$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^S_{\text{early}} = -\frac{1}{2}a^2(t_L)\,\ddot{B}(r_L\hat{n},t_L) - \frac{1}{2}a(t_L)\,\dot{a}(t_L)\,\dot{B}(r_L\hat{n},t_L) + \frac{1}{2}E(r_L\hat{n},t_L) + \frac{\delta T(r_L\hat{n},t_L)}{\bar{T}(t_L)} - a(t_L)\left[\frac{\partial}{\partial r}\left(\frac{1}{2}\dot{B}(r\hat{n},t_L) + \frac{1}{a^2(t_L)}\delta u_\gamma(r\hat{n},t_L)\right)\right]_{r=r_L}, \tag{7.1.37}$$

$$\left(\frac{\Delta T(\hat{n})}{T}\right)^S_{\text{late}} = \frac{1}{2}a^2(t_0)\,\ddot{B}(0,t_0) + \frac{1}{2}a(t_0)\,\dot{a}(t_0)\,\dot{B}(0,t_0) - \frac{1}{2}E(0,t_0) + a(t_0)\left[\frac{\partial}{\partial r}\left(\frac{1}{2}\dot{B}(r\hat{n},t_0) + \frac{\delta u_\gamma(r\hat{n},t_0)}{a^2(t_0)}\right)\right]_{r=0}, \tag{7.1.38}$$

$$\left(\frac{\Delta T(\hat{n})}{T}\right)^S_{\text{ISW}} = -\frac{1}{2}\int_{t_L}^{t_0} dt\left[\frac{\partial}{\partial t}\left(a^2(t)\ddot{B}(r\hat{n},t) + a(t)\dot{a}(t)\dot{B}(r\hat{n},t) + A(r\hat{n},t) - E(r\hat{n},t)\right)\right]_{r=s(t)} \tag{7.1.39}$$

The "late" term (7.1.38) (which was ignored earlier in this section) is the sum of a direction-independent term and a term proportional to $\hat{n}$, which has been added to represent the anisotropy due to the local cosmic gravitational field and velocity. It only affects terms in the multipole expansion of the temperature correlation function with $\ell = 0$ and $\ell = 1$, so it can be ignored if from now on we consider only multipole orders $\ell \geq 2$.

Now let us check the separate gauge invariance of the ISW, Doppler, and the remaining combined terms, at least for the limited class of gauge transformations that preserve the condition $g_{i0} = 0$, or in the notation of Eq. (5.1.32), $F = 0$. Eq. (5.3.13) tells us that these gauge transformations have

$$\epsilon_0 = -a^2\frac{\partial}{\partial t}\left(\frac{\epsilon^S}{a^2}\right),$$

and so $\Delta\dot{B} = 2\epsilon_0/a^2$. According to Eqs. (5.3.13) and (5.3.16), a gauge transformation therefore shifts the terms $-a^2\ddot{B}/2, -a\dot{a}\dot{B}/2, E/2$, and $\delta T/\bar{T}$ in the combined gravitational and intrinsic temperature fluctuations by the amounts $-a^2\partial\left(\epsilon_0/a^2\right)/\partial t, -\dot{a}\epsilon_0/a, \dot{\epsilon}_0$, and $\epsilon_0\dot{\bar{T}}/\bar{T} = -\epsilon_0\dot{a}/a$, giving no net change; it shifts the terms $a\dot{B}/2$ and $\delta u_\gamma/a$ in the Doppler contribution by ϵ_0/a and $-\epsilon_0/a$, giving no net change; and it shifts the four terms $a^2\ddot{B}, 2a\dot{a}\dot{B}, A$, and $-E$ in the integrand of the integrated Sachs-Wolfe term by the amounts $2\dot{\epsilon}_0 - 4\epsilon_0\dot{a}/a, 2\epsilon_0\dot{a}/a, 2\epsilon_0\dot{a}/a$, and $-2\dot{\epsilon}_0$, respectively, giving no net change. Thus the integrated Sachs-Wolfe term, the Doppler term, and the combined gravitational and intrinsic temperature terms are separately gauge invariant. In particular, both Newtonian and synchronous gauge will give the same results for each of these three contributions.

Let us now assume that from last scattering to the present the scalar contributions to the fluctuations are dominated by a single mode, so that
any perturbation $X(\mathbf{x},t)$ (such as $B, E, \delta u_\gamma$, or δT) can be written as

$$X(\mathbf{x},t) = \int d^3q\,\alpha(\mathbf{q})e^{i\mathbf{q}\cdot\mathbf{x}}X_q(t) \tag{7.1.40}$$

with $\alpha(\mathbf{q})$ a stochastic variable (the same for all X), normalized so that

$$\langle\alpha(\mathbf{q})\alpha^*(\mathbf{q}')\rangle = \delta^3(\mathbf{q}-\mathbf{q}'). \tag{7.1.41}$$

Then Eqs. (7.1.37) and (7.1.39) give

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^S_{\text{early}} = \int d^3q\alpha(\mathbf{q})e^{i\mathbf{q}\cdot\hat{n}r(t_L)}(F(q) + i\hat{q}\cdot\hat{n}G(q)) \tag{7.1.42}$$

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^S_{\text{ISW}} = -\frac{1}{2}\int_{t_0}^{t_L} dt \int d^3q\alpha(\mathbf{q})e^{i\mathbf{q}\cdot\hat{n}s(t)}\frac{d}{dt}\Big(a^2(t)\ddot{B}_q(t) + a(t)\dot{a}(t)\dot{B}_q(t) + A_q(t) - E_q(t)\Big) \tag{7.1.43}$$

where

$$F(q) = -\frac{1}{2}a^2(t_L)\,\ddot{B}_q(t_L) - \frac{1}{2}a(t_L)\,\dot{a}(t_L)\,\dot{B}_q(t_L) + \frac{1}{2}E_q(t_L) + \frac{\delta T_q(t_L)}{\bar{T}(t_L)} \tag{7.1.44}$$

$$G(q) = -q\left(\frac{1}{2}a(t_L)\,\dot{B}_q(t_L) + \frac{1}{a(t_L)}\delta u_{\gamma q}(t_L)\right) \tag{7.1.45}$$

As we have seen, the form factors $F(q)$ and $G(q)$ and the integrand of the ISW term are separately invariant under gauge transformations that leave g_{i0} equal to zero.

In synchronous gauge $E_q = 0$, so Eqs. (7.1.42)-(7.1.45) are the same as the previously derived results (7.1.15), (7.1.13), (7.1.17), and (7.1.18). In Newtonian gauge $B = 0$ and $E = 2\Phi$, so the form factors are

$$F(q) = \Phi_q(t_L) + \frac{\delta T_q(t_L)}{\bar{T}(t_L)} \tag{7.1.46}$$

$$G(q) = -\frac{1}{a(t_L)}\delta u_{\gamma q}(t_L) \tag{7.1.47}$$

(Of course, δT_q and $\delta u_{\gamma q}$ are different in Newtonian gauge from what they are in synchronous gauge.) Also, the integrated Sachs-Wolfe term is

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)_{\text{ISW}} = -2\int_{t_L}^{t_0} dt \int d^3q\alpha(\mathbf{q})e^{i\mathbf{q}\cdot\hat{n}s(t)}\dot{\Phi}_q(t) \tag{7.1.48}$$

It is left as an exercise for the reader to show that Φ_q is constant during the matter dominated era. Therefore, as we saw earlier in synchronous
gauge, the integrated Sachs-Wolfe effect receives contributions only from departures from strict matter dominance.

Finally, we consider the tensor contribution to temperature fluctuations. In the approximation of a sudden transition from thermal equilibrium to transparency at time t_L, the only contribution of tensor perturbations to the observed temperature anisotropy comes from the term $h_{rr}/2a^2$ in the definition (7.1.23) of N, which according to Eq. (5.1.33) contains a term $D_{rr}/2$. Using this in Eq. (7.1.29) gives the tensor contribution to the temperature fluctuation

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^T = -\frac{\hat{n}_i\hat{n}_j}{2}\int_{t_L}^{t_0}\left\{\frac{\partial}{\partial t}D_{ij}(r\hat{n},t)\right\}_{r=s(t)} dt \tag{7.1.49}$$

The gravitational wave amplitude $D_{ij}(\mathbf{x},t)$ can be expressed as a Fourier integral (5.2.21)

$$D_{ij}(\mathbf{x},t) = \sum_{\lambda=\pm 2}\int d^3q e^{i\mathbf{q}\cdot\mathbf{x}}e_{ij}(\hat{q},\lambda)\beta(\mathbf{q},\lambda)\mathcal{D}_q(t) \tag{7.1.50}$$

where $\mathcal{D}_q(t)$ is the dominant solution of the wave equation (5.2.16):

$$\ddot{\mathcal{D}}_q(t) + 3\frac{\dot{a}}{a}\dot{\mathcal{D}}_q(t) + \frac{q^2}{a^2}\mathcal{D}_q(t) = 16\pi G\pi_q^T(t), \tag{7.1.51}$$

$e_{ij}(\lambda, \hat{q})$ are polarization tensors defined in Section 5.2, and $\beta(\mathbf{q}, \lambda)$ is a stochastic variable chosen to satisfy Eq. (5.2.22). The tensor mode contribution to the temperature fluctuation is then

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^T = -\frac{1}{2}\sum_{\lambda=\pm 2}\int d^3q\hat{n}_i\hat{n}_j e_{ij}(\lambda, q)\beta(\mathbf{q}, \lambda)\int_{t_L}^{t_0} dt e^{is(t)\mathbf{q}\cdot\hat{n}}\dot{\mathcal{D}}_q(t) \tag{7.1.52}$$

This is the same as our previously derived result (7.1.18). We will return to the tensor term in C_ℓ in Section 7.3, after we have studied the scalar term in the next section.

10.7.2 7.2 Temperature multipole coefficients: Scalar modes

We will now apply the results of the previous section to the calculation of the contribution $C^S_{TT,\ell}$ of scalar modes to the multipole coefficients of temperature-temperature angular correlations:

$$C_{TT,\ell} = \frac{1}{4\pi}\int d^2\hat{n}\int d^2\hat{n}' P_\ell\left(\hat{n}\cdot\hat{n}'\right)\left\langle\Delta T(\hat{n})\Delta T\left(\hat{n}'\right)\right\rangle \tag{7.2.1}$$

where $\Delta T(\hat{n})$ is the stochastic variable giving the departure from the mean of the temperature observed in the direction $\hat{n}$, and $\langle\ldots\rangle$ denotes an average over the position of the observer, or equivalently, over the sequence of accidents that led to the particular pattern of temperature fluctuations we observe. (We are including a label TT to distinguish this multipole coefficient from those in temperature-polarization or polarization-polarization correlations, which are the subject of Section 7.4.) Of course this is not what is observed; the observed quantity is

$$C^{\rm obs}_{TT,\ell} = \frac{1}{4\pi}\int d^2\hat{n}\int d^2\hat{n}' P_\ell\left(\hat{n}\cdot\hat{n}'\right)\Delta T(\hat{n})\Delta T\left(\hat{n}'\right)$$

but as shown in Section 2.6, the cosmic variance, the mean square fractional difference between this and Eq. (7.2.1), is $2/2\ell+1$, and therefore may be neglected for $\ell \gg 1$. In this section we will consider only the contribution $C^S_{TT,\ell}$ of scalar modes to $C_{TT,\ell}$; as we saw in Section 5.2, tensor and scalar modes do not interfere, so we can take up the contribution of tensor modes separately in the following section.

First let's apply the results that were obtained in the previous section by using the kinetic theory approach described in Section 6.1. The use of the Boltzmann equation yields formulas (7.1.7)-(7.1.9) for the temperature fluctuation. To calculate the coefficients in a partial wave expansion of the temperature fluctuation, we use the familiar expansion (2.6.16) of a plane wave in Legendre polynomials, together with the addition theorem for spherical harmonics:

$$e^{i\hat{q}\cdot\hat{n}\rho} = 4\pi\sum_{\ell=0}^{\infty}\sum_{m=-\ell}^{\ell} i^\ell j_\ell(\rho)Y_\ell^m(\hat{n})Y_\ell^{m*}(\hat{q}). \tag{7.2.2}$$

Using this in Eqs. (7.1.7)-(7.1.9), and replacing factors of $i\hat{q}\cdot\hat{n}$ with derivatives of the spherical Bessel function j_ℓ, the scalar contribution to the temperature fluctuation observed in a direction $\hat{n}$ is given by

$$(\Delta T(\hat{n}))^{(S)} = \sum_{\ell m} a^S_{T,\ell m}Y_\ell^m(\hat{n}), \tag{7.2.3}$$

where

$$a^S_{T,\ell m} = 4\pi i^\ell T_0 \int d^3q \alpha(\mathbf{q}) Y^{m*}_\ell(\hat{q}) \int_{t_1}^{t_0} dt \\ \times \left[j_\ell(qr(t)) F(q,t) + j'_\ell(qr(t)) G(q,t) + j''_\ell(qr(t)) H(q,t) \right]. \tag{7.2.4}$$

Here $\alpha(\mathbf{q})$ is the stochastic parameter for the dominant scalar mode, normalized to satisfy Eq. (5.2.7):

$$\langle \alpha(\mathbf{q}) \alpha^* (\mathbf{q}') \rangle = \delta^3 (\mathbf{q} - \mathbf{q}') \tag{7.2.5}$$

t_1 is any time sufficiently early before recombination so that a photon present then would have scattered many times before the present; $r(t)$ is the radial coordinate of a point from which light emitted at time t would reach us at the present time t_0;

$$r(t) \equiv \int_t^{t_0} \frac{dt'}{a(t')} \tag{7.2.6}$$

and $F(q,t), G(q,t)$, and $H(q,t)$ are time-dependent form-factors, given by

$$\begin{aligned} F(q,t) =& \exp\left[-\int_t^{t_0} \omega_c(t') dt' \right] \\ & \times \left\{ \omega_c(t) \left[\frac{3}{4}\Phi(q,t) + \frac{3}{16}\Pi(q,t) \right.\right. \\ & \left. -\frac{1}{2}a^2(t)\ddot{B}_q(t) - \frac{1}{2}a(t)\dot{a}(t)\dot{B}_q(t) \right] \\ & \left. -\frac{1}{2}\frac{d}{dt}\left[A_q(t) + a^2(t)\ddot{B}_q(t) + a(t)\dot{a}(t)\dot{B}_q(t) \right] \right\} \end{aligned} \tag{7.2.7}$$

$$\begin{aligned} G(q,t) =& -q\omega_c(t) \exp\left[-\int_t^{t_0} \omega_c(t') dt' \right] \\ & \times \left[\delta u_{Bq}(t)/a(t) + a(t)\dot{B}_q(t)/2 \right] \end{aligned} \tag{7.2.8}$$

$$H(q,t) = \frac{3}{16}\omega_c(t) \exp\left[-\int_t^{t_0} \omega_c(t') dt' \right] \Pi(q,t) \tag{7.2.9}$$

As a reminder: $\omega_c(t)$ is the photon collision frequency at time t; $A_q(t)$ and $B_q(t)$ are the scalar fields in the perturbation to the metric in synchronous gauge, defined in Section 5.2; $\Phi(q,t)$ and $\Pi(q,t)$ are the scalar source functions, defined by Eq. (6.1.21); and $\delta u_{Bq}(t)$ is the scalar velocity potential of the baryonic plasma. A subscript T has been appended to the $a_{\ell m}$ introduced in Section 2.6, to indicate that these are partial wave coefficients in the temperature rather than the polarization, and a superscript S has been included to distinguish scalar from tensor contributions.

Together with the orthonormality property (2.6.19) of Legendre polynomials, Eqs. (7.2.1) and (7.2.3)-(7.2.5) give the scalar multipole coefficients [1]

$$C_{TT,\ell}^S = 16\pi^2 T_0^2 \int_0^\infty q^2 dq \times \mid \int_{t_1}^{t_0} dt \, [j_\ell(qr(t))F(q,t) + j'_\ell(qr(t))G(q,t) + j''_\ell(qr(t))H(q,t)] \mid^2 \quad (7.2.10)$$

This formula gives results of high accuracy, but the computer calculations used to calculate the multipole coefficients $C_{TT,\ell}^S$ in this way are not particularly revealing. Instead, we will apply a series of approximations that lead to a simple analytic formula for the $C_{TT,\ell}^S$.

First, we will neglect the integrated Sachs-Wolfe effect, given by the last term in Eq. (7.2.7). This effect is important only for relatively small values of ℓ, where cosmic variance intrudes on measurements of $C_{TT,\ell}^S$.

Next, we assume a sudden transition from perfect opacity to perfect transparency at a definite time t_L,[2] and a single dominant mode of perturbation. The fractional temperature fluctuation then takes the form (7.1.15):

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right) = \int d^3q \alpha(\mathbf{q}) e^{i\mathbf{q}\cdot\hat{n}r_L}(F(q) + i\hat{q}\cdot\hat{n}G(q)) \quad (7.2.11)$$

which was also derived at the end of Section 7.1 by following photon trajectories after the time of last scattering. (Here $r_L = r\,(t_L)$ is the co-moving radius of the surface of last scattering.) For the present we will not use formulas (7.1.16) and (7.1.17) for the form factors $F(q)$ and $G(q)$, but will proceed for general form factors, returning later to the specific form factors (7.1.16) and (7.1.17).

Using Eq. (7.2.2) in Eq. (7.2.11), and replacing $i\hat{q}\cdot\hat{n}$ in the Doppler term with $\partial/\partial\,(qr_L)$, we again have the partial-wave expansion (7.2.3), but this

time with

$$a_{T,\ell m}^S = 4\pi i^\ell T_0 \int d^3q \alpha(\mathbf{q}) Y_\ell^{m*}(\hat{q}) \left[j_\ell\,(qr_L)\,F(q) + j'_\ell\,(qr_L)\,G(q)\right]. \quad (7.2.12)$$

Inserting this in Eq. (7.2.1) and using Eq. (7.2.5) gives the multipole coefficients

$$C_{TT,\ell}^S = \frac{1}{2\ell+1}\sum_{m=-\ell}^{\ell} |a_{\ell m}|^2 = 16\pi^2 T_0^2 \int_0^\infty q^2 dq \times \left[j_\ell\,(qr_L)\,F(q) + j'_\ell\,(qr_L)\,G(q)\right]^2 \quad (7.2.13)$$

This is a standard result, but it does not provide transparent information about the dependence of $C_{TT,\ell}^S$ on ℓ. For this purpose, we now make a further approximation: we specialize to the most interesting case of large ℓ, where cosmic variance can be neglected. In this case, we can use an approximate formula for the spherical Bessel functions: [3]

[471] The derivatives of the spherical Bessel functions in Eq. (7.2.10) can be expressed as time derivatives, and then integrating by parts this can be written at the integral of a single form factor times $j_\ell(qr(t))$. The result is equivalent to Eq. (16) of M. Zaldarriaga and U. Seljak, Phys. Rev. D 55, 1830 (1997) [astro-ph/9609170], except for a difference of normalization: the source functions Π and Φ used here are 4 times those of Zaldarriaga and Seljak.

[2] To correct for whatever inaccuracy is introduced by this approximation, we will later include the effect of damping of acoustic oscillations before t_L, and average the temperature fluctuation over the time of last scattering.

$$j_\ell(\rho) \to \begin{cases} \cos b \cos[v(\tan b - b) - \pi/4]/v\sqrt{\sin b} & \rho > v \\ 0 & \rho < v \end{cases} \tag{7.2.14}$$

where $v \equiv \ell + 1/2$, and $\cos b \equiv v/\rho$, with $0 \le b \le \pi/2$. This approximation is valid for $|v^2 - \rho^2| \gg v^{4/3}$. Hence for $\ell \gg 1$, this formula can be used over most of the ranges of integration in Eq. (7.2.13). Furthermore, for $\rho > v \gg 1$ the phase $v(\tan b - b)$ in Eq. (7.2.14) is a very rapidly increasing function of ρ, so the derivative acting on the spherical Bessel function in Eq. (7.2.13) can be taken to act chiefly on this phase:

$$j'_\ell(\rho) \to \begin{cases} -\cos b\sqrt{\sin b} \sin[v(\tan b - b) - \pi/4]/v & \rho > v \\ 0 & \rho < v \end{cases} \tag{7.2.15}$$

(Letting the derivative act on the factor $1/\sqrt{\sin b}$ in Eq. (7.2.14) introduces an apparent divergence in the integral at $\rho = \nu$, but this divergence is spurious; for ρ very close to v the approximation (7.2.14) breaks down, and

there is no singularity.) Using these limits in Eq. (7.2.13) and changing the variable of integration from q to $b = \cos^{-1}(v/qr_L)$ gives

$$\begin{aligned} C^S_{TT,\ell} = & \frac{16\pi^2 v}{r_L^3} \int_0^{\pi/2} \frac{db}{\cos^2 b} \\ & \times \left[F\left(\frac{v}{r_L \cos b}\right) \cos[v(\tan b - b) - \pi/4] \right. \\ & \left. - \sin b G\left(\frac{v}{r_L \cos b}\right) \sin[v(\tan b - b) - \pi/4] \right]^2 \end{aligned} \tag{7.2.16}$$

For $v \gg 1$ the functions $\cos[v(\tan b - b) - \pi/4]$ and $\sin[v(\tan b - b) - \pi/4]$ oscillate very rapidly, so $\cos^2[\nu(\tan b - b) - \pi/4]$ and $\sin^2[\nu(\tan b - b) - \pi/4]$ average to 1/2, while $\cos[\nu(\tan b - b) - \pi/4] \sin[\nu(\tan b - b) - \pi/4]$ averages to zero. Dropping the distinction between ℓ and $v = \ell + 1/2$, and changing the variable of integration again, from b to $\beta = 1/\cos b$, Eq. (7.2.16) then becomes [4]

$$\begin{aligned} \ell(\ell+1) C^S_{TT,\ell} = & \frac{8\pi^2 \ell^3}{r_L^3} \int_1^\infty \frac{\beta d\beta}{\sqrt{\beta^2 - 1}} \\ & \times \left[F^2\left(\frac{\ell\beta}{r_L}\right) + \frac{\beta^2 - 1}{\beta^2} G^2\left(\frac{\ell\beta}{r_L}\right) \right]. \end{aligned} \tag{7.2.17}$$

We will see that the form factors $F(q)$ and $G(q)$ fall off rapidly for large q, in part because $\left|\mathcal{R}^o_q\right|^2$ decreases more or less like q^{-3}, so the integral over β converges at $\beta = \infty$, and in fact is dominated by small values of β. The integral of the F^2 term thus receives its greatest contribution from $\beta \approx 1$, or in other words, for $q \approx \ell/r_L$, or $q/a_L \approx \ell/d_A$, where $d_A = r_L a_L$ is the angular diameter distance of the surface of last scattering. On the other hand, the factor $\beta^2 - 1$ multiplying G^2 in Eq. (7.2.17) kills the contribution of β values very close to unity, so the Doppler term proportional to G^2 makes a relatively small contribution to the multipole coefficients.

Even without a detailed calculation of the form factors $F(q)$ and $G(q)$, we know that they depend on the baryon and total matter densities at last scattering, which for a given present

[473] See, e.g., I. S. Gradshteyn & I. M. Ryzhik, Table of Integrals, Series, and Products, translated, corrected and enlarged by A. Jeffrey (Academic Press, New York, 1980): formula 8.453.1.

microwave background temperature can be expressed in terms of $\Omega_B h^2$ and $\Omega_M h^2$, but since spatial curvature and dark energy are (presumably) negligible at last scattering, the form factors cannot depend on Ω_K or Ω_Λ or H_0. Thus there is a high

degree of degeneracy here; all dependence on Ω_K or Ω_Λ or H_0 can only enter in the single parameter r_L, the Robertson-Walker radius of the surface of last scattering. If we assume as commonly done that $\Omega_K = 0$, so that $\Omega_\Lambda \simeq 1 - \Omega_M$, then temperature anisotropies can tell us the values of H_0 as well as Ω_M and Ω_B, but they cannot tell us that $\Omega_K = 0$ unless we have information about H_0 from other source. Likewise, they cannot distinguish quintessence from a constant vacuum energy. Furthermore, r_L and ℓ appear in $\ell(\ell+1)C^S_{TT,\ell}$ only in the ratio ℓ/r_L, so the values of Ω_K, Ω_Λ, and H_0 can only effect the scale of the ℓ-dependence of $\ell(\ell+1)C^S_{TT,\ell}$. For instance, the values of these parameters can affect the positions of the peaks in $\ell(\ell+1)C^S_{TT,\ell}$ by a common factor, but cannot affect their heights.

We next make the approximation that the gravitational field perturbations at last scattering are dominated by perturbations in the dark matter density. We already remarked in connection with the ISW effect in the previous section that in this case $\dot{A}_q$ vanishes (because each term on the right-hand side of Eq. (5.3.38) is time-independent). The field ψ_q whose evolution we followed in Chapter 6 is defined in general as $\psi_q \equiv \left(3\dot{A}_q - q^2\dot{B}_q\right)/2$, so here $\dot{B}_q = -2\psi_q/q^2$, and since Eq. (6.5.16) gives $\psi_q \propto t^{-1/3}$, we have also $\ddot{B}_q = 2\psi_q/3tq^2$. Also, $a \propto t^{2/3}$, so Eqs. (7.1.16) and (7.1.17) give the form factors as

$$F(q) = \frac{1}{3}\delta_{\gamma q}(t_L) + \frac{a^2(t_L)\,\psi_q(t_L)}{3q^2 t_L} \tag{7.2.18}$$

$$G(q) = -q\delta u_{\gamma q}(t_L)/a(t_L) + a(t_L)\,\psi_q(t_L)/q \tag{7.2.19}$$

in which we have used $\delta T_q/\bar{T} = \delta\rho_{\gamma q}/4\bar{\rho}_\gamma = \delta_{\gamma q}/3$.
As our next approximation, we shall use the results (6.5.16), (6.5.17), and (6.5.18) of our analysis of cosmic evolution in Chapter 6, in which we neglected the baryon/dark matter density ratio:

$$\psi_q(t_L) = -\frac{3q^2 t_L \mathcal{R}^o_q \mathcal{T}(\kappa)}{5a_L^2} \tag{7.2.20}$$

$$\begin{aligned}\delta_{\gamma q}(t_L) =& \frac{3\mathcal{R}^o_q}{5}\left[\mathcal{T}(\kappa)(1+3R_L)\right.\\ &-(1+R_L)^{-1/4}\,e^{-\int_0^t L dt}\mathcal{S}(\kappa)\\ &\left.\times\cos\left(\int_0^{t_L}\frac{q dt}{a(t)\sqrt{3(1+R(t))}}+\Delta(\kappa)\right)\right]\end{aligned} \tag{7.2.21}$$

$$\begin{aligned}\delta u_{\gamma q}(t_L) =& \frac{3\mathcal{R}^o_q}{5}\left[-t_L\mathcal{T}(\kappa)\right.\\ &+\frac{a_L}{\sqrt{3}q(1+R_L)^{3/4}}e^{-\int_0^t L^2\Gamma dt}\mathcal{S}(\kappa)\\ &\left.\times\sin\left(\int_0^{t_L}\frac{q dt}{a(t)\sqrt{3(1+R(t))}}+\Delta(\kappa)\right)\right]\end{aligned} \tag{7.2.22}$$

[474] A more rigorous but rather more complicated derivation was given by S. Weinberg, Phys. Rev. D 64, 123512 (2001) [astro-ph/0103281]. The contribution of $F(q)$ had earlier been calculated by J. R. Bond, "Theory and Observations of the Cosmic Background Radiation," in Cosmology and Large Scale Structure, eds. R. Schaeffer, J. Silk, M. Spiro and J. Zinn-Justin (Elsevier, 1996), Section 5.1.3.

Here $R(t) \equiv 3\bar{\rho}_B(t)/4\bar{\rho}_\gamma(t), R_L \equiv R(t_L)$, and $a_L \equiv a(t_L); \mathcal{T}(\kappa), \mathcal{S}(\kappa)$, and $\Delta(\kappa)$ are the transfer functions defined and calculated in Section 6.5; $\kappa \equiv \sqrt{2}q/q_{\rm EQ}$, where $q_{\rm EQ}$ is the wave number that comes into the horizon at matter-radiation equality; and $\Gamma(t)$ is the acoustic damping rate (6.4.25). Using Eqs. (7.2.20)-(7.2.22) in Eqs. (7.2.18) and (7.2.19) gives the form factors as

$$\begin{aligned} F(q) =& \frac{\mathcal{R}_q^o}{5}\left[3\mathcal{T}(\kappa)R_L\right. \\ & - (1+R_L)^{-1/4}\, e^{-\int_0^{t_L}\Gamma dt}\mathcal{S}(\kappa) \\ & \left.\times\cos\left(\int_0^{t_L}\frac{qdt}{a(t)\sqrt{3(1+R(t))}} + \Delta(\kappa)\right)\right] \end{aligned} \tag{7.2.23}$$

$$\begin{aligned} G(q) =& -\frac{\sqrt{3}\mathcal{R}_q^o}{5\,(1+R_L)^{3/4}} e^{-\int_0^{t_L}\Gamma dt}\mathcal{S}(\kappa) \\ & \times\sin\left(\int_0^{t_L}\frac{qdt}{a(t)\sqrt{3(1+R(t))}} + \Delta(\kappa)\right) \end{aligned} \tag{7.2.24}$$

Note that the "slow" terms have canceled in $G(q)$, and would have canceled in $F(q)$ if it were not for a finite baryon/photon density ratio at last scattering.

Now we must take up a complication that arises only for the "fast" part of the form factors in the case of short wavelengths. We have been assuming that the opacity of the universe drops to zero instantaneously at a time t_L of last scattering, but of course the drop takes place during some finite interval of time, over which the form factors must be averaged. This makes little difference for the contribution of the slow modes, but for large wave numbers the cosines and sines in Eqs. (7.2.23) and (7.2.24) are rapidly oscillating functions of t_L, so the fast terms can be significantly reduced by this averaging. This is similar to what in other contexts is called Landau damping, except that usually Landau damping arises from a spread in the frequency of an oscillation, while here it is produced by a spread in the moment at which the oscillating amplitude is observed.

To continue with our analytic treatment, since the probability of last scattering is a sharply peaked function of time, we can approximate it as a Gaussian: the probability that last scattering occurs between t and $t+dt$ will be taken in the form

$$P(t)dt = \frac{\exp\left[-(t-t_L)^2/2\sigma_t^2\right]dt}{\sigma_t\sqrt{2\pi}} \tag{7.2.25}$$

In Eqs. (7.2.23) and (7.2.24), we must make the replacements

$$\left\{\begin{array}{c}\cos\left(\int_0^{t_L}\omega dt+\Delta\right)\\ \sin\left(\int_0^{t_L}\omega dt+\Delta\right)\end{array}\right\} \to \int_{-\infty}^{+\infty} P(t)dt \left\{\begin{array}{c}\cos\left(\int_0^{t}\omega dt+\Delta\right)\\ \sin\left(\int_0^{t}\omega dt+\Delta\right)\end{array}\right\} \tag{7.2.26}$$

where $\omega = q/a\sqrt{3(1+R)}$. For a sharply peaked distribution function $P(t)$, we can do these integrals by expanding the arguments of sines and cosines to first order in $t - t_L$:

$$\int_0^t \omega dt \simeq \int_0^{t_L}\omega dt + \omega_L\,(t-t_L)$$

The integrals (7.2.26) are now easily done

$$\int_{-\infty}^{+\infty} P(t)dt \left\{ \begin{array}{c} \cos\left(\int_0^t \omega dt + \Delta\right) \\ \sin\left(\int_0^t \omega dt + \Delta\right) \end{array} \right\}$$
$$\simeq \exp\left(-\omega_L^2\sigma_t^2/2\right) \left\{ \begin{array}{c} \cos\left(\int_0^{t_L} \omega dt + \Delta\right) \\ \sin\left(\int_0^{t_L} \omega dt + \Delta\right) \end{array} \right\} \tag{7.2.27}$$

Thus, the whole effect of this averaging is to introduce an additional damping factor $\exp\left(-\omega_L^2\sigma_t^2/2\right)$ in the fast part of the form factors. Both Γ and ω_L^2 are proportional to q^2, so we may write

$$\int_0^{t_L} \Gamma dt + \omega_L^2\sigma_t^2/2 = q^2 d_D^2/a_L^2 \tag{7.2.28}$$

where d_D is a damping length, given by Eqs. (6.4.25) and (7.2.27) as

$$d_D^2 = d_{\rm Silk}^2 + d_{\rm Landau}^2 \tag{7.2.29}$$
$$d_{\rm Silk}^2 = a_L^2 \int_0^{t_L} \frac{t_\gamma}{6a^2(1+R)} \left\{ \frac{16}{15} + \frac{R^2}{(1+R)} \right\} dt \tag{7.2.30}$$
$$d_{\rm Landau}^2 = \frac{\sigma_t^2}{6\left(1+R_L\right)} \tag{7.2.31}$$

with $t_\gamma = 1/\omega_c$ the photon mean free time, and $R \equiv 3\bar{\rho}_B/4\bar{\rho}_\gamma$.
To evaluate the Silk damping term, we recall that $R \propto a$, so

$$t_\gamma = \frac{1}{n_e \sigma_{\mathcal{T}} c} = \frac{R^3}{n_{B0} R_0^3 (1-Y) X \sigma_{\mathcal{T}} c} \tag{7.2.32}$$

where $R_0 = 3\Omega_B/4\Omega_\gamma$ is the present value of $R, Y \simeq 0.24$ is the fraction of nucleons in the form of un-ionized helium around the time of last scattering, $n_{B0} = 3H_0^2\Omega_B/8\pi G m_N$ is the present number density of baryons, and $X(R)$ is the fractional ionization, calculated in Section 2.3. Also,

$$dt = \frac{dR}{RH_0\sqrt{\Omega_M\left(R_0/R\right)^3 + \Omega_R\left(R_0/R\right)^4}} = \frac{RdR}{H_0\sqrt{\Omega_M}R_0^{3/2}\sqrt{R_{\rm EQ}+R}} \tag{7.2.33}$$

where $R_{\rm EQ} \equiv \Omega_R R_0/\Omega_M = 3\Omega_R\Omega_B/4\Omega_M\Omega_\gamma$ is the value of R at matterradiation equality. Putting this all together, the Silk damping length is given by

$$d_{\rm Silk}^2 = \frac{R_L^2}{6(1-Y)n_{B0}\sigma_{\mathcal{T}} c H_0\sqrt{\Omega_M}R_0^{9/2}} \times \int_0^{R_L} \frac{R^2 dR}{X(R)(1+R)\sqrt{R_{\rm EQ}+R}} \left\{ \frac{16}{15} + \frac{R^2}{(1+R)} \right\} \tag{7.2.34}$$

Also, the standard deviation σ_t in the time of last scattering is related to the standard deviation σ in the temperature of last scattering, calculated in Section 2.3, by $\sigma_t = 3t_L\sigma/2T_L$, so

$$d_{\rm Landau}^2 = \frac{3\sigma^2 t_L^2}{8T_L^2\left(1+R_L\right)} \tag{7.2.35}$$

The form factors (7.2.23) and (7.2.24) may now be written as explicit functions of wave number

$$F(q) = \frac{\mathcal{R}_q^o}{5}\left[3T\left(qd_T/a_L\right)R_L \right. \\ \left. -\left(1+R_L\right)^{-1/4}\mathcal{S}\left(qd_T/a_L\right)e^{-q^2d_D^2/a_L^2}\cos\left(qd_H/a_L+\Delta\left(qd_T/a_L\right)\right)\right] \tag{7.2.36}$$

$$G(q) = -\frac{\sqrt{3}\mathcal{R}_q^o}{5\left(1+R_L\right)^{3/4}}e^{-q^2d_D^2/a_L^2}\mathcal{S}\left(qd_T/a_L\right)\sin\left(qd_H/a_L+\Delta\left(qd_T/a_L\right)\right) \tag{7.2.37}$$

where d_T is a length defined by writing the argument of the transfer functions as $\kappa = qd_T/a_L$, so that Eq. (6.5.9) gives

$$d_T = \frac{\sqrt{\Omega_R}}{\left(1+z_L\right)H_0\Omega_M} = \frac{0.0177}{\Omega_M h^2}\text{Mpc} \tag{7.2.38}$$

Also, d_H is the acoustic horizon distance at last scattering, given by

$$d_H \equiv a_L\int_0^{t_L}\frac{dt}{a\sqrt{3(1+R)}} \\ = \frac{2}{H_0\sqrt{3R_L\Omega_M}\left(1+z_L\right)^{3/2}}\ln\left(\frac{\sqrt{1+R_L}+\sqrt{R_{\rm EQ}+R_L}}{1+\sqrt{R_{\rm EQ}}}\right) \tag{7.2.39}$$

where again $R_{\rm EQ} = 3\Omega_R\Omega_B/4\Omega_M\Omega_\gamma$ and $R_L = 3\Omega_B/4\Omega_\gamma\left(1+z_L\right)$.
Before using these form factors in Eq. (7.2.17), there is one more complication that needs to be mentioned. At a redshift $z_{\rm reion}$ of order 10 , the neutral hydrogen left over from the time of recombination becomes reionized by ultraviolet light from the first generation of massive stars. The photons of the cosmic microwave background have a small but nonnegligible probability $1-\exp\left(-\tau_{\rm reion}\right)$ (where $\tau_{\rm reion}$ is the optical depth of the reionized plasma) of being scattered by the electrons set free by this reionization. The temperature anisotropy ΔT is then the sum of two terms. One arises from photons that are not scattered by the reionized hydrogen, and is just equal to the anisotropy we have calculated times the probability $\exp\left(-\tau_{\rm reion}\right)$ of no scattering. The other term arises from scattered photons, and since this scattering occurs at redshifts much less than $z_L \simeq 1,090$, we see the anisotropies at a smaller distance, and hence at much lower values of ℓ. Thus the effect on $C_{TT,\ell}^S$ of scattering by the reionized plasma is simply to multiply $C_{TT,\ell}^S$ by a factor $\exp\left(-2\tau_{\rm reion}\right)$, except for very small values of ℓ, where in any case cosmic variance interferes with the interpretation of observations. This means that observations of temperature anisotropies alone cannot effectively disentangle the reionization probability from the over-all scale of the function $\mathcal{R}_q^0$ that characterizes primordial fluctuations; they can only tell us the value of $\left|\mathcal{R}_q^o\right|^2\exp\left(-2\tau_{\rm reion}\right)$. The measurement of the polarization of microwave photons (discussed in Section 7.4) produced by scattering after reionization suggests that $\exp\left(-2\tau_{\rm reion}\right)\approx 0.8$.

It is conventional to parameterize the quantity $\mathcal{R}_q^o$ in a form equivalent to

$$\left|\mathcal{R}_q^o\right|^2 = N^2q^{-3}\left(\frac{q/a_0}{k_{\mathcal{R}}}\right)^{n_S-1} \tag{7.2.40}$$

with n_S perhaps varying with wave number. This parameterization is convenient, because then

$$\left(\frac{\ell}{r_L}\right)^3 \left|\mathcal{R}^o_{\beta\ell/r_L}\right|^2 = \frac{N^2}{\beta^3}\left(\frac{\ell\beta}{k_{\mathcal{R}} d_A\,(1+z_L)}\right)^{n_S-1}$$

and it will turn out that n_S is not very different from 1 . It is only $N^2 k_{\mathcal{R}}^{1-n_S}$ that enters in the normalization of $\left|\mathcal{R}^o_q\right|^2$, so the choice of $k_{\mathcal{R}}$ is arbitrary; it is conventional to take it as $k_{\mathcal{R}} = 0.05\text{Mpc}^{-1}$.

We conclude from all this that for reasonably large values of ℓ (say, $\ell > 20$), where we can ignore cosmic variance and the integrated Sachs-Wolfe effect, use the large ℓ approximations that led to Eq. (7.2.17), and treat the effect of reionization as a simple factor $\exp(-2\tau_{\text{reion}})$, the quantity usually quoted as giving the scalar contribution to the multipole coefficients is

$$\begin{aligned}\frac{\ell(\ell+1)C^S_{TT,\ell}}{2\pi} &= \frac{4\pi T_0^2 N^2 e^{-2\tau_{\text{reion}}}}{25}\int_1^\infty d\beta \left(\frac{\beta\ell}{\ell_{\mathcal{R}}}\right)^{n_S-1} \\ &\times\left\{\frac{1}{\beta^2\sqrt{\beta^2-1}}\left[3\mathcal{T}\left(\beta\ell/\ell_T\right)R_L\right.\right. \\ &\left.-(1+R_L)^{-1/4}\,\mathcal{S}\left(\beta\ell/\ell_T\right)e^{-\beta^2\ell^2/\ell_D^2}\cos\left(\beta\ell/\ell_H+\Delta\left(\beta\ell/\ell_T\right)\right)\right]^2 \\ &\left.+\frac{3\sqrt{\beta^2-1}}{\beta^4\,(1+R_L)^{3/2}}e^{-2\beta^2\ell^2/\ell_D^2}\mathcal{S}^2\left(\beta\ell/\ell_T\right)\sin^2\left(\beta\ell/\ell_H+\Delta\left(\beta\ell/\ell_T\right)\right)\right\} \end{aligned} \tag{7.2.41}$$

where

$$\ell_D \equiv d_A/d_D, \quad \ell_T \equiv d_A/d_T, \quad \ell_H \equiv d_A/d_H, \quad \ell_{\mathcal{R}} = (1+z_L)\,k_{\mathcal{R}} d_A \tag{7.2.42}$$

and again d_A is the angular diameter distance of the surface of last scattering:
$d_A \equiv r_L a_L = \frac{1}{\Omega_K^{1/2} H_0(1+z_L)}\sinh\left[\Omega_K^{1/2}\int_{1/(1+z_L)}^1 \frac{dx}{\sqrt{\Omega_\Lambda x^4+\Omega_K x^2+\Omega_M x}}\right]$,
with Ω_R neglected, and $\Omega_K = 1-\Omega_\Lambda-\Omega_M$. If we assume as discussed earlier that the integral over β is dominated by values $\beta \approx 1$, neglect the Doppler term, and for the moment neglect the term proportional to the transfer function $\mathcal{T}$, then Eq. (7.2.41) shows that $C^S_{TT,\ell}$ has peaks at $\chi(\ell) =$
$\pi, 2\pi, 3\pi$, etc., where $\chi(\ell) = \ell/\ell_H + \Delta\left(\ell/\ell_T\right)$ is the phase of the cosine in Eq. (7.2.41) for $\beta = 1$. The presence of the positive term $3\mathcal{T}R_L$ arising from the inertia of the baryonic plasma enhances and slightly shifts the peaks for $\chi = \pi, 3\pi$, etc., where the cosine is negative, and reduces the peaks for $\chi = 2\pi$, 4π, etc., where the cosine is positive. For large ℓ the Silk and Landau damping factor $\exp(-\beta^2\ell^2/d_D^2)$ damps out all these peaks. As we will soon see, the results of numerical calculations exhibit this expected pattern, of a sequence of decreasing peaks, with odd peaks somewhat enhanced over the even peaks.

We can now read off the dependence of the quantities appearing in $C^S_{TT,\ell}$ on various cosmological parameters. Taking as fixed the well established value of the present microwave temperature, (which yields values for $\Omega_\gamma h^2$ and $\Omega_R h^2 = \Omega_\gamma h^2 + \Omega_v h^2$), and also fixing the values of t_L, z_L, and σ, which are only weakly dependent on other cosmological parameters, we see that

- $R_L \propto \Omega_B h^2$.
- The integral in Eq. (7.2.34) for d^2_{Silk} is a complicated but not very sensitive function of $\Omega_B h^2$ and $\Omega_M h^2$. Aside from the integral, d^2_{Silk} is proportional to $\left(\Omega_B h^2\right)^{-7/2}\left(\Omega_M h^2\right)^{-1/2}$.
- d^2_{Landau} depends on $\Omega_B h^2$ through a factor $(1+R_L)^{-1}$.

- $d_T \propto (\Omega_M h^2)^{-1}$
- Aside from a slowly varying logarithm, $d_H \propto (\Omega_B h^2)^{-1/2} (\Omega_M h^2)^{-1/2}$.
- Only d_A depends on $H_0, \Omega_\Lambda, \Omega_M, \Omega_B$, or Ω_K apart from a dependence on $\Omega_B h^2$ and $\Omega_M h^2$. (For any observationally allowed values of Ω_Λ or Ω_K, the effects of a constant vacuum energy or of spatial curvature would be quite negligible at times before recombination, so their effect on $C^S_{TT,\ell}$ is limited to their influence on the propagation of light after recombination, that is, on d_A.)

To see how well the various approximations we have made work in practice, we shall calculate $C^S_{TT,\ell}$ for a realistic set of values for cosmological parameters taken from a fit [5] to data on the microwave background from the CBI, ACBAR, and first-year WMAP observations (about which more below). These are the same parameters that have been used in a full-scale computer calculation whose results are readily available, [6] so that we will

conveniently be able to compare Eq. (7.2.41) with an accurate numerical calculation. The cosmological parameters of this set are

$$\Omega_M h^2 = 0.13299, \quad \Omega_B h^2 = 0.02238, \quad h = 0.71992, \quad \Omega_\Lambda = 1 - \Omega_M. \tag{7.2.44}$$

and [7]

$$\begin{aligned} n_S =& 0.95820, \quad k_{\mathcal{R}} = 0.05\text{Mpc}^{-1}, \quad N^2 = 1.736 \times 10^{-10} \\ & e^{-2\tau_{\text{reion}}} = 0.80209 \end{aligned} \tag{7.2.45}$$

We take $T_0 = 2.725$ K, which yields $\Omega_\gamma h^2 = 2.47 \times 10^{-5}$, and we assume three flavors of massless neutrinos, which gives $\Omega_R h^2 = 1.6813 \Omega_\gamma h^2 = 4.15 \times 10^{-5}$. We will also adopt the parameters describing recombination calculated in Section 2.3 (which are not very sensitive to other cosmological parameters) for $\Omega_B h^2 = 0.02$ and $\Omega_M h^2 = 0.15$; in particular,

$$1 + z_L = 1,090, \quad \sigma = 262 \text{ K}, \quad t_L = 370,000\text{yrs}. \tag{7.2.46}$$

From the values (7.2.44) of $\Omega_M h^2$ and $\Omega_B h^2$, we find

$$R_0 = 679.6, \quad R_L = 0.6234, \quad R_{\text{EQ}} = 0.2121. \tag{7.2.47}$$

Then Eqs. (7.2.38), (7.2.39), (7.2.43) give

$$d_T = 0.1331\text{Mpc}, \quad d_H = 0.1351\text{Mpc}, \quad d_A = 12.99\text{Mpc}, \tag{7.2.48}$$

while the damping lengths are given by Eqs. (7.2.34), (7.2.35) and (7.2.29):
$d_{\text{Silk}} = 0.006555\text{Mpc}$, $d_{\text{Landau}} = 0.004809\text{Mpc}$, $d_D = 0.008130\text{Mpc}$.

Finally, the parameters (7.2.42) appearing in Eq. (7.2.41) are

$$\ell_T = 97.60, \quad \ell_H = 96.15, \quad \ell_D = 1598, \quad \ell_{\mathcal{R}} = 708 \tag{7.2.50}$$

while the factor multiplying the integral is

$$\frac{4\pi T_0^2 N^2 e^{-2\tau_{\text{reion}}}}{25} = 519.7\mu \text{ K}^2. \tag{7.2.51}$$

[475] D.N. Spergel et al., Astrophys. J. Suppl. 148, 175 (2003) [astro-ph/0302209].
[6] http://lambda.gsfc.nasa.gov/data/map/powspec/wmap_lcdm_pl_model_yr1_ v1.txt

Using these values, the result of using Eq. (7.2.41) with the parameter set of reference 6 is

$$\frac{\ell(\ell+1)C^S_{TT,\ell}}{2\pi} = 519.7\mu K^2 \int_1^\infty d\beta \left(\frac{\beta\ell}{708}\right)^{-0.0418}$$
$$\times \left\{ \frac{1}{\beta^2\sqrt{\beta^2-1}}[3(0.6234)\mathcal{T}(\beta\ell/97.6)\right.$$
$$-(1.6234)^{-1/4}\mathcal{S}(\beta\ell/97.6)e^{-(\beta\ell/1598)^2}\cos(\beta\ell/96.15+\Delta(\beta\ell/97.6))\Big]^2$$
$$+\frac{3\sqrt{\beta^2-1}}{\beta^4(1.6234)^{3/2}}e^{-2(\beta\ell/1598)^2}\mathcal{S}^2(\beta\ell/97.6)$$
$$\left.\times\sin^2(\beta\ell/96.15+\Delta(\beta\ell/97.6))\right\} \qquad (7.2.52)$$

The integral over β converges very rapidly, and can be done with a cut-off at $\beta = 5$; raising the cut-off to $\beta = 50$ has a negligible effect.

The results are shown in Figure 7.1, in comparison with the more accurate Boltzmann hierarchy calculation of reference 6, based on Eq. (7.2.10). Evidently the hydrodynamic calculation does quite well; like the computer calculation of reference 6, it shows a high first peak, followed by two nearly equal lower peaks, followed by a decaying tail punctuated by successively lower peaks. To give a quantitative comparison, Tables 7.1 and 7.2 show the

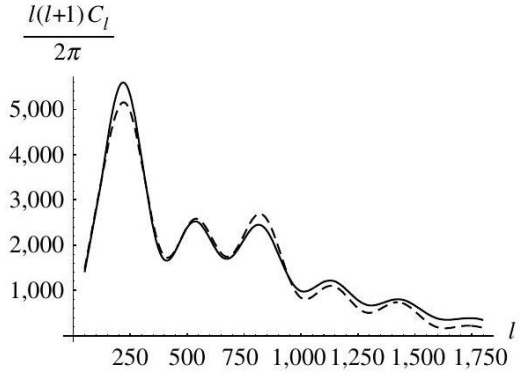

Figure 7.1: The scalar multipole coefficient $\ell(\ell+1) C_{\ell}^{S} / 2 \pi$ in square microKelvin, vs. ℓ, for the cosmological parameters given in Eqs. (7.2.44) and (7.2.45). The hydrodynamic approximation (7.2.41) is indicated by the dashed curve, while for comparison the solid curve gives the more accurate large scale computer calculation of reference 6, based on Eq. (7.2.10).

Table 7.1: Comparison of the results for the values of ℓ at the first five peaks in $\ell(\ell+1) C_{TT,\ell}^{S} / 2 \pi$, as given by Eq. (7.2.52) and as given by reference 6 .

Eq. (7.2.52):	220	541	821	1134	1425
reference 6:	219	536	813	1127	1425

[477] The parameter N^2 is related to what is often given as an "amplitude" A by $4\pi N^2 \equiv 20,000\pi A/9T_{\gamma 0}(\mu K)^2 = 2.95 \times 10^{-9}A$. For instance, see L. Verde et al., Astrophys. J. Suppl. 148, 195 (2003) [astro-ph/0302218]. It should be noted that, because of different conventions used in writing Fourier integrals, the quantity $\mathcal{R}_k$ in this paper is equal to what we have defined as $\mathcal{R}^o_{a_0 k}$ times a factor $(2\pi)^{3/2}$. Reference 6 uses $A = 0.73935$, corresponding to the value of N^2 given in Eq. (7.2.45).

Table 7.2: Comparison of the results for the values of $\ell(\ell+1) C_{T T, \ell}^{S} / 2 \pi$ (in μK^2) at the peaks listed in Table 7.1, as given by Eq. (7.2.52) and as given by reference 6.

Eq. (7.2.52):	5155	2694	2783	1126	746
Reference 6:	5591	2525	2451	1221	806

peak positions and heights calculated using Eq. (7.2.52) and those given by the results of reference 6. In all cases, the peak heights given by Eq. (7.2.52) agree with the more accurate computer results to within 10%, while the results of Eq. (7.2.52) for the peak positions are almost embarrassingly good, in no case being off by more than 1%.

Among other things, the general success of the calculations of this section shows that the evolution of cosmological perturbations is primarily hydrodynamic, in the sense that it can be well described by the equations of hydrodynamics without the full apparatus of coupled Boltzmann equations used in computer calculations like those of reference 6. The Boltzmann equation is implicit in our calculations, because in calculating the Silk damping rate we have used standard values for the shear viscosity and heat conductivity that were obtained by using the Boltzmann equation for photons in an ionized gas, but evidently not much is lost by not solving the Boltzmann equation over again in a cosmological context.

To the extent that the general formula (7.2.41) has been validated by this comparison, we can use it to see what can be learned from measurements of $C_{TT,\ell}$:

- Eq. (7.2.41) shows that the shape of the function $\ell(\ell+1)C^S_{TT,\ell}$, as for instance the set of ratios of the peak positions or of the peak heights, depends on only four quantities: d_D, d_H, d_T, and n_S. Also, with the present radiation temperature and the number of massless neutrinos fixed, the three lengths d_D, d_H, and d_T depend only on the two cosmological parameters $\Omega_B h^2$ and $\Omega_M h^2$, which can therefore be found from the shape of the function $\ell(\ell+1)C^S_{TT,\ell}$.

- Measurement of the scale of this function's ℓ-dependence (as for instance, the ℓ value of any one peak) depends on these two parameters, but also on d_A, which is a function not only of $\Omega_B h^2$ and $\Omega_M h^2$ but also of h and Ω_Λ. It is therefore impossible, without taking the integrated Sachs-Wolfe effect into account, to use measurements of $C^S_{TT,\ell}$ alone to make separate determinations of both h and Ω_Λ. It is often simply assumed that the universe is spatially flat, in which case to a good approximation $\Omega_\Lambda = 1 - \Omega_M$, and then measurements of $C^S_{TT,\ell}$ can be used to determine h as well as $\Omega_B h^2$ and $\Omega_M h^2$.

- Measurement of the magnitude of the function $\ell(\ell+1)C_{TT,\ell}$ for $\ell \gg 1$ (as for instance measurement of the height of any one peak) only tells us the quantity $N^2 \exp(-2\tau_{\rm reion})$, so as already remarked we cannot use it to make a separate determination of N^2 or $\tau_{\rm reion}$. This ambiguity is resolved by measurements of the polarization of the cosmic microwave background, discussed in Section 7.4.

The original discovery of microwave background anisotropy was made by the COBE collaboration, and is discussed in Section 2.6. This only gave information about the anisotropy for relatively small ℓ, well below the position of the first acoustic peak at $\ell \approx 200$. This discovery was followed by a series of balloon-borne and ground-based observations, [8] which gave definite evidence for the first acoustic peak, and some data on higher peaks, extending in the case of the CBI collaboration up to values of ℓ beyond the position of the fifth acoustic peak, at $\ell \approx 1400$. The accuracy of these measurements up to about $\ell \approx 600$ was then greatly improved by observations made by a remarkable satellite mission, known as the Wilkinson Microwave Anisotropy Probe, or WMAP. [9] The WMAP satellite was launched on June 30, 2001, made loops around

the moon to pick up kinetic energy from the Moon's motion, and finally reached an orbit about the equilibrium point known as L2. This point orbits the Sun at the speed needed to keep it about 1.5×10^6 km from Earth, on the other side of the earth from the sun, a location chosen to isolate the instrument from microwave radiation from the sun, earth, or moon. The satellite carries two back-to-back 1.4×1.6 meter

microwave receivers, cooled by thermal radiators to about 90 K , and measures the polarization of the microwave background as well as differences in its temperature over the whole sky.

After a year of observation, $C_{TT,\ell}$ had been measured out to $\ell \simeq 600$ with small errors arising mostly from cosmic variance and foreground emission. [10] These measurements were fit to the results of the " Λ CDM" model we have been studying, with zero curvature; the contents of the universe supposed to consist of photons, three flavors of massless neutrinos, baryonic matter, cold dark matter, and a constant vacuum energy; and a primordial spectrum of purely adiabatic fluctuations given by Eq. (7.2.40), with n_S constant. The values of cosmological parameters derived from this fit were: [11]

- $\Omega_B h^2 = 0.024 \pm 0.001$
- $\Omega_M h^2 = 0.14 \pm 0.02$
- $h = 0.72 \pm 0.05$
- $|N|^2 = (2.1 \pm 0.2) \times 10^{-10}$
- $n_S = 0.99 \pm 0.04$
- $\tau_{\rm reion} = 0.166^{+0.076}_{-0.071}$
  (Measurements of polarization were used here chiefly to measure the optical depth $\tau_{\rm reion}$ of the reionized plasma, [12] which is needed to obtain $|N|^2$ from the value of $|N|^2 \exp(-2\tau_{\rm reion})$ given by the measured values of $C^S_{TT,\ell}$.)

In March 2006 the WMAP group announced the results of the second and third years of observation. [13] The results are shown together with a best fit of $\ell(\ell+1)C^S_{TT,\ell}/2\pi$ to the Λ CDM model (with zero tensor anisotropies) in Figure 7.2. This fit gave the parameters: [14]

- $\Omega_B h^2 = 0.02229 \pm 0.00073$
- $\Omega_M h^2 = 0.1277^{+0.0080}_{-0.0079}$
- $h = 0.732^{+0.031}_{-0.032}$
- $|N|^2 = (1.93 \pm 0.12) \times 10^{-10}$

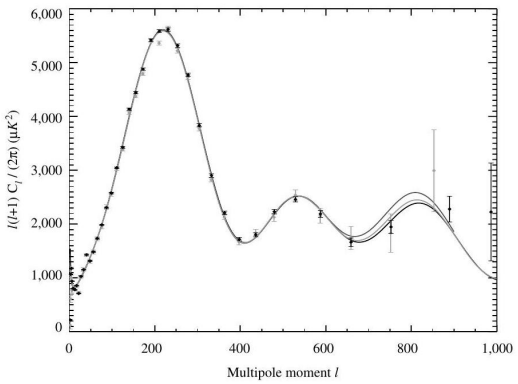

Figure 7.2: Comparison of theory and WMAP observations for the multipole coefficient $\ell(\ell+1) C_{\ell} / 2 \pi$ in square microKelvin vs. ℓ, from D. N. Spergel et al., astro-ph/0603449. The solid data points are the three-year WMAP data, and the light gray data points are the first year WMAP data. The bottom curve is the best fit to the three-year WMAP data. The top curve is the best fit to the first-year WMAP data, and the middle curve is the best fit to the first-year WMAP data combined with data from CBI and ACBAR.

- $n_S = 0.958 \pm 0.016$
- $\tau_{\rm reion} = 0.089 \pm 0.030$

The new results are consistent with those found before, but evidently there has been a significant improvement in the precision with which these parameters are known. This increased precision has now revealed the important information that n_s is very likely somewhat less than unity, as expected on the basis of typical inflationary theories, to be discussed in Chapter 10. It is also important that the optical depth of the reionized plasma found by polarization measurements is considerably less than previously found, suggesting a more plausible time of reionization. [15] Because the magnitude of $C^S_{TT,\ell}$ is proportional to $|N|^2 \exp(-2\tau_{\rm reion})$, the reduction in $\tau_{\rm reion}$ has led to a corresponding reduction in the estimated value of $|N|^2$; there has been very little change in the reported value of $|N|^2 \exp(-2\tau_{\rm reion})$.

It is truly satisfying to see that the values of $h, \Omega_M h^2$, and $\Omega_B h^2$ obtained from the cosmic microwave background anisotropies confirm the values obtained by the very different methods discussed in Chapters 1 and 3. The values of $|N|^2$ and n_s are also in good agreement with values inferred from observations of large scale structure, discussed in the next chapter. The general agreement of theory and observation, both for the microwave background anisotropies alone and for the microwave background anisotropies in conjunction with other observations, goes far to confirm the general assumptions of the cosmological model, including cold dark matter and dark energy, that we have been using.

10.7.3 7.3 Temperature multipole coefficients: Tensor modes

We next consider the contribution of cosmological gravitational radiation to the temperature multipole coefficients. [1] According to Eq. (7.1.5), in the case of a single dominant tensor mode the tensor contribution to the fractional temperature fluctuation is

$$\left(\frac{\Delta T(\hat{n})}{T_0}\right)^{(T)} = -\frac{1}{2}\sum_{\lambda=\pm 2}\int d^3q\beta(\mathbf{q},\lambda)\hat{n}_k\hat{n}_l e_{kl}(\hat{q},\lambda) \times \int_{t_1}^{t_0} dt \exp\left[i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\,(t')}\right] d(q,t) \tag{7.3.1}$$

where for brevity we have now introduced the quantity

$$d(q,t) \equiv \exp\left[-\int_t^{t_0} dt'\omega_c\,(t')\right]\left(\dot{\mathcal{D}}_q(t) - \frac{1}{2}\omega_c(t)\Psi(q,t)\right) \tag{7.3.2}$$

As a reminder: $\beta(\mathbf{q},\lambda)$ is the stochastic parameter for the mode that does not decay outside the horizon, which is assumed to dominate the tensor perturbation; $e_{kl}(\hat{q},\lambda)$ is the polarization tensor defined in Section 5.2 for a gravitational wave with wave number $\boldsymbol{q}$ and helicity λ; t_1 is any time sufficiently early before recombination so that any photon present then would have been scattered many times before the present; $\omega_c(t)$ is the photon collision rate at time t; $\mathcal{D}_q(t)$ is the gravitational wave amplitude, defined in Section 5.2; and $\Psi(q,t)$ is the tensor source function, defined by Eqs. (6.6.11) and (6.6.12).

Again using Eq. (7.2.2) to expand the exponential in spherical harmonics, the tensor temperature fluctuation has the expansion

$$(\Delta T(\hat{n}))^{(T)} = \sum_{\ell m} a^T_{T,\ell m} Y^m_\ell(\hat{n}) \tag{7.3.3}$$

where

$$a^T_{T,\ell m} = T_0\sum_{\lambda=\pm 2}\int d^3q\beta(\mathbf{q},\lambda) f_{\ell m}(\mathbf{q},\lambda) \tag{7.3.4}$$

$$f_{\ell m}(\mathbf{q},\lambda) \equiv -2\pi\int d^2\hat{n} Y^{m*}_\ell(\hat{n})\hat{n}_k\hat{n}_l e_{kl}(\hat{q},\lambda)\sum_{LM} i^L Y^M_L(\hat{n}) Y^{M*}_L(\hat{q}) \times \int_{t_1}^{t_0} dt j_L(qr(t)) d(q,t) \tag{7.3.5}$$

and $r(t)$ is again the radial coordinate of a point from which light emitted at time t would reach us at the present:

$$r(t) \equiv \int_t^{t_0}\frac{dt'}{a\,(t')} \tag{7.3.6}$$

It will be very convenient first to calculate $f_{\ell m}(\mathbf{q},\lambda)$ for $\mathbf{q}$ in the threedirection $\hat{z}$. In this case we have $Y^M_L(\hat{q}) = \delta_{M0}\sqrt{2L+1/4\pi}$. Also, using Eq. (5.2.15), for $\hat{n} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$ we have

[471] For an early calculation of the first few multipole moments, see V. A. Rubakov, M. V. Sazhin, and A. V. Veryaskin, Phys. Lett. 115B, 189 (1982). A general formula was given by R. Fabbri and M. D. Pollock, Phys. Lett. 125B, 445 (1983).

$$\hat{n}_i\hat{n}_j e_{ij}(\hat{z},\pm 2) = \frac{1}{\sqrt{2}}\sin^2\theta e^{\pm 2i\phi} = 4\sqrt{\frac{\pi}{15}}Y_2^{\pm 2}(\hat{n}) \tag{7.3.7}$$

The integral over $\hat{n}$ is given by a special case of the general formula [2]

$$\int d^2\hat{n}Y_L^M(\hat{n})Y_\Lambda^\mu(\hat{n})Y_\ell^{m*}(\hat{n}) = \sqrt{\frac{(2\Lambda+1)(2\ell+1)}{4\pi(2L+1)}}$$
$$\times C_{\ell\Lambda}(L,M;m,-\mu)C_{\ell\Lambda}(L,0;0,0) \tag{7.3.8}$$

where $C_{\ell\Lambda}(L,M;m,\mu)$ is the usual Clebsch-Gordan coefficient for combining angular momentum quantum numbers ℓ, m and Λ,μ to form

angular momentum quantum numbers L, M. Hence

$$f_{\ell m}(q\hat{z},\pm 2) = -2\sqrt{\frac{\pi(2\ell+1)}{3}}\sum_L i^L C_{\ell 2}(L,0;\pm 2,\mp 2)C_{\ell 2}(L,0;0,0)$$
$$\times \delta_{m,\pm 2}\int_{t_1}^{t_0} dt j_L(qr(t))d(q,t) \tag{7.3.9}$$

In our case we have $\Lambda = 2, \mu = \pm 2$, and $M = 0$, so the relevant ClebschGordan coefficients are

$$C_{\ell 2}(\ell+2,0;0,0) = \sqrt{\frac{3(\ell+2)(\ell+1)}{2(2\ell+1)(2\ell+3)}}$$
$$C_{\ell 2}(\ell+2,0;\pm 2,\mp 2) = \frac{1}{2}\sqrt{\frac{(\ell-1)\ell}{(2\ell+1)(2\ell+3)}}$$
$$C_{\ell 2}(\ell,0;0,0) = -\sqrt{\frac{\ell(\ell+1)}{(2\ell-1)(2\ell+3)}}$$
$$C_{\ell 2}(\ell,0;\pm 2,\mp 2) = \sqrt{\frac{3(\ell-1)(\ell+2)}{2(2\ell-1)(2\ell+3)}}$$
$$C_{\ell 2}(\ell-2,0;0,0) = \sqrt{\frac{3\ell(\ell-1)}{2(2\ell-1)(2\ell+1)}}$$
$$C_{\ell 2}(\ell-2,0;\pm 2,\mp 2) = \frac{1}{2}\sqrt{\frac{(\ell+1)(\ell+2)}{(2\ell-1)(2\ell+1)}}$$

while $C_{\ell 2}(\ell\pm 1,0;0,0) = 0$. Putting this together shows that for $\mathbf{q}$ in the three-direction, the non-vanishing values of the quantity (7.3.5) are [3]

$$f_{\ell m}(q\hat{z},\pm 2) = i^\ell\sqrt{\frac{\pi(2\ell+1)(\ell+2)!}{2(\ell-2)!}}\delta_{m,\pm 2}\int dt d(q,t)$$
$$\times\left[\frac{j_{\ell+2}(qr(t))}{(2\ell+1)(2\ell+3)} + \frac{2j_\ell(qr(t))}{(2\ell-1)(2\ell+3)} + \frac{j_{\ell-2}(qr(t))}{(2\ell-1)(2\ell+1)}\right] \tag{7.3.10}$$

[472] See, e.g., J. M. Blatt and V. F. Weisskopf, Theoretical Nuclear Physics (John Wiley & Sons, New York, 1952): Appendix A, Eq. (5.11).

This can be greatly simplified by iterating the familiar recursion relation

$$j_\ell(\rho)/\rho = \left[j_{\ell-1}(\rho) + j_{\ell+1}(\rho)\right]/(2\ell+1),$$

which gives

$$\frac{j_\ell(\rho)}{\rho^2} = \frac{j_{\ell-2}(\rho)}{(2\ell+1)(2\ell-1)} + \frac{2j_\ell(\rho)}{(2\ell+3)(2\ell-1)} + \frac{j_{\ell+2}(\rho)}{(2\ell+1)(2\ell+3)} \tag{7.3.11}$$

Using this in Eq. (7.3.10), we have

$$f_{\ell m}(q\hat{z},\pm 2) = i^\ell \sqrt{\frac{\pi(2\ell+1)(\ell+2)!}{2(\ell-2)!}}\delta_{m,\pm 2}\int_{t_1}^{t_0} dtd(q,t)\frac{j_\ell(qr(t))}{q^2r^2(t)} \tag{7.3.12}$$

The amplitude (7.3.5) can now be found for a general direction of $\mathbf{q}$ by performing a standard rotation $S(\hat{q})$ that takes the three-axis into the direction $\hat{q}$. (An explicit formula for $S(\hat{q})$ will be given in the next section; it is not needed here.) This gives

$$f_{\ell m}(\mathbf{q},\lambda) = \sum_{\pm} D^{(\ell)}_{m,m'}(S(\hat{q}))f_{\ell m'}(q\hat{z},\lambda) \tag{7.3.13}$$

The coefficients (7.3.4) are then

$$\begin{aligned} a^T_{T,\ell m} =& T_0 i^\ell \sqrt{\frac{\pi(2\ell+1)(\ell+2)!}{2(\ell-2)!}} \sum_{\pm}\int d^3q\beta(\mathbf{q},\pm 2)D^{(\ell)}_{m,\pm 2}(S(\hat{q})) \\ &\times \int_{t_1}^{t_0} dtd(q,t)\frac{j_\ell(qr(t))}{q^2r^2(t)} \end{aligned} \tag{7.3.14}$$

We can now easily calculate the multipole coefficients of the temperature correlation function, defined by

$$\left\langle a^T_{T,\ell m} a^{T*}_{T,\ell' m'}\right\rangle = \delta_{\ell\ell'}\delta_{mm'}C^T_{TT,\ell} \tag{7.3.15}$$

For this purpose, we recall that the stochastic parameter $\beta(\mathbf{q},\lambda)$ is normalized so that

$$\langle\beta(\mathbf{q},\lambda)\beta^*(\mathbf{q},\lambda)\rangle = \delta_{\lambda\lambda'}\delta^3\left(\mathbf{q}-\mathbf{q}'\right) \tag{7.3.16}$$

In the calculation of $C^T_{TT,\ell}$ we encounter an angular integral

$$\int d^2\hat{q}D^{(\ell)}_{m,\pm 2}(S(\hat{q}))D^{(\ell')}_{m',\pm 2}(S(\hat{q}))^*$$

This matrix can readily be seen to commute with all rotation matrices, so that it must be proportional to $\delta_{mm'}\delta_{\ell\ell'}$ with an m-independent coefficient. To calculate this coefficient, we can set $m = m'$ and $\ell = \ell'$ and sum m from $-\ell$ to $+\ell$; using the unitarity of the matrix $D^{(\ell)}_{m,n}(S(\hat{q}))$, this must equal $\int d^2\hat{q} = 4\pi$, so

$$\int d^2\hat{q}D^{(\ell)}_{m,\pm 2}(S(\hat{q}))D^{(\ell')}_{m',\pm 2}(S(\hat{q}))^* = \frac{4\pi}{2\ell+1}\delta_{mm'}\delta_{\ell\ell'} \tag{7.3.17}$$

Using this and Eqs. (7.3.14) and (7.3.16) in Eq. (7.3.15), we see that the sum over helicities in Eq. (7.3.14) now just yields a factor 2, so [4]

[473] This is essentially the result originally obtained by L.F. Abbott and M. B. Wise, Nucl. Phys. B244, 541 (1984), and A. A. Starobinsky, Sov. Astron. Lett. 11(3), 133 (1985), generalized to an arbitrary gravitational wave amplitude $D_q(t)$ and including the correction proportional to Ψ in Eq. (7.3.2).

$$C_{TT,\ell}^{T} = \frac{4\pi^2(\ell+2)!T_0^2}{(\ell-2)!}\int_0^\infty \frac{dq}{q^2}\left|\int_{t_1}^{t_0} dt d(q,t)\frac{j_\ell(qr(t))}{r^2(t)}\right|^2 \tag{7.3.18}$$

(This formula can be obtained more easily by a direct calculation of the temperature correlation function, without calculating the $a_{T,\ell m}^T$, but we will need the $a_{T,\ell m}^T$ in the next section to find the correlation between polarization and temperature anisotropies.)

It remains to calculate $\mathcal{D}_q(t)$ and the source function $\Psi(q,t)$, As we saw in Section 6.6, if the gravitational wave amplitude $\mathcal{D}_q(t)$ is written as a function of $\kappa \equiv q\sqrt{2}/H_{\rm EQ}a_{\rm EQ}$ and $y \equiv a(t)/a_{\rm EQ}$ instead of q and t (the subscript EQ referring to the time of radiation-matter equality), then aside from an over-all factor $\mathcal{D}_q^o$ (equal to the value of $\mathcal{D}_q(t)$ outside the horizon), the amplitude $\mathcal{D}_q(t)$ is independent of any other cosmological parameters. We write this as

$$\mathcal{D}_q(t) = \mathcal{D}_q^o D(\kappa, y) \tag{7.3.19}$$

For a spectrum of gravitational waves that is scale invariant outside the horizon, the quantity $q^3\left|\mathcal{D}_q^o\right|^2$ is a constant. To take account of more general possibilities, it is conventional to write it as proportional to a power n_T of q, or equivalently,

$$q^3\left|\mathcal{D}_q^o\right|^2 = N_T^2\left(\frac{q/a_0}{k_{\mathcal{D}}}\right)^{n_T}, \tag{7.3.20}$$

where $k_{\mathcal{D}}$ is an arbitrary wave number, often taken as $k_{\mathcal{D}} = 0.002{\rm Mpc}^{-1}$, and N_T is a constant analogous to the constant N that describes the strength

of the adiabatic scalar mode. The conventional ratio r of tensor and scalar modes is $r \equiv 4\left|N_T\right|^2/|N|^2$. Also, until vacuum energy becomes important, we have $dt = \sqrt{2}ydy/H_{\rm EQ}\sqrt{1+y}$, so we can write

$$q\int\frac{dt}{a(t)} = \kappa\int\frac{dy}{\sqrt{1+y}} = 2\kappa\sqrt{1+y}$$

The wave equation (6.6.58) then gives

$$\begin{aligned}(1+y)\frac{\partial^2 D(\kappa,y)}{\partial y^2} + \left(\frac{1}{2}+\frac{2(1+y)}{y}\right)\frac{\partial D(\kappa,y)}{\partial y} + \kappa^2 D(\kappa,y)\\ = -\frac{24f_v}{y^2}\int_0^y K\left(2\kappa\left[\sqrt{1+y}-\sqrt{1+y'}\right]\right)\frac{\partial D\left(\kappa,y'\right)}{\partial y'}dy'\end{aligned} \tag{7.3.21}$$

where $f_v \equiv \bar{\rho}_v/\bar{\rho}_R = 0.4052$ and $K(v) \equiv j_2(v)/v^2$, with the initial condition $D(\kappa,0) = 1$. Having found $D(\kappa,y)$ in this way, the source function $\Psi(q,t)$ is calculated in computer programs such as CMBfast and CAMB by using Eq. (6.6.21), with the amplitudes $\Delta_{T,\ell}^{(T)}$ and $\Delta_{P,\ell}^{(T)}$ found by a numerical solution of the coupled Boltzmann equations truncated at some maximum value of ℓ. There is an easier alternative procedure, based on the integral equation (6.6.27): [5]

$$\begin{aligned}\Psi(q,t) = \frac{3}{2}\int_{t_1}^{t} dt' \exp\left[-\int_{t'}^{t}\omega_c\left(t''\right)dt''\right]\\ \times\left[-2\dot{\mathcal{D}}_q\left(t'\right)K\left(q\int_{t'}^{t}\frac{dt''}{a\left(t''\right)}\right)+\omega_c\left(t'\right)F\left(q\int_{t'}^{t}\frac{dt''}{a\left(t''\right)}\right)\Psi\left(q,t'\right)\right]\end{aligned} \tag{7.3.22}$$

[474] This result is derived in a different way by M. Zaldarriaga and U. Seljak, Phys. Rev. D 55, 1830 (1997) [astro-ph/9609170]. Their result is the same as Eq. (7.3.18), if we take their undefined gravitational wave amplitude h to be $\mathcal{D}_q(t)/2$, with their stochastic parameter normalized so that $P_h = 1$.

where $F(v) \equiv j_0(v) - 2j_1(v)/v + 2j_2(v)/v^2$. We can also put the differential optical depth in the form

$$d\tau(y) \equiv \omega_c dt = n_e \sigma_{\mathcal{T}} c dt = \frac{A}{y^2\sqrt{1+y}} X(y) dy$$

where $X(y)$ is the fractional hydrogen ionization calculated in Section 2.3, which depends on $\Omega_B h^2$ and $\Omega_M h^2$ as well as y, and A is the dimensionless constant

$$A \equiv 0.76 \frac{3\Omega_B \Omega_M H_0 \sigma_{\mathcal{T}} c}{8\pi G m_p \Omega_R^{3/2}} = 1.9646 \times 10^5 \left(\Omega_M h^2\right) \left(\Omega_B h^2\right)$$

(It is assumed that the baryons are 76% hydrogen, with the rest un-ionized in the era of interest.) It follows that the source function takes the form

$$\Psi(q,t) = \mathcal{D}_q^o \mathcal{S}(\kappa, y) \tag{7.3.23}$$

where $\mathcal{S}$ depends only on $\Omega_M h^2$ and $\Omega_B h^2$ as well as κ and y, and satisfies the integral equation

$$\begin{aligned}\mathcal{S}(\kappa,y) = \frac{3}{2}\int_0^y dy' \exp\left[-\int_{y'}^y \frac{d\tau\,(y'')}{dy''} dy''\right] \\ \times \left[-2\frac{dD\,(\kappa,y')}{dy'} K\left(2\kappa\left[\sqrt{1+y}-\sqrt{1+y'}\right]\right)\right. \\ \left. + \frac{d\tau\,(y')}{dy'} F\left(2\kappa\left[\sqrt{1+y}-\sqrt{1+y'}\right]\right)\mathcal{S}\,(\kappa,y')\right].\end{aligned} \tag{7.3.24}$$

The multipole coefficient calculated from Eqs. (7.3.18)-(7.3.24) is shown by the solid curve in Figure 7.3. The dashed line in Figure 7.3 shows the result of simplifying the expression for the multipole coefficients in the case $\ell \gg 1$, using the approximate formula (7.2.14) for the spherical Bessel

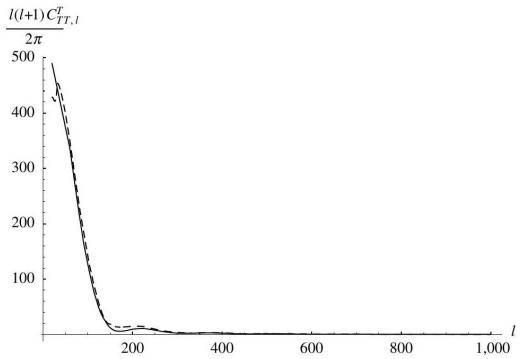

Figure 7.3: The tensor temperature-temperature multipole coefficient $\ell(\ell+1) C_{T T, \ell}^{T} / 2 \pi$ in square microKelvin, vs. ℓ, from ref. 6 . The solid line is the result of using the essentially exact formula (7.3.18); the dashed line gives the result of the large- ℓ approximation (7.3.25). The cosmological parameters used in these calculations are described in the text.

function in Eq. (7.3.18), which gives [6]

[475] S. Weinberg, Phys. Rev. D 74, 063517 (2006) [astro-ph/0607076]; D. Baskaran, L. P. Grishchuk, and A. G. Polnarev, Phys. Rev. D 74, 083005 (2006) [gr-qc/0605100].

$$\ell(\ell+1)C^T_{TT,\ell} \to 4\pi^2 T_0^2 \int_0^\infty q^2 dq \times \left| \int_{r(t)>\ell/q} dt d(q,t) \left\{ \frac{\cos^3 b}{\sqrt{\sin b}} \cos[\ell(\tan b - b) - \pi/4] \right\}_{\cos b = \ell/qr(t)} \right|^2 \tag{7.3.25}$$

The source function $\Psi(q,t)$ is calculated in both cases using the integral equation (7.3.22), instead of using the equivalent formula (6.6.21) together with the truncated Boltzmann hierarchy (6.6.18), (6.6.19). Both of these curves are calculated with a cosmological model that in most respects is consistent with current observations: We assume $\Omega_K = 0$, and constant vacuum energy, with $\Omega_B = 0.0432$, $\Omega_M = 0.257$, $\Omega_\Lambda = 0.743, h = 0.72$, and $T_0 = 2.725$ K. In calculating the photon collision frequency, we use the Recfast recombination code, [7] with helium abundance $Y = 0.24$. The parameters in Eq. (7.3.20) are taken as $N_T^2 = 4.68 \times 10^{-11}$ (corresponding approximately to the WMAP3 value of the scalar amplitude N quoted in the previous section, and $r = 1$) and $n_T = 0$. Reionization is ignored in this calculation. To take into account a different value of r or a finite optical depth τ of the reionized plasma, for $\ell > 10$ it is only necessary to multiply the multipole coefficients shown in Figure 7.3 by $r\exp(-2\tau)$. (In the approximation of a sharp transition at time t_L from thermal equilibrium, in which $\omega_c(t) \gg H(t)$ and $\Psi(q,t) = 0$, to perfect transparency, in which $\omega_c(t) = 0$, Eq. (7.3.25) becomes

$$\ell(\ell+1)C^T_{TT,\ell} \to 4\pi^2 T_0^2 \int_0^\infty q^2 dq \times \left| \int_{r_L>r(t)>\ell/q} dt \dot{\mathcal{D}}_q(t) \left\{ \frac{\cos^3 b}{\sqrt{\sin b}} \cos[\ell(\tan b - b) - \pi/4] \right\}_{\cos b = \ell/qr(t)} \right|^2 \tag{7.3.26}$$

Because of the spread of values of $\tan b - b$, we cannot here make the sort of further simplification that we made for scalar temperature fluctuations in going from Eq. (7.2.16) to Eq. (7.2.17).)

Figure 7.3 shows that $C^T_{TT,\ell}$ has an ℓ-dependence very different from that of the scalar contribution calculated in the previous section, so the agreement between existing observations and theory including only scalar perturbations sets an upper bound on the strength of the tensor perturbations. Under the assumption (as suggested by theories of inflation discussed in Chapter 10) that $\mathcal{D}^o_q$ and $\mathcal{R}^0_q$ have about the same q-dependence, the WMAP collaboration has concluded [8] after three-years of operation that $r < 0.55$, at a 95% confidence level, where $r \equiv 4\left|\mathcal{D}^0_q\right|^2 / \left|\mathcal{R}^0_q\right|^2$. This limit arises chiefly from temperature rather than polarization measurements, because of the much greater signal to noise ratio of the temperature measurements; the limit on r from polarization measurements alone is $r < 2.2$.

Strictly speaking, the limit $r < 0.55$ does rely on polarization measurements, which are used to determine the optical thickness of the reionized plasma. This is needed to determine the value of the slope parameter n_S for scalar modes, which in turn is needed in subtracting the scalar contribution to $C_{TT,\ell}$ from the observed values in order to set a limit on the tensor contribution. But cosmic variance sets a limit to the accuracy with which this subtraction can be made, and in the long run the best upper limits or the actual detection of tensor modes will come directly from polarization measurements, to which we now turn.

10.7.4 7.4 Polarization

Observations of the cosmic microwave background reveal not only its intensity in various directions, but also its polarization. The microwave background is expected to be polarized because of its scattering by free electrons, [1] such as were present around the time of recombination, or during the later period of reionization due to ultraviolet light from the first generation of stars. Polarization measurements have become of importance in learning when reionization began, and in disentangling the effects of reionization from the primordial intensity of fluctuations, and they may become even more important in future, in revealing the effects of gravitational waves

produced during inflation.

In Section 6.1 we introduced a dimensionless photon intensity perturbation matrix $J_{ij}(\mathbf{x}, \hat{p}, t)$, defined by Eq. (6.1.13). It is Hermitian, transverse in the sense that

$$\hat{p}^i J_{ij}(\mathbf{x}, \hat{p}, t) = \hat{p}^j J_{ij}(\mathbf{x}, \hat{p}, t) = 0, \tag{7.4.1}$$

and, as already noted in Section 7.1, its trace at $\mathbf{x} = 0$ and $t = t_0$ is related to the fractional photon temperature fluctuation seen from earth at present in any direction $\hat{n}$ by

$$\frac{\Delta T(\hat{n})}{T_0} = \frac{1}{4} J_{ii}\left(0, -\hat{n}, t_0\right). \tag{7.4.2}$$

For $\hat{n} = -\hat{p}$ in the three-direction $\hat{z}$, any matrix with these properties can be put in the form

$$J_{ij}\left(0, -\hat{z}, t_0\right) = \frac{2}{T_0} \begin{pmatrix} \Delta T(\hat{z}) + Q(\hat{z}) & U(\hat{z}) - iV(\hat{z}) & 0 \\ U(\hat{z}) + iV(\hat{z}) & \Delta T(\hat{z}) - Q(\hat{z}) & 0 \\ 0 & 0 & 0 \end{pmatrix} \tag{7.4.3}$$

where Q, U, and V are three real functions of direction with the dimensions of temperature, known as Stokes parameters. [2] In this case the Stokes parameters can be expressed in terms of the matrix J_{ij}, as

$$Q(\hat{z}) \pm iU(\hat{z}) = \frac{T_0}{2} e_{\pm i}(\hat{z}) e_{\pm j}(\hat{z}) J_{ij}\left(0, -\hat{z}, t_0\right) \tag{7.4.4}$$

$$V(\hat{z}) = \frac{T_0}{4} e_{-i}(\hat{z}) e_{+j}(\hat{z}) \left(J_{ij}\left(0, -\hat{z}, t_0\right) - J_{ji}\left(0, -\hat{z}, t_0\right)\right) \tag{7.4.5}$$

where $e_{\pm}(\hat{z}) = (1, \pm i, 0)/\sqrt{2}$ are the polarization vectors for a photon coming from the three-direction. Accordingly, for a photon coming from an arbitrary direction $\hat{n}$, we define the Stokes parameters as

$$Q(\hat{n}) \pm iU(\hat{n}) \equiv \frac{T_0}{2} e_{\pm i}(\hat{n}) e_{\pm j}(\hat{n}) J_{ij}\left(0, -\hat{n}, t_0\right) \tag{7.4.6}$$

$$V(\hat{n}) \equiv \frac{T_0}{4} e_{-i}(\hat{n}) e_{+j}(\hat{n}) \left(J_{ij}\left(0, -\hat{n}, t_0\right) - J_{ji}\left(0, -\hat{n}, t_0\right)\right) \tag{7.4.7}$$

[478] L. Page et al., Astrophys. J. Suppl. Ser. 170, 335 (2007) [astro-ph/0603450].

[1] M. J. Rees, Astrophys. J. 153, L1 (1968). Polarization correlations at small angular separation were considered in early papers on the polarization of the cosmic microwave background; see e.g. A. G. Polnarev, Sov. Astron. 29, 607 (1985); R. Crittenden, R. L. Davis, and P. J. Steinhardt, Astrophys. J. Lett. 417, L13 (1993); D. Coulson, R. Crittenden, and N. Turok, Phys. Rev. Lett. 73, 2390 (1994); A. Kosowsky, Ann. Phys. (N.Y.) 246, 49 (1996). Then all-sky analyses were given by U. Seljak and M. Zaldarriaga, Phys. Rev. Lett. 78, 2054 (1997) [astro-ph/9609169]; M. Zaldarriaga and U. Seljak, Phys. Rev. D 55, 1830 (1997) [astroph/9609170], and by M. Kamionkowski, A. Kosowsky, and A. Stebbins, Phys. Rev. Lett. 78, 2058 (1997) [astro-ph/9609132]; Phys. Rev. D. 55, 7368 (1997) [astro-ph/9611125].

where $e_\pm(\hat{n})$ are the polarization vectors for a photon coming from the $\hat{n}$-direction. Writing $\hat{n}$ in terms of polar and azimuthal angles θ and ϕ as

$$\hat{n} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta), \tag{7.4.8}$$

we can take

$$\mathbf{e}_\pm(\hat{n}) = (\hat{\theta} \pm i\hat{\phi})/\sqrt{2} \tag{7.4.9}$$

where $\hat{\theta}$ and $\hat{\phi}$ are orthogonal unit vectors in the plane perpendicular to $\hat{n}$, in the directions of increasing θ and ϕ, respectively:

$$\hat{\theta} \equiv (\cos\theta\cos\phi, \cos\theta\sin\phi, -\sin\theta), \quad \hat{\phi} \equiv (-\sin\phi, \cos\phi, 0) \tag{7.4.10}$$

It is the Stokes parameters that are measured in observations of the microwave background. The scattering of light by non-relativistic electrons does not produce circular polarization, and therefore we expect that all microwave background photons are linearly polarized, so that J_{ij} is real, and therefore $V = 0$. In this case the fractional intensity perturbation $e^i e^j J_{ij}$ reaches a maximum value $2\left(\Delta T + \sqrt{U^2+Q^2}\right)/T_0$ for a real polarization vector $\mathbf{e}$ in a direction $\hat{\theta}\cos\xi + \hat{\phi}\sin\xi$, where $\tan 2\xi = U/Q$. For a polarization vector in the orthogonal direction, $e^i e^j J_{ij}$ takes its minimum value $2\left(\Delta T - \sqrt{U^2+Q^2}\right)/T_0$, giving a total fractional intensity perturbation $4\Delta T/T_0$, as is necessary since the photon energy density goes as T^4.

Now we have to face a complication: As we have defined them, the Stokes parameters are not rotational scalars. That is, under an arbitrary rotation $x_i \to x'_i = R_{ij}x_j$ of the three-dimensional coordinate system, we do not have $Q'(\hat{n}') = Q(\hat{n})$ or $U'(\hat{n}') = U(\hat{n})$. This is because the polarization vectors are not really three-vectors. We note that

$$\mathbf{e}_{\pm i}(\hat{n}) = S_{ij}(\hat{n})\mathbf{e}_{\pm j}(\hat{z}) \tag{7.4.11}$$

where $S_{ij}(\hat{n})$ is a standard rotation that takes the three-axis into the direction $\hat{n}$. For $\hat{n} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$:

$$S_{ij}(\hat{n}) \equiv \begin{pmatrix} \cos\theta\cos\phi & -\sin\phi & \sin\theta\cos\phi \\ \cos\theta\sin\phi & \cos\phi & \sin\theta\sin\phi \\ -\sin\theta & 0 & \cos\theta \end{pmatrix} \tag{7.4.12}$$

and again $\mathbf{e}_\pm(\hat{z}) = (1, \pm i, 0)/\sqrt{2}$. For an arbitrary rotation R, we can write

$$\mathbf{e}_{\pm i}(R\hat{n}) \equiv S_{ij}(R\hat{n})\mathbf{e}_{\pm j}(\hat{z}) = [RS(\hat{n})]_{ik}\left[S^{-1}(\hat{n})R^{-1}S(R\hat{n})\right]_{kj}\mathbf{e}_{\pm j}(\hat{z})$$

Now, $S(R\hat{n})$ takes the three-axis into the direction $R\hat{n}$, R^{-1} takes this into the direction $\hat{n}$, and then $S^{-1}(\hat{n})$ takes this back to the direction of the threeaxis, so $S^{-1}(\hat{n})R^{-1}S(R\hat{n})$ leaves the three-direction invariant, and must
therefore be a rotation by some angle $\psi(R,\hat{n})$ around the three-direction. Acting on $\mathbf{e}_\pm(\hat{z})$, this yields a factor $e^{\pm i\psi}$, and so

$$\mathbf{e}_{\pm i}(R\hat{n}) = e^{\pm i\psi(R,\hat{n})}R_{ij}\mathbf{e}_{\pm j}(\hat{n}). \tag{7.4.13}$$

The matrix J_{ij} is an ordinary three-tensor, in the sense that an arbitrary rotation R takes J_{ij} into J'_{ij}, with

[472] The Stokes parameters are sometimes defined with extra constant factors to give them the dimensions of intensity rather than temperature.

$$J'_{ij}(R\hat{n}) = R_{ik}R_{il}J_{kl}(\hat{n})$$

Because $R^TR = 1$, a rotation R subjects the Stokes parameters (7.4.6) to the transformation $Q \to Q', U \to U'$, with

$$Q'(\hat{n}') \pm iU'(\hat{n}') = e^{\pm 2i\psi(R,\hat{n})}[Q(\hat{n}) \pm iU(\hat{n})]. \tag{7.4.14}$$

For this reason, if we were to expand the Stokes parameters in a series of ordinary spherical harmonics, as we do for scalars like the temperature fluctuation, then the expansion coefficients would not transform under rotations according to the usual representations of the rotation group. Instead, we expand the Stokes parameters $Q(\hat{n})$ and $U(\hat{n})$ seen in a direction $\hat{n}$ in a series of functions ${}^3\mathcal{Y}^m_\ell(\hat{n})$ with the same dependence on the polarization vectors as the Stokes parameters themselves:

$$\begin{aligned} Q(\hat{n}) + iU(\hat{n}) &= \textstyle\sum_{\ell=2}^{\infty}\sum_{m=-\ell}^{\ell} a_{P,\ell m}\mathcal{Y}^m_\ell(\hat{n}), \\ \mathcal{Y}^m_\ell(\hat{n}) &\equiv 2\sqrt{\tfrac{(\ell-2)!}{(\ell+2)!}}e_{+i}(\hat{n})e_{+j}(\hat{n})\tilde{\nabla}_i\tilde{\nabla}_j Y^m_\ell(\hat{n}), \end{aligned} \tag{7.4.16}$$

where $\tilde{\nabla}$ is the angular part of the gradient operator:

$$\tilde{\nabla} \equiv \hat{\theta}\frac{\partial}{\partial\theta} + \frac{\hat{\phi}}{\sin\theta}\frac{\partial}{\partial\phi} \tag{7.4.17}$$

The subscript " P " (for "polarization") on the coefficients $a_{P,\ell m}$ is introduced here to distinguish them from the coefficients entering in the expansion (2.6.1) of the temperature fluctuation, which in this chapter are denoted $a_{T,\ell m}$. Under a rotation R, the ordinary spherical harmonics transform as

$$Y^m_\ell(R\hat{n}) = \sum_{m'} D^{(\ell)}_{m'm}\left(R^{-1}\right) Y^{m'}_\ell(\hat{n}), \tag{7.4.18}$$

where $D^{(\ell)}(R)$ are the unitary irreducible matrices [4] of rank $2\ell+1$ that form a representation of the rotation group, in the sense that $D^{(\ell)}(R_1)\,D^{(\ell)}(R_2) = D^{(\ell)}(R_1R_2)$. It follows then from Eqs. (7.4.13), (7.4.16) and (7.4.18) that

$$\mathcal{Y}^m_\ell(R\hat{n}) = e^{2i\psi(R,\hat{n})}\sum_{m'} D^{(\ell)}_{m'm}\left(R^{-1}\right)\mathcal{Y}^{m'}_\ell(\hat{n}) \tag{7.4.19}$$

and hence also

$$\mathcal{Y}^{m*}_\ell(R\hat{n}) = e^{-2i\psi(R,\hat{n})}\sum_{m'} D^{(\ell)}_{mm'}(R)\mathcal{Y}^{m'}_\ell(\hat{n})^* \tag{7.4.20}$$

For this reason, $\mathcal{Y}^m_\ell$ and its complex conjugate are known as spherical harmonics of spin 2 and -2 , respectively. Just as for ordinary spherical harmonics, it follows from these transformation properties that $\int d\Omega\mathcal{Y}^{m*}_\ell\mathcal{Y}^{m'}_{\ell'}$ vanishes except for $\ell = \ell'$ and $m = m'$, and in that case is independent of m. The factor $2\sqrt{(\ell-2)!/(\ell+2)!}$ is inserted in Eq. (7.4.16) to make these functions satisfy the orthonormality condition

$$\int d\Omega\mathcal{Y}^{m*}_\ell\mathcal{Y}^{m'}_{\ell'} = \delta_{\ell\ell'}\delta_{mm'} \tag{7.4.21}$$

[473] These are a special case of functions introduced in a study of gravitational radiation by E. T. Newman and R. Penrose, J. Math. Phys. 7, 863 (1966). In their notation, which is used in some recent papers on microwave background polarization, the function $\mathcal{Y}^m_\ell$ is denoted ${}_2Y_{\ell,m}$.

just like the ordinary spherical harmonics Y_ℓ^m. Direct evaluation of Eq. (7.4.16) gives [5]

$$\begin{aligned}
\mathcal{Y}_\ell^m(\hat{n}) =& \sqrt{\frac{(\ell-2)!}{(\ell+2)!}}\left[\left(\frac{\partial}{\partial\theta}+i\csc\theta\frac{\partial}{\partial\phi}\right)^2-\cot\theta\left(\frac{\partial}{\partial\theta}+i\csc\theta\frac{\partial}{\partial\phi}\right)\right]Y_\ell^m(\hat{n})\\
=& e^{im\phi}\sqrt{\frac{(\ell-2)!}{(\ell+2)!}\frac{(\ell-|m|)!}{(\ell+|m|)!}\frac{2\ell+1}{4\pi}}\Big[-\ell(\ell+1)P_\ell^{|m|}(\mu)\\
&+\frac{2(m+\mu)(m-\ell\mu)}{1-\mu^2}P_\ell^{|m|}(\mu)\\
&+\frac{2(\ell+|m|)(m+\mu)}{1-\mu^2}P_{\ell-1}^{|m|}(\mu)\Big)\Big]\\
=& e^{im\phi}\left[\frac{(\ell+m)!(\ell-m)!}{(\ell+2)!(\ell-2)!}\frac{2\ell+1}{4\pi}\right]^{1/2}\sin^{2\ell}(\theta/2)(-1)^{(m-|m|)/2}\\
&\times\sum_r\binom{\ell-2}{r}\binom{\ell+2}{r+2-m}\\
&\times(-1)^{\ell-r+m}\cot^{2r+2-m}(\theta/2)
\end{aligned}\tag{7.4.22}$$

where $\mu\equiv\cos\theta$ and $P_\ell^m(\mu)$ are the usual associated Legendre functions. (Here we will only need the first expression in Eq. (7.4.22).) Unlike the ordinary spherical harmonics, the $\mathcal{Y}_\ell^m$ do not satisfy any simple reality condition. Rather, the complex conjugate of Eq. (7.4.15) gives

$$Q(\hat{n})-iU(\hat{n})=\sum_{\ell=2}^{\infty}\sum_{m=-\ell}^{\ell}a_{P,\ell m}^*\mathcal{Y}_\ell^m(\hat{n})^*\tag{7.4.23}$$

where

$$\mathcal{Y}_\ell^m(\hat{n})^*=2\sqrt{\frac{(\ell-2)!}{(\ell+2)!}}e_{-i}(\hat{n})e_{-j}(\hat{n})\tilde{\nabla}_i\tilde{\nabla}_jY_\ell^{-m}(\hat{n}),\tag{7.4.24}$$

in which we have used the reality property of the spherical harmonics employed here, $Y_\ell^{m*}=Y_\ell^{-m}$.

Because $\mathcal{Y}_\ell^m$ does not satisfy any simple reality condition, neither does $a_{P,\ell m}$. Instead, we can define coefficients

$$a_{E,\ell m}\equiv-\left(a_{P,\ell m}+a_{P,\ell-m}^*\right)/2,\quad a_{B,\ell m}\equiv i\left(a_{P,\ell m}-a_{P,\ell-m}^*\right)/2.\tag{7.4.25}$$

This is a useful decomposition, because of the properties of the coefficients under space inversion. If we reverse all three coordinate axes, then $\theta\to\pi-\theta$, while $\phi\to\phi\pm\pi$, so

[474] See, e.g., A. R. Edmonds, Angular Momentum in Quantum Mechanics, (Princeton University Press, Princeton, 1957): Chapter 4; M. E. Rose, Elementary Theory of Angular Momentum (John Wiley & Sons, New York, 1957): Chapter IV; L. D. Landau and E. M. Lifshitz, Quantum Mechanics - Non Relativistic Theory, 3rd edn. (Pergamon Press, Oxford, 1977): Section 58; Wu-Ki Tung, Group Theory in Physics (World Scientific, Singapore, 1985): Sections 7.3 and 8.1. Note that the rotation matrices we use are appropriate for the representation furnished by the spherical harmonics we use, with phases such that $Y_\ell^m(\hat{n})^*=Y_\ell^{-m}(\hat{n})$. The corresponding angular momentum matrices $\mathbf{J}^{(\ell)}$ are not the usual ones, for which the elements of $J_1^{(\ell)}\pm iJ_2^{(\ell)}$ are real and positive. If we changed the phase of the spherical harmonics so that $Y_\ell^m(\hat{n})^*=(-1)^mY_\ell^{-m}(\hat{n})$, then the rotation matrices would be generated by conventional angular momentum matrices, with the elements of $J_1^{(\ell)}\pm iJ_2^{(\ell)}$ real and positive, but then we would have to introduce phases into the definition (7.4.25) of the E and B-type partial wave amplitudes, different from those used by Zaldarriaga and Seljak in ref. 1.

[5] The final expression is taken from Zaldarriaga and Seljak, ref. 1, while the first expression, which is derived here from our definition (7.4.16), is their definition of the spin +2 weighted spherical harmonic.

$\hat{\theta} \to \hat{\theta}$ and $\hat{\phi} \to -\hat{\phi}$. It follows then that the polarization vectors (7.4.9) of definite helicity are interchanged under space inversion; that is, $\mathbf{e}_{\pm}(-\hat{n}) = \mathbf{e}_{\mp}(\hat{n})$, and therefore according to Eq. (7.4.6), under space inversion $Q(\hat{n}) \to Q(-\hat{n})$ while $U(\hat{n}) \to -U(-\hat{n})$ and $V(\hat{n}) \to -V(-\hat{n})$. (The reader will later be able to check these spaceinversion properties of Q and U, by noting that these are the changes that are produced if replace the stochastic parameters $\alpha(\mathbf{q})$ and $\beta(\mathbf{q}, \lambda)$ in Eqs. (7.4.31) and (7.4.40) with their space-inversion transforms $\alpha(-\mathbf{q})$ and $\beta(-\mathbf{q}, -\lambda)$, respectively.) Thus by applying a space inversion to Eq. (7.4.15), we find that space inversion takes the partial wave amplitudes $a_{P,\ell m}$ into
$a'_{P,\ell m}$, where

$$\begin{aligned}
&Q(-\hat{n}) - iU(-\hat{n}) \\
&\quad = 2\sum_{\ell=2}\sum_{\ell=0}^{\infty}\sum_{m=-\ell}^{\ell} a'_{P,\ell m}\sqrt{\frac{(\ell-2)!}{(\ell+2)!}}e_{+i}(\hat{n})e_{+j}(\hat{n})\tilde{\nabla}_i\tilde{\nabla}_j Y_\ell^m(\hat{n}) \\
&\quad = 2(-1)^\ell\sum_{\ell=0}^{\infty}\sum_{m=-\ell}^{\ell} a'_{P,\ell m}\sqrt{\frac{(\ell-2)!}{(\ell+2)!}}e_{-i}(-\hat{n})e_{-j}(-\hat{n})\tilde{\nabla}_i\tilde{\nabla}_j Y_\ell^m(-\hat{n}) \\
&\quad = (-1)^\ell\sum_{\ell=2}^{\infty}\sum_{m=-\ell}^{\ell} a'_{P,\ell m}\mathcal{Y}_\ell^{-m}(-\hat{n})^*
\end{aligned}$$

the factor $(-1)^\ell$ coming from the reflection property $Y_\ell^m(-\hat{n}) \to (-1)^\ell Y_\ell^m(\hat{n})$. Comparing this with Eq. (7.4.23), we see that space inversion changes $a_{P,\ell m}$ into $a'_{P,\ell m} = (-1)^\ell a^*_{P,\ell -m}$, so it changes $a_{E,\ell m}$ (and also the corresponding temperature multipole coefficient $a_{T,\ell m}$) by a sign$(-1)^\ell$, while it changes $a_{B,\ell m}$ by a sign $-(-1)^\ell$.

These coefficients are stochastic variables, governed by a probability distribution that is presumably invariant under space inversion, so there can be no bilinear correlation between polarization fluctuations of B and E type, or between temperature fluctuations and polarization fluctuations of B type, though there can be correlations between temperature fluctuations and polarization fluctuations of E type. Taking into account also the rotational invariance of the probability distribution, the only non-vanishing bilinear averages are of the form [6]

$$\left\langle a^*_{T,\ell m} a_{T,\ell' m'}\right\rangle = C_{TT,\ell}\delta_{\ell,\ell'}\delta_{m,m'} \tag{7.4.26}$$
$$\left\langle a^*_{T,\ell m} a_{E,\ell' m'}\right\rangle = C_{TE,\ell}\delta_{\ell,\ell'}\delta_{m,m'} \tag{7.4.27}$$
$$\left\langle a^*_{E,\ell m} a_{E,\ell' m'}\right\rangle = C_{EE,\ell}\delta_{\ell,\ell'}\delta_{m,m'} \tag{7.4.28}$$
$$\left\langle a^*_{B,\ell m} a_{B,\ell' m'}\right\rangle = C_{BB,\ell}\delta_{\ell,\ell'}\delta_{m,m'} \tag{7.4.29}$$

All $C_{XY,\ell}$ coefficients have the same dimensions, of square temperature. By their definition, the a_T, a_E, and a_B all satisfy the reality conditions

$$a^*_{T,\ell m} = a_{T,\ell -m}, a^*_{E,\ell m} = a_{E,\ell -m}, a^*_{B,\ell m} = a_{B,\ell -m}, \tag{7.4.30}$$

and hence the coefficients $C_{XY,\ell}$ are all real, while the $C_{XX,\ell}$ are all also positive. The results of measurements of correlations between temperature and/or polarization fluctuations in different directions are generally reported in terms of the $C_{XY,\ell}$.

[476] Here $a_{T,\ell m}$ is the coefficient $a_{\ell m}$ in Eq. (2.6.1). The multipole coefficients $C_{XY,\ell}$ defined here are the same as those defined by Zaldarriaga and Seljak, ref. 1. They are related to coefficients defined by Kamionkowski, Kosowsky, and Stebbins, ref. 1, by $C_\ell^G = C_{\ell,EE}I^2/2T_0^2, C_\ell^C = C_{\ell,BB}I^2/2T_0^2$, $C_\ell^{TG} = -C_{TE,\ell}I/\sqrt{2}T_0^3$, where I is the radiation intensity. (The superscripts G and C stand for "gradient" and "curl", because the pattern of polarization vectors of type E or B resemble the pattern of velocity in potential or solenoidal flow, respectively.)

Another simplification provided by the decomposition of the Stokes parameters into E and B terms is that, as we will see, scalar perturbations can only contribute to the E terms. This result is important, because it means that any sign of a primordial B-type polarization [7] will be clear evidence for cosmological gravitational waves, of the sort that we shall see in Chapter 10 are expected to be produced during inflation.

We now turn to the calculation of the multipole coefficients (7.4.27)(7.4.29). The hydrodynamic treatment that worked reasonably well for temperature correlation functions is not well suited to the treatment of polarization, so we will rely on the more accurate kinetic theory outlined in Section 6.1. Here we must distinguish between scalar and tensor modes. As already mentioned, these do not interfere, so the multipole coefficients can all be written as a sum of a scalar and a tensor term, denoted by superscripts S and T :

$$C_{XY,\ell} = C^S_{XY,\ell} + C^T_{XY,\ell}. \tag{7.4.31}$$

A. Scalar modes

For scalar modes, the matrix J_{ij} in Eq. (7.4.6) is given by the Fourier integral (6.1.18) and the line-of-sight integral (6.1.36):

$$\begin{aligned} J_{ij}\left(0,-\hat{n},t_0\right) = & \int d^3q\alpha(\mathbf{q}) \int_{t_1}^{t_0} dt \exp\left(-i\mathbf{q}\cdot\hat{p}\int_t^{t_0}\frac{dt'}{a\left(t'\right)} - \int_t^{t_0} dt'\omega_c\left(t'\right)\right) \\ & \times \Big[-\left(\delta_{ij}-\hat{n}_i\hat{n}_j\right)\left(\dot{A}_q\left(t'\right) - (\hat{n}\cdot\mathbf{q})^2\dot{B}_q\left(\prime\right)\right) \\ & + \frac{3\omega_c(t)}{2}\left(\delta_{ij}-\hat{n}_i\hat{n}_j\right)\Phi(q,t) \\ & + \frac{3\omega_c(t)}{4}\Pi(q,t)\left(\hat{q}_i-\hat{n}_i(\hat{q}\cdot\hat{n})\left(\hat{q}_j-\hat{n}_j(\hat{q}\cdot\hat{n})\right)\right. \\ & \left. + \frac{2\omega_c(t)}{a(t)}\left[\delta_{ij}-\hat{n}_i\hat{n}_j\right]\hat{n}_k\delta u_k(\mathbf{q},t)\Big]\right. . \end{aligned}$$

Since $\hat{n}_i e_{+i}(\hat{n}) = 0$ and $e_{+i}(\hat{n})e_{+i}(\hat{n}) = 0$, the only term in the integrand that contributes to the Stokes parameters is the one proportional to $\hat{q}_i\hat{q}_j$:

$$\begin{aligned} Q^S(\hat{n}) + iU^S(\hat{n}) = & \frac{3T_0}{8}e_{+i}(\hat{n})e_{+j}(\hat{n})\int d^3q\hat{q}_i\hat{q}_j\alpha(\mathbf{q}) \\ & \times\int_{t_1}^{t_0} dtP(t)\Pi(q,t)\exp\left(i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\left(t'\right)}\right) \end{aligned} \tag{7.4.32}$$

where $P(t)dt$ is the probability that the last scattering occurs between t and $t+dt$:

$$P(t) = \omega_c(t)\exp\left(-\int_t^{t_0}\omega_c\left(t'\right)dt'\right) \tag{7.4.33}$$

As a reminder: $\alpha(\mathbf{q})$ is the stochastic parameter for whatever mode (presumably the non-decaying adiabatic mode) is assumed to dominate the scalar perturbations; $\omega_c(t)$ is the photon collision rate; t_1 is any time taken early enough so that a photon present at that time would suffer many collisions before the present; and $\Pi(q,t)$ is a source function, given by Eq. (6.1.30)

[477] Weak lensing by foreground objects converts the E-type polarization produced by scalar perturbations into a B-type polarization that may be large enough to interfere with measurements of the primordial B-type polarization; M. Zaldarriaga and U. Seljak, Phys. Rev. D 58, 023003 (1998)[astroph/9803150]. For a review, see A. Lewis and A. Challinor, Phys. Rep. 429, 1 (2006) [astro-ph/0601594].

in terms of the partial wave amplitudes of the temperature and polarization perturbation amplitudes:

$$\Pi(q,t) = \Delta^{(S)}_{T,2}(q,t) + \Delta^{(S)}_{P,0}(q,t) + \Delta^{(S)}_{P,2}(q,t). \tag{7.4.34}$$

To use Eq. (7.4.31) to calculate the EE and TE multipole coefficients, we recall the familiar formula

$$\exp(i\hat{q}\cdot\mathbf{v}) = 4\pi\sum_{\ell,m} i^\ell j_\ell(v) Y^m_\ell(\hat{v}) Y^{m*}_\ell(\hat{q}),$$

where here $\mathbf{v} = \hat{n}q\int_t^{t_0} dt'/a\,(t')$. Acting on this, we can replace $\hat{q}_i$ with $-i\partial/\partial v_i$. Since $\hat{v} = \hat{n}$, we can write $\partial/\partial v_i = \hat{n}_i\partial/\partial v + \tilde{\nabla}_i/v$, where $\tilde{\nabla}$ is the angular gradient operator (7.4.17) acting on $\hat{n}$. Since $\hat{n}_i e_{+i} = 0$ and $e_{+i}e_{+i} = 0$, Eq. (7.4.31) then reads

$$\begin{aligned} Q^S(\hat{n}) + iU^S(\hat{n}) = &-\frac{3\pi T_0}{2} e_{+i}(\hat{n}) e_{+j}(\hat{n}) \tilde{\nabla}_i \tilde{\nabla}_j \sum_{\ell m} i^\ell Y^m_\ell(\hat{n}) \int d^3q \alpha(\mathbf{q}) \\ &\times Y^{m*}_\ell(\hat{q}) \int_{t_1}^{t_0} dt P(t) \Pi(q,t) \frac{j_\ell(qr(t))}{q^2 r(t)^2} \end{aligned} \tag{7.4.35}$$

where here $r(t)$ is the radial coordinate of a point from which light emitted at time t would just reach us at present

$$r(t) = \int_t^{t_0} \frac{dt'}{a\,(t')} \tag{7.4.36}$$

(Note that $\tilde{\nabla}_i\hat{n}_j$ doesn't contribute here, because it equals $\delta_{ij} - \hat{n}_i\hat{n}_j$, which vanishes when contracted with $e_{+i}e_{+j}$.) Comparing Eq. (7.4.34) with Eqs. (7.4.15) and (7.4.16), we see that the scalar contribution to $a_{P,\ell m}$ is

$$a^S_{P,\ell m} = -\frac{3\pi T_0 i^\ell}{4}\sqrt{\frac{(\ell+2)!}{(\ell-2)!}} \int d^3q \alpha(\mathbf{q}) Y^{m*}_\ell(\hat{q}) \int_{t_1}^{t_0} dt \tag{7.4.37}$$

$$\times P(t)\Pi(q,t)\frac{j_\ell(qr(t))}{q^2 r^2(t)} \tag{7.4.38}$$

To check the reality properties of $a_{P,\ell m}$, we note that Eqs. (6.1.18) and (6.1.21) require that $\alpha^*(\mathbf{q})\Pi^*(q,t) = \alpha(-\mathbf{q})\Pi(q,t)$, while $Y^m_\ell(\hat{q}) = (-1)^\ell Y^{-m*}_\ell(-\hat{q})$, and of course $i^{\ell*} = (-1)^\ell i^\ell$, so $a^{S*}_{P,\ell m} = a^S_{P,\ell -m}$. Inspection of Eq. (7.4.25) then shows that, as promised, the scalar modes contribute only an E-type polarization

$$a^S_{E,\ell m} = -a^S_{P,\ell m}, \quad a^S_{B,\ell m} = 0. \tag{7.4.39}$$

We can now give formulas for the scalar contribution to the EE and TE multipole coefficients defined by Eqs. (7.4.28) and (7.4.27). Recalling the normalization condition (7.2.5) of the scalar stochastic parameter $\alpha(\mathbf{q})$, we see from Eqs. (7.4.36) and (7.4.37) that [8]

$$C^S_{EE,\ell} = \frac{9\pi^2 T_0^2}{16}\frac{(\ell+2)!}{(\ell-2)!}\int_0^\infty q^2 dq \left|\int_{t_1}^{t_0} dt P(t)\Pi(q,t)\frac{j_\ell(qr(t))}{q^2 r^2(t)}\right|^2 \tag{7.4.40}$$

Combining Eq. (7.4.36) with the general formula (7.2.4) for the scalar contribution to the temperature partial wave amplitudes, we find in the same way that

$$C^S_{TE,\ell} = -3\pi^2 T_0^2 \sqrt{\frac{(\ell+2)!}{(\ell-2)!}} \int_0^\infty q^2 dq \times \int_{t_1}^{t_0} dt P(t) \Pi(q,t) \frac{j_\ell(qr(t))}{q^2 r^2(t)} \times \int_{t_1}^{t_0} [j_\ell(qr(t))F(q,t) + j'_\ell(qr(t))G(q,t) + j''_\ell(qr(t))H(q,t)] \quad (7.4.41)$$

7 Anisotropies in the Microwave Sky

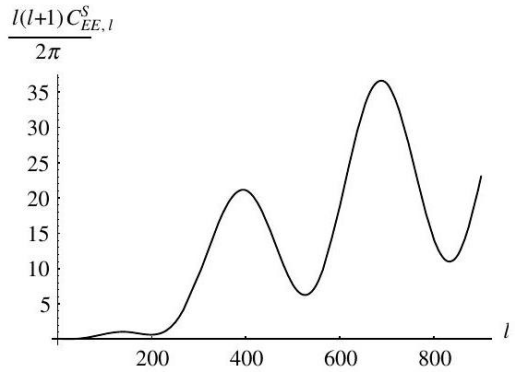

Figure 7.4: The multipole coefficient $\ell(\ell+1)C^S_{EE,\ell}/2\pi$ in square microKelvin, vs. ℓ, for the cosmological parameters given in Eqs. (7.2.44) and (7.2.45).

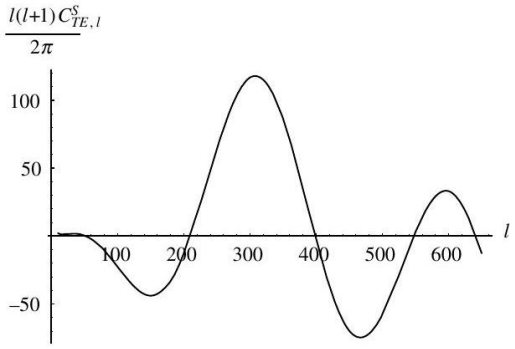

Figure 7.5: The multipole coefficient $\ell(\ell+1) C_{T E, \ell}^{S} / 2 \pi$ in square microKelvin, vs. ℓ, for the cosmological parameters given in Eqs. (7.2.44) and (7.2.45).

where $F(q,t), G(q,t)$, and $H(q,t)$ are the quantities (7.2.7)-(7.2.9). The values of $C^S_{EE,\ell}$ and $C^S_{TE,\ell}$, calculated [9] for the cosmological parameters (7.2.44)-(7.2.45), are shown in Figures 7.4 and 7.5. Comparing these figures with each other and with Figure (7.3), we see that $C^S_{EE,\ell} \ll C^S_{TE,\ell} \ll C^S_{TT,\ell}$. The microwave background polarization is small, because the universe goes swiftly at the time of recombination from a state of nearly perfect thermal equilibrium to one of nearly perfect transparency, and photons are not polarized in thermal equilibrium.

Eqs. (7.4.38) and (7.4.39) must be used for maximum numerical accuracy, but we can get a good idea of the ℓ dependence of the multipole coefficients for $\ell \gg 1$ by using much simpler

[478] This is the same as Eq. (17) of Zaldarriaga and Seljak, ref. 1, except that Π here is 4 times their Π.

approximate versions. The function $P(t)$ in Eq. (7.4.38) is sharply peaked at a time t_L of last scattering, and it has

$\int dt P(t) = 1$, so to a fair approximation we can do the integral over time by simply setting $t = t_L$ and dropping the factor $P(t)$. Also, by using the same approximations that led us from Eq. (7.2.13) to Eq. (7.2.17), we find that for $\ell \gg 1$

$$C^S_{EE,\ell} \approx \frac{9\pi^2\ell^3}{32 r_L^3} \int_1^\infty \frac{d\beta}{\beta\sqrt{\beta^2-1}} \Pi^2\left(\frac{\ell\beta}{r_L}, t_L\right).$$

This does not give a reliable result for the magnitude of $C^S_{EE,\ell}$, because the function $\Pi(q,t)$ varies rapidly around the time of recombination, but since this function falls off rapidly with q, so that the integral is dominated by $\beta \approx 1$, this approximation does suggest that the peaks and valleys in $C^S_{EE,\ell}$ arise chiefly from a factor $\Pi^2\left(\ell/r_L, t_L\right)$. On the other hand, as remarked in Section 7.2, the peaks and valleys in $C^S_{TT,\ell}$ arise chiefly from a factor $F^2\left(\ell/r_L\right)$, and by the same reasoning, the peaks and valleys in $C^S_{TE,\ell}$ arise chiefly from a factor $F\left(\ell/r_L\right)\Pi\left(\ell/r_L, t_L\right)$.

To get an idea of the q-dependence of $\Pi\left(q, t_L\right)$, we note first that, to the extent that the photon polarization arises solely from the last scattering, $\Pi(q,t)$ would be given by just the first term $\Delta^{(S)}_{T,2}(q,t)$ in Eq. (7.4.33). This is because the differential cross section for the scattering of an unpolarized photon of initial momentum $\mathbf{p}$ with $|\mathbf{p}| \ll m_e$ by a non-relativistic electron to yield a photon with real polarization vector $\mathbf{e}$ is [10]

$$\frac{d\sigma}{d\Omega} = \frac{e^4}{32\pi^2 m_e^2}\left(1 - (\hat{p}\cdot\mathbf{e})^2\right).$$

If the distribution of initial momenta $\mathbf{p}$ were spherically symmetric then the average of this cross section over initial directions would be independent of $\mathbf{e}$, so the final photon would be unpolarized. But for a direction-dependent phase space density $n_{\gamma,L}(\mathbf{p})$ of photons with momentum $\mathbf{p}$ at the position and time of last scattering, the intensity of photons after last scattering coming from direction $\hat{n}$ and having polarization vector $\mathbf{e}$ (with $\mathbf{e}^2 = 1$ and e $\cdot\hat{n} = 0$) is proportional to

$$\int d^3p p p n_{\gamma,L}(\mathbf{p})\left(1 - (\hat{p}\cdot\mathbf{e})^2\right).$$

The part of J_{ij} that contributes to the Stokes parameters is thus proportional to the traceless part of $\int d^3p p p n_{\gamma,L}(\mathbf{p})\hat{p}_i\hat{p}_j$, which in turn is proportional to the $\ell = 2$ part of $\Delta^{(S)}_T$ evaluated at the time and position of last scattering.

The additional terms $\Delta^{(S)}_{P,0}(q,t) + \Delta^{(S)}_{P,2}(q,t)$ in $\Pi(q,t)$ take account of whatever polarization the photon may already have acquired by the time of last scattering, and can be expected to be relatively small since photons must be unpolarized under conditions of rapid photon scattering. But then, according to Eq. (6.1.32),

$$\Pi\left(q, t_L\right) \simeq \Delta^{(S)}_{T,2}(q,t) \simeq q^2\pi^S_q\left(t_L\right)/\bar{\rho}_\gamma\left(t_L\right).$$

Recall that, according to the first line of Eq. (5.1.43), $\partial_i\partial_j\pi^S(\mathbf{x},t)$ is the term in the scalar part of $\delta T^i{}_j$ that is not proportional to δ_{ij}, while Eq. (B.50) tells us that for short mean free times, this term equals [11]

$$\partial_i\partial_j\pi^S = a^{-2}\eta_\gamma\partial_i\partial_j\delta\tilde{u}$$

[479] http://lambda.gsfc.nasa.gov/data/map/powspec/wmap_lcdm_pl_model_yr1_ v1.txt

[4710] See, e.g., QTF, Eq. (8.7.40). This was first calculated by O. Klein and Y. Nishina, Z. Phys. 52, 853 (1929).

where η_γ is the shear viscosity due to photon momentum transport, given in terms of the photon mean free time t_γ by [12] $\eta_\gamma = \frac{16}{45}\bar{\rho}_\gamma t_\gamma$, and $\delta\tilde{u}(\mathbf{x}, t)$ is the gauge-invariant velocity potential [13]

$$\delta\tilde{u} \equiv \delta u - aF + \frac{a^2\dot{B}}{2},$$

with F and B metric perturbations defined by Eqs. (5.1.32) and (5.1.33). Also, Eq. (7.1.45) (which was derived for a gauge in which the metric component F vanishes) gives the coefficient of the stochastic parameter $\alpha(\mathbf{q})$ in the Fourier transform of the gauge-invariant velocity potential in terms of the form factor $G(q)$ as $\delta\tilde{u}_q(t_L) = -a(t_L)\,G(q)/q$. We conclude then that

$$\Pi(q, t_L) \simeq \frac{16q^2}{45a^2(t_L)}\bar{t}_\gamma\delta\tilde{u}_q(t_L) \simeq -\frac{16q}{45a(t_L)}\bar{t}_\gamma G(q)$$

where $\bar{t}_\gamma$ is some appropriate average of $t_\gamma(t)$ during the era of recombination. Thus the peaks and valleys in $C^S_{EE,\ell}$ and in $\left|C^S_{TE,\ell}\right|$ are more-or-less the same as those in $|G(q/r_L)|^2$ and $|F(q/r_L)\,G(q/r_L)|$, respectively, and we recall that the peaks and valleys in $C^S_{TT,\ell}$ are essentially those in $|F(q/r_L)|^2$. Eqs. (7.2.23) and (7.2.24) give

$$F(q) \simeq \frac{\mathcal{R}^o_q}{5}\left[3R_L\mathcal{T}(\kappa) - (1+R_L)^{-1/4}\,e^{-\int_0^{t_L}\Gamma dt}\mathcal{S}(\kappa)\cos\chi(q)\right]$$

$$G(q) = -\frac{\sqrt{3}\mathcal{R}^o_q}{5\,(1+R_L)^{3/4}}e^{-\int_0^{t_L}\Gamma dt}\mathcal{S}(\kappa)\sin\chi(q),$$

where $\chi(q)$ is an approximately linear function of q :

$$\chi(q) \equiv \int_0^{t_L}\frac{qdt}{a\sqrt{3(1+R)}} + \Delta(\kappa)$$

and the argument κ of the transfer functions S, T, and Δ is proportional to q. As remarked in Section 7.2, the peaks in $C^S_{TT,\ell}$ are thus roughly at $\chi(\ell/r_L) = \pi, 2\pi, 3\pi, \ldots$ On the other hand, we expect the peaks in $C^S_{EE,\ell}$ to be roughly at the peaks in $|\sin(\chi(\ell/r_L))|$, or in other words, at $\chi(\ell/r_L) = \pi/2, 3\pi/2, 5\pi/2, \ldots$, and the peaks in $\left|C^S_{TE,\ell}\right|$ to be roughly at the peaks in $|\cos(\chi(\ell/r_L))\sin(\chi(\ell/r_L))|$, or in other words, at $\chi(\ell/r_L) = \pi/4, 3\pi/4, 5\pi/4, \ldots$ In particular, we expect a peak in $C^S_{EE,\ell}$ before the first peak in $C^S_{TT,\ell}$, followed by one peak in $C^S_{EE,\ell}$ between successive peaks in $C^S_{TT,\ell}$, while there should be two peaks in $\left|C^S_{TE,\ell}\right|$ before the first peak in $C^S_{TT,\ell}$, followed by two peaks in $\left|C^S_{TE,\ell}\right|$ between successive peaks in $C^S_{TT,\ell}$. This is precisely the pattern seen in computer calculations. [14] For instance, for a plausible set of cosmological parameters there are indeed two peaks in $\left|C^S_{TE,\ell}\right|$ (at $\ell = 36$ and $\ell = 144$) below the first peak in $C^S_{TT,\ell}$ at $\ell = 230$.

The E-type polarization and temperature-polarization correlation were first detected by the Degree Angular Scale Interferometer (DASI) collaboration. [15] Then the Wilkinson Microwave Anisotropy Probe (WMAP) collaboration measured the coefficients $C_{TE,\ell}$ with good accuracy over a range of multipole orders from $\ell = 2$ to $\ell \simeq 570$.[16] The results for $\ell > 10$ are in good agreement with the concordance model, assuming primordial fluctuations with a spectrum close to the Harrison-Zel'dovich form $\mathcal{R}^o_q \propto q^{-3/2}$, and a constant vacuum energy along with cold dark

[4711] Here we use the relation $\delta u^i{}_{;j} = \delta u_j{}^i = a^{-2}\delta u_{i;j} - a^{-4}h_{ij}a\dot{a}$.

[12] N. Kaiser, Mon. Not. Roy. Astron. Soc. 202, 1169 (1983). For a discussion, see footnote 5 of Section 6.4.

[13] We recognize $\delta\tilde{u}$ as the same velocity potential that appears in Eq. (7.1.37) as the Doppler contribution to the temperature shift in the class of gauges with vanishing metric component F. In the special case of Newtonian gauge we have $F = B = 0$, and $\delta\tilde{u} = \delta u$.

matter, baryonic matter, photons, and massless neutrinos, and using the same values of the cosmological parameters $\Omega_B h^2, \Omega_M h^2, h$, and N as used in fitting the model to measurements of temperature anisotropies. In particular, there is clear evidence of the second expected peak in $|C_{TE,\ell}|$, at around $\ell \simeq 140$, and the third expected peak, at $\ell \simeq 300$. More recently, the QUaD collaboration [17] has reported preliminary results from the first season of operation of a microwave polarimeter at the South Pole, which show clear evidence for the first peak in $C_{EE,\ell}$ at $\ell \simeq 350$, about where it is expected from scattering around the time of recombination. But if reionization were not included in the cosmological model, there would be a clear discrepancy between its predictions and the data for $C_{TE,\ell}$ for $\ell < 10$. This discrepancy is attributed to polarization caused by scattering in a plasma that has been reionized by ultraviolet light from a first generation of stars.

The most important application of polarization measurements so far has been in working out the history of the reionization of intergalactic matter at redshifts much less than $z_L \simeq 1090$, which contributes to the last-scattering probability distribution $P(t)$. Because nearby events subtend large angles, the additional terms in $C_{EE,\ell}$ and $C_{TE,\ell}$ due to reionization are negligible except for relatively small ℓ, in fact $\ell < 10$. After three years of operation, the WMAP collaboration [18] found on the basis of the EE correlation alone that if reionization is sudden and complete at a redshift z_r, then $z_r = 10.9^{+2.7}_{-2.3}$, corresponding to an optical depth $\tau = 0.09 \pm 0.03$. This result is in line with expectations of the onset of star formation, and it has played an essential role in the use of temperature correlations to determine the magnitude of $\mathcal{R}_q^o$ and to set an upper limit on $\mathcal{D}_q^o$, discussed in Sections 7.2 and 7.3, respectively. Scattering by the reionized plasma produces a peak in $C_{EE,\ell}$ much like the peak at $\ell \simeq 140$, but shifted to much smaller ℓ, around $\ell \simeq 4$, because it occurs at an angular diameter distance much smaller than the angular diameter distance of the era of recombination. The WMAP measurements and other measurements of $C_{EE,\ell}$ for larger values of ℓ are in good agreement with the theoretical formula (7.4.38) for $C^S_{EE,\ell}$, as shown in Figure 7.6, and future measurements are expected to further reduce the uncertainties in this comparison.

B. Tensor modes

For tensor modes, the matrix J_{ij} in Eq. (7.4.4) is given by the Fourier integral (6.6.9) and line-of-sight integral (6.6.24):

$$J_{ij}(\mathbf{x}, \hat{p}, t) = \sum_{\lambda=\pm 2} \int d^3q e^{i\mathbf{q}\cdot\mathbf{x}} \beta(\mathbf{q}, \lambda) \times \int_{t_1}^{t} dt' \exp\left(-i\mathbf{q}\cdot\hat{p} \int_{t'}^{t} \frac{dt''}{a\,(t'')} - \int_{t'}^{t} dt'' \omega_c\,(t'') \right)$$

[4714] For instance, see http://lambda.gsfc.nasa.gov/data/map/powspec/wmap_lcdm_pl_model_vr1_v1.txt.

[4718] L. Page et al., Astrophys. J. Suppl. Ser. 170, 335 (2007) [astro-ph/0603450].

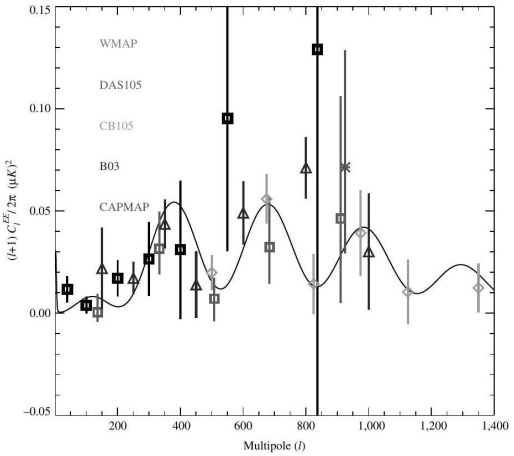

Figure 7.6: Observed values of the multipole coefficient $(\ell+1) C_{E E, \ell} / 2 \pi$ in square microKelvin, vs. ℓ, from L. Page et al., astro-ph/0603450. (Note that $C_{EE,\ell}/2\pi$ is multiplied here with $\ell+1$, rather than the usual $\ell(\ell+1)$.) Dark squares are the WMAP data; the triangles are BOOMERanG data; the lighter squares are the DASI data; the diamonds are the CBI data; and the asterisk is the CAPMAP datum. The solid curve is the theoretical curve for $(\ell+1)C^S_{EE,\ell}/2\pi$, with cosmological parameters taken from a fit to WMAP temperature and low- ℓ polarization data.

$$
\begin{aligned}
&\times \Big[-\hat{p}_k\hat{p}_l\left(\delta_{ij}-\hat{p}_i\hat{p}_j\right)e_{kl}(\hat{q},\lambda)\dot{\mathcal{D}}_q\left(t'\right)\\
&-\omega_c\left(t'\right)\Psi\left(q,t'\right)\left(e_{ij}(\hat{q},\lambda)-\hat{p}_i\hat{p}_k e_{kj}(\hat{q},\lambda)\right.\\
&\left.-\hat{p}_j\hat{p}_k e_{ik}(\hat{q},\lambda)+\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l e_{kl}(\hat{q},\lambda)\right)\Big]
\end{aligned}
$$

Again using the conditions $\hat{n}_i e_{+i}(\hat{n}) = 0$ and $e_{+i}(\hat{n})e_{+i}(\hat{n}) = 0$, we see that the only term in the integrand here that contributes to the Stokes parameters in Eq. (7.4.4) is the one proportional to $e_{ij}\Psi$. This term gives

$$
\begin{aligned}
Q^T(\hat{n}) + iU^T(\hat{n}) = &-\frac{1}{2}T_0 e_{+i}(\hat{n})e_{+j}(\hat{n})\sum_{\lambda=\pm 2}\int d^3q\beta(\mathbf{q},\lambda)\\
&\times e_{ij}(\hat{q},\lambda)\int_{t_1}^{t_0}dt\exp\left(i\mathbf{q}\cdot\hat{n}\int_t^{t_0}\frac{dt'}{a\left(t'\right)}\right)P(t)\Psi(q,t)
\end{aligned}
\tag{7.4.42}
$$

where $\beta(\mathbf{q},\lambda)$ is the stochastic parameter for a gravitational wave of wave number $\mathbf{q}$ and helicity λ; $P(t)$ is the last-scattering distribution (7.4.32); and $\Psi(q,t)$ is a source function, given by Eq. (6.6.21) in terms of the partial wave amplitudes of the temperature and polarization perturbation amplitudes:

$$
\begin{aligned}
\Psi(q,t) = &\frac{1}{10}\Delta^{(T)}_{T,0}(q,t)+\frac{1}{7}\Delta^{(T)}_{T,2}(q,t)+\frac{3}{70}\Delta^{(T)}_{T,4}(q,t)-\frac{3}{5}\Delta^{(T)}_{P,0}(q,t)\\
&+\frac{6}{7}\Delta^{(T)}_{P,2}(q,t)-\frac{3}{70}\Delta^{(T)}_{P,4}(q,t)
\end{aligned}
\tag{7.4.43}
$$

Also, $e_{ij}(\hat{q},\lambda)$ is the polarization tensor

$$
e_{ij}(\hat{q},\lambda) = S_{ik}(\hat{q})S_{jl}(\hat{q})e_{kl}(\hat{z},\lambda),
\tag{7.4.44}
$$

where $S_{ij}(\hat{q})$ is the standard three-dimensional rotation (7.4.12) that takes the three-axis into the direction of $\hat{q}$, and $e_{kl}(\hat{z},\lambda)$ is the polarization tensor (5.2.15) for waves traveling in the three-direction, with non-vanishing components

$$e_{11}(\hat{z},\pm 2) = -e_{22}(\hat{z},\pm 2) = \mp i e_{12}(\hat{z},\pm 2) = \mp i e_{21}(\hat{z},\pm 2) = \frac{1}{\sqrt{2}}. \tag{7.4.45}$$

We will first show how to find the tensor multipole coefficients $C^T_{EE,\ell}$, $C^T_{BB,\ell}$, and $C^T_{TE,\ell}$ for a given source function $\Psi(q,t)$, and then report the results of a numerical evaluation using $\Psi(q,t)$ calculated as described in Section 7.3.

We begin by deriving a formula for the coefficients $a^T_{P,\ell m}$ in the expansion of the Stokes parameters in spin-weighted spherical harmonics:

$$Q^T(\hat{n}) + iU^T(\hat{n}) = \sum_{\ell m} a^T_{P,\ell m} \mathcal{Y}^m_\ell(\hat{n}). \tag{7.4.46}$$

Using Eq. (7.4.40) and the orthonormality property (7.4.21) of the $\mathcal{Y}^m_\ell$, we have

$$\begin{aligned} a^T_{P,\ell m} &= \int d^2\hat{n} \mathcal{Y}^{m*}_\ell(\hat{n})(Q(\hat{n}) + iU(\hat{n}))^T \\ &= -\frac{T_0}{2} \sum_\lambda \int d^3q \beta(\mathbf{q},\lambda) \int_{t_1}^{t_0} dt P(t) \Psi(q,t) g_{\ell m}(qr(t),\hat{q},\lambda) \end{aligned} \tag{7.4.47}$$

where $r(t)$ is the unperturbed co-moving radial coordinate of a photon at time t that reaches us at time t_0 :

$$r(t) \equiv \int_t^{t_0} \frac{dt'}{a\,(t')} \tag{7.4.48}$$

and

$$g_{\ell m}(\rho,\hat{q},\lambda) \equiv \int d^2\hat{n} \mathcal{Y}^{m*}_\ell(\hat{n}) e^{i\rho\hat{q}\cdot\hat{n}} \sum_{ij} e_{+i}(\hat{n}) e_{+j}(\hat{n}) e_{ij}(\hat{q},\lambda) \tag{7.4.49}$$

It is convenient first to calculate the amplitude $g_{\ell m}(\rho,\hat{q},\lambda)$ for $\hat{q}$ along the direction $\hat{z}$ of the three-axis. Using the graviton polarization tensor (7.4.43) and the photon polarization vector (7.4.9), a straightforward calculation gives
$e_{+i}(\hat{n}) e_{+j}(\hat{n}) e_{ij}(\hat{z},\pm 2) = \frac{1}{\sqrt{2}} \left(e_{+1}(\hat{n}) \pm i e_{+2}(\hat{n})\right)^2 = \frac{1}{2\sqrt{2}} e^{\pm 2i\phi}(1 \mp \cos\theta)^2$,
where as usual ϕ and θ are the azimuthal and polar angles of the direction $\hat{n}$. Eq. (7.4.22) shows that $\mathcal{Y}^{m*}_\ell(\hat{n})$ is $e^{-im\phi}$ times a function of θ, so the ϕ integral in Eq. (7.4.47) vanishes unless $m = \lambda = \pm 2$, in which case it just gives a factor 2π. For $\mathcal{Y}^{\pm 2}_\ell$ we will use the top line of Eq. (7.4.22), which gives
$\mathcal{Y}^{\pm 2}_\ell(\theta,\phi) = \sqrt{\frac{(\ell-2)!}{(\ell+2)!}} \partial_\pm Y^{\pm 2}_\ell(\theta,\phi) = e^{\pm 2i\phi} \sqrt{\frac{2\ell+1}{4\pi}} \frac{(\ell-2)!}{(\ell+2)!} \partial_\pm P^2_\ell(\cos\theta)$,
where $\partial_\pm$are the differential operators

$$\begin{aligned} \partial_\pm &\equiv \left(\frac{d}{d\theta} \mp 2\csc\theta\right)^2 - \cot\theta \left(\frac{d}{d\theta} \mp 2\csc\theta\right) \\ &= \left(1-\mu^2\right) \frac{d}{d\mu^2} \pm 4\frac{d}{d\mu} + \frac{4(1\pm\mu)}{1-\mu^2} \end{aligned} \tag{7.4.52}$$

where $\mu \equiv \cos\theta$, and $P^2_\ell(\cos\theta)$ is the usual associated Legendre polynomial

$$P_\ell^2(\mu) = \left(1-\mu^2\right)\frac{d^2}{d\mu^2}P_\ell(\mu). \tag{7.4.53}$$

Putting this together, for $\mathbf{q}$ in the three-direction $\hat{z}$, Eq. (7.4.47) becomes

$$g_{\ell m}(\rho,\hat{z},\pm 2) = \delta_{m,\pm 2}\sqrt{\frac{\pi(2\ell+1)}{8}}\frac{(\ell-2)!}{(\ell+2)!}\int_{-1}^{+1} d\mu\left[\partial_\pm P_\ell^2(\mu)\right]e^{i\rho\mu}(1\mp\mu)^2 \tag{7.4.54}$$

We use (7.4.51) for the associated Legendre polynomial, use integration by parts to let the derivatives in $\partial_\pm$act on $(1\mp\mu)^2 e^{i\rho\mu}$, and apply the formula

$$\begin{aligned}&\frac{\partial^2}{\partial\mu^2}\left(\left(1-\mu^2\right)(1\mp\mu)^2 e^{i\rho\mu}\right) + \left(\mp 4\frac{\partial}{\partial\mu} + \frac{4(1\pm\mu)}{1-\mu^2}\right)(1\mp\mu)^2 e^{i\rho\mu}\\ &\quad = \left(1-\mu^2\right)\left(12\mp 8i\rho(1\mp\mu) - \rho^2(1\mp\mu)^2\right)e^{i\rho\mu}.\end{aligned}$$

Replacing μ with $-i\partial/\partial\rho$, we find

$$\begin{aligned}g_{\ell m}(\rho,\hat{z},\pm 2) =& \delta_{m,\pm 2}\sqrt{\frac{\pi(2\ell+1)}{8}}\frac{(\ell-2)!}{(\ell+2)!}\int_{-1}^{+1} d\mu P_\ell(\mu)\\ &\times\frac{\partial^2}{\partial\mu^2}\left[12\mp 8i\rho(1\mp\mu)-\rho^2(1\mp\mu)^2\right]\left(1-\mu^2\right)^2 e^{i\rho\mu}\\ =& -\delta_{m,\pm 2}\sqrt{\frac{\pi(2\ell+1)}{8}}\frac{(\ell-2)!}{(\ell+2)!}\int_{-1}^{+1} d\mu P_\ell(\mu)\\ &\times\left[12+8\rho\frac{\partial}{\partial\rho}-\rho^2+\rho^2\frac{\partial^2}{\partial\rho^2}\mp 8i\rho\mp 2i\rho^2\frac{\partial}{\partial\rho}\right]\\ &\times\left(1+\frac{\partial^2}{\partial\rho^2}\right)^2\rho^2 e^{i\rho\mu}\end{aligned}$$

The integral over μ is now simply

$$\int_{-1}^{+1} d\mu e^{i\rho\mu}P_\ell(\mu) = 2i^\ell j_\ell(\rho).$$

A straightforward though tedious calculation using the defining differential equation $j_\ell''(\rho)+(2/\rho)j_\ell'(\rho)+$ 0 gives

$$\left(1+\frac{\partial^2}{\partial\rho^2}\right)^2\rho^2 j_\ell(\rho) = \frac{(\ell+2)!}{(\ell-2)!}\frac{j_\ell(\rho)}{\rho^2},$$

so finally

$$\begin{aligned}g_{\ell m}(\rho,\hat{z},\pm 2) =& -2i^\ell\delta_{m,\pm 2}\sqrt{\frac{\pi(2\ell+1)}{8}}\\ &\times\left[12+8\rho\frac{\partial}{\partial\rho}-\rho^2+\rho^2\frac{\partial^2}{\partial\rho^2}\mp 8i\rho\mp 2i\frac{\partial}{\partial\rho}\right]\frac{j_\ell(\rho)}{\rho^2}\end{aligned} \tag{7.4.55}$$

.

Just as in Eq. (7.3.13) for temperature fluctuations, the amplitude for $\mathbf{q}$ in a general direction is given by applying the standard rotation $S(\hat{q})$ that takes the three-axis into the direction of $\mathbf{q}$:

$$g_{\ell m}(\rho,\hat{q},\pm 2)=\sum_{m'}D^{(\ell)}_{m,m'}(S(\hat{q}))g_{\ell m'}(\rho,\hat{z},\pm 2) \tag{7.4.56}$$

where $D^{(\ell)}$ is the spin- ℓ unitary representation of the rotation group. Using Eqs. (7.4.45), (7.4.54), and (7.4.53), we have then

$$\begin{aligned}a^T_{P,\ell m} =& T_0 i^\ell\sqrt{\frac{\pi(2\ell+1)}{8}}\sum_{\pm}\int d^3q\beta(\mathbf{q},\pm 2)D^{(\ell)}_{m,\pm 2}(S(\hat{q}))\\ &\times\int_{t_1}^{t_0}dtP(t)\Psi(q,t)\\ &\times\left\{\left[12+8\rho\frac{\partial}{\partial\rho}-\rho^2+\rho^2\frac{\partial^2}{\partial\rho^2}\mp 8i\rho\mp 2i\rho^2\frac{\partial}{\partial\rho}\right]\frac{j_\ell(\rho)}{\rho^2}\right\}_{\rho=qr(t)}\end{aligned} \tag{7.4.57}$$

In order to separate the E and B terms in $a^T_{P,\ell m}$, we need the reality properties of β and $D^{(\ell)}$. First, note that

$$e_{ij}(\hat{q},\pm 2)=\frac{1}{\sqrt{2}}\left(S_{i1}(\hat{q})\pm iS_{i2}(\hat{q})\right)\left(S_{j1}(\hat{q})\pm iS_{j2}(\hat{q})\right)$$

and

$$S_{i1}(\hat{q})\pm iS_{i2}(\hat{q})=(\cos\theta\cos\phi\mp i\sin\phi,\cos\theta\sin\phi\pm i\cos\phi,-\sin\theta),$$

so

$$e^*_{ij}(\hat{q},\pm 2)=e_{ij}(\hat{q},\mp 2)=e_{ij}(-\hat{q},\pm 2).$$

With the gravitational field dominated by a single mode, $\mathcal{D}^*_q(t)$ must be proportional to $\mathcal{D}_q(t)$, so that by absorbing any phase in $\beta(\mathbf{q},\pm 2)$ we can choose $\mathcal{D}_q(t)$ to be real. The reality of $D_{ij}(\mathbf{x},t)$ then requires that

$$\beta^*(\mathbf{q},\pm 2)=\beta(-\mathbf{q},\pm 2). \tag{7.4.58}$$

Also, by writing $D^{(\ell)}(S(\hat{q}))=\exp\left(-i\phi J^{(\ell)}_3\right)\exp\left(-i\theta J^{(\ell)}_2\right)$ where $J^{(\ell)}_i$ are the angular momentum matrices [19] for angular momentum ℓ, we can
show that

$$D^{(\ell)}_{m,\pm 2}(S(\hat{q}))^*=(-1)^\ell D^{(\ell)}_{-m,\pm 2}(S(-\hat{q})). \tag{7.4.59}$$

The sign $(-1)^\ell$ here cancels the same sign in $i^{-\ell}=(-1)^\ell i^\ell$. It follows that the whole effect of taking the complex conjugate of $a^T_{P,\ell m}$, and changing m to $-m$, is to replace the differential operator acting on $j_\ell(\rho)/\rho^2$ with its complex conjugate:

[4719] As noted in footnote 4, the phases in these angular momentum matrices depend on the phase convention chosen for the spherical harmonics. They are related by $\int d^2\hat{n}Y^{m'}_\ell(\hat{n})^*\mathbf{L}Y^m_\ell(\hat{n})=\mathbf{J}^\ell_{m'm}$, where $\mathbf{L}\equiv -i\mathbf{x}\times\nabla$ is the orbital angular momentum operator.

$$
\begin{aligned}
a^{T*}_{P,\ell-m} =& T_0 i^\ell \sqrt{\frac{\pi(2\ell+1)}{8}} \sum_{\pm} \int d^3q \beta(\mathbf{q},\pm 2) D^{(\ell)}_{m,\pm 2}(S(\hat{q})) \\
&\times \int_{t_1}^{t_0} dt P(t) \Psi(q,t) \\
&\times \left\{ \left[12 + 8\rho\frac{\partial}{\partial\rho} - \rho^2 + \rho^2 \frac{\partial^2}{\partial\rho^2} \pm 8i\rho \pm 2i\rho^2 \frac{\partial}{\partial\rho} \right] \frac{j_\ell(\rho)}{\rho^2} \right\}_{\rho=qr(t)}
\end{aligned}
\tag{7.4.60}
$$

The definitions (7.4.25) then give

$$
\begin{aligned}
a^T_{E,lm} =& -i^\ell T_0 \sqrt{\frac{\pi(2\ell+1)}{8}} \sum_{\pm} \int d^3q \beta(\mathbf{q},\pm 2) D^{(\ell)}_{m,\pm 2}(S(\hat{q})) \\
&\times \int_{t_1}^{t_0} dt P(t) \Psi(q,t) \\
&\times \left\{ \left[12 + 8\rho\frac{\partial}{\partial\rho} - \rho^2 + \rho^2 \frac{\partial^2}{\partial\rho^2} \right] \frac{j_\ell(\rho)}{\rho^2} \right\}_{\rho=qr(t)}
\end{aligned}
\tag{7.4.61}
$$

$$
\begin{aligned}
a^T_{B,lm} =& i^\ell T_0 \sqrt{\frac{\pi(2\ell+1)}{8}} \sum_{\pm} \pm \int d^3q \beta(\mathbf{q},\pm 2) D^{(\ell)}_{m,\pm 2}(S(\hat{q})) \\
&\times \int_{t_1}^{t_0} dt P(t) \Psi(q,t) \left\{ \left[8\rho + 2\rho^2 \frac{\partial}{\partial\rho} \right] \frac{j_\ell(\rho)}{\rho^2} \right\}_{\rho=qr(t)}
\end{aligned}
\tag{7.4.62}
$$

We can now calculate the multipole coefficients, using the stochastic averages

$$
\langle \beta(\mathbf{q},\lambda) \beta^* (\mathbf{q}',\lambda') \rangle = \delta^3 (\mathbf{q}-\mathbf{q}') \, \delta_{\lambda\lambda'},
\tag{7.4.63}
$$

and the unitarity relation (7.3.17):

$$
\int d^2\hat{q} D^{(\ell)}_{m,\pm 2}(S(\hat{q})) D^{(\ell')}_{m',\pm 2}(S(\hat{q}))^* = \frac{4\pi}{2\ell+1} \delta_{mm'} \delta_{\ell\ell'}
$$

The sum over helicities ± 2 just gives a factor 2 in the EE and BB correlations, while as expected in the EB correlation there is a complete
cancelation, due to the $\pm$ sign in Eq. (7.4.60). The tensor mode contributions to the polarization multipole coefficients are then [20]

$$
\begin{aligned}
C^T_{EE,\ell} =& \pi^2 T_0^2 \int_0^\infty q^2 dq \\
&\times \left| \int_{t_1}^{t_0} dt P(t) \Psi(q,t) \left\{ \left[12 + 8\rho\frac{\partial}{\partial\rho} - \rho^2 + \rho^2 \frac{\partial^2}{\partial\rho^2} \right] \frac{j_\ell(\rho)}{\rho^2} \right\}_{\rho=qr(t)} \right|^2
\end{aligned}
\tag{7.4.64}
$$

$$
\begin{aligned}
C^T_{BB,\ell} =& \pi^2 T_0^2 \int_0^\infty q^2 dq \\
&\times \left| \int_{t_1}^{t_0} dt P(t) \Psi(q,t) \left\{ \left[8\rho + 2\rho^2 \frac{\partial}{\partial\rho} \right] \frac{j_\ell(\rho)}{\rho^2} \right\}_{\rho=qr(t)} \right|^2
\end{aligned}
\tag{7.4.65}
$$

The results (7.4.59) and (7.4.60), together with Eq. (7.3.14), allow us also to calculate the multipole coefficients in the correlation between temperature and polarization. In C^T_{TB} the $\pm$

sign in front of the integral over wave numbers in Eq. (7.4.60) produces a cancelation between the two terms in the sum over helicities ± 2, so that as expected $C^T_{TB} = 0$. On the other hand, in C^T_{TE} the sum over helicities ± 2 just gives a factor 2, so that Eqs. (7.3.14), (7.4.61) and (7.4.59) give

$$\begin{aligned} C^T_{TE,\ell} = & -2\pi^2 T_0^2 \sqrt{\frac{(\ell+2)!}{(\ell-2)!}} \int_0^\infty q^2 dq \\ & \times \int_{t_1}^{t_0} dt P(t) \Psi(q,t) \left\{ \left[12 + 8\rho \frac{\partial}{\partial \rho} - \rho^2 + \rho^2 \frac{\partial^2}{\partial \rho^2} \right] \frac{j_\ell(\rho)}{\rho^2} \right\}_{\rho = qr(t)} \\ & \times \int_{t_1}^{t_0} dt' d(q,t') \frac{j_\ell(qr(t'))}{q^2 r^2(t')} \end{aligned} \tag{7.4.66}$$

where

$$d(q,t) \equiv \left[\dot{\mathcal{D}}_q(t) - \frac{1}{2}\omega_c(t) \right] \exp\left(-\int_t^{t_0} \omega_c(t')\, dt' \right) \tag{7.4.67}$$

The calculation of the gravitational wave amplitude $\mathcal{D}_q(t)$ and source function $\Psi(q,t)$ is described in the previous section. For the same cosmological parameters as assumed there, Eqs. (7.4.62) and (7.4.63) give the EE

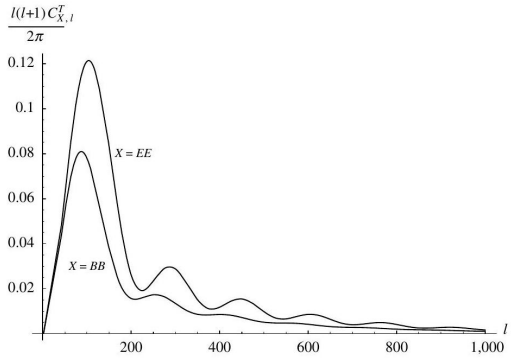

Figure 7.7: The multipole coefficients $\ell(\ell+1) C^T_{E E, \ell} / 2 \pi$ and $\ell(\ell+1)C^T_{BB,\ell}/2\pi$ in square microKelvin, vs. ℓ, for cosmological parameters given in Section 7.3, from ref. 21. The results agree to about 1% with those obtained (adopting the same cosmological parameters) by employing the computer programs CMBfast or CAMB, in which, instead of using the integral equation (7.3.22) as done here, the Boltzmann hierarchy is truncated at a maximum value of ℓ. (The results of these two computer programs also differ from each other by about the same amount.)

and BB multipole coefficients shown in Figure 7.7. (We will come to the TE coefficients below.)

The results (7.4.62)-(7.4.64) provide a basis for highly accurate computer calculations of the tensor multipole coefficients, but a casual inspection of these formulas does not provide much insight to the qualitative behavior of these coefficients as functions of ℓ. In particular, looking at Eqs. (7.4.62) and (7.4.63), we could hardly guess that $C^T_{BB,\ell} < C^T_{EE,\ell}$ for all $\ell > 15$, or that $C^T_{BB,\ell}$ and $C^T_{EE,\ell}$ approach each other for $\ell < 100$, as shown for one set of cosmological parameters in Figure 7.7.

[4720] These formulas, and also Eq. (7.4.64), are equivalent to those of Zaldarriaga and Seljak, ref. 1.

These results become much simpler and more transparent for large ℓ. Recall that for $\rho^2 - v^2 \gg v^{4/3}$ (where $v \equiv \ell + 1/2$), the spherical Bessel functions have the well-known asymptotic behavior [21]

$$j_\ell(\rho) \to \frac{\cos b}{v\sqrt{\sin b}} \cos[v(\tan b - b) - \pi/4] \tag{7.4.68}$$

where $\cos b \equiv v/\rho$, with $0 \leq b \leq \pi/2$. On the other hand, for $v^2 - \rho^2 \gg v^{4/3}$, $j_\ell(\rho)$ is exponentially small. In the range in which $|\rho^2 - v^2| < v^{4/3}$ neither approximation is valid, but $j_\ell(\rho)$ is a smooth function of ρ in this range, without the singularity at $\rho = v$ that might be suggested by the factor $1/\sqrt{\sin b}$ in Eq. (7.4.66). For $v \gg 1$ this range contributes only a small part of the range of integration, and we would expect to be able to use the approximation (7.4.66). For $\rho^2 - v^2 \gg v^{4/3} \gg 1$, the dominant contributions to derivatives of $j_\ell(\rho)/\rho^2$ come from terms in which the derivative acts only on the cosine in Eq. (7.4.66), so that

$$\left[12 + 8\rho\frac{\partial}{\partial\rho} - \rho^2 + \rho^2\frac{\partial^2}{\partial\rho^2}\right]\frac{j_\ell(\rho)}{\rho^2} \to -j_\ell(\rho) + j_\ell''(\rho)$$
$$\to -\frac{\left(1+\sin^2 b\right)\cos b}{v\sqrt{\sin b}} \cos[v(\tan b - b) - \pi/4] \tag{7.4.69}$$

$$\left[8\rho + 2\rho^2\frac{\partial}{\partial\rho}\right]\frac{j_\ell(\rho)}{\rho^2} \to 2j_\ell'(\rho) \to -\frac{2\sqrt{\sin b}\cos b}{v} \sin[v(\tan b - b) - \pi/4] \tag{7.4.70}$$

(Letting the derivatives act on $1/\sqrt{\sin b}$ would produce a non-integrable singularity at $b = 0$, but this is spurious, because the asymptotic formula (7.4.66) breaks down for ρ very near ν, where in fact there is no singularity.) Then Eqs. (7.4.62)-(7.4.64) become, for $v \equiv \ell + 1/2 \gg 1$, [22]

$$\begin{aligned} C^T_{EE,\ell} =& \frac{\pi^2 T_0^2}{v^2}\int_0^\infty q^2 dq \\ & \times \Big| \int_{r(t)>v/q} dt P(t)\Psi(q,t) \\ & \times \left\{ \frac{\left(1+\sin^2 b\right)\cos b}{\sqrt{\sin b}} \cos[v(\tan b - b) - \pi/4] \right\} \Big\}_{\cos b = v/qr(t)} \Big|^2 \\ C^T_{BB,\ell} =& \frac{\pi^2 T_0^2}{v^2}\int_0^\infty q^2 dq \Big| \int_{r(t)>v/q} dt P(t)\Psi(q,t) \\ & \times \left\{2\sqrt{\sin b}\cos b \sin[v(\tan b - b) - \pi/4]\right\}_{\cos b = v/qr(t)} \Big|^2 \end{aligned} \tag{7.4.71}$$

[4721] I. S. Gradshteyn & I. M. Ryzhik, Table of Integrals, Series, and Products, translated, corrected and enlarged by A. Jeffrey (Academic Press, New York, 1980): formula 8.453.1. The same approximation is used by J. R. Pritchard and M. Kamionkowski, Ann. Phys. 318, 2 (2005) [astro-ph/0412581], but their subsequent approximations are very different from those made here and in ref. 21.

$$
\begin{aligned}
C^T_{TE,\ell} = &- \frac{2\pi^2 T_0^2}{v^2} \int_0^\infty q^2 dq \\
&\times \int_{r(t)>v/q} dt P(t) \Psi(q,t) \\
&\times \left\{ \frac{\left(1+\sin^2 b\right)\cos b}{\sqrt{\sin b}} \cos[v(\tan b - b) - \pi/4] \right\}_{\cos b = v/qr(t)} \\
&\times \int_{r(t')>v/q} dt' d\left(q,t'\right) \\
&\times \left\{ \frac{\cos^3 b'}{\sqrt{\sin b'}} \cos\left[v\left(\tan b' - b'\right) - \pi/4\right] \right\}_{\cos b' = v/qr(t')}
\end{aligned}
\tag{7.4.72}
$$

This approximate result for $C^T_{TE,\ell}$ is compared with the exact result (7.4.64) in Figure 7.8.

For $C^T_{EE,\ell}$ and $C^T_{BB,\ell}$, we can usefully make a further approximation. The quantity $b \equiv \cos^{-1}(v/qr(t))$ does not vary appreciably within the relatively narrow range of times t in which the last-scattering probability $P(t)$ is appreciable, so we can set $r(t)$ equal to $r_L \equiv r\left(t_L\right)$ everywhere except in the phase $v(\tan b - b)$, which for $v \gg 1$ does vary over a wide range in this time interval. Furthermore, because this phase varies over a wide range, the

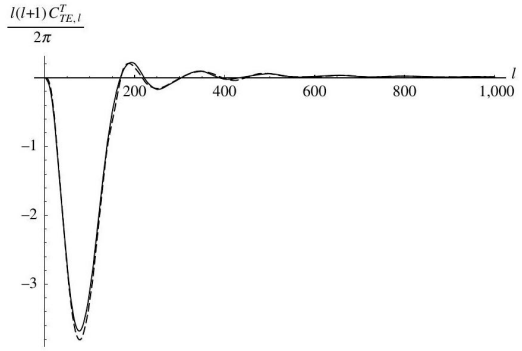

Figure 7.8: The multipole coefficient $\ell(\ell+1) C_{T E, \ell}^{T} / 2 \pi$ in square microKelvin, vs. ℓ, from ref. 21. The solid curve is taken from the exact formula (7.4.64); the dashed curve represents the approximation (7.4.71). In both cases, the method of calculating the gravitational wave amplitude and the source function, and the assumed cosmological parameters, are those described in Section 7.3.

difference between $\cos[\nu(\tan b - b) - \pi/4]$ and $\sin[\nu(\tan b - b) - \pi/4]$ is inconsequential, and we may as well replace both with $\cos[v(\tan b - b)]$. Then Eqs. (7.4.69) and (7.4.70) become [22]

$$
\begin{aligned}
\ell(\ell+1) C^T_{EE,\ell} \to \pi^2 T_0^2 &\int_{\nu/r_L}^\infty q^2 dq \left\{ \left(1+\sin^2 b_L\right)^2 \cos^2 b_L \right\}_{\cos b_L = v/qr_L} \\
&\times \left| \int_{r(t)>v/q} dt P(t) \Psi(q,t) \left\{ \frac{\cos[v(\tan b - b)]}{\sqrt{\sin b}} \right\}_{\cos b = v/qr(t)} \right|^2 ,
\end{aligned}
\tag{7.4.73}
$$

$$
\begin{aligned}
\ell(\ell+1) C^T_{BB,\ell} \to \pi^2 T_0^2 &\int_{\nu/r_L}^\infty q^2 dq \left\{ 4\sin^2 b_L \cos^2 b_L \right\}_{\cos b_L = v/qr_L} \\
&\times \left| \int_{r(t)>v/q} dt P(t) \Psi(q,t) \left\{ \frac{\cos[v(\tan b - b)]}{\sqrt{\sin b}} \right\}_{\cos b = v/qr(t)} \right|^2 .
\end{aligned}
\tag{7.4.74}
$$

(We have not set $b = b_L$ in the factors $1/\sqrt{\sin b}$ in both integrals over t, in order to avoid a divergence in the integration over q at $q = v/r_L$.) The results of using these approximate formulas are compared with the results of using the exact formulas (7.4.62) and (7.4.63) in Figures 7.9 and 7.10.

Our approximate result for $C^T_{BB,\ell}$ agrees with the exact result to about 1%, which is good enough for any practical purpose. The approximate result for $C^T_{EE,\ell}$ is not quite as good, agreeing with the exact result only to about 14%, but these approximations are evidently good enough to use them to draw qualitative conclusions. One immediate conclusion is that, since $\left(1 + \sin^2 b_L\right) \geq 4 \sin^2 b_L$ for all real b_L, we have $C^T_{EE,\ell} > C^T_{BB,\ell}$. Also, for ℓ small enough so that the wave number ℓ/r_L comes into the horizon before matter-radiation equality, say $\ell < 100$, for which $\Psi\left(\ell/r_L, t_L\right)$ is small, the integrals over q are dominated by values for which $\cos b$ is small, in which case $\left(1 + \sin^2 b\right)^2 \simeq 4 \sin^2 b$, and hence $C^T_{EE,\ell} \simeq C^T_{BB,\ell}$. As already noted, both properties are evident (for at least one set of cosmological parameters) in Figure 7.7.

The smallness of $C^T_{BB,\ell}$ makes it a difficult target for future observations, but the detection of the primordial BB mode would be of great importance to cosmology, as it would provide clear evidence of cosmological gravitational waves. The expectations for such tensor modes in theories of inflation are discussed in Chapter 10.

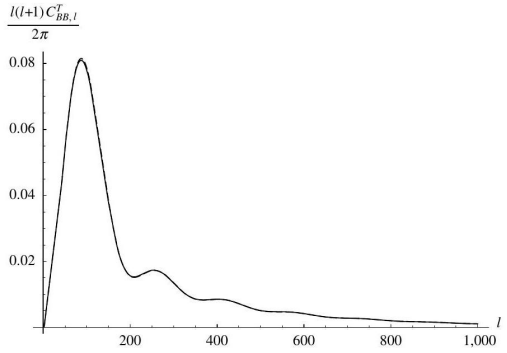

Figure 7.9: The multipole coefficient $\ell(\ell+1) C_{B B, \ell}^{T} / 2 \pi$ in square microKelvin, vs. ℓ, from ref. 22. The solid curve is taken from the exact formula (7.4.63); the dashed curve represents the approximation (7.4.70). In both cases, the method of calculating the gravitational wave amplitude and the source function, and the assumed cosmological parameters, are those described in Section 7.3.

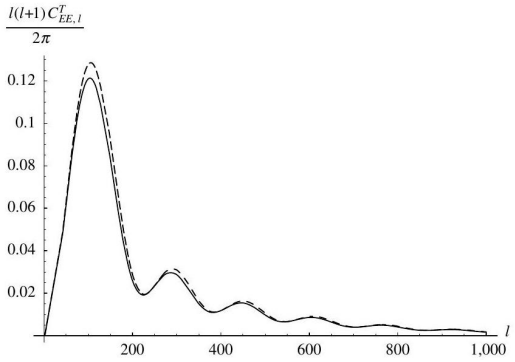

Figure 7.10: The multipole coefficient $\ell(\ell+1) C_{E E, \ell}^{T} / 2 \pi$ in square microKelvin, vs. ℓ, from ref. 22. The solid curve is taken from the exact formula (7.4.62); the dashed curve represents the approximation (7.4.69). In both cases, the method of calculating the gravitational wave amplitude and the source function, and the assumed cosmological parameters, are those described in Section 7.3.

The multipole coefficients $C_{EE,\ell}, C_{BB,\ell}$, and $C_{TE,\ell}$ may be measured by using data on correlations among the Stokes parameters and temperature fluctuations in comparison with general theoretical formulas for these
correlation functions, [23] analogous to the general formula (2.6.4) for the temperature correlation function. To derive these formulas, we start by noting from Eqs. (7.4.15) and (7.4.25) that

$$\begin{aligned} Q(\hat{n}) =& -\frac{1}{2}\sum_{\ell m} a_{E,\ell m}\left[\mathcal{Y}_{\ell}^{m}(\hat{n})+\mathcal{Y}_{\ell}^{-m}(\hat{n})^{*}\right] \\ & -\frac{i}{2}\sum_{\ell m} a_{B,\ell m}\left[\mathcal{Y}_{\ell}^{m}(\hat{n})-\mathcal{Y}_{\ell}^{-m}(\hat{n})^{*}\right] \end{aligned} \tag{7.4.75}$$

$$\begin{aligned} U(\hat{n}) =& \frac{i}{2}\sum_{\ell m} a_{E,\ell m}\left[\mathcal{Y}_{\ell}^{m}(\hat{n})-\mathcal{Y}_{\ell}^{-m}(\hat{n})^{*}\right] \\ & -\frac{1}{2}\sum_{\ell m} a_{B,\ell m}\left[\mathcal{Y}_{\ell}^{m}(\hat{n})+\mathcal{Y}_{\ell}^{-m}(\hat{n})^{*}\right] \end{aligned} \tag{7.4.76}$$

From Eqs. (7.4.28) and (7.4.29), we then find the correlation functions

$$\begin{aligned} \left\langle Q(\hat{n}) Q\left(\hat{n}'\right)\right\rangle =& \frac{1}{2}\operatorname{Re}\sum_{\ell} C_{EE,\ell}\left(F_{\ell}\left(\hat{n},\hat{n}'\right)+G_{\ell}\left(\hat{n},\hat{n}'\right)\right) \\ & +\frac{1}{2}\operatorname{Re}\sum_{\ell} C_{BB,\ell}\left(F_{\ell}\left(\hat{n},\hat{n}'\right)-G_{\ell}\left(\hat{n},\hat{n}'\right)\right), \end{aligned} \tag{7.4.77}$$

$$\begin{aligned} \left\langle U(\hat{n}) U\left(\hat{n}'\right)\right\rangle =& \frac{1}{2}\operatorname{Re}\sum_{\ell} C_{EE,\ell}\left(F_{\ell}\left(\hat{n},\hat{n}'\right)-G_{\ell}\left(\hat{n},\hat{n}'\right)\right) \\ & +\frac{1}{2}\operatorname{Re}\sum_{\ell} C_{BB,\ell}\left(F_{\ell}\left(\hat{n},\hat{n}'\right)+G_{\ell}\left(\hat{n},\hat{n}'\right)\right), \end{aligned} \tag{7.4.78}$$

$$\begin{aligned} \left\langle Q(\hat{n}) U\left(\hat{n}'\right)\right\rangle =& \frac{1}{2}\operatorname{Im}\sum_{\ell} C_{EE,\ell}\left(-F_{\ell}\left(\hat{n},\hat{n}'\right)+G_{\ell}\left(\hat{n},\hat{n}'\right)\right) \\ & +\frac{1}{2}\operatorname{Im}\sum_{\ell} C_{BB,\ell}\left(-F_{\ell}\left(\hat{n},\hat{n}'\right)-G_{\ell}\left(\hat{n},\hat{n}'\right)\right), \end{aligned} \tag{7.4.79}$$

where

$$F_\ell\left(\hat{n},\hat{n}'\right) \equiv \sum_m \mathcal{Y}_\ell^m(\hat{n})\mathcal{Y}_\ell^m\left(\hat{n}'\right)^* \tag{7.4.80}$$

$$G_\ell\left(\hat{n},\hat{n}'\right) \equiv \sum_m \mathcal{Y}_\ell^m(\hat{n})\mathcal{Y}_\ell^{-m}\left(\hat{n}'\right) \tag{7.4.81}$$

Also, using Eq. (2.6.2) (with $a_{\ell m}$ now written as $a_{T,\ell m}$) and Eqs. (7.4.27), (7.4.74) and (7.4.75), the correlation functions between temperature fluctuations and Stokes parameters are

$$\left\langle \Delta T(\hat{n})Q\left(\hat{n}'\right)\right\rangle = -\sum_\ell C_{TE,\ell}\,\mathrm{Re}\,H_\ell\left(\hat{n},\hat{n}'\right) \tag{7.4.82}$$

$$\left\langle \Delta T(\hat{n})U\left(\hat{n}'\right)\right\rangle = \sum_\ell C_{TE,\ell}\,\mathrm{Im}\,H_\ell\left(\hat{n},\hat{n}'\right) \tag{7.4.83}$$

where

$$H_\ell\left(\hat{n},\hat{n}'\right) \equiv \sum_m Y_\ell^m(\hat{n})\mathcal{Y}_\ell^m\left(\hat{n}'\right)^* \tag{7.4.84}$$

with Y_ℓ^m the ordinary spherical harmonic.
To calculate the functions $F_\ell\left(\hat{n},\hat{n}'\right)$ and $G_\ell\left(\hat{n},\hat{n}'\right)$, we note first (for instance, by inspection of the last line of Eq. (7.4.22)) that, for $\hat{n}$ in the three-direction $\hat{z}$ with $\theta = \phi = 0$,

$$\mathcal{Y}_\ell^m(\hat{z}) = \delta_{m,-2}\sqrt{\frac{2\ell+1}{4\pi}} \tag{7.4.85}$$

Then, using the definitions (7.4.16) and (7.4.11) and the transformation rule (7.4.18), we can express $\mathcal{Y}_\ell^m$ as an element of a unitary rotation matrix [24]

$$\mathcal{Y}_\ell^m(\hat{n}) = \sum_{m'} D^{(\ell)}_{m'm}\left(S^{-1}(\hat{n})\right)\mathcal{Y}_\ell^{m'}(\hat{z}) = \sqrt{\frac{2\ell+1}{4\pi}}D^{(\ell)}_{-2,m}\left(S^{-1}(\hat{n})\right) \tag{7.4.86}$$

where $S(\hat{n})$ is the rotation (7.4.12) that takes $\hat{z}$ into $\hat{n}$. Using Eq. (7.4.57), it follows then also that

$$\mathcal{Y}^{-m}(\hat{n}) = (-1)^\ell\mathcal{Y}^m(-\hat{n})^* \tag{7.4.87}$$

Hence, by using the group multiplication property $D^{(\ell)}(S)D^{(\ell)}\left(S'\right) = D^{(\ell)}\left(SS'\right)$ and the unitarity of $D^{(\ell)}(S)$, we obtain addition theorems [25] that give us the functions needed in our formulas (7.4.76)-(7.4.78) for the correlation functions

$$F_\ell\left(\hat{n},\hat{n}'\right) = \frac{2\ell+1}{4\pi}D^{(\ell)}_{-2,-2}\left(S^{-1}(\hat{n})S\left(\hat{n}'\right)\right), \tag{7.4.88}$$

$$G_\ell\left(\hat{n},\hat{n}'\right) = (-1)^\ell\frac{2\ell+1}{4\pi}D^{(\ell)}_{-2,-2}\left(S^{-1}(\hat{n})S\left(-\hat{n}'\right)\right). \tag{7.4.89}$$

[4723] General formulas for the correlation functions are presented by M. Zaldarriaga, Astrophys. J. 503, 1 (1998).

[4724] E. Newman and J. Penrose, ref. 3; J. N. Goldberg, A. J. MacFarlane, E. T. Newman, F. Rorlich, and E. C. G. Sudarshan, J. Math. Phys. 8, 2155 (1967); K. S. Thorne, Rev. Mod. Phys. 52, 299 (1980).

[25] General addition theorems for spin-weighted spherical harmonics are given by W. Hu and M. White, Phys. Rev. D 56, 596 (1997) [astro-ph/9702170].

To calculate the function $H_\ell(\hat{n},\hat{n}')$, we recall that the ordinary spherical harmonics can also be written as elements of a rotation matrix. From the formula $Y_\ell^m(\hat{z}) = \sqrt{(2\ell+1)/4\pi}\delta_{m0}$ for the case $\theta = \phi = 0$ and the transformation rule (7.4.18), we have

$$Y_\ell^m(\hat{n}) = \sqrt{\frac{2\ell+1}{4\pi}} D_{0,m}^{(\ell)}\left(S^{-1}(\hat{n})\right).$$

Hence, again using the group multiplication property of the $D^{(\ell)}$ matrices, we find

$$H_\ell(\hat{n},\hat{n}') = \frac{2\ell+1}{4\pi} D_{0,-2}^{(\ell)}\left(S^{-1}(\hat{n})S(\hat{n}')\right). \tag{7.4.90}$$

Note incidentally that

$$F_\ell(-\hat{n},-\hat{n}') = \sum_m \mathcal{Y}_\ell^{-m}(\hat{n})^*\mathcal{Y}_\ell^{-m}(\hat{n}') = F_\ell^*(\hat{n},\hat{n}'), \tag{7.4.91}$$

and

$$G_\ell(-\hat{n},-\hat{n}') = \sum_m \mathcal{Y}_\ell^{-m}(\hat{n})^*\mathcal{Y}_\ell^{m}(\hat{n}')^* = G_\ell^*(\hat{n},\hat{n}') \tag{7.4.92}$$

Also, using the property $Y_\ell^m(-\hat{n}) = (-1)^\ell Y_\ell^{-m}(\hat{n})^*$,

$$H_\ell(-\hat{n},-\hat{n}') = \sum_m Y_\ell^{-m}(\hat{n})^*\mathcal{Y}_\ell^{-m}(\hat{n}') = H_\ell^*(\hat{n},\hat{n}') \tag{7.4.93}$$

Hence the correlation functions have the reflection properties

$$\langle Q(\hat{n})Q(\hat{n}')\rangle = \langle Q(-\hat{n})Q(-\hat{n}')\rangle, \tag{7.4.94}$$
$$\langle U(\hat{n})U(\hat{n}')\rangle = \langle U(-\hat{n})U(-\hat{n}')\rangle, \tag{7.4.95}$$
$$\langle Q(\hat{n})U(\hat{n}')\rangle = -\langle Q(-\hat{n})U(-\hat{n}')\rangle, \tag{7.4.96}$$
$$\langle \Delta T(\hat{n})Q(\hat{n}')\rangle = \langle \Delta T(-\hat{n})Q(-\hat{n}')\rangle, \tag{7.4.97}$$
$$\langle \Delta T(\hat{n})U(\hat{n}')\rangle = -\langle \Delta T(-\hat{n})U(-\hat{n}')\rangle, \tag{7.4.98}$$

as expected from the space inversion properties of the Stokes parameters and temperature fluctuation and the assumed space-inversion invariance of the probability distribution over which we average.

It may be noted that, in measuring the correlation functions of the Stokes parameters observed in directions $\hat{n}$ and $\hat{n}'$, observers commonly choose the system of polar coordinates so that $\hat{n}$ and $\hat{n}'$ are on the same meridian; that is, so that $\phi = \phi'$. (This is usually expressed as the condition that the first of the two polarization vectors that are used to define the Stokes parameter should be aligned with the great circle between $\hat{n}$ and $\hat{n}$,[26] but we have defined these two polarization vectors always to lie in the directions of increasing θ and ϕ, so it amounts to the same thing.) This has the advantage that the functions $F_\ell(\hat{n},\hat{n}'), G_\ell(\hat{n},\hat{n}')$ and $H_\ell(\hat{n},\hat{n}')$ are then all real, and depend only on $\theta - \theta'$. To see this, note that by using the representation

$$D^{(\ell)}(S(\hat{n})) = \exp\left(-i\phi J_3^{(\ell)}\right)\exp\left(-i\theta J_2^{(\ell)}\right)$$

[4726] Kamionkowski, Kosowsky, and Stebbins, ref. 1.

of the standard rotation from $\hat{z}$ to $\hat{n}$ in terms of the angular momentum matrices $J_i^{(\ell)}$, we can rewrite Eqs. (7.4.87)-(7.4.89) as

$$\begin{aligned}
F_\ell(\hat{n},\hat{n}') &= \frac{2\ell+1}{4\pi}\left[\exp\left(i\theta J_2^{(\ell)}\right)\exp\left(i\phi J_3^{(\ell)}\right)\right. \\
&\quad \left.\times\exp\left(-i\phi' J_3^{(\ell)}\right)\exp\left(-i\theta' J_2^{(\ell)}\right)\right]_{-2,-2} \\
G_\ell(\hat{n},\hat{n}') &= (-1)^\ell\frac{2\ell+1}{4\pi}\left[\exp\left(i\theta J_2^{(\ell)}\right)\exp\left(i\phi J_3^{(\ell)}\right)\right. \\
&\qquad \left.\times\exp\left(-i\left[\phi'+\pi\right]J_3^{(\ell)}\right)\exp\left(-i\left[\pi-\theta'\right]J_2^{(\ell)}\right)\right]_{-2,-2} \\
H_\ell(\hat{n},\hat{n}') &= \frac{2\ell+1}{4\pi}\left[\exp\left(i\theta J_2^{(\ell)}\right)\exp\left(i\phi J_3^{(\ell)}\right)\right. \\
&\quad \left.\times\exp\left(-i\phi' J_3^{(\ell)}\right)\exp\left(-i\theta' J_2^{(\ell)}\right)\right]_{0,-2}
\end{aligned}$$

If $\phi=\phi'$, then

$$F_\ell(\hat{n},\hat{n}') = \frac{2\ell+1}{4\pi}\left[\exp\left(i\left(\theta-\theta'\right)J_2^{(\ell)}\right)\right]_{-2,-2},$$

so $F_\ell(\hat{n},\hat{n}')$ for $\phi=\phi'$ depends only on $\theta-\theta'$. Also, $iJ_2^{(\ell)}$ is a real matrix, so $F_\ell(\hat{n},\hat{n}')$ for $\phi=\phi'$ is also real. As to G_ℓ, for $\phi=\phi'$ we have

$$\begin{aligned}
G_\ell(\hat{n},\hat{n}') =& (-1)^\ell\frac{2\ell+1}{4\pi} \\
&\times\left[\exp\left(i\theta J_2^{(\ell)}\right)\exp\left(-i\pi J_3^{(\ell)}\right)\exp\left(-i\left[\pi-\theta'\right]J_2^{(\ell)}\right)\right]_{-2,-2} \\
=& (-1)^\ell\frac{2\ell+1}{4\pi} \\
&\times\left[\exp\left(i\theta J_2^{(\ell)}\right)\exp\left(+i\left[\pi-\theta'\right]J_2^{(\ell)}\right)\exp\left(-i\pi J_3^{(\ell)}\right)\right]_{-2,-2} \\
=& (-1)^\ell\frac{2\ell+1}{4\pi}\left[\exp\left(i\left(\theta-\theta'+\pi\right)J_2^{(\ell)}\right)\right]_{-2,-2}
\end{aligned}$$

so $G_\ell(\hat{n},\hat{n}')$ for $\phi=\phi'$ is real because $iJ_2^{(\ell)}$ is a real matrix, and depends only on $\theta-\theta'$. Finally, $H_\ell(\hat{n},\hat{n}')$ is real and depends only on $\theta-\theta'$, for the same reasons as for $F_\ell(\hat{n},\hat{n}')$. We conclude then that if the coordinate system is chosen so that $\phi=\phi'$, the correlation functions $\langle Q(\hat{n})Q(\hat{n}')\rangle$ and $\langle U(\hat{n})U(\hat{n}')\rangle$ and $\langle\Delta T(\hat{n})Q(\hat{n}')\rangle$ depend only on the angle $\theta-\theta'$ between $\hat{n}$ and $\hat{n}'$, while $\langle Q(\hat{n})U(\hat{n}')\rangle$ and $\langle\Delta T(\hat{n})U(\hat{n}')\rangle$ vanish. Also, $\langle Q(\hat{n})Q(\hat{n}')\rangle$ and $\langle U(\hat{n})U(\hat{n}')\rangle$ are obviously symmetric between $\hat{n}$ and $\hat{n}'$, so for $\phi=\phi'$ they actually depend only on $|\theta-\theta'|$; that is, on the angle between $\hat{n}$ and $\hat{n}'$.

10.8 The Growth of Structure

In Chapter 6 we followed the evolution of small perturbations through the radiation and matter dominated eras, up to the time of decoupling, when radiation no longer interacted effectively with matter. Now we will continue the story past the time of decoupling. In Section 8.1 we will follow the perturbations while they remained small, continuing our linear analysis. This era is increasingly becoming accessible to observation, as studies of the cosmic matter distribution are pushed to larger redshifts. As we shall see, data on the distribution of matter fluctuations already provides an important extension of results from cosmic microwave background anisotropies to smaller wavelengths, and it is hoped that eventually it may provide information of the effect of dark energy on cosmic expansion.

Of course, eventually the perturbations in the matter density became strong enough for the linear approximation to break down, as shown vividly by the existence of stars and galaxies and galaxy clusters. It is believed that these structures were formed in a two-step process. [1] First, in regions where the density was a little larger than average, the cold dark matter and baryonic matter together expanded more slowly than the universe as a whole, eventually reaching a minimum density and then recontracting. This scenario is discussed in Section 8.2. If an overdense region was sufficiently large then as shown in Section 8.3 its baryonic matter collapsed along with its cold dark matter. Then in a second stage, after this collapse, the baryonic matter lost its energy through radiative cooling, and it condensed into protogalaxies consisting of clouds of gas that eventually form stars. The cold dark matter particles could not lose their energy through radiative cooling, so they remained in large more-or-less spherical halos around these galaxies. We will not attempt a proper treatment of this second stage, which involves complications of astrophysics and mathematics that deserve a treatise to themselves.

10.8.1 8.1 Linear perturbations after recombination

After the disappearance of almost all free electrons the baryonic plasma decoupled from photons, and behaved like just another form of cold dark matter. (Effects of pressure at small wavelengths are discussed in

Section 8.3.) With the gravitational field perturbations dominated by fluctuations in the total density of cold matter, the Newtonian treatment of Appendix F is applicable, and tells us that the fractional density perturbation eventually grew as $a \propto t^{2/3}$. However, we need a relativistic analysis to connect the constant wave-number dependent factor in this growth with the strength of primordial fluctuations, characterized by the quantity $\mathcal{R}_q^0$, to describe certain small but interesting oscillations in the density fluctuations arising from the interaction of baryons and radiation before decoupling, and to carry this analysis forward to near the present, when vacuum energy became important.

In our relativistic analysis baryons and cold dark matter are treated somewhat differently, because we continue to use a synchronous gauge in which the cold dark matter velocity potential but not the baryon velocity potential vanishes. After decoupling the baryon velocity potential was no longer locked to the photon velocity potential by Thomson scattering, so to obtain the equation for baryon conservation, we may use Eq. (5.3.34) with $\bar{p}_B, \delta p_{Bq}$, and π^S_{Bq} all vanishing (because baryons move slowly), and find

$$\dot{\delta\rho}_{Bq} + 3H\delta\rho_{Bq} - \frac{q^2}{a^2}\bar{\rho}_B\delta u_{Bq} = -\bar{\rho}_B\psi_q$$

or, dividing by $\bar{\rho}_B \propto a^{-3}$,

$$\dot{\delta}_{Bq} - \left(q^2/a^2\right)\delta u_{Bq} = -\psi_q \tag{8.1.1}$$

where as before, $\delta_{Bq} \equiv \delta\rho_{Bq}/\bar{\rho}_B$. For cold dark matter there is no velocity potential, so we again have Eq. (6.2.11) for cold dark matter conservation:

$$\dot{\delta}_{Dq} = -\psi_q \tag{8.1.2}$$

It is only our choice of gauge that makes the velocity potential of the dark matter rather than the baryons vanish, so it is best to think of δu_{Bq} as the relative velocity potential of the baryons and dark matter.

The equation for baryon momentum conservation is given by Eq. (5.3.32) with zero pressure and anisotropic inertia,

[471] S. D. M. White and M. J. Rees, Mon. Not. Roy. Astron. Soc. 183, 341 (1978).

$$\partial_0 \left(\bar{\rho}_B \delta u_{Bq}\right) + 3H\bar{\rho}_B \delta u_{Bq} = 0$$

so, dividing by $\bar{\rho}_B \propto a^{-3}$, we have simply:

$$\delta \dot{u}_{Bq} = 0 \tag{8.1.3}$$

(As we will see in Section 8.3, our neglect of the baryon pressure after recombination is justified except for the smallest wavelengths.) Finally, if we neglect the contribution of photon and neutrino density fluctuations to the gravitational field perturbation, then the gravitational field equation (5.3.36) becomes

$$\frac{d}{dt}\left(a^2\psi_q\right) = -4\pi G a^2 \bar{\rho}_M \left((1-\beta)\delta_{Dq} + \beta\delta_{Bq}\right) \tag{8.1.4}$$

where β is again the constant

$$\beta \equiv \frac{\bar{\rho}_B}{\bar{\rho}_M} = \frac{\Omega_B}{\Omega_M} \approx 1/6 \tag{8.1.5}$$

We are keeping terms of order β for the present, because as we shall see they lead to effects that although small are quite distinctive.

To derive the initial conditions for these equations, we note that at times sufficiently early (say, $z > 1$), at which vacuum energy as well as curvature made a negligible contribution to the expansion rate, we have $a \propto t^{2/3}$, and $4\pi G\bar{\rho}_M = 2/3t^2$, so Eq. (8.1.4) gives

$$\frac{d}{dt}\left(t^{4/3}\psi_q\right) = -\frac{2}{3}t^{-2/3}\left((1-\beta)\delta_{Dq} + \beta\delta_{Bq}\right) \tag{8.1.6}$$

The reader can easily check that the general solution of Eqs. (8.1.1)-(8.1.3) and (8.1.6) is

$$\psi_q = a_q t^{-1/3} + b_q t^{-2} + \beta\delta u_{Bq} q^2/a^2 \tag{8.1.7}$$

$$\delta_{Bq} = -\frac{3}{2}a_q t^{2/3} + b_q t^{-1} + (1-\beta)c_q - 3(1-\beta)t\left(q^2/a^2\right)\delta u_{Bq} \tag{8.1.8}$$

$$\delta_{Dq} = -\frac{3}{2}a_q t^{2/3} + b_q t^{-1} - \beta c_q + 3\beta t\left(q^2/a^2\right)\delta u_{Bq} \tag{8.1.9}$$

where a_q, b_q, c_q, and δu_{Bq} are constants that must be found by matching these solutions to the values of $\psi_q, \delta_{Bq}, \delta_{Dq}$, and δu_{Bq} at the time of decoupling of matter and radiation. For late times, we need only keep the leading terms in this solution, with coefficient a_q; the other terms are suppressed relative to these by factors $t^{-5/3}, t^{-2/3}$, and t^{-1}. To calculate the coefficient a_q, we note that $\beta\delta_{Bq} + (1-\beta)\delta_{Dq} - t\psi_q + \beta t\left(q^2/a^2\right)\delta u_{Bq} = -5a_q t^{2/3}/2$. Setting t here equal to the time t_L of decoupling [2] (when to a good approximation

$\delta_{Bq} = \delta_{\gamma q}$ and $\delta u_{Bq} = \delta u_{\gamma q}$) then gives for $t \gg t_L$

[472] The subscript L stands for "last scattering," and indicates the time of the decoupling of radiation from matter, associated with the recombination of hydrogen. (To use a subscript R or D for this time might produce confusion with the subscripts R and D that we continue to use to denote radiation and dark matter.) Of course, this is not the moment of last scattering; some photons of the microwave background were scattered again when hydrogen became reionized at much later times. Strictly speaking, we should take t_L here as the time during recombination when a typical electron stops exchanging appreciable momentum with the photons, rather than the slightly earlier time when a typical photon stops exchanging appreciable momentum with the electrons. Because R_L is not very different from unity, there is little difference between these times.

$$\begin{aligned}\delta_{Dq}(t) \rightarrow & \delta_{Bq}(t) \rightarrow -\frac{3}{2} a_q t^{2/3} \\ & \rightarrow \frac{3}{5}\left(\frac{t}{t_L}\right)^{2/3}\left[\beta\delta_{\gamma q}(t_L) + (1-\beta)\delta_{Dq}(t_L) - t_L\psi_q(t_L)\right. \\ & \left. + \beta t_L\left(q^2/a_L^2\right)\delta u_{\gamma q}(t_L)\right]. \end{aligned} \tag{8.1.10}$$

Note that, even though the fractional density perturbations of the baryons and dark matter were quite different at decoupling, they approached each other at late times thereafter, an assumption we made in analyzing the observations of X-rays from clusters of galaxies in Section 1.9. It follows that the fractional fluctuation δ_{Mq} in the total mass density approaches

$$\delta_{Mq} \equiv \frac{\bar{\rho}_D\delta_{Dq} + \bar{\rho}_B\delta_{Bq}}{\bar{\rho}_D + \bar{\rho}_B} \rightarrow \delta_{Dq} \rightarrow \delta_{Bq} \tag{8.1.11}$$

Since these fractional density perturbations all eventually became equal, we will concentrate from now on $\delta_{Mq}(t)$. We now want to carry our calculation forward to the present, when dark energy may no longer be neglected. According to Eqs. (8.1.1)-(8.1.4), under the approximation of neglecting fluctuations in the photon and neutrino energy densities, $\delta_{Mq}(t)$ satisfies the second-order differential equation

$$\frac{d}{dt}\left[a^2\frac{d}{dt}\delta_{Mq}\right] = 4\pi G a^2\bar{\rho}_M\delta_{Mq} \tag{8.1.12}$$

The most important consequence of this equation, together with Eq. (8.1.10), is that whatever we assume about dark energy, well after recombination when the terms in $\delta_{Mq}(t)$ that decay as $1/t$ have died away, the dependence of $\delta_{Mq}(t)$ on q and t factorizes:

$$\delta_{Mq}(t) = \Delta(q)F(t) \tag{8.1.13}$$

where

$$\begin{aligned}\Delta(q) = & \beta\delta_{\gamma q}(t_L) + (1-\beta)\delta_{Dq}(t_L) \\ & - t_L\psi_q(t_L) + \beta t_L\left(q^2/a_L^2\right)\delta u_{\gamma q}(t_L), \end{aligned} \tag{8.1.14}$$

and $F(t)$ satisfies the differential equation

$$\frac{d}{dt}\left[a^2\frac{d}{dt}F\right] = 4\pi G a^2\bar{\rho}_M F \tag{8.1.15}$$

with the initial condition, that well after recombination, until dark energy becomes important,

$$F(t) \rightarrow \frac{3}{5}\left(\frac{t}{t_L}\right)^{2/3} \tag{8.1.16}$$

For instance, if we assume that the vacuum energy is constant, then the Friedmann equation for $a(t)$ reads

$$\frac{\dot{a}}{a} = \sqrt{\frac{8\pi G}{3}\left(\rho_\Lambda + \bar{\rho}_M\right)} = H_0\sqrt{\Omega_\Lambda}\sqrt{1+1/x}, \tag{8.1.17}$$

where

$$x \equiv \frac{\rho_\Lambda}{\bar{\rho}_M} = \frac{\Omega_\Lambda}{\Omega_M}\left(\frac{a}{a_0}\right)^3 \tag{8.1.18}$$

Using x instead of t as the independent variable allows us to put Eq. (8.1.15) in a parameter-free form

$$\sqrt{x(1+x)}\frac{d}{dx}\left(x^{7/6}\sqrt{1+x}\frac{dF}{dx}\right) = \frac{1}{6x^{1/3}}F. \tag{8.1.19}$$

The growing solution [3] that becomes proportional to $t^{2/3}$ for $x \ll 1$ is

$$F \propto \sqrt{\frac{1+x}{x}}\int_0^x \frac{du}{u^{1/6}(1+u)^{3/2}}$$

Eq. (8.1.16) requires that for $x \ll 1$

$$F \to \frac{3}{5}\left(\frac{a}{a_L}\right) = \frac{3}{5}(1+z_L)\left(\frac{x\Omega_M}{\Omega_\Lambda}\right)^{1/3}$$

so we can write

$$F(t) = \frac{3}{5}\left(\frac{a(t)}{a_L}\right) C\left(\frac{\Omega_\Lambda}{\Omega_M}\left(\frac{a(t)}{a_0}\right)^3\right) \tag{8.1.20}$$

where $C(x)$ is a correction factor, normalized so that $C(0) = 1$:

$$C(x) \equiv \frac{5}{6}x^{-5/6}\sqrt{1+x}\int_0^x \frac{du}{u^{1/6}(1+u)^{3/2}} \tag{8.1.21}$$

Numerical values of $C(x)$ are given in Table 8.1.

Table 8.1: Values of the function $C(x)$, giving the suppression of the growth of matter fluctuations by dark energy as a function of $x \equiv (\Omega_\Lambda / \Omega_M)(a / a_0)^3$.

We see that at all scales and times, dark energy suppresses the growth of density fluctuations.

It is $\Delta(q)$ that contains information about conditions at decoupling. In place of $\Delta(q)$, it is conventional to introduce a power spectral function $P(k)$, defined as a function of the present value $k \equiv q/a_0$ of the physical wave number, by [4]

$$P(k) \equiv (2\pi)^3 a_0^3 F^2(t_0)\left|\Delta(a_0 k)\right|^2. \tag{8.1.22}$$

Most surveys of large scale structure report their results in terms of $P(k)$.

Now we must consider how these surveys are used to measure $\Delta(q)$ or $P(k)$. We recall that for a

[473] H. Martel, Astrophys. J. 377, 7 (1991).

single dominant scalar mode (and assuming spatial flatness), the fractional density perturbation in coordinate space takes the form of a Fourier transform like Eq. (5.2.1):

$$\delta_M(\mathbf{x},t) = \int d^3q\alpha(\mathbf{q})\delta_{Mq}(t)e^{i\mathbf{q}\cdot\mathbf{x}} = F(t)\int d^3q\alpha(\mathbf{q})\Delta(q)e^{i\mathbf{q}\cdot\mathbf{x}} \tag{8.1.23}$$

where $\alpha(\mathbf{q})$ is a stochastic variable, normalized so that

$$\langle\alpha(\mathbf{q})\alpha^*(\mathbf{q}')\rangle = \delta^3(\mathbf{q}-\mathbf{q}')\,. \tag{8.1.24}$$

The quantity $\Delta(q)$ can be found either from measurements of the correlation of matter density perturbations at different points, or more directly, from an angular average of the square of a Fourier integral of the matter density perturbation over the survey volume.

According to the ergodic theorem discussed in Appendix D, as long as the survey volume V is large compared with the volume over which density fluctuations are correlated, the ensemble averages of products of density fluctuations can be found from an average of these products over the survey volume, In particular, the two-point correlation function can be found from

$$\langle\delta_M(\mathbf{x},t)\delta_M(\mathbf{y},t)\rangle = \frac{1}{V}\int_V d^3z\delta_M(\mathbf{x}+\mathbf{z},t)\delta_M(\mathbf{y}+\mathbf{z},t) \tag{8.1.25}$$

Of course, we measure density fluctuations as functions of redshifts and angular positions rather than of three-dimensional positions and times, so the correlation function actually measured is the correlation of the fractional matter density perturbation observed at a redshift z and direction $\hat{n}$ with the perturbation observed at a redshift z' and direction $\hat{n}'$:

$$\xi(z,\hat{n};z',\hat{n}') \equiv \langle\delta_M(r(z)\hat{n},t(z))\delta_M(r(z')\hat{n}',t(z'))\rangle \tag{8.1.26}$$

where $r(z)$ and $t(z)$ are the Robertson-Walker co-moving radial coordinate and emission time associated with a redshift z. Using Eqs. (8.1.23), (8.1.24), and (8.1.13), this is

$$\begin{aligned}\xi(z,\hat{n};z',\hat{n}') &= \int d^3q\delta_{Mq}(t(z))\delta^*_{Mq}(t(z'))\exp(i\mathbf{q}\cdot(r(z)\hat{n}-r(z')\hat{n}'))\\ &= F(t(z))F(t(z'))\int d^3q|\Delta(q)|^2\exp(i\mathbf{q}\cdot(r(z)\hat{n}-r(z')\hat{n}'))\end{aligned} \tag{8.1.27}$$

In terms of $P(k)$, this reads

$$\begin{aligned}\xi(z,\hat{n};z',\hat{n}') =& \frac{1}{2\pi^2}\frac{F(t(z))F(t(z'))}{F^2(t_0)}\int_0^\infty kP(k)dk\\ &\times\frac{\sin(k|d_S(z)\hat{n}-d_S(z')\hat{n}'|)}{|d_S(z)\hat{n}-d_S(z')\hat{n}'|}\end{aligned} \tag{8.1.28}$$

where $d_S(z)$ is a convenient structure distance, related to $r(z)$ and to the angular diameter and luminosity distances at a redshift z by:

$$d_S(z) \equiv a_0 r(z) = (1+z)d_A(z) = (1+z)^{-1}d_L(z)$$

[474] The factor $(2\pi)^3$ is inserted here because the position-space perturbations are usually written as Fourier transforms with an extra factor of $(2\pi)^{-3/2}$, and the factor a_0^3 is included because these threedimensional Fourier transforms are usually written as integrals over the present value of the physical wave number, $k \equiv q/a_0$, rather than the co-moving wave number q. If the reader wishes, the co-moving coordinates could be normalized so that $a_0 = 1$, in which case all q s in this section could be replaced with k s.

Eq. (8.1.28) can be used to measure the power spectral function if we know $d_S(z)$, or to measure $d_S(z)$ if we know something about features in the power spectral function. In particular, for observations at relatively low redshift,
we can use $d_S(z) \simeq z/H_0$ and $t(z) \simeq t_0$, in which case Eqs. (8.1.28) gives the correlation function as

$$\xi\left(z,\hat{n};z',\hat{n}'\right) = \frac{H_0}{2\pi^2}\int_0^\infty kP(k)dk\frac{\sin\left(\left(k/H_0\right)\left|z\hat{n}-z'\hat{n}'\right|\right)}{\left|z\hat{n}-z'\hat{n}'\right|} \tag{8.1.29}$$

Measurements of the shape of this correlation function can evidently tell us about the dependence of the power spectral function on k/H_0, rather than k itself.

It is more common in large surveys to measure $P(k)$ from the angular average of the square of a Fourier integral of the matter density perturbation over the survey volume. Define a Fourier transform as an integral over the co-moving survey volume V :

$$\delta^V_{M\mathbf{Q}}(t) \equiv \frac{1}{\sqrt{V}(2\pi)^{3/2}}\int_V d^3x e^{-i\mathbf{Q}\cdot\mathbf{x}}\delta_M(\mathbf{x},t) \tag{8.1.30}$$

(The reason for this normalization will soon be made clear.) Using Eq. (8.1.23), this is

$$\delta^V_{M\mathbf{Q}}(t) = \int d^3q\alpha(\mathbf{q})F_V(\mathbf{q}-\mathbf{Q})\delta_{Mq}(t), \tag{8.1.31}$$

where

$$F_V(\mathbf{q}) \equiv \frac{1}{\sqrt{V}(2\pi)^{3/2}}\int_V d^3x e^{i\mathbf{q}\cdot\mathbf{x}} \tag{8.1.32}$$

It is plausible, and will be shown formally at the end of this section, that as long as the co-moving survey volume V contains many co-moving wavelengths $2\pi/q$, the angular average of $\left|\delta^V_{M\mathbf{Q}}\right|^2$ is the same as its ensemble average

$$\frac{1}{4\pi}\int d^2\hat{Q}\left|\delta^V_{M\mathbf{Q}}(t)\right|^2 = \left\langle\frac{1}{4\pi}\int d^2\hat{Q}\left|\delta^V_{M\mathbf{Q}}(t)\right|^2\right\rangle \tag{8.1.33}$$

Using Eqs. (8.1.31) and (8.1.24), this is

$$\frac{1}{4\pi}\int d^2\hat{Q}\left|\delta^V_{M\mathbf{Q}}(t)\right|^2 = \frac{1}{4\pi}\int d^2\hat{Q}\int d^3q\left|F_V(\mathbf{q}-\mathbf{Q})\right|^2\left|\delta_{Mq}(t)\right|^2 \tag{8.1.34}$$

Now, for large $V, F_V(\mathbf{q}-\mathbf{Q})$ approaches $\left((2\pi)^{3/2}/\sqrt{V}\right)\delta^3(\mathbf{q}-\mathbf{Q})$, so

$$\left|F_V(\mathbf{q}-\mathbf{Q})\right|^2 \to \frac{(2\pi)^{3/2}}{\sqrt{V}}\delta^3(\mathbf{q}-\mathbf{Q})F_V(0) = \delta^3(\mathbf{q}-\mathbf{Q}) \tag{8.1.35}$$

and therefore

$$\frac{1}{4\pi}\int d^2\hat{Q}\left|\delta^V_{M\mathbf{Q}}(t)\right|^2 = \left|\delta_{MQ}(t)\right|^2 \tag{8.1.36}$$

where $Q \equiv |\mathbf{Q}|$.
Again, we measure density fluctuations as functions of direction and redshift rather than position and time. Using Eq. (8.1.30) in Eq. (8.1.36) and expressing the result in terms of the power spectral function (8.1.22), we have

$$P(k) = \frac{1}{4\pi\mathcal{V}} \int d^2\hat{Q} \left| \int_{\mathcal{V}} d^2\hat{n} dz d_S^2(z) \right.$$
$$\left. \times\, d_S'(z) \frac{F\,(t_0)}{F(t(z))} \delta_M(r(z)\hat{n}, t(z)) e^{-i\hat{n}\cdot\hat{Q}kd_S(z)} \right|^2 \tag{8.1.37}$$

where $\mathcal{V} \equiv a_0^3 V$ is the physical survey volume. As in the case of Eq. (8.1.28) for the correlation function, we can use this formula either to calculate $P(k)$ from data for surveys with relatively low redshifts, or to find $d_S(z)$ from larger redshift surveys combined with information about $P(k)$ from other sources.

Let's now consider the calculation of $\Delta(q)$ and the power spectral function. We begin by neglecting all terms of order β in Eq. (8.1.14), so that

$$\Delta(q) = \delta_{Dq}\,(t_L) - t_L \psi_q\,(t_L) \tag{8.1.38}$$

We will return at the end of this section to the very interesting effects associated with the small baryon density. Using Eqs. (6.5.5) and (6.5.6), this is

$$\Delta(q) = \frac{3q^2 t_L^2 \mathcal{R}_q^o \mathcal{T}(\kappa)}{2a_L^2} = \frac{2q^2 \mathcal{R}_q^o \mathcal{T}(\kappa)}{3H_L^2 a_L^2} \tag{8.1.39}$$

where $\mathcal{T}$ is the dimensionless transfer function given in Table 6.1, and $\kappa/\sqrt{2}$ is the ratio of the wave number q to the wave number $q_{\rm EQ}$ that comes into the horizon just at matter-radiation equality. (The second expression is derived using $t_L = 2/3H_L$, where $H_L = \sqrt{\Omega_M} H_0\,(1+z_L)^{3/2}$ is the Hubble rate at decoupling if radiation is neglected. This is more accurate than using the actual age of the universe at decoupling, because Eqs. (8.1.38) and (8.1.39) were derived using a definition of the zero of time for which $a \propto t^{2/3}$ during the matter-dominated era.) Using Eq. (8.1.20), the power spectral function (8.1.22) is then

$$P(k) = \frac{4(2\pi)^3 a_0^3 C^2\,(\Omega_\Lambda/\Omega_M)}{25\Omega_M^2 H_0^4} \mathcal{R}_{ka_0}^o k^4 \mathcal{T}^2\left(\sqrt{2}k/k_{\rm EQ}\right), \tag{8.1.40}$$

where, according to Eq. (6.4.58),

$$k_{\rm EQ} \equiv q_{\rm EQ}/a_0 = \sqrt{2} H_0 \Omega_M / \sqrt{\Omega_R} = [13.6{\rm Mpc}]^{-1} \Omega_M h^2. \tag{8.1.41}$$

In particular, if we suppose that $\mathcal{R}_q \simeq N q^{-3/2}\,(q/q_*)^{(n_S-1)/2}$ with some spectral index n_S and constant N (which for $n_S \neq 1$ depends on the arbitrary choice of the reference wave number q_*), we would have

$$P(k) = \frac{4(2\pi)^3 N^2 C^2\,(\Omega_\Lambda/\Omega_M)}{25\Omega_M^2 H_0^4 k_*^{n_S-1}} k^{n_S} \mathcal{T}^2\left(\sqrt{2}k/k_{\rm EQ}\right), \tag{8.1.42}$$

where $k_* \equiv q_*/a_0$. The shape of this function for $n_S = 1$ is shown in Figure 8.1.

Knowledge of the power spectral function allows us to calculate the mean square value σ^2 of the fractional density fluctuation:

$$\sigma^2(z) = \xi(z,\hat{n};z,\hat{n}) = \frac{1}{2\pi^2}\left(\frac{F(t(z))}{F\,(t_0)}\right)^2 \int_0^\infty P(k) k^2 dk \tag{8.1.43}$$

With $P(k)$ given by Eq. (8.1.42), for any plausible n_S this integral is convergent at $k = 0$, where $\mathcal{T}(\kappa) \to 1$, but for $n_S \geq 1$ it diverges at $k \to \infty$ like $\int k^{n_S-2} \ln^2 k dk$. (Recall that, as we saw in Section 6.5, $\mathcal{T}(\kappa) \propto \ln k/k^2$ for $k \to \infty$. On the other hand, the sine factor in the integrand in Eq. (8.1.27) makes $\xi\,(z,\hat{n};z',\hat{n}')$ finite for $z' \neq z$ or $\hat{n}' \neq \hat{n}$.)

In order to avoid the ultraviolet divergence in σ^2, it is common instead to express the intensity of the primordial fluctuations in terms of the mean square value σ_R^2 of the average of the fractional density perturbation over a

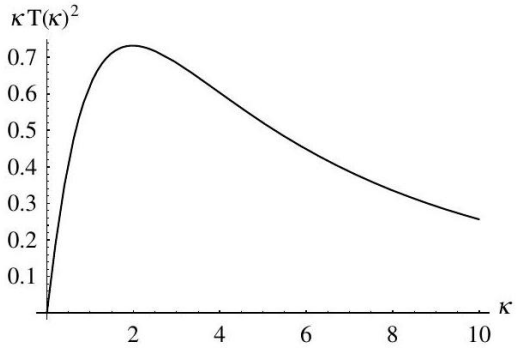

Figure 8.1: Shape of the power spectral function. This plot gives $\kappa \mathcal{T}^{2}(\kappa)$ as a function of κ, where $\mathcal{T}(\kappa)$ is the transfer function discussed in Section 6.5, $\kappa = \sqrt{2}k/k_{\rm EQ}$, and $k_{\rm EQ} = \left[13.6{\rm Mpc}^{-1}\Omega_M h^2\right.$ is the wave number that just comes into the horizon at radiationmatter equality. Eq. (8.1.42) shows that for $n_S = 1$, the power spectral function $P(k)$ is proportional to $\kappa\mathcal{T}^2(\kappa)$.

sphere of co-moving radius R/a_0 :

$$\sigma_R^2(z) \equiv \left\langle \left(\frac{3a_0^3}{4\pi R^3} \int_{a_0|\mathbf{x}|<R} d^3x \delta_M(\mathbf{x}, t(z)) \right)^2 \right\rangle \tag{8.1.44}$$

(Because of the translation invariance of the average, it would make no difference if we wrote the argument of δ_M as $\mathbf{x}+\mathbf{y}$, with $\mathbf{y}$ any fixed coordinate vector.) Again using Eqs. (8.1.22) and (8.1.23), and now also Eq. (8.1.20), we find

$$\sigma_R^2(z) = \frac{1}{2\pi^2(1+z)^2} \left(\frac{C\left(\Omega_\Lambda/\Omega_M(1+z)^3\right)}{C\left(\Omega_\Lambda/\Omega_M\right)} \right)^2 \int_0^\infty P(k)|f(kR)|^2 k^2 dk \tag{8.1.45}$$

where $f(kR)$ is the top hat distribution function

$$f(kR) \equiv \frac{3a_0^3}{4\pi R^3} \int_{a_0|\mathbf{x}|<R} d^3x e^{i\mathbf{k}\cdot\mathbf{x}a_0} = \frac{3}{(kR)^3}(\sin kR - kR\cos(kR)) \tag{8.1.46}$$

In particular, if we take $P(k)$ to be given by Eq. (8.1.42), then

$$\begin{aligned} \sigma_R^2(z) =& \frac{16\pi N^2}{25 k_*^{n_S-1}\Omega_M^2 H_0^4} \frac{C^2\left(\Omega_\Lambda/\Omega_M(1+z)^3\right)}{(1+z)^2} \\ & \times \int_0^\infty \left| \mathcal{T}\left(\sqrt{2}k/k_{\rm EQ}\right) \right|^2 |f(kR)|^2 k^{2+n_S} dk \end{aligned} \tag{8.1.47}$$

The top hat function has $f(0) = 1$, so there is no change in the infrared convergence of the integral for the mean square fluctuation, but $|f(kR)|^2$ decays as $9\cos^2(kR)/(kR)^4$ for $k \to \infty$, which is fast enough to remove the ultraviolet divergence for $n_S < 5$.

Many observations of the distribution of matter in the universe are commonly expressed in terms of a quantity called σ_8, which is the value of $\sigma_R(z)$ for $z = 0$ and $R = 8h^{-1}$Mpc. In calculating σ_8, we can evaluate the transfer function using the Dicus fitting formula (6.5.12), with the Eisenstein-Hu baryonic correction (6.5.22). Using the parameters $h = 0.72$, $\Omega_M h^2 =$

$0.14, \Omega_B h^2 = 0.024$ and $|N|^2 = 2.1 \times 10^{-10}$ which as discussed in Section 7.2 were found at the end of the first year of WMAP observations, and taking the present radiation temperature as $T_{\gamma,0} = 2.725$ K which yields $\Omega_R h^2 = 4.15 \times 10^{-5}$, Eq. (8.1.47) gives $\sigma_8 = 0.92$, in agreement with the result $\sigma_8 = 0.919$ found by the WMAP collaboration, which was calculated using the CMBfast computer program. [5] (The three-year WMAP data [6] gives a smaller value, $\sigma_8 = 0.761^{+0.049}_{-0.048}$, because the reduced optical depth inferred from three-year polarization data requires a smaller value of $|N|^2$ to give temperature correlations about the same magnitude. The reduction in $|N|^2$ also yields a corresponding decrease in the value of σ_8 calculated from Eq. (8.1.47).)

Even though Eq. (8.1.43) gives a divergent integral for $n_S \geq 1$, it suggests that $P(k)k^3$ can be used as a measure of the strength of the fluctuations of co-moving wave number $q = a_0 k$. With $P(k)$ given by Eq. (8.1.42) with $n_S \simeq 1$, we have $F^2(t)P(k)k^3 \propto t^{4/3}k^4 \left|T\left(k/k_{\rm EQ}\right)\right|^2$. This is a monotonically increasing function of k, so we can conclude that it is the perturbations of large co-moving wave number and hence small mass that become strong first, with small condensations merging into pre-galactic dark matter haloes and then ultimately into clusters of galaxies. This "bottom-up" picture of structure formation is the reverse of the "top-down" picture long advocated by Zel'dovich, [7] according to which very large condensations form first and then fragment into condensations on the scale of clusters of galaxies and finally into individual galaxies. The bottom-up picture is supported by the observation that the commonest galaxies are dwarf spheroidals, and that our galaxy and the Andromeda Nebula M31 each have about 20 smaller satellite galaxies.

Returning now to the power spectral function, inspection of Table 6.1 shows that the function $\kappa|\mathcal{T}(\kappa)|^2$ has a maximum value of 0.74 , reached at $\kappa = 2.0$. Since Eq. (6.4.58) gives k proportional to κ, with $k = \Omega_M h^2 \kappa /$ 19.3 Mpc, $P(k)$ for $n_S = 1$ has a maximum at this value of κ, corresponding to

$$k_{\rm max} = 0.10 \Omega_M h^2 {\rm Mpc}^{-1}. \tag{8.1.48}$$

Taking $C\left(\Omega_\Lambda/\Omega_M\right) = 0.767$ and $n_S = 1$, the value of the spectral function at its maximum is

$$P_{\rm max} = 7.2 \times 10^{13} \left(\Omega_M h^2\right)^{-1} |N|^2 {\rm Mpc}^3. \tag{8.1.49}$$

There are a number of measurements of the matter distribution at low redshift that have been used to calculate $P(k)$:

- There have been several surveys of galaxy positions and redshifts, of which the two most recent and detailed are the Sloan Digital Sky Survey, [8] which will include about 800,000 galaxies, and the 2 dF Survey, [9] which at its completion in 2003 had included 220,000 galaxies. Results of the Sloan Digital Sky Survey are shown in Figure 8.2.
  These two surveys give values of $P(k)$ in fair agreement with each other, for values of k ranging from about $0.015h{\rm Mpc}^{-1}$ to $0.2h{\rm Mpc}^{-1}$. (Wave numbers are given in these surveys in units of $h{\rm Mpc}^{-1}$ because distances are inferred from redshifts, and are therefore proportional to h^{-1}.) The measured $P(k)$ has a shape consistent with the result $\propto k|\mathcal{T}(\kappa)|^2$ expected from Eq. (8.1.42) for $n_S \simeq 1$, and in particular seems to reach a maximum at $k \approx 0.02h{\rm Mpc}^{-1}$, in good agreement with Eq. (8.1.48) for $\Omega_M \approx 0.3$ and $h \approx 0.7$. The value at this maximum is measured to be $P_{\rm max} \approx 5 \times 10^4 h^{-3}{\rm Mpc}^3$.

[475] D. N. Spergel et al., Astrophys. J. Suppl. 148, 175 (2003). The result $\sigma_8 = 0.9$ quoted in this reference was rounded off from $\sigma_8 = 0.919$, in order to reflect uncertainties in the input parameters.

Comparison of this result with Eq. (8.1.49) indicates a value $|N| \approx 2 \times 10^{-5}$ for the strength of primordial fluctuations, if we take $\Omega_M \approx 0.3$ and $h \approx 0.7$.

- The counts of numbers of "virialized" clusters of galaxies (like the Coma cluster) as a function of redshift gives information about the distribution of mass with distance. [10] (See Section 1.11.) Their results yield values for σ_8 ranging from 0.66 to about 1 , and can be interpreted as giving a value $P(k) \approx 6 \times 10^3 h^{-3}\text{Mpc}^3$ for $k \approx 0.1h\text{Mpc}^{-1}$, which falls on the curve provided by the above galaxy surveys.

- Other information about the distribution of mass with distance comes from correlations between the positions of intergalactic regions of higher than average density, revealed through Lyman α absorption of light from distant quasars that passes through these regions. [11] (See Section 1.10.) Their results yield values for $P(k)$ for k between about $0.1h\text{Mpc}^{-1}$ and $6h\text{Mpc}^{-1}$, which lie on the curve provided by the

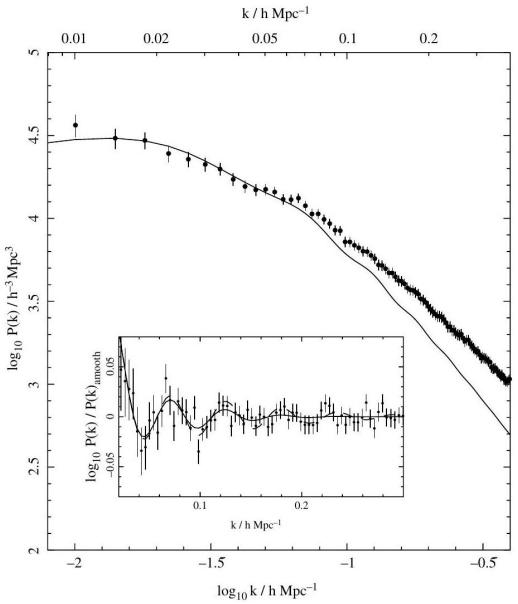

Figure 8.2: Measurement of the power spectral function by the Sloan Digital Sky Survey, from W. J. Percival et al., astro-ph/0608636. Dark circles show values of $h^{3} P(k)$, inferred from the survey of galaxy positions and redshifts, with distances calculated from redshifts using assumed cosmological parameters $\Omega_M = 0.24, \Omega_\Lambda = 0.76$. Vertical bars indicate $1 - \sigma$ errors. The solid curve is calculated using linear perturbation theory, with cosmological parameters taken from the WMAP third-year temperature and polarization data: $h = 0.73, \Omega_M = 0.24, \Omega_\Lambda = 0.76, \Omega_B/\Omega_M = 0.174$. The normalization of this curve is taken from a fit to the data for k between $0.01h\text{Mpc}^{-1}$ and $0.06h\text{Mpc}^{-1}$. The departure of the data from this theoretical curve for large k is attributed to non-linear effects on the growth of perturbations. The inset shows the effect of baryon acoustic oscillations, discussed at the end of this section. Data points give the ratio of the measured power spectral function to its value when smoothed to eliminate the oscillations. The solid curve shows the expected ratio, calculated using parameters from the third year WMAP data.

galaxy surveys for $k < 0.2h\text{Mpc}^{-1}$, and extend this curve to larger values of k, again in agreement with the expected shape $\propto k|\mathcal{T}(\kappa)|^2$.

- Yet more information about the distribution of mass comes from weak lensing of galactic images. [12] (See Section 9.5). Their results yield

values of σ_8 ranging from 0.67 to 0.97 , and can be interpreted as giving values of $P(k)$ for k in the neighborhood of $0.3h\text{Mpc}^{-1}$, that fall on the curve provided by the galaxy surveys.

These measurements are subject to various uncertainties, which raise highly technical issues of astrophysics. In relying on redshifts to give distances, these measurements are vulnerable to complications arising from the peculiar velocities of galaxies or galaxy clusters or Lyman α clouds. The theory used to interpret these measurements assumes that the concentrations of dark matter can be treated as small perturbations, so it is necessary to avoid using data for values of k where fluctuations have become non-linear. Finally, in interpreting the distribution of baryonic matter in galaxies or clusters of galaxies or Lyman α clouds in terms of the total mass density, it is necessary either to assume that this introduces no bias, or else to know what the bias is. Only the weak lensing technique directly measures fluctuations in the total mass density. For this reason, although the other techniques can give good information about

[4712] See, e.g., H. Hoekstra et al., Astrophys. J. 647, 116 (2006).

the shape of the function $P(k)$, they leave its overall normalization rather uncertain. The results from the galaxy surveys quoted above are for "no bias," that is, with the distribution of baryonic matter before perturbations become nonlinear assumed to trace the distribution of cold dark matter.

One of the striking things to emerge from the study of the cosmic microwave background described in the previous chapter is that these results for $P(k)$ obtained from studies of large scale structure agree with the strength of primordial fluctuations found from the cosmic microwave background. That is, the primordial fluctuation strength $q^3 |\mathcal{R}_q|^2$ seems to be roughly constant over a wide range of physical wave numbers $k \equiv q/a_0$, from the values $\approx 10^{-3}\text{Mpc}^{-1}$ probed by observations of the cosmic microwave background down to all but the smallest multipole orders, to values more than 1Mpc^{-1} probed by studies of large scale structure. Indeed, even before the advent of the COBE measurements discussed in Section 2.6, the study of the large scale structure of matter had led to the expectation that the cosmic microwave background would show fractional temperature fluctuations of order 10^{-5}, corresponding to $|N| \approx 10^{-5}$.

The measurements discussed so far were all at small or moderate redshifts, where the structure distance in Eq. (8.1.28) is not very different from the linear approximation $d_S(z) \simeq z/H_0$. It is widely hoped that measurements of the matter correlation function ξ at larger redshifts will provide a determination of the functional form of $d_S(z)$ (or equivalently of $d_A(z)$) beyond this approximation, which could illuminate the time dependence of the vacuum energy. But Eq. (8.1.28) shows that in the integral for $\xi(z, \hat{n}; z', \hat{n}')$ it is only wave numbers $k \gtrsim 1/r$ for which the integrand is
sensitive to the value of $r \equiv |d_S(z)\hat{n} - d_S(z')\hat{n}'|$. If $r \ll 1/k_{\rm EQ}$ (where $k_{\rm EQ}$ is the wave number that comes into the horizon just at radiationmatter equality) then for $k \gtrsim 1/r$ and $n_S \simeq 1$, the approximate formula (8.1.42) for $P(k)$ together with the asymptotic formula (6.5.11) for the transfer function give $P(k) \sim k^{-3}[\ln k + O(1)]^2$, so the part of the integral (8.1.28) for the correlation function that depends on r has the r-dependence

$$\int_{1/r}^{\infty} \frac{dk}{rk^2} \sin(ka_0 r) [\ln k + O(1)]^2$$

which varies only logarithmically with r. Thus in order to use measurements of the matter correlation function to learn something about the z-dependence of $d_S(z)$, we need either to carry the measurements of the correlation function to redshifts and angles that are sufficiently different so that $|d_S(z)\hat{n} - d_S(z')\hat{n}'|$ is at least of order $1/k_{\rm EQ} = 19.3\text{Mpc}/\Omega_M h^2$, or take advantage of the small departures of the transfer function from the asymptotic formula (6.5.11) for $k > k_{\rm EQ}$, or else take advantage of small departures from our formula (8.1.42) for $P(k)$ at $k > k_{\rm EQ}$.

Such departures from Eq. (8.1.42) for $P(k)$ are provided by terms of order $\beta \equiv \Omega_B/\Omega_M$, produced by baryon acoustic oscillations before the time of decoupling. [13] To see the effect of these oscillations, we must return to Eq. (8.1.14), and now look at the "fast" terms in the various perturbations, which oscillate with wave number for large wave number. In estimating the order of magnitude of these terms, we take $\bar{\rho}_B(t_L)$ and $\bar{\rho}_\gamma(t_L)$ to be of the same order of magnitude, so that $R(t_L)$ is of order unity, and $8\pi G\bar{\rho}_\gamma(t_L)$ is of order $\beta H^2(t_L)$. In estimating orders of magnitude we also do not distinguish between a_L and $a_{\rm EQ}$, which only differ by a factor of order 3 . Then, keeping track only of the small factors β and $a_L H_L/q$, Eqs. (6.4.45)(6.4.48) show that, aside from a common factor $\mathcal{R}_q^o \exp\left(-\int_0^{t_L} \Gamma dt\right)$, the

[4713] The influence of baryon acoustic oscillations before decoupling on the matter distribution after decoupling was recognized by P. J. E. Peebles and J. T. Yu, Astrophys. J. 162, 815 (1970); R. A. Sunyaev and Ya. B. Zel'dovich, Astrophys. Space Sci. 7, 3 (1970); J. R. Bond and G. Efstathiou, Astrophys. J. 285, L45 (1984); J. A. Holtzmann, Astrophys. J. Suppl. 71, 1 (1989); W. Hu and N. Sugiyama, Astrophys. J. 471, 30 (1996); D. J. Eisenstein and W. Hu, Astrophys. J. 496, 605 (1998). I believe that the first to suggest using redshift

fast terms in $\beta\delta_{\gamma q}(t_L), (1-\beta)\delta_{Dq}(t_L)$, and $t_L\psi_q(t_L)$ are of the order of $\beta, \beta H_L^2 a_L^2/q^2$, and $\beta H_L a_L/q$, respectively, while $\beta t_L (q^2/a_L^2)\,\delta u_{\gamma q}(t_L)$ is of order $\beta\,(q/a_L H_L)$, and is therefore dominant (aside from Silk damping) for $q/a_L H_L \gg 1$. Keeping only this term, we see that the oscillating part of $\Delta(q)$ is approximately

$$\begin{aligned}\Delta^{\rm fast}(q) &\simeq \beta t_L \left(q^2/a_L^2\right)\delta u_{\gamma q}^{\rm fast}(t_L) \\ &\simeq \frac{2\beta q \mathcal{R}_q^o}{\sqrt{3}a_L H_L (1+R_L)^{3/4}} \exp\left(-\int_0^{t_L}\Gamma dt\right)\sin(q d_H/a_L)\end{aligned} \tag{8.1.50}$$

where as usual $R \equiv 3\bar\rho_B/\bar\rho_\gamma$; d_H is the acoustic horizon distance (7.2.39) at decoupling

$$\begin{aligned}d_H &\equiv a_L\int_0^{t_L}\frac{dt}{a\sqrt{3(1+R)}} \\ &= \frac{2}{H_0\sqrt{3R_L\Omega_M}\,(1+z_L)^{3/2}}\ln\left(\frac{\sqrt{1+R_L}+\sqrt{R_{\rm EQ}+R_L}}{1+\sqrt{R_{\rm EQ}}}\right)\end{aligned} \tag{8.1.51}$$

and, for reasons explained earlier, we have replaced t_L in Eq. (8.1.14) with $2/3H_L$. Thus the ratio of $P(k)$ to the smooth curve given by Eq. (8.1.42) will have bumps at $k \simeq \pi k_H/2, 3\pi k_H/2, 5\pi k_H/2\ldots$, where $k_H = 1/d_H(1+z_L)$. These bumps have been seen in the spectral function inferred from observations by both the Sloan Digital Sky Survey [14] and the 2dF Galaxy Redshift Survey. [15] (See the inset in Figure 8.2.) The proportionality of d_H to $\Omega_M^{-1/2}$ has allowed a determination of Ω_M by matching the observed and predicted positions of these bumps [14,15]. The result [16] is $\Omega_M = 0.256^{+0.029}_{-0.024}$, or with a larger sample, [17] $\Omega_M = 0.24 \pm 0.02$. Unfortunately, these measurements are at moderate redshifts ($0.16 < z < 0.47$ for the Sloan survey, and $z < 0.3$ for the 2dF Survey), and although they give evidence for dark energy, they do not yet provide information about its time dependence.

As promised, we close by estimating the cosmic variance incurred in using Eq. (8.1.33). The mean square fractional error in this formula is

$$\begin{aligned}\Delta_V(Q,t) \equiv &\left\langle\left[\int\frac{d^2\hat Q}{4\pi}\left(\left|\delta^V_{MQ\hat Q^{(t)}}\right|^2 - \langle|\delta^V_{MQ\hat Q^{(t)}}\right|^2\rangle\right)\right]^2\right\rangle \\ &\times\left(\left\langle|\,\delta^V_{MQ\hat Q^{(t)}}\right\rangle\right)^2 = \delta_{MQ}^{-4}(t)\int\frac{d^2\hat Q}{4\pi}\int\frac{d^2\hat Q'}{4\pi} \\ &\times\left[\langle|\delta^V_{MQ\hat Q^{(t)}}\right|^2\left|\delta^V_{MQ\hat Q'}(t)\right|^2\rangle - \langle|\delta^V_{MQ\hat Q^{(t)}}\right|^2\rangle\,\langle|\delta^V_{MQ\hat Q'}(t)\right|^2\rangle\right]\end{aligned} \tag{8.1.52}$$

Assuming Gaussian statistics, this is

$$\begin{aligned}\Delta_V(Q,t) =& \delta_{MQ}^{-4}(t)\int\frac{d^2\hat Q}{4\pi}\int\frac{d^2\hat Q'}{4\pi} \\ &\times\left[|\left\langle\delta^V_{MQ\hat Q'}(t)\delta^{V*}_{MQ\hat Q'}(t)\right|^2 + \left|\left\langle\delta^V_{MQ\hat Q'}(t)\delta^V_{MQ\hat Q'}(t)\right|^2\right]\end{aligned}$$

surveys to measure $d_A(z)$ by observation of baryon acoustic oscillations were D. J. Eisenstein, W. Hu, and M. Tegmark, Astrophys. J. 504, L57 (1998), and that the suggestion to use this method to measure the evolution of dark energy is due to D. J. Eisenstein, in Next Generation Wide-Field Multi-Object Spectroscopy, eds. M. Brown and A. Dey (ASP Conference Series, vol. 280, 2002): p. 35.

[4714] D. J. Eisenstein et al., Astrophys. J. 633, 560 (2005) [astro-ph/0501171].

[15] S. Cole et al., Mon. Not. Roy. Astron. Soc. 362, 505 (2005).

[16] W. J. Percival et al., Astrophys. J. 657, 51 (2007) [astro-ph/0608635].

[17] M. Tegmark et al., Phys. Rev. 74, 123507 (2006) [astro-ph/0608632].

Using Eqs. (8.1.31) and (8.1.24) (and recalling that $\alpha(\mathbf{q}) = \alpha^*(-\mathbf{q})$ and $\delta_{Mq}(t)$ is real) then gives

$$\Delta_V(Q,t) = 2\delta_{MQ}^{-4}(t) \int \frac{d^2\hat{Q}}{4\pi} \int \frac{d^2\hat{Q}'}{4\pi} \times \left| \int d^3q F_V(\mathbf{q} - Q\hat{Q}) F_V^* \left(\mathbf{q} - Q\hat{Q}'\right) \delta_{Mq}^2(t) \right|^2$$

The large volume limit $F_V(\mathbf{q}-\mathbf{Q}) \to \left((2\pi)^{3/2}/\sqrt{V}\right) \delta^3(\mathbf{q}-\mathbf{Q})$ then gives the cosmic variance as

$$\Delta_V(Q,t) = \frac{2(2\pi)^3}{V} \int \frac{d^2\hat{Q}}{4\pi} \int \frac{d^2\hat{Q}'}{4\pi} F_V^2 \left(Q\hat{Q} - Q\hat{Q}'\right)$$

Now, $F_V^2 \left(Q\hat{Q} - Q\hat{Q}'\right)$ takes the value $V/(2\pi)^3$ for $Q\left|\hat{Q} - \hat{Q}'\right| \ll V^{-1/3}$, and vanishes exponentially for $Q\left|\hat{Q} - \hat{Q}'\right| \gg V^{-1/3}$, so aside from factors of order unity,

$$\Delta_V(Q,t) \approx \frac{1}{Q^2 V^{2/3}} \tag{8.1.53}$$

Thus the mean square fractional error in using Eq. (8.1.33) vanishes as $Q^{-2}V^{-2/3}$, and becomes negligible when the survey volume contains many
wavelengths. The numerical factor depends on the shape of the survey volume. For instance, if the survey volume is a sphere of co-moving radius R, then for $QR \gg 1$,

$$\Delta_V(Q,t) \to \frac{9}{4Q^2R^2} \tag{8.1.54}$$

10.8.2 8.2 Nonlinear growth

The study of the growth of perturbations beyond the linear approximation presents formidable mathematical difficulties. It is usually pursued by the use of computer simulations, which are beyond the scope of this book. To allow an analytic treatment, we can adopt a generalization of an idealization of nonlinear growth originally due to Peebles. [1] With Peebles, we will consider a fluctuation to have an overdensity $\Delta\rho_M$ (that is, a total density $\bar{\rho}_M + \Delta\rho_M$ greater than the cosmic average $\bar{\rho}_M$) that is uniform within a finite sphere. [2] According to the Birkhoff theorem, [3] the metric and the equations of motion of a freely falling test particle inside the sphere are independent of what is happening outside the sphere, and are therefore the same as in a homogeneous isotropic universe, described by a RobertsonWalker metric, with a density $\bar{\rho}_M(t) + \Delta\rho_M(t)$, and a curvature constant that is not in general equal to the cosmological curvature constant K. In a Robertson-Walker metric with curvature constant K, the scale factor $a(t)$ satisfies the Friedmann equation (1.5.19):

$$\dot{a}^2(t) + K = \frac{8\pi G a^2(t)}{3} \left(\bar{\rho}_M(t) + \rho_V\right) \tag{8.2.1}$$

Likewise, the scale factor $\mathcal{A}(t)$ of the Robertson-Walker metric inside the fluctuation will satisfy a Friedmann equation:

$$\dot{\mathcal{A}}^2(t) + K + \Delta K = \frac{8\pi G \mathcal{A}^2(t)}{3} \left(\bar{\rho}_M(t) + \Delta\rho_M(t) + \rho_V\right) \tag{8.2.2}$$

where $K + \Delta K$ is the curvature constant of the interior metric. We are including in the total density both a non-relativistic mass density, and a

vacuum density ρ_V (not included by Peebles) which for want of any contrary evidence is taken to be time-independent.

We will only consider the case of vanishing cosmological curvature, [4]$K = 0$. We are primarily interested in fluctuations that have a chance to stop expanding and recollapse to high density, so we shall take $\Delta K > 0$. The total matter density obeys the conservation law

$$\bar{\rho}_M(t) + \Delta\rho_M(t) \propto \mathcal{A}^{-3}(t) \tag{8.2.3}$$

while the unperturbed density satisfies

$$\bar{\rho}_M(t) \propto a^{-3}(t) \tag{8.2.4}$$

With $K = 0$, the normalization of a is arbitrary; we will find it convenient to use Eqs. (8.2.3) and (8.2.4) to normalize a so that

$$\mathcal{A}^3(t)\,(\bar{\rho}_M(t) + \Delta\rho_M(t)) = a^3(t)\bar{\rho}_M(t) \tag{8.2.5}$$

In order to provide initial conditions for this problem, we must first consider times that are sufficiently early in the matter-dominated era so that $\Delta\rho_M(t)$ and $\Delta\mathcal{A}(t) \equiv \mathcal{A}(t) - a(t)$ can be treated as small perturbations, and the vacuum energy may be neglected. As we saw in Section 1.5, in this case Eqs. (8.2.1) and (8.2.4) have the solution

$$a \propto t^{2/3}, \quad \bar{\rho}_M = \frac{1}{6\pi G t^2} \tag{8.2.6}$$

To first order in the perturbations around this solution, Eq. (8.2.2) becomes

$$2\dot{a}\Delta\dot{\mathcal{A}} + \Delta K = \frac{8\pi G a^2 \bar{\rho}_M}{3}\left(\frac{2\Delta\mathcal{A}}{a} + \frac{\Delta\rho_M}{\bar{\rho}_M}\right)$$

or, using Eq. (8.2.6)

$$\frac{\Delta K}{a^2} = \frac{4}{9t^2}\left(\frac{2\Delta\mathcal{A}}{a} + \frac{\Delta\rho_M}{\bar{\rho}_M}\right) - \frac{4}{3t}\frac{\Delta\dot{\mathcal{A}}}{a}.$$

Also, to first order in perturbations, Eq. (8.2.5) gives at early times

$$\frac{\Delta\mathcal{A}}{a} = -\frac{\Delta\rho_M}{3\bar{\rho}_M},$$

so $\Delta\mathcal{A}$ is governed at early times by the first-order differential equation

$$\frac{\Delta K}{a^2} = -\frac{4}{9t^2}\frac{\Delta\mathcal{A}}{a} - \frac{4}{3t}\frac{\Delta\dot{\mathcal{A}}}{a} \tag{8.2.7}$$

This has solutions for $t \to 0$ of the form $\Delta\mathcal{A} \propto t^{4/3}$ and $\Delta\mathcal{A} \propto t^{-1/3}$. Assuming that enough time has passed for the solution $\Delta\mathcal{A} \propto t^{-1/3}$ to die away, we have $\Delta\mathcal{A} \propto t^{4/3}$, and so

[471] P. J. E. Peebles, Astrophys. J. 147, 859 (1967).

[2] J. E. Gunn and J. R. Gott, Astrophys. J. 176, 1 (1972) took into account the infall of matter from outside a sphere of uniform overdensity, which amounts to treating the overdensity of the sphere and its surroundings as a step function of radius. A non-vanishing vacuum energy was incorporated in the Gunn-Gott model by H. Martel, P. R. Shapiro, and S. Weinberg, Astrophys. J. 492, 29 (1998), who considered fluctuations consisting of a ball with a uniform overdensity surrounded by a spherical shell with a uniform underdensity.

[3] G&C, Sec. 11.7.

[474] The case of negative cosmological curvature is considered by B. Freivogel, M. Kleban, M. N. Martinez, and L. Susskind, J. High Energy Phys. 0603, 039 (2006) [hep-th/0505232].

$$\Delta K = -\frac{20}{9}\lim_{t\to 0} t^{-2}a(t)\Delta A(t) = \frac{40\pi G}{9}\lim_{t\to 0} a^2(t)\Delta\rho_M(t) \tag{8.2.8}$$

In characterizing the initial strength of a fluctuation within a co-moving radius r, we note from Eq. (8.2.8) that at early times $\Delta\rho_M(t) \propto a^{-2}(t) \propto \bar{\rho}_M^{2/3}(t)$, so we can define a time-independent quantity, which we shall call the initial fluctuation strength:

$$\rho_1 \equiv \lim_{t\to 0}\frac{\Delta\rho_M^3(t)}{\bar{\rho}_M^2(t)} \tag{8.2.9}$$

Then Eq. (8.2.8) can be written

$$\begin{aligned}\Delta K &= \frac{40\pi G}{9}a^2(t)\bar{\rho}_M^{2/3}(t)\rho_1^{1/3} \\ &= \frac{40\pi G}{9}\mathcal{A}^2(t)\left(\bar{\rho}_M(t)+\Delta\rho_M(t)\right)^{2/3}\rho_1^{1/3}\end{aligned} \tag{8.2.10}$$

Note that we do not have to take the limit $t \to 0$ here, because $a^2\bar{\rho}_M^{2/3}$ is time-independent.

Now let's consider the development of the fluctuation at later times, when it can no longer be treated as a small perturbation. Using Eq. (8.2.10) allows us to write the Friedmann equation (8.2.2) (with $K = 0$) as

$$\dot{\mathcal{A}}^2 = \frac{8\pi G\mathcal{A}^2}{9}\left[3\left(\bar{\rho}_M+\Delta\rho_M+\rho_V\right) - 5\left(\bar{\rho}_M+\Delta\rho_M\right)^{2/3}\rho_1^{1/3}\right]$$

or, using Eq. (8.2.3),

$$\begin{aligned}&\left(\bar{\rho}_M+\Delta\rho_M\right)^{-2}\left(\frac{d}{dt}\left(\bar{\rho}_M+\Delta\rho_M\right)\right)^2 = 8\pi G \\ &\quad\times\left(3\left(\bar{\rho}_M+\Delta\rho_M+\rho_V\right) - 5\left(\bar{\rho}_M+\Delta\rho_M\right)^{2/3}\rho_1^{1/3}\right)\end{aligned} \tag{8.2.11}$$

The right-hand side vanishes at a total mass density $\bar{\rho}_M + \Delta\rho_M = \rho_c$ satisfying

$$3\left(\rho_c+\rho_V\right) = 5\rho_c^{2/3}\rho_1^{1/3} \tag{8.2.12}$$

For $\rho_c > 0$, the quantity $5\rho_c^{2/3}\rho_1^{1/3} - 3\rho_c$ takes values from $-\infty$ to $500\rho_1/243$, so Eq. (8.2.12) has a solution if and only if the fluctuation is strong enough so that [5]

$$\rho_1 \geq \frac{729}{500}\rho_V \tag{8.2.13}$$

As long as Eq. (8.2.12) has a solution, the density $\bar{\rho}_M(t) + \Delta\rho_M(t)$ will drop until it reaches the value ρ_c, and then increase again to infinity. The total time elapsed for this expansion and collapse is given by Eq. (8.2.11) as

$$t_c = \frac{2}{\sqrt{8\pi G}}\int_{\rho_c}^{\infty}\frac{d\rho}{\rho\sqrt{3\left(\rho+\rho_V\right) - 5\rho^{2/3}\rho_1^{1/3}}} \tag{8.2.14}$$

(The factor 2 appears here because it takes the same time to contract from the minimum density ρ_c to infinite density as it does to expand from infinite to minimum density.) For example, in the limit $\rho_1 \gg \rho_V$, this gives

$$t_c \to \frac{9\pi}{5^{3/2}\sqrt{8\pi G\rho_1}} \tag{8.2.15}$$

If linear perturbation theory held up to this time then instead of becoming infinite, in this case the fractional density perturbation at time t_c would be

$$\frac{\Delta\rho_M}{\bar{\rho}_M} = \left(\frac{\rho_1}{\bar{\rho}_M}\right)^{1/3} = \rho_1^{1/3}\left(6\pi G t_c^2\right)^{1/3} = \left(\frac{243\pi^2}{500}\right)^{1/3} = 1.686$$

We see that gravitational collapse occurs at a time when linear perturbation theory would predict a fractional density perturbation large enough to make obvious its own invalidity.

Of course, different fluctuations will have different initial strengths ρ_1 and co-moving radii R. In order to make contact between this analysis and observation, it is convenient to make use of an approach due to Press and Schechter. [6] By inverting Eq. (8.2.14), we can calculate the minimum initial fluctuation strength $\rho_1(t_c)$ required for collapse at or before a time t_c. For instance, for fluctuations that are sufficiently strong to collapse before vacuum energy becomes important, Eq. (8.2.15) gives $\rho_1(t_c) = 81\pi/1000Gt_c^2$. To calculate the probability that a random point in space will be in a fluctuation this strong, we assume that at an early time t, before non-linearities become significant, the probability $P_{t,R}(\Delta\rho_M)\, d\Delta\rho_M$ that the average density within a co-moving sphere of radius R is increased by a density excess

between $\Delta\rho_M$ and $\Delta\rho_M + d\Delta\rho_M$ is given by the Gaussian distribution

$$P_{t,R}(\Delta\rho_M)\, d\Delta\rho_M = \frac{d\Delta\rho_M}{\sqrt{2\pi}\sigma_R(z_t)\,\bar{\rho}_M(t)} \exp\left(-\frac{\Delta\rho_M^2}{2\sigma_R^2(z_t)\,\bar{\rho}_M^2(t)}\right) \tag{8.2.16}$$

For a Harrison-Zel'dovich spectrum of fluctuations with $\mathcal{R}_q = Nq^{-3/2}$, the standard deviation σ_R for the fractional fluctuation $\Delta\rho_M/\bar{\rho}_M$ averaged over a radius R is given by Eq. (8.1.47), which for $n_S = 1$ reads

$$\begin{aligned}\sigma_R^2(z) =& \frac{16\pi N^2}{25\Omega_M^2 H_0^4} \frac{C^2\left(\Omega_\Lambda/\Omega_M(1+z)^3\right)}{(1+z)^2} \\ & \int_0^\infty \left|\mathcal{T}\left(\sqrt{2}k/k_{\rm EQ}\right)\right|^2 |f(kR)|^2 k^3 dk\end{aligned} \tag{8.2.17}$$

where f is the top hat distribution function (8.1.46); $\mathcal{T}$ is the scalar transfer function, defined and calculated in Section 6.5; and $k_{\rm EQ}$ is the wave number (8.1.41) that comes into the horizon at matter-radiation equality. Using Eq. (8.2.9), this can be expressed as a time-independent probability $P_R(\rho_1)\, d\rho_1$ for fluctuations averaged over a co-moving sphere of radius R to have a initial strength between ρ_1 and $\rho_1 + d\rho_1$:

$$\tilde{P}_R(\rho_1)\, d\rho_1 = \frac{d\rho_1}{3\sqrt{2\pi}\rho_1^{2/3}\tilde{\sigma}_R} \exp\left(-\frac{\rho_1^{2/3}}{2\tilde{\sigma}_R^2}\right) \tag{8.2.18}$$

where $\tilde{\sigma}_R$ is a time-independent quantity, given by

$$\begin{aligned}\tilde{\sigma}_R^2 &\equiv \lim_{z\to\infty} \bar{\rho}_M^{2/3}(t(z))\sigma_R^2(z) \\ &= \frac{16\pi N^2}{25}\left(\frac{3}{8\pi G}\right)^2 \bar{\rho}_{M0}^{-4/3} \int_0^\infty \left|\mathcal{T}\left(\sqrt{2}k/k_{\rm EQ}\right)\right|^2 |f(kR)|^2 k^3 dk\end{aligned} \tag{8.2.19}$$

Because we are averaging over a sphere of co-moving radius R, it is only fluctuations whose co-moving radii are greater than R that contribute to this probability. Integrating, we see that

[475] S. Weinberg, Phys. Rev. Lett. 59, 2607 (1987).

[6] W. H. Press and P. Schechter, Astrophys. J. 239, 1 (1974).

at early times, before the fluctuations become strong, the probability that a random point in space is in a fluctuation with initial strength greater than ρ_1 and co-moving radius greater than R is

$$P\,(>\rho_1, >R) = \int_{\rho_1}^{\infty} \frac{d\rho}{3\sqrt{2\pi}\rho^{2/3}\tilde{\sigma}_R} \exp\left(-\frac{\rho^{2/3}}{2\tilde{\sigma}_R^2}\right) = \frac{1}{2}\left[1 - \mathrm{erf}\left(\rho_1^{1/3}/\sqrt{2}\tilde{\sigma}_R\right)\right] \tag{8.2.20}$$

where $\mathrm{erf}(y)$ is the usual error function

$$\mathrm{erf}(y) \equiv \frac{1}{\sqrt{2\pi}} \int_{-y\sqrt{2}}^{y\sqrt{2}} dx \exp\left(-x^2/2\right) \tag{8.2.21}$$

At early times the universe has uniform matter density, so Eq. (8.2.20) also gives the fraction of all matter that is in fluctuations with initial strength greater than ρ_1 and co-moving radius greater than R. If we now set ρ_1 in Eq. (8.2.20) equal to the critical initial strength $\rho_1(t)$ for collapse by a time t, then we find that at time t, when nonlinearities have become important, the fraction of all matter that is in collapsed structures with co-moving radii greater than R will be

$$F(>R,t) = \frac{1}{2}\left[1 - \mathrm{erf}\left(\rho_1^{1/3}(t)/\sqrt{2}\tilde{\sigma}_R\right)\right] \tag{8.2.22}$$

The mass in a sphere of co-moving radius R is the time-independent quantity $4\pi\bar{\rho}_M(t)a^3(t)R^3/3$, so at time t the number density $n(M,t)dM$ of collapsed structures with mass between M and $M + dM$ is given by

$$n(M,t) = -\frac{\bar{\rho}_M(t)}{2M}\frac{d}{dM}\,\mathrm{erf}\left(\rho_1^{1/3}(t)/\sqrt{2}\tilde{\sigma}_{R(M)}\right) = \frac{\rho_1^{1/3}(t)\bar{\rho}_M(t)}{M\sqrt{2\pi}}\left|\frac{d\tilde{\sigma}_{R(M)}^{-1}}{dM}\right| \exp\left(-\frac{\rho_1^{2/3}(t)}{2\tilde{\sigma}_{R(M)}^2}\right) \tag{8.2.23}$$

where $R(M) \equiv (3M/4\pi a^3\bar{\rho}_M)^{1/3}$. (Press and Schechter somewhat arbitrarily multiplied this by a factor 2 , to take account of the matter in regions with a negative density fluctuation. [7]) These collapsed structures eventually furnish the halos of cold dark matter that surround galaxies in the present universe. [8]

In using Eq. (8.2.23), we need to know the mass dependence of $\tilde{\sigma}_{R(M)}$. For large masses and radii, the integral (8.2.19) is dominated by low values of the wave number k, for which the transfer function $T(\kappa)$ is close to unity, so Eq. (8.2.19) gives $\tilde{\sigma}_R^2 \propto R^{-4}$, and so $\tilde{\sigma}_{R(M)}^2 \propto M^{-4/3}$. (For a primordial fluctuation spectrum $\mathcal{R}_q \propto q^{(-4+n_S)/2}$, we would have a factor $k^{2+n_S}dk$ in place of k^3dk in Eq. (8.2.19), which would give $\tilde{\sigma}_R^2 \propto R^{-3-n_S}$, and so $\tilde{\sigma}_{R(M)}^2 \propto M^{-(3+n_S)/3}$.) The argument of the exponential in Eq. (8.2.23) in this case is thus proportional for $n_S = 1$ to $M^{4/3}$, giving a rapid fall-off of the number density for large mass. On the other hand, for small masses and radii, the integral (8.2.19) is dominated by large values

[477] For a derivation of this factor of 2, see J. R. Bond, S. Cole, G. Efstathiou, and N. Kaiser, Astrophys. J. 379, 440 (1991).

[8] The effects of non-spherical collapse on the mass function $n(M,t)$ is considered by P. Monaco, Astrophys. J. 447, 23 (1995); J. Lee and S. F. Shandarin, Astrophys. J. 500, 14 (1998); R. K. Sheth and G. Tormen, Mon. Not. Roy. Astron. Soc. 308, 119 (1999); R. K. Sheth, H. J. Mo, and G. Tormen, Mon. Not. Roy. Astron. Soc. 323, 1 (2001).

of the wave number k, for which according to Eq. (6.5.11) the transfer function $T(\kappa)$ falls off like $\ln k/k^2$. The integral (8.2.19) then varies only logarithmically with R, and so the number density $n(M)$ goes for small M more-or-less like M^{-2}. The detailed M-dependence predicted by Eq. (8.2.23) is in reasonable agreement with the results of large computer simulations of the evolution of cold dark matter. [9]

10.8.3 8.3 Collapse of baryonic matter

Until now we have supposed that the baryonic matter of the universe, which after recombination consisted chiefly of neutral hydrogen and helium, had negligible pressure. In this case baryonic matter just followed along with cold dark matter in its expansion and possible recontraction. Actually, as we saw in Section 2.3, the baryonic matter retained a small residual ionization even after the nominal era of recombination, providing enough electrons for Compton scattering of photons of the cosmic microwave background to keep the temperature of baryonic matter equal to the temperature of the microwave background until the redshift dropped below about 150 . Small overdense regions did not have enough of a gravitational field to overcome the baryonic pressure, so their baryonic matter did not collapse along with the cold dark matter. This led to relatively small clumps of cold dark matter that now do not contain galaxies, and are therefore undetectable except for their gravitational effects. The question is, how small did a clump of matter have to be for its baryonic component to have resisted gravitational collapse?

Before the existence of cold dark matter was generally accepted, this question was addressed in a simple theory due originally to James Jeans. [1] According to this theory, small perturbations either oscillate or grow according to whether their wave number is greater or less than a critical wave number $k_J = \sqrt{4\pi G\bar{\rho}_B}/v_s$ (where v_s is the speed of sound) so a clump is too small to collapse if its mass is less than the Jeans mass, given by $\bar{\rho}_B\,(2\pi/k_J)^3$. This theory naturally (given its date) was not originally set in the context of an expanding universe, but not much changes

when the expansion is taken into account. [2] But as we shall see, it turns out that results are quite different when we include the effects of cold dark matter.

We are considering only non-relativistic matter during an era in which radiation contributed little to the gravitational field, so we can apply the Newtonian cosmological theory described in Appendix F. By following the same reasoning that led there to Eqs. (F.15) and (F.16), but now including both baryonic matter with a squared sound speed $\partial p_B/\partial\rho_B = v_s^2$ and cold dark matter with zero pressure, we find that the velocity potential perturbations δu_B and δu_D and the density perturbations $\delta\rho_B$ and $\delta\rho_D$ for co-moving wave number $\mathbf{q}$ are governed by the equations of continuity

$$\frac{d\delta\rho_D}{dt} + 3H\delta\rho_D - a^{-1}\bar{\rho}_D\mathbf{q}^2\delta u_D = 0 \tag{8.3.1}$$

$$\frac{d\delta\rho_B}{dt} + 3H\delta\rho_B - a^{-1}\bar{\rho}_B\mathbf{q}^2\delta u_B = 0 \tag{8.3.2}$$

and the Euler equations

$$\frac{d\delta u_D}{dt} + H\delta u_D = \frac{4\pi G a}{\mathbf{q}^2}\left[\delta\rho_D + \delta\rho_B\right] \tag{8.3.3}$$

$$\frac{d\delta u_B}{dt} + H\delta u_B = \frac{4\pi G a}{\mathbf{q}^2}\left[\delta\rho_D + \delta\rho_B\right] - \frac{v_s^2}{a\bar{\rho}_B}\delta\rho_B \tag{8.3.4}$$

[479] V. Springel et al., Nature 435, 629 (2005) [astro-ph/0504097].

[1] J. Jeans, Phil. Trans. Roy. Soc. 199A, 49 (1902), and Astronomy and Cosmogony (2nd ed., first published by Cambridge University Press in 1928; reprinted by Dover Publications, New York, 1961), pp. 345-350.

As in the relativistic case, it is convenient to introduce the fractional density perturbations $\delta_n \equiv \delta\rho_n/\bar{\rho}_n$. Using the Friedmann result that both unperturbed densities $\bar{\rho}_n$ go as $a^{-3} \propto t^{-2}$, and eliminating the velocity potentials, these equations then become

$$\ddot{\delta}_D + \frac{4}{3t}\dot{\delta}_D = \frac{2}{3t^2}\left[\beta\delta_B + (1-\beta)\delta_D\right] \tag{8.3.5}$$

$$\ddot{\delta}_B + \frac{4}{3t}\dot{\delta}_B = -\frac{2\alpha}{3t^2}\delta_B + \frac{2}{3t^2}\left[\beta\delta_B + (1-\beta)\delta_D\right] \tag{8.3.6}$$

where α and β are defined by

$$\alpha \equiv \frac{3\mathbf{q}^2 v_s^2 t^2}{2a^2} = \frac{\mathbf{q}^2 v_s^2}{4\pi G\bar{\rho}_M a^2}, \quad \beta \equiv \frac{\bar{\rho}_B}{\bar{\rho}_M} = \frac{\Omega_B}{\Omega_M} \simeq 0.17 \tag{8.3.7}$$

and $\bar{\rho}_M \equiv \bar{\rho}_D + \bar{\rho}_B$.
Note that α was constant during the era (roughly for $z > 150$) when baryonic matter had the same temperature as radiation, because $v_s^2 \propto T \propto a^{-1}$. Thus we can find power-law solutions [3] to Eqs. (8.3.5) and (8.3.6) that
apply during this era. We set

$$\delta_D \propto t^\nu, \quad \delta_B = \xi\delta_D, \tag{8.3.8}$$

where v and ξ are time-independent (but $\mathbf{q}$-dependent) quantities to be determined. Eqs. (8.3.5) and (8.3.6) then become

$$v(v-1) + \frac{4v}{3} = \frac{2}{3}[\beta\xi + (1-\beta)], \tag{8.3.9}$$

$$v(v-1) + \frac{4v}{3} + \frac{2\alpha}{3} = \frac{2}{3}[\beta + (1-\beta)/\xi]. \tag{8.3.10}$$

Eliminating ξ yields a quartic equation for v. This generically has four different solutions, so there are four independent power-law solutions of the fourth-order system of differential equations (8.3.5) and (8.3.6), which therefore form a complete set of solutions.

The general solutions of Eqs. (8.3.9) and (8.3.10) are too complicated to be illuminating, but we can find useful approximate solutions if we take into account the small value of β. In the limit of very small β, there are two baryon-poor solutions for which $\xi < 1$:

$$\begin{array}{ll} v = 2/3, & \xi = \frac{1}{1+\alpha} \\ v = -1, & \xi = \frac{1}{1+\alpha} \end{array} \tag{8.3.12}$$

and two baryon-rich solutions for which $\xi \gg 1$:

$$v = -\frac{1}{6} \pm \sqrt{\frac{1}{36} - \frac{2\alpha}{3}}, \quad \xi = -\frac{1+\alpha}{\beta} \tag{8.3.13}$$

All of these solutions decay with time, except for the first solution (8.3.11), in which the baryon and cold dark matter fractional density perturbations both grow as $t^{2/3}$. This solution therefore dominates at late times. To first order in β, the power-law exponent and baryon fraction in this mode are

$$v = 2/3 - \frac{2\beta\alpha}{5(1+\alpha)}, \quad \xi = \frac{1}{1+\alpha} - \frac{\beta\alpha^2}{(1+\alpha)^3}$$

[472] G&C, Sec. 15.9.
[3] Approximate power law solutions were given by P. J. E. Peebles, Astrophys. J. 277, 470 (1984).

The fractional baryonic corrections to v and ξ are a maximum for very short wavelengths, for which they take values $3\beta/5 \simeq 10\%$ and $\beta \simeq 17\%$, respectively.

There is nothing here like a critical wave number marking a transition from growth to oscillation, as in the classic one-component Jeans theory. The growing mode (8.3.11) grows for all wave numbers, with a growth rate that for small β depends very little on wave number. This of course is because the pressure of baryonic matter could not prevent clumps of cold dark matter from becoming increasingly denser than average. What does depend on the wave number is the fraction ξ of the baryons that follow the growing condensation of the cold dark matter. This can most conveniently be expressed in terms of the total mass M (dark and baryonic matter) in a cubic physical wavelength $2\pi a/q$:

$$M \equiv \bar{\rho}_M \left(\frac{2\pi a}{q}\right)^3 \tag{8.3.14}$$

According to the formulas for ξ and α given by Eqs. (8.3.11) and (8.3.7), the fraction of baryons that collapsed along with the cold dark matter can be written

$$\frac{\delta\rho_B/\bar{\rho}_B}{\delta\rho_D/\bar{\rho}_D} \equiv \xi = \frac{1}{1+(M_J/M)^{2/3}}, \tag{8.3.15}$$

where M_J is a sort of Jeans mass

$$M_J = \left(\frac{\pi}{G}\right)^{3/2} \frac{v_s^3}{\bar{\rho}_M^{1/2}}. \tag{8.3.16}$$

Baryons collapsed along with cold dark matter for clumps of mass much greater than M_J, while clumps of mass much less than M_J are largely free of baryonic matter.

The speed of sound for a gas of hydrogen and helium atoms at temperature T is $v_s = (5k_{\mathcal{B}}T/3\mu m_N)^{1/2}$, where μ is the mean molecular weight, which for a helium abundance by weight of 24% is $\mu = 1.22$. Since we are considering an era in which $T = T_\gamma$, and $T_\gamma^3/\bar{\rho}_M$ equals its present value $T_{\gamma 0}^3/\bar{\rho}_{M0}$, the Jeans mass can be written

$$M_J = \left(\frac{5\pi k_{\mathcal{B}} T_{\gamma 0}}{3\mu m_N G}\right)^{3/2} \bar{\rho}_{M0}^{-1/2} = 2.02\times 10^5 \left(\Omega_M h^2\right)^{-1/2} M_\odot \tag{8.3.17}$$

For $\Omega_M h^2 = 0.13$, this is $6\times 10^5 M_\odot$, corresponding to a baryonic mass $\beta M_J \simeq 10^5 M_\odot$.

After the redshift dropped to about 150, the Compton scattering of the cosmic microwave background by the residual ionized hydrogen no longer kept the temperature of baryonic matter equal to the radiation temperature. According to Eq. (1.1.23), the kinetic energy and hence the temperature of the hydrogen and helium atoms then dropped like a^{-2}. Additional baryons then began to fall into the already growing clumps of cold dark matter, until the baryons were heated again by the energy released in gravitational collapse, and eventually by the first generation of stars. The increased baryonic temperature inhibited the further accretion of baryonic matter, and may have resulted in the expulsion of some baryonic matter from the clump. This is all quite complicated, [4] but it does not change the conclusion, that a clump of cold dark matter whose mass is less than M_J will not contain a full complement of baryonic matter.

10.9 Gravitational Lenses

In 1979 Walsh, Carswell, and Weymann [1] noticed a pair of quasars at the same redshift, about 1.4 , separated by just 6″. The similarity of the spectrum of the two quasars suggested to

[474] P. R. Shapiro, M.L. Giroux, and A. Babul, Astrophys. J. 427, 25 (1994).

them that there was really just one quasar, now known as Q0957+561, split into two images by the deflection of light in the gravitational field of an intervening massive body. This suggestion was verified with the discovery of a galaxy with a redshift 0.36 between the lines of sight to the quasar. Such gravitational lenses had already been studied theoretically by many authors, and now a serious search for them was put in train. [2] Many more lensing galaxies were discovered, generally elliptical field galaxies, and also some lensing clusters of galaxies, which generally produce arc-like images. [3]

Strong gravitational lensing has been used to search for dark objects, to explore the structure of galaxy clusters, and to measure the Hubble constant. Weak lensing offers great promise in measuring the correlation function of density fluctuations. Lensing is a large subject; in this chapter we will give only an overview of its cosmological applications.

10.9.1 9.1 Lens equation for point masses

We will first consider the gravitational lens provided by a point mass, and later take up more detailed models. To analyze the splitting of images by a point mass, suppose that the lines from the earth to a point source and the earth to the lensing mass in a Robertson-Walker coordinate system centered on the earth are separated by a small angle α. (See Figure 9.1.)

This is the angle that there would be between the images of the source and lens, if their were no gravitational deflection of light. Because of the deflection of light by the lens, there is a different angle β between the actual images of the source and lens. We need to derive a lens equation, which gives the relation between β and α.

In the coordinate system centered on the earth, the light ray from the source follows a path from the source to the neighborhood of the lens that

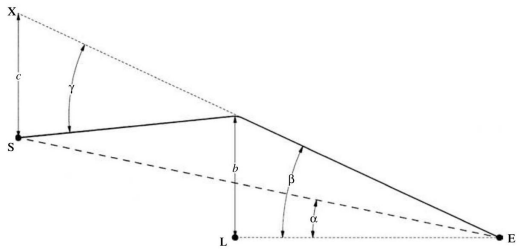

Figure 9.1: Quantities referred to in the derivation of the lens equation, (9.1.5). The bent solid line is the path of a photon from the source S past the lens L to the Earth E . The point X is the apparent position of the source. The transverse distances b and c from the lens to the light path and from the source to its apparent position are greatly exaggerated, as are the angles α, β, and γ. This is drawn for the case $K = 0$; in a Robertson-Walker coordinate system centered on the Earth, the path from the source to the bend would be curved for $|K| \neq 0$.

is curved for $K \neq 0$; is bent by the gravitational field of the lens; and then follows a straight line to the earth. The proper distance b of this path from the lens at its closest approach (which we assume to be much less than the cosmological scale $1/H_0$) is

$$b = \beta d_A(EL), \tag{9.1.1}$$

[471] D. Walsh, R. F. Carswell, and R. J. Weymann, Nature 279, 381 (1979).

[2] For a comprehensive review, see Gravitational Lenses, by P. Schneider, J. Ehlers, and E. E. Falco (Springer-Verlag, Berlin, 1992). A more recent review is given by G. Soucail, Proceedings of the XX Texas Symposium on Relativistic Astrophysics, Austin, December 2000.

[3] R. Lynds and V. Petrosian, Bull. Amer. Astron. Soc. 18, 1014 (1986); G. Soucail, B. Fort, Y. Mellier, and J. P. Picat, Astron. Astrophys. 172, L14 (1987); G. Soucail et al., Astron. Astrophys. 191, L19 (1988).

where $d_A(EL)$ is the "angular diameter distance" of the lens as seen from the earth. As discussed in Section 1.4, in general the angular diameter distance $d_A(PQ)$ of a point Q as seen from a point P is the ratio h/θ of a proper length h at Q (normal to the line PQ) to the angle θ subtended at P by this length. It is given by

$$d_A(PQ) = a\,(t_Q)\,r_P(Q), \tag{9.1.2}$$

where $r_P(Q)$ is the radial coordinate of Q in the Robertson-Walker coordinate system centered at P (in which rays of light received at P all travel on straight lines), and t_Q is the time the light leaves or arrives at Q. From Figure 9.1, we can see that the line segment SX from the true to the apparent position of the source has a proper length c given by

$$\gamma d_A(LS) = c = (\beta - \alpha) d_A(ES), \tag{9.1.3}$$

where γ is the angle of deflection of the light ray near the lens as seen from the lens, given by general relativity as [4]

$$\gamma = \frac{4MG}{b}, \tag{9.1.4}$$

and $d_A(LS)$ and $d_A(ES)$ are the angular diameter distances of the source from the lens and from the earth, respectively. From Eqs. (9.1.1), (9.1.3) and (9.1.4) we have

$$(\beta - \alpha)\beta = \frac{\gamma d_A(LS)}{d_A(ES)} \frac{b}{d_A(EL)} = \frac{4MG d_A(LS)}{d_A(ES) d_A(EL)} \equiv \beta_E^2. \tag{9.1.5}$$

This is our lens equation. It is a quadratic equation for β, the two solutions giving the directions of the two images into which the point source is split. All the effects of the large scale spacetime geometry and the expansion of the universe are contained in the angular diameter distances $d_A(EL), d_A(ES)$, and $d_A(LS)$. (In general these are independent distances; for $K \neq 0$ we do not have $d_A(ES) = d_A(EL) + d_A(LS)$.)

