w,\sigma_w\mid\{d_i\}\right] = \frac{P\left[\{d_i\}\,|w,\sigma_w\right]P\left[w,\sigma_w\right]}{P\left[\{d_i\}\right]}.$$

The denominator can be rewritten by realizing that when we integrate the probability $P\left[w,\sigma_w|d\right]$ over all values of the parameters w,σ_w, we must get 1. So the denominator is equal to the integral of the numerator over w,σ_w. As a result, the denominator does not depend on the parameters w and σ_w, so it does not affect the place in parameter space where the likelihood function peaks or the width of the likelihood function. For the most part, then, we are free to ignore it.

To get the probability we want we need the likelihood function - the first term in the numerator-and also the prior probability $P\left[w,\sigma_w\right]$. If we possess prior information about these quantities, we might use this information here. If we want to be conservative, and assume nothing, we put in a uniform prior for the parameters. Then,

$$P\left[w,\sigma_w\mid\{d_i\}\right]\propto\mathcal{L},$$

the proportionality constant being independent of the parameters and therefore of little interest. Many people find this idea of using prior information disturbing. Indeed, even the conservative choice of a uniform prior is not as innocent as it sounds. If we had taken the

parameter to be σ_w^2 instead of σ_w and we had assumed a prior uniform in σ_w^2 (i.e., that equal intervals of σ_w^2 are equally likely), we would get a different answer for the final probability (try it!). Nonetheless, the dependence on the prior is a problem only in cases where the data are not very discriminatory. If the data do have discriminatory power, then the likelihood function $P\left[\{d_i\}\,|w,\sigma_w\right]$ will be sharply peaked and any reasonable prior will not affect the final results.

We can now find best-fit values for our parameters w and σ_w. Simply find the place in parameter space where the likelihood function is largest. In this simple example, we can proceed analytically by differentiating $\mathcal{L}$ with respect to each of the parameters. First consider the derivative with respect to w.

$$\frac{\partial \mathcal{L}}{\partial w} = \frac{\sum_{j=1}^{N_\mathrm{m}} (d_j - w)}{\sigma_w^2 \left(2\pi\sigma_w^2\right)^{N_\mathrm{m}/2}} \exp\left\{ -\frac{\sum_{i=1}^{N_\mathrm{m}} (d_i - w)^2}{2\sigma_w^2} \right\}.$$

For this derivative to be zero, we set the prefactor

$$\sum_{i=1}^{N_\mathrm{m}} (d_i - w) = 0$$

or equivalently, the likelihood is a maximum when

$$w = \bar{w} = \frac{1}{N_\mathrm{m}} \sum_{i=1}^{N_\mathrm{m}} d_i$$

the expected answer. Similarly, we can find what the most probable value of σ_w^2 is by computing

$$\frac{\partial \mathcal{L}}{\partial \sigma_w^2} = \mathcal{L}\left[-\frac{N_\mathrm{m}}{2\sigma_w^2} + \frac{\sum_{i=1}^{N_\mathrm{m}} (d_i - w)^2}{2\sigma_w^4} \right]$$

and setting it equal to zero. Solving for the variance σ_w^2, we find a most probable value of

$$\sigma_w^2 = \frac{\sum_{i=1}^{N_\mathrm{m}} (d_i - \bar{w})^2}{N_\mathrm{m}}$$

again the expected result.

We have found the best-fit values of our theoretical parameters. What is the error in these best-fit values? The error is just proportional to the width of the likelihood function. A simple way to approximate the width is to assume that $\mathcal{L}$ is Gaussian in the parameters, or equivalently that $\ln \mathcal{L}$ is quadratic in the parameters. We know in general that the variance of a Gaussian distribution is twice the inverse of the coefficient of the quadratic term, so we can simply identify the variance (the square of the error) by computing this coefficient. Let's work this out explicitly for w:

$$\begin{aligned} \ln \mathcal{L}(w) &= \ln \mathcal{L}(\bar{w}) + \frac{1}{2} \frac{\partial^2 \ln \mathcal{L}}{\partial w^2}\bigg|_{w=\bar{w}} (w - \bar{w})^2 \\ &= \ln \mathcal{L}(\bar{w}) - \frac{N_\mathrm{m}}{2\sigma_w^2}(w - \bar{w})^2. \end{aligned}$$

Thus the width of the likelihood function at its maximum is $\sigma_w / N_\mathrm{m}^{1/2}$. This is the one-sigma error in our determination of w. This too is familiar: as more measurements are taken, the noise gets beaten down by a factor of 1 over the square root of the number of independent measurements. It is important to reiterate that the uncertainty on our estimate of the weight is not equal to σ_w.

Two numbers then sum up all $N_{\rm m}$ measurements: our best guess for the person's weight - in this case $\bar{w}$ given by Eq. (11.8) - and the error on this estimate, here equal to $\sigma_w/N_{\rm m}^{1/2}$. Therefore, we can compress all 100 measurements into just two by rewriting the likelihood function as

$$\mathcal{L} = \frac{1}{\sqrt{2\pi C_N}} \exp\left\{\frac{-(w-\bar{w})^2}{2C_N}\right\}$$

where the variance due to noise is now

$$C_N = \frac{\sigma_w^2}{N_{\rm m}}$$

This form of the likelihood has precisely the same maximum and width as does the form with all $N_{\rm m}$ data points. Thus it has compressed all the information in the likelihood function into two numbers, $\bar{w}$ and C_N. Moving away from the weight metaphor, we can apply the above to the CMB. Instead of a true weight, the signal s is the true CMB temperature at a given point on the sky. The many measurements of the signal correspond to many measurements of the temperature at that point. The signal at that spot is a constant, and the data are the sum of the constant signal plus noise (atmospheric, instrumental, or both). The compression of all the different measurements into one data point with an associated error as in Eq. (11.12) is called map-making. We will take this up in more detail in Section 11.5. Now, though, we must move beyond the likelihood of Eq. (11.12). For we know that no theory predicts a value for the temperature at a particular position on the sky; i.e., no theory predicts s. Rather all theories predict a distribution of temperatures, from which s at a given pixel is drawn. We must now incorporate this distribution into the likelihood function.

CMB Likelihood

Let's convert the notation of the previous subsection to the CMB. The true temperature anisotropy in a given spot on the sky s replaces w, while the data point $\bar{w}$ (really the average of many measurements) becomes the estimated value of this temperature anisotropy, call it Δ.[1] The variance of this estimator C_N, which represents the spread of the measurements, is also given. How can this set of data (Δ, C_N) be compared with theory? The simplest theories, such as inflation, predict that the signal in a given spot on the sky is drawn from a Gaussian distribution. So the probability that the sky temperature falls in a range between s and $s+ds$ is

$$P(s)ds = \frac{1}{\sqrt{2\pi C_S}} \exp\left\{\frac{-s^2}{2C_S}\right\} ds$$

Here C_S is the variance expected due to the signal alone, independent of any noise. This variance is directly related to the C_l 's in a manner we will explore in Section 11.2.

In order to get the likelihood function, we have to convolve the probability distribution of Eq. (11.14) with the likelihood function of Eq. (11.12). Schematically

$$P\left[\Delta|C_S\right] = \sum_s P[\Delta|s]P\left[s|C_S\right]$$

More concretely, the likelihood function is an integral over all possible values of the true anisotropy:

$$\mathcal{L} = \int_{-\infty}^{\infty} \frac{ds}{\sqrt{2\pi C_S}} \exp\left\{\frac{-s^2}{2C_S}\right\} \frac{1}{\sqrt{2\pi C_N}} \exp\left\{\frac{-(\Delta-s)^2}{2C_N}\right\}$$

The argument of the exponential here is quadratic in s so it is straightforward to carry out the integration over s. Let us rewrite the argument of the exponential as

[1] In Section 11.5 we explore ways to go from the raw data, the timestream, to the pixelized map represented by Δ. For now, we assume that this step has already been taken.

$$-\frac{s^2 C}{2C_S C_N} + \Delta s/C_N - \frac{\Delta^2}{2C_N} = -\frac{C}{2C_S C_N}\left[s - \frac{C_S \Delta}{C}\right]^2 + \frac{C_S \Delta^2}{2C_N} - \frac{\Delta^2}{2C_N}$$

where the full covariance matrix is defined as

$$C := C_S + C_N$$

Changing variables in the integral over s to $x := s - C_S\Delta/C$ leads to

$$\begin{aligned}\mathcal{L} &= \frac{1}{\sqrt{2\pi C_N}} \exp\left\{\frac{C_S \Delta^2}{2CC_N} - \frac{\Delta^2}{2C_N}\right\} \int_{-\infty}^{\infty} \frac{dx}{\sqrt{2\pi C_S}} \exp\left\{-\frac{Cx^2}{2C_S C_N}\right\} \\ &= \sqrt{\frac{1}{2\pi C}} \exp\left\{\frac{-\Delta^2}{2C}\right\}.\end{aligned}$$

This is our final expression for the likelihood function for a one pixel experiment. This form is exactly what one expects: the measured temperature should be distributed like a Gaussian with a variance given by the sum of the variances due to noise and signal.

We can easily generalize Eq. (11.19) to the more realistic case with a measurement of N_p pixels. Then the likelihood function is

$$\mathcal{L} = \frac{1}{(2\pi)^{N_p/2}(\det C)^{1/2}} \exp\left\{-\frac{1}{2}\Delta C^{-1}\Delta\right\}$$

where now Δ is the data vector consisting of all N_p measurements and C is the full covariance matrix. In general, the noise covariance matrix can often be close to diagonal, but the theoretical covariance matrix is not diagonal. Thus, the hard computational part of evaluating the likelihood function is taking the determinant and the inverse of the $N_p \times N_p$ matrix C. The passage from one theoretical parameter (C_S) to a full matrix of parameters creates complications besides the computational. If there was only parameter, observers could quote results in the form of one number. Now that all correlations need to be included, one needs to allow for many different theoretical parameters, in principle all $N_p\left(N_p+1\right)/2$ elements of the (symmetric) covariance matrix C_S. In practice of course this is not done. First of all, the covariance in all theories depends on the angular distance between two points, so elements of the matrix corresponding to two sets of points separated by the same distance are identical. Equivalently, a given theory is associated with a full set of C_l 's; as we will see shortly, these can be used to construct all the elements of C_S. The second simplification is that most experiments have not been sensitive to individual C_l 's but rather to the average power over a range of l, i.e., in a given band. So, analysts typically fit for bandpowers, a fitting which requires even fewer parameters to be determined.

As mentioned the matrix $C = C_S + C_N$ is typically not diagonal. However, we can get some nice insight into the likelihood function by considering the special case when C is diagonal and proportional to the identity matrix (all diagonal elements the same). In that case,

$$\mathcal{L} \propto \frac{1}{\left(C_S + C_N\right)^{N_p/2}} \exp\left\{-\frac{1}{2}\frac{\sum_{i=1}^{N_p}\Delta_i^2}{C_S + C_N}\right\}.$$

We can easily find the value of C_S which maximizes the likelihood function in this case. Differentiating with respect to C_S leads to

$$\frac{\partial \mathcal{L}}{\partial C_S} = \mathcal{L} \times \left[\frac{-\left(N_p/2\right)}{\left(C_S + C_N\right)} + \frac{1}{2}\frac{\sum_{i=1}^{N_p}\Delta_i^2}{\left(C_S + C_N\right)^2}\right].$$

If we set this to zero, we find that the likelihood function is maximized at

$$C_S = \frac{1}{N_p}\sum_{i=1}^{N_p}\Delta_i^2 - C_N$$

Thus a useful rule of thumb for estimating the signal in a CMB experiment is to calculate the variance of the data points (the first term on the right in Eq. (11.23)) and compare it with the average noise per pixel (the second term on the right). If the data has larger variance than the noise, the theoretical signal is simply the difference between the two.

We can also calculate the error on this determination of C_S. As we saw in Section 11.1.1, the error is related to the second derivative of the log of the likelihood function:

$$\sigma_{C_S} = \left(\frac{-\partial^2 \ln \mathcal{L}}{\partial C_S^2}\right)^{-1/2}$$

In this case, it is easy to calculate the derivative. Differentiating Eq. (11.22) once more leads to

$$\frac{\partial^2 \ln \mathcal{L}}{\partial {C_S}^2} = \frac{(N_p/2)}{(C_S + C_N)^2} - \frac{\sum_{i=1}^{N_p}\Delta_i^2}{(C_S + C_N)^3}$$

At the peak of the likelihood we can replace the $\sum_{i=1}^{N_p}\Delta_i^2$ by $N_p\,[C_S + C_N]$, so

$$\sigma_{C_s} = \sqrt{\frac{2}{N_p}}\,(C_S + C_N)$$

Equation (11.26) is a simplified version of a very handy, useful formula which can be used to assess how accurately a given experiment will determine parameters. This simplified version gives the errors on our one theoretical parameter, C_S. The more general formula gives the corresponding errors when the free parameters are the C_l 's themselves. In that case,

$$\sigma_{C_l} = \sqrt{\frac{2}{(2l+1)f_s}}\,(C_l + C_{N,l})\,.$$

The only change moving from Eq. (11.26) to Eq. (11.27) is that the number of pixels - or equivalently the number of independent measurements - has been replaced by $(2l+1)f_s$, where f_s is the fraction of the sky covered. This makes perfect sense, for in the full sky limit, one can measure at best $2l + 1a_{lm}$'s; that is, one can sample the distribution characterized by C_l only $2l + 1$ times. In fact, this is a fundamental limit on the accuracy with which we can measure the C_l 's. Even if there is no noise ($C_N = 0$), there remains a fundamental uncertainty in the theoretical parameters (either C_S or C_l) due to the fact that we only have one sky on which to take measurements. This limit, which we have already encountered in Chapter 8, is called sample variance, or in the limit of an all-sky survey cosmic variance.

Galaxy Surveys

At first, one might think that analysis of galaxy surveys would be completely different from CMB analysis. There are a number of differences. The galaxy distribution is fundamentally 3D, while the CMB anisotropies are a function of angular position only. Also, CMB experiments measure a continuous field, the temperature field, a function of position. Galaxy surveys count discrete objects (galaxies). A survey is simply a list of positions of these objects. Another difference is that the CMB temperatures are drawn from a Gaussian distribution, whereas the galaxies supposedly trace the underlying mass distribution, which - at least on small scales - has already "gone nonlinear." Nonlinearities inevitably produce non-Gaussianity, even if the primordial distribution is Gaussian.

Despite these, and other, differences, analysts have in recent years come to realize that many of the same techniques can be applied to data from both the CMB and galaxy surveys. To solidify the CMB-galaxy survey connection, we need to formalize the concept of a pixel. In

the case of the CMB, the notion of a pixel is so natural that I didn't even bother to define it above. For galaxy surveys, following the treatment of Tegmark et al. (1998), we can define the data in pixel i as

$$\Delta_i := \int d^3x \psi_i(\vec{x}) \left[\frac{n(\vec{x}) - \bar{n}(\vec{x})}{\bar{n}(\vec{x})} \right]$$

Here $n(\vec{x})$ is the galaxy density at $\vec{x}$ and $\bar{n}$ is the expected number of galaxies at $\vec{x}$, i.e., the number there would be if the distribution was uniform. The weighting function ψ_i, which determines the pixelization, will be discussed shortly, but first let's understand operationally how to determine n and $\bar{n}$ from a survey. A simple way is to divide the volume into small sub-volumes, each of which is much smaller than the total survey, but large enough to contain many (e.g., greater than 10) galaxies. The density of a given sub-volume is then the number of galaxies in it divided by its volume. For a uniform survey, the average density $\bar{n}$ would just be the total number of galaxies divided by the total volume. [2]

There are two popular choices for ψ_i, choices which determine the pixelization. First is "counts-in-cells," wherein

[2] A caveat: if the pixels as defined by ψ_i are overlapping, more care must be taken in computing $\bar{n}$ for then the same galaxy could appear in more than one pixel.

$$\psi_i^{\rm CIC}(\vec{x}) = \begin{cases} \bar{n}(\vec{x}) & \text{if } \vec{x} \text{ is in the } i \text{ th sub-volume} \\ 0 & \text{otherwise} \end{cases} .$$

In this case, the sub-volumes themselves are the pixels, and Δ_i is the over(under)density in the i th sub-volume. Another useful pixelization scheme is a set of Fourier pixels, which emerge from choosing

$$\psi_i^{\rm Fourier}(\vec{x}) = \frac{e^{i\vec{k}_i \cdot \vec{x}}}{V} \begin{cases} 1 & \vec{x} \text{ inside the survey volume} \\ 0 & \vec{x} \text{ outside survey volume} \end{cases} .$$

Here V is the volume of the survey. In this case, the pixels are not spatial, but rather live in the Fourier domain. Still, even in this case, Δ_i is the fractional overdensity in the pixel.

No matter which pixelization is chosen, one cannot hope to write down a simple expression for the likelihood function, the probability of getting a set of $\{\Delta_i\}$ given a theory. The theory of galaxy formation is simply too complicated. Indeed, even if one assumes that the galaxy density perfectly traces the mass overdensity, the complications from gravity alone make the likelihood function non-Gaussian. Nonetheless, progress can still be made by noting that the expectation value of Δ_i is zero by construction, with a covariance matrix [3]

$$\left\langle \Delta_i \Delta_j^* \right\rangle = (C_S)_{ij} + (C_N)_{ij}$$

exactly like the CMB case. We will discuss the signal covariance matrix in detail in Section 11.2. The noise covariance matrix is actually easier than the corresponding CMB matrix, which depends on the atmosphere, pointing, instrumental noise, scan strategy, and other experimental details. In a galaxy survey, even if there was no signal, the expected value of the square of the density, $\langle n^2(\vec{x}) \rangle$, would still differ from $\bar{n}^2$ simply because there are only a finite number of galaxies in a given subvolume. Thus, even in the absence of any intrinsic clustering of the galaxies $\langle \Delta_i \Delta_j \rangle$ would be nonzero because of Poisson noise. You can show in Exercise 3 that the covariance matrix due to Poisson noise is

$$(C_N)_{ij} = \int d^3x \frac{\psi_i(\vec{x}) \psi_j^*(\vec{x})}{\bar{n}(\vec{x})}$$

Armed with this noise covariance matrix and the signal covariance matrix we explore next, galaxy survey analysts can use many of the same techniques as the CMB analysts.

26.1.2 Signal Covariance Matrix

Theory

Until now, we have sidestepped the question of how the expected variance in a given experiment is related to the underlying power spectrum. That is, we have learned that the predictions

of a given theory are a set of C_l 's and $P(k)$. If we want to relate theory to experiment - and we do! — we need to know how to turn this set of predictions into a covariance matrix C_S.

[3] The angular brackets here denote an average over the distribution from which Δ_i is drawn.

CMB Window Functions

For simplicity, let us first consider the diagonal element of the covariance matrix:

$$C_{S,ii} := \langle s_i s_i \rangle \quad (\text{ no sum over } i)$$

where the average $\langle \ldots \rangle$ is over many realizations of the theoretical distribution and the subscript i labels the pixel. The temperature difference reported in each pixel can be expressed as

$$s_i = \int d\hat{n} \Theta(\hat{n}) B_i(\hat{n})$$

where B_i is the beam pattern at the i th pixel and Θ is the underlying temperature. As an example, the beam pattern from the MSAM experiment is shown in Figure 11.1. It is typical of the patterns produced by many CMB experiments: the difference of the temperature in two (or more) regions of the sky, and in each region the temperature is sampled by a beam which is roughly Gaussian.

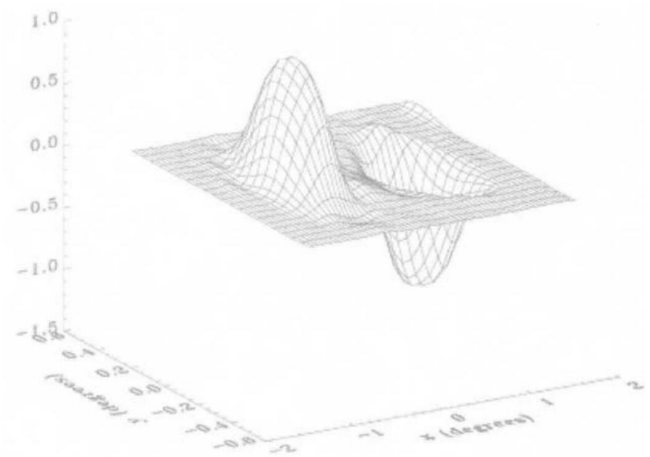

Figure 11.1. The beam pattern for the MSAM experiment (see Wilson et al., 2000, for a summary). The anisotropy reported at a given pixel is roughly the difference between the temperature at \pm 0.5 degrees from the center of the pixel. The beamwidth is also on the order of half a degree.

To find C_S we square Eq. (11.34) after expressing the temperature field as an expansion over spherical harmonics as in Eq. (8.60):

$$\frac{C_{S,ii}}{T^2} = \int d\hat{n} \int d\hat{n}' B_i(\hat{n}) B_i(\hat{n}') \sum_{lm} Y_{lm}(\hat{n}) \sum_{l'm'} Y^*_{l'm'}(\hat{n}') \langle a_{lm} a^*_{l'm'} \rangle$$

Using Eq. (8.63), we find that the sums over $l'm'$ collapse to give

$$\frac{C_{S,ii}}{T^2} = \int d\hat{n} \int d\hat{n}' B_i(\hat{n}) B_i(\hat{n}') \sum_{l} C_l \sum_{m} Y_{lm}(\hat{n}) Y^*_{lm}(\hat{n}') .$$

But $\sum_m Y_{lm}(\hat{n}) Y^*_{lm}(\hat{n}') = (2l+1) P_l(\hat{n} \cdot \hat{n}') / 4\pi$, so

$$\frac{C_{S,ii}}{T^2} = \sum_l \frac{2l+1}{4\pi} C_l W_{l.ii}$$

where the window function is defined as

$$W_{l,ii} := \int d\hat{n} \int d\hat{n}' B_i(\hat{n}) B_i(\hat{n}') P_l(\hat{n} \cdot \hat{n}')$$

Until now, we have been thinking of $\hat{n}, \hat{n}'$ as three-dimensional unit vectors. If $\hat{n}'$ and $\hat{n}$ are sufficiently close to each other, though, we can use the flat space approximation. The three-dimensional unit vectors can be safely approximated as two-dimensional vectors $\vec{x}, \vec{x}'$ in the transverse directions. The distance between $\vec{x}$ and $\vec{x}'$ (measured in radians) is then equal to the angle between $\hat{n}$ and $\hat{n}'$. In this limit, the argument of the Legendre polynomial in Eq. (11.38) becomes

$$\vec{n} \cdot \vec{n}' = \cos(|\vec{x} - \vec{x}'|).$$

The diagonal window function is therefore

$$W_{l,ii} = \int d^2x \int d^2x' B_i(\vec{x}) B_i(\vec{x}') P_l(\cos(|\vec{x} - \vec{x}'|))$$

A useful property of Legendre polynomials is that they become equal to the zeroorder Bessel function in the limit of large l (the small-angle limit we are working under here). So,

$$\begin{aligned} P_l(\cos(|\vec{x} - \vec{x}'|)) &\to J_0(l|\vec{x} - \vec{x}'|) \\ &= \frac{1}{2\pi} \int_0^{2\pi} d\phi e^{-il|\vec{x}-\vec{x}'|\cos\phi}, \end{aligned}$$

where the last line is an integral representation of the Bessel function (Eq. (C.21)). We can simplify further by promoting l to a 2D vector with direction chosen so that the angle between $\vec{l}$ and $\vec{x} - \vec{x}'$ is equal to ϕ. Then, the argument of the exponential simplifies to $-i\vec{l} \cdot (\vec{x} - \vec{x}')$. This form is so useful because the $\vec{x}$ integral for example is now

$$\int d^2x B_i(\vec{x}) e^{-i\vec{l}\cdot\vec{x}} := \tilde{B}_i(\vec{l})$$

where $\tilde{B}_i$ is the Fourier transform of the beam pattern. The $\vec{x}'$ integral is the complex conjugate of this, so the window function simplifies to

$$W_{l,ii} = \frac{1}{2\pi} \int_0^{2\pi} d\phi \left|\tilde{B}_i(\vec{l})\right|^2$$

Thus calculating the window function reduces to a two-step process: - Calculate the 2D Fourier transform of the beam pattern.

- Find the angular average of the square of this transform.

The window function is a function of the experiment only and indeed contains information about the beam size and chopping angle of the experiment. However, it is not the whole story. A complete evaluation of the likelihood function entails calculating all of the elements of the covariance matrix C_S. A given off-diagonal element of the matrix is given by Eqs. (11.37) and (11.38), with one of the indices i changed to j. The matrix is symmetric, so it is characterized by $N_p(N_p + 1)/2$ elements where N_p is the number of pixels. Thus, for an N_p-pixel experiment there are really $N_p(N_p + 1)/2$ window functions!

Examples of CMB Window Functions

Gaussian Beam. Let us take a break from formalism and calculate a simple (diagonal) window function. Consider a Gaussian beam; this is a good approximation to many CMB experiments. The beam pattern for the i th pixel is

$$B_i(\vec{x}) = \frac{1}{2\pi\sigma^2} \exp\left(-\frac{(\vec{x}-\vec{x}_i)^2}{2\sigma^2}\right)$$

We may choose $\vec{x}_i$ to be zero for the window function computation. The Fourier transform of the beam is also a Gaussian,

$$\begin{aligned}\tilde{B}_i(\vec{l}) &= \frac{1}{2\pi\sigma^2}\int d^2x e^{-i\vec{l}\cdot\vec{x}} \exp\left(-\frac{x^2}{2\sigma^2}\right) \\ &= e^{-l^2\sigma^2/2}.\end{aligned}$$

In this simple case, $\tilde{B}$ does not depend on the direction of $\vec{l}$, so there is no need to take the angular average. The window function is then simply the square of the Fourier transform,

$$W_{l,ii} = e^{-l^2\sigma^2}$$

The window function falls off sharply at large l. Large l corresponds to small angular scales. Structure on scales smaller than the beam size is inevitably washed away and undetectable. Figure 11.2 illustrates the series of steps, from beam function to Fourier transform to window function.

There are two subtleties associated with the Gaussian window function. First, one must avoid the temptation to set σ equal to the number which is often quoted in papers, the full width half maximum (FWHMI). The latter is twice the value of x: for which $B(\vec{x})$ drops to half of its maximum. So $\sigma = FWHM/(\sqrt{8\ln(2)}) = 0.4245$ FWHM. The second subtlety has to do with normalization. It is crucial to determine how observers have normalized their output. The prefactor in Eq. (11.44) ensures that if the temperature field was uniform, the reported temperture would be equal to the underlying one. In this simple case, the choice is obvious; in general factors of 2 can easily be lost.

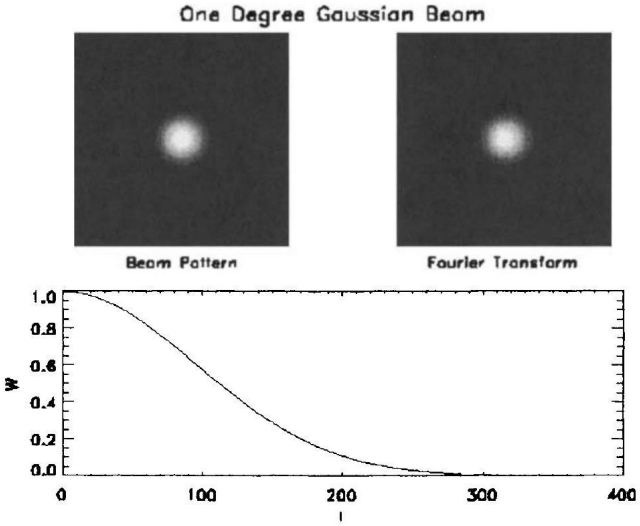

Figure 11.2. A one-degree Gaussian beam is shown in the upper left panel and its Fourier transform, also a Gaussian, in the upper right. The resulting window function is shown in the bottom panel.

Differencing a Gaussian Beam. As another straightforward example, let us consider an experiment which takes the difference between the temperatures at two adjacent points on the sky. For simplicity, let us first assume that the Gaussian beam is infinitely small, so it can be approximated as a Dirac delta function. Then,

$$B(x,y) = \delta(y)\left[\delta\left(x-x_0\right) - \delta\left(x+x_0\right)\right]$$

where the chopping angle, or the distance between the plus and minus position, is $2x_0$. The Fourier transform of this is straightforward:

$$\tilde{B}(\vec{l}) = 2i\sin\left(l_x x_0\right)$$

The window function is the angular average over all $\vec{l}$ directions. Choosing the angle between $\vec{l}$ and the x - axis to be ϕ, we have

$$\begin{aligned} W_l &= \frac{4}{2\pi}\int_0^{2\pi} d\phi \sin^2\left[l x_0 \cos\phi\right] \\ &= \frac{1}{\pi}\int_0^{2\pi} d\phi \left(1 - \cos\left[2 l x_0 \cos\phi\right]\right) \\ &= 2\left(1 - P_l\left[\cos\left(2x_0\right)\right]\right) \end{aligned}$$

where the last line follows from Eq. (11.41).

Until now, we have neglected the finite width of the beam. However, this turns out to be very simple to rectify. A realistic beam will be the convolution of the chop described by Eq. (11.47) with a finite beam size:

$$\begin{aligned} B(x,y) = \frac{1}{2\pi\sigma^2}\int dx' dy' \exp\left\{-\frac{(x-x')^2 + (y-y')^2}{2\sigma^2}\right\} \\ \times \delta\left(y'\right)\left[\delta\left(x' - x_0\right) - \delta\left(x' + x_0\right)\right] \end{aligned}$$

Recall, though, that the Fourier transform of the convolution of two functions is simply equal to the product of the two Fourier transforms. The angular averaging over this product is unaffected since the Gaussian has no angular dependence. Therefore, the final window function is

$$W_l = e^{-l^2\sigma^2}\left(1 - P_l\left[\cos\left(2x_0\right)\right]\right)$$

This window function is shown in Figs. 11.3 and 11.4 along with the beam pattern

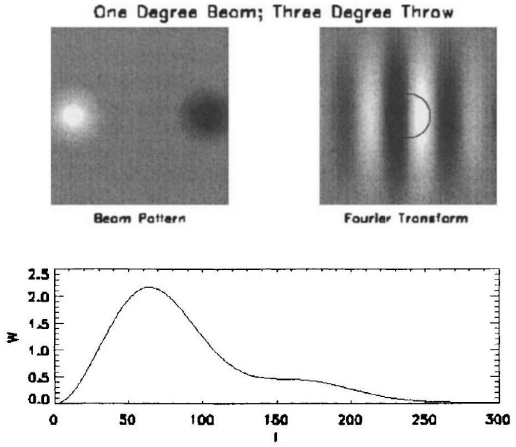

Figure 11.3. Differencing a Gaussian beam. Upper left panel shows the beam pattern and the upper right its Fourier transform. The circle in the upper right corresponds to $l = 50$. The bottom panel shows the window function. One Degrae Beam; One Degrae Throw

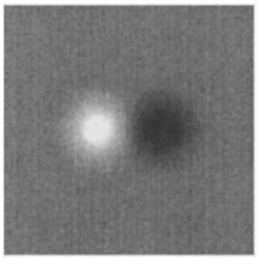
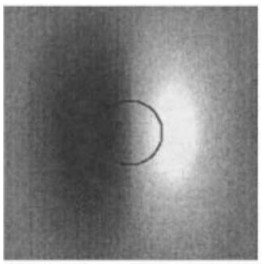


Beom Pottern



Fourler Tranefarm

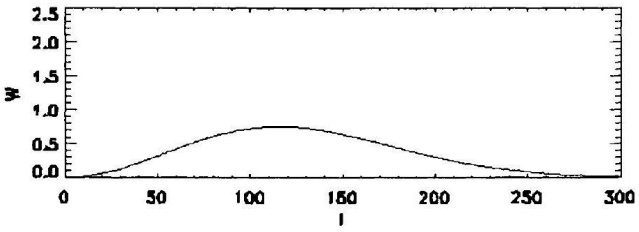


Figure 11.4. Same as Figure 11.3 except the chopping angle is now much smaller. Note the lack of support at large scales due to the reduced chopping angle. This can also be seen in the Fourier transform which vanishes near the center of the circle.

for two different chopping angles. Note that for l much smaller than $1/x_0$, the Fourier transform vanishes. So, unlike the undifferenced beam, there is no support for small l. That is, chopping removes information about structure on large scales. As the chopping angle gets larger, more and more information is obtained about large scales.

Window Functions for Galaxy Surveys

We now consider the signal covariance matrix for galaxy surveys. By setting the term in square brackets in Eq. (11.28) to $\delta(\vec{x})$, we see that the signal covariance matrix is equal to

$$(C_S)_{ij} = \langle \Delta_i \Delta_j \rangle|_{\text{no noise}} = \int d^3x d^3x' \psi_i(\vec{x}) \psi_j(\vec{x}') \, \xi(\vec{x} - \vec{x}')$$

The correlation function ξ appears here because it is equal to the expectation value of the product of two overdensities, Eq. (9.7). Since ξ is the Fourier transform of the power spectrum, we see that the signal covariance matrix for a galaxy survey is

$$\begin{aligned}(C_S)_{ij} &= \int d^3x d^3x' \int \frac{d^3k}{(2\pi)^3} \frac{d^3k'}{(2\pi)^3} \frac{d^3k''}{(2\pi)^3} \tilde{\psi}_i(\vec{k}) \tilde{\psi}_j^*\left(\vec{k}'\right) P(k'') \, e^{i\left[\vec{k}+\vec{k}''\right]\cdot\vec{x} - i\left[\vec{k}'+\vec{k}''\right]\cdot\vec{x}'} \\ &= \int \frac{d^3k}{(2\pi)^3} P(k) \tilde{\psi}_i(\vec{k}) \tilde{\psi}_j^*(\vec{k})\end{aligned}$$

The second equality follows simply after integrating over $\vec{x}$ and $\vec{x}'$ to get 3D Dirac delta functions and using these to perform the integrals over $\vec{k}'$ and $\vec{k}''$. It is convenient to define the window function as the angular part of this integral

$$W_{ij}(k) := \int \frac{d\Omega_k}{4\pi} \tilde{\psi}_\imath(\vec{k}) \tilde{\psi}_j^*(\vec{k})$$

so that

$$(C_S)_{ij} = \int_0^\infty \frac{dk}{k} \left[\frac{k^3 P(k)}{2\pi^2}\right] W_{ij}(k)$$

Notice that the window function for galaxy surveys has the identical form as that for CMB experiments. In both cases, it is the angular average of the square of the Fourier transform of the weighting function (either B or ψ). Also, you should recognize the quantity in square

brackets in Eq. (11.55) as $\Delta^2(k)$, the contribution to the variance per $\ln(k)$. Let's turn to some examples of window functions of galaxy surveys.

Volume-Limited Survey. Consider a survey which observes all galaxies within a radius R from us. If we use Fourier pixelization (Eq. (11.30)), then the Fourier transform of the weighting function is

$$\tilde{\psi}_i(\vec{k}) = \int\limits_{|\vec{x}|<R} \frac{d^3x}{V} e^{-i\vec{k}\cdot\vec{x}} e^{i\vec{k}_2\cdot\vec{x}}$$

We will shortly carry out this integral, square, and then average over all angles to get the diagonal window function of Eq. (11.54). First, though, let's ask what we expect qualitatively. Equation (11.56) is the Fourier transform of the survey volume as a function of $\vec{k} - \vec{k}_i$. The survey volume is a sphere of radius R. In general, when a function is confined to a region $x < R$, the Fourier transform is confined to $k < 1/R$. Here then, $\tilde{\psi}$ will be nonzero only when $\left|\vec{k} - \vec{k}_i\right|$ is less than $1/R$. The window function therefore should peak at $k = k_i$ and have a width of order $1/R$.

More quantitatively, the integral in Eq. (11.56) is

$$\begin{aligned}\tilde{\psi}_i(\vec{k}) &= \frac{4\pi}{V\left|\vec{k} - \vec{k}_i\right|} \int\limits_0^R dx x \sin\left(\left|\vec{k} - \vec{k}_i\right| x\right) \\ &= \frac{4\pi}{V\left(\left|\vec{k} - \vec{k}_i\right|\right)^3} \left[-\left|\vec{k} - \vec{k}_i\right| R\cos\left(\left|\vec{k} - \vec{k}_i\right| R\right) + \sin\left(\left|\vec{k} - \vec{k}_i\right| R\right)\right] (1\end{aligned}$$

The diagonal window function is the angular average of the square of this. Defining $y := \left|\vec{k} - \vec{k}_i\right| R$, this angular average is

$$\begin{aligned}W_{ii}(k) &= \frac{(4\pi R^3)^2}{V^2} \int\limits_{-1}^{1} \frac{d\mu}{2} \int\limits_0^{2\pi} \frac{d\phi}{2\pi} \frac{(\sin y - y\cos y)^2}{y^6} \\ &= \frac{8\pi^2 R^6}{V^2} \int\limits_{-1}^{1} \frac{d\mu}{y^6} (\sin y - y\cos y)^2\end{aligned}$$

where μ is the cosine of the angle between $\vec{k}$ and $\vec{k}_i$. Integrating over y instead of μ leads to

$$W_{ii}(k) = \frac{9}{2kk_iR^2} \int\limits_{|k-k,|R}^{(k+k,)R} \frac{dy}{y} j_1^2(y)$$

since the volume of the survey $V = 4\pi R^3/3$. This window function is shown in Figure 11.5 for several different values of k_iR. Notice that modes with wavelength much smaller than the size of the survey $k_iR \gg 1$ do indeed have window functions sharply peaked at $k = k_i$, with a width of order $1/R$. The largest wavelength modes, however, pick up contributions from all scales (e.g., the $k_iR = 3$ curve in Figure 11.5). Not surprisingly, surveys do not do a good job measuring the power on wavelengths comparable to their sizes.

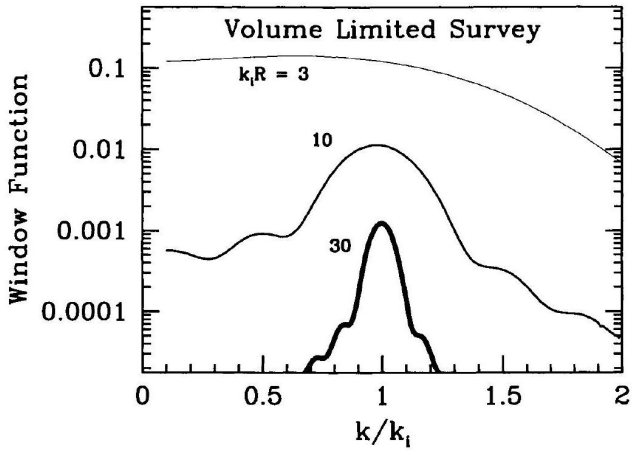

Figure 11.5. The window function for a volume-limited survey. Narrow window functions enable one to determine the power spectrum at the wavenumber of interest more accurately. Modes with wavelengths comparable to the size of the survey (e.g., here $k_iR = 3$) have broad window functions.

The height of the window function is also important, for it determines the amplitude of the signal covariance matrix. When considering modes with wavelengths k_i^{-1} much smaller than R, you will show in Exercise 7 that

$$(C_S)_{ii} \simeq \frac{P(k_i)}{V}.$$

It is instructive to compare this to the corresponding element of the noise matrix, as given in Eq. (11.32). For the diagonal elements. $|\psi_i|^2$ in the integrand is $1/V^2$ as long as $\vec{x}$ is in the survey volume. Thus,

$$(C_N)_{ii} = \frac{1}{\bar{n}V}$$

equal to the inverse of the total number of galaxies in the survey. The ratio of the diagonal elements of the signal and noise covariance matrices is therefore

$$\frac{(C_S)_{ii}}{(C_N)_{ii}} \simeq P(k_i)\,\bar{n}$$

Harking back to Eq. (11.27), we identify this ratio as the ratio of cosmic variance to Poisson noise. A rough estimate is that $\bar{n} \sim 1h^3\mathrm{Mpc}^{-3}$, so cosmic variance dominates as long as the power spectrum is larger than $1h^{-3}\mathrm{Mpc}^3$. Looking back to Figure 7.11, we see that on large scales, this is always satisfied. On small scales, eventually the power spectrum does drop beneath $1h^{-3}\mathrm{Mpc}^3$, the linear power spectrum of standard CDM at $k \sim 10h\mathrm{Mpc}^{-1}$. On very small scales, therefore, Poisson noise becomes important.

Pencil-Beam Survey. Now consider a survey which is very deep, but also very narrow, with the general shape of a pencil (Figure 11.6). The Fourier transform of the

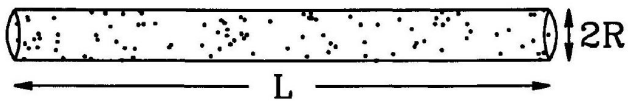

Figure 11.6. A pencil-beam survey with depth L much larger than the typical size of the narrow dimensions, R. The z-axis in the text is taken to be aligned with the long dimension.

weighting function in this case is

$$\tilde{\psi}_i(\vec{k}) = \int \frac{d^3x}{\pi R^2 L} e^{i(\vec{k}_\mathrm{k}-\vec{k})\cdot\vec{x}} \Theta(z + L/2)\Theta(L/2 - z)\Theta\left(R^2 - x^2 - y^2\right)$$

where Θ is a step function, equal to 1 if its argument is positive and zero otherwise. It is easiest to carry out this integral in cylindrical coordinates, wherein $x^2 + y^2 = r^2$. If we define $\vec{q} := \vec{k}_i - \vec{k}$, then

$$\tilde{\psi}_i(\vec{k}) = \frac{1}{\pi R^2 L} \int_{-L/2}^{L/2} dz e^{iq_z z} \int_0^R dr r \int_0^{2\pi} d\theta e^{iq_r r \cos\theta}$$

The azimuthal integral can be done using Eq. (C.17), the integral over z using Eq. (C.15), so that

$$\tilde{\psi}_i(\vec{k}) = \frac{2}{R^2} j_0\left(q_z L/2\right) \int_0^R dr r J_0\left(q_r r\right)$$

Finally the integral over r is $RJ_1\left(q_r R\right)/q_r$, which you can see by differentiating the integral with respect to $q_r R$ and then using Eq. (C.22). Therefore, the Fourier transform of the weighting function is

$$\tilde{\psi}_i(\vec{k}) = \frac{2}{(q_r R)} j_0\left(q_z L/2\right) J_1\left(q_r R\right)$$

Equation (11.66) indicates that the Fourier transform of the weighting function is anisotropic. Indeed, even before deriving the various flavors of Bessel functions, we should have expected this Fourier transform to be compact along the q_z direction and broad in the transverse plane, i.e., shaped like a disk. This flows from our intuition that the Fourier transform of a function localized within a radius R should be localized within a region $1/R$. Indeed, in the z direction, $j_0\left(q_z L/2\right)$ falls off once q_z gets larger than $2/L$. The same holds for $J_1\left(q_r R\right)$: it becomes small for $q_r > 1/R$. The ringing associated with these Bessel functions is a manifestation of the fact that the Fourier transform of a top-hat function oscillates for large wavenumbers (e.g., Exercise 6).

To get the window function for a pencil-beam survey, we need to average Eq. (11.66) over all directions $\hat{k}$. This average will differ for different $\vec{k}_i$. Let's choose $\vec{k}_i$ to point in the $\hat{z}$-direction as one concrete example. The averaging will pick up contributions only when $\vec{q} := \vec{k}_i - \vec{k}$ has z-component smaller than L^{-1} and transverse component smaller than R^{-1}. Since the transverse component of $\vec{k}_i$ is zero in this example, many $\vec{k}$ will contribute, as long as their transverse component is smaller than R^{-1}. Therefore, we expect the window function to get contributions from many wavenumbers, not to be sharply peaked around $\left|\vec{k}_i\right|$. A similar argument holds for other directions $\hat{k}_i$. Figure 11.7 shows the window function for a pencilbeam survey. As expected, it is broader than that for a symmetric, volume-limited survey: a given scale k_i picks up contributions from smaller scales $k > k_i$.

Summary

We have determined the signal covariance matrix for CMB experiments which measure a filtered version of the temperature in a given set of pixels and for galaxy surveys which measure the overdensity in a given set of pixels. Not surprisingly, the fundamental relation between the covariance matrix and and the underlying power spectrum is very similar in both cases: the connection is provided by a window function determined by the experimental/observational specifications. It is interesting to point out that we have encountered natural window functions in Chapters 9 and 10. The angular correlation function of Section 9.1 is simply the signal covariance matrix of measurements of the 2D galaxy distribution. Recall from Eq. (9.13) that this too is an integral of the 3D power spectrum convolved with a window function (we called it a kernel back then). The same is true for the peculiar velocity (Eq. (9.29)) and the shear field that can be measured with weak lensing (Eq. (10.32)). In all of those cases, the window function is determined partly by the

Pencil Beam Survey

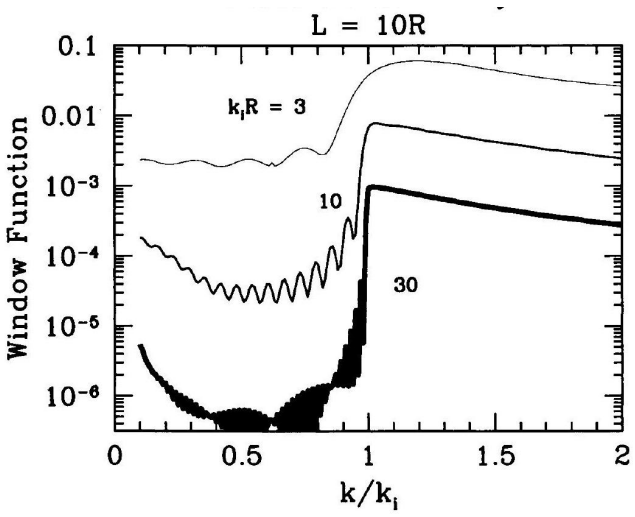

Figure 11.7. The window function for a pencil-beam survey with length 10 times larger than width. These window functions are for $\vec{k}_2$ pointing in the $\hat{z}$-direction, along the long dimension of the survey.

observational strategy (e.g., how deep one goes), but also by the intrinsic nature of the measurement itself. For example, the 2D galaxy distribution intrinsically is a projection of the 3D distribution. So it is seductive to think of CMB anisotropy experiments and 3D galaxy surveys as more pristine measurements of the power spectrum. Analysts are hard to seduce, though. They recognize that, mathematically, the different sets of measurements can all be analyzed in the same fashion. So the likelihood function can be used on virtually all cosmological observations. It is a very powerful tool.

It is also simple. Were it not for the size of modern cosmological data sets, we would be done. At least in the Gaussian case (CMB or even galaxy surveys on large scales), the likelihood function is given by Eq. (11.20). The data points are simply the pixelized temperatures or overdensities, while the covariance matrix is the sum of the noise and signal covariances. The noise covariance matrix is usually estimated from the data itself. while the signal covariance matrix is computed by convolving the theory (i.e., the C_i 's or the power spectrum) with the window function. In principle. then, one could compute this likelihood function at many points in parameter space, find its maximum (this constitutes the set of best-fit parameters), and the contour delineating the region in which. say; 95% of the volume lies. This contour would then be the 95% confidence region of the parameters. Many experiments of the previous decade, especially CMB experiments, have been analyzed in this brute-force fashion. Times are changing, though, and the bruteforce approach has already become impractical.

26.1.3 Estimating the Likelihood Function

Theory

To illustrate the need for new techniques of likelihood computation, let us consider a concrete example: the data set from the Boomerang anisotropy experiment (Netterfield et al., 2001). There are 57,000 pixels on the sky covered in this set. The theory and noise covariance matrices are both nondiagonal and both $57,000 \times 57,000$ dimensional matrices. Inverting these beasts with present computers is possible, although slow. [4] If we needed to invert only once, this might be acceptable. But, we need to evaluate the likelihood function at many points in parameter space to find its maximum and the region at which it falls to, say, 5% of its maximum. This would be barely manageable if the parameter space was one-dimensional. A onedimensional fit, though, would lose most of the information contained in the map. The data are actually sensitive to the power on many different scales. Therefore, the parameter space - the amplitude of the power on these many different scales is multidimensional, "multi-" here of order 20. The likelihood function should in principle be computed about 10 times in each dimension, for a total of 10^{20}com putations. Since each inversion takes several hours, this is not feasible. All of these estimates are for the Boomerang experiment. The MAP satellite will have 10 times as many pixels and be sensitive to a wider range of scales. Planck will be more sensitive still.

Thus, we need new techniques, shortcuts, for evaluating the likelihood function and finding its maximum and its width.

Karhunen-Love Techniques

The first technique was discovered many years ago and reinvented by a number of people over the past few years to deal with both CMB data (Bunn, 1995; Bond, 1995) and with data from galaxy surveys (Vogeley and Szalay, 1996). It is a method for speeding up the computation of the likelihood function. The fundamental idea is simple: any experiment, no matter how good, will have many modes which are useless, fundamentally contaminated by noise. [5] If it was obvious which modes were most noisy, then we could greatly simplify the likelihood calculation by not using those modes. If only 10% of the modes carried useful information - and this figure is roughly what is found in many present-day experiments - then the data set would be reduced by a factor of 10. The covariance matrices would now be $(N/10) \times (N/10)$ and the inversion (which scales as N^3) would speed up by a factor of 1000. It is a nice, simple idea. The only problem is finding the modes which are useful.

[4] Note that the problems outlined here assume that we are handed the map of 57.000 pixels. Mapmaking is actually the most difficult computational part of the analysis!

"A mode here is defined as a linear combination of the dat a points. If the signal and noise covariance matrices were diagonal, then it would be simple to ascertain which modes had high signal-to-noise. The pixels with diagonal elements $C_S > C_N$ would have signal-to-noise greater than 1 ; the others would be low-signal modes. The problem is to identify the low modes in the more realistic case where the covariance matrices are not diagonal. This is precisely what KarhunenLove does. To illustrate the technique, let us first write it down formally and then work out a simple example explicitly.

We assume there are N_p data points, Δ_i. Each data point is presumed to be the sum of both signal s_i and noise n_i. Each of these are assumed to be uncorrelated (the noise knows nothing about the signal and vice versa). Thus the full covariance matrix is

$$\langle \Delta_i \Delta_j \rangle := C_{ij} = C_{S.ij} + C_{N,ij}$$

The Karhunen-Love method takes advantage of the fact that instead of computing the likelihood function using Δ_i and its covariance matrix C, we could instead use rotated data

$$\Delta'_i := R_{ij} \Delta_j$$

where R is a real matrix. The covariance matrix associated with Δ' will be

$$\begin{aligned} C'_{ij} &= \langle (R\Delta)_i (R\Delta)_j \rangle \\ &= R_{ii'} R_{jj'} C_{i'j'} \end{aligned}$$

In matrix notation this is simply

$$C' = RCR^T$$

where R^T is the transpose of R.

The Karhunen-Love method consists of three such rotations.

1. R_1: Diagonalize C_N
2. R_2 : Set $C'_N = I$
3. R_3: Diagonalize C'_S

The first step is always possible since C_N is a real, symmetric matrix. Once C_N has been diagonalized, it is trivial to perform step 2: simply choose R_2 to be diagonal with elements equal to 1 over the square root of the diagonal elements that emerge from step 1. Finally, step 3 is straightforward since again C_S is a real symmetric matrix. Let's evaluate the new theory and noise covariance matrices. The theory matrix is

$$C'_S = R_3 R_2 R_1 C_S R_1^T R_2 R_3^T$$

Note that, since R_2 is diagonal it is equal to its transpose. The matrix C'_S is a diagonal matrix. Now consider C'_N. After step 2, it was simply the identity matrix. So we need consider only the effect of step 3. In fact, since R_3 is unitary, it has no effect $\left(R_3 I R_3^T = I\right)$. Thus, C'_N is still equal to the identity matrix. This has profound implications. It means that the elements of (the diagonal matrix) C'_S are a measure of the signal-to-noise squared of the modes! The data points

$$\Delta'_i = (R_3 R_2 R_1)_{ij}\, \Delta_j$$

then have diagonal covariance matrix

$$\left\langle \Delta'_i \Delta'_j \right\rangle = \begin{cases} 1 + C'_{S,ii} & i = j \\ 0 & i \neq j \end{cases} .$$

These modes can be ordered according to their signal-to-noise values. Modes with large C'_S can be kept; those with C'_S significantly smaller than 1 can be eliminated from the analysis.

Let us work through a simple example to see how Karhunen-Love picks out the highest signal-to-noise modes. The example is a simple two-pixel experiment with diagonal noise:

$$C_N = \begin{pmatrix} \sigma_n^2 & 0 \\ 0 & \sigma_n^2 \end{pmatrix}$$

The signal covariance matrix does have correlations between the two pixels so

$$C_S = \sigma_s^2 \begin{pmatrix} 1 & \epsilon \\ \epsilon & 1 \end{pmatrix}$$

where σ_s is the expected rms in the pixel and $-1 < \epsilon < 1$ measures how correlated the signal is between the two pixels. Steps 1 and 2 of the Karhunen-Love method are particularly simple since C_N is diagonal. Thus,

$$R_1 = I \quad ; \quad R_2 = \frac{1}{\sigma_n} I.$$

To complete step 3, we need to diagonalize

$$R_2 R_1 C_S R_1^T R_2 = \frac{\sigma_s^2}{\sigma_n^2} \begin{pmatrix} 1 & \epsilon \\ \epsilon & 1 \end{pmatrix}$$

To diagonalize the matrix in Eq. (11.77), we must solve

$$\frac{\sigma_s^2}{\sigma_n^2} \begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix} \begin{pmatrix} 1 & \epsilon \\ \epsilon & 1 \end{pmatrix} \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} = \begin{pmatrix} C'_{S,11} & 0 \\ 0 & C'_{S,22} \end{pmatrix}$$

for the rotation angle θ. Carrying out the multiplication on the left side leads to

$$\frac{\sigma_s^2}{\sigma_n^2} \begin{pmatrix} 1 + \epsilon \sin(2\theta) & \epsilon \cos(2\theta) \\ \epsilon \cos(2\theta) & 1 - \epsilon \sin(2\theta) \end{pmatrix} = \begin{pmatrix} C'_{S.11} & 0 \\ 0 & C'_{S.22} \end{pmatrix}.$$

Equality in the off-diagonal elements holds if $\theta = \pi/4$, so the new theory covariance matrix is

$$C'_S = \frac{\sigma_s^2}{\sigma_n^2} \begin{pmatrix} 1 + \epsilon & 0 \\ 0 & 1 - \epsilon \end{pmatrix}$$

The rotation matrix which diagonalized the theory matrix is the first one on the left in Eq. (11.78) with $\theta = \pi/4$, so

$$R_3 = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$$

The new modes are $\Delta' = R_3 R_2 \Delta$; explicitly, they are

$$\Delta_1' = \frac{(\Delta_1 + \Delta_2)}{\sqrt{2}\sigma_n}$$
$$\Delta_2' = \frac{(-\Delta_1 + \Delta_2)}{\sqrt{2}\sigma_n}.$$

The new modes (Eq. (11.82)) and their covariance matrix (Eq. (11.80)) are easy to understand if we consider the special cases of $\epsilon = 0$ and $\epsilon = +1$. If $\epsilon = 0$ the two modes have the same signal-to-noise, σ_s/σ_n. If the expected signal is large, these modes both carry information; if not, the noise swamps the signal. In either case, each mode - the sum and the difference - is equally (un)important. If $\epsilon = +1$ then the theory predicts the same signal in each pixel. In that case, the difference mode (Δ_2') is worthless, since only noise contributes to it. We see this from the fact that $(C_S')_{22}$ goes to zero as $\epsilon \to 1$. Its signal-to-noise is zero. The other mode - the sum of the two pixels - has signal-to-noise of $\sqrt{2}\sigma_s/\sigma_n$ since the two measurements beat down the noise by a factor of $\sqrt{2}$. This would of course have emerged from the full 2×2 likelihood analysis. But, using both modes in the analysis is a waste of time, a waste which is detected and obliterated by the Karhunen-Love method.

Bunn (1995) and Bond (1995) independently analyzed the COBE data by looking at Karhunen-Love modes. Figure 11.8 shows several such modes: clearly the ones with the highest signal-to-noise are the large-scale modes, indicating that COBE was sensitive to large-angle anisotropy. The smallest signal-to-noise modes are the small-scale modes which COBE did not have the resolution to measure.

Vogeley and Szalay (1996) first applied this technique to galaxy surveys. In this context, the Karhunen-Love method has another useful feature. Recall from Section 11.2.3 that on large scales, the signal covariance matrix is larger than Poisson noise, while on small scales the reverse is true. When we order the modes, then, large-scale modes will have the largest ratio of signal-to-noise. Thus the KarhunenLove basis will preferentially pick out large-scale modes. This is extremely useful because we are often most interested in eliminating small-scale modes - which are afflicted by nonlinearities and bias - from an analysis. The Karhunen-Love method does this automatically! An example is shown in Figure 11.9.

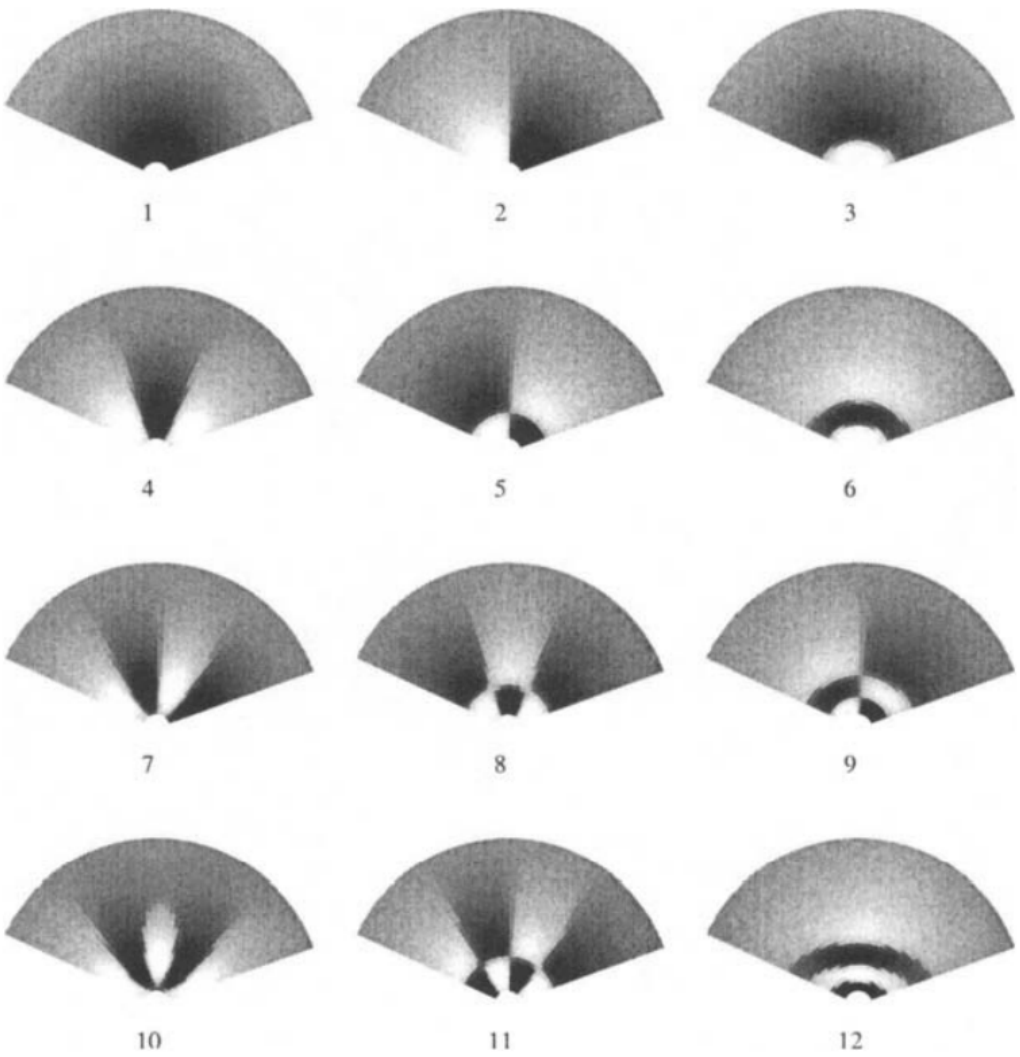

Figure 11.9. The 12 modes with highest signal-to-noise for the CFA2 survey (from Vogeley and Szalay, 1996). Modes pick out the large-scale structure of the galaxy distribution. In each case, we are at the bottom of the slice, and the top region is farthest from us.

For example, the first eigenmode roughly weights pixels only on the basis of their distance from us. It essentially takes the difference between the number of galaxies close to us and the number at moderate distances. The second mode takes a different component of the dipole, the difference between the number of galaxies on the left and the number on the right. Modes with lower weight take successively higher moments of the galaxy distribution.

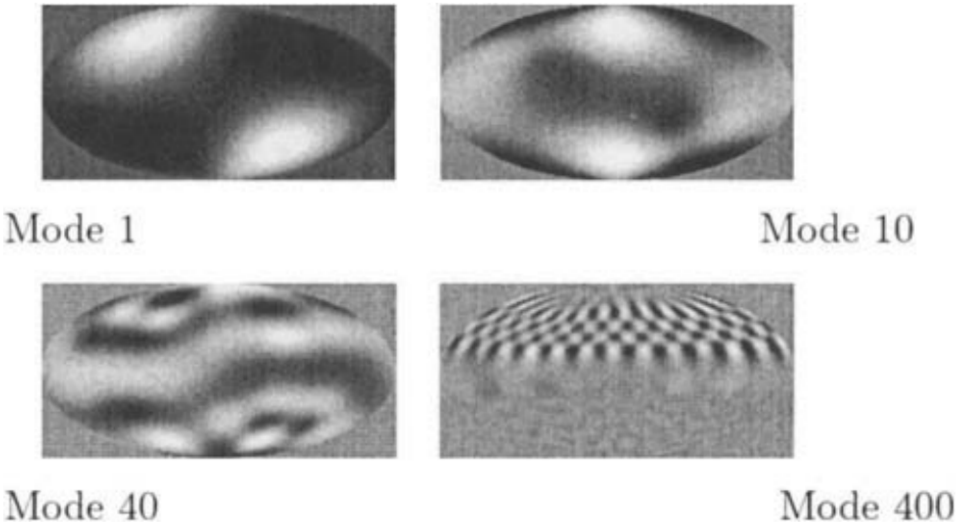

Figure 11.8. Modes of the COBE anisotropy experiment (from Bunn, 1995) ordered according to their signal-to-noise. The mode with the largest signal-to-noise (upper left) is sensitive predominantly to the quadrupole, while the mode with the smallest signal (bottom right) is sensitive to much smaller scale structure.

There are several drawbacks to the Karhunen-Love method. First, we need to assume a C_S to begin with, in order to identify the modes that are worthless. Although this might seem like a big problem - the modes that are thrown out for one choice of C_S could conceivably be important for another - people who have studied the issue assure us that it is not. They claim that the choice of the important modes is relatively insensitive to the input, assumed C_S. Another drawback is computational. Once the important modes are chosen, C'_S needs to be recalculated at many points in parameter space. In most of parameter space it will not be diagonal at all (it is only diagonal at the special point, the C_S that was chosen as the input spectrum initially). Thus at every point in parameter space, we still need to invert nondiagonal covariance matrices. This drawback is of course partially offset by the fact that - by virtue of the much smaller size of the matrices - the computation is now much faster. Nonetheless in many instances this is not enough to make the full computation managable. We must find still other ways of reducing the computational burden.

Before turning to one such way, let me mention one more use of the KarhunenLove method. It is an extremely useful consistency check. This is perhaps best illustrated with an example. The Python experiment (Coble et al., 1999) measured anisotropy over a large (for that time) area, with very low signal-to-noise. In principle, this is a good idea because the large area beats down cosmic variance. In practice, though, it presents challenges because it is difficult to check the consistency of the data. One typically wants to break up the data into several subsets and make sure that each subset sees the same signal. With Python, this was very difficult because noise dominated each subset. One way to check for consistency then is to work with Karhunen-Love modes. In this basis, each data point d'_i should be drawn from a Gaussian distribution with variance equal to $1 + C'_{S.ii}$. The histogram of $d'_i / \left(1 + C'_{S.ii}\right)^{1/2}$ should then look Gaussian. Figure 11.10 shows this histogram using a preliminary noise matrix. There were 650 measurements, but about 70 of these were eliminated for reasons that needn't concern us, so ignore the central spike at $d = 0$. If the remaining 580 data points were distributed as a Gaussian we would expect about two of them (0.3%) to have absolute value greater than 3, and none of them to have absolute value greater than 4. In fact, Figure 11.10 shows that nine modes are more than 4-sigma away from zero. The distribution is definitely not Gaussian with this noise model.

This analysis led the Python team to question the model they had constructed for the noise covariance. (Adjacent points were more correlated than they had allowed for.) Redoing the analysis with a new noise matrix led to the results in Figure 11.11. This technique for testing data quality has been used in a number of other venues, often identifying signs of trouble.

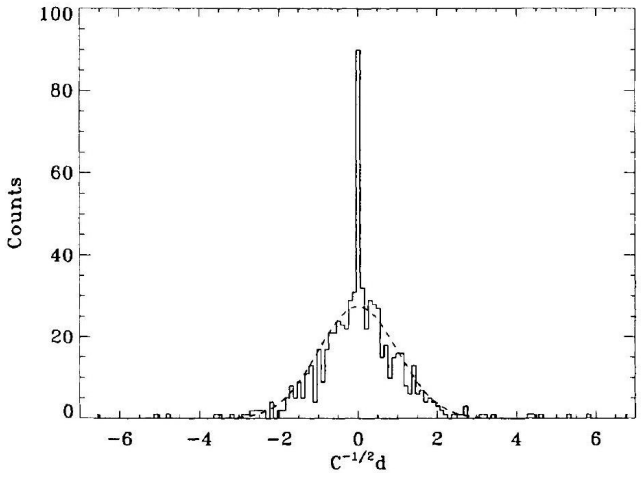

Figure 11.10. Histogram of data from one modulation of the Python CMB anisotropy measurement with a preliminary noise matrix. The data are in Karhunen-Love basis in which the covariance matrix is diagonal, so $C^{-1/2}d$ should be distributed as a Gaussian with variance equal to unity. The central spike should be ignored as 70 of the modes have been set to zero. The best fit Gaussian is the solid line. The counts are lower than the best-fit Gaussian in the central region, but above it in the tails.

Optimal Quadratic Estimator

One simple way of speeding up the likelihood calculation is to employ one of many successful root-finding algorithms. We are searching for the place where the likelihood function is a maximum, so we want to find

$$\left.\frac{\partial \mathcal{L}}{\partial \lambda}\right|_{\lambda=\bar{\lambda}} = 0$$

where for simplicity I've assumed that the likelihood function depends on only one parameter λ (we'll generalize this shortly) and $\bar{\lambda}$ is its value at the maximum of the likelihood.

An efficient way to find the root is to consider the derivative of the likelihood function evaluated at some trial point $\lambda = \lambda^{(0)}$. Expand this derivative around $\lambda^{(0)}$ in a Taylor expansion:

$$\mathcal{L}_{,\lambda}(\bar{\lambda}) = \mathcal{L}_{,\lambda}\left(\lambda^{(0)}\right) + \mathcal{L}_{,\lambda\lambda}\left(\lambda^{(0)}\right)\left(\bar{\lambda} - \lambda^{(0)}\right) + \ldots$$

where I have introduced the notation of writing partial derivatives as subscripted commas:

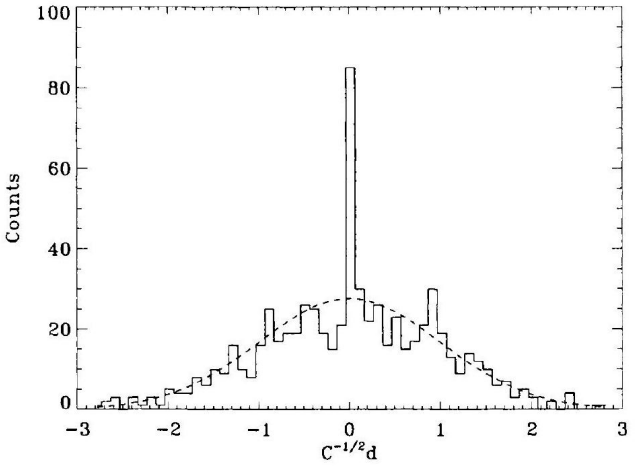

Figure 11.11. Same as Figure 11.10, but this time with an improved noise matrix. Note that there are no data points with absolute value greater than $3C^{1/2}$. The counts are consistent with a Gaussian distribution.

$$\mathcal{L}_{,\lambda} := \frac{\partial \mathcal{L}}{\partial \lambda} \quad ; \quad \mathcal{L}_{,\lambda\lambda} := \frac{\partial^2 \mathcal{L}}{\partial \lambda \partial \lambda}.$$

Since $\mathcal{L}$ is maximized at $\bar{\lambda}$, its derivative vanishes there; hence the right-hand side of Eq. (11.84) must also vanish. Setting it to zero leads to a simple expression for $\bar{\lambda}$:

$$\bar{\lambda} \simeq \lambda^{(0)} - \frac{\mathcal{L}_{,\lambda}\left(\lambda^{(0)}\right)}{\mathcal{L}_{,\lambda\lambda}\left(\lambda^{(0)}\right)}$$

where the $\simeq$ sign acknowledges that we have neglected higher order terms in the Taylor expansion in Eq. (11.84).

The solution in Eq. (11.86) assumes that the likelihood function is a quadratic function of the parameter λ. In fact, it is nothing of the sort: even in the simplest cases the likelihood function is not a quadratic function. For example, far from its maximum, $\mathcal{L}$ typically becomes exponentially small. A much better approximation therefore is that $\mathcal{L}$ is a Gaussian function, so that $\ln(\mathcal{L})$ is quadratic in λ. We can repeat the derivation above since the place where $\mathcal{L}$ is maximized is also the place where $\ln \mathcal{L}$ is a maximum. The estimator for λ is now

$$\hat{\lambda} = \lambda^{(0)} - \frac{(\ln \mathcal{L})_{,\lambda}\left(\lambda^{(0)}\right)}{(\ln \mathcal{L})_{,\lambda\lambda}\left(\lambda^{(0)}\right)}$$

Figure 11.12 illustrates the first iteration of this algorithm, called the NewtonRaphson method.

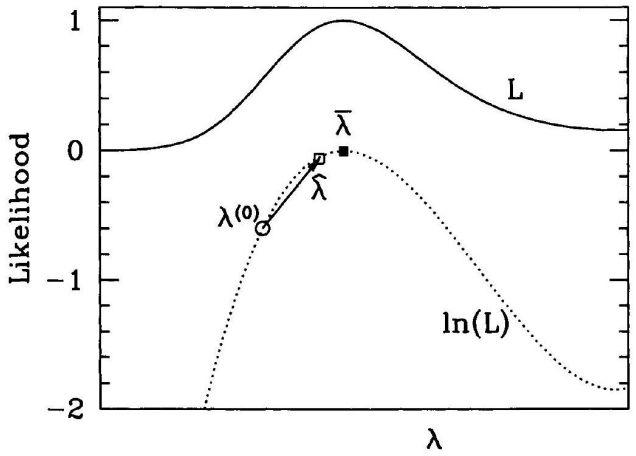

Figure 11.12. A sample likelihood function and its derivatives. The root finding alogrithm starts from the point $\lambda^{(0)}$ (open circle) and moves to $\hat{\lambda}$ (open square) which is quite close to the true maximum of the likelihood, $\bar{\lambda}$ (filled square). The Newton-Raphson technique does this by evaluating the first and second derivatives of $\ln(L)$ at the trial point $\lambda^{(0)}$. The method would not work as well if the derivatives of L were used, because L is not even approximately quadratic away from $\bar{\lambda}$.

To find an estimate for the best-fit value of λ, we need to calculate the derivatives in Eq. (11.87). In the case of the CMB, $\mathcal{L}$ is given explicitly by Eq. (11.20). Thus we need to differentiate the log of Eq. (11.20):

$$(\ln \mathcal{L})_{,\lambda} = \frac{\partial}{\partial \lambda}\left[-\frac{1}{2}\ln(\det C) - \frac{1}{2}\Delta C^{-1}\Delta\right].$$

The covariance matrix here C depends on the theoretical parameter, λ. We can use the identity $\ln\det(C) = \mathrm{Tr}\ln(C)$ and the fact that $C^{-1}_{,\lambda} = -C^{-1}C_{,\lambda}C^{-1}$ to get

$$(\ln \mathcal{L})_{,\lambda} = \frac{1}{2}\Delta C^{-1}C_{,\lambda}C^{-1}\Delta - \frac{1}{2}\,\mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\lambda}\right]$$

Here, the trace of $C^{-1}C_{,\lambda}$ is the sum of $(C^{-1})_{ij}\,\partial C_{ji}/\partial\lambda$ over all pixels i and j. Getting the second derivative requires more of the same types of steps. We find

$$(\ln \mathcal{L})_{,\lambda\lambda} = -\Delta C^{-1} C_{,\lambda} C^{-1} C_{,\lambda} C^{-1} \Delta + \frac{1}{2} \mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\lambda}\mathrm{C}^{-1}\mathrm{C}_{,\lambda}\right] + \frac{1}{2}\left(\Delta C^{-1} C_{,\lambda\lambda} C^{-1} \Delta - \mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\lambda\lambda}\right]\right).$$

Equation (11.90) gives the second derivative of $\ln \mathcal{L}$ with respect to the parameter λ. By definition, this is minus the curvature of the likelihood function:

$$\mathcal{F} = -\frac{\partial^2 \ln \mathcal{L}}{\partial \lambda^2}$$

The curvature is particularly important when evaluated at the maximum of the likelihood function, for there it measures how rapidly the likelihood falls away from the maximum (since the first derivative vanishes). If the curvature is small, then the likelihood changes slowly and the data are not very constraining: the resulting uncertainities on the parameter will be large. Conversely, large curvature translates into small uncertainties. [6]

We could take the ratio of Eqs. (11.89) and (11.90) to get an estimate for the maximum of the likelihood. This is not what is usually done. Rather, one typically sets $\Delta\Delta \to \langle \Delta\Delta \rangle = C$ in the second derivative. Upon doing this, the last line of Eq. (11.90) vanishes, and we are left with

$$\hat{\lambda} = \lambda^{(0)} + F^{-1}_{\lambda\lambda} \frac{\Delta C^{-1} C_{,\lambda} C^{-1} \Delta - \mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\lambda}\right]}{2}$$

where F is defined as

$$F_{\lambda\lambda} := \langle \mathcal{F} \rangle = \frac{1}{2} \mathrm{Tr}\left[\mathrm{C}_{,\lambda}\mathrm{C}^{-1}\mathrm{C}_{,\lambda}\mathrm{C}^{-1}\right]$$

That is, F is the average of the curvature over many realizations of signal and noise, both of which in this case are assumed to be drawn from Gaussian distributions. Here C and its derivatives are evaluated at the input point, $C\left(\lambda^{(0)}\right)$.

There are several important features about Eq. (11.92), our estimator for the value of λ which maximizes the likelihood function. As the title of this subsection promised, it is a quadratic estimator: it is of the general form $A\Delta^2 + B$. The only hard part was determining the coefficients which lead to the best algorithm for finding the root. In the spirit of the Newton-Raphson method, Eq. (11.92) is best used iteratively. One assumes an input spectrum, uses it to determine a new input parameter ($\hat{\lambda}$ in Eq. (11.92)), then uses the new input parameter to find a new best-fit value, and so on until the process converges. In practice, analysts have found that very few iterations are needed until convergence. Nonetheless, we must be somewhat wary of quadratic estimators. It is possible that they will lead us to local maxima in parameter space. Finally, the foregoing discussion assumes there

[6] The correspondence between the curvature matrix and parameter uncertainties is often more quantitative than this. See Numerical Recipes (Press et al., 1992), Chapter 15, for a detailed discussion. The bottom line, though, is that, in many cases, the inverse of the curvature matrix is a very good approximation to the error matrix on the parameters. E.g., in the one parameter case we are presently considering, the $1-\sigma, 68\%$ confidence level on λ is approximately equal to the inverse square root of the curvature matrix. is only one free parameter, but Eqs. (11.92) and (11.93) are easily generalizable to the more relevant case when many parameters are allowed to vary. If we have many parameters $\lambda_\alpha = \lambda_1, \lambda_2, \ldots$, then the quadratic estimator for each is

$$\hat{\lambda}_\alpha = \lambda^{(0)}_\alpha + F^{-1}_{\alpha\beta} \frac{\Delta C^{-1} C_{,\beta} C^{-1} \Delta - \mathrm{Tr}\left[C^{-1} C_{,\beta}\right]}{2}$$

where the Fisher matrix is defined as

$$F_{\alpha\beta} := \left\langle -\frac{\partial^2 (\ln \mathcal{L})}{\partial \lambda_\alpha \partial \lambda_\beta} \right\rangle = \frac{1}{2} \mathrm{Tr}\left[\mathrm{C}_{,\alpha}\mathrm{C}^{-1}\mathrm{C}_{,\beta}\mathrm{C}^{-1}\right].$$

Putting aside the details which led to Eq. (11.94), we can appreciate that the result is remarkable. We can now hope to find the values of the parameters which maximize the likelihood function without blindly covering the whole parameter space. A very small number of matrix manipulations suffice to determine these bestfit values. This is a huge advantage, too good to pass up considering the alternative.

We still need to find a way to evaluate the errors on the parameters. Had we evaluated $\mathcal{L}$ everywhere, we could easily identify the region in parameter space ruled out at, say, the 95% level. How do we identify such regions using the quadratic estimator? To answer this question we need to remove ourselves from the derivation above and simply notice that Eq. (11.94) is an estimator for the true best-fit values of the parameters. If we think of it in this way - rather than as the result of a rootfinding algorithm - we can study its distribution. Since the distributions for both signal and noise are known (they are assumed Gaussian with covariance matrices C_S and C_N, respectively), we can calculate the estimator's expectation value and variance.

First, let's consider its expectation value:

$$\left\langle \hat{\lambda}_\alpha \right\rangle = \lambda_\alpha^{(0)} + F_{\alpha\beta}^{-1} \frac{\langle \Delta C^{-1} C_{,\beta} C^{-1} \Delta \rangle - \mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\beta}\right]}{2}$$

Here the covariance matrix, its derivatives, and the Fisher matrix have all been evaluated at the trial point $\lambda_\alpha = \lambda_\alpha^{(0)}$. The expectation value $\langle \Delta\Delta \rangle$ on the other hand is equal to the true covariance matrix, $C\left(\bar{\lambda}_\alpha\right)$. We can expand $C\left(\bar{\lambda}_\alpha\right)$ about $\lambda_\alpha^{(0)}$:

$$C\left(\bar{\lambda}_\alpha\right) \simeq C + C_{,\alpha'}\left(\bar{\lambda}_{\alpha'} - \lambda_{\alpha'}^{(0)}\right)$$

Therefore the expectation value of the quadratic estimator is

$$\left\langle \hat{\lambda}_\alpha \right\rangle = \lambda_\alpha^{(0)} + \frac{1}{2} F_{\alpha\beta}^{-1} \left\{ \mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\beta}\mathrm{C}^{-1}\mathrm{C}\right] \right.$$

$$\left. + \mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\beta}\mathrm{C}^{-1}\mathrm{C}_{,\alpha'}\right]\left(\bar{\lambda}_{\alpha'} - \lambda_{\alpha'}^{(0)}\right) - \mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\beta}\right] \right\}$$

The first term in brackets cancels the third. The remaining trace is twice the Fisher matrix, so upon multiplying by F^{-1}, we are left with

$$\left\langle \hat{\lambda}_\alpha \right\rangle = \bar{\lambda}_\alpha$$

So the quadratic estimator we have been considering is unbiased: the expectation values of the set of $\hat{\lambda}_\alpha$ are equal to the true parameters $\bar{\lambda}_\alpha$, no matter what set of parameters are assumed at the outset.

We are also interested in the variance of the estimator:

$$\left\langle \left(\hat{\lambda}_\alpha - \bar{\lambda}_\alpha\right)\left(\hat{\lambda}_\beta - \bar{\lambda}_\beta\right) \right\rangle = \left(F^{-1}\right)_{\alpha\beta}$$

This equality, which I will leave as an exercise, holds if we are truly at the maximum of the likelihood function and if the data points really are distributed as a Gaussian. If these conditions hold, then the expected errors on the parameters are equal to the square root of the diagonal elements of F^{-1}. This is a magic limit, for there is a theorem, the Cramer-Rao inequality, that states that no method can measure the parameters with errors smaller than this (e.g., Kendall and Stuart, 1969). This makes sense since the errors from a full likelihood computation could not possibly be smaller than the width of the likelihood. This width in turn is determined by the curvature, and the Fisher matrix is simply the ensemble average of the curvature. Equation (11.100) tells us that on average, the quadratic estimator of Eq. (11.94) will reach this optimal limit.

Given any point in parameter space, we can calculate the associated Fisher matrix. Thus a simple way to assign error bars to the parameters determined via the quadratic estimator is to use the Fisher matrix evaluated at that point in parameter space. Bond, Jaffe, and Knox (1998), among others, have shown that this prescription works well: i.e., it agrees with a more complete tracing out of the likelihood contours.

Equation (11.100) is useful for other reasons as well. As is apparent from Eq. (11.95), the Fisher matrix - and hence the expected errors on any set of parameters - can be evaluated

without any data. It will serve us well in Section 11.4.3 when we set out to determine how well upcoming experiments will be able to determine parameters.

We have derived the quadratic estimator in a way which might lead you to believe that it is restricted to the CMB. Namely, our derivation assumed that the likelihood function is Gaussian, true for the CMB but not for galaxy surveys. Even without the assumption of a Gaussian likelihood function, though, the quadratic estimator of Eq. (11.94) can be applied to galaxy surveys. Like any quadratic estimator, it has a mean and a variance. We have just seen that, for Gaussian distributions, it has the lowest variance possible. On large scales, where the galaxy distribution is Gaussian, therefore, it is extremely relevant. Even on small scales, where nonlinearities add to the variance, it is often competitive with other, more traditional estimators.

26.1.4 the Fisher Matrix: Limits and Applications

The Fisher matrix plays a key role in describing the ability of a given experiment to constrain parameters. It is difficult to gain much insight, though, from the definition in Eq. (11.95). Fortunately, in the case of full sky coverage, the Fisher matrix can be computed analytically. This analytic computation can then be extended-via a plausibility argument - to the more realistic case of partial sky coverage. This calculation is presented next for both the CMB and galaxy surveys. The most popular use of the Fisher matrix is as a tool for forecasting. How well do we expect a given experiment (even a hypothetical one) to determine cosmological parameters? The Fisher matrix is ideally suited for this task, and we will see some startling expectations from upcoming experiments.

CMB

The trace in Eq. (11.95) is a sum of the diagonal elements of the matrix $[C_{,\alpha}C^{-1}C_{,\beta}C^{-1}]_{ij}$ where i, j index the pixels used in the map. There are two decisions that need to be made before the Fisher matrix can be computed. First, what pixelization scheme should we use, and second what parameters λ_α are we interested in? For a full-sky CMB experiment, we choose as our parameters the C_l 's themselves. That is, we take each individual C_l as a free parameter and ask how well an experiment can determine it. To avoid confusion (both the covariance matrix and the C_l 's are C 's), let's call each parameter λ_l instead of C_l, at least while working through the algebra. This answers the second question. The best way to deal with the first question - how to pixelize - in the case of the CMB is to use the a_{lm} 's. That is, instead of using the pixelized temperatures $\Theta(\hat{n})$, use

$$a_{lm} = \int d\Omega Y^*_{lm}(\hat{n})\Theta(\hat{n})$$

as the data values. Each pixel then is labeled by l and m, so a given row (or column) in the covariance matrix corresponds to a fixed valued of l and m. Explicitly, since we start with the quadrupole,

$$C = \begin{pmatrix} C_{l=2,m=-2;l'=2,m'=-2} & C_{2,-2;2,-1} & \cdots & C_{2,-2;2,2} & C_{2,-2;3,-3} & \cdots \\ C_{2,-1;2,-2} & C_{2,-1;2,-1} & \cdots & C_{2,-1;2,2} & C_{2,-1;3,-3} & \cdots \\ & & & \vdots & & \\ C_{3,-3;2,-2} & C_{3,-3;2,-1} & \cdots & C_{3,-3;2,2} & C_{3,-3;3,-3} & \cdots \\ & & & \vdots & & \end{pmatrix}.$$

As usual the covariance matrix is the sum of the signal and noise covariance matrices. From Eq. (8.63), the signal covariance matrix would be $\delta_{ll'}\delta_{mm'}\lambda_l$ (remember that we're using λ_l instead of C_l) if the window function were unity. Let's assume that the experiment measures the anisotropy with a beam size σ. Then the signal covariance matrix must be multiplied by $e^{-l^2\sigma^2}$. The noise covariance matrix is a little trickier. You will show in Exercise 11 that, in the case of uncorrelated, uniform noise, it is $\delta_{ll'}\delta_{mm'}w^{-1}$. Here w is the weight defined as

$$w = \left[(\Delta\Omega)\sigma_n^2\right]^{-1}$$

where $\Delta\Omega$ is the size in radians of the real space pixels and σ_n is the noise per pixel. Putting these two together, we have

$$C_{lm;l'm'} = \delta_{ll'}\delta_{mm'}\left[\lambda_l e^{-l^2\sigma^2} + w^{-1}\right]$$

With these simple assumptions, we can take the inverse of the covariance matrix C and also find its derivative with respect to the parameters, the λ_l 's. The inverse of the covariance matrix is

$$\left(C^{-1}\right)_{lm:l'm'} = \delta_{ll'}\delta_{mm'}\left[\lambda_l e^{-l^2\sigma^2} + w^{-1}\right]^{-1}$$

while the derivative of the covariance matrix with respect to the parameter λ_α is

$$C_{lm;l'm',\alpha} = \delta_{ll'}\delta_{mm'}\delta_{l\alpha}e^{-l^2\sigma^2}$$

We can now construct the Fisher matrix; the only difficult task will be keeping track of indices. Very explicitly,

$$\begin{aligned}
F_{\alpha\alpha'} &= \frac{1}{2}C_{lm;l'm',\alpha}C^{-1}_{l'm':l''m''}C_{l''m'':l'''m''',\alpha'}C^{-1}_{l'''m''':lm} \\
&= \frac{1}{2}\left(\delta_{ll'}\delta_{mm'}\delta_{l\alpha}e^{-l^2\sigma^2}\right)\left(\frac{\delta_{l'l''}\delta_{m'm''}}{\lambda_{l'}e^{-l'^2\sigma^2}+w^{-1}}\right)\left(\delta_{l''l'''}\delta_{m''m'''}\delta_{l''\alpha'}e^{-l''^2\sigma^2}\right) \\
&\times\left(\frac{\delta_{l'''l}\delta_{m'''m}}{\lambda_l e^{-l^2\sigma^2}+w^{-1}}\right)
\end{aligned}$$

with the implicit sum over $ll'l''l'''mm'm''m'''$. Consider first the Kronecker deltas with subscripts m, m', m'', and m'''. There are four of these; summing over all the subscripts besides m contracts these four to

$$\sum_{m'm''m'''}\delta_{mm'}\delta_{m'm''}\delta_{m''m'''}\delta_{m'''m} = \delta_{mm}.$$

Then, summing over all m leads to a factor of $2l+1$. The remaining sums over l and its cousins leads to a simple factor of $\delta_{\alpha\alpha'}$. Therefore in the all-sky limit, the Fisher matrix for a CMB experiment is

$$F_{ll'} = \frac{2l+1}{2}\delta_{ll'}e^{-2l^2\sigma^2}\left[C_l e^{-l^2\sigma^2} + w^{-1}\right]^{-2}$$

where I have gone back to C_l here since the covariance matrix does not appear. In an all-sky survey, therefore, the Fisher matrix for the C_l 's is diagonal. There are no correlations between adjacent C_l 's. The errors on a given C_l expected from an all-sky experiment can be read off from Eq. (11.109). The errors are equal to $\sqrt{F^{-1}}$, so

$$\delta C_l = \sqrt{\frac{2}{2l+1}}\left[C_l + w^{-1}e^{l^2\sigma^2}\right].$$

As anticipated in Eq. (11.26), there are thus two sources of error: (i) cosmic variance, proportional to the signal itself C_l and (ii) noise-atmospheric or instrumental as encoded in the weight w and the smoothing determined by the beam width σ. The factor of $2l+1$ in the denominator also traces back to Eq. (11.26); it is the number of independent samples used to estimate a given C_l.

No experiment will ever cover the entire sky, since the CMB cannot be observed in the plane of our galaxy. Even MAP and Planck, two satellites designed to map CMB anisotropy from space, will therefore cover a fraction of the sky $f_{\rm sky} < 1$. Recalling that the factor of $2l+1$ in the denominator of Eq. (11.26) counts the number of samples, we could guess that this factor must be multipled by $f_{\rm sky}$. This leads to

$$\delta C_l = \sqrt{\frac{2}{(2l+1)f_{\rm sky}}}\left[C_l + w^{-1}e^{l^2\sigma^2}\right].$$

This formula enables one to project the errors obtainable for any given experiment. The three characteristics of the experiment which determine the error on C_l are the sky coverage; the weight; and the beam width.

Galaxy Surveys

The analogue of the all-sky CMB experiment is a volume-limited galaxy survey as the volume gets arbitrarily large. This limit applies to all modes with wavelengths k^{-1} much smaller than the typical size of the survey. We have already computed the signal and noise covariance matrices in this limit, Eqs. (11.60) and (11.61), so the covariance matrix for Fourier pixels is

$$C_{\vec{k}_i,\vec{k}_j} = \frac{\delta_{ij}}{V}\left(P\left(k_i\right) + \frac{1}{\bar{n}}\right).$$

To compute the Fisher matrix, we will need the inverse of this and its derivative with respect to whatever parameters we choose. The inverse is simple,

$$C^{-1}_{\vec{k}_i,\vec{k}_j} = \frac{\delta_{ij}V}{P\left(k_i\right) + \frac{1}{n}}$$

For our parameters, we will choose the amplitude of the power spectrum in a set of narrow k-bins, each with width Δk. The power in the bin with $k_\alpha < k < k_\alpha + \Delta k$ will be denoted P_α. The derivative of the covariance matrix with respect to P_α is therefore

$$C_{ij,\alpha} := \frac{\partial C_{\vec{k}_i,\vec{k}_j}}{\partial P_\alpha} = \frac{\delta_{ij}}{V} d_{i\alpha}$$

with

$$d_{i\alpha} := \begin{cases} 1 & k_\alpha < \left|\vec{k}_i\right| < k_\alpha + \Delta k \\ 0 & \text{otherwise} \end{cases}.$$

The Fisher matrix is now

$$\begin{aligned} F_{\alpha\alpha'} &= \frac{1}{2} C_{ij,\alpha} C^{-1}_{jj'} C_{j'i',\alpha'} C^{-1}_{i'i} \\ &= \frac{1}{2}\delta_{ij} d_{i\alpha} \frac{\delta_{jj'}}{P\left(k_j\right) + \frac{1}{n}} \delta_{j'i'} d_{i'\alpha'} \frac{\delta_{i'i}}{P\left(k_i\right) + \frac{1}{n}}. \end{aligned}$$

The sums over j, j, i' are straightforward, leaving

$$F_{\alpha\alpha'} = \frac{1}{2} \frac{\sum_i d_{i\alpha} d_{i\alpha'}}{\left(P_\alpha + \frac{1}{n}\right)\left(P_{\alpha'} + \frac{1}{\bar{n}}\right)}.$$

As long as the k-bins do not overlap, k_i cannot be in two different bins so the product $d_{i\alpha} d_{i\alpha'}$ requires $\alpha = \alpha'$. The sum then is over all vectors $\vec{k}_i$ in a spherical shell with radius k_α and width Δk. This sum is $4\pi k_\alpha^2 \Delta k V$. Therefore, the Fisher matrix is diagonal, with elements

$$F_{\alpha\alpha'} = \delta_{\alpha\alpha'} \frac{4\pi k_\alpha^2 \Delta k V}{2\left(P_\alpha + \frac{1}{\bar{n}}\right)^2}.$$

The error on the power spectrum in this limit is the inverse square root,

$$\delta P_\alpha = \sqrt{\frac{2}{4\pi k_\alpha^2 \Delta k V}}\left(P_\alpha + \frac{1}{\bar{n}}\right).$$

This is identical in form to the errors on the C_l 's. The denominator in the prefactor counts the number of modes in a given estimate; the first term is cosmic variance; and the last is the noise, in this case Poisson noise.

Forecasting

One of the great promises of upcoming cosmological experiments is that they will determine many of the presently unknown cosmological parameters. How does one predict the expected uncertainties in cosmological parameters from future experiments? The answer is surprisingly simple. Let's consider a CMB experiment as an example. Start with the following:

- A set of C_l 's that are assumed to describe the true universe - The uncertainty on C_l from a given experiment, δC_l, assumed to be given by Eq. (11.111)
- The set of cosmological parameters, $\{\lambda_\alpha\}$, for which we want to forecast errors

The observed C_l 's in this universe will be close to the true C_l 's; indeed, if we form

$$\chi^2\left(\{\lambda_\alpha\}\right) = \sum_l \frac{\left(C_l\left(\{\lambda_\alpha\}\right) - C_l^{\rm obs}\right)^2}{\left(\delta C_l\right)^2},$$

then we expect this χ^2 to reach a minimum at the point in parameter space where $\lambda_\alpha = \bar{\lambda}_\alpha$, the actual values of the parameters. Of course, we do not now know what those values are, but even without that information, we can ask how quickly $\chi^2\left(\{\lambda_\alpha\}\right)$ changes as λ_α moves away from $\bar{\lambda}_\alpha$. If it increases rapidly, then the errors on the parameters will be very small; if the χ^2 changes little, then there will be large errors on the parameters.

To quantify this, we can expand χ^2 about its minimum at $\bar{\lambda}_\alpha$. Let's first do this in the case of one parameter; the generalization to many parameters will be straightforward. In the one-parameter case,

$$\chi^2(\lambda) = \chi^2(\bar{\lambda}) + \mathcal{F}(\lambda - \bar{\lambda})^2$$

The linear term in Eq. (11.121) vanishes since χ^2 is a minimum at $\bar{\lambda}$. The coefficient of the quadratic term is

$$\mathcal{F} = \frac{1}{2}\frac{\partial^2\chi^2}{\partial\lambda^2}\bigg|_{\lambda=\bar{\lambda}}$$

The curvature here, $\mathcal{F}$, measures how rapidly the χ^2 changes away from its minimum. As such, the error on λ is simply $1/\sqrt{\mathcal{F}}$. So all we need to do in order to determine the expected errors on a parameter is calculate $\mathcal{F}$. Note that $\mathcal{F}$ is the curvature of the likelihood function only if the likelihood function is equal to $e^{-\chi^2/2}$, that is, if the errors on the C_l 's are Gaussian distributed. In fact, they are not, so $\mathcal{F}$ as given by Eq. (11.122) is not really the curvature, $-\partial^2 \ln\mathcal{L}/\partial\lambda^2$. Nonetheless, the distribution is close enough to Gaussian that the error estimates that arise are expected to be quite accurate.

The second derivative of χ^2 contains two terms:

$$\mathcal{F} = \sum_l \frac{1}{\left(\delta C_l\right)^2}\left[\left(\frac{\partial C_l}{\partial\lambda}\right)^2 + \left(C_l - C_l^{\rm obs}\right)\frac{\partial^2 C_l}{\partial\lambda^2}\right]$$

The second term in the sum over l is traditionally neglected. The idea (as elucidated in Numerical Recipes) is that the difference $C_l - C_l^{\rm obs}$ will sometimes be negative, sometimes positive. On average, there will be much cancellation, so the first term will dominate. Thus, the general practice is to take

$$\mathcal{F} \to \sum_l \frac{1}{\left(\delta C_l\right)^2}\frac{\partial C_l}{\partial\lambda}\frac{\partial C_l}{\partial\lambda}$$

Equivalently, you can think of the dropping of the second term as taking an average over the whole distribution, thereby replacing the curvature matrix with the Fisher matrix (although again keeping in mind that this is not the true curvature or Fisher matrix since the C_l 's are not distributed as Gaussians). The generalization of this to many parameters is simply

$$F_{\alpha\beta} = \sum_l \frac{1}{(\delta C_l)^2} \frac{\partial C_l}{\partial \lambda_\alpha} \frac{\partial C_l}{\partial \lambda_\beta}$$

In order to predict how accurately parameters will be known, then, we simply need to know the experiment's specifications (to determine δC_l) and the derivatives of the C_l 's around their (assumed) true values.

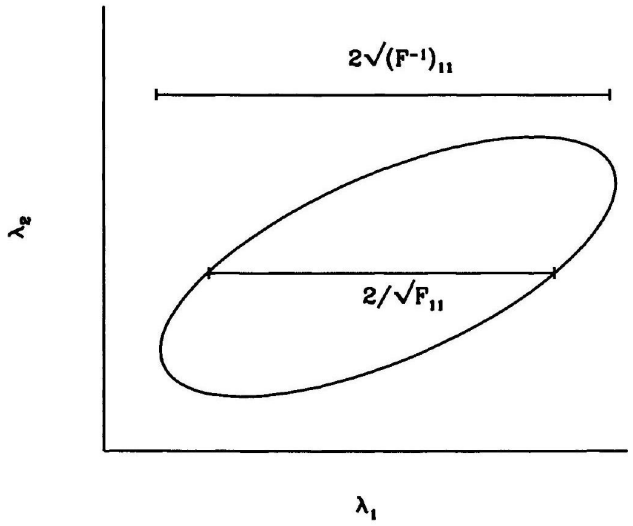

Figure 11.13. Error ellipse in a 2D parameter space. If no prior information is known about λ_2, then the error on λ_1 is $\sqrt{(F^{-1})_{11}}$. If, however, λ_2 is fixed, the error on $\lambda_1, (F_{11})^{-1/2}$ is smaller.

Assuming a Gaussian distribution, the one-sigma uncertainty on a one parameter fit is $1/\sqrt{F}$. How about if more than one parameter is allowed to vary? Figure 11.13 illustrates the situation in a two-dimensional setting. If the parameter λ_2 is assumed known, then the error on λ_1 is still $1/\sqrt{F_{11}}$. However, if λ_2 is allowed to vary, the error on λ_1 is now $\sqrt{(F^{-1})_{11}}$. It is instructive to prove this explicitly by noting that we are assuming that the joint probability for the two parameters is

$$P(\lambda_1, \lambda_2) \propto \exp\left\{-\frac{1}{2}\lambda_i F_{ij} \lambda_j\right\}$$

where I have assumed that the distribution peaks at $\lambda_i = 0$ for simplicity. Allowing λ_2 to vary is equivalent to integrating this probability distribution over all possible values of λ_2. This is referred to as marginalizing over λ_2. Then,

$$\begin{aligned} P(\lambda_1) &= \int d\lambda_2 P(\lambda_1, \lambda_2) \\ &\propto \exp\left\{-\frac{\lambda_1^2}{2}\left(\frac{F_{11}F_{22} - F_{12}F_{21}}{F_{22}}\right)\right\} \end{aligned}$$

where the second line comes from carrying out the λ_2 integration explicitly. The term in parentheses in the exponential- $-\left[F_{11}F_{22} - F_{12}F_{21}\right]/F_{22}$ - is simply equal to $1/\left(F^{-1}\right)_{11}$. So the one-sigma error is indeed given by $\sqrt{(F^{-1})_{11}}$.

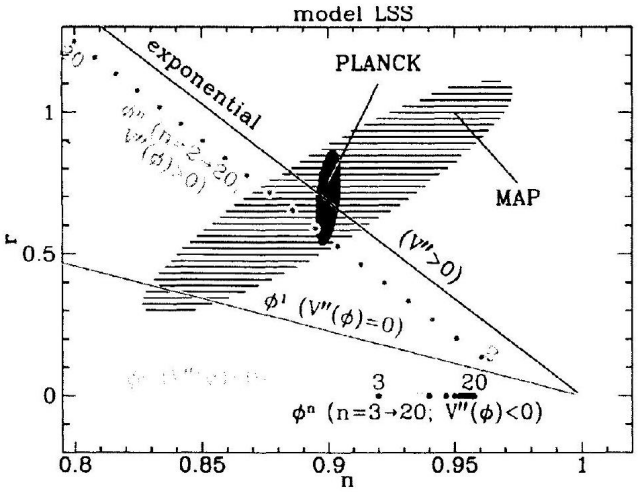

Figure 11.14. Expected 95% uncertainty on the inflationary parameters n and r from MAP and Planck (from Dodelson, Kinney, and Kolb, 1997). (See color Plate 11.14.) Three other parameters (normalization, Ω_B, and h) have been marginalized over. Every inflationary model gives a unique prediction somewhere in this plane; many such predictions are plotted.

Figure 11.14 shows the expected uncertainties from MAP and Planck for two inflationary parameters, those which determine the primordial spectrum. Note that I have fixed the "true" model to be one in which the spectral index $n = 0.9$ and the tensor-to-scalar ratio $r = 0.7$. Different fiducial models often lead to quite different error bars. The ellipse in Figure 11.14 has been drawn after marginalizing over Table 11.1. Marginalized Errors for Λ CDM for various experiments.

	Map	Planck	Map+SDSS	Planck+SDSS
h	0.22	0.13	0.029	0.022
Ω_m	0.24	0.14	0.036	0.027
Ω_Λ	0.19	0.11	0.042	0.024
$\ln(\Omega_b h^2)$	0.060	0.010	0.050	0.010
m_ν(eV)	0.58	0.26	0.33	0.21
Y_P	0.020	0.013	0.020	0.013
n	0.048	0.008	0.040	0.008
r	0.18	0.012	0.16	0.012
τ	0.022	0.004	0.021	0.004

three other cosmological parameters: normalization, baryon density, and Hubble constant. To do this, one starts with the five-dimensional Fisher matrix, inverts, and then considers only the 2×2 part of the inverse. This 2×2 part defines the ellipses drawn in the figure.

Also plotted in Figure 11.14 are the predictions from a wide variety of inflationary models. The figure argues persuasively that we will indeed be able to distinguish among different inflationary models with upcoming CMB experiments. This is a remarkable finding: we will learn about physics at 10^{15}GeV or higher using CMB data. If more parameters are allowed to vary, then the errors on any one parameter naturally get larger. However, this can be offset by using other observations, most notably those from large-scale structure. Table 11.1 presents the marginalized errors on a number of parameters expected from the MAP, Planck, and Sloan Digital Sky Survey experiments (Eisenstein, Hu, and Tegmark, 1999). Here the errors include the measurement of polarization in MAP and more importantly Planck.

26.1.5 Mapmaking and Inversion

Until now, we have discussed ways of analyzing a map, a collection of pixels with data Δ and noise covariance matrix C_N. How does one make such a map? How do we go from the timestream of data to a pixelized set of spatial Δ 's? Most work on this issue has focused on the temperature maps in the CMB, so I'll use this as an example. We will see that mapmaking is essentially an inversion problem. So the mapmaking techniques discussed here are applicable to a broad range of problems in physics and astronomy.

Let's first state the problem. An experiment amounts to a timestream of data, d_t. Each number in the timestream corresponds to data taken at a given point on the sky. The data are assumed to be composed of signal plus noise:

$$d_t = P_{ti} s_i + \eta_t$$

Here subscript t denotes a given element in the timestream; i denotes spatial pixel; P is the pointing matrix; s is the underlying temporally constant, but spatially varying signal; and η is the temporal noise. The pointing matrix encodes information about where the receiver is pointing. That is, it associates with each temporal measurement t a given pixel i. It is an $N_t \times N_p$ matrix where N_t is the number of temporal measurements and N_p is the number of spatial pixels. The pointing matrix has a special form: every row has only one nonzero entry equal to 1, corresponding to the pixel on the sky being observed at the time denoted by the row. Each column, however, typically has many nonzero entries corresponding to all the times a given spot has been observed. The noise η is assumed to be Gaussian with a covariance matrix N. There are techniques to determine N directly from the data, but to simplify the discussion, we will assume that N is known.

What is the best way to make a map from this timestream? One forms a χ^2,

$$\chi^2 := \sum_{tt'ij} \left(d_t - P_{ti} s_i\right) N^{-1}_{tt'} \left(d_{t'} - P_{t'j} s_j\right)$$

and minimizes with respect to the signal s. Indeed, if the noise is Gaussian, then the likelihood function is proportional to $e^{-\chi^2/2}$ and minimizing the χ^2 is equivalent to maximizing $\mathcal{C}$. Taking the derivative with respect to s_i leads to

$$\frac{\partial \chi^2}{\partial s_i} = -2 \sum_{tt'j} P_{ti} N^{-1}_{tt'} \left(d_{t'} - P_{t'j} s_j\right)$$

Set the derivative equal to zero:

$$\sum_{tt'j} P_{ti} N^{-1}_{tt'} P_{t'j} s_j = \sum_{tt'j} P_{ti} N^{-1}_{tt'} d_{t'}$$

The terms multiplying s_j on the left are an $N_p \times N_p$ matrix,

$$\left(C_N^{-1}\right)_{ij} := \sum_{tt'} P_{ti} N^{-1}_{tt'} P_{t'j}$$

Multiply both sides by the inverse of this (C_N itself) to find that the χ^2 is minimized when s is equal to

$$\Delta_i = C_{N,ij} P_{ti} N^{-1}_{tt'} d_{t'}$$

In matrix notation,

$$\Delta = C_N P^T N^{-1} d$$

where ^{T} denotes transpose. The noise matrix of this map is equal to

$$C_N = \left(P^T N^{-1} P\right)^{-1}$$

a fact which you can verify by taking $\langle \Delta\Delta \rangle$. A simple limit of Eq. (11.134) emerges when the timestream noise is diagonal and uniform (this is unrealistic). In that case, the elements of C_N become

$$C_{N.ij} \to N \left(\sum_t P^T_{it} P_{tj} \right)^{-1}$$

where now N is simply a number, the diagonal element of the timestream noise. Recall that for a given t, P_{ti} is nonzero for only one pixel i. So the product $P^T_{it} P_{tj}$ vanishes unless $i = j$ and the receiver at time t was pointing at pixel i. Thus the sum over t counts the number

of times the receiver sampled pixel i; call this number π_i. In this artificial case of uniform, uncorrelated noise, therefore, the noise covariance matrix for the map is diagonal with elements N/π_i. This makes sense: as a given pixel is sampled more times, the standard deviation goes down as $\pi_i^{-1/2}$. The map now becomes

$$\Delta_i \to \frac{1}{\pi_i} \sum_t P_{it}^T d_t$$

That is, one simply averages all the data points corresponding to the given pixel (exactly like Eq. (11.8))

Figure 11.15 shows a more realistic implementation of Eq. (11.134), from the long-duration balloon flight of Boomerang (Netterfield et al., 2001), launched on December 29,1998. The map covers a region a region of about 700 square degrees with 7 -arcminute pixels. Therefore, the map required $N_p \simeq 50,000$, while the timestream contained of order 2×10^8 data points. Some tricks were needed to avoid direct inversion and multiplication of the large matrices P and N. Nonetheless, the basis for the Boomerang map, indeed for all CMB maps, is Eq. (11.134).

The raw data from which the map is made need not be the timestream. Instead, the raw data could consist of a series of modulations, e.g., the difference between the temperature at two points. Reconstructing a map from a set of modulations sounds like a much different problem than doing the same from the timestream. In fact, it is mathematically identical: the data d is the sum of a signal and noise. The signal can be thought of as a matrix acting on the underlying temperature field. This matrix does not have the exact form as the pointing matrix (i.e., only one nonzero element in each row), but it is a matrix nonetheless, and all the operations in Eqs. (11.134) and (11.135) can be carried out. There is a big advantage in using a map constructed in this fashion as opposed to the modulated data themselves. Ultimately, the main use of the data will be to estimate parameters in a likelihood analysis. As we have seen, one must construct the signal covariance matrix in order to carry out such an analysis. The signal covariance matrix for a map is extremely simple - the window function is simply $P_l(\cos\theta_{ij})$ - whereas that for modulated data is quite difficult to obtain (recall Section 11.2).

Equation (11.134) and the corresponding noise matrix in Eq. (11.135) are even more general than this. They apply to any problem in which the data are a sum of some processed signal and noise, i.e., to an extraordinarily wide range of problems in physics and astronomy. Consider just two examples. First, the angular correlation

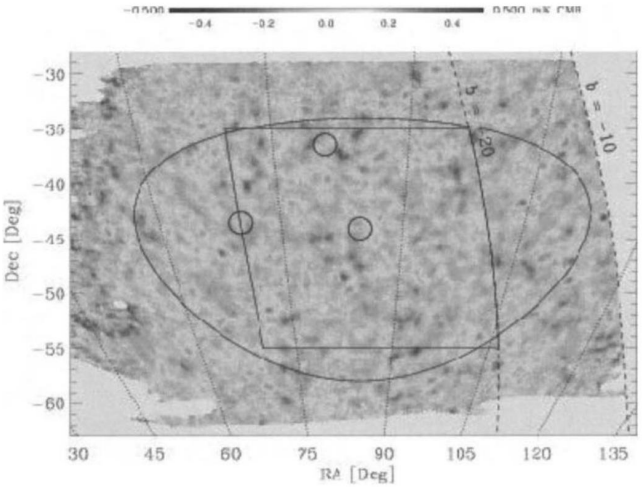

Figure 11.15. A map of the CMB temperature from observations by Boomerang (Netterfield et al., 2001), a long-duration balloon flight at the South Pole. (See also color Plate 11.15.) Hot and cold spots have amplitudes as large as 500μK. Circles shows quasars identified in these radio observations. The large elliptical region delineates data analyzed to obtain bandpowers. The rectangular region is an earlier data set.

function is a sum of the 3D power spectrum processed by a kernel plus noise. One can apply Eq. (11.134) directly to obtain the 3D power spectrum, simply replacing the pointing matrix with the kernel. In the next section, we will see another example, the extraction of the CMB signal from data contaminated by foregrounds.

26.1.6 Systematics

A systematic error is one which remains even after averaging over many data samples. Systematic errors are the most worrisome aspect of most cosmological observations. Knowing this, observers typically take many precautions against them, submitting raw data to a wide variety of consistency checks. Many of these tests are the result of common sense and intuition. Nothing much formal can be said about them. Here I want to focus on several... systematic ways of dealing with such effects.

Foregrounds

One of the biggest obstacles to observing the anisotropies in the CMB are foregrounds, other sources of radiation which also emit at microwave frequencies. The list of foregrounds is long and includes anything in space that might come between us and the radiation left over from the Big Bang. There is dust, synchrotron radiation, and free-free or bremsstrahlung emission, all emanating from our galaxy (but extending to regions of the sky far from the galactic plane). There are also extragalactic sources of radiation, point sources and clusters of galaxies. All of these have the potential to contaminate an experiment searching only for a cosmic signal. The magnitude of this problem is hinted at in the nomenclature. Usually in science, a possible source of systematic error is called a background. In CMB physics, we cannot call these things backgrounds: the "B" in CMB precludes that possibility. We must acknowledge that the cosmic signal is coming from farther away than any possible contaminant and we must deal with the real possibility that the cosmic signal will be smaller than some of these contaminants.

The problem of foregrounds has in the past few years been demonstrated to be manageable. There are a number of reasons for this good fortune (it is good fortune: if we were living deeper in the galaxy foreground amplitudes would be considerably larger). First observers have been very successful at finding the coolest portions of the sky and using only these regions. Second, foreground amplitudes have proven to be smaller than the cosmic signal in a fairly wide part of frequency space. Figure 11.16 shows the intensity of several galactic foregrounds and the CMB. The amplitudes of each of these components varies across the sky, but the relative amplitudes shown in Figure 11.16 are fairly typical. At very high frequencies, dust dominates, and at very low frequencies synchrotron and bremsstrahlung become important. But, in the range from 30 to 200GHz, the CMB anisotropies often have the largest intensities.

The final reason foregrounds can be managed - and the one I want to focus on here - can also be gleaned from Figure 11.16. The spectral shapes of the foregrounds are all different, different from one another and from the blackbody shape of the CMB anisotropy. This raises the possibility that detections at different frequencies can be used to extract the CMB signal from the foregrounds. As analysts, we must find the optimal way to perform this extraction. Given measurements at several different frequencies, what is the best algorithm for finding the cosmic signal? How effective do we expect this extraction to be?

First we need to set up some notation. Instead of intensity (or brightness) B, which has units of ergs $\mathrm{cm}^{-2}\mathrm{sec}^{-1}$ Hz^{-1}, it is convenient to introduce the brightness temperature or antenna temperature, defined as

$$\begin{aligned} T_{\mathrm{ant}} &:= \frac{B}{2\nu^2} \\ &= 2\pi\nu f, \end{aligned}$$

which has dimensions of kelvins (recall that we are working in units with $k_B = \hbar = c = 1$). The frequency ν is related to the momentum we used in earlier chapters via $p = 2\pi\nu$ and f is the familiar phase space density.

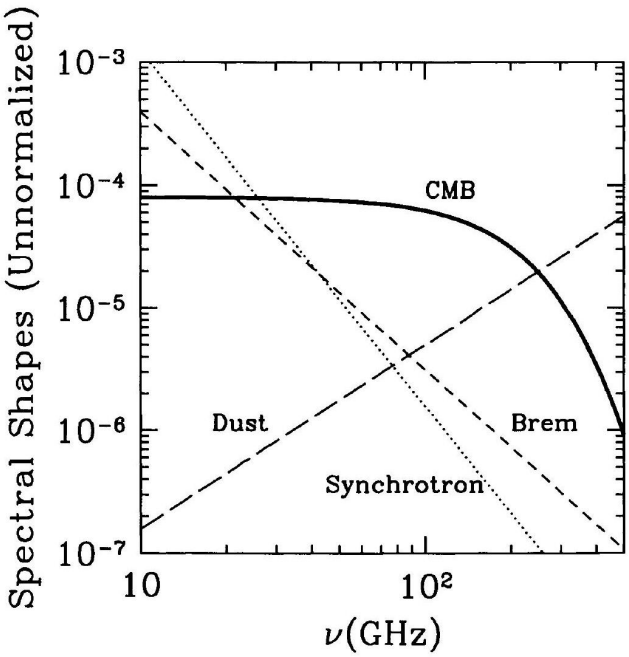

Figure 11.16. Spectral shapes of the dominant galactic foregrounds and the CMB blackbody temperature anisotropy.

For the CMB we know that f is given by Eq. (4.35), so the antenna temperature is

$$\frac{T_{\rm ant}^{\rm cmb}}{T} = \frac{x}{e^x - 1} + \Theta \frac{x^2 e^x}{(e^x - 1)^2}$$

where

$$x := \frac{p}{T} = \frac{2\pi\nu}{T}$$

The first term in Eq. (11.139) is the monopole, which does not interest us. The second contains information about the shape of the spectrum of the CMB anisotropies. It is useful then to neglect the first term and write

$$\frac{T_{\rm ant}^{\rm cmb}(\nu)}{T} = \Theta W^{\rm cmb}(2\pi\nu/T)$$

where W^α will be the shape vector for different components. That for the CMB is

$$W^{\rm cmb} = \frac{x^2 e^x}{(e^x - 1)^2}$$

Every component can be written in this fashion: the product of an amplitude (in this case Θ), which is frequency independent, and the shape vector, which carries no information about the amplitude. For a blackbody distribution like the CMB, the amplitude has a name: Θ is called the thermodynamic temperature. Note that the CMB shape vector goes to 1 in the limit of small frequencies, the Rayleigh-Jeans limit. At high frequencies, it falls off exponentially.

I have called W a shape vector implying that it has a number of components. These components are the different frequency channels at which a given experiment takes data. We will label these with a subscript c while allowing for many possible foreground components:

$$\vec{W}^\alpha = W_c^\alpha \quad c = 1, \ldots, N_{ch} \quad ; \quad \alpha = 0, \ldots, N_{\rm foregrounds}$$

Here the CMB component is associated with index $\alpha = 0$. Thus, the data from a given experiment in a given pixel (we focus on only one spatial pixel) on the sky is in the form of a set of antenna temperatures, d_c, at all the different frequency channels. Our model is that this data set is the sum of the contributions from the CMB, foregrounds, and Gaussian noise:

$$d_c = \sum_{\alpha=0}^{N_{\rm foregrounds}} W_c^\alpha \Theta^\alpha + n_c$$

We assume that we know the covariance matrix of the noise N and all the spectral shapes [7]W_c^α. The question is, how do we best determine the CMB anisotropy?

This problem has the exact same form as does the general inversion problem of Section 11.5. We want to obtain estimates of the amplitude Θ^α. We can immediately write down the minimum variance estimator for Θ^α:

$$\Delta^\alpha = (C_N)_{\alpha\beta} W_c^\beta N_{cd}^{-1} d_d$$

with covariance matrix

$$\left(C_N^{-1}\right)_{\alpha\beta} = W_c^\alpha \left(N^{-1}\right)_{cd} W_d^\beta$$

Let's work out a simple example to bring these formulae, which are so ubiquitous, to life.

7This assumption is true for the CMB, and very nearly true for synchrotron and bremsstrahlung which have shapes which are fairly constant over the sky. The assumption is worst for dust. A number of groups have explored the consequences of incorrect assumptions about the shapes or allowed for some freedom in the shapes. Consider an experiment taking measurements at two frequencies, both in the Rayleigh-Jeans regime. The shape vector for the CMIB then has two components, both equal to 1:

$$\vec{W}^0 = (1, 1)$$

Let's also assume that the noise is uncorrelated from one frequency channel to the next and is uniform with diagonal element, σ_n^2. First let's consider the case of zero foregrounds. In that case, the covariance matrix is just a single number, the inverse of

$$\begin{aligned} WN^{-1}W &\to \begin{pmatrix} 1 & 1 \end{pmatrix} \begin{pmatrix} 1/\sigma_n^2 & 0 \\ 0 & 1/\sigma_n^2 \end{pmatrix} \begin{pmatrix} 1 \\ 1 \end{pmatrix} \\ &= \frac{2}{\sigma_n^2}. \end{aligned}$$

The inverse square root of this is the noise, $\sigma_n/\sqrt{2}$. The two channels reduce the noise by a factor of the square root of 2 (if there were three channels in our example, the factor would be $\sqrt{3}$, etc.). The mimimum variance estimator is given by Eq. (11.145),

$$\begin{aligned} \Delta &\to \frac{\sigma_n^2}{2}(1,1) \begin{pmatrix} 1/\sigma_n^2 & 0 \\ 0 & 1/\sigma_n^2 \end{pmatrix} \begin{pmatrix} d_1 \\ d_2 \end{pmatrix} \\ &= \frac{d_1 + d_2}{2}. \end{aligned}$$

We simply average the two data points.

Now suppose there is one foreground to worry about, say synchrotron emission, with shape vector

$$\vec{W}^1 = (1, 1/2)$$

Typically, the intensity of synchrotron emission scales as ν^{-1} (see, e.g., Rybicki and Lightman, 1979), so its antenna temperature falls off as ν^{-3}. Thus a shape vector $(1, 1/2)$ follows from observing at, e.g., $\nu_1 = 20$GHz and $\nu_2 = 25$GHz.

Now the covariance matrix C_N is a two by two matrix. Then Eq. (11.146) becomes

$$\begin{aligned} C_N^{-1} = W_c^\alpha \left(N^{-1}\right)_{cd} W_d^\beta &= \begin{pmatrix} 1 & 1 \\ 1 & 1/2 \end{pmatrix} \begin{pmatrix} 1/\sigma_n^2 & 0 \\ 0 & 1/\sigma_n^2 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 1 & 1/2 \end{pmatrix} \\ &= \frac{1}{\sigma_n^2} \begin{pmatrix} 2 & 3/2 \\ 3/2 & 5/4 \end{pmatrix}. \end{aligned}$$

Already at this stage, we can glean some important information about the experiment. Recall from the discussion in Section 11.4 that the inverses of the diagonal elements of C_N^{-1} are the unmarginalized variances, the errors if all other parameters are known. In this case, there is one parameter besides the amplitude of the CMB, the amplitude of the foreground. If we assume that is known, then the error on the CMB temperature will be the inverse square root of the oo component of the matrix in Eq. (11.151). This is $\sigma_n/\sqrt{2}$, in agreement with the calculation above. To find the errors if we know nothing about the foreground amplitudes, take the inverse of this to find the covariance matrix,

$$C_N = 4\sigma_n^2 \begin{pmatrix} 5/4 & -3/2 \\ -3/2 & 2 \end{pmatrix}$$

The oo component of this gives the marginalized variance, $5\sigma_n^2$. The ratio of the marginalized error to the unmarginalized error is a measure of how severely the unknown foregrounds degrade our ability to determine the CMB temperature. It is called the foreground degradation factor, or simply the FDF. In this case, the FDF is equal to $\sqrt{10}$.

In this example, we can now determine the minimum variance estimator for the CMB temperature. Following Eq. (11.145), we write

$$\begin{aligned} \Delta^0 &= 4\sigma_n^2(5/4, -3/2) \begin{pmatrix} 1 & 1 \\ 1 & 1/2 \end{pmatrix} \begin{pmatrix} 1/\sigma_n^2 & 0 \\ 0 & 1/\sigma_n^2 \end{pmatrix} \begin{pmatrix} d_1 \\ d_2 \end{pmatrix} \\ &= -d_1 + 2d_2. \end{aligned}$$

This should be no surprise. The best estimator for the CMB temperature is completely insensitive to the amplitude of the foreground component. For, if the foreground really does have shape vector $(1, 1/2)$, the linear combination $-d_1 + 2d_2$ from the foreground is equal to zero.

In real life, one must find the minimum variance estimators at many different spatial pixels. The formula of Eq. (11.145) remains identical in this more general case: one simply adds an index for spatial pixel. It is often most convenient to work with the a_{lm} 's instead of the temperature as a function of angular coordinates. Then, the minimum variance estimator for a_{lm} often weights the different frequency channels differently depending upon how the noise in each channels scales with l. An example is shown in Figure 11.17, based on the five frequencies of the MAP experiment. The figure shows how the best estimator for a_{lm} weighs the five different frequencies in the absence of foregrounds. At low l, all the channels have similar noise, so the best estimator is just the average of the five. The beam size is frequency dependent, however, largest at the lowest frequencies. Therefore, at high l, the lowest channels have no signal. Only the highest frequency channel can be used. Indeed, one sees that the minimum variance estimator gradually drops a channel at a time as l gets larger.

Often prior information on the foregrounds exists, in the form of an estimate of the power spectrum of each foreground component, i.e., its C_l. This prior information can be incorporated into the minimum variance estimate; see, e.g.,

D-15.

Figure 11.18 shows the results of accounting for foregrounds in the MAP experiment. The difference between the weighting scheme in this figure and that in Figure

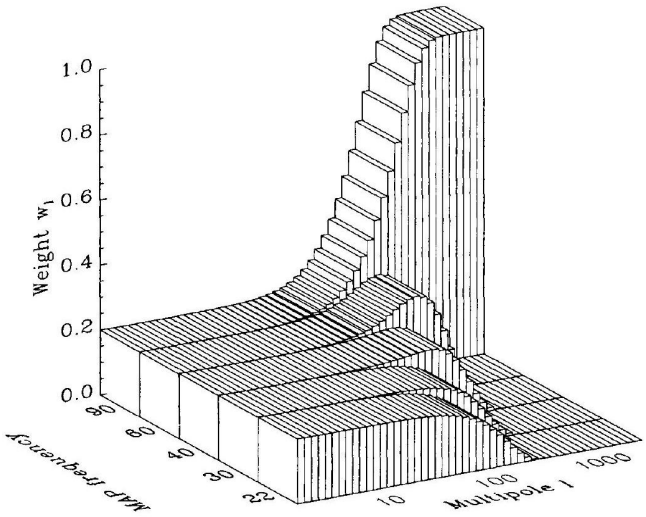

Figure 11.17. The minimum variance linear combination of the frequency channels of MAP in the absence of foregrounds (from Tegmark et al., 2000). The noise at low l is identical in all channels, so the minimum variance estimator weights them equally. At high l, the highest frequency channel has the lowest noise, so the best estimator uses only that channel.

11.17 is striking, especially at low l. No longer does one weight all the different channels identically. Rather, a complicated set of weights must be used to project out the foreground contamination.

Note that foregrounds do indeed fit the definition of a systematic effect. If one neglected synchrotron emission in the previous example, the naive estimate of the CMB temperature $(d_1 + d_2)$ would be wrong no matter how small the noise. You might argue that, over the whole sky, the average "wrongness" would cancel out, since there are an equal number of hot and cold spots of foregrounds. The power spectrum, though, the key quantity of interest, would be contaminated: it would be the sum of $C_l^{\rm CMB}$ and $C_l^{\rm synch}$, again even if there was no noise.

Mode Subtraction

A common problem in cosmological observations is that a particular mode is contaminated by some external source. An example might be a region of space very close to our galaxy, where foregrounds are particularly important. In a galaxy survey, it might be a dusty region. Dust tends to absorb high-frequency light, and so redden an object's image. This leads to less flux in blue bands, often pushing a galaxy outside the flux limits of a survey. This push can be crucial, because typ-

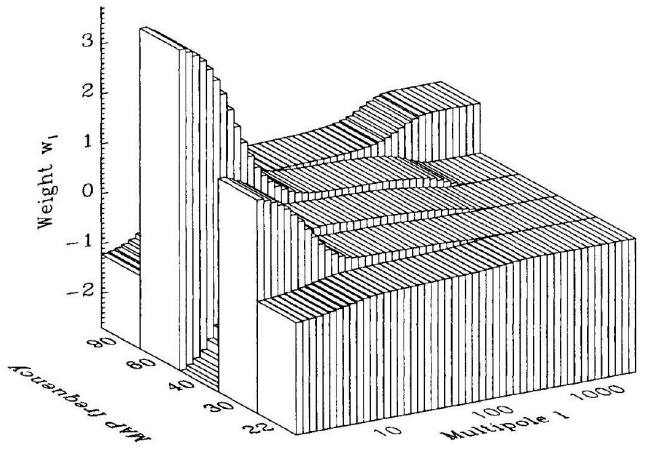

Figure 11.18. The minimum variance linear combination of the frequency channels of MAP in the presence of foregrounds (from Tegmark et al., 2000). Compare with Figure 11.17 to see that, especially at low l, foreground contamination dictates a more complicated linear combination of the channels.

ically most of a survey's galaxies lie close to the flux limits. Yet another example is a CMB experiment which has no sensitivity to the average temperature over a given set of pixels because of atmospheric contamination. Another is a galaxy survey in which a given stripe is contaminated because a CCD went bad at the time of observation. And there are many more examples.

One way of dealing with such contamination is to subtract it off. This is commonly done in galaxy surveys by applying the reddening correction due to dust from an external dust map (the best one at present is by Schlegel, Finkbeiner, and Davis, 1998).

There is another way of dealing with mode contamination, one which is rapidly growing in importance, as precision cosmology becomes a reality. This technique is based on the twin observations that (i) often there is quite a bit of uncertainty in the amplitude of the contamination and (ii) a given experiment often measures many, many modes. Since the second fact is true, we can often do without the offending mode entirely without losing too much information. Since the first fact is true, we often should do without the offending mode, for it may lead us to an incorrect place in parameter space.

How can we eliminate a contaminated mode from an experiment? Let's start with the case where the contaminated mode is a single spatial pixel. In that case, one simple way to ensure that the pixel carries no weight in the likelihood analysis is to add to the covariance matrix a huge number in the diagonal element corre- sponding to the offending pixel. Then, no matter the value observed in this pixel, the likelihood function will not be affected. This simple idea-adding large noise to a contaminated mode - can be extended to more complicated modes, those not localized to one spatial pixel.

As an example, consider a two-pixel CMB experiment, in which the atmosphere contributes identically to both pixels. Thus, the average temperature of the CMB cannot be determined. The contaminant is assumed to be 100% correlated in the two pixels, so we add to the noise covariance matrix

$$C_{\rm con} = \kappa \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$$

where κ is a very large number. Suppose the noise - in the absence of this constraint - is uniform and uncorrelated. Then the new noise covariance matrix is

$$C_N = \sigma_n^2 \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \kappa \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}.$$

In the likelihood function, we add the noise covariance matrix to the signal covariance matrix. Again, for simplicity assume that the pixels are far enough away from each other so that the signal is uncorrelated. Then, the likelihood function depends on the full covariance matrix

$$C = \begin{pmatrix} \sigma_n^2 + \sigma_s^2 + \kappa & \kappa \\ \kappa & \sigma_n^2 + \sigma_s^2 + \kappa \end{pmatrix}.$$

In particular, the likelihood function depends on the determinant and inverse of this matrix (recall Eq. (11.20)). In the limit that κ is very large, the determinant becomes $2\kappa\left(\sigma_n^2 + \sigma_s^2\right)$ and the inverse is

$$C^{-1} \to \frac{1}{2\left(\sigma_n^2 + \sigma_s^2\right)} \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}.$$

Therefore, in this limit, the likelihood function becomes,

$$\mathcal{L} \to \frac{1}{2\pi\sqrt{2\kappa\left(\sigma_n^2 + \sigma_s^2\right)}} \exp\left\{-\frac{\left(\Delta_1 - \Delta_2\right)^2}{2\left(\sigma_n^2 + \sigma_s^2\right)}\right\}$$

That is, apart from an irrelevant normalization constant, the likelihood function is a Gaussian in $\Delta_1 - \Delta_2$ (the difference between the observed temperatures in the two pixels) with variance equal to $\sigma_n^2 + \sigma_s^2$. Thus adding the constraint matrix of Eq. (11.154) is our way of telling the likelihood function to ignore the average temperature.

In this simple example, we could have written down Eq. (11.158) from the outset, but with more complicated modes, the constraint formalism is extremely powerful. What is the generalization of Eq. (11.154) for an arbitrary contamination? Suppose the contaminated mode is of the form m_i where index i labels the pixels. Thus, in the average example, m_i would be equal to $(1, 1)$. One adds to the noise covariance matrix the outer product of this vector times a large number κ:

$$(C_{\rm con})_{ij} = \kappa m_i m_j.$$

This is precisely what we did above for the average, but this expression is now completely general and allows for elimination of any contaminated mode. These matrices, often called constraint matrices, have been used extensively in recent CMB analyses, most notably in the interferometric experiment, DASI.

SUGGESTED READING

I am not a professional statistician and this chapter no doubt glosses over some important concepts in statistics. Nonetheless, I believe this chapter does do justice to the recent flurry of activity in cosmological analysis. Readers interested in more general statistics treatments might consult The Advanced Theory of Statistics (Kendall and Stuart). An essential reference is Numerical Recipes (Press et al.) for all numerical work, and Chapter 15 especially for some of the analysis issues discussed here. A couple of nice early papers on the CMB are Readhead et al. (1989) and Bond et al. (1991). The former takes the likelihood function further than we did here. For example, it deals with frequentist tests and defines such terms as significance and power, which are extremely important in statistics. The Bond et al. paper is a concise introduction to Bayesian analysis of a CMB experiment. Among the ideas explained clearly there are CMB window functions; the likelihood function; dealing with an unknown average; and, to top it off, the idea that CMB experiments will probe the baryon density.

The discussion in Section 11.1.3 is based on a similar treatment in Tegmark et al. (1998), which cemented the connection between CMB analyses and galaxy surveys. It also deals with pixelization schemes other than just the two in Section 11.1.3. Window functions for the CMB are discussed in many places. A nice recent treatment is given by Souradeep and Ratra (2001).

Karhunen and Love decompositions were introduced to the cosmology community by Bunn (1995) and Bond (1995), who used them to analyze COBE, and by Vogeley and Szalay (1996) in the context of galaxy surveys. The optimal quadratic estimator was introduced by Tegmark (1997) and Bond, Jaffe, and Knox (1998), the latter using the Newton-Raphson motivation I stressed in the text. The former focused on the minimum variance aspect, which you can prove in

D-10.

Earlier, Feldman, Kaiser, and Peacock (1994) had computed an optimal estimator for galaxy surveys which turns out to be the small-scale limit of the optimal quadratic estimator. The Fisher matrix was introduced by Fisher (1935). Knox (1995) computed the Fisher matrix in the all-sky CMB case, Tegmark et al. (1998) for galaxy surveys. Jungman et al. (1996) used the Fisher matrix (although they didn't call it that) to give the first forecast of parameter determination. There have been many follow-up papers improving and tweaking various parts of the forecast. Some of the improvements are discussed by Eisenstein, Hu, and Tegmark (1999). The curvature matrix and the covariance matrix of errors on parameters are covered in detail in Numerical Recipes.

Mapmaking and indeed many of the issues in CMB analysis are reviewed by Bond et al. (1999). Foregrounds have been discussed by many authors. The text borrows most heavily from Dodelson (1997) and Tegmark et al. (2000). Other works of note include Tegmark and Efstathiou (1996) and Bouchet and Gispert (1999). Mode subtraction along the lines discussed in Section 11.6.2 was introduced by Bond, Jaffe, and Knox (1998). A nice example of its use is in Halverson et al. (2005).

Exercises

D-1.

In the simple example of Section 11.1.1, show that a prior uniform in σ_n^2 gives a final probability distribution in σ_n different from the one in Eq. (11.5).

D-2.

In the simple example of Section 11.1.1, we found the error on the signal s. What is the error on the other theoretical parameter of the model σ_n?

D-3.

Derive the expression for the covariance matrix due to Poisson sampling, Eq. (11.32).
(a) Divide the survey region into small sub-volumes. Assume that the number of galaxies in a given sub-volume is drawn from a Poisson distribution with mean $\bar{n}$ (assume $\bar{n}$ is constant in all sub-volumes for simplicity),

$$P(n) = \frac{(\bar{n})^n e^{-\bar{n}}}{n!}$$

Determine the expectation values $\langle n \rangle$ and $\langle n^2 \rangle$ for this distribution.
(b) Rewrite Eq. (11.28) as

$$\Delta_i = v \sum_\alpha \psi_i \left(\vec{x}_\alpha\right) \left[\frac{n\left(\vec{x}_\alpha\right) - \bar{n}}{\bar{n}}\right]$$

where α indexes each sub-volume of size v. Using the results of (a), and assuming that there is no intrinsic clustering, determine $\langle \Delta_i \Delta_j \rangle$. Show that it is given by Eq. (11.32). You'll have to change the sums back into integrals.

D-4.

Determine the noise covariance matrix in a galaxy survey using countsin-cells. Assume the cells are spherical with radius R, and find $\left(C_N\right)_{ij}$ as a function of the separation between two cell centers; call it r_{ij}. Assume that the survey is volume limited, that is, that $\bar{n}$ is constant everywhere within a volume V.

D-5.

Do a full likelihood analysis of the University of California at Santa Barbara's 1990-1 CMB experiment carried out at the South Pole (Gaier et al., 1992)
(a) Determine the window function. The chopping angle was 2.1° and the beam width (FWHM) 1.35°. The anisotropy was measured at nine positions, each separated by 2.1° on the sky. Neglect off-diagonal elements.
(b) Fit a flat band power (i.e., take $\mathcal{C} := l(l+1)C_l/2\pi$ constant) to the following data:

Position	$\delta T(\mu\mathrm{K})$	$\sigma_n(\mu\mathrm{K})$
1	-30.5	25.9
2	-3.2	26.5
3	29.2	26.1
4	-10.8	26.3
5	-8.7	28.8
6	23.1	26.4
7	4.7	26.5
8	-24.7	26.6
9	20.3	25.8

Assume that the noise and the signal are both uncorrelated from pixel to pixel. (c) The likelihood function you obtain should peak at band power equal to zero. Find the 95% CL upper limit on the band power, defined by the point for which

$$\int_0^{\mathcal{C}_U} d\mathcal{C}\mathcal{L}(\mathcal{C}) = 0.95 \int_0^{\infty} d\mathcal{C}\mathcal{L}(\mathcal{C})$$

This upper limit was reported around the same time as the COBE detection of anisotropies. Compare the two results.

D-6.

Find the Fourier transform of the top-hat function $f(x) = \Theta(x+ R)\Theta(R - x)$ where Θ is the step function, equal to 1 when its argument is positive and zero otherwise.

D-7.

Find the diagonal elements of the covariance matrix C_S for a volume limited survey for modes $k_i \gg R^{-1}$. Show that they are given by Eq. (11.60).

D-8.

Compute the off-diagonal window function for the two types of galaxy surveys mentioned in Section 11.2.3, a volume-limited survey and a pencil-beam survey. Take both $\vec{k}_i$ and $\vec{k}_j$ parallel to the z-axis (which in the pencil beam survey is aligned with the long distance L). Plot the window function at $k = k_i$ as a function of k_j. At the point $k_i = k_j$, you should recapture the corresponding points in Figures 11.5 and 11.7.

D-9.

Prove Eq. (11.100). Assume there is only one parameter λ and that the likelihood function is Gaussian in the overdensities Δ. Further assume that you have iterated enough times so that the input parameter $\lambda^{(0)}$ is equal to the true value $\bar{\lambda}$.

D-10.

Derive the optimal quadratic estimator of Eq. (11.92) by minimizing the variance of a general quadratic estimator subject to the constraint that its expectation value is unbiased. Hint: Use a Lagrange multiplier to enforce the constraint.

D-11.

Consider an all-sky CMB experiment with spatial pixels of area $\Delta\Omega$. Assume that the experiment measures the temperature in each pixel with Gaussian noise σ_n. The noise is thus assumed to be uniform (the same everywhere on the sky) and uncorrelated (from one pixel to the next). Determine the noise covariance matrix for a_{lm}. If the pixel size is cut in half (for the same experiment), each pixel will get less observing time by a factor of 2. The noise will then go up for each pixel by a factor of $\sqrt{2}$. Show that these two changes (smaller pixels; more noise per pixel) leave the noise covariance matrix for a_{lm} unchanged.

D-12.

Estimate the expected errors on C_l for the following experiments: (i) COBE, (ii) Boomerang, and (iii) MAP, and (iv) Planck.

D-13.

The full-sky limits for the Fisher matrix derived in Section 11.4 can be used to find the optimal quadratic estimator. The results should not surprise you.

(a) Given a set of a_{lm} from a full-sky CMB experiment with uniform weight w, find the optimal quadratic estimator for C_l.

(b) Given a set of pixelized Fourier overdensities from a $3D$ galaxy survey, find the optimal quadratic estimator for $P(k)$.

(c) From your answers to (a) and (b), discuss qualitatively the effectiveness of the optimal quadratic estimator. When do you expect it to perform differently from the naive quadratic estimator, $\sum_m |a_{lm}|^2/(2l+1)$ for C_l and $\sum_{\vec{k}} \left|\delta_{\vec{k}}\right|^2/(4\pi k^2 \Delta k)$ for $P(k)$ (where Δk is the width of the k-bin)?

D-14.

Show that the noise covariance matrix of a map using the estimator in Eq. (11.134) is C_N, as given in Eq. (11.135)

D-15.

Suppose one had prior information about a foreground, in the form of an assumed power spectrum, C_l^α, where α labels the foreground component.

(a) Find the miminum variance estimator for the temperature and the associated covariance matrix.

(b) Consider the example of Section 11.6.1 with two frequencies in the RayleighJeans regime and one foreground with shape vector $\vec{W}^1 = (1, 1/2)$. What is the best estimator of the CMB temperature if the foreground has assumed mean equal to zero and variance equal to that of the noise (σ_n^2)? What is the new error on the determination of the CMB temperature? Compare both of these to the case treated in the text when no information about the foreground amplitude was assumed.

27 Planck 2018 results. VI. Cosmological parameters

We present cosmological parameter results from the final full-mission *Planck* measurements of the cosmic microwave background (CMB) anisotropies, combining information from the temperature and polarization maps and the lensing reconstruction. Compared to the 2015 results, improved measurements of large-scale polarization allow the reionization optical depth to be measured with higher precision, leading to significant gains in the precision of other correlated parameters. Improved modelling of the small-scale polarization leads to more robust constraints on many parameters, with residual modelling uncertainties estimated to affect them only at the $0.5\,\sigma$ level. We find good consistency with the standard spatially-flat 6-parameter ΛCDM cosmology having a power-law spectrum of adiabatic scalar perturbations (denoted "base ΛCDM" in this paper), from polarization, temperature, and lensing, separately and in combination. A combined analysis gives dark matter density $\Omega_{\rm c}h^2 = 0.120 \pm 0.001$, baryon density $\Omega_{\rm b}h^2 = 0.0224 \pm 0.0001$, scalar spectral index $n_{\rm s} = 0.965 \pm 0.004$, and optical depth $\tau = 0.054 \pm 0.007$ (in this abstract we quote 68 % confidence regions on measured parameters and 95 % on upper limits). The angular acoustic scale is measured to 0.03 % precision, with $100\theta_* = 1.0411 \pm 0.0003$. These results are only weakly dependent on the cosmological model and remain stable, with somewhat increased errors, in many commonly considered extensions. Assuming the base-ΛCDM cosmology, the inferred (model-dependent) late-Universe parameters are: Hubble constant $H_0 = (67.4 \pm 0.5)$ km s^{-1}Mpc^{-1}; matter density parameter $\Omega_{\rm m} = 0.315 \pm 0.007$; and matter fluctuation amplitude $\sigma_8 = 0.811 \pm 0.006$. We find no compelling evidence for extensions to the base-ΛCDM model. Combining with baryon acoustic oscillation (BAO) measurements (and considering single-parameter extensions) we constrain the effective extra relativistic degrees of freedom to be $N_{\rm eff} = 2.99 \pm 0.17$, in agreement with the Standard Model prediction $N_{\rm eff} = 3.046$, and find that the neutrino mass is tightly constrained to $\sum m_\nu <$

0.12 eV. The CMB spectra continue to prefer higher lensing amplitudes than predicted in base ΛCDM at over $2\,\sigma$, which pulls some parameters that affect the lensing amplitude away from the ΛCDM model; however, this is not supported by the lensing reconstruction or (in models that also change the background geometry) BAO data. The joint constraint with BAO measurements on spatial curvature is consistent with a flat universe, $\Omega_K = 0.001 \pm 0.002$. Also combining with Type Ia supernovae (SNe), the dark-energy equation of state parameter is measured to be $w_0 = -1.03 \pm 0.03$, consistent with a cosmological constant. We find no evidence for deviations from a purely power-law primordial spectrum, and combining with data from BAO, BICEP2, and Keck Array data, we place a limit on the tensor-to-scalar ratio $r_{0.002} < 0.06$. Standard big-bang nucleosynthesis predictions for the helium and deuterium abundances for the base-ΛCDM cosmology are in excellent agreement with observations. The *Planck* base-ΛCDM results are in good agreement with BAO, SNe, and some galaxy lensing observations, but in slight tension with the Dark Energy Survey's combined-probe results including galaxy clustering (which prefers lower fluctuation amplitudes or matter density parameters), and in significant, $3.6\,\sigma$, tension with local measurements of the Hubble constant (which prefer a higher value). Simple model extensions that can partially resolve these tensions are not favoured by the *Planck* data.

27.1 Introduction

Since their discovery [346], temperature anisotropies in the cosmic microwave background (CMB) have become one of the most powerful ways of studying cosmology and the physics of the early Universe. This paper reports the final results on cosmological parameters from the Planck Collaboration.[131] Our first results were presented in Planck Collaboration XVI [276, hereafter PCP13]. These were based on temperature (TT) power spectra and CMB lensing measurements from the first 15.5 months of *Planck* data combined with the Wilkinson Microwave Anisotropy Probe (WMAP) polarization likelihood at multipoles $\ell \leq 23$ [42] to constrain the reionization optical depth τ. Planck Collaboration XIII [284, hereafter PCP15] reported results from the full *Planck* mission (29 months of observations with the High Frequency Instrument, HFI), with substantial improvements in the characterization of the *Planck* beams and absolute calibration (resolving a difference between the absolute calibrations of WMAP and *Planck*). The focus of PCP15, as in PCP13, was on temperature observations, though we reported preliminary results on the high-multipole TE and EE polarization spectra. In addition, we used polarization measurements at low multipoles from the Low Frequency Instrument (LFI) to constrain the value of τ.

Following the completion of PCP15, a concerted effort by the *Planck* team was made to reduce systematics in the HFI polarization data at low multipoles. First results were presented in Planck Collaboration Int. XLVI [297], which showed evidence for a lower value of the reionization optical depth than in the 2015 results. Further improvements to the HFI polarization maps prepared for the 2018 data release are described in Planck Collaboration III [291]. In this paper, we constrain τ using a new low-multipole likelihood constructed from these maps. The improvements in HFI data processing since PCP15 have very little effect on the TT, TE, and EE spectra at high multipoles. However, this paper includes characterizations of the temperature-to-polarization leakage and relative calibrations of the polarization spectra enabling us to produce a combined TT,TE,EE likelihood that is of sufficient fidelity to be used to test cosmological models (although with some limitations, which will be described in detail in the main body of this paper). The focus of this paper, therefore, is to present updated cosmological results from *Planck* power spectra and CMB lensing measurements using temperature and polarization.

PCP13 showed that the *Planck* data were remarkably consistent with a spatially-flat ΛCDM cosmology with purely adiabatic, Gaussian initial fluctuations, as predicted in simple inflationary models. We refer to this model, which can be specified by six parameters, as "base" ΛCDM in this paper. Note that in the base ΛCDM cosmology we assume a single minimal-mass neutrino eigenstate. We investigated a grid of one- and two-parameter extensions to the base-ΛCDM cosmology (varying, for example, the sum of neutrino masses, effective number of relativistic

[131] *Planck* (https://www.esa.int/Planck) is a project of the European Space Agency (ESA) with instruments provided by two scientific consortia funded by ESA member states and led by Principal Investigators from France and Italy, telescope reflectors provided through a collaboration between ESA and a scientific consortium led and funded by Denmark, and additional contributions from NASA (USA).

degrees of freedom $N_{\rm eff}$, spatial curvature Ω_K, or dark-energy equation of state w_0), finding no statistically significant preference for any departure from the base model. These conclusions were reinforced using the full *Planck* mission data in PCP15.

The analyses reported in PCP13 and PCP15 revealed some discrepancies (often referred to as "tensions") with non-*Planck* data in the context of ΛCDM models (e.g., distance-ladder measurements of the Hubble constant and determinations of the present-day amplitude of the fluctuation spectrum), including other CMB experiments [350]. As a result, it is important to test the fidelity of the *Planck* data as thoroughly as possible. First, we would like to emphasize that where it has been possible to compare data between different experiments at the map level (therefore eliminating cosmic variance), they have been found to be consistent within the levels set by instrument noise, apart from overall differences in absolute calibration; comparisons between WMAP and *Planck* are described by Huang et al. [186], between the Atacama Cosmology Telescope (ACT) and *Planck* by Louis et al. [225], and between the South Pole Telescope (SPT) and *Planck* by Hou et al. [181]. There have also been claims of internal inconsistencies in the *Planck* TT power spectrum between frequencies [347] and between the ΛCDM parameters obtained from low and high multipoles [6]. In addition, the *Planck* TT spectrum preferred more lensing than expected in the base-ΛCDM model (quantified by the phenomenological $A_{\rm L}$ parameter defined in Sect. 27.2.3) at moderate statistical significance, raising the question of whether there are unaccounted for systematic effects lurking within the *Planck* data. These issues were largely addressed in Planck Collaboration XI [283], PCP15, and in an associated paper, Planck Collaboration Int. LI [299]. We revisit these issues in this paper at the cosmological parameter level, using consistency with the *Planck* polarization spectra as an additional check. Since 2013, we have improved the absolute calibration (fixing the amplitudes of the power spectra), added *Planck* polarization, full-mission *Planck* lensing , and produced a new low-multipole polarization likelihood from the *Planck* HFI. Nevertheless, the key parameters of the base-ΛCDM model reported in this paper, agree to better than $1\,\sigma_{2013}$[132] with those determined from the nominal mission temperature data in PCP13, with the exception of τ (which is lower in the 2018 analysis by $1.1\,\sigma_{2013}$). The cosmological parameters from *Planck* have remained remarkably stable since the first data release in 2013.

The results from *Planck* are in very good agreement with simple single-field models of inflation [279, 288]. We have found no evidence for primordial non-Gaussianity [280, 287], setting stringent upper limits. Nor have we found any evidence for isocurvature perturbations or cosmic defects [see PCP15 and 288]. *Planck*, together with Bicep/Keck [51] polarization measurements, set tight limits on the amplitude of gravitational waves generated during inflation. These results are updated in this paper and in the companion papers, describing more comprehensive tests of inflationary models [296] and primordial non-Gaussianity [295]. The *Planck* results require adiabatic, Gaussian initial scalar fluctuations, with a red-tilted spectrum. The upper limits on gravitational waves then require flat inflationary potentials, which has stimulated new developments in inflationary model building [see e.g., 129, 196, 141, 14, and references therein]. Some authors [189, 188] have come to a very different conclusion, namely that the *Planck*/Bicep/Keck results require special initial conditions and therefore disfavour inflation. This controversy lies firmly in the theoretical domain [see e.g., 157, 223], since observations of the CMB constrain only a limited number of e-folds during inflation, not the initial conditions. Post *Planck*, inflation remains a viable and attractive mechanism for accounting for the structure that we see in the Universe.

The layout of this paper is as follows. Section 27.2 describes changes to our theoretical modelling since PCP15 and summarizes the likelihoods used in this paper. More comprehensive descriptions of the power-spectrum likelihoods are given in Planck Collaboration V [293], while the 2018 *Planck* CMB lensing likelihood is described in detail in Planck Collaboration VIII [294]. Section 27.3 discusses the parameters of the base-ΛCDM model, comparing parameters derived from the *Planck* TT, TE, and EE power spectra. Our best estimates of the base-ΛCDM cosmological parameters are derived from the full *Planck* TT,TE,EE likelihood combined with *Planck* CMB lensing and an HFI-based low-multipole polarization likelihood to constrain τ. We compare the *Planck* TE and EE spectra with power spectra measured from recent ground-based experiments in Sect. 27.4.

The *Planck* base-ΛCDM cosmology is compared with external data sets in Sect. 27.5. CMB power spectrum measurements suffer from a "geometric degeneracy" [see 116] which limits their ability to constrain certain extensions to the base cosmology (for example, allowing Ω_K or w_0 to vary). *Planck* lensing measurements partially break the geometric degeneracy, but it is broken

[132]Here σ_{2013} is the standard deviation quoted on parameters in PCP13.

very effectively with the addition of baryon acoustic oscillation (BAO) measurements from galaxy surveys. As in PCP13 and PCP15 we use BAO measurements as the primary external data set to combine with *Planck*. We adopt this approach for two reasons. Firstly, BAO-scale determinations are relatively simple geometric measurements, with little scope for bias from systematic errors. Secondly, the primary purpose of this paper is to present and emphasize the *Planck* results. We therefore make minimal use of external data sets in reporting our main results, rather than combining with many different data sets. Exploration of multiple data sets can be done by others using the Monte Carlo Markov chains and *Planck* likelihoods released through the Planck Legacy Archive (PLA).[133] Nevertheless, Sect. 27.5 presents a comprehensive survey of the consistency of the *Planck* base-ΛCDM cosmology with different types of astrophysical data, including Type 1a supernovae, redshift-space distortions, galaxy shear surveys, and galaxy cluster counts. These data sets are consistent with the *Planck* base-ΛCDM cosmology with, at worst, moderate tensions at about the $2.5\,\sigma$ level. Distance-ladder measurements of the Hubble constant, H_0, are an exception, however. The latest measurement from Riess et al. [306] is discrepant with the *Planck* base-ΛCDM value for H_0 at about the $4.4\,\sigma$ level. This large discrepancy, and its possible implications for cosmology, is discussed in Sect. 27.5.4.

Section 27.6 investigates the internal consistency of the *Planck* base-ΛCDM parameters, presenting additional tests using the TE and EE spectra, as well as a discussion of systematic uncertainties. Results from our main grid of parameter constraints on one- or two-parameter extensions to the base-ΛCDM cosmology are presented in Sect. **??**. That section also includes discussions of more complex models of dark energy and modified gravity [updating the results presented in 285], primordial nucleosynthesis, reionization, recombination, and dark matter annihilation. Section 28.11 summarizes our main conclusions.

27.2 Methodology and likelihoods

27.2.1 Theoretical model

The definitions, methodology, and notation used in this paper largely follow those adopted in the earlier Planck Collaboration papers dealing with cosmological parameters (PCP13, PCP15). Our baseline assumption is the ΛCDM model with purely adiabatic scalar primordial perturbations with a power-law spectrum. We assume three neutrinos species, approximated as two massless states and a single massive neutrino of mass $m_\nu = 0.06\,\mathrm{eV}$. We put flat priors on the baryon density $\omega_\mathrm{b} \equiv \Omega_\mathrm{b}h^2$, cold dark matter density $\omega_\mathrm{c} \equiv \Omega_\mathrm{c}h^2$, an approximation to the observed angular size of the sound horizon at recombination θ_MC, the reionization optical depth τ, the initial super-horizon amplitude of curvature perturbations A_s at $k = 0.05\,\mathrm{Mpc}^{-1}$, and the primordial spectral index n_s. Other parameter definitions, prior limits, and notation are described explicitly in table 1 of PCP13; the only change is that we now take the amplitude prior to be flat in $\log A_\mathrm{s}$ over the range $1.61 < \log(10^{10}A_\mathrm{s}) < 3.91$ (which makes no difference to *Planck* results, but is consistent with the range used for some external data analyses).

Changes in our physical modelling compared with PCP15 are as follows.

- For modelling the small-scale nonlinear matter power spectrum, and calculating the effects of CMB lensing, we use the `halofit` technique [344] as before, but now replace the Takahashi et al. [354] approach with `HMcode`, the fitting method of Mead et al. [237, 236], as implemented in `camb` [221].

- For each model in which the fraction of baryonic mass in helium Y_P is *not* varied independently of other parameters, the value is now set using an updated big-bang nucleosynthesis (BBN) prediction by interpolation on a grid of values calculated using version 1.1 of the `PArthENoPE` BBN code [271, version 2.0 gives identical results]. We now use a fixed fiducial neutron decay-constant value of $\tau_\mathrm{n} = 880.2\,\mathrm{s}$, neglecting uncertainties. Predictions from `PArthENoPE` for the helium mass fraction ($Y_\mathrm{P} \approx 0.2454$, nucleon fraction $Y_\mathrm{P}^\mathrm{BBN} \approx 0.2467$ from *Planck* in ΛCDM) are lower than those from the code of Pitrou et al. [272] for the same value of τ_n by $\Delta Y_\mathrm{P} \approx 0.0005$; however, other parameter results would be consistent to well within 0.1σ. See Sect. **??** for further discussion of BBN parameter uncertainties and code variations.

[133] https://pla.esac.esa.int

Building upon many years of theoretical effort, the computation of CMB power spectra and the related likelihood functions has now become highly efficient and robust. Our main results are based upon the lensed CMB power spectra computed with the August 2017 version of the `camb`[134] Boltzmann code [221] and parameter constraints are based on the July 2018 version of `CosmoMC`[135] [219, 218]. We have checked that there is very good consistency between these results and equivalent results computed using the `class` Boltzmann code [56] and `MontePython` sampler [30, 64]. Marginalized densities, limits, and contour plots are generated using updated adaptive kernel density estimates (with corrections for boundary and smoothing biases) as calculated using the `getdist` package[136] (also part of `CosmoMC`), which improves average accuracy for a given number of posterior samples compared to the version used in our previous analyses.

A few new derived parameters have been added to the output of the `CosmoMC` chains to allow comparisons and combinations with external data sets. A full description of all parameters is provided in the tables presented in the Explanatory Supplement [274], and parameter chains are available on the PLA.

27.2.2 Power spectra and likelihoods

Since the 2015 *Planck* data release, most of the effort on the low-level data processing has been directed to improving the fidelity of the polarization data at low multipoles. The first results from this effort were reported in Planck Collaboration Int. XLVI [297] and led to a new determination of the reionization optical depth, τ. The main results presented in this paper are based on the 2018 HFI maps produced with the `SRoll` mapmaking algorithm described in detail in [291], supplemented with LFI data described in Planck Collaboration II [290].

Because *Planck*-HFI measures polarization by differencing the signals measured by polarization-sensitive bolometers (PSBs), a number of instrumental effects need to be controlled to achieve high precision in the absolute calibrations of each detector. These include: effective gain variations arising from nonlinearities in the analogue-to-digital electronics and thermal fluctuations; far-field beam characterization, including long bolometer time constants; and differences in detector bandpasses. The `SRoll` mapmaking solution for the 100–353 GHz channels minimizes map residuals between all HFI detectors at a given frequency, using absolute calibrations based on the orbital dipole, together with a bandpass-mismatch model constructed from spatial templates of the foregrounds and a parametric model characterizing the remaining systematics. We refer the reader to Planck Collaboration III [291] for details of the implementation of `SRoll`. The fidelity of the `SRoll` maps can be assessed using various null tests (e.g., splitting the data by half-mission, odd-even surveys, and different detector combinations) and by the consistency of the recovered Solar dipole solution. These tests are described in [291] and demonstrate that the Solar dipole calibration is accurate to about one part in 10^4 for the three lowest-frequency HFI channels. Large-scale intensity-to-polarization leakage, caused by calibration mismatch in the `SRoll` maps, is then reduced to levels $\lesssim 10^{-6}\mu\mathrm{K}^2$ at $\ell > 3$.

The low-multipole polarization likelihood used in this paper is based on the `SRoll` polarization maps and series of end-to-end simulations that are used to characterize the noise properties and remaining biases in the `SRoll` maps. This low-multipole likelihood is summarized in Sect. 27.2.2 and is described in more detail in Planck Collaboration V [293].

As in previous *Planck* papers, the baseline likelihood is a hybrid, patching together a low-multipole likelihood at $\ell < 30$ with a Gaussian likelihood constructed from pseudo-cross-spectrum estimates at higher multipoles. Correlations between the low and high multipoles are neglected. In this paper, we have used two independent high-multipole TT,TE,EE likelihoods.[137] The `Plik` likelihood, which is adopted as the baseline in this paper, is described in Sect. 27.2.2, while the `CamSpec` likelihood is described in Sect. 27.2.2 and Appendix **??**. These two likelihoods are in very good agreement in TT, but show small differences in TE and EE, as described below and in the main body of this paper. Section 27.2.3 summarizes the *Planck* CMB lensing likelihood, which is described in greater detail in Planck Collaboration VIII [294].

Before summarizing the high-multipole likelihoods, we make a few remarks concerning the 2018 `SRoll` maps. The main aim of the `SRoll` processing is to reduce the impact of systematics

[134] https://camb.info

[135] https://cosmologist.info/cosmomc/

[136] https://getdist.readthedocs.io/

[137] We use roman letters, such as TT,TE,EE, to refer to particular likelihood combinations, but use italics, such as TT, when discussing power spectra more generally.

at low multipoles and hence the main differences between the 2015 and 2018 HFI maps are at low multipoles. Compared to the 2015 HFI maps, the `SRoll` maps eliminate the last 1000 HFI scanning rings (about 22 days of observations) because these were less thermally stable than the rest of the mission. `SRoll` uses higher resolution maps to determine the destriping offsets compared to the 2015 maps, leading to a reduction of about 12 % in the noise levels at 143 GHz [see figure 10 of 291]. A tighter requirement on the reconstruction of Q and U values at each pixel leads to more missing pixels in the 2018 maps compared to 2015. These and other changes to the 2018 *Planck* maps have very little impact on the temperature and polarization spectra at high multipoles (as will be demonstrated explicitly in Fig. 175 below).

There are, however, data-processing effects that need to be accounted for to create an unbiased temperature+polarization likelihood at high multipoles from the `SRoll` maps. In simplified form, the power absorbed by a detector at time t on the sky is

$$P(t) = G\,\{I + \rho\,[Q\cos 2(\psi(t) + \psi_0) + U\sin 2(\psi(t) + \psi_0)]\} + n(t), \tag{1195}$$

where I, Q, and U are the beam-convolved Stokes parameters seen by the detector at time t, G is the effective gain (setting the absolute calibration), ρ is the detector polarization efficiency, $\psi(t)$ is the roll angle of the satellite, ψ_0 is the detector polarization angle, and $n(t)$ is the noise. For a perfect polarization-sensitive detector, $\rho = 1$, while for a perfect unpolarized detector, $\rho = 0$. The polarization efficiencies and polarization angles for the HFI bolometers were measured on the ground and are reported in [315]. For polarization-sensitive detectors the ground-based measurements of polarization angles were measured to an accuracy of approximately 1° and the polarization efficiencies to a quoted accuracy of 0.1–0.3 %. The `SRoll` mapmaking algorithm assumes the ground-based measurements of polarization angles and efficiencies, which cannot be separated because they are degenerate with each other. Errors in the polarization angles induce leakage from E to B modes, while errors in the polarization efficiencies lead to gain mismatch between I, Q and U. Analysis of the *Planck* TB and EB spectra (which should be zero in the absence of parity-violating physics) reported in Planck Collaboration III [291], suggest errors in the polarization angles of $\lesssim 0.5°$, within the error estimates reported in [315]. However, systematic errors in the polarization efficiencies are found to be several times larger than the [315] determinations (which were limited to characterizations of the feed and detector sub-assemblies and did not characterize the system in combination with the telescope) leading to effective calibration offsets in the polarization spectra. These polarization efficiency differences, which are detector- and hence frequency-dependent, need to be calibrated to construct a high-multipole likelihood. To give some representative numbers, the Rosset et al. [315] ground-based measurements estimated polarization efficiencies for the PSBs, with typical values of 92–96 % at 100 GHz, 83–93 % at 143 GHz, and 94–95 % at 217 GHz (the three frequencies used to construct the high-multipole polarization likelihoods). From the `SRoll` maps, we find evidence of systematic errors in the polarization efficiencies of order 0.5–1 % at 100 and 217 GHz and up to 1.5 % at 143 GHz. Differences between the main beams of the PSBs introduce temperature-to-polarization leakage at high multipoles. We use the `QuickPol` estimates of the temperature-polarization beam transfer function matrices, as described in Hivon et al. [177], to correct for temperature-to-polarization leakage. Inaccuracies in the corrections for effective polarization efficiencies and temperature-to-polarization leakage are the main contributors to systematic errors in the *Planck* polarization spectra at high multipoles.

In principle, B-mode polarization spectra contain information about lensing and primordial tensor modes. However, for *Planck*, B-mode polarization spectra are strongly noise dominated on all angular scales. Given the very limited information contained in the *Planck* B-mode spectra (and the increased complexity involved) we do not include B-mode power spectra in the likelihoods; however, for an estimate of the lensing B-mode power spectrum see Planck Collaboration VIII 294, hereafter PL2018.

The baseline `Plik` likelihood

The `Plik` high-multipole likelihood [described in detail in 293, hereafter PPL18] is a Gaussian approximation to the probability distributions of the TT, EE, and TE angular power spectra, with semi-analytic covariance matrices calculated assuming a fiducial cosmology. It includes multipoles in the range $30 \leq \ell \leq 2508$ for TT and $30 \leq \ell \leq 1996$ for TE and EE, and is constructed from half-mission cross-spectra measured from the 100-, 143-, and 217-GHz HFI frequency maps.

The TT likelihood uses four half-mission cross-spectra, with different multipole cuts to avoid multipole regions where noise dominates due to the limited resolution of the beams and to ensure foreground contamination is correctly handled by our foreground model: 100×100 ($\ell = 30$–1197); 143×143 ($\ell = 30$–1996); 143×217 ($\ell = 30$–2508); and 217×217 ($\ell = 30$–2508). The TE and EE likelihoods also include the 100×143 and 100×217 cross-spectra to improve the signal-to-noise ratio, and have different multipole cuts: 100×100 ($\ell = 30$–999); 100×143 ($\ell = 30$–999); 100×217 ($\ell = 505$–999); 143×143 ($\ell = 30$–1996); 143×217 ($\ell = 505$–1996); and 217×217 ($\ell = 505$–1996). The 100-, 143-, and 217-GHz intensity maps are masked to reduce Galactic dust, CO, extended sources, and point-source contamination (a different point-source mask is used at each frequency), as well as badly-conditioned/missing pixels, effectively retaining 66, 57, and 47 % of the sky after apodization, respectively (see equation 10 in PCP15 for a definition of the effective sky fraction). The apodization is applied to reduce the mask-induced correlations between modes, and reduces the effective sky fraction by about 10 % compared to the unapodized masks. The 100-, 143-, and 217-GHz maps in polarization are masked only for Galactic contamination and badly-conditioned or missing pixels, effectively retaining 70, 50, and 41 % of the sky after apodization, respectively.

The baseline likelihood uses the different frequency power spectra without coadding them, modelling the foreground and instrumental effects with nuisance parameters that are marginalized over at the parameter estimation level, both in temperature and in polarization. To reduce the size of the covariance matrix and data vector, the baseline `Plik` likelihood uses binned band powers, which give an excellent approximation to the unbinned likelihood for smooth theoretical power spectra. Unbinned versions of the likelihoods are also available and provide almost identical results to the binned spectra for all of the theoretical models considered in our main parameter grid (Sect. **??**).

The major changes with respect to the 2015 `Plik` likelihood are the following.

- *Beams.* In 2015, the effective beam window functions were calculated assuming the same average sky fraction at all frequencies. In this new release, we apply beam window functions calculated for the specific sky fraction retained at each frequency. The impact on the spectra is small, at the level of approximately 0.1 % at $\ell = 2000$.
- *Dust modelling in TT.* The use of intensity-thresholded point-source masks modifies the power spectrum of the Galactic dust emission, since such masks include point-like bright Galactic dust regions. Because these point-source masks are frequency dependent, a different dust template is constructed from the 545-GHz maps for each power spectrum used in the likelihood. This differs from the approach adopted in 2015, which used a Galactic dust template with the same shape at all frequencies. As in 2015, the Galactic dust amplitudes are then left free to vary, with priors determined from cross-correlating the frequency maps used in the likelihood with the 545-GHz maps. These changes produce small correlated shifts in the dust, cosmic infrared background (CIB), and point-source amplitudes, but have negligible impact on cosmological parameters.
- *Dust modelling in TE and EE.* Dust amplitudes in TE are varied with Gaussian priors as in 2015, while in EE we fix the dust amplitudes to the values obtained using the cross-correlations with 353-GHz maps, for the reasons detailed in PPL18. The choice of fixing the dust amplitudes in EE has a small impact (of the order of $0.2\,\sigma$) on the base-ΛCDM results when combining into the full "TT,TE,EE," `Plik` likelihood because EE has lower statistical power compared to TT or TE; however, dust modelling in EE has a greater effect when parameters are estimated from EE alone (e.g., fixing the dust amplitude in EE lowers $n_{\rm s}$ by $0.8\,\sigma$, compared to allowing the dust amplitude to vary.)
- *Correction of systematic effects in the polarization spectra.* In the 2015 *Planck* analysis, small differences in the inter-frequency comparisons of TE and EE foreground-corrected polarization power spectra were identified and attributed to systematics such as temperature-to-polarization leakage and polarization efficiencies, which had not been characterized adequately at the time. For the 2018 analysis we have applied the following corrections to the `Plik` spectra.

  - *Beam-leakage correction.* The TE and EE pseudo-spectra are corrected for temperature-to-polarization leakage caused by beam mismatch, using polarized beam matrices computed with the `QuickPol` code described in Hivon et al. [177]. The beam-leakage correction template is calculated using fiducial theoretical spectra computed from the best-fit ΛCDM cosmology fitted to the TT data, together with `QuickPol` estimates of the HFI polarized beam transfer-function matrices. This template is then included in our data model. The correction for beam leakage has a larger impact on TE than on EE. For base-ΛCDM cosmology, correcting for the leakage induces shifts of $\lesssim 1\,\sigma$ when constraining parameters

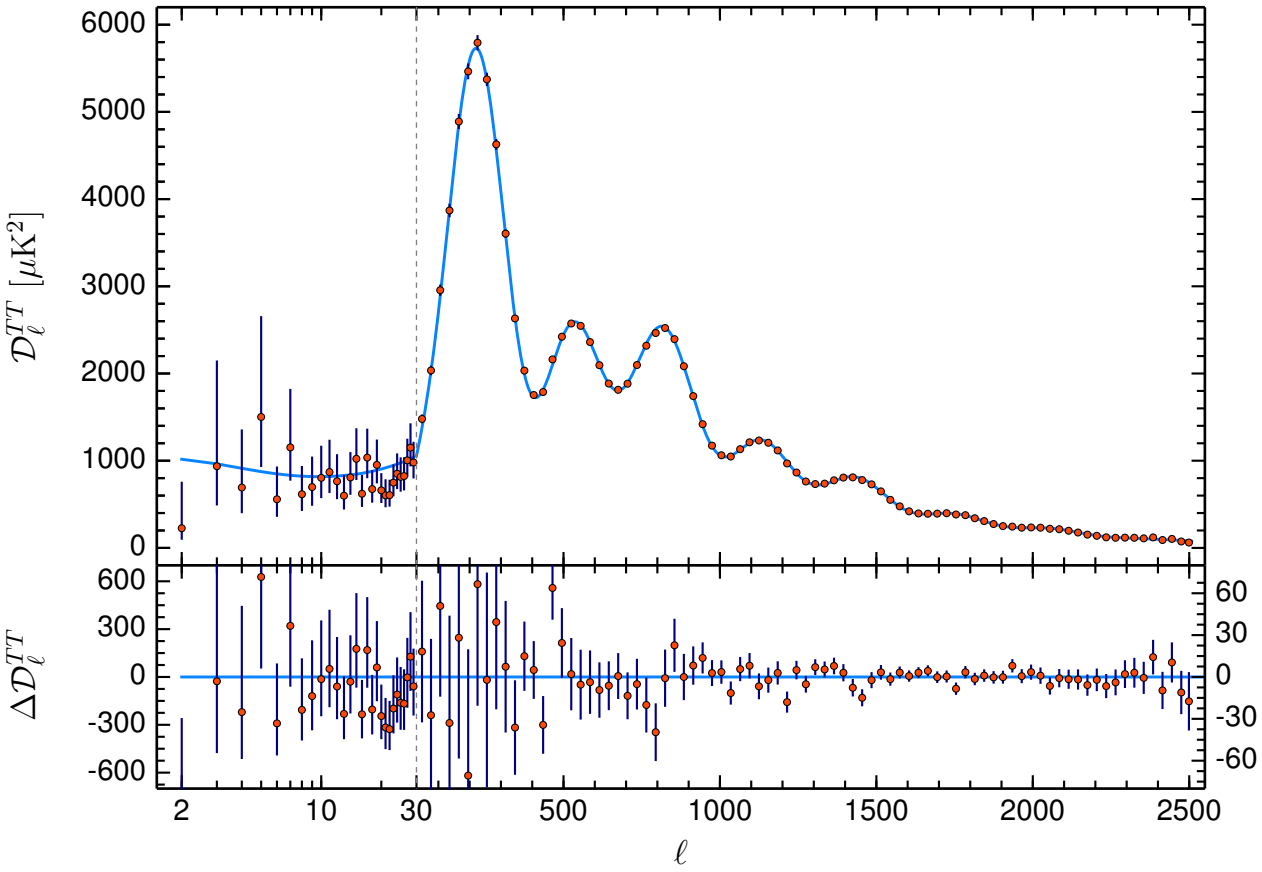

Figure 167: *Planck* 2018 temperature power spectrum. At multipoles $\ell \geq 30$ we show the frequency-coadded temperature spectrum computed from the `Plik` cross-half-mission likelihood, with foreground and other nuisance parameters fixed to a best fit assuming the base-ΛCDM cosmology. In the multipole range $2 \leq \ell \leq 29$, we plot the power spectrum estimates from the `Commander` component-separation algorithm, computed over 86 % of the sky. The base-ΛCDM theoretical spectrum best fit to the *Planck* TT,TE,EE+lowE+lensing likelihoods is plotted in light blue in the upper panel. Residuals with respect to this model are shown in the lower panel. The error bars show $\pm 1\,\sigma$ diagonal uncertainties, including cosmic variance (approximated as Gaussian) and not including uncertainties in the foreground model at $\ell \geq 30$. Note that the vertical scale changes at $\ell = 30$, where the horizontal axis switches from logarithmic to linear.

with TT,TE,EE, namely $+1.1\,\sigma$ for ω_b, $-0.7\,\sigma$ for ω_c, $+0.7\,\sigma$ for θ_MC, and $+0.5\,\sigma$ for n_s, with smaller changes for other parameters.

- *Effective polarization efficiencies.* We estimate the effective polarization efficiencies of the `SRoll` maps by comparing the frequency polarization power spectra to fiducial spectra computed from the best-fit base-ΛCDM model determined from the temperature data. The details and limitations of this procedure are described in PPL18 and briefly summarized further below. Applying these polarization efficiency estimates, we find relatively small shifts to the base-ΛCDM parameters determined from the TT,TE,EE likelihood, with the largest shifts in ω_b ($+0.4\,\sigma$), ω_c ($+0.2\,\sigma$), and n_s ($+0.2\,\sigma$). The parameter shifts are small because the polarization efficiencies at different frequencies partially average out in the coadded TE spectra (see also Fig. 175, discussed in Sect. 27.3).
- *Correlated noise in auto-frequency cross-spectra and subpixel effects.* The likelihood is built using half-mission cross-spectra to avoid noise biases from auto-spectra. However,

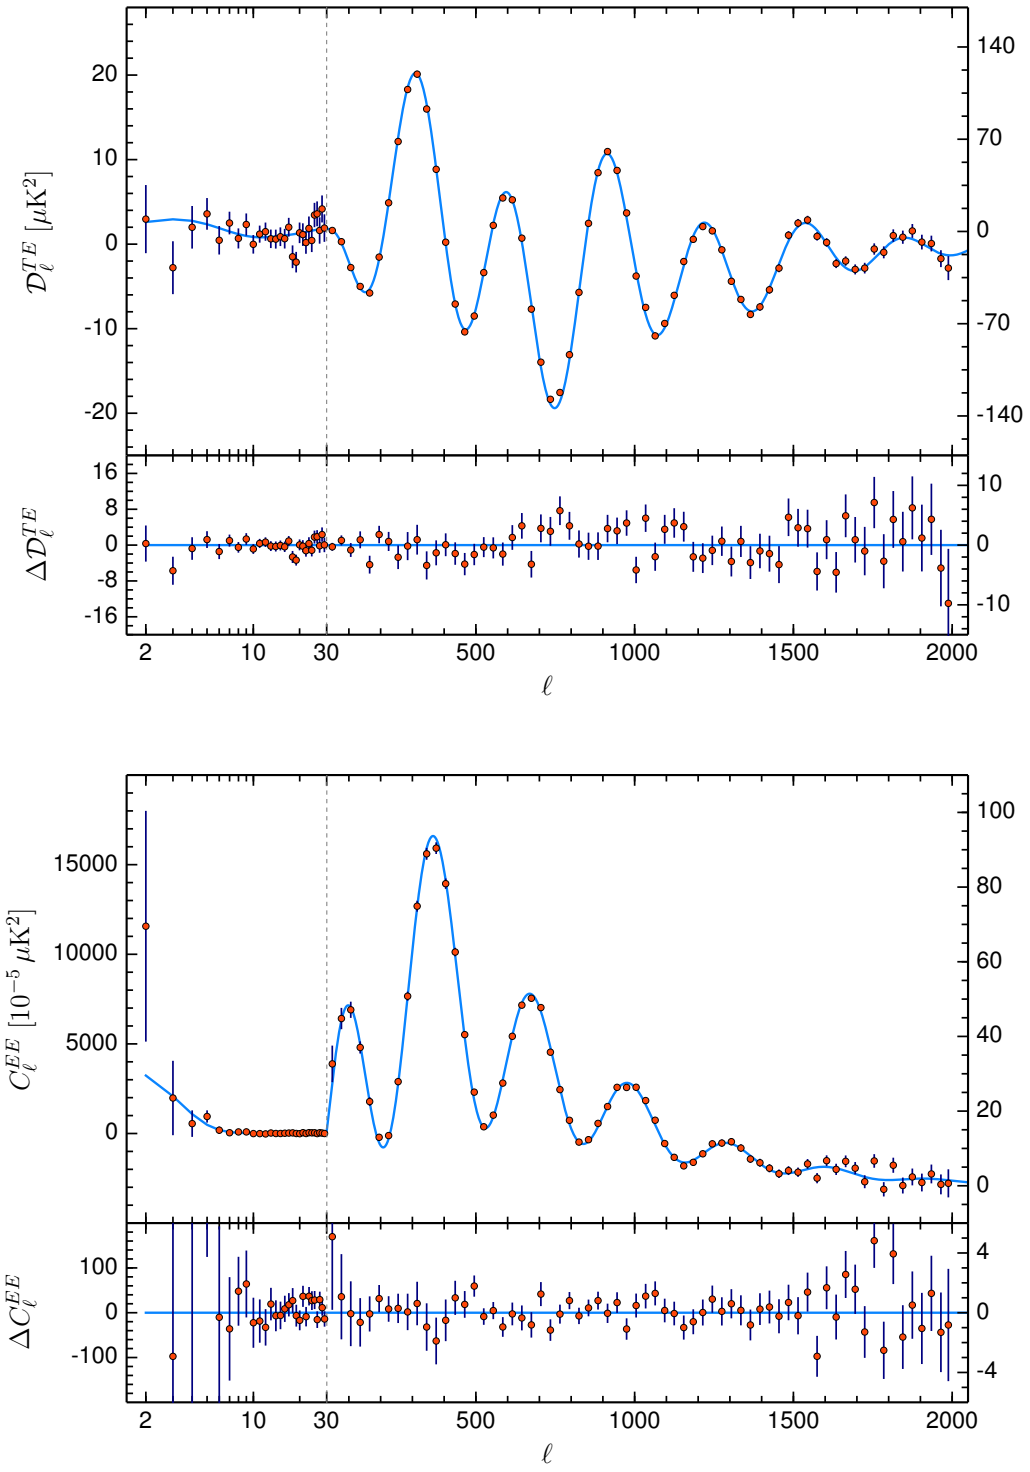

Figure 168: *Planck* 2018 TE (top) and EE (bottom) power spectra. At multipoles $\ell \geq 30$ we show the coadded frequency spectra computed from the `Plik` cross-half-mission likelihood with foreground and other nuisance parameters fixed to a best fit assuming the base-ΛCDM cosmology. In the multipole range $2 \leq \ell \leq 29$, we plot the power spectra estimates from the `SimAll` likelihood (though only the EE spectrum is used in the baseline parameter analysis at $\ell \leq 29$). The best-fit base-ΛCDM theoretical spectrum fit to the *Planck* TT,TE,EE+lowE +lensing likelihood is plotted in light blue in the upper panels. Residuals with respect to this model are shown in the lower panels. The error bars show Gaussian $\pm 1\sigma$ diagonal uncertainties including cosmic variance. Note that the vertical scale changes at $\ell = 30$, where the horizontal axis switches from logarithmic to linear.

small residual correlated noise contributions may still be present. The pixelization of the maps introduces an additional noise term because the centroid of the "hits" distribution of the detector samples in each pixel does not necessarily lie at the pixel centre. The impact of correlated noise is evaluated using the end-to-end simulations described in Planck Collaboration III [291], while the impact of subpixel effects is estimated with analytic calculations. Both effects are included in the `Plik` data model, but have negligible impact on cosmological parameters.

Of the systematic effects listed above, correction for the polarization efficiencies has the largest uncertainty. We model these factors as effective polarization calibration parameters c_ν^{EE}, defined at the power spectrum level for a frequency spectrum $\nu \times \nu$.[138] To correct for errors in polarization efficiencies and large-scale beam-transfer function errors, we recalibrate the TE and EE spectra against a fiducial theoretical model to minimize

$$\chi^2 = (C^{\rm D} - {\rm G}C^{\rm Th}){\rm M}^{-1}(C^{\rm D} - {\rm G}C^{\rm Th}), \tag{1196a}$$

with respect to the c_ν^{EE} parameters contained in the diagonal calibration matrix G with elements

$${\rm G}_{i,i} = \left(\frac{1}{\sqrt{c_\nu^{XX}c_{\nu'}^{YY}}} + \frac{1}{\sqrt{c_{\nu'}^{XX}c_\nu^{YY}}}\right)_{i,i}, \tag{1196b}$$

where the index $i = 1, N$ runs over the multipoles ℓ and frequencies $\nu \times \nu'$ of the spectra contained in the $C^{\rm D}$ data vector of dimension N; $C^{\rm D}$ contains the C_ℓ frequency spectra either for $XY = TE$ or $XY = EE$, fit separately. In Eq. (1196a), M is the covariance matrix for the appropriate spectra included in the fit, while the c_ν^{TT} temperature calibration parameters are fixed. We perform the fit only using multipoles $\ell = 200$–1000 to minimize the impact of inaccuracies in the foreground modelling or noise, and we test the stability of the results by fitting either one frequency spectrum or all the frequency spectra at the same time. The recalibration is computed with respect to a fiducial model vector $C^{\rm Th}$ because the *Planck* polarization spectra are noisy and it is not possible to inter-calibrate the spectra to a precision of better than 1 % without invoking a reference model. The fiducial theoretical spectra $C_\ell^{\rm Th}$ contained in $C^{\rm Th}$ are derived from the best-fit temperature data alone, assuming the base-ΛCDM model, adding the beam-leakage model and fixing the Galactic dust amplitudes to the central values of the priors obtained from using the 353-GHz maps. This is clearly a model-dependent procedure, but given that we fit over a restricted range of multipoles, where the TT spectra are measured to cosmic variance, the resulting polarization calibrations are insensitive to small changes in the underlying cosmological model.

In principle, the polarization efficiencies found by fitting the TE spectra should be consistent with those obtained from EE. However, the polarization efficiency at 143×143, c_{143}^{EE}, derived from the EE spectrum is about $2\,\sigma$ lower than that derived from TE (where the σ is the uncertainty of the TE estimate, of the order of 0.02). This difference may be a statistical fluctuation or it could be a sign of residual systematics that project onto calibration parameters differently in EE and TE. We have investigated ways of correcting for effective polarization efficiencies: adopting the estimates from EE (which are about a factor of 2 more precise than TE) for both the TE and EE spectra (we call this the "map-based" approach); or applying independent estimates from TE and EE (the "spectrum-based" approach). In the baseline `Plik` likelihood we use the map-based approach, with the polarization efficiencies fixed to the efficiencies obtained from the fits on EE: $\left(c_{100}^{EE}\right)_{\rm EE\,fit} = 1.021$; $\left(c_{143}^{EE}\right)_{\rm EE\,fit} = 0.966$; and $\left(c_{217}^{EE}\right)_{\rm EE\,fit} = 1.040$. The `CamSpec` likelihood, described in the next section, uses spectrum-based effective polarization efficiency corrections, leaving an overall temperature-to-polarization calibration free to vary within a specified prior.

The use of spectrum-based polarization efficiency estimates (which essentially differs by applying to EE the efficiencies given above, and to TE the efficiencies obtained fitting the TE spectra, $\left(c_{100}^{EE}\right)_{\rm TE\,fit} = 1.04$, $\left(c_{143}^{EE}\right)_{\rm TE\,fit} = 1.0$, and $\left(c_{217}^{EE}\right)_{\rm TE\,fit} = 1.02$), also has a small, but non-negligible impact on cosmological parameters. For example, for the ΛCDM model, fitting the `Plik` TT,TE,EE+lowE likelihood, using spectrum-based polarization efficiencies,

[138] Thus, the polarization efficiency for a cross-frequency spectrum $\nu \times \nu'$ in, e.g., EE is $\sqrt{c_\nu^{EE} \times c_{\nu'}^{EE}}$.

we find small shifts in the base-ΛCDM parameters compared with ignoring spectrum-based polarization efficiency corrections entirely; the largest of these shifts are $+0.5\,\sigma$ in ω_b, $+0.1\,\sigma$ in ω_c, and $+0.3\,\sigma$ in n_s (to be compared to $+0.4\,\sigma$ in ω_b, $+0.2\,\sigma$ in ω_c, and $+0.2\,\sigma$ in n_s for the map-based case). Furthermore, if we introduce the phenomenological A_L parameter (discussed in much greater detail in Sect. 27.6.2), using the baseline TT,TE,EE+lowE likelihood gives $A_L = 1.180 \pm 0.065$, differing from unity by 2.7σ (the value of A_L is unchanged with respect to the case where we ignore polar efficiencies entirely, 1.180 ± 0.065). Switching to spectrum-based polarization efficiency corrections changes this estimate to $A_L = 1.142 \pm 0.066$ differing from unity by 2.1σ. Readers of this paper should therefore not over-interpret the *Planck* polarization results and should be aware of the sensitivity of these results to small changes in the specific choices and assumptions made in constructing the polarization likelihoods, which are not accounted for in the likelihood error model. To emphasize this point, we also give results from the `CamSpec` likelihood (see, e.g., Table 24), described in the next section, which has been constructed independently of `Plik`. We also note that if we apply the `CamSpec` polarization masks and spectrum-based polarization efficiencies in the `Plik` likelihood, then the cosmological parameters from the two likelihoods are in close agreement.

The coadded 2018 `Plik` temperature and polarization power spectra and residuals with respect to the base-ΛCDM model are shown in Figs. 167 and 168.

The `CamSpec` likelihood

The `CamSpec` temperature likelihood was used as the baseline for the first analysis of cosmological parameters from *Planck*, reported in PCP13, and was described in PPL13. A detailed description of `CamSpec` and its generalization to polarization is given in [117]. For PCP15, the `CamSpec` temperature likelihood was unaltered from that adopted in PPL13, except that we used half-mission cross-spectra instead of detector-set cross-spectra and made minor modifications to the foreground model. For this set of papers, the `CamSpec` temperature analysis uses identical input maps and masks as `Plik` and is unaltered from PCP15, except for the following details.

- In previous versions we used half-ring difference maps (constructed from the first and second halves of the scanning rings within each pointing period) to estimate noise. In this release we have used differences between maps constructed from odd and even rings. The use of odd-even differences makes almost no difference to the temperature analysis, since the temperature spectra that enter the likelihood are signal dominated over most of the multipole range. However, the odd-even noise estimates give higher noise levels than half-ring difference estimates at multipoles $\lesssim 500$ (in qualitative agreement with end-to-end simulations), and this improves the χ^2 of the polarization spectra. This differs from the `Plik` likelihood, which uses the half-ring difference maps to estimate the noise levels, together with a correction to compensate for correlated noise, as described in PPL18.
- In PCP15, we used power-spectrum templates for the CIB from the halo models described in [281]. The overall amplitude of the CIB power spectrum at 217 GHz was allowed to vary as one of the "nuisance" parameters in the likelihood, but the relative amplitudes at 143×217 and 143×143 were fixed to the values given by the model. In the 2018 analysis, we retain the template shapes from [281], but allow free amplitudes at 217×217, 143×217, and 143×143. The CIB is ignored at 100 GHz. We made these changes to the 2018 `CamSpec` likelihood to reduce any source of systematic bias associated with the specific model of [281], since this model is uncertain at low frequencies and fails to match *Herschel*-SPIRE measurements [361] of the CIB anisotropies at 350 and 500 μm for $\ell \gtrsim 3000$ [228]. This change was implemented to see whether it had any impact on the value of the lensing parameter A_L (see Sect. 27.6.2); however, it has a negligible effect on A_L or on other cosmological parameters. The `Plik` likelihood retains the 2015 model for the CIB.
- In PCP15 we used a single functional form for the Galactic dust power spectrum template, constructed by computing differences of 545×545 power spectra determined using different masks. The dust template was then rescaled to match the dust amplitudes at lower frequencies for the masks used to form the likelihood. In the 2018 `CamSpec` likelihood we use dust templates computed from the 545×545 spectra, using masks with exactly the same point-source holes as those used to compute the 100×100, 143×143, 143×217, and 217×217 power spectra that are used in the likelihood. The `Plik` likelihood adopts a similar approach and the `CamSpec` and `Plik` dust templates are in very good agreement.

In forming the temperature likelihood, we apply multipole cuts to the temperature spectra

as follows: $\ell_{\rm min} = 30$, $\ell_{\rm max} = 1200$ for the 100×100 spectrum; $\ell_{\rm min} = 30$, $\ell_{\rm max} = 2000$ for the 143×143 spectrum; and $\ell_{\rm min} = 500$, $\ell_{\rm max} = 2500$ for 143×217 and 217×217. As discussed in previous papers, the $\ell_{\rm min}$ cuts applied to the 143×217 and 217×217 spectra are imposed to reduce any potential systematic biases arising from Galactic dust at these frequencies. A foreground model is included in computing the covariance matrices, assuming that foregrounds are isotropic and Gaussian. This model underestimates the contribution of Galactic dust to the covariances, since this component is anisotropic on the sky. However, dust always makes a very small contribution to the covariance matrices in the `CamSpec` likelihood. [228] describe a simple model to account for the Galactic dust contributions to covariance matrices.

It is important to emphasize that these changes to the 2018 `CamSpec` TT likelihood are largely cosmetic and have very little impact on cosmological parameters. This can be assessed by comparing the `CamSpec` TT results reported in this paper with those in PCP15. The main changes in cosmological parameters from the TT likelihood come from the tighter constraints on the optical depth, τ, adopted in this paper.

In polarization, `CamSpec` uses a different methodology to `Plik`. In temperature, there are a number of frequency-dependent foregrounds at high multipoles that are described by a physically motivated parametric model containing "nuisance" parameters. These nuisance parameters are sampled, along with cosmological parameters, during Markov chain Monte Carlo (MCMC) exploration of the likelihood. The TT likelihood is therefore a power-spectrum-based component-separation tool and it is essential to retain cross-power spectra for each distinct frequency combination. For the *Planck* TE and EE spectra, however, Galactic dust is by far the dominant foreground contribution. At the multipoles and sensitivities accessible to *Planck*, polarized point sources make a negligible contribution to the foreground [as verified by ACTPol and SPTpol; 226, 169], so the only foreground that needs to be subtracted is polarized Galactic dust emission. As described in PCP15, we subtract polarized dust emission from each TE/ET and EE spectrum using the 353-GHz half-mission maps. This is done in an analogous way to the construction of 545-GHz-cleaned temperature maps described in PCP15 and Appendix **??**. Since the 353-GHz maps are noisy at high multipoles we use the cleaned spectra at multipoles ≤ 300 and extrapolate the dust model to higher multipoles by fitting power laws to the dust estimates at lower multipoles.

The polarization spectra are then corrected for temperature-to-polarization leakage and effective polarization efficiencies as described below, assuming a fiducial theoretical power spectrum. The corrected TE/ET spectra and EE spectra for all half-mission cross-spectra constructed from 100-, 143-, and 217-GHz maps are then coadded to form a single TE spectrum and a single EE spectrum for the `CamSpec` likelihood. The polarization part of the `CamSpec` likelihood therefore contains no nuisance parameters other than overall calibration factors c_{TE} and c_{EE} for the TE and EE spectra. Since the `CamSpec` likelihood uses coadded TE and EE spectra, we do not need to bin the spectra to form a TT,TE,EE likelihood. The polarization masks used in `CamSpec` are based on 353–143 GHz polarization maps that are degraded in resolution and thresholded on $P = (Q^2 + U^2)^{1/2}$. The default `CamSpec` polarization mask used for the 2018 analysis preserves a fraction $f_{\rm sky} = 57.7\,\%$ and is apodized to give an effective sky fraction (see equation 10 of PCP15) of $f^{\rm W}_{\rm sky} = 47.7\,\%$. We use the same polarization mask for all frequencies. The `CamSpec` polarization masks differ from those used in the `Plik` likelihood, which uses intensity-thresholded masks in polarization (and therefore a larger effective sky area in polarization, as described in the previous section).

To construct covariance matrices, temperature-to-polarization leakage corrections, and effective polarization efficiencies, we need to adopt a fiducial model. For the 2018 analysis, we adopted the best-fit `CamSpec` base-ΛCDM model from PCP15 to construct a likelihood from the 2018 temperature maps. We then ran a minimizer on the TT likelihood, imposing a prior of $\tau = 0.05 \pm 0.02$, and the best-fit base-ΛCDM cosmology was adopted as our fiducial model. To deal with temperature-to-polarization leakage, we used the `QuickPol` polarized beam matrices to compute corrections to the TE and EE spectra assuming the fiducial model. The temperature-to-polarization leakage corrections are relatively small for TE spectra (although they have some impact on cosmological parameters, consistent with the behaviour of the `Plik` likelihood described in the previous section), but are negligible for EE spectra.

To correct for effective polarization efficiencies (including large-scale transfer functions arising from errors in the polarized beams) we recalibrated each TE, ET, and EE spectrum against

the fiducial model spectra by minimizing

$$\chi^2 = \sum_{\ell_1\ell_2} (C^{\rm D}_{\ell_1} - \alpha_{\rm P} C^{\rm Th}_{\ell_1}) {\rm M}^{-1}_{\ell_1\ell_2} (C^{\rm D}_{\ell_2} - \alpha_{\rm P} C^{\rm Th}_{\ell_2}), \tag{1197}$$

with respect to $\alpha_{\rm P}$, where $C^{\rm D}_\ell$ is the beam-corrected data spectrum (TE, ET, or EE) corrected for temperature-to-polarization leakage, M is the covariance matrix for the appropriate spectrum, and the sums extend over $200 \leq \ell \leq 1000$. We calibrate each TE and EE spectrum individually, rather than computing map-based polarization calibrations. Although there is a good correspondence between spectrum-based calibrations and map-based calibrations, we find evidence for some differences, particularly for the 143×143 EE spectrum in agreement with the `Plik` analysis. Unlike `Plik`, we adopt spectrum-based calibrations of polarization efficiencies in preference to map-based calibrations.

As in temperature, we apply multipole cuts to the polarization spectra prior to coaddition in order to reduce sensitivity to dust subtraction, beam estimation, and noise modelling. For TE/ET spectra we use: $\ell_{\rm min} = 30$ and $\ell_{\rm max} = 1200$ for the 100×100, 100×143 and 100×217 spectra; $\ell_{\rm min} = 30$ and $\ell_{\rm max} = 2000$ for 143×143 and 143×217; and $\ell_{\rm min} = 500$ and $\ell_{\rm max} = 2500$ for the 217×217 cross-spectrum. For EE, we use: $\ell_{\rm min} = 30$ and $\ell_{\rm max} = 1000$ for 100×100; $\ell_{\rm min} = 30$ and $\ell_{\rm max} = 1200$ for 100×143; $\ell_{\rm min} = 200$ and $\ell_{\rm max} = 1200$ for 100×217; $\ell_{\rm min} = 30$ and $\ell_{\rm max} = 1500$ for 143×143; $\ell_{\rm min} = 300$ and $\ell_{\rm max} = 2000$ for 143×217; and $\ell_{\rm min} = 500$ and $\ell_{\rm max} = 2000$ for 217×217. Since dust is subtracted from the polarization spectra, we do not include a dust model in the polarization covariance matrices. Note that at low multipoles, $\ell \lesssim 300$, Galactic dust dominates over the CMB signal in EE at all frequencies. We experimented with different polarization masks and different multipole cuts and found stable results from the `CamSpec` polarization likelihood.

To summarize, for the TT data `Plik` and `CamSpec` use very similar methodologies and a similar foreground model, and the power spectra used in the likelihoods only differ in the handling of missing pixels. As a result, there is close agreement between the two temperature likelihoods. In polarization, different polarization masks are applied and different methods are used for correcting Galactic dust, effective polarization calibrations, and temperature-to-polarization leakage. In addition, the polarization covariance matrices differ at low multipoles. As described in Appendix **??**, the two codes give similar results in polarization for base ΛCDM and most of the extensions of ΛCDM considered in this paper, and there would be no material change to most of the science conclusions in this paper were one to use the `CamSpec` likelihood in place of `Plik`. However, in cases where there are differences that could have an impact on the scientific interpretation (e.g., for $A_{\rm L}$, $\sum m_\nu$, and Ω_K) we show results from both codes. This should give the reader an impression of the sensitivity of the science results to different methodologies and choices made in constructing the polarization blocks of the high-multipole likelihoods.

The low-ℓ likelihood

The HFI low-ℓ polarization likelihood is based on the full-mission HFI 100-GHz and 143-GHz Stokes Q and U low-resolution maps, cleaned through a template-fitting procedure using LFI 30-GHz [290] and HFI 353-GHz maps,[139] which are used as tracers of polarized synchrotron and thermal dust, respectively (for details about the cleaning procedure see PPL18). Power spectra are calculated based on a quadratic maximum-likelihood estimation of the cross-spectrum between the 100- and 143-GHz data, and the multipole range used spans $\ell = 2$ to $\ell = 29$.

We only use the EE likelihood ("lowE") for the main parameter results in this paper. The likelihood code, called `SimAll`, is based on the power spectra. It is constructed using an extension of the `SimBaL` algorithm presented in Planck Collaboration Int. XLVI [297], using 300 end-to-end simulations characterizing the HFI noise and residual systematics [see 291, for details] to build an empirical probability distribution of the EE spectra (ignoring the off-diagonal correlations). The TE spectrum at low multipoles does not provide tight constraints compared to EE because of cosmic variance. However, PPL18 discusses the TE spectra at low multipoles constructed by cross-correlating the `Commander` component-separated map with the

[139] The polarized synchrotron component is fitted only at 100 GHz, being negligible at 143 GHz. For the polarized dust component, following the prescription contained in Planck Collaboration III [291], the low-ℓ HFI polarization likelihood uses the 353-GHz polarization-sensitive-bolometer-only map.

100- and 143-GHz maps. The TE spectra show excess variance compared to simulations at low multipoles, most notably at $\ell = 5$ and at $\ell = 18$ and 19, for reasons that are not understood. No attempt has been made to fold in `Commander` component-separation errors in the statistical analysis. We have therefore excluded the TE spectrum at low multipoles (with the added benefit of simplifying the construction of the `SimAll` likelihood). Little information is lost by discarding the TE spectrum. Evidently, further work is required to understand the behaviour of TE at low multipoles; however, as discussed in PPL18, the τ constraint derived from TE to $\ell_{\rm max} = 10$ ($\tau = 0.051 \pm 0.015$) is consistent with results derived from the `SimAll` EE likelihood summarized below.

Using the `SimAll` likelihood combined with the low-ℓ temperature `Commander` likelihood [see 292], varying $\ln(10^{10} A_{\rm s})$ and τ, but fixing other cosmological parameters to those of a fiducial base-ΛCDM model (with parameters very close to those of the baseline ΛCDM cosmology in this paper), PPL18 reports the optical depth measurement[140] Planck2018CosmolParam/

$$Planck2018CosmolParam/\tau = 0.0506 \pm 0.0086 \quad (68\,\%,\ \text{lowE}). \tag{1198}$$

This is significantly tighter than the LFI-based constraint used in the 2015 release ($\tau = 0.067 \pm 0.022$), and differs by about half a sigma from the result of Planck Collaboration Int. XLVI [297] ($\tau = 0.055 \pm 0.009$). The latter change is driven mainly by the removal of the last 1000 scanning rings in the 2018 `SRoll` maps, higher variance in the end-to-end simulations, and differences in the 30-GHz map used as a synchrotron tracer [see appendix A of 290]. The impact of the tighter optical depth measurement on cosmological parameters compared to the 2015 release is discussed in Sect. 27.3.6. The error model in the final likelihood does not fully include all modelling uncertainties and differences between likelihood codes, but the different approaches lead to estimates of τ that are consistent within their respective $1\,\sigma$ errors.

In addition to the default `SimAll` lowE likelihood used in this paper, the LFI polarization likelihood has also been updated for the 2018 release, as described in detail in PPL18. It gives consistent results to `SimAll`, but with larger errors ($\tau = 0.063 \pm 0.020$); we give a more detailed comparison of the various τ constraints in Sect. **??**.

The low-ℓ temperature likelihood is based on maps from the `Commander` component-separation algorithm, as discussed in detail in Planck Collaboration IV [292], with a Gibbs-sample-based Blackwell-Rao likelihood that accurately accounts for the non-Gaussian shape of the posterior at low multipoles, as in 2015. The CMB maps that are used differ in several ways from the 2015 analysis. Firstly, since the 2018 analysis does not produce individual bolometer maps (since it is optimized to reduce large-scale polarization systematics) the number of foreground components that can be constrained is reduced compared to 2015. The 2018 `Commander` analysis only fits the CMB, a single general low-frequency power-law component, thermal dust, and a single CO component with spatially constant line ratios between 100, 217, and 353 GHz. Secondly, the 2018 analysis is based only on *Planck* data and so does not including the WMAP and Haslam 408-MHz maps. Finally, in order to be conservative with respect to CO emission, the sky fraction has been reduced to 86 % coverage, compared to 93 % in 2015. The net effect is a small increase in errors, and the best-fit data points are correspondingly slightly more scattered compared to 2015. The (arbitrary) normalization of the `Commander` likelihood was also changed, so that a theory power spectrum equal to the best-fit power spectrum points will, by definition, give $\chi^2_{\rm eff} = 0$.

Likelihood notation

Throughout this paper, we adopt the following labels for likelihoods: (i) *Planck* TT+lowE denotes the combination of the high-ℓ TT likelihood at multipoles $\ell \geq 30$, the low-ℓ temperature-only `Commander` likelihood, and the low-ℓ EE likelihood from `SimAll`; (ii) labels such as *Planck* TE+lowE denote the TE likelihood at $\ell \geq 30$ plus the low-ℓ EE `SimAll` likelihood; and (iii)

[140] The corresponding marginalized amplitude parameter is $\ln(10^{10} A_{\rm s}) = 2.924 \pm 0.052$, which gives $A_{\rm s}$ about 10 % lower than the value obtained from the joint fits in Sect. 27.3. The τ constraints quoted here are lower than the joint results, since the small-scale power has a preference for higher $A_{\rm s}$ (and hence higher τ for the well-measured $A_{\rm s} e^{-2\tau}$ combination) at high multipoles, related to the preference for more lensing discussed in Sect. 27.6.

Planck TT,TE,EE+lowE denotes the combination of the combined likelihood using TT, TE, and EE spectra at $\ell \geq 30$, the low-ℓ temperature `Commander` likelihood, and the low-ℓ `SimAll` EE likelihood. For brevity we sometimes drop the "*Planck*" qualifier where it should be clear, and unless otherwise stated high-ℓ results are based on the `Plik` likelihood. TE correlations at $\ell \leq 29$ are not included in any of the results presented in this paper.

Uncertainties on cosmological parameters

To maximize the accuracy of the results, various choices can be made in the construction of the high-multipole likelihoods. Examples of these are the sky area, noise models, multipole ranges, frequencies, foreground parameterization, and priors, as detailed for this release of *Planck* data in PPL18. The cosmological parameters and their uncertainties depend on these options. It is therefore necessary to test the sensitivity of the results with respect to such choices. In particular, when removing or adding independent information (e.g., by lifting or adding priors, or by measuring parameters from different multipole ranges), we *do expect* cosmological parameters to shift. The crucial question, however, is whether these are in agreement with statistical expectations. If they are consistent with being statistical excursions, then the noise model, along with foreground and instrumental nuisance parameters (e.g., polarization efficiencies), may be a consistent representation of the data. In this case, the uncertainties quoted in this paper should accurately describe the combined noise and sample variance due to finite data. Different choices of sky area, multipole range, etc., will produce changes in the parameters, but they will be adequately described by the quoted uncertainties. On the other hand, if the shifts *do not* agree with statistical expectations, they might be an indication of unmodelled systematic effects.

In PPL18 we discuss a series of tests indicating the overall robustness of our results. Internal to the `Plik` likelihood code, we consider the CMB spectra, errors, and resulting parameters as we vary the input data, ℓ range, sky area, etc. We also consider the effect of known sources of systematic uncertainty, such as high-frequency oscillations in the raw time-ordered data and temperature-to-polarization leakage. We further test the baseline likelihood using extensive simulations; these tests demonstrate the solidity of our results. As a specific example, when lifting all priors on nuisance parameters (such as calibration and foregrounds), the posterior mean on the number of relativistic species $N_{\rm eff}$ shifts upwards by about $1\,\sigma$. We quantify in PPL18 that this is statistically not anomalous, since lifting priors reduces information and, as a consequence, error bars also increase.

Only in a small number of areas, do such tests show mild internal disagreements at the level of spectra and parameters. One example is the higher than expected χ^2 of the `Plik` TE frequency-likelihood, which can be traced back to a small mismatch between the different cross-frequency spectra. When we co-add the foreground-cleaned frequency TE spectra into one CMB spectrum (which is less sensitive to such a mismatch), the related χ^2 is in better agreement with expectations. A second example is the choice of polarization-efficiency corrections, which has a small impact on the final results and is further discussed below.

We have also compared the results from the `Plik` likelihood with those obtained with `CamSpec` in Sects. 27.2.2 and 27.2.2 and Appendix **??**, as well as in PPL18 [see also 117]. Some of the likelihood choices (e.g., sky area and multipole range) will give different detailed results within the expected sample variance. Others, such as the models for noise (bias-corrected half-ring difference for `Plik` versus odd-even rings for `CamSpec`) and polarization efficiency, may give a hint of residual systematic uncertainties. If we restrict ourselves to temperature, the `Plik` and `CamSpec` likelihoods are in excellent accord, with most parameters agreeing to better than $0.5\,\sigma$ ($0.2\,\sigma$ on the ΛCDM model). On the other hand, we find indications (discussed in more detail in PPL18) that the polarization efficiencies of the frequency-channel maps differ when measured in the TE or EE spectra, and the `Plik` and `CamSpec` likelihoods have explored different choices of polarization efficiency corrections. This and polarization-noise modelling may be responsible for differences in the details of the resulting polarization spectra and parameters.

For the base-ΛCDM model, the results from `Plik` and `CamSpec` for the TT,TE,EE likelihoods are in good agreement (see Table 24), again with most parameters agreeing to better than $0.5\,\sigma$. We also find differences between the `Plik` and `CamSpec` TTTEEE likelihoods for some extended models, especially for the single-parameter extensions with $A_{\rm L}$ (at $0.7\,\sigma$) and $\Omega_{\rm K}$ (at $0.5\,\sigma$); these differences are discussed in Sects. 27.6.2 and **??**, respectively, where we show results for both likelihoods. For both $A_{\rm L}$ and $\Omega_{\rm K}$, the `Plik` TT,TE,EE likelihood pulls away from the base-ΛCDM model with a slightly higher significance than the `CamSpec` TT,TE,EE likelihood. The

is due, at least in part, to the choice of how to model polarization efficiencies, as discussed in PPL18. For the Ω_K case, for example, the $\Delta\chi^2$ between the ΛCDM and ΛCDM+Ω_K models for TT,TE,EE+lowE is $\Delta\chi^2 = 11$, of which 8.3 $\Delta\chi$ points are due to the improvement of the `Plik` TT,TE,EE likelihood. Using spectrum-based polarization efficiencies, instead of map-based ones[141] reduces that total difference to $\Delta\chi^2 = 5.2$, of which $\Delta\chi^2 = 4.6$ is due to the `Plik` likelihood. This is in agreement with the $\Delta\chi^2$ value obtained for these models by `CamSpec`, which uses spectrum-based polarization efficiencies, with $\Delta\chi^2 = 4.3$.

Other details of choices in the likelihood functions impact the difference in parameters; however, these comprise both expected statistical fluctuations (due to differing raw data cuts and sky coverage) and possible residual systematic errors. For both extended models the *Planck* TTTEEE likelihoods are usually combined with other data to break parameter degeneracies. For these parameters, the addition of either *Planck* lensing or BAO data overwhelms any differences between the `Plik` and `CamSpec` likelihoods and so we find almost identical results.

In this paper we therefore do not explicitly model an increase in error bars due to these residual systematic errors — any such characterization would inevitably be incomplete, and it would also be impossible to give the necessary probabilistic characterization required for meaningful quantitative error bars. Instead our best-fit values, posterior means, errors and limits should (as always) be considered as conditional on the cosmological model and our best knowledge of the *Planck* instruments and astrophysical foregrounds, as captured by the baseline likelihoods.

27.2.3 The CMB lensing likelihood

The CMB photons that arrive here today traverse almost the entire observable Universe. Along the way their paths are deflected by gradients in the gravitational potentials associated with inhomogeneities in the Universe [55]. The dominant effects [e.g., 220, 161] are a smoothing of the acoustic peaks, conversion of E-mode polarization to B-mode polarization, and generation of a connected 4-point function, each of which can be measured in high angular resolution, low-noise observations, such as those from *Planck*.

Planck was the first experiment to measure the lensing signal to sufficient precision for it to become important for the determination of cosmological parameters, providing sensitivity to parameters that affect the late-time expansion, geometry, and clustering [277, hereafter PL2013]. In Planck Collaboration XV [286, hereafter PL2015] the *Planck* lensing reconstruction was improved by including polarization information. The *Planck* lensing measurement is still the most significant detection of CMB lensing to date. In this final data release we report a measurement of the power spectrum of the lensing potential, $C_L^{\phi\phi}$, from the 4-point function, with a precision of around 2.6 % on the amplitude, as discussed in detail in PL2018. We demonstrate the robustness of the reconstruction to a variety of tests over lensing multipoles $8 \leq L \leq 400$, and conservatively restrict the likelihood to this range to reduce the impact of possible systematics. Compared to 2015, the multipole range is extended from $L_{\rm min} = 40$ down to $L_{\rm min} = 8$, with other analysis changes mostly introducing random fluctuations in the band powers, due to improvements in the noise modelling and the somewhat different mixture of frequencies being used in the foreground-cleaned `SMICA` maps [see 292]. The signal-to-noise per multipole is almost the same as in 2015, which, combined with the wider multipole range, makes the likelihood just slightly more powerful than in 2015. CMB lensing can provide complementary information to the *Planck* CMB power spectra, since it it probes much lower redshifts, including $z \lesssim 2$, when dark energy becomes important. The lensing effect depends on the propagation of photons on null geodesics, and hence depends on the background geometry and Weyl potential (the combination of scalar metric perturbations that determines the Weyl spacetime curvature tensor; see e.g. [220]).

We approximate the lensing likelihood as Gaussian in the estimated band powers, making perturbative corrections for the small dependence of band powers on the cosmology, as described in PL2015. We neglect correlations between the 2- and 4-point functions, which are negligible at *Planck* sensitivity [327, 261]. As in PL2015, band powers at multipoles $L > 400$ are less robust than over $8 \leq L \leq 400$, with some evidence for a curl-test failure, and possibly also systematic differences between individual frequencies that we were unable to resolve. Multipoles at $L < 8$

[141] As explained in Sections 27.2.2 and 27.2.2, the "map-based" approach applies the same polarization efficiency corrections estimated from EE to both the TE and EE spectra, while the "spectrum-based" approach applies independent estimates obtained from TE and EE to the TE and EE spectra, respectively.

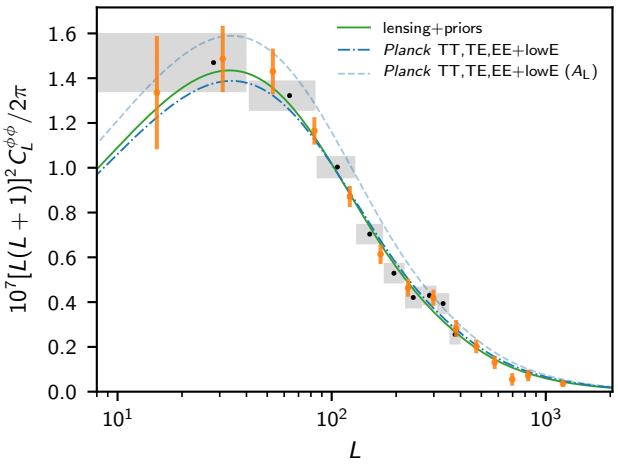

Figure 169: CMB lensing-potential power spectrum, as measured by *Planck* (see PL2018 for a detailed description of this measurement). Orange points show the full range of scales reconstructed with a logarithmic binning, while grey bands show the error and multipole range of the conservative band powers used for the likelihood, with black points showing the average multipole of the band weight. The solid line shows the best ΛCDM fit to the conservative points alone, and the dot-dashed line shows the prediction from the best fit to the *Planck* CMB power spectra alone. The dashed line shows the prediction from the best fit to the CMB power spectra when the lensing amplitude $A_{\rm L}$ is also varied ($A_{\rm L} = 1.19$ for the best-fit model; see Sect. 27.6.2 for a detailed discussion of $A_{\rm L}$).

are very sensitive to the large mean-field correction on these scales, and hence are sensitive to the fidelity of the simulations used to estimate the mean field. As described above, our baseline cosmological results therefore conservatively use only the multipole range $8 \leq L \leq 400$.

The *Planck* measurements of $C_L^{\phi\phi}$ are plotted in Fig. 169, where they are compared to the predicted spectrum from the best-fitting base-ΛCDM model of Sect. 27.3, and Fig. 170 shows the corresponding broad redshift ranges that contribute to the lensing band powers in the ΛCDM model. Fig. 169 shows that the lensing data are in excellent agreement with the predictions inferred from the CMB power spectra in the base-ΛCDM model ($\chi^2_{\rm eff} = 8.9$ for 9 binned conservative band-power measurements, $\chi^2_{\rm eff} = 14.0$ for 14 bins over the full multipole range; we discuss agreement in extensions to the ΛCDM model in more detail below). The lensing data prefer lensing power spectra that are slightly tilted towards less power on small scales compared to the best fit to the CMB power spectra. This small tilt pulls joint constraints a small fraction of an error bar towards parameters that give a lower lensing amplitude on small scales. Parameter results from the full multipole range would be a little tighter and largely consistent with the conservative band powers, although preferring slightly lower fluctuation amplitudes (see PL2018).

As described in detail in PL2018, the lensing likelihood (in combination with some weak priors) can alone provide ΛCDM parameter constraints that are competitive with current galaxy lensing and clustering, measuring Planck2018CosmolParam/

$$Planck2018CosmolParam/\sigma_8\Omega_{\rm m}^{0.25} = 0.589 \pm 0.020 \quad \begin{matrix}(68\,\%,\ Planck \\ \text{lensing}).\end{matrix} \tag{1199}$$

Combined with BAO (see Sect. 27.5.1 below) and a baryon density prior to break the main degeneracy between H_0, $\Omega_{\rm m}$, and σ_8 (described in PL2015), individual parameters H_0, $\Omega_{\rm m}$, and σ_8 can also separately be constrained to a precision of a few percent. We use $\Omega_{\rm b}h^2 = 0.0222 \pm 0.0005$ [motivated by the primordial deuterium abundance measurements of 82, see

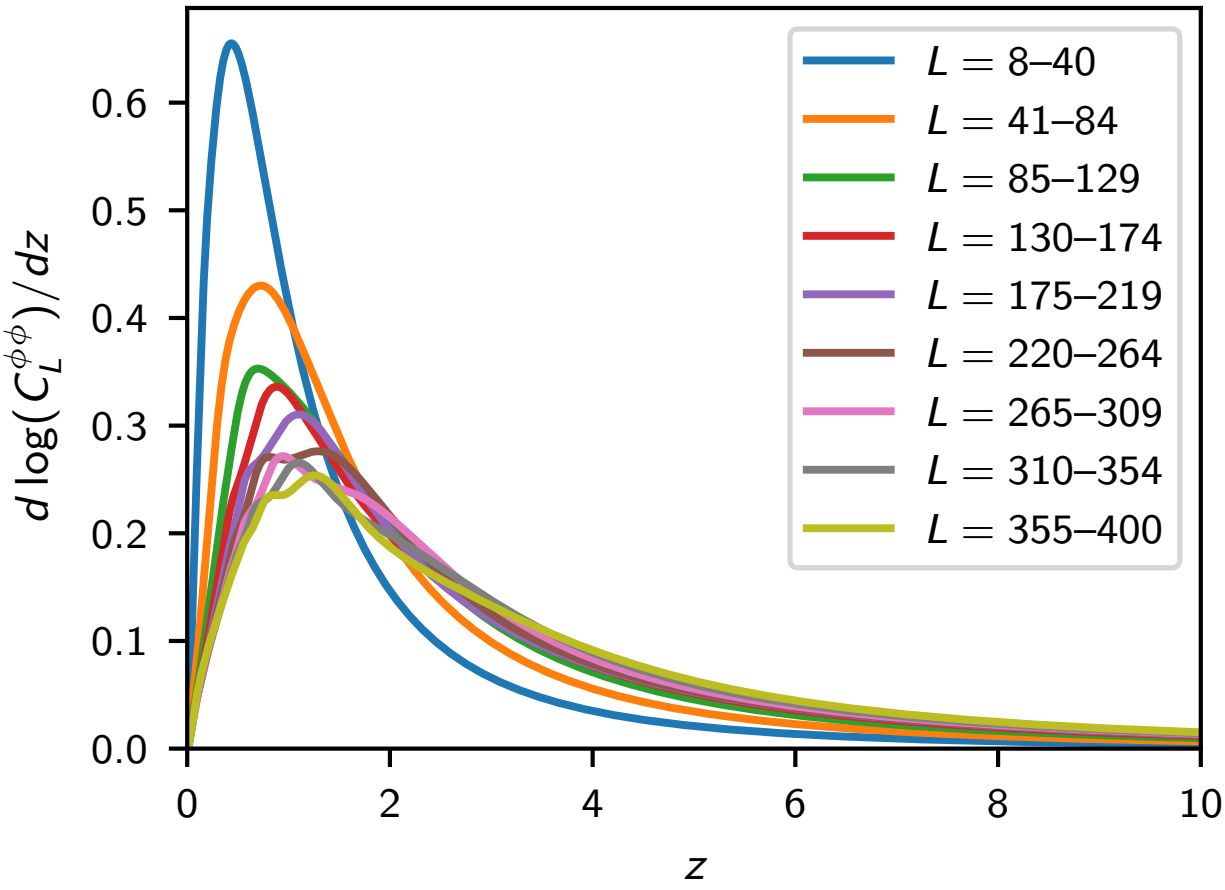

Figure 170: Contributions to the conservative CMB lensing band powers (see text and Fig. 169) as a function of redshift in the base-ΛCDM model (evaluated here, and only here, using the Limber approximation [227] on all scales). Multipole ranges of the corresponding band powers are shown in the legend.

also Sect. **??**], which gives

$$\left.\begin{aligned} Planck2018CosmolParam/H_0 &= 67.9^{+1.2}_{-1.3}\ \mathrm{km\ s^{-1}Mpc^{-1}},\\ \sigma_8 &= 0.811 \pm 0.019,\\ \Omega_\mathrm{m} &= 0.303^{+0.016}_{-0.018}, \end{aligned}\right\}\ 68\,\%, \text{lensing+BAO}. \qquad (1200)$$

The constraints of Eq. (1199) and (1200) in are in very good agreement with the estimates derived from the *Planck* power spectra and are independent of how the *Planck* power spectra depend on the cosmological model at high multipoles. This is a strong test of the internal consistency of the *Planck* data. The *Planck* lensing constraints in Eqs. (1199) and (1200), and the consistency of these results with the *Planck* power spectrum likelihoods, should be borne in mind when comparing *Planck* results with other astrophysical data (e.g., direct measurements of H_0 and galaxy shear surveys, see Sect. 27.5).

In this paper, we focus on joint constraints with the main *Planck* power spectrum results, where the lensing power spectrum tightens measurements of the fluctuation amplitude and improves constraints on extended models, especially when allowing for spatial curvature.

A peculiar feature of the *Planck* TT likelihood, reported in PCP13 and PCP15, is the favouring of high values for the lensing consistency parameter A_L (at about $2.5\,\sigma$). This result is discussed in detail in Sect. 27.6.2. It is clear from Fig. 169, however, that the *Planck* lensing likelihood prefers values of A_L close to unity and cosmological parameters that are close

to those of the best-fit base-ΛCDM parameters derived from the *Planck* TT,TE,EE+lowE +lensing likelihood (i.e., without allowing $A_{\rm L}$ to vary).

27.3 Constraints on base ΛCDM

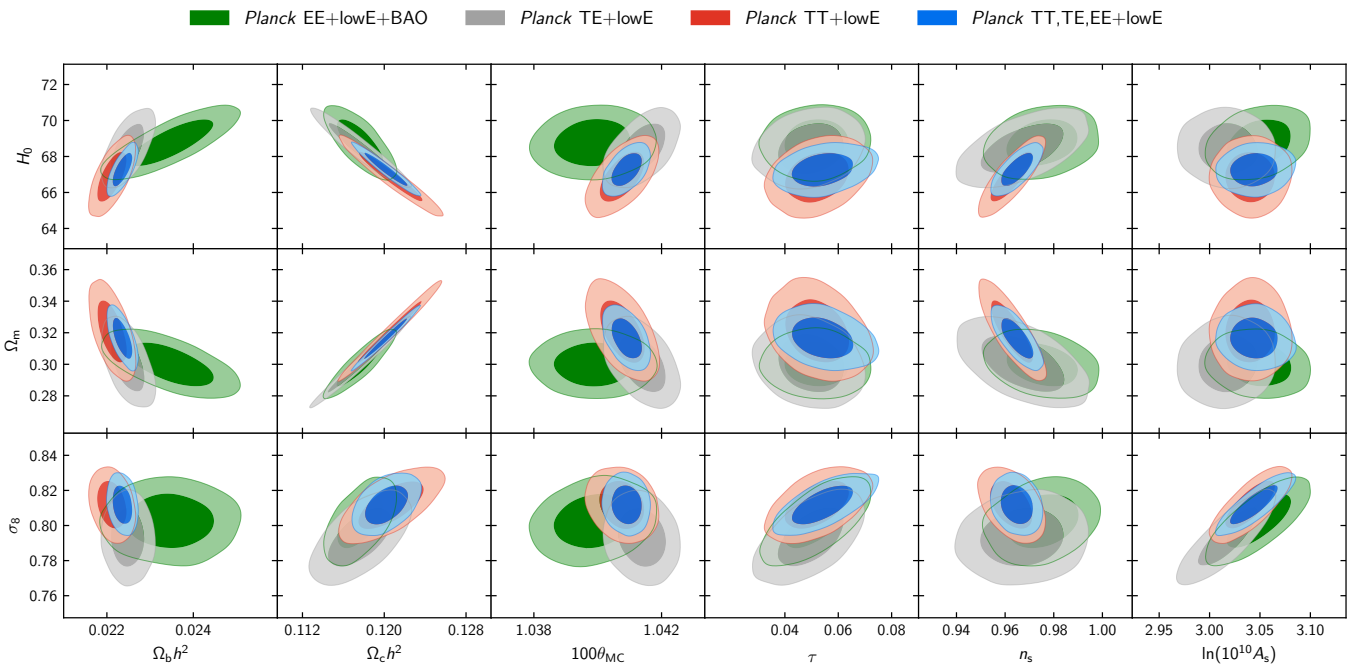

Figure 171: Constraints on parameters of the base-ΛCDM model from the separate *Planck* EE, TE, and TT high-ℓ spectra combined with low-ℓ polarization (lowE), and, in the case of EE also with BAO (described in Sect. 27.5.1), compared to the joint result using *Planck* TT,TE,EE+lowE. Parameters on the bottom axis are our sampled MCMC parameters with flat priors, and parameters on the left axis are derived parameters (with H_0 in km s^{-1}Mpc^{-1}). Contours contain 68 % and 95 % of the probability.

The *Planck* measurement of seven acoustic peaks in the CMB temperature power spectrum allows cosmological parameters to be constrained extremely accurately. In previous papers, we have focussed on parameters derived from the TT power spectrum. The TE and EE polarization spectra provide a powerful consistency check on the underlying model and also help to break some partial parameter degeneracies. The goal of this section is to explore the consistency of cosmological parameters of the base-ΛCDM cosmology determined from TT, TE, and EE spectra and to present results from the combinations of these spectra, which are significantly more precise that those determined using TT alone.

Figure 171 shows 2-dimensional marginalized constraints on the six MCMC sampling parameters of the base-ΛCDM model used to explore the parameter posteriors, plotted against the following derived parameters: the Hubble constant H_0, late-time clustering amplitude σ_8 and matter density parameter $\Omega_{\rm m}$ (defined including a 0.06-eV mass neutrino). Table 24 gives individual parameter constraints using our baseline parameter combination *Planck* TT,TE,EE +lowE+lensing. These represent the legacy results on the cosmological ΛCDM parameters from the *Planck* satellite, and are currently the most precise measurements coming from a single CMB experiment. We give the best-fit values, as well as the marginalized posterior mean values, along with the corresponding 68 % probability intervals. Table 24 also quantifies the small changes in parameters that are found when using the `Plik` and `CamSpec` high-ℓ polarization analyses described in Sect. 27.2.2 and Appendix **??**. Table 25 gives marginalized parameter constraints from the various CMB spectra, individually and without CMB lensing, including a wider variety of derived parameters of physical interest.

We now discuss in more detail the parameters that are most directly measured by the data and how these relate to constraints on individual parameters of more general interest.

Table 24: Base-ΛCDM cosmological parameters from *Planck* TT,TE,EE+lowE+lensing. Results for the parameter best fits, marginalized means and 68 % errors from our default analysis using the `Plik` likelihood are given in the first two numerical columns. The `CamSpec` likelihood results give some idea of the remaining modelling uncertainty in the high-ℓ polarization, though parts of the small shifts are due to slightly different sky areas in polarization. The "Combined" column give the average of the `Plik` and `CamSpec` results, assuming equal weight. The combined errors are from the equal-weighted probabilities, hence including some uncertainty from the systematic difference between them; however, the differences between the high-ℓ likelihoods are so small that they have little effect on the $1\,\sigma$ errors. The errors do not include modelling uncertainties in the lensing and low-ℓ likelihoods or other modelling errors (such as temperature foregrounds) common to both high-ℓ likelihoods. A total systematic uncertainty of around $0.5\,\sigma$ may be more realistic, and values should not be overinterpreted beyond this level. The best-fit values give a representative model that is an excellent fit to the baseline likelihood, though models nearby in the parameter space may have very similar likelihoods. The first six parameters here are the ones on which we impose flat priors and use as sampling parameters; the remaining parameters are derived from the first six. Note that $\Omega_{\rm m}$ includes the contribution from one neutrino with a mass of 0.06 eV. The quantity $\theta_{\rm MC}$ is an approximation to the acoustic scale angle, while θ_* is the full numerical result.

Parameter	`Plik` best fit	`Plik` [1]	`CamSpec` [2]	$([2]-[1])/\sigma_1$	Combined

27.3.1 Acoustic scale

The acoustic oscillations in ℓ seen in the CMB power spectra correspond to a sharply-defined acoustic angular scale on the sky, given by $\theta_* \equiv r_*/D_{\rm M}$ where r_* is the comoving sound horizon at recombination quantifying the distance the photon-baryon perturbations can influence, and $D_{\rm M}$ is the comoving angular diameter distance[142] that maps this distance into an angle on the sky. *Planck* measures Planck2018CosmolParam/

$$Planck2018CosmolParam/100\theta_* = 1.04097 \pm 0.00046 \quad \begin{matrix}(68\,\%,\ Planck\ \mathrm{TT} \\ +\mathrm{lowE}),\end{matrix} \tag{1201}$$

[142]The quantity $D_{\rm M}$ is $(1+z)D_{\rm A}$, where $D_{\rm A}$ is the usual angular diameter distance.

Table 25: Parameter 68 % intervals for the base-ΛCDM model from *Planck* CMB power spectra, in combination with CMB lensing reconstruction and BAO. The top group of six rows are the base parameters, which are sampled in the MCMC analysis with flat priors. The middle group lists derived parameters. The bottom three rows show the temperature foreground amplitudes $f^{TT}_{\ell=2000}$ for the corresponding frequency spectra (expressed as the contribution to $D^{TT}_{\ell=2000}$ in units of $(\mu\mathrm{K})^2$). In all cases the helium mass fraction used is predicted by BBN (posterior mean $Y_\mathrm{P} \approx 0.2454$, with theoretical uncertainties in the BBN predictions dominating over the *Planck* error on $\Omega_\mathrm{b}h^2$). The reionization redshift mid-point z_re and optical depth τ here assumes a simple tanh model (as discussed in the text) for the reionization of hydrogen and simultaneous first reionization of helium. Our baseline results are based on *Planck* TT,TE,EE +lowE+lensing (as also given in Table 24).

corresponding to a precise 0.05 % measurement of the angular scale $\theta_* = (0.^\circ59643 \pm 0.^\circ00026)$. The angular scales of the peaks in the polarization spectrum and cross-spectrum are different, since the polarization at recombination is sourced by quadrupolar flows in the photon fluid, which are out of phase with the density perturbations. The polarization spectra can, however, be used to measure the same acoustic scale parameter, giving a stringent test on the assumption of purely adiabatic perturbation driving the oscillations. From the polarization spectra we find

$$100\theta_* = 1.04156 \pm 0.00049 \quad (68\,\%,\ \textit{Planck}\ \text{TE+lowE}), \tag{1202a}$$
$$100\theta_* = 1.04001 \pm 0.00086 \quad (68\,\%,\ \textit{Planck}\ \text{EE+lowE}), \tag{1202b}$$

in excellent agreement with the temperature measurement. The constraint from TE is of similar precision to that from TT: although the polarization data are much noisier, the TE and EE spectra have more distinct acoustic peaks, which helps improve the signal-to-noise ratio of the acoustic scale measurement. Using the combined likelihood we find: Planck2018CosmolParam/

$$\textit{Planck2018CosmolParam}/100\theta_* = 1.04109 \pm 0.00030 \quad (68\,\%,\ \text{TT,TE,EE+lowE}), \tag{1203}$$

a measurement with 0.03 % precision.[143]

Because of its simple geometrical interpretation, θ_* is measured very robustly and almost independently of the cosmological model (see Table **??**). It is the CMB analogue of the transverse baryon acoustic oscillation scale $r_{\rm drag}/D_{\rm M}$ measured from galaxy surveys, where $r_{\rm drag}$ is the comoving sound horizon at the end of the baryonic-drag epoch (see Sect. 27.5.1). In ΛCDM, the CMB constraint can be expressed as a tight 0.04 %-precision relation between $r_{\rm drag}\,h$ and $\Omega_{\rm m}$ as Planck2018CosmolParam/

$$\textit{Planck2018CosmolParam}/\left(\frac{r_{\rm drag}h}{\rm Mpc}\right)\left(\frac{\Omega_{\rm m}}{0.3}\right)^{0.4} = 101.056 \pm 0.036 \quad (68\,\%,\ \text{TT,TE,EE+lowE}). \tag{1204}$$

The sound horizon $r_{\rm drag}$ depends primarily on the matter, baryon, and radiation densities, which for fixed observed CMB temperature today,[144] gives a 0.05 % constraint on the combination Planck2018CosmolParam/

$$\textit{Planck2018CosmolParam}/\Omega_{\rm m}^{0.3}h(\Omega_{\rm b}h^2)^{-0.16} = 0.87498 \pm 0.00052 \quad (68\,\%,\ \text{TT,TE,EE+lowE}). \tag{1205}$$

Marginalizing out the dependence on the baryon density, the remaining degeneracy between the matter density and Hubble parameters is well approximated by a constraint on the parameter combination $\Omega_{\rm m}h^3$ [265]. We find a 0.3 % constraint from *Planck*: Planck2018CosmolParam/

$$\textit{Planck2018CosmolParam}/\Omega_{\rm m}h^3 = 0.09633 \pm 0.00029 \quad (68\,\%,\ \text{TT,TE,EE+lowE}), \tag{1206}$$

corresponding to an anti-correlation between the matter density $\Omega_{\rm m}h^2$ and the Hubble parameter. This correlation can also be seen in Fig. 171 as an anti-correlation between the dark-matter density $\Omega_{\rm c}h^2$ and H_0, and a corresponding positive correlation between $\Omega_{\rm c}h^2$ and $\Omega_{\rm m}$.

[143] Doppler aberration due to the Earth's motion means that θ_* is expected to vary over the sky at the 10^{-3} level; however, averaged over the likelihood masks, the expected bias for *Planck* is below $0.1\,\sigma$.

[144] We take $T_0 = 2.7255$K [134], with the ±0.0006K error having negligible impact on results.

27.3.2 Hubble constant and dark-energy density

The degeneracy between $\Omega_{\rm m}$ and H_0 is not exact, but the constraint on these parameters individually is substantially less precise than Eq. (1206), giving

$$\left.\begin{array}{r} Planck2018CosmolParam/H_0 = (67.27 \pm 0.60)\ \text{km s}^{-1}\text{Mpc}^{-1}, \\ \Omega_{\rm m} = 0.3166 \pm 0.0084, \end{array}\right\} \begin{array}{l} 68\,\%,\ \text{TT,TE,EE} \\ +\text{lowE}. \end{array} \quad (1207)$$

It is important to emphasize that the values given in Eq. (1207) assume the base-ΛCDM cosmology with minimal neutrino mass. These estimates are highly model dependent and this needs to be borne in mind when comparing with other measurements, for example the direct measurements of H_0 discussed in Sect. 27.5.4. The values in Eq. (1207) are in very good agreement with the independent constraints of Eq. (1200) from *Planck* CMB lensing+BAO. Including CMB lensing sharpens the determination of H_0 to a 0.8 % constraint: Planck2018CosmolParam/

$$Planck2018CosmolParam/H_0 = (67.36 \pm 0.54)\ \text{km s}^{-1}\text{Mpc}^{-1} \quad \begin{array}{l} (68\,\%,\ \text{TT,TE,EE} \\ +\text{lowE} \\ +\text{lensing}). \end{array} \quad (1208)$$

This value is our "best estimate" of H_0 from *Planck*, assuming the base-ΛCDM cosmology.

Since we are considering a flat universe in this section, a constraint on $\Omega_{\rm m}$ translates directly into a constraint on the dark-energy density parameter, giving Planck2018CosmolParam/

$$\Omega_\Lambda = 0.6847 \pm 0.0073 \quad \begin{array}{l} (68\,\%,\ \text{TT,TE,EE+lowE} \\ +\text{lensing}). \end{array} \quad (1209)$$

In terms of a physical density, this corresponds to $\Omega_\Lambda h^2 = 0.3107 \pm 0.0082$, or cosmological constant $\Lambda = (4.24 \pm 0.11) \times 10^{-66}\,\text{eV}^2 = (2.846 \pm 0.076) \times 10^{-122}\, m_{\rm Pl}^2$ in natural units (where $m_{\rm Pl}$ is the Planck mass).

27.3.3 Optical depth and the fluctuation amplitude

Since the CMB fluctuations are linear up to lensing corrections, and the lensing corrections are largely oscillatory, the average observed CMB power spectrum amplitude scales nearly proportionally with the primordial comoving curvature power spectrum amplitude $A_{\rm s}$ (which we define at the pivot scale $k_0 = 0.05\,\text{Mpc}^{-1}$). The sub-horizon CMB anisotropies are however scattered by free electrons that are present after reionization, so the observed amplitude actually scales with $A_{\rm s}e^{-2\tau}$, where τ is the reionization optical depth (see Sect. **??** for further discussion of reionization constraints). This parameter combination is therefore well measured, with the 0.6 % constraint Planck2018CosmolParam/

$$Planck2018CosmolParam/A_{\rm s}e^{-2\tau} = (1.884 \pm 0.012) \times 10^{-9} \quad \begin{array}{l} (68\,\%,\ \text{TT,TE,EE} \\ +\text{lowE}). \end{array} \quad (1210)$$

In this final *Planck* release the optical depth is well constrained by the large-scale polarization measurements from the *Planck* HFI, with the joint constraint Planck2018CosmolParam/

$$\tau = 0.0544^{+0.0070}_{-0.0081} \quad (68\,\%,\ \text{TT,TE,EE+lowE}). \quad (1211)$$

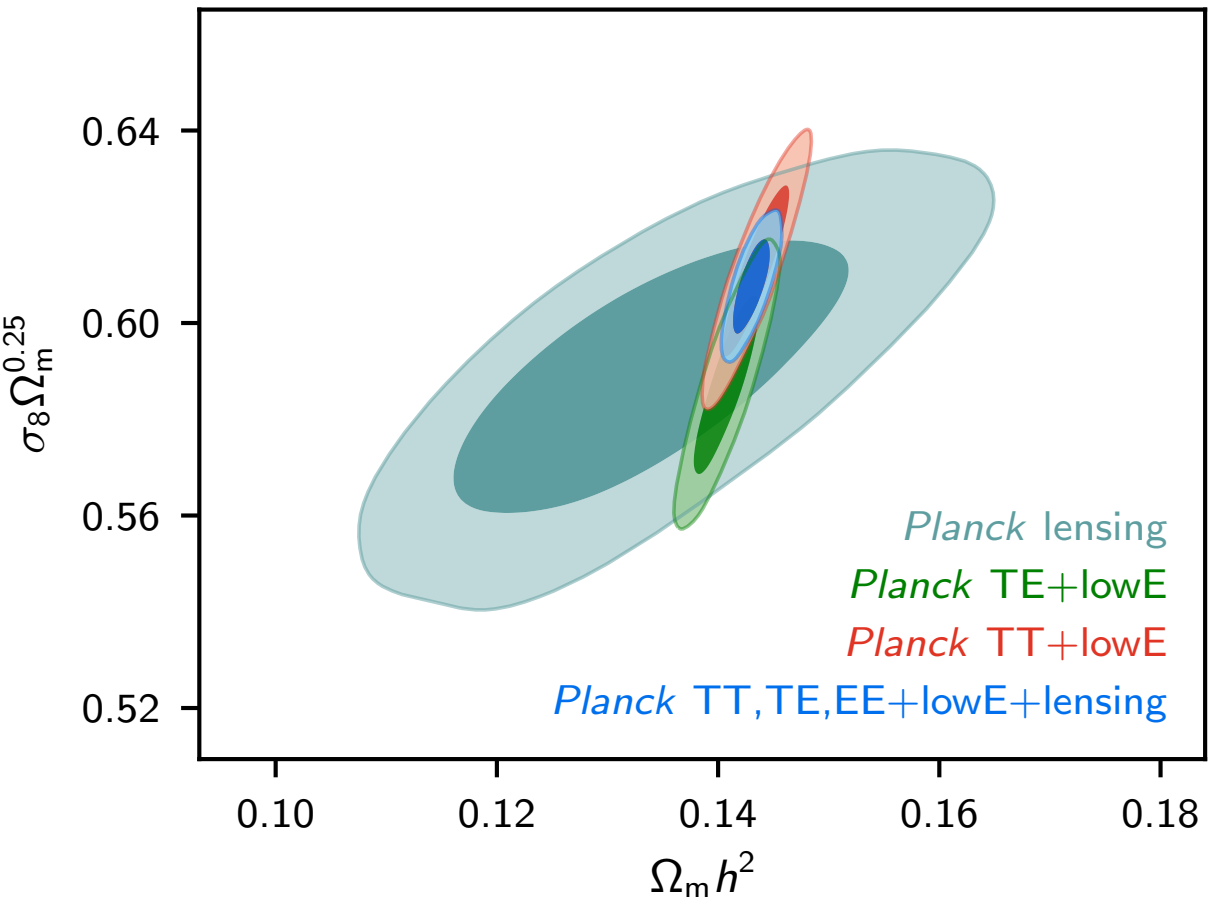

Figure 172: Base-ΛCDM 68 % and 95 % marginalized constraint contours for the matter density and $\sigma_8\Omega_m^{0.25}$, a fluctuation amplitude parameter that is well constrained by the CMB-lensing likelihood. The *Planck* TE, TT, and lensing likelihoods all overlap in a consistent region of parameter space, with the combined likelihood substantially reducing the allowed parameter space.