The lens equation (9.1.5) has two roots,

$$\beta_\pm = \frac{\alpha}{2} \pm \sqrt{\frac{\alpha^2}{4} + \beta_E^2}. \tag{9.1.6}$$

The angle α is not observed, because we cannot remove the lens. If all we measure is the angular separation between the two images of the source, then all we can learn is an upper bound on the mass of the lensing galaxy:

$$|\beta_+ - \beta_-|^2 \geq 4\beta_E^2 \tag{9.1.7}$$

For instance, if $d_A(EL) = d_A(LS) = 100\text{Mpc}, d_A(ES) = 200\text{Mpc}$, and the sources are separated by $1''$, then (remembering that $M_\odot G = 1.475$ km and $1\text{Mpc} = 3.09 \times 10^{19}$ km), we find that $M \leq 6 \times 10^9$ solar masses.

On the other hand, if the lensing galaxy and the two images are all observed, we can measure the angles $\beta_\pm$between each image and the lensing galaxy, but with α unknown the best use we can make of Eq. (9.1.6) is to eliminate α by multiplying the roots

$$\beta_+ \beta_- = -\beta_E^2 \tag{9.1.8}$$

(The minus sign just means that the two images are on opposite sides of the lensing galaxy.) This allows us to calculate the mass M, but if the distances

[474] G & C, Section 8.5.

are calculated from measurements of redshifts, then they scale with $1/H_0$, so what we really calculate in this way is MGH_0. (As we saw in Section 1.9, velocity dispersions and angular diameters also only tell us the value of MGH_0.)

In the special case where the lensing galaxy lies directly on the line between the source and the earth, the problem has cylindrical symmetry around this line of sight, and we get an Einstein ring rather than a pair of images. The angular radius of the Einstein ring is the value of β given by setting $\alpha = 0$ in Eq. (9.1.5), so it is just the angle β_E, which is why we label it with a subscript E. Einstein rings have been observed for a number of radio sources, starting with the source MG1131+0456. [5]

10.9.2 9.2 Magnification: Strong lensing and microlensing

The various images that are produced by a gravitational lens will not all have the same apparent luminosity. The apparent luminosity is the power received per receiving area, so now we need to consider light paths that end at various points on the telescope receiving area. For this purpose it is helpful to refer positions in the receiving area relative to some fixed point Y, which we can conveniently take on the axis of symmetry of the problem the line extending from a point source (or a luminous point on an extended source) through the lens and past the earth. (See Figure 9.2.) We can think of the distance h of a point on the telescope mirror from this line as a function of θ, the angle at the source between the light ray to the point on the mirror and the fixed line (in the Robertson-Walker coordinate system centered on the source) from the source through the lens. The fraction of all light that is emitted between polar angles θ and $\theta + d\theta$ (with $\theta \ll 1$) and azimuthal angles ϕ and $\phi + d\phi$ (measured at the source, around the fixed line to the lens) is $\theta d\theta d\phi/4\pi$, while the receiving area between in the rectangle with height dh and width $hd\phi$ is $hdhd\phi$, so the apparent luminosity is

$$\ell = \left| \frac{L\theta d\theta d\phi/4\pi}{hdhd\phi\,(1+z_S)^2} \right| = \frac{L}{4\pi\,(1+z_S)^2} \left| \frac{\theta d\theta}{hdh} \right| . \tag{9.2.1}$$

(The factor $(1+z_S)^{-2}$ accounts for the reduction of energy of individual photons and the reduction in the rate at which photons are emitted from the source.) From Figure 9.2, we see that

$$h = d_A(SE)\chi = d_A(SE)d_A(EL)\alpha/d_A(SL), \tag{9.2.2}$$

[475] G. H. Chen, C. S. Kochanek, and J. N. Hewitt, Astrophys. J. 447, 62 (1995).

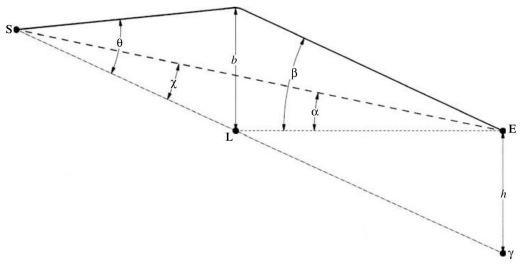

Figure 9.2: Quantities referred to in the derivation of the magnification formula, (9.2.4). The bent solid line is the path of a photon from the source S past the lens L to a point E on a telescope mirror. The point Y is a fixed point near the earth on the line from the source through the lens. The transverse distances b and h from the lens to the light path and from the point Y to the point E where the photon arrives at the telescope mirror are greatly exaggerated, as are the angles α, β, χ, and θ. As in Figure 9.1, this is drawn for the case $K = 0$; in a Robertson-Walker coordinate system centered on the earth, the path from the source to the bend would be curved for $|K| \neq 0$.

where χ is the angle between the line from the source to the point on the mirror and the line from the source to the lens, and

$$\theta = b/d_A(SL) = \beta d_A(EL)/d_A(SL). \tag{9.2.3}$$

(As in Section 9.1, for any points P and $Q, d_A(PQ)$ is the angular diameter distance of Q as seen from P.) Hence Eq. (9.2.1) gives

$$\ell = \ell_0 \left| \frac{\beta d\beta}{\alpha d\alpha} \right|, \tag{9.2.4}$$

where ℓ_0 is the luminosity that would be observed in the absence of the lens:

$$\ell_0 = \frac{L}{4\pi \left(1 + z_S\right)^2 d_A^2(SE)}. \tag{9.2.5}$$

(Note that $r_S(E) = r_E(S)$, so Eq. (9.1.2) gives $d_A(SE) = (1 + z_S)\, d_A(ES)$. According to Eq. (1.4.12), the luminosity distance of the source as seen from the earth is $d_L(S) = (1 + z_S)^2\, d_A(ES) = (1 + z_S)\, d_A(SE)$, which is the distance whose square appears in Eq. (9.2.5).)

Eq. (9.2.4) is a very general result, which applies to lenses and sources of all types. It has a particularly useful consequence for extended sources. If a
small part of the image of such a source subtends a solid angle $\beta\Delta\beta\Delta\phi$ and has an apparent luminosity $\Delta\ell$, then it has a surface brightness $\Delta\ell/\beta\Delta\beta\Delta\phi$. According to Eq. (9.2.4), this equals $\Delta\ell_0/\alpha\Delta\alpha\Delta\phi$, which is the surface brightness that this part of the image would have if there were no lens. Thus surface brightness is unaffected by lensing. This of course is because gravitational lensing changes neither the number nor the energy of photons.

Let us now specialize to the case of a point lens. The lens equation (9.1.5) gives here

$$\alpha = \beta - \beta_E^2/\beta, \tag{9.2.6}$$

so

$$\frac{\alpha d\alpha}{\beta d\beta} = 1 - \beta_E^4/\beta^4 \tag{9.2.7}$$

The luminosity (9.2.4) is then

$$\ell = \frac{\ell_0}{|1 - \beta_E^4/\beta^4|}. \tag{9.2.8}$$

When the distance [1]a of the lens from the line joining the source and observer is small, we have $\alpha \ll \beta_E$, so the two solutions (9.1.6) for β become

$$\beta_\pm \to \pm\beta_E + \frac{1}{2}\alpha. \tag{9.2.9}$$

In this case both images are amplified by a factor $|\beta_E/2\alpha|$. On the other hand, when the distance a of the lens from the line joining the source and observer is large, we have $\alpha \gg \beta_E$, so the two solutions (9.1.6) for β become

$$\beta_+ \to \alpha \gg \beta_E, \quad -\beta_- \to \beta_E^2/\alpha \ll \beta_E. \tag{9.2.10}$$

Under these conditions, the "-" ray becomes invisible, while the "+" ray has the normal brightness expected without gravitational deflection.

Roughly speaking, therefore, a point mass can only produce noticeable strong lensing, with more than one image, if it has $\alpha \leq \beta_E$, i.e., if it lies within a proper distance $a_{\max}$ of the line between the source and the observer, given by

$$a_{\max} = \beta_E d_A(EL) = \sqrt{\frac{4MGd_A(LS)d_A(EL)}{d_A(ES)}}. \tag{9.2.11}$$

Using Eq. (9.1.2), this is

$$a_{\max} = \sqrt{\frac{4MGr_L(S)r_E(L)a\left(t_L\right)}{r_E(S)}} = \sqrt{\frac{4MGr_L(S)r_E(L)a\left(t_E\right)}{r_E(S)}}\frac{1}{\sqrt{1+z_L}}, \tag{9.2.12}$$

where t_E is the time the light signal reaches the earth (elsewhere in this book called t_0), while z_L is the redshift of the lens

$$1 + z_L \equiv a\left(t_E\right)/a\left(t_L\right) \tag{9.2.13}$$

The radial coordinate $r_L(S)$ of the source in the Robertson-Walker coordinate system centered on the lens can be calculated in terms of the radial coordinates of both the source and lens in the Robertson-Walker coordinate system centered on the earth by using the condition that the threedimensional proper distance between the source and the lens is equal in these two coordinate systems

$$\int_0^{r_L(S)} \frac{dr}{\sqrt{1-Kr^2}} = \int_{r_E(L)}^{r_E(S)} \frac{dr}{\sqrt{1-Kr^2}} \tag{9.2.14}$$

This gives

$$r_L(S) = r_E(S)\sqrt{1 - Kr_E^2(L)} - r_E(L)\sqrt{1 - Kr_E^2(S)}. \tag{9.2.15}$$

If at time t there are $n(t, M)$ objects per proper volume with mass between M and $M + dM$, then (using Eq. (1.1.12)) the total number of objects that can produce a detectable splitting of the image of the source S is

[471] Here a is a proper distance transverse to the line of sight, and is not related to the Robertson-Walker scale factor, which is distinguished in this section by always writing it with a time argument, as $a(t)$.

$$N_S = \int_0^{r_E(S)} \frac{dr_E(L) a(t_L)}{\sqrt{1-Kr_E^2(L)}} \int_0^\infty \pi a_{\max}^2 n(t_L, M)\, dM$$
$$= 4\pi G a^2(t_E) \int_0^{r_E(S)} \frac{dr_E(L)\rho(t_L)}{(1+z_L)^2 \sqrt{1-Kr_E^2(L)}} \frac{r_L(S) r_E(L)}{r_E(S)} \tag{9.2.16}$$

where t_L is the time that the light from the source reaches the lens, and $\rho(t)$ is the mass density of possible lenses at time t :

$$\rho(t) \equiv \int_0^\infty n(t, M) M dM \tag{9.2.17}$$

Also, in the integrand $r_E(L)$ and t_L are related as usual by

$$\int_0^{r_E(L)} \frac{dr}{\sqrt{1-Kr^2}} = \int_{t_L}^{t_E} \frac{dt}{a(t)} \tag{9.2.18}$$

and $1 + z_L \equiv a(t_E)/a(t_L)$. If there is no evolution of the density of lensing galaxies, then $\rho(t_L) = \rho(t_E)(1+z_L)^3$, and Eq. (9.2.16) reads

$$N_S = 4\pi G a^2(t_E)\rho(t_E) \int_0^{r_E(S)} \frac{dr_E(L)(1+z_L)}{\sqrt{1-Kr_E^2(L)}} \left(\frac{r_L(S) r_E(L)}{r_E(S)} \right) \tag{9.2.19}$$

Where $N_S \ll 1$ we can ignore the possibility of multiple lensing, and interpret N_S as the probability that the image of the source S is appreciably modified by a lens near the line of sight.

For sources with $z_S \ll 1$, Eq. (9.2.19) simplifies to

$$N_S = 4\pi G a^2(t_E)\rho(t_E) \int_0^{r_E(S)} dr_E(L) \left(\frac{(r_E(S) - r_E(L)) r_E(L)}{r_E(S)} \right)$$
$$= \frac{2\pi G r_E^2(S) a^2(t_E)\rho(t_E)}{3} = \frac{2\pi G z_S^2 \rho(t_E)}{3H_0^2} = \frac{z_S^2 \Omega_L}{4} \tag{9.2.20}$$

where $\Omega_L \equiv 8\pi\rho(t_E)/3H_0^2$ is the fraction of the critical mass that at present is provided by the lensing objects. We see that even for Ω_L as large as $\Omega_M \approx 0.3$, the probability of strong lensing is small for nearby sources with $z_S \ll 1$, but the probability should become appreciable for sources at cosmological distances. [2]

For z_S of order unity or larger, the strong lensing probability turns out to depend sensitively on the cosmological model. Since the integral (9.2.19) is complicated in general, we will consider here just two extreme cases, of a flat universe dominated either by vacuum energy or by non-relativistic matter.

De Sitter model ($\Omega_\Lambda = 1, \Omega_K = \Omega_M = \Omega_R = 0$)
Here $a(t)/a(t_E) = \exp(H_0(t - t(E)))$, so

$$r_E(L) = \int_{t_L}^{t_E} \frac{dt}{a(t)} = \frac{1}{a(t_E) H_0} \left[\exp(H_0(t_E - t_L)) - 1 \right]$$

We can invert this, and find

$$a(t_L) = \frac{a(t_E)}{1 + a(t_E) H_0 r_E(L)}$$

Then Eq. (9.2.19) becomes

$$N_S = 4\pi G\rho\left(t_E\right) a^2\left(t_E\right) \times \int_0^{r_E(S)} \left(\frac{r_E(L)\left(r_E(S)-r_E(L)\right)}{r_E(S)}\right)\left(1+a\left(t_E\right)H_0 r_E(L)\right) dr_E(L)$$

It is convenient to change the variable of integration from $r_E(L)$ to the redshift z_L of the lens, which is given by

$$z_L = \left(\frac{a\left(t_E\right)}{a\left(t_L\right)}\right) - 1 = a\left(t_E\right) H_0 r_E(L)$$

so

$$\begin{aligned} N_S &= \frac{4\pi G\rho\left(t_E\right)}{H_0^2}\int_0^{z_S}\left(\frac{z_L\left(z_S-z_L\right)}{z_S}\right)\left(1+z_L\right)dz_L \\ &= \frac{\pi G\rho\left(t_E\right)}{3H_0^2}\left(z_S^3+2z_S^2\right) = \frac{\Omega_L}{8}\left(z_S^3+2z_S^2\right) \end{aligned} \tag{9.2.21}$$

Einstein-de Sitter model ($\Omega_M = 1, \Omega_K = \Omega_\Lambda = \Omega_R = 0$)
Here $a(t) = a\left(t_E\right)\left(t/t_E\right)^{2/3}$ and $1+z_L = \left(t_E/t_L\right)^{2/3}$, so

$$\begin{aligned} r_E(L) &= \int_{t_L}^{t_E}\frac{dt}{a(t)} = 3a^{-1}\left(t_E\right)\left(t_E - t_E^{2/3}t_L^{1/3}\right) \\ &= 3a^{-1}\left(t_E\right)t_E\left(1-\left(1+z_L\right)^{-1/2}\right) \end{aligned}$$

Hence Eq. (9.2.19) here becomes

$$\begin{aligned} N_S =& \frac{18\pi G\rho\left(t_E\right)t_E^2}{1-\left(1+z_S\right)^{-1/2}}\int_0^{z_S} dz_L\left(1-\left(1+z_L\right)^{-1/2}\right)\left(1+z_L\right)^{-1/2} \\ &\times\left(\left(1+z_L\right)^{-1/2}-\left(1+z_S\right)^{-1/2}\right) \\ =& \frac{8\pi G\rho\left(t_E\right)}{H_0^2}\left(-4+\frac{\sqrt{1+z_S}+1}{\sqrt{1+z_S}-1}\ln\left(1+z_S\right)\right) \\ =& 3\Omega_L\left(-4+\frac{\sqrt{1+z_S}+1}{\sqrt{1+z_S}-1}\ln\left(1+z_S\right)\right) \end{aligned} \tag{9.2.22}$$

This grows like z_S^2 for $z_S \ll 1$, in agreement with Eq. (9.2.20), but it flattens out for $z_S \gg 1$, growing only logarithmically with z_S.

We see that the probability of a given source being lensed increases much more rapidly with the redshift of the source for a vacuum-energy dominated model than for a matter-dominated model. For instance, for $z_S = 2$, Eq. (9.2.21) gives $N_S = 4\Omega_L$ for a vacuum-dominated model, while Eq. (9.2.22) gives $N_S = 0.30\Omega_L$ for a matter-dominated model.

Comparison of lensing theory (under the assumptions $K = 0$ and constant vacuum energy) with the number density of strong gravitational lenses measured as a function of redshift by the Cosmic Lens All Sky Survey [3] has given the result that

$$\Omega_M = 0.31^{+0.27}_{-0.14}(68\%\text{ stat. })^{+0.12}_{-0.1}\text{ (syst.)}$$

[472] W. H. Press and J. E. Gunn, Astrophys. J. 185, 397 (1973).

This is not yet competitive with other measurements of Ω_M, but it shows definite evidence of the effect of dark energy on the number of observed strong lenses.

The assumption that the lens can be approximated as a point mass is appropriate for so-called microlensing by stars in our galaxy. Note that for $d_A(EL) \approx 10^3\text{pc}, d_A(LS) \approx d_A(ES)$, and $MG \approx 1$ km $\approx 3\times10^{-14}$pc, the effective radius $\sqrt{4MGd_A(EL)d_A(LS)/d_A(ES)}$ of the point mass lens is of order 10^{-5}pc, which is much larger than the size of even a large star. Typically in microlensing observations a change is detected in the luminosity of a distant point source (such as a star outside our galaxy) as the star moves past the line of sight to the source. For a star that moves at 100 km/sec transverse to the line of sight, the time within which the source will be within the effective radius 10^{-5}pc of the star is about a month, which is convenient for monitoring changes in apparent luminosity. Between 13 and 17 microlensing events toward the Large Magellanic Cloud (LMC) have been seen by the MACHO collaboration, [4] and another three toward less crowded fields of the LMC by the EROS collaboration. [5] Of these, only four of the lenses have been identified, and all of them are in the LMC itself, rather than the halo of our galaxy. [6] This suggests though it does not prove that the mass of the halo does not consist of dark objects with the masses of typical stars. [7] Microlensing has also been extensively used in searches for dark stars and extra-solar planets by the Microlensing

10.9.3 9.3 Extended lenses

Observations in Astrophysics collaboration [8] and the Optical Gravitational Lensing Experiment collaboration. [9]

10.9.4 9.3 Extended lenses

The point source model is not at all valid for clusters of galaxies, and it is only marginally valid for individual galaxies. (Note that for $d_A(LS) \approx d_A(EL) \approx 10^{10}\text{pc}, d_A(ES) \approx 2\times10^{10}$pc, and $MG \approx 10^{12}$ km ≈ 0.03pc, the effective radius $\sqrt{4MGd_A(EL)d_A(LS)/d_A(ES)}$ of the point mass lens is of order 5×10^4pc, which is close to the size of the spherical halo of our own galaxy.) To deal with light rays that pass through the galaxy, it has become common to approximate the massive halos of these galaxies as spheres of matter in "isothermal" equilibrium, with a ratio of pressure p to mass density ρ given by the mean square value $\langle v^2\rangle$ of any one component of star velocity, assumed to be equal throughout the lens:

$$p(r) = \rho(r)\left\langle v^2\right\rangle. \tag{9.3.1}$$

We have already seen in Section 1.9 that the solution of the equation of hydrostatic equilibrium with this equation of state behaves at a large proper distance r from the center of the lens as

$$\rho(r) = \frac{2\rho(0)}{9\left(r/r_0\right)^2} = \frac{\langle v^2\rangle}{2\pi G r^2}, \tag{9.3.2}$$

which gives the mass contained within a sphere of radius r as

[473] K.-H. Chae et al., Phys. Rev. Lett. 89, 151301 (2002) [astro-ph/0209602].

[7] For discussion of this issue, see A. F. Zakharov, Publ. Astron. Obs. Belgrade 74, 1 (2002) [astroph/0212009]; K. C. Sahu, proceedings of the STSci symposium Dark Universe: Matter, Energy, and Gravity [astro-ph/0302325].

$$\mathcal{M}(r) = \frac{2r\,\langle v^2\rangle}{G}. \tag{9.3.3}$$

The solution departs from this result for small r, but most of the mass of the lens is at distances from the center where it is a good approximation.

The rate of change of the unit vector $\hat{\mathbf{u}}$ giving the direction of a ray of light in a gravitational field $\mathbf{g} = -\nabla\phi$ is given in the post-Newtonian approximation by [1]

$$\frac{d\hat{\mathbf{u}}}{dt} = -2\hat{\mathbf{u}} \times (\hat{\mathbf{u}} \times \mathbf{g}) \tag{9.3.4}$$

For any spherically symmetric non-relativistic distribution of matter, we have

$$\mathbf{g}(\mathbf{r}) = -\frac{G\mathcal{M}(r)}{r^3}\mathbf{r}, \tag{9.3.5}$$

which for the outer parts of an isothermal sphere becomes

$$\mathbf{g}(\mathbf{r}) = -\frac{2\,\langle v^2\rangle}{r^2}\mathbf{r}, \tag{9.3.6}$$

For a light ray that passes the center of the lens at a distance b of closest approach, the light ray direction $\hat{\mathbf{u}}$ remains very close to a fixed direction. The small change in direction then has a magnitude

$$\gamma = 4\,\langle v^2\rangle \int_{-\infty}^{\infty} \frac{b dx}{x^2 + b^2} = 4\pi\,\langle v^2\rangle \tag{9.3.7}$$

and is independent of b. (We are taking the speed of light to be unity, so that $\langle v^2\rangle^{1/2}$ is dimensionless, equal to the rms velocity in units of the speed of light.) The direction of this change is toward the center of the lens, so light can arrive at the earth from the source along two different rays, which pass on opposite sides of the lens center, and are separated in angle by $8\pi\,\langle v^2\rangle$. The "+" ray, which passes the lens on the side toward the source, makes an angle β_+at the earth with the ray from the earth to the lens given again by Eq. (9.1.3), while the '-' ray makes an angle with the earth-lens ray β_- (now taken positive), given by replacing α with $-\alpha$ in Eq. (9.1.3), so

$$\gamma d_A(LS) = (\beta_\pm \mp \alpha)\, d_A(ES) \tag{9.3.8}$$

which with Eq. (9.3.7) gives us our lens equation

$$\beta_\pm = \pm\alpha + \beta_E \tag{9.3.9}$$

where now

$$\beta_E = \frac{4\pi\,\langle v^2\rangle\, d_A(LS)}{d_A(ES)} \tag{9.3.10}$$

Here again for a lens on the line of sight from the earth to the source we have $\alpha = 0$, and the two images become an Einstein ring with angular radius β_E. Because we have now defined $\beta_\pm$to be positive the lens equation gives two images only if $\alpha < \beta_E$, which requires that the proper distance $a = d_A(EL)\alpha$ of the lens from the line between the earth and the source be less than a maximum value

[478] P. Yock et al., Proceedings of the ninth Marcel Grossman meeting, Rome, July 2000 [astroph/0007317].
[9] A. Udalski et al., Acta Astron. 54, 313 (2004) [astro-ph/0411543].
[1] See, e.g., G&C, Eq. (9.2.7). A factor -2 that was missing on the right-hand side of this equation has been supplied.

$$a_{\max} = \beta_E d_A(EL) = \frac{4\pi \langle v^2 \rangle d_A(LS) d_A(EL)}{d_A(ES)} \tag{9.3.11}$$

10.9.5 9.3 Extended lenses

The magnification of the two images is again given by Eq. (9.2.4)

$$\ell = \ell_0 \left| \frac{\beta d\beta}{\alpha d\alpha} \right|,$$

but now we must use this with the lens equation (9.3.9), which gives

$$\ell_\pm = \ell_0 \left| \frac{\beta_\pm}{\alpha} \right| = \ell_0 \left| \frac{\beta_\pm}{\beta_\pm - \beta_E} \right|. \tag{9.3.12}$$

The magnification becomes infinite as the lens approaches the line of sight between the earth and the source, in which case $\alpha \to 0, \beta_\pm \to \beta_E$, and the image pair becomes an Einstein ring. On the other hand, for a lens approaching the maximum distance (9.3.11) from the earth-source line, we have $\alpha \to \beta_E$, so $\beta_+ \to 2\alpha$ and $\beta_- \to 0$. According to Eq. (9.3.12), the ' - ' ray disappears in this limit, while the apparent luminosity of the '+' ray is doubled.

The number of possible isothermal spherical lenses that are actually able to split the image of a point source is now given by

$$\begin{aligned} N_S &= \int_0^{r_E(S)} \frac{dr_E(L) a(t_L)}{\sqrt{1 - K r_E^2(L)}} \pi a_{\max}^2 n(t_L) \\ &= 16\pi^3 \langle v^2 \rangle^2 \int_0^{r_E(S)} dr_E(L) \frac{n(t_L) a^3(t_L)}{\sqrt{1 - K r_E^2(L)}} \left(\frac{r_L(S) r_E(L)}{r_E(S)} \right)^2 \end{aligned} \tag{9.3.13}$$

where $n(t)$ is the proper number density of these lenses at time t. For simplicity, we have here taken $\langle v^2 \rangle$ the same for all lenses. If we also now take $K = 0$, so that Eq. (9.2.15) gives $r_S(L) = r_E(S) - r_E(L)$, and also assume no evolution of the population of lensing galaxies, so that $n(t)a^3(t)$ is constant, then

$$\begin{aligned} N_S &= 16\pi^3 \langle v^2 \rangle^2 n(t_E) a(t_E)^3 \int_0^{r_E(S)} \left(\frac{(r_E(S) - r_E(L)) r_E(L)}{r_E(S)} \right)^2 dr_E(L) \\ &= \frac{8\pi^2 \langle v^2 \rangle^2 n(t_E) a(t_E)^3 r_E^3(S)}{15} \\ &= \frac{8\pi^2 \langle v^2 \rangle^2 n(t_E)}{15 H_0^3} \mathcal{F}(z_S) \end{aligned} \tag{9.3.14}$$

where

$$\mathcal{F}(z) \equiv (a(t_E) H_0 r_E(S))^3 = \left(\int_1^{1+z} \frac{dy}{\sqrt{\Omega_\Lambda + \Omega_M y^3 + \Omega_R y^4}} \right)^3 \tag{9.3.15}$$

This shows that the chance of a source being lensed depends strongly on Ω_Λ. For instance, for $\Omega_\Lambda = \Omega_R = 0$ and $\Omega_M = 1$ we have $\mathcal{F}(z) = 8(1 - 1/\sqrt{1+z})^3$, which approaches the constant 8 for large z, while for $\Omega_M = \Omega_R = 0$ and $\Omega_\Lambda = 1$ we have $\mathcal{F}(z) = z^3$. The lensing probability for a source at redshift $z = 3$ is 27 times greater if the cosmic energy density is

vacuum dominated than if it is matter dominated. From direct observations of galaxies, the constant in Eq. (9.3.15) has been estimated as [2]

$$\frac{8\pi^2 \left\langle v^2 \right\rangle^2 n\left(t_E\right)}{15 H_0^3} \simeq 0.02 \tag{9.3.16}$$

so for $\Omega_M = \Omega_R = 0$ and $\Omega_\Lambda = 1$ the probability of lensing should become large when $z \approx 3.7$.

Lensing probabilities for quasars of large redshift can provide sensitive limits on Ω_Λ.[3] At one time it was thought on the basis of early surveys that strong lensing statistics ruled out the possibility that a constant vacuum energy made a dominant contribution to producing a spatially flat universe. [4] Since then, many groups have carried out such studies, with corrections for finite core radii, selection effects, etc., to set limits on Ω_Λ in flat cosmologies with $\Omega_\Lambda + \Omega_M = 1$. They find $\Omega_\Lambda < 0.9$,[5] $\Omega_\Lambda < 0.7$[6] $\Omega_\Lambda = 0.64^{+0.157}_{-0.26} \Omega_\Lambda < 0.74$,[8] $\Omega_\Lambda < 0.79$,[9] $\Omega_\Lambda = 0.7^{+0.1}_{-0.2}$,[10] and $\Omega_\Lambda \approx 0.45 - 0.75$.[11]

The deflection $\Delta\theta$ calculated in the isothermal sphere model of gravitational lenses is relevant only if the light path actually passes through the sphere. For galaxies of relatively small mass, we may have one or both of the deflected rays passing outside the galactic radius R. The deflection of light depends only on the Newtonian gravitational potential, and, as Newton showed, the gravitational potential outside a spherically symmetric distribution of matter is just the same as if all the mass were concentrated at the center of symmetry, so the motion of a light ray outside the galaxy is described by the point mass lens model considered earlier. If the light ray passes far outside the effective radius of the galaxy we have so-called weak lensing, which is typically discovered statistically, through a correlation in

the orientation of the images of several lensed galaxies, rather than by the study of individual sources. This is the subject of Section 9.5.

10.9.6 9.4 Time delay

In addition to light rays being bent by the gravitational fields of intervening objects, they are also delayed, [1] so that a fluctuation in the distant light source appears at different times on earth in the several lensed images of the source. [2] There are two effects here.

First, there is a geometrical time delay, caused by the increased length of the total light path from the source to the earth. Since this arises over very long distances, it can be calculated by idealizing the light path as a geodesic of the Robertson-Walker metric from the source to the point P of closest approach to the lens, where the light path is bent, followed by a similar geodesic from that point to the earth. The time t_E that a light signal that leaves the source at time t_S arrives at the earth is given by

$$\int_{t_S}^{t_E} \frac{dt}{a(t)} = \sigma_{SP} + \sigma_{PE} \tag{9.4.1}$$

[10] M. Chiba and Y. Yoshii, Astrophys. J. 510, 42 (1999) [astro-ph/9808321].
[11] Y-C. N. Cheng and L. M. Krauss, Astrophys. J. 511, 612 (1999) [astro-ph/9810392].

where σ_{SP} and σ_{PE} are the proper lengths (the integrals of $(\tilde{g}_{ij}dx^i dx^j)^{1/2}$) along the paths from the source to P and from P to the earth, respectively. The time t_{E0} that the light would arrive at the earth if there were no gravitational deflection is given simply by

$$\int_{t_S}^{t_{E0}} \frac{dt}{a(t)} = \sigma_{SE} \tag{9.4.2}$$

where σ_{SE} is the proper length along the geodesic from the source to the earth. Hence the geometric time delay (which is always very short compared to a Hubble time) is

$$\Delta t_{\text{geom}} \equiv t_E - t_{E0} = a\left(t_E\right)\left(\sigma_{SP} + \sigma_{PE} - \sigma_{SE}\right) \tag{9.4.3}$$

Now, it is easy to calculate proper lengths along geodesics that end at the earth:

$$\sigma_{SE} = \int_0^{r_E(S)} \frac{dr}{\sqrt{1-Kr^2}}, \quad \sigma_{PE} = \int_0^{r_E(P)} \frac{dr}{\sqrt{1-Kr^2}} \tag{9.4.4}$$

where $r_E(S)$ and $r_E(P)$ are the usual radial coordinates (in a RobertsonWalker coordinate system centered on the earth) of the source S and the point P of closest approach of the light to the lens. To calculate σ_{SP} we have to do a little more work. By using Eq. (1.1.17) for the spatial affine connection Γ^i_{jl}, we see that the equation (1.1.26) of a spatial geodesic is

$$\frac{d^2x^i}{d\sigma^2} + Kx^i = 0 \tag{9.4.5}$$

The general solution is

$$x^i(\sigma) = \begin{cases} A^i \cos\sigma + B^i \sin\sigma, & K = +1 \\ A^i + B^i\sigma, & K = 0 \\ A^i \cosh\sigma + B^i \sinh\sigma, & K = -1 \end{cases} \tag{9.4.6}$$

where A^i and B^i are constants characterizing different paths. These constants are subject to a normalization condition

$$1 = \tilde{g}_{ij}\frac{dx^i}{d\sigma}\frac{dx^j}{d\sigma} = \left(\frac{d\mathbf{x}}{d\sigma}\right)^2 + K\frac{(\mathbf{x}\cdot d\mathbf{x}/d\sigma)^2}{1-K\mathbf{x}^2}$$

which gives

$$\left(1-K\mathbf{A}^2\right)\left(1-\mathbf{B}^2\right) = K(\mathbf{A}\cdot\mathbf{B})^2. \tag{9.4.7}$$

We can determine the constants $\mathbf{A}$ and $\mathbf{B}$ for the geodesic from the source to the point P by requiring that $x^i(0) = r_E(S)\hat{n}_{ES}$ and $x^i\left(\sigma_{SP}\right) = r_E(P)\hat{n}_{EP}$, where $\hat{n}_{ES}$ and $\hat{n}_{EP}$ are the unit vectors from the earth to the source or point P, respectively. Imposing the normalization condition (9.4.7) then gives

$$\sigma_{SP} = \begin{cases} \cos^{-1}\left[r_E(P)r_E(S)\cos\theta + \sqrt{1-r_E(P)^2}\sqrt{1-r_E(S)^2}\right] & K = +1 \\ \sqrt{r_E^2(P) + r_E^2(S) - 2r_E(P)r_E(S)\cos\theta} & K = 0 \\ \cosh^{-1}\left[-r_E(P)r_E(S)\cos\theta + \sqrt{1+r_E(P)^2}\sqrt{1+r_E(S)^2}\right] & K = -1 \end{cases} \tag{9.4.8}$$

[471] The time delay of radar reflections from planets and of radio signals from artificial satellites caused by the gravitational potential of the sun has provided a fourth test of general relativity, as first proposed and measured by I. Shapiro, Phys. Rev. Lett. 13, 789 (1964). For a discussion, see G&C, Section 8.7.

[2] S. Refsdal, Mon. Not. Roy. Astron. Soc. 128, 307 (1964).

where θ is the angle between the directions from the earth to the source and to the point P. This result applies for a geodesic triangle with arbitrary angles, but of course we are interested here in the case where θ is very small. In this case, Eq. (9.4.8) becomes

$$\sigma_{SP} = \begin{cases} \sigma_{ES} - \sigma_{EP} + \frac{r_E(P) r_E(S) \theta^2}{2 \sin(\sigma_{ES} - \sigma_{EP})} & K = +1 \\ \sigma_{ES} - \sigma_{EP} + \frac{r_E(P) r_E(S) \theta^2}{2 (r_E(S) - r_E(P))} & K = 0 \\ \sigma_{ES} - \sigma_{EP} + \frac{r_E(P) r_E(S) \theta^2}{2 \sinh(\sigma_{ES} - \sigma_{EP})} & K = -1 \end{cases}$$

In the terms proportional to θ^2 we can ignore the separation of the lens from the point P of closest approach, taking $r_E(P) = r_E(L); \theta = \beta - \alpha$; and (using Eq. (9.2.14)) $\sigma_{ES} - \sigma_{EP} = \sigma_{LS}$, with errors that would introduce terms of higher order in θ. Thus, in all three cases

$$\sigma_{SP} = \sigma_{ES} - \sigma_{EP} + \frac{r_E(L) r_E(S) \theta^2}{2 r_L(S)}. \tag{9.4.9}$$

The geometric time delay (9.4.3) is then

$$\Delta t_{\text{geom}} = \frac{a\left(t_E\right) r_E(L) r_E(S) (\beta - \alpha)^2}{2 r_L(S)}. \tag{9.4.10}$$

Using Eq. (9.1.2), we can write this in terms of angular diameter distances and the redshift of the lens:

$$\Delta t_{\text{geom}} = \frac{\left(1 + z_L\right) d_A(EL) d_A(ES) (\beta - \alpha)^2}{2 d_A(LS)}. \tag{9.4.11}$$

The details of the lens enter here only in the lens equation, which for each image gives the unobservable angle α in terms of the observable angle β.

There is also a potential time delay, caused directly by the motion of the light through the gravitational potential of the lens. The calculation of these time differences is generally done on a case-by-case basis, using detailed models of the lensing galaxy rather than either the point source or isothermal sphere models. Here we will consider only the case of a general spherically symmetric lens. In a coordinate system centered on the lens with line element in the 'standard' form

$$d\tau^2 = B(r) dt^2 - A(r) dr^2 - r^2 d\theta^2 - r^2 \sin^2\theta d\varphi^2, \tag{9.4.12}$$

the time required for light to travel from a large coordinate distance r to a distance b of closest approach to the lens and then out again to r is [3]

$$2t(r, b) = 2 \int_b^r \left(\frac{A(r)/B(r)}{1 - (b/r)^2 (B(r)/B(b))} \right)^{1/2} dr \tag{9.4.13}$$

For the weak gravitational fields that concern us here, we can use the postNewtonian approximation, [4] which gives

$$A(r) = 1 + 2r\phi'(r), \quad B(r) = 1 + 2\phi(r), \tag{9.4.14}$$

where $\phi(r)$ is the Newtonian gravitational potential. Then to first order in ϕ

[3] 473 G&C, Eq. (8.7.2)

[4] G&C, Eqs. (9.1.57) and (9.1.60). It is necessary to redefine the radial coordinate in order to put the line element given by the post-Newtonian approximation in the form (9.4.12).

$$\begin{aligned} 2t(r,b) =& 2\sqrt{r^2-b^2} + 2\int_b^r \left(1-\left(\frac{b}{r}\right)^2\right)^{-1/2} (r\phi'(r)-\phi(r))\,dr \\ &+ 2\int_b^r \left(1-\left(\frac{b}{r}\right)^2\right)^{-3/2} \left(\frac{b}{r}\right)^2 (\phi(r)-\phi(b))dr \end{aligned} \tag{9.4.15}$$

We will be interested in this in the case $r \to \infty$, because the effects of the finite distance between the lens and the source and earth are already included in the geometric time delay. The second integral in Eq. (9.4.15) converges for $r \to \infty$, but the first integral diverges. Noting that for any kind of lens of mass M, the Newtonian potential at large distances goes as $-MG/r$, we can put the limit of Eq. (9.4.15) for $r \to \infty$ in the form

$$2t(t,b) \to 2r + 2MG\ln(2r) + f(b) \tag{9.4.16}$$

where

$$\begin{aligned} f(b) =& -2MG\ln b + 2\int_b^\infty \left(1-\left(\frac{b}{r}\right)^2\right)^{-1/2} \left(r\phi'(r)-\phi(r)-\frac{2MG}{r}\right) dr \\ &+ 2\int_b^\infty \left(1-\left(\frac{b}{r}\right)^2\right)^{-3/2} \left(\frac{b}{r}\right)^2 (\phi(r)-\phi(b))dr \end{aligned} \tag{9.4.17}$$

The first two terms in Eq. (9.4.16) diverge for $r \to \infty$, but they are independent of b, so when we calculate the time difference between the arrival of fluctuations in different images of the source we need only to take account of the differences in $f(b)$ for various values of b. But this would give the delay in the time used in the metric (9.4.12), which is the time told by clocks that are far enough from the lens to ignore the lens's gravitational potential, but close enough to ignore cosmological effects. Because of the cosmological redshift, the time delay observed on earth is lengthened by a factor $1+z_L$, so the potential time delay is

$$\Delta t_{\rm pot} = (1+z_L)\,f(b). \tag{9.4.18}$$

For instance, if the lens is a point mass then $\phi = -MG/r$, so the first integral in Eq. (9.4.17) vanishes and the second integral is independent of b, so the gravitational potential of the lens produces a difference in time between the arrival of fluctuations in images of the source at angles β_1 and β_2 to the image of the lens, given by

$$\begin{aligned} \Delta t_{\rm pot}(\beta_1) - \Delta t_{\rm pot}(\beta_2) &= 2MG(1+z_L)\ln(b_2/b_1) \\ &= 2MG(1+z_L)\ln(\beta_2/\beta_1)\,. \end{aligned}$$

Evidently, the potential time delay will generally be of order MG. As shown for instance in Eq. (9.1.5), if $d_A(EL), d_A(ES)$, and $d_A(LS)$ are all of the same order d, then for strong lensing the squared angle $(\beta-\alpha)^2$ is generally of order MG/d, so the geometric time delay (9.4.11) is also of order MG. For a galaxy of 10^{11} solar masses this is 5.7 days. Measurement of this delay can be used to measure the mass of the lens, without needing to know the Hubble constant. We have seen that the measurement of the angles between the source image and the lens can tell us H_0MG, while the measurement of these angles and time delays can tell us MG, so the combination of angular and time-delay measurements can yield a value of H_0. Here is a list of several lenses that have been used in this way:

- QSO 0957+561: Two images separated by $6.1''$, $z_L = 1.41, z_S = 0.36$, with time difference 417 ± 3 days (95%), gave $H_0 = 64 \pm 13$ kmsec^{-1}Mpc^{-1}, [5] subsequently recalculated [6] as 77^{+29}_{-24} kmsec^{-1}Mpc^{-1}.

- B 0218+357 : Two images separated by $0.335''$ and an Einstein ring, $z_S = 0.96, z_L = 0.68$, time difference 10.5 ± 0.4 days, gave $H_0 = 69^{+13}_{-19}$kmsec^{-1}Mpc^{-1}.7

- PKS 1830-211: Two images separated by $1.0''$, plus an Einstein ring, $z_L = 0.89$, time difference 26^{+4}_{-5} days (8.6 GHz). [8] Source redshift measured as $2.507 \pm .002$, gave $H_0 = 65^{+15}_{-9}$ kmsec^{-1}Mpc^{-1} for $\Omega_M = 1$, $\Omega_\Lambda = 0, H_0 = 76^{+19}_{-10}$ kmsec^{-1}Mpc^{-1} for $\Omega_M = 0.3, \Omega_\Lambda = 0.7$.[9]

- B 1608+656: four lensed images, with three time differences from four to ten weeks, gave $H_0 = 75$ kmsec^{-1}Mpc$^{-1} \pm 10\%$.[10]

A table of time delay measurements up to 2003 is given in the review article of Kochanek and Schecter. [11] In 2006, a survey [12] of time delays in ten gravitational lenses (under the assumptions that $\Omega_M = 0.3$ and $\Omega_\Lambda = 0.7$, and with a number of parameters for each lens found by requiring that all give the same Hubble constant) gave $H_0 = 75^{+7}_{-12}$ kmsec^{-1}Mpc^{-1}.

10.9.7 9.5 Weak lensing

For cosmology, the most promising application of gravitational lenses probably lies in surveys of weak lensing, the study of the distortion of the images of distant galaxies by numerous small deflections of light as it passes from the galaxies to us through a slightly inhomogeneous distribution of matter. Consider a ray of light from a point source on a distant galaxy at co-moving coordinates $r_S\hat{n}$, where $\hat{n}$ is a unit vector. Whether the intervening lenses are galaxies or clusters of galaxies or concentrations of intergalactic matter, we can think of the total deflection of the light ray as the sum of deflections caused by encounters with point lenses L of mass m_L, at positions $\mathbf{x}_L$. (Since we will be considering only terms of first order in the total deflection, we can think of the lenses as individual particles, even if they are aggregated into extended objects.) For weak lensing, the angle α_L between the directions to the source and the lens is much larger than the "Einstein ring" parameter β_{EL} for lens L, so as we have seen there is only a single image, given by taking the + sign in Eq. (9.1.6), which with $\alpha \ll \beta_E$ gives the amount of the deflection caused by the lens as $\beta_{+L} - \alpha_L = \beta_{EL}^2/\alpha_L$. We decompose the co-moving lens coordinate vector $\mathbf{x}_L$ into components parallel and perpendicular to the light ray:

$$\mathbf{x}_L = r_L\hat{n} + \mathbf{y}_L, \quad r_L \equiv \hat{n} \cdot \mathbf{x}_L, \quad \mathbf{y}_L \equiv \mathbf{x}_L - \hat{n}\,(\hat{n} \cdot \mathbf{x}_L) \tag{9.5.1}$$

The lens L deflects the light ray in a direction $-\hat{y}_L$, so the total deflection caused by all the lenses is

$$\Delta\hat{n} = -\sum_L \hat{y}_L\beta_{EL}^2/\alpha_L = -\sum_L \hat{y}_L \frac{4M_L G d_A(LS)}{d_A(ES)d_A(EL)\alpha_L} \tag{9.5.2}$$

where for any points P and Q, $d_A(PQ)$ is the angular diameter distance of Q as seen from P. According to the definition of the angular diameter distance $d_A(EL)$ of the lens as seen from the earth, the angle between the directions to the source and the lens is $\alpha_L = a_L |\mathbf{y}_L| / d_A(EL)$, where a_L is the Robertson-Walker scale factor at the time that the light passes the lens L. Also, it is convenient to use Eq. (9.1.2) to write $d_A(LS) = a(t_S)\, r(r_L, r_S)$ and $d_A(ES) = a(t_S)\, r_S$, where t_S is the time the light leaves the source, and $r(r_L, r_S)$ and r_S are the radial coordinates of the source in RobertsonWalker coordinate systems centered on the lens and the earth, respectively. According to Eq. (9.2.15),

$$r(r_L, r_S) = r_S\sqrt{1 - Kr_L^2} - r_L\sqrt{1 - Kr_S^2} \tag{9.5.3}$$

The deflection is then

$$\Delta\hat{n} = -\sum_L \mathbf{y}_L \frac{4M_L G r(r_L, r_S)}{r_S a_L |\mathbf{y}_L|^2} \tag{9.5.4}$$

This is not in itself a useful result, because we do not generally know where the image of a point on the source would be if there were no lenses. It is more interesting to consider the variation of the deflection with position of the ray origin. Suppose we consider a small change $\boldsymbol{\theta}$ in the undeflected direction $\hat{n}$ to the ray origin, with $\boldsymbol{\theta}$ perpendicular to $\hat{n}$ and $|\boldsymbol{\theta}| \ll 1$. The change in the vector $\mathbf{y}_L$ from the light ray to lens L at the point of closest approach due to the displacement of the source is then

$$\delta\mathbf{y}_L = -\boldsymbol{\theta}(\hat{n} \cdot \mathbf{x}_L) - \hat{n}(\boldsymbol{\theta} \cdot \mathbf{x}_L)$$

Dropping the term proportional to $\hat{n}$, we see that to first order the change in the deflection of the image normal to the line of sight is

$$\Delta\theta_a = \sum_a M_{ab}(r_S, \hat{n})\, \theta_b \tag{9.5.5}$$

with a and b running over two orthogonal directions normal to $\hat{n}$, and $M_{ab}(r_S, \hat{n})$ the 2×2 shear matrix for images of a source at a distance r_S :

$$M_{ab}(r_S, \hat{n}) = \sum_L \frac{4M_L G r(r_L, r_S)\, r_L}{r_S a_L} \left(\frac{\delta_{ab}}{|\mathbf{y}_L|^2} - \frac{2y_{La}y_{Lb}}{|\mathbf{y}_L|^4} \right) \tag{9.5.6}$$

It is conventional to write this matrix as

$$M = \begin{pmatrix} \kappa + \gamma_1 & \gamma_2 \\ \gamma_2 & \kappa - \gamma_1 \end{pmatrix}, \tag{9.5.7}$$

with κ called the convergence and γ_i known as the shear field.
We may conveniently rewrite the shear matrix in terms of the perturbation to the total Newtonian potential due to the lenses: [1]
$\delta\phi(\mathbf{x}, t) = -\sum_L \frac{M_L G}{a_L |\mathbf{x} - \mathbf{x}_L(t)|} = -\sum_L \frac{M_L G}{a_L \left((r - r_L(t))^2 + (\mathbf{y} - \mathbf{y}_L(t))^2\right)^{1/2}}$,

where $\mathbf{x} = r\hat{n} + \mathbf{y}$ with $\hat{n} \cdot \mathbf{y} = 0$. (We are here explicitly taking into account the fact that the lenses may have a time dependence, as for instance from peculiar motion or cosmological evolution. In Eq. (9.5.6) we are using the abbreviations

$$r_L \equiv r_L(t_{r_L}), \quad \mathbf{y}_L \equiv \mathbf{y}_L(t_{r_L})$$

[471] We can neglect the effect of lenses at a cosmological distance from the light ray, so the denominator, including the factor a_L, is the proper distance to the lens L. We are here representing the complete perturbation to the mass density as a set of lensing point masses, but since these may be particles as well as galaxies, this introduces no loss of generality.

where t_r is the time that a light wave that reaches us at the present moment was at a radial coordinate r, given by $r = \int_0^{t_r} dt/a(t)$.) In particular, the second transverse derivatives of the potential on the light ray are

$$\left[\frac{\partial^2}{\partial y_a \partial y_b}\delta\phi(r\hat{n}+\mathbf{y},t)\right]_{\mathbf{y}=0} = \sum_L \frac{M_L G}{a_L}\left(\frac{\delta_{ab}}{\left((r-r_L(t))^2+|\mathbf{y}_L(t)|^2\right)^{3/2}} - \frac{3y_{La}(t)y_{Lb}(t)}{\left((r-r_L(t))^2+|\mathbf{y}_L(t)|^2\right)^{5/2}}\right)$$

The functions $\left((r-r_L)^2+|\mathbf{y}_L|^2\right)^{-3/2}$ and $\left((r-r_L)^2+|\mathbf{y}_L|^2\right)^{-5/2}$ are sharply peaked at $r = r_L$, so the integral of this second derivative times any smooth function $f(r)$ (smooth, in the sense that it varies little when r varies by an amount of order $|\mathbf{y}_L|$) is

$$\int f(r)dr\left[\frac{\partial^2}{\partial y_a \partial y_b}\delta\phi(r\hat{n}+\mathbf{y},t)\right]_{\mathbf{y}=0,t=t_r} = \sum_L \frac{f(r_L)\,M_L G}{a_L}\left(\frac{2\delta_{ab}}{|\mathbf{y}_L|^2} - \frac{4y_{La}y_{Lb}}{|\mathbf{y}_L|^4}\right)$$

Comparing this with Eq. (9.5.6), we see that the shear matrix M_{ab} for a source at radial coordinate r_S is

$$M_{ab}(r_S,\hat{n}) = 2\int_0^{r_S}\frac{r(r,r_S)\,r}{r_S}\left[\frac{\partial^2}{\partial y_a \partial y_b}\delta\phi(r\hat{n}+\mathbf{y},t)\right]_{\mathbf{y}=0,t=t_r} dr \tag{9.5.9}$$

So measurement of the shear matrix can yield information about perturbations to the gravitational potential by masses al a the line of sight. In particular, by contracting the indices a and b, we see that

$$\kappa = \frac{1}{2}\,\mathrm{Tr}\,M = \int_0^{r_S}\frac{r(r,r_S)\,r}{r_S}\left[\left(\nabla^2 - \frac{\partial^2}{\partial r^2}\right)\delta\phi(r\hat{n}+\mathbf{y},t)\right]_{\mathbf{y}=0,t=t_r} dr$$

If the lensing is due to a collection of bodies (such as a cluster of galaxies), all at about the same radial coordinate r_L, then $\delta\phi$ falls off rapidly for large values of $|r-r_L|$, so that the factor $r(r,r_S)\,r$ can be replaced with $r(r_L,r_S)\,r_L$, and the integral of $\partial^2\delta\phi/\partial^2 r$ can then be set equal to zero. Using the Poisson equation $a^{-2}\nabla^2\delta\phi = 4\pi G\delta\rho_M$, we can write the resulting expression in terms of the density fluctuation $\delta\rho_M$:

$$\kappa = \frac{4\pi G a^2(t_{r_L})\,d_A(LS)d_A(EL)}{d_A(ES)}\int \delta\rho_M(r\hat{n},t_{r_L})\,a(t_{r_L})\,dr \tag{9.5.10}$$

the integral being taken over a range of r passing through the lens. Hence, assuming that we know the angular diameter distances appearing in Eq. (9.5.10), a measurement of the value of κ for sources seen in some direction can tell us the total mass density of a cluster of lensing masses that lie along that line of sight, projected onto the plane normal to the line of sight.

Now let's consider how the lensing of the images of galaxies can be used to measure the shear matrix. In order to deal with galaxies that are irregularly shaped, it is convenient to describe the shape of a galaxy by a quadrupole matrix:

$$Q_{ab} \equiv \frac{\int d^2\theta\mathcal{L}(\boldsymbol{\theta})\theta_a\theta_b}{\int d^2\theta\mathcal{L}(\boldsymbol{\theta})} \tag{9.5.11}$$

Here the integral is over the transverse displacement $\boldsymbol{\theta}$ of the direction of points on the image of the galaxy from some central point; the indices a, b, etc. run over two orthogonal

directions in the plane of this image; and $\mathcal{L}$ is the surface brightness-the apparent luminosity per solid angle-of the image. (In order for the integral in the numerator to converge, it may be necessary to replace $\mathcal{L}$ by some function of $\mathcal{L}$, such as one that equals $\mathcal{L}$ when $\mathcal{L}$ is above some threshold brightness, and otherwise vanishes. This has no effect on the following analysis.) As remarked in Section 9.2, the surface brightness of any point is the same as would be seen in the absence of lensing from the same point on the source, so

$$\mathcal{L}((1+M)\boldsymbol{\theta}) = \mathcal{L}^s(\boldsymbol{\theta}) \tag{9.5.12}$$

where $\mathcal{L}^s$ is the surface brightness of the source in the absence of lensing. Introducing a new variable of integration $\boldsymbol{\theta}'$ in Eq. (9.5.11) by writing $\theta_a = (1+M)_{ab}\theta'_b$ and using Eq. (9.5.12), we have

$$\int d^2\theta \mathcal{L}(\boldsymbol{\theta})\theta_a\theta_b = (1+M)_{ac}(1+M)_{bd}\,\mathrm{Det}(1+M)\int d^2\theta' \mathcal{L}^s\left(\boldsymbol{\theta}'\right)\theta'_c\theta'_d$$

and likewise

$$\int d^2\theta \mathcal{L}(\boldsymbol{\theta}) = \mathrm{Det}(1+M)\int d^2\theta' \mathcal{L}^s\left(\boldsymbol{\theta}'\right)$$

The determinant cancels in the ratio, so (dropping primes) we have

$$Q_{ab} = (1+M)_{ac}(1+M)_{bd}Q^s_{cd} \tag{9.5.13}$$

where Q^s is the quadrupole matrix in the absence of lensing

$$Q^s_{ab} \equiv \frac{\int d^2\theta \mathcal{L}^s(\boldsymbol{\theta})\theta_a\theta_b}{\int d^2\theta \mathcal{L}^s(\boldsymbol{\theta})} \tag{9.5.14}$$

For simplicity of presentation, we will limit ourselves here to the case of lensing that is sufficiently weak so that all elements of M have $|M_{ab}| \ll 1$, the case of greatest interest in cosmology. In this case (9.5.13) becomes

$$Q_{ab} = Q^s_{ab} + M_{ac}Q^s_{cb} + M_{db}Q^s_{ad} \tag{9.5.15}$$

Of course, we would not know the unlensed quadrupole matrix for any particular galaxy. But if we have a sample of galaxies in about the same direction and with about the same redshift, so that the shear matrix is the same for all the galaxies in this sample, then we can learn something about this shear matrix by making the reasonable assumption that the orientations of the galaxies are uncorrelated. There are at least two ways that this can be done.

Standard method [2]

In the standard method, one considers the ellipticity matrices

$$X_{ab} \equiv Q_{ab}/\,\mathrm{Tr}\,Q, \quad X^s_{ab} \equiv Q^s_{ab}/\,\mathrm{Tr}\,Q^s \tag{9.5.16}$$

which are normalized to have unit trace. To first order in M, Eq. (9.5.15) gives

$$X_{ab} = X^s_{ab} + M_{ac}X^s_{cd} + M_{bd}X^s_{ad} - 2X^s_{ab}\,\mathrm{Tr}\left(MX^s\right). \tag{9.5.17}$$

If the orientation of galaxies is random, then the average of X^s_{ab} over a sufficiently large sample will be proportional to δ_{ab}, and since these matrices are defined to have unit trace, it follows that the coefficient of proportionality must be just $1/2$:

$$\langle X^s_{ab} \rangle = \frac{1}{2}\delta_{ab}. \tag{9.5.18}$$

To deal with the term in Eq. (9.5.17) that is quadratic in X^s, we also need the average of $X^s_{ab}X^s_{cd}$. The random orientation of the galaxies and the symmetry of the product requires this average to be a linear combination of $\delta_{ab}\delta_{cd}$

and $\delta_{ac}\delta_{bd} + \delta_{ad}\delta_{bc}$, and since X^s has unit trace, this linear combination must take the form

$$\langle X^s_{ab}X^s_{cd} \rangle = \frac{1}{4}\left[\delta_{ab}\delta_{cd} + \xi\left(\delta_{ac}\delta_{bd} + \delta_{ad}\delta_{bc} - \delta_{ab}\delta_{cd}\right)\right], \tag{9.5.19}$$

where, contracting a, b with c, d in Eq. (9.5.19),

$$\xi = \left\langle \mathrm{Tr}\left(X^{s2}\right)\right\rangle - 1/2. \tag{9.5.20}$$

(For instance, if the galaxies in our sample are all spheres, then X^s has both eigenvalues equal to 1/2, and $\xi = 0$, while if they are all extremely prolate ellipsoids then one eigenvalue is unity and the other is zero, and $\xi = 1/2$. More generally, $0 \leq \xi \leq 1/2$.) Taking the average of Eq. (9.5.17) and using Eqs. (9.5.18) and (9.5.19), we have

$$\langle X_{ab} \rangle = \frac{1}{2}\delta_{ab} + (1-\xi)\left(M_{ab} - \frac{1}{2}\delta_{ab}\,\mathrm{Tr}\,M\right). \tag{9.5.21}$$

We do not observe the average of $\mathrm{Tr}\,(X^{s2})$ that appears in our formula (9.5.20) for ξ, but since ξ appears only in (9.5.21) multiplying a term that is already of first order in M, in calculating $\langle X_{ab} \rangle$ to first order in M we only need ξ to zeroth order, and to this order we can replace X^s in Eq. (9.5.20) with the observed ellipticity matrix X :

$$\xi = \left\langle \mathrm{Tr}\left(X^2\right)\right\rangle - 1/2. \tag{9.5.22}$$

This can be measured from the observed shapes of the galaxies in our sample, and Eq. (9.5.21) can then be used to find the traceless part of the shear matrix from a measurement of the average of the observed ellipticity matrix X.

A word on formalism: In the literature, in place of the real ellipticity matrix, one often encounters a complex ellipticity parameter

$$\chi \equiv X_{11} - X_{22} + 2iX_{12}, \tag{9.5.23}$$

and in place of Eq. (9.5.21) one finds a formula relating the complex shear parameter $\gamma \equiv \gamma_1 + i\gamma_2$ to averages of functions of the ellipticity parameter [3]

$$\langle \chi \rangle = 2\gamma - 2\left\langle \chi\,\mathrm{Re}\left(\chi^*\gamma\right)\right\rangle. \tag{9.5.24}$$

Using Eq. (9.5.19), it is easy to see that the average on the right is

$$\left\langle \chi\,\mathrm{Re}\left(\chi^*\gamma\right)\right\rangle = \xi\gamma, \tag{9.5.25}$$

and that therefore the relation (9.5.24) between χ and γ reads

$$\left\langle \frac{Q_{11} - Q_{22} + 2iQ_{12}}{Q_{11} + Q_{22}} \right\rangle = 2(1-\xi)\left(\gamma_1 + i\gamma_2\right), \tag{9.5.26}$$

which is the same as Eq. (9.5.21).

[472] See, e.g., M. Bartelmann and P. Schneider, Phys. Rep. 340, 291 (2001).

[473] P. Schneider and C. Seitz, Astron. Astrophys. 294, 411 (1995). This is Eq. (4.16) of ref. 2, in the limit $|\gamma_i| \ll 1$ and $|\kappa| \ll 1$.

Alternative method

It is possible to avoid the need to measure the parameter ξ for a sample of source galaxies, by considering averages of the quadrupole matrix Q_{ab} itself, rather than the matrix X_{ab} normalized to have unit trace. The random orientation of galaxies in our sample of sources tells us that the average of unlensed quadrupole matrices takes the form

$$\langle Q^s_{ab} \rangle = \frac{1}{2} \bar{Q} \delta_{ab} \tag{9.5.27}$$

with $\bar{Q}$ an unknown positive constant. Eq. (9.5.15) then gives

$$\langle Q_{ab} \rangle = \bar{Q} \left[\frac{1}{2} \delta_{ab} + M_{ab} \right] \tag{9.5.28}$$

We can eliminate the unknown $\bar{Q}$ by dividing by the average of the trace of the quadrupole moment. Eq. (9.5.28) and its trace give, to first order in M,

$$\frac{\langle Q_{ab} \rangle}{\langle \mathrm{Tr}\, Q \rangle} = \frac{1}{2} \delta_{ab} + M_{ab} - \frac{1}{2} \delta_{ab}\, \mathrm{Tr}\, M \tag{9.5.29}$$

That is,

$$\gamma_1 + i\gamma_2 = \frac{\langle Q_{11} - Q_{22} + 2iQ_{12} \rangle}{2 \langle Q_{11} + Q_{22} \rangle} \tag{9.5.30}$$

Thus we can calculate the traceless part of M_{ab} - that is, the shear field - from a measurement of the average quadrupole tensor, with no need to make a separate measurement of a parameter like ξ.

The difference between the standard and alternative methods is not just one of formalism, for they involve different kinds of averages. In the alternative method galaxies are weighted proportionally to the area of their images, while in the standard method all galaxies are weighted equally. Thus in the alternative method one does not have to worry so much about missing galaxies of small apparent area.

Frequently it is not practical to measure the redshifts of the individual galaxies whose images are distorted by weak lensing. In such cases we must assume that there is some probability distribution $\mathcal{N}(r_S)$ for these galaxies to be at a radial coordinate r_S, with $\int_0^\infty \mathcal{N}(r_S)\, dr_S = 1$. Using the alternative method described above, we can still use Eq. (9.5.29) to calculate the traceless part of the shear matrix from the average observed quadrupole matrix, but
now the average of the quadrupole matrix is calculated using all galaxies along a given line of sight, and the shear matrix is replaced with an effective shear matrix

$$\begin{aligned} M_{ab}(\hat{n}) &= \int_0^\infty \mathcal{N}(r_S)\, M_{ab}(r_S, \hat{n})\, dr_S \\ &= 2 \int_0^\infty \mathcal{N}(r_S)\, dr_S \int_0^{r_S} \frac{r(r, r_S)\, r}{r_S} \left[\frac{\partial^2}{\partial y_a \partial y_b} \delta\phi(r\hat{n} + \mathbf{y}, t_r) \right]_{\mathbf{y}=0} dr \\ &= \int_0^\infty \left[\frac{\partial^2}{\partial y_a \partial y_b} \delta\phi(r\hat{n} + \mathbf{y}, t_r) \right]_{\mathbf{y}=0} g(r) dr \end{aligned} \tag{9.5.31}$$

where

$$g(r) \equiv 2 \int_r^\infty \frac{r(r, r_S)\, r}{r_S} \mathcal{N}(r_S)\, dr_S \tag{9.5.32}$$

Similarly, using the standard method we can still calculate the traceless part of the effective shear matrix from the mean ellipticity matrix, provided there is no evolution in the shape of galaxies. In this case, Eq. (9.5.21) still applies, but with the shear matrix given by Eq. (9.5.31), and with the average squared ellipticity matrix in our formula (9.5.22) for the ξ parameter calculated by averaging over all galaxies along the line of sight. But if galaxy shapes evolve, then Eq. (9.5.31) must be modified accordingly: Instead of a factor $1-\xi$ multiplying the shear matrix in Eq. (9.5.21), it is necessary to use Eq. (9.5.22) to calculate a function $\xi(r_S)$ from the average of the squared ellipticity matrix of galaxies at a radial coordinate r_S, and include a factor $1-\xi(r_S)$ in the integrand of Eq. (9.5.31). This complication does not occur with the alternative method.

Whichever method we use to extract the shear matrix from measurements of weak lensing, we now must face a problem. We would like to use weak lensing measurements to learn about the density perturbation $\delta\rho$, but as shown in Eq. (9.5.10), it is only the convergence κ that is related in any simple way to the density perturbation, while Eqs. (9.5.21) and (9.5.29) show that measurements of weak lensing tell us about the shear field γ_i, not κ. Fortunately, although there is no simple relation between γ_i and κ, there is a simple relation among their gradients. [4] From Eq. (9.5.9), we have

$$\frac{\partial}{\partial\hat{n}_c}M_{ab}(r_S,\hat{n}) = 2\int_0^{r_S}\frac{r(r,r_S)}{r_S}\left[\frac{\partial^3}{\partial y_a\partial y_b\partial y_c}\delta\phi(r\hat{n}+\mathbf{y},t)\right]_{\mathbf{y}=0,t=t_r}dr \tag{9.5.33}$$

Similarly, from Eq. (9.5.31), we have

$$\frac{\partial}{\partial\hat{n}_c}M_{ab}(\hat{n}) = \int_0^{\infty}\left[\frac{\partial^3}{\partial y_a\partial y_b\partial y_c}\delta\phi(r\hat{n}+\mathbf{y},t_r)\right]_{\mathbf{y}=0}\frac{g(r)}{r}dr \tag{9.5.34}$$

The important point is that both expressions are completely symmetric among a, b, and c. Thus the divergence of the traceless part of the shear matrix is proportional to the gradient of the trace:

$$\frac{\partial}{\partial\hat{n}_a}\left(M_{ab}-\frac{1}{2}\delta_{ab}\,\mathrm{Tr}\,M\right) = \frac{1}{2}\frac{\partial}{\partial\hat{n}_b}\,\mathrm{Tr}\,M \tag{9.5.35}$$

where M can be either $M(r_S,\hat{n})$ or $M(\hat{n})$. In other words,

$$\frac{\partial\kappa}{\partial\hat{n}_1} = \frac{\partial\gamma_1}{\partial\hat{n}_1}+\frac{\partial\gamma_2}{\partial\hat{n}_2},\quad \frac{\partial\kappa}{\partial\hat{n}_2} = \frac{\partial\gamma_2}{\partial\hat{n}_1}-\frac{\partial\gamma_1}{\partial\hat{n}_2}. \tag{9.5.36}$$

Thus κ can be calculated from the shear field γ_i, up to an $\hat{n}$-independent constant. As mentioned earlier, the values of κ obtained in this way can be used to measure the projected mass density of lensing bodies along the line of sight. Starting in the late 1990s, numerous groups using telescopes of moderate size have detected shear due to weak lensing. [5] These measurements, together with the above analysis, have been used to map out the distribution of all matter, dark as well as baryonic, in various clusters of galaxies, such as the bullet cluster 1E0657-558 described in Section 3.4.

Now let us turn to the application of weak lensing to find the distribution of inhomogeneities in the cosmological mass density. In using weak lensing to study the large scale distribution of matter in the universe, we are not so much interested in the shear matrix in any one direction, as in its distribution around the sky. Fluctuations in the gravitational potential have random sign, so the average over the sky of the shear matrix is zero. It is most useful to consider instead the average of the product of shear matrix elements along two different lines of sight, with "average" understood in the same sense as used in the analysis of fluctuations in the cosmic

[474] N. Kaiser, Astrophys. J. 439, L1 (1995).

microwave background: either an average over positions from which the sky might be observed, or an average over the particular series of accidents that lead to a particular distribution of cosmic matter. Neither average corresponds to what we observe, but the difference vanishes for large multipole orders, for

the same reason as explained in Section 2.6 for the multipole coefficients of anisotropies in the cosmic microwave background.

Since we are now considering different directions, it is convenient to write the definition (9.5.7) of the convergence and shear fields more explicitly. If we write $\hat{n}$ in terms of polar and azimuthal angles as

$$\hat{n} = (\sin\vartheta\cos\varphi, \sin\vartheta\sin\varphi, \cos\vartheta), \tag{9.5.37}$$

and take the two orthogonal directions normal to $\hat{n}$ as

$$\hat{\vartheta} = (\cos\vartheta\cos\varphi, \cos\vartheta\sin\varphi, -\sin\vartheta), \quad \hat{\varphi} = (-\sin\varphi, \cos\varphi) \tag{9.5.38}$$

then

$$\kappa(\hat{n}) + \gamma_1(\hat{n}) = \hat{\vartheta}_i\hat{\vartheta}_j M_{ij}(\hat{n}), \tag{9.5.39}$$

$$\kappa(\hat{n}) - \gamma_1(\hat{n}) = \hat{\varphi}_i\hat{\varphi}_j M_{ij}(\hat{n}), \tag{9.5.40}$$

$$\gamma_2(\hat{n}) = \hat{\vartheta}_i\hat{\varphi}_j M_{ij}(\hat{n}). \tag{9.5.41}$$

We are here using ϑ and φ instead of the usual θ and ϕ for the polar and azimuthal angles, to avoid confusion with other uses of the symbols θ and ϕ in this section. Also, since we will now be considering different directions $\hat{n}$, we have promoted the two-valued indices a, b, etc. to three-valued indices i, j, etc. Eq. (9.5.31) for the 2×2 shear matrix M_{ab} has accordingly been extended to give a 3×3 matrix

$$M_{ij}(\hat{n}) \equiv \int_0^\infty \left[\frac{\partial^2}{\partial x_i \partial x_j}\delta\phi(\mathbf{x}, t)\right]_{\mathbf{x}=r\hat{n}, t=t_r} g(r)dr \tag{9.5.42}$$

Equivalently, we can write

$$\gamma(\hat{n}) \equiv \gamma_1(\hat{n}) + i\gamma_2(\hat{n}) = e_{+i}(\hat{n})e_{+j}(\hat{n})M_{ij}(\hat{n}), \tag{9.5.43}$$

where, as in Section 7.4, $\mathbf{e}_+ \equiv (\hat{\vartheta} + i\hat{\varphi})/\sqrt{2}$. Also, since $\hat{\vartheta}$ and $\hat{\varphi}$ span the space normal to $\hat{n}$,

$$\kappa(\hat{n}) = \frac{1}{2}\left(\delta_{ij} - \hat{n}_i\hat{n}_j\right) M_{ij}(\hat{n}) \tag{9.5.44}$$

The expansion of the convergence in spherical harmonics follows along almost the same lines as the expansion of microwave background temperature fluctuations described in Sections 2.6 and 7.2. We write the perturbation in the gravitational potential as

$$\delta\phi(\mathbf{x}, t) = \int d^3q\,\alpha(\mathbf{q})\delta\phi_q(t)e^{i\mathbf{q}\cdot\mathbf{x}} \tag{9.5.45}$$

where $\alpha(\mathbf{q})$ is the stochastic parameter for scalar perturbations, normalized so that

[475] For references to these observations and a brief general review, see D. Munshi and P. Valageas, Roy. Soc. London Trans. Ser. A 363, 2675 (2001) [astro-ph/0509216]. Comprehensive reviews of weak lensing are given by P. Schneider and M. Bartelmann, ref. 2; A. Refrigier, Ann. Rev. Astron. Astrophys. 41, 645 (2003); P. Schneider, in Gravitational Lensing: Strong, Weak, and Micro, eds. G. Meylan et al. (Springer-Verlag, Berlin, 2006): 269 [astro-ph/0509252].

$$\langle \alpha(\mathbf{q})\alpha^*(\mathbf{q}')\rangle = \delta^3(\mathbf{q}-\mathbf{q}'). \tag{9.5.46}$$

Then Eqs.(9.5.42), (9.5.44), and (9.5.45) give

$$\kappa(\hat{n}) = -\frac{1}{2}\int d^3q\alpha(\mathbf{q})\int_0^\infty g(r)\delta\phi_q(t_r)\left(\mathbf{q}^2-(\mathbf{q}\cdot\hat{n})^2\right)e^{i\mathbf{q}\cdot\hat{n}r}dr$$

The quantity $-(\mathbf{q}\cdot\hat{n})^2$ can be replaced with $\partial^2/\partial r^2$, and for the exponential we can use the familiar formula

$$e^{i\mathbf{q}\cdot\hat{n}r} = 4\pi\sum_{\ell m} i^\ell j_\ell(qr)Y_\ell^m(\hat{n})Y_\ell^{m*}(\hat{q}). \tag{9.5.47}$$

This gives the partial wave expansion for the convergence

$$\kappa(\hat{n}) = \sum_{\ell m} a_{\kappa,\ell m}Y_\ell^m(\hat{n}), \tag{9.5.48}$$

with coefficients

$$\begin{aligned} a_{\kappa,\ell m} = &-2\pi i^\ell\int d^3qq^2\alpha(\mathbf{q})Y_\ell^{m*}(\hat{q}) \\ &\times\int_0^\infty g(r)\delta\phi_q(t_r)\left(j_\ell(qr)+j_\ell''(qr)\right)dr \end{aligned} \tag{9.5.49}$$

This can be used together with Eq. (9.5.46) to calculate the correlation of the convergence with itself, or with microwave background temperature fluctuations or any other scalar perturbations. In particular, for the correlation of the convergence with itself, we have

$$\left\langle a_{\kappa,\ell m}a_{\kappa,\ell'm'}^*\right\rangle = \delta_{\ell\ell'}\delta_{mm'}C_{\kappa\kappa,\ell}, \tag{9.5.50}$$

where $C_{\kappa\kappa,\ell}$ is the multipole coefficient

$$C_{\kappa\kappa,\ell} = 4\pi^2\int_0^\infty q^6dq\left|\int_0^\infty g(r)\delta\phi_q(t_r)\left(j_\ell(qr)+j_\ell''(qr)\right)dr\right|^2. \tag{9.5.51}$$

On the other hand, comparing Eqs. (9.5.43) and (7.4.6), we see that the shear components $\gamma_1(\hat{n})$ and $\gamma_2(\hat{n})$ involve the polarization $\mathbf{e}_+(\hat{n})$ in much the same way as the Stokes parameters $Q(\hat{n})$ and $U(\hat{n})$, so for the same reason as in Section 7.4, it is necessary to expand the complex shear parameter $\gamma_1(\hat{n})+i\gamma_2(\hat{n})$ in the spin 2 spherical harmonics $\mathcal{Y}_\ell^m(\hat{n})$, defined by Eq. (7.4.16):

$$\mathcal{Y}_\ell^m(\hat{n}) \equiv 2\sqrt{\frac{(\ell-2)!}{(\ell+2)!}}e_{+i}(\hat{n})e_{+j}(\hat{n})\tilde{\nabla}_i\tilde{\nabla}_jY_\ell^m(\hat{n}), \tag{9.5.52}$$

where $\tilde{\nabla}$ is the angular part of the gradient operator:

$$\tilde{\nabla} \equiv \hat{\vartheta}\frac{\partial}{\partial\vartheta}+\frac{\hat{\varphi}}{\sin\vartheta}\frac{\partial}{\partial\varphi}. \tag{9.5.53}$$

Using Eqs. (9.5.42), (9.5.43), (9.5.45), and (9.5.47), we have

$$\gamma_1(\hat{n})+i\gamma_2(\hat{n}) = \sum_{\ell m}a_{\gamma,\ell m}\mathcal{Y}_\ell^m(\hat{n}) \tag{9.5.54}$$

with coefficients

$$a_{\gamma,\ell m} = 2\pi i^\ell \sqrt{\frac{(\ell+2)!}{(\ell-2)!}} \int d^3q \alpha(\mathbf{q}) Y_\ell^m(\hat{q})^* \int_0^\infty \delta\phi_q(t_r)\, j_\ell(qr) g(r) r^{-2} dr \tag{9.5.55}$$

The reality of $\delta\phi(\mathbf{x},t)$ requires that $\alpha^*(\mathbf{q})\delta\phi_q^*(t) = \alpha(-\mathbf{q})\delta\phi_q(t)$, while $Y_\ell^{m*}(\hat{q}) = (-1)^\ell Y_\ell^{-m}(-\hat{q})$, so $a_{\gamma,\ell m} = a^*_{\gamma,\ell-m}$. That is, the shear produced by perturbations in the mass density is of " E " rather than " B " type, in the sense of Eq. (7.4.25). Thus any observation of B-type shear, for which $a_{\gamma,lm} = -a^*_{\gamma,l-m}$, would be a sign of lensing caused by something other than density perturbations, such as gravitational waves. Unfortunately, the lensing due to gravitational waves produced in inflation is much too small to be observed. [6]

Using (9.5.46) and the orthonormality of the spin 2 spherical harmonics,

$$\left\langle a_{\gamma,\ell m} a^*_{\gamma,\ell' m'} \right\rangle = \delta_{\ell\ell'}\delta_{mm'} C_{\gamma\gamma,\ell}, \tag{9.5.56}$$

where the multipole coefficients in shear-shear correlations are

$$C_{\gamma\gamma,\ell} = \frac{4\pi^2(\ell+2)!}{(\ell-2)!} \int_0^\infty q^2 dq \left| \int_0^\infty \delta\phi_q(t_r)\, j_\ell(qr) g(r) r^{-2} dr \right|^2 . \tag{9.5.57}$$

The Poisson equation $\nabla^2\delta\phi = 4\pi G a^2 \delta\rho_M$ relates the quantity $\delta\phi_q(t)$ appearing in Eqs. (9.5.51) and (9.5.57) the power spectral function $P(q/a_0)$ of fractional density fluctuations introduced in Section 8.1:

$$\begin{aligned} q^4 |\delta\phi_q(t)|^2 &= (4\pi G)^2 a^4(t) \bar{\rho}_M^2(t) |\delta_{Mq}(t)|^2 \\ &= (4\pi G)^2 a^4(t) \bar{\rho}^2(t) P(q/a_0) \left(\frac{F(t)}{F(t_0)} \right)^2 \\ &= \frac{9\Omega_M^2 H_0^4 a_0^3}{4a^2(t)(2\pi)^3} P(q/a_0) \left(\frac{F(t)}{F(t_0)} \right)^2 , \end{aligned} \tag{9.5.58}$$

with $F(t)$ the function (8.1.20), and $a_0 \equiv a(t_0)$.

It is possible to give less complicated formulas for the multipole coefficients in the most interesting case, of $\ell \gg 1$. Let us first consider the $\kappa\kappa$ correlation. We can evaluate the integral over r in Eq. (9.5.51) by recalling that for $\ell \gg 1$, if qr differs from $\ell + 1/2$ by more than an amount of order $\ell^{-1/3}$, the spherical Bessel function $j_\ell(qr)$ is exponentially small for $qr < \ell + 1/2$ and rapidly oscillating for $qr > \ell + 1/2$, while (unlike the source functions in microwave background anisotropies) all other ingredients in the integral vary slowly with r. For $\ell \gg 1$, we can therefore replace r with ℓ/q in $g(r)$ and t_r :

$$C_{\kappa\kappa,\ell} \to 4\pi^2 \int_0^\infty dq q^6 \left| \delta\phi_q\left(t_{\ell/q}\right) \right|^2 g^2(\ell/q) \left| \int_0^\infty \left(j_\ell(qr) + j_\ell''(qr) \right) dr \right|^2 \tag{9.5.59}$$

The integral of $j_\ell(qr)$ gives [7]

$$\int_0^\infty j_\ell(qr) dr = \frac{\sqrt{\pi}}{2q} \frac{\Gamma\left(\frac{\ell+1}{2}\right)}{\Gamma\left(\frac{\ell+2}{2}\right)} \to \frac{1}{q}\sqrt{\frac{\pi}{2\ell}} \tag{9.5.60}$$

On the other hand, since for large ℓ the contributions from $r \ll \ell/q$ and $r \gg \ell/q$ are strongly suppressed, we can drop the integral over r of $j_\ell''(qr)$. Thus Eq. (9.5.58) gives, for $\ell \gg 1$,

[476] S. Dodelson, E. Rozo, and A. Stebbins, Phys. Rev. Lett. 91, 021301 (2003).

$$
\begin{aligned}
C_{\kappa\kappa,\ell} &\to \frac{2\pi^3}{\ell}\int_0^\infty dqq^4\left|\delta\phi_q\left(t_{\ell/q}\right)\right|^2 g^2(\ell/q) \\
&= 2\pi^3\ell^4\int_0^\infty drr^{-5}\left|\delta\phi_{\ell/r}\left(t_r\right)\right|^2 g^2(r) \\
&= \frac{9\Omega_M^2 H_0^4 a_0^3}{16}\int_0^\infty dr\frac{g^2(r)}{a^2\left(t_r\right)r^2}P\left(\ell/a_0 r\right)\left(\frac{F\left(t_r\right)}{F\left(t_0\right)}\right)^2
\end{aligned}
\tag{9.5.61}
$$

The large ℓ limit of the $\gamma\gamma$ multipole coefficient is precisely the same. In this limit, the factor $(\ell+2)!/(\ell-2)!$ in Eq. (9.5.57) becomes ℓ^4, and the factor r^{-2} in the integral over r in Eq. (9.5.57) can be replaced with $(q/\ell)^2$, so for large ℓ the ratio of the integrand of the q-integral in Eq. (9.5.57) to that in Eq. (9.5.51) (dropping $j_\ell''(qr)$) is

$$
\frac{\ell^4 q^2(q/\ell)^4}{q^6} = 1
$$

Hence for large ℓ,

$$
C_{\gamma\gamma,\ell} \to C_{\kappa\kappa,\ell} \to \frac{9\Omega_M^2 H_0^4 a_0^3}{16}\int_0^\infty dr\frac{g^2(r)}{a^2\left(t_r\right)r^2}P\left(\ell/a_0 r\right)\left(\frac{F\left(t_r\right)}{F\left(t_0\right)}\right)^2 \tag{9.5.62}
$$

Thus we get just the same information by measuring the shear multipole coefficients at large ℓ as we would get if we could measure the convergence multipole coefficients at the same ℓ.

For a given weighting function $g(r)$ defined by Eq. (9.5.32), observation of the ℓ dependence of $C_{\gamma\gamma,\ell}$ (or $C_{\kappa\kappa,\ell}$) provides a measurement of the k dependence of the power spectral function $P(k)$. It should be noted that if the integral receives its main contribution from radial coordinates r such that vacuum energy has not yet become important by the times t_r, then according to Eq. (8.1.20), $F(t) \propto a(t)$, so Eq. (9.5.62) simplifies further, to

$$
C_{\gamma\gamma,\ell} \to C_{\kappa\kappa,\ell} \to \frac{9\Omega_M^2 H_0^4 a_0}{16}\int_0^\infty dr\frac{g^2(r)}{r^2}P\left(\ell/a_0 r\right) \tag{9.5.63}
$$

This is the formula usually quoted. [8]

We can express the correlation functions for the shear components and microwave background temperature fluctuations by taking over results we have already found for the correlation functions of microwave background polarization and temperature fluctuations. Comparing Eq. (9.5.54) with Eqs. (7.4.15) and (7.4.25), and comparing Eq. (9.5.56) with Eq. (7.4.28), we see that we can obtain the correlation functions for the shear components from Eqs. (7.4.76)-(7.4.78) by replacing Q and U with γ_1 and γ_2 and replacing $C_{EE,\ell}$ with $C_{\gamma\gamma,\ell}$ and (since shear is purely of E-type) dropping $C_{BB,\ell}$:

$$
\left\langle\gamma_1(\hat{n})\gamma_1\left(\hat{n}'\right)\right\rangle = \frac{1}{2}\sum_\ell C_{\gamma\gamma,\ell}\,\mathrm{Re}\left(F_\ell\left(\hat{n},\hat{n}'\right)+G_\ell\left(\hat{n},\hat{n}'\right)\right), \tag{9.5.64}
$$

$$
\left\langle\gamma_2(\hat{n})\gamma_2\left(\hat{n}'\right)\right\rangle = \frac{1}{2}\sum_\ell C_{\gamma\gamma,\ell}\,\mathrm{Re}\left(F_\ell\left(\hat{n},\hat{n}'\right)-G_\ell\left(\hat{n},\hat{n}'\right)\right), \tag{9.5.65}
$$

$$
\left\langle\gamma_1(\hat{n})\gamma_2\left(\hat{n}'\right)\right\rangle = \frac{1}{2}\sum_\ell C_{\gamma\gamma,\ell}\,\mathrm{Im}\left(-F_\ell\left(\hat{n},\hat{n}'\right)+G_\ell\left(\hat{n},\hat{n}'\right)\right), \tag{9.5.66}
$$

[477] This is a special case of formula 6.561.14 of I. S. Gradshteyn and I. M. Ryzhik, Table of Integrals, Series, and Products, ed. A. Jeffrey (Academic Press, New York, 1980).

where F_ℓ and G_ℓ are functions given by Eqs. (7.4.87) and (7.4.88):

$$F_\ell\left(\hat{n},\hat{n}'\right)=\frac{2\ell+1}{4\pi}D^{(\ell)}_{-2,-2}\left(S^{-1}(\hat{n})S\left(\hat{n}'\right)\right), \tag{9.5.67}$$

$$G_\ell\left(\hat{n},\hat{n}'\right)=(-1)^\ell\frac{2\ell+1}{4\pi}D^{(\ell)}_{-2,-2}\left(S^{-1}(\hat{n})S\left(-\hat{n}'\right)\right), \tag{9.5.68}$$

with $D^{(\ell)}$ the irreducible unitary representation of the rotation group for angular momentum ℓ, and $S(\hat{n})$ the standard rotation (7.4.12) that takes the three-direction with $\vartheta=\varphi=0$ into the direction $\hat{n}$. Also, if we write the microwave background temperature fluctuation as in Eq. (2.6.1)

$$\Delta T(\hat{n})=\sum_{\ell m}a_{T,\ell m}Y^m_\ell(\hat{n}),$$

and use rotational invariance to define

$$\left\langle a_{T,\ell m}a^*_{\gamma,\ell' m'}\right\rangle=\delta_{\ell\ell'}\delta_{mm'}C_{T\gamma,\ell}, \tag{9.5.69}$$

then we can obtain the correlation functions for the shear components with microwave background temperature fluctuations from Eqs. (7.4.81) and (7.4.82) by again replacing Q and U with γ_1 and γ_2 and replacing $C_{TE,\ell}$ with $-C_{T\gamma,\ell}$:

$$\langle\Delta T(\hat{n})\gamma_1\left(\hat{n}'\right)\rangle=\sum_\ell C_{T\gamma,\ell}\,\mathrm{Re}\,H_\ell\left(\hat{n},\hat{n}'\right), \tag{9.5.70}$$

$$\langle\Delta T(\hat{n})\gamma_2\left(\hat{n}'\right)\rangle=-\sum_\ell C_{T\gamma,\ell}\,\mathrm{Im}\,H_\ell\left(\hat{n},\hat{n}'\right), \tag{9.5.71}$$

where H_ℓ is the function (7.4.89):

$$H_\ell\left(\hat{n},\hat{n}'\right)=\frac{2\ell+1}{4\pi}D^{(\ell)}_{0,-2}\left(S^{-1}(\hat{n})S\left(\hat{n}'\right)\right) \tag{9.5.72}$$

For comparison, we mention also that the convergence correlation function is given by the analog of the temperature correlation function (2.6.4):

$$\langle\kappa(\hat{n})\kappa\left(\hat{n}'\right)\rangle=\sum_\ell\frac{2\ell+1}{4\pi}C_{\kappa\kappa,\ell}P_\ell\left(\hat{n}\cdot\hat{n}'\right). \tag{9.5.73}$$

The measurement of $C_{\gamma\gamma,\ell}$ or (with the aid of Eq. (9.5.36) or (9.5.62)) of $C_{\kappa\kappa,\ell}$ can be used not only to learn about the power spectral function $P(k)$, but also to put constraints on the cosmological parameters that enter in

Eq. (9.5.32) for $g(r)$. So far, shear measurements from the Canada-FranceHawaii Telescope Wide Synoptic Legacy Survey have been used [9] to set a value for the parameter σ_8 discussed in Section 8.1: under the assumption that $\Omega_M=0.3$, it is found that $\sigma_8=0.85\pm0.06$. Although this parameter is also measured in studies of large scale structure, the weak lensing measurement has the advantage of not depending on the use of luminous sources as a tracer of dark matter. The same group also finds from cosmic shear data alone that the ratio $w\equiv\bar{p}/\bar{\rho}$, if assumed constant, is less than -0.8 at 68% confidence. Another group, [10] combining shear measurements from the CTIO lensing survey with cosmic microwave background data and measurements of Type Ia supernova redshift and luminosities, has found that $\sigma_8=0.81^{+0.15}_{0.21}$, and that (if constant) $w=-0.89^{+0.16}_{-0.21}$, with 95% confidence. The application of weak lensing surveys to cosmology has really just begun.

10.9.8 9.6 Cosmic strings

The spontaneous breakdown of symmetries in the early universe can produce linear discontinuities in fields, known as cosmic strings. [1] Cosmic strings are also common in modern string theories. [2] Unless we are unlucky enough to have a cosmic string slice through the solar system, the only way that a cosmic string can be discovered seems to be through its action as a gravitational lens. [3]

At a sufficient distance r from a string, the gravitational field becomes Newtonian. For a long straight string the solution of Laplace's equation with cylindrical symmetry has a gravitational potential of the form

$$\phi = -2G\sigma \ln r + C \tag{9.6.1}$$

where σ and C are constants of integration. If the string is non-relativistic, then σ is the string's mass per length. At a sufficient distance from the string the post-Newtonian approximation applies, and the direction $\hat{u}$ of a light

ray is governed by the equation [4]

$$\frac{d\hat{u}}{dt} = -2\hat{u} \times (\hat{u} \times \nabla\phi) \tag{9.6.2}$$

As long as the deflection of the light ray is small, it can be calculated as

$$\delta\hat{u} = -2\hat{u}_0 \times \left(\hat{u}_0 \times \int dt \nabla\phi\right) \tag{9.6.3}$$

where $\hat{u}_0$ is the photon's initial direction. An elementary integration shows that the light ray is deflected toward the string in a direction perpendicular to both the string and the light ray, by an angle

$$|\delta\hat{u}| = \frac{4\pi\sigma G}{\sin\theta} \tag{9.6.4}$$

where θ is the angle between the directions of the string and the light ray. Because the deflection is toward the string, it is in the opposite direction for rays passing the string on opposite sides, so that the image of a source behind the string is split into two parts. It is noteworthy that neither the direction nor the magnitude of this deflection depends on the distance of the light ray from the string, as long as the distance is large enough to allow the use of the non-relativistic formulas (9.6.1) and (9.6.2).

In 2003, general interest in cosmic strings was heightened by the discovery of what seemed at first to be a plausible candidate for lensing by a cosmic string. A pair of images of elliptical galaxies separated by about 1.8 arcseconds was found to have substantially the same redshift, $z = 0.46$, and the same spectra. The images were not distorted in the way that would be expected for lensing of a single galaxy by a more-or-less spherical source, but are consistent with lensing by a cosmic string. [5] Subsequently an excess of gravitationally lensed objects was found in the neighborhood of this string candidate, [6] lending further support to the view that

[3] The relativistic calculation of lensing by a cosmic string is due to J. R. Gott, Astrophys. J. 288, 422 (1985). The anisotropy in the cosmic microwave background due to cosmic strings was calculated by N. Kaiser and A. Stebbins, Nature 310, 391 (1984).

this was the image of a single galaxy lensed by a cosmic string. But in 2006 this interpretation had to be abandoned, when observations at the Hubble Space Telescope revealed that this was in fact a pair of interacting elliptical galaxies, not the result of any sort of lensing. [7] This episode illustrates how difficult it will be to detect cosmic strings through their lensing action.

10.10 Inflation as the Origin of Cosmological Fluctuations

The most exciting aspect of the inflationary cosmological theories described in Chapter 4 is that they provide a natural quantum mechanical mechanism for the origin of the cosmological fluctuations observed in the cosmic microwave background and in the large scale structure of matter, [1] and that may in the future be observed in gravitational waves. [2] We have seen in Chapter 6 that the magnitude and wavelength dependence of adiabatic scalar and tensor fluctuations depend on initial conditions only through the quantities $\mathcal{R}_q^o$ and $\mathcal{D}_q^o$, respectively. As given by Eq. (5.4.24), $\mathcal{R}_q^o$ is the value of the gauge-invariant quantity $\mathcal{R}_q(t) \equiv A_q(t)/2 + H(t)\delta u_q(t)$ outside the horizon, that is for $q/a(t) \ll H(t)$, where for adiabatic fluctuations $\mathcal{R}_q$ is time-independent. Likewise, $\mathcal{D}_q^o$ is the time-independent value of the gravitational wave amplitude $\mathcal{D}_q(t)$ for $q/a(t) \ll H(t)$. During the matter- or radiation-dominated eras $a(t)$ increased like $t^{2/3}$ or $t^{1/2}$, respectively, while $H(t) \equiv \dot{a}(t)/a(t)$ decreased like $1/t$, so any wavelength will be found outside the horizon if we go back early enough in one or the other of these eras. But during the period of inflation that is supposed to precede the radiationdominated era, $H(t)$ was roughly (perhaps very roughly) constant, while $a(t)$ increased more-or-less exponentially, so even if a perturbation was outside the horizon at the end of inflation it would inevitably have been found deep inside the horizon sufficiently early in the era of inflation. At these very early times fields oscillated much more quickly than the universe expanded, and their quantum fluctuations therefore were essentially just what they would be in ordinary Minkowski spacetime. In this chapter we will follow adiabatic scalar fluctuations and tensor fluctuations from this very early era, through the epochs when fluctuations of various wavelengths exited the horizon, to the time when $\mathcal{R}_q(t)$ and $\mathcal{D}_q(t)$ reached the constant values $\mathcal{R}_q^o$ and $\mathcal{D}_q^o$ that are measured in the cosmic microwave background and in the large scale structure of matter, and that may some day be measured through the direct detection of cosmological gravitational radiation.

10.10.1 10.1 Scalar fluctuations during inflation

We will first consider the simplest model of inflation, with a single real "inflaton" field $\varphi(x)$, and an action (B.63):

$$I_\varphi = \int d^4x \sqrt{-\operatorname{Det} g}\left[-\frac{1}{2}g^{\mu\nu}\frac{\partial\varphi}{\partial x^\mu}\frac{\partial\varphi}{\partial x^\nu} - V(\varphi)\right], \tag{10.1.1}$$

involving an arbitrary real potential $V(\varphi)$. This is not the only possibility; we will take up the question of its plausibility at the end of this section.

[474] See footnote 1 of Section 9.3.

[2] The cosmological generation of gravitational waves was considered by L. P. Grishchuk, Sov. Phys. JETP 40, 409 (1974); A. A. Starobinsky, Sov. Phys. JETP Lett. 30, 682 (1979), and calculated in the context of inflation by V. A. Rubakov, M. V. Sazhin, and A. V. Veryaskin, Phys. Lett. 115B, 189 (1982).

In line with the observed isotropy and homogeneity of the universe on the average, we take the scalar field as an unperturbed term $\bar{\varphi}(t)$ that depends only on time, plus a small perturbation $\delta\varphi(\mathbf{x},t)$:

$$\varphi(\mathbf{x},t) = \bar{\varphi}(t) + \delta\varphi(\mathbf{x},t). \tag{10.1.2}$$

Similarly, as in Chapters 5-7, the metric is given by the unperturbed Robertson-Walker metric $\bar{g}_{\mu\nu}(t)$ (with $K = 0$) plus a small perturbation $h_{\mu\nu}(\mathbf{x},t)$

$$g_{\mu\nu}(\mathbf{x},t) = \bar{g}_{\mu\nu}(t) + h_{\mu\nu}(\mathbf{x},t). \tag{10.1.3}$$

The energy momentum tensor of the scalar field is shown in Appendix B to take the perfect fluid form, with an energy density, pressure, and velocity four-vector given by Eqs. (B.66)-(B.68) as

$$\begin{aligned}
\rho &= -\frac{1}{2}g^{\mu\nu}\frac{\partial\varphi}{\partial x^\mu}\frac{\partial\varphi}{\partial x^\nu} + V(\varphi) \\
p &= -\frac{1}{2}g^{\mu\nu}\frac{\partial\varphi}{\partial x^\mu}\frac{\partial\varphi}{\partial x^\nu} - V(\varphi) \\
u^\mu &= -\left[-g^{\rho\sigma}\frac{\partial\varphi}{\partial x^\rho}\frac{\partial\varphi}{\partial x^\sigma}\right]^{-1/2} g^{\mu\tau}\frac{\partial\varphi}{\partial x^\tau}.
\end{aligned}$$

The energy-density and pressure of the unperturbed scalar field are then

$$\bar{\rho} = \frac{1}{2}\dot{\bar{\varphi}}^2 + V(\bar{\varphi}), \quad \bar{p} = \frac{1}{2}\dot{\bar{\varphi}}^2 - V(\bar{\varphi}), \tag{10.1.4}$$

while the unperturbed velocity four-vector has components

$$\bar{u}^i = 0, \quad \bar{u}^0 = 1. \tag{10.1.5}$$

The Friedmann equation (with zero spatial curvature) is here

$$H^2 = \frac{8\pi G}{3}\left(\frac{1}{2}\dot{\bar{\varphi}}^2 + V(\bar{\varphi})\right). \tag{10.1.6}$$

and the energy conservation condition $\dot{\bar{\rho}} = -3H(\bar{\rho} + \bar{p})$ yields the field equation of the unperturbed scalar field

$$\ddot{\bar{\varphi}} + 3H\dot{\bar{\varphi}} + V'(\bar{\varphi}) = 0, \tag{10.1.7}$$

where as usual $H(t) \equiv \dot{a}(t)/a(t)$.
The perturbation $\delta g_{\mu\nu} \equiv h_{\mu\nu}$ to the metric will be taken in the Newtonian gauge form (5.3.18):

$$h_{00} = -2\Psi, \quad h_{0i} = 0, \quad h_{ij} = -2a^2\delta_{ij}\Psi \tag{10.1.8}$$

(The scalar anisotropic inertia term π^S, as well as π^V and π^T, vanishes in scalar field theories, so according to Eq. (5.3.20) the other scalar gravitational perturbation Φ here equals Ψ.) The perturbations to the pressure, energy density, and velocity three-vector are given by the terms in Eqs. (B.66)-(B.68) that are of first order in perturbations:

$$\delta\rho = \dot{\bar{\varphi}}\delta\dot{\varphi} + V'(\bar{\varphi})\delta\varphi - \Psi\dot{\bar{\varphi}}^2 \tag{10.1.9}$$

$$\delta p = \dot{\bar{\varphi}}\delta\dot{\varphi} - V'(\bar{\varphi})\delta\varphi - \Psi\dot{\bar{\varphi}}^2 \tag{10.1.10}$$

$$\delta u_i = \frac{\partial\delta u}{\partial x^i} \text{ where } \delta u = -\frac{\delta\varphi}{\dot{\bar{\varphi}}} \tag{10.1.11}$$

The field equations may be taken as the Einstein equation Eq. (5.3.21) and the energy conservation condition (5.3.24), which here take the form

$$\dot{\Psi} + H\Psi = 4\pi G\dot{\bar{\varphi}}\delta\varphi \tag{10.1.12}$$

$$\delta\ddot{\varphi} + 3H\delta\dot{\varphi} + \frac{\partial^2 V(\bar{\varphi})}{\partial\bar{\varphi}^2}\delta\varphi - \left(\frac{\nabla^2}{a^2}\right)\delta\varphi = -2\Psi\frac{\partial V(\bar{\varphi})}{\partial\bar{\varphi}} + 4\dot{\Psi}\dot{\bar{\varphi}} \tag{10.1.13}$$

while the constraint (5.3.26) is here

$$\left(\dot{H} - \frac{\nabla^2}{a^2}\right)\Psi = 4\pi G(-\dot{\bar{\varphi}}\delta\dot{\varphi} + \ddot{\bar{\varphi}}\delta\varphi) \tag{10.1.14}$$

(In deriving Eq. (10.1.14), we make use of the convenient relation $\dot{H} = -4\pi G\dot{\bar{\varphi}}^2$, which follows from Eqs. (10.1.6) and (10.1.7).) The field equation (5.3.20) has already been accounted for by setting $\Phi = \Psi$, while the remaining field equations (5.3.19) and (5.3.22) and the momentum conservation equation (5.3.23) just repeat the information contained in Eqs. (10.1.12)(10.1.14).

Let us first consider the plane wave solutions of Eqs. (10.1.12)-(10.1.14), in which $\delta\varphi$ and Ψ are of the form $\exp(i\mathbf{q}\cdot\mathbf{x})\delta\varphi_q(t)$ and $\exp(i\mathbf{q}\cdot\mathbf{x})\Psi_q(t)$, respectively. We will return later to the issue of how to put these solutions
together in forming the perturbations $\delta\varphi(\mathbf{x},t)$ and $\Psi(\mathbf{x},t)$. The time dependence of the plane wave solutions is given by Eqs. (10.1.12) and (10.1.13), with $-\nabla^2$ replaced with $q^2 \equiv \mathbf{q}^2$:

$$\dot{\Psi}_q + H\Psi_q = 4\pi G\dot{\bar{\varphi}}\delta\varphi_q, \tag{10.1.15}$$

$$\begin{aligned}&\delta\ddot{\varphi}_q + 3H\delta\dot{\varphi}_q + \frac{\partial^2 V(\bar{\varphi})}{\partial\bar{\varphi}^2}\delta\varphi_q + \left(\frac{q^2}{a^2}\right)\delta\varphi_q \\ &= -2\Psi_q\frac{\partial V(\bar{\varphi})}{\partial\bar{\varphi}} + 4\dot{\Psi}_q\dot{\bar{\varphi}},\end{aligned} \tag{10.1.16}$$

while the constraint (10.1.14) now reads

$$\left(\dot{H} + \frac{q^2}{a^2}\right)\Psi_q = 4\pi G\left(-\dot{\bar{\varphi}}\delta\dot{\varphi}_q + \ddot{\bar{\varphi}}\delta\varphi_q\right). \tag{10.1.17}$$

At sufficiently early times q/a will be much larger than H or $\partial^2 V(\bar{\varphi})/\partial\bar{\varphi}^2$, so we can look for WKB solutions, for which time derivatives of fields yield factors of order q/a, of the form

$$\begin{aligned}\delta\varphi_q(t) &\to f(t)\exp\left(-iq\int_{t_*}^{t}\frac{dt'}{a\,(t')}\right) \\ \Psi_q(t) &\to g(t)\exp\left(-iq\int_{t_*}^{t}\frac{dt'}{a\,(t')}\right)\end{aligned} \tag{10.1.18}$$

where $f(t)$ and $g(t)$ vary much more slowly than the argument of the exponential, and t_* is arbitrary. The exponential factor is chosen so that the terms in Eq. (10.1.16) of second order in q/a should cancel. Eqs. (10.1.15) and (10.1.17) are both satisfied to leading order in q/a if we take

$$g/f = 4i\pi G\dot{\bar{\varphi}}a/q. \tag{10.1.19}$$

The terms in Eq. (10.1.16) of first order in q/a then give $2\dot{f} + 2Hf = 0$, so $f \propto 1/a$. For reasons that will soon become clear, we will choose the common constant factor in both f and

g so that $f = 1/(2\pi)^{3/2}\sqrt{2q}a$. With this normalization, $\delta\varphi_q(t)$ and $\Psi_q(t)$ are defined as the solution of Eqs. (10.1.15)-(10.1.17) that satisfies the initial condition, that for $a(t) \to 0$,

$$\delta\varphi_q(t) \to \frac{1}{(2\pi)^{3/2}a(t)\sqrt{2q}} \exp\left(-iq\int_{t_*}^{t}\frac{dt'}{a\,(t')}\right) \tag{10.1.20}$$

$$\Psi_q(t) \to \frac{4i\pi G\dot{\bar{\varphi}}(t)}{(2\pi)^{3/2}\sqrt{2q^3}} \exp\left(-iq\int_{t_*}^{t}\frac{dt'}{a\,(t')}\right) \tag{10.1.21}$$

The complex conjugate $\delta\varphi_q^*(t), \Psi_q^*(t)$ is another independent solution, and since the system of equations (10.1.15)-(10.1.17) is second order, these are the only solutions.

In general, the fields $\delta\varphi(\mathbf{x},t)$ and $\Psi(\mathbf{x},t)$ satisfying Eqs. (10.1.12)(10.1.14) can be written as superpositions of these two solutions, which the reality of the fields requires to take the form

$$\delta\varphi(\mathbf{x},t) = \int d^3q\left[\delta\varphi_q(t)e^{i\mathbf{q}\cdot\mathbf{x}}\alpha(\mathbf{q}) + \delta\varphi_q^*(t)e^{-i\mathbf{q}\cdot\mathbf{x}}\alpha^*(\mathbf{q})\right] \tag{10.1.22}$$

$$\Psi(\mathbf{x},t) = \int d^3q\left[\Psi_q(t)e^{i\mathbf{q}\cdot\mathbf{x}}\alpha(\mathbf{q}) + \Psi_q^*(t)e^{-i\mathbf{q}\cdot\mathbf{x}}\alpha^*(\mathbf{q})\right] \tag{10.1.23}$$

Now we must say something about the coefficients $\alpha(\mathbf{q})$ and $\alpha^*(\mathbf{q})$. For this purpose, we use the canonical commutation relations of the fields. The interaction of the scalar field with gravitation makes these commutation relations rather complicated, but they become simple at very early times. For any given q, we can find a time sufficiently early so that the expansion rate H is negligible compared with q/a. For such early times, both $\dot{\bar{\varphi}}$ and $\ddot{\bar{\varphi}}$ on the right-hand side of Eq. (10.1.17) become negligible, so Ψ_q becomes negligible, as can also be seen by noting from Eqs. (10.1.18) and (10.1.19) that the ratio of Ψ_q to $\delta\varphi_q$ vanishes like $a(t)$ for $a(t) \to 0$. At such early times, as far as $\alpha(\mathbf{q})$ and $\alpha^*(\mathbf{q})$ are concerned, we can find the canonical commutation relations by using Eq. (10.1.1) with $g_{\mu\nu}$ taken as the unperturbed Robertson-Walker metric:

$$I_\varphi = \int d^4x\mathcal{L}_\varphi, \quad \mathcal{L}_\varphi = a^3(t)\left[\frac{1}{2}\left(\frac{\partial\varphi}{\partial t}\right)^2 - \frac{1}{2a^2(t)}\frac{\partial\varphi}{\partial x^i}\frac{\partial\varphi}{\partial x^i} - V(\varphi)\right]$$

The canonical conjugate to the field φ is then $\pi = \partial\mathcal{L}_\varphi/\partial\dot{\varphi} = a^3\dot{\varphi}$. Since the unperturbed fields are c-numbers, the commutators of perturbations are the same as the commutators of the fields themselves. This gives, for very early times,

$$[\delta\varphi(\mathbf{x},t),\delta\varphi(\mathbf{y},t)] = 0, \quad [\delta\varphi(\mathbf{x},t),\delta\dot{\varphi}(\mathbf{y},t)] = ia^{-3}(t)\delta^3(\mathbf{x}-\mathbf{y}) \tag{10.1.24}$$

With $\delta\varphi_q(t)$ normalized to satisfy Eq. (10.1.20) for $a(t) \to 0$, these commutation relations imply that $\alpha(\mathbf{q})$ and $\alpha^*(\mathbf{q})$ behave as conventionally normalized annihilation and creation operators

$$[\alpha(\mathbf{q}),\alpha\,(\mathbf{q}')] = 0, \quad [\alpha(\mathbf{q}),\alpha^*\,(\mathbf{q}')] = \delta^3\,(\mathbf{q}-\mathbf{q}') \tag{10.1.25}$$

It may come as a surprise that the same annihilation and creation operators appear in the scalar field and gravitational perturbations, but it should be
kept in mind that Ψ does not represent gravitational radiation, whose quanta are created and annihilated by independent operators. Rather, Ψ is an auxiliary field, given by Eq. (10.1.14) as a functional of the inflaton field $\delta\varphi$, in much the same way that in the Coulomb gauge quantization of quantum electrodynamics, the time-component of the vector potential is a functional of the charged matter fields. [3]

It may be noted in passing that the scalar field we have constructed is in accord with the Principle of Equivalence of general relativity. As long as we do not concern ourselves with co-moving wave numbers below some infrared limit Q (as for example by confining measurements to a cube of co-moving volume less than $(2\pi/Q)^3$), then at times for which $Q/a \gg H$ the form of the scalar field $\delta\varphi(\mathbf{x},t)$ ought to be essentially the same as a free massless real scalar field $\varphi(\mathbf{x},t)$ in ordinary Minkowskian space-time:
$\int \frac{d^3k}{(2\pi)^{3/2}\sqrt{2k}} \left[A(\mathbf{k})e^{i\mathbf{k}\cdot a\mathbf{x}} \exp\left(-i\int k dt\right) + A^*(\mathbf{k})e^{-i\mathbf{k}\cdot a\mathbf{x}} \exp\left(i\int k dt\right)\right]$,
where $A(\mathbf{k})$ and $A^*(\mathbf{k})$ are annihilation and creation operators, satisfying the familiar commutation relations

$$[A(\mathbf{k}), A(\mathbf{k}')] = 0, \quad [A(\mathbf{k}), A^*(\mathbf{k}')] = \delta^3(\mathbf{k}-\mathbf{k}').$$

Note that the space coordinate appearing in the exponentials is $a\mathbf{x}$, because in the $K=0$ Robertson-Walker metric this is the vector that measures proper distances. It follows that $\mathbf{k}$ is related to the time-independent co-moving wave number vector $\mathbf{q}$ by $\mathbf{k} = \mathbf{q}/a$, so it is time-dependent, which is why we had to write the time-dependence factors as $\exp\left(\mp i\int k dt\right)$ rather than $\exp(\mp ikt)$. Also, $\delta^3(\mathbf{k}-\mathbf{k}') = a^3\delta^3(\mathbf{q}-\mathbf{q}')$, so we can define operators $\alpha(\mathbf{q})$ that satisfy (10.1.25) as $\alpha(\mathbf{q}) = a^{-3/2}A(\mathbf{k})$. Changing the variable of integration from $\mathbf{k}$ to $\mathbf{q}$ then gives the field for $a(t) \to 0$ as

$$\int \frac{d^3q/a^3}{(2\pi)^{3/2}\sqrt{2q/a}} \left[a^{3/2}\alpha(\mathbf{q})e^{i\mathbf{q}\cdot\mathbf{x}} \exp\left(-i\int q dt/a\right) + a^{3/2}\alpha^*(\mathbf{q})e^{-i\mathbf{q}\cdot\mathbf{x}} \exp\left(i\int q dt/a\right)\right]$$

in agreement with Eqs. (10.1.20) and (10.1.22).
Finally, we have to choose the quantum state of the inflaton field during inflation. Though there are other possibilities, the simplest and most natural

assumption is that the state of the universe during inflation is the vacuum $|0\rangle$, defined so that [4]

$$\alpha(\mathbf{q})|0\rangle = 0, \quad \langle 0 \mid 0\rangle = 1 \tag{10.1.26}$$

One other possibility is that it is a linear combination of α and α^* rather than α that annihilates the state $|0\rangle$.[5] Another is that inflation takes place in the presence of a thermal distribution of inflatons. [6]

But although not certain, the assumption (10.1.26) is at least plausible. The initial condition (10.1.20), which picks out a particular solution of the second-order system (10.1.15)-(10.1.17), is imposed at an early time, at which $q/a \gg H$. At such times, we can treat the action as if it were nearly time-independent, so there exists a Hamiltonian operator H which to a good approximation generates the time-dependence of the fields:

$$[H, \delta\varphi(\mathbf{x},t)] \simeq -i\dot{\varphi}(\mathbf{x},t)$$

According to Eq. (10.1.18), for $q/a \gg H$ the time dependence of the coefficient function $\varphi_q(t)$ is given approximately by

$$\dot{\varphi}_q \simeq -i(q/a)\varphi_q$$

so

[473] See QTF, Vol. I, Eq. (8.2.9).

$$[H, \alpha(\mathbf{q})] \simeq -(q/a)\alpha(\mathbf{q}).$$

Hence if a state $|\psi\rangle$ is an eigenstate of H with energy E, then $\alpha(\mathbf{q})|\psi\rangle$ is an eigenstate of H with a lower energy $\simeq E - q/a$, unless $|\psi\rangle$ is the state $|0\rangle$ for which $\alpha(\mathbf{q})|0\rangle = 0$, which is therefore the state of lowest energy. Just as in ordinary laboratory physics, we expect any other state to decay into the state $|0\rangle$ of lowest energy, although there remains a question whether the decay occurs rapidly enough to be effective in the period before horizon exit. [7]

In the state satisfying Eq. (10.1.26), quantum averages $\langle 0|\delta\varphi\left(\mathbf{x}_1, t\right)\delta\varphi\left(\mathbf{x}_2, t\right)\cdots|0\rangle$ (as well as those also involving $\Psi(\mathbf{x}, t)$) may be calculated by moving all annihilation operators $\alpha(\mathbf{q})$ to the right and all creation operators $\alpha^*(\mathbf{q})$ to the left, picking up commutators when a $\alpha(\mathbf{q})$ is moved to the right past a $\alpha^*\left(\mathbf{q}'\right)$ or a $\alpha^*(\mathbf{q})$ is moved to the left past a $\alpha\left(\mathbf{q}'\right)$. The result is then given by Wick's theorem: [8] The quantum averages of products of $\delta\varphi$ s and/or

Ψ s are Gaussian in the sense of Appendix E (except that we must keep track of the order of operators), with the pairings given by vacuum expectation values of products of the paired fields:

$$\langle 0|\delta\varphi(\mathbf{x}, t)\delta\varphi(\mathbf{y}, t)|0\rangle = \int d^3q \left|\delta\varphi_q(t)\right|^2 e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})} \tag{10.1.27}$$

$$\langle 0|\Psi(\mathbf{x}, t)\Psi(\mathbf{y}, t)|0\rangle = \int d^3q \left|\Psi_q(t)\right|^2 e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})} \tag{10.1.28}$$

$$\langle 0|\delta\varphi(\mathbf{x}, t)\Psi(\mathbf{y}, t)|0\rangle = \int d^3q \delta\varphi_q(t)\Psi_q^*(t) e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})} \tag{10.1.29}$$

$$\langle 0|\Psi(\mathbf{x}, t)\delta\varphi(\mathbf{y}, t)|0\rangle = \int d^3q \Psi_q(t)\delta\varphi_q^*(t) e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})} \tag{10.1.30}$$

For instance,

$$\begin{aligned}
&\langle 0|\delta\varphi(\mathbf{w}, t)\Psi(\mathbf{x}, t)\Psi(\mathbf{y}, t)\delta\varphi(\mathbf{z}, t)|0\rangle \\
&\quad = \langle 0|\delta\varphi(\mathbf{w}, t)\Psi(\mathbf{x}, t)|0\rangle\langle 0|\Psi(\mathbf{y}, t)\delta\varphi(\mathbf{z}, t)|0\rangle \\
&\qquad + \langle 0|\delta\varphi(\mathbf{w}, t)\Psi(\mathbf{y}, t)|0\rangle\langle 0|\Psi(\mathbf{x}, t)\delta\varphi(\mathbf{z}, t)|0\rangle \\
&\qquad + \langle 0|\delta\varphi(\mathbf{w}, t)\delta\varphi(\mathbf{z}, t)|0\rangle\langle 0|\Psi(\mathbf{x}, t)\Psi(\mathbf{y}, t)|0\rangle
\end{aligned}$$

These are quantum averages, not averages over an ensemble of classical field configurations. We see this most clearly in Eqs. (10.1.29) and (10.1.30), which give complex results for the averages of products of real fields, and consequently also depend on the order of the fields. [9] Just as in the measurement of a spin in the laboratory, some sort of decoherence must set in; the field configurations must become locked into one of an ensemble of classical configurations, with ensemble averages given by the quantum expectation values calculated as in Eqs. (10.1.27)-(10.1.30) It is not apparent just how this happens, but it is clear that decoherence cannot occur until expectation values of products of real fields become real, which for free fields will also imply that the expectation values do not depend on the order of the fields. As we shall see, this happens after perturbations leave the horizon, when the various functions $\varphi_q(t)$ and $\Psi_q(t)$ become dominated by a single solution of the field equations, which (since the field equations are real) is necessarily real up to a possible complex factor. Once the universe becomes classical

[474] This state is often called the Bunch-Davies vacuum: see T. S. Bunch and P. C. W. Davies, Proc. Roy. Soc. Ser. A 360, 117 (1978).

[7] This is studied by C. Armendariz-Picon, J. Cosm. & Astropart. Phys. 0702, 031 (2007) [astroph/0612288].

[8] See QTF, Vol. I, Sec. 9.1.

in this sense, we can invoke the Ergodic Theorem of Appendix D to interpret averages over ensembles of possible classical universes as averages over the position of the observer in our universe.

For any given potential $V(\bar{\varphi})$, it is always possible to find $\varphi_q(t)$ and $\Psi_q(t)$ by numerically solving Eqs. (10.1.15)-(10.1.17), subject to the initial

conditions (10.1.20) and (10.1.21). But this is complicated, and gives more information than we can use. Between the time of inflation and the present there intervenes a so-called reheating period when the energy of the inflaton field φ is converted into ordinary matter and radiation. We know essentially nothing about this process, so the solutions for $\delta\varphi$ and Ψ during inflation do not have an immediate interpretation in terms of observations of the present universe. Fortunately, the reheating era (and other ill-understood eras) occur when all cosmological fluctuations of observational interest are outside the horizon. The one use that we can make of the solutions for the fields during inflation is to calculate some quantity that becomes conserved outside the horizon, and that thus provides an initial condition for the evolution of perturbations after they re-enter the horizon.

Here we will concentrate on the quantity $\mathcal{R}$ discussed in Section 5.4, defined in Newtonian gauge by

$$\mathcal{R} \equiv -\Psi + H\delta u \tag{10.1.31}$$

With a single scalar field this is conserved outside the horizon during inflation, because as shown in Section 5.4 there are always two solutions for which $\mathcal{R}$ is constant for $q/a \ll H$, and as already noted the equations for inflation with a single scalar field only have two independent solutions. Using Eqs. (10.1.11) and (10.1.22)-(10.1.23) we find that during inflation

$$\mathcal{R}(\mathbf{x},t) = \int d^3q \left[\mathcal{R}_q(t)e^{i\mathbf{q}\cdot\mathbf{x}}\alpha(\mathbf{q}) + \mathcal{R}_q^*(t)e^{-i\mathbf{q}\cdot\mathbf{x}}\alpha^*(\mathbf{q})\right] \tag{10.1.32}$$

where

$$\mathcal{R}_q = -\Psi_q - H\delta\varphi_q/\dot{\bar{\varphi}} \tag{10.1.33}$$

Of course, the quantum averages of products of $\mathcal{R}(\mathbf{x},t)$ s are Gaussian in the same sense as those of $\Psi_q(t)$ and $\delta\varphi_q(t)$, with pairings given by the expectation value

$$\langle 0|\mathcal{R}(\mathbf{x},t)\mathcal{R}(\mathbf{y},t)|0\rangle = \int d^3q e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})}\,|\mathcal{R}_q(t)|^2 \tag{10.1.34}$$

Instead of calculating $\Psi_q(t)$ and $\delta\varphi_q(t)$ and then using the results to calculate $\mathcal{R}_q(t)$, it is much more convenient to solve a differential equation for $\mathcal{R}_q(t)$ itself. This equation can be derived in Newtonian gauge with some trouble from Eqs. (10.1.15)-(10.1.17), but it is more easily derived in a different gauge, defined by the conditions

$$\delta\varphi_q = 0, \quad B_q = 0$$

Inspection of Eqs. (B.66)-(B.68) shows that in this gauge

$$\delta\rho = \delta p = \frac{1}{2}h_{00}\dot{\bar{\varphi}}^2 = -\frac{1}{2}E\dot{\bar{\varphi}}^2, \quad \delta u = 0$$

Also, as mentioned in Appendix B, the energy-momentum tensor for a single real scalar field has the perfect fluid form, so the anisotropic inertia π_{ij} vanishes. The gravitational field equations (5.1.44) and (5.1.46) and the energy conservation equation (5.1.49) then give

[479] For a discussion of this point, see D. H. Lyth and D. Seery, astro-ph/0607647.

$$0 = H\dot{E} + 2\left(3H^2 + \dot{H}\right)E + a^{-2}\nabla^2 A - \ddot{A} - 6H\dot{A} + 2a^{-1}H\nabla^2 F,$$
$$0 = -HE + \dot{A}$$
$$0 = -\frac{1}{2}\frac{\partial}{\partial t}(E\dot{H}) - 3H\dot{H}E - a^{-1}\dot{H}\nabla^2 F + \frac{3}{2}\dot{H}\dot{A},$$

in which we have again used the relation $\dot{H} = -4\pi G|\dot{\bar{\varphi}}|^2$. Eliminating E and F yields a differential equation for A :

$$\ddot{A} + \left(3H - \frac{2\dot{H}}{H} + \frac{\ddot{H}}{\dot{H}}\right)\dot{A} - \frac{1}{a^2}\nabla^2 A = 0.$$

The gauge invariant formula (5.4.22) tells us that in this gauge $\mathcal{R} = A/2$, so the same equation applies to $\mathcal{R}$. Going over to its Fourier transform, this gives what is sometimes known as the Mukhanov-Sasaki equation: [10]

$$\frac{d^2\mathcal{R}_q}{d\tau^2} + \frac{2}{z}\frac{dz}{d\tau}\frac{d\mathcal{R}_q}{d\tau} + q^2\mathcal{R}_q = 0, \tag{10.1.35}$$

where τ is the conformal time

$$\tau \equiv \int_{t_*}^{t} \frac{dt'}{a\,(t')} \tag{10.1.36}$$

with t_* an arbitrary time, to be chosen later, and

$$z \equiv \frac{a\dot{\bar{\varphi}}}{H}. \tag{10.1.37}$$

The initial condition is provided by returning to Newtonian gauge, and using Eqs. (10.1.20) and (10.1.21) in Eq. (10.1.33). Assuming that $a(t)\dot{\bar{\varphi}}^2(t)/H(t)$ vanishes in the limit $a(t) \to 0$, only the term in Eq. (10.1.33) proportional to $\delta\varphi_q$ contributes in this limit, and we find that for $a(t) \to 0$:

$$\mathcal{R}_q(t) \to -\frac{H(t)}{(2\pi)^{3/2}\sqrt{2q}a(t)\dot{\bar{\varphi}}(t)}\exp(-iq\tau) \tag{10.1.38}$$

For a given potential we must integrate Eq. (10.1.35) out from $a = 0$ to beyond the horizon, where $q/a \ll H$. In this limit we can drop the $q^2\mathcal{R}_q$ term in Eq. (10.1.35), which then has two solutions, a dominant solution with $\mathcal{R}_q$ a non-zero constant, and a solution for which $\mathcal{R}_q$ approaches zero with $d\mathcal{R}_q/d\tau$ decaying as $1/z^2$. It is the constant limit $\mathcal{R}_q^o$ of $\mathcal{R}_q(t)$ outside the horizon that we need. (As we saw in Section 5.3, the value of the quantity ζ_q that is sometimes used in analyses of cosmological fluctuations is given far outside the horizon by $\zeta_q^o = \mathcal{R}_q^o$.)

It is striking that within the scope of the general assumptions made here, it is not necessary to make any arbitrary assumptions about the strength of cosmological fluctuations. For any given potential, we need only solve equation (10.1.35) with the initial condition (10.1.38), and carry the solution forward in time to when $\mathcal{R}_q(t)$ reaches its constant value $\mathcal{R}_q^o$ outside the horizon.

On what features of the potential does $\mathcal{R}_q^o$ depend? The initial behavior (10.1.38) of $\mathcal{R}_q(t)$ deep inside the horizon is independent of the nature of the potential, while outside the horizon $\mathcal{R}_q(t)$ simply becomes constant. Thus $\mathcal{R}_q^o$ can depend only on the behavior of the potential

[4][7][10] V. S. Mukhanov, JETP Lett. 41, 493 (1986); S. Sasaki, Prog. Theor. Phys. 76, 1036 (1986); V. S. Mukhanov, H. A. Feldman, and R.H. Brandenberger, Phys. Rep. 215, 203 (1992); E. D. Stewart and D. H. Lyth, Phys. Lett. B 302, 171 (1993).

$V(\varphi)$ for values of φ near the value taken by $\bar{\varphi}(t)$ at the time the perturbation leaves the horizon.

This has an important implication for the part of the era of inflation that can be revealed through observations of scalar fluctuations. As we have just seen, in observing a fluctuation with co-moving wave number q, we learn about the time t_q of horizon exit during inflation, when $q/a\left(t_q\right) = H\left(t_q\right)$. To put this another way, the number of e-foldings $\mathcal{N}(q)$ between the time t_q that we learn about in observing a perturbation of wave number q and the beginning of the radiation-dominated era at a time t_1 is [11]

$$\mathcal{N}(q) \equiv \ln\left(\frac{a\left(t_1\right)}{a\left(t_q\right)}\right) = \mathcal{N}_0 + \ln\left(\frac{a\left(t_0\right) H\left(t_0\right)}{q}\right) + \ln\left(\frac{H\left(t_q\right)}{H\left(t_1\right)}\right) \tag{10.1.39}$$

where

$$\mathcal{N}_0 \equiv \ln\left(\frac{a\left(t_1\right) H\left(t_1\right)}{a\left(t_0\right) H\left(t_0\right)}\right) \tag{10.1.40}$$

and as usual t_0 is the present time. In particular, we cannot observe any fluctuation unless q is large enough to have entered the horizon by the present time, which requires that the present physical wavelength $a\left(t_0\right)/q$ be less than the present horizon distance $\approx 1/H\left(t_0\right)$, so the maximum number of e-foldings before the beginning of the radiation-dominated era that can

ever be observed is

$$\mathcal{N}_{\max} = \mathcal{N}_0 + \ln\left(\frac{H(t)}{H\left(t_1\right)}\right)_{\max}, \tag{10.1.41}$$

in which the second term on the right is the maximum value of $\ln[H(t)/\ H\left(t_1\right)]$ for t within the last $\mathcal{N}_{\max}$ e-foldings of inflation. In general we expect energy to be lost during inflation and in the reheating phase at the end of inflation, so $H\left(t_{\text{exit}}\right) > H\left(t_1\right)$ and hence $\mathcal{N}_{\max} > \mathcal{N}_0$, but for slow roll inflation it may not be a bad approximation to neglect this energy loss, in which case the second term in Eq.(10.1.41) can be neglected, and

$$\mathcal{N}_{\max} \simeq \mathcal{N}_0. \tag{10.1.42}$$

The reason that we have chosen to write the formula for $\mathcal{N}(q)$ as in Eq. (10.1.39) is that we have already calculated $\mathcal{N}_0$ in Section 4.1; it is

$$\mathcal{N}_0 = \ln\left(\frac{\rho_1^{1/4}}{0.037h\text{eV}}\right), \tag{10.1.43}$$

where ρ_1 is the energy density at the beginning of the radiation-dominated era. For instance, if we take $h = 0.7$ and $\rho_1 = G^{-2} = [1.2 \times 10^{19}\text{GeV}]^4$, then $\mathcal{N}_0 \simeq 68$, and according to Eq.(10.1.42) we can only explore the final 68 e-foldings of inflation. We will re-evaluate this bound in Section 10.3, with a better estimate of ρ_1.

There is one form of the potential for which the constant $\mathcal{R}_q^o$ can be calculated analytically, with no further approximations. [12] It is the exponential potential

$$V(\varphi) = ge^{-\lambda\varphi} \tag{10.1.44}$$

(with g and λ arbitrary real constants) which we have already considered in Section 4.2. Of course, the potential cannot have this form for all φ, or inflation would never end, but

[4711] A. R. Liddle and S. M. Leach, Phys. Rev. D 68, 103503 (2003) [astro-ph/0305263].

as remarked in the previous paragraph, in the calculation of $\mathcal{R}_q^o$ it is only relevant that the potential should take this form for values of the field near the value it takes at horizon crossing.

The solution of Eqs. (10.1.6) and (10.1.7) for the exponential potential is

$$\bar{\varphi}(t) = \frac{1}{\lambda} \ln\left(\frac{8\pi G g \epsilon^2 t^2}{3-\epsilon}\right), \tag{10.1.45}$$

and

$$H = 1/\epsilon t \tag{10.1.46}$$

where ϵ is the positive dimensionless quantity

$$\epsilon \equiv -\frac{\dot{H}}{H^2} = \frac{\lambda^2}{16\pi G} \tag{10.1.47}$$

Inflation with this potential is often called power-law inflation, because $a \propto t^{1/\epsilon}$. It is convenient for the moment to normalize the co-moving coordinates so that

$$a = t^{1/\epsilon}. \tag{10.1.48}$$

Note that $a\dot{\bar{\varphi}}^2/H \propto t^{(1-\epsilon)/\epsilon}$, so our previous assumption that $a\dot{\bar{\varphi}}^2/H$ vanishes for $a(t) \to 0$ is satisfied if $\epsilon < 1$, as we will assume.

For this potential it is convenient to take the constant t_* in the definition (10.1.36) of conformal time as $t_* = \infty$, in which case the conformal time is negative

$$\tau = -\left(\frac{\epsilon}{1-\epsilon}\right) t^{-(1-\epsilon)/\epsilon} \tag{10.1.49}$$

As t and $a(t)$ run from zero to infinity, τ runs from $-\infty$ to zero. In terms of τ, Eq. (10.1.35) now reads

$$\frac{d^2\mathcal{R}_q}{d\tau^2} - \frac{2}{(1-\epsilon)\tau}\frac{d\mathcal{R}_q}{d\tau} + q^2\mathcal{R}_q = 0 \tag{10.1.50}$$

whose solutions are proportional to τ^ν times a Hankel function $H_\nu^{(1)}(-q\tau)$ or $H_v^{(2)}(-q\tau)$, where

$$v = \frac{1}{2}\left(1 + \frac{2}{1-\epsilon}\right) = \frac{3}{2} + \frac{\epsilon}{1-\epsilon}. \tag{10.1.51}$$

For large real x the first Hankel function has the asymptotic behavior

$$H_v^{(1)}(x) \to \sqrt{\frac{2}{\pi x}} \exp(ix - iv\pi/2 - i\pi/4)$$

and $H_\nu^{(2)}(x) = H_\nu^{(1)*}(x)$, so the initial condition (10.1.38) picks out the solution $\propto \tau^\nu H_\nu^{(1)}(-q\tau)$, and fixes its normalization so that

$$\begin{aligned}\mathcal{R}_q(t) = &-\frac{\lambda\sqrt{\pi}}{4(2\pi)^{3/2}\epsilon}\left(\frac{\epsilon}{1-\epsilon}\right)^{-1/(1-\epsilon)} \\ &\times \exp\left(\frac{i\pi v}{2} + \frac{i\pi}{4}\right)(-\tau)^v H_v^{(1)}(-q\tau)\end{aligned} \tag{10.1.52}$$

[4712] L. F. Abbott and M. B. Wise, Nucl. Phys. B 244, 541 (1984); F. Lucchin and S. Matarrese, Phys. Rev. D 32, 1316 (1985); Phys. Lett. B 164, 282 (1985); D. H. Lyth and E. D. Stewart, Phys. Lett. B 274, 168 (1992).

For small real x

$$H_v^{(1)}(x) \to \frac{-i\Gamma(v)}{\pi}\left(\frac{x}{2}\right)^{-v}$$

so outside the horizon, in the limit $q/a \ll H$ where $-q\tau \ll 1$, the quantity $\mathcal{R}_q$ approaches a constant $\mathcal{R}_q^o$, given by Eq. (10.1.52) as

$$\mathcal{R}_q^o = i\frac{\lambda\Gamma(\nu)}{8\sqrt{2}\pi^2\epsilon}\left(\frac{\epsilon}{1-\epsilon}\right)^{-1/(1-\epsilon)}\exp\left(\frac{i\pi\nu}{2}+\frac{i\pi}{4}\right)\left(\frac{q}{2}\right)^{-\nu}. \tag{10.1.53}$$

For purposes of comparison with results for other potentials, it is convenient to rewrite this in terms of quantities at the time t_q of horizon crossing, defined by

$$q/a\,(t_q) = H\,(t_q)\,. \tag{10.1.54}$$

Solving this gives $t_q = (\epsilon q)^{\epsilon/(1-\epsilon)}$ and $H\,(t_q) = q^{-\epsilon/(1-\epsilon)}\epsilon^{-1/(1-\epsilon)}$. It is also convenient to use Eq. (10.1.47) to express λ in terms of ϵ and G. Then Eq. (10.1.53) can be written
$\zeta_q^o = \mathcal{R}_q^o = i\sqrt{16\pi G}q^{-3/2}H\,(t_q)\,\frac{\Gamma(v)2^{\nu-3/2}}{4\pi^2\sqrt{\epsilon}}(1-\epsilon)^{1/(1-\epsilon)}\exp\left(\frac{i\pi\nu}{2}+\frac{i\pi}{4}\right)$.

Note that this formula does not depend on the convention we have chosen in Eq. (10.1.48) for the constant factor in $a(t)$.

To have a sufficient number of e-foldings in inflation, it is necessary for the potential to be fairly flat, so we are chiefly interested in the case where ϵ is small. For $\epsilon \ll 1$, we use $\Gamma(3/2) = \sqrt{\pi}/2$, and write Eq. (10.1.55) as

$$\zeta_q^o = \mathcal{R}_q^o = -i\sqrt{16\pi G}q^{-3/2}H\,(t_q)\,\frac{1}{8\pi^{3/2}\sqrt{\epsilon}}. \tag{10.1.56}$$

The most important point is that for a nearly flat potential, for which $H\,(t_q)$ is nearly q-independent, $\mathcal{R}_q^o$ is nearly proportional to $q^{-3/2}$. This result is not limited to potentials of exponential form, as long as the potential is fairly flat for fields near $\bar{\varphi}\,(t_q)$.

The approximate $q^{-3/2}$ dependence of $\mathcal{R}_q^o$ on q is well supported by observation. We saw in Section 8.1 that the power spectral function $P(k)$ that governs the distribution of dark matter has a dependence on the physical wave number k that for small k is given by a factor $k^4\left|\mathcal{R}_{ka_0}^o\right|^2$, so any potential that is fairly flat for fields near $\bar{\varphi}\,(t_q)$ gives a spectrum close to the HarrisonZel'dovich spectrum, $P(k) \propto k$ for small k. Also, as we saw in Section 6.3, the spectral function $\mathcal{P}_\phi(q)$ for the Newtonian gravitational potential is
proportional for long wavelengths to $\left|\mathcal{R}_q^o\right|^2$, which as shown in Section 2.6 implies that (aside from the integrated Sachs-Wolfe effect and the effects of reionization) the quantity $\ell(\ell+1)C_\ell$ becomes independent of ℓ for small ℓ. And we saw in Sections 7.2 and 7.4 that the near proportionality of $\mathcal{R}_q^o$ to $q^{-3/2}$ gives results for the correlations of temperature and polarization fluctuations in the cosmic microwave background at larger values of ℓ in good agreement with observation.

To be more precise, Eq. (10.1.53) shows that for the exponential potential, the scalar spectral index defined in Section 7.2 by $\left|\mathcal{R}_q^o\right|^2 \propto q^{-4+n_S}$ has the constant value

$$n_S = 4 - 2v = 1 - \frac{2\epsilon}{1-\epsilon}$$

The third-year WMAP result $n_S = 0.958 \pm 0.016$ quoted in Section 7.2 thus shows that for the exponential potential, $\epsilon = 0.021 \pm 0.008$. This is small enough so that we can use the approximate formula (10.1.56). Writing $\left|\mathcal{R}_q^o\right|^2 \simeq |N|^2 q^{-3}$, we see that for the exponential potential

$$|N|^2 \simeq \frac{GH_{\rm exit}^2}{4\pi^2\epsilon}$$

where $H_{\rm exit}$ is the expansion rate at horizon exit, now ignoring its weak dependence on q. The third-year WMAP result $|N|^2 = (1.93 \pm 0.12) \times 10^{-10}$ quoted in Section 7.2 thus shows that for the exponential potential, $H_{\rm exit} \simeq 2\pi|N|\sqrt{\epsilon/G} \simeq 1.5 \times 10^{14}$GeV, corresponding to an energy density $3H_{\rm exit}^2/8\pi G \simeq [2.6 \times 10^{16}{\rm GeV}]^4$.

Of course, the exponential potential is just one special case, with the special property that $V''/V = (V'/V)^2$, so there is no reason to expect these results to apply in detail for other potentials. In Section 10.3 we will see what to expect for general potentials, under the slow-roll approximation. But within the slow-roll approximation, the results for general potentials are similar in order of magnitude to those we have already found for the exponential potential.

We are now in a position to consider the plausibility of the assumption that the action has the simple form (10.1.1). [13] With a single real scalar field χ, there is no loss of generality in taking the action in the form (10.1.1) if

we assume that the action contains at most two spacetime derivatives. The most general action in this case is

$$I_\chi = \int d^4x \sqrt{-\,{\rm Det}\, g}\left[-\frac{1}{2}K(\chi)g^{\mu\nu}\frac{\partial\chi}{\partial x^\mu}\frac{\partial\chi}{\partial x^\nu} - U(\chi)\right],$$

where K and U are real functions of χ that are arbitrary, except that unitarity requires $K \geq 0$. This can be put in the form (10.1.1) by introducing $\varphi = \int d\chi K^{1/2}(\chi)$.

But why should the terms in the action contain no more than two spacetime derivatives? This is only one of a number of similar questions: Why should the action of gravitation contain only the Einstein term, proportional to $\int d^4x\sqrt{-\,{\rm Det}g}R$, and not other generally covariant terms with more than two derivatives of the metric? And why should the action of the standard electroweak model or quantum chromodynamics contain only renormalizable terms?

We do not know the answers to any of these questions with any certainty, but we have at least a plausible possible answer. Any of these additional terms in the action would involve operators of higher dimensionality, but dimensional analysis requires that such terms must be accompanied by coefficients containing additional negative powers of some fundamental mass. If that mass is large enough enough, then the additional terms in the action are suppressed under ordinary conditions. For the success of general relativity, it is only necessary that the length $1/M$ be sub-macroscopic, but unless we impose a condition of baryon and lepton conservation, the fundamental mass appearing in the action of quarks and leptons has to be at least of order 10^{16}GeV, in order to suppress proton decay below experimental bounds.

The inflaton field is considered to take values of the order of the Planck mass, so there is nothing to suppress arbitrary powers of the scalar field in the inflaton action, which is why we take the potential $V(\varphi)$ as an arbitrary function. But spacetime derivatives of the inflaton field yield factors of order q/a, so each additional spacetime derivative would introduce a factor of order q/aM. At horizon exit, q/a equals H, which we have seen is of order 10^{14}GeV, while we would expect M to be much larger, somewhere

[47][13] There is a large literature on other possibilities. Here is a partial list: C. Armendariz-Picon, T. Damour, and V. Mukhanov, Phys. Lett. B 458, 209 (1999) [hep-th/9904075]; J. Martin and R. H. Brandenberger, Phys. Rev. D 63, 1235012 (2001) [hep-th/0005209]; R. H. Brandenberger and J. Martin, Mod. Phys. Lett. A 16, 999 (2001) [astro-ph/0005432]; J. C. Niemeyer, Phys. Rev. D 63, 123502 (2001) [astro-ph/0005533]; J. C. Niemeyer and R. Parentani, Phys. Rev. D 64, 101301 (2001) [astro-ph/0101451]; A. Kempf and J. C. Niemeyer, Phys. Rev. D 64, 103501 (2001) [astro-ph/0103225]; R. Easther, B. R. Greene, W. H. Kinney, and G. Shiu, Phys. Rev. D 64, 103502 (2001) [hep-th/0104102];

[47]Phys. Rev. D 66, 023518 (2002); Phys. Rev. D 67, 063508 (2003) [hep-th/0110226]; R. H. Brandenberger, S. E. Joras, and J. Martin, Phys. Rev. D 66, 083514 (2002) [hep-th/0112122]; N. Kaloper, M. Kleban,

in the range from $|V|^{1/4} \approx 10^{16}$GeV to $1/\sqrt{G} \simeq 10^{19}$GeV. Hence it is plausible that at and after horizon exit, and for some time before horizon exit, terms with more than the minimum number of spacetime derivatives are suppressed. This is all we need to justify the calculations of this section, at least as a good first approximation, as long as we stick to a single inflaton field. The possibility of more than one inflaton field will be discussed in Section 10.4.

10.10.2 10.2 Tensor fluctuations during inflation

The fluctuations in the tensor field $D_{ij}(\mathbf{x}, t)$ during inflation can be treated in much the same way as the scalar fluctuations considered in the previous section. Since the tensor anisotropic inertia π^T_{ij} vanishes for scalar field theories, the field equation (5.1.53) for the tensor modes takes the simple form

$$\nabla^2 D_{ij} - a^2 \ddot{D}_{ij} - 3a\dot{a}\dot{D}_{ij} = 0. \tag{10.2.1}$$

We recall also that D_{ij} satisfies conditions that eliminate any vector or scalar contributions:

$$D_{ij} = D_{ji}, \quad D_{ii} = 0, \quad \partial_i D_{ij} = 0 \tag{10.2.2}$$

The plane wave solutions have the form $e_{ij}\mathcal{D}_q(t)e^{i\mathbf{q}\cdot\mathbf{x}}$, where $\mathcal{D}_q(t)$ satisfies the differential equation

$$\ddot{\mathcal{D}}_q + 3H\dot{\mathcal{D}}_q + \left(q^2/a^2\right)\mathcal{D}_q = 0 \tag{10.2.3}$$

and e_{ij} is a time-independent polarization tensor satisfying the conditions

$$e_{ij} = e_{ji}, \quad e_{ii} = 0, \quad q_i e_{ij} = 0 \tag{10.2.4}$$

We recall from Section 5.2 that for a given unit vector $\hat{q}$, there are two independent polarization tensors satisfying these conditions. For $\hat{q}$ in the three-direction, these can be chosen to have components

$$e_{11} = -e_{22} = 1/\sqrt{2}, \quad e_{12} = e_{21} = \pm i/\sqrt{2}, \quad e_{3i} = e_{i3} = 0. \tag{10.2.5}$$

For $\hat{q}$ in any other direction we define e_{ij} to be the tensor obtained by applying to (10.2.5) the standard rotation (7.4.12) that takes the three-axis into the direction of $\hat{q}$. The polarization tensors constructed in this way are called $e_{ij}(\hat{q}, \pm 2)$, because Eq. (10.2.5) describes a wave of helicity ± 2.

At early times, when $q/a \gg H$, Eq. (10.2.3) has WKB solutions of the form

$$\mathcal{D}_q(t) \to h(t) \exp\left(-iq \int_{t_*}^{t} \frac{dt'}{a\,(t')}\right) \tag{10.2.6}$$

where $h(t)$ varies much more slowly than the argument of the exponential, and t_* is arbitrary. Then the terms in Eq. (10.2.3) of second order in q/a cancel, while the terms of first order give $2\dot{h} + 2Hh = 0$, so that $h \propto a^{-1}$. From now on we will define $\mathcal{D}_q(t)$ as the solution of Eq. (10.2.3) which is normalized so that, for $a(t) \to 0$,

A. Lawrence, and S. Shenker, Phys. Rev. D 66, 123510 (2002) [hep-th/0201158]; N. Kaloper, M. Kleban, A. Lawrence, S. Shenker, and L. Susskind, J. High Energy Phys. 0211, 037 (2002) [hep-th/0209231]; U. H. Danielsson, Phys. Rev. D 66, 023511 (2002); L. Bergström and U. H. Danielsson, J. High Energy Phys. 12, 38 (2002); C. P. Burgess, J. M. Cline, F. Lemieux, and R. Holman, J. High Energy Phys. 2, 48 (2003); J. Martin and R. Brandenberger, Phys. Rev. D 68, 063513 (2003); J. Martin and C. Ringeval, Phys. Rev. D 69, 083515 (2004); T. Okamoto and E. A. Lim, Phys. Rev. D 69, 083519 (2004). R. de Putter and E. V. Linder, 0705.0400.

$$\mathcal{D}_q(t) \to \frac{\sqrt{16\pi G}}{(2\pi)^{3/2}\sqrt{2q}a(t)} \exp\left(-iq\int_{t_*}^{t}\frac{dt'}{a\left(t'\right)}\right). \tag{10.2.7}$$

Since $\mathcal{D}_q(t)$ and $\mathcal{D}_q^*(t)$ are a complete set of solutions of Eq. (10.2.3), the most general real tensor field satisfying the conditions (10.2.1) and (10.2.2) takes the form

$$\begin{aligned} D_{ij}(\mathbf{x},t) = \sum_{\lambda=\pm 2}\int d^3q \left[\mathcal{D}_q(t)e^{i\mathbf{q}\cdot\mathbf{x}}\beta(\mathbf{q},\lambda)e_{ij}(\hat{q},\lambda)\right. \\ \left.+\mathcal{D}_q^*(t)e^{-i\mathbf{q}\cdot\mathbf{x}}\beta^*(\mathbf{q},\lambda)e_{ij}^*(\hat{q},\lambda)\right] \end{aligned} \tag{10.2.8}$$

(That is, instead of characterizing two independent solutions $\mathcal{D}_{1q}(t)$ and $\mathcal{D}_{2q}(t)$ of Eq. (10.2.3) by their behavior at late times, as we did in Section 5.2, we now take them as $\mathcal{D}_q(t)$ and $\mathcal{D}_q^*(t)$, characterized by their behavior at early times.) With $\mathcal{D}_q(t)$ normalized to satisfy Eq. (10.2.7), the canonical commutation relations require that

$$\left[\beta(\mathbf{q},\lambda),\beta\left(\mathbf{q}',\lambda'\right)\right]=0, \quad \left[\beta(\mathbf{q},\lambda),\beta^*\left(\mathbf{q}',\lambda'\right)\right]=\delta^3\left(\mathbf{q}-\mathbf{q}'\right)\delta_{\lambda\lambda'}. \tag{10.2.9}$$

Thus $\beta(\mathbf{q},\lambda)$ and $\beta^*(\mathbf{q},\lambda)$ can be interpreted as the annihilation and creation operators for a graviton of helicity λ.

As in the case of scalar perturbations, we assume that during inflation the universe is in a quantum state $|0\rangle$ satisfying the vacuum condition $\beta(\mathbf{q},\lambda)|0\rangle = 0$. Then expectation values of products of D s are Gaussian, with pairings

$$\langle 0|D_{ij}(\mathbf{x},t)D_{kl}(\mathbf{y},t)|0\rangle = \int d^3q e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})}\left|\mathcal{D}_q(t)\right|^2\Pi_{ij,kl}(\hat{q}) \tag{10.2.10}$$

where $\Pi_{ij,kl}(\hat{q})$ is the helicity sum given by Eq. (5.2.25):

$$\begin{aligned} \Pi_{ij,k\ell}(\hat{q}) \equiv& \sum_{\lambda} e_{ij}(\hat{q},\lambda)e_{k\ell}^*(\hat{q},\lambda) \\ =&\delta_{ik}\delta_{j\ell}+\delta_{i\ell}\delta_{jk}-\delta_{ij}\delta_{k\ell}+\delta_{ij}\hat{q}_k\hat{q}_\ell+\delta_{k\ell}\hat{q}_i\hat{q}_j-\delta_{ik}\hat{q}_j\hat{q}_\ell-\delta_{i\ell}\hat{q}_j\hat{q}_k \\ &-\delta_{jk}\hat{q}_i\hat{q}_\ell-\delta_{j\ell}\hat{q}_i\hat{q}_k+\hat{q}_i\hat{q}_j\hat{q}_k\hat{q}_\ell \end{aligned} \tag{10.2.11}$$

For any given potential, the function $\mathcal{D}_q(t)$ is to be calculated by integrating the differential equation (10.2.3) with the initial condition (10.2.7).

Outside the horizon, for $q/a \ll H$, the solution becomes a constant $\mathcal{D}_q^o$, which provides an initial condition for the gravitational wave when it re-enters the horizon. In carrying this out, it is again useful to replace ordinary time as the independent variable with conformal time

$$\tau \equiv -\int_t^\infty \frac{dt'}{a\left(t'\right)} \tag{10.2.12}$$

and take $t_* = \infty$ in Eq. (10.2.7). Eq. (10.2.3) then becomes

$$\frac{d^2\mathcal{D}_q}{d\tau^2}+2Ha\frac{d\mathcal{D}_q}{d\tau}+q^2\mathcal{D}_q=0 \tag{10.2.13}$$

Note that

$$Ha=\frac{da}{dt}=\frac{1}{a}\frac{da}{d\tau}$$

Thus Eq. (10.2.13) is the same as the Mukhanov-Sasaki equation (10.1.35) except that $z \equiv a\dot{\bar{\varphi}}/H$ is replaced with a.

The initial condition (10.2.7) for $q/aH \gg 1$ is independent of the details of the potential, while for $q/aH \ll 1$ the tensor amplitude $\mathcal{D}_q(t)$ simply approaches a constant $\mathcal{D}_q^o$. Hence, just as for the scalar amplitude $\mathcal{R}_q^0$, the tensor amplitude $\mathcal{D}_q^o$ outside the horizon can only depend on the behavior of the potential at values of $\bar{\varphi}(t)$ at around the time of horizon exit, when q/aH is of order unity. Thus the measurements of the tensor amplitude after horizon re-entry can only tell us about the last $\mathcal{N}e$-foldings of inflation, with $\mathcal{N}$ bounded by Eq. (10.1.40), just as for scalar modes.

As for scalar modes, it is useful to consider as a test case the one potential for which $\mathcal{D}_q^o$ can be calculated analytically without relying on the slow-roll approximation, the exponential potential (10.1.44). For this potential $\dot{\bar{\varphi}}/H$ is the constant $2\epsilon/\lambda$, so Eq. (10.1.37) gives $z \propto a$, and in this case Eq. (10.2.13) is precisely the same as the Mukhanov-Sasaki equation. Also, the initial condition (10.2.7) is the same as the initial condition (10.1.38), except for a factor $-2\epsilon\sqrt{16\pi G}/\lambda = -2\sqrt{\epsilon}$. Hence for the exponential potential:

$$\mathcal{D}_q(t)/\mathcal{R}_q(t) = -2\epsilon\sqrt{16\pi G}/\lambda = -2\sqrt{\epsilon} \tag{10.2.14}$$

Of course, the values $\mathcal{D}_q^o$ and $\mathcal{R}_q^o$ outside the horizon then also have this ratio. This is usually expressed in terms of a scalar tensor ratio, conventionally defined as

$$r_q \equiv 4\left|\mathcal{D}_q^o/\mathcal{R}_q^o\right|^2 \tag{10.2.15}$$

We see that for the exponential potential, r_q has the wavelength-independent value

$$r = 16\epsilon \tag{10.2.16}$$

We saw in the previous section that for the exponential potential the thirdyear WMAP results give $\epsilon = 0.021 \pm 0.008$, so that $r = 0.34 \pm 0.13$. This is almost incompatible with the upper bound $r < 0.3$ on r set (for this value of ϵ) by the third-year WMAP results, [1] so a potential $V(\varphi)$ that is exponential around the value that φ takes at the time of horizon exit is almost ruled out. (Of course, we already knew that the potential could not be exponential over the whole range of φ, for then inflation would never end, but we are here not relying on any assumption about the form of the potential except for the values of φ taken around the time of horizon exit.) To analyze tensor as well as scalar perturbations for more general potentials, we need to invoke the slow-roll approximation, to which we turn in the next section.

10.10.3 10.3 Fluctuations during inflation: The slow-roll approximation

It is not possible to calculate the scalar and tensor perturbations $\mathcal{R}_q(t)$ and $\mathcal{D}_q(t)$ analytically for general potentials. However, the need (discussed in Chapter 4) for a substantial number of e-foldings of expansion during inflation suggests that H should have been slowly varying during an era long compared with $1/H$. We will therefore now assume that H varies little throughout a "slow-roll" era, during which q/aH goes from much less to much greater than unity. We saw in Sections 10.1 and 10.2 that the asymptotic values $\mathcal{R}_q^o$ and $\mathcal{D}_q^o$ depend only on the evolution of the fields around the time of horizon crossing, when $q/a \approx H$, so it will not be necessary for us to assume that the slow-roll era extends back to the beginning of the expansion, or forward to the end of inflation.

We will work with the Mukhanov-Sasaki equation (10.1.35): [1]

$$\frac{d^2\mathcal{R}_q}{d\tau^2} + \frac{2}{z}\frac{dz}{d\tau}\frac{d\mathcal{R}_q}{d\tau} + q^2\mathcal{R}_q = 0, \tag{10.3.1}$$

where τ is the conformal time, and

$$z \equiv \frac{a\dot{\bar{\varphi}}}{H}. \tag{10.3.2}$$

Recalling once again that $\dot{H} = -4\pi G\dot{\bar{\varphi}}^2$, we can write

$$\frac{1}{z}\frac{dz}{d\tau} = aH(1+\delta+\epsilon) \tag{10.3.3}$$

where for a general potential

$$\epsilon \equiv -\dot{H}/H^2, \quad \delta \equiv \ddot{H}/2H\dot{H} \tag{10.3.4}$$

We also need a formula for aH in terms of τ. For this purpose, we note that

$$\frac{d}{d\tau}\left(\frac{1}{aH}\right) = -1+\epsilon \tag{10.3.5}$$

So far, everything is exact. The slow-roll approximation requires that ϵ and δ are small during the era of horizon crossing, which has the consequence that ϵ varies little during this era, because

$$\dot{\epsilon} = 2\epsilon(\epsilon+\delta)H \tag{10.3.6}$$

We will also assume that δ varies little. [2] (Of course, ϵ and δ cannot be strictly constant except for an exponential potential, for which $H \propto 1/t$ and therefore $\delta = -\epsilon$.) Integrating Eq. (10.3.5) then gives, for a suitable choice of an additive constant in τ,

$$aH = -\frac{1}{(1-\epsilon)\tau} \tag{10.3.7}$$

As in the case of the exponential potential, τ is negative, and its magnitude goes from $-\tau \gg 1/q$ early in inflation when $q/aH \gg 1$, to $-\tau \ll 1/q$ for $q/aH \ll 1$. Using Eqs. (10.3.3) and (10.3.7) in Eq. (10.3.1) then gives, to first order in ϵ and δ,

$$\frac{d^2\mathcal{R}_q}{d\tau^2} - \frac{2(1+\delta+2\epsilon)}{\tau}\frac{d\mathcal{R}_q}{d\tau} + q^2\mathcal{R}_q = 0 \tag{10.3.8}$$

The general solution of this equation for constant δ and ϵ is a linear combination of $\tau^\nu H_\nu^{(1)}(-q\tau)$ and $\tau^\nu H_\nu^{(2)}(-q\tau)$, where now

$$v = \frac{3}{2} + 2\epsilon + \delta \tag{10.3.9}$$

This agrees to first order in ϵ with the result (10.1.51) for the exponential potential, for which $\delta = -\epsilon$.

Now, we are not assuming that the slow-roll approximation applies all the way back to the beginning of the expansion, but fortunately this is not necessary. Eq. (10.1.38) should

[471] See Figure 14 of D. Spergel et al., Astrophys. J. Suppl. Ser. 170, 377 (2007) [astro-ph/0603449].

[1] This is usually given in the equivalent form

$$\frac{d^2u_q}{d\tau^2} + \left[q^2 - \frac{1}{z}\frac{d^2z}{d\tau^2}\right]u_q = 0$$

where $u_q \equiv z\mathcal{R}_q$. It is easier to work with it in the form (10.3.1), if only because in this way we only need to calculate the first derivative of z.

[472] This is the case for a power-law potential, under the same condition $|\varphi| \gg 1/\sqrt{4\pi G}$ that was found necessary in Section 4.2 to justify the slow-roll approximation. For the consequences of dropping this assumption, see S. Dodelson and E. D. Stewart, Phys. Rev. D 65, 101301 (2002) [astro-ph/0109354]; E. D. Stewart, Phys. Rev. D 65, 103508 (2002) [astro-ph/0110322].

still apply by the beginning of the slow-roll era, when q/aH is still very large, so this initial condition fixes the solution during the whole of the slow-roll era as

$$\mathcal{R}_q(t) = -\frac{\sqrt{-\pi\tau}}{2(2\pi)^{3/2}z(\tau)}e^{i\pi v/2+i\pi/4}H_v^{(1)}(-q\tau). \tag{10.3.10}$$

(Note that Eqs. (10.3.3) and (10.3.7) give $z(\tau) \propto \tau^{-v+1/2}$ during the slowroll era.) Then late in the slow-roll era, when $q/aH \ll 1$, Eq. (10.3.10) has the asymptotic value

$$\mathcal{R}_q^o = i\frac{\sqrt{-\tau}\Gamma(v)}{2\sqrt{\pi}(2\pi)^{3/2}z(t)}e^{i\pi v/2+i\pi/4}\left(\frac{-q\tau}{2}\right)^{-v}, \tag{10.3.11}$$

which is constant because Eqs. (10.3.3) and (10.3.7) give $z \propto \tau^{-v+1/2}$. Thus $\mathcal{R}_q^o$ has the q-dependence [3]

$$\mathcal{R}_q^o \propto q^{-\nu} = q^{-3/2-2\epsilon-\delta} \tag{10.3.12}$$

This may be regarded as a generalization of the result $\mathcal{R}_q^o \propto q^{-3/2-\epsilon}$ that we found for the exponential potential, to the case where $\delta \neq -\epsilon$.

Because $\mathcal{R}_q^o$ is time-independent, it can be calculated by setting t in Eq. (10.3.11) to any convenient value. We shall evaluate it at the time t_q of horizon crossing, defined as in Sections 10.1 and 10.2 by

$$q/a\left(t_q\right) = H\left(t_q\right). \tag{10.3.13}$$

(But note that Eq. (10.3.10) with $t = t_q$ does not give the correct value of $\mathcal{R}_q^o$.) Ignoring corrections of order ϵ or δ except in exponents, Eq. (10.3.7) gives

$$\tau\left(t_q\right) = -\frac{1}{(1-\epsilon)q} \simeq -\frac{1}{q}. \tag{10.3.14}$$

Also, $\dot{H} = -4\pi G\dot{\bar{\varphi}}^2$, so

$$\dot{\bar{\varphi}}\left(t_q\right) = \pm\sqrt{-\dot{H}\left(t_q\right)}/\sqrt{4\pi G} = \pm H\left(t_q\right)\sqrt{\epsilon\left(t_q\right)}/\sqrt{4\pi G}.$$

and so

$$z\left(t_q\right) = \frac{\pm\sqrt{\epsilon\left(t_q\right)}q}{H\left(t_q\right)\sqrt{4\pi G}} \tag{10.3.15}$$

The slow-roll approximation thus gives [4]

$$\mathcal{R}_q^o = \mp i\frac{\sqrt{16\pi G}q^{-3/2}H\left(t_q\right)}{8\pi^{3/2}\sqrt{\epsilon\left(t_q\right)}} \tag{10.3.16}$$

This is the same as the result (10.1.56) for an exponential potential, except that the factor $1/\sqrt{\epsilon\left(t_q\right)}$ now contributes to the q-dependence of $\mathcal{R}_q^o$. (To check that the q dependence of $H\left(t_q\right)$ and $\epsilon\left(t_q\right)$ gives the extra factor $q^{-2\epsilon-\delta}$, we differentiate Eq. (10.3.13) with respect to q, and find

[473] E. D. Stewart and D. H. Lyth, Phys. Lett. B 302, 171 (1993). This calculation was carried to the next order of the slow-roll approximation by A. R. Liddle and M. S. Turner, Phys. Rev. D 50, 758 (1994). For a review, see J. E. Lidsey, A. R. Liddle, E. W. Kolb, E. J. Copeland, T. Barreiro, and M. Abney, Rev. Mod. Phys. 69, 373 (1997).

$$\frac{dt_q}{dq} = \frac{1}{a\left(t_q\right)\left(H^2\left(t_q\right) + \dot{H}\left(t_q\right)\right)}$$

Then

$$\frac{q}{H\left(t_q\right)}\frac{dH\left(t_q\right)}{dq} = \frac{\dot{H}\left(t_q\right)}{H^2\left(t_q\right) + \dot{H}\left(t_q\right)} = -\frac{\epsilon\left(t_q\right)}{1-\epsilon\left(t_q\right)}$$

and Eq. (10.3.6) gives

$$\frac{q}{\epsilon\left(t_q\right)}\frac{d\epsilon\left(t_q\right)}{dq} = \frac{2\left(\epsilon\left(t_q\right) + \delta\left(t_q\right)\right)}{1-\epsilon\left(t_q\right)}$$

Hence, replacing the denominators $1-\epsilon$ with unity, $H\left(t_q\right) \propto q^{-\epsilon}$ and $\epsilon\left(t_q\right) \propto q^{2\epsilon+2\delta}$, and so $H\left(t_q\right)/\sqrt{\epsilon\left(t_q\right)} \propto q^{3/2-v}$, which gives Eq. (10.3.16) the q-dependence (10.3.12).)

Now let us apply the slow-roll approximation to the tensor modes. In general, the tensor wave equation (10.2.3) can be written as

$$\frac{d^2\mathcal{D}_q}{d\tau^2} + 2aH\frac{d\mathcal{D}_q}{d\tau} + q^2\mathcal{D}_q = 0 \tag{10.3.17}$$

During the slow-roll era, we can use Eq. (10.3.7) to put this in the form

$$\frac{d^2\mathcal{D}_q}{d\tau^2} - \frac{2}{(1-\epsilon)\tau}\frac{d\mathcal{D}_q}{d\tau} + q^2\mathcal{D}_q = 0 \tag{10.3.18}$$

The general solution for constant ϵ is a linear combination of $\tau^\mu H_\mu^{(1)}(-q\tau)$ and $\tau^\mu H_\mu^{(2)}(-q\tau)$, with

$$\mu = \frac{3}{2} + \frac{\epsilon}{1-\epsilon}. \tag{10.3.19}$$

The solution during the slow-roll era that satisfies the initial condition (10.2.7) is

$$\mathcal{D}_q(t) = \frac{\sqrt{16\pi G}}{(2\pi)^{3/2}\sqrt{2q}a(t)}\sqrt{\frac{-q\tau\pi}{2}}\exp(i\mu\pi/2 + i\pi/4)H_\mu^{(1)}(-q\tau). \tag{10.3.20}$$

(Note that Eq. (10.3.7) gives $(\tau/a)da/d\tau = aH\tau = -1/(1-\epsilon)$, so $a \propto \tau^{-1/(1-\epsilon)}$ and therefore $\sqrt{-\tau}/a \propto \tau^\mu$.) The asymptotic solution for $q/a \ll H$ is then

$$\mathcal{D}_q^o = -i\frac{\sqrt{16\pi G}\Gamma(\mu)\sqrt{-\tau}}{2\sqrt{\pi}(2\pi)^{3/2}a(t)}\exp(i\mu\pi/2 + i\pi/4)\left(\frac{-q\tau}{2}\right)^{-\mu}. \tag{10.3.21}$$

Thus $\mathcal{D}_q^o$ has the q-dependence [3]

$$\mathcal{D}_q^o \propto q^{-\mu} \simeq q^{-3/2-\epsilon}. \tag{10.3.22}$$

In contrast with the case of the exponential potential, the asymptotic q-dependence of the tensor modes is in general different from that of the scalar modes.

We can give a more convenient expression for $\mathcal{D}_q^o$ by setting $t = t_q$ in Eq. (10.3.21). Then using Eq. (10.3.14) and $a\left(t_q\right) = q/H\left(t_q\right)$ and taking $\epsilon \to 0$ everywhere but in the q-dependence of $H\left(t_q\right)$, Eq. (10.3.21) gives [5]

[474] S. W. Hawking, Phys. Lett. B 115, 295 (1982); A. A. Starobinsky, Phys. Lett. B 117, 175 (1982); A. Guth and S.-Y. Pi, Phys. Rev. Lett. 49, 1110 (1982); J. M. Bardeen, P. J. Steinhardt and M. S. Turner, Phys. Rev. D 28, 679 1983); D. H. Lyth, Phys. Lett. B 147, 403 (1984); B 150, 465 (1985); Phys. Rev. D 31, 1792 (1985).

$$\mathcal{D}_q^o = i\frac{\sqrt{16\pi G}H\left(t_q\right)}{4\pi^{3/2}q^{3/2}}. \tag{10.3.23}$$

It is conventional to write the q-dependence of the squared magnitudes of the tensor and scalar amplitudes outside the horizon as

$$\left|\mathcal{D}_q^o\right|^2 \propto q^{-3+n_T(q)}, \quad \left|\mathcal{R}_q^o\right|^2 \propto q^{-4+n_S(q)}. \tag{10.3.24}$$

Then in the slow-roll approximation, Eqs. (10.3.12) and (10.3.22) give

$$n_T(q) = -2\epsilon\left(t_q\right), \quad n_S(q) = 1 - 4\epsilon\left(t_q\right) - 2\delta\left(t_q\right). \tag{10.3.25}$$

(As a check, recall that for the exponential potential $\delta = -\epsilon$, so Eq. (10.3.25) gives $n_S = 1 - 2\epsilon$, in agreement with the result of Section 10.1.) Also,
comparison of Eqs. (10.3.16) and (10.3.23) yields the relation

$$r(q) = 16\epsilon\left(t_q\right) = -8n_T(q) \tag{10.3.26}$$

where, with the conventional definition of $r, r(q) \equiv 4\left|\mathcal{D}_q^o/\mathcal{R}_q^o\right|^2$. This relation among measurable quantities is known in the literature as the slow-roll consistency condition. For any potential other than the exponential potential the scalar/tensor ratio r depends on q.

For inflation with a single inflaton field, the relation $\dot{H} = -4\pi G\dot{\bar{\varphi}}^2$ tells us that $\epsilon(t)$ is always positive, but $\delta(t)$ can have either sign, so in general Eq. (10.3.25) gives $n_T(q) < 0$, while $n_S(q)$ can be greater or less than unity. Nevertheless, experience with many models shows [6] that physically plausible potentials that are not finely tuned tend to have $n_S(q)$ less than unity, and even less than 0.98 . But for slow-roll inflation, ϵ and δ are small, so $n_S(q)$ cannot be very much less than unity. Thus the general picture of slow-roll inflation received some support from the third-year WMAP result quoted in Section 7.2, that $n_S = 0.958 \pm 0.016$.

As we saw in Chapter 7, the quantities $q^3\left|\mathcal{D}_q^o\right|^2$ and $q^3\left|\mathcal{R}_q^o\right|^2$ provide a measure of the contribution of tensor and scalar fluctuations to the multipole coefficients $C_{TT,\ell}$ in the angular distribution of the cosmic microwave background temperature. From Eq. (10.3.26) we can see that the tensor modes are likely to contribute much less to the $C_{TT,\ell}$ than the scalar modes. Also, Eq. (10.3.16) and the fact that anisotropies in the cosmic microwave background temperature are small but not too small to be observed indicates that the Hubble constant during the slow-roll era must be small compared with the Planck mass $1/\sqrt{G}$, but not too small. In the slow-roll limit, where $v \simeq 3/2$, we can write $\left|\mathcal{R}_q^o\right|^2 = |N|^2 q^{-3}$, and Eq. (10.3.16) shows that

$$|N|^2 = \frac{16\pi G H_{\rm exit}^2}{64\pi^3\left|\epsilon_{\rm exit}\right|} = \frac{(8\pi G)^2\bar{\rho}_{\rm exit}}{96\pi^3\left|\epsilon_{\rm exit}\right|},$$

where the subscript "exit" denotes the time of horizon exit, and in accordance with the slow-roll approximation we here ignore the weak dependence of this time on q. As we saw in Section 7.2, the factor $|N|^2$ has the value $(1.93 \pm 0.12) \times 10^{-10}$, so

$$\frac{\bar{\rho}_{\rm exit}}{\left|\epsilon_{\rm exit}\right|} = \left[(6.70 \pm 0.10) \times 10^{16}{\rm GeV}\right]^4 \tag{10.3.27}$$

Measurements of cosmic microwave background anisotropies have so far been sensitive only to the spectral index of the scalar rather than the tensor modes, and therefore have yielded

[475] A. A. Starobinsky, JETP Lett. 30, 683 (1979).

Efstathiou and K. J. Mack, J. Cosm. Astropart. Phys. 05, 008 (2005); L. A. Boyle, P. J. Steinhardt, and N. Turok, Phys. Rev. Lett. 96, 111301 (2006).

information only on $\delta + 2\epsilon$, not ϵ, but unless there is a cancelation between δ and 2ϵ, these measurements suggest that $|\epsilon|$ is probably not much greater than a few percent. If for instance we take $|\epsilon|_{\rm exit} = 0.05$, then $\bar\rho_{\rm exit} \simeq [3.2 \times 10^{16}{\rm GeV}]^4$. In any case, we now see that in inflationary theories, the smallness of cosmic fluctuations before horizon re-entry is simply a reflection of the fact that, for reasons that are still mysterious, the energy scale defined by the energy density of the universe at horizon exit is a few orders of magnitude less than the Planck energy scale, $(8\pi G)^{-1/2} = 2.4 \times 10^{18}{\rm GeV}$.

This mystery is strongly reminiscent of another mystery encountered in elementary particle physics: the unification energy scale, where the three coupling constants of the electroweak and strong interactions all come together, [7] is about $2 \times 10^{16}{\rm GeV}$, also a few orders of magnitude less than the Planck energy scale $(8\pi G)^{-1/2}$. Perhaps they are the same mystery.

The measured values of n_S and $|N|$ and the observational upper limit on the tensor/scalar ratio r already allow us to put useful constraints on the inflaton potential. We saw in the previous section that this data is close to ruling out any potential $V(\bar\varphi)$ with an exponential dependence on $\bar\varphi$ for the values that $\bar\varphi(t)$ takes around the time of horizon exit. To go further, it is useful first to express ϵ and δ in terms of the potential. Using the general relation (4.2.3)

$$\dot H = -4\pi G\dot{\bar\varphi}^2,$$

and the slow-roll formula (4.2.8)

$$\dot{\bar\varphi} = -\frac{V'(\varphi)}{3H} = -\frac{V'(\varphi)}{\sqrt{24\pi G V(\varphi)}},$$

gives

$$\epsilon(t) = \frac{1}{16\pi G}\left(\frac{V'(\bar\varphi(t))}{V(\bar\varphi(t))}\right)^2. \tag{10.3.28}$$

Also, the time-derivative of Eq. (4.2.3) gives $\ddot H = -8\pi G\dot{\bar\varphi}\ddot{\bar\varphi}$, and using Eq. (4.2.12) then gives

$$\delta(t) = \frac{1}{16\pi G}\left(\frac{V'^2(\bar\varphi(t))}{V^2(\bar\varphi(t))} - \frac{2V''(\bar\varphi(t))}{V(\bar\varphi(t))}\right). \tag{10.3.29}$$

10.10.4 10.3 Fluctuations during inflation: The slow-roll approximation

For instance, for a power-law potential $V(\varphi) \propto \varphi^\alpha$, we have

$$\epsilon(t) = \frac{\alpha^2}{16\pi G\bar\varphi^2(t)}, \quad \delta(t) = \frac{2\alpha - \alpha^2}{16\pi G\bar\varphi^2(t)}, \tag{10.3.30}$$

so $\delta(t) = (2/\alpha - 1)\epsilon(t)$, and therefore

$$n_S(q) = 1 - \frac{(\alpha+2)r(q)}{8\alpha} \tag{10.3.31}$$

The experimental bound on n_S depends on the value assumed for r, so observations define an allowed region in the $n_S - r$ plane. [8] At present, the straight line (10.3.31) intersects the (68% confidence level) allowed region for all positive α, even when WMAP three year data is combined with data from the CBI and VSA microwave backgrounds, or from the Sloan or 2 dF

[477] See e.g. QTF, Vol. II, Sec. 28.2.

sky surveys. However, low values of α are favored, and even a modest shrinking of the allowed area would rule out high values of α.

To go further, we need to say something about the value of the scalar field at horizon exit. For this purpose, we can make use of the relation (4.2.14), which gives the number $\Delta\mathcal{N}$ of e-foldings when the scalar field goes from φ_1 to φ_2, under the assumption that the slow-roll approximation holds over this period, as

$$\Delta\mathcal{N} = -\int_{\varphi_1}^{\varphi_2} \left(\frac{8\pi G V(\varphi)}{V'(\varphi)}\right) d\varphi \tag{10.3.32}$$

If $|V'/V| \simeq \sqrt{16\pi G\epsilon}$ is essentially constant over the range of φ from φ_1 to φ_2, then the number of e-foldings associated with this change in φ is

$$\Delta\mathcal{N} = \Delta\varphi\sqrt{4\pi G/\epsilon} \tag{10.3.33}$$

Lyth [9] has used this relation in the case where φ_1 and φ_2 are the field values at horizon exit for wave numbers corresponding to $\ell \simeq 1$ and $\ell \simeq 100$, for which $\Delta\mathcal{N} = \ln 100 = 4.6$, to show that if ϵ is large enough to give a detectable tensor mode, then the scalar field must change by an amount that is at least as large as the Planck scale $1/\sqrt{4\pi G}$.

If we make the strong assumption that the slow roll approximation holds over the whole era from horizon exit to the end of inflation, but do not now assume that ϵ is necessarily constant through this era, then for a power-law

potential $V(\varphi) \propto \varphi^\alpha$, Eq. (10.3.32) gives the number of e-foldings from horizon exit for a wave number q to the end of inflation as

$$\mathcal{N}(q) = \frac{4\pi G}{\alpha}\left[\bar{\varphi}^2(t_q) - \bar{\varphi}^2(t_{\rm end})\right], \tag{10.3.34}$$

where t_q and $t_{\rm end}$ are the times of horizon exit and the end of inflation, respectively. If we further assume that $|\bar{\varphi}(t_{\rm end})| \ll |\bar{\varphi}(t_q)|$, then

$$\bar{\varphi}^2(t_q) \simeq \frac{\alpha\mathcal{N}(q)}{4\pi G}, \tag{10.3.35}$$

so Eq. (10.3.30) gives

$$\epsilon(t_q) \simeq \frac{\alpha}{4\mathcal{N}(q)}, \quad \delta(t_q) \simeq \frac{2-\alpha}{4\mathcal{N}(q)}$$

and therefore [10]

$$n_S(q) \simeq 1 - \frac{\alpha+2}{2\mathcal{N}(q)}, \quad r(q) = \frac{4\alpha}{\mathcal{N}(q)}. \tag{10.3.36}$$

We noted in Section 10.1 that if the energy density at the beginning of the radiation-dominated era is the Planck density G^{-2}, then $\mathcal{N}(q) \simeq 68$ for wave numbers that are just coming into the horizon at the present, and correspondingly less for larger wave numbers; for instance, for wave numbers corresponding to $\ell = 100, \mathcal{N}$ would be less by an amount $\ln 100 = 4.6$. To derive a better estimate of $\mathcal{N}$, we can use Eq. (10.3.27). Under the risky assumption that the energy density ρ_1 at the beginning of the radiationdominated era is the same as at horizon exit, and taking $\epsilon = O(.02)$, we have $\rho_1 \simeq [2.5 \times 10^{16}\text{GeV}]^{1/4}$, so Eq. (10.1.43) with $h = 0.7$ shows that for a wave number that just enters the horizon at the present, $\mathcal{N} \simeq 62$, while for the

[478] See Figure 14 of D. Spergel et al., Astrophys. J. Suppl. Ser. 170, 377 (2007) [astro-ph/0603449].

[9] D. H. Lyth, Phys. Rev. Lett. 78, 1861 (1997) [hep-ph/9606387]. Also see G. Efstathiou and K. J. Mack, J. Cosm. & Astropart. Phys. 05, 008 (2005) [astro-ph/0503360]; R. Easther, W. H. Kinney, and B. A. Powell, J. Cosm. Astropart. Phys. 08, 004 (2006) [astro-ph/0601276].

wave number corresponding to $\ell \simeq 100, \mathcal{N} \simeq 57$. Taking $\mathcal{N} = 60$, for a quadratic potential Eq. (10.3.36) gives $n_S = .97$ and $r = 0.13$, which is consistent with the WMAP third-year results, while for a quartic potential Eq. (10.3.35) gives $n_S = 0.95$ and $r = 0.26$, which is barely outside the range allowed by WMAP. [11] Any $\alpha > 4$ is ruled out. But this conclusion is contingent on the assumption of a slow-roll inflation from the time of horizon exit until the end of inflation, with $V(\bar{\varphi}(t)) \propto \bar{\varphi}^\alpha(t)$ over this whole period.

10.10.5 10.4 Multifield inflation

Observations of the cosmic microwave background and large scale structure indicate that the primordial scalar fluctuations outside the horizon are

- nearly Gaussian,
- adiabatic,
- nearly scale invariant, in the sense that $\mathcal{R}_q^o$ is nearly proportional to $q^{-3/2}$,
- weak, in the sense that $q^{3/2}\mathcal{R}_q^o \ll 1$. (We saw in Section 7.2 that $q^{3/2}\mathcal{R}_q^o$ is of order 10^{-5}.)

We have seen in Sections 10.1 and 10.3 that these properties of primordial scalar fluctuations follow under the assumptions that

1. The energy density during inflation receives appreciable contributions from just a single real "inflaton" scalar field. This implies that the fluctuations are adiabatic during inflation, in which case they remain so thereafter.

2. During the era of horizon exit (say, for q/aH falling from 10 to 0.1), H is sufficiently small so that q/a is less than whatever fundamental scale (such as the grand unification scale or the Planck scale) characterizes the theory, not only during this era but for some time before it. (For the case considered in Section 10.1, we estimated that $H \approx 10^{14}$GeV, which is probably small enough.) This implies that during this era the scalar field is described by a simple effective action, involving no more than two spacetime derivatives. It follows that for some time before the era of horizon exit the inflaton behaves like a free field, so that the fluctuations are Gaussian.

3. For observed fluctuations, in the era of horizon exit inflation is "slowroll," in the sense that $|\dot{H}|/H^2 \ll 1$ and $|\ddot{H}/H\dot{H}| \ll 1$. Together with assumptions 1 and 2, this implies that the fluctuations are nearly scale invariant.

But there is no particular reason to believe that the energy density during inflation is dominated by a single scalar field, so we are naturally led to consider the case of several inflaton fields $\varphi^n(x)$. We shall show that the same properties of primordial scalar fluctuations follow if we make assumptions 2 and 3 , but replace assumption 1 with

1*. The energy in all the scalar fields is converted at the end of inflation into ordinary matter and radiation in local thermal equilibrium, in which all chemical potentials vanish. (Baryon and lepton number would then have to be generated later, as discussed in Section 3.3.)

Whatever the number of scalar fields, under assumption 2, the effective action of the scalar fields is dominated by terms with a minimum number of spacetime derivatives during and after

[4710] D. H. Lyth and A. Riotto, Phys. Rep. 314, 1 (1999).

[11] D. Spergel, ref. 8.

the era of horizon exit and for some time before it. For arbitrary numbers of scalar fields, the most general such action takes the form

$$I_\varphi = \int d^4x \sqrt{-\operatorname{Det} g}\left[-\frac{1}{2}g^{\mu\nu}\gamma_{nm}(\varphi)\frac{\partial\varphi^n}{\partial x^\mu}\frac{\partial\varphi^m}{\partial x^\nu} - V(\varphi)\right], \tag{10.4.1}$$

where $V(\varphi)$ is an arbitrary real potential, repeated scalar field indices are summed, and $\gamma_{nm}(\varphi)$ is an arbitrary real symmetric positive-definite matrix, which we shall call the field metric. (This matrix must be positive-definite to give the right sign to commutators of fields and their time derivatives.) The energy-momentum tensor, which serves as the source of the gravitational field, is derived as described in Appendix B from the action (10.4.1), and takes the form

$$T_{\mu\nu} = g_{\mu\nu}\left[-\frac{1}{2}g^{\rho\sigma}\gamma_{nm}(\varphi)\frac{\partial\varphi^n}{\partial x^\rho}\frac{\partial\varphi^m}{\partial x^\sigma} - V(\varphi)\right] + \gamma_{nm}(\varphi)\frac{\partial\varphi^n}{\partial x^\mu}\frac{\partial\varphi^m}{\partial x^\nu}. \tag{10.4.2}$$

The scalar field equations are derived from the principle that I_φ must be stationary with respect to infinitesimal variations in the the scalar fields, and take the Euler-Lagrange form

$$\begin{aligned}\frac{\partial}{\partial x^\mu}\left(\sqrt{-\operatorname{Det} g}\,g^{\mu\nu}\gamma_{nm}(\varphi)\frac{\partial\varphi^n}{\partial x^\nu}\right) &= \sqrt{-\operatorname{Det} g}\\ \times\left(\frac{1}{2}g^{\mu\nu}\frac{\partial\gamma_{lm}(\varphi)}{\partial\varphi^n}\frac{\partial\varphi^l}{\partial x^\mu}\frac{\partial\varphi^m}{\partial x^\nu} + \frac{\partial V(\varphi)}{\partial\varphi^n}\right).\end{aligned} \tag{10.4.3}$$

We take each scalar field $\varphi^n(x)$ as an unperturbed term $\bar\varphi^n(t)$ that depends only on time, plus a small perturbation $\delta\varphi^n(\mathbf{x},t)$:

$$\varphi^n(\mathbf{x},t) = \bar\varphi^n(t) + \delta\varphi^n(\mathbf{x},t). \tag{10.4.4}$$

Similarly, as in Chapters 5-8, the metric is assumed to be given by the unperturbed Robertson-Walker metric $\bar g_{\mu\nu}(t)$ (with $K = 0$) plus a small perturbation $h_{\mu\nu}(\mathbf{x},t)$

$$g_{\mu\nu}(\mathbf{x},t) = \bar g_{\mu\nu}(t) + h_{\mu\nu}(\mathbf{x},t). \tag{10.4.5}$$

The unperturbed energy-momentum tensor is of the perfect fluid form (5.1.35), with unperturbed energy density, pressure, and velocity

$$\bar\rho = \frac{1}{2}\gamma_{nm}(\bar\varphi)\dot{\bar\varphi}^n\dot{\bar\varphi}^m + V(\bar\varphi) \tag{10.4.6}$$

$$\bar p = \frac{1}{2}\gamma_{nm}(\bar\varphi)\dot{\bar\varphi}^n\dot{\bar\varphi}^m - V(\bar\varphi) \tag{10.4.7}$$

$$\bar u^0 = 1, \quad \bar u^i = 0 \tag{10.4.8}$$

The scalar field equation (10.4.3) for the unperturbed fields is

$$\ddot{\bar\varphi}^n + \gamma^n_{ml}(\bar\varphi)\dot{\bar\varphi}^m\dot{\bar\varphi}^l + 3H\dot{\bar\varphi}^n + \gamma^{nm}(\bar\varphi)\frac{\partial V(\bar\varphi)}{\partial\bar\varphi^m} = 0 \tag{10.4.9}$$

where γ^{nm} is the reciprocal of the matrix γ_{nm}, γ^n_{ml} is the affine connection in field space:

$$\gamma^n_{ml}(\bar\varphi) = \frac{1}{2}\gamma^{nk}(\bar\varphi)\left(\frac{\partial\gamma_{km}(\bar\varphi)}{\partial\bar\varphi^l} + \frac{\partial\gamma_{kl}(\bar\varphi)}{\partial\bar\varphi^m} - \frac{\partial\gamma_{ml}(\bar\varphi)}{\partial\bar\varphi^k}\right) \tag{10.4.10}$$

and H is the expansion rate $H \equiv \dot{a}/a = \sqrt{8\pi G\bar{\rho}/3}$. The reader may check that Eq. (10.4.9) guarantees that the energy-conservation equation $\dot{\bar{\rho}} = -3H(\bar{\rho}+\bar{p})$ is satisfied by the quantities (10.4.6) and (10.4.7). From Eqs. (10.4.6) and (10.4.9) we find the convenient formula

$$\dot{H} = -4\pi G\gamma_{nm}(\bar{\varphi})\dot{\bar{\varphi}}^n\dot{\bar{\varphi}}^m \tag{10.4.11}$$

For more than one scalar field $T_{\mu\nu}$ is not of the perfect fluid form (5.1.35) to all orders in perturbations, but by comparing the first-order terms in Eq. (10.4.2) with Eqs. (5.1.39)-(5.1.41), we see that to first order the anisotropic inertia vanishes, and the perturbations to the energy density, pressure, and velocity potential are

$$\begin{aligned}\delta\rho =&\gamma_{nm}(\bar{\varphi})\dot{\bar{\varphi}}^n\delta\dot{\varphi}^m + \frac{1}{2}\dot{\bar{\varphi}}^n\dot{\bar{\varphi}}^m\frac{\partial\gamma_{nm}(\bar{\varphi})}{\partial\bar{\varphi}^k}\delta\varphi^k\\ &+\frac{\partial V(\bar{\varphi})}{\partial\bar{\varphi}^n}\delta\varphi^n + \frac{1}{2}h_{00}\gamma_{nm}(\bar{\varphi})\dot{\bar{\varphi}}^n\dot{\bar{\varphi}}^m \qquad (10.4.12)\\ \delta p =&\gamma_{nm}(\bar{\varphi})\dot{\bar{\varphi}}^n\delta\dot{\varphi}^m + \frac{1}{2}\dot{\bar{\varphi}}^n\dot{\bar{\varphi}}^m\frac{\partial\gamma_{nm}(\bar{\varphi})}{\partial\bar{\varphi}^k}\delta\varphi^k\\ &-\frac{\partial V(\bar{\varphi})}{\partial\bar{\varphi}^n}\delta\varphi^n + \frac{1}{2}h_{00}\gamma_{nm}(\bar{\varphi})\dot{\bar{\varphi}}^n\dot{\bar{\varphi}}^m \qquad (10.4.13)\\ \delta u =&-\frac{\gamma_{nm}(\bar{\varphi})\dot{\bar{\varphi}}^n\delta\varphi^m}{\gamma_{kl}(\bar{\varphi})\dot{\bar{\varphi}}^k\dot{\bar{\varphi}}^l} \qquad (10.4.14)\end{aligned}$$

The reader can easily check that these formulas reduce to Eqs. (10.1.9)(10.1.11) in the single-field case, with $\gamma_{11} = 1$.

Since there is no first-order anisotropic inertia, in Newtonian gauge we have $\Phi = \Psi$, so $h_{00} = -2\Psi$, and the Einstein field equation Eq. (5.3.21) takes the form

$$\dot{\Psi} + H\Psi = 4\pi G\gamma_{nm}(\bar{\varphi})\dot{\bar{\varphi}}^n\delta\varphi^m, \tag{10.4.15}$$

The terms of first order in the field equation Eq. (10.4.3) are much simplified if we now adopt a notation that reveals the transformation of quantities under redefinitions $\varphi^n \to \varphi'^n(\varphi)$ of the scalar fields. Under such transformations, quantities like $\dot{\bar{\varphi}}^n$ and $\delta\varphi^n$ transform as contravariant vectors, in the sense that

$$\delta\varphi'^n = \frac{\partial\bar{\varphi}'^n}{\partial\bar{\varphi}^m}\delta\varphi^m, \quad \dot{\bar{\varphi}}'^n = \frac{\partial\bar{\varphi}'^n}{\partial\bar{\varphi}^m}\dot{\bar{\varphi}}^m \tag{10.4.16}$$

For any vector v^n that transforms in this way, we can define a rate of change that is also a vector:

$$\frac{D}{Dt}v^n \equiv \frac{\partial}{\partial t}v^n + \gamma^n_{lm}(\bar{\varphi})\dot{\bar{v}}^l v^m. \tag{10.4.17}$$

With this notation, the first-order terms in the field equation (10.4.3) give

$$\begin{aligned}&\frac{D^2}{Dt^2}\delta\varphi^n + 3H\frac{D}{Dt}\delta\varphi^n + \gamma^{nm}(\bar{\varphi})\frac{\partial^2 V(\bar{\varphi})}{\partial\bar{\varphi}^m\partial\bar{\varphi}^l}\delta\varphi^l - \left(\frac{\nabla^2}{a^2}\right)\delta\varphi^n\\ &\quad = -2\gamma^{nm}(\bar{\varphi})\Psi\frac{\partial V(\bar{\varphi})}{\partial\bar{\varphi}^m} + 4\dot{\Psi}\dot{-}^n + \gamma^n{}_{lmk}(\bar{\varphi})\dot{\bar{\varphi}}^l\dot{\bar{\varphi}}^m\delta\varphi^k \qquad (10.4.18)\end{aligned}$$

where $\gamma^n{}_{lmk}(\bar{\varphi})$ is the Riemann-Christoffel tensor in field space:

$$\gamma^n_{lmk}(\bar\varphi) \equiv \frac{\partial\gamma^n_{ml}(\bar\varphi)}{\partial\bar\varphi^k} - \frac{\partial\gamma^n_{mk}(\bar\varphi)}{\partial\bar\varphi^l} + \gamma^r_{lm}(\bar\varphi)\gamma^n_{kr}(\bar\varphi) - \gamma^r_{lk}(\bar\varphi)\gamma^n_{mr}(\bar\varphi). \tag{10.4.19}$$

(The scalar fields can be redefined to make $\gamma_{nm} = \delta_{nm}$ if and only if $\gamma^n{}_{lmk} = 0$. We are not assuming that this is the case.) Also, the constraint (5.3.26) is here

$$\left(\dot H - \frac{\nabla^2}{a^2}\right)\Psi = 4\pi G\gamma_{nm}(\bar\varphi)\left(-\dot{\bar\varphi}^n\frac{D}{Dt}\delta\varphi^m + \delta\varphi^m\frac{D}{Dt}\dot{\bar\varphi}^n\right). \tag{10.4.20}$$

The solutions are written as superpositions of plane waves

$$\delta\varphi^n(\mathbf{x},t) = \sum_N\int d^3q\left[\delta\varphi^n_{Nq}(t)e^{i\mathbf{q}\cdot\mathbf{x}}\alpha(\mathbf{q},N) + \delta\varphi^{n*}_{Nq}(t)e^{-i\mathbf{q}\cdot\mathbf{x}}\alpha^*(\mathbf{q},N)\right] \tag{10.4.21}$$

$$\Psi(\mathbf{x},t) = \sum_N\int d^3q\left[\Psi_{Nq}(t)e^{i\mathbf{q}\cdot\mathbf{x}}\alpha(\mathbf{q},N) + \Psi^*_{Nq}(t)e^{-i\mathbf{q}\cdot\mathbf{x}}\alpha^*(\mathbf{q},N)\right] \tag{10.4.22}$$

Here N labels different solutions of the coupled equations (10.4.15)(10.4.17), with ∇^2 replaced with $-q^2$:

$$\dot\Psi_{Nq} + H\Psi_{Nq} = 4\pi G\gamma_{nm}(\bar\varphi)\dot{\bar\varphi}^n\delta\varphi^m_{Nq} \tag{10.4.23}$$

$$\frac{D^2}{Dt^2}\delta\varphi^n_q + 3H\frac{D}{Dt}\delta\varphi^n_q + \gamma^{nm}(\bar\varphi)\frac{\partial^2V(\bar\varphi)}{\partial\bar\varphi^m\partial\bar\varphi^l}\delta\varphi^l_q + \left(\frac{q^2}{a^2}\right)\delta\varphi^n_q$$
$$= -2\gamma^{nm}(\bar\varphi)\Psi_q\frac{\partial V(\bar\varphi)}{\partial\bar\varphi^m} + 4\dot\Psi_q\dot{\bar\varphi}^n + \gamma^n{}_{lmk}(\bar\varphi)\dot{\bar\varphi}^l\dot{\bar\varphi}^m\delta\varphi^k_q \tag{10.4.24}$$

$$\left(\dot H + \frac{q^2}{a^2}\right)\Psi_q = 4\pi G\gamma_{nm}(\bar\varphi)\left(-\dot{\bar\varphi}^n\frac{D}{Dt}\delta\varphi^m_q + \delta\varphi^m_q\frac{D}{Dt}\dot{\bar\varphi}^n\right) \tag{10.4.25}$$

There is one second-order equation for each scalar field, and one firstorder equation for Ψ, so with one constraint on first derivatives the number of independent solutions equals twice the number of scalar fields. Since $\left(\delta\varphi^n_{Nq}, \Psi_{Nq}\right)$ and $\left(\delta\varphi^{n*}_{Nq}, \Psi^*_{Nq}\right)$ are all independent solutions, the index N takes as many values as the index n.

To find the initial conditions for Eqs. (10.4.23)-(10.4.25), and to find the commutation relations for the operators $\alpha(\mathbf{q})$ and $\alpha^*(\mathbf{q})$ in Eqs. (10.4.21) and (19.4.22), we note that for some time before the era of horizon exit we will have $q/a \gg H$, and q^2/a^2 much greater than any element of $\partial^2V/\partial\bar\varphi^n\partial\bar\varphi^m$. Hence the solutions up to the beginning of the era of horizon exit take the WKB form

$$\delta\varphi^n_{Nq}(t) \to f^n_{Nq}(t)\exp\left(-iq\int_{t_1}^t\frac{dt'}{a\left(t'\right)}\right)$$
$$\Psi_{Nq}(t) \to g_{Nq}(t)\exp\left(-iq\int_{t_1}^t\frac{dt'}{a\left(t'\right)}\right) \tag{10.4.26}$$

where $f^n_{Nq}(t)$ and $g_{Nq}(t)$ vary much more slowly than the argument of the exponential, and t_1 is arbitrary. Eqs. (10.4.23) and (10.4.25) are both satisfied to leading order in q/a if we take

$$g_{Nq} = \frac{4i\pi Ga}{q}\gamma_{nm}(\bar{\varphi})\dot{\bar{\varphi}}^n f^m_{Nq} \tag{10.4.27}$$

The terms in Eq. (10.4.24) of first order in q/a then give

$$\frac{D}{Dt}f^n_{Nq} + Hf^n_{Nq} = 0 \tag{10.4.28}$$

To solve this, we note that, because $\gamma^{nm}(\bar{\varphi}(t))$ is positive-definite, it can be written in terms of a set of vielbein vectors $e^n_N(t)$ (with N running over as many values as n), as

$$\gamma^{nm}(\bar{\varphi}(t)) = \sum_N e^n_N(t)e^m_N(t). \tag{10.4.29}$$

These vielbeins can be defined to satisfy the equation of parallel transport [1]

$$\frac{D}{Dt}e^n_{Nq} = 0, \tag{10.4.30}$$

so the solution of Eq. (10.4.28) is

$$f^n_{Nq}(t) \propto a^{-1}(t)e^n_N(t) \tag{10.4.31}$$

For reasons that will soon become apparent, we shall normalize these solutions so that, for $q/a \gg H$,

$$f^n_{Nq} = (2\pi)^{-3/2}(2q)^{-1/2}a^{-1}e^n_N.$$

With this normalization, at the beginning of the era of horizon exit we have [2]

$$\delta\varphi^n_{Nq}(t) = \frac{1}{(2\pi)^{3/2}a(t)\sqrt{2q}}e^n_N(t)\exp\left(-iq\int_{t_1}^t\frac{dt'}{a\,(t')}\right) \tag{10.4.32}$$

$$\Psi_{Nq}(t) = \frac{4i\pi G\gamma_{nm}(\bar{\varphi})e^m_N(t)\dot{\bar{\varphi}}^n(t)}{(2\pi)^{3/2}\sqrt{2q^3}}\exp\left(-iq\int_{t_1}^t\frac{dt'}{a\,(t')}\right) \tag{10.4.33}$$

For times early enough so that $q/a \gg H$ the commutation relations for φ^n can be obtained from the action (10.4.1) with Ψ neglected, and therefore take the form:

$$[\varphi^n(\mathbf{x},t),\varphi^m(\mathbf{y},t)] = 0$$
$$[\varphi^n(\mathbf{x},t),\dot{\varphi}^m(\mathbf{y},t)] = ia^{-3}(t)\gamma^{nm}(\bar{\varphi}(t))\delta^3(\mathbf{x}-\mathbf{y})$$

[471] We define the vectors $e^n_{Nq}(t)$ to satisfy the first-order differential equation (10.4.30), and, as an initial condition, to satisfy Eq. (10.4.29) at some initial time $t = t_1$. From Eq. (10.4.30) and the definition (10.4.10) it follows that for all times

$$\dot{D}^n_m = \left[-\gamma^n_{lk}D^k_m + \gamma^k_{lm}D^n_k\right]\dot{\bar{\varphi}}^l,$$

where

$$D^n_m \equiv \sum_N e^n_N e^k_N\gamma_{km}$$

This differential equation for D^n_m has a solution $D^n_m = \delta^n_m$, and our initial condition tells us that $D^n_m = \delta^n_m$ at $t = t_1$, so this is the solution for all times. It follows that the vectors $e^n_{Nq}(t)$ defined in this way satisfy the condition (10.4.29) for vielbeins for all times.

[2] A result equivalent to Eq. (10.4.32) is given in Eq. (4.4) of H.-C. Lee, M. Sasaki, E. D. Stewart, T. Tanaka, and S. Yokoyama, J. Cosm. & Astropart. Phys. 0510, 004 (2005) [astro-ph/0506262], using a " δN " formalism due to M. Sasaki and E. D. Stewart, Prog. Theor. Phys. 95, 71 (1996) [astroph/9507001]. But their paper does not reach the conclusion (10.4.41) found in this section.

With $\delta\varphi^n$ normalized as in Eq. (10.4.32), this implies that the timeindependent operator coefficients in Eqs. (10.4.21) and (10.4.22) satisfy the commutation relations

$$[\alpha(\mathbf{q},N),\alpha\left(\mathbf{q}',N'\right)]=0,\quad [\alpha(\mathbf{q},N),\alpha^*\left(\mathbf{q}',N'\right)]=\delta^3\left(\mathbf{q}-\mathbf{q}'\right)\delta_{NN'}. \tag{10.4.34}$$

Assuming that there is enough time before horizon exit for the state of the world to decay into the Bunch-Davies vacuum $|0\rangle$, with $\alpha(\mathbf{q},N)|0\rangle=0$, it follows then from Eqs. (10.4.21) and (10.4.22) that the observed perturbations will be Gaussian, just as in the single-field case.

According to assumption 3, during the era when q/a drops from being somewhat larger to somewhat smaller than H - say, from $10H$ to $0.1H$, the scalar fields are rolling slowly down the potential hill. We assume that $V(\varphi)$ satisfies whatever flatness conditions are necessary to allow us to drop all terms in Eqs. (10.4.23)-(10.4.25) proportional to $\dot{\bar{\varphi}}^n_N$ or $\ddot{\bar{\varphi}}^n_N$ and to ignore the second derivative of the potential in Eq. (10.4.24). Then during the era of horizon exit Eq. (10.4.24) is approximately

$$\delta\ddot{\varphi}^n_{Nq}+3H\delta\dot{\varphi}^n_{Nq}+\left(\frac{q^2}{a^2}\right)\delta\varphi^n_{Nq}=0. \tag{10.4.35}$$

H is roughly constant during this era, [3] so the independent solutions of Eq. (10.4.35) are proportional to $(1+iq\tau)\exp(-iq\tau)$ and its complex conjugate, where τ is again the conformal time

$$\tau=\int_\infty^t\frac{dt'}{a\left(t'\right)}\simeq-\frac{1}{\mathrm{Ha}(t)}$$

The scalar field perturbations at the beginning of the era of horizon exit are given by Eq. (10.4.32), so during this era we have

$$\delta\varphi^n_{Nq}\simeq\frac{1}{(2\pi)^{3/2}\sqrt{2q}}\left(\frac{1}{a}+\frac{iH}{q}\right)e^{+iq/aH}e^n_N. \tag{10.4.36}$$

By the end of the era of horizon exit we have $q/a\ll H$, and the scalar field perturbations approach the quantities

$$\delta\varphi^n_{Nq}\to\frac{iH}{(2\pi)^{3/2}\sqrt{2q^3}}e^n_N. \tag{10.4.37}$$

Since H and e^n_N are slowly varying, they can be evaluated at the time of horizon exit, and depend weakly on q.

At some time after the era of horizon exit the slow-roll conditions must become violated, if only in order that the energy in the inflaton fields can eventually be converted into ordinary matter and radiation. The potential term on the left-hand side of Eq. (10.4.24) is then no longer negligible, and things get complicated. But once q/a becomes much less than H, the subsequent evolution of the scalar fields during inflation cannot depend on q, so until horizon re-entry all scalar field perturbations $\delta\varphi^n_{Nq}$ will have the same wave number dependence, close to $q^{-3/2}$, as given by Eq. (10.4.37) at the end of the era of horizon exit. The same applies to the scalar metric perturbations; when a becomes sufficiently large so that $q^2/a^2\ll|\dot{H}|$, Eq. (10.4.25) gives Ψ_{Nq} approximately proportional to $q^{-3/2}$.

In general, it is not easy to see what these results imply for the perturbations observed in the cosmic microwave background or large scale structure. However, there is one case where an important conclusion can be reached. If according to assumption 1* the energy in all the scalar fields is converted at the end of inflation into ordinary matter and radiation in local thermal

[473] The fractional change in H during the era of horizon exit is $|\dot{H}/H|\times\ln(100)/H$, which is small if $|\dot{H}|/H^2\ll 1/\ln(100)=0.22$.

equilibrium, and if at this time all conserved quantities like electric charge have zero density, then as remarked in Section 5.4, the perturbations become adiabatic, with $\mathcal{R}_q$ taking a constant value $\mathcal{R}_q^o$ until horizon re-entry. For small fluctuations, $\mathcal{R}_q^o$ will be some linear combination of the perturbations $\delta\varphi_{Nq}^n$ and Ψ_{Nq} at the end of the era of horizon exit. We do not know the coefficients in this linear combination, which in general will depend on the shape of the potential experienced as the field evolves until the end of inflation, as well as on the mechanism of energy transfer to matter and radiation. But we can be sure that these coefficients are independent of wave number, because once the era of horizon exit is over the perturbations are far outside the horizon. Hence we can conclude that in this case $\mathcal{R}_q^o$ will have the same wave number dependence as $\delta\varphi_{Nq}^n$ and Ψ_{Nq} at the end of the era of horizon exit, which for slow-roll inflation will be close to $q^{-3/2}$.

The ubiquity of the $q^{-3/2}$ wavelength dependence can be understood on very general grounds. For negligible spatial curvature, nothing should depend on how the co-moving coordinate vector $\mathbf{x}$ is normalized, so suppose we change its scale by a transformation $\mathbf{x} \to \lambda\mathbf{x}$, with λ constant. To keep $\mathbf{q}\cdot\mathbf{x}$ unchanged, we must then change the scale of co-moving wave numbers by a transformation $\mathbf{q} \to \lambda^{-1}\mathbf{q}$. Consider any perturbation $Z(\mathbf{x},t)$ that, like $\delta\varphi^n(\mathbf{x},t)$ and $\Psi(\mathbf{x},t)$, is given by a Fourier integral

$$Z(\mathbf{x},t) = \sum_N \int d^3q \left[e^{i\mathbf{q}\cdot\mathbf{x}} a(\mathbf{q},N) z_{Nq}(t) + e^{-i\mathbf{q}\cdot\mathbf{x}} a^*(\mathbf{q},N) z_{Nq}^*(t)\right]$$

where N labels the various solutions of the field equations, and $a(\mathbf{q},N)$ and $a^*(\mathbf{q},N)$ are annihilation and creation operators satisfying the commutation relations

$$[a(\mathbf{q},N), a^*(\mathbf{q}',N')] = \delta_{NN'}\delta^3(\mathbf{q}-\mathbf{q}')$$

Under the transformation $\mathbf{q} \to \lambda^{-1}\mathbf{q}$, the delta function in this commutation relation transforms as $\delta^3(\mathbf{q}-\mathbf{q}') \to \lambda^3\delta^3(\mathbf{q}-\mathbf{q}')$, so we must have $a(\mathbf{q},N) \to \lambda^{3/2}a(\mathbf{q},N)$. Also, of course $d^3q \to \lambda^{-3}d^3q$. Hence in order for $Z(\mathbf{x},t)$ to be unaffected by this change of scale, we must have $z_{Nq}(t) \to \lambda^{3/2}z_{Nq}(t)$. This condition is satisfied if $z_{Nq}(t)$ has a q-dependence $\propto q^{-3/2}$, and if it does not depend on the scale of $a(t)$. Of course, to keep the physical coordinate vector $\mathbf{x}a(t)$ independent of the normalization chosen for the co-moving coordinates, $a(t)$ has the scale transformation $a(t) \to \lambda^{-1}a(t)$, so $q/a(t)$ is scale-invariant, and if $z_{Nq}(t)$ depends on the scale of the function $a(t)$ then we cannot conclude that it is proportional to $q^{-3/2}$. But if $z_{Nq}(t)$, like $\delta\varphi_{Nq}^n(t)$ and $\Psi_{Nq}(t)$, takes a nearly time-independent value z_{Nq}^o after horizon exit, then outside the horizon it will not depend strongly on $a(t)$. It could still depend on $H(t_q), \dot{H}(t_q)$, etc., where t_q is the time of horizon exit, defined by the scale-invariant condition $q/a(t_q) = H(t_q)$, but in the limit of very slow roll inflation $H, \dot{H}$, etc. depend only weakly on time, so z_{Nq}^o can depend only weakly on the scale of the function a, and the scale-invariance of $Z(\mathbf{x},t)$ requires that z_{Nq}^o be nearly proportional to $q^{-3/2}$.

The intensity of observed adiabatic fluctuations is related to the quantity $\mathcal{R}$ defined by Eq. (5.4.1). Using Eqs. (10.4.14), (10.4.11), (10.4.21), and (10.4.22), during inflation this is

$$\begin{aligned}
\mathcal{R}(\mathbf{x},t) &\equiv -\Psi(\mathbf{x},t) + H(t)\delta u(\mathbf{x},t) \\
&= -\Psi(\mathbf{x},t) + \frac{4\pi G H(t)}{\dot{H}(t)} \gamma_{nm}(\bar{\varphi}(t))\dot{\bar{\varphi}}^n(t)\delta\varphi^m(\mathbf{x},t) \\
&= \sum_N \int d^3q \left[e^{i\mathbf{q}\cdot\mathbf{x}} a(\mathbf{q},N)\mathcal{R}_{Nq}(t) + e^{-i\mathbf{q}\cdot\mathbf{x}} a^*(\mathbf{q},N)\mathcal{R}_{Nq}^*(t)\right]
\end{aligned} \tag{10.4.38}$$

where

$$\mathcal{R}_{Nq}(t) = -\Psi_{Nq}(t) + \frac{4\pi G H(t)}{\dot{H}(t)} \gamma_{nm}(\bar{\varphi}(t)) \dot{\bar{\varphi}}^n(t) \delta\varphi^m_{Nq}(t) \tag{10.4.39}$$

Because of the factor $\dot{H}$ in the denominator, at the end of the era of horizon exit the second term in Eq. (10.4.39) dominates over the term $-\Psi_{Nq}$, and Eq. (10.4.37) then gives at this time

$$\mathcal{R}_{Nq} \to i \frac{4\pi G H^2}{(2\pi)^{3/2}\sqrt{2q^3}\dot{H}} \gamma_{nm}(\bar{\varphi}) \dot{\bar{\varphi}}^n e^m_N. \tag{10.4.40}$$

The definition (10.4.29) of the vielbeins and the formula (10.4.11) then lead immediately to a sum rule

$$\left(\sum_N |\mathcal{R}_{Nq}|^2 \right)^{1/2} = \frac{\sqrt{G} H^2}{2\pi q^{3/2} \sqrt{|\dot{H}|}}. \tag{10.4.41}$$

That is, the root-mean-square value of the quantities $|\mathcal{R}_{Nq}|$ at the end of the era of horizon exit is the same as the value of $|\mathcal{R}_q|$ outside the horizon in the single-field case, given by Eq. (10.3.16). But Eqs. (10.4.38) and (10.4.34) tell us that the correlation function of $\mathcal{R}$ in the Bunch-Davies vacuum is

$$\int d^4x e^{-i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})} \langle \mathcal{R}(\mathbf{x},t) \mathcal{R}(\mathbf{y},t) \rangle = (2\pi)^3 \sum_N |\mathcal{R}_{Nq}|^2 \tag{10.4.42}$$

So from Eq. (10.4.41) it follows that the correlation function $\langle \mathcal{R}(\mathbf{x},t) \mathcal{R}(\mathbf{y},t) \rangle$ is the same at the end of the era of horizon exit as in the single field case. With more than one scalar field the correlation function (10.4.42) is not in general time-independent outside the horizon, but it is plausible that the value of $|\mathcal{R}_q|$ during a period of thermal equilibrium after inflation will not be orders of magnitude different from Eq. (10.4.41) at the end of the era of horizon exit. Thus the observed strength and spectral shape of anisotropies in the cosmic microwave background suggests a value of H at horizon exit of order 10^{14}GeV, as in the single field case.

One can derive stronger results in the case where all but one of the eigenvalues of the matrix $\gamma^{nm}(\bar{\varphi}) \partial^2 V(\bar{\varphi}) / \partial\bar{\varphi}^m \partial\bar{\varphi}^l$ in Eq. (10.4.23) are large and positive. In this case, the unperturbed scalar fields roll along the direction of the eigenvector for the small eigenvalue, and the only significant perturbations lie in that direction. The problem then reduces to the single field case; we have an essentially adiabatic perturbation, with the amplitude $\mathcal{R}^o_q$ given in the slow-roll approximation by Eq. (10.3.16), and the slope $n_S(q)$ given in this approximation by Eq. (10.3.25), where ϵ and δ are to be calculated in terms of the time-derivatives of the expansion rate by Eq. (10.3.4). But there is no known reason why the potential should have the properties needed to justify these results. On the other hand, tensor perturbations during inflation are governed by Eq. (10.3.17) however many scalar fields there are, and the only role played by the scalar fields is to contribute to the

Hubble rate H. Thus for slow-roll inflation with any number of scalar fields, the tensor amplitude $\mathcal{D}^o_q$ is given by Eq. (10.3.23), and the slope parameter $n_T(q)$ is given by Eq. (10.3.25), just as in the single field case.

The fact that observations of cosmic microwave background anisotropies and large scale structure indicate that scalar fluctuations outside the horizon are adiabatic and Gaussian, with $\mathcal{R}^o_q$ approximately proportional to $q^{-3/2}$, and with $q^{3/2}\mathcal{R}^o_q \ll 1$, evidently is consistent with a very large class of models of inflation. This is encouraging, because it supports the general idea of slow-roll inflation, but also disappointing, because it shows that these observations so far do not really tell us anything specific about the details of inflation. With further improvements in experimental precision, we can look forward to a more decisive test of theories of the early universe.

10.12 Appendix B Review of General Relativity

In this appendix we offer a brief introduction to the General Theory of Relativity, Einstein's theory of gravitation. This appendix is not a substitute for a thorough treatment of the theory, but it outlines the parts of the theory that are used in this book, and it serves to establish our notation.

1 The Equivalence Principle

General Relativity is based on the Principle of the Equivalence of Gravitation and Inertia, or the Equivalence Principle for short. The Equivalence Principle is a generalization of the familiar observation that, because of the equality of gravitational and inertial mass, freely falling observers do not feel the effects of gravitation. According to the Equivalence Principle, at any spacetime point in an arbitrary gravitational field there is a "locally inertial" coordinate system in which the effects of gravitation are absent in a sufficiently small spacetime neighborhood of that point. This Principle allows us to write the equations governing any sufficiently small physical system in a gravitational field if we know the equations governing it in the absence of gravitation: it is only necessary to write the equations in a form which is generally covariant - that is, whose form is independent of the spacetime coordinates used - and which reduce to the correct equations in the absence of gravitation. Such equations will be true in the presence of a gravitational field, because general covariance guarantees that they are true in any set of coordinates if they are true in any other set of coordinates, and the Equivalence Principle tells us that there is a set of coordinates in which the equations are true - the set of coordinates that is locally inertial at the spacetime location of the system in question. In general there will be more than one set of generally covariant equations that reduce to the correct equations in the absence of gravitation, but the differences between these equations always involve terms with extra spacetime derivatives, which become negligible if we restrict ourselves to a spacetime

[472] From Allen's Astrophysical Quantities, ed. A. N. Cox (AIP Press, New York, 2000).

region that is small compared with the scale of distances and times over which the gravitational and other fields vary appreciably.

2 The metric: Ticking clocks

As an example of this procedure, consider the equation that governs the rate at which clocks tick in a gravitational field. Special Relativity tells us that if
a clock ticks once in every time interval dT when at rest in the absence of a gravitational field, then the separation $d\xi^\alpha$ between the spacetime locations of successive ticks when the clock is moving in the absence of a gravitational field is governed by the relation

$$\eta_{\alpha\beta} d\xi^\alpha d\xi^\beta = -dT^2. \tag{B.1}$$

(Here ξ^1, ξ^2, and ξ^3 are the Cartesian space coordinates, using units of length in which the speed of light c is unity; $\xi^0 \equiv t; \eta_{\alpha\beta}$ is the Minkowski metric, the diagonal matrix with $\eta_{11} = \eta_{22} = \eta_{33} = 1$ and $\eta_{00} = -1$; and repeated indices are summed.) The correct equation governing the ticking of the clock in a general gravitational field is then

$$g_{\mu\nu}(x) dx^\mu dx^\nu = -dT^2, \tag{B.2}$$

where $g_{\mu\nu}(x)$ is the metric, a field defined by the two properties that, first, a transformation to a coordinate system x'^μ changes the metric to

$$g'_{\rho\sigma}(x') = g_{\mu\nu}(x) \frac{\partial x^\mu}{\partial x'^\rho} \frac{\partial x^v}{\partial x'^\sigma}, \tag{B.3}$$

and, second, in coordinates that are locally inertial and Cartesian at a point x, the metric at x is $\eta_{\alpha\beta}$ and its first derivatives at x vanish. (In Eq. (B.3), x^μ and x'^μ are the coordinates of the same physical point in two different coordinate systems.) Eq. (B.2) is generally covariant, because the coordinate differentials have the obvious transformation property

$$dx'^\rho = \frac{\partial x'^\rho}{\partial x^\mu} dx^\mu \tag{B.4}$$

so that
$g'_{\rho\sigma}(x')\, dx'^\rho dx'^\sigma = g_{\mu\nu}(x) \frac{\partial x^\mu}{\partial x'^\rho} \frac{\partial x^\nu}{\partial x'^\sigma} \frac{\partial x'^\rho}{\partial x^\kappa} dx^\kappa \frac{\partial x'^\sigma}{\partial x^\lambda} dx^\lambda = g_{\mu\nu}(x) dx^\mu dx^\nu$.
To repeat our general argument, Eq. (B.2) is true, because in locally inertial Cartesian coordinates it reduces to the equation (B.1) that describes clocks in the absence of gravitation, and its general covariance means that if it is true in one set of coordinates then it is true in any other set of coordinates. In the same way, the spacetime separation dx^μ of the ends of a small ruler whose length is dL when measured at rest in the absence of gravitation will in general be given by

$$g_{\mu\nu}(x) dx^\mu dx^\nu = +dL^2.$$

Likewise, the differences dx^μ between the spacetime coordinates of two successive positions along a ray of light are governed by the equation

$$g_{\mu\nu}(x) dx^\mu dx^\nu = 0.$$

3 Tensors, vectors, scalars

Quantities that transform as in (B.3) and (B.4) are known as covariant tensors and contravariant vectors, respectively. In general, contravariant and covariant quantities are labeled

with upper and lower indices, respectively, and for each such index there is a factor in the transformation rule of $\partial x'/\partial x$ or $\partial x/\partial x'$, respectively. It is also possible to have mixed quantities, with some upper and some lower indices. For instance, there is a mixed tensor δ^μ_ν, defined in any coordinate system by

$$\delta^\mu_v \equiv \begin{cases} 1 & \mu = v \\ 0 & \mu \neq v \end{cases} . \tag{B.5}$$

Even though its components are the same in all coordinate systems this is a tensor because

$$\delta^\mu_\nu \frac{\partial x'^\rho}{\partial x^\mu}\frac{\partial x^\nu}{\partial x'^\sigma} = \frac{\partial x'^\rho}{\partial x^\mu}\frac{\partial x^\mu}{\partial x'^\sigma} = \delta^\rho_\sigma.$$

There is also a contravariant tensor $g^{\mu\nu}$, defined as the inverse of the metric

$$g^{\mu\lambda}g_{\lambda v} = \delta^\mu_v. \tag{B.6}$$

To see that this is a tensor, just note that

$$\left(g^{\rho\sigma}(x)\frac{\partial x'^\mu}{\partial x^\rho}\frac{\partial x'^\lambda}{\partial x^\sigma}\right) g'_{\lambda\nu}(x') = g^{\rho\sigma}(x)\frac{\partial x'^\mu}{\partial x^\rho}\frac{\partial x'^\lambda}{\partial x^\sigma}\frac{\partial x^\eta}{\partial x'^\lambda}\frac{\partial x^\tau}{\partial x'^\nu}g_{\eta\tau}(x)$$
$$= g^{\rho\sigma}(x)\frac{\partial x'^\mu}{\partial x^\rho}\delta^\eta_\sigma\frac{\partial x^\tau}{\partial x'^\nu}g_{\eta\tau}(x) = \delta^\rho_\tau\frac{\partial x'^\mu}{\partial x^\rho}\frac{\partial x^\tau}{\partial x'^\nu} = \delta^\mu_\nu$$

Thus the quantity in parenthesis in the first line is the reciprocal of the transformed metric

$$g^{\rho\sigma}(x)\frac{\partial x'^\mu}{\partial x^\rho}\frac{\partial x'^\lambda}{\partial x^\sigma} = g'^{\mu\lambda}(x')$$

verifying that the reciprocal of the metric is a contravariant tensor.
A scalar $s(x)$ is a quantity whose value at a physical spacetime point is not changed by a coordinate transformation; that is, using a set of coordinates x'^μ it is

$$s'(x') = s(x) \tag{B.7}$$

The derivative $v_\mu \equiv \partial s/\partial x^\mu$ of a scalar $s(x)$ is a covariant vector:

$$v'_\rho \equiv \frac{\partial s'}{\partial x'^\rho} = \frac{\partial s}{\partial x^\mu}\frac{\partial x^\mu}{\partial x'^\rho} = v_\mu\frac{\partial x^\mu}{\partial x'^\rho}. \tag{B.8}$$

Scalars and vectors may be regarded as tensors with no indices or one index, respectively. We can make tensors out of other tensors by taking the direct product; for instance, if $A^\mu{}_\nu$ and $B_{\rho\sigma}$ are tensors, then so is the direct product $C^\mu{}_{\nu\rho\sigma} \equiv A^\mu{}_\nu B_{\rho\sigma}$. We can also make tensors with fewer indices out of other tensors by contracting upper and lower indices, as Eqs. (B.2) and (B.6). As a special case, we often lower (or raise) an index on a tensor by taking the direct product of the tensor with the metric (or its inverse) and then contracting an upper (or lower) index on the tensor with an index on the metric (or its inverse). For instance, if $A^{\mu\nu}$ is a tensor, then so is $A_\rho{}^\nu \equiv g_{\mu\rho}A^{\mu\nu}$, while if $B_\rho{}^\nu$ is a tensor then so is $B^{\sigma\nu} = g^{\sigma\rho}B_\rho{}^\nu$. Note that raising and lowering the same index just gives back the original tensor; for instance $g^{\sigma\rho}(g_{\mu\rho}A^{\mu\nu}) = A^{\sigma\nu}$. Any equation that states the equality of two tensors of the same type or that a tensor of any type vanishes is generally covariant.

4 The affine connection: Falling bodies

But not everything is a tensor. For instance, Eq. (B.4) tells us that the first derivative of the coordinate x^μ of a particle with respect to some scalar quantity u that parameterizes position along the particle's trajectory (such as the time on some fixed clock) is a vector

$$\frac{dx'^\rho}{du} = \frac{\partial x'^\rho}{\partial x^\mu}\frac{dx^\mu}{du}, \tag{B.9}$$

but the second derivative is not a vector

$$\begin{aligned}\frac{d^2x'^\rho}{du^2} &= \frac{d}{du}\left(\frac{\partial x'^\rho}{\partial x^\mu}\frac{dx^\mu}{du}\right)\\ &= \frac{\partial x'^\rho}{\partial x^\mu}\frac{d^2x^\mu}{du^2} + \frac{\partial^2 x'^\rho}{\partial x^\mu \partial x^\nu}\frac{dx^\mu}{du}\frac{dx^\nu}{du}.\end{aligned} \tag{B.10}$$

This means that the correct generalization of the equation $d^2\xi^\alpha/du^2 = 0$ for the motion of a particle in the absence of gravitation is not $d^2x^\mu/du^2 = 0$, because this equation is not generally covariant. Instead, to cancel the second term on the right-hand side of Eq. (B.10) we must introduce a quantity $\Gamma^\lambda_{\mu\nu}(x)$ defined by the transformation property

$$\Gamma'^\tau_{\sigma\rho} = \frac{\partial x'^\tau}{\partial x^\lambda}\frac{\partial x^\mu}{\partial x'^\sigma}\frac{\partial x^\nu}{\partial x'^\rho}\Gamma^\lambda_{\mu\nu} - \frac{\partial^2 x'^\tau}{\partial x^\mu \partial x^\nu}\frac{\partial x^\mu}{\partial x'^\sigma}\frac{\partial x^\nu}{\partial x'^\rho}, \tag{B.11}$$

and the proviso that $\Gamma^\lambda_{\mu\nu}(x)$ vanishes in a coordinate system that is locally inertial and Cartesian at x. The correct equation of motion for a particle
that is freely falling in a gravitational field is then

$$\frac{d^2x^\lambda}{du^2} + \Gamma^\lambda_{\mu\nu}\frac{dx^\mu}{du}\frac{dx^\nu}{du} = 0, \tag{B.12}$$

because this is generally covariant, and reduces to the correct equation of motion $d^2\xi^\alpha/du^2 = 0$ in the absence of gravitation. The field $\Gamma^\lambda_{\mu\nu}$ is known as the affine connection, and of course is not a tensor.

There is a simple formula for the affine connection in terms of the metric

$$\Gamma^\lambda_{\mu\nu} = \frac{1}{2}g^{\lambda\rho}\left[\frac{\partial g_{\rho\mu}}{\partial x^\nu} + \frac{\partial g_{\rho\nu}}{\partial x^\mu} - \frac{\partial g_{\mu\nu}}{\partial x^\rho}\right]. \tag{B.13}$$

It is straightforward to check that this is generally covariant, and it is true in a locally inertial Cartesian coordinate system because in such a system both sides vanish, so it is correct for general gravitational fields and coordinate systems.

A trajectory that satisfies Eq. (B.12) is called a spacetime geodesic, because on such a trajectory the integral

$$\int_{u_1}^{u_2}\sqrt{g_{\mu\nu}(x(u))\frac{dx^\mu(u)}{du}\frac{dx^\nu(u)}{du}}du$$

is stationary under variations that leave $x^\mu(u)$ fixed at the endpoints u_1 and u_2. Often instead of specifying the metric we specify the line element $ds^2 = g_{\mu\nu}dx^\mu dx^\nu$ for arbitrary differentials dx^μ.

The equation of motion (B.12) is not valid for just any choice of the parameter u. To see this, note that Eq. (B.12) implies a conservation law

$$\frac{d}{du}\left[g_{\mu\nu}\frac{dx^\mu}{du}\frac{dx^\nu}{du}\right] = \frac{\partial g_{\mu\nu}}{\partial x^\lambda}\frac{dx^\mu}{du}\frac{dx^\nu}{du}\frac{dx^\lambda}{du} + g_{\mu\nu}\frac{d^2x^\mu}{du^2}\frac{dx^\nu}{du} + g_{\mu\nu}\frac{dx^\mu}{du}\frac{d^2x^\nu}{du^2}$$
$$= \left(\frac{\partial g_{\mu\nu}}{\partial x^\lambda} - g_{\mu\kappa}\Gamma^\kappa_{\nu\lambda} - g_{\nu\kappa}\Gamma^\kappa_{\mu\lambda}\right)\frac{dx^\mu}{du}\frac{dx^\nu}{du}\frac{dx^\lambda}{du}$$
$$= 0 \tag{B.14}$$

It follows that u must be a linear function of the proper time τ, defined by

$$d\tau \equiv \sqrt{-g_{\mu\nu}dx^\mu dx^\nu}, \tag{B.15}$$

which according to Eq. (B.2) is the time told by a clock that falls freely along with the particle. The only exception to this conclusion is for massless particles like photons, whose spacetime trajectory satisfies the same equation of motion (B.12) as for a massive particle, but for which the conserved quantity
$d\tau/du$ vanishes. For a massless particle or a ray of light we need to choose the parameter u as the time told by some other freely falling clock.

In the case of non-zero mass m, it is convenient to take the affine parameter u as $u = \tau/m$, for then we can define the energy-momentum four-vector as

$$p^\mu = m\frac{dx^\mu}{d\tau} = \frac{dx^\mu}{du},$$

and, using Eq. (B.15),

$$g_{\mu\nu}p^\mu p^\nu = -m^2.$$

For massless particles we have $g_{\mu\nu}\left(dx^\mu/du\right)\left(dx^\nu/du\right) = 0$ however u is normalized, so we can simply suppose that it is normalized in such a way that the energy-momentum four-vector is $p^\mu = dx^\mu/du$.

5 Gravitational time dilation

These results allow us to derive one of the most important consequences of the Equivalence Principle. For a slowly moving particle, dx^i/du is much less than dx^0/du, so Eq. (B.12) becomes

$$\frac{d^2x^i}{du^2} + \Gamma^i_{00}\frac{dx^0}{du}\frac{dx^0}{du} = 0. \tag{B.16}$$

For a weak gravitational field, the metric $g_{\mu\nu}$ is nearly equal to the Minkowski metric $\eta_{\mu\nu}$, so

$$g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}, \tag{B.17}$$

with the components of $h_{\mu\nu}$ much less than unity. We then can take $u = \tau \simeq x^0 \equiv t$, so the equation of motion of a freely falling slowly moving particle in a weak gravitational field is

$$\frac{d^2x^i}{dt^2} = -\Gamma^i_{00}, \tag{B.18}$$

where i runs over the values $1, 2, 3$, labeling spatial directions in a Cartesian coordinate system. The affine connection for a weak gravitational field is

$$\Gamma^\lambda_{\mu\nu} \simeq \frac{\eta^{\lambda\rho}}{2}\left[\frac{\partial h_{\rho\mu}}{\partial x^\nu} + \frac{\partial h_{\rho\nu}}{\partial x^\mu} - \frac{\partial h_{\mu\nu}}{\partial x^\rho}\right]. \tag{B.19}$$

In particular, for a weak time-independent gravitational field we have

$$\Gamma^i_{00} \simeq -\frac{1}{2}\frac{\partial h_{00}}{\partial x^i}. \tag{B.20}$$

Eqs. (B.18) and (B.20) allow us to identify $-h_{00}/2$ as the Newtonian gravitational potential ϕ, so in a weak static gravitational field we have

$$g_{00} \simeq -1 - 2\phi. \tag{B.21}$$

Now consider a clock at rest in such a field. According to Eq. (B.2), if the time between ticks in the absence of a gravitational field is dT, then in the presence of the field it is dt, where

$$(-1 - 2\phi)dt^2 \simeq -dT^2.$$

Hence the time between ticks is no longer dT, but rather

$$dt \simeq (1 - \phi)dT. \tag{B.22}$$

In the negative gravitational potential at the surface of a star clocks therefore tick more slowly than in interstellar space, or in the much weaker gravitational potential at the surface of the earth. This could not be observed on the star's surface, since all physical processes would be slowed there by the same factor, but it is observed at a distance, by measuring the decrease in the frequency of photons emitted from atomic transitions on the star's surface. The gravitational time dilation is measured most accurately by observing the shift of spectral lines as photons rise or fall in the earth's gravitational field.

6 Covariant derivatives

Although the spacetime derivative of a scalar field is a vector, the derivative of a vector or a tensor field is in general not a tensor. For instance, a contravariant vector field v^μ has the transformation property

$$v'^\rho = \frac{\partial x'^\rho}{\partial x^\mu} v^\mu, \tag{B.23}$$

so that

$$\frac{\partial v'^\rho}{\partial x'^\sigma} = \frac{\partial x'^\rho}{\partial x^\mu}\frac{\partial x^\nu}{\partial x'^\sigma}\frac{\partial v^\mu}{\partial x^\nu} + \frac{\partial^2 x'^\rho}{\partial x^\mu \partial x^\nu}\frac{\partial x^\nu}{\partial x'^\sigma} v^\mu. \tag{B.24}$$

To construct a tensor we must add a term that cancels the second term in this transformation law. In this way we are led to introduce a covariant derivative

$$v^\mu_{;v} \equiv \frac{\partial v^\mu}{\partial x^v} + \Gamma^\mu_{v\lambda} v^\lambda, \tag{B.25}$$

which does transform as a mixed tensor

$$v'^\rho_{;\sigma} = \frac{\partial x'^\rho}{\partial x^\mu}\frac{\partial x^\nu}{\partial x'^\sigma} v^\mu_{;\nu}. \tag{B.26}$$

Likewise, the covariant derivative of a covariant vector is defined by

$$v_{v;\mu} \equiv \frac{\partial v_\nu}{\partial x^\mu} - \Gamma^\lambda_{\mu\nu} v_\lambda, \tag{B.27}$$

and is a covariant tensor. More generally, the covariant derivative of a tensor with any number of upper and/or lower indices is given by similar formulas, with a $+\,\Gamma$ for every upper

index and a $-\Gamma$ for every lower index. It is easy to check that the covariant derivatives $g_{\mu\nu;\lambda}$ of the metric tensor all vanish, as they must, since in a locally inertial Cartesian frame the covariant derivative is an ordinary derivative and the first derivatives of the metric vanish, so that the covariant derivatives vanish, and a tensor $g_{\mu\nu;\lambda}$ that vanishes in one coordinate system must vanish in all coordinate systems.

7 Effects of gravitation: The Maxwell equations

Given the equations that govern some set of fields in the absence of gravitation, we can find the equations that apply (at least in sufficiently small regions) in a gravitational field by replacing all Minkowski metrics η with metric tensors and all derivatives with covariant derivatives. As mentioned earlier, the procedure does not give a unique result, since there are tensors formed from second and higher derivatives of the metric that vanish in the absence of gravitation, but the effect of including such tensors in the generally covariant field equations would be negligible in a sufficiently small spacetime region.

For instance, in Cartesian coordinates in the absence of gravitation electric and magnetic fields are governed by Maxwell's equations

$$\partial_\alpha F^{\alpha\beta} = -J^\beta, \tag{B.28}$$

$$\partial_\alpha F_{\beta\gamma} + \partial_\beta F_{\gamma\alpha} + \partial_\gamma F_{\alpha\beta} = 0, \tag{B.29}$$

where $F^{\alpha\beta}$ is the electromagnetic field strength tensor (with $F^{01} = E_1$, $F^{23} = B_1$, etc.), J^α is the electric current four-vector (with J^0 the charge density and J^1, J^2, J^3 the electric current density), and

$$F_{\alpha\beta} \equiv \eta_{\alpha\gamma}\eta_{\beta\delta}F^{\gamma\delta}. \tag{B.30}$$

Hence in the presence of gravitation the field equations are

$$F^{v\mu}_{\ ;v} = -J^\mu \tag{B.31}$$

$$F_{\mu v;\lambda} + F_{v\lambda;\mu} + F_{\lambda\mu;\nu} = 0, \tag{B.32}$$

with

$$F_{\mu\nu} \equiv g_{\mu\lambda}g_{\nu\kappa}F^{\lambda\kappa} \tag{B.33}$$

We use the same letter of the alphabet for tensors like $F_{\mu\nu}$ and $F^{\mu\nu}$ that are related by raising and lowering indices by contraction with the metric, because they represent the same physical quantity.

8 Currents and conservation laws

For a system of particles labeled by an index n, with spacetime coordinates $x^\mu_n(u)$ and electric charges e_n, the electric current four-vector is given by

$$\begin{aligned} J^\mu(x) &\equiv \frac{1}{\sqrt{-\operatorname{Det} g(x)}} \int du \sum_n e_n \delta^4\left(x_n(u) - x\right) \frac{dx^\mu(u)}{du} \\ &= \frac{1}{\sqrt{-\operatorname{Det} g(x)}} \sum_n e_n \delta^3\left(\mathbf{x}_n(t) - \mathbf{x}\right) \frac{dx^\mu(t)}{dt} \end{aligned} \tag{B.34}$$

Here $\delta^4(z)$ is a fictitious function with an infinitely narrow and infinitely high peak at $z = 0$, normalized so that, for any smooth function $f(z)$,

$$\int d^4x f(y)\delta^4(y-x) = f(x)$$

and $\delta^3(\mathbf{z})$ is the same in three dimensions. In particular, the integral of $\sqrt{-\text{ Detg }}J^0$ over a finite three-dimensional volume equals the total electric charge within that volume. (In cosmology we would be more interested in the baryon current, with the baryon number of the nth particle or the nth galaxy appearing instead of e_n.) The factor $1/\sqrt{-\text{Det}\, g(x)}$ is needed here, because the four-dimensional delta function is not a scalar. We can see this by noting that, under a transformation from coordinates x^μ to coordinates x'^μ, the differential spacetime volume element is changed to

$$d^4x' = \left|\frac{\partial x'}{\partial x}\right| d^4x \tag{B.35}$$

where $|\partial x'/\partial x|$ is the Jacobian of the coordinate transformation - that is, the determinant of the matrix whose components are $\partial x'^\mu/\partial x^\nu$. The Jacobian can be expressed in terms of the determinants of the metrics; by taking the determinant of Eq. (B.3), we find

$$\text{Det}\, g' = \left|\frac{\partial x'}{\partial x}\right|^{-2} \text{Det}\, g. \tag{B.36}$$

Hence it is the spacetime volume $d^4x\sqrt{-\text{Det}\, g}$ rather than d^4x that transforms as a scalar. (A minus sign is inserted in front of the determinant of the metric, because in physical spacetimes this determinant is negative.) From the defining equation of the delta function

$$\begin{aligned} f(y) &= \int d^4x f(x)\delta^4(x-y) \\ &= \int \left(d^4x\sqrt{-\text{Det}\, g(x)}\right) f(x) \left(\delta^4(x-y)/\sqrt{-\text{Det}\, g(x)}\right) \end{aligned}$$

we see that it is the ratio $\delta^4\left(x_n - x\right)/\sqrt{-\text{Det}\, g(x)}$ appearing in the current (B.34) rather than the delta function itself that transforms as a scalar. This current satisfies the conservation law

$$\partial_\mu\left(\sqrt{-\text{Det}\, g(x)}J^\mu(x)\right) = \int du \frac{d}{du}\sum_n e_n\delta^4\left(x_n(u) - x\right) = 0, \tag{B.37}$$

provided x is not at the value of any $x_n(u)$ at either endpoint of the integral. This is the same as the generally covariant conservation law

$$0 = J^\mu_{;\mu} \equiv \frac{\partial}{\partial x^\mu}J^\mu + \Gamma^\mu_{\nu\mu}J^\nu \tag{B.38}$$

because

$$\Gamma^\nu_{\mu\nu} = \frac{1}{2}g^{\nu\lambda}\partial_\mu g_{\nu\lambda} = \frac{1}{2}\partial_\mu \ln(-\text{Det}\, g).$$

This is the correct conservation condition, because in the absence of gravitation there is a current that in Cartesian coordinate systems satisfies the conservation law $\partial_\mu J^\mu = 0$, and therefore in general coordinates in a gravitational field must satisfy the generally covariant generalization (B.38).

9 The energy-momentum tensor

Likewise, in the absence of gravitation any set of particles and/or fields will have a symmetric energy-momentum tensor $T^{\alpha\beta}$, which is conserved in the sense that

$$\frac{\partial T^{\alpha\beta}}{\partial x^\beta} = 0. \tag{B.39}$$

Just as J^β is the β component of the current of electric charge, we can think of $T^{\alpha\beta}$ as the β component of the current of p^α. In the presence of a gravitational field the conservation law becomes

$$T^{\mu\nu}{}_{;\nu} \equiv \frac{\partial T^{\mu\nu}}{\partial x^\nu} + \Gamma^\mu_{\kappa\nu} T^{\kappa\nu} + \Gamma^\nu_{\kappa\nu} T^{\mu\kappa} = 0. \tag{B.40}$$

The final Γ term here is a geometric effect, similar to what we found for conserved currents, but the other Γ term represents the exchange of energy and momentum between gravitation and the other fields.

For instance, for an ideal gas of particles that move freely except for gravitational forces and perhaps for collisions that are localized in space, the energy-momentum tensor is given by replacing e_n in Eq. (B.34) with the energy-momentum four-vector $p^\mu_n = E_n dx^\mu_n/dt$, whose spatial components are the components of the three-momentum, and $p^0_n = E_n$:

$$\begin{aligned} T^{\mu v}(x) &= \frac{1}{\sqrt{-\operatorname{Det} g(x)}} \int du \sum_n \delta^4\left(x_n(u) - x\right) \frac{dx^\mu_n(u)}{du} p^v_n(u) \\ &= \frac{1}{\sqrt{-\operatorname{Det} g(x)}} \sum_n \delta^3\left(\mathbf{x}_n(t) - \mathbf{x}\right) p^\mu_n(t) p^v_n(t)/E_n(t). \end{aligned} \tag{B.41}$$

In particular, T^{00} is the energy density. Direct calculation using the equation of motion (B.12) shows that this satisfies the covariant conservation law (B.40).

10 Perfect and imperfect fluids

A perfect fluid is defined as a medium for which at every point there is a locally inertial Cartesian frame of reference, moving with the fluid, in which the fluid appears the same in all directions. In such a locally inertial co-moving frame the components of the energy momentum tensor must take the form

$$T^{ij} = \delta_{ij} p, \quad T^{i0} = T_{0i} = 0, \quad T^{00} = \rho,$$

where i and j run over the three Cartesian coordinate directions 1,2,3. (This is because non-zero value of T^{i0} and any term in T^{ij} other than one proportional to δ_{ij} would select out special directions in space, such as the direction of T^{i0}, or of one of the non-degenerate eigenvectors of T^{ij}.) The coefficients p and ρ are known as the pressure and energy density, respectively. Then in a locally inertial Cartesian frame with an arbitrary velocity, the energymomentum tensor takes the form

$$T^{\alpha\beta} = p\eta^{\alpha\beta} + (p + \rho) u^\alpha u^\beta, \tag{B.42}$$

where ρ and p are defined to be the same as in the co-moving inertial frame, and u^α is defined by the conditions that it transforms as a fourvector under Lorentz transformations, and that in the locally Cartesian co-moving inertial frame it has components $u^0 = 1$ and $u^i = 0$. This fourvector, known as the velocity vector, is normalized so that, in any inertial

frame, $\eta_{\alpha\beta}u^\alpha u^\beta = -1$. It follows that in a general gravitational field the energy-momentum tensor of a perfect fluid is

$$T^{\mu\nu} = pg^{\mu\nu} + (p+\rho)u^\mu u^\nu, \quad g_{\mu\nu}u^\mu u^\nu = -1 \tag{B.43}$$

where p and ρ are defined by the condition that they are equal to the coefficients in the energy-momentum tensor in a locally co-moving inertial coordinate system, so that they are scalars, and u^μ is defined by the conditions that it transforms as a four-vector under general coordinate transformations and has the components $u^0 = 1$ and $u^i = 0$ in the locally co-moving Cartesian inertial frame. This formula for $T^{\mu\nu}$ is correct because it is generally covariant and it is true in locally inertial Cartesian coordinate systems. The equations of relativistic hydrodynamics in a gravitational field are derived by imposing the conservation condition (B.40) on this tensor. In addition, if the pressure depends on the density n of some conserved quantity such as baryon number as well as on the energy density ρ, then we need the equation of conservation, which in locally inertial Cartesian frames reads

$$\frac{\partial}{\partial x^\alpha}(nu^\alpha) = 0. \tag{B.44}$$

Thus in a general coordinate system in an arbitrary gravitational field, we have

$$(nu^\mu)_{;\mu} = 0. \tag{B.45}$$

For an imperfect fluid, there is a small correction $\Delta T^{\alpha\beta}$ to formula (B.42) for the energy-momentum tensor in locally inertial Cartesian coordinate system:

$$T^{\alpha\beta} = p\eta^{\alpha\beta} + (p+\rho)u^\alpha u^\beta + \Delta T^{\alpha\beta} \tag{B.46}$$

and a small correction ΔN^α to whatever current may be conserved

$$\frac{\partial}{\partial x^\alpha}(nu^\alpha + \Delta N^\alpha) = 0. \tag{B.47}$$

The scalar ρ is defined as the energy density observed in a co-moving frame in which $u^i = 0$, so that in this frame $\Delta T^{00} \equiv 0$. This implies that in all locally inertial Cartesian frames $u_\alpha u_\beta \Delta T^{\alpha\beta} = 0$, since this quantity is a scalar and vanishes in a co-moving frame. The scalar n can be defined as the value of the conserved density observed in such a co-moving frame, so by the same reasoning in all locally inertial Cartesian frames we have $u_\alpha \Delta N^\alpha = 0$. The pressure can be defined as whatever function of ρ and perhaps n gives
the pressure in a static homogeneous fluid. (A different definition is used in Chapter 5 et seq.) But the definition of the velocity four-vector u^α remains somewhat ambiguous. We could define u^i to be the velocity of particle transport, [1] in which case in a co-moving frame with $u^i = 0$ we would have $\Delta N^i = 0$ as well as $\Delta N^0 = 0$, so that in general locally inertial Cartesian frames $\Delta N^\alpha = 0$. Instead we will define u^i to be the velocity of energy transport, [2] so that in co-moving frames we also have $T^{i0} = \Delta T^{i0} = 0$, and so $u_\beta \Delta T^{\alpha\beta} = \Delta T^{\alpha 0} = 0$ in this frame, which implies that $u_\beta \Delta T^{\alpha\beta} = 0$ in all locally inertial Cartesian frames, but in general $\Delta N^\alpha \neq 0$. With this definition of velocity, the second law of thermodynamics together with the conditions $u_\beta \Delta T^{\alpha\beta} = 0$ and $u_\alpha \Delta N^\alpha = 0$ gives [3]

$$\Delta T_{\alpha\beta} = -\eta\left(\frac{\partial u_\alpha}{\partial x^\beta} + \frac{\partial u_\beta}{\partial x^\alpha} + u_\beta u^\gamma \frac{\partial u_\alpha}{\partial x^\gamma} + u_\alpha u^\gamma \frac{\partial u_\beta}{\partial x^\gamma}\right) - \left(\zeta - \frac{2}{3}\eta\right)\frac{\partial u^\gamma}{\partial x^\gamma}\left(\eta_{\alpha\beta} + u_\alpha u_\beta\right) \tag{B.48}$$

$$\Delta N_\alpha = -\chi\left(\frac{nT}{\rho + p}\right)^2 \left[\frac{\partial}{\partial x^\alpha}\left(\frac{\mu}{T}\right) + u_\alpha u^\beta \frac{\partial}{\partial x^\beta}\left(\frac{\mu}{T}\right)\right]. \tag{B.49}$$

Here η, ζ, and χ are the positive coefficients of shear viscosity, bulk viscosity, and heat conduction, respectively, and μ is the chemical potential associated with the conserved quantum number, defined by the condition that the entropy density is $(p + \rho - \mu n)/T$. It is then an immediate consequence of the Equivalence Principle that in general coordinate systems in arbitrary gravitational fields that vary little over a mean free path or mean free time,

$$\Delta T_{\mu\nu} = -\eta\left(u_{\mu;\nu} + u_{\nu;\mu} + u_\nu u^\kappa u_{\mu;\kappa} + u_\mu u^\kappa u_{\nu;\kappa}\right) - \left(\zeta - \frac{2}{3}\eta\right) u^\kappa_{;\kappa}\left(g_{\mu\nu} + u_\mu u_\nu\right), \tag{B.50}$$

$$\Delta N_\mu = -\chi\left(\frac{nT}{\rho + p}\right)^2 \left[\frac{\partial}{\partial x^\mu}\left(\frac{\mu}{T}\right) + u_\mu u^\nu \frac{\partial}{\partial x^\nu}\left(\frac{\mu}{T}\right)\right]. \tag{B.51}$$

11 The action principle

There is a general algorithm for deriving the energy-momentum tensor for systems that may be more complicated than an ideal gas or perfect fluid, provided only that they are governed by an action principle. According to the action principle, the differential equations governing the behavior of particles and fields can be expressed as the statement that the "matter action," a functional I_m of the fields and particle trajectories, is stationary with respect to infinitesimal variations of the fields and particles. The Equivalence Principle tells us to include the metric in the matter action in such a way that I_m is invariant under general coordinate transformations. Then the change in the action when we make an infinitesimal change $\delta g_{\mu\nu}$ in the metric (leaving all other dynamical variables unchanged) must be of the form

$$\delta I_m = \frac{1}{2}\int d^4x \sqrt{-\operatorname{Det} g(x)}\, T^{\mu v}(x)\delta g_{\mu v}(x) \tag{B.52}$$

where $T^{\mu\nu}(x)$ is a symmetric tensor, which we identify as the energymomentum tensor.

For instance, the action for a gas of charged particles with masses m_n, charges e_n, and trajectories $x^\mu_n(u)$ interacting with electromagnetic fields is taken as

[471] This is the option adopted by C. Eckart, Phys. Rev. 58, 919 (1940), and also in Secs. 2.11 and 15.10 of G&C.

[2] This is the definition used by L. D. Landau and E. M. Lifschitz, Fluid Mechanics, trans. by J. B. Sykes and W. H. Reid (Pergamon Press, London, 1959), Section 127. We will adopt this definition of velocity in this book, because it imposes the maximum possible constraint on the energy-momentum tensor at the cost of putting less of a constraint on the current of conserved quantities, and in cosmology we frequently have to do with situations in which there are either no non-zero conserved quantities at all, such as in the early universe before cosmological leptogenesis or baryongenesis, or no conserved quantities that are large enough to seriously affect the relation between pressure and density, as in the radiation-dominated era at temperatures above about 10^4 K.

[3] Landau & Lifschitz, op. cit.

$$I_m = -\frac{1}{4}\int d^4x\sqrt{-\operatorname{Det} g}F_{\mu\nu}F_{\rho\sigma}g^{\mu\rho}g^{\nu\sigma}$$
$$-\sum_n m_n\int du\left[-g_{\mu\nu}\left(x_n(u)\right)\frac{dx_n^\mu(u)}{du}\frac{dx_n^\nu(u)}{du}\right]^{1/2}$$
$$+\sum_n e_n\int du\frac{dx_n^\mu(u)}{du}A_\mu(u)$$

in which the homogeneous Maxwell equations (B.29) are enforced by writing the field strength tensor in terms of a vector potential A_μ as $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$. The reader can verify that the conditions for the matter action to be stationary with respect to arbitrary small variations in $A_\mu(x)$ and $x_n^\mu(u)$ (arbitrary, except that they vanish for $x^\mu \to \infty$ or $u \to \pm\infty$) are the inhomogeneous Maxwell equations (B.28) together with the equations of motion of charged particles in a combined gravitational and electromagnetic fields

$$m_n\left[\frac{d^2x_n^\mu}{d\tau_n^2} + \Gamma^\mu_{\nu\rho}\frac{dx_n^\nu}{d\tau_n}\frac{dx_n^\rho}{d\tau_n}\right] = e_n\frac{dx_n^\nu}{d\tau_n}F^\mu_\nu\left(x_n\right),$$

where τ_n is the invariant proper time along the nth particle trajectory, defined by

$$\frac{d\tau_n}{du} \equiv \left[-g_{\mu\nu}\left(x_n(u)\right)\frac{dx_n^\mu(u)}{du}\frac{dx_n^\nu(u)}{du}\right]^{1/2}.$$

Eq. (B.52) gives an energy-momentum tensor

$$T^{\mu\nu}(x) = [-\operatorname{Det} g(x)]^{-1/2}\sum_n m_n\int d\tau_n\frac{dx_n^\mu}{d\tau_n}\frac{dx_n^\nu}{d\tau_n}\delta^4\left(x - x_n\right)$$
$$+ F^{\rho\mu}(x)F_\rho{}^\nu(x) - \frac{1}{4}g^{\mu\nu}(x)F^{\rho\sigma}(x)F_{\rho\sigma}(x)$$

which is the same as Eq. (B.41), with extra terms representing the energy and momentum in the electromagnetic field. (In the derivation we use the relations $\delta\operatorname{Det} g = \operatorname{Det} g g^{\mu\nu}\delta g_{\mu\nu}$ and $\delta g^{\mu\rho} = -g^{\mu\nu}\delta g_{\nu\sigma}g^{\sigma\rho}$.)

The justification of the identification of $T^{\mu\nu}$ in Eq. (B.52) is that this tensor is conserved, in the sense of Eq. (B.40). To show this, note that in general our assumption that I_m is a scalar tells us that it is unchanged if we simultaneously make the replacements

$$d^4x \to d^4x', \quad \frac{\partial}{\partial x^\mu} \to \frac{\partial}{\partial x'^\mu}, \tag{B.53}$$

$$x_n^\mu(u) \to x_n'^\mu(u), \quad A_\mu(x) \to A'_\mu\left(x'\right) = \frac{\partial x^\nu}{\partial x'^\mu}A_\nu(x), \tag{B.54}$$

$$g_{\mu\nu}(x) \to g'_{\mu\nu}\left(x'\right) = \frac{\partial x^\rho}{\partial x'^\mu}\frac{\partial x^\sigma}{\partial x'^\nu}g_{\rho\sigma}(x), \tag{B.55}$$

and likewise for any other fields entering in the action. But the coordinate x'^μ (unlike $x_n'^\mu(u)$) is just a variable of integration, so we can change x'^μ back to x^μ everywhere without changing I_m. It follows that I_m is unchanged by the replacements

$$x_n^\mu(u) \to x_n'^\mu(u) \tag{B.56}$$

$$A_\mu(x) \to A'_\mu(x) = \frac{\partial x^\nu}{\partial x'^\mu}A_\nu(x) - \left[A'_\mu\left(x'\right) - A'_\mu(x)\right] \tag{B.57}$$

$$g_{\mu\nu}(x) \to g'_{\mu\nu}(x) = \frac{\partial x^\rho}{\partial x'^\mu}\frac{\partial x^\sigma}{\partial x'^\nu}g_{\rho\sigma}(x) - \left[g'_{\mu\nu}\left(x'\right) - g'_{\mu\nu}(x)\right] \tag{B.58}$$

with x^μ and $\partial/\partial x^\mu$ now left unchanged. (This combination of a coordinate transformation and a relabeling of coordinates is sometimes called a gauge transformation.) For a general infinitesimal coordinate transformation we have $x^\mu \to x^\mu + \epsilon^\mu(x)$, with $\epsilon^\mu(x)$ arbitrary infinitesimal functions of x.

Then the transformations (B.56)-(B.58) become

$$x_n^\mu(u) \to x_n^\mu(u) + \epsilon^\mu\left(x_n\right) \tag{B.59}$$

$$A_\mu(x) \to A_\mu(x) - \frac{\partial\epsilon^\nu(x)}{\partial x^\mu}A_\nu(x) - \frac{\partial A_\mu(x)}{\partial x^\nu}\epsilon^\nu(x) \tag{B.60}$$

$$\begin{aligned} g_{\mu\nu}(x) \to & g_{\mu\nu}(x) - \frac{\partial\epsilon^\rho(x)}{\partial x^\mu}g_{\rho\nu}(x) - \frac{\partial\epsilon^\sigma(x)}{\partial x^\nu}g_{\mu\sigma}(x) \\ & - \frac{\partial g_{\mu\nu}(x)}{\partial x^\rho}\epsilon^\rho(x) \end{aligned} \tag{B.61}$$

Now, as long as the equations of motion of particles and the field equations for "matter" (including electromagnetic) fields are satisfied, the action is unaffected by any infinitesimal changes in particle trajectories and matter fields. On the other hand, unlike the total action of matter plus gravitation, the matter action is not stationary under variations in the metric, even when the field equations are satisfied. For a general infinitesimal coordinate transformation, using Eq. (B.61) in Eq. (B.52) lets us write the condition that I_m is a scalar as

$$\begin{aligned} 0 = \delta I_m = \int d^4x\sqrt{-\operatorname{Det} g(x)}T^{\mu v}(x)\Bigg[& -\frac{\partial\epsilon^\rho(x)}{\partial x^\mu}g_{\rho v}(x) - \frac{\partial\epsilon^\rho(x)}{\partial x^\nu}g_{\mu\rho}(x) \\ & -\frac{\partial g_{\mu\nu}(x)}{\partial x^\rho}\epsilon^\rho(x)\Bigg] \end{aligned} \tag{B.62}$$

Integrating by parts and setting the coefficient of $\epsilon^\rho(x)$ equal to zero then yields the conservation condition (B.40).

12 Scalar field theory

We will frequently encounter cosmological models involving a scalar field $\varphi(x)$, with an action [4]

$$I_\varphi = -\int d^4x\sqrt{-\operatorname{Det} g}\left[\frac{1}{2}g^{\mu\nu}\frac{\partial\varphi}{\partial x^\mu}\frac{\partial\varphi}{\partial x^\nu} + V(\varphi)\right], \tag{B.63}$$

where $V(\varphi)$ is a function known as the potential. The field equations for φ in a gravitational field are given by the condition that this be stationary with respect to variations in φ :

$$\frac{1}{\sqrt{-\operatorname{Det} g}}\frac{\partial}{\partial x^\mu}\left[\sqrt{-\operatorname{Det} g}g^{\mu\nu}\frac{\partial\varphi}{\partial x^\nu}\right] = \frac{\partial V(\varphi)}{\partial\varphi}. \tag{B.64}$$

The energy-momentum tensor for the scalar field is found by varying the metric and comparing with Eq. (B.40):

$$T_\varphi^{\mu\nu} = -g^{\mu\nu}\left[\frac{1}{2}g^{\rho\sigma}\frac{\partial\varphi}{\partial x^\rho}\frac{\partial\varphi}{\partial x^\sigma} + V(\varphi)\right] + g^{\mu\rho}g^{\nu\sigma}\frac{\partial\varphi}{\partial x^\rho}\frac{\partial\varphi}{\partial x^\sigma}. \tag{B.65}$$

[474] In general, the coefficient of the first term in square brackets might depend on φ, but such a fielddependent coefficient can always be eliminated by a redefinition of the scalar field. This simplification is not generally possible, however, with more than one scalar field, the case discussed in Section 10.4.

This has the same form as the energy-momentum tensor (B.43) for a perfect fluid, with energy density, pressure, and velocity four-vector given by [5]

$$\rho = -\frac{1}{2} g^{\mu\nu} \frac{\partial\varphi}{\partial x^\mu} \frac{\partial\varphi}{\partial x^\nu} + V(\varphi) \tag{B.66}$$

$$p = -\frac{1}{2} g^{\mu\nu} \frac{\partial\varphi}{\partial x^\mu} \frac{\partial\varphi}{\partial x^\nu} - V(\varphi) \tag{B.67}$$

$$u^\mu = -\left[-g^{\rho\sigma} \frac{\partial\varphi}{\partial x^\rho} \frac{\partial\varphi}{\partial x^\sigma} \right]^{-1/2} g^{\mu\tau} \frac{\partial\varphi}{\partial x^\tau} \tag{B.68}$$

(The sign of u^μ does not affect the energy-momentum tensor, so it cannot be found by comparing Eqs. (B.65) and (B.43). It is chosen here so that u^0 should have the value $u^0 = +1$ in the case considered in Chapter 4− a spacetime with $g^{00} = -1$ and a scalar field that does not depend on position and increases with time - provided the square root is understood to be positive.) The reader can check that $T^{\mu\nu}_{\varphi}$ is conserved in the sense of Eq. (B.40) as a consequence of the field equation (B.64) for φ.

13 Parallel transport

A body carried along an orbit $x^\mu = x^\mu(t)$ may be characterized by one or more t-dependent vectors or tensors. If these vectors or tensors do not change at time t in a frame of reference that is locally inertial at $x^\mu(t)$, then

in an arbitrary frame of reference they will undergo a change known as parallel transport. For instance, a contravariant vector $v^\mu(t)$ will have a rate of change

$$\frac{dv^\mu(t)}{dt} = -\Gamma^\mu_{\nu\lambda}(x(t)) v^\nu(t) \frac{dx^\lambda(t)}{dt}. \tag{B.69}$$

To check that this is valid, we note that it is assumed to be true at time t in frames of reference in which the affine connection $\Gamma^\mu_{\nu\lambda}(x(t))$ vanishes, and it is generally covariant, and it is therefore true in all frames if it is true in such locally inertial frames. In particular, Eq. (B.12) shows that the momentum $p^\mu = dx^\mu/du$ satisfies the equation of parallel transport. Similarly, any tensor carried along an orbit that does not change in a frame that is locally inertial at a point along the orbit will have a rate of change in general frames at that point given by a sum of terms like the right-hand side of Eq. (B.69), with $a - \Gamma$ for every contravariant index and $a + \Gamma$ for every covariant index. For instance, for a covariant tensor $J_{\mu\nu}$, the equation of parallel transport is

[475] This result for pressure is different from that given (without explanation) by E. W. Kolb and M. S. Turner, The Early Universe (Addison-Wesley, Redwood City, CA, 1990), Eq. (8.21), according to whom the pressure of a scalar field in a Robertson-Walker metric is

$$p = \dot{\varphi}^2/2 - V(\varphi) - (\nabla\varphi)^2/6a^2,$$

instead of the result for a Robertson-Walker metric given by Eq. (B.67)

$$p = \dot{\varphi}^2/2 - V(\varphi) - (\nabla\varphi)^2/2a^2.$$

The Kolb-Turner result is obtained if we define the pressure as the value of $T^i{}_i/3$ measured by an observer in a locally inertial coordinate system moving with four-velocity v_μ

$$p \equiv \frac{1}{3} \left(g_{\mu\rho} + v_\mu v_\rho \right) T^{\rho\sigma} \left(\delta^\mu_\sigma + v_\sigma v^\mu \right),$$

but take the velocity v^μ to have components $v^0 = 1, v^i = 0$. It seems more natural in using this formula for pressure to take v^μ as the velocity u^μ given by Eq. (B.68), for this is the velocity that appears in the perfect fluid formula (B.43) for the energy-momentum tensor. This choice of v^μ leads to Eq. (B.67).

$$\frac{dJ_{\mu\nu}(t)}{dt} = +\Gamma^{\rho}_{\mu\lambda}(x(t))J_{\rho\nu}(t)\frac{dx^{\lambda}(t)}{dt} + \Gamma^{\rho}_{\nu\lambda}(x(t))J_{\mu\rho}(t)\frac{dx^{\lambda}(t)}{dt}.$$

14 The gravitational field equations

It remains only to give the equations that govern the gravitational field itself. These must satisfy two requirements: they must be generally covariant, and for weak slowly changing gravitational fields they must yield the Poisson equation for the Newtonian potential ϕ in Eq. (B.21)

$$\nabla^2\phi = 4\pi G T^{00}, \tag{B.70}$$

where G is Newton's constant. If we limit ourselves to partial differential equations that (like the Poisson equation) have just two spacetime derivatives of the metric, then the field equations are unique:

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}g^{\lambda\kappa}R_{\lambda\kappa} = -8\pi G T_{\mu\nu}, \tag{B.71}$$

where $T_{\mu\nu}$ is the energy-momentum tensor with lowered indices

$$T_{\mu\nu} \equiv g_{\mu\lambda}g_{\nu\kappa}T^{\lambda\kappa} \tag{B.72}$$

and $R_{\mu\nu}$ is the Ricci tensor:

$$R_{\mu\nu} \equiv \frac{\partial\Gamma^{\lambda}_{\mu\lambda}}{\partial x^{\nu}} - \frac{\partial\Gamma^{\lambda}_{\mu\nu}}{\partial x^{\lambda}} + \Gamma^{\kappa}_{\mu\lambda}\Gamma^{\lambda}_{\nu\kappa} - \Gamma^{\kappa}_{\mu\nu}\Gamma^{\lambda}_{\lambda\kappa}. \tag{B.73}$$

For weak static fields the time-time component of this equation is the same as the Poisson equation (B.70), provided g_{00} is related to ϕ by Eq. (B.21). The tensor appearing on the left-hand side of Eq. (B.71) satisfies a set of differential Bianchi identities:

$$\left[g^{\lambda\nu}\left(R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}g^{\rho\kappa}R_{\rho\kappa}\right)\right]_{;\lambda} = 0. \tag{B.74}$$

This is why this is the linear combination of the tensors $R_{\mu\nu}$ and $g_{\mu\nu}g^{\lambda\kappa}R_{\lambda\kappa}$ that appears on the left-hand side of the field equations; otherwise the field equations would not be consistent with the energy-momentum conservation law (B.40). The field equations could have been derived more easily by including a gravitational term in the action

$$I_g = -\frac{1}{16\pi G}\int d^4x\sqrt{-\operatorname{Det} g(x)}\,g^{\lambda\kappa}(x)R_{\lambda\kappa}(x). \tag{B.75}$$

The Bianchi identities (B.74) can be derived from the fact that I_g is automatically invariant under general coordinate transformations of the metric, and the field equations (B.71) can be derived from the condition that the total action $I_g + I_m$ be stationary with respect to arbitrary variations of the metric.

If we allow terms in the gravitational field equation with fewer than two spacetime derivatives, then it is possible to include a term on the lefthand side of the field equation (B.71) proportional to $g_{\mu\nu}$. This is the so-called cosmological constant term, discussed in Section 1.5. It can be regarded as a "vacuum-energy" correction to $T_{\mu\nu}$. Aside from a cosmological constant, the only other possible modification of the left-hand side of Eq. (B.71) would involve terms with more than two spacetime derivatives. (They can be derived, for instance, by including terms in the integrand of the gravitational action proportional to $\sqrt{-\operatorname{Det} g}R^{\mu\nu}R_{\mu\nu}$ or $\sqrt{-\operatorname{Det} g}\,(R^{\mu}{}_{\mu})^2$.) Dimensional analysis tells us that such terms would have coefficients whose

dimensionality (relative to that of the factor $1/16\pi G$ in Eq. (B.75)) is a positive power of length. The experimental success of General Relativity shows that this length is much smaller than the scale of the solar system, so the effect of such terms would be completely negligible at cosmological distance scales.

10.13 Appendix C Energy Transfer between Radiation and Electrons

One often needs to know the rate at which a photon will lose or gain energy when passing through an ionized gas. For instance, we need this information in calculating the Sunyaev-Zel'dovich effect, discussed in Section 2.5, and in understanding the preservation of thermal equilibrium between matter and radiation, treated in Section 2.2. This appendix will first derive formulas for the mean and the mean square change in energy of a photon in striking a single electron, and will then use these results to derive the rate of change of the photon energy distribution function in passing through an ionized gas. For the purposes of this section, we take $\hbar = c = 1$.

Suppose that an electron traveling in the three-direction with momentum four-vector

$$p = (0, 0, p_e, E_e)\,, \quad E_e \equiv \sqrt{p_e^2 + m_e^2}, \tag{C.1}$$

is struck by a photon with energy ω moving along a direction with polar and azimuthal angles η and ϕ, giving the photon a new energy ω' and a new direction with polar and azimuthal angles η' and ϕ'. That is, the initial four-momentum q and final four-momentum q' of the photon take the forms

$$q = (\sin\eta\cos\phi, \sin\eta\sin\phi, \cos\eta, 1)\omega, \tag{C.2}$$
$$q' = (\sin\eta'\cos\phi', \sin\eta'\sin\phi', \cos\eta', 1)\,\omega'. \tag{C.3}$$

To calculate the cross section for this scattering event, we perform a Lorentz transformation to a frame of reference in which the electron is initially at rest, in which case the cross section takes a simple and well-known form. In the electron rest-frame, the initial and final photon four-momenta are Lq and Lq', where $L^\mu{}_\nu$ is the Lorentz transformation

$$L = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \gamma & -\beta\gamma \\ 0 & 0 & -\beta\gamma & \gamma \end{pmatrix}, \tag{C.4}$$

where $\beta \equiv p_e/E_e$ is the electron velocity, and $\gamma \equiv (1-\beta^2)^{-1/2}$. This gives the initial and final photon four-momenta in the electron rest frame as

$$Lq = (\sin\alpha\cos\phi, \sin\alpha\sin\phi, \cos\alpha, 1)k \tag{C.5}$$
$$Lq' = (\sin\alpha'\cos\phi', \sin\alpha'\sin\phi', \cos\alpha', 1)\,k' \tag{C.6}$$

where the initial and final photon energies in the electron rest frame are

$$k = (-\beta\gamma\cos\eta + \gamma)\omega, \quad k' = (-\beta\gamma\cos\eta' + \gamma)\,\omega' \tag{C.7}$$

while the initial and final polar angles of the photon's velocity in this frame are given by

$$\cos\alpha = \frac{\cos\eta - \beta}{1 - \beta\cos\eta}, \quad \cos\alpha' = \frac{\cos\eta' - \beta}{1 - \beta\cos\eta'} \tag{C.8}$$

and there is no change in the azimuthal angles. We also recall that the conservation of energy and momentum in the electron rest frame gives the final photon energy in this frame as [1]

$$k' = \frac{k}{1 + (k/m_e)\,(1 - \cos\theta)}, \tag{C.9}$$

where θ is the scattering angle in the electron rest frame

$$\cos\theta \equiv \widehat{Lq} \cdot \widehat{Lq'} = \cos\alpha\cos\alpha' + \cos(\phi - \phi')\sin\alpha\sin\alpha'. \tag{C.10}$$

The fractional change in the photon energy in the original frame of reference can then be expressed in terms of quantities in the electron rest frame by

$$\frac{\omega' - \omega}{\omega} = \frac{1}{1 + \beta\cos\alpha}\left(\frac{1 + \beta\cos\alpha'}{1 + (k/m_e)\,(1 - \cos\theta)} - \beta\cos\alpha - 1\right). \tag{C.11}$$

In most cases of interest k/m_e and β are much less than unity, so we will keep only terms of first order in k/m_e and zeroth order in β together with terms of (for the moment) arbitrary order in β and zeroth order in k/m_e :

$$\frac{\omega' - \omega}{\omega} \simeq -(k/m_e)\,(1 - \cos\theta) + \frac{\beta\,(\cos\alpha' - \cos\alpha)}{1 + \beta\cos\alpha} \tag{C.12}$$

For an electron at rest and for photon energy $k \ll m_e$, the cross-section differential (summed over final spins and polarizations, and averaged over initial spins and polarizations) is [2]

$$d\sigma = \frac{3\sigma_{\mathcal{T}}}{16\pi}\left(1 + \cos^2\theta\right) d\,(\cos\alpha')\,d\phi' \tag{C.13}$$

where $\sigma_{\mathcal{T}}$ is the Thomson cross section $e^4/6\pi m_e^2$. The cross-section differential is itself Lorentz invariant, though the variables on which it depends are not, so the average photon energy change per collision is

$$\begin{aligned}
\langle\omega' - \omega\rangle &= \frac{1}{\sigma_{\mathcal{T}}}\int(\omega' - \omega)\,d\sigma \\
&= \frac{3}{16\pi}\int_{-1}^{1} d\,(\cos\alpha')\int_0^{2\pi} d\phi'\,(\omega' - \omega)\left(1 + \cos^2\theta\right) \\
&= -\frac{\beta\omega\cos\alpha}{1 + \beta\cos\alpha} - \frac{k\omega}{m_e}
\end{aligned} \tag{C.14}$$

We must average this over the electron direction of motion, or equivalently over α. In calculating this average we must keep in mind that it is $\cos\eta$ rather than $\cos\alpha$ whose distribution function in the interval from -1 to +1 is flat. Also, the transition probability is proportional not only to $d\sigma$ but also to the relative speed [3]

$$u = \frac{|p \cdot q|}{E_e\omega} = 1 - \beta\cos\eta = \frac{1 - \beta^2}{1 + \beta\cos\alpha}. \tag{C.15}$$

[471] QTF, Vol. I, Eq. (8.7.14).
[2] QTF, Vol. I, Eq. (8.7.42).