Assuming simple tanh parameterization of the ionization fraction,[145] this implies a mid-point redshift of reionization Planck2018CosmolParam/

$$z_{\rm re} = 7.68 \pm 0.79 \quad (68\,\%,\ \text{TT,TE,EE+lowE}), \tag{1212}$$

and a one-tail upper limit of $z_{\rm re} < 9.0$ (95 %). This is consistent with observations of high-redshift quasars that suggest the Universe was fully reionized by $z \approx 6$ [61]. We do not include the astrophysical constraint that $z_{\rm re} \gtrsim 6.5$ in our default parameter results, but if required results including this prior are part of the published tables on the Planck Legacy Archive

[145] For reference, the ionization fraction $x_{\rm e} = n_{\rm e}/n_{\rm H}$ in the tanh model is assumed to have the redshift dependence [217]:

$$x_e = \frac{1 + n_{\rm He}/n_{\rm H}}{2}\left[1 + \tanh\left(\frac{y(z_{\rm re}) - y(z)}{\Delta y}\right)\right],$$

where $y(z) = (1+z)^{3/2}$, $\Delta y = \frac{3}{2}(1+z_{\rm re})^{1/2}\Delta z$, with $\Delta z = 0.5$. Helium is assumed to be singly ionized with hydrogen at $z \gg 3$, but at lower redshifts we add the very small contribution from the second reionization of helium with a similar tanh transition at $z = 3.5$.

(PLA). A more detailed discussion of reionization histories consistent with *Planck* and results from other *Planck* likelihoods is deferred to Sect. **??**.

The measurement of the optical depth breaks the $A_s e^{-2\tau}$ degeneracy, giving a 1.5 % measurement of the primordial amplitude: Planck2018CosmolParam/

$$Planck2018CosmolParam/A_s = (2.101^{+0.031}_{-0.034}) \times 10^{-9} \quad \begin{matrix}(68\,\%,\ \mathrm{TT,TE,EE} \\ +\mathrm{lowE}).\end{matrix} \tag{1213}$$

Since the optical depth is reasonably well constrained, degeneracies with other cosmological parameters contribute to the error in Eq. (1213). From the temperature spectrum alone there is a significant degeneracy between $A_s e^{-2\tau}$ and $\Omega_m h^2$, since for fixed θ_*, larger values of these parameters will increase and decrease the small-scale power, respectively. This behaviour is mitigated in our joint constraint with polarization because the polarization spectra have a different dependence on $\Omega_m h^2$; polarization is generated by causal sub-horizon quadrupole scattering at recombination, but the temperature spectrum has multiple sources and is also sensitive to non-local redshifting effects as the photons leave the last-scattering surface [see, e.g., 142, for further discussion].

Assuming the ΛCDM model, the *Planck* CMB parameter amplitude constraint can be converted into a fluctuation amplitude at the present day, conventionally quantified by the σ_8 parameter. The CMB lensing reconstruction power spectrum also constrains the late-time fluctuation amplitude more directly, in combination with the matter density. Figure 172 shows constraints on the matter density and amplitude parameter combination $\sigma_8 \Omega_m^{0.25}$ that is well measured by the CMB lensing spectrum (see PL2015 for details). There is good consistency between the temperature, polarization, and lensing constraints here, and using their combination significantly reduces the allowed parameter space. In terms of the late-time fluctuation amplitude parameter σ_8 we find the combined result Planck2018CosmolParam/

$$\sigma_8 = 0.8111 \pm 0.0060 \quad \begin{matrix}(68\,\%,\ \textit{Planck}\ \mathrm{TT,TE,EE} \\ +\mathrm{lowE}+\mathrm{lensing}).\end{matrix} \tag{1214}$$

Measurements of galaxy clustering, galaxy lensing, and clusters can also measure σ_8, and we discuss consistency of these constraints within the ΛCDM model in more detail in Sect. 27.5.

27.3.4 Scalar spectral index

The scale-dependence of the CMB power spectrum constrains the slope of the primordial scalar power spectrum, conventionally parameterized by the power-law index n_s, where $n_s = 1$ corresponds to a scale-invariant spectrum. The matter and baryon densities also affect the scale-dependence of the CMB spectra, but in a way that differs from a variation in n_s, leading to relatively mild degeneracies between these parameters. Assuming that the primordial power spectrum is an exact power law we find Planck2018CosmolParam/

$$n_s = 0.9649 \pm 0.0042 \quad \begin{matrix}(68\,\%,\ \textit{Planck}\ \mathrm{TT,TE,EE} \\ +\mathrm{lowE}+\mathrm{lensing}),\end{matrix} \tag{1215}$$

which is $8\,\sigma$ away from scale-invariance ($n_s = 1$), confirming the red tilt of the spectrum at high significance in ΛCDM. Section **??** and [296] discuss the implications of this result for models of inflation and include constraints on models with primordial tensor modes and a scale-dependent scalar spectral index.

27.3.5 Matter densities

The matter density can be measured from the CMB spectra using the scale-dependence of the amplitude, since for fixed θ_* a larger matter density reduces the small-scale CMB power.

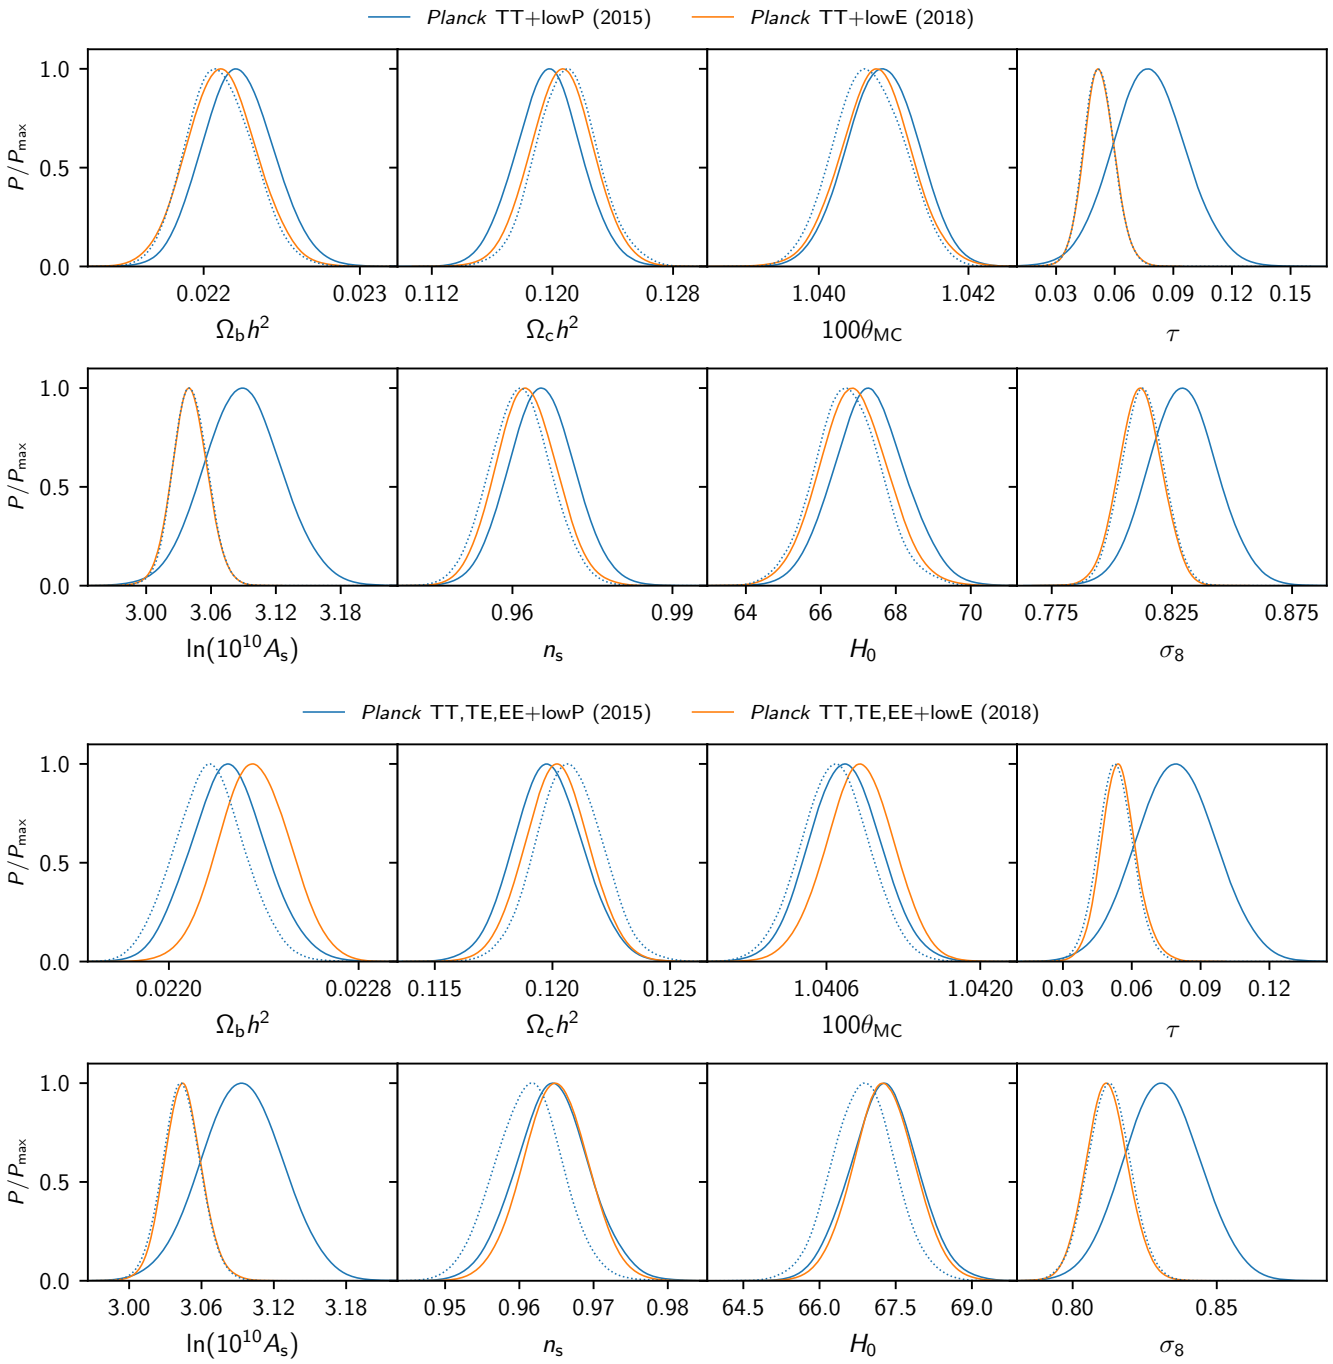

Figure 173: Comparison between the 2015 and 2018 marginalized ΛCDM parameters. Dotted lines show the 2015 results, replacing the 2015 "lowP" low-ℓ polarization likelihood with the new 2018 "lowE" `SimAll` likelihood, isolating the impact of the change in the low-ℓ polarization likelihood (and hence the constraints on τ).

The matter density also affects the amount of lensing in the CMB spectra and the amplitude of the CMB-lensing reconstruction spectrum. The matter density is well constrained to be

Planck2018CosmolParam/

$$Planck2018CosmolParam/\Omega_{\rm m}h^2 = 0.1430 \pm 0.0011 \quad \begin{array}{l}(68\,\%,\ Planck\\ \text{TT,TE,EE+lowE}\\ \text{+lensing}).\end{array} \tag{1216}$$

The matter mostly consists of cold dark matter, with density constrained at the percent level: Planck2018CosmolParam/

$$Planck2018CosmolParam/\Omega_{\rm c}h^2 = 0.1200 \pm 0.0012 \quad \begin{array}{l}(68\,\%,\ Planck\\ \text{TT,TE,EE+lowE}\\ \text{+lensing}).\end{array} \tag{1217}$$

Changes in the baryon density affect the spectrum in characteristic ways, modifying the relative heights of the even and odd acoustic peaks, due to the effect of baryons on the depth of first and subsequent acoustic (de)compressions. Despite comprising less than a sixth of the total matter content, the baryon effects on the power spectra are sufficiently distinctive that the baryon-density parameter is measured at sub-percent level accuracy with *Planck*: Planck2018CosmolParam/

$$Planck2018CosmolParam/\Omega_{\rm b}h^2 = 0.02237 \pm 0.00015 \quad \begin{array}{l}(68\,\%,\ Planck\\ \text{TT,TE,EE+lowE}\\ \text{+lensing}).\end{array} \tag{1218}$$

There is a partial degeneracy with $n_{\rm s}$, which can also affect the relative heights of the first few peaks. This is most evident in TE, but is reduced in TT because of the larger range of scales that are measured by *Planck* with low noise.

27.3.6 Changes in the base-ΛCDM parameters between the 2015 and 2018 data releases

Figure 173 compares the parameters of the base-ΛCDM model measured from the final data release with those reported in PCP15. To differentiate between changes caused by the new lowE polarization likelihood, and therefore generated by the change in the measured optical depth to reionization, we also show the result of using the 2015 likelihoods in combination with the 2018 lowE polarization likelihood at low multipoles. Figure 173 includes the results for both *Planck* TT+lowE and *Planck* TT,TE,EE+lowE.[146]

The main differences in ΛCDM parameters between the 2015 and the 2018 releases are caused by the following effects.

• New polarization low-ℓ likelihood. The use of the new HFI low-ℓ polarization likelihood in place of the 2015 LFI likelihood is the largest cause of shifts between the 2015 and 2018 parameters. The lowering and tightening of the constraint on τ is responsible for a $1\,\sigma$ decrease of $\ln(10^{10}A_{\rm s})$ through the $A_{\rm s}e^{-2\tau}$ degeneracy. This in turn decreases the smoothing due to gravitational lensing at high multipoles, which is compensated by an increase of about $1\,\sigma$ in $\omega_{\rm c}$. This decreases the amplitude of the first acoustic peak, so $n_{\rm s}$ shifts to a lower value by about $0.5\,\sigma$ to restore power. Further adjustments are then achieved by the changes of θ_* and $\omega_{\rm b}$ by about $0.5\,\sigma$.

[146] The published 2015 parameter constraints and chains had a small error in the priors for the polarization Galactic foregrounds, which was subsequently corrected in the published likelihoods. The impact on cosmological parameters was very small. Here we compare with the uncorrected 2015 chains, not the published 2015 likelihood.

• Polarization corrections in the high-ℓ likelihood. As described in detail in Sect. 27.2.2, the largest changes from 2015 are caused by corrections applied to the polarization spectra. To isolate the causes of shifts introduced by changes in the high-ℓ likelihood, Fig. 174 compares 2018 results neglecting corrections to the polarization spectra with results from the 2015 high-ℓ likelihood combined with the 2018 lowE likelihood (so that both sets of results are based on similar constraints on τ). The shift towards larger values in $\omega_{\rm b}$ by around $1\,\sigma$ is mainly caused by the beam-leakage correction in the TE high-ℓ likelihood, which is also responsible for an increase of approximately $0.5\,\sigma$ in $n_{\rm s}$, compensating for the shift in $n_{\rm s}$ as a result of the change in τ since 2015. The beam-leakage correction also changes $\omega_{\rm c}$ (by $-0.7\,\sigma$) and $\theta_{\rm MC}$ ($+0.7\,\sigma$). The other corrections implemented in 2018 have a smaller impact on the ΛCDM parameters, as described in detail in Planck Collaboration V [293].

Figure 175 presents the differences between the coadded spectra from 2018 and 2015. This plot shows the stability of the TT spectra, while also demonstrating that the main differences in polarization between the 2015 and 2018 releases are caused by the 2018 corrections for polarization efficiencies and beam leakage.

27.4 Comparison with high-resolution experiments

As discussed in PCP13 and PCP15, *Planck* TT spectra are statistically much more powerful than temperature data from current high-resolution experiments such as the Atacama Cosmology Telescope [ACT, e.g., 92] and the South Pole Telescope [SPT, e.g., 350, 146]. As a result, the *Planck* temperature data dominate if they are combined with ACT and SPT data. In PCP15, the high-resolution temperature data were used only to constrain low-amplitude components of the foreground model, which are otherwise weakly constrained by *Planck* data alone (with very little impact on cosmological parameters). We adopt the same approach in this paper.

Since the publication of PCP15, [181] have performed a direct map-based comparison of the SPT temperature data at 150 GHz with the *Planck* 143-GHz maps over the same area of sky (covering 2540 deg^2), finding no evidence for any systematic error in either data set after accounting for an overall difference in calibration. Temperature power spectrum comparisons between *Planck* and SPT are reported in a companion paper by Aylor et al. [32]. They find cosmological parameters for base ΛCDM derived from *Planck* and SPT over the same patch of sky and multipole range to be in excellent agreement. In particular, by comparing parameters determined over the multipole range 650–2000 from both experiments, the reduction in sample variance allows a test that is sensitive to systematic errors that could cause shifts in parameter posteriors comparable to the widths of the PCP15 posteriors. The parameters determined over the SPT sky area differ slightly, but not significantly, from the best-fit ΛCDM parameters reported in PCP15 based on a much larger area of sky. [32] also find a tendency for the base-ΛCDM parameters derived from SPT to shift as the multipole range is increased, but at low statistical significance.

Polarization measurements have become a major focus for ground-based CMB experiments. High resolution TE and EE spectra have been measured by the ACT Polarimeter (ACTPol) and the polarization-sensitive receiver of SPT (SPTpol). Following two seasons of observations, ACTPol has covered 548 deg^2 along the celestial equator at 149 GHz with data and analysis presented in Naess et al. [244] and Louis et al. [226]. The ACTPol spectra span the multipole range $350 < \ell < 9000$. SPTpol polarization spectra from 100 deg^2 in the southern hemisphere at 150 GHz were first reported in Crites et al. [87] and recently extended to 500 deg^2 [169]. The SPTpol spectra span the multipole range $50 < \ell < 8000$. In contrast, the *Planck* TE and EE power spectra lose statistical power at multipoles $\gtrsim 1500$. The ACTPol and SPTpol spectra are compared with the *Planck* TE and EE spectra in Fig. 176. The polarization spectra measured from these three very different experiments are in excellent agreement.

For the base-ΛCDM cosmology, the cosmological parameters should have converged close to their true values by multipoles ~ 2000. Since ACTPol and SPTpol cover a much smaller sky area than *Planck* the errors on their TE and EE spectra are larger than those of *Planck* at low multipoles (see Fig. 176). As a consequence, the current ACTPol and SPTpol polarization constraints on the parameters of the base-ΛCDM cosmology are much weaker than those derived from *Planck*. The ACTPol results [226] are consistent with the *Planck* base-ΛCDM parameters and showed a small improvement in constraints on extensions to the base cosmology that affect the damping tail. Similar results were found by SPTpol, though Henning et al. [169] noted a

Table 26: Minimum χ^2 values fitting the SPTpol spectra to the best-fit *Planck* and SPTpol ΛCDM cosmologies (as described in the text). N_b gives the number of band powers in each spectrum. The deviation of χ^2_min from the expectation $\langle\chi^2_\mathrm{min}\rangle = N_\mathrm{dof}$ is given by the columns labelled N_σ, where $N_\sigma = (\chi^2_\mathrm{min} - N_\mathrm{dof})/\sqrt{2N_\mathrm{dof}}$, and $N_\mathrm{dof} = N_\mathrm{b} - 8$. The last two columns give χ^2_p for parameter differences (Eq. 1219) and the associated PTEs.

		Planck cosmology		SPT cosmology			
SPTpol spectrum	N_b	χ^2_min	N_σ	χ^2_min	N_σ	χ^2_p	PTE
$TE + EE$	112	146.1	2.91	137.4	2.31	9.85	0.08
TE	56	71.4	2.38	70.3	2.27	3.38	0.64
EE	56	67.3	1.96	61.4	1.37	8.21	0.15

$\gtrsim 2\,\sigma$ tension with the base-ΛCDM model and found a trend for the parameters of the base-ΛCDM model to drift away from the *Planck* solution as the SPTpol likelihood is extended to higher multipoles. To assess these results we have performed some tests of the consistency of the latest *Planck* results and the SPTpol spectra.

As a reference model for SPTpol we adopt the base-ΛCDM parameters for the combined TE+EE fit to the SPTpol data from table 5 of [169]. It is worth noting that the best-fit SPTpol cosmology is strongly excluded by the *Planck* TT spectra and by the *Planck* $TE+EE$ spectra. We use the *Planck* TT,TE,EE+lowE+lensing base-ΛCDM best-fit cosmology (as plotted in Fig. 176) as a reference model for *Planck*. For each model, we ran the public version of the SPTpol likelihood code,[147] sampling the nuisance parameters using the same priors as in [169]. The best-fit values of χ^2 are listed in Table 26. As in [169], in assigning significance levels to these values, we take the number of degrees of freedom to be equal to the number of band powers minus eight, corresponding to five cosmological parameters (ω_b, ω_c, θ_MC, n_s, $A_\mathrm{s}e^{-2\tau}$) and three nuisance parameters with flat priors.

As found by [169], the SPTpol TE spectrum gives nearly identical values of χ^2 for both the SPTpol and *Planck* cosmologies and so does not differentiate between them; however, the χ^2 values are high, at the $2.3\,\sigma$ level. The SPTpol EE spectrum provides weaker constraints on cosmological parameters than the TE spectrum and is clearly better fit by the SPTpol cosmology. If the SPTpol covariance matrix is accurate, the combined TE+EE SPTpol data disfavour the *Planck* ΛCDM cosmology quite strongly and disfavour any 6-parameter ΛCDM cosmology. For ΛCDM models, outliers distributed over a wide range of multipoles contribute to the high χ^2 values, notably at $\ell = 124$, 324, 1874, 2449, and 3249 in TE, and $\ell = 1974$ and 6499 in EE.

We can assess consistency of the parameter differences, $\mathbf{\Delta p}$, between the two experiments by computing,

$$\chi^2_p = \mathbf{\Delta p}^\mathsf{T} \mathrm{C}_p^{-1} \mathbf{\Delta p}, \tag{1219}$$

where C_p is the covariance matrix for SPTpol parameters (we neglect the errors in the *Planck* parameters, which are much smaller). Values for χ^2_p are given in Table 26 together with probabilities to exceed (PTEs) computed from a χ^2 distribution with five degrees of freedom. We find no evidence for any statistically significant inconsistency between the two sets of parameters, even for the combined $TE + EE$ SPTpol likelihood. We also note that the parameter $A_\mathrm{s}e^{-2\tau}$ makes quite a large contribution to χ^2_p for the $TE + EE$ and EE spectra, but is sensitive to possible systematic errors in the SPTpol polarization efficiency calibration [169, which, as discussed, is not well understood]. Varying the maximum multipole used in the SPTpol likelihood (ℓ_max), we find that the parameters of the SPTpol TE+EE cosmology converge by $\ell_\mathrm{max} = 2500$; higher multipoles do not contribute significantly to the SPTpol base-ΛCDM solution.

[169] reported a trend for the parameters of the base-ΛCDM cosmology to change as the SPTpol likelihood is extended to higher multipoles, which they suggested may be an indication

[147] Downloaded from http://pole.uchicago.edu/public/data/henning17/ . Note that we discovered errors in the way that the covariances matrices were loaded for separate TE and EE analyses, which have been corrected in the analysis presented here.

of new physics. However, this effect is not of high statistical significance and cannot be tested by the *Planck* spectra, which become less sensitive than the SPTpol spectra at multipoles $\gtrsim 1500$. The consistency of the base-ΛCDM cosmology at high multipoles in polarization should become clearer in the near future as more polarization data are accumulated by ACTPol and SPTpol.

27.5 Comparison with other astrophysical data sets

27.5.1 Baryon acoustic oscillations

As in PCP13 and PCP15 baryon acoustic oscillation (BAO) measurements from galaxy redshift surveys are used as the primary non-CMB astrophysical data set in this paper. The acoustic scale measured by BAOs, at around 147 Mpc, is much larger than the scale of virialized structures. This separation of scales makes BAO measurements insensitive to nonlinear physics, providing a robust geometrical test of cosmology. It is for this reason that BAO measurements are given high weight compared to other non-CMB data in this and in previous *Planck* papers. BAO features in the galaxy power spectrum were first detected by [80] and [119]. Since their discovery, BAO measurements have improved in accuracy via a number of ambitious galaxy surveys. As demonstrated in PCP13 and PCP15 BAO results from galaxy surveys have been consistently in excellent agreement with the best-fit base-ΛCDM cosmology inferred from *Planck*. More recently, the redshift reach of BAO measurements has been increased using quasar redshift surveys and Lyman-α absorption lines detected in quasar spectra.

Figure 177 summarizes the latest BAO results, updating figure 14 of PCP15. This plot shows the acoustic-scale distance ratio $D_{\rm V}(z)/r_{\rm drag}$ measured from surveys with effective redshift z, divided by the mean acoustic-scale ratio in the base-ΛCDM cosmology using *Planck* TT,TE,EE +lowE+lensing. Here $r_{\rm drag}$ is the comoving sound horizon at the end of the baryon drag epoch and $D_{\rm V}$ is a combination of the comoving angular diameter distance $D_{\rm M}(z)$ and Hubble parameter $H(z)$:

$$D_{\rm V}(z) = \left[D_{\rm M}^2(z)\frac{cz}{H(z)}\right]^{1/3}. \tag{1220}$$

The grey bands in the figure show the $\pm1\,\sigma$ and $\pm2\,\sigma$ ranges allowed by *Planck* in the base-ΛCDM cosmology.

Compared to figure 14 of PCP15, we have replaced the Baryon Oscillation Spectroscopic Survey (BOSS) LOWZ and CMASS results of Anderson et al. [23] with the latest BOSS data release 12 (DR12) results summarized by [15]. That paper reports "consensus" results on BAOs (weighting together different BAO analyses of BOSS DR12) reported by [314], [359], and [50] in three redshift slices with effective redshifts $z_{\rm eff} = 0.38$, 0.51, and 0.61. These new measurements, shown by the red triangles in Fig. 177, are in good agreement with the *Planck* base-ΛCDM cosmology.

By using quasars, it has become possible to extend BAO measurements to redshifts greater than unity. [28] have measured the BAO scale D_V at an effective redshift of $z_{\rm eff} = 1.52$ using a sample of quasars from the extended Baryon Oscillation Survey (eBOSS). This measurement is shown by the red circle in Fig. 177 and is also in very good agreement with *Planck*. The results of the Ata et al. [28] analysis also agree well with other analyses of the eBOSS quasar sample [e.g., 147].

At even higher redshifts BAOs have been measured in the Lyman α spectra of quasars [102, 136, 37, 114, 96, 57]. In the first preprint version of this paper, we compared the *Planck* results with those from BAO features measured from the flux-transmission correlations of Sloan Digital Sky Survey (SDSS) DR12 quasars [37] and with the cross-correlation of the Ly α forest with SDSS quasars [114]. The combined result on $D_{\rm M}/r_{\rm drag}$ from these analyses was about $2.3\,\sigma$ lower than expected from the best-fit *Planck* base-ΛCDM cosmology. The [37] and du Mas des Bourboux et al. [114] analyses have been superseded by equivalent studies of a larger sample of SDSS DR14 quasars reported in [96] and [57]. The combined result for $D_{\rm M}/r_{\rm drag}$ from these analyses [as quoted by 57] is plotted as the orange hexagon on Fig. 177 and lies within $1.7\,\sigma$ of the *Planck* best-fit model. The errors on these high-redshift BAO measurements are still quite large in comparison with the galaxy measurements and so we do not include them in our default BAO compilation.[148]

[148]The first preprint version of this paper showed that the inclusion of the [37] and du Mas des Bourboux

The more recent BAO analyses solve for the positions of the BAO feature in both the line-of-sight and transverse directions (the distortion in the transverse direction caused by the background cosmology is sometimes called the Alcock-Paczynski effect, Alcock & Paczynski 16), leading to joint constraints on the angular diameter distance $D_{\rm M}(z_{\rm eff})$ and the Hubble parameter $H(z_{\rm eff})$. These constraints for the BOSS DR12 analysis are plotted in Fig. 178. Samples from the *Planck* TT+lowE and *Planck* TT,TE,EE+lowE+lensing likelihood are shown in green and red, respectively, demonstrating that BAO and *Planck* polarization data with lensing consistently pull parameters in the same direction (towards slightly lower $\Omega_{\rm c}h^2$). We find the same behaviour for *Planck* when adding polarization and lensing to the *TT* likelihood separately. This demonstrates the remarkable consistency of the *Planck* data, including polarization and CMB lensing with the galaxy BAO measurements. Evidently, the *Planck* base-ΛCDM parameters are in good agreement with both the isotropized $D_{\rm V}$ BAO measurements plotted in Fig. 177, and with the anisotropic constraints plotted in Fig. 178.

In this paper, we use the 6dFGS and SDSS-MGS measurements of $D_{\rm V}/r_{\rm drag}$ [47, 313] and the final DR12 anisotropic BAO measurements of Alam et al. [15]. Since the WiggleZ volume partially overlaps that of the BOSS-CMASS sample, and the correlations have not been quantified, we do not use the WiggleZ results in this paper. It is clear from Fig. 177 that the combined BAO likelihood for the lower redshift points is dominated by the BOSS measurements.

In the base-ΛCDM model, the *Planck* data constrain the Hubble constant H_0 and matter density $\Omega_{\rm m}$ to high precision:

$$\left.\begin{aligned} Planck2018CosmolParam/H_0 &= (67.36 \pm 0.54)\ \text{km s}^{-1}\text{Mpc}^{-1}, \\ \Omega_{\rm m} &= 0.3158 \pm 0.0073, \end{aligned}\right\}\ \begin{array}{l}68\,\%,\ \text{TT,TE,EE} \\ \text{+lowE+lensing.}\end{array} \tag{1221}$$

With the addition of the BAO measurements, these constraints are strengthened to

$$\left.\begin{aligned} Planck2018CosmolParam/H_0 &= (67.66 \pm 0.42)\ \text{km s}^{-1}\text{Mpc}^{-1}, \\ \Omega_{\rm m} &= 0.3111 \pm 0.0056, \end{aligned}\right\}\ \begin{array}{l}68\,\%,\ \text{TT,TE,EE} \\ \text{+lowE+lensing} \\ \text{+BAO.}\end{array} \tag{1222}$$

These numbers are in very good agreement with the constraints given in Eq. (1200), which exclude the high-multipole *Planck* likelihood. Section 27.5.4 discusses the consistency of direct measurements of H_0 with these estimates and Hubble parameter measurements from the line-of-sight component of BAOs at higher redshift.

As discussed above, we have excluded Ly α BAOs from our default BAO compilation. The full likelihood for the combined Ly α and Ly α-quasar cross-correlations reported in du Mas des Bourboux et al. [114] is not yet available; nevertheless, we can get an indication of the impact of including these measurements by assuming uncorrelated Gaussian errors on $D_{\rm M}/r_{\rm drag}$ and $r_{\rm drag}H$. Adding these measurements to *Planck* TT,TE,EE+lowE and our default BAO compilation shifts H_0 higher, and $\Omega_{\rm m}h^2$ and σ_8 lower, by approximately $0.3\,\sigma$. The joint *Planck*+BAO result then gives $D_{\rm M}/r_{\rm drag}$ and $r_{\rm drag}H$ at $z = 2.4$ lower by 0.25 and 0.3 of *Planck*'s σ, leaving the overall $2.3\,\sigma$ tension with these results almost unchanged. As shown by Aubourg et al. [29], it is difficult to construct well-motivated extensions to the base-ΛCDM model that can resolve the tension with the Ly α BAOs. Further work is needed to assess whether the discrepancy between *Planck* and the Ly α BAO results is a statistical fluctuation, is caused by small systematic errors, or is a signature of new physics.

27.5.2 Type Ia supernovae

The use of type Ia supernovae (SNe) as standard candles has been of critical importance to cosmology, leading to the discovery of cosmic acceleration [307, 266]. For ΛCDM models,

et al. [114] Ly α BAO results had a minor impact on the parameters of the base-ΛCDM cosmology. The impact of the more recent Ly α results of [96] and [57] will be even lower, since they are in closer agreement with the *Planck* best-fit cosmology.

however, SNe data have little statistical power compared to *Planck* and BAO and in this paper they are used mainly to test models involving evolving dark energy and modified gravity. For these extensions of the base cosmology, SNe data are useful in fixing the background cosmology at low redshifts, where there is not enough volume to allow high precision constraints from BAO.

In PCP15 we used the "Joint Light-curve Analysis" (JLA) sample constructed from the SNLS and SDSS SNe plus several samples of low redshift SNe described in Betoule et al. [46, 45] and Mosher et al. [241]. In this paper, we use the new "Pantheon" sample of Scolnic et al. [329], which adds 276 supernovae from the Pan-STARRS1 Medium Deep Survey at $0.03 < z < 0.65$ and various low-redshift and HST samples to give a total of 1048 supernovae spanning the redshift range $0.01 < z < 2.3$. The Pantheon compilation applies cross-calibrations of the photometric systems of all of the sub-samples used to construct the final catalogue [328], reducing the impact of calibration systematics on cosmology[149]. The Pantheon data are compared to the predictions of the *Planck* TT,TE,EE+lowE+lensing base-ΛCDM model best fit in Fig. 179. The agreement is excellent. The JLA and Pantheon samples are consistent with each other (with Pantheon providing tighter constraints on cosmological parameters) and there would be no significant change to our science conclusions had we chosen to use the JLA sample in this paper. To illustrate this point we give results for a selection of models using both samples in the parameter tables available in the PLA; Fig. 183, illustrating inverse-distance-ladder constraints on H_0 (see Sect. 27.5.4), shows a specific example.

27.5.3 Redshift-space distortions

The clustering of galaxies observed in a redshift survey exhibits anisotropies induced by peculiar motions (known as redshift-space distortions, RSDs). Measurement of RSDs can provide constraints on the growth rate of structure and the amplitude of the matter power spectrum [e.g., 263]. Since it uses non-relativistic tracers, RSDs are sensitive to the time-time component of the metric perturbation or the Newtonian potential. A comparison of the amplitude inferred from RSDs with that inferred from lensing (sensitive to the Weyl potential, see Sect. **??**). provides a test of General Relativity.

Measurements of RSDs are usually quoted as constraints on $f\,\sigma_8$, where for models with scale-independent growth $f = d\ln D/d\ln a$. For ΛCDM, $d\ln D/d\ln a \approx \Omega_{\rm m}^{0.55}(z)$. We follow PCP15, defining

$$f\,\sigma_8 \equiv \frac{\left[\sigma_8^{(\rm vd)}(z)\right]^2}{\sigma_8^{(\rm dd)}(z)}, \tag{1223}$$

where $\sigma_8^{(\rm vd)}$ is the density-velocity correlation in spheres of radius $8\,h^{-1}$Mpc in linear theory.

Measuring $f\,\sigma_8$ requires modelling nonlinearities and scale-dependent bias and is considerably more complicated than estimating the BAO scale from galaxy surveys. One key problem is deciding on the precise range of scales that can be used in an RSD analysis, since there is a need to balance potential systematic errors associated with modelling nonlinearities against reducing statistical errors by extending to smaller scales. In addition, there is a partial degeneracy between distortions caused by peculiar motions and the Alcock-Paczynski effect. Nevertheless, there have been substantial improvements in modelling RSDs in the last few years, including extensive tests of systematic errors using numerical simulations. Different techniques for measuring $f\,\sigma_8$ are now consistent to within a few percent [15].

Figure 180, showing $f\,\sigma_8$ as a function of redshift, is an update of figure 16 from PCP15. The most significant changes from PCP15 are the new high precision measurements from BOSS DR12, shown as the red points. These points are the "consensus" BOSS D12 results from Alam et al. [15], which averages the results from four different ways of analysing the DR12 data [49, 153, 323, 324]. These results are in excellent agreement with the *Planck* base ΛCDM cosmology (see also Fig. 181) and provide the tightest constraints to date on the growth rate of fluctuations. We have updated the VIPERS constraints to those of the second public data release [269] and added a data point from the Galaxy and Mass Assembly (GAMA) redshift survey [53]. Two new surveys have extended the reach of RSD measurements (albeit with large

[149]We use the November 2018 data file available from https://github.com/dscolnic/Pantheon/, which includes heliocentric redshifts and no bulk-flow corrections for $z > 0.08$.

errors) to redshifts greater than unity: the deep FASTSOUND emission line redshift survey [250]; and the BOSS DR14 quasar survey [373]. We have also added a new low redshift estimate of $f\,\sigma_8$ from [187] at an effective redshift of $z_{\rm eff} = 0.023$, which is based on correlating deviations from the mean magnitude-redshift relation of SNe in the Pantheon sample with estimates of the nearby peculiar velocity field determined from the 6dF Galaxy Survey [348]. As can be seen from Fig. 180, these growth rate measurements are consistent with the *Planck* base-ΛCDM cosmology over the entire redshift range $0.023 < z_{\rm eff} < 1.52$.

Since the BOSS-DR12 estimates provide the strongest constraints on RSDs, it is worth comparing these results with *Planck* in greater detail. Here we use the "full-shape consensus" results[150] on D_V, $f\,\sigma_8$, and $F_{\rm AP}$ for each of the three redshift bins from [15] and the associated 9×9 covariance matrix, where $F_{\rm AP}$ is the Alcock-Paczinski parameter,

$$F_{\rm AP}(z) = D_{\rm M}(z)\frac{H(z)}{c}. \tag{1224}$$

Figure 181 shows the constraints from BOSS-DR12 on $f\,\sigma_8$ and $F_{\rm AP}$ marginalized over D_V. *Planck* base-ΛCDM constraints are shown by the red and green contours. For each redshift bin, the *Planck* best-fit values of $f\,\sigma_8$ and $F_{\rm AP}$ lie within the 68 % contours from BOSS-DR12. Figure 181 highlights the impressive consistency of the base-ΛCDM cosmology from the high redshifts probed by the CMB to the low redshifts sampled by BOSS.

27.5.4 The Hubble constant

Perhaps the most controversial tension between the *Planck* ΛCDM model and astrophysical data is the discrepancy with traditional distance-ladder measurements of the Hubble constant H_0. PCP13 reported a value of $H_0 = (67.3 \pm 1.2)$ km s^{-1}Mpc^{-1} for the base-ΛCDM cosmology, substantially lower that the distance-ladder estimate of $H_0 = (73.8 \pm 2.4)$ km s^{-1}Mpc^{-1} from the SH0ES[151] project [308] and other H_0 studies [e.g., 137, 140]. Since then, additional data acquired as part of the SH0ES project [309, 310, hereafter R18] has exacerbated the tension. R18 conclude that $H_0 = (73.48 \pm 1.66)$ km s^{-1}Mpc^{-1}, compared to our *Planck* TT,TE,EE +lowE+lensing estimate from Table 1 of $H_0 = (67.27 \pm 0.60)$ km s^{-1}Mpc^{-1}. Using Gaia parallaxes Riess et al. [311] slightly tightened their measurement to $H_0 = (73.52 \pm 1.62)$ km s^{-1}Mpc^{-1}. Recently Riess et al. [306] then used improved measurements of LMC Cepheids to further tighten[152] the constraint to $H_0 = (74.03 \pm 1.42)$ km s^{-1}Mpc^{-1}. Interestingly, the central values of the SH0ES and *Planck* estimates have hardly changed since the appearance of PCP13, but the errors on both estimates have shrunk so that the discrepancy has grown from around $2.5\,\sigma$ in 2013 to $3.5\,\sigma$ today [$4.4\,\sigma$ using 306]. This discrepancy has stimulated a number of investigations of possible systematic errors in the either the *Planck* or SH0ES data, which have failed to identify any obvious problem with either analysis [e.g., 347, 6, 299, 115, 69, 375, 135]. It has also been argued that the Gaussian likelihood assumption used in the SH0ES analysis leads to an overestimate of the statistical significance of the discrepancy [127].

Recently, [138] have reported a determination of H_0 using the tip of the red giant branch as a distance estimator. This analysis gives $H_0 = (69.8 \pm 1.9)$ km s^{-1}Mpc^{-1}, i.e., intermediate between the SH0ES measurement and the *Planck* base-ΛCDM value. There has been some controversy (see Yuan et al. [369]) concerning the calibration of the tip of the red giant branch adopted in Freedman et al. [138], though a recent reanalysis by Freedman et al. [139] yields a value of H_0 that is almost identical to that reported in Freedman et al. [138].

Measurements of the Hubble constant using strong gravitational-lensing time delays are also higher than the *Planck* base-ΛCDM value. The most recent results, based on six strongly lensed quasars, give $H_0 = 73.3^{+1.7}_{-1.8}$ km s^{-1}Mpc^{-1} [366], which is about $3.2\,\sigma$ higher than the *Planck* value. A number of other techniques have been used to infer H_0, including stellar

[150] When using RSDs to constraint dark energy in Sect. **??**, we use the alternative $D_{\rm M}$, H, and $f\,\sigma_8$ parameterization from [15] for consistency with the DR12 BAO-only likelihood that we use elsewhere.

[151] SN, H0, for the Equation of State of dark energy.

[152] By default in this paper (and in the PLA) we use the Riess et al. [310] number (available at the time we ran our parameter chains) unless otherwise stated; using the updated number would make no significant difference to our conclusions.

ages [e.g., 193, 151], distant megamasers [305, 208, 144] and gravitational-wave standard sirens [3]. These measurements span a range of values. Nevertheless, there is a tendency for local determinations to sit high compared to the *Planck* base-ΛCDM value, with the SH0ES Cepheid-based measurement giving the most statistically significant discrepancy.

In this paper, we take the R18 estimate at face value and include it as a prior in combination with *Planck* in some of the parameter tables available on the PLA. The interested reader can then assess the impact of the R18 measurement on a wide range of extensions to the base-ΛCDM cosmology.

We already mentioned in Sect. 27.5.1 that BAO measurements along the line of sight constrain $H(z)r_{\rm drag}$. *Planck* constrains $r_{\rm drag}$ to a precision of 0.2 % for the base-ΛCDM model and so the BAO measurements can be accurately converted into absolute measurements of $H(z)$. This is illustrated by Fig. 182, which shows clearly how well the *Planck* base-ΛCDM cosmology fits the BAO measurements of $H(z)$ over the redshift range 0.3–2.5, yet fails to match the R18 measurement of H_0 at $z = 0$. The model is also consistent with the most recent Ly α BAO measurements at $z \approx 2.3$.

PCP13 and PCP15 emphasized that this mismatch between BAO measurements and forward distance-ladder measurements of H_0 is not sensitive to the *Planck* data at high multipoles. For example, combining WMAP with BAO measurements leads to $H_0 = (68.14 \pm 0.73)$ km s^{-1}Mpc^{-1} for the base-ΛCDM cosmology, which is discrepant with the R18 value at the 2.9 σ level.

Heavens et al. [164], Cuesta et al. [88], and Aubourg et al. [29] showed that the combination of CMB, BAO, and SNe data provides a powerful "inverse-distance-ladder" approach to constructing a physically calibrated distance-redshift relation down to very low redshift. For the base-ΛCDM model, this inverse-distance-ladder approach can be used to constrain H_0 without using any CMB measurements at all, or by only using constraints on the CMB parameter $\theta_{\rm MC}$ [see also 44, 7, 105, 213]. This is illustrated in Fig. 183, which shows how the constraints on H_0 and $\Omega_{\rm m}$ converge to the *Planck* values as more data are included. The green contours show the constraints from BAO and the Pantheon SNe data, together with a BBN constraint on the baryon density ($\Omega_{\rm b}h^2 = 0.0222 \pm 0.0005$) based on the primordial deuterium abundance measurements of Cooke et al. [82, see Sect. **??**]. The dashed contours in this figure show how the green contours shift if the Pantheon SNe data are replaced by the JLA SNe sample. Adding *Planck* CMB lensing (grey contours) constrains $\Omega_{\rm m}h^2$ and shifts H_0 further away from the R18 measurement. Using a "conservative" *Planck* prior of $100\theta_{\rm MC} = 1.0409 \pm 0.0006$ (which is consistent with all of the variants of ΛCDM considered in this paper to within 1 σ, see Table **??**) gives the red contours, with $H_0 = (67.9 \pm 0.8)$ km s^{-1}Mpc^{-1} and $\Omega_{\rm m} = 0.305 \pm 0.001$, very close to the result using the full *Planck* likelihood (blue contours). Evidently, there is a significant problem in matching the base-ΛCDM model to the R18 results and this tension is not confined exclusively to the *Planck* results.

The question then arises of whether there is a plausible extension to the base-ΛCDM model that can resolve the discrepancy. Table **??** summarizes the *Planck* constraints on H_0 for variants of ΛCDM considered in this paper. H_0 remains discrepant with R18 in all of these cases, with the exception of models in which we allow the dark energy equation of state to vary. For models with either a fixed dark energy equation-of-state parameter, w_0, or time-varying equation of state parameterized by w_0 and w_a (see Sect. **??** for definitions and further details), *Planck* data alone lead to poor constraints on H_0. However, for most physical dark energy models where $p_{\rm de} \geq -\rho_{\rm de}$ (so $w_0 > -1$), and the density is only important after recombination, H_0 can only decrease with respect to ΛCDM if the measured CMB acoustic scale is maintained, making the discrepancy with R18 worse. If we allow for $w_0 < -1$, then adding BAO and SNe data is critical to obtain a useful constraint [as pointed out by 29], and we find

$$H_0 = (68.34 \pm 0.81) \text{ km s}^{-1}\text{Mpc}^{-1}, \quad (w_0 \text{ varying}), \tag{1225a}$$

$$H_0 = (68.31 \pm 0.82) \text{ km s}^{-1}\text{Mpc}^{-1}, \quad (w_0, w_a \text{ varying}), \tag{1225b}$$

for the parameter combination *Planck* TT,TE,EE+lowE+lensing+BAO+Pantheon. Modifying the dark energy sector in the late universe does not resolve the discrepancy with R18.

If the difference between base ΛCDM and the R18 measurement of H_0 is caused by new physics, then it is unlikely to be through some change to the late-time distance-redshift relationship. Another possibility is a change in the sound horizon scale. If we use the R18 measurement of H_0, combined with Pantheon supernovae and BAO, the acoustic scale is $r_{\rm drag} = (136.4 \pm 3.5)$ Mpc. The difficulty is to find a model that can give this much smaller

value of the sound horizon (compared to $r_{\rm drag} = (147.05 \pm 0.3)$ Mpc from *Planck* TT,TE,EE +lowE in ΛCDM), while preserving a good fit to the CMB power spectra and a baryon density consistent with BBN. We discuss some extensions to ΛCDM in Sect. **??** that allow larger H_0 values (e.g., $N_{\rm eff} > 3.046$); however, these models are not preferred by the *Planck* data, and tend to introduce other tensions, such as a higher value of σ_8.[153]

The tension between base ΛCDM and the SH0ES H_0 measurement is intriguing and emphasizes the need for independent measurements of the distance scale. It will be interesting in the future to compare the Cepheid distance scale in more detail with other distance indicators, such as the tip of the red giant branch [138], and with completely different techniques such as gravitational-lensing time delays [352] and gravitational-wave standard sirens [180, 3, 74, 128].

27.5.5 Weak gravitational lensing of galaxies

The distortion of the shapes of distant galaxies by lensing due to large-scale structure along the line of sight is known as galaxy lensing or cosmic shear [see e.g., 35, for a review]. It constrains the gravitational potentials at lower redshift than CMB lensing, with tomographic information and completely different systematics, so the measurements are complementary. Since the source galaxy shapes and orientations are in general unknown, the lensing signal is a small effect that can only be detected statistically. If it can be measured robustly it is a relatively clean way of measuring the Weyl potential (and hence, in GR, the total matter fluctuations); however, the bulk of the statistical power comes from scales where the signal is significantly nonlinear, complicating the cosmological interpretation. The measurement is also complicated by several other issues. Intrinsic alignment between the shape of lensed galaxies and their surrounding potentials means that the galaxy shape correlation functions actually measure a combination of lensing and intrinsic alignment effects [176]. Furthermore, to get a strong statistical detection, a large sample of galaxies is needed, so most current results use samples that rely mainly on photometric redshifts; accurate calibration of the photometric redshifts and modelling of the errors are required in order to use the observed lensing signal for cosmology.

Cosmic shear measurements are available from several collaborations, including CFHTLenS [171, 121, which we discussed in PCP15], `DLS` [192], and more recently the Dark Energy Survey [DES, 106], Hyper Suprime-Cam [HSC, 172, 158], and KiDS [174, 200, 175]. The CFHTLenS and KiDS results found a modest tension with the *Planck* ΛCDM cosmology, preferring lower values of $\Omega_{\rm m}$ or σ_8. A combined analysis of KiDS with GAMA [358] galaxy clustering has found results consistent with *Planck*, whereas a similar analysis combining KiDS lensing measurements with spectroscopic data from the 2-degree Field Lensing Survey and BOSS claims a $2.6\,\sigma$ discrepancy with *Planck* [194]. [356] have shown that a more accurate treatment of the intrinsic galaxy shape noise, multiplicative shear calibration uncertainty, and angular scale of each bin can significantly change earlier KiDS results (by about $1\,\sigma$), making them more consistent with *Planck*. At the time of running our chains the DES lensing results had been published and included this improved modelling, while an updated analysis from KiDS was not yet available; we therefore only consider the DES results in detail here. [356] reports consistent results from DES and their new analysis of KiDS, and HSC also report results consistent with *Planck*. However, the more recent KiDS analysis by [175] still finds a $2.3\,\sigma$ discrepancy with *Planck*, and [195] claim that a recalibration of the DES redshifts gives results compatible with KiDS and a combined $2.5\,\sigma$ tension with *Planck*.

The DES collaboration analysed 1321 deg^2 of imaging data from the first year of DES. They analysed the cosmic shear correlation functions of 26 million source galaxies in four redshift bins [355], and also considered the auto- [120] and cross-spectrum [302] of 650 000 lens galaxies in five redshift bins. To be conservative they restricted their parameter analysis to scales that are only weakly affected by nonlinear modelling (at the expense of substantially reducing the statistical power of the data). To account for modelling uncertainties, the cosmic shear analysis marginalizes over 10 nuisance parameters, describing uncertainties in the photometric redshift

[153] To obtain simultaneously higher values of H_0, lower values of σ_8, and consistent values of $\Omega_{\rm m}$ it is necessary to invoke less common extensions of the ΛCDM model, such as models featuring non-standard interactions in the neutrino, dark-matter, dark-radiation, and/or dark-energy sector [see e.g., 267, 215, 285, 24, 209, 251, 108, 65, 301, 206, 11, 222, 25] . Such models are likely to be highly constrained by the *Planck*, BAO, and supernova data used in this paper and by future CMB observations and surveys of large-scale structure.

distributions, shear calibrations, and intrinsic alignments; the joint analysis adds an additional 10 nuisance parameters describing the bias and redshift uncertainty of the lens galaxies.

We use the first-year DES lensing (cosmic shear) likelihood, data cuts, nuisance parameters, and nuisance parameter priors, as described by Troxel et al. [355], DES Collaboration [106], Krause et al. [205]. We implement the theory model code independently, but use the same physical model and assumptions as the DES analysis,[154] treating the nuisance parameters as fast parameters for sampling in `CosmoMC`. In this section we adopt the cosmological parameter priors assumed by Troxel et al. [355], but to be consistent with our other ΛCDM analyses, we assume a single minimal-mass eigenstate rather than marginalizing over the neutrino mass, and use `HMcode` for the nonlinear corrections.[155] The shear correlation data points and parameter fits are shown in Fig. 184. Note that intrinsic alignments contribute significantly to the observed shear correlation functions (as shown by the dotted lines in the figure). This introduces additional modelling uncertainty and a possible source of bias if the intrinsic alignment model is not correct. The DES model is validated in [355, 205].

Figure 185 shows the constraints in the $\Omega_{\rm m}$–σ_8 plane from DES lensing, compared to the constraints from the CMB power spectra and CMB lensing. The DES cosmic shear constraint is of comparable statistical power to CMB lensing, but due to the significantly lower mean source redshift, the degeneracy directions are different (with DES cosmic shear approximately constraining $\Omega_{\rm m}\sigma_8^{0.5}$ and CMB lensing constraining $\Omega_{\rm m}\sigma_8^{0.25}$). The correlation between the DES cosmic shear and CMB lensing results is relatively small, since the sky area of the CMB reconstruction is much larger than that for DES, and it is also mostly not at high signal-to-noise ratio. Neglecting the cross-correlation, we combine the DES and *Planck* lensing results to break a large part of the degeneracy, giving a substantially tighter constraint than either alone. The lensing results separately, and jointly, are both consistent with the main *Planck* power-spectrum results, although preferring σ_8 and $\Omega_{\rm m}$ values at the lower end of those allowed by *Planck*. The DES joint analysis of lensing and clustering is also marginally consistent, but with posteriors preferring lower values of $\Omega_{\rm m}$ (see the next subsection). Overlap of contours in a marginalized 2D subspace does not of course guarantee consistency in the full parameter space. However, the values of the Hubble parameter in the region of $\Omega_{\rm m}$–σ_8 parameter space consistent with *Planck* $\Omega_{\rm m}$ and σ_8 are also consistent with *Planck*'s value of H_0. A joint analysis of DES with BAO and a BBN baryon-density constraint gives values of the Hubble parameter that are very consistent with the *Planck* power spectrum analysis [105].

27.5.6 Galaxy clustering and cross-correlation

The power spectrum of tracers of large-scale structure can yield a biased estimate of the matter power spectrum, which can then be used as a probe of cosmology. For adiabatic Gaussian initial perturbations the bias is expected to be constant on large scales where the tracers are out of causal contact with each other, and nearly constant on scales where nonlinear growth effects are small. Much more information is available if small scales can also be used, but this requires detailed modelling of perturbative biases out to $k \approx 0.3$–$0.6\,{\rm Mpc}^{-1}$, and fully nonlinear predictions beyond that. Any violation of scale-invariant bias on super-horizon scales would be a robust test for non-Gaussian initial perturbations protected by causality [91]. However, using the shape of the biased-tracer power spectrum on smaller scales to constrain cosmology requires at least a model of constant bias parameters for each population at each redshift, and, as precision is increased, or smaller scales probed, a model for the scale dependence of the bias. Early galaxy surveys provided cosmology constraints that were competitive with those from CMB power spectrum measurements [e.g., 264], but as precision has improved, focus has mainly moved away to using the cleaner BAO and RSD measurements and, in parallel, developing ways to get the quasi-linear theoretical predictions under better control. Most recent studies of galaxy clustering have focussed on investigating bias rather than background cosmology, with the notable exception of WiggleZ [253].

[154] Except for the modified-gravity models in Sect. **??** where we calculate the lensing spectrum directly from the power spectrum of the Weyl potential (rather than from the matter power spectrum assuming standard GR).

[155] The results are quite sensitive to the choice of cosmological parameter priors, see PL2018 for an analysis using the different priors assumed by the *Planck* CMB lensing analysis. Here we assume consistent (DES) priors for DES and CMB lensing results; however, the *Planck* power spectrum constraints are much less sensitive to priors and we use our default priors for those.

Here we focus on the first-year DES survey measurement of galaxy clustering [120] and the cross-correlation with galaxy lensing [302, "galaxy-galaxy lensing"]. By simultaneously fitting for the clustering, lensing, and cross-correlation, the bias parameters can be constrained empirically [106]. Similar analyses using KiDS lensing data combined with spectroscopic surveys have been performed by van Uitert et al. [358] and Joudaki et al. [194].

To keep the theoretical model under control (nearly in the linear regime), DES exclude all correlations on scales where modelling uncertainties in the nonlinear regime could begin to bias parameter constraints (at the price of substantially reducing the total statistical power available in the data). Assuming a constant bias parameter for each of the given source redshift bins, parameter constraints are obtained after marginalizing over the bias, as well as a photometric redshift window mid-point shift parameter to account for redshift uncertainties. Together with galaxy lensing parameters, the full joint analysis has 20 nuisance parameters. Although this is a relatively complex nuisance-parameter model, it clearly does not fully model all possible sources of error: for example, correlations between redshift bins may depend on photometric redshift uncertainties that are not well captured by a single shift in the mean of each window's population. However, Troxel et al. [355] estimate that the impact on parameters is below $0.5\,\sigma$ for all more complex models they considered. The DES theoretical model for the correlation functions (which we follow) neglects redshift-space distortions, and assumes that the bias is constant in redshift and k across each redshift bin; these may be adequate approximations for current noise levels and data cuts, but will likely need to be re-examined in the future as statistical errors improve.

Using the full combined clustering and lensing DES likelihood, for a total of 457 data points [106], the best-fit ΛCDM model has $\chi^2_{\rm eff} \approx 500$ or 513 with the *Planck* best-fit cosmology. Parameter constraints from the galaxy auto- and cross-correlation are shown in Fig. 186, together with the joint constraint with DES lensing (the comparison with DES galaxy lensing and CMB lensing alone is shown in Fig. 185).

Using the joint DES likelihood in combination with DES cosmological parameter priors gives (for our base-ΛCDM model with $\sum m_\nu = 0.06\,\text{eV}$)

$$\left.\begin{aligned} Planck2018CosmolParam/S_8 \equiv \sigma_8(\Omega_{\rm m}/0.3)^{0.5} &= 0.793 \pm 0.024, \\ \Omega_{\rm m} &= 0.256^{+0.023}_{-0.031}, \end{aligned}\right\} \quad 68\,\%,\ \text{DES}. \tag{1226}$$

Planck TT,TE,EE+lowE+lensing gives a higher value of $S_8 = 0.832 \pm 0.013$, as well as larger $\Omega_{\rm m} = 0.315 \pm 0.007$. As shown in the previous section, the DES lensing results are quite compatible with *Planck*, although peaking at lower $\Omega_{\rm m}$ and σ_8 values. The full joint DES likelihood, however, shrinks the error bars in the σ_8–$\Omega_{\rm m}$ plane so that only 95 % confidence contours overlap with *Planck* CMB data, giving a moderate (roughly 2 % PTE) tension, as shown in Fig. 186. The dotted contour in Fig. 186 shows the result using the `CamSpec` *Planck* likelihood, which gives results slightly more consistent with DES than the default `Plik` likelihood. The *Planck* result is therefore sensitive to the details of the polarization modelling at the $0.5\,\sigma$ level, and the tension cannot be quantified robustly beyond this level.

Combining DES with the baseline *Planck* likelihood pulls the *Planck* result to lower $\Omega_{\rm m}$ and slightly lower σ_8, giving

$$\left.\begin{aligned} Planck2018CosmolParam/S_8 &= 0.811 \pm 0.011, \\ \Omega_{\rm m} &= 0.3040 \pm 0.0060, \\ \sigma_8 &= 0.8062 \pm 0.0057, \end{aligned}\right\} \quad \begin{array}{l} 68\,\%,\ Planck \\ \text{TT,TE,EE+lowE} \\ \text{+lensing+DES}. \end{array} \tag{1227}$$

A similar shift is seen without including *Planck* lensing, and is disfavoured by *Planck* CMB with a total $\Delta\chi^2_{\rm eff} \approx 13$ for the CMB likelihoods (comparing the *Planck*-only best fit to the fit when combined with DES). The shift in parameters is also larger than would be expected for Gaussian distributions, given the small change in parameter covariance. The corresponding change in $\chi^2_{\rm eff}$ for the DES likelihood is $\Delta\chi^2_{\rm eff} \approx 10$, which is high, but less surprising given the 4–5 contribution expected from the number of parameters that are much better constrained by *Planck*. The summary consistency statistic $\chi^2_{\rm eff,joint} - \chi^2_{\rm eff,DES} - \chi^2_{\rm eff,Planck} \approx 14$, which is high at the roughly 1 % PTE level, given the expected value of 4, assuming roughly Gaussian statistics [304].

In summary, the DES combined probes of ΛCDM parameters are in moderate percent-level tension with *Planck*. Whether this is a statistical fluctuation, evidence for systematics, or new physics is currently unclear. In this paper, we follow the philosophy of PCP13 and PCP15 of making minimal use of other astrophysical data in combination with *Planck*, using BAO as our primary complementary data set. We therefore do not include DES results in most of the parameter constraints discussed in this paper. We do, however, consider the impact of the DES weak lensing results on dark-energy and modified-gravity constraints in Sect. **??** and on neutrino masses in Sect. **??**. We also include DES for a wider range of models in the *Planck* parameter tables available on the PLA.

27.5.7 Cluster counts

Counts of clusters of galaxies provide an additional way of constraining the amplitude of the power spectrum at low redshifts [e.g., 270, 204, and references therein]. *Planck* clusters, selected via the thermal Sunyaev-Zeldovich (tSZ) signature, were used to explore cosmological parameters in [278]. This analysis was revisited using a deeper sample of *Planck* clusters in [289]. We have not produced a new tSZ cluster catalogue in the 2018 *Planck* data release and so the results presented in this section are based on the 439 clusters in the MMF3 cluster cosmology sample, as analysed in [289]. Comparison with the 2018 CMB *Planck* power spectrum results show differences primarily from changes to the base-ΛCDM model parameters caused by the tighter constraints on τ. The impact of the lower value of τ reported in [297] on the interpretation of cluster counts has been discussed by [321].

We first review the main results from [289]. There has been increasing recognition that the calibration of cluster masses is the dominant uncertainty in using cluster counts to estimate cosmological parameters. In the analysis of *Planck* clusters, the cluster tSZ observable was related to the cluster mass M_{500}[156] using X-ray scaling relations [26], calibrated against a subsample of the *Planck* clusters. The X-ray masses are, however, derived assuming hydrostatic equilibrium and are expected to be biased low [e.g., 245]. This was accounted for by multiplying the true masses by a so-called "hydrostatic mass bias" factor of $(1-b)$. The strongest constraints on this bias factor come from weak gravitational lensing estimates of cluster masses. Planck Collaboration XXIV [289] considered three lensing mass calibrations[157]: $(1-b) = 0.69 \pm 0.07$ from 22 *Planck* clusters from the Weighing the Giants lensing programme [364]; $(1-b) = 0.78 \pm 0.08$ from 37 *Planck* clusters calibrated by the Canadian Cluster Comparison Project [178]; and $1/(1-b) = 0.99 \pm 0.19$ from *Planck* CMB-lensing mass estimates of the MMF3 cluster sample [289]. More recently, Sereno et al. [337] have analysed 35 *Planck* clusters with galaxy shear data from the CFHTLenS [170] and RCSLenS [173] surveys, finding $(1-b) \approx 0.77 \pm 0.11$ for all clusters and $(1-b) = 0.68 \pm 0.11$ for the 15 clusters in the cosmological sample. Additionally, Penna-Lima et al. [262] use gravitational lensing measurements from HST images of 21 *Planck* clusters finding $(1-b) = 0.73 \pm 0.10$.

The determination of cosmological parameters such as σ_8 and Ω_m from *Planck* cluster counts is strongly dependent on the prior adopted for the mass bias parameter. In this paper, we use the *Planck* TT,TE,EE+lowE+lensing likelihood in combination with the *Planck* cluster counts to derive a constraint on $(1-b)$ (following similar analyses described in Planck Collaboration XX 288 and Salvati et al. 321). This gives Planck2018CosmolParam/

$$Planck2018CosmolParam/(1-b) = 0.62 \pm 0.03 \quad \begin{array}{l}(68\,\%,\ Planck\ \text{TT,TE,EE} \\ +\text{lowE}+\text{lensing}),\end{array} \tag{1228}$$

compared to 0.58 ± 0.04 using the 2015 TT,TE,EE+lowP likelihood [288]. The roughly $1\,\sigma$ upward shift in Eq. (1228) is mainly caused by the 2018 change in the τ constraint. The mass bias of Eq. (1228) is at the lower end of the weak-lensing mass estimates, but is about $2\,\sigma$ lower that the *Planck* CMB-lensing mass calibration reported in [288].

Zubeldia & Challinor [378] have revisited the *Planck* CMB-lensing mass calibration, incorporating the CMB-lensing mass estimates within a likelihood describing the *Planck* cluster

[156] The mass contained within a sphere of radius R_{500}, centred on the cluster, where R_{500} is the radius at which the mean density is 500 times the critical density at the redshift of the cluster.

[157] See [340] for a discussion of dynamical mass estimates for SZ-selected clusters.

counts, together with a *Planck* prior on $\theta_{\rm MC}$. This study corrects for significant biases in the analysis reported in [288]. [378] find $(1-b) = 0.71 \pm 0.10$ and $\sigma_8(\Omega_{\rm m}/0.33)^{0.25} = 0.765 \pm 0.035$. These results, based entirely on *Planck* data, are consistent with the base-ΛCDM parameters from the *Planck* power spectra and with the inferred mass bias of Eq. (1228).

Since PCP15 there have been a number of new analyses of cluster counts using other surveys. Two recent studies [231, 95], with very different selection criteria, use weak gravitational lensing mass determinations from the Weighing the Giants programme to calibrate cluster scaling relations. [95] analysed a sample of 377 clusters at $z > 0.25$ identified with SPT, finding $\sigma_8(\Omega_{\rm m}/0.27)^{0.3} = 0.797 \pm 0.031$, while Mantz et al. [231] analysed an X-ray-selected sample of clusters from the ROSAT All-Sky survey, finding $\sigma_8(\Omega_{\rm m}/0.3)^{0.17} = 0.81 \pm 0.03$. These measurements can be compared to our baseline ΛCDM constraints (*Planck* TT,TE,EE+lowE +lensing) of $\sigma_8(\Omega_{\rm m}/0.27)^{0.3} = 0.849 \pm 0.010$ and $\sigma_8(\Omega_{\rm m}/0.3)^{0.17} = 0.817 \pm 0.076$.

Schellenberger & Reiprich [326] have analysed a sample of 64 of the brightest X-ray clusters using a prior on the hydrostatic mass bias from [52]. These authors find $\Omega_{\rm m} = 0.303 \pm 0.009$, $\sigma_8 = 0.790^{+0.030}_{-0.028}$, and $S_8 = \sigma_8(\Omega_{\rm m}/0.3)^{1/2} = 0.792 \pm 0.054$. Each of these numbers is within about $1\,\sigma$ of the *Planck* base-ΛCDM best-fit cosmology reported in this paper. Finally, we mention the analysis of ROSAT-observed X-ray clusters carried out by Böhringer et al. [58, 59]. These authors choose a central value for the hydrostatic mass bias of $(1-b) = 0.9$, although they allow for small variations in the slope (7 %) and normalization (14 %) of the X-ray luminosity-mass relation; they find constraints the σ_8–$\Omega_{\rm m}$ plane in tension with *Planck* at about $2.5\,\sigma$.

In summary, accurate calibrations of cluster masses are essential if cluster counts are to be used as cosmological probes. Given the uncertainties in these calibrations, we do not use cluster counts in our main parameter grid. Consistency of cluster counts with the best-fit *Planck* base-ΛCDM cosmology requires hydrostatic mass biases (Eq. 1228) that are at the lower end, but within about $1\,\sigma$ of bias factors estimated from weak-lensing cluster masses. The combined *Planck* CMB-lensing and cluster-count analysis reported by [378] is in good agreement with the *Planck* base-ΛCDM cosmology. At this time, there is no compelling evidence for a discrepancy between *Planck*-, SPT-, or X-ray-selected cluster counts and the base-ΛCDM model.

27.6 Internal consistency of ΛCDM model parameters

In this section we briefly discuss a couple of curious features of the *Planck* data that lead to moderate tensions in parameter consistency tests. We first discuss how parameters vary between high and low multipoles, and the relevant features in the power spectra that may be responsible for these shifts. We then discuss the related issue of how the full multipole range appears to prefer more lensing than predicted by ΛCDM fits. We end this section with a discussion of systematic uncertainties.

27.6.1 Consistency of high and low multipoles

The *Planck* CMB temperature power spectrum shows a conspicuous dip over the multipole range $20 \lesssim \ell \lesssim 30$ compared to ΛCDM fits, as can be seen in Fig. 167. This feature was first observed by WMAP [43], and was discussed in detail in PCP13. Since it is detected consistently by both WMAP and *Planck* at multiple frequencies, it cannot plausibly be explained by an instrumental systematic or foreground. The large-scale *Planck* temperature map is signal dominated, so the dip feature is almost identical in this final release. PCP13 also noted an approximately $2.7\,\sigma$ mismatch between the best-fit ΛCDM cosmology and the amplitude of the measured temperature power spectrum at $\ell \leq 30$. However, with the tighter optical depth constraints used in this paper and improvements in the high multipole likelihoods we find no strong evidence for an amplitude mismatch. The *Planck* TT,TE,EE+lowE+lensing best-fit ΛCDM model provides a good overall fit to the temperature multipoles at $\ell < 30$ ($\chi^2_{\rm eff} \approx 23$ for 28 data points), and because of the skewed χ^2-like distribution of the CMB spectrum estimators, it is expected that typically more than half of the data points are below the theoretical model values (see Fig. 167). The statistical significance of the dip feature is hard to quantify, since it was identified a posteriori, but PPL15 suggest a significance of about 2.8 % after maximizing over extremal ℓ ranges found in simulations. This could be an indication of new physics at large scales, for example associated with a sharp feature in the inflationary potential [as considered by 260, and many subsequent researchers]. Alternatively, it could just be a statistical fluctuation,

which is our baseline assumption. However, since the dip is a relatively unusual fluctuation and it is near one end of the multipole range, it tends to pull cosmological parameters more than would be expected in typical realizations of a ΛCDM cosmology. This needs to be borne in mind in assessing parameter shifts between low and high multipoles.

WMAP measured the CMB temperature fluctuations up to $\ell \approx 800$ [42]. The higher-resolution data from *Planck* substantially increases the multipole range of the temperature power spectrum out to $\ell \approx 2500$. Cosmological parameters are therefore expected to shift (usually towards the truth) from the mean posterior values measured by WMAP, together with a reduction in the error bars. This is what is seen, with the *Planck* values of H_0 and n_s decreasing, and Ω_m and $\Omega_m h^2$ increasing, along with substantially smaller errors. However as noted in PCP13 the magnitudes of the shifts appear to be slightly larger than might be expected statistically, assuming the base-ΛCDM cosmology. This stimulated additional work on the consistency of the *Planck* power spectra reported in PPL15 and to further investigations of the consistency of cosmological parameters measured from high and low multipoles from *Planck* [6, 299]. As noted in the introduction, there is a very good agreement between *Planck* and WMAP temperature maps on the scales observed by WMAP [282, 186], but an inconsistency with high multipoles could indicate either new physics beyond ΛCDM, or the presence of some unidentified systematics associated with the *Planck* data and/or the foreground model. Planck Collaboration Int. LI [299] find that although some cosmological parameters differ by more than $2\,\sigma$ between $\ell < 800$ and $\ell > 800$, accounting for the multi-dimensional parameter space including correlations between parameters, the shifts are at the 10 % level and hence not especially unusual. Nonetheless, parameter shifts, particularly in the fluctuation amplitude and Hubble parameter (which are directly relevant for the ΛCDM-comparison with external data, as discussed in Sect. 27.5) are worth a brief re-examination using the additional information provided by the *Planck* polarization spectra.

Constraints on cosmological parameters from power spectra at high multipoles require a foreground model. Previous studies have shown that results are not very sensitive to the specific assumptions that are made within the broad context of slowly varying foreground spectra expected on physical grounds [6, 299]. In this section, we use the `plik_lite` *Planck* likelihood, described in detail in PPL18, which has the standard `Plik` foreground and nuisance parameters marginalized out without further assumptions on the cosmology.[158] For standard model extensions `plik_lite` accurately reproduces results from the full `Plik` likelihood. It allows us to explore the high-ℓ likelihood accounting for foreground uncertainties, but with the foregrounds constrained in a sensible way from their spectra over the full multipole range. We consider the multipole ranges $\ell \leq 801$ and $\ell \geq 802$ (corresponding to the boundary of one of the `plik_lite` bins), so that the low-multipole range is roughly comparable to WMAP and the two ranges have similar statistical power on most parameters. Results splitting at $\ell \approx 1000$ are similar, but with larger errors in the high multipole range.

Figure 187 shows a comparison of the high and low multipole ranges, both for temperature (lower triangle, as previously discussed by Addison et al. 6 and Planck Collaboration Int. LI 299), and new results for the combined temperature-polarization likelihood (upper triangle). Part of the difference between the low- and high-multipole ranges is caused by the large-scale temperature dip discussed above; if we exclude multipoles $\ell < 30$ (unfilled grey contours), the contours from $\ell \leq 801$ shift towards the area of consistency with the high multipoles. This could indicate that the low-multipole results have been pulled unusually far from the truth by the large-scale power spectrum dip; if so, the WMAP temperature results would also have been pulled at a similar (but not identical) level. The region of overlap of the high- and low-multipole parameter constraints is consistent with constraints from the nearly-independent combination of EE polarization and lensing with a conservative $\Omega_b h^2$ prior (green contours). This is consistent with a statistical fluctuation pulling the low and high multipoles in opposite directions, so that their intersection is closer to the truth if ΛCDM is correct.

Figure 188 shows marginalized individual parameter constraints, and also a comparison with the results from the polarization likelihoods at high and low multipoles. The $\ell \geq 802$ temperature results pull parameters to a region of higher matter density and fluctuation amplitude (and to lower n_s and H_0) than the lower multipole range, and predict a CMB lensing amplitude parameter $\sigma_8 \Omega_m^{0.25} = 0.649 \pm 0.018$. This is in tension with the CMB lensing-reconstruction

[158] We do not attempt to quantify likelihood modelling differences in this section, but a `CamSpec`-based likelihood gives slightly less tension between high and low multipoles (especially with polarization), associated with the weaker preference for $A_L > 1$, as discussed in more detail in Sect. 27.6.2.

measurement of $\sigma_8\Omega_{\rm m}^{0.25} = 0.589 \pm 0.020$ at $2.2\,\sigma$ (as pointed out by Addison et al. 6 with 2015 data; also see the closely-related discussion in the next subsection). As shown in Fig. 188, combining the $\ell \geq 802$ CMB likelihood with the lensing reconstruction, all parameter results move back towards the same region of parameter space as combining with $\ell \leq 801$, consistent with the high-ℓ temperature result having fluctuated high along the main degeneracy direction. As discussed in Sects. 27.2.3 and 27.3.3, the combined CMB power spectrum results over the full multipole range are consistent with the lensing likelihood.

It is also interesting to compare to parameter constraints from the CMB power spectrum multipoles $\ell \leq 801$ combined with the lensing and BAO, which gives

$$\left.\begin{aligned} Planck2018CosmolParam/H_0 &= (67.85 \pm 0.52)\ \text{km s}^{-1}\text{Mpc}^{-1}, \\ \sigma_8 &= 0.8058 \pm 0.0063, \\ \Omega_{\rm m} &= 0.3081 \pm 0.0065. \end{aligned}\right\} \begin{array}{l} 68\,\%,\ \text{TT,TE,EE} \\ [\ell \leq 801] \\ +\text{lowE} \\ +\text{lensing} \\ +\text{BAO}. \end{array} \tag{1229}$$

These results are entirely independent of the cosmological parameter fit to the $\ell \geq 801$ power spectra, but agree well at the $1\,\sigma$ level with the full joint results in Table 24 (which have similar errors on these parameters). An equivalent result could be obtained using WMAP data after replacing their low-ℓ polarization with the *Planck* HFI measurement (i.e., lowE).

For the temperature likelihoods, the difference between the low- and high-multipole constraints remains evident, with $\Omega_{\rm m}h^2$ differing at the $2.8\,\sigma$ level. Adding polarization, the results from the multipole ranges are more consistent, as shown in Fig. 188, though the difference in $\Omega_{\rm m}h^2$ is still unusual at the roughly $2\,\sigma$ level. However, the shifts in the different parameters are all highly correlated, due to partial parameter degeneracies, so the significance of any individual large shift is lower after accounting for the number of parameters [299]. The internal tensions between multipole ranges appear to be consistent with moderate statistical fluctuations, related to the low-ℓ dip at large scales and correlated with the lensing amplitude on small scales. The large-scale feature is well determined by both WMAP and *Planck* and very robustly measured. The internal consistency of the *Planck* power spectra between different frequencies and detectors (PPL15, PPL18) argues against systematics driving large parameter shifts at high multipoles. Equation (1229) also demonstrates that any effect from the high-multipole spectra alone cannot be pulling our baseline parameters by more than about $1\,\sigma$. In the next subsection we describe in more detail the apparent preference for a higher lensing amplitude, and the features in the observed spectrum that could be responsible for it.

27.6.2 Lensing smoothing and $A_{\rm L}$

In addition to the direct measurement of CMB lensing described in Sect. 27.2.3 and PL2018, lensing can be seen in the *Planck* CMB power spectra via the lensing-induced smoothing of the acoustic peaks and transfer of power to the damping tail. This effect is modelled in our main parameter analysis, and can be calculated accurately from the unlensed CMB power spectra and the CMB lensing potential power spectrum in each model [332, 220]. Interesting consistency checks include testing if the amplitude of the smoothing effect in the CMB power matches expectation and whether the amplitude of the smoothing is consistent with that measured by the lensing reconstruction. To do this, the theoretical prediction for the lensing spectrum in each model is often scaled by an "$A_{\rm L}$" consistency parameter, where the theoretical expectation is that $A_{\rm L} = 1$ [66].

As shown in Fig. 169, the *Planck* lensing-reconstruction power spectrum is consistent with the amplitude expected for ΛCDM models that fit the CMB spectra, so the *Planck* lensing measurement is compatible with $A_{\rm L} = 1$. However, the distributions of $A_{\rm L}$ inferred from the CMB power spectra alone are shown in Fig. 189 for various different data combinations, and these indicate a preference for $A_{\rm L} > 1$, with

$$A_{\rm L} = 1.243 \pm 0.096 \quad (68\,\%,\ \textit{Planck}\ \text{TT+lowE}), \tag{1230a}$$
$$A_{\rm L} = 1.180 \pm 0.065 \quad (68\,\%,\ \textit{Planck}\ \text{TT,TE,EE+lowE}), \tag{1230b}$$

assuming a ΛCDM+$A_{\rm L}$ model. The TE polarization data alone slightly prefer $A_{\rm L} < 1$, with the EE data slightly preferring $A_{\rm L} > 1$; however, both are consistent with $A_{\rm L} = 1$ within $2\,\sigma$. The

joint combined likelihood shifts the value preferred by the TT data downwards towards $A_{\rm L} = 1$, but the error also shrinks, increasing the significance of $A_{\rm L} > 1$ to $2.8\,\sigma$ (99.8 % of parameter samples have $A_{\rm L} > 0$, so the one-tailed limit is almost exactly $3\,\sigma$). Moreover, combining with the lensing likelihood further pulls the constraint towards $A_{\rm L} = 1$, which is then consistent with the data to within $2\,\sigma$; we see that the preference for $A_{\rm L} > 1$ is driven by the CMB power spectra alone.

The preference for high $A_{\rm L}$ is not just a volume effect in the full parameter space (see PCP13 for discussion of such effects in multi-parameter fitting), with the best fit improved by $\Delta\chi^2_{\rm eff} = -8.7$ when adding $A_{\rm L}$ for TT+lowE and $\Delta\chi^2_{\rm eff} = -9.7$ for TT,TE,EE+lowE. The bulk of the $\Delta\chi^2_{\rm eff}$ comes from the high-ℓ likelihood (mostly in the range $600 < \ell < 1500$); however, the low-ℓ temperature `commander` likelihood fit is also improved if $A_{\rm L}$ is free, with $\Delta\chi^2_{\rm eff} = -2.3$ and $\Delta\chi^2_{\rm eff} = -1.3$ for the TT+lowE and TT,TE,EE+lowE, respectively, due to the lower amplitude of the $A_{\rm L}$ fit on large scales. The change in fit to the low-ℓ polarization is not very significant ($\Delta\chi^2_{\rm eff} = -0.2$ and $\Delta\chi^2_{\rm eff} = -0.4$).

The determination of $A_{\rm L}$ from the high-ℓ polarization data and the TT,TE,EE+lowE joint combination depends on the calibration of the polarization channels, and is affected by different ways of modelling the polarization efficiencies, as discussed in Sect. 27.2.2. The results from the `CamSpec` likelihood (which uses spectrum-based rather than map-based calibrations for TE and EE) are somewhat shifted with respect to the `Plik` likelihood, as shown by the dotted lines in Fig. 189, and have larger errors, giving

$$A_{\rm L} = 1.246^{+0.092}_{-0.100} \quad (68\,\%,\ \text{TT+lowE [CamSpec]}), \tag{1231a}$$

$$A_{\rm L} = 1.149 \pm 0.072 \ (68\,\%,\ \text{TT,TE,EE+lowE [CamSpec]}). \tag{1231b}$$

Using `CamSpec` there is still a clear preference for $A_{\rm L} > 1$, but the joint result with polarization is now only just over $2\,\sigma$ above $A_{\rm L} = 1$. The differences between these `Plik` and `CamSpec` results arise from differences in the methodologies used to create the likelihoods. Although both likelihoods clearly show a preference for $A_{\rm L} > 1$, this cannot be claimed to be a robust detection at much over $2\,\sigma$ [see also 117].

The preference for $A_{\rm L} > 1$ within the ΛCDM model is a curious feature of the *Planck* CMB power spectrum data, and has already been discussed extensively in PCP13, PCP15, and Planck Collaboration Int. LI [299], although it is now slightly more significant. In temperature, over half of the small (approximately 0.02) upward shift in $A_{\rm L}$ compared to 2015 is explained by the lower optical depth from the 2018 low-ℓ likelihood: lower τ implies lower $A_{\rm s}$ to match the high-ℓ CMB fluctuation amplitude, and hence larger $A_{\rm L}$ to yield a lensing amplitude and hence amount of smoothing at the same level as 2015. In polarization about 40 % of the shift in $A_{\rm L}$ is explained by changes in τ, with changes in the maps, modelling for beam leakage, and polarization efficiencies explaining the rest.

The high-ℓ temperature likelihood preference for more lensing smoothing than allowed by ΛCDM can be seen by eye in the smoothed data residuals plotted in Fig. 190; over almost all the allowed ΛCDM parameter space there is an oscillatory residual in the range $1100 \lesssim \ell \lesssim 2000$ that matches the shape of the lensing smoothing[159] (although in other multipole ranges it does not match at all). The residual is not obviously anomalous, with the TT ΛCDM best fit improving by $\Delta\chi^2 \approx 4$ if a best-fit oscillatory residual (with $A_{\rm L} \approx 1.1$) is added to the best-fit ΛCDM theory model. The stronger preference for $A_{\rm L} > 1$ when $A_{\rm L}$ varies arises because degeneracies between $A_{\rm L}$, cosmological parameters, and foregrounds improves the fit at both high and lower multipoles, as shown by the black dashed line in Fig. 190. In ΛCDM the lensing amplitude can be increased by increasing $\Omega_{\rm m}h^2$; however, the model then becomes a bad fit because of the poorer agreement at $\ell < 1000$). Varying $A_{\rm L}$ allows a high $A_{\rm L}$ to remove the oscillatory residual at high multipoles that appears in ΛCDM with lower $\Omega_{\rm m}h^2$, giving best fits with lower $\Omega_{\rm m}h^2$ and higher H_0 (by 1.5–2.0 σ, depending on the exact combination of data used) that are not favoured in the physical ΛCDM model. Lower values of $\Omega_{\rm m}h^2$ give higher values of $n_{\rm s}$, lowering the theory prediction on large scales, so high $A_{\rm L}$ models are also slightly

[159] Although the oscillatory pattern looks most similar to lensing at high multipoles, an increase in the foreground model amplitude can decrease the oscillation amplitude in the theory contribution to the spectrum, and hence appear as an oscillatory difference. For example $\Delta n_{\rm s} \approx -0.02$, combined with an implausibly large change in the foreground model, gives a difference in the predicted spectrum with an oscillatory component that has similar amplitude to $\Delta A_{\rm L} \approx 0.1$; see the related discussion in Planck Collaboration Int. LI [299].

preferred by the dip in the $\ell < 30$ *Planck* temperature data. The parameter degeneracies are illustrated in Fig. 191.

The $A_{\rm L}$ results appear to be robust to changes in foreground modelling in the baseline likelihood, with the `CamSpec` 545 GHz cleaned likelihood (see Appendix **??**) giving very similar results. However, the dip in the residuals at $1420 \lesssim \ell \lesssim 1480$, part of the oscillatory feature that looks like additional lensing, nearly coincides with an approximately $3\,\sigma$ discrepancy (for the best-fit foreground cosmology model) between the 143-GHz and 217-GHz power spectra at $1450 \lesssim \ell \lesssim 1510$, with the 217-GHz spectrum pulling the coadded spectrum low compared to 143 GHz by an amount comparable to the coadded residual (at $\ell = 1480$ the 217-GHz spectrum is $\mathcal{D}_\ell \approx 7\mu{\rm K}^2$ lower than 143 GHz with smoothing $\sigma_\ell = 40$; see PPL18). This may be an indication that the preference for $A_{\rm L}$ at high multipoles is partly due to unknown systematics or foregrounds. However, tightly cutting the ℓ range that contributes to the $3\,\sigma$ frequency difference does not in itself shift $A_{\rm L}$ to substantially lower values (though cutting all of $1420 \lesssim \ell \lesssim 1480$ does), and the significance of the oscillatory feature in the ΛCDM CMB residual is in any case not very high. If it is largely a statistical fluctuation, it would be expected to vary with changes in sky area; that is somewhat the case, with around 80 % sky area giving a substantially less oscillatory residual to the same best-fit ΛCDM model at $\ell \lesssim 1600$, but still favouring high $A_{\rm L}$. Different power spectrum analyses have also shown the preference for $A_{\rm L}$ [347, 83], though with varying significance, which could indicate that our roughly $3\,\sigma$ significance is partly an issue of analysis choices, e.g., the sky areas included and foreground priors chosen.

The dashed line in Fig. 169 shows the lensing power spectrum in the *Planck* TT,TE,EE +lowE best-fit ΛCDM+$A_{\rm L}$ model, which is clearly inconsistent with the lensing reconstruction, since it lies above almost all of the measured data points. Because the amplitude of the lensing smoothing effect can be calculated from the lensing potential power spectrum alone, which we can also empirically measure, it is impossible to increase the lensing smoothing of the CMB peaks without also increasing the measured lensing reconstruction amplitude. This remains true if the lensing power spectrum is allowed to vary in shape [242]. The actual lensing smoothing effect can also partly be removed by delensing, as shown by [212] and [70]. In PL2018 we update these delensing analyses, and show (using the internal lensing reconstruction, a *Planck* CIB map as a tracer of the lensing potential, and a combined estimate) that the amount of peak sharpening observed after delensing is consistent with theoretical expectations (e.g., for the TT spectrum, we measure a reduction in lensing smoothing of 0.411 ± 0.028, compared to the expected value of 0.375 when using a combination of CIB and *Planck* lensing reconstruction).

Although the residuals shown in Fig. 190 between the data and the ΛCDM best fit temperature spectrum show what looks like an oscillatory lensing residual at high ℓ, the fit itself is determined by the entire range of multipoles (and the low-ℓ polarization than constrains τ). The preference for $A_{\rm L} > 1$ could therefore be attributed to other scales when considering the CMB spectra alone. For example, after removing $\ell < 30$ in both temperature and polarization, $A_{\rm L}$ from TT is consistent with unity to within $1\,\sigma$. However, in this case the ΛCDM lensing amplitudes are still large, giving a value of $\Omega_{\rm m}\sigma_8^{0.25}$, in $2\,\sigma$ tension with the lensing reconstruction. This is another reflection of the tension noted in Sect. 27.6.1 between the lensing reconstruction and the lensing amplitude predicted using temperature multipoles $\ell \gtrsim 800$: the two tensions are therefore not independent and largely driven by the same features of the ΛCDM fit to the temperature and low-ℓ polarization data.

If $A_{\rm L} > 1$ is not just a statistical fluctuation, but comes from new physics changing the theoretical predictions, it could be something that mimics the smoothing effect in the CMB peaks. The *lensing* smoothing effect comes from averaging over the sky a spectrum that is locally varying (due to magnification and shear locally changing the scale and shape of the CMB peaks). Conceptually, the temperature lensing reconstruction works by looking for this spatial variation in scale and shear of the local power. Any non-lensing isotropic change in the amplitude of the small-scale peaks and troughs, either from new physics or random fluctuations, would therefore only have a small effect on the lensing reconstruction, which is sensitive to scale and shape, not amplitude.

One locally anisotropic physical effect that has been considered as a possible explanation is the presence of large-scale compensated isocurvature modes, discussed in detail in [296]. Because the large-scale isocurvature modes locally vary the baryon-to-photon ratio, they can partially mimic the lensing smoothing effect by spatially varying the acoustic scale [243, 357]. However, because they have a similar local effect to lensing, they also affect the large-scale lensing reconstruction [345]. Combining with the *Planck* 2018 lensing reconstruction, which

now extends down to $L = 8$, as shown in [296] this model therefore does not offer a significant improvement in overall fit ($\Delta\chi^2_{\rm eff} = -3.3$ with *Planck* TT,TE,EE+lowE+lensing).

If the $A_{\rm L} > 1$ preference is simply a statistical excursion (perhaps the most likely explanation), this indicates that there are random features in the spectrum that are pulling some parameters unusually far from expected values.[160] There are several theoretical models that can fit the CMB power spectra and also predict larger lensing amplitudes. These include ΛCDM models with spatial curvature, for which we find $\Omega_K < 0$ at over $3\,\sigma$ (Sect. **??**) from the CMB power spectra, and some dark energy and modified gravity models (Sect. **??**). For extensions to base-ΛCDM, parameters that decrease the lensing amplitude are more constrained by the *Planck* power spectra than might otherwise be expected; for example, higher neutrino masses lower the predicted lensing power compared to base ΛCDM, leading to surprisingly tight constraints (Sect. **??**). Adding the lensing-reconstruction information significantly reduces the parameter space of larger lensing amplitudes and partially mitigates these effects. However, the statistical power of the *Planck* power spectra is sufficiently high that the joint constraints prefer lensing amplitudes in the higher range allowed by the lensing data.

Even within ΛCDM, the fact that the data prefer more lensing leads to a preference for higher fluctuation amplitudes, hence the high-ℓ data yield higher $A_{\rm s}$ and higher τ than we infer in combination with large-scale E-mode polarization (Sect. 27.2.2) or lensing reconstruction. Since these preferences are degenerate with $\Omega_{\rm m}h^2$, $n_{\rm s}$, and H_0 (see PCP13, PCP15), these parameters are also pulled ($\Omega_{\rm m}h^2$ higher, $n_{\rm s}$ and H_0 lower). Our baseline best-fit results include both the "lowE" data and the lensing reconstruction, each of which restrict the range of allowed variation, so the remaining pulls should be modest; however, it should not perhaps be too much of a surprise if the central values of the parameters inferred from *Planck* turn out to be slightly more shifted than typical with respect to the ultimate truth if the base-ΛCDM model is correct.

[160] It is not trivial to assess how unlikely a fluctuation in a consistency parameter like this is given the number of different cosmological and consistency test parameters we might have looked at. We are only discussing $A_{\rm L}$ in detail here because it comes out high; other consistency parameters, for example the relative amplitude of ISW, Doppler, and Sachs-Wolfe contributions to the temperature spectrum, come out perfectly consistent with expectations.

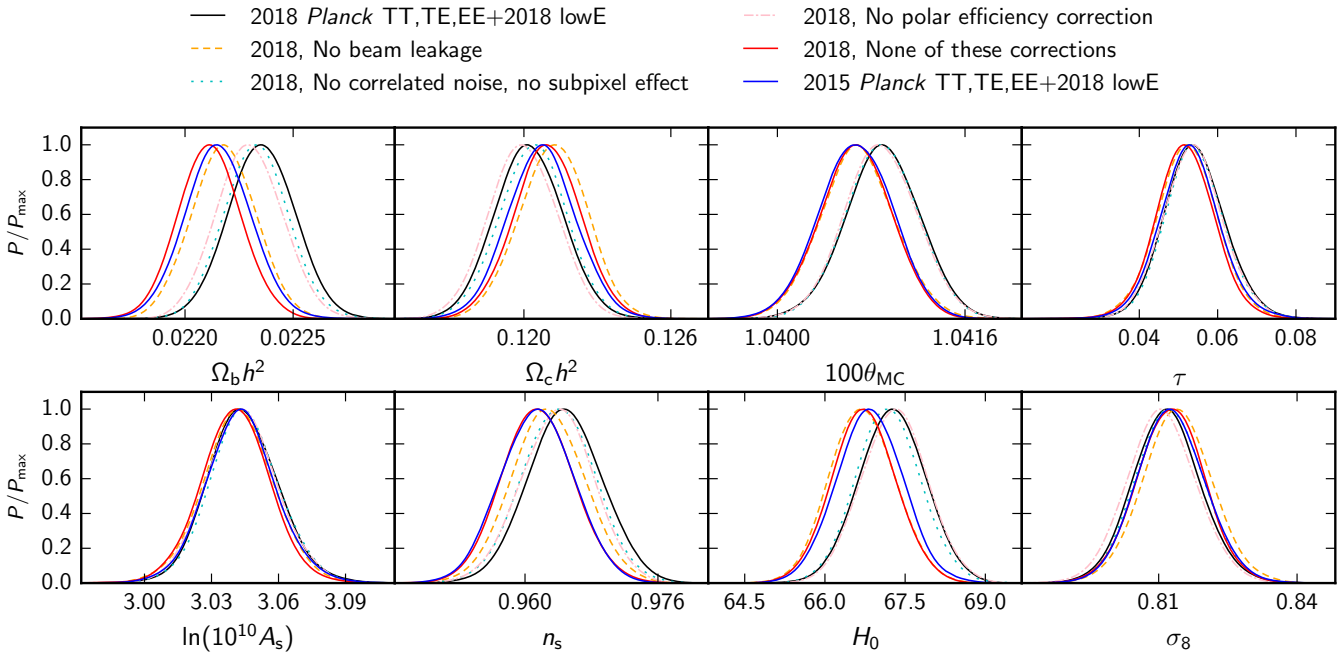

Figure 174: Impact of corrections for systematic effects on 2018 marginalized ΛCDM parameters from *Planck* TT,TE,EE+lowE. The plot shows the baseline results (black solid line), and the baseline result excluding corrections for various effects: beam leakage (dashed orange); polarization efficiencies (dot-dashed pink); and subpixel effects and correlated noise (dotted cyan). The impact of not including any of these corrections is shown in solid blue, and agree fairly well with the 2015 results if the 2015 low-ℓ polarization likelihood is replaced with 2018 lowE likelihood (2015 *Planck* TT,TE,EE+2018 lowE). This shows that corrections for polarization systematics account for most of the small changes between the 2015 and 2018 results that are not caused by the change in optical depth.

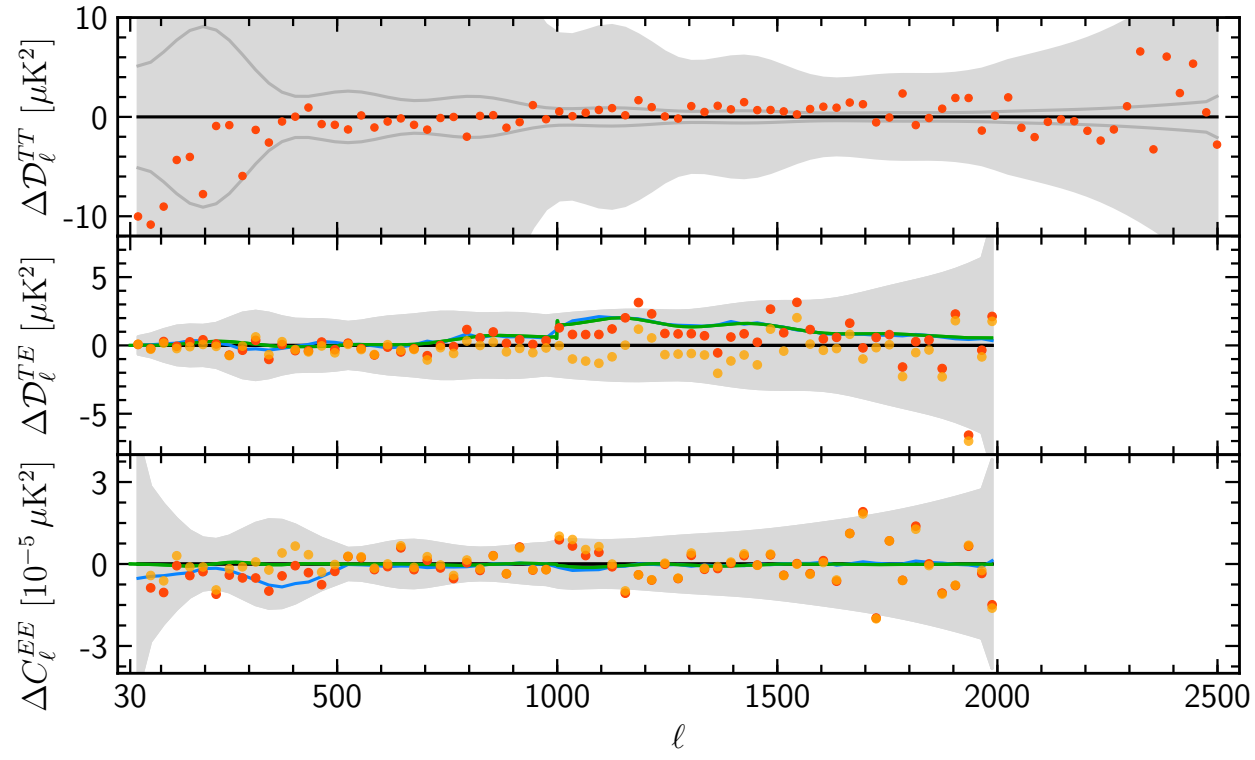

Figure 175: Differences between the 2018 and 2015 coadded power spectra at high ℓ in TT, TE, and EE from top to bottom (red points). The 2015 TT spectrum has been recalibrated by a factor of 1.00014. For TE and EE, the orange points show the same differences but without applying the polar-efficiency and beam-leakage corrections to the 2018 spectra. This shows

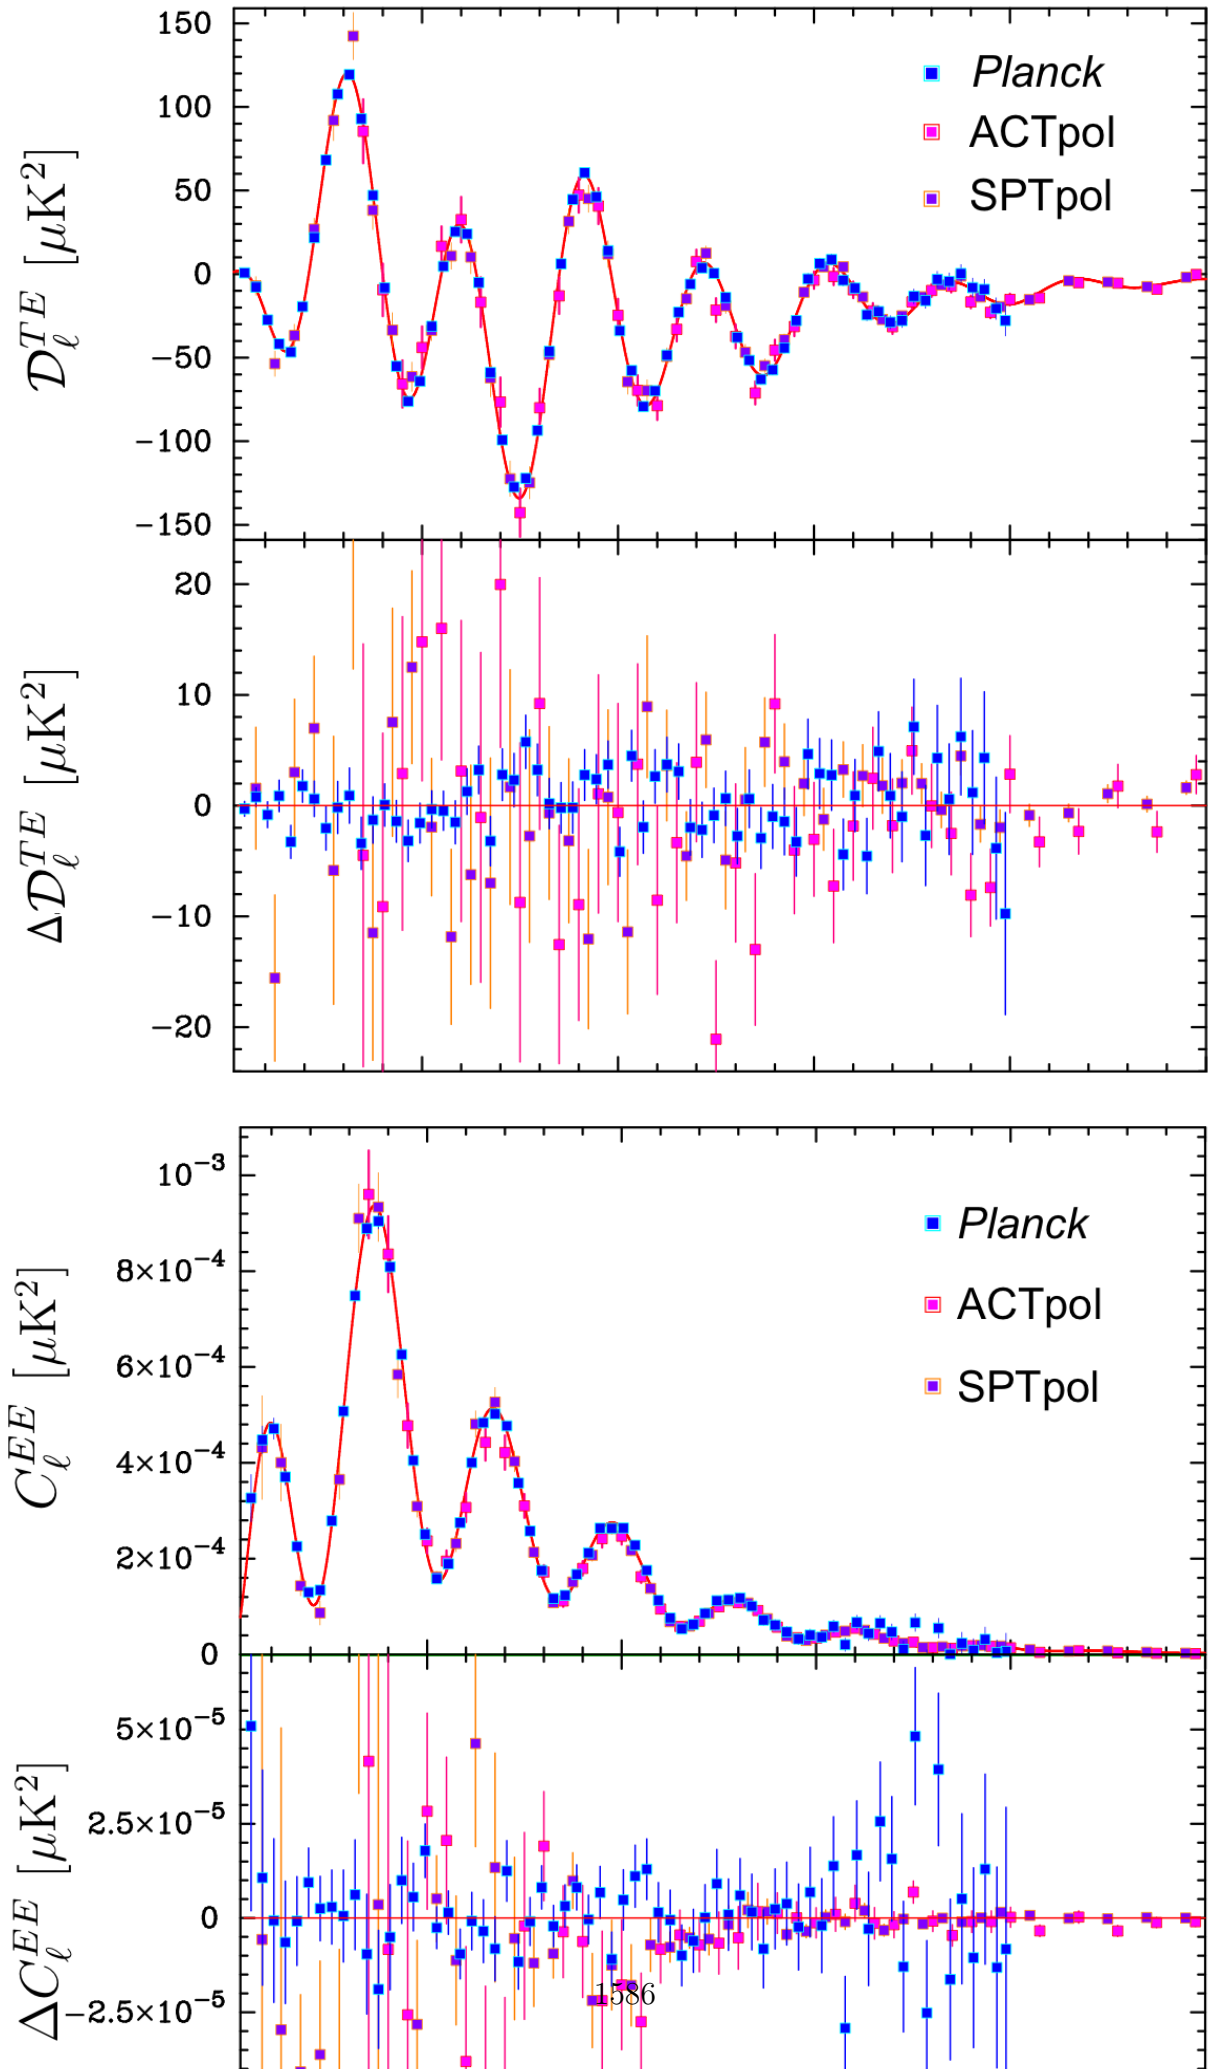

Planck
ACTpol
SPTpol
$\mathcal{D}_\ell^{TE}$ [μK^2]
$\Delta\mathcal{D}_\ell^{TE}$ [μK^2]
C_ℓ^{EE} [μK^2]
ΔC_ℓ^{EE} [μK^2]

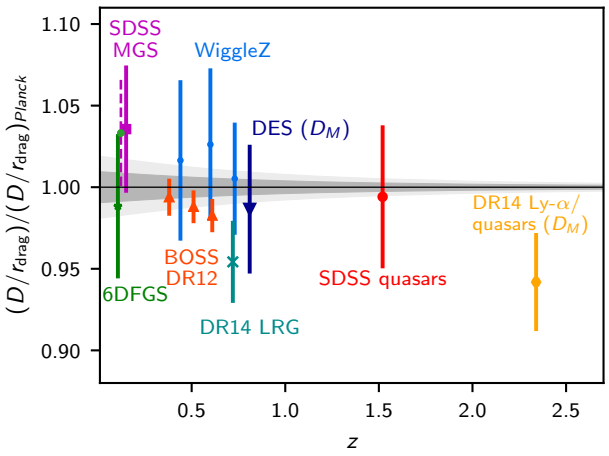

Figure 177: Acoustic-scale distance measurements divided by the corresponding mean distance ratio from *Planck* TT,TE,EE+lowE+lensing in the base-ΛCDM model. The points, with their $1\,\sigma$ error bars are as follows: green star, 6dFGS [47]; magenta square, SDSS MGS [313]; red triangles, BOSS DR12 [15]; small blue circles, WiggleZ [as analysed by 199]; large dark blue triangle, DES [107]; cyan cross, DR14 LRG [38]; red circle, SDSS quasars [28]; and orange hexagon, which shows the combined BAO constraints from BOSS DR14 Lyman-α [96] and Lyman-α cross-correlation with quasars, as cited in [57]. The green point with magenta dashed line is the 6dFGS and MGS joint analysis result of Carter et al. [71]. All ratios are for the averaged distance $D_{\rm V}(z)$, except for DES and BOSS Lyman-α, where the ratio plotted is $D_{\rm M}$ (results for $H(z)$ are shown separately in Fig. 182). The grey bands show the 68 % and 95 % confidence ranges allowed for the ratio $D_{\rm V}(z)/r_{\rm drag}$ by *Planck* TT,TE,EE+lowE+lensing (bands for $D_{\rm M}/r_{\rm drag}$ are very similar).

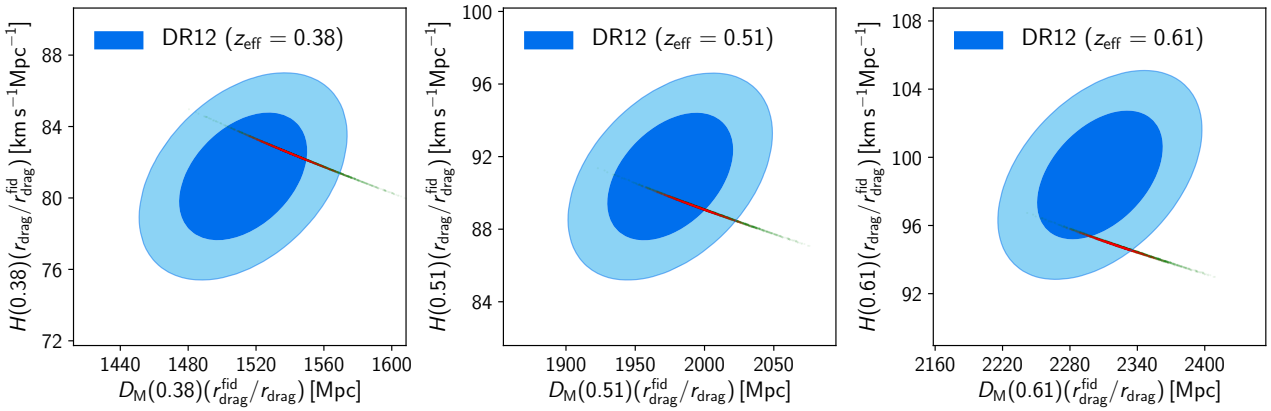

Figure 178: Constraints on the comoving angular diameter distance $D_{\rm M}(z)$ and Hubble parameter $H(z)$ at the three central redshifts of the Alam et al. [15] analysis of BOSS DR12. The dark blue and light blue regions show 68 % and 95 % CL, respectively. The fiducial sound horizon adopted by Alam et al. [15] is $r^{\rm fid}_{\rm drag} = 147.78\,$Mpc. Green points show samples from *Planck* TT +lowE chains, and red points corresponding samples from *Planck* TT,TE,EE+lowE+lensing, indicating good consistency with BAOs; one can also see the shift towards slightly lower $D_{\rm M}$ and higher H as more CMB data are added.

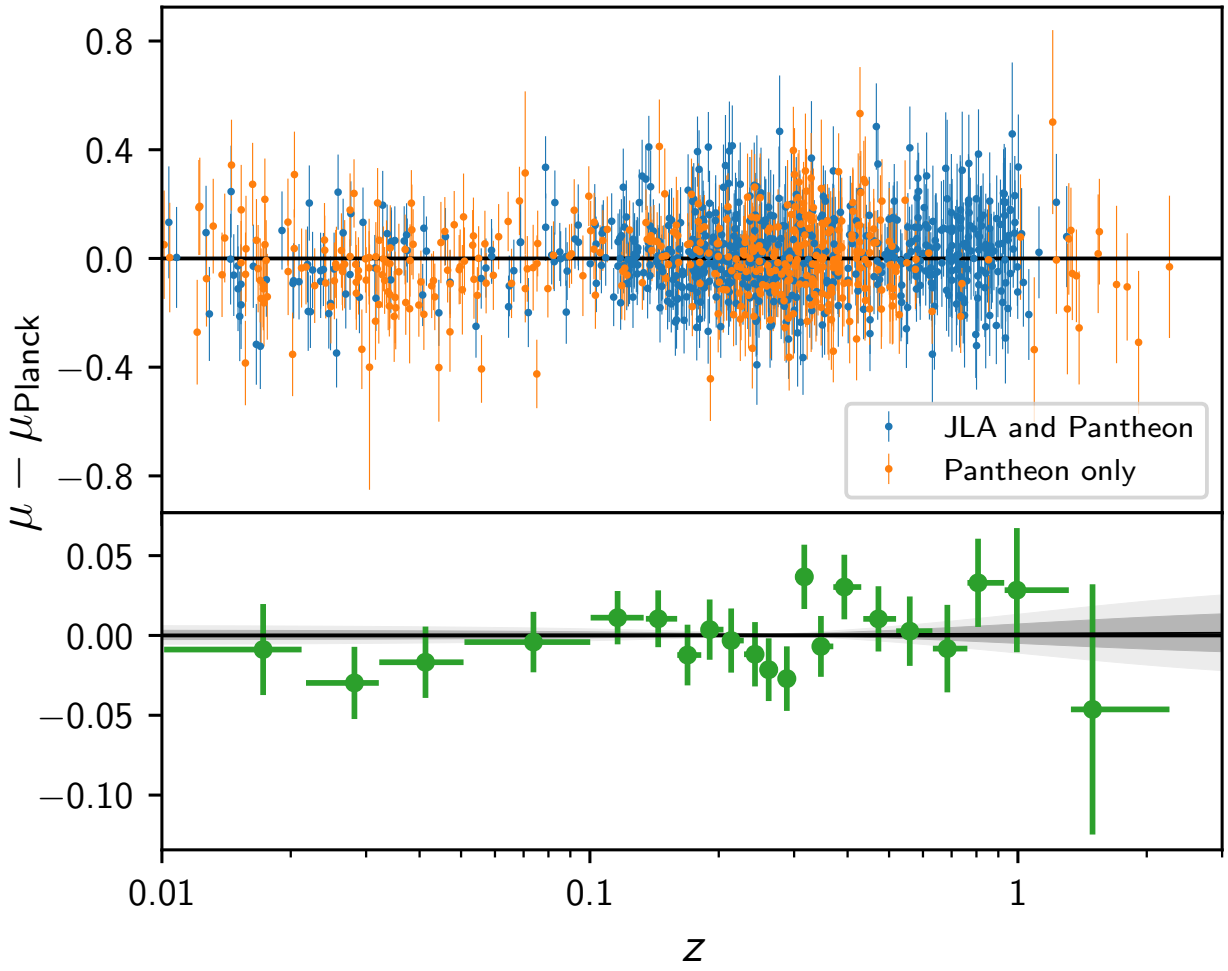

Figure 179: Distance modulus $\mu = 5\log_{10}(D_L) + \text{constant}$ (where D_L is the luminosity distance) for supernovae in the Pantheon sample [329] with $1\,\sigma$ errors, compared to the *Planck* TT,TE,EE +lowE+lensing ΛCDM best fit. Supernovae that were also in the older Joint Lightcurve Analysis [45, JLA] sample are shown in blue. The peak absolute magnitudes of the SNe, corrected for light-curve shape, colour, and host-galaxy mass correlations [see equation 3 of 329], are fixed to an absolute distance scale using the H_0 value from the *Planck* best fit. The lower panel shows the binned errors, with equal numbers of supernovae per redshift bin (except for the two highest redshift bins). The grey bands show the ± 1 and $\pm 2\,\sigma$ bounds from the *Planck* TT,TE,EE+lowE+lensing chains, where each model is calibrated to the best fit, as for the data.

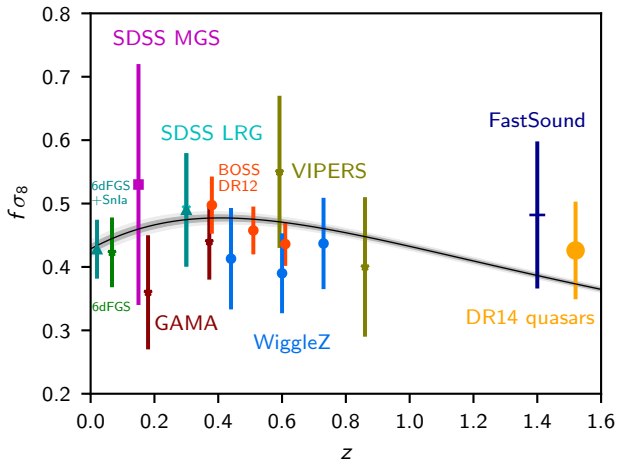

Figure 180: Constraints on the growth rate of fluctuations from various redshift surveys in the base-ΛCDM model: dark cyan, 6dFGS and velocities from SNe Ia [187]; green, 6dFGRS [48]; purple square, SDSS MGS [182]; cyan cross, SDSS LRG [249]; dark red, GAMA [54]; red, BOSS DR12 [15]; blue, WiggleZ [53]; olive, VIPERS [269]; dark blue, FastSound [250]; and orange, BOSS DR14 quasars [373]. Where measurements are reported in correlation with other variables, we here show the marginalized posterior means and errors. Grey bands show the 68 % and 95 % confidence ranges allowed by *Planck* TT,TE,EE+lowE+lensing.

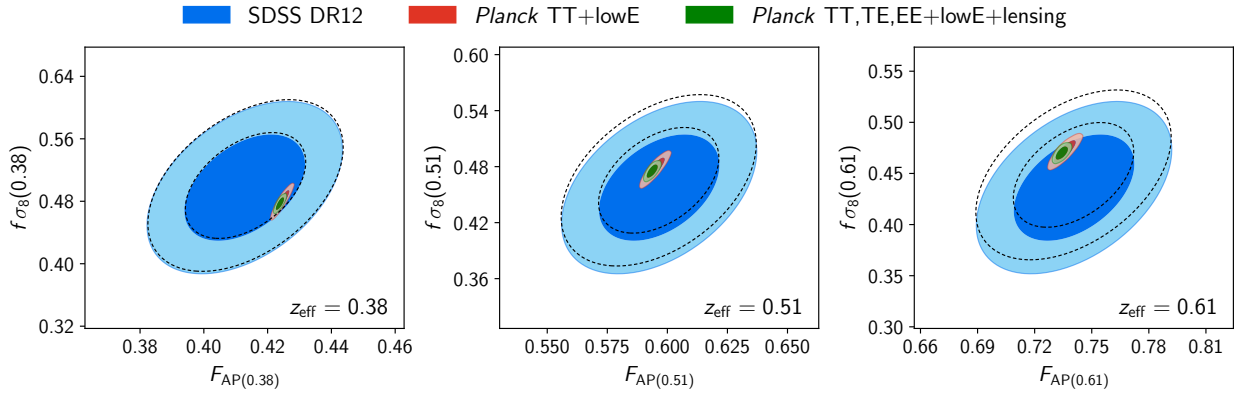

Figure 181: Constraints on $f\,\sigma_8$ and $F_{\rm AP}$ (see Eqs. 1223 and 1224) from analysis of redshift-space distortions. The blue contours show 68 % and 95 % confidence ranges on $(f\,\sigma_8, F_{\rm AP})$ from BOSS-DR12, marginalizing over D_V. Constraints from *Planck* for the base-ΛCDM cosmology are shown by the red and green contours. The dashed lines are the 68 % and 95 % contours for BOSS-DR12, conditional on the *Planck* TT,TE,EE+lowE+lensing constraints on D_V.

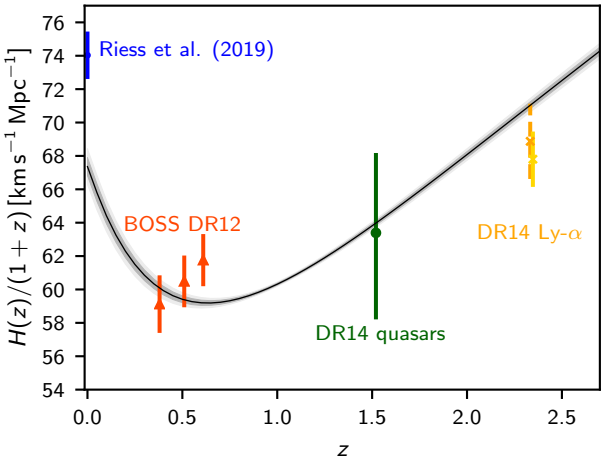

Figure 182: Comoving Hubble parameter as a function of redshift. The grey bands show the 68 % and 95 % confidence ranges allowed by *Planck* TT,TE,EE+lowE+lensing in the base-ΛCDM model, clearly showing the onset of acceleration around $z = 0.6$. Red triangles show the BAO measurements from BOSS DR12 [15], the green circle is from BOSS DR14 quasars [373], the orange dashed point is the constraint from the BOSS DR14 Ly α auto-correlation at $z = 2.34$ [96], and the solid gold point is the joint constraint from the Ly α auto-correlation and cross-correlation with quasars from Blomqvist et al. [57]. All BOSS measurements are used in combination with the *Planck* base-model measurements of the sound horizon $r_{\rm drag}$, and the DR12 points are correlated. The blue point at redshift zero shows the inferred forward-distance-ladder Hubble measurement from Riess et al. [306].

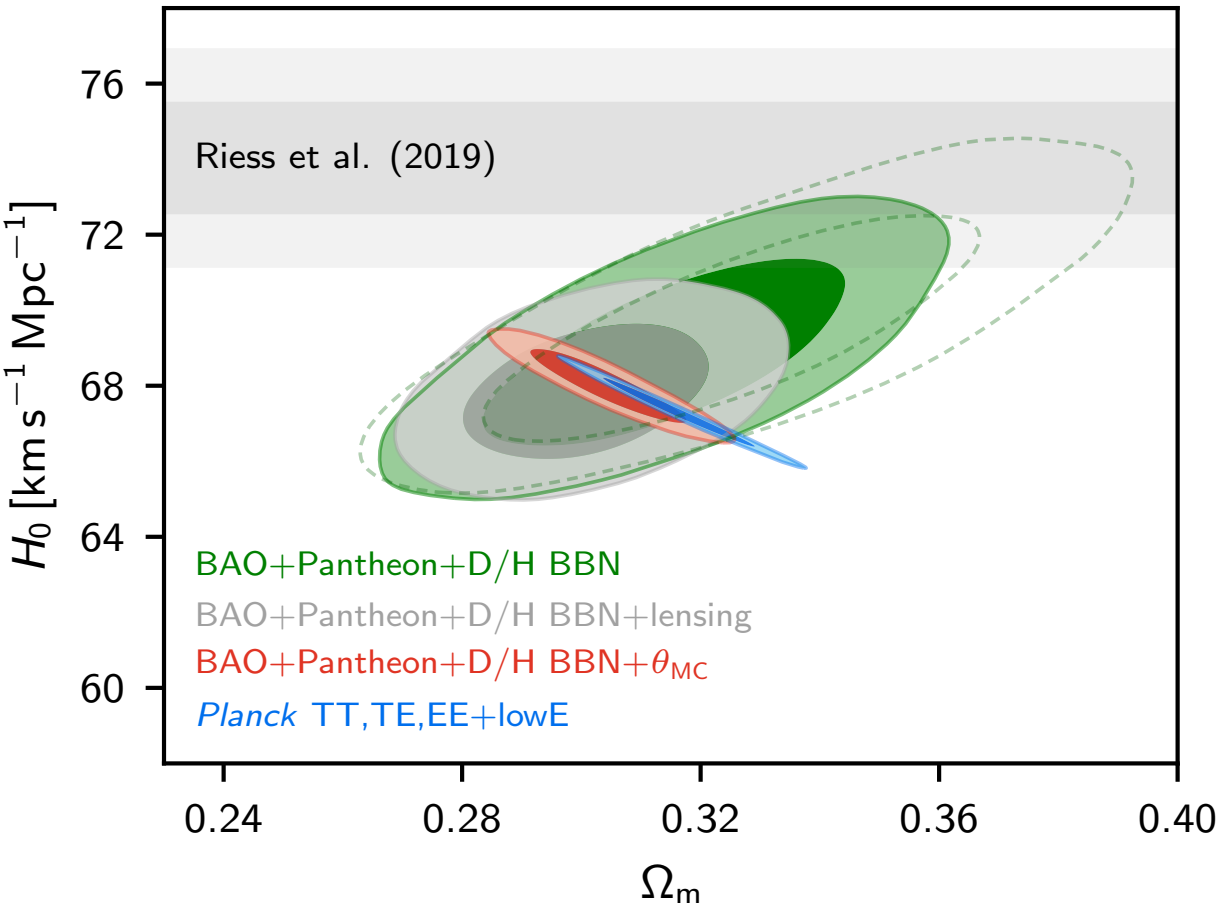

Figure 183: Inverse-distance-ladder constraints on the Hubble parameter and Ω_m in the base-ΛCDM model, compared to the result from the full *Planck* CMB power-spectrum data. BAO data constrain the ratio of the sound horizon at the epoch of baryon drag and the distances; the sound horizon depends on the baryon density, which is constrained by the conservative prior of $\Omega_b h^2 = 0.0222 \pm 0.0005$, based on the measurement of D/H by Cooke et al. [82] and standard BBN with modelling uncertainties. Adding *Planck* CMB lensing constrains the matter density, or adding a conservative *Planck* CMB "BAO" measurement ($100\theta_{MC} = 1.0409 \pm 0.0006$) gives a tight constraint on H_0, comparable to that from the full CMB data set. Grey bands show the local distance-ladder measurement of Riess et al. [306]. Contours contain 68 % and 95 % of the probability. Marginalizing over the neutrino masses or allowing dark energy equation of state parameters $w_0 > -1$ would only lower the inverse-distance-ladder constraints on H_0. The dashed contours show the constraints from the data combination BAO+JLA+D/H BBN .

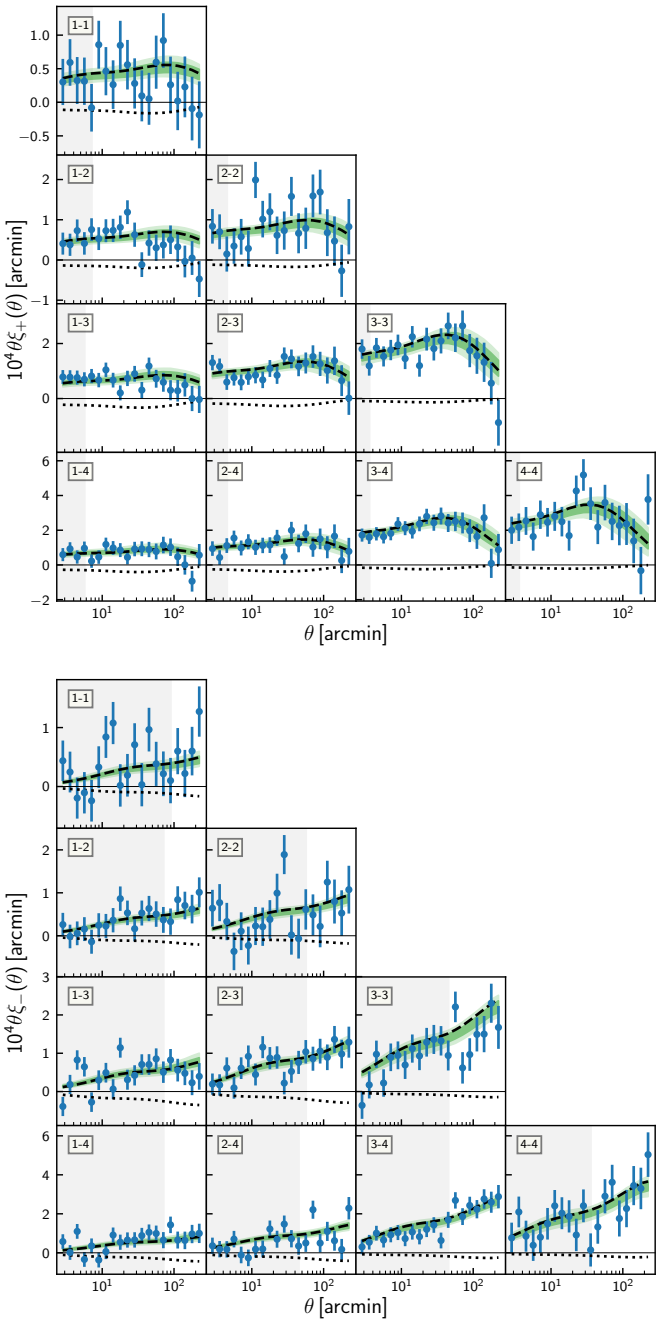

Figure 184: Dark Energy Survey (DES) shear correlations functions, ξ_+ (left) and ξ_- (right), for the auto- and cross-correlation between the four DES source redshift bins [355]. Green bands show the 68 % and 95 % distribution of model fits in the DES lensing-only base-ΛCDM parameter fits. The dashed line shows the DES lensing parameter best fit when the cosmological parameters are fixed to the best fit model for *Planck* TT,TE,EE+lowE only; dotted lines show the size of the contribution of intrinsic alignment terms to the dashed lines. Grey bands show the scales excluded from the DES analysis, in order to reduce sensitivity to nonlinear effects.

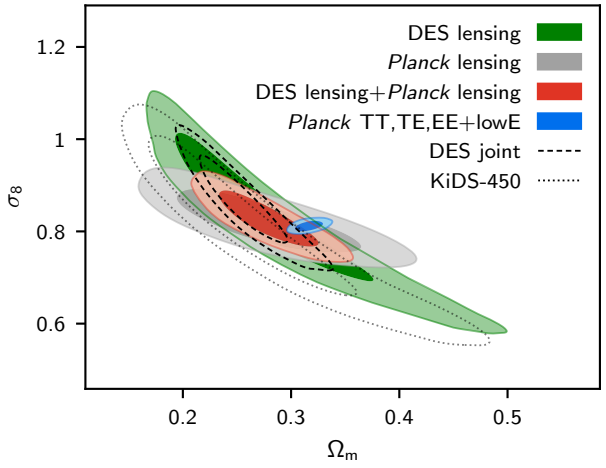

Figure 185: Base-ΛCDM model 68 % and 95 % constraint contours on the matter-density parameter Ω_m and fluctuation amplitude σ_8 from DES lensing [355, green], *Planck* CMB lensing (grey), and the joint lensing constraint (red). For comparison, the dashed line shows the constraint from the DES cosmic shear plus galaxy-clustering joint analysis [106], the dotted line the constraint from the original KiDS-450 analysis [174, without the corrections considered in Troxel et al. 356], and the blue filled contour shows the independent constraint from the *Planck* CMB power spectra.

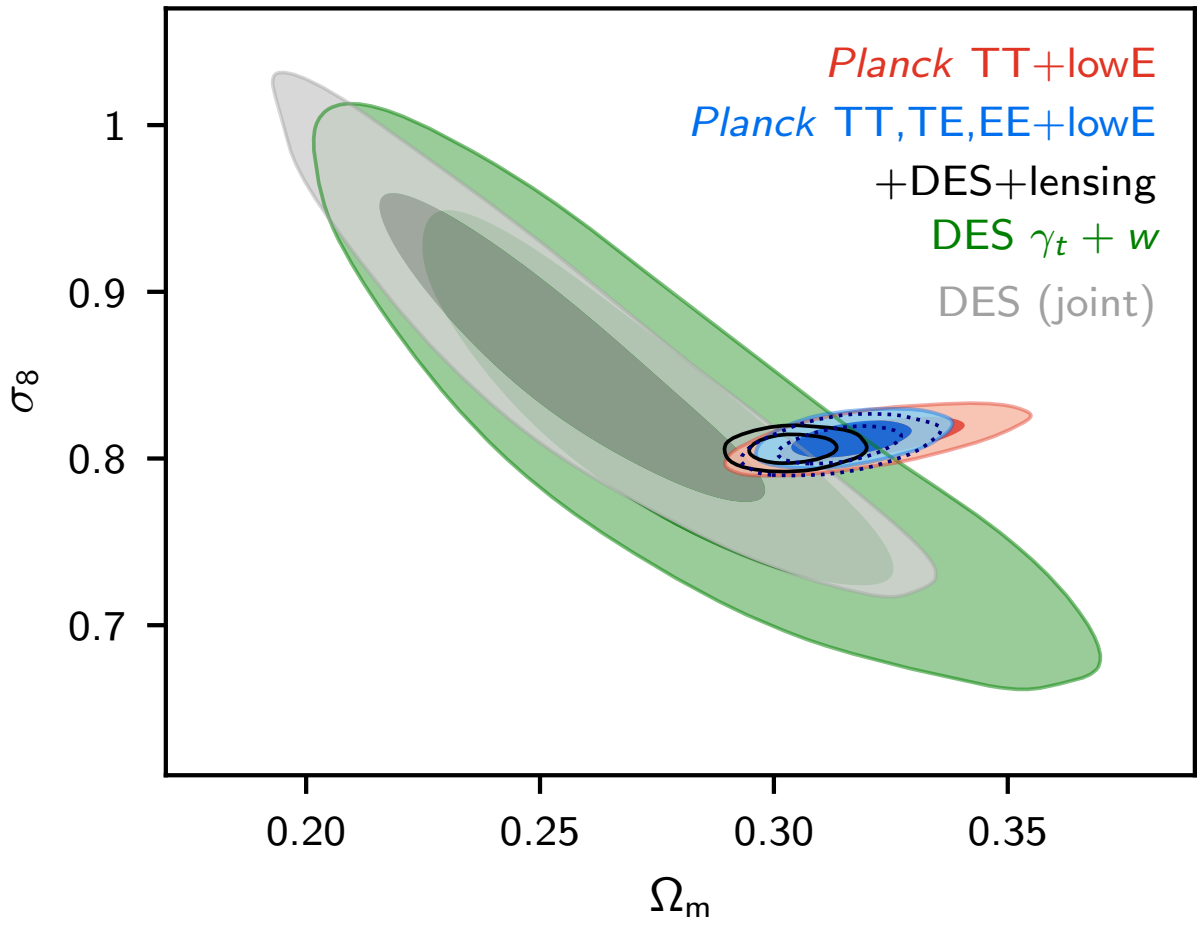

Figure 186: Base-ΛCDM model constraints from the Dark Energy Survey (DES), using the shear-galaxy correlation and the galaxy auto-correlation data (green) and the joint result with DES lensing (grey), compared with *Planck* results using TT+lowE and TT,TE,EE+lowE. The black solid contours show the joint constraint from *Planck* TT,TE,EE+lowE+lensing+DES, assuming the difference between the data sets is purely statistical. The dotted line shows the *Planck* TT,TE,EE+lowE result using the `CamSpec` likelihood, which is slightly more consistent with the DES contours than using the default `Plik` likelihood. Contours contain 68 % and 95 % of the probability.

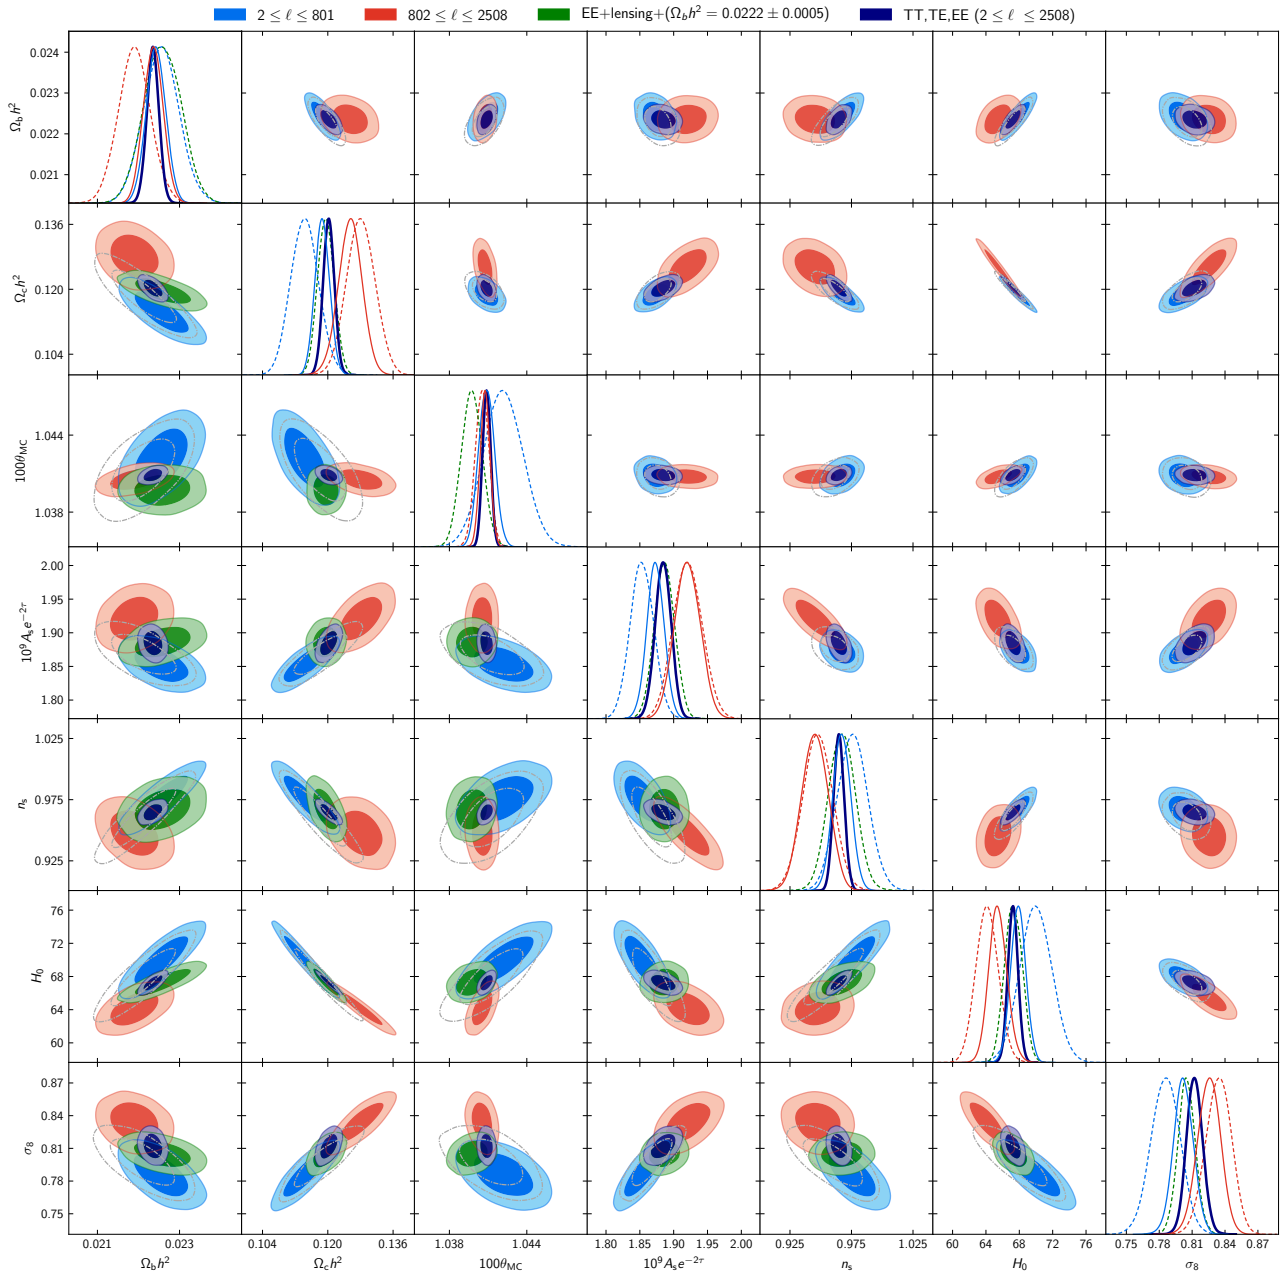

Figure 187: Base-ΛCDM 68 % and 95 % parameter constraint contours from the CMB power spectra using $\ell \leq 801$ (blue), compared to $\ell \geq 802$ (red). All results use the `plik_lite` *Planck* likelihood, and also include the low-ℓ `SimAll` "lowE" likelihood to constrain the optical depth τ; the `Commander` likelihood is used for temperature multipoles $\ell < 30$. The lower triangle contains the *Planck* temperature likelihoods, which show a moderate tension between high and low multipoles; however, they intersect in a region of parameter space consistent with the nearly-independent constraint from EE+lensing combined with a conservative prior $\Omega_{\rm b}h^2 = 0.0222 \pm 0.0005$, motivated by element-abundance observations (green). The upper triangle shows the equivalent results from *Planck* TT,TE,EE+lowE at low and high multipoles. The full combined result from *Planck* TT,TE,EE+lowE is shown as the navy contours. The unfilled grey contours show the result for multipoles $30 \leq \ell \leq 801$ (that is, removing the low-ℓ `Commander` likelihood that pulls parameters to give lower temperature power, due to the dip below $\ell \approx 30$). The diagonal plots are the marginalized parameter constraints, where results corresponding to the lower triangle are shown dashed, while the upper triangle are the solid curves.

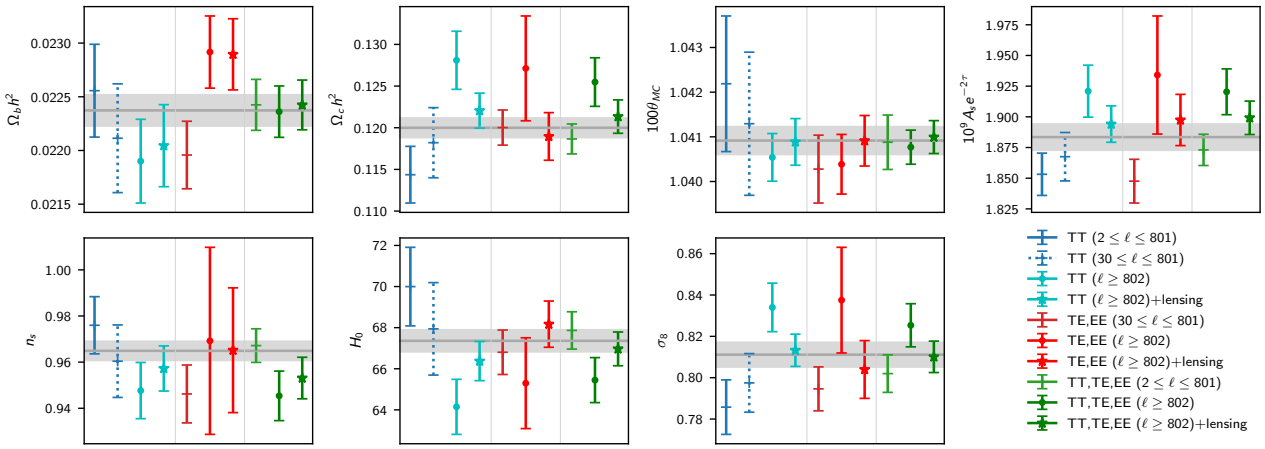

Figure 188: Base-ΛCDM 68 % marginalized parameter constraints for various combinations of power spectrum ranges (all using `plik_lite` and also including low-ℓ polarization "lowE"). Points marked with a cross are from $2 \le \ell \le 801$, while points marked with a circle are from $\ell \ge 802$. Dotted errors are the result from $30 \le \ell \le 801$, without the `Commander` large-scale temperature likelihood, showing that $\ell < 30$ pulls the low-multipole parameters further from the joint result. Points marked with a star are from $\ell \ge 802$ combined with the lensing likelihood, showing that constraining the lensing amplitude pulls all the results from high multipoles towards better consistency with the results from lower multipoles. The grey horizontal band shows the combined 68 % constraint from *Planck* TT,TE,EE+lowE+lensing.

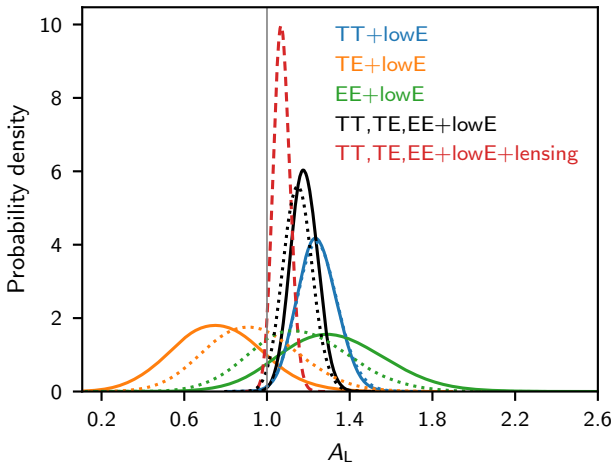

Figure 189: Constraints on the value of the consistency parameter A_L, as a single-parameter extension to the base-ΛCDM model, using various combinations of *Planck* data. When only power spectrum data are used, $A_L > 1$ is favoured at about $3\,\sigma$, but including the lensing reconstruction the result is consistent at $2\,\sigma$ with $A_L = 1$. The dotted lines show equivalent results for the `CamSpec` likelihood, which peak slightly nearer to $A_L = 1$, indicating some sensitivity of the A_L results to choices made in constructing the high-multipole likelihoods.

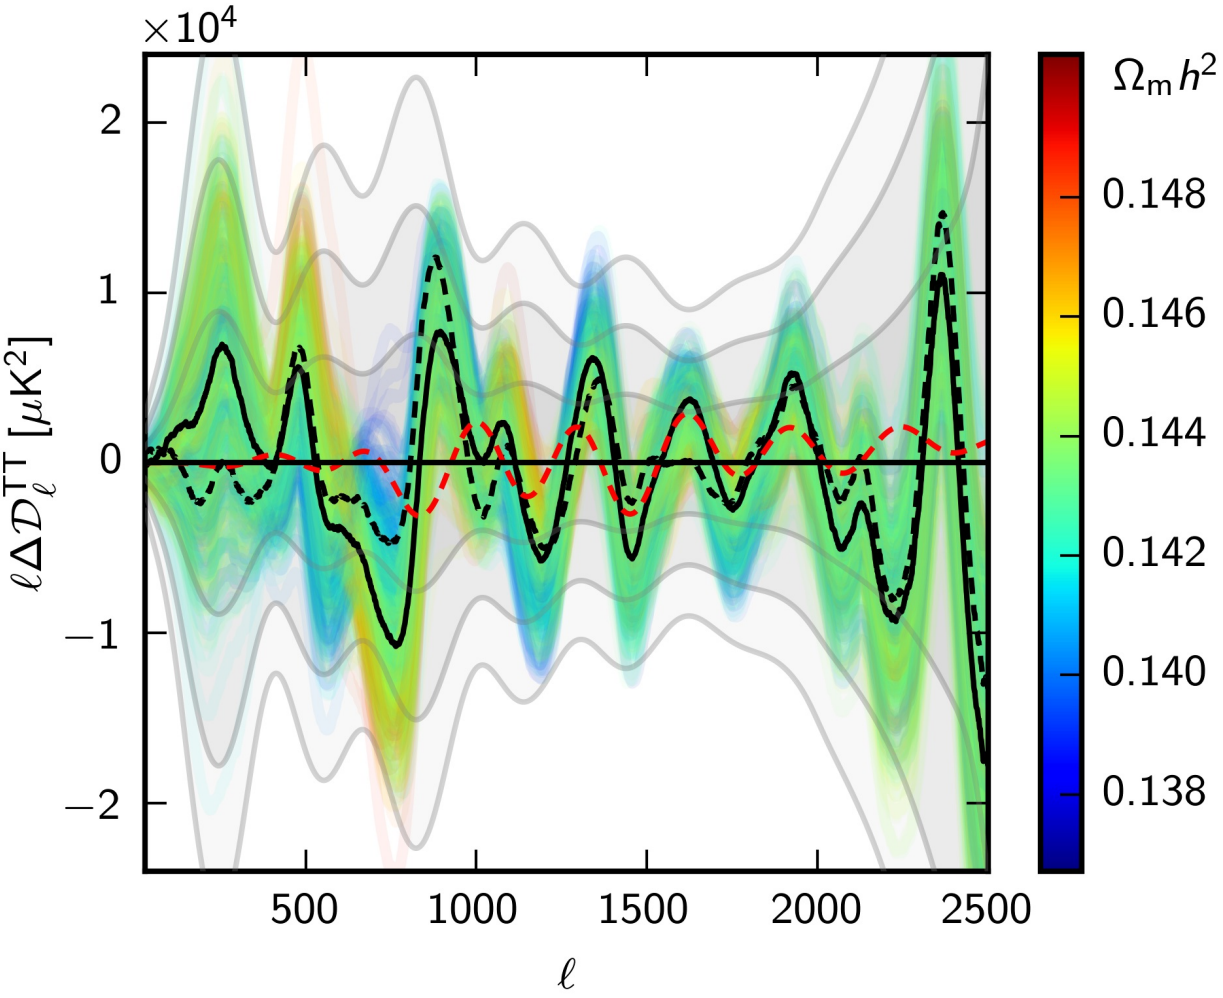

Figure 190: Base-ΛCDM model ($A_{\rm L} = 1$) TT power spectrum residuals smoothed with a Gaussian kernel of width $\sigma_\ell = 40$. The black line shows the smoothed difference between the coadded data points and the theoretical model for the *Planck* TT+lowE best-fit model, while coloured lines show the residuals for samples over the allowed parameter space coloured by the value of $\Omega_{\rm m}h^2$. Grey bands show the 1, 2, and 3 σ diagonal range expected for the smoothed residuals in the best-fit model. The red dashed line shows 10 % of the lensing-smoothing difference predicted in the best-fit model, displaying the oscillatory signal expected if there were more lensing of the acoustic peaks. The data residuals are not particularly anomalous, but the residuals have a similar pattern to the lensing smoothing difference over the approximate range $\ell = 1100$–2000, giving a preference for around 10 % more lensing at fixed cosmological parameters. Allowed models with lower $\Omega_{\rm m}h^2$ (and hence higher H_0) predict less lensing and give a larger oscillatory residual, preferring relatively more lensing smoothing than models with high matter density. The black dashed line shows the smoothed residual for the *Planck* TT +lowE best fit to ΛCDM+$A_{\rm L}$ (with $A_{\rm L} = 1.19$).

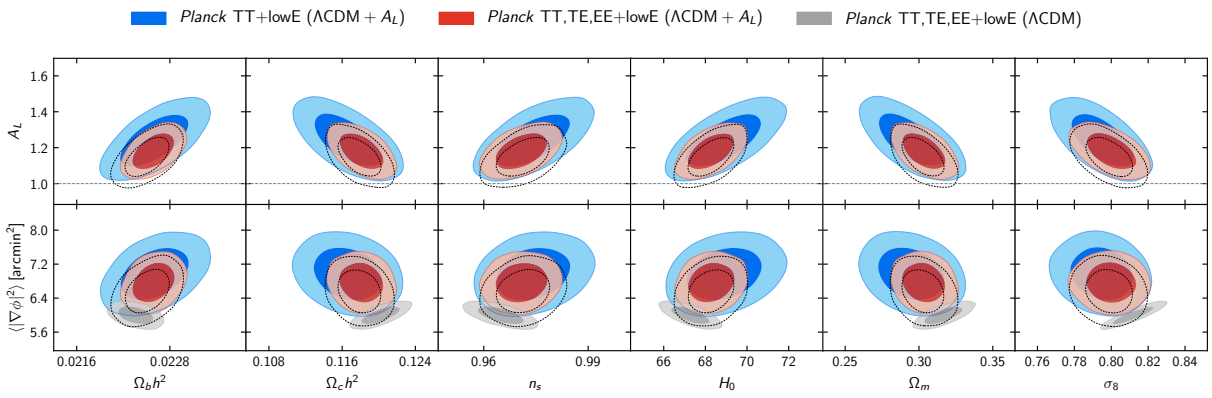

Figure 191: Marginalized 68 % and 95 % parameter constraint contours when adding $A_{\rm L}$ as a single-parameter extension to the base-ΛCDM model, with (red) and without (blue) small-scale polarization, compared to the constraints in the base-ΛCDM model (grey). The dashed contours show equivalent results for *Planck* TT,TE,EE+lowE when using the `CamSpec` likelihood, which gives results with $A_{\rm L}$ nearer unity and with slightly larger errors. The second row of subplots show, on the left axis, the predicted lensing deflection angle variance (from lensing multipoles $2 \leq L \leq 2000$), which is a measure of the amount of actual lensing: the TT,TE,EE+lowE likelihood prefers about 10 % more actual lensing power (associated with lensing smoothing), but in the (unphysical) varying-$A_{\rm L}$ case this can be achieved using cosmological parameters that predict less lensing than in ΛCDM but substantially larger $A_{\rm L}$, giving a preference for $A_{\rm L} \approx 1.2$.

28 Planck 2018 results. X. Constraints on inflation

We report on the implications for cosmic inflation of the 2018 release of the *Planck* cosmic microwave background (CMB) anisotropy measurements. The results are fully consistent with those reported using the data from the two previous *Planck* cosmological releases, but have smaller uncertainties thanks to improvements in the characterization of polarization at low and high multipoles. *Planck* temperature, polarization, and lensing data determine the spectral index of scalar perturbations to be $n_{\rm s} = 0.9649 \pm 0.0042$ at 68 % CL. We find no evidence for a scale dependence of $n_{\rm s}$, either as a running or as a running of the running. The Universe is found to be consistent with spatial flatness with a precision of 0.4 % at 95 % CL by combining *Planck* with a compilation of BAO data. The *Planck* 95 % CL upper limit on the tensor-to-scalar ratio, $r_{0.002} < 0.10$, is further tightened by combining with the BICEP2/Keck Array BK15 data to obtain $r_{0.002} < 0.056$. In the framework of standard single-field inflationary models with Einstein gravity, these results imply that: (a) the predictions of slow-roll models with a concave potential, $V''(\phi) < 0$, are increasingly favoured by the data; and (b) based on two different methods for reconstructing the inflaton potential, we find no evidence for dynamics beyond slow roll. Three different methods for the non-parametric reconstruction of the primordial power spectrum consistently confirm a pure power law in the range of comoving scales $0.005\,{\rm Mpc}^{-1} \lesssim k \lesssim 0.2\,{\rm Mpc}^{-1}$. A complementary analysis also finds no evidence for theoretically motivated parameterized features in the *Planck* power spectra. For the case of oscillatory features that are logarithmic or linear in k, this result is further strengthened by a new combined analysis including the *Planck* bispectrum data. The new *Planck* polarization data provide a stringent test of the adiabaticity of the initial conditions for the cosmological fluctuations. In correlated, mixed adiabatic and isocurvature models, the non-adiabatic contribution to the observed CMB temperature variance is constrained to 1.3 %, 1.7 %, and 1.7 % at 95 % CL for cold dark matter, neutrino density, and neutrino velocity, respectively. *Planck* power spectra plus lensing set constraints on the amplitude of compensated cold dark matter-baryon isocurvature perturbations that are consistent with current complementary measurements. The polarization data also provide improved constraints on inflationary models that predict a small statistically anisotropic quadupolar modulation of the primordial fluctuations. However, the polarization data do not support physical models for a scale-dependent dipolar modulation. All these findings support the key predictions of the standard single-field inflationary models, which will be further tested by future cosmological observations.

28.1 Introduction

[!tbp]

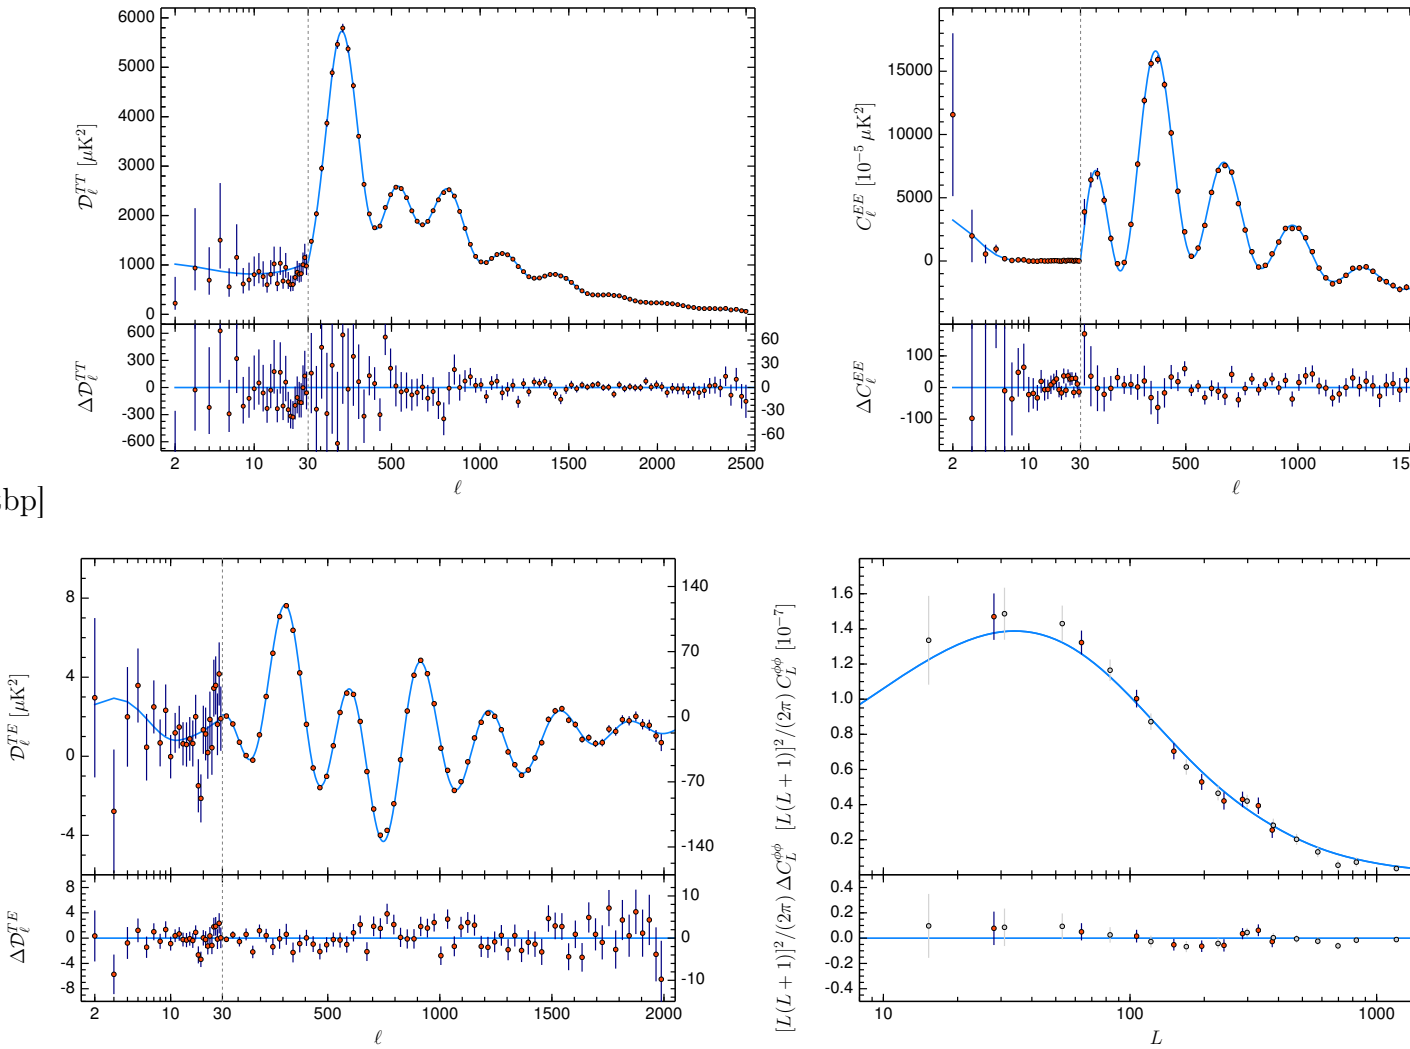

Figure 192: *Planck* 2018 CMB angular power spectra, compared with the base-ΛCDM best fit to the *Planck* TT,TE,EE+lowE+lensing data (blue curves). For each panel we also show the residuals with respect to this baseline best fit. Plotted are $\mathcal{D}_\ell = \ell(\ell+1)C_\ell/(2\pi)$ for TT and TE, C_ℓ for EE, and $L^2(L+1)^2C_L^{\phi\phi}/(2\pi)$ for lensing. For TT, TE, and EE, the multipole range $2 \leq \ell \leq 29$ shows the power spectra from `Commander` (TT) and `SimAll` (TE, EE), while at $\ell \geq 30$ we display the co-added frequency spectra computed from the `Plik` cross-half-mission likelihood, with foreground and other nuisance parameters fixed to their best-fit values in the base-ΛCDM cosmology. For the *Planck* lensing potential angular power spectrum, we show the conservative (orange dots; used in the likelihood) and aggressive (grey dots) cases. Note some of the different horizontal and vertical scales on either side of $\ell = 30$ for the temperature and polarization spectra and residuals.

This paper, one of a set associated with the 2018 release of data from the *Planck*[161] mission, presents the implications for cosmic inflation of the 2018 *Planck* measurements of the cosmic microwave background (CMB) anisotropies. In terms of data, this paper updates [279]

[161] *Planck* (`http://www.esa.int/Planck`) is a project of the European Space Agency (ESA) with instruments provided by two scientific consortia funded by ESA member states and led by Principal Investigators from France and Italy, telescope reflectors provided through a collaboration between ESA and a scientific consortium led and funded by Denmark, and additional contributions from NASA (USA).

(henceforth **(alias?)**), which was based on the temperature data of the nominal *Planck* mission ("PR1"), including the first 14 months of observations, and [288] (henceforth **(alias?)**), which used temperature data and a first set of polarization data from the full *Planck* mission ("PR2"), comprising 29 and 52 months of observations for the high frequency instrument (HFI) and low frequency instrument (LFI), respectively.

The ideas underlying cosmic inflation were developed during the late 1970s and early 1980s in order to remedy a number of defects of the hot big-bang cosmological model (e.g., the horizon, smoothness, flatness, and monopole problems) [44, 260, 153, 247, 119, 170, 15, 171]. Subsequently, it was realized that, on account of quantum vacuum fluctuations, cosmic inflation also provides a means to generate the primordial cosmological perturbations [205, 206, 130, 121, 261, 18, 204]. The development of cosmic inflation is one of the major success stories of modern cosmology, and in this paper we explore how the latest 2018 release of the *Planck* data constrains inflationary models.

Planck data currently provide the best constraints on the CMB anisotropies, except on very small angular scales beyond the resolution limit of *Planck* . The *Planck* data set has enabled a precision characterization of the primordial cosmological perturbations and has allowed cosmological parameters to be constrained at the sub-percent level. One of the main data products, described in more detail in the following section, is the *Planck* TT, TE, EE, and lensing power spectra, which are shown in Fig. 192, together with the residuals from the six-parameter concordance Λ cold dark matter (ΛCDM) model using the best-fit parameter values.

In order to provide a quantitative estimate of the improvement achieved by *Planck*, as well as to show where *Planck* stands compared to an ultimate cosmic-variance-limited survey, we consider an idealistic estimator for the number of modes [i.e., the effective number of $a_{\ell m}$'s measured [282]]:

$$N^{XY}_{\rm modes}(\ell) \equiv 2\sum_{\ell'=2}^{\ell}\left(\frac{C^{XY}_{\ell'}}{\Delta C^{XY}_{\ell'}}\right)^2 , \tag{1232}$$

where C^{XY}_ℓ (ΔC^{XY}_ℓ) is the (error on the) angular power spectrum of the XY channel [282, 249]. The number of modes measured by *Planck* is 1 430 000 and 109 000 for temperature ($XY = TT$ up to $\ell = 2500$) and polarization ($XY = EE$ up to $\ell = 2000$), respectively [230]. The number of modes measured is increased by approximately a factor of 7 (570) for temperature (polarization) with respect to the WMAP 9-year measurement, but there is still a factor of 3 (40) to gain for a cosmic-variance-limited experiment up to $\ell = 2500$ accessing 70 % of the sky. The additional modes measured by *Planck* play a key role in improving the constraints on the initial conditions for the cosmological perturbations and on models of inflation with respect to previous measurements of CMB anisotropies.

Planck data have also greatly improved the constraints on bispectral non-Gaussianity, both for the "local" pattern, as predicted by many inflationary models, and for other templates such as the equilateral one, as analysed and reported in detail in the dedicated *Planck* non-Gaussianity papers [280, 287, 295]. The constraints on the non-Gaussianity parameter $f_{\rm NL}$ are limited by a combination of cosmic variance and instrumental noise. An order-of-magnitude estimate for the signal-to-noise ratio for the local pattern (with $f^{\rm loc}_{\rm NL} = 1$) is given by

$$\left(\frac{S}{N}\right)^2 \propto \Omega_{\rm sky}\ell^2_{\rm max}\ln\left(\frac{\ell_{\rm max}}{\ell_{\rm min}}\right) . \tag{1233}$$

For the local shape, the logarithm enters because most of the signal derives from detecting the modulation of the small-scale power by the large-scale CMB anisotropy, highlighting the importance of full-sky maps for this kind of analysis. For other shapes such as equilateral, one instead has $(S/N)^2 \sim \Omega_{\rm sky}\ell^2_{\rm max}$. *Planck* has significantly sharpened the constraints on $f_{\rm NL}$, largely on account of its measurement of high multipoles with higher signal-to-noise ratio compared to past surveys. Some improvement has also been obtained from including polarization.

The *Planck* measurements have significantly constrained the physics of inflation. The hypothesis of adiabatic Gaussian scalar fluctuations with a power spectrum described by a simple power law, which is the key prediction of the standard single-field slow-roll inflationary models, has been tested to unprecedent accuracy (**(alias?)**, **(alias?)**;Planck Collaboration XXIV 280, Planck Collaboration XVII 287). *Planck* has set tight constraints on the amount of inflationary gravitational waves by exploiting the shape of the CMB temperature spectrum [**(alias?)**]. These results have inspired a resurgence of activity in inflationary model building.

For more details, see, for example, the following review articles and references therein: Linde [168]; Martin et al. [182]; Guth et al. [120]; and Burgess et al. [49]. *Planck* analysis and interpretation have also sparked a debate on the likelihood of initial conditions for some inflationary models [144, 143, 169], which is primarily of theoretical interest and is not addressed in this paper. In combination with more sensitive B-mode ground-based polarization measurements, as from BICEP-Keck Array [**(alias?)**], *Planck* has convincingly ruled out the slow-roll inflationary model with a quadratic potential [**(alias?)**]. In terms of physics beyond the simplest slow-roll inflationary models, the pre-*Planck* hints of a running spectral index [139] or of large non-Gaussianities [31] have disappeared as a result of the *Planck* measurements. How to interpret anomalies on the largest angular scales and at high multipoles is a question motivating the search for new non-standard inflationary models. We discuss how the *Planck* 2018 release data further test these ideas.

This paper is organized as follows. In Sect. 28.2 we describe the statistical methodology, the *Planck* likelihoods, and the complementary data sets used in this paper. In Sect. 28.3 we discuss the updated constraints on the spectral index of the scalar perturbations, on spatial curvature, and on the tensor-to-scalar ratio. Section 28.4 is devoted to constraining slow-roll parameters and to a Bayesian model comparison of inflationary models, taking into account the uncertainties in connecting the inflationary expansion to the subsequent big-bang thermalized era. In Sect. 28.5 the potential for standard single-field inflation is reconstructed using two different methodologies. Section 28.6 describes the primordial power spectrum reconstruction using three different approaches. In Sect. 28.7, the parametric search for features in the primordial scalar power spectrum is described, including a dedicated study of the axion monodromy model. In Sect. 28.8, the *Planck* power spectrum data are combined with information from the *Planck* bispectrum in a search for oscillations in the primordial spectra. The constraints on isocurvature modes are summarized in Sect. 28.9. Section 28.10 updates and extends the constraints on anisotropic inflationary models of inflation. We summarize our conclusions in Sect. 28.11, highlighting the key results and the legacy of *Planck* for inflation.

28.2 Methodology and data

The general theoretical background and analysis methods applied in this paper closely match those of the previous *Planck* inflation papers [**(alias?)**, **(alias?)**]. Consequently, in this section we provide only a brief summary of the methodology and focus on changes in the *Planck* likelihood relative to previous releases.

28.2.1 Cosmological models and inference

For well over a decade, the base-ΛCDM model has been established as the simplest viable cosmological model. Its six free parameters can be divided into primordial and late-time parameters. The former describe the state of perturbations on observable scales (corresponding to a wavenumber range of $10^{-4}\,\mathrm{Mpc}^{-1} \lesssim k \lesssim 10^{-1}\,\mathrm{Mpc}^{-1}$ today) prior to re-entering the Hubble radius around recombination. In base ΛCDM, the initial state of perturbations is assumed to be purely adiabatic and scalar, with the spectrum of curvature perturbations given by the power law

$$\ln \mathcal{P}_{\mathcal{R}}(k) = \ln A_{\mathrm{s}} + (n_{\mathrm{s}} - 1)\ln(k/k_*) \equiv \ln \mathcal{P}_0(k), \tag{1234}$$

where k_* denotes an arbitrary pivot scale. The late-time parameters, on the other hand, determine the linear evolution of perturbations after re-entering the Hubble radius. By default we use the basis $(\omega_{\mathrm{b}}, \omega_{\mathrm{c}}, \theta_{\mathrm{MC}}, \tau)$[162] for the late-time parameters, but occasionally also consider non-minimal late-time cosmologies. Because of the inflationary perspective of this paper, we are mainly interested in exploring modifications of the primordial sector and their interpretation in terms of the physics of the inflationary epoch.

Perturbations produced by generic single-field slow-roll models of inflation are typically well

[162] Refer to Table 27 for definitions.

Table 27: Baseline and optional late-time parameters, primordial power spectrum parameters, and slow-roll parameters. All primordial quantities are evaluated at a pivot scale of $k_* = 0.05\,\mathrm{Mpc}^{-1}$, unless otherwise stated.

Parameter	**Definition**
$\omega_\mathrm{b} \equiv \Omega_\mathrm{b} h^2$	Baryon density today
$\omega_\mathrm{c} \equiv \Omega_\mathrm{c} h^2$	Cold dark matter density today
θ_MC	Approximation to the angular size of sound horizon at last scattering
τ	Optical depth to reionization
N_eff	Effective number of neutrino species
Σm_ν	Sum of neutrino masses
Ω_K	Spatial curvature parameter
w_0	Dark energy equation of state parameter
A_s	Scalar power spectrum amplitude
n_s	Scalar spectral index
$\mathrm{d}n_\mathrm{s}/\mathrm{d}\ln k$	Running of scalar spectral index
$\mathrm{d}^2 n_\mathrm{s}/\mathrm{d}(\ln k)^2$	Running of running of scalar spectral index
r	Tensor-to-scalar power ratio
n_t	Tensor spectral index
$\epsilon_1 = -\dot{H}/H^2$	First Hubble slow-roll parameter
$\epsilon_{n+1} = \dot{\epsilon}_n/(H\epsilon_n)$	$(n+1)$st Hubble slow-roll parameter $(n \geq 1)$
$\epsilon_V = M_\mathrm{pl}^2 V_\phi^2/(2V^2)$	First potential slow-roll parameter, where $_\phi \equiv \mathrm{d}/\mathrm{d}\phi$
$\eta_V = M_\mathrm{pl}^2 V_{\phi\phi}/V$	Second potential slow-roll parameter
$\xi_V^2 = M_\mathrm{pl}^4 V_\phi V_{\phi\phi\phi}/V^2$	Third potential slow-roll parameter
$\varpi_V^3 = M_\mathrm{pl}^6 V_\phi^2 V_{\phi\phi\phi\phi}/V^3$	Fourth potential slow-roll parameter

approximated by the following form of the adiabatic scalar and tensor components:

$$\ln \mathcal{P}_\mathcal{R}(k) = \ln \mathcal{P}_0(k) + \frac{1}{2}\frac{d\ln n_\mathrm{s}}{d\ln k}\ln(k/k_*)^2 + \frac{1}{6}\frac{d^2\ln n_\mathrm{s}}{d\ln k^2}\ln(k/k_*)^3 + \ldots, \tag{1235}$$

$$\ln \mathcal{P}_\mathrm{t}(k) = \ln(rA_\mathrm{s}) + n_\mathrm{t}\ln(k/k_*) + \ldots, \tag{1236}$$

which allows for a weak scale dependence of the scalar spectral index, n_s, modelled by a running, $d\ln n_\mathrm{s}/d\ln k$, or a running of the running, $d^2\ln n_\mathrm{s}/d(\ln k)^2$.[163] The power spectrum parameterization in Eq. 1235 can be extended to address wider classes of inflation-related questions, (e.g., the search for isocurvature perturbations, specific primordial features in the spectra, etc.), as described in subsequent sections. We also go beyond simple functions to parameterize the primordial power spectrum. In the spirit of reconstructing the primordial spectrum from the data, we consider some general parameterizations (e.g., taking the power spectrum as an interpolation between knots of freely varied amplitudes at fixed or varying wavenumbers).

One could argue that the primordial power spectra are merely intermediate quantities and assess theories directly from more fundamental parameters. By using the slow-roll approximation, or by evolving the mode equations to obtain exact numerical predictions for the spectra without resorting to the slow-roll approximation, we can relate the primordial perturbations to the dynamics of the Hubble parameter during inflation or to the inflaton potential and its derivatives, thus constraining these quantities directly.

For any given model, theoretical predictions of CMB-related and other cosmological observables are calculated using appropriately modified versions of the Boltzmann codes `CAMB` [166] or `CLASS` [56]. As in [**(alias?)**, **(alias?)**], we compare models $\mathcal{M}_1$ and $\mathcal{M}_2$ by the difference in the logarithm of the likelihood of their best fits, or *effective* $\Delta\chi^2 \equiv 2\,[\ln \mathcal{L}_\mathrm{max}(\mathcal{M}_1) - \ln \mathcal{L}_\mathrm{max}(\mathcal{M}_2)]$.

[163] Unless explicitly stated otherwise, we adopt a default pivot scale $k_* = 0.05\,\mathrm{Mpc}^{-1}$ in this work. As in previous *Planck* releases, we will also quote the tensor-to-scalar ratio $r_{0.002}$ at $k_* = 0.002\,\mathrm{Mpc}^{-1}$ in order to facilitate comparison with earlier primordial tensor-mode constraints.

We apply Bayesian statistical methods to infer the posterior probability distributions of the model parameters and select between competing models [270], using either the Metropolis-Hastings Markov-chain Monte Carlo (MCMC) sampling algorithm, as implemented in `CosmoMC` [164] and `Monte Python` [30], or software based on nested sampling [253], such as `MultiNest` [88, 89] or `PolyChord` [126, 127]. The latter can simultaneously estimate the Bayesian evidence $\mathcal{E}_i$ of a model $\mathcal{M}_i$, allowing the comparison between different models via the Bayes factor, $B = \mathcal{E}_2/\mathcal{E}_1$, where $|\ln B| > 5$ is commonly considered "strong" evidence for or against the respective model [147, 268].

28.2.2 Data

Planck data

The *Planck* data processing has improved in a number of key aspects with respect to the previous 2015 cosmological release. We briefly summarize the main points here, referring the interested reader to [290] and [291] for details.

The flagging procedure in the LFI 2018 pipeline has been made more aggressive, in particular for the first 200 operational days. However, the most important improvement in the LFI pipeline is in the calibration approach. Whereas in the 2015 release, the main calibration source for LFI was the *Planck* orbital dipole (i.e., the amplitude modulation of the CMB dipole induced by the satellite orbit) of each single radiometer model, the 2018 procedure also includes the Galactic emission along with the orbital dipole in the calibration model and becomes iterative [290].

The HFI data for the 2018 release have also been made more conservative, cutting approximately 22 days of observations under non-stationary conditions with respect to 2015. The main change in the HFI data processing is the use of a new map making and calibration algorithm called `SRoll`, whose first version was introduced in [297] for the initial analysis of HFI polarization on large angular scales. This algorithm employs a generalized polarization destriper which uses the redundancy in the data to extract several instrumental systematic-effect parameters directly from the data [291].

These improvements have a minor impact on *Planck* temperature maps, but are much more important for polarization, particularly on large angular scales, allowing, for instance, the removal of the high-pass filtering adopted in the 2015 study of isotropy and statistics [226].

In the following, we summarize the essentials of the *Planck* inputs used in this paper (i.e., the *Planck* likelihood approach to the information contained in the 2-point statistics of the temperature and polarization maps and the *Planck* CMB lensing likelihood). As for previous cosmological releases, the *Planck* likelihood approach is hybridized between low- and high-multipole regions, which therefore are summarized separately below. We refer the interested reader to the relevant papers Planck Collaboration V [293] (henceforth **(alias?)**) and Planck Collaboration VIII [294] (henceforth **(alias?)**) for a more complete description of these inputs.

Planck low-ℓ likelihood

As in the *Planck* 2015 release, several options are available for evaluating the temperature likelihood on large angular scales, each with its own computational complexity and approximations. One option is based on the `Commander` framework and implements full Bayesian sampling of an explicit parametric model that includes both the cosmological CMB signal and non-cosmological astrophysical signals, such as thermal dust, CO, and low-frequency foregrounds. This framework is described in earlier papers [see Planck Collaboration XI [283] and Planck Collaboration Int. XLVI [297] and references therein for details]. The only changes since the 2015 implementation concern the data and model selection. As described in Planck Collaboration IV [292], we only use the *Planck* 2018 data in the current data release, whereas the previous 2015 version additionally included WMAP [33] and Haslam [129] observations. With fewer frequencies available, this requires a simpler model, and in particular we now fit for only a single low-frequency foreground component, rather than individual synchrotron, free-free, and spinning dust emission components, and we only fit a single CO component, rather than for individual CO line components at 100, 217, and 353 GHz. On the one hand, this results in fewer internal foreground degeneracies compared to the 2015 version, and a likelihood that only depends on *Planck* data, but at the same time the simpler foreground modelling also requires a slightly larger Galactic mask. Overall, the two versions are very compatible in terms

of the recovered CMB power spectra, as discussed in **(alias?)**. For additional details on the `Commander` temperature analysis, see Planck Collaboration IV [292].

The HFI low-ℓ polarization likelihood is based on the full-mission HFI 100-GHz and 143-GHz Q and U low-resolution maps cleaned through a template-fitting procedure with LFI 30 GHz and HFI 353 GHz information[164] used as tracers of polarized synchrotron and thermal dust, respectively (see **(alias?)** for details about the cleaning procedure). The likelihood method, called `SimAll`, represents a follow-up of the `SimBaL` algorithm presented in Planck Collaboration Int. XLVI [297] and uses the FFP10 simulations to construct empirically the probability for the EE and BB spectra. The method is based on the quadratic maximum likelihood estimation of the cross-spectrum between 100 and 143 GHz, and its multipole range spans from $\ell = 2$ to $\ell = 29$. We only built the likelihood for EE and BB and not for TE, due to the poor statistical consistency of the TE spectrum for $\ell > 10$, and due to the difficulty of describing accurately the correlation with TT and EE, given the limited number of simulations available; see discussions in section 2.2.6 of **(alias?)**. Further details about the method and consistency tests are presented in **(alias?)**. When combined with the low-ℓ temperature likelihood (based on the `Commander` CMB solution), the low-ℓ polarization likelihood implies $\tau = 0.051 \pm 0.009$ and $r_{0.002} < 0.41$ at 95 % CL.

As an alternative to the `Commander` and `SimAll` low-ℓ likelihood, an update of the joint temperature and polarization pixel-based low-ℓ LFI likelihood used in 2015 is part of this *Planck* data release. Its methodology (see **(alias?)** for details) is similar to that of 2015 [283], i.e., a pixel-based approach in TQU at $N_{\rm side} = 16$, and employs the `Commander` solution in temperature along with the LFI 70-GHz linear polarization maps, foreground cleaned using the *Planck* 30-GHz and 353-GHz channels as tracer templates for synchrotron and dust, respectively. This 2018 version allows for a larger sky fraction in polarization (66.4 %, compared to the previous 46 %) and retains the sky surveys 2 and 4 that were excluded in 2015. By performing a two-parameter estimate for $A_{\rm s}$ and τ restricted to $\ell < 30$, we find using this likelihood that $\tau = 0.063 \pm 0.020$ and $\ln(10^{10} A_{\rm s}) = 2.975 \pm 0.056$ at 68 % CL. The latter value has been derived by varying the TT, EE, and TE CMB spectra.

Planck high-ℓ likelihood

The 2018 baseline high-ℓ likelihood (`Plik`) is an update of the 2015 baseline version. The `CamSpec` likelihood is also used to explore alternative data cuts and modelling of the data and is described below. Both approaches implement a Gaussian likelihood approximation using cross-spectra between the 100-, 143-, and 217-GHz maps. `Plik` covers the multipoles $30 \leq \ell \leq 2509$ in temperature and $30 \leq \ell \leq 1997$ in polarization (i.e., for TE and EE). In order to avoid noise bias, the high-ℓ likelihood relies only on half-mission map cross-spectra, which have been demonstrated to be largely free of correlated noise. The spectra are computed on masked maps in order to reduce the anisotropic Galactic contamination (dominated by dust emission), and in the case of TT also strong point sources and CO emission. The `Plik` masks, identical to the 2015 masks, are tailored to each frequency channel and differ in temperature and polarization to take into account differing foreground behaviour and channel beams. The `Plik` intensity (polarization) masks effectively retain 66, 57, and 47 % (70, 50, and 41 %) of the sky after apodization for the 100, 143, and 217 GHz channels, respectively. Unlike in 2015, when the map beams were computed for an average sky fraction, they are now computed for the exact sky fraction used at each frequency. The data vector used in the likelihood approximation discards multipoles that are highly contaminated by foregrounds or have low signal-to-noise ratios.

The `Plik` power spectra are binned using the same scheme as in 2015. Unbinned likelihoods are also available. When forming the data vector, individual cross-frequency spectra are not co-added. This allows for independent exploration of the calibration, nuisance, and foreground parameter space for each cross-spectrum using dedicated templates in the theory vector.

The `Plik` (and `CamSpec`) covariance matrices are computed for a fixed fiducial CMB including the latest estimate of the foreground and systematics, which are all assumed to be Gaussian. As verified in 2015, after the masks have been applied this is a reasonable assumption. The covariance matrix computation uses an approximation to account for mask-induced correla-

[164] The polarized synchrotron component is fitted only at 100 GHz, being negligible at 143 GHz. For the polarized dust component, following the prescription in Planck Collaboration III [291], the low-ℓ HFI polarization likelihood used the 353-GHz map constructed only from polarization-sensitive bolometers.

tions. Plik uses only the large Galactic mask in the analytic computation and then takes extra correlations due to the point-source mask into account using a Monte Carlo estimate of the extra variance induced. Missing pixels are ignored in the covariance. In 2015 its was shown that this approach (i.e., Gaussian approximation and approximate covariance) induced only a less than 0.1σ bias on $n_{\rm s}$ (from the $30 < \ell < 100$ modes).

The Plik noise model has been re-estimated on the latest HFI maps using the same methodology as in 2015, based on a comparison between noise-biased auto-spectra and cross-spectra. This procedure avoids correlated glitch residuals, which had biased previous noise estimates [283], particularly in polarization at $\ell \lesssim 500$.

The 2018 HFI data processing pipeline has refined the maps used in the likelihood relative to 2015. For example, an improved destriping procedure reduced the residual scatter in the polarization maps, in particular at 143 GHz (yielding about 12 % lower noise on the half-mission cross-spectrum). More stringent selection cuts resulted in the discarding of the last 1000 rings of data, increasing the noise in the temperature half-mission spectrum by about 3 %. Also, a higher threshold was imposed on the conditioning of the TQU intra-pixel noise covariance matrix for a pixel to be considered well-measured, resulting in more missing pixels relative to 2015.

The data modelling has also significantly improved, in particular for polarization, making cosmological constraints from polarization more reliable. In 2015, the polarization spectra (TE and EE) displayed relatively large inter-frequency disagreements. A plausible explanation (at least for TE) was the temperature-to-polarization leakage induced by beam and calibration differences (so-called "beam leakage"). The beam-leakage modelling has improved substantially in 2018 [137] so that we can now propagate the beams, gain differences, polarization angles, etc. to compute a reliable template for the beam leakage and thus remove these leakage effects. These improvements substantially reduce the TE inter-frequency disagreements.

We also reassessed the estimates of the polarization efficiency for the polarized channels. Comparing different data-based estimates demonstrates that the ground-based polarization efficiency uncertainty estimates (of the order of a fraction of a percent) were too optimistic by a factor of 5 to 10. Correcting for the observed polarization efficiency errors (at the percent level) very significantly reduces the EE inter-frequency disagreements. This calibration correction relies on cosmological priors (using the TT best-fit cosmology). Calibrating using either the TE or the EE spectra yields generally consistent results, except at 143 Ghz where there is disagreement at more than 2σ. At this level, this discrepancy can be caused either by a statistical fluctuation, or by an unknown residual.

The Plik baseline likelihood implements a map-based calibration. The TE calibration is deduced from the TT and EE calibrations, including at 143 GHz. Other improvements over the 2015 version are the following. The dust model has been improved in temperature and polarization, using also the latest version of the 353-GHz maps. The level of synchrotron contamination in the 100-GHz and 143-GHz maps has been estimated and shown to be negligible. Sub-pixel noise has been included in TT and EE (and demonstrated to have a negligible effect on the cosmological parameters). Finally, a correlated component of the noise has been observed in the end-to-end HFI simulation, affecting the large scales and very small scales of the EE auto-frequency spectra. The large-scale contribution affects the dust correction and the $n_{\rm s}$ constraints. We constructed an empirical model of this correlated noise from our simulations, which is included in the Plik likelihood.

CamSpec was the baseline for the 2013 release and was described in detail in Planck Collaboration XV [275], and used cross-spectra formed from detector-set temperature maps using data from the nominal mission period. It was extended for the 2015 release to include both polarization and temperature-polarization cross-spectra and to use the data from the full mission period. Similarly to Plik, CamSpec switched from detector-set cross-spectra to cross-spectra formed from frequency maps constructed from separate halves of the full mission data in order to mitigate the effects of noise correlated between detectors. In 2015, the foreground modelling was also modified and the sky fraction retained at each frequency was increased, using common masks with Plik in temperature. CamSpec used a more conservative mask in polarization than Plik.

Differently from Plik, CamSpec corrects each TE and EE cross-frequency spectrum with a fixed dust and temperature-to-polarization leakage template before co-adding them to form the EE and TE components of its data vector and bases its noise estimate on differences between maps constructed using alternating pointing periods. Note also that CamSpec uses an

individual-spectrum-based calibration scheme, where the TE calibrations are not fixed to be those inferred from the TT and EE ones.

In the 2018 release further improvements in the `CamSpec` foreground modelling have been implemented. The dust model in temperature has been updated in a way similar to `Plik`. `CamSpec` now uses a richer model of the cosmic infrared background, allowing for the exploration of any impact on the cosmological parameters. As explained above, the noise modelling was also modified. Further modifications of the masking have been made for polarization, still using the same masks for each frequency channel, but different from the `Plik` mask. As we discussed above, beam-leakage and polarization-efficiency corrections are applied to the individual polarization spectra before their addition for inclusion in the likelihood. More details on the `Plik` and `CamSpec` likelihoods can be found in **(alias?)**.

As in 2015, the high-ℓ `Plik` and `CamSpec` likelihoods are in excellent agreement for temperature. The different assumptions for the polarization-efficiency parameters and the masks [283] propagate into differences in cosmological parameter estimates. For the baseline ΛCDM model, the difference in cosmological parameters between the `Plik` likelihood and the `CamSpec` likelihood (using joint TT,TE,EE in combination with `Commander`, `SimAll`, and lensing) is at most 0.5σ (for $\Omega_b h^2$) (Planck Collaboration XIII 284, henceforth **(alias?)**). Similar differences in cosmological parameters occur in extended cosmological models. The differences between the `Plik` and `CamSpec` parameters are dominated by calibration-model differences for the joint TT,TE,EE and TE-only cases, and by mask differences for the EE-only case. To a large extent, the `CamSpec` results can be reproduced within the `Plik` framework simply by changing in `Plik` the calibration model (for TE) and the polarization mask (for EE). Below we use `Plik` as the *Planck* baseline high-ℓ likelihood. `CamSpec` results are used to assess the residual uncertainty from modelling and mask choices. We quote values obtained with `CamSpec` only for a few cases.

We use the following conventions for naming the *Planck* likelihoods: (i) *Planck* TT+lowE denotes the combination of the high-ℓ TT likelihood at multipoles $\ell \geq 30$ and the low-ℓ temperature-only `Commander` likelihood, plus the `SimAll` low-ℓ EE-only likelihood in the range $2 \leq \ell \leq 29$; (ii) *Planck* TE and *Planck* EE denote the TE and EE likelihood at $\ell \geq 30$, respectively; (iii) *Planck* TT,TE,EE+lowE denotes the combination of the combined likelihood using TT, TE, and EE spectra at $\ell \geq 30$, the low-ℓ temperature `Commander` likelihood, and the low-ℓ `SimAll` EE likelihood; and (iv) *Planck* TT,TE,EE+lowP denotes the combination of the likelihood using TT, TE, and EE spectra at $\ell \geq 30$ and the alternative joint temperature-polarization likelihood at $2 \leq \ell \leq 29$, based on the temperature `Commander` map and the 70-GHz polarization map. Unless otherwise stated, high-ℓ results are based on the `Plik` likelihood and low-ℓ polarization information is based on `SimAll`.

Planck CMB lensing likelihood

The *Planck* 2018 lensing likelihood, presented in **(alias?)**, uses the lensing trispectrum to estimate the power spectrum of the lensing potential $C_L^{\phi\phi}$. This signal is extracted using a minimum-variance combination of a full set of temperature- and polarization-based quadratic lensing estimators [210] applied to the `SMICA` CMB map over approximately 70 % of the sky using CMB multipoles $100 \leq \ell \leq 2048$, as described in **(alias?)**. We use the lensing bandpower likelihood, with bins spanning lensing multipoles $8 \leq L \leq 400$, which has been validated with numerous consistency tests. Because its multipole range has been extended down to $L = 8$ (compared to $L = 40$ for the *Planck* 2015 analysis), the statistical power of the lensing likelihood used here is slightly greater.

Non-*Planck* data

While the data derived exclusively from *Planck* observations are by themselves already extremely powerful at constraining cosmology, external data sets can provide helpful additional information. The question of consistency between *Planck* and external data sets is discussed in detail in Planck Collaboration VI [235] (henceforth **(alias?)**). Here we focus on two data sets that are particularly useful for breaking degeneracies and whose errors can be assessed reliably. We consider the measurement of the CMB B-mode polarization angular power spectrum by the BICEP2/Keck Array collaboration and measurements of the baryon acoustic oscillation

(BAO) scale. The supplementary B-mode data provide independent constraints on the tensor sector, which are better than those that can be derived from the *Planck* data alone (based on the shape of the scalar power spectrum). The BAO data, on the other hand, do not directly constrain the primordial perturbations. These data, however, provide invaluable low-redshift information that better constrain the late-time cosmology, especially in extensions of ΛCDM, and thus allow degeneracies to be broken.

BICEP2/Keck Array 2015 B-mode polarization data

Although *Planck* measured the CMB polarization over the full sky, its polarization sensitivity in the cosmological frequency channels is not sufficient to compete with current suborbital experiments surveying small, particularly low-foreground patches of the sky very deeply using many detectors. In **(alias?)**, constraints on r using the joint BICEP2/Keck Array and *Planck* (BKP) analysis [51] were reported. Here we make use of the most recent B-mode polarization data available from the analysis of the BICEP2/Keck field (Ade et al. 11, henceforth **(alias?)**), unless otherwise stated. The BK15 likelihood draws on data from the new Keck array at 220 GHz in addition to those already in use for the **(alias?)** [10] likelihood, i.e., the 95 and 150-GHz channel, as well as from *Planck* and WMAP to remove foreground contamination. The BK15 observations measure B-mode polarization using 12 auto- and 56 cross-spectra between the BICEP2/Keck maps at 95, 150, and 220 GHz, the WMAP maps at 23 and 33 GHz, and the *Planck* maps at 30, 44, 70, 100, 143, 217, and 353 GHz, using nine bins in multipole number. By using B-mode information only within the BK15 likelihood, a 95 % upper limit of $r < 0.07$ is found [**(alias?)**], which improves on the corresponding 95 % CL $r < 0.09$ [**(alias?)**] based on the BK14 likelihood.

Baryon acoustic oscillations

Acoustic oscillations of the baryon-photon fluid prior to recombination are responsible for the acoustic peak structure of the CMB angular power spectra. The counterpart to the CMB acoustic peaks in the baryon distribution are the BAOs, which remain imprinted into the matter distribution to this day. In the position-space picture, the BAOs of the power spectrum correspond to a peak in the correlation function, defining a characteristic, cosmology-dependent length scale that serves as a standard ruler and can be extracted (e.g., from galaxy redshift surveys). The transverse information of a survey constrains the ratio of the comoving angular diameter distance and the sound horizon at the drag epoch (i.e., when the baryon evolution becomes unaffected by coupling to the photons), D_M/r_d, whereas the line-of-sight information yields a measurement of $H(z)r_\mathrm{d}$. Sometimes, these two observables are combined to form the direction-averaged quantity $D_V/r_\mathrm{d} \equiv \left[czD_M^2(z)H^{-1}(z)\right]^{1/3}/r_\mathrm{d}$.

For our BAO data compilation, we use the measurements of D_V/r_d from the 6dF survey at an effective redshift $z_\mathrm{eff} = 0.106$ [47], and the SDSS Main Galaxy Sample at $z_\mathrm{eff} = 0.15$ [313], plus the final interpretation of the SDSS III DR12 data [15], with separate constraints on $H(z)r_\mathrm{d}$ and D_M/r_d in three correlated redshift bins at $z_\mathrm{eff} = 0.38$, 0.51, and 0.61. In [9], the same set of BAO data combined with either non-*Planck* CMB data or measurements of the primordial deuterium fraction was shown to favour a cosmology fully consistent with, but independent of, *Planck* data.

28.3 *Planck* 2018 results for the main inflationary observables

As in **(alias?)** and **(alias?)**, we start by describing *Planck* measurements of the key inflationary parameters. Some of the results reported in this section can be found in the Planck Legacy Archive.[165]

Parameter	TT+lowE	EE+lowE	TE+lowE	TT,TE,EE+lowE	TT,TE,EE
$\Omega_b h^2$	0.02212 ± 0.00022	0.0240 ± 0.0012	0.02249 ± 0.00025	0.02236 ± 0.00015	0.0223

Table 28: Confidence limits for the cosmological parameters in the base-ΛCDM model from *Planck* temperature, polarization, and temperature-polarization cross-correlation separately and combined, in combination with the EE measurement at low multipoles.

28.3.1 Results for the scalar spectral index

Planck temperature data in combination with the *EE* measurement at low multipoles determine the scalar spectral tilt in the ΛCDM model as

$$n_s = 0.9626 \pm 0.0057 \quad (68\,\%\ \text{CL},\ \textit{Planck}\ \text{TT+lowE})\,. \tag{1237}$$

This result for n_s is compatible with the *Planck* 2015 68 % CL value $n_s = 0.9655 \pm 0.0062$ for *Planck* TT+lowP [**(alias?)**]. The slightly lower value for n_s is mainly driven by a corresponding shift in the average optical depth τ, now determined as

$$\tau = 0.052 \pm 0.008 \quad (68\,\%\ \text{CL},\ \textit{Planck}\ \text{TT+lowE})\,, \tag{1238}$$

which is to be compared with the *Planck* 2015 value $\tau = 0.078 \pm 0.022$ [**(alias?)**]. This more precise determination of τ is due to better noise sensitivity of the HFI 100- and 143-GHz channels employed in the low-ℓ `SimAll` polarization likelihood, compared to the joint temperature-polarization likelihood based on the LFI 70-GHz channel in 2015. Because of the degeneracy between the average optical depth and the amplitude of the primordial power spectrum, A_s and σ_8 are also lower than in the *Planck* 2015 release. These shifts from the *Planck* 2015 values for the cosmological parameters have been anticipated with the first results from the HFI large-angular polarization pattern [297, 298].

The trend toward smaller values for (n_s,τ) with respect to the *Planck* 2015 release also occurs for different choices for the low-ℓ likelihood. By substituting `Commander` and `SimAll` with the updated joint temperature-polarization pixel likelihood coming from the LFI 70-GHz channel, we obtain in combination with high-ℓ temperature data:

$$n_s = 0.9650 \pm 0.0061 \quad (68\,\%\ \text{CL},\ \textit{Planck}\ \text{TT+lowP})\,; \tag{1239}$$

$$\tau = 0.072 \pm 0.016 \quad (68\,\%\ \text{CL},\ \textit{Planck}\ \text{TT+lowP})\,. \tag{1240}$$

Although with larger errors, these latter results are consistent with the shifts induced by a determination of a lower optical depth than in the *Planck* 2015 release,[166] as found in Eqs. (1237) and (1238). Given this broad agreement and the consistency in the values of τ derived with `SimAll` separately from the three cross-spectra 70 × 100, 70 × 143, and 100 × 143 [**(alias?)**], we will mainly use the baseline low-ℓ likelihood in the rest of the paper.

As anticipated in 2015, the information in the high-ℓ polarization *Planck* data is powerful for breaking degeneracies in the parameters and to further decrease parameter uncertainties

[165] http://www.cosmos.esa.int/web/planck/pla

[166] As in 2015, the combination with high-ℓ data pulls τ to larger values than the low-ℓ pixel likelihood alone, i.e. $\tau = 0.063 \pm 0.020$ at 68 % CL; see Sect. 28.2. This effect is less pronounced for the `SimAll` likelihood.

compared to temperature data alone. The addition of high-ℓ polarization leads to a tighter constraint on $n_{\rm s}$:

$$n_{\rm s} = 0.9649 \pm 0.0044 \quad (68\,\%\ \text{CL},\ \textit{Planck}\ \text{TT,TE,EE+lowE}). \tag{1241}$$

This is in good agreement with the *Planck* 2015 TT,TE,EE+lowP 68 % CL result, $n_{\rm s} = 0.9645 \pm 0.0049$. In this 2018 release the mean value of $n_{\rm s}$ is approximately 0.5σ larger than the temperature result in Eq. (1237). This pull is mainly due to a higher value for the scalar tilt preferred by *Planck* 2018 polarization and temperature-polarization cross-correlation data only:

$$n_{\rm s} = 0.969 \pm 0.009 \quad (68\,\%\ \text{CL},\ \textit{Planck}\ \text{TE,EE+lowE})\,. \tag{1242}$$

This pull is then mitigated in combination with temperature due to the larger uncertainty in the determination by TE,EE only. Similar considerations hold for the alternative `CamSpec` high-ℓ likelihood, which leads to a 68 % CL result $n_{\rm s} = 0.9658 \pm 0.0045$, consistent with the baseline `Plik` reported in Eq. (1241). Overall, the cosmological parameters from *Planck* baseline temperature, polarization, and temperature-polarization cross-correlation separately and combined are very consistent, as can be seen from Table 28 and Fig. 193 for the ΛCDM model.

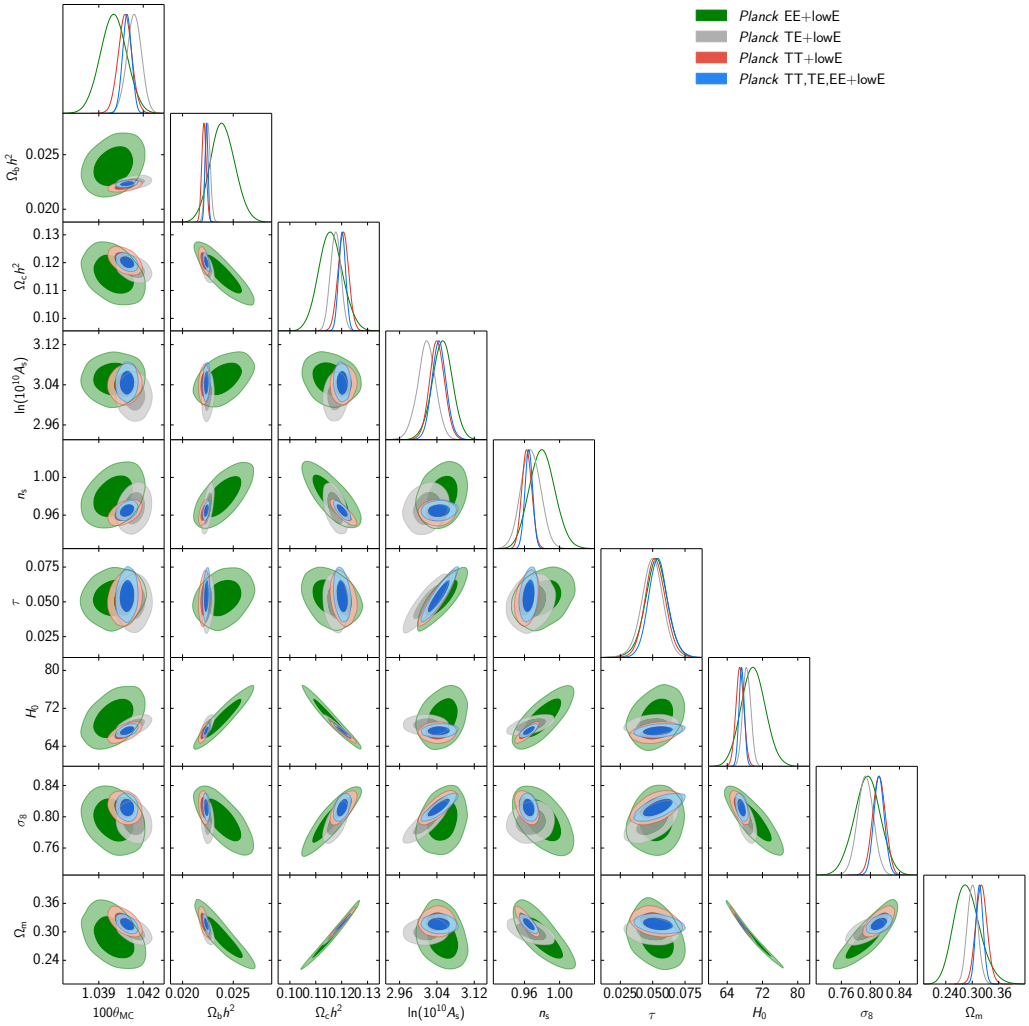

Figure 193: Marginalized joint 68 % and 95 % CL regions for the cosmological parameters in ΛCDM with *Planck* TT, EE, TE, and joint TT,TE,EE, all in combination with the EE likelihood at low multipoles.

After combining with *Planck* lensing, we obtain

$$n_s = 0.9634 \pm 0.0048 \quad (68\,\%\ \text{CL},\ \textit{Planck}\ \text{TT+lowE+lensing}), \tag{1243}$$

$$n_s = 0.9649 \pm 0.0042 \quad (68\,\%\ \text{CL},\ \textit{Planck}\ \text{TT,TE,EE+lowE+lensing}). \tag{1244}$$

The shift in n_s (and, more generally, in the cosmological parameters of the base-ΛCDM model) obtained when *Planck* lensing is combined with TT,TE,EE+lowE is smaller than in 2015 because of the improved polarization likelihoods. The combination with lensing is, however, powerful for breaking parameter degeneracies in extended cosmological models, and, therefore, for this 2018 release we will consider the full information contained in temperature, polarization, and lensing, i.e., TT,TE,EE+lowE+lensing, as the baseline *Planck* data set. Figure 194 shows a comparison of the *Planck* 2018 baseline results with those from alternative likelihoods and from the 2015 baseline for the ΛCDM cosmological parameters.

As in 2013 and 2015, BAO measurements from galaxy surveys are consistent with *Planck*. When BAO data are combined, we obtain for the base-ΛCDM cosmology:

$$n_s = 0.9665 \pm 0.0038 \quad (68\,\%\ \text{CL},\ \textit{Planck}\ \text{TT,TE,EE+lowE+lensing+BAO})\,. \tag{1245}$$

The combination with BAO data decreases (increases) the marginalized value of $\Omega_c h^2$ ($\Omega_b h^2$) obtained by *Planck*, and this effect is compensated for by a shift in n_s towards slightly larger values.

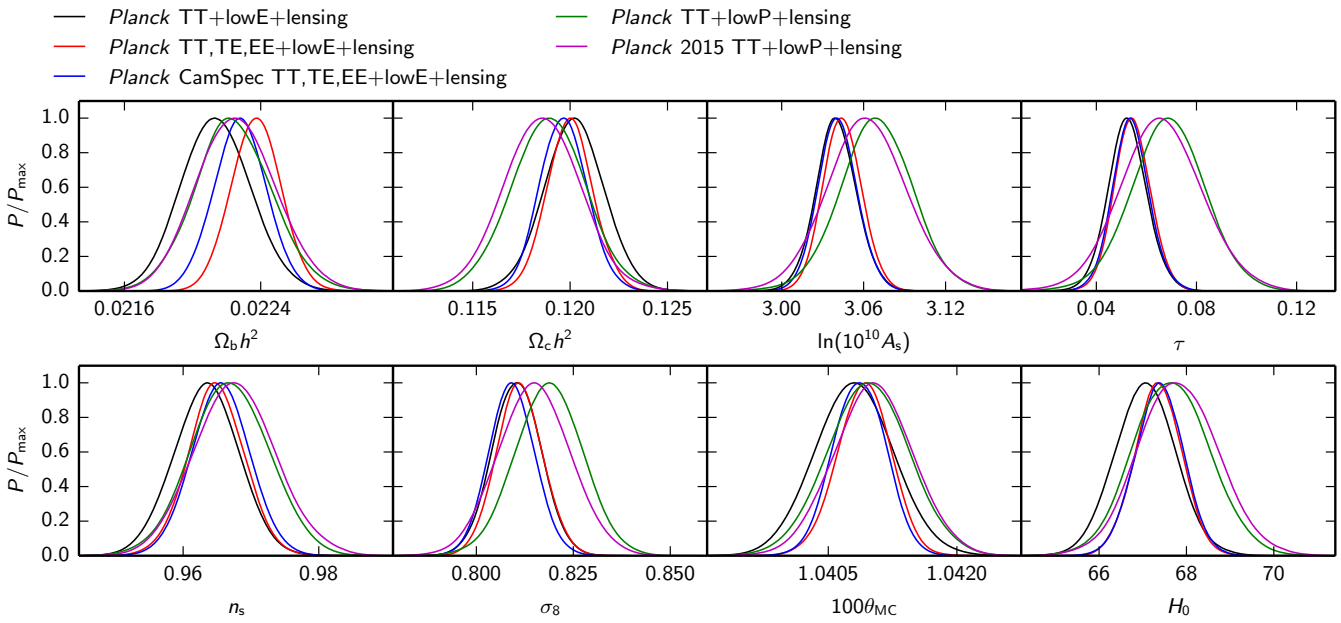

Figure 194: Comparison of the marginalized probability density of the primary parameters and $(\sigma_8\,, H_0)$ for the baseline cosmological model from *Planck* TT+lowE+lensing (black curves), TT,TE,EE+lowE+lensing (red curves), and the alternative likelihood `Camspec`. For comparison we also display the *Planck* 2018 TT+lowP+lensing (blue curves) and the corresponding *Planck* 2015 TT+lowP+lensing (green curves) results.

28.3.2 Ruling out $n_s = 1$

One of the main findings drawn from previous *Planck* releases was that the scale-independent Harrison-Zeldovich (HZ) spectrum [128, 282, 214] is decisively ruled out. This conclusion is reinforced in this release: in standard ΛCDM late-time cosmology, the scalar spectral index from Table 28 lies 6.6, 8.0, and 8.4σ away from $n_s = 1$, for *Planck* TT+lowE, *Planck* TT,TE,EE+lowE,

and *Planck* TT,TE,EE+lowE+lensing, respectively. The corresponding effective $\Delta\chi^2$ between the power-law spectrum and the best-fit HZ model are $\Delta\chi^2 = 43.9$, 66.9, and 72.4.

Simple one-parameter modifications of the cosmological model are not sufficient to reconcile a scale-invariant power spectrum with *Planck* data. For instance, when the effective number of neutrino species $N_{\rm eff}$ is allowed to float for a cosmology with a scale-invariant spectrum, the effective $\Delta\chi^2$ with respect to the power-law spectrum are $\Delta\chi^2 = 12.9$, 27.5, and 30.2, respectively.

When instead the assumption of flat spatial sections is relaxed,[167] we obtain effective $\Delta\chi^2$ values of $\Delta\chi^2 = 11.8$, 28.8, and 40.9, respectively, for the same data sets. Therefore, the corresponding closed cosmological models fitting *Planck* TT+lowE ($\Omega_K = -0.122^{+0.039}_{-0.029}$, $H_0 = 44.2^{+3.1}_{-4.3}\,{\rm km\,s^{-1}\,Mpc^{-1}}$ at 68 % CL), *Planck* TT,TE,EE+lowE ($\Omega_K = -0.095^{+0.029}_{-0.019}$, $H_0 = 47.1 \pm 3.2\,{\rm km\,s^{-1}\,Mpc^{-1}}$ at 68 % CL), and *Planck* TT,TE,EE+lowE+lensing ($\Omega_K = -0.032^{+0.006}_{-0.007}$, $H_0 = 58.9 \pm 2.0\,{\rm km\,s^{-1}\,Mpc^{-1}}$ at 68 % CL) provide a worse fit compared to the tilted flat ΛCDM model.[168]

28.3.3 Constraints on the scale dependence of the scalar spectral index

The *Planck* 2018 data are consistent with a vanishing running of the scalar spectral index. Using *Planck* TT,TE,EE+lowE+lensing we obtain

$$\frac{dn_{\rm s}}{d\ln k} = -0.0045 \pm 0.0067 \quad (68\,\%\ {\rm CL})\,. \tag{1246}$$

These results are consistent with, and improve on, the *Planck* 2015 result, $dn_{\rm s}/d\ln k = -0.008 \pm 0.008$ [**(alias?)**].

As discussed in **(alias?)** and **(alias?)**, a better fit to the temperature low-ℓ deficit was found in 2015, thanks to a combination of non-negative values for the running and the running of the running. The *Planck* 2018 release has significantly reduced the parameter volume of this extension of the base-ΛCDM model. The *Planck* 2018 TT(TT,TE,EE)+lowE+lensing constraints for the model including running of running are

$$n_{\rm s} = 0.9587 \pm 0.0056 \ (0.9625 \pm 0.0048)\,, \tag{1247}$$

$$dn_{\rm s}/d\ln k = 0.013 \pm 0.012 \ (0.002 \pm 0.010)\,, \tag{1248}$$

$$d^2n_{\rm s}/d\ln k^2 = 0.022 \pm 0.012 \ (0.010 \pm 0.013)\,, \tag{1249}$$

all at 68 % CL. It is interesting to note that the high-ℓ temperature data still allow a sizable value for the running of the running, although slightly decreased with respect to the *Planck* 2015 results [**(alias?)**]. However, when high-ℓ *Planck* 2018 polarization data are also included, $dn_{\rm s}/d\ln k$ and $d^2n_{\rm s}/d\ln k^2$ are tightly constrained.

The model including a scale-dependent running can produce a better fit to the low-ℓ deficit at the cost of an increase of power at small scales; this latter effect is constrained in this release. As an example of a model with suppression only on large scales, we also reconsider the phenomenological model with an exponential cutoff:

$$\mathcal{P}_{\mathcal{R}}(k) = \mathcal{P}_0(k)\left\{1 - \exp\left[-\left(\frac{k}{k_{\rm c}}\right)^{\lambda_{\rm c}}\right]\right\}, \tag{1250}$$

which can be motivated by a short stage of inflation [63, 62] (see also Kuhnel & Schwarz [158], Hazra et al. [131], and Gruppuso et al. [118] for other types of large-scale suppressions). We

[167] For non-flat models the power spectra encode the eigenvalues of the corresponding Laplacian operator of the spatial sections and scale invariance holds at scales much smaller than the curvature radius.

[168] This is not a new result based on the *Planck* 2018 release, but just an update of a similar conclusion also reached with the *Planck* 2015 data. Compared to the flat ΛCDM tilted model, we obtain $\Delta\chi^2 = 12.3$, 34.8, and 45 with *Planck* 2015 TT+lowP, *Planck* 2015 TT,TE,EE+ lowP, and *Planck* 2015 TT,TE,EE+lowP+lensing, respectively. Therefore, even with *Planck* 2015 data, a closed model with $n_{\rm s} = 1$ provides a worse fit than tilted ΛCDM and is not compelling as claimed in [211].

do not find any statistically significant detection of k_c using either logarithmic or linear priors and for different values of λ_c, with any combination of *Planck* baseline likelihoods. We have also checked that these results depend only weakly on the exclusion of the EE quadrupole in `SimAll` and are stable to the substitution of `Commander` and `SimAll` with the joint temperature-polarization likelihood based on the 70-GHz channel.

28.3.4 Constraints on spatial curvature

Table 29: Constraints on the tensor-to-scalar ratio r and scalar tilt n_s for the ΛCDM+r model and some important extensions and different data sets. For each model we quote 68 % confidence limits on measured parameters and 95 % upper bounds on other parameters.

Since the vast majority of inflation models predict that the Universe has been driven towards spatial flatness, constraints on the spatial curvature provide an important test of the standard scenario. Therefore in this subsection we extend the base-ΛCDM model with the addition of the spatial curvature parameter, Ω_K. For the case of *Planck* TT,TE,EE+lowE+lensing, we find a constraint of

$$\Omega_K = -0.011^{+0.013}_{-0.012} \quad (95\,\%\ \mathrm{CL})\,. \tag{1251}$$

The inclusion of *Planck* lensing information only weakly breaks the geometrical degeneracy [76] which results in the same primary fluctuations while varying the total matter density parameter, Λ, and H_0. The degeneracy can be effectively broken with the addition of BAO data, in which case *Planck* TT,TE,EE+lowE+lensing+BAO gives

$$\Omega_K = 0.0007 \pm 0.0037 \quad (95\,\%\ \mathrm{CL})\,. \tag{1252}$$

Although Ω_K is one of the cosmological parameters exhibiting some differences between `Plik` and `Camspec`, the constraints in Eqs. (1251) and (1252) are quite robust due to the inclusion of lensing (and BAO) information.

A constraint on the curvature parameter can be translated into a constraint on the radius of curvature, R_K, via

$$R_K = \left(a_0 H_0 \sqrt{|\Omega_K|}\right)^{-1}, \tag{1253}$$

in units such that $c = 1$. For the case of *Planck* TT,TE,EE+lowE+lensing+BAO we find

$$R_K > 67\,\mathrm{Gpc} \quad \text{(open)}, \tag{1254}$$

$$R_K > 81\,\mathrm{Gpc} \quad \text{(closed)}, \tag{1255}$$

both at 95 % confidence. These lengths are considerably greater than our current (post-inflation) particle horizon, at 13.9 Gpc.

Our tightest constraint, Eq. (1252), tells us that our observations are consistent with spatial flatness, with a precision of about 0.4 %. However, even if inflation has driven the background curvature extremely close to zero, the presence of fluctuations implies a fundamental "cosmic variance" for measurements of curvature confined to our observable volume. In particular, the known amplitude of fluctuations implies a standard deviation for Ω_K of roughly 2×10^{-5} [280]. Therefore our best constraint is still a factor of roughly 10^2 above the cosmic variance limit for a flat universe. A future measurement of negative curvature above the cosmic variance floor would point to open inflation [112, 113, 46, 281, 242, 175], while a measurement of positive curvature could pose a problem for the inflationary paradigm due to the difficulty of producing closed inflationary models [155].

Alternatively, excess spatial curvature might be evidence for the intriguing possibility that there was "just enough" inflation to produce structure on the largest observable scales. Indeed an upper limit on spatial curvature implies a lower limit on the total number of e-folds of inflation (see, e.g., Komatsu et al. 157). We can relate these limits to the number of e-folds of inflation, $N_* = N(k_*)$, after scale k_* left the Hubble radius during inflation, to be given explicitly in Eq. (1278). We define the (constant) curvature scale, k_K, as the inverse of the comoving radius of curvature, i.e.,

$$k_K \equiv aH\sqrt{|\Omega_K|}. \tag{1256}$$

In the absence of special initial conditions, inflation will begin with a curvature parameter of order unity. Equation (1256) then implies that $k_K \sim aH$ at the start of inflation, i.e., the curvature scale is "exiting the horizon" at that time. Then the lower limit on the number of e-folds of inflation will simply be $N_K \equiv N(k_K)$, i.e., the number of e-folds after scale k_K left the Hubble radius during inflation. With Eq. (1278) this gives[169]

$$N_K = \ln\frac{k_*}{a_0 H_0} - \frac{1}{2}\ln|\Omega_K| + N_*. \tag{1257}$$

With the pivot scale of $k_* = 0.002\,\mathrm{Mpc}^{-1}$ (for comparison with the values in Sect. 28.4.2) and our tightest upper limit on Ω_K from Eq. (1252), this becomes

$$N_K \gtrsim 4.9 + N_*. \tag{1258}$$

That is, our constraint on spatial curvature implies that inflation must have lasted at least about 5 e-folds longer than required to produce the pivot scale k_*. Equation (1258) provides a model-independent comparison between the e-folds required to solve the flatness problem (to current precision) and to produce large-scale fluctuations (at scale k_*). We stress that this limit assumes a unity curvature parameter at the start of inflation (although the dependence on this assumption, being logarithmic, is weak).

For comparison with the result of Komatsu et al. [157], we can simplify to the case of instantaneous thermalization and constant energy density during inflation. Then we find

$$N_K \gtrsim 34.2 + \ln\frac{T_{\mathrm{end}}}{1\,\mathrm{TeV}}, \tag{1259}$$

where T_{end} is the reheating temperature.

[169] This expression ignores a negligible correction, $(1/2)\ln V_{k_K}/V_{k_*}$, due to the different inflationary potential scales at k_* and k_K exit.

28.3.5 Constraints on the tensor-to-scalar ratio

This subsection updates constraints on the tensor-to-scalar ratio r assuming that the tensor tilt satisfies the consistency relation, $n_{\rm t} = -r/8$, which is the case for slow-roll inflation driven by a single scalar field with a canonical kinetic term.

By combining *Planck* temperature, low-ℓ polarization, and lensing we obtain

$$r_{0.002} < 0.10 \quad (95\,\%\ \text{CL},\ \textit{Planck}\ \text{TT+lowE+lensing})\,. \tag{1260}$$

This constraint slightly improves on the corresponding *Planck* 2015 95 % CL bound, i.e., $r_{0.002} < 0.11$ [**(alias?)**], and is unchanged when high-ℓ polarization data are also combined. Note that by using `CAMspec` instead of `Plik` as the high-ℓ joint temperature-polarization likelihood, we obtain a slightly looser bound, i.e., $r_{0.002} < 0.14$ at 95 % CL. By including the *Planck* B-mode information at $2 < \ell < 30$ in the low-ℓ polarization likelihood, the 95 % CL constraint is essentially unchanged.

Since inflationary gravitational waves contribute to CMB temperature anisotropies mostly at $\ell \lesssim 100$, the low-ℓ temperature deficit contributes in a nontrivial way to the *Planck* bound on r. By excising the $2 \leq \ell \leq 29$ temperature data, the constraint on r with *Planck* TT,TE,EE+lensing+lowEB relaxes to

$$r_{0.002} < 0.16 \quad (95\,\%\ \text{CL})\,. \tag{1261}$$

This result improves on the 2015 95 % CL result, i.e., $r \lesssim 0.24$ [**(alias?)**], because of the inclusion of high-ℓ polarization and of the improved determination of τ.

Since this *Planck* constraint on r relies on temperature and E-mode polarization, the *Planck*-only limit depends somewhat on the underlying cosmological model. Table 29 shows the constraints on $n_{\rm s}$ and r for a few important extensions of ΛCDM plus tensors, which include a non-zero running, a non-zero spatial curvature, and a non-minimal neutrino sector. We observe that the bound on r is relaxed by at most 30 % when the scale dependence of the scalar tilt is allowed to vary. In all the other extensions the *Planck* r bound is modified at most by 10 %, demonstrating the constraining power of the *Planck* 2018 release in reducing the degeneracy of the tensor-to-scalar ratio with other cosmological parameters. As far as the scalar tilt is concerned, we find the largest shift (by roughly 1σ higher) when the assumption of spatial flatness is relaxed.

A B-mode polarization measurement can further tighten the constraint on r and help in reducing its degeneracies with other cosmological parameters that may appear when using only temperature and E-mode polarization data. After the release of the first BICEP-Keck Array-*Planck* [**(alias?)**] joint cross-correlation, constraints on r from B-mode polarization data alone have become tighter than those based on *Planck* data alone, thanks to the inclusion of the 95-GHz channel [**(alias?)**] and of the 220-GHz channel [**(alias?)**]. By combining the *Planck* 2018 and BK15 data we obtain

$$\begin{aligned} r_{0.002} < 0.056 \quad & (95\,\%\ \text{CL},\ \textit{Planck}\ \text{TT,TE,EE} \\ & +\text{lowE+lensing+BK15})\,. \end{aligned} \tag{1262}$$

This bound improves on the corresponding one obtained in combination with **(alias?)**, i.e., $r_{0.002} < 0.064$ at 95 % CL. Note that by using `CAMspec` instead of `Plik` as high-ℓ TT,TE,EE likelihood, we obtain a slightly looser bound, i.e., $r_{0.002} < 0.069$ at 95 % CL. The effectiveness of the combination with the **(alias?)** likelihood in constraining r is also remarkable in the extensions of ΛCDM plus tensors, as can be seen from Table 29. By further combining with BAO the limits for r are only slightly modified.

The *Planck* 2018 baseline plus BK15 constraint on r is equivalent to an upper bound on the energy scale of inflation when the pivot scale exits the Hubble radius of

$$V_* = \frac{3\pi^2 A_{\rm s}}{2}\, r\, M_{\rm Pl}^4 < (1.6 \times 10^{16}\ \text{GeV})^4 \quad (95\,\%\ \text{CL})\,. \tag{1263}$$

Equivalently, this last result implies an upper bound on the Hubble parameter during inflation of

$$\frac{H_*}{M_{\rm Pl}} < 2.5 \times 10^{-5} \quad (95\,\%\ \text{CL})\,. \tag{1264}$$

28.3.6 Beyond the tensor-to-scalar ratio consistency condition

The increasing constraining power of B-mode polarization data allows us to set upper bounds on r without imposing the consistency condition for the tensor tilt, $n_t = -r/8$, which is motivated by standard slow-roll single-scalar-field inflation. Deviations can occur in multifield inflation [21, 279, 52], in the models with generalized Lagrangians [103, 156], in gauge inflation [178], or in a more radical way in alternative models to inflation [104, 41, 43].

As the current data do not lead to a detection of a non-zero tensor amplitude, virtually any value of n_t would give a good fit as long as r is close enough to zero. Therefore, as in **(alias?)**, we characterize the tensor perturbations by two well-constrained parameters that we choose to be r at two different scales, (r_{k_1}, r_{k_2}), with $k_1 = 0.002\,\mathrm{Mpc}^{-1}$ and $k_2 = 0.02\,\mathrm{Mpc}^{-1}$, and assume a power-law power spectrum. We call this two-parameter extension of the ΛCDM model the "ΛCDM+$r_{0.002}$+$r_{0.02}$" model. We also quote our results in terms of $(r_{\tilde{k}}, n_t)$, calculated from the primary parameters as $n_t = [\ln(r_{k_2}/r_{k_1}) \,/\, \ln(k_2/k_1)] + n_s - 1$ and $r_{\tilde{k}} = r_{k_1}(\tilde{k}/k_1)^{n_t - n_s + 1}$. For $\tilde{k}$ we choose $0.01\,\mathrm{Mpc}^{-1}$, which corresponds roughly to the decorrelation scale of r and n_t when using the *Planck* and BK15 data.

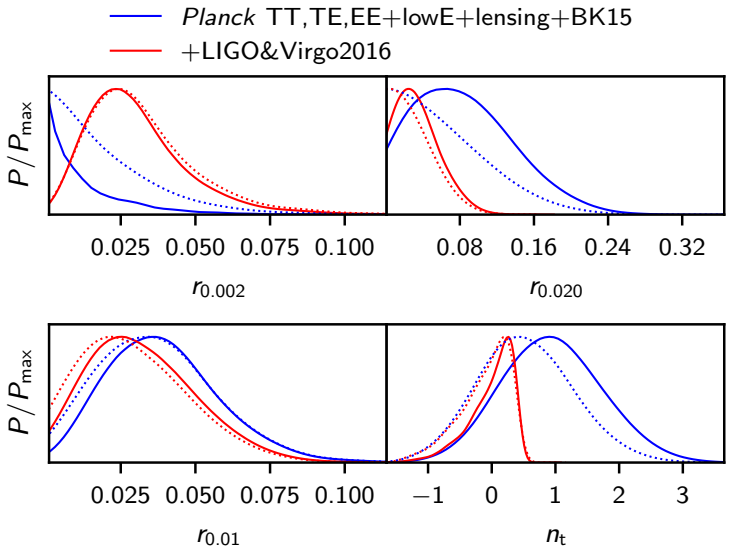

Figure 195: Posterior probability density of the tensor-to-scalar ratio at two different scales in the ΛCDM+$r_{0.002}$+$r_{0.02}$ model, i.e., when the inflationary consistency relation is relaxed (top panels). The solid contours show the results when $r_{0.002}$ and $r_{0.02}$ are used as sampling parameters with uniform priors, which leads to non-uniform priors for the derived parameters $r_{0.01}$ and n_t (bottom panels). The dotted contours indicate the results after weighting the posterior by the Jacobian $J = r_{0.01}/[r_{0.002} r_{0.02} \ln(0.02/0.002)]$ of the transformation $(r_{0.002}, r_{0.02}) \to (r_{0.01}, n_t)$, giving the result we would have obtained had we assigned uniform priors on $r_{0.01}$ and n_t.

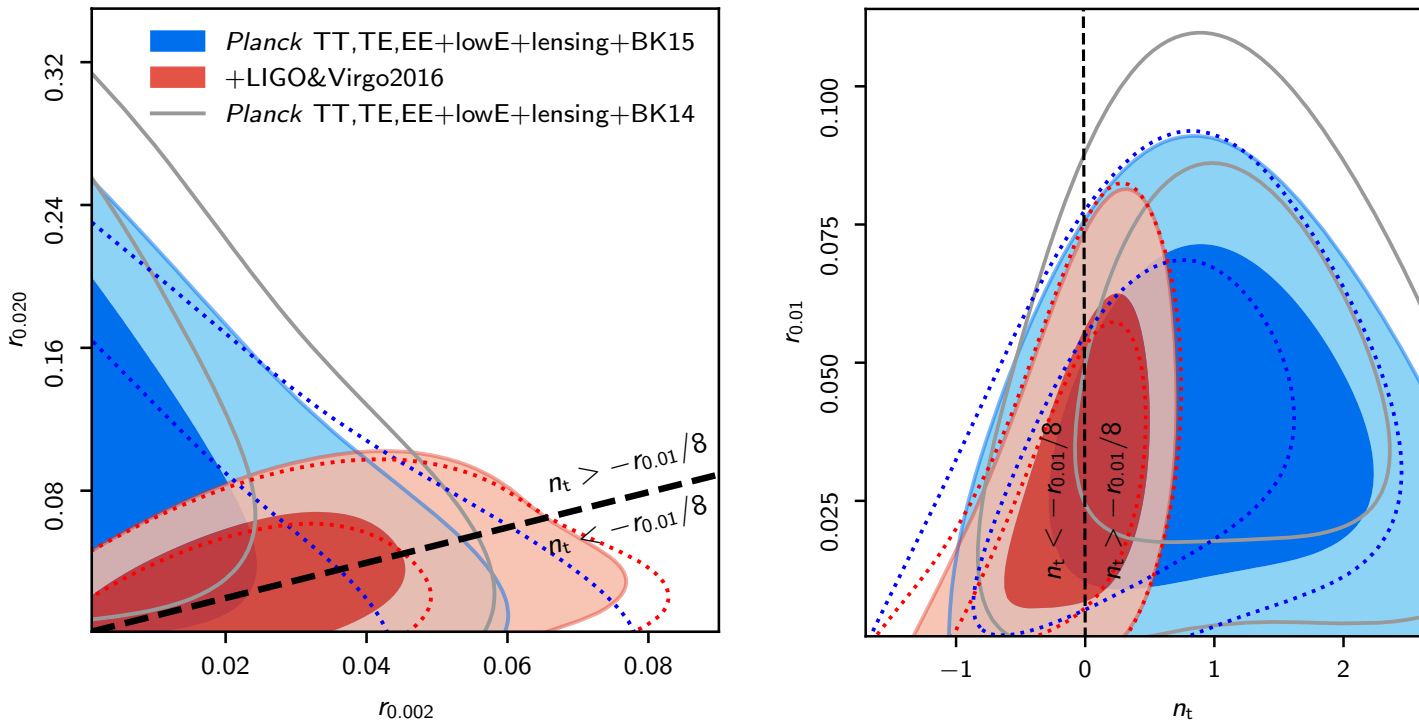

Figure 196: 68 % and 95 % CL constraints on tensor perturbations in the ΛCDM+$r_{0.002}$+$r_{0.02}$ model, i.e., when the inflationary consistency relation is relaxed. Filled contours in the left panel show the results for our independent primary parameters $r_{0.002}$ and $r_{0.02}$, which have uniform priors, and in the right panel for the derived parameters n_t and $r_{0.01}$, which have non-uniform priors. The dotted lines assume uniform priors on $r_{0.01}$ and n_t, calculated as in Fig. 195. The scale $k = 0.01\,\mathrm{Mpc}^{-1}$ is near the decorrelation scale of (n_t, r) for the *Planck*+BK15 data. In both panels the dashed black line indicates the inflationary consistency condition, $n_t = -r_{0.01}/8$. (The grey contours follow if we use the older BK14 data instead of the BK15 data.)

The one-dimensional posteriors are displayed in Fig. 195 (which also shows an additional data set, "LIGO&Virgo2016," discussed at the end of this subsection). We obtain for the ΛCDM+$r_{0.002}$+$r_{0.02}$ model:

$$\left.\begin{aligned} r_{0.002} &< 0.044 \\ r_{0.02} &< 0.184 \end{aligned}\right\} \begin{array}{l}(95\,\%\ \mathrm{CL},\ \textit{Planck} \\ \mathrm{TT,TE,EE} \\ +\mathrm{lowE}+\mathrm{lensing}+\mathrm{BK15}).\end{array} \tag{1265}$$

The constraints on the derived tensor parameters are $r_{0.01} < 0.076$ and $-0.55 < n_t < 2.54$ at 95 % CL.

The left and right panels of Fig. 196 show the two-dimensional contours for the primary parameters $(r_{0.002}, r_{0.02})$ and the derived ones $(r_{0.01}, n_t)$, respectively. The consistency condition, $n_t = -r/8$, denoted by the dashed lines, is fully compatible with *Planck*+BK15 data. However, a very blue tensor tilt with $n_t \simeq 2$ and $r_{0.01} \simeq 0.05$ is still within the 68 % CL region. Indeed, despite the larger amplitude of the primordial tensor power spectrum at small scales for blue n_t, the tensor modes are suppressed when re-entering the Hubble radius, which leads to damping of the observational signal at high k. This explains why the 68 % CL CMB constraint on $r_{0.02}$ is about a factor of four weaker than the one on $r_{0.002}$. Fig. 196 also shows a slight improvement of constraints by BK15 compared to the older BK14 data.

A stochastic background of gravitational waves (GWs) with a blue tensor tilt could be further constrained at much shorter wavelengths, such as those probed by ground-based interferometers dedicated to the direct detection of GWs. For example, assuming a scale-invariant tensor spectrum and using the frequency range (20–85.8) Hz, which corresponds to the wavenumbers

$k = 2\pi f = (1.3\text{–}5.5) \times 10^{16}\,\mathrm{Mpc}^{-1}$, LIGO and Virgo set an upper bound on the GW density parameter of $\Omega_{\rm GW}(f) \leq 1.7 \times 10^{-7}$ at 95 % CL [2]. While these scales are likely to be dominated by astrophysical sources, such as GWs from binary mergers, we next examine what constraints the LIGO&Virgo upper bound sets on primordial tensor perturbations, if we assume that they had a power-law spectrum all the way from CMB scales to ultra-short scales. We refer the interested reader to Meerburg et al. [187] and Cabass et al. [53] for the use of alternative data on short scales or of additional constraints on the effective energy-momentum tensor of the stochastic background of GWs averaged over wavelengths.

We obtain a conservative upper limit on the *primordial* contribution by demanding that the GW density from our scale-dependent primordial tensor perturbations [187, 2, 53],

$$\Omega_{\rm GW}(k) = \frac{k}{\rho_{\rm critical}} \frac{d\rho_{\rm GW}}{dk} = \frac{A_{\rm t}(k)}{24 z_{\rm eq}} = \frac{A_{\rm t1}(k/k_1)^{n_{\rm t}}}{24 z_{\rm eq}}, \tag{1266}$$

stays below the above-quoted limit at least at $k = 1.3 \times 10^{16}\,\mathrm{Mpc}^{-1}$ ($f = 20\,\mathrm{Hz}$). The posterior probability densities when this constraint is included in the analysis as a half-Gaussian prior are compared with those obtained by *Planck*+BK15 alone in Figs. 195 and 196. LIGO&Virgo sets a very high upper bound[170] on r at ultra-high k, separated from CMB scales by a factor of 10^{18} in k. Due to the long arm length, this effectively provides a cutoff for $n_{\rm t}$ and excludes the bluest spectra that were allowed by the CMB alone, leading to

$$\left.\begin{aligned} r_{0.002} &< 0.064 \\ r_{0.02} &< 0.081 \end{aligned}\right\} \begin{array}{l} (95\,\%\ \text{CL, } \textit{Planck} \\ \text{TT,TE,EE+lowE} \\ \text{+lensing+BK15+LIGO\&Virgo2016}), \end{array} \tag{1267}$$

or $r_{0.01} < 0.066$ and $-0.76 < n_{\rm t} < 0.52$. The consistency condition $n_{\rm t} = -r/8$ is also compatible with these tighter constraints, as can be seen by comparing the red contours and dashed black lines in Fig. 196. As LIGO&Virgo pushes $r_{0.02}$ down (and we assume a power-law tensor spectrum), the upper bound on $r_{0.002}$ becomes weaker than with the CMB alone. This is not surprising, since the system is analogous to a see-saw with a pivot point at $k \sim 0.01\,\mathrm{Mpc}^{-1}$, where the data are the most sensitive to the tensor perturbations (taking into account also the transfer function from primordial tensor perturbations to the observable B-mode signal). Once one end of the see-saw is pushed down the other end can go up without disturbing the spectrum too much at the middle scales. We will observe analogous behaviour with isocurvature perturbations, for which we also assume a power-law spectrum and have only an upper bound (not a detection); see Sect. 28.9.3.

28.4 Implications for single-field slow-roll inflationary models

In this section we discuss the implications of the *Planck* 2018 likelihood for standard single-field slow-roll inflation. We first update the results for the Hubble flow functions (HFFs) ϵ_i and the potential slow-roll parameters obtained by the analytic perturbative expansion in terms of the HFFs for the primordial spectra of fluctuations. For definitions of the HFF hierarchy and the potential slow-roll parameters see Table 27. We then present a Bayesian comparison for a representative selection of standard slow-roll inflationary models.

[170] Using Eq. (1266), the upper bound $\Omega_{\rm GW}(f = 20\,\mathrm{Hz}) \leq 1.7 \times 10^{-7}$ corresponds to a tensor perturbation amplitude $A_{\rm t}(k = 1.3 \times 10^{16}\,\mathrm{Mpc}^{-1}) \leq 24 z_{\rm eq} \times 1.7 \times 10^{-7} = 1.4 \times 10^{-2}$, where we used $z_{\rm eq} \simeq 3400$. Assuming further for the scalar perturbations that $n_{\rm s} = 0.9659$ and $\ln(10^{10} A_{\rm s}) = 3.044$ at $k = 0.05\,\mathrm{Mpc}^{-1}$, this can be converted into an upper bound $r \leq 2.6 \times 10^{7}$ at $k = 1.3 \times 10^{16}\,\mathrm{Mpc}^{-1}$.

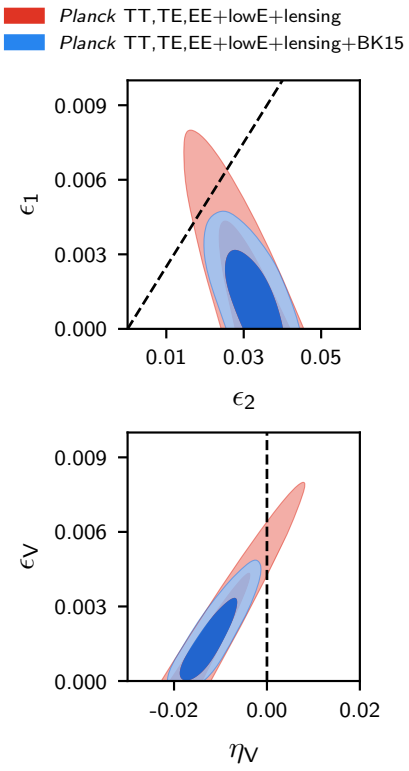

Figure 197: Marginalized joint two-dimensional 68 % and 95 % CL regions for $(\epsilon_1\,,\epsilon_2)$ (top panel) and $(\epsilon_V\,,\eta_V)$ (bottom panel) for *Planck* TT,TE,EE+lowE+lensing (red contours), compared with *Planck* TT,TE,EE+lowE+lensing+BK15 (blue contours). The dashed lines divide between convex and concave potentials.

28.4.1 Constraints on slow-roll parameters

Exploiting the approximate analytic expressions for the primordial power spectrum of scalar and tensor fluctuations obtained by the Green's function method [264, 107, 162], we can construct constraints on the slow-roll parameters.