Hence the average of the energy change over the relative direction of the initial electron and photon is

$$\begin{aligned}\langle\langle\omega'-\omega\rangle\rangle &= \int_{-1}^{+1}\langle\omega'-\omega\rangle\, ud\cos\eta \Big/ \int_{-1}^{+1} ud\cos\eta \\ &= \frac{1}{2}\int_{-1}^{+1}\frac{(1-\beta^2)^2}{(1+\beta\cos\alpha)^3}\left[-\frac{\beta\omega\cos\alpha}{1+\beta\cos\alpha}-\frac{k\omega}{m_e}\right]d\cos\alpha \end{aligned} \tag{C.16}$$

The terms of first order in β make no contribution to the integral over α, so the leading terms in the fractional energy transfer are those of second order in β or first order in ω/m_e :

$$\langle\langle\omega'-\omega\rangle\rangle/\omega \simeq \frac{4}{3}\beta^2-\frac{k}{m_e}\simeq\frac{4}{3}\beta^2-\frac{\omega}{m_e} \tag{C.17}$$

Since the mean photon fractional energy change contains terms of order β^2 and ω/m_e, we will be interested in any terms in the average squared fractional energy change of the same order. Inspection of Eq. (C.12) shows that to this order, we have

$$(\omega'-\omega)^2/\omega^2 \simeq \beta^2(\cos\alpha'-\cos\alpha)^2 \tag{C.18}$$

To this order we can neglect the difference between u and unity and between $d\cos\eta$ and $d\cos\alpha$, so that

$$\begin{aligned}\left\langle\left\langle(\omega'-\omega)^2\right\rangle\right\rangle \simeq& \frac{3\beta^2\omega^2}{32\pi}\int_{-1}^{+1}d\cos\alpha\int_{-1}^{+1}d\cos\alpha' \\ &\times\int_0^{2\pi}d\phi'\,(\cos\alpha'-\cos\alpha)^2\left(1+\cos^2\theta\right) \\ =& \frac{2}{3}\beta^2\omega^2 \end{aligned} \tag{C.19}$$

All this is for an electron of a fixed speed β. If the number of electrons with speed between β and $\beta+d\beta$ is given by the Maxwell-Boltzmann distribution with electron temperature T_e, and is hence proportional to $\beta^2\exp\left(-m_e\beta^2/2k_{\mathcal{B}}T_e\right)d\beta$, the average value of β^2 is $3k_{\mathcal{B}}T_e/m_e$, and Eqs. (C.17) and (C.19) become

$$\langle\langle\omega'-\omega\rangle\rangle \simeq \frac{4k_{\mathcal{B}}T_e}{m_e}\omega-\frac{\omega^2}{m_e}, \tag{C.20}$$

and

$$\left\langle\left\langle(\omega'-\omega)^2\right\rangle\right\rangle = \frac{2k_{\mathcal{B}}T_e}{m_e}\omega^2 \tag{C.21}$$

Now suppose that photons with a number $N(\omega)d\omega$ with energies between ω and $\omega+d\omega$ interact with a gas of non-relativistic electrons. For photon energies $\omega \ll m_e$, the rate of change of the distribution function is

$$\begin{aligned}\dot{n}(\omega)d\omega =& n_e\int d\omega' n(\omega')\,R(\omega'\to\omega)\,d\omega(1+N(\omega)) \\ &- n_e n(\omega)d\omega\int d\omega' R(\omega\to\omega')\,(1+N(\omega')) \end{aligned} \tag{C.22}$$

[473] QTF, Vol. I, Eq. (3.4.17).

Here n_e is the number density of electrons; $R(\omega \to \omega')\, d\omega'$ is the average of $ud\sigma$ over initial electron velocities for collisions in which a photon of initial energy ω is given an energy between ω' and $\omega' + d\omega'$; $N(\omega) = (2\pi\hbar)^3 n(\omega) d\omega / 8\pi\omega^2 d\omega$ is the number of photons per quantum state of energy ω (the denominator is $8\pi\omega^2 d\omega$ instead of $4\pi\omega^2 d\omega$ because of the two polarization states of photons); and the factors $1 + N(\omega)$ and $1 + N(\omega')$ are included to take account of the stimulated emission of photons into states that are already occupied. The first term in Eq. (C.22) gives the increase in $n(\omega)$ due to scattering of photons of any initial energy ω' into energy ω, while the second term gives the decrease in $n(\omega)$ due to scattering of photons of energy ω into any final energy ω'. We saw that collisions of photons of energy $\omega \ll m_e$ with a non-relativistic gas of electrons at
temperature T typically change photon energies by only small fractional amounts, of order ω/m_e or $k_{\mathcal{B}}T/m_e$, so the rate constants $R(\omega' \to \omega)$ and $R(\omega \to \omega')$ are sharply peaked around $\omega' \simeq \omega$. It is therefore convenient to change the variable of integration from ω' to $\Delta \equiv \omega - \omega'$ in the first term and to $\Delta \equiv \omega' - \omega$ in the second term of Eq. (C.22). Also canceling the unintegrated differential $d\omega$ and multiplying with $(2\pi\hbar)^3/8\pi\omega^2$, this formula now reads

$$\begin{aligned}\dot{N}(\omega) =& \frac{n_e}{\omega^2} \int_{-\infty}^{\infty} d\Delta (\omega - \Delta)^2 N(\omega - \Delta) R(\omega - \Delta \to \omega)(1 + N(\omega)) \\ & - n_e N(\omega) \int d\Delta R(\omega \to \omega + \Delta)(1 + N(\omega + \Delta)) \end{aligned} \tag{C.23}$$

Since the rate coefficients $R(\omega - \Delta \to \omega)$ and $R(\omega \to \omega + \Delta)$ are sharply peaked around $\Delta = 0$, we can expand the other factors in Eq. (C.23) (and the difference between $R(\omega - \Delta \to \omega)$ and $R(\omega \to \omega + \Delta)$) to second order in Δ :

$$\begin{aligned}\dot{N}(\omega) =& -\frac{n_e}{\omega^2} \int_{-\infty}^{\infty} d\Delta \Delta (1 + N(\omega)) \frac{\partial}{\partial \omega} \left[\omega^2 N(\omega) R(\omega \to \omega + \Delta)\right] \\ & + \frac{n_e}{2\omega^2} \int_{-\infty}^{\infty} d\Delta \Delta^2 (1 + N(\omega)) \frac{\partial^2}{\partial \omega^2} \left[\omega^2 N(\omega) R(\omega \to \omega + \Delta)\right] \\ & - n_e N(\omega) \int_{-\infty}^{\infty} d\Delta \Delta \frac{\partial N(\omega)}{\partial \omega} R(\omega \to \omega + \Delta) \\ & - \frac{n_e}{2} N(\omega) \int_{-\infty}^{\infty} d\Delta \Delta^2 \frac{\partial^2 N(\omega)}{\partial \omega^2} R(\omega \to \omega + \Delta). \end{aligned}$$

This can be rewritten as

$$\begin{aligned}\dot{N}(\omega) =& -\frac{n_e}{\omega^2} \int_{-\infty}^{\infty} d\Delta \Delta \frac{\partial}{\partial \omega} \left[\omega^2 N(\omega) R(\omega \to \omega + \Delta)(1 + N(\omega))\right] \\ & + \frac{n_e}{2\omega^2} \int_{-\infty}^{\infty} d\Delta \Delta^2 \frac{\partial^2}{\partial \omega^2} \left[\omega^2 N(\omega) R(\omega \to \omega + \Delta)(1 + N(\omega))\right] \\ & - \frac{n_e}{\omega^2} \int_{-\infty}^{\infty} d\Delta \Delta^2 \frac{\partial}{\partial \omega} \left[\omega^2 N(\omega) R(\omega \to \omega + \Delta) \frac{\partial N(\omega)}{\partial \omega}\right]. \end{aligned}$$

Inverting the order of integration and differentiation, this becomes

$$\begin{aligned}\dot{N}(\omega) =& -\frac{n_e \sigma_{\mathcal{T}}}{\omega^2} \left[\frac{\partial}{\partial \omega} \left(\omega^2 N(\omega)(1 + N(\omega)) \left\langle\left\langle \omega' - \omega \right\rangle\right\rangle\right) \right. \\ & - \frac{1}{2} \frac{\partial^2}{\partial \omega^2} \left(\omega^2 N(\omega)(1 + N(\omega)) \left\langle\left\langle (\omega' - \omega)^2 \right\rangle\right\rangle\right) \\ & \left. + \frac{\partial}{\partial \omega} \left(\omega^2 N(\omega) \left\langle\left\langle (\omega' - \omega)^2 \right\rangle\right\rangle \frac{\partial N(\omega)}{\partial \omega}\right)\right], \end{aligned} \tag{C.24}$$

in which we use

$$\int_{-\infty}^{\infty} d\Delta \Delta R(\omega \to \omega + \Delta) = \sigma_{\mathcal{T}} \langle\langle \omega' - \omega \rangle\rangle$$
$$\times \int_{-\infty}^{\infty} d\Delta \Delta^2 R(\omega \to \omega + \Delta) = \sigma_{\mathcal{T}} \left\langle \left\langle (\omega' - \omega)^2 \right\rangle \right\rangle \tag{C.25}$$

Inserting the values (C.20) and (C.21) of $\langle\langle \omega' - \omega \rangle\rangle$ and $\left\langle \left\langle (\omega' - \omega)^2 \right\rangle \right\rangle$ gives the Kompaneets equation: [4]

$$\dot{N}(\omega) = \frac{n_e \sigma_{\mathcal{T}} k_{\mathcal{B}} T_e}{m_e \omega^2} \frac{\partial}{\partial \omega} \left[\omega^4 \frac{\partial N(\omega)}{\partial \omega} \right] + \frac{n_e \sigma_{\mathcal{T}}}{m_e \omega^2} \frac{\partial}{\partial \omega} \left[\omega^4 N(\omega)(1 + N(\omega)) \right]. \tag{C.26}$$

As a check, we may note that if the photon distribution function is given by the Planck formula with photon temperature equal to the electron temperature, so that $N(\omega) = [\exp(\omega/k_{\mathcal{B}} T_e) - 1]^{-1}$, then the two terms in Eq. (C.26) cancel, giving no change in $N(\omega)$, as of course must be the case for photons in equilibrium with electrons. As a further check, we note that (as long as $\omega^4 N(\omega)$ and $\omega^4 \partial N/\partial \omega$ both vanish at $\omega = 0$ and $\omega \to \infty$) the total number density of photons $\int_0^\infty 4\pi\omega^2 N(\omega) d\omega$ does not change with time, as could also be seen by integrating Eq. (C.22) over ω, and interchanging ω and ω' in the second term.

10.14 Appendix D The Ergodic Theorem

In cosmology we often have to deal with position-dependent variables like temperature or density or scalar fields whose fluctuations are governed by some sort of probability distribution. In this appendix we will consider a general real random variable $\varphi(x)$ depending on a D-dimensional Euclidean coordinate x. The generalization to several random variables will be obvious.

We will assume that the distribution function giving the probabilities of various functional forms for $\varphi(x)$ is homogeneous, in the sense that the average of any product of φ s with different arguments depends only on the differences of the arguments. That is, for arbitrary z,

$$\langle \varphi(x_1) \varphi(x_2) \cdots \varphi(x_n) \rangle = \langle \varphi(x_1 + z) \varphi(x_2 + z) \cdots \varphi(x_n + z) \rangle. \tag{D.1}$$

In cases where x is a time coordinate, such distributions are said to be stationary.

We will further assume that the φ s at distant arguments are uncorrelated. To put this formally, we assume that for $|u| \to \infty$,

$$\begin{aligned} &\langle \varphi(x_1 + u) \varphi(x_2 + u) \cdots \varphi(y_1 - u) \varphi(y_2 - u) \cdots \rangle \\ &\quad \to \langle \varphi(x_1 + u) \varphi(x_2 + u) \cdots \rangle \langle \varphi(y_1 - u) \varphi(y_2 - u) \cdots \rangle \\ &\quad = \langle \varphi(x_1) \varphi(x_2) \cdots \rangle \langle \varphi(y_1) \varphi(y_2) \cdots \rangle \end{aligned} \tag{D.2}$$

with the final expression justified by Eq. (D.1).

Under these conditions, we can prove an important result known as the Ergodic Theorem: If the limit in Eq. (D.2) is approached sufficiently rapidly, then the root mean square difference between any product $\varphi(x_1 + z) \varphi(x_2 + z) \cdots$, averaged over a range R of z values around an arbitrary point z_0, and the ensemble average of the same product, vanishes as $R^{-D/2}$ for large R. That is, if we define

[474] A. Kompaneets, Zh. Exper. Teor. Fiziki 312+, 876 (1956).

$$\Delta_R^2(x_1, x_2, \ldots) \equiv \left\langle \left(\int d^D z N_R(z) \varphi(x_1 + z)\, \varphi(x_2 + z) \cdots - \langle \varphi(x_1)\, \varphi(x_2) \cdots \rangle \right)^2 \right\rangle \tag{D.3}$$

where [1]

$$N_R(z) \equiv (\sqrt{\pi} R)^{-D} \exp\left(- |z - z_0|^2 / R^2 \right), \tag{D.4}$$

then for $R \to \infty$,

$$\Delta_R \to O\left(R^{-D/2} \right). \tag{D.5}$$

To prove this theorem, we first use the condition $\int N_R(z) d^D z = 1$ to rewrite Eq. (D.3) as

$$\Delta_R^2(x_1, x_2, \ldots) = \left\langle \left(\int d^D z N_R(z) \left[\varphi(x_1 + z)\, \varphi(x_2 + z) \cdots - \langle \varphi(x_1)\, \varphi(x_2) \cdots \rangle \right] \right)^2 \right\rangle$$

Expanding the square and again using Eq. (D.1) and the normalization condition for N_R, and introducing new integration variables $u \equiv (z - w)/2$ and $v \equiv (z + w)/2$, we have

$$\begin{aligned}
\Delta_R^2 &= \int d^D z N_R(z) \int d^D w N_R(w) \\
&\quad \times \left[\langle \varphi(x_1 + z)\, \varphi(x_2 + z) \cdots \varphi(x_1 + w)\, \varphi(x_2 + w) \cdots \rangle \right. \\
&\quad \left. - \langle \varphi(x_1)\, \varphi(x_2) \cdots \rangle^2 \right] \\
&= \left(\frac{2}{\pi R^2} \right)^D \int d^D v \exp\left(-2 |v - z_0|^2 / R^2 \right) \int d^D u \exp\left(-2|u|^2 / R^2 \right) \\
&\quad \times \left[\langle \varphi(x_1 + u)\, \varphi(x_2 + u) \cdots \varphi(x_1 - u)\, \varphi(x_2 - u) \cdots \rangle \right. \\
&\quad \left. - \langle \varphi(x_1)\, \varphi(x_2) \cdots \rangle^2 \right] \\
&= \left(\frac{2}{\pi R^2} \right)^{D/2} \int d^D u \exp\left(-2|u|^2 / R^2 \right) \\
&\quad \times \left[\langle \varphi(x_1 + u)\, \varphi(x_2 + u) \cdots \varphi(x_1 - u)\, \varphi(x_2 - u) \cdots \rangle \right. \\
&\quad \left. - \langle \varphi(x_1)\, \varphi(x_2) \cdots \rangle^2 \right].
\end{aligned}$$

Assuming that the limit in Eq. (D.2) is approached sufficiently rapidly, the u integral would converge even without the factor $\exp(-2|u|^2/R^2)$, so for $R \to \infty$ we can take this factor as unity, and find our final expression

$$\begin{aligned}
\Delta_R^2 \to \left(\frac{2}{\pi R^2} \right)^{D/2} & \int d^D u \\
& \times \left[\langle \varphi(x_1 + u)\, \varphi(x_2 + u) \cdots \varphi(x_1 - u)\, \varphi(x_2 - u) \cdots \rangle \right. \\
& \left. - \langle \varphi(x_1)\, \varphi(x_2) \cdots \rangle^2 \right]
\end{aligned} \tag{D.6}$$

thus confirming Eq. (D.5).

[471] The specific form (D.4) for the function N_R is not essential. It is only important that the function be constant for $|z - z_0|^2 \ll R^2$, vanish rapidly for $|z - z_0|^2 \gg R^2$, and be normalized so that $\int N_R(z) d^D z = 1$.

10.15 Appendix E Gaussian Distributions

Consider a random variable $\varphi(x)$ depending on a D-dimensional coordinate x. We will define it to have zero average value, by subtracting from φ any non-zero average it may have. The distribution function governing φ is said to be Gaussian if the average of a product of an even number of φ s is the sum over all ways of pairing φ s with each other of a product of the average values of the pairs:

$$\langle \varphi(x_1)\,\varphi(x_2)\cdots\rangle = \sum_{\text{pairings}}\prod_{\text{pairs}}\langle\varphi\varphi\rangle, \tag{E.1}$$

(with the sum over pairings not distinguishing those which interchange coordinates in a pair, or which merely interchange pairs), while the average of the product of any odd number of φ s vanishes. For instance

$$\begin{aligned}\langle \varphi(x_1)\,\varphi(x_2)\,\varphi(x_3)\,\varphi(x_4)\rangle &= \langle \varphi(x_1)\,\varphi(x_2)\rangle\,\langle \varphi(x_3)\,\varphi(x_4)\rangle \\ &+ \langle \varphi(x_1)\,\varphi(x_3)\rangle\,\langle \varphi(x_2)\,\varphi(x_4)\rangle + \langle \varphi(x_1)\,\varphi(x_4)\rangle\,\langle \varphi(x_2)\,\varphi(x_3)\rangle\,.\end{aligned} \tag{E.2}$$

(Of course, there is no way of pairing all of an odd number of φ s, which is why for Gaussian distributions the average of any odd number of φ s must vanish.) More generally, in the average of a product of $2n$ factors of φ, each of $(\ 2n\ )!$ permutations of the coordinates defines a pairing (with the first permuted φ paired with the second, the third with the fourth, and so on), but $2^n n!$ of these differ only by permutations of the two coordinates within a pair or permutations of the n pairs, so in general this average contains $(\ 2n\ )!/2^n n!$ terms.

If $\varphi(x)$ is governed by a Gaussian distribution, then so is any linear functional of $\varphi(x)$. For instance, consider a set of linear functionals of the form

$$F_i[\varphi] \equiv \int d^D x f_i(x)\varphi(x) \tag{E.3}$$

By multiplying Eq. (E.2) by $f_1(x_1)\,f_2(x_2)\,f_3(x_3)\,f_4(x_4)$ and integrating, we find

$$\langle F_1F_2F_3F_4\rangle = \langle F_1F_2\rangle\,\langle F_3F_4\rangle + \langle F_1F_3\rangle\,\langle F_2F_4\rangle + \langle F_1F_4\rangle\,\langle F_2F_3\rangle\,. \tag{E.4}$$

Such distributions are called Gaussian because of the form taken by the probability distribution of general linear functionals $F[\varphi] = \int d^D x f(x)\varphi(x)$ of φ. In $\langle F^{2n}[\varphi]\rangle$, each of the $(\ 2n\ )!\ /2^n n\ !$ terms makes the same contribution
$\langle F^2[\varphi]\rangle^n$, so

$$\left\langle F^{2n}[\varphi]\right\rangle = \left\langle F^2[\varphi]\right\rangle^n (2n)!/2^n n!. \tag{E.5}$$

This implies that the probability $P(F)dF$ that the functional is between F and $F+dF$ is the Gaussian function

$$P(F)dF = \frac{1}{\sqrt{2\pi\,\langle F^2\rangle}}\exp\left(-\frac{F^2}{2\,\langle F^2\rangle}\right)dF. \tag{E.6}$$

Distributions of this sort arise commonly when $\varphi(x)$ is the sum of a large number of independently fluctuating terms. The central limit theorem tells us that in this case the distribution of the sum is Gaussian. In the application that most concerns us here, the fluctuations in the temperature of the cosmic microwave background are believed to be nearly Gaussian because they arise (as discussed in Chapter 10) from the quantum fluctuations of one or more nearly free quantum fields.

10.16 Appendix F Newtonian Cosmology

During the era when the energy density of the universe is dominated by cold dark matter, the behavior of perturbations can be adequately treated by the methods of Newtonian mechanics. This has applications both for our introductory study of anisotropies in the cosmic microwave background in Section 2.6, and for the treatment of the large scale structure of matter in Section 8.1.

The equations of non-relativistic hydrodynamics and Newtonian gravitational theory for a fluid with mass density ρ, velocity $\mathbf{v}$, zero pressure, and gravitational potential ϕ are the equation of continuity

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\mathbf{v}\rho) = 0 \tag{F.1}$$

the Euler equation

$$\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} = -\nabla\phi \tag{F.2}$$

and the Poisson equation

$$\nabla^2 \phi = 4\pi G\rho. \tag{F.3}$$

These equations have an unperturbed solution (distinguished by bars) of the form

$$\bar{\rho} = \rho_0 \left(a_0/a\right)^3, \quad \overline{\mathbf{v}} = H\mathbf{X}, \quad \bar{\phi} = 2\pi G\bar{\rho}\mathbf{X}^2/3 \tag{F.4}$$

where $H \equiv \dot{a}/a; a_0$ and ρ_0 are constants; and $a(t)$ satisfies the equation

$$\dot{a}^2 + K = 8\pi G\bar{\rho}a^2/3, \tag{F.5}$$

with K a constant. (We use $\mathbf{X}$ to denote the ordinary Euclidean coordinate vector, to distinguish it from the co-moving coordinate vector $\mathbf{x}$.) This of course corresponds to a cosmological theory with a RobertsonWalker metric, and indeed we have already encountered this solution in Section 1.5, as an alternative approach to the derivation of the Friedmann equation (F.5). In particular, the solution of the equation $d\mathbf{X}/dt = \overline{\mathbf{v}} = H\mathbf{X}$ for the motion of a co-moving object is $\mathbf{X}(t) = [a(t)/a\,(t_0)]\,\mathbf{X}\,(t_0)$, in agreement with Eq. (1.5.22). The co-moving coordinate is thus $\mathbf{x} = \mathbf{X}/a$.

To this unperturbed solution for $\rho, \mathbf{v}$, and ϕ we now add small perturbations $\delta\rho, \delta\mathbf{v}$, and $\delta\phi$. The terms in Eqs. (F.1)-(F.3) of first
order in these perturbations are

$$\frac{\partial \delta\rho}{\partial t} + 3H\delta\rho + H\mathbf{X} \cdot \nabla\delta\rho + \bar{\rho}\nabla \cdot \delta\mathbf{v} = 0 \tag{F.6}$$

$$\frac{\partial \delta\mathbf{v}}{\partial t} + H\mathbf{X} \cdot \nabla\delta\mathbf{v} + H\delta\mathbf{v} = -\nabla\delta\phi \tag{F.7}$$

$$\nabla^2 \delta\phi = 4\pi G\delta\rho \tag{F.8}$$

Eqs. (F.6)-(F.8) do not appear translation-invariant, but the underlying spatial homogeneity of this problem can be restored by writing the equations in terms of the co-moving coordinate $\mathbf{X}/a$. This is brought out most conveniently if we write the perturbations as Fourier transforms in the co-moving coordinate:

$$\delta\rho(\mathbf{X}, t) = \int d^3q \exp\left(\frac{i\mathbf{q} \cdot \mathbf{X}}{a(t)}\right) \delta\rho_{\mathbf{q}}(t), \tag{F.9}$$

and likewise for $\delta\mathbf{v}$ and $\delta\phi$. The partial differential equations (F.6)-(F.8) then become the ordinary differential equations

$$\frac{d\delta\rho_{\mathbf{q}}}{dt} + 3H\delta\rho_{\mathbf{q}} + ia^{-1}\bar{\rho}\mathbf{q}\cdot\delta\mathbf{v}_{\mathbf{q}} = 0 \tag{F.10}$$

$$\frac{d\delta\mathbf{v}_{\mathbf{q}}}{dt} + H\delta\mathbf{v}_{\mathbf{q}} = -ia^{-1}\mathbf{q}\delta\phi_{\mathbf{q}} \tag{F.11}$$

$$\mathbf{q}^2\delta\phi_{\mathbf{q}} = -4\pi G a^2\delta\rho_{\mathbf{q}} \tag{F.12}$$

The solutions of Eqs. (F.10)-(F.12) can be classified according to the transformation properties of the dependent variables under three-dimensional rotations:

Vector modes: In these modes, all scalars vanish: not only $\delta\rho_{\mathbf{q}}$ and $\delta\phi_{\mathbf{q}}$, but also $\mathbf{q}\cdot\delta\mathbf{v}_{\mathbf{q}}$. Then Eqs. (F.10) and (F.12) are automatically satisfied, while Eq. (F.11) becomes

$$\frac{d\delta\mathbf{v}_{\mathbf{q}}}{dt} + H\delta\mathbf{v}_{\mathbf{q}} = 0, \tag{F.13}$$

whose solution is simply $\delta\mathbf{v}_{\mathbf{q}} \propto 1/a$. Because the vector modes simply decay, they are widely ignored.

Scalar Modes: In these modes, the velocity perturbation $\delta\mathbf{v}(\mathbf{X},t)$ can be expressed as the gradient (with respect to $\mathbf{x} = \mathbf{X}/a$) of a scalar potential perturbation $\delta u(\mathbf{X},t)$. For the Fourier transforms, this means that

$$\delta\mathbf{v}_{\mathbf{q}} = i\mathbf{q}\delta u_{\mathbf{q}}. \tag{F.14}$$

Then, using Eq. (F.12) to eliminate $\delta\phi_{\mathbf{q}}$, Eq. (F.11) becomes

$$\frac{d\delta u_{\mathbf{q}}}{dt} + H\delta u_{\mathbf{q}} = -a^{-1}\delta\phi_{\mathbf{q}} = \frac{4\pi G a}{\mathbf{q}^2}\delta\rho_{\mathbf{q}}, \tag{F.15}$$

while Eq. (F.10) gives

$$\frac{d\delta\rho_{\mathbf{q}}}{dt} + 3H\delta\rho_{\mathbf{q}} - a^{-1}\bar{\rho}\mathbf{q}^2\delta u_{\mathbf{q}} = 0. \tag{F.16}$$

For $K = 0$ we have $4\pi G\bar{\rho} = 3H^2/2$. Using $\bar{\rho} \propto a^{-3}$ and the definition of H, we can eliminate $\delta u_{\mathbf{q}}$ from these coupled equations and write them as a second-order differential equation for the fractional density perturbation

$$\frac{d}{dt}\left(a^2\frac{d}{dt}\left(\frac{\delta\rho_{\mathbf{q}}}{\bar{\rho}}\right)\right) - \frac{3}{2}H^2a^2\left(\frac{\delta\rho_{\mathbf{q}}}{\bar{\rho}}\right) = 0, \tag{F.17}$$

or, recalling that for $K = 0$ we have $a \propto t^{2/3}$ and $H = 2/3t$,

$$\frac{d}{dt}\left(t^{4/3}\frac{d}{dt}\left(\frac{\delta\rho_{\mathbf{q}}}{\bar{\rho}}\right)\right) - \frac{2}{3}t^{-2/3}\left(\frac{\delta\rho_{\mathbf{q}}}{\bar{\rho}}\right) = 0. \tag{F.18}$$

The general solution of this equation is a linear combination of the powers $t^{2/3}$ and t^{-1}. It is reasonable to suppose that by the time of last scattering only the leading mode with $\delta\rho_{\mathbf{q}}/\bar{\rho} \propto t^{2/3} \propto a$ will have survived. Since the mean density $\bar{\rho}(t)$ is proportional to $a^{-3}(t)$, we have $\delta\rho_{\mathbf{q}}(t) \propto a^{-2}(t)$. Eq. (F.12) then shows that $\delta\phi_{\mathbf{q}}$ is time independent, a result used in Section 2.6.

To verify that these are the most general solutions of Eqs. (F.10)-(F.12), we need only count equations and solutions. With $\delta\phi_{\mathbf{q}}(t)$ eliminated by use of Eq. (F.12), Eqs. (F.10) and (F.11) are a set of $1+3=4$ coupled first-order differential equations, so they have four linearly

independent solutions. We have found two independent vector modes (corresponding to the two directions perpendicular to $\boldsymbol{q}$) and two independent scalar modes (with $\delta\rho_{\mathbf{q}}/\bar{\rho}$ proportional to $t^{2/3}$ or t^{-1}), so these are indeed the most general solutions.

The cases of non-zero pressure or $K \neq 0$ are treated in detail in Section 15.9 of G&C.

10.17 Appendix GPhoton Polarization

The polarization of photons is of great interest in cosmology, not only because it can be observed in the cosmic microwave background, but also because it affects the anisotropic inertia terms appearing in the gravitational field equations for both scalar and tensor perturbations. This appendix will review the description of the spin state of an individual photon in terms of photon polarization vectors and the related density matrix, and the somewhat unusual parallel transport equation that governs the time dependence of photon polarization vectors and density matrices in gravitational fields.

Let us first recall how we describe the polarization of a photon in the absence of gravitational fields. The most general pure state of a single photon is a linear superposition $\alpha_+\Psi_+ + \alpha_-\Psi_-$, where $\Psi_\pm$are states of helicity ∓ 1 (that is, eigenstates of the component of angular momentum in the direction $\hat{n}$ from which the photon is coming [1] with eigenvalues $\sigma = \pm\hbar$, and normalization $(\Psi_\sigma, \Psi_{\sigma'}) = \delta_{\sigma\sigma'}$) and $\alpha_\pm$are complex numbers satisfying the normalization condition $|\alpha_+|^2 + |\alpha_-|^2 = 1$. We represent such a state by a polarization vector $\mathbf{e} = \alpha_+\mathbf{e}_+ + \alpha_-\mathbf{e}_-$with $\mathbf{e}^* \cdot \mathbf{e} = 1$, where $\mathbf{e}_\pm$is the polarization vector for photons of helicity ∓ 1. For instance, for a photon that is seen coming from the direction [2]

$$\hat{n} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta), \tag{G.1}$$

we can take

$$\mathbf{e}_\pm = (\hat{\theta} \pm i\hat{\phi})/\sqrt{2}, \tag{G.2}$$

where $\hat{\theta}$ and $\hat{\phi}$ are orthogonal unit vectors in the plane perpendicular to $\hat{n}$:

$$\hat{\theta} \equiv (\cos\theta\cos\phi, \cos\theta\sin\phi, -\sin\theta), \hat{\phi} \equiv (-\sin\phi, \cos\phi, 0). \tag{G.3}$$

A linearly polarized photon has $|\alpha_+| = |\alpha_-|$, and hence a polarization vector that is real up to an unimportant over-all phase factor. The opposite case is circular polarization, for which either $|\alpha_+|$or $|\alpha_-|$vanishes. Between these

two extremes is elliptic polarization, for which $|\alpha_+|$and $|\alpha_-|$are unequal, but neither vanishes.

An individual photon will in general have probabilities P_m of being in any one of various pure states $\Psi_m = \alpha_{m+}\Psi_+ + \alpha_{m-}\Psi_-$, so according to the rules of quantum mechanics, the probability of finding it in a particular state $\Psi = \alpha_+\Psi_+ + \alpha_-\Psi_-$represented by a polarization vector $\mathbf{e} = \alpha_+\mathbf{e}_+ + \alpha_-\mathbf{e}_-$, will be

$$P(\mathbf{e}) = \sum_m P_m \left|(\Psi_m, \Psi)\right|^2 = \sum_m P_m \left|\alpha^*_{m+}\alpha_+ + \alpha^*_{m-}\alpha_-\right|^2 = \mathbf{e}^{*i}\mathbf{e}^j N^{ij} \tag{G.4}$$

where N^{ij} is the density matrix for that photon

[471] This is the opposite of the direction of the photon's motion, so the helicity, which is defined as the component of angular momentum along the direction of the photon's motion, is the negative of the component along the direction from which it is coming. This is why we use a label $\pm$ to indicate photons of helicity ∓ 1.

[2] For correlations between polarizations in a small patch of sky, one can choose the three-axis to be in the direction $\hat{n}$ of this patch, in which case the polarization vectors for helicity ∓ 1 could be chosen simply as $(1, \pm i, 0)/\sqrt{2}$.

$$N^{ij} \equiv \sum_m P_m e^i_m e^{j*}_m \tag{G.5}$$

(Repeated indices i, j, etc. are summed over the coordinate indices 1,2,3.) Because the probabilities are real and positive, the matrix N^{ij} is hermitian and positive:

$$N^{ij*} = N^{ji}, \quad N^{ij}\xi^i\xi^{j*} \geq 0 \text{ for all } \xi^i, \tag{G.6}$$

and because $\sum_m P_m = 1$ and $e^i_m e^{i*}_m = 1$ (not summed over m), this matrix has unit trace

$$N^{ii} = 1. \tag{G.7}$$

Of course, the photon polarization vectors are all orthogonal to the photon's direction of motion $-\hat{n}$, so also

$$N^{ij}\hat{n}^i = N^{ij}\hat{n}^j = 0, \tag{G.8}$$

The scattering of light by non-relativistic electrons does not produce circular polarization, and therefore we expect that all microwave background photons are linearly polarized, in which case N^{ij} is real.

So far, we have defined the polarization vector e^i in the absence of gravitation as a unit three-vector, transverse to the photon's direction of motion. We can if we like define it in a gravitational field as the spatial part of a four-component object e^μ that happens to have $e^0 = 0$, and that satisfies

$$p_i e^i = p_\mu e^\mu = 0, \quad g_{ij}e^i e^{j*} = g_{\mu\nu}e^\mu e^{\nu*} = 1 \tag{G.9}$$

where $p^\mu = g^{\mu\nu}p_\nu$ is the photon four-momentum. [3] But since this object obviously does not transform as a four-vector there is no reason to think that its time dependence would be given by the equation (B.69) of parallel transport. Indeed, it cannot evolve by parallel transport, for if it did then the condition $e^0 = 0$ would not be preserved along the photon trajectory $x^i = x^i(t)$ unless it so happened that $\Gamma^0_{ij}(\mathbf{x}(t), t)$ vanishes, which is not usually the case. Instead, we expect that in a locally inertial frame of reference in which the affine connection $\Gamma^\mu_{\nu\lambda}(x(t))$ vanishes, the polarization vector of a photon will be time-independent only up to a gauge transformation $e^\mu \to e^\mu + \alpha p^\mu$, so that gauge-invariant quantities like the field strength $p^\mu e^\nu - p^\nu e^\mu$ will be time-independent. Then in a general frame of reference, a photon polarization vector will undergo parallel transport up to a gauge transformation:

$$\frac{de^\mu(t)}{dt} = -\Gamma^\mu_{v\lambda}(x(t))e^v(t)\frac{dx^\lambda(t)}{dt} + \alpha(t)\frac{dx^\mu(t)}{dt} \tag{G.10}$$

The gauge transformation parameter $\alpha(t)$ can then be determined from the condition that $e^0 = 0$, so that $de^0/dt = 0$:

$$\alpha(t) = \Gamma^0_{\nu\lambda}(x(t))e^\nu(t)\frac{dx^\lambda(t)}{dt} \tag{G.11}$$

With $e^0 = 0$, Eq. (G.10) then reads

$$\frac{de^j(t)}{dt} = \left[-\Gamma^j_{i\lambda}(x(t)) + \Gamma^0_{i\lambda}(x(t))\frac{dx^j(t)}{dt}\right] e^i(t)\frac{dx^\lambda(t)}{dt} \tag{G.12}$$

Note that the conditions (G.9) are preserved with time, for $p_\mu e^\mu$ and $g_{\mu\nu}e^\mu e^\nu$ are preserved by ordinary parallel transport because they are scalars, and are preserved under gauge transformations because $p_\mu p^\mu = 0$ and $p_\mu e^\mu = 0$.

In a gravitational field we continue to define the statistical matrix N^{ij} by Eq. (G.5), and it continues to satisfy the hermiticity and positivity conditions (G.6), but now instead of (G.7) and (G.8) we have

$$g_{ij}N^{ij} = 1, \quad p_i N^{ij} = p_j N^{ij} = 0 \tag{G.13}$$

It follows from Eq. (G.12) that the statistical matrix of a photon moving in a gravitational field satisfies the parallel transport equation

$$\begin{aligned}\frac{dN^{ij}(t)}{dt} =& \left[-\Gamma^i_{k\lambda}(x(t)) + \Gamma^0_{k\lambda}(x(t))\frac{dx^i(t)}{dt}\right] N^{kj}(t)\frac{dx^\lambda(t)}{dt} \\ &+ \left[-\Gamma^j_{k\lambda}(x(t)) + \Gamma^0_{k\lambda}(x(t))\frac{dx^j(t)}{dt}\right] N^{ik}(t)\frac{dx^\lambda(t)}{dt}\end{aligned} \tag{G.14}$$

10.18 Appendix H The Relativistic Boltzmann Equation

In this appendix we derive the Boltzmann equations for neutrinos and photons, that govern the evolution of the distribution of these relativistic particles in phase space. This will provide the basis for our account in Section 6.1 of the widely used numerical calculations of the evolution of scalar perturbations. In addition, these results will be needed in Section 6.6, where we evaluate the damping of tensor modes due to the anisotropic inertia of free-streaming neutrinos, and in Section 7.4, where we calculate the polarization of the microwave background produced by the scattering of an anisotropic distribution of photons by non-relativistic electrons. This appendix will first consider the simpler case of neutrinos, for which scattering may be neglected, and then turn to the more complicated case of photons, for which scattering plays an essential role. In an elementary application of the results for photons, we will derive a formula for the rate of damping of acoustic waves in a medium of photons and charged particles, used in Section 6.4.

Throughout this appendix we shall adopt a coordinate system for which

$$g_{00} = -1, \quad g_{i0} = 0 \tag{H.1}$$

while $g_{ij}(\mathbf{x}, t)$ is unconstrained. In the linear approximation, this form of the metric is automatic for tensor modes, and follows if we work in synchronous gauge for scalar modes. However, we will not specialize to the case of linear perturbations until later. With this metric, the only non-vanishing components of the affine connection are

$$\Gamma^k_{ij} = \frac{1}{2}g^{kl}\left(\frac{\partial g_{li}}{\partial x^j} + \frac{\partial g_{lj}}{\partial x^i} - \frac{\partial g_{ij}}{\partial x^l}\right), \tag{H.2}$$

$$\Gamma^j_{i0} = \frac{1}{2}g^{jk}\dot{g}_{ki}, \quad \Gamma^0_{ij} = \frac{1}{2}\dot{g}_{ij}. \tag{H.3}$$

[473] We can construct e^μ in a gravitational field in a general coordinate system x^μ from the polarization vector $e^i_{\rm flat}$ of the photon in a locally inertial frame with coordinates ξ^α, as

$$e^\mu = \frac{\partial x^\mu}{\partial \xi^i} e^i_{\rm flat} + \beta p^\mu$$

with β adjusted to make $e^0 = 0$.

1 Neutrinos

It will be convenient to work with a neutrino distribution function $n_\nu(\mathbf{x}, \mathbf{p}, t)$, defined by

$$n_v(\mathbf{x}, \mathbf{p}, t) \equiv \sum_r \left(\prod_{i=1}^{3} \delta\left(x^i - x_r^i(t)\right) \right) \left(\prod_{i=1}^{3} \delta\left(p_i - p_{ri}(t)\right) \right), \tag{H.4}$$

with r labeling trajectories of individual neutrinos (or antineutrinos). This expression has the defining property of a number density, that the integral
of n_ν over any volume of phase space equals the number of neutrinos in that volume. According to Section 4 of Appendix B, the momentum variable in Eq. (H.4) is defined by $p_{ri} = g_{ij}p_r^j$, where p^μ is the momentum four-vector

$$p_r^\mu \equiv dx_r^\mu / du_r \tag{H.5}$$

where u_r is a suitably normalized affine parameter for which the spacetime trajectory satisfies Eq. (B.12):

$$\frac{d^2 x_r^\lambda}{du_r^2} + \Gamma_{\mu\nu}^\lambda (x_r) \frac{dx_r^\mu}{du_r} \frac{dx_r^\nu}{du_r} = 0 \tag{H.6}$$

Then between collisions the rate of change of the momentum is simply given by

$$\dot{p}_{ri} = \frac{1}{2p_r^0} p_r^j p_r^k \left(\frac{\partial g_{jk}}{\partial x^i} \right)_{\mathbf{x}=\mathbf{x}_r} \tag{H.7}$$

while the rate of change of the coordinate is

$$\dot{x}_r^i = p_r^i / p_r^0 \tag{H.8}$$

It follows then directly from Eqs. (H.4), (H.7), and (H.8) that in the absence of collisions, n_ν satisfies a Boltzmann equation

$$\frac{\partial n_v}{\partial t} + \frac{\partial n_v}{\partial x^i} \frac{p^i}{p^0} + \frac{\partial n_v}{\partial p_i} \frac{p^j p^k}{2p^0} \frac{\partial g_{jk}}{\partial x^i} = 0. \tag{H.9}$$

It should be understood that p^i and p^0 are expressed here in terms of the independent variable p_i by $p^i = g^{ij}(\mathbf{x}, t)p_j$ and $p^0 = \left(g^{ij}(\mathbf{x}, t)p_i p_j\right)^{1/2}$, so they depend on position and time as well as on p_i.

We now specialize to the case of a small perturbation. The spatial metric is then of the form

$$g_{ij}(\mathbf{x}, t) = a^2(t)\delta_{ij} + \delta g_{ij}(\mathbf{x}, t) \tag{H.10}$$

with δg_{ij} small. With only a small perturbation to the metric, the neutrino distribution function never gets very different from its equilibrium form, so we write

$$n_v(\mathbf{x}, t) = \bar{n}_v \left(a(t) \sqrt{g^{ij}(\mathbf{x}, t) p_i p_j} \right) + \delta n_v(\mathbf{x}, t), \tag{H.11}$$

where

$$\bar{n}_v(p) \equiv \frac{1}{(2\pi)^3} \left[\exp\left(p / k_{\mathcal{B}} a(t) \bar{T}(t) \right) + 1 \right]^{-1} \tag{H.12}$$

and δn_ν is a small perturbation. (Note that the factor $a(t)$ in the argument of $\bar{n}$ in Eq. (H.11) is canceled by the factor $a(t)$ multiplying $\bar{T}(t)$ in Eq. (H.12); this factor has been

included in Eqs. (H.11) and (H.12) because at times of interest, when $\bar{T} < 10^{10}$ K, we have $\bar{T}(t) \propto 1/a(t)$, so that Eq. (H.12) defines $\bar{n}_\nu$ as a time-independent function of its argument.) The first term in Eq. (H.11) is the neutrino distribution we would expect according to the Principle of Equivalence in a perturbed gravitational field, if the distribution in locally inertial frames were just the equilibrium distribution $\bar{n}_\nu(p)$; the second term δn_ν thus represents the departure of the neutrino distribution from its equilibrium form.

We can derive an initial condition for δn_ν by noting that, at a time t_1 corresponding to a temperature $\bar{T}_1 \approx 10^9$ K, the neutrino scattering rate had already dropped well below the expansion rate, but there had not yet been time for the perturbations in the metric to distort the neutrino distribution away from local thermal equilibrium, but with a perturbed temperature. Thus as a convenient initial condition we may take

$$\delta n_\nu\left(\mathbf{x}, \mathbf{p}, t_1\right) = -p\bar{n}'_\nu(p)\left[\frac{\delta T\left(\mathbf{x}, t_1\right)}{\bar{T}\left(t_1\right)} + \frac{\hat{p}_k \cdot \delta u_k\left(\mathbf{x}, t_1\right)}{a\left(t_1\right)}\right] \tag{H.13}$$

where $\bar{T}\left(t_1\right) \approx 10^9$ K. The second term in square brackets represents the Doppler shift due to a possible neutrino streaming velocity $\delta\mathbf{u}$, analogous to that given for microwave background photons by Eqs. (2.4.5) and (2.4.6). In local thermal equilibrium this is the same velocity perturbation as for baryons and photons. (Note that the metric position vector is ax^k, so the metric velocity vector is $au^k = a^{-1}u_k$.)

To first order in metric and density perturbations, Eq. (H.9) reads

$$\begin{aligned} 0 =& \frac{\partial \delta n_v(\mathbf{x}, \mathbf{p}, t)}{\partial t} + \frac{\partial \delta n_v(\mathbf{x}, \mathbf{p}, t)}{\partial x^i}\frac{p_i}{a(t)p} \\ &+ \frac{\bar{n}'_v(p)}{2p}\frac{\partial}{\partial t}\left(a^2(t)\delta g^{ij}(\mathbf{x}, t)\right) p_i p_j \\ &+ \frac{a(t)\bar{n}'_v(p)}{2p^2}\frac{\partial \delta g^{ij}(\mathbf{x}, t)}{\partial x^k} p_i p_j p_k \\ &+ \bar{n}'_v(p)\frac{p_i p_j p_k}{2a^3(t)p^2}\frac{\partial \delta g_{ij}(\mathbf{x}, t)}{\partial x^k} \end{aligned}$$

where here $p \equiv \sqrt{p_i p_i}$. (The third from last and penultimate terms on the right-hand side arise from the dependence of the argument of $\bar{n}_\nu$ in Eq. (H.11) on t and $\mathbf{x}$ through the combination $a^2(t)g^{ij}\left(\mathbf{x}, t_1\right) p_i p_j$.) To first order, we have $g^{ij} = a^{-2}\delta_{ij} - a^{-4}\delta g_{ij}$, so the penultimate and last terms on
the right-hand side cancel, leaving us with the much simpler result

$$\frac{\partial \delta n_v(\mathbf{x}, \mathbf{p}, t)}{\partial t} + \frac{\hat{p}_i}{a(t)}\frac{\partial \delta n_v(\mathbf{x}, \mathbf{p}, t)}{\partial x^i} = \frac{p\bar{n}'(p)}{2}\hat{p}_i\hat{p}_j\frac{\partial}{\partial t}\left(a^{-2}(t)\delta g_{ij}(\mathbf{x}, t)\right), \tag{H.14}$$

where again $p \equiv \sqrt{p_k p_k}$, and as usual we write $\hat{p}_i \equiv p_i/p$.

2 Photons

The Boltzmann equation for photons is considerably more complicated than for neutrinos, because of the necessity of taking photon scattering into account. Since scattering can change the polarization of photons, we can no longer write a separate Boltzmann equation for each helicity state of photons, as we did for neutrinos. Instead, we now define a number density matrix:

$$n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t) \equiv \sum_r \left(\prod_{k=1}^{3} \delta\left(x^k - x_r^k(t)\right)\right)\left(\prod_{k=1}^{3} \delta\left(p_k - p_{rk}(t)\right)\right) N_r^{ij}(t) \tag{H.15}$$

with r here labeling trajectories of individual photons, and $N_r^{ij}(t)$ the polarization density matrix of the r th photon. As discussed in Appendix G , if an individual photon can have any one of several polarization vectors e_m^i, with probabilities P_m, then it has a polarization density matrix

$$N^{ij} \equiv \sum_m P_m e_m^i e_m^{j*} \tag{H.16}$$

If we observe whether the polarization of a photon with polarization density matrix N^{ij} is in a particular direction e^i rather than in an orthogonal direction, we find a probability $g_{ik}g_{jl}e^{*i}e^j N^{kl}$. Recall that for a photon of three-momentum p_i in a general three-metric g_{ij}, the photon polarization vectors are defined so that

$$p_i e^i = 0, \quad g_{ij}e^i e^{j*} = 1 \tag{H.17}$$

so the polarization density matrix of photon r satisfies

$$p_{ri}(t)N_r^{ij}(t) = p_{ri}(t)N_r^{ji}(t) = 0, \quad g_{ij}\left(\mathbf{x}_r(t),t\right)N_r^{ij}(t) = 1 \tag{H.18}$$

and the number density matrix correspondingly satisfies

$$p_i n_\gamma^{ij}(\mathbf{x},\mathbf{p},t) = p_i n_\gamma^{ji}(\mathbf{x},\mathbf{p},t) = 0, \quad g_{ij}(\mathbf{x},t)n_\gamma^{ij}(\mathbf{x},\mathbf{p},t) = n_\gamma(\mathbf{x},\mathbf{p},t), \tag{H.19}$$

where $n_\gamma(\mathbf{x},\mathbf{p},t)$ is the phase space number density of photons, defined just as in Eq. (H.4). By their definition, both $N_r^{ij}(t)$ and $n_\gamma^{ij}(\mathbf{x},\mathbf{p},t)$ are Hermitian matrices.

As discussed in Appendix G, between collisions the time dependence of the polarization vectors is given by a combination of parallel transport with a gauge transformation that keeps the time component of $e_r^\mu(t)$ vanishing:

$$\frac{de_r^j(t)}{dt} = \left[-\Gamma_{i\lambda}^j\left(\mathbf{x}_r(t),t\right) + \Gamma_{i\lambda}^0\left(\mathbf{x}_r(t),t\right)\frac{dx_r^j(t)}{dt}\right]e_r^i(t)\frac{dx_r^\lambda(t)}{dt} \tag{H.20}$$

and consequently the time dependence of the density matrix of the r th photon is

$$\begin{aligned}\frac{dN_r^{ij}(t)}{dt} = &\left[-\Gamma_{k\lambda}^i\left(\mathbf{x}_r(t),t\right) + \Gamma_{k\lambda}^0\left(\mathbf{x}_r(t),t\right)\frac{dx_r^i(t)}{dt}\right]N_r^{kj}(t)\frac{dx_r^\lambda(t)}{dt} \\ &+ \left[-\Gamma_{k\lambda}^j\left(\mathbf{x}_r(t),t\right) + \Gamma_{k\lambda}^0\left(\mathbf{x}_r(t),t\right)\frac{dx_r^j(t)}{dt}\right]N_r^{ik}(t)\frac{dx_r^\lambda(t)}{dt}.\end{aligned} \tag{H.21}$$

The time dependence of the variables $p_{ri}(t)$ and $x_r^i(t)$ is given by the same equations (H.7) and (H.8) as for neutrinos. It follows then directly from Eqs. (H.15), (H.21), (H.7) and (H.8) that $n_\gamma^{ij}(\mathbf{x},\mathbf{p},t)$ satisfies a Boltzmann equation:

$$\begin{aligned}&\frac{\partial n_\gamma^{ij}}{\partial t} + \frac{\partial n_\gamma^{ij}}{\partial x^k}\frac{p^k}{p^0} + \frac{\partial n_\gamma^{ij}}{\partial p_k}\frac{p^l p^m}{2p^0}\frac{\partial g_{lm}}{\partial x^k} \\ &\quad + \left(\Gamma_{k\lambda}^i - \frac{p^i}{p^0}\Gamma_{k\lambda}^0\right)\frac{p^\lambda}{p^0}n_\gamma^{kj} \\ &\quad + \left(\Gamma_{k\lambda}^j - \frac{p^j}{p^0}\Gamma_{k\lambda}^0\right)\frac{p^\lambda}{p^0}n_\gamma^{ik} = C^{ij}\end{aligned} \tag{H.22}$$

where C^{ij} is a term representing the effect of photon scattering. (As a reminder, we note that in Eq. (H.22) p^i and p^0 are functions of $\mathbf{x},t$, and the p_j, given by $p^i \equiv g^{ij}p_j$ and $p^0 = \left[g^{ij}p_i p_j\right]^{1/2}$.)

To evaluate the collision term C^{ij} in Eq. (H.22), let us first consider the case of flat spacetime, where $g_{ij} = \delta_{ij}$. Since the Thomson scattering of an unpolarized or linearly polarized photon can only produce linearly polarized photons, we will limit ourselves here to the case of linear polarization, for which polarization vectors can be taken to be real, and the polarization density matrix and number density matrices are real and symmetric. We will first consider the case of electrons at rest, and later (in dealing with scalar perturbations) take up the case of a non-zero plasma velocity.

The scattering of photons of momentum $\mathbf{p}$ into some other direction causes a decrease in $n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t)$ which is simply given by a term in C^{ij} :

$$C_-^{ij}(\mathbf{x}, \mathbf{p}, t) = -\omega_c(t) n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t), \tag{H.23}$$

where $\omega_c(t)$ is the total collision rate. (We hold here to the convention of writing n_γ^{ij} and C^{ij} with upper indices, though of course in flat spacetime there is no distinction between contravariant and covariant spatial tensors.) There is also an increase in $n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t)$ caused by the scattering of photons with some initial momentum $\mathbf{p}_1$ into momentum $\mathbf{p}$, with energy conservation requiring (assuming that $|\mathbf{p}| \ll m_e$) that $|\mathbf{p}_1| = |\mathbf{p}|$. The Klein-Nishina formula [1] tells us that when a photon with momentum p_{1i} and real polarization vector e_1^i is scattered by an electron at rest, the probability of finding a photon in the final state with real polarization vector e^i is proportional to $(e \cdot e_1)^2$, with no dependence on the initial photon momentum p_{1i} or the final photon momentum p_i, except of course that e_1^i and e^i must be orthogonal to p_{1i} and p_i, respectively. If the initial photon can have various polarizations e_{1n}^i with probabilities P_n, then correspondingly the probability of finding the photon in the final state with polarization e^i is proportional to $e^i e^j N_1^{ij}$, where $N_1^{ij} = \sum_n P_n e_{1n}^i e_{1n}^j$. As already mentioned, this probability must equal $e^i e^j N^{ij}$, where N^{ij} is the polarization density matrix of the photon in the final state. Together with the conditions that $p_i N^{ij} = 0$ and $N^{ii} = 1$, this tells us that the scattered photon has polarization density matrix

$$N^{ij}(\hat{p}) = S^{-1}(\hat{p}) \left[N_1^{ij} - \hat{p}_i \hat{p}_k N_1^{kj} - \hat{p}_j \hat{p}_k N_1^{ik} + \hat{p}_i \hat{p}_j \hat{p}_k \hat{p}_l N_1^{kl} \right], \tag{H.24}$$

where

$$S(\hat{p}) \equiv 1 - \hat{p}_i \hat{p}_j N_1^{ij} \tag{H.25}$$

The rate of increase in $n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t)$ due to scattering of photons from an arbitrary direction $\hat{p}_1$ into direction $\hat{p}$ is then

$$\begin{aligned} C_+^{ij}(\mathbf{x}, \mathbf{p}, t) = n_e \int d^2\hat{p}_1 \frac{d^2\sigma}{d^2\hat{p}} \\ \times S^{-1}(\hat{p}) \left[n_\gamma^{ij}(\mathbf{x}, |\mathbf{p}|\hat{p}_1, t) - \hat{p}_i \hat{p}_k n_\gamma^{kj}(\mathbf{x}, |\mathbf{p}|\hat{p}_1, t) \right. \\ \left. - \hat{p}_j \hat{p}_k n_\gamma^{ik}(\mathbf{x}, |\mathbf{p}|\hat{p}_1, t) + \hat{p}_i \hat{p}_j \hat{p}_k \hat{p}_l n_\gamma^{kl}(\mathbf{x}, |\mathbf{p}|\hat{p}_1, t) \right] \end{aligned} \tag{H.26}$$

where n_e is the electron density, and $d^2\sigma/d^2\hat{p}$ is the differential scattering cross section. Summing $(e \cdot e_1)^2$ over final polarizations gives a differential cross section proportional to $S(\hat{p})$, and $\int d^2\hat{p} S(\hat{p}) = 8\pi/3$, so equating
$\int d^2\hat{p} \, (d^2\sigma/d^2\hat{p})$ to the Thomson scattering cross section $\sigma_\mathcal{T}$, we have

$$\frac{d^2\sigma}{d^2\hat{p}} = \frac{3\sigma_\mathcal{T}}{8\pi} S(\hat{p}) \tag{H.27}$$

[471] See, e.g., QTF, Vol. I, Sec. 8.7.

Then Eqs. (H.23), (H.26), and (H.27) give a net change in $n_\gamma^{ij}(\mathbf{x},\mathbf{p},t)$ equal to

$$\begin{aligned} C^{ij}(\mathbf{x},\mathbf{p},t) &= C_-^{ij}(\mathbf{x},\mathbf{p},t) + C_+^{ij}(\mathbf{x},\mathbf{p},t) \\ &= -\omega_c(t) n_\gamma^{ij}(\mathbf{x},\mathbf{p},t) + \frac{3\omega_c(t)}{8\pi}\int d^2\hat{p}_1 \\ \times \left[n_\gamma^{ij}\left(\mathbf{x},|\mathbf{p}|\hat{p}_1,t\right) - \hat{p}_i\hat{p}_k n_\gamma^{kj}\left(\mathbf{x},|\mathbf{p}|\hat{p}_1,t\right) - \hat{p}_j\hat{p}_k n_\gamma^{ik}\left(\mathbf{x},|\mathbf{p}|\hat{p}_1,t\right)\right. \\ \left. + \hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l n_\gamma^{kl}\left(\mathbf{x},|\mathbf{p}|\hat{p}_1,t\right)\right] \end{aligned} \tag{H.28}$$

in which we use $\omega_c(t) = n_e(t)\sigma_{\mathcal{T}}$.
As a check, it is easy to see that the collision term (H.28) vanishes in local thermal equilibrium. In equilibrium photons are unpolarized, so $n_\gamma^{ij} \propto \delta_{ij} - \hat{p}_i\hat{p}_j$, and their momentum distribution is homogeneous and isotropic, so the coefficient of proportionality f depends only on $|\mathbf{p}|$ and t :

$$n_{\rm eq}^{ij}(\mathbf{x},\mathbf{p},t) = f(|\mathbf{p}|,t)\left[\delta_{ij} - \hat{p}_i\hat{p}_j\right].$$

Then

$$\int d^2\hat{p}_1 n_{\rm eq}^{ij}\left(\mathbf{x},|\mathbf{p}|\hat{p}_1,t\right) = \frac{8\pi}{3} f(|\mathbf{p}|,t)\delta_{ij}$$

Using this in Eq. (H.28) shows that in equilibrium the two terms in C^{ij} cancel, as of course they must.

To find the result for an arbitrary three-metric g_{ij}, we must simply write Eq. (H.28) in a form that is invariant under general three-dimensional coordinate transformations, and reduces to Eq. (H.28) in the case of a flat three-metric with $g_{ij} = \delta_{ij}$. In this way, we find

$$\begin{aligned} C^{ij}(\mathbf{x},\mathbf{p},t) &= -\omega_c(t) n_\gamma^{ij}(\mathbf{x},\mathbf{p},t) \\ &+ \frac{3\omega_c(t)}{8\pi}\int \frac{d^3p_1\sqrt{\mathrm{Det}\, g(\mathbf{x},t)}}{p^{02}(\mathbf{x},\mathbf{p},t)}\delta\left(p^0(\mathbf{x},\mathbf{p},t) - p^0\left(\mathbf{x},\mathbf{p}_1,t\right)\right) \\ &\times \left[n_\gamma^{ij}\left(\mathbf{x},\mathbf{p}_1,t\right) - \frac{g^{ik}(\mathbf{x},t)p_k p_l}{p^{02}(\mathbf{x},\mathbf{p},t)} n_\gamma^{lj}\left(\mathbf{x},\mathbf{p}_1,t\right)\right. \\ &- \frac{g^{jk}(\mathbf{x},t)p_k p_\ell}{p^{02}(\mathbf{x},\mathbf{p},t)} n_\gamma^{il}\left(\mathbf{x},\mathbf{p}_1,t\right) \\ &\left. + \frac{g^{ik}(\mathbf{x},t)g^{jl}(\mathbf{x},t)p_k p_l p_m p_n}{p^{04}(\mathbf{x},\mathbf{p},t)} n_\gamma^{mn}\left(\mathbf{x},\mathbf{p}_1,t\right)\right] \end{aligned} \tag{H.29}$$

where

$$p^0(\mathbf{x},\mathbf{p},t) \equiv \sqrt{g^{ij}(\mathbf{x},t)p_i p_j} \tag{H.30}$$

We now again specialize to the case of a small perturbation, writing the metric as in Eq. (H.10), and putting the photon number density matrix in a form analogous to Eq. (H.11):

$$\begin{aligned} n_\gamma^{ij}(\mathbf{x},\mathbf{p},t) = \frac{1}{2}\bar{n}_\gamma\left(a(t)p^0(\mathbf{x},\mathbf{p},t)\right)\left[g^{ij}(\mathbf{x},t) - \frac{g^{ik}(\mathbf{x},t)g^{jl}(\mathbf{x},t)p_k p_l}{p^{02}(\mathbf{x},\mathbf{p},t)}\right] \\ + \delta n_\gamma^{ij}(\mathbf{x},\mathbf{p},t) \end{aligned} \tag{H.31}$$

where $\bar{n}_\gamma(p)$ is the equilibrium phase space number density, a timeindependent function of its argument

$$\bar{n}_\gamma(p) \equiv \frac{1}{(2\pi)^3}\left[\exp\left(p/k_{\mathcal{B}}a(t)T(t)\right)-1\right]^{-1} \tag{H.32}$$

and δn^{ij} is a small perturbation. Fortunately, to first order in perturbations the Boltzmann equation (H.22) is greatly simplified by the fact that the quantity in square brackets in Eq. (H.31) satisfies a collisionless Boltzmann equation

$$\begin{aligned} 0 = &\left(\frac{\partial}{\partial t}+\frac{p^k}{p^0}\frac{\partial}{\partial x^k}+\frac{p^l p^m}{2p^0}\frac{\partial g_{lm}}{\partial x^k}\frac{\partial}{\partial p^k}\right)\left[g^{ij}-\frac{p^i p^j}{p^{02}}\right] \\ &+\frac{p^\lambda}{p^0}\left(\Gamma^i_{k\lambda}-\frac{p^i}{p^0}\Gamma^0_{k\lambda}\right)\left[g^{kj}-\frac{p^k p^j}{p^{02}}\right] \\ &+\frac{p^\lambda}{p^0}\left(\Gamma^j_{k\lambda}-\frac{p^j}{p^0}\Gamma^0_{k\lambda}\right)\left[g^{ik}-\frac{p^i p^k}{p^{02}}\right]. \end{aligned} \tag{H.33}$$

(This can be proved directly, or more easily by noting that if we set $p_i = p_{ri}(t)$ and $x^i = x^i_r(t)$, then the quantity in square brackets is the sum over two orthogonal polarizations of the quantity $e^i_r(t)e^j_r(t)$, and therefore satisfies Eq. (H.33) as a consequence of Eq. (H.20). Since Eq. (H.33) holds in this sense for any photon trajectory, it is necessary for it to hold for arbitrary x^i and p_i.) Acting on the factor $\bar{n}_\gamma\left(ap^0\right)$, the derivative operators in Eq. (H.22) give to first order

$$\begin{aligned} \left(\frac{\partial}{\partial t}+\frac{p^k}{p^0}\frac{\partial}{\partial x^k}+\frac{p^l p^m}{2p^0}\frac{\partial g_{lm}}{\partial x^k}\frac{\partial}{\partial p_k}\right)\bar{n}_\gamma\left(ap^0\right) &= -\frac{1}{2}\sqrt{p_i p_i} \\ \times\bar{n}'_\gamma\left(\sqrt{p_i p_i}\right)\hat{p}_k\hat{p}_l\frac{\partial}{\partial t}\left(a^{-2}\delta g_{kl}\right) & \end{aligned} \tag{H.34}$$

with the effect of the position and momentum derivative terms in parentheses on the left-hand side canceling. There is another simplification provided by the fact that the the first term in Eq. (H.31) does not contribute to the collision term, since even in a gravitational field collisions by themselves do not alter equilibrium distribution functions. Keeping only terms of first order in perturbations, the Boltzmann equation (H.22) then becomes

$$\begin{aligned} &\frac{\partial\delta n^{ij}_\gamma(\mathbf{x},\mathbf{p},t)}{\partial t}+\frac{\hat{p}_k}{a(t)}\frac{\partial\delta n^{ij}_\gamma(\mathbf{x},\mathbf{p},t)}{\partial x^k}+\frac{2\dot{a}(t)}{a(t)}\delta n^{ij}_\gamma(\mathbf{x},\mathbf{p},t) \\ &-\frac{1}{4a^2(t)}p\bar{n}'_\gamma(p)\hat{p}_k\hat{p}_l\frac{\partial}{\partial t}\left(a^{-2}\delta g_{kl}(\mathbf{x},t)\right)\left(\delta_{ij}-\hat{p}_i\hat{p}_j\right) \\ &=-\omega_c(t)\delta n^{ij}_\gamma(\mathbf{x},\mathbf{p},t)+\frac{3\omega_c(t)}{8\pi}\int d^2\hat{p}_1 \\ &\times\left[\delta n^{ij}_\gamma\left(\mathbf{x},p\hat{p}_1,t\right)-\hat{p}_i\hat{p}_k\delta n^{kj}_\gamma\left(\mathbf{x},p\hat{p}_1,t\right)-\hat{p}_j\hat{p}_k\delta n^{ik}_\gamma\left(\mathbf{x},p\hat{p}_1,t\right)\right. \\ &\left.+\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l\delta n^{kl}_\gamma\left(\mathbf{x},p\hat{p}_1,t\right)\right] \end{aligned} \tag{H.35}$$

where again $p \equiv \sqrt{p_i p_i}$, and $\hat{p} \equiv \mathbf{p}/p$. As a check, note that Eq. (H.35) is consistent with the condition $p_i\delta n^{ij} = 0$. As a further check, note that the first-order perturbation to the photon phase space number density $g_{ij}n^{ij}_\gamma$ is $a^2\delta n^{ii}$, and according to the trace of Eq. (H.35), the Boltzmann equation for $a^2\delta n^{ii}_\gamma$ is the same as the Boltzmann equation (H.14) for the perturbation to the neutrino phase space density, aside from the presence of the collision term and the appearance of $\bar{n}'_\gamma$ instead of $\bar{n}'_\nu$.

For tensor modes, Eq. (H.35) can be used as it stands, but in dealing with scalar (or vector) modes, we need to take up a complication that has been ignored until now: in general the plasma has a small velocity $\delta\mathbf{u}(\mathbf{x},t)$ (which in Section 6.1 et seq. is denoted $\delta\mathbf{u}_B(\mathbf{x},t)$). Since $\delta\mathbf{u}$ is itself a first-order perturbation, in calculating its effect on the collision term C^{ij}, to first order we can ignore any perturbations to the gravitational field or the photon number density matrix. The effect of the plasma velocity is to shift the energy $|\mathbf{p}_1|$ of the incident photon that when scattered yields a final photon with momentum $\mathbf{p}$. To calculate this effect, let's first consider the case of flat spacetime. Since photon energy is conserved in the rest frame of the plasma, in which the plasma metric four-velocity is simply $v^\mu = (0,0,0,1)$, we have $(p_1 - p)\cdot v = 0$; evaluating this scalar in the "lab" frame in which the plasma velocity four-vector is $v^\mu = \left[\delta\mathbf{v}, \sqrt{1-(\delta\mathbf{v})^2}\right]$ we have

$$0 = v_\mu (p_1 - p)^\mu = \delta\mathbf{v}\cdot(\mathbf{p}_1 - \mathbf{p}) - \sqrt{1-(\delta\mathbf{v})^2}\left(p_1^0 - p^0\right),$$

or, to first order in velocity,

$$|\mathbf{p_1}| = |\mathbf{p}|\left[1 + (\hat{p}_1 - \hat{p})\cdot\delta\mathbf{v}\right].$$

As already noted, the flat-space velocity components v^k are related to the velocity components in a Robertson-Walker three-metric $g_{ij} = a^2\delta_{ij}$ by $v^k = au^k = a^{-1}u_k$, so

$$|\mathbf{p_1}| = |\mathbf{p}|\left[1 + \frac{(\hat{p}_1 - \hat{p})_k\,\delta u_k}{a}\right]. \tag{H.36}$$

As a result, the two terms in the collision term (H.28) do not cancel even when we set the three-metric g_{ij} equal to $a^2\delta_{ij}$ and set the photon number density matrix equal to the form it would have in equilibrium with this three-metric:

$$n^{ij}_{\gamma,\mathrm{eq}}(\mathbf{x},\mathbf{p},t) = \frac{1}{2a^2(t)}\bar{n}_\gamma(|\mathbf{p}|)\left[\delta_{ij} - \hat{p}_i\hat{p}_j\right].$$

Since in this case these two terms in C^{ij} would cancel if $|\mathbf{p_1}|$ were equal to $|\mathbf{p}|$, we find a new term in $C^{ij}(\mathbf{x},\mathbf{p},t)$, equal to the difference between the term $-\omega_c(t)n^{ij}_{\gamma,\,\mathrm{eq}}(\mathbf{x},\mathbf{p},t)$ and the same term with $|\mathbf{p}|$ replaced with $|\mathbf{p_1}|$, averaged over $\hat{p}_1$. The linearized Boltzmann equation (H.35) now becomes

$$\begin{aligned}
&\frac{\partial\delta n^{ij}_\gamma(\mathbf{x},\mathbf{p},t)}{\partial t} + \frac{\hat{p}_k}{a(t)}\frac{\partial\delta n^{ij}_\gamma(\mathbf{x},\mathbf{p},t)}{\partial x^k} + \frac{2\dot{a}(t)}{a(t)}\delta n^{ij}_\gamma(\mathbf{x},\mathbf{p},t)\\
&\quad -\frac{1}{4a^2(t)}p\bar{n}'_\gamma(p)\hat{p}_k\hat{p}_l\frac{\partial}{\partial t}\left(a^{-2}(t)\delta g_{kl}(\mathbf{x},t)\right)(\delta_{ij} - \hat{p}_i\hat{p}_j)\\
&\qquad = -\omega_c(t)\delta n^{ij}_\gamma(\mathbf{x},\mathbf{p},t) + \frac{3\omega_c(t)}{8\pi}\int d^2\hat{p}_1\\
&\times\left[\delta n^{ij}_\gamma(\mathbf{x},p\hat{p}_1,t) - \hat{p}_i\hat{p}_k\delta n^{kj}_\gamma(\mathbf{x},p\hat{p}_1,t) - \hat{p}_j\hat{p}_k\delta n^{ik}_\gamma(\mathbf{x},p\hat{p}_1,t)\right.\\
&\qquad \left. + \hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l\delta n^{kl}_\gamma(\mathbf{x},p\hat{p}_1,t)\right]\\
&\quad -\frac{\omega_c(t)}{2a^3(t)}\left(p_k\delta u_k(\mathbf{x},t)\right)\bar{n}'_\gamma(p)\left[\delta_{ij} - \hat{p}_i\hat{p}_j\right]
\end{aligned} \tag{H.37}$$

(The term in Eq. (H.36) proportional to $\hat{p}_{1k}\delta u_k$ gives no contribution to the integral over $\hat{p}_1$.)

In an important application of Eq. (H.37), we may derive the decay rate of acoustic waves in a homogeneous and time-independent plasma in flat

spacetime (with $a = 1$ and ω_c time-independent) when the collision rate is much larger than the sound frequency. (This result will be used in Section 6.4.) We seek a solution of the Boltzmann equation (H.37) of the form

$$\delta n_\gamma^{ij}(\mathbf{x}, \mathbf{p}, t) = e^{i\mathbf{k}\cdot\mathbf{x}} e^{-i\omega t} \delta n_\gamma^{ij}(\mathbf{p}), \quad \delta u_j(\mathbf{x}, t) = e^{i\mathbf{k}\cdot\mathbf{x}} e^{-i\omega t} \delta u_j. \tag{H.38}$$

Then with $a = 1$ and ω_c constant, Eq. (H.37) becomes

$$\begin{aligned}
&[\omega_c - i\omega + i\hat{p}\cdot\mathbf{k}]\, \delta n_\gamma^{ij}(\mathbf{p}) \\
&= \frac{3\omega_c}{8\pi} \int d^2\hat{p}_1 \\
&\quad \times \left[\delta n_\gamma^{ij}(p\hat{p}_1) - \hat{p}_i\hat{p}_k \delta n_\gamma^{kj}(p\hat{p}_1) - \hat{p}_j\hat{p}_k \delta n_\gamma^{ik}(p\hat{p}_1) + \hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l \delta n_\gamma^{kl}(p\hat{p}_1)\right] \\
&\quad - \frac{\omega_c}{2}(\mathbf{p}\cdot\delta\mathbf{u})\bar{n}_\gamma'(p)\left[\delta_{ij} - \hat{p}_i\hat{p}_j\right].
\end{aligned} \tag{H.39}$$

We now need a formula for the plasma velocity δu_j. For this purpose, we note that in flat space the first-order photon and baryonic plasma contributions to the energy-momentum tensor have

$$\delta T_{\gamma j}^i = \int d^3p a^2 n_\gamma^{kk}(\mathbf{p}) |\mathbf{p}| \hat{p}_i \hat{p}_j, \quad \delta T_{\gamma j}^0 = \int d^3p a^2 n_\gamma^{kk}(\mathbf{p}) |\mathbf{p}| \hat{p}_j, \tag{H.40}$$

and

$$\delta T_{Bj}^i = 0, \quad \delta T_{Bj}^0 = \bar{\rho}_B \delta u_j, \tag{H.41}$$

so the equation of momentum conservation may be written

$$\omega \bar{\rho}_B \delta u_j = \int d^3p a^2 \delta n_\gamma^{kk}(\mathbf{p}) p_j (\mathbf{k}\cdot\hat{p} - \omega). \tag{H.42}$$

To evaluate the right-hand side, multiply Eq. (H.39) with p_j and integrate over $\mathbf{p}$; this gives

$$i \int d^3p (\mathbf{k}\cdot\hat{p} - \omega) p_j \delta n_\gamma^{kk}(\mathbf{p}) = -\omega_c \int d^3p p p_j \delta n_\gamma^{kk}(\mathbf{p}) + \frac{4\omega_c}{3} \delta u_j \bar{\rho}_\gamma,$$

where $\bar{\rho}_\gamma = \int d^3p p \bar{n}_\gamma(p) = -(1/4) \int d^3p p^2 \bar{n}_\gamma'(p)$. Using this in Eq. (H.42) gives our formula for $\delta\mathbf{u}$:

$$\left(\omega\bar{\rho}_B + \frac{4i\omega_c}{3}\bar{\rho}_\gamma\right) \delta u_j = i\omega_c \int d^3p p p_j \delta n_\gamma^{kk}(\mathbf{p}). \tag{H.43}$$

For scalar modes, $\mathbf{k}$ is the only parameter in the problem with a sense of direction, so we can express the integrals appearing in Eqs. (H.39) and
(H.43) as

$$\int d^3p |\mathbf{p}| \delta n_\gamma^{ij}(\mathbf{p}) = \bar{\rho}_\gamma \left[X\delta_{ij} + Y\hat{k}_i\hat{k}_j\right] \tag{H.44}$$

$$\int d^3p \delta n_\gamma^{ii}(\mathbf{p}) p_j = \bar{\rho}_\gamma Z \hat{k}_j \tag{H.45}$$

where X, Y, and Z are here functions of $k \equiv |\mathbf{k}|$ and ω. Eq. (H.43) then lets us express $\delta\mathbf{u}$ in terms of Z :

$$\delta\mathbf{u} = \frac{3Z}{4\left[1 - i\omega t_c R\right]}\hat{k} \tag{H.46}$$

where $R \equiv 3\bar{\rho}_B/4\bar{\rho}_\gamma$, and $t_c \equiv 1/\omega_c$ is the mean time between collisions. Using Eqs. (H.44) and (H.46) in Eq. (H.39) then yields a formula for the perturbed intensity:

$$\begin{aligned} 4\pi \int \delta n_r^{ij}(p\hat{p})p^3 dp = &\frac{3\bar{\rho}_\gamma}{2\left[1 - i\omega t_c + i\hat{p}\cdot\mathbf{k}t_c\right]}\left[\left(X + \frac{Z(\hat{p}\cdot\hat{k})}{1 - i\omega t_c R}\right)(\delta_{ij} - \hat{p}_i\hat{p}_j)\right. \\ &\left. + Y\left(\hat{k}_i - \hat{p}_i(\hat{p}\cdot\hat{k})\right)\left(\hat{k}_j - \hat{p}_j(\hat{p}\cdot\hat{k})\right)\right] \end{aligned} \tag{H.47}$$

By inserting this back in the definitions (H.44) and (H.45), we find three homogeneous linear relations among X, Y, and Z. For these to be consistent, the determinant of the coefficients must vanish, which yields a relation between ω and $k = |\mathbf{k}|$.

The resulting dispersion relation is quite complicated, but it becomes much simpler in the case of small mean free time t_c. As an ansatz, we can try taking Y/X of first order in t_c, while Z/X is of order unity, leaving it for later to check whether this leads to a consistent solution. To second order in t_c, the terms in Eq. (H.44) proportional to δ_{ij} and $\hat{k}_i\hat{k}_j$ and the coefficient of $\hat{k}_i$ in Eq. (H.45) yield the homogeneous linear relations

$$\begin{aligned} 0 = &\left(i\omega t_c - \omega^2 t_c^2 - \frac{2}{5}k^2 t_c^2\right)X + \frac{1}{10}\left(1 + i\omega t_c\right)Y \\ &+\frac{2}{5}\left(-ikt_c + \omega k t_c^2(2 + R)\right)Z \end{aligned} \tag{H.48}$$

$$\begin{aligned} 0 = &\frac{1}{5}k^2 t_c^2 X + \left(-\frac{3}{10} + \frac{7i}{10}\omega t_c\right)Y \\ &+\left(\frac{i}{5}kt_c - \frac{(2 + R)}{5}\omega k t_c^2\right)Z \end{aligned} \tag{H.49}$$

$$\begin{aligned} 0 = &\left(-ikt_c + 2\omega k t_c^2\right)X - \frac{1}{5}ikt_c Y \\ &+\left(i\omega t_c(1 + R) - \omega^2 t_c^2\left(1 + R + R^2\right) - \frac{3}{5}k^2 t_c^2\right)Z. \end{aligned} \tag{H.50}$$

(As anticipated, these relations are consistent with the assumption that Y is of order t_c relative to X and Z.) To first order in t_c, the vanishing of the determinant of the coefficients in these relations yields the condition

$$0 = 15(1 + R)\omega^2 - 5k^2 + i\omega^3 t_c\left[-5 - 5R + 15R^2\right] + 7i\omega k^2 t_c$$

This has the solution, again to first order in t_c :

$$\omega = \pm\frac{k}{\sqrt{3(1 + R)}} - i\Gamma \tag{H.51}$$

where Γ is the decay rate

$$\Gamma = \frac{k^2 t_c}{6(1 + R)}\left\{\frac{16}{15} + \frac{R^2}{1 + R}\right\} \tag{H.52}$$

This is the same as the formula (6.4.25) for the damping rate given in Section 6.4, originally derived by Kaiser. [2] As discussed there, it is equivalent to the formulas (6.4.24) for the coefficients of shear viscosity and heat conduction of a non-relativistic plasma in which momentum and energy are transported by photons.

10.19 Glossary of Symbols

(These are symbols used in more than one section. Numbers following the symbol give the section in which the symbol is first used.)

a	1.1	scale factor in Robertson-Walker metric
$a_{\mathcal{B}}$	2.1	radiation energy constant
$a_{\ell m}$	2.6	temperature partial wave amplitude (same as $a_{T,\ell m}$)
A	5.1	one of scalar perturbations to metric
B	3.3	baryon number
	5.1	one of scalar perturbations to metric
	6.1	subscript denoting baryonic plasma
C_i	5.1	one of vector perturbations to metric
C_ℓ	2.6	temperature multipole coefficient (same as $C_{TT,\ell}$)
d	1.2	proper distance
d_A	1.4	angular diameter distance
d_H	2.6	horizon distance
d_L	1.4	luminosity distance
D	6.1	subscript denoting cold dark matter
$D^{(\ell)}$	7.4	representative of the rotation group for spin ℓ
D_{ij}	5.1	tensor perturbation to metric
$\mathcal{D}_q$	5.2	gravitational wave amplitude
$\mathcal{D}_q^o$	6.6	constant gravitational wave amplitude outside horizon
e_{ij}	5.2	graviton polarization tensor
E	5.1	one of scalar perturbations to metric
EQ	6.2	subscript indicating the time of matter-radiation equality
F	5.1	one of scalar perturbations to metric
	6.6	function appearing in tensor anisotropic inertia
	7.1	form factor in scalar temperature fluctuation
g	3.1	multiplicity of states
$g_{\mu\nu}$	1.1	spacetime metric
$\tilde{g}_{ij}$	1.1	spatial part of Robertson-Walker metric
G	1.5	Newton's gravitational constant
	7.1	form factor in scalar temperature fluctuation
G_i	5.1	one of vector perturbations to metric
h	1.3	Hubble constant in units of 100 kmsec^{-1}Mpc^{-1}
	2.4	Planck's constant $= 2\pi\hbar$
$h_{\mu\nu}$	5.1	perturbation to the metric
H	2.2	expansion rate $\dot{a}(t)/a(t)$
H_0	1.2	Hubble constant $\dot{a}\left(t_0\right)/a\left(t_0\right)$

[472] N. Kaiser, Mon. Not. Roy. Astron. Soc. 202, 1169 (1983).

$H_v()$	10.1	Hankel functions
I	1.12	action
ISW	2.6	contribution of integrated Sachs-Wolfe effect
j_ℓ	2.6	spherical Bessel function
J	6.1	dimensionless neutrino intensity
J^μ	1.1	current four-vector
J_{ij}	6.1	dimensionless photon intensity matrix
k	8.1	physical wave number at present $= q/a_0$
$k_{\mathcal{B}}$	2.2	Boltzmann constant
K	1.1	curvature constant in Robertson-Walker metric
	6.6	function appearing in tensor anisotropic inertia
ℓ	1.3	apparent luminosity
	2.6	multipole order
L	1.3	absolute luminosity
	2.1	subscript indicating time of last scattering
	3.3	lepton number
m	1.3	apparent magnitude
	1.5	particle mass
M	1.3	absolute magnitude
	1.9	total mass
Mpc	1.3	million parsecs
n	1.10	number density
n^{ij}	6.1	photon number density matrix
n_S	7.2	slope parameter in $\mathcal{R}_q^o$
N	7.2	coefficient of $q^{-3/2}$ in $\mathcal{R}_q^o$
$\mathcal{N}$	3.1	effective number of particle types
	4.1	number of e-foldings in inflation
p	1.1	pressure
pc	1.3	parsec
P_ℓ	2.4	Legendre polynomials
P	8.1	power spectral function of density fluctuations
$\mathcal{P}_\phi$	2.6	power spectral function of gravitational potential
q	2.6	co-moving wave number vector
q_0	1.4	deceleration parameter
r	1.1	radial coordinate in Robertson-Walker metric
	7.3	tensor/scalar ratio
R	2.6	3/4 the ratio of baryon to photon energy density
$R_{\mu\nu}$	1.5	Ricci tensor
$\mathcal{R}$	5.4	curvature perturbation
$\mathcal{R}^o$	6.2	constant curvature perturbation outside horizon
s	1.1	proper length
	3.1	entropy density

S	7.1	superscript indicating scalar mode
$S_{\mu\nu}$	1.5	source term in Einstein field equation
$S(\hat{n})$	7.4	standard rotation from three-axis to direction $\hat{n}$
$\mathcal{S}$	6.5	a scalar transfer function
SW	2.6	contribution of Sachs-Wolfe effect
t	1.1	time
t_0	1.5	present age of universe
t_1	6.1	initial time in solution of Boltzmann equation
T	2.1	temperature
	7.1	superscript indicating tensor mode
$T_{\mu\nu}$	1.1	energy-momentum tensor
$\mathcal{T}$	6.5	the main scalar transfer function
u	1.1	affine parameter
	5.1	velocity potential
u_μ	5.1	velocity four-vector
$\mathcal{U}$	6.6	a tensor transfer function
v_s	2.6	sound speed
V	1.12	scalar field potential
w	1.1	ratio of pressure to density
x	1.1	co-moving spatial coordinate
X	2.3	fractional ionization
X	1.9	Newtonian spatial coordinate
y	6.3	ratio of matter and radiation densities $= a/a_{\rm EQ}$
Y_ℓ^m	2.6	ordinary spherical harmonics
$\mathcal{Y}_\ell^m$	7.4	spin +2 spherical harmonics
z	1.2	redshift
	10.1	quantity $a\dot{\bar{\varphi}}/H$ in Mukhanov-Sasaki equation
α	5.2	stochastic parameter of scalar modes
	9.1	angle between gravitational lens and true source positions
β	5.2	stochastic parameter of tensor modes
	6.4	ratio of baryon and total matter densities
	9.1	angle between gravitational lens and apparent source positions
β_E	9.1	angular radius of Einstein ring
γ	6.1	subscript denoting photons
	6.4	Euler constant
Γ	6.4	acoustic decay rate
$\Gamma^\mu_{\nu\kappa}$	1.1	affine connection
$\tilde{\Gamma}^i_{jk}$	1.1	spatial affine connection for Robertson-Walker metric
δ_{ij}	1.1	Kronecker delta
δ_{Xq}	6.2	$\delta\rho_{Xq}/\left(\bar{\rho}_X + \bar{p}_X\right)$ (for $X = B, D, \gamma, \nu$)
Δ	5.3	change due to gauge transformation

	6.5	a scalar transfer function
$\Delta_T^{(S)}$	6.1	scalar photon temperature amplitude
$\Delta_P^{(S)}$	6.1	scalar photon polarization amplitude
$\Delta_T^{(T)}$	6.6	tensor photon temperature amplitude
$\Delta_P^{(T)}$	6.6	tensor photon polarization amplitude
ϵ	10.1	$-\dot{H}/H^2$
ϵ_0, ϵ^S	5.3	gauge transformation parameters
ζ	5.4	perturbation conserved outside horizon
η	3.2	baryon/photon ratio
$\eta_{\mu\nu}$	1.5	Minkowski spacetime metric
θ	1.1	polar angle (except in Sec. 9.5)
κ	6.2	dimensionless rescaled wave number
μ	3.1	chemical potential
ν	1.2	frequency
	6.1	subscript denoting neutrinos & antineutrinos
Ξ	6.6	a tensor transfer function
π_{ij}	1.5	total anisotropic inertia tensor
π^S	1.5	scalar anisotropic inertia
π_{iT}	1.5	vector anisotropic inertia
π_{ij}^T	1.5	tensor anisotropic inertia
Π	6.1	a scalar source function
ρ	1.1	energy density
σ	1.10	cross section
	2.2	entropy per baryon
	8.1	standard deviation of density perturbations
τ	1.1	proper time
	1.10	optical depth
	5.3	parameter for transformation between synchronous gauges
	10.1	conformal time
ϕ	1.1	azimuthal angle (except in Sec. 9.5)
	2.6	gravitational potential
φ	1.12	scalar field
Φ	5.3	a scalar metric perturbation in Newtonian gauge
	6.1	a scalar source function
ψ	5.3	a scalar metric perturbation in synchronous gauge
Ψ	5.3	a scalar metric perturbation in Newtonian gauge
	6.6	tensor source function
Ω_K	1.5	$-K/a_0^2H_0^2$
Ω_M	1.5	ratio of matter density to critical density
Ω_R	1.5	ratio of radiation density to critical density
Ω_Λ	1.5	ratio of vacuum density to critical density

10.20 Assorted Problems

1. Consider a universe described by a Robertson-Walker metric with $K = +1$. Give a transformation of co-moving space coordinates that leaves the metric unchanged, and that takes the point $\mathbf{x} = (0, 0, r)$ into a point $\mathbf{x} = (0, 0, r')$, with no change in the time. (Hint: Consider the three-dimensional space as the surface of a four-dimensional ball, construct this transformation as a rotation in four dimensions, and then express it in

terms of the Robertson-Walker coordinates.) Also give the corresponding transformation for $K = -1$.

2. Suppose that the total pressure and energy density of the universe are related by $p = -\rho + \rho^2/\rho_1$, where ρ_1 is a constant. Assume zero spatial curvature. Calculate ρ as a function of the Robertson-Walker scale factor a, taking $a = a_1$ when $\rho = \infty$. Calculate a and ρ as functions of time, taking $t = 0$ as the time when $\rho = \infty$. Calculate the age of the universe and the deceleration parameter q_0 for a given present density ρ_0.

3. Consider the empty cosmology, with $\Omega_M = \Omega_R = \Omega_\Lambda = 0$. Calculate the luminosity distance and angular diameter distance as functions of redshift in this cosmological model. What is the age of the universe as a function of the present Hubble constant?

4. Suppose that astronomers measure the age of a galaxy with redshift $z = 2.5$. How old would this galaxy have to be (at the time the light from it was emitted) in order to rule out the hypothesis that $\Omega_M = 1$ with negligible vacuum and radiation energy density. Use $H_0 = 70$km/sec/Mpc.

5. Suppose that $\Omega_M = 0.25$ and $\Omega_V = 0.75$, with Ω_R negligible. What is the redshift at which the expansion of the universe stopped decelerating and began to accelerate?

6. Suppose that the gravitational potential energy of any pair of galaxies with separation r decreases as r^{-n} instead of r^{-1}. What combination of the mass of a virialized cluster of galaxies and the Hubble constant could be calculated from measurements of angular separations and velocity dispersions of its individual galaxies?

7. Suppose that the fluctuations in the temperature of the cosmic microwave background are governed by a Gaussian isotropic
translation-invariant probability distribution. Calculate the quantity

$$\left\langle \left(C_\ell^{\rm obs} - C_\ell\right)^3 \right\rangle / C_\ell^3$$

as a function of ℓ.

8. Suppose that there is some new massless elementary particle that effectively decouples from everything else at a temperature 10^{16} K. Suppose that the particles with mass less (and in fact much less) than 1 TeV are those of the minimal Standard Model: three generations of quarks, leptons, antiquarks, and antileptons with helicity $\pm 1/2$; the $W^\pm$and Z^0 with helicity ± 1 and 0 ; the photon and eight massless gluons with helicity ± 1; and a single neutral boson of helicity zero; together with their antiparticles (where distinct from the particles). What is the ratio at present of the temperature of the new massless particles and the temperature of photons?

9. Suppose that the binding energy of deuterium were 5% less. Estimate the effect that this would have on the abundance of He^4 produced in the early universe.

10. Suppose that instead of $B - L$, only the combination $3B - L$ of baryon number and lepton number were conserved, along with the usual conserved quantities of the Standard Model. Taking account of the particles of the minimal (non-supersymmetric) Standard Model, what is the density of baryon number and lepton number in thermal equilibrium for a given density of $3B - L$?

11. Suppose that the Robertson-Walker scale factor increases during inflation by a factor e^{50}; that the scale factor at the beginning of the radiation-dominated era was the same as at the end of inflation; that the energy density at the end of inflation was $[2 \times 10^{16}\text{GeV}]^4$; and that the energy density at the beginning of the radiation-dominated era was $[2 \times 10^{15}\text{GeV}]^4$. Over what range of angles would you expect the cosmic microwave background now to have a nearly

uniform temperature?
12. Use the "slow-roll" approximation to calculate the inflaton field $\varphi(t)$ as a function of time for a potential $V(\varphi) = g\varphi^n$, where g and n are positive constants.
13. Find the two independent solutions of the field equations and conservation equations for scalar perturbations far outside the horizon in Newtonian gauge in the case of a perfect fluid having $p = w\rho$, with
w constant. Use the results to calculate $\mathcal{R} \equiv -\Psi + H\delta u$ for each solution.
14. Consider the equations for scalar fluctuations in Newtonian gauge in a universe containing only cold dark matter. Find the two solutions of the coupled equations for Φ_q and δu_q. (You can normalize these solutions any way you like, but keep it simple.) For each solution, calculate $\mathcal{R}_q, \delta\rho_q$, and ζ_q. Do not make any assumption about the magnitude of the wave number.
15. Consider a vector field

$$V^\mu(\mathbf{x}, t) = \bar{V}^\mu(t) + \delta V^\mu(\mathbf{x}, t)$$

where the unperturbed space components $\bar{V}^i$ are zero, and the unperturbed time component $\bar{V}^0$ is some non-zero function only of time. What is the change in δV^0 and δV^i induced by a general gauge transformation?
16. Re-do the analysis of Section 5.2, but for vector fluctuations.
17. Suppose that the differential scattering cross section of neutrinos on all other particles were a constant, independent of direction or energy. (It isn't.) For a given total neutrino collision rate $\omega_c(t)$, derive the Boltzmann equation that would be satisfied by the neutrino phase space distribution function $n_\nu(\mathbf{x}, \mathbf{p}, t)$ in a spacetime metric with $g_{00} = -1$, $g_{i0} = 0$, and $g_{ij}(\mathbf{x}, t)$ arbitrary. For the case where $g_{ij}(\mathbf{x}, t) = a^2(t)\delta_{ij} + \delta g_{ij}(\mathbf{x}, t)$, derive the Boltzmann equation for the phase space density perturbation $\delta n_\nu(\mathbf{x}, t)$ defined by Eq. (6.1.39), to first order in δg_{ij} and δn_ν.
18. Suppose that H_0 were doubled, and Ω_B and Ω_M reduced by a factor four. What would be the qualitative effect on the plot of $\ell^2 C_\ell$ vs. ℓ for $\ell \gg 1$?
19. Assume that $C^S_{TT,\ell}$ is dominated by a co-moving wave number at last scattering equal to ℓ/r_L, where r_L is the co-moving radial coordinate of the surface of last scattering. Also, neglect the Doppler effect, and use $\mathcal{S} = 5$ and $\mathcal{T} = 1$ for the transfer functions. With these assumptions, give an approximate formula for the ratio of the heights of the first and second acoustic peaks in $C^S_{TT,\ell}$.
20. What value of the multipole order ℓ corresponds to a co-moving wavelength equal to the diameter of a co-moving sphere that encloses the total mass $10^{15} M_\odot$ (including cold dark matter) of a cluster of galaxies?
21. Define a mean square matter density fluctuation as

$$\sigma_R^2 \equiv \left\langle \left(\frac{1}{(\sqrt{\pi}R)^3} \int d^3x \delta_M(\mathbf{x}, t) e^{-\mathbf{x}^2/R^2} \right)^2 \right\rangle$$

where the integral extends over all space. At what time does σ_R^2 become equal to 0.1 for R equal to the diameter of a co-moving sphere that encloses the total mass $10^{12} M_\odot$ (including cold dark matter) of a large galaxy? Assume a Harrison-Zel'dovich primordial spectrum with $|N| = 2 \times 10^{-5}$.
22. Derive a formula for the multipole coefficients in the correlation between fluctuations in the cosmic microwave background temperature in a direction $\hat{n}$ and the cosmic mass density fluctuation at a redshift z and direction $\hat{n}'$. Use any approximation that you think is reasonable, but make it clear what approximations you are using.
23. What is the effect of a general infinitesimal rotation on the polarization tensor $e_{ij}(\hat{n}, \pm 2)$ of a gravitational wave travelling in a direction $\hat{n}$ along the 1 -axis?

24. Suppose that the probability distribution of tensor fluctuations respected the symmetries of translation and rotation invariance, but not invariance under space inversion. What would that imply for the average $\langle\beta(\mathbf{q},\lambda)\beta^*(\mathbf{q}',\lambda')\rangle$, where $\beta(\mathbf{q},\lambda)$ is the stochastic parameter for wave number $\mathbf{q}$ and helicity λ ? Give a formula for the multipole coefficient $C^T_{EB,\ell}$ in this case.
25. Suppose that light passing a galaxy is deflected toward the center of the galaxy by an angle A/b^n, where A and n are constants, and b is the distance of closest approach of the light to the galaxy center. Find the lens equation, i.e. a relation between the observed angle β between the lines of sight from the earth to the lensing galaxy and a more distant source of light and the angle α that there would be between these lines of sight if light were not deflected by the galaxy. Give a formula for the apparent luminosity of the image of the source in terms of β.
26. Define multipole coefficients $C_{\gamma E,\ell}$ by

$$\left\langle a_{\gamma,\ell m} a^*_{E,\ell' m'}\right\rangle = \delta_{\ell\ell'}\delta_{mm'}C_{\gamma E,\ell},$$

where $a_{\gamma,\ell m}$ and $a_{E,\ell m}$ are the coefficients in the partial wave expansion of the shear and the Stokes parameters, defined in Sections 9.5 and 7.4. Give a formula for the correlation functions $\langle\gamma_1(\hat{n})Q(\hat{n}')\rangle$,
$\langle\gamma_2(\hat{n})Q(\hat{n}')\rangle, \langle\gamma_1(\hat{n})U(\hat{n}')\rangle, \langle\gamma_2(\hat{n})U(\hat{n}')\rangle$ of the shear and Stokes parameters in terms of these multiipole coefficients.
27. Assume that inflation is driven by a single inflation field φ, with a potential $V(\varphi) = g\exp(-\lambda\varphi^2)$. What are the conditions on λ and φ to allow the use of the slow-roll approximation? Assuming these conditions to be satisfied, give values for the scalar and tensor slope parameters n_S and n_T. By how many e-foldings does the universe expand when φ changes by a factor 100 ?
28. In multi-field inflation, what is the dependence of scalar field perturbations on wave number outside the horizon when you take account of a slight variation of the potential during the era of horizon exit?

11 Challenges for ΛCDM: An update by Perivolaropoulos, Skara

Abstract

A number of challenges to the standard ΛCDM model have been emerging during the past few years as the accuracy of cosmological observations improves. In this review we discuss in a unified manner many existing signals in cosmological and astrophysical data that appear to be in some tension (2σ or larger) with the standard ΛCDM model as specified by the Cosmological Principle, General Relativity and the Planck18 parameter values. In addition to the well-studied 5σ challenge of ΛCDM (the Hubble H_0 tension) and other well known tensions (the growth tension, and the lensing amplitude A_L anomaly), we discuss a wide range of other less discussed less-standard signals which appear at a lower statistical significance level than the H_0 tension some of them known as 'curiosities' in the data) which may also constitute hints towards new physics. For example such signals include cosmic dipoles (the fine structure constant α, velocity and quasar dipoles), CMB asymmetries, BAO Lyα tension, age of the Universe issues, the Lithium problem, small scale curiosities like the core-cusp and missing satellite problems, quasars Hubble diagram, oscillating short range gravity signals etc. The goal of this pedagogical review is to collectively present the current status (2022 update) of these signals and their level of significance, with emphasis on the Hubble tension and refer to recent resources where more details can be found for each signal. We also briefly discuss theoretical approaches that can potentially explain some of these signals.

Contents

11.1 Introduction

The concordance or standard Λ Cold Dark Matter (ΛCDM) cosmological model [1418, 1422, 449] is a well defined, predictive and simple cosmological model [see 391, for a review]. It is defined by a set of simple assumptions:

- The Universe consists of radiation (photons, neutrinos), ordinary matter (baryons and leptons), cold (non-relativistic) dark matter (CDM) [1912, 1913, 739, 1547, 1546, 343, 292] being responsible for structure formation and cosmological constant Λ [451, 449], a homogeneous form of energy which is responsible for the late time observed accelerated expansion. The cosmological constant is currently associated with a dark energy or vacuum energy whose density remains constant even in an expanding background [see 1422, 1393, 1394, 1819, for a review].

- General Relativity (GR) [659] is the correct theory that describes gravity on cosmological scales. Thus, the action currently relevant on cosmological scales reads

$$S = \int d^4x\sqrt{-g}\left[\frac{1}{16\pi G}(R - 2\Lambda) + \frac{1}{4\alpha}F_{\mu\nu}F^{\mu\nu} + \mathcal{L}_m(\psi, A)\right] \tag{33}$$

  where α is the fine structure constant, G is Newton's constant, $F_{\mu\nu}$ is the electromagnetic field-strength tensor and $\mathcal{L}_m$ is the Lagrangian density for all matter fields ψ_m.

- The Cosmological Principle (CP) states that the Universe is statistically homogeneous and isotropic in space and matter at sufficiently large scales ($\gtrsim 100\,Mpc$).

- There are six independent (free) parameters: the baryon $\omega_b = \Omega_{0b}h^2$ and cold dark matter $\omega_c = \Omega_{0c}h^2$ energy densities (where $h = H_0/100\ km\ s^{-1}\ Mpc^{-1}$ is the dimensionless Hubble constant and $\Omega_X \equiv \rho_X/\rho_{crit}$ is the density of component X relative to the critical density, $\rho_{crit} = 3H^2/8\pi G$), the angular diameter distance to the sound horizon at last scattering θ_s, the amplitude A_s and tilt n_s of primordial scalar fluctuations and the reionization optical depth τ.

- The spatial part of the cosmic metric is assumed to be flat described by the Friedmann-Lemaitre-Roberson-Walker (FLRW) metric

$$ds^2 = dt^2 - a(t)^2(dr^2 + r^2d\theta^2 + r^2sin^2\theta d\phi^2) \tag{34}$$

  which emerges from the CP.

  Assuming this form of the metric and Einstein's field equations with a Λ-term we obtain the Friedmann equations which may be written as

$$H^2 \equiv \frac{\dot{a}^2}{a^2} = \frac{8\pi G\rho + \Lambda c^2}{3} \tag{35}$$

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}(\rho + \frac{3p}{c^2}) + \frac{\Lambda c^2}{3} \tag{36}$$

where a is the scale factor $a = \frac{1}{1+z}$ (with z the redshift). The cosmological constant may also be viewed as a cosmic dark energy fluid with equation of state parameter

$$w = \frac{p_\Lambda}{\rho_\Lambda} = -1 \tag{37}$$

where ρ_Λ and p_Λ are the energy density and the pressure of the dark energy respectively.

- A primordial phase of cosmic inflation (a period of rapid accelerated expansion) is also assumed in order to address the horizon and flatness problems [260, 119, 170, 15]. During this period, Gaussian scale invariant primordial fluctuations are produced from quantum fluctuations in the inflationary epoch.

Fundamental generalizations of the standard ΛCDM model may be produced by modifying the defining action (33) by generalizing the fundamental constants to dynamical variables in the existing action or adding new terms. Thus the following extensions of ΛCDM emerge:

- Promoting Newton's constant to a dynamical degree of freedom by allowing it to depend on a scalar field Φ as $G \to G(\Phi(r,t))$ where the dynamics of Φ is determined by kinetic and potential terms added to the action. This class of theories is known as 'scalar-tensor theories' with its most general form with second order dynamical equations the Horndeski theories [909, 573] [see also 1014, 1078, for a comprehensive review].

- Promoting the cosmological constant to a dynamical degree of freedom by the introduction of a scalar field (quintessence) with $\Lambda \to V(\Phi(r,t))$ and the introduction of a proper kinetic term.

- Allowing for a dynamical Fine Structure Constant (Maxwell Dilaton theories) with $\alpha \to \alpha(\Phi(r,t))$ [248, 1582, 225, 224, 223] [see also 1248, for a review].

- Addition of new terms to the action which may be functions of the Ricci scalar, the torsion scalar or other invariants $((f(R), f(T), \dots))$ [260, 1360, 1362, 569, 1674, 708, 1342, 413, 435].

The ΛCDM model has been remarkably successful in explaining most properties of a wide range of cosmological observations including the accelerating expansion of the Universe [1524, 1445], the power spectrum and statistical properties of the cosmic microwave background (CMB) anisotropies [1395], the spectrum and statistical properties of large scale structures of the Universe [288, 391] and the observed abundances of different types of light nuclei hydrogen, deuterium, helium, and lithium [1605, 1683, 944, 539].

Despite of its remarkable successes and simplicity, the validity of the cosmological standard model ΛCDM is currently under intense investigation [see 30, 386, 615, 1604, 139, 1599, for a review]. This is motivated by a range of profound theoretical and observational difficulties of the model.

The most important theoretical difficulties that plague ΛCDM are the fine tuning [1819, 1242, 396] and coincidence problems [1684, 1769]. The first fundamental problem is associated with the fact that there is a large discrepancy between observations and theoretical expectations on the value of the cosmological constant Λ (at least 60 orders of magnitude) [1819, 508, 1242, 1662] and the second is connected to the coincidence between the observed vacuum energy density Ω_Λ and the matter density Ω_m which are approximately equal nowadays despite their dramatically different evolution properties. The anthropic principle has been considered as a possible solution to these problems. It states that these 'coincidences' result from a selection bias towards the existence of human life in the context of a multiverse [1692, 1818].

In addition to the above theoretical challenges, there are signals in cosmological and astrophysical data that appear to be in some tension (2σ or larger) with the standard ΛCDM model as specified by the Planck18 parameter values [72, 68]. The most intriguing large scale tensions are the following[48] [30] [see also 620, 619, for a recent overview of the main tensions]:

- **The Hubble tension ($> 4\sigma$):** (see Section 11.2) Using a distance ladder approach, the local (late or low redshift) measurements of the Hubble constant H_0 are measured to values that are significantly higher than those inferred using the angular scale of fluctuations of the CMB in the context of the ΛCDM model. Combined local direct measurements of H_0 are in 5σ tension (or more if combinations of local measurements are used) with CMB indirect measurements of H_0 [366, 596, 1519]. The Planck/ΛCDM best fit value is $H_0 = 67.4 \pm 0.5\ km\ s^{-1} Mpc^{-1}$ [72] while the local measurements using Cepheid calibrators by the SH0ES Team indicate $H_0 = 73.04 \pm 1.04\ km\ s^{-1} Mpc^{-1}$ ($\sim 5\sigma$) [1529] [see 615, 1624, 1585, for a review]. In the previous analysis by the SH0ES Team [1521] using the Gaia Early Data Release 3 (EDR3) parallaxes [751] a value of $H_0 = 73.2 \pm 1.3$ is obtained, at a 4.2σ tension with the prediction from Planck18 CMB observations. A wide range of local observations appear to be consistently larger than the Planck/ΛCDM measurement of H_0 at various levels of statistical significance [366, 596, 1519]. Theoretical models addressing the Hubble tension utilize either a recalibration of the Planck/ΛCDM standard ruler (the sound horizon) assuming new physics before the time of recombination [1011, 301, 11] or a deformation of the Hubble expansion rate $H(z)$ at late times [102, 612] or a transition/recalibration of the SnIa absolute luminosity due to late time new physics [1238] [see in 1436, for a relevant talk]. Also, for more detailed discussions of the proposed new-physics models see in [1772, 615, 1604, 139].

- **The growth tension ($2 - 3\sigma$):** (see Subsection 11.3.1) Direct measurements of the growth rate of cosmological perturbations (Weak Lensing, Redshift Space Distortions (peculiar velocities), Cluster Counts) indicate a lower growth rate than that indicated by the Planck/ΛCDM parameter values at a level of about $2 - 3\sigma$ [995, 106, 234]. In the context of General Relativity such lower growth rate would imply a lower matter density and/or a lower amplitude of primordial fluctuation spectrum than that indicated by Planck/ΛCDM [1220, 1344, 1027, 1646].

- **CMB anisotropy anomalies ($2-3\sigma$):** (see Subsection 11.3.2) These anomalies include lack of power on large angular scales, small vs large scales tension (different best fit values of cosmological parameters), cold spot anomaly, hints for a closed Universe (CMB vs BAO), anomaly on super-horizon scales, quadrupole-octopole alignment, anomalously strong ISW effect, cosmic hemispherical power asymmetry, lensing anomaly, preference for odd parity correlations, parity violating rotation of CMB linear polarization (cosmic birefringence) etc. [see 1608, 88, for a review].

- **Cosmic dipoles ($2 - 5\sigma$):** (see Subsection 11.3.3) The large scale velocity flow dipole [1808, 1017], the Hubble flow variance in the cosmic rest frame [1831], the dipole anisotropy in radio source count [263], the quasar density dipole [1614] and the fine structure constant dipole (quasar spectra) [1065, 1809] indicate that the validity of the cosmological principle may have to be reevaluated.

- **Baryon Acoustic Oscillations (BAO) curiosities ($2.5-3\sigma$):** (see Subsection 11.3.4) There is a discrepancy between galaxy and Lyman-α (Lyα) BAO at an effective redshift of $z \sim 2.34$ [532, 683, 9].

[48] We use the term 'curiosity' as a term describing a discrepancy between datasets in ΛCDM best fit parameter values at a level with a statistical significance $\lesssim 3\sigma$.

- **Parity violating rotation of CMB linear polarization (Cosmic Birefringence):** (see Subsection 11.3.5) The recent evidence of the non zero value of birefringence poses a problem for standard ΛCDM cosmology and indicates a hint of a new ingredient beyond this standard model. In particular using a novel method developed in Minami *et al.* [1294], Minami [1291], Minami and Komatsu [1293], a non-zero value of the isotropic cosmic birefringence $\beta_a = 0.35 \pm 0.14$ deg (68% C.L) was recently detected in the Planck18 polarization data at a 2.4σ statistical significance level by Minami and Komatsu [1292].

- **Small-scale curiosities:** (see Subsection 11.3.6) Observations on galaxy scales indicate that the ΛCDM model faces several problems (core-cusp problem, missing satellite problem, too big to fail problem, angular momentum catastrophe, satellite planes problem, baryonic Tully-Fisher relation problem, void phenomenon etc.) in describing structures at small scales [see 575, 393, for a review].

- **Age of the Universe:** (see Subsection 11.3.7) The age of the Universe as obtained from local measurements using the ages of oldest stars in the Milky Way (MW) appears to be marginally larger and in some tension with the corresponding age obtained using the CMB Planck18 data in the context of ΛCDM cosmology [1771].

- **The Lithium problem $(2-4\sigma)$:** (see Subsection 11.3.8) Measurements of old, metal-poor stars in the Milky Way's halo find 5 times less lithium than that BBN predicts [712].

- **Quasars Hubble diagram $(\sim 4\sigma)$:** (see Subsection 11.3.9) The distance modulus-redshift relation for the sample of 1598 quasars at higher redshift ($0.5 < z < 5.5$) is in some tension with the concordance ΛCDM model indicating some hints for phantom late time expansion [1532, 210, 1213].

- **Oscillating signals in short range gravity experiments:** (see Subsection 11.3.10) A reanalysis of short range gravity experiments has indicated the presence of an oscillating force signal with sub-millimeter wavelength [1435, 146].

- **Anomalously low baryon temperature $(\sim 3.8\sigma)$:** (see Subsection 11.3.11) The Experiment to Detect the Global Epoch of Reionization Signature (EDGES) collaboration [349] using global (sky-averaged) 21-cm absorption signal, reports anomalously low baryon temperature $T_b \approx 4K$ at $z \approx 17$ (half of its expected value).

- **Colliding clusters with high velocity $(\sim 6\sigma)$:** (see Subsection 11.3.12) The El Gordo (ACT-CL J0102-4915) galaxy cluster at $z = 0.87$ is in its formation process which occurs by a collision of two subclusters with mass ratio 3.6 merging at a very high velocity $V_{infall} \simeq 2500 km/s$. Such cluster velocities at such a redshift are extremely rare in the context of ΛCDM as demonstrated by Asencio *et al.* [172] using the estimation of Kraljic and Sarkar [1102] for the expected number of merging clusters from interrogation of the DarkSky simulations.

The well known Hubble tension and the other less discussed curiosities of ΛCDM at a lower statistical significance level may hint towards new physics [see 933, for a review].

In the context of the above observational puzzles the following strategic questions emerge

- What are the current cosmological and astrophysical datasets that include the above non-standard signals?

- What is the statistical significance of each signal?

- Is there a common theoretical framework that may explain simultaneously many non-standard signals?

These questions will be discussed in what follows. There have been previous works [1431, 1432] collecting and discussing signals in data that are at some statistical level in tension with the standard ΛCDM model but these are by now outdated and the more detailed and extended update provided by the present review may be a useful resource.

The plan of this review is the following: In the next section (11.2) we focus on the Hubble tension. We provide a list of observational probes that can lead to measurements of the Hubble constant, point out the current tension level among different probes and discuss some of the possible generic extensions of ΛCDM model that can address this tension. In section 11.3 we present the current status of other less significant tensions, their level of significance and refer to recent resources where more details can be found for each signal. We also discuss possible theoretical approaches that can explain the non-standard nature of these signals. Finally, in section 11.4 we conclude and discuss potential future directions of the reviewed research.

In Table 23 of of the Appendix 11.5 we list the acronyms used in this review.

11.2 Hubble tension

11.2.1 Methods for measuring H_0 and data

The measurement of the Hubble constant H_0 which is the local expansion rate of the Universe, is of fundamental importance to cosmology. This measurement has improved in accuracy through number of probes [see 1817, for a review of most well established probes].

Distances to cosmological objects constitute the most common way to probe the cosmic metric and the expansion history of the Universe. In this subsection we review the use of the two main cosmological distances used to probe the cosmic expansion history.

- **Luminosity distance**

  Consider a luminous cosmological source of absolute luminosity L (emitted power) and an observer (Fig. 116) at a distance d_L from the luminous source. In a static cosmological setup, the power radiated by the luminous source is conserved and distributed in the spherical shell with area $4\pi d_L^2$ and therefore the apparent luminosity l (energy flux) detected by the observer is

  $$l = \frac{L}{4\pi d_L^2} \tag{38}$$

  Eq. (38) defines the quantity d_L known as *luminosity distance*. It is straightforward to show that in an expanding flat Universe, where the energy is not conserved due to the increase of the photon wavelength and period with time, the luminosity distance can be expressed as [629, 1430]

  $$d_L(z)_{th} = c(1+z)\int_0^z \frac{dz'}{H(z')} \tag{39}$$

  The luminosity distance is an important cosmological observable that is measured using standard candles (see Subsection 11.2.1)

- **Angular diameter distance**

  Consider a source (standard ruler) with a physical scale r that subtends an angle θ in the sky (Fig. 117). In Euclidean space, assuming that θ is small, the physical angular

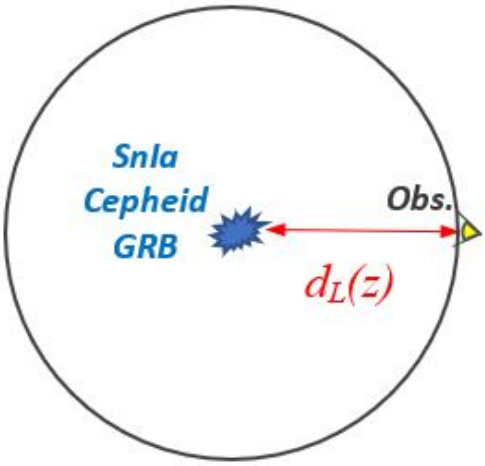

Figure 116: The luminosity distance is obtained from the apparent and absolute luminosities.

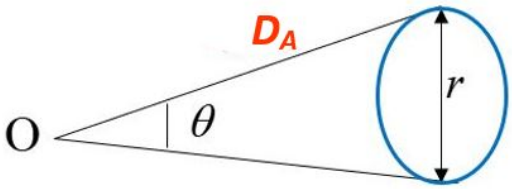

Figure 117: The angular diameter distance is obtained from the angular and physical scales.

diameter distance D_A is defined as [e.g. 629, 901]

$$D_A(z) = \frac{r}{\theta} \tag{40}$$

A particularly useful standard ruler is the sound horizon at recombination calibrated by the peaks of the CMB anisotropy spectrum and observed either directly through the CMB anisotropies or through its signatures in the large scale structure (Baryon Acoustic Oscillations (BAO)) (see Subsection 11.2.1).

It is straightforward to show that in an expanding flat Universe the physical angular diameter distance can be expressed as [e.g. 629]

$$D_A(z)_{th} = \frac{c}{(1+z)} \int_0^z \frac{dz'}{H(z')} \tag{41}$$

The luminosity and angular diameter distances can be measured using standard candles and standard rulers thus probing the cosmic expansion rate at both the present time ($H(z=0) \equiv H_0$) and at higher redshifts ($H(z)$).

Standard candles as probes of luminosity distance

The luminosity distance to a source may be probed using standardizable candles like Type Ia supernovae (SnIa) ($z < 2.3$) [1524, 1445, 293, 329] and gamma-ray bursts (GRBs) ($0.1 < z \lesssim 9$) [122, 121, 1573, 1704, 1578, 1593, 531, 1799, 577, 1701, 439, 1048, 1047, 551, 550, 627, 578, 428, 1212, 427, 1199, 918, 547, 1211].

Surveys can indicate the distance-redshift relation of SnIa by measuring their peak luminosity that is tightly correlated with the shape of their characteristic light curves (luminosity as a function of time after the explosion) and the redshifts of host galaxies. The latest and largest SnIa dataset available that incorporates data from six different surveys is the Pantheon sample consisting of a total of 1048 SnIa in the redshift range $0.01 < z < 2.26$ (the number of SnIa with $z > 1.4$ is only six) [329]. More recently, the Pantheon+ sample which comprises 18 different samples has been released [380, 1611] [see also 1448, 384]. Brout *et al.* [380], Scolnic *et al.* [1611] present 1701 light curves of 1550 distinct SnIa in the redshift range $0.001 < z < 2.26$ including SnIa which are in very nearby galaxies ($z \lesssim 0.01$) with measured Cepheid distances. For determination of H_0 the SH0ES team [1529] use as calibrator sample 42 SnIa in the 37 Cepheid hosts and 277 SnIa in the Hubble flow ($0.0233 < z < 0.15$) from the Pantheon+ sample.

The apparent magnitude[49] m_{th} of SnIa in the context of a specified form of $H(z)$, is related to their luminosity distance $d_L(z)$ of Eq. (39) in Mpc as

$$m(z)_{th} = M + 5\log_{10}\left[\frac{d_L(z)}{Mpc}\right] + 25 \tag{43}$$

Using now the dimensionless Hubble free luminosity distance

$$D_L(z) = \frac{H_0 d_L(z)}{c} \tag{44}$$

the apparent magnitude can be written as

$$m(z)_{th} = M + 5\log_{10}\left[D_L(z)\right] + 5\log_{10}\left[\frac{c/H_0}{Mpc}\right] + 25 \tag{45}$$

The use of Eq. (45) to measure H_0 using the measured apparent magnitudes of SnIa requires knowledge of the value of the SnIa absolute magnitude M which can be obtained using calibrators of local SnIa at $z < 0.01$ (closer than the start of the Hubble flow) in the context of a distance ladder [e.g. 1579] using calibrators like Cepheid stars.

In the cosmic distance ladder approach each step of the distance ladder uses parallax methods and/or the known intrinsic luminosity of a standard candle source to determine the absolute (intrinsic) luminosity of a more luminous standard candle residing in the same galaxy. Thus highly luminous standard candles are calibrated for the next step in order to reach out to high redshift luminosity distances.

SnIa standard candles and their calibration

- **SnIa-Cepheid:** Geometric anchors may be used to calibrate the Cepheid variable star standard candles at the local Universe (primary distance indicators) whose luminosities are correlated with their periods of variability[50]. The MW, the Large Magellanic Cloud (LMC) and NGC 4258 are used as distance geometric anchor galaxies. For Cepheids in the anchor galaxies there are three different ways of geometric distance calibration of their luminosities: trigonometric parallaxes in the MW [258, 1146, 452, 1520, 1187,

[49] The apparent magnitude m of an astrophysical source detected with flux l is defined as

$$m = -2.5\, log_{10}\left(\frac{l}{l_0}\right) \tag{42}$$

where l_0 is a reference flux (zero point). The absolute magnitude M of an astrophysical source is the apparent magnitude the source would have if it was placed at a distance of $10\,pc$ from the observer.

[50] The period–luminosity (PL) relation is also called the Leavitt law [1141, 1142].

1528, 311, 1521], Detached Eclipsing Binary Stars (DEBs) in the LMC [1456] and water masers (see Subsection 11.2.1) in NGC 4258 [1885, 1502]. The DEBs technique relies on surface-brightness relations and is a one-step distance determination to nearby galaxies independent from Cepheids [1457].

Using the measured distances of the calibrated Cepheid stars the intrinsic luminosity of nearby SnIa residing in the same galaxies as the Cepheids is obtained. This SnIa calibration which fixes M is then used for SnIa at distant galaxies to measure H_0 ($z \in [0.01, 0.1]$) and $H(z)$ ($z \in [0.01, 2.3]$).

- **SnIa-TRGB:** Instead of Cepheid variable stars, the Tip of the Red Giant Branch (TRGB) stars in the Hertzsprung-Russell diagram [245, 735] and Miras [924, 923] [see also 543, for a review] can be used as calibrators of SnIa. The Red Giant stars have nearly exhausted the hydrogen in their cores and have just began helium burning (helium flash phase). Their brightness can be standardized using parallax methods and they can serve as bright standard candles visible in the local Universe for the subsequent calibration of SnIa.

- **SnIa-Miras:** Miras (named for the prototype star Mira) are highly evolved low mass variable stars at the tip of asymptotic giant branch (AGB) stars [e.g. 936]. The water megamaser as distance indicator (see Subsection 11.2.1) can be used to calibrate the Mira period–luminosity (PL) relation [924]. Miras with short period (< 400 days) have low mass progenitors and are present in all galaxy types or in the halos of galaxies, eliminating the necessity for low inclination SnIa host galaxies.

- **SBF:** Another method to determine the Hubble constant based on calibration of the peak absolute magnitude of SnIa is the Surface Brightness Fluctuations (SBF) method [974, 426, 1052]. SBF is a secondary[51] luminosity distance indicator that uses stars in the old stellar populations (II) and can reach larger distances than Cepheids even inside the Hubble flow region where the recession velocity is larger than local peculiar velocities ($z > 0.01$) [1719, 1720, 313, 1277, 300, 315, 312]. For SBF calibration Blakeslee *et al.* [314] use both Cepheids and TRGB demonstrating that these calibrators are consistent with each other.

  Assume that a galaxy includes a finite number of stars covering a range of luminosity. Using SBF in the galaxy image for the determination of its distance, the ratio $\bar{L}$ of the second and first moments of the stellar luminosity function in the galaxy is used along with the mean flux per star $\bar{l}$ as follows [1719, 313]

$$d^2 = \frac{\bar{L}}{4\pi \bar{l}} \tag{46}$$

  where

$$\bar{L} = \frac{\int n(L) L^2 dL}{\int n(L) L dL} = \frac{\sigma_L^2}{\langle L \rangle} \tag{47}$$

  where $n(L)$ is the expectation number of stars with luminosity L. Thus SBF can be viewed as providing an average brightness. A galaxy with double distance appears with double smoothness due to the effect of averaging.

[51] Nearby Cepheids or stellar population models are used for the empirical or theoretical calibration of the SBF distances respectively.

Alternative cosmological standard candles

- **SneII:** An independent method to determine the Hubble constant utilizes Type II supernovae (SneII) as cosmic distance indicators [959]. SneII are characterised by the presence of hydrogen lines in their spectra [713, 714]. This feature distinguishes SneII from other types of supernovae. Their light curve shapes include a plateau of varying steepness and length differ significantly from those of SnIa. The use of SneII as standard candles is motivated by the fact that they are more abundant than SnIa [1168, 817] [although 1-2 mag fainter 1517] and are produced by different stellar populations than SnIa which are more difficult to standardize. The SneII progenitors (red super giant stars) however are better understood than those of SnIa.

  Different SneII distance-measurement techniques have been proposed and tested. These include, the expanding photosphere method [1067, 649, 585], the spectral-fitting expanding atmosphere method [221, 586], the standardized candle method [843], the photospheric magnitude method [1534] and the photometric color method [960]. For example, the standardized candle method is based on the relation between the luminosity and the expansion velocity of the photosphere [843, 1385, 961, 962].

- **GRBs:** In addition to SnIa and SneII, GRBs are widely proposed as standard candles to trace the Hubble diagram at high redshifts [1132, 235, 1795, 1048, 1047]. However GRBs distance calibration is not easy and various cosmology independent methods [e.g. 1195] or phenomenological relations [e.g. 123, 782] have been proposed for their calibration.

  Furthermore GRBs can be combined with other probes to study the redshift evolution of Hubble constant [553] [see 1309, for a review].

Using SnIa to measure H_0 and $H(z)$:

The best fit values of the parameter H_0 and the deceleration parameter q_0 may be obtained[52] [420] using local distance ladder measurements (e.g. Cepheid calibration up to $z \simeq 0.01$) to measure directly M, low z measurements of the SnIa apparent magnitude $m(z)$ and a kinematic local expansion of $D_L(z)$ ($z < 0.1$) as [e.g. 1820]

$$D_L(z, q_0) = z\left[1 + \frac{1}{2}(1 - q_0)z\right] \tag{48}$$

Alternatively, q_0 may be fixed to its ΛCDM value $q_0 = -0.55$ and H_0 may be fit as a single parameter [308, 1526, 306].

Using higher z SnIa the best fit parameters of ΛCDM may be obtained by fitting the ΛCDM expansion rate $H(z)$

$$H^2(z) = H_0^2\left[\Omega_{0m}(1+z)^3 + (1 - \Omega_{0m})\right] \tag{49}$$

where Ω_{0m} is the matter density parameter today. Using Eqs. (39), (44) and (49), the Hubble free luminosity distance can be written as

$$D_L(z, \Omega_{0m}) = (1+z)\int_0^z \frac{dz'}{\left[\Omega_{0m}(1+z')^3 + (1 - \Omega_{0m})\right]^{1/2}} \tag{50}$$

A key assumption in the use of SnIa in the measurement of H_0 and $H(z)$ is that they are standardizable and after proper calibration they have a fixed absolute magnitude independent of

[52] q_0 is the deceleration parameter $q_0 \equiv -\frac{1}{H_0^2}\frac{d^2a(t)}{dt^2}\Big|_{t=t_0}$

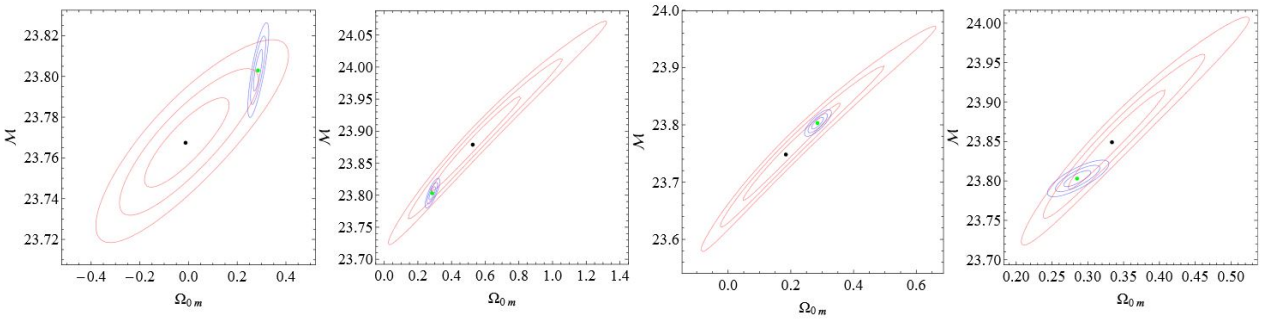

Figure 118: The $1\sigma - 3\sigma$ confidence contours in the parametric space (Ω_{0m}, $\mathcal{M}$). The blue contours correspond to the $1\sigma - 3\sigma$ full Pantheon dataset (1048 SnIa datapoints) best fit, while the red contours describe the $1\sigma - 3\sigma$ confidence contours of the four bins (from left to right). The black points represent the best fit of each bin, while the green dot represents the best fit value indicated by the full Pantheon dataset ($\Omega_{0m} = 0.285$ and $\mathcal{M} = 23.803$) [from 1029].

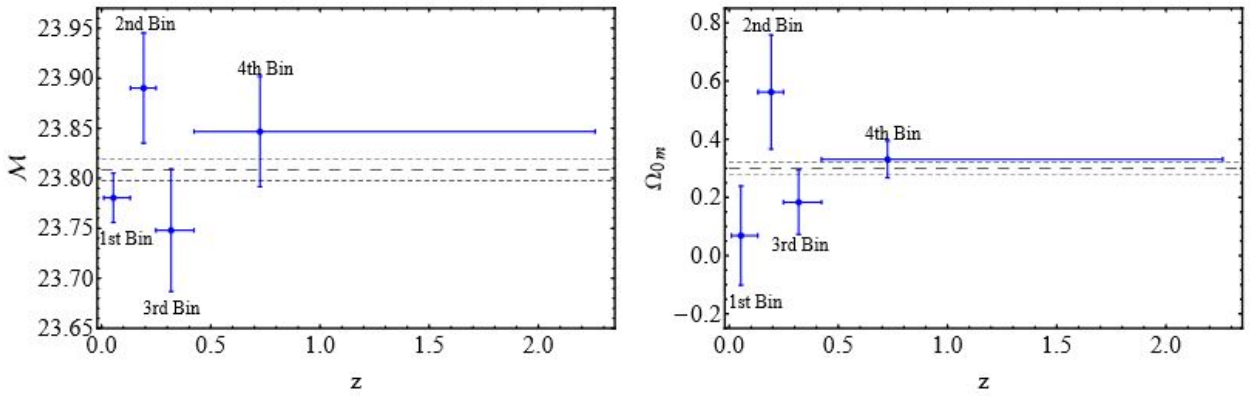

Figure 119: The best fit values of $\mathcal{M}$ (left panel) and Ω_{0m} (right panel) as well as the 1σ errors for the four bins, including the systematic uncertainties. This oscillating behaviour relatively improbable in the context of constant underlying $\mathcal{M}$ and Ω_{0m} [from 1029].

redshift[53]. This assumption has been tested in Colgáin [494], Kazantzidis and Perivolaropoulos [1028, 1029], Sapone *et al.* [1584], Koo *et al.* [1095], Kazantzidis *et al.* [1026], Luković *et al.* [1208], Tutusaus *et al.* [1743, 1744], Drell *et al.* [636].

Using the degenerate combination

$$\mathcal{M} = M + 5\log_{10}\left[\frac{c/H_0}{Mpc}\right] + 25 \tag{51}$$

into Eq. (45) we obtain

$$m(z, M, H_0, \Omega_{0m})_{th} = \mathcal{M}(M, H_0) + 5\log_{10}\left[D_L(z, \Omega_{0m})\right] \tag{52}$$

The theoretical prediction (52) may now be used to compare with the observed m_{obs} data and to obtain the best fits for the parameters $\mathcal{M}$ and Ω_{0m}. Using the maximum likelihood analysis the best fit values for these parameters may be found by minimizing the quantity

$$\chi^2(\mathcal{M}, \Omega_{0m}) = \sum_i \frac{\left[m_{obs,i} - m_{th}(z_i; \mathcal{M}, \Omega_{0m})\right]^2}{\sigma_i^2} \tag{53}$$

The results from the recent analysis by Kazantzidis and Perivolaropoulos [1029] using the latest SnIa (Pantheon) data [329] (consisting of 1048 datapoints in the redshift range $0.01 < z < 2.3$ sorting them from lowest to highest redshift and dividing them in four equal uncorrelated bins) in the context of a ΛCDM model are shown in Figs. 118 and 119[54]. An oscillating signal for $\mathcal{M}$ and Ω_{0m} (2σ) is apparent in Fig. 119 and its statistical significance may be quantified using simulated data [1026, 1095].

The presence of large scale inhomogeneities at low z including voids or a supercluster [814] can be a plausible physical explanation for this curious behavior. In the context of a local void model the analysis by Kazantzidis and Perivolaropoulos [1029] indicated that the value of H_0 increases by $2-3\%$ which is less than the 9% required to address the Hubble tension. The bias and systematics induced by such inhomogeneities on the Hubble diagram within a well-posed fully relativistic framework [light cone averaging formalism 765] has been discussed in Fanizza *et al.* [689].

Marra and Perivolaropoulos [1238] have pointed out that this H_0 tension is related to the mismatch between the SnIa absolute magnitude calibrated by Cepheids at $z < 0.01$ [420, 421]

$$M^{<} = -19.2334 \pm 0.0404 \tag{54}$$

and the SnIa absolute magnitude using the parametric free inverse distance ladder calibrating SnIa absolute magnitude using the sound horizon scale [419]

$$M^{>} = -19.401 \pm 0.027 \tag{55}$$

Thus a transition in the absolute magnitude with amplitude $\Delta M \simeq 0.2$ may provide a solution to this tension [see Subsection 11.2.2 and in 103, 1238]. Alternatively if this discrepancy is not due to systematics [135, 1772], it could be an indication of incorrect estimate of the sound horizon scale due e.g. to early dark energy [480] or to late phantom dark energy [102].

Note also that Rameez and Sarkar [1492] find discrepancies between 'Joint Light-curve Analysis' (JLA) SnIa and Pantheon SnIa datasets which imply an uncertainty in the calibration of the absolute magnitude or equivalently of the Hubble constant which is large enough to undermine the claim for Hubble tension.

[53]The possibility for intrinsic luminosity evolution of SnIa with redshift was first pointed out by Tinsley [1713]. Also, the assumption that the luminosity of SnIa is independent of host galaxy properties (e.g. host age, host morphology, host mass) and local star formation rate has been discussed in Kang *et al.* [1006], Rose *et al.* [1535], Jones *et al.* [987], Rigault *et al.* [1530], Kim *et al.* [1064].

[54]For $M = -19.24$ as indicated by Cepheid calibrators [420] of SnIa at $z < 0.01$ and the SnIa local determination $H_0 = 74\,km\,s^{-1}Mpc^{-1}$ [306] Kazantzidis and Perivolaropoulos [1029] find $\mathcal{M} = 23.80$ which is consistent with the full Pantheon SnIa best fit shown in Fig. 118.

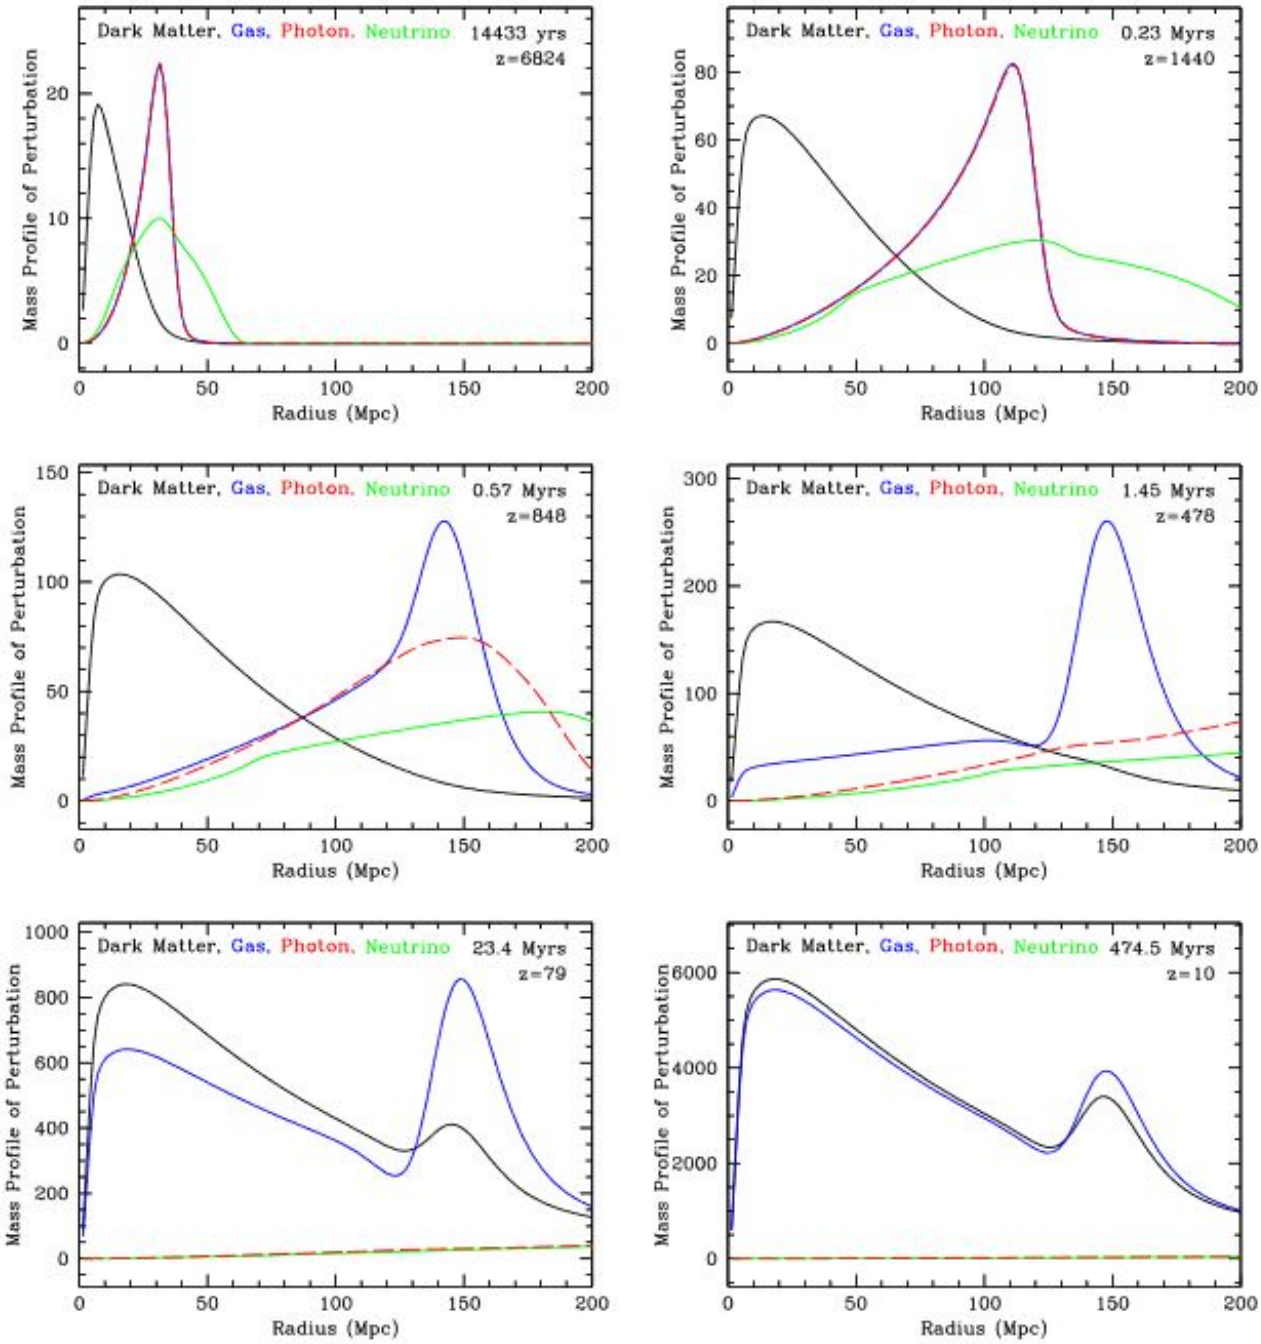

Figure 120: The snapshots show the radial mass profile of perturbation as a function of the comoving radius of an initially point-like overdensity located at the origin for redshifts $z = 6824, 1440, 848, 478, 79, 10$. The time after the Big Bang are given in each snapshots. The black, blue, red, and green lines correspond to the dark matter, baryons, photons, and neutrinos (all perturbations are fractional for that species), respectively. The top snapshots are for the early time before recombination where the overdensities in photons and baryons evolve together, the middle snapshots for soon after but close to recombination where the baryons freeze at the location reached with the photons forming a thick spherical shell, and the bottom snapshots are for long after recombination where the baryon overdensities start to gravitationally grow like dark matter overdensities [from 662].

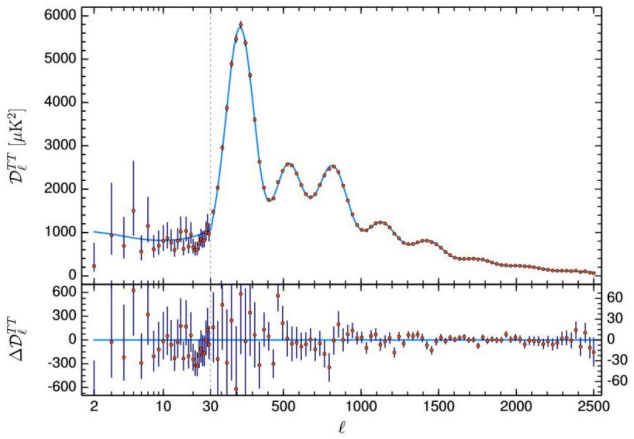

Figure 121: The Planck18 CMB angular power spectrum $\mathcal{D}_l^{TT} \equiv l(l+1)/(2\pi)C_l^{TT}$ (top) and residual angular power spectrum (bottom) of temperature fluctuations as a function of multipole moment l. The light blue line in the upper panel is the best-fitting to the Planck TT, TE, EE+lowE+lensing likelihoods assuming the base-ΛCDM cosmology. The red points correspond to the binned Planck data. The lowest multipole range ($l \leq 30$) is dominated by cosmic variance (approximated as Gaussian), while positions and amplitudes of the acoustic peaks are accurately constrained [from 72].

Observational data - Constraints:

- **SnIa-Cepheid:** Using the analysis of the Hubble Space Telescope (HST) observations [1579] the Hubble constant H_0 value has been measured from Cepheid-calibrated supernovae (using 70 long-period Cepheids in the LMC) by the Supernovae H_0 for the Equation of State (SH0ES) of dark energy collaboration [308, 1526, 306]. The analysis by the SH0ES Team using this local model-independent measurement refers $H_0 = 73.04 \pm 1.04\ km\ s^{-1}Mpc^{-1}$ [1529], which results in 5σ tension with the value estimated by CMB Planck18 [72] assuming the ΛCDM model while in previous analysis by SH0ES Team [1521] using the Gaia Early Data Release 3 (EDR3) parallaxes [751] and reaching 1.8% precision by improving the calibration a value of $H_0 = 73.2 \pm 1.3$ is obtained, a 4.2σ tension with the prediction from Planck18 CMB observations. Riess *et al.* [1528] analysing the HST data, using Cepheids as distance calibrators reports $H_0 = 73.48 \pm 1.66\ km\ s^{-1}Mpc^{-1}$. A reanalysis of the SH0ES collaboration results using a cosmographic method allowing also the deceleration parameter q_0 to be a free parameter by [421] leads to $H_0 = 74.30 \pm 1.45\ km\ s^{-1}Mpc^{-1}$.

  Breuval *et al.* [370] considered companion and average cluster parallaxes instead of direct Cepheid parallaxes and obtained $H_0 = 72.8 \pm 1.9\,(statistical + systematics) \pm 1.9$ (ZP) $km\ s^{-1}Mpc^{-1}$ when all Cepheids are considered and $H_0 = 73.0 \pm 1.9\,(statistical + systematics) \pm 1.9$ (ZP) $km\ s^{-1}Mpc^{-1}$ for fundamental mode pulsators only (where ZP is the second Gaia data release (GDR2) [381] parallax zero point).

  Various other previous estimates of H_0 have been obtained by treatments of the distance ladder [591, 397, 698]. In particular, Dhawan *et al.* [591] find $H_0 = 72.8 \pm 1.6$ (statistical)± 2.7 (systematic) $km\ s^{-1}Mpc^{-1}$ using SnIa as standard candles in the near-infrared (NIR), Burns *et al.* [397] find $H_0 = 73.2 \pm 2.3\ km\ s^{-1}Mpc^{-1}$ analysing the final data release of the Carnegie Supernova Project[55] (CSP) I [1108] and Feeney *et al.* [698] find $H_0 = 73.15 \pm 1.78\ km\ s^{-1}Mpc^{-1}$ using a Bayesian hierarchical model of the local

[55] https://csp.obs.carnegiescience.edu

distance ladder.

- **SnIa-TRGB:** The Carnegie–Chicago Hubble Program[56] (CCHP) [245] using calibration of SnIa with the TRGB method estimates $H_0 = 69.8 \pm 0.8\,(\pm 1.1\%stat) \pm 1.7\,(\pm 2.4\%sys)$ $km\ s^{-1}Mpc^{-1}$ [738] and a revision of their measurements has lead to $H_0 = 69.6 \pm 0.8\,(\pm 1.1\%stat) \pm 1.7\,(\pm 2.4\%sys)$ $km\ s^{-1}Mpc^{-1}$ [735]. Recently, the updated TRGB calibration applied to a distant sample of SnIa from the CCHP lead to a value of the Hubble constant of $H_0 = 69.8 \pm 0.6\,(\text{stat}) \pm 1.6\,(\text{sys})\,\text{km s}^{-1}\,\text{Mpc}^{-1}$ [734]. Using the LMC and the NGC 4258 as TRGB calibration of the SnIa distance ladder, the SH0ES team finds $H_0 = 72.4 \pm 2$ $km\ s^{-1}Mpc^{-1}$ [1886] and $H_0 = 71.1 \pm 1.9\,\text{km s}^{-1}\,\text{Mpc}^{-1}$ [1502] respectively. Freedman [734], Freedman *et al.* [735], Hoyt [915] argue that the difference in the derived value of H_0 by SH0ES team compared to CCHP was due to incorrect assumptions regarding calibration of the TRGB in the LMC made by Yuan *et al.* [1886]. A value of $H_0 = 65.8 \pm 3.5\,(\text{stat}) \pm 2.4\,(\text{sys})\,\text{km s}^{-1}\,\text{Mpc}^{-1}$ is obtained by Kim *et al.* [1063] using peculiar velocities and TRGB distances of 33 galaxies located between the Local Group and the Virgo cluster ($\sim 16.5\,Mpc$) [mainly the sample of Virgo infall galaxies from 1009].

  More recently, Soltis *et al.* [1672] have reported a measurement of $H_0 = 72.1 \pm 2.0$ $km\ s^{-1}Mpc^{-1}$ using the TRGB distance indicator calibrated from the European Space Agency (ESA) Gaia mission Early Data Release 3 (EDR3) trigonometric parallax of Omega Centauri [751]. Anand *et al.* [133] find $H_0 = 71.5 \pm 1.8\,km\,s^{-1}\,Mpc^{-1}$ combining TRGB measurements with either the Pantheon or CSP samples of supernova. Finally, Jones *et al.* [988] using NIR only cosmological analysis and TRGB distances to calibrate the SnIa luminosity of the CSP and RAISIN (an anagram for "SnIa in the IR") samples [986, 379] and Dhawan *et al.* [592] using TRGB calibration of SnIa observed by the Zwicky Transient Facility (ZTF) [253, 813] report $H_0 = 72.4 \pm 3.3\,\text{km s}^{-1}\,\text{Mpc}^{-1}$ and $H_0 = 76.94 \pm 6.4\,\text{km s}^{-1}\,\text{Mpc}^{-1}$ respectively.

- **SnIa-Miras:** Calibration of SnIa in the host NGC 1559 galaxy with the Miras method using a sample of 115 oxygen-rich Miras[57] discovered in maser host NGC 4258 galaxy, has lead to a measurement of the Hubble constant as $H_0 = 73.3 \pm 4$ $km\ s^{-1}Mpc^{-1}$ [923].

- **SBF:** Calibrating the SnIa luminosity with SBF method and extending it into the Hubble flow by using a sample of 96 SnIa in the redshift range $0.02 < z < 0.075$, extracted from the Combined Pantheon Sample has lead to the measurement $H_0 = 70.50 \pm 2.37$ (stat)$\pm$3.38 (sys) $km\,s^{-1}Mpc^{-1}$ by Khetan *et al.* [1052]. Previously Cantiello *et al.* [426] combining distance measurement with the corrected recession velocity of NGC 4993 reported a Hubble constant $H_0 = 71.9 \pm 7.1\,km\,s^{-1}Mpc^{-1}$. A new measurement of the Hubble constant $H_0 = 73.3 \pm 0.7 \pm 2.4 km\,s^{-1}Mpc^{-1}$ has recently been obtained based on a set of 63 SBF [314] distances extending out to $100\,Mpc$.

- **SneII:** SneII have also been used for the determination of H_0. Using 7 SneII as cosmological standardisable candles with host-galaxy distances measured from Cepheid variables or the TRGB the Hubble constant was measured to be $H_0 = 75.8^{+5.2}_{-4.9}\,km\,s^{-1}Mpc^{-1}$ [959]. More recently, de Jaeger *et al.* [958] find $H_0 = 75.4^{+3.8}_{-3.7}\,km\,s^{-1}\,Mpc^{-1}$ using 13 SneII.

Sound horizon as standard ruler: early time calibrators

Before recombination ($z > 1100$), the primeval plasma of coupled baryons to photons (baryon-photon fluid) oscillates as spherical sound waves emanating from baryon gas perturbations are driven by photon pressure. At recombination when the Universe has cooled enough the

[56] https://carnegiescience.edu/projects/carnegie-hubble-program
[57] Miras can be divided into oxygen- and carbon-rich Miras.

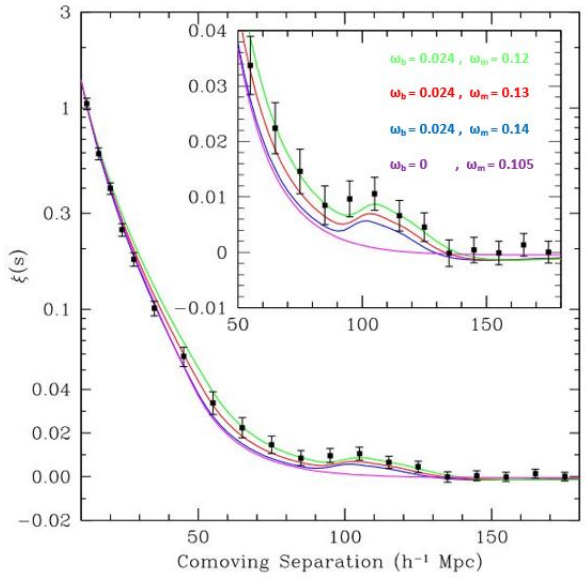

Figure 122: The signature of baryonic acoustic oscillations in galaxy two-point correlation function $\xi(s)$ as measured by Eisenstein *et al.* [663] using the luminous red galaxy samples of the Sloan Digital Sky Survey. The data show the existence of a baryonic acoustic peak in the galaxy correlation function $\xi(s)$ around the comoving separation scale $100\,h^{-1}Mpc$. The solid green, red, and blue lines correspond to model predictions with $\Omega_{0m}h^2 = 0.12, 0.13$ and 0.14, respectively. All models are taken to have the same $\Omega_{0b}h^2 = 0.024$ and $n = 0.98$. The magenta line corresponds to a model with no baryons and $\Omega_{0m}h^2 = 0.105$, which has no acoustic peaks [from 663].

electrons and protons combine to form hydrogen [e.g. 1415], photons decouple from baryons and propagate freely since the pressure becomes negligible. Thus the spherical sound wave shells of baryons become frozen. This process which was first detected in the galaxy power spectrum by Cole *et al.* [493], Eisenstein *et al.* [663] is illustrated in Fig. 120. It inflicts a unique Baryon Acoustic Oscillations (BAO) scale on the CMB anisotropy spectrum peaks shown in Fig. 121 and on the matter large scale structure (LSS) power spectrum on large scales at the radius of the sound horizon (the distance that the sound waves have traveled before recombination). This scale emerges as a peak in the correlation function $\xi(s)$[58] as illustrated in Fig. 122 or equivalently as damped oscillations in the LSS power spectrum [661, 663, 1278, 1254]. The characteristic BAO scale is also imprinted in the Lyman-α (Lyα) forest absorption lines of neutral hydrogen in the intergalactic medium (IGM) detected in quasar (QSO) spectra.

The measured angular scale of the sound horizon θ_s at the drag epoch when photon pressure vanishes can be used to probe the Hubble expansion rate using the standard ruler relation [e.g. 1417, 126]

$$\theta_s = \frac{r_s}{d_A} \tag{57}$$

where $d_A \equiv \frac{D_A}{a} \equiv (1+z)\,D_A = c\int_0^z \frac{dz'}{H(z')}$ is the comoving angular diameter distance to last

[58]The correlation function is defined as the excess probability of one galaxy to be found within a given distance of another. Using the Landy-Szalay estimator [1136] this function can be computed [663]

$$\xi(s) \equiv \langle \delta(x)\delta(x+s)\rangle = \frac{DD(s) - 2DR(s) + RR(s)}{RR(s)} \tag{56}$$

where s is the comoving galaxy separation distance and $DD(s)$, $RR(s)$ and $DR(s)$ correspond to the number of galaxy pairs with separations s in real-real, random-random and real-random catalogs, respectively.

scattering (at redshift $z \approx 1100$) and r_s is the radius of sound horizon at last scattering.

The radius r_s of the sound horizon at last scattering can be calculated by the distance that sound can travel from the Big Bang, $t = 0$, to time t_d at the drag epoch when the photon pressure can no longer prevent gravitational instability in baryons. This happens shortly after the time t_s of the last scattering when the optical depth due to Thomson scattering reaches unity [661]. Thus [29]

$$r_s = \int_0^{t_d} \frac{c_s(a)}{a(t)} dt = \int_{z_d}^{\infty} \frac{c_s(z)}{H(z;\rho_b,\rho_\gamma,\rho_c)} dz = \\ = \int_0^{a_d} \frac{c_s(a)}{a^2 H(a;\rho_b,\rho_\gamma,\rho_c)} da \tag{58}$$

where the drag redshift z_d corresponds to time t_d, ρ_b, ρ_c and ρ_γ denote the densities for baryon, cold dark matter and radiation (photons) respectively and c_s is the sound speed in the photon-baryon fluid given by [653, 157]

$$c_s = \frac{c}{\sqrt{3\left(1+\frac{3\rho_b}{4\rho_\gamma}\right)}} = \frac{c}{\sqrt{3\left(1+\frac{3\omega_b}{4\omega_\gamma}a\right)}} \tag{59}$$

The expansion rate $H(z)$ depends on the ratio of the matter density to radiation density and the sound speed determined by the baryon-to-photon ratio. Both the matter-to-radiation ratio and the baryon-to-photon ratio can be estimated from the details of the acoustic peaks in CMB anisotropy power spectrum [e.g. 921]. Thus the CMB is possible to lead to an independent determination of the radius of sound horizon. Alternatively an independent determination of the radius of sound horizon can obtained using primordial deuterium measurements [49, 9]. Now using the Eqs. (41) and (57) we can write the angular size of the sound horizon as

$$\theta_s = \frac{H_0 r_s}{c\int_0^{z_d} \frac{dz'}{E(z')}} \tag{60}$$

where $E(z)$ is the dimensionless normalized Hubble parameter and for a flat ΛCDM model is given by

$$E(z) \equiv \frac{H(z)}{H_0} = \left[\Omega_{0m}(1+z)^3 + (1-\Omega_{0m})\right]^{1/2} \tag{61}$$

Eq. (60) indicates that there is a degeneracy between r_s, H_0 and $E(z)$. Thus H_0 can not be derived using the BAO data alone which constrain $E(z)$ and the degeneracy is broken when r_s is fixed using either CMB power spectra [373] or deuterium abundance [49, 9].

For example $r_s = 147.05 \pm 0.30 Mpc$ is inferred from Planck18 TT,TE,EE+lowE CMB data [72]. Using the independent determination of r_s, measuring the angular acoustic scale θ_s from the location of the first acoustic peak in the CMB spectrum and fitting the integral in Eq. (60) using low z BAO or SnIa data, the Hubble constant H_0 can be derived. This is the 'inverse distance ladder' approach [29, 88, 407] which uses the sound horizon scale calibrated by the CMB peaks or by Big Bang Nucleosynthesis (BBN) [1600] instead of the SnIa absolute magnitude M calibrated by Cepheid stars to obtain H_0.

The deformation of the expansion rate $H(a)$ before recombination using additional components like early dark energy that increase $H(a)$ in Eq. (58) and thus decrease r_s and increase the predicted value of H_0 for fixed measured θ_s in Eq. (60), has been used as a possible approach to the solution of the Hubble tension. A challenge for this class of models is the required fine-tuning so that the evolution of $H(z)$ returns quickly to its standard form after recombination for consistency with lower z cosmological probes and growth measurements [1468]. The assumed increase of $H(z)$ at early times has been claimed to lead to a worsened growth tension [971] as discussed below even though the issue is under debate [1651, 481].

Observational data - Constraints

- **CMB:** The measurement of the Hubble constant H_0 using the sound horizon at recombination as standard ruler calibrated by the CMB anisotropy spectrum is model dependent and is based on assumptions about the nature of dark matter and dark energy as well as on an uncertain list of relativistic particles [see 459, for a review]. The best fit value obtained by the Planck18/ΛCDM CMB temperature, polarization, and lensing power spectra is $H_0 = 67.36 \pm 0.54\ km\ s^{-1}Mpc^{-1}$ [72]. The measurements of the CMB from the combination Atacama Cosmology Telescope (ACT)[59] and Wilkinson Microwave Anisotropy Probe (WMAP) estimated the Hubble constant to be $H_0 = 67.6 \pm 1.1\,km\,s^{-1}Mpc^{-1}$ and from ACT alone to be $H_0 = 67.9 \pm 1.5\,km\,s^{-1}Mpc^{-1}$ [80]. Note that the analysis of the nine-year data release of WMAP [895] alone prefers a value for the Hubble constant $H_0 = 70.0 \pm 2.2\,km\,s^{-1}Mpc^{-1}$. More recently, Balkenhol *et al.* [205] obtain CMB-based constraints on Hubble parameter $H_0 = 67.49 \pm 0.53\,km\,s^{-1}Mpc^{-1}$ using combined South Pole Telescope[60] (SPT), Planck, and ACT DR4 datasets. Dutcher *et al.* [643] find $H_0 = 68.8 \pm 1.5\,km\,s^{-1}Mpc^{-1}$ using SPT-3G data alone, while a previous analysis of SPT data by Henning *et al.* [876] results in $H_0 = 71.3 \pm 2.1\,km\,s^{-1}Mpc^{-1}$.

- **BAO:** The analysis of the wiggle patterns of BAO is an independent way of measuring cosmic distance using the CMB sound horizon as a standard ruler. This measurement has improved in accuracy through a number of galaxy surveys which detect this cosmic distance scale: the Sloan Digital Sky Survey (SDSS) supernova survey [1882, 1707] encompassing the Baryon Oscillation Spectroscopic Survey (BOSS) which has completed three different phases [566]. Its fourth phase (SDSS-IV) [317] encompasses the Extended Baryon Oscillation Spectroscopic Survey (eBOSS) [567] [see also 94, 792, 1350, 1491, 911], the WiggleZ Dark Energy Survey [638, 308, 53], the 2-degree Field Galaxy Redshift Survey (2dFGRS) [500, 493], the 6-degree Field Galaxy Survey (6dFGS) [985, 47, 48].

  More recently, BAO measurements have been extended in the context of quasar redshift surveys and Lyα absorption lines of neutral hydrogen in the IGM detected in QSO spectra using the complete eBOSS survey. The measurement of BAO scale using first the auto-correlation of Lyα function [576, 96, 37] and then the Lyα-quasar cross-correlation function [724, 57] or both the auto- and cross-correlation functions [346] pushed BAO measurements to higher redshifts ($z \sim 2.4$). Recent studies present BAO measurements from the Lyα using the eBOSS sixteenth data release (DR16) [78] of the SDSS IV [e.g. 346].

  As discussed in subsection 11.2.1 BAO data alone cannot constrain H_0 because BAO observations measure the combination $H_0 r_s$ rather than H_0 and r_s individually (where r_s is the radius of sound horizon). Using the CMB calibrated physical scale of the sound horizon and the combination of BAO with SnIa data (i.e inverse distance ladder) the value $H_0 = 67.3 \pm 1.1\ km\ s^{-1}Mpc^{-1}$ was reported which is in agreement with the value obtained by CMB data alone [29]. The analysis by Wang *et al.* [1805] using a combination of BAO measurements from 6dFGS [47], Main Galaxy Sample (MGS) [313], BOSS DR12 and eBOSS DR14 quasar sample in a flat ΛCDM cosmology reports $H_0 = 69.13 \pm 2.34\ km\ s^{-1}Mpc^{-1}$. Using BAO measurements and CMB data from WMAP, Zhang and Huang [1901] reported the constraints of $H_0 = 68.36^{+0.53}_{-0.52}$. The analysis by Addison et al. [9] combining galaxy and Lyα forest BAO with a precise estimate of the primordial deuterium abundance (BBN) results in $H_0 = 66.98 \pm 1.18\,km\,s^{-1}Mpc^{-1}$ for the flat ΛCDM model. Alam *et al.* [95] find $H_0 = 67.35 \pm 0.97\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ using BOSS galaxy and eBOSS,

[59] https://act.princeton.edu
[60] https://pole.uchicago.edu

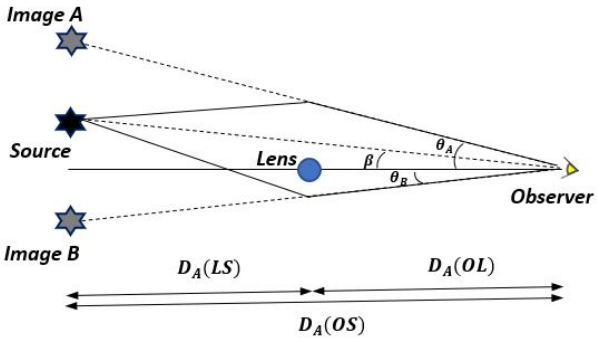

Figure 123: Schematic illustration of a typical gravitational lens system.

with the BBN prior independent from the CMB anisotropies. D'Amico *et al.* [556] obtain $H_0 = 68.5 \pm 2.2\, km\, s^{-1} Mpc^{-1}$ performing a analysis for the cosmological parameters of the DR12 BOSS data using the Effective Field Theory of Large-Scale Structure (EFTofLSS) formalism[61] and Colas *et al.* [492] obtain $H_0 = 68.7 \pm 1.5\, km\, s^{-1} Mpc^{-1}$ assuming a BBN prior on the baryon fraction of the energy density instead of the baryon/dark-matter ratio.

Recently, Pogosian *et al.* [1469] report the constraints of $H_0 = 69.6 \pm 1.8\, km\, s^{-1} Mpc^{-1}$ using BAO data, including the released eBOSS DR16, and CMB data from Plank. Zhang *et al.* [1898] infer $H_0 = 68.19 \pm 0.99$ imposing BBN priors on the baryon density and combining the BOSS Full Shape with the BAO measurements from BOSS and eBOSS. Also, a new analysis of galaxy 2-point functions in the BOSS survey, including full-shape information and post-reconstruction BAO by Chen *et al.* [468] results in $H_0 = 69.23 \pm 0.77\, km\, s^{-1} Mpc^{-1}$ and a full-shape analysis of BOSS DR12 by Philcox and Ivanov [1453] results in $H_0 = 68.31^{+0.83}_{-0.86}\, km\, s^{-1} Mpc^{-1}$. A previous analysis of BOSS DR12 on anisotropic galaxy clustering in Fourier space by Ivanov *et al.* [953] gives $H_0 = 67.9 \pm 1.1\, km\, s^{-1}\, Mpc^{-1}$. Finally, analyzing the BOSS DR12 galaxy power spectra using a new approach based on the horizon scale at matter-radiation equality Farren *et al.* [694] find $H_0 = 69.5^{+3.0}_{-3.5}\, km\, s^{-1} Mpc^{-1}$ and adding Planck lensing Philcox *et al.* [1454] find $H_0 = 70.6^{+3.0}_{-5.4}\, km\, s^{-1} Mpc^{-1}$.

Time delays: gravitational lensing

Gravitational lensing time-delay cosmography can be used to measure H_0. This approach was first proposed by Refsdal [1500] and recently implemented by Shajib *et al.* [1625], Wong et al. [366], Birrer *et al.* [299] [see also 1724, 1693, for clear reviews]. Strong gravitational lensing [1500] arises from the gravitational deflection of light rays of a background source when an intervening lensing mass distribution (e.g. a massive galaxy or cluster of galaxies) exists along the line of sight. The light rays go through different paths such that multiple images of the background source appear around the intervening lens [1381].

The time delay Δt_{AB} between two images $\theta_\mathbf{A}$ and $\theta_\mathbf{B}$ by a single deflector originating from the same source at angle β shown in Fig. 123 is given as [1694]

$$\Delta t_{AB} = \frac{1 + z_L}{c} \frac{D_A(OL) D_A(OS)}{D_A(LS)} \left[\phi(\theta_\mathbf{A}, \beta) - \phi(\theta_\mathbf{B}, \beta)\right] \tag{62}$$

where z_L is the lens redshift, $D_A(OL)$ is the angular diameter distance to the lens, $D_A(OS)$ is the angular diameter distance to the source, $D_A(LS)$ is the angular diameter distance between

[61] The EFTofLSS formalism can provide a prediction of the LSS clustering in the mildly non-linear regime [558, 239, 444, 1471, 1444].

the lens and the source and $\phi(\theta, \beta)$ is the Fermat potential [e.g. 1694]

$$\phi(\theta, \beta) = \frac{(\theta - \beta)^2}{2} - \psi(\theta) \tag{63}$$

with $\psi(\theta)$ the lensing potential at the image direction. The time delay Δt_{AB} in Eq. (62) is thus connected to the time delay distance defined as [e.g. 1694, 1696]

$$D_{\Delta t} = \frac{1 + z_L}{c} \frac{D_A(OL) D_A(OS)}{D_A(LS)} \tag{64}$$

This distance is inversely proportional to H_0

$$D_{\Delta t} \propto \frac{1}{H_0} \tag{65}$$

and thus its measurement constrains H_0. Strongly lensed quasars (bright and time variable sources) lensed by a foreground lensing mass are used to measure the above observable time delay on cosmologically interesting scales [1037, 1080, 1380, 340, 366]. Active galactic nuclei (AGN) constitute another background source which may be used to measure the time delay [1083, 696, 658]. Recently, Qi *et al.* [1488] proposed the strongly lensed SnIa as a precise late-universe probe to improve the measurements on the Hubble constant and cosmic curvature. The inference of H_0 from $D_{\Delta t}$ is relatively insensitive to the assumed background cosmology.

Note that a source of systematic effects in time delay cosmography is the uncertainty of the mass along the line of sight modeling with respect to the mass sheet transformation (MST). This is a mathematical degeneracy [e.g. 687, 808, 1558, 1602, 1079, 1081] and can bias the strong lensing determination of Hubble constant [1082].

Observational data - Constraints:

Strong gravitational lensing time delay measurements of H_0 are consistent with the local measurements using late time calibrators and in mild tension with Planck [e.g. 340]. The method of the measurement of H_0 Lenses in COSMOGRAIL's Wellspring (H0LiCOW) collaboration [366] is independent of the cosmic distance ladder and is based on time delays between multiple images of the same source, as occurs in strong gravitational lensing.

Using joint analysis of six gravitationally lensed quasars with measured time delays from the COSmological MOnitoring of GRAvItational Lenses (COSMOGRAIL) project, the value $H_0 = 73.3^{+1.7}_{-1.8}\ km\ s^{-1} Mpc^{-1}$ was obtained which is in 3.1σ tension with Planck CMB. Assuming the Universe is flat and using lensing systems from the lensing program H0LiCOW and the Pantheon supernova compilation a value of $H_0 = 72.2 \pm 2.1\ km\ s^{-1} Mpc^{-1}$ was reported by the analysis of Ref. [1174]. A similar value of $H_0 = 72.8^{+1.6}_{-1.7}\ km\ s^{-1} Mpc^{-1}$ was found using updated H0LiCOW dataset consisting of six lenses [1175]. The reanalysis of the four publicly released lenses distance posteriors from the H0LiCOW by Yang *et al.* [1852] leads to $H_0 = 73.65^{+1.95}_{-2.26}\ km\ s^{-1} Mpc^{-1}$. The analysis of the strong lens system DES $J0408 - 5354$ by Shajib *et al.* [1625] for strong lensing insights into dark energy survey collaboration (STRIDES), infers $H_0 = 74.2^{+2.7}_{-3.0}\ km\, s^{-1} Mpc^{-1}$ in the ΛCDM cosmology. The analysis by Birrer *et al.* [299] based on the strong lensing and using Time-Delay COSMOgraphy (TDCOSMO[62, 63]) data set alone infers $H_0 = 74.5^{+5.6}_{-6.1}\ km\ s^{-1} Mpc^{-1}$ and using a joint hierarchical analysis of the TDCOSMO and Sloan Lens ACS (SLACS) [333] sample reports $H_0 = 67.4^{+4.1}_{-3.2}\ km\ s^{-1} Mpc^{-1}$. Chen *et al.*

[62] TDCOSMO collaboration [1290] was formed by members of H0LiCOW, STRIDES, COSMOGRAIL and SHARP.

[63] http://www.tdcosmo.org/

[465] based on a joint analysis of 3 strong lensing system, using ground-based adaptive optics (AO) from SHARP AO effort and the HST find $H_0 = 76.8 \pm 2.6\ km\ s^{-1} Mpc^{-1}$. A reanalysis of six of the TDCOSMO lenses using a power-law mass profile model results in $H_0 = 74.2 \pm 1.6\ km\ s^{-1} Mpc^{-1}$ [1290]. Analysing 8 strongly, quadruply lensing systems Denzel *et al.* [579] present a determination of the Hubble constant $H_0 = 71.8^{+3.9}_{-3.3}\ km\ s^{-1} Mpc^{-1}$ which is consistent with both early and late Universe observations. The value $H_0 = 73.6^{+1.8}_{-1.6}\ km\, s^{-1}\, Mpc^{-1}$ was reported by Qi *et al.* [1489] by combining the observations of ultra-compact structure in radio quasars and strong gravitational lensing with quasars acting as background source.

Standard sirens: gravitational waves

An independent and potentially highly effective approach for the measurement of $H(z)$ and the Hubble constant is the use of gravitational wave (GW) observations and in particular those GW bursts that have an electromagnetic counterpart (standard sirens) [1607, 180, 554, 1358, 1357]. In analogy with the traditional standard candles, it is possible to use standard sirens to directly measure the luminosity distance d_L of the GW source.

Standard sirens involve the combination of a GW signal and its independently observed electromagnetic (EM) counterpart. Such counterpart may involve short gamma-ray bursts (SGRBs) signal from binary neutron star mergers [657] or associated isotropic kilonova emission [525, 1653] and enables the immediate identification of the host galaxy. In contrast to traditional standard candles such as SnIa calibrated by Cepheid variables, standard sirens do not require any form of cosmological distance ladder. Instead they are calibrated in the context of general relativity through the observed GW waveform.

The simultaneous observations of the GW signal and its EM counterpart (multi-messenger observations) of nearby compact-object merger leads to a measurement of the luminosity distance which depends on the inclination angle of the binary orbit with respect to the line of sight and the redshift (measured using photons) of the host galaxy respectively. An EM counterpart detected with a GW observation can further constrain the inclination angle and may also indicate the source's sky position and the GW merger's time and phase [e.g. 1357].

In the case of GW events with small enough localization volumes without an observed EM counterpart (dark sirens) [466] a statistical analysis over a set of potential host galaxies within the event localization region may provide redshift information. A candidate for such statistical method is a merger of stellar-mass binary black holes[64] (BBH) which is usually not expected to result in bright EM counterparts unless it takes place in significantly gaseous environment [812]. For example, GW190521 [20] is a possible candidate with EM counterpart corresponding to a stellar-origin BBH merger in active galactic nucleus (AGN) disks [1272] detected by ZTF [253, 813].

Alternatively, in the absence of an EM counterpart the redshift can be determined by exploiting information on the properties of the source (e.g. the knowledge of neutron star equation of state) to derive frequency-dependent features in the waveform [1285] or using the gravitational waveform to determine the redshift of the mass distribution of the sources [1706, 693]. Also, Leandro *et al.* [1140] use an alternative method, presented in Ding *et al.* [626], for redshift determination by the statistical knowledge of the redshift distribution of sources. Trott and Huterer [1725] argue that any absolute determination of H_0 may be biased due to the fundamental degeneracy between redshift and H_0 and therefore can not lead to reliable determination of H_0. According to Trott and Huterer [1725] the reliable determination of H_0 with GW can only be achieved using standard sirens.

The luminosity distance-redshift relation Eq. (39) determines the Universe's expansion

[64] The stability analysis of the structures around black holes have been widely employed in the literature [see e.g. 1069, 249, 535, 159, 104].

history and the associated cosmological parameters including the Hubble constant H_0 [10, 715]. In particular using the mergers of binary neutron stars (BNS), or a binary of a neutron star with a stellar-mass black hole (NS-BH), which are excellent standard sirens, both the luminosity distance (from the gravitational wave waveform) and redshift of the host galaxy (from the electromagnetic counterpart) can be measured.

Using a BNS or a NS-BH merger, the distance to the source can be estimated from the detected amplitude $\langle h \rangle$ (r.m.s. - averaged over detector and source orientations) of the GW signal by the expression [1607, 141, 966, 1091, 1090]

$$d = C f^{-2} \langle h \rangle^{-1} \tau^{-1} \tag{66}$$

where f is the gravitational wave frequency, $\tau \equiv f/\dot{f}$ is the timescale of frequency change, C is a known numerical constant. Assuming a flat[65] Universe the luminosity distance can then be obtained from the relation

$$d(z) = \frac{1}{1+z} d_L(z) \tag{67}$$

For nearby sources, the recession velocity using the Hubble's law is determined by the expression

$$v(z) = H_0 d(z) \tag{68}$$

and using Eqs. (39), (44) and (67) is given by

$$v(z) = \frac{H_0 d_L(z)}{1+z} = \frac{c D_L(z)}{1+z} = c H_0 \int_0^z \frac{dz'}{H(z')} \tag{69}$$

At low redshifts using the local expansion Eq. (48) we obtain

$$v(z) = \frac{cz}{1+z} \left[1 + \frac{1}{2}(1-q_0) z \right] \tag{70}$$

which is approximated for $d \leq 100\ Mpc$ (or $z \leq 0.03$) as

$$v(z) = cz = H_0 d \tag{71}$$

Using Eqs. (68) and (70), the equation for the determination of H_0 as a function of observables, z and d is [e.g. 1895]

$$H_0 = \frac{cz}{d(1+z)} \left[1 + \frac{1}{2}(1-q_0) z \right] \tag{72}$$

where the deceleration parameter may be set by a fit to the GW data or may be fixed to its Planck/ΛCDM best fit form ($q_0 = -0.55$).

Observational data - Constraints:

The first multi-messenger detection of a BNS merger, GW170817, by LIGO [2] and Virgo [41] interferometers enabled the first standard siren measurement of the Hubble constant H_0. Using the BNS merger GW170817, the distance to the source was estimated to be $d = 43.8^{+2.9}_{-6.9}$ Mpc (i.e. at redshift $z \sim 0.01$) from the detected amplitude $\langle h \rangle$ (r.m.s. - averaged over detector and source orientations) of the GW signal by the Eq. (66) [10]. Also using the Hubble flow velocity $v_H = 3017 \pm 166\ km\ s^{-1}$ inferred from measurement of the redshift of the host galaxy,

[65] In an open (closed) Universe the distance in Hubble's law is given $d(z) = \frac{1}{1+z} \frac{\chi}{\sinh \chi} d_L(z)$ ($d(z) = \frac{1}{1+z} \frac{\chi}{\sin \chi} d_L(z)$)

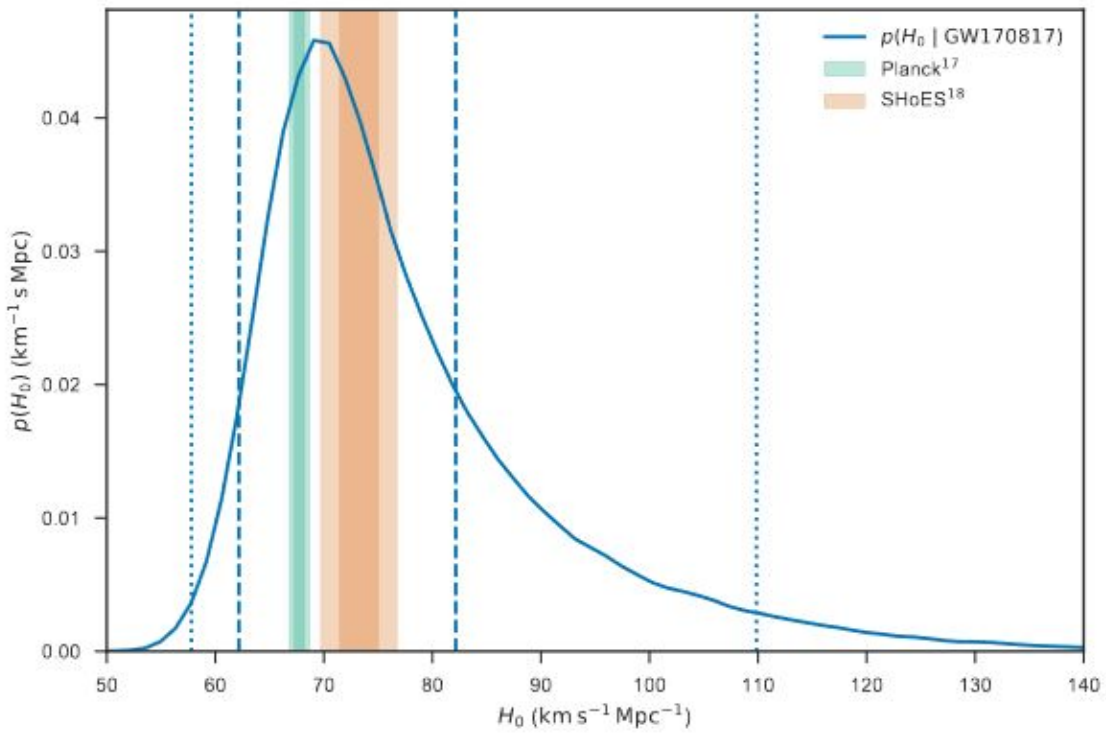

Figure 124: The probability of different values of H_0 with the maximum at $H_0 = 70.0^{+12.0}_{-8.0}$ $km\ s^{-1}Mpc^{-1}$ (solid blue curve) derived by BNS event GW170817. The dashed and dotted lines show minimal 68.3% (1σ) and 95.4% (2σ) credible intervals. The shaded green and orange bands show the 1σ and 2σ constraints from the analysis of the CMB data obtained by the Planck [50] and from the analysis of the SnIa data obtained by SH0ES [1526] respectively [from 10].

NGC 4993 (NGC 4993 was identified as the unique host galaxy), the Hubble constant was determined to be $H_0 = 70.0^{+12.0}_{-8.0}$ $km\ s^{-1}Mpc^{-1}$ [10] (see Fig. 124) by using Eq. (71).

Using continued monitoring of the the radio counterpart of GW17081 combining with earlier GW and EM data Hotokezaka *et al.* [910] obtain a improved measurement of $H_0 = 68.9^{+4.7}_{-4.6}$ $km\ s^{-1}Mpc^{-1}$. Note that using the BNS merger GW170817 in Fishbach *et al.* [715] and a statistical analysis (as first proposed in Schutz [1607]) over a catalog of potential host galaxies, the Hubble constant was determined to be $H_0 = 77.0^{+37.0}_{-18.0}$ $km\ s^{-1}Mpc^{-1}$. Using density-estimation Likelihood-Free Inference (LFI) Gerardi *et al.* [780] focused on the inference of the cosmological expansion H_0 from GW-selected catalogues of BNS mergers with EM counterparts.

Also using the BBH merger GW170814 as a standard (dark) siren in the absence of an electromagnetic counterpart, combined with a photometric redshift catalog from the Dark Energy Survey (DES) [25] the analysis by Soares-Santos *et al.* [1654] results in $H_0 = 75^{+40}_{-32}$ $km\ s^{-1}Mpc^{-1}$. Using multiple GW observations (the BNS event GW170817 and the BBH events observed by advanced LIGO and Virgo in their first and second observing runs) in Abbott *et al.* [17] the Hubble constant was constrained as $H_0 = 69.0^{+16.0}_{-8.0}$ $km\ s^{-1}Mpc^{-1}$. Using the event GW190814 from merger of a black hole with a lighter compact object the Hubble constant was measured to be $H_0 = 75^{+59}_{-13}$ $km\ s^{-1}Mpc^{-1}$ [18]. In Mukherjee *et al.* [1327] the BBH merger GW190521 was analysed choosing the NRSur7dq4 waveform[66] for the estimation of luminosity distance, after marginalizing over matter density Ω_{0m} when the ΛCDM model is considered and using its EM counterpart ZTF19abanrhr[67] as identified in Graham *et al.* [812] the Hubble constant was measured to be $H_0 = 50.4^{+28.1}_{-19.5}$ $km\ s^{-1}Mpc^{-1}$. The same study [1327] choosing different types of waveform finds $H_0 = 43.1^{+24.6}_{-11.4}$ $km\ s^{-1}Mpc^{-1}$ and $H_0 = 62.2^{+29.5}_{-19.7}$ $km\ s^{-1}Mpc^{-1}$. Combining their results with the binary neutron star event GW170817 leads to $H_0 = 67.6^{+4.3}_{-4.2}$ $km\ s^{-1}Mpc^{-1}$. In Chen *et al.* [467] for the same GW-EM event, assuming a flat wCDM model has obtained $H_0 = 48^{+23}_{-10}$ $km\ s^{-1}Mpc^{-1}$.

The analysis by Abbott *et al.* [21] using 47 gravitational-wave sources from the Third LIGO–Virgo–KAGRA Gravitational-Wave Transient Catalog (GWTC–3), infers $H_0 = 68^{+12}_{-7}$ $km\ s^{-1}Mpc^{-1}$. Palmese *et al.* [1397] find $H_0 = 72.77^{+11.0}_{-7.55}\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ using the best available gravitational wave events, uniform galaxy catalog from the Dark Energy Spectroscopic Instrument (DESI) [64, 65] Legacy Survey and combining with the GW170817. The value $H_0 = 88.6^{+17.1}_{-34.3}$ $km\ s^{-1}Mpc^{-1}$ for GW190521 event was reported, and $H_0 = 73.4^{+6.9}_{-10.7}$ $km\ s^{-1}Mpc^{-1}$ was obtained when combing the GW190521 with the results of the neutron star merger GW170817 [767]. More recently, Mukherjee *et al.* [1328] report $H_0 = 67^{+6.3}_{-3.8}\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ combining the bright standard siren measurement from GW170817 with a better measurement of peculiar velocity.

Megamaser technique

Observations of water megamasers which are found in the accretion disks around supermassive black holes (SMBHs) in active galactic nuclei (AGN) have been demonstrated to be powerful one-step geometric probes for measuring extragalactic distances [880, 931, 1504].

Assuming a Keplerian circular orbit around the SMBH, the centripetal acceleration and the

[66] NRSur7dq4 is a numerical relativity surrogate 7-dimensional approximate waveform model of binary black hole merger with mass ratios $q \equiv \frac{m_1}{m2} \leq 4$ [1765]. This model is made publicly available through the gwsurrogate (see `https://pypi.org/project/gwsurrogate`) and surfinBH (see `https://pypi.org/project/surfinBH`) Python packages.

[67] The ZTF19abanrhr event was reported by ZTF [253]. This candidate EM counterpart is flare after a kicked BBH merger in the accretion disk of an AGN [1272] with peak luminosity occurred 50 days after the BBH event GW19052. The ZTF19abanrhr was first observed after 34 days from the GW detection at the sky direction ($RA = 192.42625^0$, $Dec = 34.82472^0$) and was associated with an AGN J124942.3 + 344929 at redshift $z = 0.438$ [812].

velocity of a masing cloud are given as [1504]

$$A = \frac{V^2}{r} \tag{73}$$

$$V = \sqrt{\frac{GM}{r}} \tag{74}$$

where G is the Newton's constant, M is the mass of the central supermassive black hole, and r is the distance of a masing cloud from the supermassive black hole.

The angular scale θ subtended by r is given by

$$\theta = \frac{r}{d} \tag{75}$$

where d is the distance to the galaxy.

Thus, from the velocity and acceleration measurements obtained from the maser spectrum, the distance to the maser may be determined

$$d = \frac{V^2}{A\theta} \tag{76}$$

where A is measured from the change in Doppler velocity with time by monitoring the maser spectrum on month timescales. Using Hubble's law the Hubble constant may be approximated as [1504]

$$H_0 \approx \frac{\upsilon}{d} \tag{77}$$

where υ is the measured recessional velocity.

In order to constrain the Hubble constant the Megamaser Cosmology Project (MCP) [1503] uses angular diameter distance measurements to disk megamaser-hosting galaxies well into the Hubble flow ($50-200\,Mpc$). These distances are independent of standard candle distances and their measurements do not rely on distance ladders, gravitational lenses or the CMB [1447]. Early measurements of H_0 using masers tended to favor lower values of $H_0 \simeq 67\ km\,s^{-1}Mpc^{-1}$ while more recent measurements favor higher values $H_0 \simeq 73\ km\,s^{-1}Mpc^{-1}$ as shown e.g. in Table 17.

Observational data - Constraints:

Recently, the Megamaser Cosmology Project (MCP) [1503] using geometric distance measurements to megamaser-hosting galaxies and assuming a global velocity uncertainty of 250 $km\ s^{-1}$ associated with peculiar motions of the maser galaxies constrains the Hubble constant to be $H_0 = 73,9 \pm 3\ km\ s^{-1}Mpc^{-1}$ [1447]. Previously the MCP reported results on galaxies, UGC 3789 with $H_0 = 68.9 \pm 7.1\,km\,s^{-1}Mpc^{-1}$ [1504], NGC 6264 with $H_0 = 68.0 \pm 9.0\,km\,s^{-1}Mpc^{-1}$ [1123], NGC 6323 with $H_0 = 73^{+26}_{-22}\,km\,s^{-1}Mpc^{-1}$ [1124] and NGC 5765b with $H_0 = 66.0 \pm 6.0\,km\,s^{-1}Mpc^{-1}$ [757]. Reid *et al.* [1502] use a improved distance estimation of the maser galaxy NGC 4258 (also known as Messier 106) to calibrate the Cepheid-SN Ia distance ladder combined with geometric distances from MW parallaxes and DEBs in the LMC. The measured value of the Hubble constant is $H_0 = 73.5 \pm 1.4\,km\,s^{-1}Mpc^{-1}$.

Tully-Fisher relation (TFR) as distance indicator

The Tully-Fisher (TF) method is a historically useful distance indicator based on the empirical relation between the intrinsic total luminosity (or the stellar mass) of a spiral galaxy[68] and

[68]Similarly, in the case of a elliptical galaxy the Faber–Jackson (FJ) empirical power-law relation $L \propto \sigma^{\gamma_{FJ}}$ (where L is the luminosity of galaxy, σ the velocity dispersion of its stars and γ_{FJ} is a index close to 4) [684]

its rotation velocity (or neutral hydrogen (HI) 21 cm emission line width) [1737]. This method has been used widely in measuring extragalactic distances [e.g. 1562].

The Baryonic Tully Fisher relation (BTFR) [1270, 1773, 829, 1267] connects the rotation speed V_c and total baryonic mass M_b (stars plus gas) of a spiral galaxy as

$$M_b = A_c V_c^s \tag{78}$$

where s [with $s \approx 3-4$ 1270, 1267, 1150] is a parameter and $\log A_c$ is the zero point in a log-log BTFR plot. This relation has been measured for hundreds of galaxies. The rotation speed V_c can be measured independently of distance while the total baryonic mass M_b may be used as distance indicator since it is connected to the intrinsic luminosity. Thus, the BTFR is a useful cosmic distance indicator approximately independent of redshift and thus can be used to obtain H_0.

The BTFR has a smaller amount of scatter with a corresponding better accuracy as a distance indicator than the classic TF relation [1150]. In addition the BTFR recovers two decades in velocity and six decades in mass [1270, 1267, 1266, 945, 1151, 1603].

A simple heuristic analytical derivation for the BTFR is obtained [1] by considering a star rotating with velocity v in a circular orbit of radius R around a central mass M. Then the star velocity is connected with the central mass as

$$v^2 = G\, M_b/R \implies v^4 = (G\, M_b/R)^2 \sim M_b\, S\, G^2 \tag{79}$$

where G is Newton's constant and S the surface density $S \equiv M/R^2$ which may be shown to be approximately constant [740]. From Eqs. (78) and (79) we have

$$A_c \sim G^{-2} S^{-1} \tag{80}$$

which indicates that the zero point intercept of the BTFR can probe both galaxy formation dynamics (through e.g. S) and possible fundamental constant dynamics (through G) [100].

Observational data - Constraints:

The analysis by Kourkchi *et al.* [1097] using infrared (IR) data of sample galaxies and the Tully Fisher relation determined the value of Hubble constant to be $H_0 = 76.0 \pm 1.1(stat.) \pm 2.3(sys.)\, km\, s^{-1} Mpc^{-1}$. In Schombert *et al.* [1603] a value of $H_0 = 75.1 \pm 2.3(stat.) \pm 1.5(sys.)\, km\, s^{-1} Mpc^{-1}$ was found using Baryonic Tully Fisher relation for 95 independent Spitzer photometry and accurate rotation curves (SPARC) galaxies[69] (up to distances of $\sim 130 Mpc$).

Extragalactic background light γ-ray attenuation

This method is based on the fact that the extragalactic background light (EBL) which is a diffuse radiation field that fills the Universe from ultraviolet (UV) through infrared wavelength induces opacity for very high energy (VHE) photons ($\geq 30\, GeV$) induced by photon-photon interaction [861]. In this process a γ-ray and an EBL photon in the intergalactic medium may annihilate and produce an electron-positron pair [811]. The induced attenuation in the spectra of γ-ray sources is characterized by an optical depth $\tau_{\gamma\gamma}$ that scales as $n\sigma_T l$ (where n is the photon density of the EBL, σ_T is the Thomson cross section, and l is the distance from the

can be used as a distance indicator. The FJ relation is the projection of the fundamental plane (FP) of elliptical galaxies which defined as $R_{eff} \propto \sigma^{s_1} I_{eff}^{s_2}$ (where R_{eff} is the effective radius and I_{eff} is the mean surface brightness within R_{eff}) [628].

[69] The SPARC catalogue contains 175 nearby (up to distances of $\sim 130 Mpc$) late-type galaxies (spirals and irregulars) [1149, 1150]. The SPARC data are publicly available at http://astroweb.cwru.edu/SPARC.

γ-ray source to Earth). The cosmic evolution and the matter content of the Universe determine the γ-ray optical depth and the amount of γ-ray attenuation along the line of sight [633, 1892]. Thus a derivation of H_0 can be obtained by measuring the γ-ray optical depth with the γ-ray telescopes [632]. This derivation is independent and complementary to that based on the distance ladder and cosmic microwave background (CMB) and seems to favor lower values of H_0 as shown in Table 17.

Observational data - Constraints:

The analysis by Domínguez *et al.* [633] using extragalactic background light γ - ray attenuation data from Fermi Large Area Telescope (Fermi-LAT) derives $H_0 = 67.4^{+6.0}_{-6.2}\, km\, s^{-1} Mpc^{-1}$ and $\Omega_{0m} = 0.14^{+0.06}_{-0.07}$. The analysis by Zeng and Yan [1892] fitting the $> 10\, GeV$ extragalactic background data with modeled extragalactic background spectrum results in $H_0 = 64.9^{+4.6}_{-4.3}\, km\, s^{-1} Mpc^{-1}$ and $\Omega_{0m} = 0.31^{+0.13}_{-0.14}$.

Cosmic chronometers

Cosmic chronometers are objects whose evolution history is known. For instance such objects are some types of galaxies. The observation of these objects at different redshifts and the corresponding differences in their evolutionary state has been used to obtain the value of $H(z)$ at each redshift z.

The cosmic chronometer technique for the determination of H_0 was originally suggested in Jimenez and Loeb [980] and is based on the quasi-local ($0.07 \lesssim z \lesssim 2.36$) measurements along the Hubble flow of the Hubble parameter expressed as

$$H(z) = -\frac{1}{1+z}\frac{dz}{dt} \tag{81}$$

Thus, the expansion rate may be obtained by measuring the age difference Δt between two old and passively evolving galaxies[70] which are separated by a small redshif interval Δz, to infer the dz/dt [1308, 1307].

This approach determines the $H_0 = H(z = 0)$ independent of the early-Universe physics and is not based on the distance ladder [e.g. 980, 469, 692, 1884, 798]. The estimated H_0 values are more consistent with the values estimated from recent CMB and BAO data than those values estimated from SnIa. The value of H_0 can not be derived using the cosmic chronometers observations alone because there is a background degeneracy between H_0 and Ω_{0m} and this degeneracy is broken when these observations are combined.

Observational data - Constraints:

In Chen *et al.* [469] the value of Hubble constant was found to be $H_0 = 68.3^{+2.7}_{-2.6}$ in the flat ΛCDM model relying on 28 $H(z)$ measurements and their extrapolation to redshift zero. Analysing 31 $H(z)$ data determined by the cosmic chronometric (CCH) method, and 5 $H(z)$ data by BAO observations and using the Gaussian Process (GP) method [1616, 1622, 1846, 992] to determine a continuous $H(z)$ function the Hubble constant is estimated to be $H_0 \sim 67 \pm 4\, km\, s^{-1} Mpc^{-1}$ by Yu *et al.* [1884]. Also using the GP an extension of this analysis by Gómez-Valent and Amendola [798], including the $H(z)$ measurements obtained from Pantheon compilation and HST CANDELS and CLASH Multi-Cycle Treasury (MCT) programs, finds $H_0 = 67.06 \pm 1.68\, km\, s^{-1} Mpc^{-1}$ which is more consistent again with the lower range of values

[70] These galaxies form only a few new stars and become fainter and redder with time. The time that has elapsed since they stopped star formation can be deduced.

for H_0. The GP method [1495] is used as a 'non-parametric' technique which does not assume any parametrization or any cosmological model [see 1375, for a discussion about GP as model independent method]. The GP modeling approach has been performed by several authors to reconstruct cosmological parameters and thus to extract cosmological information directly from data [see e.g 271, 675, 1508, 906, 1034, 905, 262, 1897, 400, 1615, 1559, 1162, 1163, 1237, 1512, 268, 339, 338, 1688, 675, 589, 1326, 1035, 191, 1549, 1633, 1511, 1371, 1164, 252, 1459, 410, 849, 1896, 1791, 1623, 265, 264, 371, 1166].

Recently, a analysis by Moresco *et al.* [1309] reports $H_0 = 67.8^{+8.7}_{-7.2}\, km\, s^{-1}\, Mpc^{-1}$ and $H_0 = 66.5 \pm 5.4\, km\, s^{-1}\, Mpc^{-1}$ for a generic open wCDM and for a flat ΛCDM respectively. The analysis by Moresco *et al.* [1309] examine the possible effects that can systematically bias the measurement and can affect the CC method. It should be pointed out however that the quality and reliability of cosmic chronometer data has been challenged by some authors. This is partly due to the fact that these datapoints are not model independent and are obtained by combining several datasets [798]. This has improved significantly in the context of the aforementioned analysis by Moresco *et al.* [1309] where a detailed study of the covariance matrix and the effects of systematics has been implemented.

HII galaxy measurements

The ionized hydrogen gas (HII) galaxies (HIIG) emit massive and compact bursts generated by the violent star formation (VSF) in dwarf irregular galaxies. The HIIG measurements can be used to probe the background evolution of the Universe. This method of H_0 determination is based on the standard candle calibration provided by a $L-\sigma$ (luminosity-velocity dispersion) relation. This relation exists in HIIGs and Giant extragalactic HII regions (GEHR) in nearby spiral and irregular galaxies. The turbulent emission line ionized gas velocity dispersion σ of the prominent Balmer lines[71] H-alpha ($H\alpha$) and H-beta ($H\beta$) relates with its integrated emission line luminosity L [1282, 1637, 1466, 462, 463, 1708, 1815, 461, 1880, 805]. The relationship between $L(H\beta)$ and $\sigma(H\beta)$ has a small enough scatter to define a cosmic distance indicator (that can be utilized out to $z \sim 4$) independently of redshift and can be approximated as [462, 463, 1708, 1815, 1139, 461, 1880, 1541, 805]

$$\log L(H\beta) = \nu \log \sigma(H\beta) + \kappa \tag{82}$$

where ν and κ are constants representing the slope and the logarithmic luminosity at $\log \sigma(H\beta) = 0$.

From Eq. (38) the luminosity $L(H\beta)$ is given by

$$L(H\beta) = 4\pi d_L^2 l(H\beta) \tag{83}$$

Thus using Eq. (82), the distance modulus $\mu \equiv m - M$ of an HIIG can be obtained [1815, 1139, 461, 1880, 1541, 805]

$$\mu_{obs} = 2.5\left[\nu \log \sigma(H\beta) + \kappa - \log l(H\beta)\right] - 100.2 \tag{84}$$

This observational distance modulus can be compared with the theoretical distance modulus. From the Eq. (43) this is given

$$\mu(z)_{th} = 5 \log_{10}\left[\frac{d_L(z)}{Mpc}\right] + 25 \tag{85}$$

[71] The Balmer series, or Balmer lines is one of a set of six named series describing the spectral line emissions of the hydrogen atom. This is characterized by the electron transitioning from $n \geq 3$ to $n = 2$ (where n is the principal quantum number of the electron. The transitions $n = 3$ to $n = 2$ and $n = 4$ to $n = 2$ are called H-alpha and H-beta respectively.

Using now the dimensionless Hubble free luminosity distance Eq. (44) this can be written as

$$\mu(z)_{th} = 5\log_{10}\left[D_L(z)\right] + 5\log_{10}\left[\frac{c/H_0}{Mpc}\right] + 25 \tag{86}$$

In order to obtain the best fit values for the parameters Ω_{0m} and H_0 this theoretical prediction may now be used to compared with the observed μ_{obs} data. Using the maximum likelihood analysis the best fit values for these parameters may be found in the usual manner by minimizing the quantity

$$\chi^2(H_0, \Omega_{0m}) = \sum_i \frac{\left[\mu_{obs,i} - \mu_{th}(z_i; H_0, \Omega_{0m})\right]^2}{\varepsilon_i^2} \tag{87}$$

where ε_i is the uncertainty of the ith measurement.

Observational data - Constraints:

Using 156 HII galaxy measurements as a new distance indicator and implementing the model-independent GP, the Hubble constant was found to be $H_0 = 76.12^{+3.47}_{-3.44}\, km\, s^{-1} Mpc^{-1}$ which is more consistent with the recent local measurements [1790]. Using data of 130 giant HII regions in 73 galaxies with Cepheid determined distances the best estimate of the Hubble parameter is $H_0 = 71.0 \pm 2.8\,(random) \pm 2.1\,(systematic)\, km\, s^{-1} Mpc^{-1}$ [707].

Combinations of data

The Hubble constant H_0 values at 68% CL through direct and indirect measurements obtained by the different methods described in subsection 11.2.1 are shown in Table 17 and described in more detail below in Fig. 125. Also the relative probability density value of H_0 was derived by recently published studies in the literature are shown in Fig. 126.

Cosmological parameter degeneracies from each individual probe can be broken using combination of probes. The multi-probe analysis are crucial for independent H_0 determination and are required in order to reduce systematic uncertainties [1695, 464] [see 1309, for a review].

The analysis by Wong et al. [366] using a combination of SH0ES and H0LiCOW results reports $H_0 = 73.8 \pm 1.1\ km\ s^{-1} Mpc^{-1}$ which raises the Hubble tension to 5.3σ between late Universe determinations of H_0 and Planck. This has been discredited by Kochanek [1082] who points out that an artificial reduction of the allowed degrees of freedom can lead to very precise but inaccurate estimates of H_0 based on gravitational lens time delays.

The analysis by DES Collaboration [105] using a combination of the Dark Energy Survey (DES) [355, 106, 205] clustering and weak lensing measurements with BAO and BBN experiments assuming a flat ΛCDM model with minimal neutrino mass ($\Sigma m_\nu = 0.06\ eV$) finds $H_0 = 67.2^{+1.2}_{-1.0}\ km\ s^{-1} Mpc^{-1}$ which is consistent with the value obtained with CMB data.

Using an extension of the standard GP formalism, and a combination of low-redshift expansion rate data (SnIa+BAO+CC) the Hubble constant was estimated to be $H_0 = 68.52^{+0.94+2.51(sys)}_{-0.94}\, km\, s^{-1} M$ by Haridasu *et al.* [849]. Using an alternative method Baxter and Sherwin [243] analysing the current CMB lensing data from Planck combined with Pantheon supernovae and using conservative priors, find an r_s independent constraint of $H_0 = 73.5 \pm 5.3\ km\ s^{-1} Mpc^{-1}$. Analysing low-redshift cosmological data from SnIa, BAO, strong gravitanional lensing, $H(z)$ measurements using cosmic chronometers and growth measurements from LSS observations for ΛCDM model Dutta *et al.* [644] find $H_0 = 70.30^{+1.36}_{-1.35}\, km\, s^{-1} Mpc^{-1}$ which is in $\sim 2\sigma$ tension with various low and high redshift observations.

More recently, the joint analysis of lower-redshift, non-CMB, data such as BAO, $H(z)$, SnIa, QSO, HII and GRBs by Cao and Ratra [429] gives a model-independent determinations of the Hubble constant, $H_0 = 69.7 \pm 1.2\ km\ s^{-1}Mpc^{-1}$ [see also 432, 433, 430, 431, for previous joint analyses].

Many other estimates of H_0 have been obtained in the literature within the standard ΛCDM model or in alternative scenarios by using joint analysis [338, 1512]. In addition, many analyses using various combinations of data assuming a ΛCDM model or a extended model beyond ΛCDM cosmology investigate whether the H_0 tension persists (or not). For example Okamatsu *et al.* [1382] use non-CMB data and specifically adopt the data from BAO, BBN, and SnIa to study the H_0 tension. They show that this tension exists in a broad framework beyond the standard ΛCDM model.

The current status - Historic evolution

Hubble's initial value in 1929 for the expansion rate, now called the Hubble constant, was approximately $500 km\, s^{-1}Mpc^{-1}$. From the 1970s, through the 80s and into the 90s the value of H_0 was estimated to be between 50 and 100 $km\, s^{-1}Mpc^{-1}$ [1736]. Of interest is the historical Hubble constant debate between, for example, long series of papers by Gérard de Vaucouleurs, who claimed that the value of H_0 is $90 < H_0 < 100\, km\, s^{-1}Mpc^{-1}$ [e.g. 571, 570], and Allan Sandage , who claimed the value is $50 < H_0 < 55\, km\, s^{-1}Mpc^{-1}$ [1580, 1581] [see 1741, for a historical review].

During the last decades there has been remarkable progress in measuring the Hubble constant. The available technology and measurement methods determine the accuracy of this quantity. The Hubble constant as a function of publication date, using a set of different methods is shown in Fig. 127. The values of H_0 determined in the late Universe with a calibration based on the Cepheid distance scale and the derived values of H_0 from analysis of the CMB anisotropy spectrum data are shown. The uncertainties in these values have been decreasing for both methods and the recent measurements disagree beyond 4σ.

Furthermore the comoving Hubble expansion rate as a function of redshift obtained from the Planck18 CMB is shown in Fig. 128 along with a few relevant data-points demonstrating the Hubble tension.

The basic strategic questions emerge

- How can $H(z)$ derived from Cepheid late time calibrators (blue point in Fig. 128) become consistent with $H(z)$ derived from the sound horizon early time calibrator (black line in Fig. 128)?

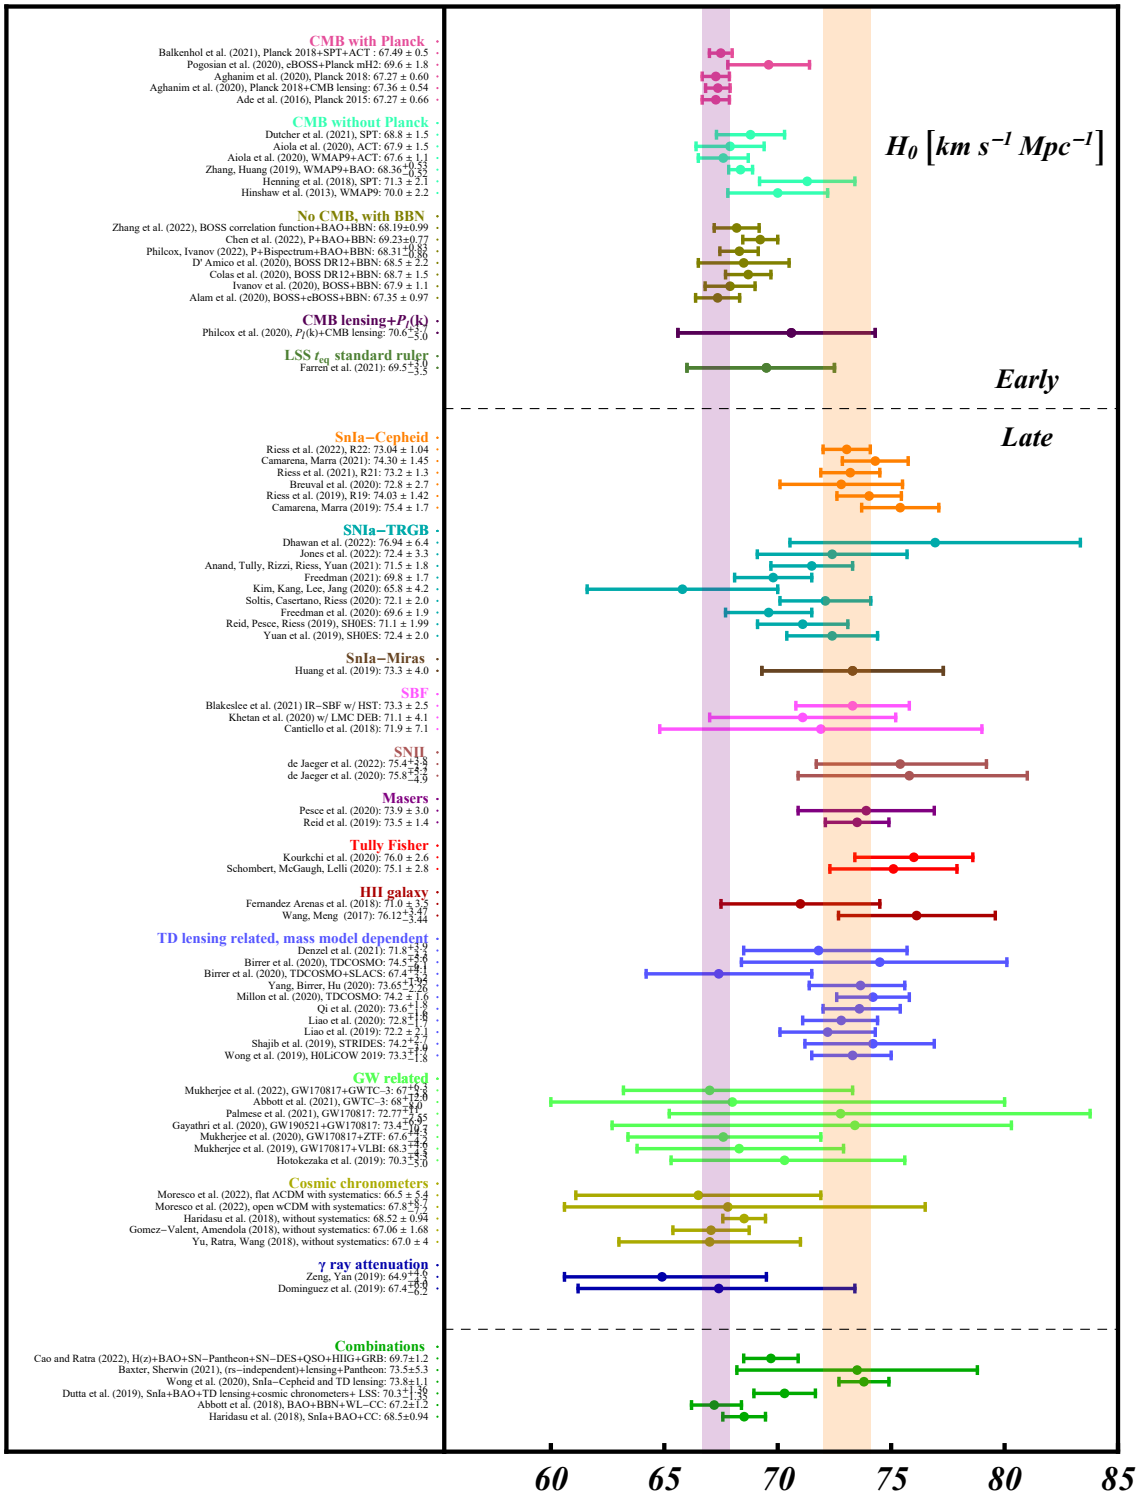

Figure 125: The Hubble constant H_0 values with the 68% CL constraints derived by recent measurements. The value of the Hubble constant H_0 is derived by early time approaches based on sound horizon, under the assumption of a ΛCDM background.

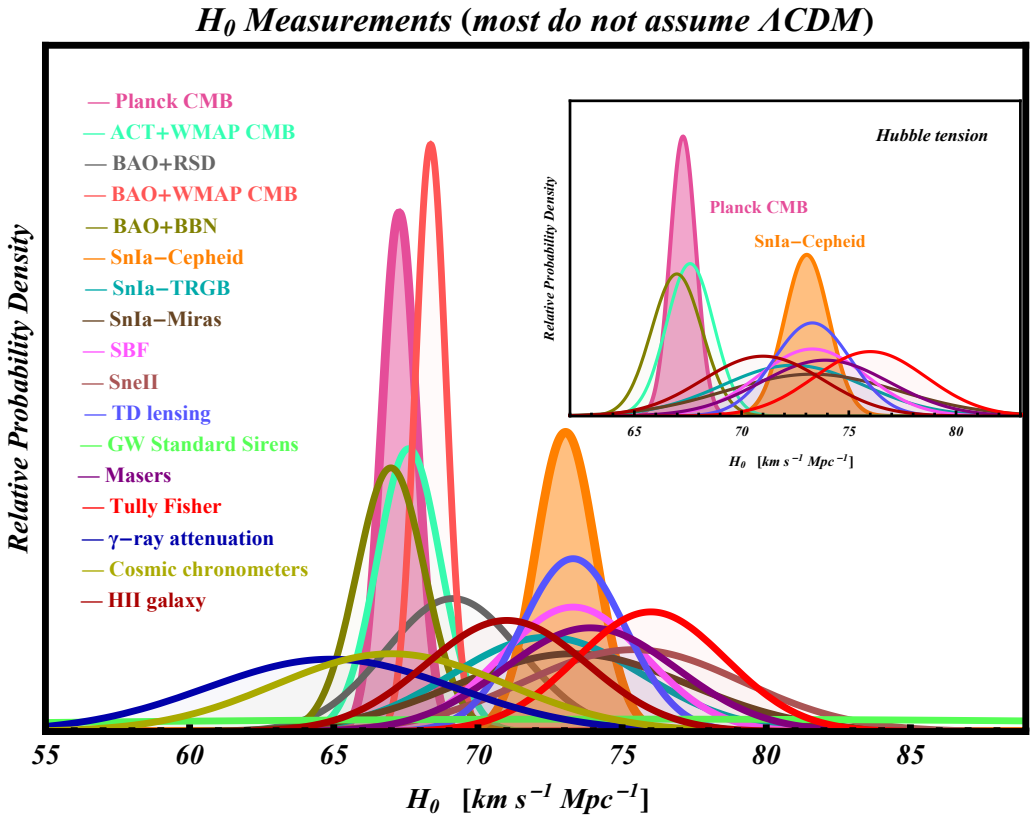

Figure 126: The one dimensional relative probability density value of H_0 derived by recent measurements (Planck CMB [72], ACT+WMAP CMB [80], BAO+RSD [1805], BAO+WMAP CMB [1901], BAO+BBN [9], SnIa-Cepheid [1529], SnIa-TRGB [988], SnIa-Miras [923], SBF [314], SneII [958], TD lensing [366], GW Standard Sirens [18], Masers [1447], Tully Fisher [1097], γ-ray attenuation [1892], cosmic chronometers [1884], HII galaxy [707]). All measurements are shown as normalized Gaussian distributions. Notice that the tension is not so much between early and late time approaches but more between approaches that calibrate based on low z ($z \lesssim 0.01$) gravitational physics and those that are independent of this assumption. For example cosmic chronometers and γ-ray attenuation which are late time but independent of late gravitational physics are more consistent with the CMB-BAO than with late time calibrators.

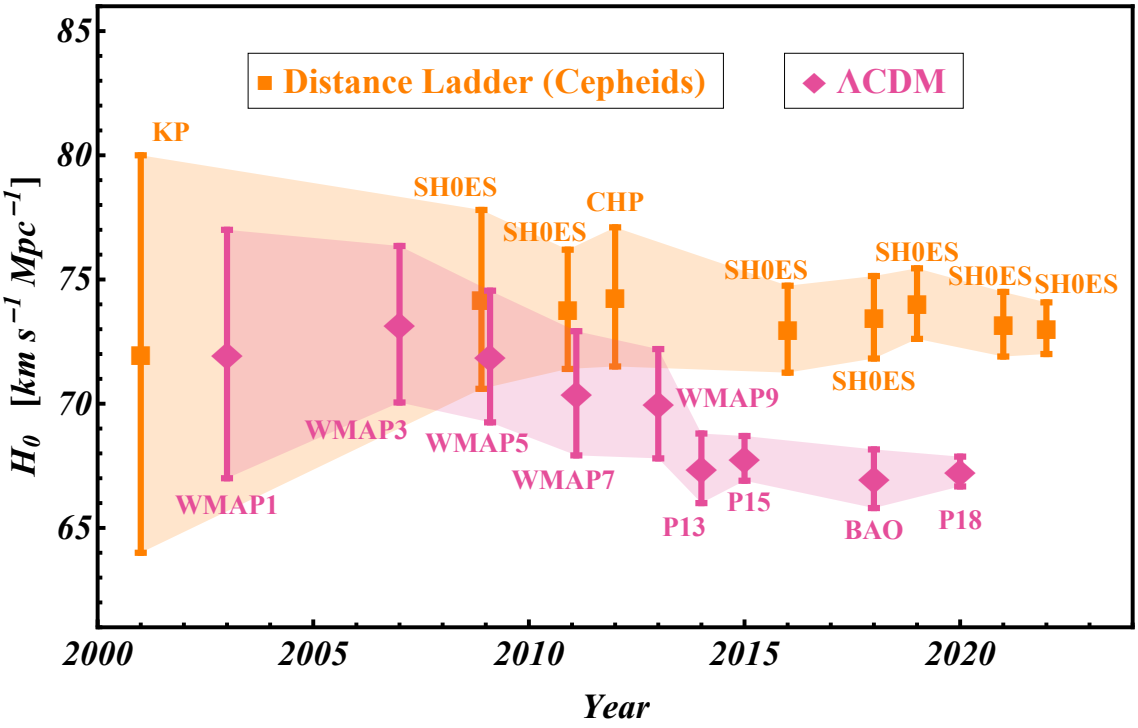

Figure 127: The Hubble constant as a function of publication date, using a set of different tools. Symbols in orange denote values of H_0 determined in the late Universe with a calibration based on the Cepheid distance scale (Key Project (KP) [737], SH0ES [1525, 308, 1526, 1528, 306, 1521, 1529], Carnegie Hubble Program (CHP) [736]). Symbols in purple denote derived values of H_0 from analysis of the CMB data based on the sound horizon standard ruler (First Year WMAP (WMAP1) [1676], Three Year WMAP (WMAP3) [1677], Five Year WMAP (WMAP5) [641], Seven Year WMAP (WMAP7) [1093], Nine Year WMAP (WMAP9) [42], Planck13 (P13) [55], Planck15 (P15) [50], Planck18 (P18) [72], BAO [9]). The orange and purple shaded regions demonstrate the evolution of the uncertainties in these values which have been decreasing for both methods. The most recent measurements disagree at greater than 4σ.

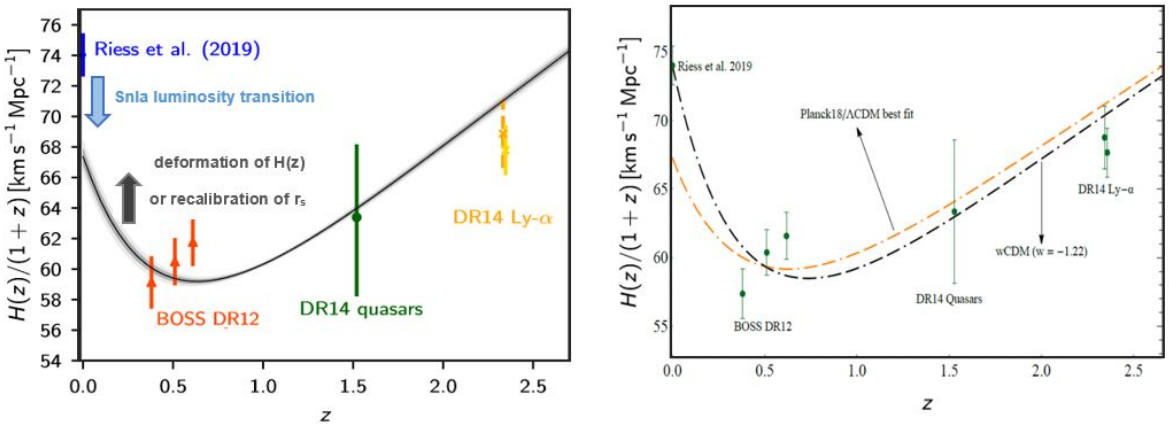

Figure 128: Left panel: The comoving Hubble parameter as a function of redshift. The black line corresponds to the best fit obtained from the Planck18 CMB when the ΛCDM model is considered, while the grey areas are the 1σ regions. The blue point at redshift zero denotes the inferred Hubble measurement by HST survey [306]. The orange points, green point, and yellow points correspond to BAO data from BOSS DR12 survey [15], BOSS DR14 quasar sample [373], and SDSS DR12 Lyα sample [1528] respectively. The arrows indicate approaches for the resolution of the Hubble tension: Down arrow (blue) corresponds to decrease of the Riess et. al. datapoint due to systematics or transition of the absolute magnitude M (light blue arrow). Up arrow (black) corresponds to recalibration of r_s which shifts the whole curve up or and late time deformation of $H(z)$ [adapted from 72]. Right panel: The comoving Hubble parameter as a function of redshift for a wCDM phantom modification of ΛCDM model which drives upward the low z part of the $H(z)$ curve shown in left panel. Thus it brings the $z = 0$ prediction of the CMB closer to the H_0 result of the local measurements (late time $H(z)$ deformation).

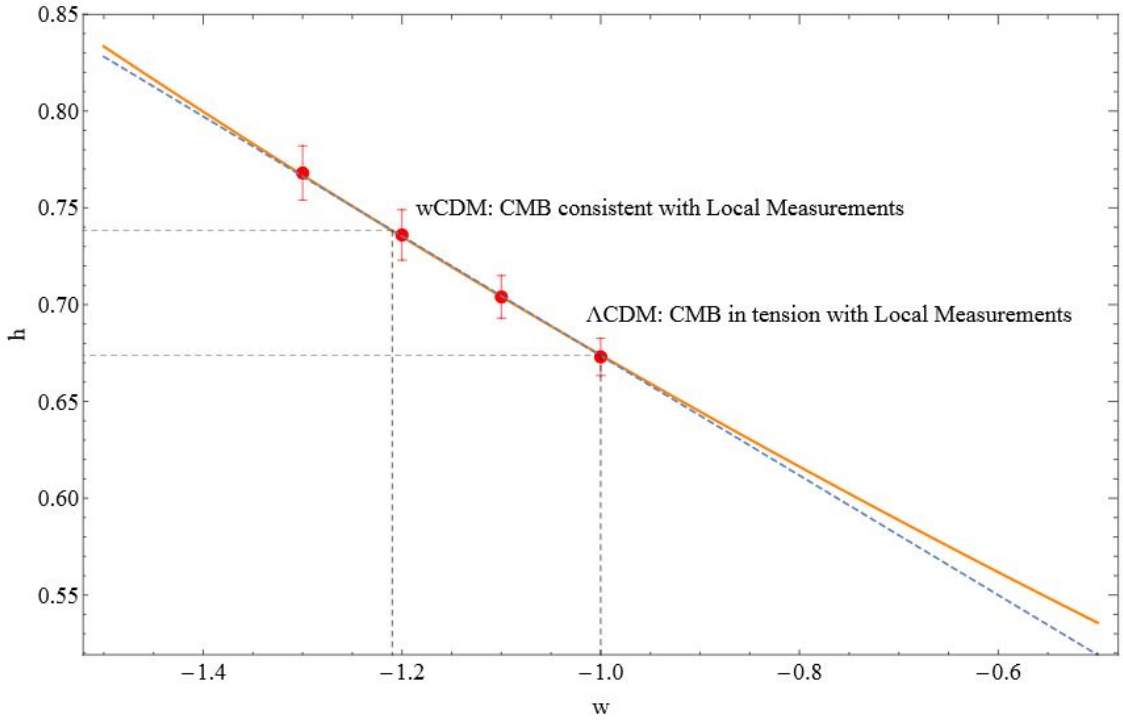

Figure 129: The predicted value of h as a function of the fixed w assuming one parameter dark energy (wCDM) model. The theoretically predicted best fit values of h for different values of w in the case of the wCDM model (orange line), whereas the linear fitting that has been made (dashed blue line). The redpoints correspond to the actual best fit values, including the errorbars, of h for specific values of w obtained by fitting these models to the CMB TT anisotropy [from 102].

- What type of systematics could move the blue point down or shift black line up in Fig. 128 in early and late time calibrators?
- To what extend can dynamical dark energy address the Hubble tension by distorting the black line in Fig. 128?

These important Hubble tension questions will be discussed in the next subsection.

11.2.2 Theoretical models

A wide range of models have been used to address the H_0 tension by introducing additional degrees of freedom to ΛCDM model where additional parameters are allowed to vary such as quintessence [746, 728, 1823, 1822, 1497, 473, 709, 710, 507, 417, 1909, 1733, 1595, 1685, 1180], in which a scalar field plays the role of dark energy or modified gravity [679, 125, 697, 1361, 1429, 330], in which General Relativity is modified on cosmological scales [see 508, 208, for a review].

The extensions of ΛCDM model which can be used to resolve the Hubble constant H_0 tension fall into two categories: models with late time and models with early time modification (in the epoch before the recombination) [see 1772, 615, 1604, for a review].

The models with late time modification can be divided in four broad classes: deformations of the Hubble expansion rate $H(z)$ at late times [e.g. late time phantom dark energy 102, 612], deformations of the Hubble expansion rate $H(z)$ with additional interactions/degrees of freedom (e.g. interacting dark energy Di Valentino *et al.* 607, Yang *et al.* 1869 and decaying dark matter Berezhiani *et al.* 283), deformations of the Hubble expansion rate $H(z)$ due to

inhomogeneous/anisotropic modifications [e.g. inhomogeneous causal horizons 729] and transition/recalibration of the SnIa absolute luminosity [1029] [or combination of the previous classes e.g. late $w - M$ phantom transition 103].

Model selection statistical tools and approaches include the Akaike Information Criterion (AIC) [81], the Bayesian Information Criterion (BIC) [1610] and the Deviance Information Criterion (DIC) [1678] and Bayesian model comparison [e.g. 1343, 1560, 1275, 1032, 1094]. These tools have been developed and used to test, discriminate and compare the proposed models [1177, 1178, 160, 1046] [see also 30, for a list of statistical tools].

Late time deformations of the Hubble expansion rate $H(z)$

These late time models for the solution of the Hubble tension use a late time smooth deformation of the Hubble expansion rate Planck18/ΛCDM $H(z)$ so that it can match the locally measured value of H_0 while keeping the radius r_s of the sound horizon at the last scattering surface (see Subsection 11.2.1). Many of these models effectively fix the comoving distance to the last scattering surface and the matter energy density $\omega_m = \Omega_{0m}h^2$ to values consistent with Planck/ΛCDM to maintain consistency with the CMB anisotropy spectrum while introducing late time phantom dark energy to deform $H(z)$ so that it matches the local measurements of $H(z)$. The required phantom behavior of such $H(z)$ deformations can not be provided by minimally coupled quintessence models and therefore such models have been shown to be unable to resolve the Hubble tension [209, 1143]. These models have three problems

- They tend to worsen the fit to low z distance probes such as BAO and SnIa [e.g. 102]
- They tend to worsen level of the growth tension [105].
- They tend to predict a lower value of SnIa absolute magnitude than the one determined by local Cepheid calibrators shown in Eq. (43) [1238, 420, 421].

Thus, these models can not fully resolve the Hubble tension [see also 101, 100, 1859, 261, 652, 157, 1709, 1110, 286, 1757, 408, 407, 675, 271].

Physical models where the deformation of $H(z)$ may be achieved include the following: phantom dark energy [e.g. 102] (see in Paragraph 11.2.2), running vacuum model [e.g. 1667] (see in Paragraph 11.2.2), phenomenologically emergent dark energy [1170] (see in Paragraph 11.2.2), vacuum phase transition [e.g. 602] (see in Paragraph 11.2.2), phase transition in dark energy [e.g. 1053] (see in Paragraph 11.2.2). Plethora of late dark energy models with an equation of state $w \neq -1$ ($w < -1$ or $w > -1$) both constant or dynamical with redshift [e.g. 1244] were proposed to address the Hubble tension. Recently, using a model-independent approach and a fully analytical analysis Heisenberg *et al.* [870, 871] derive a set of necessary conditions that any late dark energy model must satisfy in order to potentially address both the Hubble and the growth tensions. In particular, solving the H_0 tension requires $w(z) < -1$ at some z and solving both the H_0 and σ_8 tensions demands time-varying dark energy equation of state which cross the phantom divide. However Alestas and Perivolaropoulos [105] have shown that $H(z)$ deformation approaches to the Hubble tension tend to worsen the σ_8 growth tension.

The following models may be classified in this class of theories: the holographic dark energy [827, 546, 495, 1486, 1487, 1638, 877, 60], the considering Chevallier - Polarski - Linder (CPL) [471, 1190, 1068] parameterization [1865], the considering w dependence on non-vanishing spatial curvature [1286], the phantom brane dark energy [96, 197], the negative cosmological constant [1780, 416, 1618], the negative dark energy [645], the graduated dark energy [82], the simple-graduated dark energy [43], the Λ_sCDM model (sign-switching) [83], the transitional dark energy [1031], the frame dependent dark energy [62], the running H_0 with redshift [552, 1109], the varying gravitational constant [1564], the deviation from the cold dark matter

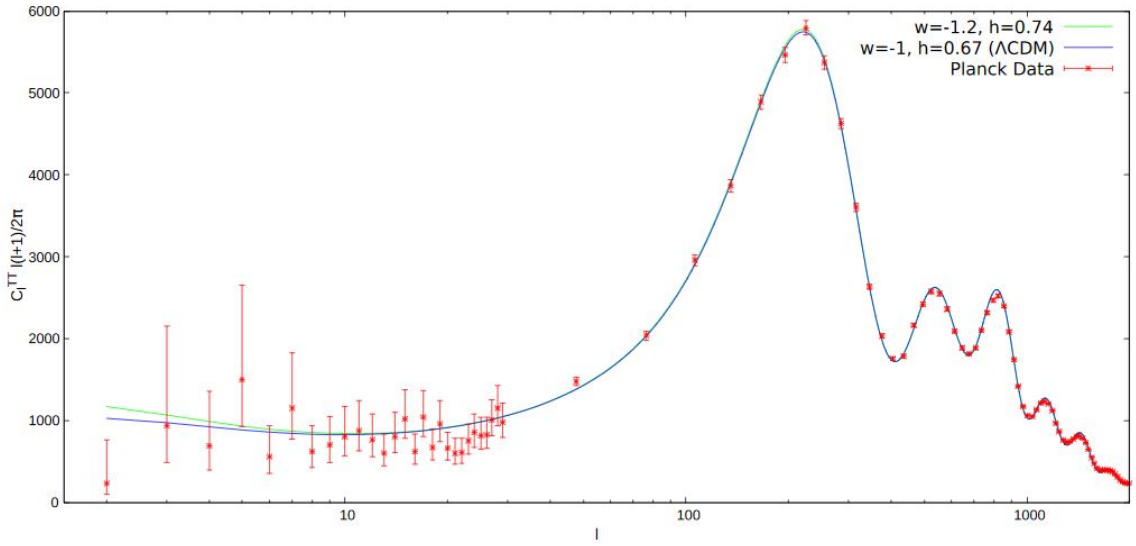

Figure 130: The predicted form of the CMB TT anisotropy spectrum with $w = -1$, $h = 0.67$, $\Omega_{0m} = 0.314$ for ΛCDM (blue line) and with $w = -1.2$, $h = 0.74$, $\Omega_{0m} = 0.263$ (green line). Red points correspond to the binned high-l and low-l Planck data [from 102].

[665] and the phantom crossing [617]. For example in the case of the holographic dark energy model [546] and phantom crossing [617] models the tension on H_0 appears to be significantly alleviated within 1σ even though the three problems mentioned above do remain.

Phantom dark energy:

The deformation of $H(z)$ through the implementation of late time phantom dark energy [102, 612, 606, 614, 1752, 926] can address the Hubble tension as shown in Fig. 128.

The analysis by Alestas *et al.* [102] indicates that mildly phantom models with mean equation of state parameter $w = -1.2$ have the potential to alleviate this tension. It was shown that the best fit value of H_0 in the context of the CMB power spectrum is degenerate with a constant equation of state parameter w. The CMB anisotropy spectrum was shown to be unaffected when changing $H(z)$ provided that specific parameter combinations remain unchanged. These cosmological parameters fix to high accuracy the form of the CMB anisotropy spectrum. The values of these parameters as determined by the Planck/ΛCDM CMB temperature power spectrum are the following [72].

$$\omega_{m,Planck} = 0.1430 \pm 0.0011 \tag{88}$$
$$\omega_{b,Planck} = 0.02237 \pm 0.00015 \tag{89}$$
$$\omega_{r,Planck} = (4.64 \pm 0.3)\ 10^{-5} \tag{90}$$
$$\omega_{k,Planck} = -0.0047 \pm 0.0029 \tag{91}$$
$$d_{A,Planck} = (4.62 \pm 0.08)\ (\ 100\ km\ s^{-1} Mpc^{-1})^{-1} \tag{92}$$

where $\omega_{i,Planck} = \Omega_{0i,Planck} h^2$ is the energy density of component i and $d_{A,Planck}$ is the comoving angular diameter distance.

Using the Eq. (41) the comoving angular diameter distance d_A to the recombination surface is ($c = 1$)

$$d_A = \int_0^{z_r} \frac{dz}{H(z)} = \int_0^{z_r} \frac{dz}{h(z)\ 100\ km\ s^{-1} Mpc^{-1}} \tag{93}$$

where $z_r \simeq 1100$ is the redshift of recombination and $h(z) = H(z)(\,100\,km\,s^{-1}Mpc^{-1})^{-1}$ is the dimensionless Hubble parameter which in general takes the form

$$h(z) = \big[\omega_r(1+z)^4 + \omega_m(1+z)^3 + \\ +(h^2 - \omega_r - \omega_m) f_{DE}(z)\big]^{1/2} \tag{94}$$

where $h = h(z=0)$ and $f_{DE}(z)$ determines the evolution of dark energy.

In the context of a simple one parameter parametrization where the equation of state w remains constant in time and redshift (wCDM model), $f_{DE}(z)$ takes the simple form

$$f_{DE}(z) = (1+z)^{3(1+w)} \tag{95}$$

If the four energy densities Eqs. (88), (89), (90) and (91) and the observed value of the comoving angular diameter Eq. (92) are fixed then they provide the analytically predicted best fit value of the Hubble parameter H_0 (or h) given the dark energy equation of state parameter $w(w_0, w_1, ..., z)$ where w_0, w_1,... are the parameters entering the $w(z)$ parametrization. Thus assuming a flat Universe ($\omega_k = 0$) and solving the following equation with respect to h

$$d_A(\omega_{m,Planck}, \omega_{r,Planck}, \omega_{b,Planck}, h = 0.674, w = -1) = \\ d_A(\omega_{m,Planck}, \omega_{r,Planck}, \omega_{b,Planck}, h, w) \tag{96}$$

it is straightforward to derive the degeneracy function $h(z = 0, w) \equiv h$ shown in Fig. 129 (continuous orange line). In the range $w \in [-1.5, -1]$, $h(w)$ is approximated as a straight line (dashed blue line in Fig. 129)

$$h(w) \approx -0.3093w + 0.3647 \tag{97}$$

For $w = -1$, this linear degeneracy equation leads to the best fit dimensionless Hubble constant $h = 0.674$ as expected while for $w = -1.217$ the corresponding predicted CMB best fit is $h = 0.74$ which is consistent with the value obtained by local distance ladder measurements. The invariance of the CMB power spectrum when the cosmological parameters are varied along the above described degeneracy directions is shown in Fig. 130. This method of Alestas *et al.* [102] can be used to find general degeneracy relations between $f_{DE}(z)$ and H_0 and fixing $h = 0.74$ gives infinite $f_{DE}(z)$, $w(z)$ forms that can potentially resolve the H_0 problem if they can also properly fit the low z date (e.g. BAO, SnIa, Cepheid value of absolute luminosity M). Low z distance data (BAO and SnIa) will determine which one of these forms is observationally favored. However, none of these forms can provide a quality of fit to low z data equally good or better than ΛCDM despite the introduced additional parameters. In addition, these models suffer from the other two problems mentioned above (worse growth tension and lower value of SnIa absolute magnitude).

Running vacuum model:

The running vacuum models (RVM) [1667, 1666, 1631, 1629, 1630, 236, 1427, 229, 1427, 1732, 213, 695, 231, 1181, 1306, 230, 1257, 1515, 1260, 1261, 1628, 232] [see 1425, 1661, 1662, 1665, 1663, 1664, 1259, 1258, for a review] attempts to address both the Hubble constant H_0 tension [1658] and the σ_8 growth tension using a mechanism that has common features with the IDE models [e.g. 1656, 1657, 795, 796, 1668, 1671] (for relaxing the growth tension, see Subsection 11.3.1).

The RVM of the cosmic evolution is well motivated by the generic idea of renormalization group formalism which is used in Quantum Field Theory (QFT) [1660, 1626, 1627] [see also

1306, 1305, for a approach using adiabatic regularization and renormalization techniques]. In the RVM the cosmological constant, the corresponding vacuum energy density and pressure are assumed to be functions of the Hubble rate e.g. a power series of the Hubble rate and its cosmic time derivative with even time derivatives of the scale factor [799]

$$\Lambda = a_0 + \sum_{k=1} a_k H^{2k} + \sum_{k=1} b_k \dot{H}^k, \tag{98}$$

$\rho_\Lambda = \rho_\Lambda(H) = \frac{\Lambda(H)}{8\pi G}$ and $p_\Lambda = p_\Lambda(H) = -\rho_\Lambda(H)$ respectively.

For the current Universe the vacuum energy density can be written in the relatively simple form [e.g. 1665, 799, 1659, 1658]

$$\rho_\Lambda(H) = \frac{\Lambda(H)}{8\pi G} = \frac{3}{8\pi G}(c_0 + \nu H^2) \tag{99}$$

where $c_0 = H_0^2(\Omega_{0\Lambda} - \nu) \simeq \frac{\Lambda_0}{3}$ (with Λ_0 the current value) is an integration constant which is fixed by the boundary condition $\rho_\Lambda(H_0) = \rho_{\Lambda,0}$ (with $\rho_{\Lambda,0}$ the current value) and ν is a dimensionless running parameter which characterizes the dynamics of the vacuum at low energy. For $\nu = 0$ the vacuum energy remains constant at all times and for $\nu > 0$ the vacuum energy density decreases with the time. In QFT the running parameter is $|\nu| \simeq 10^{-6} - 10^{-3}$ [1660] but in RVM it has been treated as a free parameter by fitting to the observational data [e.g. 799, 1659].

Phenomenologically emergent dark energy:

Phenomenologically emergent dark energy (PEDE) is a zero freedom dark energy scenario proposed by Li and Shafieloo [1170]. In this model the dark energy density has the following form

$$\tilde{\Omega}_{DE}(z) = \Omega_{0DE}\left[1 - \tanh\left(\log_{10}(1+z)\right)\right] \tag{100}$$

where $\Omega_{0DE} = 1 - \Omega_{0m} - \Omega_{0r}$.

The dark energy in this model has no effective presence in the past and emerges at the later times and with the same number (six) of parameters compared to the spatially flat ΛCDM scenario. It has the potential for alleviating the H_0 tension [1170, 1401, 1856, 1200, 1514, 1857, 600]. The generalised emergent dark energy (GEDE) model has one extra dimensionless free parameter Δ including both ΛCDM model as well as the PEDE model as two of its special limits introduced by Li and Shafieloo [1171]. In the GEDE model the dark energy density has the following form [1858]

$$\tilde{\Omega}_{DE}(z) = \Omega_{0DE}\frac{1 - \tanh\left(\Delta \log_{10}(\frac{1+z}{1+z_t})\right)}{1 + \tanh\left(\Delta \log_{10}(1+z_t)\right)} \tag{101}$$

where z_t is the transition redshift where dark energy density equals to matter density. For $\Delta = 0$ and $\Delta = 1$ this model recovers ΛCDM and PEDE model respectively. Using the latest observational Hubble dataset Hernández-Almada *et al.* [878] revisited and constrained the free parameters of the PEDE and GEDE models.

Other versions of the PEDE model are the Modified Emergent Dark Energy (MEDE) [257] and the Transitional Dark Energy (TDE) [1908] models. The MEDE model with one extra degree of freedom reduces the Hubble tension to 2.4σ [257] even though it also suffers from the three problems of the late time $H(z)$ deformation models.

Vacuum phase transition:

Vacuum phase transition [602, 603, 618, 600] based on vacuum metamorphosis (VM) or vacuum cold dark matter model (VCDM) [1407, 1408, 418] has the potential to address the H_0 tension. This mechanism with six free parameters as the spatially flat ΛCDM. It also assumes a phase transition in the nature of the vacuum similar to Sakharov's induced gravity [1563]. The phase transition occurs when the evolving Ricci scalar curvature R becomes equal to the value of scalar field mass squared m^2 [602]

$$R = 6(\dot{H} + H^2) = m^2 \tag{102}$$

where the dot corresponds to the derivative with respect to cosmic time t. After the transition the Ricci scalar curvature remains constant with $R = m^2$ and this changes the expansion rate below ($z < z_t$) due to the phase transition

$$\frac{H^2}{H_0^2} = \Omega_{0m}(1+z)^3 + \Omega_{0m}(1+z)^3 + \\ + M\left\{1 - \left[3\left(\frac{4}{3\Omega_{om}}\right)^4 M(1-M)^3\right]^{-1}\right\}, \; z > z_t \tag{103}$$

$$\frac{H^2}{H_0^2} = (1-M)(1+z)^4 + M, \; z \leq z_t \tag{104}$$

where $M = \frac{m^2}{12H_0^2}$ and $z_t = -1 + \frac{3\Omega_{0m}}{4(1-M)}$ is the transition redshift.

Phase transition in dark energy:

- Phase transition in dark energy explored by Khosravi *et al.* [1053], Banihashemi *et al.* [215, 216], Moshafi *et al.* [1315] can address the Hubble tension. Generalizing this model by assigning a more realistic time evolution of dark energy Banihashemi *et al.* [214] propose the critically emergent dark energy (CEDE) model.

  In Farhang and Khosravi [690] the form of phase transition parametrized phenomenologically by a hyperbolic tangent function. This scenario for dark energy is similar used independently as PEDE and GEDE.

- Late dark energy (LDE) transition [261] at redshifts $z \ll 0.1$ can reduce the Hubble tension. This class of $H(z)$ deformation models has a more intense form of the third problem of the deformation class as they predict a significantly lower value of the SnIa absolute magnitude than the other $H(z)$ deformation models [103, 421].

  In this scenario the true Hubble constant is given by [1311, 261]

  $$H_0^2 = \tilde{H}_0^2(1 + 2\delta) \tag{105}$$

  where $\tilde{H}_0$ is the prediction for a flat ΛCDM model in the context of a CMB sound horizon calibration.

  In Benevento *et al.* [261], Dhawan *et al.* [590] it was shown that this model can not fully resolve the Hubble problem as it would imply a transition in the SnIa apparent magnitude which is not observed. These models however become viable in the context of a SnIa absolute magnitude transition [103, 1238].

Deformations of the Hubble expansion rate $H(z)$ with additional interactions/degrees of freedom

There exist several varieties of the models for the solution of the Hubble tension which use deformations of the Hubble expansion rate $H(z)$ with additional interactions/degrees of freedom. For example the interacting dark energy models [e.g. 607, 1869] (see in Paragraph 11.2.2) with an extra non-gravitational interaction between the components of the Universe and the decaying dark matter models [e.g. 283] (see in Paragraph 11.2.2) with additional degrees of freedom are able to alleviate the Hubble constant H_0 tension.

The following models may be classified in this class of theories: multi-interacting dark energy [1205], new interacting dark energy [758], interacting vacuum energy [1118], metastable dark energy [1172, 1855], Quintom dark energy [1405], cannibal dark matter [387], baryons-dark energy interacting [978] [see also 1759, 704], swampland conjectures [1374, 497, 75], non-local gravity [39, 250], late time transitions in the quintessence field [599], Galileon gravity [1510, 1911, 1424, 744, 869], $f(R)$ gravity [1378, 545, 1789, 981], $f(T)$ gravity [1367, 1792, 1507, 414, 858, 371, 270, 201, 1508], $f(T, B)$ gravity [674], $f(Q)$ gravity [1227], Brans-Dicke gravity [1669, 1670], minimal theory of massive gravity [149], scale–dependent gravity [115], unimodular gravity [1426, 1185], the screened fifth forces [583, 584], the minimally modified gravity [568], the Lifshitz cosmology [280], the Milne cosmology [1779], 4D Gauss-Bonnet gravity [1793], the generalized Chaplygin gas [1872], the unified cosmologies [1871], the Λ-gravity [830, 831], the $\Lambda(t)$-model [260, 259], the bulk viscous cosmology [666, 1639, 1864, 1364] and the surface tension hypothesis [1390]. For instance in the case of the metastable dark energy [1855], generalized Chaplygin gas [1872] and Galileon gravity [1510] models the tension on H_0 appears to be significantly alleviated to within about 1σ even though the there problems of the $H(z)$ deformation models remain to be addressed.

Interacting dark energy:

In the cosmological interacting dark energy (IDE) models [1370, 1193, 904, 1226, 1632, 446, 445, 21, 1803, 1571, 521, 1478, 1449, 1572, 1119, 1842, 1120, 1763, 607, 1868, 1873, 1867, 1861, 1863, 1167, 131, 801, 1122, 1403, 1860, 1869, 794, 109, 609, 1243, 608, 1875, 1874, 1206, 1854, 1853, 128, 984, 1400] [see 1788, 332, for a review] the dark components of the Universe i.e dark matter (DM) and dark energy (DE) have an extra non-gravitational interaction. The IDE model was proposed to address the coincidence problem [e.g. 501, 928, 411, 1410, 1900, 424, 284, 425, 866]. In addition the interaction between the dark fluids has been shown to be effective in substantially alleviating the Hubble constant H_0 tension [1861, 1863, 607, 610, 1400, 1119, 1869, 1206, 1800, 763, 1368, 826, 1402] or in addressing the structure growth σ_8 tension between the values inferred from the CMB and the WL measurements [1479, 132, 222, 422] (see Subsection 11.3.1) or in solving the two tensions simultaneously [1120, 1122, 609].

In IDE cosmology assuming spatially flat Friedmann-Lemaitre-Roberson-Walker background and pressureless dark matter ($w_c = 0$) the equations of evolution of the dark matter and dark energy densities ρ_c and ρ_{DE} respectively are given by [766]

$$\dot{\rho}_c + 3H\rho_c = Q(t) \tag{106}$$

$$\dot{\rho}_{DE} + 3H(1 + w_{DE})\rho_{DE} = -Q(t) \tag{107}$$

where the dot corresponds to the derivative with respect to cosmic time t, $w_{DE} = \frac{p_{DE}}{\rho_{DE}}$ is the equation of state of dark energy and Q represents the interaction rate between the dark sectors (i.e. the rate of energy transfer between the dark fluids). For $Q < 0$ energy flows from dark matter to dark energy, whereas for $Q > 0$ the energy flow is opposite.

These models combine the deformation of $H(z)$ with an extra modification of the growth rate of perturbations due to the tuned evolution of $\Omega_m(z)$ induced by the interaction term Q.

This additional tuning allows for a simultaneous improvement of the growth tension in contrast to models that involve a simple $H(z)$ deformation.

Various phenomenological IDE models were proposed in the literature where the rate of the interaction Q has a variety of possible functional forms [1399]. For example in some classes of IDE models the rate of the interaction Q is proportional to the energy density of dark energy $Q = \delta\, H \rho_{DE}$ [1120, 1122, 1869, 609] or cold dark matter $Q = \delta\, H \rho_c$ [1119] (where δ is a constant and $\delta = 0$ in the ΛCDM cosmology), or some combination of the two. Note that in the case of functional form $Q = \delta\, H \rho_c$ instabilities develop in the dark sector perturbations at early times [867].

Decaying dark matter:

Decaying dark matter into dark radiation (i.e. an unknown relativistic species that is not directly detectable), which has been first analysed by Ichiki *et al.* [937] and studied by **?** Chudaykin *et al.* [483], Bjaelde *et al.* [304], Wang *et al.* [1802], Anchordoqui *et al.* [137], Xiao *et al.* [1843], Choi *et al.* [475, 474], Nygaard *et al.* [1373], provides a promising scenario to relieve the Hubble constant H_0 tension [e.g. 283]. Also, it has been shown that this scenario can resolve the σ_8 growth tension [668, 36] or the two tensions simultaneously [1404] by a similar mechanism as in the IDE models. However, using the Planck data the analysis of the model by Poulin *et al.* [1474], Chudaykin *et al.* [482] has shown that the cosmological tensions are only slightly alleviated [see 373, for a different result].

In these models assuming spatially flat Friedmann-Lemaitre-Roberson-Walker Universe, pressureless dark matter, $w_c = 0$ and equation of state of dark radiation $w_{DR} = 1/3$, the equations of evolution of the dark matter and dark radiation densities ρ_c and ρ_{DR} respectively are given by [766]

$$\dot{\rho}_c + 3H\rho_c = -\Gamma\rho_c \tag{108}$$

$$\dot{\rho}_{DR} + 4H\rho_{DR} = \Gamma\rho_c \tag{109}$$

where $\Gamma = \frac{1}{\tau}$ is the decay rate of dark matter particles (with τ the particle's lifetime). In the literature a variety of possible functional forms of the decay rate has been explored [668, 215, 1474, 373]. For example in some cases the decay rate is proportional to the Hubble rate, $\Gamma \propto H$ [1404]. Constraints on the decay rate of dark matter have been obtained by the analysis of Ando and Ishiwata [143], Enqvist *et al.* [668].

A model with decaying dark matter into dark radiation in early/late Universe ($\tau \ll t_s$ / $\tau \gg t_s$, where t_s is the time of last scattering) increases/decreases the expansion rate $H(a; \rho_b, \rho_\gamma, \rho_c, \rho_{DR}, \rho_{DE})$ at high/low redshifts as it predicts a smaller matter content and a larger radiation content as time evolves (the early/late Universe is dominated by the radiation/matter and the dark radiation density decreases more rapidly than the matter density, $\rho_{DR} \propto a^{-4}$ and $\rho_c \propto a^{-3}$). In the case of $\tau \ll t_s$, the faster cosmological expansion $H(z)$ decreases the scale of the sound horizon r_s in Eq. (58) because the baryon-to-photon ratio, and thus c_s in Eq. (59), is tightly constrained by CMB fluctuations and BBN [57]. In the context of the degeneracy $H_0 r_s$ shown in Eq. (60) the lower scale of the sound horizon r_s yields a larger value of H_0. In the case of $\tau \gg t_s$, the lower dimensionless normalized Hubble rate $E(z)$ in the late-time leads to a larger value of H_0 since θ_s and r_s must be kept fixed in Eq. (60). Accordingly, both early and late decaying dark matter model are able to alleviate the Hubble constant H_0 tension [see 135, 138, for a detailed discussion].

There are alternative decaying dark matter models such as the light dark matter [99], the dynamical dark matter [582], the many-body or 2-body decaying cold dark matter scenarios [305] and the decaying warm dark matter scenario [322]. In the 2-body decaying cold dark matter scenario the decaying dark matter produces two particles, one massive warm dark matter

particle and one massless relativistic particle (dark radiation). This scenario can address the Hubble constant H_0 tension [1766, 488, 850] and the σ_8 growth tension [35].

A self-interacting dark matter model with a light force mediator coupled to dark radiation studied by Binder *et al.* [297], Hryczuk and Jodlowski [916]. This model can simultaneously reduce the tension between CMB and low-redshift astronomical observations of H_0 and σ_8.

Jaeckel and Yin [956] pointed out that a dark particle from reheating [957] can alleviate the H_0 tension through its decay to relativistic component which contributes to the dark radiation.

Recently, Ly-α constraints on possible models of dark-matter physics have been evaluated by Dienes *et al.* [625]. In particular the Ly-α bounds on different classes of dark-matter velocity distributions have been obtained.

Deformations of the Hubble expansion rate $H(z)$ with inhomogeneous/anisotropic modifications

Models where the cosmological principle and the FLRW metric are relaxed by considering inhomogeneous/anisotropic modifications have the potential to resolve the Hubble problem [1013]. Physical models where the deformation of $H(z)$ may be achieved with inhomogeneous/anisotropic modifications, include the following: Chameleon dark energy [e.g. 406] (see in Paragraph 11.2.2), cosmic voids [1840] (see also Paragraph 11.2.2) and inhomogeneous causal horizons [729] (see also Paragraph 11.2.2), charged dark matter [977, 254, 255], Bianchi type I spacetime [84] and emerging spatial curvature [868, 331].

Chameleon dark energy:

Chameleon dark energy [1057, 1056] [see also 364, 211, 562, 366, 1798, 1748, 1055, 1758, 269] attempts to address the Hubble constant H_0 tension by introducing a cosmic inhomogeneity in the Hubble expansion rate at late-time from the chameleon field coupled to the local matter overdensities [406]. This field trapped at a higher potential energy density acts as an effective cosmological constant and results in a faster local expansion rate than that of the background with lower matter density.

Cosmic voids:

In cosmic void models the local H_0 departs significantly from the cosmic mean H_0 because of the presence of an under-dense region (local void) [1201]. However in Wu and Huterer [1840], Kenworthy *et al.* [1045] it was shown that this alternative theory is inconsistent with current observations. The analysis was based on the assumption of the validity of standard ΛCDM and a study of the sample variance in the local measurements of the Hubble constant this alternative theory has been shown inconsistent with current observations. Wu and Huterer [1840] estimated that the required radius of void to resolve the tension in H_0 is about 150 Mpc and density contrast of $\delta \equiv \frac{\rho-\bar{\rho}}{\bar{\rho}} \simeq -0.8$ which is inconsistent at $\sim 20\sigma$ with the ΛCDM cosmology [1045, 859].

In the context of this inconsistency, Haslbauer *et al.* [859] considered a cosmological Milgromian dynamics or modified Newtonian dynamics (MOND) model [1288] with the presence of $11eV/c^2$ sterile neutrinos[72] to show that the Keenan-Barger-Cowie (KBC) void[73] has the potential to resolve the Hubble tension.

[72]Sterile neutrinos are a special kind of neutrino with right handed chirality that might interact only through gravity [113, 352] [see 1127, 8, 637, for a review]. They have been proposed to resolve some anomalies in neutrino data.

[73]The KBC void [1036] is a large local underdensity between 40 and 300 Mpc (i.e. $0.01 \lesssim z \lesssim 0.07$) around the Local Group.

Inhomogeneous Causal Horizons:

Fosalba and Gaztañaga [729] proposed a simple solution to the H_0 tension based on causally disconnected regions of the CMB temperature anisotropy maps from Planck [69]. It was pointed out that CMB maps show 'causal horizons' where cosmological parameters have distinct values. This could be justified by the fact that these regions of the Universe have never been in causal contact. Thus it was shown that the Hubble constant H_0 takes values which differ up to 20% among different causally disconnected regions. These cosmological parameter inhomogeneities are in agreement with the model of the Universe proposed in Gaztanaga [768] (see also Gaztanaga 769, 772, 770 for details) where the cosmological constant is simply formulated as a boundary term in the Einstein equations and where 'Causal Horizons' naturally arise. Thus if there are similar 'causal horizons' in the local universe (i.e, $z < 1100$), then 20% variations between the local and high-z measures of H_0 are indeed to be expected [729].

Late time modifications - Transition/Recalibration of the SnIa absolute luminosity

This class of models can address the problems of the $H(z)$ deformation models (especially the low M problem) by assuming a rapid variation (transition) of the SnIa intrinsic luminosity and absolute magnitude due e.g. to a gravitational physics transition at a redshift $z_t \lesssim 0.01$ [1238, 103, 100].

Gravity and evolution of the SnIa intrinsic luminosity:

As shown in the recent analysis by Kazantzidis and Perivolaropoulos [1029] there are abnormal features which may be interpreted as evolution of the measured parameter combination $\mathcal{M}$ (see Section 11.2.1). This measured parameter combination $\mathcal{M}$ in Eq. (51) depends on the absolute magnitude M and on the Hubble constant H_0 (M and H_0 are degenerate parameters). Any variation of the parameter $\mathcal{M}$ is due to a variation of M which could be induced by a varying $\mu_G(z) \equiv \frac{G(z)}{G_0}$ (where G_0 is the local value of the Newton's constant $G(z)$). If the calibrated SnIa absolute magnitude M were truly constant then the parameter $\mathcal{M}$ should also be constant (independent of redshift).

A possible variation of the absolute magnitude M and equivalently of the absolute luminosity

$$L \sim 10^{-2M/5} \tag{110}$$

could be due to a variation of the fine structure constant α or the Newton's constant G.

If the absolute luminosity is proportional to the Chandrasekhar mass $L \sim M_{Chandr}$ we have [759, 771]

$$L \sim G^{-3/2} \tag{111}$$

Thus L will increase as G decreases[74].

Under these assumptions, we obtain

$$M(z) - M_0 = \frac{15}{4} \log \mu_G(z) \tag{112}$$

where M_0 corresponds to a reference local value of the absolute magnitude and $\mu_G \equiv \frac{G}{G_0}$ is the relative effective gravitational constant (with G the strength of the gravitational interaction and G_0 the locally measured Newton's constant).

[74] Adopting a semi-analytical model which takes into account the stretch of SnIa light curves but assumes fixed mass of Ni, obtains SnIa light curves in the context of modified gravity Wright and Li [1837] have claimed that L will increase as G increases.

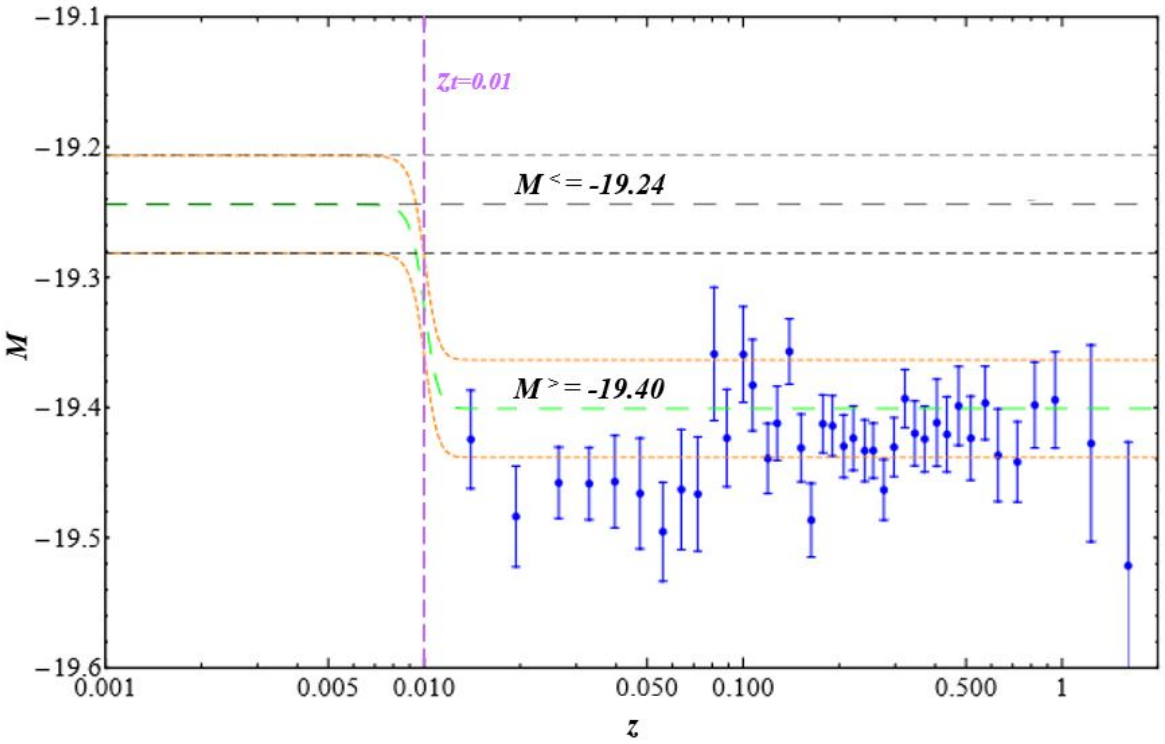

Figure 131: The Pantheon binned SnIa absolute magnitudes Eq. (117) M_i (blue points) [329] for a Planck/ΛCDM luminosity distance. The data are inconsistent with the SnIa absolute magnitude $M^< = -19.24$ calibrated by Cepheids but the inconsistency disappears if there is a transition in the absolute magnitude with amplitude $\Delta M \simeq -0.2$ at redshift $z_t \simeq 0.01$ [from 1238].

Then, the Eq. (51) takes the following form

$$\mathcal{M}(z) = M_0 + \frac{15}{4}\log\mu_G(z) + 5\log_{10}\left[\frac{c/H_0}{Mpc}\right] + 25 \tag{113}$$

and the apparent magnitude Eq. (52) can be written as

$$m(z, H_0, \Omega_{0m})_{th} = \mathcal{M}(z, H_0) + 5\log_{10}\left[D_L(z, \Omega_{0m})\right] \tag{114}$$

A mild tension at 2σ level in the best fit value of $\mathcal{M}$ was found in between the low-redshfit ($z \lesssim 0.2$) data and the full Pantheon dataset in the context of a ΛCDM model. This tension can be interpreted as [1029]

- a locally higher value of H_0 by about 2%, corresponding to a local matter underdensity.
- a time variation of Newton's constant which implies an evolving Chandrasekhar mass and thus an evolving absolute luminosity L and absolute magnitude M of low z SnIa.

In addition, the oscillating features shown in Fig. 119 hint also to the possibility of evolutionary effects of M. As discussed below such evolutionary effects if they exist in the form of a transition may provide a solution to the Hubble and growth tensions.

Transition of the SnIa absolute magnitude M at a redshift $z \simeq 0.01$:

Recently, Marra and Perivolaropoulos [1238] have proposed that a rapid transition (abrupt deformation) at a transition redshift $z_t \simeq 0.01$ in the value of the SnIa absolute magnitude M

of the form

$$M^{>}(z) = M^{<} + \Delta M\, \Theta(z - z_t) \tag{115}$$

(where Θ is the Heaviside step function) due to a rapid transition of the gravitational constant can address the Hubble tension.

In particular the analysis by Marra and Perivolaropoulos [1238] has shown that a 10% rapid transition in the value of the relative effective gravitational constant μ_G at $z_t \simeq 0.01$ is sufficient to induce the required reduction of M

$$\Delta M \equiv M^{>} - M^{<} \simeq -0.2 \tag{116}$$

where $M^{<}$ is the SnIa absolute magnitude of Eq. (54) calibrated by Cepheids at $z < 0.01$ [420, 421] and $M^{>}$ is the SnIa absolute magnitude of Eq. (55) using the parametric-free inverse distance ladder of Camarena and Marra [419]. Fig. 131 shows the Pantheon SnIa absolute magnitudes for a Planck/ΛCDM luminosity distance [329] obtained from

$$M_i = m_i - 5\log_{10}\left[\frac{d_L(z_i)}{Mpc}\right] - 25 \tag{117}$$

where m_i are the apparent magnitude datapoints.

The data are in disagreement with the SnIa absolute magnitude $M^{<}$ calibrated by Cepheids but they become consistent if there is a transition in the absolute magnitude with amplitude $\Delta M \simeq -0.2$ [1238]. Thus, this class of M-transition models avoids the M-problem of late time $H(z)$ deformation models.

Assuming the power law dependence Eq. (111) and using RSD and WL data [107, 1646, 102] reported a best fit value $\Delta\mu_G \equiv \mu_G^{>} - \mu_G^{<} = -0.19 \pm 0.09$ ($\mu_G^{>}$ corresponds to $z > 0.01$ and $\mu_G^{<}$ corresponds to $z < 0.01$) in the context of a ΛCDM background $H(z)$. The analysis by Marra and Perivolaropoulos [1238] showed that a rapid $\sim 10\%$ increase of the effective gravitational constant roughly 150 million years ago can also solve Ω_m-σ_8 growth tension.

Recently, Alestas and Perivolaropoulos [105] have demonstrated that this model has an advantage over both early time and late time deformations of $H(z)$ to fully resolve the Hubble tension while at the same time improving the level of the Ω_m-σ_8 growth tension. In addition it has the potential to provide equally good fit to low z distance probes such as BAO and SnIa as the Planck18/ΛCDM model.

More recently, Perivolaropoulos and Skara [1442] generalized the symmetron screening mechanism[75] [896, 897] by allowing for an explicit symmetry Z_2 breaking of the symmetron ϕ^4 potential. The explicit symmetry breaking can create an asymmeron wall network pinned on matter overdensities separating regions with distinct gravitational properties which could constitute a physical mechanism for the realization of gravitational transitions in redshift space that could help in the resolution of the Hubble and growth tensions. Another theoretical model leading to a gravitational transition could include a pressure non-crushing cosmological singularity in the recent past [1377].

Late (low-redshift) $w - M$ phantom transition:

The late (low-redshift) $w - M$ phantom transition [103] is a late time approach involving a combination of the previous two classes: the transition of the SnIa absolute luminosity and

[75] For reviews of modified gravity theories with screening mechanisms, such as the Vainshtein [1760, 166, 572] and the chameleon [1057, 1056, 825, 363, 362, 1747, 1318, 1319, 365, 366] models see [1054, 399, 1565, 368, 964, 564, 929, 398, 997, 367, 204, 1566] and for screening effects see [1509].

the deformation of the Hubble expansion rate $H(z)$. A rapid phantom transition of the dark energy equation of state parameter w at a transition redshift $z_t < 0.1$ of the form

$$w(z) = -1 + \Delta w\, \Theta(z_t - z) \tag{118}$$

with $\Delta w < 0$ and a similar transition in the value of the SnIa absolute magnitude M of the form

$$M(z) = M_C + \Delta M\, \Theta(z - z_t) \tag{119}$$

with $\Delta M < 0$ due to evolving fundamental constants can address the Hubble tension [103]. Where Θ is the Heaviside step function, M_C is the SnIa absolute magnitude Eq. (54) calibrated by Cepheids [421, 420] at $z < 0.01$ and ΔM, Δw are parameters to be fit by the data. Alestas *et al.* [103] find $\Delta M \simeq -0.1$, $\Delta w \simeq -4$ for $z_t = 0.02$ which imply a lower value of μ_G at $z > 0.02$ (about 6%) compared to the pure M-transition model.

The late (low-redshift) $w - M$ phantom transition (LwMPT) can lead to a resolution of the Hubble tension in a more consistent manner than smooth deformations of the Hubble tension and other types of late time transitions such as the Hubble expansion rate transition [261, 590]. Its main advantages include the consistency in the predicted value of the SnIa absolute magnitude M and the potential for simultaneous resolution of the growth tension.