When restricting to parameters first order in the HFFs, we obtain with *Planck* TT,TE,EE+lowE+lensing

$$\epsilon_1 < 0.0063 \qquad (0.0039) \qquad (95\,\%\ \mathrm{CL})\,, \tag{1268}$$

$$\epsilon_2 = 0.030^{+0.007}_{-0.005} \qquad (0.031 \pm 0.005) \qquad (68\,\%\ \mathrm{CL})\,. \tag{1269}$$

The *Planck* TT,TE,EE+lowE+lensing(+BK15) constraints on the slow-roll potential parameters ϵ_V and η_V can be obtained by an exact remapping of the constraints on the HFF parameters [162, 92] given above:

$$\epsilon_V < 0.0063 \qquad (0.0039) \qquad (95\,\%\ \mathrm{CL})\,, \tag{1270}$$

$$\eta_V = -0.010^{+0.004}_{-0.008} \qquad \left(-0.012^{+0.004}_{-0.005}\right) \qquad (68\,\%\ \mathrm{CL})\,. \tag{1271}$$

As can be seen from Fig. 197, the 95 % CL allowed contours are in the region of concave potentials when BK15 is combined with *Planck* 2018 data.

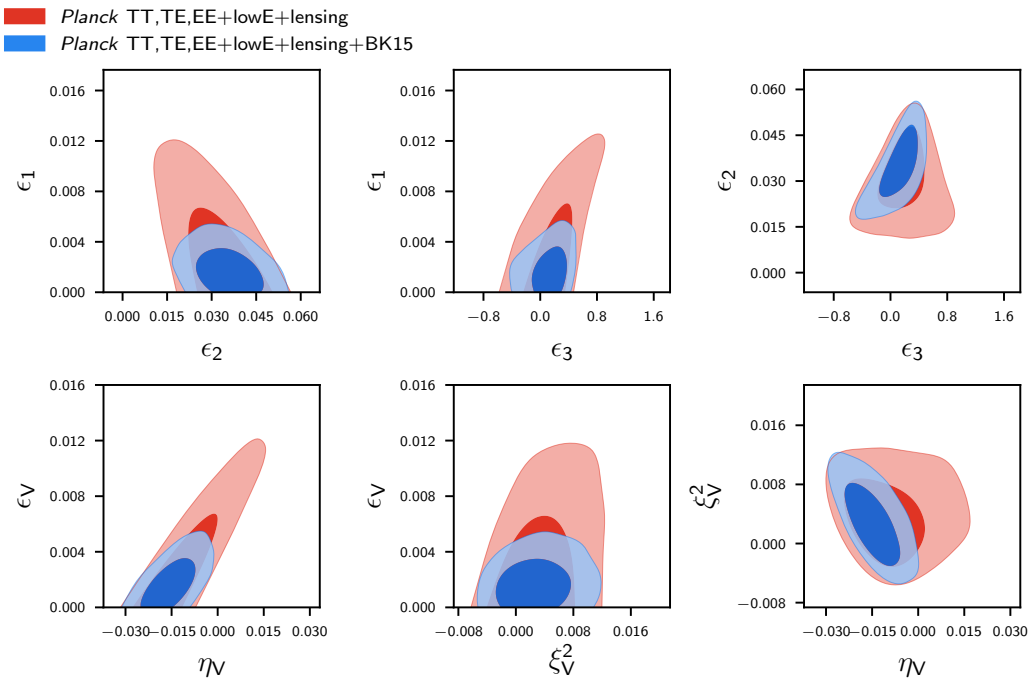

Figure 198: Marginalized joint two-dimensional 68 % and 95 % CL regions for combinations of $(\epsilon_1\,,\epsilon_2\,,\epsilon_3)$ (upper panels) and $(\epsilon_V\,,\eta_V,\xi^2_V)$ (lower panels) for *Planck* TT,TE,EE+lowE+lensing (red contours), compared with *Planck* TT,TE,EE+lowE+lensing+BK15 (blue contours).

When contributions to the primordial power spectra that are second-order in the HFFs are included, for *Planck* TT,TE,EE+lowE+lensing(+BK15) we obtain the following constraints on the slow-roll HFFs:

$$\epsilon_1 < 0.0097 \qquad (0.0044) \qquad (95\,\%\ \mathrm{CL})\,, \tag{1272}$$
$$\epsilon_2 = 0.032^{+0.009}_{-0.008} \qquad (0.035 \pm 0.008) \qquad (68\,\%\ \mathrm{CL})\,, \tag{1273}$$
$$\epsilon_3 = 0.19^{+0.55}_{-0.53} \qquad \left(0.12^{+0.36}_{-0.42}\right) \qquad (95\,\%\ \mathrm{CL})\,, \tag{1274}$$

and on the slow-roll potential parameters we obtain:

$$\epsilon_V < 0.0097 \qquad (0.0044) \qquad (95\,\%\ \mathrm{CL})\,, \tag{1275}$$
$$\eta_V = -0.010^{+0.007}_{-0.011} \qquad (-0.015 \pm 0.006) \qquad (68\,\%\ \mathrm{CL})\,, \tag{1276}$$
$$\xi^2_V = 0.0035^{+0.0078}_{-0.0072} \qquad \left(0.0029^{+0.0073}_{-0.0069}\right) \qquad (95\,\%\ \mathrm{CL})\,. \tag{1277}$$

The marginalized 68 % and 95 % CLs for the slow-roll HFF and potential parameters, allowing $\epsilon_3 \neq 0$, with *Planck* data alone or in combination with BK15, are displayed in Fig. 198.

Table 30: Priors for cosmological parameters used in the Bayesian comparison of inflationary models.

Parameter range	Prior type
$0.019 < \Omega_{\rm b}h^2 < 0.025$	uniform
$0.095 < \Omega_{\rm c}h^2 < 0.145$	uniform
$1.03 < 100\,\theta_{\rm MC} < 1.05$	uniform
$0.01 < \tau < 0.4$	uniform

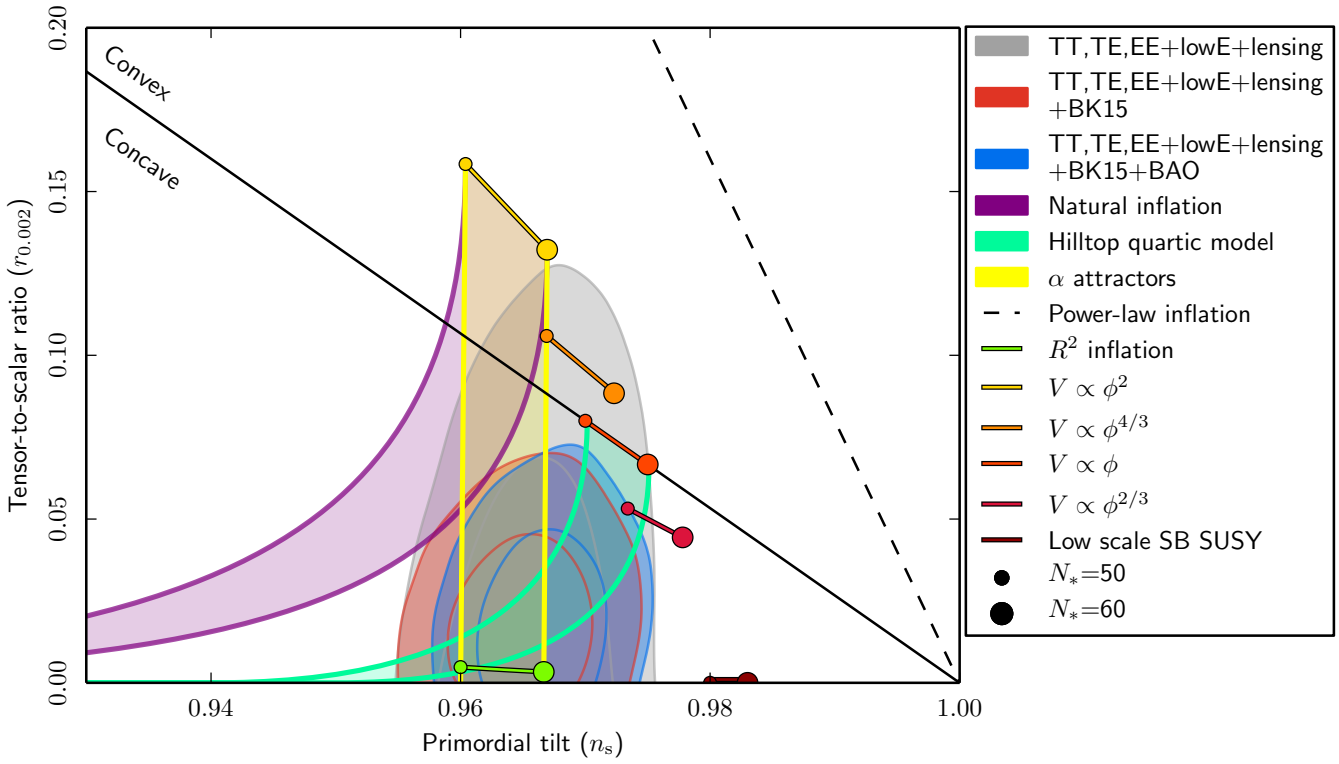

Figure 199: Marginalized joint 68 % and 95 % CL regions for $n_{\rm s}$ and r at $k = 0.002\,{\rm Mpc}^{-1}$ from *Planck* alone and in combination with BK15 or BK15+BAO data, compared to the theoretical predictions of selected inflationary models. Note that the marginalized joint 68 % and 95 % CL regions assume $dn_{\rm s}/d\ln k = 0$.

28.4.2 Implications for selected slow-roll inflationary models

The predictions for $(n_{\rm s}, r)$ to first order in the slow-roll approximation for a few inflationary models are shown in Fig. 199, which updates figure 12 of **(alias?)** and figure 1 of **(alias?)** with the same notation. These predictions are calculated for scale $k = 0.002\,{\rm Mpc}^{-1}$ and include an uncertainty in the number of e-folds of $50 < N_* < 60$.

In the following we discuss the implications of the *Planck* 2018 data release by taking into account the uncertainties in the entropy generation stage for a selection of representative standard single-field slow-roll inflationary models, updating the analysis reported in **(alias?)** and **(alias?)**. As in **(alias?)**, we use the primordial power spectra of cosmological fluctuations generated during slow-roll inflation parameterized by the HFFs, ϵ_i, to second order, which can be expressed in terms of the parameters of the inflationary model and the number of e-folds to the end of inflation, N_* [167, 181], given by [**(alias?)**]

$$N_* \simeq 67 - \ln\left(\frac{k_*}{a_0 H_0}\right) + \frac{1}{4}\ln\left(\frac{V_*^2}{M_{\rm pl}^4\,\rho_{\rm end}}\right)$$

$$+\frac{1-3w_{\rm int}}{12(1+w_{\rm int})}\ln\left(\frac{\rho_{\rm th}}{\rho_{\rm end}}\right)-\frac{1}{12}\ln(g_{\rm th})\,, \tag{1278}$$

where $\rho_{\rm end}$ is the energy density at the end of inflation, a_0H_0 is the present Hubble scale, V_* is the potential energy when k_* left the Hubble radius during inflation, $w_{\rm int}$ characterizes the effective equation of state between the end of inflation and the thermalization energy scale $\rho_{\rm th}$, and $g_{\rm th}$ is the number of effective bosonic degrees of freedom at the energy scale $\rho_{\rm th}$. We fix $g_{\rm th}=10^3$ and $\epsilon_{\rm end}=1$, and we use modified routines of the public code `ASPIC`[171] [183]. In order to make contact with Fig. 199, we consider the pivot scale $k_*=0.002\,{\rm Mpc}^{-1}$ in this subsection. We assume the uniform priors for the cosmological parameters listed in Table 30, and logarithmic priors on $10^{10}A_{\rm s}$ (over the interval $[e^{2.5},e^{3.7}]$) and $\rho_{\rm th}$ (over the interval $[(1\,{\rm TeV})^4,\rho_{\rm end}]$). Prior ranges for additional parameters in the inflationary models considered are listed in Table 31. In this paper we consider the implications of the *Planck* 2018 data for the selection of representative models studied in **(alias?)** by restricting ourselves to $w_{\rm int}=(p-2)/(p+2)$, when the potential can be approximated as $V(\phi)\propto\phi^p$ during the coherent oscillation regime after inflation, or simply $w_{\rm int}=0$ when the potential considered describes only the inflationary stage.[172] For data we use the full constraining power of *Planck*, i.e., *Planck* TT,TE,EE+lowE+lensing, in combination with BK15.

[171] http://cp3.irmp.ucl.ac.be/~ringeval/aspic.html

[172] Note that some inflationary potentials in this selection are a valid model for all stages, from the slow-roll phase all the way to coherent oscillations around the minimum during reheating, while others are "incomplete" in the sense that they only describe the slow-roll regime. The hilltop, D-brane, potential with exponential tails, and spontaneously broken SUSY models fall into the latter category and rely on additional terms, denoted by the ellipses, to complete the potential at the end of inflation. With the increasing precision of CMB data and accompanying accuracy requirements for theoretical predictions, the precise form of the additional terms may affect the scientific interpretation of some incomplete models, as pointed out for the case of quadratic hilltop and double-well inflationary models in **(alias?)**.

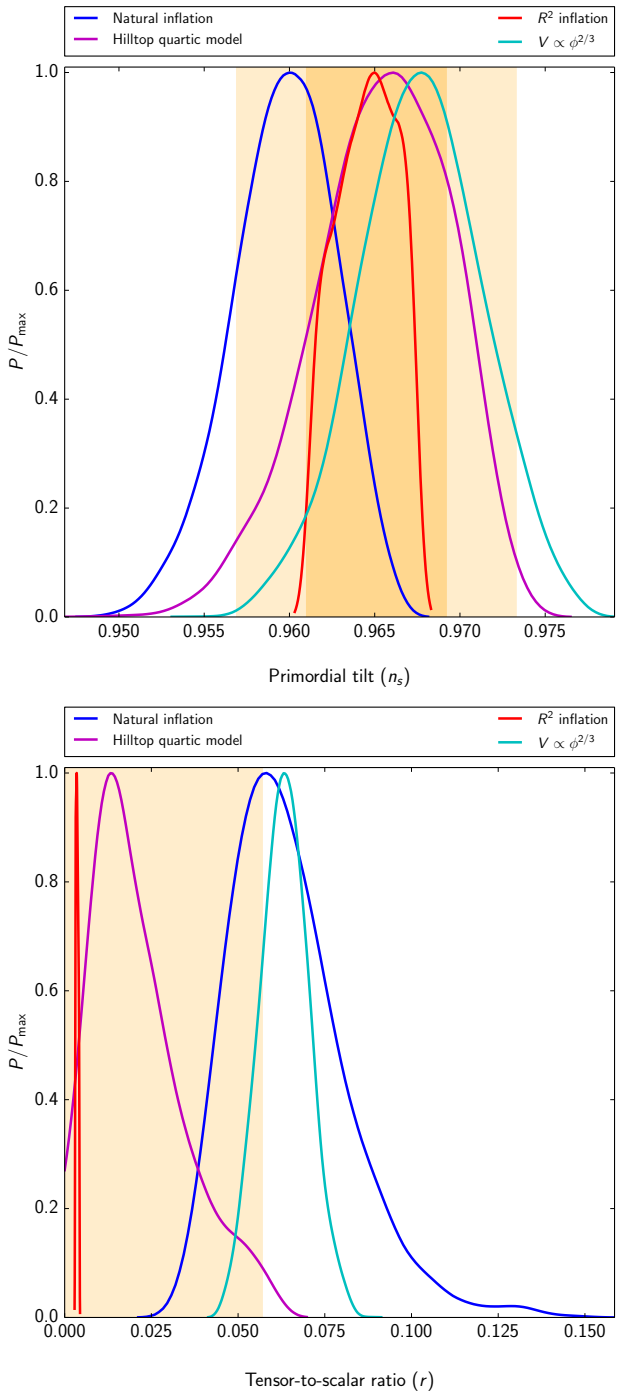

Figure 200: Marginalized probability densities of the scalar tilt n_s (top panel) and r (bottom panel) at $k = 0.002\,\mathrm{Mpc}^{-1}$ for natural, R^2, hilltop quartic, and $V(\phi) \propto \phi^{2/3}$ inflation, obtained by marginalizing over the uncertainties in the entropy generation stage, compared to the corresponding 68 % and 95 % CL limits obtained from a ΛCDM-plus-tensor fit.

The $\Delta\chi^2$ and the Bayesian evidence values for a selection of inflationary models with respect to the R^2 model [260, 205, 259] are shown in Table 31. Figure 200 shows the resulting marginalized probability densities of n_s and r at $k = 0.002\,\mathrm{Mpc}^{-1}$ for a few inflationary models with the above specified priors, compared to the corresponding 68 % and 95 % CL limits obtained from a ΛCDM-plus-tensor fit. We refer the interested reader to **(alias?)** for a concise description of the inflationary models studied here and we limit ourselves here to a summary of the main results of this analysis.

- The inflationary predictions [205, 259] originally computed for the R^2 model [260] to

Inflationary model	Potential $V(\phi)$	Parameter range
$R + R^2/(6M^2)$	$\Lambda^4 \left(1 - e^{-\sqrt{2/3}\phi/M_{\rm Pl}}\right)^2$	...

Power-law potential	$\lambda M_{\rm Pl}^{8/3} \phi^{4/3}$	...
Power-law potential	$\lambda M_{\rm Pl}^2 \phi^2$	...
Power-law potential	$\lambda M_{\rm Pl} \phi^3$	...
Power-law potential	$\lambda \phi^4$	...
Non-minimal coupling	$\lambda^4 \phi^4 + \xi \phi^2 R/2$	$-4 < \log_{10} \xi < 4$
Natural inflation	$\Lambda^4 \left[1 + \cos\left(\phi/f\right)\right]$	$0.3 < \log_{10}(f/M_{\rm Pl}) < 2.5$
Hilltop quadratic model	$\Lambda^4 \left(1 - \phi^2/\mu_2^2 + \dots\right)$	$0.3 < \log_{10}(\mu_2/M_{\rm Pl}) < 4.85$
Hilltop quartic model	$\Lambda^4 \left(1 - \phi^4/\mu_4^4 + \dots\right)$	$-2 < \log_{10}(\mu_4/M_{\rm Pl}) < 2$
D-brane inflation ($p = 2$)	$\Lambda^4 \left(1 - \mu_{\rm D\,2}^2/\phi^p + \dots\right)$	$-6 < \log_{10}(\mu_{\rm D\,2}/M_{\rm Pl}) < 0.3$
D-brane inflation ($p = 4$)	$\Lambda^4 \left(1 - \mu_{\rm D\,4}^4/\phi^p + \dots\right)$	$-6 < \log_{10}(\mu_{\rm D\,4}/M_{\rm Pl}) < 0.3$
Potential with exponential tails	$\Lambda^4 \left[1 - \exp\left(-q\phi/M_{\rm Pl}\right) + \dots\right]$	$-3 < \log_{10} q < 3$
Spontaneously broken SUSY	$\Lambda^4 \left[1 + \alpha_h \log\left(\phi/M_{\rm Pl}\right) + \dots\right]$	$-2.5 < \log_{10} \alpha_h < 1$
E-model ($n = 1$)	$\Lambda^4 \left\{1 - \exp\left[-\sqrt{2}\phi \left(\sqrt{3\alpha_1^{\rm E}} M_{\rm Pl}\right)^{-1}\right]\right\}^{2n}$	$-2 < \log_{10} \alpha_1^{\rm E} < 4$
E-model ($n = 2$)	$\Lambda^4 \left\{1 - \exp\left[-\sqrt{2}\phi \left(\sqrt{3\alpha_2^{\rm E}} M_{\rm Pl}\right)^{-1}\right]\right\}^{2n}$	$-2 < \log_{10} \alpha_2^{\rm E} < 4$
T-model ($m = 1$)	$\Lambda^4 \tanh^{2m}\left[\phi \left(\sqrt{6\alpha_1^{\rm T}} M_{\rm Pl}\right)^{-1}\right]$	$-2 < \log_{10} \alpha_1^{\rm T} < 4$
T-model ($m = 2$)	$\Lambda^4 \tanh^{2m}\left[\phi \left(\sqrt{6\alpha_2^{\rm T}} M_{\rm Pl}\right)^{-1}\right]$	$-2 < \log_{10} \alpha_2^{\rm T} < 4$

Table 31: Bayesian comparison for a selection of slow-roll inflationary models with $w_{\rm int}$ fixed (see text for more details). We quote 0.3 as the error on the Bayes factor. Models are strongly disfavoured when $\ln B < -5$.

lowest order,

$$n_{\rm s} - 1 \simeq -\frac{2}{N}\,, \quad r \simeq \frac{12}{N^2}, \tag{1279}$$

are in good agreement with *Planck* 2018 data, confirming the previous 2013 and 2015 results. The 95 % CL allowed range $49 < N_* < 59$ is compatible with the R^2 basic predictions $N_* = 54$, corresponding to $T_{\rm reh} \sim 10^9$ GeV [37]. A higher reheating temperature $T_{\rm reh} \sim 10^{13}$ GeV, as predicted in Higgs inflation [36], is also compatible with the *Planck* data.

- Monomial potentials [171] $V(\phi) = \lambda M_{\rm Pl}^4 \left(\phi/M_{\rm Pl}\right)^p$ with $p \geq 2$ are strongly disfavoured with respect to the R^2 model. For these values the Bayesian evidence is worse than in 2015 because of the smaller level of tensor modes allowed by **(alias?)**. Models with $p = 1$ or $p = 2/3$ [251, 184, 185] are more compatible with the data.

- There are several mechanisms which could lower the predictions for the tensor-to-scalar ratio for a given potential $V(\phi)$ in single-field inflationary models. Important examples are a subluminal inflaton speed of sound due to a non-standard kinetic term [103], a non-minimal coupling to gravity [258, 174, 245, 82], or an additional damping term for the inflaton due to dissipation in other degrees of freedom, as in warm inflation [34, 24].

In the following we report on the constraints for a non-minimal coupling to gravity of the type $F(\phi)R$, with $F(\phi) = M_{\rm Pl}^2 + \xi\phi^2$, and a quartic potential. For this model we compute the theoretical predictions in terms of HFFs and number of e-folds to the end of inflation in the Einstein frame as for the R^2 model above, but we omit the technical details for the sake of brevity.[173] Our results show that a quartic potential, which would be excluded at high statistical significance for a minimally-coupled scalar inflaton as seen from Table 31, can be reconciled with the *Planck* and BK15 data for $\xi > 0$: we obtain a 95 % CL lower limit $\log_{10}\xi > -1.5$ with $\ln B = -2.4$.

- Natural inflation [99, 7] is strongly disfavoured by the *Planck* 2018 plus BK15 data with a Bayes factor $\ln B = -6.6$.
- Within the class of hilltop inflationary models [40] we find that a quartic potential provides a better fit than a quadratic one. In the quartic case we find the 95 % CL lower limit $\log_{10}(\mu_2/M_{\rm Pl}) > 1.0$.
- D-brane inflationary models [148, 69, 101] provide a good fit to *Planck* and BK15 data for a large portion of their parameter space.
- For the simple class of inflationary potentials with exponential tails [106, 263, 70, 48, 61] we find $\ln B = -1.0$.
- *Planck* 2018 and BK15 data strongly disfavour the hybrid model driven by logarithmic quantum corrections in spontaneously broken supersymmetric (SB SUSY) theories [71], with $\ln B = -6.8$.
- *Planck* and BK15 data set tight constraints on α attractors [149, 91]. We obtain $\log_{10}\alpha_1^{\rm E} < 1.3$ and $\log_{10}\alpha_2^{\rm E} < 1.1$ at 95 % CL for the E-model. We obtain slightly tighter 95 % CL bounds for the T-model, i.e., $\log_{10}\alpha_1^{\rm T} < 1.0$ and $\log_{10}\alpha_2^{\rm T} < 1.0$. Given the relation $|R_K| = 2/(3\alpha)$ between the curvature of the Kähler geometry R_K and α in some of the T-models motivated by supergravity, *Planck* and BK15 data imply a lower bound on $|R_K|$, which is still in the low-curvature regime. The discrete set of values $\alpha = i/3$ with an integer i in the range $[1, 7]$ motivated by maximal supersymmetry [90, 150] is compatible with the current data.

28.5 Reconstruction of the inflaton potential

28.5.1 Taylor expansion of $V(\phi)$ in the observable region

In this section, as in section 6 of **(alias?)** and section 7.1 of **(alias?)**, we try to reconstruct the inflaton potential only in its observable window, making no assumptions about the end of inflation. The motivation for being so conservative is that what happens after the inflaton rolls down beyond this range might not be captured by the simplest descriptions. More elaborate treatments would be required, for instance, in the case of a non-trivial potential shape before the end of inflation, a waterfall transition involving extra scalar fields, or several short inflationary stages between the time at which CMB scales exit the Hubble radius and the nucleosynthesis epoch. The analysis of this section relies, however, on the assumption that the potential is smooth enough inside the observable window to be described by a Taylor expansion up to order four. Note that this assumption is much weaker than assuming that a Taylor expansion is valid up to the end of inflation. However, it excludes from the analysis potentials with sharp features in the observable window, such as those studied in the next sections.

We perform the Taylor expansion around the value ϕ_* of the inflaton field evaluated precisely at the time t_* when the pivot scale $k_* = 0.05\,{\rm Mpc}^{-1}$ fulfills the relation $k_* = a(t_*)H(t_*)$. We separately study the cases where the expansion is performed at order $n = 2$, $n = 3$, or $n = 4$. We compute the primordial spectrum with a full integration of the Fourier mode evolution, using the inflationary module of the `CLASS` code. Although this method assumes no slow-roll approximation at any point, we speed up the convergence of the Markov Chain by taking flat

[173] In this model the potential in the Einstein frame is known only in implicit form (see, for instance, Garcia-Bellido et al. [100]) and the algebra is therefore more complicated.

priors not directly on the five Taylor coefficients $\{V, V_\phi, \ldots, V_{\phi\phi\phi\phi}\}$, but on combinations of them matching the definitions of the potential slow-roll parameters $\{\epsilon_V, \eta_V, \xi_V^2, \varpi_V^3\}$ presented in table 2 of **(alias?)**. Even beyond the slow-roll approximation, these combinations provide nearly linear contributions to the tilt, running, running of the running, etc., of the scalar and tensor spectrum. Hence, they are directly related to observable quantities and well constrained by the data. Instead, if we ran with flat priors on $\{V, V_\phi, \ldots, V_{\phi\phi\phi\phi}\}$, the convergence would be plagued by complicated parameter degeneracies.

The results of this analysis are shown in the panels of Fig. 201 and Table 32 for $n = 2$, 3, and 4, using two data sets for each: *Planck* TT,TE,EE+lowE alone; or *Planck* TT,TE,EE+lowE+lensing+BK1
The plot in Fig. 201 deliberately has a lot of white space because, for the sake of comparison, we plotted it over the same parameter ranges as the same plot in **(alias?)**. We notice some significant improvement. Comparing *Planck* TT,TE,EE+lowE results from 2015 and 2018, we find that error bars on individual parameters have typically been reduced by 30 % thanks to improved polarization data. Including BK data provides further constraining power. Comparing *Planck* 2015 TT+lowP+BAO and *Planck* 2018 TT,TE,EE+lowE+lensing+BK15, we find that the error bars on $\{\epsilon_V, \eta_V, \xi_V^2, \varpi_V^3\}$ shrink by factors of 2 to 4. The new data tend to resolve degeneracies which previously appeared in the $n = 4$ case and could be understood as a compensation mechanism between potentials with large running of the tilt, running of the running, tensor contribution, etc. The parameters ξ_V^2 and ϖ_V^3 are perfectly compatible with zero (see Fig. 201 and Table 32), and so are $V_{\phi\phi\phi}$ and $V_{\phi\phi\phi\phi}$ (see the contours on the parameters $\{V, V_\phi, \ldots, V_{\phi\phi\phi\phi}\}$ in Fig. 202). This is consistent with the fact that the new data set brings no evidence for running or running of the running. It also explains why the results of this section are close to those of Sect. 28.4.1, obtained under the slow-roll approximation. Similar to 2015, the best-fit value of running for $n = 3$ is negative, but has moved down from -0.013 to -0.007, and remains compatible with zero at the 1.0σ level. For $n = 4$, the trend observed in 2015 to fit the data slightly better with a non-zero tensor contribution has disappeared. The decrease of the minimum effective χ^2 when moving from $n = 2$ to $n = 3$ is insignificant and even smaller than in 2015, showing that the data do not require anything more complicated than an approximately parabolic shape for the inflaton potential within the observable window.

This can be checked by considering the random sample of well-fitting potentials presented in Fig. 203. Actually, for $n = 4$, a few of the plotted potentials have a non-parabolic "spoon-like" shape (with a kink and a plateau), because non-negligible values of $|V_{\phi\phi\phi\phi}|$ are still allowed. However, this sub-class of models is by no means preferred over simpler parabolic-like potentials with a negligible $|V_{\phi\phi\phi\phi}|$; otherwise, we would have obtained a better $\chi^2_{\rm eff}$ for $n = 4$. Hence one should *not* take from Fig. 203 the message that special potentials with a kink and a plateau are favoured by the *Planck* data. Comparing this plot to figure 15 of **(alias?)**, we see that the models with the largest $V(\phi)$ amplitude are excluded by stronger bounds on the tensor modes.

Finally, it is interesting to notice that the predictions for the parameters of the minimal ΛCDM model, such as $n_{\rm s}$ or τ, remain extremely stable when increasing the freedom in the inflaton potential.

Table 32: Numerical reconstruction of the potential slow-roll parameters *beyond* any slow-roll approximation, when the potential is Taylor-expanded to nth order, using *Planck* TT,TE,EE+lowE+lensing+BK15. We also show the corresponding bounds on some related parameters (here n_s, $dn_\mathrm{s}/d\ln k$, and $r_{0.002}$ are derived from the numerically computed primordial spectra). All error bars are at the 68 % CL and all upper bounds at the 95 % CL. The effective χ^2 value of model n is given relative to model $n-1$.

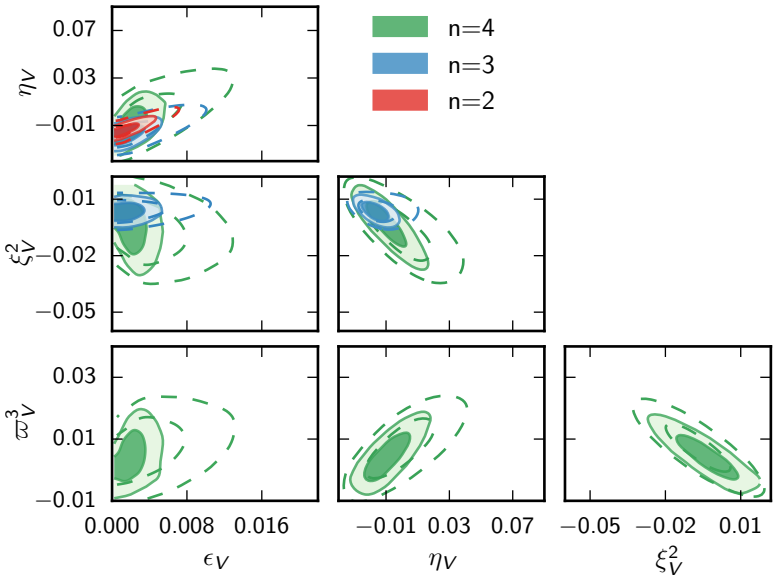

Figure 201: Taylor expansion of $V(\phi)$ at order $n = 2$, 3, and 4 in the observable region, making no assumption about the end of inflation. The parameters are combinations of Taylor coefficients with flat priors. Dashed contours are *Planck* TT,TE,EE+lowE, while solid contours are *Planck* TT,TE,EE+lowE+lensing+BK15. The scales are the same as in **(alias?)**.

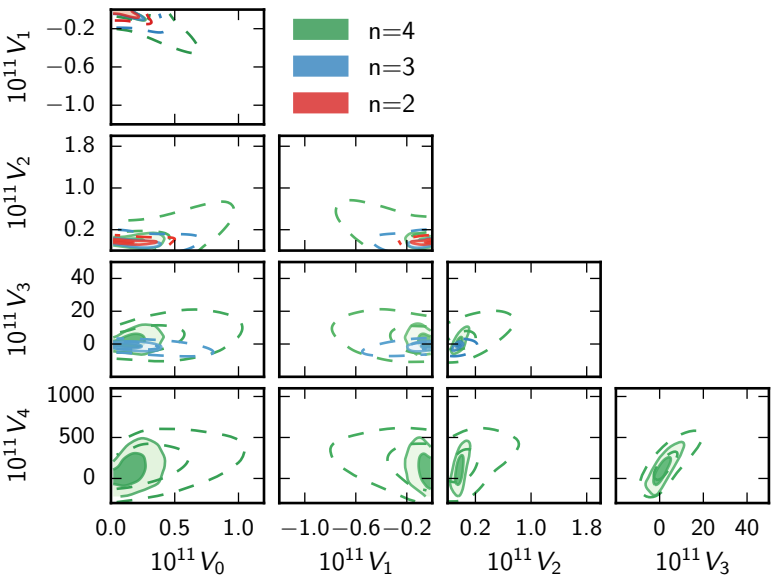

Figure 202: Taylor expansion of $V(\phi)$ at order $n = 2$, 3, and 4 in the observable region, making no assumption about the end of inflation. In natural units (where $\sqrt{8\pi}M_{\rm Pl} = 1$). The parameters are the Taylor coefficients, obtained here as derived parameters with non-flat priors. Dashed contours are *Planck* TT,TE,EE+lowE, while solid contours are *Planck* TT,TE,EE+lowE+lensing+BK15. The scales are the same as in **(alias?)**.

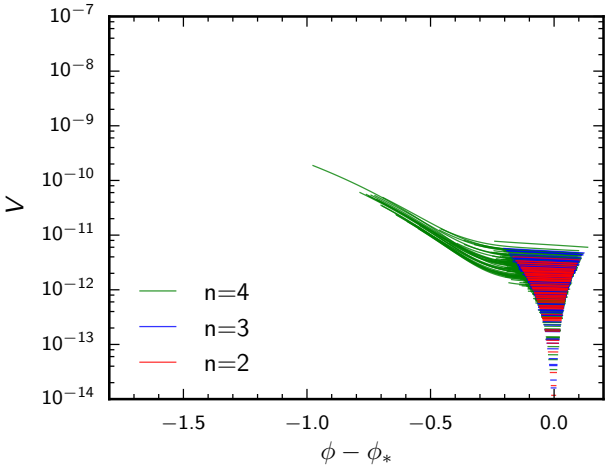

Figure 203: Representative sample of the observable region of inflaton potentials allowed at the 95 % CL, when the potential is Taylor-expanded at order $n = 2$, 3, and 4 in the observable region, making no assumption about the end of inflation, and using *Planck* TT,TE,EE+lowE+lensing+BK15. In natural units (where $\sqrt{8\pi}M_{\rm Pl} = 1$). We use the same scales as in **(alias?)**. Note that there is another branch of solutions that is symmetric under $(\phi - \phi_*) \to -(\phi - \phi_*)$.

28.5.2 Taylor expansion of $H(\phi)$ in the observable region

To assess the robustness of our method, in this section we repeat the analysis with a Taylor expansion of the Hubble function $H(\phi)$ in the observable window, as we did in 2015. We refer the reader to section 7.2 of **(alias?)** for a precise description of this analysis, and we recall that the difference with respect to the $V(\phi)$ reconstruction is more than a mere change of priors. For each value of n, the new parameterization covers a slightly different range of potentials, and, more importantly, it naturally includes a marginalization over the uncertainty in the initial value of the derivative $\dot{\phi}$ when the inflaton enters the observable window. Instead,

n	2	3	4
ϵ_H	< 0.0041	< 0.0046	< 0.0041
η_H	$-0.0139^{+0.0026}_{-0.0038}$	$-0.0170^{+0.0044}_{-0.0048}$	$-0.0158^{+0.0057}_{-0.0056}$
ξ^2_H	...	$0.046^{+0.043}_{-0.045}$	$0.021^{+0.071}_{-0.076}$
ϖ^3_H	...	...	$0.16^{+0.64}_{-0.37}$
τ	$0.0548^{+0.0075}_{-0.0074}$	$0.0556^{+0.0076}_{-0.0078}$	$0.0563^{+0.0073}_{-0.0078}$
n_s	$0.9651^{+0.0040}_{-0.0044}$	$0.9637^{+0.0042}_{-0.0046}$	$0.9637^{+0.0042}_{-0.0048}$
$10^3 \frac{dn_\mathrm{s}}{d\ln k}$	$-0.25^{+0.20}_{-0.12}$	$-7.5^{+7.0}_{-6.7}$	$-5.1^{+7.8}_{-8.1}$
$r_{0.002}$	< 0.059	< 0.065	< 0.057
$\Delta\chi^2_\mathrm{eff}$	...	$\Delta\chi^2_{3/2} = -1.60$	$\Delta\chi^2_{4/3} = -2.32$

Table 33: Numerical reconstruction of the Hubble slow-roll parameters *beyond* any slow-roll approximation, using *Planck* TT,TE,EE+lowE+lensing+BK15. We also show the corresponding bounds on some related parameters (here n_s, $dn_\mathrm{s}/d\ln k$, and $r_{0.002}$ are derived from the numerically computed primordial spectra). All error bars are at the 68 % CL and all upper bounds at the 95 % CL. The effective χ^2 value of model n is given relative to model $n-1$.

in the previous analysis, $\dot\phi$ was assumed to have reached the inflaton attractor solution, i.e., there was an implicit assumption that inflation started well before that time. In the analysis based on $H(\phi)$, inflation models with a minimal duration are not excluded by the priors.

The improvement with respect to the 2015 results is even more impressive in this case. Bounds on the $n = 4$ parameters are typically 3 to 4 times stronger compared with 2015, as can be checked from Table 33 and Fig. 204. We found that a factor of 2 improvement comes from switching to the new set of low-ℓ likelihoods, and another factor of 2 from adding the BK likelihood. On the other hand, the use of more recent high-ℓ and lensing likelihoods has a modest impact.

A consequence of these improved constraints can be seen in Fig. 205, when we compare it to its counterpart from 2015 (figure 20 in **(alias?)**). Again, for a better comparison Fig. 205 uses the same scale as figure 20 of **(alias?)**. For $n = 4$, the previously best-fitting models included many scenarios starting with a fast-roll stage, producing a tail with large $V(\phi)$ before pivot-scale crossing. These models are now excluded by better polarization data and tensor constraints.

Going beyond the parabolic approximation for $H(\phi)$ does not improve the goodness-of-fit: as in the potential-based analysis of Sect. 28.5.1, the $\Delta\chi^2$s between $n = 2$, $n = 3$, and $n = 4$ are negligible, and the parameters ξ^2_H and ϖ^3_H related to $H_{\phi\phi\phi}$ and $H_{\phi\phi\phi\phi}$ are compatible with zero.

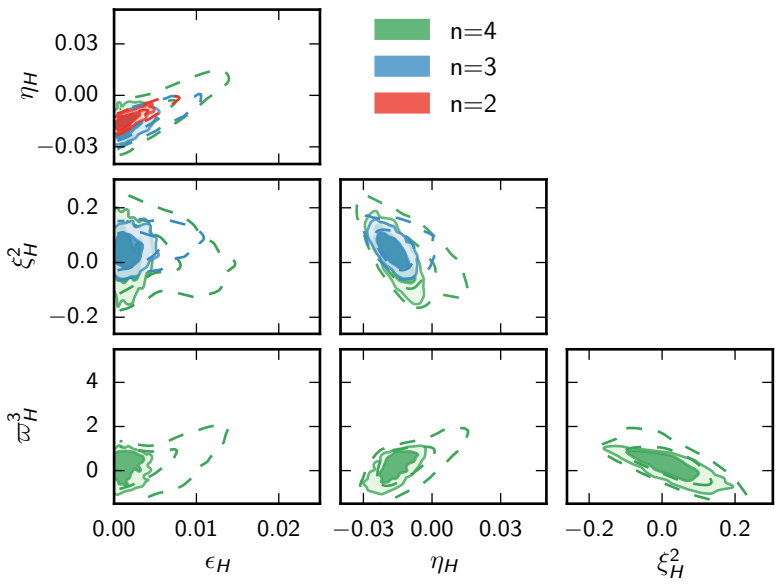

Figure 204: Taylor expansion of $H(\phi)$ at order $n = 2$, 3, and 4 in the observable region, making no assumption about the end of inflation. The parameters are combinations of Taylor coefficients with flat priors. Dashed contours are *Planck* TT,TE,EE+lowE, while solid contours are *Planck* TT,TE,EE+lowE+lensing+BK15. The scales are the same as in **(alias?)**.

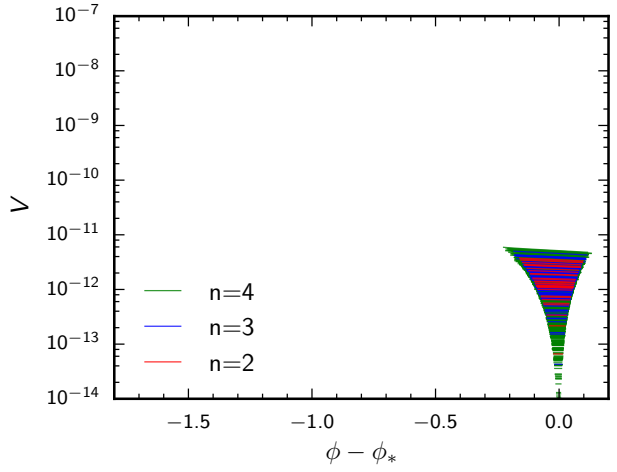

Figure 205: Representative sample of the observable region of inflaton potentials allowed at the 95 % CL, inferred from $H(\phi)$ when that function is Taylor-expanded at order $n = 2$, 3, and 4 in the observable region, making no assumption about the end of inflation, and using *Planck* TT,TE,EE+lowE+lensing+BK15. In natural units (where $\sqrt{8\pi}M_{\rm Pl} = 1$). The scales are the same as in **(alias?)**. Note that there is another branch of solutions symmetric under $(\phi - \phi_*) \to -(\phi - \phi_*)$.

28.5.3 Taylor expansion of full $V(\phi)$

We now present a new analysis with less conservative assumptions than in the previous subsections. We switch to the hypothesis that the inflaton potential is very smooth not only within its observable window, but also until the end of inflation, such that its whole shape can be captured by a Taylor expansion. We further assume that inflation ends when the first slow-roll condition is violated ($\epsilon_V = 1$), without invoking any other field. Finally, we fix the number of e-folds between Hubble crossing of the pivot scale and the end of inflation to $N_* = 55$, which implicitly relies on the hypothesis that no further inflationary stage took place at a later epoch.

Technically, the analysis pipeline for this case is similar to that of Sect. 28.5.1, except for an extra step in which the `CLASS` inflationary module integrates the background equations until the end of inflation, goes backwards in time by 55 e-folds, and imposes that the Hubble crossing for the pivot scale $k_* = 0.05\,\mathrm{Mpc}^{-1}$ matches that time.

These models are much more constrained than those of Sects. 28.5.1 and 28.5.2, since the e-fold condition is imposed in addition to having a potential with a good shape within the observable window. The constraining power is then sufficient for running the MCMC chains directly with flat priors on $\{V, V_\phi, \ldots, V_{\phi\phi\phi\phi}\}$.

Our results are presented in Figs. 206 and 207 and in Table 34. For models with a purely quadratic potential, the numerically computed tilt and tensor-to-scalar ratio depend almost exclusively on N_*, thus they remain fixed to $n_s = 0.963$ and $r_{0.002} = 0.136$. Such a large r is in tension with the *Planck* data, and even more so with the *Planck*+BK data. Thus the effective χ^2 is poor in the $n = 2$ case and improves considerably when adding some freedom in going to $n = 3$. Indeed, the presence of an additional cubic term allows us to reach smaller values of the tensor-to-scalar ratio for roughly the same scalar tilt, and lowers $\chi^2_{\rm eff}$ by more than 13. Instead, when also adding a quartic term, we find no significant improvement in the goodness of fit, and the coefficient of the ϕ^4 term is consistent with zero.

These findings are consistent with the global picture that *Planck* data prefer potentials which are concave in the observable window. The blue and green curves in the lower left panel of Fig. 207 illustrate the preference of the *Planck*+lensing+BK15 data for potentials with an inflection point, appearing qualitatively similar to scalar field potentials associated with spontaneous symmetry breaking models, hilltop models, new inflation, natural inflation, etc.

In these runs, the value of the scalar tilt running is always very precisely constrained around a value of $dn_{\rm s}/d\ln k \simeq -6 \times 10^{-4}$. This does not come as a surprise if we keep in mind that these bounds are not imposed directly by the data, but rather by the class of inflationary potentials considered here, with potential parameters fixed by observational bounds on the *amplitude* and *tilt* of the scalar and tensor spectra. In other words, the running is not directly measured, but rather predicted as a function of the scalar/tensor amplitudes and scalar tilt. Interestingly, if combinations of future CMB and large-scale structure data with a wide lever arm in wavenumber space could become directly sensitive to such tiny values (which would require a factor of around 10 improvement in sensitivity compared to current CMB+BAO data), a very large class of currently successful inflationary models could be either confirmed or ruled out.

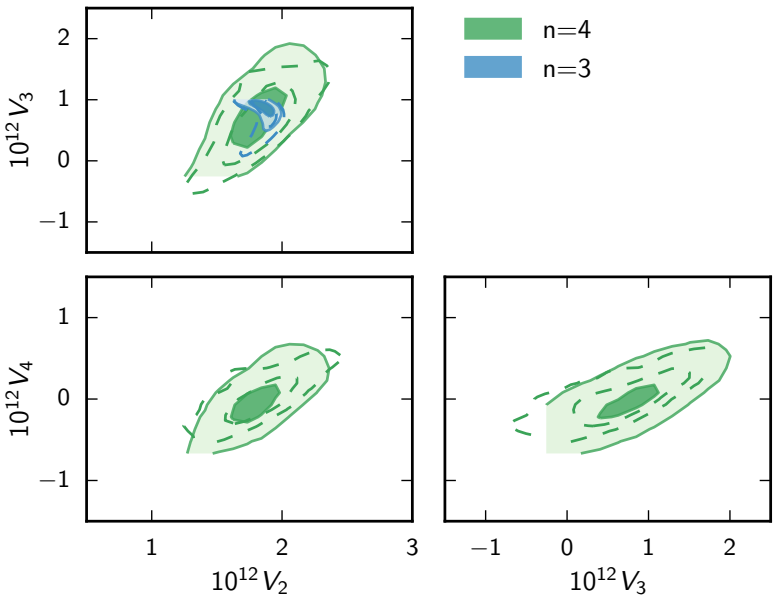

Figure 206: Taylor expansion of the full $V(\phi)$ at order $n = 3$ and 4, trusted until the end of inflation, in natural units (where $\sqrt{8\pi}M_{\rm Pl} = 1$). The parameters are the Taylor coefficients with flat priors. Dashed contours are *Planck* TT,TE,EE+lowE, while solid contours are *Planck* TT,TE,EE+lowE+lensing+BK15.

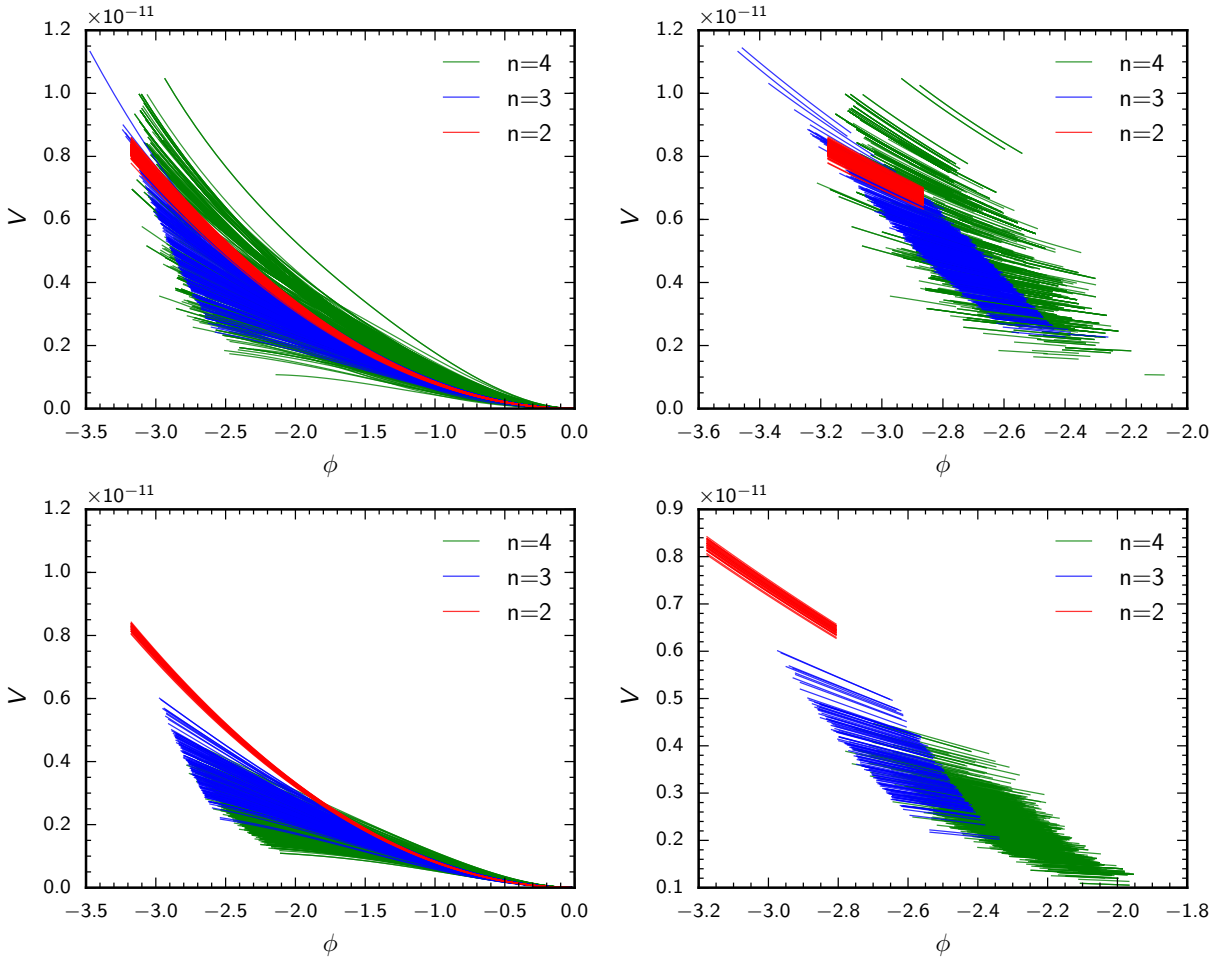

Figure 207: Representative sample of the inflaton potentials allowed at the 95 % CL, when the potential is Taylor-expanded at order $n = 2$, 3, and 4 and trusted until the end of inflation, and under the assumption of $N_* = 55$ e-folds of inflation between Hubble-radius crossing for the pivot scale and the end of inflation. In natural units (where $\sqrt{8\pi}M_{\rm Pl} = 1$). *Left panels:* Full potential from the beginning of the observable window till the end of inflation. *Right:* Zoom on the observable window directly constrained by inflation. *Top: Planck* TT,TE,EE+lowE. *Bottom: Planck* TT,TE,EE+lowE+lensing+BK15. Note that there is another branch of solutions that is symmetric under $\phi \to -\phi$.

28.5.4 Free-form potential reconstruction

As a complementary analysis to the previous three subsections, we next perform a free-form reconstruction of the inflationary potential with cubic splines, in a manner akin to the reconstructions of **(alias?)** and Sect. 28.6.2. Further plots and theoretical detail can be found in Handley et al. [125].

A free-form reconstruction usually proceeds by parameterizing the function of interest via a spline and taking the locations of the interpolation knots as free parameters in a posterior distribution. These are then varied along with any other model parameters, and then marginalized out to yield a model-independent reconstruction of the function of interest. The analysis is run for differing numbers of knots, N, and the Bayesian evidence is computed to allow for model comparison to determine how many knots are appropriate from the perspective of the data.

To reconstruct the inflationary potential $V(\phi)$, one cannot take a linear interpolating spline (as in Sect. 28.6.2), since the equations of motion in general depend on first (and sometimes second) derivatives of V. We therefore choose to parameterize the *second derivative* of the log-potential as a linear spline. The log-potential is computed by integrating this function twice,

n	2	3	4
$10^{12}V_2$	$1.631^{+0.022}_{-0.022}$	$1.81^{+0.12}_{-0.06}$	$1.86^{+0.25}_{-0.23}$
$10^{12}V_3$	...	$0.89^{+0.10}_{-0.03}$	$0.85^{+0.46}_{-0.64}$
$10^{12}V_4$	...	...	$0.044^{+0.26}_{-0.35}$
τ	$0.0518^{+0.0066}_{-0.0066}$	$0.0501^{+0.0078}_{-0.0069}$	$0.05628^{+0.0075}_{-0.0087}$
n_s	0.963	$0.9599^{+0.0034}_{-0.0018}$	$0.9656^{+0.0035}_{-0.0043}$
$10^3\frac{dn_\mathrm{s}}{d\ln k}$	$-0.6731^{+0.0005}_{-0.0005}$	$-0.534^{+0.079}_{-0.096}$	$-0.74^{+0.16}_{-0.13}$
$r_{0.002}$	0.136	$0.066^{+0.010}_{-0.016}$	$0.042^{+0.009}_{-0.014}$
$\Delta\chi^2_\mathrm{eff}$	...	$\Delta\chi^2_{3/2} = -13.18$	$\Delta\chi^2_{4/3} = -3.50$

Table 34: Numerical reconstruction of the potential parameters *beyond* any slow-roll approximation, when the potential is Taylor-expanded to nth order, trusted until the end of inflation, and using *Planck* high-ℓ TT,TE,EE+lowE+lensing+BK15. We also show the corresponding bounds on some related parameters (here n_s, $dn_\mathrm{s}/d\ln k$, and $r_{0.002}$ are derived from the numerically computed primordial spectra). All error bars are at the 68 % CL and all upper bounds at the 95 % CL. The effective χ^2 value of model n is given relative to model $n-1$.

yielding a function with two additional free parameters—a global offset and a gradient. Our reconstruction function is therefore

$$\ln V = \ln V_* + (\phi-\phi_*)\frac{d\ln V_*}{d\phi} + \int_{\phi_*}^{\phi} d\phi' \int_{\phi_*}^{\phi'} d\phi''\, \mathrm{LS}(\phi'';\theta), \tag{1280}$$

$$\theta = \left(\phi_1,\ldots,\phi_N, \frac{d^2\ln V_1}{d\phi^2},\ldots,\frac{d^2\ln V_N}{d\phi^2}\right), \tag{1281}$$

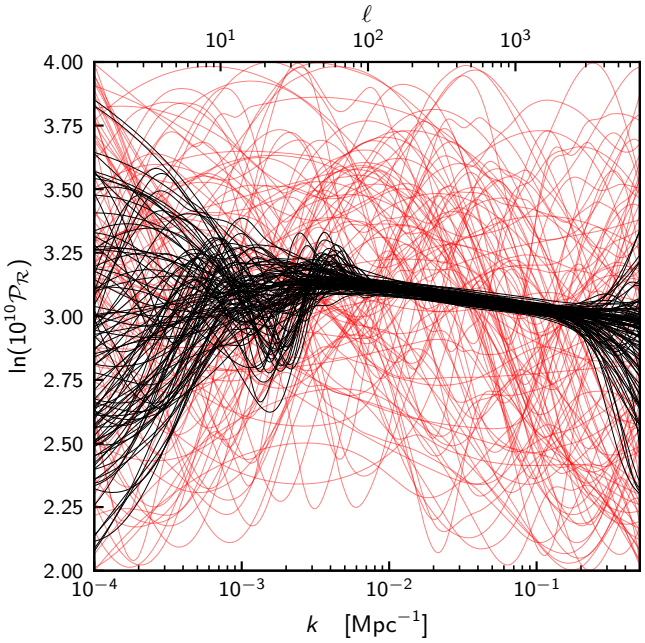
$$\mathrm{LS}(\phi;\theta) = \left\{ \frac{d^2\ln V_i}{d\phi^2}\frac{\phi-\phi_{i+1}}{\phi_i-\phi_{i+1}} + \frac{d^2\ln V_{i+1}}{d\phi^2}\frac{\phi-\phi_i}{\phi_{i+1}-\phi_i} \quad : \phi_i < \phi < \phi_{i+1} \right. . \tag{1282}$$

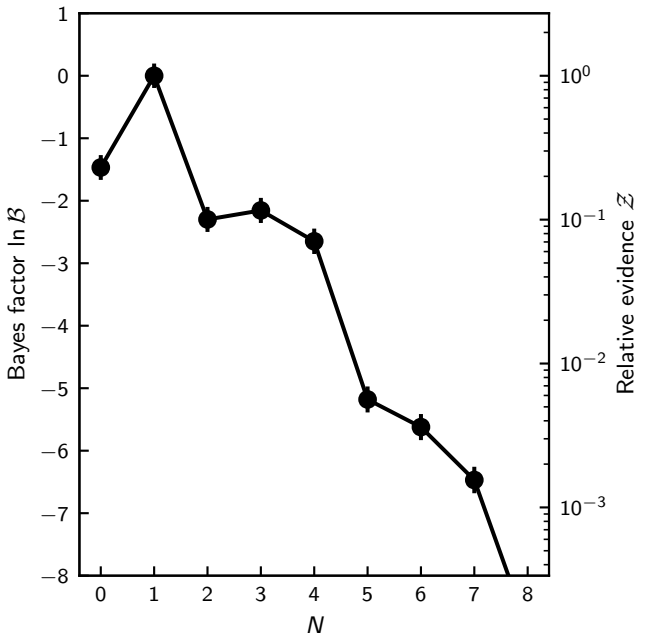
Here $\mathrm{LS}(\phi;\theta)$ is a standard linear spline dependent on N knots, $\ln V_*$ is the potential at the pivot scale, and $d\ln V_*/d\phi$ is the gradient of the log-potential at the pivot scale.

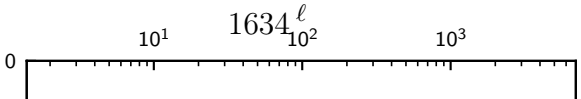
In general, any reconstruction of the potential will be sensitive only to the observable window of inflation in $\phi \in [\phi_\mathrm{min}, \phi_\mathrm{max}]$, where ϕ_min and ϕ_max are defined as the field values when the largest and smallest observable scales k_min and k_max exit the Hubble radius during inflation. Regions of the potential outside these ϕ values are unconstrained by current CMB data. In our analysis, we take $k_\mathrm{min} = 10^{-4}\,\mathrm{Mpc}^{-1}$ and $k_\mathrm{max} = 10^{-0.3}\,\mathrm{Mpc}^{-1}$, which encompasses the multipole range constrained by *Planck* (see Sect. 28.6.2). The locations $\phi_1,\ldots,\phi_N$ of the reconstruction knots should be distributed throughout this observable window. Whilst the locations $\phi_1,\ldots\phi_N$ and heights $d^2\ln V_1/d\phi^2,\ldots,d^2\ln V_N/d\phi^2$ themselves influence the size of the observable window, a reasonable approach is to first estimate it using the unperturbed potential (i.e., setting $N=0$). This gives an alternative range $\phi \in [\tilde{\phi}_\mathrm{min}, \tilde{\phi}_\mathrm{max}]$. The priors on all our variables are indicated in Table 35.

Parameters	Prior type	Prior range
N	Discrete uniform	$[0, 8]$
$\ln V_*$	Uniform	$[-25, -15]$
$d\ln V_*/d\phi$	Log-uniform	$[10^{-3}, 10^{-0.3}]$
$d^2\ln V_1/d\phi^2, \ldots, d^2\ln V_N/d\phi^2$	Uniform	$[-0.5, 0.5]$
$\phi_1, \ldots, \phi_N$	Sorted uniform	$[\tilde{\phi}_{\rm min}\,, \tilde{\phi}_{\rm max}]$
$\ln 10^{10}\mathcal{P}_\mathcal{R}(k)$	Indirect constraint	$[2, 4]$

Table 35: Parameters of the free-form potential reconstruction analysis and details of the priors. There is a further prior constraint in that we require that the inflaton should evolve in an inflating phase throughout the observable window, that the inflaton should be rolling downhill from negative to positive ϕ throughout, and that any primordial power spectra generated sit in the range $2 < \ln 10^{10}\mathcal{P}_\mathcal{R}(k) < 4$.







Our results are detailed in Fig. 208. The Bayesian evidence shows that the reconstruction preferred by the data is that using $N = 1$, corresponding to a constant non-zero $d^2 \ln V/d\phi^2$. This indicates that the *Planck* data do not significantly constrain the inflationary potential within the window any further than up to a quadratic term in a Taylor expansion. It is illuminating, however, to consider adding further structure to the potential, and Fig. 208 shows reconstructions for $N = 8$.

Considering the predictive posterior of the primordial power spectrum, we see that our parameterization is sufficient to exhibit the deficit at $\ell \simeq 30$, cosmic variance at low ℓ, and the loss of resolution at high ℓ, as seen in Sect. 28.6.2. Consistent with the rest of the analyses, ε_V is unconstrained, whilst the *Planck* data provide relatively powerful constraints on η_V within the observable window of inflation.

28.6 Primordial power spectrum reconstruction

This section reports results for the non-parametric reconstruction of the primordial scalar power spectrum using the new *Planck* 2018 likelihoods, as well as comparisons with the previously reported results for the *Planck* 2013 and 2015 releases. The objective here is to search for deviations from a simple power-law primordial power spectrum (i.e., $\mathcal{P}_\mathcal{R}(k) = A_\mathrm{s}(k/k_*)^{n_\mathrm{s}-1}$) in a manner that does not presuppose any particular theoretical model giving rise to such deviations. This work is complementary to the searches considered in Sect. 28.7, where particular functional forms for such deviations motivated by theory are investigated.

Here we apply three distinct nonparametric methods. In 2013 only the first method was used to reconstruct the primordial power spectrum, the so-called "penalized likelihood" method, for which the 2018 results are presented in Sect. 28.6.1. In 2015 two additional methods were also used: a linear spline method (discussed in Sect. 28.6.2) for which both the number of knots and their positions were allowed to vary, and ideas from Bayesian model selection were applied to determine the appropriate number of knots; and a method using cubic splines (discussed in Sect. 28.6.3). Although the discussion below includes some description of each method in order to make the paper self-contained, for details the reader is referred to the 2013 and 2015 papers. Here we specify only those details specific to the 2018 analysis or different from the choices in the 2013 and 2015 analyses. See references in **(alias?)** and Hunt & Sarkar [141], Hazra et al. [133], and Hunt & Sarkar [142] for other approaches to non-parametric reconstruction of the primordial power spectrum.

28.6.1 Penalized likelihood

The underlying idea of the penalized likelihood approach is to add a term to the log-likelihood that penalizes deviations from a perfect power-law spectrum. We parameterize the power spectrum as

$$\mathcal{P}_\mathcal{R}(k) = \mathcal{P}_0(k) \exp\bigl[f(k)\bigr], \tag{1283}$$

where $\mathcal{P}_0(k) = A_\mathrm{s}(k/k_*)^{n_\mathrm{s}-1}$, and add the following term to $-2\ln\mathcal{L}$:

$$\begin{aligned}\mathbf{f}^\mathrm{T}\,\mathbf{R}(\lambda,\alpha)\,\mathbf{f} \equiv \lambda \int_{\kappa_\mathrm{min}}^{\kappa_\mathrm{max}} d\kappa\, \left(\frac{\partial^2 f(\kappa)}{\partial\kappa^2}\right)^2 \\ + \alpha \int_{-\infty}^{\kappa_\mathrm{min}} f^2(\kappa) + \alpha \int_{\kappa_\mathrm{max}}^{+\infty} f^2(\kappa),\end{aligned} \tag{1284}$$

where $\kappa = \ln k$. The interval $[\kappa_\mathrm{min}, \kappa_\mathrm{max}]$ is chosen to cover the range over which the likelihood is able to constrain the data. The two α terms serve to pin the reconstruction to the simple power law where the data have almost no constraining power. One may imagine that $\alpha > 0$ should be infinite, but for numerical reasons a large but finite value is used to simplify the numerics. Numerically, for each λ the dimension of $\mathbf{f}$ is chosen to be so large that the continuum version of the penalty given in Eq. (1284) has been accurately approximated. For more details see [105] and the extensive references therein to prior literature, as well as **(alias?)** and **(alias?)**.

In Fig. 209 we show the results using *Planck* TT+lowE and in Fig. 210 we show the results for *Planck* TT,TE,EE+lowE. In both cases we have assumed the usual base-ΛCDM model specified in **(alias?)**, except that the power spectrum is now parameterized by a set of spline

points. In addition to these spline points, we also maximize the likelihood with respect to the dimensionless Hubble parameter, h, and the baryon, $\Omega_{\rm b}h^2$, and CDM, $\Omega_{\rm c}h^2$, densities. All other cosmological and nuisance parameters are the same as those quoted in **(alias?)**.

For the TT-only case, the maximum deviations are 1.55σ, 2.10σ, 1.80σ, and 1.65σ for $\lambda = 10^3$, 10^4, 10^5, and 10^6, respectively, for which the probabilities to exceed are 13 %, 28 %, 31 %, and 23 % (where we have taken into account the look-elsewhere effect). Similarly, for the TT,TE,EE case, the maximum deviations are 2.07σ, 1.77σ, 1.77σ, and 1.08σ for $\lambda = 10^3$, 10^4, 10^5, and 10^6, respectively, for which the probabilities to exceed are 29 %, 23 %, 32 %, and 25 %. We consequently find no statistically significant evidence for a deviation from the simple power-law hypothesis. This result is consistent with the results previously reported for the *Planck* 2013 and 2015 releases using essentially the same method. It is likewise consistent with the results below in Sects. 28.6.2 and 28.6.3, which use different methods.

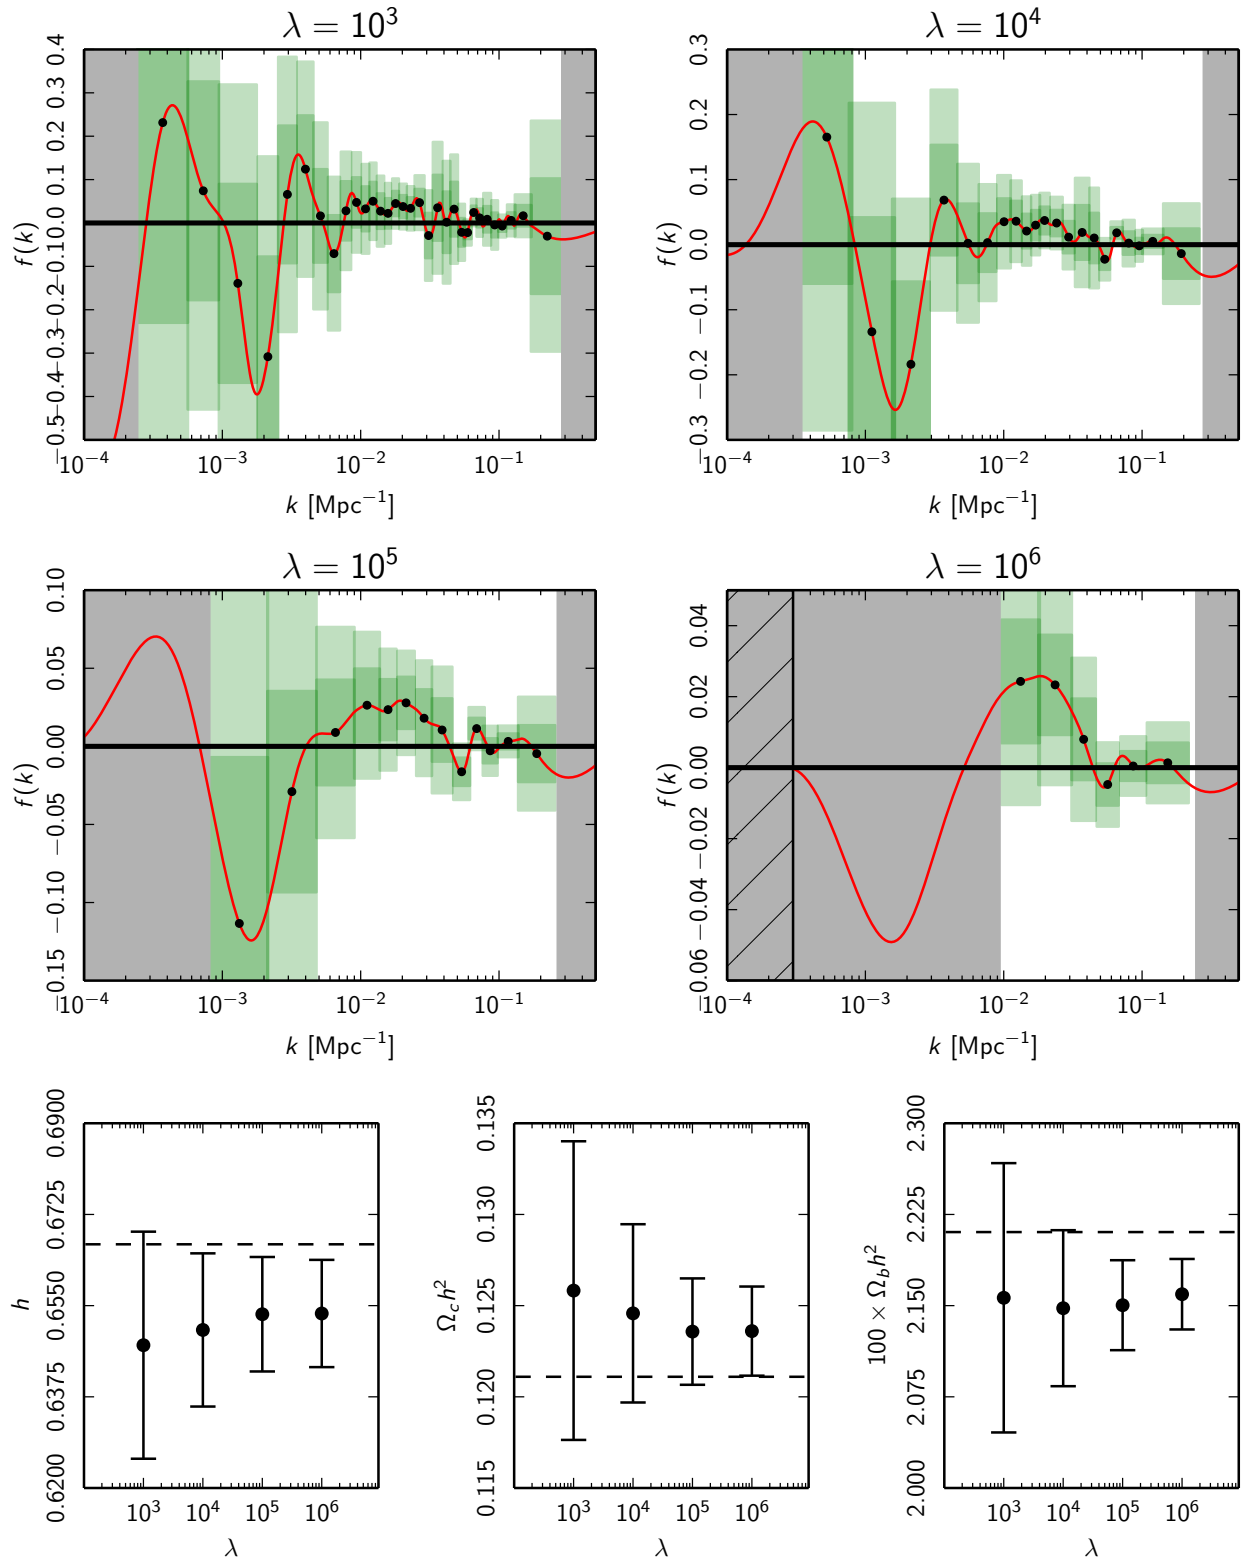


Figure 209: *Planck* TT+lowE penalized likelihood primordial power spectrum reconstruction. *Top four panels*: The deviation $f(k)$ for four different roughness penalties. The red curves indicate the best-fit deviation, while the vertical extents of the dark and light green error bars indicate the $\pm 1\sigma$ and $\pm 2\sigma$ errors, respectively. The width of the error bars indicates the minimum reconstructible width (the minimum width for a Gaussian feature such that the mean square deviation of the reconstruction is less than 10 %). The grey regions display where the minimum reconstructible width is undefined, meaning that the reconstruction in these regions is untrustworthy. The hatched region in the $\lambda = 10^6$ plot indicates where the fixing penalty has been applied. *Lower three panels:* $\pm 1\sigma$ error bars for the three non-primordial-specctrum cosmological parameters included in the reconstruction. The respective best-fit fiducial model values are indicated by the dashed lines.

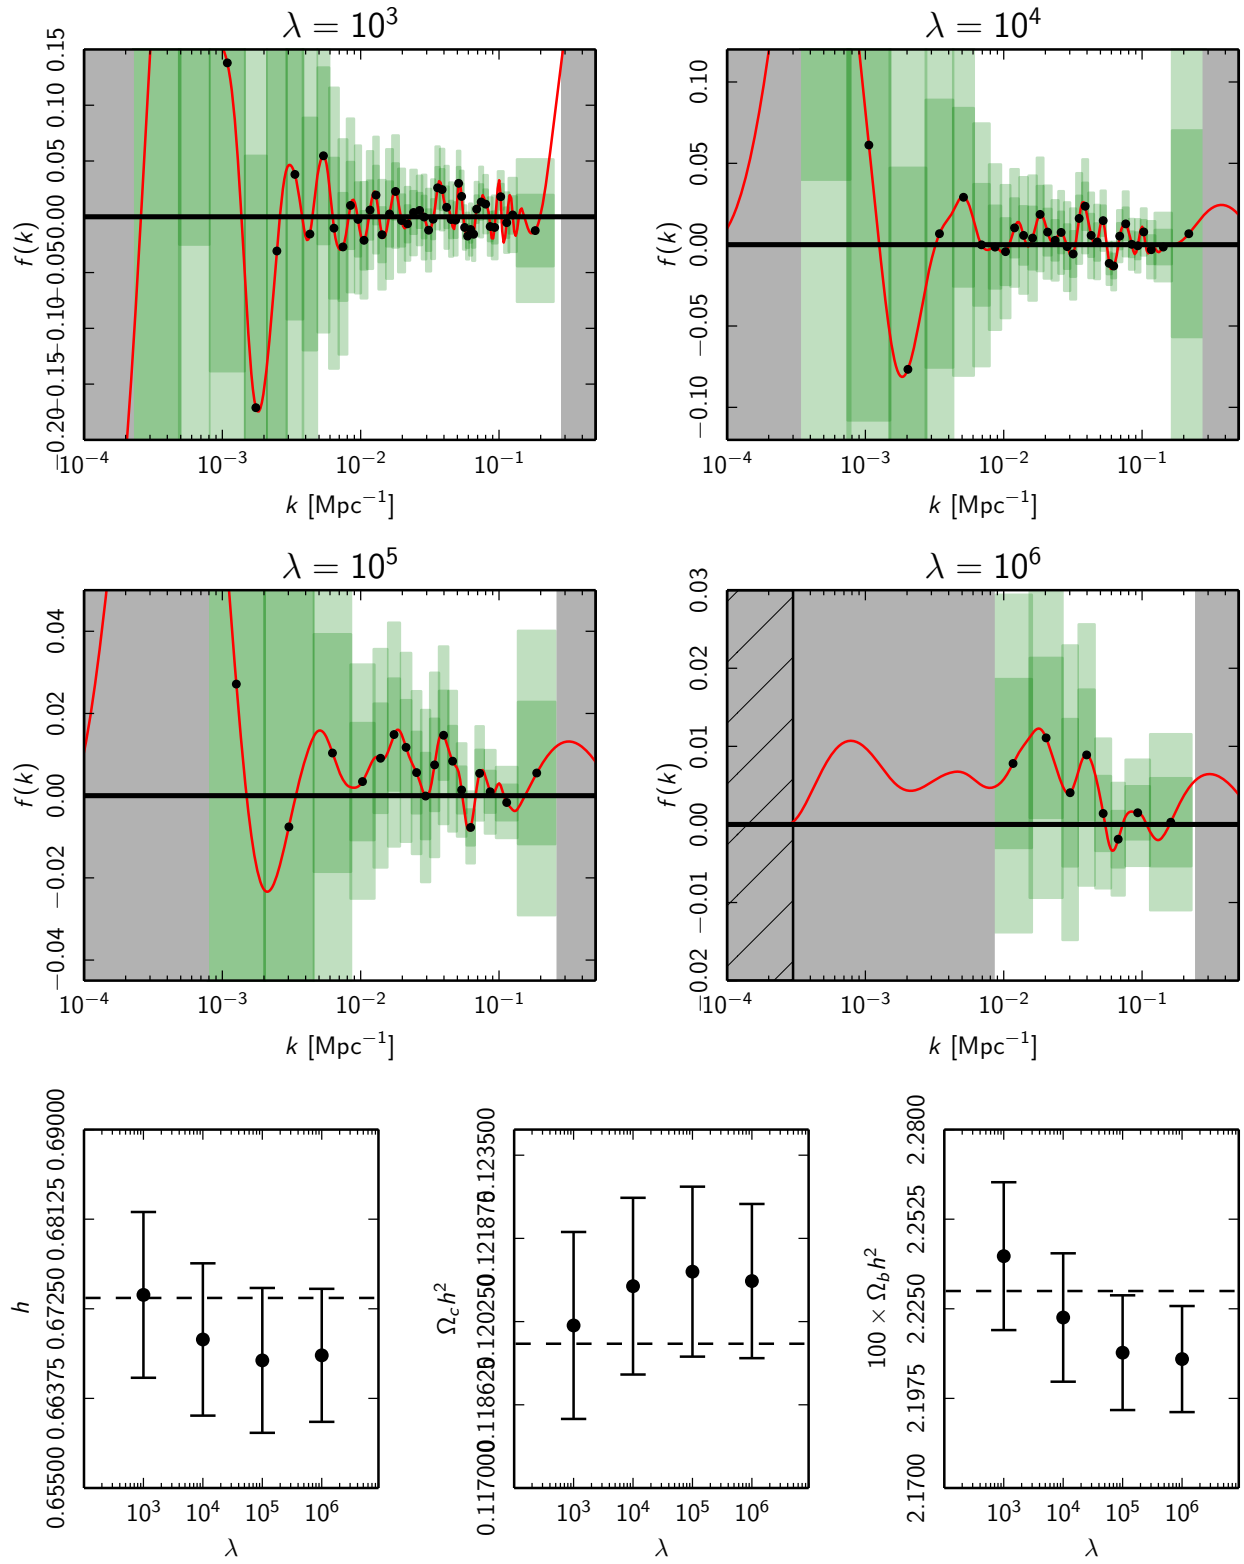

Figure 210: Penalized likelihood reconstruction, as Fig. 209 but for *Planck* TT,TE,EE+lowE.

28.6.2 Bayesian reconstruction

To reconstruct the primordial power spectrum of curvature perturbations, we follow the methodology of section 8.2 of **(alias?)**, using an N-point interpolating logarithmic spline with the positions of the knots considered as free parameters in the full posterior distribution. The positions of the points in the $(k, \mathcal{P})$ plane are treated as likelihood parameters with log-uniform priors. Further, the k-positions are sorted a priori such that $k_1 < k_2 < \cdots < k_N$, with k_1 and k_N fixed. We compute posteriors and evidence values (conditioned on N) using `PolyChord` [126, 127], also varying all cosmological and nuisance parameters. We then use evidence values for each model to correctly marginalize out the number of knots N.

To plot our reconstructions of $\mathcal{P}(k)$, we compute the marginalized posterior distribution of $\ln \mathcal{P}$ conditioned on k. The iso-probability confidence intervals are then plotted in the $(k, \mathcal{P})$ plane (see, e.g., Fig. 211), using code recorded in [124]. To quantify the constraining power of a given experiment, we use the conditional Kullback-Leibler (KL) divergence as exemplified by [135]. For two distributions $P(\theta)$ and $Q(\theta)$, the KL divergence is defined as

$$D_{KL}(P|Q) = \int \ln \left[\frac{P(\theta)}{Q(\theta)}\right] P(\theta) d\theta, \tag{1285}$$

and may be interpreted as the information gain in moving from a prior Q to a posterior P [243]. For our reconstructions, we compute the KL divergence of each distribution conditioned on k and N, and then marginalize over N using evidence values to produce a k-dependent number which quantifies the compression or information that each data set provides at each value of k. Further plots and theoretical detail can be found in Handley et al. [125].

Update on *Planck* 2015

In **(alias?)**, our analysis focussed predominantly on the TT+lowTEB data set. Here we present results for TT,TE,EE+lowE+lensing. First, in updating to the lowE likelihood, we find that there is a marked tightening in the constraint on the amplitude of the reconstructed spectrum at all values of k. The improvement in the constraint can be seen directly in the predictive posterior plots (Fig. 211, top-left panel, and Fig. 212), and is quantified in Fig. 211 (bottom-right) via the KL divergence. The reason for the high-ℓ constraint provided by a low-ℓ likelihood change is due to the reduced uncertainty on τ that `SimAll` EE provides. This can be seen by examining the shifts in the underlying cosmological parameters in Fig. 193.

Upon adding TE and EE data, we find that the hint of a feature at $\ell \simeq 30$ is still present, in spite of the additional constraining power provided by polarization. Using polarization data, the $N = 3$ case is now the most strongly favoured model by the evidence criterion. This indicates that there is some scope for models which account for low-ℓ cosmic variance to be preferred in a Bayesian sense. The other underlying cosmological parameters are unaffected by the additional degrees of freedom in the primordial power spectrum provided by the reconstruction.

In order to combine *Planck* polarization data with BK15, we also allow the tensor-to-scalar ratio r to vary, and fix the tensor tilt n_t via the inflationary consistency condition. As can be seen in the bottom-left panel of Fig. 211, upon adding BK15, the effect of the low-ℓ deficit is softened, but with otherwise little change to the reconstruction. We repeated our analysis with `CamSpec` in place of `Plik` and found our results to be qualitatively and quantitatively unchanged.

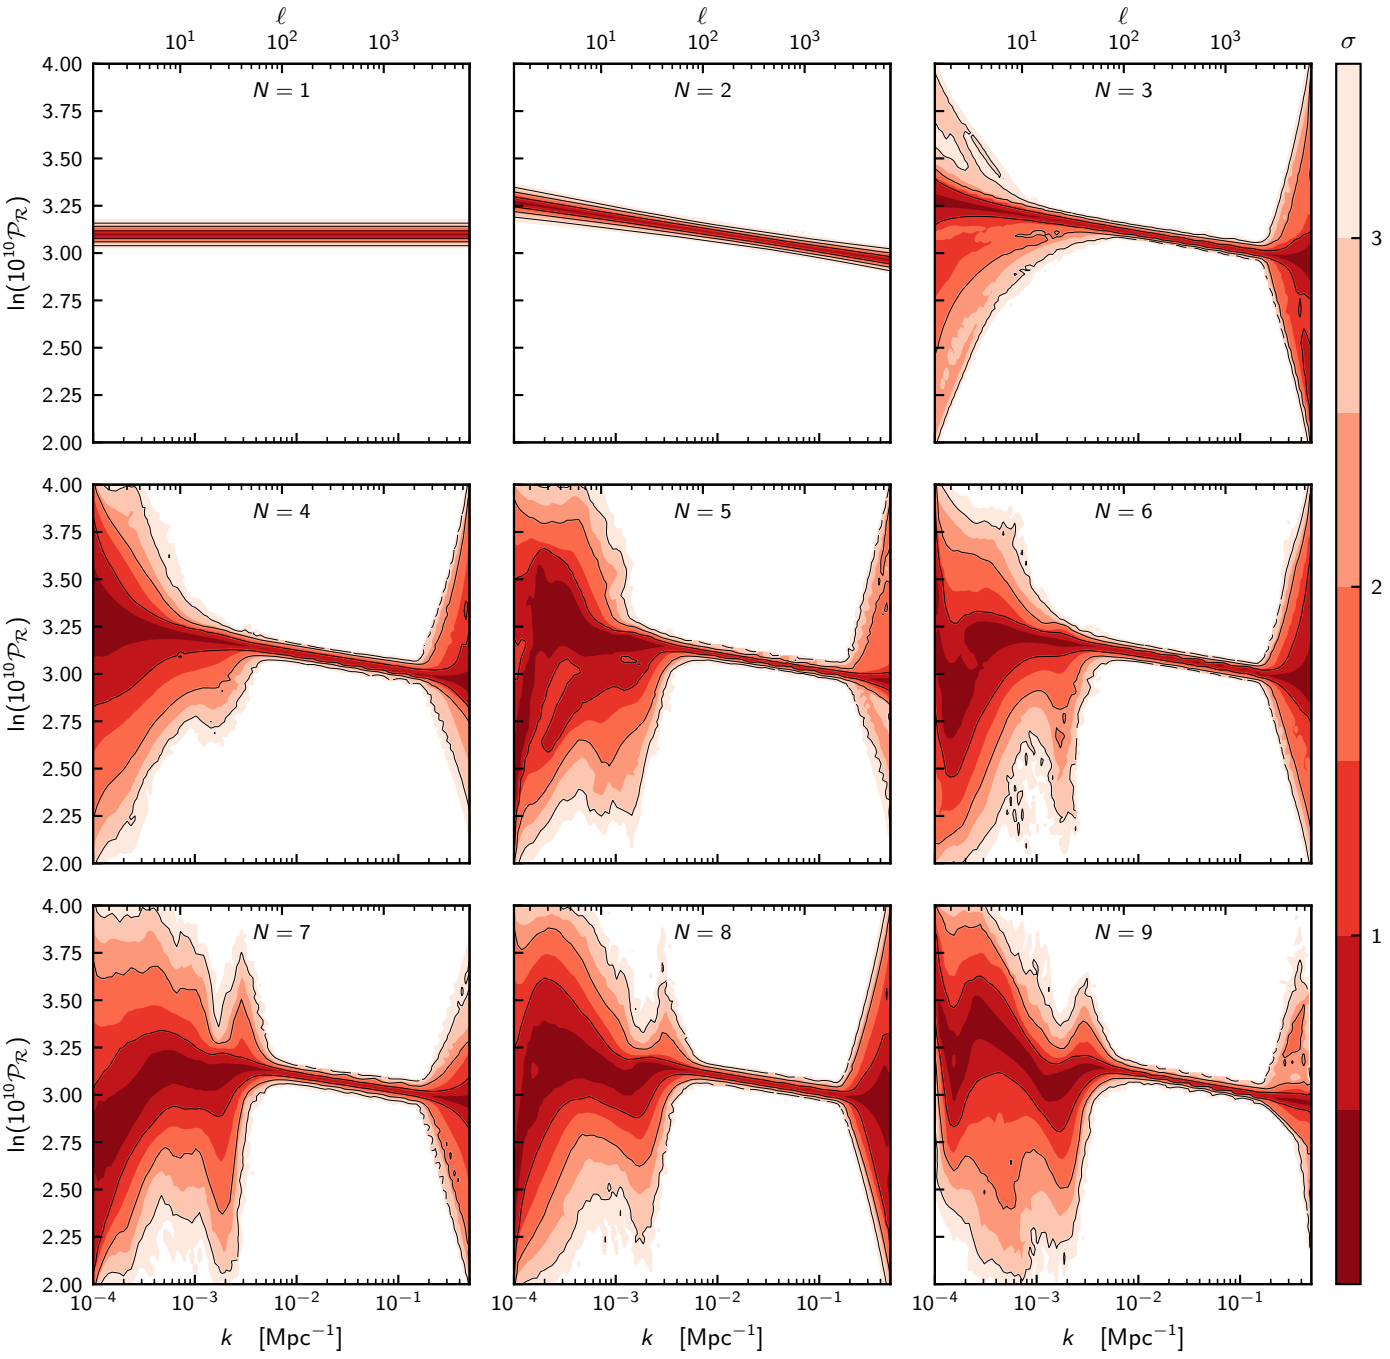

Figure 212: Free-form Bayesian reconstruction of the primordial power spectrum for varying numbers of knots (Sect. 28.6.2) using TT,TE,EE+lowE+lensing. The amplitude and tilt are consistent with the rest of the results with the same combination of likelihoods. As more knots are added, the $\ell \simeq 30$ feature in the C_ℓ temperature spectrum is visible as a dip to lower power.

Parameter	Prior	Range
$k_i, k_{\max}$	Sorted uniform	$0 < k_1 < \cdots < k_N < 0.2\,\mathrm{Mpc}^{-1}$
d_i	Uniform	$0 < d_1, \ldots, d_N < 0.01\,\mathrm{Mpc}^{-1}$
$k_i, k_{\max}$	Sorted log-uniform	$-4 < \log_{10} k_1 \cdots \log_{10} k_N < -0.3$
d_i	Log-uniform	$0 < \log_{10} d_1, \cdots, \log_{10} d_N < 1$
h_i	Uniform	$-1 < h_1, \ldots, h_N < 1$
$\ln(10^{10} A_\mathrm{s})$	Uniform	$2 < \ln(10^{10} A_\mathrm{s}) < 4$
n_s	Uniform	$0.8 < n_\mathrm{s} < 1.2$

Table 36: Priors for the search for sharp features in the primordial power spectrum. Units for k and d are Mpc^{-1}.

Free-form search for features

Next we examine the effect that sharp features in the primordial power spectrum can have on cosmological parameters. We model sharp features in the spectrum as a variable number of top-hat functions with varying widths, heights, and locations. On top of the traditional $A_\mathrm{s}, n_\mathrm{s}$ parameterization of the power spectrum, we place N sharp top-hat features into the spectrum at locations k_i with widths d_i and heights h_i $(i = 1, \ldots, N)$. That is, we set

$$\ln \mathcal{P}_\mathcal{R}(k) = \ln A_\mathrm{s} + (n_\mathrm{s} - 1) \ln \left(\frac{k}{k_*} \right) + \sum_{i=1}^{N} h_i \left[|k - k_i| < \frac{d_i}{2} \right], \tag{1286}$$

where the square brackets in the summation denote a logical truth function as introduced by Graham et al. [114]. For values of $N = 0, \ldots, 8$, we treat the variables in parameterization (1286) as parameters in a posterior distribution along with the traditional cosmological and *Planck* nuisance parameters, with priors as detailed in Table 36. We run with both linear and logarithmic priors on the k-locations of the features, as this alters the sensitivity to the type of features uncovered. We sample the posteriors using `PolyChord` [126, 127].

Figures 213 and 214 show our results. With the linear priors case, there are statistically insignificant features corresponding to the peaks of the TT spectrum, which arise due to the enhanced cosmic variance at these locations. With the logarithmic priors case, a stronger but still statistically insignificant feature is detected at $\ell \simeq 30$, with a small deficit and surrounding enhancement of power. This case reproduces the results found in Sect. 28.6.2. In both cases, the Bayesian evidence shows preference for a no-features spectrum, and steadily declines as more features are added. The cosmological parameters remain unperturbed despite the introduction of features.

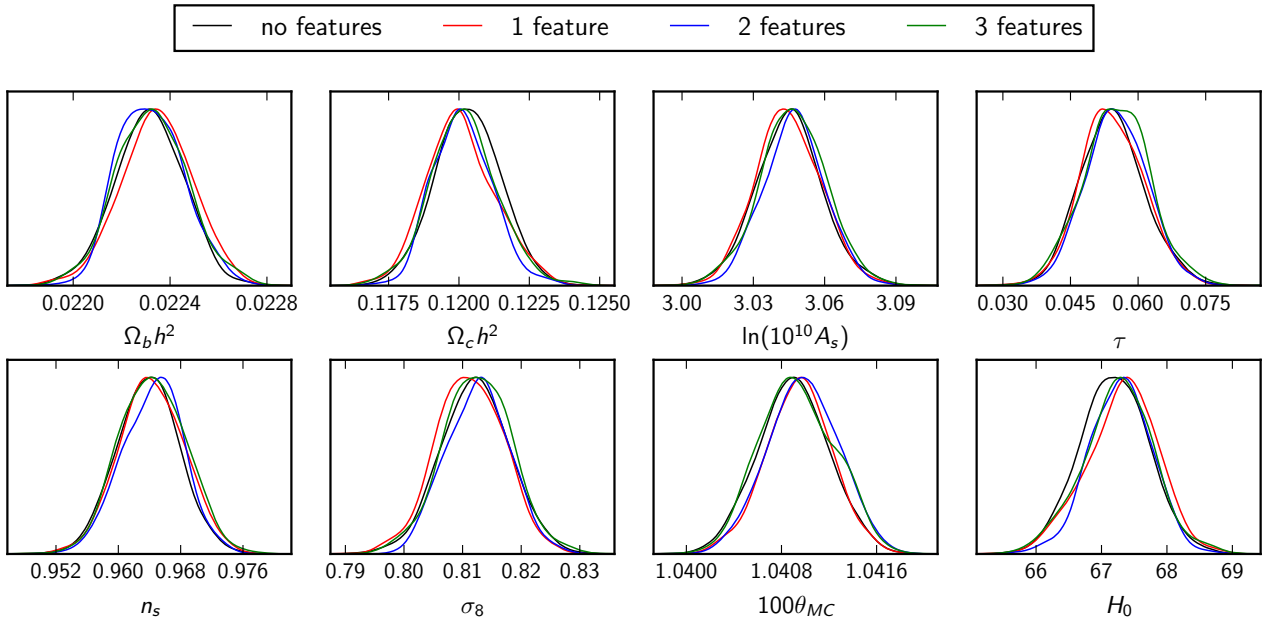

Figure 214: The effect on the underlying cosmological parameters of the free-form Bayesian search for features (Sect. 28.6.2), for $N = 0, \ldots, 3$ features with linear k-priors. The parameters remain stable up to $N = 8$ features, and when changing to logarithmic k-priors.

28.6.3 Cubic spline reconstruction

In this subsection we update the third method of reconstruction used in **(alias?)**, in which $\ln \mathcal{P}_\mathcal{R}(\ln(k))$ was expanded in cubic splines localized in $\ln(k)$ about uniformly spaced "knots," $\{\ln(k_b), b = 1, \ldots, N\}$, whose range was chosen to cover all relevant cosmological scales, from $10^{-4}\,\mathrm{Mpc}^{-1}$ to $O(1)\,\mathrm{Mpc}^{-1}$. We single out the standard scalar power spectrum pivot scale as a "pivot knot" $b{=}p$, with $k_p = k_* = 0.05\,\mathrm{Mpc}^{-1}$. Its associated power $\ln A_\mathrm{s} = \ln \mathcal{P}_\mathcal{R}(k_*)$ is assigned a uniformly distributed prior. A tilted primordial power spectrum $\mathcal{P}_{\mathcal{R},\mathrm{fid}} \equiv A_\mathrm{s}(k/k_*)^{n_{\mathrm{s,fid}}-1}$, with fixed spectral index $n_{\mathrm{s,fid}}$ is used as the fiducial baseline from which deviations are measured, expressed in terms of $N-1$ relative spectral shape parameters: $q_b = \ln\left(\mathcal{P}_\mathcal{R}(k_b)/\mathcal{P}_{\mathcal{R},\mathrm{fid}}(k_b)\right)$ for $b \neq p$. For the results presented here, $n_{\mathrm{s,fid}} = 0.967$ was chosen. As in **(alias?)** we continue to use cubic splines for the k-space modes we expand in, with natural boundary conditions (i.e., vanishing second derivatives at the first and last knots). The treatment here is therefore quite analogous to that in Sect. 28.5.4, where the inflaton potential rather than the curvature power spectrum is expanded in cubic splines. Knot numbers up to 18 were reported in **(alias?)**, and it was shown that 12 were sufficient to capture the variations desired by the *Planck* CMB data. The mode functions were also varied. For example, linear interpolation leads to similar reconstructions as long as enough knots are used. A weak uniform prior $(-1 \leq q_b \leq 1)$ was imposed on q_b. Outside of the spline coverage region $[k_1, k_N]$ we set $\ln\left(\mathcal{P}_\mathcal{R}(k)/\mathcal{P}_{\mathcal{R},\mathrm{fid}}(k)\right)$ to be q_1 for $k < k_1$ and q_N for $k > k_N$. The prior on q_b and boundary condition choices have little impact on the reconstructions over most of the k-range.

The current *Planck* TT,TE,EE+lowE+lensing+BK15 data give only upper limits to the allowed values of the tensor amplitude, $r < 0.06$. Consequently, adding shape degrees of freedom to the tensor power spectrum would yield a completely prior-driven result. Instead we adopt the standard model power-law parameterization for tensors, $\mathcal{P}_\mathrm{t}(k) = rA_\mathrm{s}(k/k_*)^{n_\mathrm{t}}$, with the tensor spectral index constrained by the consistency relation $n_\mathrm{t} = -r/8$. Without B-mode constraints and with enough knots one could deform the primordial scalar spectrum to mimic a tensor contribution to the CMB power. However, this near-degeneracy is broken with direct B-mode observations, effectively so even if there are only upper limits as for the BK15 data. Our reconstructions here focus on letting r float over a prior range $0 \leq r \leq 1$, but the posterior is strongly constrained by the BK15 data.

The joint probability distributions of $\{q_b, b \neq p\}$, $\ln A_\mathrm{s}$, and the other cosmic and nuisance parameters are determined by `CosmoMC` modified to incorporate the N-knot parameterization

for fixed knot number N. Figure 215 shows the reconstruction. Apart from the mean and 1σ and 2σ limits on the ensemble of trajectories allowed by the posterior probability, we also show a set of individual trajectories with parameters taken from 1σ samples to illustrate the knot-to-knot coherence (dashed curves). The tensor trajectories are straight lines, as required by the adopted tensor power model.

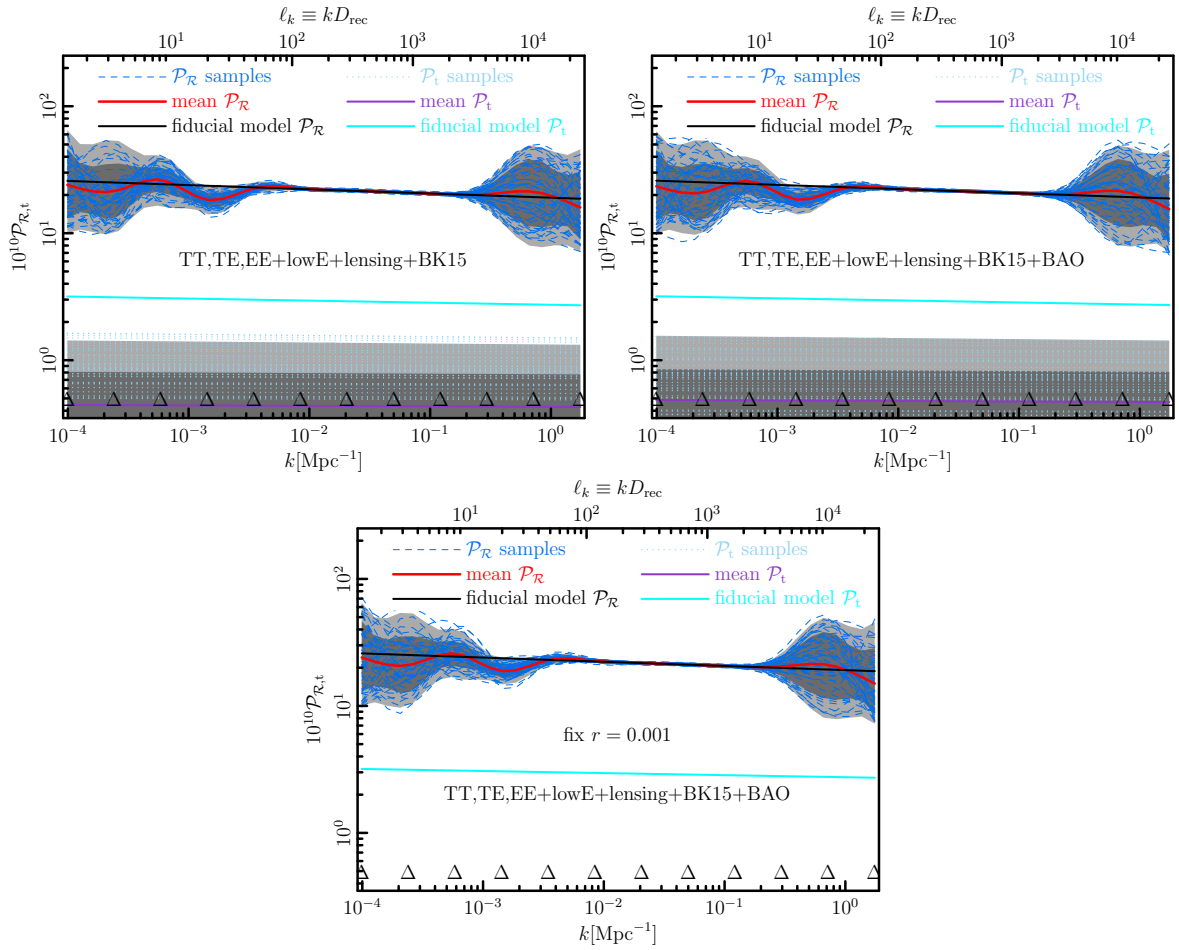

Figure 215: Reconstructed primordial scalar power spectrum derived using *Planck* TT,TE,EE+lowE+lensing+BK15 data and 12 knots for the cubic spline interpolation (with positions marked as Δ at the bottom of each panel). Mean (ensemble-averaged) spectra are heavy lines, allowed $\pm1\sigma$ and $\pm2\sigma$ regions for trajectories are the shaded regions, and the dashed lines denote selected trajectories with parameters sampled within the $\pm1\sigma$ posterior. Below the scalar power is the tensor power reconstruction. The addition of the BAO likelihood shown in the middle panel makes almost no visual difference to the reconstructions. In the bottom panel, fixing the tensor-to-scalar ratio to $r = 0.001$ also produces only small differences in reconstruction. Knot positions in k roughly translate to multipoles through $kD_{\rm rec}$, where $D_{\rm rec}$ is the comoving distance to recombination.

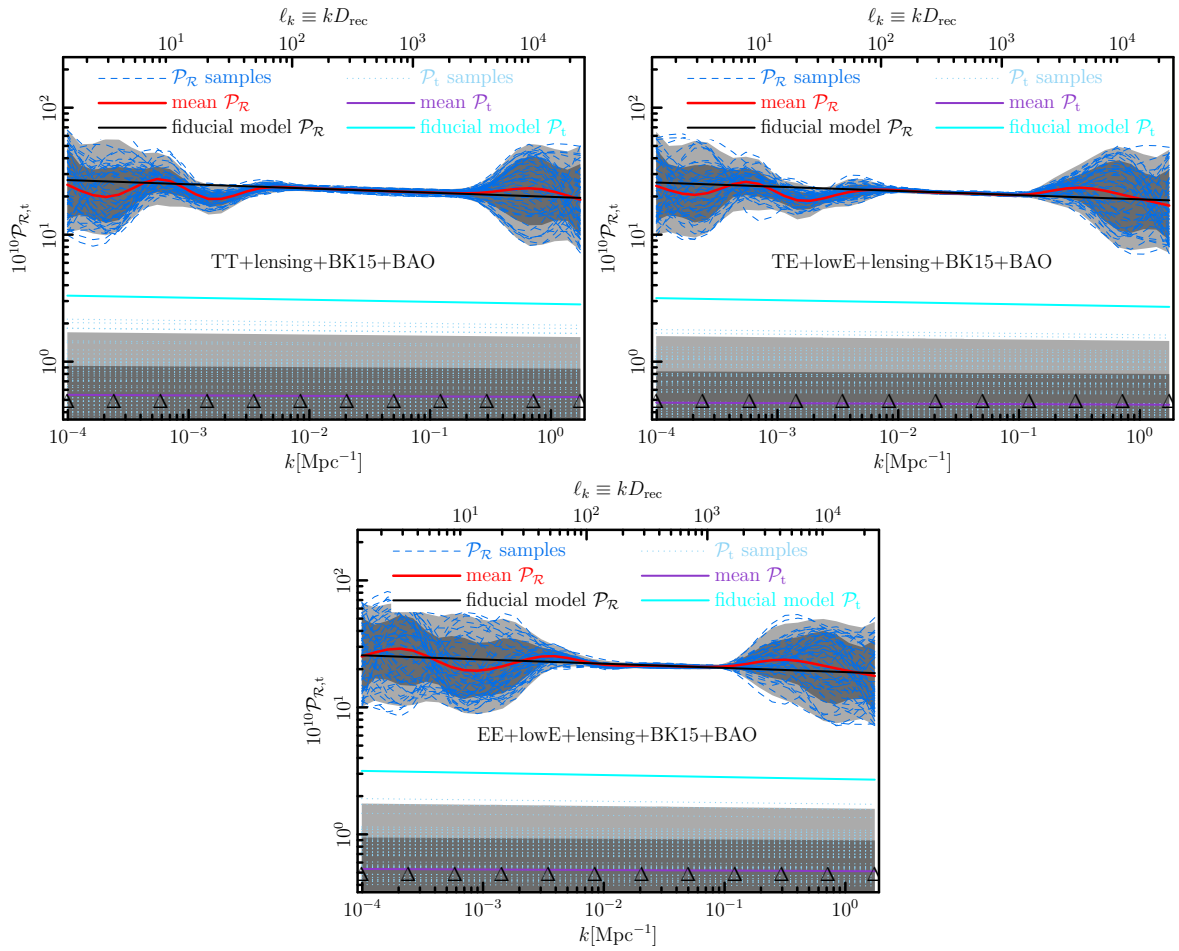

Figure 216: Reconstructed 12-knot power spectra. The robustness of the reconstruction is apparent when sub-selections of the *Planck* data are used: *Planck* TT+lowE+lensing+BK15 (top); *Planck* TE+lowE+lensing+BK15 (middle); and *Planck* EE+lowE+lensing+BK15 (bottom).

In spite of the extra scalar shape freedom in the k-space region over which the tensor modes affect the CMB, the 12 knot reconstruction still leads to a strong constraint of $r < 0.069$, rather close to the $r < 0.06$ limit obtained if the only shape parameter is $n_{\rm s}$. In fact we find that the current limits on r are such that the scalar-power reconstructions are not sensitive to the details of the r distribution. To illustrate this, the lower panel of Fig. 215 shows the spectrum when r is fixed at the tiny value of $r = 0.001$. One could regard this as a theoretical prior for low-energy inflation models or a forecast for a future in which r is measured or tightly constrained by B-mode experiments.

In **(alias?)**, the main cubic spline reconstruction included non-CMB data to help pin down cosmological parameters such as H_0, τ, and the late-time expansion history. The improvements in the data from 2015 to 2018, especially the decreased errors on τ, result in no non-CMB data being needed. Although τ and $\ln A_{\rm s}$ are about 90 % correlated, as they are in the standard power-law model, neither are very correlated with the q_b. The strongest is about 40 % for q_3 at $k \simeq 0.0006\,{\rm Mpc}^{-1}$, corresponding to $\ell \sim 10$ where reionization is kicking in. The second strongest is about 30 % for $k \simeq 0.02\,{\rm Mpc}^{-1}$, similar to the correlation of τ and $n_{\rm s}$ in the standard power-law model. (The correlations among the q_b are also relatively small, except for the high k bands $b = 10$ and 11, where the data are not constraining.)

The middle panel in Fig. 215 shows the effect of adding the BAO constraint. Although apparently visually identical, there are slight differences. For example, the 1σ error on q_b at $k \simeq 0.02\,{\rm Mpc}^{-1}$ decreases by about 7 %, from 0.0090 to 0.0084, while at $k \simeq 0.1\,{\rm Mpc}^{-1}$ the decrease is about 5 %. The restriction to $r = 0.001$ does not change the error bars over the

floating r case. At intermediate k for modes 5 to 8 the errors on q_b are so close to zero that the reconstruction is quite compatible with a simple power law, corresponding to a straight line in Fig. 215. This was also a main result of the 2015 *Planck* reconstructions.

The errors on the q_b grow above ± 0.1 for $b = 4$ as a consequence of increased cosmic variance, giving more freedom in the allowed trajectories. Unfortunately this is also the region of relevance to the TT power spectrum deficit in the $\ell \simeq 20$–30 range. The most significant deviation from zero occurs for q_4 at $k \simeq 0.0014\,\mathrm{Mpc}^{-1}$: -0.254 ± 0.127, -0.255 ± 0.125, and -0.235 ± 0.128 for the three cases. Thus the anomaly in terms of deviation from the power law of the standard model hovers at around the 2σ level. More precisely, the 95 % upper confidence limits on q_4 are -0.011, -0.018, and $+0.017$, for the respective cases. This 2σ level of the anomaly was also the conclusion of the 2015 *Planck* reconstructions. Therefore, even though the low-k deficit is robust against the various choices for the reconstruction, we conclude that it is not statistically significant. The associated TT, TE, EE, and BB power spectra responses to the allowed primordial power variations are derived from the mode expansion, and match the $\mathcal{D}_\ell^{XY}$ data well, in particular following the dip in TT at $\ell \simeq 20$–30.

In Fig. 216 we show the reconstructed power spectra using only the TT, TE, and EE data in conjunction with BK15. The fixed $r = 0.001$ cases look very similar. Except at high k, the polarization data using either EE or TE also enforce a nearly uniform $n_\mathrm{s}(k)$ over a broad range in k, with values in excellent agreement with those obtained from TT alone, from TE and EE used in combination, and from the combined TT,TE,EE results. For example, the ± 0.0087 and ± 0.0060 1σ errors at $k \simeq 0.02\,\mathrm{Mpc}^{-1}$ and $k \simeq 0.1\,\mathrm{Mpc}^{-1}$, respectively, increase only slightly for TT only, to ± 0.012 and ± 0.0068, but, more significantly, to ± 0.017 and ± 0.069 with EE alone. The deficit region remains about the same, with the TT,TE,EE result for q_4 of -0.255 ± 0.125 quoted above changing slightly for TT alone, to -0.252 ± 0.130, but with no hint of an anomaly for EE alone, at -0.126 ± 0.460. If just the TE cross data are used, the values are closer to the TT case, namely, -0.232 ± 0.163, now under a 2σ excursion from the tilted fiducial model.

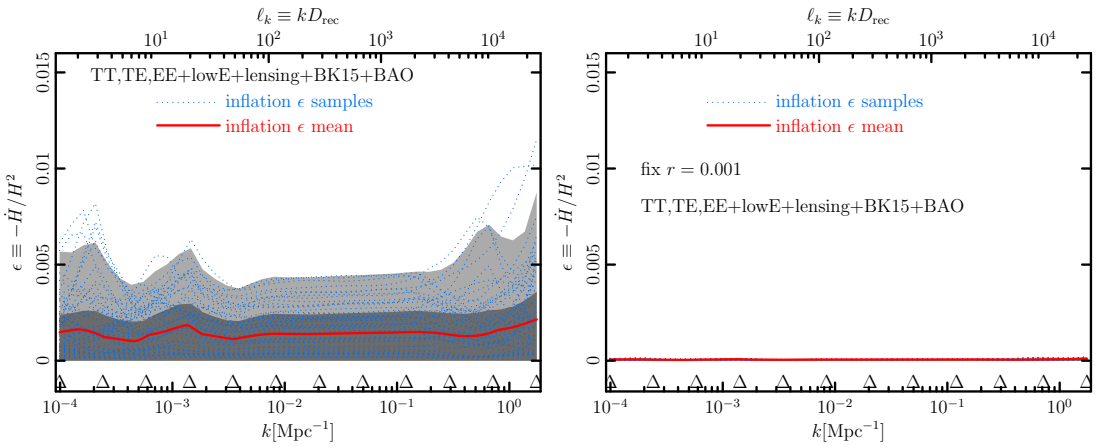

Figure 217: Acceleration history $\epsilon(k)$ for reconstructed trajectories using 12 knots (marked as Δ at the bottom of the figure), with cubic-spline interpolation and the *Planck* TT,TE,EE+lowE+lensing+BK15+BAO data for the two cases of floating r and r fixed at 0.001. Sample 1σ trajectories for the floating r case allow wide variability, which is naturally greatly diminished if r is fixed to $r = 0.001$.

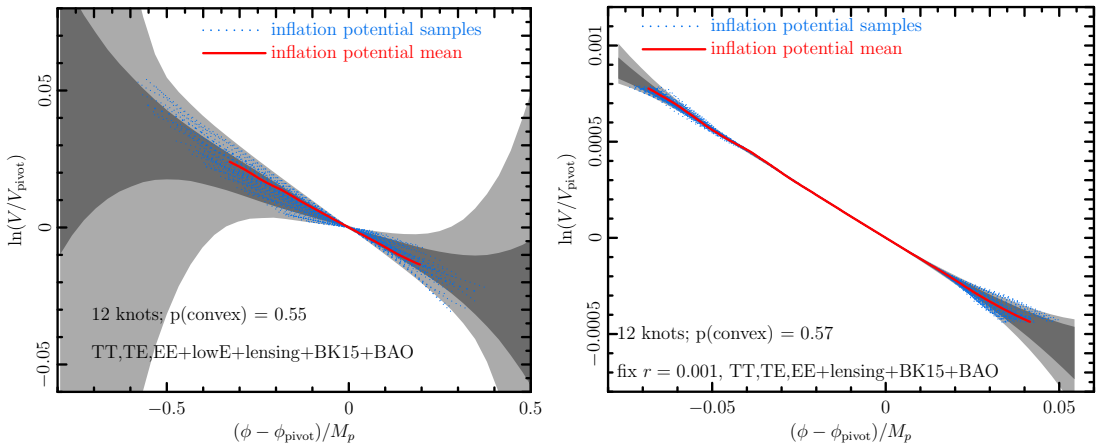

Figure 218: *Top:* Reconstructed shape of the single-field inflaton potential from the cubic-spline power spectra mode-expansion using 12 knots and the *Planck* TT,TE,EE+lowE+lensing+BK15+BAO data. *Bottom:* Result when r is fixed at 0.001. Instead of plotting as a function of wavenumber k we plot $\ln V(\phi)/V_{\rm pivot}$ about a pivot field value $\phi_{\rm pivot}$. Note that the range on the ϕ axis is quite different for the small r case than the floating case. The probability of local convexity evaluated at $\phi_{\rm pivot}$ is denoted as p(convex).

As in **(alias?)**, we can use the $\mathcal{P}_\mathcal{R}(k) \propto H^2/\epsilon$ and $\mathcal{P}_t(k)/\mathcal{P}_\mathcal{R}(k) \simeq 16\epsilon$ reconstructions to get an idea of the history of the acceleration of the Universe as a function of time over the significant number of e-folds of the cosmic expansion that the CMB data probe, codified by the dynamical slow-roll parameter $\epsilon(k) = -\dot{H}/H^2|_{k=aH}$, considered as a function of aH, the value of the wavenumber at Hubble crossing. Results with floating r and r fixed to 0.001 are shown in Fig. 217. For the dynamical time variable we use $k = aH$ for the horizontal axis for ease in comparing with the $\mathcal{P}_\mathcal{R}(k)$ curves of Fig. 215. The wide spread in the ϵ trajectories for the floating r case is a consequence of being able to fit the $n_{\rm s}(k)$ shape by a combination of $\epsilon(k)$ and $d\ln\epsilon(k)/d\ln k$. When r is small, $n_{\rm s}(k)$ is almost entirely determined by $d\ln\epsilon/d\ln k$, and the $\epsilon(k)$ values cluster near $r/16$.

The Hamilton-Jacobi energy constraint equation relates the potential to ϵ and H via $V = 3M_P^2H^2(1-\epsilon/3)$. Figure 218 shows the reconstructed inflationary potential shapes in the region over which the allowed inflationary potentials are constrained by the data for the floating r and fixed r cases. Instead of using k for the horizontal axis, we translate into inflaton-field ϕ-space using the relation between ϕ and $\sqrt{\epsilon}$, referenced to the pivot position $\phi_{\rm pivot}$. For the vertical axis we plot $\ln V/V_{\rm pivot}$, with the overall normalization $V_{\rm pivot}$ removed. Its value is set by r, hence there is a distribution of constant $V_{\rm pivot}$ amplitudes to superimpose if we want the total V. The radically different visual appearance for the floating r and fixed r cases is due to the observable k range being compressed through the smallness of ϵ into a small precisely determined field range, whereas this range has a distribution in the floating r case. One can monitor whether the shapes of the individual realizations of the potential trajectories bend upwards or downwards or do both, an indication of convexity. The sample trajectories shown are not exclusively convex or concave, and a measure of the probability that they are convex can be made from the ensemble. As indicated in Fig. 218 for the 12 knot case, the ensemble-averaged potentials are roughly exponential, with individual trajectories bending away from the mean, but with no strong tendency for convexity or concavity. (The roughly 50 % probability changes somewhat depending upon the combination of data used, whether TT,TE,EE or the individual data sets.)

The standard cosmological parameter determinations are highly robust to the addition of these spline shape degrees of freedom. The mean values change little and the error bars grow slightly, by around 10 % for $\ln A_{\rm s}$, τ, and H_0. The largest error increase is for σ_8, with $\sigma_8 = 0.812 \pm 0.0058$ becoming 0.814 ± 0.0096. The main conclusions of this section on ϵ and V, and $\mathcal{P}_\mathcal{R}(k)$, remain as in **(alias?)**, but the results have been noticeably sharpened by the improvements in the *Planck* 2018 data sets.

28.7 Search for primordial features in the *Planck* power spectrum

The "bottom-up" power spectrum reconstruction methods of the previous section are an excellent way to search for coarse features in the spectrum, but lack the resolution to detect the higher-frequency features generically predicted by various physical mechanisms [see, e.g., [59] for a review]. It is therefore useful to complement power spectrum reconstruction with a "top-down" approach by fitting specific feature models to the data. In this section we will analyse a representative range of power spectrum templates which parameterize features in terms of a handful of new parameters.

With *Planck*'s temperature and polarization data, we have two essentially independent probes of features at our disposal and will pay particular attention to examining the consistency between the two [197].

28.7.1 Power spectrum templates with features

	Log osc	Running log osc	Lin osc	Step	Kin cutoff	Rad cutoff	Kink cuto
$\mathcal{A}_X$	[0,0.5]	[0,0.5]	[0,0.5]	...	...	...	...
$\log_{10}\omega_X$	[0,2.1]	[0,2.1]	[0,2]	...	...	...	...
$\varphi_X/(2\pi)$	[0,1]	[0,1]	[0,1]	...	...	...	...
$\alpha_{\rm rf}$	...	[−0.1,0.1]	...	...	...	...	...

$R_{\rm c}$	...	...	...	...	...	...	[−1,0.7]

Table 37: Prior ranges for the parameters of the feature model templates of Sect. 28.7.1.

Global oscillation models

Periodic or quasi-periodic modulations of the power spectrum which extend over the entire observable range of wavenumbers can occur in a variety of models [cf., e.g., Danielsson [66], Martin & Brandenberger [180], Bozza et al. [42], Chen [56], Jackson & Shiu [145]]. A general parameterization of models with a sinusoidal modulation of the primordial power spectrum reads

$$\mathcal{P}_{\mathcal{R}}^{X}(k) = \mathcal{P}_{\mathcal{R}}^{0}(k)\left[1 + \mathcal{A}_X \cos\left(\omega_X \Xi_X(k) + \varphi_X\right)\right], \tag{1287}$$

where $X \in \{\log, \mathrm{lin}, \mathrm{rf}\}$. Defining $\kappa \equiv k/k_*$,[174] we consider the logarithmic oscillation model, given by $\Xi_{\log} \equiv \ln\kappa$, and the linear oscillation model, $\Xi_{\rm lin} \equiv \kappa$. In addition, we investigate a logarithmic model with running frequency, $\Xi_{\rm rf} \equiv \ln\kappa\,(1 + \alpha_{\rm rf}\ln\kappa)$. For $0 \leq \alpha_{\rm rf} \lesssim 0.01$, this is a good approximation for the scalar power spectrum in the axion monodromy model [96], which will be analysed in more detail below, but here we allow for a wider range of the running parameter $\alpha_{\rm rf}$, including negative values (i.e., decreasing frequency with increasing k).