Mortsell *et al.* [1312, 1313], Perivolaropoulos and Skara [1441] have analyzed the color-luminosity relation of Cepheids in anchor galaxies and SnIa host galaxies by identifying the color-luminosity relation for each individual galaxy instead of enforcing a universal color-luminosity relation to correct the NIR Cepheid magnitudes. A systematic brightening of Cepheids at distances larger than about 20 Mpc which could be enough to resolve the Hubble tension was found. In addition, Perivolaropoulos and Skara [1441] investigating the effects of variation of the Cepheid calibration empirical parameters (the color-luminosity parameter or the Cepheid absolute magnitude) find hints for the presence of a fundamental physics transition taking place at a time more recent than 100 Myrs ago. The magnitude of the transition lead to value of H_0 that is consistent with the CMB inferred value thus eliminating the Hubble tension. The distance range/timescale corresponding to this transition is consistent with solar system history data [1438] indicating an increase of the rate of impactors on the Moon and Earth surfaces by about a factor of 2-3 during the past 100Myrs which correspond to $z < 0.008$ [1636, 774, 1265, 819, 1806, 1262, 344] and low redshift galaxy surveys data [106]. Such a transition is also consistent with a recent analysis by Alestas *et al.* [100] indicating a transition in the context of the Tully-Fisher data.

In particular, using a robust dataset of 118 Tully-Fisher datapoints Alestas *et al.* [100] have demonstrated that evidence for a transition in the evolution of BTFR appears at a level of more than 3σ. Such effect could be interpreted as a transition of the effective Newton's constant. The amplitude and sign of the gravitational transition are consistent with the mechanisms for the resolution of the Hubble and growth tension discussed above [1238, 103] [see in 1437, for a talk of the tensions of the ΛCDM and a gravitational transition].

Early time modifications of sound horizon

Modifying the scale of sound horizon r_s (i.e. the scale of the standard ruler) by introducing new physics before recombination that deform $H(z)$ at prerecombination redshifts $z \gtrsim 1100$ can increase the CMB inferred value of H_0 [44, 1472, 194, 1074] and thus resolve the Hubble tension. Such deformation may be achieved by introducing various types of additional to the standard model components [see 171, for a review]. These models have the problem of predicting stronger growth of perturbations than implied by dynamical probes like redshift space distortion (RSD) and weak lensing (WL) data and thus may worsen the Ω_m-σ_8 growth tension [971, 105].

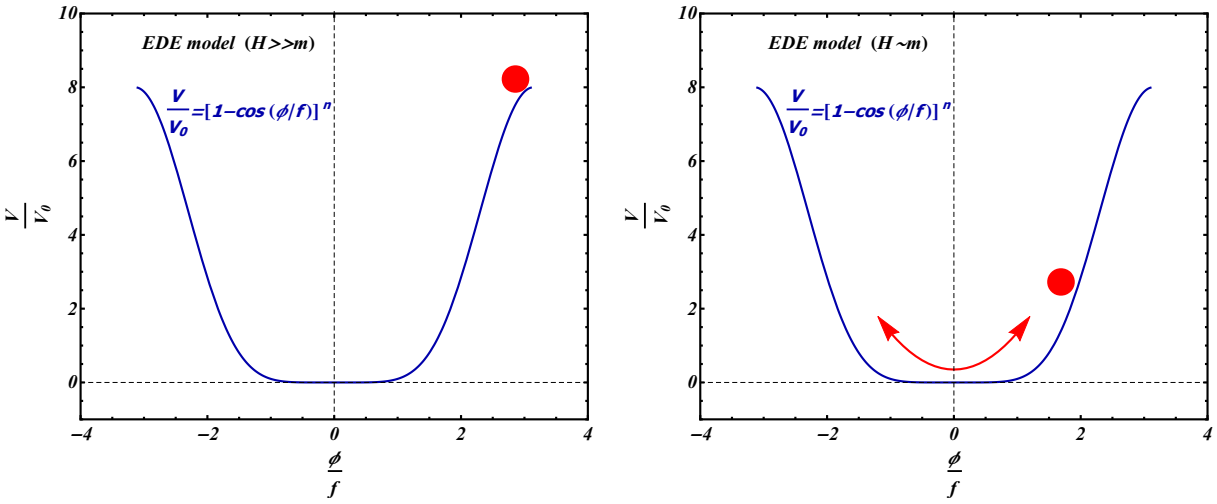

Figure 132: The potential V/V_0 (with $V_0 = m^2 f^2$, $n = 3$ in Eq. (121)) as a function of ϕ/f at early times ($H \gg m$) (left panel) when the field ϕ is initially frozen in its potential due to Hubble friction and acts as a cosmological constant with equation of state $w_\phi = -1$, and at a critical redshift z_c when the Hubble parameter drops below some value ($H \sim m$) (right panel) and the field becomes dynamical and begins to oscillate around its minimum which is locally $V \sim \phi^{2n}$.

A wide range of mechanisms has been proposed for the decrease of the the sound horizon scale at recombination. These mechanisms include the introduction of early dark energy, extra neutrinos or some other dark sector at recombination, features in the primordial power spectrum, modified scenarios of recombination etc. The following models and theories may be classified in this class of mechanisms: early dark energy [e.g. 301] (see Paragraph 11.2.2), dark radiation [e.g. 818] (see Paragraph 11.2.2), neutrino self-interactions [e.g 206] (see Paragraph 11.2.2), large primordial non-Gaussianities [59] (see Paragraph 11.2.2), Heisenberg's uncertainty principle [436] (see Paragraph 11.2.2), early modified gravity [358] (see Paragraph 11.2.2), cosmological inflation physics [1703, 158, 864, 1723, 598, 616, 828, 472, 605, 1196, 1033, 1876, 1697], dark matter - photon coupling [1121, 1845], dark matter-neutrino interactions [1409], interacting dark radiation [324], ultralight dark photon [717], primordial black holes [1348, 720], primordial magnetic fields [972, 970, 1710], non-standard recombination [1197], unparticles dark energy [170], varying fundamental constants [732, 854, 1617, 855, 856], early-time thermalization of cosmic components [1767], CMB monopole temperature shift [951], open and hotter universe [342, 266], Axi-Higgs cosmology [750, 749], string Cosmology [134, 136] and dark massive vector fields [140]. In this list of proposed cosmological models the tension on H_0 is alleviated with a significance ranging from the 1σ to the 3σ level.

Early dark energy:

In the early dark energy (EDE) model [1072, 879, 1128, 800, 723, 892, 1475, 1363, 1316, 1451, 301, 1011, 1567, 11, 222, 285, 1650, 1204, 107, 1322, 1002, 1331, 797, 851, 1649] an additional dynamical scalar field behaves like a cosmological constant at early times (near matter-radiation equality but before recombination). This field decays rapidly after recombination thus leaving the rest of the expansion history practically unaffected up to a rescaling which modifies H_0. This rescaling allows for the resolution of the Hubble constant tension. Using the Eq. (58) in a EDE model the radius of sound horizon at last scattering can be calculated by

$$r_s = \int_0^{t_d} \frac{c_s(a)}{a(t)} dt =$$

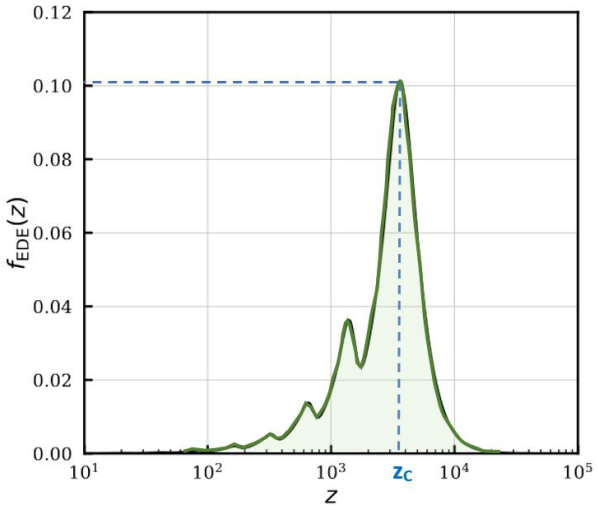

Figure 133: Fractional contribution of EDE to the cosmic energy budget as a function of redshift [adapted from 952].

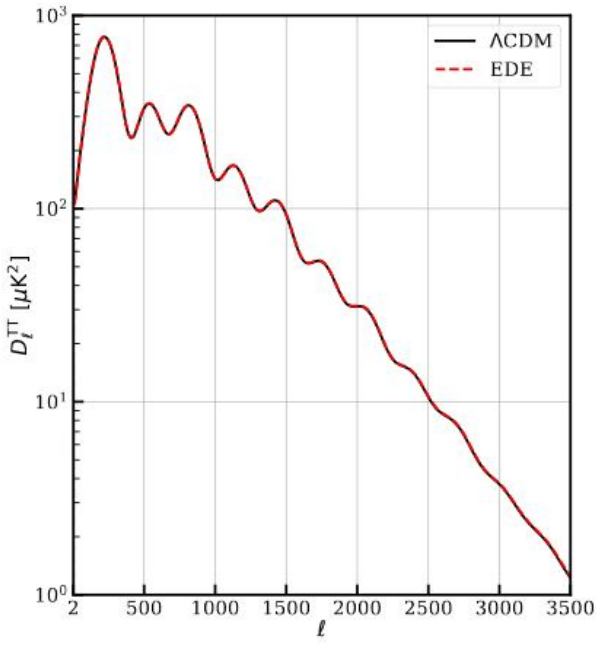

Figure 134: CMB TT power spectrum. The black solid and the red dashed lines correspond to ΛCDM model with $H_0 = 68.07\ km\ s^{-1}Mpc^{-1}$ and EDE model with $H_0 = 71.15\ km\ s^{-1}Mpc^{-1}$ respectively [from 952].

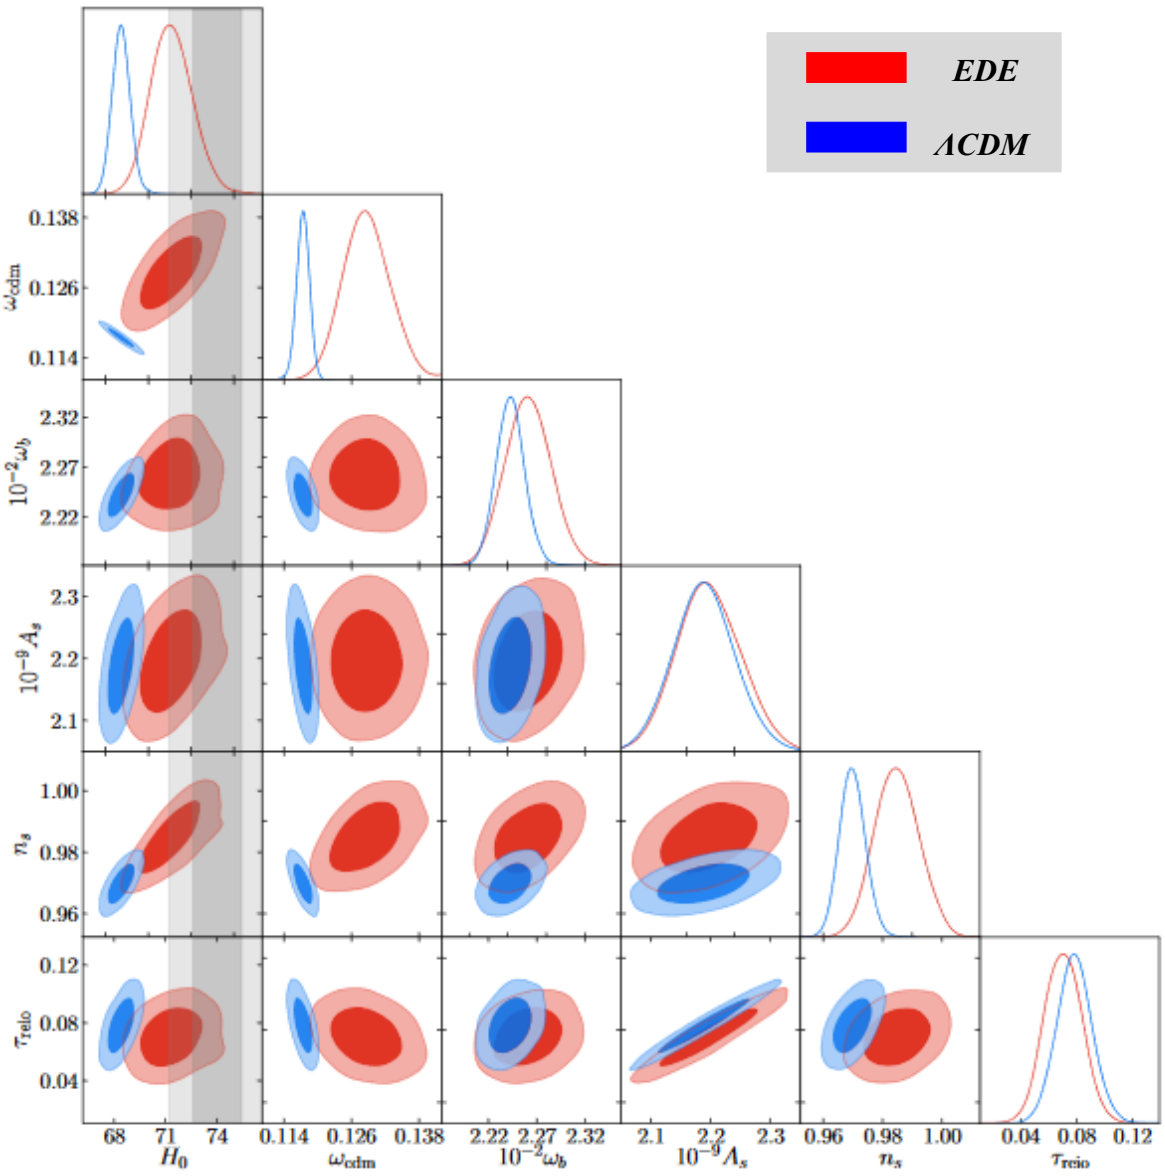

Figure 135: Posterior 1D and 2D distributions of the cosmological ΛCDM parameters reconstructed from a run to all data (including Planck high l polarization) in EDE (red) and the ΛCDM (blue) scenario. The gray bands correspond to the SH0ES determination of H_0 [adapted from 1650].

$$= \int_{z_d}^{\infty} \frac{c_s(z)}{H(z;\rho_b,\rho_\gamma,\rho_c,\rho_{DE})} dz = \\ = \int_0^{a_d} \frac{c_s(a)}{a^2 H(a;\rho_b,\rho_\gamma,\rho_c,\rho_{DE})} da \quad (120)$$

The baryon-to-photon ratio, and thus c_s in Eq. (59), is tightly constrained by CMB fluctuations and BBN [57]. As a consequence a EDE phase before and around the recombination epoch would increase $H(z)$ and thus decrease the scale of the sound horizon r_s in Eq. (120). In the context of the degeneracy $H_0 r_s$ shown in Eq. (60) this decrease of r_s leads to an increased value of H_0 for a fixed measured value of θ_s.

An EDE model can be implemented by several functional forms of scalar field which contribute to the cosmic energy shortly before matter-radiation equality. Possible functional forms of scalar field are the axion-like potential (higher-order periodic potential) inspired by string axiverse scenarios for dark energy [1239, 179, 1004, 1011, 1476], the single axion-like particle potential consisting of two cosine functions which unifies the inflaton and DM while reheating the universe [548, 549], the power-law potential [11], the acoustic dark energy [222, 1184, 1881], the α-attractor-like potential [359] and others.

Poulin et al. [301] consider two physical models. One that involves an oscillating scalar field and another with a slowly-rolling scalar field. In the case of the first model of the proposal of Poulin et al. [301], the potential of the scalar field ϕ is a generalization of the axion potential of the form

$$V(\phi) = m^2 f^2 \left(1 - cos(\phi/f)\right)^n \quad (121)$$

where m is the field mass (for ultralight scalar field $m \sim 10^{-28}\ eV$) and f is a decay constant.

Consider the time evolution of the EDE scalar field which may be written as

$$\ddot{\phi} + 3H\dot{\phi} + V'(\phi) = 0 \quad (122)$$

where the dot and the prime denote the derivatives with respect to cosmic time t and field ϕ respectively.

At early times, deep in the radiation era the field ϕ is initially frozen in its potential due to Hubble friction ($H \gg m$) and acts as a cosmological constant with equation of state $w_\phi = -1$ (hence the name Early Dark Energy), but when the Hubble parameter drops below some value ($H \sim m$) at a critical redshift z_c (for EDE this happens when $z_c \sim z_d$ for $m \sim 10^{-27}\ eV$) the field becomes dynamical and begins to oscillate around its minimum which is locally $V \sim \phi^{2n}$ (Fig. 132). It thus begins to behave like a fluid with an equation of state [1739]

$$w_\phi = \frac{n-1}{n+1} \quad (123)$$

The energy density of the field dilutes as $a^{-3(1+w_\phi)}$ and thus when $n = 1$, $n = 2$ and $n \geq 3$ dilutes as cold dark matter (a^{-3}, $w_\phi = 0$), as radiation (a^{-4}, $w_\phi = 1/3$) and faster than radiation (a^{-x} with $x > 4$, $w_\phi > 1/3$) respectively. Also when $n \to \infty$ the energy density dilutes as free scalar field (stiff matter [460]) (a^{-6}, $w_\phi = 1$) i.e. the scalar field is fully dominated by its kinetic energy.

The EDE models are parameterized by the critical redshift z_c , the dimensionless quantity $\theta_i = \phi_i/f$ (with ϕ_i the initial value of the scalar field and $0 < \theta_i < \pi$) and the peak EDE energy density fraction of the Universe $f_{EDE}(z_c)$ which is given by

$$f_{EDE}(z_c) \equiv \frac{\Omega_\phi(z_c)}{\Omega_{tot}(z_c)} = \frac{\rho_{EDE}(z_c)}{3M_{pl}^2 H(z_c)^2} \quad (124)$$

where Ω_ϕ is the EDE energy density which evolves as [1476, 301]

$$\Omega_\phi(z) = \frac{2\Omega_\phi(z_c)}{[(1+z_c)/(1+z)]^{3(w_n+1)}+1} \tag{125}$$

The fractional contribution of EDE to the cosmic energy budget as a function of redshift, i.e. $f_{EDE}(z)$, is shown in Fig. 133 [from the analysis by 952]. Clearly, for $z \simeq z_c$ the EDE contributes the most to the total energy density ($\sim 10\%$), for $z > z_c$ the EDE is not dynamically important while for $z < z_c$ decays away as radiation or faster than radiation leaving the later evolution of the Universe relatively unchanged. By construction, the EDE models can nicely match the CMB TT power spectrum of ΛCDM and therefore of Planck as illustrated in Fig. 134. The black solid and the red dashed lines (almost identical) correspond to ΛCDM model with $H_0 = 68.07\ km\ s^{-1}Mpc^{-1}$ and EDE model with $H_0 = 71.15\ km\ s^{-1}Mpc^{-1}$ respectively [952].

EDE models face the fine-tuning issues [1567] and suffer from a coincidence problem [1451]. Sakstein and Trodden [1567], Carrillo González *et al.* [447] proposed a natural explanation for this coincidence using the idea of neutrino-assisted early dark energy.

EDE modifies growth and $H(z)$ at early times (around recombination) and higher matter density is required to compensate for this effect in the CMB. Higher matter density contradicts the required low value of matter density at late times from weak lensing and growth data as shown in Fig. 135. In particular the analysis by Hill *et al.* [891], Clark *et al.* [487] has shown that an EDE model can not practically resolve the Hubble tension because it results in higher value of the late-time density fluctuation amplitude σ_8 and thus the tension with LSS dynamical probes WL, RSD and CC data can get worse. In addition Jedamzik *et al.* [971] argued that any model which attempts to reconcile the CMB inferred value of H_0 by solely reducing the sound horizon results into tension with either the BAO or the galaxy weak lensing data. Thus, a compelling and full resolution of the Hubble tension may require multiple modifications (more than just the size of the sound horizon) of the ΛCDM cosmology.

Recent studies by Smith *et al.* [1651], Chudaykin *et al.* [481] reexamining the above issue and using combined data method show that the EDE scenario remains a potential candidate solution to the Hubble tension. Future observations will provide data with improved quality and thus will enable more detailed tests of the EDE model.

Many alternative models have been proposed to implement the basic EDE scenario such as Chain EDE [741], Axion EDE [559, 976], Anti-de Sitter EDE [1796, 1877, 1879, 1878, 975, 976], assisted quintessence EDE [1552], EDE with extra radiation [1620], EDE in the framework of the ultralight scalar decay to massless fields [802] and New EDE (NEDE) [1356, 1353, 1354, 1352, 1355] which can potentially address the Hubble tension. In NEDE a vacuum first-order phase transition of the NEDE scalar field is assumed to have taken place before recombination in the early Universe. The NEDE sudden transition can be described by a scalar field whose potential at some critical point develops two non-degenerate minima (true and false vacuum)[76]. Allali *et al.* [110] develop a phenomenological dark sector with decaying dark energy and ultra-light axions which addresses the Hubble tension similarly to the EDE and NEDE scenarios and simultaneously can resolve the S_8 tension. Karwal *et al.* [1012], Sabla and Caldwell [1553], McDonough *et al.* [1264] argue that a EDE model may require a more complicated dynamics in order to soften both the H_0 and S_8 tensions. In particular, McDonough *et al.* [1264] introduced the Early Dark Sector (EDS) model considering an EDE-dependence of the mass of dark matter. The considering form of the potential is given by Eq. (121) (with

[76]It has recently been pointed out [1238, 103, 106, 1442, 1438, 1441, 100] that a similar mechanism in the context of the ultra late transition taking place at a redshift $z \lesssim 0.01$ can lead to a resolution of the Hubble tension.

$n = 3$) and the form of the field-dependent mass given by

$$m(\phi) = m_0 \exp(\frac{c\phi}{M_{pl}}) \tag{126}$$

as motivated by the the Swampland Distance Conjecture (SDC) [1389] and its extension to axions [1070, 1592, 327, 240].

Dark radiation:

Modifications in the light relic sector can relieve the tension by changing the early-time dynamics of the Universe [209, 65]. The dark radiation model assumes an increased number of light relics [786, 1841, 153, 42, 321, 503, 1781, 647, 1147, 44, 112, 702, 1752, 1621, 789, 38] which are weakly interacting components of radiation (i.e. relativistic species). For example the addition of hidden photons, sterile neutrinos [701, 443, 776, 775], Goldstone bosons, Majoron [706], axions [824, 581, 533] which are predicted in many extensions of the Standard Model (SM) increases the value in the effective number of relativistic particles N_{eff} beyond its canonical expectation value $N_{eff}^{SM} \simeq 3.044$ [1230, 100, 85, 678, 277, 743]. These extra particles modify the time of matter-radiation equality and would lead to a lower r_s sound horizon. As a consequence a lower expansion rate of the Universe and a higher value of H_0 emerges from early-time physics [818] (see Eq. (60)).

Another interesting approach was presented by Lesgourgues et al. [215], Cyr-Racine *et al.* [540], Schewtschenko *et al.* [1596], Buen-Abad *et al.* [388], Chacko *et al.* [455], Ko and Tang [1076, 1077], Tang [1702], Buen-Abad et al. [65], Krall *et al.* [1104], Archidiacono *et al.* [150], Archidiacono et al. [25], Ko *et al.* [1075], Becker *et al.* [247], Choi *et al.* [476], in which dark matter (DM) interacts with a new form of dark radiation (DR) aimed at solving H_0 tension. Assuming the Effective Theory of Structure Formation (ETHOS) paradigm [542, 1782] the interaction between the dark matter and dark radiation components is a 2-to-2 scattering DM + DR $\leftrightarrow$ DM + DR.

Neutrino self-interactions:

The strong (massive) neutrino self-interactions cosmological model can provide a larger value of H_0 and smaller σ_8, hence can resolve the tensions between cosmological datasets [206]. The strong neutrino self-interactions were proposed in Cyr-Racine and Sigurdson [541] and further studied in Lancaster et al. [209], Oldengott et al. [251]. The introduction of strong self-interacting neutrinos increases the value in the effective number of relativistic particles $N_{eff} = 4.02 \pm 0.29$ without extra neutrino species. This model modifies the standard neutrino free-streaming in the early Universe. The onset of neutrino free-streaming is delayed until close to the matter radiation equality epoch. This late-decoupling of the neutrinos shifts the CMB power spectra peaks towards smaller scales as compared to ΛCDM model. This shift modifies the scale of sound horizon r_s that can resolve the Hubble constant H_0 tension [206].

Furthermore self-interactions between the neutrinos or between other additional light relics was studied by Das and Ghosh [560], Roy Choudhury *et al.* [1539], Mazumdar *et al.* [1263], Forastieri *et al.* [727], He *et al.* [865], Berbig *et al.* [279], Lyu *et al.* [1217], Hannestad *et al.* [845], Archidiacono *et al.* [154], Chu et al. [78], Blinov *et al.* [323], Ghosh *et al.* [785], Brinckmann *et al.* [372], Archidiacono *et al.* [152], Corona *et al.* [520], Archidiacono *et al.* [155], Archidiacono et al. [24]. The strong neutrino self-interactions models are basically excluded by various existing data or experimental tests [323, 1217, 385, 580, 369]. The analysis by Brinckmann *et al.* [372] leads to conclusion that these models can not ease the Hubble tension more effectively than the ΛCDM+N_{eff} approach alone.

Models with nonstandard neutrinos - dark matter interactions were studied by Huang and Rodejohann [925], Escudero and Witte [677], Boyarsky *et al.* [351], Mangano *et al.* [1229], Wilkinson *et al.* [1829], Mosbech *et al.* [1314], Stadler *et al.* [1680], Choi *et al.* [477], Di Valentino et al. [108], Arias-Aragon *et al.* [161], Escudero and Witte [676]. These models increase the value in the effective number of relativistic particle N_{eff} and thus can provide a solution to the Hubble problem. However, in this class of models it is not possible to solve simultaneously the Hubble and growth tensions [108].

Large primordial non-Gaussianities:

The presence of large primordial non-Gaussianity in the CMB can affect the higher-order n-point correlation functions statistics. A non-vanishing primordial trispectrum ($n = 4$) which is the Fourier transform of the connected four-point correlation function leads to the non-Gaussian covariance of the angular power spectrum estimators [919, 1648, 58]. The trispectrum is nonzero when there is a strong coupling between long-wavelength (super-CMB) modes and short-wavelength modes. The non-Gaussian covariance scenario (Super-ΛCDM model) has two extra free parameters relative to those in ΛCDM and provides a larger value of H_0 reducing tension with late Universe measurements of the Hubble constant [59].

Heisenberg's uncertainty principle:

The Heisenberg's uncertainty principle [872, 1533] and the generalized uncertainty Principle [1274, 1222, 1221, 1223, 1043, 893, 1042, 1041, 1652, 1849, 1010, 61, 176, 178, 179, 175, 1365, 686, 108, 1298, 685, 1130, 1906, 1750, 1131] [see 1705, for a review] can provide constraints to the values for certain pairs of physical quantities of a particle and raise the possibility of the existence of observational signatures in cosmological data [e.g. 1434, 1645]. Capozziello *et al.* [436] have argued that the Heisenberg's uncertainty principle can provide an explanation for the Hubble constant H_0 tension. In particular the authors equate the luminosity distance (expanded for low z as in Eqs. (44) and (48)) with the photon (assumed massive) Compton wavelength

$$\lambda\!\!\!^{-}_C = \frac{\hbar}{m\,c} \tag{127}$$

and express the corresponding effective "rest mass" of the photon as a function of the cosmological redshift

$$m = \frac{\hbar H_0}{zc^2\left[1 + \frac{z}{2}(1 - q_0)\right]} \tag{128}$$

Thus, choosing $z = 1$, fixing $q_0 = -1/2$ and setting $H_0 = 74\ km\ s^{-1}Mpc^{-1}$ and $H_0 = 67\ km\ s^{-1}Mpc^{-1}$ in Eq. (128) find $m = 1.61 \times 10^{-69}kg$ and $m = 1.46 \times 10^{-69}kg$ respectively[77]. Thus using these results infer that the tension on the H_0 measurements can be the effect of the uncertainty on the photon mass i.e.

$$\frac{\Delta m}{m} = \frac{\Delta H_0}{H_0} \simeq 0.1 \tag{129}$$

Note that the non-zero photon mass could emerge through the Heisenberg's uncertainty principle and through the recent analysis of the Standard-Model Extension[78] [336, 337].

[77] The current upper limit on the photon mass is $m = 10^{-54}kg$ [1700].

[78] For studies of the massive photons in the Standard-Model Extension, see Helayël-Neto and Spallicci [873], Spallicci *et al.* [1675].

Early modified gravity:

A scalar tensor modified gravity model can be described by the following action

$$S = \int d^4x\sqrt{-g}\left[\frac{F(\sigma)}{2}R - \frac{g^{\mu\nu}}{2}\partial_\mu\sigma\partial_\nu\sigma - \Lambda - V(\sigma)\right] + S_m \tag{130}$$

where, R is the Ricci scalar, Λ is the cosmological constant, S_m is the action for matter fields, σ is a scalar field non-minimally coupled to the Ricci scalar, $F(\sigma)$ is the coupling to the Ricci scalar and $V(\sigma)$ is the potential for the scalar field. A variety of possible types of the non-minimal coupling of the scalar field to the Ricci $F(\sigma)$ and of the potential for the scalar field which can alleviate the H_0 tension by reducing the sound horizon scale through modified early cosmic expansion, has been considered in the literature [206, 357, 1537, 207, 3].

In particular Braglia *et al.* [358] introduce a model of early modified gravity[79]. This model has a non-minimal coupling of the form [358]

$$F(\sigma) = M_{pl}^2 + \xi\sigma^2 \tag{131}$$

and a quartic potential

$$V(\sigma) = \frac{\lambda\sigma^4}{4} \tag{132}$$

where λ and ξ are dimensionless parameters. For $\xi = 0$ this model reduces to the EDE model of Agrawal et al. [11]. In the early modified gravity model, gravity changes with redshift in such a way that the H_0 estimate from CMB can have larger values. Braglia *et al.* [358] have shown that this model can resolve the Hubble tension and at the same time, in contrast to an EDE model, results in lower value of the late-time density fluctuation amplitude σ_8 and thus the tension with LSS dynamical probes WL, RSD and CC data can be at least partially resolved. In general early modified gravity model compared to the EDE can provide a better fit to LSS data and can imply better predictions on LSS observables.

11.3 Other Tensions - Curiosities

In this section we provide a list of the non-standard signals in cosmological data and the curiosities of the ΛCDM cosmology beyond the Hubble tension which is currently the most widely studied and among the most statistically significant tensions. In many cases the signals are controversial and there is currently debate in the literature on the possible physical or systematic origin of these signals. For completeness we refer to all signals we could identify in the literature referring also to references that dispute the physical origin of these signals.

11.3.1 Growth tension

The Planck/ΛCDM parameter values in the context of GR indicate stronger growth of cosmological perturbations than the one implied by observational data of dynamical probes. In this section we review the observational evidence for this tension also known as the $\Omega_{0m} - \sigma_8$ tension or simply 'growth tension'.

[79] It should not be confused with the previously introduced differed model with the same name 'Early Modified Gravity' [361, 1450, 1182]. In this model gravity is allowed to be modified after BBN, before and during recombination.

Methods and data

The value of the growth parameter combination $S_8 \equiv \sigma_8(\Omega_{0m}/0.3)^{0.5}$ (where σ_8 is discussed in more detail in what follows) is found by weak lensing (WL) [838, 173, 200, 995, 174, 106, 26], cluster counts (CC) [1493, 1540, 1231, 53, 523, 524] and redshift space distortion (RSD) data [1220, 234, 1344, 1557, 1027, 1028, 1439, 1646, 162] to be lower compared to the Planck CMB (TT,TE,EE+lowE) value $S_8 = 0.834 \pm 0.016$ [72] at a level of about $2-3\sigma$ as shown[80] in Table 18 and in Fig. 136 [see 619, 30, for a recent review of this tension]. The tension is also confirmed by the latest ACT+WMAP CMB analysis [80] which finds $S_8 = 0.840 \pm 0.030$.

This is also expressed by the fact that dynamical cosmological probes (WL, RSD, CC) favor lower value of the matter density parameter $\Omega_{0m} \approx 0.26 \pm 0.04$ [94] than geometric probes (CMB, BAO, SnIa). This could be a signal of weaker gravity than the predictions of General Relativity in the context of a ΛCDM background [1220, 1734, 1344, 1027, 1646] [for a recent study on a weak gravity in the context of a ΛCDM background, see 755].

The observational evidence for weaker growth indicated by the dynamical probes of the cosmic expansion and the gravitational law on cosmological scales may be reviewed as follows:

Weak lensing:

The weak gravitational lensing from matter fluctuations along the line of sight slightly distorts the shapes (shear) and size (magnification) of distant galaxies [see 35, 1058, 1228, for a review]. This distortion is a powerful and principal cosmological probe of the mass distribution which can be predicted theoretically [195, 1001, 1832, 1785]. Using various statistical methods shape distortions can be measured by analyzing the angular shear correlation function, or its Fourier transform, the shear power spectrum [172, 174]. A special type of WL is the galaxy-galaxy lensing (GGL) [360, 927] which is the slight distortion of shapes of source galaxies in the background of a lens galaxy arising from the gravitational deflection of light due to the gravitational potential of the lens galaxy along the line of sight.

The WL surveys, the Kilo Degree Survey (KiDS) [989, 990, 991, 1116], the Subaru Hyper Suprime-Cam lensing survey (HSC) [1296, 79] and the Dark Energy Survey (DES) [23, 967] provide data useful for cosmic shear studies. In particular WL measurements of S_8 obtained from the shear catalogues by the lensing analysis of the Canada-France-Hawaii Telescope Lensing (CFHTLenS) [171, 887, 121, 882, 1289, 993] and the KiDS [174, 200] appear to be lower compared to the Planck value at a level of about 3σ. The analysis by Hildebrandt et al. [174] adopting a spatially flat ΛCDM model and using the KiDS-450 data reports $S_8 = 0.745 \pm 0.039$ which results in 2.3σ tension with the value estimated by Planck15. This KiDS-Planck discordance has also been investigated in Köhlinger et al. [200] where applying the quadratic estimator to KiDS-450 shear data reports $S_8 = 0.651 \pm 0.058$ which is in tension with the Planck2015 results at the 3.2σ level.

Using a combination of the measurements of KiDS-450 and VISTA Kilo-Degree infrared Galaxy Survey (VIKING) [169], Hildebrandt et al. [175] find $S_8 = 0.737^{+0.040}_{-0.036}$ which is discrepant with measurements from the Planck analysis at the 2.3σ level. For the KiDS+VIKING-450 (or KV450) Wright *et al.* [1836] report an updated constraint of $S_8 = 0.716^{+0.043}_{-0.038}$. Meanwhile, using the DES first year (DES-Y1) data assuming a ΛCDM model Troxel et al. [355] report $S_8 = 0.782^{+0.027}_{-0.027}$ which is in $\sim 2.3\sigma$ tension[83] with the Planck18 result. The constraint on S_8

[80]The definition $S_8 = \sigma_8(\Omega_{0m}/0.3)^{\alpha}$ with $\alpha = 1/2$ has been uniformly used for all points. In those cases where $\alpha \neq 1/2$ has been used in some references, the value of S_8 with $\alpha = 1/2$ was recalculated (along with the uncertainties) using the constraints on σ_8 and Ω_{0m} shown in those references, assuming their errors σ_{σ_8} and $\sigma_{\Omega_{0m}}$ are Gaussian. The errors of the S_8 constraints are propagated according to $\sigma^2_{S_8} = (\Omega_{0m}/0.3)^{2\alpha}\sigma^2_{\sigma_8} + \sigma^2_8\alpha^2(\Omega_{0m}/0.3)^{2\alpha-2}\sigma^2_{\Omega_{0m}}$, with $\alpha = 1/2$.

[83]This tension was calculated by Lemos *et al.* [1152]. The authors have explored a number of different methods

Table 18: The value of the structure growth parameter combination $S_8 \equiv \sigma_8(\Omega_{0m}/0.3)^{0.5}$, the matter density parameter Ω_{0m} and the the power spectrum amplitude σ_8 at 68% CL through direct and indirect measurements by different methods.

from the combined tomographic weak lensing analysis of KiDS + VIKING + DES-Y1 adopting a flat ΛCDM model by Joudaki et al. [195] is $S_8 = 0.762^{+0.025}_{-0.024}$ which is in 2.5σ tension with Planck18 result and by Asgari *et al.* [173] is $S_8 = 0.755^{+0.019}_{-0.021}$ which is in 3.2σ tension with Planck18 result. Analysing the most recent KiDS cosmic shear data release (KiDS-1000 Kuijken *et al.* 1117) alone and assuming a spatially flat ΛCDM model the value $S_8 = 0.759^{+0.024}_{-0.021}$ was estimated by Asgari *et al.* [174]. Analysing the first-year data of HSC in the context of the flat ΛCDM model and using the pseudo-spectrum (pseudo-C_l) method[84], Hikage et al. [172] find $S_8 = 0.780^{+0.030}_{-0.033}$ and adopting the standard two-point correlation functions (TPCF) estimators, $\xi_\pm$, Hamana et al. [158] find $S_8 = 0.804^{+0.032}_{-0.029}$. Recently, a analysis of the KiDS-1000 data using pseudo-C_l method by Loureiro *et al.* [1202] has lead to $S_8 = 0.754^{+0.027}_{-0.029}$. The latest cosmic shear analysis of the DES third Year (DES-Y3) [129, 1613] in the context of the ΛCDM model constrains the clustering amplitude as $S_8 = 0.759^{+0.025}_{-0.023}$. Also, recently Chang *et al.* [458] found $S_8 = 0.73^{+0.04}_{-0.03}$ using the cross-correlations of galaxy positions and shears from DES-Y3 with CMB lensing maps from SPT and Planck.

The analysis of galaxy clustering and weak gravitational lensing of the DES-Y1 data combining three two-point functions (the so-called 3×2pt analysis) of gravitational lensing and galaxy positions (the cosmic shear correlation function, the galaxy clustering angular autocorrelation function, the galaxy-galaxy lensing cross-correlation function) by DES Collaboration [106] gives $S_8 = 0.773^{+0.026}_{-0.020}$ and $\Omega_{0m} = 0.267^{+0.030}_{-0.017}$ in flat ΛCDM model. This value is in $\sim 2.3\sigma$ tension with Planck18 result. In the latest analysis by Abbott *et al.* [29] the constraints $S_8 = 0.776^{+0.017}_{-0.017}$ and $\Omega_{0m} = 0.339^{+0.032}_{-0.031}$ in flat ΛCDM model are obtained using an improvement in signal-to-noise of the DES-Y3 3×2pt data relative to DES-Y1 by a factor of 2.1. Also, Heymans *et al.* [883] using 3×2pt analysis of KiDS-1000+BOSS+ 2-degree Field Lensing Survey[85] (2dFLenS) [311] data finds $S_8 = 0.766^{+0.020}_{-0.014}$. While previous analyses 3×2pt of KiDS+GAMA data and KiDS-450+BOSS+2dFLenS data by van Uitert et al. [358] and Joudaki *et al.* [995] obtained $S_8 = 0.800^{+0.029}_{-0.027}$ and $S_8 = 0.742 \pm 0.035$ respectively. A combined analysis of KiDS+VIKING-450+BOSS data by Tröster *et al.* [1727] resulted in $S_8 = 0.728 \pm 0.026$. Performing a Joint analysis of galaxy-galaxy weak lensing and galaxy clustering from first-year data of HSC and SDSSS-III/BOSS DR11 Miyatake *et al.* [1295] found $S_8 = 0.795^{+0.049}_{-0.042}$. Also, from a combined analysis of KiDS-1000 and DES-Y1 cosmic shear and galaxy clustering, eBOSS quasars, DESI, Planck CMB lensing data García-García *et al.* [761] obtains a constraint $S_8 = 0.7781 \pm 0.0094$.

Clearly, the tension between WL and CMB measurements is a level more than 2σ as seen in Table 18 and in Fig. 136. In addition, the tension with more recent measurements persists at the level of $\sim 2\sigma$. Finally, combined analyses of WL with galaxy clustering does not change the tension level.

Cluster counts:

Galaxy clusters which are related to peaks in the matter density field on large scales constitute a probe of the growth history of structures [682, 1421] [see 111, 1106, for a review]. Current analyses from the number counts of galaxy clusters use catalogs from surveys at different wavelengths of the electromagnetic spectrum. Such surveys include Planck[86], South Pole Telescope (SPT) and Atacama Cosmology Telescope (ACT) in the microwave (millimeter) via

to quantify the tension relative to the best-fit Planck2018 cosmology.

[84] For a realistic experiment the pseudo-C_l statistics from cut-sky maps which provide incomplete data are applied in order to obtain unbiased estimates of the angular power and cross-power spectra by correcting for the convolution with the survey window [see 899, 383, 113, 1787, for details of this method].

[85] https://2dflens.swin.edu.au

[86] https://www.cosmos.esa.int

the thermal Sunyaev-Zel'dovich (tSZ) effect[87] [1689, 1690, 1691], extended Roentgen survey with an imaging telescope array (eROSITA[88]) [1482, 1284, 1458, 902] in the X-ray that finds extended sources and measures the X-ray luminosity and temperature, Sloan Digital Sky Survey[89] (SDSS) and Dark Energy Survey[90] (DES) in the optical/NIR. These surveys find peaks in the galaxy distribution and measure the richness of the corresponding clusters. The microwave/tSZ and X-ray surveys detection techniques are based on the hot ICM [860, 319] and in some cases require auxiliary data to obtain useful constraints e.g. redshift estimates [see 1071, 318, for recent methods].

The CC method is based on the predicted halo abundance (number density) $n(M, z)$ of halos with mass less than M at redshift z which is also known as the halo mass function (HMF). This formalism was originally introduced by Press and Schechter [1483]. A general mathematical form for the comoving number density expression of haloes is [e.g. 973, 1634, 1827, 1807, 1712]

$$\frac{dn}{dM} = f(\sigma)\frac{\bar{\rho}_m}{M}\frac{d\ln\sigma^{-1}}{dM} \tag{133}$$

where $\bar{\rho}_m = \rho_{crit}\Omega_m$ is the mean matter density of the Universe, σ is the rms variance of the linear density field smoothed on a spherical volume containing a mass M, and $f(\sigma)$ is a model-dependent 'universal' halo multiplicity function[91]. There are numerous parametrizations of the multiplicity function $f(\sigma)$ based on numerical N-body simulations or theoretical models. A popular parametrization provided by Tinker *et al.* [1712] is

$$f(\sigma) = A\left[\left(\frac{\sigma}{b}\right)^{-\chi} + 1\right]e^{-c/\sigma^2} \tag{134}$$

where A, χ, b, c are four free parameters that depend on the halo definition and need to be calibrated.

Measurements of the abundance of galaxy clusters $n(M, z)$ provide consistent constraints on the density of matter Ω_{0m}, the root mean square density fluctuation σ_8, the parameter combination $S_8(\alpha) = \sigma_8(\Omega_{0m}/0.3)^\alpha$ [e.g. 1059, 172, 174] (where $\alpha \sim 0.2 - 0.6$ and $S_8 \equiv S_8(\alpha = 0.5)$), the dark energy equation-of-state w and the sum of the neutrino masses $\sum m_\nu$ (massive neutrinos can suppress the matter power spectrum on small scales and this directly affect the growth of cosmic structure) [1817]. More recently, Sabti *et al.* [1555, 1554] used a method of clustering measurements at higher redshift ($z = 4-10$) based on UV galaxy luminosity function data from the Hubble Space Telescope [see e.g. 187, 347]. They derive the large-scale matter clustering amplitude to be $\sigma_8 = 0.76^{+0.12}_{-0.14}$.

Using cluster abundance analysis in the SDSS DR8 for a flat ΛCDM cosmological model with massive neutrinos Costanzi *et al.* [523] find $S_8 = 0.79^{+0.05}_{-0.04}$. Mantz *et al.* [1232] using Weighting the Giant (WtG) [1189, 147] lensing analysis of the X-ray ROentgen SATellite (ROSAT) cluster catalogs [1728] find $S_8 = 0.77 \pm 0.05$. The analysis of the counts and weak lensing signal of of the DES-Y1 dataset by Abbott *et al.* [26] gives $S_8 = 0.65 \pm 0.04$ and $\Omega_{0m} = 0.267^{+0.030}_{-0.017}$ in flat ΛCDM. Also, assuming a flat ΛCDM model and performing a galaxy cluster abundance analysis in the AMICO KiDS-DR3 catalogue Lesci *et al.* [1154] obtains $S_8 = 0.78 \pm 0.04$.

Using galaxy clusters observed in millimeter wavelengths through the tSZ effect Salvati et al. [321] report $S_8 = 0.785 \pm 0.038$ assuming ΛCDM model. The analysis of the Planck 2015

cluster counts via the tSZ signal by Ade *et al.* [53] finds $S_8 = 0.792 \pm 0.056$. Recently, assuming a flat ΛCDM model, in which the total neutrino mass is a free parameter, the analysis of SPT tSZ cluster counts by Bocquet *et al.* [328] results in $S_8 = 0.749 \pm 0.055$. Using X-ray clusters detected from the XMM-XXL survey [1455] for a flat ΛCDM cosmological model Pacaud *et al.* [1391] report $S_8 = 0.83 \pm 0.10$. Also, constraints on structure growth parameter combination S_8 from cluster abundance data have been obtained by de Haan et al. [95], Abdullah *et al.* [31], Kirby *et al.* [1066], Schellenberger & Reiprich [326], Ntampaka *et al.* [1366], Zubeldia & Challinor [378]. For example using GalWCat19 [32], a catalog of 1800 galaxy clusters was derived from the SDSS-DR13 [97] and assuming a flat ΛCDM cosmology Abdullah *et al.* [31] measured the matter density and the amplitude of fluctuations to be $\Omega_m = 0.310^{+0.023}_{-0.027} \pm 0.041$ (systematic) and $\sigma_8 = 0.810^{+0.031}_{-0.036} \pm 0.035$ (systematic) respectively.

The results of S_8 from all cluster count experiments as seen in Table 18 and in Fig. 136 are in agreement with WL measurements and similarly prefer a lower value compared to the CMB measurements.

Redshift space distortion-Galaxy clustering:

Peculiar motions of galaxies falling towards overdense region generate large scale galaxy clustering, anisotropic in redshift space. Measuring this illusory anisotropy that distorts the distribution of galaxies in redshift space (i.e. RSD) we can quantify the galaxy velocity field. This important probe of LSS can be used to constrain the growth rate of cosmic structures [1000, 840, 841].

In particular the RSD is sensitive to the cosmological growth rate of matter density perturbations f which depends on the theory of gravity and is defined as [1801, 1191, 1470]

$$f(a) \equiv \frac{d \ln \delta(a)}{d \ln a} \simeq [\Omega_m(a)]^{\gamma(a)} \tag{135}$$

where $a = \frac{1}{1+z}$ is the scale factor, $\delta \equiv \frac{\delta\rho_m}{\rho_m}$ is the matter overdensity field (with ρ_m is the matter density of the background) and γ is the growth index [e.g. 1129]. The nearly constant and scale-independent value $\gamma \simeq \frac{6}{11} \simeq 0.545$ corresponds to General Relativity (GR) prediction in the context of ΛCDM [e.g. 1191].

The observable combination $f\sigma_8(a) \equiv f(a) \cdot \sigma(a)$ is measured at various redshifts by different surveys as a probe of the growth of matter density perturbations. The theoretically predicted value of this product can be obtained from the solution $\delta(a)$ of the equation [1347]

$$\delta''(a) + \left(\frac{3}{a} + \frac{H'(a)}{H(a)}\right)\delta'(a) - \frac{3}{2}\frac{\Omega_{0m} G_{eff}(a)/G}{a^5 H(a)^2/H_0^2}\delta(a) = 0 \tag{136}$$

using the definition

$$\sigma(a) \equiv \sigma_8 \frac{\delta(a)}{\delta(a=1)} \tag{137}$$

where G is Newton's constant as measured by local experiments, G_{eff} is the effective gravitational coupling which is related to the growth of matter perturbation, $\sigma(a)$ is the redshift dependent rms fluctuations of the linear density field within spheres of radius $R = 8h^{-1}Mpc$ and σ_8 is its value today.

Hence, the more robust bias free quantity $f\sigma_8$ is given by

$$f\sigma_8(a) = \frac{\sigma_8}{\delta(a=1)}\, a\, \delta'(a) \tag{138}$$

RSD growth data in the form of $f\sigma_8$[92] have been provided by wide variety of surveys including the 2-degree Field Galaxy Redshift Survey (2dFGRS) [1414, 862], VIMOS-VLT Deep Survey (VVDS) [834], SDSS [1707, 1577, 1501, 1716, 479, 182], WiggleZ [309], 6dFGS [48, 982], Galaxy and Mass Assembly (GAMA) [1640], BOSS [1825, 15, 1173, 793], Subaru Fiber Multi-Object Spectrograph (FMOS) galaxy redshift survey (FastSound) [250], VIMOS Public Extra-galactic Redshift Survey (VIPERS) [1722, 269, 1297], eBOSS [1904, 1699, 1902, 242, 1905, 1255, 94], DESI [64, 65]. Using such data the Ω_{0m} and σ_8 parameters in the context of a ΛCDM background can be constrained. Thus, Kazantzidis and Perivolaropoulos [1027] using a compilation of 63 RSD datapoints find the ΛCDM best fit value $\Omega_{0m} = 0.279 \pm 0.028$ and $\sigma_8 = 0.775 \pm 0.018$. Benisty [268] using RSD selected data and assuming ΛCDM model report $S_8 = 0.700^{+0.038}_{-0.037}$, $\Omega_{0m} = 0.201^{+0.036}_{-0.033}$ and $\sigma_8 = 0.857^{+0.044}_{-0.042}$ which are in 3σ tension with the Planck 2018 results. Recently, using RSD data and the RSD+BAO+Pantheon and RSD+BAO+Pantheon+CC dataset combinations Nunes and Vagnozzi [1369] find $S_8 = 0.739^{+0.036}_{-0.040}$, $S_8 = 0.762^{+0.030}_{-0.025}$ and $S_8 = 0.777^{+0.026}_{-0.027}$ respectively.

Galaxy clustering methods, such as the galaxy power spectrum and bispectrum have also been used to constrain S_8. Constraints from the BOSS galaxy power spectrum [953] gave $S_8 = 0.703 \pm 0.045$ and from BOSS DR12 bispectrum [1453] gave $S_8 = 0.751 \pm 0.039$. Previous analysis of the BOSS DR12 data by Tröster *et al.* [1727] gave $S_8 = 0.729 \pm 0.048$. A analysis of the power spectrum of eBOSS by Ivanov [950] resulted in $S_8 = 0.720 \pm 0.042$. Recently, using the BOSS power spectra Chen *et al.* [468] found $S_8 = 0.736 \pm 0.051$. Also, the combination of the auto- and cross-correlation signal of unWISE [93] galaxies [1598] and Planck CMB lensing maps [73] by Krolewski *et al.* [1111] gave $S_8 = 0.784 \pm 0.015$. Finally, using the luminous red galaxies of the DESI in combination with Planck CMB lensing maps White *et al.* [1826] found $S_8 = 0.73 \pm 0.03$.

Clearly, as seen in Table 18 and in Fig. 136 the analyses of RSD data gives S_8 values in tension with CMB measurements at level more than 2σ, in agreement with other dynamical cosmological probes (WL and CC).

Theoretical models

Non-gravitational mechanisms can address the S_8 tension [see 947, for a review]. Such mechanisms include the following:

- Dynamical dark energy models [1538, 1190, 506, 651, 182, 471, 1821, 700, 1345, 968, 218, 1862, 1280, 1870, 1398, 1513, 994, 639, 1754, 1903, 1133, 1388, 1866, 272, 558] and running vacuum models [1656, 1657, 795, 796, 1804, 496, 1671, 256], which modify the cosmological background $H(z)$ to a form different from ΛCDM (see Subsection 11.2.2). This modification may involve the presence of dynamical dark energy dominant at late cosmological times or at times before recombination.

- Interacting dark energy models, which modify the equation for the evolution of linear matter fluctuations as well as the $H(z)$ cosmological background [1479, 132, 222, 422] as discussed in Subsection 11.2.2. This class of models can address the structure growth σ_8 tension between the values inferred from the CMB and the WL measurements.

[92] For an extensive compilation of RSD data points $f\sigma_8$, see in Skara and Perivolaropoulos [1646] and for other compilations, see in Basilakos and Nesseris [233], Nesseris *et al.* [1344], Kazantzidis and Perivolaropoulos [1027], Sagredo *et al.* [1557], Kazantzidis *et al.* [1030]. Also for a publicly available RSD likelihood for MontePython see in Arjona *et al.* [162], Cardona *et al.* [438].

[93] Wide-field Infrared Survey Explorer (WISE) [1838] is a NASA infrared astronomy space telescope and is mapping the whole sky.

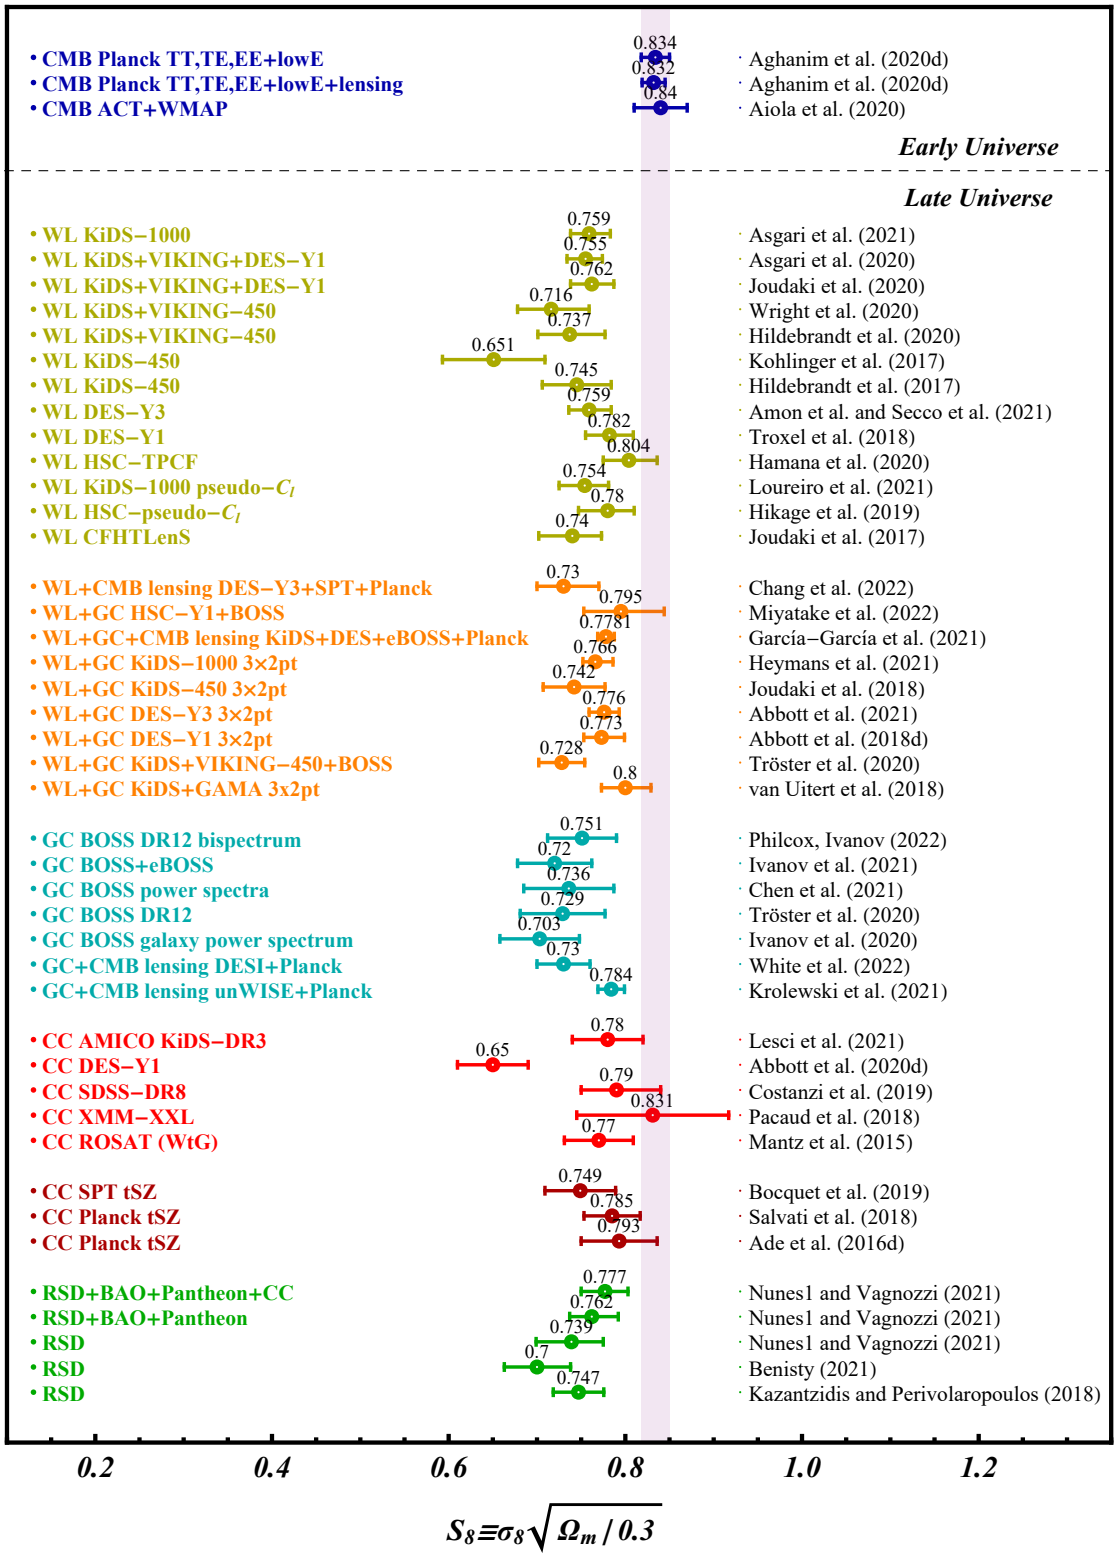

Figure 136: The value of S_8 with the 68% CL constraints derived by recent measurements.

- Effects of massive neutrinos [1250, 238, 522, 994, 1893, 1472, 623, 302] which are relativistic at early times and contribute to radiation while at late times they become non-relativistic but with significant velocities (hot dark matter) [see 216, 1835, 1157, 1158, for a review]. The change of radiation to hot dark matter affects the Hubble expansion. Simultaneously the residual streaming velocities are still large enough at late times to slow down the growth of structure [335]. This effect of massive neutrinos slows down the growth as required by the RSD data and relieves the S_8 tension coming from WL data [623].

- Primordial magnetic fields [972, 212] [see 642, 1687, 1749, for a review] induce additional mildly non-linear, small-scale baryon inhomogeneities present in the plasma before recombination. The required field results in a reduction of the sound horizon scale at recombination and has the potential to resolve both the H_0 and S_8 tension [970, 1494, 1710].

- Non-thermal dark radiation [563] seems to help alleviate the S_8 tension to a great extent. However, the inclusion of BAO data reduces significantly the quality of fit of this model.

In addition to these non-gravitational mechanisms discussed above that can slow down growth at low redshifts a possible interesting new fundamental physics approach can also reduce the S_8 tension. Such an approach is most likely to affect three basic observable parameters: the Hubble parameter $H(z, w)$ (with w the dark energy equation of state parameter), as well as the effective Newton constants for growth of perturbations

$$\mu_G(z,k) \equiv \frac{G_{eff}(z,k)}{G} \tag{139}$$

and lensing

$$\Sigma(z,k) \equiv \frac{G_L(z,k)}{G} \tag{140}$$

where G is the locally measured value of the Newton's constant. According to ΛCDM $H(z) = H(z, w = -1)$, $\mu_G = 1$, $\Sigma = 1$.

The Bardeen potentials [219] (the Newtonian potential Ψ and the spatial curvature potential Φ) appear in the scalar perturbed Friedmann-Lemaître-Robertson-Walker (FLRW) metric in the conformal Newtonian gauge [1325, 1218, 679]

$$ds^2 = -(1+2\Psi)dt^2 + a^2(1-2\Phi)d\vec{x}^2 \tag{141}$$

The LSS probes are sensitive to the Bardeen potentials Ψ and Φ. In particular the WL probe is sensitive to $\nabla^2(\Psi+\Phi)$. The galaxy clustering arises from the gravitational attraction of matter and is sensitive only to the potential Ψ. The RSD probe is sensitive to the rate of growth of matter density perturbations f (see Eq. (135)) and provides measurements of $f\sigma_8$ (see Eq. (138)) that depends on the potential Ψ.

At linear level, in modified gravity models, using the perturbed metric Eq. (141) and the gravitational field equations the following phenomenological equations in Fourier space emerge for the scalar perturbation potentials defining the functions $\mu_G(a,k)$ and $\Sigma(a,k)$ on subhorizon scales (i.e. $k/aH \gg 1$)

$$k^2(\Psi+\Phi) = -8\pi G\Sigma(a,k)a^2\rho\Delta \tag{142}$$

$$k^2\Psi = -4\pi G\mu_G(a,k)a^2\rho\Delta \tag{143}$$

where ρ_m is the matter density of the background, Δ the comoving matter density contrast defined as $\Delta \equiv \delta + 3Ha(1+w)v/k$ which is gauge-invariant [1468], $w = p/\rho$ is the equation-of-state parameter and $v^i = -\nabla^i u$ is the irrotational component of the peculiar velocity u [330].

Using the gravitational slip parameter η (or anisotropic stress parameter) which describes the possible inequality [1467, 964] of the two Bardeen potentials that may occur in modified gravity theories

$$\eta(a,k) = \frac{\Phi(a,k)}{\Psi(a,k)} \tag{144}$$

the two LSS parameters μ_G and Σ are related via

$$\Sigma(a,k) = \frac{1}{2}\mu_G(a,k)\,[1+\eta(a,k)] \tag{145}$$

The the Hubble parameter $H(z)$ is usually parametrized as wCDM

$$H(z) = H_0\left[\Omega_{0m}(1+z)^3 + (1-\Omega_{0m})(1+z)^{3(1+w)}\right]^{1/2} \tag{146}$$

while the two LSS parameters μ_G and Σ do not have a commonly accepted parametrization. A model and scale independent parametrization for μ_G and Σ which reduce to the GR value at early times and at the present time as indicated by solar system (ignoring possible screening effects) and BBN constraints ($\mu_G = 1$ and $\mu_G' = 0$ for $a = 1$ and $\mu_G = 1$ for $a \ll 1$) [1330, 1461, 756] is of the form [1346, 1344, 1027, 1646]

$$\mu_G = 1 + g_a(1-a)^n - g_a(1-a)^{2n} = 1 + g_a(\frac{z}{1+z})^n - g_a(\frac{z}{1+z})^{2n} \tag{147}$$

$$\Sigma = 1 + g_b(1-a)^m - g_b(1-a)^{2m} = 1 + g_b(\frac{z}{1+z})^m - g_b(\frac{z}{1+z})^{2m} \tag{148}$$

where g_a and g_b are parameters to be fit and n and m are integer parameters with $n \geq 2$ and $m \geq 2$.

Alternatively, a rapid transition parametrization is of the form [103, 1238]

$$\mu_G^{>}(z) = \mu_G^{<} + \Delta\mu_G\,\Theta(z-z_t) \tag{149}$$

$$\Sigma^{>}(z) = \Sigma^{<} + \Delta\Sigma\,\Theta(z-z_t) \tag{150}$$

where Θ is the Heaviside step function, z_t is a transition redshift, $\mu_G^{>}$ and $\Sigma^{>}$ correspond to $z > z_t$ and $\mu_G^{<}$ and $\Sigma^{<}$ correspond to $z < z_t$.

Various studies utilize modified gravity theories including Teleparallel theories of gravity[94] [544, 804] [see 199, for a review], Horndeski theories [1044, 1192] or theories beyond Horndeski [557] to reduce the effective Newton's constant G_{eff} at low redshifts and slow down growth at low redshifts. The above parametrizations can be realized in the context of physical models based on the above theories.

11.3.2 CMB anisotropy anomalies

There is a wide range of other less discussed no-standard signals and statistical anomalies of the large angle fluctuations in the CMB [1496] with a typical 2 to 3σ significance. As mentioned a main assumption of the ΛCDM model is that the fluctuations are Gaussian and statistically homogeneous and isotropic. Diverse anomalies have been noticed in the CMB at large angular scales by the space missions Cosmic Background Explorer (COBE) [1252], Wilkinson Microwave Anisotropy Probe (WMAP) [274] and Planck satellite [44], which appear to violate this assumption [see 1608, 88, for a review]. Perivolaropoulos [1433] presents possible explanations of the observed CMB anomalies and Cayuso and Johnson [453] explore the kinetic

[94] Many authors have studied the extensions of the Teleparallel gravity such as the scalar-torsion theories of gravity [777, 778, 803, 1396, 1647, 1085, 1153] and the Teleparallel Horndeski theories [622, 289, 198, 200, 202].

and the polarized Sunyaev-Zel'dovich effects as potential probes of physical models of these anomalies.

In what follows we discuss some of these signals. Note that some of these may not be independent[95]. Some of these signals have been attributed to the look-elsewhere effect. Based on this effect any large dataset will have a small number of peculiar features when there is a careful search for such features. However, this argument may not be applicable when the considered statistics are simple and generic as are most of the signals discussed below [see 244, 1423, 820, for a detailed discussion].

Hints for a closed Universe (CMB vs BAO)

The Universe under the assumption of the cosmological principle is described by the Friedmann-Lemaître-Roberson-Walker (FLRW) metric

$$ds^2 = dt^2 - a(t)^2 \left[\frac{dr^2}{1 - Kr^2} + r^2(d\theta^2 + sin^2\theta d\phi^2) \right] \tag{151}$$

where K characterizes the constant spatial curvature of the spatial slices with $K = -1, 0, +1$ corresponding to open hyperbolic space (negative spatial curvature), flat Euclidean space (zero spatial curvature), and closed hyperspherical space (positive spatial curvature) respectively. The curvature density parameter is defined as $\Omega_K \equiv -K/(Ha)^2$ so that a closed Universe corresponds to $\Omega_K < 0$ and an open Universe to $\Omega_K > 0$. This parameter plays a crucial role in determining the evolution of the Universe, and is closely related with the early Universe physics.

The Planck18 temperature and polarization data [72] show a preference ($\sim 3.4\sigma$) for a closed Universe ($\Omega_K < 0$) in the context of ΛCDM. In particular using these data from Planck18 the curvature density parameter was constrained to be $-0.095 < \Omega_K < -0.007$ at 99 % C.L [72, 71]. This anomaly may be connected with other asymmetries of the CMB anisotropy spectrum discussed below. The preference for closed universe however disappears when the CMB data are combined with the BAO data. Di Valentino *et al.* [621, 613], Handley [844] pointed out that Planck+BAO can give a biased result because Planck and BAO are in disagreement at more than 3σ. Combining Planck18 data with recent BAO measurements the curvature density parameter was estimated to be $\Omega_K = 0.0008 \pm 0.0019$ [621, 613, 844] in agreement with a spatially flat Universe. Using the full-shape galaxy power spectrum measurements $P(k)$, Vagnozzi *et al.* [1755] has also confirmed that the Planck data are in tension with both the full-shape power spectrum and BAO with respect to Ω_K. The recent study by Efstathiou and Gratton [655] confirms the tension between Planck and BAO data in the context of cosmic curvature. Efstathiou and Gratton [655] used a new statistical analysis (the alternative Planck CamSpec likelihood TTTEEE instead of Plik as discussed in Efstathiou and Gratton [654]) to show that Planck favors a closed Universe at more than 99% CL. However, Planck+BAO was again found to be in agreement with a spatially flat Universe with $\Omega_K = 0.0004 \pm 0.0018$ thus confirming previous studies by Di Valentino *et al.* [613], Handley [844] .

In an effort to further investigate this tension between Planck and BAO data, the analysis of Vagnozzi *et al.* [1756] combined Planck18 CMB temperature and polarization data with cosmic chronometer measurements and was lead to confirm that the Universe is consistent with spatial flatness to $\mathcal{O}(10^{-2})$ level.

A positive curvature (closed Universe) may be a plausible source of the anomalous lensing amplitude [621, 613, 844] (see Subsection 11.3.2).

[95] The covariance of CMB anomalies in the standard ΛCDM model has been studied by Muir *et al.* [1324]. This study focusing on the correlation of observed anomalies (i.e. the relationship or connection between all of them) examines the independence of large-angle CMB feature quantities.

Anomalously strong ISW effect

The decay of cosmological large-scale gravitational potential Ψ causes the integrated Sachs-Wolfe (ISW) effect [1556] which imprints tiny secondary anisotropies to the primary fluctuations of the CMB and is a complementary probe of dark energy [1086, 730, 788, 999]. Using a stacking technique in the CMB data [see 1233, 52, for a detailed discussion] anomalously strong integrated Sachs–Wolfe (ISW) signal ($> 3\sigma$) has been detected for supervoids and superclusters on scales larger than $100h^{-1}Mpc$ [815, 816]. This stronger than expected within standard ΛCDM signal of the ISW effect first emphasised in Hunt and Sarkar [932] has been studied by Nadathur *et al.* [1334], Flender *et al.* [718], Ilic *et al.* [939], Cai *et al.* [412], Kovács *et al.* [1100], Kovács [1098], Kovács *et al.* [1099], Dong *et al.* [634].

In particular the analysis by Kovács *et al.* [1099] for DES data alone found an excess ISW imprinted profile with $A_{ISW} \equiv \Delta T^{data}/\Delta T^{theory} \approx 4.1 \pm 2.0$ amplitude (where $A_{ISW} = 1$ corresponds to the ΛCDM prediction). Also a combination with independent BOSS data leads to $A_{ISW} = 5.2 \pm 1.6$. This is in 2.6σ tension with ΛCDM cosmology.

The average expansion rate approximation (AvERA) inhomogeneous cosmological simulation [1490] uses the separate Universe conjecture to calculates the spatial average of the expansion rate of local mini-Universes predicts. It indicates under the inhomogeneity assumption, about $\sim 2-5$ times higher ISW effect than ΛCDM depending on the l index of the spherical power spectrum [246]. Thus large scale spatial inhomogeneities could provide an explanation to this ISW excess signal. Giannantonio *et al.* [787] use angular cross-correlation techniques and combines several tracer catalogues to report $A_{ISW} \approx 1.38 \pm 0.32$.

Vagnozzi [1753] investigated the early Integrated Sachs-Wolfe (eISW) effect [see e.g. 348, 753] which is assumed to occur soon after recombination ($30 < z < 1100$), due to the presence of a non-negligible radiation. Constraints were thus imposed on the parameter A_{eISW} introduced by Hou *et al.* [913]. Using Planck CMB data, this parameter was constrained to $A_{eISW} = 0.988 \pm 0.027$, in perfect agreement with ΛCDM. Note that in previous studies the parameter A_{eISW} was constrained to $A_{eISW} = 0.979 \pm 0.055$ using data from WMAP7+SPT [913], to $A_{eISW} = 1.06 \pm 0.04$ from the Planck 2015 data release [404], and to $A_{eISW} = 1.064 \pm 0.042$ from the Planck 2018 temperature data alone [998].

In general the reported A_{ISW} amplitude varies in the literature depending on the dataset and the assumptions of the analysis. Further investigation of this issue is needed.

CMB cold spot

The cold (blue) spot was first found in WMAP 1-year temperature data by Vielva *et al.* [1777] and was confirmed in Planck data [56, 52, 88] in the southern hemisphere at the galactic longitude and latitude $(l, b) = (209^0, -57^0)$. It is a statistical anomaly of the large-angle fluctuations in the CMB indicating non-Gaussian features. This inconsistency with Gaussian simulations has a p-value of $\sim 1\%$.

The cold spot is an unusually large region of low temperature with the mean temperature decrement $\Delta T \approx -100\,\mu K$ and is not consistent with the prediction of gaussianity of the standard ΛCDM model [529, 530, 527].

Zhang and Huterer [1899], Nadathur *et al.* [1335], Kovács [1098] pointed out that the anomalous nature of the cold spot corresponds to a rather cold area with an angular radius in the sky of about $5^0 - 10^0$ from the centre surrounded by a hot ring.

Possible approaches for the explanation of the Cold Spot include: non-Gaussian feature due to a large statistical fluctuation [1777], an artifact of inflation [529], the foreground [530, 847], multiple voids [1336], the imprint of a supervoid (about $140-200Mpc$ radius completely empty void at $z \leq 1$) through the ISW effect [940, 941, 1548, 815], the axis of rotation of the Universe [963], cosmic texture [529, 1907], adiabatic perturbation on the last scattering surface [1762]

[see 528, 1776, for a review].

Cosmic hemispherical power asymmetry

The cosmic hemispherical power asymmetry (or dipolar asymmetry) is a directional dependency of the CMB angular power spectrum [672, 846, 673, 1392]. The continuous dipolar modulation of hemispherical power asymmetry corresponds to a hemispherical temperature variance asymmetry (signal in the CMB temperature field) [672, 846, 1301, 903, 86, 291, 52, 88, 1379].

The dipolar modulated/observed CMB temperature fluctuation $\frac{\Delta T}{T}|_{mod}$ in the direction $\hat{n}$ which appears to extend to $l_{max} \simeq 64$ can be expressed as [806, 275, 86][96]

$$\frac{\Delta T}{T}|_{mod}(\hat{n}) = [1 + A_{dm}\hat{n} \cdot \hat{p}] \frac{\Delta T}{T}|_{iso}(\hat{n}) \tag{152}$$

where $\frac{\Delta T}{T}|_{iso}$ is a statistically unmodulated/isotropic temperature fluctuation, A_{dm} denotes the amplitude of dipolar modulation and $\hat{n} \cdot \hat{p}$ corresponds to the dipolar modulation between the line-of-sight (LOS) of the observer (with unit vector $\hat{n}$) and the preferred dipolar direction (with unit vector $\hat{p}$). The amplitude of dipolar modulation A_{dm} is large at large angular scales $2 < l \lesssim 64$ ($k \lesssim 0.035 Mpc^{-1}$), small at small angular scales $l \gtrsim 64$ and vanishes by a multipole moment of $\sim 500-600$ [56, 52, 88]. The scale dependence of the hemispherical power asymmetry was suggested by Erickcek *et al.* [671], Liddle and Cortês [1179], Lyth [1216], Wang *et al.* [1794], Mukherjee and Souradeep [1329], Yang *et al.* [1850], Byrnes *et al.* [402, 403, 401], Ashoorioon and Koivisto [177], Jazayeri *et al.* [969] and was investigated by Shiraishi *et al.* [1635], Li *et al.* [1165].

According to the hemispherical asymmetry nearly aligned with the Ecliptic, the temperature fluctuations are larger on one side of the CMB sky than on the other, resulting in an unexpected dipole configuration in the CMB power spectrum with an anomalously lower value of the variance in the northern sky compared to the southern sky [56]. The preferred direction for the asymmetry from the Planck18 data is $(l, b) = (221^0, -20^0)$ in galactic coordinates and the amplitude is $A_{dm} \sim 0.07$ with statistically significant at the $\sim 3\sigma$ level [88]. This amplitude is ~ 2 times higher than expected asymmetry due to cosmic variance ($A_{dm} \sim 0.03$) and it is inconsistent with isotropy ($A_{dm} = 0$) at the $\sim 3\sigma$ level. The hemispherical power asymmetry in CMB can be explained by assuming a superhorizon perturbation [807, 806] or asymmetric initial states of the quantum perturbations [177].

Quadrupole-octopole alignment

The fluctuations in the standard ΛCDM model are Gaussian and statistically isotopic. Thus in harmonic space the quadrupole ($l = 2$) and octopole ($l = 3$) harmonics are expected to have independent and random orientations and shapes. The quadrupole and octopole have been observed to be planar and unexpectedly aligned with each other [1386, 1609, 510, 509, 512, 515]. This implies a violation of statistical isotropy.

In particular in this low multipole moment anomaly the quadrupole and octopole planes are found to be mutually aligned with the direction of the cosmic dipole or CMB dipole (see Subsection 11.3.3 and Table 19) and perpendicular to the Ecliptic [1608].

In order to study this large-angle anomaly one can use the maximum angular momentum dispersion [1386]

$$\langle\psi|(\hat{\mathbf{n}}_l \cdot \mathbf{L})^2|\psi\rangle = \sum_{m=-l}^{l} m^2 |a_{lm}(\hat{\mathbf{n}}_l)|^2 \tag{153}$$

[96] Note that the hemispherical dipole is distinct from the usual CMB dipole. In the former case the *power spectrum* is assumed modulated discontinuously across a circle on the sky and in the second the actual temperature map has a component modulated by a smooth cosine function across the sky [275].

where the CMB map is represented by a wave function

$$\frac{\Delta T}{T}(\hat{\mathbf{n}}_l) \equiv \psi(\hat{\mathbf{n}}_l) \tag{154}$$

Here $a_{lm}(\hat{\mathbf{n}}_l)$ correspond to the spherical harmonic coefficients of the CMB map in a coordinate system with its z-axis in the the $\hat{\mathbf{n}}_l$-direction.

The preferred axis $\hat{\mathbf{n}}_l$ is the axis around which the angular momentum dispersion is maximized. The directions of the quadrupole $\hat{\mathbf{n}}_2$ and the octopole $\hat{\mathbf{n}}_3$ are [1386]

$$\hat{\mathbf{n}}_2 = (-0.1145, -0.5265, 0.8424) \tag{155}$$

$$\hat{\mathbf{n}}_3 = (-0.2578, -0.4207, 0.8698) \tag{156}$$

with

$$|\hat{\mathbf{n}}_2 \cdot \hat{\mathbf{n}}_3| \simeq 0.9838 \tag{157}$$

This unexpected alignment of the $\hat{\mathbf{n}}_2$ and $\hat{\mathbf{n}}_3$ directions has only a 1/62 probability of happening.

An approach in the analysis of this large-angle anomaly may also involve the use the multipole vectors [516] (an alternative to the spherical harmonics) where each multipole order l is represented by l unit vectors i.e a dipole $l = 1$ can be constructed by a vector, a quadrupole by the product of two vectors/dipoles, an octopole from three vectors/dipoles etc.

The alignment of low multipoles indicates the existence of a preferred direction in the CMB temperature anisotropy. Furthermore possible relation between the quadrupole-octopole alignment and the dipolar asymmetry has been investigated by Hoftuft *et al.* [903], Gordon [806]. A negligible relation between these anomalies was reported. However the analysis by Marcos-Caballero and Martínez-González [1234] has shown that a particular dipolar modulation including the scale dependence may be connected with the quadrupole-octopole alignment.

Lack of large-angle CMB temperature correlations

There is a lack of large-angle CMB temperature correlations as first was observed by COBE satellite [894] and was confirmed by the WMAP [43, 1676] and Planck [52, 88] temperature maps in the range $l = 2$ to 32. This is in tension with the ΛCDM prediction.

This anomaly is directly connected to the temperature T two-point angular correlation function $C^{TT}(\theta)$ of the CMB at large angular scale ($\theta \gtrsim 60^0$) which is unexpectedly close to zero [511, 512, 514]. In angular space the two-point angular correlation function is defined as

$$C^{TT}(\theta) \equiv \langle T(\hat{n}_1) T(\hat{n}_2) \rangle = \frac{1}{4\pi} \sum_l (2l+1) C_l P_l(\cos\theta) \tag{158}$$

where the average is over all pairs of directions $\hat{n}$ with $\hat{n}_1 \cdot \hat{n}_2 = \cos\theta$, $P_l(\cos\theta)$ are the Legendre polynomials and C_l is the angular power spectrum

$$C_l \equiv \frac{1}{2l+1} \sum_{m=-l}^{l} |a_{lm}|^2 \tag{159}$$

with a_{lm} the spherical harmonic coefficients of the temperature fluctuations.

The simplest and most useful statistic is $S_{1/2}$ first introduced in the WMAP first-year release [1676] in order to measure the deviation of the angular correlation function from zero at angular scales $60^0 < \theta < 180^0$. It is defined as

$$S_{1/2} = \int_{\mu_2}^{\mu_1} \left[C^{TT}(\theta)\right]^2 d(\cos\theta) \tag{160}$$

with $\mu_1 \equiv \cos\theta_1 = \cos 60^0 = 1/2$ and $\mu_2 \equiv \cos\theta_2 = \cos 180 = -1$.

A number of alternative statistics have been proposed in the literature [837, 656, 821, 88]. For example a generalization of the $S_{1/2}$ statistic suggested by Copi *et al.* [513]. This statistic known as S^{TQ} uses the two-point angular correlation function between fluctuations in the temperature T and the Stokes parameter[97] Q, $C^{TQ}(\theta)$, which can be expressed in terms of the two-point angular power spectrum, C_l^{TE} (with E the gradient mode of polarization). The significance of a test statistic can be quantified by using the p-value[98], suggested by Ade *et al.* [56].

No sufficient explanation has yet been suggested for this large-angle anomaly. Copi *et al.* [517] study the ISW effect, Aurich *et al.* [189], Bernui *et al.* [290] explore a non-trivial spatial topology of the Universe and Pranav *et al.* [1481] study the topology of the Planck CMB temperature fluctuations in order to find a possible explanation to the suppression of large-angle CMB temperature correlations. Also the low observed power in the quadrupole is a potential explanation for the lack of correlation in the temperature maps. Copi *et al.* [511] argue that there is a cancellation between the combined contributions of C_l with multipoles $l \leq 5$ and the contributions of C_l with multipoles $l \geq 6$.

Anomaly on super-horizon scales

Pranav [1480] analysed the topological characteristics of the CMB temperature fluctuation. Using mathematical investigations on persistent homology to describe the cosmic mass distribution and performing experiments on Planck 2020 data release 4 (DR4) (based on the NPIPE data processing pipeline Akrami *et al.* 90), Pranav [1480] claimed a detection of an anomalous topological signature in the Planck CMB maps indicating non-Gaussian fluctuations. In particular Pranav [1480] reports an anomaly in the behavior of the loops (a 4σ deviation in the number of loops) in the observed sky compared to the analysis of the redshift evolution of structure on simulations when the ΛCDM model is considered.

The lensing anomaly

The recent Planck18 release by Aghanim *et al.* [72] has confirmed the higher compared to that expected in the standard ΛCDM model, anomalous, lensing contribution in the CMB power spectra which is quantified by the phenomenological parameter, A_L [66, 1889]. This weak lensing parameter A_L rescales the lensing potential power spectrum as[99]

$$C_l^{\Psi} \rightarrow A_L C_l^{\Psi} \tag{161}$$

where $A_L = 0$ corresponds to unlensed while $A_L = 1$ is the expected lensed result [66] measuring the lensing effect in the CMB temperature power spectrum.

Since the main impacts of lensing on the CMB temperature power spectrum are to add power at small scales and to smooth the structure of the acoustic peaks and troughs (the peaks are reduced slightly, and the troughs between them filled in) [220, 51] the adding of parameter A_L changes the amount of smoothing of the CMB primary spectra peaks and troughs. A higher lensing amplitude ($A_L > 1$) than predicted in the flat ΛCDM cosmology ($A_L = 1$) by roughly

[97] The Stokes parameters Q and U [for the Stokes parameters formalism see 955] are used to describe the state of CMB polarization [e.g. 1888, 629]. These parameters are directly related to the E and B modes [197, 1161, 395]. The polarization amplitude is given by $P = \sqrt{Q^2 + U^2}$.

[98] The probability value or p-value is the probability of measuring a test statistic equal to or more extreme as the observed one, considering that the null hypothesis is correct [56]. It provides the lower value of significance at which the model would be ruled out. A low p-value means that there is strong indication of new physics beyond the null hypothesis.

[99] Note that this is not the usual C_l but it is the additional contribution due to lensing.

10% (at the level of 2.8σ) has been found in the temperature power spectra by the Planck team [72].

It should be noted that the oscillatory residuals between the Planck temperature power spectra and the best-fit ΛCDM model in the multipole range $l \in [900, 1700]$ are in opposite phase compared to the CMB and thus phenomenologically similar to the effects of gravitational lensing [67, 1320].

A plausible explanation of the anomalous lensing amplitude is a positive curvature (closed Universe) which was investigated by Di Valentino *et al.* [621, 613], Handley [844]. Other possible sources which explain the lensing anomaly by mimicking a lensing effect are: a component of cold dark matter isocurvature (CDI) perturbation with a blue tilt [see 89, for a detailed discussion] and oscillations in the primordial power spectrum which have the same frequency but opposite phase with the acoustic peaks [72]. All these effects are degenerate with the smoothing effect of lensing.

Furthermore, the modified gravity models could be candidates for a solution of the lensing anomaly [57, 611, 1315, 601]. In particular the hints for $\Sigma_0 > 1$ (where Σ_0 the current value of parameter Σ which modifies the equation for the lensing potential i.e. Eq. (142)) are directly connected to the lensing anomaly as characterized by $A_L > 1$ [611, 601].

High-low l consistency

Addison et al. [6] pointed out that there are internal inconsistencies in the Planck TT power spectrum. The ΛCDM parameter values derived by the high l part of the CMB anisotropy spectrum ($l > 1000$) are in $2-3\sigma$ tension with the corresponding values of these parameters derived from the low l part of the spectrum ($1 < 1000$). For example the low l multipoles predict a lower value of the cold dark matter density parameter ω_c than the high l multipoles, with discrepancy at 2.5σ [6]. In addition it has been shown that the value of H_0 predicted by Planck from $l > 1000$, $H_0 = 64.1 \pm 1.7\ km\ s^{-1}Mpc^{-1}$, disagrees with the value predicted by Planck from $l < 1000$, $H_0 = 69.7 \pm 1.7\ km\ s^{-1}Mpc^{-1}$ at the 2.3σ level. Thus it is found that the value of H_0 depends on the CMB l-range examined.

This anomaly is probably related to the lensing anomaly i.e. the fact that ΛCDM is more consistent with the low l part of the spectrum that this not affected by the lensing anomaly [see 1526, 67, 71, for a discussion].

The preference for odd parity correlations

There is an anomalous power excess (deficit) of odd (even) l multipoles in the CMB anisotropy spectrum on the largest angular scales ($2 < l < 30$), [1135, 1061, 1060, 1062, 822, 823, 88]. A map consisting of odd (even) multipoles possesses odd (even) parity thus this effect may be considered as power (spectrum) asymmetry between even and odd parity map which is known as parity asymmetry.

In order to compare even and odd multipoles Kim and Naselsky [1060] consider the parity asymmetry statistic defined as the ratio $P \equiv P^+/P^-$ of quantities P^+ and P^- which represent the mean power in even and odd only multipoles respectively for the range $2 \leq l \leq l_{max}$

$$P^{\pm} = \sum_{2}^{l_{max}} \frac{\left[1 \pm (-1)^l\right] l(l+1)C_l}{4\pi} \tag{162}$$

A different statistic to quantify the parity asymmetry has been proposed by Aluri and Jain [114].

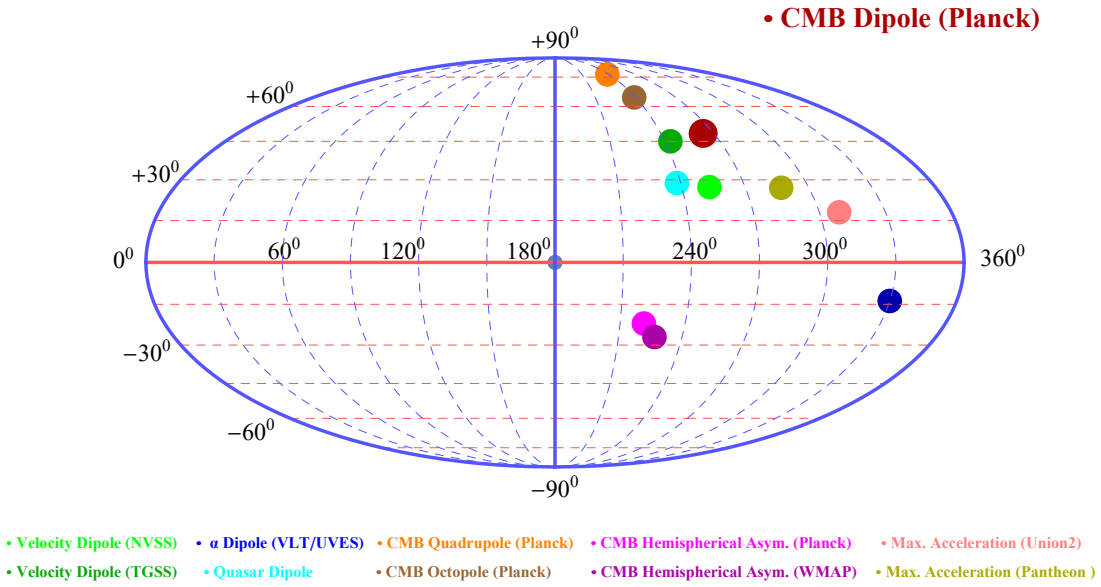

Figure 137: Mollweide-projection view of preferred directions in galactic coordinates for different cosmological observations (see Table 19).

11.3.3 Cosmic dipoles

There have been studies pointing out the presence of signals which indicate the violation of the cosmological principle. A physical mechanism producing such violation on Hubble scales is studied by Bueno Sanchez and Perivolaropoulos [390]. Various other possible mechanisms have been suggested to explain the observed violations of statistical isotropy e.g. superhorizon perturbations which introduce a preferred direction in our Universe [807, 670] [see also 1433, for a review]. The dipole amplitudes and the directions (l, b) (galactic coordinates) from the different cosmological observations described below are shown in Fig. 137 and along with the corresponding references in Table 19.

The physical origin of these dipoles is described in the following subsections.

Velocity radio dipole

A large scale velocity flow dipole[101] was pointed out in Watkins *et al.* [1808], Kashlinsky *et al.* [1017]. The dipole moment of the peculiar velocity field (dipole bulk flow) which is a sensitive probe of the amplitude and growth rate of fluctuations on large scales [1084] was investigated by Watkins *et al.* [1808], Feldman *et al.* [699], Kashlinsky *et al.* [1017, 1016], Nusser and Davis [1372], Ma and Scott [1219], Turnbull *et al.* [1738], Kashlinsky *et al.* [1015], Hong *et al.* [908]. In many cases the results are controversial and there is a debate in the literature on the consistency with the ΛCDM model.

A recent detailed analysis has indicated that 'tilted observers' within the bulk flow can be misled into inferring acceleration [1729, 1730, 1731] [see also 186, for observational constraints of the deceleration parameter in a tilted universe].

[101] For peculiar velocities as variation of the Hubble expansion produced by nearby nonlinear structures see in Wiltshire *et al.* [1831] and for dipole anisotropy in radio source count, see in Bengaly *et al.* [263].

Table 19: The amplitudes and the directions (l, b) (galactic coordinates) from different cosmological observations (Fig. 137) along with the corresponding references . The amplitude of CMB dipole has derived using the Eq. (165) [e.g. 1614].

Observations	$l\,[deg]$	$b\,[deg]$	Amplitude	Re

Colin *et al.* [499] use SnIa JLA data to demonstrate that the indications for cosmic acceleration found in the SnIa data disappears if a bulk flow induced anisotropy is allowed in the SnIa data. Thus, a bulk flow dipole (at 3.9σ) aligned with the local bulk flow is identified while any monopole (which can be attributed to Λ) is consistent with zero (at 1.4σ).[102]

It is usually assumed that our local (solar system) peculiar motion with respect to the CMB rest frame produces the CMB dipole anisotropy ($l = 1$) [1087, 716] [also known as solar dipole 66, 70]. In the standard model, this implies that the LSS distribution should have a similar kinematic dipole known as the velocity dipole or radio dipole which arises from the Doppler boosting of the CMB monopole and from special relativistic aberration effects [949].

In order to describe the origin of this dipole, a population of sources with power-law spectra depending on frequency ν is usually assumed

$$S_\nu \propto \nu^{-\alpha} \tag{163}$$

where S_ν is the flux density and α[103] is an individual spectral index with typically assumed value $\alpha \sim 0.75$ [196]. The integral source counts per unit solid angle above some limiting flux density S_ν can be approximated by a power law

$$\frac{dN}{d\Omega}(> S) \propto S_\nu^{-x} \tag{164}$$

where $x \sim 1$ and can be different for each survey. An observer moving with velocity $v \ll c$ with respect to the frame in which these sources are isotropically distributed sees a dipole anisotropy

[102] A recent model independent analysis of SnIa data (Pantheon) data Arjona and Nesseris [163] implementing machine learning has confirmed a $\sim 4.5\sigma$ detection of the accelerated expansion even though that analysis did not allow for anisotropic dipole effects.

[103] The individual spectral index α should not be confused with the fine-structure constant α.

$1 + D\cos\theta$ over the sky with amplitude [667]

$$D = [2 + x(1+\alpha)]\frac{\upsilon}{c} \tag{165}$$

According to the most recent measurements the inferred velocity of the Sun relative to the CMB rest frame is [69, 70]

$$\beta \equiv \frac{\upsilon}{c} = (1.23357 \pm 0.00036) \times 10^{-3} \tag{166}$$

$$or \quad \upsilon = 369.82 \pm 0.11\, km\, s^{-1} \tag{167}$$

along the direction with galactic longitude and latitude $(l, b) = (264.021^0 \pm 0.011^0, 48.253^0 \pm 0.005^0)$ or $RA \sim 168^0$, $Dec \sim -7^0$ [69, 70].

The CMB rest frame is conventionally taken to correspond to the standard of cosmic rest frame and is assumed to be statistically homogeneous and isotropic in the context of the FLRW model. In this rest frame the Hubble flow should be most uniform (minimum Hubble variation frame) and the comoving observers should not see a kinematic dipole. However it has been observed [1831, 1271] that the dipole structure of the velocity field is less in the reference frame of the Local Group of galaxies than in the CMB frame. This persistence of the dipole structure of the velocity flow in the CMB frame at large distances is not unexpected if we are located in an underdensity [1103].

According to the standard model if the Universe is isotropic our velocity with respect to the CMB rest frame and our velocity relative to the LSS should be identical. However, as was first noted by Singal [1641], while the direction of the radio dipole is consistent with that of the CMB, the velocity of our local motion obtained from the radio dipole exceeds that obtained from the CMB dipole. Radio continuum surveys which sample the Universe at intermediate redshifts ($z \sim 1$) have been used as an excellent probe to large scale isotropy and a discrepancy between the predicted and measured amplitudes of the velocity have been revealed [791, 1545, 1714, 1715, 498, 263]. In particular the analysis by Bengaly *et al.* [263] has shown that the radio dipole using the sky distribution of radio sources from the NRAO VLA Sky Survey (NVSS) dataset [502] and TIFR GMRT Sky Survey (TGSS) dataset [263, 942, 1642] is ~ 2 and ~ 5 times larger than predicted by the mock realisations within the context of ΛCDM cosmology respectively. The above observed discrepancy between the radio and CMB dipoles has been confirmed by independent groups and could imply the existence of an anisotropic Universe.

Possible explanations of the violation of statistical isotropy are: systematics due to the incomplete sky coverage of the radio continuum surveys [307, 791, 1715], intrinsic dipole in the local LSS [705], nearby nonlinear structures of voids and walls and filaments [1831], remnant of the pre-inflationary Universe [1740] and superhorizon perturbation [784, 561].

Quasar dipole

The distribution of quasars across the sky may provide independent probe of the cosmological principle [1643]. As previously discussed there is an expected anisotropy related to the CMB dipole anisotropy (about 1 part in 1000) due to our motion with respect to the CMB rest frame.

Secrest *et al.* [1614] used mid-infrared data from the Wide-field Infrared Survey Explorer (WISE) [1838] to create reliable AGN/quasar catalogs and a custom quasar sample from the new CatWISE2020 data release [660]. It was shown that there is a statistically significant dipole in the density of distant quasars with direction $(l, b) = (238.2^0, 28.8^0)$ which is 27.8^0 away from the direction of the CMB dipole. Its amplitude was found to be 0.01554, ~ 2 times larger than predicted, with statistical significance at the 4.9σ level (or with a p-value of 5×10^{-7}) for a normal distribution. This result is in conflict with the cosmological principle.

Fine structure constant α dipole

In the past 20 years there has been interest in the possibility of the variation of the fine structure constant $\alpha \equiv e^2/(4\pi\epsilon_0\hbar c)$ (where e, ϵ_0, $\hbar$, and c are the electron charge, the vacuum permittivity, the reduced Planck's constant, and the speed of light) [1332, 1809, 1299, 282, 1812, 681, 203, 917, 1287, 1144] [for review of varying fine structure constant, see 1248].

The analysis by King *et al.* [1065], Webb *et al.* [1809] uses the "many multiplet" (MM) method [1810, 648, 1811, 1333] to analyze quasar absorption line spectra obtained using the Ultraviolet and Visual Echelle Spectrograph (UVES) [574] on the Very Large Telescope (VLT). It indicates both the violation of the cosmological principle and the spatial variation of the fine structure constant α which is approximated as a spatial dipole with direction $(l, b) = (330^0 \pm 15^0, -13^0 \pm 10^0)$ and amplitude $0.97^{+0.22}_{-0.20} \times 10^{-5}$, preferred over a simple monopole model with significance at the 4.2σ [for possible systematics in this analysis, see 423, 1005, 1159].

The variation of α across the sky was shown to be well fit by an angular dipole model of the form [1065]

$$\frac{\Delta\alpha}{\alpha} \equiv \frac{\alpha - \alpha_0}{\alpha} = C_A \cos\theta + C_B \tag{168}$$

where α_0 is the present local value, θ is the angle with respect to the dipole direction, C_A is the angular amplitude of the dipole term and C_B is a monopole term.

It is worth to note that the analysis by Martins and Pinho [1249] suggests that there are no robust indications of time or space variations of α. However recent measurements of quasar absorption-line spectra indicate a spatially dependent value of fine structure constant α at a $\sim 4\sigma$ significance level over a simple monopole (no-variation) model [640, 1828]. In addition, it is found that the fine structure constant α dipole is anomalously aligned with other dipoles and the preferred direction in $\Delta\alpha/\alpha$ is correlated with the one in the distribution of SNIa [1235, 1236].

11.3.4 BAO curiosities

As mentioned above (see Subsection 11.2.1) the BAO measurements can be classified in two classes: galaxy BAO and Lyα BAO (with Lyα auto-correlation function and Lyα-quasar cross-correlation function). A $2.5 - 3\sigma$ discrepancy between the BAO peak position in the Lyα at an effective redshift of $z \sim 2.34$ and the CMB predictions from Planck/ΛCDM cosmological model has been found [724, 29, 114].

For example, Aubourg et al. [29] use the Lyα auto-correlation function and the Lyα-quasar cross-correlation function to report the measurements of the BAO scale in the line-of-sight direction

$$D_H(z = 2.40)/r_s = 8.94 \pm 0.22 \tag{169}$$

and in the transverse direction

$$D_M(z = 2.40)/r_s = 36.6 \pm 1.2 \tag{170}$$

where $D_H(z) \equiv \frac{c}{H(z)}$ is the Hubble distance and $D_M(z) \equiv (1+z)D_A(z) = d_A(z)$ is the comoving angular diameter distance. These values are in $\sim 2.3\sigma$ tension with CMB predictions $D_H(z = 2.40)/r_s = 8.586 \pm 0.021$ and $D_M(z = 2.40)/r_s = 39.77 \pm 0.09$ by Planck 2015 flat ΛCDM cosmology [50].

The galaxy BAO peak position in the matter correlation function $\xi(s)$ (see Eq. (56) and Fig. 122) and the measurements $D_H(z = 2.40)/r_s$ and $D_M(z = 2.40)/r_s$ were found to be consistent with CMB predictions. This discrepancy between galaxy and Lyα BAO constitutes the BAO anomaly which has been investigated in Cuceu *et al.* [532], Evslin [683], Addison et al. [9].

Using new Lyα BAO measurements from the BOSS survey and from its extended version eBOSS in the SDSS DR14 the tension with CMB predictions was reduced to $\sim 1.7\sigma$ [57, 96] and from eBOSS in the SDSS DR16 to only $\sim 1.5\sigma$ [346].

Evslin [683] argues that this anomaly arises by cosmological effects at $z < 2.34$ and the tension is caused by evolution of dark energy equation of state $w(z)$ for redshift range $0.57 < z < 2.34$.

11.3.5 Parity violating rotation of CMB linear polarization (Cosmic Birefringence)

In the standard model of elementary particles and fields, parity violation is observed only in the weak interaction sector [1145, 1839]. A certain class of quintessence models should generically generate such parity asymmetric physics [450, 448]. In particular a parity violating (nearly) massless axionlike scalar field ϕ (dark matter or dark energy) would rotate CMB polarisation angles of CMB photons as they travel from the last scattering surface ($z \approx 1000$) to the present by a non-zero angle β_a (cosmic birefringence).

A Chern–Simons coupling between a time-dependent axionlike field $\phi(t)$ and the electromagnetic tensor and its dual in the Lagrangian density [e.g. 1351, 1742, 450]

$$\mathcal{L} = \frac{1}{4} g_{\phi\gamma} \phi F_{\mu\nu} \tilde{F}^{\mu\nu} \tag{171}$$

induces a cosmic isotropic birefringence angle [e.g. 848, 747]

$$\beta_a = \frac{1}{2} g_{\phi\gamma} \int_{t_s}^{t_0} \dot{\phi} dt \tag{172}$$

and produces a non-zero observed EB spectrum [1207]

$$C_l^{EB} = \frac{1}{2} \sin(4\beta_a)(C_l^{EE} - C_l^{BB}) \tag{173}$$

where $g_{\phi\gamma}$ is a Chern-Simons coupling constant which has mass-dimension -1, $\tilde{F}^{\mu\nu}$ is the dual of the electromagnetic tensor of $F_{\mu\nu}$, and t_0 and t_s are the times at present and last scattering surface, respectively.

Using a novel method developed in Minami *et al.* [1294], Minami [1291], Minami and Komatsu [1293], a non-zero value of the isotropic cosmic birefringence $\beta_a = 0.35 \pm 0.14$ deg (68% C.L) was recently detected in the Planck18 polarization data at a 2.4σ statistical significance level by Minami and Komatsu [1292]. More recently, using the latest Planck public data release 4 [91] a birefringence angle of $\beta_a = 0.30 \pm 0.11$ deg (68% C.L) was reported by Diego-Palazuelos *et al.* [624].

These recent evidences of the non zero value of birefringence poses a problem for standard ΛCDM cosmology and indicates a hint of a new ingredient beyond this model.

An axion or an axion-like particle with a weak coupling to photon as a possible source of the cosmic birefringence was investigated by Fujita *et al.* [748] and a two-axion alignment model with periodic potential was investigated by Obata [1376]. Takahashi and Yin [1698] showed that if an ultralight axion coupled to photons forms domain walls due to inflationary fluctuations, the domain-wall network can explain the hint for isotropic cosmic birefringence found by Minami and Komatsu [1292]. This model predicts a testable peculiar anisotropic cosmic birefringence as well. In contrast to the approach of Fujita *et al.* [748], this scenario explains the birefringence with the photon anomalous coefficient of the axion-like particle $\sim O(1)$. Furthermore, birefringence inducing axion-like particles could be candidates for an early dark energy resolution to the Hubble tension [748]. Bianchini *et al.* [296], Namikawa *et al.* [1338] study the anisotropic birefringence and constraints are derived. The axion field fluctuations over space and time generate anisotropic birefringence.

11.3.6 Small-scale curiosities

On small scales (on scales of hundreds of *kpc* and below) the predictions of ΛCDM model are in many cases inconsistent with observations [1114, 1816, 1337]. In particular observations on galaxy scales indicate that the ΛCDM model faces several problems in describing structures at small scales ($\lesssim 1Mpc$) [see 1112, 1113, 575, 393, 1570, for a review]. Alternative models that modify the nature of dark matter have been used to solve these problems e.g. warm [329, 5, 1775, 1601, 1774], fuzzy [920, 930, 1597, 946], self-interacting [441, 320, 760, 1735] and meta-cold dark matter [1686] [see also 1247, for a review]. Other models which have the potential to provide a solution to these problems have been proposed by Foot and Vagnozzi [725, 726], Sawala *et al.* [1590], Schewtschenko *et al.* [1596], Vogelsberger *et al.* [1782], Archidiacono *et al.* [150]. In particular Foot and Vagnozzi [725, 726] argued that the existence of a dissipative hidden dark matter sector (dark matter coupled to a massless dark photon) can solve some of these problems (core-cusp, missing satellites, and plane of satellites problem).

These small scale signals include the following:

The core-cusp curiosity

The core-cusp curiosity [1302, 721, 325] (see also Cooke *et al.* 505, Lelli 1148) refers to a discrepancy between the density of a dark matter halo profile of low-mass galaxies $\rho(r) \propto r^{-x}$ in N-body simulations (an important tool for evaluating the predictions of the ΛCDM model) with $1 \lesssim x \lesssim 1.5$ (cusp profile)[104] [1341, 1339, 1304, 711] and the astronomical observed profile with $x \sim 0$ (core profile) [1302, 565, 1341, 1339, 721, 237, 1786, 130, 779]. McGaugh and de Blok [1269] probe this problem in low surface brightness galaxies.

The missing satellites problem (or dwarf galaxy problem)

The missing satellites problem (or dwarf galaxy problem) [1018, 1073, 1303, 392] refers to an over-abundance of the predicted number of halo substructures in detailed collisionless N-body simulations compared to the observed number of satellite galaxies in the Local Group. In particular the ΛCDM model predicts orders of magnitude larger number of satellites (~ 1000) than the observed number of dwarf galaxies (~ 50) [1251, 1303].

The Too Big To Fail (TBTF) problem

The Too Big To Fail (TBTF) problem [354, 355, 764, 1406, 1717, 1007] refers to an inconsistency between the predicted mass of dark matter subhaloes in ΛCDM theory and the observed central mass of brightest satellite galaxies in the Local Group [764, 1406] (also in the MW Boylan-Kolchin *et al.* 354, 355 or in the Andromeda (M31) Tollerud *et al.* 1717).

In particular the ΛCDM predicted central densities of the most massive dark matter subhalos are systematically larger than the inferred from kinematics of the brightest Local Group satellites [1498, 355, 764]. An observed bright satellite is more likely to reside in subhalos with lower mass than is expected in a ΛCDM model. The simulated massive dark matter subhalos *'failed'* to form a comparatively bright satellite galaxy.

This problem is possibly related to the missing satellites problem but it is a distinct problem which dependents on the internal structure of subhalos or the central shapes of density profiles of satellite halos [764].

Alternative models that modify the nature of dark matter have been investigated to solve this problem: non-trivial dark matter physics [1203, 356], interaction between the dark matter and dark radiation components [1596, 1782], self-interacting dark matter [1891, 1783] and fuzzy dark matter [1597]

[104] The well know Navarro–Frenk–White profile [1340, 1341] is cusped with $\rho(r \to 0) \sim r^{-1}$.

The problem of satellite planes

In the problem of satellite planes [1115, 934, 504, 1413, 1411] several satellite galaxies of the MW, of neighboring Andromeda galaxy (M31), and of Centaurus A (CenA) are part of thin plane that is approximately perpendicular to the Galactic disk. Moreover measurement of the motions of satellite galaxies has shown that their orbits appear to be correlated [1412, 935, 1655]. This flattened structure and coherent motions of satellite galaxy systems is in inconsistency with the prediction of the ΛCDM model as inferred from simulations [1411]. The simulations based on ΛCDM cosmology indicate uncorrelated and close to isotropic satellite structures [1176, 1894]. In these simulations the observed structure formations with spatial and kinematic coherence distribution are very rare with a probability $\sim 10^{-3}$ [1413, 1411].

The angular momentum catastrophe

The angular momentum catastrophe [341] concerns a catastrophic angular momentum loss of gas during disk galaxies formation in Smooth Particle Hydrodynamics (SPH) [1300] simulations. The formed disks in simulations according to the predictions of ΛCDM have smaller scale lengths by a factor of $2-3$ compared with observed ones [394]. An axion dark matter model may resolve this discrepancy between the observed and predicted angular momentum distributions of baryons (ordinary cold dark matter) in the dwarf galaxies [217].

Baryonic Tully-Fisher Relation (BTFR)

Baryonic Tully-Fisher Relation (BTFR) [1268, 1150]. As mentioned above, the well known Tully-Fisher (TF) [1737] empirical relation connects the velocity of rotation of a spiral galaxy with its intrinsic luminosity while the Baryonic Tully-Fisher Relation (BTFR) [1270, 1773, 829] Eq. (78) is a scaling relation between the observed total baryonic mass M_b (stars plus gas) of a spiral galaxy and its rotation velocity V_c (see Subsection 11.2.1). The problem for ΛCDM model as inferred from simulations [e.g. 646] is that the BTFR leads to existence of a higher intrinsic scatter ($\sim 0.15\,dex$) and a lower slope ($s = 3$) compared to the observed ($\sim 0.10\,dex$ and $s \sim 4$) [1150]. McGaugh [1266] suggests the Modified Newtonian Dynamics (MOND) [1288] as a possible solution to this problem. However some simulations or semi-analytic approaches of galaxy formation within a ΛCDM cosmological context can reproduce a realistic BTFR slope but not its small scatter [e.g. 1569, 595, 773, 1583].

The void phenomenon

The void phenomenon[1419] refers to the emptiness of voids (the number of small galaxies in the void). Cosmological N-body simulations in the context of ΛCDM have established a clear prediction [809] that many small dark matter haloes should reside in voids [1420, 1416]. This is consistent with observations on large scales but is inconsistent with observations on small scales. In particular the local void contains much fewer galaxies than expected from ΛCDM theory [1711].

11.3.7 Age of the Universe

A lower limit can be set on the age of the Universe by the ages of the oldest stars (or oldest astrophysical objects) because on cosmological timescales they form shortly after the Big Bang. In the context of ΛCDM cosmology, the standard theory [836, 376, 33, 377, 375] and cosmological numerical simulations [1883, 898, 1844] predict that the first stars, the so-called population III (Pop III), formed in dark matter minihaloes of typical mass $M \sim 10^5 - 10^6 M_\odot$

at redshifts $z \sim 20 - 30$ (about 100 million years after the Big Bang i.e. about around the end of the cosmic dark ages) [for models indicating late, $z \sim 2 - 7$, Pop III star formation, see 1721, 983].

The age of the Universe t_* as obtained from local measurements using the ages of oldest observed stars (the so-called population II (Pop II)) in the MW appears to be larger and in some tension with the corresponding age of the Universe t_U obtained using the CMB Planck data in the context of ΛCDM [1771].

The age of the Universe in the flat ΛCDM model is an observable determined by the integral

$$t(z) = \int_0^{z_t} \frac{dz'}{(1+z')H(z')} = \frac{1}{H_0}\int_0^{z_t} \frac{dz'}{(1+z')\left[\Omega_{0m}(1+z')^3 + \Omega_{0r}(1+z')^4 + (1-\Omega_{0m})\right]^{1/2}} \tag{174}$$

where t is the cosmic time corresponding to redshift z_t. Thus the age of the Universe is $t_U = t(z_t = \infty)$.

For example the age of the MW Population II halo, metal deficient, high velocity subgiant HD-140283 (also known as Methuselah star) is estimated to be $t_* = 14.46 \pm 0.31\, Gyr$ by Bond *et al.* [334] and using new sets of stellar models is estimated to be $t_* = 14.27 \pm 0.80\, Gyr$ by VandenBerg *et al.* [1764]. These estimates of the age of this star are slightly higher ($\sim 2\sigma$) than the age of Universe $t_U = 13.800 \pm 0.024\, Gyr$ inferred by CMB Planck18 data [72] but within the errors it does not conflict with this age.

Despite of the above indications the analysis by Jimenez *et al.* [979] using new parallaxes from the Gaia space mission [1446, 1484] in place of the older HST, reports a revision of the age of HD-140283 to $t_* = 13.5 \pm 0.7\, Gyr$ which is more compatible with the age t_U inferred by Planck data. Also the analysis by Valcin *et al.* [1761] using populations of stars in globular clusters (very-low-metallicity stars) reports age of the Universe constrained to be larger than $t_* = 13.5^{+0.16}_{-0.14}\, Gyr$.

Clearly, Eq. (174) indicates that in a ΛCDM Universe the quantities H_0, t_U and Ω_{0m} are related. Therefore the determination of the age of older objects based on local Universe observations provides a test of the current cosmological model and plays an important role in the studies of Hubble and spatial curvature tensions [979, 613, 621, 1814].

11.3.8 The Lithium problem

It has long been known (since the early 80's) that absorption lines in the photospheres of old, metal-poor (Population II) halo stars in the Milky Way's halo indicate ~ 3.5 times less primordial abundance of lithium isotope ^7Li compared to the prediction of the standard BBN theory [536, 181, 538]. The observed value of the lithium abundance[105] $^7Li/H = (1.6 \pm 0.3) \times 10^{-10}$ [1914] is smaller than the theoretically expected value $^7Li/H = (5.62 \pm 0.25) \times 10^{-10}$ [272] at a level $\sim 5\sigma$. This constitutes the lithium problem [712]. No such problem exists for the observed abundances of other light elements ^2H (or D), ^3He, and ^4He that are in broad quantitative agreement with BBN predictions + WMAP/Planck cosmic baryon density Ω_b which is deduced by the CMB [539, 1700].

A number of theoretical or experimental studies in the literature have attempted to address the lithium problem [e.g. 842, 1464, 1847, 1126, 1473, 1588, 810, 1575, 912, 491, 1310, 863, 948, 938]. For example the analysis by Clara and Martins [486] shows that the variations in Nature's fundamental constants on primordial nucleosynthesis provide a possible solution to the lithium problem. Specifically, they determined that if the value of the fine-structure constant α at the primordial nucleosynthesis epoch was larger than the present one by ten parts per million of relative variation, the lithium problem could be resolved.

[105] Usually in the literature the abundance of lithium is expressed by $A(^7Li) = 12 + \log_{10}[n(^7Li)/n(H)]$ where n is the number density of atoms and 12 is the solar hydrogen abundance.

It was also proposed by Di Bari *et al.* [594] that decaying dark matter into dark radiation in the early Universe can solve the long-standing lithium problem, leaving completely unaffected the abundance of other light elements. This mechanism was also proposed to alleviate the H_0 tension (see Subsection 11.2.2) but is severely constrained by the Planck data [135].

Measurements of lithium [e.g. 1591, 1279] may not be representative of the cosmological production mechanism [1679, 943]. It is thus possible that the solution to the lithium problem lies in the effects of stars in the lithium abundance. Therefore a precise knowledge of the stellar formation process and physics of stellar atmosphere is necessary to provide a fully satisfactory solution. Thus, possible solutions to this persistent problem can be classified into four categories [see 712, 539, 1253, for a review]:

- Cosmological solutions (e.g. new theory beyond the standard BBN including variations of fundamental constants) [732, 486, 1137, 1089, 281, 1025, 470, 490, 912, 1210]
- Nuclear Physics solutions (e.g. reactions destroy lithium during or after BBN) [537, 353, 456, 489, 374, 1310, 863, 948]
- Astrophysical solutions (e.g. stars destroy lithium after BBN) [1460, 1516, 1096, 745]
- Extensions of the standard model (e.g. simultaneous imposition of photon cooling after BBN, X-particle decay and a primordial magnetic field [1847, 1848], destruction of ^{7}Be due to the decay of a sterile neutrino [1575] and including new particles or interactions [810].

11.3.9 Quasars Hubble diagram

The quasar distances can be estimated from their X-ray (coronal) emission generated by a plasma of hot relativistic electrons around the accretion disk. The emission is induced through inverse-Compton scattering processes and UV emission generated by the accretion disk where the gravitational energy of the infalling material is partially converted to radiation [1532, 1213].

In recent years model independent derivation[106] of the distance modulus–redshift relation using high-z quasars ($z \lesssim 7$) as distance indicators (quasars Hubble diagram) provides a new bright standard candle in the higher redshifts and earlier times beyond SnIa. The method used is based on a non-linear relation between the X-ray and the UV emissions at low redshift which is of the form [192, 1214, 1682, 1531, 1532]

$$\log_{10} L_X = \gamma_q \log_{10} L_{UV} + \beta_q \tag{175}$$

where L_X and L_{UV} are the rest-frame monochromatic luminosities at 2 keV and at 2500 Å, respectively [192]. Also $\gamma_q \sim 0.6$ [1682, 1214, 1576, 1778, 1751, 301, 1532] and β_q are fitting parameters of the luminosities.

Extending a Hubble diagram up to redshift $z = 5.5$ shows hints for phantom dark energy [1532, 210, 1213]. In particular the distance modulus-redshift relation for a sample of 1598 quasars at higher redshift ($0.5 < z < 5.5$) is in disagreement with the concordance model at a $\sim 4\sigma$ significance level[107] [1532]. Moreover, the analysis by Lusso *et al.* [1213] building a Hubble diagram by combining three samples of Pantheon, quasars, and gamma-ray bursts (GRBs) reported tension at more than the $\sim 4\sigma$ statistical level with the flat ΛCDM model.

[106] Yang *et al.* [1851] argued that even though the data used in this approach are valid, their analysis involves significant uncertainties as it may lead to spurious artificial tensions.

[107] The analyses of the high$-z$ quasar data has lead to a wide range of conclusions [1281, 1851, 1049, 1169, 1768]. For example Yang *et al.* [1851] concludes that the log polynomial expansion generically fails to recover flat ΛCDM beyond $z \sim 2$, thus implying that the previously derived $\sim 4\sigma$ tension may be artificial.

However Khadka and Ratra [1050] using an updated, larger QSO dataset [1215] containing 2421 QSO measurements with redshifts up to $z \sim 7.5$ have demonstrated that the L_X-L_{UV} relation parameter values depend on the cosmological model thus cannot be used to constrain cosmological parameters. Recently Khadka and Ratra [1051] demonstrated that the parameter values of the largest of seven sub-samples in this QSO dataset depend on the cosmological model while the second and third biggest sub-samples appear standardizable.

11.3.10 Oscillating signals in short range gravity experiments

The most constraining test of gravity at very short distance (sub-millimeter) scales looking for departures from Newtonian gravity is implemented via torsion balance experiments. A reanalysis of short range gravity experiments has indicated the presence of an oscillating force signal with sub-millimeter wavelength [1435, 146]. In particular Perivolaropoulos [1435] has indicated the presence of a signal at 2σ level of spatially oscillating new force residuals in the torsion balance data of the Washington experiment [1008]. As an extension of the previous analysis the study by Antoniou and Perivolaropoulos [146] using Monte Carlo simulation and analysing the data of the Stanford Optically Levitated Microsphere Experiment (SOLME) which involves force measurements an optically levitated microsphere as a function of its distance z from a gold coated silicon cantilever [1518] reports a oscillating signal at about 2σ level.

The sub-millimeter scale of the quantum nature of dark energy may be written as

$$\lambda_{de} \equiv \sqrt[4]{\frac{\hbar c}{\rho_{de}}} \approx 0.085\, mm \tag{176}$$

where it is assumed that $\Omega_{0m} = 0.3$ and $H_0 = 70\ km\ s^{-1}\ Mpc^{-1}$.

Thus, if the accelerating expansion of the Universe is connected with effects of modified gravity due to quantum gravity [46] it would be natural to expect some modification of Newton's law at the submillimeter scale.

The deviations from Newton's law of gravitation is usually described in the context of scalar-tensor [679, 756] and flat extra dimension theories [164, 165, 144, 1443, 1428, 719, 1039] by a short range Yukawa type potential of the form

$$V_{eff} = -G\frac{M}{r}\left(1 + \alpha_Y e^{-mr}\right) \tag{177}$$

where α_Y and m are parameters to be constrained by the data.

Alternatively, a power law ansatz may also generalize the gravitational potential to the form

$$V_{eff} = -G\frac{M}{r}\left[1 + \bar{\beta}^k \left(\frac{1}{mr}\right)^{k-1}\right] \tag{178}$$

This power law parametrization is motivated by some brane world models [635, 267, 378, 1359].

For $m^2 < 0$ the Yukawa gravitational potential becomes oscillating and takes the form

$$V_{eff} = -G\frac{M}{r}\left[1 + \alpha_Y \cos\left(mr + \theta\right)\right] \tag{179}$$

where θ is a parameter.

Recently a reanalysis of the data of the Washington experiment searching for modifications of Newton's Law on sub-millimeter scales by Perivolaropoulos and Kazantzidis [1439] has indicated that a spatially oscillating signal is hidden in this dataset. In addition it is shown that even

though this signal cannot be explained in the context of standard modified gravity theories[108] (viable scalar tensor and $f(R)$ theories), it occurs naturally in nonlocal (infinite derivative) gravity theories [650, 1038, 742] that predict such spatial oscillations without the presence of ghosts (instabilities) and has a well-defined Newtonian limit.

The origin of oscillating signals could be due to three possible effects:

- A statistical fluctuation of the data.
- A periodic distance-dependent systematic feature in the data.
- A signal for a short distance modification of GR (e.g. non-local modified theory of gravity).

In the later case, it is important to identify modified theories that are consistent with such an oscillating signal and are not associated with instabilities [e.g. 1718, 303].

11.3.11 Anomalously low baryon temperature

The Experiment to Detect the Global Epoch of Reionization Signature (EDGES) collaboration [349] report anomalously low baryon temperature $T_b \approx 4K$ at $z \approx 17$ (half of its expected value). This temperature was inferred from the detection of global (sky-averaged) 21-cm absorption signal which is centred at a frequency of $\sim 78\ MHz$. The absorption depth of cosmic CMB photons at redshifts range $15 \lesssim z \lesssim 20$ estimated by EDGES is more than twice the maximal value expected in the ΛCDM model, at $\sim 3.8\sigma$ significance.

Possible explanations of this discrepancy were investigated and various models were proposed [e.g. 890, 733, 1323, 350]. For example Hill and Baxter [890] argue that EDE can explain this anomaly.

The EDGES observation has been used to constrain various cosmological models of dark matter and dark energy [e.g. 1872, 220, 1101, 890].

11.3.12 Colliding clusters with high velocity

Observed galaxy clusters like the massive ($\sim 10^{15} M_\odot$) high-redshift ($z = 0.87$) interacting pair known as El Gordo (ACT-CL J0102-4915) [1283] have a very high relative velocity. This implies that formation of large structures may have taken place earlier than expected in ΛCDM cosmology. Asencio *et al.* [172] based on light cone tomography estimated that the too-early formation of El Gordo rules out ΛCDM cosmology at 6.16σ confidence. The early and rapid formation of clusters which consist of two colliding massive galaxy clusters at a high redshift may constitute a problem of the ΛCDM model. Asencio *et al.* [172] argue that MOND with light sterile neutrinos model as suggested by Haslbauer *et al.* [859] can resolve this issue.

[108] For a free massive scalar Perivolaropoulos and Skara [1440] investigate the physical conditions that can eliminate the tachyonic instabilities or at least drastically change their lifetime.

Table 20: Some existing and upcoming large-scale structure missions/experiments.

Experiments	Type	Probes	Redshift	Wavelengths	Operator
Euclid	Space	WL, BAO	$z \lesssim 6$	$550\,nm - 2\,\mu m$	ESA
Vera C. Rubin Obs.	Ground	WL, BAO	$z \lesssim 7.5$	$320 - 1060\,nm$	LSST
Gaia	Space	Astrometry	$z \simeq 0$	$320 - 1000\,nm$	ESA
JWST	Space	WL	$z \lesssim 15$	$0.6 - 28.3\,\mu m$	NASA-ESA-CSA
GAUSS	Space	WL 3×2pt	$z \lesssim 5$	$0.5 - 5\,nm$	

Table 21: Some existing and upcoming CMB missions/experiments.

Experiments	Type	Detectors	Frequencies[109] (GHz)	Resolution[110] $(arcmin)$	Sensitivity[111] $(\mu K\,arcmin)$	Sky Cover
Planck	Space	74	$25 - 1000$	$5 - 33$	~ 30	All
CMB S4	Ground	$500 \cdot 10^3$	$30 - 270$	$0.8 - 11$	~ 1	70%
SO LAT	Ground	$30 \cdot 10^3$	$27 - 280$	0.1	~ 6	40%
SO SATs	Ground	$30 \cdot 10^3$	$90 - 280$	0.5	~ 2	10%
SPT-3G:	Ground	$16 \cdot 10^3$	$90 - 280$	1	$\sim 3.5, 6$	10%

Table 22: Some existing and upcoming GW experiments/observatories

Experiments	Type/Detectors	Arms	Frequencies[112] (Hz)	Location	L
Adv. LIGO	Ground/Laser interf.	$2 \times 4\,km$	$10 - 10^3$	Hanford, USA	
Adv. LIGO	Ground/Laser interf.	$2 \times 4\,km$	$10 - 10^3$	Livingston, USA

ET	Undergr./Laser interf.	$3 \times 2 \times 10\,km$	$1 - 10^4$		

11.4 Conclusions-Discussion-Outlook

In the present review, we discussed in a unified manner many existing curiosities in cosmological and astrophysical data that appear to be in some tension (2σ or larger) with the standard ΛCDM model as specified by the Planck18 parameter values. The Hubble tension is the most significant observational indication that the current standard model ΛCDM may need to be modified after more than 20 years since its establishment.

In addition to the well known tensions (H_0 tension, S_8 tension and A_L anomaly), we provided a list of the non-standard cosmological signals in cosmological data. We presented the current status of these signals and their level of significance and also referred to recent resources where more details can be found for each signal. These signals have a lower statistical significance level than the H_0 tension but may also constitute hints towards new physics. We also briefly discussed possible theoretical approaches that have been considered in order to explain the non-standard nature of these signals.

We also discussed the possible generic extensions of ΛCDM model. Generic extensions of ΛCDM may allow for a redshift dependence of the parameters w, μ_G, Σ and α as well as a possible large scale spatial dependence of these parameters which could violate the cosmological principle. *Varying fundamental constants* can potentially address the Hubble tension, the fine structure constant α dipole, the lithium problem, the growth tension, the curious SnIa M signals (variation of the SnIa absolute magnitude $\mathcal{M}$), quasar signals and the ISW CMB signal.

The strategic approach required for the identification of new physics may include the following three steps:

- Tune current missions towards verification or rejection of non-standard signals.
- Identify favored parametrizations of $H(z, w(z), r)$, $\mu_G(z, r)$, $\Sigma(z, r)$, $\alpha(z, r)$ assuming that at least some of the non-standard signals are physical.
- Identify theoretical models (field Lagrangians) that are consistent with these parametrizations that can address simultaneously more than one of these tensions. Interestingly, for example only a small subset of modified gravity models is consistent with the weak gravity + ΛCDM background [1833, 1465, 755, 754] suggested in the context of the S_8 tension.

In the next decades new observational data from existing and upcoming missions/experiments (see Tables 20, 21 and 22) will improve measurements and open up a wide range of new directions in the explanation of the curiosities of ΛCDM cosmology and understanding of cosmological physics. Here we provide an incomplete list of these missions:

- **Euclid:** The European Space Agency (ESA) Euclid mission [1138] is planned for launch in July-December 2022. The goals of Euclid are to investigate the nature of dark matter, dark energy and gravity and thus to provide a better knowledge of the origin of the accelerated expansion of the Universe [1138, 1499, 484, 1586, 127]. The optical and NIR Euclid survey using the cosmological WL and BAO probes will detect a high number of galaxy clusters up to redshift $z \sim 2$ (and possibly higher) in a redshift range that is sensitive to dark energy [45] and will provide consistent growth rate data in both the low-z and high-z regimes. Therefore, Euclid will improve significantly the constraints on cosmological parameters such as σ_8 and the mass density parameter Ω_{0m} with a precision of $\sim 10^{-3}$ for ΛCDM [1586]. The Euclid survey will also measure the equation of state parameter of dark energy w_{DE} with higher precision ($\sim 1\%$) than precursor surveys. Stochastic inhomogeneities are expected to lead to an intrinsic uncertainty in the values of cosmological parameters obtained with such high redshift surveys. The corresponding cosmic variance in the context of Euclid for the measurement of H_0 has been shown to be limited to about 0.1% [688]. Thus Euclid and other deep surveys ($z \gtrsim 0.15$) will

provide an estimation of the H_0 which will be more precise than the low redshift surveys ($z \lesssim 0.15$). Such improved constraints from Euclid in combination with contemporary surveys [1245, 1246, 1349] will allow the verification or rejection of many of the non-standard signals discussed in this review and will also help distinguish among the favored theoretical models that have been proposed for the explanation of these signals.

- **Vera C. Rubin Observatory Legacy Survey of Space and Time:** The Large Synoptic Survey Telescope (LSST), recently renamed the Vera C. Rubin Observatory LSST [954, 34] is a future survey of the southern sky planned for the beginning in 2022. The Vera C. Rubin Observatory based in Chile with an $8.4\,m$ ($6.5\,m$ effective) telescope in six bands, targeting at least $18,000\,deg^2$ of high galactic latitude sky, will provide databases including 25 billion galaxies with $\gtrsim 0.2$ arcsecond pixel sampling [1241]. The main cosmological goals of the Vera C. Rubin Observatory ground-based project are to investigate the nature of dark matter and the dynamical behavior of dark energy by measuring WL and BAO [1241]. Vera C. Rubin observatory will detect enormous number of galaxies and in combination with the Euclid BAO survey will probe an unprecedented range of redshifts. These surveys can determine $w_{DE}(z)$ in bins of redshift and their dark energy constraining power could be orders of magnitude greater than that of precursor surveys [4]. The provided improved constraints on cosmological parameters allow to address potential systematics and to ensure that any measured tension is robust. In addition, the Vera C. Rubin project would be a useful tool in testing the models which have been used to explain these tensions.

- **CMB-S4:** The fourth generation[113] (Stage-4) ground-based CMB experiment (CMB-S4) [1, 6, 7], is planned to start observations in 2027. It is anticipated to be the definitive CMB polarization experiment. The goals of CMB-S4 are to detect the signature of primordial gravitational waves in order to shed light on models of inflation, to search for previously undiscovered light relic particles in order to study the dark Universe, to map normal and dark matter in the cosmos separately and to explore the time-variable millimeter-wave sky [1]. The CMB-S4 survey in combination with external cluster surveys which are sensitive to different redshift ranges such as the Vera C. Rubin will provide detailed cluster data [1]. These data will be used to study the growth of cluster scale perturbations, to improve constraints on cosmological parameters and to test the alternative models or extensions of ΛCDM which can be used to clarify the origin of many of the tensions and non-standard signals referred in the present review. The CMB-S4 will also contribute to neutrino cosmology providing compelling sensitivity in the constraint of the effective number of relativistic species, N_{eff} and of the sum of the neutrino masses $\sum m_\nu$ (see Aghanim *et al.* 72, Di Valentino and Melchiorri 604, for cosmological constraints and Capozzi *et al.* 434, for three-neutrino analysis). This project has also the potential to constrain $\Delta N_{eff} \equiv N_{eff} - N_{eff}^{SM} \simeq 0.060$ at 95% confidence level [6]. Planck has provided a constraint $\Delta N_{eff} \simeq 0.126$ at 95% confidence level using temperature and polarization TT, TE, EE + lowE data [72]. The improved constraints on N_{eff} will enable us to test the scenarios with modifications of ΛCDM model in the light relic sector.

- **Gaia:** The Gaia satellite was launched at the end of 2013 [1446, 1484]. This European Space Agency (ESA) mission Gaia provides data that allow us to determine with high accuracy positions, parallaxes and proper motions for more than 1 billion sources. There have been two data releases GDR1 [382] and GDR2 [381] of Gaia results. Using quasars Lindegren *et al.* [1188] found that the GDR2 suffer from the parallax zero point (ZP) error. Riess *et al.* [1521] refer to this additional error as parallax offset because it is not a

[113] Planck was the third generation space mission which mapped the anisotropies of CMB.

single value but depends on the color or/and magnitude of the source and its position on the sky. Riess et al. [311] found that the parallax offset can be measured directly from the Cepheids, but with a reduced precision of the distance scale from GDR2. This reduction leads to a increased uncertainty of the determination of H_0 value by a factor of 2.5.

Recently the Gaia team presented the Gaia Early Data Release 3 (EDR3) (the full Gaia DR3 release is expected in 2022) [751] with improved parallaxes since GDR2. Using the EDR3 parallaxes and Cepheid PL relation the latest analysis of the SH0ES Team [1521] achieved a precision of 1.0% in the geometric calibration of Cepheid luminosities. The precision of the geometric calibration of Cepheids will approach 0.5% by Gaia DR4 [1521]. This higher precision will be sufficient to confirm the present H_0 tension.

- **James Webb Space Telescope:** The James Webb Space Telescope (JWST or 'Webb') [1551, 762] is a joint NASA-ESA-CSA (National Aeronautics and Space Administration -European Space Agency-Canadian Space Agency) large, cold (under $50\,K$), infrared optimized ($0.6 < \lambda < 28.3.0\,\mu m$), space telescope and its launch is currently planned for 31 October 2021. JWST is a scientific successor to HST and will extend its discoveries to higher redshifts. It is nearly twice as big as HST with $6.6\,m$ gold-plated primary mirror much larger than $2.4\,m$ of HST.

  The two main goals of this upcoming, next-generation telescope are to look much closer to the Big Bang and to investigate the light from the first stars and galaxies that formed in the Universe [see 762, for other goals]. The observational data of this mission will essentially enhance our understanding of the formation and evolution of galaxies, stars, and planetary systems. The JWST will detect galaxies out to a redshift of $z \geq 15$. It will probably be able to detect Pop III stars (see Subsection 11.3.7) in the high-redshift galaxies [1887, 1550] in a mass range $140 - 260\,M_{\odot}$ as pair-instability supernovae [1824, 857]. Various projects using the JWST observations will provide stronger nucleosynthesis constraints inside the first supernova [375] and constraints on the nature of dark matter [1606, 1225]. These constraints and other unprecedented information from JWST could potentially help address the lithium problem, explain small-scale curiosities and improve constraints on the age of Universe.

- **Simons Observatory:** The Simons Observatory (SO) [752, 54, 37] is a next generation CMB ground-based experiment. SO consists of one $6\,m$ Large Aperture Telescope (LAT) and three $0.42\,m$ Small Aperture Telescopes (SATs) at the Atacama Desert, Chile. It will provide more accurate measurements of the primary CMB temperature and polarization signals. The main targets of SO as described by Ade *et al.* [54] are: primordial perturbations, effective number of relativistic species, neutrino mass, deviations from ΛCDM, galaxy evolution (feedback efficiency and non-thermal pressure in massive halos) and reionization (measurement of duration). Also a goal of SO survey is to provide a catalog of 16.000 galaxy clusters and more than 20.000 extragalactic sources. The sky region from SO survey overlaps with many surveys such as LSST, DES, DESI and Euclid at different wavelengths [54]. This overlap is extremely beneficial as it will allow data cross correlation tests [for a detailed discussion, see 630]. Like CMB-S4, SO will provide improved constraints on the effective number of relativistic species N_{eff}, the sum of the neutrino masses $\sum m_{\nu}$ and the dark energy equation of state w_{DE} [see 54, for the forecast constraints on cosmological parameters]. Also the SO and CMB-S4 experiments will measure the primordial tensor-to-scalar ratio r to a target sensitivity of $\sigma_r \sim 0.002$ (for an $r = 0$ model). This will be an improvement by a factor of approximately 5 compared to Planck sensitivity. In addition the uncertainty of the determinations of H_0 from SO will be two and five times better than that inferred from Planck and local direct measurement

respectively. Therefore, the SO data will enable us to improve constraints on extensions of ΛCDM which alleviate its tensions and curiosities. In addition the improved quality of lensing data from SO as well as CMB-S4 will improve our understanding of the CMB anisotropy anomalies.

- **SPT-3G:** This is a third generation CMB experiment [278, 643]. It uses the third survey camera SPT-3G which was installed on the South Pole Telescope (SPT) in 2017. The SPT-3G with the 10-meter diameter telescope targets at least $1,500\,deg^2$ region of low-foreground sky in three spectral bands centered at 95, 150, and $220\,GHz$ with $\sim 16,000$ detectors (10 times more than its predecessor SPTpol Austermann *et al.* 190, Keisler *et al.* 1040).

  Its scientific goals aim to constrain the physics of the cosmic inflation, to explore the neutrino sector, and to constrain the relativistic energy density of the Universe [278, 643]. The SPT-3G survey in combination with the deep and wide optical survey DES, will provide detailed data on $\sim 200\,Mpc$ scales which may be used to test General Relativity. The SPT-3G will also provide stringent and improved constraints on the effective number of relativistic species, N_{eff} and on the sum of the neutrino masses $\sum m_\nu$ by synergy with Planck.

- **GAUSS:** This space mission concept combines the WL and galaxy clustering probes using three two-point correlation functions (3×2pt analysis) of gravitational lensing and galaxy positions: the cosmic shear, the galaxy clustering and galaxy-galaxy lensing. GAUSS aims to fully map the cosmic web up to redshift $z \sim 5$ and to provide a catalog with the spectroscopic redshifts and the shapes of 10 billions of galaxies [316] increased by a factor of approximately 10^3 compared to DESI which measures the spectra of 35 million galaxies and quasars [64]. The very large sky coverage and the high galaxy density provided by the GAUSS will facilitate the construction of the 3D matter power spectrum of all scales (large and small) in detail. The 3×2pt correlation functions in combination with 3D matter power spectrum will provide stronger constraints and break parameter degeneracies [316]. The constraining power of the GAUSS will be an order of magnitude larger than that of any currently planned projects such as Euclid and Vera C. Rubin Observatory.

- **Laser Interferometer Gravitational-Wave Observatory:** The Laser Interferometer Gravitational-Wave Observatory (LIGO) proposed by Abramovici *et al.* [39] is a large-scale experiment that uses ground-based laser interferometers with $L = L_x = L_y = 4\,km$ long orthogonal arms to detect GWs[114].

  There are two identical LIGO instruments, one in Hanford (LHO) and one in Livingston (LLO) separated by roughly $3000\,km$. The principle of operation of laser interferometers [781, 1317] is similar to that of a simple interferometer, such as that used by Michelson and Morley. Detection of GWs with strain amplitude $h \sim 10^{-21}$ by a ground detector with arms of length $L = 4\,km$ requires length change measurement [781]

$$\Delta L = \delta L_x - \delta L_y \sim hL \sim 4 \cdot 10^{-18}\,m \tag{180}$$

[114] Another class of GW detectors are the resonant mass antennas [1463, 1224, 76, 185] in the frequency range from $15\,Hz$ to few kHz. The principle of operation of mass resonance detectors is related to the periodic dimensional changes caused by the ripple effect of GWs on solid bodies. The Weber bar [1813] is a first generation resonant mass detector, the ALLEGRO [1256], NAUTILUS [116, 183, 184], EXPLORER [485], AURIGA [454], NIOBE [306, 875] are the second generation and Mario Schenberg [77], MiniGRAIL [1784] are the third generation.

For the period between 2002 and 2010, the two LIGO observatories were unable to detect GWs. The detectors were later replaced by much improved Advanced LIGO versions [2, 852]. The improved detectors that officially went into operation in 2015 have about ten times the sensitivity to detect GWs in the frequency range around $\sim 100\,Hz$ compared to the initial LIGO interferometers [2]. In addition Advanced LIGO extends the low frequency end from $40\,Hz$ down to $10\,Hz$. Much of the research and development work for LIGO/Advanced LIGO projects was based on the groundbreaking work of the GEO 600 detector [1830, 63] which is a $600\,m$ interferometer in Hanover, Germany.

On February 11, 2016 the LIGO Scientific Collaboration [12] and the Virgo Collaboration [790, 40] announced the first directly observed GWs from a signal detected on September 14, 2015 by the Advanced LIGO devices (the Virgo was not working at the time due to an upgrade). The detected signal was named GW150914 and its source was the merger of two stellar-mass BHs [13].

The Advanced Virgo [41] with $3\,km$ arm length interferometer contributes to the reliability of Advanced LIGO experimental device detections allowing for greater accuracy in locating the source in the sky (triangulation i.e 3-detector localization) [1644] and more accurate reconstruction of the signal waveform [for the relevant method, see 518, 1194, 519, 555, 783]. For example, in the case of the event GW170814 the three detectors improved the sky localization of the source, reducing the area of the 90% credible region from $1160\,deg^2$ using only the two LIGO detectors to $60\,deg^2$ using all three LIGO/Virgo detectors and reduced the luminosity distance uncertainty from $570^{+300}_{-230}\,Mpc$ to $540^{+130}_{-210}\,Mpc$ [15].

In 2019 the Advanced LIGO [2], the Advanced Virgo [41] and the Japanese successor of the Tama300 [142, 148], Kamioka Gravitational (KAGRA) wave detector [180, 1673, 92] (previously called LCGT Kuroda 1125) signed collaboration agreement to begin joint observation. The LIGO, Virgo and KAGRA collaboration will be probably complemented by other interferometers like the planned Indian LIGO by the Indian Initiative in Gravitational Wave Observations (IndIGO) consortium [1746]. In addition a future third-generation ground-based detector the Cosmic Explorer (CE) [14, 1506, 1505] is envisioned to begin operation in the 2030s in the USA. It will contribute to the GW Astronomy beyond LIGO. CE with ten times longer arms ($40\,km$) than Advanced LIGO's will amplify the amplitude of the observed signals [680, 457] and will significantly increase the sensitivity of the observations [1505, 1506].

Many events (~ 50 compact binary coalescences) were observed by the Advanced LIGO/Virgo interferometers during three observing run periods (O1, O2 and O3)[115]. The full three-detector network provided data which enabled the standard siren measurement of the Hubble constant H_0 (see Subsections 11.2.1). These data are not yet sufficiently constraining the Hubble constant but in the future they are expected to improve significantly.

- **Laser Interferometer Space Antenna:** The Laser Interferometer Space Antenna (LISA) [437, 120] is a large-scale space mission proposed by ESA, planned for launch in 2034. It will consist of three spacecrafts placed in an equilateral triangle with arms 2.5 million kilometers long which will be placed near the Earth in a heliocentric orbit. In order to pave the way for the LISA mission ESA launched LISA Pathfinder in 2015 and it was operational from 2016 to 2017 [167, 168]. The results from scientific research show

[115] For the first Gravitational Wave Transient Catalog (GWTC-1) during O1 and O2, see Abbott *et al.* [11], for second Gravitational Wave Transient Catalog (GWTC-2) from the first part of the third observing run (O3a), see Abbott *et al.* [19] and for third Gravitational Wave Transient Catalog (GWTC-3) from the second part of the third observing run (O3a), see Abbott *et al.* [22]

that LISA Pathfinder works exactly five times better than required, with a successful demonstration of the basic technologies for a large gravitational wave observatory.

LISA is designed to detect GWs in the frequency range from $0.1\,mHz$ to $10^{-1}\,Hz$ [119, 118] targeting very different source populations from ground-based detectors such as LIGO, Virgo and KAGRA which operate in the frequency range[116] from $10\,Hz$ to $10^{3}\,Hz$ [16].

There are many different sources of GWs [see 1587, 833, 405, for a review of GW physics]. LIGO and Virgo can detect the merger events of binaries with masses $\lesssim 100 M_{\odot}$ while LISA will be able to detect the merger of massive BHs ($10^{5} - 10^{7} M_{\odot}$) with higher signal-to-noise ratio (SNR) and thus to perform precision tests in the strong gravity regime of ΛCDM model. LISA will detect events lasting weeks, months or years allowing us to observe a much larger volume of the Universe. It may improve our understanding of the early Universe. In addition the LISA mission will be able to detect sources like primordial BHs ($\sim 10^{-12} M_{\odot}$) which correspond to the mHz frequency [227, 228, 409]. This possibility can help to test primordial BH dark matter scenario. Finally, LISA and the Big Bang Observer (BBO) [526, 853], which is a proposed LISA's successor will detect many other known or currently unknown exotic sources. Thus it will enable us to explore alternative gravity theories and to address the problems of the ΛCDM cosmology.

- **Taiji:** Taiji [1542, 922] meaning 'supreme ultimate' is a Chinese large-scale space mission, planned for launch in 2033. Like LISA, Taiji is a laser interferometric GW detector which will consist of three spacecraft placed in an equilateral triangle with arms 2 million kilometers long in orbit around the Sun. Taiji will detect GWs in the frequency range from $0.1\,mHz$ to $10^{-1}\,Hz$. Like LISA, Taiji can detect many possible GW sources such as a stochastic GW background generated in the early Universe and the merger of two super massive BHs.

  A potential LISA-Taiji network was explored by Ruan *et al.* [1543, 1544]. This network with a separation distance of about $0.7\,AU$ can accurately localize the sky position of a GW source and may completely identify the host galaxy.

- **TianQin:** TianQin [1209, 1276] is a Chinese large-scale space mission. It aims to launch a laser interferometric GW detector around 2035. Like other space-base observatories, TianQin observatory consist of three spacecrafts placed in an equilateral triangle with arms $\sim 0.1\,Gm$ long but in geocentric orbit with an orbital radius of about $10^{5}\,km$ [1209, 1276]. TianQin aims to detect GWs in the frequency range from $10^{-4}\,Hz$ to $1\,Hz$ (overlapping with that of LISA near $10^{-4}\,Hz$ and with that of DECIGO near $1\,Hz$). It will search for GW signals from various cosmological sources such as the inspiral of supermassive BBH [703], stellar-mass BBH [1198], the merger of massive BBHs [1797] and stochastic GW background originating from primordial BHs [593] and/or cosmic strings [1387]. As a precursor mission of TianQin, TianQin-1 experimental satellite has been launched on 20 December 2019. The results from scientific research shows that TianQin-1 satellite has exceeded all of its mission requirements.

- **Deci-hertz Interferometer Gravitational wave Observatory:** The DECi-hertz Interferometer Gravitational wave Observatory (DECIGO) is a Japanese large-scale space mission [1022, 1020, 1021, 1019] which was proposed by Seto *et al.* [1619] and is planned for launch in 2027. DECIGO consists of four clusters (with two of them at the same position) and each cluster consists of three spacecrafts placed in an equilateral triangle with $1000\,km$ arm lengths in heliocentric orbit [1024]. As a precursor mission of DECIGO,

[116] The frequency range from $0.1\,mHz$ to $10^{-1}\,Hz$ is unobservable by any proposed ground based detectors, due to seismic noise.

B-DECIGO (smaller version of DECIGO) will be launched before 2030 with 100 km arm lengths orbiting around the earth at 2000 km altitude above the surface of the earth [1589, 1023, 1024].

DECIGO is designed to detect GWs in the frequency range from 0.1 Hz to 10 Hz which is located in a gap between the frequency band of the LISA/Taiji and ground-based detectors such as advanced LIGO, advanced Virgo, and KAGRA. It aims to observe the primordial gravitational waves i.e. the beginning of the universe ($10^{-36} - 10^{-34}\,sec$ right after the birth of the Universe), the formation of giant black holes in the center of galaxies and the compact binaries, such as white dwarf binaries [691].

- **Einstein Telescope:** Einstein Telescope (ET) or Einstein Observatory is a European proposed underground laser interferometric GW detector [1485]. It will be located underground at a depth of about $100 - 300\,m$ in order to reduce the seismic noises. ET will consist of three nested detectors placed in an equilateral triangle, each in turn composed of two interferometers with arms 10 km long. Using two arms in each side of the triangle will enable the determination of the polarisation of GWs. As a third-generation observatory is targeting a sensitivity 10 times better than of current second-generation laser-interferometric detectors such as advanced LIGO, advanced Virgo, and KAGRA [885]. ET will reduce thermal noise compared to the first and second generations of GW detectors by operating the mirrors at cryogenic temperatures as low as 10 K [886]. It is planned to start observations in 2035 with two candidate sites: north of Lula in Sardinia (Italy) and in Meuse-Rhine Euroregion (the border area of Belgium, Germany, and the Netherlands) [117]. ET will detect GWs in the frequency range from $\sim 1\,Hz$ to $\sim 10\,kHz$. This will allow the detection of BNS up to a redshift of $z \sim 2$, stellar-mass BBH at $z \sim 15$, and intermediate-mass BBH ($10^2 - 10^4 M_\odot$) at $z \sim 5$. The observations of these standard sirens will be useful to calibrate the cosmic distance ladder and will improve the estimation of the Hubble constant.

Cosmology is entering an even more exciting era! The combination of the existing puzzling observational signals discussed in this review, along with the upcoming revolutionary improvement in the quality and quantity of data creates anticipation for exciting new effects and new physics discoveries in the coming two decades.

11.5 Appendix

In this appendix we present the list of used acronyms.

Table 23: List of used acronyms.

Acronym	Meaning	Acronym	Meaning
ACS	Advanced Camera for Surveys	KiDS	Kilo Degree Survey
ACT	Atacama Cosmology Telescope	LAT	Large Aperture Telescope
AEDGE	Atomic Experiments for Dark Matter and Gravity Exploration	LDE	Late Dark Energy

Part IV
Properties of the Universe in Detail

12 Theory by Dodelson

12.1 The Standard Model and Beyond

Einstein's discovery of general relativity in the last century enabled us for the first time in history to come up with a compelling, testable theory of the universe. The realization that the universe is expanding and was once much hotter and denser allows us to modernize the deep age-old questions "Why are we here?" and "How did we get here?" The updated versions are now "How did the elements form?", "Why is the universe so smooth?", and "How did galaxies form from this smooth origin?" Remarkably, these questions and many like them have quantitative answers, answers that can be found only by combining our knowledge of fundamental physics with our understanding of the conditions in the early universe. Even more remarkable, these answers can be tested against astronomical observations.

This chapter describes the idea of an expanding universe, without using the equations of general relativity. The success of the Big Bang rests on three observational pillars: the Hubble diagram exhibiting expansion; light element abundances which are in accord with Big Bang nucleosynthesis; and the blackbody radiation left over from the first few hundred thousand years, the cosmic microwave background. After introducing these pieces of evidence, I move beyond the Standard Model embodied by the three pillars. Developments in the last two decades of the 20^{th} century - both theoretical and observational - point to

- the existence of dark matter and perhaps even dark energy
- the need to understand the evolution of perturbations around the zero order, smooth universe
- inflation, the generator of these perturbations

The emergent picture of the early universe is summarized in the time line of Figure 1.15.

12.1.1 The Expanding Universe

We have good evidence that the universe is expanding. This means that early in its history the distance between us and distant galaxies was smaller than it is today. It is convenient to describe this effect by introducing the scale factor a, whose present value is set to one. At earlier times a was smaller than it is today. We can picture space as a grid as in Figure 1.1 which expands uniformly as time evolves. Points on the grid maintain their coordinates, so the comoving distance between two points - which just measures the difference between coordinates remains constant. However, the physical distance is proportional to the scale factor, and the physical distance does evolve with time.

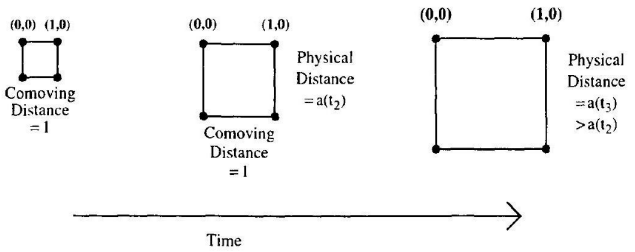

Figure 1.1. Expansion of the universe. The comoving distance between points on a hypothetical grid remains constant as the universe expands. The physical distance is proportional to the comoving distance times the scale factor, so it gets larger as time evolves.

In addition to the scale factor and its evolution, the smooth universe is characterized by one other parameter, its geometry. There are three possibilities: flat, open, or closed universes. These different possibilities are best understood by considering two freely traveling particles which start their journeys moving parallel to each other. A flat universe is Euclidean: the particles remain parallel as long as they travel freely. General relativity connects geometry to energy. Accordingly, a flat universe is one in which the energy density is equal to a critical value, which we will soon see is approximately 10^{-29} g cm^{-3}. If the density is higher than this value, then the universe is closed: gradually the initially parallel particles converge, just as all lines of constant longitude meet at the North and South Poles. The analogy of a closed universe to the surface of a sphere runs even deeper: both are said to have positive curvature, the former in three spatial dimensions and the latter in two. Finally, a low-density universe is open, so that the initially parallel paths diverge, as would two marbles rolling off a saddle.

To understand the history of the universe, we must determine the evolution of the scale factor a with cosmic time t. Again, general relativity provides the connection between this evolution and the energy in the universe. Figure 1.2 shows how the scale factor increases as the universe ages. Note that the dependence of a on t varies as the universe evolves. At early times, $a \propto t^{1/2}$ while at later times the dependence switches to $a \propto t^{2/3}$. How the scale factor varies with time is determined by the energy density in the universe. At early times, one form of energy, radiation, dominates, while at later times, nonrelativistic matter accounts for most of the energy density. In fact, one way to explore the energy content of the universe is to measure changes in the scale factor. We will see that, partly as a result of such exploration, we now believe that, very recently, a has stopped growing as $t^{2/3}$, a signal that a new form of energy has come to dominate the cosmological landscape.

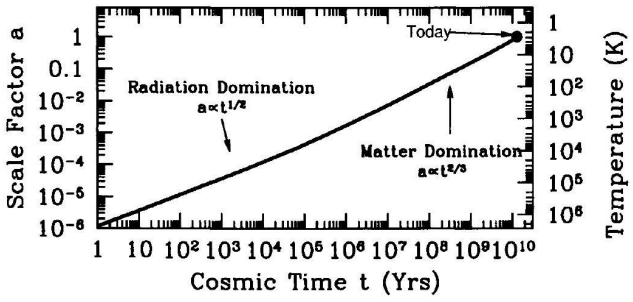

Figure 1.2. Evolution of the scale factor of the universe with cosmic time. When the universe was very young, radiation was the dominant component, and the scale factor increased as $t^{1/2}$. At later times, when matter came to dominate, this dependence switched to $t^{2/3}$. The right axis shows the corresponding temperature, today equal to 3 K.

To quantify the change in the scale factor and its relation to the energy, it is first useful to define the Hubble rate

$$H(t) := \frac{da/dt}{a}$$

which measures how rapidly the scale factor changes. For example, if the universe is flat and matter-dominated, so that $a \propto t^{2/3}$, then $H = (2/3)t^{-1}$. Thus a powerful test of this cosmology is to measure separately the Hubble rate today, H_0, and the age of the universe today. Here and throughout, subscript 0 denotes the value of a quantity today. In a flat, matter-dominated universe, the product $H_0 t_0$ should equal 2/3.

More generally, the evolution of the scale factor is determined by the Friedmann equation

$$H^2(t) = \frac{8\pi G}{3}\left[\rho(t) + \frac{\rho_{\rm cr} - \rho_0}{a^2(t)}\right]$$

where $\rho(t)$ is the energy density in the universe as a function of time with ρ_0 the present value. The critical density

$$\rho_{\rm cr} := \frac{3H_0^2}{8\pi G}$$

where G is Newton's constant. To use Einstein's equation, we must know how the energy density evolves with time. This turns out to be a complicated question because ρ in Eq. (1.2) is the sum of several different components, each of which scale differently with time. Consider first nonrelativistic matter. The energy of one such particle is equal to its rest mass energy, which remains constant with time. The energy density of many of these is therefore equal to the rest mass energy times the number density. When the scale factor was smaller, the densities were necessarily larger. Since number density is inversely proportional to volume, it should be proportional to a^{-3}. Therefore the energy density of matter scales as a^{-3}.

The photons which make up the cosmic microwave background (CMB) today have a well-measured temperature $T_0 = 2.725 \pm 0.002K$ (Mather et al., 1999). A photon with an energy $k_B T_0$ today has a wavelength $\hbar c/k_B T_0$. Early on, when the scale factor was smaller than it is today, this wavelength would have been correspondingly smaller. Since the energy of a photon is inversely proportional to its wavelength, the photon energy would have been larger than today by a factor of $1/a$. This argument applied to the thermal bath of photons implies that the temperature of the plasma as a function of time is

$$T(t) = T_0/a(t).$$

At early times, then, the temperature was higher than it is today, as indicated in Figure 1.2. The energy density of radiation, the product of number density times average energy per particle, therefore scales as a^{-4}.

Evidence from distant supernovae (Chapter 2; Riess et al., 1998; Perlmutter et al., 1999) suggests that there may well be energy, dark energy, besides ordinary matter and radiation. One possibility is that this new form of energy remains constant with time, i.e., acts as a cosmological constant, a possibility first introduced (and later abandoned) by Einstein. Cosmologists have explored other forms though, many of which behave very differently from the cosmological constant. We will see more of this in later chapters.

Equation (1.2) allows for the possibility that the universe is not flat: if it were flat, the sum of all the energy densities today would equal the critical density, and the last term in Eq. (1.2) would vanish. If the universe is not flat, the curvature energy scales as $1/a^2$. In most of this book we will work within the context of a flat universe. In such a universe, the evolution of perturbations is much easier to calculate than in open or closed universes. Further, there are several persuasive arguments, both theoretical and more recently observational, which strongly support the flatness of the universe. More on this in Chapters 2 and 8.

Figure 1.3 illustrates how the different terms in Eq. (1.2) vary with the scale factor. While today matter, and possibly a cosmological constant dominate the landscape, early on, because of the a^{-4} scaling, radiation was the dominant constituent of the universe.

Let's introduce some numbers. The expansion rate is a measure of how fast the universe is expanding, determined (Section 1.2) by measuring the velocities of distant galaxies and dividing by their distance from us. So the expansion is often

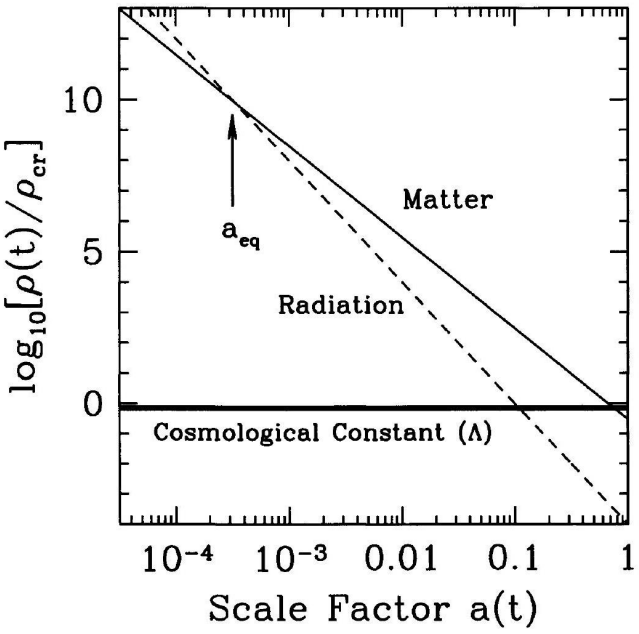

Figure 1.3. Energy density vs scale factor for different constituents of a flat universe. Shown are nonrelativistic matter, radiation, and a cosmological constant. All are in units of the critical density today. Even though matter and cosmological constant dominate today, at early times, the radiation density was largest. The epoch at which matter and radiation are equal is $a_{\rm eq}$.

written in units of velocity per distance. Present measures of the Hubble rate are parameterized by h defined via

$$\begin{aligned} H_0 &= 100h \text{ kmsec}^{-1}\text{Mpc}^{-1} \\ &= \frac{h}{0.98 \times 10^{10} \text{ years}} = 2.133 \times 10^{-33} h\text{eV}/\hbar \end{aligned}$$

where h has nothing to do with Planck's constant $\hbar$. The astronomical length scale of a megaparsec (Mpc) is equal to 3.0856×10^{24} cm. Current measurements set $h = 0.72 \pm 0.08$ (Freedman et al., 2001).

The predicted age for a flat, matter-dominated universe, $(2/3)H_0^{-1}$, is then of order 8 to 10 Gyr. The current best estimate for the age of the universe is 12.6Gyr, with a 95% confidence level lower limit of 10.4 Gyr (Krauss and Chaboyer, 2001), so this test suggests that a flat, matter-dominated universe is barely viable. You will show in Exercise 2 that the age of the universe with a cosmological constant is larger (for fixed h); in fact one of the original arguments in favor of this excess energy was to make the universe older.

Newton's constant in Eq. (1.3) is equal to 6.67×10^{-8} cm^3 g^{-1}sec^{-2}. This, together with Eq. (1.5), enables us to get a numerical value for the critical density:

$$\rho_{\rm cr} = 1.88h^2 \times 10^{-29} \text{ g cm}^{-3}.$$

An important ramification of the higher densities in the past is that the rates for particles to interact with each other, which scale as the density, were also much higher early on. Figure 1.4 shows some important rates as a function of the scale

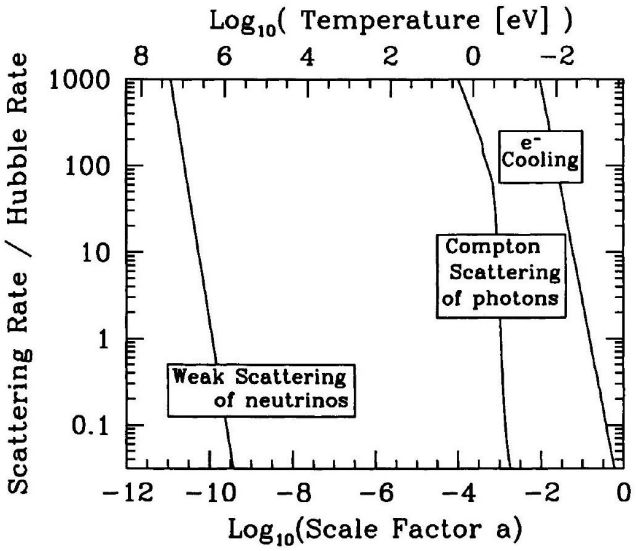

Figure 1.4. Rates as a function of the scale factor. When a given rate becomes smaller than the expansion rate H, that reaction falls out of equilibrium. Top scale gives (k_B times) the temperature of the universe, an indication of the typical kinetic energy per particle.

factor. For example, when the temperature of the universe was greater than several MeV/k_B, the rate for electrons and neutrinos to scatter was larger than the expansion rate. Thus, before the universe could double in size, a neutrino scattered many times off background electrons. All these scatterings brought the neutrinos into equilibrium with the rest of the cosmic plasma. This is but one example of a very general, profound fact: if a particle scatters with a rate greater than the expansion rate, that particle stays in equilibrium. Since rates were typically quite large, the early universe was a relatively simple environment: not only was it very smooth, but many of its constituents were in equilibrium. Chapter 2 explores some manifestations of the equilibrium conditions, while Chapter 3 touches on several cases where equilibrium could not be maintained because the reaction rates dropped beneath the expansion rate.

12.1.2 The Hubble Diagram

If the universe is expanding as depicted in Figure 1.1, then galaxies should be moving away from each other. We should therefore see galaxies receding from us. Recall that the wavelength of light or sound emitted from a receding object is stretched out so that the observed wavelength is larger than the emitted one. It is convenient to define this stretching factor as the redshift z:

$$1 + z := \frac{\lambda_{\text{obs}}}{\lambda_{\text{emit}}} = \frac{1}{a}.$$

For low redshifts, the standard Doppler formula applies and $z \simeq \frac{v}{c}$. So a measurement of the amount by which absorption and/or emission lines are redshifted is a direct measure of how fast the structures in which they reside are receding from us.

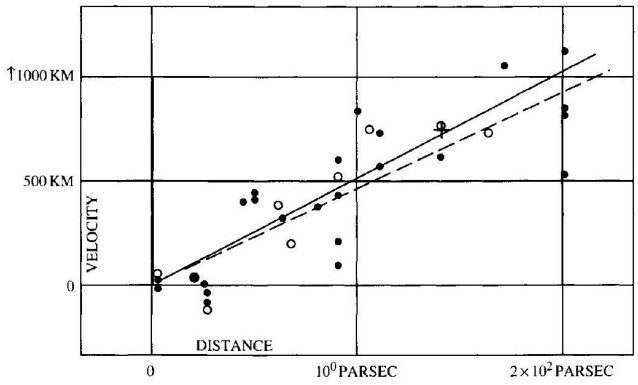

Figure 1.5. The original Hubble diagram (Hubble, 1929). Velocities of distant galaxies (units should be kmsec^{-1}) are plotted vs distance (units should be Mpc). Solid (dashed) line is the best fit to the filled (open) points which are corrected (uncorrected) for the sun's motion.

Hubble (1929) first found that distant galaxies are in fact receding from us. He also noticed the trend that the velocity increases with distance. This is exactly what we expect in an expanding universe, for the physical distance between two galaxies is $d = ax$ where x is the comoving distance. In the absence of any comoving motion ($\dot{x} = 0$, no peculiar velocity) the relative velocity $v = \dot{d}$ is therefore equal to $\dot{a}x = Hd$. Therefore, velocity should increase linearly with distance (at least at low redshift) with a slope given by H, the Hubble constant. Hubble's Hubble constant can be easily extracted from Figure 1.5. It is simply $H = 1000/2$ kmsec^{-1}Mpc^{-1}, almost a factor of 10 higher than current estimates. Also notice that Hubble's data went out to redshift $z = 1000$ kmsec$^{-1}/c \simeq 0.003$.

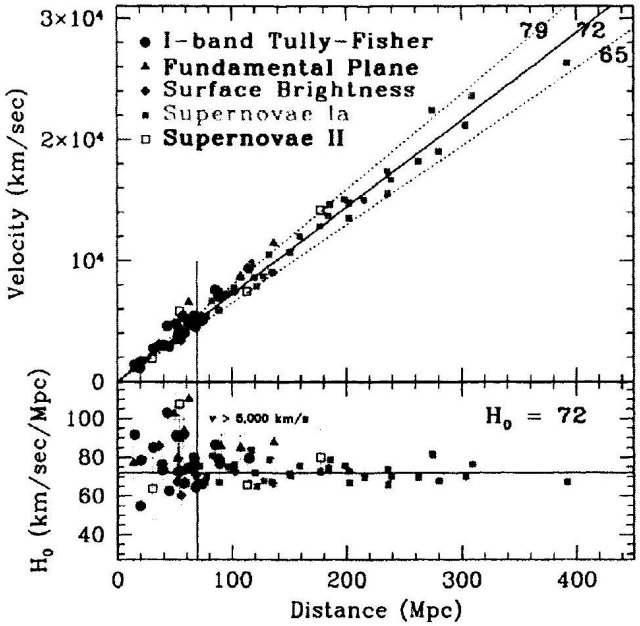

Figure 1.6. Hubble diagram from the Hubble Space Telescope Key Project (Freedman et al., 2001) using five different measures of distance. Bottom panel shows H_0 vs distance with the horizontal line equal to the best fit value of 72 kmsec^{-1}Mpc^{-1}.

The Hubble diagram is still the most direct evidence we have that the universe is expanding. Current incarnations use the same principle as the original: find the distance and the redshift of distant objects. Measuring redshifts is straightforward; the hard part is determining distances for objects of unknown intrinsic brightness. One of the most popular techniques is to try to find a standard candle, a class of objects which have the same intrinsic brightness. Any difference between the apparent brightness of two such objects then is a result of their different distances

from us. This method is typically generalized to find a correlation between an observable and intrinsic brightness. For example, Cepheid variables are stars for which intrinsic brightness is tightly related to period. The Hubble Space Telescope measured the periods of thousands of Cepheid variables in galaxies as far away as 20Mpc. With distances to these galaxies fixed, five different distance measures were used to go much further, as far away as 400Mpc. Figure 1.6 shows that all of these five indicators agree with one another and have converged on $H_0 = 72$ kmsec Mpc^{-1} with 10% errors.

As shown in Figure 1.6 the standard candle that can be seen at largest distances is a Type Ia supernova. Since they are so bright, supernovae can be used to extend the Hubble diagram out to very large redshifts (the current record is of order $z \simeq 1.7$), a regime where the simple Doppler law ceases to work. Figure 1.7 shows a recent Hubble diagram using very these very distant objects. In the next chapter, we will derive the correct expression for the distance (in this case the luminosity distance) as a function of redshift. For now, I simply point out that this expression depends on the energy content of the universe. The three curves in Figure 1.7 depict three different possibilities: flat matter dominated; open; and flat with a cosmological constant (Λ). The high-redshift data are now good enough to distinguish among these possibilities, strongly disfavoring the previously favored flat, matter-dominated universe. The current best fit is a universe with about 70% of the energy in the form of a cosmological constant, or some other form of dark energy. More on this in Chapter 2.

12.1.3 Big Bang Nucleosynthesis

When the universe was much hotter and denser, when the temperature of order an MeV/k_B, there were no neutral atoms or even bound nuclei. The vast amounts of radiation in such a hot environment ensured that any atom or nucleus produced would be immediately destroyed by a high energy photon. As the universe cooled well below the binding energies of typical nuclei, light elements began to form. Knowing the conditions of the early universe and the relevant nuclear cross-sections, we can calculate the expected primordial abundances of all the elements (Chapter 3).

Figure 1.8 shows the predictions of Big Bang Nucleosynthesis (BBN) for the light element abundances [1]. The boxes and arrows in Figure 1.8 show the current estimates for the light element abundances. These are consistent with the predictions, and this consistency test provides yet another ringing confirmation of the Big Bang. The measurements do even more though. The theoretical predictions, which we will explore in detail in Chapter 3, depend on the density of protons and neutrons at the time of nucleosynthesis. The combined proton plus neutron density

[1] Recall nuclear notation: The 4 in ^{4}He refers to the total number of nucleons (protons and neutrons). So ^{4}He has two neutrons and two protons, while ^{3}He has two protons and one neutron. See the box on page 63 for more details.

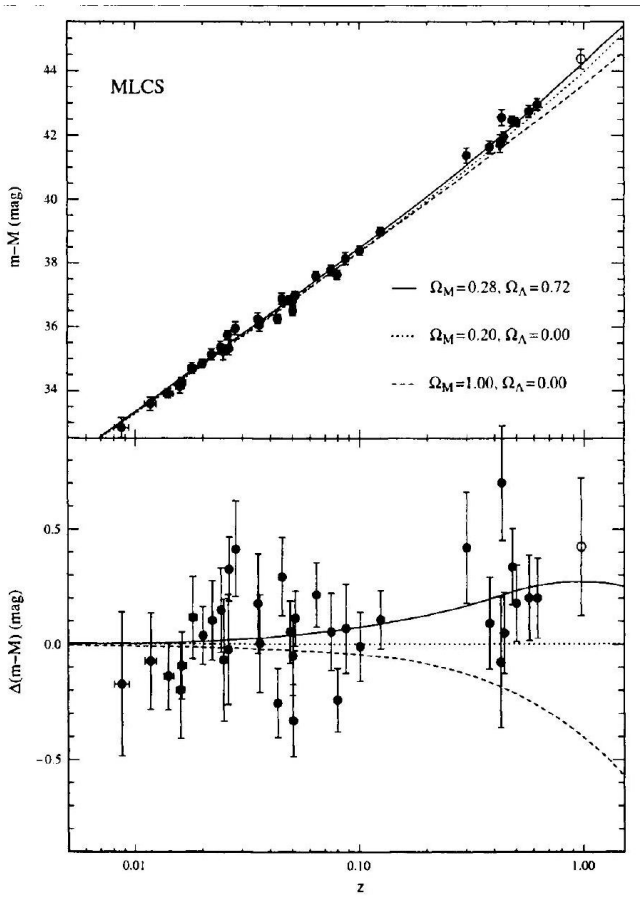

Figure 1.7. Hubble diagram from distant Type la supernovae. Top panel shows apparent magnitude (an indicator of the distance) vs redshift. Lines show the predictions for different energy contents in the universe, with Ω_M the ratio of energy density today in matter compared to the critical density and Ω_Λ the ratio of energy density in a cosmological constant to the critical density. Bottom panel plots the residuals, making it clear that the high-redshift supernovae favor a Λ-dominated universe over a matter-dominated one.

is called the baryon density since both protons and neutrons have baryon number one and these are the only baryons around at the time. Thus, BBN gives us a way of measuring the baryon density in the universe. Since we know how those densities scale as the universe evolves (they fall as a^{-3}), we can turn the measurements of light element abundances into measures of the baryon density today.

In particular, the measurement of primordial deuterium pins down the baryon density extremely accurately to only a few percent of the critical density. Ordinary matter (baryons) contributes at most 5% of the critical density. Since the total matter density today is almost certainly larger than this-direct estimates give values of order $20 - 30\%$ - nucleosynthesis provides a compelling argument for nonbaryonic dark matter.

The deuterium measurements (Burles and Tytler, 1998) are the new developments in the field. These measurements are so exciting because they explore the deuterium abundance at redshifts of order $3 - 4$, well before much processing could have altered the primordial abundances. Figure 1.9 shows one such detection. The basic idea is that light from distant QSOs is absorbed by intervening neutral hydrogen systems. The key absorption feature arises from transition from the $(n = 1)$

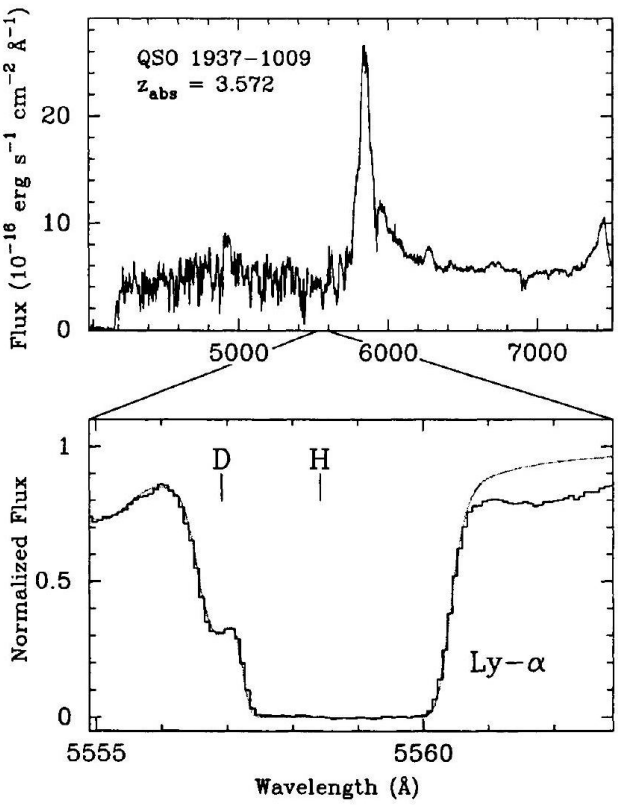

Figure 1.9. Spectrum from a distant QSO (Burles, Nollett, and Turner, 1999). Absorption of photons with rest wavelength 1216Å corresponding to the $n = 1$ to $n = 2$ state of hydrogen is redshifted up to $1216(1 + 3.572)$Å. Bottom panel provides details of the spectrum in this range, with the the presence of deuterium clearly evident.

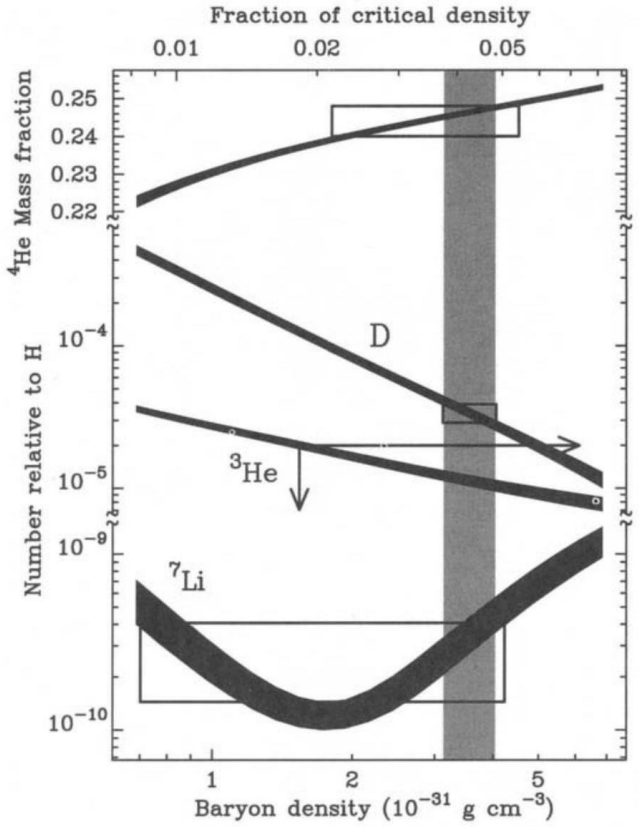

Figure 1.8. Constraint on the baryon density from Big Bang Nucleosynthesis (Burles, Nollett, and Turner, 1999). Predictions are shown for four light elements- ^{4}He, deuterium, ^{3}He,

and lithium - spanning a range of 10 orders of magnitude. The solid vertical band is fixed by measurements of primordial deuterium. The boxes are the observations; there is only an upper limit on the primordial abundance of ^{3}He.

ground state of hydrogen to the first excited state ($n = 2$), requiring a photon with wavelength $\lambda = 1215.7$Å. Since photons are absorbed when exciting hydrogen in this fashion, there is a trough in the spectrum at $\lambda = 1215.7$Å, redshifted by a factor of $1 + z$. The corresponding line from deuterium should be (i) shifted over by $0.33(1 + z)$Å (see Exercise 3) and (ii) much less damped since there is much less deuterium. Figure 1.9 shows just such a system; there are now half a dozen with detections precisely in the neighborhood shown in Figure 1.8. Note that the steep decline in deuterium as a function of baryon density helps here: even relatively large errors in D measurements translate into small errors on the baryon density. COSMIC MICROWAVE BACKGROUND SPECTRUM FROM COBE

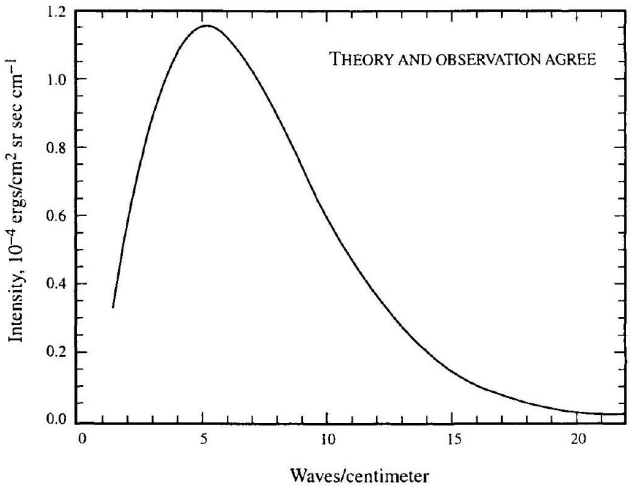

Figure 1.10. Intensity of cosmic microwave radiation as a function of wavenumber from Far InfraRed Absolute Spectrophotometer (FIRAS) (Mather et al., 1994), an instrument on the COBE satellite. Hidden in the theoretical blackbody curve are dozens of measured points, all of which have uncertainties smaller than the thickness of the curve!

12.1.4 The Cosmic Microwave Background

The CMB offers us a look at the universe when it was only 300,000 years old. The photons in the cosmic microwave background last scattered off electrons at redshift 1100 ; since then they have traveled freely through space. When we observe them today, they literally come from the earliest moments of time. They are therefore the most powerful probes of the early universe. We will spend an inordinate amount of time in this book working through the details of what happened before the epoch of last scattering and also developing the mathematics of the freestreaming process since then. A crucial fact about this history, though, is that the collisions with electrons before last scattering ensured that the photons were in equilibrium. That is, they should have a blackbody spectrum.

The specific intensity of a gas of photons with a blackbody spectrum is

$$I_\nu = \frac{4\pi\hbar\nu^3/c^2}{\exp\{2\pi\hbar\nu/k_BT\} - 1}$$

Figure 1.10 shows the remarkable agreement between this prediction (see Exercise 4) of Big Bang cosmology and the observations by the FIRAS instrument aboard the COBE spacecraft. We have been told [2] that detection of the 3 K background by Penzias and Wilson in the mid-1960s was sufficient evidence to decide the controversy in favor of the Big Bang over the Steady

State universe. Penzias and Wilson, though, measured the radiation at just one wavelength. If even their one-wavelength result was enough to tip the scales, the current data depicted in Figure 1.10 should send skeptics from the pages of physics journals to the far reaches of radical Internet chat groups.

The most important fact we learned from our first 25 years of surveying the CMIB was that the early universe was very smooth. No anisotropies were detected in the CMB. This period, while undoubtedly frustrating for observers searching for anisotropies, solidified the view of a smooth Big Bang. We are now moving on. We have discovered anisotropies in the CMB, indicating that the early universe was not completely smooth. There were small perturbations in the cosmic plasma. To understand these, we must go beyond the Standard Model.

12.1.5 Beyond the Standard Model

While the three pillars put the Big Bang model on firm footing, other observations cry out for more details. I hinted above at one of these, the notion that there must be nonbaryonic matter in the universe. Dark matter is a familiar concept to astronomers; the first suggestion was put forth by Zwicky in 1933(!). Figure 1.11 illustrates the way dark matter can be found in galaxies, with the use of rotation curves probing the gravitational field. Indeed, a mismatch between the matter inferred from gravity and that we can see exists on almost all observable scales.

Because of the limits inferred from Big Bang nucleosynthesis, the dark matter, or at least an appreciable fraction of it, must be nonbaryonic. What is this new form of matter? And how did it form in the early universe? The most popular idea currently is that the dark matter consists of elementary particles produced in the earliest moments of the Big Bang. In Chapter 3, we will explore this possibility in detail, arguing that dark matter was likely produced when the temperature of the universe was of order hundreds of GeV/k_B. As we will see, the hypothesis that dark matter consists of fundamental relics from the early universe may soon be tested experimentally.

The last decades of the 20$^{\text{th}}$ century saw a number of large surveys of galaxies designed to measure structure in the universe. These culminated in two large surveys, the Sloan Digital Sky Survey and the Two Degree Field Galaxy (Figure 1.12) Redshift Survey, which between them will compile the redshifts of, and hence the distances to, a million galaxies. Galaxies in Figure 1.12 are clearly not distributed randomly: the universe has structure on large scales. To understand this structure, we must go beyond the Standard Model not only by including dark matter, but also by allowing for deviations from smoothness. We must develop the tools to study

[2] For a fascinating first-hand account of the history of the discovery of the CMB, see Chapter 1 of Partridge (1995).

(b)

Figure 1.11. (a) Image of spiral galaxy M33. The inner brightest region has a radius of several kpc. (b) Rotation curve for M33 (Corbelli and Salucci, 2000). Points with error bars come from the $21-$cm line of neutral hydrogen. Solid line is a model fitting the data. Different contributions to the total rotation curve are: dark matter halo (dot-dashed line), stellar disk (short dashed line), and gas (long dashed line). At large radii, dark matter dominates.

perturbations around the smooth background of the Standard Model. We will see in Chapters 4 and 5 that this is straightforward in theory, as long as the perturbations remain small.

The best ways to learn about the evolution of structure and to compare theory with observations are to look at anisotropies in the CMB and at how matter is distributed on large scales. To compare theory with observations, we must at first try to avoid scales dominated by nonlinearities. As an extreme example, we can never hope to understand cosmology by carefully examining rock formations on Earth. The intermediate steps - collapse of matter into a galaxy; molecular cooling; star formation; planetary formation; etc. - are much too complicated to allow comparison between linear theory and observations. While perturbations to the matter on small scales (less than about 10Mpc) have grown nonlinear, large-scale perturbations are still small. So they have been processed much less than the corresponding small-scale structure. Similarly, anisotropies in the CMB have remained small because the photons that make up the CMB do not clump.

Identifying large-scale structure and the CMB as the two most promising areas of study solves just one issue. Another very important challenge is to understand how to characterize

these distributions so that theory can be compared to experiment. It is one thing to look at a map and quite another to quantitative tests of cosmological models. To make such tests, it is often useful to take the Fourier transform of the distribution in question; as we will see, working in Fourier space makes it easier to separate large from small scales. The most important statistic in the cases of

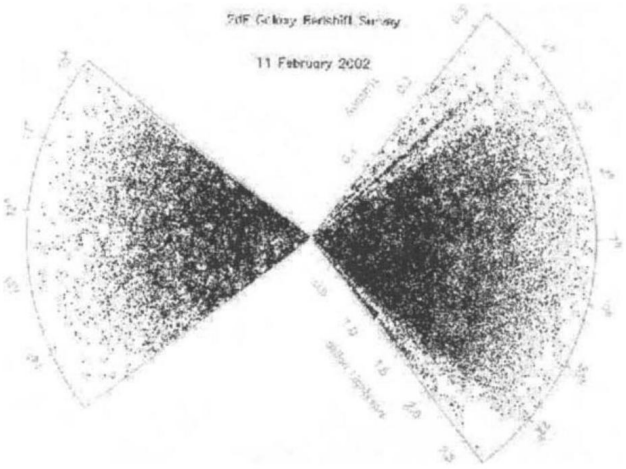

Figure 1.12. Distribution of galaxies in the Two Degree Field Galaxy Redshift Survey (2dF) (Colless et al., 2001). By the end of the survey, redshifts for 250,000 galaxies will have been obtained. As shown here, they probe structure in the universe out to $z = 0.3$, corresponding to distances up to 1000 h^{-1}Mpc away from us (we are located at the center). See color Plate 1.12.

both the CMB and large-scale structure is the two-point function, called the power spectrum in Fourier space. If the mean density of the galaxies is $\bar{n}$, then we can characterize the inhomogeneities with $\delta(\vec{x}) = (n(\vec{x}) - \bar{n})/\bar{n}$, or its Fourier transform $\tilde{\delta}(\vec{k})$. The power spectrum $P(k)$ is defined via

$$\left\langle \tilde{\delta}(\vec{k})\tilde{\delta}\left(\vec{k}'\right)\right\rangle = (2\pi)^3 P(k)\delta^3\left(\vec{k} - \vec{k}'\right)$$

Here the angular brackets denote an average over the whole distribution, and $\delta^3()$ is the Dirac delta function which constrains $\vec{k} = \vec{k}'$. The details aside, Eq. (1.9) indicates that the power spectrum is the spread, or the variance, in the distribution. If there are lots of very under- and overdense regions, the power spectrum will be large, whereas it is small if the distribution is smooth. Figure 1.13 shows the power spectrum of the galaxy distribution. Since the power spectrum has dimensions of k^{-3} or (length) ^{3}, Figure 1.13 shows the combination $k^3P(k)/2\pi^2$, a dimensionless number which is a good indication of the clumpiness on scale k.

The best measure of anisotropies in the CMB is also the two-point function of the temperature distribution. There is a subtle technical difference between the two power spectra which are used to measure the galaxy distribution and the CMB, though. The difference arises because the CMB temperature is a two-dimensional field, measured everywhere on the sky (i.e., with two angular coordinates). Instead of Fourier transforming the CMB temperature, then, one typically expands it in

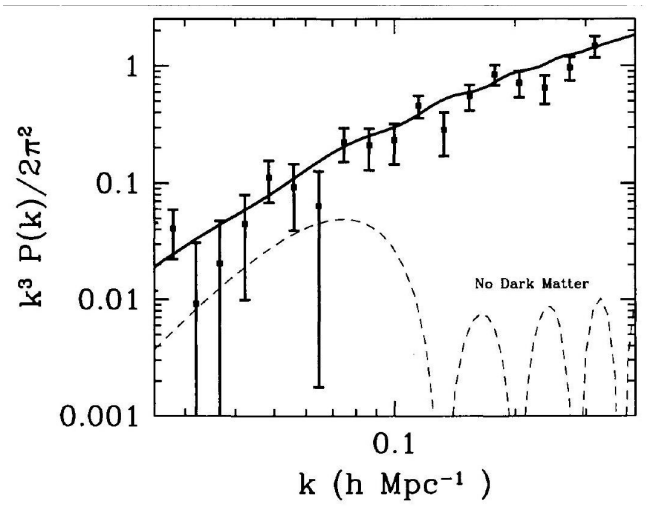

Figure 1.13. The variance $\Delta^2 := k^3P(k)/2\pi^2$ of the Fourier transform of the galaxy distribution as a function of scale. On large scales, the variance is smaller than unity, so the distribution is smooth. The solid line is the theoretical prediction from a model in which the universe contains dark matter, a cosmological constant, with perturbations generated by inflation. The dashed line is a theory with only baryons and no dark matter. Data come from the PSCz survey (Saunders et al., 2000) as analyzed by Hamilton and Tegmark (2001).

spherical harmonics, a basis more appropriate for a 2D field on the surface of a sphere. Therefore the two-point function of the CMB is a function of multipole moment l, not wave number k. Figure 1.14 shows the measurements of dozens of groups since 1992, when COBE first discovered large-angle (low l in the plot) anisotropies.

Figures 1.13 and 1.14 both have theoretical curves in them which appear to agree well with the data. The main goal of much of this book is to develop a firstprinciples understanding of these theoretical predictions. Indeed, understanding the development of structure in the universe has become a major goal of most cosmologists today. Note that this second aspect of cosmology beyond the Standard Model reinforces the first: i.e., observations of structure in the universe lead to the conclusion that there must be dark matter. In particular, the dashed curve in Figure 1.13 is the prediction of a model with baryons only, with no dark matter. The inhomogeneities expected in this model (when normalized to the CMB observations) are far too small. In Chapter 7, we will come to understand the reason why a baryon-only universe would be so smooth. For now, though, the message is clear: Dark matter is needed not only to explain rotation curves of galaxies but to explain

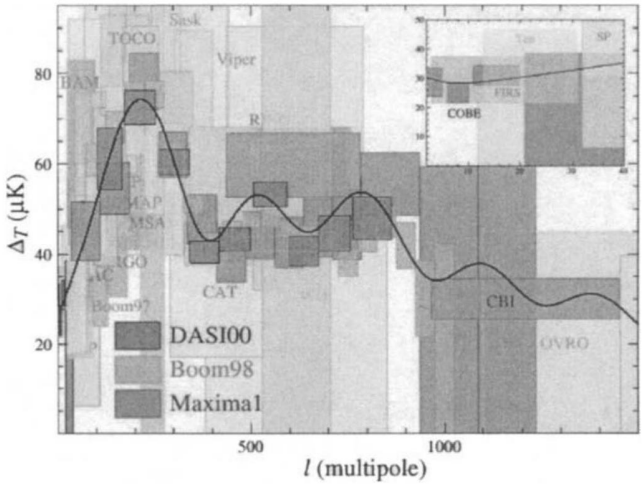

Figure 1.14. Anisotropies in the CMB predicted by the theory of inflation compared with observations. x-axis is multipole moment (e.g., $l = 1$ is the dipole, $l = 2$ the quadrupole) so

that large angular scales correspond to low l; y-axis is the root mean square anisotropy (the square root of the two-point function) as a function of scale. The characteristic signature of inflation is the series of peaks and troughs, a signature which has been verified by experiment. See color Plate 1.14.

structure in the universe at large!

While trying to understand the evolution of structure in the universe, we will be forced to confront the question of what generated the initial conditions, the primordial perturbations that were the seeds for this structure. This will lead us to a third important aspect of cosmology beyond the Standard Model: the theory of inflation. Chapter 6 introduces this fascinating proposal, that the universe expanded exponentially fast when it was but 10^{-35} sec old. Until recently, there was little evidence for inflation. It survived as a viable theory mainly because of its aesthetic appeal. The discoveries of the past several years have changed this. They have by and large confirmed some of the basic predictions of inflation. Most notably, this theory makes concrete predictions for the initial conditions, predictions that have observable consequences today. For me, the most profound and exciting discovery in cosmology has been the observation of anisotropies in the CMB, with a characteristic pattern predicted by inflation.

The theory encompassing all these Beyond the Standard Model ingredients-dark matter plus evolution of structure plus inflation - is called Cold Dark Matter, or CDM. The "Cold" part of this moniker comes from requiring the dark matter particles to be able to clump efficiently in the early universe. If they are hot instead, i.e., have large pressure, structure will not form at the appropriate levels.

SUGGESTED READING

There are many good textbooks covering the homogeneous Big Bang. I am most familiar with The Early Universe (Kolb and Turner), which has especially good discussions on nucleosynthesis and inflation. Peacock's Cosmological Physics is the most up-to-date and perhaps the broadest of the standard cosmology texts, with more of an emphasis on extragalactic astronomy than either The Early Universe or this book. A popular account which still captures the essentials of the homogeneous Big Bang (testifying to the success of the model: it hasn't changed that much in 25 years) is The First Three Minutes (Weinberg). More recently, three books of note are: The Whole Shebang (Ferris), The Little Book of the Big Bang (Hogan), and *A* Short History of the Universe (Silk).

A nice article summarizing the evidence for an expanding universe and some methods to quantify it is Freedman (1998). Two of the pioneers in the field of Big Bang nucleosynthesis, Schramm and Turner, wrote a very clear review article (1998) right before a tragic accident took the life of the first author. An excellent account of the evidence for dark matter in spiral galaxies is Vera Rubin's 1983 article in Scientific American.

I have not attempted to record the history of the discovery of the Big Bang. Three books I am familiar with which treat this history in detail are Blind Watchers of the Sky (Kolb), 3K: The Cosmic Microwave Background (Partridge), and Three Degrees Above Zero: Bell Labs in the Information Age (Bernstein). An article which sheds light on this history is Alpher and Herman (1988).

D-1.

Suppose (incorrectly) that H scales as temperature squared all the way back until the time when the temperature of the universe was $10^{19}\mathrm{GeV}/k_B$ (i.e., suppose the universe was radiation dominated all the way back to the Planck time). Also suppose that today the dark energy is in the form of a cosmological constant Λ, such that ρ_Λ today is equal to $0.7\rho_{\mathrm{cr}}$ and ρ_Λ remains constant throughout the history of the universe. What was $\rho_\Lambda/\left(3H^2/8\pi G\right)$ back then?

D-2.

Assume the universe today is flat with both matter and a cosmological constant, the latter with energy density which remains constant with time. Integrate Eq. (1.2) to find the present age of the universe. That is, rewrite Eq. (1.2) as

$$dt = H_0^{-1} \frac{da}{a} \left[\Omega_\Lambda + \frac{1 - \Omega_\Lambda}{a^3} \right]^{-1/2}$$

where Ω_Λ is the ratio of energy density in the cosmological constant to the critical density. Integrate from $a = 0$ (when $t = 0$) until today at $a = 1$ to get the age of the universe today. In both cases below the integral can be done analytically.

(a) First do the integral in the case when $\Omega_\Lambda = 0$.

(b) Now do the integral in the case when $\Omega_\Lambda = 0.7$. For fixed H_0, which universe is older?

D-3.

Using the fact that the reduced mass of the electron-nucleus in the D atom is larger than in hydrogen, and the fact that the Lyman $\alpha (n = 1 \to n = 2)$ transition in H has a wavelength 1215.67Å, find the wavelength of the photon emitted in the corresponding transition in D. Astronomers often define

$$v := c \frac{\Delta\lambda}{\lambda}$$

to characterize the splitting of two nearby lines. What is v for the H-D pair?

D-4.

Convert the specific intensity in Eq. (1.8) into an expression for what is plotted in Figure 1.10, the energy per square centimeter per steradian per second. Note that the x-axis is $1/\lambda$, the inverse wavelength of the photons. Show that the peak of a 2.73 K blackbody spectrum does lie at $1/\lambda = 5$ cm^{-1}.

12.2 The Smooth, Expanding Universe

Just as the early navigators of the great oceans required sophisticated tools to help them find their way, we will need modern technology to help us work through the ramifications of an expanding universe. In this chapter I introduce two of the necessary tools, general relativity and statistical mechanics. We will use them to derive some of the basic results laid down in Chapter 1: the expansion law of Eq. (1.2), the dependence of different components of energy density on the scale factor which governs expansion, the epoch of equality $a_{\rm eq}$ shown in Figure 1.3, and the luminosity distance needed to understand the implications of the supernovae diagram in Figure 1.7. Indeed, with general relativity and statistical mechanics, we can go a long way toward performing a cosmic inventory, identifying those components of the universe that dominate the energy budget at various epochs.

Implicit in this discussion will be the notion that the universe is smooth (none of the densities vary in space) and in equilibrium (the consequences of which will be explored in Section 2.3). In succeeding chapters, we will see that the deviations from equilibrium and smoothness are the source of much of the richness in the universe. Nonetheless, if only in order to understand the framework in which these deviations occur, a basic knowledge of the "zero order" universe is a must for any cosmologist.

In this chapter, I begin using units in which

$$\hbar = c = k_B = 1$$

Many papers employ these units, so it is important to get accustomed to them. Please work through Exercise 1 if you are uncomfortable with the idea of setting the speed of light to 1.

12.2.1 General Relativity

Most of cosmology can be learned with only a passing knowledge of general relativity. One must be familiar with the concept of a metric, understand geodesics, and be able to apply the Einstein equations to the Friedmann-Robertson-Walker (FRW) metric thereby relating the parameters in the metric to the density in the universe. Eq. (1.2) is the result of applying the Einstein equations to the zero order universe. We will derive it in this section. Chapters 4 and 5 apply them to the perturbed universe. With the experience we gain in this section, there will be nothing difficult about these subsequent chapters. The principles are identical; only the algebra will be a touch harder.

The Metric

Figure 1.1 from Chapter 1 highlights the fact that even if one knows the components of a vector, say the difference between two grid points there, the physical distance associated with this vector requires additional information. In the case of a smooth expanding universe, the scale factor connects the coordinate distance with the physical distance. More generally, the metric turns coordinate distance into physical distance and so will be an essential tool in our quest to make quantitative predictions in an expanding universe.

We are familiar with the metric for the Cartesian coordinate system which says that the square of the physical distance between two points separated by dx and dy in a 2D plane is $(dx)^2 + (dy)^2$. However, were we to use polar coordinates instead, the square of the physical distance would no longer be the sum of the square of the two coordinate differences. Rather, if the differences dr and $d\theta$ are small, the square of the distance between two points is $(dr)^2 + r^2(d\theta)^2 \neq (dr)^2 + (d\theta)^2$. This distance is invariant: an observer using Cartesian coordinates to find it would get the same result as one using polar coordinates. Thus another way of stating what a metric does is this: it turns observer-dependent coordinates into invariants. Mathematically, in the 2D plane, the invariant distance squared $dl^2 = \sum_{i,j=1,2} g_{ij} dx^i dx^j$. The metric g_{ij} in this 2D example is a 2×2 symmetric matrix. In Cartesian coordinates the metric is diagonal with each element equal to 1. In polar coordinates (taking $x^1 = r$ and $x^2 = \theta$) it is also diagonal with $g_{11} = 1$, but g_{22} which multiplies $(d\theta)^2$ is equal to r^2.

There is yet another way of thinking about a metric, using pictures. When handed a vector, we immediately think of a line with an arrow attached, the length of the line corresponding to the length of the vector and the arrow to its direction. In fact, this notion is rooted too firmly in Euclidean space. In actuality, the length of the vector depends on the metric. An intuitive way of understanding this is to consider the contour map in Figure 2.1. The number of lines crossed by a vector is a measure of the vertical distance traveled by a hiker. Vectors of the same apparent 2D length - corresponding to identical coordinate distances - can correspond to significantly different physical distances. Mathematically the surface of the Earth can be parametrized by two coordinates, say θ and ϕ. Then the metric is a very nontrivial function of θ and ϕ which accounts for all the elevation changes on the surface.

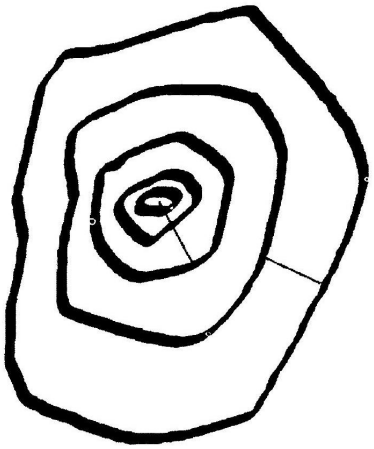

Figure 2.1. Contour map of a mountain. The closely spaced contours near the center correspond to rapid elevation gain. The two thin lines correspond to hikes of significantly different difficulty even though they appear to be of the same length. Similarly, the true length of a vector requires knowledge of the metric.

The great advantage of the metric is that it incorporates gravity. Instead of thinking of gravity as an external force and talking of particles moving in a gravitational field, we can include gravity in the metric and talk of particles moving freely in a distorted or curved space-time, one in which the metric cannot be converted everywhere into Euclidean form.

In four space-time dimensions the invariant includes time intervals as well, so

$$ds^2 = \sum_{\mu,\nu=0}^{3} g_{\mu\nu} dx^\mu dx^\nu$$

where the indices μ and ν range from 0 to 3 (see the box on page 27), with the first one reserved for the time-like coordinate ($dx^0 = dt$) and the last three for spatial coordinates. Here I have explicitly written down the summation sign, but from now on we will use the convention that repeated indices are summed over. The metric $g_{\mu\nu}$ is necessarily symmetric, so in principle has four diagonal and six off-diagoral components. It provides the connection between values of the coordinates and the more physical measure of the interval ds^2 (sometimes called proper time). Special relativity is described by Minkowski space-time with the metric: $g_{\mu\nu} = \eta_{\mu\nu}$, with

$$\eta_{\mu\nu} = \begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

What is the metric which describes the expanding universe? Let us return to the grid depicted in Figure 1.1. We said earlier that two grid points move away from each other, so that the distance between the two points is always proportional to the scale factor. If the comoving distance today is x_0, the physical distance between the two points at some earlier time t was $a(t)x_0$. At least in a flat (as opposed to open or closed) universe, the metric then is almost identical to the Minkowski metric, except that distance must be multiplied by the scale factor. This suggests that the metric in an expanding, flat universe is

$$g_{\mu\nu} = \begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & a^2(t) & 0 & 0 \\ 0 & 0 & a^2(t) & 0 \\ 0 & 0 & 0 & a^2(t) \end{pmatrix}.$$

This is called the Friedmann-Robertson-Walker (FRW) metric.

As noted in Eq. (1.2), which we will shortly derive, the evolution of the scale factor depends on the density in the universe. When perturbations are introduced, the metric will become more complicated, and the perturbed part of the metric will be determined by the inhomogeneities in the matter and radiation.

Indices

In three dimensions, a vector $\vec{A}$ has three components, which we refer to as A^i, superscript i taking the values 1,2, or 3. The dot product of two vectors is then

$$\vec{A} \cdot \vec{B} = \sum_{i=1}^{3} A^i B^i := A^i B^i$$

where I have introduced the Einstein summation convention of not explicitly writing the $\sum$ sign when an index (in this case i) appears twice. Similarly, matrices can be written in component notation. For example, the product of two matrices **M** and **N** is

$$(\mathbf{MN})_{ij} = M_{ik} N_{kj}$$

again with implicit summation over k.

In relativity, two generalizations must be made. First, in relativity a vector has a fourth component, the time component. Since the spatial indices run from 1 to 3, it is conventional to use 0 for the time component. Greek letters are used to represent all four components, so $A^\mu = (A^0, A^i)$. The second, more subtle, feature of relativity is the distinction between upper and lower indices, the former associated with vectors and the latter with 1 -forms. One goes back and forth with the metric tensor, so

$$A_\mu = g_{\mu\nu} A^\nu \quad ; \quad A^\mu = g^{\mu\nu} A_\nu$$

A vector and a 1 -form can be contracted to produce an invariant, a scalar. For example, the statement that the four-momentum squared of a massless particle must vanish is

$$P^2 := P_\mu P^\mu = g_{\mu\nu} P^\mu P^\nu = 0.$$

This contraction is the equivalent of counting the contours crossed by a vector, as depicted in Figure 2.1.

Just as the metric can turn an upper index on a vector into a lower index, the metric can be used to raise and lower indices on tensors with an arbitrary number of indices. For example, raising the indices on the metric tensor itself leads to

$$g^{\mu\nu} = g^{\mu\kappa} g^{\nu\beta} g_{\alpha\beta}$$

If the index $\alpha = \nu$, then the first term on the right is equal to the term on the left, so if the combination of the last two terms on the right force α to be equal to ν, then the equation is satisfied. Therefore,

$$g^{\nu\beta} g_{\alpha\beta} = \delta^\nu_\alpha$$

where $\delta^\nu{}_\alpha$ is the Kronecker delta equal to zero unless $\nu = \alpha$ in which case it is 1.

The Geodesic Equation

In Minkowski space, particles travel in straight lines unless they are acted on by a force. Not surprisingly, the paths of particles in more general space-times are more complicated. The notion of a straight line gets generalized to a geodesic, the path followed by a particle in the absence of any forces. To express this in equations, we must generalize Newton's law with no forces. $d^2\vec{x}/dt^2 = 0$, to the expanding universe.

The machinery necessary to generalize $d^2\vec{x}/dt^2 = 0$ is perhaps best introduced by starting with a simple example: particle motion in a Euclidean 2D plane. In that case, the equations of motion in Cartesian coordinates $x^i = (x, y)$ are

$$\frac{d^2x^2}{dt^2} = 0$$

However, if we use polar coordinates $x'^2 = (r, \theta)$ instead, the equations for a free particle look significantly different. The fundamental difference between the two coordinate systems is that the basis vectors for polar coordinates $\hat{r}, \hat{\theta}$ vary in the plane. Therefore, $d^2\vec{x}'/dt^2 = 0$ does not imply that each coordinate r and θ satisfies $d^2 \cdot r'^i/dt^2 = 0$

To determine the equation satisfied by the polar coordinates, we can start from the Cartesian equation and then transform. In particular,

$$\frac{dx^i}{dt} = \frac{\partial x^i}{\partial x'^j}\frac{dx'^j}{dt}$$

$\partial x^i/\partial x'^j$ is called the transformation matrix going from one basis to another. In the case of Cartesian to polar coordinates in 2D, $x^1 = x'^1 \cos x'^2$ and $x^2 = x'^1 \sin x'^2$, so the transformation matrix is

$$\frac{\partial x^i}{\partial x'^3} = \begin{pmatrix} \cos x'^2 & -x'^1 \sin x'^2 \\ \sin x'^2 & x'^1 \cos x'^2 \end{pmatrix}$$

Therefore, the geodesic equation becomes

$$\frac{d}{dt}\left[\frac{dx'}{dt}\right] = \frac{d}{dt}\left[\frac{\partial x^i}{\partial x'}\frac{dx'}{dt}\right] = 0$$

The derivative with respect to time acts on both terms inside the brackets. If the transformation from the Cartesian basis to the new basis was linear, then the derivative acting on the transformation matrix would vanish, and the geodesic equation in the new basis would still be $d^2x'^i/dt^2 = 0$. In the case of polar coordinates, though, the transformation is not linear, and we need the fact that

$$\frac{d}{dt}\left(\frac{\partial x'}{\partial x'^j}\right) = \frac{\partial}{\partial x'^j}\left(\frac{dx'}{dt}\right)$$

$$= \frac{\partial^2 x^i}{\partial x'^j \partial x'^k}\frac{dx'^k}{dt}$$

where the first equality holds since derivatives commute and the second comes from inserting dx^i/dt from Eq. (2.12), changing dummy indices from $j \to k$. The geodesic equation in the new coordinates therefore becomes

$$\frac{d}{dt}\left[\frac{\partial x^i}{\partial x'^j}\frac{dx'^j}{dt}\right] = \frac{\partial x^i}{\partial x'^j}\frac{d^2x'^j}{dt^2} + \frac{\partial^2 x^i}{\partial x'^j \partial x'^k}\frac{dx'^k}{dt}\frac{dx'^j}{dt} = 0.$$

To get this in a more recognizable form, note that the term multiplying the second time derivative is the transformation matrix. If we multiply the equation by the inverse of this transformation matrix, then the second time derivative will stand alone, leaving

$$\frac{d^2x'^l}{dt^2} + \left[\left(\left\{\frac{\partial x}{\partial x'}\right\}^{-1}\right)_i^l \frac{\partial^2 x^i}{\partial x'^j \partial x'^k}\right] \frac{dx'^k}{dt}\frac{dx'^j}{dt} = 0$$

You can check that this rather cumbersome expression does indeed give the correct equations of motion in polar coordinates. More importantly, by keeping things general, we have derived the geodesic equation in a non-Cartesian basis.

It is convenient to define the Christoffel symbol, $\Gamma^l{}_{jk}$, to be the coefficient of the $\left(dx'^k/dt\right)\left(dx'^j/dt\right)$ term in Eq. (2.17). Note that by definition it is symmetric in its lower indices j and k. In a Cartesian coordinate system, the Christoffel symbol vanishes and the geodesic equation is simply $d^2x^i/dt^2 = 0$. But in general, the Christoffel symbol does not vanish; its presence describes geodesics in nontrivial coordinate systems. The reason why this generalized geodesic equation is so powerful is that in a nontrivial space-time such as the expanding universe it is not possible to find a fixed Cartesian coordinate system, so we need to know how particles travel in the more general case.

There are two small changes we need to make when importing the geodesic equation (2.17) into relativity. The first is trivial: allow the indices to range from 0 to 3 to include time and the three spatial dimensions. The second is also not surprising: since time is now one of our coordinates, it will not do to use it as the evolution parameter. Instead introduce a parameter λ which monotonically increases along the particle's path as in Figure 2.2. The geodesic equation then

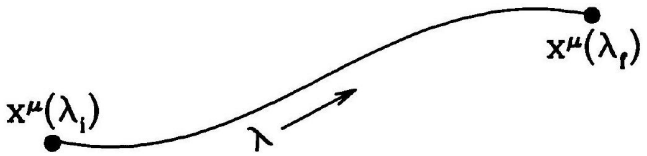

Figure 2.2. A particle's path is parametrized by λ, which monotonically increases from its

initial value λ_i to its final value λ_f. becomes

$$\frac{d^2x^\mu}{d\lambda^2} = -\Gamma^\mu_{\alpha\beta}\frac{dx^\alpha}{d\lambda}\frac{dx^\beta}{d\lambda}$$

We derived this equation transforming from a Cartesian basis, so that the Christoffel symbol is given by the term in square brackets in Eq. (2.17). It is almost always more convenient, however, to obtain the Christoffel symbol from the metric directly. A convenient formula expressing this dependence is

$$\Gamma^\mu_{\alpha,\beta} = \frac{g^{\mu\nu}}{2}\left[\frac{\partial g_{\alpha\nu}}{\partial x^\beta} + \frac{\partial g_{\beta\nu}}{\partial x^\alpha} - \frac{\partial g_{\alpha\beta}}{\partial x^\nu}\right]$$

Note that the raised indices on $g^{\mu\nu}$ are important: $g^{\mu\nu}$ is the inverse of $g_{\mu\nu}$ (see the box on page 27). So $g^{\mu\nu}$ in the flat, FRW metric is identical to $g_{\mu\nu}$ except that its spatial elements are $1/a^2$ instead of a^2.

Using the general expression in Eq. (2.19) and the FRW metric in Eq. (2.4), we can derive the Christoffel symbol in an expanding, homogeneous universe. First we compute the components with upper index equal to zero, $\Gamma^0{}_{\alpha\beta}$. Since the metric is diagonal, the factor of $g^{0\nu}$ vanishes unless $\nu = 0$ in which case it is -1. Therefore,

$$\Gamma^0_{\alpha\beta} = \frac{-1}{2}\left[\frac{\partial g_{\alpha 0}}{\partial x^\beta} + \frac{\partial g_{\beta 0}}{\partial x^\alpha} - \frac{\partial g_{\alpha\beta}}{\partial x^0}\right]$$

The first two terms here reduce to derivatives of g_{00}. Since the FRW metric has constant g_{00}, these terms vanish, and we are left with

$$\Gamma^0_{\alpha\beta} = \frac{1}{2}\frac{\partial g_{\alpha\beta}}{\partial x^0}$$

The derivative is nonzero only if α and β are spatial indices, which will be identified with Roman letters i, j running from 1 to 3. Since $x^0 = t$, we have

$$\begin{aligned}\Gamma^0_{00} &= 0\\ \Gamma^0_{0i} &= \Gamma^0_{i0} = 0\\ \Gamma^0_{ij} &= \delta_{ij}\dot{a}a\end{aligned}$$

where overdots indicate derivatives with respect to time. [1] It is a straightforward, but useful, exercise to show that $\Gamma^i_{\alpha\beta}$ is nonzero only when one of its lower indices is zero and one is spatial, so that

$$\Gamma^i_{0j} = \Gamma^i_{j0} = \delta_{ij}\frac{\dot{a}}{a}$$

with all other $\Gamma^i_{\alpha\beta}$ zero.

[1] I will use this convention until Chapter 4. After that, overdots will denote derivatives with respect to conformal time. This has been a long, rather formal subsection, opening with the generalization of the geodesic equation to curved space-time and then proceeding with a calculation of the Christoffel symbol in the expanding universe described by the FRW metric. Before completing our main task and using the Einstein equations to derive Eq. (1.2), let's take a break and apply the geodesic equation to a single particle. In particular let's see how a particle's energy changes as the universe expands. We'll do the calculation here for a massless particle; an almost identical problem for a massive particle is relegated to

D-4.

Start with the four-dimensional energy-momentum vector $P^\alpha = (E, \vec{P})$, whose time component is the energy. We use this four-vector to define the parameter λin Eq. (2.18):

$$P^\alpha = \frac{dx^\alpha}{d\lambda}$$

This is an implicit definition of λ. Fortunately, one never needs to find λ explicitly, for it can be directly eliminated by noting that

$$\begin{aligned}\frac{d}{d\lambda} &= \frac{dx^0}{d\lambda}\frac{d}{dx^0}\\ &= E\frac{d}{dt}.\end{aligned}$$

The zeroth component of the geodesic equation (2.18) then becomes

$$E\frac{dE}{dt} = -\Gamma^0_{ij}P^iP^j$$

where the equality holds since only the spatial components of $\Gamma^0{}_{\alpha\beta}$ are nonzero. Inserting these components leads to a right-hand side equal to $-\delta_{ij}a\dot{a}P^iP^j$. A massless particle has energy-momentum [2] vector $(E, \vec{P})$ with zero magnitude:

$$g_{\mu\nu}P^\mu P^\nu = -E^2 + \delta_{ij}a^2 P^i P^j = 0$$

which enables us to write the right hand side of Eq. (2.26) as $-(\dot{a}/a)E^2$. Therefore, the geodesic equation yields

$$\frac{dE}{dt} + \frac{\dot{a}}{a}E = 0$$

the solution to which is

$$E \propto \frac{1}{a}.$$

This confirms our hand-waving argument in Chapter 1 that the energy of a massless particle should decrease as the universe expands since it is inversely proportional to its wavelength, which is being stretched along with the expansion. In Chapter 4 we will rederive this result in yet another way using the Boltzmann equation.

[2] Note that $\vec{P}$ measures motion on the comoving (nonexpanding) grid. The physical momentum which measures changes in physical distance is related to $\vec{P}$ by a factor of a. Hence the factor of a^2 in Eq. (2.27).

Einstein Equations

If you did a word search on the previous two subsections, you might be surprised to discover that the words "general relativity" never appeared. The concept of a metric and the realization that nontrivial metrics affect geodesics both exist completely independently of general relativity. The part of general relativity that is hidden above is that gravitation can be described by a metric, in our case by Eq. (2.4). There is a second aspect of general relativity, though: one which relates the metric to the matter and energy in the universe. This second part is contained in the Einstein equations, which relate the components of the Einstein tensor describing the geometry to the energy-momentum tensor describing the energy:

$$G_{\mu\nu} := R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}\mathcal{R} = 8\pi G T_{\mu\nu}$$

Here $G_{\mu\nu}$ is the Einstein tensor; $R_{\mu\nu}$ is the Ricci tensor, which depends on the metric and its derivatives; $\mathcal{R}$, the Ricci scalar, is the contraction of the Ricci tensor ($\mathcal{R} := g^{\mu\nu}R_{\mu\nu}$) : G is Newton's constant; and $T_{\mu\nu}$ is the energy-momentum tensor. We will spend some time on the energy-momentum tensor in Section 2.3. For now, all we need to know is that it's a symmetric tensor describing the constituents of the universe. The left-hand side of Eq. (2.30) is a function of the metric, the right a function of the energy: the Einstein equations relate the two.

The Ricci tensor is most conveniently expressed in terms of the Christoffel symbol,

$$R_{\mu\nu} = \Gamma^\alpha_{\mu\nu,\alpha} - \Gamma^\alpha_{\mu\alpha,\nu} + \Gamma^\alpha_{\beta\alpha}\Gamma^\beta_{\mu\nu} - \Gamma^\alpha_{\beta\nu}\Gamma^\beta_{\mu\alpha}.$$

Here commas denote derivatives with respect to x. So, for example, $\Gamma^\alpha{}_{\mu\nu,\alpha} := \partial\Gamma^\alpha{}_{\mu\nu}/\partial x^\alpha$. Although this expression looks formidable, we have already done the hard work by computing the Christoffel symbol in an FRW universe. It turns out that there are only two sets of nonvanishing components of the Ricci tensor: one with $\mu = \nu = 0$ and the other with $\mu = \nu = i$.

Consider

$$R_{00} = \Gamma^\alpha_{00,\alpha} - \Gamma^\alpha_{0\alpha.0} + \Gamma^\alpha_{\beta\alpha}\Gamma^\beta{}_{00} - \Gamma^\alpha{}_{\beta 0}\Gamma^\beta{}_{0\alpha}.$$

Recall that the Christoffel symbol vanishes if its two lower indices are zero, so the first and third terms on the right vanish. Similarly, the indices α and β in the second and fourth terms must be spatial. We are left with

$$R_{00} = -\Gamma^{i}_{0i.0} - \Gamma^{i}{}_{j0}\Gamma^{j}{}_{0i}.$$

Using Eq. (2.23) leads directly to

$$\begin{aligned} R_{00} &= -\delta_{ii}\frac{\partial}{\partial t}\left(\frac{\dot{a}}{a}\right) - \left(\frac{\dot{a}}{a}\right)^2 \delta_{ij}\delta_{ij} \\ &= -3\left[\frac{\ddot{a}}{a} - \frac{\dot{a}^2}{a^2}\right] - 3\left(\frac{\dot{a}}{a}\right)^2 \\ &= -3\frac{\ddot{a}}{a} \end{aligned}$$

The factors of 3 on the second line arise since δ_{ii} means sum over all three spatial indices, counting one for each. I will leave the space-space component as an exercise; it is

$$R_{ij} = \delta_{ij}\left[2\dot{a}^2 + a\ddot{a}\right]$$

The next ingredient in the Einstein equations is the Ricci scalar, which we can now compute since

$$\begin{aligned} \mathcal{R} &:= g^{\mu\nu}R_{\mu\nu} \\ &= -R_{00} + \frac{1}{a^2}R_{ii} \end{aligned}$$

Again the sum over i leads to a factor of 3, so

$$\mathcal{R} = 6\left[\frac{\ddot{a}}{a} + \left(\frac{\dot{a}}{a}\right)^2\right]$$

To understand the evolution of the scale factor in a homogeneous universe, we need consider only the time-time component of the Einstein equations:

$$R_{00} - \frac{1}{2}g_{00}\mathcal{R} = 8\pi G T_{00}$$

The terms on the left sum to $3\dot{a}^2/a^2$, and the time-time component of the energymomentum tensor is simply the energy density ρ. So we finally have

$$\left(\frac{\dot{a}}{a}\right)^2 = \frac{8\pi G}{3}\rho$$

To get this into the form of Eq. (1.2), recall that the left-hand side here is the square of the Hubble rate and that the critical density was defined as $\rho_{\rm cr} := 3H_0^2/8\pi G$. So, dividing both sides by H_0^2 leads to

$$\frac{H^2(t)}{H_0^2} = \frac{\rho}{\rho_{\rm cr}}$$

Here the energy density ρ counts the energy density from all species: matter, radiation, and the dark energy. In our derivation, we have assumed the universe is flat, so Eq. (2.40) does not contain a term corresponding to the curvature of the universe. I leave it as an exercise to derive the Einstein equation in an open universe.

12.2.2 Distances

We can anticipate that measuring distance in an expanding universe will be a tricky business. Referring back to the expanding grid of Figure 1.1, we immediately see two possible ways to measure distance, the comoving distance which remains fixed as the universe expands or the physical distance which grows simply because of the expansion. Frequently, neither of these two measures accurately describes the process of interest. For example light leaving a distant QSO at redshift 3 starts its journey towards us when the scale factor was only a quarter of its present value and ends it today when the universe has expanded by a factor of 4. Which distance do we use in that case to relate, say, the luminosity of the QSO to the flux we see?

The fundamental distance measure, from which all others may be calculated, is the distance on the comoving grid. If the universe is flat, as we will assume through most of this book, then computing distances on the comoving grid is easy: the distance between two points $\vec{x}_1$ and $\vec{x}_2$ is equal to $\left[(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - \ z_2)^2\right]^{1/2}$.

One very important comoving distance is the distance light could have traveled (in the absence of interactions) since $t = 0$. In a time dt, light travels a comoving distance $dx = dt/a$ (recall that we are setting $c = 1$), so the total comoving distance light could have traveled is

$$\eta := \int_0^t \frac{dt'}{a\left(t'\right)}$$

The reason this distance is so important is that no information could have propagated further (again on the comoving grid) than η since the beginning of time. Therefore, regions separated by distance greater than η are not causally connected. If they appear similar, we should be suspicious! We can think of η then as the comoving horizon. We can also think of η, which is monotonically increasing, as a time variable and call it the conformal time. Just like the time t, the temperature T, the redshift z, and the scale factor a, η can be used to discuss the evolution of the universe. In fact, for most purposes η is the most convenient time variable, so when we begin to study the evolution of perturbations, we will use it instead of t. In some simple cases, η can be expressed analytically in terms of a (Exercise 11). For example, in a matter-dominated universe, $\eta \propto a^{1/2}$, while $\eta \propto a$ in a radiation-dominated universe.

Another important comoving distance is that between a distant emitter and us. In that case, the comoving distance out to an object at scale factor a (or redshift $z = 1/a - 1$) is

$$\chi(a) = \int_{t(a)}^{t_0} \frac{dt'}{a\left(t'\right)} = \int_a^1 \frac{da'}{a'^2 H\left(a'\right)}.$$

Here I have changed the integration over t' to one over a', which brings in the additional factor of $da/dt = aH$ in the denominator. Typically we can see objects out to $z \lesssim 6$; at these late times radiation can be ignored (recall Figure 1.3). If the universe is purely matter dominated at such times, then $H \propto a^{-3/2}$ and we can do the integral in Eq. (2.42) analytically,

$$\chi^{\text{Flat.MD}}\left(a\right) = \frac{2}{H_0}\left[1 - a^{1/2}\right]$$

$$= \frac{2}{H_0}\left[1 - \frac{1}{\sqrt{1+z}}\right]$$

This comoving distance goes as z/H_0 for small z (verifying our hand-waving discussion of the small- z Hubble diagram in Section 1.2) and then asymptotes to $2/H_0$ as z gets very large.

A classic way to determine distances in astronomy is to measure the angle θ subtended by an object of known physical size l. The distance to that object (assuming the angle subtended is small) is then

$$d_A = \frac{l}{\theta}$$

The subscript $_A$ here denotes angular diameter distance. To compute the angular diameter distance in an expanding universe, we first note that the comoving size of the object is l/a. The comoving distance out to the object is given by Eq. (2.42), so the angle subtended is $\theta = (l/a)/\chi(a)$. Comparing with Eq. (2.44), we see that the angular diameter distance is

$$d_A^{\rm flat} = a\chi = \frac{\chi}{1+z}$$

Note that the angular diameter distance is equal to the comoving distance at low redshift, but actually decreases at very large redshift. At least in a flat universe, objects at large redshift appear larger than they would at intermediate redshift! The superscript here is a warning that this result holds only in a flat universe. In an open or closed universe, the curvature density is defined as $\Omega_k = 1 - \Omega_0$ where Ω_0 is the ratio of total to critical density today, including contributions from matter, radiation, and any other form of energy such as a cosmological constant. If the curvature is nonzero, the angular diameter distance generalizes to

$$d_A = \frac{a}{H_0\sqrt{|\Omega_k|}} \begin{cases} \sinh\left[\sqrt{\Omega_k} H_0 \chi\right] & \Omega_k > 0 \\ \sin\left[\sqrt{-\Omega_k} H_0 \chi\right] & \Omega_k < 0 \end{cases}$$

Note that both of these expressions reduce to the flat case in the limit that the curvature density Ω_k goes to zero. Figure 2.3 shows the angular diameter distance in a flat universe, both with and without a cosmological constant.

Another way of inferring distances in astronomy is to measure the flux from an object of known luminosity. Recall that (forgetting about expansion for the moment) the observed flux F a distance d from a source of known luminosity L is

$$F = \frac{L}{4\pi d^2}$$

since the total luminosity through a spherical shell with area $4\pi d^2$ is constant. How does this result generalize to an expanding universe? Again it is simplest to work

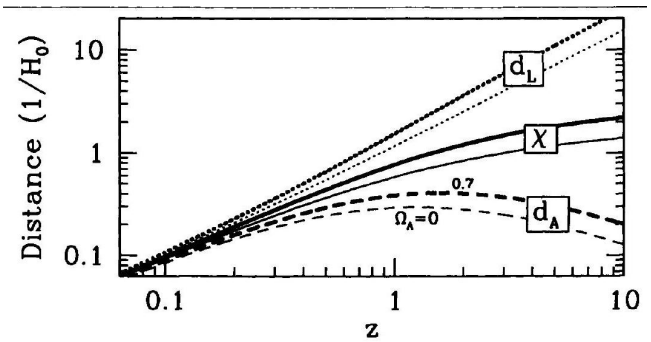

Figure 2.3. Three distance measures in a flat expanding universe. From top to bottom, the luminosity distance, the comoving distance, and the angular diameter distance. The pair of lines in each case is for a flat universe with matter only (light curves) and 70% cosmological constant Λ (heavy curves). In a Λ-dominated universe, distances out to fixed redshift are larger than in a matter-dominated universe.

on the comoving grid, this time with the source centered at the origin. The flux we observe is

$$F = \frac{L(\chi)}{4\pi\chi^2(a)}$$

where $L(\chi)$ is the luminosity through a (comoving) spherical shell with radius $\chi(a)$. To further simplify, let's assume that the photons are all emitted with the same energy. Then $L(\chi)$ is this energy multiplied by the number of photons passing through a (comoving) spherical shell per unit time. In a fixed time interval, photons travel farther on the comoving grid at early times than at late times since the associated physical distance at early times is smaller. Therefore, the number of photons crossing a shell in the fixed time interval will be smaller today than at emission, smaller by a factor of a. Similarly, the energy of the photons will be smaller today than at emission, because of expansion. Therefore, the energy per unit time passing through a comoving shell a distance $\chi(a)$ (i.e., our distance) from the source will be a factor of a^2 smaller than the luminosity at the source. The flux we observe therefore will be

$$F = \frac{La^2}{4\pi\chi^2(a)}$$

where L is the luminosity at the source. We can keep [3] Eq. (2.47) in an expanding universe as long as we define the luminosity distance

$$d_L := \frac{\chi}{a}$$

[3] Actually there is one more difference that needs to be accounted for: the observed luminosity is related to the emitted luminosity at a different wavelength. Here we have assumed a detector which counts all the photons. The luminosity distance is shown in Figure 2.3.

All three distances are larger in a universe with a cosmological constant than in one without. This follows from the fact that the energy density, and therefore the expansion rate, is smaller in a Λ-dominated universe. The universe was therefore expanding more slowly early on, and light had more time to travel from distant objects to us. These distant objects will therefore appear fainter to us than if the universe was dominated by matter only.

12.2.3 Evolution of Energy

Let us return to the energy-momentum tensor on the right-hand side of the Einstein equations. We will eventually include perturbations to $T^\mu{}_\nu$, but in the spirit of this chapter, first consider the case of a perfect isotropic fluid. Then,

$$T^\mu{}_\nu = \begin{pmatrix} -\rho & 0 & 0 & 0 \\ 0 & \mathcal{P} & 0 & 0 \\ 0 & 0 & \mathcal{P} & 0 \\ 0 & 0 & 0 & \mathcal{P} \end{pmatrix}$$

where $\mathcal{P}$ is the pressure of the fluid.

How do the components of the energy-momentum tensor evolve with time? Consider first the case where there is no gravity and velocities are negligible. The pressure and energy density in that case evolve according to the continuity equation, $\partial\rho/\partial t = 0$, and the Euler equation, $\partial\mathcal{P}/\partial x^2 = 0$. This can be promoted to a 4 component conservation equation for the energy-momentum tensor: $\partial T^\mu{}_\nu/\partial x^\mu = 0$. In an expanding universe, however, the conservation criterion must be modified. Instead, conservation implies the vanishing of the covariant derivative:

$$T^{\mu}{}_{\nu;\mu} := \frac{\partial T^{\mu}{}_{\nu}}{\partial x^{\mu}} + \Gamma^{\mu}{}_{\alpha\mu}T^{\alpha}{}_{\nu} - \Gamma^{\alpha}{}_{\nu\mu}T^{\mu}{}_{\alpha}.$$

The vanishing of $T^{\mu}_{\nu;\mu}$ is four separate equations; let's consider the $\nu = 0$ component. This is

$$\frac{\partial T^{\mu}{}_{0}}{\partial x^{\mu}} + \Gamma^{\mu}_{\alpha\mu}T^{\alpha}_{0} - \Gamma^{\alpha}_{0\mu}T^{\mu}_{\alpha} = 0$$

Since we are assuming isotropy, $T^{i}{}_{0}$ vanishes, so the dummy indices μ in the first term and α in the second must be equal to zero:

$$\frac{-\partial\rho}{\partial t} - \Gamma^{\mu}{}_{0\mu}\rho - \Gamma^{\alpha}{}_{0\mu}T^{\mu}{}_{\alpha} = 0.$$

From Eq. (2.23), $\Gamma^{\alpha}_{0\mu}$ vanishes unless α, μ are spatial indices equal to each other, in which case it is $\dot{a}/a$. So, the conservation law in an expanding universe reads

$$\frac{\partial\rho}{\partial t} + \frac{\dot{a}}{a}[3\rho + 3\mathcal{P}] = 0$$

Rearranging terms, we have

$$a^{-3}\frac{\partial\left[\rho a^{3}\right]}{\partial t} = -3\frac{\dot{a}}{a}\mathcal{P}$$

The conservation law can be applied immediately to glean information about the scaling of both matter and radiation with the expansion. Matter has effectively zero pressure, so

$$\frac{\partial\left[\rho_{\mathrm{m}}a^{3}\right]}{\partial t} = 0$$

implying that the energy density of matter $\rho_{\mathrm{m}} \propto a^{-3}$. We anticipated this result in Chapter 1 based on the simple notion that the mass remains constant, while the number density scales as the inverse volume. The application to radiation also offers no surprises. Radiation has $\mathcal{P} = \rho/3$ (Exercise 14), so working from Eq. (2.55),

$$\begin{aligned}\frac{\partial\rho_{r}}{\partial t} + \frac{\dot{a}}{a}4\rho_{r} &= a^{-4}\frac{\partial\left[\rho_{r}a^{4}\right]}{\partial t}\\ &= 0.\end{aligned}$$

Therefore, the energy density of radiation $\rho_r \propto a^{-4}$, accounting for the decrease in energy per particle as the universe expands.

Through most of the early universe, reactions proceeded rapidly enough to keep particles in equilibrium, different species sharing a common temperature. We will often want to express the energy density and pressure in terms of this temperature. For this reason, and many others which will emerge over the next few chapters, it is convenient to introduce the occupation number, or distribution function, of a species. This counts the number of particles in a given region in phase space around position $\vec{x}$ and momentum $\vec{p}$[4] The energy of a species is then obtained by summing the energy over all of phase space elements: $\sum f(\vec{x},\vec{p})E(p)$ with $E(p) = \sqrt{p^2+m^2}$. How many phase space elements are there in a region of "volume" d^3xd^3p? By Heisenberg's principle, no particle can be localized into a region of phase space smaller than $(2\pi\hbar)^3$, so this is the size of a fundamental element. Therefore, the number of phase space elements in d^3xd^3p is $d^3xd^3p/(2\pi\hbar)^3$ (see Figure 2.4), and the energy density is

$$\rho_i = g_i\int\frac{d^3p}{(2\pi)^3}f_i(\vec{x},\vec{p})E(p)$$

where i labels different species, g_i is the degeneracy of the species (e.g., equal to 2 for the photon for its spin states), and I have gone back to $\hbar = 1$. In equilibrium at temperature T, bosons such as photons have Bose-Einstein distributions,

$$f_{\rm BE} = \frac{1}{e^{(E-\mu)/T} - 1}$$

and fermions such as electrons have Fermi-Dirac distributions,

[4] By p here I mean not the comoving momentum defined in Eq. (2.24), but rather the proper momentum which decreases with the expansion. See Exercise 15 for a discussion.

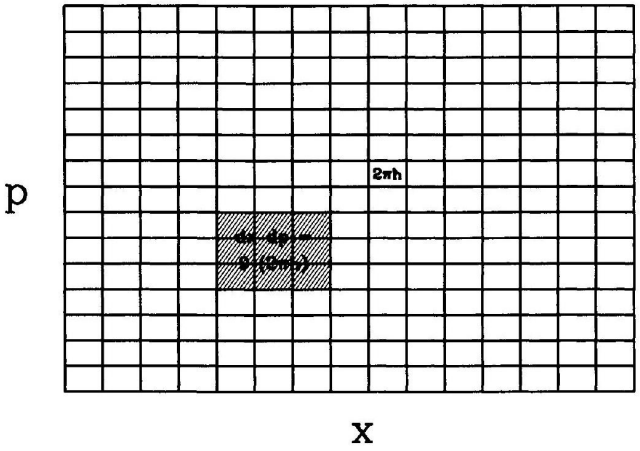

Figure 2.4. Phase space of position and momentum in one dimension. Volume of each cell is $2\pi\hbar$, the smallest region into which a particle can be confined because of Heisenberg's principle. Shaded region has infinitesmal volume $dxdp$. This covers nine cells. To count the appropriate number of cells, therefore, the phase space integral must be $\int dxdp/(2\pi\hbar)$.

$$f_{\rm FD} = \frac{1}{e^{(E-\mu)/T} + 1}$$

with μ the chemical potential. It should be noted that these distributions do not depend on position $\vec{x}$ or on the direction of the momentum $\hat{p}$, simply on the magnitude p. This is a feature of the zero-order, smooth universe. When we come to consider inhomogenities and anisotropies, we will see that the distribution functions have small perturbations around these zero order values, and the perturbations do depend on position and on the direction of propagation.

The pressure can be similarly expressed as an integral over the distribution function,

$$\mathcal{P}_i = g_i \int \frac{d^3p}{(2\pi)^3} f_i(\vec{x}, \vec{p}) \frac{p^2}{3E(p)}$$

For almost all particles at almost all times in the universe, the chemical potential is much smaller than the temperature. To a good approximation, then, the distribution function depends only on E/T and the pressure satisfies (Exercise 14)

$$\frac{\partial \mathcal{P}_i}{\partial T} = \frac{\rho_i + \mathcal{P}_i}{T}$$

This relation can be used to show that the entropy density in the universe scales as a^{-3}. To see this, let's rewrite Eq. (2.56) as

$$a^{-3} \frac{\partial \left[(\rho + \mathcal{P})a^3\right]}{\partial t} - \frac{\partial \mathcal{P}}{\partial t} = 0$$

The derivative of the pressure with respect to time can be written as $(dT/dt)(\partial\mathcal{P}/\partial T)$ so

$$a^{-3}\frac{\partial\left[(\rho+\mathcal{P})a^3\right]}{\partial t}-\frac{dT}{dt}\frac{\rho+\mathcal{P}}{T}=a^{-3}T\frac{\partial}{\partial t}\left[\frac{(\rho+\mathcal{P})a^3}{T}\right]$$
$$=0.$$

So the entropy density [5]

$$s:=\frac{\rho+\mathcal{P}}{T}$$

scales as a^{-3}. Although we have framed the argument in terms of a single species, this scaling holds for the total entropy including all species in equilibrium. In fact, even if two species have different temperatures, the sum of their entropy densities still scales as a^{-3}. We will make use of this fact shortly when computing the relative temperatures of neutrinos and photons in the universe.

12.2.4 Cosmic Inventory

Armed with an expression for the energy density of a given species (Eq. (2.59)), and a knowledge of how it evolves in time (Eq. (2.56)), we can now tackle quantitatively the question of how much energy is contributed by the different components of the universe.

Photons

The temperature of the CMB photons has been measured extraordinarily precisely by the FIRAS instrument aboard the COBE satellite, $T=2.725\pm0.002$ K (Mather et al., 1999). The energy density associated with this radiation is

$$\rho_\gamma=2\int\frac{d^3p}{(2\pi)^3}\frac{1}{e^{p/T}-1}p$$

The factor of 2 in front of Eq. (2.67) accounts for the two spin states of the photon. The energy of a given state is simply equal to p since the photon is massless. The chemical potential is zero; we expect this theoretically because early in the universe, photon number is not conserved (e.g., electrons and positrons can annihilate to produce photons). We also know it observationally because the spectrum of the CMB has been measured so accurately. The limits on a chemical potential are $\mu/T<9\times10^{-5}$ (Fixsen et al., 1996), so μ can be safely ignored. Since there is

[5] Technically, there is another term in the entropy density-proportional to the chemical potential-but, as mentioned above, this term is usually irrelevant in cosmology. Even with nonzero chemical potential, though, the entropy density scales as a^{-3}. no angular dependence in the integrand of Eq. (2.67). the angular integral yields a factor of 4π and we are left with a ome-dimensional integral. Define a dummy variable $x:=p/T$; then

$$\rho_\gamma=\frac{8\pi T^4}{(2\pi)^3}\int_0^\infty\frac{dxx^3}{e^x-1}$$

The integral can be expressed in terms of the Riemann ζ function; it is $6\zeta(4)=\pi^4/15$, so

$$\rho_\gamma=\frac{\pi^2}{15}T^4$$

Since we derived (Eq. (2.58)) that the energy density of radiation scales as a^{-4}, the temperature of the CMB must scale as a^{-1}.

It will be useful to have all energy densities in the same units. The simplest way to do this is to divide all energy densities by the critical density today. [6] Thus,

$$\frac{\rho_\gamma}{\rho_{\rm cr}} = \frac{\pi^2}{15}\left(\frac{2.725\ {\rm K}}{a}\right)^4 \frac{1}{8.098\times 10^{-11}h^2{\rm eV}^4}$$
$$= \frac{2.47\times 10^{-5}}{h^2a^4}$$

where to get the last line, it is useful to remember the conversion between kelvin and eV : 11605 K = 1eV. To reiterate an important point, the photon energy density in Eq. (2.70) depends on time via the scale factor, but has no spatial dependence. This is because we have used the zero-order distribution function, the Bose-Einstein function, for the photons. In fact there are small perturbations around this zeroorder distribution function. These do have a spatial dependence and correspond to the anisotropies in the CMB.

Baryons

Unlike the CMB, baryons [7] cannot be simply described as a gas with a temperature and zero chemical potential. Therefore, the baryon density must be measured directly, not via a temperature. There are now four established ways of measuring the baryon density, and these all seem to agree reasonably well (Fukugita, Hogan, and Peebles 1998). These are all measurements at different redshifts, and we know that the density scales as a^{-3}, so to facilitate comparison, one defines Ω_b via

$$\frac{\rho_b}{\rho_{\rm cr}} = \Omega_b a^{-3}$$

That is, Ω_b is the ratio of the baryon density to the critical density today.

[6] The critical density - just like the Hubble rate which defines it - changes with time. However, it is common to define $\rho_{\rm cr}$ to be a constant, the critical density today, and I will follow this convention.

'I refer to all the nuclei and electrons in the universe as baryons. This is technically incorrect (electrons are leptons), but nuclei are so much more massive than electrons that virtually all the mass is in the baryons. The simplest way is to observe the baryons today in galaxies. The greatest contribution to the density, though, comes not from stars in galaxies, but rather from gas in groups of galaxies. In these groups, Ω_b is about 0.02. The second way to count baryons is by looking at the spectra of distant quasars. The amount of light absorbed from these beacons is a measure of the intervening hydrogen, and hence the baryon density. These estimates (Rauch et al., 1997) suggest $\Omega_b h^{1.5} \simeq 0.02$ with a fairly large uncertainty. A third method is to infer the baryon density by careful scrutiny of the anisotropies in the universe. As we will see in Chapter 8, these depend on the baryon density. Preliminary results (Pryke et al., 2001; Netterfield et al., 2001) give $\Omega_b h^2 = 0.024^{+0.004}_{-0.003}$ from the CMB. Finally, we will see in Chapter 3 that the light element abundances are sensitive to the baryon density, and that estimates of these abundances pin down $\Omega_b h^2 = 0.0205 \pm 0.0018$.

Remarkably, then, these estimates of the baryon density with very different techniques all agree. [8] They all place the baryon density at roughly $2-5\%$ of the critical density. The total matter density in the universe is higher than this, so there must be matter in the universe that is nonbaryonic.

Matter

All of the methods of measuring the baryon density mentioned above involve the interaction of matter and radiation. For example, simply counting stars works at some level because we

roughly know how much mass is required to output the light from a typical star. There are, however, methods of measuring the mass of matter that do not rely on the way light and matter interact. These classically have involved measuring the gravitational field in a given system, thereby inferring information about the mass responsible for that field. Figure 2.5 shows the inferred mass-tolight ratios of many systems, ranging from galaxies to superclusters. Historically this ratio was measured on small scales first, suggesting that the density in the universe was far less than critical. As more large-scale data were obtained, the steady increase in the mass/light ratio led some cosmologists to speculate that eventually we would find that the density was critical. Bahcall and collaborators (Bahcall, Lubin, and Dorman 1995; Bahcall et al., 2000), however, have argued that mass-to-light ratios do not increase past $R \sim 1$Mpc; a leveling off occurs consistent with a matter density $\Omega_m \simeq 0.3$, where Ω_m is the ratio of the total matter density today to the critical density and

$$\rho_{\rm m} = \Omega_m \rho_{\rm cr} a^{-3}.$$

Recently a number of other techniques for inferring the matter density have emerged. We will see in Chapter 7 that the distribution of galaxies in the universe, in particular the power spectrum of this distribution, is very sensitive to $\Omega_m h$;

[8] Whether or not agreement holds is subject to debate. There have been claims (e.g., Persic and Salucci, 1992) that there is a missing baryon problem because the present-day abundance appears to be lower than that inferred from the light element abundances.

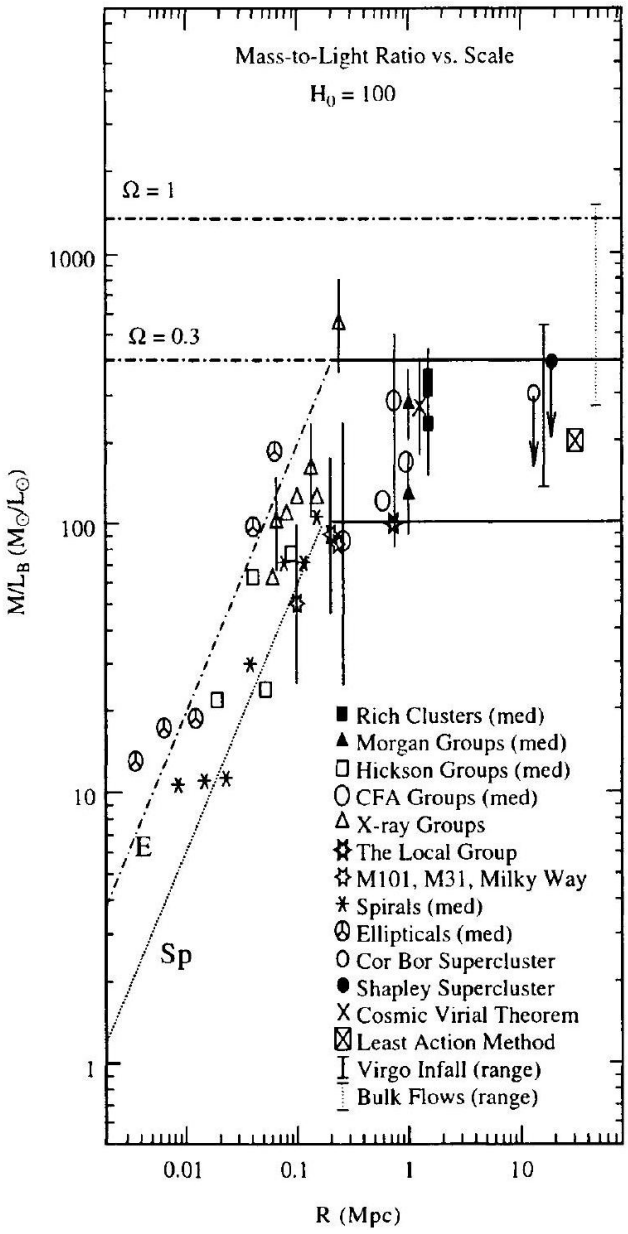

Figure 2.5. Mass vs. light ratio as a function of scale (Bahcall et al., 2000). On the largest scales, the ratio flattens so that $\Omega_m \simeq 0.3$.

virtually all galaxy surveys [9] have inferred $\Omega_m h \simeq 0.2$. Another cosmological probe

[9] To mention three examples, the Automated Plate Measuring (APM) Survey, to be discussed further in Chapter 9, has been analyzed by Efstathiou and Moody (2001); the Two Degree Field (2DF) by Percival et al. (2001), and early data from the Sloan Digital Sky Survey by Dodelson *et* al. (2001). These groups found $\Omega_m h = 0.14^{+0.24}_{-0.09}, 0.20 \pm 0.03$, and $0.14^{+0.11}_{-0.06}$, respectively. we will encounter in Chapter 9 is the cosmic velocity field (Strauss and Willick, 1995) and its relation to the observed galaxy distribution. These are related by the continuity equation, a relation sensitive to Ω_n. Again most of the measurements are clustered around $\Omega_m \simeq 0.3$.

Another way of measuring the total mass density is to pick out observations sensitive to Ω_b/Ω_m and use the apparent value of Ω_b to infer the matter density. For example, most of the baryonic mass in a galaxy cluster is in the form of hot gas. The ratio of the mass of gas in clusters of galaxies to the total mass can be measured either by looking for X-ray emission (White et al., 1993) or by looking at the electron-heated CMB in the direction of the cluster (Grego et al., 2001). If this ratio is characteristic of the universe as a whole - and it probably

is, because clusters are so large - then the cosmic baryon to matter ratio is around 20%. Since baryons make up only about 5% of the critical density, the total matter density is inferred to be about 0.25. Another way of inferring the baryon/matter ratio is by looking for features in the power spectrum of galaxies; if the baryon fraction is truly of order 20%, then there will be wiggles in the spectrum (again Chapter 7). There are tentative hints of these wiggles in the early data from the Two Degree Field (2DF) survey (Percival et al., 2001). These pin down $\Omega_b/\Omega_m = 0.15 \pm 0.07$, consistent with the cluster observations. Finally, the anisotropies in the CMB (Chapter 8) are sensitive to the matter density $\Omega_m h^2$. Recent determinations indicate $\Omega_m h^2 = 0.16 \pm 0.04$ (Pryke et al., 2001; Netterfield et al., 2001). Given the fact that current best estimates of the Hubble constant give $h = 0.72$, the CMB observations also are consistent with a matter density equal to 30% of the critical density.

We therefore have an enormous amount of evidence telling us that the baryon density is of order 5% the critical density, while the total matter density is some five times larger. Most of the matter in the universe must not be baryons. It must be some new form of matter: dark matter.

Neutrinos

The next component we need consider is the neutrino. Unlike photons and baryons, cosmic neutrinos have not been observed, so arguments about their contribution to the energy density are necessarily theoretical. However, these theoretical arguments are quite strong, based on very well-understood physics.

A basic understanding of the interaction rates of neutrinos enables us to argue that neutrinos were once kept in equilibrium with the rest of the cosmic plasma. Since they are fermions, their distribution was Fermi-Dirac with zero chemical potential. At late times, they lost contact with the plasma because their interactions are weak. Nonetheless, their distribution remained Fermi-Dirac, with their temperature simply falling as a^{-1}. The main task therefore is to relate the neutrino temperature to the photon temperature today. The tricky part of this is the annihilation of electrons and positrons when the cosmic temperature was of order the electron mass. Neutrinos lost contact with the cosmic plasma slightly before this annihilation, so they did not inherit any of the associated energy. The photons, which did, are therefore hotter than the neutrinos.

We can account for the annhilation of electrons and positrons by using the fact that the total entropy density s (Eq. (2.66)) scales as a^{-3}. Massless bosons contribute $2\pi^2 T^3/45$ to the entropy density for each spin state, while massless fermions contribute 7/8 this, and massive particles contribute negligibly (Exercise 17). Before annihilation, the fermions are electrons)2 spin states), positrons (2), neutrinos (3 generations and one spin state) and anti-neutrinos (3). The bosons are photons (2 spin states). So at a_1 before annihilation,

$$\begin{aligned} s\left(a_1\right) &= \frac{2\pi^2}{45} T_1^3 [2 + (7/8)(2+2+3+3)] \\ &= \frac{43\pi^2}{90} T_1^3 \end{aligned}$$

where T_1 is the common temperature at a_1. After annihilation, the electrons and positrons have gone away and the photon and neutrino temperatures are no longer identical: we must distinguish between them. Therefore, the entropy density is

$$s\left(a_2\right) = \frac{2\pi^2}{45}\left[2T_\gamma^3 + \frac{7}{8}6T_\nu^3\right].$$

Equating $s\left(a_1\right)a_1^3$ with $s\left(a_2\right)a_2^3$ leads to

$$\frac{43}{2}\left(a_1 T_1\right)^3 = 4\left[\left(\frac{T_\gamma}{T_\nu}\right)^3 + \frac{21}{8}\right]\left(T_\nu\left(a_2\right)a_2\right)^3.$$

But the neutrino temperature scales throughout as a^{-1}, so $a_1 T_1 = a_2 T_\nu\left(a_2\right)$. Therefore, the ratio of the two temperatures is

$$\frac{T_\nu}{T_\gamma} = \left(\frac{4}{11}\right)^{1/3}$$

We can now evaluate the energy density of neutrinos in the universe. Let's sum up what we know about the cosmic abundance of neutrinos

- One spin degree of freedom for neutrinos
- Neutrino has antiparticle
- Three generations of neutrinos
- Neutrinos are fermions $\rightarrow$ Fermi-Dirac distribution function
- Neutrino temperature is lower by a factor of $(4/11)^{1/3}$ since photons are heated by e^+e^-annihilation

The first three items on the list then imply that the degeneracy factor of neutrinos is equal to six. The fourth means we need to change the denominator in the integrand in Eq. (2.67) to $e^{p/T}+1$. The Fermi-Dirac integral is then smaller by a factor of 7/8. Finally, since the energy density of a massless particle scales as T^4, the last item implies that the neutrino energy density is smaller than the photon density by $(4/11)^{4/3}$. Putting all these factors together leads to

$$\rho_\nu = 3\frac{7}{8}\left(\frac{4}{11}\right)^{4/3}\rho_\gamma$$

Equivalently, if there were three species of massless neutrinos today, then their contribution to the energy density would be

$$\Omega_\nu := \left.\frac{\rho_\nu}{\rho_{\rm cr}}\right|_{\rm today} = \frac{1.68\times10^{-5}}{h^2} \quad m_\nu = 0.$$

In reality, all the neutrinos do not appear to be massless. Observations of neutrinos from both the sun (Bahcall, 1989) and from our atmosphere (Fukuda et al., 1998) strongly suggest that neutrinos of different flavors (generations) oscillate into each other. This can happen only if the neutrinos have mass. The atmospheric neutrino observations in particular imply that at least one neutrino has a mass larger than 0.05eV.[10] The energy density of a massive neutrino is

$$\rho_\nu = 2\int\frac{d^3p}{(2\pi)^3}\frac{\sqrt{p^2+m_\nu^2}}{e^{p/T_\nu}+1}$$

At high temperatures, this reduces to Eq. (2.77) (without the 3), so when considering neutrinos in the early universe, it is often sufficient to use Eq. (2.77). Indeed, we will do this shortly when we come to esimtate the epoch at which the energy density of matter equals that of radiation. At late times, the massive neutrino energy density is $m_\nu n_\nu$, with the neutrino number density equal to $3n_\gamma/11$ (Exercise 18). As can be seen from Figure 2.6, the transition takes place when $T_\nu \sim m_\nu$. Therefore,

$$\Omega_\nu = \frac{m_\nu}{94h^2\text{eV}} \quad m_\nu \neq 0$$

Those who trafficked in both astrophysics and particle physics (Gerstein and Zel'dovich, 1966; Marx and Szalay, 1972; Cowsik and McClelland, 1972) early on noted that the simple observation that the total density was not much greater than the critical density leads to constraints on neutrino mass, constraints much more stringent than those obtainable at accelerators. When the need for nonbaryonic dark matter first became evident, a number of cosmologists (e.g., Gunn et al., 1978) proposed neutrinos as the natural candidate. Subsequent studies (Bond, Efstathiou, and Silk, 1980; White, Frenk, and Davis 1983) of the structure of the universe with neutrinos as the dominant dark matter component looked significantly different from the actual universe. Nonetheless, the possibility that neutrinos might make up a fraction of the total density reemerged in the 1990s. We can then hope to detect a trace amount - corresponding to masses smaller than an eV - by observing its effect on large-scale structure.

10 The oscillation experiments are sensitive to mass differences, $m_2^2 - m_1^2$, so the actual constraint is that the mass squared difference is of order 10^{-3}. This could also be accomodated with two nearly degenerate masses with a small splitting.

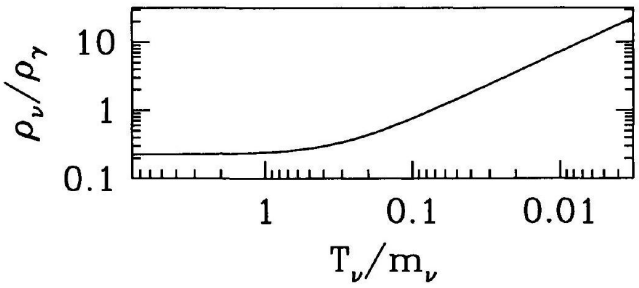

Figure 2.6. Energy density of one generation of massive neutrinos as compared with the density in the CMB. At high temperatures, the ratio is a fixed constant; at low temperatures, the neutrino behaves like nonrelativistic matter (scaling as a^{-3}) and so begins to dominate over the photon density (which scales as a^{-4}).

Dark Energy

There are two sets of evidence pointing toward the existence of something else, something beyond the radiation and matter itemized above. The first comes from a simple budgetary shortfall. The total energy density of the universe is very close to critical. We expect this theoretically (Chapter 6) and we observe it in the anisotropy pattern of the CMB (Chapter 8). Yet, the total matter density inferred from observations is only a third critical. The remaining two-thirds of the density in the universe must be in some smooth, unclustered form, dubbed [11] dark energy. The second set of evidence is more direct. Given the energy composition of the universe, one can compute a theoretical distance vs redshift diagram. This relation can then be tested observationally.

In 1998, two groups (Riess et al., 1998, Perlmutter et al., 1999) observing supernovae reported direct evidence for dark energy. The evidence is based on the difference between the luminosity distance in a universe dominated by dark matter and one dominated by dark energy. As Figure 2.3 indicates, the luminosity distance is larger for objects at high redshifts in a dark-energy-dominated universe. Therefore, objects of fixed intrinsic brightness will appear fainter if the universe is composed of dark energy.

[11] After the discovery, quite a bit of attention was focused on choosing an appropriate name. Cosmological constant, everyone's initial moniker, is too restrictive in that the energy density is constant at all times, and we do not yet know that this is true of the dark energy.

Variable cosmological constant fixes that problems but introduces an inherent contradiction ("variable" and "constant"?). Variable Lambda using the Greek letter reserved for the cosmological constant is too obscure. Quintessence is a good choice: it expresses the fact that, after cosmological photons, baryons, neutrinos, and dark matter, there is a fifth essence in the universe. It seems to me that dark energy has become a bit more popular, with quintessence referring to the subset of models in which the energy density can be associated with a time-dependent scalar field. More concretely, the luminosity distance of Eq. (2.50) can be used to find the apparent magnitude m of a source with absolute magnitude M. Magnitudes are related to fluxes via $m = -(5/2)\log(F)+$ constant. Since the flux scales as d_L^{-2}, the apparent magnitude $m = M + 5\log(d_L) +$ constant. The convention is that

$$m - M = 5\log\left(\frac{d_L}{10\text{pc}}\right) + K$$

where K is a correction for the shifting of the spectrum into or out of the wavelength range measured due to expansion.

The two groups measured the apparent magnitudes of dozens of Type Ia supernovae, which are known to be standard candles, i.e., they have nearly identical absolute magnitudes. Although they were able to place tight constraints on dark energy using the many supernovae that they detected, we can get a feel for the measurement by simply considering two of these. Consider then Supernova 1997ap, found at redshift $z = 0.83$ with apparent magnitude $m = 24.32$, and Supernova 1992P, found at low redshift $z = 0.026$ with apparent magnitude $m = 16.08$. Since the absolute magnitudes of these are the same, the difference in apparent magnitudes is due solely to the difference in luminosity distance:

$$24.32 - 16.08 = 5\log\left(d_L(z = 0.83)\right) - 5\log\left(d_L(z = 0.026)\right).$$

The nearby luminosity distance is independent of cosmology, simply equal to $z/H_0 = 0.026/H_0$. Therefore, the only unknown remaining in Eq. (2.82) is fxed by the observations to be

$$H_0 d_L(z = 0.83) = 1.16$$

In a flat, matter-dominated universe ($\Omega_m = 1$), the luminosity distance out to $z = 0.83$ is equal to $0.95H_0^{-1}$, whereas a universe with $\Omega_m = 0.3$ and a cosmological constant $\Omega_\Lambda = 0.7$ has a luminosity distance of 1.23H_0^{-1}. The apparent magnitude of this single distant supernova then suggests that dark energy pervades the universe.

Of course, the discussion of the previous paragraph does not account for uncertainties (typical uncertainties in the magnitudes are of order 0.2), nor does it do a careful fit to all known supernovae, allow for extinction by dust, or allow for the variation of the absolute magnitude correlated with the duration. The supernova groups did all of those things, and emerged with the constraints shown in Figure 2.7. The two free cosmological parameters are the matter density Ω_m and a cosmological constant Ω_Λ, something we now recognize as one possible form of dark energy, one in which the energy density is constant. Note that the "theorists' dream" universe - flat and matter-dominated ($\Omega_m = 1$) - is excluded with high confidence. Indeed, even a pure open universe with $\Omega_m = 0.3, \Omega_\Lambda = 0$ is strongly disfavored by the supernova data.

While highly popular, Figure 2.7 suffers from two drawbacks. It allows for too much freedom in one sector and too little in another. Most of the region in the figure is taken up by a universe with both dark energy and nonzero curvature (not flat).

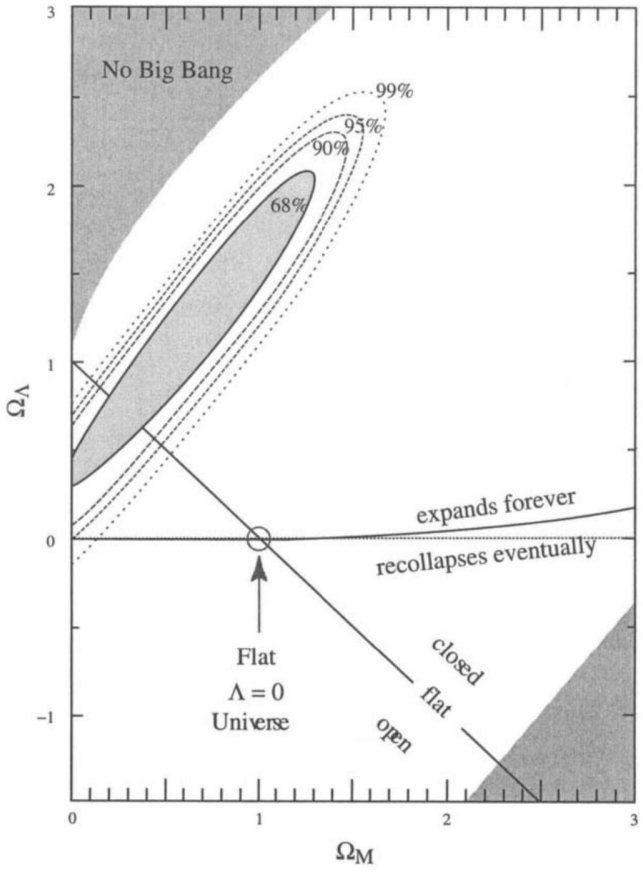

Figure 2.7. Constraints from Type la supernovae on the parameters $(\Omega_m, \Omega_\Lambda)$ (Perlmutter et al., 1999). Flat, matter-dominated universe, the dot with $\Omega_m = 1, \Omega_\Lambda = 0$, is ruled out with high confidence. The line extending from upper left to lower right corresponds to a flat universe.

Although one or the other of these has been argued for, seldom have cosmologists suggested that the universe contains both. Thus, except for the "flat" line and the $\Omega_\Lambda = 0$ line, most of the region in Figure 2.7 is, at least aesthetically, unappealing: the figure allows for too much freedom. On the other hand, the only form of dark energy budgeted for is the cosmological constant. To open up other possibilities,

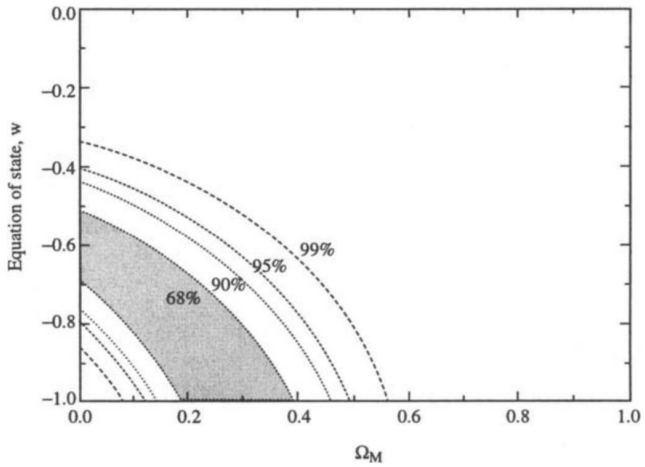

Figure 2.8. Constraints in a flat universe from Type la supernovae on the matter density (Ω_m) and equation of state of the dark energy (w) (Perlmutter et al., 1999). Cosmological constant corresponds to $w = -1$, matter to $w = 0$.

consider Eq. (2.55) as applied to the cosmological constant. The only way for this equation to be satisfied with constant energy density is if the pressure is equal to $-\rho$. One might imagine energy with a slightly different pressure and therefore energy evolution. Define

$$w := \frac{\mathcal{P}}{\rho}$$

A cosmological constant corresponds to $w = -1$, matter to $w = 0$, and radiation to $w = 1/3$. With this new freedom, let's see what the supernova data imply for the equation of state of the dark energy if we fix the universe to be flat. Figure 2.8 shows that values of w greater than ~ -0.5 are disfavored; a cosmological constant is consistent with the data, but it is by no means the only possibility. Equation (2.55) can be integrated to find the evolution of the dark energy,

$$\rho_{\rm de} \propto \exp\left\{-3\int^{a}\frac{da'}{a'}\left[1+w\left(a'\right)\right]\right\}$$

Note that - if w is constant - this expression agrees with our knowledge of the cases explicated above $w = 1/3, 0, -1$.

Epoch of Matter-Radiation Equality

The epoch at which the energy density in matter equals that in radiation is called matter-radiation equality. It has a special significance for the generation of large- scale structure and for the development of CMB anisotropies, because perturbations grow at different rates in the two different eras. It is therefore a useful exercise to calculate the epoch of matter-radiation equality. To do this, we need to compute the energy density of both matter and radiation, and then find the value of the scale factor at which they were equal.

Using Eqs. (2.70) and (2.78), we see that the total energy density in radiation is

$$\frac{\rho_r}{\rho_{\rm cr}} = \frac{4.15\times10^{-5}}{h^2a^4} := \frac{\Omega_r}{a^4}.$$

To calculate the epoch of matter-radiation equality, we equate Equations (2.86) and (2.72) to find

$$a_{\rm eq} = \frac{4.15\times10^{-5}}{\Omega_m h^2}.$$

A different way to express this epoch is in terms of redshift z; the redshift of equality is

$$1 + z_{\rm eq} = 2.4\times10^4\Omega_m h^2.$$

Note that - obviously - as the amount of matter in the universe today, $\Omega_m h^2$, goes up, the redshift of equality also goes up. For our purposes it will be very important that the redshift of equality is at least several times larger than the redshift when photons decouple from matter, $z_* \simeq 10^3$. Thus, we expect photons to decouple when the universe is already well into the matter-dominated era.

SUGGESTED READING

My favorite book on general relativity at this level is A First Course in General Relativity (Schutz), which gives many simple examples to introduce the seemingly profound ideas of general relativity. Also very good are Flat and Curved Spacetimes (Ellis and Williams) and

Essential Relativity (Rindler). Slightly more advanced is Gravitation and Cosmology: Principles and Applications of the General Theory of Relativity (Weinberg), which also has a nice discussion of the early universe in Chapter 15. Two more advanced books are General Relativity (Wald) and the classic Gravitation (Misner, Thorne, and Wheeler). Some of the thermodynamics and statistical mechanics introduced in this chapter is presented in The Early Universe (Kolb and Turner). The distance formulae of Section 2.2 are covered in all standard texts. Neutrinos and their relation to cosmology are covered in the standard texts as well, but there are also several other good books focused solely on neutrinos and astrophysics, Neutrino Astrophysics by the pioneer of the field, Bahcall, and Massive Neutrinos in Physics and Astrophysics by Mohapatra and Pal.

A number of papers treat the topics in this chapter at an accessible level. An especially coherent review of all the different distance measures is given by Hogg (1999). Fukugita, Hogan, and Peebles (1999) do the baryon inventory outlined in Section 2.4.2. Since the supernova discoveries in the late 1990s, many popular articles have appeared attempting to explain the dark energy. The two seminal articles though - Perlmutter et al. (1999) and Riess et al. (1998) - are extremely clear and well worth reading.

D-1.

Convert the following quantities by inserting the appropriate factors of $c, \hbar$, and k_B:

- $T_0 = 2.725$ K $\rightarrow$ eV
- $\rho_\gamma = \pi^2 T_0^4/15 \rightarrow \mathrm{eV}^4$ and gcm^{-3}
- $1/H_0 \rightarrow$ cm
- $m_{\rm Pl} := 1.2 \times 10^{19}\mathrm{GeV} \rightarrow \mathrm{K}, \mathrm{cm}^{-1}, \mathrm{sec}^{-1}$

D-2.

Show that the geodesic equation gets the correct equations of motion for a particle traveling freely in two dimensions using polar coordinates. You can get the Christoffel symbols one of two ways (or both!) and then proceed to (b).

(a) Get the Christoffel symbol either directly from the term in brackets in Eq. (2.17) or from the 2D metric

$$g_{ij} = \begin{pmatrix} 1 & 0 \\ 0 & r^2 \end{pmatrix}$$

using Eq. (2.19). Show that the only nonzero Christoffel symbols are

$$\Gamma^2_{12} = \Gamma^2_{21} = \frac{1}{r} \quad ; \quad \Gamma^1_{22} = -r$$

with 1,2 corresponding to r, θ. (b) Write down the two components of the geodesic equation using these Christoffel symbols. Show that these give the proper equations of motion for a particle traveling in a plane.

D-3.

The metric for a particle traveling in the presence of gravitational field is $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$ where $h_{00} = -2\phi$ where ϕ is the Newtonian gravitational potential; $h_{i0} = 0$; and $h_{ij} = -2\phi\delta_{ij}$. Find the equation of motion for a massive particle traveling in this field.

(a) Show that $\Gamma^0_{00} = \partial\phi/\partial t$ and $\Gamma^i{}_{00} = \delta^{ij}\partial\phi/\partial x^j$.

(b) Show that the time component of the geodesic equation implies that energy $p^0 + m\phi$ is conserved.

(c) Show that the space components of the geodesic equation lead to $d^2x^i/dt^2 = -m\delta^{ij}\partial\phi/\partial x^j$ in agreement with Newtonian theory. Use the fact that the particle is nonrelativistic so $p^0 \gg p^i$.

D-4.

Find how the energy of a massive, nonrelativistic particle changes as the universe expands. Recall that in the massless case we used the fact that $g_{\mu\nu}P^\mu P^\nu = 0$. In this case, it is equal not to zero, but to $-m^2$.

D-5.

Fill in some of the blanks left in our derivation of the Einstein equations.

(a) Compute the Christoffel symbol $\Gamma^i_{\alpha\beta}$ for a flat FRW metric.

(b) Compute the spatial components of the Ricci tensor in a flat FRW universe, R_{ij}. Show that the space-time component, R_{i0}, vanishes.

D-6.

Show that the space-space component of the Einstein equations in a flat universe is

$$\frac{d^2a/dt^2}{a} + \frac{1}{2}\left(\frac{da/dt}{a}\right)^2 = -4\pi G\mathcal{P}$$

where $\mathcal{P}$ is the pressure, the T^i_i (no sum over i) component of the energymomentum tensor.

D-7.

Find and apply the metric, Christoffel symbols, and Ricci scalar for a particle trapped on the surface of a sphere with radius r.

(a) Using coordinates t, θ, ϕ, the metric is

$$g_{\mu\nu} = \begin{pmatrix} -1 & 0 & 0 \\ 0 & r^2 & 0 \\ 0 & 0 & r^2\sin^2\theta \end{pmatrix}.$$

Show that the only nonvanishing Christoffel symbols are $\Gamma^\theta_{\phi\phi}, \Gamma^\phi_{\phi\theta}$, and $\Gamma^\phi_{\theta\phi}$. Express these in terms of θ.

(b) Use these and the geodesic equation to find the equations of motion for the particle. (c) Find the Ricci tensor. Show that contraction of this tensor leads to

$$\mathcal{R} := g^{\mu\nu}R_{\mu\nu} = \frac{2}{r^2}.$$

D-8.

Apply the Einstein equations to the case of an open universe. The interval in an open universe is

$$ds^2 = -dt^2 + a^2(t)\left\{\frac{dr^2}{1+\Omega_k H_0^2 r^2} + r^2\left(d\theta^2 + \sin^2\theta d\phi^2\right)\right\}$$

where r, θ, ϕ are the standard 3D spherical coordinates, and Ω_k is the curvature density.

(a) First compute the Christoffel symbols. Show that the only nonzero ones are equal to

$$\Gamma^i_{0j} = H\delta^i_j \quad \Gamma^0_{ij} = g_{ij}H$$
$$\Gamma^i_{jk} = \frac{g^{il}}{2}\left[g_{lj,k} + g_{lk,j} - g_{jk,l}\right].$$

(b) Show that the components of the Ricci tensor are

$$R_{00} = -3\frac{\ddot{a}}{a}$$
$$R_{ij} = g_{ij}\left[\frac{\ddot{a}}{a} + 2H^2 - \frac{2\Omega_k H_0^2}{a^2}\right].$$

(c) From these, compute the Ricci scalar, and then derive the time-time component of Einstein equations.

D-9.

Show that the geodesic equation we derived in a flat universe implies that

$$\frac{d^2\vec{x}}{d\eta^2} = 0$$

where η is the conformal time.

D-10.

Assume that there is only matter and radiation in the universe (no cosmological constant) and that the universe is flat ($\rho_0 = \rho_{\rm cr}$). Integrate Eq. (1.2) to determine the times when the cosmic temperature was 0.1MeV and 1/4eV.

D-11.

Derive some simple expressions for the conformal time η as a function of a.

(a) Show that $\eta \propto a^{1/2}$ in a matter dominated universe and a in one dominated by radiation.
(b) Consider a universe with only matter and radiation, with equality at $a_{\rm eq}$. Show that

$$\eta = \frac{2}{\sqrt{\Omega_m H_0^2}}\left[\sqrt{a + a_{\rm eq}} - \sqrt{a_{\rm eq}}\right]$$

What is the conformal time today? At decoupling?

D-12.

Consider a galaxy of physical (visible) size 5kpc. What angle would this galaxy subtend if situated at redshift 0.1? Redshift 1? Do the calculation in a flat universe, first matter-dominated and then with 30% matter and 70% cosmological constant.

D-13.

How is the energy density of a gas of photons with a blackbody spectrum related to the specific intensity of the radiation? That is, what is the relation between ρ_γ and I_ν defined in Eq. (1.8)?

D-14.

(a) Compute the pressure of a relativistic species in equilibrium with temperature T. Show that $\mathcal{P} = \rho/3$ for both Fermi-Dirac and Bose-Einstein statistics.

(b) Suppose the distribution function depends only on E/T as it does in equilibrium. Find $d\mathcal{P}/dT$. A simple way to do this is to rewrite df/dT in the integral as $-(E/T)df/dE$ and then integrate Eq. (2.62) by parts.

D-15.

The general relativistic expression for the energy-momentum tensor in terms of the distribution functions is given by

$$T^{\mu}{}_{\nu}(\vec{x},t)|_{\text{species i}} = g_i \int \frac{dP_1 dP_2 dP_3}{(2\pi)^3} \left(-\det\left[g_{\alpha\beta}\right]\right)^{-1/2} \frac{P^{\mu}P_{\nu}}{P^0} f_i(\vec{x},\vec{p},t)$$

where P_μ was defined in Eq. (2.24), g_i is the number of spin states for species i, and $\det[g_{\mu\nu}]$ is the determinant of the 4D matrix $g_{\mu\nu}$. Eliminate the comoving momenta P_μ in favor of the magnitude of the proper momentum defined via

$$p^2 := g^{ij}P_iP_j$$

and the direction vector $\hat{p}$. Note that while the comoving momenta P_i remain constant as the universe expands, p falls off as a^{-1}. Show that the time-time component of Eq. (2.101) agrees with the expression for the energy density given in Eq. (2.59). Use the fact that $P^2 := g_{\mu\nu}P^\mu P^\nu = -m^2$ for a particle of mass m.

D-16.

Plot $m - M$ as a function of redshift for a flat, matter-dominated universe (this can be done analytically) and for a flat universe with $\Omega_\Lambda = 0.7, \Omega_m = 0.3$ (for this you need to evaluate numerically a 1D integral). Neglect the K correction. Compare with Figure 1.7.

D-17.

Consider the entropy density, s, defined in Eq. (2.66). For a massless particle, you showed in Exercise 14 that $\mathcal{P} = \rho/3$, so $s = 4\rho/3T$. Express s as a function of T for both bosons and fermions (assumed massless) in equilibrium with zero chemical potential. Show that the entropy density for a massive particle in equilibrium ($T \ll m; \mu = 0$) is exponentially small.

D-18.

Show that the number density of one generation of neutrinos and anti-neutrinos in the universe today is

$$n_\nu = \frac{3}{11} n_\gamma = 112 \text{ cm}^{-3}$$

For this calculation, you will also have to compute the photon number density; both can be expressed in terms of Riemann zeta functions (Eq. (C.27)). Using this result, verify Eq. (2.80)

D-19.

We computed the epoch of equality in the event that all three neutrinos are massless. Suppose instead that two are massless, but the third has mass $m = 0.1$eV. What is a_{eq} is this case?

12.3 Beyond Equilibrium

The very early universe was hot and dense. As a result, interactions among particles occurred much more frequently than they do today. As an example, a photon today can travel across the observable universe without deflection or capture, so it has a mean free path greater than 10^{28} cm. When the age of the universe was equal to 1 sec, though, the mean free path of a photon was about the size of an atom. Thus in the time it took the universe to expand by a factor of 2, a given photon interacted many, many times. These multiple interactions kept the consitituents in the universe in equilibrium in most cases. Nonetheless, there were times when reactions could not proceed rapidly enough to maintain equilibrium conditions. These times are -perhaps not coincidentally - of the utmost interest to cosmologists today.

Indeed, we will see in this chapter that out-of-equilibrium phenomena played a role in (i) the formation of the light elements during Big Bang nucleosynthesis; (ii) recombination of electrons and protons into neutral hydrogen when the temperature was of order 1/4eV; and quite possibly in (iii) production of dark matter in the early universe. Each of these three periods, for obvious reasons, is the subject of intense study by many different groups. Often these studies are carried out in parallel, without the link among the three mentioned. I think it is important to understand that all three phenomena are the result of nonequilibrium physics and that all three can be studied with the same formalism: the Boltzmann equation. Section 3.1 introduces the Boltzmann equation and some approximations to it that are common to all three processes. The remaining three sections of the chapter are simply applications of this general formula.

Beyond the intrinsic importance of these nonequilibrium phenomena, this chapter also serves as a bridge between the smooth, homogeneous universe described in Chapter 2 and the inhomogeneous perturbations we will explore in the rest of the book. One way to think of this transition is in terms of phase-space distributions f of Eqs. (2.60) and (2.61). Until now, we have assumed that the chemical potentials are zero and temperatures uniform. In this chapter, we will have to abandon the idea of trivial chemical potentials in order to track abundances of particles losing contact with the plasma. In succeeding chapters, we will move beyond uniformity and explore temperatures which depend on both position and direction of propagation.

12.3.1 Boltzmann Equation for Annihilation

The Boltzmann equation formalizes the statement that the rate of change in the abundance of a given particle is the difference between the rates for producing and eliminating that species. Suppose that we are interested in the number density n_1 of species 1. For simplicity, let's suppose that the only process affecting the abundance of this species is an annihilation with species 2 producing two particles, imaginatively called 3 and 4. Schematically, $1 + 2 \leftrightarrow 3 + 4$; i.e., particle 1 and particle 2 can annihilate producing particles 3 and 4, or the inverse process can produce 1 and 2. The Boltzmann equation for this system in an expanding universe is

$$\begin{aligned} a^{-3}\frac{d\left(n_1 a^3\right)}{dt} = & \int \frac{d^3p_1}{(2\pi)^3 2E_1}\int \frac{d^3p_2}{(2\pi)^3 2E_2}\int \frac{d^3p_3}{(2\pi)^3 2E_3}\int \frac{d^3p_4}{(2\pi)^3 2E_4} \\ & \times (2\pi)^4\delta^3\left(p_1+p_2-p_3-p_4\right)\delta\left(E_1+E_2-E_3-E_4\right)|\mathcal{M}|^2 \\ & \times \left\{f_3 f_4\left[1\pm f_1\right]\left[1\pm f_2\right]-f_1 f_2\left[1\pm f_3\right]\left[1\pm f_4\right]\right\} \end{aligned}$$

In the absence of interactions, the left-hand side of Eq. (3.1) says that the density times the scale factor cubed is conserved. This reflects the nature of the expanding universe: as the comoving grid expands, the volume of a region containing a fixed number of particles grows as a^3. Therefore, the physical number density of these particles falls off as a^{-3}. Interactions are included in the right-hand side of the Boltzmann equation. Let's consider the interaction

term starting from the last line and moving up. Putting aside the $1 \pm f$ terms on the last line, we see that the rate of producing species 1 is proportional to the occupation numbers of species 3 and 4, f_3 and f_4. Similarly the loss term is proportional to $f_1 f_2$. The $1 \pm f$ terms, with plus sign for bosons such as photons and minus sign for fermions such as electrons, represent the phenomena of Bose enhancement and Pauli blocking. If particles of type 1 already exist, a reaction producing more such particles is more likely to occur if 1 is a boson and less likely if a fermion. I have suppressed the momentum dependence of f, but of course all the occupation numbers depend on the corresponding momentum (e.g., $f_1 = f_1(p_1)$). Moving upward, the Dirac delta functions on the second line in Eq. (3.1) enforce energy and momentum conservation; the factors of 2π are the result of moving from discrete Kronecker δ 's to the continuous Dirac version. The energies here are related to the momenta via $E = \sqrt{p^2 + m^2}$. The amplitude on the second line $\mathcal{M}$ is determined from the fundamental physics in question. For example, if we were interested in the Compton scattering of electrons off of photons, $\mathcal{M}$ would be proportional to α, the fine structure constant. In almost all cases of interest, this amplitude is reversible, identical for $1 + 2 \to 3 + 4$ and $3 + 4 \to 1 + 2$. Indeed, reversibility has been assumed in Eq. (3.1). The last two lines of Eq. (3.1) depend on the momenta of the particles involved. To find the total number of interactions, we must sum over all momenta. The integrals on the first line do precisely that. As in Figure 2.4, the factors of $(2\pi)^3$ [really $(2\pi\hbar)^3$] represent the volume of one unit of phase space; we want to sum over all such units. Finally, the factors of $2E$ in the denominator arise because, relativistically, the phase space integrals should really be four-dimensional, over the three components of momentum and one of energy. However, these are constrained to lie on the 3 -sphere fixed by $E^2 = p^2 + m^2$. In equations,

$$\int d^3p \int_0^\infty dE \delta\left(E^2 - p^2 - m^2\right) = \int d^3p \int_0^\infty dE \frac{\delta\left(E - \sqrt{p^2 + m^2}\right)}{2E}$$

Performing the integral over E with the delta function yields the factor of $2E$.

Equation (3.1) is an integrodifferential equation for the phase space distributions. Further, in principle at least, it must be supplemented with similar equations for the other species. In practice, these formidable obstacles can be overcome for many practical cosmological applications. The first, most important realization is that scattering processes typically enforce kinetic equilibrium. That is, scattering takes place so rapidly that the distributions of the various species take on the generic Bose-Einstein/Fermi-Dirac forms (Eqs. (2.61) and (2.60)). This form condenses all of the uncertainty in the distribution into a single function of time μ. If annihilations were also in equilibrium, μ would be the chemical potential, and the sum of the chemical potentials in any reaction would have to balance. For example, the reaction $e^+ + e^- \leftrightarrow \gamma + \gamma$ would cause $\mu_{e^+} + \mu_{e^-} = 2\mu_\gamma$. In the out-of-equilibrium cases we will study, the system will not be in chemical equilibrium and we will have to solve a differential equation for μ. The great simplifying feature of kinetic equilibrium, though, is that this differential equation will be a single ordinary differential equation, as opposed to the very complicated form of Eq. (3.1).

We will typically be interested in systems at temperatures smaller than $E - \mu$. In this limit, the exponential in the Bose-Einstein or Fermi-Dirac distribution is large and dwarfs the \pm 1 in the denominator. Thus, another simplification emerges: we can ignore the complications of quantum statistics. The distributions become

$$f(E) \to e^{\mu/T} e^{-E/T}$$

and the Pauli blocking/Bose enhancement factors in the Boltzmann equation can be neglected.

Under these approximations, the last line of Eq. (3.1) becomes

$$f_3 f_4 \left[1 \pm f_1\right]\left[1 \pm f_2\right] - f_1 f_2 \left[1 \pm f_3\right]\left[1 \pm f_4\right] \\ \to e^{-(E_1+E_2)/T}\left\{e^{(\mu_3+\mu_4)/T} - e^{(\mu_1+\mu_2)/T}\right\}.$$

Here I have used energy conservation. $E_1 + E_2 = E_3 + E_4$. We will use the number densities themselves as the time-dependent functions to be solved for. instead of μ. The number density of species i is related to μ_i via Table 3.1. Reactions in This Chapter: $1 + 2 \leftrightarrow 3 + 4$

	1	2	3	4
Neutron-Proton Ratio	n	ν_e or e^+	p	e^-or $\bar{\nu}_e$
Recombination	e	p	H	γ
Dark Matter Production	X	X	l	l

$$n_i = g_i e^{\mu_i/T}\int \frac{d^3p}{(2\pi)^3} e^{-E_i/T}$$

where g_i is the degeneracy of the species, e.g., equal to 2 for the two spin states of the photon. It will also be useful to define the species-dependent equilibrium number density as

$$n_i^{(0)} := g_i \int \frac{d^3p}{(2\pi)^3} e^{-E_i/T} = \begin{cases} g_i \left(\frac{m_i T}{2\pi}\right)^{3/2} e^{-m_i/T} & m_i \gg T \\ g_i \frac{T^3}{\pi^2} & m_i \ll T \end{cases}.$$

With this defintion, $e^{\mu_i/T}$ can be rewritten as $n_i/n_i^{(0)}$, so the last line of Eq. (3.1) is equal to

$$e^{-(E_1+E_2)/T}\left\{\frac{n_3 n_4}{n_3^{(0)} n_4^{(0)}} - \frac{n_1 n_2}{n_1^{(0)} n_2^{(0)}}\right\}$$

With these approximations the Boltzmann equation now simplifies enormously. Define the thermally averaged cross section as

$$\langle\sigma v\rangle := \frac{1}{n_1^{(0)} n_2^{(0)}}\int \frac{d^3p_1}{(2\pi)^3 2E_1}\int \frac{d^3p_2}{(2\pi)^3 2E_2}\int \frac{d^3p_3}{(2\pi)^3 2E_3}\int \frac{d^3p_4}{(2\pi)^3 2E_4} e^{-(E_1+E_2)/T} \\ \times (2\pi)^4 \delta^3\left(p_1 + p_2 - p_3 - p_4\right)\delta\left(E_1 + E_2 - E_3 - E_4\right)|\mathcal{M}|^2$$

Then, the Boltzmann equation becomes

$$a^{-3}\frac{d\left(n_1 a^3\right)}{dt} = n_1^{(0)} n_2^{(0)}\langle\sigma v\rangle\left\{\frac{n_3 n_4}{n_3^{(0)} n_4^{(0)}} - \frac{n_1 n_2}{n_1^{(0)} n_2^{(0)}}\right\}$$

We thus have a simple ordinary differential equation for the number density. Although the details will vary from application to application (see Table 3.1), we will in the remainder of the chapter start from this equation when tracking abundances.

One qualitative note about Eq. (3.9). The left-hand side is of order n_1/t, or, since the typical cosmological time is $H^{-1}, n_1 H$. The right-hand side is of order $n_1 n_2\langle\sigma v\rangle$. Therefore, if the reaction rate $n_2\langle\sigma v\rangle$ is much larger than the expansion rate, then the terms on the right side will be much larger than the one on the left. The only way to maintain equality then is for the individual terms on the right to cancel. Thus, when reaction rates are large,

$$\frac{n_3 n_4}{n_3^{(0)} n_4^{(0)}} = \frac{n_1 n_2}{n_1^{(0)} n_2^{(0)}}$$

This equation, which follows virtually by inspection from the Boltzmann equation, goes under different names in different venues. The particle physics community, which first studied the production of heavy relics in the early universe, tends to call it chemical equilibrium. In the context of Big Bang nucleosynthesis, it is called nuclear statistical equilibrium (NSE), while students of recombination, the process of electrons and protons combining to form neutral hydrogen, use the terminology Saha equation.

12.3.2 Big Bang Nucleosynthesis

As the temperature of the universe cools to 1MeV, the cosmic plasma consists of:

- Relativistic particles in equilibrium: photons, electrons and positrons. These are kept in close contact with each other by electromagnetic interactions such as $e^+e^- \leftrightarrow \gamma\gamma$. Besides a small difference due to fermion/boson statistics, these all have the same abundances.
- Decoupled relativistic particles: neutrinos. At temperatures a little above 1 MeV, the rate for processes such as $\nu e \leftrightarrow \nu e$ which keep neutrinos coupled to the rest of the plasma drops beneath the expansion rate. Neutrinos therefore share the same temperature as the other relativistic particles, and hence are roughly as abundant, but they do not couple to them.
- Nonrelativistic particles: baryons. If there had been no asymmetry in the initial number of baryons and anti-baryons, then both would be completely depleted by 1MeV. However, such an asymmetry did exist: $(n_b - n_{\bar{b}})/s \sim 10^{-10}$ initially, [1] and this ratio remains constant throughout the expansion. By the time the temperature is of order 1MeV, all anti-baryons have annihilated away (Exercise 12) so

$$\eta_b := \frac{n_b}{n_\gamma} = 5.5 \times 10^{-10} \left(\frac{\Omega_b h^2}{0.020}\right)$$

There are thus many fewer baryons than relativistic particles when $T \sim$ MeV.

Our task in this section will be to determine how the baryons end up. Were the system to remain in equilibrium throughout, the final state would be dictated solely by energetics, and all baryons would relax to the nuclear state with the lowest energy per baryon, iron (Figure 3.1). However, nuclear reactions, which scale as the second - or higher - power of the density, are too slow to keep the system in equilibrium as the temperature drops. So, in principle, we need to solve the

[1] s is the entropy density which scales as a^{-3}, as we saw in Chapter 2.

equivalent of Eq. (3.9) for all the nuclei, i.e., a set of coupled differential equations. In practice, at least for a qualitative understanding of the result, we can make use of two simplifications that obviate the need to solve the full set of differential equations.

Lightning Introduction to Nuclear Physics

A single proton is a hydrogen nucleus, referred to as ^{1}H or simply p; a proton and a neutron make up deuterium, ^{2}H or D; one proton and two neutrons make tritium, ^{3}H or T. Nuclei with two protons are helium; these can have one neutron (^{3}He) or two (^{4}He). Thus unique elements have a fixed number of protons, and isotopes of a given element have differing numbers of neutrons. The total number of neutrons and protons in the nucleus, the atomic number, is a superscript before the name of the element.

The total mass of a nucleus with Z protons and $A - Z$ neutrons differs slightly from the mass of the individual protons and neutrons alone. This difference is called the binding energy, defined as

$$B := Zm_p + (A - Z)m_n - m$$

where m is the mass of the nucleus. For example, the mass of deuterium is 1875.62MeV while the sum of the neutron and proton masses is 1877.84MeV, so the binding energy of deuterium is 2.22MeV. Nuclear binding energies are typically in the MeV range, which explains why Big Bang nucleosynthesis occurs at temperatures a bit less than 1MeV even though nuclear masses are in the GeV range.

Neutrons and protons can interconvert via weak interactions:

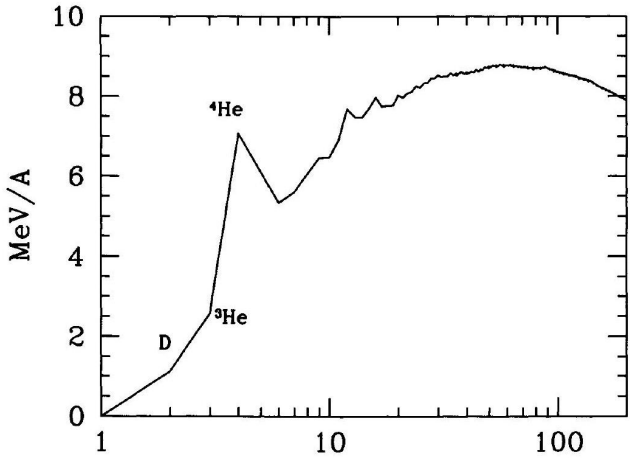
$$p + \bar{\nu} \leftrightarrow n + e^+ \quad ; \quad p + e^- \leftrightarrow n + \nu \quad ; \quad n \leftrightarrow p + e^- + \bar{\nu}$$

where all the reactions can proceed in either direction. The light elements are built up via electromagnetic interactions. For example, deuterium forms from $p + n \rightarrow \mathrm{D} + \gamma$. Then, $\mathrm{D} + \mathrm{D} \rightarrow n + {}^3\mathrm{He}$, after which ${}^3\mathrm{He} + \mathrm{D} \rightarrow p + {}^4\mathrm{He}$ produces ${}^4\mathrm{He}$.

The first simplification is that essentially no elements heavier than helium are produced at appreciable levels. [2] So the only nuclei that need to be traced are hydrogen and helium, and their isotopes: deuterium, tritium, and ${}^3\mathrm{He}$. The second simplification is that, even in the context of this reduced set of elements, the physics splits up neatly into two parts since above $T \simeq 0.1\mathrm{MeV}$, no light nuclei form: only free protons and neutrons exist. Therefore, we first solve for the neutron/proton ratio and then use this abundance as input for the synthesis of helium and isotopes such as deuterium.

[2] An exception is lithium, produced at a part in $10^9 - 10^{10}$, and this trace abundance may be observable today. See, e.g., Pinsonneault et al. (2001).

Binding Energy per Nucleon



A

Figure 3.1. Binding energy of nuclei as a function of mass number. Iron has the highest binding energy, but among the light elements, ${}^4\mathrm{He}$ is a crucial local maximum. Nucleosynthesis in the early universe essentially stops at ${}^4\mathrm{He}$ because of the lack of tightly bound isotopes at $A = 5 - 8$. In the high-density environment of stars, three ${}^4\mathrm{He}$ nuclei fuse to form ${}^{12}\mathrm{C}$, but the low baryon number precludes this process in the early universe.

Both of these simplifications - no heavy elements at all and only n/p above 0.01 MeV - rely on the physical fact that, at high temperatures, comparable to nuclear binding energies, any time a nucleus is produced in a reaction, it is destroyed by a high-energy photon. This

fact is reflected in the fundamental equilibrium equation (3.10). To see how, let's consider this equation applied to deuterium production, $n + p \leftrightarrow \mathrm{D} + \gamma$. Since photons have $n_\gamma = n_\gamma^{(0)}$, the equilibrium condition becomes

$$\frac{n_D}{n_n n_p} = \frac{n_D^{(0)}}{n_n^{(0)} n_p^{(0)}}$$

The integrals on the right, as given in Eq. (3.6), lead to

$$\frac{n_D}{n_n n_p} = \frac{3}{4}\left(\frac{2\pi m_D}{m_n m_p T}\right)^{3/2} e^{[m_n+m_p-m_D]/T},$$

the factor of 3/4 being due to the number of spin states)3 for D and 2 each for p and n). In the prefactor, m_D can be set to $2m_n = 2m_p$, but in the exponential the small difference between $m_n + m_p$ and m_D is important: indeed the argument of the exponential is by defintion equal to the binding energy of deuterium, $B_D = 2.22$ MeV. Therefore, as long as equilibrium holds,

$$\frac{n_D}{n_n n_p} = \frac{3}{4}\left(\frac{4\pi}{m_p T}\right)^{3/2} e^{B_D/T}$$

Both the neutron and proton density are proportional to the baryon density, so roughly,

$$\frac{n_D}{n_b} \sim \eta_b \left(\frac{T}{m_p}\right)^{3/2} e^{B_D/T}$$

As long as B_D/T is not too large, the prefactor dominates this expression. And the prefactor is very small because of the smallness of the baryon-to-photon ratio, Eq. (3.11).

The small baryon to photon ratio thus inhibits nuclei production until the temperature drops well beneath the nuclear binding energy. At temperatures above 0.1 MeV, then, virtually all baryons are in the form of neutrons and protons. Around this time, deuterium and helium are produced, but the reaction rates are by now too low to produce any heavier elements. We could have anticipated this by considering Figure 3.1. The lack of a stable isotope with mass number 5 implies that heavier elements cannot be produced via ${}^4\mathrm{He} + p \to X$. In stars, the triple alpha process ${}^4\mathrm{He} + {}^4\mathrm{He} + {}^4\mathrm{He} \to {}^{12}\mathrm{C}$ produces heavier elements, but in the early universe, densities are far too low to allow three nuclei to find one another on relevant time scales.

Neutron Abundance

We begin by solving for the neutron-proton ratio. Protons can be converted into neutrons via weak interactions, $p + e^- \to n + \nu_e$ for example. As we will see, reactions of this sort keep neutrons and protons in equilibrium until $T \sim$ MeV. Thereafter, one must solve the rate equation (3.9) to track the neutron abundance.

From Eq. (3.6), the proton/neutron equilibrium ratio in the nonrelativistic limit ($E = m + p^2/2m$) is

$$\frac{n_p^{(0)}}{n_n^{(0)}} = \frac{e^{-m_p/T}\int dp p^2 e^{-p^2/2m_p T}}{e^{-m_n/T}\int dp p^2 e^{-p^2/2m_n T}}$$

The integrals here are proportional to $m^{3/2}$, but the resulting ratio $(m_p/m_n)^{3/2}$ is sufficiently close to unity that we can neglect the mass difference. However, in the exponential the mass difference is very important, and we are left with

$$\frac{n_p^{(0)}}{n_n^{(0)}} = e^{\mathcal{Q}/T}$$

with $\mathcal{Q} := m_n - m_p = 1.293\text{MeV}$. Therefore, at high temperatures, there are as many neutrons as protons. As the temperature drops beneath 1MeV, the neutron fraction goes down. If weak interactions operated efficiently enough to maintain equilibrium indefinitely, then it would drop to zero. The main task of this section is to find out what happens in the real world where weak interactions are not so efficient.

It is convenient to define

$$X_n := \frac{n_n}{n_n + n_p}$$

that is, X_n is the ratio of neutrons to total nuclei. In equilibrium,

$$X_n \to X_{n,\text{EQ}} := \frac{1}{1 + \left(n_p^{(0)}/n_n^{(0)}\right)}$$

To track the evolution of X_n, let's start from Eq. (3.9), with 1 = neutron, 3 = proton, and $2, 4$ = leptons in complete equilibrium $\left(n_l = n_l^{(0)}\right)$. Then,

$$a^{-3}\frac{d\left(n_n a^3\right)}{dt} = n_l^{(0)}\langle\sigma v\rangle\left\{\frac{n_p n_n^{(0)}}{n_p^{(0)}} - n_n\right\}.$$

We have already determined the ratio $n_n^{(0)}/n_p^{(0)} = e^{-\mathcal{Q}/T}$ and we can identify $n_l^{(0)}\langle\sigma v\rangle$ as λ_{np}, the rate for neutron $\to$ proton conversion since it multiplies n_n in the loss term. Also if we rewrite n_n on the left as $(n_n + n_p)\,X_n$, then the total density times a^3 can be taken outside the derivative, leaving

$$\frac{dX_n}{dt} = \lambda_{np}\left\{(1 - X_n)\,e^{-\mathcal{Q}/T} - X_n\right\}$$

Equation (3.23) is a differential equation for X_n as a function of time, but it contains the temperature T and the reaction rate λ_{np}, both of which have complicated time dependences. It is simplest therefore to recast the equation using as the evolution variable

$$x := \frac{\mathcal{Q}}{T}.$$

The left-hand side of Eq. (3.23) then becomes $\dot{x}dX_n/dx$, so we need an expression for $dx/dt = -x\dot{T}/T$. Since $T \propto a^{-1}$,

$$\frac{1}{T}\frac{dT}{dt} = -H = -\sqrt{\frac{8\pi G\rho}{3}},$$

the second equality following from Eq. (2.39). Nucleosynthesis occurs in the radiation-dominated era, so the main contribution to the energy density ρ comes from relativistic particles. Recall from Chapter 2 that the contribution to the energy density from relativistic particles is

$$\rho = \frac{\pi^2}{30}T^4\left[\sum_{i=\text{ bosons}} g_i + \frac{7}{8}\sum_{i=\text{ fermions}} g_i\right] \quad (i \text{ relativistic })$$

$$:= g_*\frac{\pi^2}{30}T^4$$

The effective numbers of relativistic degrees of freedom, g_*, is a function of temperature. At temperatures of order 1MeV, the contributing species are: photons ($g_\gamma = 2$), neutrinos ($g_\nu = 6$), and electrons and positrons ($g_{e^+} = g_{e^-} = 2$). Adding up leads to $g_* \simeq 10.75$, roughly constant throughout the regime of interest. Then, Eq. (3.23) becomes

$$\frac{dX_n}{dx} = \frac{x\lambda_{np}}{H(x=1)} \left\{ e^{-x} - X_n \left(1 + e^{-x}\right) \right\}$$

with

$$H(x=1) = \sqrt{\frac{4\pi^3 G \mathcal{Q}^4}{45}} \times \sqrt{10.75} = 1.13\text{sec}^{-1}.$$

Finally, we need an expression for the neutron-proton conversion rate, λ_{np}. Under the approximations we are using, the rate is (Bernstein 1988 or Exercise 3)

$$\lambda_{np} = \frac{255}{\tau_n x^5} \left(12 + 6x + x^2\right)$$

with the neutron lifetime $\tau_n = 886.7$ sec. Thus, when $T = \mathcal{Q}$ (i.e., when $x = 1$), the conversion rate is 5.5sec^{-1}, somewhat larger than the expansion rate. As the temperature drops beneath 1MeV, though, the rate rapidly falls below the expansion rate, so conversions become inefficient.

We can now integrate Eq. (3.27) numerically to track the neutron abundance (Exercise 4). Figure 3.2 shows the results of this integration. Note that the result agrees extremely well at temperatures above ~ 0.1MeV with the exact solution which includes proper statistics, nonzero electron mass, and changing g_*. The neutron fraction X_n does indeed fall out of equlibrium once the temperature drops below 1MeV: it freezes out at 0.15 once the temperature drops below 0.5MeV.

At temperatures below 0.1MeV, two reactions we have not included yet become important: neutron decay ($n \to p + e^- + \bar{\nu}$) and deuterium production ($n + p \to \text{D} + \gamma$). Decays can be added trivially by adding in a factor of e^{-t/τ_n} to the results of Figure 3.2. By the time decays become important, electrons and positrons have annihilated, so g_* in Eq. (3.26) is 3.36 and the time-temperature relation is (Exercise 5):

$$t = 132\,\text{sec} \left(\frac{0.1\text{MeV}}{T}\right)^2$$

We will see shortly that production of deuterium, and other light elements, begins in earnest at $T \sim 0.07$MeV. By then, decays have depleted the neutron fraction by a factor of $\exp\left[-(132/886.7)(0.1/0.07)^2\right] = 0.74$. So the neutron abundance at the onset of nucleosynthesis is 0.15×0.74, or

$$X_n\left(T_{\text{nuc}}\right) = 0.11$$

We now turn to light element formation to understand the ramifications of this number.

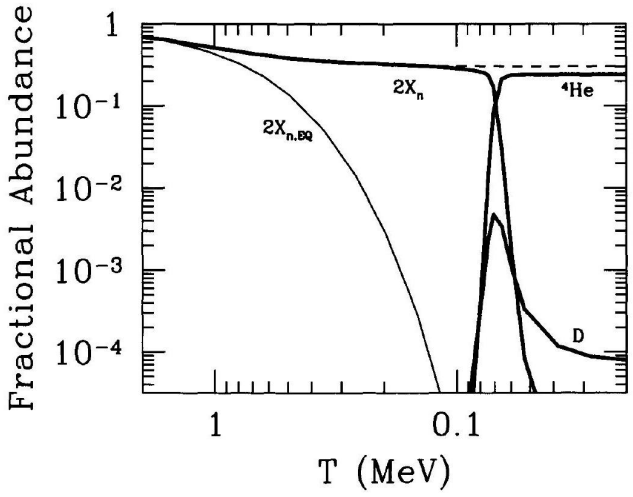


Figure 3.2. Evolution of light element abundances in the early universe. Heavy solid curves are results from Wagoner (1973) code; dashed curve is from integration of Eq. (3.27); light solid curve is twice the neutron equilibrium abundance. Note the good agreement of Eq. (3.27) and the exact result until the onset of neutron decay. Also note that the neutron abundance falls out of equilibrium at $T \sim$ MeV.

Light Element Abundances

A useful way to approximate light element production is that it occurs instantaneously at a temperature $T_{\rm nuc}$ when the energetics compensates for the small baryon to photon ratio. Let's consider deuterium production as an example, with Eq. (3.17) as our guide. The equilibrium deuterium abundance is of order the baryon abundance (i.e. if the universe stayed in equilibrium, all neutrons and protons would form deuterium) when Eq. (3.17) is of order unity, or

$$\ln\left(\eta_b\right) + \frac{3}{2}\ln\left(T_{\rm nuc}\,/m_p\right) \sim -\frac{B_D}{T_{\rm nuc}}.$$

Equation (3.32) suggests that deuterium production takes place at $T_{\rm nuc} \sim 0.07$ MeV, with a weak logarithmic dependence on η_b.

Since the binding energy of helium is larger than that of deuterium, the exponential factor $e^{B/T}$ favors helium over deuterium. Indeed, Figure 3.2 illustrates that helium is produced almost immediately after deuterium. Virtually all remaining neutrons at $T \sim T_{\rm nuc}$ then are processed into ^{4} He. Since two neutrons go into ^{4}He, the final ^{4}He abundance is equal to half the neutron abundance at $T_{\rm nuc}$. Often, results are quoted in terms of mass fraction; then,

$$X_4 := \frac{4n_4He}{n_b} = 2X_n\left(T_{\rm nuc}\right)$$

Figure 3.2 shows that this relation holds. Indeed, to find the final helium mass fraction, we need only take the neutron fraction at $T_{\rm nuc}$, Eq. (3.31), and multiply by 2, so the final helium mass fraction is 0.22. This rough estimate, obtained by solving a single differential equation, is in remarkable agreement with the exact solution, which can be fit via (Olive, 2000; Kolb and Turner, 1990)

$$Y_p = 0.2262 + 0.0135\ln\left(\eta_b/10^{-10}\right)$$

One important feature of this result is that it depends only logarithmically on the baryon fraction. We saw in Eq. (3.32) that $T_{\rm nuc}$ has this dependence. You might think that the

exponential sensitivity to $T_{\rm nuc}$ in the decay fraction would turn this into linear dependence. However, $T_{\rm nuc}$ is sufficiently early that only a small fraction of neutrons have decayed: the exponential in this regime is linear in the time. Therefore, the final helium abundance maintains only logarithmic dependence on the baryon density.

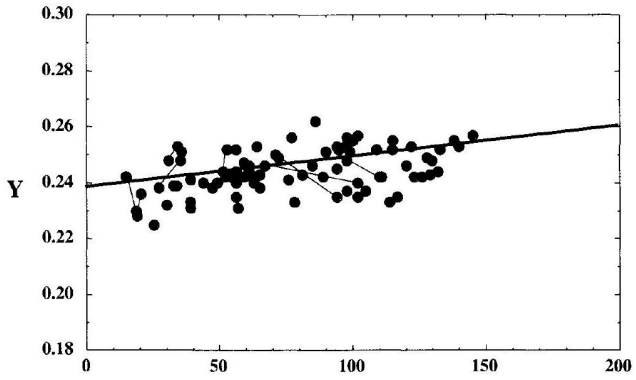

Figure 3.3. Helium abundance ($Y := Y_p$) as a function of oxygen/hydrogen ratio. Lower oxygen systems have undergone less processing, so the helium abundance in those systems is closer to primordial. Line, and extrapolation to $Y_p = 0.238$, from Olive (2000). Data from Pagel et al. (1992), Skillman and Kennicutt (1993), Skillman et al. (1994), and Izotov and Thuan (1998). Short lines connect the same region observed by different groups.

The prediction agrees well with the observations, as indicated in Figure 3.3. The best indication of the primordial helium abundance comes from the most unprocessed systems, typically identified by low metallicities. As Figure 3.3 indicates, the primordial abundance almost certainly lies between 0.22 and 0.25. Although there have been claims of discord in the past, the agreement remains one of the pillars of observational cosmology.

Figure 3.2 shows that not all of the deuterium gets processed into helium. A trace amount remains unburned, simply because the reaction which eliminates it ($\mathrm{D} + p \to {}^3\mathrm{He} + \gamma$) is not completely efficient. Figure 3.2 shows that after $T_{\rm nuc}$, deuterium is depleted via these reactions, eventually freezing out at a level of order $10^{-5} - 10^{-4}$. If the baryon density is low, then the reactions proceed more slowly, and the depletion is not as effective. Therefore, low baryon density inevitably results in more deuterium; the sensitivity is quite stark, as illustrated in Figure 1.8. As a result, deuterium is a powerful probe of the baryon density. Complementing this sensitivity is the possiblity of measuring deuterium in gas clouds as $z \sim 3$ by looking for absorbtion in the spectra of distant QSOs. For example, O'Meara et al. (2001) combine the measurements of primordial deuterium in four systems to obtain, $\mathrm{D/H} = 3.0 \pm 0.4 \times 10^{-5}$, corresponding to $\Omega_b h^2 = 0.0205 \pm 0.0018$.

12.3.3 Recombination

As the temperature drops to $\sim$ 1eV, photons remain tightly coupled to electrons via Compton scattering and electrons to protons via Coulomb scattering. It will come as no surprise that at these temperatures, there is very little neutral hydrogen. Energetics of course favors the production of neutral hydrogen with a binding energy of $\epsilon_0 = 13.6$eV, but the high photon/baryon ratio ensures that any hydrogen atom produced will be instantaneously ionized. This phenomenon is identical to the delay in the production of light nuclei we saw above, replayed on the atomic scale.

As long as the reaction ${}^3e^- + p \leftrightarrow \mathrm{H} + \gamma$ remains in equilibrium, the condition in Eq. (3.10) (with $1 = e, 2 = p, 3 = \mathrm{H}$) ensures that

$$\frac{n_e n_p}{n_H} = \frac{n_e^{(0)} n_p^{(0)}}{n_H^{(0)}}$$

We can go further here by recognizing that the neutrality of the universe ensures that $n_e = n_p$. Let's define the free electron fraction

$$X_e := \frac{n_e}{n_e + n_H} = \frac{n_p}{n_p + n_H}$$

the denominator equal to the total number of hydrogen nuclei. Carrying out the integrals on the right of Eq. (3.35) leads then to

$$\frac{X_e^2}{1 - X_e} = \frac{1}{n_e + n_H} \left[\left(\frac{m_e T}{2\pi} \right)^{3/2} e^{-[m_e + m_p - m_H]/T} \right]$$

where we have made the familiar approximation of neglecting the small mass difference of H and p in the prefactor. The argument of the exponential is $-\epsilon_0/T$.

[3] Here p stands for free protons and H for neutral hydrogen, i.e., a proton with an electron attached. Neglecting the relatively small number of helium atoms, the denominator $n_e + n_H$ (or $n_p + n_H$) is equal to the baryon density, $\eta_b n_\gamma \sim 10^{-9} T^3$. So when the temperature is of order ϵ_0, the right-hand side is of order $10^9 \, (m_e/T)^{3/2} \simeq 10^{15}$. In that case, Eq. (3.37) can be satisfied only if the denominator on the left is very small, that is if X_e is very close to 1: all hydrogen is ionized. Only when the temperature drops far below ϵ_0 does appreciable recombination take place. As X_e falls, the rate for recombination also falls, so that equilibrium becomes more difficult to maintain. Thus, in order to follow the free electron fraction accurately, we need to solve the Boltzmann equation, just as we did for the neutron-proton ratio.

In this case, Eq. (3.9) for the electron density becomes

$$\begin{aligned} a^{-3} \frac{d \left(n_e a^3 \right)}{dt} &= n_e^{(0)} n_p^{(0)} \langle \sigma v \rangle \left\{ \frac{n_H}{n_H^{(0)}} - \frac{n_e^2}{n_e^{(0)} n_p^{(0)}} \right\} \\ &= n_b \langle \sigma v \rangle \left\{ (1 - X_e) \left(\frac{m_e T}{2\pi} \right)^{3/2} e^{-\epsilon_0/T} - X_e^2 n_b \right\} \end{aligned}$$

where the last line follows since the ratio $n_e^{(0)} n_p^{(0)} / n_H^{(0)}$ is equal to the term in square brackets in Eq. (3.37). Meanwhile, since $n_b a^3$ is constant it can be passed through the derivative on the left after expressing n_e as $n_b X_e$, so that

$$\frac{dX_e}{dt} = \left\{ (1 - X_e) \, \beta - X_e^2 n_b \alpha^{(2)} \right\}$$

where the ionization rate is typically denoted

$$\beta := \langle \sigma v \rangle \left(\frac{m_e T}{2\pi} \right)^{3/2} e^{-\epsilon_0/T}$$

and the recombination rate

$$\alpha^{(2)} := \langle \sigma v \rangle$$

The recombination rate has superscript (2) because recombination to the ground ($n = 1$) state is not relevant. Ground-state recombinations lead to production of an ionizing photon, and this photon immediately ionizes a neutral atom. The net effect of such a recombination is

zero: no new neutral atoms are formed this way. The only way for recombination to proceed is via capture to one of the excited states of hydrogen; to a good approximation, this rate is

$$\alpha^{(2)} = 9.78\frac{\alpha^2}{m_e^2}\left(\frac{\epsilon_0}{T}\right)^{1/2}\ln\left(\frac{\epsilon_0}{T}\right)$$

The Saha approximation, Eq. (3.37), does a good job predicting the redshift of recombination, but fails as the electron fraction drops and the system goes out of equilibirium. Therefore, the detailed evolution of X_e must be obtained by a numerical integration of Eq. (3.39) (Exercise 8). Results from numerical integration of Eq. (3.39) are shown in Figure 3.4.

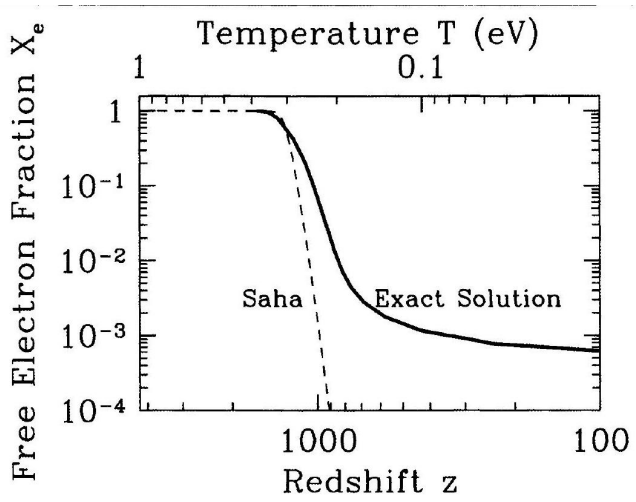

Figure 3.4. Free electron fraction as a function of redshift. Recombination takes place suddenly at $z \sim 1000$ corresponding to $T \sim 1/4$eV. The Saha approximation. Eq. (3.37), holds in equilibrium and correctly identifies the redshift of recombination, but not the detailed evolution of X_e. Here $\Omega_b = 0.06, \Omega_m = 1, h = 0.5$.

The computation of the neutron/proton ratio affects the abundance of light elements today. Similarly, the evolution of the free electron abundance has major ramifications for observational cosmology. Recombination at $z_* \sim 1000$ is directly tied to the decoupling of photons from matter. [4] This decoupling, in turn, directly affects the pattern of anisotropies in the CMB that we observe today.

Decoupling occurs roughly when the rate for photons to Compton scatter off electrons becomes smaller than the expansion rate. [5] The scattering rate is

$$n_e\sigma_T = X_e n_{\rm b}\sigma_T$$

where $\sigma_T = 0.665\times10^{-24}$ cm^2 is the Thomson cross section, and I continue to ignore helium, thereby assuming that the total number of hydrogen nuclei (free protons + hydrogen atoms) is equal to the total baryon number. Since the ratio of the

[4] Notice from Figure 1.4 that even though photons stop scattering off electrons at $z \sim 1000$, electrons do scatter many times off photons until much later. This is not a contradiction: there are many more photons than baryons. In any event, many cosmologists shy away from the word decoupling to describe what happens at $z \sim 1000$ for this reason.

[5] In Chapter 8 we will define a more precise measure of decoupling, making use of the visibility function, the probability that a photon last scattered at a given redshift. Using the visibility function, we will show that a CMB photon today most likely last scattered at a slightly higher redshift than inferred by the simple $n_e\sigma_T = H$ criterion. baryon density to the critical density is $m_p n_{\rm b}/\rho_{\rm cr} = \Omega_b a^{-3}$, n_b can be eliminated in Eq. (3.43) in favor of Ω_b:

$$n_e\sigma_T = 7.477 \times 10^{-30}\ \mathrm{cm}^{-1} X_e \Omega_b h^2 a^{-3}.$$

Dividing by the expansion rate leads to

$$\frac{n_e\sigma_T}{H} = 0.0692 a^{-3} X_e \Omega_b h \frac{H_0}{H}.$$

The ratio on the right depends on the Hubble rate, which is given in Eq. (1.2). From that equation or from Figure 1.3, we see that at early times, the main contribution comes from either matter or radiation, so $H/H_0 = \Omega_m^{1/2} a^{-3/2} \left[1 + a_{\mathrm{eq}}/a\right]^{1/2}$. Then,

$$\frac{n_e\sigma_T}{H} = 113 X_e \left(\frac{\Omega_b h^2}{0.02}\right) \left(\frac{.15}{\Omega_m h^2}\right)^{1/2} \left(\frac{1+z}{1000}\right)^{3/2} \left[1 + \frac{1+z}{3600}\frac{0.15}{\Omega_m h^2}\right]^{-1/2}.$$

Here I have normalized with "best fit" values for the baryon and matter densities. When the free electron fraction X_e drops below $\sim 10^{-2}$, photons decouple. From Figure 3.4, we see that X_e drops very quickly from unity to 10^{-3}. Therefore, decoupling takes place during recombination.

Let's forget all we just learned and ask what would happen if the universe remained ionzied throughout its history. In that hypothetical case, $X_e = 1$, and Eq. (3.46) can be trivially solved to find the redshift of decoupling. Setting the right hand side to 1 leads to

$$1 + z_{\mathrm{decouple}} = 43 \left(\frac{0.02}{\Omega_b h^2}\right)^{2/3} \left(\frac{\Omega_m h^2}{0.15}\right)^{1/3} \qquad \text{(no recombination)}.$$

Equation (3.47) tells us that even if the electrons remained ionized throughout the history of the universe, eventually the photons decoupled simply because expansion made it more difficult to find the increasingly dilute electrons. In theory, we do not expect the electrons to remain ionized throughout, so this calculation would appear academic. However, Eq. (3.47) is relevant for a more general reason. We do expect that at some late time. the electrons were reionized. We expect this because the universe we observe back to redshift $z \sim 6$ appears to be ionized. If the universe was reionized at very late times, much after the z_{decouple} of Eq. (3.47), there would not be a huge change in the CMIB anisotropy pattern. However, if the universe was reionized earlier than this redshift, multiple scattering of the photons would dramatically alter the primordial anisotropy pattern set up at $z \sim 1000$. Observations of the most distant quasars (Becker et al., 2001; Fan et al., 2002) suggest that reionization took place at $z \simeq 6$, so the alteration is expected to be slight.

12.3.4 Dark Matter

There is strong evidence for nonbaryonic dark matter in the universe, with $\Omega_{\mathrm{dm}} \simeq 0.3$. Perhaps the most plausible candidate for dark matter is a weakly interacting massive particle (WIMP), which was in close contact with the rest of the cosmic plasma at high temperatures, but then experienced freeze-out as the temperature dropped below its mass. Freeze-out is the inability of annihilations to keep the particle in equlibrium. Indeed, were it kept in equilibrium indefinitely, its abundance would be suppressed by $e^{-m/T}$: there would be no such particles in the observable universe. The purpose of this section, then, is to solve the Boltzmann equation for such a particle, determining the epoch of freeze-out and its relic abundance. The hope is that, by fixing its relic abundance so that $\Omega_{\mathrm{dm}} \simeq 0.3$, we will learn something about the fundamental properties of the particle, such as its mass and cross section. We then might use this knowledge to detect the particles in a laboratory.

In the generic WIMP scenario, two heavy particles X can annihilate producing two light (essentially massless) particles l. The light particles are assumed to be very tightly coupled

to the cosmic plasma, so they are in complete equilibrium (chemical as well as kinetic), with $n_l = n_l^{(0)}$. There is then only one unknown, n_X, the abundance of the heavy particle. We can use Eq. (3.9) to solve for this abundance:

$$a^{-3}\frac{d\left(n_X a^3\right)}{dt} = \langle\sigma v\rangle\left\{\left(n_X^{(0)}\right)^2 - n_X^2\right\}$$

To go further, recall that the temperature typically scales as a^{-1}, so if we multiply and divide the factor of $n_X a^3$ inside the parentheses on the left by T^3, we can remove $(aT)^3$ outside the derivative, leaving $T^3 d\left(n_X/T^3\right)/dt$. Let's define then

$$Y := \frac{n_X}{T^3}$$

The differential equation for Y becomes

$$\frac{dY}{dt} = T^3\langle\sigma v\rangle\left\{Y_{\rm EQ}^2 - Y^2\right\}$$

with $Y_{\rm EQ} := n_X^{(0)}/T^3$.

To go further, as in the neutron-proton case, it is convenient to introduce a new time variable,

$$x := m/T$$

where m, the mass of the heavy particle, sets a rough scale for the temperature during the region of interest. Very high temperature corresponds to $x \ll 1$, in which case reactions proceed rapidly so $Y \simeq Y_{\rm EQ}$. Since the X particles are relativistic at these epochs, the $m \ll T$ limit of Eq. (3.6) implies that $Y \simeq 1$. For high x, the equilibrium abundance $Y_{\rm EQ}$ becomes exponentially suppressed (e^{-x}). Ultimately, X particles will become so rare because of this suppression that they will not be able to find each other fast enough to maintain the equilibrium abundance. This is the onset of freeze-out. To change from t to x, we need the Jacobian $dx/dt = Hx$. Dark matter production typically occurs deep in the radiation era where the energy density scales as T^4, so $H = H(m)/x^2$. Then the evolution equation becomes

$$\frac{dY}{dx} = -\frac{\lambda}{x^2}\left\{Y^2 - Y_{\rm EQ}^2\right\}$$

where the ratio of the annihilation rate to the expansion rate is parameterized by

$$\lambda := \frac{m^3\langle\sigma v\rangle}{H(m)}.$$

In many theories λ is a constant, but in some, the thermally averaged cross section is temperature dependent; this leads to slight numerical changes in the following but unchanged qualitative solutions.

Equation (3.52) is a form of the Riccati equation, for which in general there are no analytic solutions. In this case, though, we can make use of our understanding of the freeze-out process to get an analytic expression for the final freeze-out abundance $Y_\infty := Y(x = \infty)$. Let's review this understanding in the context of Eq. (3.52). The left-hand side is of order Y (for $x \sim 1$) while the right is of order $Y^2\lambda$. We will see that λ is typically quite large, so as long as Y is not too small, the right-hand side must zero itself by setting $Y = Y_{\rm EQ}$. At late times, as $Y_{\rm EQ}$ drops precipitously, the terms on the right-hand side will no longer be much larger than the one on the left. In fact, well after freeze-out, Y will be much larger than $Y_{\rm EQ}$: the X particles will not be able to annihilate fast enough to maintain equilibrium. Thus at late times,

$$\frac{dY}{dx} \simeq -\frac{\lambda Y^2}{x^2} \quad (x \gg 1).$$

Integrate this analytically from the epoch of freeze-out x_f until very late times $x = \infty$ to get

$$\frac{1}{Y_\infty} - \frac{1}{Y_f} = \frac{\lambda}{x_f}.$$

Typically Y at freeze-out Y_f is significantly larger than Y_∞, so a simple analytic approximation is

$$Y_\infty \simeq \frac{x_f}{\lambda}.$$

This approximation is incomplete, in that it depends on the freeze-out temperature, which we have not determined. Although more precise determinations are possible (Exercise 10), a simple order-of-magnitude estimate for the dark matter problem is $x_f \sim 10$.

Figure 3.5 shows the numerical solution to Eq. (3.52) for several different values of λ. The abundances do track the equilibrium abundances until $m/T \sim 10$, after which they level off to a constant. The rough estimate $Y_\infty \sim 10/\lambda$ is seen to be a reasonable approximation for the relic abundance. Note that particles with larger cross sections (e.g. in the figure, $\lambda = 10^{10}$) freeze out later, and this later freeze-out carries along with it a lower relic abundance. Also note from the inset in Figure 3.5 that the distinction between Bose-Einstein, Fermi-Dirac, and Boltzmann statistics is important only at temperatures above the particle's mass. For temperatures relevant to the freeze-out process, our use of Boltzmann statistics is completely warranted.

There is one more piece of physics needed in order to determine the present-day abundance of these heavy particle relics. After freeze-out, the heavy particle density

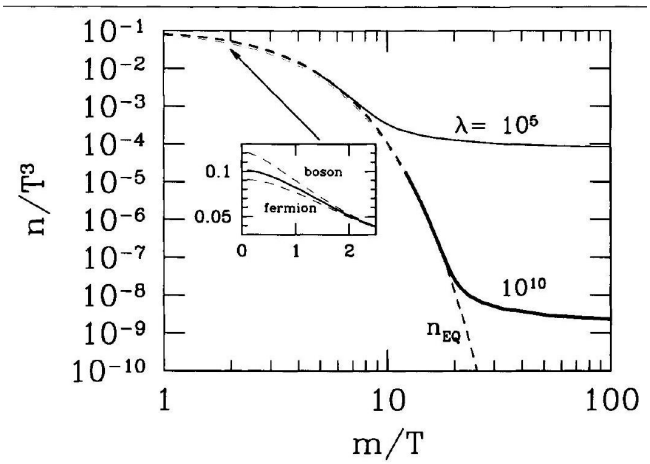

Figure 3.5. Abundance of heavy stable particle as the temperature drops beneath its mass. Dashed line is equilibrium abundance. Two different solid curves show heavy particle abundance for two different values of λ, the ratio of the annihilation rate to the Hubble rate. Inset shows that the difference between quantum statistics and Boltzmann statistics is important only at temperatures larger than the mass.

simply falls off as a^{-3}. So its energy density today is equal to $m\,(a_1/a_0)^3$ times its number density where a_1 corresponds to a time sufficiently late that Y has reached its aymptotic value, Y_∞. The number density at that time is $Y_\infty T_1^3$, so

$$\rho_X = m Y_\infty T_0^3 \left(\frac{a_1 T_1}{a_0 T_0}\right)^3 \simeq \frac{m Y_\infty T_0^3}{30}$$

The second equality here is nontrivial. You might expect that aT remains constant through the evolution of the universe, so that the ratio a_1T_1/a_0T_0 would be unity. It is not, for the same reason that the CMB and neutrinos have different temperatures. We saw in Chapter 2 that photons are heated by $e^{\pm}$annihilation, while neutrinos which have already decoupled are not. Similarly, as the universe expands, photons are heated by the annihilation of the zoo of particles with masses between 1MeV and 100GeV, so T does not fall simply as a^{-1}. You can show in Exercise 11 that as a result $(a_1T_1/a_0T_0)^3 \simeq 1/30$. Finally, to find the fraction of critical density today contributed by X, insert our expression for Y_∞ and divide by $\rho_{\rm cr}$:

$$\begin{aligned}\Omega_X &= \frac{x_f}{\lambda}\frac{mT_0^3}{30\rho_{\rm cr}} \\ &= \frac{H(m)x_fT_0^3}{30m^2\langle\sigma v\rangle\rho_{\rm cr}}.\end{aligned}$$

To find the present density of heavy particles, then, we need to compute the Hubble rate when the temperature was equal to the X mass, $H(m)$, for which we need the energy density when the temperature was equal to m. The energy density in the radiation era is given by Eq. (3.26) with g_* a function of temperature. Therefore,

$$\Omega_X = \left[\frac{4\pi^3 G g_*(m)}{45}\right]^{1/2}\frac{x_fT_0^3}{30\langle\sigma v\rangle\rho_{\rm cr}}$$

We see that Ω_X does not explicitly depend on the mass of the X particle. [6] So it is mainly the cross section which determines the relic abundance.

Let's now see what order of magnitude is needed to get dark matter today, i.e., to get $\Omega_X = \Omega_{\rm dm} \simeq 0.3$. At the temperatures of interest for dark matter production, $T \sim 100$GeV, $g_*(m)$ includes contributions from all the particles in the standard model (three generations of quarks and leptons, photons, gluons, weak bosons, and perhaps even the Higgs boson) and so is of order 100. Normalizing $g_*(m)$ and x_f by their nominal values leads to

$$\Omega_X = 0.3h^{-2}\left(\frac{x_f}{10}\right)\left(\frac{g_*(m)}{100}\right)^{1/2}\frac{10^{-39}\ {\rm cm}^2}{\langle\sigma v\rangle}.$$

The fact that this estimate is of order unity for cross sections of order 10^{-39} cm^2 is taken as a good sign: there are several theories which predict the existence of particles with cross sections this small.

Perhaps the most notable of these theories is supersymmetry, the theory which predicts that every particle has a partner with opposite statistics. For example, the supersymmetric partner of the spin zero Higgs boson is the spin- 1/2 Higgino (fermion). Initially it was hoped that the observed fermions could be the partners of the observed bosons, but this hope is not realized in nature. Instead, supersymmetry must be broken and all the supersymmetric partners of the known particles must be so massive that they have not yet been observed even in accelerators: they must have masses greater than 10 to 100GeV. Which of the supersymmetric partners is the best candidate for the dark matter today? The particle must be neutral since the evidence points to dark matter that is truly dark, i.e., does not interact much with the known particles and especially does not emit photons. The particle must also be stable: if it could decay to lighter particles, then decays would have kept it in equilibrium throughout the early universe and there would be none left today. The first of these criteria restricts the dark matter to be the partner of one of the neutral particles, such as the Higgs or the photon. [7] The second requires the particle to be the lightest (LSP for lightest supersymmetric partner) of these, for any heavier particles could decay into the lightest one plus some ordinary particles.

[6] There is a slight implicit dependence on mass in the freeze-out temperature x_f and in g_*, which is to evaluated when $T = m$.

7'he other neutral boson in the Standard Model is the Z vector boson. The lightest supersymmetric partner is likely a linear combination of the partners of all of these.

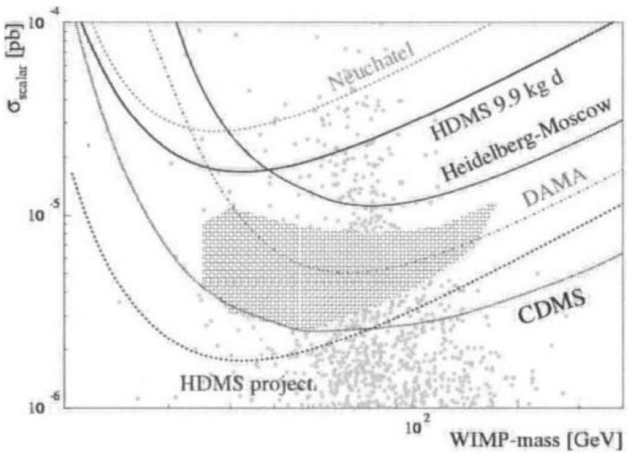

Figure 3.6. Constraints on supersymmetric dark matter (Baudis et al., 2000). Region above the solid curves is excluded, while filled region is reported detection by DAMA (Bernabei et al., 1999). Lowest curve (labled HDMS project) is only a projected limit based on one future experiment. The CDMS experiment (Abusaidi et al., 2000) appears to rule out the DAMA detection. Points scattered throughout correspond to different parameter choices in a class of supersymmetric models. Note the limits on the cross section are in units of picobarns)1 picobarn = 10^{-36} cm^2).

Not only would weakly interacting particles such as LSP's annihilate in the early universe, but if they were around today they would scatter off ordinary matter. Although it is difficult to detect these reactions because the rate is so low, a number of experiments have been performed searching for dark matter particles. Figure 3.6 shows the limits on the masses and cross sections of dark matter from these experiments (note that the scattering cross section, while related to the annihilation cross section, is not identically equal to it). Apart from a tantalizing detection from the DAMA experiment, so far we have only upper limits. However, as indicated in the figure, in the coming years the experiments are expected to pierce into the region predicted by supersymmetric theories.

The fact that a thermal relic with a cross section characteristic of the weak interaction gives the right dark matter abundance is called the WIMP miracle.

SUMMARY BEYOND EQUILIBRIUM

The light elements in the universe formed when the temperature of the cosmic plasma was of order 0.1MeV. Roughly a quarter of the mass of the baryons is in the form of ^{4}He, the remaining in the form of free protons with only trace amounts of deuterium, ^{3}He, and lithium. These elements remain ionized until the temperature of the universe drops well below the ionization energy of hydrogen. The epoch of recombination - at which time electrons and protons combine to form neutral hydrogen - is at redshift $z \sim 1000$ corresponding to a temperature $T \sim 0.25$eV. Before recombination, photons and electrons and protons are tightly coupled with one another because of Compton and Coulomb scattering. After this time, photons travel freely through the universe without interacting, so the photons in the CMB we observe today offer an excellent snapshot of the universe at $z \sim 1000$. The importance of this snapshot cannot be overstated.

The details of both nucleosynthesis and recombination are heavily influenced by the fact that the reactions involved eventually become too slow to keep up with the expansion rate.

This feature may also be responsible for the production of dark matter in the universe. We explored the popular scenario wherein a massive, neutral stable particle stops annihilating when the temperature drops significantly beneath its mass. The present-day abundance of such a particle can be deterimined in terms of its annihilation cross section, as in Eq. (3.60). Larger cross sections correspond to more efficient annhilation and therefore a lower abundance today. Roughly cross sections of order 10^{-40} are needed to get the dark matter abundance observed today. Such cross sections and the requisite stable, neutral particles emerge fairly natrually in extensions of the Standard Model of particle physics, such as supersymmetry, and may well be tested by accelerator experiments in the near future.

SUGGESTED READING

The Early Universe (Kolb and Turner) contains especially clear treatments of the heavy particle freeze-out problem and Big Bang nucleosynthesis, also based on the Boltzmann equation. Kinetic Theory in an Expanding Universe (Bernstein) offers some semianalytic solutions to these problems, as well as the requisite Boltzmannology.

Work on nucleosynthesis in the early universe dates back to Gamow and collaborators, summarized in Alpher, Follin, and Herman (1953). The first post-CMB papers were Peebles (1966) and Wagoner, Fowler, and Hoyle (1967); these got the basics right: 25% helium and roughly the correct amount of deuterium. Yang et al. (1984) helped many people of my generation understand that the baryonic density could be constrained with observations of the light elements. A nice review article on nucleosynthesis is Olive, Steigman, and Walker (2000).

As I tried to indicate in the text, the process of recombination is very rich; it involves some subtle physics. The original paper which worked through all the details was by Peebles (1968). Ma and Bertschinger (1996) however managed to describe the physics succintly in just one page in their Section 5.8. Seager, Sasselov, and Scott (1999) have presented a more accurate treatment (although, as they emphasize, Peebles' more intuitive work holds up remarkably well), including many small effects previously neglected.

Jungman, Kamionkowski, and Griest (1996) is a comprehensive review of all aspects of supersymmetric dark matter. Many papers have explored limits on supersymmetric dark matter candidates from cosmology and accelerators. To mention just several: Roszkowski (1991) showed that the Higgsino is likely not the lightest supersymmetric partner; Nath and Arnowitt (1992) and Kane et al. (1994) showed that the bino, the partner of the initial gauge eigenstate B, is the most likely both from the point of view of physics and cosmology - LSP; Ellis et al. (1997) combined accelerator constraints with those from cosmology to place a lower limit on the mass of the LSP; Edsjo and Gondolo (1997) included some subtle effects in the relic abundance calculation which affects the limits if the LSP is composed primarily of the partner of the Higgs boson; and Bottino et al. (2001) explored the consequences if the signal seen in the DAMA signal is due to dark matter particles.

D-1.

Compute the equilibrium number density (i.e., zero chemical potential) of a species with mass m and degeneracy $g = 2$ in the limits of large and small m/T. Take these limits for all three types of statistics: Boltzmann, BoseEinstein, and Fermi-Dirac. You will find Eqs. (C.26) and (C.27) helpful for the high- T Bose-Einstein and Fermi-Dirac limits.

D-2.

In the text, we treated $e^{\pm}$as relevant to the energy density at temperatures above m_e, but irrelevant afterwards (Eq. (3.30) and the discussion leading up to it). Track the $e^{\pm}$density

through annihilation assuming $n_{e^\pm} = n_{e^\pm}^{(0)}$. This equality holds during the BBN epoch because electromagnetic interactions (e.g., $e^+ + e^- \leftrightarrow \gamma + \gamma$) are so strong. When does the density fall to 1% of the photon energy density? If $\eta_b \simeq 6 \times 10^{-10}$, at what temperature do you expect $n_{e^-}$to depart from $n_{e^-}^{(0)}$?

D-3.

Compute the rate for neutron-to-proton conversion, λ_{np}. Show that it is equal to Eq. (3.29). There are two processes which contribute to $\lambda_{np} : n + \nu_e \to p + e^-$and $n + e^+ \to p + \bar{\nu}_e$. Assume that all particles can be described by Boltzmann statistics and neglect the mass of the electron. With these approximations the two rates are identical.

(a) Use Eq. (3.8) to write down the rate for $n + \nu_e \to p + e^-$. Perform the integrals over heavy particle momenta to get

$$\lambda_{np} = n_{\nu_e}^{(0)} \langle \sigma v \rangle = \frac{\pi}{4m^2} \int \frac{d^3 p_\nu}{(2\pi)^3 2 p_\nu} e^{-p_\nu / T} \times \int \frac{d^3 p_e}{(2\pi)^3 2 p_e} \delta \left(\mathcal{Q} + p_\nu - p_e \right) |\mathcal{M}|^2 .$$

(b) The amplitude squared is equal to $|\mathcal{M}|^2 = 32 G_F^2 \left(1 + 3 g_A^2\right) m_p^2 p_\nu p_e$, where g_A is the axial-vector coupling of the nucleon. The present best measurement of g_A is via the neutron lifetime, $\tau_n = \lambda_0 G_F^2 \left(1 + 3 g_A^2\right) m_e^5 / \left(2\pi^3\right)$, where the phase space integral

$$\lambda_0 := \int_1^{\mathcal{Q}/m_e} dx x \left(x - \mathcal{Q}/m_e\right)^2 \left(x^2 - 1\right)^{1/2} = 1.636$$

Carry out the integrals in Eq. (3.61) to get the rate, λ_{np} in terms of τ_n. Don't forget to multiply by 2 for the two different reactions.

D-4.

Solve the rate equation (3.27) numerically to determine the neutron fraction as a function of temperature. Ignore decays. There are (at least) two ways to perform this computation. The first is to treat it as a simple ordinary differential equation and solve numerically. The second is to proceed analytically and reduce the problem to an evaluation of a single numerical integral. This second method, which I'll lead you through here, is based on a numerical coincidence noted by Bernstein, Brown, and Feinberg (1988).

(a) Using standard differential equation techniques, show that a formal solution to Eq. (3.27) is

$$X_n(x) = \int_{x_i}^{x} dx' \frac{\lambda_{np}\left(x'\right) e^{-x'}}{x' H\left(x'\right)} e^{\mu(x') - \mu(x)}$$

where x_i is some initial, very high temperature, and

$$\mu(x) := \int_{x,}^{x} \frac{dx'}{x' H\left(x'\right)} \lambda_{np}\left(x'\right) \left[1 + e^{-x'}\right] .$$

(b) Use Eqs. (3.29) and (3.26) to compute the integrating factor μ analytically. Show that it is equal to

$$\mu = -\frac{255}{\tau_n \mathcal{Q}} \left[\frac{4\pi^3 G \mathcal{Q}^2 g_*}{45}\right]^{-1/2} \times \left[\left(\frac{4}{x^3} + \frac{3}{x^2} + \frac{1}{x}\right) + \left(\frac{4}{x^3} + \frac{1}{x^2}\right) e^{-x}\right]\Bigg|_{x_i}^{x}.$$

The simple form for μ is the result of numerical coincidence alone.

(c) With the results of part (b), do the single numerical integral in (a) numerically. Compare the asymptotic result at $x = \infty$ with the result in the text, $X_n(x = \infty) = 0.15$.

D-5.

Integrate the Friedmann equation (1.2) to verify the time-temperature relation in Eq. (3.30) in the epoch after $e^{\pm}$annihilation, but before matter domination.

D-6.

Determine η_b in terms of $\Omega_b h^2$. Show that it is given by Eq. (3.11).

D-7.

An important parameter for CMB anisotropies is the sound speed at decoupling. This is determined by the ratio of baryons to photons.

(a) Find

$$R := \frac{3\rho_b}{4\rho_\gamma}$$

as a function of a. Evaluate it at decoupling. Your answer should depend on $\Omega_b h^2$. (b) We will see in Chapter 8 that the sound speed of the combined photon/baryon fluid is

$$c_s = \sqrt{\frac{1}{3(1+R)}}.$$

Use your answer from (a) to plot the sound speed at decoupling as a function of $\Omega_b h^2$.

D-8.

Solve for the evolution of the free electron fraction. Do not compare your results with Figure 3.4 until you finish part (d). Throughout, take parameters $\Omega_m = 1, \Omega_b = 0.06, h = 0.5$.

(a) Use as an evolution variable $x := \epsilon_0/T$ instead of time in Eq. (3.39). Rewrite the equation in terms of x and the Hubble rate at $T = \epsilon_0$.

(b) Using the methods of Section 3.4, find the final freeze-out abundance of the free electron fraction, $X_e(x = \infty)$.

(c) Numerically integrate the equation from (a) from $x = 1$ down to $x = 1000$. What is the final frozen-out X_e?

(d) Peebles (1968) argued that even captures to excited states would not be important except for the fraction of times that the $n = 2$ state decays into two photons or expansion redshifts the Lyman alpha photon so that it cannot pump up a groundstate atom. Quantitatively, he multiplied the right-hand side of Eq. (3.39) by the correction factor,

$$C = \frac{\Lambda_\alpha + \Lambda_{2\gamma}}{\Lambda_\alpha + \Lambda_{2\gamma} + \beta^{(2)}}$$

where the two-photon decay rate is $\Lambda_{2\gamma} = 8.227\text{sec}^{-1}$; Lyman alpha production is $\beta^{(2)} = \beta e^{3\epsilon_0/4T}$; and

$$\Lambda_\alpha = \frac{H\left(3\epsilon_0\right)^3}{(8\pi)^2}$$

Do this and show how it changes your final answer. Now compare the freeze-out abundance with the result of (c) and the evolution with Figure 3.4.

D-9.

Find the redshift of decoupling as a function of Ω_b. If you do not have the evolution code of Exercise 8, use the Saha equation to determine X_e.

D-10.

Find an approximation to the freeze-out temperature of annihilating heavy particles by setting x_f such that $n^{(0)}\left(x_f\right)\langle\sigma v\rangle = H\left(x_f\right)$

D-11.

Typically the temperature of the cosmic plasma cools as a^{-1} with the expansion. However, when particles annihilate, they deposit energy into the plasma, thereby slowing the cooling. (Scherrer and Turner, 1986, showed that the annihilations do not actually heat the universe: T never increases, it simply decreases more slowly than a^{-1}.) Use the fact that the entropy density (Eq. (2.66)) scales as a^{-3} to compute the ratio of $(aT)^3$ at $T = 10\text{GeV}$ (roughly the time when WIMPs decouple) to its present value today.

D-12.

Suppose that there were no baryon asymmetry so that the number density of baryons exactly equaled that of anti-baryons. Determine the final relic density of (baryons+anti-baryons). At what temperature is this asymptotic value reached?

D-13.

There is a fundamental limitation on the annihilation cross section of a particle with mass m. Because of unitarity, $\langle\sigma v\rangle$ must be less than or equal to $1/\text{m}^2$, give or take a factor of order unity. Determine Ω_X for a particle which saturates this bound, i.e., for a particle with $\langle\sigma v\rangle = 1/m^2$. For what value of m is Ω_X equal to 1? (Keep x_f and g_* equal to the nominal values given in Eq. (3.60).) Note that if m is greater than this critical value, $\Omega_X > 1$, which is ruled out. This is a strong argument against stable particles (and therefore dark matter candidates) with masses above this critical value.

12.4 The Boltzmann Equations

We are interested in the anisotropies in the cosmic distribution of photons and inhomogeneities in the matter. Figure 4.1 shows why these are complicated to calculate. The photons are affected by gravity and by Compton scattering with free electrons. The electrons are tightly coupled to the protons. Both of these, of course, are also affected by gravity. The metric which determines the gravitational forces is influenced by all these components plus the neutrinos and the dark matter. Thus to solve for the photon and dark matter distributions, we need to simultaneously solve for all the other components.

There is a systematic way to account for all of these couplings. We write down a Boltzmann equation for each species in the universe. We have already encountered the Boltzmann equation in its integrated form in Chapter 3. There we were interested solely in the number density of the dark matter, the neutrons, and the free electrons. The number density is the integral over all momenta of the distribution function. Here we will be interested in more detailed information, not just the integrated number density, but the full distribution of photons, say, as a function of momentum. We then need a more primitive version of Eq. (3.1). Schematically, the unintegrated Boltzmann equation is

$$\frac{df}{dt} = C[f]$$

The right-hand side of the Boltzmann equation contains all possible collision terms. These terms in general are complicated functionals of the distribution functions of the various components. In the absence of collisions, the distribution function obeys $df/dt = 0$. This seemingly innocent equation says that the number of particles in a given element of phase space does not change with time. The catch is that the phase space elements themselves are moving in time in complicated ways due to the nontrivial metric. This catch makes the problem more difficult than it seems from Eq. (4.1). Nonetheless, we can still progress systematically by reexpressing the full derivative in terms of partial derivatives.

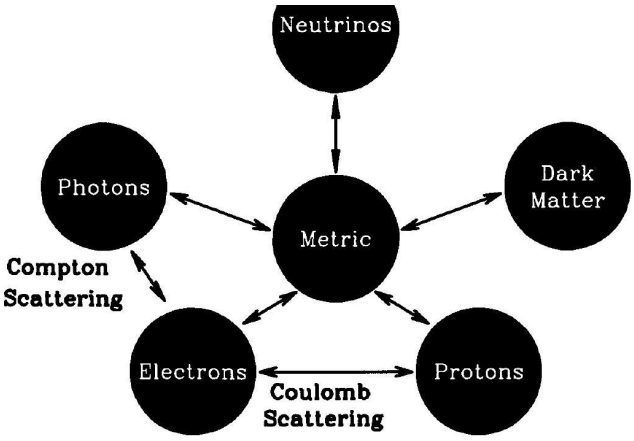

Figure 4.1. The ways in which the different components of the universe interact with each other. These connections are encoded in the coupled Boltzmann-Einstein equations.

In this chapter, we derive the Boltzmann equations for photons, eletrons, protons, dark matter, and massless neutrinos. This set of equations governs the evolution of perturbations in the universe.

12.4.1 The Boltzmann Equation for the Harmonic Oscillator

Before tackling the problem of interest - the Boltzmann equation for all species in an expanding universe - let us treat a much simpler example of the Boltzmann equation: the nonrelativistic harmonic oscillator. This simple example is very similar to the full general relativistic version we will encounter in the next section, but the algebra is much less cumbersome. So here the physics will be quite transparent. It will be useful to keep this example in mind when the algebra threatens to obscure the physics in the next section.

Consider a one-dimensional harmonic oscillator with energy

$$E = \frac{p^2}{2m} + \frac{1}{2}kx^2$$

The distribution function of the harmonic oscillator depends on time t, position x, and momentum p. Thus, the full time derivative in Eq. (4.1) can be rewritten as

$$\frac{df(t,x,p)}{dt} = \frac{\partial f}{\partial t} + \frac{\partial f}{\partial x}\frac{dx}{dt} + \frac{\partial f}{\partial p}\frac{dp}{dt}.$$

Figure 4.2 illustrates the movement through phase space of a distribution of collisionless ($C = 0$) oscillators. The full time derivative df/dt vanishes since the number of particles in the bunch at t_1 equals that at t_2. What has changed is the location of the phase space elements $x(t)$ and $p(t)$ themselves. Alternatively, we can think of x and p as independent variables (not dependent on t) and take partial derivatives of f with respect to t, x, and p. All of these partial derivatives are nonzero, but the appropriate weighted sum of the three vanishes.

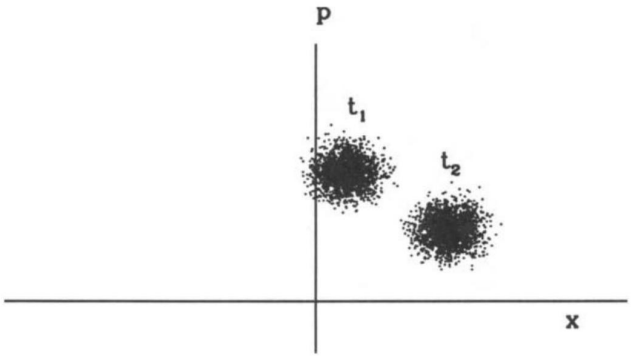

Figure 4.2. Distribution function for a set of collisionless harmonic oscillators. The initial distribution at t_1 moves in phase space by time t_2. The distribution function $f(t, x, p)$ remains constant as long as the evolution of $x(t)$ and $p(t)$ is accounted for.

To determine the coefficients dx/dt and dp/dt we must use the equations of motion. By the definition of momentum,

$$\frac{dx}{dt} := \frac{p}{m}$$

This equation will be generalized to a fully relativistic, three-dimensional version in the next section. Indeed we already got a preview of this when we defined $P^\mu := dx^\mu/d\lambda$ in Chapter 2. Newton's equation governing the motion of the oscillator is

$$\frac{dp}{dt} = -kx$$

The analogue of this familiar equation in the next section will be the geodesic equation of general relativity.

The collisionless Boltzmann equation for the harmonic oscillator is thus

$$\frac{\partial f}{\partial t} + \frac{p}{m}\frac{\partial f}{\partial x} - kx\frac{\partial f}{\partial p} = 0$$

The second term here governs how rapidly the oscillator moves in real space; the coefficient in front is just the velocity, p/m. The last term governs how quickly particles lose momentum.

In order to solve the Boltzmann equation, we need to know the initial conditions on the distribution function. Even without these, though, the Boltzmann equation offers some useful physics. Consider the equilibrium distribution, wherein $\partial f/\partial t = 0$. A general solution for the equilibrium distribution is

$$f(p,x) = f_{\rm EQ}(E)$$

that is, f is a function only of energy E. To see that this is indeed a solution, consider

$$\frac{p}{m}\frac{\partial f(E)}{\partial x} - kx\frac{\partial f(E)}{\partial p} = \frac{df}{dE}\left[\frac{p}{m}\frac{\partial E}{\partial x} - kx\frac{\partial E}{\partial p}\right] = 0.$$

So any function of the energy alone is an equilibrium distribution. Of course, in general, there will be interactions, or collisions. The only way for the full Boltzmann equation to be satisfied is if the collision terms also vanish. This will in general drive f to one of the familiar equilibrium distributions, e.g., $e^{-E/T}$ for the classical Maxwell-Boltzmann distribution.

12.4.2 The Collisionless Boltzmann Equation for Photons

Let us begin then by considering the left hand side of Eq. (4.1) for massless photons. First we must specify the form of the metric, accounting for perturbations around the smooth universe described by Eq. (2.4). Whereas the smooth universe is characterized by a single function, $a(t)$, which depends only on time and not on space, the perturbed universe requires two more functions, Ψ and Φ, both of which depend on both space and time. In terms of them, the metric can be written as

$$\begin{aligned} g_{00}(\vec{x},t) &= -1 - 2\Psi(\vec{x},t) \\ g_{0i}(\vec{x},t) &= 0 \\ g_{ij}(\vec{x},t) &= a^2\delta_{ij}(1 + 2\Phi(\vec{x},t)). \end{aligned}$$

In the absence of Ψ and Φ, Eq. (4.9) is simply the FRW metric of the zero-order homogeneous, flat cosmology. Similarly, in the absence of expansion ($a = 1$) this metric describes a weak gravitational field (

D-2.

3). The perturbations to the metric are Ψ, which corresponds to the Newtonian potential, and Φ, the perturbation to the spatial curvature. Since the perturbations in the universe are small at the times and scales of interest, we will treat these Ψ and Φ as small quantities, dropping all terms quadratic in them. There are two technical points about the metric in Eq. (4.9) which you don't need to worry about for most of this book, but which nonetheless are important to be aware of, if only to better understand the literature. First, one can break up perturbations into those behaving as scalars, vectors, and tensors under a transformation from one 3D coordinate system to another. Equation (4.9) contains only scalar perturbations. In principle, it is possible that the metric of our universe also has vector or tensor perturbations. If so, $g_{\mu\nu}$ would require other functions besides Ψ and Φ to fully describe all perturbations. For example, the off-diagonal elements become nonzero if there are vector perturbations. Indeed, there are many cosmological theories wherein there are both tensor and vector perturbations. For example, inflation tends to predict that there will be tensor perturbations, while models based on topological defects tend to produce large vector perturbations. For now we focus solely on the scalar perturbations; these are the only ones that couple to matter perturbations and are the most important that couple to photon perturbations as well.

The other feature of Eq. (4.9) worth noting is that its form corresponds to a choice of gauge. The simplest way to understand this gauge freedom is to think back to electricity and magnetism. There, the vector potential A_μ and its derivatives contain all possible information about the electric and magnetic fields. Since the physical $\vec{E}$ and $\vec{B}$ fields remain unchanged if a constant is added to A_μ, there is some residual freedom in choosing the potential. (For example, one often chooses $A_0 = 0$ or $\partial_\mu A^\mu = 0$.) In our case of perturbations to the metric, a similar

freedom exists. Even if only scalar perturbations are considered, there is still considerable freedom in the variables one chooses to describe the fluctuations. Although any physical results must be insensitive to the gauge choice, it is possible to use a gauge which looks quite different from Eq. (4.9) and still describes the same physics. For the record, the gauge in Eq. (4.9) is called the conformal Newtonian gauge. [1]

We want to reexpress the total derivative in Eq. (4.1) as a sum of partial derivatives. The distribution function depends on the space-time point $x^\mu = (t, \vec{x})$ and also on the momentum vector defined as

$$P^\mu := \frac{dx^\mu}{d\lambda}$$

where λ again parametrizes the particle's path, as in Eq. (2.18) (and again we will not need to specify λ explicitly). Thus, in principle, f is a function defined in an 8 -dimensional space. However, not all the components of the momentum vector are independent since the masslessness of the photon implies that

$$P^2 := g_{\mu\nu} P^\mu P^\nu = 0$$

[1] Historically, the initial ground-breaking work on the evolution of fluctuations was carried out in synchronous gauge (Peebles and Yu, 1970; Wilson and Silk, 1981; Peebles 1982; Bond and Szalay, 1983; Bond and Efstathiou, 1984). Recently, the physics of the anisotropies has been elucidated most clearly by using conformal Newtonian gauge (e.g., Hu and Sugiyama, 1995). Exercise 2 works out some of the relevant equations in synchronous gauge. So there are only three independent components of the momentum vector. Before we choose which three we will use, let us enforce the constraint of Eq. (4.11), using the metric of Eq. (4.9).

$$P^2 = 0 = -(1 + 2\Psi)\left(P^0\right)^2 + p^2 = 0$$

where I have defined

$$p^2 := g_{ij} P^i P^j$$

We can use the constraint equation then to eliminate the time component of P^μ:

$$P^0 = \frac{p}{\sqrt{1 + 2\Psi}} = p(1 - \Psi)$$

This last equality holds since we are doing first-order perturbation theory in the small quantity Ψ. With our sign convention, an overdense region has $\Psi < 0$. Therefore, in an overdense region, the term in parentheses on the right-hand side here is greater than one. Thus, Eq. (4.14) tells us photons lose energy-redshift-as they move out of a potential well.

Equation (4.14) is the generalization of the relativistic expression $E = pc$ to a perturbed Friedmann-Robertson-Walker metric. It allows us to eliminate P^0 whenever it occurs in favor of p, the generalized magnitude of the momentum. Recall that in the harmonic oscillator case, we did not include a term proportional to $\partial f/\partial E$ in Eq. (4.3). Here, too, we do not need to include a term proportional to $\partial f/\partial P^0$ when expanding the total time derivative. We need include only the dependence of f on the momentum: both the magnitude p and the angular direction. For the direction vector, we'll use the unit vector $\hat{p}^i = \hat{p}_i$, which by definition satisfies $\delta_{ij}\hat{p}^i\hat{p}^j = 1$.

We can now write Eq. (4.1) as

$$\frac{df}{dt} = \frac{\partial f}{\partial t} + \frac{\partial f}{\partial x^i} \cdot \frac{dx^i}{dt} + \frac{\partial f}{\partial p}\frac{dp}{dt} + \frac{\partial f}{\partial \hat{p}^i} \cdot \frac{d\hat{p}^i}{dt}.$$

The easiest term in Eq. (4.15) is the last one since it does not contribute at first order in perturbation theory. To see this, first recall that the zero-order distribution function is simply the Bose-Einstein function which depends only on p, not on the direction $\hat{p}^i$. Therefore, $\partial f/\partial \hat{p}^i$ is nonzero only if we consider the perturbation to the zero-order f; i.e., it is a first-order term. But so is the term which multiplies it, $d\hat{p}^i/dt$, for the direction of a photon changes only in the presence of potentials Φ and Ψ. In the absence of these potentials, a photon moves in a straight line. Thus the last term is the product of two first-order terms, rendering it a second-order term. We can neglect it.

Next let us reexpress the second term on the right-hand side of Eq. (4.15) by recalling that (Eq. (4.10)) $P^i := dx^i/d\lambda$ and $P^0 := dt/d\lambda$. Therefore,

$$\frac{dx^i}{dt} = \frac{dx^i}{d\lambda}\frac{d\lambda}{dt}$$

$$= \frac{p^i}{p^0}.$$

We want to reexpress this ratio in terms of our favored variables p and $\hat{p}^i$. Equation (4.14) does this for P^0; let's do the same for the numerator P^i. The comoving momentum P^i is proportional to $\hat{p}^i$; call the proportionality constant C:

$$P^i := C\hat{p}^i$$

To determine the coefficient C, we can use Eq. (4.13):

$$\begin{aligned} p^2 &= g_{ij}\hat{p}^i\hat{p}^j C^2 \\ &= a^2(1+2\Phi)\delta_{ij}\hat{p}^i\hat{p}^j C^2 \\ &= a^2(1+2\Phi)C^2 \end{aligned}$$

where the last equality holds because the direction vector is a unit vector. Equation (4.18) tells us that $C = p(1-\Phi)/a$ so whenever we encounter P^i, we can always eliminate it in terms of $p, \hat{p}^i$ via

$$P^i = p\hat{p}^i\frac{1-\Phi}{a}$$

From Eqs. (4.16) and (4.19), we see that

$$\frac{dx^i}{dt} = \frac{\hat{p}^i}{a}(1+\Psi-\Phi)$$

An overdense region has $\Psi < 0$ and $\Phi > 0$, rendering the term in parentheses less than one. So, Eq. (4.20) says that a photon slows down (dx/dt becomes smaller) when traveling through an overdense region. This makes perfect sense: we expect the gravitational force of an overdense region to slow down even photons. Having said that, I now claim that we can neglect the potentials in Eq. (4.20). For, in the Boltzmann equation they multiply $\partial f/\partial x^i$ which is a first-order term. (Again, the zero-order distribution function does not depend on position.) So collecting terms up to this point, we have

$$\frac{df}{dt} = \frac{\partial f}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial f}{\partial x^i} + \frac{\partial f}{\partial p}\frac{dp}{dt}$$

The remaining term to be calculated is dp/dt. Alas, unlike the harmonic oscillator, here $dp/dt \neq -kx$. Rather we will need the geodesic equation from general relativity and more fortitude to compute dp/dt for photons in a perturbed FRW metric.

To begin, let us recall that the time component of the geodesic equation (2.18) can be written as

$$\frac{dP^0}{d\lambda} = -\Gamma^0_{\alpha\beta} P^\alpha P^\beta.$$

We can rewrite the derivative with respect to λ as a derivative with respect to time multiplied by $dt/d\lambda = P^0$. Also, we can use Eq. (4.14) to eliminate P^0 in terms of our favored variable p. Then the geodesic equation reduces to

$$\frac{d}{dt}[p(1-\Psi)] = -\Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p}(1+\Psi)$$

Expand out the time derivative to get

$$\frac{dp}{dt}(1-\Psi) = p\frac{d\Psi}{dt} - \Gamma^0_{\alpha\beta}\frac{P^\alpha p^\beta}{p}(1+\Psi).$$

Now we multiply both sides by $(1+\Psi)$; drop all terms quadratic in Ψ; and reexpress the total time derivative of Ψ in terms of partial derivatives so that

$$\frac{dp}{dt} = p\left\{\frac{\partial\Psi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}\right\} - \Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p}(1+2\Psi).$$

In order to evaluate dp/dt then we need to evaluate the product $\Gamma^0_{\alpha\beta}P^\alpha P^\beta/p$. Recall that the Christoffel symbol is best written as a sum of derivatives of the metric (Eq. (2.19)). Here we are interested only in the $\Gamma^0_{\alpha\beta}$ component. It multiplies $P^\alpha P^\beta$, which is symmetric in α, β. Thus, the first two metric derivatives contribute equally, and we have

$$\Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p} = \frac{g^{0\nu}}{2}\left[2\frac{\partial g_{\nu\alpha}}{\partial x^\beta} - \frac{\partial g_{\alpha\beta}}{\partial x^\nu}\right]\frac{P^\alpha P^\beta}{p}$$

Now $g^{0\nu}$ is nonzero only when $\nu = 0$, in which case it is simply the inverse of g_{00}, so

$$\Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p} = \frac{-1+2\Psi}{2}\left[2\frac{\partial g_{0\alpha}}{\partial x^\beta} - \frac{\partial g_{\alpha\beta}}{\partial t}\right]\frac{P^\alpha P^\beta}{p}$$

Once again, $g_{0\alpha}$ in the first term in brackets is nonzero only when $\alpha = 0$, in which case its derivative is $-2\partial\Psi/\partial x^\beta$. The second term in brackets multiplied by the product of momenta is

$$\begin{aligned}-\frac{\partial g_{\alpha\beta}}{\partial t}\frac{P^\alpha P^\beta}{p} &= -\frac{\partial g_{00}}{\partial t}\frac{P^0 P^0}{p} - \frac{\partial g_{ij}}{\partial t}\frac{P^i P^j}{p} \\ &= 2\frac{\partial\Psi}{\partial t}p - a^2\delta_{ij}\left[2\frac{\partial\Phi}{\partial t} + 2H(1+2\Phi)\right]\frac{P^i P^j}{p}\end{aligned}$$

But, via Eq. (4.19), $\delta_{ij}P^iP^j = p^2(1-2\Phi)/a^2$, so we have

$$\begin{aligned}\Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p} = \frac{-1+2\Psi}{2}\Bigg[&-4\frac{\partial\Psi}{\partial x^\beta}P^\beta + 2p\frac{\partial\Psi}{\partial t} \\ &-p\left\{2\frac{\partial\Phi}{\partial t} + 2H(1+2\Phi)\right\}(1-2\Phi)\Bigg]\end{aligned}$$

The last line here simplifies since $(1+2\Phi)(1-2\Phi) \to 1$ at first order, and $1-2\Phi$ can be set to 1 when multiplying $\partial\Phi/\partial t$. Summing over the index β in the first term then leads to

$$\Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p} = \frac{-1+2\Psi}{2}\left[-4\left(\frac{\partial\Psi}{\partial t}p + \frac{\partial\Psi}{\partial x^i}\frac{p\hat{p}^i}{a}\right) + 2p\frac{\partial\Psi}{\partial t} - p\left\{2\frac{\partial\Phi}{\partial t} + 2H\right\}\right]$$
$$= \{-1+2\Psi\}\left[-\frac{\partial\Psi}{\partial t}p - 2\frac{\partial\Psi}{\partial x^i}\frac{p\hat{p}^i}{a} - p\left\{\frac{\partial\Phi}{\partial t} + H\right\}\right]$$

We can insert this into Eq. (4.25) to get

$$\frac{dp}{dt} = p\left\{\frac{\partial\Psi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}\right\} - \frac{\partial\Psi}{\partial t}p - 2\frac{\partial\Psi}{\partial x^i}\frac{p\hat{p}^i}{a} - p\left\{\frac{\partial\Phi}{\partial t} + H\right\}.$$

Collecting terms, we finally have

$$\frac{1}{p}\frac{dp}{dt} = -H - \frac{\partial\Phi}{\partial t} - \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}$$

Equation (4.32) is what we were after. It describes the change in the photon momentum as it moves through a perturbed FRW universe. The first term accounts for the loss of momentum due to the Hubble expansion. To understand the significance of the next two terms in Eq. (4.32), we first need to remember that an overdense region has $\Phi > 0$ and $\Psi < 0$ with our sign conventions. Therefore, the second term says that a photon in a deepening gravitational well ($\partial\Phi/\partial t > 0$) loses energy. This is understandable: the deepening well makes it more difficult for the photon to emerge, thereby increasing the magnitude of the redshift. Finally, a photon traveling into a well ($\hat{p}^i\partial\Psi/\partial x^i < 0$) gains energy because it is being pulled toward the center. Conversely, as it leaves the well, it gets redshifted.

We are now in a position to write down the Boltzmann equation for photons. Using Eq. (4.32) in Eq. (4.21) leads to

$$\frac{df}{dt} = \frac{\partial f}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial f}{\partial x^i} - p\frac{\partial f}{\partial p}\left[H + \frac{\partial\Phi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}\right]$$

This equation incorporates much of the physics with which we are already familiar, such as the fact that photons redshift in an expanding universe. It also leads directly to the equations governing anisotropies. Working through the terms on the right, the first two are familiar from standard hydrodynamics; when integrated, they lead to the continuity and Euler equations (Exercise 1). The third term dictates that photons lose energy in an expanding universe. We saw some of this in Chapter 2 when considering geodesics. Shortly, we will see how the Boltzmann formalism enforces this result. Finally, the last two encode the effects of under-/overdense regions on the photon distribution function. To go further we must now expand the photon distribution function f about its zero-order Bose-Einstein value. I will do this in a way that may seem odd at first. Let us write

$$f(\vec{x}, p, \hat{p}, t) = \left[\exp\left\{\frac{p}{T(t)[1+\Theta(\vec{x},\hat{p},t)]}\right\} - 1\right]^{-1}$$

Here the zero-order temperature T is a function of time only (i.e., scales as a^{-1}), not space. The perturbation to the distribution function is characterized by Θ, which could also be called $\delta T/T$. In the smooth zero-order universe, photons are distributed homogeneously, so T is independent of $\vec{x}$, and isotropically, so T is independent of the direction of propagation $\hat{p}$. Now that we want to describe perturbations about this smooth universe, we need to allow for inhomogeneities in the photon distribution (so Θ depends on $\vec{x}$) and anisotropies (so Θ depends on $\hat{p}$). There is one assumption built into Eq. (4.34). I have explicitly written down that Θ depends on $\vec{x}, \hat{p}$, and t. This assumes that it does not depend on the magnitude of the momentum p. We will soon see that this is a valid assumption, following directly from that

fact that the magnitude of the photon momentum is virtually unchanged during a Compton scatter. The perturbation Θ is small, so we can expand (again keeping only terms up to first order)

$$\begin{aligned} f &\simeq \frac{1}{e^{p/T}-1} + \left(\frac{\partial}{\partial T}\left[\exp\left\{\frac{p}{T}\right\}-1\right]^{-1}\right) T\Theta \\ &= f^{(0)} - p\frac{\partial f^{(0)}}{\partial p}\Theta. \end{aligned}$$

In the last line I have identified the zero-order distribution function as the BoseEinstein distribution with zero chemical potential,

$$f^{(0)} := \left[\exp\left\{\frac{p}{T}\right\}-1\right]^{-1}$$

and made use of the fact that for this function $T\partial f^{(0)}/\partial T = -p\partial f^{(0)}/\partial p$.

Zero-Order Equation

We can now set about systematically collecting the terms of similar order in Eq. (4.33). Let us start with the zero-order terms, those with no Φ, Ψ, or Θ. These lead immediately to

$$\left.\frac{df}{dt}\right|_{\text{zero order}} = \frac{\partial f^{(0)}}{\partial t} - Hp\frac{\partial f^{(0)}}{\partial p} = 0.$$

I have set df/dt here equal to zero, i.e., set the collision term on the right of Eq. (4.1) to zero. I could justify this by claiming that we are now looking only at the collisionless Boltzmann equation. But there is a much deeper justification. In fact, even when we come around to including collisions, we will see that there is no zero-order collision term. That is, the collision terms will be proportional to Θ and other perturbatively small quantities. There is a profound reason for this: the zero-order distribution function is set precisely by the requirement that the collision term vanishes. Another, perhaps more familiar, way of saying this is to point out that any collision term includes the rate for the given reaction and for its inverse. If the distribution functions are set to their equilibrium values, the rate for the reaction precisely cancels the rate for its inverse. If a given component is out of equilibrium, collisions will drive it toward its equilibrium distribution. This is the reason we expected a Bose-Einstein distribution in the first place. Its observation is convincing evidence that photons were at one point in the early universe tightly coupled to the electrons.

Returning to Eq. (4.37), we can rewrite the time derivative as

$$\frac{\partial f^{(0)}}{\partial t} = \frac{\partial f^{(0)}}{\partial T}\frac{dT}{dt} = -\frac{dT/dt}{T}p\frac{\partial f^{(0)}}{\partial p}$$

so that the zero-order equation becomes

$$\left[-\frac{dT/dt}{T} - \frac{da/dt}{a}\right]\frac{\partial f^{(0)}}{\partial p} = 0$$

Thus $dT/T = -da/a$ or

$$T \propto \frac{1}{a}$$

This is precisely what we expected from the heuristic argument about the photon's wavelength getting stretched as the universe expands (Section 1.1) and the more concrete argument of Section 2.1. It is reassuring to see this result emerge from the Boltzmann treatment.

First-Order Equation

We now return to Eq. (4.33) and extract the equation for the deviation of the photon temperature from its zero-order value, i.e., an equation for Θ. To do this, everywhere we encounter f in Eq. (4.33), we insert the expansion of Eq. (4.35):

$$\left.\frac{df}{dt}\right|_{\text{first order}} = -p\frac{\partial}{\partial t}\left[\frac{\partial f^{(0)}}{\partial p}\Theta\right] - p\frac{\hat{p}^i}{a}\frac{\partial\Theta}{\partial x^i}\frac{\partial f^{(0)}}{\partial p} + Hp\Theta\frac{\partial}{\partial p}\left[p\frac{\partial f^{(0)}}{\partial p}\right]$$
$$- p\frac{\partial f^{(0)}}{\partial p}\left[\frac{\partial\Phi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}\right].$$

Consider the first term on the right-hand side here. The time derivative can be rewritten as a temperature derivative so

$$-p\frac{\partial}{\partial t}\left[\frac{\partial f^{(0)}}{\partial p}\Theta\right] = -p\frac{\partial f^{(0)}}{\partial p}\frac{\partial\Theta}{\partial t} - p\Theta\frac{dT}{dt}\frac{\partial^2 f^{(0)}}{\partial T\partial p}$$
$$= -p\frac{\partial f^{(0)}}{\partial p}\frac{\partial\Theta}{\partial t} + p\Theta\frac{dT/dt}{T}\frac{\partial}{\partial p}\left[p\frac{\partial f^{(0)}}{\partial p}\right]$$

The second line follows here since $\partial f^{(0)}/\partial T = -(p/T)\partial f^{(0)}/\partial p$. The second term on this second line cancels the third term on the right in Eq. (4.40), so we can finally write down the equation governing the perturbation θ:

$$\left.\frac{df}{dt}\right|_{\text{first order}} = -p\frac{\partial f^{(0)}}{\partial p}\left[\frac{\partial\Theta}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Theta}{\partial x^i} + \frac{\partial\Phi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}\right]$$

The first two terms here account for "free streaming," which translates into anisotropies on increasingly small scales as the universe evolves. The last two account for the effect of gravity. Note that every time x appears it is multiplied by a, the scale factor. This must happen, for physical distances are ax.

12.4.3 Collision Terms: Compton Scattering

Our task in this section is to determine the influence Compton scattering has on the photon distribution function. The scattering process of interest is

$$e^-(\vec{q}) + \gamma(\vec{p}) \leftrightarrow e^-(\vec{q}') + \gamma(\vec{p}')$$

where I have explicitly indicated the momentum of each particle.

We are interested in the change of distribution of photons with momentum $\vec{p}$ (with magnitude p and direction $\hat{p}$). Therefore we must sum over all other momenta $(\vec{q}, \vec{q}', \vec{p}')$ which affect $f(\vec{p})$. Schematically, then, the collision term is

$$C[f(\vec{p})] = \sum_{\vec{q},\vec{q}',\vec{p}'} |\text{ Amplitude }|^2 \{f_e(\vec{q}')f(\vec{p}') - f_e(\vec{q})f(\vec{p})\}$$

The amplitude is reversible so it multiplies both the reaction and its inverse. The products of the electron distribution function f_e and the photon distribution function simply count the number of particles with the given momenta. I have neglected stimulated emission and Pauli blocking, which would lead to factors of $1 + f$ and $1 - f_e$ with the appropriate momenta. At first order this turns out to be a valid assumption. If one were to go to second order, though, stimulated emission would have to be included. Pauli blocking is never important after electron-positron annihilation because the occupation numbers f_e are very small (Exercise 4).

Unfortunately, the collision term becomes a bit messier than the schematic version when we put in all the factors of 2π to properly account for the sums over phase space. Explicitly, the collision term is [2]

$$C[f(\vec{p})] = \frac{1}{p}\int \frac{d^3q}{(2\pi)^3 2E_e(q)} \int \frac{d^3q'}{(2\pi)^3 2E_e\left(q'\right)} \int \frac{d^3p'}{(2\pi)^3 2E\left(p'\right)} |\mathcal{M}|^2 (2\pi)^4$$

[2] Most of the phase space factors here follow from our discussion in Section 3.1, the exception being the factor of $1/p$ in front. You may have wondered about one other feature of the Boltzmann equation presented in this chapter: I started at the outset taking df/dt; does not general relativity require us to take the derivative with respect to the affine parameter λ? Exercise 5 illustrates how these problems solve each other.

$$\begin{aligned} &\times \delta^3[\vec{p}+\vec{q}-\vec{p}'-\vec{q}']\,\delta\left[E(p)+E_e(q)-E\left(p'\right)-E_e\left(q'\right)\right] \\ &\quad \times \times \left\{f_e\left(\vec{q}'\right) f\left(\vec{p}'\right) - f_e(\vec{q}) f(\vec{p})\right\} \end{aligned}$$

Here the delta functions enforce energy momentum conservation. The energies at this order are the relativistic limit for photons and non-relativistic limit for electrons: $E(p) = p$ and $E_e(q) = m_e + q^2/\left(2m_e\right)$. Note the similarity between this collision term and the general one (Eq. (3.1)) we considered in Chapter 3. The only difference is that I have not integrated this collision term over all photon momenta $\vec{p}$, so there are only three momentum integrals. Again, this reflects our need to understand how photons traveling in different directions interact: we will see that the collision term depends on $\hat{p}$.

Since the kinetic energy of the electrons is very small at the epochs of interest compared with their rest energy, the factors of E_e in the denominator of Eq. (4.45) may be replaced with m_e. Then using the three-dimensional momentum delta function to do the $\vec{q}'$ integral, we have

$$\begin{aligned} C[f(\vec{p})] = \frac{\pi}{4m_e^2 p}\int \frac{d^3q}{(2\pi)^3} \int \frac{d^3p'}{(2\pi)^3 p'} \delta\left[p + \frac{q^2}{2m_e} - p' - \frac{\left(\vec{q}+\vec{p}-\vec{p}'\right)^2}{2m_e}\right] \\ \times |\mathcal{M}|^2 \left\{f_e\left(\vec{q}+\vec{p}-\vec{p}'\right) f\left(\vec{p}'\right) - f_e(\vec{q}) f(\vec{p})\right\} \end{aligned}$$

To go further, we need to understand the kinematics of nonrelativistic Compton scattering. The most important feature of this process for our purposes is that very little energy is transferred. In particular,

$$\begin{aligned} E_e(q) - E_e\left(\vec{q}+\vec{p}-\vec{p}'\right) &= \frac{q^2}{2m_e} - \frac{\left(\vec{q}+\vec{p}-\vec{p}'\right)^2}{2m_e} \\ &\simeq \frac{\left(\vec{p}'-\vec{p}\right)\cdot\vec{q}}{m_e}, \end{aligned}$$

where the last approximate equality holds since q is much larger than $\vec{p}$ and $\vec{p}'$. In nonrelativistic Compton scattering, $p' \simeq p$, scattering is nearly elastic. Therefore, $\vec{p}'-\vec{p}$ is of order p, of order the ambient temperature T. So the right-hand side of Eq. (4.47) is of order $Tq/m_e \sim Tv_{\rm b}$ where the baryonic velocity $v_{\rm b}$ is very small. The change in the electron energy due to Compton scattering is therefore of order $Tv_{\rm b}$. Since the typical kinetic energy of the electrons is also of order T, the fractional energy change in a single Compton collision is very small, of order $v_{\rm b}$. It makes sense, therefore, to expand the final electron kinetic energy $\left(\vec{q}+\vec{p}-\vec{p}'\right)^2/\left(2m_e\right)$ around its zero-order value of $q^2/\left(2m_e\right)$. The delta function can be expanded as

$$\delta\left[p+\frac{q^2}{2m_e}-p'-\frac{\left(\vec{q}+\vec{p}-\vec{p}'\right)^2}{2m_e}\right]\simeq\delta\left(p-p'\right)$$
$$+\left(E_e\left(q'\right)-E_e(q)\right)\left.\frac{\partial\delta\left(p+E_e(q)-p'-E_e\left(q'\right)\right)}{\partial E_e\left(q'\right)}\right|_{E_e(q)=E_e(q')}$$
$$=\delta\left(p-p'\right)+\frac{\left(\vec{p}-\vec{p}'\right)\cdot\vec{q}}{m_e}\frac{\partial\delta\left(p-p'\right)}{\partial p'}$$

where the second equality makes use of the fact that for a general function f of the sum of two variables, $\partial f(x-y)/\partial x=-\partial f(x-y)/\partial y$. This formal expansion appears ill-defined at present, but when integrating over momenta, the derivatives of delta functions will be handled by integrating by parts. With this expansion, and using the fact that $f_e\left(\vec{q}+\vec{p}-\vec{p}'\right)\simeq f_e(\vec{q})$, the collision term becomes

$$C[f(\vec{p})]=\frac{\pi}{4m_e^2p}\int d^3q\frac{f_e(\vec{q})}{(2\pi)^3}\int\frac{d^3p'}{(2\pi)^3p'}|\mathcal{M}|^2$$
$$\times\left\{\delta\left(p-p'\right)+\frac{\left(\vec{p}-\vec{p}'\right)\cdot\vec{q}}{m_e}\frac{\partial\delta\left(p-p'\right)}{\partial p'}\right\}\left\{f\left(\vec{p}'\right)-f(\vec{p})\right\}.$$

To proceed further, we need the amplitude for Compton scattering. This can be computed using Feynman rules as explicated for example in Bjorken and Drell (1965). We will take it to be constant:

$$|\mathcal{M}|^2=8\pi\sigma_Tm_\epsilon^2$$

where σ_T is the Thomson cross-section. This is wrong, and it is wrong for two reasons. First of all, the amplitude squared has an angular dependence $\propto(1+\cos^2[\hat{p}\cdot\hat{p}\prime])$. Ignoring this angular dependence, as I now propose to do, makes a small difference in the final collision term. It needs to be included in calculations which aspire to 1% accuracy. But it would simply distract us here, so let us ignore it for the present. The second reason a constant amplitude is wrong is a little more subtle and, when properly accounted for, opens up a whole new branch of CMB study. In particular, the amplitude squared has a polarization dependence $\left(\propto\left|\hat{\epsilon}\cdot\hat{\epsilon}'\right|^2\right.$, where $\hat{\epsilon}$ and $\hat{\epsilon}'$ are the polarizations of the incoming and outgoing photons) which I have implicitly summed over here. The dependence on polarization means that at a small level the CMB will be polarized due to Compton scattering (Bond and Efstathiou, 1984; Polnarev, 1985). It turns out that the information carried by the polarization spectrum is as valuable as that carried by the temperature spectrum (Seljak, 1997; Seljak and Zaldarriaga, 1997; Kamionkowski, Kosowsky, and Stebbins, 1997a,b). We will devote considerable time in Chapter 10 to understanding polarization. Even if we were not concerned with polarization, the temperature anisotropies are coupled to the polarization field, so an accurate determination of the former requires a treatment of the latter. Again, though, I will neglect this small effect here in the derivation of the collision term. It is straightforward to include both the effects of polarization and the angular dependence of Compton scattering using the same formalism we are now in the midst of. The algebra is simply a bit more tedious.

Once we have assumed that $|\mathcal{M}|^2$ is constant, we can multiply out the terms in brackets in Eq. (4.49) keeping only terms first order in energy transfer. Also, the $\vec{q}$ integral simply gives a factor of n_e (or $n_e\vec{v}_{\rm b}$ for the term which has a factor of $\vec{q}/m_e$). So

$$
\begin{aligned}
C[f(\vec{p})] =& \frac{2\pi^2 n_e \sigma_T}{p} \int \frac{d^3p'}{(2\pi)^3 p'} \left\{ \delta\left(p-p'\right) + \left(\vec{p}-\vec{p}'\right)\cdot\vec{v}_{\rm b} \frac{\partial \delta\left(p-p'\right)}{\partial p'} \right\} \\
& \times \left\{ f\left(\vec{p}'\right) - f(\vec{p}) - p' \frac{\partial f^{(0)}}{\partial p'} \Theta\left(\hat{p}'\right) + p \frac{\partial f^{(0)}}{\partial p} \Theta(\hat{p}) \right\} \\
=& \frac{n_e \sigma_T}{4\pi p} \int_0^\infty dp' p' \int d\Omega' \left[\delta\left(p-p'\right) \left(-p' \frac{\partial f^{(0)}}{\partial p'} \Theta\left(\hat{p}'\right) + p \frac{\partial f^{(0)}}{\partial p} \Theta(\hat{p}) \right) \right. \\
& \left. + \left(\vec{p}-\vec{p}'\right)\cdot\vec{v}_{\rm b} \frac{\partial \delta\left(p-p'\right)}{\partial p'} \left(f^{(0)}\left(p'\right) - f^{(0)}(p) \right) \right]
\end{aligned}
$$

where Ω' is the solid angle spanned by the unit vector $\hat{p}'$. On the first line, I have broken up the difference $f\left(\vec{p}'\right) - f(\vec{p})$ into a zero-order piece, [3] which doesn't contribute when multiplying $\delta\left(p-p'\right)$, and a first-order part which can be neglected when multiplying the velocity term.

There are only two terms in Eq. (4.51) which depend on $\hat{p}'$ and therefore which must be accounted for when integrating over solid angle Ω'. First, there is the perturbation to the distribution function, $\Theta\left(\hat{p}'\right)$. It is convenient at this stage to introduce the notation

$$
\Theta_0(\vec{x},t) := \frac{1}{4\pi} \int d\Omega' \Theta\left(\hat{p}', \vec{x}, t\right)
$$

So Θ_0 does not depend on the direction vector; it is an integral of the perturbation over all directions. In other words, it is the monopole part of the perturbation. Note that we cannot absorb this monopole into the definition of the zero order temperature since the latter is constant over all space. The perturbation Θ_0 therefore represents the deviation of the monopole at a given point in space from its average in all space. Later on we will generalize Eq. (4.52) to all other multipoles.

The second term in Eq. (4.51) which depends on $\hat{p}'$ is the explicit factor $\hat{p}'\cdot\vec{v}_{\rm b}$. This term integrates to zero since $\vec{v}_{\rm b}$ is a fixed vector. Thus, the integration over solid angle leaves

$$
\begin{aligned}
C[f(\vec{p})] = \frac{n_e \sigma_T}{p} \int_0^\infty dp' p' & \left[\delta\left(p-p'\right) \left(-p' \frac{\partial f^{(0)}}{\partial p'} \Theta_0 + p \frac{\partial f^{(0)}}{\partial p} \Theta(\hat{p}) \right) \right. \\
& \left. + \vec{p}\cdot\vec{v}_{\rm b} \frac{\partial \delta\left(p-p'\right)}{\partial p'} \left(f^{(0)}\left(p'\right) - f^{(0)}(p) \right) \right].
\end{aligned}
$$

Now the p' integral can be done: in the first line by trivially integrating over the delta function and in the second by integrating by parts. We are left with

[3] Note that we are expanding in two small quantities simultaneously, the small perturbations and the small energy transfer. Here, we are breaking up $f(\vec{p}) - f(\vec{p})$ into terms zero and first order in the small perturbations.

$$
C[f(\vec{p})] = -p \frac{\partial f^{(0)}}{\partial p} n_e \sigma_T \left[\Theta_0 - \Theta(\hat{p}) + \hat{p}\cdot\vec{v}_b \right]
$$

Already, we can anticipate the effect of Compton scattering on the photon distribution. In the absence of a bulk velocity for the electrons ($v_{\rm b} = 0$), the collision terms serve to drive Θ to Θ_0. That is, when Compton scattering is very efficient, only the monopole perturbation survives; all other moments are washed out (Figure 4.3). Intuitively, strong scattering means that the mean free path of a photon is very small. Therefore, photons arriving at a given point in space last scattered off very nearby electrons if Compton scattering is efficient. These nearby electrons most likely had a temperature very similar to the point of observation. Therefore,

photons from all directions have the same temperature. This is the characteristic signature of a monopole distribution: the temperature on the sky is uniform.

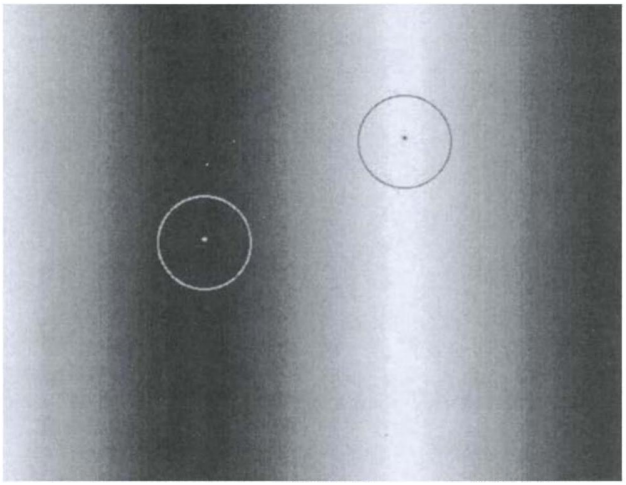

Figure 4.3. A plane wave perturbation in the matter and its effect on tightly coupled photons. Dark (white) regions represent hot (cold) spots in the electron temperature. If Compton scattering is very efficient then photons last scattered very near the point of observation. Circles denote last scattering surfaces for observation points indicated by stars. The temperature on these surfaces is very close to uniform, so the distribution is almost all monopole. Note though that different circles (corresponding to different observers) have different temperatures due to the perturbation. So the monopole varies in space.

The situation changes slightly if the electrons carry a bulk velocity. In that case, the photons will also have a dipole moment, fixed by the amplitude and direction of the electron velocity. Even in this case, though, all higher moments will vanish. Thus Compton scattering produces a photon distribution which is extremely simple to categorize: it has only a nonvanishing monopole and dipole. This is equivalent to saying that the photons behave like a fluid. Indeed, strong scattering, or tight coupling, produces a situation wherein the photons and electrons behave as a single fluid.

12.4.4 The Boltzmann Equation for Photons

We can now collect the left- and right-hand sides of the Boltzmann equations from the previous two sections. A few more definitions will complete the first goal of this chapter, a linear equation for the perturbation to the photon distribution. Equating Eqs. (4.42) and (4.54) leads to

$$\frac{\partial \Theta}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial \Theta}{\partial x^i} + \frac{\partial \Phi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial \Psi}{\partial x^i} = n_e \sigma_T \left[\Theta_0 - \Theta + \hat{p} \cdot \vec{v}_{\rm b}\right]$$

At this point, it is convenient to reintroduce the conformal time η, defined in Eq. (2.41), as our time variable. In terms of the conformal time, the Boltzmann equation becomes

$$\dot{\Theta} + \hat{p}^i \frac{\partial \Theta}{\partial x^i} + \dot{\Phi} + \hat{p}^i \frac{\partial \Psi}{\partial x^i} = n_e \sigma_T a \left[\Theta_0 - \Theta + \hat{p} \cdot \vec{v}_{\rm b}\right]$$

Here, and from now on, overdots represent derivatives with respect to conformal time.

Equation (4.56) is a partial differential linear equation coupling Θ to other variables Φ, Ψ, and $\vec{v}_{\rm b}$ which also evolve linearly. If we Fourier transform all these variables, so that $\partial/\partial x^i \to k_i \, (:= k^i)$, the resulting Fourier amplitudes obey ordinary differential equations, which are much simpler to solve. In the case of small perturbations around a smooth universe, there is an added

benefit of Fourier transforming. Since the background is smooth, the only $\vec{x}$ dependence in Eq. (4.56) is hidden in the perturbation variables themselves. In general, an equation of the form

$$aA(\vec{x}) = bB(\vec{x})$$

gets transformed into

$$a\tilde{A}(\vec{k}) = b\tilde{B}(\vec{k})$$

That is, every Fourier mode evolves independently: $A\left(\vec{k}_1\right)$ can be evolved even if we know nothing of $A\left(\vec{k}_2\right)$. So the Fourier transform of Eq. (4.56) produces a set of ordinary differential equations for the Fourier modes, and this set of equations is uncoupled. Instead of solving an infinite number of coupled equations, we can solve for one k-mode at a time.

Note that this simplification arises because the perturbations are small (equivalently the equations are linear). In this case, the different Fourier modes all evolve independently. Perturbations to the CMB remain small at all cosmological epochs, so Fourier transforms are very useful. In contrast, perturbations to matter are more complicated. Initially they are small. and they remain small until relatively recently. The largest scales today are still in the linear regime, so Fourier transforming is certainly useful for the matter perturbations as well. However, to completely characterize the matter field today requires accounting for nonlinearities, and for this purpose, Fourier transforms lose much of their appeal. Different Fourier modes couple when nonlinear behavior becomes important, so the codes which follow matter perturbations all the way until today work in real space. Even these codes, however, start at $z \sim 20$ with the initial conditions set by linear evolution.

Our Fourier convention will be

$$\Theta(\vec{x}) = \int \frac{d^3k}{(2\pi)^3} e^{i\vec{k}\cdot\vec{x}} \tilde{\Theta}(\vec{k})$$

We will often characterize a mode by the magnitude of its wavevector [4] : $k = \sqrt{k^i k^i}$.

Before rewriting Eq. (4.56) in terms of Fourier modes, let us make two final definitions. First, define the cosine of the angle between the wavenumber $\vec{k}$ and the photon direction $\hat{p}$ to be

$$\mu := \frac{\vec{k}\cdot\hat{p}}{k}$$

From now on, μ will be the variable describing the direction of photon propagation. A good way to think of μ is to go back to Figure 4.3. The wavevector $\vec{k}$ is pointing in the direction in which the temperature is changing, so it is perpendicular to the gradient ($\vec{k}$ is horizontal in the figure). When $\mu = 1$ then the photon direction is aligned with $\vec{k}$, so the photon is traveling in the direction along which the temperature is changing. A photon traveling in a direction in which the temperature remains the same (vertically in the figure) has $\mu = 0$. We will typically assume that the velocity points in the same direction as $\vec{k}$ (this is equivalent to saying that the velocity is irrotational), so $\tilde{\vec{v}}_{\rm b}\cdot\hat{p} = \tilde{v}_{\rm b}\mu$. Next, we define the optical depth

$$\tau(\eta) := \int_{\eta}^{\eta_0} d\eta' n_e \sigma_T a$$

At late times, the free electron density is small, so $\tau \ll 1$, while at early times, it is very large. Note that I have defined the limits of integration in such a way that

$$\dot{\tau} := \frac{d\tau}{d\eta} = -n_e \sigma_T a$$

With these definitions, we are finally left with

$$\dot{\tilde{\Theta}} + ik\mu\tilde{\Theta} + \dot{\tilde{\Phi}} + ik\mu\tilde{\Psi} = -\dot{\tau}\left[\tilde{\Theta}_0 - \tilde{\Theta} + \mu\tilde{v}_{\rm b}\right].$$

[4] Note that k^i is a 3D vector in Eudclidean space so that $k_i = k^i$: you do not need a factor of g_{ij} to go back and forth. The same goes for the velocity v_b^i.

12.4.5 The Boltzmann Equation for Cold Dark Matter

We can apply the formalism developed in the previous sections to derive the Boltzmann equation for any other constituent in the universe. Of particular importance is the evolution of the dark matter. In almost all currently popular models of structure formation, dark matter plays an important role in structure formation and in determining the gravitational field in the universe.

It is perhaps simplest to derive the evolution equations for dark matter by imposing conservation of the energy-momentum tensor, as we did in Chapter 2 in the homogeneous case. Unlike the photons, the dark matter always behaves like a fluid so can always be described completely by $T_{\mu\nu}$. Nonetheless, here we will sacrifice simplicity and use the Boltzmann formalism to derive the dark matter equations. This will (i) reinforce the calculations of the previous sections and also (ii) pave the way for the electron/proton equations of the next section.

There are several ways in which the dark matter distribution differs from that of the photons. First, by definition, "dark" matter does not interact with any of the other constituents in the universe. Thus we need not deal with any collision terms. Second, cold dark matter, in contrast to the photons, is nonrelativistic. So we need to redo some of the kinematics which led to the left side of the Boltzmann equation. In particular, the constraint Eq. (4.11) now becomes

$$g_{\mu\nu}P^\mu P^\nu = -m^2$$

where m is the mass of the dark matter particle. It is also useful to define the energy as

$$E := \sqrt{p^2 + m^2}$$

where p is defined exactly as in Eq. (4.13): $p^2 = g_{ij}P^iP^j$. In the massless case, of course, Eq. (4.65) says that $E = p$, so E is superfluous. Here it will be convenient to let E replace p as one of the variables on which the distribution function depends (in addition to position $\vec{x}$, time t, and the direction vector $\hat{p}$). We can now derive the equivalent of equations (4.14) and (4.19) for the four-momentum of a massive particle:

$$P^\mu = \left[E(1-\Psi), p\hat{p}^i\frac{1-\Phi}{a}\right].$$

Only the time component is different from that of a massless particle, with E replacing p.

Using E as one of the dependent variables means that the total time derivative of the dark matter distribution function $f_{\rm dm}$ is

$$\frac{df_{\rm dm}}{dt} = \frac{\partial f_{\rm dm}}{\partial t} + \frac{\partial f_{\rm dm}}{\partial x^i}\frac{dx^i}{dt} + \frac{\partial f_{\rm dm}}{\partial E}\frac{dE}{dt} + \frac{\partial f_{\rm dm}}{\partial \hat{p}^i}\frac{d\hat{p}^i}{dt}.$$

Once again, the last term here vanishes since it is the product of two first-order terms. Because of the change in the constraint equation, the coefficients of the derivatives of the distribution function with respect to x^i and E are slightly different than they were in the

massless case. Working through the algebra, which is otherwise identical to the calculation presented in Section 4.2, leads to the collisionless Boltzmann equation for nonrelativistic matter:

$$\frac{\partial f_{\rm dm}}{\partial t} + \frac{\hat{p}^i}{a}\frac{p}{E}\frac{\partial f_{\rm dm}}{\partial x^i} - \frac{\partial f_{\rm dm}}{\partial E}\left[\frac{da/dt}{a}\frac{p^2}{E} + \frac{p^2}{E}\frac{\partial \Phi}{\partial t} + \frac{\hat{p}^i p}{a}\frac{\partial \Psi}{\partial x^i}\right] = 0$$

Equation (4.68) reduces to Eq. (4.33) in the massless limit as it must. The main difference between the two is the presence of factors of p/E, or velocity. For dark matter particles, these velocity factors suppress any free streaming, as we will shortly see.

In the massless case, to proceed further we used our knowledge of the distribution function. Namely, we knew that the zero-order distribution function was Bose-Einstein, and we perturbed around this zero-order solution. For cold dark matter particles, we do not need such detailed information about the zero-order distribution function. All we need to know is that these particles are very nonrelativistic. So we can neglect the thermal motion of the dark matter (Exercise 9). We cannot however neglect p/m completely, because the density perturbations themselves induce velocity flows in the dark matter via the continuity equation. These coherent flows give rise to $p/m \sim v$ terms, which must be retained. What we can do, however, in our linear treatment, is to neglect terms second-order in p/E.

Instead of assuming a form for $f_{\rm dm}$, we will take moments of Eq. (4.68). First, multiply both sides by the phase space volume $d^3p/(2\pi)^3$ and integrate. This leads to

$$\frac{\partial}{\partial t}\int \frac{d^3p}{(2\pi)^3} f_{\rm dm} + \frac{1}{a}\frac{\partial}{\partial x^i}\int \frac{d^3p}{(2\pi)^3} f_{\rm dm}\frac{p\hat{p}^i}{E} - \left[\frac{da/dt}{a} + \frac{\partial \Phi}{\partial t}\right]\int \frac{d^3p}{(2\pi)^3}\frac{\partial f_{\rm dm}}{\partial E}\frac{p^2}{E}$$
$$-\frac{1}{a}\frac{\partial \Psi}{\partial x^i}\int \frac{d^3p}{(2\pi)^3}\frac{\partial f_{\rm dm}}{\partial E}\hat{p}^i p = 0$$

Note that, since they are independent variables, the integral over p passes through the partial derivatives with respect to x^i and t. The last term here can be neglected since the integral over the direction vector is nonzero only for the perturbed part of $f_{\rm dm}$. Thus the integral is first order and it multiplies the first-order term $\partial\Psi/\partial x^i$. The rest of the terms are all relevant, though. To simplify, let us recall that the dark matter density is [5]

$$n_{\rm dm} = \int \frac{d^3p}{(2\pi)^3} f_{\rm dm}$$

while the velocity is defined as

$$v^i := \frac{1}{n_{\rm dm}}\int \frac{d^3p}{(2\pi)^3} f_{\rm dm}\frac{p\hat{p}^i}{E}$$

[5] Here I have incorporated the spin degeneracy $g_{\rm dm}$ into the phase space distribution $f_{\rm dm}$. We implicitly did the same thing in the last section for the electrons. The first two terms in Eq. (4.69), then. can be simply expressed in terms of the velocity and the density. The third term is a bit more subtle: to relate it to the density, we need to integrate by parts. Since $dE/dp = p/E$, the integrand can be reexpressed as $p\partial f_{\rm din}/\partial p$. Thus, the integral becomes

$$\begin{aligned}\int \frac{d^3p}{(2\pi)^3} p\frac{\partial f_{\rm dm}}{\partial p} &= \frac{4\pi}{(2\pi)^3}\int_0^\infty dp p^3\frac{\partial f_{\rm dm}}{\partial p} \\ &= -3\frac{4\pi}{(2\pi)^3}\int_0^\infty dp p^2 f_{\rm dm} \\ &= -3n_{\rm dn}.\end{aligned}$$

So the zeroth moment of the Boltzmann equation leads to the cosmological generalization of the continuity equation:

$$\frac{\partial n_{\rm dm}}{\partial t} + \frac{1}{a}\frac{\partial\left(n_{\rm dm}v^i\right)}{\partial x^i} + 3\left[\frac{da/dt}{a} + \frac{\partial\Phi}{\partial t}\right] n_{\rm dm} = 0.$$

The first two terms here are the standard continuity equation from fluid mechanics. The last term arises due to the FRW metric and its perturbations.

To go further, we can collect zero-order and first-order terms in Eq. (4.73). The velocity is first order as is Φ, so the only zero-order terms are

$$\frac{\partial n^{(0)}_{\rm dm}}{\partial t} + 3\frac{da/dt}{a} n^{(0)}_{\rm dm} = 0$$

where $n^{(0)}_{\rm dm}$ is the zero-order, homogeneous part of the density. Equivalently, we have

$$\frac{d\left(n^{(0)}_{\rm dm}a^3\right)}{dt} = 0 \Longrightarrow n^{(0)}_{\rm dm} \propto a^{-3}$$

a relation we anticipated back in Chapter 1 as an obvious ramification of the expansion. We also proved this scaling in Chapter 2 by using the conservation of the energy momentum tensor.

Now let us extract the first-order part of Eq. (4.73). All factors of $n_{\rm dm}$ multiplying the first-order quantities v and Φ may be set to $n^{(0)}_{\rm dm}$. Everywhere else, we need to expand $n_{\rm dm}$ out to include a first-order perturbation. In particular, we will set

$$n_{\rm dm} = n^{(0)}_{\rm dm}[1 + \delta(\vec{x}, t)].$$

which defines the first-order piece as $n^{(0)}_{\rm dm}\delta$. Since the energy density of matter is equal to mass times n, δ is also the fractional overdensity, $\delta\rho/\rho$, of the dark matter. After dividing by $n^{(0)}_{\rm dm}$, the first-order equation is therefore

$$\frac{\partial\delta}{\partial t} + \frac{1}{a}\frac{\partial v^i}{\partial x^i} + 3\frac{\partial\Phi}{\partial t} = 0.$$

As it stands, we have introduced two new perturbation variables for the dark matter, the density perturbation δ and the velocity $\vec{v}$. Equation (4.77) is only one equation, though, for these two variables. We need another. To get it. we return to the unintegrated Boltzmann equation (4.68). We have just taken its zeroth moment: to extract a second equation, let us take its first moment. In particular, multiply Eq. (4.68) by $d^3p(p/E)\hat{p}^j/(2\pi)^3$ and then integrate. The first moment equation is then

$$\begin{aligned} 0 = &\frac{\partial}{\partial t}\int\frac{d^3p}{(2\pi)^3} f_{\rm dm}\frac{p\hat{p}^j}{E} + \frac{1}{a}\frac{\partial}{\partial x^i}\int\frac{d^3p}{(2\pi)^3} f_{\rm dm}\frac{p^2\hat{p}^i\hat{p}^j}{E^2} \\ &- \left[\frac{da/dt}{a} + \frac{\partial\Phi}{\partial t}\right]\int\frac{d^3p}{(2\pi)^3}\frac{\partial f_{\rm dm}}{\partial E}\frac{p^3\hat{p}^j}{E^2} - \frac{1}{a}\frac{\partial\Psi}{\partial x^i}\int\frac{d^3p}{(2\pi)^3}\frac{\partial f_{\rm dm}}{\partial E}\frac{\hat{p}^i\hat{p}^j p^2}{E} \end{aligned}$$

The first two terms are straightforward: the first is the time derivative of $n_{\rm dm}v^i$ while the second can be safely neglected since it is of order $\langle(p/E)^2\rangle$. The last sets of terms must be handled more carefully, though, because of the partial derivatives. Since $(p/E)\partial/\partial E = \partial/\partial p$ the third term is actually of order p/E while the last is independent of velocity. Let us do the integration by parts explicitly in the third term. The integral is:

$$\int \frac{d^3p}{(2\pi)^3}\frac{\partial f_{\rm dm}}{\partial p}\frac{p^2\hat{p}^j}{E} = \int \frac{d\Omega\hat{p}^j}{(2\pi)^3}\int_0^\infty dp\frac{p^4}{E}\frac{\partial f_{\rm dm}}{\partial p}$$
$$= -\int \frac{d\Omega\hat{p}^j}{(2\pi)^3}\int_0^\infty dp f_{\rm dm}\left(\frac{4p^3}{E}-\frac{p^5}{E^3}\right)$$

The p^5/E^3 term is completely negligible, so the only relevant contribution to the integral comes from the $-4p^3/E$ term: its integral is $-4n_{\rm dm}v^j$. The same steps carry through for the last term in Eq. (4.78); the one additional fact we need is that

$$\int d\Omega\hat{p}^i\hat{p}^j = \delta^{ij}\frac{4\pi}{3}$$

So the first moment of the Boltzmann equation is

$$\frac{\partial\left(n_{\rm dm}v^j\right)}{\partial t} + 4\frac{da/dt}{a}n_{\rm dm}v^j + \frac{n_{\rm dm}}{a}\frac{\partial\Psi}{\partial x^j} = 0.$$

This equation has no zero-order parts, since the velocity is a first-order quantity. Therefore, we need extract only the first-order terms, which allows us to set $n_{\rm dm}\to n_{\rm dm}^{(0)}$ everywhere. Using the time dependence we found in Eq. (4.75) we arrive at

$$\frac{\partial v^j}{\partial t} + \frac{da/dt}{a}v^j + \frac{1}{a}\frac{\partial\Psi}{\partial x^j} = 0$$

Equations (4.77) and (4.82) are the two equations governing the evolution of the density and the velocity of the cold, dark matter. The momentum conservation equation (4.82) does not have the standard $(\vec{v}\cdot\nabla)\vec{v}$ term, since any term with two factors of v is manifestly second order. An interesting feature of the two equations is generic to this process of integrating the Boltzmann equations to get the fluid equations. Note that the equation for the density depends on the next highest moment, the velocity. This is general: the integrated Boltzmann equation for the lth moment depends on the $l+1$ moment. In principle, then, this process of integrating leads to an infinite heirarchy of equations for the moments of the distribution function. Indeed, we will see that this is one way of solving the Boltzmann equation for the photons, Eq. (4.63), which we have not yet integrated over. One might expect, then, that the velocity equation would depend on the next highest moment, the quadrupole, of the dark matter distribution. Why doesn't it? The answer lies in our assumption that the dark matter is cold. We have explicitly dropped all terms of order $(p/E)^2$ and higher. These terms correspond to the higher moments of the distribution, but since we are dealing with cold, dark matter they are irrelevant. Thus, the set of two equations, (4.77) and (4.82), are a closed set of equations for the cold, dark matter distribution. [6] If we were interested in dark matter particles with much smaller masses, such as massive neutrinos, we would need to keep these higher moments.

Let us finally rewrite Eqs. (4.77) and (4.82) in terms of conformal time η and the Fourier transforms. The density equation becomes

$$\dot{\tilde{\delta}} + ik\tilde{v} + 3\dot{\tilde{\Phi}} = 0$$

where I have assumed that the velocity is irrotational so $\tilde{v}^i = (k^i/k)\,\tilde{v}$. The velocity equation is

$$\dot{\tilde{v}} + \frac{\dot{a}}{a}\tilde{v} + ik\tilde{\Psi} = 0$$

12.4.6 The Boltzmann Equation for Baryons

The final components of the universe which require a set of Boltzmann equations are the electrons and protons. These components are often grouped together and called baryons, nomenclature which is obviously ridiculous (electrons are leptons, not baryons) but nonetheless common.

Electrons and protons are coupled by Coulomb scattering ($e + p \to e + p$). The Coulomb scattering rate is much larger than the expansion rate at all epochs of interest (Exercise 12). This tight coupling forces the electron and proton overdensities to a common value:

$$\frac{\rho_e - \rho_e^{(0)}}{\rho_e^{(0)}} = \frac{\rho_p - \rho_p^{(0)}}{\rho_p^{(0)}} := \delta_b$$

where we bow to common usage with the subscript b. Similarly the velocities of the two species are forced to a common value,

[6] Of course, we still need equations for the gravitational potentials Φ and Ψ. These come from Einstein's equations, as does the zero-order equation for a.

$$\vec{v}_e = \vec{v}_p := \vec{v}_\mathrm{b}$$

We need to derive equations then for δ_b and v_b. The starting point will be the unintegrated equations for electrons and protons:

$$\frac{df_e(\vec{x}, \vec{q}, t)}{dt} = \langle c_{ep} \rangle_{QQ'q'} + \langle c_{e\gamma} \rangle_{pp'q'}$$
$$\frac{df_p(\vec{x}, \vec{Q}, t)}{dt} = \langle c_{ep} \rangle_{qq'Q'} \, .$$

The notation here is more compact, and therefore more deceiving, than that in previous sections. We will need this compactness in what follows, so let's walk through it slowly. First, notice that initial and final momenta for the photon are $\vec{p}$ and $\vec{p}'$; for electron $\vec{q}$ and $\vec{q}'$; and the proton has been assigned $\vec{Q}$ and $\vec{Q}'$. Consider the Compton collision term in the equation for the electron distribution function. I have defined the unintegrated part of the collision term as

$$c_{e\gamma} := (2\pi)^4 \delta^4 \left(p + q - p' - q'\right) \frac{|\mathcal{M}|^2}{8E(p)E\left(p'\right) E_e(q) E_e\left(q'\right)} \left\{ f_e\left(q'\right) f_\gamma\left(p'\right) - f_e(q) f_\gamma(p) \right\}$$

and the angular brackets denote integration over all momenta in the subscripts:

$$\langle (\ldots) \rangle_{pp'q'} := \int \frac{d^3p}{(2\pi)^3} \int \frac{d^3p'}{(2\pi)^3} \int \frac{d^3q'}{(2\pi)^3} (\ldots)$$

The Coulomb collision term is similar, the main difference being the amplitude for the two processes.

In principle, Eq. (4.88) should contain a term accounting for scattering of protons off photons. In practice, though, the cross section for this process is much smaller than for Compton scattering off electrons (in each case the cross section is inversely proportional to the mass squared). So the interactions of the combined electron-proton fluid with the photons is driven by Compton scattering of electrons, and the proton-photon process can be ignored. Also, in principle, we should include ionization and recombination terms in Eqs. (4.87) and (4.88). These however would merely distract us here, so we treat all electrons as ionized.

With this notation defined, we can now proceed and derive equations for δ_b and v_b. First, multiply both sides of Eq. (4.87) by the phase space volume $d^3q/(2\pi)^3$ and integrate. The left-hand side then becomes identical to the left-hand side we derived for dark matter in Eq. (4.73). So we can immediately write

$$\frac{\partial n_e}{\partial t} + \frac{1}{a}\frac{\partial \left(n_e v_{\rm b}^i\right)}{\partial x^i} + 3\left[\frac{da/dt}{a} + \frac{\partial \Phi}{\partial t}\right] n_e = \left\langle c_{ep}\right\rangle_{QQ'q'q} + \left\langle c_{e\gamma}\right\rangle_{pp'q'q}$$

Both terms on the right vanish. The mathematical way to see this is to realize that the integration measure in the first term on the right, e.g., is completely symmetric under the interchange of $Q \leftrightarrow Q'$ and $q \leftrightarrow q'$. Because of the factors of the distribution function, the integrand $-c_{ep}$ - is antisymmetric under this interchange. So the full integral vanishes. More intuitively, the processes we are considering conserve electron number so they certainly cannot contribute to dn/dt. That is, the integral over $f_e\left(q'\right) f_p\left(Q'\right)$ counts the total number of electrons that are produced in Coulomb scattering. But this is obviously equal to the integral over $f_e(q) f_p(Q)$, which counts the number of electrons lost in Coulomb scattering. More generally, any time we multiply an unintegrated collision term by a conserved quantity and then integrate we will get zero.

The perturbed version of Eq. (4.91) equation is therefore identical to Eq. (4.77). Switching to Fourier space and using conformal time leads to

$$\dot{\tilde{\delta}}_b + ik\tilde{v}_{\rm b} + 3\dot{\tilde{\Phi}} = 0$$

The second equation for the baryons is obtained by taking the first moments of both Eqs. (4.87) and (4.88) and adding them together. We did something similar for the dark matter; there we first multiplied by $\vec{p}/E$ and then integrated over all momenta. Here we will take the moments by first multiplying the unintegrated equations by $\vec{q}$ (and $\vec{Q}$ for the protons) instead of by $\vec{q}/E$. Therefore, our results from the dark matter case carry over as long as we multiply them by a factor of m. The left-hand side of the integrated electron equation, for example, will look exactly like the left-hand side of Eq. (4.81) except it will be multiplied by m_e. The proton equation will be multiplied by m_p. Since the proton mass is so much larger than the electron mass, the sum of the two left-hand sides will be dominated by the protons. So, following Eq. (4.81), we have

$$\begin{aligned} m_p\frac{\partial \left(n_{\rm b} v_{\rm b}^j\right)}{\partial t} + 4\frac{da/dt}{a} m_p n_{\rm b} v_{\rm b}^j + \frac{m_p n_{\rm b}}{a}\frac{\partial \Psi}{\partial x^i} \\ = \left\langle c_{ep}\left(q^j + Q^j\right)\right\rangle_{QQ'q'q} + \left\langle c_{e\gamma} q^j\right\rangle_{pp'q'q}. \end{aligned}$$

The right-hand side here is the sum of that from both the electron and proton equations. Both equations have the Coulomb term, so it is weighted by $\vec{q}$ (by which we multiplied the electron equation) $+\vec{Q}$ (from the proton equation). Only the electron equation has the Compton term, so there is only the factor of $\vec{q}$ there. Once again we can use a conservation law, this time conservation of momentum, to argue that the integral of $c_{ep}(\vec{q}+\vec{Q})$ over all momenta vanishes. So dividing both sides by ${}^7\rho_b = m_p n_{\rm b}^{(0)}$, we are left with

$$\frac{\partial v_{\rm b}^j}{\partial t} + \frac{da/dt}{a} v_{\rm b}^j + \frac{1}{a}\frac{\partial \Psi}{\partial x^j} = \frac{1}{\rho_b}\left\langle c_{e\gamma} q^j\right\rangle_{pp'q'q}$$

Here I have used the by now familiar $n_{\rm b}^{(0)} \propto a^{-3}$ scaling to eliminate the $n_{\rm b}^{(0)}$ time derivative and three of the four factors of the da/dt term on the left.

[7] Note that convention here, which I will stick with, that ρ_b is the zero order baryon energy density. The total baryon density is therefore $\rho_b\left(1+\delta_{\rm b}\right)$. The final step is to evaluate the average momentum $\vec{q}$ in Compton scattering. As before, we can use the conservation of total momentum $\vec{q}+\vec{p}$ to argue that

$$\left\langle c_{e\gamma}\vec{q}\right\rangle_{pp'q'q} = -\left\langle c_{e\gamma}\vec{p}\right\rangle_{pp'q'q}$$

Now switch to Fourier space and multiply both sides of Eq. (4.94) by $\hat{k}^j$. Since $\hat{k}\cdot\vec{p} = p\mu$, the right-hand side of Eq. (4.94) becomes $-\langle c_{e\gamma} p\mu\rangle_{pp'q'q}/\rho_b$. We have already computed $\langle c_{e\gamma}\rangle_{p'q'q}$ in Eq. (4.54). We need simply multiply this by $p\mu$ and integrate over all $\vec{p}$ to find the right-hand side of Eq. (4.94):

$$\begin{aligned} -\frac{\langle c_{e\gamma} p\mu\rangle_{pp'q'q}}{\rho_b} &= \frac{n_e\sigma_T}{\rho_b}\int\frac{d^3p}{(2\pi)^3}p^2\frac{\partial f^{(0)}}{\partial p}\mu\left[\tilde{\Theta}_0 - \tilde{\Theta}(\mu) + \tilde{v}_{\rm b}\mu\right] \\ &= \frac{n_e\sigma_T}{\rho_b}\int_0^\infty\frac{dp}{2\pi^2}p^4\frac{\partial f^{(0)}}{\partial p}\int_{-1}^{1}\frac{d\mu}{2}\mu\left[\tilde{\Theta}_0 - \tilde{\Theta}(\mu) + \tilde{v}_{\rm b}\mu\right]. \end{aligned}$$

The integral over p can be done by integrating by parts: it is $-4\rho_\gamma$. The μ-integration over the first and third terms is straightforward (first term vanishes and second gives $v_{\rm b}/3$). The second term is the first moment of the perturbation Θ. Recall that the zeroth moment was defined as Θ_0. It makes sense therefore to define the first moment as

$$\Theta_1 := i\int_{-1}^{1}\frac{d\mu}{2}\mu\Theta(\mu)$$

where the factor of i is a convention and the definition holds in either real or Fourier space.

We now have an expression for the collision term which can be inserted into Eq. (4.94), and after switching to conformal time, we have:

$$\dot{\tilde{v}}_{\rm b} + \frac{\dot{a}}{a}\tilde{v}_{\rm b} + ik\tilde{\Psi} = \dot{\tau}\frac{4\rho_\gamma}{3\rho_b}\left[3i\tilde{\Theta}_1 + \tilde{v}_{\rm b}\right].$$

Why is there a factor of ρ_b in the denominator? That is, since photons scatter primarily off electrons, why does the total baryon density (which is dominated by protons) appear in this velocity equation? Physically, it arises from the fact that moving electrons is difficult because they are tightly coupled to protons via Coulomb scattering. If the proton was infinitely heavy, so $\rho_b \to \infty$, Compton scattering would not change the electron velocity at all; it would not have any impact on the combined proton-electron fluid. We derived Eq. (4.98) by setting $n_e = n_p = n_b$, but it turns out to be valid even if there is an appreciable amount of neutral hydrogen, so that $n_e \neq n_b$. Indeed after recombination, most protons are bound in neutral hydrogen atoms. And even before recombination, a small fraction are in helium atoms or ions. You might be tempted therefore to replace ρ_b in the denominator of Eq. (4.98) by the density of free protons. In fact, though, even neutral hydrogen and helium are tightly coupled to electrons and protons (see Exercise 12), so all baryons should be included. Equation (4.98) quite generally governs the evolution of the baryon velocity.

SUGGESTED READING

In the 1960s a national magazine ran a cartoon showing dozens of businessmen and -women walking the streets of Manhattan looking very important and serious. Thought bubbles over each head revealed their true focus: each was imagining a raucus sex scene. In at least some ways, the Boltzmann equation plays a similar role for physicists and astronomers: no one ever talks about it, but everyone is always thinking about it.

Two excellent astronomy textbooks which do make abundant use of the Boltzmann equation - either explicitly or implicitly - are Radiative Processes in Astrophysics (Rybicki and Lightman) and Galactic Dynamics (Binney and Tremaine). In the context of cosmology, in addition to the

books mentioned in Chapter 1, The Large Scale Structure of the Universe (Peebles), written by the field's pioneer, uses the Boltzmann equation extensively, working in synchronous gauge. If you struggled through Section 4.3, you will be amused (angered?) to see §92 of Peebles' book, where he takes much less space to derive terms due to Compton scattering.

A number of papers deriving the Boltzmann equation for cosmological perturbations are well worth reading. There is the path-breaking work by Lifshitz (1946), Peebles and Yu (1970), and Bond and Szalay (1983). A nice review was written by Efstathiou (1990). The treatment of Compton scattering presented here is based on Dodelson and Jubas (1995). If you were to read just one paper in this area, I would recommend Ma and Bertschinger (1995), which skips many of the steps presented here but has all the relevant formulae and the added virtue of equations in both conformal Newtonian and synchronous gauges. For derivation of the polarization terms in the Boltzmann equations, see Kosowsky (1996). The first paper to present the Boltzmann equation for tensors was Crittenden et al. (1993).

We will not spend too much time in this book on different gauges or on the decomposition of perturbations into scalar, vector, and tensor parts. Two excellent review articles which discuss both of these topics in detail are Mukhanov, Feldman, and Brandenberger (1992) and Kodama and Sasaki (1984). Both of these are also very good on the subjects of the next two chapters, the perturbed Einstein equations and inflation.

D-1.

Derive the fluid equations for the collisionless, one-dimensional harmonic oscillator by taking the moments of Eq. (4.6). The relevant quantities are the number density and the velocity defined as integrals over the distribution function:

$$n := \int_{-\infty}^{\infty} \frac{dp}{2\pi} f \quad ; \quad v := \frac{1}{n} \int_{-\infty}^{\infty} \frac{dp}{2\pi} \frac{p}{m} f$$

D-2.

The metric in a synchronous gauge is

$$g_{00}(\vec{x}, t) = -1$$

$$g_{0i}(\vec{x}, t) = 0$$
$$g_{ij}(\vec{x}, t) = a^2 \left[\delta_{ij} + h_{ij}\right],$$

with perturbations

$$h_{ij} = \begin{pmatrix} -2\tilde{\eta} & 0 & 0 \\ 0 & -2\tilde{\eta} & 0 \\ 0 & 0 & h + 4\tilde{\eta} \end{pmatrix}$$

where $\tilde{\eta}$ has nothing to do with conformal time. Here I have chosen the wavevector $\vec{k}$ to lie in the $\hat{z}$ direction. Derive the equivalent of Eq. (4.63) in synchronous gauge:

$$\dot{\Theta} + ik\mu\Theta - \frac{\mu^2 \dot{h}}{2} - \mathcal{P}_2(\mu)\dot{\tilde{\eta}} = -\dot{\tau}\left[\Theta_0 - \Theta + \mu v\right].$$

D-3.

Start from the zero-order unintegrated Boltzmann equation (4.37). Integrate this equation over all momenta to show that the number density falls off as a^3. In the course of this, you will have justified the left-hand side of Eq. (3.1).

D-4.

Show that the Pauli blocking factor $1 - f_e$ can be set to 1 for all epochs of interest. First find f_e as a function of temperature and number density using the results/approximations of Section 3.1 (i.e. assume that $T_e \ll m_e$). Then, show that as long as the temperature is much less than m_e, f_e is much less than 1.

D-5.

Suppose we started this chapter by writing

$$\frac{df}{d\lambda} = C'$$

Change from this form to the one in Eq. (4.1) (with df/dt) on the left. How is the collision term here, C' related to C in Eq. (4.1)? Argue that the first-order perturbations in the factor relating the two collision terms can be dropped since the collision terms themselves are first-order.

D-6.

Derive Eq. (4.68), the unintegrated Boltzmann equation for a massive particle.

D-7.

Account for the angular dependence of Compton scattering. Start from Eq. (4.49) but instead of assuming the amplitude is constant, take

$$|\mathcal{M}|^2 = 6\pi\sigma_T m_e^2 \left(1 + \cos^2\left[\hat{p} \cdot \hat{p}'\right]\right).$$

Show that correctly accounting for the angular dependence introduces the factor of $(1/2)\mathcal{P}_2(\mu)\Theta_2$ presented in Eq. (4.100).

D-8.

Show that the temperature of nonrelativistic matter scales as a^{-2} in the absence of interactions. Start from the zero-order part of Eq. (4.68) and assume a form $f_{\rm dm} \propto e^{-E/T} = e^{-p^2/2mT}$. Note that this argument does not apply to electrons and protons: as long as they are coupled to the photons, their temperature scales as a^{-1}.

D-9.

In Exercise 8, you showed that a thermal distribution of nonrelativistic particles which do not interact has a temperature which scales as a^{-2}, as opposed to that of relativistic particles which we have seen scales as a^{-1}. So $T_{\rm dm} \propto T^2$. Fix the normalization by requiring $T_{\rm dm} = T$ when each is equal to the dark matter mass. Estimate the typical thermal velocity of a dark matter particle with mass equal to 100GeV when the photon temperature is 1eV.

D-10.

The purpose of this problem is to derive the results of Section 2.3 using the Boltzmann equation. Multiply the zero-order part of Eq. (4.68) by $d^3pE(p)/(2\pi)^3$ and integrate. Show that the resulting equation is identical to Eq. (2.55).

D-11.

Consider the effect of a massive neutrino on the evolution equations. (a) Start from the Boltzmann equation for a massive particle (4.68). Turn it into an equation for $\mathcal{N}$, the perturbation to the massive neutrino distribution function. Use the fact that to first order the neutrino distribution function is

$$f_\nu = f_\nu^{(0)} + \frac{\partial f_\nu^{(0)}}{\partial T_\nu} T_\nu \mathcal{N}$$

where $f_\nu^{(0)} = \left[e^{p/T_\nu} + 1\right]^{-1}$. Express the final equation in Fourier space using conformal time as the evolution variable.

(b) Recent experiments measuring the atmospheric neutrino flux suggest that the mass of the tau neutrino is 0.07eV, far larger than either the electron or muon neutrino. Find the contribution of a $0.07 - \text{eV}$ neutrino to the energy density today. You may assume it is nonrelativistic.

(c) Consider the following two scenarios. Each has energy density equal to the critical density divided up between only two components: a cold, dark matter particle and a neutrino. The neutrino in each case has the standard abundance and temperature. The only difference between the two scenarios is in one the neutrino is massless while in the other it has a mass of 0.07eV. Plot the energy density as a function of scale factor in each of the these scenarios. Note that they should agree very early on (in each case there is only a relativistic neutrino early on) and very late. The only difference comes in the middle.

D-12.

Show that ordinary matter is tightly coupled during the relevant epochs in the early universe.

(a) Compute the ratio of the Coulomb scattering rate to the Hubble rate. You may assume that all electrons and protons are ionized.

(b) Show that the rate for neutral hydrogen to scatter off ionized protons is always much larger than the expansion rate even when the ionization fraction is on the order of 10^{-1}.

D-13.

Consider tensor perturbations to the metric. These do not perturb $g_{00}(= -1)$ or $g_{0i}(= 0)$. However, the spatial part of the metric is now

$$g_{ij} = a^2 \begin{pmatrix} 1 + h_+ & h_\times & 0 \\ h_\times & 1 - h_+ & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Derive the equation for the photon distribution function in the presence of tensor perturbations. Unlike scalar perturbations. tensor perturbations induce an azimuthal dependence in Θ_l, so decompose the anisotropy due to tensors into

$$\Theta^T(k, \mu, \phi) = \Theta_+^T(k, \mu)\left(1 - \mu^2\right)\cos(2\phi) + \Theta_\times^T(k, \mu)\left(1 - \mu^2\right)\sin(2\phi).$$

Show that both the $+$ and the $\times$ component satisfy

$$\frac{d\Theta_i^T}{d\eta} + ik\mu\Theta_i^T + \frac{1}{2}\frac{dh_i}{d\eta} = \dot{\tau}\left[\Theta_i^T - \frac{1}{10}\Theta_{i,0}^T - \frac{1}{7}\Theta_{i,2}^T - \frac{3}{70}\Theta_{i,4}^T\right]$$

where i stands for either $\times$ or $+$, and the moments are defined as were the scalar moments, in Eq. (4.99).

12.5 Einstein Equations

The previous chapter set up the formalism to describe how perturbations in the gravitational field affect particle distributions. This formalism led to the set of equations (4.100) -(4.107). We need to supplement these equations with an account of how the perturbations to the particle distributions affect the gravitational field. For this, we need the Einstein equations of general relativity. The calculation detailed in this chapter expands the Einstein equations perturbatively around the zeroorder homogeneous solution. Far from being subtle or complex as one might expect from general relativity's reputation, this calculation is completely straightforward, although a bit long. Still, working through it is a "must-do-once" exercise, so the steps are presented in some detail.

12.5.1 The Perturbed Ricci Tensor and Scalar

The fundamental equation of general relativity (2.30) is a 4D tensor equation, so in principle it represents 16 separate equations. However, since both sides of the equation are symmetric tensors, only 10 of these are distinct. We are interested though in only two of the 10, since the metric we are focusing on has only two independent functions, Φ and Ψ.

Evaluating the left-hand side of the Einstein equation requires three pre-steps:

- Compute the Christoffel symbols, $\Gamma^{\mu}{}_{\alpha\beta}$, for the perturbed metric of Eq. (4.9).
- From these, form the Ricci tensor, $R_{\mu\nu}$, using Eq. (2.31).
- Contract the Ricci tensor to form the Ricci scalar, $\mathcal{R} := g^{\mu\nu}R_{\mu\nu}$.

Note that, unfortunately, even if we are interested in only several components of the Einstein equations, we need to compute all the elements of the Ricci tensor. For all the components of the Einstein tensor $G_{\mu\nu} := R_{\mu\nu} - g_{\mu\nu}\mathcal{R}/2$ depend on the Ricci scalar, which depends on all elements of $R_{\mu\nu}$.

Christoffel Symbols

We have already computed the zero-order Christoffel symbols in Eqs. (2.22) and (2.23). Now we need to look at the first-order terms, those that are linear in Φ and/or Ψ. First let us consider $\Gamma^0_{\mu\nu}$, which by definition is

$$\Gamma^0_{\mu\nu} = \frac{1}{2}g^{0\alpha}\left[g_{\alpha\mu,\nu} + g_{\alpha\nu,\mu} - g_{\mu\nu,\alpha}\right]$$

where again $_{,\alpha}$ means the derivative with respect to x^α. The only nonzero component of $g^{0\alpha}$ is the time component, [1] which is the inverse of $g_{00} = -1 - 2\Psi$. So, to first-order in the perturbations, $g^{00} = -1 + 2\Psi$, and

$$\Gamma^0_{\mu\nu} = \frac{-1+2\Psi}{2}\left[g_{0\mu,\nu} + g_{0\nu,\mu} - g_{\mu\nu,0}\right].$$

Take each component in turn: first the one with $\mu = \nu = 0$. Each of the terms in square brackets is identical, so the brackets give $g_{00,0} = -2\Psi_{,0}$. Since we are interested only in first-order terms the factor of 2Ψ out in front can be dropped and we are left with

$$\Gamma^0_{00} = \Psi_{,0}.$$

The next possibility is that one of the indices μ or ν is spatial and the other time. It doesn't matter which, since the Christoffel symbol is symmetric in its lower indices. In this case, only one of terms in brackets in Eq. (5.2) is nonzero, $g_{00,i} = -2\Psi_{,i}$. Once again since this is first-order, we can drop the factor of 2Ψ in front, leading to

$$\Gamma^0_{0i} = \Gamma^0_{i0} = \Psi_{,i} = ik_i\Psi$$

The final equality here moves to Fourier space, where we will stay from now on. Recall our convention of not using s for Fourier transformed variables: Ψ on the far right is really $\tilde{\Psi}$.

Finally, if both lower indices in Eq. (5.2) are spatial, the first two terms in brackets vanish since $g_{0i} = 0$ and only the last term survives, leaving

$$\Gamma^0_{ij} = \frac{1-2\Psi}{2}\frac{\partial}{\partial t}\left[\delta_{ij}a^2(1+2\Phi)\right]$$

There is a zero-order term here, the one we computed in Eq. (2.22), and three first-order terms:

$$\Gamma^0_{ij} = \delta_{ij}a^2\left[H + 2H(\Phi-\Psi) + \Phi_{,0}\right]$$

with $H = (da/dt)/a$.

Computing the Christoffel symbols, $\Gamma^i_{\mu\nu}$, will be left as an exercise. They are

$$\Gamma^i_{00} = \frac{ik^i}{a^2}\Psi$$

[1] We will do the calculation with $x^0 = t$, not conformal time. Therefore, $\Psi_{,0}$ for example means derivative with respect to time. Since our convention is now $\dot{\Psi} := \partial\Psi/\partial\eta$, $\Psi_{,0} = \dot{\Psi}/a$.

$$\Gamma^i_{j0} = \Gamma^i{}_{jj} = \delta_{ij}\left(H + \Phi_{,0}\right)$$
$$\Gamma^i{}_{jk} = i\Phi\left[\delta_{ij}k_k + \delta_{ik}k_j - \delta_{jk}k_i\right].$$

Note that the only nonvanishing zero-order component is $\Gamma^i{}_{j0}$, in agreement with Eq. (2.23). Also remember that both δ_{ij} and the 3 -vector k_i live in Euclidean space, so we can freely interchange their upper and lower indices.

Ricci Tensor

The Ricci tensor is most easily expressed in terms of the Christoffel symbols, as in Eq. (2.31). First, consider the time-time component:

$$R_{00} = \Gamma^\alpha_{00,\alpha} - \Gamma^\alpha_{0\alpha,0} + \Gamma^\alpha_{\beta\alpha}\Gamma^\beta_{00} - \Gamma^\alpha_{\beta 0}\Gamma^\beta_{0\alpha}.$$

All of these terms contribute at first-order. One simplification comes from considering the $\alpha = 0$ part of all these terms. The first and second terms are equal and opposite to each other as are the last two. So the sum over the index α contributes only when α is spatial. Let's consider each of the terms one by one.

- The first is

$$\Gamma^i_{00,i} = \frac{-k^2}{a^2}\Psi$$

using the first of equations (5.7).

- The second term in Eq. (5.8) is

$$-\Gamma^i_{0i,0} = -3\left(\frac{d^2a/dt^2}{a} - H^2 + \Phi,00\right)$$

using the second of equations (5.7). The factor of 3 in front comes from the implicit sum in δ_{ii}.

- The next term is $\Gamma^i{}_{i\beta}\Gamma^\beta{}_{00}$. Note that $\Gamma^\beta{}_{00}$ is first order no matter what β is, so we need keep only the zero-order part of $\Gamma^i_{i\beta}$. However, the last of equations (5.7) shows that $\Gamma^i{}_{i\beta}$ is first-order unless $\beta = 0$. So to first-order,

$$\begin{aligned}\Gamma^i{}_{i\beta}\Gamma^\beta{}_{00} &= \Gamma^i{}_{i0}\Gamma^0{}_{00}\\ &= 3H\Psi_{,0}.\end{aligned}$$

- Finally the last term is $-\Gamma^i{}_{\beta 0}\Gamma^\beta{}_{0i}$. In this case, if $\beta = 0$ both Γ 's are first-order, so their product is second-order and can be neglected. Therefore, only spatial β need be considered, leading to

$$\begin{aligned}-\Gamma^i{}_{30}\Gamma^\beta{}_{0i} &= -\Gamma^i{}_{j0}\Gamma^j{}_{0i}\\ &= -3\left(H^2 + 2H\Phi_{,0}\right).\end{aligned}$$

Collecting these four sets of terms gives

$$R_{00} = -3\frac{d^2a/dt^2}{a} - \frac{k^2}{a^2}\Psi - 3\Phi_{.00} + 3H\left(\Psi_{.0} - 2\Phi_{.0}\right).$$

Note that the zero-order term agrees with Eq. (2.34).
The space-space part of the Ricci tensor is left as an exercise. It is

$$\begin{aligned}R_{ij} =&\delta_{ij}\left[\left(2a^2H^2 + a\frac{d^2a}{dt^2}\right)(1 + 2\Phi - 2\Psi)\right.\\ &\left.+a^2H\left(6\Phi_{,0} - \Psi_{,0}\right) + a^2\Phi_{,00} + k^2\Phi\right] + k_ik_j(\Phi + \Psi).\end{aligned}$$

We can now contract the indices on the Ricci tensor and find the Ricci scalar:

$$\begin{aligned}\mathcal{R} :=&g^{\mu\nu}R_{\mu\nu} = g^{00}R_{00} + g^{ij}R_{ij}\\ =&[-1 + 2\Psi]\left[-3\frac{d^2a/dt^2}{a} - \frac{k^2}{a^2}\Psi - 3\Phi_{.00} + 3H\left(\Psi_{,0} - 2\Phi_{,0}\right)\right]\\ &+\left[\frac{1 - 2\Phi}{a^2}\right]\left[3\left\{\left(2a^2H^2 + a\frac{d^2a}{dt^2}\right)(1 + 2\Phi - 2\Psi)\right.\right.\\ &\left.\left.+a^2H\left(6\Phi_{,0} - \Psi_{,0}\right) + a^2\Phi_{.00} + k^2\Phi\right\} + k^2(\Phi + \Psi)\right].\end{aligned}$$

First let us check the zero-order part of $\mathcal{R}$. Combining terms, we find that it is $6\left(H^2 + \frac{d^2a/dt^2}{a}\right)$, in agreement with Eq. (2.37). To get the first-order part, $\delta\mathcal{R}$, we go through the by-now-familiar routine of multiplying terms, keeping only those first-order in Φ and Ψ. This gives

$$\begin{aligned}\delta\mathcal{R} =& -6\Psi\frac{d^2a/dt^2}{a} + \frac{k^2}{a^2}\Psi + 3\Phi_{,00} - 3H\left(\Psi_{,0} - 2\Phi_{,0}\right)\\ & - 6\Psi\left(2H^2 + \frac{d^2a/dt^2}{a}\right) + 3H\left(6\Phi_{.0} - \Psi_{,0}\right)\\ & + 3\Phi_{,00} + 4\frac{k^2\Phi}{a^2} + \frac{k^2\Psi}{a^2},\end{aligned}$$

where the first line contains the terms from R_{00} (the second line in Eq. (5.15)) and the last two from R_{ij} (the last two lines in Eq. (5.15)). Combining these leads to

$$\begin{aligned}\delta\mathcal{R} =& -12\Psi\left(H^2 + \frac{d^2a/dt^2}{a}\right) + \frac{2k^2}{a^2}\Psi + 6\Phi_{,00}\\ & - 6H\left(\Psi_{,0} - 4\Phi_{,0}\right) + 4\frac{k^2\Phi}{a^2}.\end{aligned}$$

12.5.2 Two Components of the Einstein Equations

We can now derive the evolution equations for Φ and Ψ, the perturbations to the Friedmann-Robertson-Walker metric. There is some freedom here because the Einstein equations

$$G^\mu_\nu = 8\pi G T^\mu_\nu$$

have 10 components and we need only two. All of the other eight components will either be zero at first-order or be redundant. [2]

The first component we will use is the time-time component. Thus we need to evaluate

$$\begin{aligned}G^0_0 &= g^{00}\left[R_{00} - \frac{1}{2}g_{00}\mathcal{R}\right]\\ &= (-1+2\Psi)R_{00} - \frac{\mathcal{R}}{2}\end{aligned}$$

Here one of the indices has been raised by multiplying G_{00} by g^{00} (recall that g^{0i} vanish). This turns out to simplify the energy-momentum tensor (see Exercise 3) which sources the Einstein tensor. Also note that the second line follows from the first since $g^{00}g_{00} = 1$. We have computed the time-time component of the Ricci tensor (Eq. (5.13)) and the perturbed Ricci scalar (Eq. (5.17)), so the first-order part of the time-time component of the Einstein tensor is

$$\begin{aligned}\delta G^0_0 =& -6\Psi\frac{d^2a/dt^2}{a} + \frac{k^2}{a^2}\Psi + 3\Phi_{,00} - 3H\left(\Psi_{,0} - 2\Phi_{,0}\right)\\ & + 6\Psi\left(H^2 + \frac{d^2a/dt^2}{a}\right) - \frac{k^2}{a^2}\Psi - 3\Phi_{,00}\\ & + 3H\left(\Psi_{.0} - 4\Phi_{,0}\right) - 2\frac{k^2\Phi}{a^2}\end{aligned}$$

Combining terms leads to

$$\delta G^0_0 = -6H\Phi_{.0} + 6\Psi H^2 - 2\frac{k^2\Phi}{a^2}$$

Einstein's equation equates G^0_0 with $8\pi G T^0_0$ where $T_{\mu\nu}$ is the energymomentum tensor. To complete our derivation of the first evolution equation for Φ and Ψ, therefore, we need to compute the first-order part of the source term, T^0_0. Recall from Section 2.3 that $-T^0_0$ is the energy density of all the particles

[2] This is true for scalar perturbations. When we come to conside tensor perturbations, some of the other components will be useful. in the universe, and that the contribution from each species is an integral over the distribution function (Eq. (2.59)),

$$T_0^0(\vec{x},t) = -\sum_{\text{all species } i} g_i \int \frac{d^3p}{(2\pi)^3} E_i(p) f_i(\vec{p},\vec{x},t).$$

Recall also that g_i is the spin degeneracy of the species (has nothing to do with the metric); $E_i = \sqrt{p^2+m_i^2}$ is the energy of a particle with momentum p and mass m_i; and f_i is the distribution function. In Section 2.3, we considered the zero-order distributions of the smooth universe. To get the first-order part of the energy-momentum tensor, we must naturally consider the first-order part of the distribution functions, i.e. the perturbation variables we defined in Chapter 4 for the photons, neutrinos, dark matter, and baryons. This is easiest for the dark matter and baryons. For we defined the right-hand side as $-\rho_i\,(1+\delta_i)$ where i labels either dark matter or baryons. For photons, a little more care is required. Using the definition of Θ in Eq. (4.35), we have

$$T_0^0 = -2\int \frac{d^3p}{(2\pi)^3} p\left[f^{(0)} - p\frac{\partial f^{(0)}}{\partial p}\Theta\right] \qquad \text{(photons)}.$$

The first term here is just the zero-order photon energy density, ρ_γ. To reduce the second term, we first do the angular integral, which picks out the monopole Θ_0 from Θ. Then, we do the radial integral by parts. This changes the sign and introduces a factor of 4 since $\partial p^4/\partial p = 4p^3$, leading to

$$T_0^0 = -\rho_\gamma\,[1+4\Theta_0] \qquad \text{(photons)}.$$

The factor of 4 here is obvious in retrospect. The perturbation variable Θ is the fractional temperature change, while the energy momentum tensor is interested in the perturbed energy density, $\delta\rho$. We should have expected that since $\rho \propto T^4$, $\delta\rho/\rho = 4\delta T/T$. In any event, it falls out of the algebra. I harp on it only to warn those who turn to the literature that authors are virtually split between those who define Θ as $\delta\rho/\rho$ and those who opt for the convention we use here. Finally, note that the first-order contribution from massless neutrinos is identical in form,

$$T_0^0 = -\rho_\nu\,[1+4\mathcal{N}_0] \qquad \text{(neutrinos)}\ .$$

In principle, we should also include a term for the perturbation to the dark energy. In practice, though, most models of the dark energy predict that (i) it should be smooth and (ii) it should be important only very recently. Both of these features are inherent in the cosmological constant model for example. There are some models which deviate from one or both of these conditions, but for the most part we are justified in neglecting the dark energy as a source of perturbations to the metric. Returning to Einstein's equation, we equate Eq. (5.21) with $8\pi G$ times the firstorder part of the time-time component of the energy-momentum tensor. Dividing both sides by 2 leads to

$$-3H\Phi_{,0} + 3\Psi H^2 - \frac{k^2\Phi}{a^2} = -4\pi G\left[\rho_{\rm dm}\delta + \rho_b\delta_{\rm b} + 4\rho_\gamma\Theta_0 + 4\rho_\nu\mathcal{N}_0\right]$$

It is again useful to write the equation in terms of conformal time. This introduces an extra factor of $1/a$ every time a time derivative appears, so

$$k^2\Phi + 3\frac{\dot{a}}{a}\left(\dot{\Phi} - \Psi\frac{\dot{a}}{a}\right) = 4\pi G a^2\left[\rho_{\rm dm}\delta + \rho_b\delta_{\rm b} + 4\rho_\gamma\Theta_0 + 4\rho_\nu\mathcal{N}_0\right]$$

This is our first evolution equation for Φ and Ψ. In the limit of no expansion ($a =$ constant), Eq. (5.27) reduces to the ordinary Poisson equation for gravity (in Fourier space). The left-hand side is $-\nabla^2\Phi$ while the right-hand side is $4\pi G\delta\rho$. The terms proportional to $\dot{a}$ account for expansion and are typically important for modes with wavelengths ($\sim a/k$) comparable to, or larger than, the Hubble radius, H^{-1}. We need this general relativistic expression when we consider the evolution of parturbations, because almost all modes of interest today used to have wavelengths larger than the Hubble radius. More on this in Chapter 6.

We now obtain a second evolution equation for Φ and Ψ. Since we have already dealt with the time-time component of the Einstein tensor, let's focus on the spatial part of G^μ_ν,

$$G^i{}_j = g^{ik}\left[R_{kj} - \frac{g_{kj}}{2}\mathcal{R}\right] = \frac{\delta^{ik}(1-2\Phi)}{a^2}R_{kj} - \frac{\delta_{ij}}{2}\mathcal{R}$$

From Eq. (5.14), we see that most of the terms in R_{kj} are proportional to δ_{kj}. When contracted with δ^{ik} this will lead to a host of terms proportional to δ_{ij}, in addition to the last term here, the one proportional to $\mathcal{R}$. Therefore,

$$G^i{}_j = A\delta_{ij} + \frac{k_ik_j(\Phi+\Psi)}{a^2}$$

where A has close to a dozen terms which we would rather not write down. Since all of these terms are proportional to δ_{ij} they all contribute to the trace of $G^i{}_j$. To avoid dealing with these terms, consider the longitudinal, traceless part of $G^i{}_j$, which can be extracted by contracting $G^i{}_j$ with $\hat{k}_i\hat{k}^j - (1/3)\delta^j_i$, a projection operator. That is, it picks out the piece which is longitudinal, traceless and only that part (Exercise 4). This projection operator kills all terms proportional to δ_{ij}, leaving only

$$\left(\hat{k}_i\hat{k}^j - (1/3)\delta^j_i\right)G^i{}_j = \left(\hat{k}_i\hat{k}^j - (1/3)\delta^j_i\right)\left(\frac{k^ik_j(\Phi+\Psi)}{a^2}\right) = \frac{2}{3a^2}k^2(\Phi+\Psi).$$

This is to be equayed with the longitudinal, traceless part of the energymomentum tensor, extracted in the same fashion:

$$\left(\hat{k}_i\hat{k}^j - (1/3)\delta^j_i\right)T^i{}_j = \sum_{\text{all species i}} g_i\int\frac{d^3p}{(2\pi)^3}\frac{p^2\mu^2 - (1/3)p^2}{E_i(p)}f_i(\vec{p}).$$

We can immediately recognize the combination $\mu^2 - 1/3$ as proportional to the second Legendre polynomial, more precisely equal to $(2/3)\mathcal{P}_2(\mu)$. Therefore, the integral picks out the quadrupole part of the distribution. Of course the zero-order part of the distribution function has no quadrupole, so the source term is first order, proportional to Θ_2, which is nonzero only for neutrinos and photons. The integral in Eq. (5.31) for photons is

$$\begin{aligned}-2\int\frac{dpp^2}{2\pi^2}p^2\frac{\partial f^{(0)}}{\partial p}\int_{-1}^{1}\frac{d\mu}{2}\frac{2\mathcal{P}_2(\mu)}{3}\Theta(\mu) &= 2\frac{2\Theta_2}{3}\int\frac{dpp^2}{2\pi^2}p^2\frac{\partial f^{(0)}}{\partial p}\\ &= -\frac{8\rho^{(0)}\Theta_2}{3}\end{aligned}$$

where the first equality follows from the definition of the quadrupole and the second from an integration by parts. This component of the energy-momentum tensor is called the anisotropic stress. Nonrelativistic particles, such as baryons and dark matter, do not contribute anisotropic stress.

For the second Einstein equation, we therefore equate Eq. (5.30) with $8\pi G$ times the photon and neutrino anisotropic stresses:

$$k^2(\Phi + \Psi) = -32\pi G a^2 \left[\rho_\gamma \Theta_2 + \rho_\nu \mathcal{N}_2\right].$$

That is, the two gravitational potentials are equal and opposite unless the photons or neutrinos have appreciable quadrupole moments. In practice, the photons' quadrupole contributes little to this sum, because it is very small during the time when it has appreciable energy density. [Recall the argument after Eq. (4.54).] Only the collisionless neutrino has an appreciable quadrupole moment early on when radiation dominates the universe.

12.5.3 Tensor Perturbations

Until now, we have focused almost exclusively on scalar perturbations to the homogeneous FRW universe. Formally, this means that the perturbations $\Phi(\vec{x}, t)$ and $\Psi(\vec{x}, t)$ transform as scalars as $\vec{x} \to \vec{x}'$; i.e., they remain unchanged under a spatial coordinate transformation. This focus is reasonable: as we have seen, scalar perturbations to the metric are sourced by density fluctuations and vice versa. For the most part, the density fluctuations that led to the structure of the universe are our primary interest.

Nonetheless, many theories of structure formation produce, in addition to scalar fluctuations, tensor perturbations to the metric. These are potentially detectable because they produce observable distortions in the CMB, especially on large scales. Sprinkled throughout the book, therefore, are exercises (with hints) relating to tensor perturbations. The tools needed to study these are precisely those we crafted when studying scalar perturbations. For the most part, therefore, I regard the evolution of tensor perturbations as one rather large homework problem, one which introduces no new physics.

One question which naturally arises when working out these exercises, though, is why consider scalar and tensor perturbations separately? To answer this question (and to alleviate the homework load) this section derives Einstein's equations for tensor perturbations. We will see that scalar and tensor perturbations decouple; that is, they evolve completely independently. So the presence of tensor perturbations does not affect the scalars and vise versa. Contrast this with Φ and Ψ. We have just shown that they are quite tightly coupled to each other. It is impossible to learn about Φ without also solving for Ψ. The decoupling of scalars and tensors is a manifestation of the decomposition theorem. Needless to say, it is much more instructive to work out an example of this theorem than to prove it abstractly. Incidentally, as you would expect, the same theorem can be applied to vector perturbations. These too are produced by some early-universe models (but not as ubiquitously as tensors) and can be treated completely independently.

Tensor perturbations can be characterized by a metric with $g_{00} = -1$, zero space-time components $g_{0i} = 0$, and spatial elements

$$g_{ij} = a^2 \begin{pmatrix} 1 + h_+ & h_\times & 0 \\ h_\times & 1 - h_+ & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

That is, the perturbations to the metric are described by two functions, $h_+$and $h_\times$, assumed small. For definiteness, I have chosen the perturbations to be in the $x - y$ plane. This corresponds to an implicit choice of axes; in particular, it corresponds to choosing the z-axis to be in the direction of the wavevector, $\vec{k}$. More generally, h_+ and $h_\times$are two components of a divergenceless, traceless, symmetric tensor. If this perturbation tensor is written as $\mathcal{H}_{ij}$, divergenceless means that $k^i \mathcal{H}_{ij} = k^j \mathcal{H}_{ij} = 0$. This is clearly satisfied by Eq. (5.34) since there are no components in the $\hat{k} = \hat{z}$ direction. Tracelessness is also satisfied since the sum of the perturbations along the diagonal vanishes.

Once the metric in Eq. (5.34) has been written down, we can blast away and derive the Einstein equations. Once again the derivation proceeds in three steps: (i) Christoffel symbols, (ii) Ricci tensor, and (iii) Ricci scalar.

Christoffel Symbols for Tensor Perturbations

First consider $\Gamma^0_{\alpha\beta}$. The metric we are considering in Eq. (5.34) has constant g_{00} and vanishing g_{0i}. Recall that the Christoffel symbol is a sum of derivatives of the metric. The only terms that will be nonzero are those which involve derivatives of the spatial part of the metric, $g_{ij,\alpha}$. Therefore, we can immediately argue that

$$\Gamma^0{}_{00} = \Gamma^0_{i0} = 0$$

The term with two lower spatial indices is

$$\begin{aligned}\Gamma^0_{ij} &= -\frac{g^{00}}{2} g_{ij,0} \\ &= \frac{1}{2} g_{ij,0}.\end{aligned}$$

Let's use the notation mentioned earlier: the 3D matrix $\mathcal{H}_{ij}$ contains the perturbations, which in this basis (with $\hat{k}$ in the $\hat{z}$ direction) is equal to

$$\mathcal{H}_{ij} = \begin{pmatrix} h_+ & h_\times & 0 \\ h_\times & -h_+ & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

so that $g_{ij} = a^2 (\delta_{ij} + \mathcal{H}_{ij})$. Therefore,

$$g_{ij,0} = 2H g_{ij} + a^2 \mathcal{H}_{ij,0}$$

where the Hubble rate H is not to be confused with tensor perturbations $\mathcal{H}$. The first nonzero Christoffel symbol is therefore

$$\Gamma^0_{ij} = H g_{ij} + \frac{a^2 \mathcal{H}_{ij,0}}{2}$$

When both lower indices on Γ are 0, the Christoffel symbol vanishes. The two remaining components are $\Gamma^i{}_{0j}$ and $\Gamma^i{}_{jk}$. The former is

$$\Gamma^i_{0j} = \frac{g^{ik}}{2} g_{jk,0}$$

The time derivative of g_{jk} acts on both the scale factor and on the perturbations $h_{+,x}$, as in Eq. (5.38), so

$$\Gamma^i{}_{0j} = \frac{g^{ik}}{2} \left[2H g_{jk} + a^2 \mathcal{H}_{jk,0} \right]$$

But $g^{ik} g_{jk} = \delta_{ij}$, so the first term here is simply $\delta_{ij} H$. To get the second, we can set $g^{jk} = \delta_{jk}/a^2$ (i.e., neglect first-order terms) since it multiplies the first-order $\mathcal{H}$. So,

$$\Gamma^i_{0j} = H \delta_{ij} + \frac{1}{2} \mathcal{H}_{ij,0},$$

where I have used the fact that $\mathcal{H}_{ij}$ is symmetric.

The last Christoffel symbol we need is Γ^i_{jk}. In Exercise 7 you will show that

$$\Gamma^i{}_{jk} = \frac{i}{2} \left[k_k \mathcal{H}_{ij} + k_j \mathcal{H}_{ik} - k_i \mathcal{H}_{jk} \right]$$

Ricci Tensor for Tensor Perturbations

Following the same steps as in the scalar perturbation case, we now combine these Christoffel symbols to form the Ricci tensor. First we compute the time-time component of the Ricci tensor:

$$R_{00} = \Gamma^{\alpha}_{00,\alpha} - \Gamma^{\alpha}_{0\alpha,0} + \Gamma^{\alpha}_{\beta\alpha}\Gamma^{\beta}_{00} - \Gamma^{\alpha}_{\beta 0}\Gamma^{\beta}{}_{0\alpha}.$$

We have shown that the Christoffel symbol vanishes for tensor perturbations when the two lower indices are time-time. Therefore, the first and third terms here are zero. Using the same argument, the indices α and β in the second and fourth terms must be spatial, so

$$R_{00} = -\Gamma^{i}_{0i,0} - \Gamma^{i}{}_{j0}\Gamma^{j}{}_{0i}.$$

Using Eq. (5.42) for Γ^{i}_{j0} which is the only element appearing, we find that

$$\begin{aligned} R_{00} = &- 3\frac{dH}{dt} - \frac{1}{2}\mathcal{H}_{ii,00} \\ &- \left(H\delta_{ij} + \frac{1}{2}\mathcal{H}_{ij,0}\right)\left(H\delta_{ij} + \frac{1}{2}\mathcal{H}_{ij,0}\right). \end{aligned}$$

On the first line, the trace $\mathcal{H}_{ii}$ vanishes since h_{+}appears in the metric with opposite signs along the diagonal. Expanding the second line out to first-order leads to a similar cancellation: $\mathcal{H}_{ij}$ is multiplied by δ_{ij}, so there are no first-order terms. The zero-order terms combine to form

$$R_{00} = -3\frac{d^2a/dt^2}{a}$$

an equation in which we are by now quite confident since this is the third time we have derived it (see equations (2.34) and (5.13)). Of course the big news here is not that we have correctly derived the zero-order term, but rather that tensor perturbations do not appear at first-order in R_{00}. Looking ahead, we will soon see that the Ricci scalar also has no tensor contribution (even though R_{ij} does). Therefore, we can anticipate that the time-time component of Einstein's equations contains no tensor perturbations. This is important for it tells us that density perturbations - which form the right hand side of the time-time component as shown in Eq. (5.26) - do not induce any tensor perturbations. We are beginning therefore to get a glimmer of the decomposition theorem. Density perturbations and scalar perturbations to the metric are coupled; indeed their names are often used as synonyms. Tensor perturbations, however, are decoupled from these and evolve on their own.

The spatial components of the Ricci tensor do depend on the tensor perturbation variables. We now turn to

$$R_{ij} = \Gamma^{\alpha}_{ij,\alpha} - \Gamma^{\alpha}_{i\alpha,j} + \Gamma^{\alpha}_{\alpha\beta}\Gamma^{\beta}_{ij} - \Gamma^{\alpha}_{\beta j}\Gamma^{\beta}_{i\alpha}.$$

Let's consider the first two terms together. Expanding out leads to

$$\Gamma^{\alpha}_{ij,\alpha} - \Gamma^{\alpha}_{i\alpha,j} = \Gamma^{0}_{ij.0} + \Gamma^{k}_{ij,k} - \Gamma^{k}_{ik,j}$$

since $\alpha = 0$ does not contribute in $\Gamma^{\alpha}_{i\alpha.j}$ because of Eq. (5.35). The hardest (i.e., longest) term here is the first, which involves multiple time derivatives. Let's postpone its calculation by recalling that $\Gamma^{0}{}_{ij} = g_{ij.0}/2$ so that the first term can be written in shorthand as $g_{ij,00}/2$. The last term in Eq. (5.49) vanishes since $\Gamma^{k}_{ik} = 0$ for tensor perturbations. Combining the other terms then leads to

$$\Gamma^{\alpha}_{ij,\alpha} - \Gamma^{\alpha}_{i\alpha,j} = \frac{g_{ij,00}}{2} + \frac{1}{2}\left[-k_ik_k\mathcal{H}_{jk} - k_jk_k\mathcal{H}_{ik} + k^2\mathcal{H}_{ji}\right]$$

Recall that we chose $\vec{k}$ to be along the z-axis. Therefore, the indices i and k in the first term in brackets must be equal to 3. But these multiply $\mathcal{H}_{jk} = \mathcal{H}_{j3} = 0$ so this term and its cousin $k_j k_k \mathcal{H}_{ik}$ must both vanish. Therefore,

$$\Gamma^{\alpha}{}_{ij,\alpha} - \Gamma^{\alpha}{}_{i\alpha,j} = \frac{g_{ij.00}}{2} + \frac{k^2}{2}\mathcal{H}_{ji}$$

The third term in Eq. (5.48), $\Gamma^{\alpha}_{\alpha\beta}\Gamma^{\beta}{}_{ij}$, is nonzero only when the index α is spatial, so

$$\Gamma^{\alpha}_{\alpha\beta}\Gamma^{\beta}{}_{ij} = \Gamma^{k}_{k0}\Gamma^{0}_{ij} + \Gamma^{k}_{kl}\Gamma^{l}_{ij}.$$

But each of the Christoffel symbols in the second term here are first-order, so their product vanishes. In the first term, the sum over k makes the first-order terms go away, so Γ^{k}_{k0} is purely zero-order, $3H$. Therefore,

$$\Gamma^{\alpha}{}_{\alpha\beta}\Gamma^{\beta}{}_{ij} = \frac{3}{2}H g_{ij,0}$$

The final term in Eq. (5.48) will be left as an exercise; it is

$$\Gamma^{\alpha}{}_{\beta j}\Gamma^{\beta}_{i\alpha} = 2H^2 g_{ij} + 2a^2 H\mathcal{H}_{ij,0}.$$

We can now combine all four terms in Eq. (5.48) to get

$$\begin{aligned} R_{ij} = \frac{g_{ij,00}}{2} + \frac{k^2}{2}\mathcal{H}_{ji} + \frac{3}{2}H g_{ij,0} \\ - 2H^2 g_{ij} - 2a^2 H\mathcal{H}_{ij,0}. \end{aligned}$$

We now need to expand out the time derivatives of the metric. Using Eq. (5.38), one finds

$$g_{ij,00} = 2g_{ij}\left(\frac{d^2a/dt^2}{a} + H^2\right) + 4a^2 H\mathcal{H}_{ij,0} + a^2\mathcal{H}_{ij,00}.$$

Therefore the Ricci tensor is

$$\begin{aligned} R_{ij} = g_{ij}\left(\frac{d^2a/dt^2}{a} + 2H^2\right) + \frac{3}{2}a^2 H\mathcal{H}_{ij,0} \\ +a^2\frac{\mathcal{H}_{ij,00}}{2} + \frac{k^2}{2}\mathcal{H}_{ij} \end{aligned}$$

Again we see that we have successfully recaptured the zero-order part of the Ricci tensor. Remarkably, we will see that the first-order parts - when used in Einstein's equations – do not couple to the scalar perturbations.

First, though, we must compute the Ricci scalar:

$$\mathcal{R} = g^{00}R_{00} + g^{ij}R_{ij}$$

The time-time product is all zero-order, so we can neglect it when considering the first-order piece $\delta\mathcal{R}$. The space-space contraction has two types of terms. First, there are the terms in Eq. (5.57) proportional to the metric g_{ij}. But $g^{ij}g_{ij} = 3$, so there are no first-order terms here. All the other terms in Eq. (5.57) are proportional to $\mathcal{H}_{ij}$, so when contracting them we can set g^{ij} to its zero-order value, δ_{ij}/a^2. This corresponds to taking the trace of the first-order terms in Eq. (5.57). Since all first-order terms are proportional to $\mathcal{H}_{ij}$, the trace vanishes. Therefore, tensor perturbations do not affect (at first order) the Ricci scalar.

Einstein Equations for Tensor Perturbations

Now let's read off the perturbations to the Einstein tensor induced by tensor modes. Since the Ricci scalar is unperturbed by tensor perturbations, the first-order Einstein tensor is simply

$$\delta G^i_j = \delta R^i_j$$

To get R^i_j, we contract $g^{ik}R_{kj}$, using the Ricci tensor we computed in Eq. (5.57). The first term, proportional to the contraction of $g^{ik}g_{kj} = \delta^i_j$, has no first-order piece; the remaining terms are explicitly first-order in $\mathcal{H}$, so we can set $g^{ik} = \delta^{ik}/a^2$, leading to

$$\delta G^i{}_j = \delta^{ik}\left[\frac{3}{2}H\mathcal{H}_{kj,0} + \frac{\mathcal{H}_{kj,00}}{2} + \frac{k^2}{2a^2}\mathcal{H}_{kj}\right]$$

We can now derive a set of equations governing the evolution of the tensor variables, $h_+$and $h_\times$.

To derive an equation for h_+, let us consider the difference between the $_1$ and $^2_2$ components of the Einstein tensor. The Einstein tensor in Eq. (5.60) is proportional to $\mathcal{H}_{ij}$ and its derivatives. Since $\mathcal{H}_{11} = -\mathcal{H}_{22} = h_+, \delta G^1{}_1$ is equal and opposite to $\delta G^2{}_2$. Therefore,

$$\delta G^1{}_1 - \delta G^2{}_2 = 3Hh_{+,0} + h_{+,00} + \frac{k^2 h_+}{a^2}.$$

Change to conformal time so that $h_{+,0} = \dot{h}_+/a$ and $h_{+,00} = \ddot{h}_+/a^2 - (\dot{a}/a^3)\,\dot{h}_+$. Then,

$$a^2\left[\delta G^1_1 - \delta G^2_2\right] = \ddot{h}_+ + 2\frac{\dot{a}}{a}\dot{h}_+ + k^2 h_+$$

The right-hand side of this component of Einstein's equations is zero (Exercise 8), and $h_\times$obeys the same equation (Exercise 9), so the tensor modes are governed by

$$\ddot{h}_\alpha + 2\frac{\dot{a}}{a}\dot{h}_\alpha + k^2 h_\alpha = 0$$

where $\alpha = +, \times$. Equation (5.63) is a wave equation, and the corresponding solutions are called gravity waves. For example, if we neglect the expansion of the universe so that the damping term in Eq. (5.63) vanishes, we immediately see that the two solutions are $h_\alpha \propto e^{\pm ik\eta}$. In real space, then the perturbation to the metric is of the form

$$h_\alpha(\vec{x},\eta) = \int d^3k e^{i\vec{k}\cdot\vec{x}}\left[Ae^{ik\eta} + Be^{-ik\eta}\right] \qquad \text{(no expansion)}$$

The two modes here corresponds to waves traveling in the $\pm\hat{z}$ direction at the speed of light.

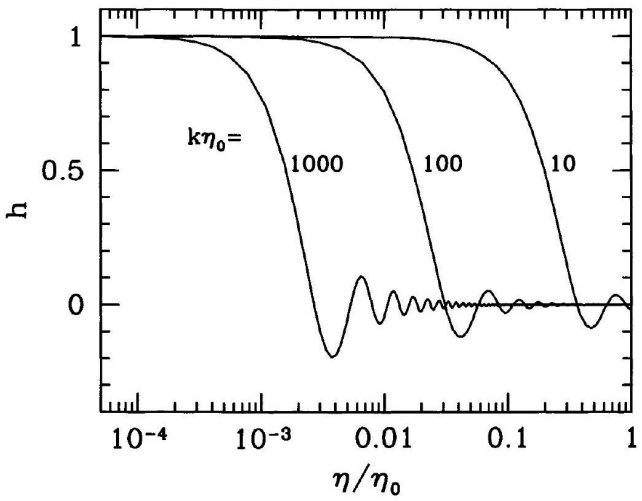

Figure 5.1. Evolution of gravity waves as a function of conformal time. Three different modes are shown, labeled by their wave numbers. Smaller scale modes decay earlier.

Equation (5.63) is a generalization of the wave equation to an expanding universe. Exercise 12 illustrates that if the universe is purely radiation or matter dominated, exact analytic solutions can be obtained. These are oscillatory, like the simple ones in Eq. (5.64), but also damp out. Figure 5.1 shows the evolution of h_α for three different wavelength modes. The large-scale mode (with $k\eta_0 = 10$) remains constant at early times when its wavelength is larger than the horizon $k\eta < 1$. Once its wavelength becomes comparable to the horizon, the amplitude begins to die off, oscillating several times until the present. The small-scale mode $k\eta_0 = 1000$ shown in Figure 5.1 also begins to decay when its wavelength becomes comparable to the horizon. Its entry into the horizon occurs much earlier, though, so the decay is much more efficient. By today, the amplitude is extremely small.

An important point about the effect of gravity waves on the CMB anisotropy spectrum can be gleaned from Figure 5.1. Because small-scale modes decay earlier than large-scale modes, at decoupling (at $\eta/\eta_0 \simeq 0.02$) only modes with $k\eta_0$ less than about 100 persist. All smaller scale modes can be neglected. Therefore, anisotropies on small angular scales will not be affected by gravity waves. Only the large-scale anisotropies are impacted by gravity waves.

12.5.4 The Decomposition Theorem

The decomposition theorem states that perturbations to the metric can be divided up into three types: scalar, vector, and tensor. Each of these types of perturbations evolves independently. That is, if some physical process in the early universe sets up tensor perturbations, these do not induce scalar perturbations. Conversely, to determine the evolution of scalar perturbations, we will not have to worry about possible vector or tensor perturbations.

Now that we have computed the contributions to the Einstein tensor $G_{\mu\nu}$ from scalars and tensors, we can demonstrate the decomposition of these two types of perturbations. To do this, remember that we obtained the scalar equations by considering the two components of Einstein's tensor:

$$G^0_0 \quad ; \quad \left(\hat{k}_i\hat{k}_j - (1/3)\delta_{ij}\right) G^i_j.$$

Inserting these components into Einstein's equations led to equations (5.27) and (5.33). If we can show that tensor perturbations do not contribute to these two components, then we will have convinced ourselves of at least part of the decomposition theorem, namely that the equations governing scalar equations are not affected by tensors.

It is easy to see that tensor perturbations do not contribute to $G^0{}_0$. For $G^0{}_0$ depends on R_{00} and $\mathcal{R}$. But we have seen that both of these do not depend on h_+ or $h_\times$.

Now let's show that $\left(\hat{k}_i\hat{k}_j - \delta_{ij}/3\right) G^i{}_j$ also does not pick up a contribution from tensor perturbations. Multiply Eq. (5.60) by the projection operator:

$$\left(\hat{k}_i\hat{k}_j - (1/3)\delta_{ij}\right) \delta G^i{}_j = (\delta_{i3}\delta_{j3} - (1/3)\delta_{ij}) \times \left[\frac{3}{2}H\mathcal{H}_{ij,0} + \frac{\mathcal{H}_{ij,00}}{2} + \frac{k^2}{2a^2}\mathcal{H}_{ij}\right]$$

where the equality holds since we have chosen $\hat{k}$ to lie in the $\hat{z}$ direction. The terms in which indices i and j are set to 3 vanish since $\mathcal{H}_{33} = 0$. The only remaining terms are those proportional to δ_{ij}. But the Kronecker delta instructs us to take the trace of $\mathcal{H}$. This too vanishes. The scalar equations we derived in the previous section are therefore unchanged by the presence of tensor modes. This is a manifestation of the decomposition theorem.

12.5.5 from Gauge to Gauge

Let's go back to scalar perturbations. Until now, we have characterized these with Ψ and Φ in the form of Eq. (4.9). This corresponds to a choice of gauge or a choice of a coordinate system with which to study the space-time. If we changed the coordinate system we use, we would get a metric of a different form, i.e., a different gauge. Although we will work almost exclusively in the gauge corresponding to Eq. (4.9), the conformal Newtonian gauge, historically many other gauges have been used, and for different parts of the "cosmological perturbation" problem, different gauges have their advantages. Indeed, we will see in Section 6.5.3 that people who work on the theory of inflation sometimes prefer a gauge with spatially flat slicing (g_{ij} unperturbed), since the equations for the perturbations generated by inflation simplify considerably. Also, the code currently used by most people to compute anisotropies and inhomogeneities in the universe uses synchronous gauge, partly because the equations are better behaved numerically in that gauge. So the ability to move back and forth between different gauges is useful, and I want to spend a few pages describing how to do this.

Most generally, scalar perturbations to the metric can be written down as

$$\begin{aligned} g_{00} &= -(1+2A) \\ g_{0i} &= -aB_{,i} \\ g_{ij} &= a^2\left(\delta_{ij}[1+2\psi] - 2E_{,ij}\right). \end{aligned}$$

There are four functions which characterize scalar perturbations to the metric: A, B, ψ, and E. They all depend on space and time, and they are all scalars. For example, the g_{0i} components are the derivatives of a scalar function, not an independent vector function with its own orientation. In conformal Newtonian gauge, $A = \Psi$ and $\psi = \Phi$, while $B = E = 0$.

How do we transform from one gauge to another? The invariant distance of Eq. (2.2) does not change if different coordinates $\tilde{x}$ are used instead of x. Therefore,

$$\tilde{g}_{\alpha\beta}(\tilde{x})d\tilde{x}^\alpha d\tilde{x}^\beta = g_{\mu\nu}(x)dx^\mu dx^\nu,$$

where I have used a different set of dummy indices on both sides to make the upcoming few lines clearer. One of the differentials on the left-hand side can be written as $d\tilde{x}^\alpha = (\partial\tilde{x}^\alpha/\partial x^\mu)\,dx^\mu$ and similarly with the other differential, so equating coeffients of $dx^\mu dx^\nu$ leads to

$$\tilde{g}_{\alpha\beta}(\tilde{x})\frac{\partial\tilde{x}^\alpha}{\partial x^\mu}\frac{\partial\tilde{x}^\beta}{\partial x^\nu} = g_{\mu\nu}(x).$$

This equation is what we are after: a prescription for how the metric changes under a coordinate transformation.

The most general coordinate transformation is generated by

$$\begin{aligned} t \to \tilde{t} &= t + \xi^0(t,\vec{x}) \\ x^i \to \tilde{x}^i &= x^i + \delta^{ij}\xi_{,j}(t,\vec{x}), \end{aligned}$$

where we take ξ^0 and ξ to be small perturbations of the same order as the variables characterizing the perturbations. Let's examine how the metric changes under such a transformation. I'll work out one component explicitly and leave the rest as an exercise. Consider the oo component of Eq. (5.69):

$$\tilde{g}_{\alpha\beta}(\tilde{x})\frac{\partial\tilde{x}^\alpha}{\partial t}\frac{\partial\tilde{x}^\beta}{\partial t} = -[1+2A].$$

I claim that the only term that contributes to the left-hand side is the one with $\alpha = \beta = 0$. Consider for example $\alpha = 0$ and $\beta = i$. The off-diagonal component of the metric $\tilde{g}_{0i}$ is

proportional to $\tilde{B}_{,i}$ a first-order perturbation. But $\partial\tilde{x}^i/\partial t$ is proportional to the first-order variable ξ, so the product is second-order and can be neglected. A similar argument holds for the $\alpha = i; \beta = j$ terms. Therefore, the left-hand side is simply

$$-[1+2\tilde{A}]\left(\frac{\partial\tilde{t}}{\partial t}\right)^2 = -[1+2\tilde{A}]\left(1+\frac{\partial\xi^0}{\partial t}\right)^2$$
$$\simeq -1-2\tilde{A}-2\frac{\partial\xi^0}{\partial t}.$$

Equating this with g_{00} leads to

$$-2\tilde{A}-2\frac{\partial\xi^0}{\partial t} = -2A$$

so under the coordinate transformation specified by Eq. (5.70)

$$A \rightarrow \tilde{A} = A - \frac{1}{a}\dot{\xi}^0.$$

In a similar vein, the other components of the metric transform into

$$\tilde{\psi} = \psi - H\xi^0$$

$$\tilde{B} = B - \frac{\xi^0}{a} + \dot{\xi}$$
$$\tilde{E} = E + \xi.$$

One technical point: Eqs. (5.74) and (5.75) describe how the components of the metric tensor transform under general coordinate changes. These equations, which have become standard, are a bit misleading, though, because each of the individual functions, A for example, transforms as a scalar, i.e., does not change under a spatial coordinate transformation. Here we have transformed the metric and accomodated the resulting changes in new definitions of A, B, ψ, and E. This is not the same thing as seeing how A by itself changes under a transformation.

To sum up, then, there are four functions which characterize scalar perturbations, but these can be manipulated with two other functions which characterize coordinate transformations. For example, starting with a metric in which $E \neq 0$, it is trivial to make a transformation to eliminate E: simply choose $\xi = -E$, and the resulting $\tilde{E} = 0$. Thus, there are really only $4 - 2 = 2$ functions which matter. Indeed, this is the reason that we had only Φ and Ψ in conformal Newtonian gauge. More generally, one might hope to construct two gauge invariant variables, those which remain unchanged under a general coordinate transformation. Bardeen (1980) first identified two such variables:

$$\Phi_A := A + \frac{1}{a}\frac{\partial}{\partial\eta}[a(\dot{E}-B)]$$
$$\Phi_H := -\psi + aH(B-\dot{E}).$$

In conformal Newtonian gauge, in which $E = B = 0, \Phi_A = \Psi$ and $\Phi_H = -\Phi$. These invariants are very useful: if equations simplify in a particular gauge, then one can do calculations in that gauge, form the gauge-invariant variables, and then turn these into the perturbations in any other gauge. We will do precisely this in Section 6.5.3. In other words, Φ_A and Φ_H are useful shortcuts or recipes for transforming from one gauge to another.

Under a general coordinate transformation, the components of the energymomentum tensor $T_{\mu\nu}$ also change. In exact analogy with the metric tensor,

$$\tilde{T}_{\mu\nu}(\tilde{x}) = \frac{\partial x^\alpha}{\partial \tilde{x}^\mu}\frac{\partial x^\beta}{\partial \tilde{x}^\nu}T_{\alpha\beta}(x)$$

Again, though, Bardeen found combinations of the components of $T_{\mu\nu}$ which remain invariant and therefore facilitate mapping from one gauge to another. In particular, in Fourier space

$$v := ikB + \frac{\hat{k}^i T_i^0}{(\rho + \mathcal{P})a}$$

remains invariant under a coordinate transformation. In conformal Newtonian gauge, for matter, v is indeed equal to the v we defined in Chapter 4. For radiation, $v = -3i\Theta_{r,1}$, i.e., proportional to the dipole, again in conformal Newtonian gauge. A second invariant is the generalized perturbation to the energy density,

$$\epsilon_m := -1 - \frac{T_0^0}{\rho} + \frac{3H}{k^2\rho}k^i T_i^0$$

For matter, in conformal Newtonian gauge, $\epsilon_m = \delta + (3aHv/k)$; i.e., it reduces to the ordinary overdensity δ on scales smaller than the horizon. For radiation, $\epsilon_m = 4\Theta_{r,0} - 12i\Theta_{r,1}aH/k$, again reducing to the standard overdensity on small scales.

12.6 Initial Conditions

In order to understand structure in the universe, we have derived the equations governing perturbations around a smooth background. Before we start solving these equations, we need to know the initial conditions. This quest for initial conditions will lead to an entirely new realm of physics, the theory of inflation. Inflation was introduced (Guth, 1981; Linde 1982; Albrecht and Steinhardt, 1982) partly to explain how regions which could not have been in causal contact with each other have the same temperature. It was soon realized (Starobinsky, 1982; Guth and Pi, 1982; Hawking, 1982; Bardeen, Steinhardt, and Turner, 1983; Brandenberger, Kahn, and Press, 1983; Guth and Pi, 1985) that the very mechanism that explains the uniformity of the temperature in the universe can also account for the origin of perturbations in the universe. Therefore, in order to produce a set of initial conditions, we will need to detour into the world of inflation. One warning: we are not sure that inflation is the mechanism that generated the initial perturbations. It is very difficult to test a theory based on energy scales well beyond the reach of accelerators. Nonetheless, it is by far the most plausible explanation. Indeed, one of the current problems in cosmology is that there is really no viable alternative to inflation. Also, the next generation of CMB and large-scale structure observations will put inflation to some stringent tests.

12.6.1 The Einstein-Boltzmann Equations at Early Times

Theory

Chapters 4 and 5 contain nine first-order differential equations for the nine perturbation variables we need to track. In principle, we need initial conditions for $\therefore$ 'l of these variables. In practice, though, a combination of arguments will relate many of these variables to each other, and we need only determine the initial conditions for one of these. This section determines the way all variables depend on the gravitational potential Φ at early times; the remaining sections work out the initial conditions for Φ.

Let us consider first the Boltzmann equations (4.100)-(4.107) at very early times. In particular, we want to consider times so early that for any k-mode of interest, $k\eta \ll 1$. This

inequality immediately leads to several important simplifications. Consider the terms $\dot{\Theta}$ and $ik\mu\Theta$ in Eq. (4.100). The first term is of order Θ/η, while the second is of order $k\Theta$. Therefore, the first is larger than the second by a factor of order $1/(k\eta)$, which, by assumption, is much greater than 1. In a similar way, we can argue that all terms in the Boltzmann equations multiplied by k can be neglected at early times. Physically, this means that, at early times, all perturbations of interest have wavelengths ($\sim k^{-1}$) much larger than the distance over which causal physics operates. A hypothetical observer then who sees only photons from within his causal horizon will see a uniform sky. Thus higher multipoles $(\Theta_1, \Theta_2, \ldots)$ are much smaller than the monopole, Θ_0. Therefore, the perturbations to the photon and neutrino temperatures evolve according to

$$\dot{\Theta}_0 + \dot{\Phi} = 0$$
$$\dot{\mathcal{N}}_0 + \dot{\Phi} = 0.$$

The same principles can be applied to the matter distributions. The overdensity equations reduce to

$$\dot{\delta} = -3\dot{\Phi}$$
$$\dot{\delta}_{\rm b} = -3\dot{\Phi}.$$

The velocities are comparable to the first moments of the radiation distributions, so they are smaller than the overdensities by a factor of order $k\eta$ and may be set to zero initially. In fact, the baryon velocity is not only comparable to the photon first moment, Θ_1: it is equal to it by virtue of the strength of Compton scattering. That is, the largeness of $\dot{\tau}$ in Eq. (4.106) ensures that $v_{\rm b} = -3i\Theta_1$. We will use this later when reexamining the Boltzmann equations closer to decoupling. For now, we are interested in times so early that the only relevant fact is that higher moments are all negligibly small.

Now let us turn to the Einstein equations at early times. First consider Eq. (5.27). The first term there contains a factor of k^2 so may be neglected. Also the two matter terms on the right are negligible at early times since radiation dominates. Therefore, we have

$$3\frac{\dot{a}}{a}\left(\dot{\Phi} - \frac{\dot{a}}{a}\Psi\right) = 16\pi G a^2 \left(\rho_\gamma \Theta_0 + \rho_\nu \mathcal{N}_0\right)$$

But since radiation dominates, $a \propto \eta$ (recall Eq. (2.100) and the discussion immediately afterward) so $\dot{a}/a = 1/\eta$. Therefore,

$$\begin{aligned}\frac{\dot{\Phi}}{\eta} - \frac{\Psi}{\eta^2} &= \frac{16\pi G\rho a^2}{3}\left(\frac{\rho_\gamma}{\rho}\Theta_0 + \frac{\rho_\nu}{\rho}\mathcal{N}_0\right) \\ &= \frac{2}{\eta^2}\left(\frac{\rho_\gamma}{\rho}\Theta_0 + \frac{\rho_\nu}{\rho}\mathcal{N}_0\right)\end{aligned}$$

where the last equality follows by virtue of the zero-order Einstein equation. To simplify further, we can define the ratio of neutrino energy density to the total radiation density as

$$f_\nu := \frac{\rho_\nu}{\rho_\gamma + \rho_\nu}$$

Then multiplying Eq. (6.4) by η^2 leads to

$$\dot{\Phi}\eta - \Psi = 2\left(\left[1 - f_\nu\right]\Theta_0 + f_\nu \mathcal{N}_0\right)$$

Recall that Eq. (6.1) relates the derivative of the monopoles to the derivative of the potential. We can therefore eliminate both monopoles from Eq. (6.6) by differentiating both right- and left-hand sides. Then,

$$\ddot{\Phi}\eta + \dot{\Phi} - \dot{\Psi} = -2\dot{\Phi}$$

where the right-hand side follows since both $\dot{\Theta}_0$ and $\dot{\mathcal{N}}_0$ are equal to $-\dot{\Phi}$ for these large scale modes.

So far we have used only one Einstein equation. The second, Eq. (5.33), describes how the higher moments of the photon and neutrino distributions cause $\Psi + \Phi$ to be nonzero. Let us here neglect these higher order moments, which cause the sum of the gravitational potentials to be slightly nonzero. [1] Under this approximation, we can eliminate Ψ everywhere by simply setting it to $-\Phi$. Then,

$$\ddot{\Phi}\eta + 4\dot{\Phi} = 0$$

Setting $\Phi = \eta^p$ leads to the algebraic equation

$$p(p-1) + 4p = 0$$

which allows two solutions: $p = 0, -3$. The $p = -3$ mode is the decaying mode. If it is excited very early on, it will quickly die out and have no impact on the universe. The $p = 0$ mode, on the other hand, does not decay if excited. It is the mode we are interested in. If some mechanism can be found which excites this mode, this mechanism may well be responsible for the perturbations in the universe.

Focusing therefore on only the $p = 0$ mode, we see that Eq. (6.6) relates the gravitational potential to the neutrino and photon overdensities:

$$\Phi = 2\left(\left[1 - f_\nu\right]\Theta_0 + f_\nu \mathcal{N}_0\right)$$

Both Θ_0 and $\mathcal{N}_0$ are also constant in time. In most models of structure formation, they are equal since whatever causes the perturbations tends not to distinguish between photons and neutrinos. Therefore, we will set

$$\Theta_0\left(k, \eta_i\right) = \mathcal{N}_0\left(k, \eta_i\right)$$

which leads to

$$\Phi\left(k, \eta_i\right) = 2\Theta_0\left(k, \eta_i\right)$$

where I have explicitly written the k-dependence of all these variables and the fact that we are setting up the initial conditions at some early time η_i.

[1] See Exercise 2 for a careful accounting of the effect of the neutrino quadrupole; the photon quadrupole is kept minuscule by Compton scattering, so it really does not contribute to Eq. (5.33). The initial conditions for matter, both δ and $\delta_{\rm b}$, depend upon the nature of the primordial perturbations. Combining the first of equations (6.1) and (6.2) leads to

$$\delta = 3\Theta_0 + \text{ constant}$$

for the dark matter overdensity, with an identical equation for the baryon overdensity. Primordial perturbations are often divided into those for which the constant in Eq. (6.13) is zero (adiabatic perturbations) and those for which the constant is nonzero (isocurvature perturbations). Adiabatic perturbations have a constant matter-to-radiation ratio everywhere since

$$\frac{n_{\rm dm}}{n_\gamma} = \frac{n_{\rm dmm}^{(0)}}{n_\gamma^{(0)}}\left[\frac{1+\delta}{1+3\Theta_0}\right].$$

The prefactor, the ratio of zero-order number densities, is a constant in both space and time. For the ratio of matter to radiation number density to be uniform, therefore, the combination inside the brackets which linearizes to $1 + \delta - 3\Theta_0$ must be independent of space. So the perturbations must sum to zero,

$$\delta = 3\Theta_0$$

for adiabatic perturbations. By similar arguments for the baryons, $\delta_b = 3\Theta_0$. There are models based on isocurvature perturbations, but these have not been very successful to date; we will focus on adiabatic initial conditions.

For the most part, velocities and dipole moments are negligibly small in the very early universe. However, we will encounter situations where we need to know the initial conditions for these as well. You will show in Exercise 3 that the appropriate initial conditions are

$$\begin{aligned}\Theta_1 = &\mathcal{N}_1 = \frac{iv_b}{3} = \frac{iv}{3} \\ &= -\frac{k\Phi}{6aH}.\end{aligned}$$

12.6.2 The Horizon

Theory

If this book were a novel or a biography, a better title for this section might be Midlife Crisis. The main character would have attended a good high school, studied hard, and gone on to a solid university. There he fell in love with an exciting, but sensible, woman; upon graduating, he set up some interviews, and got a good job downtown. He married his college girlfriend, and after several years in the city, they moved to the suburbs and had three kids. Our hero contributed to the community and was recognized all over town as a solid citizen. He was moving up fast in his company and there was talk about a political position. Just when he was about to declare his candidacy, he began to have doubts. "What have I been doing with my life? What is really important? Were all those years of study and work simply a 'track'? Did I take this path just because everyone else was moving in the same direction? Where is the innovation and the signature that my life is mine?" And worse, he has a secret, an underlying feeling that everything he has built is based on a fallacy.

OK, maybe it wouldn't be a bestseller, but it does serve as a useful metaphor for our study of perturbations in the universe. Until now, we have done everything in a systematic, proper way. We reviewed the standard Big Bang cosmology. We expanded about this zero-order smooth universe, getting evolution equations for the perturbations to the particle distributions and to the gravitational fields. We realized that these coupled differential equations needed initial conditions so in the last section we set those up. However, now we must ask, What caused those initial perturbations? It is one thing to say that $\Phi = 2\Theta_0$ initially. It is quite another to explain what caused Φ to be nonzero in the first place.

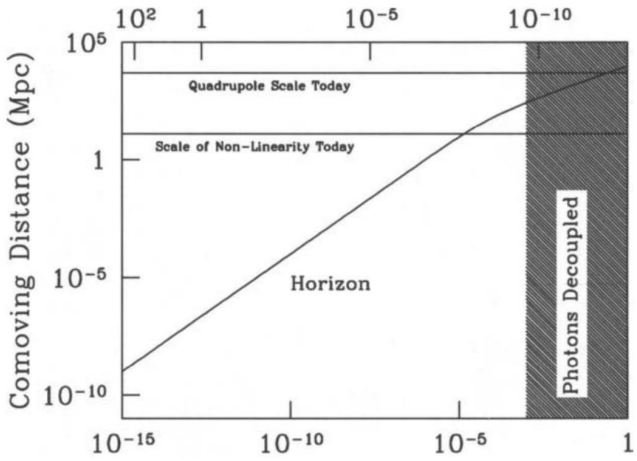
And it is worse than that. To understand why let us recall the physical meaning of the conformal time η: it is the maximum comoving distance traveled by light since the beginning of the universe. Equivalently, objects separated by comoving distances larger than η today were not ever in causal contact: there is simply no way information could have propagated over distances larger than η. For this reason, η is called the comoving horizon.

With this in mind, we can now revisit the condition used in the previous section that $k\eta \ll 1$. The wavenumber k is roughly equal to the inverse of the wavelength of the mode in question (give or take a factor of 2π). Therefore $k\eta$ is the ratio of the comoving horizon to the comoving wavelength of the perturbation. If this ratio is much smaller than 1, then the mode in question

has a wavelength so large that no causal physics could possibly have affected it. A picture worth remembering is shown in Figure 6.1. The horizon grows as the scale factor increases. On the other hand, comoving wavelengths remain constant. All modes of cosmological interest therefore had wavelengths much larger than the horizon early on. Eventually these cosmological modes enter the horizon; after that, causal physics begins to operate on them.

The truly disturbing feature of this realization is most apparent when considering the microwave background today. On all scales observed the CMB is very close to isotropic. How can this be? The largest scales observed have entered the horizon just recently, long after decoupling. (An example is the scale corresponding to the quadrupole moment of the CMB, shown in Figure 6.1.) Before decoupling, the wavelengths of these modes are so large that no causal physics could force deviations from smooothness to go away. After decoupling, the photons do not interact at all; they simply freestream. So even though it is technically possible that photons reaching us today from opposite directions had a chance to communicate with each other and equilibrate to the same temperature, practically this could not have happened. Why then is the CMB temperature so uniform? This is a profound problem that we have glossed over by simply assuming that the temperature is uniform and that perturbations about the zero-order temperature are small.

T(GeV)



a

Figure 6.1. The comoving horizon as a function of the scale factor. Also shown are two comoving wavelengths, which remain constant with time. Early in the history of the universe, both of these modes - as well as all other modes of cosmological interest — had wavelengths much larger than the horizon. The CMB comes from the last scattering surface at $a \simeq 10^{-3}$. At that time, the largest scales (e.g., the one labeled "quadrupole") were still outside the horizon. The horizon problem asks how regions separated by distances larger than the horizon at the last scattering surface can have the same temperature.

A more intuitive picture of the horizon problem is shown in Figure 6.2. At any given time, the region within the cone is causally connected to us (at the center). Photons that we observe today from the last scattering surface were well outside our horizon when they were first emitted. The most disturbing aspect of this is the observation of large-angle isotropy, an indication that photons apparently separated by many horizons at the last scattering surface nonetheless shared the same temperature (to a part in 10^5).

12.6.3 Inflation

Theory

This section describes a beautiful solution to the horizon problem outlined in the previous section. First, we explore a logical way out of the previous argument by realizing that an early epoch of rapid expansion solves the horizon problem. Then we consider the Einstein equations to tell us what type of energy is needed in order to produce this rapid expansion, showing that negative pressure is required.

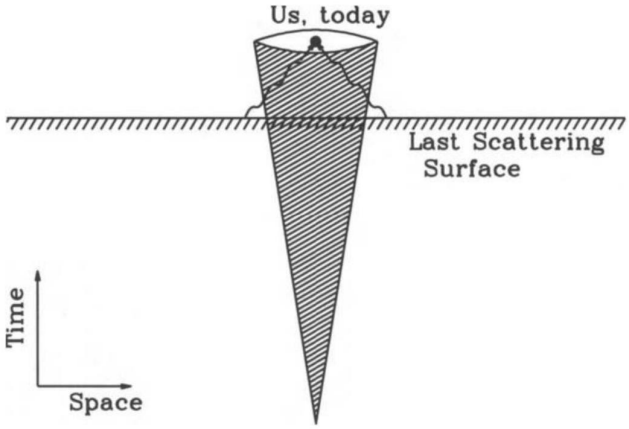


Figure 6.2. The horizon problem. The region inside the cone at any time is causally connected to us (at the center). Photons emitted from the last scattering surface (at redshift ~ 1000) started outside of this region. Therefore, at the last scattering surface, they were not in causal contact with us and certainly not with each other. Yet their temperatures are almost identical.

Finally, we consider a scalar field theory and show that negative pressure is easy to accommodate in such a theory.

Two comments about the field theory implementation. First, field theory has a reputation as a difficult subject. It is, but the part we will need for inflation is decidedly simple. Indeed, almost all we will need to know about field theory we've already used in the previous chapter on general relativity. The second point is that there is no known scalar field which can drive inflation. (A skeptic might point out that there is no known fundamental scalar field at all!) Therefore, it may well be true that the idea of inflation is correct but it is driven by something other than a scalar field. Having said that, there are a number of reasons to work with scalar fields, as we will do whenever we need to specify the source of inflation. Almost all fundamental particle physics theories contain scalar fields. In fact, historically it was particle physicists studying high-energy extensions of the Standard Model (in particular Grand Unified Theories) who proposed the idea of inflation driven by a scalar field as a natural byproduct of some of these extensions. Indeed, almost all current work on inflation is based on a scalar field (or sometimes two). The alternative from a particle physics point of view is to use a vector field (such as the electromagnetic potential) or a set of fermions (similar to the way condensates induce superconductivity) to drive inflation. Neither of these choices works very well, but they both complicate things severely, so we will stick to a scalar field.

A Solution to the Horizon Problem

To motivate a solution to the horizon problem, let me rewrite the comoving horizon as

$$\eta = \int_0^a \frac{da'}{a'} \frac{1}{a' H\left(a'\right)}$$

The comoving horizon then is the logarithmic integral of the comoving Hubble radius, $1/aH$. The Hubble radius is the distance over which particles can travel in the course of one expansion time, i.e., roughly the time in which the scale factor doubles. So the Hubble radius is another way of measuring whether particles are causally connected with each other: if they are separated by distances larger than the Hubble radius, then they cannot currently communicate. There is a subtle distinction between the comoving horizon η and the comoving Hubble radius $(aH)^{-1}$. If particles are separated by distances greater than η, they never could have communicated with one another; if they are separated by distances greater than $(aH)^{-1}$, they cannot talk to each other now. It is therefore possible that η could be much larger than $(aH)^{-1}$ now, so that particles cannot communicate today but were in causal contact early on. This might happen if the comoving Hubble radius early on was much larger than it is now so that η got most of its contribution from early times. This could happen, but it does not happen during matter- or radiationdominated epochs. In those cases, the comoving Hubble radius increases with time, so typically we expect the largest contribution to η to come from the most recent times. Indeed, this is precisely what Figure 6.1 indicates.

Look again at Figure 6.1. On top of the figure I have drawn an axis which depicts the temperature of the cosmic plasma for the given value of the scale factor. We know quite a bit about physics going up to the limits on the plot, several hundred GeV. Beneath these energies, the standard model of particle physics works very well. Beyond those energies, although we have ideas, there is no experimental reason to prefer one theory over another. Since the energy content of the universe determines $a(t)$, when you mentally extrapolate the horizon in Figure 6.1 back to $a = 0$, or equivalently to infinitely high temperatures, you are really making an assumption. You are assuming that nothing strange happened early on, in particular that the universe was always radiation dominated at early times. If this were true, then it does indeed follow that the comoving horizon received a negligible contribution from the very early universe, that photons can travel only very small distances in the first fraction of a second after the Big Bang.

This suggests a solution to the horizon problem: perhaps early on, the universe was not dominated by either matter or radiation. Perhaps, for at least a brief time, the comoving Hubble radius decreased. Then, we would have the situation depicted in Figure 6.3. The comoving Hubble radius would decrease dramatically during this epoch. In that case, the comoving horizon would get most of its contribution not from recent times, but rather from primordial epochs before the rapid expansion of the grid. Particles separated by many Hubble radii today, for example those outside the circle in the bottom panel of the figure, were in causal contact - were inside the Hubble circle in the top panel - before this epoch of rapid expansion.

How must the scale factor evolve in order to solve the horizon problem? We can first answer this question qualitatively. If the comoving Hubble radius is to decrease, then aH must increase. That is,

$$\frac{d}{dt}\left[a\frac{da/dt}{a}\right] = \frac{d^2a}{dt^2} > 0$$

So to solve the horizon problem, the universe must go through a period in which it is accelerating, expanding ever more rapidly. This is the origin of the term inflation. To understand the epoch of inflation more quantitatively, let me give away the punchline that most inflationary models typically operate at energy scales of order 10^{15}GeV or larger. How big was the comoving Hubble radius when the temperature was 10^{15}GeV? We can get an order of magnitude estimate by ignoring the relatively brief epoch of recent matter domination and assuming that the universe has been radiation dominated since the end of inflation (you can correct this assumption in Exercise 6). Then H scales as a^{-2} so $a_0H_0/a_eH_e = a_e$ where a_e is the scale factor at the end of inflation. If a_e corresponds to a time at which the temperature was 10^{15}GeV, then

$a_e \simeq T_0/10^{15}\text{GeV} \simeq 10^{-28}$. So the comoving Hubble radius at the end of inflation was 28 orders of magnitude smaller than it is today. For inflation to work, the comoving Hubble radius at the onset of inflation had to be larger than the largest scales observable today, i.e., larger than the current comoving Hubble radius. So during inflation, the comoving Hubble radius had to decrease by some 28 orders of magnitude.

The most common way to arrange this is to construct a model wherein H is constant during inflation. In that case, since $da/a = Hdt$, the scale factor evolves as

$$a(t) = a_e e^{H(t-t_e)} \quad t < t_e$$

where t_e is the time at the end of inflation. The decrease in the comoving Hubble radius $(aH)^{-1}$ is now due solely to the exponential increase in the scale factor. For the scale factor to increase by a factor of 10^{28}, the argument of the exponential must be of order $\ln(10^{28}) \sim 64$ (but remember the corrections in Exercise 6), so inflation can solve the horizon problem if the universe expands exponentially for more than 60 e-folds.

Thus, consider Figure 6.4, which shows the comoving Hubble radius as a function of the scale factor. The right side of this plot is virtually identical to Figure 6.1, which tells us that the comoving scales of interest to us were much larger than the Hubble radius in the standard cosmology. The left-hand side of the plot though shows that an inflationary epoch reduces the comoving Hubble radius dramatically. This makes sense: since the scale factor is inflating very rapidly, it becomes increasingly difficult for photons to move along the comoving grid (which is itself expanding with a). Before inflation started, the comoving Hubble radius was very large, larger than any scale of cosmological interest today, so all such scales were well within the horizon.

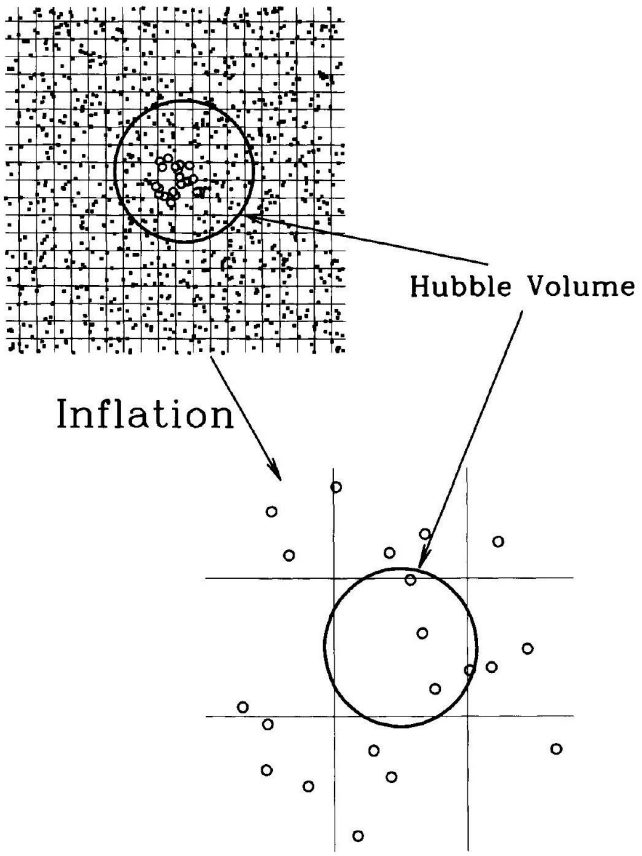

Figure 6.3. Particles on the comoving grid before (top) and after (bottom) inflation. Open circles are the same particles on top and bottom. Before inflation, the comoving Hubble radius was quite large, encompassing dozens of cells on the grid. After inflation, the comoving Hubble

radius has shrunk to just one cell. (In this caricature, the scale factor has grown by a factor of order 7 ; during inflation the scale factor increases by greater than e^{60}.) The shrinkage of the comoving Hubble radius means that particles which were initially in causal contact with one another (within the large circle at top) can now no longer communicate. Note that the physical Hubble radius, depicted by large circles on the top and bottom grids, remains roughly constant during inflation.

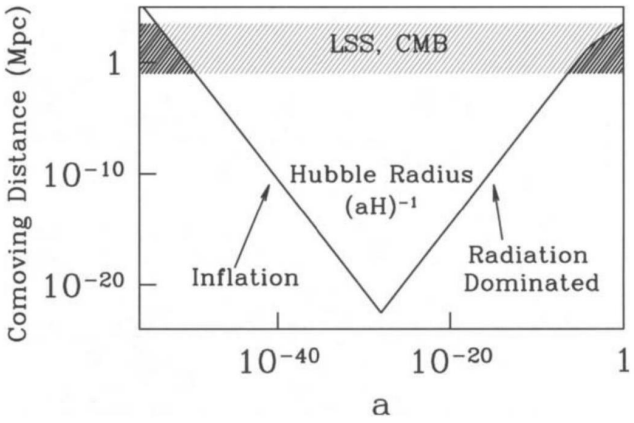

Figure 6.4. The comoving Hubble radius as a function of scale factor. Scales of cosmological interest (shaded band) were larger than the Hubble radius until $a \sim 10^{-5}$. Dark shaded regions show when these scales were smaller than the Hubble radius, and therefore susceptible to microphysical processes. Very early on, before inflation operated, all scales of interest were smaller than the Hubble radius and therefore susceptible to microphysical processing. Similarly, at very late times, scales of cosmological interest came back within the Hubble radius.

Note the symmetry in Figure 6.4. Scales just entering the horizon todayroughly 60 e-folds after the end of inflation - left the horizon 60 e-folds before the end of inflation. The amplitude of the perturbations on these scales remained constant as long as they were super-horizon. So, when we measure them today, we are actually seeing them as they were when they first left the horizon during the inflationary era (modulo whatever processing has taken place since they reentered the horizon, processing we will study in great detail in Chapters 7 and 8). To explain the structure in the universe today, then, it is clearly important to understand the generation of perturbations during inflation.

We have until now discussed inflation in comoving coordinates. But it is also profitable to think of the exponential expansion in physical coordinates. The idea that the horizon blows up early on is depicted in Figure 6.5. The physical size (a times the comoving size) of a causally connected region blows up exponentially quickly during inflation. So regions that we observe to be astronomical today were actually microscopically small before inflation, and they were in causal contact with each other.

The total comoving horizon ceases to be an effective time parameter after inflation because it becomes large very early on, and then changes very little as the universe expands during the matter- and radiation-dominated eras. A simple way to rectify this is to subtract off its primordial part $\eta_{\rm prim}$, and redefine η as

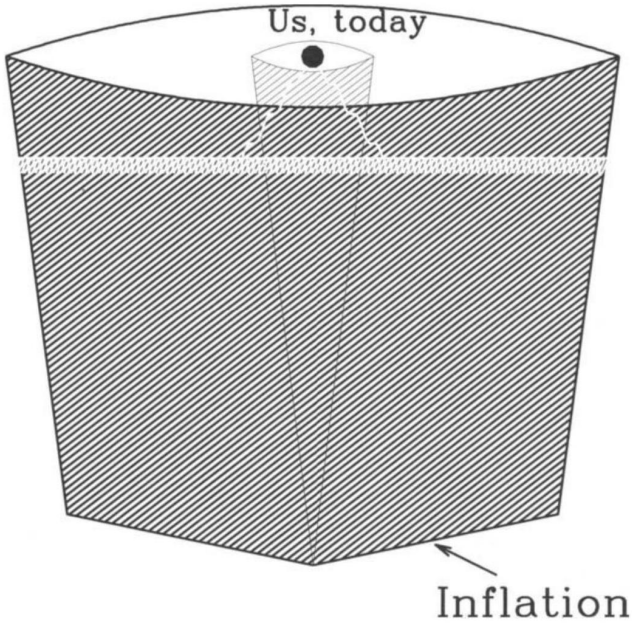

Figure 6.5. Inflationary solution to the horizon problem. Larger cone shows the true horizon in an inflationary model; smaller inner cone shows the horizon without inflation. During inflation, the physical horizon blows up very rapidly. All scales in the shaded region were once in causal contact so it is not surprising that the temperature is uniform.

$$\eta = \int_{t_e}^{t} \frac{dt'}{a\left(t'\right)}$$

so that the total comoving horizon is $\eta_{\rm prim} + \eta$. This is the convention we will follow; note that this means that during inflation, η is negative, but always monotonically increasing. A scale leaves the horizon in the sense of Figure 6.4 when $k|\eta|$ becomes less than 1, and returns at late times when $k\eta$ becomes larger than 1.

To sum up, inflation - an epoch in which the universe accelerates – solves the horizon problem. During the accelerated expansion the physical Hubble radius remains fixed, so particles initially in causal contact with one another can no longer communicate. Regions which are separated by vast distances today were actually in causal contact before and during inflation. At that time, these regions were given the necessary initial conditions, the smoothness we observe today, but also, as we will soon see, the small perturbations about smoothness that eventually grew into galaxies and other structure in the universe.

Negative Pressure

We have shown that an accelerating universe can solve the horizon problem. Since general relativity ties the expansion of the universe to the energy in it, we now need to ask what type of energy can produce acceleration. We can get an immediate answer if we appeal to the time-time and space-space components of the zero-order Einstein equations. They are (Eqs. (2.39) and (2.93))

$$\left(\frac{da/dt}{a}\right)^2 = \frac{8\pi G}{3}\rho$$

$$\frac{d^2a/dt^2}{a} + \frac{1}{2}\left(\frac{da/dt}{a}\right)^2 = -4\pi G\mathcal{P}$$

Multiplying the first of these by one-half and then subtracting one from the other eliminates the first derivative of a, leaving

$$\frac{d^2a/dt^2}{a} = -\frac{4\pi G}{3}(\rho + 3\mathcal{P}).$$

Acceleration is defined to mean that d^2a/dt^2 is positive. For this to happen, the terms in parentheses on the right must be negative. So inflation requires

$$\mathcal{P} < -\frac{\rho}{3}$$

Since the energy density is always positive, the pressure must be negative. This result is perhaps not surprising: we saw back in Chapter 2 that the accelerated expansion which cause supernovae to appear very faint can be caused only by dark energy with negative pressure. Inflation was apparently driven by the a similar form of energy, one with $\mathcal{P} < 0$. To reiterate what we emphasized in Chapter 2, negative pressure is not something with which we have any familiarity. Nonrelativistic matter has small positive pressure proportional to temperature divided by mass, while a relativistic gas has $\mathcal{P} = +\rho/3$, again positive. So whatever it is that drives inflation is not ordinary matter or radiation.

Implementation with a Scalar Field

We have become familiar with the fields $\Psi(\vec{x}, t)$ and $\Phi(\vec{x}, t)$, deriving equations for them which govern their evolution (the Einstein equations) and the evolution of particles which are affected by them. These two fields are parts of the multicomponent field, the metric $g_{\mu\nu}$. The metric is one of the fundamental fields in physics, but there are others. Every elementary particle - the electron, neutrino, quarks, photon, etc. - is associated with its own field. It would be wonderful if one of these fields, the electromagnetic potential associated with photons say, could serve as the source for an inflationary model. Unfortunately we do not yet have such a concrete model. Instead, I will discuss inflation in terms of a generic scalar field (not a fermion like the quarks and leptons or a vector like the electromagnetic field). The simplest version of the standard model does indeed have within it one such field, the Higgs field. But, again unfortunately, we know too much about the Higgs of the standard model. Its interactions and properties are constrained enough for us to know that it cannot serve as the source for inflation. So we will drop any pretensions of connecting the generic scalar field which drives inflation to known physics. Making this connection is left as a homework problem for a future Nobel laureate.

We want to know if a scalar field - which I will call $\phi(\vec{x}, t)$, not to be confused with the metric perturbation $\Phi(\vec{x}, t)$ - can have negative $\rho + 3\mathcal{P}$. So our first task is to write down the energy-momentum tensor for ϕ. This is

$$T^\alpha_\beta = g^{\alpha\nu}\frac{\partial\phi}{\partial x^\nu}\frac{\partial\phi}{\partial x^\beta} - g^\alpha_\beta\left[\frac{1}{2}g^{\mu\nu}\frac{\partial\phi}{\partial x^\mu}\frac{\partial\phi}{\partial x^\nu} + V(\phi)\right].$$

Here $V(\phi)$ is the potential for the field. For example a free field with mass m has a potential $V(\phi) = m^2\phi^2/2$. A warning about signs: if you delve into the literature you will invariably find different signs than those in Eq. (6.24). These are dictated by the choice of metric. Although our metric signature $(-,+,+,+)$ is probably most common in the context of cosmology, it is probably not as common in particle physics. Beware. We will assume that ϕ is mostly homogeneous, consisting of a zero-order part, $\phi^{(0)}(t)$, and a first-order perturbation, $\delta\phi(\vec{x}, t)$. In this section we will derive information about the zero-order homogeneous part, its energy density and pressure, and its time evolution. Later we will consider its perturbations, $\delta\phi$, and how they are generated.

For the homogeneous part of the field, only time derivatives of ϕ are relevant so the indices α and β in the first term in Eq. (6.24) and μ, ν in the second must be equal to zero. The energy-momentum tensor then reduces to

$$T_{\beta}^{(0)\alpha} = -g^{\alpha}{}_{0} g^{0}_{\beta} \left(\frac{d\phi^{(0)}}{dt} \right)^2 + g^{\alpha}{}_{\beta} \left[\frac{1}{2} \left(\frac{d\phi^{(0)}}{dt} \right)^2 - V\left(\phi^{(0)}\right) \right].$$

The time-time component of T^0_0 is equal to $-\rho$, so the energy density is

$$\rho = \frac{1}{2} \left(\frac{d\phi^{(0)}}{dt} \right)^2 + V\left(\phi^{(0)}\right)$$

The first term here is the kinetic energy density of the field, the second its potential energy density. A homogeneous scalar field therefore has much the same dynamics as a single particle moving in a potential [think of $\phi^{(0)}(t)$ as the position of the particle $x(t)$]. In fact this analogy dominates even the language used to describe inflation. The pressure for the homogeneous field is $\mathcal{P} = T_i^{(0)i}$ (no sum over spatial index i), so

$$\mathcal{P} = \frac{1}{2} \left(\frac{d\phi^{(0)}}{dt} \right)^2 - V\left(\phi^{(0)}\right)$$

A field configuration with negative pressure is therefore one with more potential energy than kinetic. An example is shown in Figure 6.6, in which a field is trapped in a false vacuum, i.e., a local, but not the global, minimum of the potential.

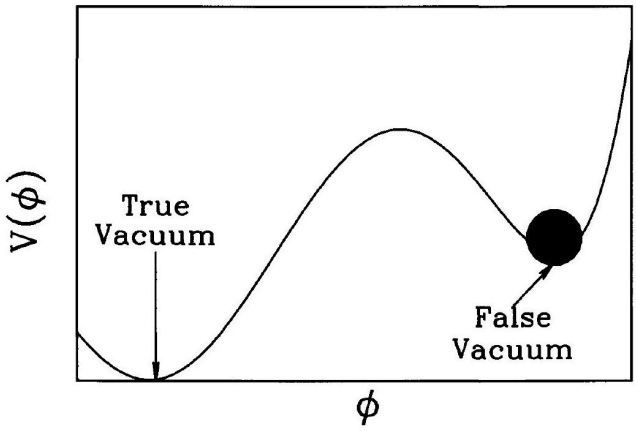

Figure 6.6. A scalar field trapped in a false vacuum. Since it is trapped, it has little kinetic energy. The potential energy is nonzero, however, so the pressure is negative. The global minimum of the potential is called the true vacuum, since a homogeneous field sitting at the global minimum of the potential is in the ground state of the system.

There is something important to notice about a field trapped in a false vacuum. Since $\phi^{(0)}$ is constant, its energy density, which is all potential, remains constant with time. Constant energy density is much different than anything with which we are familiar. The densities of both matter and radiation, for example, fall off very rapidly as the universe expands. Therefore, even if the universe initially contains a mixture of matter, radiation, and false vacuum energy, it will quickly become dominated by the vacuum energy. For a trapped field, it is trivial to determine the evolution of the scale factor. Since the energy density is constant, Einstein's equation for the evolution of a is

$$\frac{da/dt}{a} = \sqrt{\frac{8\pi G\rho}{3}} = \text{ constant}$$

We immediately see that a field trapped in a false vacuum produces exponential expansion as in Eq. (6.19), with $H \propto \rho^{1/2}$ constant. The primordial comoving horizon, that generated before the end of inflation, is then obtained by integrating the inverse of Eq. (6.19) over time,

$$\eta_{\rm prim} = \frac{1}{H_e a_e}\left(e^{H(t_e - t_b)} - 1\right)$$

where t_b is the beginning of inflation. So if the field is trapped for at least 60 e-foldings ($H\,(t_e - t_b) > 60$), the horizon problem is solved. Guth's (1981) initial formulation of inflation used a scalar field trapped in a false minimum of the potential, but it was quickly realized (Guth and Weinberg, 1983; Hawking, Moss, and Stewart, 1982) that such a scenario is not viable. The only way for the field to evolve to its true minimum is similar to the way an alpha particle migrates out of the potential barrier in a nucleus: it tunnels quantum mechanically. Thus, initially small localized regions tunnel from the false to the true vacuum. These bubbles of the true vacuum state must coalesce in order for the universe as a whole to move to the true vacuum state. Careful calculations showed that these bubbles would never coalesce, that the regions of false vacuum would expand rapidly and remain, so that the true vacuum state of the universe would never be attained.

To avoid the problem of the universe never reaching its true vacuum state, subsequent models of inflation (Linde, 1982; Albrecht and Steinhardt, 1982) made use of a scalar field slowly rolling toward its true ground state. The energy density of such a field is also very close to constant (if the potential is not too steep) so it quickly comes to dominate. To determine the evolution of $\phi^{(0)}$ in general when the field is not trapped, we return to the Einstein equations as given in Eq. (6.21). Consider the first of these. If the dominant component in the universe is ϕ, then the energy density on the right-hand side becomes $\left(d\phi^{(0)}/dt\right)^2/2 + V$. Differentiating this first equation therefore leads to

$$2\frac{da/dt}{a}\left[\frac{d^2a/dt^2}{a} - \left(\frac{da/dt}{a}\right)^2\right] = \frac{8\pi G}{3}\left[\left(\frac{d\phi^{(0)}}{dt}\right)\left(\frac{d^2\phi^{(0)}}{dt^2}\right) + V'\frac{d\phi^{(0)}}{dt}\right]$$

where V' is defined as the derivative of V with respect to the field $\phi^{(0)}$. We can replace the first term in brackets on the left by $-4\pi G(\rho/3 + \mathcal{P})$ as in Eq. (6.22). Similarly the second term on the left is $8\pi G\rho/3$. The left-hand side therefore becomes

$$\frac{da/dt}{a}8\pi G[-(\rho/3) - \mathcal{P} - 2\rho/3] = -8\pi G H\left(\frac{d\phi^{(0)}}{dt}\right)^2$$

Equating this to the right side of Eq. (6.30) leads to the evolution equation for a homogeneous scalar field in an expanding universe,

$$\frac{d^2\phi^{(0)}}{dt^2} + 3H\frac{d\phi^{(0)}}{dt} + V' = 0.$$

A more useful form for us will be with the conformal time η as the time variable; then it is straightforward (Exercise 8) to show that

$$\ddot{\phi}^{(0)} + 2aH\dot{\phi}^{(0)} + a^2V' = 0$$

where overdots still denote derivatives with respect to conformal time η.

Most models of inflation are slow roll models, in which the zero-order field, and hence the Hubble rate, vary slowly. Therefore, a simple relation between the conformal time η and the expansion rate holds. In particular, during inflation

$$\eta := \int_{a_e}^{a} \frac{da}{Ha^2}$$
$$\simeq \frac{1}{H}\int_{a_e}^{a} \frac{da}{a^2}$$
$$\simeq \frac{-1}{aH}$$

where the rough equality on the second line holds because H is nearly constant, and the one on the third because the scale factor at the end of inflation is much larger than in the middle ($a_e \gg a$). To quantify slow roll, cosmologists typically define two variables which vanish in the limit that ϕ remains constant. First, define

$$\epsilon := \frac{d}{dt}\left(\frac{1}{H}\right) = \frac{-\dot{H}}{aH^2}$$

Since H is always decreasing, ϵ is always positive. During inflation, it is typically small, whereas it is equal to 2 during a radiation era. In fact, one definition of an inflationary epoch is one in which $\epsilon < 1$. A complementary variable which also quantifies how slowly the field is rolling is:

$$\delta := \frac{1}{H}\frac{d^2\phi^{(0)}/dt^2}{d\phi^{(0)}/dt} = \frac{-1}{aH\dot{\phi}^{(0)}}\left[aH\dot{\phi}^{(0)} - \ddot{\phi}^{(0)}\right]$$
$$= \frac{-1}{aH\dot{\phi}^{(0)}}\left[3aH\dot{\phi}^{(0)} + a^2V'\right]$$

Here the paucity of Greek letters becomes a hindrance. The second slow-roll parameter is more conventionally defined as η, but we obviously cannot follow that convention as η is our conformal time. (Early universe cosmologists use τ for conformal time, freeing up η, but we do not have that luxury since we need τ for optical depth.) My choice of δ is also fairly common, but we need to bear in mind that this has nothing to do with the overdensities introduced in Chapter 4. The second line here follows from Eq. (6.33). Again, in most models δ is small. We will see in Section 6.6 that some unique features of inflation, deviations from the simplest possible spectrum and the production of gravity waves, are proportional to ϵ and δ. If these features are one day measured, they will not only be unique signatures of inflation but also allow us to learn something about the physics driving inflation.

12.6.4 Gravity Wave Production

Theory

Inflation does more than solve the horizon problem. The power of inflation is its ability to correlate scales that would otherwise be disconnected. The zero-order scheme outlined in the previous section ensures that the universe will be uniform on all scales of interest today. There are perturbations about this zero-order scheme, though, and these perturbations - produced early on when the scales are causally connected - persist long after inflation has terminated.

We are most interested in scalar perturbations to the metric since these couple to the density of matter and radiation and ultimately are responsible for most of the inhomogeneities and anisotropies in the universe. In Section 6.5 we will study these in detail. In addition to scalar perturbations, though, inflation also generates tensor fluctuations in the gravitational metric, so-called gravity waves. As we saw in Chapter 5, these are not coupled to the density and so

are not responsible for the large-scale structure of the universe, but they do induce fluctuations in the CMB. In fact, these fluctuations turn out to be a unique signature of inflation and offer the best window on the physics driving inflation, so they are clearly worthy of our study. I choose to study the production of tensor perturbations first before scalar perturbations for a subtle technical reason. Tensor perturbations to the metric are not coupled to any of the other perturbation variables, [2] so when we consider them, we will be looking at the fluctuations in a single field. Scalar perturbations to the metric couple to energy density fluctutations. The coupled fields fluctuate together and this coupling requires a bit of work to understand. This work, while important, is not the main point: the most important idea is that quantum mechanical fluctuations during inflation are responsible for the variations around the smooth background that so fascinate us. This idea is best introduced in the much simpler context of a single field, so we start with tensor perturbations.

During inflation, the universe consists primarily of a uniform scalar field and a uniform background metric. Against this background, the fields fluctuate quantum mechanically. At any given time, the average fluctuation is zero, because there are regions in which the field is slightly larger than its average value and regions in which it is smaller. The average of the square of the fluctuations (the variance), however, is not zero. Our goal is to compute this variance and see how it evolves as inflation progresses. Looking ahead, once we know this variance, we can draw from a distribution with this variance to set the initial [3] conditions.

Quantizing the Harmonic Oscillator

In order to compute the quantum fluctuations in the metric, we need to quantize the field. The way to do this, in the case of both tensor and scalar perturbations, is to rewrite the problem so that it looks like a simple harmonic oscillator. Once that is done, we will appeal to our knowledge of this simple system. Therefore, let's first record some basic facts about the quantization of the harmonic oscillator.

- A simple harmonic oscillator with unit mass and frequency ω is governed by the equation

$$\frac{d^2x}{dt^2} + \omega^2 x = 0$$

- Upon quantization, x becomes a quantum operator

$$\hat{x} = v(\omega, t)\hat{a} + v^*(\omega, t)\hat{a}^\dagger$$

[2] This is not quite true. The quadrupole moments act as sources for tensor perturbations, but these vanish if a scalar field drives inflation. See Exercise 10

[3] Initial here means those when the modes of interest are still far outside the horizon. This is well before any processing can take place, but well after inflation has generated them. where $\hat{a}$ is a quantum operator which acts on the state of the system, and v is a solution to Eq. (6.37), $v \propto e^{-i\omega t}$.

- In particular, $\hat{a}$ annihilates the vacuum state $|0\rangle$, in which there are no particles. It also satisfies the commutation relation

$$\left[\hat{a}, \hat{a}^\dagger\right] := \hat{a}\hat{a}^\dagger - \hat{a}^\dagger\hat{a} = 1.$$

Other commutators vanish: $[\hat{a}, \hat{a}] = \left[\hat{a}^\dagger, \hat{a}^\dagger\right] = 0$. It is straightforward to show (Exercise 9) that these commutation relations are equivalent to the (perhaps more familiar) relations between $\hat{x}$ and its momentum $\hat{p}$:

$$[\hat{x}, \hat{p}] = i,$$

as long as v is normalized via

$$v(\omega, t) = \frac{e^{-i\omega t}}{\sqrt{2\omega}}$$

These facts enable us to compute the quantum fluctuations of the operator $\hat{x}$ in the ground state $|0\rangle$:

$$\begin{aligned}\left\langle |\hat{x}|^2 \right\rangle &:= \left\langle 0 \left| \hat{x}^\dagger \hat{x} \right| 0 \right\rangle \\ &= \left\langle 0 \left| \left(v^* \hat{a}^\dagger + v\hat{a}\right)\left(v\hat{a} + v^*\hat{a}^\dagger\right) \right| 0 \right\rangle .\end{aligned}$$

Since $\hat{a}|0\rangle = 0$, the first term in the second set of parentheses vanishes. Similarly, $\langle 0|\hat{a}^\dagger = (a|0\rangle)^\dagger = 0$, so we are left with

$$\begin{aligned}\left\langle |\hat{x}|^2 \right\rangle &= |v(\omega, t)|^2 \left\langle 0 \left| \hat{a}\hat{a}^\dagger \right| 0 \right\rangle \\ &= |v(\omega, t)|^2 \left\langle 0 \left| \left[\hat{a}, \hat{a}^\dagger\right] + \hat{a}^\dagger\hat{a} \right| 0 \right\rangle .\end{aligned}$$

The second term again vanishes since $\hat{a}$ annihilates the vacuum, while the first is unity, so the variance in $\hat{x}$ is

$$\left\langle |\hat{x}|^2 \right\rangle = |v(\omega, t)|^2,$$

in this case $1/2\omega$. This is (almost) all we need to know about quantum fluctuations in order to compute the fluctuations in the early universe generated by inflation.

Tensor Perturbations

Recall that tensor perturbations to the metric are described by two functions h_+ and $h_\times$, each of which obeys Eq. (5.63),

$$\ddot{h} + 2\frac{\dot{a}}{a}\dot{h} + k^2 h = 0.$$

We would like to massage this equation into the form of a harmonic oscillator, so that h can be easily quantized. To do this, define [4]

$$\tilde{h} := \frac{ah}{\sqrt{16\pi G}}$$

Derivatives of h with respect to conformal time can be rewritten as

$$\frac{\dot{h}}{\sqrt{16\pi G}} = \frac{\dot{\tilde{h}}}{a} - \frac{\dot{a}}{a^2}\tilde{h}$$

and

$$\frac{\ddot{h}}{\sqrt{16\pi G}} = \frac{\ddot{\tilde{h}}}{a} - 2\frac{\dot{a}}{a^2}\dot{\tilde{h}} - \frac{\ddot{a}}{a^2}\tilde{h} + 2\frac{(\dot{a})^2}{a^3}\tilde{h}$$

Inserting these into Eq. (6.45), and multiplying by $\sqrt{16\pi G}$, gives

$$\frac{\ddot{\tilde{h}}}{a} - 2\frac{\dot{a}}{a^2}\dot{\tilde{h}} - \frac{\ddot{a}}{a^2}\tilde{h} + 2\frac{(\dot{a})^2}{a^3}\tilde{h} + 2\frac{\dot{a}}{a}\left(\frac{\dot{\tilde{h}}}{a} - \frac{\dot{a}}{a^2}\tilde{h}\right) + k^2\frac{\tilde{h}}{a}$$
$$= \frac{1}{a}\left[\ddot{\tilde{h}} + \left(k^2 - \frac{\ddot{a}}{a}\right)\tilde{h}\right] = 0.$$

This is precisely the form we know how to use. It has no damping term ($\alpha\dot{\tilde{h}}$) so we can immediately write down an expression for the quantum operator

$$\hat{\tilde{h}}(\vec{k},\eta) = v(k,\eta)\hat{a}_{\vec{k}} + v^*(k,\eta)a^\dagger_{\vec{k}},$$

where the coefficients of the creation and annihilation operators satisfy the equation

$$\ddot{v} + \left(k^2 - \frac{\ddot{a}}{a}\right)v = 0$$

We will shortly solve Eq. (6.51), but first let's see how the eventual solution determines the power spectrum of the fluctuations of the tensor perturbations.

[4] Regarding the factor of $\sqrt{16\pi G}$ here, the only way I know of deriving this is to write down the action for the fields $h_{+,\times}$. The kinetic term is then multiplied by a factor of $1/32\pi G$. A canonical scalar field has prefactor equal to a half. So the additional $16\pi G$ must be absorbed into a redefinition of the field. The hard part of this is writing down the action to second order in perturbation variables. We have seen that even first-order perturbations are cumbersome to track. On the other hand, by dimensional analysis - the fact that $h(\vec{x})$ is dimensionless while a canonical scalar field has dimensions equal to mass - we could have guessed that the factor of $m_{\rm Pl} = G^{-1/2}$ is required. Note that this prefactor does not affect the equation for $\tilde{h}$; it simply provides the normalization that becomes important when trying to determine the amplitude of the gravity-wave spectrum. Using our harmonic oscillator analogy, we can write the variance of perturbations in the $\tilde{h}$ field as

$$\left\langle \hat{\tilde{h}}^\dagger(\vec{k},\eta)\hat{\tilde{h}}\left(\vec{k}',\eta\right)\right\rangle = |v(\vec{k},\eta)|^2(2\pi)^3\delta^3\left(\vec{k}-\vec{k}'\right)$$

There is one difference between this expression and the analogous expression for the one-dimensional harmonic oscillator in Eq. (6.44). A quantum field is defined in all space, so it can be considered as a collection, an infinite collection, of oscillators, each at a different spatial position (or, in Fourier space, at different values of $\vec{k}$). The quantum fluctuations in each of these oscillators are independent (as long as the equations are linear) so $\hat{\tilde{h}}(\vec{k})$ is completely uncorrelated with $\hat{\tilde{h}}\left(\overrightarrow{k'}\right)$ if $\vec{k} \neq \vec{k}'$. The Dirac delta function in Eq. (6.52) enforces this independence; the $(2\pi)^3$ allows for the fact that we have moved to the continuum limit. Recalling that $\tilde{h} = ah/\sqrt{16\pi G}$, we see that

$$\left\langle \hat{h}^\dagger(\vec{k},\eta)\hat{h}\left(\vec{k}',\eta\right)\right\rangle = \frac{16\pi G}{a^2}|v(k,\eta)|^2(2\pi)^3\delta^3\left(\vec{k}-\vec{k}'\right)$$
$$:= (2\pi)^3 P_h(k)\delta^3\left(\vec{k}-\vec{k}'\right)$$

where the second line defines the power spectrum of the primordial perturbations to the metric. Conventions for the power spectrum abound in the literature; the one I've chosen in Eq. (6.53) is not the most popular in the early universe community. Often a factor of k^{-3} is added so that the power spectrum is dimensionless. I prefer to omit this factor to be consistent with the large scale structure community which likes its power spectra to have dimensions of k^{-3}. In any event, with this definition,

$$P_h(k) = 16\pi G \frac{|v(k,\eta)|^2}{a^2}$$

We have now reduced the problem of determining the spectrum of tensor perturbations produced during inflation to one of solving a second-order differential equation for $v(k,\eta)$, Eq. (6.51). To solve this equation, we first need to evaluate $\ddot{a}/a$ during inflation. Recall that overdots denote derivative with respect to conformal time, so $\dot{a} = a^2 H \simeq -a/\eta$ by virtue of Eq. (6.34). Therefore, the second derivative of a in Eq. (6.51) is

$$\begin{aligned}\frac{\ddot{a}}{a} &\simeq -\frac{1}{a}\frac{d}{d\eta}\left(\frac{a}{\eta}\right) \\ &\simeq \frac{2}{\eta^2}\end{aligned}$$

So the equation for v is

$$\ddot{v} + \left(k^2 - \frac{2}{\eta^2}\right) v = 0$$

The initial conditions necessary to solve this equation come from considering v at very early times before inflation has done most of its work. At that time, $-\eta$ is large, of order $\eta_{\rm prim}$, so the k^2 term dominates, and the equation reduces precisely to that of the simple harmonic oscillator. In that case, we know (Eq. (6.41)) that the properly normalized solution is $e^{-ik\eta}/\sqrt{2k}$. This knowledge enables us to choose (Exercise 11) the proper solution to Eq. (6.56),

$$v = \frac{e^{-ik\eta}}{\sqrt{2k}}\left[1 - \frac{i}{k\eta}\right]$$

This obviously goes into the correct solution when the mode is well within the horizon ($k|\eta| \gg 1$). Even if you don't work through Exercise 11 (which arrives at the relatively simple solution of Eq. (6.57) in a rather tortured way), you should at least check that the v given here is indeed a solution to Eq. (6.56).

After inflation has worked for many e-folds $k|\eta|$ becomes very small. Now that v has been normalized, we can determine the amplitude of v, and hence the variance of the super-horizon gravitational wave amplitude, by taking the small argument limit of Eq. (6.57):

$$\lim_{-k\eta\to 0} v(k,\eta) = \frac{e^{-ik\eta}}{\sqrt{2k}}\frac{-i}{k\eta}$$

Figure 6.7 shows the evolution of $h \propto v/a$ during inflation. At early times h falls as $1/a$ as inflation reduces the amplitude of the modes. Once $-k\eta$ becomes smaller than unity, the mode leaves the horizon, after which h remains constant.

The primordial power spectrum for tensor modes, which scales as $|v|^2/a^2$, is therefore constant in time after inflation has stretched the mode to be larger than the horizon. This constant determines the initial conditions for the gravity waves, those with which to start off $h_{+,x}$ at early times (where in this context "early" means well after inflation has ended but before decoupling). Equations (6.54) and (6.58) show that this constant is

$$\begin{aligned}P_h(k) &= \frac{16\pi G}{a^2}\frac{1}{2k^3\eta^2} \\ &= \frac{8\pi G H^2}{k^3}.\end{aligned}$$

The second line here follows from Eq. (6.34). We have assumed that H is constant in deriving this result; more generally, H is to be evaluated at the time when the mode of interest

leaves the horizon. This is our final expression for the primordial power spectrum of gravity waves. Detection of these waves would, quite remarkably, measure the Hubble rate during inflation. Since potential energy usually dominates kinetic energy in inflationary models, a measure of H would be tantamount to measuring the potential V, again quite remarkable in view of the likelihood that inflation was generated by physics at energy scales above 10^{15}GeV, 12 orders of magnitude beyond the capacity of present-day accelerators. There is no guarantee that gravity waves produced during inflation will be detectable. Indeed, since $H^2 \propto \rho/m_{\rm Pl}^2$, the power spectrum is proportional to $\rho/m_{\rm Pl}^4$, the energy density at the time

Tensor Modes (Unnormalized)

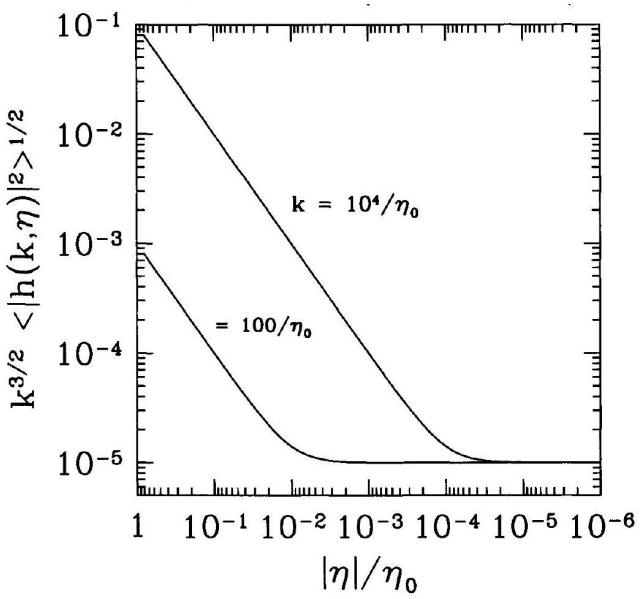

Figure 6.7. The root mean square fluctuations in the tensor field during inflation for two different k-modes. Time evolves from left to right: η is negative but gets closer to zero during inflation. Once a mode "leaves the horizon" ($\eta \sim -1/k$), its RMS amplitude remains constant. Note that after a mode has left the horizon, its RMS amplitude times $k^{3/2}$ is the same for all modes. This is called a scale-free spectrum, strictly true only if the Hubble rate is constant when the scale of interest leaves the horizon (the choice here).

of inflation in units of the Planck mass. If inflation takes place at scales sufficiently smaller than the Planck scale, then primordial gravity waves will not be detected. Later in the book, we will develop the machinery necessary to answer the question, How small can the gravity wave component be and still be detected?