Localized oscillatory features: inflation with a step

A sudden transient event in the evolution of the inflation field, triggered by a sharp feature in the inflaton potential, or a sharp turn in field space, generically leads to a localized oscillatory feature in the power spectrum [8, 57, 5, 196, 19]. As an example of this class of feature models,

[174] Throughout this section, we take $k_* = 0.05\,{\rm Mpc}^{-1}$.

we consider here the case of a tanh-step in an otherwise smooth inflaton potential [8], whose power spectrum can be parameterized as [195]

$$\ln \mathcal{P}^{\rm s}_{\mathcal{R}}(k) = \ln \mathcal{P}^{0}_{\mathcal{R}}(k) + \mathcal{I}_0(k) + \ln\left(1 + \mathcal{I}_1^2(k)\right), \tag{1288}$$

where the first- and second-order terms are given by

$$\mathcal{I}_0 = \mathcal{A}_{\rm s}\, \mathcal{W}_0(k/k_{\rm s})\, \mathcal{D}\left(\frac{k/k_{\rm s}}{x_{\rm s}}\right), \tag{1289}$$

$$\mathcal{I}_1 = \frac{1}{\sqrt{2}}\left[\frac{\pi}{2}(1-n_{\rm s}) + \mathcal{A}_{\rm s}\, \mathcal{W}_1(k/k_{\rm s})\, \mathcal{D}\left(\frac{k/k_{\rm s}}{x_{\rm s}}\right)\right], \tag{1290}$$

with window functions

$$\mathcal{W}_0(x) = \frac{1}{2x^4}\left[\left(18x - 6x^3\right)\cos 2x + \left(15x^2 - 9\right)\sin 2x\right], \tag{1291}$$

$$\mathcal{W}_1(x) = -\frac{3}{x^4}(x\cos x - \sin x)\left[3x\cos x + \left(2x^2 - 3\right)\sin x\right], \tag{1292}$$

and damping function

$$\mathcal{D}(x) = \frac{x}{\sinh x}. \tag{1293}$$

In this model, the parameter $\mathcal{A}_{\rm s}$ determines the amplitude of the oscillatory feature, the step scale $k_{\rm s}$ sets the position of the step in k-space, and the damping parameter $x_{\rm s}$ determines the width of the envelope function.

Models with suppressed power at large scales

The apparent lack of power at the largest scales in the temperature power spectrum with respect to the expectation of base ΛCDM serves as a motivation for models with a suppression of primordial perturbations below a cutoff scale $k^{\rm c}$. Physically, this effect may be due to fluctuations at the largest observable scales being generated at the onset of the inflationary phase after a prior era of, e.g., kinetic or radiation domination [278, 63], or due to an isolated event such as a kink in the inflaton potential [262].

In these scenarios, the primordial spectrum can generally be analytically approximated by an expression of the form

$$\ln \mathcal{P}^{Y}_{\mathcal{R}}(k) = \ln \mathcal{P}^{0}_{\mathcal{R}}(k) + \ln \Upsilon_Y(k/k^{\rm c}_Y), \tag{1294}$$

with $Y \in \{\mathrm{kin}, \mathrm{rad}, \mathrm{kink}\}$, where Υ_Y is a function with $\ln \Upsilon_Y \to 0$ in the limit $k \gg k^{\rm c}_Y$ that describes the shape of the cutoff and the transition to a power-law spectrum at smaller scales.

Initial kinetic domination

If inflation is preceded by an era dominated by the kinetic energy of the inflaton field (i.e., fast roll), we have

$$\Upsilon_{\rm kin}(y) = \frac{\pi}{16}\, y\, |C_{\rm c}(y) - D_{\rm c}(y)|^2, \tag{1295}$$

with

$$C_{\rm c}(y) = e^{-iy}\left[H_0^{(2)}\left(\frac{y}{2}\right) - \left(\frac{1}{y} + i\right) H_1^{(2)}\left(\frac{y}{2}\right)\right], \tag{1296}$$

$$D_{\rm c}(y) = e^{iy}\left[H_0^{(2)}\left(\frac{y}{2}\right) - \left(\frac{1}{y} - i\right) H_1^{(2)}\left(\frac{y}{2}\right)\right], \tag{1297}$$

where $H_n^{(2)}$ denotes the Hankel function of the second kind [63].

Initial radiation domination

If inflation begins immediately after a radiation-dominated phase, the cutoff function reads [278]

$$\Upsilon_{\rm rad}(y) = \frac{1}{4y^4}\left|e^{-2iy}\,(1+2iy) - 1 - 2y^2\right|^2 . \tag{1298}$$

Kink in the inflaton potential (Starobinsky model)

A kink in the inflaton potential, first discussed by [262], leads to a spectrum approximately given by

$$\begin{aligned}\Upsilon_{\rm kink}(y) = 1 - 3(R_{\rm c}-1)\frac{1}{y}\left[\left(1-\frac{1}{y^2}\right)\sin 2y + \frac{2}{y}\cos 2y\right] \\ + \frac{9}{2}(R_{\rm c}-1)^2\frac{1}{y^2}\left(1+\frac{1}{y^2}\right)\left[1+\frac{1}{y^2}+\left(1-\frac{1}{y^2}\right)\cos 2y - \frac{2}{y}\sin 2y\right],\end{aligned} \tag{1299}$$

with the parameter $R_{\rm c}$ expressing the ratio of the slopes of the inflaton potential before and after the kink [252].

28.7.2 Data analysis

We employ a modified version of `CAMB` with suitably increased numerical precision settings to calculate the CMB angular power spectra for the feature models. Since variations of the primordial spectrum may be degenerate with late-time cosmology parameters [209], we explore a parameter space consisting of the base-ΛCDM parameters and the respective additional free parameters of the feature models (see Table 37 for the prior ranges). Note that we take primordial tensor perturbations to be absent in our analysis. In the results presented in Sect. 28.7.3, nuisance parameters are assumed to be uncorrelated with the feature parameters and kept fixed to their base-ΛCDM best-fit values.

In order to maximize sensitivity to narrow features, we use only the *unbinned* versions of the *Planck* high-ℓ likelihoods in the following combinations: (i) temperature data, *Planck* TT(unbinned)+lowE; (ii) E-polarization data only, *Planck* EE(unbinned)+lowE; and (iii) temperature plus polarization data, *Planck* TT,TE,EE(unbinned)+lowE.

For all combinations of feature models and data, the parameter space is sampled with the nested sampling algorithm as implemented in `MultiNest`. The improvement in the fit due to the introduction of a feature is quantified by the effective $\Delta\chi^2 \equiv -2(\ln\mathcal{L}^{\rm best\,fit}_{\Lambda\rm CDM} - \ln\mathcal{L}^{\rm best\,fit}_{\rm feature})$. Being more complex than a power-law spectrum, feature models will in general have a negative $\Delta\chi^2$. However, determining whether the improvement in fit is due to overfitting scatter in the data or due to an actual feature is not straightforward and requires model-dependent simulations [**(alias?)**] or analytic estimates [83] to determine the expected $\Delta\chi^2$ under the null-hypothesis of an underlying power-law spectrum. In the Bayesian approach, a feature model's general performance relative to base ΛCDM can be expressed in terms of the Bayesian evidence $\mathcal{E}$ [268], which is also evaluated by `MultiNest`.

28.7.3 Feature candidates and their evidence

We list the best-fit effective $\Delta\chi^2$ and Bayes factors with respect to a power-law spectrum in Tables 38 and 39. Examining the effective $\Delta\chi^2$ for the feature models previously considered in **(alias?)** reveals only minor differences, with a general trend towards smaller improvements due to features. The $\Delta\chi^2$ of the oscillation and step models fall well within the expected range of $\Delta\chi^2 \sim 10$ found in **(alias?)**. Of note are the relatively high values of the radiation and kink cutoff models for polarization-only data, partially driven by the high quadrupole of the EE data. However, the best-fit parameters and spectra (see Fig. 221) do not match their counterparts in the temperature data at all, which strongly suggests that this is not a physical effect. The same observation can also be made for the step model: the best fit to the EE data is clearly out of phase with the temperature best fit.

	Step			Kin cutoff			Rad cutoff			
	TT	EE	TT,TE,EE	TT	EE	TT,TE,EE	TT	EE	TT,TE,EE	T
$\Delta\chi^2_{\rm eff}$	−7.0	−5.2	−5.4	−1.2	0.0	−0.9	−0.2	−4.7	−0.0	−2
$\ln B$	0.0	−0.2	0.1	0.0	−0.2	0.0	−0.8	0.0	−0.7	−0
$\mathcal{A}_{\rm s}$	0.29	0.19	0.38	...	...	...	...	...	...	..
$\log_{10}(k_{\rm s})$	−3.11	−3.47	−3.09	...	...	...	...	...	...	..
$\ln x_{\rm s}$	0.57	2.17	0.15	...	...	...	...	...	...	..
$\log_{10}(k_Y^{\rm c})$	...	...	...	−3.70	−4.98	−3.72	−4.87	−3.48	−4.86	−3
$R_{\rm c}$	...	...	...	...	...	...	...	...	...	−0

Table 38: Best-fit effective $\Delta\chi^2$ and logarithm of the Bayes factors with respect to a featureless power spectrum, as well as best-fit feature parameters, for the step and cutoff models. Negative values of $\ln B$ indicate a preference for a power-law spectrum, while positive ones prefer the feature model. Wavenumbers are in units of Mpc^{-1}.

	Log osc			Running log osc			Lin osc		
	TT	EE	TT,TE,EE	TT	EE	TT,TE,EE	TT	EE	TT,TE,EE
$\Delta\chi^2_{\rm eff}$	−8.5	−13.5	−11.0	−9.3	−16.5	−11.4	−4.2	−9.0	−10.8

$\alpha_{\rm rf}$	...	...	...	−0.028	0.022	−0.021	...	...	...

Table 39: Same as Table 38, but for the oscillatory feature models.

We find a similar conclusion for the three oscillation models. As can be seen from the profile likelihood of the frequency parameters in Fig. 222, the likelihood peaks in the modulation frequencies do not match up between the TT and EE data sets. Furthermore, the preferred modulation amplitude for the EE data is in all cases much larger than that for the TT or TT,TE,EE data—given that the polarization data are noisier, this behaviour would be expected for a procedure that is overfitting the data.

Consequently, the Bayesian evidence for all combinations of models and data lies between barely worth mentioning and substantial evidence against the feature model on the Jeffreys scale. This implies that, currently, the *Planck* data do not show a preference for the feature models considered here.

Conversely, within the frequency ranges given by our priors, the relative modulation of the power spectrum is constrained to not exceed roughly 3 %, as shown in Fig. 219 for the logarithmic and linear oscillation models.

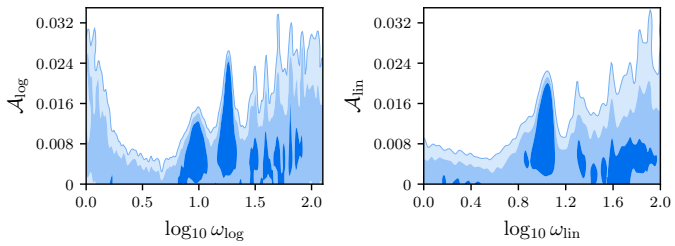

Figure 219: Marginalized joint 68 %, 95 %, and 99 % CL regions of the modulation amplitude versus frequency parameter using the TT,TE,EE data set for the logarithmic (*left*) and linear (*right*) oscillation models.

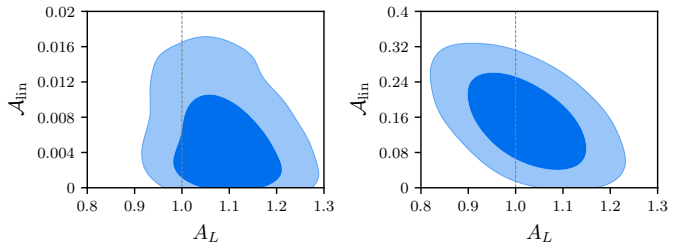

Figure 220: Marginalized joint 68 % and 95 % CL regions for the lensing parameter $A_{\rm L}$ and the modulation amplitude parameter $\mathcal{A}_{\rm lin}$ using the TT data set. *Left:* Linear oscillation model with $\log_{10}\omega_{\rm lin} = 1.158$ and $\varphi_{\rm lin} = \pi$. *Right:* Modified linear oscillation model with a Gaussian envelope function (see text) and $\log_{10}\omega_{\rm lin} = 1.158$, $\varphi_{\rm lin} = \pi$, $\mu_{\rm env} = 0.2\,{\rm Mpc}^{-1}$, and $\sigma_{\rm env} = 0.057\,{\rm Mpc}^{-1}$.

It may also be worth pointing out that in models with oscillations linear in k, the wavelength of the corresponding modulation of the angular power spectra matches that of the CMB's acoustic oscillations, $\Delta\ell \simeq 300$, if $\log_{10}\omega_{\rm lin} \simeq 1.158$. One might therefore suspect that features with frequencies around this value and carefully tuned amplitudes and phases could in principle mimic the (unphysical) effect of a lensing parameter, $A_{\rm L} \neq 1$. However, for a model with a modulation at the BAO frequency and a k-independent modulation amplitude $\mathcal{A}_{\rm lin}$, it can be seen in the left panel of Fig. 220 that we find no correlation between $A_{\rm L}$ and $\mathcal{A}_{\rm lin}$. This is due to a different ℓ-dependence of the respective $\Delta\mathcal{D}_\ell$'s. Explaining the lensing discrepancy would thus require a model with a carefully arranged scale-dependent linear modulation of the primordial spectrum. We demonstrate this possibility for a shaped modulation with a Gaussian envelope of the form $\mathcal{P}_{\mathcal{R}}(k) = \mathcal{P}^0_{\mathcal{R}}(k)\,[1 + \mathcal{A}_{\rm lin}\,\exp(-(k-\mu_{\rm env})^2/2\sigma^2_{\rm env})\,\cos\,(\omega_{\rm lin}k/k_* + \varphi_{\rm lin})]$ in the right panel of Fig. 220, but it should be noted that this particular example is of course highly tuned to produce the desired effect.

Additionally, while the phenomenology of $A_{\rm L}$ and linear modulation models is similar for temperature and polarization spectra individually, the two scenarios are in principle distinguishable by a combination of temperature and polarization data. This is due to the phase difference of the acoustic peaks in TT, TE, and EE, which leads to similar phase differences for the residuals when varying $A_{\rm L}$—unlike modifications of the primordial spectrum which do not shift phase in the same way. However, for features with an amplitude chosen to resemble the apparent lensing excess in the *Planck* TT data, the *Planck* TE and EE data are not sensitive enough to make this distinction.

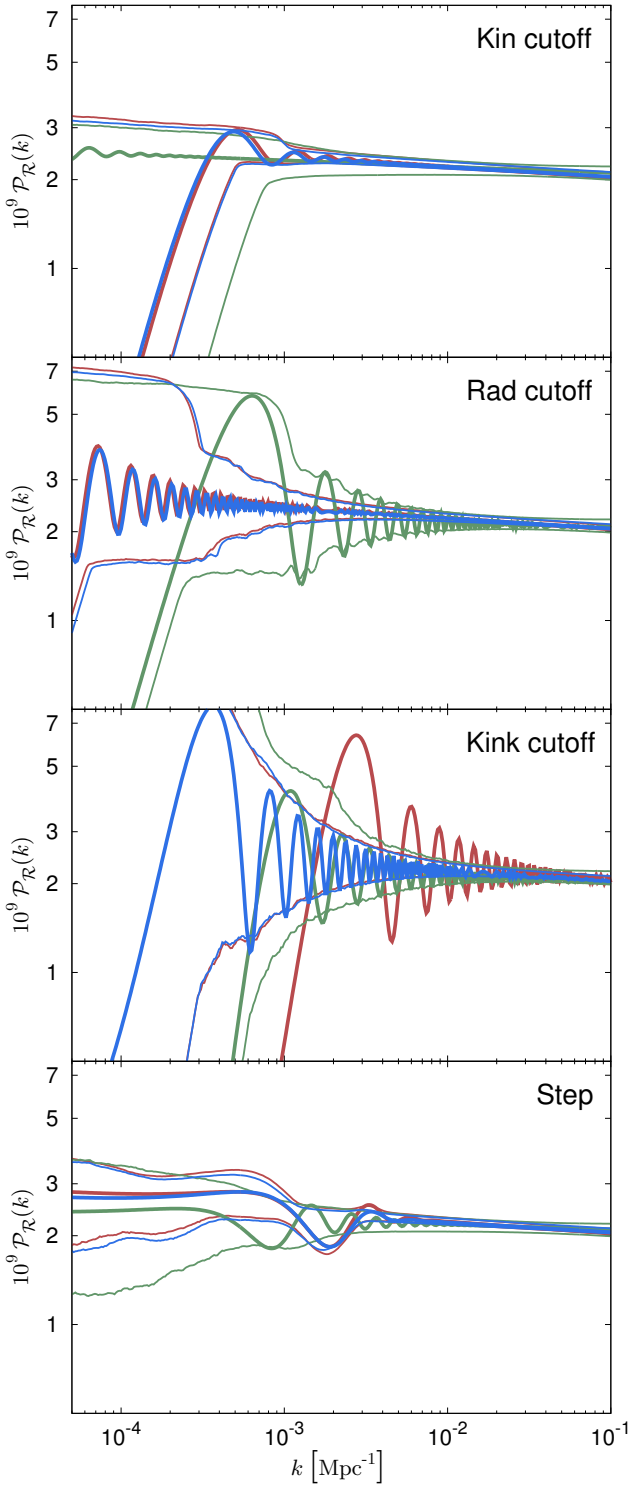

Figure 221: Best-fit and central 95 % CL regions for the primordial power spectrum in the three cutoff and the step models for TT data (red curves), EE data (green), and TT,TE,EE data (blue). Note that for the combination of kink cutoff model and TT data, the best-fit value for the cutoff scale $k^c_{\rm kink}$ lies close to the prior boundary, and therefore the best-fit spectrum does not fall within the *central* 95 %-credible band.

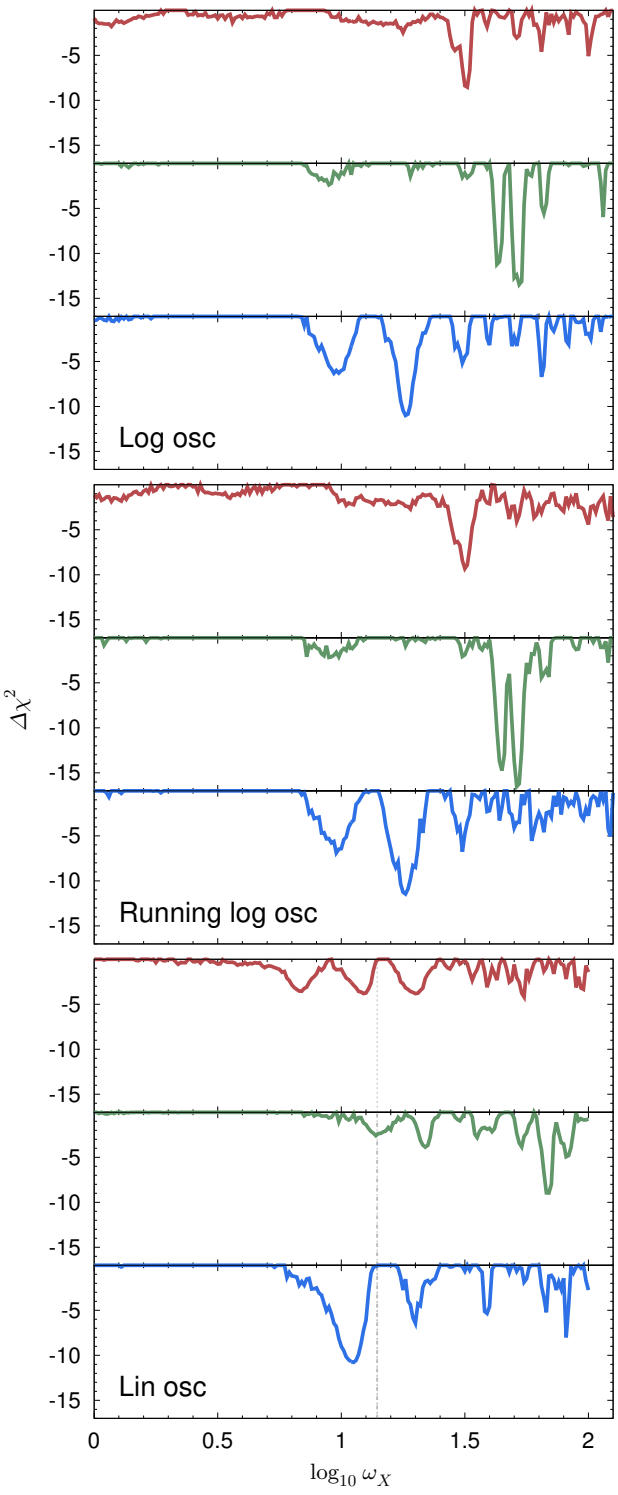

Figure 222: Profile likelihood of the frequency parameter in the three oscillatory feature models for TT (red curves), EE (green), and TT,TE,EE data (blue). The dotted grey line in the bottom panels marks the frequency for which the linear oscillation model leads to a modulation of the angular power spectra whose wavelength roughly matches that of the CMB's acoustic oscillations. Note the lack of alignment between the temperature and polarization likelihood peaks in the vicinity of this frequency.

28.7.4 Axion monodromy

As in section 10.3 of **(alias?)**, we next derive constraints on the underlying parameters in axion monodromy inflation [251, 184, 151, 96], which within string theory motivates a broad class of inflationary potentials of the form

$$V(\phi) = \mu^{4-p}\phi^p + \Lambda_0^4 e^{-C_0(\phi/\phi_0)^{p_\Lambda}} \cos\left(\gamma_0 + \frac{\phi_0}{f}\left(\frac{\phi}{\phi_0}\right)^{p_f+1}\right), \tag{1300}$$

where μ, Λ_0, f, and ϕ_0 are constants which have dimensions of mass, while C_0, p, p_Λ, p_f, and γ_0 are dimensionless. In the literature, one can find theoretically motivated models with $p = 3$, 2, 4/3, 1, and 2/3 [251, 184, 185]. In the following, we neglect a possible amplitude drift in the modulation amplitude by fixing $C_0 = p_\Lambda = 0$, focussing instead on a possible frequency drift p_f, as was done in previous analyses [215, 72, 146, 190, 193, 191, 192].

Due to its oscillating nature, a numerical study of this model is restrictive [215]. As such, we employ the semi-analytic template [96] used in previous analyses, namely

$$\mathcal{P}_\mathcal{R}(k) = \mathcal{P}_\mathcal{R}(k_*)\left(\frac{k}{k_*}\right)^{n_\mathrm{s}-1}\left\{1 + \delta n_\mathrm{s}\cos\left[\frac{\phi_0}{f}\left(\frac{\phi_k}{\phi_0}\right)^{p_f+1} + \Delta\phi\right]\right\}. \tag{1301}$$

We neglect the effect of small oscillations in the tensor primordial spectrum, and approximate it as a power law with a very small spectral index n_t (fixed by the single-field slow-roll self-consistency condition). The most well studied case to date is for $p = 4/3$, but given the high tensor-to-scalar ratio predicted by this model and the current upper bounds on r given in Sect. 28.3.5, we extend our study to the cases of $p = 1$ and $p = 2/3$. Furthermore, to completely specify this template, we assume instantaneous reheating, which, for a pivot scale of $k_* = 0.05\,\mathrm{Mpc}^{-1}$, corresponds to $N_* \approx 57.5$, and $\phi_0 = 12.38 M_\mathrm{Pl}$ with $\phi_\mathrm{end} = 0.59 M_\mathrm{Pl}$. This leads to definite predictions for (r, n_s); namely, $(0.0922, 0.971)$ for $p = 4/3$, $(0.0692, 0.974)$ for $p = 1$, and $(0.0462, 0.977)$ for $p = 2/3$.

To constrain this model, we carry out a Bayesian analysis using a modified version of `CLASS` [163, 56], which has been adapted to allow for a full parameter exploration, using the aforementioned template. As part of these modifications, special care needs to be taken to ensure that a correct sampling Δk in wavenumber space is chosen, at two different levels in the Boltzmann code: when computing an interpolation table for the primordial spectrum of scalars and tensors; and when performing the integral over the squared photon transfer functions multiplied by the primordial spectra to get the multipoles C_ℓ. This sampling needs to be fine enough to guarantee that no features are smoothed out or lost in this convolution, and we checked carefully that this is the case in our runs. The grid of ℓ values at which the C_ℓ's are actually computed and not just interpolated also needs to be refined.

We fit to the data the five cosmological parameters $\{\omega_\mathrm{b}, \omega_\mathrm{c}, \theta, A_\mathrm{s}, \tau\}$ plus the frequency f of the underlying axion decay constant, the frequency drift p_f, and the oscillation amplitude δn_s. We adopt the same priors used in previous analyses: $-4 \leq \log_{10}(f/M_\mathrm{Pl}) \leq -1$ for the frequency; $-0.75 < p_f < 1$ for the frequency drift; and an upper bound on the amplitude of $\delta n_\mathrm{s} < 0.5$. Furthermore, for the phase parameter $\Delta\phi$ we take a uniform prior of $-\pi < \Delta\phi < \pi$.

In Figs. 223, 224, and 225 we show the joint posterior constraints on pairs of primordial parameters for the semi-analytic template, for $p = 4/3$, $p = 1$, and $p = 2/3$, respectively.

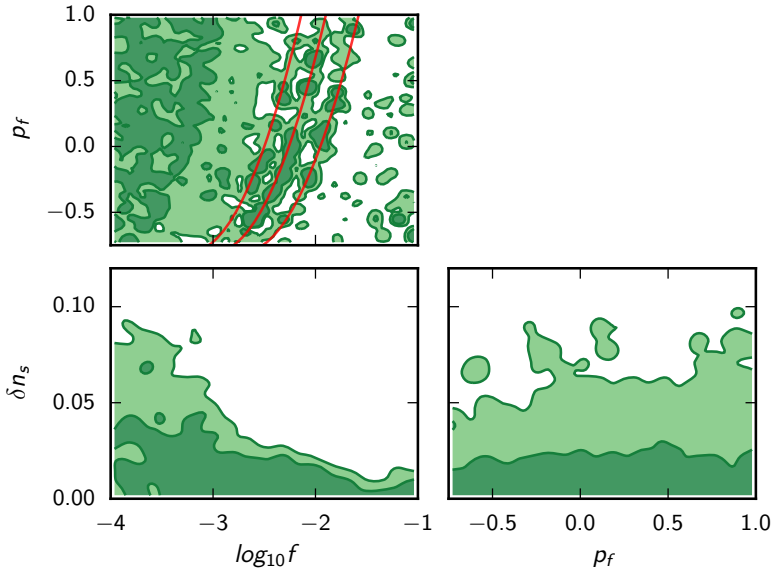

Figure 223: Joint 68 % and 95 % CL constraints on the axion monodromy parameters using *Planck* (unbinned) TT,TE,EE+lowE+BK14, for the case of $p = 4/3$. All smoothing has been turned down in the $p_f - \log_{10}(f/M_{\rm Pl})$ posterior to avoid smoothing the features highlighted in red.

In all three cases, we find two expected asymptotic behaviours. First, when the frequency is very high (which means that f is small in our parameterization), the oscillations in the primordial spectrum are smoothed out in the angular power spectrum, and the oscillation amplitude parameter $\delta n_{\rm s}$ becomes irrelevant and unconstrained. Second, in the limit of a very small amplitude parameter $\delta n_{\rm s}$, the oscillations become undetectable and the parameter f is also unconstrained. In all cases, no preferred frequency drift is found, which is compatible with previous analyses.

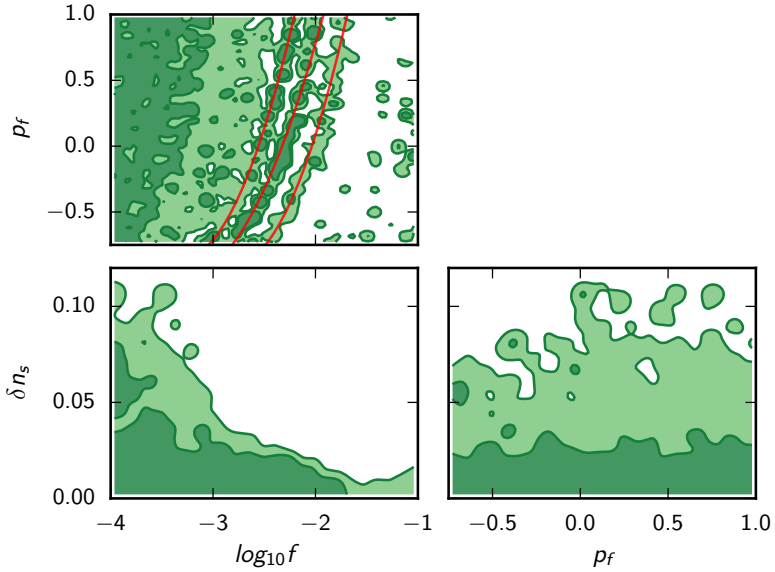

Figure 224: Same as Fig. 223, but for the case of $p = 1$.

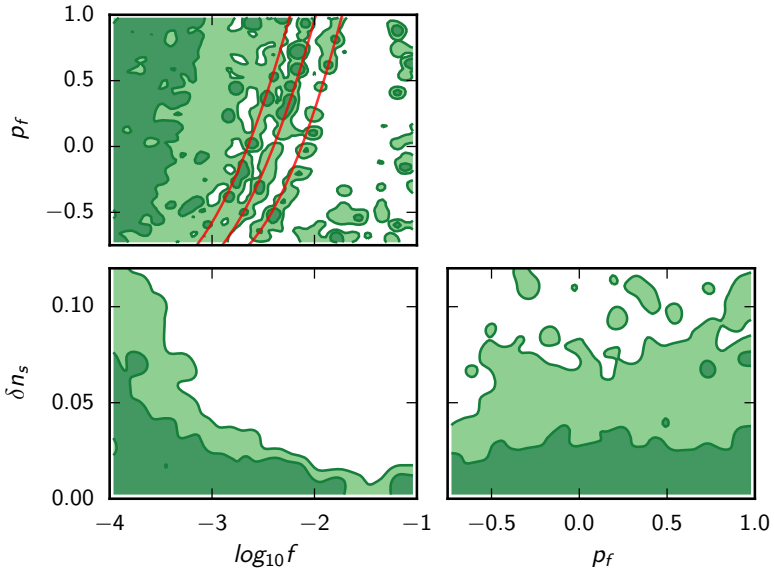

Figure 225: Same as Fig. 223, but for the case of $p = 2/3$.

We recover the complex structures (highlighted in red in Figs. 223, 224, and 225) found in previous analyses in the frequency-frequency drift parameter space, which, as was discussed in **(alias?)**, arise due to underlying modulations in the data and the model [73]. These structures become more apparent as we reduce the index p.

We perform a χ^2 comparison with the minimal 6-parameter ΛCDM model, and find $\Delta\chi^2_{(p=4/3)/\Lambda\mathrm{CDM}} = 0.4$, $\Delta\chi^2_{(p=1)/\Lambda\mathrm{CDM}} = 0.6$ and $\Delta\chi^2_{(p=2/3)/\Lambda\mathrm{CDM}} = 1.2$. The reason for higher χ^2 in the axion monodromy models, despite the addition of extra parameters, is that the predicted r values are in tension with the CMB data. This shows that, overall, axion monodromy models are disfavoured due to their high tensor-mode amplitude.

In order to check specifically whether the data give any hint of oscillatory patterns in the primordial spectrum matching the axion monodromy template, as well as to compare with the results discussed in the previous subsection, we fitted the data with ΛCDM+r models in which r and n_s were fixed to the same values as in the axion monodromy model with $p = 2/3$, 1, and 4/3. In each case, the comparison between axion monodromy and ΛCDM+r with the same (r, n_s) gives $\Delta\chi^2_{(p=4/3)/\Lambda\mathrm{CDM}+r} = -7.8$, $\Delta\chi^2_{(p=1)/\Lambda\mathrm{CDM}+r} = -7.6$ and $\Delta\chi^2_{(p=2/3)/\Lambda\mathrm{CDM}+r} = -8$. That is, in all cases we find $\Delta\chi^2 \sim 10$, which is compatible with the general results shown in Table 39. With three more free parameters, these improvements are statistically insignificant, and we conclude that the data show no preference for axion monodromy models.

28.8 Combined power spectrum and bispectrum analysis for oscillatory features

28.8.1 Approach

This section establishes constraints on oscillatory models using the power spectrum and the bispectrum simultaneously. Oscillatory features can appear in multiple correlation functions [58, 194, 94, 98, 5, 12, 4, 96, 97] (see, e.g., [59] for a recent review). More powerful constraints result when spectra of various orders are combined [212, 200, 108]. Past work has suggested that the statistical weight of the oscillations in the bispectrum (or higher-order correlation functions) is less than that in the power spectrum [26]; however, counterexamples exist as well (see, e.g., Behbahani & Green 27). The analysis in Sect. 28.7 used the *Planck* data to establish stringent constraints on the presence of features in the power spectrum. The 2015 *Planck* data were analyzed to constrain non-Gaussianties containing features [287], where, as in the power spectrum analysis, several candidate features were identified at low statistical significance. The analysis here focuses on the *location,* or frequency, of the feature. Joint analyses of the power spectrum and bispectrum were discussed in several studies [83, 84, 189]. We apply some of the tools developed there to the *Planck* temperature and polarization data.

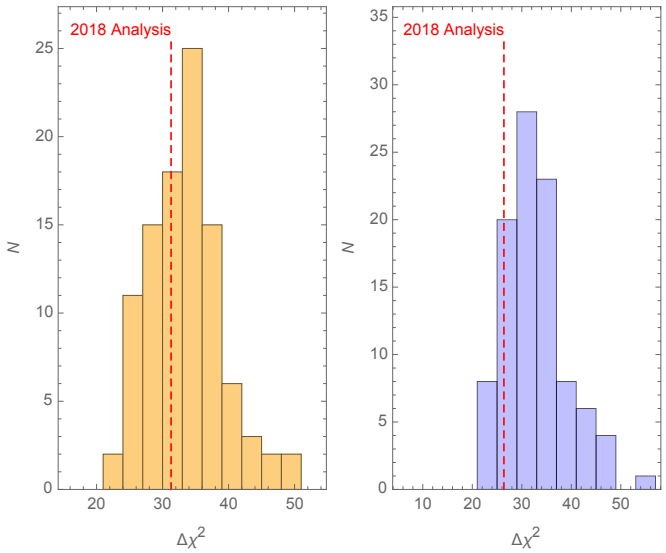

Figure 226: Typical best-fit improvement in units of $\Delta\chi^2$ in 100 simulations compared to the real data (red dashed lines) for the log feature (left) and the linear feature (right) models.

The analysis here is incomplete and limited in several respects. First, we analyse the bispectrum keeping all cosmological parameters fixed. Second, the parameters varied in the bispectrum are not varied in the Bayesian sense. The bispectrum is analyzed using a best-fit analysis based on how well a template shape fits the data. Third, the data suggest the primary bispectrum is close to zero and its covariance dominated by the scalar contributions in the power spectrum. We find that an ideal Bayesian analysis is not computationally feasible (see, e.g., Verde et al. 277).

The output from the bispectrum analysis for features provides us with a map that specifies the significance of a feature in units of σ, given the location (frequency) and the phase of the feature. We can turn this map into a likelihood, which we can simply add to that of the power spectrum; in other words, we take

$$\begin{aligned}\ln \mathcal{L}_{\rm tot} &= \ln \mathcal{L}_{\rm PS}(c, f, \omega_{\rm P}, A_{\rm P}, \phi_{\rm P}|{\rm dat}) \\ &+ \ln \mathcal{L}_{\rm BS}(A_{\rm B}, \omega_{\rm B}, \phi_{\rm B}|{\rm dat}),\end{aligned} \tag{1302}$$

where c represents the standard cosmological parameters, f the foregrounds, $\omega_{\rm P,B}$ the frequency, $A_{\rm P,B}$ the amplitude, and $\phi_{\rm P,B}$ the phase of the modulation in, respectively, the power spectrum and the bispectrum. We assume vanishing covariance between the power spectrum and the bispectrum, which has been shown to be a good approximation [83, 84, 189]. Furthermore, the likelihood $\ln \mathcal{L}_{\rm BS}$ is not normalized (more precisely $\ln \mathcal{L}_{\rm tot}$ is not normalized in a universe with a non-zero bispectrum).

Strictly speaking, we do not have a likelihood that measures $A_{\rm B}$ with a certain probability. Furthermore, several studies have shown that the frequency parameter, in combination with the amplitude and the phase, does not obey a χ^2 fitting to the data [123, 192, 193, 191, 186, 72]. Removing the frequency from the search results in a χ^2 distribution with two degrees of freedom. Since $\ln \mathcal{L}_{\rm tot}$ is rather large (of order 10^4 when combining all data), we can change the equation above by limiting ourselves only to improvements that are driven by $\omega_{\rm B} \sim \omega_{\rm P} \equiv \omega$, that is,

$$\begin{aligned}\ln \mathcal{L}_{\rm tot} &= \ln \mathcal{L}_{\rm PS}(c, f, \omega, A_{\rm P}, \phi_{\rm P}|{\rm dat}) \\ &+ \Delta \ln \mathcal{L}_{\rm BS}(A_{\rm B}, \omega, \phi_{\rm B}|{\rm dat}).\end{aligned} \tag{1303}$$

Assuming that $\phi_{\rm B}$ and $A_{\rm B}$ are well described by a two-parameter χ^2 distribution, we can now convert our σ map into a χ^2 improvement via

$$\chi^2 = -2 \log \left[{\rm Erf}\left(\sigma/\sqrt{2}\right) + 1 \right], \tag{1304}$$

or, in terms of the likelihoods,

$$-2\ln\mathcal{L}_{\rm tot} = -2\ln\mathcal{L}_{\rm PS}\left(c, f, \omega, A_{\rm P}, \phi_{\rm P}|{\rm dat}\right) + 2\log\left\{{\rm Erf}\left[\sigma(\omega, A_{\rm B}, \phi_{\rm B})/\sqrt{2}\right] + 1\right\}. \tag{1305}$$

We will use the above expression to derive the posterior of the joint fit.

28.8.2 Models

We will focus on two models: the local or linear feature model and the log feature model. For the log model we set $\{A_{\rm P}, \omega, \phi_{\rm P}, A_{\rm B}, \phi_{\rm B}\} = \{A_{\log}, \omega_{\log}, \phi_{\log}, B_{\log}, \tilde{\phi}_{\log}\}$ and use for the power spectrum

$$\mathcal{P}_{\log}(k) = \mathcal{P}_0(k)\left[1 + A_{\log}\cos\left(\omega_{\log}\log\frac{k}{\tilde{k}_0} + \phi_{\log}\right)\right], \tag{1306}$$

with $\mathcal{P}_0(k) = A_{\rm s}(k/k_*)^{n_{\rm s}-1}$. For the bispectrum we use [55]

$$B_{\log}(k_1, k_2, k_3) = \frac{B_{\log}A_{\rm s}}{k_1^2k_2^2k_3^2}\cos\left(\omega_{\log}\log\sum\frac{k_i}{\tilde{k}_0} + \tilde{\phi}_{\log}\right). \tag{1307}$$

The above parameterized spectra are examples that could be generated in axion monodromy inflation [95, 98], but generally are expected to appear in models where there exists an oscillatory potential.

For the linear model we follow [84] with $\{A_{\rm P}, \omega_{\rm P}, \phi_{\rm P}, A_{\rm B}, \phi_{\rm B}\} = \{A_{\rm lin}, \omega_{\rm lin}, \phi_{\rm lin}, B_{\rm lin}, \tilde{\phi}_{\rm lin}\}$ and write

$$\mathcal{P}_{\rm lin}(k) = \mathcal{P}_0(k)\left[1 + A_{\rm lin}\sin\left(2\omega_{\rm lin}\frac{k}{\tilde{k}_0} + \phi_{\rm lin}\right)\right] \tag{1308}$$

and [57]

$$B_{\rm lin}(k_1, k_2, k_3) = \frac{B_{\rm lin}A_{\rm s}}{k_1^2k_2^2k_3^2}\cos\left[\omega_{\rm lin}\left(\sum\frac{k_i}{\tilde{k}_0}\right) + \tilde{\phi}_{\rm lin}\right]. \tag{1309}$$

In both models we choose $\tilde{k}_0 = 1\,{\rm Mpc}^{-1}$, *which is different from the choice in Sect. 28.7 for the linear model.* As a result the linear frequencies can be related using $\omega_{\rm lin,Sect8} = 10\omega_{\rm lin,Sect7}$. The pivot scale is set to the usual value $k_* = 0.05\,{\rm Mpc}^{-1}$. The above parameterization is a proxy for models that contain sharp oscillatory features [55, 140, 13], although typically such effects would generate decaying features, which will not be considered here.

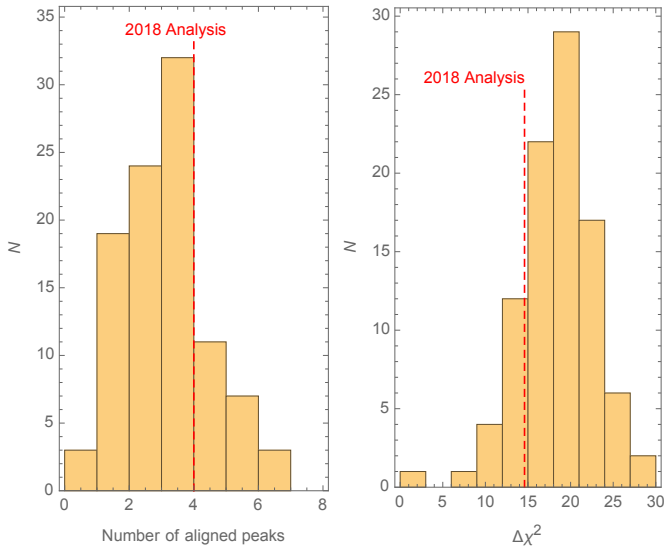

Figure 227: *Left:* Number of aligned peaks in the power spectrum and the bispectrum for the log feature model. *Right:* Mean improvement of those same peaks in 100 simulated bispectra combined with the unbinned high-ℓ likelihood.

28.8.3 Data analysis

Power spectrum

Our analysis uses a modified version of `CAMB` [166], which is capable of adaptively changing the sampling in both k and ℓ depending on the frequency of the feature, allowing us to scan a wide range of frequencies. As in the previous section, we use the unbinned versions of the *Planck* high-ℓ likelihoods for temperature plus polarization, in combination with lensing and large-scale temperature and polarization (i.e., lowE). We compared the power spectrum results for the limited frequency range considered in Sect. 28.7 for the log and linear model, and find excellent agreement (sampled with `Multinest`). We developed a bispectrum likelihood module based on Eq. (1305) using the 2015 data analysis [287] for both the log and linear feature models, obtained using optimal estimators following Münchmeyer et al. [207, 208] and Meerburg & Münchmeyer [188]. For the log model, the frequency range is set to $10 \leq \omega_{\rm log} \leq 1000$, while for the linear model we consider the frequency range $10 \leq \omega_{\rm lin} \leq 3000$. This joint analysis excludes the very low frequencies known to (weakly) correlate with cosmological parameters. The cosmological parameters are held fixed in the bispectrum analysis. We consider amplitudes $0 \leq A_{\rm log,lin} \leq 0.9$; the highest amplitudes will only be allowed for high frequencies where projection suppresses the power of the oscillating part in the power spectrum significantly. The phase is varied and marginalized over in the joint analysis. We use the `PolyChord` sampler [126, 127], which is powerful enough to include foregrounds (with $n_{\rm live} = 512$).

Bispectrum

The bispectrum likelihood is derived from the posterior distributions generated in [295]. Although the linear bispectrum of Eq. (1309) can easily be factorized, the log bispectrum of Eq. (1307) is not of the factorized form. Using modal techniques developed by Fergusson & Shellard [87] and Fergusson et al. [85, 86], any shape can be factorized, with a close-to-optimal estimator. The modal method converts the angular-average bispectrum into a set of factorizable orthogonal mode functions. These functions can be directly constrained using foreground-cleaned CMB maps. From these measurements, a large number of bispectra can be reconstructed and constrained by appropriately weighting the mode functions. The convergence of this method, in terms of how many mode functions are required to accurately reconstruct the shape of interest, depends on the choice of the mode functions. In the 2015 analysis, two different mode functions were used: a polynomial-based reconstruction; and a trigonometric-based reconstruction. The latter was developed by [207, 208] and relies on expanding around linear oscillations. The polynomial-based reconstruction is extremely powerful for most bispectra, but is non-optimal for oscillatory bispectra, which require a large number of modes (e.g., more than 2000 for $\omega_{\rm log} = 50$). Trigonometric modes allow for faster convergence and provide good reconstruction for much higher frequencies, both for linear- and log-type modulations. For low frequencies, both methods can be compared and results show excellent agreement [287]. In addition, both methods were developed independently, which provides further confidence in the results. In the analysis presented here, we use the results obtained using the trigonometric mode functions. Further details can be found in Planck Collaboration IX [295].

28.8.4 Estimating significance

Next we will estimate the significance of the improvements driven by the joint analysis. For this purpose we generate 100 mock spectra as in [189] *without features* and perform an analysis jointly with true CMB power spectrum data, i.e., we use the same power spectrum likelihood (real data) in combination with the simulated bispectrum likelihoods (mock data). We will do this for both the linear and the log models, with 100 simulations in total. Each analysis requires a similar amount of time as does the real data analysis, using about 12 000 CPU hours for the linear feature and about 40 000 CPU hours for the log feature *per simulation*. More details on the simulated spectra can be found in [295].

These simulations help us assess the statistical significance of our results. Improvement in fit is given in units of χ^2 compared to a no-feature model as defined the previous section [i.e., $\Delta\chi^2 \simeq -2(\ln \mathcal{L}^{\rm best\,fit}_{\Lambda{\rm CDM}} - \ln \mathcal{L}^{\rm best\,fit}_{\rm feature})$]. The left panel of Fig. 226 shows the typical best-fit improvement from a set of simulations for the log feature model. This first analysis shows that the best fit in the data is perfectly consistent with a standard ΛCDM universe, without features,

with $P(\Delta\chi^2 \geq \Delta\chi^2_{\rm data}) = 28\,\%$. This outcome is not unexpected, given earlier analyses for the power spectrum (see, e.g., Meerburg et al. 193, Easther & Flauger 72, Benetti 30, Miranda & Hu 195, Fergusson et al. 83, Planck Collaboration XX 288, Hazra et al. 132) and the significance of features in the bispectrum alone [284]. The look-elsewhere effect lowers the significance of features and by jointly constraining features in the power spectrum and the bispectrum it is possible to alleviate some of this suppression. To quantify this, we consider the following two questions: 1) considering the various frequencies with $\Delta\chi^2$ improvement over no features in the joint analysis, how many of those were present in the power spectrum analysis only; and 2) what is the mean improvement, in units of $\Delta\chi^2$, of these fits? We compare the results of the simulations, which do not contain any real features, to the data.

Before we answer these questions we need a criterion to decide if two frequencies will be considered the same or not, i.e., we need a frequency correlation measure. We will consider a simple ansatz, which will have an analytical solution and will serve to estimate the correlation between frequencies, by defining

$$f_{\log}[\omega_1, \omega_2, \phi] \simeq \int dx \cos[\omega_1 \log x + \phi] \cos[\omega_2 \log x + \phi]. \tag{1310}$$

Next we marginalize over phase, defining

$$\begin{aligned} g_{\log}[\omega_1, \omega_2] &= \int d\phi f_{\log}[\omega_1, \omega_2, \phi] \\ &= \frac{\pi}{1 + \Delta\omega_{12}^2} \{x_{\rm max} \cos\left[\Delta\omega_{12} \log\left(x_{\rm max}\right)\right] \\ &\quad - \cos\left[\Delta\omega_{12} \log\left(x_{\rm min}\right)\right] x_{\rm min} \\ &\quad + \Delta\omega_{12} \left[\sin\left[\Delta\omega_{12} \log\left(x_{\rm max}\right)\right] x_{\rm max}\right. \\ &\quad \left. - \sin\left[\Delta\omega_{12} \log\left(x_{\rm min}\right)\right] x_{\rm min}\right]\}\,, \end{aligned} \tag{1311}$$

where $\Delta\omega_{12} = \omega_1 - \omega_2$. For linear oscillations we can derive a similar measure, with

$$\begin{aligned} g_{\rm lin}[\omega_1, \omega_2] &= \frac{\pi}{2\Delta\omega_{12}} \left[\sin\left(2\Delta\omega_{12} x_{\rm max}\right)\right. \\ &\quad \left. - \sin\left(2\Delta\omega_{12} x_{\rm min}\right)\right]. \end{aligned} \tag{1312}$$

The correlation is given by

$$\mathrm{Cor}(\omega_1, \omega_2) \quad = \frac{g[\omega_1, \omega_2]}{\sqrt{g[\omega_1, \omega_1] g[\omega_2, \omega_2]}}. \tag{1313}$$

The parameters $x_{\rm min}$ and $x_{\rm max}$ play a role in determining the correlation length. Although strictly speaking they correspond to the minimum and maximum scales observable in the CMB, they can be used to model the correlator to allow for shifts in the frequency coming from a non-optimal analysis. We argue that this is reasonable given the low number of peaks in the analysis. We tested the above on various nearby peaks in the data and found that demanding $\mathrm{Cor}(\omega_1, \omega_2) \leq 0.1$ is generally sufficient to effectively identify independent peaks. We explored the sensitivity of the results to the correlation criterion of 0.1. First we increased it to 0.3 and found that in this case many peaks were missed when counting the number of aligned peaks (with little effect on determining the peaks). When we lowered the criterion to 0.01, we obtained many aligned peaks that should not be aligned. Small changes in the correlation criterion have minimal effect on the results presented here. Ideally, more simulations should be generated, which would help to establish the best choice for the correlation criterion. We found that the choice of $x_{\rm min}$ does not affect the correlator as long as $x_{\rm min} \ll 1$. We set $x_{\rm max} = 0.05$ for linear oscillations, which roughly correlates peaks with $\Delta\omega_{\rm lin} \sim 10$, which is within the tails of the observed widths of the peaks in the power and bispectrum analysis. For log oscillations we choose $x_{\rm max} = 1$, which has the advantage that the correlator has no zero-crossings near the peak (but hardly effects the correlation length). We find $\Delta\omega_{\log} \sim 1$ at $\omega_{\log} = 100$, which seems reasonable in light of the power and bispectrum peak widths (see Fig. 222).

In Fig. 227 we show the number of peaks in the joint analysis that have improved (left panel) as well as their mean improvement (right) over a no-feature analysis. We find $P(\#\text{peaks} \geq$

$\#\text{peaks}_{\text{data}}) = 16\,\%$ and those peaks do not lead to significant improvements in the joint χ^2, with $P(\Delta\chi^2_{\text{peaks}} \geq \Delta\chi^2_{\text{peaks,data}}) = 83\,\%$. Assuming that these 100 simulations provide a fair sample of the noisy data, we conclude that there are no significant features present in both the power spectrum and the bispectrum for the models considered within the chosen range of feature parameters.

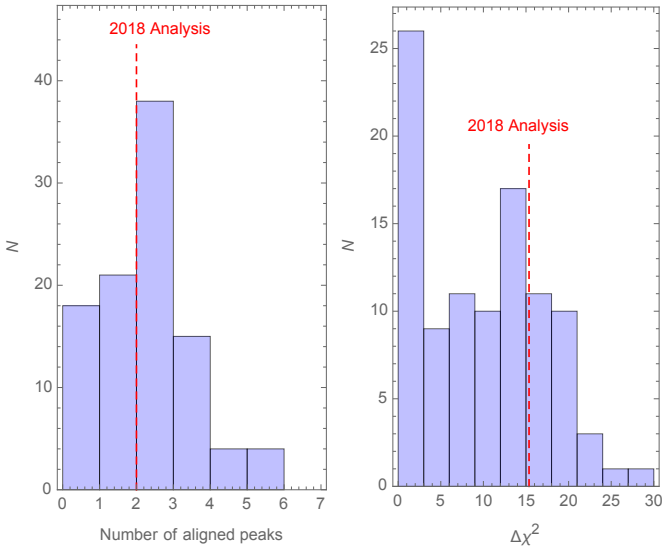

Figure 228: *Left:* Number of aligned peaks in the power spectrum and the bispectrum for the linear feature model. *Right:* Mean improvement of those same peaks in 100 simulated bispectra combined with the unbinned high-ℓ likelihood.

We carry out the same analysis for linear features and show the results in Fig. 226 (right panel), deriving a typical best fit from 100 simulated noisy spectra. The true best fit, as derived from the joint analysis of the 2018 bispectrum and the 2018 power spectrum, shows a relatively small improvement with $P(\Delta\chi^2 \geq \Delta\chi^2_{\text{data}}) = 85\,\%$. Further correlated-features searches find 2 features within the frequency window which may be considered aligned, with a mean $\Delta\chi^2$ of 12.3, as illustrated in Fig. 228. Compared to 100 simulated noisy spectra, we obtain $P(\#\text{peaks} \geq \#\text{peaks}_{\text{data}}) = 42\,\%$ and $P(\Delta\chi^2_{\text{peaks}} \geq \Delta\chi^2_{\text{peaks,data}}) = 26\,\%$. Since the overall improvement from fitting these aligned peaks does not exceed the 3σ threshold, we conclude that there is no statistically significant evidence for any of these features.

We conclude that the simple parameterization considered in this analysis does not provide any evidence for features. The two models analyzed are representive of a broad class and have well-studied phenomenological spectra; however, other classes of models exist. Features, for example, can have scale dependence [i.e., an "envelope" [55, 3, 267]]. Likewise, more realistic modelling of axion models shows that the frequency could depend on scale [i.e., "running" [96, 97]]. Both these possibilities could substantially change the spectra and likely the joint analysis and significance.

Here we have not imposed an explicit relation between the amplitude of the bispectrum and the frequency of the power spectrum. In the simplest form of axion monodromy, one has $f_{\text{NL}} = A_{\log}\omega^2_{\log}/8$. On account of the quadratic scaling with frequency and the fact that the constraint on the amplitude tends to become poorer as the frequency increases due to projection (see, e.g., Fig. 223), it was already pointed out in [288] that there is no evidence for this relation in the data, and with the current data set this situation remains unchanged.

Table 40: Constraints on mixed adiabatic and isocurvature models. We report 95 % CL intervals or upper bounds on the isocurvature fraction $\beta_{\rm iso}$ at three scales ($k_{\rm low} = 0.002\,{\rm Mpc}^{-1}$, $k_{\rm mid} = 0.050\,{\rm Mpc}^{-1}$, and $k_{\rm high} = 0.100\,{\rm Mpc}^{-1}$), the scale-independent correlation fraction, $\cos\Delta$, and the non-adiabatic contribution to the CMB temperature variance, $\alpha_{\rm non\text{-}adi}$. Here $\Delta\chi^2$ is the difference between the χ^2 of the best-fit mixed and pure adiabatic models. In the last column we give the difference between the log of Bayesian evidences. (A negative $\ln B$ means that Bayesian model comparison disfavours the mixed model.) The number of extra parameters compared with ΛCDM is denoted by Δn in the first column. Note that the uniform priors on the primordial powers at two scales lead to non-uniform priors on the parameters reported in this table. This is particularly significant for $\beta_{\rm iso}(k_{\rm mid})$, where the prior peaks at a non-zero value. The baseline *Planck* 2018 TT,TE,EE+lowE+lensing results are highlighted in bold.

28.9 Constraints on isocurvature fluctuations

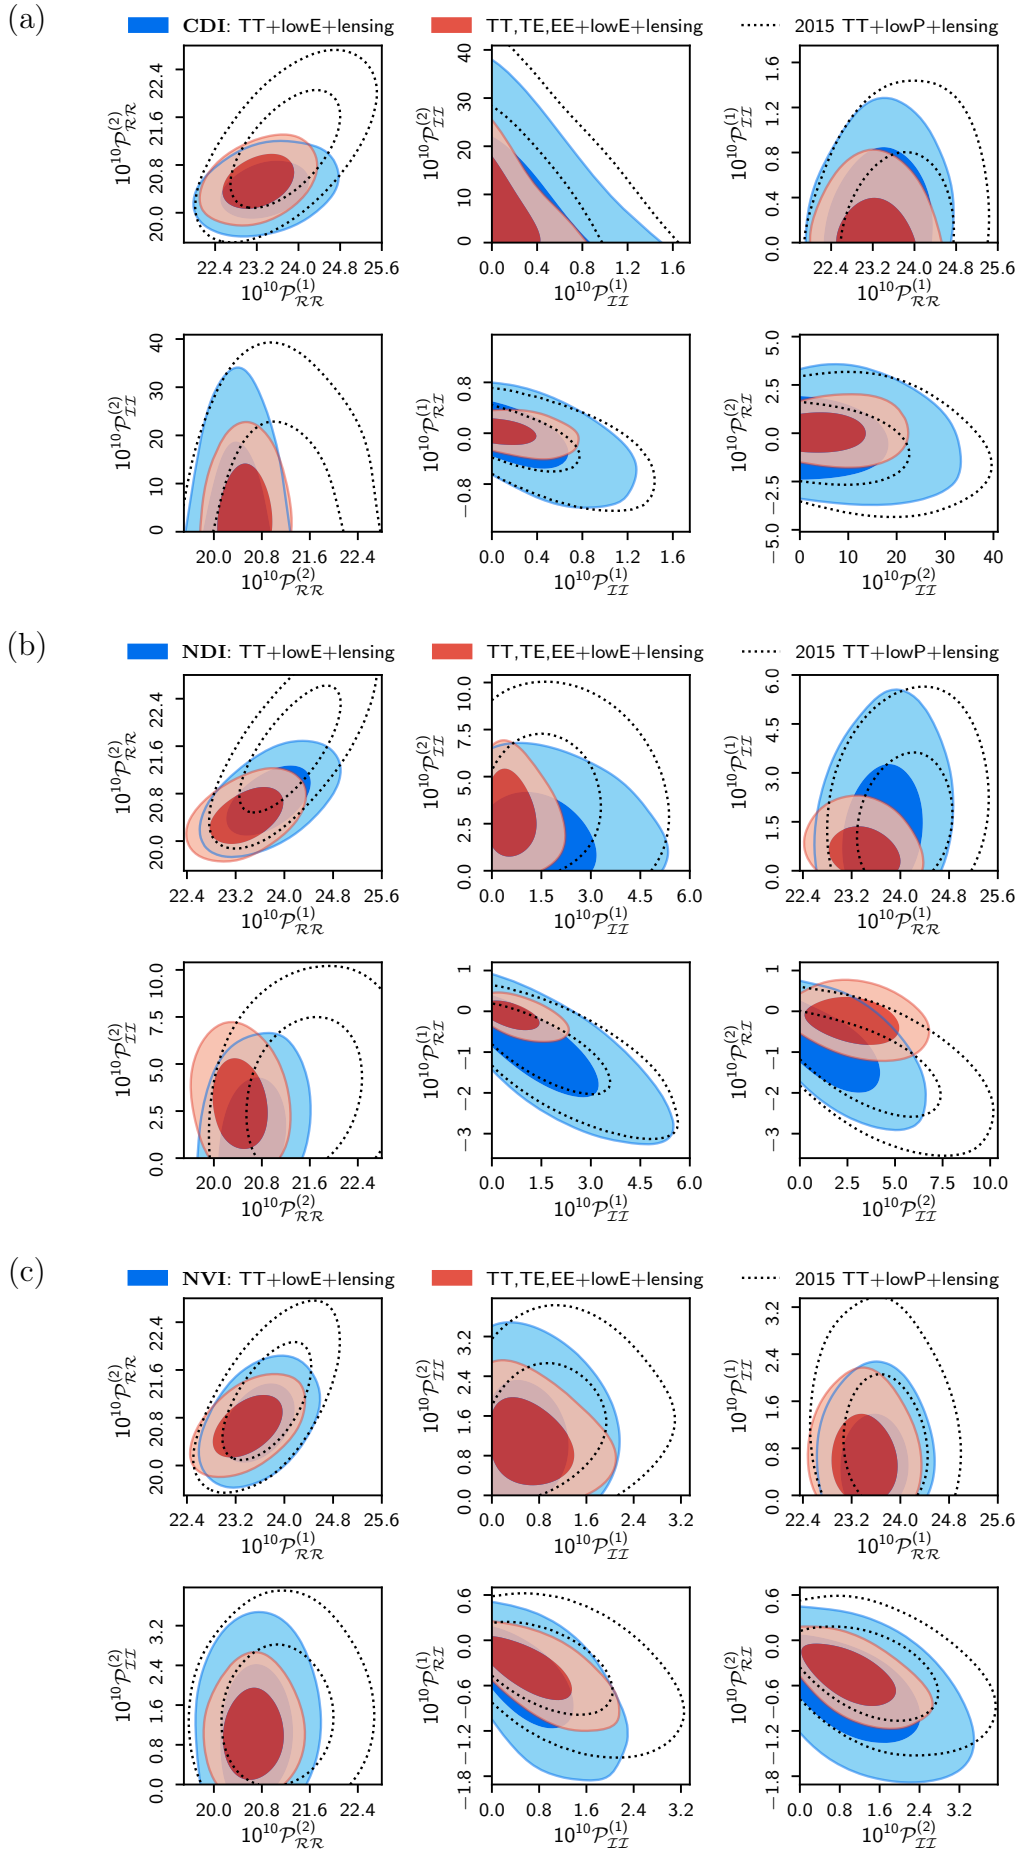

Figure 229: Constraints on the primordial perturbation power in generally correlated ADI+CDI (a), ADI+NDI (b), and ADI+NVI (c) models at two scales, $k_1 = 0.002\,\mathrm{Mpc}^{-1}$ (1) and $k_2 = 0.100\,\mathrm{Mpc}^{-1}$ (2). Note that in our modelling $\mathcal{P}^{(2)}_{\mathcal{RI}}$ is not an independent parameter.

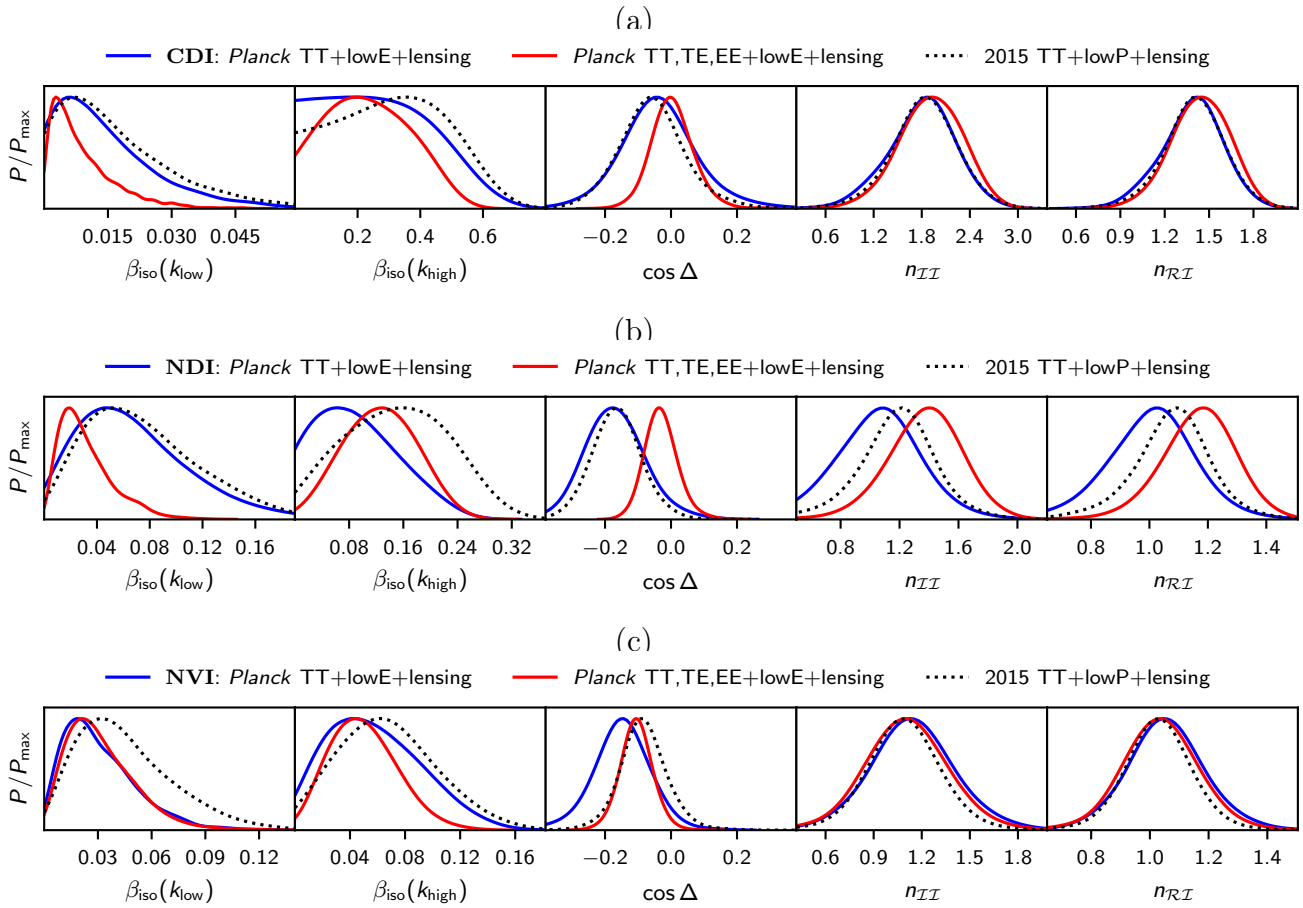

Figure 230: Constraints on the primordial isocurvature fraction, $\beta_{\rm iso}$, at $k_{\rm low} = 0.002\,{\rm Mpc}^{-1}$ and $k_{\rm high} = 0.100\,{\rm Mpc}^{-1}$; the primordial correlation fraction, $\cos\Delta$; the isocurvature spectral index, $n_{\mathcal{II}}$; and the correlation spectral index, $n_{\mathcal{RI}} = (n_{\mathcal{RR}}+n_{\mathcal{II}})/2$, for the generally correlated mixed ADI+CDI model (a), for the ADI+NDI model (b), and for the ADI+NVI model (c). All these parameters are derived, and the distributions shown here result from a uniform prior on the primary parameters shown in Fig. 229. However, the effect of the non-flat derived-parameter priors is negligible for all parameters except for $n_{\mathcal{II}}$ (and $n_{\mathcal{RI}}$) where the prior biases the distribution toward unity. Note that these spectral indices are not well constrained, since we do not have a detection of non-zero isocurvature or correlation amplitude. With a sufficiently small isocurvature or correlation amplitude, an arbitrarily small or large spectral index leads to a very good fit to the data, since the model is then practically adiabatic over the range covered by the *Planck* data.

28.9.1 Background and modeling

Single-field inflation with a canonical kinetic term gives rise to primordial super-Hubble comoving curvature perturbations, $\mathcal{R}$. In this case the relative number densities of the various particle species are spatially constant, i.e., the perturbations are adiabatic. Typically photons are chosen as a reference species. Then adiabaticity implies that for every particle species with number density n_i the quantity $\delta(n_i/n_\gamma)$ vanishes. However, in addition to $\mathcal{R}$, multi-field inflation can stimulate isocurvature modes, $\mathcal{I}_i$, where at primordial times n_i/n_γ varies spatially [172, 241, 173, 102]. In this section we consider all possible non-decaying modes of this type [47]: cold dark matter density isocurvature (CDI); baryon density isocurvature (BDI); and neutrino density isocurvature (NDI) modes. For completeness, we also constrain the fourth non-decaying mode, neutrino velocity isocurvature (NVI), although there are no known mechanisms to excite it. Finally, we consider compensated isocurvature perturbations (CIP) between baryons and CDM [115, 116]. In this case, opposite BDI and CDI perturbations cancel in such a way that the total matter isocurvature perturbation vanishes and there is no first-order isocurvature

signal in the CMB. However, we utilize a higher-order lensing-like effect from this mode to obtain constraints on CIP from *Planck* temperature and polarization power spectra. We find the most powerful power-spectra-based constraints on this mode by exploiting the cosmological information in the low-L lensing potential reconstruction in Sect. 28.9.5, but leave the use of *Planck* trispectra in constraining CIP for future work.

As the positions of the peaks and dips of the CMB angular power spectra in the density isocurvature models are roughly in opposite phase compared to the pure adiabatic (ADI) spectrum, the primordial CDI, BDI, and NDI modes leave a very distinctive observational imprint on the CMB, whereas the imprint of the NVI mode more closely resembles the pure ADI mode; see, e.g., figure 43 in **(alias?)**. Prior to the detection of CMB anisotropies, studies such as Peebles & Yu [213] and Efstathiou & Bond [74, 75] discussed the possibility that isocurvature perturbations were the sole source of cosmological fluctuations. However, at least after the detection of the first acoustic peak in TT, it became clear that the density isocurvature mode(s) had to be subdominant [77, 78], while the adiabatic mode led to a good agreement with observations. Several pre-*Planck* isocurvature constraints were obtained [265, 217, 161, 16, 216, 274, 45, 199, 28, 159, 67, 25, 269, 154, 157, 273].

The mixture of curvature and isocurvature perturbations can be uncorrelated, but typically an arbitrary amount of correlation arises between them if the trajectory in field space is curved between Hubble radius exit and the end of multi-field inflation [111]. In extreme cases, such as the simplest curvaton models, there is full correlation or full anticorrelation between $\mathcal{R}$ and $\mathcal{I}$. In the following subsections, we start with the generic case of generally correlated adiabatic and CDI, NDI, or NVI perturbations. Then we deal with various special CDI (or BDI) cases with no correlation or full (anti)correlation.

We parameterize the primordial perturbations as in **(alias?)**, following the notation described there. The primary perturbation parameters scanned by `MultiNest` (in addition to the four standard ΛCDM background cosmological parameters and the *Planck* nuisance parameters) are the primordial abiabatic perturbation power and isocurvature perturbation power at two scales, corresponding to $k_1 = k_{\rm low} = 0.002\,{\rm Mpc}^{-1}$ and $k_2 = k_{\rm high} = 0.1\,{\rm Mpc}^{-1}$, namely, $\mathcal{P}^{(1)}_{\mathcal{RR}}$, $\mathcal{P}^{(2)}_{\mathcal{RR}}$, $\mathcal{P}^{(1)}_{\mathcal{II}}$, $\mathcal{P}^{(2)}_{\mathcal{II}}$, and the correlation power between $\mathcal{R}$ and $\mathcal{I}$ at k_1, i.e., $\mathcal{P}^{(1)}_{\mathcal{RI}}$. We assume a power-law form for the adiabatic and isocurvature power spectra and denote the spectral indices that can be calculated from the primary parameters by $n_{\mathcal{RR}}$ and $n_{\mathcal{II}}$. The correlation spectrum is also assumed to obey a power law, with spectral index $n_{\mathcal{RI}} = (n_{\mathcal{RR}} + n_{\mathcal{II}})/2$. Thus $\mathcal{P}^{(2)}_{\mathcal{RI}}$ is not an independent parameter. This ensures that the correlation fraction $\cos\Delta = \mathcal{P}_{\mathcal{RI}}/(\mathcal{P}_{\mathcal{RR}}\mathcal{P}_{\mathcal{II}})^{1/2}$ stays inside the interval $(-1, 1)$ at every k, as long as we reject any $\mathcal{P}^{(1)}_{\mathcal{RI}}$ which does not obey this requirement. While the correlation fraction is k-independent in our modelling, the primordial isocurvature fraction $\beta_{\rm iso}(k) = \mathcal{P}_{\mathcal{II}}(k)/\left[\mathcal{P}_{\mathcal{RR}}(k) + \mathcal{P}_{\mathcal{II}}(k)\right]$ depends on k, unless $n_{\mathcal{II}} = n_{\mathcal{RR}}$. We also report $\beta_{\rm iso}$ at an intermediate scale, $k_{\rm mid} = 0.05\,{\rm Mpc}^{-1}$.

We do not separately quote constraints on BDI or the total matter density isocurvature (MDI), since these modes are observationally indistinguishable from the CDI case.[175]

Numerical results for various isocurvature models and selected derived parameters are reported in Table 40, utilizing various data combinations. The table is divided into three main sections: generally correlated models (discussed in Sect. 28.9.2); one-isocurvature-parameter CDI models (discussed in Sects. 28.9.4 and 28.9.4); and, finally, two-isocurvature-parameter CDI models (discussed in Sects. 28.9.4, 28.9.4, and 28.9.4). For generally correlated CDI we study the stability of constraints (see Sect. 28.9.3) by using several different subsets of the *Planck*

[175] If we assume no NVI or NDI perturbations, then the MDI perturbation (i.e., the spatial perturbation in the relative number densities of matter particles and photons) is

$$\mathcal{I}_{\rm MDI} = \frac{\Omega_{\rm c}}{\Omega_{\rm m}}\mathcal{I}_{\rm CDI} + \frac{\Omega_{\rm b}}{\Omega_{\rm m}}\mathcal{I}_{\rm BDI}\,. \tag{1314}$$

As we will see, the posteriors for $\Omega_{\rm c}h^2$ and $\Omega_{\rm b}h^2$ are insensitive to the assumed initial conditions. Thus it is a good approximation to use the mean values obtained in the generally correlated mixed adiabatic and CDI model with TT,TE,EE+lowE+lensing data, namely $\Omega_{\rm c}/\Omega_{\rm m} \simeq 0.842$, $\Omega_{\rm b}/\Omega_{\rm m} \simeq 0.158$, $\Omega_{\rm c}/\Omega_{\rm b} \simeq 5.33$, and $(\Omega_{\rm c}/\Omega_{\rm b})^2 \simeq 28.4$. For example, to convert our CDI upper bound on $\mathcal{P}_{\mathcal{II}}$ to a BDI bound, we should multiply the constraint by $(\Omega_{\rm c}/\Omega_{\rm b})^2 = 28.4$, and to convert the CDI $\mathcal{P}_{\mathcal{RI}}$ to BDI, we should multiply the constraint by $\Omega_{\rm c}/\Omega_{\rm b} \simeq 5.33$. If $\beta_{\rm iso} \ll 1$, then this also can be converted to a BDI constraint by multiplying the CDI constraint by 28.4. The constraint on $\cos\Delta$ will be the same for the CDI and BDI cases, since the conversion factor cancels out.

data: (1) only high-ℓ TT; (2) high-ℓ TT+lensing; (3) TT,TE,EE; and (4) TT,TE,EE+lensing. For comparison, some *Planck* 2015 and WMAP results are also cited. Table 40 also includes comparisons to the pure adiabatic model in terms of the difference in the best-fit χ^2 and the natural logarithm of the Bayesian evidence ("model probability") ratios $\ln B$, negative $\ln B$ being evidence against the mixed models.[176]

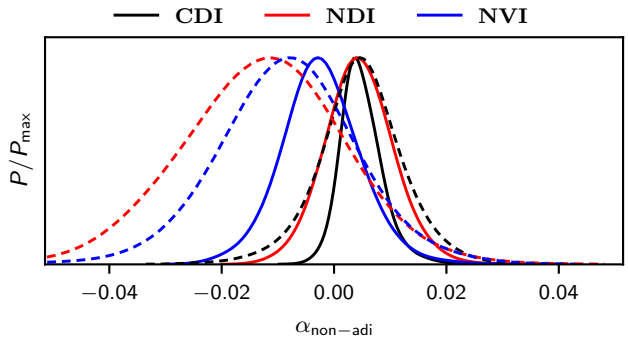

Figure 231: Posterior probability density of the observable non-adiabatic fraction of the CMB temperature variance, assuming a generally correlated mixed adiabatic and isocurvature model. These results used *Planck* TT+lowE+lensing data (dashed lines) and TT,TE,EE+lowE+lensing data (solid lines).

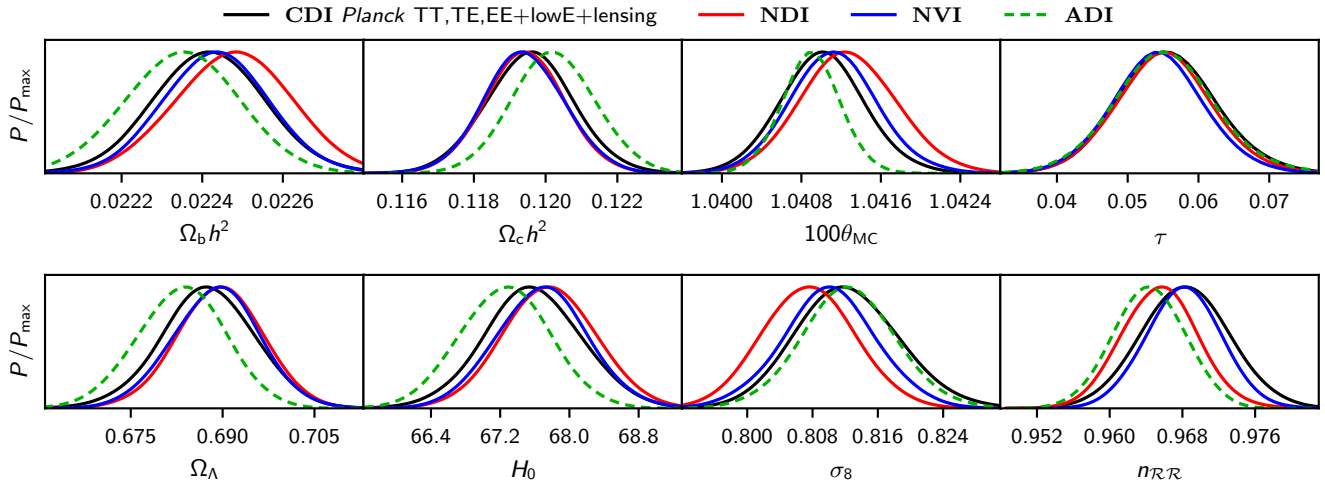

Figure 232: Comparison of posterior probability density for the standard cosmological parameters in mixed adiabatic and isocurvature models (solid lines) to those in pure adiabatic ΛCDM model (ADI, dashed green lines), using *Planck* TT,TE,EE+lowE+lensing data.

[176]The values of $\ln B$ depend on the priors. We adopt uniform priors in the range $(15, 40) \times 10^{-10}$ for the adiabatic, $(0, 100) \times 10^{-10}$ for the isocurvature, and $(-100, 100) \times 10^{-10}$ for the primordial correlation power parameter.

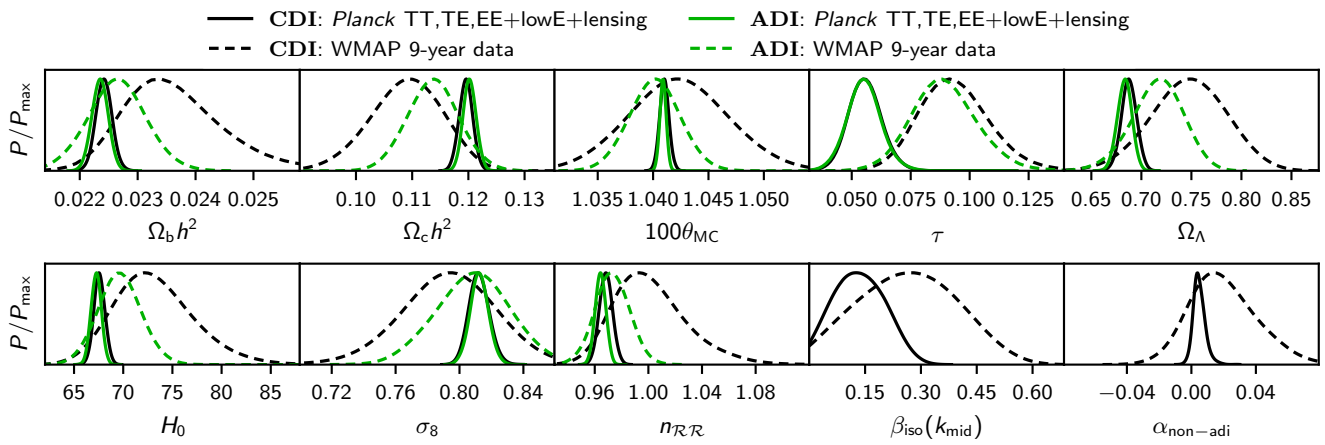

Figure 233: Comparison of posterior probability density for selected cosmological parameters with *Planck* data and pre-*Planck* (i.e., WMAP 9-year) data. Black lines indicate the results obtained for the generally correlated mixed CDI+ADI model, and green lines for the pure adiabatic model.

28.9.2 Results for generally correlated adiabatic and isocurvature modes

This subsection explores mixed adiabatic and isocurvature models where only one isocurvature mode at a time is considered. We consider the CDI, NDI, and NVI modes using the *Planck* 2018 TT(,TE,EE)+lowE(+lensing) data. All five primordial perturbation power amplitudes (of which three describe the isocurvature perturbations) are free parameters. It follows that $n_{\mathcal{II}}$ and $n_{\mathcal{RR}}$ are independent and $\cos\Delta$ varies between -1 and $+1$. The constraints for the primary perturbation parameters and the derived parameter $\mathcal{P}^{(2)}_{\mathcal{RI}}$ are shown in Fig. 229.

In all three cases the *Planck* TT+lowE+lensing results are very similar to the previous results from the *Planck* 2015 TT+lowP+lensing likelihood. As expected, the lower value of τ preferred by the 2018 (lowE) data is reflected in the adiabatic amplitudes $\mathcal{P}^{(1)}_{\mathcal{RR}}$ and $\mathcal{P}^{(2)}_{\mathcal{RR}}$. For CDI and NDI there is no significant shift in the constraints on isocurvature parameters, but we find slightly tighter constraints than in 2015. For NVI, a minor shift towards more negative correlations is observed (see the last two panels of Fig. 229c). As in 2015, adding the high-ℓ TE,EE data significantly tightens the constraints in all three cases.

When fitting the generally correlated three-isocurvature-parameter models, the *Planck* data are consistent with null detection, i.e., with the pure adiabatic model, $\left(\mathcal{P}^{(1)}_{\mathcal{II}}, \mathcal{P}^{(2)}_{\mathcal{II}}\right) = (0,0)$ and $\mathcal{P}^{(1)}_{\mathcal{RI}} = 0$ (and $\mathcal{P}^{(2)}_{\mathcal{RI}} = 0$). The natural logarithm of the ratio of model probabilities [i.e., the Bayes factor $\ln B = \ln(P_{\rm ISO}/P_{\rm ADI})$] is below -10.9, corresponding to odds of less than $1:54\,000$ for all three (CDI, NDI, NVI) models. If there were an undetected subdominant isocurvature contribution to the primordial perturbations, a negative correlation between $\mathcal{R}$ and $\mathcal{I}$ would be favoured, in particular for NDI and NVI (see the last two panels of Figs. 229a,b,c). With our sign convention, this leads to a negative contribution to the Sachs-Wolfe effect and hence reduces the amplitude of the temperature angular power spectrum at low multipoles.

Figure 230 updates the 2015 *Planck* constraints on the derived primordial fractions and spectral indices. At large scales we find with *Planck* TT,TE,EE+lowE+lensing that $\beta_{\rm iso}(k_{\rm low}) < 2.5\,\%$ for the CDI, $7.4\,\%$ for the NDI, and $6.8\,\%$ for the NVI model, all at $95\,\%$ CL. Figure 231 shows the non-adiabatic fraction in the observed CMB temperature variance, defined as

$$\alpha_{\rm non-adi} = 1 - \frac{(\Delta T)^2_{\mathcal{RR}}(\ell = 2, 2500)}{(\Delta T)^2_{\rm tot}(\ell = 2, 2500)}, \tag{1315}$$

where

$$(\Delta T)^2_{\rm X}(\ell = 2, 2500) = \sum_{\ell=2}^{2500} (2\ell+1) C^{TT}_{{\rm X},\ell}. \tag{1316}$$

The non-adiabatic fraction $|\alpha_{\rm non-adi}|$ is below 1.7 % with *Planck* TT,TE,EE+lowE+lensing data for all three cases at 95 % CL.

Since the *Planck* data do not allow a significant isocurvature contribution, the determination of standard cosmological parameters depends only very weakly on the assumed initial conditions, as seen in Fig. 232. We place this result in historical perspective in Fig. 233 (and Table 40) where the parameter determinations of the mixed CDI model and the pure adiabatic model are compared to the pre-*Planck* constraints set by the WMAP 9-year data.[177] *Planck* has dramatically tightened the constraint on the adiabatic spectral index. Its value is now 8.4σ below unity (scale-invariance) in the pure ADI case. Allowing for generally correlated CDI reduces the significance of this detection only slightly, to 7σ, whereas the WMAP 9-year data were consistent with a blue tilt as large as $n_{\mathcal{RR}} = 1.06$ at 95 % CL. The non-adiabatic contribution to the CMB temperature variance is constrained (about zero) 5 times more tightly than by WMAP. Finally, the allowed range for the sound horizon angle has shrunk by a factor of 10 in the CDI case, thanks to the *Planck* data covering more acoustic peaks beyond the first three peaks detected by WMAP.

[177] The pivot scales $k_{\rm low}$ and $k_{\rm high}$ used here to parameterize the primary perturbation amplitudes are not optimal for WMAP, since the WMAP data extend only to $k \simeq k_{\rm mid}$. Nevertheless, an analysis tailored to WMAP [see Savelainen et al. [248], who used $k_{\rm mid}$ as an upper pivot k] gives a similar posterior range for $\alpha_{\rm non-adi}$.

28.9.3 Role of lensing parameter $A_{\rm L}$ and likelihood choices

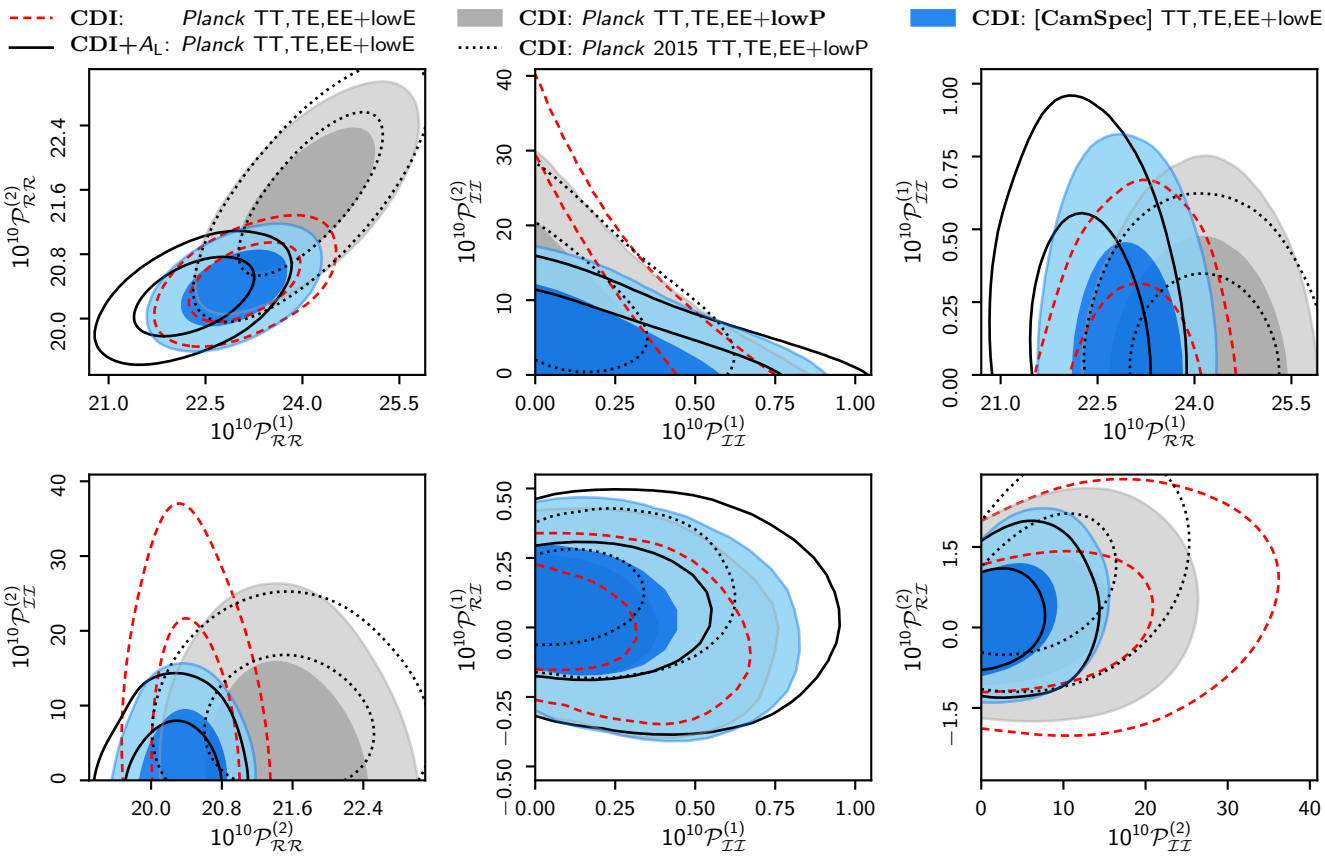

Figure 234: Comparison of the effect of *Planck* 2018 likelihood choices and phenomenological lensing amplitude, $A_{\rm L}$, on the constraints on the generally correlated mixed adiabatic and CDI model. The reference case, indicated by the red dashed curves, is for the 2018 baseline `Plik` high-ℓ likelihood supplemented by the low-ℓ `Commander` TT likelihood and the low-ℓ `SimAll` EE likelihood. This combination is the same as in Fig. 230a (red curves), except now without the lensing likelihood, which to some extent hides the differences between other likelihoods and the effect of $A_{\rm L}$. Black solid contours show the results using the same likelihood as in the reference case, but now for the mixed adiabatic and CDI model when simultaneously allowing $A_{\rm L}$ to vary. The remaining two curves are for the mixed adiabatic and CDI model (with $A_{\rm L} = 1$), but now changing the low-ℓ likelihood from `Commander` TT+`SimAll` EE to LFI 70 GHz T,E,B (grey), or high-ℓ likelihood from `Plik` to `CamSpec` (blue).

The small-scale primordial CDI amplitude is extremely sensitive to the details of the high-ℓ temperature and polarization power spectra and to choices made in constructing the likelihoods. Therefore the general CDI model serves as a robustness test of the *Planck* data and likelihoods. We now discuss a few curious aspects related to CMB lensing and likelihoods.

Lensing smooths the peaks of the CMB power spectra. This effect is taken into account in our theoretical predictions for the mixed adiabatic and isocurvature models by first calculating the total unlensed CMB spectra as a sum of adiabatic, isocurvature, and correlation C_ℓ's, and performing a similar summation for the lensing potential power spectrum [332, 220]. The total lensing potential is then used to lens the total CMB spectra. Starting with the WMAP data, accounting for CMB lensing became necessary for calculating constraints on isocurvature models, as [275] showed that there is a strong degeneracy between the lensing effect and the CDI contribution in the generally correlated mixed models. Fixing $n_{\mathcal{II}} = 1$ or $n_{\mathcal{II}} = n_{\mathcal{RR}}$ (as is done in the next subsection) makes this degeneracy disappear. This is because in these models the CDI contribution modifies only the low-ℓ part of the angular power spectra. The transfer

function mapping the primordial CDI mode to the TT (and EE) angular power is suppressed by a factor $(k/k_{\rm eq})^{-2} \sim (\ell/\ell_{\rm eq})^{-2}$ relative to the adiabatic mode. Therefore, to be observable at high ℓ, the CDI mode must be blue tilted ($n_{\mathcal{II}} > 1$). A blue-tilted CDI mode affects the total angular power spectra in a manner somewhat similar to lensing. Since the acoustic peaks of the CDI mode have the opposite phase compared to the adiabatic mode, a CDI admixture can "smooth" the peaks and dips of adiabatic acoustic oscillations. The NDI mode does not have precisely the opposite phase and is not damped relative to the adiabatic mode (see figure 43 in **(alias?)**). Thus we expect a weaker impact of lensing on the *primordial* NDI amplitude than in the CDI case. Therefore in this subsection we explore the general CDI model as an example.

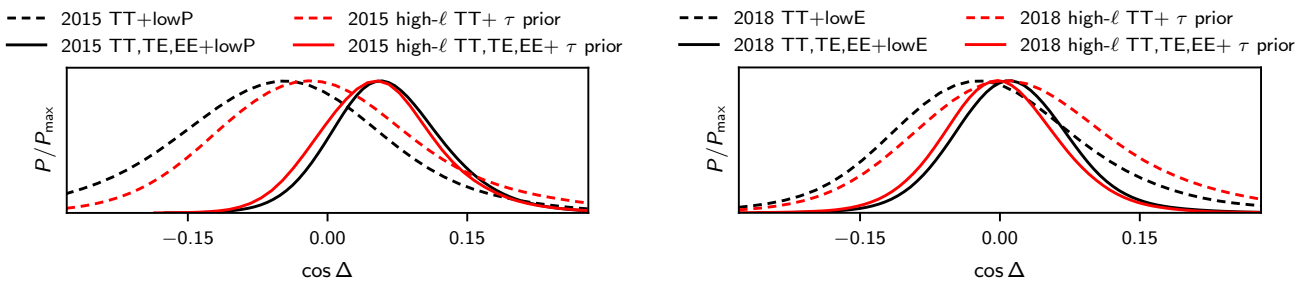

Figure 235: Scale-independent primordial correlation fraction in the mixed adiabatic and CDI model. The black curves are with *Planck* high-ℓ and low-ℓ data, while the red ones result from using only the high-ℓ `Plik` likelihood supplemented with a Gaussian prior on the optical depth. For the 2015 data (top panel) this prior was $\tau = 0.078 \pm 0.019$, whereas for the 2018 case (bottom panel) we have adopted $\tau = 0.055 \pm 0.007$ from the *Planck* 2018 TT,TE,EE+lowE+lensing CDI chain.

Starting with the *Planck* 2013 release, the consistency of the smoothing effect with the adiabatic ΛCDM model has been routinely tested by multiplying the lensing power spectrum by a phenomenological lensing consistency parameter, $A_{\rm L}$, prior to lensing the unlensed CMB spectra [66]. The expectation is that $A_{\rm L} = 1$. However, the *Planck* temperature and polarization data prefer a higher level of lensing-like smoothing ($A_{\rm L} > 1$) than expected in the adiabatic ΛCDM model. In the 2018 release [**(alias?)**] we have

$$A_{\rm L} = 1.243 \pm 0.096 \quad (68\,\%\ {\rm CL},\ \textit{Planck}\ {\rm TT{+}lowE}), \tag{1317}$$
$$A_{\rm L} = 1.180 \pm 0.065 \quad (68\,\%\ {\rm CL},\ \textit{Planck}\ {\rm TT,TE,EE{+}lowE}). \tag{1318}$$

Adding the *Planck* CMB lensing likelihood pulls these constraints towards $A_{\rm L} = 1$ (see also Table 41). The measurement of $A_{\rm L}$ when TT,TE,EE data are included depends on the calibration of the polarization channels. This procedure and the details of the sky masks differ between the *Planck* baseline `Plik` TT,TE,EE and the alternative *Planck* `CamSpec` TT,TE,EE likelihood, as discussed in **(alias?)** and **(alias?)**. The *Planck* `CamSpec` TT,TE,EE likelihood prefers a smaller value of $A_{\rm L}$ than `Plik`, but still lying about 2σ above unity.

Given the above motivation, we check the response of the generally correlated CDI model to the various possible choices of likelihoods available in the *Planck* 2018 release, and, on the other hand, we gauge how the baseline `Plik` likelihood reacts when allowing $A_{\rm L}$ to vary. For clarity, in Fig. 234 we restrict the analysis to high-ℓ TT,TE,EE and low-ℓ TT,EE(,BB) data without the lensing reconstruction data, but in Table 40 we also report TT+lowE and TT+lowP results, and include *Planck* lensing in some cases.

We notice a considerable variation in the constraints on the isocurvature power at high k, $\mathcal{P}^{(2)}_{\mathcal{II}}$, which corresponds to the high-ℓ region in the observed power spectra. In Fig. 234 we can compare the red dashed reference contours (obtained with the *Planck* baseline `Plik` TT,TE,EE+lowE likelihood) for the CDI model (where $A_{\rm L} = 1$) with the solid black contours (obtained with the same data) for the CDI+$A_{\rm L}$ model, where $A_{\rm L}$ is allowed to vary. In many cases, adding an extra free parameter is expected to weaken the constraints on the other parameters, but in this case adding $A_{\rm L}$ tightens the 95 % CL constraint on $\mathcal{P}^{(2)}_{\mathcal{II}}$ by a factor of 2.5 from 28.6×10^{-10} to 11.4×10^{-10}. This is reflected in the derived primordial isocurvature fraction

$\beta_{\rm iso}(k_{\rm high})$, whose upper bound changes from 0.58 to 0.36, according to Table 40. Therefore, we conclude that, when $A_{\rm L} = 1$, the CDI mode partially accounts for the extra lensing-like smoothing effect required by the *Planck* TT(,TE,EE) data. Once we allow the lensing amplitude to vary, there is not much need for the CDI contribution at high ℓ, which should be kept in mind when interpreting the results. In Table 40 we report four cases where $A_{\rm L}$ is allowed to vary. In all the other cases we have fixed $A_{\rm L} = 1$. In these cases the constraints at high k are "conservative", i.e., weaker than the *Planck* data were expected to be capable of [93], due to CDI (or NDI) partially fitting the lensing anomaly. Furthermore, again comparing the red dashed and black solid contours, we observe a slight weakening of the constraint for $\mathcal{P}^{(1)}_{\mathcal{II}}$ in the CDI+$A_{\rm L}$ model. This is due to the rigidity of the assumed power-law spectrum. When the high-ℓ data allow much less CDI, the low-ℓ (low-k) CDI amplitude can be larger without much affecting the middle-ℓ range of the CMB power spectra between the first and third acoustic peaks, which is the most sensitive region to departures from adiabaticity. (This is the same see-saw effect discussed in the end of Sect. 28.3.6 in the case of tensor perturbations.) Finally, in the $\left(\mathcal{P}^{(1)}_{\mathcal{RR}}, \mathcal{P}^{(2)}_{\mathcal{RR}}\right)$ panel we see a minor shift toward smaller amplitudes, which is an indication of the well-known degeneracy between $A_{\rm L}$ and the overall primordial perturbation amplitude.

From Table 40 it is obvious that adding the lensing data reduces the differences discussed above. This is again as expected, since the lensing data favour values of $A_{\rm L}$ only mildly above unity. For example, with *Planck* TT,TE,EE+lowE+lensing we obtain $\beta_{\rm iso}(k_{\rm high}) < 0.49$ for CDI+$A_{\rm L}$ and 0.47 for the CDI model.

We now proceed to a comparison of the likelihoods. The grey shaded contours in Fig. 234 indicate the results for the same CDI model as the red dashed contours, but changing the low-ℓ likelihood from the combination `Commander` TT+`SimAll` EE to the LFI 70 GHz pixel-based low T,E,B, which is by its methodology and construction very similar to the 2015 baseline low-ℓ likelihood (dotted contours). Indeed, this can be seen in the results: most of the isocurvature parameters follow more closely the 2015 results with this likelihood combination than with the 2018 baseline. This implies that when it comes to isocurvature, not much has changed in high-ℓ TT. 2018 lowP favours slightly smaller values of the optical depth τ than the 2015 version, hence the small shift towards smaller values of the adiabatic amplitude in the $\left(\mathcal{P}^{(1)}_{\mathcal{RR}}, \mathcal{P}^{(2)}_{\mathcal{RR}}\right)$ panel. With respect to the red dashed contours, the grey contours prefer higher adiabatic amplitudes and have a long degeneracy line in the $\left(\mathcal{P}^{(1)}_{\mathcal{RR}}, \mathcal{P}^{(2)}_{\mathcal{RR}}\right)$ plane. This is due to lowP having a higher central value and larger uncertainty on τ.

Finally, the blue shaded contours in Fig. 234 represent the results when using the `CamSpec` likelihood, to be compared to the red dashed contours obtained by the baseline `Plik` likelihood. All the other parameters shown are relatively stable against the high-ℓ likelihood, but $\mathcal{P}^{(2)}_{\mathcal{II}}$ stands out. `CamSpec` leads to an upper bound of 12.6×10^{-10}, whereas the baseline `Plik` result was 28.6×10^{-10}, or for $\beta_{\rm iso}(k_{\rm high})$ 0.38 versus 0.58 at 95 % CL, according to Table 40. This difference is not surprising, given the different responses of these likelihoods to $A_{\rm L}$ in the adiabatic ΛCDM+$A_{\rm L}$ model, and keeping in mind the $A_{\rm L}$–CDI degeneracy in the CDI model. However, this difference is not as concerning as it might appear at first sight: all the cases shown in Fig. 234 are fully consistent with zero isocurvature. It is only the upper bound that varies, with the baseline `Plik` likelihood and CDI model with $A_{\rm L} = 1$ leading to the most conservative (i.e., weakest or safest) upper bounds.

For CDI the 2015 release *Planck* high-ℓ TT data favoured a negative correlation fraction but the preliminary high-ℓ TT,TE,EE data favoured a slightly positive correlation. This was confirmed using only the high-ℓ `Plik` likelihood (and a prior on τ), as shown by the red curves in the top panel of Fig. 235. Including the low-ℓ data (black curves) did not significantly alter this tension between TT and TT,TE,EE results. In the present 2018 *Planck* release this tension has disappeared. Both high-ℓ TT and TT,TE,EE data lead to a correlation fraction posterior peaking at zero, as demonstrated in the bottom panel of Fig. 235. Including the low-ℓ TT data (black dashed curve) still shifts the posterior slightly towards negative values, due to the low TT power at low multipoles in the data.

28.9.4 Specific CDI models

In this subsection we constrain CDI models with only one or two isocurvature parameters. The two-parameter cases were not studied in the 2013 and 2015 *Planck* releases.

First we fix $n_{\mathcal{II}}$ to unity and assume no correlation between the CDI and adiabatic modes ("axion"), or we fix $n_{\mathcal{II}} = n_{\mathcal{RR}}$ and assume full (anti)correlation between the CDI and adiabatic modes ("curvaton I/II"). These models are less sensitive to any residual systematic effects in the high-ℓ data (such as the determination of polarization efficiencies or foreground modeling) than the generally correlated models, since CDI now modifies the angular power spectra insignificantly at $\ell \gtrsim 200$ (see figure 43 in **(alias?)**). As seen in the middle section of Table 40, the Bayesian evidence values for the one-parameter extensions of the adiabatic ΛCDM model are higher than for the three-parameter extensions, but all Bayes factors fall below −5. None of the one-parameter extensions improve χ^2 over the adiabatic ΛCDM model. The two-parameter extensions in the bottom section of Table 40 are even more strongly disfavoured, except for the uncorrelated case with free $n_{\mathcal{II}}$ ("axion II"), which is actually the only model that improves the best-fit χ^2 by slightly more than the number of extra parameters.

Uncorrelated ADI+CDI ("axion I")

Particularly insensitive to any $\ell \gtrsim 30$ data is the "axion I" case, since the CDI transfer function has a $(k/k_{\rm eq})^{-2}$ suppression and there is no correlation component whose amplitude would be higher than that of the isocurvature alone and hence would modify the adiabatic spectrum. The "axion I" case is achieved in our parameterization by setting $\mathcal{P}_{\mathcal{RI}} = 0$ and $\mathcal{P}^{(2)}_{\mathcal{II}} = \mathcal{P}^{(1)}_{\mathcal{II}}$. Thus the only varied isocurvature parameter is $\mathcal{P}^{(1)}_{\mathcal{II}}$. This uncorrelated case with $n_{\mathcal{II}} = 1$ is a good approximation for many multi-field inflationary models where the slow-roll parameter (in the isocurvature field perturbation direction) η_{ss} is negligible and the background trajectory in field space is straight between Hubble radius exit and the end of inflation. The predictions for the spectral indices (to first order in the slow-roll parameters) are $n_{\mathcal{RR}} = 1-6\epsilon+2\eta_{\sigma\sigma}$ and $n_{\mathcal{II}} = 1-2\epsilon+2\eta_{ss}$, where $\epsilon \geq 0$ and $\eta_{\sigma\sigma}$ is the second slow-roll parameter in the "adiabatic" direction (i.e., along the trajectory) in the field space. (An exact match with our model would require $\eta_{ss} = \epsilon$.) The axion model [see, e.g., a recent review by Marsh [179] and references therein], which was originally proposed to solve the strong CP problem and provides a dark matter candidate, can produce this type of isocurvature modes with $n_{\mathcal{II}} \simeq 1$ under the following assumptions (**(alias?)**, **(alias?)**): the Peccei-Quinn symmetry should be broken before inflation; it should not be restored by quantum fluctuations of the inflaton nor by thermal fluctuations when the Universe reheats; and axions produced through the misalignment angle should form a significant fraction of the dark matter.

Table 40 indicates a slight tightening of the "axion I" constraints using TT+lowE+lensing with respect to 2015 TT+lowP+lensing. This is due to the change of the baseline low-ℓ data from the 2015 LFI 70-GHz pixel-based T,E,B to the 2018 combination of `Commander` TT and `SimAll` EE, which in the generally correlated cases also gave tighter constraints at low k. As expected, the addition of high-ℓ TE,EE data only marginally improves the constraints, since the standard (non-isocurvature) parameters are better constrained now. For $n_{\mathcal{II}} = 1$ uncorrelated CDI, we obtain

$$\left.\begin{array}{r} \beta_{\rm iso}(k_{\rm mid}) < 0.038 \\ 0 \leq \alpha_{\rm non-adi} < 1.55\,\% \end{array}\right\} \begin{array}{l} (95\,\%\ \text{CL, } \textit{Planck} \\ \text{TT,TE,EE} \\ \text{+lowE+lensing}). \end{array} \tag{1319}$$

Using equation (73) of **(alias?)**, we convert the constraint on the primordial isocurvature fraction to a bound on the inflationary energy scale. If all the dark matter is in axions, the above $\beta_{\rm iso}(k_{\rm mid})$ constraint corresponds to the same limit we quoted in 2015, that is,

$$H_{\rm inf} < 0.86 \times 10^7\,{\rm GeV} \left(\frac{f_a}{10^{11}\,{\rm GeV}}\right)^{0.408} \qquad (95\,\%\ \text{CL})\,, \tag{1320}$$

where $H_{\rm inf}$ is the expansion rate at Hubble radius exit of the scale corresponding to $k_{\rm mid}$ and f_a is the Peccei-Quinn symmetry-breaking energy scale.

Fully (anti)correlated ADI+CDI ("curvatonI/II")

If $n_{\mathcal{II}} = n_{\mathcal{RR}}$, the low-$\ell$ data are maximally sensitive to the fully correlated isocurvature perturbations. In this case the correlation component is a geometric average of the adiabatic and isocurvature components, and hence much larger than the isocurvature component alone. We achieve this case in our parameterization by setting $\mathcal{P}^{(2)}_{\mathcal{II}} = \left(\mathcal{P}^{(2)}_{\mathcal{RR}}/\mathcal{P}^{(1)}_{\mathcal{RR}}\right)\mathcal{P}^{(1)}_{\mathcal{II}}$ and $\mathcal{P}^{(1)}_{\mathcal{RI}} = \pm\left(\mathcal{P}^{(1)}_{\mathcal{RR}}\mathcal{P}^{(1)}_{\mathcal{II}}\right)^{1/2}$, i.e., $\cos\Delta = \pm 1$. The only isocurvature parameter to be varied is again $\mathcal{P}^{(1)}_{\mathcal{II}}$. Since $n_{\mathcal{II}} = n_{\mathcal{RR}}$, the derived isocurvature fraction $\beta_{\rm iso}$ is independent of k. A physically motivated example of this type of model is the simplest curvaton model, where a light scalar field χ that is subdominant (and hence irrelevant for the inflationary dynamics) starts to oscillate at the bottom of its potential after the end of inflation, causing its average energy density to evolve like non-relativistic matter. Once fully (or almost fully) dominating the energy density of the Universe, this curvaton field decays either to CDM or to other species [198, 173, 79, 201, 177, 20, 176]. The amount of isocurvature and non-Gaussianity present after curvaton decay depends on the "curvaton decay fraction," $r_D = 3\bar\rho_\chi/(3\bar\rho_\chi + 4\bar\rho_{\rm radiation})$, evaluated at curvaton decay time. Under a number of (very) restrictive assumptions discussed in **(alias?)**, the curvaton model can lead to fully (anti)correlated CDI (or BDI) and adiabatic perturbations.

Not surprisingly, both in the fully correlated and anticorrelated cases, the constraint on $\beta_{\rm iso}$ is much (about 40 times) stronger than in the uncorrelated case. At 95 % CL, *Planck* TT,TE,EE+lowE+lensing leads to

$$\beta_{\rm iso} < 0.00095 \quad \text{(Fully correlated, "curvaton I")}, \tag{1321}$$

$$\beta_{\rm iso} < 0.00107 \quad \text{(Fully anticorrelated, "curvaton II")}, \tag{1322}$$

both rounded to 0.001 in Table 40. As in 2015, the TT data favour anticorrelation, due to the low power in the low-ℓ temperature compared to the expectation of the adiabatic ΛCDM model. But when the TE,EE data (which do not particularly favour negative correlation) are added, a very tight (one part per thousand) constraint on the primordial isocurvature fraction results.

Fully correlated perturbations are obtained, e.g., in case 4 described in Gordon & Lewis [109]. Many models giving anticorrelation produce too large an isocurvature fraction to be consistent with the above limit, but case 9 of Gordon & Lewis [109] survives. After the curvaton decay, the primordial isocurvature fraction in these models will be $\beta_{\rm iso} \simeq 9(1-\tilde r)^2/[r_D^2 + 9(1-\tilde r)^2]$, where $\tilde r = r_D$ for the fully correlated CDI case and $\tilde r = r_D/R_{\rm c} \geq 1$ for the fully anticorrelated CDI case, and $R_{\rm c} = \bar\rho_{\rm c}/(\bar\rho_{\rm c} + \bar\rho_{\rm b})$ is the CDM fraction of the total non-relativistic matter.

On the other hand, the nonlinearity parameter describing non-Gaussianity is [246]

$$f_{\rm NL}^{\rm local} = \left(1 + \Delta_s^2\right)\frac{5}{4r_D} - \frac{5}{3} - \frac{5r_D}{6}, \tag{1323}$$

where $\Delta_s^2 = \langle\delta\chi^2\rangle_s/\bar\chi^2$ is the small-scale variance of the curvaton perturbations, or the ratio of the energy density carried by the curvaton particles to the energy density of the curvaton field (if there is significant production of curvaton particles). The parameter $f_{\rm NL}^{\rm local}$ cannot be smaller than $-5/4$, which is obtained when $r_D = 1$ and $\Delta_s^2 = 0$, as implicitly assumed, for example, in Bartolo et al. [22, 23]. The above $\beta_{\rm iso}$ limits correspond to the following r_D and $f_{\rm NL}^{\rm local}$ constraints (assuming $\Delta_s^2 = 0$):[178]

$$0.98982 < r_D \leq 1 \qquad \text{("curvaton I")}$$
$$\Rightarrow -1.2500 \leq f_{\rm NL}^{\rm local} < -1.2287, \tag{1324}$$
$$0.84347 \leq r_D < 0.85129 \qquad \text{("curvaton II")}$$
$$\Rightarrow -0.9077 < f_{\rm NL}^{\rm local} \leq -0.8876. \tag{1325}$$

[178] The quoted precision of these constraints does not reflect the precision of the sampling of the likelihood surface, but we report several digits here since the constraints are so tight that rounding to, e.g., two significant digits would give empty or almost empty ranges.

Even with the maximal allowed isocurvature fraction, the local non-Gaussianity in the curvaton model is well within the observational *Planck* limits presented in Planck Collaboration IX [295]. The residual isocurvature peturbations in the two studied curvaton models set much tighter constraints on the curvaton decay fraction than do constraints on the observed (consistent with zero) non-Gaussianity.

Uncorrelated ADI+CDI with free $n_{\mathcal{II}}$ ("axion II")

Axion models do not necessarily produce nearly scale-invariant isocurvature perturbations. In particular, even highly blue-tilted spectra (in the observable CMB range) are possible. For example, Kasuya & Kawasaki [152] construct a model with $n_{\mathcal{II}} = 2$–4. This motivates studying a two-isocurvature-parameter model, where adiabatic and isocurvature modes are uncorrelated, but the isocurvature fraction and spectral index are free to vary. In our parameterization this is achieved by setting $\mathcal{P}^{(1)}_{\mathcal{RI}} = 0$, and varying $\mathcal{P}^{(1)}_{\mathcal{II}}$ and $\mathcal{P}^{(2)}_{\mathcal{II}}$ independently. The results for this model are presented in the first two rows of the third section of Table 40. The low-ℓ temperature data do not favour any extra contribution beyond the (already too high) abiabatic contribution, whereas the fit to the high-ℓ temperature and polarization data can be improved slightly by the "smoothing" caused by the CDI mode. This leads to a very blue isocurvature spectrum. *Planck* TT,TE,EE+lowE+lensing gives at 95 % CL $1.55 < n_{\mathcal{II}} < 3.67$, consistent with the recent findings of Chung & Upadhye [60]. Even the very large upper bound $\beta_{\rm iso}(k_{\rm high}) < 77\,\%$ corresponds to a contribution of less than order 1% to the observable CMB TT (or EE) power spectra at $\ell \simeq 1400$. The uncertainty in the *Planck* TT spectrum at these high multipoles is $\Delta\mathcal{D}^{TT}_\ell \sim 10\,\mu{\rm K}^2$ and the actual spectrum is $\mathcal{D}^{TT}_\ell \sim 1000\,\mu{\rm K}^2$. Thus the allowed CDI contribution is only of the same 1 % order as the observable uncertainty. Consequently the non-adiabatic contribution to the observed CMB temperature variance, $\alpha_{\rm non-adi}$, is also vanishingly small, between 7×10^{-4} and 7×10^{-3}.

Arbitrarily correlated ADI+CDI with $n_{\mathcal{II}} = n_{\mathcal{RR}}$ ("curvaton III")

Apart from the extremes of ±100 % correlation, some curvaton models predict an arbitrary degree of correlation. The generic feature of most curvaton models is that the isocurvature and adiabatic spectral indices are equal. This is because both perturbations typically arise from the same source. In the next-to-simplest models, the correlation fraction can be written as $\cos\Delta = \sqrt{\lambda/(1+\lambda)}$, where $\lambda = (8/9)r_D^2\epsilon_*(M_{\rm Pl}/\bar\chi_*)^2$. Therefore, the model is fully correlated only if $\lambda \gg 1$, in which case the results of "curvaton I" apply. If the slow-roll parameter ϵ_* is very close to zero or the curvaton field value $\bar\chi_*$ is large compared to the Planck mass, this model leads to almost uncorrelated perturbations and the constraints are well approximated by "axion I." Any other case leads to an arbitrary degree of positive correlation between the CDI and adiabatic modes.

Modulated reheating with thermal or non-thermal production of gravitinos can lead to positive or negative correlation, respectively [266]. While the correlation could in principle be arbitrarily large, the observational constrains on $\beta_{\rm iso}$ favour only small correlations.

Arbitrarily correlated ADI+CDI with $n_{\mathcal{II}} = n_{\mathcal{RR}}$ is also a good approximation for those two-field (or multi-field) slow-roll models [e.g., double quadratic inflation [160, 29]] where the trajectory in field space is curved between the Hubble radius exit of perturbations during inflation and the end of inflation. The fraction of isocurvature perturbations converted to adiabatic depends on how the trajectory is curved and this part of the adiabatic perturbations will be fully (anti)correlated with the isocurvature modes, whereas the adiabatic perturbations already present at Hubble radius exit are uncorrelated with isocurvature modes to first order in the slow-roll parameters, and only slightly correlated to second order. [See, e.g., Gordon et al. [111], Amendola et al. [16], van Tent [276], and Byrnes & Wands [52].] The result is a non-zero correlation between isocurvature and total adiabatic perturbations. The spectral indices of both components are typically $1 - \mathcal{O}$(slow-roll parameters), which is well approximated by $n_{\mathcal{II}} = n_{\mathcal{RR}}$ since the data indicate $n_{\mathcal{RR}} \simeq 0.965$.

As expected, the *Planck* data favour negative correlations, since these $n_{\mathcal{II}} = n_{\mathcal{RR}}$ models modify only the low-ℓ part of the CMB spectra, where TT power is lower than predicted by the adiabatic ΛCDM model. With TT,TE,EE+lowE+lensing we find, at 95 % CL, $\beta_{\rm iso} < 0.039$ and $-0.41 < \cos\Delta < 0.31$.

Fully (anti)correlated ADI+CDI with free $n_{\mathcal{II}}$

The remaining two-parameter CDI extensions of the adiabatic ΛCDM model are those where the perturbations are fully (anti)correlated, as in the simplest curvaton models, but the isocurvature spectral index is not fixed to the adiabatic one. In this case the free isocurvature parameters are $\mathcal{P}^{(1)}_{\mathcal{II}}$ and $\mathcal{P}^{(2)}_{\mathcal{II}}$, while $\mathcal{P}^{(1)}_{\mathcal{RI}} = \pm\left(\mathcal{P}^{(1)}_{\mathcal{RR}}\mathcal{P}^{(1)}_{\mathcal{II}}\right)^{1/2}$. These models are somewhat difficult to motivate, since full (anti)correlation typically implies that the curvature and isocurvature perturbations have their origin in (the decay products of) the same field. Then one would expect equal spectral indices, as in the curvaton model. The conversion of isocurvature perturbations to adiabatic ones (e.g., between Hubble radius exit and the end of inflation, or by curvaton-type decay, or by reheating/thermalization) should be scale dependent in order to obtain $n_{\mathcal{II}} \neq n_{\mathcal{RR}}$. Slow-roll two-field inflation leads to an exact match, $n_{\mathcal{II}} = n_{\mathcal{RR}}$, in the case where $\cos^2\Delta = 1$. [See, e.g., Byrnes & Wands [52]]. Nevertheless, for completeness we report constraints on these phenomenological models in the last four rows of Table 40. Since the low-ℓ TT data favour negative correlation, a larger isocurvature fraction is allowed in the fully anticorrelated case at low k. This leads to scale-invariant isocurvature perturbations being in the favoured region of parameter space, namely $-0.28 < n_{\mathcal{II}} < 1.86$ with TT,TE,EE+lowE+lensing at 95 % CL. In contrast, in the fully correlated case the low-ℓ TT data disfavour any isocurvature contribution, and hence prefer a blue spectrum, with $1.37 < n_{\mathcal{II}} < 3.65$.