Two final technical points are in order regarding Eq. (6.59). Although I have not emphasized this feature of the spectrum of these primordial perturbations, the fluctuations in h are Gaussian, just as are the quantum-mechanical fluctuations of the simple harmonic oscillator. Gaussianity is a fairly robust prediction of inflation; as such, many studies have been undertaken searching for signs of primordial nonGaussianity in CMB and large-scale structure data, signs that would jeopardize the inflationary picture. Although there have been some hints, none have held up under greater scrutiny, so this prediction of inflation too appears to be verified. Second, Eq. (6.59) is the power spectrum for $h_+$and $h_\times$separately; these are uncorrelated, so the power spectrum for all modes must be multiplied by a factor of 2.

12.6.5 Scalar Perturbations

Theory

The goal of this chapter is to find the perturbation spectrum of Ψ (or Φ; we assume throughout that they are equal in magnitude) emerging from inflation. With that spectrum, we can

use the relations in Section 6.1 to determine the spectrum of the other perturbation variables. Finding the spectrum for Ψ, however, turns out to be complicated, more so than was the tensor case considered earlier. The primary complication is the presence of perturbations in the scalar field driving inflation, perturbations which are coupled to Ψ.

To deal with this problem, we will first ignore it: in Section 6.5.1, we compute the spectrum of perturbations in the scalar field ϕ generated during inflation, neglecting Ψ. This turns out to be relatively simple to do, since it is virtually identical to the tensor calculation we went through above. Why are we justified in neglecting Ψ and how do the perturbations get transferred from ϕ to Ψ? The next two subsections take turns answering this question from two different points of view. First, Section 6.5.2 argues that - in a sense to be defined there - until a mode moves far outside the horizon, Ψ is indeed negligibly small. Once it is far outside the horizon, this no longer holds, but we will find that a linear combination of Ψ and $\delta\phi$ (the perturbations to the scalar field driving inflation) is conserved. This will allow us to convert the initial spectrum for $\delta\phi$ into a final spectrum for Ψ. The second way of justifying the neglect of perturbations to the metric is to switch gauges and work in a gauge in which the spatial part of the metric is unperturbed, a so-called spatially flat slicing. In such a gauge, the calculation of Section 6.5.1 is exact; the only question remaining is how to convert back to conformal Newtonian gauge to move on with the rest of the book. In Section 6.5.3, we identify a gauge-invariant variable, one which does not change upon a gauge transformation, which is proportional to $\delta\phi$ in a spatially flat slicing. It is then a simple matter to determine this variable in conformal Newtonian gauge, thereby linking Ψ in conformal Newtonian gauge to $\delta\phi$ in spatially flat slicing. Note that the two solutions to the coupling problem, as worked out in Sections 6.5.2 and 6.5.3, are simply alternative approaches to the same problem. If you are comfortable with gauge transformations, Section 6.5.3 is probably a more elegant approach; the more brute-force approach of Section 6.5.2 gives the same answer though and requires less formalism and background.

Scalar Field Perturbations around a Smooth Background

Let's decompose the scalar field into a zero-order homogeneous part and a perturbation,

$$\phi(\vec{x},t) = \phi^{(0)}(t) + \delta\phi(\vec{x},t),$$

and find an equation governing $\delta\phi$ in the presence of a smoothly expanding universe, i.e., with metric $g_{00} = -1; g_{ij} = \delta_{ij}a^2$. Consider the conservation of the energymomentum tensor,

$$T^{\mu}_{\nu;\mu} = \frac{\partial T^{\mu}_{\nu}}{\partial x^{\mu}} + \Gamma^{\mu}_{\alpha\mu}T^{\alpha}_{\nu} - \Gamma^{\alpha}_{\nu\mu}T^{\mu}_{\alpha} = 0$$

The $\nu = 0$ component of this equation, expanded out to first order, gives the desired equation for $\delta\phi$. Since we are assuming a smooth metric, the only first-order pieces are perturbations in the energy-momentum tensor. All the Γ 's are either zero-order $\left(\Gamma^{0}_{ij} = \delta_{ij}a^2H\right.$ and $\left.\Gamma^{i}_{0j} = \Gamma^{i}_{j0} = \delta_{ij}H\right)$ or zero (the rest of the components), as we found in Eqs. (2.22) and (2.23). So, writing the perturbed part of the energymomentum tensor as δT^{μ}_{ν} and considering the $\nu = 0$ component of the perturbed conservation equation leads to

$$0 = \frac{\partial \delta T^{0}_{0}}{\partial t} + ik_i\delta T^{i}_{0} + 3H\delta T^{0}_{0} - H\delta T^{i}_{i}$$

It remains to determine the perturbations to the energy-momentum tensor in terms of the perturbations to the scalar field.

First let's compute δT^{i}_{0}. Since the time-space components of the scalar metric are zero, the second set of terms in Eq. (6.24), those with prefactor g^{α}_{β}, vanish. Therefore,

$$T^{i}_{0} = g^{i\nu}\phi_{,\nu}\phi_{,0}$$

where I have returned to using.ν to denote the derivative with respect to x^ν. Since $g^{i\nu} = a^{-2}\delta_{i\nu}$, the index ν must be equal to i. Recall that the zero-order field $\phi^{(0)}$ is homogeneous, so $\phi^{(0)}_{,i} = 0$. The space-time component of the energy-momentum tensor therefore has no zero-order piece. To extract the first-order piece, we can set $\phi_{,i}$ to $\delta\phi_{,i} = ik_i\delta\phi$. Then, setting all other factors to their zero-order values leads to

$$\delta T^i_0 = \frac{ik_i}{a^3}\dot{\phi}^{(0)}\delta\phi$$

The additional factor of a enters the denominator here because $\phi^{(0)}_{,0} = \dot{\phi}^{(0)}/a$ (recall that ' is derivative with respect to conformal time).

The time-time component of the energy-momentum tensor is a little more difficult:

$$T^0_0 = g^{00}\left(\phi_{,0}\right)^2 - \frac{1}{2}g^{\alpha 3}\phi_{.\alpha}\phi_{,\beta} - V$$

Setting $\phi = \phi^{(0)} + \delta\phi$ leads to

$$T^0_0 = \frac{-1}{2}\left(\phi^{(0)}_{,0} + \delta\phi_{.0}\right)^2 - \frac{1}{2a^2}\delta\phi_{,i}\delta\phi_{.i} - V\left(\phi^{(0)} + \delta\phi\right).$$

The spatial derivatives come in pairs, and pairs of first-order variables ($\delta\phi_{.i}$) lcad to second-order terms. These may therefore be neglected. The potential may be expanded as a zero-order term, $V\left(\phi^{(0)}\right)$ plus a first-order correction, $V'\delta\phi$, so the first-order correction to the energy-momentum tensor is

$$\begin{aligned}\delta T^0{}_0 &= -\phi^{(0)}_{.0}\delta\phi, 0 - V'\delta\phi \\ &= \frac{-\dot{\phi}^{(0)}\dot{\delta\phi}}{a^2} - V'\delta\phi.\end{aligned}$$

Similarly, you can show that the space-space component is

$$\delta T^i{}_j = \delta_{ij}\left(\frac{\dot{\phi}^{(0)}\dot{\delta\phi}}{a^2} - V'\delta\phi\right)$$

Therefore, the conservation equation (6.62) becomes

$$\left(\frac{1}{a}\frac{\partial}{\partial\eta} + 3H\right)\left(\frac{-\dot{\phi}^{(0)}\dot{\delta\phi}}{a^2} - V'\delta\phi\right) - \frac{k^2}{a^3}\dot{\phi}^{(0)}\delta\phi - 3H\left(\frac{\dot{\phi}^{(0)}\dot{\delta\phi}}{a^2} - V'\delta\phi\right) = 0.$$

Carrying out the time derivatives (the only subtle one is $\partial V'/\partial\eta = V''\dot{\phi}^{(0)}$), multiplying by a^3, and collecting terms leads to

$$-\dot{\phi}^{(0)}\ddot{\delta\phi} + \dot{\delta\phi}\left(-\ddot{\phi}^{(0)} - 4aH\dot{\phi}^{(0)} - a^2V'\right) + \delta\phi\left(-a^2V''\dot{\phi}^{(0)} - k^2\dot{\phi}^{(0)}\right) = 0$$

The V'' term here is typically small, proportional to the slow-roll variables ϵ and δ (Exercise 14), so it can be neglected. The coefficient of $\dot{\delta\phi}$, the first set of parentheses, is equal to $-2aH\dot{\phi}^{(0)}$ using the zero-order equation (6.33), so after dividing by $-\dot{\phi}^{(0)}$, we are left with

$$\ddot{\delta\phi} + 2aH\dot{\delta\phi} + k^2\delta\phi = 0$$

This equation for perturbations to $\delta\phi$ is identical to Eq. (6.45) for tensor perturbations to the metric. Thus we can trivially copy our result from Section 6.4.2 and write immediately that the power spectrum of fluctuations in $\delta\phi$ is equal to

$$P_{\delta\phi} = \frac{H^2}{2k^3}$$

Compare this with Eq. (6.57). It is identical apart from a factor of $16\pi G$. Recall that we inserted this factor (with a bit of hand-waving: see the footnote on page 158) in the tensor case to turn the dimensionless h into a field with dimensions of mass. To get the result for $\delta\phi$ which is already a scalar field with the proper dimensions, we simply remove this factor.

Super-Horizon Perturbations

Until now, we have neglected the metric perturbations. When the wavelength of the perturbation is of order the horizon or smaller. this approximation is valid, as we will shortly see. In the process of seeing this, we will also find that, by the end of inflation, the metric perturbation has become important. So, although the inflationinduced perturbations start out all- " $\delta\phi$," they end up as a linear combination of Ψ and $\delta\phi$ or more generally as a linear combination of Ψ and perturbations to the energy-momentum tensor. The trick is to find the linear combination which is conserved outside the horizon. The value of this conserved linear combination is determined by $\delta\phi$ at horizon crossing; we can then evaluate it after inflation solely in terms of Ψ. The resulting equation will be of the form $\Psi \propto \delta\phi$ with the left-hand side the post-inflation metric perturbation and the right the scalar field perturbation produced during inflation (the power spectrum for which we have calculated above). We can then finally relate P_Ψ (and the spectra of all other perturbation variables using the results of Section 6.1) to the $P_{\delta\phi}$ of Eq. (6.72).

Let's begin by rewriting the equation for conservation of energy, this time in the presence of the metric perturbation. It is straightforward to show that Eq. (6.62) gets generalized to

$$\frac{\partial \delta T^0_0}{\partial t} + ik_i \delta T^i_0 + 3H\delta T^0_0 - H\delta T^i_i = -3(\mathcal{P}+\rho)\frac{\partial \Psi}{\partial t}$$

where $\mathcal{P}$ and ρ are the zero-order pressure and energy density. Were we correct to neglect Ψ in the last section? We were, as long as the right-hand side is significantly smaller than the individual terms on the left. Taking the first term on the left as an example, we require

$$\Psi \ll \frac{\delta T^0_0}{\mathcal{P}+\rho}$$

A simple way to see that this inequality holds is to use the Einstein equations we derived in Chapter 5. The most convenient for these purposes is the time-time (Eq. (5.21)) component:

$$k^2\Psi + 3aH(\dot{\Psi} + aH\Psi) = 4\pi G a^2 \delta T^0_0$$

Here I have simply copied the results from Chapter 5, replacing Φ with $-\Psi$. The left-hand side here is of order $k^2\Psi \sim a^2H^2\Psi$ for modes which are crossing the horizon. Therefore,

$$\begin{aligned}\Psi &\sim G\frac{\delta T^0_0}{H^2} \sim \frac{\delta T^0_0}{\rho} \\ &= \frac{\mathcal{P}+\rho}{\rho}\left(\frac{\delta T^0_0}{\mathcal{P}+\rho}\right).\end{aligned}$$

The left-hand side must be much less than the term in parentheses; equivalently, the prefactor $(\mathcal{P}+\rho)/\rho$ must be small. In fact, during inflation, the pressure is almost equal to minus the energy density, so this prefactor is very small. In terms of the slow-roll parameters, it is equal to $2\epsilon/3$. So, at least in slow-roll models of inflation, we are justified in neglecting metric perturbations when computing the spectrum of $\delta\phi$.

The above argument holds only for modes that have not yet passed outside the horizon. Super-horizon modes, on the other hand, require more careful treatment. Indeed, it is inevitable that the inequality of Eq. (6.74) will break down sometime before the end of inflation. To see this, recall that after inflation, when the universe is dominated by radiation, $\delta T^0{}_0 = -4\rho_r\Theta_0$ and $\mathcal{P} + \rho = 4\rho_r/3$. Therefore, after inflation, the right-hand side of Eq. (6.74) is $-3\Theta_0$. According to Eq. (6.12), $\Psi = -2\Theta_0$ right after inflation, so it is certainly not true that the inequality of Eq. (6.74) is satisfied for all times. At some point before inflation ends, perturbations to Ψ must grow in importance relative to those in the energy-momentum tensor.

One way to deal with the coupling between the metric perturbations and those to the energy density is to define

$$\zeta := -\frac{ik_i\delta T^0_i H}{k^2(\rho + \mathcal{P})} - \Psi$$

For sub-horizon modes and those which have just left the horizon, Ψ is negligible; $P + \rho = \left(\dot{\phi}^{(0)}/a\right)^2$ from Eqs. (6.26) and (6.27); and Eq. (6.64) fixes the numerator of the first term in ζ. We are left with

$$\zeta = -aH\delta\phi/\dot{\phi}^{(0)}$$

around the time of horizon crossing. After inflation ends, $ik_i\delta T^0{}_i = 4ak\rho_r\Theta_1$, proportional to the dipole of the radiation. Since the pressure of radiation is equal to a third of the energy density,

$$\begin{aligned}\zeta &= -\frac{3aH\Theta_1}{k} - \Psi \\ &= -\frac{3}{2}\Psi \quad \text{(post inflation)}.\end{aligned}$$

The second equality follows from the initial conditions relating the dipole to the potential (Eq. (6.16)).

The variable ζ is so important because it is conserved when the perturbation moves outside the horizon (Figure 6.8). We will show that ζ is conserved shortly, but first let's appreciate the importance of this conservation. Since we know that, after inflation, $\zeta = -3\Psi/2$, we can immediately relate Ψ coming out of inflation to the $\delta\phi$ at horizon crossing,

$$\Psi|_{\text{post inflation}} = \frac{2}{3}aH\frac{\delta\phi}{\dot{\phi}^{(0)}}\bigg|_{\text{horizon crossing}}.$$

Equivalently, the post-inflation power spectrum of Ψ is simply related to the horizon-crossing spectrum of $\delta\phi$:

$$P_\Psi = \frac{4}{9}\left(\frac{aH}{\dot{\phi}^{(0)}}\right)^2 P_{\delta\phi}\bigg|_{aH=k}$$

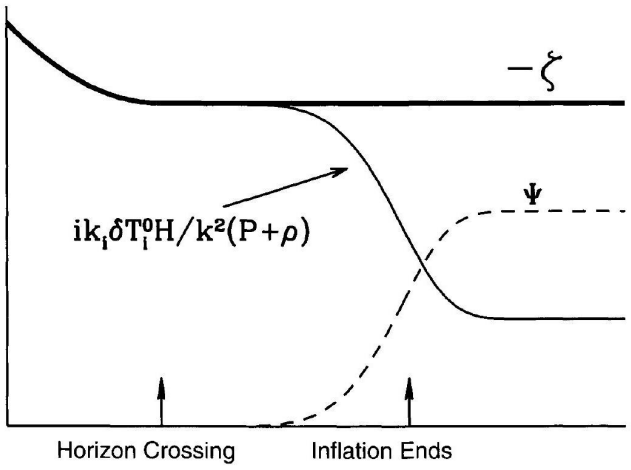

Figure 6.8. Cartoon view of the evolution of scalar, adiabatic perturbations during inflation in conformal Newtonian gauge. When a mode is sub-horizon, quantum-mechanical fluctuations are set up in the scalar field driving inflation $\left(ik_i\delta T^0_i H/k^2(\rho+\mathcal{P}) = aH\delta\phi/\dot{\phi}^{(0)}\right)$. Scalar perturbations to the metric are negligible at this time. Once the mode leaves the horizon, the linear combination $\zeta = -ik_i\delta T^0{}_i H/k^2(\rho+\mathcal{P}) - \Psi$ is conserved. Well after inflation has ended, the metric perturbation has grown in importance, but the linear combination ζ remains unchanged.

$$= \frac{2}{9k^3}\left(\frac{aH^2}{\dot{\phi}^{(0)}}\right)^2\Bigg|_{aH=k}$$

the second line following from Eq. (6.72). Another way to express the power spectrum of scalar perturbations is to eliminate $\dot{\phi}^{(0)}$ in favor of the slow-roll parameter ϵ. You will show (Exercise 12) that $\left(aH/\dot{\phi}^{(0)}\right)^2 = 4\pi G/\epsilon$, so

$$P_\Psi = P_\Phi(k) = \frac{8\pi G}{9k^3}\frac{H^2}{\epsilon}\Bigg|_{aH=k}.$$

The first equality here follows from our ubiquitous assumption that anisotropic strsses are small, so that $\Psi = -\Phi$. Comparing to Eq. (6.59), we see that the ratio of scalar to tensor modes is of order $1/\epsilon$; that is, we expect scalar modes to dominate. Finally, another way of writing the scalar power spectrum is to eliminate ϵ in favor of the potential and its derivative, using the result of Exercise 14,

$$P_\Phi(k) = \frac{128\pi^2 G^2}{9k^3}\left(\frac{H^2V^2}{V'^2}\right)\Bigg|_{aH=k}.$$

It remains to prove that ζ is conserved on super-horizon scales. To see this, let's turn to the conservation equation, Eq. (6.73). On large scales, $k_i\delta T^i{}_0$ is proportional to k^2 and so can be ignored, leaving

$$\frac{\partial\delta T^0_0}{\partial t} + 3H\delta T^0_0 - H\delta T^i_i = -3(\mathcal{P}+\rho)\frac{\partial\Psi}{\partial t}.$$

On large scales, you will show (Exercise 13) that the energy-momentum tensor satisfies

$$\frac{ik_i\delta T^0{}_i H}{k^2} = \frac{\delta T^0_0}{3}$$

Therefore, on large scales

$$\zeta = -\Psi - \frac{1}{3}\frac{\delta T^0_0}{\rho + \mathcal{P}}$$

Eliminating Ψ in favor of ζ in the conservation equation leads to

$$\frac{\partial \delta T^0 0}{\partial t} + 3H\delta T^0{}_0 - H\delta T^i{}_i = 3(\mathcal{P}+\rho)\frac{\partial \zeta}{\partial t} + (\rho+\mathcal{P})\frac{\partial}{\partial t}\left[\frac{\delta T^0{}_0}{\rho+\mathcal{P}}\right]$$

The partial derivative on the right acting on $\delta T^0{}_0$ cancels the first term on the left, leaving

$$\delta T^0_0\left[3H + \frac{1}{\rho+\mathcal{P}}\left(\frac{d\rho}{dt} + \frac{d\mathcal{P}}{dt}\right)\right] - H\delta T^i_i = 3(\mathcal{P}+\rho)\frac{\partial\zeta}{\partial t}$$

Recall from Eq. (2.55) that $d\rho/dt = -3H(\rho+\mathcal{P})$, so the first term in brackets cancels the second, and

$$\frac{\partial\zeta}{\partial t} = \frac{-1}{3(\rho+\mathcal{P})^2}\left[H(\rho+\mathcal{P})\delta T^i{}_i - \delta T^0_0\frac{d\mathcal{P}}{dt}\right].$$

I claim that the two terms in brackets on the right cancel for the class of perturbations we are considering. To see this, first rewrite $H(\rho+\mathcal{P})$ as $-(1/3)d\rho/dt$. Thus, the terms in brackets are proportional to

$$\frac{\delta T^i_i}{3} + \frac{d\mathcal{P}}{d\rho}\delta T^0_0 = \delta\mathcal{P} - \frac{d\mathcal{P}}{d\rho}\delta\rho$$

since $-\delta T^0{}_0$ is the perturbation to the energy density, while $\delta T^i{}_i/3$ is the perturbation to the pressure. If we know the background pressure-energy density relation $d\mathcal{P}/d\rho$, then given an overdensity $\delta\rho$, we expect the pressure perturbation to be proportional to the overdensity with coefficient $d\mathcal{P}/d\rho$. Indeed, this is the characteristic feature of adiabatic perturbations, precisely those set up during inflation. Thus, ζ is indeed conserved on large scales.

Spatially Flat Slicing

The treatment of the previous subsection is complete, but it is not the most elegant way to understand scalar perturbations in inflation. A much simpler way is to move back and forth between different gauges, making use along the way of the concept of a gauge-invariant variable, one which does not change under these transformations. Here I outline this method, leaving some of the more detailed calculations as problems.

We saw earlier that one of the major complications in conformal Newtonian gauge was that perturbations to the scalar field $\delta\phi$ are coupled to the potential Ψ. It would obviously be nice to transform to a gauge in which these perturbations decoupled. Consider a gauge with spatially flat slicing, with the spatial part of the metric $g_{ij} = \delta_{ij}a^2$. In this gauge the line element is

$$ds^2 = -(1+2A)dt^2 - 2aB_{,i}dx^i dt + \delta_{ij}a^2 dx^i dx^j$$

i.e., there are two functions A and B characterizing the perturbations. In this case, the equation for $\delta\phi$ is given exactly (Exercise 16) by Eq. (6.71): the perturbations in the scalar field do not couple to those in the gravitational metric. Therefore, without having to neglect any couplings, we can identify the power spectrum for $\delta\phi$ as given by Eq. (6.72)

The next step is to identify a gauge-invariant variable, one which remains the same when transforming from one gauge to the next. Bardeen (1980) identified several such variables, two characterizing scalar perturbations to the metric and two characterizing perturbations to the

matter. Of course any linear combination of these is still gauge invariant. We would like to identify the combination that is proportional to $\delta\phi$ in the gauge with spatially flat slicing. In this gauge, Bardeen's velocity (Eq. (5.78)) is

$$v = ikB - \frac{ik\dot{\phi}^{(0)}\delta\phi}{(\rho+\mathcal{P})a^2} \quad \text{(spatially flat slicing)}$$

where I have evaluated δT^0_i with Eq. (6.64). Thus, we can create a gauge-invariant variable proportional to $\delta\phi$ in a spatially flat slicing if we subtract off the kB term. Bardeen's Φ_H (Eq. (5.76)) is simply equal to aHB, so the combination

$$\zeta := -\Phi_H - \frac{iaH}{k}v$$

is gauge invariant and in spatially flat slicing is equal to

$$\zeta = -\frac{aH}{\dot{\phi}^{(0)}}\delta\phi \quad \text{(spatially flat slicing)}$$

We can immediately relate the power in ζ to the power in $\delta\phi$,

$$P_\zeta = \left(\frac{aH}{\dot{\phi}(0)}\right)^2 P_{\delta\phi}$$

We know $P_{\delta\phi}$ from Eq. (6.72) and the prefactor is $4\pi G/\epsilon$, so

$$P_\zeta = \left.\frac{2\pi G H^2}{\epsilon k^3}\right|_{aH=k}.$$

Equation (6.96) is very useful, for it expresses the power spectrum of a gauge invariant quantity. Although we computed it in a gauge of the form in Eq. (6.91), once we have this answer, we can compute ζ in any gauge and then relate the power in the perturbation variables of that gauge to P_ζ.

Throughout this book, we have been working in conformal Newtonian gauge. In this gauge, $\Phi_H = -\Phi$, so ζ as defined in Eq. (6.93) is indeed given by Eq. (6.77). We argued in Section 6.5.2 that in conformal Newtonian gauge, after inflation, $\zeta = 3\Phi/2$, so $P_\Phi = 4P_\zeta/9$, or using Eq. (6.96),

$$P_\Phi = \left.\frac{8\pi G H^2}{9\epsilon k^3}\right|_{aH=k}$$

in exact agreement with our earlier calculation finalized in Eq. (6.82).

This is the end of the calculation, but not quite the end of the story. Bardeen and others have argued that Φ_H has a nice geometrical interpretation, one shared by ζ in certain gauges. In particular, the curvature of the three-dimensional space at fixed time is equal to $4k^2\Phi_H/a^2$. Therefore, perturbations in Φ_H represent curvature perturbations: even though the zero-order space is flat, perturbations induce a curvature which varies from place to place. In conformal Newtonian gauge or in a spatially flat slicing this interpretation would seem irrelevant to perturbations in ζ, since ζ is a combination of both Φ_H and the velocity. However, if one moves to a comoving gauge, one in which the velocities vanish, then ζ is equal to Φ_H. In comoving gauges, then, it is clear that a perturbation to ζ is a curvature perturbation, and indeed the scalar perturbations generated during inflation are often called curvature perturbations.

Other topics about initial conditions

12.7 Inhomogeneities

Having set up the system of equations to be solved and the initial conditions for the perturbations, we can now calculate the inhomogeneities and anisotropies in the universe. In this first solutions chapter, we start with the perturbations to the dark matter. In principle these are coupled to all other perturbations. In practice, though, perturbations to the dark matter depend very little on the details of the radiation perturbations. Dark matter, by definition, is affected by radiation only indirectly, through the gravitational potentials. At late times, when the universe is dominated by matter, these potentials are independent of the radiation. At early times, while it is true that the potentials are determined by the radiation, it is also true that the radiation perturbations are relatively simple, so that all moments beyond the monopole and dipole can be neglected. The converse is not true, as we will see in the next chapter: To treat the anisotropies properly we will need to know how the matter perturbations behave.

The ultimate goal of this exercise is to compare theory with observations. We will solve for the evolution of each Fourier mode, $\delta(k, \eta)$. Given this solution, and the initial power spectrum generated by inflation, we can construct the power spectrum of matter today. At least on large scales, this is the most important observable. On small scales, comparison with observation today is more difficult: one must worry about nonlinearities and gas dynamics when comparing with the galaxy distribution. Nonetheless, even on small scales, the linear power spectrum, which we compute in this chapter, is often the starting point for any quantitative statement about the distribution of matter.

12.7.1 Prelude

Gravitational instability is a powerful idea, easy to understand, and most likely responsible for the structure in our universe. As time evolves, matter accumulates in initially overdense regions. It doesn't matter how small the initial overdensity was (e.g., in typical cosmological scenarios, the overdensity was of order 1 part in 10^5); eventually enough matter will be attracted to the region to form structure.

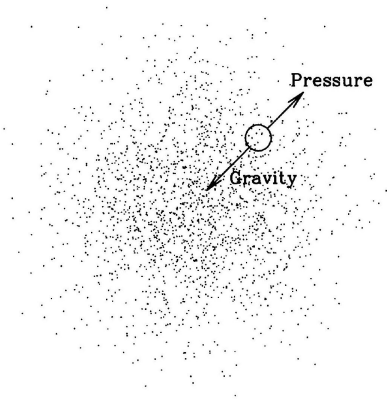

Figure 7.1. Gravitational instability. Mass near an overdense region is attracted to the center by gravity but repelled by pressure. If the region is dense enough, gravity wins and the overdensity grows with time.

The $F = ma$ of gravitational instability is the equation governing overdensities δ. Schematically, it reads

$$\ddot{\delta} + [\text{ Pressure } - \text{ Gravity }]\delta = 0$$

These basic forces, depicted in Figure 7.1, act in opposite directions. Gravity acts to increase overdensities, grabbing more matter into the region. Since there are more particles in an overdense region, random thermal motion causes a net loss of mass in an overdense region. Therefore, if pressure is strong, inhomogeneities do not grow. As indicated by the cartoon equation (7.1), if pressure is low, δ grows exponentially; if it is large, δ oscillates with time.

We will see many manifestations of the simple form of gravitational instability depicted in Eq. (7.1). Different ambient cosmological conditions alter the growth rate. For example, in a matter-dominated universe, δ grows only as a power of time, not exponentially, whereas in a radiation-dominated universe, the growth is but logarithmic. We will treat super-horizon versions of this equation as well as the more familiar sub-horizon version. When going though the math, though, it is useful to bear in mind the dueling concepts of gravity and pressure.

Three Stages of Evolution

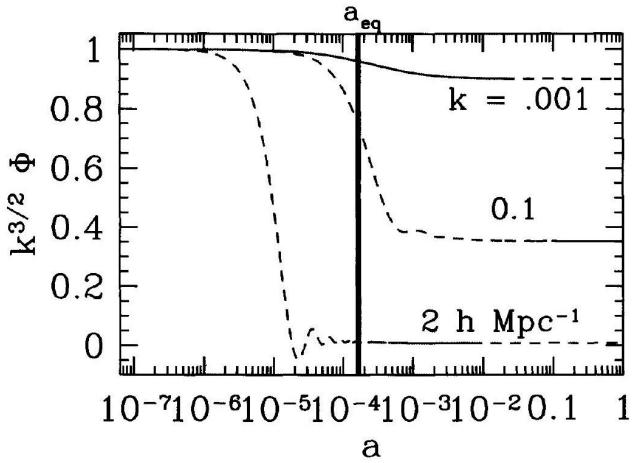

Figure 7.2. The linear evolution of the gravitional potential Φ. Dashed line denotes that the mode has entered the horizon. Evolution through the shaded region is described by the transfer function. The potential is unnormalized, but the relative normalization of the three modes is as it would be for scale-invariant perturbations. Here baryons have been neglected, $\Omega_m = 1$, and $h = 0.5$.

The evolution of cosmological perturbations breaks up naturally into three stages. To see this, let's cheat and look at the solutions for several different modes. Figure 7.2 shows the gravitational potential as a function of scale factor for long-, medium-, and short-wavelength modes. Early on, all of the modes are outside the horizon ($k\eta \ll 1$) and the potential is constant. At intermediate times (shaded in the figure), two things happen: the wavelengths fall within the horizon and the universe evolves from radiation domination ($a \ll a_{\rm eq}$) to matter domination ($a \gg a_{\rm eq}$). Without getting into the details, we see that the order of these epochs ($a_{\rm eq}$ and the epoch of horizon crossing) greatly affects the potential. The large-scale mode, which enters the horizon well after $a_{\rm eq}$, evolves much differently than the small-scale mode, which enters the horizon before equality. Finally, at late times, all the modes evolve identically again, in this case (where $\Omega_m = 1$) remaining constant. We are able to observe the distribution of matter predominantly at late epochs, in the third stage of evolution, when all modes are evolving identically. If we wish to relate the potential during these times to the primordial potential set up during inflation, and we do, we can write schematically

$$\Phi(\vec{k}, a) = \Phi_{\rm p}(\vec{k}) \times \{\text{Transfer Function } (k)\} \times \{\text{ Growth Function } (a)\}$$

where Φ_p is the primordial value of the potential, set during inflation. The transfer function describes the evolution of perturbations through the epochs of horizon cossing and radiation/matter transition (the shaded region in Figure 7.2), while the growth factor describes the

wavelength-independent growth at late times. This schematic equation is indeed roughly how the growth factor and the transfer function are defined, with two caveats, both due to convention. Notice from Figure 7.2 that even the largest wavelength perturbations decline slightly as the universe passes through the epoch of equality. This decline is conventionally removed so that the transfer function on large scales is equal to 1. Therefore, the transfer function is defined as

$$T(k) := \frac{\Phi\left(k, a_{\rm late}\right)}{\Phi_{\text{Large-Scale}}\left(k, a_{\rm late}\right)}$$

where $a_{\rm late}$ denotes an epoch well after the transfer function regime and the LargeScale solution is the primordial Φ decreased by a small amount. We will derive in Section 7.2 that - neglecting anisotropic stresses - this factor is equal to (9/10). The second caveat concerns the growth function. The ratio of the potential to its value right after the transfer function regime is defined to be

$$\frac{\Phi(a)}{\Phi\left(a_{\rm late}\right)} := \frac{D_1(a)}{a} \quad (a > a_{\rm late})$$

where D_1 is called the growth function. In the flat, matter-dominated case depicted in Figure 7.2, then, the potential is constant so $D_1(a) = a$. With these conventions, we have

$$\Phi(\vec{k}, a) = \frac{9}{10}\Phi_{\rm p}(\vec{k})T(k)\frac{D_1(a)}{a} \quad (a > a_{\rm late})\,.$$

The easiest way to probe the potential is to measure the matter distribution. Figure 7.3 shows the evolution of the matter overdensity for three different modes. Notice that at late times - when the potential is constant and all the modes are within the horizon - the overdensity grows with the scale factor ($\delta \propto a$). This explains the seemingly odd nomenclature above (Why is it called a growth function if the potential remains constant?): D_1 describes the growth of the matter perturbations at late times. This growth is completely consistent with our intuition that as time evolves, overdense regions attract more and more matter, thereby becoming more overdense.

We can now express the power spectrum of the matter distribution in terms of the primordial power spectrum generated during inflation, the transfer function, and the growth function. The simplest way to relate the matter overdensity to the

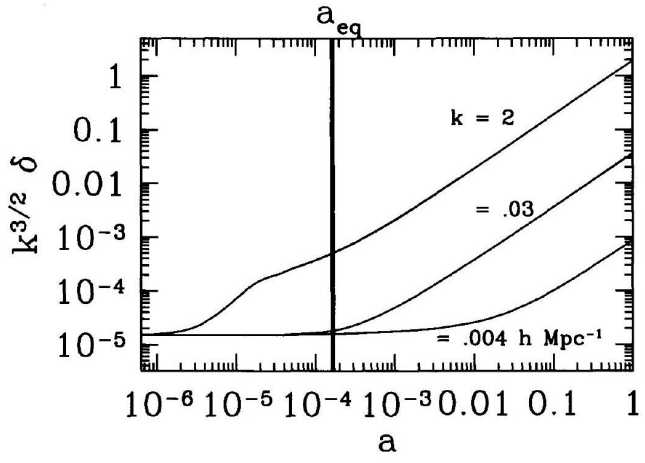

Figure 7.3. The evolution of perturbations to the dark matter in the same model as plotted in Figure 7.2. Amplitude starts to grow upon horizon entry (different times for the three different modes shown here). Well after $a_{\rm eq}$, all sub-horizon modes evolve identically, scaling as

the growth factor. In the case plotted, a flat, matter dominated universe, the growth factor is simply equal to a.

potential at late times is to use Poisson's equation (the large- k, no-radiation limit of Eq. (5.81))

$$\Phi = \frac{4\pi G \rho_{\rm m} a^2 \delta}{k^2} \quad (a > a_{\rm late})$$

The background density of matter is $\rho_{\rm m} = \Omega_m \rho_{\rm cr}/a^3$, and $4\pi G \rho_{\rm cr} = (3/2)H_0^2$, so

$$\delta(\vec{k}, a) = \frac{k^2 \Phi(\vec{k}, a) a}{(3/2)\Omega_m H_0^2} \quad (a > a_{\rm late}\,).$$

This, together with Eq. (7.5), allows us to relate the overdensity today to the primordial potential

$$\delta(\vec{k}, a) = \frac{3}{5}\frac{k^2}{\Omega_m H_0^2}\Phi_{\rm p}(\vec{k}) T(k) D_1(a) \quad (a > a_{\rm late}\,)$$

Equation (7.8) holds regardless of how the initial perturbation Φ_p was generated. In the context of inflation, $\Phi_{\rm p}(\vec{k})$ is drawn from a Gaussian distribution with mean zero and variance (Eq. (6.100)) $P_\Phi = (50\pi^2/9k^3)\,(k/H_0)^{n-1}\,\delta_H^2\,(\Omega_m/D_1(a=1))^2$. So the power spectrum of matter at late times is

$$P(k, a) = 2\pi^2 \delta_H^2 \frac{k^n}{H_0^{n+3}} T^2(k) \left(\frac{D_1(a)}{D_1(a=1)}\right)^2 \quad (a > a_{\rm late}\,).$$

The power spectrum has dimensions of (length $)^3$. If we want to express the power as a dimensionless function, then, we must multiply by k^3. More precisely, one often associates $d^3k P(k)/(2\pi)^3$ with the excess power in a bin of width dk centered at k. After integrating over all orientations of $\vec{k}$, this becomes $(dk/k)\Delta^2(k)$, with

$$\Delta^2(k) := \frac{k^3 P(k)}{2\pi^2}$$

Small Δ then corresponds to small inhomogeneities, while large Δ indicates nonlinear perturbations. Note that, with our conventions, a Harrison-Zel'dovich-Peebles spectrum today has $\Delta^2 = \delta_H^2$ on a horizon-sized scale ($k = H_0$).

Figure 7.4 shows the power spectrum today for two different models. Note that in both of the models $P \propto k$ on large scales, where the transfer function is unity. This behavior is apparent from Eq. (7.9) and corresponds to the simplest inflationary model, wherein $n = 1$. On small scales the power spectrum turns over. To understand this, look back at Figure 7.2. The small-scale mode there ($k = 2h$ Mpc^{-1}) enters the horizon well before matter/radiation equality. During the radiation epoch the potential decays, so the transfer function is much smaller than unity. The effect of this on matter perturbations can be seen in Figure 7.3, where the growth of δ is retarded starting at $a \simeq 10^{-5}$ after the mode has entered the horizon and ending at $a \simeq 10^{-4}$ when the universe becomes matter dominated. Modes that enter the horizon even earlier undergo more suppression. Thus, the power spectrum is a decreasing function of k on small scales.

This leads to the realization that there will be a turnover in the power spectrum at a scale corresponding to the one which enters the horizon at matter/radiation equality. The power of this realization is apparent in Figure 7.4, which shows two different models: one corresponding to a flat, matter-dominated universe today (often called standard Cold Dark Matter or SCDM) and the other a universe with a cosmological constant today (Lambda Cold Dark Matter or Λ

CDM). The major difference between the two models is that sCDM has more matter ($\Omega_m = 1$) and hence an earlier $a_{\rm eq}$. An earlier $a_{\rm eq}$ means only the very small scales enter the horizon during the radiation-dominated epoch, and therefore the turnover occurs on smaller scales. Finally, another important scale to keep in mind is the scale above which nonlinearities cannot be ignored. This is roughly set by $\Delta(k_{\rm nl}) \simeq 1$, which corresponds to $k_{\rm nl} \simeq 0.2h{\rm Mpc}^{-1}$ in most models. The power spectra shown in Figure 7.4 are the linear power spectra today. On scales smaller than $k_{\rm nl}$, one cannot blindly compare the spectra from Figure 7.4 with the matter distribution today.

Method

What are the evolution equations for the dark matter overdensity? In principle, these are the full set of Boltzmann equations derived in Chapter 4 and the pair of Einstein equations from Chapter 5. In practice, though, the full set of equations is not needed. To understand why, recall that early on (before recombination at

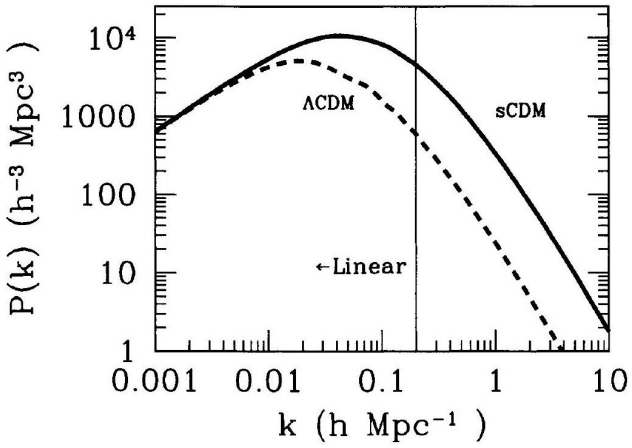

Figure 7.4. The power spectrum in two Cold Dark Matter models, with (ΛCDM) and without (sCDM) a cosmological constant. The spectra have been normalized to agree on large scales. The spectrum in the cosmological constant model turns over on larger scales because of a later $a_{\rm eq}$. Scales to the left of the vertical line are still evolving linearly.

$a = a_*$), the photon distribution can be characterized by only two moments, the monopole Θ_0 and the dipole Θ_1. All other moments are suppressed because the photons are tightly coupled to the electron/proton gas. After decoupling this ceases to be true, and to completely characterize the photon distribution we will need to follow high moments. However, for the purposes of the matter distribution, what the photons are doing after a_* is irrelevant. For, by that time, which is typically well into the matter era, the potential is dominated by the dark matter itself. To sum up then, we can neglect all photon moments except for the monopole and dipole when we are considering the evolution of the matter distribution.

Neglecting the higher radiation moments, the four relevant Boltzmann equations (Section 4.7) become

$$\dot{\Theta}_{r.0} + k\Theta_{r.1} = -\dot{\Phi}$$
$$\dot{\Theta}_{r.1} - \frac{k}{3}\Theta_{r.0} = \frac{-k}{3}\Phi$$
$$\dot{\delta} + ikv = -3\dot{\Phi}$$
$$\dot{v} + \frac{\dot{a}}{a}v = ik\Phi$$

Even with the assumption that only the monopole and dipole are retained, getting from Eq. (4.100) to Eqs. (7.11) and (7.12) requires some explanation and work. First, the explanation: The subscript $_r$ here refers to radiation, both neutrinos and photons. Both species contribute to the gravitational potential (which is our interest in this chapter) and both start out with the same initial conditions. It is not quite as obvious that both follow the same evolution equations (the $\dot{\tau}$ terms can be neglected in Eq. (4.100)) or that these evolution equations are the ones given in (7.11) and (7.12). But it is true, at least in the limit of small baryon density, and again only for the purposes of following the matter evolution. You can work out the details in Exercise 1, and we will explore the full photon evolution equation in the next chapter.

To close the set of equations for the dark matter density, we need an equation for the gravitational potential Φ. You may have noticed that in Eqs. (7.11)-(7.14), I set $\Psi \to -\Phi$, an approximation valid in the limit that there are no quadrupole moments (Eq. (5.33)). Since some of the Einstein equations are redundant, we have several choices for one last equation relating Φ to the radiation and matter overdensities. We can use the time-time component, Eq. (5.27),

$$k^2\Phi + 3\frac{\dot{a}}{a}\left(\dot{\Phi} + \frac{\dot{a}}{a}\Phi\right) = 4\pi G a^2\left[\rho_{\rm dm}\delta + 4\rho_r\Theta_{r,0}\right]$$

Here, again I have set Ψ to $-\Phi$, neglected the baryons, [1] and merged the neutrino and photon contributions to the potential. The alternative is to use the algebraic (no time derivatives) equation (5.81):

$$k^2\Phi = 4\pi G a^2\left[\rho_{\rm dm}\delta + 4\rho_r\Theta_{r,0} + \frac{3aH}{k}\left(i\rho_{\rm dm}v + 4\rho_r\Theta_{r,1}\right)\right].$$

Both of these equations will be useful to us at various times, although only one is necessary to close the set of equations for the five variables $\delta, v, \Theta_{r,0}, \Theta_{r,1}$, and Φ.

At this stage, the simplest thing to do is solve the set of five coupled equations numerically (Exercise 2). If Eq. (7.15) is used, there are no numerical difficulties, and with very little work, you can have a code which computes the transfer function (in the absence of baryons) in less than a second.

Analytic solutions for the dark matter density are harder to come by. I know of no analytic solution valid on all scales at all times. To make progress, we will have to take some limits which reduce the full set of five equations to a more managable two or three. The cost is that these limits will be valid only for certain scales at certain times. Patching these analytic solutions together to obtain a reasonable transfer function is as much art as science.

As a guide to this analytic work which will occupy us much of the rest of this chapter, consider Figure 7.5. The solid curve is the comoving horizon (conformal time), which increases with time, equal to about $30h^{-1}$Mpc at the epoch of

[1] This is a fairly good approximation since in most models, the baryon density is much smaller than the dark matter density. We will explore the effects of baryons in Section 7.6.

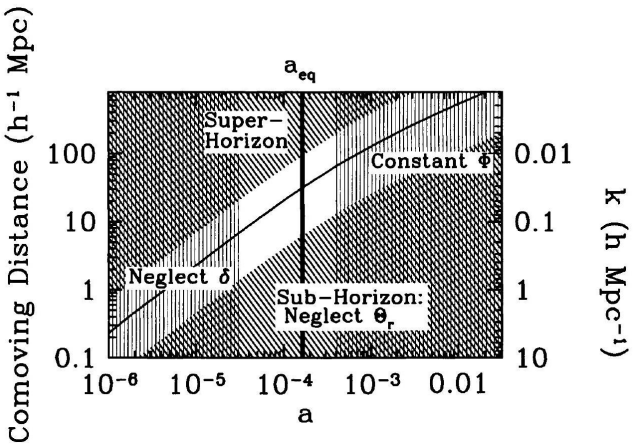

Figure 7.5. Physics of the transfer function. Hatched regions show where analytic expressions exist. The gaps in the center show that no analytic solutions exist to capture the full evolution of intermediate scale modes. The curve monotonically increasing from bottom left to top right is the comoving horizon.

equality. [2] A given comoving scale remains constant with time. Take for example, a comoving distance of $10h^{-1}$Mpc, corresponding to wavenumber $k = 0.1h\text{Mpc}^{-1}$. At early times ($a < 10^{-5}$) this distance is larger than the horizon, so $k\eta \ll 1$. We can then drop all terms proportional to k in the evolution equations. In Section 7.2.1, we will derive an exact solution for the potential in this super-horizon limit. Unfortunately, Figure 7.5 indicates that, for the mode in question, this superhorizon solution is valid only until $a \simeq 10^{-5}$. At much later times ($a > 10^{-3}$) the mode is well within the horizon and the radiation perturbations have become irrelevant (since the universe is matter dominated). We will see in Section 7.3.2 that, under these conditions, another analytic solution can be found. The difficulty is matching the super-horizon solution to the sub-horizon solution.

The problem of matching the super-horizon solution to the sub-horizon solution can be solved for very large scale $\left(k < 0.01h\text{Mpc}^{-1}\right)$ and very small scale ($k > 0.5h$ Mpc^{-1}) modes. In the large-scale case, we will see in Section 7.2.2 that once the universe becomes matter dominated, $\Phi =$ constant is a solution to the evolution

[2]This is model dependent; the plot shows SCDM, with $h = 0.5$. equations even as the mode crosses the horizon. This fact serves as a bridge between the super- and sub-horizon solutions, both of which have constant Φ in the matterdominated regime. In the small-scale case, we can neglect matter perturbations as the mode crosses the horizon, since these modes cross the horizon when the universe is deep in the radiation era. Then, once the mode is sufficiently within the horizon, radiation perturbations decay away, and we can match on to the sub-horizon, noradiation perturbation solution of Section 7.3.2.

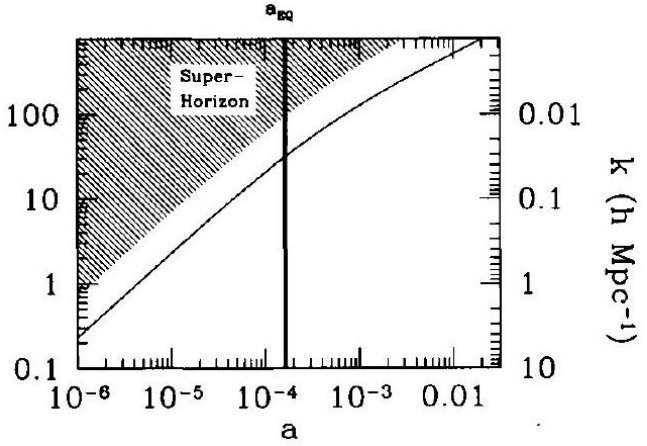
With analytic expressions on both large and small scales, we can obtain a good fit to the transfer function by splining the two solutions together. We will see in Section 7.4 that this works, primarily because the transfer function is so smooth, monotonically decreasing from unity on large scales.

12.7.2 Large Scales

On very large scales, we can get analytic solutions for the potential first through the matter-radiation transition and then through horizon crossing. We start with the super-horizon solution valid through the matter-radiation transition. The results of Section 7.2.1 will be that the potential drops by a factor of 9/10 as the universe goes from radiation to matter domination.

Super-horizon Solution

For modes that are far outside the horizon, $k\eta \ll 1$ and we can drop all terms in the evolution equations dependent on k. From Eqs. (7.11) and (7.13), we see that, in this limit, the velocities (v and $\Theta_{r,1}$) decouple from the evolution equations. This immediately reduces the number of equations to solve from five to three. For the third equation, we notice that Eq. (7.16) has terms inversely propor-



tional to k. These will be difficult to deal with, so let us choose Eq. (7.15) instead. We are left with

$$\begin{aligned}
\dot{\Theta}_{r,0} &= -\dot{\Phi} \\
\dot{\delta} &= -3\dot{\Phi} \\
3\frac{\dot{a}}{a}\left(\dot{\Phi} + \frac{\dot{a}}{a}\Phi\right) &= 4\pi G a^2 \left[\rho_{\rm dm}\delta + 4\rho_r\Theta_{r,0}\right].
\end{aligned}$$

We can go a step further by realizing that the first two equations require $\delta - 3\Theta_{r,0}$ to be constant. Further, we know that this constant is zero (these are the initial conditions). So let us use the dark matter equation (7.18) and the Einstein equation with $\Theta_{r,0}$ set to $\delta/3$. The Einstein equation is then

$$3\frac{\dot{a}}{a}\left(\dot{\Phi} + \frac{\dot{a}}{a}\Phi\right) = 4\pi G a^2 \rho_{\rm dm}\delta\left[1 + \frac{4}{3y}\right]$$

Here I have introduced

$$y := \frac{a}{a_{\rm eq}} = \frac{\rho_{\rm dm}}{\rho_r}$$

which we will use as an evolution variable instead of η or a. Again I emphasize that we are ignoring baryons, so $a_{\rm eq}$ is determined solely by $\rho_{\rm dm}$; in the real world, the numerator in the last term in Eq. (7.21) would be $\rho_{\rm m}$, accounting for all matter including baryons.

Equations (7.18) and (7.20) are two first-order equations for the two variables δ and Φ. The stategy will be to turn these two first-order equations into one secondorder equation and then solve. First, though, let us rewrite the equations in terms of the new variable y. The derivative with respect to y is related to that with respect to η via the Jacobian,

$$\begin{aligned}
\frac{d}{d\eta} &= \frac{dy}{d\eta}\frac{d}{dy} \\
&= aHy\frac{d}{dy},
\end{aligned}$$

where the second line follows from the definition of y and the fact that $\dot{a} = a^2 H$. In terms of y then, the Einstein equation becomes

$$\begin{aligned} y\Phi' + \Phi &= \frac{y}{2(y+1)}\delta\left[1 + \frac{4}{3y}\right] \\ &= \frac{3y+4}{6(y+1)}\delta \end{aligned}$$

where prime denotes derivatives with respect to y and the right side of the first line follows since $8\pi G\rho_{\rm dm}/3 = (8\pi G\rho/3)y/(y+1) = H^2 y/(y+1)$.

In general, to turn two first-order equations into one second-order equation, the trick is to differentiate one of them. Here, to simplify the algebra, we first rewrite Eq. (7.23) as an expression for δ; then differentiate with respect to y; and finally set δ' to $-3\Phi'$ thanks to the dark matter equation (7.18). This leads to

$$-3\Phi' = \frac{d}{dy}\left\{\frac{6(y+1)}{3y+4}\left[y\Phi' + \Phi\right]\right\}$$

Carrying out the derivative is tedious but straightforward. We are left with

$$\Phi'' + \frac{21y^2 + 54y + 32}{2y(y+1)(3y+4)}\Phi' + \frac{\Phi}{y(y+1)(3y+4)} = 0.$$

Remarkably, Kodama and Sasaki (1984) found an analytic solution to Eq. (7.25). They introduced a new variable

$$u := \frac{y^3}{\sqrt{1+y}}\Phi$$

In terms of this variable, you will show (Exercise 4) that Eq. (7.25) becomes

$$u'' + u'\left[\frac{-2}{y} + \frac{3/2}{1+y} - \frac{3}{3y+4}\right] = 0$$

That is, there is no term proportional to u. Instead of a second-order equation for Φ, then, we have a first-order equation for u'. Fortunately, this first-order equation is integrable. Starting from

$$\frac{du'}{u'} = dy\left[\frac{2}{y} - \frac{3/2}{1+y} + \frac{3}{3y+4}\right]$$

we can integrate to get

$$\ln(u') = \text{ constant } + 2\ln(y) - (3/2)\ln(1+y) + \ln(3y+4)$$

Then exponentiating gives

$$u' = A\frac{y^2(3y+4)}{(1+y)^{3/2}}$$

where A is a constant to be determined.

We are one integral away from an analytic expression for the gravitational potential. Remembering the definition of u (Eq. (7.26)), we can integrate Eq. (7.30) to obtain

$$\frac{y^3}{\sqrt{1+y}}\Phi = A\int_0^y dy' \frac{y'^2(3y'+4)}{(1+y')^{3/2}}$$

Note that there should be another constant, $u(0)$, here. However, since $y^3\Phi \to 0$ early on, this constant is vanishes. By similar logic, we can determine the constant A even before performing the integral. For small y, the integrand becomes $4y'^2$, so for small y, Eq. (7.31) becomes $\Phi = 4A/3$. Therefore, $A = 3\Phi(0)/4$. The integral can be done analytically (Exercise 4 again) leaving

$$\Phi = \frac{\Phi(0)}{10}\frac{1}{y^3}\left[16\sqrt{1+y} + 9y^3 + 2y^2 - 8y - 16\right]$$

Equation (7.32) is our final expression for the potential on super-horizon scales. Although it is not obvious, at small y this expression sets $\Phi = \Phi(0)$, a constant. This must be so, since we chose the two constants of integration with precisely this condition. At large y, once the universe has become matter-dominated, the y^3 term in the brackets dominates, so $\Phi \to (9/10)\Phi(0)$. This is precisely the result we were after: the potential on even the largest scales drops by 10% as the universe passes through the epoch of equality.

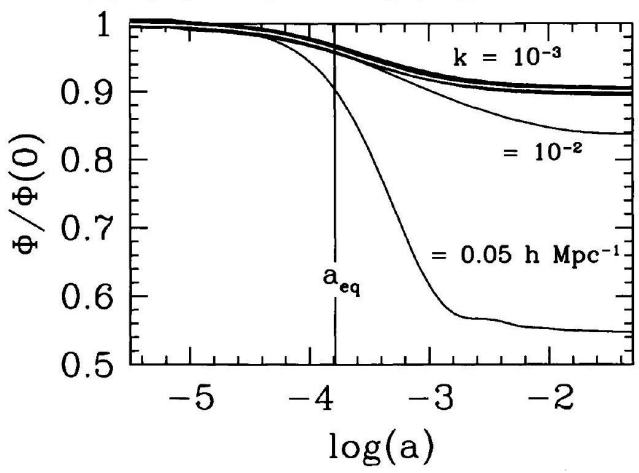


Figure 7.6. Super-horizon evolution of the potential in a CDM model with no baryons, $h = 0.5$ and $\Omega_m = 1$. Thick solid line shows the analytic result of Eq. (7.32), valid only on large scales. White curve within is for the mode $k = 0.001h\text{Mpc}^{-1}$. Two other smaller scale modes are shown.

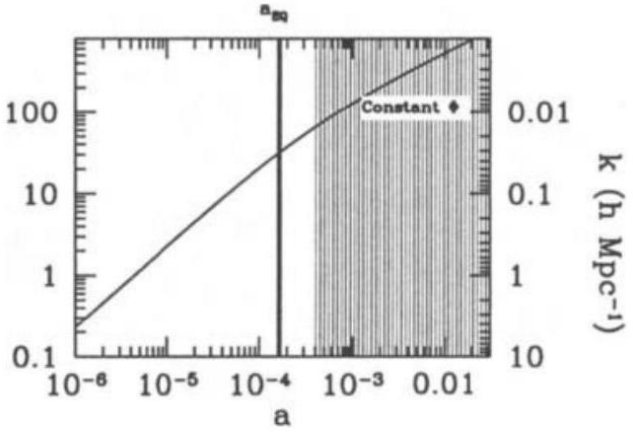
Let us compare this analytic result, valid only when modes are super-horizon, with the numerical results. Figure 7.6 shows that the solution works perfectly on the largest scales and even tolerably well (better than 10%) for scales as small as $k = 0.01$ hMpc^{-1}. This is slightly better than we had anticipated from a crude estimate of where the super-horizon solution is valid (Figure 7.5) and will be important for us later on when spline together the large and small scales solutions. A feature of the analytic solution which may be surprising to you is that, although it is true that the (large scale) potentials are constant in both the matter and radiation epochs, the transition between the pure matter and pure radiation eras is quite long. For example, and this is an important example for the purposes of the CMB as we will see in the next chapter, the potentials, even for the largest scale modes, are still decaying as late as $a \simeq 10^{-3}$, significantly after $a_{\rm eq}$. In models with less matter, $a_{\rm eq}$ is pushed even closer to 10^{-3} so the decay of the potentials becomes even more apparent at the time of recombination.

Through Horizon Crossing

One interesting feature of Figure 7.6 which you should take note of is that large-scale potential (the numerical solution) becomes constant at very late times ($a \gtrsim 10^{-2}$). For $k = 10^{-3}h$ Mpc^{-1}, the mode enters the horizon at $\eta \sim k^{-1} = 1000h^{-1}$Mpc which corresponds to

$a \sim 0.03$ in the flat, matter-dominated universe depicted in Figure 7.6. The potential remains constant as the mode crosses the horizon.



This result is valid as long as the universe is matter dominated. We now set out to prove it.

We are interested then in our set of five equations in the limit that radiation is not important. The potential depends only on the matter inhomogeneities, so we can neglect the two radiation equations, (7.11) and (7.12). In addition to the two matter equations, we now keep the second of Einstein's equations (7.16). This is an algebraic equation, meaning that we could in principle eliminate Φ in the two matter equations and be left with a system of two first-order differential equations. These two first-order equations in general have two solutions. Instead of solving them directly, though, we can cheat using our knowledge of the initial conditions. Here is the idea: we just learned that, deep in the matter epoch, super-horizon potentials are constant. Therefore, the initial conditions for our problem are that the potential is constant ($\dot{\Phi} = 0$). If we can show that constant Φ is one of the two general solutions to the set of matter-dominated equations, then we don't care what the other solution is. For, the initial conditions ensure that the constant Φ solution will be the solution.

We want to see, then, if the set of equations

$$\begin{aligned} \dot{\delta} + ikv &= 0 \\ \dot{v} + aHv &= ik\Phi \\ k^2\Phi &= \frac{3}{2}a^2H^2\left[\delta + \frac{3aHiv}{k}\right] \end{aligned}$$

admits a solution with Φ a constant in time. We can use the algebraic equation (7.35) to eliminate δ from the other two equations. In the matter dominated era, $H \propto a^{-3/2}$, so $d(aH)/d\eta = -a^2H^2/2$. Replacing δ in Eq. (7.33) with Φ and v therefore leads to

$$\frac{2k^2\dot{\Phi}}{3a^2H^2} + \frac{2k^2\Phi}{3aH} - \frac{3aHiv}{k} + \frac{3a^2H^2iv}{2k} + ikv = 0$$

We now have two first-order equations for Φ and v. The strategy is to turn these two equations into one second-order equation for Φ. First eliminate $\dot{v}$ from Eq. (7.36) by using the velocity equation. This leaves

$$\frac{2k^2\dot{\Phi}}{3a^2H^2} + \left[\frac{iv}{k} + \frac{2\Phi}{3aH}\right]\left(\frac{9a^2H^2}{2} + k^2\right) = 0$$

If the second-order equation is of the form $\alpha\ddot{\Phi} + \beta\dot{\Phi} = 0$, that is, if it has no terms proportional to Φ, then $\Phi =$ constant is a solution to the equations. So we differentiate Eq. (7.37) with respect to η but consider only the terms proportional to Φ, dropping all terms proportional to derivatives of Φ. Using the fact that $(d/d\eta)(aH)^{-1} = 1/2$, we see that the remaining terms are

$$\left[\frac{i\dot{v}}{k}+\frac{\Phi}{3}\right]\left(\frac{9a^2H^2}{2}+k^2\right)+\left[\frac{iv}{k}+\frac{2\Phi}{3aH}\right]\frac{d}{d\eta}\frac{9a^2H^2}{2}$$
$$=-\left[\frac{iaHv}{k}+\frac{2\Phi}{3}\right]\left(9a^2H^2+k^2\right)$$

where I have eliminated $\dot{v}$ by using the velocity equation again. But Eq. (7.37) tells us that the term in square brackets on the right here is proportional to $\dot{\Phi}$. So there are no terms in the second-order equation proportional to Φ. Constant potentials are therefore a solution in the matter-dominated era. Since the initial conditions pick out this mode, constant potential is the solution in the matter-dominated era.

Potentials remain constant as long as the universe is matter dominated. At much later times ($a > 1/10$), it is conceivable that the universe becomes dominated by some other form of energy - dark energy for example - or, less likely, by curvature. If so, then the potentials will decay. This decay is described by the growth function, though (Section 7.5), and does not affect the transfer function. The main result of this section is that the transfer function as defined in Eq. (7.3) is very close to unity on all scales that enter the horizon after the universe becomes matter dominated. That is, it is unity for all $k \ll a_{\rm eq}H\,(a_{\rm eq})$, the inverse comoving Hubble radius at equality. You will show in Exercise 5 that the relevant scale is

$$k_{\rm eq} = 0.073{\rm Mpc}^{-1}\Omega_m h^2$$

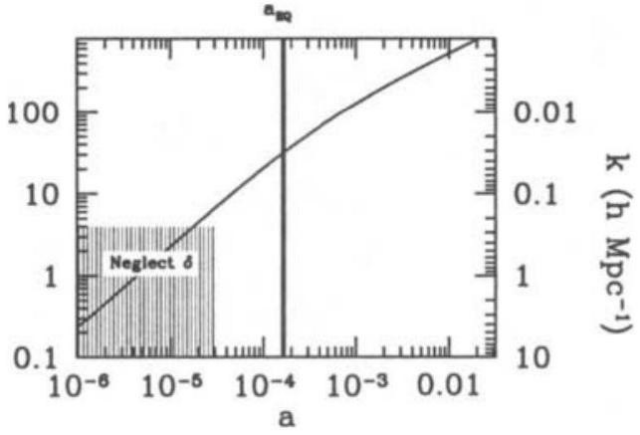
In the limit in which we are working, where baryons and anisotropic stresses are neglected, the transfer function depends only on $k/k_{\rm eq}$. To get a feel for when the large-scale approximations of this section are valid, look back at Figure 7.6, plotted for the standard CDM model with $\Omega_m = 1$ and $h = 0.5$. The transfer function for the curve labeled 10^{-2} is 7% lower (0.84/0.9) than unity. For that mode, $k/k_{\rm eq} = 0.01/(0.073h) = 0.27$. So if we are interested in 10% accuracy in the transfer function, then we can use the large-scale approximation for $k \lesssim k_{\rm eq}/3$.

12.7.3 Small Scales

We were able to solve for the evolution of large-scale perturbations in the previous section because the modes crossed the horizon well after the epoch of equality. Therefore, the problem neatly divided into (i) super-horizon modes passing through the epoch of equality and then (ii) modes in the matter-dominated era which cross the horizon. The converse is true for the small-scale modes considered in this section. They cross the horizon when the universe is deep in the radiation era. So the problem divides neatly into (i) modes in the radiation era crossing the horizon and then (ii) sub-horizon modes passing through the epoch of equality. Step (i) we treat in Section 7.3.1, step (ii) in Section 7.3.2. Notice that we are unable to treat analytically modes which enter the horizon around the epoch of equality.

Horizon Crossing

When the universe is radiation dominated, the potential is determined by perturbations to the radiation. The dark matter perturbations - the ones we are interested in in this chapter are influenced by the potential, but do not themselves influence the potential. So the situation is as depicted in Figure 7.7. To solve for matter perturbations in this epoch, therefore, is a twostep problem. First, we must solve the



coupled equations for $\Theta_{r,0}, \Theta_{r,1}$, and Φ. Then we solve the equation for matter evolution using the potential as an external driving force.

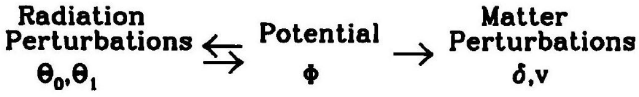


Figure 7.7. Coupling of perturbations in the radiation era. Radiation perturbations and the gravitational potential affect each other. Matter perturbations do not affect the potential but are driven by it.

To solve for the potential in the radiation dominated era, we choose Eq. (7.16). Dropping the matter source terms, we have

$$\Phi = \frac{6a^2H^2}{k^2}\left[\Theta_{r,0} + \frac{3aH}{k}\Theta_{r,1}\right]$$

since $H^2 = 8\pi G\rho_r/3$ in the radiation era. Also in the radiation era, $aH = 1/\eta$. Armed with this fact, we can use Einstein's equation (7.40) to eliminate $\Theta_{r,0}$ from the two radiation equations, (7.11) and (7.12). These become

$$-\frac{3}{k\eta}\dot{\Theta}_{r,1} + k\Theta_{r,1}\left[1 + \frac{3}{k^2\eta^2}\right] = -\dot{\Phi}\left[1 + \frac{k^2\eta^2}{6}\right] - \Phi\frac{k^2\eta}{3}$$

$$\dot{\Theta}_{r,1} + \frac{1}{\eta}\Theta_{r,1} = \frac{-k}{3}\Phi\left[1 - \frac{k^2\eta^2}{6}\right]$$

We can turn these two first order-equations for Φ and $\Theta_{r,1}$ into one second-order equation for the potential. Use Eq. (7.42) to eliminate $\dot{\Theta}_{r,1}$ from the first equation, which then becomes

$$\dot{\Phi} + \frac{1}{\eta}\Phi = \frac{-6}{k\eta^2}\Theta_{r,1}$$

We now have an expression for $\Theta_{r,1}$ solely in terms of the potential and its first derivative. To arrive at a second-order equation for Φ, we differentiate. When we do, we will encounter terms proportional to $\Theta_{r,1}$ and its derivative. Each of these can be eliminated with Eq. (7.42) and Eq. (7.43). The resulting second-order equation is

$$\ddot{\Phi} + \frac{4}{\eta}\dot{\Phi} + \frac{k^2}{3}\Phi = 0$$

To determine the behavior of the potential in the radiation-dominated era, we must solve Eq. (7.44) subject to the initial conditions that Φ is constant. It can be solved analytically by defining $u := \Phi\eta$. Then Eq. (7.44) becomes

$$\ddot{u} + \frac{2}{\eta}\dot{u} + \left(\frac{k^2}{3} - \frac{2}{\eta^2}\right) u = 0.$$

This is the spherical Bessel equation of order 1 (see Eq. (C.13)) with solutions $j_1(k\eta/\sqrt{3})$ - the spherical Bessel function - and $n_1(k\eta/\sqrt{3})$ - the spherical Neumann function. The latter blows up as η gets very small, so we discard it on the basis of the initial conditions. The spherical Bessel function of order 1 can be expressed in terms of trigonometric functions (Eq. (C.14)), so

$$\Phi = 3\Phi_{\rm p}\left(\frac{\sin(k\eta/\sqrt{3}) - (k\eta/\sqrt{3})\cos(k\eta/\sqrt{3})}{(k\eta/\sqrt{3})^3}\right)$$

where $\Phi_{\rm p}$ is the primordial value of Φ. The factor of 3 in front here arises because the $\eta \to 0$ limit of the expression in parentheses is 1/3.

Equation (7.46) tells us that, as soon as a mode enters the horizon during the radiation-dominated era, its potential starts to decay. After decaying, the potential oscillates, as depicted in Figure 7.8. Qualitatively, we could have anticipated as much. From the qualitative discussion surrounding Eq. (7.1), we expected that when the pressure is large, as it is when radiation dominates, perturbations will oscillate in time. If perturbations to the dominant component (here radiation) do not grow, then the potential in an expanding universe will begin to decay simply due to the dilution of the zero-order density. This is evident in Eq. (7.40) which (neglecting the dipole well within the horizon) says that $\Phi \sim \Theta_0/\eta^2$. Since Θ_0 oscillates with fixed amplitude, the potential also ocillates, but with an amplitude decreasing as η^{-2}. Indeed, this is precisely the large $k\eta$ limit of Eq. (7.46). The decay and oscillation of the potential is shown in Figure 7.8, with both the analytic

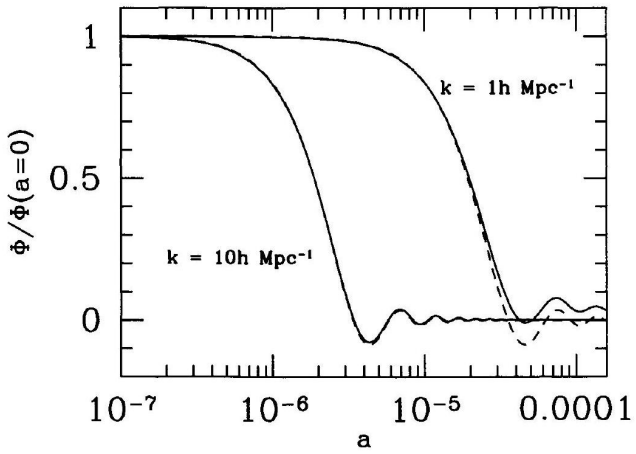

Figure 7.8. Evolution of the potential in the radiation-dominated era. For two small scale modes which enter the horizon well before equality, the exact (solid curve) solution is shown along with the approximate analytic solution (dashed curve) of Eq. (7.46).

expression of Eq. (7.46) and the numerical solution including matter perturbations. Note that the approximate description - in which the effect of matter on the potential is neglected - is valid only deep in the radiation era. The analytic solution for the $k = 1\,h$ Mpc^{-1} mode already begins to depart from the exact solution at $a \simeq 3 \times 10^{-5}$, well before equality (here, in the sCDM model I have taken for illustrative purposes, at $a \simeq 2 \times 10^{-4}$).

Armed with knowledge of the potential in the radiation dominated era, we can now determine the evolution of the matter perturbations, the second half of Figure 7.7. To do this, we turn the two matter evolution equations- (7.13) and (7.14) into one second-order equation with

the potentials serving as an external source. Differentiate Eq. (7.13) and use Eq. (7.14) to eliminate $\dot{v}$:

$$\ddot{\delta} + ik\left(-\frac{\dot{a}}{a}v + ik\Phi\right) = -3\ddot{\Phi}.$$

Now we can use Eq. (7.13) to eliminate v, leading to

$$\ddot{\delta} + \frac{1}{\eta}\dot{\delta} = S(k,\eta)$$

where the source term is

$$S(k,\eta) = -3\ddot{\Phi} + k^2\Phi - \frac{3}{\eta}\dot{\Phi}$$

The two solutions to the homogeneous equation ($S = 0$) associated with Eq. (7.48) are $\delta =$ constant and $\delta = \ln(a)$ (or, equivalently in the radiationdominated era, $\ln[\eta]$). In general, the solution to a second-order equation is a linear combination of the two homogeneous solutions and a particular solution. In the absence of a revelation about the particular solution, one can construct it from scratch from the two homogeneous solutions (call them s_1 and s_2) and the source terms. It is the integral of the source term weighted by the Green's function $\left[s_1(\eta)s_2\left(\eta'\right) - s_1\left(\eta'\right)s_2(\eta)\right] / \left[\dot{s}_1\left(\eta'\right)s_2\left(\eta'\right) - s_1\left(\eta'\right)\dot{s}_2\left(\eta'\right)\right]$. So here, we have

$$\delta(k,\eta) = C_1 + C_2\ln(\eta) - \int_0^\eta d\eta' S\left(k,\eta'\right)\eta'\left(\ln\left[k\eta'\right] - \ln[k\eta]\right).$$

At very early times the integral is small, so our initial conditions (δ constant) dictate that the coefficient of $\ln(\eta), C_2$, vanishes and $C_1 = \delta(k,\eta = 0) = 3\Phi_{\rm p}/2$. Now let us consider the integral in Eq. (7.50). The source function decays to zero along with the potential as the mode enters the horizon. Thus, the dominant contribution to the integral comes from the epochs during which $k\eta$ is of order 1. The integral over $S\left(\eta'\right)\ln\left(k\eta'\right)$ therefore will just asymptote to some constant, while the integral over $S\left(\eta'\right)\ln(k\eta)$ will lead to a term proportional to $\ln(k\eta)$ with the constant of proportionality being just that, a constant. Thus, we expect that after the mode has entered into the horizon,

$$\delta(k,\eta) = A\Phi_{\rm p}\ln(Bk\eta)$$

i.e., a constant ($A\Phi_{\rm p}\ln[B]$) plus a logarithmic growing mode ($A\Phi_{\rm p}\ln[k\eta]$).

We can determine the constants A and B in Eq. (7.51) by referring to the relevant parts of Eq. (7.50). The constant term, $A\Phi_{\rm p}\ln(B)$, is equal to C_1 plus the integral over $\ln\left(\eta'\right)$, or

$$A\Phi_{\rm p}\ln(B) = \frac{3}{2}\Phi_{\rm p} - \int_0^\infty d\eta' S\left(k,\eta'\right)\eta'\ln\left(k\eta'\right)$$

while the coefficient of the $\ln(k\eta)$ term is set by the remaining integral

$$A\Phi_{\rm p} = \int_0^\infty d\eta' S\left(k,\eta'\right)\eta'$$

Note that in both integrals here, I have set the upper limit to infinity in accord with our expectation that the integrals asymptote to some constant value at large η. Using the expression for the source term, Eq. (7.49), and our analytic approximations to the potential, Eq. (7.46),

we can evaluate the integrals here and determine A and B. I find $A = 9.0$ and $B = 0.62$. Hu and Sugiyama (1996), who introduced this method for following the dark matter evolution at early times, found that integrating the exact potentials (instead of the approximate ones of Eq. (7.46)) leads to slightly different values, $A = 9.6$ and $B = 0.44$.

Figure 7.9 shows the exact solution for δ in the radiation era along with the approximation of Eq. (7.51). Setting aside the details for a moment, we see that

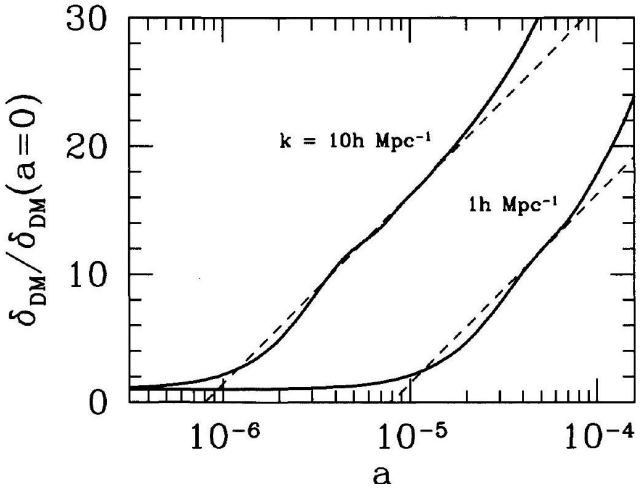

Figure 7.9. Matter perturbations in the radiation-dominated era. The two scales shown here both enter the horizon in the radiation era and lock onto the logarithmically growing mode after some oscillations. Heavy solid curves are the exact solutions, light dashed curves the logarithmic mode of Eq. (7.51). The perturbations have been artificially normalized by their values at early times: inflation actually predicts a larger initial amplitude (by a factor of $10^{3/2}$) for the larger scale mode.

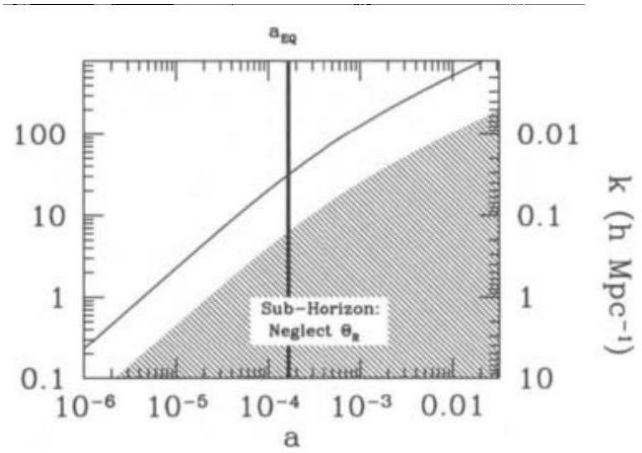
matter perturbations do indeed grow even during the radiation era. The growth is not as prominent as during the matter era (when the constant potentials derived in Section 7.2imply$\delta \propto a$) due to the pressure of the radiation, but it still exists. For both scales shown in Figure 7.9 the perturbations do indeed settle into the logarithmic growing mode once they enter the horizon. As the universe gets closer to matter domination, though, the pressure of the radiation becomes less important, and the perturbations begin to grow faster. Indeed, you might be worried that our approximation for the $k = 1h\mathrm{Mpc}^{-1}$ mode is not very useful. Fortunately, we will be using these solutions only to set the initial conditions for growth in the subhorizon epoch (next subsection), so the approximation need be valid only for a very limited range of times. As long as we choose the matching epoch appropriately, the logarithmic approximation will be extremely good.

Sub-horizon Evolution

We saw in the last subsection that radiation pressure causes the gravitational potentials to decay as modes enter the horizon during the radiation era. Although I did not focus on the radiation perturbations themselves (we will do this in the next chapter), you might expect that the pressure suppresses any growth in $\Theta_{r,0}$. This is correct, and it is in sharp contrast to the matter perturbations which, we



just saw, grow logarithmically. Although initially the potential is determined by the radiation (since the universe is radiation dominated), eventually the growth in the matter perturbations more than offsets the fact that there is more radiation than matter. That is, eventually $\rho_{\rm dm}\delta$ becomes larger than $\rho_r\Theta_{r,0}$ even if $\rho_{\rm dm}$ is smaller than ρ_r. Once this happens, the gravitational potential and the dark matter perturbations evolve together and do not care what happens to the radiation. In this subsection, we want to solve the set of equations governing the matter perturbations and the potential and then match on to the logarithmic solution (7.51) set up during the epoch in which the potential decays.

Once again our starting point is the set of equations governing dark matter evolution, (7.13) and (7.14), and the algebraic equation for the gravitational potential (7.16). And, once again, we want to reduce this set of three equations (two of which are first-order differential equations) to one second-order equation. We will want to follow the sub-horizon dark matter perturbations through the epoch of equality, so it proves convenient again to use y (Eq. (7.21)) - the ratio of the scale factor to its value at equality - as the evolution variable. In terms of y, the three equations become

$$\begin{aligned}\delta' + \frac{ikv}{aHy} &= -3\Phi' \\ v' + \frac{v}{y} &= \frac{ik\Phi}{aHy} \\ k^2\Phi &= \frac{3y}{2(y+1)}a^2H^2\delta.\end{aligned}$$

Several comments are in order about this version of our fundamental equations. First, notice that the time derivatives in the first two equations have been replaced by derivatives with respect to y (indicated by primes), and this transformation leads to the factors of $\dot{y} = aHy$ in the denominators of the unprimed terms. Second, the gravitational potential is now expressed solely in terms of δ: there is no dependence on radiation perturbations because of our arguments above that these are subdominant, and there is no aHv/k dependence because the perturbations are well within the horizon and $aH/k \ll 1$. Finally, the coefficient of the δ source term is $4\pi G\rho_{\rm dm}a^2 \to (3/2)a^2H^2y/(y+1)$ since we are interested in times early enough that any curvature or dark energy is negligible.

We now go through the familiar routine of turning Eqs. (7.54) and (7.55) into a second-order equation for δ: differentiate the first of these to get

$$\delta'' - \frac{ik(2+3y)v}{2aHy^2(1+y)} = -3\Phi'' + \frac{k^2\Phi}{a^2H^2y^2}$$

where v' has been eliminated using the velocity equation. Also I have used the fact that $d(1/aHy)/dy = -(1+y)^{-1}(2aHy)^{-1}$. The first term on the right is much smaller than the

second, since the latter is multiplied by $(k/aH)^2$, and we are focusing on sub-horizon modes. Using Eq. (7.56), we recognize this second term as $3\delta/[2y(y+1)]$. We can rewrite the velocity on the left using Eq. (7.54) but neglecting the potential which on sub-horizon scales is much smaller than δ. Thus, the combination $ikv/(aHy)$ can be simply replaced by $-\delta'$ leaving

$$\delta'' + \frac{2+3y}{2y(y+1)}\delta' - \frac{3}{2y(y+1)}\delta = 0$$

This is the Meszaros equation governing the evolution of sub-horizon cold, dark matter perturbations once radiation perturbations have become negligible.

To understand the growth of dark matter perturbations, we need to obtain the two independent solutions to the Meszaros equations and then match on to the logarithmic mode established in the previous subsection. To solve this differential equation, we can use our knowledge of the solution deep in the matter era. We know that sub-horizon perturbations in the matter era grow with the scale factor, so one of the solutions to Eq. (7.58) is a polynomial in y of order 1. Therefore, for one mode at least, δ'' vanishes. Therefore, the equation governing this first mode, the growing mode,[3] is $D_1'/D_1 = 3/(2+3y)$, the solution to which is

$$D_1(y) = y + 2/3$$

To find the second solution, notice that the Meszaros equation tells us that $u := \delta/D_1$ satisfies

$$(1+3y/2)u'' + \frac{u'}{y(y+1)}\left[(21/4)y^2 + 3y + 1\right] = 0$$

Since there is no term proportional to u, Eq. (7.60) is actually a first-order equation [4] for u'. We can therefore integrate to obtain a solution for u' and then integrate again to get the second Meszaros solution. The first integral gives

[3] D_1 is the growth function mentioned in Section 7.1. Note though that in this section we are assuming that only matter, and not curvature or dark energy, dominates the landscape. Therefore, our expression for the growth function will be valid only when $a \lesssim 0.1$. For the generalization to later times, see Section 7.5.

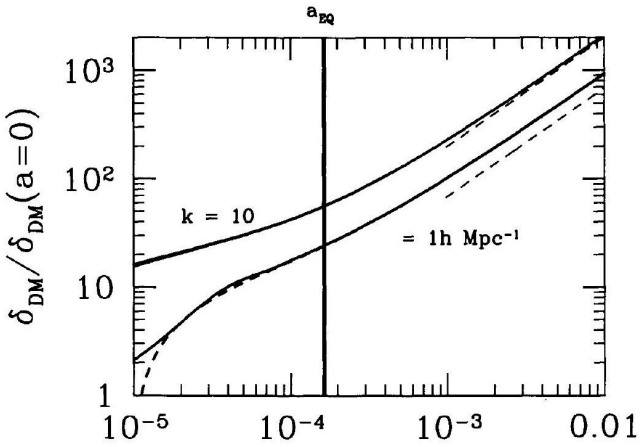
[4] Indeed this is a general trick for obtaining the second solution to a differential equation once the first is known. We will use it again later on to obtain the growth factor.

$$u' \propto (y+2/3)^{-2} y^{-1} (y+1)^{-1/2}$$

Integrating again leads to the second Meszaros solution

$$D_2(y) = D_1(y) \ln\left[\frac{\sqrt{1+y}+1}{\sqrt{1+y}-1}\right] - 2\sqrt{1+y}$$

At late times ($y \gg 1$), the growing solution D_1 scales as y while the decaying mode D_2 falls off as $y^{-3/2}$.



a

Figure 7.10. Evolution of small-scale, sub-horizon, dark matter perturbations. Solid curves are exact solutions; dashed curves (almost imperceptible because the goodness of fit in the $10\,h$ Mpc^{-1} case) the Meszaros solution with coefficients given by the matching condition, Eq. (7.64). The dashed straight lines at $a > 10^{-3}$ are the asymptotic solution of Eq. (7.67).

The general solution to the Meszaros equation is therefore

$$\delta(k, y) = C_1 D_1(y) + C_2 D_2(y) \quad y \gg y_H$$

where y_H is the scale factor when the mode enters the horizon divided by the scale factor at equality (Exercise 6). To determine the constants C_1 and C_2 we can match on to the logarithmic solution of Eq. (7.51). That solution is valid within the horizon but before equality: $y_H \ll y \ll 1$. So we can hope to arrive at a reasonable approximation for the evolution of dark matter perturbations only for those modes that enter the horizon before equality. For those modes, we match the two solutions and their first derivatives

$$A\Phi_{\rm p} \ln\left(By_m/y_H\right) = C_1 D_1\left(y_m\right) + C_2 D_2\left(y_m\right)$$

$$\frac{A\Phi_{\rm p}}{y_m} = C_1 D_1'\left(y_m\right) + C_2 D_2'\left(y_m\right)$$

where the matching epoch y_m must satisfy $y_H \ll y_m \ll 1$. Note that I have replaced the argument of the log in Eq. (7.51) — $k\eta$ — with y/y_H, valid as long as the matching epoch is deep in the radiation era. Figure 7.10 shows the evolution of two modes along with the analytic solutions to the Meszaros equation with coefficients set by the matching conditions laid out in Eq. (7.64). Not suprisingly, for larger scale modes than the ones shown the approximation breaks down.

12.7.4 Numerical Results and Fits

In Section 7.2 and Section 7.3, we derived analytic solutions following the dark matter perturbations deep into the matter era. Here, we assimilate these results and spline them together to form the transfer function. Also, I will present a wellknown fitting function for the transfer function.

First, we need to transform our expression ((7.63) along with Eqs. (7.64)) for the small-scale matter density into an expression for the transfer function. The transfer function is determined by the behavior of δ well after equality when the decaying mode has long since vanished. We can extract an even simpler form for δ in this $a \gg a_{\rm eq}$ limit. The key constant in that case is

C_1, the coefficient of the growing mode. Multiplying the first matching condition in Eq. (7.64) by D_2' and the second by D_2 and then subtracting leads to

$$C_1 = \frac{D_2'(y_m)\, A \ln(By_m/y_H) - D_2(y_m)\,(A/y_m)}{D_1(y_m)\, D_2'(y_m) - D_1'(y_m)\, D_2(y_m)} \Phi_{\rm p}$$

The denominator $D_1 D_2' - D_1' D_2 = -(4/9) y_m^{-1} (y_m + 1)^{-1/2}$, which is approximately equal to $-4/9y_m$ since $y_m \ll 1$. Similarly for small y_m, $D_2 \to (2/3)\ln(4/y) - 2$ and $D_2' \to -2/3y$. Therefore,

$$C_1 \to \frac{-9A\Phi_{\rm p}}{4} \left[\frac{-2}{3} \ln(By_m/y_H) - (2/3)\ln(4/y_m) + 2 \right]$$

which fortuitously does not depend on y_m. Therefore, at late times we have an approximate solution for the small-scale dark matter perturbations

$$\delta(\vec{k}, a) = \frac{3A\Phi_{\rm p}(\vec{k})}{2} \ln\left[\frac{4Be^{-3} a_{\rm eq}}{a_H} \right] D_1(a) \quad a \gg a_{\rm eq}$$

On very small scales, the argument of the log simplifies because $a_{\rm eq}/a_H = \sqrt{2}k/k_{\rm eq}$ (Exercise 6). To turn Eq. (7.67) into a transfer function, we need to remember how δ is related to $\Phi_{\rm p}$. Comparing Eq. (7.8) with Eq. (7.67) leads to an analytic expression for the transfer function on small scales:

$$T(k) = \frac{5A\Omega_m H_0^2}{2k^2 a_{\rm eq}} \ln\left[\frac{4Be^{-3}\sqrt{2}k}{k_{\rm eq}} \right] \quad k \gg k_{\rm eq}$$

Recall that the wavenumber entering the horizon at equality is defined as $k_{\rm eq} := a_{\rm eq} H(a_{\rm eq}) = \sqrt{2} H_0 a_{\rm eq}^{-1/2}$, so the prefactor is also a function of $k/k_{\rm eq}$ only. Then, plugging in numbers leads to

$$T(k) = \frac{12 k_{\rm eq}^2}{k^2} \ln\left[\frac{k}{8k_{\rm eq}} \right] \quad k \gg k_{\rm eq}.$$

Figure 7.11 shows the power spectrum for a standard CDM model ($n = 1$; $h = 0.5$; but no baryons) matching the large-scale transfer function ($T = 1$) with the small-scale transfer function of Eq. (7.69). Also shown is the exact solution

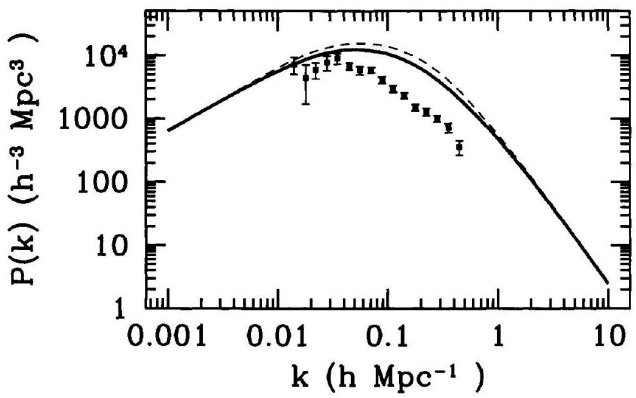


Figure 7.11. The power spectrum in a standard CDM model with a Harrison-Zel'dovich-Peebles spectrum. The thick solid curve uses the BBKS transfer function; the dashed curve interpolates between the analytic transfer function on large scales (equal to 1) and small scales

(Eq. (7.68)). The data points are a compilation (and interpretation) by Peacock and Dodds (1994).

(again in the no-baryon limit), or equivalently, the fitting form of Bardeen, Bond, Kaiser, and Szalay (1986, BBKS),

$$T\left(x := k/k_{\rm eq}\right) = \frac{\ln[1+0.171x]}{(0.171x)}\left[1+0.284x+(1.18x)^2+(0.399x)^3 +(0.490x)^4\right]^{-0.25}.$$

Note that the BBKS form agrees very well with the analytic solution on small scales; i.e., both aymptote to $\ln(k)/k^2$ with the same coefficients. Since wavenumbers are measured in units of $h{\rm Mpc}^{-1}$, the ratio $k/k_{\rm eq}$ depends on $\Omega_m h$. So defining $\Gamma := \Omega_m h$, the BBKS transfer function can also be written as $T\left(q := k/\Gamma h{\rm Mpc}^{-1}\right) = \frac{\ln[1+2.34q]}{(2.34q)}\left[1+3.89q+(16.2q)^2+(5.47q)^3+(6.71q)^4\right]^{-0.25}$.

Several final comments are in order. First, our analytic work has enabled us to understand the origin of the asymptotic, small-scale behavior of the power spectrum. Had there been no logarithmic growth in the radiation era, the modes which entered very early on would have experienced no growth from horizon entry until the epoch of equality. Their amplitude relative to large-scale modes would then have been suppressed by a factor of order $\left(k_{\rm eq}/k\right)^2$. The logarithmic growing mode in the radiation era somewhat ameliorates this suppression. Second, although our analytic expression and its BBKS counterpart are good approximations, it is important to be aware of some small effects which affect the transfer function in the real world. We have assumed no anisotropic stresses ($\Phi = -\Psi$). Dropping this assumption changes the factor of 9/10 by which the potential drops for large-scale modes to 0.86, resulting in a corresponding rise in the small-scale transfer function. Including a realistic amount of baryons leads to even more severe small-scale changes. We will address these in Section 7.6. Third, all of our work in this section has been on the transfer function, i.e., on the evolution of perturbations early on when the only components of the universe were matter and radiation. At very late times, the growth function depends on other hypothetical components, the most likely of which is dark energy. Finally, the theoretical power spectrum in Figure 7.11 has been normalized by fixing δ_H in Eq. (7.9) using the observations of CMB anisotropies on large scales (more on this in Chapter 8). We see that (i) the large-scale normalization is roughly correct and that (ii) the shape of the standard CDM power spectrum is wrong. The sCDM power spectrum turns over on relatively small scales, in distinct disagreement with the data. The universe as we observe it appears to have a smaller $k_{\rm eq}$ than sCDM. This observation motivates consideration of variations of sCDM; we will consider these in Section 7.6.

12.7.5 Growth Function

At late times ($z \lesssim 10$) all modes of interest have entered the horizon. You might think then, that the $y \gg 1$ limit of the Meszaros equation, which describes subhorizon modes in the matter era, would apply. This is true if $\Omega_m = 1$. If the energy budget of the universe has another item at late times - either dark energy or curvature - then we must retrace the steps which led to the Meszaros equation. Before doing this, I want to point out that, no matter what constitutes the energy budget today, all modes will experience the same growth factor. We saw this in the previous section, where the Meszaros equation was independent of k. And we will soon see it again, when we generalize the Meszaros equation to account for other forms of energy. This uniform growth is a direct result of the fact that cold, dark matter has zero pressure. Therefore, once a mode enters the horizon, there is no way for pressure to smooth out the inhomogeneities and all modes evolve identically. We want to derive an evolution equation analagous to the Meszaros equation, but allowing for the possibility of energy other than matter or radiation. We can take the $y \gg 1$ limit of Eqs. (7.54)-(7.56), but we must rethink the coefficient of the source

term in the Poisson equation. Since radiation can be ignored, the coefficient multiplying δ in Eq. (7.56) is now $4\pi G\rho_{\rm dm} = (3/2)H_0^2\Omega_m a^{-3}$. Also when differentiating Eq. (7.54) previously, we set $(1/aHy)' = -(1+y)^{-1}(2aHy)^{-1}$; here we need to account for other contributions to H' so Eq. (7.57) becomes

$$\delta'' + ikv\left(\frac{d(aHy)^{-1}}{dy} - \frac{1}{aHy^2}\right) = \frac{3\Omega_m H_0^2}{2y^3a^2H^2a_{\rm eq}}\delta$$

Replacing the velocity term using the continuity equation as before leads to

$$\frac{d^2\delta}{da^2} + \left(\frac{d\ln(H)}{da} + \frac{3}{a}\right)\frac{d\delta}{da} - \frac{3\Omega_m H_0^2}{2a^5H^2}\delta = 0$$

Here I have divided by $a_{\rm eq}^2$ and we will now use a as the variable instead of y. In this large y limit, all factors of $a_{\rm eq}$ disappear.

There are two solutions to Eq. (7.73). One solution is $\delta \propto H$. It is easy to check this if all the energy is nonrelativistic matter, so that the solution is proportional to $a^{-3/2}$. Then all three terms scale as $a^{-7/2}$; the coefficient of the first is $15/4$, the second $-9/4$, and the last $3/2$. The sum of these does indeed vanish. In Exercise 7, you will be asked to show that $\delta \propto H$ is a solution if there are other components of energy in the universe. This solution is pretty, but it is not the one we want since almost all current models of the universe have a nonincreasing Hubble rate. The modes we are interested in - those that remain long after horizon crossing-are the growing modes. So we are interested in the other solution of Eq. (7.73).

To obtain the growing mode, we try a solution of the form $u = \delta/H$. The evolution equation for u then becomes

$$\frac{d^2u}{da^2} + 3\left[\frac{d\ln(H)}{da} + \frac{1}{a}\right]\frac{du}{da} = 0$$

This first-order equation for u' can be integrated to obtain

$$\frac{du}{da} \propto (aH)^{-3}.$$

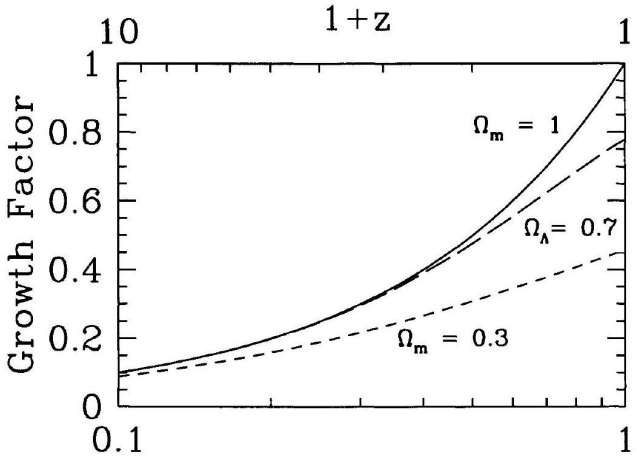
Integrating again and remembering that the second solution, the growth factor, is uH leads to an expression for the growth factor

$$D_1(a) \propto H(a)\int^a \frac{da'}{\left(a'H\left(a'\right)\right)^3}.$$

I have glossed over the proportionality constant. This is fixed by the definition of Eq. (7.4), which says that, early on when matter still dominates (say at $z \simeq 10$), D_1 should be equal to a. At those times, $H = H_0\Omega_m^{1/2}a^{-3/2}$ so the growth factor is

$$D_1(a) = \frac{5\Omega_m}{2}\frac{H(a)}{H_0}\int_0^a \frac{da'}{\left(a'H\left(a'\right)/H_0\right)^3}.$$

The growth factor in an open universe without dark energy can be computed analytically (see Exercise 8).



a

Figure 7.12. The growth factor in three cosmologies. Top two curves are for flat universes without and with a cosmological constant. Bottom curve is for an open universe.

Figure 7.12 shows the growth factor for three different cosmologies. As mentioned above, if the universe is flat and matter dominated, the growth factor is simply equal to the scale factor. In both open and dark energy cosmologies, though, growth is suppressed at late times. This leads to an important qualitative conclusion: structure in an open or dark energy universe developed much earlier than in a flat, matter-dominated universe. There has been relatively little evolution at recent times if the universe is open or dark energy-dominated. Therefore, whatever structure is observed today was likely in place at much earlier times. We will see some quantitative implications of this in Section 9.5.

12.7.6 Beyond Cold Dark Matter

There is more to the universe than just cold dark matter. Although CDM is the main component in most cosmological models, so that the transfer function we derived earlier is a good approximation to reality, there are trace amounts of other stuff. To be completely accurate we need to account for this other stuff. Here I

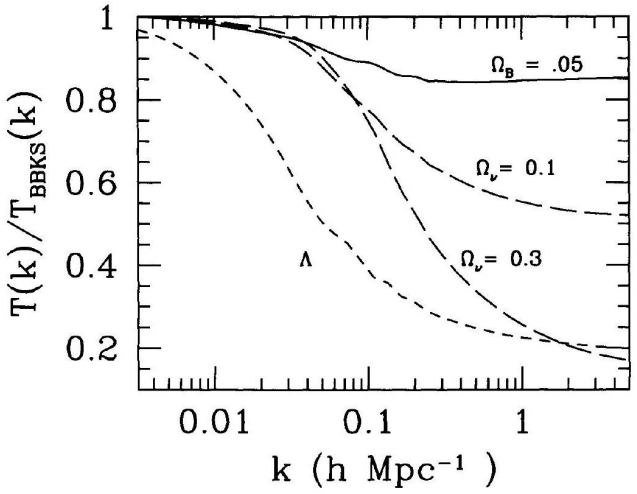


Figure 7.13. The ratio of the transfer function to the BBKS transfer function (Eq. (7.70)) which describes dark-matter-only (no baryons) perturbations. Top curve (and all other curves as well) has 5% baryons. Two middle curves show different values for a massive neutrino. Bottom curve has a cosmological constant $\Omega_\Lambda = 0.7$.

focus on three additional components. First, we consider the effect of the baryons, which constitute roughly 10% of the total matter in most models, on the transfer function. Then, we entertain the possibility that neutrinos have mass and examine the resultant effect on the transfer function. Finally, dark energy - one model for which is the cosmological constant - is considered.

Figure 7.13 shows the transfer functions accounting for these components. A realistic baryon fraction suppresses the transfer function on small scales. A massive neutrino does the same, with the nature and amplitude of the suppression depending on the neutrino mass. Dark energy, here in the form of a cosmological constant, moves the epoch of equality to later times, thereby reducing $k_{\rm eq}$. The break in the transfer function therefore comes on much larger scales than in the standard CDM model, in apparent agreement with the data exhibited in Figure 7.11.

Baryons

Baryons account for about 4% of the total energy density in the universe. As such, their effect on the matter power spectrum is small. A careful examination of Figure 7.13 reveals two signatures of a nonzero baryon density. The first is that the power spectrum is suppressed on small scales. This is not surprising: at early times, before decoupling, baryons are tightly coupled to photons. Therefore, just as radiation perturbations decay when entering the horizon, so too do baryon overdensities. After decoupling, baryons are released from the relatively smooth radiation field and fall into the gravitational potentials set up by the dark matter. The depth of these wells is smaller than we estimated in Section 7.3, though, because only a fraction $\Omega_{\rm cdm}/\Omega_m$ of the total matter was involved in the collapse.

The second effect of baryons is less noticable in Figure 7.13 and indeed may never get measured in real life either. Nonetheless, it is extremely important if only because it hints at a fundamental feature of the radiation field. In all the curves in Figure 7.13, except the $\Omega_\nu = 0.3$ case, you can see small oscillations in the transfer function centered around $k \simeq 0.1h{\rm Mpc}^{-1}$. These are not numerical artifacts. Rather, they are manifestations of the oscillations that the combined baryon/photon fluid experience before decoupling. We got a glimpse of these in Section 7.3.2 (e.g., Figure 7.8) when we considered the potential in the radiation-dominated era. Just as the potential oscillates in this era, the baryon/photon fluid also oscillates. It is the traces of these oscillations that are imprinted on the matter transfer function. They are barely (if at all) detectable because baryons are such a small fraction of the total matter. In the baryon-only model plotted in Figure 1.13, the oscillations were much more noticeable. [5] And these oscillations are also prominent in the spectrum of the radiation perturbations, as we will see in the next chapter.

Massive Neutrinos

Neutrinos are known to exist, and the standard Big Bang model gives a definite prediction for how many there are in the universe (Eq. (2.77)). Massive neutrinos may play an important role in structure formation. Conversely, an accurate measurement of the power spectrum may enable us to infer neutrino masses. For orientation, recall the difference between massless (Eq. (2.78)) and massive (Eq. (2.80)) neutrino energy densities. The best bet from experiments is that the most massive neutrino has a mass of order 0.05eV, therefore contributing $\Omega_\nu \simeq 10^{-3}$. Even this trace amount might eventually be detectable if the power spectrum can be measured accurately enough. There is also the possibility that one or more neutrinos has a larger mass (see the footnote on Page 46). Current upper limits from structure formation hover around 2eV (Elgaroy et al., 2002).

The reason why even a small admixture of massive neutrinos affects the power spectrum is that, especially if they are light, neutrinos can move fast (they are not cold dark matter)

and stream out of high-density regions. Perturbations on scales smaller than the free-streaming scale are therefore suppressed. Indeed, a long time ago, cosmologists considered the possibility that all the dark matter in the universe was in the form of neutrinos. If this were so, then there would be no power on small scales and structure would have to form from the "top down."

We can estimate the scale on which perturbations are damped by computing the comoving distance a massive neutrino can travel in one Hubble time at equality.

[5] Incidentally, we now also understand why the power in Figure 1.13 is so low in the baryon-only universe: there is no dark matter which can cluster before recombination. This calculation is trivial, however, if the neutrino mass is in the eV range. For then, the average velocity, T_ν/m_ν, is of order unity at equality. So neutrinos can freestream out of horizon-scale perturbations at equality. This leads to a suppression in power on all scales smaller than $k_{\rm eq}$.

Figure 7.13 shows this suppression. Note, though, that the effect is a little subtle. A lighter neutrino can free-stream out of larger scales, so the suppression begins at lower k for the $\Omega_\nu = 0.1$ mass than for the $\Omega_\nu = 0.3$ case. On the other hand, the more massive neutrino constitutes more of the total density so it suppresses small-scale power more than does the lighter neutrino.

Dark Energy

Cosmologists have recently accumulated tantalizing evidence for dark energy in the universe above and beyond the dark matter that we have spent so much time on in this chapter. If dark energy exists, how does it affect the matter perturbations?

The first effect of dark energy is indirect. Since theoretical prejudice and evidence both indicate that the universe is flat, $\Omega_{\rm de} \simeq 0.6 - 0.7$ implies that the matter density, Ω_m, is less than 1. This has a huge impact on the power spectrum, because we have seen that the power spectrum turns over at $k_{\rm eq}$, which is proportional to Ω_m. So dark energy leads to a turnover in the power spectrum on a scale much larger than predicted in standard CDM. In fact, as we saw in Figure 7.11, this is one of the pieces of evidence for dark energy. The turnover in the power spectrum does not appear on the scale predicted by standard CDM.

The second effect is again related to the smaller matter density in most models of dark energy. As a result of the Poisson equation (7.7), overdensities are inversely proportional to Ω_m for a fixed potential. Therefore, the amplitude of the power spectrum increases as the matter decreases, or equivalently in a flat universe as the dark energy content goes up. With a few caveats to be discussed in Chapter 8, large-angle CMB anisotropies fix the potential on large scales. When normalizing to these large-angle results, therefore, the power spectrum for a model with dark energy is normalized higher than one without.

The third effect of the dark energy on the density inhomogeneities is more direct and more model dependent. At late times, amplification of perturbations is controlled by the growth factor of Eq. (7.77). The evolution of the Hubble rate depends on the model of dark energy, so different models of dark energy predict different growth factors. If we parameterize the dark energy by its equation of state (2.84), then the Hubble rate in a flat universe evolves as

$$\frac{H(z)}{H_0} = \left[\frac{\Omega_m}{a^3} + \frac{\Omega_{\rm de}}{a^{3[1+w]}}\right]^{1/2}$$

at late times. Using this time dependence, it is straightforward to perform the integral in Eq. (7.77) and find the growth factor for a given equation of state (see Exercise 11). To sum up, dark energy affects the power spectrum by changing $k_{\rm eq}$ and the normalization (this depends only on $\Omega_{\rm de}$) and by changing the growth factor at late times (depends on both $\Omega_{\rm de}$ and w). Careful observations of the matter spectrum therefore may enable us to learn about dark energy.

SUGGESTED READING

Once again The Large Scale Structure of the Universe (Peebles) is a useful reference. Since it was written before the implications of cold dark matter and inflation were explored, though, it does not contain a transfer function or power spectrum such as the ones we have derived (although Peebles himself was instrumental in computing these things several years after the book was published). A more up-to-date book, which is particularly strong on large-scale structure is Structure Formation in the Universe (Padmanabhan).

The first papers to work out the CDM transfer function are particularly instructive to read, not least because they also focus on some of the physical implications of the hierarchical theories. See Blumenthal et al. (1984) and Peebles (1982). The most important recent paper is Seljak and Zaldarriaga (1996), not so much because it contains a concise description of the set of coupled equations to be solved (although it does that), but because it makes available CMBFAST, a code which computes transfer functions and CMB anisotropy spectra. It is currently available at http://physics.nyu.edu/matiasz/CMBFAST/cmbfast.html. The treatment in this chapter follows most closely the small scale analytic solution of Hu and Sugiyama (1996), a paper which is extremely rich and well worth reading. A more recent paper by Eisenstein and Hu (1998) employs the analytic small-scale solution to derive accurate fitting formulae that move beyond those presented by Bardeen, Bond, Kaiser, and Szalay (1986, BBKS).

12.8 Anisotropies

The primordial perturbations set up during inflation manifest themselves in the radiation as well as in the matter distribution. By understanding the evolution of the photon perturbations, we can make predictions about the expected anisotropy spectrum today. This evolution is again completely determined by the EinsteinBoltzmann equation we derived in Chapters 4 and 5, and one way to go would be to simply stick all the relevant equations in those chapters on a computer and solve them numerically. Historically, this is a pretty good caricature of what happened. Long before we developed deep insight into the physics of anisotropies, various groups had codes which determined the expected spectra from different models. Only much later did we come to understand both qualitatively and quantitatively why the spectra look like they do. [1] In this chapter, I will mangle the history and simply explain what we have learned about the physics of anisotropies.

Perturbations to the photons evolved completely differently before and after the epoch of recombination at $z \simeq 1100$. Before recombination, the photons were tightly coupled to the electrons and protons; all together they can be described as a single fluid (dubbed the "baryon-photon" fluid). After recombination, photons free-streamed from the "surface of last scattering" to us today. After an overview which qualitatively explains the anisotropy spectrum, Sections 8.2-8.4 work through the physics of the baryon-photon fluid before recombination. Then Sections 8.58.6 treat the post-recombination era, culminating in the predicted spectrum of anisotropies today. Finally Section 8.7 discusses how these spectra vary when the cosmological parameters change.

[1] Understanding the anisotropies actually helped make the codes much more efficient. The prime example of this is the popular code CMBFAST (Seljak and Zaldarriaga, 1996) which is based in part on the analytic solution presented in this chapter.

12.8.1 Overview

Let's begin as we did in the last chapter, by cheating and looking at the answers first. Figure 8.1 shows the evolution of the perturbations to the photons. Four Fourier modes corresponding to perturbations on four different scales are shown. Qualitatively, the most important feature of

Figure 8.1 is that perturbations to the photons do not grow appreciably with time. This stands in stark contrast to the matter perturbations, which do grow. And this contrast is something we should have expected: the pressure of the photons is so large that it can withstand the tendency toward collapse. This means that the small perturbations set up during inflation stay small; they remain linear all the way up to the present.

Before going further and examining the evolution of the different modes in more detail, a technical note: I have plotted not simply the perturbation to the photons but rather the combination $k^{3/2}(\Theta_0 + \Psi)$. The $k^{3/2}$ factor balances the fact that the amplitude of the perturbations (in a simple inflationary model) scales as $k^{-3/2}$. I have added the gravitational potential Ψ because the photons we see today had to travel out of the potentials they were in at the time of recombination. As they emerged from these potential wells, their wavelengths were stretched (if the region was overdense and $\Psi < 0$), thereby decreasing their energy. Thus, the temperature we see today is actually Θ_0 at recombination plus Ψ.

The large-scale mode in Figure 8.1 evolves hardly at all. This is not surprising: no causal physics can affect perturbations with wavelengths larger than the horizon, so a super-horizon mode should exhibit little evolution. This means that when we observe large-scale anisotropies - which are sensitive to modes with wavelengths larger than the horizon at recombination - we are observing perturbations in their most pristine form, as they were set down at very early times, presumably during inflation.

Figure 8.1 shows that the smaller scale modes evolve in a more complicated way than the super-horizon modes. Consider the curve labeled "First Peak." As the mode enters the horizon, the perturbation begins to grow until it reaches an apparent maximum at the time of recombination. If we observe anisotropies on scales corresponding to this mode, we would expect to see large fluctuations. Hence the label: the anisotropy spectrum will have a peak at the angular scales corresponding to the mode which has just reached its peak at recombination.

The mode in Figure 8.1 which enters the horizon slightly earlier peaks earlier and then turns over so that its amplitude at recombination is zero. By recombination, it has undergone half of an oscillation; so we see our first clear signal of the acoustic oscillations due to the pressure of the relativistic photons. The phase of this mode is such that, at recombination its amplitude is zero. Therefore, when we observe anistropies today corresponding to these scales, we expect very small fluctuations. There will be a trough in the anisotropy spectrum on these angular scales.

And on it goes. The curve labeled "Second Peak" entered the horizon even earlier and has gone through one full oscillation by recombination. As such, this mode will have large fluctuations and lead to a second peak in the anisotropy spectrum. You

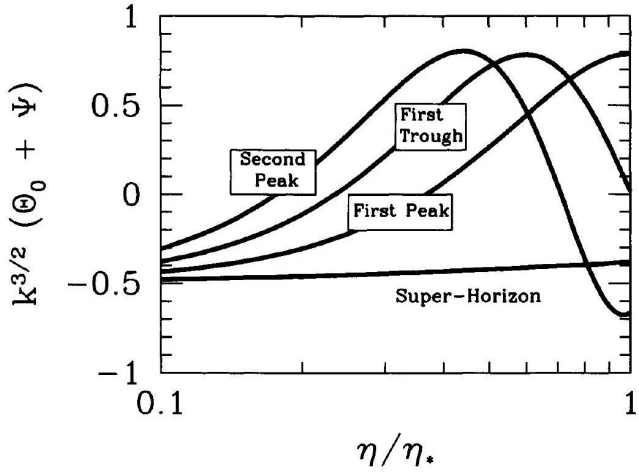

Figure 8.1. Evolution of photon perturbations of four different modes before recombination at η_*. Normalization is arbitrary, but the relative normalization of the 4 curves is appropriate for

perturbations with a Harrison-Zel'dovich-Peebles ($n = 1$) spectrum. Model is standard CDM with $h = 0.5, \Omega_m = 1$, and $\Omega_b = 0.06$. Starting from the bottom left and moving upward, the wavenumbers for the modes are $k = (7 \times 10^{-4}, 0.022, 0.034, 0.045)\,\mathrm{Mpc}^{-1}$ or $(8, 260, 400, 540)/\eta_0$

might expect that there will be a never-ending series of peaks and troughs in the anisotropy spectrum corresponding to modes that entered the horizon earlier and earlier. And you would be right: this is exactly what happens.

We can see this more clearly by looking at the spectrum of perturbations at one time, the time of recombination. Figure 8.2 shows this spectrum for two different models, one with a very low baryon content. We do indeed see this pattern of peaks and troughs. There are two more quantitative features of these oscillations that are important. First, note that - at least in the higher baryon model - the heights of the peaks seem to alternate: the odd peaks seem higher than the even peaks. Second, and this is clearest in the low baryon model, perturbations on small scales $k\eta_0 \gtrsim 500$ are damped.

To understand the first of these features, we can write down a cartoon version of the equation governing perturbations. Very roughly, this equation is

$$\ddot{\Theta}_0 + k^2 c_s^2 \Theta_0 = F$$

where F is a driving force due to gravity and c_s is the sound speed of the combined baryon-photon fluid. This is the equation of a forced harmonic oscillator (see box on page 220). Qualitatively, it predicts the oscillations we have seen above. But it also

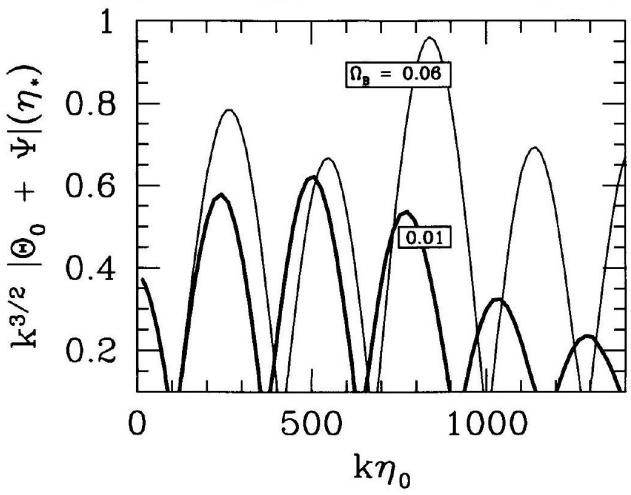

Figure 8.2. Perturbations to the photon distribution at recombination in two models. The larger damping length of the low- Ω_b model is clearly evident in the suppression of perturbations for modes with $k > 500/\eta_0$.

explains something about the heights of the peaks. As we add more baryons to the universe, the sound speed goes down (baryons are heavy so they reduce the speed). Thus the frequency of the oscillations goes down. The peaks at $n\pi/\omega$ are shifted to larger k (you really should read that box!), and the spacing between peaks gets correspondingly larger. Further, as the frequency goes down, the disparity between the heights of the odd and even peaks gets larger. We clearly see both of these features in Figure 8.2. Another way of understanding the alternating peak heights is to note that the perturbations for the first peak mode have been growing since they entered the horizon. By decreasing the pressure (or equivalently increasing the importance of gravity) these modes will grow even more. The second peak mode on the other hand, corresponds to an underdensity of photons in the potential wells. Decreasing the pressure makes it harder for photons to escape the well and therefore reduces the magnitude of the perturbation (makes it less underdense). Consider a simple harmonic oscillator with mass m and force constant k. In

addition to the restoring force, the oscillator is acted on by an external force F_0. Thus the full force is $F_0 - kx$ where x is the oscillator's position. The equation of motion is

$$\ddot{x} + \frac{k}{m}x = \frac{F_0}{m}$$

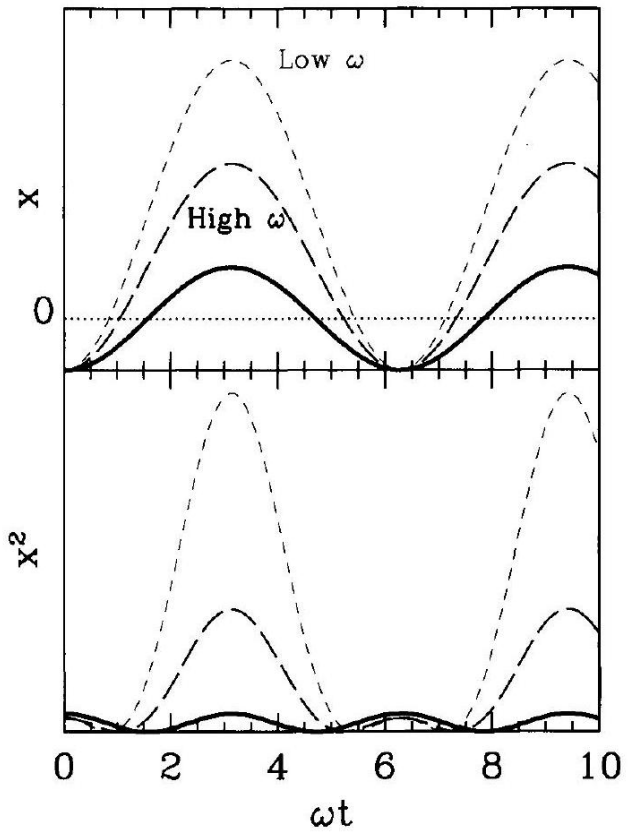
The term on the right-hand side-representing the external force-is driving the oscillator to large values of x. The restoring force on the other hand tries to keep the oscillator as close to the origin as possible. The solution therefore will be that oscillations will be set up around a new zero point, at positive x.

The solution to Eq. (8.2) is the sum of the general solution to the homogeneous equation (with the right-hand side set to zero) and a particular solution. The general solution has two modes, best expressed as a sine and cosine with arguments ωt, with the frequency ω defined as $\omega := \sqrt{\frac{k}{m}}$. A particular solution to Eq. (8.2) is constant $x = F_0/m\omega^2$, so the full solution is the sum of the sine and cosine modes plus this constant. Let us assume that the oscillator is initially at rest. Then, since $\dot{x}(0)$ is proportional to the coefficient of the sine mode, this coefficient must vanish, leaving

$$x = A\cos(\omega t) + \frac{F_0}{m\omega^2}.$$

This solution is shown in the figure at right. The solid line is the unforced solution: oscil-

Forced Harmonic Oscillator



lations about the origin. The dashed curves are the forced solutions for two different choices of frequencies. In both cases, the oscillations are not around $x = 0$ as they would be if the system was unforced. Once an external force is introduced, the zero point of the oscillations shifts in the direction of the force. Two curves are drawn to show that this shift is more dramatic for lower frequencies. The bottom panel shows the square of the oscillator position as a function of time. All three oscillators experience a series of peaks at $t = n\pi/\omega$ corresponding to the minima/maxima of the cosine mode. (Note that if only the sine mode was present these peaks would be at $t = (2n + 1)\pi/\omega$.) The heights of these peaks are identical in the case of the

unforced oscillator and equal to the height at $t = 0$. In the forced case, though, the height of the odd peaks - those at $t = (2n + 1)\pi/\omega$ - is greater than that of the even peaks. The effect is most dramatic for low frequencies. If the frequency is low, the force has a greater effect, producing the greater zero-point offset, and hence the greater odd/even disparity. The other feature of this example is that the even peaks correspond to negative positions of the oscillator: points at which it is farthest from where the force wants it to go.

Photon Diffusion

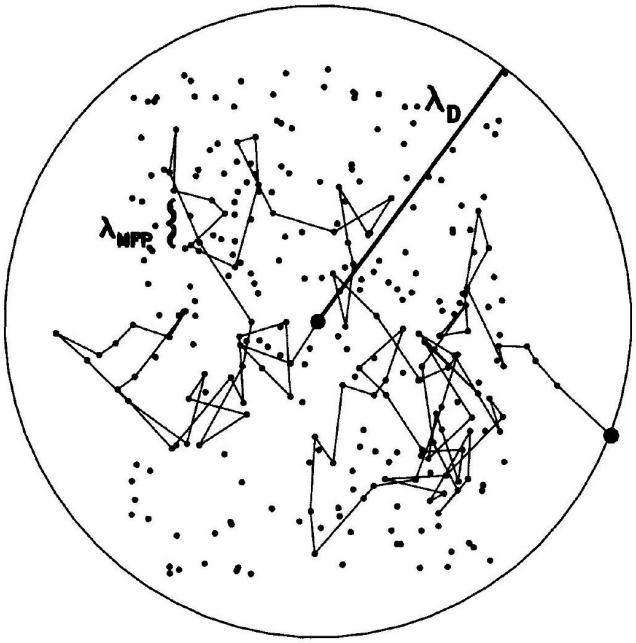


Figure 8.3. Photon diffusion through the electron gas. Electrons are denoted as points. Shown is a typical photon path as it scatters off electrons. The mean free path is λ_{MFP}. After a Hubble time, the photon has scattered many times, so that it has moved a distance of order λ_D.

To understand the damping evident in Figure 8.2, we need to remember that the approximation of the photons and electrons and baryons moving together as a single fluid is just that, an approximation. It is valid only if the scattering rate of photons off of electrons is infinite. Of course this condition is not met: photons travel a finite distance in between scatters. Consider Figure 8.3, which depicts the path of a single photon as it scatters off a sea of electrons. It travels a mean distance $\lambda_{\rm MFP}$ in between each scatter. In our case this distance is $(n_e\sigma_T)^{-1}$. If the density of electrons is very large, then the mean free path is correspondingly small. In the course of a Hubble time, H^{-1}, a photon scatters of order $n_e\sigma_T H^{-1}$ times (simply the product of the rate and the time). As depicted in Figure 8.3, each scatter contributes to the random walk of the photon. We know that the total distance traveled in the course of a random walk is the mean free path times the square root of the total number of steps. Therefore, a cosmological photon moves a mean distance

$$\begin{aligned}\lambda_D &\sim \lambda_{\rm MFP}\sqrt{n_e\sigma_T H^{-1}} \\ &= \frac{1}{\sqrt{n_e\sigma_T H}}\end{aligned}$$

in a Hubble time. Any perturbation on scales smaller than λ_D can be expected to be washed out. In Fourier space this will correspond to damping of all high k modes. Note that this crude estimate gets the Ω_b dependence right. Models with small baryon density have a larger λ_D (since n_e is proportional to Ω_b when the universe is ionized). Therefore, the damping sets in at larger scales, or smaller k. This is precisely what we saw in Figure 8.2.

The final step is to relate the perturbations at recombination, as depicted in Figure 8.2, to the anisotropies we observe today. The math of this is a little complicated, but the physics is perfectly straightforward. Consider one Fourier mode, a plane-wave perturbation. Figure 8.4 shows the temperature variations for one mode at recombination. Photons from hot and cold spots separated by a typical (comoving) distance k^{-1} travel to us coming from an angular separation $\theta \simeq k^{-1}/(\eta_0 - \eta_*)$ where $\eta_0 - \eta_*$ is the (comoving) distance between us and the surface of last scattering. [2] If we decompose the temperature field into multipole moments, then an angular scale θ roughly corresponds to $1/l$. So, using the fact that $\eta_* \ll \eta_0$, we project inhomogeneities on scales k onto anisotropies on angular scales $l \simeq k\eta_0$.

There is one final caveat to this picture of free-streaming. We have been implicitly assuming that nothing happens to the photons on their journey from the last scattering surface to Earth. In fact, if the universe was flat and matter dominated through this whole time, then gravitational potentials remain constant, and this assumption is correct. However, recombination takes places not too much later than the epoch of equality, so the remnant radiation density means potentials are not exactly constant right after recombination. Also, at late times, dark energy does not behave like matter and leads to potential decay. You can imagine other disruptions to matter domination. All of these so-called integrated Sachs-Wolfe effects produce new perturbations to the photons, leading to changes typically of order 10%.

And that's it; we now understand how primordial perturbations are processed to form the present-day anisotropy spectrum. Let's work through it again quantitatively.

12.8.2 Large-Scale Anisotropies

Theory

To find the large-scale solution for the photon perturbation, we make use of the super-horizon equation, (7.17). This immediately tells us that $\Theta_0 = -\Phi$ plus a

[2] This is true only in a flat universe. In an open universe, the distance to the last scattering surface is larger, so the same physical scale is projected onto a smaller angular scale.

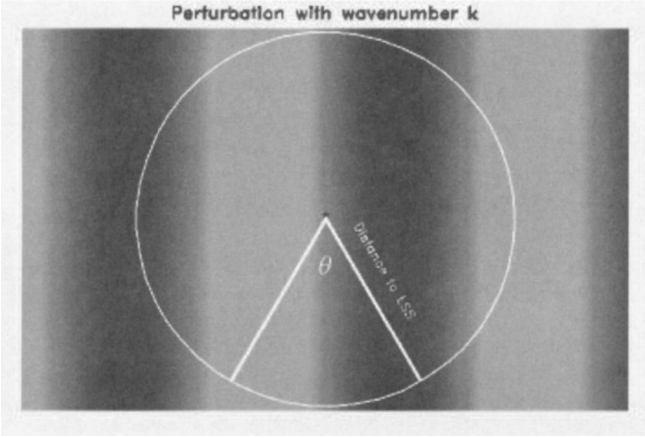

Figure 8.4. Free-streaming. Perturbations in the temperature at recombination from one plave wave with wavenumber k. Hot and cold spots are shaded light and dark. After recombination, photons from the hot and cold spots travel freely to us, here denoted by the star at the center. This mode contributes anisotropy on a scale $\theta \sim k^{-1}/$ (Distance to last scattering surface).

constant. The initial conditions are such that $\Theta_0 = \Phi/2$, so the constant is $3\Phi_{\mathbf{p}}/2$, where $\Phi_{\rm p}$ is the primordial potential set up during inflation. We have an exact expression for the large-scale evolution of Φ, Eq. (7.32). If recombination takes place long after the epoch of

equality, then we can take the $y \gg 1$ limit of this expression, $\Phi \rightarrow 9\Phi_{\rm p}/10$. Therefore, at recombination, large-scale photon perturbations satisfy

$$\begin{aligned}\Theta_0\left(k,\eta_*\right) &= -\Phi\left(k,\eta_*\right) + \frac{3\Phi_{\rm p}(k)}{2} \\ &= \frac{2\Phi\left(k,\eta_*\right)}{3}.\end{aligned}$$

The observed anisotropy is $\Theta_0 + \Psi$, which to a good approximation is $\Theta_0 - \Phi$ since $\Psi \simeq -\Phi$. Therefore,

$$\left(\Theta_0 + \Psi\right)\left(k,\eta_*\right) = \frac{1}{3}\Psi\left(k,\eta_*\right)$$

Another useful way of expressing the large-scale perturbations at recombination is in terms of the density field. The initial conditions derived in Chapter 6 were that $\delta = 3\Phi/2$. Integrating the large-scale evolution equation, $\dot{\delta} = -3\dot{\Phi}$, leads to

$$\begin{aligned}\delta\left(\eta_*\right) &= \frac{3}{2}\Phi_{\rm p} - 3\left[\Phi\left(\eta_*\right) - \Phi_{\rm p}\right] \\ &= 2\Phi\left(\eta_*\right)\end{aligned}$$

So the observed anisotropy expressed in terms of the dark matter overdensity is

$$\left(\Theta_0 + \Psi\right)\left(k,\eta_*\right) = -\frac{1}{6}\delta\left(\eta_*\right)$$

Equations (8.6) and (8.8) will be useful to us when we compute the largescale anisotropy spectrum. However, even now, they contain a fascinating piece of information. From the Fourier transform of Eq. (8.8), we see that the observed anisotropy of an overdense region will be negative. This is such a surprising result that it is worth repeating. For large-scale perturbations, overdense regions do indeed contain hotter photons at recombination than do underdense regions: i.e., $\Theta_0 > 0$ when $\Psi < 0$. However, to get to us today, these photons must travel out of their potential wells. In so doing they lose energy, and this energy loss more than compensates for the fact that the photons were initially hotter than average: i.e., $\Theta_0 + \Psi$ is negative when $\Psi < 0$. To sum up, when we observe large-scale hot spots on the sky today, we are actually observing regions that were underdense at the time of recombination.

The other important feature of Eq. (8.8) is the coefficient 1/6. It enables us to relate " $\delta T/T$" (the left-hand side) to " $\delta\rho/\rho$" (the right). Very roughly speaking, an anisotropy of order 10^{-5} corresponds to an overdensity of 6×10^{-5}. One of the important questions which must be addressed by the picture of gravitational instability is whether the observed anisotropy is consistent with the overdensities needed to form structure by today. This factor of 6 is a huge help. In almost all models of structure formation other than inflation, this factor of 6 is replaced by a number much closer to unity (see Exercise 1 for a specific example). Therefore, they struggle with the fact that the observed level of anisotropy is too small to account for the clustering of matter in the universe. Equivalently, when normalized to large-angle anisotropies, the matter power spectrum is too small. [3]

12.8.3 Acoustic Oscillations

Tightly Coupled Limit of the Boltzmann Equations

When all electrons were ionized, before η_*, the mean free path for a photon was much smaller than the horizon of the universe. Compton scattering caused the electron-proton fluid

to be tightly coupled with the photons. We now proceed to explore this regime quantitatively using the Boltzmann equations.

The tightly coupled limit corresponds to the scattering rate being much larger than the expansion rate: $\tau \gg 1$, where τ is the optical depth defined in Eq. (4.61). I

[3] This realization has been most important in theories in which structure is generated by cosmic strings. Several papers which pointed out the problem in the aftermath of the COBE detection include: Albrecht and Stebbins (1992), Perivolaropoulos and Vachaspati (1994), and Pen and Spergel (1995). want to argue that in the $\tau \gg 1$ limit, the only nonnegligible moments, Θ_l, are the monopole ($l = 0$) and the dipole ($l = 1$). All others are suppressed. In this sense, photons behave just like a fluid, which can be described with only two variables: the density ρ and the velocity $\vec{v}$. In order to show this, let's go back to the Boltzmann equation (4.100) for photons. We want to turn this differential equation for $\Theta(\eta, \mu)$ into an infinite set of coupled equations for $\Theta_l(\eta)$. The advantage is that - as we will see - the higher moments are small and so can be neglected. The strategy is to multiply by $\mathcal{P}_l(\mu)$ and then integrate over μ. Using Eq. (4.99), the Boltzmann equation for $l > 2$ becomes

$$\dot{\Theta}_l + \frac{k}{(-i)^{l+1}} \int_{-1}^{1} \frac{d\mu}{2} \mu \mathcal{P}_l(\mu) \Theta(\mu) = \dot{\tau} \Theta_l.$$

Note that all other terms (e.g., $-\dot{\Phi}$) have simple μ dependence (scale as μ^0 or μ^1) so all $l > 2$ moments vanish for them. To do the integral, we make use of the recurrence relation for Legendre polynomials, Eq. (C.3), to get

$$\dot{\Theta}_l - \frac{kl}{2l+1} \Theta_{l-1} + \frac{k(l+1)}{2l+1} \Theta_{l+1} = \dot{\tau} \Theta_l.$$

Let us consider the order of magnitude of the terms in Eq. (8.10). The first term on the left is of order Θ_l/η which is much smaller than the term on the right which is of order $\tau\Theta_l/\eta$. Neglecting the Θ_{l+1} term for the moment, this tells us that in the tightly coupled regime

$$\Theta_l \sim \frac{k\eta}{2\tau} \Theta_{l-1}$$

For horizon size modes $k\eta \sim 1$, this means that $\Theta_l \ll \Theta_{l-1}$. (By the way, this is justification for throwing out the Θ_{l+1} term in making our estimate.) This estimate is valid for all modes higher than the dipole, so all such modes are very small compared to the monopole and dipole.

Before making use of this fact and deriving the tightly coupled equations in the limit in which only the monopole and dipole are nonzero (the fluid approximation), I want to explain why higher moments are damped in a tightly coupled environment. Indeed this observation is extremely important not only in cosmology but in all settings in which the fluid approximation is used. To understand the fluid approximation, consider one plane-wave perturbation as depicted in Figure 8.5. An observer sitting at the center of the perturbation sees photons arriving from a distance of order the mean free path, η/τ. A wavelength of order the horizon η is much larger than this distance, so the photons arriving at the observer all have the same temperature. There is very little anisotropy. You might think that a perturbation with a very small wavelength (with $k\eta \sim \tau$) would lead to anisotropy. In fact, though, such a mode has a wavelength much smaller than the damping scale. So all perturbations on such small scales are smoothed out, again leading to no anisotropy. The bottom line is there is essentially no anisotropy beyond the monopole and the dipole in the tightly coupled regime. Tightly Coupled Limit

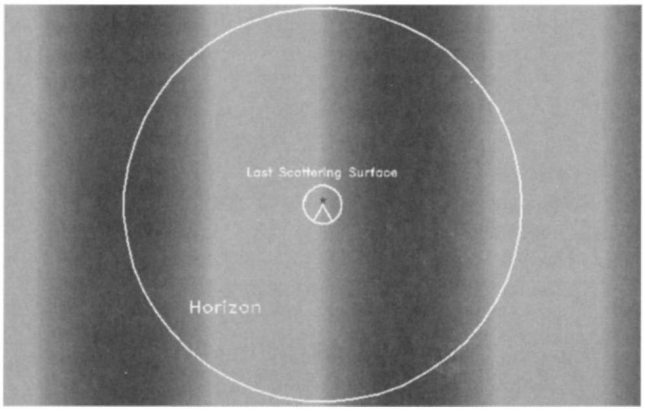

Figure 8.5. Anisotropies in the tightly coupled era. Perturbations on the scale of the horizon cannot be observed by an observer [denoted by the star here], for the photons observed come from the last scattering surface a distance η/τ away. This last scattering surface is so close that photons arriving from all angles have virtually identical temperatures.

Armed with this knowledge, we can now turn to the equations for the first two moments, which - after disposing of Θ_2 - read:

$$\dot{\Theta}_0 + k\Theta_1 = -\dot{\Phi}$$
$$\dot{\Theta}_1 - \frac{k\Theta_0}{3} = \frac{k\Psi}{3} + \dot{\tau}\left[\Theta_1 - \frac{iv_\mathrm{b}}{3}\right]$$

These follow by mutiplying Eq. (4.100) by $\mathcal{P}_0(\mu)$ and $\mathcal{P}_1(\mu)$ and integrating over μ. They are supplemented by the equations for the electron-baryon fluid, Eqs. (4.105) and (4.106). Let us first rewrite the velocity equation, (4.106), as

$$v_\mathrm{b} = -3i\Theta_1 + \frac{R}{\dot{\tau}}\left[\dot{v}_\mathrm{b} + \frac{\dot{a}}{a}v_\mathrm{b} + ik\Psi\right]$$

The second term on the right here is much smaller than the first since it is suppressed by a relative factor of order τ^{-1}. Thus, to lowest order, $v_\mathrm{b} = -3i\Theta_1$. A systematic way to expand, then, is to use this lowest order expression everywhere in the second term, leading to

$$v_\mathrm{b} \simeq -3i\Theta_1 + \frac{R}{\dot{\tau}}\left[-3i\dot{\Theta}_1 - 3i\frac{\dot{a}}{a}\Theta_1 + ik\Psi\right].$$

Now let us insert this expression into Eq. (8.13), eliminating v_b. After rearranging terms, we find

$$\dot{\Theta}_1 + \frac{\dot{a}}{a}\frac{R}{1+R}\Theta_1 - \frac{k}{3[1+R]}\Theta_0 = \frac{k\Psi}{3}.$$

We now have two first-order coupled equations for the first two photon moments, Eqs. (8.12) and (8.16). We can turn these into one second-order equation by differentiating Eq. (8.12) and using Eq. (8.16) to eliminate $\dot{\Theta}_1$:

$$\ddot{\Theta}_0 + k\left[\frac{k\Psi}{3} - \frac{\dot{a}}{a}\frac{R}{1+R}\Theta_1 + \frac{k}{3[1+R]}\Theta_0\right] = -\ddot{\Phi}$$

Finally, we use Eq. (8.12) to eliminate Θ_1 here. This leaves

$$\ddot{\Theta}_0 + \frac{\dot{a}}{a}\frac{R}{1+R}\dot{\Theta}_0 + k^2c_s^2\Theta_0 = -\frac{k^2}{3}\Psi - \frac{\dot{a}}{a}\frac{R}{1+R}\dot{\Phi} - \ddot{\Phi} := F(k,\eta)$$

where I have defined the forcing function on the right as F and the sound speed of the fluid as

$$c_s := \sqrt{\frac{1}{3(1+R)}}$$

The sound speed depends on the baryon density in the universe. In the absence of baryons, it has the standard value for a relativistic fluid, $c_s = 1/\sqrt{3}$. The presence of baryons, though, makes the fluid heavier, thereby lowering the sound speed. We will see shortly that the fluid oscillates in both space and time, with a period which is determined by the sound speed, and hence by the baryon density. Note that Eq. (8.18) is the "grown-up" version of Eq. (8.1); it differs only through the $\dot{\Theta}_0$ damping [4] term (see Exercise 2). The presence of this term does not change any of the qualitiative conlcusions we reached in Section 8.1. Finally, note that Φ enters on the right in a very similar way as Θ_0 does on the left. An alternate version of Eq. (8.18) takes adavantage of this:

$$\left\{\frac{d^2}{d\eta^2} + \frac{\dot{R}}{1+R}\frac{d}{d\eta} + k^2 c_s^2\right\}[\Theta_0 + \Phi] = \frac{k^2}{3}\left[\frac{1}{1+R}\Phi - \Psi\right]$$

Tightly Coupled Solutions

The equation we have derived governing acoustic oscillations of the photon-baryon fluid, (8.20), is a second-order ordinary differential equation. To solve it, we will again (as in Section 7.3.1) use Green's method to find the full solution. First we find the two solutions to the homogeneous equation. Then we use these to construct the particular solution.

In prnciple, to obtain the homogeneous solutions, we must solve the damped, harmonic oscillator equation, (8.20) with the right-hand side equal to zero. In practice, the damping term is of order $R(\Theta_0 + \Phi)/\eta^2$ while the pressure term is much

"This "damping" term is not to be confused with the damping of perturbations on small scales treated in the next section. They are completely different effects. larger, of order $k^2 c_s^2(\Theta_0 + \Phi)$ (at least it's larger when modes are within the horizon or when R is small). Physically we expect pressure to induce oscillations in the photon temperature; the time scale for these oscillations is much shorter than the damping introduced by the expansion of the universe. To a first approximation, then, let us neglect the damping term and simply obtain the oscillating solutions. [5] In this limit, the two homogeneous solutions are

$$S_1(k,\eta) = \sin[k r_s(\eta)] \quad ; \quad S_2(k,\eta) = \cos[k r_s(\eta)]$$

where I have defined the sound horizon as

$$r_s(\eta) := \int_0^\eta d\eta' c_s(\eta')$$

Since c_s is the sound speed, the sound horizon is the comoving distance traveled by a sound wave by time η.

The tightly coupled solution for the photon temperature can be constructed from the homogeneous solutions of Eq. (8.21):

$$\Theta_0(\eta) + \Phi(\eta) = C_1 S_1(\eta) + C_2 S_2(\eta) + \frac{k^2}{3}\int_0^\eta d\eta' [\Phi(\eta') - \Psi(\eta')] \frac{S_1(\eta') S_2(\eta) - S_1(\eta) S_2(\eta')}{S_1(\eta')\dot{S}_2(\eta') - \dot{S}_1(\eta') S_2(\eta')}$$

Here again, I have dropped all occurences of R except in the arguments of the rapidly varying sines and cosines. That is, the argument of S_1, for example, is still taken to be kr_s with its nonzero value of R. We can fix the constants C_1 and C_2 in Eq. (8.23) by appealing to the initial conditions, when both Θ_0 and Φ are constants. The coefficient of the sine term therefore, C_1, must vanish, and $C_2 = \Theta_0(0) + \Phi(0)$. The denominator in the integrand reduces to $-kc_s(\eta') \rightarrow -k/\sqrt{3}$ in the limit in which we are working. Finally, the difference of the products in the numerator of the integrand is simply $-\sin[k(r_s - r_s')]$, so

$$\Theta_0(\eta) + \Phi(\eta) = [\Theta_0(0) + \Phi(0)]\cos(kr_s) + \frac{k}{\sqrt{3}}\int_0^\eta d\eta' [\Phi(\eta') - \Psi(\eta')]\sin[k(r_s(\eta) - r_s(\eta'))]$$

Equation (8.24) is an expression for the anisotropy in the tightly coupled limit, first derived by Hu and Sugiyama in 1995. If you are not impressed with this solution since it still involves an integral over the gravitational potentials, I urge you to reconsider. First, look at Figure 8.6, which compares the solution of Eq. (8.24) with exact results obtained by integrating the full set of coupled Einstein-Boltzmann equations. The approximate solution gets the peak locations dead on, and it does fairly well with the heights as well. The later peaks - those at $k\eta_0 > 500$-are

[5] You can rectify this by applying the WKB approximation in

D-5.

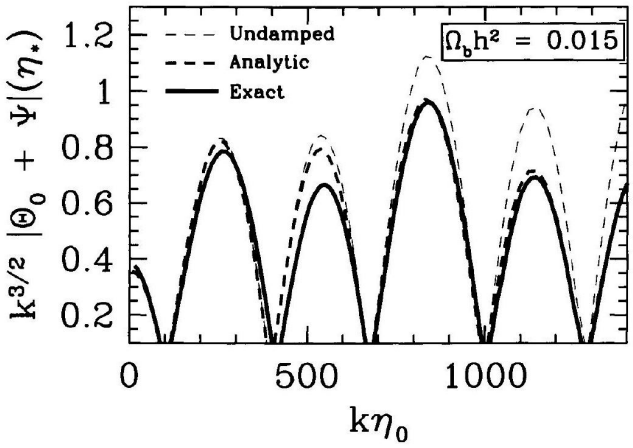

Figure 8.6. The monopole at recombination in a standard CDM model. The exact solution is the heavily weighted solid line. The light dashed line is the undamped solution of Section 8.3, Eq. (8.24); the heavier curve in the middle accounts for damping using the treatment of Section 8.4.

clearly overestimated by our solution, but we will shortly rectify this when we include damping due to diffusion in the next section. A second reason to respect the approximate solution is that it divides the problem neatly into first (i) a calculation of the external gravitional potentials generated by the dark matter and then (ii) the effect of these potentials on the anisotropies. Third, the solution clearly illustrates that the cosine mode is the one excited by inflationary models. This is important, because it is very hard to imagine this mode excited by any other mechanism. If causality is respected, then there should be no perturbations with $k\eta \ll 1$ early on. We know that inflation evades this constraint by changing the true horizon; it is tempting to say that if this mode is observed, we are seeing evidence for inflation. Fourth, we now have a more accurate expression for the frequency of oscillations and therefore for the locations of the acoustic peaks. In the limit that the first term in Eq. (8.24) dominates, the peaks should appear at the extrema of $\cos(kr_s)$, e.g., at

$$k_{\rm p} = n\pi/r_s \quad n = 1, 2, \ldots$$

And the final reason Eq. (8.24) is impressive is that the full set of EinsteinBoltzmann equations involve literally thousands of coupled variables (e.g., the Θ_l 's). Reducing those thousands of differential equations to just one is a huge leap in knowledge. In addition to the monopole, the photon distribution has a nonnegligible dipole at recombination. Using Eq. (8.12), we can obtain an analytic solution for the dipole by differentiating Eq. (8.24):

$$\Theta_1(\eta) = \frac{1}{\sqrt{3}}\left[\Theta_0(0) + \Phi(0)\right]\sin\left(kr_s\right) - \frac{k}{3}\int_0^\eta d\eta'\left[\Phi\left(\eta'\right) - \Psi\left(\eta'\right)\right]\cos\left[k\left(r_s(\eta) - r_s\left(\eta'\right)\right)\right].$$

The first term is completely out of phase with the monopole ($\sin\left(kr_s\right)$ versus $\cos\left(kr_s\right)$). Figure 8.7 shows that this feature remains even after accounting for the integral term. This mismatch of phase will have important implications for the final anisotropy spectrum.

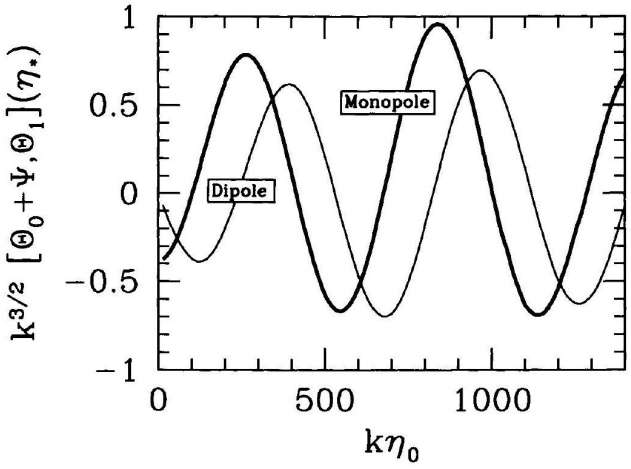

Figure 8.7. The monopole and dipole at recombination in a standard CDM model. The dipole vanishes for the longest wavelength modes that have not entered the horizon by recombination. It is completely out of phase with the monopole.

12.8.4 Diffusion Damping

Figure 8.6 makes it clear that we must account for diffusion to get accurate CMB spectra. To analyze diffusion quantitatively, we must return to the equations for the moments of the photon distribution, Eqs. (8.12), (8.13) and (8.10). Until now, we have neglected Θ_2 and all higher moments. Diffusion is characterized by a small but nonnegligible quadrupole. We must therefore supplement the set of equations we wrote down in the last section with an equation for the quadrupole, Θ_2. Our task is somewhat simplified by the fact that we will be interested in phenomena occurring only on small scales. On these scales, recall from Chapter 7 (e.g., Figure 7.8) that the potentials are very small because of radiation pressure, so we can drop Φ and Ψ everywhere. Also, we will see that diffusion manifests itself in the moments by making each successive moment proportional to a higher power of $1/\dot{\tau}$. Thus we will need to keep only the $l = 2$ mode; all higher ones can be neglected. With these approximations, we have

$$\dot{\Theta}_0 + k\Theta_1 = 0$$
$$\dot{\Theta}_1 + k\left(\frac{2}{3}\Theta_2 - \frac{1}{3}\Theta_0\right) = \dot{\tau}\left(\Theta_1 - \frac{iv_\mathrm{b}}{3}\right)$$
$$\dot{\Theta}_2 - \frac{2k}{5}\Theta_1 = \frac{9}{10}\dot{\tau}\Theta_2.$$

These three equations need to be supplemented by an equation for v_b. This is best expressed as a slight rewriting of Eq. (8.14):

$$3i\Theta_1 + v_\mathrm{b} = \frac{R}{\dot{\tau}}\left[\dot{v}_\mathrm{b} + \frac{\dot{a}}{a}v_\mathrm{b}\right],$$

where again I have dropped the gravitational potential.

To solve this set of equations, we appeal to the high-frequency nature of damping. Let us write the time dependence of the velocity as

$$v_\mathrm{b} \propto e^{i\int \omega d\eta}$$

and similarly for all other variables. We already know that $\omega \simeq kc_s$ in the tightly coupled limit. Now we are searching for damping, an imaginary part to ω. Since damping occurs on small scales, or high frequencies,

$$\dot{v}_\mathrm{b} = i\omega v_\mathrm{b} \gg \frac{\dot{a}}{a}v_\mathrm{b}$$

$\dot{a}/a$ is of order η^{-1} while ω is of order k. So we can drop the second term on the right in Eq. (8.30) and the velocity equation then becomes

$$v_\mathrm{b} = -3i\Theta_1\left[1 - \frac{i\omega R}{\dot{\tau}}\right]^{-1}$$
$$\simeq -3i\Theta_1\left[1 + \frac{i\omega R}{\dot{\tau}} - \left(\frac{\omega R}{\dot{\tau}}\right)^2\right]$$

where I have expanded out to $\dot{\tau}^{-2}$ because $v_\mathrm{b} + 3i\Theta_1$ is multiplied by $\dot{\tau}$ in Eq. (8.28). The equation for the second moment of the photon field, (8.29), can be reduced similarly. First we can drop the $\dot{\Theta}_2$ term since it is much smaller than $\dot{\tau}\Theta_2$. This leaves simply

$$\Theta_2 = -\frac{4k}{9\dot{\tau}}\Theta_1$$

which shows that our approximation scheme is controlled: higher moments are suppressed by additional powers of $k/\dot{\tau}$. The equation for the zeroth moment becomes

$$i\omega\Theta_0 = -k\Theta_1$$

Inserting all of these into Eq. (8.28) gives the dispersion relation

$$i\omega - \frac{8k^2}{27\dot{\tau}} + \left(k^2/3i\omega\right) = \dot{\tau}\left(1 - \left[1 + \frac{i\omega R}{\dot{\tau}} - \left(\frac{\omega R}{\dot{\tau}}\right)^2\right]\right).$$

Collecting terms we get

$$\omega^2(1+R) - \frac{k^2}{3} + \frac{i\omega}{\dot{\tau}}\left[\omega^2 R^2 + \frac{8k^2}{27}\right] = 0$$

The first two terms on the left, the leading ones in the expansion of $1/\dot{\tau}$, recover the result of the previous section, that the frequency is the wavenumber times the speed of sound. We can write the frequency as this zero-order piece plus a firstorder correction, $\delta\omega$. Then, inserting the zero-order part into the terms inversely proportional to $\dot{\tau}$ leads to

$$\delta\omega = -\frac{ik^2}{2(1+R)\dot{\tau}}\left[c_s^2 R^2 + \frac{8}{27}\right]$$

Therefore, the time dependence of the perturbations is

$$\Theta_0, \Theta_1 \sim \exp\left\{ik\int d\eta c_s\right\}\exp\left\{-\frac{k^2}{k_D^2}\right\}$$

where the damping wavenumber is defined via

$$\frac{1}{k_D^2(\eta)} := \int_0^\eta \frac{d\eta'}{6(1+R)n_e\sigma_T a\,(\eta')}\left[\frac{R^2}{(1+R)} + \frac{8}{9}\right]$$

Putting aside factors of order unity, this equation says that $1/k_D \sim [\eta/n_e\sigma_T a]^{1/2}$, which agrees with our heuristic estimate at the beginning of this chapter.

As a first estimate of the damping scale, we can work in the prerecombination limit, in which all electrons (except those in helium) are free. In Chapter 3 we estimated the optical depth in this limit, but ignored helium. The mass fraction of helium is usually denoted as Y_p and is approximately 0.24. Since each helium nucleus contains four nucleons, the ratio of helium to the total number of nuclei is $Y_p/4$. Each of these absorbs two electrons (one for each proton), so when counting the number of free electrons before hydrogen recombination, we must multiply our estimate of Eq. (3.46) by $1 - Y_p/2$. Using the fact that $H_0 = 3.33 \times 10^{-4}$ hMpc^{-1}, we have, in the prerecombination limit,

$$n_e\sigma_T a = 2.3 \times 10^{-5}\mathrm{Mpc}^{-1}\Omega_b h^2 a^{-2}\left(1 - \frac{Y_p}{2}\right)$$

Using this, you can show (Exercise 8) that an approximation for the damping scale is

$$k_D^{-2} = 3.1 \times 10^6 \mathrm{Mpc}^2 a^{5/2} f_D\,(a/a_{\rm eq})\left(\Omega_b h^2\right)^{-1}\left(1 - \frac{Y_p}{2}\right)^{-1}\left(\Omega_m h^2\right)^{-1/2}$$

where f_D, defined in Eq. (8.88), goes to 1 as $a/a_{\rm eq}$ gets large.

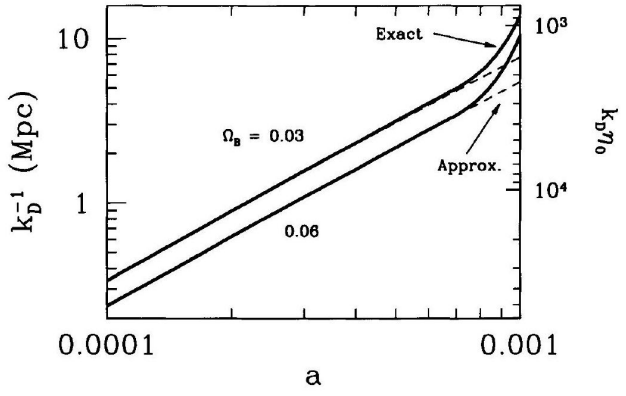

Figure 8.8. Damping scale as a function of the scale factor for two different values of Ω_b (with $h = 0.5$). Heavy curves (exact) numerically integrate over the standard recombination

history, while light curves use the approximation of Eq. (8.42) which assumes electrons remain ionized. Right axis shows the equivalent $k_D\eta_0$; damping occurs on angular scales $l > k_D\eta_0$.

Figure 8.8 shows the evolution of the damping scale before recombination. Neglecting recombination is a good approximation at early times but, as expected, leads to quantitative errors right near η_*, when using Eq. (8.41) for the free electron density does not accurately account for the electrons swept up into neutral hydrogen. In the absence of recombination, k_D scales as $\Omega_b^{1/2}$. Note from the late time behavior in Figure 8.8 that the messy details of recombination change this simple scaling: k_D for the $\Omega_b = 0.06$ case is less than $2^{0.5}$ as big as the $\Omega_b = 0.03$ case.

Figure 8.8 requires one final comment. The damping of anisotropies due to photon diffusion is sometimes referred to as being caused by the "finite thickness of the last scattering surface." That is, it is argued that if recombination took place instantaneously at η_*, then there would be no damping. Figure 8.8 shows that this is patently false. Even if recombination had occurred in this way, the universe before recombination would not have been inifinitely optically thick. Photons would still stream a reasonable distance and hence damp anisotropies. In the examples shown, the damping scale would have been smaller (larger l) by less than a factor of 2 if recombination had occurred instantaneously. On the other hand, we will see in the next section that the anisotropies today are determined by integrating over the visibility function, essentially a filter centered at the epoch of recombination but broadened due to the finite thickness of the last scattering surface. When incorporating the effects of damping (Seljak, 1994; Hu and Sugiyama, 1995), one must account for this finite thickness by integrating the damping function e^{-k^2/k_D^2} weighted by the visibility function. Thus the finite thickness of the last scattering surface has both qualitative and quantitative effects on the final anisotropy spectrum.

12.8.5 Inhomogeneities to Anisotropies

We now have a good handle on the perturbations to the photons at recombination. It is time to transform this understanding into predictions for the anisotropy spectrum today. First, we will solve for the moments Θ_l today in the next subsection. Then we will spend a bit of time relating these moments to the observables. Thus the main purpose of the following subsections is to derive Eq. (8.56), which relates the moments today to the monopole and dipole at recombination, and Eq. (8.68), which expresses the CMB power spectrum in terms of the Fourier moments today.

Free Streaming

We want to derive a formal solution for the photon moments today $\Theta_l(\eta_0)$ in terms of the monopole and dipole at recombination. A formal solution can be obtained by returning to Eq. (4.100). Subtracting $\dot\tau\Theta$ from both sides leads to

$$\dot\Theta + (ik\mu - \dot\tau)\Theta = e^{-ik\mu\eta+\tau}\frac{d}{d\eta}\left[\Theta e^{ik\mu\eta-\tau}\right] = \tilde S$$

where the source function is defined as

$$\tilde S := -\dot\Phi - ik\mu\Psi - \dot\tau\left[\Theta_0 + \mu v_{\rm b} - \frac{1}{2}\mathcal{P}_2(\mu)\Pi\right].$$

Hold your curiosity about the in the definition. Multplying both sides of Eq. (8.43) by the exponential and then integrating over η leads directly to

$$\Theta\left(\eta_0\right) = \Theta\left(\eta_{\rm init}\right) e^{ik\mu(\eta_{\rm init}-\eta_0)} e^{-\tau(\eta_{\rm init})} + \int_{\eta_{\rm init}}^{\eta_0} d\eta \tilde{S}(\eta) e^{ik\mu(\eta-\eta_0)-\tau(\eta)}$$

where I have used the fact that $\tau\left(\eta=\eta_0\right)=0$ since τ is defined as the scattering rate integrated from η up to η_0. We also know that, if the initial time $\eta_{\rm init}$ is early enough, then the optical depth $\tau\left(\eta_{\rm init}\right)$ will be extremely large. Therefore, the first term on the right side of Eq. (8.45) vanishes. This corresponds to the fact that any initial anisotropy is completely erased by Compton scattering. By the same reasoning, we can set the lower limit on the integral to zero: any contribution to the integrand from $\eta < \eta_{\rm init}$ is completely negligible. Thus, the solution for the perturbations is

$$\Theta\left(k,\mu,\eta_0\right) = \int_0^{\eta_0} d\eta \tilde{S}(k,\mu,\eta) e^{ik\mu(\eta-\eta_0)-\tau(\eta)}.$$

Equation (8.46) looks simple, but of course all of the complication is hidden in the source function $\tilde{S}$. Notice that $\tilde{S}$ depends somewhat on the angle μ. If it did not depend on μ, we could immediately turn Eq. (8.46) into an equation for each of the Θ_l 's. For, we could multiply each side by the Legendre polynomial $\mathcal{P}_l(\mu)$ and then integrate over all μ. By Eq. (4.99), the left side would give $(-i)^l\Theta_l$ and the right would contain the integral

$$\int_{-1}^{1} \frac{d\mu}{2} \mathcal{P}_l(\mu) e^{ik\mu(\eta-\eta_0)} = \frac{1}{(-i)^l} j_l\left[k\left(\eta-\eta_0\right)\right]$$

where j_l is the spherical Bessel function. This approach looks so promising that we should pursue it to its end, again forgetting for the moment that $\tilde{S}$ really does have some μ dependence. The expression for Θ_l would be

$$\Theta_l\left(k,\eta_0\right) = (-1)^l \int_0^{\eta_0} d\eta \tilde{S}(k,\eta) e^{-\tau(\eta)} j_l\left[k\left(\eta-\eta_0\right)\right]$$

What about the μ dependence in $\tilde{S}$? We can account for this by noting that $\tilde{S}$ multiplies the exponential $e^{ik\mu(\eta-\eta_0)}$ in Eq. (8.46). Thus, everywhere we encounter a factor of μ in $\tilde{S}$ we can replace it with a time derivative:

$$\mu \to \frac{1}{ik}\frac{d}{d\eta}$$

Let me demonstrate this explicitly with the $-ik\mu\Psi$ term in $\tilde{S}$. The integral is

$$\begin{aligned} -ik\int_0^{\eta_0} d\eta \mu\Psi e^{ik\mu(\eta-\eta_0)-\tau(\eta)} &= -\int_0^{\eta_0} d\eta \Psi e^{-\tau(\eta)} \frac{d}{d\eta} e^{ik\mu(\eta-\eta_0)} \\ &= \int_0^{\eta_0} d\eta e^{ik\mu(\eta-\eta_0)} \frac{d}{d\eta}\left[\Psi e^{-\tau(\eta)}\right] \end{aligned}$$

where the last line follows by integration by parts. Note that the surface terms can be dropped: at $\eta=0$ they are damped by the $e^{-\tau(0)}$ factor. The terms at $\eta=\eta_0$ are not small, but they are irrelevant since they have no angular dependence. They alter the monopole, an alteration which we cannot detect. Thus, accounting for the integration by parts changes the

substitution rule of Eq. (8.49) by a minus sign, with the understanding that the derivative does not act on the oscillating part of the exponential, $e^{ik\mu(\eta-\eta_0)}$. The solution in Eq. (8.48) therefore becomes

$$\Theta_l\left(k,\eta_0\right) = \int_0^{\eta_0} d\eta S(k,\eta) j_l\left[k\left(\eta_0-\eta\right)\right]$$

with the source function now defined as

$$\begin{aligned} S(k,\eta) := e^{-\tau}&\left[-\dot{\Phi}-\dot{\tau}\left(\Theta_0+\frac{1}{4}\Pi\right)\right] \\ &+\frac{d}{d\eta}\left[e^{-\tau}\left(\Psi-\frac{iv_{\rm b}\dot{\tau}}{k}\right)\right]-\frac{3}{4k^2}\frac{d^2}{d\eta^2}\left[e^{-\tau}\dot{\tau}\Pi\right]. \end{aligned}$$

In Eq. (8.51), I have also used the property of spherical Bessel functions: $j_l(x) = (-1)^l j_l(-x)$. At this stage, it is useful to introduce the visibility function

$$g(\eta) := -\dot{\tau}e^{-\tau}.$$

The visibility function has some interesting properties. The integral $\int_0^{\eta_0} d\eta g(\eta) = 1$, so we can think of it as a probability density. It is the probability that a photon last scattered at η. In the standard recombination, since τ is so large early on, this probability is essentially zero for η earlier than the time of recombination. It also declines rapidly after recombination, because the prefactor $-\dot{\tau}$, which is the scattering rate, is quite small. Figure 8.9 shows the visibility function for two values of the baryon density.

The source function in Eq. (8.52) can now be expressed in terms of the visibility function. If we drop the polarization tensor Π in the source since it is very small, then the source function becomes

$$\begin{aligned} S(k,\eta) \simeq\ & g(\eta)\left[\Theta_0(k,\eta)+\Psi(k,\eta)\right] \\ &+\frac{d}{d\eta}\left(\frac{iv_{\rm b}(k,\eta)g(\eta)}{k}\right) \\ &+e^{-\tau}[\dot{\Psi}(k,\eta)-\dot{\Phi}(k,\eta)]. \end{aligned}$$

We can take our analytic solution one step further by performing the time integral in Eq. (8.51). The source term proportional to $v_{\rm b}$ is best treated by integrating by parts. Then,

$$\begin{aligned} \Theta_l\left(k,\eta_0\right) =& \int_0^{\eta_0} d\eta g(\eta)\left[\Theta_0(k,\eta)+\Psi(k,\eta)\right] j_l\left[k\left(\eta_0-\eta\right)\right] \\ &-\int_0^{\eta_0} d\eta g(\eta)\frac{iv_{\rm b}(k,\eta)}{k}\frac{d}{d\eta}j_l\left[k\left(\eta_0-\eta\right)\right] \end{aligned}$$

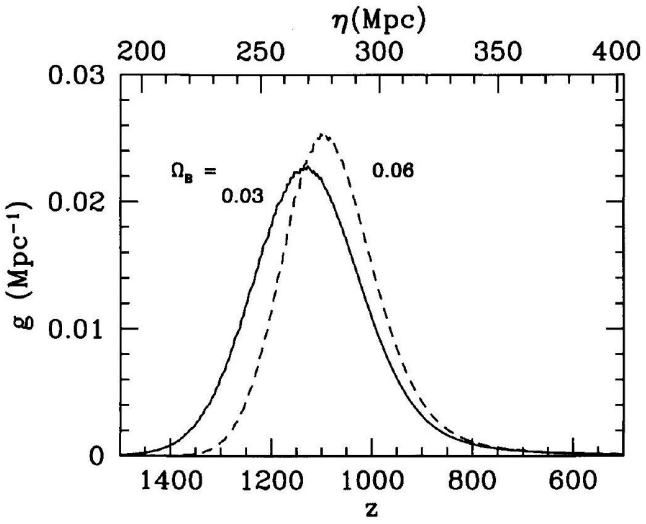

Figure 8.9. The visibility function. Most electrons last scatter at around $z \simeq 1100$ with little dependence on the baryon density. Note that the integral of g over conformal time is 1. Here $h = 0.5$.

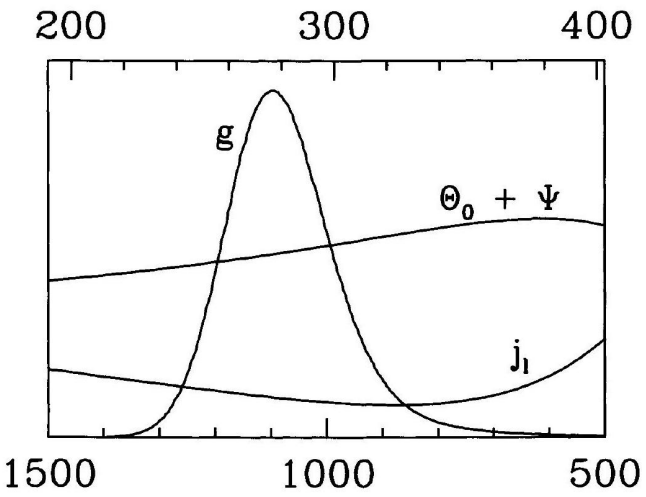
$$+\int_0^{\eta_0} d\eta e^{-\tau}[\dot{\Psi}(k,\eta) - \dot{\Phi}(k,\eta)]j_l\left[k\left(\eta_0 - \eta\right)\right].$$

There are two types of terms in Eq. (8.55). First, there are those wherein the integral is weighted by $e^{-\tau}$. These contribute as long as $\tau \lesssim 1$, that is, at all times after recombination. Note that these are also proportional to derivatives of the potentials. If the potentials are constant after recombination, these terms vanish. In many theories, as we saw in Chapter 7, this is precisely what happens: the universe is purely matter dominated after recombination and in such an environment, the potentials generally remain constant. The corrections due to changing potentials are therefore important to get things right quantitatively, but do not affect the qualitative structure of the anisotropy spectrum. Rather, the dominant terms in Eq. (8.55) are the second types of terms, the ones with integrals weighted by the visibility function.

Since the visibility function is so sharply peaked, the integrals in the first two terms become very simple. To see why, consider Figure 8.10 which shows the three parts of the integrand of the first term (the monopole) in Eq. (8.55). Since the visibility function changes rapidly compared with the other two functions, we can evaluate those other functions at the peak of the visibility function, i.e., at $\eta = \eta_*$, and remove them from the integral. But then, the integral is simply $\int d\eta g(\eta) = 1$. Thus, we are left with η(Mpc)



Z

Figure 8.10. The three components of the integrand in the monopole term of Eq. (8.55). The visibility function is sharply peaked, so it changes rapidly compared with the monopole $\Theta_0 + \Psi$ and the Bessel function $j_l\left(k\left[\eta - \eta_0\right]\right)$. Figure is for $l = 100, k = 0.013h\mathrm{Mpc}^{-1}$.

$$\begin{aligned}\Theta_l\left(k,\eta_0\right) \simeq & \left[\Theta_0\left(k,\eta_*\right) + \Psi\left(k,\eta_*\right)\right] j_l\left[k\left(\eta_0 - \eta_*\right)\right] \\ & + 3\Theta_1\left(k,\eta_*\right)\left(j_{l-1}\left[k\left(\eta_0 - \eta_*\right)\right] - \frac{(l+1) j_l\left[k\left(\eta_0 - \eta_*\right)\right]}{k\left(\eta_0 - \eta_*\right)}\right) \\ & + \int_0^{\eta_0} d\eta e^{-\tau}[\dot{\Psi}(k,\eta) - \dot{\Phi}(k,\eta)] j_l\left[k\left(\eta_0 - \eta\right)\right]\end{aligned}$$

Here I have used the spherical Bessel function identity of Eq. (C.18) to rewrite the Bessel function derivative in the velocity term and also the fact that $v_\mathrm{b} \simeq -3i\Theta_1$ at η_*. On scales much smaller than the one shown in Figure 8.10, $\Theta_0 + \Psi$ changes more rapidly because of the rapid change in the damping scale around recombination. However, this effect can be incorporated by modifying the damping function from

$$e^{-k^2/k_D(\eta_*)^2} \rightarrow \int d\eta g(\eta) e^{-k^2/k_D(\eta)^2}$$

Equation (8.56) is the basis for semianalytic calculations (Seljak, 1994; Hu and Sugiyama, 1995) of C_l spectra which agree with the exact (numerical) solutions to within 10%. From Eq. (8.56), we see that, to solve for the anisotropies today, we must know the monopole (Θ_0), dipole (Θ_1), and potential (Ψ) at the time of recombination. Further, there will be small but noticable corrections if the potentials are time dependent. These corrections, encoded in the last line of Eq. (8.56), are often called integrated Sachs-Wolfe (ISW) terms.

The monopole term - the first in Eq. (8.56) - is precisely what we expected from the rough arguments of Section 8.1. In particular, the spherical Bessel function, $j_l\left[k\left(\eta_0 - \eta_*\right)\right]$, determines how much anisotropy on an angular scale l^{-1} is contributed by a plane wave with wavenumber k. On very small angular scales,

$$\lim_{l\rightarrow\infty} j_l(x) = \frac{1}{l}\left(\frac{x}{l}\right)^{l-1/2}$$

That is, $j_l(x)$ is extremely small for large l when $x < l$. In our case, this means that $\Theta_l\left(k,\eta_0\right)$ is very close to zero for $l > k\eta_0$. This makes sense physically. Returning to Figure 8.4, we see that very small angular scales will see little anisotropy from a perturbation with a large wavelength. The converse is also true: angular scales larger than $1/\left(k\eta_0\right)$ get little contribution from such a perturbation. To sum up, a perturbation with wavenumber k contributes predominantly on angular scales of order $l \sim k\eta_0$. One last comment about the monopole term: the final anisotropy today depends on not just Θ_0, but rather $\Theta_0 + \Psi$, again something we anticipated since photons must climb out of their potential wells to reach us today.

The C_l 's

How is the observed anisotropy pattern today related to the rather abstract $\Theta_l\left(k,\eta_0\right)$? To answer this question, we must first describe the way in which the temperature field is characterized today and then relate this characterization to Θ_l.

Recall that in Eq. (4.34), we wrote the temperature field in the universe as

$$T(\vec{x},\hat{p},\eta) = T(\eta)[1 + \Theta(\vec{x},\hat{p},\eta)]$$

Although this field is defined at every point in space and time, we can observe it only here (at $\vec{x}_0$) and now (at η_0) [6] Our only handle on the anisotropies is their dependence on the direction of the incoming photons, $\hat{p}$. So all the richness we observe comes from the changes in the temperature as the direction vector $\hat{p}$ changes. Observers typically makes maps, wherein the temperature is reported at a number of incoming directions, or "spots on the sky." These spots are labeled not by the $\hat{p}_x, \hat{p}_y, \hat{p}_z$ components of $\hat{p}$, but rather by polar coordinates θ, ϕ. However, it

[6] We do make small excursions from this point in space-time. For example, satellites are not located on Earth and anisotropy measurements have been made over the past 30 years. These are completely insignificant on scales over which the temperature is varying, which are of order the Hubble time (or distance). is a simple matter to move back and forth between the 3D unit vector $\hat{p}$ and polar coordinates. [7] I'll stick with $\hat{p}$ in the ensuing derivation.

We now expand the field in terms of spherical harmonics. That is, we write

$$\Theta(\vec{x}, \hat{p}, \eta) = \sum_{l=1}^{\infty} \sum_{m=-l}^{l} a_{lm}(\vec{x}, \eta) Y_{lm}(\hat{p}).$$

The subscripts l, m are conjugate to the real space unit vector $\hat{p}$, just as the variable $\vec{k}$ is conjugate to the Fourier transform variable $\vec{x}$. We are all familiar with Fourier transforms, so it is useful to think of the expansion in terms of spherical harmonics as a kind of generalized Fourier transform. Whereas the complete set of eigenfunctions for the Fourier transform are $e^{i\vec{k}\cdot\vec{x}}$, here the complete set of eigenfunctions for expansion on the surface of a sphere are $Y_{lm}(\hat{p})$. All of the information contained in the temperature field T is also contained in the space-time dependent amplitudes a_{lm}. As an example of this, consider an experiment which maps the full sky with an angular resolution of 7°. The full sky has 4π radians $^2 \simeq 41,000$ degrees ^{2}, so there are 840 pixels with area of $(7^\circ)^2$. Thus, such an experiment would have 840 independent pieces of information. Were we to characterize this information with a_{lm} 's instead of temperatures in pixels, there would be some $l_{\max}$ above which there is no information. One way to determine this $l_{\max}$ is to set the total number of recoverable a_{lm} 's as $\sum_{l=0}^{l_{\max}} (2l+1) = (l_{\max}+1)^2 = 840$. So the information could be equally well characterized by specifying all the a_{lm} 's up to $l_{\max} = 28$. Incidentally, this is a fairly good caricature of the COBE experiment (Smoot et al., 1992; Bennett et al., 1996). They presented temperature data over many more pixels, but many of these pixels were overlapping. So, the independent information was contained in multipoles up to $l \sim 30$. Experiments currently under way or well along in the planning stage are capable of measuring the moments all the way up to $l \sim 10^4$.

We want to relate the observables, the a_{lm} 's, to the Θ_l we have been dealing with. To do this, we can use the orthogonality property of the spherical harmonics. The Y_{lm} 's are normalized via Eq. (C.11),

$$\int d\Omega Y_{lm}(\hat{p}) Y^*_{l'm'}(\hat{p}) = \delta_{ll'}\delta_{mm'}$$

where Ω is the solid angle spanned by $\hat{p}$. Therefore the expansion of Θ in terms of spherical harmonics, Eq. (8.60), can be inverted by multiplying both sides by $Y^*_{lm}(\hat{p})$ and integrating:

$$a_{lm}(\vec{x}, \eta) = \int \frac{d^3k}{(2\pi)^3} e^{i\vec{k}\cdot\vec{x}} \int d\Omega Y^*_{lm}(\hat{p}) \Theta(\vec{k}, \hat{p}, \eta)$$

Here I have written the right-hand side in terms of the Fourier transform ($\Theta(\vec{k})$ instead of $\Theta(\vec{x})$), since that is the quantity for which we obtained solutions.

[7] $\hat{p}_z = \cos\theta, \hat{p}_x = \sin\theta\cos\phi$, and $\hat{p}_y = \sin\theta\sin\phi$.

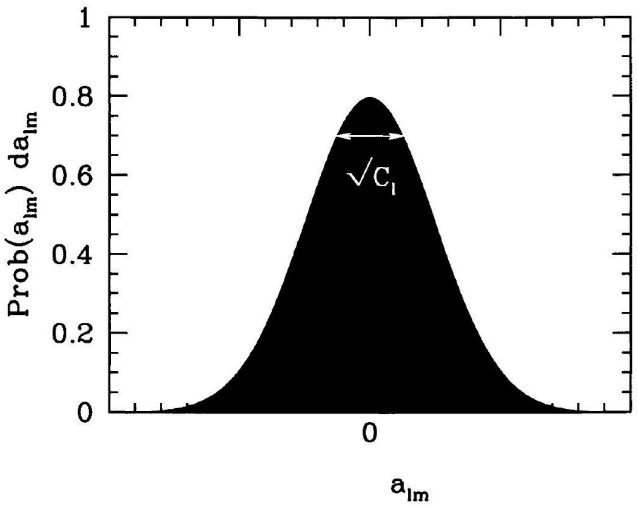


Figure 8.11. The distribution from which the a_{lm} 's are drawn. The distribution has expectation equal to zero and a width of $C_l^{1/2}$.

As with the density perturbations, we cannot make predictions about any particular a_{lm}, just about the distribution from which they are drawn, a distribution which traces its origin to the quantum fluctuations first laid down during inflation. Figure 8.11 illustrates this distribution. The mean value of all the a_{lm} 's is zero, but they will have some nonzero variance. The variance of the a_{lm} 's is called C_l. Thus,

$$\langle a_{lm} \rangle = 0 \quad ; \quad \langle a_{lm} a^*_{l'm'} \rangle = \delta_{ll'} \delta_{mm'} C_l$$

It is very important to note that, for a given l, each a_{lm} has the same variance. For $l = 100$, say, all $201 a_{100,m}$'s are drawn from the same distribution. When we measure these 201 coefficients, we are sampling the distribution. This much information will give us a good handle on the underlying variance of the distribution. On the other hand, if we measure the five components of the quadrupole ($l = 2$), we do not get very much information about the underlying variance, C_2. Thus, there is a fundamental uncertainty in the knowledge we may get about the C_l 's. This uncertainty, which is most pronounced at low l, is called cosmic variance. Quantitatively, the uncertainty scales simply as the inverse of the square root of the number of possible samples, or

$$\left(\frac{\Delta C_l}{C_l} \right)_{\text{cosmic variance}} = \sqrt{\frac{2}{2l+1}}$$

We can now obtain an expression for C_l in terms of $\Theta_l(k)$. First we square a_{lm} in Eq. (8.62) and take the expectation value of the distribution. For this we need $\left\langle \Theta(\vec{k}, \hat{p}) \Theta^* \left(\vec{k}', \hat{p}' \right) \right\rangle$, where from now on we will keep the η dependence implicit. This expectation value is complicated because it depends on two separate phenomena: (i) the initial amplitude and phase of the perturbation is chosen during inflation from a Gaussian distribution and (ii) the evolution we have studied in this chapter turns this initial perturbation into anisotropies, i.e. produces the dependence on $\hat{p}$. To simplify then, it makes sense to separate these two phenomena and write the photon distribution as $\delta \times (\Theta/\delta)$, where the dark matter overdensity δ does not depend on any direction vector. The ratio Θ/δ is precisely what we have solved for in the last two chapters: given the initial amplitude of a mode, we have learned how to evolve forward in time. The ratio does not depend on the initial amplitude, so it can be removed from the averaging over the distribution. Therefore,

$$\left\langle \Theta(\vec{k},\hat{p})\Theta\left(\vec{k}',\hat{p}'\right)\right\rangle = \left\langle \delta(\vec{k})\delta^*\left(\vec{k}'\right)\right\rangle \frac{\Theta(\vec{k},\hat{p})}{\delta(\vec{k})}\frac{\Theta^*\left(\vec{k}',\hat{p}\right)}{\delta^*\left(\vec{k}'\right)}$$
$$= (2\pi)^3\delta^3\left(\vec{k}-\vec{k}'\right)P(k)\frac{\Theta(k,\hat{k}\cdot\hat{p})}{\delta(k)}\frac{\Theta^*\left(k,\hat{k}\cdot\hat{p}'\right)}{\delta^*(k)},$$

where the second equality uses the definition of the matter power spectrum $P(k)$, but also contains a subtlety in the ratio Θ/δ. This ratio, which is determined solely by the evolution of both δ and Θ, depends only on the magnitude of $\vec{k}$ and the dot product $\hat{k}\cdot\hat{p}$. Two modes with the same k and $\hat{k}\cdot\hat{p}$ evolve identically even though their initial amplitudes and phases are different.

After squaring Eq. (8.62), we see that the anisotropy spectrum is

$$C_l = \int \frac{d^3k}{(2\pi)^3}P(k)\int d\Omega Y^*_{lm}(\hat{p})\frac{\Theta(k,\hat{k}\cdot\hat{p})}{\delta(k)}\int d\Omega' Y_{lm}\left(\hat{p}'\right)\frac{\Theta^*\left(k,\hat{k}\cdot\hat{p}'\right)}{\delta^*(k)}.$$

Now we can expand $\Theta\left(k,\hat{k}\cdot\hat{p}'\right)$ and $\Theta\left(k,\hat{k}\cdot\hat{p}'\right)$ in spherical harmonics using the inverse of Eq. (4.99), $\Theta(k,\hat{k}\cdot\hat{p}) = \sum_l (-i)^l(2l+1)\mathcal{P}_l(\hat{k}\cdot\hat{p})\Theta_l(k)$. This leaves

$$C_l = \int \frac{d^3k}{(2\pi)^3}P(k)\sum_{l'l''}(-i)^{l'}(i)^{l''}\left(2l'+1\right)\left(2l''+1\right)\frac{\Theta_{l'}(k)\Theta^*_{l''}(k)}{|\delta(k)|^2}$$
$$\times\int d\Omega\mathcal{P}_{l'}(\hat{k}\cdot\hat{p})Y^*_{lm}(\hat{p})\int d\Omega'\mathcal{P}_{l''}\left(\hat{k}\cdot\hat{p}'\right)Y_{lm}\left(\hat{p}'\right).$$

The two angular integrals here (Exercise 9) are identical. They are nonzero only if $l' = l$ and $l'' = l$, in which case they are equal to $4\pi Y_{lm}(\hat{k})/(2l+1)$ (or the complex conjugate). The angular part of the d^3k integral then becomes an integral over $|Y_{lm}|^2$, which is just equal to 1, leaving

$$C_l = \frac{2}{\pi}\int_0^\infty dk k^2 P(k)\left|\frac{\Theta_l(k)}{\delta(k)}\right|^2$$

For a given l, then, the variance of a_{lm}, C_l, is an integral over all Fourier modes of the variance of $\Theta_l(\vec{k})$. We can now use Eqs. (8.56) and (8.68) to plot the anisotropy spectrum today.

12.8.6 The Anisotropy Spectrum Today

Sachs-Wolfe Effect

Large-angle anisotropies are not affected by any microphysics: at the time of recombination, the perturbations responsible for these anisotropies were on scales far larger than could be connected via causal processes. On these largest of scales, only the monopole contributes to the anisotropy; this is the first term in Eq. (8.56). So the large-angle anisotropy is determined by $\Theta_0 + \Psi$ evaluated at recombination. The large-scale solution we found in Eq. (8.6) was that this combination is equal to $\Psi(\eta_*)/3$. In most cosmological models, recombination occurs far enough after matter/radiation equality that we can approximate the potential back then to be equal to the potential today modulo the growth factor, so

$$\Theta_0(\eta_*) + \Psi(\eta_*) \simeq \frac{1}{3D_1(a=1)}\Psi(\eta_0) = -\frac{1}{3D_1(a=1)}\Phi(\eta_0)$$

The last equality holds here because at very late times, there are no appreciable anisotropic stresses, and $\Phi = -\Psi$.

We may use Eq. (7.7) to express the potential Φ today in terms of the dark matter distribution, so that

$$\Theta_0(\eta_*) + \Psi(\eta_*) \simeq -\frac{\Omega_m H_0^2}{2k^2 D_1(a=1)}\delta(\eta_0)$$

This gives us what we need: an expression for the sum of $\Theta_0 + \Psi$ at recombination that we can plug into the monopole term in Eq. (8.56). To get the anisotropy spectrum today, we then integrate as in Eq. (8.68), leaving

$$C_l^{\rm SW} \simeq \frac{\Omega_m^2 H_0^4}{2\pi D_1^2(a=1)} \int_0^\infty \frac{dk}{k^2} j_l^2\left[k(\eta_0 - \eta_*)\right] P(k)$$

where the superscript denotes Sachs-Wolfe, in honor of the first people to compute the large-angle anisotropy (Sachs and Wolfe, 1967). The power spectrum is given by Eq. (7.9) with the transfer function set to 1 (since we're considering very large scales). Therefore,

$$C_l^{\rm SW} \simeq \pi H_0^{1-n}\left(\frac{\Omega_m}{D_1(a=1)}\right)^2 \delta_H^2 \int_0^\infty \frac{dk}{k^{2-n}} j_l^2\left[k(\eta_0 - \eta_*)\right]$$

The large-scale anisotropies in Eq. (8.72) can be computed analytically. First, we will use the fact that $\eta_* \ll \eta_0$ and define the dummy variable $x := k\eta_0$. Then the spectrum can be rewritten as

$$C_l^{\rm SW} \simeq \pi(\eta_0 H_0)^{1-n}\left(\frac{\Omega_m}{D_1(a=1)}\right)^2 \delta_H^2 \int_0^\infty \frac{dx}{x^{2-n}} j_l^2(x)$$

The integral over the spherical Bessel functions can be analytically expressed (Eq. (C.17) from Gradshteyn and Ryzhik, 6.574.2) in terms of gamma functions, leaving

$$C_l^{\rm SW} \simeq 2^{n-4}\pi^2(\eta_0 H_0)^{1-n}\left(\frac{\Omega_m}{D_1(a=1)}\right)^2 \delta_H^2 \frac{\Gamma\left(l + \frac{n}{2} - \frac{1}{2}\right)}{\Gamma\left(l + \frac{5}{2} - \frac{n}{2}\right)} \frac{\Gamma(3-n)}{\Gamma^2\left(2 - \frac{n}{2}\right)}.$$

If the spectrum is Harrison-Zel'dovich-Peebles, $n = 1$, then the first ratio of the gamma functions $\Gamma(l)/\Gamma(l+2)$ is equal to $[l(l+1)]^{-1}$ using Eq. (C.24). The remaining ratio of gamma functions $\Gamma(2)/\Gamma^2(3/2) = 4/\pi$ using Eq. (C.25), so

$$l(l+1)C_l^{\rm SW} = \frac{\pi}{2}\left(\frac{\Omega_m}{D_1(a=1)}\right)^2 \delta_H^2$$

a constant. Indeed, this is the reason why workers in the field typically plot $l(l+1)C_l$: at low l, where the Sachs-Wolfe approximation is a good one, we expect a plateau.

Figure 8.12 shows the COBE measurements of the large-angular-scale anisotropies along with the Boltzmann solutions of three CDM models. Note that, even for $n = 1$, the true spectrum is not completely flat as suggested by Eq. (8.75). The dipole at recombination (neglected in Eq. (8.74)) contributes slightly. The integrated Sachs-Wolfe effect also is not completely negligible, especially in the Λ model, wherein the potential starts to decay once the

universe becomes Λ dominated at late times. For an $n = 1$ spectrum, the best fit values of δ_H from COBE are

$$\delta_H = 1.9 \times 10^{-5} \quad \Omega_m = 1$$
$$\delta_H = 4.6 \times 10^{-5} \quad \Omega_m = 0.3; \Omega_\Lambda = 0.7.$$

Also shown in Figure 8.12 is a tilted model, one in which the primordial spectral index n is not equal to 1. In such models, the anisotropy should scale as l^{n-1} compared with the Harrison-Zel'dovich-Peebles $n = 1$ spectrum. You can see this scaling from Eq. (8.74) or more directly from the integral in Eq. (8.73). The integrand peaks at $x \sim l$, so very roughly every appearence of x there can be replaced by l. The generalization of the integrand from x^{-1} to x^{n-2} therefore leads to a change in the spectrum that scales as l^{n-1}. As indicated in Figure 8.12, the COBE data have the greatest weight at $l \sim 10$, but cover a range of l spanning an order of magnitude. Extreme values of tilt are therefore ruled out by COBE. To get much better constraints on the tilt, though, measurements spanning a larger range of l are necessary.

Small Scales

The small-scale anisotropy spectrum depends not only on the monopole, but also on the dipole and the integrated Sachs-Wolfe effect. Figure 8.13 shows all these contributions to the spectrum. Let's consider each in turn.

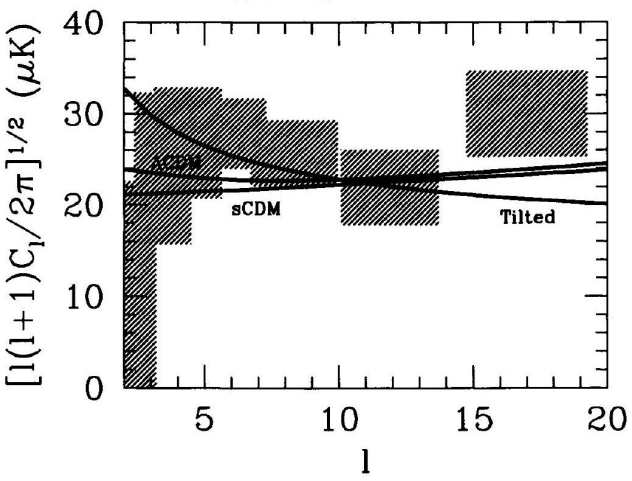

Figure 8.12. Large-scale anisotropies. Hatched boxes show measurements by COBE satellite (Bennett et al., 1996). Curves show the spectra for standard CDM and ACDM (both with $n = 1$). The tilted model is identical to standard CDM, except $n = 0.5$. The late time integrated Sachs-Wolfe effect enhances anisotropy on the largest scales in ΛCDM. Note that here, and in subsequent C_l figures, the root mean square anisotropy is plotted, proportional to $C_l^{1/2}$.C_l is dimensionless so the units of μK come from multiplying by the present background temperature, $T = 2.73$ K.

The monopole at recombination $(\Theta_0 + \Psi)(k, \eta_*)$ free-streams to us today, creating anisotropies on angular scales $l \sim k\eta_0$. This is what we expected back in Figure 8.4, showed to be true in Eq. (8.56), and can now see directly in the top panel of Figure 8.13. There are two interesting features of the quantitative aspect of the free-streaming process. First, note that the "zeroes" in the monopole spectrum, here at 400,650, and 970, are smoothed out because many modes contribute to anisotropy on a given angular scale. If only the $k = 400/\eta_0$ modes contributed to the anisotropy at $l = 400$, then C_{400} would really be zero. But many nonzero modes, with wavenumber greater than $400/\eta_0$, contribute. These change the zero to a trough in the C_l spectrum.

The second feature of free-streaming worth noticing is that our initial estimate tof the peak positions is not exactly right. Inhomogeneity on scale k does not show up as anisotropy precisely on angular scale $l = k\eta_0$. Rather, There is a noticable shift in the top panel, suggesting that a given k-mode contributes to slightly smaller l than we anticipated. This shift arises from the spherical Bessel function in Eq. (8.56). As indicated in Figure 8.14, the peak in the Bessel function comes not when $l = k\eta_0$, but rather at slightly smaller values of l. In addition, our initial

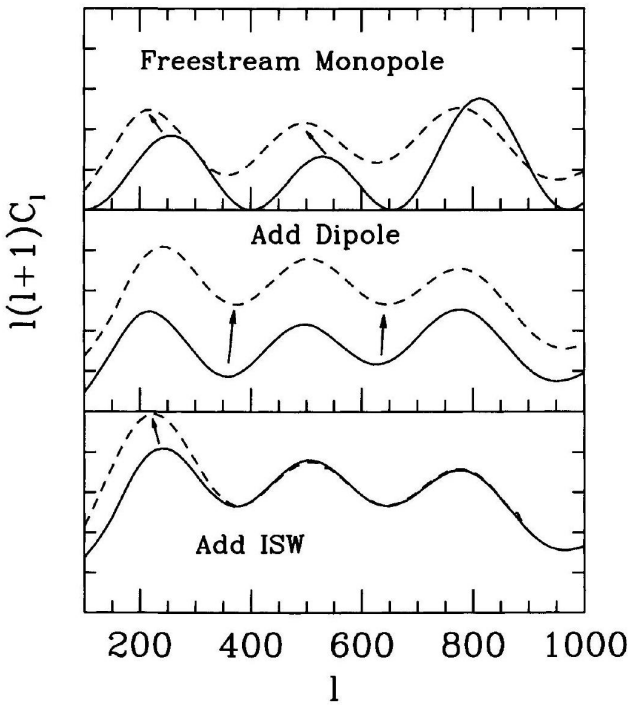

Figure 8.13. Small-scale anisotropy. Top panel: The monopole at recombination $(\Theta_0 + \Psi)\,(k = l/\eta_0, \eta_*)$ contains most of the structure of the final anisotropy spectrum. When free-streamed via the integral in Eq. (8.56), the spectrum shifts slightly to lower l. Middle panel: Accounting for the dipole raises the anisotropy spectrum. Since the dipole is out of phase with the monopole, the troughs become less pronounced. Bottom panel: The integrated Sachs-Wolfe effect enhances the anisotropy on scales comparable to the horizon. In this case, the potential changes near recombination since the universe is not purely matter dominated then. Thus the first peak gets most of the excess power. Throughout, $h = 0.5, \Omega_b = 0.06, \Omega_m = 1$.

estimate for the location of the peaks in k-space, Eq. (8.25), is also slightly high. For example, the expected position of the first peak, $\pi\eta_0/r_s$, for the model depicted in Figure 8.13 is a little over 280. The first peak in the monopole in k-space, however, appears at $k\eta_0 \sim 260$. These two effects - fixed k projects to slightly smaller l and peaks on slightly larger scales than expected from Eq. (8.25) - serve to move the predicted positions of the peaks to lower l. A better approximation for the first

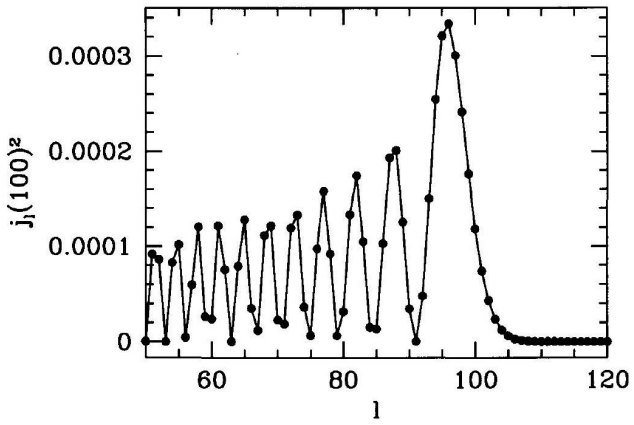

Figure 8.14. The spherical Bessel function, $j_l(100)$. Note that the peak occurs at $l \simeq 90$, slightly smaller than the argument.

peak position is $l_p \simeq 0.75\pi\eta_0/r_s$.

The dipole at recombination is smaller than the monopole and out of phase with it. The middle panel in Figure 8.13 shows that adding in the dipole raises the overall anisotropy level, but particularly fills in the troughs. Without the dipole (in this model) the ratio of the height of the first peak (at $l \sim 200$) to the height of the first trough (at $l \sim 400$) is about 2.5 : 1; the dipole lowers this ratio to 1.5 : 1. This is a direct manifestation of the dipole and monopole being out of phase with one another. That is, at the places where the monopole contributes least to the anisotropies, at its troughs, the dipole contributes the most. One other comment about the relation between the monopole and the dipole: they add incoherently. By incoherently, I mean that the cross term of Θ_l from the monopole multiplied by Θ_l from the dipole vanishes when integrating over all k-modes to get the C_l 's. This can be seen mathematically from the properties of the spherical Bessel function (Exercise 12). Incoherence implies that the dipole is not as important in the power spectrum as one might naively think. If the amplitude of the dipole is 30% of that of the monopole at recombination, the dipole's contribution to the C_l 's is only 10% $(1^2 + 0.3^2 = 1.1)$

The integrated Sachs-Wolfe effect is also important if the potential changes after recombination. To see which scales are affected by the ISW effect, consider the integral in Eq. (8.56). Suppose the potential changes at time η_c, with all subhorizon scales ($k\eta_c > 1$) being affected. The Bessel function peaks at $l \sim k\,(\eta_0 - \eta_c)$; so all angular scales $l > (\eta_0 - \eta_c)\,/\eta_c$ are affected. The largest effect is typically at the horizon.

The best, and most prevalent, example of the ISW effect is that due to residual radiation at recombination. If the universe were purely matter dominated, there would be no such effect. But, the transition to pure matter domination is not abrupt, and even for $a_{\rm eq} \sim 10^{-4}$, an ISW effect occurs right after recombination. This early ISW effect is particularly important because it adds coherently with the monopole. To see this, integrate the last term in Eq. (8.56) by parts. Then, the dominant contribution comes from $\eta \simeq \eta_*$, so the Bessel function can be evaluated there, leaving the trivial integral which gives

$$\Theta_l\,(k,\eta_0)^{\text{early ISW}} = [\Psi\,(k,\eta_0) - \Psi\,(k,\eta_*) - \Phi\,(k,\eta_0) + \Phi\,(k,\eta_*)]\,j_l\,[k\,(\eta_0 - \eta_*)]\,.$$

This adds exactly in phase with the monopole (which is proportional to the same Bessel function) so even though the magnitude of the effect on Θ_l is much smaller than is the dipole, the effect on the anisotropy spectrum is disproportionate. A 30% dipole leads to a 10% shift in the C_l 's, while a 5% ISW effect leads to the same 10% shift in the C_l 's. The bottom panel shows that the large scales, those with $l \sim \eta_0/\eta_*$, get a big boost from this early ISW effect.

12.8.7 Cosmological Parameters

The anisotropy spectrum depends on cosmological parameters. This fundamental realization initially caused great consternation ("We will never be able to measure any one parameter because there is too much degeneracy"). As more quantitative studies were carried out, the pendulum swung to the other side ("We will be able to disentangle the degeneracies and measure cosmological parameters to percent accuracy"). More recently, the community has settled into a state of cautious optimism. Indeed, just a decade after the initial discovery of large scale anisotropies by COBE, there were a host of experiments which together seemed to pin down one parameter (the total energy density) by measuring the location of the first peak. Several of these had measured the subsequent two peaks, allowing an inference of the baryon density, the parameter which most affects the heights and locations of these peaks.

We now have developed the theoretical tools needed to participate in the parameter determination discussion. In this section, we apply these tools to understand how the anisotropy spectrum varies as cosmological parameters vary.

One very important decision that must be made is which parameters will be allowed to vary. I will consider eight parameters:

- Curvature density, $\Omega_k := 1 - \Omega_m - \Omega_\Lambda$
- Normalization, C_{10}
- Primordial tilt, n
- Tensor modes, r (for a precise definition, see Exercise 18)
- Reionization, parametrized by τ back to recombination
- Baryon density, $\Omega_b h^2$
- Matter density, $\Omega_m h^2$
- Cosmological constant energy density, Ω_Λ There are two aspects of this list worth stressing. The first is that obviously it does not include all possible cosmological parameters. Some favorites missing are a neutrino mass (I will set all masses to zero in the following), the equation of state for dark energy w (will be fixed at -1 corresponding to a cosmological constant), and tensor tilt n_T (fixed at zero). The second important point is that I have deliberately chosen very specific combinations of these parameters, e.g., $\Omega_b h^2$, not Ω_b and h separately. While there is good reason for this (e.g., the alternating peaks effect depends on $\Omega_b h^2$), it also is a source of confusion. A common complaint is that, within the context of a flat universe (the first parameter, the curvature density, equal to zero), why should both the cosmological constant and the matter density be allowed to vary? Mustn't their sum equal 1? It is true that $\Omega_m + \Omega_\Lambda$ must equal 1 in a flat universe. But that does not preclude us from varying both $\Omega_m h^2$ and Ω_Λ, since h can change while the sum of the two densities is 1.

To harp on this point, consider two analysts. Analyst A works in the context of a flat universe and uses $\Omega_m h^2$ and Ω_Λ as her two free parameters. Analyst B also assumes the universe is flat, but takes h and Ω_Λ as his two parameters. When A raises Ω_Λ, the matter density ($\Omega_m h^2$) is kept fixed, so the epoch of equality is kept fixed. However, when analyst B raises his Ω_Λ, to keep the universe flat, he must lower Ω_m. He is therefore also lowering the matter density (since h is kept fixed), thereby moving $a_{\rm eq}$ closer to today. That change in $a_{\rm eq}$ will lead to an enhanced ISW effect, and therefore a larger first peak. Analyst A, who had the

foresight to separate out this effect by choosing $\Omega_m h^2$ as one of her parameters, sees no such enhancement. And, indeed the enhancement is caused only indirectly by Ω_Λ: rather it is the direct result of a smaller $\Omega_m h^2$.

Let's now consider the effect of each parameter in turn.

Curvature

If the universe is not flat, then the simple picture of Figure 8.4 is no longer accurate since the geodesics of massless particles are such that photons starting out parallel to each other slowly diverge. Consider the implication of this divergence for anisotropies. Suppose the identical pattern of inhomogeneities was in place at recombination in both a flat and open universe. As shown in Figure 8.15, the physical scale with maximal anisotropy (the first peak) gets projected onto a much smaller angular scale in an open universe. The peaks should therefore be shifted to higher l. As shown in Figure 8.16, this is precisely what happens.

The magnitude of this effect is determined by the comoving angular diameter distance to the last scattering surface, in a flat universe simply equal to $\eta_0 - \eta_*$, and in a universe with curvature given by Eq. (2.46) out to z_*. Figure 8.17 shows this distance as a function of the curvature density with all other parameters held fixed. The angular diameter distance scales as $(1 - \Omega_k)^{-0.45}$, so that it is a factor of 1.7 larger in an open $\Omega_k = 0.7$ universe than in a flat universe. Notice from Figure 8.16 that this is precisely the factor by which the first peak shifts from one model to

Freestreaming in on open unlyerse

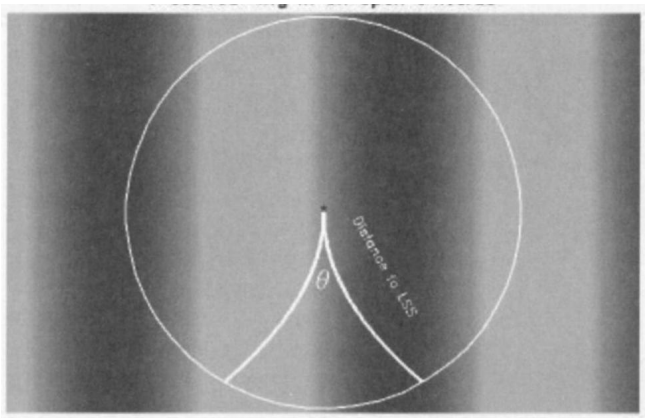

Figure 8.15. Photon trajectories in an open universe diverge. Perturbations at last scattering turn up on smaller scales in an open universe than they do in a flat universe.

the other. Of all the parameters under consideration, curvature by far causes the largest shift in the location of the peaks.

Figure 8.16 also shows data circa 2002. There is a clear rise up to a first peak at $l \sim 200$ and an equally clear fall past this first peak. When the data first started coming in (around 1998), a skeptic could plausibly claim that no one data set spanned the whole peak, and it is difficult to combine data sets. Within a year or two, though, this objection vanished as larger data sets such as TOCO (Miller et al., 1999), Boomerang (de Bernardis et al., 2000), and Maxima (Hanany et al., 2000) all contained enough information by themselves to rule out an open universe. The DASI detection (Halverson et al., 2002), together with the reanalyzed Boomerang and Maxima data, cemented the case for a flat universe.

Of course, a truly flat universe is only one point in parameter space, the point at which the sum of the energy densities exactly equals the critical density, and no data will ever rule out all values except for this one point. Rather, the data now suggest that the total density is equal to the critical density with an error of about 5%. The classic open universe once favored by astronomers had 30% of the critical density, and so is ruled out with very high confidence.

Degenerate Parameters

Figure 8.18 shows the results of varying four parameters. Before considering each in turn, it is important to state the obvious. All of these parameters change the spectrum in very similar ways. The shape of the spectrum varies hardly at all; rather, these parameters simply move the spectrum up and down.

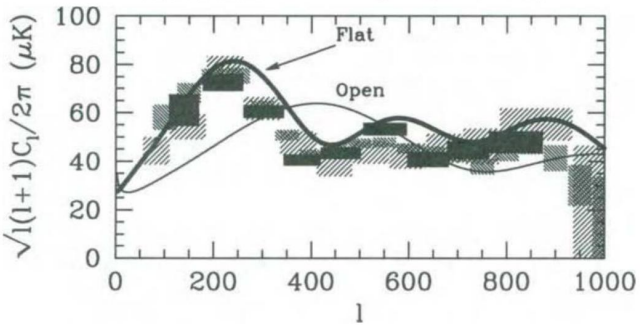

Figure 8.16. The anisotropy spectrum in flat versus open universe. Also shown are data from three small-scale experiments: DASI (darkest; Halverson et al., 2002), Boomerang (medium; Netterfield et al., 2002), and Maxima (lightest; Lee et al., 2001). The pattern of peaks and troughs persists in the open universe but is shifted to smaller scales. The data clearly favor the flat case. Both curves have identical parameters $n = 1, \Omega_m h^2 = 0.15, \Omega_b h^2 = 0.02$ with no reionization, tensors, or cosmological constant. Open curve has $\Omega_k = 1 - \Omega_m = 0.7$; flat has the same parameters except $\Omega_k = 0$.

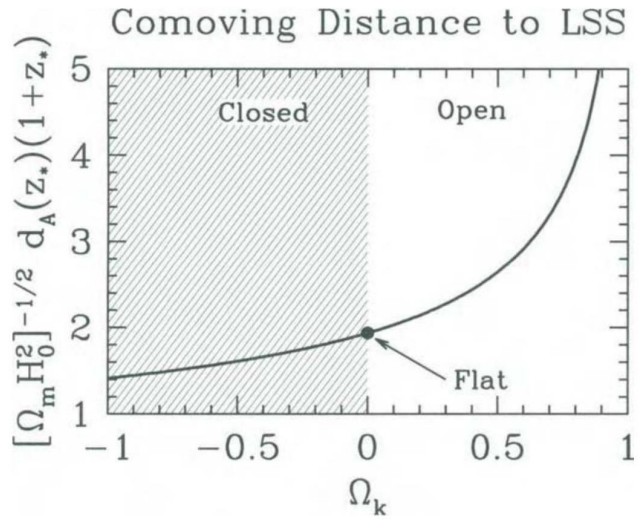

Figure 8.17. Comoving angular diameter distance back to the last scattering surface at $z_* \simeq 1100$ as a function of curvature. The distance is larger in an open universe than in a closed universe.

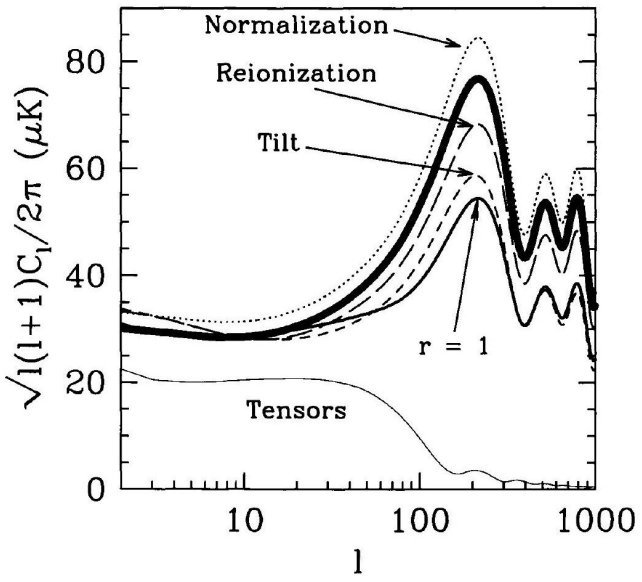

Figure 8.18. Changes in the anisotropy spectrum as C_{10}, τ, r, and n vary. The base model (thick curve) is a flat universe with no reionization or tensors, $n = 1, \Omega_m h^2 = 0.16$, $\Omega_b h^2 = 0.021$, and $\Omega_\Lambda = 0.7$. The thin curves vary one parameter each. Reionization corresponds to letting the optical depth back to the last scattering surface equal 0.2 instead of zero; tilt has a primordial spectum with $n = 0.8; r = 1$ has an equal contribution of scalars and tensors to the quadrupole; and normalization has $C_{10}10\%$ higher than the base model. The curve labeled tensors is the contribution to the anisotropy from tensors only. Only the $r = 1$ curve includes this contribution; all others assume no anisotropy from tensors.

Normalization. The parameter C_{10} trivially moves the spectrum up or down. Note that, of the four parameters varied in Figure 8.18, it is the only one which can raise the amplitude of the spectrum.

Tilt. We have already considered the large-angle effects of a tilted ($n \neq 1$) spectrum. If $n < 1$, then the small-scale anisotropies are smaller than in the $n = 1$ model. Figure 8.18 shows that, as smaller and smaller scales are probed, the effect becomes more pronounced. So of the four parameters considered here, tilt has the most distinctive shape - it is not a simple up-down shift - and perhaps will be most easily extracted. Quantitatively, the spectrum scales as

$$\frac{C_l(n)}{C_l(n=1)} \simeq \left(\frac{l}{l_{\rm pivot}}\right)^{n-1}$$

where here $l_{\rm pivot} = 10$ since we are fixing C_{10}. Accounting for the fact that $\sqrt{C_l}$ is plotted in Figure 8.18, we see from the point at $l = 1000$ that this scaling works extremely well.

Reionization. The universe was almost certainly reionized at late times. We see this in the absorption spectra of high-redshift quasars, where no evidence is seen of a uniform background of neutral hydrogen until we go back as least as far as $z \sim 6$ (Becker et al., 2001; Fan et al., 2002). Reionization brings the CMB back in contact with electrons. If enough scattering takes place, that is, if the optical depth back to the last scattering surface is high enough, isotropy is restored; equivalently, primordial anisotropies are washed out.

There are several ways to see the effect of reionization quantitatively. One is to imagine a photon traveling in our direction with temperature $T[1 + \Theta]$, where T is the background temperature and Θ is the perturbation for which we have solved. If these photons hit a region with optical depth τ, only a fraction $e^{-\tau}$ will escape and continue on their way to us. In addition to these, we will also get a fraction $1 - e^{-\tau}$ from the ionized region. All of these have the equilibrated temperature, T. So the temperature we see today is

$$T[1+\Theta]e^{-\tau} + T\left(1-e^{-\tau}\right) = T\left[1+\Theta e^{-\tau}\right]$$

Subtracting from this the mean temperature T tells us that the fractional anisotropy will be Θ, the primordial one set up at $z \simeq 1100$, multiplied by $e^{-\tau}$. Of course this argument can affect only those scales within the horizon at the time of reionization,

so multipoles l larger than $\eta_0/\eta_{\rm reion}$ will be suppressed by $e^{-\tau}$; small l will be

unaffected. This is seen in Figure 8.18, where the reionization curve falls on top of the base model on large scales but is uniformly suppressed on small scales.

Tensors. We saw in Chapter 5 that once they enter the horizon, the amplitude of gravitational waves dies away. Therefore, gravity waves affect the anisotropy spectrum only on scales larger than the horizon at recombination. Typically, this translates into angular scales $l < 100$. Indeed the tensors curve in Figure 8.18 shows that tensors die out after $l > 100$. We can observe only the sum of anisotropies due to tensors and scalars. So if tensor perturbations were produced during inflation, and if the total (scalar plus tensor) anisotropy spectrum is fit to the large-scale (COBE) data, then the small-scale scalar amplitude is smaller than it would otherwise be. Therefore, on scales $l > 100$ where only scalars remain, the anisotropy spectrum is identical to the base model in Figure 8.18, but with a lower amplitude.

Distinct Imprints

The final variations we will consider are changes in the baryon density $\Omega_b h^2$, the matter density $\Omega_m h^2$, and the cosmological constant. As can be seen from Figure 8.19, these changes lead to richer variations in the anisotropy spectrum; as such they are somewhat harder to understand (but easier to extract from the data!) than the parameters in the previous subsection.

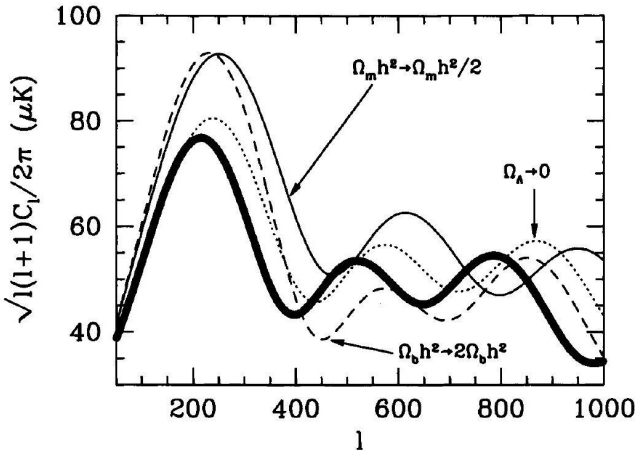

Figure 8.19. Changes in the anisotropy spectrum as baryon density, matter density, and cosmological constant vary. Same base model as Figure 8.18.

Each of these parameters induces a small shift in the locations of the peaks and troughs in the spectrum. To understand these shifts, it is important to recall that since inhomogenities on scales k show up at $l = k\eta_0$ in a flat universe, the peaks in a flat universe will show up at $l_p \simeq k_{\rm p}\eta_0 \simeq n\pi\eta_0/r_s\,(\eta_*)$ (Eq. (8.25), but also see the discussion on page 247 that argues that the actual value of l_p is $\sim 25\%$ lower). Figure 8.20 shows this ratio as a function of matter and baryon density. It is more sensitive to the matter density, so the peak spacing increases as the matter density goes down. But there is also a little sensitivity to the baryon density. With the densities fixed, introducing a cosmological constant does not change the sound horizon, but it does slightly affect η_0, so the peaks shift in that cases as well.

Baryon density. In addition to the lateral shift in the spectrum due to the change in the sound horizon, changes in the baryon density affect the heights of the peaks as well. We have

already touched on the ways in which the anisotropy spectrum depends on the baryon density. The foremost, clearly visible in Figure 8.19, is that odd peaks (first and third in the figure) are higher than the even peaks when the baryon density is large. This is a direct ramification of the lower frequency of oscillations due to the massive baryons. This change is virtually unique, making the baryon density one of the easiest parameters to extract from the CMB. Observations as of 2001 (e.g., Pryke et al., 2001) pin down $\Omega_b h^2 = 0.022 \pm 0.04$, and this constraint will undoubtedly get tighter with data from the Map and Planck satellites. The second change due to $\Omega_b h^2$ is that an increased baryon density reduces the diffusion length. Therefore, a larger baryon density means damping moves to smaller angular scales, so the anisotropy spectrum on scales $l > 1000$ is larger in a high- $\Omega_b h^2$ model.

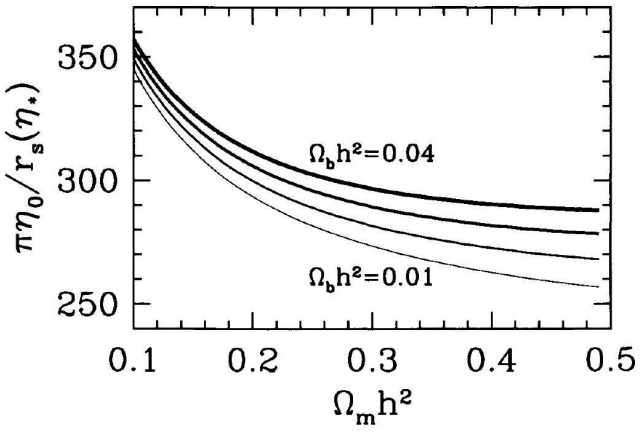

Figure 8.20. The inverse sound horizon at recombination. In a flat universe, the spacing between the acoustic peaks in the CMB is equal to $\pi\eta_0/r_s(\eta_*)$.

Cosmological constant. The cosmological constant is a late-time phenomenon. It was not around at recombination, and therefore could not have affected perturbations then. Therefore, the only possible effects of a cosmological constant are on freestreaming and on the largest angular scales just entering the horizon at recent times. The change due to free-streaming is evident in Figure 8.19. The spectrum is shifted to smaller angular scales if there is no cosmological constant. You will show in Exercise 13 that this small shift can be readily explained by comparing the conformal times in a Λ universe and a matter-dominated universe. Figure 8.19 also shows that the anisotropy spectrum is slightly lower on small scales in a Λ universe. This is a direct result of the large-angle normalization. In a Λ universe, there is a late-time ISW effect, which enhances the anisotropies on large angles. If we normalize on these scales, then the small-scale anisotropy gets correspondingly smaller.

Matter density. If the matter density is low, the epoch of equality occurred closer to recombination, so that the radiation density must be accounted for in computing the inhomogeneities at recombination. In particular, the decaying potential due to the inability of the radiation to cluster provides a strong driving force for the oscillations. Therefore, $\Theta_0(\eta_*)$ is larger than in a purely matter-dominated universe. Further, after recombination, since the potential is not constant, the ISW effect also contributes significantly to the final anisotropy spectrum. Therefore, the small-scale anisotropies increase if the matter density is low. This effect too has apparently been detected, with measurements (Pryke et al., 2001) implying $\Omega_m h^2 = 0.16 \pm 0.04$.

SUGGESTED READING

The large-scale Sachs-Wolfe effect was first predicted by Sachs and Wolfe (1967), just several years after the discovery of the CMB. Several groups initiated the study of anisotropies in the tightly coupled limit: Doroshkevich, Zel'dovich, and Sunyaev (1978), Atrio-Barandela and Doroshkevich (1994), and Jorgenson et al. (1995). The approach was perfected by Seljak (1994)

and Hu and Sugiyama (1995), the latter of which is the basis for the semianalytic treatment of this chapter. Again, CMBFAST described in Seljak and Zaldarriaga (1996) is a crucial tool for fast, accurate numerical work. Diffusion damping is sometimes called Silk damping because of the Silk (1968) paper recognizing its importance. Two other papers of interest are Zaldarriaga and Harari (1995) which discusses the effect of polarization on the damping scale (see Exercise 7) and Hu and White (1997a) which, among other things, gives fits to the damping scale valid for a wide range of parameters.

The question of how the anisotropy spectrum depends on cosmological parameters has been explored in literally hundreds of papers over the past decade. I remember Dick Bond, one of the pioneers in the field, giving a talk in 1992 at a conference about the early COBE data waving his hands through an invisible multidimensional parameter space, explaining that our goal now was to navigate through this space. Among the most important realizations were the dependence on curvature (Kamionkowski, Spergel, and Sugiyama 1994), the degeneracy of the height of the first peak (Bond et al., 1994), and breaking of this degeneracy by smaller scale information (Jungman et al., 1995). More recently, Hu et al. (2000) is a good reference.

I have given short shrift (or no shrift) to some important parameters. The effect of dark energy on the CMB has now been well studied: first by Coble, Dodelson, and Frieman (1997) and then more generally by Caldwell, Dave, and Steinhardt (1998). Massive neutrinos affect the anisotropy spectrum at the $5-10\%$ level (Ma and Bertschinger, 1995 and Dodelson, Gates and Stebbins, 1996). The anisotropies due to tensors became a hot topic after the COBE discovery. For a semianalytic treatment and references to the dozens of papers relating the tensor anisotropy to parameters in the potential, see Turner, White and Lidsey (1993). Although the effect of reionization on the primary anisotropies generated before recombination is well understood, a hot topic now is secondary anisotropies, those generated after reionization. These will likely be probed by the next generation of experiments.

3K: The Cosmic Microwave Background (Partridge) is a good introduction to some of the experimental issues I have neglected in this book. The COBE discovery paper is Smoot et al. (1992) with the 4-year observations presented in Bennett et al. (1996). There were many good analyses papers written on the COBE data; I've relied on Bunn and White (1997), which is especially good for using COBE to normalize the matter power spectrum, and Tegmark (1997), from which the points in Figure 8.12 are taken. The two satellite experiments are Map (http://map.gsfc.nasa.gov) and Planck (http://sci.esa.int/planck/). Map was launched in 2001, and Planck is scheduled to be launched in 2007.

12.9 Cosmological perturbations by J. Lesgorgues

Abstract

We present a self-contained summary of the theory of linear cosmological perturbations. We emphasize the effect of the six parameters of the minimal cosmological model, first, on the spectrum of Cosmic Microwave Background temperature anisotropies, and second, on the linear matter power spectrum. We briefly review at the end the possible impact of a few non-minimal dark matter and dark energy models.

Purposes

Cosmology is progressing by leaps and bounds thanks to a spectacular amount of observational data. It provides crucial clues for particle physics, and more generally for high energy physics. A key role is played by Cosmic Microwave Background (CMB) and Large Scale Structure (LSS) data. Their interpretation relies on the *theory of cosmological perturbations*.

The aim of this course is to introduce this theory, staying at the linear level, and hopefully with a simple, self-contained and original approach. It is targeted at PhD students in

astrophysics and cosmology, as well as researchers in particle physics willing to follow current developments in cosmology. We discuss in particular the effect of the parameters of the minimal cosmological model on the spectrum CMB temperature anisotropies, and on the matter power spectrum. We briefly review at the end the possible impact of non-minimal dark matter and dark energy models.

These notes are based on a cycle of five lectures of 90 minutes. Since this is not much for introducing linear cosmological perturbation theory, the lectures remained at a qualitative level, with more emphasis on physical ideas than on the algebra. These written notes contain roughly the same amount of information as the lectures. After reading these few pages, the reader may wish to improve his/her level of understanding, while sticking to the same structure and same notations. For this purpose, we suggest to read chapters 2, 5 and 6 of Ref. [1]: they contain a similar presentation, still simple and qualitative, but more detailed. Optionally, the reader can also grab there a description of neutrino effects, which are completely neglected here.

For a quantitative description of perturbation theory, gauge transformations, CMB physics and linear or non-linear structure formation, the reader should refer to the specialized literature. In the bibliography, we list a very incomplete selection of outstanding references.

Sections 12.9.2 and 12.9.3 of these notes are illustrated with several figures that represent the qualitative evolution of cosmological perturbations. It would have been easy to produce them with a Boltzmann code, as we did in Ref. [1]. We deliberately chose instead to include only scanned hand-drawings. The first reason is that drawings offer the possibility to exaggerate some effects for pedagogical purposes: they are often more illuminating than exact numerical plots. The second reason is that they better render the conviviality of the blackboard presentation at TASI.

12.9.1 Linear cosmological perturbations

Classification

We decompose the metric and stress-energy tensor of the universe into spatial averages and linear perturbations,

$$g_{\mu\nu}(t,\vec{x}) = \bar{g}_{\mu\nu}(t) + \delta g_{\mu\nu}(t,\vec{x}) \ , \tag{181}$$

$$T_{\mu\nu}(t,\vec{x}) = \bar{T}_{\mu\nu}(t) + \delta T_{\mu\nu}(t,\vec{x}) \ , \tag{182}$$

where $\bar{g}_{\mu\nu}$ stands for the metric of the homogeneous and isotropic Friedmann–Lemaître (FL) model. Being symmetric, the two perturbed tensors contain ten degrees of freedom each, describing different aspects of gravity. Bardeen showed in 1980 that they can be decomposed on the basis of scalars, vectors and tensors under spatial rotations (spatial rotations play a special role because they leave the FL background invariant). These three sectors are decoupled at first order in perturbation theory.

In the vacuum, scalar and vector perturbations vanish, while tensor perturbations can propagate if they have been excited: they account for gravitational waves, the only "real" (propagating) gravitational degrees of freedom in General Relativity (GR). In the presence of matter, scalars represent the response of the metric to an irrotational distribution of matter, and generalize Newton's theory of gravitation. Vectors represent the response of the metric to vorticity, and describe phenomena with no equivalent in Newton's theory, called "gravito-magnetism".

In minimal cosmological models, the vorticity of the various matter components decays with time, and vectors can be neglected. Tensors may play a small role in CMB anisotropies, that we will mention briefly in Sec. 12.9.2. They can be studied separately, since they decouple from the scalar sector at first order in perturbations. Hence this course will be essentially focused on scalar perturbations.

The four scalar components of both the metric and stress-energy perturbed tensors are contained in:

1. the (00) term,
2. the trace of the (ij) matrix,
3. the irrotational part of the $(0i)$ vector,
4. the traceless longitudinal part of the (ij) tensor.

For the perturbed metric $\delta g_{\mu\nu}$, these components correspond (in the same order) to:

1. the generalized gravitational potential ψ,
2. the local distortion ϕ of the average scale factor $a(t)$: the "local scale factor" is given by $(1-\phi)a$,
3. the potential b such that $\delta g_{0i} = \partial_i b$,
4. the potential μ of the metric shear: $\delta g_{ij} = (\partial_i\partial_j - \frac{1}{3}\delta_{ij}\Delta)\mu$.

For the perturbed stress-energy tensor $\delta T_{\mu\nu}$, these components (still in the same order) represent:

1. the energy density perturbations $\delta\rho$ (we will usually refer to the relative perturbations $\delta \equiv \delta\rho/\bar{\rho}$),
2. the pressure perturbations δp,
3. the potential v of the irrotational component of the flux of energy, $\delta T^0_i = \partial_i v$ (v is sometimes called the velocity potential, since in the case of a fluid it is related to the bulk velocity),
4. the potential s of the shear stress or anisotropic stress: $\delta T^i_j = (\partial_i\partial_j - \frac{1}{3}\delta_{ij}\Delta)s$.

It is equivalent to use as a variable the "velocity potential" v or the "velocity divergence" θ defined as

$$\partial_i \delta T^0_i \equiv (\bar{\rho} + \bar{p})\theta = \Delta v \ . \tag{183}$$

Similarly, we can use the function σ instead of s, with the definition

$$(\partial_i\partial_j - \frac{1}{3}\delta_{ij}\Delta)\delta T^i_j \equiv (\bar{\rho} + \bar{p})\sigma = \Delta(\Delta s) \ . \tag{184}$$

The function σ is usually called the anisotropic stress, although the true anisotropic stress is the component of δT^i_j deriving from the potential s. The factors $(\bar{\rho} + \bar{p})$ in the two previous equations are introduced in the definitions in order to obtain simple equations (some authors use alternative notations without these factors or with different ones). To summarize, we see that we can manipulate four degrees of freedom representing the scalar perturbations of matter fields, that can be chosen to be the density fluctuation, pressure perturbation, velocity divergence and anisotropic stress: $\{\delta, \delta p, \theta, \sigma\}$.

Gauges

In an idealised FL universe, there is only one time slicing compatible with the assumption of homogeneity. Instead, in a perturbed universe, there is an infinity of time slicings compatible with perturbation theory (i.e. such that on each slice, all quantities remain close to their average value).

The perturbation of any quantity in a given point is the difference between the true and the average quantity in this point. For instance, for the total energy density ρ,

$$\delta\rho(t,\vec{x}) = \rho(t,\vec{x}) - \bar{\rho}(t) \ . \tag{185}$$

While $\rho(t,\vec{x})$ is a locally, unambiguously defined quantity, $\bar{\rho}(t)$ depends on the choice of equal-time hypersurface going through the point $(t,\vec{x})$. With a different choice, $\rho(t,\vec{x})$ would be compared to the average performed on a different sheet, that would take a different value. Hence $\delta\rho(t,\vec{x})$ also depends on the choice of time slicing.

A gauge is a choice of time slicing. Gauge transformations are induced by coordinate transformations $x_\mu \mapsto x_\mu + \epsilon_\mu$ mapping the points of one time slicing to those of another time slicing. All coordinate transformations do not induce a valid gauge transformation: the condition that perturbations must still be linear after the transformation restricts ϵ_μ to be small in every point.

A naive study of the equations of motion of perturbed quantities would be plagued by the freedom to change the gauge without changing physical results: some solutions of the full equations would be "gauge modes" with no observable consequences. To deal with this issue, one can adopt one of two point of views:

- one can derive gauge-invariant quantities (i.e., non-trivial integro-differential combinations of the metric and stress-energy tensor components left invariant by a gauge transformation), and gauge-invariant equations of motions for these quantities. Note that there are four scalar degrees of freedom in $\delta g_{\mu\nu}$ and two scalar degrees of freedom in the four-vector field ϵ_μ inducing gauge transformations: namely, ϵ_0 and the potential e such that $\epsilon_i = \partial_i e$. Hence we can use gauge transformations to cancel two scalar degrees of freedom, and build up two independent gauge-invariant scalars. One way to define them is through the two Bardeen potentials $\Phi_{\rm A}$ and Φ_H, defined by Bardeen (1980) as two integro-differential combinations of ψ, ϕ, b, μ.

- one can fix the gauge, i.e. introduce a condition such that the time slicing is unique. Then the number of independent solutions to the equations will be the same as in the gauge-invariant formalism. In any case, one can show that truly observable quantities are always independent of the gauge. Obtaining them after solving equations in the gauge-invariant formalism or in one particular gauge should not make any difference in practice.

A convenient gauge choice for a pedagogical introduction to CMB and matter scalar perturbations is the so-called Newtonian gauge or longitudinal gauge, in which one imposes that non-diagonal scalar perturbations of the metric vanish: $b = \mu = 0$. This prescription can be showed to fix a unique time slicing. In this gauge, adopting units such that $c = 1$ and using proper time t, the line element reads:

$$ds^2 = -(1+2\psi)dt^2 + (1-2\phi)a^2 d\vec{l}^{\,2} \ , \tag{186}$$

where $d\vec{l}^{\,2}$ stands for the cartesian measure $(dx^2 + dy^2 + dz^2)$ for a flat FL model, or for $(1 \pm kr^2)^{-1}dr^2 + r^2(\sin\theta^2 d\theta^2 + d\varphi^2)$ for an open/closed FL model in spherical coordinates. We are still free to redefine time (by definition, a time redefinition leaves the time slicing invariant). Lots of results in cosmological perturbation theory look simpler when using conformal time η,

defined up to a constant by $d\eta = dt/a$. In this course we fix the constant in such way that $\eta \longrightarrow 0$ at the vicinity of the initial singularity, when $\rho \longrightarrow \infty$ (this prescription would not work if we were studying cosmological inflation, but in this course, we are not). Conformal time is convenient because photons traveling in a flat unperturbed FL universe along geodesics crossing the origin of the system of coordinates obey to $dr = d\eta$ (this comes from $a\,dl = dt$, i.e. from $ds = 0$ with the restriction $d\theta = d\phi = 0$). Hence conformal time is a measure of time based on the comoving distance travelled by a photon[117], and the comoving distance to a given object coincides with its "look-back conformal time". In this course we will use dots for derivatives with respect to proper time and primes for derivatives with respect to conformal time. The Hubble parameter (or expansion rate parameter) reads

$$H = \frac{\dot{a}}{a} = \frac{a'}{a^2} \ , \tag{187}$$

the Hubble radius is $R_H = 1/H$, and the condition that a Fourier mode of physical wavelength λ crosses the Hubble radius is

$$\lambda = R_H \quad \Leftrightarrow \quad \frac{2\pi}{k}a = \frac{1}{H} \quad \Leftrightarrow \quad k \sim aH = \frac{a'}{a} \ . \tag{188}$$

One advantage of the Newtonian gauge is that the gauge-invariant Bardeen potentials $\{\Phi_{\rm A}, \Phi_H\}$ reduce in this gauge to the metric perturbations $\{\phi, \psi\}$: the evolution of the Newtonian metric perturbations informs us directly on that of two gauge-invariant quantities. Other interesting properties of $\{\phi, \psi\}$ appear when writing the Einstein equations in the Newtonian gauge. The full Einstein equations linearized at first order in perturbations feature four equations relating scalar degrees of freedom. One of them, associated to the traceless longitudinal part of $\delta G^i_j = 8\pi G T^i_j$, gives (assuming a flat FL background)

$$\frac{2}{3}(k/a)^2(\phi - \psi) = 8\pi G \sum_x (\bar{\rho}_x + \bar{p}_x)\sigma_x \ , \tag{189}$$

where the index x runs over all the species contributing to the total stress-energy tensor. This means that when the universe contains only shearless components with $\sigma_x = 0$ (as would be the case in the presence of perfect fluids), the two metric perturbations are equal. Next, the Einstein equation $\delta G^0_0 = 8\pi G T^0_0$ gives (still assuming a flat FL background)

$$2a^{-2}\left[k^2\phi + 3\frac{a'}{a}\left(\phi' + \frac{a'}{a}\psi\right)\right] = -8\pi G \sum_x \bar{\rho}_x \delta_x \ . \tag{190}$$

The term on the right-hand side involves the total energy perturbation $\delta\rho_{\rm tot} = \sum_x \bar{\rho}_x \delta_x$. In the short scale (more precisely, sub-Hubble) limit, the term containing k^2 dominates the other terms in the square brackets, and we recover the Poisson equation

$$-\frac{k^2}{a^2}\phi = 4\pi G\, \delta\rho_{\rm tot} \ , \tag{191}$$

where the factor $-k^2/a^2$ represents the Fourier transform of the physical Laplace operator in an expanding universe. Note that in the Poisson equation one may have expected to see the generalized gravitational potential ψ instead of ϕ: however, in the sub-Hubble limit, the shear of individual components is usually either null or negligible, so that $\phi = \psi$.

[117] In a universe with non-zero spatial curvature, this remains true, provided that the comoving distance is defined not like r, but like $\chi \equiv \int (1 \pm kr^2)^{-1/2} dr$.

Equations of motion

In the minimal cosmological scenario, the universe features several species with spatial fluctuations, described with different equations because of their distinct properties: cold dark matter (CDM) is non-relativistic and collisionless, neutrinos are ultra-relativistic and collisionless at the times of interest, baryons are non-relativistic and smoothly interpolating from a strongly coupled to decoupled regime, and finally photons are ultra-relativistic and interpolating between the same two regimes.

The equation of conservation of the total stress-energy tensor, $D_\mu T^\mu_\nu = 0$ (deriving from Bianchi identities), yields two scalar and two vector equations. The scalar ones are the conservation of energy equation and the Euler equation.

For an single component experiencing no interaction with other species (other than gravitational), the equation $D_\mu T^\mu_\nu = 0$ applies to the individual stress-energy tensor: it gives one continuity and one Euler equation for that component. The evolution of single component experiencing interactions is also given by the continuity and Euler equation, but with an extra source term accounting for stress-energy injection/leak caused by the interaction.

We have seen that the perturbations of each component x can be described by four variables $\{\delta_x, \delta p_x, \theta_x, \sigma_x\}$. Hence, in general, two equations of motion are not sufficient for closing the system. However:

- for a perfect fluid, microscopic interactions impose local thermodynamical equilibrium. The pressure is then isotropic[118], with $\sigma_x = 0$. In addition, pressure perturbations obey to $\delta p_x = c_{\rm a}^2 \delta\rho_x$, where $c_{\rm a}$ is the adiabatic sound speed inferred from the equation of state of the fluid. If σ_x vanishes and δp_x is a function of $\delta\rho_x$, perturbations in the fluid are described by only two independent functions $\delta_x \equiv \delta\rho_x/\bar{\rho}_x$ and θ_x. If the collision term also vanishes or is specified, the two equations of motion (continuity and Euler) are sufficient for closing the system and computing the evolution of perturbations.

- for a decoupled or weakly interacting species, there are no such simplifications concerning the anisotropic stress and pressure perturbation. Hence, in general, the two equations inferred from stress-energy conservation are not sufficient. For such species, one has to use the more general Boltzmann equation, giving the evolution of each phase-space distribution:
$$\frac{d}{d\eta} f_x = \sum_y C_{xy}[f_x, f_y] \ , \tag{192}$$
where the sum holds over the species y coupled with x. Each phase-space distribution can be decomposed into a background and perturbation part:
$$f_x(\eta, \vec{x}, \vec{p}) = \bar{f}_x(\eta, |\vec{p}|) + \delta f_x(\eta, \vec{x}, \vec{p}) \ , \tag{193}$$
where $\vec{p}$ stands for momentum, $|\vec{p}|$ for its modulus, and the background part does not depend on the direction of $\vec{p}$ by assumption of isotropy.

- fully decoupled CDM is a particular case of a collisionless species with negligible velocity dispersion (the word "cold" refers precisely to this last assumption). Hence, it behaves in the same way as a pressureless perfect fluid, although in reality it has no interactions and should not be called a fluid. Since the velocity dispersion is negligible, in a given

[118] An anisotropic shear stress $\sigma \neq 0$ reflects the fact that in each given point, particles travel with different velocities (due to some intrinsic velocity dispersion and/or a superposition of several flows in phase space), leading to anisotropic pressure. This contradicts the assumption of a perfect fluid, in which local interactions result in a unique bulk velocity (after coarse-graining over microscopic scales), and erase anisotropic pressure.

point, all particles share the same velocity, imposed by gravitational flows (while for non-cold collisionless species, the velocity would get two contributions, one from gravitational flows, and one from the phase-space distribution function). Hence the anisotropic pressure vanishes (see the previous footnote). The pressure perturbation δp_x is also related to the velocity dispersion in a given point, anf can be neglected with respect to the density perturbation in the CDM case. Hence CDM is formally equivalent to a perfect fluid with no anisotropic stress and no pressure perturbation (or in other words, with a sound speed $c_\mathrm{s} = 0$). In that case, the two equations of motion inferred from $D_\mu T^\mu_\nu = 0$ are sufficient, like for a fluid.

Gravitational interactions between species are accounted by the presence of metric perturbations in each equation of motion (more specifically, terms in $k^2\psi$ accounting for gravitational forces, and terms in ϕ' accounting for dilation effects, i.e. for local distortions of the scale factor with respect to a). Hence, in order to close the full system of equations, we still need two independent relations, to be chosen among the four scalar Einstein equations: they provide the value of $k^2\psi$ and ϕ' at each time, as a function of all matter fields.

Initial conditions

We wish to study the evolution of matter perturbations, starting from some early time at which all Fourier modes of interest (those which are observable in the CMB spectrum and in the matter power spectrum on linear or mildly non-scales) are still outside the Hubble radius. Indeed, super-Hubble modes experience a trivial evolution, unaffected by small scale interactions (Thomson or Coulomb scattering, usual gravitational force $\vec{\nabla}\phi$, etc.) Hence, the perturbations evaluated at some arbitrary time but on super-Hubble scales reflect directly the mechanism responsible for the formation of perturbations in the very early universe. In the standard cosmological model, these initial conditions can be inferred from inflation.

Typically, a good time for setting initial conditions is when the redshift $z = a_0/a - 1$ is of the order of 10^5: at this time, all comoving scales that are observable in the CMB and linear matter power spectrum still verify $k \ll aH$.

It is crucial to understand that, as long as the background cosmology is assumed to be of the FL type, the perturbed stress-energy momentum tensor δT^ν_μ must be diagonal on super-Hubble scales. Indeed, the background tensor $\bar{T}^\nu_\mu$ is diagonal, and of the form: $\mathrm{diag}(-\bar{\rho}, \bar{p}, \bar{p}, \bar{p})$. This can be showed to be the most general assumption compatible with homogeneity and isotropy. Let us assume that we Taylor-expand δT^ν_μ in powers of the variable $(k\eta)$. For any power-law scale factor, aH is given by $1/\eta$ times a factor of order one. Hence the limit $k\eta \ll 1$ represents precisely the super-Hubble limit. In the Taylor expansion, the zero mode should share the same properties as the background solution, and be diagonal. Higher order terms account for contributions to δT^ν_μ growing with time, and possibly becoming important around the time of Hubble crossing.

The total scalar perturbations $\delta\rho$ and δp are the only one preserving the diagonal form of δT^ν_μ: we conclude that they are the only one that do not vanish at order zero in the $(k\eta)$ expansion. Using stress-energy conservation equations, one can show that the part of δT^ν_μ associated with the velocity divergence is of order one in $(k\eta)$, while the part associated to the total anisotropic stress is of order two.

Suppose that the universe contains initially N uncoupled perfect fluids[119], with N known sound speeds $c_x^2 = \delta p_x/\delta\rho_x$. There are $2N$ independent initial conditions, corresponding to

[119]The discussion presented in this section could be generalized to N coupled species, not all of them being perfect fluids: the conclusions would not change qualitatively, and we restrict here to N uncoupled fluid for simplicity.

possible initial values of each δ_x and each δ'_x. Importantly, in the $2N$-dimensional basis of IC's, one basis vector is very special, as we shall see below.

Before studying perturbations, one should have solved for the background evolution: all background quantities should be known, including for instance the density $\bar{\rho}_x(\eta)$ and pressure $\bar{p}_x(\eta)$ of each species x. Now, let us assume that the real universe is perturbed initially by a single degree of freedom (one may say, by a single initial time shifting function). This is the case in single-field inflationary cosmology: during inflation, there is a single clock (the inflaton), and perturbations arise from a single time shifting function (the inflaton perturbation).

As long as we are dealing with super-Hubble modes, we can neglect microscopic interactions and say that the evolution in each point (in fact, in each Hubble patch) is still given by homogeneous cosmology, taking this shift function $\delta\eta(\vec{x})$ into account:

$$\begin{aligned} \forall x, \qquad \rho_x(\eta,\vec{x}) &= \bar{\rho}_x\left(\eta+\delta\eta(\vec{x})\right) = \bar{\rho}_x(\eta) + \bar{\rho}'_x(\eta)\,\delta\eta(\vec{x}) \\ p_x(\eta,\vec{x}) &= \bar{p}_x\left(\eta+\delta\eta(\vec{x})\right) = \bar{p}_x(\eta) + \bar{p}'_x(\eta)\,\delta\eta(\vec{x}) \end{aligned} \tag{194}$$

where in the last equalities, terms of order two or higher in $\delta\eta$ have been neglected. The above ansatz restricts a lot the choice of possible initial conditions. Indeed, for each uncoupled species, the energy conservation law for the background gives

$$\bar{\rho}'_x = -3\frac{a'}{a}(\bar{\rho}_x + \bar{p}_x) \ . \tag{195}$$

Combining this equation with the above ansatz, we get

$$\forall x, \qquad \frac{\delta\rho_x}{\bar{\rho}_x+\bar{p}_x} = -3\frac{a'}{a}\frac{\delta\rho_x}{\bar{\rho}'_x} = -3\frac{a'}{a}\,\delta\eta(\vec{x}) \ . \tag{196}$$

Since the last term is independent of the index x, we see that for each pair of fluids,

$$\forall x, y, \qquad \frac{\delta\rho_x}{\bar{\rho}_x+\bar{p}_x} = \frac{\delta\rho_y}{\bar{\rho}_y+\bar{p}_y} \ . \tag{197}$$

Note that this famous relation is a consequence of Eqs. (194). It shows that in presence of such initial conditions, everything is fixed up to a single function of $\vec{x}$. Let us take the example of a universe containing only photons, baryons, cold dark matter and neutrinos. We can use the fact that for non-relativistic species $\bar{p}_x \ll \bar{\rho}_x$, while for ultra-relativistic ones $\bar{p}_x = \bar{\rho}_x/3$. Hence, if one function is known — for instance, $\delta_\gamma(\vec{x})$ at initial time — the others can be derived from

$$\delta_{\rm b} = \delta_{\rm cdm} = \frac{3}{4}\delta_\nu = \frac{3}{4}\delta_\gamma \ . \tag{198}$$

It is a simple exercise to prove that the ansatz of Eqs. (194) implies additional important relations:

- first,

$$\forall x, \qquad \delta p_x(\eta,\vec{x}) = \frac{\bar{p}'_x(\eta)}{\bar{\rho}'_x(\eta)}\,\delta\rho_x(\eta,\vec{x}) \ , \tag{199}$$

  i.e., as long as we are dealing with super-Hubble modes and Eqs. (194) are satisfied, each component features an adiabatic sound speed independent of x, obeying to $c_x^2(\eta) \equiv \bar{p}'_x(\eta)/\bar{\rho}'_x(\eta)$,

- second,

$$\delta p_{\rm tot}(\eta,\vec{x}) = c_{\rm s}^2(\eta)\,\delta\rho_{\rm tot}(\eta,\vec{x}) \ , \tag{200}$$

  where the squared total sound speed $c_{\rm s}^2$ can be easily expressed as a weighted average over the squared adiabatic sound speed of individual components. Hence, the total matter content resulting from the sum of all components also features an adiabatic sound speed.

For the reason expressed in the last item, such initial conditions are usually called *adiabatic initial conditions*. The word adiabatic refers to thermodynamics, but it is actually more helpful to think of adiabatic initial conditions as resulting from the assumption of a single inhomogeneous degree of freedom in the early universe: then Eqs. (194) stands for the true definition of adiabatic initial conditions, and Eqs. (197, 198, 199, 200) for its consequences.

More general initial conditions not obeying to Eqs. (194) can be expanded on different bases. A famous basis is formed by (i) the adiabatic mode; (ii) $(N-1)$ non-decaying isocurvature modes, getting their name from the property that for each of them, the total density (and spatial curvature) perturbations vanish asymptotically in the super-Hubble limit, while two species have opposite density perturbations compensating each other; (iii) N decaying modes that are irrelevant for most purposes.

It is clear from the previous discussion that non-adiabatic initial conditions should only be considered when assuming that primordial perturbations are generated by more than one degree of freedom (for instance, two inflaton fields, or one inflaton and one axion, etc.) The assumption of several degrees of freedom is necessary but not sufficient. The primordial universe may contain a mixture of adiabatic and isocurvature modes until a time at which all species are brought in thermal equilibrium. At that time, if we further assume that all chemical potentials vanish, the perturbations of each species can be inferred from those of temperature, $T(\eta,\vec{x}) = \bar{T}(\eta) + \delta T(\eta,\vec{x})$. Then, temperature plays precisely the role of a single time-shifting function. Any non-adiabatic initial condition is washed out and becomes irrelevant. Hence, isocurvature modes can be observable — for instance in the CMB — only under additional assumptions. For instance, one species carrying isocurvature perturbations might remain out of equilibrium at all times, or might feature a chemical potential with spatial fluctuations. There exist a few non-minimal, but still reasonable scenarii featuring isocurvature perturbations (with axions, curvatons etc.). Ultimately, the presence of isocurvature modes is to be tested with observations. Current CMB observations put strong limits on the amplitude of such modes, and prefer purely adiabatic initial conditions. We will restrict to this case in the rest of this course.

For adiabatic initial conditions, we found the relation (197) holding between density fluctuations. Also, if we do not consider the case of species with a non-zero anisotropic stress, we can assume that $\phi = \psi$ at initial time. By plugging Eqs. (198), (200) and $\phi = \psi$ into the Einstein equations, one is led to a second-order differential equation for ψ only. During the radiation dominated era, one can show that this equation has two solutions, one constant in time, and one decaying. The (00) Einstein equation then shows that the constant solution is related to density fluctuations through

$$-2\psi = -2\phi = \delta_{\rm tot} \simeq \delta_\gamma = \text{constant} \ . \tag{201}$$

Hence, in the Newtonian gauge and for adiabatic initial conditions, super-Hubble metric fluctuations and density fluctuations are static. In fact, on super-Hubble scales, there can only be some time evolution when the universe changes of total equation of state (or equivalently, of expansion law). This is the case at the time of equality between radiation and matter. During matter domination and on super-Hubble scales, they freeze out again. Then, the relation $-2\psi = -2\phi = \delta_{\rm tot}$ and Eq. (198) are still satisfied, but now $\delta_{\rm tot} \simeq \delta_{\rm b} = \delta_{\rm cdm} = \frac{3}{4}\delta_\gamma$. This detail will become important when studying the Sachs-Wolfe effect in section 12.9.2.

Power spectra and transfer functions

The theory of cosmological perturbations is a stochastic theory: the fluctuations of a given quantity in a given point, $A(\eta,\vec{x})$, obey to a distribution of probability. As long as we stick to linear perturbation theory, there is a "linear transport of probability" from one time to another

time. Let the probability of A in a given point at time η_1 be $\mathcal{P}_1(A)$. In the same point and at η_2, the linear evolution would have transformed each value A into αA, where α is the linear growth (or decrease) factor of A between η_1 and η_2. So the probability of A at time η_2 is given by $\mathcal{P}_2(A) = \mathcal{P}_1(A/\alpha)$. This "linear transport of probability" implies that the linear evolution respects the shape of the probability distribution, and rescales all its statistical moments of order n by α^n. In particular, if the initial probability is Gaussian, the statistics will remain Gaussian at any later time, and the evolution of the system can be formulated as an evolution of the root mean square of all quantities. In summary, as long as we assume linear perturbations with Gaussian initial conditions, our goal is to solve for the evolution of the root mean squares of the fluctuations.

The equal-time 2-point correlation function of any quantity A in real space is given by

$$\langle A(\eta,\vec{x})A(\eta,\vec{x}')\rangle \equiv \xi(\eta,\vec{x},\vec{x}') \overset{SHI}{=} \xi(\eta,|\vec{x}'-\vec{x}|) \ , \tag{202}$$

where the last equality holds as a consequence of Statistical Homogeneity and Isotropy (SHI, assumed to hold in a perturbed FL universe). Indeed, the correlation function should be invariant under spatial translations and rotations.

We can go to Fourier space and use the same letter to denote the Fourier transform of A. If A is real, $A(\eta,-\vec{k}) = A^*(\eta,\vec{k})$. It is easy to show that the previous equation (using the assumption of SHI) implies that the two-point correlation function in Fourier space reads

$$\langle A(\eta,\vec{k})A^*(\eta,\vec{k}')\rangle \overset{SHI}{=} \delta_D(\vec{k}'-\vec{k})P_{\rm A}(k) \ , \tag{203}$$

where δ_D is the Dirac distribution. Here, statistical homogeneity is responsible for the fact that the two-point correlation vanishes for $\vec{k} \neq \vec{k}'$, and statistical isotropy for the fact that $P_{\rm A}$ only depends on the modulus $k = |\vec{k}|$. The function $P_{\rm A}(k)$ is usually called the power spectrum of A. Some authors prefer to refer to the "dimensionless power spectrum", defined as

$$\mathcal{P}_{\rm A}(k) \equiv \frac{k^3}{2\pi^2}P_{\rm A}(k) \ . \tag{204}$$

The reason is that typical expressions for the average of various quantitites in real space consist in the convolution of the power spectrum with some window function $f(k)$, like in

$$\int \frac{d^3\vec{k}}{(2\pi)^3}P_{\rm A}(k)f(k) = \int \frac{4\pi k^2 dk}{(2\pi)^3}P_{\rm A}(k)f(k) = \int d\log k \ \mathcal{P}_{\rm A}(k)f(k) \ . \tag{205}$$

Hence the dimensionless spectrum $\mathcal{P}_{\rm A}(k)$ stands for the weight of each logarithmic interval in the integral. The term "scale-invariant spectrum" refers to $\mathcal{P}_{\rm A}(k)$ being independent of k, i.e. $P_{\rm A}(k) \propto k^{-3}$.

We know that for adiabatic initial conditions, all perturbations are related to each other through Eqs. (198, 201). Hence, with Gaussian adiabatic initial conditions, specifying the primordial power spectrum of one quantity is sufficient for knowing everything about the system. For instance, if we assume that the power spectrum of the metric perturbation ψ is a given function $P_\psi(k)$, then we infer from Eqs. (198, 201) that the photon and baryon primordial spectra are given by $P_\gamma(k) = 4P_\psi(k)$ and $P_{\rm b}(k) = \frac{9}{16}P_\gamma(k) = \frac{9}{4}P_\psi(k)$.

By convention, the primordial spectrum is usually given for the variable $\mathcal{R}$, which represents the spatial curvature perturbation on one initial comoving hypersurface (i.e. an hypersurface orthogonal to the energy flux of the total cosmic fluid in each point). The advantage of using this quantity is that it is conserved on super-Hubble scales for adiabatic initial conditions (while ϕ and ψ get rescaled when the equation of state of the universe changes, e.g. at radiation-matter equality). In the Newtonian gauge, $\mathcal{R}$ relates to ψ and to the total density perturbation through

$$\mathcal{R} = \psi - \frac{1}{3}\frac{\delta\rho_{\rm tot}}{\bar{\rho}_{\rm tot}+\bar{p}_{\rm tot}} \ . \tag{206}$$

The power spectrum of a given quantity at some arbitrary time can be decomposed into two parts, one accounting for initial conditions, and one accounting for linear evolution with time:

$$\langle A(\eta,\vec{k})A^*(\eta,\vec{k'})\rangle = \delta_D(\vec{k'}-\vec{k})\left[\frac{A(\eta,\vec{k})}{\mathcal{R}(\vec{k})}\right]^2 P_{\mathcal{R}}(k)\ . \tag{207}$$

In the above equation, there is no time argument for $\mathcal{R}(\vec{k})$ since this quantity is conserved on super-Hubble scales. We just assume that $\mathcal{R}$ is evaluated at a time such that $k \ll aH$ for all modes of interest. In a FL universe, the equations of motion of all perturbations respect isotropy, and do not depend on the direction of the wavector $\vec{k}$. Hence the ratio between brackets in the last equation is a function of k, not $\vec{k}$. This function accounts for the linear evolution, independently of initial conditions. It is called the "transfer function" of A. In this course, we will denote transfer functions with the same letter as the perturbations themselves, but with the modulus of k as an argument, i.e.

$$A(\eta,k) \equiv \frac{A(\eta,\vec{k})}{\mathcal{R}(\vec{k})}\ . \tag{208}$$

In summary of this section, solving for cosmological perturbations (in a model with adiabatic Gaussian IC's) amounts in

- postulating a primordial spectrum, or calculating it within the framework of a model, for instance of inflation;
- solving the equations of motion of all perturbations, with quantities normalized initially to $\mathcal{R}(\vec{k}) = 1$, in such a way to obtain all transfer functions $A(\eta,k)$ and to infer the evolution of the various root mean squares.

12.9.2 CMB temperature anisotropies by Lesgourgues

From now on, we will assume for simplicity that the universe is flat.

Photon scattering rate

CMB physics consists is the study of electron, baryon and photon perturbations on cosmological scales, taking into account their gravitational coupling with collisionless species such as decoupled neutrinos and CDM. Electrons and baryons carry opposite electric charges and are coupled to each other through very efficient Coulomb scattering processes. Electrons and photons are coupled through Thomson scattering, which is the limit of Compton scattering when electrons are non-relativistic and photons carry a smaller energy than the rest mass of the electron. Then, the scattering process results mainly in a deflection of the photon, with a negligible transfer of energy between the two particles. The leading interaction between baryons and photons is the gravitational one.

In units such that $c = 1$, the Thomson scattering rate (with respect to conformal time) is given by $\Gamma = \sigma_T a n_e x_e$, where σ_T is the Thomson scattering rate, a is the scale factor, n_e is the total electron number density (scaling like a^{-3} due to dilution), and x_e is the ionized electron fraction. The product an_e scales like a^{-2}. The ionized fraction is close to one at high energy. Then, at the time of recombination between electrons and nuclei (around $z \sim 1080$), which falls at the beginning of matter domination, n_e drops abruptly to very small values. This causes Thomson scattering to become suddenly very inefficient, and photons to decouple from electrons.

Hence photon decoupling is the story of Thomson scattering becoming inefficient, while Coulomb scattering remains very strong. For that reason, one can describe electrons and baryons as a single tightly-coupled fluid. People often refer only to baryons for simplicity. At early time, the full system of (electrons)-baryons-photons is also tightly coupled, but later on, it splits progressively into two collisonless species, (electrons)-baryons on the one hand, photons on the other hand.

The thermodynamical description of recombination is very technical, due to the different energy level of atoms (in particular, of hydrogen). In order to understand CMB anisotropies, we only need to describe the main results of recombination studies at a very qualitative level.

- The free electron fraction $x_e(\eta)$ starts from one at high redshift. It decreases sharply at the recombination time (corresponding to $z \sim 1080$ or $T \sim 0.3$ eV), and freezes at a very small value (due to departure from thermal equilibrium). Around $z \sim 10$, star formation causes a reionization of the universe, and x_e goes up again to one.

- The Thomson scattering rate $\Gamma = \sigma_T a n_e x_e$ evolves like $a^{-2} x_e$. Before recombination, $\Gamma \gg \frac{a'}{a}$, and the universe is opaque. The sudden drop of x_e at recombination renders the universe transparent: $\Gamma \ll \frac{a'}{a}$. Due to the dilution factor coming from n_e, Γ remains much smaller than $\frac{a'}{a}$ even during reionization, and the universe keeps being transparent (this is why despite of reionization, most photons emitted at recombination do not interact anymore, and allow us to observe anisotropies on the last scattering surface).

- The optical depth $\tau(\eta) \equiv \int_{\eta}^{\eta_0} d\eta \Gamma(\eta)$ represents the opacity of the universe at a given time, when seen from today (when $\eta = \eta_0$). It tends to infinity when $\eta \longrightarrow 0$, falls below one at recombination and stabilize at a value of the order of 0.1 between recombination and reionization. After reionization it decreases smoothly and reaches zero today by definition.

- The visibility function $g(\eta) \equiv -\tau' e^{-\tau}$ gives the probability that a CMB photon seen today experienced its last scattering at time η. It starts from negligible values at high redshift (suppressed by the $e^{-\tau}$ factor). It has a narrow spike around the time of recombination, and then it falls again to negligible values due to the smallness of τ' between recombination and reionization. It develops a second smaller and wider spike around reionization. This function shows that most CMB photons did not interact between the last scattering surface and today, while a minority rescattered at reionization. The width of the recombination spike gives an indication on the thickness of the last scattering "surface".

- The diffusion length $\lambda_{\rm d}(\eta)$ is an important quantity for understanding the damping of temperature anisotropies on small scales. At any given time, the comoving mean free-path (mfp) of photons is given by $r_{\rm mfp} = 1/\Gamma(\eta)$ (still in units where $c = 1$). If the photons experience a random walk analogous to Brownian motion in a gas, the comoving distance over which they travel between time $\eta_{\rm ini}$ and η can be approximated by

$$r_{\rm d} \sim \left[\int_{\eta_{\rm ini}}^{\eta_0} d\eta \; \Gamma \; r_{\rm mfp}^2 \right]^{1/2} = \left[\int_{\eta_{\rm ini}}^{\eta_0} d\eta \; \Gamma^{-1} \right]^{1/2} . \qquad (209)$$

  This physical diffusion length of photons is given in this approximation by $\lambda_{\rm d} \simeq a r_{\rm d}$. It grows quickly from very small to very large scales (comparable to the Hubble scale) around the time of recombination.

Sketch of connection of Γ and τ by Craps (? need to learn it better?)

Idea is to consider a logarithm.
(???)

$$\Gamma(\eta)(1-\Gamma(\eta+\Delta\eta)\Delta\eta)(1-\Gamma(\eta+2\eta\Delta\eta)\Delta\eta)\cdots =$$

$$\prod_{n=1}^{\frac{\eta_0-\eta}{\Delta\eta}}(1-\Gamma(\eta+\Delta\eta)\Delta\eta)$$

take log:

$$\ln\prod_{n=1}^{\frac{\eta_0-\eta}{\Delta\eta}}(1-\Gamma(\eta+\Delta\eta)\Delta\eta)=\sum_{n=1}^{\frac{\eta_0-\eta}{\Delta\eta}}\ln(1-\Gamma(\eta+\Delta\eta)\Delta\eta)=-\int_{\eta}^{\eta_0}d\tilde{\eta}\Gamma(\tilde{\eta})=-\tau$$

(???)

$$\frac{dP}{d\eta}=\Gamma e^{-\eta}=-\dot{\eta}e^{-\eta}=g(\eta)$$

Thus

$$\tau=\int\Gamma(\tilde{\eta})d\tilde{\eta}$$

Γ is not σ (?)

(more explanation and illustrations are needed!)

Boltzmann equation

Since photons decouple from baryons near the recombination time, we cannot describe them with fluid equations, and need to solve the Boltzmann equation

$$\frac{d}{d\eta}f=C\left[f,f_e\right] \tag{210}$$

at order one in perturbations. The right-hand side stands for the photon-electron coupling due to Thomson scattering. As explained in the previous section, electrons and baryons are so tightly coupled that it makes no difference to think of this term as a photon-electron or photon-baryon coupling term. Solving this equation is involved because the photon phase-space distribution f involves many arguments, $f(\eta,\vec{x},\vec{p})$. Fortunately one can reduce the dimensionality of the problem. First, we notice that as long as photons are in thermal equilibrium with electrons (and hence with baryons), they are entirely described in any point by the local value of the equilibrium temperature $T(\eta,\vec{x})$. The phase space distribution is then of the Bose-Einstein form:

$$f(\eta,\vec{x},\vec{p})=\frac{1}{e^{\frac{p}{T(\eta,\vec{x})}}-1}\ . \tag{211}$$

It can be expanded into a background part and a first-order perturbation, $f=\bar{f}+\delta f$, with:

$$\bar{f}(\eta,p)=\frac{1}{e^{\frac{p}{\bar{T}(\eta)}}-1}\ ,\qquad \delta f(\eta,\vec{x},\vec{p})=\frac{d\bar{f}}{d\log p}\ \frac{\delta T(\eta,\vec{x})}{\bar{T}(\eta)}\ . \tag{212}$$

We see that in the tightly-coupled regime we could replace the variable $f(\eta,\vec{x},\vec{p})$ by the lower-dimensional variable $\Theta(\eta,\vec{x})\equiv[\delta T(\eta,\vec{x})/\bar{T}(\eta)]$. The Boltzmann equation leads to an equation of motion for $\Theta(\eta,\vec{x})$.

At later times, when photons decouple, the shape of the Bose-Eisntein distribution of photons is preserved. This can be infered from the geodesic equation. This equation tells how the individual momentum p of photons evolve when they are decoupled and they travel in the perturbed universe. In the Newtonian gauge, it reads

$$\frac{d(a\,p)}{d\eta} = -a\,p\,\phi' - a\,\epsilon\,\hat{n}\cdot\vec{\nabla}\psi \ . \tag{213}$$

The left-hand side represents the time evolution of the product (ap) for a photon of momentum p traveling over a geodesic. In a perfectly homogeneous universe, the photon would only experience the average cosmological redshifting, $p \propto a^{-1}$, and the product (ap) would be conserved. Due to presence of perturbations in the universe, photons experience gravitational interactions and the product (ap) varies. The first term $-a\,p\,\phi'$ accounts for dilation, i.e. for the fact that locally, the expansion of the universe is a bit more advanced or delayed than the average (remember that $a(1+\phi)$ can be seen as the "local scale factor"). This means that the redshifting of the photon is also a bit more advanced or delayed locally. The second term accounts for the gravitational blueshifting of photons falling in gravitational potential wells (or redshifting of those leaving potential wells). The energy $\epsilon \equiv \sqrt{p^2+m^2}$ can be simply replaced by p for massless photons. In that case we can rewrite the geodesic equation as

$$\frac{d\ln(a\,p)}{d\eta} = -\phi' - \hat{n}\cdot\vec{\nabla}\psi \ . \tag{214}$$

The fact that p disappeared from the right-hand side is crucial: it shows that photons of different momenta traveling in the perturbed universe along a given geodesic all experience the same relative momentum variation. The consequence is that there can be no distortions of the Bose-Einstein shape of f. However, photons traveling along different geodesics and in different directions experience different redshifting. Hence the distribution function acquires a dependence on one extra argument, the direction $\hat{n}$ of propagation ($\hat{n} \equiv \vec{p}/p$):

$$f(\eta,\vec{x},\vec{p}) = \frac{1}{e^{\frac{p}{T(\eta,\vec{x},\hat{n})}} - 1} \ . \tag{215}$$

We can perform the same decomposition in terms of background and perturbations as in Eq. (212). The difference is that $\Theta = \frac{\delta T}{T}$ is now a function of $(\eta,\vec{x},\hat{n})$. The Boltzmann equation can now be used to derive an equation of motion for $\Theta(\eta,\vec{x},\hat{n})$.

If we work in Fourier space, we can derive the equation of motion for the function $\Theta(\eta,\vec{k},\hat{n})$. Because of the statistical isotropy of the FL universe, this equation does not depend explicitly on $\vec{k}$ nor $\hat{n}$, since there is no preferred direction: it depends only on the direction of propagation relatively to the considered wavenumber, i.e. on the product $(\vec{k}\cdot\hat{n})$. Hence the equation of motion can be written in terms of k and of the angle θ such that $(\vec{k}\cdot\hat{n}) = k\cos\theta$. The initial conditions for Θ do depend on the wavevector $\vec{k}$ (since each mode gets random initial conditions), but they also depend only on θ rather than $\hat{n}$, for a reason that will become clear in the paragraphs below. Hence we can entirely eliminate $\hat{n}$ from the problem, and solve the equation of motion for $\Theta(\eta,\vec{k},\theta)$.

Finally, we can expand the temperature anisotropy with respect to θ using a Legendre transformation:

$$\Theta(\eta,\vec{k},\theta) = \sum_l (-i)^l(2l+1)\Theta_l(\eta,\vec{k})P_l(\cos\theta) \ . \tag{216}$$

Here the Θ_l's are the temperature anisotropy multipoles, and P_l the Legendre polynomials. It can be shown that the monopole Θ_0 is related to the photon density fluctuation δ_γ in a given point, the dipole Θ_1 to its velocity divergence θ_γ, and the quadrupole Θ_2 to its anisotropic stress

σ_γ. The Boltzmann equation can be written as an infinite hierarchy of equations of motion for the coupled multipoles Θ_l.

Actually, the equation of motion for Θ takes a striking form when written in real space, before Fourier and Legendre expansions:

$$\Theta' + \hat{n}\cdot\vec{\nabla}\Theta - \phi' + \hat{n}\cdot\vec{\nabla}\psi = -\Gamma\left(\Theta - \Theta_0 - \hat{n}\cdot\vec{v}_e\right) . \tag{217}$$

We recall that Γ is the conformal Thomson scattering rate, Θ_0 the temperature monopole (i.e. the average of $\Theta(\eta,\vec{x},\hat{n})$ over all directions $\hat{n}$), and $\vec{v}_e$ the bulk velocity of electrons, equal to that of baryons due to tight Coulomb interactions. We recall that the variable $\theta_{\rm b}$ is defined as the divergence of $\vec{v}_{\rm b} = \vec{v}_e$.

This equation is illuminating, since it shows that at early times, when photons, electrons and baryons form a tightly-coupled fluid, the fact that Γ is huge forces Θ to evolve in such way that the parenthesis on the right-hand side vanishes. When this is the case, Θ can only have two non-zero component: a monopole Θ_0, and a dipole equal to $\hat{n}\cdot\vec{v}_{\rm b}$. The condition on the dipole can be written equivalently as $\theta_\gamma = \theta_{\rm b}$.