28.9.5 Compensated BDI–CDI mode

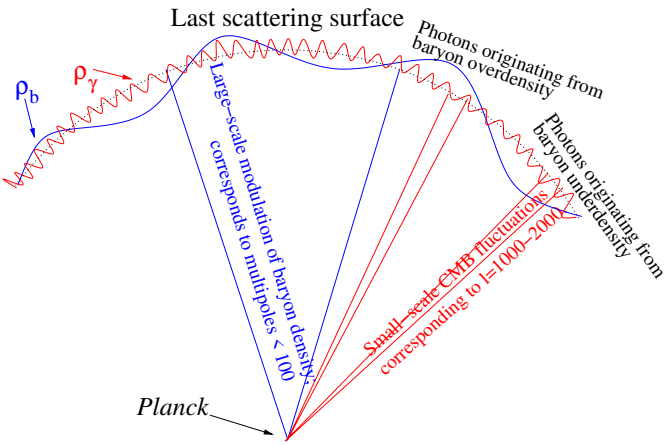

Figure 236: Illustration of how the large-scale modulation of the baryon density by CIP gets converted into a small-scale "smoothing" effect of the temperature and polarization anisotropies.

This subsection presents constraints on uncorrelated adiabatic and scale-invariant CIP modes and discusses the strong degeneracy between the phenomenological lensing parameter $A_{\rm L}$ and the CIP amplitude [357]. Assuming that there are no NVI or NDI perturbations, the total matter density isocurvature perturbation $\mathcal{I}_{\rm MDI}$, given by Eq. (1314), vanishes if

$$\mathcal{I}_{\rm CDI} = -\frac{\Omega_{\rm b}}{\Omega_{\rm c}}\mathcal{I}_{\rm BDI}. \tag{1326}$$

This mode, where the anticorrelated CDI and BDI perturbations cancel even though their individual amplitudes can be large, is called a compensated baryon and cold dark matter isocurvature mode. The CIP mode does not leave a linear-order isocurvature signal in the CMB or matter power spectra [109], although it modifies the trispectrum [115, 117]. However, at the next order there is a smoothing effect on the high-ℓ TT, TE, and EE spectra. A formal derivation can be found, for example, in Smith et al. [345]. Here we summarize the heuristic arguments of Muñoz et al. [243].

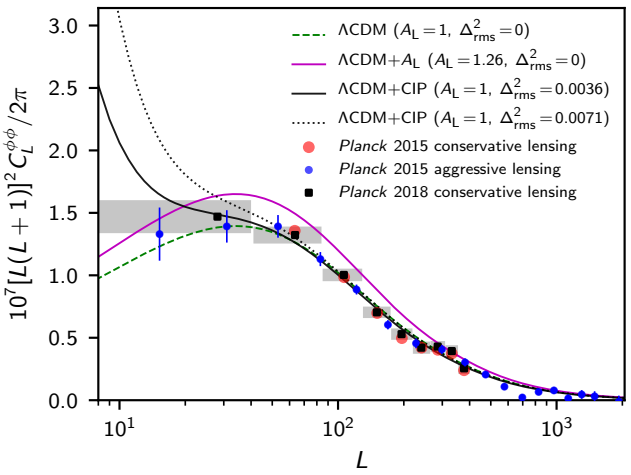

Figure 237: Conservative *Planck* 2015 lensing data (red points), aggressive *Planck* 2015 lensing data (blue points with error bars), and conservative *Planck* 2018 lensing data (black squares in grey boxes), along with the best-fit models to the *Planck* data: the best-fit adiabatic ΛCDM model to 2018 TT+lowE (green dashed line); the best-fit ΛCDM+A_L model to 2018 TT+lowE (magenta solid line, $A_L = 1.26$); and the best-fit ΛCDM+CIP model to 2018 TT,TE,EE+lowE and conservative lensing data (black solid line, $\Delta^2_{rms} = 0.0036$) and to 2015 TT,TE,EE+lowP and conservative lensing data (black dotted line, $\Delta^2_{rms} = 0.0071$). As CIP modifies only the very low-L part of the lensing power spectrum, the conservative 2015 lensing data ($40 \leq L \leq 400$) are insensitive to CIP even when $\Delta^2_{rms} = 0.0071$. On the other hand, the first two data points of the 2015 aggressive lensing data disfavour the large CIP amplitude [345], which gives a very good fit to all the other data. *Planck* 2018 conservative lensing data cover the range $8 \leq L \leq 400$ and consequently disfavour CIP variances $\Delta^2_{rms} \gtrsim 0.004$.

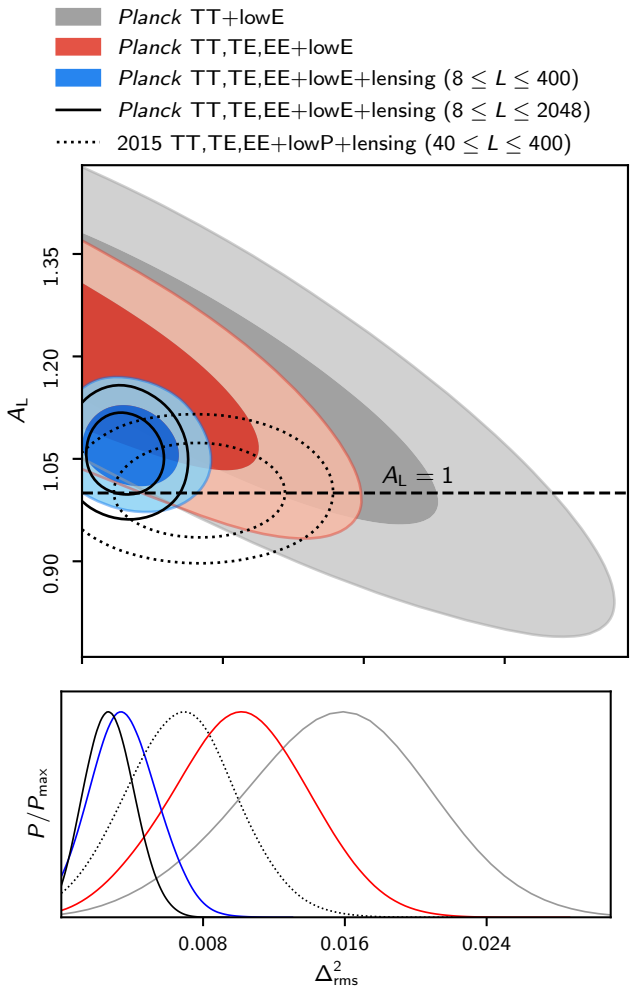

Figure 238: Degeneracy between $A_{\rm L}$ and $\Delta^2_{\rm rms}$ in the ΛCDM+$A_{\rm L}$+CIP model (top panel) and constraints on $\Delta^2_{\rm rms}$ in the ΛCDM+CIP model, where $A_{\rm L} = 1$ (bottom panel).

On scales larger than the sound horizon, condition (1326) is preserved until last scattering and can be written as

$$\delta\rho_{\rm c}(\vec{x}) \simeq -\delta\rho_{\rm b}(\vec{x})\,. \tag{1327}$$

Consequently, CIP can be described as a large scale modulation of the baryon and CDM density [243, 136, 357], with

$$\Omega_{\rm b}(\vec{\hat{n}}) = [1+\Delta(\vec{\hat{n}})]\bar{\Omega}_{\rm b}\,, \qquad \Omega_{\rm c}(\vec{\hat{n}}) = \bar{\Omega}_{\rm c} - \Delta(\vec{\hat{n}})\bar{\Omega}_{\rm b}\,. \tag{1328}$$

Here the overbar denotes an average over the whole sky and $\Delta(\vec{\hat{n}})$ a small perturbation about this average in the direction $\vec{\hat{n}}$, as illustrated in Fig. 236. In patches of sky where the CMB photons originate from baryon-overdense regions, the odd acoustic peaks at high-ℓ are more pronounced relative to the even peaks compared to the patches where the photons originate from baryon-underdense regions. Averaging over the sky leads to a lensing-like smoothing of the high-ℓ peaks.

A convenient measure of CIP is the variance $\Delta^2_{\rm rms} \equiv \langle|\Delta(\hat{n})|^2\rangle \simeq \mathcal{P}_{\mathcal{I}_{\rm BDI}\mathcal{I}_{\rm BDI}}$. If Δ is a Gaussian random variable, the observed angular power of TT, TE, or EE will be

$$\begin{aligned} &C_\ell^{\rm obs}(\bar{\Omega}_{\rm b}, \bar{\Omega}_{\rm c}, \tau, H_0, n_{\rm s}, A_{\rm s}) \\ &= \frac{1}{\sqrt{2\pi\Delta^2_{\rm rms}}} \int C_\ell\big(\Omega_{\rm b}(\Delta), \Omega_{\rm c}(\Delta), \tau, H_0, n_{\rm s}, A_{\rm s}\big)\, e^{-\Delta^2/(2\Delta^2_{\rm rms})} d\Delta\,, \end{aligned} \tag{1329}$$

where $\Omega_{\rm b}(\Delta) = (1+\Delta)\bar{\Omega}_{\rm b}$ and $\Omega_{\rm c}(\Delta) = \bar{\Omega}_{\rm c} - \bar{\Omega}_{\rm b}\Delta$. For brevity, we will denote the power spectrum in the integrand by $C_\ell|_{\Delta=\delta}$. For each δ it can be calculated by assuming adiabatic

initial conditions. Approximating the integrand by the first three terms of its Taylor series about $\Delta = 0$, we end up with

$$C_\ell^{\rm obs} \simeq C_\ell|_{\Delta=0} + \frac{1}{2}\left.\frac{d^2 C_\ell}{d\Delta^2}\right|_{\Delta=0} \Delta^2_{\rm rms}\,. \tag{1330}$$

In the following we describe parameter scans where we vary the six standard (adiabatic) ΛCDM parameters, the *Planck* nuisance parameters, and the CIP variance $\Delta^2_{\rm rms}$, calling this one-parameter extension of the ΛCDM model the "ΛCDM+CIP" model. We evaluate the right-hand side of Eq. (1330) at each point in parameter space using a finite-difference approximation for the second derivative:

$$\frac{1}{2}\left.\frac{d^2 C_\ell}{d\Delta^2}\right|_{\Delta=0} \Delta^2_{\rm rms} \simeq \frac{\frac{1}{2}C_\ell|_{\Delta=\delta} - C_\ell|_{\Delta=0} + \frac{1}{2}C_\ell|_{\Delta=-\delta}}{\delta^2}\,, \tag{1331}$$

where δ should be "sufficiently small." In practice, good numerical accuracy is achieved if δ is of order $\sqrt{\Delta^2_{\rm rms}}$. So at each point in our `MultiNest` scan we set $\delta = \sqrt{\Delta^2_{\rm rms}}$ for the point currently under evaluation, and thus the result of Eq. (1330) simplifies to

$$C_\ell^{\rm obs} \simeq \frac{C_\ell\big|_{\Delta=\sqrt{\Delta^2_{\rm rms}}} + C_\ell\big|_{\Delta=-\sqrt{\Delta^2_{\rm rms}}}}{2}\,. \tag{1332}$$

With this method each angular power spectra evaluation takes twice as long as for the pure adiabatic case since the spectra are now an average of two spectra, resulting from different values of $\Omega_{\rm b}$ and $\Omega_{\rm c}$.[179]

Unlike the high-ℓ TT, TE, and EE spectra, the high-L lensing potential power spectrum is virtually unaffected by CIP. Instead, CIP modifies the low multipoles of $[L(L+1)]^2 C_L^{\phi\phi}/(2\pi)$ by, approximately, adding a term $\Delta^2_{\rm rms} \times (L/0.053)^{-2}$. For details, see table II in Smith et al. [345]. As illustrated in Fig. 237, when using the *Planck* 2015 conservative lensing data ($40 \le L \le 400$) this term does not affect the results. In contrast, the *Planck* 2018 conservative lensing data also contain the range $8 \le L < 40$ and thus CIP variances $\Delta^2_{\rm rms} \gtrsim 0.004$ fit the first data point of the 2018 lensing power spectrum ($8 \le L \le 400$) worse than in ΛCDM. However, even in this case the joint fit of the ΛCDM+CIP model to the TT, TE, EE, and lensing data is better than that of the ΛCDM model, the improvement being of the same order as for the ΛCDM+$A_{\rm L}$ model.

The top panel of Fig. 238 shows the $A_{\rm L}$–$\Delta^2_{\rm rms}$ degeneracy in the ΛCDM+$A_{\rm L}$+CIP model and how it can be broken by the lensing data. The value $A_{\rm L} = 1$ provides a good fit to the TT+lowE data, if $\Delta^2_{\rm rms} \simeq 0.016$, and to the TT,TE,EE+lowE data, if $\Delta^2_{\rm rms} \simeq 0.010$. The ΛCDM+CIP model (where $A_{\rm L} = 1$) with $\Delta^2_{\rm rms} \simeq 0.008$ provides a better simultaneous fit to the *Planck* 2015 TT,TE,EE and conservative lensing data ($40 \le L \le 400$) than does the ΛCDM+$A_{\rm L}$ model. When using the *Planck* 2018 conservative lensing data ($8 \le L \le 400$), the best-fit value of $\Delta^2_{\rm rms}$ decreases to 0.0036. This is due to the extra term $\propto L^{-2}$ brought by CIP to the lensing power estimator, as discussed above and shown in Fig. 237.

Since *Planck* TT,TE,EE+lowE and lensing data can be fit well by $A_{\rm L} = 1$ in the CIP model, we show in the bottom panel of Fig. 238 the one-dimensional posterior of $\Delta^2_{\rm rms}$ in the ΛCDM+CIP model. A non-zero value of $\Delta^2_{\rm rms}$ is preferred at the 2.9σ (2.5σ) level by *Planck* 2018 (2015) TT+lowE(lowP) data and at the 2.6σ (1.8σ) level by the TT,TE,EE+lowE(lowP) data. Without lensing the 2018 data thus more strongly favour the non-zero CIP amplitude than the 2015 data, which is as we would expect, since the favoured $A_{\rm L}$ value in the ΛCDM+$A_{\rm L}$ model has also increased. When using 2018 TT,TE,EE+lowE and the 2018 conservative lensing data the significance decreases to 2.0σ, while switching to the aggressive lensing data ($8 \le L \le 2048$) leads to 2.1σ. The 68 % CL ranges of $\Delta^2_{\rm rms}$ in the ΛCDM+CIP model, obtained with the baseline high-ℓ `Plik` likelihood in combination of other *Planck* data, are highlighted in Table 41. Replacing `Plik` with `CamSpec` (in particular `CamSpec` TT,TE,EE) leads to somewhat lower

[179] Actually, we call `CAMB` three times (i.e., also with $\bar{\Omega}_{\rm b}$ and $\bar{\Omega}_{\rm c}$, or $\Delta = 0$), in order to obtain some auxiliary parameters such as σ_8 correctly, although we do not report them here.

Data and model	Constraints $1000\Delta^2_{\rm rms}$	Constraints $A_{\rm L}$	Best fit $1000\Delta^2_{\rm rms}$	Best fit $A_{\rm L}$	Best fit $\Delta\chi^2$	$\ln B$

Table 41: Comparison of ΛCDM+CIP, ΛCDM+$A_{\rm L}$, and ΛCDM+$A_{\rm L}$+CIP models with various *Planck* datasets, when using the baseline `Plik` likelihood at high ℓ. The first two columns ("Constraints") are the 68% CL ranges or the 95% CL upper bounds on $1000\Delta^2_{\rm rms}$ (highlighted in bold for ΛCDM+CIP) and $A_{\rm L}$. The remaining columns give the best-fit pameter values, and the difference of the best-fit χ^2 and the difference of the log of the Bayesian evidence with respect to the pure adiabatic ΛCDM model. A negative $\Delta\chi^2$ means that the quoted model fits the data better than ΛCDM, while a positive $\ln B$ means that the Bayesian model comparison favours the quoted model, when adopting the uniform priors $0 \le 1000\Delta^2_{\rm rms} < 75$ and $0.3 \le A_{\rm L} \le 1.7$.

values,

$$1000\Delta^2_{\rm rms} = \begin{cases} 14.1^{+5.2}_{-5.2} \text{ TT+lowE}, \\ 6.5^{+3.0}_{-4.2} \text{ TT,TE,EE+lowE}, \\ 2.8^{+1.2}_{-2.2} \text{ TT,TE,EE+lowE+lensing (conserv.)}, \\ 2.2^{+1.0}_{-1.5} \text{ TT,TE,EE+lowE+lensing (aggr.)}, \end{cases} \tag{1333}$$

and reduced significance above zero: 2.7σ, 1.9σ, 1.7σ, and 1.9σ, respectively.

In order to check that the preference for $\Delta^2_{\rm rms} > 0$ or $A_{\rm L} > 1$ is not just a parameter-space volume effect upon marginalization over other parameters, we also report in Table 41 the difference of χ^2 between the best fit in extended models and the base adiabatic ΛCDM model. With all data sets, all three extended models lead to an improvement of χ^2 which clearly exceeds the number of extra parameters of the model (1 for ΛCDM+CIP and ΛCDM+$A_{\rm L}$, and 2 for ΛCDM+$A_{\rm L}$+CIP). Although the inclusion of lensing data reduces this improvement of fit, the ΛCDM+CIP model gives a rather impressive $\Delta\chi^2 = -4$ with *Planck* TT,TE,EE+lowE and aggressive lensing data.

Since we observe a moderate preference for a non-zero CIP amplitude, it might be tempting to "solve" the *Planck* lensing anomaly by using CIP. However, this explanation seems quite unlikely, since in our treatment the CIP and adiabatic perturbations should be uncorrelated with each other, whereas CDI and BDI should be fully anticorrelated (and have a few orders of magnitude larger amplitude than the adiabatic modes while keeping the perturbations nearly Gaussian). It is difficult to imagine a physical model that could lead to this situation. For example, some variants of curvaton model would naturally lead to anticorrelated CDI and BDI, but in these models there would be a correlation with the adiabatic mode too [109, 134].

The above-studied compensated BDI-CDI mode falls into a similar category to NVI: it is an interesting theoretical setup, but a compelling early-Universe model for stimulating this mode has still to be discovered.

Nevertheless, the baseline *Planck* `Plik` TT,TE,EE+lowE plus conservative lensing result, $\Delta^2_{\rm rms} = 0.0037^{+0.0016}_{-0.0021}$, is fully compatible with current complementary observations, in particular, the WMAP 95 % CL trispectrum constraint, $\Delta^2_{\rm rms} \lesssim 0.012$ [117], and the upper bound, $\Delta^2_{\rm rms} \lesssim 0.006$, following from the direct measurements of the variation of the baryon fraction in galaxy clusters [138, 117]. It will be interesting to learn what other future CMB anisotropy [1, 357, 93] and complementary measurements, such as observations of the distribution of neutral hydrogen using 21 cm absorption lines [110], BAO [256, 257], or CMB spectral distortion anisotropies [122], will tell us about the possible contribution of CIP to the primordial perturbations.

28.10 Constraints on anisotropic models of inflation

In this section we will test specific physical models for statistical anisotropy in the primordial fluctuations. More phenomenological multipole- or map-space tests are performed in the companion paper, Planck Collaboration VII [236]. Here we update the results of the 2015 release [**(alias?)**] with polarization and new temperature analyses. Incorporating polarization into these tests is particularly important, due to the mild statistical significance of temperature anomalies such as the dipolar asymmetry. Polarization offers the potential to confirm or refute a physical origin for such anomalies via the measurement of independent fluctuation modes. We perform such a new test with k-space dipolar modulation models. In cases such as quadrupolar asymmetry, where no detection has been claimed with temperature, polarization offers the prospect of tightening existing constraints.

Some asymmetry models predict a modification to the *isotropic* power spectra, in addition to a dipolar or quadrupolar asymmetry. In other words, for these models, as well as non-zero *off-diagonal* multipole covariance elements, we expect departures in the *diagonal* elements relative to the standard ΛCDM prediction. Therefore the isotropic spectra can provide independent tests of such models even using temperature data alone [64]. The curvaton dipole modulation model we examine in Sect. 28.10.1 exhibits this property, and can be constrained via its predictions for isotropic isocurvature power. Similarly, some versions of the quadrupolar modulation model we study in Sect. 28.10.2 modify the isotropic spectra via a monopole term. In both cases these isotropic constraints will be important in narrowing the viable parameter space.

28.10.1 Dipolar asymmetry

A dipolar temperature power asymmetry has long been observed at the largest scales in the CMB [81], although its statistical significance is not high and is subject to a posteriori (look-elsewhere) corrections [32, 220, 226]. Nevertheless, its large-scale character suggests potential links with inflationary physics and various models have been proposed to explain it. In this subsection we examine several physical models for a dipolar modulation. Some models where a generic CDM density isocurvature (CDI) or tensor component is dipole modulated have already been ruled out due to their isotropic predictions [64], so we do not consider these further here.

Curvaton model

First we update our 2015 study [**(alias?)**] of a specific inflationary model for the dipolar asymmetry: namely, the modulated curvaton model of Erickcek et al. [80]. In that study we showed that that model could not explain the observed asymmetry. Here, we generalize the curvaton model to allow for a non-scale-invariant uncorrelated CDI component. In addition, we treat the power spectrum (isotropic) constraints in a fully unified way with the asymmetry likelihood. Finally, we incorporate polarization.

The modulated curvaton model employs a gradient in a background curvaton field to explain the observed large-scale power asymmetry. The curvaton, via coupling κ, produces nearly scale-invariant CDI fluctuations, as well as a fraction, ξ, of the adiabatic fluctuations. Both of these components will be modulated. Up to a sign, ξ is equal to the correlation parameter, and is also

a measure of the amplitude of dipolar modulation. The isocurvature fraction can be written in terms of these two parameters as

$$\beta_{\rm iso} = \frac{9\kappa^2\xi}{1+9\kappa^2\xi}. \tag{1334}$$

Full details of this model and our treatment of it can be found in Erickcek et al. [80] and **(alias?)**.

Using the dipolar asymmetry estimator from **(alias?)** we find the posteriors for the dipolar modulation parameters κ and ξ; the results are presented in Fig. 239 (red contours). We see that a substantial amount of asymmetry (as measured by amplitude ξ) can be captured by the model. This preference for asymmetry simply means that the curvaton model can explain the well-known dipolar asymmetry in temperature. However, isocurvature constraints from the power spectra via Eq. (1334), which we refer to as the *isotropic* constraints, can provide independent information [64]. This is also shown in Fig. 239, with the blue contours. Here we see that the asymmetry and isotropic posteriors only weakly overlap, and the independent isotropic data do not support the presence of asymmetry for this model. No evidence for asymmetry (i.e., no preference for $\xi > 0$) is present in the joint constraints, which treat the isotropic and asymmetry data as independent. In other words, we have no reason to prefer this model over base ΛCDM.

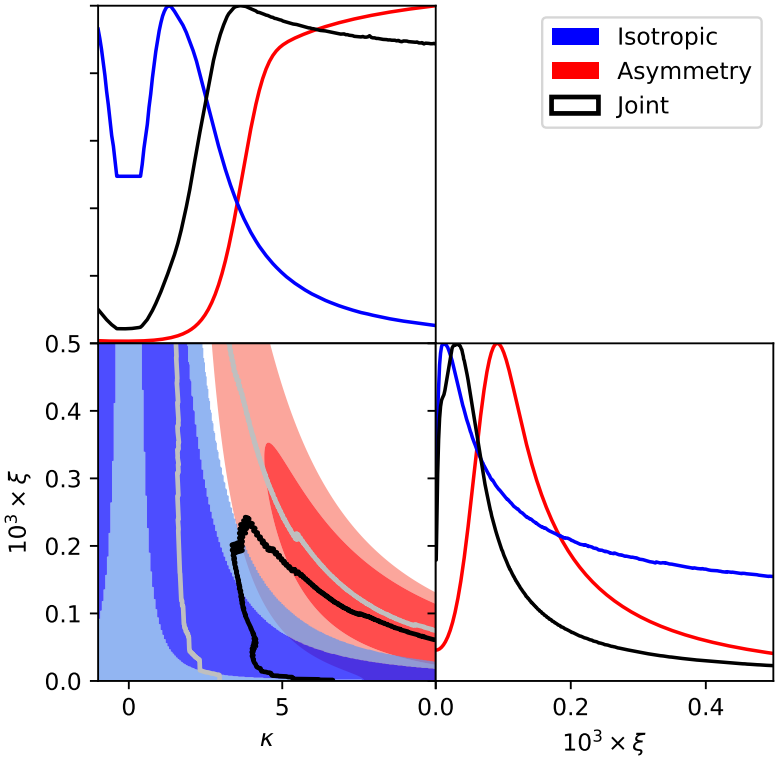

Figure 239: Posteriors for the curvaton dipolar modulation model parameters κ and ξ. Contours enclose 68 % and 95 % of the posteriors. The model can explain the well-known dipolar asymmetry: note the preference for $\xi > 0$ in the asymmetry constraint (red contours and curves). However, the modulation preferred by the asymmetry constraint is reduced substantially when the isotropic constraint (blue) is added (black). The asymmetry constraint here uses `SMICA`, while the isotropic constraint uses *Planck* TT,TE,EE+lowE+lensing. Resolution is reduced at very small κ due to the sampling in $\beta_{\rm iso}$.

Adiabatic models

In the presence of a sufficiently large bispectrum it is possible that a long-wavelength mode can induce a dipolar asymmetry in the two-point function across our observable volume, although such scenarios appear to require fine tuning [51]. Nevertheless, examples have been constructed which satisfy the *Planck* $f_{\rm NL}$ constraints [50]. In this subsection we consider adiabatic

models of this type, in which the isotropic power spectra agree with standard ΛCDM, while a scale-dependent dipolar asymmetry is present in the off-diagonal multipole covariance [65, 64]. As proposed in Contreras et al. [65], we fit the asymmetry model parameters to the temperature data and then use those parameters to predict the asymmetry in polarization. We then compare those predictions with the *Planck* polarization data as a test for a physical modulation. Importantly, a position- (or k-) space model for the modulation is needed for reliable polarization predictions—it is not enough to restrict considerations to multipole space [65].[180]

As discussed in detail in Contreras et al. [65], we take a portion $\widetilde{\mathcal{R}}^{\rm lo}(x)$ of the adiabatic primordial fluctuations to be spatially linearly modulated according to

$$\widetilde{\mathcal{R}}^{\rm lo}(\vec{x}) = \mathcal{R}^{\rm lo}(\vec{x})\left(1 + A\frac{\vec{x}\cdot\hat{\vec{d}}}{r_{\rm LS}}\right), \tag{1335}$$

where $\mathcal{R}^{\rm lo}(\vec{x})$ is statistically isotropic with power spectrum $\mathcal{P}^{\rm lo}_{\mathcal{R}}(k)$, $A \leq 1$ and $\hat{\vec{d}}$ are the amplitude and direction of modulation, respectively, and $r_{\rm LS}$ is the comoving radius to last scattering. This leads, to a good approximation, to the total temperature or polarization multipole covariance

$$C_{\ell m\ell' m'} \equiv \langle a_{\ell m} a^*_{\ell' m'}\rangle \tag{1336}$$

$$= C_\ell \delta_{\ell\ell'}\delta_{mm'} + \frac{\delta C_{\ell\ell'}}{2}\sum_M \Delta X_M \xi^M_{\ell m\ell' m'}, \tag{1337}$$

to first order in A. Here C_ℓ is the usual ΛCDM anisotropy power spectrum; $\delta C_{\ell\ell'} \equiv 2(C^{\rm lo}_\ell + C^{\rm lo}_{\ell'})$, where $C^{\rm lo}_\ell$ is the power spectrum calculated in the usual way from $\mathcal{P}^{\rm lo}_{\mathcal{R}}(k)$; ΔX_M is the multipole decomposition of $A\hat{\vec{n}}\cdot\hat{\vec{d}}$; and the $\xi^M_{\ell m\ell' m'}$ coefficients couple ℓ to $\ell \pm 1$ via

$$\xi^M_{\ell m\ell' m'} \equiv \sqrt{\frac{4\pi}{3}}\int Y_{\ell' m'}(\hat{\vec{n}}) Y_{1M}(\hat{\vec{n}}) Y^*_{\ell m}(\hat{\vec{n}}) d\Omega. \tag{1338}$$

In principle the scale dependence of the asymmetry spectrum $\mathcal{P}^{\rm lo}_{\mathcal{R}}(k)$ is completely free, but here we take three phenomenological forms which are capable of producing a large-scale asymmetry with a small number of parameters. First, we consider a simple power-law modulation,

$$\mathcal{P}^{\rm lo}_{\mathcal{R}}(k) = \mathcal{P}^0_{\mathcal{R}}\left(k^{\rm lo}_0\right)\left(\frac{k}{k^{\rm lo}_0}\right)^{n^{\rm lo}_{\rm s}-1}, \tag{1339}$$

where $\mathcal{P}^0_{\mathcal{R}}(k)$ is the usual ΛCDM spectrum, and $n^{\rm lo}_{\rm s}$ and $k^{\rm lo}_0$ are the tilt and pivot scale of the modulation. We consider only red asymmetry tilts with $n^{\rm lo}_{\rm s} \leq n_{\rm s}$, and choose $k^{\rm lo}_0 = 1.5 \times 10^{-4}\,{\rm Mpc}^{-1}$. We also consider a tanh model, defined according to

$$\mathcal{P}^{\rm lo}_{\mathcal{R}}(k) = \frac{1}{2}\mathcal{P}^0_{\mathcal{R}}(k)\left[1 - \tanh\left(\frac{\ln k - \ln k_{\rm c}}{\Delta\ln k}\right)\right]. \tag{1340}$$

This spectrum approaches that of ΛCDM on scales larger than $k_{\rm c}$, with a width determined by $\Delta\ln k$. That is, scales well above the cutoff $k_{\rm c}$ will be modulated with amplitude A, and scales below will be unmodulated. Finally, we consider a model with a linear gradient in the scalar tilt, $n_{\rm s}$, across our volume. In this case the asymmetry spectrum can be written as

$$C^{\rm lo}_\ell = -\frac{\Delta n_{\rm s}}{2}\frac{dC_\ell}{dn_{\rm s}}, \tag{1341}$$

with modulation amplitude $\Delta n_{\rm s}$. There will be an implicit dependence on the pivot scale k_* for this model.

[180] E.g., if we observe a dipolar modulation in T at, say, 5 % to $\ell = 65$, there is no reason to expect a modulation of the same amplitude and to the same scale in E, due to the different T and E transfer functions [65].

Given the multipole covariance, Eq. (1337), we can construct a maximum likelihood estimator for the modulation, ΔX_M. In the noise-free, full-sky case this takes the form [202, 226]

$$\Delta\hat{X}_M = \frac{1}{4}\sigma_X^2 \sum_{\ell m \ell' m'} \frac{\delta C_{\ell\ell'}}{C_\ell C_{\ell'}} \xi^M_{\ell m \ell' m'} a^*_{\ell m} a_{\ell' m'}, \tag{1342}$$

where the cosmic variance of the estimator is given by

$$\sigma_X^2 = 12 \left(\sum_\ell (\ell+1) \frac{\delta C^2_{\ell\ell+1}}{C_\ell C_{\ell+1}} \right)^{-1}. \tag{1343}$$

The modifications we use to deal with realistic skies are described in detail in Planck Collaboration XVI [226] and Contreras et al. [65].

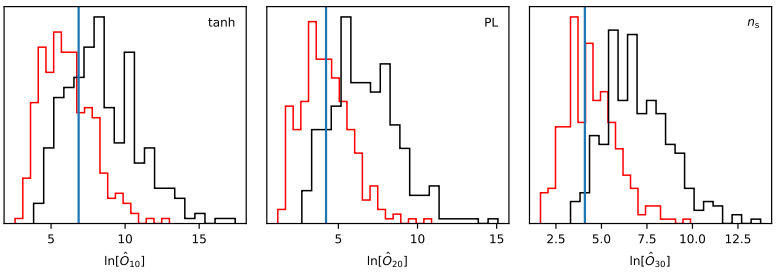

Figure 240: Histograms of the quantity $\hat{O}_{j0}$ for the tanh, power-law, and n_s gradient modulation models using *Planck* temperature data combined with 300 statistically isotropic polarization simulations (red outlines) or 300 polarization simulations modulated according to the best-fit parameters from the temperature data (black). The blue lines indicate the values for the actual SMICA polarization data. A large value relative to the isotropic (red) simulations would indicate that the modulation model is preferred over ΛCDM.

To decide whether the polarization data support the modulation model or not, we consider the quantity $\hat{O}_{j0}$, which is the ratio of the maximum likelihood for modulation model j to that of ΛCDM [65]. In Fig. 240 we plot for the three adiabatic models histograms of $\hat{O}_{j0}$ calculated for 300 statistically isotropic polarization simulations (sharing the required TE correlation with the real T data) added to the *Planck* temperature data (red outlines). This indicates our expectation for $\hat{O}_{j0}$ for the scenario that the temperature asymmetry is due to a statistical fluctuation and not to a physical modulation. We also plot in Fig. 240 histograms for 300 polarization simulations modulated with the best-fit parameters from the *Planck* temperature data (black outlines), to represent the scenario that the asymmetry is due to a physical modulation. In both cases the polarization simulations contain realistic levels of noise for *Planck*. By comparing the isotropic and modulated histograms, we can see that the quantity $\hat{O}_{j0}$ can serve to distinguish the two scenarios, but only relatively weakly for *Planck* noise [65]. The blue lines indicate the values using the actual SMICA polarization data (the results for the other component-separation methods are similar). We see that for these models the data do not help to decide whether we have a physical modulation or not, with p-values of 43 %, 30 %, and 57 % for the power-law, tanh, and n_s gradient models, respectively, relative to the isotropic simulations.

28.10.2 Quadrupolar asymmetry

We will next explore models that predict a quadrupolar direction dependence in the primordial power spectrum. In **(alias?)** we found no evidence for such a modulation, but several inflationary models have been constructed which predict this effect [6, 255, 271]. Therefore it is important to extend those results with the improved polarization data. We now attempt to reduce the effect of unresolved point sources using the bias-hardened estimator approach of

Planck Collaboration XV [286]. In **(alias?)** we pointed out that some models of quadrupolar asymmetry predict a modification to the angular power spectra as well. Here we will account for such modifications in our analysis, increasing the constraining power of temperature data, in particular for tilted models with non-scale-invariant modulation spectral index. Note that independent searches relaxing our approximation of power-law spectra have also been carried out [68].

We assume a modulation of the primordial comoving curvature power spectrum of the form

$$\mathcal{P}_{\mathcal{R}}(\vec{k}) = \mathcal{P}^0_{\mathcal{R}}(k)\left[1 + g(k)\left(\hat{\vec{k}}\cdot\hat{\vec{d}}\right)^2\right], \tag{1344}$$

which can be rewritten as

$$\mathcal{P}_{\mathcal{R}}(\vec{k}) = \mathcal{P}^0_{\mathcal{R}}(k)\left[1 + \frac{1}{3}g(k) + \sum_m g_{2m}(k)\,Y_{2m}(\hat{\vec{k}})\right]. \tag{1345}$$

Here

$$g_{2m}(k) \equiv \frac{8\pi}{15}g(k)\,Y^*_{2m}(\hat{\vec{d}}), \tag{1346}$$

with $g_{2m}(k)$ satisfying $g_{2,-m}(k) = (-1)^m\, g^*_{2m}(k)$. We parameterize the scale dependence of the modulation as $g(k) = g_*(k/k_*)^q$, with pivot scale $k_* = 0.05\,\mathrm{Mpc}^{-1}$. For $q \neq 0$, in addition to producing a quadrupolar modulation of the anisotropies, this model affects the CMB isotropic power spectra via the term $g(k)/3$ in Eq. (1345). We therefore consider a joint constraint with the isotropic power spectra likelihood to improve constraints over the modulation alone.

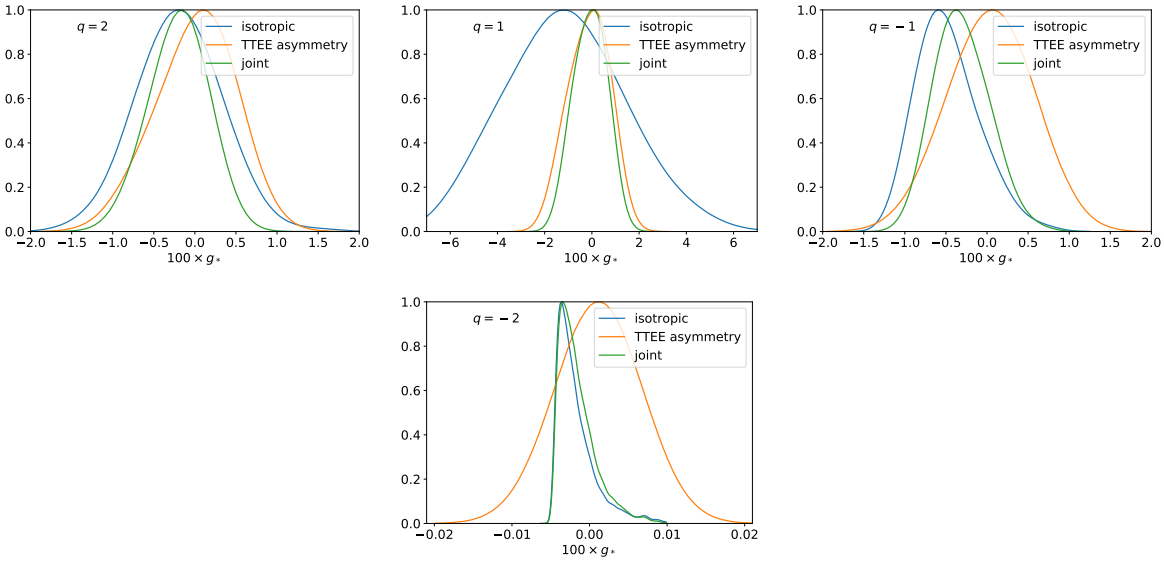

Figure 241: Marginalized posteriors for quadrupolar modulation parameter g_*, using `SMICA` data for the TT+EE asymmetry constraints (orange curves) and *Planck* TT,TE,EE+lowE for the isotropic constraints (blue curves), which probe the modification to the power spectrum via Eq. (1345). *Top:* constraints for $q = 2$ and 1 (left and right, respectively). *Bottom:* constraints for $q = -1$ and -2 (left and right, respectively). Strongly negative g_* is suppressed for $q < 0$, due to the unphysical prediction of negative power.

As in **(alias?)**, we obtain constraints on the modulation parameters by forming quadratic maximum-likelihood estimates, $\hat{g}_{2m}$, for the data and simulations. For this we use the component-separated data and 300 simulations provided by `NILC`, `SEVEM`, `SMICA`, and `COMMANDER`. For brevity we only show the `SMICA` results. We can then compute a covariance G and likelihood as

$$\mathcal{L} \propto |G|^{-1/2}\exp\left[-\frac{1}{2}M^{\mathsf{T}}G^{-1}M\right],$$

Table 42: Minimum-χ^2 g_* values for quadrupolar modulation, determined from the SMICA foreground-cleaned maps. Also given are p values, defined as the fraction of isotropic simulations with larger $|g_*|$ than the data. The TT results use $\ell_{\rm min} = 2$ and $\ell_{\rm max} = 1200$, while EE uses $\ell_{\rm min} = 2$ and $\ell_{\rm max} = 850$. These results indicate that the data are consistent with cosmic variance in statistically isotropic skies.

	TT		EE		$TT+EE$	
q	g_*	p value [%]	g_*	p value [%]	g_*	p value [%]
-2	-6.83×10^{-5}	75.7	1.23×10^{-4}	54.7	-6.90×10^{-5}	75.0
-1	-8.56×10^{-3}	64.7	1.44×10^{-2}	30.0	-6.15×10^{-3}	86.0
0	1.08×10^{-2}	82.7	3.17×10^{-2}	55.3	1.07×10^{-2}	83.0
1	7.77×10^{-3}	82.7	5.09×10^{-2}	24.0	7.75×10^{-3}	82.3
2	4.92×10^{-3}	78.3	5.62×10^{-2}	17.0	4.92×10^{-3}	78.7

Table 43: As for Table 42, but for the quantity $g_2 \equiv \sqrt{\sum_m |g_{2m}|^2/5}$ for a completely general quadrupolar modulation.

	TT		EE		$TT+EE$	
q	g_2	p value [%]	g_2	p value [%]	g_2	p value [%]
-2	3.30×10^{-5}	82.3	9.00×10^{-5}	27.0	3.32×10^{-5}	81.0
-1	4.34×10^{-3}	66.0	6.81×10^{-3}	40.0	3.24×10^{-3}	87.0
0	7.65×10^{-3}	51.7	1.79×10^{-2}	45.7	7.62×10^{-3}	51.7
1	5.39×10^{-3}	58.0	2.95×10^{-2}	12.7	5.38×10^{-3}	58.3
2	3.15×10^{-3}	58.7	3.39×10^{-2}	16.0	3.15×10^{-3}	58.7

where

$$M \equiv \hat{g}_{2m} - g_{2m}(g_*, \vec{\hat{d}}). \tag{1347}$$

We then evaluate the marginalized (over the angles) posterior for g_*. For the isotropic constraints we simply include the modulation parameters in a CosmoMC run using *Planck* TT,TE,EE+lowE data, and then evaluate the marginalized (over all other ΛCDM parameters) posterior for g_*.

For $q > 0$ the effect of g_* on the isotropic spectra occurs mainly at high ℓ, and is highly degenerate with $n_{\rm s}$. This degeneracy leads to slightly less stringent constraints than what one would achieve with a fixed $n_{\rm s}$. We show the marginalized posteriors for this case in the top panels of Fig. 241, where we see that the isotropic constraints are roughly comparable in strength to (and fully consistent with) the constraints from the asymmetry data.

For $q < 0$ the isotropic constraints are much more constraining than the modulation constraints, as seen in the bottom panels of Fig. 241. This is because for large scales the factor k_*/k can become large and a negative g_* will decrease isotropic power on those scales, which is compensated for by increasing $A_{\rm s}$ and τ. Strongly negative g_* values are disallowed by predicting unphysical negative power spectra at low ℓ. Note that even the parameter ranges in which the power spectra are reduced to close to zero are likely beyond the perturbative regime for the models in question, and so should be approached with caution. The isotropic constraints still prefer a slightly negative g_*, likely due to being able to fit the power deficit at large scales. The joint constraint in this case is then greatly improved by the isotropic data.

Minimum-χ^2 and p values (relative to isotropic simulations) for g_* are presented in Table 42. The addition of polarization does not affect the temperature results greatly.

Finally, when allowing the completely general form of quadrupolar modulation, i.e.,

$$\mathcal{P}_{\mathcal{R}}(\vec{k}) = \mathcal{P}^0_{\mathcal{R}}(k)\left[1 + \sum_m g_{2m}\,(k/k_*)^q\; Y_{2m}(\vec{\hat{k}})\right], \tag{1348}$$

with no restriction on the g_{2m}, we present results for the quantity $g_2 \equiv \sqrt{\sum_m |g_{2m}|^2/5}$ in Table 43. In all cases there is no significant detection of quadrupolar modulation, as quantified by the p values.

28.11 Conclusions

This paper summarizes the status of cosmic inflation in light of the *Planck* 2018 release. The main improvements are in the *Planck* polarization likelihoods. The 2018 release now includes a low-ℓ HFI polarization likelihood based on the 100- and 143-GHz channels. This likelihood is now the baseline, whereas the *Planck* 2015 likelihood was based only on the LFI 70-GHz channel data, which also have been updated in this release. Corrections for beam-leakage effects, which had been flagged in the 2015 release as the main limitation of the TE and EE data at that time, have improved the accuracy of the high-ℓ polarization likelihoods. Our analyses focus on the results obtained using the *Planck* baseline likelihoods alone, but results supplemented by the BK15 likelihood (when tensors are included) and a compilation of BAO likelihoods are also given in order to help break cosmological parameter degeneracies. We summarize the main results of this paper in the form of responses to a number of key questions.

1. *What is the value of the scalar tilt?*

   Using a characterization of polarization anisotropy better at all multipoles in this release, we find that $n_{\rm s} = 0.9649 \pm 0.0042$ at 68 % CL, including the full information provided by *Planck* (TT,TE,EE+lowE+lensing). The 2018 uncertainty is approximately 2/3 of that obtained with the *Planck* 2015 baseline likelihood. Importantly, this determination rules out perfect scale invariance (i.e., $n_{\rm s} = 1$) at 8.4σ. From an inflationary perspective, this result is consistent with slow-roll inflation evolving towards a natural exit.

2. *Does $n_{\rm s}$ depend on the wavelength?*

   We investigated the possibility of a running spectral index, as well as a running of the running [i.e., the next two (subleading) terms in a power series expansion of $\ln(\mathcal{P}_{\mathcal{R}})$ in $\ln(k)$], corresponding to non-negligible third- and fourth-order derivatives of the inflationary potential. Starting with its first 2013 cosmological release, *Planck* has removed any hint of a running spectral index, which had been suggested by pre-*Planck* data and would have pointed to inflationary models beyond the slow-roll approximation. *Planck* 2018 sets $dn_{\rm s}/d\ln k = -0.005 \pm 0.013$ as the tightest 95 % CL constraint, when $d^2n_{\rm s}/d\ln k^2 = 0$. No hints of further extensions, such as running of the running, are found with *Planck* 2018 data. These results are consistent with the simplest slow-roll dynamics for the inflaton. A detection of running at the level predicted by slow-roll models will require a combination of future ambitious CMB anisotropy experiments and galaxy surveys.

3. *Is the Universe spatially flat?*

   Most simple models of inflation predict a spatially flat universe, although inflationary models with a minimum degree of fine tuning producing a hyperbolic universe have been constructed. *Planck* has been the first experiment to constrain the spatial curvature at the percent level without any external information, thanks to the CMB lensing likelihood. Although negative values of $\Omega_K \sim -0.01$ provide a non-statistically significant improvement to the fit of *Planck* temperature and polarization data (compared to the minimal ΛCDM model), *Planck* 2018 data including lensing constrain $\Omega_K = -0.011^{+0.013}_{-0.012}$ at 95 % CL. Combining with BAO data further tightens the uncertainty, constraining Ω_K to lie within 0.4 % of a flat spatial geometry (at 95 % CL).

4. *Are tensor modes required?*

   Inflationary models predict that tensor modes were also excited during the nearly exponential expansion, with a power spectrum amplitude proportional to the energy scale of inflation. Using the measurement of CMB temperature and E-mode polarization anisotropies from the quadrupole into the acoustic peak region, *Planck* has reduced the degeneracy between the tensor-to-scalar ratio r and $n_{\rm s}$, establishing the bound $r_{0.002} < 0.10$ at 95 % CL, assuming $n_{\rm t} = -r/8$ as predicted by the simplest inflationary models. When the *Planck* likelihood is combined with the B-mode polarization likelihood of the BICEP2-Keck Array experiment, a tight 95 % CL upper limit of $r_{0.002} < 0.056$ is obtained, corresponding to a 95 % CL bound on the energy scale of inflation of $V_*^{1/4} < 1.6 \times 10^{16}$ GeV. *Planck* 2018 and BK15 data also set tight bounds on gravitational waves generated in the early Universe when r and $n_{\rm t}$ are varied independently, complementary to the results obtained by the direct-detection interferometers LIGO and VIRGO at much higher frequencies.

5. *Which inflationary models are best able to account for the data?*

   Starting with the 2013 release using only a part of the data, *Planck* has substantially tightened the constraints on slow-roll inflationary models, ruling out hybrid models with $n_s > 1$ and power-law inflation [**(alias?)**]. In combination with the BK15 data, *Planck* 2018 now strongly disfavours monomial models with $V(\phi) \propto \phi^p$ and $p > 1$, natural inflation, and low-scale SUSY models. Within the representative cases studied in this paper, inflationary models such as R^2, T and E α-attractor models, D-brane inflation, and those having a potential with exponential tails provide good fits to *Planck* and BK15 data. We used two methods to reconstruct the inflaton potential beyond the slow-roll approximation: by Taylor expanding the inflaton potential or Hubble parameter in the observable region; and through a free-form reconstruction of the potential with cubic splines. No statistically significant detection beyond the second derivative of the potential was found, suggesting that the slow-roll approximation is adequate for the *Planck* 2018 likelihood in combination with the BK15 data.

6. *What model-independent constraints can be placed on the primordial power spectrum?*

   We reported on three different methods for the non-parametric reconstruction of the primordial power spectrum (penalized likelihood, a Bayesian spline reconstruction. and a method based on cubic splines). All three methods give broadly consistent results. In no case is any statistically significant evidence for a deviation from a pure power law found. The constraints on the deviations are at the few-percent level for wavenumbers in the range $0.005\,\mathrm{Mpc}^{-1} \lesssim k \lesssim 0.2\,\mathrm{Mpc}^{-1}$ probed by the CMB, the precise constraint depending on the level of smoothing allowed.

7. *Is there evidence for features in the primordial power spectrum?*

   We explored several classes of theoretically motivated parametric models with strong departures from a power law for the primordial power spectra and tested their predictions using combinations of *Planck* temperature and polarization power spectra. We also carried out an analysis using bispectrum data as well. No statistically significant evidence for features was found.

8. *Were the primordial cosmological perturbations solely adiabatic?*

   A key question is whether the primordial cosmological fluctuations consisted exclusively of adiabatic growing-mode perturbations or whether isocurvature perturbations, possibly correlated with the adiabatic mode and with each other, were also excited. The new polarization data has helped to sharpen constraints on the allowed isocurvature fraction compared to the *Planck* 2015 results. In correlated mixed adiabatic and isocurvature models, the 95 % CL upper bound for the non-adiabatic contribution to the observed CMB temperature variance is $|\alpha_{\text{non-adi}}| < 1.3\,\%$, $1.7\,\%$, and $1.7\,\%$ for CDM, neutrino density, and neutrino velocity isocurvature, respectively. For this release we also report constraints on a scale-invariant compensated baryon-CDM isocurvature mode, which is uncorrelated with the adiabatic mode. This mode would cause an additional lensing-like smoothing at high ℓ and modify the lensing potential at $\ell \lesssim 40$. By using the temperature, polarization, and lensing data, we obtain the constraint $\Delta^2_{\text{rms}} = 0.0037^{+0.0016}_{-0.0021}$ at 68 % CL for the variance of the baryon isocurvature density perturbation. A detection of isocurvature modes would suggest the need for a theory beyond single-field inflation, which is able to excite only one mode.

9. *Were the primordial fluctuations statistically isotropic?*

   The *Planck* analysis has confirmed evidence at low statistical significance of anomalies in the CMB temperature anisotropies on large angular scales that are not alleviated in models with nontrivial topology or an anisotropic expansion [228]. This motivates an exploration of inflation-based models giving such violation of statistical isotropy. We have found no statistically significant evidence in favour of a curvaton model for dipolar asymmetry (compared to the base-ΛCDM model), nor any evidence for a quadrupolar asymmetry in the temperature or polarization anistropies. Theoretical models producing the observed temperature dipolar asymmetry make a prediction for the polarization dipolar asymmetry. We tested whether the fit to the temperature dipolar asymmetry gives a prediction for the polarization asymmetry consistent with the data. We found

no statistically significant evidence that the pattern seen in temperature is repeated in polarization. However, the discriminating power of this test is weak, due to the low polarization signal-to-noise ratio on large angular scales.

The *Planck* 2013, 2015, and 2018 releases have substantially improved the constraints on the space of inflationary models, as described above. Future CMB polarization data will be crucial for further constraining those inflationary models that currently provide an adequate fit to *Planck* and other data. Forthcoming E-mode polarization data will be decisive for determining whether the intriguing features in the temperature power spectrum, such as the deficit at $\ell \simeq 20$–30, the smaller average amplitude at $\ell \lesssim 40$, and other anomalies at higher multipoles require new physics or whether these features are simply the result of statistical fluctuations plus instrumental noise. Improved measurements of the B modes promise to constrain inflation even more tightly and it will be interesting to see how the search for B modes evolves. One possibility would be a convincing detection of inflationary gravitational waves, but a tighter upper limit of $r \lesssim 10^{-3}$ is also an achievable outcome. Either case would substantially advance our understanding of inflation and the constraints on the physics of the very early Universe.

Part VIII
Consequences of High Energy Physics on Cosmology

29 Inflation in String Theory by Baumann's 5th lecture

Abstract

We end this lecture series with a discussion of a slightly more advanced topic: inflation in string theory. We provide a pedagogical overview of the subject based on a recent review article with Liam McAllister [16]. The central theme of the lecture is the sensitivity of inflation to Planck-scale physics, which we argue provides both the primary motivation and the central theoretical challenge for realizing inflation in string theory. We illustrate these issues through two case studies of inflationary scenarios in string theory: warped D-brane inflation and axion monodromy inflation. Finally, we indicate opportunities for future progress both theoretically and observationally.

29.1 Why Combine Two Speculative Ideas?

In the previous lectures we have seen that inflation is remarkably successful as a phenomenological model for the dynamics of the very early universe. However, a detailed understanding of the physical origin of the inflationary expansion has remained elusive. Inflation and string theory are both ambitious attempts to understand the physical universe at the highest energies. Both inflation and string theory are speculative theories that still await experimental confirmation. One may therefore wonder why it is timely to address the problem of inflation in string theory.

In this lecture we will highlight specific aspects of inflation that depend sensitively on the ultraviolet (UV) completion of quantum field theory and gravity, *i.e.* on the field content and interactions at energies approaching the Planck scale. Such issues are most naturally addressed in a theory of Planck-scale physics, for which string theory is arguably the best-developed candidate. This motivates understanding the physics of inflation in string theory.

Readers less interested in the details of the string theory constructions in §29.3 might still find the generic effective field theory arguments in §29.2 informative.

29.2 UV Sensitivity of Inflation

29.2.1 Effective Field Theory and Inflation

As a phenomenon in Quantum Field Theory coupled to General Relativity, inflation does not appear to be natural. In particular, the set of Lagrangians suitable for inflation is a minute subset of the set of all possible Lagrangians. Moreover, in wide classes of models, inflation emerges only for rather special initial conditions, *e.g.* initial configurations with tiny kinetic energy, in the case of small-field scenarios. Although one would hope to explore and quantify the naturalness both of inflationary Lagrangians and of inflationary initial conditions, the question of initial conditions appears inextricable from the active yet incomplete program of understanding measures in eternal inflation (see §7.7.2 for a critical evaluation). In this lecture we will focus on the question of how (un)natural it is to have a Lagrangian suitable for inflation.

For a single inflaton field with a canonical kinetic term, the necessary conditions for inflation can be stated in terms of the inflaton potential (see **Lecture 1**). Inflation requires a potential that is quite flat in Planck units

$$\epsilon_{\rm v} = M_{\rm pl}^2 \left(\frac{V_{,\phi}}{V}\right)^2 \ll 1\,, \qquad \eta_{\rm v} = \frac{M_{\rm pl}^2}{2}\frac{V_{,\phi\phi}}{V} \ll 1\,. \tag{1349}$$

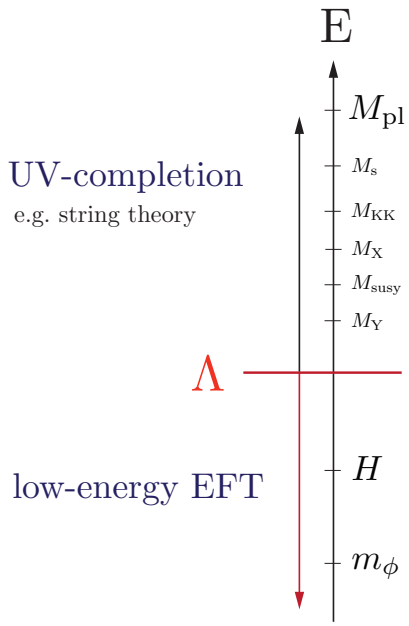

Figure 242: The Effective Field Theory (EFT) of Inflation. The cut-off Λ of the EFT is defined by the mass of the lightest particle that is not included in the spectrum of the low-energy theory. Particles with masses above the cut-off are integrated out, correcting the Lagrangian for the light fields such as the inflaton.

As we now argue, this condition is sensitive to Planck-scale physics.

Let us recall that the presence of some form of new physics at the Planck scale is required in order to render graviton-graviton scattering sensible, just as unitarity of W-W scattering requires new physics at the TeV scale. Although we know that new degrees of freedom must emerge, we cannot say whether the physics of the Planck scale is a finite theory of quantum gravity, such as string theory, or is instead simply an effective theory for some unimagined physics at yet higher scales. However, the structure of the Planck-scale theory has meaningful – and, in very favorable cases, testable – consequences for the form of the inflaton potential.

As usual, the effects of high-scale physics above some cutoff Λ are efficiently described by the coefficients of operators in the low-energy effective theory (see Fig. 242). Integrating out particles of mass $M \geq \Lambda$ gives rise to operators of the form

$$\boxed{\frac{\mathcal{O}_\delta}{M^{\delta-4}}}\,, \tag{1350}$$

where δ denotes the mass dimension of the operator.

Sensitivity to such operators is commonplace in particle physics: for example, bounds on flavor-changing processes place limits on physics above the TeV scale, and lower bounds on the proton lifetime even allow us to constrain GUT-scale operators that would mediate proton decay. However, particle physics considerations alone do not often reach beyond operators of dimension $\delta = 6$, nor go beyond $M \sim M_{\rm GUT}$. (Scenarios of gravity-mediated supersymmetry breaking are one exception.) Equivalently, Planck-scale processes, and operators of very high dimension, are irrelevant for most of particle physics: they decouple from low-energy phenomena.

In inflation, however, the flatness of the potential in Planck units introduces sensitivity to $\delta \leq 6$ *Planck-suppressed* operators, such as

$$\frac{\mathcal{O}_6}{M_{\rm pl}^2}\,. \tag{1351}$$

An understanding of such operators is required to address the smallness of the eta parameter, *i.e.* to ensure that the theory supports at least 60 e-folds of inflationary expansion. This sensitivity to dimension-six Planck-suppressed operators is therefore common to all models of inflation.

For large-field models of inflation the UV sensitivity of the inflaton action is dramatically enhanced. In this important class of inflationary models the potential becomes sensitive to an *infinite* series of operators of arbitrary dimension (see §29.2.3).

29.2.2 The Eta Problem

In the absence of any specific symmetries protecting the inflaton potential, contributions to the Lagrangian of the general form

$$\boxed{\frac{\mathcal{O}_6}{M_{\rm pl}^2} = \frac{\mathcal{O}_4}{M_{\rm pl}^2}\,\phi^2} \tag{1352}$$

are allowed. If the dimension-four operator $\mathcal{O}_4$ has a vacuum expectation value (vev) comparable to the inflationary energy density, $\langle \mathcal{O}_4 \rangle \sim V$, then this term corrects the inflaton mass by order H, or equivalently corrects the eta parameter by order one, leading to an important problem for inflationary model-building. Let us reiterate that contributions of this form may be thought of as arising from integrating out Planck-scale degrees of freedom. In this section we discuss this so-called *eta problem* first in effective field theory, §29.2.2, and then illustrate the problem in a supergravity example, §29.2.2.

Radiative Instability of the Inflaton Mass

In a generic effective theory with cutoff Λ (see Fig. 242), the mass of a scalar field runs to the cutoff scale unless it is protected by some symmetry. Since the cutoff for an effective theory of inflation is at least the Hubble scale, $\Lambda \geq H$, this implies that a small inflaton mass ($m_\phi \ll H$) is radiatively unstable. Equivalently, the eta parameter receives radiative corrections,

$$\Delta\eta_{\rm v} = \frac{\Delta m_\phi^2}{3H^2} \geq 1\,, \tag{1353}$$

preventing prolonged inflation.

The difficulty here is analogous to the Higgs hierarchy problem, but supersymmetry does not suffice to stabilize the inflaton mass: the inflationary energy necessarily breaks supersymmetry, and the resulting splittings in supermultiplets are of order H, so that supersymmetry does not protect a small inflaton mass $m_\phi \ll H$.

In §29.3.3 we discuss the natural proposal to protect the inflaton potential via a shift symmetry $\phi \to \phi + const.$, which is equivalent to identifying the inflaton with a pseudo-Nambu-Goldstone-boson. In the absence of such a symmetry the eta problem seems to imply the necessity of fine-tuning the inflationary action in order to get inflation.

Supergravity Example

An important instance of the eta problem arises in locally-supersymmetric theories, *i.e.* in supergravity [102]. This case is relevant for many string theory models of inflation because four-dimensional supergravity is the low-energy effective theory of supersymmetric string compactifications [103, 104].

In $\mathcal{N} = 1$ supergravity, a key term in the scalar potential is the F-term potential,

$$V_F = e^{K/M_{\rm pl}^2}\left[K^{\varphi\bar{\varphi}} D_\varphi W \overline{D_\varphi W} - \frac{3}{M_{\rm pl}^2}|W|^2\right], \tag{1354}$$

where $K(\varphi, \bar{\varphi})$ and $W(\varphi)$ are the Kähler potential and the superpotential, respectively; φ is a complex scalar field which is taken to be the inflaton; and we have defined $D_\varphi W \equiv \partial_\varphi W + M_{\rm pl}^{-2}(\partial_\varphi K)W$. For simplicity of presentation, we have assumed that there are no other light degrees of freedom, but generalizing our expressions to include other fields is straightforward.

The Kähler potential determines the inflaton kinetic term, $-K_{,\varphi\bar{\varphi}}\,\partial\varphi\partial\bar{\varphi}$, while the superpotential determines the interactions. To derive the inflaton mass, we expand K around

some chosen origin, which we denote by $\varphi \equiv 0$ without loss of generality, *i.e.* $K(\varphi, \bar{\varphi}) = K_0 + K_{,\varphi\bar{\varphi}}|_0\, \varphi\bar{\varphi} + \cdots$. The inflationary Lagrangian then becomes

$$\mathcal{L} \approx -K_{,\varphi\bar{\varphi}}\, \partial\varphi\partial\bar{\varphi} - V_0\Big(1 + K_{,\varphi\bar{\varphi}}|_0\, \frac{\varphi\bar{\varphi}}{M_{\rm pl}^2} + \dots\Big) \tag{1355}$$

$$\equiv -\partial\phi\partial\bar{\phi} - V_0\Big(1 + \frac{\phi\bar{\phi}}{M_{\rm pl}^2}\Big) + \dots\,, \tag{1356}$$

where we have defined the canonical inflaton field $\phi\bar{\phi} \approx K_{\varphi\bar{\varphi}}|_0\, \varphi\bar{\varphi}$ and $V_0 \equiv V_F|_{\varphi=0}$. We have retained the leading correction to the potential originating in the expansion of $e^{K/M_{\rm pl}^2}$ in Eqn. (1354), which could plausibly be called a universal correction in F-term scenarios. The omitted terms, some of which can be of the same order as the terms we keep, arise from expanding

$$\left[K^{\varphi\bar{\varphi}} D_\varphi W \overline{D_\varphi W} - \frac{3}{M_{\rm pl}^2}|W|^2\right] \tag{1357}$$

in Eqn. (1354) and clearly depend on the model-dependent structure of the Kähler potential and the superpotential.

The result is of the form of Eqn. (1351) with

$$\mathcal{O}_6 = V_0\, \phi\bar{\phi} \tag{1358}$$

and implies a large model-independent contribution to the eta parameter

$$\Delta\eta_{\rm v} = 1\,, \tag{1359}$$

as well as a model-dependent contribution which is typically of the same order. It is therefore clear that in an inflationary scenario driven by an F-term potential, eta will generically be of order unity.

Under what circumstances can inflation still occur, in a model based on a supersymmetric Lagrangian? One obvious possibility is that the model-dependent contributions to eta (1357) approximately cancel the model-independent contribution (1356), so that the smallness of the inflaton mass is a result of fine-tuning. In the case study of §29.3.2 we will provide a concrete example in which the structure of all relevant contributions to eta can be computed, so that one can sensibly pursue such a fine-tuning argument.

Clearly, it would be far more satisfying to exhibit a mechanism that *removes* the eta problem by ensuring that all corrections are small, $\Delta\eta_{\rm v} \ll 1$. This requires either that the F-term potential is negligible, or that the inflaton does not appear in the F-term potential. The first case does not often arise, because F-term potentials play an important role in presently-understood models for stabilization of the compact dimensions of string theory [105]. However, in §29.3.3 we will present a scenario in which the inflaton is an axion and does not appear in the Kähler potential, or in the F-term potential, to any order in perturbation theory. This evades the particular incarnation of the eta problem that we have described above.

29.2.3 The Lyth Bound

In **Lecture 2** we derived the Lyth bound [106]:

$$\frac{\Delta\phi}{M_{\rm pl}} \simeq \mathcal{O}(1)\left(\frac{r}{0.01}\right)^{1/2}\,, \tag{1360}$$

where r is the value of the tensor-to-scalar ratio on CMB scales. In any model with $r > 0.01$ one must therefore ensure that $\epsilon_{\rm v}, |\eta_{\rm v}| \ll 1$ over a super-Planckian range $\Delta\phi > M_{\rm pl}$. This result implies two necessary conditions for *large-field inflation*:

i) an obvious requirement is that large field ranges are *kinematically* allowed, *i.e.* that the scalar field space (in canonical units) has diameter $> M_{\rm pl}$. This is nontrivial, as in typical string compactifications many fields are not permitted such large excursions.

ii) the flatness of the inflaton potential needs to be controlled *dynamically* over a super-Planckian field range. We discuss this challenge in effective field theory in §29.2.4 and in string theory in §29.3.3.

29.2.4 Super-Planckian Fields and Flat Potentials

To begin, let us consider super-Planckian field excursions in the context of Wilsonian effective field theory.

No Shift Symmetry

In the absence of any special symmetries, the potential in large-field inflation becomes sensitive to an infinite series of Planck-suppressed operators. The physical interpretation of these terms is as follows: as the inflaton expectation value changes, any other fields χ to which the inflaton couples experience changes in mass, self-coupling, etc. In particular, any field coupled with at least gravitational strength to the inflaton experiences significant changes when the inflaton undergoes a super-Planckian excursion. These variations of the χ masses and couplings in turn feed back into changes of the inflaton potential and therefore threaten to spoil the delicate flatness required for inflation. Note that this applies not just to the light degrees of freedom, but even to fields with masses near the Planck scale: integrating out Planck-scale degrees of freedom generically (*i.e.*, for couplings of order unity) introduces Planck-suppressed operators in the effective action. For nearly all questions in particle physics, such operators are negligible, but in inflation they play an important role.

The particular operators which appear are determined, as always, by the symmetries of the low-energy action. As an example, imposing only the symmetry $\phi \to -\phi$ on the inflaton leads to the following effective action:

$$\boxed{\mathcal{L}_{\rm eff}(\phi) = -\frac{1}{2}(\partial\phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{1}{4}\lambda\phi^4 - \sum_{p=1}^{\infty}\left[\lambda_p\phi^4 + \nu_p(\partial\phi)^2\right]\left(\frac{\phi}{M_{\rm pl}}\right)^{2p} + \cdots}\,. \tag{1361}$$

Unless the UV theory enjoys further symmetries, one expects that the coefficients λ_p and ν_p are of order unity. Thus, whenever ϕ traverses a distance of order $M_{\rm pl}$ in a direction that is not protected by a suitably powerful symmetry, the effective Lagrangian receives substantial corrections from an infinite series of higher-dimension operators. In order to have inflation, the potential should of course be approximately flat over a super-Planckian range. If this is to arise by accident or by fine-tuning, it requires a conspiracy among infinitely many coefficients, which has been termed 'functional fine-tuning' (compare this to the eta problem which only requires tuning of one mass parameter).

Shift Symmetry

There is a sensible way to control this infinite series of corrections: one can invoke an approximate symmetry that forbids the inflaton from coupling to other fields in any way that would spoil the structure of the inflaton potential. Such a shift symmetry,

$$\phi \to \phi + const.\,, \tag{1362}$$

protects the inflaton potential in a natural way.

In the case with a shift symmetry, the action of chaotic inflation [171]

$$\mathcal{L}_{\rm eff}(\phi) = -\frac{1}{2}(\partial\phi)^2 - \lambda_p\,\phi^p\,, \tag{1363}$$

with small coefficient λ_p is 'technically natural'. However, because we require that this symmetry protects the inflaton even from couplings to Planck-scale degrees of freedom, it is essential that the symmetry should be approximately respected by the Planck-scale theory – in other words, the proposed symmetry of the low-energy effective action should admit a UV-completion. Hence, large-field inflation should be formulated in a theory that has access to information about approximate symmetries at the Planck scale. Let us remark that in effective field theory in general, UV-completion of an assumed low-energy symmetry is rarely an urgent question. The present situation is different because we do *not* know whether all reasonable effective actions can in fact arise as low-energy limits of string theory, and indeed it has been conjectured that many effective theories do not admit UV-completion in string theory [108, 1389, 110]. Therefore, it

is important to verify that any proposed symmetry of Planck-scale physics can be realized in string theory.

To construct an inflationary model with detectable gravitational waves, we are therefore interested in finding, in string theory, a configuration that has both a large kinematic range, and a potential protected by a shift symmetry that is approximately preserved by the full string theory.

29.3 Inflation in String Theory

29.3.1 From String Compactifications to the Inflaton Action

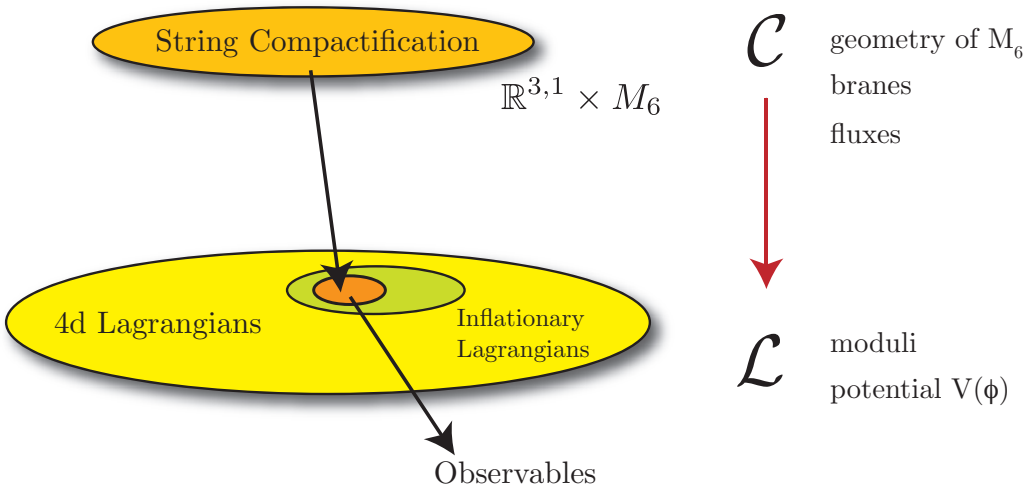

Figure 243: From 10d Compactification Data to 4d Action.

Elements of String Compactifications

It is a famous fact that the quantum theory of strings is naturally defined in more than four spacetime dimensions, with four-dimensional physics emerging upon compactification of the additional spatial dimensions. For concreteness, we will focus on compactifications of the critical ten-dimensional type IIB string theory on six-dimensional Calabi-Yau spaces.[181]

The vast number of distinct compactifications in this class are distinguished by their topology, geometry, and discrete data such as quantized fluxes and wrapped D-branes. A central task in string theory model-building is to understand in detail how the ten-dimensional sources determine the four-dimensional effective theory (see Fig. 243). If we denote the ten-dimensional compactification data by $\mathcal{C}$, the procedure in question may be written schematically as

$$\mathcal{S}_{10}[\mathcal{C}] \quad \rightarrow \quad \mathcal{S}_4\,. \tag{1364}$$

Distinct compactification data $\mathcal{C}$ give rise to a multitude of four-dimensional effective theories $\mathcal{S}_4$ with varied field content, kinetic terms, scalar potentials, and symmetry properties (this is the *landscape* of solutions to string theory). By understanding the space of possible data $\mathcal{C}$ and the nature of the map in Eqn. (1364), we can hope to identify, and perhaps even classify, compactifications that give rise to interesting four-dimensional physics.

The Effective Inflaton Action

For our purposes, the most important degrees of freedom of the effective theory are four-dimensional scalar fields. Scalar fields known as *moduli* arise from deformations of the compactification manifold, typically numbering in the hundreds for the Calabi-Yau spaces under

[181] Readers unfamiliar with this terminology may find a useful Stringlish-to-English dictionary in [111].

Figure 244: Elements of Flux Compactifications: Fluxes and Wrapped Branes.

consideration, and from the positions, orientations, and gauge field configurations of any D-branes. From given compactification data one can compute the kinetic terms and scalar potentials of the moduli; in turn, the expectation values of the moduli determine the parameters of the four-dimensional effective theory. In the presence of generic ten-dimensional sources of stress-energy, such as D-branes and quantized fluxes, there is an energy cost for deforming the compactification, and many (though not always all) of the moduli fields become massive [112].

It is useful to divide the scalar fields arising in $\mathcal{S}_4$ into a set of light fields ϕ, ψ with masses below the Hubble scale ($m_\phi, m_\psi \ll H$) and a set of heavy fields χ with masses much greater than the Hubble scale ($m_\chi \gg H$). Here one of the light fields, denoted ϕ, has been identified as the inflaton candidate.

To understand whether successful inflation can occur, one must understand all the scalar fields, both heavy and light. First, sufficiently massive moduli fields are effectively frozen during inflation, and one should integrate them out to obtain an effective action for the light fields only,

$$\mathcal{S}_4(\phi, \psi, \chi) \quad \rightarrow \quad \mathcal{S}_{4,\text{eff}}(\phi, \psi)\,. \tag{1365}$$

Integrating out these heavy modes generically induces contributions to the potential of the putative inflaton: that is, *moduli stabilization contributes to the eta problem.* This is completely analogous to the appearance of corrections from higher-dimension operators in our discussion of effective field theory in §29.2.1.

Next, if scalar fields in addition to the inflaton are light during inflation, they typically have important effects on the dynamics, and one should study the evolution of all fields ψ with masses $m_\psi \ll H$. Moreover, even if the resulting multi-field inflationary dynamics is suitable, light degrees of freedom can create problems for late-time cosmology. Light scalars absorb energy during inflation and, if they persist after inflation, they can release this energy during or after Big Bang nucleosynthesis, spoiling the successful predictions of the light element abundances. Moreover, light moduli would be problematic in the present universe, as they mediate fifth forces of gravitational strength. To avoid these late-time problems, it suffices to ensure that $m_\psi \gg 30$ TeV, as in this case the moduli decay before Big Bang nucleosynthesis. A simplifying assumption that is occasionally invoked is that all fields aside from the inflaton should have $m \gg H$, but this is not required on physical grounds: it serves only to arrange that the effective theory during inflation has only a single degree of freedom.

29.3.2 *Case Study:* Warped D-brane Inflation

In string theory models of inflation the operators contributing to the inflaton potential can be enumerated, and in principle even their coefficients can be computed in terms of given compactification data. To illustrate these issues, it is useful to examine a concrete model in detail. In the following we therefore present a case study of a comparatively well-understood model of small-field inflation, *warped D-brane inflation.*

D3-branes in Warped Throat Geometries

In this scenario inflation is driven by the motion of a D3-brane in a warped throat region of a stabilized compact space [46]. To preserve four-dimensional Lorentz (or de Sitter) invariance, the D3-brane fills our four-dimensional spacetime and is pointlike in the extra dimensions (see Figure 245). The global compactification is assumed to be a warped product of four-dimensional

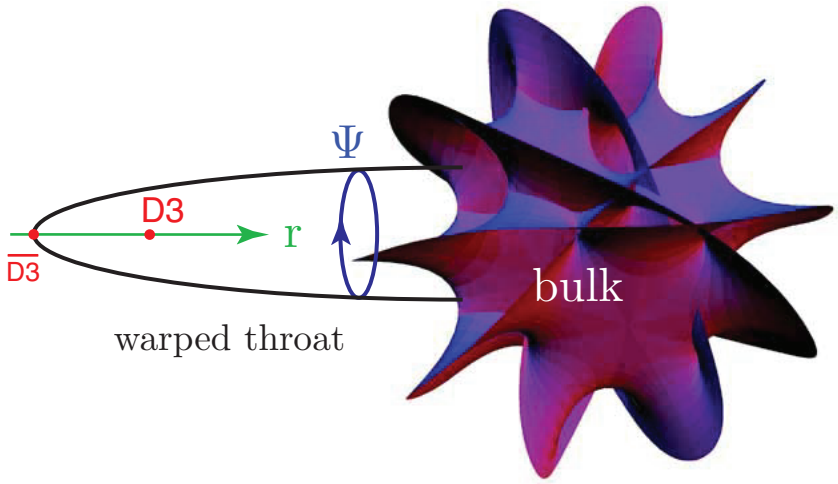

Figure 245: D3-brane inflation in a warped throat geometry. The D3-branes are spacetime-filling in four dimensions and therefore pointlike in the extra dimensions. The circle stands for the base manifold X_5 with angular coordinates Ψ. The brane moves in the radial direction r. At $r_{\rm UV}$ the throat attaches to a compact Calabi-Yau space. Anti-D3-branes minimize their energy at the tip of the throat, $r_{\rm IR}$.

spacetime (with metric $g_{\mu\nu}$) and a conformally-Calabi-Yau space,

$$ds^2 = e^{2A(y)} g_{\mu\nu} dx^\mu dx^\nu + e^{-2A(y)} g_{mn} dy^m dy^n \,, \tag{1366}$$

with g_{mn} a Calabi-Yau metric that can be approximated in some region by a cone over a five-dimensional Einstein manifold X_5,

$$g_{mn} dy^m dy^n = dr^2 + r^2 ds^2_{X_5} \,. \tag{1367}$$

A canonical example of such a throat region is the Klebanov-Strassler (KS) geometry [113], for which X_5 is the $\Big(SU(2) \times SU(2)\Big)/U(1)$ coset space $T^{1,1}$, and the would-be conical singularity at the tip of the throat, $r = 0$, is smoothed by the presence of appropriate fluxes. The tip of the throat is therefore located at a finite radial coordinate $r_{\rm IR}$, while at $r = r_{\rm UV}$ the throat is glued into an unwarped bulk geometry. In the relevant regime $r_{\rm IR} \ll r < r_{\rm UV}$ the warp factor may be written as [114]

$$e^{-4A(r)} = \frac{R^4}{r^4} \ln \frac{r}{r_{\rm IR}} \,, \qquad R^4 \equiv \frac{81}{8} (g_s M \alpha')^2 \,, \tag{1368}$$

where

$$\ln \frac{r_{\rm UV}}{r_{\rm IR}} \approx \frac{2\pi K}{3 g_s M} \,. \tag{1369}$$

Here, M and K are integers specifying the flux background [113, 27].

Warping sourced by fluxes is commonplace in modern compactifications, and there has been much progress in understanding the stabilization of the moduli of such a compactification [112]. Positing a stabilized compactification containing a KS throat therefore seems reasonable given present knowledge.

The Field Range Bound

Before addressing the complicated problem of the shape of the inflationary potential let us ask if these models can ever source a large gravitational wave amplitude. It turns out that this question can be phrased in purely geometrical terms and does not depend on the details of inflationary dynamics [116]. By the Lyth bound we know that a large gravitational wave signal requires super-Planckian field variation. As a minimal requirement we therefore ask if super-Planckian field values are accessible in warped D-brane inflation.

The inflaton kinetic term is determined by the Dirac-Born-Infeld (DBI) action for a probe D3-brane, and leads to an identification of the canonical inflaton field with a multiple of the radial coordinate, $\phi^2 \equiv T_3 r^2$. Here, $T_3 \equiv [(2\pi)^3 g_s \alpha'^2]^{-1}$ is the D3-brane tension, with g_s the string coupling and $2\pi\alpha'$ the inverse string tension. The length of the throat, $\Delta r = r_{\rm UV} - r_{\rm IR} \approx r_{\rm UV}$ provides an upper limit on the inflaton field variation

$$\Delta\phi^2 \;<\; T_3\, r_{\rm UV}^2 \,. \tag{1370}$$

Naively, it seems that this could be made arbitrarily large by simply increasing the length of the throat. However, this changes the volume of the compact space which affects the four-dimensional Planck mass, the unit in which we should measure the inflaton variation. To take this effect into account, we notice that dimensional reduction relates the four-dimensional Planck mass, $M_{\rm pl}$, to the ten-dimensional gravitational coupling, $\kappa_{10}^2 = \frac{1}{2}(2\pi)^7 g_s^2 (\alpha')^4$,

$$M_{\rm pl}^2 = \frac{V_6}{\kappa_{10}^2} \,, \tag{1371}$$

where $V_6 \equiv \int {\rm d}^6 y \sqrt{g} e^{2A(y)}$ is the (warped) volume of the internal space. Since we are interested in an upper limit on $\Delta\phi/M_{\rm pl}$ we bound V_6 from below by the volume of the throat region (including an estimate of the bulk volume would only strengthen our conclusions)

$$V_6 \;>\; (V_6)_{\rm throat} = {\rm Vol}(X_5) \int_0^{r_{\rm UV}} {\rm d}r\, r^5 e^{2A(r)} = 2\pi^4 g_s N (\alpha')^2 r_{\rm UV}^2 \,, \tag{1372}$$

where $N \equiv MK$ measures the background flux. For control of the supergravity approximation (and to achieve sufficient warping of the background) we require $N \gg 1$. Combining the above results we find [116]

$$\boxed{\frac{\Delta\phi}{M_{\rm pl}} \;<\; \frac{2}{\sqrt{N}}} \,. \tag{1373}$$

Since $N \gg 1$, this implies that the inflaton variation will always be sub-Planckian, $\Delta\phi \ll M_{\rm pl}$, and the gravitational wave amplitude is necessarily small. We emphasize again that this argument was purely geometrical and didn't depend on the complicated details of the inflationary potential which we discuss next.

The D3-brane Potential

Inflation proceeds as a D3-brane moves radially inward in the throat region, towards an anti-D3-brane that is naturally situated at the tip of the throat. The exit from inflation occurs when open strings stretched between the approaching pair become tachyonic and condense, annihilating the branes.

In this simplified picture, inflation is driven by the extremely weak (warping-suppressed) Coulomb interaction of the brane-antibrane pair [46]. The true story, however, is more complex, as moduli stabilization introduces new terms in the inflaton potential which typically overwhelm the Coulomb term and drive more complicated dynamics [46, 117, 118, 47, 119, 48]. This pattern is precisely what we anticipated in our effective field theory discussion: integrating out moduli fields can be expected to induce important corrections to the potential.

An important correction induced by moduli stabilization is the inflaton mass term arising from the supergravity F-term potential, §29.2.2. In a vacuum stabilized by an F-term potential,

i.e. by superpotential terms involving the moduli, one finds the mass term $H_0^2\phi^2 = \frac{1}{3}V_0(\phi_\star)\frac{\phi^2}{M_{\rm pl}^2}$ [46], where $\phi_\star$ is an arbitrary reference value for the inflaton field and the parameter H_0 should not be confused with the present-day Hubble constant.

However, one expects additional contributions to the potential from a variety of other sources, such as additional effects in the compactification that break supersymmetry [48]. Let us define $\Delta V(\phi)$ to encapsulate all contributions to the potential aside from the Coulomb interaction $V_0(\phi)$ and the mass term $H_0^2\phi^2$; then the total potential and the associated contributions to the eta parameter may be written as

$$V(\phi) = V_0(\phi) + H_0^2\phi^2 + \Delta V(\phi) \tag{1374}$$

$$\eta_{\rm v}(\phi) = \eta_0 + \frac{2}{3} + \Delta\eta_{\rm v}(\phi) = ? \tag{1375}$$

where $\eta_0 \ll 1$ because the Coulomb interaction is very weak. (More generally, $V_0(\phi)$ can be *defined* to be all terms in $V(\phi)$ with negligible contributions to η. Besides the brane-antibrane Coulomb interaction, this can include any other sources of nearly-constant energy, *e.g.* bulk contributions to the cosmological constant.)

Clearly, $\eta_{\rm v}$ can only be small if ΔV can cancel the mass term in Eqn. (1374). We must therefore enumerate all relevant contributions to ΔV, and attempt to understand the circumstances under which an approximate cancellation can occur. Note that identifying a subset of contributions to ΔV while remaining ignorant of others is insufficient.

Warped D-brane inflation has received a significant amount of theoretical attention in part because of its high degree of computability. Quite generally, if we had access to the full data of an explicit, stabilized compactification with small curvatures and weak string coupling, we would in principle be able to compute the potential of a D-brane inflaton to any desired accuracy, by performing a careful dimensional reduction. This is not possible at present for a generic compact Calabi-Yau, for two reasons: for general Calabi-Yau spaces hardly any metric data is available, and examples with entirely explicit moduli stabilization are rare.

However, a sufficiently long throat is well-approximated by a *noncompact* throat geometry (*i.e.*, a throat of infinite length), for which the Calabi-Yau metric can often be found, as in the important example of the Klebanov-Strassler solution [113], which is entirely explicit and everywhere smooth. Having complete metric data greatly facilitates the study of probe D-brane dynamics, at least at the level of an unstabilized compactification. Furthermore, we will now explain how the effects of moduli stabilization and of the finite length of the throat can be incorporated systematically. The method involves examining perturbations to the supergravity solution that describes the throat in which the D3-brane moves. For concreteness we will work with the example of a KS throat, but the method is far more general. Our treatment will allow us to give explicit expressions for the correction terms ΔV in Eqn. (1374), and hence to extract the characteristics of inflation in the presence of moduli stabilization.

Sketch of the Supergravity Analysis

In the following we describe the computation of the inflaton potential for warped D3-brane inflation. This is only meant to give a flavor of the challenges involved in understanding the full potential. For more details we refer the reader to [46, 117, 47, 48, 118].

Type IIB string theory contains a good dozen of fields (going by names such as dilaton, p-form fluxes, warp factors, metric perturbations, etc.). In principle, we would have to worry that all those fields could couple to the inflaton degree of freedom and hence have to be considered when computing the inflaton potential to the desired accuracy. However, D3-branes are special in that they only couple to a specific combination of the warp factor and the five-form flux and are blind to perturbations in all other fields

$$V_{\rm D3}(\phi) = T_3(e^{4A} - \alpha) \equiv T_3\Phi_-\,, \tag{1376}$$

where the scalar function $\alpha(\phi)$ is related to the five-form flux F_5. We are therefore interested in perturbations of the object $\Phi_- = e^{4A} - \alpha$. In the KS background Φ_- vanishes, but coupling of the throat to the bulk geometry and interaction with moduli-stabilizing degrees of freedom like wrapped D7-branes, induces a non-zero Φ_-. To study the induced Φ_- perturbations, we

investigate the supergravity equation of motion

$$\boxed{\nabla^2\Phi_- = \frac{1}{24}|\mathcal{G}_-|^2 + R}\,, \tag{1377}$$

where $\mathcal{G}_-$ is a special (imaginary anti-self-dual) combination of 3-form fluxes and R is the 4-dimensional Ricci scalar. During inflation R is given by the square of the Hubble parameter H.

All fields are expressed as harmonic expansions on the five-dimensional base manifold $X_5 = T_{1,1}$, *e.g.*

$$\Phi_-(\phi, \Psi) = \sum_{LM} \Phi_{LM} \left(\frac{\phi}{\phi_{\rm UV}}\right)^{\Delta(L)} Y_{LM}(\Psi) + c.c.\,, \tag{1378}$$

where Ψ parameterizes five angles on $T_{1,1}$ and the scaling dimension Δ is determined by the eigenvalues of the angular Laplacian. The spectrum of eigenvalues hence determines the radial scaling of correction terms.

1. *Homogeneous solution*

   The solution to the homogeneous equation

   $$\nabla^2\Phi_- = 0\,, \tag{1379}$$

   was found in Ref. [48]. The leading corrections have the following radial scalings

   $$\Delta \;=\; \frac{3}{2}\,,\, 2\,,\, \cdots\,. \tag{1380}$$

2. *Inhomogeneous solution*

   (a) *Curvature-induced correction*

   The Ricci scalar of the four-dimensional de Sitter spacetime couples to the inflaton. This is reflected by a source term in Φ_- equation of motion

   $$\nabla^2\Phi_- = R\,. \tag{1381}$$

   For constant $R = 12H^2$ this induces a correction to the inflaton mass. This is precisely the Hubble scale inflaton mass term found by KKLMMT [46].

   (b) *Flux-induced corrections*

   Imaginary anti-self dual 3-form fluxes[182], $\star_6\mathcal{G}_- = -i\mathcal{G}_-$, also source corrections of the D3-brane potential [121]

   $$\nabla^2\Phi_- = \frac{1}{24}|\mathcal{G}_-|^2\,. \tag{1382}$$

   Consistently also solving the $\mathcal{G}_-$ equation of motion, $\mathrm{d}\mathcal{G}_- = 0$, we find the following leading corrections

   $$\Delta \;=\; 1\,,\frac{5}{2}\,,\, \cdots\,. \tag{1383}$$

In summary, solving Eqn. (1377) we found [48]

$$V_{\rm D3} = T_3\Phi_- = \sum_\Delta \phi^\Delta f_\Delta(\Psi)\,, \tag{1384}$$

where

$$\boxed{\Delta \;=\; 1\,,\, \frac{3}{2}\,,\, 2\,,\, \cdots}\,. \tag{1385}$$

The discrete *spectrum* (1385) of corrections to the inflaton potential determines the phenomenology of the model.

[182] Here, $\star_6$ is the six-dimensional Hodge star operator, see *e.g.* [120].

Phenomenological Implications

Two different scenarios arise depending on whether the $\Delta = \frac{3}{2}$ or the $\Delta = 2$ correction is the dominant contribution to $\Delta\eta_{\rm v}$ at small ϕ (note that $\Delta = 1$ doesn't contribute to $\eta_{\rm v}$):

1. *Quadratic case*

   If the $\Delta = \frac{3}{2}$ mode is projected out of the spectrum (this can be achieved by imposing discrete symmetries on the UV boundary conditions, see Ref. [48]), the effective radial potential is

   $$V(\phi) = V_0(\phi) + \beta H^2 \phi^2 \,. \tag{1386}$$

   The phenomenology of these types of potentials was first studied analytically by [46] and [122], and numerically by [123].

2. *Fractional case*

   If the fractional mode $\Delta = \frac{3}{2}$ is present, it leads to inflection point models [48, 47, 118, 119] (see Fig. 246).

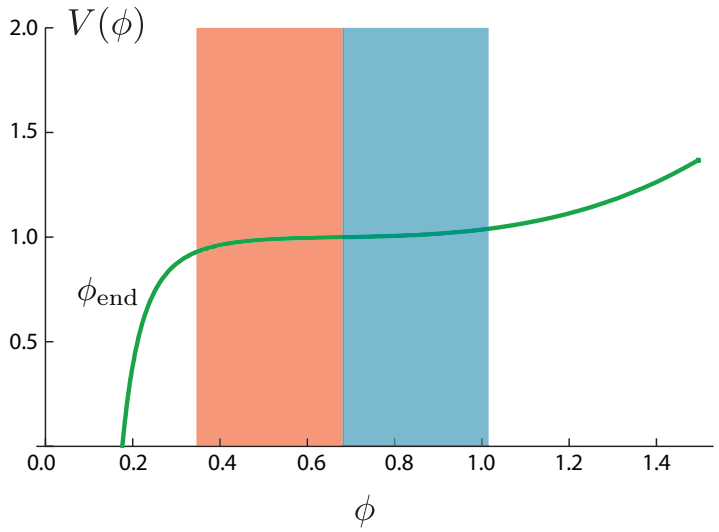

Figure 246: Inflection Point Inflation.

Summary and Perspective

In §29.2.1 we explained how the eta problem is sensitive to dimension-six Planck suppressed operators. In effective field theory models of inflation one can of course always *assume* a solution to the eta problem by a cancellation of the contributing correction terms; in other words, one can postulate that a flat potential $V(\phi)$ arises after an approximate cancellation among dimension-six Planck-suppressed corrections. In string theory models of inflation, to follow this path would be to abdicate the opportunity to use Planck-suppressed contributions as a (limited) window onto string theory. Moreover, once ϕ is identified with a physical degree of freedom of a string compactification, the precise form of the potential is in principle fully specified by the remaining data of the compactification. (Mixing conjecture into the analysis at this stage would effectively transform a 'string-derived' scenario into a 'string-inspired' scenario; the latter may be interesting as a cosmological model, but will not contribute to our understanding of string theory.) Thus, overcoming the eta problem becomes a detailed computational question. One can in principle compute the full potential from first principles, and in practice one can often classify corrections to the leading-order potential.

In this section, we have enumerated the leading corrections for warped D-brane inflation and showed that an accidental cancellation (or fine-tuning) allows small eta over a limited range of inflaton values. This gives a non-trivial existence proof for inflationary solutions in warped throat models with D3-branes.

29.3.3 *Case Study:* Axion Monodromy Inflation

We now turn to our second case study, an example of large-field inflation in string theory. As we have discussed in §29.2.4, the particular challenge in these models is the need to control an infinite series of contributions to the inflaton potential, arising from couplings of the inflaton to degrees of freedom with masses near the Planck scale. Direct enumeration and fine-tuning of such terms (as in the small-field example in §29.3.2) is manifestly impractical, and it appears essential to develop a symmetry argument controlling or forbidding these terms.

An influential proposal in this direction is Natural Inflation [124] (see **Lecture 1**), in which a pseudo-Nambu-Goldstone boson (*i.e.*, an axion) is the inflaton. At the perturbative level, the axion field a enjoys a continuous shift symmetry $a \to a + const$ which is broken by non-perturbative effects to a discrete symmetry $a \to a + 2\pi$. The nonperturbative effects generate a periodic potential

$$V(\phi) = \frac{\Lambda^4}{2}\left[1 - \cos\left(\frac{\phi}{f}\right)\right] + \dots , \tag{1387}$$

where Λ is a dynamically-generated scale, f is known as the axion decay constant, $\phi \equiv af$, and the omitted terms are higher harmonics.

As explained above, an important question, in any proposed effective theory in which a super-Planckian field range is protected by a shift symmetry, is whether this structure can be UV-completed. We should therefore search in string theory for an axion with decay constant $f > M_{\rm pl}$.

Axions in String Theory

Axions from p-Forms

Axions are plentiful in string compactifications, arising from p-form gauge potentials integrated on p-cycles of the compact space. For example, in type IIB string theory, there are axions $b_i = 2\pi \int_{\Sigma_i} B$ arising from integrating the Neveu-Schwarz (NS) two-form B over two-cycles Σ_i, as well as axions $c_i = 2\pi \int_{\Sigma_i} C$ arising from the Ramond-Ramond (RR) two-form C. In the absence of additional ingredients such as fluxes and space-filling wrapped branes, the potential for these axions is classically flat and has a continuous shift symmetry which originates in the gauge invariance of the ten-dimensional action. Instanton effects break this symmetry to a discrete subgroup, $b_i \to b_i + 2\pi$ ($c_i \to c_i + 2\pi$). This leads to a periodic contribution to the axion potential whose periodicity we will now estimate. We will find that the axion decay constants are smaller than $M_{\rm pl}$ in known, computable limits of string theory [125, 126]. Readers less familiar with string compactifications can accept this assertion and skip to §29.3.3 without loss of continuity.

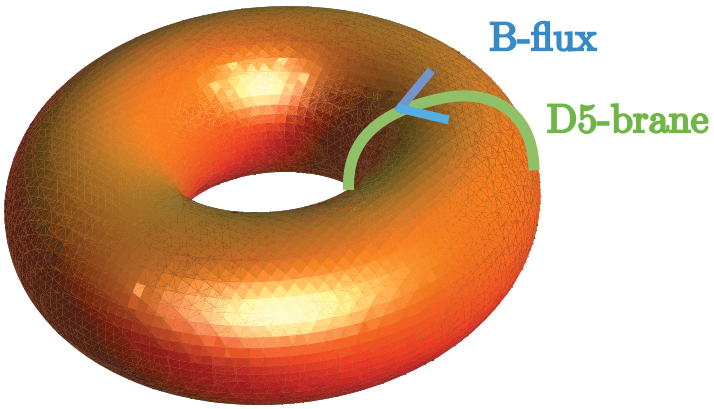

Figure 247: Axion Monodromy

Axion Decay Constants in String Theory

Let ω^i be a basis for $H^2(X, Z)$, the space of two-forms on the compact space X, with $\int_{\Sigma_i} \omega^j = \alpha' \delta_i{}^j$. The NS two-form potential B may be expanded as

$$B = \frac{1}{2\pi} \sum_i b_i(x)\, \omega^i \,, \tag{1388}$$

with x the four-dimensional spacetime coordinate. The axion decay constant can be inferred from the normalization of the axion kinetic term, which in this case descends from the ten-dimensional term

$$\frac{1}{(2\pi)^7 g_s^2 \alpha'^4} \int \mathrm{d}^{10}x\, \frac{1}{2} |\mathrm{d}B|^2 \quad \supset \quad \frac{1}{2} \int \mathrm{d}^4x \sqrt{-g}\, \gamma^{ij} (\partial^\mu b_i \partial_\mu b_j) \,, \tag{1389}$$

where

$$\gamma^{ij} \equiv \frac{1}{6(2\pi)^9 g_s^2 \alpha'^4} \int_X \omega^i \wedge \star_6\, \omega^j \tag{1390}$$

and $\star_6$ is the six-dimensional Hodge star operator. By performing the integral over the internal space X and diagonalizing the field space metric as $\gamma^{ij} \to f_i^2 \delta_{ij}$, one can extract the axion decay constant f_i.

It is too early to draw universal conclusions, but a body of evidence suggests that the resulting axion periodicities are always smaller than $M_{\rm pl}$ in computable limits of string theory [125, 126]. As this will be essential for our arguments, we will illustrate this result in a simple example. Suppose that the compactification is isotropic, with typical length-scale L and volume L^6. Then using

$$\alpha' M_{\rm pl}^2 = \frac{2}{(2\pi)^7} \frac{L^6}{g_s^2 \alpha'^3} \tag{1391}$$

we find from Eqn. (1390) that

$$f^2 \approx M_{\rm pl}^2 \frac{\alpha'^2}{6(2\pi)^2 L^4} \,. \tag{1392}$$

In controlled compactifications we require $L \gg \sqrt{\alpha'}$, so that $f \ll M_{\rm pl}$. Qualitatively similar conclusions apply in much more general configurations [125, 126].

Axion Inflation in String Theory

The above result would seem to imply that Natural Inflation from a single axion field cannot be realized in known string compactifications: string theory provides many axions, but none of these has a sufficiently large field range. However, there are at least two reasonable proposals to circumvent this obstacle.

N-flation

The first suggestion was that a collective excitation of many hundreds of axions could have an effective field range large enough for inflation [43, 127]. The role of the inflaton is played by the collective field

$$\phi^2 = \sum_{i=1}^{N} \phi_i^2 \,. \tag{1393}$$

Even if each individual field has a sub-Planckian field range, $\phi_i < M_{\rm pl}$, for sufficiently large number of fields N, the effective field ϕ can have a super-Planck excursion. This 'N-flation' proposal is a specific example of assisted inflation [128], but, importantly, one in which symmetry helps to protect the axion potential from corrections that would impede inflation. Although promising, this scenario still awaits a proof of principle demonstration, as the presence of a large number of light fields leads to a problematic renormalization of the Newton constant, and hence to an effectively reduced field range. For recent studies of N-flation see [129, 130].

Axion Monodromy

We will instead describe an elementary mechanism, *monodromy*, which allows inflation to persist through multiple circuits of a single periodic axion field. A system is said to undergo monodromy if, upon transport around a closed loop in the (naive) configuration space, the system reaches a new configuration. A spiral staircase is a canonical example: the naive configuration space is described by the angular coordinate, but the system changes upon transport by 2π. (In fact, we will find that this simple model gives an excellent description of the potential in axion monodromy inflation.) The idea of using monodromy to achieve controlled large-field inflation in string theory was first proposed by Silverstein and Westphal [251], who discussed a model involving a D4-brane wound inside a nilmanifold. In this section we will focus instead on the subsequent axion monodromy proposal of Ref. [44], where a monodromy arises in the four-dimensional potential energy upon transport around a circle in the field space parameterized by an axion.

Monodromies of this sort are possible in a variety of compactifications, but we will focus on a single concrete example. Consider type IIB string theory on a Calabi-Yau orientifold, *i.e.* a quotient of a Calabi-Yau manifold by a discrete symmetry that includes worldsheet orientation reversal and a geometric involution. Specifically, we will suppose that the involution has fixed points and fixed four-cycles, known as O3-planes and O7-planes, respectively. If in addition the compactification includes a D5-brane that wraps a suitable two-cycle Σ and fills spacetime, then the axion $b = 2\pi \int_\Sigma B$ can exhibit monodromy in the potential energy. (Similarly, a wrapped NS5-brane produces monodromy for the axion $c = 2\pi \int_\Sigma C$.) In other words, a D5-brane wrapping Σ carries a potential energy that is *not* a periodic function of the axion, as the shift symmetry of the axion action is broken by the presence of the wrapped brane; in fact, the potential energy increases without bound as b increases.

In the D5-brane case, the relevant potential comes from the Dirac-Born-Infeld action for the wrapped D-brane,

$$S_{\rm DBI} = \frac{1}{(2\pi)^5 g_s \alpha'^3} \int_{\mathcal{M}_4 \times \Sigma} \mathrm{d}^6\xi \, \sqrt{\det(G+B)} \tag{1394}$$

$$= \frac{1}{(2\pi)^6 g_s \alpha'^2} \int_{\mathcal{M}_4} \mathrm{d}^4 x \, \sqrt{-g} \, \sqrt{(2\pi)^2 \ell_\Sigma^4 + b^2} \,, \tag{1395}$$

where ℓ_Σ is the size of the two-cycle Σ in string units. The brane energy, Eqn. (1395), is clearly not invariant under the shift symmetry $b \to b + 2\pi$, although this is a symmetry of the corresponding compactification without the wrapped D5-brane. Thus, the DBI action leads directly to monodromy for b. Moreover, when $b \gg \ell_\Sigma^2$, the potential is asymptotically *linear* in the canonically-normalized field $\varphi_b \propto b$.

The qualitative inflationary dynamics in this model is as follows: One begins with a D5-brane wrapping a curve Σ, upon which $\int_\Sigma B$ is taken to be large. In other words, the axion b has a large initial vev. Inflation proceeds by the reduction of this vev, until finally $\int_\Sigma B = 0$ and the D5-brane is nearly 'empty', *i.e.* has little worldvolume flux. During this process the D5-brane does not move, nor do any of the closed-string moduli shift appreciably. For small axion vevs, the asymptotically linear potential we have described is inaccurate, and the curvature of the potential becomes non-negligible; see Eqn. (1395). At this stage, the axion begins to oscillate around its origin. Couplings between the axion and other degrees of freedom, either closed string modes or open string modes, drain energy from the inflaton oscillations. If a sufficient fraction of this energy is eventually transmitted to visible-sector degrees of freedom – which may reside, for example, on a stack of D-branes elsewhere in the compactification – then the hot Big Bang begins. The details of reheating depend strongly on the form of the couplings between the Standard Model degrees of freedom and the inflaton, and this is an important open question, both in this model and in string inflation more generally.

Compactification Considerations

Having explained the essential idea of axion monodromy inflation, we must still ensure that the proposed inflationary mechanism is compatible with moduli stabilization and can be realized in a consistent compactification. An immediate concern is whether there are additional contributions to the potential, beyond the linear term identified above, that could have important effects during inflation. As we have emphasized throughout this review, one expects that in the absence of a symmetry protecting the inflaton potential, generic corrections due to moduli stabilization will contribute $\Delta\eta \sim \mathcal{O}(1)$. It is therefore essential to verify that the continuous shift symmetry which protects the inflaton potential is preserved to an appropriate degree by the stabilized compactification. For the special case of moduli stabilization in which nonperturbative effects play a role, ensuring that the shift symmetry is not spoiled can be quite subtle. This is described in detail in Ref. [44].

Summary and Perspective

The Lyth bound shows that an observable gravitational wave signal correlates with the inflaton field moving over a super-Planckian distance during inflation. Effective field theory models of large-field inflation then require a shift symmetry to protect the flatness of the potential over a super-Planckian range. It has therefore become an important question whether such shift symmetries arise in string theory and can be used to realize large-field inflation.

In this section, we argued that the first examples of shift symmetries in string theory that protect the potential over a super-Planckian range are becoming available. We explained the dual role of the monodromy: i) it results in a large kinematic field range $\Delta\phi > M_{\rm pl}$ by allowing a small fundamental domain to be traversed repeatedly, and ii) in combination with the shift symmetry it controls corrections to the potential over a super-Planckian range. The shift symmetry, only weakly broken by V, controls corrections ΔV within a fundamental domain, and furthermore relates corrections in one fundamental domain to those in any other. Monodromy therefore effectively reduces a large-field problem to a small-field problem [251].

Although more work is required to understand these models and the compactifications in which they arise, monodromy appears to be a robust and rather promising mechanism for realizing large-field inflation, and hence an observable gravitational wave signal, in string theory.

29.4 Outlook

29.4.1 Theoretical Prospects

As we hope this lecture has illustrated, theoretical progress in recent years has been dramatic. A decade ago, only a few proposals for connecting string theory to cosmology were available, and the problem of stabilizing the moduli had not been addressed. We now have a wide array of inflationary models motivated by string theory, and the best-studied examples among these incorporate some information about moduli stabilization. Moreover, a few mechanisms for inflation in string theory have been shown to be robust, persisting after full moduli stabilization with all relevant corrections included.

Aside from demonstrating that inflation is possible in string theory, what has been accomplished? In our view the primary use of explicit models of inflation in string theory is as test cases, or toy models, for the sensitivity of inflation to quantum gravity. On the theoretical front, these models have underlined the importance of the eta problem in general field theory realizations of inflation; they have led to mechanisms for inflation that might seem unnatural in field theory, but are apparently natural in string theory; and they have sharpened our understanding of the implications of a detection of primordial tensor modes.

It is of course difficult to predict the direction of future theoretical progress, not least because unforeseen fundamental advances in string theory can be expected to enlarge the toolkit of inflationary model-builders. However, it is safe to anticipate further gradual progress in moduli stabilization, including the appearance of additional explicit examples with all moduli stabilized; entirely explicit models of inflation in such compactifications will undoubtedly follow. At present, few successful models exist in M-theory or in heterotic string theory, and under mild assumptions, inflation can be shown to be impossible in certain classes of type IIA compactifications [131, 132, 133]. It would be surprising if it turned out that inflation is much

more natural in one weakly-coupled limit of string theory than in the rest, and the present disparity can be attributed in part to the differences among the moduli-stabilizing tools presently available in the various limits. Clearly, it would be useful to understand how inflation can arise in more diverse string vacua.

The inflationary models now available in string theory are subject to stringent theoretical constraints arising from consistency requirements (*e.g.*, tadpole cancellation) and from the need for some degree of computability. In turn, these limitations lead to correlations among the cosmological observables, *i.e.* to predictions. Some of these constraints will undoubtedly disappear as we learn to explore more general string compactifications. However, one can hope that some constraints may remain, so that the set of inflationary effective actions derived from string theory would be a proper subset of the set of inflationary effective actions in a general quantum field theory. Establishing such a proposition would require a far more comprehensive understanding of string compactifications than is available at present.

29.4.2 Observational Signatures?

The theoretical aspects of inflation described in this lecture are interesting largely because they can be *tested* experimentally using present and future cosmological data (see **Lecture 3**).

As we have repeatedly emphasized throughout these lectures, the most dramatic confirmation of inflation would come from a detection of B-mode polarization, which would establish the energy scale of inflation and would indicate that the inflaton traversed a super-Planckian distance. As we have argued in this lecture, super-Planckian displacements are a key instance in which the inflaton effective action is particularly sensitive to the physics of the Planck scale. As a concrete example of the discriminatory power of tensor perturbations, any detection of primordial gravitational waves would exclude the warped D3-brane inflation scenario of §29.3.2 [116], while an upper bound $r < 0.07$ (or a detection with $r \gg 0.07$) would exclude the axion monodromy scenario of §29.3.3 [44].

A further opportunity arises because single-field slow-roll inflation predicts null results for many cosmological observables, as the primordial scalar fluctuations are predicted to be scale-invariant, Gaussian and adiabatic to a high degree. A detection of non-Gaussianity, isocurvature fluctuations or a large scale-dependence (running) would therefore rule out single-field slow-roll inflation. Inflationary effective actions that do allow for a significant non-Gaussianity, non-adiabaticity or scale-dependence often require higher-derivative interactions and/or more than one light field, and such actions arise rather naturally in string theory. Although we have focused in this lecture on the sensitivity of the inflaton potential to Planck-scale physics, the inflaton kinetic term is equally UV-sensitive, and string theory provides a promising framework for understanding the higher-derivative interactions that can produce significant non-Gaussianity [92, 77].

Finally, CMB temperature and polarization anisotropies induced by relic cosmic strings or other topological defects provide probes of the physics of the end of inflation or of the post-inflationary era. Cosmic strings are automatically produced at the end of brane-antibrane inflation [134, 135], and the stability and phenomenological properties of the resulting cosmic string network are determined by the properties of the warped geometry. Detecting cosmic superstrings via lensing or through their characteristic bursts of gravitational waves is an exciting prospect.

30 Scalar Speed Limits and Cosmology: Acceleration from D-cceleration by Silverstein, Tong

Causality on the gravity side of the AdS/CFT correspondence restricts motion on the moduli space of the $\mathcal{N} = 4$ super Yang Mills theory by imposing a speed limit on how fast the scalar field may roll. This effect can be traced to higher derivative operators arising from integrating out light degrees of freedom near the origin. In the strong coupling limit of the theory, the dynamics is well approximated by the Dirac-Born-Infeld Lagrangian for a probe D3-brane moving toward the horizon of the AdS Poincare patch, combined with an estimate of the (ultimately suppressed) rate of particle and string production in the system. We analyze the

motion of a rolling scalar field explicitly in the strong coupling regime of the field theory, and extend the analysis to cosmological systems obtained by coupling this type of field theory to four dimensional gravity. This leads to a mechanism for slow roll inflation for a massive scalar at subPlanckian VEV without need for a flat potential (realizing a version of k-inflation in a microphysical framework). It also leads to a variety of novel FRW cosmologies, some of which are related to those obtained with tachyon matter.

30.1 Introduction

It is now almost 100 years since Einstein introduced the concept of a universal speed limit for all physical systems propagating in spacetime. However, in general, motion on the configuration space of a physical system is not constrained to obey a speed limit. For example, the vacuum expectation values (VEVs) of light scalar fields naturally move in an internal moduli space where motion is uninhibited; within classical, relativistic field theory there is no restriction on the rate of change of the VEV. The purpose of this paper is to show that this situation does not necessarily continue to hold in the quantum theory. We exhibit situations where the strong coupling dynamics do impose a speed limit on an internal moduli space, and examine applications to cosmology, including a mechanism for slow roll inflation.

We focus on the $\mathcal{N} = 4$ supersymmetric Yang Mills (SYM) theory. Although the (supersymmetry-protected) metric on the moduli space is flat, the quantum induced speed limit ensures that a rolling scalar field slows down as it approaches the origin. This fact can be seen immediately from the gravity side of the AdS/CFT correspondence, where the process corresponds to a D3-brane domain wall in AdS_5 moving toward the horizon. The familiar causal speed-limit in the bulk translates into a speed limit on moduli space which becomes more pronounced as the brane approaches the origin. Indeed, from the perspective of a boundary observer, the probe brane takes an infinite time to cross the horizon (though as we will discuss, the probe approximation breaks down due to back reaction at very late times). This speed limit on the moduli space, arising from causality in the bulk, was first stressed by Kabat and Lifschytz [1].

On the field theory side of the correspondence, this result reflects the breakdown of the moduli space σ-model approximation as a scalar field approaches a locus with new light degrees of freedom where higher derivative terms become important. In AdS/CFT dual pairs, we can use the gravity side of the correspondence to determine the net effect of these higher-derivative corrections where they are summed into a Dirac-Born-Infeld (DBI) action. The resulting dynamics is dramatically different from naive expectation based on the supersymmetric moduli space metric.

In this paper, we will study the dynamics explicitly, both in quantum field theory in its own right and in the cosmological context arising from quantum field theory coupled to four dimensional gravity. We use the dual picture of $D3$-branes and anti-$D3$-branes moving in an AdS-like throat and we exhibit late time solutions describing the physics as the scalar field approaches the origin. Among our results, we find that the slowing down of the scalar field (relative to the behavior predicted by the two derivative action) can lead to new regimes exhibiting inflationary behavior.

The idea of obtaining inflation from $\overline{D3}$ and $D3$ branes in a warped throat was studied recently in [2]. In particular, the authors observe that one can gain extra control from the warping, but some obstacles to obtaining explicit inflationary models in string compactifications were identified. Our results here concern the effects of the crucial higher derivative terms in the effective action and allow us to probe a different regime from that studied in [2] which may

help address the challenges of [2]. In particular the slow motion of the scalar field, enforced by higher derivative terms, leads to a new mechanism for slow roll inflation.

A scalar field mass is required to obtain our simplest inflationary solution. The required mass scale is not finely tuned in ordinary four dimensional effective field theory terms, which provides an interesting distinction from the usual inflationary models. In the case of the $\mathcal{N} = 4$ super Yang Mills theory coupled to gravity, we propose some effective field theory couplings to other sectors generating such a mass while leaving intact the form of the crucial kinetic corrections to the moduli space approximation of the field theory. However, we should note that the couplings of Kaluza Klein modes in the corresponding brane throat to other sectors may be important and may require tuned coefficients to avoid destabilization of the throat; this is a little understood aspect of current compactification technology. Because of the plethora of independent ingredients (and types of domain wall branes) available in string compactifications, we expect the combination of approximate AdS-metric induced kinetic terms and scalar masses generated from other couplings is likely to be available in some set of examples. It remains the main weakness of our results however that we will not exhibit an explicit example here. The other field theoretic and cosmological phases we will exhibit are not tied to this subtlety.

Our results have further relations to previous work. The use of higher derivative terms to change scalar field dynamics in ways interesting for cosmology has been dubbed "k-inflation" [3] or "k-essence" [4]. A particularly well-studied example occurs in the effective field theory describing the decay of branes and antibranes leading to "tachyon matter" [5, 6, 7] and the associated cosmology [8, 9]. While our system shares many features with the rolling tachyon story, including the existence of a pressureless dust equation of state, it also differs in several ways important for cosmology. In particular, we shall argue that particle and string production is suppressed in our system and the dynamics is governed to good approximation by our equations of motion. For a few examples of previous works studying the application of rolling moduli to string cosmology see [10, 11, 12] and the review [13]. The crucial physics of our model is ultimately extracted from the dynamics of D-branes; there are of course many interesting investigations in this area, for example [14, 15, 16].

The manner in which higher derivative terms can drastically affect the dynamics of a system raises many questions concerning potential applications to real models of cosmology as well as more theoretical issues. Among the latter set is the question of whether or not motion toward other finite distance singularities in field theory and string theory moduli spaces (such as the conifold singularity) also exhibits similar slowing down effects for some regime of the couplings. Noticeably, recent studies of the flop transition, which explore the effects of the states which become light at the singularity, suggest that the rolling scalar field does indeed become stuck in the region of the singularity [17, 18].

The paper is organized as follows. We start in Section 2 by describing our basic set-up, stressing the appearance of a speed limit on the moduli space. In Section 3 we study the consequences of this speed limit for the dynamics in the global conformal field theory. We then couple our system to gravity in Section 4. We take particular care to describe the possible deformations of the system arising from other sectors in a string compactification, including the generation of a potential on the moduli space and the effects this has on the AdS geometry seen by the probe brane. In Section 5 we study cosmologies arising from our low-energy effective actions. In Section 6, we check that our solutions are not destabilised by perturbations or particle production.

30.2 The Basic Setup

Typically studies of scalar field dynamics consider an effective field theory Lagrangian containing a kinetic term (up to two derivatives) together with a potential energy on the space of scalar fields:

$$S_{two\ deriv} = \int d^4x\sqrt{g}\left(G_{ij}(\phi)g^{\mu\nu}\partial_\mu\phi^i\partial_\nu\phi^j - V(\phi)\right) \tag{30.1396}$$

In supersymmetric situations, the moduli space metric G_{ij} and the form of the potential energy V are highly constrained, and much of the recent work on such quantum field theories has focused on determining these quantities and the BPS spectrum of states exactly.

It is well known however that the moduli space approximation (in which the physics is governed by the action (30.1396) along flat directions of the potential $V(\phi)$) can break down due to the presence of new light degrees of freedom arising on special loci of the space of scalar field VEVs.

In the $U(N)$ $\mathcal{N} = 4$ SYM theory, one has scalar fields in the adjoint representation of the gauge group which can be represented by $N \times N$ matrices Φ. The moduli space of the field theory is parameterized by diagonal (commuting) matrices, with eigenvalues $\phi_1, \ldots, \phi_N$ whose moduli space metric, including quantum corrections, is flat. Away from the origin $\phi_i = 0$ of this moduli space, the low energy gauge symmetry is generically $U(1)^N$ and off diagonal matrix elements of the scalar fields, fermions, and gauge bosons obtain masses. We shall refer to these modes collectively as "W bosons". In particular, we will consider a configuration in which $\langle\phi_1\rangle \equiv \langle\phi\rangle \neq 0$ but all the other ϕ_i, $i \neq 1$ have vanishing VEVs. This means that the theory has a low energy unbroken gauge symmetry $U(N-1) \times U(1)$ with massive W bosons in the $(\mathbf{N-1}, +) \oplus (\overline{\mathbf{N-1}}, -)$ representation. The W bosons are BPS protected states with mass

$$m_W = \phi \tag{30.1397}$$

We will work expanding about the large N limit of the theory, in which the natural parameters in the field theory are the rank N and the 't Hooft coupling $\lambda = g_{YM}^2 N$ in terms of the Yang Mills coupling g_{YM}.

30.2.1 The System at Weak Coupling

At weak coupling in the field theory, the effective action for ϕ gets contributions from virtual W bosons. For large $\langle\phi\rangle$, these contributions scale like powers of $\lambda\dot{\phi}^2/\phi^4$ in the planar limit (see [19] for a comprehensive discussion of these higher derivative corrections). If we send the scalar field rolling toward the origin from a finite point on the Coulomb branch, the classical action (30.1396) would predict a constant velocity $\dot{\phi} = v_0$, but the form of the corrections just noted shows that the action (30.1396) becomes unreliable at the distance

$$\phi^2 = \sqrt{\lambda}\, v_0 \tag{30.1398}$$

The question then arises about how to take into account these corrections. However, in the weak coupling regime, the point is moot as we have another issue to confont before we get this close to the origin. Since the W bosons become light, they may be produced on shell during the evolution. The time dependent mass leads to particle production controlled by the parameter $\dot{m}_W/m_W^2$, which therefore becomes important at the distance,

$$\phi^2 = v_0 \tag{30.1399}$$

For $\lambda \ll 1$, we first reach the production point (30.1399).

Naively extrapolating the above perturbative results to the strong coupling regime, we reach the point (30.1398) first and therefore expect that the dynamics will be governed by the effective action for ϕ taking into account the $\lambda\dot{\phi}^2/\phi^4$ corrections arising from virtual W bosons. In the following section we shall confirm this expectation and show that the scale (30.1398) is where the speed limit on the moduli space first becomes apparent.