This should remind us of the discussion of Sec. 12.9.1, when we noticed that a perfect fluid can be described in terms of δ_x, $c_{\rm s}^2$ and θ_x only, with a vanishing anisotropic stress σ_x. Here, we see concretely how this conclusion emerges from the Boltzmann equation in the tightly-coupled regime: Θ_2 (related to σ_γ) and all higher multipoles vanish; the photon perturbations can be described in terms of only two independent variables Θ_0 and Θ_1 (or δ_γ and θ_γ), like in a perfect fluid.

The fact that in the tightly-coupled limit the system is driven towards $\theta_\gamma = \theta_{\rm b}$ simply shows that the interaction imposes a common bulk velocity to photons, baryons and electrons, as it should be the case in any tightly-coupled fluid (note that we are referring to bulk velocities, not to individual velocities of particles, which are still equal to c for interacting photons).

In the tightly-coupled regime, the dipole component of $\Theta(\eta,\vec{x},\hat{n})$ is given by $\hat{n}\cdot\vec{v}_{\rm b}$, with $\theta_{\rm b} \equiv \vec{\nabla}\cdot\vec{v}_{\rm b}$. Hence in Fourier space this component reads $i(\hat{n}\cdot\vec{k})k^{-2}\theta_{\rm b} = i(\cos\theta)k^{-1}\theta_{\rm b}$. This justifies the fact that initial conditions for Θ in Fourier space depend on θ, but not on the two degrees of freedom of $\hat{n}$. As mentioned above, this property is preserved by the isotropic equations of motion, so that at all times we can study Θ as a function of the arguments $(\eta,\vec{k},\theta)$ instead of $(\eta,\vec{k},\hat{n})$.

Temperature anisotropy in a given direction

The map of temperature anisotropies that we observe today ($\eta = \eta_0$) in our location of the universe ($\vec{x} = \vec{o}$ with a proper choice of origin) when looking in a direction $\hat{n}$ is represented mathematically by

$$\frac{\delta T}{\bar{T}}(\hat{n}) = \Theta(\eta,\vec{o},-\hat{n}) \tag{218}$$

(since in a direction $\hat{n}$, we see photons traveling towards $-\hat{n}$). Our scope is now to relate this quantity to perturbations on the point of the last scattering surface seen in the same direction $\hat{n}$. This can be done by integrating the Boltzmann equation along the corresponding line-of-sight.

A good starting point consists in computing the total derivative of the product $e^\tau(\Theta+\psi)$ along the trajectory of photons between the last scattering surface and the observer. The reason for choosing this product rather than just Θ will become clear in a few lines: the derivative of this term will be easy to simplify, using the Boltzmann equation.

The total derivative of an arbitrary function $\mathcal{F}$ of $(\eta,\vec{x},\hat{n})$ along the trajectory of photons going in a direction $\hat{n}$ reads

$$\frac{d}{d\eta}\mathcal{F}(\eta,\vec{x},\hat{n}) = \mathcal{F}' + \frac{dx_i}{d\eta}\frac{\partial\mathcal{F}}{\partial x_i} + \frac{dn_i}{d\eta}\frac{\partial\mathcal{F}}{\partial n_i} . \tag{219}$$

If $\mathcal{F}$ is of order one in perturbations, the first two terms on the right-hand side are also of order one. Instead the last term is of order two, since $\frac{dn_i}{d\eta}$ is of order one (this is clear from the fact that in an unperturbed universe, photons would travel in straight line with $\frac{dn_i}{d\eta} = 0$). Hence we can drop this term in first-order perturbation theory, and for $\frac{dx_i}{d\eta}$ we only need to keep the zero-th order contribution, that can be computed assuming a homogeneous universe:

$$\frac{dx_i}{d\eta} = \hat{n} \ . \tag{220}$$

The previous relation is just telling that photons are traveling in the direction $\hat{n}$ and at the velocity of light: hence, in units where $c = 1$, $d\vec{x}^2 = d\eta^2$. In summary, the total derivative of $\mathcal{F}$ is given at first order by

$$\frac{d}{d\eta}\mathcal{F}(\eta, \vec{x}, \hat{n}) = \mathcal{F}' + \hat{n} \cdot \vec{\nabla}\mathcal{F} \ . \tag{221}$$

Let us now replace the generic function $\mathcal{F}$ by

$$\mathcal{F}(\eta, \vec{x}, \hat{n}) = e^{-\tau(\eta)} \left(\Theta(\eta, \vec{x}, \hat{n}) + \psi(\eta, \vec{x})\right) \ . \tag{222}$$

The total derivative of this function reads

$$\frac{d}{d\eta}\left[e^{-\tau}(\Theta + \psi)\right] = e^{-\tau}\left(\Theta' + \psi' + \hat{n} \cdot \vec{\nabla}(\Theta + \psi)\right) - \tau' e^{-\tau}(\Theta + \psi) \ . \tag{223}$$

We now use the linearized Boltzmann equation (217) and the fact that $\tau' = -\Gamma$ to write the result as

$$\frac{d}{d\eta}\left[e^{-\tau}(\Theta + \psi)\right] = -e^{-\tau}\tau'(\Theta_0 + \psi + \hat{n} \cdot \vec{v}_{\rm b}) + e^{-\tau}(\phi' + \psi') \ . \tag{224}$$

Finally, using the definition of the visibility function g given in Sec. 12.9.2, we get

$$\frac{d}{d\eta}\left[e^{-\tau}(\Theta + \psi)\right] = g\left(\Theta_0 + \psi + \hat{n} \cdot \vec{v}_{\rm b}\right) + e^{-\tau}(\phi' + \psi') \ . \tag{225}$$

We can integrate this relation along the line of sight, i.e. along a straight line seen by the observer in a given direction $-\hat{n}$ (since the photons go in the direction $\hat{n}$), starting from an early time *before* recombination (such that $e^{-\tau(\eta_{\rm ini})} \simeq 0$) until the present time at which photons reach the observer (with by definition $e^{-\tau(\eta_0)} = 1$). The result reads

$$(\Theta + \psi)|_{\rm obs} = \int_{\eta_{\rm ini}}^{\eta_0} d\eta \left[g\left(\Theta_0 + \psi + \hat{n} \cdot \vec{v}_{\rm b}\right) + e^{-\tau}(\phi' + \psi')\right] \ , \tag{226}$$

where the notation $|_{\rm obs}$ means "evaluated at the observer location, along this line of sight", i.e. at the coordinate $(\eta_0, \vec{o}, \hat{n})$.

We can gain further intuition from this equation if we use the instantaneous decoupling approximation, in which all photons are assumed to decouple precisely at the time $\eta_{\rm dec}$. In this limit, we can replace the visibility function g by the Dirac function $\delta_D(\eta - \eta_{\rm dec})$, and $e^{-\tau}$ by the Heaviside function $H(\eta - \eta_{\rm dec})$. Note that the approximation $g(\eta) = \delta_D(\eta - \eta_{\rm dec})$ is correctly normalized, since the definition of g implies $\int d\eta\, g(\eta) = 1$. In the instantaneous decoupling limit, Eq. (226) reads:

$$(\Theta + \psi)|_{\rm obs} = \left(\Theta_0 + \psi + \hat{n} \cdot \vec{v}_{\rm b})\right)|_{\rm dec} + \int_{\eta_{\rm dec}}^{\eta_0} d\eta\, (\phi' + \psi') \ , \tag{227}$$

where the notation $|_{\rm dec}$ means "evaluated on the last scattering surface, along this line of sight", i.e. at the coordinate $(\eta_{\rm dec}, -r_{\rm dec}\hat{n}, \hat{n})$ (here $r_{\rm dec}$ is the comoving radius of the last scattering surface). Let us now give the interpretation of each term in this crucial equation.

First, $\Theta|_{\rm obs}$ is the temperature anisotropy measured by the observer in the direction $-\hat{n}$, while $\Theta_0|_{\rm dec}$ is the temperature anisotropy in the point of the last scattering surface seen in the same direction. If only these two terms where present, this relation would simply tell us that that the temperature anisotropy seen today in a given direction is equal to the intrinsic anisotropy in the point where the observed photons last scattered.

Second, the term $\hat{n} \cdot \vec{v}_{\rm b}|_{\rm dec}$ stands for the correction to this temperature coming from by the usual Doppler. Indeed, this correction is caused by the velocity of the baryon-photon fluid (that we assumed to be tightly coupled until $\eta_{\rm dec}$) projected along the line of sight.

Next, we expect a correction from gravitational effects. The redshifting and blueshifting of the photons traveling along gravitational potential fluctuations should affect the observed temperature anisotropy relatively to the intrinsic one. It turns out that if the gravitational potential was constant in time (but, of course, not in space), this effect would be conservative, and would only depend on $\psi|_{\rm obs} - \psi|_{\rm dec}$. This explains the second term on the left-hand and right-hand sides. But if ψ varies in time, the effect is not conservative anymore: intuitively, the amount of blueshifting and redshifting experienced by photons traveling across a potential well do not compensate each other if the gravitational well gets deeper between the time at which the photon enters and leaves the well. This explains the addition term $\int d\eta\, \psi$. A similar effect is caused by dilation effects along the line-of-sight, and contributes like $\int d\eta\, \phi$.

Finally, we can drop the second term on the left-hand side, because this term represents only a tiny *isotropic* correction to the observed anisotropies. It is impossible to measure it with the CMB map only, because it is formally equivalent to a redefinition of the average temperature $\bar{T}$, but only by a tiny amount of the order of $10^{-5}\bar{T}$.

Let us write once more our result, dropping this unobservable correction, and grouping the terms in a particular way:

$$\Theta|_{\rm obs} = \underbrace{(\Theta_0 + \psi)|_{\rm dec}}_{\rm SW} + \underbrace{\hat{n} \cdot \vec{v}_{\rm b}|_{\rm dec}}_{\rm Doppler} + \underbrace{\int_{\eta_{\rm dec}}^{\eta_0} d\eta\, (\phi' + \psi')}_{\rm ISW} \quad . \tag{228}$$

The first term is conventionally called the Sachs-Wolfe (SW) term, and includes the intrinsic temperature term Θ_0 and the "gravitational Doppler shift" term ψ at one point on the last scattering surface. The second term is the conventional Doppler term. The last term is called the Integrated Sachs-Wolfe (ISW) term and contains all non-conservative gravitational effects occurring in a universe with non-static metric fluctuations.

We can gain further insight on the Sachs-Wolfe term. We will try to find a simpler expression for $(\Theta_0 + \psi)|_{\rm dec}$, that applies at least for describing large angular patterns on CMB maps, i.e. maps smoothed over small scales. For instance, this expression would describe very well the map of the COBE satellite, which had limited angular resolution. In more precise terms, we wish to calculate the contribution to the Sachs-Wolfe term of large wavelengths, which are bigger than the Hubble radius at the time of recombination.

Let us first focus on the term $\Theta_0|_{\rm dec}$. We have seen that on super-Hubble scales, temperature anisotropies only have a monopole and a dipole component, related respectively to δ_γ and θ_γ. We can be more precise now. We know from thermodynamics that the local value of the photon density is proportional to the temperature to the power four. Taking the derivative of $\log \rho_\gamma = \log T^4$, we get $\delta_\gamma = 4\,\delta T/\bar{T}$, where on the right-hand side the temperature anisotropy is averaged over all directions $\hat{n}$: hence $\delta_\gamma = 4\Theta_0$.

Let us now focus on the term $\psi|_{\rm dec}$. We have seen in Sec. 12.9.1 that on super-Hubble scales and for adiabatic initial conditions, $\delta_\gamma = \frac{4}{3}\delta_{\rm b}$. Also, we know that decoupling takes place at the beginning of matter domination, and we mentioned at the very end of section 12.9.1 that for super-Hubble scales and during matter domination, one has $-2\phi = -2\psi = \delta_{\rm tot} = \delta_{\rm b} = \delta_{\rm cdm}$. Hence, $-2\psi = \frac{3}{4}\delta_\gamma$. Putting all these equalities together, we conclude that on the last scattering surface,

$$\Theta_0 + \psi = \frac{1}{4}\delta_\gamma + \psi = (-\frac{1}{4}\,2\,\frac{4}{3} + 1)\,\psi = (-\frac{2}{3} + 1)\,\psi = \frac{1}{3}\psi \ . \tag{229}$$

Moreover, on super-Hubble scales, we can neglect the Doppler term, which can be shown to be important only on sub-Hubble scales. We will see later that the integrated Sachs-Wolfe term plays a role on large scales, but only a small role, because ϕ and ψ are static during most of the evolution after decoupling. Hence we get an approximation for CMB anisotropies smoothed over small scales (that was first derived by Sachs and Wolfe in 1967):

$$\Theta|_{\rm obs,\,large\,scales} \simeq \frac{1}{3}\psi|_{\rm dec} = -\frac{1}{8}\delta_\gamma|_{\rm dec} \ . \tag{230}$$

In this calculation, we have seen that the term ψ wins over the term Θ_0, leading to a minus sign in front of δ_γ in the above relation. This means that an over-density on the last scattering surface ($\delta_\gamma > 0$), corresponding to a potential well ($\psi < 0$), leads to a cold spot in the observed map ($\Theta < 0$). Conversely, a hot spot corresponds to an under-density. Hence, due to the "gravitational Doppler shift" effect accounted by the term ψ (often called the Sachs-Wolfe effect), the patterns that we observe on CMB map are inverted with respect to intrinsic fluctuations on the last scattering surface.

Equation (228) (and its large-scale approximation (230)) are important for pedagogical purposes, but they have no practical application: indeed, what we wish to calculate and to compare to observations is a theoretical prediction for the statistical properties of CMB anisotropies. Hence, we need to compute at least the CMB two-point correlation function.

Spectrum of temperature anisotropies

Definition. The map of CMB temperature anisotropies can be expanded in spherical harmonics:

$$\frac{\delta T}{\bar{T}}(\hat{n}) = \Theta(\eta_0, \vec{o}, -\hat{n}) = \sum_{lm} a_{lm} Y_{lm}(\hat{n}) \ . \tag{231}$$

Using the Legendre expansion of Θ introduced in Eq. (216), and some basic relations between Legendre polynomials and spherical harmonics, it is easy to express a_{lm} as a function of Θ_l:

$$a_{lm} = (-i)^l \int \frac{d^3\vec{k}}{2\pi^2} Y_{lm}(\hat{k}) \Theta_l(\eta_0, \vec{k}) \ , \tag{232}$$

where we recall that hats denote unit vectors: $\hat{k} \equiv \vec{k}/k$. In linear perturbation theory and assuming Gaussian initial conditions, both Θ_l and a_{lm} are Gaussian random variables. Using the orthogonality relation of spherical harmonics and the definitions given in Sec. 12.9.1, we can infer the two-point correlation function of the a_{lm}'s as a function of the power spectrum of Θ_l, or even better, of the primordial curvature power spectrum:

$$\langle a_{lm} a^*_{l'm'} \rangle = \delta^K_{ll'} \delta^K_{mm'} \left[\frac{1}{2\pi^2} \int \frac{dk}{k} \Theta_l^2(\eta_0, k) \mathcal{P}_{\mathcal{R}}(k) \right] \ . \tag{233}$$

Here $\delta^K_{ll'}$ represents the Kronecker symbol. The fact that $\langle a_{lm} a^*_{l'm'} \rangle$ vanishes for $l \neq l'$ or $m \neq m'$ comes out of the algebra, but physically, it is a consequence of the homogeneity of the universe

— just like the fact that all power spectra in Fourier space are proportional to $\delta_D(\vec{k}' - \vec{k})$. Similarily, the fact that the quantity between brackets is a function of l but not of m is a consequence of isotropy — like the fact that in Fourier space, power spectra are functions of k but not $\vec{k}$.

The quantity between brackets is usually denoted C_l, and is called the power spectrum of temperature anisotropies in harmonic space, or the temperature harmonic power spectrum:

$$C_l \equiv \frac{1}{2\pi^2} \int \frac{dk}{k} \Theta_l^2(\eta_0, k) \mathcal{P}_{\mathcal{R}}(k) \ . \tag{234}$$

In a universe with linear and Gaussian perturbations, the C_l's encode all the information concerning the cosmological model describing our universe that is contained in the CMB temperature map.

It is worth coming back on the meaning of the averaging symbols $\langle ... \rangle$ in Eq. (233). Since the theory of cosmological perturbation is stochastic, the a_{lm}'s should be seen as random numbers, and the average is meant over many realizations of the theory. In a sense, "a given realization" means "a given universe", and the average holds over many universes, all obeying to the same cosmological model, which is encoded in the spectrum C_l.

However, we observe CMB anisotropies in our universe, i.e. in only one realization. CMB maps allow us to measure a definite value of each a_{lm}. Hence the squares $|a_{lm}|^2$ are not expected to be equal to C_l, even if we postulated the right model: there should be some scattering around C_l. This scattering limits the possibility to find the best theory matching the observations. However we can reduce considerably the scattering by noticing that for any fixed l, the statistical distribution of $|a_{lm}|^2$ is independent of m (as a consequence of isotropy, and as expressed by Eq. (234)). Hence, for an ideal full-sky CMB experiment, the best estimator of the underlying C_l's is the average between all observed coefficients $|a_{lm}|^2$ with fixed l,

$$C_l^{obs} \equiv \frac{1}{2l+1} \sum_{-l \leq m \leq l} |a_{lm}^{obs}|^2 \ . \tag{235}$$

In a typical universe, this quantity should be closer to the underlying C_l than a single $|a_{lm}^{obs}|^2$. The way to see this mathematically is to consider again the theoretical (stochastic) a_{lm}'s, and to define

$$\hat{C}_l \equiv \frac{1}{2l+1} \sum_{-l \leq m \leq l} |a_{lm}|^2 \ . \tag{236}$$

By performing averages in the same sense as in equation (233), one can easily show that for Gaussian a_{lm}'s,

$$\langle \hat{C}_l \rangle = C_l \qquad \text{and} \qquad \langle (\hat{C}_l - C_l)^2 \rangle = \frac{2}{2l+1} C_l^2 \ . \tag{237}$$

The first equality shows that the observed C_l's defined in Eq. (235) are unbiased estimators of the true underlying C_l's. The second equality gives the typical scattering between the theory and the observations. Since for larger l we perform an average over more values of m, the relative scattering decreases. This is the case with true data points, which are distributed qualitatively like in Fig. 138. This scattering is called cosmic variance. It can be seen as a theoretical error: because of cosmic variance, we cannot reconstruct the underlying model with infinite precision, even if we have infinitely precise observations. Cosmic variance is large for small l's, meaning that the shape of the true underlying C_l's will always be poorly known at low l.

Line-of-sight integral in Fourier space. According to equation (234), for a given primordial spectrum, the shape of the CMB spectrum C_l depends on the square of the transfer function

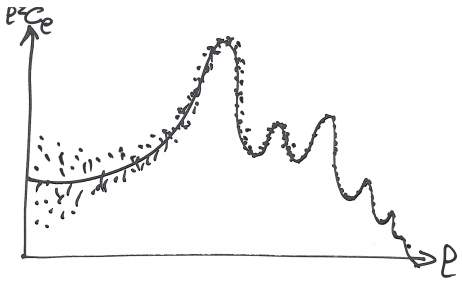

Figure 138: Observed values of the temperature harmonic spectrum, C_l^{obs}, are expected to be scattered around the true underlying C_l's. The scattering, called cosmic variance, decreases with increasing l.

$\Theta_l(\eta_0, k)$. We would like to understand this shape at least qualitatively. In real space, we did learn a lot on the behavior of $\Theta(\eta, \vec{x}, \hat{n})$ by using the line-of-sight integral approach presented in section 12.9.2. A similar approach can be worked out in Fourier and harmonic space, i.e. for the variable $\Theta_l(\eta, k)$. We do not present here the intermediate steps, which can be found in Ref. [2]. The final result shows many similarity with its real space counterpart, Eq. (226). It can be decomposed into:

$$\begin{aligned} \Theta_l(\eta_0, k) &= \int_{\eta_{\rm ini}}^{\eta_0} d\eta \; S_T(\eta, k) \; j_l(k(\eta_0 - \eta)) \; , \\ S_T(\eta, k) &\equiv \underbrace{g \, (\Theta_0 + \psi)}_{\rm SW} + \underbrace{\left(g \, k^{-2} \theta_{\rm b}\right)'}_{\rm Doppler} + \underbrace{e^{-\tau}(\phi' + \psi')}_{\rm ISW} \; . \end{aligned} \tag{238}$$

We see that $\Theta_l(\eta_0, k)$ is given by the convolution of spherical Bessel functions $j_l(x)$ with a function $S_T(\eta, k)$, called the temperature source function, which contains the usual three terms: Sachs-Wolfe, Doppler, and Integrated Sachs-Wolfe. Like in the previous section, we can use the instantaneous decoupling approximation, integrate the Doppler term by part, and write $\Theta_l(\eta_0, k)$ as:

$$\begin{aligned} \Theta_l(\eta_0, k) \simeq & \left[\Theta_0(\eta_{\rm dec}, k) + \psi(\eta_{\rm dec}, k)\right] j_l(k(\eta_0 - \eta_{\rm dec})) \\ & + k^{-1} \theta_{\rm b}(\eta_{\rm dec}, k) \; j_l'(k(\eta_0 - \eta_{\rm dec})) \\ & + \int_{\eta_{\rm dec}}^{\eta_0} d\eta \; \left[\phi'(\eta, k) + \psi'(\eta, k)\right] j_l(k(\eta_0 - \eta)) \end{aligned} \tag{239}$$

(note that in the second line, i.e. in the Doppler term, the prime stands for the derivative of the function $j_l(x)$ with respect to its argument, not with respect to conformal time). This approximate result can be plugged into Eq. (234) to obtain the final spectrum C_l. We see that each C_l can be decomposed into six terms: the power spectrum $C_l^{\rm SW}$ of the SW term, coming from the first line of Eq. (239) squared, that of the Doppler term, coming from the second line of Eq.(239) squared, that of the Integrated Sachs-Wolfe term, coming from the third line of Eq. (239) squared, and finally the three cross-spectra involving each pair of terms.

For large values of l, the spherical Bessel functions $j_l(x)$ and $j_l'(x)$ are very peaked near $x \simeq l$. Hence, for the Sachs-Wolfe and Doppler contributions to the spectrum C_l, the integral over k in Eq. (234) will pick up mainly modes with $k(\eta_0 - \eta_{\rm dec}) \simeq l$. This shows that the SW contribution to C_l is given by the product of the primordial spectrum with the squared transfer function $(\Theta_0 + \psi)$ at a given value of η and k:

$$C_l^{\rm SW} \sim \left[\Theta_0(\eta_{\rm dec}, k) + \psi(\eta_{\rm dec}, k)\right]^2 \mathcal{P}_{\mathcal{R}}(k) \; , \qquad k \simeq \frac{l}{(\eta_0 - \eta_{\rm dec})} \tag{240}$$

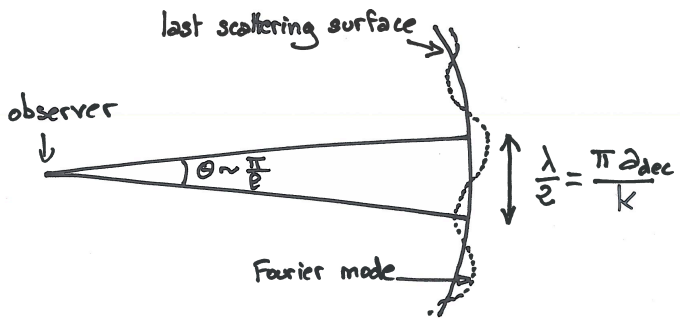

Figure 139: A multipole l refers to structures seen on the last scattering surface under an angle $\theta = \pi/l$. These structures are seeded by Fourier modes with a half wavelength $\frac{\lambda}{2} = \frac{\pi a_{\rm dec}}{k}$.

(for simplicity, we did not write numerical factors and powers of l or k in front of this expression). In other words, $C_l^{\rm SW}$ depends on the power spectrum of the perturbation $(\Theta_0 + \psi)$, evaluated at the time of decoupling, and for wavenumbers in the vicinity of $k = \frac{l}{(\eta_0 - \eta_{\rm dec})}$,

$$C_l^{\rm SW} \sim \langle |\Theta_0 + \psi|^2 \rangle_{(\eta,k) \simeq (\eta_{\rm dec},\, l/(\eta_0 - \eta_{\rm dec}))} \ . \tag{241}$$

We reached this result with mathematical arguments, but it has a very simple geometrical interpretation, illustrated in Fig. 139. The spectrum C_l encodes the correlation between structures on CMB maps seen under an angle $\theta = \pi/l$. This angle subtends a given physical scale on the last scattering surface, namely $\theta \times d_{\rm a}(z_{\rm dec})$, where $d_{\rm a}(z)$ is the angular diameter distance to objects of redshift z. Since the Sachs-Wolfe term $(\Theta_0 + \psi)$ contributes to the temperature map only at the time $\eta \simeq \eta_{\rm dec}$, the spectrum $C_l^{\rm SW}$ should depend on the power spectrum of the Sachs-Wolfe term $\langle |\Theta_0 + \psi|^2 \rangle$ at that time, and for a wavenumber such that

$$\frac{\lambda}{2} = \frac{\pi a(\eta_{\rm dec})}{k} = \theta \, d_{\rm a}(z_{\rm dec}) \ . \tag{242}$$

The reason for which λ has been divided by two is that for spherical harmonics, $\theta = \pi/l$ is the angle between a maximum and a minimum, while for a Fourier mode the distance between a maximum and a minimum is one half of the wavelength, $\frac{\lambda}{2} = \frac{\pi a}{k}$. Eq. (242) leads to

$$\frac{a(\eta_{\rm dec})}{k} = \frac{d_{\rm a}(z_{\rm dec})}{l} \ . \tag{243}$$

We recall that in a flat FL universe the angular diameter distance is given by

$$d_{\rm a}(z) = a(t(z)) \int_{t(z)}^{t_0} \frac{dt}{a} \ , \tag{244}$$

$t(z)$ being the proper time at which an object seen today with a redshift z emitted light. The conformal time $\eta(z)$ is defined similarly. In terms of conformal time,

$$d_{\rm a}(z) = a(\eta(z)) \int_{\eta(z)}^{\eta_0} d\eta = a(\eta(z)) \ [\eta_0 - \eta(z)] \ , \tag{245}$$

and for the case of a point located on the last scattering surface,

$$d_{\rm a}(z_{\rm dec}) = a(\eta_{\rm dec}) \ (\eta_0 - \eta_{\rm dec}) \ . \tag{246}$$

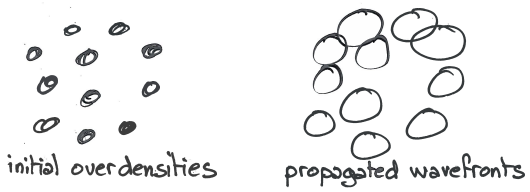

Figure 140: Initial over-densities in the early universe propagate in the form of wavefronts. The distance travelled by any wavefront at a given time is given by the sound horizon in the photon-baryon fluid. Here, we represent initial over-densities as spherical patterns at a given scale, while in the real universe primordial over-densities result from a superposition of structures on all scales.

Hence, Eq. (243) can be written as

$$\frac{1}{k} = \frac{(\eta_0 - \eta_{\rm dec})}{l} \ , \tag{247}$$

which is the same relation between k and l as in Eqs. (240, 241). In those equations, we implicitly performed a small-angle approximation. For large angles (small l's), it is inaccurate to say that a given angle/mutipole corresponds to a single Fourier mode on the last-scattering surface, and it is important to keep the spherical Bessel function of Eq. (238) and the integral over k of Eq.(234). In summary, Eqs. (240, 241) represent the instantaneous decoupling *and* small-angle limit of the true power spectrum $C_l^{\rm SW}$.

Using the same two limits, a similar discussion can be carried for the Doppler and Integrated Sachs-Wolfe power spectra. The Doppler term depends on the power spectrum of the baryon velocity divergence evaluated roughly at the same time and scale,

$$C_l^{\rm Doppler} \sim \langle |\theta_{\rm b}|^2 \rangle_{(\eta,k) \simeq (\eta_{\rm dec},\, l/(\eta_0 - \eta_{\rm dec}))} \ , \tag{248}$$

while the ISW term can be written approximately in terms of the integral

$$C_l^{\rm ISW} \sim \int_{\eta_{\rm dec}}^{\eta_0} d\eta \, (\eta_0 - \eta) \, \langle |\phi' + \psi'|^2 \rangle_{(\eta,k) \simeq (\eta,\, l/(\eta_0 - \eta))} \ . \tag{249}$$

Again, for simplicity, we did not write numerical factors and powers of l and k in front of these expressions.

In the next sections, we will infer the shape of the full spectrum C_l from that of the three power spectra appearing in Eqs. (241, 248, 249):

$$\begin{array}{lcll} \text{SW} & : & \langle |\Theta_0 + \psi|^2 \rangle & \text{at } (\eta, k) \simeq (\eta_{\rm dec},\ l/(\eta_0 - \eta_{\rm dec})) \ , \\ \text{Doppler} & : & \langle |\theta_{\rm b}|^2 \rangle & \text{at } (\eta, k) \simeq (\eta_{\rm dec},\ l/(\eta_0 - \eta_{\rm dec})) \ , \\ \text{ISW} & : & \langle |\phi' + \psi'|^2 \rangle & \text{for all } (\eta, k) \simeq (\eta,\ l/(\eta_0 - \eta)) \ . \end{array}$$

Before entering into details, we can make a guess. Even if the primordial spectrum $\mathcal{P}_{\mathcal{R}}(k)$ is smooth, the temperature spectrum C_l should contain some structure. Indeed, as illustrated by Fig. 140, any primordial over-density is expected to propagate. In Fig. 140, we represented naively the primordial over-densities with little dots, giving rise to spherical wavefronts at later time. In the real universe, wavefront patterns are less visible, because primordial over-densities result from a superposition of structures on all scales. However, there is always a characteristic scale in this problem: namely, the distance by which a wavefront travels between some time

in the primordial universe and the time of photon decoupling. This distance, called the sound horizon at decoupling $d_{\rm s}(\eta_{\rm dec})$, obeys to

$$d_{\rm s} \equiv a \int_{t_{\rm ini}}^{t} \frac{c_{\rm s} dt}{a} = a \int_{\eta_{\rm ini}}^{\eta} c_{\rm s} d\eta \ , \tag{250}$$

where $c_{\rm s}$ is the sound speed in the photon-baryon fluid (in units of the speed of light). Two points on the last scattering surface separated by this distance should be partially correlated, since density waves have propagated from one point to the other. Hence, in angular space, the two-point correlation function of CMB anisotropies should exhibit a characteristic feature for angular scales corresponding to the sound horizon at decoupling, $\theta \sim d_{\rm s}(\eta_{\rm dec})/d_{\rm a}(z_{\rm dec})$. Similarly, the harmonic power spectrum C_l should exhibit a feature at the corresponding scale, $l \sim \pi/\theta \sim \pi\, d_{\rm a}(z_{\rm dec})/d_{\rm s}(\eta_{\rm dec})$, and also for all the harmonics of this scale. We will get a confirmation of this in the next section.

Acoustic oscillations

As long as electrons, baryons and photons are tightly coupled, they form an effective single fluid in which density waves propagate at the sound speed

$$c_{\rm s}^2 = \frac{\delta p_\gamma + \delta p_{\rm b}}{\delta \rho_\gamma + \delta \rho_{\rm b}} \tag{251}$$

(the density and pressure of electrons is always negligible with respect to that of photons). The density fluctuation δ_x of each species $x = \gamma, b$ can be inferred from the local value of the equilibrium temperature. The fact that $\rho_{\rm b} \propto T^3$ and $\rho_\gamma \propto T^4$ implies $\delta_\gamma = \frac{4}{3}\delta_{\rm b}$, and tight coupling imposes $\theta_\gamma = \theta_{\rm b}$, as we already saw in Sec. 12.9.2. We can simplify the expression of the sound speed, using also the fact that $|\delta p_{\rm b}| \ll |\delta p_\gamma|$. The result reads

$$c_{\rm s}^2 = \frac{1}{3(1+R)} \ , \quad R \equiv \frac{4\bar{\rho}_{\rm b}}{3\bar{\rho}_\gamma} \propto a \ . \tag{252}$$

It is possible to derive a simple equation of motion for the photon temperature fluctuation $\Theta_0(\eta, \vec{x})$ in the tightly-coupled regime:

$$\Theta_0'' + \frac{R'}{1+R}\Theta_0' + k^2 c_{\rm s}^2 \Theta_0 = -\frac{k^2}{3}\psi + \frac{R'}{1+R}\phi' + \phi'' \ . \tag{253}$$

This equation follows from the combination of the continuity and Euler equations for photons and baryons. Given that R is proportional to the scale factor, we could replace R' by $(a'/a)R = aHR$. The second term on the left-hand side is a damping term, increasing with the contribution of baryons to the total energy of the fluid. The third term accounts for pressure forces in the effective fluid. The first term on the right-hand side accounts for the gravitational force, and the last two terms for dilation effects.

This equation would be that of a simple harmonic oscillator if R was a constant (no friction term, constant sound speed) and in absence of gravitational source terms. Then, the solution would be of the form

$$\Theta_0 = \Theta_{\rm ini} \cos(k c_{\rm s} \eta + \varphi) \ , \tag{254}$$

with two constants of integration $(\Theta_{\rm ini}, \varphi)$. We know that for adiabatic initial conditions and in the Newtonian gauge, photon density/temperature fluctuations should be constant in the super-Hubble limit, $k\eta \ll 1$: this fixes the phase to $\varphi = 0$. In the opposite limit, this solution corresponds to the propagation of acoustic oscillations. Actually, the limit between the constant

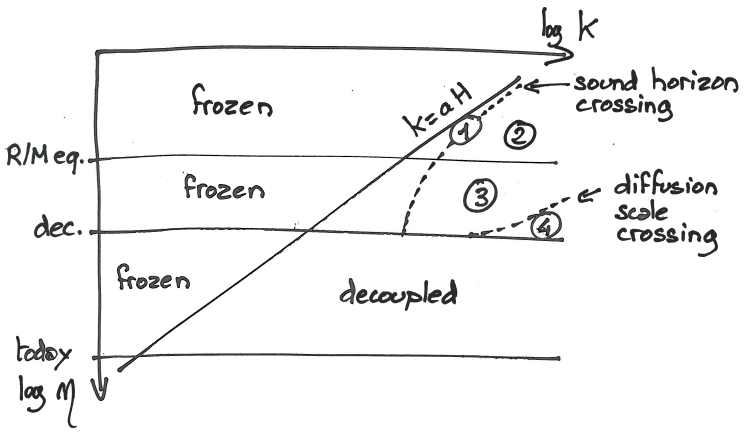

Figure 141: Different regions in (k, η) space, corresponding to qualitatively different behaviors for photon (and baryon) perturbations.

and oscillatory regime is not set by the value of $k\eta$, but by that of $kc_{\rm s}\eta$. In fact, the condition $kc_{\rm s}\eta \ll 1$ is equivalent to $\lambda \gg d_{\rm s}$, where λ is a physical wavelength ($\lambda = 2\pi a/k$), and $d_{\rm s}$ is the physical sound horizon, given in the case of a constant sound speed by:

$$d_{\rm s} = a \int_{\eta_{\rm ini}}^{\eta} c_{\rm s} d\eta \simeq a c_{\rm s} \eta \tag{255}$$

(assuming $\eta \gg \eta_{\rm ini}$). Hence, the phase $kc_{\rm s}\eta$ of the cosine stands for the ratio $2\pi d_{\rm s}/\lambda$. Modes start oscillating when their wavelength becomes smaller than the sound horizon, and later on, the number of oscillations is given by the ratio between these two scales.

In reality, R grows with time (and crosses one roughly around the time of decoupling). In addition, the gravitational source terms in Eq. (253) can play a role in some regimes. Let us describe qualitatively the evolution of Θ_0 in the different regions in (k, η) space shown in Fig. 141. In this figure, the horizontal axis corresponds to wavenumbers k (large wavelengths are on the left), and the vertical axis to conformal time, flowing from top to bottom. The super-Hubble and sub-Hubble regions are separated by the solid diagonal line corresponding to $k = aH$ (equivalent to $k\eta = 1$ during radiation domination). From top to bottom, the horizontal lines correspond to the time of equality between radiation and matter, to the time of photon decoupling, and to the time today. The upper dashed line separates wavelengths bigger/smaller than the sound horizon in the baryon-photon fluid before decoupling (after decoupling, this notion does not make sense anymore). As we have just seen, this limit corresponds to $\lambda = d_{\rm s}$, or (up to a factor 2π) to $k = (a/d_{\rm s})$. At early times, $c_{\rm s} = 1/\sqrt{3}$, and this condition reads $k\eta = \sqrt{3}$. Just before decoupling, R becomes large, $c_{\rm s}$ goes to zero, and the comoving sound horizon $(d_{\rm s}/a)$ becomes asymptotically constant, explaining the shape of the upper dashed line. Finally, the lower dashed line separates wavelengths bigger/smaller than the diffusion length defined in section 12.9.2: this line corresponds to $k = 1/r_{\rm d}$, where $r_{\rm d}$ is given in first approximation by Eq. (209).

The evolution of Θ_0 in the super-Hubble region is trivial: as long as $k\eta \ll 1$ — and *a fortiori* $kc_{\rm s}\eta \ll 1$ — the fluctuation Θ_0 is frozen, and remains approximately equal to its initial value.

The region marked with a ① in the figure corresponds to modes that are crossing the sound horizon before decoupling. This is precisely the region in which gravitational source terms are important. They shift the zero point of oscillations, and boost their amplitude (due to gravitational forces and dilution effects). This happens during a limited amount of time, because the metric fluctuations quickly decay inside the sound horizon during radiation

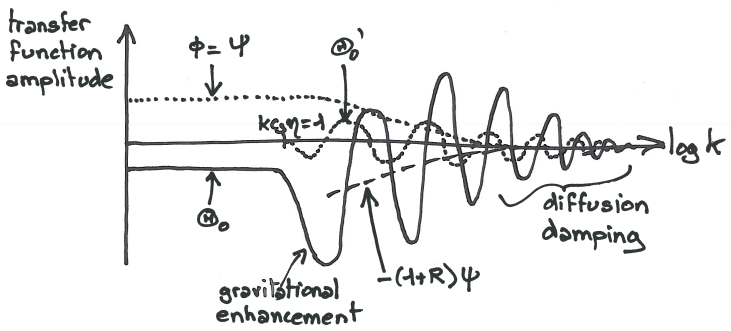

Figure 142: Transfer functions at the time of decoupling.

domination, making the gravitational source terms negligible. An approximation for the zero-point of oscillations can be found by setting Θ_0'' and Θ_0' to zero in equation (253), and by keeping only the first gravitational term:

$$\Theta_0^{equilibrium} = -\frac{1}{3c_{\rm s}^2}\psi = -(1+R)\psi \ . \tag{256}$$

Since the gravitational potential is non-zero on super-Hubble scales (we have seen that for adiabatic initial conditions $-2\psi = \delta_{\rm tot}$), the equilibrium point is shifted away from zero on those scales. It reaches asymptotically zero on sub-sound-horizon scales.

Region ② corresponds to wavelengths smaller than the sound horizon during radiation domination. In this regime, the metric fluctuations have decayed, so the source term in Eq. (253) can be neglected. The friction term can also be neglected, because during radiation domination, $R \ll 1$. Finally the effective mass $k^2c_{\rm s}^2$ is constant in time because $R \ll 1$ implies $c_{\rm s}^2 = 1/3$. Hence we are in the simple case discussed before, and the solution is proportional to $\cos(kc_{\rm s}\eta)$, corresponding to stationary oscillations, symmetric around $\Theta_0 = 0$.

Region ③ refers to wavelengths smaller than the sound horizon during the intermediate stage between the time of equality and that of photon decoupling. In this region, the metric perturbations have decayed, but R cannot be neglected (baryons and photons contribute to the total energy density with the same order of magnitude). Hence the oscillator equation has a non-negligible friction term (increasing with time), and a time-varying effective mass (decreasing with time). The solution of the equation corresponds to damped oscillations. Physically, this damping is caused by the increasing inertia and decreasing pressure of the baryon-photon fluid when the energy density of non-relativistic baryons takes over.

Region ④ refers to modes with smaller wavelength than the diffusion scale in the photon-baryon fluid. We have defined this scale in section 12.9.2. At early times, in the tightly-coupled limit, the mean free path of particles in the fluid is negligible, and cosmologically interesting scales are all well above the diffusion length. At the approach of decoupling, the diffusion length suddenly increases, and encompasses most of sub-sound-horizon wavelengths. In this regime, the oscillator equaion (253) does not apply anymore, because we cannot describe baryons and photons in terms of a perfect fluid. Perturbations are then strongly damped, since diffusion tends to average out any small-scale fluctuation.

After describing these different regions, we are ready for understanding the qualitative behavior of the various relevant transfer functions, evaluated at the time of decoupling. Figure 142 shows the transfer functions $\Theta_0(\eta_{\rm dec}, k)$ (solid line), $\psi(\eta_{\rm dec}, k)$ (upper dotted line) and $\Theta_0'(\eta_{\rm dec}, k)$ (middle dotted line) as a function of $\log k$. For simplicity, we neglect the role of the anisotropic stress generated by neutrinos (and to a lesser extent by photons near decoupling time). Hence we can assume $\phi = \psi$ at all times. For scales above the sound horizon ($kc_{\rm s}\eta \ll 1$),

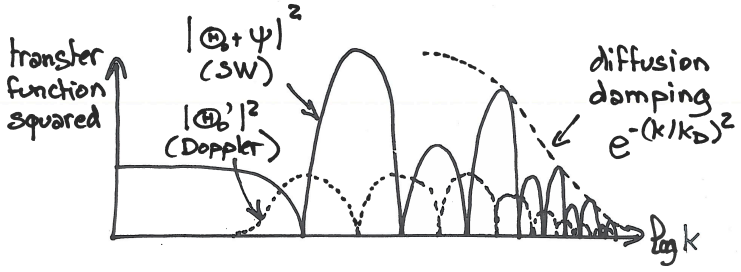

Figure 143: Squared transfer functions at the time of decoupling.

the transfer functions are constant: indeed we know that, on those scales and in the Newtonian gauge, density and metric fluctuations are frozen. Adiabatic initial conditions impose $-2\psi = \delta_{\rm tot} \simeq \delta_{\rm b} \simeq \frac{3}{4}\delta_\gamma \simeq 3\Theta_0$. The opposite sign of Θ_0 and ψ reflects the fact that an overdensity corresponds to a temperature excess and a gravitational potential well (and vice-versa). We remember that transfer functions are all normalized to $\mathcal{R}(\vec{k}) = 1$ (see section 12.9.1): this corresponds to a negative δ_γ (and Θ_0) and to a positive ψ, like in the figure.

Because of the decay of metric fluctuations inside the Hubble radius, the ψ curve smoothly decreases and tends towards zero in the small wavelength limit. The behavior of Θ_0 is more complicated. Modes which are just crossing the sound horizon near $\eta = \eta_{\rm dec}$ are experiencing the boost caused by gravitational source terms in Eq. (253): this explains the first bump in the solid line. For smaller wavelengths, we see oscillatory patterns corresponding to acoustic oscillations. Smaller wavelengths crossed the sound horizon earlier, and had more time for oscillating before decoupling. The maxima observed at the time of decoupling correspond to modes that could experience 0.5, 1, 1.5, 2,..., periods of oscillations before that time. The zero point of oscillations follows $-(1+R)\psi$, represented on the figure with a dashed line: this zero point reaches zero well inside the sound horizon. The amplitude of the oscillations is maximal for the first oscillatory pattern, i.e. for modes that crossed the sound horizon very recently. The second oscillatory pattern is reduced by the fact that those modes stayed for a longer time inside the sound horizon during the matter dominated regime, and experienced more damping due to baryons. The third and higher oscillatory patterns are reduced even more by diffusion damping just before photon decoupling. Temperature fluctuations on very small wavelengths are completely suppressed by photon diffusion.

Figure 142 also shows qualitatively the behavior of the time derivative $\Theta_0'(\eta_{\rm dec}, k)$, which exhibits oscillations that are out of phase with respect to those of $\Theta_0(\eta_{\rm dec}, k)$. This will be important in a few paragraphs, when discussing the Doppler effect.

Now that we understand qualitatively the behavior of the metric and photon transfer functions, we can go back to the decomposition of the CMB temperature spectrum C_l in three terms (Sachs-Wolfe, Doppler and integrated Sachs-Wolfe) discussed in section 12.9.2.

Sachs-Wolfe contribution. We have seen that the Sachs-Wolfe contribution to C_l is approximately given by the power spectrum of the combination $(\Theta_0 + \psi)$ at $\eta = \eta_{\rm dec}$, with a correspondence between k and l given by Eq. (247). We know that this power spectrum is given by the product of the primordial spectrum $\mathcal{P}_\mathcal{R}(k)$ (that we can choose to be scale-invariant in first approximation) by the square of the transfer function $(\Theta_0 + \psi)^2$. The qualitative behavior of the latter has no more secrets for us. We can pick up the solid and upper dotted lines in figure 142, add them up, and square the result. The result is shown in figure 143 as a function of $\log k$. For modes with $kc_{\rm s}^2\eta \ll 1$, we see a flat plateau: there, our previous calculation of the Sachs-Wolfe effect would apply (this part of the curve is actually called the Sachs-Wolfe plateau). We then observe a series of peaks. Due to the shift of the zero-point of oscillations given by $-(1+R)\psi$ for Θ_0, and hence by $-R\psi$ for the Sachs-Wolfe term $(\Theta_0 + \psi)$, there is an

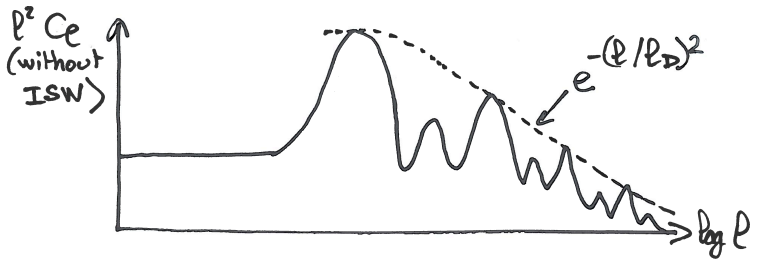

Figure 144: Contribution to the C_l's from the SW and Doppler terms.

asymmetry between the first few odd and even peaks, with odd peaks being enhanced. Moreover the overall amplitude of the peaks is suppressed in the large k limit by diffusion damping. A bit of algebra would show us that the envelope of the peaks is given in first approximation by the function $\exp[-(k/k_{\rm d})^2]$, where $k_{\rm d}$ is the diffusion wavenumber, related to the diffusion comoving scale of Eq. (209) by $k_{\rm d} r_{\rm d} = 1$.

Doppler contribution. Next, we know that the C_l's receive a second contribution from the Doppler effect, related to the power spectrum of $\theta_{\rm b}$, which is equal to θ_γ until baryon and photons decouple from each other. It turns out that the photon velocity divergence θ_γ is itself related to the time derivative of the temperature fluctuation Θ_0. At a very qualitative level, we can infer the Doppler contribution from the shape of the transfer function $\Theta_0'(\eta_{\rm dec}, k)$. This contribution is null for scales above the sound horizon, since in this regime there are no oscillations and no significant dynamics in the fluid. On smaller scales, the Doppler contribution has oscillatory patterns, that are out of phase with respect to those of the Sachs-Wolfe term. The Doppler contribution is represented schematically as a dotted line in figure 143.

We can now sum up the Sachs-Wolfe and Doppler contributions. Also, we can transpose our results for power spectra as a function of k in terms of C_l's as a function of l. We have already seen in section 12.9.2 that there is a mapping betwwen the two, at least in the small-angle and instantaneous decoupling approximation, with a correspondence between values of k and l given by Eq. (247). The result is shows in figure 144. Note that the vertical axis stands for $l^2 C_l$, for the following reason. If the primordial spectrum was scale invariant ($\mathcal{P}_{\mathcal{R}}(k) =$ constant) and the transfer functions were flat (as it is the case for large wavelengths/small l's), the quantity $l(l+1)C_l$ would also be flat and independent of l. This would follow from Eq. (240) if we had been more carefull in keeping all the factors. It is convenient to plot $l^2 C_l$ or $l(l+1)C_l$ instead of C_l, in order to display a roughly constant curve, just modulated by acoustic oscillations and diffusion damping.

Diffusion damping effect. In Fig. 144, we can identify all the features mentioned before: the flat Sachs-Wolfe plateau, the series of oscillations with enhanced odd peaks, and the exponentially decaying envelope of the peaks for large l. The envelope is now given by $\exp[-(l/l_{\rm d})^2]$, where $l_{\rm d}$ is the diffusion multipole, related to the diffusion angle by $l_{\rm d} = \pi/\theta_{\rm d}$. The diffusion angle is related to the diffusion scale $r_{\rm d}$ by the usual angular diameter distance relation,

$$\theta_{\rm d}\, d_{\rm a}(\eta_{\rm dec}) = \lambda_{\rm d} = a(\eta_{\rm dec}) r_{\rm d}(\eta_{\rm dec}). \tag{257}$$

At this point, we are almost done with the qualitative description of the CMB temperature spectrum C_l. We only missed the integrated Sachs-Wolfe contribution, and the effect of reionization.

Integrated Sachs-Wolfe contribution. We have seen that the integrated Sachs-Wolfe effect is given by an integral over $(\psi' + \phi')$ between photon decoupling and today. In fact, $(\psi' + \phi')$ remains vanishingly small in a large part of the space (k, η). In Figure 145, we

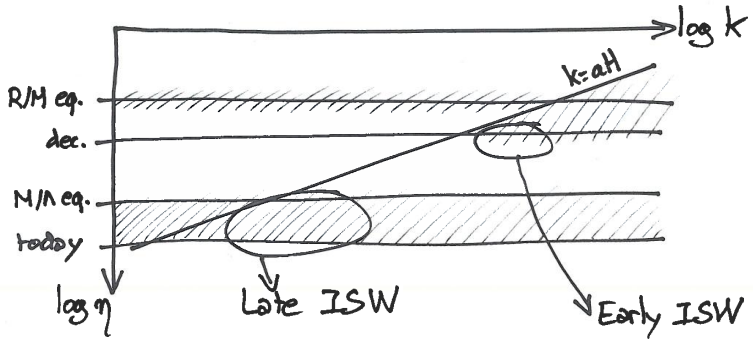

Figure 145: Regions in (k, η) space where metric fluctuations are expected to vary with time (giving rise potentially to an ISW effect after decoupling).

hatched all the regions in (k, η) space where metric fluctuations are expected to vary with time. Let us discuss these different regions.

Before photon decoupling, we know that metric fluctuations decay inside the sound horizon. Instead, in the Newtonian gauge, they remain frozen outside the Hubble radius, excepted near times at which the equation of state of the universe changes: namely, at the time of equality between radiation and matter.

Let us now discuss the variation of metric perturbations after photon decoupling (this is the relevant epoch for the ISW effect). Deep inside the matter dominated regime, one can show that metric fluctuations are static, even inside the Hubble radius (at least within linear perturbation theory). We will justify this result in section 12.9.3. Hence in figure 145 there are no hatches during matter domination on whatever scales. Note however that at the beginning of matter domination, it takes some time for sub-sound-horizon metric fluctuations to freeze around a constant value: hence the hatches continue below the line corresponding to the time of equality, and extend till the line corresponding to photon decoupling.

Later on, during the Λ (or dark energy) dominated regime, the equation of state of the universe changes again, so metric fluctuations vary on all scales, like at the time of equality. A simple calculation based on Einstein equations would show that metric fluctuations are damped during this stage.

In summary, contribution to the integrated Sachs-Wolfe effect can only come from two regions:

- just after photon decoupling, on sub-sound-horizon scales, and
- during Λ domination, on all scales.

These two distinct contributions are usually called the Early Integrated Sachs-Wolfe (EISW) and Late Integrated Sachs-Wolfe (LISW) effects. One can show that both effects decrease with wavelength, for geometrical reasons. Hence the EISW effect is maximal for scales crossing the sound horizon just at the time of photon decoupling, while the LISW effect is maximal for the largest observable scales today. In multipole space, this means that the EISW effect contributes mainly to the scale of the first peak, i.e. to $l \sim 200$, while the LISW contributes mainly to the smallest multipoles $l = 2, 3, 4$, etc. The two ISW contributions are drawn on figure 146. The EISW effect enhances the first peak, while the LISW effect tilts the Sachs-Wolfe plateau even if the primordial spectrum is exactly scale invariant.

Reionization effect. The last effect that we omitted to describe is that of reionization. We have seen in section 12.9.2 that at small redshift ($z \simeq 10$), the reionization of the universe produces a small secondary bump in the visibility function, corresponding physically to a small

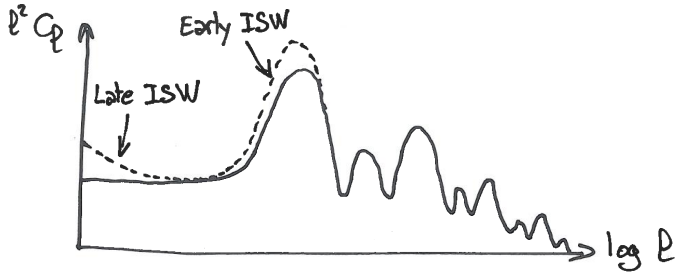

Figure 146: ISW contribution to the temperature spectrum.

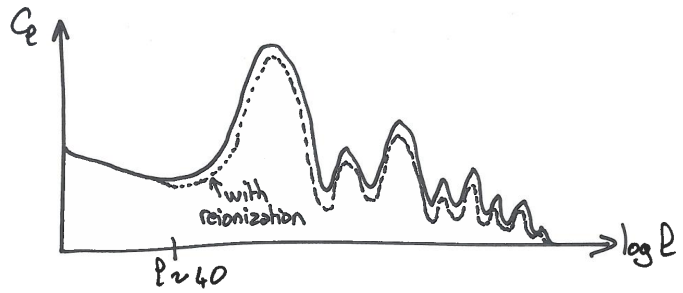

Figure 147: Impact of reionization on the temperature spectrum.

probability for CMB photons to rescatter at late times. This rescattering will tend to smooth out any temperature anisotropy pattern. Hence, reionization lowers the overall amplitude of the C_l', but only a small amount (by approximately 15%). Note that the suppression of power is not uniform over the whole multipole range: smoothing effects cannot reach the largest observable scales (corresponding to the smallest values of l). Hence the effect of reionization is step-like shaped, and saturates for l of the order of 40 or so (as illustrated on figure 147).

Parameter dependence of the temperature spectrum

We summarized in the last section the various physical effect contributing to the shape of the CMB temperature spectrum C_l. We will now recapitulate the effect of the various cosmological parameters on the C_l's, within the framework of the minimal ΛCDM model.

This model assumes zero spatial curvature, and a power-law primordial spectrum of scalar perturbations:

$$\mathcal{P}_\mathcal{R}(k) = A_\mathrm{s}(k/k_*)^{n_\mathrm{s}-1} \ , \tag{258}$$

where k_* is an arbitrary fixed pivot scale, A_s is the spectrum amplitude at this scale, and n_s is called the scalar tilt (the exponent is chosen to be $n_\mathrm{s}-1$ rather than just n_s for historical reasons; with such notations, a scale-invariant spectrum corresponds to $n_\mathrm{s}=1$).

We recall that the Hubble parameter today, H_0, can be expressed in terms of a dimensionless reduced Hubble parameter h:

$$H_0 \equiv 100\,h\,\mathrm{km.s^{-1}.Mpc^{-1}} \tag{259}$$

The physical energy density of a given component x today can be expressed in terms of a dimensionless parameter $\omega_x \equiv \Omega_x h^2$:

$$\rho_x^0 = \Omega_x \rho_\mathrm{crit}^0 = \Omega_x \frac{3H_0^2}{8\pi G} = \beta\,\omega_x \tag{260}$$

where $\beta = \frac{3(H_0/h)^2}{8\pi G}$ is a fixed number, with the dimension of an energy per volume.

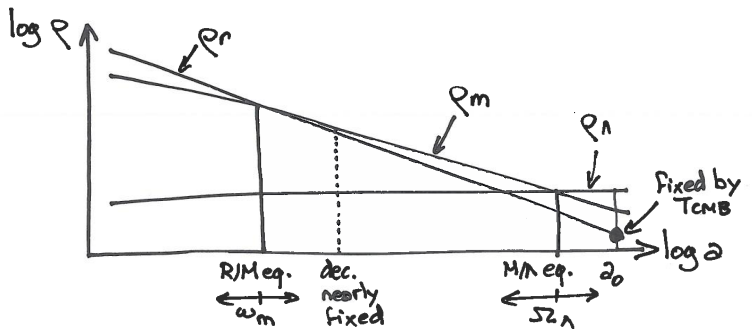

Figure 148: In the minimal ΛCDM model, evolution of the background density of radiation, matter and cosmological constant as a function of the scale factor.

The six free parameters of the minimal ΛCDM model can be chosen to be

$$\{A_{\rm s}, n_{\rm s}, \omega_{\rm b}, \omega_{\rm m}, \Omega_\Lambda, \tau_{\rm reio}\}, \tag{261}$$

where $\tau_{\rm reio}$ is the optical depth to recombination, which is non-zero because of reionization in the recent universe. At first order, this is the only parameter that one needs to introduce for describing reionization. For a very accurate description, one should introduce other parameters specifying the full reionization history, but these extra parameters are very difficult to probe experimentally. Hence, they are usually not specified.

The above parameter basis specifies the baryon density $\omega_{\rm b}$, the total non-relativistic (baryons + CDM) matter density $\omega_{\rm m}$, and the fractional density of cosmological constant Ω_Λ. The photon density is implicitly assumed to match the measured value of the CMB temperature ($T = 2.725$ K implies $\omega_\gamma \sim 2.10^{-5}$). Neutrinos are assumed to be still relativistic today, with an abundance relative to photons given by the prediction of the standard neutrino decoupling model[120]. Finally, we did not include the parameter H_0 (or h) in the parameter basis (261). Given that we are assuming a flat universe, h can be inferred from other parameters in (261): $h = \sqrt{\omega_{\rm m}/(1-\Omega_\Lambda)}$.

The parameters basis (261) is just one particular choice. Many other bases would be valid, for instance, $\{A_{\rm s}, n_{\rm s}, \omega_{\rm b}, \omega_{\rm cdm}, H_0, \tau_{\rm reio}\}$). The choice of (261) is dictated by purely pedagogical considerations: we will show that the shape of the CMB spectrum can easily be related to these parameters.

We summarize in Fig. 148 the evolution of background densities in the minimal ΛCDM model. The normalization of the radiation density ρ_r is fixed by the CMB temperature and by the standard neutrino decoupling model. The normalization of the matter density $\rho_{\rm m}$ and of the cosmological constant density ρ_Λ is given respectively by the parameters $\omega_{\rm m}$ and Ω_Λ. The scale factor at radiation/matter equality is given by

$$\rho_r = \rho_{\rm m} \quad \Longrightarrow \quad \omega_r \left(\frac{a_0}{a_{\rm eq}}\right)^4 = \omega_{\rm m} \left(\frac{a_0}{a_{\rm eq}}\right)^3 \quad \Longrightarrow \quad \frac{a_{\rm eq}}{a_0} = \frac{\omega_r}{\omega_{\rm m}} \, . \tag{262}$$

Since ω_r is considered as fixed, the redshift of equality is controlled by $\omega_{\rm m}$ only. The scale factor at matter/Λ equality is given by

$$\rho_{\rm m} = \rho_\Lambda \quad \Longrightarrow \quad \omega_{\rm m} \left(\frac{a_0}{a_\Lambda}\right)^3 = \Omega_\Lambda h^2 \quad \Longrightarrow \quad \frac{a_\Lambda}{a_0} = \left(\frac{1-\Omega_\Lambda}{\Omega_\Lambda}\right)^{1/3} \, , \tag{263}$$

[120] In this course, for simplicity, we do not discuss the effect of neutrinos; this effect is far from being negligible, but since we consider the abundance of neutrinos as fixed, and their mass as irrelevant, we can explain the effect of other free parameters without taking neutrinos into account. Neutrino effects are described in Ref. [1].

so it is controlled by Ω_Λ only. The scale factor at photon decoupling has a small (logarithmic) dependence on $\omega_{\rm b}$, that we can neglect — we will consider that decoupling takes place at a fixed temperature, and hence a fixed scale factor and redshift.

Among the various physical effects described in the previous section, we can identify eight independent leading effect. We summarize them in Table ??, and show by which parameters they are governed.

Independent leading effects controlling the shape of the CMB temperature power spectrum C_l in the minimal ΛCDM model.

	Effect	Relevant quantity	Parameter
(C1)	**Peak scale**	$\theta_{\rm peak} = \dfrac{\pi}{l_{\rm peak}} \sim \dfrac{d_{\rm s}\|_{\rm dec}}{d_{\rm a}\|_{\rm dec}}$	$\leftarrow \omega_{\rm m}, \omega_{\rm b}$ $\leftarrow \Omega_\Lambda, \omega_{\rm m}$
(C2)	**Odd/even peak amplitude ratio**	$R\|_{\rm dec}$	$\omega_{\rm b}$
(C3)	**Overall peak amplitude**	$\frac{a_{\rm dec}}{a_0}$	$\omega_{\rm m}$
(C4)	**Damping enveloppe**	$\theta_{\rm d} = \dfrac{\pi}{l_{\rm d}} = \dfrac{a_{\rm dec} r_{\rm d}\|_{\rm dec}}{d_{\rm a}\|_{\rm dec}}$	$\leftarrow \omega_{\rm m}, \omega_{\rm b}$ $\leftarrow \Omega_\Lambda, \omega_{\rm m}$
(C5)	**Global amplitude**	$\mathcal{P}_\mathcal{R}(k_*)$	$A_{\rm s}$
(C6)	**Global tilt**	$\frac{d\log\mathcal{P}_\mathcal{R}}{d\log k}$	$n_{\rm s}$
(C7)	**Additional plateau tilting (LISW)**	$\frac{a_\Lambda}{a_0}$	Ω_Λ
(C8)	**Amplitude for $l \geq 40$ only**	$\tau_{\rm reio}$	$\tau_{\rm reio}$

Below, we give more details on these effects.

(C1) Since all peaks in multipole space correspond to the harmonics of a single correlation length in real space, the scale of the peak is controlled (in good approximation) by a single number $l_{\rm peak}$. It depends on the ratio of the sound horizon at decoupling by the angular diameter distance to decoupling. The first quantity depends on the evolution prior to decoupling, and in particular on the expansion history and sound speed. Hence it depends on $\omega_{\rm m}$ (governing the time of equality) and $\omega_{\rm b}$ (governing $c_{\rm s}^2$ as a function of a). The second quantity depends on the expansion and geometry of the universe after decoupling, i.e. on Ω_Λ and H_0, or in our parameter basis Ω_Λ and $\omega_{\rm m}$.

(C2) When studying the SW contribution to the C_l's, we have seen that the asymmetry between the amplitude of odd and even peaks depends on the shift of the zero-point of acoustic oscillations by a term $-R\psi$. The value of the ratio R at decoupling is governed in our parameter basis by $\omega_{\rm b}$.

(C3) A shift in the time of radiation/matter equality affects the amplitude of all peaks for two reasons: it controls the duration of the intermediate stage between equality and decoupling, during which acoustic oscillations are damped by baryonic effects, and the EISW. Both effects go in the same direction. If equality takes place earlier, there is less time for damping (hence all peaks are increased). The metric fluctuations are also less stabilized at decoupling, and the EISW is larger (hence the first peak is increased even more).

(C4) Diffusion damping near the time of recombination controls the envelope of the peaks (the function $\exp[-(l/l_{\rm d})^2]$ suppresses them, starting essentially from the third one). It depends on the ratio of the damping scale at decoupling by the angular diameter distance to decoupling. The first quantity depends on the Thomson scattering rate prior to decoupling, and in particular on $\omega_{\rm m}$ (governing the value of conformal time at equality) and $\omega_{\rm b}$ (governing the ionization fraction as a function of a). The second quantity depends on the expansion and geometry of the universe after decoupling, i.e. on Ω_Λ and H_0, or in our parameter basis Ω_Λ and $\omega_{\rm m}$. The parameter dependence of effects (C1) and (C4) could be thought to be similar: in fact, it is not, because the sound horizon and the diffusion scale depend on very different combinations of $\omega_{\rm m}$ and $\omega_{\rm b}$.

(C5) The global amplitude of the C_l's depends trivially on that of the primordial spectrum, fixed by $A_{\rm s}$.

(C6) The global slope of the C_l's depends trivially on the tilt of the primordial spectrum, fixed by $n_{\rm s}$.

(C7) The LISW effect tilts the Sachs-Wolfe plateau (on top of the effect of $n_{\rm s}$). The plateau is more lifted at small l's if Λ domination is longer, i.e. if metric fluctuations decay during a larger amount of time. Hence this effect is enhanced by large values of Ω_Λ.

(C8) The C_l amplitude is suppressed if reionization takes place early, i.e. if $\tau_{\rm reio}$ is large, but without affecting the largest scales (small l's).

We see that in the framework of the minimal ΛCDM model, six parameters control eight distinct physical effects with different impacts on the C_l's. This suggests that an accurate enough measurement of the temperature spectrum is sufficient for fixing the six parameters of the cosmological model describing our universe, at least if the data is consistent with ΛCDM. This conclusion is roughly correct, but must be refined with some words of caution. Indeed, we remember that for small l's, cosmic variance is large, so that the average C_l's of the "true model" describing our universe cannot be measured precisely, even in the case of an ideal experiment. However, two of the previous effects **(C1)** - **(C8)** can only affect the smallest multipoles:

- effect **(C7)** affects only the Sachs-Wolfe plateau,
- a combination of effects **(C5)** and **(C8)**, corresponding to the product $e^{-2\tau_{\rm reio}} A_{\rm s}$, controls the global amplitude for $l \gg 40$, but a variation of both $\tau_{\rm reio}$ and $A_{\rm s}$ with the previous product being kept fixed would only affect the smallest multipoles.

Hence, the measurement of the CMB temperature spectrum is sufficient for constraining the six parameters of the ΛCDM model, but with a relatively large error bar for Ω_Λ and for a particular combination of $\tau_{\rm reio}$ and $A_{\rm s}$. In the next section, we will say a few words on the measurement of CMB polarization, which allows to better constrain reionization: polarization data allow to remove the degeneracy between $\tau_{\rm reio}$ and $A_{\rm s}$. Instead, the error bar on Ω_Λ can only be improved by combining CMB data with other cosmological probes (e.g. supernovae luminosity or large scale structure data).

A quick word on polarization

The Bolztmann equation presented in Eq. (217) was a bit over-simplified. We did as if the only degree of freedom describing photons with a blackbody spectrum was their temperature. In fact, photons are described by more degrees of freedom, called the Stokes parameters, involving also their polarization. In Eq. (217), the Thomson scattering rate was integrated over polarization parameters, but in reality some polarized correction terms are present.

Well before decoupling, photons remain unpolarized on average. Indeed, we have seen in section 12.9.2 that, throughout the tight-coupling regime and in the frame comoving with the fluid (i.e. such that $\theta_{\rm b} = \theta_\gamma = 0$), the photon temperature is isotropic is every point. This isotropy (resulting from frequent interactions) implies that photons acquire no net polarization patterns when they scatter over electrons.

Instead, at the approach of decoupling, when Thomson scattering becomes inefficient, the photon temperature is no longer isotropic in the frame comoving with the electrons. This means that a given electron will scatter simultaneously some hotter photons coming from one direction, and some colder photons coming from another direction. What is important for polarization is the quadrupolar component of the the temperature distribution in each point. This component starts from zero and grows at the approach of decoupling. When it becomes significant, photon scattering leads to a net linear polarization. Hence, today, CMB photons have a different polarization amplitude and orientation in each direction of the sky.

The map of CMB temperature anisotropies is a scalar map: it can be represented with a one-dimensional color code. The map of CMB polarization can be represented with sticks of different size and orientation in different points of the map. Roughly speaking, the size and orientation of the sticks can be related to the magnitude and orientation of the quadrupole anisotropy in each point of the last scattering surface. Since these quadrupolar patterns reflect variations of temperature in the region of the last scattering surface, it is clear that there is a non-zero correlation between temperature and polarization maps. Still, both maps contain some independent information.

In general, a vector field can be decomposed into a gradient and a curl component, like the electric and magnetic fields. Similarly, CMB polarization maps can be expanded in two scalar maps called, by analogy, E-type and B-type polarization maps.

One can show that primordial scalar perturbations can produce both temperature anisotropies and E-type polarization anisotropies. If the early universe only features Gaussian scalar perturbations on cosmological scales, all the information contained in CMB maps is encoded in the temperature power spectrum C_l^{TT}, the E-type polarization power spectrum C_l^{EE}, and the cross-correlation power spectrum C_l^{TE}. The later really contains additional independent information, because polarization patterns are only partially correlated with temperature patterns (in mathematical terms, $[C_l^{TE}]^2 \leq C_l^{TT} C_l^{EE}$).

We will mention in the next section the possibility that a significant amount of tensor perturbations are produced in the primordial universe. Such perturbations can also generate B-type polarization. If this is the case, all the information is encoded in C_l^{TT}, C_l^{EE}, C_l^{TE} and C_l^{BB}. We did not include in this list the cross-correlation spectra C_l^{TB} and C_l^{EB}, because the parity symmetry imposes that they should vanish (at the level of primary anisotropies).

Mapping the CMB polarization is interesting because it contains additional information with respect to temperature anisotropies.

First, reionization has a very distinct effect on the polarization spectrum. The small fraction of photons rescattered around the time of reionization acquire additional polarization that will show up in the form of a peak in the small-l branch of C_l^{EE} (see figure 149) and C_l^{TE}. We have seen in the previous section that with temperature data only, cosmic variance limits our ability to measure $\tau_{\rm reio}$, and *a fortiori* to constrain additional parameters describing the reionization history. The effect of reionization in the small-l branch of C_l^{EE} and C_l^{TE} is so big that despite of cosmic variance, $\tau_{\rm reio}$ can be well measured using polarization data.

So the effect of reionization, described before as **(C8)**, is very different for temperature and polarization. Instead, the other effects **(C1)** - **(C7)** have a qualitatively similar impact on C_l^{EE} and C_l^{TE}. Still, measuring polarization is interesting, because temperature anisotropies feature a particular combination of the SW, Doppler and ISW effects, while polarization provides information on the quadrupole Θ_2 on the last scattering surface, which is correlated with

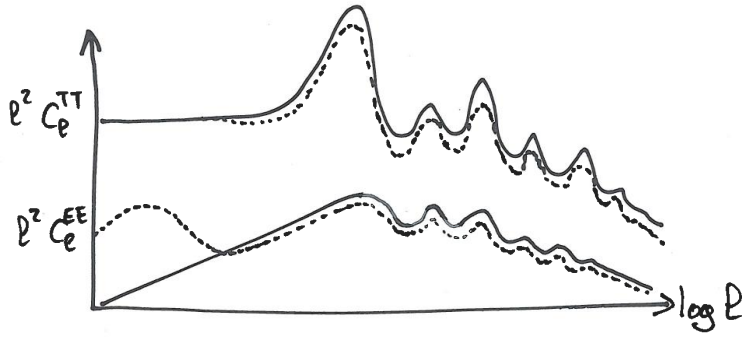

Figure 149: Typical shape of the temperature and E-type polarization power spectra in a ΛCDM model without (solid lines) or with (dotted lines) reionization of the universe at small redshift.

the SW and Doppler terms, but probing a different combination of them. Hence the role of polarization measurements is to remove some of the parameter degeneracies appearing in the analysis of temperature data.

Note that in the full Boltzmann equation, the equation of motion of temperature and polarization degrees of freedom are coupled. In the last sections, we neglected such a coupling. In fact, the impact of polarization on the evolution of temperature anisotropies is very small. Hence our qualitative discussion of the various effects affecting CMB temperature remains valid.

A quick word on tensors

We have seen in section 12.9.1 that tensor modes are related to the traceless divergenceless components of the metric and stress-energy tensor, obeying to

$$\sum_i \delta T_{ii} = 0 \qquad \text{and} \qquad \forall j, \quad \sum_i \partial_i \delta T_{ij} = 0 \ . \tag{264}$$

Since these relations impose four constraints on the six degrees of freedom of the 3×3 symmetric matrix δT_{ij} (or δg_{ij}), there are two tensor degrees of freedom in $g_{\mu\nu}$ and $T_{\mu\nu}$.

The two degrees of freedom in δg_{ij} are the two degrees of polarization of gravitational waves, that can propagate even in the vacuum. In the presence of matter with a non-diagonal stress tensor δT_{ij}, gravitational waves can be seeded by the tensor components δT_{ij}.

If tensor perturbations are sufficiently large at recombination or later, they can generate CMB temperature and polarization anisotropies: one can show that they interact with CMB photons, and produce effects similar to the SW and ISW ones. As mentioned in the previous section, gravitational waves can even seed B-type polarization.

The stress-energy tensor is diagonal for perfect fluids, and negligible for pressureless components like CDM. Hence, during radiation and matter domination, tensor perturbations can only be seeded by decoupled neutrinos and/or decoupled photons. However, neutrino and photon tensor modes are far too small for generating a detectable amount of CMB anisotropies. However, in the early universe, other mechanisms may produce gravitational waves on scales sufficiently large to be observable in the CMB. The most famous one is related to inflation. During inflation, quantum fluctuations of the metric can excite primordial tensor perturbations at a level that will produce a detectable signature in CMB maps. The amplitude of this signal is directly proportional to the energy scale of inflation. If this scale is large enough, tensors can contribute to C_l^{TT}, but only on small l's, because gravitational waves decay quickly inside the Hubble radius. Hence, one way to detect tensors would be through a small distortion of the

C_l^{TT} spectrum shape for $l \leq 100$ (i.e. for scales that are equal or larger than the Hubble radius at the time of decoupling).

However, if the tensor signal is small with respect to the error bars associated to cosmic variance, it will remain undetectable. In that case, further sensitivity could be obtained by measuring C_l^{BB}: in absence of tensors, C_l^{BB} would vanish, so even if the tensor amplitude is very small it can still dominate the C_l^{BB} signal. Unfortunately, this is true only up to some extent, because secondary anisotropies (in particular, those generated by weak lensing) produce a non-zero C_l^{BB} that could mask the primary tensor anisotropy spectrum.

It is very challenging for CMB experiments to reach the sensitivity level required for detecting a C_l^{BB} signal, even for that generated by weak lensing. Current limits on the tensor primordial spectrum (and on the energy scale of inflation) mainly come from the observation of C_l^{TT} at small l by WMAP. The sensitivity of Planck to tensors will also mainly come from temperature. Future experiments dedicated to CMB polarization will improve the sensitivity to B-type polarization and obtain more precise bounds, until they reach the theoretical limit set by the lensing contamination.

12.9.3 Matter power spectrum by Lesgourgues

Definition

The total energy perturbation in the universe can be expanded as

$$\delta\rho_{\rm tot} = \delta\rho_\gamma + \delta\rho_{\rm b} + \delta_{\rm cdm} + \delta\rho_\nu \,(+\,\delta\rho_{\rm de} + ...) \tag{265}$$

where $\delta\rho_{\rm de}$ refers to possible Dark Energy (DE) perturbations, and the three dots for extra relics. In the minimal ΛCDM model, only the first four components are present.

Many Large-Scale Structure (LSS) observables are related to the power spectrum of $\delta\rho_{\rm tot}$, at different wavenumbers and redshifts. This is the case of the galaxy and of the halo correlation function, of the cluster mass function, of CMB lensing, of the cosmic shear spectrum, etc.

All these observations probe the power spectrum during matter or Λ/DE domination, when photons are subdominant and $\delta\rho_\gamma$ can be neglected. If neutrinos are still ultra-relativistic today, $\delta\rho_\nu$ can also be neglected (in this course, we do not have time to discuss the impact of small neutrino masses, for which we refer the reader to Ref. [1]). If the acceleration of the universe is caused by a cosmological constant, there is no term $\delta\rho_{de}$. More generally, most Dark Energy models would predict a negligible amount of DE perturbations. In summary, in a wide category of cosmological scenarii including ΛCDM, we can use $\delta\rho_{\rm tot} \simeq \delta_{\rm m} \equiv \delta\rho_{\rm b} + \delta_{\rm cdm}$. Hence, in the context of LSS observations, it is customary to refer to the power spectrum of the non-relativistic matter fluctuation $\delta_{\rm m}$, defined as

$$\delta_{\rm m} = \frac{\delta\rho_{\rm m}}{\bar\rho_{\rm m}} = \frac{\delta\rho_{\rm b} + \delta\rho_{\rm cdm}}{\bar\rho_{\rm b} + \bar\rho_{\rm cdm}} \,, \tag{266}$$

which is indistinguishable from the ratio $\delta\rho_{\rm tot}/\bar\rho_{\rm m}$. Only in models with large dark energy perturbations or modifications of Einstein gravity, the two quantities might be different, and special care about the definition of the matter power spectrum is needed.

The matter power spectrum $P(z,k)$ of $\delta_{\rm m}$ is defined like in section 12.9.1:

$$\langle \delta_{\rm m}(z,\vec{k}) \delta^*_{\rm m}(z,\vec{k}') \rangle = \delta_D(\vec{k} - \vec{k}') \; P(z,k) \,. \tag{267}$$

Here we used the redshift as a time variable, but we could have indifferently used proper or conformal time. We have seen in section 12.9.1 that for Gaussian initial conditions and as long as perturbations are linear, the power spectrum at a given time can be written as the product

of the primordial spectrum by the square of the relevant transfer function, in our case $\delta_{\rm m}(z,k)$. Sticking to the same conventions as in section 12.9.1 and assuming a power-law primordial spectrum like in section 12.9.2, this gives

$$P(z,k) = \frac{2\pi^2}{k^3} A_{\rm s} \left(\frac{k}{k_*}\right)^{n_{\rm s}-1} \delta_{\rm m}^2(z,k) \ . \tag{268}$$

Hence, by studying qualitatively the evolution of the transfer function $\delta_{\rm m}(z,k)$, we will get some insight on the cosmological information encoded in the matter power spectrum.

Transfer function evolution

CDM dominated universe. In order to simplify the presentation, let us first assume that we leave in a ΛCDM universe with a negligible amount of baryons: $\Omega_{\rm b} \ll \Omega_{\rm cdm}$ and $\delta_{\rm m} \simeq \delta_{\rm cdm}$. In section 12.9.2, we wrote the master equation governing the evolution of photon perturbations during the tightly-coupled regime. Similarly, by combining the continuity and Euler equation of CDM perturbations, we can write here a master equation for $\delta_{\rm cdm}$, actually valid in all regimes:

$$\delta''_{\rm cdm} + \frac{a'}{a}\delta'_{\rm cdm} = -k^2\psi + 3\phi'' + 3\frac{a'}{a}\phi' \ . \tag{269}$$

In an expanding universe, the clustering rate depends on the expansion rate: expansion increases distances, weakens gravitational forces, and slows down clustering processes. In the above equation, this is accounted by the second term, often called the Hubble friction term. On the right-hand side, the first term represents gravitational forces, and the last two terms account for dilation effects.

On super-Hubble scales, we have seen that in the Newtonian gauge, adiabatic ICs predict constant density fluctuations $\delta_{\rm cdm}$. To be precise, ϕ and $\delta_{\rm cdm}$ vary on super-Hubble scales only when the total equation of state of the universe changes (i.e. around the time of radiation/matter equality, and during Λ domination). Instead, they remain constant on those scale during the radiation and matter dominated regime.

Inside the Hubble radius, we can neglect dilation terms, and replace the gravitational potential term:

$$\delta''_{\rm cdm} + \frac{a'}{a}\delta'_{\rm cdm} - \frac{3}{2}\left(\frac{a'}{a}\right)^2 \Omega_{\rm cdm}(a)\ \delta_{\rm cdm} = 0 \ , \tag{270}$$

where $\Omega_{\rm cdm}(a)$ is the fraction of the critical density coming from CDM at a given value of time (or of the scale factor). This equation is often called the Mészáros equation. It can be obtained by combining Eq. (269) with the (00) component of the Einstein equation (or its Poisson limit) and the Friedmann equation. The careful reader might have noticed something suspicious: the gravitational force term $k^2\psi$ has been eliminated in favor of $\delta_{\rm cdm}$, while the first Einstein equation (or its Poisson limit) involves the total density fluctuation. Hence, shouldn't Eq. (270) feature also δ_γ, $\delta_{\rm b}$ and δ_ν? Actually, it turns out that the above equation is a really good approximation for the CDM equation of evolution in all regimes, under our assumption $\Omega_{\rm b} \ll \Omega_{\rm cdm}$. It applies even during radiation domination, when photon fluctuations are potentially large. In this course, we do not have enough time for justifying this point, but we refer the reader to Weinberg[3, 4] for a detailed explanation.

During radiation domination, the Friedmann equation gives $a \propto \eta$, and $\Omega_{\rm cdm}$ is much smaller than one. Hence we can neglect the last term in the Mészáros equation, and find that the two solutions are $\delta_{\rm cdm} =$ constant and $\delta_{\rm cdm} \propto \log\eta$. Hence CDM fluctuations grow logarithmically. During matter domination, $a \propto \eta^2$ and $\Omega_{\rm cdm} \simeq 1$, so the solutions are $\delta_{\rm cdm} \propto \eta^2$ and $\delta_{\rm cdm} \propto \eta^{-3}$. Then, CDM fluctuations grow quadratically with η. (These are only asymptotic solutions, but the Mészáros equation can actually be solved analytically at all times). During Λ domination,

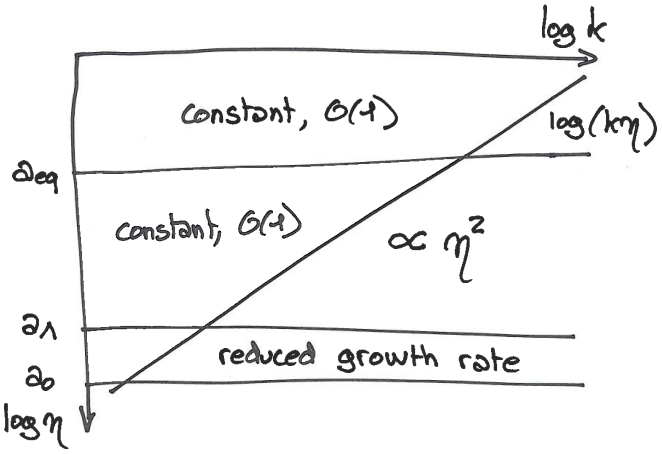

Figure 150: Qualitative evolution of the transfer function $\delta_{\rm cdm}(\eta, k)$ (normalized as usual to $\mathcal{R}(k) = 1$ at initial time) in different regimes: during radiation domination, matter domination, Λ domination, and on super/sub-Hubble scales.

the function $a(\eta)$ is more complicated, and $\Omega_{\rm cdm}$ decreases. With a bit of work, one can show that $\delta_{\rm cdm}$ grows at a smaller rate than during matter domination (i.e. slowlier than η^2), and that the reduction of the growth rate does not depend on k.

In summary, during radiation domination, $\delta_{\rm cdm}(\eta, k)$ is constant on super-Hubble scales and grows logarithmically on sub-Hubble scales. A more precise calculation would show that up to a numerical factor of order one, $\delta_{\rm cdm}$ is given on sub-Hubble scales by $\delta_{\rm cdm}(\eta, k) = \log(k\eta)$. During matter domination, $\delta_{\rm cdm}(\eta, k)$ is still constant on super-Hubble scales, and grows like η^2 on sub-Hubble scales. Finally, during Λ domination, it grows more slowly. These different behaviors are reported in Fig. 150.

This simple discussion is sufficient for understanding the shape of the matter power spectrum at different time. Like in a cartoon, Fig. 151 shows this shape at four different times: at some initial time when all relevant modes are super-Hubble; at radiation/matter equality; at matter/Λ equality; and today. Let us comment these plots. We first need to define the comoving wavenumbers corresponding to wavelengths crossing the Hubble radius at the time of radiation/matter equality, of matter/Λ equality, and today:

$$k_{\rm eq} = a_{\rm eq} H_{\rm eq} \ , \qquad k_\Lambda = a_\Lambda H_\Lambda \ , \qquad k_0 = a_0 H_0 \ . \tag{271}$$

We can now review the evolution of $P(k)$ with respect to time, following the same steps as in Fig. 151.

1. At initial time, if we assume a scale-invariant spectrum with $n_{\rm s} = 1$, we see from Eq. (268) that $P(k) \propto k^{-3}$, with an amplitude given by $A_{\rm s}$.

2. During radiation domination, modes grow logarithmically inside the Hubble radius, like $\log(k\eta)$. At equality, super-Hubble modes ($k_{\rm eq}\eta \ll 1$) are still shaped like at initial time, while sub-Hubble modes ($k_{\rm eq}\eta \gg 1$) have been enhanced by a factor $[\delta_{\rm cdm}(\eta_{\rm eq}, k)/\delta_{\rm cdm}(\eta_{\rm ini}, k)]^2 \simeq [\log(k\eta_{\rm eq})]^2$. The two asymptots of $P(k)$ are then given by k^{-3} for $k \ll k_{\rm eq}$ and $k^{-3}[\log(k)]^2$ for $k \gg k_{\rm eq}$.

3. At the end of matter domination, when $a = a_\Lambda$, modes still outside the Hubble radius keep being shaped like at initial time. This concerns all modes with $k \ll k_\Lambda$. Modes $k \gg k_{\rm eq}$ have been amplified during matter domination by a factor $[\delta_{\rm cdm}(\eta_\Lambda, k)/\delta_{\rm cdm}(\eta_{\rm eq}, k)]^2 \simeq$

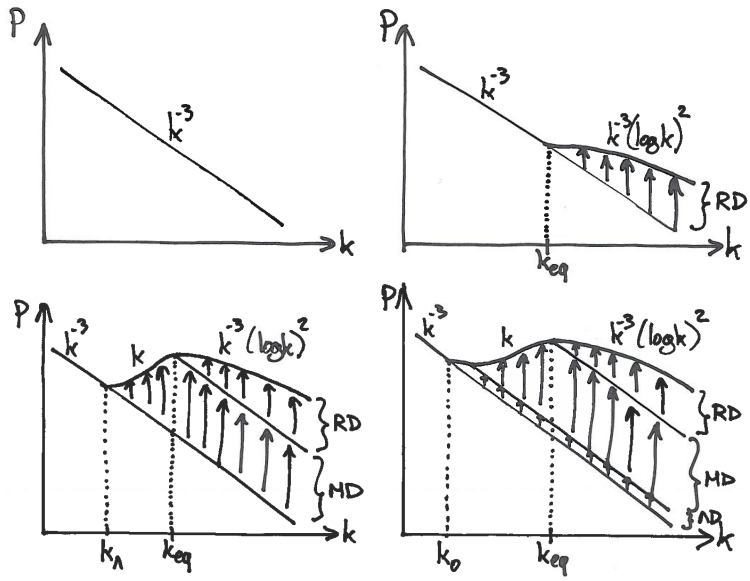

Figure 151: Shape of the matter power spectrum $P(k)$ (log-log scale) at four different times: *(upper left)* when initial conditions are imposed (and all wavenumbers are super-Hubble); *(upper right)* at radiation/matter equality (arrows show the logarithmic growth during radiation domination); *(lower left)* at matter/Λ equality (lower set of arrows show the growth during matter domination); *(lower right)* today (lower set of arrows show the growth during Λ domination).

$(\eta_\Lambda/\eta_{\rm eq})^4$. This factor does not depend on k and preserves the shape of the power spectrum on those scales. Finally, intermediate modes entering the Hubble scale during matter domination have been amplified by $(\eta_\Lambda/\eta_*)^4$, where η_* is their time of Hubble crossing, given approximately by $\eta_* = 1/k$. Hence they have been amplified by $(k\eta_\Lambda)^4$. Putting all these informations together, we see that the spectrum has three branches, scaling respectively like:

- $P(k) \propto k^{-3}$ for $k < k_\Lambda$,
- $P(k) \propto k^{-3}k^4 = k$ for $k_\Lambda < k < k_{\rm eq}$,
- $P(k) \propto k^{-3}(\log k)^2$ for $k > k_{\rm eq}$.

4. During Λ domination, $\delta_{\rm cdm}(k,\eta)$ grows more slowly than η^2, but it still grows at the same rate for all sub-Hubble modes. So the shape of the power spectrum today is unaltered by this stage, and given by:

   - $P(k) \propto k^{-3}$ for $k < k_0$,
   - $P(k) \propto k^{-3}k^4 = k$ for $k_\Lambda < k < k_{\rm eq}$,
   - $P(k) \propto k^{-3}(\log k)^2$ for $k > k_{\rm eq}$.

   We do not enter into details for the small range of modes obeying $k_0 < k < k_\Lambda$.

All this discussion was carried under the assumption of a scale-invariant primordial spectrum. If $n_{\rm s} \neq 1$, the above shape should simply be rescaled by $k^{n_{\rm s}-1}$, and the three branches of the power spectrum are given by:

- $P(k) \propto k^{n_{\rm s}-4}$ for $k < k_0$,
- $P(k) \propto k^{n_{\rm s}}$ for $k_\Lambda < k < k_{\rm eq}$,
- $P(k) \propto k^{n_{\rm s}-4}(\log k)^2$ for $k > k_{\rm eq}$.

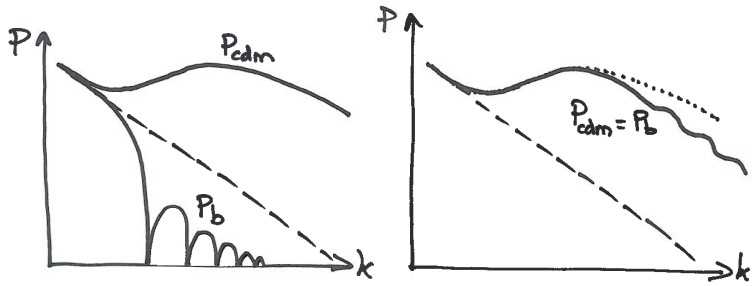

Figure 152: *(Left)* Shape of the baryon and CDM power spectra just before the baryon drag time, compared to the shape of the primordial spectrum (dashed line). *(Right)* Shape of the matter power spectrum well after the baryon drag time, when baryons and CDM perturbations have reached gravitational equilibrium, compared to the shape of the primordial spectrum (dashed lines) and to the spectrum of a CDM-dominated universe (dotted line).

This closes the presentation of the shape of $P(z,k)$ in the limit $\Omega_{\rm b} \ll \Omega_{\rm cdm}$. What remains to be seen is the impact of a non-negligible baryon fraction on the power spectrum.

Baryon corrections. We must define a new important time in the evolution of the universe: the baryon drag time. The photon decoupling time was defined through the maximum of the photon visibility function $g(\eta)$. But there are many more photons than baryons in the universe. Hence, for some amount of time after photon decoupling, baryons keep tracking photon perturbations: in other words, the baryon population decouples later than the photon population (seen as a whole).

Until the baryon drag time, we know that $\delta_{\rm b} = \frac{3}{4}\delta_\gamma$. After that time, baryons do not experience significant Thomson scattering anymore. They only feel gravity, and collapse in gravitational potential wells.

We know qualitatively the behavior of the baryon transfer function $\delta_{\rm b}(\eta,k)$ just before baryon drag, since in the CMB section we have studied the behavior of the photon transfer function. We know that $\delta_{\rm b} = \frac{3}{4}\delta_\gamma$ is constant on super-sound-horizon scales, experiences stationary oscillations on sub-sound-horizon scales during radiation domination, and finally damped oscillations on sub-sound-horizon scales during matter domination. Moreover, we expect that at any time — and particularly at the approach of decoupling — the relation $\delta_{\rm b} = \frac{3}{4}\delta_\gamma$ breaks on very small wavelengths comparable to the mean free path of baryons in the imperfect baryon-photon fluid, but here we will not discuss such small scales.

The behavior of the CDM transfer function $\delta_{\rm cdm}(\eta,k)$ before baryon drag is still given by the Mészáros equation: deep inside the sound horizon, baryons are much less clustered than CDM, so that CDM is almost self-gravitating.

In the left plot of Fig. 152, we sketch the qualitative behavior of the individual power spectrum of baryons and CDM just before baryon drag ($P_{\rm b}(k)$ and $P_{\rm cdm}(k)$ are defined as in Eq. (268), with $\delta_{\rm m}$ replaced either by $\delta_{\rm b}$ or $\delta_{\rm cdm}$).

After baryon drag, baryons collapse in potential gravitational wells. Since $\delta_{\rm b}$ grows, CDM will start to feel the gravity of baryons. Finally, because CDM and baryons are two collisionless species feeling the same gravitational forces, they will equilibrate with $\delta_{\rm b} = \delta_{\rm cdm}$. The gravitational potential is then related to this common value by the (00) Einstein equation (or its Poisson sub-Hubble limit). This is not true however on very small scales, for which the baryon pressure cannot be neglected, but here we do not discuss such small scales.

Hence, after a quick relaxation period, the two power spectra of baryons and CDM are equal to each other, $P_{\rm b}(k) = P_{\rm cdm}(k) = P(k)$. In order to relate this common power spectrum to the individual power spectrum of baryons and CDM before baryon drag, one must follow a

Independent leading effects controlling the shape of the matter power spectrum $P(k)$ in the minimal ΛCDM model.

	Effect	Relevant quantity	Parameter
(P1)	**scale of the maximum**	$k_{\rm eq}$	$\omega_{\rm m}, \Omega_\Lambda$
(P2)	**slope for $k \gg k_{\rm eq}$ and BAO amplitude**	$\Omega_{\rm b}/\Omega_{\rm cdm}$	$\omega_{\rm b}, \omega_{\rm m}$
(P3)	**BAO scale**	$r_{\rm s}(\eta_{\rm drag})$	$\omega_{\rm b}, \omega_{\rm m}$
(P4)	**Global amplitude**	**amplitude of primordial spectrum and duration of ΛD**	$A_{\rm s}, \Omega_\Lambda$
(P5)	**Global tilt**	**tilt of primordial spectrum**	$n_{\rm s}$

matching process described in details in Einsteinstein and Hu [661]. Intuitively, the matching depends on the relative weight of baryons and CDM, i.e. on the ratio $\Omega_{\rm b}/\Omega_{\rm cdm}$. In the limit $\Omega_{\rm b} \ll \Omega_{\rm cdm}$, what we wrote at the beginning of this section applies. In the limit $\Omega_{\rm b} \gg \Omega_{\rm cdm}$, the power spectrum is very suppressed with respect to the CDM-dominated case, with a much more negative slope on average, and some large oscillations corresponding to photon-baryon acoustic waves before decoupling. Finally, if $\Omega_{\rm b}$ is a bit smaller than $\Omega_{\rm cdm}$ but not negligible (as it is the case in our universe), the power spectrum departs slightly from a pure CDM one, with a smooth step-like suppression plus small oscillatory patterns, which are the smoking gun in the recent universe of baryon-photon acoustic oscillations happening before photon decoupling. This is illustrated on the right plot of Fig. 152. These oscillations are called Baryon Acoustic Oscillations (BAO).

LSS observations can only probe the power spectrum on scales much smaller than the radius of the observable universe, i.e. than the current Hubble radius. For this reason, the first of the three branches described above is unobservable[121]. We can only measure the second and third branches, behaving respectively like $P(k \ll k_{\rm eq}) \propto k^{n_{\rm s}}$ and, in first approximation, $P(k \gg k_{\rm eq}) \propto [k^{n_{\rm s}-4}(\log k)^2]$, plus the titling and superimposed oscillations coming from baryons.

Parameter dependence

The discussion presented in the previous section allows us to understand which effects and which parameters impact the shape of the matter power spectrum in the minimal (flat) ΛCDM model, parametrized by

$$\{A_{\rm s}, n_{\rm s}, \omega_{\rm b}, \omega_{\rm m}, \Omega_\Lambda, \tau_{\rm reio}\} \tag{272}$$

(see Sec. 12.9.2 for details on this parametrization). We can already notice that the reionization optical depth is relevant for the CMB spectrum but not for $P(k)$, since it only impacts the scattering rate of photons in the recent universe. Other effects are described in Table **??**. Below, we give more details on these effects.

[121] The first unobservable branch is actually gauge-dependent: it behaves like $k^{n_{\rm s}-4}$ in the Newtonian gauge, but not in other gauges. Note that truly observable quantities are always gauge-invariant. We have been a bit uncareful when saying that LSS data probes the power spectrum of $\delta_{\rm m}$. In fact, different LSS observations probe different quantities, each of them being gauge-invariant. However, well inside the Hubble region, all these quantities coincide with each other and with the spectrum of $\delta_{\rm m}$ computed in an arbitrary gauge (up to small corrections that may become important in the future, but not with current experimental sensitivities).

(P1) The time of equality determines the scale $k_{\rm eq}$ of the power spectrum peak. More precisely, if this scale is expressed in units of $h\,{\rm Mpc}^{-1}$, which is the usual convention, then one can show that the scale of the maximum depends on both $z_{\rm eq}$ and $\Omega_{\rm m}$ (i.e. on our parameter basis on $\omega_{\rm m}$ and $\Omega_\Lambda = 1 - \Omega_{\rm m}$).

(P2) The baryon abundance (relative to CDM) is crucial at the matching time: a high baryon abundance leads to more suppression of the power spectrum for $k \geq k_{\rm eq}$, and to more pronounced BAOs.

(P3) We have seen that the scale of acoustic oscillations is set by the sound horizon at a given time. Since photons decouple at $\eta_{\rm dec}$, the scale of oscillations on the last scattering surface is set by $d_s(\eta_{\rm dec})$, corresponding to the comoving scale $r_s(\eta_{\rm dec}) = d_s(\eta_{\rm dec})/a(\eta_{\rm dec})$. Similarly, since baryons decoupled at $\eta_{\rm drag}$, the scale of BAOs depends on $d_s(\eta_{\rm drag})$ at baryon drag, corresponding to the comoving scale $r_s(\eta_{\rm drag}) = d_s(\eta_{\rm drag})/a(\eta_{\rm drag})$. As explained in Sec. 12.9.2, the sound horizon at a given time depends on $\omega_{\rm b}$ and $\omega_{\rm m}$. In the case of $d_s(\eta_{\rm drag})$ the dependence on $\omega_{\rm b}$ is even stronger because the time of baryon drag itself depends strongly on the baryon abundance.

(P4) The global amplitude depends of course on the primordial spectrum amplitude, i.e. on $A_{\rm s}$. Also, we have seen that during Λ domination, the growth rate of fluctuations is reduced with respect to matter domination, but is independent of k for all sub-Hubble scales. Hence, Ω_Λ also affects the global amplitude of the power spectrum.

(P5) The global tilt depends of course on the primordial spectrum tilt, i.e. on $n_{\rm s}$.

This discussion shows that in principle, a precise measurement of the matter power spectrum today (or at a given redhsift) would allow to measure independently $\omega_{\rm b}$, $\omega_{\rm m}$, $n_{\rm s}$, $A_{\rm s}$ and Ω_Λ (assuming a flat ΛCDM universe). In practice, given the limited precision of current data sets, some of the effects described above are degenerate with each other, and matter power spectrum observations are mainly useful in combination with CMB observations, since they bring independent and complementary information.

Future experiments will use all the discriminating power of the matter power spectrum. They will perform accurate measurements of $P(k,z)$ at different redshifts. This is crucial for at least two reasons:

- First, the effect of Ω_Λ in **(P5)** is redshift dependent: at different redshifts, fluctuations have spent more or less time during the Λ dominated regime, and the power spectrum amplitude has been more or less affected. Hence, the comparison of the amplitude at different redshifts allows to measure Ω_Λ, or more generally to test the compatibility of the data with a cosmological constant (rather than some dynamical Dark Energy model).

- Second, BAOs appear at a fixed comoving wavenumber $k_{\rm BAO}$ in Fourier space (related to $r_s(\eta_{\rm drag})$), but if we measure it in different LSS datasets at different redshifts (corresponding to different shells in real space), this scale will be seen under different angles[122]. By comparing the BAO angle at different redshifts, one can reconstruct the angular diameter distance, and therefore the expansion history at different redshifts. This is another way of measuring Ω_Λ or testing the Λ model versus DE models.

[122]Here we are assuming that the BAO scale is measured in each redshift shell transversally, i.e. in the direction orthogonal to the line of sight. Real experiments probe the BAO scale both transversally and longitudinally, so the situation is a bit more subtle than in this simplified discussion.

Effects of dark matter on CMB and matter spectrum

The existence of Dark Matter (DM) was first postulated by astronomers in order to account for the velocity of stars in the Milky Way (Oort, 1932), and that of galaxies in the Coma cluster (Zwicky, 1933). Later on, it has been firmly established that if general relativity applies to galactic scales and above, some form of DM halo must be present in most galaxies and clusters.

Most of the dark matter is cold. If DM is made of collisionless and stable particles, the only DM property that can be probed by cosmological perturbations is its velocity distribution.

At the level of homogeneous cosmology, the DM phase-space distribution f only depends on momentum p. The number of particles in a given momentum bin is given by $dp\,p^2 f(p)$. If $p^2 f(p)$ is very peaked near $p = 0$ or the DM mass is very large, DM particles have a negligible velocity dispersion. In this case, they can be represented effectively as a pressureless fluid, as explained in Sec. 12.9.1. We recall that they are not forming a real fluid, due to the absence of interactions, but since their velocity dispersion is negligible, all particles have approximately the same bulk velocity in each point (described by the divergence $\theta_{\rm cdm}$). In that case the DM component is called Cold Dark Matter (CDM).

If $p^2 f(p)$ is not very peaked near $p = 0$ or the DM mass is not very large, a significant fraction of DM particles may have a velocity p/m comparable to the speed of light, or at least to that of astrophysical objects. Typically, if the velocity dispersion is of the order of 10^{-3} (in units of c) or larger, it cannot be neglected when studying the CMB or LSS spectra. In that case, the velocity of individual particles results from two physical mechanisms: the dynamics imposed by gravitational forces, plus an intrinsic velocity distributed stochastically, according to the phase-space distribution. The notion of "velocity dispersion" refers to the second component, since the first effect tends to impose the same bulk velocity to all particles in a given point. DM with a large velocity dispersion cannot be described by fluid equations like CDM. A famous example of DM particles with a large velocity dispersion is neutrinos. The velocity dispersion is then fixed by the neutrino mass, and by their Fermi-Dirac distribution. Such DM is called Hot Dark Matter. Possible DM species with a smaller (but still significant) velocity dispersion are called Warm Dark Matter[123].

Since CDM is a very generic limit, and neutrinos are know to exist since the 1950's, the two most popular DM models until the 1990's were CDM and HDM. CDM can be motivated by many possible extensions of the standard model of particle physics (supersymmetry, Peccei-Quinn symmetry, etc.), predicting some early decoupled stable particles, with a very small velocity dispersion. HDM was motivated at that time by massive neutrinos with masses of the order of ~ 10 eV.

These two models lead to very different predictions for the matter power spectrum. We have discussed before the case of CDM. A study of perturbations in a HDM (or ΛHDM) model would show that for $k \geq k_{\rm eq}$, the power spectrum $P(k)$ would decrease with a much steeper slope. The physical explanation is that the velocity dispersion of HDM particles prevents them from clustering on small scales: hence the growth rate of $\delta_{\rm m}$ inside the Hubble radius is considerably reduced in the HDM model.

In the 90's, the first estimates of the matter power spectrum $P(k)$ (or of some related quantities) on galaxy scales and cluster scales showed clearly that the HDM scenario was ruled out. Today, using more accurate LSS data, it is firmly established that most of the DM must be cold (or eventually, warm, but with such a small velocity dispersion that WDM would be indistinguishable from CDM at least on the largest observable scales). Still, we cannot exclude

[123]The limit between HDM and WDM is usually placed in the following way: both types of particles have a sizable velocity dispersion, but most HDM particles become non-relativistic after radiation/matter equality, while most WDM particles become non-relativistic before that time.

the presence of a subdominant hot or warm component. In fact, since we know that neutrinos have a small mass (of the order of ~ 0.1 eV), we do expect that a few percents of DM is hot. Since the signature of this sub-leading component has not yet been detected, the minimal model is still ΛCDM.

In the ΛCDM case, cosmological perturbations can only measure one DM-related parameter: its relic density, parametrized by $\omega_{\rm cdm}$. This is better than nothing: the value of $\omega_{\rm cdm}$ can be used to constrain some fundamental parameters governing DM production, within the framework of a postulated model.

Measuring $\omega_{\rm cdm}$ with the CMB. Going back to Sec. 12.9.2, we see that $\omega_{\rm cdm}$ can be measured "indirectly" using CMB observations: effect **(C2)** measures $\omega_{\rm b}$, effect **(C3)** measures $\omega_{\rm m}$, and $\omega_{\rm cdm}$ is given by the difference between these two parameters.

There is no more "direct" effect of CDM that could be probed with the CMB. A priori, we could think that photons are affected by gravitational forces generated by CDM. This gravitational interaction could only be relevant before photon decoupling, and around the time of sound horizon crossing for each given wavelength (we have seen in Sec. 12.9.2 that well inside the sound horizon, photons do not feel gravitational forces anymore, because pressure forces are much larger). But around sound horizon crossing, photons feel mainly the gravitational forces generated by themselves, by neutrinos, and to a lesser extent by baryons. In fact, in this regime, CDM and other components are effectively decoupled[3].

Hence the CMB probes the CDM abundance only indirectly, as a "missing mass", exactly like in astrophysics: it measures the total matter density through the time of equality, the baryon density through the ratio between odd and even peaks, and the difference must be attributed to a non-relativistic component not interacting with the photons: Dark Matter.

In this discussion, we concentrated only on effects **(C2)** and **(C3)**. Indeed, effects **(C1)** and **(C4)** are also sensitive to $\omega_{\rm b}$ and $\omega_{\rm cdm}$, but only in combination with other parameters. So, unlike **(C2)**+**(C3)**, they do not bring a robust and nearly model-independent evidence for DM.

Measuring $\omega_{\rm cdm}$ with the matter power spectrum. The overall shape of $P(k)$ for $k \geq k_{\rm eq}$ brings very strong support for CDM (or eventually WDM with a small enough velocity dispersion). Indeed, a universe with only baryonic matter, or baryonic plus hot dark matter, would have a radically different power spectrum (with a very steep slope for $k \geq k_{\rm eq}$, and eventually huge BAOs in the purely baryonic case). More precisely, data on the matter power spectrum allows to measure the ratio $\omega_{\rm b}/\omega_{\rm cdm}$ through effect **(P2)** of Sec. 12.9.3. Hence the matter power spectrum probes the CDM abundance independently of the CMB. This probe is more direct, since $P(k)$ is really sensitive to the gravitational clustering of CDM inside the Hubble radius.

Signatures of DM annihilation or decay in the CMB. Depending on the underlying particle physics model, DM particles could either annihilate or decay. Of course, the annihilation or decay rate should be very small, since we need a stable dark matter population. Still, a small annihilation or decay rate could play a role in the recent thermal history of the universe, and in particular in the evolution of the ionized fraction of atoms, $x_e(z)$, to which the CMB is sensitive. Indeed, DM annihilation/decay products may include photons that could directly ionize hydrogen atoms, or particles that could reheat the inter-galactic medium. These mechanisms tend to increase x_e at a given time. Their efficiency depends on the mass of DM particles, on their cross-section in the case of annihilation, and on their lifetime in the case of decay.

Before recombination and photon decoupling, the ionization fraction is anyway very close to one. In the minimal cosmological model, x_e drops abruptly after recombination, freezes out when particles leave chemical equilibrium, and increases again to one at the time of reionization, due to ionizing photons emitted at star formation. DM annihilation or decay could potentially

modify this picture and play two roles:

- at high redshift (typically $600 < z < 1100$), it could slow down the drop of x_e after recombination, and increase its freeze-out value. This would appear in the CMB as a shift in the time of decoupling (impacting effect **(C1)** and **(C4)** of Sec. 12.9.2), as a broadening of the peak of the visibility function $g(\eta)$ (i.e. the last scattering "surface", which is in fact more like a shell, would be thicker, impacting **(C4)**), and as an increase of the optical depth to recombination (impacting **(C8)**, but not on the same scales as reionization).

- at small redshift (typically $z < 40$), the concentration of DM in halos could enhance its annihilation/decay rate, and annihilation/decay products could reionize atoms and increase x_e. This would be equivalent to some extra reionization: it could modify the reionization time or history, and impact **(C8)**.

The recent literature shows that for realistic models, CDM annihilation could play these two roles: hence, interesting bounds on DM annihilation can be derived from the CMB. These bounds are complementary from those inferred from cosmic ray data, or direct detection experiments.

DM decay could play the second role, but the bounds on the DM lifetime inferred in this way from the CMB are not as strong as those from cosmic ray data.

These effects had to be mentioned in this section, because they are part of the interplay between DM physics and cosmological perturbation theory. We do not discuss here bounds on DM annihilation/decay from cosmic ray data, since they have little to do with the evolution of linear cosmological perturbations.

What else could we learn on DM from CMB or LSS data? In the simplest cosmological scenario, cosmological perturbations only probe the relic abundance of DM particles. If we are lucky, they may provide some hint of DM annihilation. There are other properties of DM that can be tested with cosmological perturbations, even if at the moment, everything is consistent with the minimal ΛCDM picture:

- the small mass of neutrinos implies a small fraction of HDM, with distinct effects on the CMB and LSS power spectrum[1] (effects on $P(k)$ are larger: a small neutrino mass implies a step-like suppression of the power spectrum on small scales, by at least 4% if we assume the smallest possible neutrino masses that are consistent with neutrino oscillations experiments).

- a non-negligible velocity dispersion of the dominant DM component (like in the WDM model) or of a fraction of it (in the case of several DM species) would also induce a suppression of the small-scale matter power spectrum, at a scale and with a shape depending on the mass and momentum distribution of the warm species. However, such a feature is clearly not observed in the matter power spectrum on linear scales. Such a signature could only be found on smaller scales, affected by non-linear gravitational clustering.

- instead of being treated as collisionless, DM could experience small interactions with itself or with other species (photons, neutrinos baryons). All these possibilities require a case-by-case analysis, and usually predict observable features similar to WDM. Both the CMB and the matter power spectrum can be used to put very strong bounds on a possible DM interactions.

In conclusion of this section, it appears that CMB and LSS observations bring some crucial information concerning the abundance and the nature of Dark Matter. But as long as everything is compatible with the minimal ΛCDM scenario, CMB and LSS data are only telling us what DM cannot consist of, rather than what it is.

Effects of dark energy on CMB and matter spectrum

In this course, we assumed for simplicity that the (at least apparent) acceleration of the universe is caused by a cosmological constant. The possibility that acceleration would be caused by a dynamical component, called generically Dark Energy (DE), is one of the most investigated questions in cosmology. Of course, the acceleration could also be caused by some alternative theory of gravity, different from General Relativity on very large scales. Even in that case, everything could be reformulated in terms of a dark energy component (by moving new terms from the left to the right hand-side of the Einstein equation). Hence, measuring DE parameters is a rather generic way to look for deviations from a simple cosmological constant[124].

Possible Dark Energy parameters. At the background level, the stress-energy tensor of any species compatible with the assumption of a homogeneous and isotropic FL universe must be diagonal, involving only two function $\bar{\rho}_{\rm de}(a)$ and $\bar{p}_{\rm de}(a)$, related to each other by an equation of conservation of energy. Hence these two functions are not independent of each other, at least as long as DE is not interacting with other species. Even if in general a DE model has no reasons to obey to an equation of state, one can always define the function $w(a) \equiv \bar{p}_{\rm de}(a)/\bar{\rho}_{\rm de}(a)$.

A cosmological constant corresponds to $w(a) = -1$, i.e. to a constant density $\bar{\rho}_{\rm de} = -\bar{p}_{\rm de}$, parametrized by the value of $\Omega_\Lambda = \Omega_{\rm de} \equiv \bar{\rho}_{\rm de}/\rho_{\rm crit}$ today.

A simple extension of this model is the wCDM scenario, in which one assumes a linear and constant equation of state $\bar{p}_{\rm de} = w\bar{\rho}_{\rm de}$, leading to $\bar{\rho}_{\rm de} \propto a^{-3(1+w)}$ by virtue of energy conservation. This model has two independent DE parameters, $\Omega_{\rm de}$ and w.

However, w could in principle vary with time. In a purely phenomenological approach, after confronting the wCDM model to observations, one can test a model with one more free parameter, accounting for the variation of w today. Then, there are three DE parameters, for instance $\Omega_{\rm de}$, $w(a_0)$ and $\frac{dw}{da}(a_0)$.

At the level of perturbations, different DE models with a given background evolution could differ through their pressure perturbation, or their anisotropic stress. First, let us stress that DE cannot be a perfect fluid. If this was the case, DE would have an adiabatic sound speed obeying to

$$c_a^2 \equiv \frac{\bar{p}'}{\bar{\rho}'} = \frac{(w\bar{\rho})'}{\bar{\rho}'} = w + \frac{w'}{3\frac{a'}{a}(1+w)} \tag{273}$$

where in the last equality we have used energy conservation. Given observational constraints on w and w' today, the squared adiabatic sound speed of dark energy must be negative. If the actual squared sound speed $c_s^2 \equiv \frac{\delta p_{\rm de}}{\delta \rho_{\rm de}}$ was negative, then DE perturbations would be unstable, and would explode exponentially, in contradiction with observations. This proves that for DE, $c_s^2 \neq c_a^2$. The stability of DE perturbations imposes $c_s^2 > 0$. On the other hand, the absence of superluminal propagation in conventional physics imposes an upper bound, $c_s^2 \leq 1$.

In phenomenological studies of DE models, the default assumptions concerning DE perturbations is that *(i)* pressure perturbations are related to density perturbations through $c_s^2 = 1$, and that *(ii)* anisotropic stress is negligible. This is justified by the fact that DE could be a scalar field (often called quintessence). If this is the case, one can easily show that the sound speed is indeed equal to one[125], while anisotropic stress only appears at second order in perturbations.

[124] Note that alternatively, the observed apparent acceleration might be the consequence of a departure from the homogeneous Friemann-Lemaître model, but we will not discuss such a possibility (which is very constrained and maybe already excluded by observations) in this course.

[125] Actually, the quantity $\delta p_{\rm de}/\delta\rho_{\rm de}$ is gauge dependent. Everything becomes clearer if one decides to call "sound speed" the ratio $\delta p_{\rm de}/\delta\rho_{\rm de}$ calculated *in the frame comoving with the DE fluid*, i.e. in a gauge such that the velocity divergence $\theta_{\rm de}$ vanishes. If the sound speed of a given component derives from some fundamental principle, it should take a simple form precisely in this frame. Actually, it is only when this condition is imposed that one finds $\delta p_{\rm de} = \delta\rho_{\rm de}$ for a scalar field.

A DE model with $c_s^2 = 1$ cannot lead to sizable DE perturbations. Indeed, $c_s^2 = 1$ implies that pressure forces in the fluid resist to gravitational collapse. Astrophysicists like to formulate this problem in terms of the Jeans instability. In this language, $c_s^2 = 1$ means that the Jeans length in the fluid is as large as the Hubble radius. Then DE perturbations remain as small as in the primordial universe (of the level of 10^{-5}), and can never leave an observable signature, even during DE domination.

Only if c_s^2 is assumed to be very small, DE perturbations can grow and impact LSS observables. Indeed, if c_s^2 goes to zero, the Jeans length can be arbitrarily small, and perturbations on cosmological scales can be amplified by the Jeans instability. In that case, one needs to postulate whether DE perturbations feature anisotropic stress or not. In a phenomenological approach, one may try to parameterize the anisotropic stress using some effective parameter (like a viscosity parameter). One should stress that a very small sound speed can be assumed, but these models sound artificial: $c_s^2 \ll 1$ is not a generic prediction of "realistic" DE models (if any such model exist).

Probing DE models with CMB and LSS data. If the DE sound speed is not very small, DE models can only be probed through their impact on the background evolution, which affects indirectly the evolution of metric and matter perturbations.

Since the background expansion at late time impacts the angular diameter distance, the CMB is sensitive to DE through effects **(C1)** and **(C4)** of Sec 12.9.2, both depending on $d_{\rm a}(z_{\rm dec})$. However, **(C1)** and **(C4)** are also sensitive to many other quantities, so this probe is only useful in combination with other ones: in the best case it may remove parameter degeneracies.

The LISW effect **(C7)** probes the duration of the DE dominated era, and could bring one bit of information on DE models. In practise, it is however impossible to infer precise constraints from **(C7)** due to the large cosmic variance affecting the C_l's on the scale of the Sachs-Wolfe plateau.

We have seen in Sec 12.9.3 that LSS data can be useful especially if the matter power spectrum is measured accurately at several distinct redshifts. Then, both the evolution of the power spectrum amplitude (in other words, of the linear growth factor) and of the BAO apparent scale encode information on the expansion rate at several redshifts, and therefore on w or even $w(a)$. This is why measurements of $P(k, z)$ with future ambitious programs, like for instance the Large Synoptic Survey Telescope or the Euclid satellite, are expected to provide the most accurate tests of DE models.

In summary, the CMB is not very useful for testing DE models, but can bring a few independent pieces of information; while LSS data at different redshifts is sensitive to the evolution of the background DE density. LSS data should anyway be used in combination with other probes of homogeneous cosmology (like supernovae luminosity) in order to get a maximum amount of information on DE.

The situation that we depicted would change radically if:

- DE would account for a significant fraction of the total energy density even at early times ($z \gg 1$), like in "early dark energy" models: then, DE could affect the CMB more strongly than assumed in the previous discussion;
- large DE perturbations would develop as a consequence of a very small sound speed $c_s^2 \ll 1$: then the total power spectrum (including DE fluctuations) may depart significantly from the ΛCDM one.

Both possibilities are still open, but no such effects are indicated by current data, and there are no solid theoretical motivations for our universe to fall in one of these two cases.

Conclusions and bibliography

We hope that this short — but very dense — introduction to cosmological perturbations was clear enough, and that the reader will feel like going further.

Some readers might regret that, after exposing in details the effect of cosmological parameters on the CMB and LSS spectra (in Secs. 12.9.2, 12.9.3, 12.9.3 and 12.9.3), we did not show concrete bounds from current experiments. There are three reasons for this. First, the duration of the lectures and the length of these notes would have exploded. Second, such information would be outdated very quickly by new data releases. Third, it is actually a very good exercise (and an efficient way to digest this course) to look at published bounds on cosmological parameters (inferred from CMB data, or LSS data, or from both), and to figure out by oneself whether everything is consistent with these notes: we encourage the reader to check that the best and worst constrained parameter combinations can be related to the physical effects described here.

We promised a bibliography in the introduction. We already mentioned Ref. [1], in which one can find a similar but more detailed presentation, plus a discussion of neutrino effects. We have cited in the core of the text three seminal papers (Refs. [2, 3, 661]) providing explicit calculations on precise topics: the line-of-sight integral in Fourier space[2], the justification of the Mészáros equation and of the fact that CDM behaves effectively as a self-gravitating species during radiation domination[3], and the matching between CDM and baryon perturbations around the time of baryon drag, in view of computing analytically baryon effects in the matter power spectrum[661].

Specialists of the field refer regularly to a concise paper of Ma & Bertschinger [1218], containing a remarkably clear presentation of gauge issues and of all equations of motion in two gauges (including the Newtonian one).

Many recent textbooks cover most topics in cosmology, including linear perturbations, CMB and large scale structure. We only mention in the reference list those of S. Dodelson[7], V. Mukhanov[8] and S. Weinberg[4], all three outstanding, but there exist many excellent alternatives. For a presentation more focused on the CMB, we recommend the thesis of W. Hu[9] and the book of R. Durrer[10].

12.10 Probes of Inhomogeneities

The power spectra we have explored in the previous two chapters $-P(k)$ of the density field and C_l of the anisotropies - are the most obvious first tests of any cosmological model. The most direct way of measuring $P(k)$ is to do a redshift survey, wherein the angular positions and the redshifts (which are a measure of radial distance) of galaxies are recorded. There are, however, a number of problems with redshift surveys and their interpretation. The first is the simple fact that taking redshifts is time consuming: it is much easier to get the angular positions of galaxies than it is to also measure redshifts. In the same time that a 10,000 galaxy redshift survey, say, could be completed, a million angular positions of galaxies could be obtained. With the much greater statistics, angular surveys often compensate for the lack of radial information. Indeed, some claim that the best information we have on large-scale clustering comes from angular surveys. Clearly, then, one skill we must acquire is the ability to make predictions about the angular correlation function $w(\theta)$. In Section 9.1 we will see that the angular correlation function is an integral over the 3D power spectrum.

Redshift surveys suffer from another, more profound problem than the fact that they are time consuming. While is true that the redshift gives a reasonable estimate of radial distance (by radial distance I simply mean distance from us), it is not true that this estimate is completely accurate. Recall that a galaxy's velocity is determined solely by the Hubble expansion (and hence redshift is a perfect indicator of distance) only if the galaxy is stationary on the comoving grid. Most galaxies have nonnegligible peculiar velocities; that is, they are moving on this grid.

A galaxy's total velocity, which is measurable, is

$$\vec{v} = \vec{v}_{\rm pec} + \hat{x} v_{\rm H}$$

where the Hubble velocity $v_{\rm H} := \chi da/dt = \chi a H$. Recall that χ is the comoving distance between us and a distant galaxy, so its physical distance from us is $a\chi$. In the absence of peculiar velocities, $\hat{x} \cdot \vec{v}/H$ is a perfect distance indicator. In the real world, though, where peculiar velocities do not vanish, even an accurate measurement of a galaxy's recession velocity does not translate into an unambiguous measurement of its radial distance away from us.

The ambiguity introduced by peculiar velocities offers an opportunity. In linear theory, peculiar velocities are determined by the surrounding density field, so we can correct for the distortions induced by working with redshifts. Indeed, we can go even further and use these distortions to learn about the growth of perturbations, for the precise way in which velocities are related to the density field is determined by the rate at which perturbations grow. Since this rate is determined in cosmology by Ω_m, studying the distribution of galaxies in redshift space is one of the more promising ways to measure Ω_m.

Finally, another way of gleaning information about the underlying mass density is by studying clusters of galaxies. Although strictly speaking, this topic falls in the realm of nonlinear evolution of the density field, and therefore beyond the boundary of this book, the Press-Schechter method of approximating cluster abundances is only a very small step away from linear theory and has been shown to be quite accurate in its predictions. Further, the study of clusters is advancing at an extraordinarily rapid rate, since clusters can now be probed with many different astronomical techniques. Section 9.5 introduces the basic predictions of the Press-Schechter theory and the implications for cold dark matter models.

12.10.1 Angular Correlations

Theory

Figure 9.1 shows the angular positions of over a million galaxies from the Automated Plate Measuring (APM) Survey. In an angular survey such as this, what statistic can be computed that can be compared with theory? The simplest statistic is the two-point function: in real space it is $w(\theta)$ the angular correlation function. In Fourier space, the relevant function is the Fourier transform of w, $P_2(l)$, the two-dimensional power spectrum. In this section we compute both of these very important functions, relating them to the three-dimensional power spectrum.

First let me introduce some notation. Figure 9.2 shows the geometry: a given galaxy is at comoving distance $\chi(z)$ (Eq. (2.42)) away from us. The z-axis is typically chosen so that it points to the center of the distribution of galaxies. In the plane perpendicular to this axis, a galaxy's position is determined by the twodimensional vector $\vec{\theta} = (\theta_1, \theta_2)$. Therefore, the three-dimensional position vector $\vec{x}$ has components

$$\vec{x}(\chi(z), \vec{\theta}) = \chi(z)\,(\theta_1, \theta_2, 1)\,.$$

The assumption that all galaxies are located near the z-axis clearly breaks down if the survey measures structure on very large angular scales. As an example the APM survey in Figure 9.1 covers roughly 50 by 100 square degrees. From this data, one can measure the correlation function accurately out to about 10° or 0.17 radians, safely smaller than unity.

We measure all galaxies along the line of sight, effectively integrating over $\chi(z)$. Therefore an overdensity at angular position $\vec{\theta}$ is

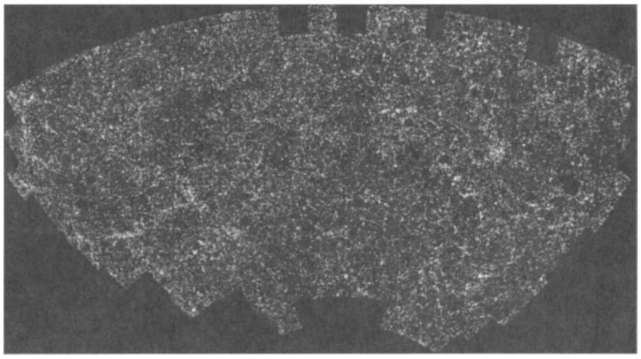

Figure 9.1. The distribution of galaxies in the APM survey. Blacked-out regions were not observed during the survey.

$$\delta_2(\vec{\theta}) = \int_0^{\chi\infty} d\chi W(\chi)\delta(\vec{x}(\chi,\vec{\theta}))$$

where the subscript $_2$ denotes the fact that δ on the left is the angular-or twodimensional - overdensity, while δ on the right is the full three-dimensional overdensity. (And I will stick with this convention: for example P_2 is the 2D power spectrum while P denotes the $3D$ spectrum.) The upper limit on the χ integral corresponds to $z \to \infty$, equal to $\chi_\infty = 2/H_0$ in a flat, matter-dominated universe. In practice, the magnitude-limited surveys that have yielded the most cosmological information to date have probed $z \lesssim 0.5$. The selection function $W(\chi)$ encodes this information: it is the probability of observing a galaxy a comoving distance χ from us. Galaxies at large distances are too faint to be included in a survey, whereas there are relatively few galaxies at very low redshift simply because the volume is small. Since it is a probability, the selection function is normalized so that $\int_0^{\chi\infty} d\chi W(\chi) = 1$

The 2D vector conjugate to $\vec{\theta}$ will be $\vec{l}$, so that the Fourier transform of $\delta_2(\vec{\theta})$ is

$$\tilde{\delta}_2(\vec{l}) = \int d^2\theta e^{-i\vec{l}\cdot\vec{\theta}}\delta_2(\vec{\theta})$$

The two-dimensional power spectrum is defined just as was the 3D:

$$< \tilde{\delta}_2(\vec{l})\tilde{\delta}_2^*(\vec{l}) >= (2\pi)^2\delta^2(\vec{l}-\vec{l})P_2(l)$$

here $\delta^2()$ is the 2D Dirac delta function, not to be confused with the overdensities $\delta_2(\vec{\theta})$. Integrating, we can therefore write the 2D power spectrum as

$$P_2(l) = \frac{1}{(2\pi)^2}\int d^2l' \left\langle \delta_2(\vec{l})\delta_2^*(\vec{l}) \right\rangle$$

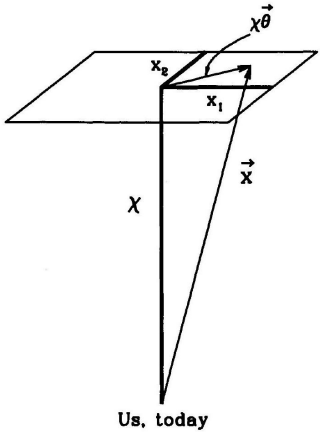

Figure 9.2. A distant galaxy is located at position $\vec{x}$ with respect to us at the origin today. This position can also be expressed in terms of $\chi(z)$, the comoving distance out to the redshift of the galaxy. The $x_1 - x_2$ plane is perpendicular to a suitably chosen x_3-axis. In this plane, a galaxy's position is given by the two-dimensional vector $\chi\vec{\theta}$, so $\vec{x} \simeq \chi(z)\,(\theta_1, \theta_2, 1)$.

$$= \frac{1}{(2\pi)^2} \int d^2l' \int d^2\theta \int d^2\theta' e^{-i\vec{l}\cdot\vec{\theta}} e^{i\vec{l}\cdot\vec{\theta}'} \times \int_0^{\chi_\infty} d\chi W(\chi) \int_0^{\chi_\infty} d\chi' W\left(\chi'\right) \left\langle \delta(\vec{x}(\chi,\vec{\theta}))\delta\left(\vec{x}'\left(\chi',\vec{\theta}'\right)\right)\right\rangle .$$

The integral over $\vec{l}'$ gives $(2\pi)^2$ times a Dirac delta function in $\vec{\theta}'$ and the brackets give the 3D correlation function,

$$\xi\left(\vec{x} - \vec{x}'\right) := \left\langle \delta(\vec{x})\delta\left(\vec{x}'\right)\right\rangle = \int \frac{d^3k}{(2\pi)^3} P(k) e^{i\vec{k}\cdot(\vec{x}-\vec{x}')}$$

The average here $\langle \ldots \rangle$ is over all realizations of the density field. At very small distance, we expect galaxies to be clustered strongly as a result of gravity, so ξ is positive. As the distance gets larger, correlations die off and ξ gets smaller and eventually goes negative. The second line follows since the correlation function is the Fourier transform of the power spectrum (Exercise 1).

Performing the integral over $\vec{\theta}'$ in Eq. (9.6) then leads to

$$P_2(l) = \int d^2\theta e^{-i\vec{l}\cdot\vec{\theta}} \int_0^{\chi_\infty} d\chi W(\chi) \int_0^{\chi_\infty} d\chi' W\left(\chi'\right) \int \frac{d^3k}{(2\pi)^3} P(k) e^{i\vec{k}\cdot\left[\vec{x}(\chi,\vec{\theta}) - \vec{x}(\chi',0)\right]}$$

The argument of the exponential at the end here is $i\left[k_1\chi\theta_1 + k_2\chi\theta_2 + k_3\left(\chi - \chi'\right)\right]$, so the integral over angles $\vec{\theta}$ gives Dirac delta functions setting $l_1 = \chi k_1$ and $l_2 = \chi k_2$. We can use these delta functions to do the k_1 and k_2 parts of the d^3k integration, remembering to divide by the derivative of the argument, in this case putting a factor of χ^2 in the denominator. We are thus left with

$$P_2(l) = \int_0^{\chi_\infty} d\chi \frac{W(\chi)}{\chi^2} \int_0^{\chi_\infty} d\chi' W\left(\chi'\right) \int_{-\infty}^{\infty} \frac{dk_3}{(2\pi)} P\left(\sqrt{k_3^2 + l^2/\chi^2}\right) e^{ik_3[\chi - \chi']}$$

Until now, we have been doing math; to complete the calculation of the power spectrum we need to introduce some physics. I claim that the only 3D Fourier modes that contribute to the integral are those with k_3 very small, much smaller than l/χ. To see why, we first need to estimate l, the variable conjugate to θ. Roughly, l^{-1} is of order the angular scales probed by the survey [1]. Since we are working in the small angle approximation, $l/\chi \sim 1/(\chi\theta) \gg 1/\chi$. Now let's consider Figure 9.3. There

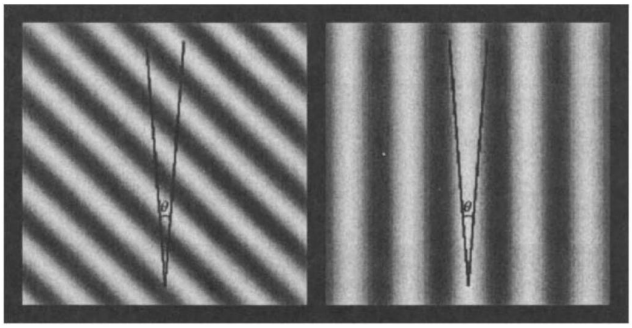

Figure 9.3. Two plane-wave perturbations and their contributions to the 2D power spectrum. Left panel shows a perturbation with longitudinal wavenumber $k_3 \gg \chi^{-1}$ (the $\hat{z}$ direction is vertical). Right panel shows a mode with $k_3 \sim \chi^{-1}$. Angular correlations due to the large k_3 mode (left panel) are negligible since there are many cancellations along the line of sight.

[1] In this sense, l is very similar to the degree of the Legendre polynomials introduced in Chapter 8 to study anisotropies. In the same sense, $P_2(l)$ is very similar to C_l; indeed in Exercise 5 you will show that they are identical on small scales. we see that modes with longitudinal wavenumber k_3 much greater than χ^{-1} do not give rise to angular correlations because of cancellations along the line of sight. Only modes with k_3 smaller than χ^{-1} lead to angular correlations. Therefore, the relevant transverse wavenumbers l/χ are much larger than the relevant longitudinal wavenumbers, and we can safely set the argument of the 3D power spectrum to l/χ (see Exercise 2 for a more systematic justification). With this approximation, the k_3 integral gives a Dirac delta function in $\chi - \chi'$ so

$$P_2(l) = \int_0^{\chi\infty} d\chi \frac{W^2(\chi)}{\chi^2} P(l/\chi)$$

This is an expression for the 2D power spectrum as an integral over the line of sight. We can change dummy variables from $\chi \to k := l/\chi$ to rewrite the integral as

$$P_2(l) = \frac{1}{l} \int_0^{\infty} dk P(k) W^2(l/k)$$

The angular correlation function is the Fourier transform of the 2D power spectrum, so

$$w(\theta) = \int \frac{d^2l}{(2\pi)^2} e^{il\cdot\vec{\theta}} P_2(l).$$

Since P_2 depends only on the magnitude of $\vec{l}$, the angular part of the integration over l is $\int_0^{2\pi} d\phi e^{il\theta\cos\phi}$, which is proportional to $J_0(l\theta)$, the Bessel function of order zero (Eq. (C.21)). Therefore,

$$\begin{aligned} w(\theta) &= \int_0^{\infty} \frac{dl}{2\pi} l P_2(l) J_0(l\theta) \\ &= \int_0^{\infty} dk k P(k) F(k,\theta), \end{aligned}$$

where the second line follows from changing the order of integration. Here the kernel for the angular correlation function is

$$F(k,\theta) := \frac{1}{k}\int_0^\infty \frac{dl}{2\pi} J_0(l\theta) W^2(l/k)$$

The kernel is plotted in Figure 9.4 for two surveys. Note that it is a function of $k\theta$ (see Exercise 3). The kernel is constant at small $k\theta$ and then begins damped oscillations. The contribution from small k though is suppressed because the integral in Eq. (9.13) is over the kernel weighted by $kP(k)$, and the latter goes to zero as $k \to 0$. Therefore, the modes that contribute most to $w(\theta)$ are typically those with wavenumbers of order the first turnover in the kernel, $k\theta \sim 0.2h\mathrm{Mpc}^{-1}$ degrees for APM and a factor of 3 smaller for the deeper Sloan Digital Sky Survey (SDSS). This means that the angular correlation function at 5° in APM is most sensitive to power at $k = 0.04h\mathrm{Mpc}^{-1}$. The wavenumbers contributing to $w(\theta)$ in a deeper

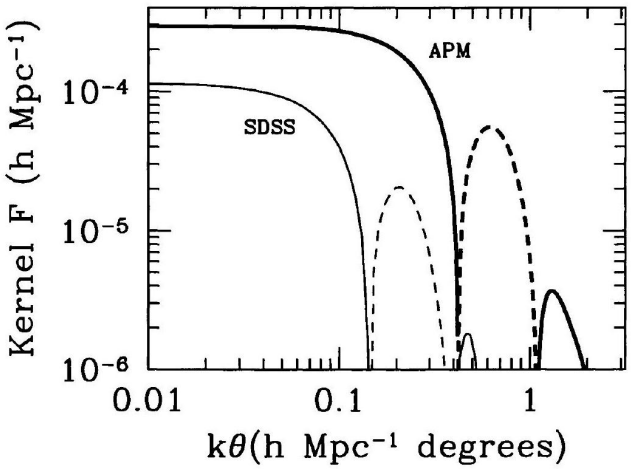

Figure 9.4. The kernel relating the angular correlation function to the 3D power spectrum in two surveys. Kernel is negative when line is dashed, positive otherwise. APM Survey probes galaxies brighter than apparent magnitude $m = 20$, while the Sloan Digital Sky Survey (SDSS) will go much deeper, potentially sensitive to galaxies brighter than $m = 23$.

angular survey are smaller. This makes sense: the same angle probes larger physical scales in a deeper survey.

Figure 9.5 shows the measurements of the angular correlation function from the APM survey. The most important conclusion from the data is that standard Cold Dark Matter - with $\Omega_m = 1$ and $h = 0.5$ - is a bad fit. To quote from the abstract of the Maddox et al. (1990) paper which measured the correlation function, "more large-scale clustering than predicted by popular versions of the Cold Dark Matter cosmogony is implied." Although sCDM has died many deaths since its inception in the early 1980s, the death from APM was perhaps its most celebrated. Despite long, hard work by many people trying to find systematic problems with this and other surveys, nothing significant has changed over the past decade to alter the conclusion that the standard Cold Dark Matter model of structure formation fails to predict accurately the observed pattern of large-scale clustering. Having said that, I want to emphasize that the situation is not quite as severe as you might imagine from a cursory examination of Figure 9.5. Consider the prediction from a Λ CDM model, also shown in Figure 9.5. Although the agreement is much better than with sCDM, there are clear discrepancies on both large and small scales. The small-scale discrepancies are completely illusory, though, because I have used the linear power spectrum to compute $w(\theta)$. Nonlinearites become important on scales of order $k \sim 0.2h\mathrm{Mpc}^{-1}$ as we saw in Chapter 7 (Exercise 10). These scales

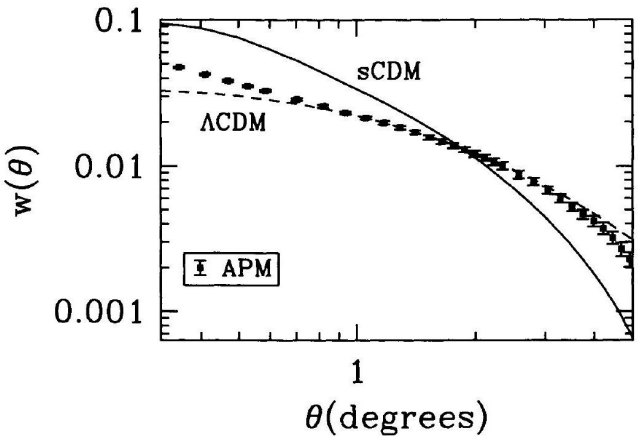

Figure 9.5. Angular correlation function in the APM survey and two theoretical models. Standard CDM (solid curve) is a bad fit to the data, while a model with a cosmological constant (here $\Omega_\Lambda = 0.7$) fits well. The apparent disagreements between the data and Λ CDM on small and large scales are illusory; see text.

contribute to $w(\theta)$ in APM when θ is of order 1°. So to compare to the data fairly, we really need to account for nonlinearities; I have not done this, so we cannot take the small-angle discrepancy seriously. On large angles, people have begun to realize that the data have been overinterpreted. The basic problem is that the points on large angles are highly correlated. So the slight discrepancy between the data and ΛCDM on large angles looks worse than it really is.

The angular correlation function can be inverted to obtain the 3D power spectrum: the results from the APM Survey are shown in the top panel of Figure 9.6. We will discuss inversion techniques in Chapter 11, but you should be aware that the points in Figure 9.6 are the result of a long process (i.e., many papers), in the midst of which error bars were often vastly underestimated. Using only the results on large scales (where nonlinear effects are irrelevant and the relation between mass overdensity and galaxy overdensity is expected to be simple), Efstathiou and Moody (2001) placed constraints on CDM models, shown in the bottom panel of Figure 9.6. We found in Chapter 7 that the CDMI transfer function depends only on $k/k_{\rm eq}$. Since $k_{\rm eq}$ scales as $\Omega_m h^2$ and since surveys measure the wavenumber k in units of hMpc^{-1}, the combination $\Omega_m h$ determines the shape of the power spectrum. For this reason, fits to large-scale structure data are often given in terms of the shape parameter $\Gamma := \Omega_m h$ (sometimes modified to account for baryons: see Exercise 8). Standard CDM with $h = 0.5$ and $\Omega_m = 1$ corresponds to $\Gamma = 0.5$; if the index of the primordial spectrum is $n = 1$, then the bottom right panel of Figure 9.6 shows

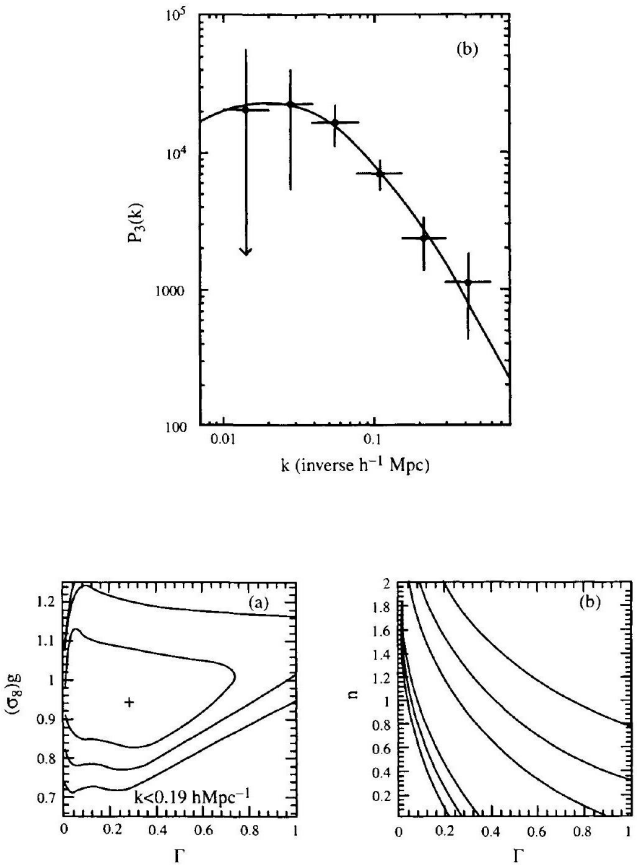

Figure 9.6. Results from the APM Survey (Efstathiou and Moody 2001). Top panel. The 3D power spectrum inferred from the angular correlation function. The curve is a CDM model with $\Gamma\,(\simeq \Omega_m h) = 0.2$, normalized to fit the data. Bottom Panel. Constraints on CDM models from the power spectrum. Three parameters - the shape parameter Γ, the amplitude σ_8, and the index of the primordial power spectrum n - were varied. Contours delineate one-, two-, and three-sigma regions. Left panel shows constraints after integrating over n; right after integrating over the amplitude. Standard CDM has $n = 1; \Gamma = 0.5$; and (COBE-normalized) $\sigma_8 = 1.15$ that sCDM is ruled out at the 2 -sigma level. ΛCDM has $\Gamma \simeq 0.2$ and is indeed a better fit to the data if n is close to 1.

12.10.2 Peculiar Velocities

Theory

In linear theory, velocities are related in a simple way to nearby overdensities. We first derive this relation in this section and then consider some of its ramifications. In particular, we will see that by measuring both the peculiar velocity field and the density field, one can infer the present value of the matter density, Ω_m.

In linear theory, we have already derived the equation which determines the velocity field. On scales well within the horizon, the continuity equation (4.103) reduces to

$$\dot{\delta} + ikv = 0.$$

At late times, though, we have solved for the evolution of δ: we know that it scales as the growth factor D_1, so

$$v(k,\eta) = \frac{i}{k}\frac{d}{d\eta}\left[\frac{\delta}{D_1}D_1\right] = \frac{i\delta(k,\eta)}{kD_1}\frac{dD_1}{d\eta}$$

A function commonly employed to relate the velocity to the density is the dimensionless linear growth rate,

$$f := \frac{a}{D_1}\frac{dD_1}{da}$$

Since $d/d\eta = a^2 H d/da$, the velocity is related to the density via

$$v(k,a) = \frac{ifaH\delta(k,a)}{k}$$

The linear growth rate can be computed from Eq. (7.77). Most probes of the velocity field to date have been limited to relatively nearby objects, $z \lesssim 0.1$, so it is a reasonable approximation to evaluate f today and neglect its evolution. Figure 9.7 shows the linear growth rate today as a function of the matter density. For small Ω_m there is less growth: mass collapsing into overdense regions has lower velocity than if there was a critical density of matter. This makes sense since an overdensity in a lower density universe has less mass and therefore exerts a weaker gravitational pull on infalling matter. Figure 9.7 shows that, for all practical purposes, the growth rate depends only on the matter density and not, say, on the cosmological constant. Also, the approximation

$$f = \Omega_m^{0.6}$$

is seen to work extremely well (see Exercise 7 for a slightly better fit to a flat universe).

There are two important points about the relation between the density and the velocity in Eq. (9.18) that should be emphasized. First, we need to remember that

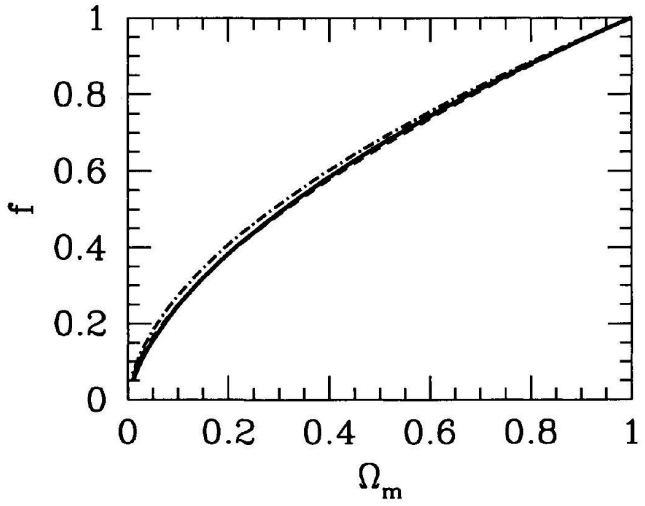

Figure 9.7. The linear growth rate as a function of matter density. There are three curves here, nearly indistinguishable. One (solid) is for an open universe with $\Omega_\Lambda = 0$; another (dot-dashed) for a flat universe with $\Omega_\Lambda = 1 - \Omega_m$; and the last (dashed) is $\Omega_m^{0.6}$.

the velocity is of course a vector and v in Eq. (9.18) is the Fourier component of the velocity parallel to $\vec{k}$. Explicitly, at low redshift we have

$$\vec{v}(\vec{k}) = ifH_0\delta(\vec{k})\frac{\vec{k}}{k^2}$$

The second point about the relation between the velocity and the density is that it holds only in linear theory. This has turned out to be a big problem for those who have tried to extract information from velocity studies. Velocities are easiest to obtain on small scales, but easiest to compare with theory on large scales.

12.10.3 Direct Measurements of Peculiar Velocities

Theory

A number of surveys have directly measured peculiar velocities. Measuring radial velocities is relatively easy: one just looks for shifted features in the spectrum of the galaxy. The hard part is breaking the radial velocity into the part due to the Hubble expansion and the remainder, the peculiar velocity. Subtracting off the Hubble expansion requires independent (i.e., other than the redshift) knowledge of the galaxy's distance from us. How accurate must a distance indicator be to be useful? Very roughly, typical peculiar velocities are of order 500 kmsec^{-1}, while the Hubble velocity is $H_0\chi = 100$ kmsec$^{-1}h(\chi/\mathrm{Mpc})$ for a galaxy a distance χ away. So a galaxy 50Mpc away has a Hubble velocity roughly 10 times as large as its peculiar velocity. To be useful, therefore, a distance indicator for such galaxies much have an accuracy of order 10%. Indeed this is roughly the best one can hope for, so 50Mpc is roughly the farthest one can hope to go in a velocity survey.

There are a number of ways of extracting cosmologically useful information from a velocity survey, but I will focus on just one of these: the two point function. With enough velocities, a survey can hope to measure the correlation function

$$\xi_v\left(\vec{x}_1, \vec{x}_2\right) := \left\langle \vec{v}\left(\vec{x}_1\right) \cdot \hat{x}_1 \vec{v}\left(\vec{x}_2\right) \cdot \hat{x}_2 \right\rangle$$

where the radial components $\vec{v} \cdot \vec{x}$ appear because these are all that can be measured using redshifts. Let us compute this correlation function using linear theory. We will see that it is an integral over the power spectrum, so - just like the angular correlation function of galaxies we considered in Section 9.1-the radial velocity correlation function is a probe of the power spectrum. The observational obstacles involved in obtaining accurate peculiar velocities are daunting. However, the promise of measuring the matter power spectrum (the velocities are due to the matter, which may or may not be aligned with the galaxies) as opposed to the galaxy power spectrum sampled by $w(\theta)$ is so alluring that it is likely that peculiar velocity surveys will continue to play an important role in cosmology.

To evaluate the velocity correlation function, we can Fourier transform the velocities appearing in Eq. (9.21) so that

$$\xi_v\left(\vec{x}_1, \vec{x}_2\right) = \int \frac{d^3k}{(2\pi)^3} e^{i\vec{k}\cdot\vec{x}_1} \int \frac{d^3k'}{(2\pi)^3} e^{-i\vec{k}'\cdot\vec{x}_2} \left\langle \vec{v}(\vec{k}) \cdot \hat{x}_1 \vec{v}^*\left(\vec{k}'\right) \cdot \hat{x}_2 \right\rangle$$

Using linear theory for $\vec{v}$(9.20) and the fact that $\left\langle \delta(\vec{k})\delta^*\left(\vec{k}'\right)\right\rangle = (2\pi)^3\delta^3\left(\vec{k}-\vec{k}'\right)P(k)$ leads to

$$\xi_v\left(\vec{x}_1, \vec{x}_2\right) = f^2 H_0^2 \int_0^\infty \frac{dk k^2}{(2\pi)^3} P(k) \int d\Omega_k e^{i\vec{k}\cdot\left(\vec{x}_1-\vec{x}_2\right)} \frac{\vec{k}\cdot\hat{x}_1\vec{k}\cdot\hat{x}_2}{k^4}$$

One way to do the angular integral here is to write the occurrences of $\vec{k}$ in the integrand as

$$\vec{k}e^{i\vec{k}\cdot\vec{x}} = \frac{1}{i}\frac{\partial}{\partial\vec{x}}e^{i\vec{k}\cdot\vec{x}}$$

where

$$\vec{x} := \vec{x}_1 - \vec{x}_2$$

Then taking the derivatives outside leads to an angular integral over the exponential, which has no azimuthal dependence. The integral of $e^{ikx\mu}$ over μ is is $4\pi j_0(kx)$ (Eq. (C.15)). So we have

$$\xi_v\left(\vec{x}_1,\vec{x}_2\right) = -f^2H_0^2\hat{x}_{1,2}\hat{x}_{2,j}\int_0^\infty \frac{dk}{2\pi^2k^2}P(k)\frac{\partial^2}{\partial x_i\partial x_j}j_0(kx)$$

The first partial derivative here is

$$\frac{\partial j_0(kx)}{\partial x_j} = \frac{\partial(kx)}{\partial x_j}j_0'(kx) = k\frac{x_j}{x}j_0'(kx)$$

where the prime here is derivative with respect to the argument kx. The second derivative then gives

$$\frac{\partial}{\partial x_i}\left[k\frac{x_j}{x}j_0'(kx)\right] = k^2\left[\left\{\delta_{ij}-\hat{x}_i\hat{x}_j\right\}\frac{j_0'(kx)}{kx}+\hat{x}_i\hat{x}_jj_0''(kx)\right].$$

Then, the velocity correlation function is

$$\begin{aligned}\xi_v\left(\vec{x}_1,\vec{x}_2\right) &= -f^2H_0^2\hat{x}_{1,i}\hat{x}_{2,j}\int_0^\infty\frac{dk}{2\pi^2}P(k)\left[\left\{\delta_{ij}-\hat{x}_i\hat{x}_j\right\}\frac{j_0'(kx)}{kx}+\hat{x}_i\hat{x}_jj_0''(kx)\right]\\ &:= \hat{x}_{1,i}\hat{x}_{2,j}\left\{\delta_{ij}-\hat{x}_i\hat{x}_j\right\}\xi_{v,\perp}+\hat{x}_{1,i}\hat{x}_{2,j}\hat{x}_i\hat{x}_j\xi_{v:\parallel}.\end{aligned}$$

The definitions here reflect the fact that the first term is sensitive to the component of velocity perpendicular to the line connecting two galaxies, while the second probes the velocity parallel to this line. Finally let's define the angles

$$\cos\theta_1 := \hat{x}_1\cdot\hat{x} \quad ; \quad \cos\theta_2 := \hat{x}_2\cdot\hat{x}$$

With the aid of Figure 9.8 we see that $\hat{x}_1\cdot\hat{x}_2$ is equal to $\cos\left(\theta_1-\theta_2\right)$, so performing the sums over i,j leads to

$$\xi_v\left(\vec{x}_1,\vec{x}_2\right) = \sin\theta_1\sin\theta_2\xi_{v,1}+\cos\theta_1\cos\theta_2\xi_{v,\parallel}.$$

Both components of ξ_v are integrals over the power spectrum. We can write

$$\begin{pmatrix}\xi(x)\\ \xi_{v,\perp}(x)\\ \xi_{v,\parallel}(x)\end{pmatrix} = \int_0^\infty\frac{dk}{2\pi^2k}P(k)\begin{pmatrix}k^3j_0(kx)\\ -f^2H_0^2j_0'(kx)/x\\ -f^2H_0^2kj_0''(kx)\end{pmatrix}$$

The weighted kernels are shown in Figure 9.9 and compared with the correlation function of the density. The key feature of Figure 9.9 is that, at fixed distance x, the density correlation function probes power on smaller scales than do the velocity correlation functions. Put another way, velocity surveys may be limited in how far out they go, but they pack an extra punch since they are sensitive to long wavelength modes. This is a direct result of the fact that $v\propto\delta/k$. The extra factor of $1/k$ gives additional weight to large scales.

Before going further and looking at some results from a velocity survey, I nust digress to make note of an important feature in Figure 9.9. The density correlation function, as oppossed to the velocity correlation functions, gets its contribution at a fixed distance from many Fourier modes. The figure shows the contributions to $\xi\left(50h^{-1}\mathrm{Mpc}\right)$. Naively, we would expect the main contribution to $\xi\left(50h^{-1}\mathrm{Mpc}\right)$ to come from Fourier modes with $k\sim x^{-1}=0.02h\mathrm{Mpc}^{-1}$. Since overdensities are small, i.e., still in the linear regime, on these scales, the naive expectation is

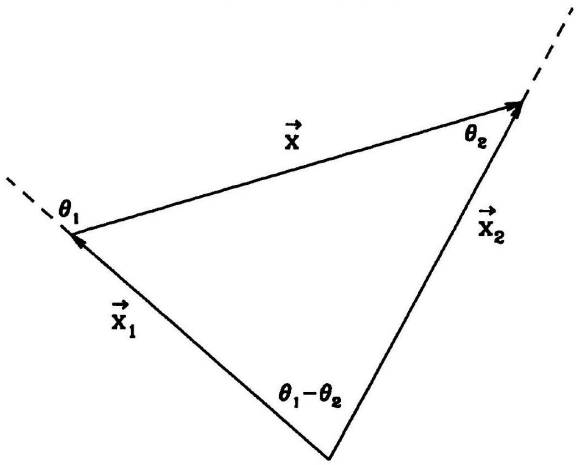

Figure 9.8. The vectors and angles of the the velocity correlation function. $\vec{x}$ is the difference vector; since the angle complementary to θ_1 is $\pi - \theta_1$, and since the three angles in the triangle must sum to π, the angle between the two galaxies is $\theta_1 - \theta_2$.

that $\xi\,(50h^{-1}\mathrm{Mpc})$ probes the linear power spectrum. Figure 9.9 shows that this expectation is incorrect. Modes with k as small as 0.02 hMpc^{-1} do contribute to the correlation function, but contributions extend out to $k \sim 0.3h\mathrm{Mpc}^{-1}$ and beyond. This means that even on scales you would think would be safely linear, the correlation function depends on the small-scale power. Ultimately we want to compare theory with observations, and we are most confident doing so for modes that are still linear. The correlation function mixes up linear and nonlinear modes, so makes it difficult to compare theory with observations. For this reason, the power spectrum has gained preeminence as the statistic of choice for large-scale structure.

Returning to the velocity correlations, let's consider Figure 9.10. It shows one attempt (Freudling et al.1999) to extract cosmological information from a velocity survey, using 1300 velocities in the all-sky SFI catalogue (Haynes et al.1999), which goes out to 70 h^{-1}Mpc. The power spectrum was parameterized by an amplitude A and the Γ parameter in the BBKS transfer function. For the analysis shown in Figure 9.10, the primordial spectral index was set to 1. The standard COBEnormalized CDM model, with critical matter density and $h = 0.5$, has an amplitude of $A = 0.29A_0$ (Eq. (7.9)) and shape parameter $\Gamma = 0.5$, so the SFI survey rules out this model at many sigma.

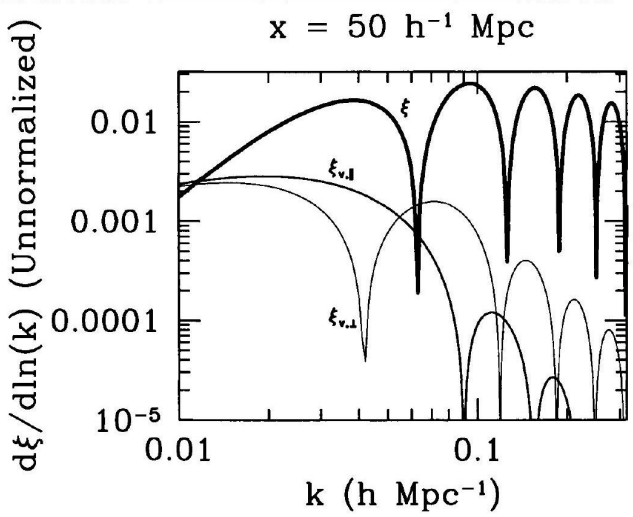

Figure 9.9. Contribution to various correlation functions from wavenumber k. Note that the velocity correlation functions get most of their contribution from smaller k than does the ordinary density correlation function.

12.10.4 Redshift Space Distortions

Theory

Redshift surveys supplement the angular information about galaxies with an estimator for the radial position, the redshift. The simplest guess about the radial position of a galaxy with redshift z is that it lies a distance

$$\chi_s(z) = \frac{z}{H_0}$$

away from us, where the subscript $_s$ denotes redshift space. Redshift space then corresponds to assigning Cartesian coordinates to a galaxy equal to

$$\vec{x}_s = \frac{z}{H_0}(\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$$

This assignment neglects several unpleasant realities. First, the comoving distance out to a galaxy at redshift z is equal to z/H_0 only at relatively low redshifts. A glance back at Figure 2.3 should convince you that this approximation is off by as much as 50% at $z = 1$. Fortunately, this first problem has not yet been much of a problem since most redshift surveys to date have probed $z \lesssim 0.1$.

A second, more pernicious, problem with redshift space is that the estimate for the distance in Eq. (9.33) neglects peculiar velocities. Figure 9.11 illustrates the

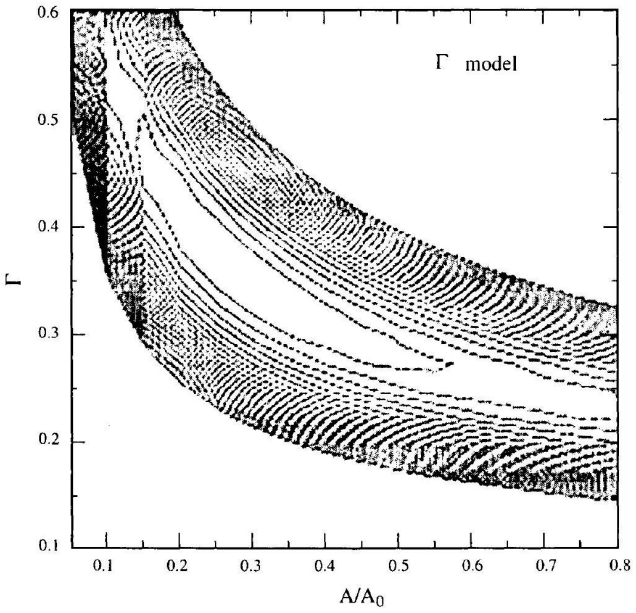

Figure 9.10. Likelihood contours on the amplitude A of the power spectrum and the shape parameter $\Gamma := \Omega_m h$ from the SFI peculiar velocity survey. The amplitude is given in units of $A_0 = 2 \times 10^6\,(h^{-1}\mathrm{Mpc})^4$, and the contours indicate shifts in the likelihood function by successive factors of $1/e$. The allowed region-delineated by banana-shaped contour in the center - is consistent with $\triangle$ CDM, but strongly disfavors standard CDM, which has $\Gamma = 0.5$ and $A = 0.29A_0$. From Freudling et al. (1999).

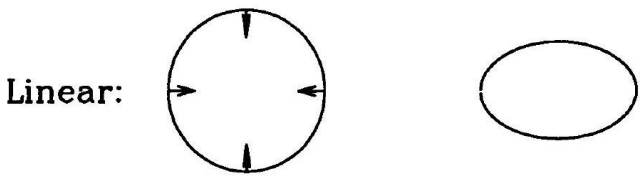
distortions that appear in redshift space. A slightly overdense region which is just beginning to collapse appears squashed in redshift space: the galaxies closest to us are moving toward the center of the overdense region and hence away from us, so they appear farther from us (and closer to the center of the overdense region) than they actually are. Similarly, galaxies on the "other side" of the perturbation are moving toward us, so they appear closer to us than they

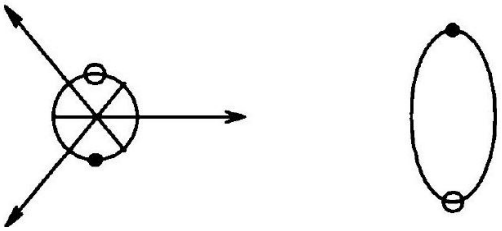
actually are. The overall effect is to induce an apparent quadrupole moment in an otherwise circular overdensity.

As a region becomes more overdense, the nature of the redshift space distortion changes. The bottom part of Figure 9.11 shows that a more collapsed object gets distorted in a much different way. It is elongated along the line of sight. More quantitatively, its quadrupole moment has the opposite sign as does a linear overdensity. It is clear then that accounting for redshift space distortions will be a tricky busi-

Real Space Redshift Space



Nonlinear Collapse:



Observer Figure 9.11. Redshift space distortions. In each case, a contour of constant density (circular in real space) is distorted in redshift space so that it looks asymmetric. Arrows denote direction and magnitude of velocity. In the case of nonlinear collapse, the velocities are so large that a point on "our side" (the bottom) of the center is mapped onto a point on the opposite side (compare the position of the solid dot on the bottom left and right).

ness, requiring careful treatment not only of linear overdensities, but also of the much more complicated effects of nonlinearities. We will content ourselves with a quantitative treatment of linear distortions, since this applies on large scales and is the starting point for all further work.

Suppose we measure the power spectrum in redshift space. How is this distorted power spectrum related to the underlying true spectrum in real space? Kaiser (1987) first solved this problem, working within the context of linear theory. The starting point is the realization that the number of galaxies in a particular region is the same, whether we use redshift-space or real-space coordinates. Therefore,

$$n_s\left(\vec{x}_s\right) d^3x_s = n(\vec{x}) d^3x$$

where n is the density of galaxies at $\vec{x}$ in real space, and n_s is the density in redshift space. The infinitesimal volume around a point in redshift space is $d^3x_s = dx_s x_s^2 \sin\theta d\theta d\phi$, while the volume around a point in real space is $d^3x = dx x^2 \sin\theta d\theta d\phi$. The angular volume elements are identical, so

$$n_s\left(\vec{x}_s\right) = n(\vec{x}) J$$

where the Jacobian J is given by

$$J := \left|\frac{d^3x}{d^3x_s}\right| = \frac{dx}{dx_s}\frac{x^2}{x_s^2}.$$

To compute the Jacobian, we use the fact that the observed redshift is the sum of two terms:

$$z = H_0 x + \vec{v} \cdot \hat{x}$$

The first term is the standard Hubble law, which says that redshift is proportional to distance; the second is the velocity along the line of sight. Recalling that redshift space corresponds to equating a galaxy's redshift with its distance from us, we see that, after dividing by H_0, this equation becomes

$$x_s = x + \frac{\vec{v} \cdot \hat{x}}{H_0}.$$

The Jacobian can be now be read off as

$$J = \left(1 + \frac{\partial}{\partial x}\left[\frac{\vec{v} \cdot \hat{x}}{H_0}\right]\right)^{-1} \left(1 + \frac{\vec{v} \cdot \hat{x}}{H_0 x}\right)^{-2}.$$

Kaiser realized that the correction term due to the derivative of the velocity is much more important than the $\vec{v} \cdot \hat{x}/H_0 x$ term. The argument goes as follows. For a plane wave perturbation, the term with the derivative of the velocity is of order $v'/H_0 \sim kv/H_0$, while the other correction is of order $v/H_0 x$. That is, the first correction term is larger than the second by a factor of order kx. Why do I say it's larger? That is, why is kx larger than unity? Kaiser's argument is that x is of order the size of the survey, while k is of order the Fourier modes we can hope to measure in the survey. Perturbations on the largest scale probed by the survey $k \sim x^{-1}$ are very poorly determined, since there are only a handful of Fourier modes with wavelength of order the survey size. Modes with smaller wavelength are much easier to measure since there are many such modes, and we effectively average over all of them to get an estimate of the power spectrum. Therefore, we are really interested only in modes with $kx \gg 1$. Expanding the remaining denominator about $v = 0$, we see that

$$J \simeq \left(1 - \frac{\partial}{\partial x}\left[\frac{\vec{v} \cdot \hat{x}}{H_0}\right]\right).$$

The number densities in real and redshift space are $n = \bar{n}(1 + \delta)$ and $n_s = \bar{n}\,(1 + \delta_s)$, respectively, with $\bar{n}$ the average number density. In light of Eq. (9.36), the overdensity in redshift space is

$$1 + \delta_s = [1 + \delta]\left(1 - \frac{\partial}{\partial x}\left[\frac{\vec{v} \cdot \hat{x}}{H_0}\right]\right).$$

Expanding to first order, we see that the overdensity in redshift space is actually a sum of the overdensity in real space and a correction due to peculiar velocity,

$$\delta_s(\vec{x}) = \delta(\vec{x}) - \frac{\partial}{\partial x}\left[\frac{\vec{v}(\vec{x}) \cdot \hat{x}}{H_0}\right]$$

Now I want to introduce the distant observer approximation. The idea is that, in most cases of interest, the direction vector $\vec{x}$ is fixed, varying little from galaxy to galaxy. To see this, go back to Figure 9.2 : $\vec{x}$ is mostly radial, with only small components in the transverse direction (proportional to the θ_1 and θ_2). As long as the galaxies are relatively close to each other in this plane, we can approximate $\hat{x} \cdot \vec{v} \to \hat{z} \cdot \vec{v}$, where $\hat{z}$ is a radial vector pointing to the center of the galaxies of interest.

In the distant observer approximation, we can compute the Fourier transform of the redshift space overdensity (here denoting the Fourier-transformed density by $\tilde{\delta}$ to avoid confusion),

$$\tilde{\delta}_s(\vec{k}) = \int d^3x e^{-i\vec{k}\cdot\vec{x}} \left[\delta(\vec{x}) - \frac{\partial}{\partial x}\left[\frac{\vec{v}(\vec{x})\cdot\hat{z}}{H_0}\right]\right]$$
$$= \tilde{\delta}(\vec{k}) - if\int d^3x e^{-i\vec{k}\cdot\vec{x}}\frac{\partial}{\partial x}\left[\int \frac{d^3k'}{(2\pi)^3}e^{i\vec{k}'\cdot\vec{x}}\tilde{\delta}\left(\vec{k}'\right)\frac{\vec{k}'}{k'^2}\cdot\hat{z}\right],$$

the first equality following from our Fourier convention and Eq. (9.43) and the second from Eq. (9.20) for linear velocities. The derivative with respect to the length x acts on the exponential, bringing down a factor of $i\vec{k}'\cdot\hat{x}$, which we again set to $i\vec{k}'\cdot\hat{z}$, so

$$\tilde{\delta}_s(\vec{k}) = \tilde{\delta}(\vec{k}) + \int \frac{d^3k'}{(2\pi)^3}\tilde{\delta}\left(\vec{k}'\right)\left[f\left(\hat{k}'\cdot\hat{z}\right)^2\right]\int d^3x e^{i\left(\vec{k}'-\vec{k}\right)\cdot\vec{x}}$$

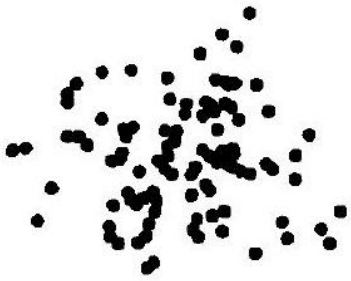
The $\vec{x}$ integral gives a Dirac delta function, equating $\vec{k}'$ with $\vec{k}$. Therefore, in the distant observer approximation,

$$\tilde{\delta}_s(\vec{k}) = \left[1 + f\mu_{\mathbf{k}}^2\right]\tilde{\delta}(\vec{k})$$

Here $\mu_{\mathbf{k}}$ is defined to be $\hat{z}\cdot\hat{k}$, the cosine of the angle between the line of sight and the wavevector $\hat{k}$. Equation (9.46) quantifies what we should have anticipated about (linear) redshift space distortions. First of all, since $f\mu_{\mathbf{k}}^2 \geq 0$, the apparent overdensity in redshift space is larger than in real space. This is clear from Figure 9.12. The central region of the galaxies is clearly more overdense in redshift space than in real space, the enhancement due to the illusion that infalling galaxies are located close to the center. The second feature of Eq. (9.46) worth noting is that the enhancement is for waves with wavevector parallel to the line of sight. A plane wave perturbation with $\vec{k}$ perpendicular to the line of sight - one in which the density along the line of sight is constant - experiences no redshift space distortion.

The power spectrum in redshift space depends not only on the magnitude of $\vec{k}$ but also on its direction, which we are parameterizing with μ. It follows immediately from Eq. (9.46) that

Real Space



Redshift Space

Figure 9.12. A hundred galaxies in real space squashed in redshift space due to linear velocities. The apparent overdensity in redshift space is much larger near the center than it is in real space. We, the observers, are sitting at the bottom of the page.

$$P_s(\vec{k}) = P(k)\left[1 + \beta\mu_{\mathbf{k}}^2\right]^2$$

Here I have introduced the parameter β, which you might think is simply equal to f, the linear growth rate. There is an additional factor in β, though, due to the fact that the mass overdensity δ is not necessarily equal to the overdensity in galaxies, δ_g. The velocity field samples the mass overdensity. So if we define the bias

$$b := \frac{\delta_g}{\delta}$$

then $\vec{v} \propto \delta \propto \delta_g/b$. Therefore, the correction due to redshift space distortions in Eq. (9.47) is proportional to

$$\beta = \frac{f}{b} \simeq \frac{\Omega_m^{0.6}}{b}$$

The redshift space distortion in the power spectrum, encoded in Eq. (9.47), is both good news and bad news. The good news is that by measuring the distortion in the redshift space power spectrum, we can hope to measure β, a combination of the density and bias. A quantitative way to do this is to measure the ratio of the quadrupole to the monopole of the power spectrum:

$$\frac{P_s^{(2)}(k)}{P_s^{(0)}(k)} := \frac{5\int_{-1}^{1} \frac{d\mu_{\mathbf{k}}}{2} \mathcal{P}_2\left(\mu_{\mathbf{k}}\right) P_s(\vec{k})}{\int_{-1}^{1} \frac{d\mu_{\mathbf{k}}}{2} \mathcal{P}_0\left(\mu_{\mathbf{k}}\right) P_s(\vec{k})}$$

Recall that $\mathcal{P}_l$ is the Legendre polynomial of order l, while P_s is the redshift-space power spectrum. Since (Exercise 11)

$$\left(1+\beta\mu_{\mathbf{k}}^2\right)^2 = \left[1+\frac{2}{3}\beta+\frac{1}{5}\beta^2\right]\mathcal{P}_0\left(\mu_{\mathbf{k}}\right) + \left[\frac{4}{3}\beta+\frac{4}{7}\beta^2\right]\mathcal{P}_2\left(\mu_{\mathbf{k}}\right) + \frac{8}{35}\beta^2\mathcal{P}_4\left(\mu_{\mathrm{k}}\right)$$

the orthogonality of the Legendre polynomials (Eq. (C.2)) implies that the ratio of the quadrupole to the monopole in linear theory is

$$\frac{P_s^{(2)}(k)}{P_s^{(0)}(k)} = \frac{\frac{4}{3}\beta+\frac{4}{7}\beta^2}{1+\frac{2}{3}\beta+\frac{1}{5}\beta^2}$$

Figure 9.13 shows Hamilton's efforts to measure the quadrupole-to-monopole ratio in two different redshift surveys. In both cases, nonlinearities are very important

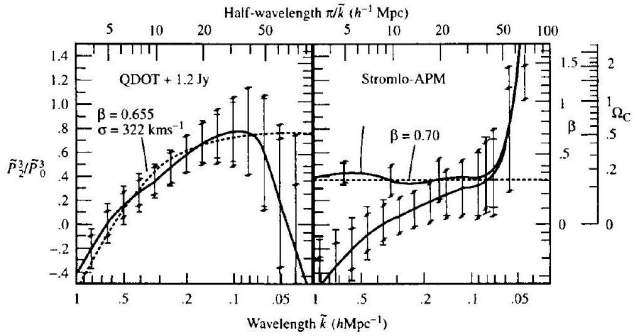


Figure 9.13. The quadrupole-to-monopole ratio for two redshift surveys (Hamilton, 1998). Left panel shows data from two redshift surveys which selected galaxies from the Infrared Astronomical Satellite (IRAS): QDOT (Lawrence et al., 1999) picked one out of six galaxies brighter than 0.6 Jansky and the 1.2Jy survey (Strauss et al., 1992) picked all galaxies above

that brightness limit. Stromlo-APM survey (Loveday et al., 1996) in right panel contains redshifts for 1 in 20 galaxies seen in APM (Figure 9.1).

and must be handled carefully. In the infrared-selected surveys depicted at left in the figure, Hamilton modeled the nonlinearities with a parameter measuring the small-scale velocity dispersion, σ. Only on scales of order $k \sim 0.1h\mathrm{Mpc}^{-1}$ does the ratio begin to asymptote to ~ 0.75, implying a value of $\beta \sim 0.7$. The right panel shows a survey of optically selected galaxies. For these, the ratio does not seem to asymptote at all (lower curve) unless nonlinear structures are removed by hand (upper curve). In that case, Hamilton finds a quadrupole-to-monopole ratio closer to 0.4, implying $\beta = 0.3$. Figure 9.14 gives a broader view of the spread in measures of β from redshift and peculiar velocity surveys.

That was the good news. The bad news is that, even if we were to give up hope of measuring β from redshift surveys, we still need to account for redshift space distortions if we want to measure the power spectrum. Blindly measuring the power spectrum by averaging over all directions $\mu_{\mathbf{k}}$ is actually a measure of

$$P_s^{(0)}(k) = \left[1 + \frac{2}{3}\beta + \frac{1}{5}\beta^2\right] P(k),$$

the equality holding only in linear theory. That is, $P_s^{(0)}$ overestimates the power spectrum by as much as a factor of 2. On even moderate scales, as suggested by Figure 9.13, nonlinear effects must be taken into account. The Peacock and Dodds compilation in Figure 7.11 uses a model of the small-scale velocities to do this.

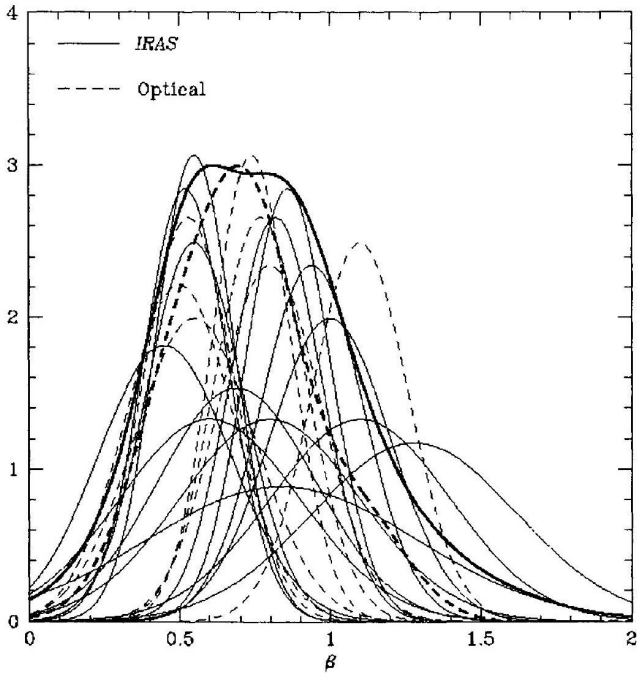

Figure 9.14. Compilation of the likelihood of β from redshift and peculiar velocity surveys (Strauss and Willick, 1995).

12.10.5 Galaxy Clusters

Theory

Until now, we have focused solely on the two-point function: the angular correlation function, the velocity covariance, and the power spectrum. You might have wondered why little has been said about one-point functions, the number density of galaxies for example. To answer this

question, first consider an extreme example. How many people are there in the universe? This clearly is an impossible question to answer with the tools we have developed. Putting aside the thorny question of the definition of a "person," we still would have to develop theories of star formation out of the gas in galaxies, then planet formation around stars, then the evolution of life via various biological processes. A prediction of the "person density" in the universe is beyond the scope of... this book, to say the least.

In a similar, but less extreme, way, a prediction of the galaxy density of the universe from what we have learned about the distribution of matter in the universe involves complicated issues we do not have the tools to address. What fraction of the matter has collapsed into nonlinear structures? How do these nonlinear structures evolve? Do galactic-size nonlinear structures merge? If so, how often? Upon collapse, how do stars form? How are stars distributed? In spiral patterns? Elliptical? One of the exciting developments of the 1990s was the evolution of a number of techniques to answer these questions. In addition to the brute-force approach of numerical simulations, several groups (e.g., Kauffman et al., 1999; Somerville and Primack, 1999; Colberg et al., 2000; Benson et al., 2001; Cooray and Sheth, 2002) developed semianalytic techniques which have been remarkably successful at predicting properties and abundances of different galaxy types. Although we will not study these techniques directly here, the one technique we will encounter - the Fress-Schechter formalism - forms the basis for much of this work.

Perhaps the fundamental difficulty encountered by one attempting to make predictions about the number density of galaxies is that the galactic scale has already gone nonlinear. Recall from Ex. 7.9 that scales smaller than $\sim 10h\mathrm{Mpc}^{-1}$ have gone non-linear. What scale in the unperturbed universe encloses the mass of a typical galaxy, $M = 10^{12}M_\odot$? The density in a spherical region of radius R is

$$\rho_{\mathrm{m}} = \frac{M}{4\pi R^3/3}$$

Since $\rho_{\mathrm{m}} = \Omega_m \rho_{\mathrm{cr}}$, we can invert this to find

$$R = 0.951 h^{-1}\mathrm{Mpc}\left(\frac{Mh}{10^{12}\Omega_m M_\odot}\right)^{1/3}$$

So a galaxy comes from matter within a radius of about 1Mpc, corresponding to fluctuations on scales of order $k \sim 1h\mathrm{Mpc}^{-1}$, well into the nonlinear regime.

This answers a question ("Why not try to predict the number density of galaxies?") but begs another: Are there objects, corresponding to scales closer to the linear regime, for which one might be able to make reliable predictions about abundances? If we invert Eq. (9.55) to get the mass enclosed within a sphere of radius R

$$M = 1.16 \times 10^{15}\Omega_m h^{-1} M_\odot \left(\frac{R}{10h^{-1}\mathrm{Mpc}}\right)^3$$

then we see that clusters of galaxies - with masses up to $10^{15}M_\odot$ - arise from perturbations on just the right scales.

How, then, to predict the abundance of galaxy clusters? The basic insight comes from a paper by Press and Schechter (1974), and the resulting framework is called Press-Schechter theory. To understand their argument, consider the onedimensional density field in Figure 9.15. The average inhomogeneity is zero, of course. There are regions with relatively large excursions in both the positive and negative direction. Underdensities cannot get smaller than -1 (when the density is zero), but there are some regions in the figure with densities more than three times the average density. It is these rare regions of large overdensity that we are interested in: they collapse, accumulate so much excess matter that local gravity becomes more important

than the Hubble flow. Particles in this region stop expanding away from each other and are trapped in the local gravitational field.

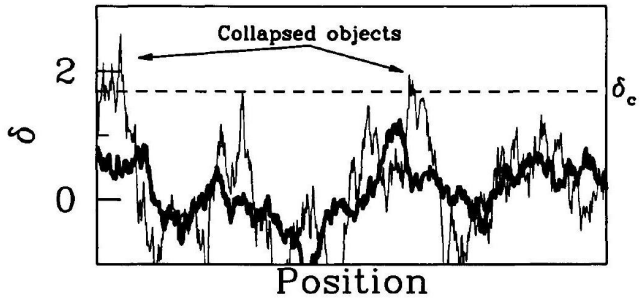

Figure 9.15. Inhomogeneities as a function of 10 position. Dark curve is the same field smoothed on larger scales. Several small-scale fluctuations have collapsed, while the large scale density field does not have any overdensities greater than δ_c, the critical value for collapse.

The Press-Schechter theory predicts the fraction of the volume that has collapsed,

$$f_{\rm coll}\,(M(R),z) = \frac{2}{\sqrt{2\pi}\sigma(R,z)}\int_{\delta_c}^{\infty} d\delta e^{-\delta^2/2\sigma^2(R,z)}.$$

Here R is the radius over which the density field has been smoothed. This radius is used to compute $\sigma(R,z)$, the rms of the smoothed density field (Ex. 7.9). As you can see from Figure 9.15, the smoothing scale matters. Typically, inhomogeneities on large scales are smaller in magnitude than those on small scales, so small scales collapse first. As time evolves, overdensities grow (proportional to the growth function), so eventually some large-scale inhomogeneities will also collapse. The right-hand side of Eq. (9.57) counts all parts of the Gaussian distribution for which the overdensity is greater than some critical density δ_c. There are several pieces of magic in this formula. First, it assumes that the distribution of inhomogeneities is Gaussian. This is impossible since δ, by definition, never gets smaller than -1. And indeed, it is possible to show that gravity skews an initially Gaussian distribution, producing more underdense regions and a nonnegligible tail of highly overdense regions. Second, the normalization is a bit of a cheat: one would naively not include the factor of 2. Finally, the rms σ in the formula is the linear rms, specifically ignoring nonlinear effects. On small scales, there is a huge difference between σ calculated with the linear power spectrum and that with the true nonlinear spectrum. Press-Schechter tells us that the collapsed fraction can be obtained using the linear σ. These peculiarities of the Press-Schechter formalism do not detract from its effectiveness. Numerical simulations (e.g., White, Efstathiou and Frenk, 1993) have shown that it works extremely well. Further, a number of groups (Peacock and Heavens, 1990; Bond et al., 1991) have justified theoretically some of the aspects of the formula that initially appeared ad-hoc.

To get the collapsed fraction into a form more comparable with observations, first differentiate $f_{\rm coll}$ with respect to M and multiply by a small interval dM. This gives the fraction of the volume collapsed into objects with mass between M and $M + dM$. Multiply this by the average number density of such objects $\rho_{\rm m}/M$ to get the the number density of collapsed objects with mass between M and $M + dM$,

$$dn(M,z) = -\frac{\rho_{\rm m}}{M}\frac{df_{\rm coll}(M(R),z)}{dM}dM.$$

The minus sign appears here since $f_{\rm coll}$ is a decreasing function of the mass M. Carry out the derivative using the fact that $dM/dR = 3M/R$. Then,

$$\frac{dn(M,z)}{dM} = \sqrt{\frac{2}{\pi}}\frac{\rho_{\rm m}\delta_c}{3M^2\sigma}e^{-\delta_c^2/2\sigma^2}\left[-\frac{R}{\sigma}\frac{d\sigma}{dR}\right].$$

The term in brackets here, the logarithmic derivative, is close to 1 for most models of interest. The dominant factor in Eq. (9.59), at least for large masses, is the exponential. If σ on a given scale is small, then the number density of collapsed objects on that scale is exponentially suppressed.

Until now, I have sidestepped the question of the numerical value of δ_c, the critical overdensity above which objects collapse. There are two approaches to obtaining δ_c; fortunately, both appear to agree. The first is to rely on a simple model of collapse, a model in which the overdensity is perfectly spherical. One can show that collapse occurs in such a model when $\delta = 1.686$ (for $\rho_{\rm m} = \rho_{\rm cr}$). The other way is simply to treat δ_c as a free parameter and calibrate it with numerical simulations (e.g., Eke, Cole and Frenk, 1996). The δ_c obtained this way is close enough to the spherical value that typically one simply adopts $\delta_c = 1.686$.

Measuring the cluster abundance, and therefore testing theories with Eq. (9.59), is a subtle business. One class of difficulties is identifying a cluster. Sophisticated algorthims have been developed to find clusters in a galaxy survey. The second set of difficulties revolves around determining the mass of the cluster. There are several methods of mass determination:

- X-Ray Temperatures Hot ionized gas in a cluster emit radiation with a cutoff frequency which is determined by the temperature of the gas. This temperature can be related to the mass of the cluster under certain assumptions.
- Sunyaev-Zeldovich Distortion Photons from the CMB pasing through clusters get scattered by the hot gas. This scattering distorts the CMB spectrum as a function of frequency, inducing a decrement at low frequency and excess at high frequency (low-energy photons gain energy from the hot electrons). The shape of the distortion is fixed; the amplitude is another measure of the temperature of the gas, which, again under certain assumptions, can be translated into a measurement of the mass. - Weak Lensing Images of background galaxies are distorted by a foreground cluster. The larger the mass of the cluster, the larger the distortions. Weak lensing is therefore becoming a fabulous tool for measuring masses of clusters without using the temperature.

At least in the first two techniques, the direct measurement is of the cluster temperature. So let's work through a relation between the mass and temperature of a cluster under a simple set of assumptions. Suppose a cluster has virialized so that its kinetic energy is equal to minus half its potential energy. Suppose also that the cluster is spherical with radius $R_{\rm vir}$ with potential (gravitational) energy is equal to $-3GM^2/5R_{\rm vir}$. Then,

$$\frac{1}{2}Mv^2 = \frac{3}{10}\frac{GM^2}{R_{\rm vir}}$$

The overdensity of the cluster $\Delta_{cl} := \rho_{cl}/\rho_{\rm m}$ then allows us to eliminate the radius, since

$$\Delta_{cl} := \frac{M}{4\pi R_{\rm vir}^3\rho_{\rm m}/3}.$$

The temperature is equally apportioned among three directions, so the average velocity squared is $v^2 = 3T/m_p$, where m_p is the proton mass. The temperature can now be expressed in terms of the total mass of the system,

$$T = \frac{m_p}{5}\left[GMH_0\sqrt{\frac{\Delta_c}{2}}\right]^{2/3}$$

when $\Omega_m = 1$. Invert to get

$$M = 8.2 \times 10^{13} h^{-1} M_\odot \left(\frac{T}{\mathrm{keV}}\right)^{3/2} \sqrt{\frac{178}{\Delta_{cl}}}.$$

Here I have normalized Δ_{cl} by its value in the spherical collapse model (with $\rho_{\rm m} = \rho_{\rm cr}$), although again simulations have verified the numerical value.

Figure 9.16 shows the cluster density as a function of temperature for the standard CDM model with $\Omega_m = 1$. One of the most important points made immediately after the COBE detections of anisotropies in 1992 was that this plain-vanilla model predicts too many clusters. Indeed, the abundance of clusters today is often used as an excellent way of normalizing a power spectrum. A typical value for σ_8 from cluster abundances (e.g., Wang and Steinhardt, 1998) is

$$\sigma_8 = 0.5 \Omega_m^{-.33-.35\Omega_m}$$

with error estimates ranging from just a few percent up to 20%, the latter probably more accurately reflecting uncertainties in the mass determinations.

Another exciting application of the Press-Schechter prediction for cluster abundances is the evolution with redshift. The basic point stems from the exponential.

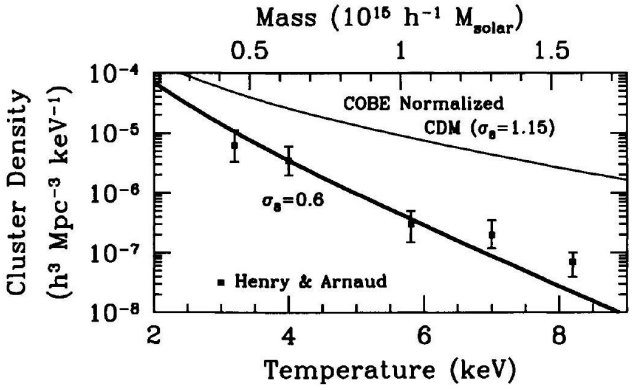

Figure 9.16. The cluster density as a function of temperature. Data from Henry and Arnaud (1991). The two theoretical curves are the Press-Schechter estimates (Eq. (9.59)) of models with $\Omega_m = 1, h = 0.5, \Omega_b = .05$. The only difference between the two is the normalization.

dependence in Eq. (9.59). At high redshift, $\sigma(R, z)$ is necessarily smaller, but how much smaller depends on the underlying cosmology. The growth is fastest in a model with $\Omega_m = 1$ (see Figure 7.12), so for a fixed abundance today, one expects many fewer clusters in such a model. Figure 9.17 illustrates this effect. An $\Omega_m = 1$ model predicts a factor of 700 fewer clusters with masses greater than $3.5 \times 10^{14} M_\odot$ at redshift 0.5 than at redshift zero. By contrast, Λ CDM predicts just a factor of 4 decline. With the observational assault on clusters just getting off the ground, we can expect strong constraints on cosmology to emerge in the coming decade.

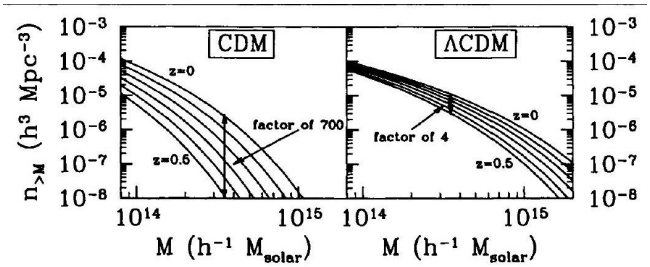

Figure 9.17. The number density of clusters with mass greater than M at different redshifts. Left panel: CDM model with $\Omega_m = 1, h = 0.5, \Omega_b = 0.05$ but normalized to give the correct abundance at $z = 0\,(\sigma_8 = 0.5)$. Curves give the abundances in redshift increments of $\delta z = 0.1$ starting from $z = 0$ going out to $z = 0.5$. Right panel: Λ CDM model which fits CMB and other data ($\Omega_m = 0.35, h = 0.7, \Omega_b h^2 = 0.02$). Note the relatively slow evolution of clusters with mass $\sim 3 \times 10^{14} M_\odot$ as compared with the critical density model.

12.10.6 Lyth bound (??)

(wiki, later I'll learn this better)

In cosmological inflation, within the slow-roll paradigm, the Lyth argument places a theoretical upper bound on the amount of gravitational waves produced during inflation, given the amount of departure from the homogeneity of the cosmic microwave background (CMB).

Summary

- During slow-roll inflation, the ratio of gravitational waves to inhomogeneities of the CMB is correlated to the inflationary potential steepness.

- Temperature inhomogeneities of the CMB were successfully and accurately measured. [1][2][3] in the CMB.

- There are current CMB polarization experiments [4][5] (see this article for instance for an overview of gravitational wave observatories) aimed at measuring the primordial gravitational wave signature in the CMB.

- However, to date, a significant signal of primordial gravitational waves was not detected. Thus the ratio cannot exceed a certain value.

- Thus the steepness of the inflationary potential is bounded.

12.11 Weak Lensing and Polarization

The traditional methods of measuring clustering - angular and redshift surveys are powerful probes of the power spectrum but share a common deficiency. They are measures of the distribution of galaxies, not the distribution of mass. Theories of the early universe can make very accurate predictions about the latter, but not about the former. A very exciting new technology which probes the mass - not the light distribution is introduced in this chapter. We will see that the inhomogeneities of the matter induce distortions in the observed shapes of distant galaxies due to gravitational lensing. Further, the statistics of these distortions are directly related to the matter power spectrum.

The anisotropies in the CMB are subject to none of the uncertainties or ambiguities which plague the density field.

- We know exactly where the CMB comes from (the surface of last scattering) so there is no analogue of peculiar velocity distortions.

- There is nothing like the mass vs light problem which afflicts the interpretation of galaxy surveys.

- In addition, the mass distribution has gone nonlinear, so a simple comparison of the linear power spectrum derived in Chapter 7 with the data is dangerous. Anisotropies in the CMB are still at the part-in-a-hundred-thousand level, so nonlinearities are for the most part irrelevant.

The C_l 's then are easy to interpret and extract information from. Nonetheless, here too we can go beyond what we have already done. Until now we have focused on anisotropies in the

temperature field. Compton scattering before decoupling also induced polarization anisotropies. Polarization opens up a new dimension in the study of the CMB. At the very least, it doubles the amount of information contained in the CMB. As we will see in this chapter, the promise of polarization goes well beyond this doubling. Gravity waves – tensor perturbations– produce a particular pattern of polarization that cannot be mimicked by scalar perturbations. Therefore, polarization offers a unique way of searching for gravity waves produced during inflation. Gravitational lensing and polarization belong in the same chapter primarily because the mathematics describing them is so similar. Both effects can be quantified with a two-by-two symmetric matrix. In lensing, this matrix is the distortion tensor encoding information about image distortion. The polarization tensor has a longer history with more famous components Q and U. It is identical mathematically, though. So, the technologies used to study both of these effects are very similar.

12.11.1 Gravitational Distortion of Images

Theory

The cosmological gravitational field distorts the paths traveled by light from distant sources to us. This fundamental fact carries with it an enormous amount of cosmological promise. Most important is the idea that light paths respond to mass. If we can measure distortions, then, we might be able to infer something about the distribution of mass in the universe. The importance of this inference cannot be overstated: most of what we think we know about this distribution comes from our observations of the galaxy distribution. We hope that, on large scales at least, the two - the mass and the galaxy distribution - are not too different. If we observe the mass distribution directly via distortion of light rays, though, then we need not rely on this hope. We can then directly compare observations with theoretical predictions. For cosmology, therefore, we expect the most important aspect of light ray distortion to be weak lensing, wherein the shapes of distant galaxies are distorted (slightly) by intervening foreground mass overdensities. We begin with an overview of image distortion along with a brief discussion of some other applications.

The idea that gravitational fields might distort distant images is as old as general relativity. Indeed, even before Einstein finalized general relativity, he understood the importance of measuring this distortion. Early notebooks of his contain calculations of the magnification of images and of the possibility of a double image of a single source (Renn, Sauer, and Stachel, 1997). And it was detection of gravitational distortion that led to the acceptance of general relativity. In 1919, Eddington led a voyage to the Southern Hemisphere to observe the deflection of starlight during a solar eclipse. The magnitude of this effect (Dyson, Eddington, and Davidson, 1920) was in good agreement with Einstein's new theory.

One of the most spectacular manifestations of gravity bending light paths is strong gravitational lensing. In 1979, Walsh, Carswell, and Weymann observed a multiply imaged quasar, thereby confirming Einstein's early speculations. Light rays leaving the quasar in different directions are focused on the same point (us) by an intervening galaxy. Since then, dozens of multiply imaged quasars have been observed, and we are on the verge of discovering many hundred more in the near future. Exactly what fraction of quasars is lensed is a question that may depend on the background cosmology. In particular, it has been argued that there should be more multiply imaged quasars in a universe with a cosmological constant than in one without (see Exercise 1 and Kochanek, 1996). There are other examples of gravitational lensing that have an impact on cosmology. Light rays that take different routes to the same endpoint typically arrive at that endpoint at different times. Therefore, two light rays emitted from the same source at the same time which we detect from different directions due to lensing typically arrive at different times. We can measure this time delay by studying sources with variable

emission. The delay turns out generally to depend on the Hubble constant, so astronomers have made very accurate measures of H_0 looking for time delays (e.g., Kundic et al., 1997). Another example is microlensing, wherein a lens moves into the line connecting a source to us. When it does, the image is magnified, so that we observe a characteristic variability in the distant source. Microlensing has been used in recent years to find massive compact halo objects (MACHOs) in our galaxy (Alcock et al., 1993). It now appears that MACHOs do not make up all, or even most, of the dark matter in our galaxy. Nonetheless, exactly what and where they are is still a mystery of cosmic significance.

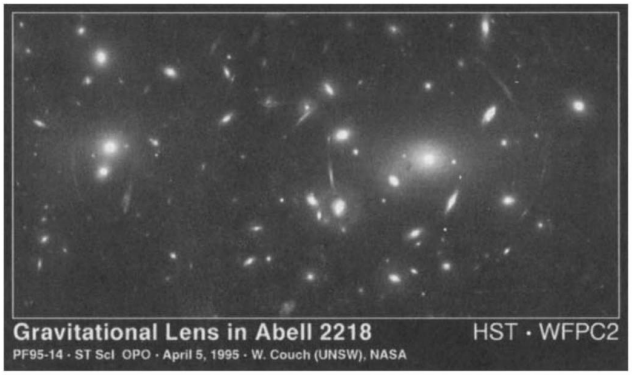

Figure 10.1. Foreground galaxies in the cluster Abell 2218 distort the images of background galaxies. Elliptical arcs surround the central region of the cluster at right.

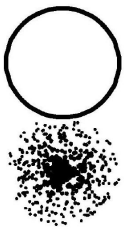
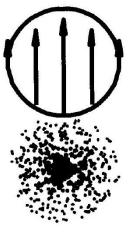
Yet another spectacular manifestation of gravitational lensing is shown in Figure 10.1. The large cluster in the foreground, Abell 2218, distorts the shapes of the background galaxies. This leads to a distinctive pattern of elliptical arcs surrounding the central region of the cluster. Why do the background galaxies appear stretched out elliptically in Figure 10.1? Consider a circular galaxy sitting behind a large mass density with an observer out of the page as in Figure 10.2a. Since the light rays are distorted, we do not expect to see a circular image. Rather, light rays coming from the "bottom" of this source - the ones that pass closer to the central mass region - are bent more than those that do not come as close to the mass. The light rays are bent such that objects at the bottom appear to be farther away from



(a)



(b)

(c)

Figure 10.2. (a) Circular galaxy, the source, sits behind a foreground mass distribution represented by points at bottom. The observer is out of the page so that the foreground mass is between the observer and the source. (b) Light rays from source are deflected as they pass by mass distribution. Rays traveling closest to mass get deflected the most. (c) Resulting image is an arc.

the mass. (This is the only subtle part of the argument: rays are bent toward the mass distribution, so that as you extrapolate backward, the source appears farther away. See Figure 10.4.) Images will therefore be distorted as in Figure 10.2b. The net effect, therefore, is to turn a circular galaxy into the arc shown in panel c.

A very active field of research uses background galaxies to try to infer the mass distribution of clusters (e.g., Clowe et al., 1998). Most times, the images are not as dramatic as those shown in Figure 10.1. The lack of drama is offset by the huge numbers of background galaxies. By adding up many small distortions, observers have succeeded in obtaining mass estimates for a number of clusters. This idea of statistically averaging small distortions is the hailmark of weak lensing. The mass estimates are important information for cosmologists: several cosmological constraints are based on cluster masses and abundances (e.g., Section 9.5, Carlberg et al., 1997; Bahcall et al., 2000).

We will be interested in weak lensing not by a single identifiable lens such as a cluster, but rather by the generic large-scale structure in the universe. Inferring the distribution of the dark matter - i.e., pointing to a spot on the sky and identifying it as an overdense region - is not necessarily the goal. Rather, we should be satisfied if we can measure some simple statistics, for example the correlation function or its Fourier transform, the power spectrum. Indeed, these are the quantities we, as cosmologists, are most interested in anyway. We don't care where the overdense and underdense regions are; we simply want to compare theory with observations. So our main goal here is to relate the observations (which have already begun) of distortions of galaxy images to the underlying mass power spectrum. (a)

(b) (c)

Figure 10.3. Different lensing patterns. Panels (a) and (b) could be produced by a mass distribution (a) above or below the distorted images and (b) in between or on either side of the images. But the alignment in panel (c) could not be produced by lensing.

One final note concerning the correlations of distortions expected from gravitational lensing. We might expect to find the images of two (circular) galaxies to be distorted so that they look like Figure 10.3a if, for example, there is a large overdensity above or beneath this galaxy pair.

We might also expect images similar to those in Figure 10.3b if an overdensity exists between them or to either side. However, lensing cannot produce the alignment sketched in panel (c). This fact, which we will shortly prove, is often used as a check against systematic problems afflicting an observation.

12.11.2 Geodesics and Shear

Theory

We want to solve for the path of a light ray as it leaves a distant source and travels through the inhomogeneous universe. Figure 10.4 shows the geometry and notation, which will be similar to that set up in our discussion of the angular correlation function. The position of the photon at any time is given by $\vec{x}$, with the x_3 component equal to the radial distance χ and the transverse components equal to $\chi\vec{\theta}$. The intensity we observe from a source is

$$I_{\rm obs}(\vec{\theta}) = I_{\rm true}\ \left(\vec{\theta}_S\right)$$

a source whose image appears at $\vec{\theta}$ is actually at $\vec{\theta}_S$.

To solve for the path of a light ray, we need to use the machinery of general relativity. Recall that in Chapter 4, we used the time component of the geodesic equation to find dp/dt, the rate of change of the magnitude of the momentum. Here we are interested in deflections, so we will need the spatial component,

$$\frac{d^2x^i}{d\lambda^2} = -\Gamma^i_{\alpha\beta}\frac{dx^\alpha}{d\lambda}\frac{dx^\beta}{d\lambda}$$

in particular, we will need the transverse part. Let's first consider the left side of this equation. We can express the derivatives with respect to affine parameter λ in terms of derivatives with respect to χ using the fact that

$$\frac{d\chi}{d\lambda} = \frac{d\chi}{dt}\frac{dt}{d\lambda}$$

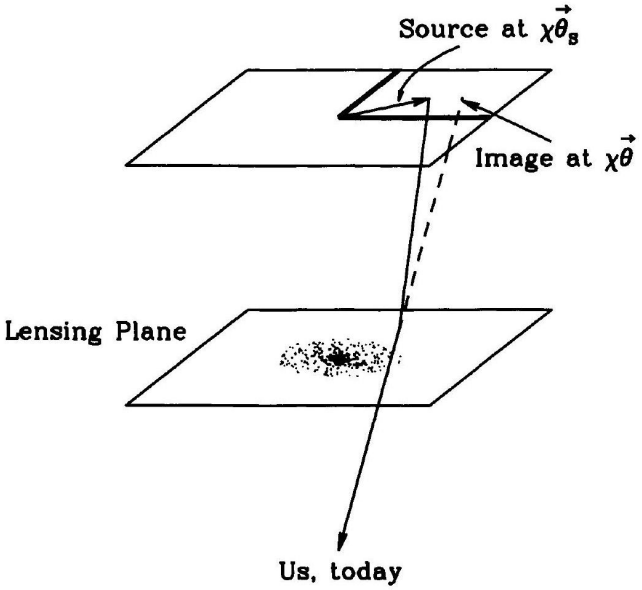


Figure 10.4. A light ray leaving a distance source is distorted as it passes by an intervening overdense region. At all times, the position of the light ray can be characterized by a $2D$ vector

specifying its angular distance from the center of the lens. The ray starts with angular vector $\overrightarrow{\theta_S}$, but appears to us to be coming from $\vec{\theta}$.

$$= \frac{-1}{a} p(1-\Psi)$$

The first part of this equality ($d\chi/dt = -1/a$) follows from Eq. (2.42), while the second part comes from Eq. (4.14). The transverse part of $\vec{x}^i$ is equal to $\chi\theta^i$, so the left-hand side of the geodesic equation is

$$\frac{d^2x^i}{d\lambda^2} = \frac{1}{a} p \frac{d}{d\chi}\left[\frac{p}{a}\frac{d}{d\chi}\left(\chi\theta^i\right)\right]$$

Here I have dropped the (small) gravitational potential because it multiplies the (small) angle θ^i. We can reduce further by remembering that (at zero order) the momentum p times a remains constant, so removing pa outside the derivative leads to

$$\frac{d^2x^i}{d\lambda^2} = p^2 \frac{d}{d\chi}\left[\frac{1}{a^2}\frac{d}{d\chi}\left(\chi\theta^i\right)\right]$$

Now let's consider the right side of the geodesic equation. Again, changing the derivatives with respect to λ to those with respect to χ leads to

$$\Gamma^i_{\alpha\beta}\frac{dx^\alpha}{d\lambda}\frac{dx^\beta}{d\lambda} = \left(\frac{p}{a}\right)^2 (1-\Psi)^2 \Gamma^i_{\alpha\beta}\frac{dx^\alpha}{d\chi}\frac{dx^\beta}{d\chi}.$$

There are three types of terms in the sum over α and β: those with $\alpha = \beta = 0$, those with one index spatial and the other temporal, and finally those in which both α and β are spatial. We have already derived the relevant Christoffel symbols, given in Eq. (5.7). Let's work through the terms one by one:

- When $\alpha = \beta = 0$, we have

$$\Gamma^i_{00}\left(\frac{dt}{d\chi}\right)^2 = \Psi_{,i} = -\Phi_{,i}$$

where the second equality holds since in the late universe there are no anisotropic stresses so $\Phi = -\Psi$.

- When one of the indices is spatial, Γ^i_{0j} is nonzero only when $i = j$. Therefore, the spatial index j must be transverse with $x^j = \chi\theta^j$. Since θ^j is small, we can drop the potential in the Christoffel symbol leading to

$$\Gamma^i_{0j}\frac{dt}{d\chi}\frac{dx^j}{d\chi} = -aH\frac{d}{d\chi}\left[\chi\theta^i\right]$$

with of course an identical term coming from Γ^i_{j0}.

- When both indices are spatial, the Christoffel symbol is proportional to the (small) gravitational potential. When multiplied by the small transverse distance, these terms will be negligible, so we need consider only the term $\Gamma^i_{jk}\left(dx^j/d\chi\right)\left(dx^k/d\chi\right)$ in which $j = k = 3$ along the radial direction. In that case $x^3 = \chi$, the derivative is trivial, and we have

$$\Gamma^i_{jk}\frac{dx^j}{d\chi}\frac{dx^k}{d\chi} = -\Phi_{,i}$$

Collecting these terms leads to the geodesic equation for transverse motion,

$$\frac{d}{d\chi}\left[\frac{1}{a^2}\frac{d}{d\chi}\left(\chi\theta^i\right)\right] = \frac{2}{a^2}\left[\Phi_{,i} + aH\frac{d}{d\chi}\left[\chi\theta^i\right]\right]$$

The derivative on the left acting on a^{-2} exactly cancels the term proportional to aH on the right, so our final equation for the transverse displacement is

$$\frac{d^2}{d\chi^2}\left(\chi\theta^i\right) = 2\Phi_{.i}.$$

This geodesic equation tells us that in a uniform potential, the angular direction $\left(\chi\theta^i\right)'$ remains constant, whereas a changing potential perturbs it. The sign is correct: An overdensity centered at $x = y = 0$ has $\Phi > 0$ there, and therefore the derivative of Φ with respect to x ($\Phi_{,i}$ with $i = 1$) is negative for $x > 0$. As such, the force on a light ray passing the overdensity on the positive x-axis is negative, i.e., inward toward the overdensity, as we expect. Equation (10.11) can be integrated to find the image angle as a function of the source angle. Integrating once gives

$$\frac{d}{d\chi}\left(\chi\theta^i\right) = 2\int_0^\chi d\chi'\Phi_{,i}\left(\vec{x}\left(\chi'\right)\right) + \text{ constant}$$

we'll fix the constant momentarily. Integrating again leads to

$$\theta^i_S = \frac{2}{\chi}\int_0^\chi d\chi''\int_0^{\chi''} d\chi'\Phi_{,i}\left(\vec{x}\left(\chi'\right)\right) + \text{ constant}$$

since $\theta^i(\chi) := \theta^i_S$, the value of $\vec{\theta}$ at the source. We now see that the constant is equal to θ^i - the observed angle - since the angle retains its initial value if there is no perturbation. The integral in the χ', χ'' plane is restricted to the shaded region in Figure 10.5 so we can change orders of integration with the χ'' integral ranging

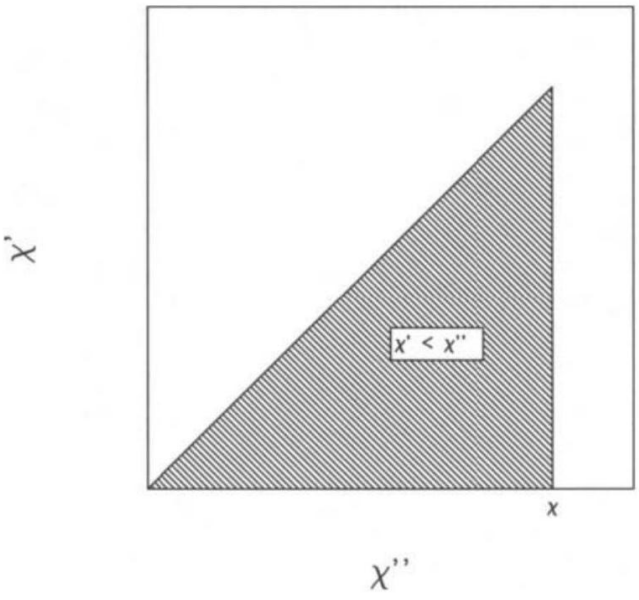

Figure 10.5. Range of integration in the double integral of Eq. (10.13). The shaded region can be expressed as $0 < \chi'' < \chi, 0 < \chi' < \chi''$ or as $\chi' < \chi'' < \chi, 0 < \chi' < \chi$. The latter is more convenient here, since the χ'' integral is then trivial.

from χ' to χ. The χ'' integral is then trivial (since $\Phi_{,i}$ depends only on χ') so

$$\theta_S^i = \theta^i + 2\int_0^\chi d\chi' \Phi_{,i}\left(\vec{x}\left(\chi'\right)\right)\left(1 - \frac{\chi'}{\chi}\right).$$

To describe the shift in the angle experienced by a light ray, it is conventional to define the 2×2 symmetric transformation matrix,

$$A_{ij} := \frac{\partial \theta_S^i}{\partial \theta^j}$$

$$:= \begin{pmatrix} 1 - \kappa - \gamma_1 & -\gamma_2 \\ -\gamma_2 & 1 - \kappa + \gamma_1 \end{pmatrix}$$

The parameter κ is called the convergence; it describes how an image is magnified. Although this magnification has many important ramifications (e.g., microlensing and multiple images) it is not what is important for the distortions studied in weak lensing. Rather, these distortions are governed by the two components of the shear,

$$\gamma_1 = -\frac{A_{11} - A_{22}}{2}$$
$$\gamma_2 = -A_{12}.$$

Equation (10.15) says that the components of shear involve derivatives of Eq. (10.14) with respect to angle $\vec{\theta}$.[1] The only dependence on $\vec{\theta}$ is in the argument of the potential, where $\vec{x}\left(\chi'\right) = \chi'\vec{\theta}$ (for the transverse components). Therefore, the derivative with respect to θ^j can be written as a derivative with respect to x^j (in our notation,j) times χ'. Therefore,

$$A_{ij} - \delta_{ij} = \begin{pmatrix} -\kappa - \gamma_1 & -\gamma_2 \\ -\gamma_2 & -\kappa + \gamma_1 \end{pmatrix} = 2\int_0^\chi d\chi' \Phi_{,ij}\left(\vec{x}\left(\chi'\right)\right)\chi'\left(1 - \frac{\chi'}{\chi}\right)$$

So γ_1 and γ_2 are well-defined functions of the potential. The next section shows how they influence the shapes of galaxy images.

12.11.3 Ellipticity as an Estimator of Shear

Theory

We expect lensing to turn circular images into elliptical ones. To describe this effect, then, we need to come up with quantitative measures of ellipticity, and then see how these are related to the components of shear defined above. The simplest measure of ellipticity starts with the definition of the quadrupole moments of an image. Imagine centering an image at the $\theta_x - \theta_y$ origin such that it has no dipole moment ($\langle\theta_x\rangle = \langle\theta_y\rangle = 0$ where angular brackets are averages over the intensity). Then the quadrupole moments are defined as

$$q_{ij} := \int d^2\theta I_{\rm obs}(\theta)\theta_i\theta_j$$

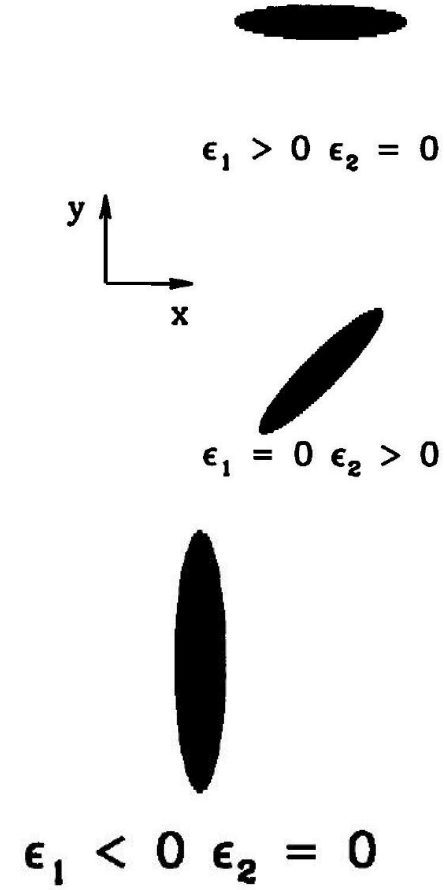
A circular image has $q_{xx} = q_{yy}$ and $q_{xy} = 0$. Therefore, two good measures of ellipticity are

$$\epsilon_1 := \frac{q_{xx} - q_{yy}}{q_{xx} + q_{yy}}$$

[1] The derivative is formally with respect to the observed angle $\vec{\theta}$, while the right-hand side of Eq. (10.14) depends on the potential at the true position of the light ray. In principle, then, the derivatives which go into the definition of A_{ij} are quite complicated. In practice, though, deflections are sufficiently small that we can ignore the distinction between the final angle $\vec{\theta}$ and the actual angle everywhere along the trajectory. Therefore, on the right-hand side of Eq. (10.14) we evaluate the potential along the undistorted path parameterized by $\vec{\theta}$.

$$\epsilon_2 := \frac{2q_{xy}}{q_{xx} + q_{yy}}$$

Figure 10.6 shows different orientations of elliptical images and the associated



$\epsilon_1 < 0 \epsilon_2 = 0$

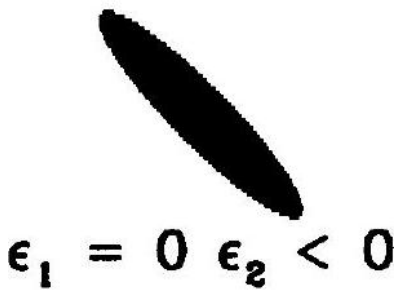


Figure 10.6. Definition of ellipticities ϵ_1 and ϵ_2. Circular images have both ellipticities equal to zero.

values of the ϵ_1 and ϵ_2. With these definitions, we can make more precise the statement at the end of Section 10.1 about correlations of ellipticities. Panel (a) in Figure 10.3 has two galaxies at $\vec{\theta}_1$ and $\vec{\theta}_2$, each with ϵ_1 positive; in panel (b) both galaxies have ϵ_1 negative. In both possible cases, then, the product $\epsilon_1\left(\vec{\theta}_1\right)\epsilon_1\left(\vec{\theta}_2\right)$ is positive if the x-axis is chosen along the direction connecting the two galaxies. The impossible case is depicted in panel (c) wherein the product is negative. Therefore, we do not expect lensing to produce $\epsilon_1\left(\vec{\theta}_1\right)\epsilon_1\left(\vec{\theta}_2\right) < 0$.

How are the ellipticities defined in Eq. (10.19) related to the shear defined in Eq. (10.16)? Let's assume that the source is spherical and compute the ellipticity of the image. Focusing on ϵ_1, we have

$$\epsilon_1 = \frac{\int d^2\theta I_{\rm true}\left(\vec{\theta}_S\right)\left[\theta_x\theta_x - \theta_y\theta_y\right]}{\int d^2\theta I_{\rm true}\left(\vec{\theta}_S\right)\left[\theta_x\theta_x + \theta_y\theta_y\right]}$$

where I have used the equality of Eq. (10.1). The integrals here are over the observed angles $\vec{\theta}$, while the integrands depend in part on the angle from which the photon started at the source, θ_S. For small angles, these are related via $\theta_i = \left(A^{-1}\right)_{ij}\theta_{Sj}$. To do the integrals, then, change dummy variables in the integral to $\vec{\theta}_S$, and write all occurences of θ_i as $\left(A^{-1}\theta_S\right)_i$. This leads to

$$\epsilon_1 = \frac{\sum\limits_{ij}\left[\left(A^{-1}\right)_{xi}\left(A^{-1}\right)_{xj} - \left(A^{-1}\right)_{yi}\left(A^{-1}\right)_{yj}\right]\int d^2\theta_S I_{\rm true}\left(\vec{\theta}_S\right)\theta_{S_i}\theta_{Sj}}{\sum\limits_{ij}\left[\left(A^{-1}\right)_{xi}\left(A^{-1}\right)_{xj} + \left(A^{-1}\right)_{yi}\left(A^{-1}\right)_{yj}\right]\int d^2\theta_S I_{\rm true}\left(\vec{\theta}_S\right)\theta_{Si}\theta_{Sj}}.$$

Now the integral over the (true) circular image vanishes unless $i = j$ and so is proportional to δ_{ij}. The proportionality constant is irrelevant since it appears in both the numerator and denominator, so

$$\begin{aligned}\epsilon_1 &= \frac{\left(A^{-1}\right)_{xi}\left(A^{-1}\right)_{xi} - \left(A^{-1}\right)_{yi}\left(A^{-1}\right)_{yi}}{\left(A^{-1}\right)_{xi}\left(A^{-1}\right)_{xi} + \left(A^{-1}\right)_{yi}\left(A^{-1}\right)_{yi}} \\ &= \frac{\left(A^{-1}_{xx}\right)^2 - \left(A^{-1}_{yy}\right)^2}{\left(A^{-1}_{xx}\right)^2 + \left(A^{-1}_{yy}\right)^2 + 2\left(A^{-1}_{xy}\right)^2}.\end{aligned}$$

It is easy to compute the inverse of the 2×2 matrix A:

$$A^{-1} = \frac{1}{(1-\kappa)^2 - \gamma_1^2 - \gamma_2^2}\begin{pmatrix} 1-\kappa+\gamma_1 & \gamma_2 \\ \gamma_2 & 1-\kappa-\gamma_1 \end{pmatrix},$$

so we see that the ellipticity ϵ_1 can be expressed in terms of the shear as

$$\begin{aligned}\epsilon_1 &= \frac{\left(1-\kappa+\gamma_1\right)^2 - \left(1-\kappa-\gamma_1\right)^2}{\left(1-\kappa+\gamma_1\right)^2 + \left(1-\kappa-\gamma_1\right)^2 + 2\gamma_2^2} \\ &= \frac{4\gamma_1(1-\kappa)}{2(1-\kappa)^2 + 2\gamma_1^2 + 2\gamma_2^2}.\end{aligned}$$

If all the distortions are small, then

$$\epsilon_1 \simeq 2\gamma_1$$

the desired result. A similar equality holds for ϵ_2. By measuring ellipticities of distant galaxies, therefore, we can get an estimate of the shear field, a field which depends manifestly on the underlying gravitational potential via Eq. (10.17).

12.11.4 Weak Lensing Power Spectrum

Theory

We can now compute the simplest statistics of the shear field, which can be estimated by measuring background galaxy ellipticities. Let's remove the identity from the transformation matrix A,

$$\psi_{ij} := A_{ij} - \delta_{ij}.$$

In the absence of inhomogeneities, the apparent angle θ is equal to the source angle θ_S, so $A = I$. Therefore, by removing the identity matrix from A, we have extracted the part describing the distortion of the light ray path due to inhomogeneities. As such, we will refer to ψ as the distortion tensor. The last term in (10.17) is ψ_{ij} for a background galaxy (or galaxies) at distance $\chi(z)$ from us. In general, a survey contains a distribution of redshifts. Let's call this distribution $W(\chi)$, just as we did when studying angular correlations in Chapter 9. Again, let's normalize W so that $\int d\chi W(\chi) = 1$. Then, the distortion tensor is

$$\psi_{ij} = 2 \int_0^{\chi_\infty} d\chi W(\chi) \int_0^{\chi} d\chi' \Phi_{,ij} \left(\vec{x}\left(\chi'\right)\right) \chi' \left(1 - \frac{\chi'}{\chi}\right).$$

We can simplify here by changing orders of integration (almost exactly as depicted in Figure 10.5). Then

$$\psi_{ij}(\vec{\theta}) = \int_0^{\chi_\infty} d\chi \Phi_{,ij}(\vec{x}(\chi)) g(\chi)$$

where I have dropped the prime and defined

$$g(\chi) := 2\chi \int_\chi^{\chi_\infty} d\chi' \left(1 - \frac{\chi}{\chi'}\right) W\left(\chi'\right)$$

On average, each of the components of the distortion tensor is zero: $\langle \psi_{ij} \rangle = 0$. To make our money, therefore, we need to do just what we did for the CMB and galaxy distributions, compute the two-point function, either the angular correlation functions of the different components of ψ_{ij} or their Fourier transforms, the power spectra. To compute these two-point functions, we will be able to essentially copy the results from Section 9.1 as long as we are careful to account for the indices on ψ_{ij}.

To compute the power spectrum of the distortion tensor, $P^{\psi}_{ijkl}(\vec{l})$, let's recall the steps we took when we analyzed the angular correlation function of galaxies (see Table 10.1).

- The distortion tensor in Eq. (10.28) is a function of the 2D vector $\vec{\theta}$ since the argument of the potential is $\vec{x} \simeq \chi\left(\theta_1, \theta_2, 1\right)$. As in the case of the galaxy density field, we can Fourier transform ψ_{ij} so that it depends on the 2D vector conjugate to $\vec{\theta}, \vec{l}$.
- In the case of the angular galaxy overdensity, we expressed the 2D overdensity as an integral over the 3D overdensity with some weighting function (Eq. (9.3)). Here the situation is identical: g in Eq. (10.29) plays the role of the selection function W there while the 3D field here is not the overdensity δ, but rather $\Phi_{,ij}$.

- Next we found that - in the small-angle limit - the 2D power spectrum is given by an integral over the 3D power spectrum, Eq. (9.10). Here, too, the 2D power spectrum of ψ_{ij} can be expressed as an integral over the 3D power spectrum of the gravitational potential Φ. The only slightly tricky part is computing the 3D power spectrum of $\Phi_{,ij}$. The Fourier transform of $\Phi_{,ij}$ is $-k_i k_j \tilde{\Phi}$ with a variance

$$k_i k_j k'_l k'_m \left\langle \tilde{\Phi}(\vec{k}) \tilde{\Phi}^* \left(\vec{k'}\right) \right\rangle = (2\pi)^3 k_i k_j k_l k_m \delta^3 \left(\vec{k} - \vec{k'}\right) P_\Phi(k).$$

So the 3D power spectrum we need - the one associated with the Fourier transform of $\Phi_{,ij}$ - is $k_i k_j k_l k_m P_\Phi(k)$. Table 10.1. Similarity between Agular Correlations of Galaxies and Weak Lensing.

	Angular galaxy distribution	Weak lensing
2D observation	$\delta_2(\vec{\theta})$	Distortion tensor $\psi_{ij}(\vec{\theta})$
Weighting function	$W(\chi)$	$g(\chi)$
3D field	δ	$\Phi_{,ij}$
3D power spectrum	$\left\langle \tilde{\delta}\tilde{\delta}^* \right\rangle \sim P(k)$	$\left\langle \tilde{\Phi}_{,ij} \dot{\Phi}^*_{,lm} \right\rangle \sim k_i k_j k_l k_m P_\Phi(k)$
2D power spectrum	$P_2(l)$	$P^\psi_{ijlm}(\vec{l})$

I will keep things in terms of P_Φ, but if you are more comfortable with the density power spectrum, you can see from Eq. (7.7) that you need only multiply P_Φ by $9\Omega_m^2 H_0^4 (1+z)^2/\left(4k^4\right)$. Applying Eq. (9.10) then leads to

$$\left\langle \tilde{\psi}_{ij}(\vec{l}) \tilde{\psi}_{lm}(\vec{l}) \right\rangle = (2\pi)^2 \delta^2(\vec{l} - \vec{l}) P^\psi_{ijlm}(\vec{l})$$

with the 2D power spectrum

$$P^\psi_{ijlm}(\vec{l}) = \int_0^{\chi\infty} d\chi \frac{g^2(\chi)}{\chi^2} \frac{l_i l_j l_l l_m}{\chi^4} P_\Phi(l/\chi)$$

Equation (10.32) is an expression for the power spectrum of the different components of the distortion tensor. We can turn these into power spectra for the convergence κ and two different components of shear by using Eq. (10.16). Let's work this out for one of the shear components explicitly; the other two are relegated to a problem. Since $\gamma_1 = \left(\psi_{22} - \psi_{11}\right)/2$, the power spectrum of γ_1 is 1/4 times $P^\psi_{2222} + P^\psi_{1111} - 2P^\psi_{2211}$. If we decompose the 2D vector $\vec{l}$ into a radial part l and an angle ϕ_l, then $l_1 = l\cos\phi_l$ and $l_2 = l\sin\phi_l$, so

$$P_{\gamma_1}(l, \phi_l) = \left(\sin^4\phi_l + \cos^4\phi_l - 2\sin^2\phi_l \cos^2\phi_l\right) \left[\frac{l^4}{4} \int_0^{\chi\infty} d\chi \frac{g^2(\chi)}{\chi^6} P_\Phi(l/\chi)\right].$$

Since $\sin^4\phi_l + \cos^4\phi_l + 2\cos^2\phi_l \sin^2\phi_l = 1$, the term in parentheses here is equal to $1 - 4\sin^2\phi_l\cos^2\phi_l = 1 - \sin^2(2\phi_l)$ or $\cos^2(2\phi_l)$. You will show in Exercise 6 that the expression in square brackets is equal to the power spectrum of the convergence,

$$P_\kappa = \frac{l^4}{4} \int_0^{\chi\infty} d\chi \frac{g^2(\chi)}{\chi^6} P_\Phi(l/\chi)$$

Therefore, the power spectrum of γ_1 is

$$P_{\gamma_1}(l, \phi_l) = \cos^2(2\phi_l)\, P_\kappa(l).$$

You will show in Exercise 6 that the power spectrum of γ_2 is also proportional to P_κ,

$$P_{\gamma_2}(l, \phi_l) = \sin^2(2\phi_l)\, P_\kappa(l).$$

Thus, the power spectra of the two components of shear depend not only on the magnitude of $\vec{l}$ but also on its direction. Figure 10.7 shows the convergence power

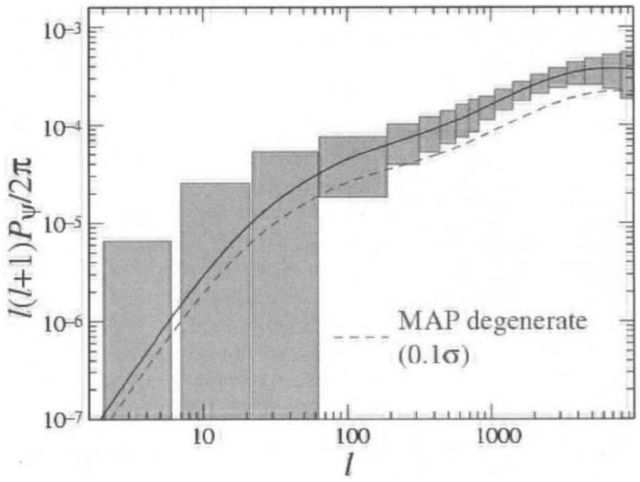

Figure 10.7. The power spectrum of the convergence for two CDM models (Hu and Tegmark, 1999). The models are indistinguishable using CMB data alone, so future weak lensing data (depicted by the error boxes) add invaluable information. The projected error boxes assume a 3° survey down to 25 th magnitude.

spectrum for two models. Note that, unlike the CMB or even the matter power spectrum, it is essentially featureless.

The power spectra of both shear components are proportional to P_κ, with a prefactor depending on the angle between $\vec{l}$ and a fixed x-axis. You might expect then that a linear combination of the two components depends only on $P_\kappa(l)$ with no dependence on the angle ϕ_l. This is correct. Even more interesting, though, is the possibility that a different linear combination would have a vanishing power spectrum. This also turns out to be correct, and extremely useful. Such a mode has no expected cosmological signal, so any nonzero value is a measure of some systematic effect. By focusing on this "zero" mode, one can identify and eliminate contaminating effects in an experiment. I want to spend some time on this decomposition into two modes - one with signal and one without - not only because of its importance in this case of weak lensing, but also because an exact analogy exists in the case of polarization of the CMB, which we will take up in the next sections. To get ahead of myself, in the case of polarization, the "zero" mode is zero only for scalar perturbations, whereas tensor perturbations do contribute to it. Therefore, we will see in Section 10.9 that this decomposition is a powerful tool with which to detect primordial gravity waves.

Consider then the following two linear combinations of the shear:

$$E(\vec{l}) := \cos(2\phi_l)\, \gamma_1(\vec{l}) + \sin(2\phi_l)\, \gamma_2(\vec{l})$$
$$B(\vec{l}) := -\sin(2\phi_l)\, \gamma_1(\vec{l}) + \cos(2\phi_l)\, \gamma_2(\vec{l}).$$

The power spectrum of each of these modes is easily obtainable in terms of the spectra of γ_1 and γ_2. First the E-mode:

$$P_E = \cos^2(2\phi_l)\, P_{\gamma_1} + \sin^2(2\phi_l)\, P_{\gamma_2} + 2\sin(2\phi_l)\cos(2\phi_l)\, P_{\gamma_1\gamma_2}.$$

This expression involves the power spectrum corresponding to $\langle\gamma_1\gamma_2\rangle$, which is equal to $\cos(2\phi_l)\sin(2\phi_l)$ times the ubiquitous convergence power spectrum. Therefore, P_E is proportional to P_κ with proportionality constant $\cos^4(2\phi_l) + \sin^4(2\phi_l) + 2\cos^2(2\phi_l)\sin^2(2\phi_l) = \left(\cos^2(2\phi_l) + \sin^2(2\phi_l)\right)^2 = 1$, or

$$P_E = P_\kappa$$

independent of the angle ϕ_l. The calculation for the B-mode is similar:

$$\begin{aligned} P_B &= \sin^2(2\phi_l)\, P_{\gamma_1} + \cos^2(2\phi_l)\, P_{\gamma_2} - 2\sin(2\phi_l)\cos(2\phi_l)\, P_{\gamma_1\gamma_2} \\ &= 0. \end{aligned}$$

You can also check that the cross power spectrum $\langle EB\rangle$ vanishes.

The field of weak lensing due to large-scale structure is its infancy. The year 2000 saw the first detections by four independent groups (Van Waerbecke et al., 2000; Bacon, Refregier, and Ellis, 2000; Wittman et al., 2000; Kaiser, Wilson, and Luppino, 2000). They presented the shear correlation function, one example of which is shown in Figure 10.10. We can easily translate the power spectra derived above into angular correlation functions that can be compared with data.

Let's focus on the angular correlation function of γ_1, the Fourier transform of P_{γ_1},

$$w_{\gamma_1}(\vec{\theta}) = \int \frac{d^2l}{(2\pi)^2} e^{i\vec{l}\cdot\vec{\theta}} \cos^2(2\phi_l) \left[\frac{l^4}{4}\int_0^{\chi_\infty} d\chi \frac{g^2(\chi)}{\chi^6} P_\Phi(l/\chi)\right]$$

The variable ϕ_l we are integrating over is the angle between the 2D vector $\vec{l}$ and an arbitrary external x-axis. If we do the angular integral over ϕ_l, then-as you can see from Figure 10.8 - the argument of the exponential is quite complicated: $il\theta\cos(\phi_l - \phi)$. Instead, let's integrate over the angle between $\vec{l}$ and $\vec{\theta}$, call it ϕ'. Then,

$$w_{\gamma_1}(\vec{\theta}) = \int_0^\infty \frac{dl}{(2\pi)^2}\frac{l^5}{4}\int_0^{\chi_\infty} d\chi \frac{g^2(\chi)}{\chi^6} P_\Phi(l/\chi) \int_0^{2\pi} d\phi' e^{il\theta\cos\phi'} \left[\cos\left(2\left(\phi' + \phi\right)\right)\right]^2.$$

The cosine squared in the integrand is equal to

$$\left[\cos(2\phi')\cos(2\phi) - \sin(2\phi')\sin(2\phi)\right]^2$$

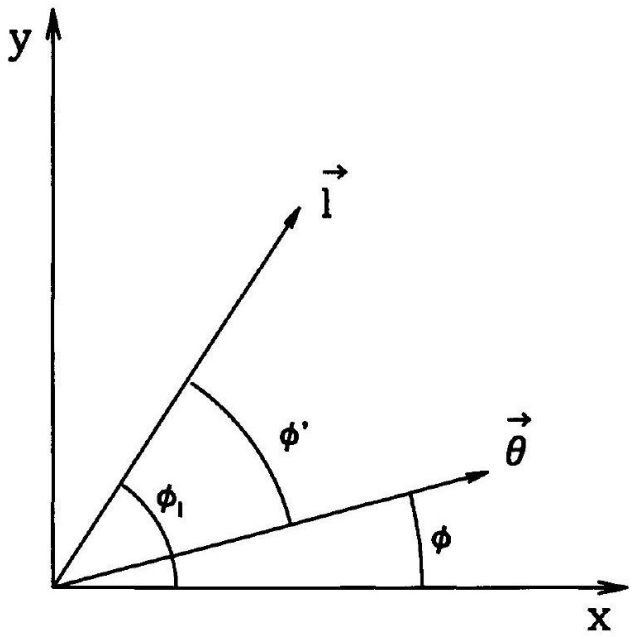

Figure 10.8. Angles made by $\vec{\theta}$ and $\vec{l}$ with respect to an external fixed $x-y$ coordinate system. The angle between $\vec{\theta}$ and $\vec{l}$ is ϕ'.

$$= \cos^2(2\phi')\cos^2(2\phi) - \sin(4\phi')\sin(4\phi)/2 + \sin^2(2\phi')\sin^2(2\phi)$$

Thus there are three terms to be integrated over. To do the integral over $\cos^2(2\phi')$, first rewrite it as $(1+\cos(4\phi'))/2$; then recall that the integral of $\cos(n\phi')\, e^{iz\cos\phi'}$ is equal to $2\pi i^n J_n(z)$ (Eq. (C.21)). Therefore, the integral of $\cos^2(2\phi')$ gives a factor of π times $J_0(l\theta) + J_4(l\theta)$. Using exactly the same arguments, you can see that the integral of $\sin^2(2\phi')$ gives π times $J_0(l\theta) - J_4(l\theta)$. Less obvious is the fact that the integral of $\sin(4\phi')$ vanishes (change integration variable to $\phi'' = \phi' - \pi$ and argue that the integrand is antisymmetric). Therefore,

$$w_{\gamma_1}(\vec{\theta}) = \frac{1}{16\pi}\int_0^\infty dl l^5 \int_0^{\chi\infty} d\chi \frac{g^2(\chi)}{\chi^6} P_\Phi(l/\chi) \times \left\{\cos^2(2\phi)\left[J_0(l\theta)+J_4(l\theta)\right] + \sin^2(2\phi)\left[J_0(l\theta)-J_4(l\theta)\right]\right\} \cdot (10$$

There are many angles floating around, so let me reiterate that $\vec{\theta} = (\theta\cos\phi, \theta\sin\phi)$; that is, ϕ is the angle that $\vec{\theta}$ makes with the x-axis. By changing the l integral into one over 3D wavenumber $k = l/\chi$, we can rewrite this angular correlation function in terms of kernels,

$$w_{\gamma_1}(\vec{\theta}) = \int_0^\infty dk k^5 P_\Phi(k)\left[F_+(k\theta)\cos^2(2\phi) + F_-(k\theta)\sin^2(2\phi)\right]$$

Note that here I have assumed that the potential remains constant with time, an assumption which breaks down at late times because of nonlinearities or non-matter domination. The kernels are integrals over radial distance χ modulated by the Bessel functions,

$$F_\pm(k\theta) := \frac{1}{16\pi}\int_0^{\chi\infty} d\chi g^2(\chi)\left[J_0(k\chi\theta) \pm J_4(k\chi\theta)\right]$$

Figure 10.9 shows these two kernels for background galaxies at redshift $z = 0.9$.

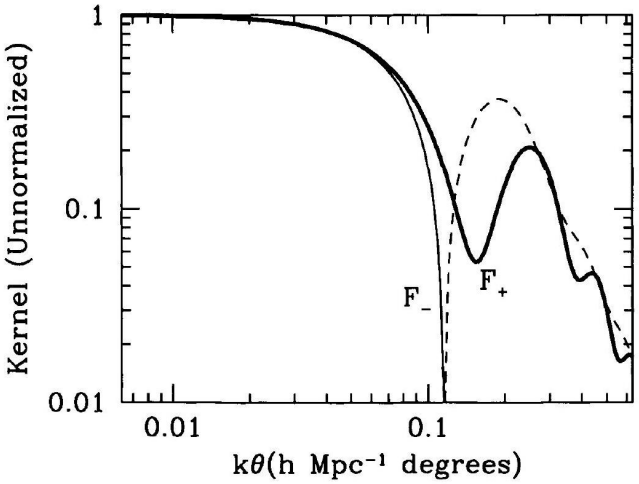

Figure 10.9. The kernels for the shear correlation function assuming all background galaxies are at $z = 0.9$. Dashed region corresponds to negative kernel. If the x-axis is chosen along the line connecting pairs of galaxies, then the + kernel is for $\langle\gamma_1\gamma_1\rangle$ and the - for $\langle\gamma_2\gamma_2\rangle$. Note that the former is always positive.

If we choose the x-axis to be along the line connecting pairs of galaxies, then we are evaluating the correlation function at $\vec{\theta} = (\theta, 0)$, that is, with $\phi = 0$. In that case, Figure 10.9 shows that w_{γ_1} is always positive, a result we anticipated pictorially in Section 10.1. The correlation function for γ_2, on the other hand, is identical to that in Eq. (10.45) except that $F_{\pm}$are interchanged. Therefore, w_{γ_2} can, and indeed does, go negative, usually on large angular scales. The final point to take away from the kernels in Figures 10.9 is the rough sense that the shear on a scale of a tenth of degree probes the power spectrum at $k \sim 1h\text{Mpc}^{-1}$ since this is where the kernel breaks.

Consider then Figure 10.10, which shows results from a survey of three "blank" (i.e., no known clusters of galaxies present) fields over a period of several years. There is a clear detection of ellipticity, presumably due to cosmic shear. The root mean square amplitude of the shear is the square root of the typical numbers on the y-axis, around 0.01. Thus, shear due to large-scale structure has been detected

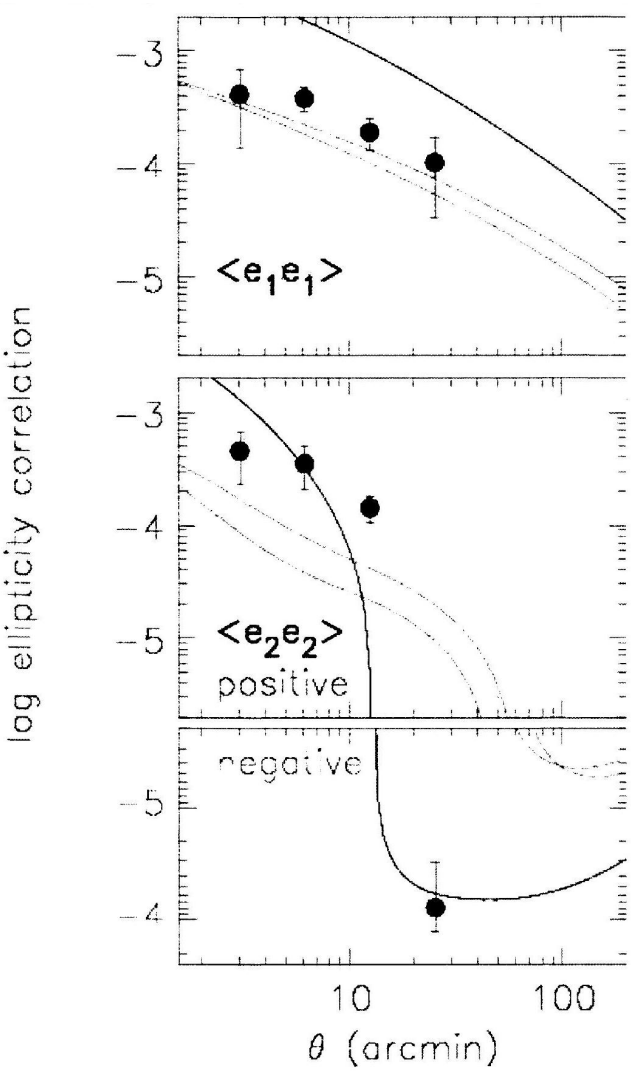

Figure 10.10. Measurement of the shear correlation functions using 145, 000 background galaxies (Wittman et al., 2000). Also shown are a variety of CDM models; topmost in top panel is standard CDM, ruled out here at many sigma. Note that $w_{\gamma_1} = \langle e_1 e_1 \rangle$ remains positive on all angular scales. See color Plate 10.10. with an amplitudeof order 10^{-2} on angular scales ranging from $1'$ out to about $1°$. Observations planned in the coming years will go far beyond these preliminary results; from these observations we will learn much about the mass distribution of the universe.

12.11.5 Polarization: The Quadrupole and the Q/U Decomposition

Theory

The radiation in the CMB is expected to be polarized because of Compton scattering at the time of decoupling. A polarization pattern shares a number of mathematical features with the shear induced by gravitational lensing that we have just studied. In addition to these mathematical similarities, they also share similar experimental histories. Whereas anisotropies in the temperature of the CMB and inhomogeneities in the density field were discovered back in the 20th century, weak lensing by large scale structure and polarization of the CMB have just been detected. They are true 21st century phenomena. Therefore, they are both fields rich for study: We are just beginning our observations of them, and they both promise to deliver much cosmological information.

Light traveling in the x-direction corresponds to electric and magnetic fields oscillating in

the y - z plane, i.e., transverse to the direction of propagation. If the intensity along the two transverse directions is equal, then the light is unpolarized. Until now, when we have considered the CMB, we have been implicitly studying this case. Now we must account for the possibility that the intensities in the two transverse directions are unequal: that the radiation is polarized.

At first glance, Compton scattering is a perfect mechanism for producing polarized radiation. It allows all transverse radiation to pass through unimpeded, while completely stopping any radiation parallel to the outgoing direction. To see this, consider Figure 10.11 which shows a ray incident from the $+\hat{x}$ direction. This (unpolarized) ray has equal intensity in the $\hat{y}$ and $\hat{z}$ directions. It scatters off an electron at the origin and gets deflected into the $+\hat{z}$ direction. [2] Since the outgoing direction is along the z-axis, none of the (incoming) intensity along the z-axis gets transmitted. By contrast, all of the intensity along the y-axis (which is perpendicular to both the incoming and outgoing directions) is transmitted. The net result is outgoing polarization in the $\hat{y}$ direction.

Obviously, we cannot content ourselves with studying one incoming ray; we must generalize to radiation incident on an electron from all directions. When we do so, we begin to realize that producing polarization will not be quite as easy as it appears from Figure 10.11. Consider first Figure 10.12, which shows a caricature of a much more relevant case: isotropic radiation incident on the electron from all directions. I say "caricature" because I have shown incoming rays from only two directions, the $+\hat{x}$ - and $+\hat{y}$-directions. The intensity of the outgoing ray along the

[2] Of course radiation gets scattered into all directions with varying probability. Here we consider just one outgoing direction for simplicity. In the next section we account for this probability.

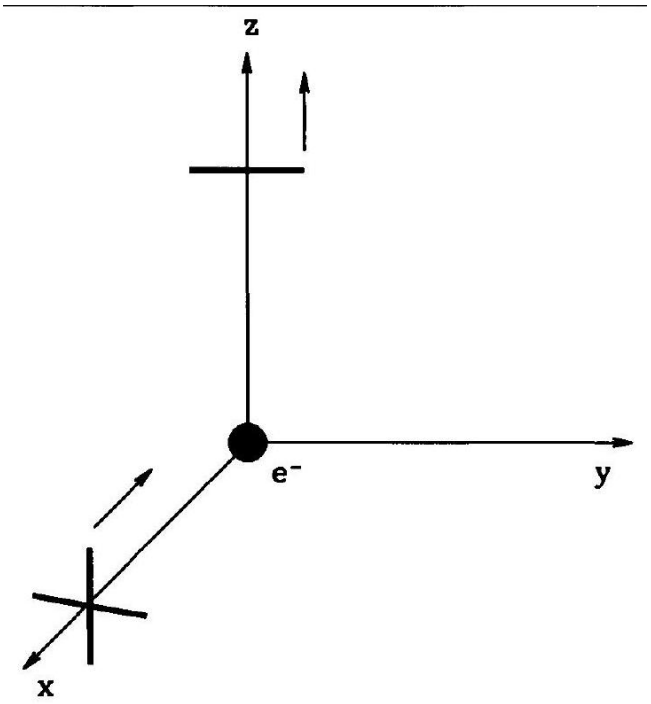

Figure 10.11. Unpolarized radiation moving toward the origin along the x-axis is scattered by an electron into the $+\hat{z}$ direction. Only the $\hat{y}$ component of the radiation remains after scattering. Since there was no incoming $\hat{x}$ polarization, the outgoing radiation is polarized in the $\hat{y}$ direction. (This and the next three figures are adapted from Hu and White, 1997b).

x-axis comes from the radiation incident from the $\hat{y}$ direction, while the outgoing y-intensity comes from the radiation incident from the $\hat{x}$-axis. Since the radiation from both directions has equal intensity (isotropic radiation), though, the outgoing wave is has equal intensity along the $\hat{x}$ - and $\hat{y}$-axes: it is unpolarized.

Can anisotropic radiation produce polarization? The simplest example of anisotropy is a dipole pattern, a caricature of which is shown in Figure 10.13. Now the outgoing intensity along the x-axis comes from the $\pm\hat{y}$-incident radiation, which has the average temperature. The outgoing intensity along the y-axis is also neither hot nor cold because it comes from a cold spot (the $-\hat{x}$-direction) and a hot spot (the $+\hat{x}$-direction). The dipole pattern leads therefore only to cancellations and unpolarized outgoing radiation.

To produce polarized radiation, the incoming radiation must have a nonzero quadrupole. Figure 10.14 illustrates the polarization produced by an incoming quadrupole. The hotter (colder) radiation incident from the $\hat{x}$ - ($\hat{y}-$) direction produces higher (lower) intensity along the y - ($x-$) axis for the outgoing wave. Therefore, the intensity of the outgoing wave is greater along the y-axis than along the x-axis: the outgoing radiation is polarized.

The fact that Compton scattering produces polarization only when the incident field has a quadrupole moment has important ramifications for cosmology. We need Compton scattering to produce the polarization, so we need to focus on the epoch

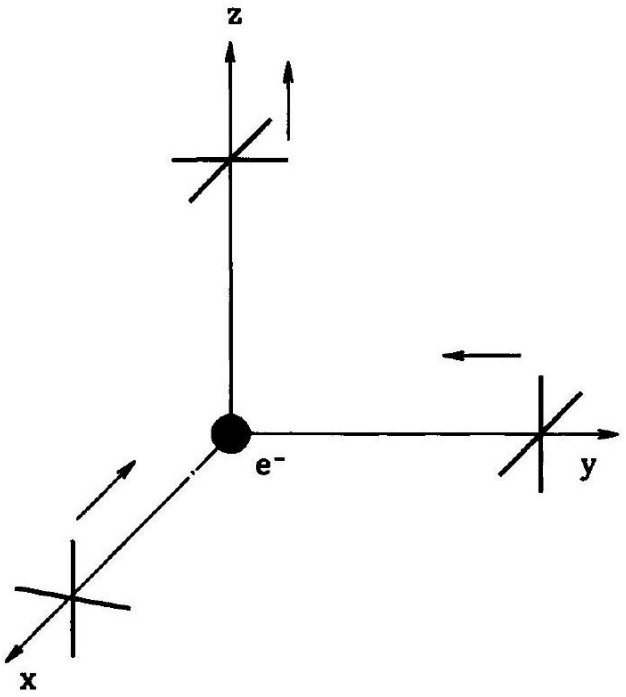

Figure 10.12. Incoming isotropic radiation produces no polarization. Here, since the incoming amplitudes from the $\hat{x}$ - and $\hat{y}$-directions are equal, the outgoing intensities along both of these directions are equal, leading to unpolarized radiation.

before electrons and photons have completely decoupled from each other. However, in this epoch electrons and photons are tightly coupled, which we have seen leads to a very small quadrupole. Therefore, we expect polarization from the standard decoupling epoch to be smaller than the anisotropies. Late reionization enhances the polarization at large scales, but does not modify the qualitative conclusion that the polarization signal is expected to be small.

Figure 10.14 depicts polarization in the $x-y$ plane, preferentially in the $\hat{y}$ direction. Alternatively, had the incoming rays been rotated by 45° in the $x-y$ plane, the outgoing polarization would have been along the axis 45° from the x and y-axes. Polarization therefore can be depicted as a headless vector, with a length corresponding to its magnitude and the orientation of the line describing the axis along which the intensity is greatest. In the 2D plane perpendicular to the direction of propagation, we therefore decompose the intensity into

$$I_{ij} = \begin{pmatrix} T+Q & U \\ U & T-Q \end{pmatrix}.$$

The diagonal elements T are the temperature we studied in Chapter 8 (with a uniform part and a perturbation Θ); the two new variables Q and U describe polarization. The pattern in Figure 10.14 has $Q < 0$ and $U = 0$. Note that these definitions of Q and U are identical to the definitions of shear and ellipticity in Section 10.2. Especially relevant is Figure 10.6 where we simply replace ϵ_1 with Q

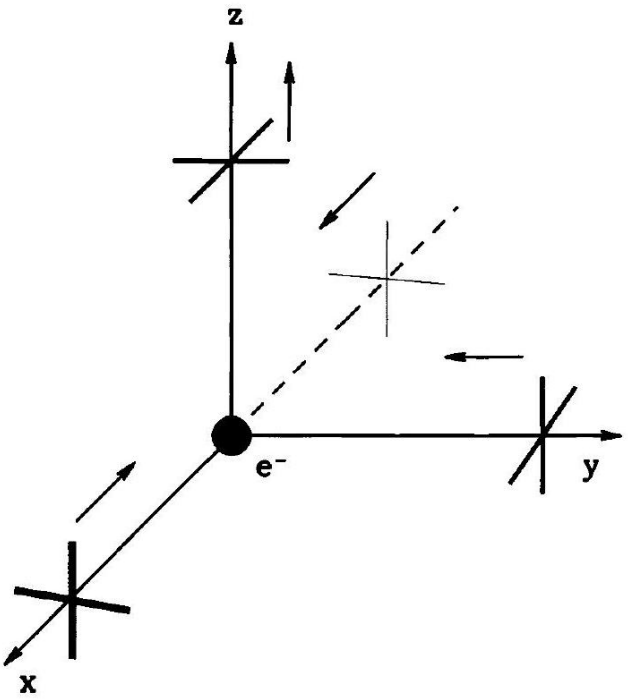

Figure 10.13. Incoming dipole radiation also produces no polarization. (See also color Plate 10.13.) Heavy (thin) lines denote hot (cold) spots. Here the incoming radiation is hotter than average (average is medium thickness) from the $+\hat{x}$-direction, and colder than average from the $-\hat{x}$-direction. The two rays from the $\pm\hat{x}$-directions therefore produce the average intensity for the outgoing ray along the $\hat{y}$-direction. The outgoing intensity along the $\hat{x}$-direction is produced by the ray incident from the $\pm\hat{y}$-directions. Since these have the average intensity, the outgoing intensity is also the average along the $\hat{x}$-direction. The net result is outgoing unpolarized light.

and ϵ_2 with U. A final note: students of electricity and magnetism will no doubt recognize T, Q, and U as three of the four Stokes parameters used to describe polarization. The fourth, V, is nonzero only if polarization is circularly polarized, a phenomenon we do not expect in the early universe, so I have implicitly set $V = 0$ here.

12.11.6 Polarization from a Single Plane Wave

Theory

The pictures of the previous subsection are important to gain a qualitative understanding of how Compton scattering produces polarization, but they are inefficient tools with which to study the phenomenon quantitatively. The proper tool is the Boltzmann equation. We could proceed now by simply writing down the Boltzmann equation for the Q and U polarization states. In doing so, however, we would lose some of the intuition just gained, so I will take an intermediate tack. We will generalize the discussion of the previous section by summing o: er all incident rays, not just a handful. This will enable us to make the connection with the distribution Θ

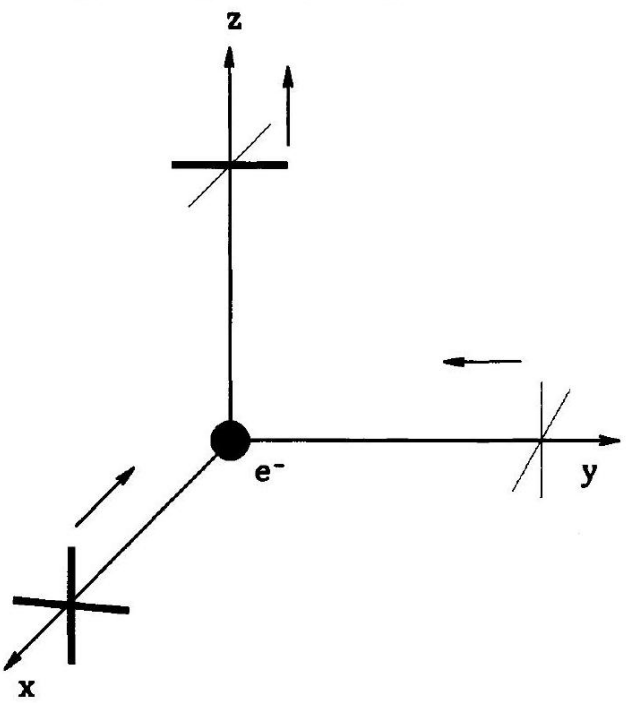

Figure 10.14. Incoming quadrupole radiation produces outgoing polarized light. See also color Plate 10.14.) The outgoing radiation has greater intensity along the y-axis than in the $\hat{x}$-direction. This is a direct result of the hotter radiation incident from the $\hat{x}$-direction.

we have used until now to characterize the photons.

We first need to define the polarization axes in the most general case when the incoming photon arrives from direction $\hat{n}'$. When that direction was $\hat{x}$, as in the previous section, it was clear that polarization was defined as the difference in the intensity along the two perpendicular directions, $\hat{y}$ and $\hat{z}$. In the general case, depicted in Figure 10.15, the direction of the incoming photon is depicted by $\hat{n}'$, and we must integrate over all incoming directions. The two axes perpendicular to this direction are most conveniently taken to be $\hat{\theta}'$ and $\hat{\phi}'$, the standard unit vectors perpendicular to the position vector. These are called $\hat{\epsilon}'_1$ and $\hat{\epsilon}'_2$. We still are interested in the polarization of outgoing photons in the $\hat{z}$-direction, so we can choose the two outgoing polarization axes as $\hat{\epsilon}_1 = \hat{x}$ and $\hat{\epsilon}_2 = \hat{y}$. In short, the incoming polarization vectors are $\hat{\epsilon}'_i$, the outgoing are $\hat{\epsilon}_i$.

The idea that Compton scattering allows the fields transverse to the outgoing direction to pass through unimpeded, while stopping those parallel to the outgoing direction, can be encapsulated by saying that the cross-section for outgoing photons polarized in the $\hat{\epsilon}_i$ direction is proportional to

$$\sum_{j=1}^{2} \left| \hat{\epsilon}_i(\hat{n}) \cdot \hat{\epsilon}'_j\left(\hat{n}'\right) \right|^2 .$$

The Q polarization is the difference between this cross-section for $i = 1$ and $i = 2$, i.e., the difference between the field strength in $\hat{x}$ - and $\hat{y}$-directions:

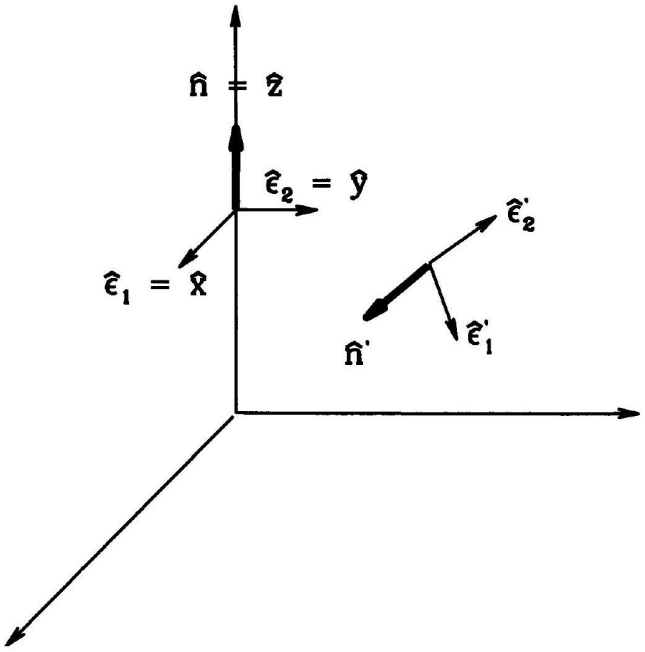

Figure 10.15. Incoming photon from direction $\hat{n}'$ Compton scatters off an electron at the origin producing outgoing photon in direction $\hat{n} = \hat{z}$. The plane perpendicular to the incoming direction is spanned by the two polarization vectors, $\hat{\epsilon}'_1 = \hat{\theta}'$ and $\hat{\epsilon}'_2 = \hat{\phi}'$. The outgoing photon is in the $\hat{z}$ direction, so the polarization vectors are $\hat{\epsilon}_1 = \hat{x}$ and $\hat{\epsilon}_2 = \hat{y}$.

$$\sum_{j=1}^{2} \left|\hat{\epsilon}_1(\hat{n}) \cdot \hat{\epsilon}'_j\left(\hat{n}'\right)\right|^2 - \sum_{j=1}^{2} \left|\hat{\epsilon}_2(\hat{n}) \cdot \hat{\epsilon}'_j\left(\hat{n}'\right)\right|^2 = \sum_{j=1}^{2} \left(\left|\hat{x} \cdot \hat{\epsilon}'_j\left(\hat{n}'\right)\right|^2 - \left|\hat{y} \cdot \hat{\epsilon}'_j\left(\hat{n}'\right)\right|^2\right)$$

Integrating over all incoming $\hat{n}'$ directions leads to

$$Q(\hat{z}) = A \int d\Omega_{n'} f\left(\hat{n}'\right) \sum_{j=1}^{2} \left(\left|\hat{x} \cdot \hat{\epsilon}'_j\left(\hat{n}'\right)\right|^2 - \left|\hat{y} \cdot \hat{\epsilon}'_j\left(\hat{n}'\right)\right|^2\right)$$

Here A is a normalization constant which will not concern us for now, and $f\left(\hat{n}'\right)$ is the intensity of the radiation incoming from the $\hat{n}'$-direction, and we integrate over all such directions. Note that f depends only on $\hat{n}'$, but not on ϵ'_j: this corresponds to the assumption that the incident radiation is unpolarized.

To take the dot products in Eq. (10.50), we will find it useful to express $\hat{\epsilon}'_1$ and $\hat{\epsilon}'_2$ in terms of their Cartesian coordinates. Since they are equal to $\hat{\theta}'$ and $\hat{\phi}'$, respectively, we have

$$\begin{aligned}
\hat{\epsilon}'_1\left(\theta', \phi'\right) &= \left(\cos\theta' \cos\phi', \cos\theta' \sin\phi', -\sin\theta'\right) \\
\hat{\epsilon}'_2\left(\theta', \phi'\right) &= \left(-\sin\phi', \cos\phi', 0\right)
\end{aligned}$$

Now, the dot products become trivial, and we find

$$\begin{aligned}
Q(\hat{z}) &= A \int d\Omega_{n'} f\left(\hat{n}'\right) \left[\cos^2\theta' \cos^2\phi' + \sin^2\phi' - \cos^2\theta' \sin^2\phi' - \cos^2\phi'\right] \\
&= -A \int d\Omega_{n'} f\left(\hat{n}'\right) \sin^2\theta' \cos 2\phi'.
\end{aligned}$$

You might recognize the combination of angles here as being propotional to the sum of the spherical harmonics $Y_{2,2} + Y_{2,-2}$ (Eq. (C.10)). Since the spherical harmonics are orthogonal, the integral will pick out the $l = 2, m = \pm 2$ components of the distribution f. That is, nonzero Q will be produced only if the incident radiation has a quadrupole moment. This verifies

the argument-by-pictures given in the previous subsection. It is straightforward to derive the corresponding expression for the U component of polarization (Exercise 10),

$$U(\hat{z}) = -A \int d\Omega_{n'} f(\hat{n}') \sin^2\theta' \sin(2\phi')$$

The combination of sines here is proportional to $Y_{2,2} - Y_{2,-2}$. Again, only an incident quadrupole produces U polarization.

We can now relate the outgoing Q and U to the moments of the incident unpolarized distribution. We'll do this in four steps, in increasing generality.

- First, we'll consider the polariztion induced by a wavevector $\vec{k}$ in the $\hat{x}$-direction. - Next, we allow $\vec{k}$ to lie anywhere in the $\hat{x} - \hat{z}$ plane.
- Then, we consider the most general possible wavevector.
- The first three steps will give us Q and U of the outgoing radiation along the z-axis. We need to generalize this to arbitrary outgoing directions.

The reason that we need to move so slowly is that the photon distribution, $f(\hat{n}')$, takes its cue from the direction of the wavevector. Recall that, in Chapter 4, we wrote the photon distribution as the sum of a zero-order piece - the uniform Planck distribution - and a perturbation, characterized by $\Theta(k,\mu)$ (e.g., Eq. (4.35)). There μ was the dot product of the wave vector $\hat{k}$ and the direction of propagation. Here we have labeled the direction of propagation of the incident photon as $\hat{n}'$, so $\mu = \hat{k}\cdot\hat{n}'$. Thus, $f(\hat{n}')$ in Eq. (10.52) will be an expansion in Legendre polynomials with argument $\hat{k}\cdot\hat{n}'$. This argument is not equal to the cosine of θ', since θ' is the angle between the external z-axis and $\hat{n}'$. Relating μ to θ' and ϕ' therefore is not trivial, and we will proceed slowly. Let's first consider the wave vector $\vec{k}$ to lie in the $\hat{x}$-direction. Then,

$$\begin{aligned}\mu := \hat{k}\cdot\hat{n}' &= \left(\hat{n}'\right)_x \\ &= \sin\theta'\cos\phi'.\end{aligned}$$

Recall that we decomposed the perturbation Θ into a sum over Legendre polynomials, so

$$\begin{aligned}\Theta\left(k, \hat{k}\cdot\hat{n}'\right) &= \sum_l (-i)^l (2l+1)\Theta_l(k)\mathcal{P}_l\left(\hat{k}\cdot\hat{n}'\right) \\ &\rightarrow -5\Theta_2(k)\mathcal{P}_2\left(\sin\theta'\cos\phi'\right),\end{aligned}$$

where the last line follows by substituting our expression for μ (Eq. (10.54)) and considering only the relevant quadrupole part of the sum.

A plane wave with wavevector $\vec{k}$ pointing in the $\hat{x}$-direction therefore has

$$Q(\hat{z}, \vec{k}\|\hat{x}) = 5A\Theta_2(k)\int_0^\pi d\theta' \sin\theta' \int_0^{2\pi} d\phi' \mathcal{P}_2\left(\sin\theta'\cos\phi'\right)\sin^2\theta'\cos 2\phi'$$

Recall that $\mathcal{P}_2(\mu) = (3\mu^2 - 1)/2$. The $-1/2$ part of this gives no contribution to the integral since the ϕ' integral over $\cos(2\phi')$ vanishes. Therefore, we are left with

$$Q(\hat{z}, \vec{k}\|\hat{x}) = \frac{15A\Theta_2(k)}{2}\int_0^\pi d\theta' \sin^5\theta' \int_0^{2\pi} d\phi' \cos^2\phi' \cos 2\phi'$$

The ϕ' integral is $\pi/2$, while the θ' integral — easily done by defining $\mu' = \cos\theta'$??? is 16/15. So

$$Q(\hat{z}, \vec{k} \| \hat{x}) = 4\pi A \Theta_2(k)$$

We've now made part of the connection between polarization - represented by Q here - and the formalism of anisotropies - described by Θ in general and Θ_2 specifically for the quadrupole. This expression though applies only in the very simple case that the wavevector points along the x-axis, perpendicular to the line of sight.