30.2.2 The System at Strong Coupling and the Speed Limit

At strong coupling $\lambda \gg 1$, the effective description of the theory is via gravity and string theory using the AdS/CFT correspondence [20]. A point on the Coulomb branch is described on the gravity side in the Poincare patch via a D3-brane at fixed radial position r in the metric

$$ds^2 = \frac{r^2}{R^2}\left(-dt^2 + dx^2\right) + \frac{R^2}{r^2}\,dr^2 \tag{30.1400}$$

and at a point on the S^5. The field theory coordinate ϕ on the Coulomb branch translates into r/α' in the gravity variables. We further have the relations $R = (g_s N)^{1/4}\sqrt{\alpha'}$ and $g_{YM}^2 = 4\pi g_s$.

As in other applications of AdS/CFT [20] and Randall-Sundrum [21], the warp factor in (30.1400) plays an important role in understanding the energy spectrum of the system. The string mass scale at position r is related to that at position r' by the ratio of warp factors r/r'. The open string oscillator modes on the brane at position $r = \langle\phi\rangle\alpha'$ have masses of order

$$m_s(\langle\phi\rangle) = \frac{\phi}{\lambda^{1/4}} \tag{30.1401}$$

As in the Randall Sundrum scenario, the effective cutoff for modes on the brane is at this warped string energy scale (30.1401) rather than the UV string scale $1/\sqrt{\alpha'}$.

The W bosons are strings stretched from the brane to the horizon at $r = 0$. Although this is an infinite proper distance for the string to stretch, the warp factor r/R reduces the effective tension of the string enough to produce a finite total mass $m_W = \phi$ in accord with the BPS formula (30.1397).

We would now like to highlight the simple feature of our system which lies behind most of our detailed results to follow. It is immediately clear from (30.1400) that, for a boundary observer using coordinates (t, x), a probe brane takes infinite time to reach the origin of the Coulomb branch at $r = 0$. (In our solutions it will turn out that the proper time for the probe to fall to the origin will be finite.) The radial velocity of the $D3$-brane in the AdS space is limited by the speed of light which, translated in field theory variables, becomes

$$\dot{\phi} \le \dot{\phi}_c = \frac{\phi^2}{\sqrt{\lambda}} \tag{30.1402}$$

This restriction was noted previously by Kabat and Lifschytz [1], who discussed some interesting aspects of the phenomenon. Note that the probe brane takes infinite time despite the fact that the moduli space metric in (30.1396) for the $\mathcal{N} = 4$ SYM theory is uncorrected quantum mechanically; the distance to the origin in the field theory moduli space metric is finite for any value of the coupling. As discussed above, the fact that it takes an infinite time to reach the origin arises from crucial corrections to the moduli space approximation. These corrections apply to *any* physical process in which the scalar rolls toward the origin of the Coulomb branch.

Note that the $\lambda\dot{\phi}^2/\phi^4$ corrections, while they are higher derivative corrections, are not suppressed by powers of the Planck mass; as we discussed above they are suppressed only by the W boson mass ϕ. Let us compare this situation to a brane in flat space: such an object has a Lagrangian proportional to $\sqrt{1-v^2}$ where v is the proper velocity of the brane. Written in terms of canonically scaled brane fields ϕ, this becomes (for a D3-brane) $\sqrt{1-\dot{\phi}^2\alpha'^2}$ which expands to a series of higher derivative terms which are suppressed by powers of the string mass m_s. In the global limit $m_s \to \infty$, these corrections die and the motion on ϕ space is unconstrained. It is the warp factor in (30.1400) that produces higher derivative effects that are crucial at the field theory level, as we will see in detail in our analysis.

30.3 The Global CFT

The corrections to the moduli space approximation, and the resulting dynamics, can be understood rather explicitly in a controlled analysis on the gravity side in which the rolling scalar VEV is modelled by a moving D3-brane probe in AdS_5. In this section we examine the resulting dynamics of the scalar field.

30.3.1 Effective Action and Approximation Scheme

On the gravity side, the effective Lagrangian appropriate for a probe D-brane at arbitrary velocity (less than or equal to the speed of light) but low proper acceleration is the Dirac-Born-Infeld Lagrangian. This Lagrangian describes the effects of virtual open strings at the planar level; it includes the effects of the background geometry and field strengths but does not include production of on shell closed strings or W bosons or loops of closed strings. We will analyze the motion of the 3-brane starting from this Lagrangian, and check for self consistency of the resulting solutions. This requires checking that the proper acceleration is small and taking the string coupling to be small so that the DBI action is a good approximation to the effective action of the probe. It further requires determining the range of parameters and times for which the energy in the probe does not back react significantly on the geometry, so that the probe approximation remains valid. Finally, we must also check that fluctuations about the solution, density perturbations, and particle and string production are not too large. In Section 4 we will consider generalizations of this system to include coupling to four dimensional gravity and other sectors, including effects of a cutoff throat in the IR; we will take into account new contributions to the action at the level of its most relevant terms at low energy.

In this section we start by writing down the effective action applicable to the pure conformal field theory (CFT) without gravity (infinite AdS space). The DBI action for a probe D3-brane moving in $AdS_5 \times S^5$ can be found in [20] and we will use their conventions. We concentrate only on radial fluctuations, and set the field strength on the brane to vanish. Working in field theory variables $\phi \equiv r/\alpha'$, we have

$$S = -\frac{1}{g_{YM}^2} \int dt\, d^3x\, f(\phi)^{-1} \left[-\det\left(\eta_{\mu\nu} + f(\phi)\,\partial_\mu\phi\,\partial_\nu\phi\right)^{1/2} - 1 \right] \tag{30.1403}$$

where for now we take the background brane metric to be flat $\eta_{\mu\nu} = \mathrm{diag}(-1,1,1,1)$, and $f(\phi)$ is the harmonic function

$$f(\phi) = \frac{\lambda}{\phi^4} \tag{30.1404}$$

Expanding the action out in derivatives leads to a canonical kinetic term for $\phi \equiv r/\alpha'$ and a series of higher order derivative interactions. The potential cancels out, reflecting the BPS

nature of the D3-brane. In fact, for a single excited scalar field ϕ, this form of the higher derivative action can be shown to hold even at weak coupling [22] without recourse to a dual gravitational description: it is fixed by the requirement of a non-linearly realised conformal invariance, together with known non-renormalisation theorems.

So in general the dynamics of ϕ in our strongly coupled CFT differs in two important ways from a naive scalar field system governed by (30.1396). Firstly, the kinetic term is corrected to that in (30.1403); as discussed above we will find that the proper velocity approaches the speed of light so that the quantity in the square root approaches zero, resulting in a system far away from the regime where the two derivative action suffices. Secondly, there is no potential $V(\phi)$. In later sections we shall remedy the latter issue by generalizing to systems in which potentials are generated, both by anti-branes and by considering a field theory coupled to other sectors. The speed limit will remain a crucial ingredient in our generalizations.

30.3.2 Dynamics

Let us now study more explicitly the approach of the $\mathcal{N} = 4$ SYM theory to the origin of its Coulomb branch, using the action (30.1403). Since we are interested only in the time dependence of the solution, we shall ignore the spatial derivatives, leaving us with the action,

$$S = -\frac{N}{\lambda^2}\int d^4x\phi^4\left(\sqrt{1-\lambda\dot{\phi}^2/\phi^4}-1\right) \tag{30.1405}$$

To determine the late time behaviour[183] of this system, we first compute the conserved energy density E, given by (up to a factor of $1/g_{YM}^2$)

$$E = \frac{1}{\lambda}\phi^4\left(\frac{1}{\sqrt{1-\lambda\dot{\phi}^2/\phi^4}}-1\right) \approx \tfrac{1}{2}\dot{\phi}^2 + \tfrac{1}{8}\frac{\lambda\dot{\phi}^4}{\phi^4} + \dots \tag{30.1406}$$

where, in the second line, we have expanded around large ϕ. The first term is the canonical kinetic energy for a rolling scalar field, with subsequent terms becoming important at small ϕ, capturing the effect of virtual W bosons.

As mentioned above, the Born-Infeld action is valid for arbitrarily high velocities $\dot{\phi}$ but only for small proper accelaration a,

$$a\sqrt{\alpha'} = \frac{\lambda^{1/4}}{\phi}\frac{d}{dt}\left(\frac{\sqrt{\lambda}\,\dot{\phi}}{\phi^2}\right)$$

So in order for our analysis to be self-consistent, we must check that the proper acceleration is much smaller than string scale in our solution. Inverting (30.1406) to solve for $\dot{\phi}$, and subsequently taking the time derivative, it is simple to see that we can trust the DBI analysis when we are in the strong coupling regime $\lambda \gg 1$.

[183] Readers who prefer $u = 1$ units may make the substitution in all expressions of this type.

Integrating once, the trajectory of the scalar ϕ is given by,

$$t - t_0 = \frac{1}{\sqrt{E}} \int_{\phi_0}^{\phi} d\varphi \, \frac{1}{\varphi^2} \frac{\lambda E + \varphi^4}{\sqrt{\lambda E + 2\varphi^4}}$$

We are interested in the dynamics of the scalar field after we hit the critical point on moduli space defined by (30.1398). Using the classical expectation $E \sim v_0^2$, this means we are interested in the regime

$$\phi^4 \ll \lambda E \tag{30.1407}$$

Here we find the late time behaviour,

$$\phi(t) \to \frac{\sqrt{\lambda}}{t} \tag{30.1408}$$

saturating the speed limit (30.1402). We therefore find that from the perspective of the field theory observer, Xeno is vindicated and the scalar field takes an infinite time to reach the origin as advertised.

Background Check

The above calculation treated the $D3$-brane as a probe and is valid only when the back reaction can be neglected. Since the brane travels at almost the speed of light at late times on the gravity side, it carries a lot of energy and we must determine the conditions under which its back reaction does not destabilize the AdS background.[184] The gravitational field surrounding a highly boosted object in locally flat space is given by the Aichelburg-Sexl metric [23], which in our case of codimension 6 is given by

$$h_{--} \sim \frac{l_s^8 g_s E_p}{r_\perp^3} \delta(x^-) \tag{30.1409}$$

Here $E_p = E(R/r)^4$ is the proper energy density of the probe (related to the Poincare observer's energy density E by the appropriate powers of the warp factor r/R), $r_\perp$ is the distance from the probe in the transverse dimensions, and x^- is the light cone coordinate with respect to which the brane trajectory is localized in locally flat coordinates. If we insist that the corresponding curvature $\mathcal{R}_{10} \sim h_{--}/r_\perp^2$ smeared over a string scale distance across the brane be smaller than the ambient AdS curvature $1/R^2$ at a distance R from the probe, this gives the condition

$$E < \frac{\phi^4}{\lambda^{1/4} g_s} \tag{30.1410}$$

If we impose this condition, we still obtain a window

$$\lambda^{1/4} g_s E < \phi^4 < \lambda E$$

in which our back reaction constraint (30.1410) intersects with our regime (30.1407) of limiting speed.

[184] This constraint was obtained via discussions with M. Fabinger.

This constraint (30.1410) may be too strong, since the novel behavior we found for ϕ based on the DBI action depends only on the AdS geometry. We can estimate the back reaction of our probe on the AdS geometry as follows. The probe forms a domain wall of energy density E_p in the five dimensional gravity theory obtained by dimensional reduction on the S^5. Such a wall will jump the warp factor accross it. By dimensional analysis, this gives the relation

$$\frac{1}{R'} - \frac{1}{R} \sim E_p l_5^3 \tag{30.1411}$$

in terms of the five dimensional Planck length l_5, where R' is the curvature radius on the IR side of the domain wall. Using $l_5^3 \sim l_{10}^8/R^5 = l_s^8 g_s^2/R^5$, the condition that the jump in warp factor is smaller than the original AdS warp factor is

$$E < \frac{\phi^4}{g_s}$$

Again, this leads to a window at strong coupling in which the rolling scalar field saturates its speed limit (30.1408) in the regime

$$g_s E < \phi^4 < \lambda E \tag{30.1412}$$

Similar back reaction criteria apply to all the cases discussed in the paper, and we will derive a related bound in our interesting inflationary phase. It would be interesting to explore what happens when this condition is violated. We will discuss the other consistency conditions for our background (including ruling out significant back reaction from particle production) in Section 6.

30.3.3 Antibranes

Here we introduce the first of our generalizations: anti-D3-branes moving in the AdS background (30.1400). The action for the $\overline{D3}$-brane probe in AdS_5 differs from the $D3$-brane case (30.1405) merely by a change of sign in the final term,

$$S = -\frac{N}{\lambda^2} \int d^4x \phi^4 \left(\sqrt{1 - \lambda \dot{\phi}^2/\phi^4} + 1 \right) \tag{30.1413}$$

Upon expanding the square-root in powers of $\lambda\dot{\phi}^2/\phi^4$, this gives rise to a potential which is quartic in ϕ. There is no quadratic $m^2\phi^2$ term. This may be at first sight surprising since the system has broken supersymmetry in the presence of the antibrane, and loops of open strings which probe the susy breaking are included at the level of the action (30.1413). However this result is to be expected using simple Randall-Sundrum ideas. The local string scale at the position of the brane is $\phi/\lambda^{1/4}$ (30.1401). Similarly all hard masses are warped down by a factor of $r/R = \phi\sqrt{\alpha'}/\lambda^{1/4}$ at position ϕ in the throat. Applying this to the susy breaking scale m_{SUSY}, a potential $V \sim m_{SUSY}^2\phi^2$ really scales like ϕ^4. Said differently, there is no independent scale in the CFT on the Coulomb branch beyond the position ϕ.

The ϕ^4 potential implies that the $\overline{D3}$-brane experiences a force towards the horizon at $r = 0$. Nonetheless, it is a simple matter to check that the late time dynamics is dominated by the speed limit and is identical to that of the $D3$-brane (30.1408).

In some sense, the $\overline{D3}$-brane probe in AdS space can be thought of as a strong coupling limit of the usual tachyon matter system. Indeed, we shall see in Section 5 that the resulting dynamics bears some similarity to the results that have been obtained for the much-studied open string tachyon decay in the weakly coupled brane-antibrane system (see [24] for recent review of this system). However, there are some differences which we stress here. At weak coupling, the $\overline{D3}$-brane system has tachyons from strings stretching between the antibrane and the $N-1$ D3-branes described by the AdS throat. However, at strong coupling $\lambda \gg 1$, it is easy to see from (30.1397) and (30.1401) that this mode is not tachyonic. The negative contribution to the would-be tachyon mass squared, scaling like the (warped) string scale $m_s(\langle\phi\rangle)^2$, is dwarfed by the positive contribution m_W^2 to the mass squared from the stretching of the string from the antibrane to the AdS horizon. Thus the brane-antibrane system at strong 't Hooft coupling (obtained by taking many branes and a single antibrane) has no tachyon. The system *is* unstable – as we will discuss in detail the antibrane falls towards the horizon. However this evolution is not condensation of a brane-antibrane tachyon since none exists; as in [25] the annihilation of the antibrane against the unit of $D3$-brane charge encoded in the RR flux is a nonperturbative effect.

30.4 Coupling to Gravity

In both the brane and antibrane cases, we will be interested in two further important generalizations. One is coupling to four dimensional gravity, as well as to other sectors suppressed by higher dimension operators that may arise in the corresponding string compactifications. The other is a generalization to a throat which is capped off in the region corresponding to the IR behavior of the field theory – i.e. the system with a mass gap. In a string theoretic setup, these effects can be achieved by gluing an AdS-throat like solution onto a compactification geometry which acts as a UV-brane as in [26, 27].

In this section we shall discuss the effective actions which result from these generalizations, focusing on the relative strength of corrections to the potential energy and DBI kinetic energy terms in the effective action. Our motivation for considering these theories is the application of the speed limit mechanism to cosmology. We will postpone a full discussion of this until Section 5. To avoid undue suspense, let us here summarize some of the important results.

Because our matter sector itself slows the scalar field ϕ in its progress toward the origin (in the field theory variables), the conditions for slow roll inflation are modified in a useful way. In a situation with a strong enough additional potential energy for ϕ (which may arise for example from a setup with a brane or antibrane in a cutoff AdS throat coupled to other sectors) we will indeed find a phase of slow roll inflation. This can be obtained at subPlanckian VEV for ϕ, with the slow roll provided by the DBI kinetic term corrections rather than from the usual gravitational damping or from an unnaturally flat potential. This allows us to evade some of the problems discussed in [2]. While we have not yet produced a complete model of real-world inflation from this mechanism, it seems a very promising ingredient.

More generally, we will find some familiar behaviors for the FRW scale factor $a(t)$ but arising in unusual ways from our matter sector. For example, as in "tachyon matter" we will find a dust equation of state for motion of a D3-brane toward the origin of the Coulomb branch, though in our case production of massive matter is suppressed. With other potentials, we also find a novel steady state late-time behaviour for the universe that does not involve fine tuning of initial conditions.

The motion of the moduli themselves is an important aspect of string cosmology, and the basic result of the previous sections leads to interesting novelties in this area. In particular, if the moduli field ϕ corresponding to the motion of the threebrane heads toward the origin of the Coulomb branch, it gets slowed down and, at least in the probe limit, takes an infinite time to reach the origin. This is radically different from the naive treatment based on the moduli space metric in which it would shoot past the origin without pausing. Furthermore, if the scalar relaxes into a potential well surrounding the origin, it does not oscillate around the minimum in the same manner as moduli treated with the usual action (30.1396). However in the cases when the ϕ sector with all the DBI corrections leads to a dust equation of state, it can cause similar problems to the usual moduli problem.

30.4.1 CFT Coupled to Gravity

We firstly ask what becomes of the low-energy effective action (30.1403) when the gauge theory is coupled to gravity by introducing a dynamical background metric $g_{\mu\nu}$. At the same time, we add a potential term $V(\phi)$ to the action that may arise when the system is coupled to four dimensional gravity and other sectors involved in a full string compactification. A simple four dimensional covariantization of (30.1403) is

$$\mathcal{L}_0 = -\frac{1}{g_{YM}^2}\sqrt{-g}\left(f(\phi)^{-1}\sqrt{1+f(\phi)\,g^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi}+V(\phi)\mp f(\phi)^{-1}\right) \tag{30.1414}$$

where the $\pm$ refers to the $D3$-brane and $\overline{D3}$-brane respectively while $f(\phi)=\lambda/\phi^4$ as before.

In the presence of four dimensional gravity, there are in general further corrections to the action (30.1414) coming from the following considerations. Dynamical $4d$ gravity leads generically to nontrivial four dimensional curvature $\mathcal{R}$. In effective field theory, this leads to series of contributions of the form

$$\mathcal{R}\phi^2(1+c_1\mathcal{R}/\phi^2+\dots). \tag{30.1415}$$

More generally each contribution in the action (30.1414) could be corrected by terms suppressed by powers of $\mathcal{R}/\phi^2$. In particular, there will be corrections depending on $\mathcal{R}$ and $\partial\phi$, which will be outside the scope of our analysis; our results will be contingent on these corrections being subdominant (which may require tuning in appropriate circumstances). In the weakly coupled $\mathcal{N}=4$ SYM theory coupled to four dimensional gravity, such corrections are evident from diagrams containing loops of W bosons. At strong coupling, such corrections were found in [28, 29] starting from the DBI action for curved slices. From all these points of view, the coefficients c_i in (30.1415) are expected to be of order one (i.e. not parametrically large or small as a function of λ).

In our solutions, we will find that these curvature corrections are negligible. Our strategy will be to simply ignore them at this stage, analyze the dynamics, and then check that this is self consistent (in Section 5.3 below). In any case, we can collect these effects in an effective Lagrangian containing both gravity and matter:

$$S=\int\left(\tfrac{1}{2}\sqrt{-g}\,(M_p^2+\phi^2)\,\mathcal{R}+\mathcal{L}_0+\dots\right) \tag{30.1416}$$

where the $\dots$ refers to corrections to the terms in (30.1416) which are down by powers of $\mathcal{R}/\phi^2$ from the leading terms. The final action is a special case of those considered in k-inflation and k-essence scenarios [3, 4]. In our case, the higher derivative terms in $\mathcal{L}_0$ follow from the strong coupling dynamics of the field theory near the origin of its moduli space.

Let us now discuss the reliability and plausibility of this action including the coupling to four dimensional gravity. In string theory, such a coupling is obtained by embedding the AdS geometry into a compactification as a throat emanating from a Calabi Yau compactification of type IIB string theory [26, 27]. The first question that arises is whether this geometrical combination exists or if instead the coupling of the AdS to the Calabi Yau produces a large deformation of the AdS space. If such a geometry exists, we may move onto the second question: whether the low energy effective field theory action is given by (30.1414) to a good approximation for the system we wish to study, and what is the order of magnitude of the parameters in the potential V. Thirdly, in the end we must check that the time dependent solutions we find are stable against small fluctuations, particle production, and density perturbations. (This is in addition to the checks for small acceleration and small back reaction of the probe energy of the sort we completed in Section 3 for the global case.) This last question will be addressed in section 6.

As far as the first question goes, as discussed in [26, 27], the AdS throat is obtained from a collection of many D3-branes at a smooth point on the Calabi Yau. At the level of the no scale potential obtained for CY compactifications of type IIB at large radius in the absence of α' corrections and nonperturbative effects [27], the scalars on the D3-branes have a potential identical to that in the global quantum field theory on their worldvolume. They are mutually BPS and, in this sense, are also mutually BPS with the rest of the compactification. This follows from the analysis in [27], and may be related to the fact that in the $\mathcal{N} = 4$ SYM at strong coupling, the operator $tr\Phi^2$, which is relevant at weak coupling, is highly irrelevant at strong coupling (something exploited by e.g. [32]). The quantum mechanical corrections to the Kahler potential and the superpotential of the model, which are important for fixing the Kahler moduli, will in general also determine the positions of the D3-branes. Since the configuration corresponding to their being on top of each other at a smooth point in the Calabi Yau is an enhanced symmetry point, it is likely that an order one fraction of the models have a minimum containing to a good approximation an AdS throat arising from such a collection of D3-branes. We will momentarily estimate the size of corrections to this geometry as seen by our probe.

Now let us discuss the second question about the reliability of our effective action and the parameters in the potential. Attached to the Calabi Yau, our AdS throat is coupled to four dimensional gravity and other sectors. We will start by discussing the effects of the coupling of these sectors to ϕ in effective field theory. Then we will discuss the geometrical description of these effects. We will argue that (consistently in both descriptions) significant corrections to the mass term in the potential can naturally arise from these couplings while corrections to the kinetic terms arising from them are subleading to those in the original action. This ensures that we can preserve our slow roll effect for the scalar field coming from the kinetic terms while introducing potential energy sources for gravity which lead to interesting, and in one case accelerating, cosmologies. As we will also discuss, it is an interesting open question whether this setup requires tuning couplings of throat Kaluza Klein modes to other sectors to avoid further effects on the kinetic terms for ϕ.

Effective Field Theory Description of Corrections

As well as curvature couplings such as $\mathcal{R}\phi^2$ arising from the introduction of gravity, we will generically have further couplings of ϕ to other sectors. These could be of the form,

$$\phi^2\eta^2 \quad \text{or} \quad \frac{\phi^2(\partial\eta)^2}{M_*^2} \tag{30.1417}$$

where η is a field from another sector and M_* is a mass scale (such as the GUT, string, or Planck scale) in the system above the energies we wish to consider. In the next subsection we will explain why we expect such couplings to be available naturally in string compactifications, but

we have not constructed an explicit example and will largely treat these couplings by effective field theory in our analysis of the cosmology.

We should emphasize that the effective field theory description we use in this subsection makes use of the weak coupling expansion available on the gravity side of AdS/CFT; it is just the couplings of the ϕ fields to the new sectors involved in the compactification which we will treat here via effective field theory. A full treatment of the 4d effective field theory on the gravity side also requires understanding the couplings and effects of the Kaluza Klein modes. This involves understanding what tuning is required to preserve an (approximate) AdS throat in a Calabi Yau compactification in the absence of a probe brane. This is not well understood. In any case, as we will discuss in the next subsection and in Section 5, the probe approximation for the brane in a large-radius approximate AdS throat is consistent with the presence of a large enough mass on the probe brane for interesting cosmological effects such as inflation.

More generally, we may view (30.1417) as coupling the strongly coupled CFT to the η sector by hand in effective field theory. The action (30.1414) contains no closed string (gravity) loops, or loops of η from couplings such as (30.1417). We must estimate contributions to our effective actions from these loop effects. We will assume a weak enough string coupling for perturbative string theory to be valid on the gravity side.

Out first important task is to determine the scale of any relevant or marginal corrections to the action that may arise from the couplings involving ϕ. Let us start by discussing the potential $V(\phi)$, considering a power series expansion

$$V \equiv V_0 + V_2\phi^2 + V_4\phi^4 + \dots \tag{30.1418}$$

The most relevant term in the Lagrangian at low energies is the hard cosmological constant V_0. This gets contributions in principle from all sectors in the system. In effective field theory (and approximately in string theory using the Bousso Polchinski mechanism [30]) we may tune this (close) to the value of interest for a given application. We will make use of this freedom in our analysis.

Now let us move on to the ϕ-dependent couplings, starting with the mass term $V_2\phi^2$. As we discussed in the global case, in an exact conformal field theory (which is either not coupled to gravity and other sectors or is not destabilized by their presence), a mass coupling $m_*^2\phi^2$ with m_* a constant mass parameter is ruled out by the conformal invariance encoded in the effects of the warping in the AdS throat. Thus, with an exact AdS throat geometry, the potential is expected to receive corrections starting with the quartic $V_4\phi^4$ coupling. However, in general the couplings to gravity and other sectors can generate corrections to the theory (30.1416) which violate conformal invariance. For example, corrections to the scalar mass coming from loops containing virtual gravitons yield a contribution,

$$m_*^2 \sim \Lambda_{UV}^4/M_p^2 \tag{30.1419}$$

where the fourth power of the UV loop momentum cutoff Λ_{UV} can be traced to the fact that the Feynman diagrams contain derivative couplings. Similar contributions arise from couplings to other sectors (30.1417). A mass for ϕ can be generated either from a VEV for η, or from loop corrections involving the derivative coupling, giving rise to respective contributions of the form

$$m_*^2 \sim \langle\eta\rangle^2 \quad \text{or} \quad m_*^2 \sim \Lambda_{UV}^4/M_*^2 \tag{30.1420}$$

We should also note that the quartic and higher couplings $V_4\phi^4 + \dots$ in the effective potential will also get corrections from interactions such as (30.1417). In our strategy for obtaining inflation below, we will require the net quartic and higher couplings to be small enough relative to the quadratic coupling. This will not require significant tuning of parameters in our solutions.

Now let us consider the strength of corrections to the crucial generalized kinetic terms in the DBI action (i.e. the series in $v_p^2 = \lambda\dot{\phi}^2/\phi^4$) appearing in the action. Importantly, the corrections to these terms coming from (30.1417) are suppressed relative to the existing terms that generate our slow roll effect (in contrast to the situation for the soft mass term just described, for which the (30.1420) constitutes the leading effect.) For example, if we compute the effect of the coupling (30.1417) on the $\dot{\phi}^4$ term in the effective action via a loop of ηs, we obtain a contribution scaling like

$$\left(\frac{\dot{\phi}}{M_*}\right)^4 \log(\Lambda_{UV}/M_*)$$

This is much smaller than the original contribution $N\dot{\phi}^4/\phi^4$ in the small ϕ regime of interest: $\phi^4 \ll NM_*^4$.

The fact that the DBI kinetic terms are robust against large corrections from (30.1417) arises from the fact that they are marginal and get logarithmic corrections suppressed by the coupling constants in terms like (30.1417). There are no soft contributions to the derivative terms in the action–they would have to be of the form $(m_*/\phi)^n(\dot{\phi}^2/\phi^4)$. Such corrections would be more infrared divergent as $\phi \to 0$ than the existing ones in (30.1403). There are no perturbative diagrams producing such effects, and we find it implausible also in the strong coupling regime that coupling to gravity could worsen the IR behavior of the system.

Although these corrections to the DBI kinetic terms are small, they are nonzero in general. Since the kinetic terms arose from the DBI action given by the volume of the brane embedded in the ambient geometry, corrections to them correspond to corrections to the AdS geometry at least as seen by our probe brane. Indeed once we generate (or add by hand in effective field theory) a deformation of the theory by a mass term for ϕ, we expect deviations from exact AdS geometry in the IR. However, as above these deviations are small effects on our probe evolution relative to the effects of the original kinetic terms. In particular, if we deform the Lagrangian to introduce an $m^2\phi^2$ term, we can estimate its effects on the higher derivative terms in the DBI action. These came from integrating out "W bosons", with the importance of the higher derivative terms arising from the fact that these modes become light at the origin $\phi \to 0$. The mass term for ϕ will at some order induce new contributions to the mass of the W bosons; up to logarithms these will at most scale like

$$m_W^2 \to \phi^2 + g_{YM}^2 m^2 \tag{30.1421}$$

In this manner, the contributions of virtual W bosons to the DBI Lagrangian for ϕ become a series in $\lambda\dot{\phi}^2/(\phi^2 + g_{YM}^2 m^2)^2$. This means that for $\phi \gg g_{YM}^2 m$, the evolution is well approximated by that given by the original DBI Lagrangian. As we will see, this constraint preserves a window of interesting behavior for ϕ dictated by,

$$\phi^2 > g_s m^2 \tag{30.1422}$$

In Section 5.1, we shall see that the same constraint arises on the gravity side by requiring small back reaction so that the probe approximation holds.

In summary, the same couplings which give rise to a mass m for ϕ do not badly alter the generalised kinetic terms for $\phi \gg m$. In fact, the mass term itself is a small effect on the overall probe evolution as we will see from the ϕ equation of motion in which the DBI kinetic terms dominate. However, the mass term in the potential will be an important source for the four dimensional spacetime geometry in our cosmological solutions. The corrections on the kinetic terms for $\phi < m$ do mean that ultimately the geometry is probably better approximated by a cut off throat. We will turn to this analysis in subsection 4.2.

As emphasized above, the four dimensional effective field theory however contains more than just ϕ and the BPS W bosons, but also Kaluza Klein modes in the AdS. It is important to check whether couplings similar to (30.1417) and curvature couplings appear with ϕ replaced by Kaluza Klein modes. If so, and if the induced masses m_{KK} of these Kaluza Klein modes were as big as m, the corresponding deformation of the geometry in the IR region would remove our inflationary solution to be described in section 5. In the context of effective field theory, we may tune away these couplings if necessary, and as discussed in the next section we generically expect such tuning to be possible in string theory. It would be interesting to determine whether such tuning is necessary or if $m_{KK} \ll m$ appears naturally.

Gravity Description of Corrections

In the previous subsection, we gave arguments based on simple effective field theory couplings that the (soft) mass term for ϕ generated by (30.1417) will generically be affected more strongly (relative to the original mass term for ϕ in the Lagrangian) than the generalized kinetic terms (relative to the original generalized kinetic terms in the Lagrangian). At first sight, this may appear surprising from the point of view of the geometrical picture of a brane probe. Such a probe has kinetic terms determined by the metric of the ambient spacetime, and potential terms introduced via couplings to other background fields (such as the five form RR field strength in the $AdS_5 \times S^5$ solution of type IIB supergravity). There is no general relation between these two effects, though in particular examples they are related in particular ways via the coupled equations of motion for the metric curvature and the other low energy fields. In familiar examples, such as the $AdS_5 \times S^5$ solution, or the Klebanov Strassler solution [31], the strength of the potential is smaller than the effects we found in the previous subsection.

These classical solutions however do not include the effects introduced by the other sectors (mocked up by η in the above analysis) located in the bulk of a Calabi Yau to which the throat attaches. In general, the relation between the spacetime metric and the other background fields is different from that obtained in the familiar classical solutions. More general flux backgrounds (including AdS solutions) with different types of brane probes will have a different balance between fluxes felt by the probe and metric curvature due to the contribution of other ingredients. Our results in the above subsection reflect an aspect of this in the context of a coupling of ϕ in the familiar solutions to other sectors via, for example, an embedding in a Calabi Yau.

To make this more concrete, let us use known scales of couplings between different sectors of a Calabi Yau geometry to estimate the effective field theory parameters M_* and Λ_{UV} in the effective field theory analysis of the last subsection. In [33] couplings between brane throats were computed. The results were consistent with couplings between a brane throat and another sector (which could be a much smaller throat) suppressed by powers of $M_* \sim 1/R$. Taking the UV cutoff Λ_{UV} of the second sector to also be of order $1/R$, one obtains an estimate for the mass m of order $m \sim 1/l_s\lambda^{1/4}$. As discussed in the previous section, the same coupling yields

a suppressed correction to the kinetic terms if we lie within the window

$$\frac{1}{l_s\lambda^{1/4}} < \phi < \frac{N^{1/4}}{l_s\lambda^{1/4}} \tag{30.1423}$$

To summarise: the important corrections to the mass term for ϕ we derived via effective field theory couplings in the last subsection fit with known properties of geometrical embedding of brane probes, taking into account effects generated by sectors outside the brane throat corresponding to our original CFT. Therefore we find it likely that such a mass term is available (and potentially generic given the presence of a large brane throat) in explicit string models. In any case, a mass for ϕ is physically consistent with a probe approximation for ϕ. This follows from the above considerations regarding the many independent ways of assembling ingredients such as the target space metric and other background fields, combined with the self consistency against back reaction (to be checked in section 5) of the brane energy carried in the ϕ mass term.

However, we have not constructed an explicit example of this in a full compactification model. It is a subtle problem to determine the couplings among sectors in a full string compactification [33][2], and we plan to pursue it systematically in future work.

30.4.2 QFT with Mass Gap Coupled to Gravity

Motivated by the discussion above, we here consider geometries dual to theories with a mass gap, where the AdS throat is cut off at the IR end. The prototypical example of such a geometry is the Klebanov-Strassler solution of [31]. The effects of such an IR cut-off include the following. The warp factor $f(\phi)$ in (30.1404) is changed, and further corrections to the action may arise if we start from a cutoff throat at the classical level. Here we shall consider only a toy model in which we focus on the effect on $f(\phi)$; similar comments to those in the previous subsection apply to the question of further corrections to the action.

For the purposes of our discussion, we replace the full Klebanov-Strassler solution with a simple toy model which reproduces the relevant features. We motivate this by considering a theory in which the formula for the W boson mass (30.1397) is deformed to

$$m_W^2 = \phi^2 + \mu^2 \tag{30.1424}$$

where, in the effective field theory discussion above, we had $\mu^2 \sim g_{YM}^2 m^2$. In general μ will be related to m in a similar fashion, but for the purposes of this section we keep it arbitrary. To model the W mass (30.1424) from the holographic perspective, we keep the action (30.1414), but replace the warp factor f with the appropriate function. For simplicity we shall consider,

$$f(\phi) = \frac{\lambda}{(\phi^2 + \mu^2)^2} \tag{30.1425}$$

Such a geometry does not satisfy Einstein's equations by itself, but nonetheless exhibits the important features of a capped off throat.

In the DBI Lagrangian (30.1414) for the cutoff throat (30.1425) in the antibrane case, there is a hard mass of order

$$m_{DBI}^2 \sim \mu^2/\lambda \tag{30.1426}$$

Loop corrections arising from the ϕ^4 interactions drive this up to $m_{DBI}^2 \sim \Lambda_\phi^2/\lambda$ where Λ_ϕ is the ultra-violet cut-off pertaining to the ϕ loop.

In our cutoff geometry we also have corrections to the masses and other couplings as discussed in the last subsection (where now there may be some new sectors associated with the physics at scale μ). Again the effects on the kinetic terms are subleading but the mass corrections are important.

30.5 Cosmological Solutions

In Section 3, we saw that the scalar field motion in our system is radically different from the naive expectation based on the finite distance to the origin of the moduli space in the metric appearing in the two derivative action (30.1396). Here we shall ask what effects this novel matter sector has on cosmological solutions. We will investigate this in detail by studying the possible FRW cosmologies solutions which follow from (30.1414). We consider only spatially flat cosmologies,

$$ds^2 = -dt^2 + a(t)^2 dx^2$$

Since spatially inhomogeneous terms are redshifted away during inflation, we consider the scalar field ansatz $\phi = \phi(t)$. With this ansatz, the equations of motion can be concisely expressed by first defining the analog of the Lorentz contraction factor in special relativity,

$$\gamma \equiv \frac{1}{\sqrt{1 - f(\phi)\dot{\phi}^2}} \tag{30.1427}$$

Our stategy is to analyze the solutions following from (30.1414) by first ignoring the effects of the curvature coupling $\mathcal{R}\phi^2$, and later showing that its effects are self consistently negligible on our solutions (unlike the situation in usual inflationary models based on (30.1396)). The energy density ρ and pressure p following from (30.1414) (taking the + sign, corresponding to a D3-brane, for definiteness) are given by,

$$\rho = \frac{\gamma}{f} + (V - f^{-1}) \tag{30.1428}$$

$$p = -\frac{1}{f\gamma} - (V - f^{-1}) \tag{30.1429}$$

These definitions do not include the overall coefficient of $1/g_{YM}^2$ in (30.1414) which instead combines with M_p in the Einstein equations so that the scale $(M_p\sqrt{g_s}) = M_p g_{YM}$ appears in all equations. The Friedmann equations read,

$$3H^2 = \frac{1}{g_s M_p^2}\,\rho \tag{30.1430}$$

$$2\frac{\ddot{a}}{a} + H^2 = -\frac{1}{g_s M_p^2}\,p \tag{30.1431}$$

where $H = \dot{a}/a$ is the usual Hubble parameter. Finally, the equation of motion for ϕ reads,

$$\ddot{\phi} + \frac{3f'}{2f}\dot{\phi}^2 - \frac{f'}{f^2} + \frac{3H}{\gamma^2}\dot{\phi} + \left(V' + \frac{f'}{f^2}\right)\frac{1}{\gamma^3} = 0 \tag{30.1432}$$

where prime denotes a derivative with respect to ϕ. Note that at as we approach the speed limit on moduli space, so $\gamma \to \infty$, both the friction term and the potential term in the equation of motion for ϕ become subdominant. It is a simple matter to check that the second Friedmann equation (30.1431) follows from the first (30.1430) together with the equation of motion (30.1432). The effective equation of state of our system, defined by $p = \omega\rho$, is therefore given by

$$\omega = \frac{-\gamma^{-2} - (Vf - 1)\gamma^{-1}}{1 + (Vf - 1)\gamma^{-1}} \tag{30.1433}$$

The Hamilton-Jacobi Formalism

As occurred in the global case, we will find solutions in which the brane asymptotes to the speed of light at late times in the gravity side background. This means that the quantity γ grows as t gets large, and the behavior of ρ will be substantially different from the usual case of $\rho = \frac{1}{2}\dot{\phi}^2 + V$ to which it reduces for small proper velocity.

Firstly, we want to re-write the Friedmann equations (30.1430) and (30.1432) in a more tractable form. In fact, they can be integrated once. In the inflation literature this is referred to as the "Hamilton-Jacobi" formalism [34]. Another perspective can be obtained by viewing the resulting cosmology as a Wick rotation of a BPS domain wall; the first order Friedmann equations are related to the Bogomoln'yi equations derived in [35].

To derive the Hamilton-Jacobi equations the important step is to view the scalar field ϕ as the time variable. In practice, this means we consider $H = H(\phi)$ with $\phi = \phi(t)$. This immediately puts a limitation on the dynamics since it assumes ϕ is monotonic and H is a single valued function of ϕ and therefore does not allow for oscillatory behaviour in ϕ. We start by taking the time derivative of (30.1430) and, using (30.1432) along the way, we find

$$6HH'\dot{\phi} = -\frac{1}{g_s M_p^2}\, 3H\gamma\dot{\phi}^2$$

which can clearly be solved simply by

$$\dot{\phi} = -2(g_s M_p^2)\,\frac{H'}{\gamma}$$

Since (γ^{-1}) depends on $\dot{\phi}$, it's useful to invert this to give us

$$\dot{\phi} = \frac{-2H'}{\sqrt{1/(g_s^2 M_p^4) + 4fH'^2}} \tag{30.1434}$$

Finally, we can substitute this expression for $\dot{\phi}$ into (30.1430), using the full expression for ρ from (30.1428) to get an expression for the potential $V(\phi)$ in terms of the Hubble parameter $H(\phi)$,

$$V = 3(g_s M_p^2)\,H^2 - \frac{(g_s M_p^2)}{f}\sqrt{1/(g_s^2 M_p^4) + 4fH'^2} + \frac{1}{f} \tag{30.1435}$$

The advantage of these equations is that they can be solved sequentially. Given a potential V, we solve (30.1435) to find $H(\phi)$. This can then be plugged into (30.1434) to find $\phi(t)$. Finally, this can be substituted back into $H(\phi)$ to find the dynamics of the universe. We shall now solve for the late time behaviour of these equations, both in the AdS throat where $f = \lambda/\phi^4$, and in our toy model for the cut-off geometry with $f = \lambda/(\phi^2 + \mu^2)^2$.

30.5.1 Cosmology in the AdS Throat

We start by considering cosmology in the CFT, corresponding to a brane moving in the full AdS throat. In this case, the first order Friedmann equations (30.1434) and (30.1435) read

$$\dot{\phi} = \frac{-2H'}{\sqrt{1/(g_s^2 M_p^4) + 4\lambda H'^2/\phi^4}} \tag{30.1436}$$

and

$$\lambda V = 3\lambda(g_s M_p^2)\, H^2 - (g_s M_p^2)\phi^4\sqrt{1/(g_s^2 M_p^4) + 4\lambda H'^2/\phi^4} + \phi^4 \tag{30.1437}$$

We will consider potentials of the form

$$V = V_0 + V_2\phi^2 + V_4\phi^4 + \dots \tag{30.1438}$$

and determine the behaviour of the scale factor as $\phi \to 0$. For now, we will simply introduce these parameters by hand to analyze the equations but, as mentioned above, there are constraints on these coefficients in the $\mathcal{N} = 4$ SYM and in this theory coupled to gravity which we should include in the final analysis. For now however, we work with the ad hoc potential above. There there are three possible cases, depending on which of V_0, V_2 or V_4 is the first non-vanishing coefficient. (We shall in fact see that if the first two vanish, and the potential is positive, then the result is universal).

Case A: $V_0 \neq 0$

If V is simply a constant then equation (30.1437) is solved by $H = \sqrt{V_0/3(g_s M_p^2)}$, in which case equation (30.1436) shows that $\phi = \text{const}$, and we get a standard de Sitter phase. Of course, our kinetic terms aren't playing a role here since ϕ isn't moving. Note that equation (30.1436) requires $V_0 > 0$ here.

Suppose instead that we take $V = V_0 + V_4\,\phi^4$ which suffices to get ϕ moving. Then for small ϕ, we may choose the simple ansatz $H = h_0 + h_4\phi^4 + \dots$ where, from (30.1437) we must choose the coefficients $h_0 = \sqrt{V_0/3(g_s M_p^2)}$ and $h_4 = V_4/6(g_s M_p^2)\, h_0$. Substituting this into the first of the Friedmann equations, we have the late time behaviour for ϕ,

$$\phi \to \frac{1}{4(M_p\sqrt{g_s})\sqrt{h_4}}\,\frac{1}{\sqrt{t}}$$

We see that, as in the case of the global CFT considered in Section 3, the scalar field takes infinite time to reach the origin. However, in this case the friction from the expanding universe means that ϕ does not saturate the speed limit (30.1402). From the late time behaviour of ϕ, we may immediately determine the late time behaviour of the scale factor. We have,

$$H = \sqrt{\frac{V_0}{3(g_s M_p^2)}}\left(1 + \frac{3}{2^7 V_4 (g_s M_p^2)}\,\frac{1}{t^2}\right)$$

This result highlights the peculiar cosmologies that can arise due to strong coupling effects of the gauge theory. Here we find a standard de Sitter phase, superposed with a cosmology in which the scale factor has the form $a(t) \sim exp(-c/tM_p)$. We shall see more cosmologies with this characteristic exponential behaviour in Case D.

Case B: $V_0 = 0$

Let us now consider the interesting case that will give rise to inflation. We suppose that $V_2 \neq 0$ so that this quadratic mass term dominates at late times when ϕ is small.

We work with the simple ansatz,

$$H = h_1\phi + \dots \tag{30.1439}$$

Substituting this into (30.1437), we get contributions to V_2 from both the H^2 term as well the $\sqrt{\cdots}$ term. We find the potential takes the form,

$$V = \left(3h_1^2 - \frac{2h_1}{\sqrt{\lambda}}\right)(g_s M_p^2)\,\phi^2 + \mathcal{O}(\phi^4) \equiv V_2\phi^2 + \mathcal{O}(\phi^4) \tag{30.1440}$$

which, solving for h_1 in terms of V_2 gives

$$h_1 = \frac{1}{3\sqrt{\lambda}}\left(1 + \sqrt{1 + 3V_2\lambda/(g_s M_p^2)}\right) \tag{30.1441}$$

Substituting our ansatz for H into the equation (30.1436), we find

$$\dot{\phi} = \frac{-2h_1\phi^2}{\sqrt{\phi^4/(g_s^2 M_p^4) + 4\lambda h_1^2}}$$

As $\phi \to 0$, we simply throw away the ϕ^4 term in the denominator to find the late time behaviour

$$\phi \to \frac{\sqrt{\lambda}}{t} + \dots$$

This coincides with the result (30.1408) from the global analysis of Section 3; in this theory the slowing down of the scalar field is driven by the speed limit rather than friction from the expanding spacetime. We now substitute this back into our ansatz (30.1439) to find the late time behaviour of the scale factor,

$$a(t) \to a_0\, t^{h_1\sqrt{\lambda}} \tag{30.1442}$$

Using (30.1441), the exponent is

$$h_1\sqrt{\lambda} = \frac{1}{3}\left(1 + \sqrt{1 + \frac{3V_2\lambda}{(g_s M_p^2)}}\right) \approx \sqrt{\frac{V_2\lambda}{3(g_s M_p^2)}} \tag{30.1443}$$

where the approximation is true only for $V_2\lambda \gg g_s M_p^2$. We see that we can orchestrate an inflationary universe if the potential V_2 is sufficiently large. Specifically

$$\frac{V_2\lambda}{g_s M_p^2} > 1 \tag{30.1444}$$

It is amusing to recall that usual slow roll inflation occurs only if the potential is suitably flat. Here we find the opposite result: with a speed limit on the scalar field, inflation occurs only if V_2 corresponds to a high enough mass scale (we see from (30.1444) that this mass scale can be much lower than M_p, but the acceleration gets stronger for larger V_2).

Interestingly, we have obtained a form of power law inflation, since the scale factor behaves as a power of t. However it arises in the case of a polynomial (quadratic) potential, which under the usual circumstances (30.1396) leads to exponential inflation $a \sim e^{Ht}$. (The potential required to obtain power law inflation from (30.1396) is exponential in ϕ.)

Naively it appears that this result suggests an alternative to the usual quintessence scenario where a scalar field rolls towards an asymptotic regime of moduli space. Here the scalar field could roll a finite distance in the field theory moduli space metric in the interior of the moduli space and still lead to asymptotic acceleration. However, we are limited to a finite period of controlled speed of light evolution because of the back reaction of the probe on the geometry. In the global case we determined this backreaction in (30.1412). It is a simple matter to repeat the calculation here where the energy of the brane is dominated by the potential $V_2\phi^2$. Once again, translating from the proper energy E_p to the observers energy density $E = E_p(r/R)^4$, we have the constraint

$$E_p l_5^3 \sim \frac{V_2\phi^2}{g_{YM}^2}\left(\frac{R}{r}\right)^4 \frac{\alpha'^4 g_s^2}{R^5} < \frac{1}{R}$$

which gives us the constraint that our solution is only to be trusted for ϕ greater than

$$\phi^2 > g_s V_2$$

Notice that this is identical to the lower bound on ϕ arising derived in Section 4 by calculating one-loop corrections to the W-boson mass using effective field theory methods (30.1422). Despite this infra-red cut-off to our inflationary phase, we shall shortly argue that we still retain a viable window of inflation in this scenario.

Case C: $V_0 = 0$ **and** $V_2 = 0$

Let us now suppose that the potential has only $V_4 \neq 0$. As we have seen, such a potential is generated by a $\overline{D3}$-brane moving in the AdS throat. The late-time analysis of the Hamilton-Jacobi equations (30.1436) and (30.1437) is actually just a special case of the above discussion, where we put $h_1 = 2/3\sqrt{\lambda}$. We can read of the final result from (30.1442): we have

$$a \to a_0\, t^{2/3}$$

which looks like dust. In fact, for any potential for which $V_0 = V_2 = 0$ with higher order terms non-vanishing, the speed limit on the moduli space ensures that the rolling scalar field looks has equation of state $\omega \approx 0$: a kinetic dust.

Case D: $V < 0$

To find equations of state with $\omega > 0$, we require negative V_2. From (30.1441), we see that for $0 < h_1 < 2/3\sqrt{\lambda}$ we have

$$-\lambda(g_s M^2)^2\,\frac{\lambda}{3} < V_2 < 0$$

The late time behaviour of the scale factor is once again given by (30.1442). During this expansion, the scalar field is rolling up the inverted harmonic oscillator potential. Without the higher kinetic terms, the scalar would overshoot the top and roll down the other side. However, the speed limit does not allow this to happen, and slows the field to prevent it reaching the top at $\phi = 0$ in finite time.

Let us now consider the case $V_2 = 0$ with $V_4 < 0$. We can generate such a potential by considering, for example, $H = h_3\phi^3$ which gives rise to the potential $V = V_4\phi^4 + V_6\phi^6$ where

$$\lambda V_4 = -\sqrt{1 + 36\lambda h_3^2\,(g_s^2 M_p^4)} + 1 \qquad \lambda V_6 = 3\lambda h_3^2\,(g_s M_p^2)$$

At late times the scalar field rolls like $\phi \sim 1/t$, and the equation of state parameter diverges: $\omega \to \infty$. Meanwhile, the scale factor a has the peculiar behaviour

$$a = a_0 \exp\left(-\frac{(1/(g_s M_p^2) + 36\lambda h_3^2)^{3/2}}{2^4\, 3^3\, h_3^2} \frac{1}{t^2} \right)$$

which undergoes a period of accelerated expansion before settling down to a steady-state cosmology at late times. The period of acceleration coincides with the period when the $V_6\phi^6$ term dominates over the $V_4\phi^4$ term in the potential; in the solution this also correlates with a period in which the potential dominates in the gravitational dynamics determined by ω (30.1433). As in case B, the effect becomes stronger with a stronger potential (so a flat potential is not required for slow roll since this is provided by the DBI kinetic terms).

Scale factors with the characteristic $\exp(-1/t^2)$ behaviour also occur in standard cosmology, but only for very finely tuned inital conditions. The novelty here is that such dynamics is generic for a large enough intitial velocity. A similar steady state dynamics also arises from $H = h_4\phi^4$, this time with $a \sim \exp(1/M_p t)$. Each of these scenarios finds Xeno exonerated and Hoyle happy.

30.5.2 Cosmology in the Cut-Off Throat

The interesting Case B of the previous section has $V_2 \neq 0$ which is not compatible with the conformal symmetry implied by an exact AdS throat. Instead, one ultimately expects a geometry in which the throat is cut off in the infra-red. We described such geometries in Section 4. Here we will work with the toy model in which the warp factor is taken to be

$$f(\phi) = \frac{\lambda}{(\phi^2 + \mu^2)^2}$$

For $\phi \gg \mu$, the geometry is essentially that of the AdS throat and the analysis of the previous sections holds. However, for $\phi \leq \mu$, the speed limit becomes simply

$$\dot{\phi} \leq \frac{\mu^2}{\sqrt{\lambda}}$$

So the scalar field can now reach the origin in finite time and happily sail right through at finite speed. This has the advantage that at late times the field oscillates around the minimum of the potential as usual and reheating may occur (depending on the couplings to the Standard Model). However, we must check that we can still arrange for a period of acceleration. The condition for acceleration requires large enough V_2 as we saw in (30.1444) Generally we have

$$V_2 = m^2$$

where masses m^2 which could be generated in various ways were listed in Section 4 and include contributions from graviton loop (30.1419), couplings to other sectors (30.1420) and a hard mass from the deformed geometry (30.1426).

Let us start by examining the upper limit for ϕ. In fact, we are quite entitled to take ϕ as large as we wish and, for $\phi \gg M_p$, one finds the standard slow roll expansion of chaotic inflation. However, as we shall discuss in Section 5.3, models with superPlanckian VEVs suffer from destabilization from a slew of quantum corrections involving for example gravitational curvature couplings $\mathcal{R}\phi^2$ [2]. To avoid this, we shall instead restrict ourselves to *subPlanckian* VEVs

$$\phi \ll M_p, \tag{30.1445}$$

where, as the speed limit is saturated, we may still obtain inflationary behaviour.[185]

In our cut-off geometry we also need ϕ to be suitably large so that the probe brane is experiencing the AdS throat-like background before the cut-off is reached. It can be checked that the solution described in Case B of Section 5.1 continues to hold in the cut-off geometry provided $\phi \gg \mu$. We therefore find our window of inflation when the scalar field lives in the regime,

$$\mu \ll \phi \ll M_p \tag{30.1446}$$

during which time we have the cosmological solution $a(t) = a_0 t^{h_1\sqrt{\lambda}}$ while the scalar field slows down as $\phi = \sqrt{\lambda}/t$. Let us assume that this solution actually holds all the way to the end points (30.1446). This may be overly optimistic, but it gives us a quick and ready way to calculate the number of e-foldings. We require that at the initial time $t = t_0$ we have $\phi(t_0 = 0) = M_p$, while at the final time $t = t_f$ we have $\phi(t = t_f) = \mu$. Then,

$$t_0 = \frac{\sqrt{\lambda}}{M_p} \quad \text{and} \quad t_f = \frac{\sqrt{\lambda}}{\mu}$$

The number of e-foldings is therefore given by,

$$n = \log\left(\frac{a(t = t_f)}{a(t = 0)}\right) = h_1\sqrt{\lambda}\log\left(M_p/\mu\right)$$

The argument of the logarithm is roughly the distance travelled by the scalar field. Any large number of efoldings comes from the prefactor. Using (30.1443) we have

$$n \sim h_1\sqrt{\lambda} \sim \frac{m\sqrt{\lambda}}{\sqrt{g_s}M_p} \geq 100 \tag{30.1447}$$

This criterion is the same as the criterion that the potential V dominate in the equation of state (in particular in ρ).

This inflationary phase is novel in several ways. Most importantly, the inflation can occur on a steeper potential hill than works for ordinary slow roll inflation. Moreover, at least before considering observational constraints from density perturbations, we find inflation to occur at sub-Planckian field strength for ϕ. We will show in section 5.3 that, when combined with the novel form of the equation of motion for ϕ, this allows us to avoid destabilizing effects from a curvature coupling $\mathcal{R}\phi^2$, circumventing some of the difficulties involved in placing inflation within a string compactification [2]. Moreover, as noted in Section 5.1, we have obtained *power-law* inflation from a quadratic potential.

At later times, the brane reaches the end of the cutoff throat and the novelties of the DBI action wear off. At this stage, we expect to reduce to an ordinary matter or radiation dominated phase, though we have not yet controlled the details of the exit from our inflationary stage.

[185] In our subsequent analysis of density perturbations [39], we discovered that to satisfy all the observational constraints including those on non-Gaussianity, we require starting inflation at Planck scale ϕ, which may require fine tuning.

The number of e-foldings (30.1447) can be made large if we can generate a large mass term $m^2\phi^2$ for our scalar field. In Section 4, we discussed possible mechanisms for generating such a term and argued that corrections to our crucial higher derivative terms were sub-leading. The simplest of the mass corrections was the hard contributions (30.1426) from the DBI action itself: $m_{DBI} \sim \mu/\sqrt{\lambda}$. Comparing with (30.1447) we immediately see that in our strong coupling regime $\lambda \gg 1$ there is no inflationary window with such a mass: we need another mechanism. As discussed at length in Section 4, such a mechanism may arise from coupling to other sectors which (depending on the strength of the couplings and cutoff scales for the other sectors in the system) may produce a large enough mass. More simply, as discussed above we may consider deforming the theory by a mass term for ϕ and note that this induces only subdominant corrections to the DBI kinetic terms. Again, it would be very interesting to determine the magnitude of mass m arising in specific string compactifications.

A Comment on V_4 Terms

In the above discussion, we concentrated on the possible mass terms that could be generated, and the associated window of applicability of the inflationary solution described in Case B of Section 5.1. However, the solution itself is valid only if the quadratic term in the potential dominates over the quartic term; otherwise we obtain the dust-like evolution of Case C. We therefore require,

$$V_4\phi^2 < m^2 \Rightarrow \phi^2 < m^2/V_4 \tag{30.1448}$$

If V_4 is too big, then this constraint on ϕ would be much stronger than (30.1445) and potentially ruin our window of inflation. Let us therefore examine the possible V_4 couplings.

In the DBI action, V_4 scales like $1/\lambda$. However, quantum corrections change this. Let's focus on the virtual effects of other sectors, since these were successful in giving us an inflationary window. The derivative coupling (30.1417), leads to a contribution of order

$$\Delta V_4 \sim \Lambda_{UV}^4/M_*^4 \tag{30.1449}$$

while at the same time inducing a mass $m_* \sim \Lambda_{UV}^2/M_*$ (30.1420) as we discussed earlier. Plugging this into (30.1448) leads to the constraint $\phi < M_*$ which is stronger than (30.1445). At the level of our effective field theory analysis (in terms of an unknown UV cutoff parameter Λ_{UV} and a coupling scale $1/M_*$), this is consistent with our inflationary window for appropriate values of these parameters.

30.5.3 Curvature Corrections

Let us now restore into our analysis the curvature coupling $\mathcal{R}\phi^2$ and the other curvature corrections scaling as powers of $\mathcal{R}/\phi^2$. We will consider the regime of our solutions where $\phi \ll M_p$, and show that the solutions are not destabilized by the addition of these curvature couplings (in other regimes more fine tuning would be required [39]). We should note here that the *conformal* coupling required to render the stress energy tensor traceless in the case of large γ will be more complicated than a $\mathcal{R}\phi^2$ coupling.

Let us first consider the $\mathcal{R}/\phi^2$ corrections to the terms in the Lagrangian (30.1416) which scale like H^2/ϕ^2. In our inflating solution, these terms are of the order m^2/M_p^2. As long as this quantity is sufficiently smaller than 1, then the correction terms are negligible compared to the terms in (30.1416) that we did include in the initial analysis. In the noninflating solutions, $H \sim 1/t$ and these corrections are suppressed by powers of λ which makes them very safe from affecting the results above.

Now let us turn to the curvature coupling $\mathcal{R}\phi^2$. First, let us consider the Einstein equations for the metric. The effect of the conformal coupling is to replace M_p^2 with $M_p^2 + \phi^2$ in these equations, changing the effective Planck mass. Since $\phi \ll M_p$, this does not change the solutions for $a(t)$ significantly. Similar comments apply to the $H^2\phi^2$ terms which plague F-term inflation in supergravity models.

Secondly, we must check whether the scalar field equation of motion is self consistently solved by the original solution in the presence of a curvature coupling. The coupling $\xi\mathcal{R}\phi^2$ contributes to the equation of motion for ϕ, (30.1432), as

$$\frac{\lambda\ddot{\phi} - 6\lambda\dot{\phi}^2/\phi + 4\phi^3}{(1-\lambda\dot{\phi}^2/\phi^4)^{3/2}} + \frac{3\lambda H\dot{\phi}}{(1-\lambda\dot{\phi}^2/\phi^4)^{1/2}} + (V' + 2\xi\mathcal{R}\phi - 4\phi^3) = 0 \tag{30.1450}$$

Because $\gamma(t)^{-1} = \sqrt{1-\lambda\dot{\phi}^2/\phi^4}$ is going to zero at late times, the terms involving V and $\mathcal{R}$ are subdominant in this regime. This is reflected in the fact that, for Cases B and C of Section 5.1, the late time behaviour of the scalar field saturates the speed limit and is independent of the potential.

In summary, the curvature couplings we have considered here do not change our results. This is in contrast to the usual situation (30.1396), where for example the slow roll conditions for inflation in a polynomial potential are impossible to satisfy in the presence of the coupling $\mathcal{R}\phi^2$. This point was emphasized for the case of 3-branes in warped throats in [2]. Here see that near the origin, where the DBI velocity corrections are crucial, the structure of the scalar equation of motion is dramatically different due to the factors of $\gamma(t)$ in the denominator in (30.1450).

30.5.4 Relation to other Works

The behavior of our system, especially in Case C in Section 5.1, bears a strong resemblance to the tachyon matter system studied in recent years [5, 8]. Indeed, the anti-brane moving in the *AdS* throat is, in some sense, a strong coupling limit of the tachyon matter system. There are important differences between our case and the weakly coupled tachyon matter system, most notably the fact that as we discussed above in our situation the tachyon has been lifted and, as we shall see, particle production is suppressed. Moreover, the spectra of particles and strings in the two backgrounds differ.

A simple field redefinition can be used to relate the effective field theories in the two cases as follows. In tachyon cosmology, the action for the tachyon is of the form [36]

$$\mathcal{L} = -F(T)\sqrt{1-\dot{T}^2} \tag{30.1451}$$

which, upon expanding the square-root, has a potential term $F(T)$. We can simply generalise this action to include a further potential term $G(T)$, which we could use either to cancel F or simply to make the potential different from the coefficient of the kinetic terms. Such a potential may be generated in situations where the brane antibrane system is embedded in a compactification. We therefore consider,

$$\mathcal{L} = -F(T)\sqrt{1-\dot{T}^2} - G(T)$$

The stress-energy tensor and pressure can be easily calculated to yield energy density

$$\rho = \frac{F}{\sqrt{1-\dot{T}^2}} + G \qquad p = -F\sqrt{1-\dot{T}^2} - G$$

Tachyon cosmologists work with this Lagrangian imposing $G = 0$. Of particular relevance for the present work is the observation [9] that the power-law inflationary phase of Case B can be obtained by the choice $F(T) \sim 1/T^2$ in the Lagrangian (30.1451). It was further shown that higher order (inverse) potentials give rise to dust behaviour as we saw in Case C. To return to our favourite Lagrangian and compare these results with those above, we employ the field redefinitions

$$T = \frac{\sqrt{\lambda}}{\phi} \qquad F(T) = \frac{\lambda^2}{T^4} \qquad G(T) = V(\phi) - \phi^4$$

It is very interesting to ask how generally motion on internal scalar field configuration spaces can be imbued with a geometric interpretation (and therefore a speed limit induced by causality). It is intriguing that the tachyon Lagrangian (30.1451) has a structure reminiscent that of a relativistic particle moving in spacetime.

The motion of the probe brane in the cut-off geometry is also somewhat similar to the discussion of [37]. These authors consider the induced mirage cosmology [38] on a probe brane as it moves in the Klebanov-Strassler geometry [31]. This differs from our analysis in two important respects: firstly, in [37] the probe brane was taken to move slowly through the background geometry, so that the DBI action could be approximated by two-derivative terms. Secondly, the cosmology was viewed from an observer on the probe brane, rather than from the perspective of a boundary observer as is relevant for our discussion.

30.6 Perturbations and Particle Production

We now come to the promised self consistency checks of our time dependent evolution. In order to trust our results in the previous sections, we must check that particle and string production and fluctuations about the solution do not destabilize it. We have already checked that acceleration is small enough to avoid closed string production, and that back reaction from the probe's large kinetic energy is small in the window (30.1412).

30.6.1 W boson and String Production

Firstly, we consider the production of massive strings on the brane and W-bosons. Our effective DBI action is blind to the possible on-shell creation of these modes and we must check by hand that the production is suppressed in the $\lambda \gg 1$ regime. This is rather simple. The time dependent solution we found entails time dependent masses for both W-bosons (30.1397) and massive string modes on the brane (30.1401) since these masses are proportional to $\phi \sim \sqrt{\lambda}/t$.

The strength of particle production for a time dependent frequency $\omega(t)$ is controlled by $\dot{\omega}/\omega^2$. This is a rough estimate which can be obtained by starting from the requirement for adiabatic evolution for a frequency which changes over a time period δt:

$$\delta t \gg 1/\omega_{min} \tag{30.1452}$$

where ω_{min} is the smallest value of ω obtained in the evolution. Dividing by the change $\delta\omega$ arising in the process yields

$$\delta t/\delta\omega \gg 1/(\omega_{min}\delta\omega) \tag{30.1453}$$

Consider a long enough evolution so that $\delta\omega$ is of order ω_{max}. Replacing $\delta\omega$ on the right hand side by ω_{max} and replacing $\omega_{max}\omega_{min}$ by ω^2 yields a condition under which particle production may be consistently neglected:

$$\dot{\omega} \ll \omega^2 \tag{30.1454}$$

This can be thought of as expressing the fact that (on average) the energy from the time dependence of the frequency is smaller than the jump in energy needed to produce an on shell particle. We find in our situation that the inequality (30.1454) is satisfied parametrically in λ for large λ. In particular for the W boson zero modes we find

$$\frac{\dot{m}_W}{m_W^2} \sim \frac{1}{\sqrt{\lambda}} \tag{30.1455}$$

which is suppressed in our large λ regime. Nonzero modes are more suppressed. We also need to check the production of open string oscillator modes on the brane. The masses for these modes are given by the warped value $m_s(\phi) \sim \phi/\lambda^{1/4}$. If they were created at rest, a similar calculation to the one above would yield again parametric suppression of $\dot{m}_s/m_s^2 \sim 1/\lambda^{1/4}$. Since the brane is moving with a large velocity $\sqrt{\lambda}\dot{\phi}/\phi^2$, the strings created on the brane have energies boosted to

$$\omega \sim \gamma\sqrt{N_{osc}m_s(\phi)^2 + \vec{p}^2} \tag{30.1456}$$

where N_{osc} is an integer coming from the oscillator level of the string. These energies are large, and we find that again the time dependent background does not inject enough energy to create these states. Therefore our solution is stable against string and W boson production in the strong coupling regime.

30.6.2 Perturbations of ϕ

In the remainder of this section, we will analyze the fluctuations of ϕ itself about the solutions we have found. Our main goal will be to determine in what regime the perturbations are not dangerous for our solutions above. These results also pertain to the spectrum of density perturbations produced in our inflationary phase. We will defer a detailed discussion of any predictions of that model for the CMBR to a later investigation. We perturb our solutions as,

$$\phi(t) \to \phi(t) + \alpha(x,t)$$

Expanding in Fourier modes, $\alpha(x,t) = \alpha_k(t)e^{ikx}$, the equation of motion for α obtained by expanding the action (30.1414) is,

$$\ddot{\alpha}_k + \left(\frac{6}{t} + 3H\right)\dot{\alpha}_k + \left(\frac{6}{t^2} + \frac{6H}{t} + \frac{k^2}{\gamma_0^2 a^2 t^4}\right)\alpha_k = 0$$

where we have used the late time behavior of the function γ defined in (30.1427) which, for most of our solutions, is $\gamma \to t^2/\gamma_0$ for constant γ_0. In particular, for the inflationary solution of Case B we have $\gamma_0 \sim mM_p/\sqrt{\lambda}$.

If we analyze this equation of motion in the global case, where $H = 0$, we obtain the results $\delta\phi \propto t^{-2}$ and $\delta\phi \propto t^{-3}$ for the $k = 0$ mode. For the $k \neq 0$ modes, the perturbations will be further suppressed. So we see that the perturbations do not grow relative to the background solution $\phi \sim \sqrt{\lambda}/t$; i.e. these perturbations are non-tachyonic.

Let us now analyze the equation with gravity turned on, focusing on the inflationary solution. We would like to estimate the density perturbations that result from the fluctuation $\delta\phi$ in the field. In our inflationary phase, we have

$$H = \frac{1}{\epsilon_0 t} \tag{30.1457}$$

where, from (30.1442), we have $\epsilon_0 = (h_1\sqrt{\lambda})^{-1}$. Since we have $\epsilon_0 \ll 1$, in the inflationary phase the terms involving H and H/t dominate over the terms involving $1/t$ and $1/t^2$ respectively. The relative importance of the k-terms depends on the wavelength under consideration. In general, we therefore have

$$\ddot{\alpha}_k + \frac{3}{\epsilon_0 t}\dot{\alpha}_k + \left(\frac{6}{\epsilon_0 t^2} + \frac{ck^2\lambda}{M_p^2 m^2}\frac{1}{a^2 t^4}\right)\alpha_k = 0 \tag{30.1458}$$

where c is a constant of order one, parameterising our ignorance of γ_0.

For superhorizon fluctuations, defined by $k^2 \ll a^2H^2$, where aH is the comoving horizon size, we may neglect the spatial kinetic terms in (30.1458). This leads to a simple pair of solutions to the classical equation (30.1458) for the modes:

$$\alpha^{(0)} \sim \frac{\alpha_0(k)}{t^2} \tag{30.1459}$$

and

$$\alpha^{(1)} \sim \frac{\alpha_1(k)}{t^{3/\epsilon_0}} \tag{30.1460}$$

These modes decay faster at large t than the perturbations of the scalar field in ordinary slow roll inflation based on (30.1396), which go to a constant as the modes cross the horizon. There are reasonable regimes of parameters for which all the subPlanckian k/a modes have the gradient term in (30.1458) suppressed relative to the effective mass squared term there.

To obtain a prediction for the observed density perturbations, we must be careful to follow them as they re-enter the horizon at later times. For now, let us simply check that the perturbations do not destabilize our inflationary phase.

During inflation, the density perturbations are simply

$$\left.\frac{\delta\rho}{\rho}\right|_{k,\ during\ inflation} \sim \frac{V'\delta\phi_k}{V} \tag{30.1461}$$

For our polynomial potentials, this yields $\delta\phi/\phi$. As we have seen, our perturbations die faster than in ordinary inflation due to the stronger role for the mass term in (30.1458), and they certainly do not compete with ϕ in magnitude. Thus our density perturbations during inflation are small enough to avoid back reaction. The question of whether one obtains eternal inflation depends on the magnitude of $H\delta\phi/\dot{\phi}$, which can be small in our speed of light phase. We plan to pursue in future work a detailed study of the predictions of our inflationary models, as well as an analysis of reheating and other required features.

Part IX
Appendix

обсудим математические методы, которые используются в тех или иных задачах.

A Introduction and Overview of Cosmology

A.1 Another Motivation for Cosmology

A.1.1 Other General Motivation

Если мы изучаем глубоко любую теорию, то очень быстро можно задаться вопросом про то, что же было во Вселенной?

Поэтому это достаточно типичный предмет, и знать его очень прямо полезно, потому что про многое можно сказать, зная его основы. Не следует считать, что это особенный предмет, до которого сложно дойти. На самом деле задаться вопросами про космологию можно очень часто.

современное представление о мире основано на космологии

Просто интересно разные модели Вселенной рассматривать

Конечно, такой подход физически никакого не имеет смысла, потому что чем вертеть теории, можно задаваться вопросами, какая из них верная? Вот - гораздо важнее вопросы. Тем не менее, если бы какие-то параметры Вселенной были бы другими, то что бы было? Такие задачи тоже интересно порешать.

после ОТО запросто взять, узнать интересные модели

то есть это не сложно.

Круто изучать раннюю Вселенную

типа интересно, что там было?

Множество приложений

Укажем приложения
(потом раскрою)

Польза в плане развития как профессионала

(потом раскрою)

Польза в плане саморазвития

(потом раскрою)

Результаты

Обсудим, что полезного и важного человечество получило, поняв этот предмет.

Мотивация к разделам

(потом раскрою в параграфах)

A.1.2 Motivation for Exotic Theories in Cosmology

(пока хз, какие разделы есть)

К квантовой космологии

Будет что ответить эзотерикам

а то альтернативных версий, что там со вселенной происходит полно, и как же хочется четко ответить, что в какой степени верно, в какой нет! и свою версию четко рассказывать. Максимально круто ведь!

A.1.3 Amazing Facts

(????)

A.2 Mindset of a Professional in Cosmology

A.2.1 Isn't 21st Century Cosmology Bullshit? (????)

Что-то я подозреваю, что является, как минимум потому что образование в ней такое, что все самые принципиальные вопросы совершенно плохо раскрыты.
(не знаю, постоянно этот вопрос есть, потом отвечу развернуто на него)

Очень часто приходится останавливаться на том, что такая-то есть модель и так-то с ней работаем. Нормально понять, почему именно ее используем, как она экспериментально подтверждается, как про нее догадаться времени никогда нет во время первого отличного прохождения курса космологии. Это минус, но, видимо, потом это понимание может прийти

Это тоже сильно указывает на то, что космология может быть херней. Потому что мало кто обсуждает очень важные вопросы. А может быть, просто в образовании по космологии проблемы и через 100 лет будут эти же вещи рассказывать, но в другом совершенно формате?

Очень неприятно, когда люди используют утверждения, которые и близко не могут доказать. И в космологии это почти везде

То встречается отсылка к стандартной модели, то к квантовой теории поля при конечной температуре, то еще к чему-то. И откуда-то мы должны знать и понимать какую-то формулу, которая вообще-то в их курсе и не встречается. Вероятность, что формула неверная может быть большой, потому что проверить верность их нет времени, очень много времени скорее всего ушло бы.
Поэтому такая космология сейчас, может быть это все и херня, фундаментально на вопросы ответов скорее всего у профессоров не будет, будут отсылки к каким-то работам кого-то, или к другим книгам. Или может быть нужно просто лучшего космолога встретить?

A.2.2 A Cosmologist's View of the World (???)

(потом сформулирую, я еще крайне далек, чтобы из формул и теории вывести хотя бы какой-то вывод и написать ответ на вопросы ниже)

Что такое гармония в мире, если ты понимаешь историю Вселенно?

Какие основные законы функционирования мира, если ты понимаешь историю Вселенно?

По каким законам лучше всего жить людям, если ты понимаешь историю Вселенно?

A.2.3 How to Derive and Solve Equations in Cosmology?

(отдельный раздел про это, потому что часы ушли только на этот вывод. Аккуратно смотреть, где какие буковки и что они обозначают. так только будет движение вепред, космология отлично этот навык тренирует, без него ничего не докажется.)
(general discussion how to get to the very important equations in cosmology)

Без четкости и аккуратности в космологии ничего не достичь. Можно даже сказать, что тренировки по обычным задачам в космологии - уже стоят того, чтобы ее изучать, потому что это очень хороший способ прокачать эти навыки.

(потом раскрою эту мысль)

О задачах, где есть пара уравнений и нужно в каком-то приближении найти решения (!!!!!)

(задача про квантовую космологию така!!!! укажу тут, как ее решить, хорошая ведь задача!!!)

A.2.4 Equations in Cosmology: Important Features of Particular Cases

(напишу потом, тоже много про это соображений будет с опытом)

Всегда решение начинается с того, что убеждаешься в том, правильно ли ты понимаешь обозначения, особенно, по какому параметру от сложной ($f(g(x))$) или простой ($f(x)$) функции чего производные!

Никогда решение задач в космологии не начинается с другого!
Самое важное - всегда смотреть, в каком времени взяты производные! Иначе минус дни только лишь на то, чтобы осознать, что на самом деле производные в уравнениях в конформном времени записаны, оказывается.
Поэтому имеет смысл вообще напротив каждого уравнения это напоминать себе. Так лучше, чем понадеяться, что на прошлой странице написано, так что можно восстановить.

О задачах про инфляцию

(!! скоро их прорешаю, одно из первых занятий в космологии в планах!)

В разделе про инфляцию всегда следим, по чему именно берем производные, по ϕ, τ или t, не забываем, что часто нужно брать именно сложные производные!

(раскрою потом эту важную мысль. поэтому я всегда и указываю с боку, какое время?)

Что делать, если типичная задача про инфляцию не решается?

(еще потренируюсь, пока тут, потом мб в дополнения перенесу)

- Подумай, по какому времени у нас производная: по конформному или по обычному?

  Может, всю инфляцию нужно переписать, чтобы путаницы в этом не было? Потому что столько путаницы в этих временах, столько часов уходит только лишь на то, что оказывается, там именно от конформного времени производная! Пока важно просто это помнить, это очень неприятно.

  (уже писал в дополнениях, но пусть уж лучше пока 2 раза будет записано, потом мб удалю отсюда)

- Если ты дифференцируешь, то следует помнить, какая функция от какого аргумента или функции зависит, а какой штрих или точка что обозначает.

  Часто от этого возникают дополнительные множители, без которых выражение будет не верным.

A.2.5 Ways to Earn Money by Knowing Cosmology and Most Used Topics (??)

(?????)

A.2.6 Overview of Misconceptions About Cosmology (??)

Examples of misconceptions or easily misinterpreted statements in the literature by Davis Lineweaver

(хорошие авторы их собрали, спасибо им, может, посмотрю когда-то)

In text books and works of popular science it is often standard practice to simplify arguments for the reader. Some of the quotes below fall into this category. We include them here to point out the difficulty encountered by someone starting in this field and trying to decipher what is really meant by 'the expansion of the Universe'.

[1] Feynman, R. P. 1995, *Feynman Lectures on Gravitation (1962/63)*, (Reading, Mass.: Addison-Wesley) p. 181, "It makes no sense to worry about the possibility of galaxies receding from us faster than light, whatever that means, since they would never be observable by hypothesis."
[2] Rindler, W. 1956, MNRAS, **6**, 662-667, *Visual Horizons in World-Models*, Rindler acknowledged that faster than c expansion is implicit in the mathematics, but expresses discomfort with the concept: "... certain physical difficulties seem to be inherent in models possessing a particle-horizon: if the model postulates point-creation we have material particles initially separating at speeds exceeding those of photons."
[31] [3] McVittie, G. C. 1974, QJRAS, **15**, 246-263, *Distances and large redshifts*, Sect. 4, "These fallacious arguments would apparently show that many quasars had 'velocities of recession' greater than that of light, which contradicts one of the basic postulates of relativity theory."
[?] [4] Weinberg, S. 1977, *The First Three Minutes*, (New York: Bantum Books), p. 27, "The conclusion generally drawn from this half century of observation is that the galaxies are receding from us, with speeds proportional to the distance (at least for speeds not too close to that of light).", see also p. 12 and p. 25. Weinberg makes a similar statement in his 1972 text *Gravitation and Cosmology* (New York: Wiley), p. 417, "a *relatively close* galaxy will move away from or toward the Milky Way, with a radial velocity $[v_{\rm rec} = \dot{R}(t_0)\chi]$." (emphasis ours). Shortly thereafter he adds a caution about SR and distant sources: "it is neither useful nor strictly correct to interpret the frequency shifts of light from very distant sources in terms of a special-relativistic Döppler shift alone. [The reader should be warned though, that astronomers conventionally report even large frequency shifts in terms of a recessional velocity, a "red shift" of v km/sec meaning that $z = v/(3 \times 10^5)$.]"
[?] [5] Field, G. 1981, *This Special Galaxy*, in Section II of *Fire of life, the book of the Sun*, (Washington, DC: Smithsonian Books) "The entire universe is only a fraction of a kilometer across [after the first millionth of a second], but it expands at huge speeds — matter quite close to us being propelled at almost the speed of light."
[?] [6] Schutz, B. F. 1985, *A first course in General Relativity*, (Cambridge: Cambridge U. Press) p. 320, "[v=HD] cannot be exact since, for $D > 1.2 \times 10^{26} m = 4000$ Mpc, the velocity exceeds the velocity of light! These objections are right on both counts. Our discussion was a *local* one (applicable for recession velocity

<< 1) and took the point of view of a particular observer, ourselves. Fortunately, the cosmological expansion is slow..."
[?] [7] Peebles, P. J. E., Schramm, D. N., Turner, E. L. and Kron, R. G. 1991, Nature **352**, 769, *The case for the relativistic hot Big Bang cosmology*, "There are relativistic corrections [to Hubble's Law, $v = H_0 D$,] when v is comparable to the velocity of light c." However, Peebles, in his 1993 text *Principles of Physical Cosmology*, (Princeton: Princeton University Press), p. 98, explains: "Since equation [$D = R\chi$] for the proper distance [D] between two objects is valid whatever the coordinate separation, we can apply it to a pair of galaxies with separation greater than the Hubble length... Here the rate of change of the proper separation, [$\dot{D} = HD$], is greater than the velocity of light. This is not a violation of special relativity;" Moreover, in the next paragraph Peebles makes it clear that, dependent upon the cosmological parameters, we can actually observe objects receding faster than the speed of light.
[?] [8] Peacock, J. A. 1999, *Cosmological Physics*, (Cambridge: Cambr Univ. pr.) p. 6, "...objects at a vector distance $\mathbf{r}$ appear to recede from us at a velocity $\mathbf{v} = H_0\mathbf{r}$, where H_0 is known as Hubble's constant (and is not constant at all as will become apparent later.) This law is only strictly valid at small distances, of course, but it does tell us that objects with $r \simeq c/H_0$ recede at a speed approaching that of light. This is why it seems reasonable to use this as an upper cutoff in the radial part of the above integral." However, Peacock makes it very clear that cosmological redshifts are not due to the special relativistic Doppler shift, p72, "it is common but misleading to convert a large redshift to a recession velocity using the special-relativistic formula $1 + z = [(1 + v/c)/(1 - v/c)]^{1/2}$. Any such temptation should be avoided"
[26] [?] [9] Davies, P. C. W. 1978, *The Runaway Universe* (London: J. M. Dent & Sons Ltd) p. 26, "...galaxies several billion light years away seem to be increasing their separation from us at nearly the speed of light. As we probe still farther into space the redshift grows without limit, and the galaxies seem to fade out and become black. When the speed of recession reaches the speed of light we cannot see them at all, for no light can reach us from the region beyond which the expansion is faster than light itself. This limit is called our horizon in space, and separates the regions of the universe of which we can know from the regions beyond about which no information is available, however powerful the instruments we use."
[?] [10] Berry, M. 1989, *Principles of Cosmology and Gravitation*, (Bristol, U.K.: IOP Publishing) p. 22 "...if we assume that Euclidean geometry may be employed, ...galaxies at a distance $D_{max} = c/H \sim 2 \times 10^{10}$ light years $\sim 6 \times 10^9$ pc are receding as fast as light. Light from more distant galaxies can never reach us, so that D_{max} marks the limit of the observable universe; it corresponds to a sort of *horizon*."
[?] [11] Raine, D. J. 1981, *The Isotropic Universe*, (Bristol: Adam Hilber Ltd) p. 87, "One might suspect special relativistic effects to be important since some quasars are observed to exhibit redshifts, z, in excess of unity. This is incompatible with a Newtonian interpretation of the Doppler effect, since one would obtain velocities $v = cz$ in excess of that of light. The special relativistic Doppler formula $1 + z = (c + v)/(c - v)^{1/2}$ always leads to sub-luminal velocities for objects with arbitrarily large redshifts, and is at least consistent. In fact we shall find that the strict special relativistic interpretation is also inadequate. Nevertheless, at the theoretical edge of the visible Universe we expect at least in principle to see bodies apparently receding with the speed of light."
[?] [12] Liddle, A. R. 1988, *An introduction to Modern Cosmology*, (Sussex: John Wiley & Sons Ltd) p. 23, Sect 3.3, "...ants which are far apart on the balloon could easily be moving apart at faster than two centimetres per second if the balloon is blown up fast enough. But if they are, they will never get to tell each other about it, because the balloon is pulling them apart faster than they can move together, even at full speed."
[?] [13] Krauss, L. M. and Starkman, G. D. 1999, ApJ, 531(1), 22–30, *Life, the universe and nothing: Life and death in an ever-expanding universe*, "Equating this recession velocity to the speed of light c, one finds the physical distance to the so-called de Sitter horizon... This horizon, is a sphere enclosing a region, outside of which no new information can reach the observer at the center". This would be true if only applied to empty universes with a cosmological constant - de Sitter universes. However this is not its usage: "the universe became Λ-dominated at about 1/2 its present age. The 'in principle' observable region of the Universe has been shrinking ever since.... Objects more distant than the de Sitter horizon [Hubble Sphere] now will forever remain unobservable."
[?] [14] Harrison, E. R. 1991, ApJ, 383, 60–65, *Hubble spheres and particle horizons*, "All accelerating universes, including universes having only a limited period of acceleration, have the property that galaxies at distances $L < L_H$ are later at $L > L_H$, and their subluminal recession in the course of time becomes superluminal. Light emitted outside the Hubble sphere and traveling through space toward the observer recedes and can never enter the Hubble sphere and approach the observer. Clearly, there are events that can never be observed, and such universes have event horizons." The misleading part of this quote is subtle – there will be an event horizon in such universes (accelerating universes), but it needn't coincide with the Hubble sphere. Unless the universe is accelerating so quickly that the Hubble sphere does not expand (exponential expansion) we will still observe things from beyond the Hubble sphere, even though there is an event horizon (see Fig. 17).
[?] [15] Harwit, M. 1998, *Astrophysical Concepts*, 3rd Ed., (New York: Springer-Verlag) p. 467, "Statement (i) [In a model without an event horizon, a fundamental observer can sooner or later observe any event.] depends

on the inability of particles to recede at a speed greater than light when no event horizon exists."
[?] [16] Hubble, E. and Humason, M. L. 1931, ApJ, 74, 443–480, *The Velocity-Distance relation among Extra-Galactic Nebulae*, pp. 71–72, "If an actual velocity of recession is involved, an additional increment, equal to that given above, must be included in order to account for the difference in the rates at which the quanta leave the source and reach the observer[1].", Footnote 1: "The factor is $\sqrt{\frac{1+v/c}{1-v/c}}$ which closely approximates $1 + d\lambda/\lambda$ for red-shifts as large as have been observed. A third effect due to curvature, negligible for distances observable at present, is discussed by R. C. Tolman..."
[?] [17] Lightman, A. P., Press, W. H., Price, R. H. and Teukolsky, S. A. 1975, *Problem book in relativity and gravitation*, (Princeton, U.S.A.: Princeton U. Press) Prob. 19.7
[18] Halliday, D., Resnick, R. and Walker, J. 1974, *Fundamentals of Physics*, (USA: John Wiley & Sons) 4th Ed., Question 34E, "Some of the familiar hydrogen lines appear in the spectrum of quasar 3C9, but they are shifted so far toward the red that their wavelengths are observed to be three times as large as those observed for hydrogen atoms at rest in the laboratory. (a) Show that the classical Doppler equation gives a relative velocity of recession greater than c for this situation. (b) Assuming that the relative motion of 3C9 and the Earth is due entirely to recession, find the recession speed that is predicted by the relativistic Doppler equation." See also Questions 28E, 29E and 33E.
[19] Seeds, M. A. 1985, *Horizons - Exploring the Universe*, (Belmont, California: Wadsworth Publishing) pp. 386–387, "If we use the classical Doppler formula, a red shift greater than 1 implies a velocity greater than the speed of light. However, as explained in Box 17-1, very large red shifts require that we use the relativistic Doppler formula.... *Example:* Suppose a quasar has a red shift of 2. What is its velocity? *Solution:* [uses special relativity]"
[20] Kaufmann, W. J. and Freedman, R. A. 1988, *Universe*, (New York: W. H. Freeman & Co.) Box 27-1, p. 675, "... quasar PKS2000-330 has a redshift of $z = 3.78$. Using this value and applying the full, relativistic equation to find the radial velocity for the quasar, we obtain $v/c = (4.78^2 - 1)/(4.78^2 + 1) = ... = 0.92$. In other words, this quasar appears to be receding from us at 92% of the speed of light."
[21] Taylor, E. F. and Wheeler, J. A. 1991, *Spacetime Physics: introduction to special relativity*, (New York: W. H. Freeman & Co.) p. 264, Ex. 8-23
[22] Hu, Y., Turner, M. S. and Weinberg, E. J. 1993, Phys. Rev. D, 49(8), 3830–3836, *Dynamical solutions to the horizon and flatness problems*, "... many viable implementations of inflation now exist. All involve two key elements: a period of superluminal expansion..." They define superluminal expansion later in the paper as "Superluminal expansion might be most naturally defined as that where any two comoving points eventually lose causal contact." Their usage of superluminal conforms to this definition, and as long as the reader is familiar with this definition there is no problem. Nevertheless, we should use this definition with caution because even if the recession velocity between two points is $\dot{D} > c$ this does not mean those points will eventually lose causal contact.
[23] Khoury, J., Ovrut, B. A., Steinhardt, P. J. and Turok, N. 2001, Phys. Rev. D, 64(12), 123522, *Ekpyrotic universe: Colliding branes and the origin of the hot big bang*, "The central assumption of any inflationary model is that the universe underwent a period of superluminal expansion early in its history before settling into a radiation-dominated evolution." They evidently use a definition of 'superluminal' that is common in inflationary discussions, but again, a definition that should be used with caution.
[24] Lovell, B. 1981, *Emerging Cosmology*, (New York: Columbia U. Press) p. 158, "... observations with contemporary astronomical instruments transfer us to regions of the universe where the concept of distance loses meaning and significance, and the extent to which these penetrations reveal the past history of the universe becomes a matter of more sublime importance"
[25] McVittie, G. C. 1974, QJRAS, 15(1), 246–263, *Distance and large redshifts*,"... conclusions derived from the assertion that this or that object is 'moving with the speed of light' relative to an observer must be treated with caution. They have meaning only if the distance and time used are first carefully defined and it is also demonstrated that the velocity so achieved has physical significance."

A.2.7 General Approach to a Research in Cosmology

Ожидай, что много не очень умных людей этим занимаются, так что лучше иметь отличную подготовку по другим предметам, только с ней заниматься космологией

Без этого слишком большая вероятность, что будешь фигней страдать.

A.2.8 Ways to Guess the Main Ideas (???)

незаменимая часть нормального понимания предмета.

A.2.9 Effective Studying of Cosmology

Не трать особо время на то, в чем ты не понимаешь обозначения and also if you don't understand mathematical transformations

В космологии очень много обозначений, и часто один параметр может значить многое разное.

Так что я всегда и указываю после уравнения, что чем является!! (проверю потом, так ли это!!!)

И это огромная трата времени думать про что-то, что не определено рядом с уравнением!!! Не делай так, и можешь просто недели сэкономить. Не читай такие места в книгах или записях лекций!!!

Огромная трата времени думать про что-то, в чем ты не понимаешь параметры, так что обходи это стороной.

(I'll write later here, that there are not so hard mathematical transformations, one just needs to understand, what is really meant by what is written. since sometimes it is explained very bad, there could be days wasted. I'd recommend that if the formula is not reproduced in some reasonable time by all reasonable methods, then just assume it and don't be stuck on derivations! this can save even 5 days during 30 days of research in cosmology!)

чтобы начать заниматься космологией, собери просто основы теории поля и начинай.

как начать заниматься космологией?

казалось бы, в космосе может происходить что угодно, как вообще подступиться к описанию чего-то там?

подробно подумаю, как начать

основы дифференциальной геометрии должны быть взяты

думаю, без этого никак.

A.3 Acknowledgements

Currently, no one except me has worked on the sections of this note (with the exception of sections taken from books).

A.4 Literature on Cosmology

A.4.1 Main Literature

Basic educational literature

[?] D. Baumann Cosmology Part III Mathematical Tripos (Cambridge University)

165 страниц (с решениями). Хорошие лекции для введения, многое очень компактно и достаточно понятно написано, но некоторые темы совсем мало раскрыты там. Не уверен, что этих лекций достаточно для понимания темы.

David Tong Cosmology http://www.damtp.cam.ac.uk/user/tong/cosmo.html

Вроде хорошие компактные лекции, многое уже выгружено и скорее всего все темы отсюда у меня тоже будут написаны.

[?] J. Lesgourgues Cosmological perturbations

Вроде хорошие лекции по возмущениям в космологии, точно не на пару дней изучения. Обещаются качественные обсуждения возмущений, что очень круто.

Edward L. Wright. course for Ucla university https://www.astro.ucla.edu/~wright/cosmolog.htm (2005)
Очень крутые онлайн страницы с очень интересной информацией. Есть секция ответов на вопросы и очень много ссылок.

Курс университета Калифорнии https://phys.libretexts.org/Courses/University_of_California_Davis/UCD%3A_Physics_156_-_A_Cosmology_Workbook/Workbook
Кроме того, что интересные и важные темы написаны, там есть некоторые интерактивные игры-квизы, что просто прекрасно. Может, когда-нибудь такое везде будет обучение? Очень хорошая идея - почитать их.

K. Zhou Lecture notes on cosmology https://knzhou.github.io/notes/cos.pdf
Хороший обзор космологии от студента Стенфорда, примерно такой объем тем и входит в минимальную подготовку по космологии.

Основная профессиональная литература

[2] Scott Dodelson Modern Cosmology
Книга, где очень много всего написано, многие на нее ссылаются, так что и я пока считаю ее основной, скорее всего многое из нее выгружу.

Books With Many Solved Problems

Лайтман Пресс Прайс Тюкольски Сборник задач по ОТО и гравитации
Шикарный задачник, в котором также есть раздел про космологию.

A.4.2 Articles on Different Effects

Статьи про явления во Вселенной

[?] Perlmutter, S. and Aldering, G. and Goldhaber, G. Measurements of Ω and Λ from 42 High-Redshift Supernovae
Статья о том, что все-таки Вселенная расширяется по средствоим наблюдения дальних звезд, за которую дали Нобелевскую премию.

[?] Type Ia Supernova Discoveries at z > 1 from the Hubble Space Telescope: Evidence for Past Deceleration and Constraints on Dark Energy EvolutionAdam G. Riess and Louis-Gregory Strolger and John Tonry and Stefano Casertano et al.
Известная статья о том, что где-то что ли Вселенная замедляется? Не особо разбирался, но многие ее цитируют.

Max Tegmark's website https://space.mit.edu/home/tegmark/movies.html
Красивая анимация, которая показывает, как изменится спектр СМБ и разное другое, если поменять космологические параметры. Самый быстрый способ ответить на вопросы про это - нажать туда на кнопку и посмотреть эти анимации.

О квантовых эффектах в начале Вселенной

[?], Coleman, Sidney and De Luccia, Frank Gravitational effects on and of vacuum decay
Там во время фазовых переходов образуются пузыри и с ними происходили фазовые переходы в начале Вселенной. Вот описание этого. Отдельная заморочка на самом деле, но интересная теория. Слушал про это лекцию.

Углубленная литература и литература с дополнительными темами

[?] Viatcheslav Mukhanov Physical Fundations of Cosmology https://sites.astro.caltech.edu/~george/ay21/readings/Mukhanov_PhysFoundCosm.pdf
Тоже интересная, большая книга, многое из нее не знаю, наверное, много хороших идей, которых в других книгах не прочитать.

[?] Landau L. D. Field theory
A couple of simple and interesting models have been discussed, uploaded, but I'm not sure if these models are used with notebooks at all? Then I'll continue to sort it out, somehow these topics turned out to be not very necessary.

Обзорные статьи сложных явлений или многих моделей

The Best Inflationary Models After Planck Jerome Martin, Christophe Ringeval, Roberto Trotta, Vincent Vennin https://arxiv.org/abs/1312.3529v3
Шикарная статья с обзором инфляционных моделей, очень интересно потом почитать ее будет.

Daniele Bertacca, Nicola Bartolo, Sabino Matarrese Unified Dark Matter Scalar Field Models https://arxiv.org/abs/1008.0614
Статья с обзором моделей темной материи, полистал, пройду основы - будет смысл добавить разные модели, подумать про них. Должна быть полезной, но сейчас слишком слабая теория.

Статьи про основы космологии

Я. В. Зельдович Космологическая Постоянная И Теория Элементарных Частиц
Выглядит как очень хорошая статья, так что если захочу про основы космологии узнать лучше, дня 2 ее только и буду читать.

Shawn Westmoreland Energy Conditions And Scalar Field Cosmology
Там много условий на энергии есть и разные детали, интересно будет посмотреть на то, какие условия что говорят. Пока забил, потому что отдельно рыться долго в этих основах, займусь только после прохождения базовых курсов и понимании основ космологии.

Статьи про инфляцию и раннюю Вселенную

Robert Brandenberger, Jurg Frohlich, Ryo Namba Unifed Dark Matter, Dark Energy and Baryogenesis via a Cosmological Wetting Transition arXiv:1907.06353v2
Насколько понял, порешали динамику двух скалярных полей в спонтанно нарушенном симметрией потенциале, вывели фазовый переход. Звучит интересно, не уверен, насколько модель полезная, но как проработаю обычные разделы по космологии и теории поля - поизучаю, если захочу.

Статьи про CMB

[?] Kogut, A. et al. Dipole Anisotropy in the COBE Differential Microwave Radiometers First-Year Sky Maps
По идее тут ответ про то, что такое диполь СМБ. пока не знаю, но чуть что скорее всего ее и буду читать.

Статьи про другие эффекты

Job Feldbruggea Rien van de Weygaertb Johan Hiddingb,c Joost Feldbrugged Caustic Skeleton & Cosmic Web
крутая статья про микроволновой фон и теорию катастроф, скорее всего потом добавлю из неё темы и сюда и в математику. Второстепенно, но выглядит очень круто.

[?] Husain, Viqar and Tasic, Vladimir An Indeterminate Universe: Dark Energy and Norton's Dome
Статья про неопределенность вселенной, темную материю. звучит интересно, в школе по космологии на нее ссылка была.

[?] Martin, Jerome Everything you always wanted to know about the cosmological constant problem (but were afraid to ask
Очень много обзора космологической постоянной, возможно, показан ее вывод из стандартной модели.

[?] Job Feldbrugge, Jean-Luc Lehners, Neil Turok Lorentzian Quantum Cosmology
Что-то написано про квантовую космологию, особо ничего не понял, не уверен, что статья полезная, но тем не менее, может быть когда-то почитаю и пойму её.

По квантовой космологии

(вроде их много, мб дойду до этого, но очень не скоро)

A.4.3 Additional, Popular, Literature for Help

Другая обучающая и методическая

[?] Вайнберг С. Космология
много всего, потом им дополню когда-то то, что уже тут написал.

Tom Theuns Physical Cosmology http://icc.dur.ac.uk/~tt/Lectures/UA/L4/cosmology.pdf
Еще одни лекции, где другим деталям уделено внимание, так что думаю, что посидеть над ними хотя бы 4 дня точно стоит того. Выглядит, как очень неплохой вариант изложения космологии.

Galsxies and Cosmology Ay 21 lectures George Djorgovski, Caltech https://sites.astro.caltech.edu/~george/ay21/ https://www.youtube.com/watch?v=pUbLsA6g1us&list=PLdoUUpjpM9818MBicKyIuXebavZggG&index=2&ab_channel=ArindamKumarChatterjee
Очень крутые лекции, объясняющие, что же происходит в обычной теории Баумана например. Интересные, и очень углубленные в приложения и астронию лекции, теоретики такого вообще не проходят. Разве что это отдельный большой курс, так что за выходные его не пройти, даже если прошел обычную космологию. Также на сайте курса много хороших ссылок на статьи и т.п.

Theoretical AstroPhysics Including Relativity and Cosmology at Caltech Physics 217bc: The Standard Model - Cosmology. http://www.tapir.caltech.edu/~chirata/ph217/
Крутые компактные лекции, где много интересных тем, которых нет в других курсах, полезно тоже досмотреть их.

[?] Davis, Tamara M. and Lineweaver, Charles H. Expanding Confusion: Common Misconceptions of Cosmological Horizons and the Superluminal Expansion of the Universe
25 страниц, обсуждается расширение Вселенной, много нетривиального рассказывается, очень полезная для понимания этого важного вопроса.

Wannie Hu's lectures http://background.uchicago.edu/~whu/Courses/
Тоже много хорошего изложения типичных тем.

[?] PhD thesis Wandering in the Background: A Cosmic Microwave Background Explorer Wannie Hu http://background.uchicago.edu/~whu/thesis/thesis.pdf
200 страниц углубленной теории, я даже не выгружал, потому что мне такие детали не нужны, основы еще доучивать нужно, ну да и нет пока проектов по космологии.

Stackexchange questions https://physics.stackexchange.com/questions/tagged/cosmology
It can be a good practice and it was a source of some questions in my section of problems.

Физическая в помощь

Мизнер Торн Уиллер т. 1
Наверное, крутая книга, очень подробная, очень многое прописать нужно, прежде чем будет потребность в этих деталях.

Мизнер Торн Уиллер т. 2
Наверное, крутая книга, очень подробная, очень многое прописать нужно, прежде чем будет потребность в этих деталях.

Мизнер Торн Уиллер т. 3
Наверное, крутая книга, очень подробная, очень многое прописать нужно, прежде чем будет потребность в этих деталях.

Популярные и почти популярные книги

[**?**] Хокинг С., Пенроуз Природа пространства и времени
Название крутое, темы интересные, не уверен, что что-то полезное будет написано. После основных тем только посмотрю.
Barbara Ryden Introduction to Cosmology
Наверное, хорошая книга, но не знаю, зачем мне она, потому что вроде все это уже в других книгах обсуждается. Может, когда-то почитаю, дополню ей свою запись.

A.4.4 Suggested Readings from Good Books

SUGGESTED READING EINSTEIN EQUATIONS

Most cosmology books offer some treatment of the perturbed Einstein equations in cosmology. Again The Large Scale Structure of the Universe (Peebles) is a useful reference, especially for synchronous gauge. Cosmological Inflation and Large Scale Structure (Liddle and Lyth) has a very nice treatment which, among other virtues, explains the physics of gauge choices. Probably the two most comprehensive works are the review articles by Mukhanov, Feldman, and Brandenberger (1992) and Kodama and Sasaki (1984), with the former slightly more accessible and the latter more general. These are both based on the seminal Bardeen (1980) article which is remarkable for its clarity and conciseness in its treatment of gauge invariant variables.

The general relativity books mentioned in Chapter 2 all have good discussions of gravity waves. Before turning to any of the technical literature, though, you must read Black Holes and Time Warps (Thorne), a wonderful mixture of the history, science, and personalities associated with 20th-century general relativity. It is the best popular science book I have ever read.

SUGGESTED READING SCALAR PERTURBATIONS

The 30 or so pages on inflation in this chapter, which were heavily slanted toward production of perturbations, offer but a glimpse into the many facets of this remarkable theory. Recently, Guth wrote a popular account of his discovery of inflation, The Inflationary Universe. One of the other originators of the theory, Linde, has a more technical book, Inflation and Quantum Cosmology, which emphasizes model building much more than I have here. As I mentioned earlier, The Early Universe (Kolb and Turner) has an excellent chapter on inflation. The recent Cosmological Inflation and Large Scale Structure (Liddle and Lyth) is most similar in spirit to this book, with a heavy emphasis on perturbations. The discussion there of the perturbation spectrum is laden with less algebra than the one in Section 6.5 so is worth reading. (Beware that their Planck mass is our $m_{\rm Pl}/\sqrt{8\pi}$.)

An extremely clear and deep look into inflation is given in 300 Years of Gravitation (ed. Hawking and Israel) in the article by Blau and Guth. Many other articles in that thick compilation volume are also fascinating. The initial article by Guth (1981) is completely accessible and as clear a statement possible of the problems that led to inflation and the initial attempt (old inflation) to solve them. Indeed, I would recommend reading Guth's initial article because this chapter motivates inflation with the horizon problem, while Guth had several different problems in mind, including the monopole problem and the flatness problem (Exercise 4).

There have been many papers reviewing the production of perturbations during inflation. Two clear reviews are Lidsey et al. (1997) and Lyth and Riotto (1999). The former focuses on methods for going beyond the predictions elucidated here, which are accurate only to first order in the slow-roll parameters ϵ and δ, and on extracting the potential V from observations. The latter summarizes efforts to tie inflation to realistic particle physics models. The eight-page paper of Stewart and Lyth (1993) is a remarkably concise treatment of the techniques used to go beyond the first-order slow-roll approximation. Hollands and Wald (2002) have written a thoughtful critique of inflation, which is a refreshing antidote to some of the euphoria emanating from the discoveries of the late 1990s. Besides the importance of this critique in its own right, the paper has one of the clearest qualitative descriptions of perturbation generation during inflation that I have ever read.

The initial conditions relating the various perturbations described in Section 6.1 are perhaps most clearly discussed in the review article by Efstathiou (1990). Isocurvature perturbations, for the most part ignored here, are treated in detail there.

I have ignored the possibility of perturbations produced by topological defects. These theories, while fascinating, have not succeeded in making robust predictions; to the extent that predictions can be extracted from them, they are wrong. Nonetheless the numerics involved in their study is sufficiently complicated that I would not be shocked to see them make a comeback some day. There exist many books with comprehensive discussions of topological defects. Amorig them are Cosmic Strings and Other Topological Defects (Vilenkin and Shellard) and The Formation and Evolution of Cosmic Strings (ed. Gibbons, Hawking, and Vachaspati).

SUGGESTED READING PROBES OF INHOMOGENEITIES

The Large Scale Structure of the Universe (Peebles) has a good description and derivation of the angular correlation function, using Limber's (1953) original derivation. The derivation given in Section 9.1 is based on the Appendix of Kaiser's (1992) work on weak lensing. This derivation has the advantage of being physically intuitive and also generally applicable. It will allow us to easily compute the weak lensing correlation functions we encounter in Chapter 10.

The data discussed in Section 9.1 come from the APM Survey (Maddox et al., 1990). Other recent angular results of note include the Edinburgh/Durham Southern Galaxy Catalogue (EDSGC, Collins, Nichol, and Lumsden, 1992) and the Sloan Digital Sky Survey (York et al., 2000), the first analysis of which is presented in Scranton et al. (2002). As I hinted in the text, analysis of these data sets has gotten progressively more sophisticated over time. Baugh and Efstathiou (1993) first inverted the APM angular correlation function and extracted the 3D power spectrum, confirming that it was quite different from the standard CDM power spectrum on large scales. Dodelson and Gaztanaga (2000) pointed out that the resultant errors on the power spectrum are correlated and that an accurate treatment would also account for the fact that the errors in $w(\theta)$ are also correlated. Eisenstein and Zaldarriaga (2001) and then Efstathiou and Moody (2001) accounted for these correlations leading to the softened conclusions summarized in Figure 9.6. The Eisenstein and Zaldarriaga paper also contains a clear discussion of the relation between $w(\theta)$ and the 2D power spectrum, or the C_l 's. They observed that errors on the C_l 's are much less correlated, which leads me to believe that C_l 's will ultimtely replace $w(\theta)$ as the statistic of choice for angular surveys. Indeed, Huterer, Knox, and Nichol (2001) have analyzed the EDSGC survey with C_l 's, and Tegmark et al. (2002) obtained C_l 's from early SDSS data.

Cosmological Physics (Peacock) is a good resource for peculiar velocities and their effect on redshift surveys. Two important and informative review articles are Strauss and Willick (1995) and Hamilton (1998), the former particularly good for experimental issues involved in determining peculiar velocities and the latter for analyzing galaxy surveys in the presence of redshift space distortions. Another leader in the field, Dekel (1997), has written a good review of the cosmological implications of the peculiar velocity field.

The seminal work on redshift space distortions is by Kaiser (1987), who solved the problem working in Fourier space for linear distortions in the distant-observer, low redshift approximation. Hamilton (1992) found the analogue of this solution in real space. Recently, with large-area, relatively deep surveys coming on line, the generalization for cosmological corrections (i.e., distance is not equal to cz/H_0 as z gets large) and all-sky analysis has been carried out by a number of authors. As examples of the work currently going on in the field, Szalay, Matsubara, and Landy (1998) generalized Kaiser's work to large angles while Magira, Ying, and Suto (2000) accounted for cosmological distortions and also nonlinearities and evolution.

Peacock and Dodds (1994) analyzed a variety of surveys, arguing that - accounting for redshift space distortions, nonlinearities, and bias properly - the power spectrum has been well measured. Undoubtedly, with the upcoming Sloan Digital Sky Survey, Two Degree Field, and others, more will be learned about the power spectrum in coming years. The semianalytic work referred to on Page 283 is based on the seminal papers of White and Rees (1978) and White and Frenk (1991). Related, but separate form these semianalytic models, is the halo model (reviewed by Cooray and Sheth, 2002) which postulates that all the dark matter is in halos, thereby reducing the clustering problem to (i) the clustering of the halos and (ii) the distribution of matter and galaxies within the halo. Good descriptions of what the halo model is and how it can be used to compare theories with redshift surveys can be found in White (2001); Seljak (2000); and Berlind and Weinberg (2001).

The prediction of the cluster abundance is treated nicely in Cosmological Physics (Peacock) and Cosmological Inflation and Large Scale Structure (Liddle and Lyth). Structure Formation in the Universe (Padmanabhan) has a detailed section on the spherical collapse model, which is the source of the numbers 1.686 and 178 in Section 9.5. In addition to the papers cited in the text, some important cluster normalization papers are Viana and Liddle (1996, 1999) and Pierpaoli, Scott, and White (2001).

SUGGESTED READING WEAK LENSING AND POLARIZATION

Gravitational lensing is described in exquisite detail in Gravitational Lenses (Schneider, Ehlers, and Falco). An excellent, comprehensive review of weak lensing is in Bartelmann and Schneider (2001). Electromagnetic polarization is a textbook subject, covered in, for example, Classical Electrodynamics (Jackson) and Radiative Processes in Astrophysics (Rybicki and Lightman). Initial papers on gravitational lensing by large scale structure include Blandford et al. (1991), Miralda-Escude (1991), and Kaiser (1992).

Recent theoretical work connecting lensing observations to cosmological parameters includes Jain and Seljak (1997); Bernardeau, van Waerbecke, and Mellier (1997); and Hu and Tegmark (1999). The onset of the new millenium saw the first detections of lensing by large scale structure in van Waerbecke et al. (2000); Wittman et al. (2000); Bacon, Refrgier, and Ellis (2000); Kaiser, Wilson and Luppino (2000); and Maoli et al. (2001). Active work continues. The future will undoubtedly bring observations of weak lensing on large fields. Two proposal for such observations are the SuperNova Acceleration Probe (SNAP; http://snap.Ibl.gov), which presently plans to devote $\sim$ 20% of its time to weak lensing, and the Large Scale Synaptic Telescope (LSST; http://ww. dmtelescope.org).

Polarization of the CMB was studied in the seminal papers of the 1980 s by Bond and Efstathiou (1984) and Polnarev (1985). Kosowsky's thesis (1996) is a lucid Boltzmann-esque discussion of this work. The first papers to recognize the importance of the E/B decomposition were Stebbins (1996); Seljak (1997);

Kamionkowski, Kosowsky, and Stebbins (1997a,b), and Zaldarriaga and Seljak (1997). I've followed the treatment of Seljak who worked in the small angle limit because the algebra is simpler. The review article of Hu and White (1997b) is perhaps the most accessible introduction into the recent literature on polarization of the CMB, but it is a difficult subject. Even this lucid review with its illuminating pictures requires a lot of effort to understand.

DASI (Kovac et al., 2002) detected polarization at the 5-sigma level. Previous stringent upper limits, which are still valuable on large scales, were obtained by Hedman et al. (2000) and Keating et al. (2001).

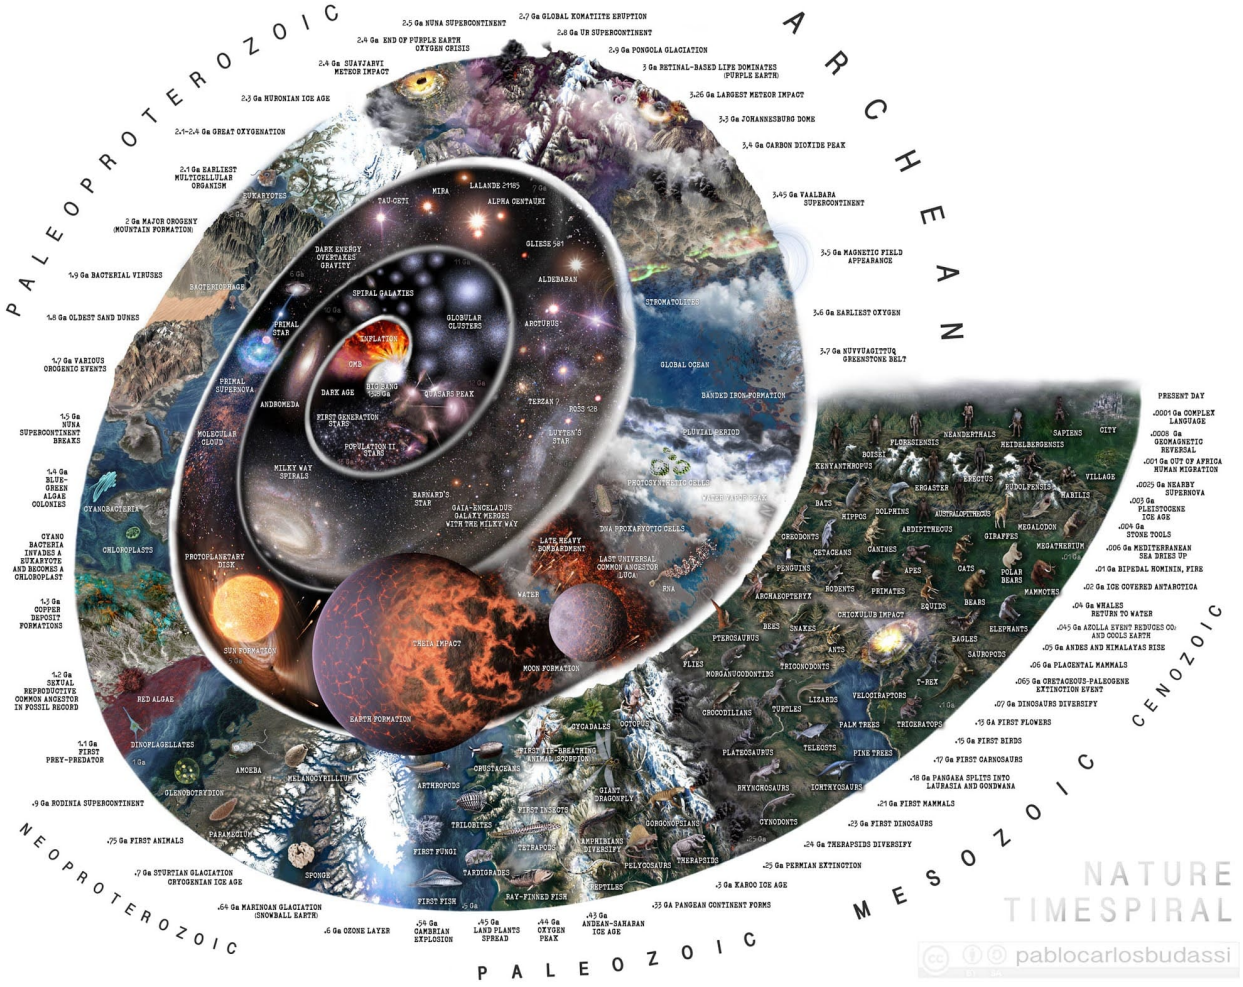
A.5 History of Cosmology in a Nutshell (???)

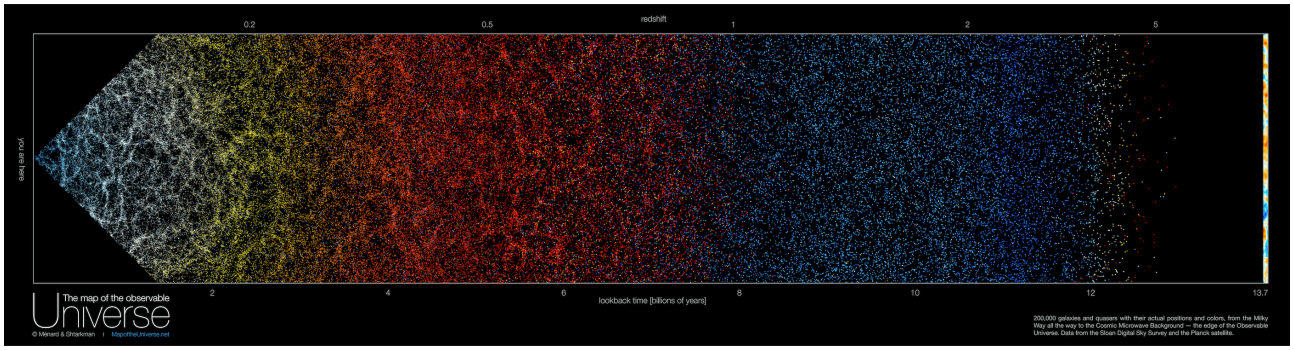
(хз пока что)

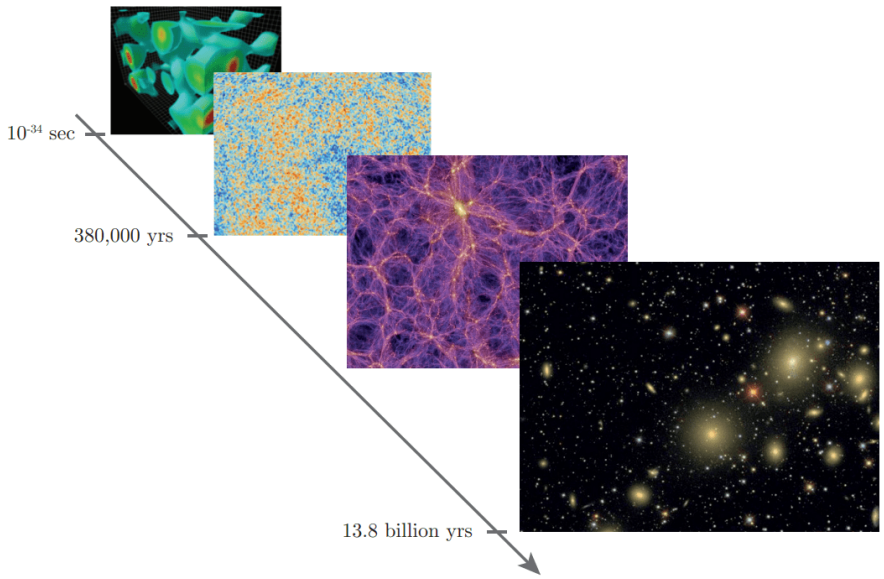
A.6 Overview of Cosmology

A.6.1 Popular Overview of Cosmology

Общие закономерности







(абзац с пояснениями)

A.8 Cosmological Puzzles for Different Cases

сбалансирую и наберу потом по интересности

A.8.1 Puzzles about Construction of Cosmology

Идейно, как описать Вселенную?

Есть метрика, записываю то есть уравнения Фридамана.

A.8.2 General Questions about the Universe

является ли классическая физика и космология детерминированной?

(а вот я не знаю, потом займусь ответом, тут пока выгрузка из школы по космологии)
Let us consider a simple mechanical model: Norton's Dome.
A classical point particle finds itself at some maximum of the potential

$$V = V_0 - V_1 x^{\frac{3}{2}}, \quad V_0 > 0, \quad V_1 > 0$$

To such a potential corresponds a surface which is not spherical but has some kind of cusp at the top.

The second Newton law for the particle is

$$\ddot{x} = \frac{3}{2} V_1 x^{\frac{1}{2}}$$

...

The Friedmann equations for a flat universe filled with a perfect fluid with

$$p = w\rho, -1 > w > -\frac{2}{3}$$

are written in such a form that they are nonsingular at $a = 0$ and permit both the solutions $a(t) = 0$ and

Что есть настоящее расширение Вселенной?

Говорят, это расширение метрики, но о многом тут можно подумать.

Почему вселенная расширяется?

где граница вселенной?

A.8.3 General Questions about What Cosmologists are Doing

Почему космология как наука вообще возможна

(Кант утверждал, что её нет, потом порассуждаю про это)

О возникновении всего из ничего

(тоже типичный вопрос)

A.8.4 Questions for Those Who Say They Have Mastered Cosmology

В чем состоит интегральный эффект Сакса-Вульфа? (?????)

(не знаю, там много нужно знать, чтобы до него дойти в принципе)

B Some Physics for Cosmology

B.0.1 Some General Theory of Relativity