Let's generalize this expression to wavevectors pointing in an arbitrary direction in the $\hat{x}$ - $\hat{z}$ plane: $\hat{k} = (\sin\theta_k, 0, \cos\theta_k)$. In this case, the factor of $\left(\hat{k} \cdot \hat{n}'\right)^2$ coming from $\mathcal{P}_2$ is $\sin^2\theta_k \sin^2\theta' \cos^2\phi' + \cos^2\theta_k \cos^2\theta'$. The first term is identical to the $\hat{k} \| \hat{x}$ case just derived, multiplied by $\sin^2\theta_k$. The second term introduces no new ϕ' dependence; since the integral over $\cos(2\phi')$ vanishes, it does not contribute. Therefore

$$Q(\hat{z}, \vec{k} \perp \hat{y}) = 4\pi A \sin^2\theta_k \Theta_2(k)$$

In Exercise 10 you will show that there is no U-polarization from this type ($\vec{k}$ in the $\hat{x} - \hat{z}$ plane): the polarization is all Q.

For any single plane wave, we can always rotate our coordinate system around the z-axis to ensure that the plane wave lies in the $\hat{x}$ - $\bar{z}$ plane, so that Eq. (10.59) applies. When we come to consider the real universe, however, with its superposition of many plane-wave perturbations, we won't have this luxury. Instead, we will need to account for the most general wavevector with orientation $\hat{k} = (\sin\theta_k \cos\phi_k, \sin\theta_k \sin\phi_k, \cos\theta_k)$. For this more general perturbation, you can go through (Exercise 9) exactly the same types of calculations as went into Eq. (10.59) to show that

$$Q(\vec{z}, \vec{k}) = 4\pi A \sin^2\theta_k \cos(2\phi_k) \Theta_2(k)$$
$$U(\vec{z}, \vec{k}) = 4\pi A \sin^2\theta_k \sin(2\phi_k) \Theta_2(k).$$

We must make one final generalization. Until now, we have focused solely on the outgoing radiation along the z-axis. Of course, not all outgoing rays will be along the z-axis. (This is what we are looking for: difference in polarization as a function of angle.) To account for arbitrary directions, we need to allow the polar angle θ_k in Eq. (10.60) to be the angle between the observation direction $\hat{n}$ and $\hat{k}$. So $\cos\theta_k \to \hat{n} \cdot \hat{k}$, and of course $\sin^2\theta_k$ becomes $1 - (\hat{n} \cdot \hat{k})^2$. Therefore, for observations near the z-axis, the outgoing polarization induced by incoming unpolarized incident radiation is

$$Q(\hat{n}, \vec{k}) = 4\pi A \left[1 - (\hat{n} \cdot \hat{k})^2\right] \cos(2\phi_k) \Theta_2(k)$$
$$U(\hat{n}, \vec{k}) = 4\pi A \left[1 - (\hat{n} \cdot \hat{k})^2\right] \sin(2\phi_k) \Theta_2(k).$$

These expressions are valid only for directions $\hat{n}$ near the z-axis. This restriction is due to the dependence on the azimuthal angle, ϕ_k. Far from the z-axis, $\cos(2\phi_k)$ and $\sin(2\phi_k)$ give way to much more complicated expressions depending on both $\hat{n}$ and $\hat{k}$. Near the z-axis, though, the relatively simple sine and cosine describe the dependence on azimuthal angle. Thus, we will work in the small angle limit, where all observation directions are close to one another, clustered around the z-axis.

Equations (10.61) allow us to draw polarization patterns around the z-axis for arbitrary $\hat{k}$ modes. Consider the four patterns in Figure 10.16. In each case, the z-axis is out of the page in the center of the panel. For $\vec{k}$ in the $\hat{x} - \hat{y}$ plane ($\theta_k = 90°$), Eq. (10.61) says that the strength of the polarization as a function of $\hat{n}_x$ and $\hat{n}_y$ varies as

$$1 - (\hat{n} \cdot \hat{k})^2 = 1 - \left(\hat{n}_x \hat{k}_x + \hat{n}_y \hat{k}_y\right)^2$$

That is, deviations from the maximum at $\hat{n}_x = \hat{n}_y = 0$ are small, quadratic in $\hat{n}_x, \hat{n}_y$. The orientation of the polarization in these cases can be either Q (top left panel, $\phi_k = 0$) or U (bottom left panel, $\phi_k = 45°$). For $\vec{k}$ out of the $\hat{x} - \hat{y}$ plane, we begin to observe changes in the polarization strength. The two right panels in Figure 10.16 illustrate these changes. Again there can be either Q or U polarization. The most important feature of these patterns is that the polarization strength is always changing in the direction parallel or perpendicular to the sense of the

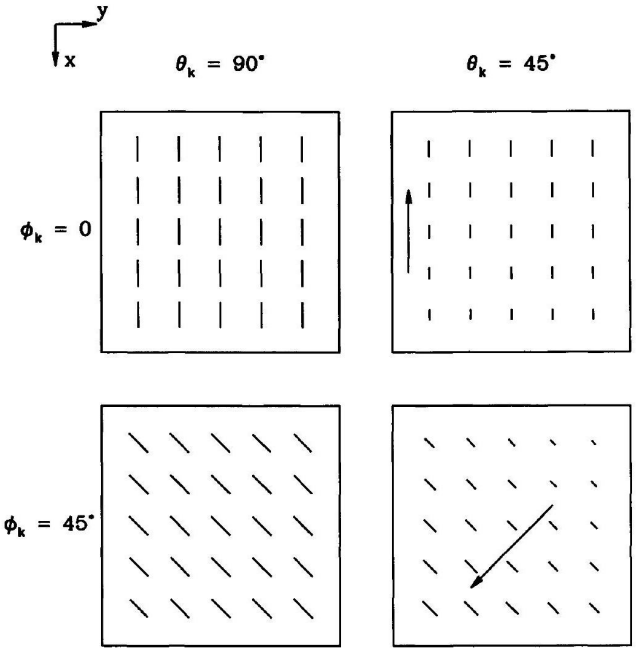

Figure 10.16. Polarization patterns near the z-axis arising from four plane wave perturbations with different $\vec{k}$. E.g., upper left arises from $\vec{k}$ along the x-axis ($\theta_k = 90°, \phi_k = 0$). For $\hat{k}$ in the $\hat{x} - \hat{y}$ plane (two left panels with $\theta_k = 90°$), polarization is at a maximum at $\hat{z}$, so little variation is seen. Arrows in right panel show direction in which polarization strength increases. This direction (or the direction perpendicular to it along which polarization remains constant) is aligned with the polarization pattern. This alignment is the hallmark of an E-mode.

polarization. In the top right panel, polarization is aligned with the x-axis, and this is the direction in which the polarization strength is changing. In the bottom right panel, polarization is aligned along $\hat{x} + \hat{y}$, and the change is along the perpendicular direction $\hat{x} - \hat{y}$. We will soon decompose polarization into E and B modes, just as we did the shear pattern in weak lensing. The patterns observed here are all pure E. Indeed, scalar perturbations generate only E modes.

We can also begin to understand the E/B decomposition. The polarization generated by scalar perturbations, the E mode, varies in strength in the same direction as its orientation. This conjures images of an electric field. An electric field from a point source, $\vec{E} = q\hat{r}/r^2$, varies in strength as one moves away from the point source. The electric field is pointed in the same direction: radially away from the source. As one moves in the direction of the field, the strength of the field decreases. In Section 10.9, we will encounter the B mode, and see that - just like a magnetic field - the B mode of polarization varies in strength in a different direction from that in which it is pointing.

12.11.7 Boltzmann Solution

Theory

To make quantitative predictions for the polarization expected in the CMB, we must go beyond the treatment of the previous section. There, we sat a single electron at the origin and

considered the polarization emerging from incoming radiation with a given distribution. The real problem has lots of electrons coupled to an evolving photon distribution. For this, we need the Boltzmann equation. We wrote down the relevant equations in Chapter 4, although it will take a little bit of work to relate the variable we used there, Θ_P, to Q and U introduced above. The relevant equations ((4.101) and (4.102)) from Chapter 4 are

$$\dot{\Theta}_P + ik\mu\Theta_P = -\dot{\tau}\left[-\Theta_P + \frac{1}{2}\left(1 - \mathcal{P}_2(\mu)\right)\Pi\right]$$
$$\Pi = \Theta_2 + \Theta_{P2} + \Theta_{P0}$$

where $\mu := \hat{k}\cdot\hat{n}$, and Θ_{P0} and Θ_{P2} are the monopole and quadrupole, respectively, of the polarization field.

We are left with the question of the relationship between Θ_P and $Q, U.\Theta_P$ is the strength of the polarization, while Q and U together describe both the strength and the orientation. In Chapter 4, we implicitly chose $\hat{k}$ to to lie in the $\hat{x}$ - $\hat{z}$ plane in Chapter 4. In that case, we have just seen that the polarization is all Q, so

$$\begin{aligned} Q(\hat{z},\vec{k}) &= \Theta_P(\hat{z},\vec{k}) \\ U(\hat{z},\vec{k}) &= 0 \qquad\qquad \hat{k}\perp\hat{y}. \end{aligned}$$

More generally, for arbitrary $\vec{k}$, at least for directions $\hat{n}$ close to $\hat{z}$, we have

$$\begin{aligned} Q(\vec{k},\hat{n}) &= \Theta_P(\hat{k}\cdot\hat{n})\cos\left(2\phi_k\right) \\ U(\vec{k},\hat{n}) &= \Theta_P(\hat{k}\cdot\hat{n})\sin\left(2\phi_k\right). \end{aligned}$$

Equation (10.66) is a crucial connection between the polarization pattern $Q(\hat{n}), U(\hat{n})$ we are interested in and $\Theta_P(\mu := \hat{k}\cdot\hat{n})$ for which we have Boltzmann equations. Now all we need to do is solve the Boltzmann equations for Θ_P, and then use Eq. (10.66) to construct power spectra for Q and U. We attack the first task in this section and the second in the next.

First, though, to solidify this connection between Θ_P and Q, U, it is instructive to rederive the result of the previous section for an incoming unpolarized wave using the Boltzmann equation. We found there (Eq. (10.59)) that the outgoing polarization (for $\hat{k}$ in the $\hat{x}-\hat{z}$ plane) was proportional to $(1-\mu^2)\,\Theta_2$ where μ is the cosine of the angle between $\hat{k}$ and $\hat{z}$. Can we get this from the Boltzmann equation? In the absence of any prior polarization, Eq. (10.63) reduces to

$$\begin{aligned} \dot{\Theta}_P &= -\dot{\tau}\frac{1-\mathcal{P}_2(\mu)}{2}\Pi \\ &= \frac{-3\dot{\tau}}{2}\left(1-\mu^2\right)\Theta_2. \end{aligned}$$

Integrating over η, we find that the polarization induced by Compton scattering from incident unpolarized radiation is

$$\Theta_P = \frac{3\tau}{2}\left(1-\mu^2\right)\Theta_2$$

i.e. the optical depth times the quadrupole modulated by the geometric factor $1-\mu^2$, in agreement with the less formal derivation advanced above. We also see that the strength of the polarization generated is proportional to the optical depth, τ, the integral along the line of sight of the free electron density times the Thomson cross-section.

Now let's solve the Boltzmann equation for the polarization. In analogy to Eq. (8.46), the formal solution to Eq. (10.63) for Θ_P is

$$\Theta_P(\hat{n},\vec{k}) = \int_0^{\eta_0} d\eta e^{i\vec{k}\cdot\hat{n}(\eta-\eta_0)-\tau(\eta)} S_P(k,\mu,\eta),$$

where the source term is

$$S_P(k,\mu,\eta) = -\frac{3}{4}\dot{\tau}\left(1-\mu^2\right)\Pi.$$

Remember that the visibility function is defined as $-\dot{\tau}e^{-\tau}$, so

$$\Theta_P(\hat{n},\vec{k}) = \frac{3}{4}\left(1-\mu^2\right)\int_0^{\eta_0} d\eta e^{i\vec{k}\cdot\hat{n}(\eta-\eta_0)} g(\eta)\Pi(k,\eta).$$

A reasonable approximation is to assume that we can evaluate the integrandexcept for the rapidly changing visibility function - at the time of decoupling (for standard recombination). Then, since the visibility function integrates to unity,

$$\Theta_P(\hat{n},\vec{k}) \simeq \frac{3\Pi\left(k,\eta_*\right)}{4}\left(1-\mu^2\right)e^{i\vec{k}\cdot\hat{n}(\eta_*-\eta_0)}.$$

Neglecting η_* compared with η_0 and rewriting the factors of μ as derivatives leads to

$$\Theta_P(k,\mu) \simeq \frac{3\Pi\left(k,\eta_*\right)}{4}\left(1+\frac{\partial^2}{\partial\left(k\eta_0\right)^2}\right)e^{-ik\eta_0\mu}.$$

To get the moments Θ_{Pl}, we must multiply Eq. (10.73) by $\mathcal{P}_l(\mu)$ and integrate over all μ as in Eq. (4.99). This gives (Eq. (C.15))

$$\Theta_{Pl}(k) \simeq \frac{3\Pi\left(k,\eta_*\right)}{4}\left(1+\frac{\partial^2}{\partial\left(k\eta_0\right)^2}\right)j_l\left(k\eta_0\right).$$

The sum of the spherical Bessel function and its second derivative can be rewritten using the spherical Bessel equation (C.13) as

$$j_l + j_l'' = -\frac{2j_{l-1}}{k\eta_0} + \frac{2(l+1)}{\left(k\eta_0\right)^2}j_l + \frac{l(l+1)}{\left(k\eta_0\right)^2}j_l.$$

Of the three terms on the right, the last one dominates on small scales. To see this, remember that the spherical Bessel function peaks roughly at $k\eta_0 \sim l$. Physically, this means that anisotropy on an angular scale l is determined by perturbations with wavelength $k^{-1} \sim \eta_0/l$. For our order-of-magnitude estimate, this means that we can take $k\eta_0$ to be of order l in the three terms on the right-hand side. The first is then of order l^{-1}, the second of order l^{-1}, and the last of order $l^2/\left(k\eta_0\right)^2 \sim 1$: the last term dominates. Therefore,

$$\Theta_{Pl}(k) \simeq \frac{3\Pi\left(k,\eta_*\right)}{4}\frac{l^2}{\left(k\eta_0\right)^2}j_l\left(k\eta_0\right).$$

In the tight coupling limit, we can express Π in terms of the quadrupole, which in turn is related to the dipole. As you can show in Exercise 12, $\Pi = 5\Theta_2/2$. Therefore, the polarization moments today are

$$\Theta_{Pl}(k) \simeq \frac{15\Theta_2\left(k,\eta_*\right)}{8}\frac{l^2}{\left(k\eta_0\right)^2}j_l\left(k\eta_0\right).$$

We can go one step further by noting that - in the tightly coupled limit - the quadrupole is proportional to the dipole (Eq. (8.34)). Therefore,

$$\Theta_{Pl}(k) \simeq -\frac{5k\Theta_1(k,\eta_*)}{6\dot{\tau}(\eta_*)}\frac{l^2}{(k\eta_0)^2}j_l(k\eta_0).$$

Equation (10.78) is a final expression for the polarization moments today assuming the tightly coupled limit. Three features are worthy of note. First, and most important, the polarization spectrum is seen to be smaller than the anisotropy spectrum by a factor of order k/τ at the time of decoupling. We will quantify this in the next section, but we now understand that it is a direct result of the twin facts that polarization is generated by a quadrupole moment and the quadrupole is suppressed in the early universe due to Compton scattering. Second, we expect there to be oscillations in the polarization power spectrum because $\Theta_{Pl} \propto \Theta_1$, which undergoes acoustic oscillations. More quantitatively, we expect the polarization oscillations, just like the dipole, to be out of phase with the monopole. The peaks and troughs in the temperature anisotropy spectrum, arising primarily from oscillations in the monopole, should then be out of phase with the peaks and troughs in the polarization power spectrum. Finally, there is no analogue here to the integrated Sachs-Wolfe effect which impacts the temperature anisotropy spectrum. Polarization cannot be induced by photons moving through changing gravitational potentials. Therefore, the polarization spectrum today is in some senses a more pristine view of the early universe, uncontaminated by later developments.

12.11.8 Polarization Power Spectra

Theory

Equation (10.78) is an expression for the polarization moments from a single plane wave. In the real universe, we have not just one plane wave, but a superposition of many waves, all with differing amplitudes $\Theta_P(\vec{k},\hat{n})$. The angular power spectrum from a superposition of plane waves follows from the identical calculation on the temperature anisotropies (Eq. (8.68)):

$$C_{P,l} = \frac{2}{\pi}\int_0^\infty dk k^2 |\Theta_{Pl}(k)|^2$$

For quite a while, cosmologists computed this power spectrum without reference to Q or U. In 1997, a flurry of papers appeared which derived the power spectra for Q and U. These exploited Eq. (10.66) or large-angle generalizations of it.

Based on our solution for the power spectra of the different components of shear in Section 10.4, we have a sense of what to expect for the power spectra of Q and U. Consider first Figure 10.17. In the small angle limit, Q for example is a function of the 2D vector $\vec{\theta}$, the projection of $\hat{n}$ onto the plane perpendicular to the $\hat{z}$ axis. Thus, we can Fourier transform Q just as we Fourier transformed the shear fields above; its transform will depend on $\vec{l}$, the vector conjugate to $\vec{\theta}$. Based on our experience with weak lensing, we expect the power spectrum of $\tilde{Q}$ to depend not only on the magnitude of $\vec{l}$ but also on its orientation. Looking back at Eq. (10.66), we will not be surprised to find that this power spectrum, $C_{QQ}(\vec{l})$ is proportional to $C_{P,l}$. The proportionality constant is $\cos^2(2\phi_l)$, where ϕ_l is the angle $\vec{l}$ makes with the x-axis. Thus, the factor of $\cos(2\phi_k)$ in Eq. (10.66) becomes $\cos(2\phi_l)$ when we sum over all $\vec{k}$. Similarly, the power spectrum of $\tilde{U}$ is $\sin^2(2\phi_l)C_{P,l}$.

Let's derive this connection between the power spectra of Q and U and that of Θ_P explicitly. We can write the Q polarization as a sum over all plane waves:

$$Q(\vec{\theta}) = \int \frac{d^3k}{(2\pi)^3}\Theta_P(\vec{\theta},\vec{k})\cos(2\phi_k)$$

The modulating factor $e^{i\vec{x}\cdot\vec{k}}$ is set to 1 here, since we observe from only one position, and we are calling that position $\vec{x} = 0$. To deal with the $\cos(2\phi_k)$ factor, first note that it is equal to $\cos^2\phi_k - \sin^2\phi_k$, or in terms of the Cartesian components of $\vec{k}$:

$$\cos(2\phi_k) = \frac{k_x^2 - k_y^2}{k_x^2 + k_y^2}.$$

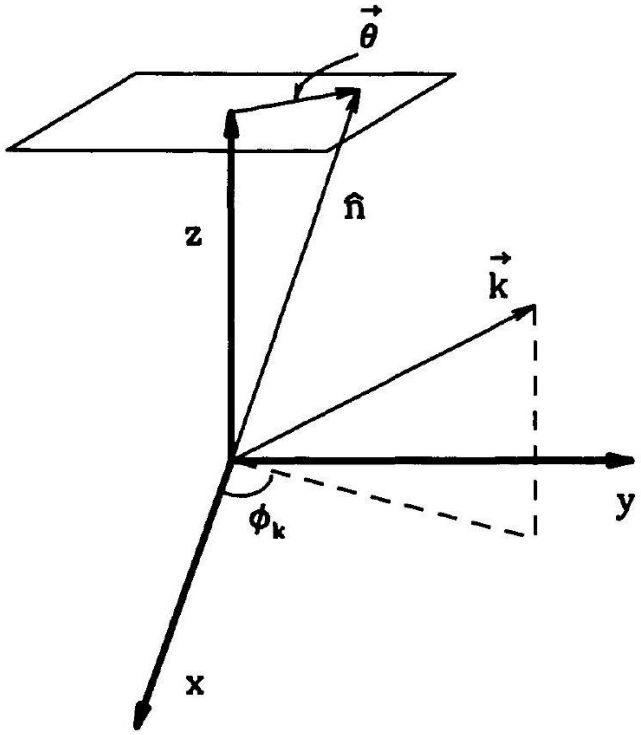

Figure 10.17. Different vectors in polarization. We observe radiation with incoming direction $\hat{n}$, also parameterized by 2D angle θ. Wavevector $\vec{k}$ has an azimuthal angle ϕ_k.

Since Θ_P has the exponential factor $e^{-i\vec{k}\cdot\hat{n}\eta_0}$ (e.g. Eq. (10.69)), and since $\hat{n}_x = \theta_x$ and $\hat{n}_y = \theta_y$, we can rewrite these Cartesian coordinates as derivatives with respect to the $\vec{\theta}$. For example, $k_x \to [-i\eta_0]^{-1}\,\partial/\partial\theta_x$. The full $\cos(2\phi_k)$ factor therefore can be written solely as derivatives with respect to $\vec{\theta}$:

$$\cos(2\phi_k) = D_Q(\vec{\theta}) := \left[\frac{\partial^2}{\partial\theta_x^2} + \frac{\partial^2}{\partial\theta_y^2}\right]^{-1}\left(\frac{\partial^2}{\partial\theta_x^2} - \frac{\partial^2}{\partial\theta_y^2}\right)$$

This expression looks formidable, but it is extremely useful for summing up many different k-modes. We can replace Eq. (10.80) with

$$\begin{aligned} Q(\vec{\theta}) &= D_Q(\vec{\theta})\int\frac{d^3k}{(2\pi)^3}\Theta_P(\vec{\theta},\vec{k}) \\ &= D_Q(\vec{\theta})\Theta_P(\vec{\theta}) \end{aligned}$$

Both $Q(\vec{\theta})$ and $\Theta_P(\vec{\theta})$ can be written in terms of their Fourier transforms, so that Eq. (10.83) becomes

$$\int\frac{d^2l}{(2\pi)^2}e^{i\vec{l}\cdot\vec{\theta}}Q(\vec{l}) = D_Q(\vec{\theta})\int\frac{d^2l}{(2\pi)^2}e^{i\vec{l}\cdot\vec{\theta}}\Theta_{Pl}$$

Now D_Q, which is so very complicated in θ-space, becomes very simple, for we know exactly what it looks like when it acts on the exponential $e^{i\vec{l}\cdot\vec{\theta}}$. In that case, it simply becomes $\cos(2\phi_l)$,

where ϕ_l is the angle that the 2D vector $\vec{l}$ makes with the x-axis. Therefore, the Fourier transform of $Q(\vec{\theta})$ is

$$\tilde{Q}(\vec{l}) = \tilde{\Theta}_{Pl} \cos(2\phi_l)$$

An identical argument says that $U(\vec{l}) = \Theta_{Pl} \sin(2\phi_l)$. Therefore, the power spectra of $\tilde{Q}$ and $\tilde{U}$ are

$$C_{QQ}(\vec{l}) = C_{P,l} \cos^2(2\phi_l)$$
$$C_{UU}(\vec{l}) = C_{P,l} \sin^2(2\phi_l) .$$

Recall that in the case of weak lensing, we noticed that one could take linear combinations of γ_1 and γ_2 such that the power spectrum of one of the linear combinations vanishes (Eq. (10.40)), while the other is equal to the convergence power spectrum (Eq. (10.39)). Here we can do exactly the same thing. If we define

$$E(\vec{l}) := \tilde{Q}(\vec{l}) \cos(2\phi_l) + \tilde{U}(\vec{l}) \sin(2\phi_l)$$
$$B(\vec{l}) := -\tilde{Q}(\vec{l}) \sin(2\phi_l) + \tilde{U}(\vec{l}) \cos(2\phi_l)$$

then

$$C_{BB}(\vec{l}) = 0$$

In the small-scale limit, the power in the E-mode is precisely equal to C_P:

$$\lim_{l \gg 1} C_{EE}(\vec{l}) = C_{P,l}$$

Figure 10.18 shows the resultant power spectrum, both the exact numerical result and the approximation of Eq. (10.78) integated over all modes as dictated by Eq. (10.79). Also shown is the spectrum of temperature anisotropies from Chapter 8. As expected it is higher in amplitude, since polarization is suppressed in the tightly coupled limit. Also as anticipated, the oscillations in the polarization spectrum are out of phase with those in the temperature spectrum. In 2002, the DASI experiment announced the first detection of polarization, a detection shown in Figure 10.18. This is akin to the first detection of shear by large scale structure, the beginning of our journey down promising new paths in cosmology.

The spectrum in Figure 10.18 is shown only on small scales; on larger scales, the treatment of this section needs to be modified (Kamionkowski, Kosowsky, and Stebbins, 1997a; Seljak and Zaldarriaga, 1997). The resultant spectrum has no surprises: it falls off very rapidly on large scales. Since the polarization is proportional to the dipole, which vanishes for large-scale modes, we could have anticipated this result as well. Although I won't go into the technical details of this large-angle

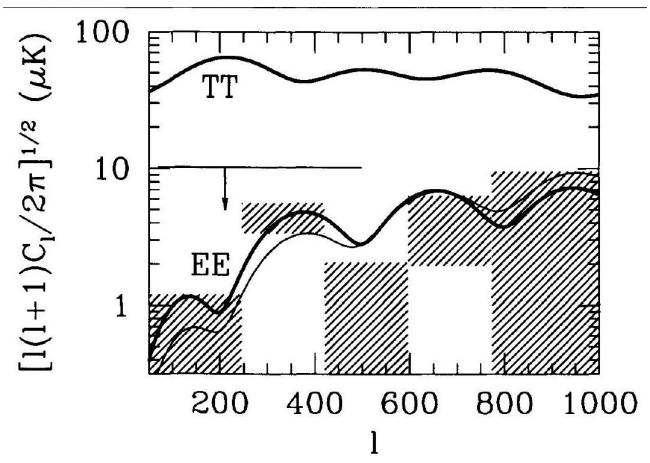

Figure 10.18. Power spectra of temperature and E-mode polarization for the standard CDM model. Thick curves show exact results; thin curve is the tight coupling approximation of Eq. (10.78). Only scalar perturbations have been assumed, so there is no power in the B-mode. Straight line at 10μK is an upper limit from Hedman et al., 2002, while the hatched boxes are the first detection by the DASI experiment (Kovac et al., 2002).

result, the basic idea is that instead of expanding polarization in terms of Legendre polynomials, or ordinary spherical harmonics, one must use tensor spherical harmonics.

One final comment: we have been implicitly assuming until now that the perturbations of interest are scalar. We inserted this assumption early on by writing the plane-wave perturbation as Eq. (10.55). If the perturbations were tensor, the decomposition would have included an azimuthal dependence; recall Eq. (4.115).

12.11.9 Detecting Gravity Waves

Theory

There is a fundamental difference between the scalar perturbations we have considered in the previous sections and tensor perturbations. A scalar plane-wave perturbation has one direction associated with it: the direction of the wavevector $\vec{k}$. Once this direction is specified, all photon moments depend only on the angle between the incoming photon and the wavevector. Once this angle is specified, there is an azimuthal symmetry about the $\hat{k}$ direction. This rotational symmetry is the reason that only the E mode is produced by scalar perturbations. There are two directions in a polarization field: (i) the direction in which the polarization strength is changing and (ii) the orientation of the polarization. For scalar perturbations, we saw in Figure 10.16 that these directions must be aligned (or perpendicular to each other). Intuitively, each direction looks to the only vector it knows $-\vec{k}$ - for guidance, and they each arrive at the same end. This alignment is the salient characteristic of the E mode.

The photon distribution from tensor perturbations is not rotationally symmetric about the $\vec{k}$-direction. Gravity waves are pulsations in the metric; these induce an azimuthal dependence to the photon distribution. Recall from Eq. (4.115) that the resultant distribution varies as $\sin(2\phi)$ or $\cos(2\phi)$, where ϕ is the azimuthal angle about the $\vec{k}$-axis. This dependence on ϕ means that there is an additional direction to choose from when the polarization field gets induced. We might expect then that the orientation of the polarization will not necessarily be aligned with the direction of changing polarization strength. That is, we might expect that gravity waves will produce B-mode polarization. This is exactly what we will show in this section.

Before working through the algebra, we need to pause to understand the importance of the B-mode generated by tensor perturbations. Let's start with the difficulty of detecting tensors through the E-mode. Both scalars and tensors contribute to the E-mode, so the only way to disentangle them is to take advantage of differences in their spectra as a function of l. We saw in the case of temperature anisotropies that this is a tricky game, though, for other parameters can change spectra in ways similar to tensors. So even if we had perfect knowledge of the $C_{E,l}$ spectrum (no noise), we would still not necessarily know whether tensors were present. The B-mode is different. There is no contamination from scalar perturbations, so if we observe a B-mode in polarization, we know that it comes from gravity waves. In principle, this realization has unlimited power: no matter how small the tensor signal from inflation (no matter how small $H/m_{\rm Pl}$), we can ultimately detect this signal by searching for a B-mode. In practice, there are contaminants due to nonlinearities, but these are quite small. Estimates (Knox and Song, 2002; Kesden, Cooray, and Kamionkowski, 2002) suggest that the lowest obtainable limit on r, the tensor-to-scalar ratio, is of order 10^{-4}.

Let's compute the polarization pattern from a single plane wave generated by tensor perturbations. This problem is identical to that treated in Section 10.6. To find the outgoing polarization near the z-axis, we need to integrate over the incoming photon distribution. As in Eqs. (10.52) and (10.53), we want

$$\begin{aligned}\begin{pmatrix} Q \\ U \end{pmatrix} &\propto -\int d\Omega' \Theta^T(\Omega') \sin^2\theta' \begin{pmatrix} \cos(2\phi') \\ \sin(2\phi') \end{pmatrix} \\ &\propto -\int d\Omega' \Theta^T(\Omega') \begin{pmatrix} Y_{2,2}(\Omega') + Y_{2,-2}(\Omega') \\ \frac{1}{i}\left[Y_{2,2}(\Omega') - Y_{2,-2}(\Omega')\right] \end{pmatrix},\end{aligned}$$

where I have inserted the photon distribution due to tensor perturbations, Θ^T; recognized the combination of $\sin^2\theta'$ and the azimuthal dependence as $Y_{2,2} \pm Y_{2,-2}$; and neglected the absolute normalization of the polarization.

To complete the calculation, we need to find the angular dependence of Θ^T. This is a bit more difficult than one might expect. Although we know that this angular dependence is $\sin^2\theta' \cos(2\phi')$ (for h_+) or $\sin^2\theta' \sin(2\phi')$ ($h_\times$)for $\vec{k}$ lying along the z-axis, we need the dependence for a general wavevector $\vec{k}$. One way of finding this dependence is to rotate the coordinate system so that a unit vector pointing in the $\hat{z}$-direction gets rotated so that it points in the $\hat{k}$-direction. The relevant rotation matrix is

$$R = \begin{pmatrix} \cos\theta_k \cos\phi_k & -\sin\phi_k & \sin\theta_k \cos\phi_k \\ \cos\theta_k \sin\phi_k & \cos\phi_k & \sin\theta_k \sin\phi_k \\ -\sin\theta_k & 0 & \cos\theta_k \end{pmatrix}.$$

You should verify that R really does take $\hat{z} \to \hat{k}$ and work through a simple derivation of R (Exercise 13). We want to know what R does to Θ^T. To be concrete, let's focus on h_χ, so that $\Theta^T \propto \sin^2\theta' \sin(2\phi')$. First, we can reexpress this angular dependence in terms of the unit vector $\hat{n}'$ describing the direction of the incident photon:

$$\begin{aligned}\sin^2\theta' \sin(2\phi') &= 2\sin^2\theta' \sin\phi' \cos\phi' \\ &= 2\hat{n}'_x \hat{n}'_y.\end{aligned}$$

Now let's rotate the coordinate system so that the z-axis points in the direction of $\vec{k}$. The anisotropies due to the h_x-mode used to be proportional to $\hat{n}'_x \hat{n}'_y$. In the new coordinate system, they become

$$\Theta^T \propto \left(R^t \hat{n}'\right)_x \left(R^t \hat{n}'\right)_y$$

where ^{t} denotes transpose.

Now we work through the matrix multiplication and find

$$\begin{aligned}&\Theta^T \propto (\cos\theta_k \cos\phi_k \sin\theta' \cos\phi' + \cos\theta_k \sin\phi_k \sin\theta' \sin\phi' - \sin\theta_k \cos\theta') \\ &\times (-\sin\theta' \sin\phi_k \cos\phi' + \cos\phi_k \sin\theta' \sin\phi') \\ &= \sin\theta' \sin(\phi' - \phi_k)(\cos\theta_k \sin\theta' \cos(\phi' - \phi_k) - \sin\theta_k \cos\theta') \\ &= \frac{1}{2}\cos\theta_k \sin^2\theta' \sin[2(\phi' - \phi_k)] - \sin\theta' \cos\theta' \sin\theta_k \sin(\phi' - \phi_k).\end{aligned}$$

This last combination can be reexpressed in terms of spherical harmonics: it is a linear combination of $Y_{2,\pm2}, Y_{2,\pm1}$, and $Y_{2,0}$. That is, the anisotropy pattern about the wavevector $\vec{k}$ due to gravity waves (the $h_\times$mode) has a $Y_{2,2} - Y_{2,-2}$ dependence when $\hat{k}$ is along the z-axis. When $\hat{k}$ is general, this dependence gets mixed up among all the $Y_{2,m}$'s. We are interested in the polarization pattern generated by Θ^T; from Eq. (10.90) and the orthogonality property of

the spherical harmonics, this means we are interested only in the $Y_{2,\pm 2}$ components of Θ^T. We can now extract these from Eq. (10.94). The last term on the right has a factor of $\sin(\phi' - \phi_k)$, so it is proportional to $Y_{2,\pm 1}$, and we can neglect it. The first term is

$$\frac{1}{2}\cos\theta_k \sin^2\theta' \sin\left[2\left(\phi' - \phi_k\right)\right] = -\sqrt{\frac{32\pi}{15}}\frac{\cos\theta_k}{4i}\left[e^{-2i\phi_k}Y^*_{2,-2}\left(\Omega'\right) - e^{2i\phi_k}Y^*_{2,2}\left(\Omega'\right)\right]$$

To find Q and U, we dot this into $Y_{2,2} \pm Y_{2,-2}$, so that the integral in Eq. (10.90) leads to

$$\begin{pmatrix} Q(\hat{z}) \\ U(\hat{z}) \end{pmatrix} \propto \Theta_0^T \cos\theta_k \begin{pmatrix} -\sin\left(2\phi_k\right) \\ \cos\left(2\phi_k\right) \end{pmatrix}$$

If we move small angles away from the $\hat{z}$-direction, then the azimuthal dependence does not change, and $\cos\theta_k \to \hat{n}\cdot\hat{k}$, so that

$$\begin{pmatrix} Q(\hat{n}) \\ U(\hat{n}) \end{pmatrix} \propto \Theta_0^T \hat{n}\cdot\hat{k} \begin{pmatrix} -\sin\left(2\phi_k\right) \\ \cos\left(2\phi_k\right) \end{pmatrix}$$

The polarization pattern described by Eq. (10.97) has a nonzero B-mode. To see this, first consider the definition of B in Eq. (10.87). This definition is in Fourier space, but we remember that using the operator $D_{Q,U}$, we can replace $\vec{l}$ with $\vec{k}$, the wavevector. Therefore, for $\vec{k}$ in the $\hat{x}$ - $\hat{z}$ plane ($\phi_k = 0$), the B-mode corresponds to only U polarization. Indeed this is precisely what Eq. (10.97) says is produced by the $h_\times$mode of gravity waves. So the anisotropies due to gravity waves do produce the B-mode of polarization.

Figure 10.19 shows the polarization patterns due to a single plane wave $h_\times \propto e^{i\vec{k}\cdot\vec{x}}$ for four different wavevectors $\vec{k}$. For example, the top left panel considers $\vec{k}$ lying along the x-axis. In that case, since $\phi_k = 0$, Eq. (10.97) says that the polarization is all U and that the strength scales as

$$\hat{n}\cdot\hat{k} = \hat{n}_x$$

The strength of the polarization therefore increases as one moves away from the y-axis. The important feature of this pattern, which characterizes the B-mode, is that the strength of the polarization varies in the $\hat{x}$-direction, while the orientation is in the $\hat{x} \pm \hat{y}$ direction. These two directions (varying strength and polarization orientation) are not aligned or perpendicular to each other. The other panels show the same feature.

Figure 10.20 shows the anisotropy spectrum in a standard CDM model with an equal amount of tensors and scalars. The T and E spectra are similar to the tensorless case depicted in Figure 10.18. With tensors, the B spectrum is now nonzero, albeit small. Studies suggest that polarization searches will help significantly in the quest to detect small r.

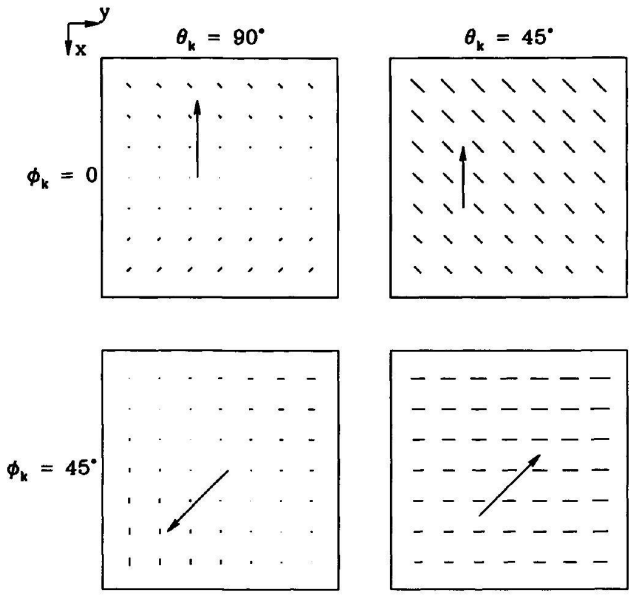

Figure 10.19. Polarization patterns from a single plane wave $h_\times(\vec{k})$ in a plane perpendicular to the z-axis ($\hat{z}$ out of the paper). Patterns from four different $\vec{k}$ are shown. Arrows depict direction of increasing polarization strength. This direction is not aligned with the orientation of the polarization.

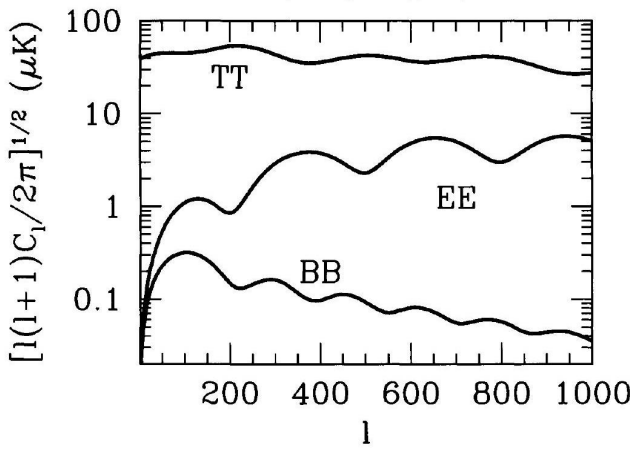

Figure 10.20. Anisotropy spectrum from a standard CDM model with equal amounts of scalar and tensor perturbations ($r = 1$). The T and E spectra come from both scalars and tensors, whereas the B-mode is due solely to tensors.

Part V
Problems

13 Typical problems of modern cosmology

13.1 Problems about Homogeneous Dynamics and Thermal History

13.1.1 Mathematical Problems for Basic Preparation to Cosmology

(я не уверен, что тут, но мб там диффгем или кинетика какая-то нужна будет)

13.1.2 Typical Problems about Friedman Universe (?!??!)

Leuven-2023hw1 **1.2. Universe with matter and a cosmological constant**

Consider a spatially flat Friedmann-Lemaitre-Robertson-Walker (FLRW) universe filled with only matter and a cosmological constant (i. e. no radiation).

a) Show that solving the Friedmann equation (normalized to $a(t_0) = 1$ at present time t_0) leads to the following solution for the scale factor:

$$a(t) = \left[\frac{\Omega_{\mathrm{m},0}}{1-\Omega_{\mathrm{m},0}} \sinh^2\left(\frac{3}{2}\left(1-\Omega_{\mathrm{m},0}\right)^{1/2} H_0 t\right)\right]^{1/3},$$

where $\Omega_{\mathrm{m},0}$ is the current density parameter for matter and H_0 is today's Hubble parameter. Discuss the evolution of the scale factor for $t \to \infty$ and $t \to 0$.

b) Derive an expression for the age of the universe t_0 in terms of H_0 and $\Omega_{\mathrm{m},0}$. Sketch the dependence $t_0(\Omega_{\mathrm{m},0})$ and evaluate it explicitly for the case $\Omega_{\mathrm{m},0} = 0.3$ and for an Einstein-de Sitter universe ($\Omega_{\mathrm{m},0} = 1$). Which universe is older (for fixed H_0)?

c) Show that the energy density of the universe becomes dominated by the cosmological constant at the following redshift: $z_\Lambda = \left(\Omega_{\mathrm{m},0}^{-1} - 1\right)^{1/3} - 1$.

a) Solving Friedman equations

Basically the dependence is $a(t) \sim \mathrm{sh}^{2/3}(\mathrm{const} \cdot t)$. The Friedmann-Lemaitre equation will give us:

$$\frac{\dot{a}^2}{a} = H_0^2\left(\frac{\Omega_{m,0}}{a^3} + 1 - \Omega_{m,0}\right) \qquad \text{because } \Omega_\lambda + \Omega_{m,0} = 1.$$

$$\frac{da}{dt} = H_0 a\left(\frac{\Omega_{m,0}}{a^3} + 1 - \Omega_{m,0}\right)^{1/2},$$

$$\int \frac{\sqrt{a}}{\sqrt{\Omega_{m,0} + \left(1-\Omega_{m,0}a^3\right)}} da = H_0 t.$$

Defining x such that $x^2 = \frac{1-\Omega_{m,0}}{\Omega_{m,0}} a^3 \equiv ca^3$, we have $da = 2xdx/(3ca^2)$, so $\sqrt{a}da = \sqrt{a}2\sqrt{c}a^{3/2}dx/(3ca^2) = 2dx/(3\sqrt{c})$ and

$$\frac{2}{3\sqrt{1-\Omega_{m,0}}} \int \frac{dx}{\sqrt{1+x^2}} = H_0 t.$$

Since $\int \frac{dx}{\sqrt{1+x^2}} = \mathrm{sh}\, x + C$ and $a(0) = 0$, we have

$$a(t) = \left[\frac{\Omega_{m,0}}{1-\Omega_{m,0}} \mathrm{sh}^2\left(\frac{3}{2}\left(1-\Omega_{m,0}\right)^{1/2} H_0 t\right)\right]^{1/3}.$$

For $t \to 0$ curvature $a \to 0$, so $\Omega_m \to 1$, so we would expect the universe to be matter dominated and hence from $H^2(a) \sim 1/a^3$ we expect $a \sim t^{2/3}$. From our solution we have the same

$$a \sim \left(\frac{(1-\Omega_{m,0})t^2}{1-\Omega_{m,0}} \right)^{1/3} \sim t^{2/3}.$$

If time gets large, the cosmological constant starts to dominate, $\Omega_m = 0$ and from $H^2(a) \sim$const we expect an exponential dependence. From our formula since for t large $\operatorname{sh} t \sim e^t$,

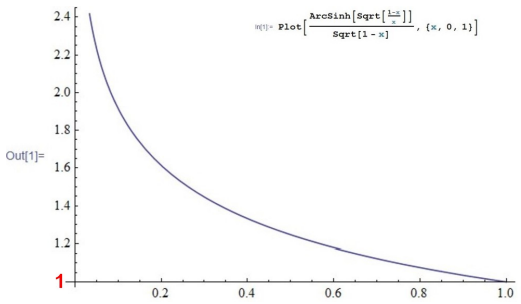
$$a \sim e^{(1-\Omega_{m,0})^{1/2}t}.$$

b) Finding age of the Universe

Now $a(t_0) = 1$, so after inverting $a(t)$ we get

$$t_0 = \frac{2}{3\left(1-\Omega_{m,0}\right)^{1/2} H_0} \operatorname{ArcSh}\left(\sqrt{\frac{1-\Omega_{m,0}}{\Omega_{m,0}}} \right).$$

The sketch:



For the case $\Omega_{\mathrm{m},0} = 1$ we should or solve Friedmann equations again or take the limit $\Omega_{m,0} \to 1$:

$$t_0 = \frac{0.66}{H_0} \approx 0.66 \cdot 14.4\text{bl years} \approx 9.5 \text{ bl years}.$$

For $\Omega_{m,0} = 0,3$

$$t_0 = \frac{0.66 \cdot 1.44}{H_0} \approx 0.95 \cdot 14.4\text{bl years} \approx 13.7 \text{ bl years}.$$

We see that if $\Omega_{\mathrm{m},0}$ greater, than its lifetime is smaller.

c) Critical energy density

Critical point we have $\Omega_{m,0}/a^3 = \Omega_\Lambda$. The redshift parameter z is such that $1+z = 1/a$, so from the main

$$\Omega_m(1+z)^3 = 1-\Omega_m$$

we get

$$z = \sqrt[3]{\frac{1}{\Omega_m} - 1} + 1.$$

Leuven-2023hw1.3. Horizon scale at matter-radiation equality

Solve the Friedmann-Lemaitre equation for a flat universe containing only matter and radiation in terms of the conformal time η. Then show that the conformal time at matter-radiation equality a_{eq} is given by:

$$\eta_{\mathrm{eq}} = 2(\sqrt{2}-1) H_0^{-1} \Omega_{\mathrm{m},0}^{-1/2} a_{\mathrm{eq}}^{1/2}$$

Solution

Friedman'e equations:

$$\frac{H^2}{H_0^2} = \frac{\Omega_{r,0}}{a^4} + \frac{\Omega_{m,0}}{a^3}.$$

at equality $\frac{\Omega_{r,0}}{a_{eq}^4} = \frac{\Omega_{m,0}}{a_{eq}^3}$, so $a_{eq} = \frac{\Omega_r}{\Omega_m}$ and from $d\eta := \frac{dt}{a}$ we have $\frac{\dot{a}}{a} = \frac{da}{a^2 d\eta}$ and

$$\frac{1}{H_0^2}\left(\frac{da}{a^2 d\eta}\right)^2 = \Omega_m\left(\frac{a_{eq}}{a^4} + \frac{1}{a}\right)$$

$$d\eta = \frac{da}{\Omega_m^{1/2} H_0 (a_{eq} + a)^{1/2}}$$

$$\eta_{eq} - 0 = \frac{a_{eq}^{1/2}}{\Omega_m^{1/2} H_0} \int_1^2 \frac{d(1 + a/a_{eq})}{1 + a/a_{eq}}$$

$$\eta_{eq} = \frac{2(\sqrt{2} - 1)\sqrt{a_{eq}}}{\Omega_m^{1/2} H_0 a_{eq}}$$

(???? дальше нужно додумывать!!!)
I didn't understand the second question, but we can obtain a particle horizon of about

$$H_p\left(t_{\rm CMB}\right) = c\eta_{\rm CMB} = 284{\rm Mpc} = 8.9 \times 10^{-3} H_p\left(t_0\right)$$

which corresponds to a proper size at that time of:

$$a_{\rm CMB} H_p\left(t_{\rm CMB}\right) = 261{\rm kpc}$$

Since we observe the CMB to be emitted essentially from our particle horizon (284Mpc $\ll$ 14.4Gpc), our expectation is that parts of the cosmic microwave background (CMB) that are separated by about a fraction of a great circle across the sky of

$$f = \frac{H_p\left(t_{\rm CMB}\right)}{H_p\left(t_0\right)}$$

(an angular size of $\theta \sim 1.7^\circ$) should be out of causal contact with each other.

Leuven-2023hw1.4. Unstability of matter and Λ

Identify what conditions have to be fulfilled such that a Universe with matter and a cosmological constant is static.
a) Show that this universe is unstable.
b) Find the radius of the Universe.

Solution

The acceleration equation

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3c^2}(\rho + 3P)$$

tells us that a static universe is only possible if $\rho = -3P$. Obviously this is not possible if we have only matter ρ_m with $P_m = 0$ or only a cosmological constant $\rho_\Lambda = -P_\Lambda$. But in a universe with both, we can have

$$\rho = \rho_m + \rho_\Lambda = -3P = 3\rho_\Lambda \quad \Rightarrow \quad \rho_m = 2\rho_\Lambda$$

The Friedmann equation $H^2 = \frac{8\pi G}{3c^2}\rho + \frac{\Lambda}{3} - \frac{kc^2}{R^2 a^2}$ is then

$$H^2 = \frac{8\pi G}{3c^2}\left(\rho_m + \rho_\Lambda\right) - \frac{kc^2}{R^2 a^2}$$

and the right-hand side vanishes if we take a positively curved universe, $k = +1$, with radius

$$Ra = \frac{c^4}{8\pi G \rho_\Lambda} = \frac{c^2}{\Lambda}$$

This is the Einstein static universe. It is unstable. If a is a little smaller than the critical value Ra then $\rho_m \sim a^{-3}$ is a little larger and the acceleration equation $\frac{\ddot{a}}{a} = -\frac{4\pi G}{3c^2}(\rho + 3P)$ says that a will decrease further. Similarly, if a is larger than the critical value it will increase further.

(??? про радиус так и не понял, откуда он в этом уравнении??? не верное уравнение - удалю этот вопрос!!!)

Leuven-2023hw1.5. Singularity theorem for FLRW universes (????)

Ordinary matter with energy density ρ and pressure p satisfies the strong energy condition (SEC), which reads:

$$\rho + 3p \geq 0$$

Prove that in a FLRW universe, if the matter content always satisfies the SEC, then there must have been a Big Bang singularity $a(t) = 0$ at a time t such that $t_0 - t \leq H_0^{-1}$, where $H_0 > 0$ is the present Hubble parameter.

This shows that General Relativity does not allow for a universe that transitions from a contracting to an expanding phase (assuming SEC).

Solution

(я по итогу забил на эту задачу вообще, так и не разобрался, потом подумаю мб)

Solution We need to prove that in $t > 0$ there is another big bang in this model. This is obvious, because from

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3c^2}(\rho + 3P)$$

the second derivative will be bigger and bigger in it absolute value and negative, so our convex expansion will be never to infinity, but definitely will come back to 0.

(???? дальше какой-то текст, я забыл)

We have the equation

$$\ddot{a} = -\frac{4\pi G}{3}(\rho + 3p)a.$$

If the strong energy condition is satisfied, then this informs us that the second derivative of the scale factor is always negative. We now show that this leads to a singularity. Because the universe is expanding, we know that if we go back in time, the scale factor decreases. To avoid reaching zero in finite time, we have two possibilities:

1. The scale factor has a local minimum at some point. However, this is not possible because at this point the second derivative will be positive.

2. The scale factor asumptotes to zero at minus infinity. Thus, the first derivative also approaches zero. Because we know this is positive for all times up to present day (since there are no local minima), this implies that the second derivative should be positive for some early times, which is also not possible.

Hence, this proves that we reach zero in a finite amount of time. To estimate this time, we use Taylor's theorem. Denote by t_0 the present time. Then for all times $t < t_0$ we have by the theorem some $t < t_1 < t_0$ which satisfies

$$a(t) = 1 + H_0\,(t - t_0) + \frac{\ddot{a}\,(t_1}{2}\,(t - t_0)^2\,.$$

Since the second derivative is negative, we thus have that for all times $t < t_0$

$$a(t) < 1 + H_0\,(t - t_0)\,.$$

The right hand side becomes 0 at the time t with $t_0 - t = H_0^{-1}$. Hence, it follows that a should become zero at some earlier time. (Note that this also gives a more concrete less descriptive proof of the assertion that we reach zero at some finite time.)

(ниже что-то не про задачу написано.)

Eq. $\chi_{\rm ph}(\tau) = \tau - \tau_i = \int\limits_{t_i}^{t} \frac{\mathrm{d}t}{a(t)}$ can be written as

$$\chi_{\rm ph}(\tau) = \int\limits_{t_i}^{t} \frac{\mathrm{d}t}{a} = \int\limits_{a_i}^{a} \frac{\mathrm{d}a}{a\dot{a}} = \int\limits_{\ln a_i}^{\ln a} (aH)^{-1}\ \mathrm{d}\ln a,$$

where $a_i \equiv 0$ corresponds to the Big Bang singularity. The causal structure of the spacetime can hence be related to the evolution of the comoving Hubble radius $(aH)^{-1}$. For a universe dominated by a fluid with constant equation of state $w \equiv P/\rho$, we get

$$(aH)^{-1} = H_0^{-1} a^{\frac{1}{2}(1+3w)}.$$

With SEC $1+3w > 0$ the integral above is dominated by the upper limit and receives vanishing contributions from early times. We see this explicitly in the example of a perfect fluid. We find

$$\chi_{\rm ph}(a) = \frac{2H_0^{-1}}{(1+3w)}\left[a^{\frac{1}{2}(1+3w)} - a_i^{\frac{1}{2}(1+3w)}\right] \equiv \tau - \tau_i.$$

The fact that the comoving horizon receives its largest contribution from late times can be made manifest by defining

$$\tau_i \equiv \frac{2H_0^{-1}}{(1+3w)} a_i^{\frac{1}{2}(1+3w)} \overset{a_i \to 0, w > -\frac{1}{3}}{\longrightarrow} 0.$$

Leuven.exam.1.1 Recombination (8 p)

Around 380,000 years after the Big Bang, protons and electron combined to form hydrogen atoms, an epoch called recombination.

(i) Given the interaction rate Γ for the process $e^- + p^+ \leftrightarrow H + \gamma$, describe how we can determine when the reaction is in thermal equilibrium in the context of an expanding universe.

(ii) Show that, using the Boltzmann equation in equilibrium (the Saha equation), the electron fraction X_e prior to recombination is given by

$$\frac{X_e^2}{1-X_e} = \frac{\pi^2}{2\zeta(3)}\eta\left(\frac{m_e}{2\pi T}\right)^{3/2} e^{-\varepsilon_0/T}$$

where $\varepsilon_0 = m_e + m_p - m_H$ is the binding energy of H. You can assume that the universe is neutral and that $n_b = n_p + n_H$. (Masses and the value of ϵ_0 were given).

(iii) Define the temperature of recombination $T_{\rm rec}$ such that $X_e\left(T_{rec}\right) = 10^{-1}$. Show that $T_{\rm rec} \sim 0.3$eV. You can use that $\ln\left(10^{17}\right) \sim 40$. Why is this much lower than the value of ϵ_0?

(iv) Discuss qualitatively electron freeze-out and photon decoupling, two important consequences of recombination. Make a sketch of $X_e(T)$ (from high to low temperature) and clearly denote $T_{\rm rec}$ and $T_{\rm dec}$ (temperature of photon decoupling) in your plot. Also show the prediction by the Saha equation.

Solution

13.1.3 Other Problems about Friedman Universe (?!??!)

Weak field limit

Show that in the weak field limit of General Relativity the source of gravity is the quantity $(\rho + 3p)$.

Solution

Then we linearize the Einstein equations

$$R_{\mu\nu} = 8\pi G\left(T_{\mu\nu} - \frac{1}{2}T g_{\mu\nu}\right)$$

with respect to $h_{\mu\nu}$. In the first order of approximation we can neglect terms quadratic on Γ in the Ricci tensor

$$R_{\nu\sigma} = \Gamma^{\mu}_{\nu\sigma,\mu} - \Gamma^{\mu}_{\nu\mu,\sigma} + \Gamma^{\alpha}_{\nu\sigma}\Gamma^{\mu}_{\alpha\mu} - \Gamma^{\alpha}_{\nu\mu}\Gamma^{\mu}_{\alpha\sigma}$$

Also, for stationary metrics the second term in the 00 component equals to zero, so

$$R_{00} = \partial_\alpha\Gamma^{\alpha}_{00} = \frac{1}{2}\Delta g_{00} = \Delta\Phi.$$

It is easy to see that $T_{\mu\nu}$ is of the first order of smallness with respect to Φ, so from the 00 component of the Einstein equation we obtain

$$\Delta\Phi = 8\pi G\left(T_{00} - \frac{1}{2}T\right) = 8\pi G\left(\rho - \frac{1}{2}(\rho - 3p)\right) = 4\pi G(\rho + 3p).$$

Therefore the source of gravitational field is not ρ, but the combination $\rho + 3p$. In particular, an object satisfying the condition $\rho + 3p < 0$, will repel, rather than attract, non-relativistic particles.

Leuven-exam.1.2 Big Bang and Quantum Cosmology (4 p)

Given that the matter content of the universe always satisfied the strong energy condition $\rho + 3P \geq 0$, prove that the universe always had a Big Bang in the past at a time $t(a(t) = 0)$ such that $t_0 - t < 1/H_0$. How does quantum cosmology solve this problem? Describe what form the solution would take, and what we might learn from this (max 1/2 page).

Solution

13.1.4 Solutions by Dodelson to Chapter 1

Solution to Dodelson-1.1

The ratio

$$\frac{\rho_\Lambda}{3H^2/(8\pi G)} = (\rho_\Lambda/\rho_c)_0 \left(\frac{H_0}{H}\right)^2$$

where subscript 0 means evaluate today, where it is assumed to be 0.7. Again, by assumption, the universe is forever radiation dominated (clearly not true today, but a good approximation early on), so $H/H_0 = a^{-2}$. The temperature also scales as a^{-1}, so $H/H_0 = (T/T_0)^2$ with $T_0 = 2.7$ K $= 2.3 \times 10^{-4}$eV. So,

$$\frac{\rho_\Lambda}{3H^2/(8\pi G)} = 0.7 \left(\frac{T_0}{T}\right)^4$$

At the Planck scale, $T_0/T = 2.3 \times 10^{-4}/1.22 \times 10^{28}$, so

$$\frac{\rho_\Lambda}{3H^2/(8\pi G)} = 9 \times 10^{-128}$$

This is the so-called fine-tuning problem: for the cosmological constant to be important today, it had to have been fine-tuned to an absurdly small value at early times. It's a deep problem.

Solution to Dodelson-1.2

We need to do the integral

$$t_0 = \frac{1}{H_0} \int_0^1 \frac{da}{a} \left[\Omega_\Lambda + \frac{1-\Omega_\Lambda}{a^3}\right]^{-1/2}$$

for $\Omega_\Lambda = 0.7$ and 0. The latter case can be done analytically:

$$\int_0^1 \frac{da}{a} a^{3/2} = \frac{2}{3}$$

So $t_0 = 2/3H_0 = 0.67 \times 10^{10} h^{-1}$ yrs. When Ω_Λ is not zero, the integral needs to be done numerically. I find

$$\int_0^1 \frac{da}{a} \left[0.7 + \frac{0.3}{a^3}\right]^{-1/2} = 0.96$$

So for fixed Hubble constant, a cosmological constant universe is older than a matter-dominated one, older by a factor of $0.96/0.67 = 1.43$. For $h = 0.7$, a cosmological constant universe has an age of 14 billion years, in accord with other observations of the age of the universe.

Solution to Dodelson-1.4

An inverse wavelength is ν/c, so replacing ν everywhere in Eq. (1.8) by c/λ leads to

$$I_\nu = \frac{4\pi\hbar c}{\lambda^3} \frac{1}{\exp\{2\pi\hbar c/\lambda k_B T\} - 1}.$$

This is energy per Hz; we want energy per cm^{-1}, so we need to multiply by c, leaving

$$I_{1/\lambda} = \frac{4\pi\hbar c^2}{\lambda^3} \frac{1}{\exp\{2\pi\hbar c/\lambda k_B T\} - 1}.$$

Plugging in numbers leads to

$$I_{1/\lambda} = 1.2 \times 10^{-5} \text{ergsec}^{-1}\ \text{cm}^{-1}\text{sr}^{-1} \left(\frac{\text{cm}}{\lambda}\right)^3 \frac{1}{\exp\{0.53\ \text{cm}/\lambda\} - 1}.$$

A quick check verifies that this agrees with Figure 1.10.
To find the peak, differentiate I with respect to $1/\lambda$ and set equal to zero. This leaves

$$\lambda = \frac{1}{3}\frac{(2\pi\hbar c/k_B T)}{1-\exp\{-2\pi\hbar c/\lambda k_B T\}}.$$

So $1/\lambda_{\text{peak}}$ is $3/.53\ \text{cm}^{-1}$. The exact coefficient, accounting for the exponential is 2.82, so $1/\lambda_{\text{peak}} = 5.3\ \text{cm}^{-1}$, exactly where it occurs in Figure 1.10.

13.1.5 Problems on thermal history (!!?)

(добавлю в условия теор указания также потом про то, что тут происходит)

Leuven-2023hw2.1. Graviton decoupling

1) Estimate the temperature today of primordial gravitons which decoupled at $T \sim m_{\text{pl}}$ in
(i) the Standard Model with $g_{*S} = 106.75$ for all $T > 1\text{TeV}$
(ii) a large GUT model which has $g_{*S} \approx 10^3$ for $T > 10^{16}\text{GeV}$.
2) What was the graviton temperature at $T = 1\text{MeV}$?
Hint: (?? here is a little theory about what is going on????)

Solution

(???? пока не понял, что нужно понимать, чтобы это было очевидно???)
If the thermal degrees of freedom before decoupling are $g^{th}_{*S,b}$ and those after are $g^{th}_{*S,a}$, then $T_g = T_{\gamma,b}$. Indices "a" and "b" mean "after" and "before".
Because $g^{\text{th}}_{*S} \cdot (aT_\gamma)^3$ is constant, we find that

$$T_g = \left(\frac{g^{th}_{*S,a}}{g^{th}_{*S,b}}\right)^{1/3} T_{\gamma,a}.$$

But what if not all the relativistic degrees of freedom decouple at the same time? Then suppose we have a series of two decouplings. Denoting things at these two stages by the subscript a_i for $i = 1, 2$ and doing the calculation above, we find

$$T_g = \left(\frac{g^{th}_{*S,a_2}}{g^{th}_{*S,a_1}}\right)^{1/3}\left(\frac{g^{th}_{*S,a_1}}{g^{th}_{*S,b}}\right)^{1/3} T_{\gamma,a},$$

which yields the same result. Hence, we can just calculate as if all the degrees of freedom are decoupling at the same stage.
1. In the case of the standard model, we have $2 + 106,75$ degrees of freedom before decoupling. (The extra 2 are those of the graviton) After decoupling, the only degrees of freedom left are the 2 of the photon. Using $T_\gamma = 2,725K$ for the cosmic microwave background, we get

$$T_g = 0,719K$$

2. For the large GUT model, we have $2 + 10^3 \sim 10^3$ degrees of freedom before decoupling, and still only 2 after. This gives

$$T_g = 0,343K$$

We now repeat the calculation for $T = 1\text{MeV}$. This corresponds to $T = 1,16 \cdot 10^{10}$ K. Another change is that the electron and positron have not yet decoupled at this temperature. Thus the degrees of freedom after is now 5,5. Repeating the calculation then gives

$$T_g = 4,29 \cdot 10^9\ \text{K} \qquad \text{(Standard Model)}$$

$$T_g = 2,05 \cdot 10^9\ \text{K} \qquad \text{(Large GUT theories)}$$

Leuven-2023hw2.2. Relic baryon density

Consider massive particles b and antiparticles $\bar{b}$ with mass m and number densities $n(t)$ and $\bar{n}(t)$ respectively. Consider an interaction of the form

$$b + \bar{b} \leftrightarrow \ell + \bar{\ell}$$

where the particle and antiparticle are annihilated creating a lepton ℓ and an antilepton ℓ with a thermally averaged cross section $\langle \sigma v \rangle$, while the opposite reaction is also possible. Consider also that the leptons are at equilibrium, i.e., their number density is at the chemical equilibrium value $n_\ell = n_\ell^{\rm eq}$.

a) Express the Boltzmann equation for the particle density n as follows

$$\frac{\mathrm{d}n}{\mathrm{d}t} = -\frac{3\dot{a}}{a} n - \langle \sigma v \rangle \left(n\bar{n} - n^{eq}\bar{n}^{eq} \right),$$

where a is the scale factor of the FLRW metric, and $n^{\rm eq}$ and $n^?$ are the equilibrium particle (b) and antiparticle ($\bar{b}$) densities, respectively. Identify the significance of each term appearing in this equation. By considering also the evolution of the antiparticles, show that

$$(n - \bar{n})a^3 = \text{ const.}$$

b) Assuming particle-antiparticle symmetry, show that

$$\frac{1}{a^3}\frac{\mathrm{d}\left(na^3\right)}{\mathrm{d}t} = -\langle \sigma v \rangle \left[n^2 - \left(n^{(a)} \right)^2 \right]$$

Define $Y := n/T^3$ and $x := m/T$, where T is the temperature, and show that

$$\frac{\mathrm{d}Y}{\mathrm{d}x} = -\frac{\lambda}{x^2}\left[Y^2 - (Y^{\rm eq})^2 \right], \qquad \text{with} \qquad \lambda := \frac{m^3 \langle \sigma v \rangle}{H_{(T=m)}},$$

in a radiation dominated cosmology.

c) If λ is constant, show that at late times Y approaches a constant value given by

$$Y_\infty = \frac{x_f}{\lambda}$$

where x_f corresponds to the freeze-out temperature. Explain the dependence of Y_∞ on $\langle \sigma v \rangle$ and sketch the schematic evolution of Y versus x for both a strongly and a weakly interacting population of annihilating particles and antiparticles. If there was a speed-up in the expansion rate of the universe caused by the addition of extra low-mass neutrino species what would happen to the abundance of the surviving massive particles b and why?

d) Now consider that the particles in question are protons and antiprotons. You may use that $\langle \sigma v \rangle \sim 100\mathrm{GeV}^{-2}$. Show that the freeze-out temperature is

$$T_f \sim 20\mathrm{MeV}$$

e) Also compute

$$\frac{n}{n_\gamma} = \frac{\bar{n}}{n_\gamma} \sim 10^{-19}$$

where n_γ is the density of photons. How does this compare to observational data? What do you conclude about the abundances of protons and antiprotons in the early universe?

Solution a)

The Boltzmann equation for the baryons is given by

$$\frac{1}{a^3}\frac{d\left(na^3\right)}{dt} = -\langle \sigma v \rangle n\bar{n} + \langle \sigma v \rangle \cdot \left(\frac{n\bar{n}}{n_l \bar{n}_l} \right)_{eq} n_l \bar{n}_l,$$

Because the leptons are in equilibrium $n_l\bar{n}_l, = (n_l\bar{n}_l)_{eq}$,

$$\frac{dn}{dt} = -3n\frac{\dot{a}}{a} - \langle \sigma v \rangle \left(n\bar{n} - n_{eq}\bar{n}_{eq} \right).$$

The density of antiparticles $\bar{n}$ obeys the similar equation, so after subtraction

$$\frac{dn}{dt} - \frac{d\bar{n}}{dt} = -3\frac{\dot{a}}{a}(n - \bar{n}).$$

$$\frac{d}{dt}\ln(n - \bar{n}) + 3\frac{d}{dt}\ln a = 0.$$

$$\frac{d}{dt}\left(a^3(n - \bar{n}) \right) = 0.$$

Solution b)

With particle antiparticle symmetry $n = \bar{n}$ the Boltzmann equation is

$$\frac{1}{a^3}\frac{d\left(na^3\right)}{dt} = -\langle\sigma v\rangle\Big(n^2 - \left(n_{eq}\right)^2\Big).$$

With $Y := \frac{n}{T^3}$ and $x := \frac{m}{T}$ and knowing that $T(a) = T_0/a$, we then find

$$\begin{aligned}\frac{dY}{dx} &= \frac{dY}{dT}\left(\frac{dx}{dT}\right)^{-1} = \left(\frac{dn/dT}{T^3} - \frac{3n}{T^4}\right)\left(-\frac{m}{T^2}\right)^{-1} = \frac{1}{m}\left(-\frac{dn/dT}{T} + \frac{3n}{T^2}\right) = \\ &= \frac{1}{m}\left(-\frac{dn}{da}\frac{da}{T} + \frac{3na^2}{T_0^2}\right) = \frac{1}{m}\left(\frac{dn}{da}\frac{a^2}{T_0}\frac{a}{T_0} + \frac{3na^2}{T_0^2}\right) = \frac{1}{mT_0^2}\left(\frac{dn}{da}a^3 + 3na^2\right) = \\ &= \frac{d(a^3n)}{mT_0 da \cdot \frac{dt}{dt}\frac{a}{a}} = \frac{d(a^3n)}{dt}\frac{1}{mT_0 Ha}\end{aligned}$$

Then the Boltzmann equation gives

$$\frac{dY}{dx} = -\frac{T^4}{mH}\langle\sigma v\rangle\left(Y^2 - \left(Y_{eq}\right)^2\right).$$

Because in the radiation era $a \sim t^{1/2}$ and always $T \sim 1/a$, we should have $H \sim T^2$ or $H = H(m)/x^2$, because $T \equiv m/x$. We get

$$\frac{dY}{dx} = -\frac{\lambda}{x^2}\left(Y^2 - \left(Y_{eq}\right)^2\right), \qquad \lambda := \frac{m^3\langle\sigma v\rangle}{H_{(T=m)}}.$$

Solution c)

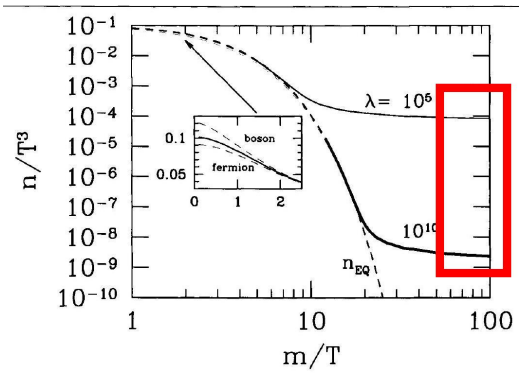
The solution is:

$$\frac{1}{Y_\infty} - \frac{1}{Y_f} = -\lambda\left(\frac{1}{Y_\infty} - \frac{1}{x_f}\right).$$

For late times $T \to 0$, so $1/Y_f \to 0$,. Integrating the resulting equation gives

$$Y_\infty = \frac{x_f}{\lambda}.$$

Because $\lambda \sim \langle\sigma v\rangle$, it is clear that Y_∞ will be inversely proportional to the interaction cross section. This is also logical since an efficient interaction means that more particles have annihilated. The dependence is sketched here:



If the expansion sped up, then the freezeout temperature would be reached earlier, which gives a larger abundance.

Solution d)

$$\Gamma \sim H$$

$$\Gamma = n\langle\sigma v\rangle, \qquad H \sim T^2/M_{pl}, \qquad n_p^{\rm eq} = g_p \left(\frac{m_p T}{2\pi}\right)^{3/2} \exp\left(\frac{\mu_i - m_p}{T}\right)$$

we look for a temperature T_f such that

$$g_p \left(\frac{mT_f}{2\pi}\right)^{3/2} e^{-m/T_f} \frac{M_{pl}}{T_f^2} \sim 1.$$

This gives

$$T_f^{-1/2} e^{-m/T_f} \sim 10^{-19}$$

which is solved by $T_f \sim 20$MeV.

Solution e)

Using the formulas we have derived, we find

$$\frac{n}{n_\gamma} = \frac{\pi^2}{2\zeta(3)} \frac{x_f}{\lambda}$$

Using $T_f = 20$MeV and filling in the numbers, we get

$$\frac{n}{n_\gamma} \sim 10^{-19}.$$

This is nowhere near the observed 10^{-9}. Hence, our assumption of baryon symmetry in the early universe is wrong.

Вопросы на додумать

(!!!??? там какая-то идея есть за этими преобразованиями, нужно ее продумать еще раз!!! пока слабо понимаю, почему именно в таких переменных решаем?)

Leuven-2023hw2.3a. Primordial Nucleosynthesis

Compute the ratio of the ^{3}He and proton number densities at equilibrium and discuss its dependence on the baryon-to-photon ratio η.
Hint: ^{3}He is produced in the reaction $D + p^+ \leftrightarrow He^3 + \gamma$.

Solution

The Saha equilibrium formula for the reaction $D + p^+ \leftrightarrow {}^3\mathrm{He} + \gamma$ gives us

$$\left(\frac{n_{He}}{n_D n_p}\right)_{eq} = \frac{g_{He}}{g_D g_p} \left(\frac{m_{He}}{m_D m_p} \frac{2\pi}{T}\right)^{3/2} e^{-(m_{He} - m_D - m_p)/T}.$$

$$(n_{He})_{eq} = (n_D n_p)_{eq} \frac{4}{3 \cdot 2} \left(\frac{3m_p}{2m_p \cdot m_p} \frac{2\pi}{T}\right)^{3/2} e^{-(m_{He} - m_D - m_p)/T}.$$

And from the reaction $n + p^+ \leftrightarrow \mathrm{D} + \gamma$ we know that

$$\left(\frac{n_{\rm D}}{n_p}\right)_{\rm eq} \approx \eta \left(\frac{T}{m_p}\right)^{3/2} e^{B_{\rm D}/T}; \qquad n_b = \eta n_\gamma = \eta \cdot \frac{2\zeta(3)}{\pi^2} T^3,$$

where $\eta := 5.5 \times 10^{-10} \left(\Omega_b h^2 / 0.020\right)$ is the baryon-to-photon ratio.

We get

$$(n_{He})_{eq} = \eta \left(\frac{T}{m_p}\right)^{3/2} \left(n_p^2\right)_{eq} \frac{2}{3} \left(\frac{3\pi}{m_p T}\right)^{3/2} e^{B_{He}/T} =$$
$$= \frac{2}{3}\eta \left(\frac{3\pi}{m_p^2}\right)^{3/2} \left(n_p^2\right)_{eq} e^{B_{He}/T}$$

Because η is very small, we need to drop to temperatures below B_{He} to get a significant contribution of the exponential. Hence, if η gets smaller, the freezeout temperature also gets lower.

Leuven-2023hw2.3b. Factors of ^{4}He and deuterium production

Discuss briefly the effect of the following on the production of ^{4}He and deuterium during primordial nucleosynthesis:
(i) The baryon density today (and thus the parameter η) is increased.
(ii) The neutron decay time is longer than supposed.
(iii) There are many more neutrinos than antineutrinos or photons in the universe today or, conversely, there are many more antineutrinos than neutrinos or photons.
(iv) The neutron mass is increased (but the binding energies of ^{3}He, D and ^{4}He are the same).
(v) The gravitational constant G varies with time and was larger in the past.

Solution

Our basic reactions and main equations for them are:

$$\mathrm{D} + p^+ \leftrightarrow {}^3\mathrm{He} + \gamma,$$
$$\mathrm{D} + {}^3\mathrm{He} \leftrightarrow {}^4\mathrm{He} + p^+.$$

$$\left(\frac{n_\mathrm{D}}{n_p}\right)_\mathrm{eq} \approx \eta \left(\frac{T}{m_p}\right)^{3/2} e^{B_\mathrm{D}/T}$$

$$(n_{He})_{eq} = \frac{2}{3}\eta \left(\frac{3\pi}{m_p^2}\right)^{3/2} \left(n_p^2\right)_{eq} e^{B_{He}/T}$$

So we just look at them and get all the answers. Ans also from some common sense.
1. If η increases, then because the freezeout temperature becomes earlier, we have more He^3 left. Hence, the quantities of He^4 produced will also get larger.
2. If the neutron lifetime is longer, more neutrons get to participate in the reactions, and hence the produced He^4 will increase.
3. The (anti)neutrinos do not participate in the required interactions and hence will not influence the produced quantities.
4. Similar to the neutrinos, the gravitons do not interact (at the relevant temperatures, the gravitational interaction becomes too weak), so they do not influence it.
5. Baumann shows that $G_F^2 T_f^5 \sim \sqrt{G_N g_\star} T_f^2$, so the freezout temperature would be reached earlier resulting in more production of He^4.

Leuven-2021hw-2.2. Chemical potential for electrons

a) If the chemical potential is vanishing $\mu \sim 0$, there is an equal number of particles and antiparticles. If $\mu \neq 0$, show that the net particle number $n - \bar{n}$ of a given particle species in the relativistic limit ($T \gg m$) is given by

$$n - \bar{n} = \frac{gT^3}{6\pi^2}\left[\pi^2 \left(\frac{\mu}{T}\right) + \left(\frac{\mu}{T}\right)^3\right].$$

You may use the integral $\int_0^\infty \mathrm{d}y \frac{y}{\mathrm{e}^y+1} = \frac{\pi^2}{12}$.

b) Use this result to evaluate the chemical potential of electrons in the relativistic limit. You may use the fact that the universe is neutral.

Solution

(типичная задача, допишу скоро, у Баумана тоже решена)

13.1.6 Problems on homogeneous inflation 1

(todo: solve them again!!!)

Leuven-2023hw2.4. The flatness problem

Assume that the universe is dominated by a perfect fluid with energy density $\rho(a)$, pressure $P(a)$ and equation of state $P = w\rho$, where $w = \text{const}$. Show that the density parameter $\Omega(a)$ defined with respect to the critical density $\rho_{\text{crit}}\,(a) = 3H^2(a)/(8\pi G)$ as $\Omega := \rho/\rho_{\text{crit}}$ fulfills the following differential equation:

$$\frac{\mathrm{d}\Omega}{\mathrm{d}(\ln a)} = (1+3w)\Omega(\Omega-1).$$

Show that the value $\Omega = 1$ is an unstable fixed point for $w > -1/3$, but corresponds to an attractor for $w < -1/3$. Describe briefly how this relates to the flatness problem and its resolution by an inflationary phase.

Solution

To derive the equation, we use the FL equations

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}(\rho + 3p),$$
$$H^2 = \frac{8\pi G}{3}\rho - \frac{k}{a^2} \qquad \Leftrightarrow \qquad \dot{a}^2(\Omega-1) = k. \qquad \left(\Omega := \frac{8\pi G}{3H^2}\rho\right)$$

Taking a time derivative of this equation and using $\frac{d\Omega}{dt} = \dot{a}\frac{d\Omega}{da}$, we find

$$2\ddot{a}(\Omega-1) + \dot{a}^2\frac{d\Omega}{da} = 0$$

Inserting the second Friedmann equation and using our equation of state, we arrive at

$$\frac{8\pi G}{3}\rho a(1+3w)(\Omega-1) = \frac{d\Omega}{da}\dot{a}^2.$$

Eliminating ρ in favour of Ω yields

$$\frac{d\Omega}{d\ln a} = a\frac{d\Omega}{da} = (1+3w)\Omega(\Omega-1).$$

We can easily solve this differential equation by integrating

$$\int \frac{1}{\Omega(\Omega-1)}d\Omega = \int (1+3w)d(\ln a).$$

This equation tells us that when $\Omega \neq 0, 1$ (in these cases, the solution is that Ω remains constant of course)

$$\left|\frac{\Omega-1}{\Omega}\right| = e^{(1+3w)\ln a}.$$

As we go forward in time, $\ln a$ increases. Hence, we see that if $w < -\frac{1}{3}$ the value of Ω will be driven towards 1, whereas in the other case, it will move away from 1. Thus, in the first case we have an attractor, and in the other case an unstable fixed point. Thus, if we had an inflationary phase with some strange matter satisfying $w < -\frac{1}{3}$, this phase would have driven Ω close to 1, which would explain why it is still so close to 1 today.

Leuven-2023hw2.5. The horizon problem

Show that if you assume that the universe was always dominated by ordinary matter or radiation early on, the comoving horizon at the (very small) scale factor a_{E} can be expressed in terms of the comoving horizon today, a_0 and the Hubble parameters at a_{E} and a_0 as follows:

$$\chi_{\text{ph}}\,(a_{\text{E}}) = \frac{a_0 H_0}{a_{\text{E}} H_{\text{E}}}\chi_{\text{ph}}\,(a_0)\,.$$

Compute the ratio $a_0 H_0/\,(a_{\text{E}} H_{\text{E}})$ assuming that the universe has been dominated by radiation since a_{E} and that the temperature at a_{E} was $T_{\text{E}} \sim 10^{15}\text{GeV}$. For today's temperature you can use the temperature of the CMB. The horizon problem is solved if there was an inflationary phase before the radiationdominated phase, such that the comoving Hubble radius at the beginning of inflation a_{I} was larger than the comoving Hubble radius today

$$(a_{\text{I}} H_{\text{I}})^{-1} > (a_0 H_0)^{-1}\,.$$

Use this criterion to give an estimate for the number of e-folds the universe has to expand during inflation to solve the horizon problem. To do so, assume that a_{E} with $T_{\text{E}} \sim 10^{15}\text{GeV}$ corresponds to the end of inflation and that the Hubble parameter during inflation was almost constant.

Solution

Since we assume that the universe is dominated by ordinary matter, we know that the strong energy condition holds $1+3w>0$, and

$$(aH)^{-1}=H_0^{-1}a^{\frac{1}{2}(1+3w)}.$$

The particle horizon $\chi_{ph}(a):=\int\limits_{\ln a_i}^{\ln a}(aH)^{-1}d\ln a$ is:

$$\chi_{ph}(a)=\frac{2}{1+3w}(aH)^{-1}.$$

If a_E corresponds to the end of inflation and a_0 to our present day, then we thus have

$$\chi_{ph}\left(a_E\right)=\chi_{ph}\left(a_0\right)\frac{a_0H_0}{a_EH_E}.$$

Next, we suppose that the universe is radiation dominated, and in this case, we know that $H\sim a^{-2}$. Thus, we find that

$$\frac{a_0H_0}{a_EH_E}=\frac{a_E}{a_0}.$$

Using that $T\sim a^{-1}$ we have

$$\frac{a_0H_0}{a_EH_E}=\frac{T_0}{T_E}\sim 10^{-28}.$$

Now, inflation will solve the horizon problem if the observable universe fits inside the Hubble radius before inflation. Denoting by I times before inflation, we thus need

$$\left(a_IH_I\right)^{-1}>\left(a_0H_0\right)^{-1}\sim\left(a_EH_E\right)^{-1}10^{28}.$$

Since we assume the Hubble rate to be constant during inflation, we thus have

$$\frac{a_E}{a_I}\sim 10^{28}.$$

The universe should have expanded at least $\ln 10^{28}\approx 64$ many e-folds.

Leuven-2023hw4.1 Derive $T_{\mu\nu}=\partial_\mu\phi\partial_\nu\phi-\frac{1}{2}g_{\mu\nu}g^{\rho\sigma}\partial_\rho\phi\partial_\sigma\phi-g_{\mu\nu}V(\phi)$ and $P=\frac{1}{2}\left(\frac{d\phi}{dt}\right)^2-V(\phi)$ for a typical model of a scalar field inflation

Solution

The energy-momentum tensor is obtained by variation by metric of the action of the scalar field in a general curved space-time, then pressure - is just its component.

$$S=\int d^4x\sqrt{-g}\left(-\frac{1}{2}g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi-V(\phi)\right)$$

$$T_{\mu\nu}\equiv-\frac{2}{\sqrt{-g}}\frac{\delta S}{\delta g^{\mu\nu}}=-\frac{2}{\sqrt{-g}}\left(\frac{\delta\sqrt{-g}}{\delta g^{\mu\nu}}\left(-\frac{1}{2}g^{\rho\sigma}\partial_\rho\phi\partial_\sigma\phi-V(\phi)\right)-\sqrt{-g}\frac{\delta\left(\frac{1}{2}g^{\rho\sigma}\partial_\rho\phi\partial_\sigma\phi\right)}{\delta g^{\mu\nu}}\right)$$

Let's use $\delta g/\delta g^{\mu\nu}=-gg_{\mu\nu}$, so $\frac{\delta\sqrt{-g}}{\delta g^{\mu\nu}}=-\frac{\delta g/\delta g^{\mu\nu}}{2\sqrt{-g}}=-\sqrt{-g}g_{\mu\nu}/2$ and

$$T_{\mu\nu}=-\frac{2}{\sqrt{-g}}\left(g_{\mu\nu}\frac{\sqrt{-g}}{2}\left(\frac{1}{2}g^{\rho\sigma}\partial_\rho\phi\partial_\sigma\phi+V(\phi)\right)-\frac{\sqrt{-g}}{2}\delta^\rho_\mu\delta^\sigma_\nu\partial_\rho\phi\partial_\sigma\phi\right)$$

So

$$T_{\mu\nu}=\partial_\mu\phi\partial_\nu\phi-\frac{1}{2}g_{\mu\nu}g^{\rho\sigma}\partial_\rho\phi\partial_\sigma\phi-g_{\mu\nu}V(\phi).$$

$$T^\nu{}_\mu=g^{\nu\lambda}\partial_\lambda\phi\partial_\mu\phi-\frac{1}{2}g^\nu{}_\mu g^{\rho\sigma}\partial_\rho\phi\partial_\sigma\phi-g^\nu{}_\mu V(\phi).$$

Then let's substitute $\partial_i\phi=0,(i=1,2,3)$ and $ds^2=-dt^2+a^2(t)d\mathbf{x}^2$

$$\rho\equiv-T^0{}_0=-\left((-1)\partial_0\phi\partial_0\phi-\frac{1}{2}\cdot1\cdot(-1)\cdot\partial_0\phi\partial_0\phi-(+1)V(\phi)\right)=\frac{1}{2}\left(\frac{d\phi}{dt}\right)^2+V(\phi)$$

$$P\equiv\delta^i_jT^j{}_i=0-\frac{1}{2}\cdot1\cdot(-1)\cdot\partial_0\phi\partial_0\phi-(+1)V(\phi)=\frac{1}{2}\left(\frac{d\phi}{dt}\right)^2-V(\phi)$$

Leuven-2023hw4 **4.2 Derive** $\frac{d^2\phi}{dt^2} + 3H\frac{d\phi}{dt} = -V'(\phi)$

Solution

From $\mathcal{L} = \left(-\frac{1}{2}g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - V(\phi)\right)\sqrt{-g}$ the Euler-Lagrange equations are:

$$-\partial_\mu\left(\sqrt{-g}g^{\mu\nu}\partial_\nu\phi\right) + \sqrt{-g}V'(\phi) = 0$$

which you usually rearrange as:

$$-\frac{1}{\sqrt{-g}}\partial_\mu\left(\sqrt{-g}g^{\mu\nu}\partial_\nu\phi\right) + V'(\phi) = 0$$

If $\phi(t)$, and considering $g \propto -a^6$, we have

$$-\frac{1}{\sqrt{-g}}\frac{d}{dt}(-\sqrt{-g}\dot{\phi}) + V'(\phi) = 0$$
$$\ddot{\phi} + 3H\phi + V'(\phi) = 0$$

where $H = \frac{\dot{a}}{a}$ and dot is derivative wrt ordinary time t.

Leuven-2023hw4 **4.3. Show that** $\epsilon = \frac{1}{16\pi G}\left(\frac{V'}{V}\right)^2, \quad \delta = \epsilon - \frac{1}{8\pi G}\frac{V''}{V}$

Solution

a)

$\epsilon = -\frac{H'}{H^2}$, so we need to find H' and H.

If we substitute $\rho_\phi = \frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 + V(\phi)$ and $P_\phi = \frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 - V(\phi)$ into the second Friedmann equation $H' = -\left(\rho_\phi + P_\phi\right)/\left(2M_{\rm pl}^2\right)$, we get

$$H' = -\frac{1}{2}\frac{\phi'^2}{M_{\rm pl}^2}.$$

Equation of motion is approximately $3H\phi' \approx -V'$, so $\phi' = -V'/(3H)$ and

$$H' = -\frac{1}{18}\frac{V'^2}{M_{\rm pl}^2 H^2}.$$

From Friedmann equation $H^2 = \rho_\phi/\left(3M_{\rm pl}^2\right)$ with $\rho_\phi = \frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 + V(\phi)$ and $\frac{\partial\phi}{\partial t} \ll V$ we get

$$H^2 = \frac{1}{3M_{\rm pl}^2}\left[\frac{1}{2}\phi'^2 + V\right] \approx \frac{V}{3M_{\rm pl}^2}.$$

Finally

$$\epsilon = -\frac{H'}{H^2} = \frac{1}{18}\frac{V'^2}{M_{\rm pl}^2 H^4} = \frac{1}{18}\frac{V'^2}{M_{\rm pl}^2}\frac{9M_{\rm pl}^4}{V^2} = \frac{M_{\rm pl}^2}{2}\frac{V'^2}{V^2} = \frac{1}{16\pi G}\left(\frac{V'}{V}\right)^2.$$

b)

Taking the time-derivative of Klein Gordon equation $3H\dot{\phi} \approx -V'$, we have

$$3\dot{H}\dot{\phi} + 3H\ddot{\phi} = -V''\dot{\phi},$$

$$\ddot{\phi} = \frac{-V''\dot{\phi}}{3H} - \frac{\dot{H}\dot{\phi}}{H}$$

so

$$\delta \equiv -\frac{\ddot{\phi}}{H\dot{\phi}} = -\frac{V''}{3H^2} - \frac{\dot{H}}{H^2} = -M_{\rm pl}^2\frac{V''}{V} + \epsilon = \epsilon - \frac{1}{8\pi G}\frac{V''}{V}.$$

13.1.7 Problems on homogeneous inflation 2

Leuven-2023hw4.4. Derive $S = S\left[\phi^{(0)}\right] + \frac{1}{2}\int d^4x \left(\dot{\chi}^2 - (\nabla\chi)^2 + \frac{\ddot{a}}{a}\chi^2\right)$

Solution

We know that we have equations

$$\ddot{\phi}^{(0)} + 2\frac{\dot{a}}{a}\dot{\phi}^{(0)} = -a^2 V'\left(\phi^{(0)}\right)$$

and

$$\delta\ddot{\phi} + 2\frac{\dot{a}}{a}\delta\dot{\phi} - \nabla^2\delta\phi = -a^2 V''\left(\phi^{(0)}\right)\delta\phi \approx 0$$

So to prove that the action $S = S\left[\phi^{(0)}\right] + \frac{1}{2}\int d^4x \left(\dot{\chi}^2 - (\nabla\chi)^2 + \frac{\ddot{a}}{a}\chi^2\right)$ can give them, we need 1) prove that from it comes the equation of motion $\ddot{\chi} = \nabla^2\chi + \frac{\ddot{a}}{a}\chi$, and then 2) prove that it is the same equation as one for $\delta\phi$.

Preparation:

$$\frac{\partial L}{\partial\chi} = \frac{2}{2}\frac{\ddot{a}}{a}\chi, \qquad \frac{\partial L}{\partial\partial_t\chi} = \frac{2}{2}\dot{\chi} \qquad \frac{\partial L}{\partial\partial_x\chi} = -\frac{2}{2}\partial_x\chi$$

Euler-Lagrangian equations $-\frac{\partial L}{\partial\chi} + \partial_t\frac{\partial L}{\partial\partial_t\chi} + \nabla\frac{\partial L}{\partial\nabla\chi} = 0$ are

$$-\frac{\ddot{a}}{a}\chi + \ddot{\chi} - \nabla^2\chi = 0$$

Then let's imply $\chi = a\delta\phi$. Preparation:

$$\dot{\chi} = \dot{a}\delta\phi + a\delta\dot{\phi}, \qquad \ddot{\chi} = \ddot{a}\delta\phi + 2\dot{a}\delta\dot{\phi} + a\delta\ddot{\phi}, \qquad \nabla^2\chi = a\nabla^2\delta\phi$$

and we get

$$-\frac{\ddot{a}}{a}a\delta\phi + \ddot{a}\delta\phi + 2\dot{a}\delta\dot{\phi} + a\delta\ddot{\phi} - a\nabla^2\delta\phi = 0$$

$$\delta\ddot{\phi} + 2\frac{\dot{a}}{a}\delta\dot{\phi} - \nabla^2\delta\phi = 0$$

So indeed, the action should be as we stated.

Leuven-2023hw4.5. Equivalency of commutators

a)

Let's show that $[\chi(\eta,\mathbf{x}),\chi(\eta,\mathbf{y})] = [\pi(\eta,\mathbf{x}),\pi(\eta,\mathbf{y})] = 0, [\chi(\eta,\mathbf{x}),\pi(\eta,\mathbf{y})] = i\delta(\mathbf{x}-\mathbf{y}) \Longrightarrow [a_\mathbf{k}, a_\mathbf{l}] = 0, \left[a_\mathbf{k}, a_\mathbf{l}^\dagger\right] = \delta(\mathbf{k}-\mathbf{l})$

b)

Let's show that $[a_\mathbf{k}, a_\mathbf{l}] = 0, \left[a_\mathbf{k}, a_\mathbf{l}^\dagger\right] = \delta(\mathbf{k}-\mathbf{l}) \Longrightarrow [\chi(\eta,\mathbf{x}),\chi(\eta,\mathbf{y})] = [\pi(\eta,\mathbf{x}),\pi(\eta,\mathbf{y})] = 0, [\chi(\eta,\mathbf{x}),\pi(\eta,\mathbf{y})] = i\delta(\mathbf{x}-\mathbf{y})$

Leuven-2023hw4.6. Verify that comoving curvature perturbation ζ equals a) during inflation $\zeta = -aH\frac{\delta\phi}{\dot{\phi}^{(0)}}$ and b) after inflation $\zeta = -\frac{3}{2}\Psi$

(here dot is a derivative wrt. conformal time)

Solution to a)

By definition $\zeta \equiv -\Psi + \frac{1}{3}\frac{\delta\rho}{\rho+P}$.
During slow-roll inflation, for modes inside the horizon and those which have just left the horizon, $\Psi \approx 0$.
From $P = \frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 - V(\phi), \rho = \frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 + V(\phi)$ and $\frac{d}{dt} = \frac{1}{a}\frac{d}{d\eta}$, we have $\frac{1}{\rho+P} = \frac{a^2}{\dot{\phi}^{(0)2}}$.
Using $\delta\rho = V'\left(\phi^{(0)}\right)\delta\phi$ and from KG equation $V' \approx 3H\frac{d\phi^{(0)}}{dt}$, where $\frac{d\phi}{dt} = \frac{1}{a}\frac{d\phi}{d\eta} \equiv \frac{\dot{\phi}}{a}$.
Totally:

$$\zeta = 0 + \frac{1}{3}\frac{a^2}{\dot{\phi}^{(0)2}}V'\left(\phi^{(0)}\right)\delta\phi = -\frac{1}{3}\frac{a^2}{\dot{\phi}^{(0)2}}\cdot 3H\frac{\dot{\phi}^{(0)}}{a}\delta\phi = -aH\frac{\delta\phi}{\dot{\phi}^{(0)}}$$

Solution to b)

By definition $\zeta \equiv -\Psi + \frac{1}{3}\frac{\delta\rho}{\rho+P}$. After inflation $P = \rho/3, \delta_\gamma = \frac{\delta\rho}{\rho}$ and $\Psi = -\frac{1}{2}\delta_\gamma$, so

$$\zeta = -\Psi + \frac{1}{3}\frac{\delta\rho}{\rho+P} = -\Psi + \frac{1}{4}\frac{\delta\rho}{\rho} = -\Psi + \frac{1}{4}\delta_\gamma = -\Psi - \frac{\Psi}{2} = -\frac{3}{2}\Psi.$$

(??? need to add a comment, why such relations between deltas and Ψ)

Long solution to b) by Dodelson (???)

Let's follow Dodelson's notation. We know that we can also defint ζ as

$$\zeta \equiv -\frac{ik_i\delta T_i^0 H}{k^2(\rho+\mathcal{P})} - \Psi$$

After inflation ends, $ik_i\delta T_i^0 = 4ak\rho_r\Theta_1$, proportional to the dipole of the radiation. Since $\mathcal{P} = \rho/3$,

$$\zeta = -\frac{3aH\Theta_1}{k} - \Psi$$

It is well known that $\Theta_1 = \mathcal{N}_1 = \frac{iv_b}{3} = \frac{iv}{3} = -\frac{k\Phi}{6aH}$.
The Eq. (5.33) of Dodelson describes how the higher moments of the photon and neutrino distributions cause $\Psi + \Phi$ to be nonzero. Let us here neglect these higher order moments, which cause the sum of the gravitational potentials to be slightly nonzero. Under this approximation, we can eliminate Ψ everywhere by simply setting it to $-\Phi$. Then,

$$\zeta = \frac{3aH}{k}\frac{k\Phi}{6aH} - \Psi = \frac{\Phi}{2} - \Psi = -\frac{3}{2}\Psi$$

Leuven-2023hw4 **4.7. Verify** $4\pi G\left(\dot{\phi}^{(0)}\right)^2 = \epsilon a^2 H^2$

(Here "(0)" means 0-th order, dot means derivative wrt. conformal time)

Solution "in two lines"

Second Friedmann equation $\frac{dH}{dt} = -\frac{(\rho_\phi + P_\phi)}{\left(2M_{\rm pl}^2\right)}$ with $\rho_\phi = \frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 + V(\phi)$ and $P_\phi = \frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 - V(\phi)$ is

$$H_t' = -4\pi G(\phi_t')^2.$$

We just put here $\epsilon := \frac{d}{dt}\left(\frac{1}{H}\right) = -\frac{H_t'}{H^2}$ and $\phi_t' = \frac{1}{a}\frac{d\phi}{d\eta} \equiv \frac{1}{a}\dot{\phi}$, so

$$4\pi G\dot{\phi}^2 = \epsilon a^2 H^2.$$

Solution by rewriting left hand side

$$\epsilon a^2 H^2 = -a^2 H^2 \left(\frac{1}{H^2}\frac{dH}{dt}\right) = -a^2 \frac{d}{dt}\left(\frac{da}{dt}\frac{1}{a}\right) = -a^2 \left(\left(\frac{1}{a}\frac{d^2a}{dt^2} - \frac{da}{dt}\right)^2 \frac{1}{a^2}\right).$$

Insert the Friedmann equations $\left(\frac{\dot{a}}{a}\right)^2 = \frac{8\pi G}{3}\rho$; $\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}(\rho + 3P)$ and get

$$\epsilon a^2 H^2 = 4\pi G a^2 (\rho + P).$$

Scalar field has the property $\rho + P = \left(\frac{d\phi}{dt}\right)^2 = \frac{\dot{\phi}^2}{a^2}$, thus finally

$$\epsilon a^2 H^2 = 4\pi G \dot{\phi_0}^2$$

Leuven-2023hw4 **4.8. Verify $\frac{d\epsilon}{d\eta} = 2aH\epsilon(\epsilon + \delta)$, where $\epsilon \equiv \frac{d}{dt}\left(\frac{1}{H}\right)$, $\delta \equiv \frac{1}{H}\frac{d^2\phi/dt^2}{d\phi/dt}$**

Solution

Second Friedmann equation $\frac{dH}{dt} = -\frac{(\rho_\phi + P_\phi)}{(2M_{\rm pl}^2)}$ with $\rho_\phi = \frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 + V(\phi)$ and $P_\phi = \frac{1}{2}\left(\frac{d\phi}{dt}\right)^2 - V(\phi)$ is

$$H_t' = -4\pi G(\phi_t')^2.$$

We differentiate and use $H_t' \equiv -\varepsilon H^2$:

$$4\pi G \cdot 2\phi_t'\phi_t'' = \frac{d\varepsilon}{a d\eta}H^2 + \varepsilon \cdot 2H\frac{dH}{dt}$$

$$4\pi G(\phi_t')^2 \cdot 2H\frac{\phi_t''}{H\phi_t'} = \frac{d\varepsilon}{a d\eta}H^2 - \varepsilon H^2 \cdot 2\varepsilon H$$

$$\frac{d\varepsilon}{d\eta}\frac{H^2}{a} = H^2\varepsilon \cdot 2H\delta + 2\varepsilon H^2 \cdot \varepsilon H$$

$$\frac{d\varepsilon}{d\eta} = 2\varepsilon a H(\delta + \varepsilon).$$

13.1.8 Problems on Einstein equations

D-1.

Derive the Christoffel symbols, $\Gamma^i{}_{\mu\nu}$, given in Eq. (5.7).
(?? впишу)
When doing this, you will need g^{ij}. Show that it is equal to $\delta_{ij}(1 - 2\Phi)/a^2$.

D-2.

Show that R_{ij} is given by Eq. (5.14).

D-3.

Use the full general relativistic expression for the energy momentum tensor given in Eq. (2.101), which holds even in the presence of metric perturbations. Show that, with scalar perturbations to the metric, the phase space integral for the time-time component reduces to that in Eq. (5.22). Show that the contribution from species α to T_i^0 is

$$T_i^0 = g_\alpha a \int \frac{d^3p}{(2\pi)^3} p_i f_\alpha(\vec{p}, \vec{x}, t)$$

Note the extra factor of a.

D-4.

Consider a 3D matrix with components $G_{ij} = \left(\hat{k}_i\hat{k}_j - \delta_{ij}/3\right) G^L$. Show that this form is traceless and satisfies $\epsilon_{ijk}G_{kl,jl} = 0$ so it is the proper form for the longitudinal component.

D-5.

Compute the time-space component of the Einstein tensor. Show that, in Fourier space,

$$G^0_i = 2ik_i \left(\frac{\dot{\Phi}}{a} - H\Psi\right)$$

Combine with the energy-momentum tensor derived in Exercise 3 to show that

$$\dot{\Phi} - aH\Psi = \frac{4\pi G a^2}{ik} \left[\rho_{\rm dm} v + \rho_b v_{\rm b} - 4i\rho_\gamma \Theta_1 - 4i\rho_\nu \mathcal{N}_1\right]$$

The time-space component of Einstein's equations adds no new information once we already have the two equations derived in the text. Deciding which two to use is a matter of convenience.

D-6.

Take the Newtonian limit of Einstein's equations. Combine the timetime equation (5.27) with the time-space equation of Exercise 5 to obtain the algebraic (i.e., no time derivatives) equation for the potential given in Eq. (5.81). Show that this reduces to Poisson's equation (with the appropriate factors of a) when the wavelength is much smaller than the horizon ($k\eta \gg 1$).

D-7.

Fill in the blanks in the derivation of the tensor equation.
(a) Show that Γ^i_{jk} is given by Eq. (5.43) in the presence of tensor perturbations.
(b) Show that the last term in Eq. (5.48) is given by Eq. (5.54).

D-8.

We defined the perturbations to the photon distribution function via Eq. (4.34). Show that, if Θ depends only on μ, the cosine of the angle between $\hat{k}$ ($:= \hat{z}$ here) and $\hat{p}$, then $T^1_1 - T^2_2$ vanishes. This is indeed the dependence we have been dealing with so far. This is yet another aspect of the decomposition theorem: the terms Θ that source the scalar perturbations (and are sourced by them) do not affect tensor perturbations. Anisotropies induced by tensor perturbations will have Θ of the form

$$\Theta(\mu, \phi) = \left(1 - \mu^2\right) \cos(2\phi)\Theta_+(\mu)$$

for those perturbations generated by $h_+$and a similar expression for $h_\times$with the cos replaced by a sin. These, however, have a negligible impact on the evolution of the gravity waves, so we are justified in setting the right-hand side of Eq. (5.63) to zero.

D-9.

Use the $\frac{1}{2}$ component of the Einstein equations to show that $h_\times$obeys the same equation as does h_+.

D-10.

Show that scalar perturbations (Φ and Ψ) do not contribute to either $G^1{}_1 - G^2_2$ or to G^1_2. This completes the demonstration of the decomposition theorem for scalars and tensors.

D-11.

Consider vector perturbations to the metric. These can be described by two function h_{xz} and h_{yz} where again only the spatial part of the metric is perturbed. The perturbative part of g_{ij} is

$$h^V_{ij} = \begin{pmatrix} 0 & 0 & h_{xz} \\ 0 & 0 & h_{yz} \\ h_{xz} & h_{yz} & 0 \end{pmatrix}$$

Show that h_{xz} and h_{yz} do not affect any of the equations we have derived so far for scalar or tensor evolution - yet another aspect of the decomposition theorem.

D-12.

Solve the wave equation (5.63) if the universe is purely matter dominated. Do the same for the radiation-dominated case.

D-13.

Define the transfer function for gravity wave evolution as

$$T(k) := \frac{h_\alpha(k,\eta)}{h_\alpha(k,\eta=0)} \left(\frac{k\eta}{3j_1(k\eta)} \right).$$

You should recognize the term in parentheses as the inverse of the matter-dominated solution you derived in

D-12.

Solve Eq. (5.63) numerically and compute the transfer function. Compare your solution with the fit of Turner, White, and Lidsey (1993),

$$T(y) = \left[1 + 1.34y + 2.5y^2\right]^{1/2}$$

where $y := (k\eta_0/370h)$ (with h parametrizing the Hubble constant). Assume the universe today is flat and matter dominated, but account for transition from matter to radiation.

D-14.

Derive the transformations in the metric components given by Eq. (5.75). Show that Φ_A and Φ_H do not change under a general coordinate transformation.

13.2 Problems about Inhomogeneities and Anisotropies

13.2.1 Problems about initial conditions

D-1.

Find the ratio of neutrino to radiation energy density, f_ν. Assume that there are three species of massless neutrinos.

D-2.

Account for the neutrino quadrupole moment when setting up initial conditions.
(a) Start with Eq. (4.107). This is an equation for $\mathcal{N}(\mu)$. Turn this into a hierarchy of equations for the neutrino moments:

$$\begin{aligned} \dot{\mathcal{N}}_0 + k\mathcal{N}_1 &= -\dot{\Phi} \\ \dot{\mathcal{N}}_1 - \frac{k}{3}(\mathcal{N}_0 - 2\mathcal{N}_2) &= \frac{k}{3}\Psi \\ \dot{\mathcal{N}}_2 - \frac{2}{5}k\mathcal{N}_1 &= 0. \end{aligned}$$

To do this, you need to recall the definition of these moments, which is equivalent to that for photons, Eq. (4.99). A good way to reduce Eq. (4.107) into this hierarchy is to multiply it first by $\mathcal{P}_0$ and then integrate over $\int_{-1}^{1} d\mu$. This leads to the first equation above. Then multiply Eq. (4.107) by $\mathcal{P}_1$ to get the second and $\mathcal{P}_2$ to get the third. More details are given in Section 8.3, where we go through the same exercise for the photon moments. In the third equation you may neglect $\mathcal{N}_3$ because it is smaller than $\mathcal{N}_2$ by a factor of order $k\eta$ (prove this!).
(b) Eliminate $\mathcal{N}_1$ from these equations and show that

$$\ddot{\mathcal{N}}_2 = \frac{2k^2}{15}(\Psi + \mathcal{N}_0 - 2\mathcal{N}_2)$$

Drop $\mathcal{N}_2$ on the right-hand side because it is much smaller than $\Psi + \mathcal{N}_0$.

(c) Rewrite Einstein's equation (5.33) as

$$\mathcal{N}_2 = -(k\eta)^2 \frac{\Phi + \Psi}{12 f_\nu}$$

This neglects the photon quadrupole. Argue that Compton scattering sets $\Theta_2 \ll \mathcal{N}_2$ so this is a reasonable assumption.

(d) Now differentiate this form of Einstein's equation twice to get an expression for $\ddot{\mathcal{N}}_2$. Equate this to the expression for $\ddot{\mathcal{N}}_2$ derived in part (b). (You may drop all derivatives of Φ and Ψ when doing this since the mode of interest is the $p = 0$ constant mode.) Use this equation to express $\mathcal{N}_0$ in terms of Φ and Ψ.

(e) Finally assume that $\Theta_0 = \mathcal{N}_0$ and use your expression for $\mathcal{N}_0$ to rewrite Eq. (6.12) as a relation between the two gravitational potentials. Show that this relation is

$$\Phi = -\Psi \left(1 + \frac{2 f_\nu}{5}\right)$$

D-3.

Show that the initial conditions for the velocities and dipoles of matter and radiation are as given in Eq. (6.16).

D-4.

Inflation also solves the flatness problem. This is the question of why the energy density today is so close to critical.

(a) Suppose that

$$\Omega(t) := \frac{8\pi G \rho(t)}{3H^2(t)}$$

is equal to 0.3 today, where ρ counts the energy density in matter and radiation (assume zero cosmological constant). From Eq. (1.2), plot $\Omega(t) - 1$ as a function of the scale factor. How close to one would $\Omega(t)$ have been back at the Planck epoch (assuming no inflation took place so that the scale factor at the Planck epoch was of order 10^{-32})? This fine-tuning of the initial conditions is the flatness problem. If not for the fine tuning, an open universe would be obviously open (i.e., Ω would be almost exactly zero) today.

(b) Now show that inflation solve the flatness problem. Extrapolate $\Omega(t) - 1$ back to the end of inflation, and then through 60 e-folds of inflation. What is $\Omega(t) - 1$ right before these 60 e-folds of inflation?

D-5.

Another way of looking at the problems that inflation solves is to consider the entropy within our Hubble volume. This is proportional to the total number of particles in the volume, with a proportionality constant of order unity. How many photons are there within our Hubble volume today? Explain how inflation produces entropy this large.

D-6.

We showed that, if the universe was always dominated by ordinary matter or radiation early on, then the comoving horizon when the scale factor was a_e (very small) was $a_0 H_0 / a_e H_e$ times the comoving Hubble radius today. Compute this ratio assuming that the temperature was equal to 10^{15}GeV at a_e. Account for the radiation-to-matter transition at $a \sim 10^{-4}$.

D-7.

Consider a free, homogeneous scalar field with mass m. The potential for this field is $V = m^2\phi^2/2$. Show that, if $m \gg H$, the scalar field oscillates with frequency equal to its mass. Also show that its energy density falls off as a^{-3}, so it behaves exactly like ordinary nonrelativistic matter.

D-8.

Show that Eq. (6.33) follows from Eq. (6.32) by changing variables from t to η.

D-9. Well-known properties of the quantized harmonic oscillator.

(a) The momentum of the harmonic oscillator with unit mass is $p = dx/dt$. Compute

$$[\hat{x}, \hat{p}]$$

and show that it is equal to i. You can obtain the operator $\hat{p}$ by differentiating $\hat{x}$ (Eq. (6.38)) with respect to time.

(b) Compute the zero-point energy of the harmonic oscillator with unit mass. Do this by quantizing the energy

$$E = \frac{p^2}{2} + \frac{\omega^2 x^2}{2}$$

and then computing its expectation value in the ground state: $\langle 0|\hat{E}|0\rangle$.

D-10.

Show that gravity waves are not sourced by the scalar field during inflation. To do this, recall that the right-hand side of Eq. (6.45) is

$$\delta T_1^1 - \delta T_2^2$$

where δT is the perturbation to the energy-momentum tensor (assumed to be dominated by ϕ) and, as in the derivation of Eq. (5.63), I have chosen $\vec{k}$ to be in the $\hat{z}$ direction. Show that this right-hand side is indeed zero for the scalar field.

D-11.

Show that Eq. (6.57) is the appropriate solution to Eq. (6.56).

(a) Define $\tilde{v} = v/\eta$ and rewrite Eq. (6.56) in terms of $\tilde{v}$.

(b) The resulting equation is the spherical Bessel equation. Write down the general solution to this as a linear combination of two functions of $k\eta$.

(c) Use the boundary conditions of Eq. (6.58) to determine the coefficients of part (b). Show that Eq. (6.57) is the correct solution for these boundary conditions.

D-12.

Derive some useful identities involving the slow-roll parameters during inflation.

(a) Show that

$$\frac{d}{d\eta}\left(\frac{1}{aH}\right) = \epsilon - 1$$

(b) Show that

$$4\pi G\left(\dot{\phi}^{(0)}\right)^2 = \epsilon a^2 H^2$$

(c) Using the definitions of ϵ and δ, show that

$$\frac{d\epsilon}{d\eta} = -2aH\epsilon(\epsilon + \delta)$$

Use this to show that $d\ln\epsilon|_{aH=k}/d\ln(k) = -2(\epsilon + \delta)$.

D-13.

Show that on large scales Eq. (6.85) holds. One way to do this is to combine Einstein's equations, the time-time (5.27) and time-space (Exercise 5 of Chapter 5) components, and take the large-scale limit.

D-14.

Express the slow-roll parameters ϵ and η in terms of the potential V and its derivatives with respect to ϕ. Show that, to lowest order,

$$\epsilon = \frac{1}{16\pi G}\left(\frac{V'}{V}\right)^2$$

and

$$\delta = \epsilon - \frac{1}{8\pi G}\frac{V''}{V}$$

where primes denote derivatives with respect to $\phi^{(0)}$.

D-15.

There are a number of ways of describing pressure in the universe and of relating the pressure to the energy density. One was introduced back in Chapter 2, the equation of state,

$$w := \frac{\mathcal{P}}{\rho}$$

The second is the sound speed,

$$c_s^2 := \frac{d\mathcal{P}}{d\rho}$$

The way to compute c_s^2 is to differentiate both $\mathcal{P}$ and ρ with respect to time and take the ratio. Finally, there is the ratio of perturbations in the energy density to those in the pressure,

$$\frac{\delta\mathcal{P}}{\delta\rho} = \frac{-3\delta T_0^0}{\delta T_i^i}$$

where the minus sign accounts for the fact the the time-time component of the energy-momentum tensor is minus the energy density with our convention, and the factor of 3 negates the sum over the three spatial indices. For adiabatic perturbations, $\delta\mathcal{P}/\delta\rho = c_s^2$. Show that this holds for three separate cases: matter, radiation, and a single scalar field during inflation at the time of horizon crossing. For the last case, it is enough to show that the difference $\delta\mathcal{P}/\delta\rho - c_s^2$ is of order the slow-roll parameters ϵ and δ.

Solution

D-16.

Show that in a gauge given by Eq. (6.91), the equation governing the perturbations to a scalar field $\delta\phi$ is Eq. (6.71).
(a) Bardeen's equation for the gauge-invariant density in the absence of anisotropic stress is

$$\frac{d}{d\eta}\left(a^3\rho\epsilon_m\right) = -(\rho + \mathcal{P})a^3 kv$$

with gauge-invariant density defined as

$$\rho\epsilon_m = -\rho - \delta T_0^0 + \frac{3iH}{k^2}k_i\delta T_i^0$$

and velocity v via Eq. (6.92). Compute $\rho\epsilon_m$ for a scalar field in a gauge with spatially flat slicing. Show that, to lowest order in slow-roll parameters ϵ (not ϵ_m) and δ, the equation reduces to

$$\frac{d}{d\eta}\left(a^3\dot{\phi}^{(0)}\dot{\delta\phi}\right) = -k^2 a\dot{\phi}^{(0)}\delta\phi$$

(b) Again using the slow-roll approximation reduce Eq. (6.119) to the form of Eq. (6.45).

Solution

D-17.

Show that the curvature in conformal Newtonian gauge is equal to $4k^2\Phi/a^2$. To do this, compute the three-dimensional Ricci scalar arising from the spatial part of the metric $g_{ij} = \delta_{ij}a^2(1+2\Phi)$.

Solution

D-18.

Determine the predictions of an inflationary model with a quartic potential,

$$V(\phi) = \lambda\phi^4$$

(a) Compute the slow roll parameters ϵ and δ in terms of ϕ.
(b) Determine ϕ_e, the value of the field at which inflation ends, by setting $\epsilon = 1$ at the end of inflation.
(c) To determine the spectrum, you will need to evaluate ϵ and δ at $-k\eta = 1$. Choose the wavenumber k to be equal to $a_0 H_0$, roughly the horizon today. Show that the requirement $-k\eta = 1$ then corresponds to

$$e^{60} = \int_0^N dN' \frac{e^{N'}}{\left(H\left(N'\right)/H_e\right)}$$

where H_e is the Hubble rate at the end of inflation, and N is defined to be the number of e-folds before the end of inflation:

$$N := \ln\left(\frac{a_e}{a}\right).$$

(d) Take the Hubble rate to be a constant in the above with H/H_e equal to 1. This implies that $N \simeq 60$. Turn this into an expression for ϕ. The simplest way to do this is to note that $N = \int_t^{T_e} dt' H\left(t'\right)$ and assume that H is dominated by potential energy. Show that this mode leaves the horizon when $\phi^2 = 60 m_{\rm Pl}^2/\pi$.
(e) Determine the predicted values of n and n_T.
(f) Estimate the scalar amplitude in terms of λ. As a rough estimate, assume that $k^3 P_\Phi(k)$ for this mode is equal to 10^{-8} (we will find a more precise value when we normalize to large-angle anisotropies in Chapter 8). What value does this imply for λ?
This model illustrates many of the features of contemporary models. In it, (i) the field is of order - even greater than – the Planck scale, but (ii) the energy scale V is much smaller because of (iii) the very small coupling constant.

Solution

Baumann-4.3. Tensors and the Lyth Bound

(a) Show that the tensor-to-scalar ratio predicted by slow-roll inflation is

$$r \equiv \frac{A_t}{A_s} = \frac{8\dot{\phi}^2}{M_{\rm pl}^2 H^2}.$$

(b) Show that the inflaton field travels a "distance" $\Delta\phi \equiv |\phi_E - \phi_\star|$ during (observable) inflation

$$\frac{\Delta\phi}{M_{\rm pl}} = \frac{N_\star}{60}\sqrt{\frac{r}{0.002}},$$

where $N_\star$ is the total number of e-folds between the time when the CMB scales exited the horizon and the end of inflation. [You may assume that $\varepsilon \approx$ const. during inflation] Comment on the implication of this result for observable gravitational waves. [Realistically, we require $r > 0.001$ to have a fighting chance of detecting gravitational waves via CMB polarisation.]
(c) Derive the following relationship between the energy scale of inflation, $V^{1/4}$, and the tensor-to-scalar ratio,

$$V^{1/4} = \left(\frac{3\pi^2}{2} r A_s\right)^{1/4} M_{\rm pl}.$$

Use $A_s = 2.5 \times 10^{-9}$ to determine $V^{1/4}$ for $r = 0.01$. How does that compare to the energy scales probed by the LHC?

Solution

Solution some problems by Dodelson chapter 6

Solution to

5 There are 411 photons per cm^{-3} today; the Hubble volume is $(4\pi/3)\left[3000h^{-1}\mathrm{Mpc}\right]^3 = 3.3\times10^{84}h^{-3}$ cm^3. So the total number of photons is $1.4\times10^{87}h^{-3}$. This number remains roughly constant throughout the matter and radiation eras since the number density scales as T^3, the physical volume as a^3, and the temperature as a^{-1}. So another problem of the classical cosmology is: Why is the entropy of the universe so large?

Inflation solves this problem. At first the solution seems obvious: inflation makes the scale factor grow exponentially fast, thereby increasing the product aT and hence the entropy. In fact, the solution is not quite that simple because during inflation, the exponential expansion is adiabatic: the temperature still falls as a^{-1}. So near the end of inflation the temperature has dropped rapidly enough so that if the entropy was initially of order unity, it remained of order unity.

The production of entropy actually takes place at the end of inflation during the reheating process. Even though the temperature at the end of inflation is extremely small, the energy density (which is almost completely in the scalar field) is not. When the energy in the scalar field transforms into radiation, the temperature of the radiation shoots up from its very low value of T to $\rho^{1/4} \gg T$. Thus, the reheating process is responsible for the large entropy we see today. Another way to say this is to point out that inflation is a very ordered state: the universe supercools while the field is trapped in a false vacuum. The transition to the true vacuum is a transition to the very disordered state of equilibrium.

Solution to

11 (a) With this substitution, the equation becomes

$$\frac{d^2\tilde{v}}{d\eta^2} + \frac{2}{\eta}\frac{d\tilde{v}}{d\eta} + \left(k^2 - \frac{2}{\eta^2}\right)\tilde{v}$$

Defining $x \equiv k\eta$, we see that $\tilde{v}$ satisfies the spherical Bessel equation of order 1 (Eq. (C.13)). (b) The two general solutions are $j_1(x)$ and $y_1(x)$. The general solution is therefore $Aj_1 + By_1$. Writing these out explicitly leads to

$$\begin{aligned} v = \eta\tilde{v} &= \eta\left(A\frac{\sin x - x\cos x}{x^2} - B\frac{\cos x + x\sin x}{x^2}\right) \\ &= \frac{1}{2k^2\eta}\left(e^{ik\eta}[-iA - Ak\eta - B + iBk\eta]\right. \\ &\quad \left. + e^{-ik\eta}[iA - Ak\eta - B - iBk\eta]\right). \end{aligned}$$

When $k\eta$ is very large and negative, we want $v \to e^{-ik\eta}/\sqrt{2k}$, so the coefficient of $e^{+ik\eta}$ in this limit, proportional to $-A + iB$, must vanish. Thus, $A = iB$. The coefficient of $e^{-ik\eta}$ is

$$\frac{1}{2k^2\eta}[-2Ak\eta] = \frac{-A}{k}$$

This must equal $(2k)^{-1/2}$, so $A = -(k/2)^{1/2}$. Therefore the correct solution is

$$v = \frac{-1}{\sqrt{2k}k\eta}\left(e^{-ik\eta}[i - k\eta]\right)$$

in agreement with Eq. (6.57).

Solution to

13 The two components of Einstein's equations are

$$\begin{aligned} k^2\Psi + 3aH(\dot{\Psi} + aH\Psi) &= 4\pi Ga^2\delta T_0^0 \\ ik_i(\dot{\Psi} + aH\Psi) &= -4\pi Ga\delta T_i^0 \end{aligned}$$

Here I have simply copied the results from Chapter 5, replacing Φ with $-\Psi$. Multiply the second of these by $3iaHk_i/k^2$, and then add the two equations to get

$$k^2\Psi = 4\pi Ga^2\left[\delta T_0^0 - \frac{3Hk_i\delta T_i^0}{k^2}\right]$$

On large scales, the left-hand side is negligible, so the terms in brackets on the right must sum to zero, giving Eq. (6.85).

13.2.2 Problems on inhomogeneities

D-1.

Derive Eqs. (7.11) and (7.12).
(a) First neglect the scattering term in Eq. (4.100), the one proportional to $\dot{\tau}$. Then the photon evolution equation is identical to the neutrino evolution equation (4.107). Show that this collisionless equation reduces to the two equations for the monopole and dipole. To get the monopole equation, multiply Eq. (4.107) by $(d\mu/2)\mathcal{P}_0(\mu) = d\mu/2$ and integrate from $\mu = -1$ to 1. To get the dipole, multiply by $(d\mu/2)\mathcal{P}_1(\mu)$ and integrate.
(b) Show that, in the limit of small baryon density, the scattering term in Eq. (4.100) can indeed be neglected. Neglect Π, since the quadrupole and polarization are very small. Then show that the scattering term is proportional to $R, 3/4$ times the baryon-to-photon ratio. You will want to use Eq. (4.106). It cannot be emphasized enough that this series of approximations is valid only for the purposes of this chapter, wherein we are interested in the matter distribution.

D-3.

The four subsections in Sections 7.2 and 7.3 correspond to four different approximations to the full set of Einstein-Boltzmann equations. In the following table, fill in the regime of validity for each approximation:

	$a \ll a_{\rm eq}$	$a \sim a_{\rm eq}$	$a \gg a_{\rm eq}$
$k\eta \ll 1$			
$k\eta \sim 1$			
$k\eta \gg 1$			

For example, the super-horizon solution of Section 7.2.1 is valid along the whole top row, since it sets $k\eta \to 0$. Note that time evolves from upper left to bottom right, so the fact that none of the approximations work in the center square means that only those scales that enter the horizon well before or well after equality will be subject to analytic techniques.

D-4.

Fill in some of the algebraic detail left out of Section 7.2.1.
(a) Show that Eq. (7.24) leads to Eq. (7.25) by carrying out the differentiation.
(b) Show that Eq. (7.25) is equivalent to Eq. (7.27) when the definition of u from Eq. (7.26) is used.
(c) Show that the integral in Eq. (7.31) can be done analytically with the result given in Eq. (7.32). One way to do the integral is to define a dummy variable $x := \sqrt{1+y}$

D-5.

Find the wavenumber of the mode which equals the inverse comoving Hubble radius at equality. That is, define $k_{\rm eq}$ to be equal to $a_{\rm eq}H\,(a_{\rm eq})$. Show that this definition implies

$$k_{\rm eq} = \sqrt{\frac{2\Omega_m H_0^2}{a_{\rm eq}}}$$

Then use Eq. (2.87) to show that $k_{\rm eq}$ is given by Eq. (7.39). Show that if you define $k_{\rm eq}$ by setting it to $1/\eta_{\rm eq}$, you get a number 17% lower.

D-7.

Show that $\delta \propto H$ is a solution to the evolution equation (7.73) if the universe is flat with a cosmological constant. You will need to use Eq. (1.2). Show also that the solution is valid if the universe has zero cosmological constant, but is open with $\Omega_m < 1$.

D-8.

Derive the growth factor for an open universe with $\Omega_m < 1$:

$$D_1\,(a, \Omega_m) = \frac{5\Omega_m}{2\,(1-\Omega_m)}\left[3\frac{\sqrt{1+x}}{x^{3/2}}\ln(\sqrt{1+x}-\sqrt{x}) + 1 + \frac{3}{x}\right]$$

where $x := (1-\Omega_m)\,a/\Omega_m$. There may be easier ways to do this (e.g., you might want to check The Large Scale Structure of the Universe, Section 11), but I found it easiest to define a dummy variable $y := \Omega_m/a$; write the integral of Eq. (7.77) as

$$\int_{\Omega_m/a}^{\infty} \frac{dy}{y^2\,(y+1-\Omega_m)^{3/2}} = 2\left[\frac{d}{d\epsilon}\frac{d}{d\lambda}\int_{\Omega_m/a}^{\infty}\frac{dy}{(y+\epsilon)\sqrt{y+\lambda}}\right]_{\epsilon=0,\lambda=1-\Omega_m};$$

and then use 2.246 from Gradshteyn and Ryzhik.

D-9.

One popular way to characterize power on a particular scale is to compute the expected RMS overdensity in a sphere of radius R,

$$\sigma_R^2 := \left\langle \delta_R^2(x)\right\rangle$$

Here

$$\delta_R(\vec{x}) := \int d^3x'\delta\left(\vec{x}'\right) W_R\left(\vec{x}-\vec{x}'\right)$$

where $W_R(x)$ is the tophat window function, equal to 1 for $x < R$ and 0 otherwise; the angular brackets denote the average over all space.

(a) By Fourier transforming, express σ_R in terms of an integral over the power spectrum.

(b) Use the BBKS transfer function to compute $\sigma_8\left(R = 8h^{-1}\mathrm{Mpc}\right)$ for a standard CDM model ($h = 0.5, n = 1, \Omega_m = 1$). We will see in Chapter 8 that COBE normalization for this model is

$$\delta_H = 1.9\times 10^{-5}.$$

The value of σ_8 you find is yet another sign of the sickness of the model. For galaxies, σ_8 is known to be unity (or less, depending on galaxy type). A model with $\sigma_8 > 1$ then requires galaxies to be less clustered than the dark matter. Present models of galaxy formation suggest that this is unlikely. There are even direct measures of σ_8 of the mass (e.g., Section 9.5); these too constrain σ_8 to be less than one. (c) In the same model, plot σ_R as a function of R. Since σ_R monotically increases, small scales tend to go nonlinear before large scales, the signature of a hierarchical model.

D-10.

Rewrite σ from Exercise 9 as

$$\sigma_R^2 = \int_0^{\infty}\frac{dk}{k}\Delta^2(k)\tilde{W}_R^2(k),$$

where $\tilde{W}_R$ is the Fourier tranform of the tophat window function and $\Delta^2 = d\sigma^2/d\ln(k)$ is the contribution to the variance per $\ln(k)$. A useful transition point is the value of k at which Δ exceeds 1. Scales larger than this are linear, while smaller scales have gone nonlinear. Find $k_{\rm nl}$ defined in this way for the sCDM model described in

D-9.

D-11.

Compute the growth factors in a universe with $\Omega_{\rm de} = 0.7, \Omega_m = 0.3$, and $w = -0.5$. Plot as a function of a. Compare with the cosmological constant model ($w = -1$) with the same $\Omega_{\rm de}, \Omega_m$.

Leuven-2023hw3.1. Gauge-invariant variables $(4p)$

Show that the Bardeen potentials Φ_A and Φ_H defined as

$$\begin{cases}\Phi_A = A + \frac{1}{a}\frac{\partial}{\partial\eta}(a(\dot{E}-B))\\ \Phi_H = -\psi + aH(B-\dot{E})\end{cases}$$

(dot is $\frac{d}{d\eta}$) in a notation $g_{00} \equiv -(1+2A), g_{0i} \equiv -aB_{.i}, g_{ij} \equiv a^2\left(\delta_{ij}[1+2\psi] - 2E_{.ij}\right)$ are invariant under infinitesimal coordinate transformations of the form

$$t \to t + \zeta(t,\vec{x}), \quad x^i \to x^i + \partial^i\xi(t,\vec{x}),$$

Solution

We consider a coordinate transformation given by

$$\begin{cases} \tilde{t} = t + \xi^0(t, \vec{x}) \\ \tilde{x^i} = x^i + \delta^{ij}\partial_j \xi(t, \vec{x}) \end{cases}$$

where ξ and ξ^0 are small perturbations. Under such a transformation, the scalars transform as

$$\begin{cases} \tilde{A} = A - \frac{1}{a}\dot{\xi}, \\ \tilde{\psi} = \psi - H\xi^0, \\ \tilde{B} = B - \frac{\xi^0}{a} + \dot{\xi}, \\ \tilde{E} = E + \xi, \end{cases}$$

as indicated on p. 133-134 of Dodelson. Filling these expressions into the expressions for the Bardeen potentials, we easily calculate

$$\begin{aligned} \tilde{\Phi}_A &= A - \frac{1}{a}\dot{\xi}^0 + \frac{1}{a}\frac{\partial}{\partial\eta}\left[a\left(\dot{E} + \dot{\xi} - B + \frac{\xi^0}{a} - \dot{\xi}\right)\right] \\ &= A - \frac{1}{a}\dot{\xi}^0 + \frac{1}{a}\frac{\partial}{\partial\eta}\left[a(\dot{E} - B) + \xi^0\right] \\ &= A + \frac{1}{a}\frac{\partial}{\partial\eta}(a(\dot{E} - B)) \\ &= \Phi_A \end{aligned}$$

and

$$\begin{aligned} \tilde{\Phi}_H &= -\psi + H\xi^0 + aH\left(B - \frac{\xi^0}{a} + \dot{\xi} - \dot{E} - \dot{\xi}\right) \\ &= -\psi + aH(B - \dot{E}) \\ &= \Phi_H. \end{aligned}$$

This proves the invariance of the Bardeen potentials.

Leuven-2023hw3 3.2. Geodesic equation for photons (4p)

Consider the perturbed FLRW metric in the Newtonian gauge

$$\mathrm{d}s^2 = -(1 + 2\Psi)\mathrm{d}t^2 + a^2(t)(1 + 2\Phi)\delta_{ij}\ \mathrm{d}x^i\ \mathrm{d}x^j.$$

Use the zeroth component of the geodesic equation for massless particles to derive the equation for the time variation of the magnitude of the physical momentum p as a function of the perturbations in the metric

$$\frac{\mathrm{d}}{\mathrm{d}t}\ln(pa) = -\partial_t\Phi - \frac{\hat{p}^i}{a}\partial_i\Psi,$$

where $p = \sqrt{g_{ij}P^iP^j}$, P^i is the space component of the four-momentum $P^\mu = \mathrm{d}x^\mu/\mathrm{d}\lambda$, λ is the affine parameter of the geodesic, and $\hat{p}^i$ is the unit vector (i.e. $\delta_{ij}\hat{p}^i\hat{p}^j = 1$) determining the direction of the momentum.

Solution

We start from the line element

$$ds^2 = -(1 + 2\Psi)dt^2 + a^2(1 + 2\Phi)\delta_{ij}dx^idx^j.$$

Because the photons are constrained by $P^2 = 0$, we find that

$$P^0 = \frac{p}{\sqrt{1 + 2\Psi}} \sim p(1 - \Psi),$$

to first order. The first component of the geodesic equation is

$$\frac{dP^0}{d\lambda} = -\Gamma^0_{\alpha\beta}P^\alpha P^\beta.$$

Since $\frac{dt}{d\lambda} = P^0$, we thus have

$$p(1-\Psi)\frac{d}{dt}[p(1-\Psi)] = -\Gamma^0_{\alpha\beta}P^\alpha P^\beta,$$

or to first order

$$\frac{d}{dt}[p(1-\Psi)] = -\Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p}(1+\Psi).$$

Expanding the derivative on the left hand side and multiplying by $(1+\Psi)$, we find

$$\frac{dp}{dt} = p\left[\frac{\partial\psi}{\partial t} + \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}\right] - \Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p}(1+2\Psi).$$

Dodelson calculates on p. 91-92 that

$$\Gamma^0_{\alpha\beta}\frac{P^\alpha P^\beta}{p} = [-1+2\Psi]\left[-\frac{\partial\Psi}{\partial t} - 2\frac{\partial\Psi}{\partial x^i}\frac{\hat{p}^i}{a} - p\left(\frac{\partial\Phi}{\partial t} + H\right)\right].$$

Inserting this expression and dividing by p, we arrive at

$$\frac{1}{p}\frac{dp}{dt} = -H - \frac{\partial\Phi}{\partial t} - \frac{\hat{p}^i}{a}\frac{\partial\Psi}{\partial x^i}.$$

The left hand side is just the derivative of $\ln p$. Furthermore from the definition of H, it is also clear that this is the derivative of $\ln a$ with respect to time. Hence, we indeed arrive at

$$\frac{d\ln(pa)}{dt} = -\partial_t\Phi - \frac{\hat{p}^i}{a}\partial_i\Psi$$

Leuven-2023hw3 3.3. Large-scale super-horizon potential modes

In this exercise we consider the evolution of the gravitational potential Φ for largescale super-horizon modes.
a) Show that the set of evolution equations for large-scale perturbations ($k\eta \ll 1$)

$$\dot{\Theta}_0 = -\dot{\Phi}, \quad \dot{\delta} = -3\dot{\Phi}, \quad \frac{3\dot{a}}{a}\left(\dot{\Phi} + \Phi\frac{\dot{a}}{a}\right) = 4\pi G a^2\left(\rho_{\rm m}\delta + 4\rho_{\rm r}\Theta_0\right)$$

can be combined into a single second-order equation of the following form

$$\Phi'' + \frac{21y^2+54y+32}{2y(y+1)(3y+4)}\Phi' + \frac{\Phi}{y(y+1)(3y+4)} = 0$$

by using the variable

$$y := \frac{a}{a_{\rm eq}} = \frac{\rho_{\rm m}}{\rho_{\rm r}},$$

where a dot indicates a derivative with respect to η and a prime indicates a derivative with respect to y.
b) Introduce the variable

$$u := \frac{y^3}{\sqrt{1+y}}\Phi$$

and show that (1) can be written as

$$u'' + u'\left[-\frac{2}{y} + \frac{3}{2(1+y)} - \frac{3}{3y+4}\right] = 0.$$

c) Show by means of (3) that a solution to (1) can be expressed as

$$\frac{y^3}{\sqrt{1+y}}\Phi = A\int_0^y \mathrm{d}\tilde{y}\frac{\tilde{y}^2(3\tilde{y}+4)}{(1+\tilde{y})^{3/2}}.$$

Show that this integral can be computed analytically and gives

$$\Phi = \frac{2A}{15}\frac{1}{y^3}\left(16\sqrt{1+y} + 9y^3 + 2y^2 - 8y - 16\right).$$

Hint: Use the dummy variable $x = \sqrt{1+y}$.
d) Show that (4) asymptotes to a constant for $y \to 0$ and $y \to \infty$. What is the ratio of Φ at late times to Φ at early times?

Solution

In this exercise we consider the evolution of the gravitational potentials Φ for large-scale superhorizon modes and fill some gaps that were left in the lecture a) Consider the set of evolution equations for large-scale perturbations

$$\begin{aligned}\dot{\Theta}_0 &= -\dot{\Phi},\\ \dot{\delta} &= -3\dot{\Phi},\\ \frac{3\dot{a}}{a}\left(\dot{\Phi}-\Phi\frac{\dot{a}}{a}\right) &= 4\pi G a^2\left(\rho_{\rm m}\delta+4\rho_{\rm r}\Theta_0\right),\end{aligned}$$

where a dot indicates a derivative with respect to η. First of all, consider the variable $y\equiv\frac{a}{a_{\rm eq}}=\frac{\rho_{\rm m}}{\rho_{\rm x}}$ as defined in the assignment. A prime will indicate a derivative with respect to y. Let us first rewrite the equations in (1-3) in the variable y. For this purpose, note that by chain rule we have

$$\frac{\mathrm{d}}{\mathrm{d}\eta}=\frac{\mathrm{d}y}{\mathrm{d}\eta}\frac{\mathrm{d}}{\mathrm{d}y}=\frac{\dot{a}}{a_{\rm eq}}\frac{\mathrm{d}}{\mathrm{d}y}=aHy\frac{\mathrm{d}}{\mathrm{d}y}$$

where we used that $H=\frac{da/dt}{a}=\frac{\dot{a}}{a^2}$. Now using this the left-hand side of the third evolution equation (3) gives

$$\frac{3\dot{a}}{a}\left(\dot{\Phi}+\Phi\frac{\dot{a}}{a}\right)=3Hya'\left(aHy\Phi'+\Phi Hya'\right)=3H^2y^2\left(a'\Phi'+\left(a'\right)^2\Phi\right)$$

Next combining (1) and (2) yields

$$\dot{\delta}-3\dot{\Theta}_0=0\Rightarrow\delta-3\Theta_0=c$$

where c is an constant. However, using the adiabatic initial conditions, we have that $c=0$. If we now use (6) in the third evolution equation (3) we have

$$3H^2y^2\left(a'\Phi'+\left(a'\right)^2\Phi\right)=4\pi Ga^2\left(\rho_{\rm m}\delta+4\rho_{\rm r}\Theta_0\right)=4\pi Ga^2\rho_m\delta\left(1+\frac{4}{3y}\right).$$

Next, rewrite the first Friedmann equation as

$$\frac{8\pi G\rho_m}{3}=\frac{8\pi Gp}{3}\frac{y}{y+1}=H^2\frac{y}{y+1}$$

where we used that $\rho=\rho_m+\rho_r$ and the definition for the variable y. Substituting this in the right-hand side expression from (7) yields

$$3H^2y^2\left(a'\Phi'+\left(a'\right)^2\Phi\right)=\frac{3H^2}{2}\frac{y}{y+1}a^2\delta\left(1+\frac{4}{3y}\right)$$

Rewriting this gives

$$\frac{a'}{a}y\Phi'+\left(\frac{a'}{a}\right)^2y\Phi=\frac{\delta}{2(y+1)}\left(1+\frac{4}{3y}\right)$$

Now by using the definition of the variable y and setting δ to one side yields

$$\delta=\frac{6(y+1)}{3y+4}\left(y\Phi'+\Phi\right)$$

In the second evolution equation (2) we can interchange the η-derivative with y-derivative so that the above intermediate expression (11) becomes

$$-3\Phi'-\frac{\mathrm{d}}{\mathrm{d}y}\left[\frac{6(y+1)}{3y+4}\left(y\Phi'+\Phi\right)\right]=\frac{6(3y+4)-18(y+1)}{(3y+4)^2}\left(y\Phi'+\Phi\right)+\frac{6(y+1)}{3y+4}\left(2\Phi'+y\Phi''\right)$$

which by some simple algebraic manipulation reduces to the requested equation

$$\Phi''+\frac{21y^2+54y+32}{2y(3y+4)(y+1)}\Phi'+\frac{1}{y(3y+4)(y+1)}\Phi=0$$

Next, introduce the new variable

$$u \equiv \frac{y^3}{\sqrt{1+y}}\Phi$$

The derivatives with respect to the variable y of above expression yield

$$\Phi' = -\frac{5y+6}{2\sqrt{1+y}y^4}u + \frac{\sqrt{1+y}}{y^3}u'$$
$$\Phi'' = \frac{-10(1+y)y+(5y+6)(5y+8)}{4(1+y)y^5\sqrt{1+y}}u - \frac{5y+6}{y^4\sqrt{1+y}}u' + \frac{\sqrt{1+y}}{y^3}u''$$

Now, if we substitute these derivatives into (13) and collect all terms proportional to u one finds

$$\frac{-10(1+y)y+(5y+6)(5y+8)}{4(1+y)y^5\sqrt{1+y}} - \frac{5y+6}{2\sqrt{1+y}y^4}\frac{21y^2+54y+32}{2y(y+1)(3y+4)} + \frac{1}{y(3y+4)(y+1)}\frac{\sqrt{1+y}}{y^3}$$

Letting Mathematica come to the rescue yields that these vanishes. The remaining expression to reduce is

$$\frac{\sqrt{1+y}}{y^3}u'' + \left[\frac{\left(21y^2+54y+32\right)}{2y^4(y+1)(3y+4)} - \frac{2(5y+6)(3y+4)}{2y^4(y+2)(3y+4)}\right]\sqrt{1+y}u' = 0$$

Further reducing the denominator yields

$$u'' - \frac{\left(9y^2+22y+16\right)}{2y(y+1)(3y+4)}u' = 0$$

which again by invoking Mathematica yields

$$u'' + u'\left[-\frac{2}{y} + \frac{3}{2(1+y)} - \frac{3}{3y+4}\right]$$

c) Note that equation (19) is an first order differential equation in u' which can be expressed as

$$\frac{du'}{u'} = dy\left[\frac{2}{y} - \frac{3/2}{1+y} + \frac{3}{3y+4}\right]$$

Integrating both sides yields

$$\ln(u') = C + 2\ln(y) - (3/2)\ln(1+y) + \ln(3y+4),$$

where C is an constant. If we now exponentiate both side we have

$$u' = A\frac{y^2(3y+4)}{(1+y)^{3/2}}$$

where $A = \exp(C)$. Again integrating both sides and using the definition of u (14)

$$\frac{y^3}{\sqrt{1+y}}\Phi = A\int_0^y dy'\frac{y'^2(3y'+4)}{(1+y')^{3/2}}$$

As explained in Dodelson there should be another constant here, arising from the integration. However, because $y^3\Phi \to 0$ early on, one can take it to be zero. Let us now perform the integral. Given as hint in the assignment introduce the variable $x = \sqrt{1+y}$ which gives

$$\int_0^y dy'\frac{y'^2(3y'+4)}{(1+y')^{3/2}} = 2\int_1^{\sqrt{1+y}}\frac{\left(x^2-1\right)^2\left(3x^2+1\right)}{x^2}\,\mathrm{d}x$$
$$= \int_1^{\sqrt{1+y}}\left(6x^4-10x^2+2+\frac{2}{x^2}\right)\mathrm{d}x$$
$$= \frac{6}{5}(1+y)^{5/2} - \frac{10}{3}(1+y)^{3/2} + 2(1+y)^{1/2} - \frac{2}{(1+y)^{1/2}} - \frac{32}{15}.$$

Substituting this back into (23) yiels

$$\begin{aligned}\Phi &= A\frac{\sqrt{1+y}}{y^3}\left[\frac{6}{5}(1+y)^{5/2}-\frac{10}{3}(1+y)^{3/2}+2(1+y)^{1/2}-\frac{2}{(1+y)^{1/2}}-\frac{32}{15}\right]\\ &= \frac{2A}{15}\frac{1}{y^3}\left[9\left(y^3+3y^2+3y+1\right)-25\left(1+2y+y^2\right)+15(1+y)-16\sqrt{1+y}\right]\\ &= \frac{2A}{15}\frac{1}{y^3}\left[16\sqrt{1+y}+9y^3+2y^2-8y-16\right].\end{aligned}$$

d) We must calculate the limit

$$\lim_{y\to 0}\Phi(y)=\lim_{y\to 0}\frac{2A}{15}\left(\frac{16\sqrt{1+y}+9y^3+2y^2-8y-16}{y^3}\right)$$

Looking at the dominant behavior for small y, we notice that the limit is of the form $\frac{0}{0}$. Luckily, we can use l'Hopital rule [1], as both nominator and denominator are differentiable. This gives the limit

$$\lim_{y\to 0}\frac{2A}{15}\left(\frac{\frac{8}{\sqrt{1+y}}+27y^2+4y-8}{3y^2}\right)$$

Unfortunately, the limit again yields $\frac{0}{0}$. Nevertheless, using l'Hopital rule two more times yields

$$\lim_{y\to 0}\Phi(y)=\frac{2A}{15}\lim_{y\to 0}\frac{6(1+y)^{-5/2}+54}{6}=\frac{4A}{3}$$

the same result that can be found in Dodelson.

Leuven-2023hw3.4. Hubble radius and equality scale

(a) Find the wavenumber of the mode that equals the inverse comoving Hubble radius at matter-radiation equality, i.e. define $k_{\rm eq}:=a_{\rm eq}H\left(a_{\rm eq}\right)$. Show that this definition implies

$$k_{\rm eq}=\sqrt{\frac{2\Omega_m H_0^2}{a_{\rm eq}}}.$$

(b) Now define a_H, the scale factor at which wavelength k equals the comoving Hubble radius, via $a_H H\left(a_H\right)=k$. Express a_H/a_{eq} only in terms of k and k_{eq}. Show that in the limit $k\gg k_{\rm eq}$, this expression reduces to

$$\frac{a_H}{a_{eq}}\overset{k\gg k_{eq}}{\sim}\frac{k_{eq}}{\sqrt{2}k}.$$

Solution to (a)

Let us try to find the wavenumber of the mode that equals the inverse comoving Hubble radius at matter-radiation equality, i.e. $k_{\rm eq}\equiv a_{\rm eq}H\left(a_{\rm eq}\right)$. At matter-radiation equality we have $\rho_m=\rho_r$ or equivalently $\frac{\Omega_m}{a_{eq}}=\frac{\Omega_\gamma}{a_{cq}}$. Hence, by the first Friedmann equation

$$H^2\left(a_{\rm eq}\right)=H_0^2\left(\frac{\Omega_r}{a_{\rm eq}^4}+\frac{\Omega_m}{a_{\rm eq}^3}\right)=\frac{2\Omega_m H_0^2}{a_{\rm eq}^3}$$

Therefore, we have

$$k_{eq}=\sqrt{\frac{2\Omega_m\left(\frac{H_o}{c}\right)^2}{a_{eq}}}.$$

where we have reinstated the factor for the speed of light c to have the right units. Remember that $a_{eq}=4.15\times10^{-5}\left(\Omega_m h^2\right)^{-1}$ and $H_0=100$ km skpc^{-1} so that the wavenumber becomes

$$k_{\rm eq}=\sqrt{\frac{2(100/299792.458)^2}{4.15\times10^{-5}}}{\rm Mpc}^{-1}\Omega_m h^2=0.073{\rm Mpc}^{-1}\Omega_m h^2.$$

Suppose that we had defined $k_{eq}=\eta_{eq}^{-1}$. Remember that in first homework we found

$$\eta_{\rm eq}=2(\sqrt{2}-1)H_0^{-1}\Omega_m^{-1/2}a_{\rm eq}^{1/2}$$

and indeed when reinstating the speed of light c we find

$$k_{\rm eq}=\frac{H_0\Omega_m^{1/2}}{2(\sqrt{2}-1)a_{\rm eq}^{1/2}}=\frac{100/299792.458}{2(\sqrt{2}-1)\left(4.15\times10^{-5}\right)^{1/2}}{\rm Mpc}^{-1}\Omega_m h^2=0.0625{\rm Mpc}^{-1}\Omega_m h^2$$

Solution to (b)

Let us define a_H the scale factor at which wavelength k equals the comoving Hubble radius, via $k = a_H H(a_H)$. Furthermore, the first Friedmann equation gives

$$H^2(a_H) = H_0^2\left(\frac{\Omega_m}{a_H^3} + \frac{\Omega_r}{a_H^4}\right).$$

and therefore

$$k = H_0\sqrt{\frac{\Omega_m}{a_H} + \frac{\Omega_r}{a_H^2}}$$

Using (30) we can write

$$\frac{k^2}{k_{eq}^2} = \frac{\frac{\Omega_m}{a_H} + \frac{\Omega_r}{a_H^2}}{\frac{2\Omega_m H_0^2}{a_{eq}}} = \frac{a_{eq}}{2}\frac{(a_H\Omega_m + \Omega_r)}{a_H^2 H_0^2\Omega_m} = \frac{a_{eq}a_H + a_{eq}^2}{a_H^2} = \frac{1}{2}\left(\frac{a_{eq}}{a_H}\right)^2 + \frac{1}{2}\frac{a_{eq}}{a_H}$$

where we used that $\Omega_r = \Omega_m a_{eq}$. The expression above is quadratic with a positive solution given by

$$\frac{a_{eq}}{a_H} = \frac{1}{2}\sqrt{1 + 8\frac{k^2}{k_{eq}^2}} - 1$$

In the limit

$$\lim_{k\gg k_{eq}}\frac{a_H}{a_{eq}} = \lim_{k\gg k_{eq}}\frac{1}{2}\sqrt{1 + 8\frac{k^2}{k_{eq}^2}} - 1 = \frac{1}{2}\sqrt{8\frac{k^2}{k_{eq}^2}} = \frac{k_{eq}}{\sqrt{2}k}$$

D-6.

Define a_H, the scale factor at which wavelength k equals the comoving Hubble radius, via $a_H H(a_H) := k$. Express $a_H/a_{\rm eq}$ in terms of k and $k_{\rm eq}$. Show that in the limit $k \gg k_{\rm eq}$, this expression reduces to

$$\lim_{k\gg k_{\rm eq}}\frac{a_H}{a_{\rm eq}} = \frac{k_{\rm eq}}{\sqrt{2}k}$$

Baumann 3.4. Growth of Matter Perturbations I: Early Times and Meszarous equation

At early times, the universe was dominated by radiation (r) and pressureless matter (m). You may ignore baryons.

(a) Show that the conformal Hubble parameter satisfies

$$\mathcal{H}^2 = \frac{\mathcal{H}_0^2\Omega_m^2}{\Omega_r}\left(\frac{1}{y} + \frac{1}{y^2}\right),$$

where $y \equiv a/a_{\rm eq}$ is the ratio of the scale factor to its value when the energy density of the matter and radiation are equal.

(b) Describe qualitatively the behaviour of the Newtonian-gauge fractional density perturbations δ_r and δ_m for a scalar perturbation at scale k, with adiabatic initial conditions, that re-enters the Hubble radius well before $a_{\rm eq}$.

(c) For perturbations on scales much smaller than the Hubble radius, the fluctuations in the radiation can be neglected. Assuming that Φ evolves on a Hubble timescale, show that

$$\delta_m'' + \mathcal{H}\delta_m' - 4\pi G a^2\bar{\rho}_m\delta_m \approx 0.$$

(d) Show that, in terms of the variable y, eq. ($\star$) becomes

$$\frac{d^2\delta_m}{dy^2} + \frac{2+3y}{2y(1+y)}\frac{d\delta_m}{dy} - \frac{3}{2y(1+y)}\delta_m = 0.$$

Hence verify that the solutions are

$$\delta_m \propto \begin{cases} 2+3y \\ (2+3y)\ln\left(\frac{\sqrt{1+y}+1}{\sqrt{1+y}-1}\right) - 6\sqrt{1+y} \end{cases}$$

Determine how δ_m grows with y for $y \ll 1$ (RD) and $y \gg 1$ (MD).

(a) Friedmann Equation

The conformal-time Friedmann equation is

$$\mathcal{H}^2 = \frac{8\pi G}{3} a^2 \left(\rho_m + \rho_r\right)$$

Defining $y = a/a_{\rm eq}$, we have

$$\rho_m = \rho_{\rm eq} y^{-3}$$
$$\rho_r = \rho_{\rm eq} y^{-4}$$

so that the Friedmann equation is

$$\begin{aligned}\mathcal{H}^2 &= \frac{8\pi G}{3} a^2 \rho_{\rm eq} \left(y^{-3} + y^{-4}\right) \\ &= \frac{8\pi G}{3} a_{\rm eq}^2 \rho_{\rm eq} \left(y^{-1} + y^{-2}\right).\end{aligned}$$

As usual, we can define

$$\Omega_m = \frac{8\pi G}{3\mathcal{H}_0^2}\rho_{m,0},$$
$$\Omega_r = \frac{8\pi G}{3\mathcal{H}_0^2}\rho_{r,0},$$

where $a = 1$ today. We can write these as

$$\Omega_m = \frac{8\pi G}{3\mathcal{H}_0^2}\rho_{\rm eq} a_{\rm eq}^3,$$
$$\Omega_r = \frac{8\pi G}{3\mathcal{H}_0^2}\rho_{\rm eq} a_{\rm eq}^4.$$

Their ratio is

$$\frac{\Omega_m}{\Omega_r} = \frac{1}{a_{\rm eq}}.$$

Putting these together, we obtain

$$\mathcal{H}^2 = \mathcal{H}_0^2 \frac{\Omega_m^2}{\Omega_r}\left(y^{-1} + y^{-2}\right).$$

(b) Qualitative Behaviours

Radiation perturbations oscillate with constant amplitude around $\delta_r = 0$. Dark matter perturbations in the radiation era on subhorizon scales grow logarithmically, as the universe expands too quickly for matter to cluster much. In particular, perturbations should be frozen, but because they enter the horizon with non-negligible $\dot{\delta}, \delta$ continues to grow a bit after horizon entry until its initial velocity is redshifted away, hence the log growth. (c) Matter Perturbations Combining the continuity and Euler equations for pressureless perturbations,

$$\delta_m' = -\nabla \cdot \boldsymbol{v}_m$$
$$\boldsymbol{v}_m' = -\mathcal{H}\boldsymbol{v}_m - \nabla\Phi$$

we find

$$\delta_m'' + \mathcal{H}\delta_m' = \nabla^2\Phi.$$

Because radiation oscillates quickly compared to the Hubble time on small scales, averaging over time the gravitational potential is only sourced by matter fluctuations, so the Poisson equation is only sensitive to matter,

$$\nabla^2\Phi = 4\pi G a^2 \bar{\rho}_m \delta_m.$$

Therefore, we find

$$\delta_m'' + \mathcal{H}\delta_m' - 4\pi G a^2 \bar{\rho}_m \delta_m = 0.$$

This next step involves a bit of algebra, but it's nothing outside your powers. Starting from (8.3.239), there are two things we want to do before anything else. One is that, of course, we want to switch from τ to y as the time coordinate. The other is that we want to replace the $4\pi G a^2 \bar{\rho}$ term with something in the Ω and y

language that we've used elsewhere in this problem. Let's do that first: using (8.3.229) and (8.3.233), we can write

$$\begin{aligned} 4\pi G a^2 \rho_m &= \frac{3}{2}\mathcal{H}_0^2 a^2 \frac{\rho_m}{\rho_{m,0}}\Omega_m \\ &= \frac{3}{2}\mathcal{H}_0^2 \Omega_m a^{-1} \\ &= \frac{3}{2}\mathcal{H}_0^2 \Omega_m a_{\rm eq}^{-1} y^{-1} \\ &= \frac{3}{2}\mathcal{H}\mathcal{H}_0^2 \frac{\Omega_m^2}{\Omega_r} y^{-1} \end{aligned}$$

Let's keep this in our back pockets. Next, we'll do the variable change, noting first that, differentiating (8.3.234) with respect to y, we have

$$\frac{d\mathcal{H}}{dy} = -\frac{\mathcal{H}_0^2}{2\mathcal{H}}\frac{\Omega_m^2}{\Omega_r}\left(y^{-2}+2y^{-3}\right).$$

With this in mind, we can easily take derivatives to find

$$\begin{aligned} \delta_m' &= \mathcal{H} y \frac{d\delta_m}{dy} \\ \delta_m'' &= \mathcal{H}^2 y^2 \left[\frac{d^2\delta_m}{dy^2} + \frac{1}{y}\frac{d\delta_m}{dy} - \frac{\mathcal{H}_0^2}{2\mathcal{H}^2}\frac{\Omega_m^2}{\Omega_r}\left(y^{-2}+2y^{-3}\right)\frac{d\delta_m}{dy}\right] \end{aligned}$$

Plugging all this into (8.3.239) and dividing out $\mathcal{H}^2 y^2$, we obtain

$$\frac{d^2\delta_m}{dy^2} + \frac{2}{y}\frac{d\delta_m}{dy} - \frac{\mathcal{H}_0^2}{2\mathcal{H}^2}\frac{\Omega_m^2}{\Omega_r}\left(y^{-2}+2y^{-3}\right)\frac{d\delta_m}{dy} - \frac{3}{2y^3}\frac{\mathcal{H}_0^2}{\mathcal{H}^2}\frac{\Omega_m^2}{\Omega_r}\delta_m = 0.$$

We can simplify two of these terms with the help of (8.3.234), finding

$$\frac{\mathcal{H}_0^2}{\mathcal{H}^2}\frac{\Omega_m^2}{\Omega_r} = \frac{y^2}{1+y}$$

Plugging this into our equation and combining terms, we obtain the Meszaros equation,

$$\frac{d^2\delta_m}{dy^2} + \frac{2+3y}{2y(1+y)}\frac{d\delta_m}{dy} - \frac{3}{2y(1+y)}\delta_m = 0.$$

By plugging and checking, we can confirm that the two solutions are

$$\begin{aligned} \delta_m &\propto 2+3y \\ \delta_m &\propto (2+3y)\ln\left(\frac{\sqrt{1+y}+1}{\sqrt{1+y}-1}\right) - 6\sqrt{1+y}. \end{aligned}$$

During radiation domination ($y \ll 1$), the first mode is clearly constant while the second, Taylor expanding, contains a constant term and a piece evolving as $\ln y \sim \ln a$. During matter domination ($y \gg 1$), the first solution is $\delta \sim y \sim a$, while the second decays as $y^{-3/2}$. These confirm the results from the lectures: matter clusters very slowly, growing logarithmically, during radiation domination, and then grows, $\delta \sim a$, during matter domination.

Baumann 3.5. Growth of Matter Perturbations II: Late Times

At late times, the universe is dominated by pressureless matter (m) and dark energy (Λ). Assuming that the dark energy doesn't cluster, the gravitational potential is only sourced by the matter.

(a) Use the Einstein equations to show that the comoving-gauge matter density contrast, $\Delta_m \equiv \delta_m - 3\mathcal{H}v_m$, evolves as

$$\Delta_m'' + \mathcal{H}\Delta_m' - 4\pi G a^2 \bar{\rho}_m \Delta_m = 0.$$

(b) Show that $u \equiv \Delta_m/H$ satisfies

$$\frac{d^2u}{da^2} + 3\frac{d\ln(aH)}{da}\frac{du}{da} = 0.$$

Confirm that the decaying mode is $\Delta_m \propto H$, while the growing mode can be written as

$$\Delta_m \propto H\int_a^{a_i}\frac{{\rm d}\tilde{a}}{(\tilde{a}\tilde{H})^3}.$$

(c) What are the growing and decaying modes of Δ_m in the matter-dominated era? What is the asymptotic limit ($a \to +\infty$) of the growing mode solution in the dark energy-dominated era?

Solution for (a) Evolution Equation

Recall that the Poisson equation can be conveniently written in terms of Δ_m as

$$\nabla^2\Phi = 4\pi G a^2 \bar{\rho}_m \Delta_m,$$

where we have defined $\Delta_m \equiv \delta_m - 3\mathcal{H}v_m$. Because $\bar{\rho}_m \sim a^{-3}$, this implies (for a given k mode)

$$\Phi \sim \frac{\Delta_m}{a}.$$

Plugging this into (E3),

$$\Phi'' + 3\mathcal{H}\Phi' + \left(2\mathcal{H}' + \mathcal{H}^2\right)\Phi = 0,$$

we find that the matter density perturbations in comoving gauge obey the equation

$$\Delta_m'' + \mathcal{H}\Delta_m + \left(\mathcal{H}' - \mathcal{H}^2\right)\Delta_m = 0.$$

Let's simplify this using the Friedmann equation,

$$\mathcal{H}^2 = \frac{8\pi G}{3} a^2 \left(\bar{\rho}_m + \bar{\rho}_\Lambda\right).$$

Taking a derivative of this, and using the fact that $\bar{\rho}_m' + 3\mathcal{H}\bar{\rho}_m = 0$ while $\bar{\rho}_\Lambda' = 0$, we find

$$\mathcal{H}' = \mathcal{H}^2 - 4\pi G a^2 \bar{\rho}_m.$$

Therefore, we see that Δ_m obeys the equation

$$\Delta_m'' + \mathcal{H}\Delta_m - 4\pi G a^2 \bar{\rho}_m \Delta_m = 0.$$

The second term is the usual friction due to the expansion of the universe, while the last term describes gravitational instability.

Solution for (b) Matter and Dark Energy

Let's define $u \equiv \Delta/H$, where the cosmic-time Hubble parameter H is related to the conformal-time version by $\mathcal{H} = aH$. We'll use overdots to denote derivatives with respect to a, so we have

$$\begin{aligned}
\Delta &= \frac{\mathcal{H}}{a} u, \\
\Delta' &= \mathcal{H}^2 \dot{u} - \frac{\mathcal{H}^2}{a} u + \mathcal{H}\dot{\mathcal{H}} u \\
\Delta'' &= a\mathcal{H}\left(\mathcal{H}^2 \ddot{u} + 3\mathcal{H}\dot{\mathcal{H}}\dot{u} - \frac{\mathcal{H}^2}{a}\dot{u} + \frac{\mathcal{H}^2}{a^2} u - \frac{2\mathcal{H}\dot{\mathcal{H}}}{a} u + \dot{\mathcal{H}}^2 u + \mathcal{H}\ddot{\mathcal{H}} u\right)
\end{aligned}$$

Plugging these into our master equation, many terms cancel and we find

$$\mathcal{H}^2 \ddot{u} + 3\mathcal{H}\dot{\mathcal{H}}\dot{u} + \left(\dot{\mathcal{H}}^2 - \frac{\mathcal{H}\dot{\mathcal{H}}}{a} + \mathcal{H}\ddot{\mathcal{H}} - 4\pi G\bar{\rho}_m\right) u = 0$$

Taking a derivatives of the Friedmann equation, $3\mathcal{H}^2 = 8\pi G\left(\rho_m + \rho_\Lambda\right)$, with $\rho_m = \rho_{m,0} a^{-3}$ and ρ_Λ constant, we find

$$\begin{aligned}
\mathcal{H}\dot{\mathcal{H}} &= \frac{\mathcal{H}^2}{a} - 4\pi G a \bar{\rho}_m, \\
\dot{\mathcal{H}}^2 + \mathcal{H}\ddot{\mathcal{H}} &= \frac{\mathcal{H}^2}{a^2}.
\end{aligned}$$

Plugging these back into our fluctuation equation, we find that the terms in square brackets all cancel, leaving us with

$$\mathcal{H}^2 \ddot{u} + 3\mathcal{H}\dot{\mathcal{H}}\dot{u} = 0.$$

Dividing by $\mathcal{H}^2$ and using $\mathcal{H} = aH$, we have this in the desired form,

$$\frac{d^2u}{da^2} + 3\frac{d\ln(aH)}{da}\frac{du}{da} = 0.$$

There are two solutions, in general, to (8.3.263). One is obvious: $u = $ const. is a solution, corresponding to $\Delta = uH \sim H$. This is generally a decaying mode, as H decreases over time in all reasonable (i.e., $w > -1$) cosmologies. The second solution can be obtained by straighforwardly integrating (8.3.263). Solving for $\dot{u}$, we find

$$d\ln\dot{u} = d\ln(aH)^{-3},$$

which has the solution

$$\dot{u} \sim (aH)^{-3}.$$

Integrating this we obtain the growing-mode solution,

$$\Delta \sim H\int_a^{a_i}\frac{d\tilde{a}}{(\tilde{a}H)^3}.$$

Solution for (c) Solutions and Behaviours

In the matter-dominated era, with $\rho_\Lambda \approx 0$, we have $H^2 \propto \rho_m \propto a^{-3} \propto (1+z)^3$, so the decaying mode behaves as

$$D_-(z) \propto H(z) \propto a^{-3/2}.$$

The growing mode instead goes as

$$D_+(z) \propto (1+z)^{3/2}\int_z^\infty \frac{1+z'}{(1+z')^{9/2}}\,\mathrm{d}z' \propto \frac{1}{1+z} = a.$$

This results confirm the expected behaviours for a matter-dominated universe. Now let us consider a universe with $\rho_\Lambda \neq 0$ so that eventually the universe tends to de Sitter with $H(z) \to$ const in the asymptotic future. The "decaying mode" then trivially goes to a constant at late times. In fact, the "growing mode" has the same behaviour. From eq. (8.3.266), we see that the integral over $\tilde{z}$ gives a finite answer as $z \to -1$ (the asymptotic future) because the integrand goes to zero near the lower limit of integration. (The asymptotic growth in the matter-dominated case happens because the integrand diverges near the lower limit.) Thus we see that the growth of structure eventually halts as dark energy comes to dominate.

Leuven-2023hw6.5. The evolution of small-scale sub-horizon modes and Meszarous equations

a) Rewrite the set of evolution equations for dark matter overdensities δ on small sub-horizon scales (Θ_0, Θ_1 neglected; $aH/k \ll 1$),

$$\dot{\delta} + \mathrm{i}kv = -3\dot{\Phi}, \quad \dot{v} + \frac{\dot{a}}{a}v = \mathrm{i}k\Phi, \quad k^2\Phi = 4\pi G a^2\rho_\mathrm{m}\delta,$$

in terms of the variable y defined above in (10) and use them to derive the Meszaros equation:

$$\delta'' + \frac{2+3y}{2y(1+y)}\delta' - \frac{3}{2y(y+1)}\delta = 0.$$

b) Verify that the solutions to the Meszaros equation are

$$\delta \propto \begin{cases} y + \frac{2}{3} \\ \left(y+\frac{2}{3}\right)\ln\left(\frac{\sqrt{1+y}+1}{\sqrt{1+y}-1}\right) - 2\sqrt{1+y} \end{cases}$$

and discuss their behavior for late times ($y \gg 1$).

Solution

Leuven-2023hw3.5. Transfer function of dark matter

Solve the set of five equations

$$\begin{aligned}\dot{\Theta}_{r,0} + k\Theta_{r,1} &= -\dot{\Phi},\\ \dot{\Theta}_{r,1} - \frac{k}{3}\Theta_{r,0} &= -\frac{k}{3}\Phi,\\ \dot{\delta} + ikv &= -3\dot{\Phi},\\ \dot{v} + \frac{\dot{a}}{a}v &= ik\Phi\end{aligned}$$

and

$$k^2\Phi + 3\frac{\dot{a}}{a}\left(\dot{\Phi} + \frac{\dot{a}}{a}\Phi\right) = 4\pi G a^2\left(\rho_{dm}\delta + 4\rho\Theta_{r,0}\right)$$

numerically to obtain the transfer function for dark matter. Use the initial conditions derived in Chapter 6 of Dodelson's book. The one numerical problem you may encounter using (5) occurs on small scales when you try to evolve all the way to the present. The photon moments then become difficult to track, and even a good differential equation solver will balk at late times. However, there are several simple solutions to this: (i) by the late times in question, the potential is constant so there is no need to evolve all the way to the present or (ii) stop following the photon moments after a certain time; they don't have any effect on the matter distribution at late times anyway. Plot the evolution of the gravitational potential Φ for a few different values of k for sCDM (with Hubble constant $h = 0.5$) and ΛCDM (with $\Omega_\Lambda = 0.7$ and $h = 0.7$). Normalize Φ to 1 at early times in this plot. Also plot the transfer function for sCDM and ΛCDM and compare with the BBKS transfer function

$$T\left(x \equiv k/k_{eq}\right) = \frac{\ln[1+0.171x]}{0.171x}\left[1 + 0.284x + (1.18x)^2 + (0.399x)^3 + (0.490x)^4\right]^{-0.25}.$$

Solution

(no one has time for it)

D-2.

Solve the set of five equations ((7.11)-(7.14) and (7.15)) numerically to obtain the transfer function for dark matter. Use the initial conditions derived in Chapter 6. The one numerical problem you may encounter using Eq. (7.15) occurs on small scales when you try to evolve all the way to the present. The photon moments then become difficult to track, and even a good differential equation solver will balk at late times. However, there are several simple solutions to this: (i) by the late times in question, the potential is constant so there is no need to evolve all the way to the present or (ii) stop following the photon moments after a certain time; they don't have any effect on the matter distribution at late times anyway. Plot the transfer function for sCDM (with Hubble constant $h = 0.5$) and $\triangle CDM$ (with $\Omega_\Lambda = 0.7$ and $h = 0.7$). Compare with the BBKS transfer function of Eq. (7.70).

Solution

Solution some problems by Dodelson chapter 7

Solution to

4 (c) To do the integral, introduce a new dummy variable $x \equiv \sqrt{1+y}$. Then Eq. (7.31) becomes

$$\Phi = \frac{3\Phi(0)}{2}\frac{\sqrt{1+y}}{y^3}\int_1^{\sqrt{1+y}} dx \frac{\left(x^2-1\right)^2\left(3x^2+1\right)}{x^2}.$$

Now integrate by parts using the fact that the integral of $1/x^2$ is equal to $-1/x$. The surface term is proportional to the numerator and so vanishes at the lower limit, when $x = 1$. Therefore,

$$\begin{aligned}\Phi &= \frac{3\Phi(0)}{2}\frac{\sqrt{1+y}}{y^3}\left[-\frac{y^2(4+3y)}{\sqrt{1+y}} + \int_1^{\sqrt{1+y}} dx\left(18x^4 - 20x^2 + 2\right)\right]\\ &= \frac{3\Phi(0)}{2}\frac{\sqrt{1+y}}{y^3}\left[-\frac{y^2(4+3y)}{\sqrt{1+y}} + \left(\frac{18}{5}x^5 - \frac{20}{3}x^3 + 2x\right)\Big|_1^{\sqrt{1+y}}\right].\end{aligned}$$

Evaluating the terms in parentheses at the upper and lower limits leads to Eq. (7.32).

Solution to

9

$$\sigma_R^2 = \left\langle \left[\int d^3x \delta(x) W_R(x) \right]^2 \right\rangle$$
$$= \left\langle \left[\frac{d^3k}{(2\pi)^3} \tilde{\delta}(\vec{k}) \tilde{W}_R^*(\vec{k}) \right]^2 \right\rangle$$

where denotes Fourier transform, and I have used the fact that since $W_R(x)$ is real, $\tilde{W}_R(\vec{k}) = \tilde{W}_R^*(-\vec{k})$. Also I have evaluated δ_R at the origin; and the angular brackets denote the average, now over all realizations of $\tilde{\delta}(\vec{k})$. Squaring and using the fact that

$$\left\langle \delta(\vec{k}) \delta\left(\vec{k}'\right) \right\rangle = (2\pi)^3 \delta^3\left(\vec{k} + \vec{k}'\right) P(k)$$

leads to

$$\sigma_R^2 = \int \frac{d^3k}{(2\pi)^3} P(k) \left| \tilde{W}_R(\vec{k}) \right|^2$$

It remains only to compute the Fourier transform of the top-hat window function,

$$\tilde{W}_R(\vec{k}) = \int d^3x W_R(\vec{x}) e^{-i\vec{k}\cdot\vec{x}}$$
$$= \frac{2\pi}{V_R} \int_0^R dx x^2 \int_{-1}^1 d\mu e^{ikx\mu}.$$

Note that I have normalized the window function so that the integral over it is unity; hence the factor of $V_R = 4\pi R^3/3$. Carrying out the remaining angular and radial integrals leads to

$$\tilde{W}_R(k) = \frac{3}{kR^3} \int_0^R dx x \sin(kx)$$

$$= \frac{3}{k^3 R^3} [-kR\cos(kR) + \sin(kR)]$$

By way of solving

Solution to

10, note that

$$\Delta^2(k) = \frac{4\pi}{(2\pi)^3} k^3 P(k)$$

13.2.3 Problems on Anisotropies

D-1.

Most of this book is devoted to understanding adiabatic perturbations with the initial conditions derived in Chapter 6. Another class of perturbations are isocurvature perturbations with initial conditions $\Theta_0 = \Psi = \Phi = 0$. Show that these initial conditions imply that

$$\Theta_0(\eta_*) + \Psi(\eta_*) = 2\Psi(\eta_*).$$

D-2.

The equation for a damped harmonic oscillator is

$$m\ddot{x} + b\dot{x} + kx = 0.$$

Find the solutions to this equation if $k/m > (b/2m)^2$. What is the frequency of oscillations? How does this differ from the undamped ($b = 0$) solution? What is the other effect of nonzero b besides the change in frequency?

D-3.

Determine $R(\eta_*)$ when $\Omega_b h^2 = 0.01, 0.02$. Plot the sound speed as a function of the scale factor for these two values of $\Omega_b h^2$.

D-4.

Show that the sound horizon can be expressed in terms of the conformal time as

$$r_s(\eta) = \frac{2}{3k_{\rm eq}}\sqrt{\frac{6}{R(\eta_{\rm eq})}}\ln\left\{\frac{\sqrt{1+\bar{R}}+\sqrt{R+R(\eta_{\rm eq})}}{1+\sqrt{R(\eta_{\rm eq})}}\right\},$$

where $k_{\rm eq}$ is given in Eq. (7.39).

D-5.

Obtain the WKB solution to Eq. (8.18). Write

$$\Theta_0 = Ae^{iB}$$

with A and B real. Show that the homogeneous part of Eq. (8.18) breaks up into two equations, coming from the real and imaginary part:

$$\text{Real: } -(\dot{B})^2 + \frac{\ddot{A}}{A} + \frac{\dot{R}}{1+R}\frac{\dot{A}}{A} + k^2c_s^2 = 0$$
$$\text{Imaginary } : 2\dot{B}\frac{\dot{A}}{A} + \ddot{B} + \frac{\dot{R}}{1+R}\dot{B} = 0.$$

Find B using the real part and the fact that B changes much more rapidly than A. Then, use the imaginary equation to determine A. Show that the homogeneous solutions obtained in this way differ from the simple oscillatory solutions of Eq. (8.21) by a factor of $(1+R)^{1/4}$.

D-6.

Obtain a semianalytic solution for $\Theta_0 + \Psi$ and Θ_1 at recombination by carrying out the integrals in Eqs. (8.24) and (8.26). To do this you will need expressions for the gravitational potentials. Hu and Sugiyama (1995) provided the following convenient fits:

$$\Phi(k,y) = \bar{\Phi}(k,y)\left\{[1-T(k)]\exp\left[-0.11\,(ky/k_{\rm eq})^{1.6}\right] + T(k)\right\}$$
$$\Psi(k,y) = \bar{\Psi}(k,y)\left\{[1-T(k)]\exp\left[-0.097\,(ky/k_{\rm eq})^{1.6}\right] + T(k)\right\}$$

where $y := a/a_{\rm eq}, T(k)$ is the BBKS transfer function and the large-scale potentials are

$$\bar{\Phi}(k,y) = \frac{3}{4}\left(\frac{k_{\rm eq}}{k}\right)^2\frac{y+1}{y^2}\bar{\Delta}_T(y)$$
$$\bar{\Psi}(k,y) = -\frac{3}{4}\left(\frac{k_{\rm eq}}{k}\right)^2\frac{y+1}{y^2}\left(\Delta_T(y) + 0.65N_2/(1+y)\right).$$

Finally the two functions N_2 and Δ_T are

$$N_2(y) = -0.1\frac{20y+19}{3y+4}\frac{y^2}{y+1}\Phi_{ls} - \frac{8}{3}\frac{y}{3y+4} + \frac{8}{9}\ln[3y/4+1]$$
$$\Delta_T = \left[1.16 - \frac{0.48y}{y+1}\right]\Phi_{ls}\frac{y^2}{y+1}.$$

Here Φ_{ls} is the large-scale solution of Eq. (7.32).

D-7.

Our treatment of diffusion damping neglected the effect of polarization. Go through the same expansion in $\dot{\tau}^{-1}$ that we carried out in Section 8.4 this time accounting for polarization. Show that this changes the factor of 8/9 in Eq. (8.40) to 16/15. This beautiful result was obtained by Zaldarriaga and Harari (1996) when the first author was an undergraduate!

D-8.

Assume that all electrons associated with hydrogen stay ionized and set $R = 0$. Evaluate the damping scale, k_D, defined in Eq. (8.40). Show that in this limit, the damping scale is given by Eq. (8.42), where

$$f_D(y) = 5\sqrt{1+1/y} - \frac{20}{3}(1+1/y)^{3/2} + \frac{8}{3}\left[(1+1/y)^{5/2} - 1/y^{5/2}\right].$$

D-9.

Show that

$$\int d\Omega Y_{lm}(\hat{p})\mathcal{P}_l(\hat{p}\cdot\hat{k}) = \frac{4\pi}{2l+1}$$

D-10.

There is a different way to go from the inhomogeneous temperature field at recombination, $\Theta_0\left(\vec{x},\eta_*\right)$ or $\Theta_0\left(\vec{k},\eta_*\right)$, to the anisotropy pattern today, a_{lm}, than that given in the text.

(a) Assume that the photons we see today from direction $\hat{p}$ come from the surface of last scattering: $\Theta\left(\vec{x}_0,\hat{p},\eta_0\right) = \left(\Theta_0+\Psi\right)\left(\vec{x}=\chi_*\hat{p},\eta_*\right)$ where x_0 is our position. Fourier transform the right-hand side and expand the left in terms of spherical harmonics to get

$$\sum_{lm} a_{lm}Y_{lm}(\hat{p}) = \int \frac{d^3k}{(2\pi)^3} e^{i\vec{k}\cdot\hat{p}\chi_*}\left(\tilde{\Theta}+\tilde{\Psi}\right)\left(\vec{k},\eta_*\right).$$

Now expand the exponential using Eq. (C.16) and then expand the resulting Legendre polynomial using Eq. (C.12). Equate the coefficients of $Y_{lm}(\hat{p})$ to get an expression for a_{lm}.

(b) Square the a_{lm} you got in (a) and take the expectation value to get an expression for C_l. You should recapture the expression in Eq. (8.68) with Θ_l given by the first term in Eq. (8.56).

D-11.

A simple way to estimate the COBE normalization of δ_H is to fix C_{10}. From Figure 8.12, estimate C_{10}. Use this and the Sachs-Wolfe formula, Eq. (8.75), to estimate δ_H for a flat, matter-dominated universe. Compare with the number given in Eq. (8.76)

D-12.

Show that the cross-terms from the monopole and dipole vanish when summing over all modes. The monpole is proportional to $j_l\left(k\eta_0\right)$ while the dipole is proportional to $j_l'\left(k\eta_0\right)$. Compute the three possible integrals

$$\int_0^\infty dx j_l j_l \quad ; \quad \int_0^\infty dx j_l j_l' \quad ; \quad \int_0^\infty dx j_l' j_l'.$$

Show that the integrals of the squares $\left(j_l^2 \text{ and } \left(j_l'\right)^2\right)$ are much larger than the integral of the cross-term $j_l j_l'$. Do the integrals for $l = 10$ up to $l = 50$.

D-13.

Determine the shift in the locations of the peaks and troughs in the CMB anisotropy spectrum if the universe is flat with a cosmological constant as opposed to flat and matter dominated. Keep the sound horizon fixed in this calculation by fixing $\Omega_m h^2 = 0.15$. The peak positions then depend only on the distance to the last scattering surface, $\eta_0 - \eta_*$. Consider two flat models: (i) $\Omega_\Lambda = 0$ (so that $\Omega_m = 1$) and (ii) $\Omega_\Lambda = 0.7$ (so that $\Omega_m = 0.3$). What value of h is needed in the two cases to keep $\Omega_m h^2$ fixed? Determine $\eta_0 - \eta_*$ in each case (in the the cosmological constant case, you will have to do the integral numerically). Compare your result with the fitting formula: $\eta_0 \propto 1 + \ln\left(\Omega_m^{0.085}\right)$ and with the shift in Figure 8.19.

D-14.

Compute the conformal time today in a flat model with dark energy $\Omega_{\rm de} = 0.7$ today with $w = -0.5$. Compare the expected shift in the anisotropy spectrum with the cosmological constant model of the previous problem.

D-15.

Determine the effects of reionization using the Boltzmann equation. Neglect the gravitational potentials, the velocity, and Θ_0 in the Boltzmann equation for photons. Start with a spectrum $\Theta_l(\eta)$ and evolve till today. Show that the moments are indeed suppressed by $e^{-\tau}$.

D-16.

Assume that recombination took place instantaneously. Show that the solution for the lth moment due to tensor perturbations (Eq. (4.116)) is

$$\Theta_l^T = -\frac{1}{2}\int_{\eta_*}^{\eta_0} d\eta \dot{h} j_l \left[k\left(\eta_0 - \eta\right)\right]$$

D-17.

Using the decomposition for tensor modes given in Eq. (4.115), find the contribution to the C_l 's from $\Theta_l^T(k)$. That is, show that the analogue of Eq. (8.68) for tensors is

$$C_{l,i}^T = \frac{(l-1)l(l+1)(l+2)}{\pi}\int_0^\infty dk k^2 \left|\frac{\Theta_{l-2,i}^T}{(2l-1)(2l+1)} + 2\frac{\Theta_{l,i}^T}{(2l-1)(2l+3)} + \frac{\Theta_{l+2,i}^T}{(2l+1)(2l+3)}\right|^2,$$

where i denotes the two different components $+$ and x.

D-18.

Determine the spectrum of anisotropies due to gravity waves produced during inflation.
(a) Combine the results of the previous two problems, your solution to

D-5.

12, and the primordial amplitude of gravity waves in Eq. (6.100) to find the large-angle C_l 's due to inflation-produced gravity waves.
(b) Tensor anisotropies are often parametrized by

$$r := \frac{C_2^T}{C_2^S}$$

where C_2^T is the variance of the quadrupole due to tensors and C^S is the same due to scalars. [8] We already derived an expression for the scalar C_2 in Eq. (8.75). Find C_2^T and compute r to first order in the slow roll parameter ϵ.
(c) The results of part (b) and Eq. (6.104) imply a consistency relation - a robust prediction of inflation - between the two observables n_T and r. What is the consistency relation?
[8] Note that this convention is not universal; r is sometimes defined to the (more precisely constrained) ratio at $l \sim 10$.

Solution some problems by Dodelson chapter 8

Solution to

2 Assume a solution of the form $x = e^{i\omega t}$. The damping equation then becomes a quadratic equation for ω:

$$\omega^2 - \frac{ib}{m}\omega - \frac{k}{m} = 0$$

Solving with $k/m > \gamma^2 \equiv (b/2m)^2$ leads to

$$\omega = i\gamma \pm \omega_1$$

The frequency is now $\omega_1 \equiv \left[k/m - \gamma^2\right]^{1/2}$, smaller than in the undamped case. The amplitude is also damped by $e^{-\gamma t}$.

Solution to

9 Use the addition theorem of spherical harmonics (C.12) to write

$$\mathcal{P}_{l'}(\hat{\gamma}\cdot\hat{k}) = \frac{4\pi}{2l+1}\sum_{m'} Y^*_{l'm'}(\hat{\gamma})Y_{l'm'}(\hat{k})$$

Then the angular integral becomes an integral over the product of two spherical harmonics, which - because of orthogonality - is equal to 1 if $l' = l$ and $m' = m$ and zero otherwise. This leads directly to the desired reult.

Solution to

12 I get the result show in Figure A.1. The integral of the cross-term is significantly smaller than that of either of the squares, so there is no interefence between the monopole and dipole.

Solution to

17 The generalization of Eq. (8.67) to tensors gives

$$C_l^T = \sum_{l'l''}(-i)^{l'+l''}\,(2l'+1)\,(2l''+1)\int\frac{d^3k}{(2\pi)^3}\Theta_{l'}^T(k)\Theta_{l''}^{T,*}(k)I_{lml'}(k)I^*_{lml''}(k)$$

where I have defined

$$I_{lml'}(k) \equiv \sqrt{\frac{8\pi}{15}}\int d\Omega\mathcal{P}_{l'}(\hat{k}\cdot\hat{\gamma})Y_{lm}(\Omega)\left[Y_{22}(\Omega)+Y_{2-2}(\Omega)\right]$$

The factor of $[8\pi/15]^{1/2}\left[Y_{22}+Y_{2-2}\right]$ is the combination $\sin^2\theta\cos(2\phi)$ which appears in Eq. (4.115), so this expression is valid only for the + mode. However, the × mode gives exactly the same result.

The integral $I_{lml'}$ is not trivial. By rewriting the Legendre polynomial as $\left[4\pi/\left(2l'+1\right)\right]^{1/2}Y_{l'0}/i^{l'}$, we can turn $I_{ll'}$ into an integral over the product of three

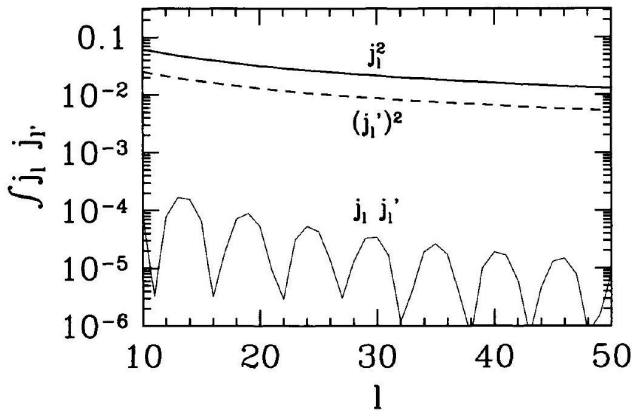


Figure A.1. The integrals of products of spherical Bessel functions.

spherical harmonics. Such integrals are intensively studied in quantum mechanics and can be expressed in terms of the Wigner 3-j symbols. By the way, my favorite reference for these things - especially useful for this integral-is Quantum Mechanics (Landau and Lifshitz), like all the other texts in their Course of Theoretical Physics a wonderful investment. The integral is then

$$I_{lml'} = \sqrt{\frac{32\pi^2}{15\left(2l'+1\right)}}\frac{1}{i^{l'}}\left\langle lm\left|Y_{22}+Y_{2-2}\right|l'0\right\rangle$$

which vanishes unless $m = 2$ or $m = -2$. When m takes on one of these two values, the matrix element is

$$\left\langle l2\left|Y_{22}+Y_{2-2}\right|l'0\right\rangle = i^{l'-l}\begin{pmatrix} l & 2 & l' \\ 0 & 0 & 0\end{pmatrix}\left[\frac{5\left(2l'+1\right)\left(2l+1\right)}{4\pi}\right]^{1/2}\begin{pmatrix} l & 2 & l' \\ -2 & 2 & 0\end{pmatrix}.$$

The first 3 -j symbol here, the one with the bottom row all zero, vanishes unless the sum of the elements in the top row $l + l' + 2$ is even. And of course l' cannot differ from l by more than 2 since the combination of $Y_{22}Y_{l'0}$ leads to angular momenta ranging from $l' - 2$ to $l' + 2$. So the only time the matrix element is nonzero is when $l' = l - 2, l, l + 2$. Using Table 9 in Section 106 of Quantum Mechanics leads to the final result:

$$I_{lml'} = \sqrt{\frac{8\pi}{3}}\sqrt{2l+1}i^{-l}\left(\delta_{m,2} + \delta_{m,-2}\right)\left[c_{-2}\delta_{l',l-2} + c_0\delta_{l',l} + c_2\delta_{l',l+2}\right]$$

where here $\delta_{m,2}$ (and all other δ 's) is the Kronecker delta, equal to 1 if $m = 2$ and zero otherwise. The coefficients are

$$\begin{aligned} c_{-2} &= \frac{\sqrt{6}}{4}\frac{\left[(l-1)l(l+1)(l+2)\right]^{1/2}}{(2l-3)(2l-1)(2l+1)} \\ c_0 &= \frac{-2\sqrt{6}}{4}\frac{\left[(l-1)l(l+1)(l+2)\right]^{1/2}}{(2l-1)(2l+1)(2l+3)} \\ c_2 &= \frac{\sqrt{6}}{4}\frac{\left[(l-1)l(l+1)(l+2)\right]^{1/2}}{(2l+1)(2l+3)(2l+5)}. \end{aligned}$$

The result in Eq. (8.93) then follows.

Solution to

18
(a) On large scales, we can take the matter-dominated solution for h, so

$$\Theta_{l,i} = \frac{-1}{2}\int_{\eta_*}^{\eta_0} d\eta j_l\left[k\left(\eta_0 - \eta\right)\right]\frac{d}{d\eta}\left[\frac{3j_1(k\eta)}{k\eta}\right]P_h^{1/2}$$

Here I have used the fact that the initial amplitude of the gravity waves is $P_h^{1/2}$ with the time dependence given in the square brackets. Plug this into Eq. (8.93) to get

$$\begin{aligned} C_l^T =& 2\frac{9(l-1)l(l+1)(l+2)}{4\pi}\int_0^\infty dk k^2 P_h(k)\Big|\int_0^{\eta_0} d(k\eta)\frac{j_2(k\eta)}{k\eta} \\ &\times\left[\frac{j_{l-2}\left(k\left[\eta_0-\eta\right]\right)}{(2l-1)(2l+1)} + 2\frac{j_l\left(k\left[\eta_0-\eta\right]\right)}{(2l-1)(2l+3)} + \frac{j_{l+2}\left(k\left[\eta_0-\eta\right]\right)}{(2l+1)(2l+3)}\right]\Big|^2, (\end{aligned}$$

where I have set the lower limit on the time integral to zero since $\eta_* \ll \eta_0$. Also, I have used the identity $(j_1/x)' = -j_2/x$. The factor of 2 out in front comes from the sum over the + and × components. Using Eq. (6.100) for P_h (in the slow-roll approximation $\epsilon = 0$ and $\nu = 3/2$) and defining new integration variables $y \equiv k\eta_0$ and $x \equiv k\eta$ leads to

$$\begin{aligned} C_l^T =& 36\left(\frac{H_{\rm inf}}{m_{\rm Pl}}\right)^2(l-1)l(l+1)(l+2)\int_0^\infty\frac{dy}{y}\Big|\int_0^y dx\frac{j_2(x)}{x} \\ &\times\left[\frac{j_{l-2}(y-x)}{(2l-1)(2l+1)} + 2\frac{j_l(y-x)}{(2l-1)(2l+3)} + \frac{j_{l+2}(y-x)}{(2l+1)(2l+3)}\right]\Big|^2. \end{aligned}$$

Here $H_{\rm inf}$ denotes the Hubble rate during inflation, or more precisely the Hubble rate when the modes in question crossed the horizon (when $k\eta = -1$ early on). This expression does well on the low multipoles. To get even better results stick in the transfer function of Eq. (5.88).

(b) For the $l = 2$ mode, the double integral in Eq. (A.107) is equal to 2.139×10^{-4}, so $C_2^T = 0.185\left(H/m_{\rm PI}\right)^2$. The scalar C_2 is equal to $\pi\delta_H^2/12$. Using Eq. (6.100) for δ_H leads to

$$r = 13.86\epsilon$$

(c) Combining with Eq. (6.104), we expect

$$r = -6.93 n_T.$$

For many models, the inflationary parameter $\delta = -\epsilon$, so

$$n - 1 = -n_T$$

13.2.4 Problems from probes of inhomogeneities by Dodelson (??????)

(вообще таким не занимался, ничего про это пока не знаю.)

D-1.

Suppose the correlation function is defined as

$$\xi(\vec{r}) := \langle \delta(\vec{x})\delta(\vec{x}+\vec{r})\rangle$$

By Fourier expanding each of the δ 's and using Eq. (C.20), show that this definition implies that the correlation function is the Fourier transform of the power spectrum.

D-2.

Expand the 3D power spectrum in the integral of Eq. (9.9) about $k_3 = 0$. The leading term is the one we considered. Show that the next term is of order $(1/l)^2$, compared with the leading term.

D-3.

Rewrite the kernel in Eq. (9.14) as an integral over χ. Show that F is a function of $k\theta$ only.

D-4.

Give an order-of-magnitude estimate for the kernel of the angular correlation function.
(a) Consider a shell in Fourier space with radius k and width dk. What fraction of the volume of this shell has $|k_3| < \chi^{-1}$?
(b) Argue that only Fourier modes with $|k_3| < \chi^{-1}$ contribute to the angular correlation function with a weight $\Delta^2(k) = k^3P(k)/2\pi^2$. Combine this argument with the fraction computed in part (a) to estimate the kernel relating $w(\theta)$ to $P(k)$. Compare this estimate with Eq. (9.13).

D-5.

Decompose the angular correlation function into a sum over spherical harmonics,

$$w(\theta) = \sum_l \frac{2l+1}{4\pi} C_l^{\rm matter} \mathcal{P}_l(\cos\theta)$$

where the superscript matter distinguishes these C_l 's from the ones characterizing anisotropies in the CMB, and $\mathcal{P}_l$ here are the Legendre polynomials. Express $C_l^{\rm matter}$ as an integral over the 3D power spectrum. Show that on small scales $C_l^{\rm matter} = P_2(l)$, where P_2 is the 2D power spectrum introduced in Section 9.1.

D-6.

In Section 9.1 we implicitly neglected the evolution of the power spectrum. That is, we assumed that $P(k)$ remains constant with time. Allow $P(k)$ to scale as $(1+z)^\beta$. What is β for linear modes in a flat, matter-dominated universe? Rewrite the kernel in terms of an integral over z, accounting for this evolution.

D-7.

Compute (numerically) the linear growth rate f today in an open universe and compare with the approximation $\Omega_m^{0.6}$. What is the fractional error between the approximation and the exact result? Now assume that the universe is flat, with $\Omega_m + \Omega_\Lambda = 1$. Again compare the exact linear growth rate with $\Omega_m^{0.6}$. Show that

$$f = \Omega_m^{0.6} + \frac{\Omega_\Lambda}{70}\left(1 + \frac{\Omega_m}{2}\right)$$

is a better approximation, with no worse than 4% accuracy for $\Omega_m > 0.025$.

D-8.

Using CMBFAST, compute the transfer function for standard CDM ($\Omega_m = 1; h = 0.5$) with $\Omega_b = 0.01, 0.05$, and 0.1. Show that the BBKS transfer function is still a reasonable fit as long as

$$\Gamma = \Omega_m h \to \Omega_m h e^{-2\Omega_b}.$$

D-9.

Using CMBFAST or the BBKS transfer function, compute COBEnormalized σ_8 for ΛCDM with $h = 0.7, \Omega_\Lambda = 0.7, \Omega_m = 0.26$, and $\Omega_b = 0.04$. Locate the model on the bottom left panel of Figure 9.6. What does this imply about the relation between σ_8 (of the mass, which you have just computed) and $(\sigma_8)_g$ (of the galaxies, which APM is sensitive to)?

D-10.

Assume that the universe is flat with matter and a cosmological constant. Expand the comoving distance out to a galaxy at redshift z (neglecting peculiar velocities) about $z = 0$. The first-order term in the expansion should give back the redshift space answer. What is the second-order term, the leading correction to redshift space? Express your answer in terms of Ω_m.

D-11.

Derive (9.51), using the fact that $\mathcal{P}_4(x) = 35x^4/8 - 15x^2/4 + 3/8$. Show that the definition of the moments in Eq. (9.50) $- P_s^{(l)}(k) = (2l+1) \int_{-1}^{1} (d\mu_{\mathbf{k}}/2)\, \mathcal{P}_l(\mu_{\mathbf{k}})\, P_s(k, \mu_{\mathbf{k}})$ - means that

$$P_s(k, \mu_{\mathbf{k}}) = \sum_l \mathcal{P}_l(\mu_{\mathbf{k}})\, P_s^{(l)}(k)$$

D-12.

In the text we showed how redshift space distortions affect the power spectrum. Show how the redshift space distortions affect the correlation function. Assume linear theory. You will probably need to consult Hamilton (1992), which transforms Kaiser's result to the correlation function in a single (dense) paragraph.

Solution some problems by Dodelson chapter 9

Solution to

2 Expand the power spectrum about $k_3 = 0$:

$$P\left(\sqrt{k_3^2 + (H_0\kappa/\chi)^2}\right) = P(H_0\kappa/\chi) + \frac{1}{2k}\frac{dP}{dk}\bigg|_{k_3=0} k_3^2 + \ldots$$

For a smooth power spectrum dP/dk is of order P/k, so the coefficient of k_3^2 is of order P/k^2. For us, $k = H_0\kappa/\chi$, so this coefficient is of order $P\chi^2/(H_0\kappa)^2$. We can write k_3^2 as $-H_0^2\partial^2/\partial\chi^2$ acting on the exponential of Eq. (9.9). Assuming the selection function is relatively smooth, this is of order H_0^2/χ^2. So the first correction to the leading term is of order $1/\kappa^2$, which is small as long as the angular scales probed are not too large.

Solution to

3 Define the dummy variable $\chi \equiv H_0\kappa/k$. Then

$$F = H_0 \int \frac{d\chi}{2\pi\chi} J_0(k\theta\chi/H_0)\, W^2(\chi)$$

an expression which clearly depends only on the combination $k\theta$.

Solution to

5 To express $C_l^{\rm matter}$ in terms of w, multiply both sides of Eq. (9.66) by $\mathcal{P}_{l'}(\cos\theta)$ and integrate over $\mu \equiv \cos\theta$. This gives

$$C_l^{\rm matter} = 2\pi \int_{-1}^{1} d\cos\theta \mathcal{P}_l(\cos\theta) w(\theta)$$

Express w as an integral over the 2D power spectrum as in the first line of Eq. (9.13). Then,

$$C_l^{\rm matter} = \int_0^\infty dl' l' P_2(l') \int_{-1}^{1} d\cos\theta \mathcal{P}_l(\cos\theta) J_0(l'\theta)$$

Note the difference in P 's: the first P_2 here is the 2D power spectrum, the second $\mathcal{P}_l$ is the Legendre polynomial. In the limit that l' is large, the Bessel function becomes

$$J_0(l'\theta) \to \mathcal{P}_{l'}(\cos\theta)$$

Therefore, the integral over θ vanishes unless $l = l'$, in which case it is equal to $2/(2l+1)$. The integral over l' is identical to a sum over l' at large l' since $dl' \to 1$. The factor of $2/(2l+1)$ in the denominator cancels the factor of l' in the numerator, leaving the desired equality between the 2D power spectrum and $C_l^{\rm matter}$.

13.2.5 *Problem Sets* by Baumann's TASI lectures

Problem 1 (Homogeneous and Isotropic Spaces)**.** *Homogeneous and isotropic spaces are characterized by translational and rotational invariance. Convince yourself that in three dimensions there exist only three types of homogeneous and isotropic spaces with simple topology:*

i) flat space

ii) a three-dimensional sphere with constant positive curvature

iii) a three-dimensional hyperbolic space with constant negative curvature.

It is easier to visualize the two-dimensional analogues. Consider the embedding of a two-dimensional sphere in a three-dimensional Euclidean space

$$x^2 + y^2 + z^2 = a^2\,, \tag{274}$$

where a is the radius of the sphere. Show that the induced metric on the surface of the sphere is

$$\mathrm{d}\ell_2^2 = \frac{\mathrm{d}r'^2}{1-(r'^2/a^2)} + r'^2\mathrm{d}\phi^2\,, \tag{275}$$

where $x = r'\cos\phi$ and $y = r'\sin\phi$. The limit $a^2 \to \infty$ corresponds to flat space (a plane). Negative a^2 corresponds to a space with constant negative curvature. It cannot be embedded in three-dimensional Euclidean space. (Consider the embedding of $x^2+y^2-z^2 = -a^2$ in a space with metric $\mathrm{d}\ell_2^2 = \mathrm{d}x^2 + \mathrm{d}y^2 - \mathrm{d}z^2$ instead.)

By rescaling the radial coordinate the metric can be brought into the form

$$\mathrm{d}\ell_2^2 = |a^2|\left(\frac{\mathrm{d}r^2}{1-kr^2} + r^2\mathrm{d}\phi^2\right)\,, \tag{276}$$

where $k = +1$ for the sphere ($a^2 > 0$), $k = -1$ for the hyperbolic space ($a^2 < 0$) and $k = 0$ for the plane ($a^2 = 0$).

Generalize the above argument to the embedding of homogeneous and isotropic three-dimensional spaces in four-dimensional Euclidean space. Show that their metric is

$$\mathrm{d}\ell_3^2 = a^2\left(\frac{\mathrm{d}r^2}{1-kr^2} + r^2\mathrm{d}\Omega^2\right)\,, \qquad \mathrm{d}\Omega^2 \equiv \mathrm{d}\theta^2 + \sin^2\theta\mathrm{d}\phi^2\,, \tag{277}$$

or

$$\mathrm{d}\ell_3^2 = a^2\left[\mathrm{d}\chi^2 + \begin{pmatrix}\sinh^2\chi\\ \chi^2\\ \sin^2\chi\end{pmatrix}\mathrm{d}\Omega^2\right] \quad \begin{matrix}k=-1\\k=0\\k=+1\end{matrix}\,. \tag{278}$$

Convince yourself that the only time-dependent four-dimensional spacetime that preserves homogeneity and isotropy of space is the FRW metric

$$\mathrm{d}s^2 = \mathrm{d}t^2 - a^2(t)\left(\frac{\mathrm{d}r^2}{1-kr^2} + r^2\mathrm{d}\Omega^2\right)\,. \tag{279}$$

Problem 2 (Conformal Time)**.** *Derive some simple expressions for the conformal time τ as a function of a.*

1. *Show that $\tau \propto a^{1/2}$ in a matter-dominated universe and $\tau \propto a$ in one dominated by radiation.*

2. *Consider a universe with only matter and radiation, with equality at* $a_{\rm eq}$. *Show that*

$$\tau = \frac{2}{\sqrt{\Omega_m H_0^2}}\left[\sqrt{a+a_{\rm eq}} - \sqrt{a_{\rm eq}}\right] . \tag{280}$$

What is the conformal time today? At decoupling?

3. *Use your favorite software (say Mathematica or Maple) to compute the conformal time numerically for our universe (filled with dark energy, matter and radiation). Compute the conformal time today and at decoupling. What is the percentage error between this result and the analytical result for a matter/radiation only universe, Eqn. (280)?*

Problem 3 (Friedmann Equations)**.** *Derive the Ricci tensor and the Ricci scalar for the FRW spacetime (328)*

$$R_{00} = -3\frac{\ddot{a}}{a}\,, \qquad R_{ij} = \delta_{ij}\left[2\dot{a}^2 + a\ddot{a} + 2\frac{k}{a^2}\right], \qquad R = g^{\mu\nu}R_{\mu\nu} = 6\left[\frac{\ddot{a}}{a} + \left(\frac{\dot{a}}{a}\right)^2 + \frac{k}{a^2}\right] . \tag{281}$$

Confirm that the 00-component of the Einstein Equation (340) gives the Friedmann Equation

$$\left(\frac{\dot{a}}{a}\right)^2 = \frac{8\pi G}{3}\rho - \frac{k}{a^2}\,. \tag{282}$$

Confirm that the trace of the Einstein Equation (340) gives the acceleration equation

$$\frac{\ddot{a}}{a} = -\frac{4\pi G}{3}(\rho + 3p)\,. \tag{283}$$

Show that the two Friedmann Equations imply the continuity equation

$$\dot{\rho} = -3H(\rho + p)\,. \tag{284}$$

Derive the continuity equation from

$$\nabla_\mu T^\mu_{\ \nu} = 0\,. \tag{285}$$

(Hint: Contract Eqn. (285) with U^μ*, use the energy-momentum tensor for a perfect fluid and the properties of the 4-velocity. No need for Christoffel symbols!)*

Problem 4 ($\lambda\phi^4$ Inflation)**.** *Derive the slow-roll dynamics for* $\lambda\phi^4$ *inflation.*

Problem 5 (The Phase Space of $m\phi^2$ Inflation)**.** *Read about the attractor behavior of* $m^2\phi^2$ *inflation in Mukhanov's book [9].*

Problem 6 (Vacuum Selection)**.** *Read about the* **Unruh effect** *in your favorite resource for QFT in curved spacetime.*

Problem 7 (Slow-Roll Mode Functions)**.** *In this problem we compute the mode functions and the power spectrum of curvature perturbations to first order in the slow-roll approximation.*

Recall the mode equation

$$v_k'' + \left(k^2 - \frac{z''}{z}\right)v_k = 0\,, \qquad z^2 = 2a^2\varepsilon\,. \tag{286}$$

1. *Show that*

$$\frac{z''}{z} = \frac{\nu^2 - 1/4}{\tau^2}\,, \qquad \nu \approx \frac{3}{2} + 3\varepsilon - \eta\,, \tag{287}$$

at first order in the slow-roll parameters

$$\varepsilon \equiv -\frac{\dot{H}}{H^2}\,, \qquad \eta \equiv 2\varepsilon - \frac{\dot{\varepsilon}}{2H\varepsilon}\,. \tag{288}$$

The solution can then be expressed as a linear combination of Hankel functions

$$v_k(\tau) = x^{1/2}\left[c_1 H_\nu^{(1)}(x) + c_2 H_\nu^{(2)}(x)\right], \qquad x \equiv k|\tau|\,. \tag{289}$$

In the far past, $x = k|\tau| \to \infty$*, the Hankel functions have the asymptotic limit*

$$H_\nu^{(1,2)}(x) \to \sqrt{\frac{2}{\pi x}}\exp\left[\pm i\left(x - \frac{\nu\pi}{2} - \frac{\pi}{4}\right)\right] \tag{290}$$

2. *Show that the boundary condition (506) implies*

$$v_k = a_1(\pi x/4k)^{1/2} H_\nu^{(1)}(x)\,, \tag{291}$$

where

$$a_1 = \exp[i(2\nu+1)\pi/4] \tag{292}$$

is a k-independent complex phase factor.

3. *Compute the power spectrum of $\mathcal{R} = v/z$ at large scales, $k \ll aH$.*
Hint: Use the identity

$$H_\nu^{(1)}(k|\tau|) \;\to\; \frac{i}{\pi}\Gamma(\nu)\left(\frac{k|\tau|}{2}\right)^{-\nu}, \quad \text{for} \quad k\tau \to 0\,, \tag{293}$$

and $\Gamma(3/2) = \sqrt{\pi}/2$.
Show that this reproduces the result of perfect de Sitter in the limit $\varepsilon = \eta = 0$.

4. *Read off the scale-dependence of the spectrum.*

Problem 8 (Predictions of $\lambda\phi^4$ Inflation)**.** *Determine the predictions of an inflationary model with a quartic potential*

$$V(\phi) = \lambda\phi^4\,. \tag{294}$$

1. *Compute the slow-roll parameters ϵ and η in terms of ϕ.*

2. *Determine $\phi_{\rm end}$, the value of the field at which inflation ends.*

3. *To determine the spectrum, you will need to evaluate ϵ and η at horizon crossing, $k = aH$ (or $-k\tau = 1$). Choose the wavenumber k to be equal to a_0H_0, roughly the horizon today. Show that the requirement $-k\tau = 1$ then corresponds to*

$$e^{60} = \int_0^N {\rm d}N' \frac{e^{N'}}{H(N')/H_{\rm end}}\,, \tag{295}$$

where $H_{\rm end}$ is the Hubble rate at the end of inflation, and N is defined to be the number of e-folds before the end of inflation

$$N \equiv \ln\left(\frac{a_{\rm end}}{a}\right)\,. \tag{296}$$

4. *Take this Hubble rate to be a constant in the above with $H/H_{\rm end} = 1$. This implies that $N \approx 60$. Turn this into an expression for ϕ. This simplest way to do this is to note that $N = \int_t^{t_{\rm end}} {\rm d}t' H(t')$ and assume that H is dominated by potential energy. Show that this mode leaves the horizon when $\phi = 22M_{\rm pl}$.*

5. *Determine the predicted values of $n_{\rm s}$, r and $n_{\rm t}$. Compare these predictions to the latest WMAP5 data (see* **Lecture 3***).*

6. *Estimate the scalar amplitude in terms of λ. Set $\Delta_{\rm s}^2 \approx 10^{-9}$. What value does this imply for λ?*

This model illustrates many of the features of generic inflationary models: (i) the field is of order – even greater than – the Planck scale, but (ii) the energy scale V is much smaller than Planckian because of (iii) the very small coupling constant.

Problem 9 (Plots of Bispectra)**.** *Reproduce the plots of the bispectra for the local and equilateral shapes (Figs. 83 and 84, respectively). Then plot the bispectra for slow-roll inflation, the DBI model and for models with excited initial states, i.e. $\mathcal{S}^{\rm SR}(1,x_2,x_3)$ (Eqn. (627)), $\mathcal{S}^{\rm DBI}(1,x_2,x_3)$ (Eqn. (642)) and $\mathcal{S}^{\rm folded}(1,x_2,x_3)$ (Eqn. (643)).*

13.2.6 Solution some problems by Dodelson chapter 2

Solution to

1 (a) To get from kelvin to eV, use $k_B = \text{eV}/(11605\text{ K})$. So $2.725\text{ K} \to k_B 2.725\text{ K} = (2.725/11605)\text{eV}$. Or $2.348 \times 10^{-4}\text{eV}$. (b) Since $T_0 = 2.348 \times 10^{-4}\text{eV}$,

$$\rho_\gamma = \frac{\pi^2 T_0^4}{15} = 2.000 \times 10^{-15}\text{eV}^4$$

To get this in gcm^{-3}, first divide by $(\hbar c)^3 = \left(1.973 \times 10^{-5}\text{eVcm}\right)^3$ to get 0.2604eVcm^{-3}. Then to change from eV to grams, remember that the mass of the proton is either 1.673×10^{-24} g or 0.9383×10^9eV, so $1\text{eV} = 1.783 \times 10^{-33}$ g. Therefore, $\rho_\gamma = 4.643 \times 10^{-34}$ g cm^{-3}.

(c) We have parametrized $H_0 = 100h$ kmsec^{-1}Mpc^{-1}, or using the fact that one Mpc is equal to 3.1×10^{19} km, $H_0 = 3.23h \times 10^{-18}\text{sec}^{-1}$. To get this into inverse cm, divide by the speed of light, $c = 3 \times 10^{10}$ cmsec^{-1}; then $H_0 = 1.1\text{ h} \times 10^{-28}$ cm. Or $H_0^{-1} = 9.3h^{-1} \times 10^{27}$ cm.

(d) To get the Planck mass $\left(1.2 \times 10^{28}\text{eV}\right)$ into kelvins, multiply by $k_B^{-1} = 11605\text{ K/eV}$; then $m_{\rm Pl} = 1.4 \times 10^{32}$ K. To get it into inverse cm, divide by $\hbar c = 1.97 \times 10^{-5}$eVcm to get $m_{\rm Pl} = 6.1 \times 10^{32}$ cm^{-1}. To get this is units of time, multiply by the speed of light to get $m_{\rm Pl} = 6.1 \times 10^{32} \times 3 \times 10^{10}$ cmsec^{-1}, or $m_{\rm Pl} = 1.8 \times 10^{43}\text{sec}^{-1}$.

Solution to

7
Start with

$$\Gamma^0_{\mu\nu} = \frac{g^{0\alpha}}{2}\left[\frac{\partial g_{\alpha\mu}}{\partial x^\nu} + \frac{\partial g_{\alpha\nu}}{\partial x^\mu} - \frac{\partial g_{\mu\nu}}{\partial x^\alpha}\right]$$

where μ, ν range from 0 t 02,0 being the time index, 1 corresponding to θ, and 2 to ϕ. Since the metric is diagonal, $g^{0\alpha}$ is nonzero only when $\alpha = 0$ in which case it is -1. So

$$\Gamma^0_{\mu\nu} = \frac{-1}{2}\left[\frac{\partial g_{0\mu}}{\partial x^\nu} + \frac{\partial g_{0\nu}}{\partial x^\mu} - \frac{\partial g_{\mu\nu}}{\partial t}\right]$$

All of these terms vanish: the first two since g_{00} is a constant, and the last because none of the metric elements depend on $x^0 = t$. So $\Gamma^0_{\mu\nu} = 0$ for all μ, ν.

Next consider

$$\Gamma^\theta_{\mu\nu} = \frac{g^{\theta\alpha}}{2}\left[\frac{\partial g_{\alpha\mu}}{\partial x^\nu} + \frac{\partial g_{\alpha\nu}}{\partial x^\mu} - \frac{\partial g_{\mu\nu}}{\partial x^\alpha}\right]$$

Again since the metric is diagonal, and $g^{\theta\theta} = 1/r^2$, this reduces to

$$\Gamma^\theta_{\mu\nu} = \frac{1}{2r^2}\left[\frac{\partial g_{\theta\mu}}{\partial x^\nu} + \frac{\partial g_{\theta\nu}}{\partial x^\mu} - \frac{\partial g_{\mu\nu}}{\partial \theta}\right].$$

Only the $g_{\phi\phi}$ component depends on one of our variables, so only it is nonzero when differentiated. Therefore, the first two terms vanish and the last is nonzero only when $\mu = \nu = \phi$, in which case it is

$$\Gamma^\theta_{\phi\phi} = \frac{1}{2r^2}\left[-r^2\frac{\partial \sin^2\theta}{\partial\theta}\right] = -\sin\theta\cos\theta.$$

Finally, when the upper index is ϕ, we have

$$\Gamma^\phi_{\mu\nu} = \frac{1}{2r^2\sin^\theta}\left[\frac{\partial g_{\phi\mu}}{\partial x^\nu} + \frac{\partial g_{\phi\nu}}{\partial x^\mu} - \frac{\partial g_{\mu\nu}}{\partial \phi}\right]$$

The last term vanishes since none of the metric elements depend on ϕ; the first two are nonzero only if one of the indices μ, ν is equal to ϕ and the other is θ, so

$$\Gamma^\phi_{\phi\theta} = \Gamma^\phi_{\theta\phi} = \frac{\cos\theta}{\sin\theta}$$

The geodesic equation is

$$\frac{d^2x^\mu}{d\lambda^2} = -\Gamma^\mu_{\alpha\beta}P^\alpha P^\beta$$

with

$$P^\mu \equiv \frac{dx^\mu}{d\lambda}$$

Let's apply this to the $\mu = \theta$ component. The left-hand side is

$$\frac{d^2\theta}{d\lambda^2} = \frac{d}{\lambda}\frac{dt}{d\lambda}\dot{\theta} = E^2\ddot{\theta}$$

since $E = dt/d\lambda$ is constant. The Christoffel symbol on the right-hand side $\Gamma^\theta_{\alpha\beta}$ is nonzero only when $\alpha = \beta = \phi$ in which case it is $-\sin\theta\cos\theta$. So,

$$\ddot{\theta} - \sin\theta\cos\theta(\dot{\phi})^2 = 0$$

For the second equation, consider the ϕ component of the geodesic equation,

$$\frac{d^2\phi}{d\lambda^2} = -\Gamma^\phi_{\alpha\beta}P^\alpha P^\beta$$

Again the left-hand side is simply $E^2\ddot{\phi}$. The right-hand side gets nonzero contributions when $\alpha = \theta, \beta = \phi$ or an identical term when $\alpha = \phi, \beta = \theta$. Therefore,

$$\ddot{\phi} + 2\frac{\cos\theta}{\sin\theta}\dot{\theta}\dot{\phi} = 0$$

Incidentally this is equivalent to

$$\frac{d}{dt}\left(\dot{\phi}\sin^2\theta\right) = 0$$

and the conserved quantity in parentheses is the angular momentum.
The Ricci scalar is

$$\mathcal{R} = g^{\mu\nu}R_{\mu\nu} = -R_{00} + \frac{1}{r^2}R_{\theta\theta} + \frac{1}{r^2\sin^2\theta}R_{\phi\phi}$$

The time-time component vanishes since all Γ 's with time components are zero. We need to compute the two spatial components. First, consider

$$R_{\theta\theta} = \frac{\partial\Gamma^\alpha{}_{\theta\theta}}{\partial x^\alpha} - \frac{\partial\Gamma^\alpha{}_{\theta\alpha}}{\partial\theta} + \Gamma^\alpha{}_{\beta\alpha}\Gamma^\beta{}_{\theta\theta} - \Gamma^\alpha{}_{\beta\theta}\Gamma^\beta{}_{\theta\alpha}.$$

The first and third terms vanish since the Christoffel symbol with two lower θ 's vanishes. For the same reason, the index α in the second term must be equal to ϕ, and both β and α in the last term must equal ϕ:

$$R_{\theta\theta} = -\frac{\partial(\cos\theta/\sin\theta)}{\partial\theta} - \left(\frac{\cos\theta}{\sin\theta}\right)^2.$$

Carrying out the derivative then gives

$$R_{\theta\theta} = \left[1 + \frac{\cos^2\theta}{\sin^2\theta}\right] - \left(\frac{\cos\theta}{\sin\theta}\right)^2 = 1.$$

The other spatial component is

$$R_{\phi\phi} = \frac{\partial\Gamma^\alpha_{\phi\phi}}{\partial x^\alpha} - \frac{\partial\Gamma^\alpha_{\phi\alpha}}{\partial\phi} + \Gamma^\alpha_{\beta\alpha}\Gamma^\beta_{\phi\phi} - \Gamma^\alpha_{\beta\phi}\Gamma^\beta_{\phi\alpha}.$$

The Christoffel symbol in the first term is nonzero only if $\alpha = \theta$, while the one in the second term is always zero. In the third term β must be equal to θ to make the second Christoffel symbol be nonzero, and then $\alpha = \phi$. In the last term β can be θ and $\alpha = \phi$ or vice versa, so

$$R_{\phi\phi} = \frac{\partial\Gamma^\theta_{\phi\phi}}{\partial\theta} + \Gamma^\phi{}_{\theta\phi}\Gamma^\theta_{\phi\phi} - \Gamma^\phi{}_{\theta\phi}\Gamma^\theta_{\phi\phi} - \Gamma^\theta_{\phi\phi}\Gamma^\beta_{\phi\theta}.$$

The middle two terms cancel leaving

$$R_{\phi\phi} = -\frac{\partial(\sin\theta\cos\theta)}{\partial\theta} + \sin\theta\cos\theta\frac{\cos\theta}{\sin\theta}.$$

Carrying out the derivative gives

$$R_{\phi\phi} = -\cos^2\theta + \sin^2\theta + \cos^2\theta = \sin^2\theta.$$

Summing up, we get

$$\mathcal{R} = \frac{1}{2r^2}$$

The Ricci scalar is therefore a measure of the curvature of the space.

Solution to

9 Accumulating the various Γ 's leads to

$$\frac{d^2x^i}{d\lambda^2} = -2\frac{\dot{a}}{a}\frac{dt}{d\lambda}\frac{dx^i}{d\lambda}$$

Change to differentiation with respect to η using the facts that $dt/d\lambda = E$ and $d\eta/d\lambda = E/a$. Then the geodesic equation becomes

$$\frac{E}{a}\frac{d}{d\eta}\left(\frac{E}{a}\frac{dx^i}{d\eta}\right) = -2\frac{\dot{a}}{a}\frac{E^2}{a}\frac{dx^i}{d\eta}$$

Since $E/a \propto a^{-2}$, when the derivative on the left acts on E/a, the resulting term (proportional to $dx^i/d\eta$) exactly cancels the term on the right, leaving the result of Eq. (2.99).

Solution to

10 The age integral is

$$t(a) = \int_0^a \frac{da'}{a'H\left(a'\right)}.$$

Since we are assuming only matter and radiation, we can take

$$H(a) = H_0\sqrt{\rho/\rho_{\rm cr}} = \sqrt{\frac{1}{a^3} + \frac{\Omega_r}{a^4}}$$

where the $1/a^3$ term is from matter with density equal to the critical density. When the density in matter is equal to critical, $\Omega_r = a_{\rm eq} = 4.15 \times 10^{-5}h^{-2}$. Therefore, the age integral is

$$t = \frac{1}{H_0}\int_0^a \frac{da'a'}{\sqrt{a' + a_{\rm eq}}}$$

Integrate by parts to get

$$H_0 t = 2a\sqrt{a + a_{\rm eq}} - 2\int_0^a da'\sqrt{a' + a_{\rm eq}}.$$

Carrying out the last integral leads to

$$H_0 t = 2a\sqrt{a + a_{\rm eq}} - \frac{4}{3}\left\{\left[a + a_{\rm eq}\right]^{3/2} - a_{\rm eq}^{3/2}\right\}.$$

At very early times, such as when the temperature was $0.1{\rm MeV}$, a is much smaller than $a_{\rm eq}$, so

$$t \to \frac{a^2}{2H_0\sqrt{a_{\rm eq}}} \quad ; \quad a \ll a_{\rm eq}.$$

This limit is easiest to see directly in the integral of Eq. (A.39), but you can also get it by Taylor expanding Eq. (A.41). When the temperature is 0.1MeV, the scale factor is $2.35 \times 10^{-4}{\rm eV}/0.1{\rm MeV} = 2.35 \times 10^{-9}$, the temperature today divided by 0.1MeV. Plugging in numbers leads to

$$t(0.1{\rm MeV}) = 4.28 \times 10^{-16} \times 9.78 \times 10^9{\rm yr} = 130{\rm sec}.$$

At $T = 1/4{\rm eV}, a = 9.4 \times 10^{-4}$, significantly larger than $a_{\rm eq} = 8.5 \times 10^{-5}$ with $h = 0.7$, so $H_0 t \to (2/3)a^{3/2}$. So,

$$t(1/4{\rm eV}) = 270,000{\rm yr}$$

Solution to

12 The angle subtended is the physical distance divided by the angular diameter distance

$$\theta(z) = \frac{5\text{kpc}(1+z)}{\chi(z)}$$

In a flat, matter-dominated universe, χ is given by Eq. (2.43). When $z = 0.1$ (1), the term in brackets in Eq. (2.43) is equal to 0.0465(0.293). The comoving distance out to z is, therefore,

$$\chi = \begin{cases} 280h^{-1}\text{Mpc} & z = 0.1 \\ 1760h^{-1}\text{Mpc} & z = 1 \end{cases} .$$

Carrying out the division and converting radians to arcsec)1 radian equals 2.06×10^5 arcsec) leads to

$$\theta = \begin{cases} 4.0h'' & z = 0.1 \\ 1.2h'' & z = 1 \end{cases} .$$

In a universe with $\Omega_\Lambda = 0.7, \Omega_m = 0.3, \chi$ must be computed numerically. At $z = 1$, I find χ to be larger than in the flat, matter-dominated case by a factor of 1.3, so the angular size will be smaller by this factor, down to $0.9h''$. At $z = 0.1$ the difference in comoving distances is only 5%, so the angular size goes down to $3.8h''$ in the cosmological constant case.

Solution to

13 Rewriting Eq. (1.8) in terms of momentum $p = h\nu/c = 2\pi\hbar\nu/c$ and recognizing the denominator there as $1/f$ leads to

$$I_\nu = f\frac{4\pi p^3}{(2\pi)^3}$$

with $\hbar = c = 1$. So the energy density is the integral of this over all frequencies, with a factor of 4π to count photons from all directions (i.e., I_ν is per steradian):

$$\rho_\gamma = 4\pi \int_0^\infty d\nu I_\nu$$

This can be converted into an integral over momentum, with $d\nu = dp/(2\pi)$:

$$\rho_\gamma = 2 \int_0^\infty dp I_\nu.$$

Solution to

15 We want to compute $\rho = -T^0_0$. Setting $\mu = \nu = 0$ leads to

$$T^0_0 = -g_i \int \frac{dP_1 dP_2 dP_3}{(2\pi)^3} \left(-\det\left[g_{\mu\nu}\right]\right)^{-1/2} P^0 f_i$$

The matrix $g_{\mu\nu}$ is diagonal, so the determinant is simply the product of the diagonal elements, $-a^6$. By definition, $p^2 = g^{ij}P_iP_j = a^{-2}\delta_{ij}P_iP_j$. So $p_i \equiv \hat{p}_i p = P_i/a$ with $\hat{p}_i$ a unit vector pointing in the direction of the momentum. Therefore, $d^3P = a^3 d^3p$ and the factors of a precisely cancel those coming from the determinant. We're left with

$$T^0_0 = -g_i \int \frac{d^3p}{(2\pi)^3} P^0 f_i$$

The four vector P_μ squared is equal to $-m^2$, the mass of the particle, so $g_{00}\left(P^0\right)^2 = -m^2 - g_{ij}P^iP^j = -m^2 - p^2$. Since $g_{00} = -1, P^0 = \sqrt{p^2 + m^2}$, in accord with Eq. (2.59).

Solution to

17 The energy density of a massless boson is $g\pi^2T^4/30$, while that of a fermion is 7/8 times this. So,

$$s = \frac{2\pi^2}{45}\left[\sum_{i=\text{ bosons}} g_i T_i^3 + \frac{7}{8}\sum_{i=\text{ fermions}} g_i T_i^3\right]$$

accounting for the possibility that different species have different temperatures.

13.2.7 Solution some problems by Dodelson chapter 3

Solution to

1 The number density of a species with degeneracy $g = 2$ is

$$n = 2\int \frac{d^3p}{(2\pi)^3} f(p)$$

For the distributions we will consider, the phase space density f depends only on the magnitude of the momentum, so the angular part of the integral can be performed leading to the a factor of 4π; therefore,

$$n = \frac{1}{\pi^2}\int_0^\infty dp p^2 f(p)$$

First let's consider the high m/T limit. In this case, the limit of the Boltzmann distribution is $\exp\left[-\left(m + p^2/2m\right)/T\right]$. I claim, though, that this is precisely the limit of both the Fermi-Dirac and Bose-Einstein distributions:

$$\frac{1}{e^{E/T} \pm 1} \to e^{-E/T}$$

since $E \simeq m \gg T$ so that the exponential in the denominator dwarfs the 1. Therefore the low-temperature limit of all three distributions is

$$n^{\text{low T}} = \frac{e^{-m/T}}{\pi^2}\int_0^\infty dp p^2 e^{-p^2/2mT}$$

To do the integral, define a dimensionless parameter $x \equiv p/\sqrt{2mT}$. In terms of the variable $dpp^2 = [2mT]^{3/2} dx x^2$, so

$$n^{\text{low T}} = \frac{e^{-m/T}}{\pi^2}[2mT]^{3/2}\int_0^\infty dx x^2 e^{-x^2}$$

But the integral is equal to $\sqrt{\pi}/2$, so we have

$$n^{\text{lowT}} = 2e^{-m/T}\left(\frac{mT}{2\pi}\right)^{3/2}$$

The high-temperature Boltzmann limit is

$$n^{\text{HiT, Boltz}} = \frac{1}{\pi^2}\int_0^\infty dp p^2 e^{-p/T}.$$

Defining the dummy variable $x \equiv p/T$ leads to

$$n^{\text{HiT, Boltz}} = \frac{1}{\pi^2}T^3\int_0^\infty dx x^2 e^{-x}.$$

The x integral is equal to 2. So,

$$n^{\text{Hi T. Boltz}} = \frac{2T^3}{\pi^2}$$

The Bose-Einstein and Fermi-Dirac integrals similarly are

$$n^{\rm Hi}{\rm T,BE/FD} = \frac{T^3}{\pi^2}\int_0^\infty \frac{dx x^2}{e^x \mp 1}$$

The integrals can be written in terms of the Riemann zeta function, via Eq. (C.27). So the integral in Eq. (A.63) with the minus sign - the Bose-Einstein distribution-is $\zeta(3)\Gamma(3) = 2\zeta(3)$. The integral with the plus sign - the Fermi-Dirac distribution - is $3\zeta(3)\Gamma(3)/4 = 3\zeta(3)/2$, so

$$n^{\rm HiT} = \frac{\zeta(3)T^3}{\pi^2}\begin{cases} 2 & \text{Bose-Einstein} \\ 3/2 & \text{Fermi-Dirac} \end{cases}.$$

By the way, $\zeta(3) \simeq 1.202$, so there are more bosons than fermions for the same temperature, and these bracket the Boltzman amount. All of course are proportional to T^3.

Solution to

6 The photon number density is 411 cm^{-3}, while the baryon number density is $n_b = \rho_b/m_p = \rho_{\rm cr}\Omega_b/m_p$. Plugging in numbers gives

$$n_b = \Omega_b \frac{1.879h^2 \times 10^{-29}\ {\rm g\ cm^{-3}}}{1.673 \times 10^{-24}\ {\rm g}} = 1.12 \times 10^{-5}\Omega_b h^2\ {\rm cm^{-3}}.$$

So η_b, the ratio of the baryon to the photon number density, is indeed given by Eq. (3.11).

Solution to

11 To find this ratio, we compute the entropy density $(\mathcal{P}+\rho)/T$ at the two times. In both cases, only relativistic particles contribute to the entropy density significantly so that Eq. (A.53) holds. At high temperatures, the following particles contribute to the energy density: quarks ($g_* = 5 \times 3 \times 2$ for the five least massive types - up, down, strange, charm, bottom - each with three colors and two spin states); anti-quarks ($g_* = 30$ again); leptons ($g_* = 6 \times 2$ for the six types - $e, \nu_e, \mu, \nu_\mu, \tau, \nu_\tau$ - each with two spin states); anti-leptons ($g_* = 12$ again); photons (2); and gluons ($g_* = 8 \times 2$ for eight possible colors each with two spin states). This totals up to

$$g_* = 2 + 16 + \frac{7}{8}(30 + 30 + 12 + 12) = 91.5$$

The sixth quark, the top quark, does not contribute because it is too heavy to be around at these temperatures $m_t \simeq 175$GeV. Today entropy comes only from photons and neutrinos. The former contribute 2 to g_*; the latter contribute $(7/8)\times\ 3 \times 2 \times (4/11)^{4/3} = 1.36$, so today $g_* = 3.36$. Since the product sa^3 remains constant, we have
Therefore,

$$\left[g_*(aT)^3\right]\big|_{T=10{\rm Gev}} = \left[g_*(aT)^3\right]\big|_{T_0}$$

$$\frac{(aT)^3\big|_{T=10{\rm Gev}}}{(a_0T_0)^3} = \frac{3.36}{91.5} = \frac{1}{27}$$

13.2.8 Solution some problems by Dodelson chapter 4

Solution to

1 First integrate Eq. (4.6) over all momentum. This gives

$$\frac{\partial n}{\partial t} + \frac{\partial (nv)}{\partial x} = 0$$

the $\partial f/\partial p$ term vanishing after integrating by parts and noticing that $f = 0$ at $p = \pm\infty$ (there are no particles with infinite momentum). This is the continuity equation. To get the Euler equation, first multiply by p/m and then integrate over all momentum. This gives

$$\frac{\partial (nv)}{\partial t} + \frac{\partial}{\partial x}\int_{-\infty}^{\infty}\frac{dp}{2\pi}\frac{p^2}{m^2} + \frac{kx}{m}n = 0$$

where the last term follows from an integration by parts. The integral over p^2 yields two terms, one a bulk velocity term, v^2, and the second a pressure term, P. Using the continuity equation reduces this to

$$\dot{v} + v\frac{\partial v}{\partial x} + \frac{1}{n}\frac{\partial P}{\partial x} + \frac{kx}{m} = 0.$$

Solution to

4 From Eq. (3.3), the electron distribution function peaks at zero momentum, with a maximum value of $e^{(\mu - m_e)/T}$. To relate the chemical potential to the density, recall that $n = e^{\mu/T} n^{(0)}$, so in the low-temperature limit (Eq. (3.6)):

$$e^{\mu/T} = \frac{n_e}{2}\left(\frac{2\pi}{m_e T}\right)^{3/2} e^{m_e/T}.$$

So the maximum value of f_e is $(n_e/2)\,(2\pi/m_e T)^{3/2}$. Divide Eq. (3.44) by the Thomson cross-section to get $n_e = 1.12 \times 10^{-5}\Omega_B h^2$ cm^{-3} today including both ionized and captured electrons. Taking the electron temperature to be equal to the photon temperature today gives $2\pi/m_e T = 2.04 \times 10^{-11}$ cm^2. Putting back in the factors of a leads to

$$f_e^{\rm MAX} = 10^{-21}\Omega_B h^2 a^{-3/2}.$$

This expression holds only up to $T \leq m_e$, corresponding to $a \simeq 4.6 \times 10^{-10}$. So, as long as the temperature is well below the electron mass, f_e is very small.

Solution to

7 The difference between the amplitude we used in the derivation in Section 4.3 and the more accurate one given in the problem is $2\pi\sigma_T m_e^2[3\cos(\hat{p}.\ \hat{p}') - 1]$. The combination is square brackets is twice the second Legendre polynomial. Rewrite using the addition formula of spherical harmonics; then the difference becomes

$$2\pi\sigma_T m_e^2 \frac{8\pi}{5}\sum_{m=-2}^{2} Y_{2m}(\hat{p}) Y_{2m}^*(\hat{p}')\,.$$

This is the quantity we need to insert into the multiple integral in Eq. (4.49) in place of $\mathcal{M}^2$. When we do this, only the $m = 0$ term will contribute since all other $Y_{2m}(\hat{p}')$ have an azimuthal dependence which integrates to zero. Therefore, the new collision term due to anisotropic Compton scattering is

$$\delta C[f(\vec{p})] = \frac{\pi^2 n_e \sigma_T}{p}\mathcal{P}_2(\mu)\int \frac{d^3p'}{(2\pi)^3 p'}\mathcal{P}_2\left(\hat{\gamma}'\cdot\hat{k}\right) \times\left\{\delta\left(p-p'\right) + \left(\vec{p}-\vec{p}'\right)\cdot\vec{v}\frac{\partial\delta\left(p-p'\right)}{\partial p'}\right\}\left\{f\left(\vec{p}'\right) - f(\vec{p})\right\},$$

where I have used the fact that $Y_{20} = -\sqrt{5}\mathcal{P}_2/\sqrt{4\pi}$. The only term which survives the angular integral is the one proportional to $\delta\left(p-p'\right) f\left(\vec{p}'\right)$, leaving

$$\delta C[f(\vec{p})] = -\frac{n_e\sigma_T}{2p}\mathcal{P}_2(\mu)\int_0^\infty dp' p'\delta\left(p-p'\right)p'\frac{\partial f^{(0)}}{\partial p'} \times\int_{-1}^{1}\frac{d\mu}{2}\mathcal{P}_2(\mu)\Theta(\mu).$$

The angular integral gives $-\Theta_2$. Then integrating over the Dirac δ-function yields

$$\delta C[f(\vec{p})] = +p\frac{\partial f^{(0)}}{\partial p}\frac{n_e\sigma_T}{2p}\mathcal{P}_2(\mu)\Theta_2$$

This adds a factor of $-\mathcal{P}_2\Theta_2/2$ inside the square brackets of Eq. (4.54) and explains the corresponding factor in Eq. (4.100).

13.2.9 Solution some problems by Dodelson chapter 5

Solution to

4 In Fourier space,

$$\begin{aligned}\epsilon_{ijk}\left(\hat{k}_k\hat{k}_l-\delta_{kl}/3\right)G^L_{.jl} &= -k^2\epsilon_{ijk}\left(\hat{k}_k\hat{k}_j-\hat{k}_j\hat{k}_k/3\right)G^L\\ &= -2k^2/3\epsilon_{ijk}\hat{k}_j\hat{k}_kG^L=0\end{aligned}$$

since ϵ_{ijk} is antisymmetric under interchange of j and k while $\hat{k}_j\hat{k}_k$ is symmetric. The combination is also traceless since $\delta_{ij}\left(\hat{k}_i\hat{k}_j-\delta_{ij}/3\right)=0$.

Solution to

7 (a) By definition,

$$\Gamma^i_{jk}=\frac{g^{ii'}}{2}\left[g_{i'j,k}+g_{i'k,j}-g_{jk,i'}\right].$$

All derivatives here are spatial, and the only spatially varying part of the metric is the first-order piece $\mathcal{H}$. Therefore, we can again use the zero-order $g^{ii'}=\delta_{ii'}/a^2$, leaving Eq. (5.43).

(b) The product $\Gamma^\alpha_{\beta j}\Gamma^\beta_{i\alpha}$ vanishes when both indices α and β are zero (because $\Gamma^0_{0i}=0$) and when both indices are spatial (because then each Christoffel symbol is first order). Therefore, this product is

$$\begin{aligned}\Gamma^\alpha_{ij}\Gamma^\beta_{i\alpha} &= \Gamma^0_{hj}\Gamma^k_{i0}+\Gamma^k_{0j}\Gamma^0_{ik}\\ &= \Gamma^0_{kj}\Gamma^k_{i0}+(i\leftrightarrow j).\end{aligned}$$

But

$$\begin{aligned}\Gamma^0_{kj}\Gamma^k_{i0} &= \frac{1}{2}\left(2Hg_{jk}+a^2\mathcal{H}_{jk,0}\right)\left(H\delta_{ik}+\frac{1}{2}\mathcal{H}_{ik,0}\right)\\ &= (H)^2g_{ij}+a\frac{da}{dt}\mathcal{H}_{ij,0}.\end{aligned}$$

We must remember to add back in the same set of terms with i and j interchanged. This just introduces a factor of 2, so

$$\Gamma^\alpha_{\beta j}\Gamma^\beta_{i\alpha}=2(H)^2g_{ij}+2a\frac{da}{dt}\mathcal{H}_{ij,0}$$

13.2.10 Solution some problems by Dodelson chapter 11

Solution to 4

The noise matrix is

$$(C_N)_{ij}=\frac{1}{\bar{n}}\int d^3x\psi_i(\vec{x})\psi_j(\vec{x})$$

in this case of constant $\bar{n}$. Let's consider first the diagonal elements of the matrix. For these, both ψ_i and ψ_j require x to be within a radius R of the center of the i th cell, so

$$(C_N)_{ii}=\bar{n}\int\limits_{x<R}d^3x=\frac{4\pi\bar{n}R^3}{3}$$

(no sum over i intended). For cells separated by more than $2R$, the integral vanishes since $\vec{x}$ cannot be within a distance R of both cell centers. For distances less than $2R$ there is some overlap and the integral becomes

$$\bar{n}\int\limits_{x<R}d^3x\Theta(R-|\vec{x}-\vec{r}|)=2\pi\bar{n}\int\limits_0^R dxx^2\int\limits_{-1}^1 d\mu\Theta\left(R-\sqrt{x^2+r^2-2xr\mu}\right)$$

where $\vec{r}$ is the difference between the positions of the two cell centers and Θ is the step function equal to 1 if its argument is positive and zero otherwise. The μ integral therefore goes runs from $\left(x^2+r^2-R^2\right)/2xr$ up to 1. If this lower limit is greater than 1, then the μ integral vanishes; otherwise it is unity. The only contribution then comes when the lower limit is less than 1, which happens when x lies between $r \pm R$. The integral is therefore

$$\int_{r-R}^{R} dx x^2 \left[1 - \frac{x^2+r^2-R^2}{2xr}\right] = \frac{1}{2r}\int_{r-R}^{R} dx x \left[2xr - \left(x^2+r^2-R^2\right)\right].$$

The x integral here is then tedious but completely straightforward since the integrand is simply powers of x. I find that

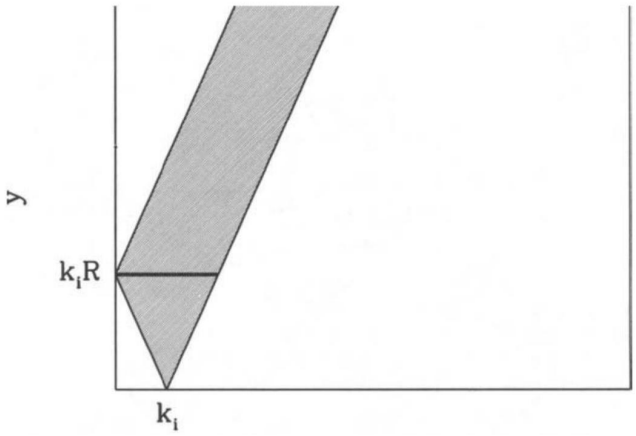
$$(C_N)_{ij} = \frac{\pi \bar{n} R^3}{12}\left(2 - \frac{r_{ij}}{R}\right)^2\left(4 + \frac{r_{ij}}{R}\right).$$

Solution to 7

We need to compute the integral of Eq. (11.55). Since the window function is sharply peaked for small scale modes, we can set k everywhere to k_i. Then inserting our explicit expression for the window function in a volume-limited survey (Eq. (11.59)), we are left with

$$(C_S)_{ii} \simeq \frac{9P(k_i)}{4\pi^2 R^2}\int_0^\infty dk \int_{|k-k_i|R}^{(k+k_i)R} \frac{dy}{y} j_1^2(y)$$

The best way to do the integrals here is to switch orders of integration. Consider the Figure A.2, which shows the region of integration. The region below the horizontal



k

Figure A.2. Region of integration for the double integral in Eq. (A.128). The region below the horizontal line constitutes the first term, above the second term.

line corresponds to $y < k_i R$ and $k_i - y/R < k < k_i + y/R$. In the region above k is bounded by $y/R \pm k_i$. Therefore,

$$\int_0^\infty dk \int_{|k-k_i|R}^{(k+k_i)R} \frac{dy}{y} j_1^2(y) = \int_0^{k_i R} \frac{dy}{y} j_1^2(y) \int_{k_i - y/R}^{k_i + y/R} dk + \int_{k_i R}^\infty \frac{dy}{y} j_1^2(y) \int_{y/R - k_i}^{k_i + y/R} dk$$
$$= \frac{2}{R}\int_0^{k_i R} dy j_1^2(y) + 2k_i \int_{k_i R}^\infty \frac{dy}{y} j_1^2(y).$$

In the limit $k_i R \gg 1$, the first term here is much larger than the second (since $j_1^2(y)$ goes as $1/y^2$ for large y). In the first integral, we may replace the upper limit by infinity, again since $k_i R$ is large. The resulting integral is (Eq. (C.17)) $\pi\Gamma(3/2)/4\Gamma(5/2) = \pi/6$. Multiplying this by $2/R$ and then by $9/4\pi^2 R^2$ leads to a factor of $1/V$.

Solution to 9

We want to compute the variance

$$\left\langle (\hat{\lambda} - \bar{\lambda})^2 \right\rangle = \left\langle \left(F^{-1}_{\lambda\lambda} \frac{\Delta C^{-1} C_{,\lambda} C^{-1} \Delta - \mathrm{Tr}\left[C^{-1}\mathrm{C}_{,\lambda}\right]}{2} \right)^2 \right\rangle$$

where the estimator $\hat{\lambda}$ is given by Eq. (11.92), and I have assumed that $\lambda^{(0)} = \bar{\lambda}$, i.e., we are at the true maximum of the likelihood function. Upon squaring there are terms with no Δ; those with two Δ 's; and those with four. The ones with two Δ 's can be simply evaluated by using

$$\langle \Delta_i \Delta_j \rangle = C_{ij}$$

where the indices label the pixels. Since the distribution is assumed Gaussian, the expectation value of four Δ 's is

$$\langle \Delta_i \Delta_j \Delta_k \Delta_l \rangle = C_{ij}C_{kl} + C_{ik}C_{jl} + C_{il}C_{jk}$$

Putting in these expectation values leads to

$$\left\langle (\hat{\lambda} - \bar{\lambda})^2 \right\rangle = \frac{F^{-2}_{\lambda\lambda}}{4} \left\{ \left[C^{-1}C_{,\lambda}C^{-1}\right]_{ij} \left[C^{-1}C_{,\lambda}C^{-1}\right]_{kl} (C_{ij}C_{kl} + C_{ik}C_{jl} + C_{il}C_{jk}) - \left(\mathrm{Tr}\left[C^{-1}C_{,\lambda}\right]\right)^2 \right\}.$$

The $C_{ij}C_{kl}$ terms lead to $\left(\mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\lambda}\right]\right)^2$, cancelling the similar term on the last line, so

$$\left\langle (\hat{\lambda} - \bar{\lambda})^2 \right\rangle = \frac{F^{-2}_{\lambda\lambda}}{4} \left[C^{-1}C_{,\lambda}C^{-1}\right]_{ij} \left[C^{-1}C_{,\lambda}C^{-1}\right]_{kl} (C_{ik}C_{jl} + C_{il}C_{jk})$$

Both terms here contribute identically (giving one factor of 2). The matrix multiplication simplifies since all matrices are symmetric. For example,

$$\left[C^{-1}C_{,\lambda}C^{-1}\right]_{ij} \left[C^{-1}C_{,\lambda}C^{-1}\right]_{kl} C_{ik}C_{jl} = \mathrm{Tr}\left[\mathrm{C}^{-1}\mathrm{C}_{,\lambda}\mathrm{C}^{-1}\mathrm{C}_{,\lambda}\right]$$

and we recognize the right-hand side as $2F_{\lambda\lambda}$ (another factor of 2). Therefore,

$$\left\langle (\hat{\lambda} - \bar{\lambda})^2 \right\rangle = F^{-1}_{\lambda\lambda}$$

It is important to keep in mind that this equality holds only if the overdensities are distributed as Gaussians and if we truly have reached the point in parameter space which is the true maximum.

Solution to

15 (a) Use a likelihood approach. The likelihood function for the parameters, here the amplitudes of the different components Θ^α, is proportional to $e^{-\chi^2/2}$ with

$$\chi^2 = (d - W\Theta)N^{-1}(d - W\Theta) + \sum_{\alpha=1}^{N_{\mathrm{foregrounds}}} (\Theta^\alpha)^2 / C^\alpha$$

The first term is identical to that generated by Eq. (11.144). The second accounts for the prior, that Θ^α has mean zero and variance C^α. Maximizing the likelihood corresponds to minimizing the χ^2, with respect to the parameters Θ. Since the χ^2 is quadratic, the minimization leads to a linear equation for Δ^α, the minimum variance estimator of Θ^α:

$$\Delta = \left(WN^{-1}W + C^{-1}\right)^{-1} WN^{-1}d$$

The new covariance matrix is the first term on the right,

$$C_N = \left(WN^{-1}W + C^{-1}\right)^{-1}$$

Here the matrix C is diagonal with $_{00}$ element equal to zero, and the other diagonal elements equal to the assumed power spectra of the foregrounds.

(b) If there is only one foreground with shape vector $W^1 = (1, 1/2)$, and if this foreground has assumed power equal to the noise, then the new inverse covariance matrix goes from that in Eq. (11.151) to the same matrix with $1/\sigma_n^2$ added to the 11 component. Thus,

$$C_N^{-1} = \frac{1}{\sigma_n^2} \begin{pmatrix} 2 & 3/2 \\ 3/2 & 9/4 \end{pmatrix}$$

Note that the 0_0 component of this is unchanged, as it must be since it is the inverse covariance if all foregrounds are known. The inverse of this gives the new covariance matrix,

$$C_N = \frac{4\sigma_n^2}{9}\begin{pmatrix} 9/4 & -3/2 \\ -3/2 & 2 \end{pmatrix}$$

Immediately, we see that the noise in the presence of foregrounds is σ_n. This is a factor of $\sqrt{5}$ smaller than if we had no prior knowledge of the foreground amplitude. It is only a factor of $\sqrt{2}$ larger than the case without foregrounds; thus the new FDF in this case is $\sqrt{2}$. The minimum variance estimator is

$$\begin{aligned}\Delta^0 &= \frac{4\sigma_n^2}{9}(9/4, -3/2)\begin{pmatrix} 1 & 1 \\ 1 & 1/2 \end{pmatrix}\begin{pmatrix} 1/\sigma_n^2 & 0 \\ 0 & 1/\sigma_n^2 \end{pmatrix}\begin{pmatrix} d_1 \\ d_2 \end{pmatrix} \\ &= \frac{d_1 + 2d_2}{3}.\end{aligned}$$

14 Extra Problems about Basic Models

(some not very important problems are here)

14.1 General questions

14.1.1 Short problems for checking basics of modern cosmology

(многое можно спросить, вот и напишу потом)

Typical questions about geometry and dynamics

(a) What is conformal time? Why is it useful?

(b) How do the energy densities in radiation (ρ_r), matter (ρ_m) and a cosmological constant (ρ_Λ) evolve with the scale factor $a(t)$?

(c) What is $a(t)$ for a flat universe dominated by radiation, matter or a cosmological constant?

(d) What is the redshift of matter-radiation equality if $\Omega_r = 9.4 \times 10^{-5}$ and $\Omega_m = 0.32$?

(e) What is H_0^{-1} in sec and in cm?

Typical questions about thermal history

(c) Describe $g_\star(T)$ given the particle content of the Standard Model.

(d) Why does the neutrino temperature scale as $T_\nu \propto a^{-1}$ after decoupling?

(e) Why is today's photon temperature larger than that of neutrinos?

(f) Why is the recombination temperature much lower than the ionization energy of hydrogen?

Typical questions about structure formation

(a) How do density perturbations in a pressureless fluid grow (i) in a static space and (ii) in an expanding space?

(b) What is the gauge problem?

(c) What are adiabatic fluctuations?

(d) Explain the Meszaros effect.

(e) Explain the relevance of the conservation of the comoving curvature perturbation $\mathcal{R}$ on superhorizon scales.

14.1.2 Short questions and problems for knowledge checking

(!!! later I'll make sure that all these questions are answered in 1st part or in theory)

Discuss the methods to achieve an accurate determination of the Hubble parameter

Discuss the results of the WMAP satellite. What else can PLANCK add to this?

How did it come to be that a significant mass of the universe is made up of dark matter?

Use the action to derive the equation of motion of the scalar field $phi(t, x^{dot})$ in a flat LFRW universe.What does the equation of motion reduce to if V(phi) is homogenous.

Inflation predicts a nearly scalar invarious spectrum of density pertubations. Give the 2 main reasons why this is a very important result.

Discuss the different evidences for dark matter

In which way can one derive different cosmological parameters from the frequency and intensity of the CMB?

Speeds (???)

The max velocity of matter is c, and 13.7 Gyr ago everything was together in the big bang. The radiation of the CMB travels with the velocity of light. Why is it possible that we can see it, and that it did not already pass us? You may chose in which way you want to explain this to or a 10 year old kid, a student of a different master or a 75 old person.

Use the formula for f(x), the Gaussian expectation value of 2 fourier coefficients to calculate the 2 point correlation function. (Both equations were given)

Derive the formula for the redshift

Why is the observation of the cosmological constant a relief for astrophysicists and a problem for theoretical physicists?

(??? do we observe it???)

How can the He abundance tell us about the conditions of the early Universe?

Short questions about homogeneous inflation

What is the horizon problem? How does inflation solve it?

How can we prove that indeed there was an inflation?

What are the conditions for successful slow-roll inflation?

Why do we need slow-rolling of inflation?

Slow roll inflation is quantified in terms of a sequence of parameters which measure the local smoothness of the inflaton potential. The lowest-order parameter is $\epsilon \propto (V'/V)^2$, the next-lowest is $\eta \propto V''/V$, and so on. Higher-order parameters measure ever more localized kinks in the potential.

The values of ϵ, η, etc are constrained by a few different things. For one, inflation needs to last long enough to solve the horizon and flatness problems. Inflation occurs as long as $\epsilon < 1$, and its rate of change is

$$\frac{\mathrm{d}\epsilon}{\mathrm{d}N} = 2\epsilon(\eta - \epsilon)$$

where N is a time variable denoting the number of e-folds before the end of inflation: current estimates require that ΔN be at least around 60. So if ϵ is too large (the potential has too steep a grade), then the field rolls down too quickly to drive sufficient inflation. Also, if η is too large (the potential has too much curvature) then a similar fate awaits. So the first reason we want inflation to be "slow roll" is that we want to get enough inflation, and we need a reasonably flat potential to achieve that.

The other big reason that slow roll inflation is desired is due to the influence that inflationary dynamics have on the shape of the density perturbation spectrum, $P(k)$. Measurements of the cosmic microwave background and large scale structure surveys have revealed that $P(k)$ is very nearly scale invariant, $P(k) \sim k^{n-1}$ with $n \approx 1$. A lengthy and involved (though fun and rewarding) calculation reveals that we can connect the spectral parameters directly to the inflationary dynamics in terms of the slow roll parameters. In particular,

$$n - 1 = 4\epsilon - 2\eta,$$

revealing that slow roll inflation leads to a nearly scale invariant power spectrum.

None of this is to say that there cannot be non-slow roll behavior during inflation, just that it needs to be the exception rather than the rule. There are many models involving localized, transient kinks in the potential that create interesting features in the spectrum on specific scales. People have also looked at "fast roll" inflation in which, though the potential may be flat, the field velocity is high compared to the expansion rate. This is also non-slow roll behavior and one finds that the resulting power spectrum deviates from a power law on the affected scales (fast rolling fields tend to slow down even as they roll down hill during inflation, due to Hubble drag, and so slow roll inflation can be achieved even with initially fast-rolling fields).

Lastly, we only have observations across a limited range of scales (maybe the first dozen or so e-folds of inflation), and so the potential could do all sorts of non-slow roll tricks on these scales (both larger and smaller) as long as sufficient inflation is achieved and there aren't dramatic spikes in the power spectrum (that might, for example, generate unacceptable amounts of primordial black holes.)

Can we produce the CMB power spectrum from a given model of inflation, theoretically? If yes, how?

Absolutely! This is how we learn about the physics of inflation. Given an inflaton potential, we can work out the spectrum of density perturbations it generates. With this power spectrum (plus several so-called "late-time" parameters), we can compute the expected CMB temperature and polarization anisotropies. This is a very involved, multi-step analysis so I will only highlight the main parts here.

Given the scalar inflaton field with potential $V(\phi)$, we write the field as a perturbation about a homogeneous value, $\phi(\mathbf{x}, t) = \phi_0(t) + \delta\phi(\mathbf{x}, t)$, drop it into the Klein Gordon Equation, and obtain,

$$\ddot{\delta\phi} + 3H\dot{\delta\phi} - \left(\frac{\nabla^2}{a^2} - \left.\frac{\mathrm{d}^2 V(\phi)}{\mathrm{d}\phi^2}\right|_{\phi=\phi_0}\right)\delta\phi = 0.$$

Moving to Fourier space gives

$$\ddot{\delta\phi_k} + 3H\dot{\delta\phi_k} + \left(\frac{k}{a}\right)^2 \delta\phi_k = 0.$$

This equation has no general analytic solution, but we can solve it exactly for de Sitter expansion ($H = const$) and then add perturbations to the solution to study the quasi-de Sitter expansion observed during real inflation (so-called *slow roll* inflation, in which time derivatives of H are increasingly suppressed at higher-order). The quantity of interest is the variance (or mean squared amplitude) of the fluctuation,

$$\langle|\delta\phi_k|^2\rangle = \frac{H^2}{2k^3}.$$

This is the variance of the field on horizon scales, where the quantum fluctuation is becoming classical. The variance of the full fluctuation also includes a piece from the *classical* evolution of the field, which is $H^2/\dot{\phi}^2$, giving

$$\langle|\delta_k|^2\rangle = \frac{H^2}{\dot{\phi}^2}\langle|\delta\phi_k|^2\rangle = \frac{H^4}{2\dot{\phi}^2 k^3}.$$

From the total variance, we can form the *power spectrum*, defined

$$P(k) = \frac{k^3}{2\pi^2}\langle|\delta_k|^2\rangle = \frac{1}{4\pi}\frac{H^4}{\dot{\phi}^2}.$$

Notice that the k-dependence is not explicit in this expression: it actually arises from the time-dependence of the cosmological quantities H and $\dot{\phi}$. As modes evolve in time, their amplitudes freeze once they cross the horizon, $k = aH$, and so this expression is to be evaluated at that time. Once we have the power spectrum across the scales of interest, we use it to "seed" the density perturbations in the baryon-photon plasma. These perturbations are what are observed as anisotropies in the temperature and polarization of the CMB.

Since the observed CMB is influenced by more than simply the initial spectrum (the growth of the perturbations from their birth up until last scattering depends on things like the baryon and CDM densities, for example), we must specify several more quantities to obtain the final CMB spectrum. Thankfully, there is publicly-available software that does this (e.g. CAMB). So, for a given initial spectrum $P(k)$ and values for these other quantities, we obtain a set of CMB spectra we can use to compare our model with observations.

Slow roll inflation gives rise to a *power law* spectrum,

$$P(k) = P(k_0)\left(\frac{k}{k_0}\right)^{n-1},$$

where the various parameters can be written in terms of the inflaton potential and field. For example, the *spectral index*, which governs the *tilt* of the spectrum, is determined by the first and second derivatives of the potential,

$$n - 1 = \frac{m_{\rm Pl}^2}{4\pi}\left[\frac{3}{2}\left(\frac{V'}{V}\right)^2 - \frac{V''}{V}\right].$$

This is an example of how a determination of the spectral index (inferred through the CMB anisotropies) can be used to learn about the shape of the inflaton potential. Other spectral parameters, like the overall amplitude and higher-order k-dependence of the spectrum, tell us about the height of the potential and the higher-order ϕ-terms in its Taylor expansion, respectively.

This has been a very high-level and terse answer, since easily an entire textbook could be written that addresses just this topic.

Can there be a non-slow rolling inflation?

What is the value of the pressure in the slow-roll model? Compare to the value in the regular model.

(?? we need negative pressure (? why?) but it is not only in SR, right???)

Short questions about inhomogeneous inflation and initial conditions

Why is the power spectrum of the perturbed scalar field in slow roll inflation related to the power spectrum of density perturbations? (Use equations to proof this)

Short questions about thermal history

Short questions about structure formation

Short questions about anisotropies and CMB

(i) Why do the simplest inflation models predict nearly Gaussian-like perturbations?

(ii) Given a field $f(\mathbf{x})$ and its Fourier expansion with modes $f_{\mathbf{k}}$, with $f_{\mathbf{x}} = a_{\mathbf{k}} + ib_{\mathbf{k}}$, and given the distribution $p\,(a_{\mathbf{k}}, b_{\mathbf{k}})$, argue why p is homogeneous and isotropic.

(iii) For the temperature anisotropy in a given direction, the integrated Sachs-Wolfe term is given by the integral $\frac{\delta T}{T}(\hat{p}) = \int_{\eta_{\mathbf{dec}}}^{\eta_0} (\dot{\psi} - \dot{\phi}) d\eta$. Explain all the symbols in the right hand side. Naively, one might think that the integral over a derivative reduces to the contribution from the two boundaries. Discuss why this is not the case.

(iv) Discuss the significance of the polarization spectra to determine the optical depth to recombination.

Why is statistics necessary to compare the CMB to theoretical predictions?

Below you see a plot of CMB. What should we do to get some information about the Universe?

15 Problems about Special Modesl

15.0.1 Problems about Weak Lensing and Polarization 1

D-1.

The probability that there will be a galaxy massive enough to act as a lens between a quasar at redshift z and us is roughly proportional to the volume between us. Compute

$$V(z) := \int_{x<\chi(z)} d^3x$$

The integral is trivial, but the dependence on z is not. Numerically compute $V(z)$ in a flat universe with cosmological constant. Plot $V(z)$ vs Ω_Λ for $z = 2, 3, 4$. If the galaxy density does not depend on cosmology, then the expected number of lenses scales simply as this volume. For $z = 3$, what is the ratio of lenses expected in a flat universe with $\Omega_\Lambda = 0.7$ as compared with a flat, matter-dominated universe? Be warned that Keeton (2002), among others, has made a strong case that the expected lensing frequency does not vary this dramatically with cosmology because of differences in the galaxy densities in the different models.

D-2.

Compute the magnification of an image in terms of the convergence κ and shear γ_1 and γ_2. Show that, in the limit of weak fields, the magnification μ is related to the convergence via

$$\mu \simeq 1 + 2\kappa$$

D-3.

It is often useful to write observable properties of lenses - such as deflection angles and shear - in terms of a projected potential ϕ.

(a) Using Eq. (10.14), determine the ϕ such that $\vec{\theta}_S = \vec{\theta} + \nabla\phi$ where ∇ is the gradient with respect to the 2D angular variable $\vec{\theta}$.

(b) Express the transformation matrix defined in Eq. (10.15) in terms of the projected potential.

D-4.

When the lens is at a fixed redshift (e.g., a single galaxy or a cluster as opposed to large-scale structure in general) z_L corresponding to comoving distance χ_L from us, show that the projected potential ϕ from the previous problem reduces to

$$\phi\left(\vec{\theta}; z_L\right) = 4G\frac{\chi_S - \chi_L}{\chi_S\chi_L}\int d^2R\Sigma(\vec{R})\ln\left|\vec{R} - \chi_L\vec{\theta}\right|$$

Here χ_S is the comoving distance out to the source; $\vec{R}$ is the radius in the plane perpendicular to the line of sight; and $\Sigma(\vec{R})$ is the projected surface density in this plane.

D-5.

Compute the observed component of ellipticity ϵ_2 from an intrinsically circular source; express it in terms of the components of the transformation matrix, κ, γ_1, and, most importantly, γ_2.

D-6.

(a) Show that the power spectrum of the convergence is given by Eq. (10.35). Show that the power spectrum of γ_2 is given by Eq. (10.36).

(b) Using CMBFAST or the BBKS transfer function, compute numerically P_κ for standard CDM with $\Omega_m = 1, h = 0.5, n = 1$. Assume all background galaxies are at redshift $z = 1$. At what l do you expect your result - based on the linear power spectrum - to lose validity due to nonlinear effects?

D-7.

Equation (10.34) gives the power spectrum of the convergence in the small angle limit ($l \gg 1$). The more general expression is (Stebbins, 1996, the extra factor of $(2\pi)^3$ here due to differing power spectrum conventions)

$$C_{\kappa,l} = 4\pi l^2(l+1)^2\int\frac{d^3k}{(2\pi)^3}k^2I_l^2(k\chi)P_\Phi(k)$$

when all background galaxies are at comoving distance χ and

$$I_l(x) := \int_0^1\frac{dy}{y}(1-y)j_l(xy)$$

(a) Verify, either analytically or numerically, that in the small-angle limit Eq. (10.102) reduces to the expression for $P_\kappa(l)$ in Eq. (10.34).

(b) Redo the calculation of the convergence power spectrum for the sCDM model of Exercise 6, this time using the general expression in Eq. (10.102).

D-8.

In the text, we computed the angular correlations of galaxies (Chapter 9) and the weak lensing correlation function (this chapter). One can also compute the cross-correlation, which measures how correlated the galaxies are with the mass. One way to measure this is to separate a galaxy sample into foreground and background galaxies and measure the cross-correlation between the two samples. Since they are separated by such large distances, the only possible correlation arises because the background galaxies have been magnified by the foreground mass. This problem allows you to work out the background/foreground correlation function (e.g., Moessner and Jain, 1998). Incidentally, this cross-correlation function can also be measured by the QSO/galaxy correlation function. Suppose the 2D overdensity of foreground galaxies is due solely to intrinsic inhomogenities, so that it is given by Eq. (9.3). Assume that the 2D overdensity of background galaxies arises only from magnification. That is, galaxies that should not be included in the survey because they are intrinsically fainter than the magnitude limit are magnified and so appear brighter, thereby making the cut. If the magnification is μ, then the number of background galaxies in an angular patch is

$$n_b = \bar{n}_b\mu^{2.5s-1}$$

Here $\bar{n}_b$ is the average number of background galaxies, and s is defined as $d\log N(m)/dm$ where $N(m)$ is the number of galaxies at the magnitude limit m. For the present problem, don't worry about where this relation comes from (see Broadhurst, Taylor, and Peacock, 1995, for an explanation).

(a) Express δ_b, the background overdensity, in terms of κ and s using Eq. (10.100). (b) Find an expression for the convergence $\kappa(\vec{\theta})$ in terms of the mass overdensity. First express it in terms of the relevant components of transformation matrix A of Eq. (10.17), but then eliminate the potential there in favor of the density field δ.

(c) Using these two expressions - Eq. (9.3) and your answer in (b) - for the foreground and background overdensities, compute the angular cross-correlation function $w_{bg}(\theta) := \langle\delta_b(\theta)\delta_g(0)\rangle$

D-9.

As the wavevector $\vec{k}$ moves out of the $\hat{x}-\hat{z}$ plane, show that the Q polarization (for outgoing radiation in the $\hat{z}$-direction) changes as $\cos(2\phi_k)$. To do this, first compute $\hat{k}\cdot\hat{n}'$, and then integrate $\mathcal{P}_2\left(\hat{k}\cdot\hat{n}'\right)$ over solid angle, with the weighting factor $\sin^2\theta'\cos(2\phi')$ derived in Eq. (10.52).

15.0.2 Problems about Weak Lensing and Polarization 2

D-10.

This problem focuses on the U-component of polarization.

(a) We showed that the Q-component of polarization from unpolarized incident radiation is given by Eq. (10.52), which stems from Eq. (10.50). The Q-component thus depends on the difference between $|\hat{\epsilon}_i\cdot\hat{x}|^2$ and $|\hat{\epsilon}_i\cdot\hat{y}|^2$. For the U-component, $\hat{x}$ and $\hat{y}$ must be replaced by unit vectors rotated 45°, i.e., $(\hat{x}+\hat{y})/\sqrt{2}$ and $(\hat{x}-\hat{y})/\sqrt{2}$. With this replacement, derive Eq. (10.53).

(b) Show that a plane-wave perturbation with wavevector $\vec{k}$ lying in the $\hat{x}-\hat{z}$ plane does not produce any U-polarization in the outgoing $\hat{z}$-direction.

(c) For the most general orientation of the wavevector, $\hat{k} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$, show that U-polarization is given by Eq. (10.60).

D-11.

Draw the polarization patterns near the z-axis arising from a planewave scalar perturbation with (a) $\theta_k = \pi/8, \phi_k = \pi/8$; (b) $\theta_k = 3\pi/4, \phi_k = \pi/4$; (c) $\theta_k = 3\pi/4, \phi_k = 0$; and (d) $\theta_k = 3\pi/2, \phi_k = 0$. In each case, show that the sense of polarization is aligned with (or perpendicular to) the direction in which the polarization strength is changing.

D-12.

In the tight coupling limit, find an expression for $\Pi := \Theta_2 + \Theta_{P2} + \Theta_{P0}$.

(a) When $\dot{\tau}$ is very large, the terms multiplying it on the right hand side of Eq. (10.63) must cancel. Write down this equality for $\Theta_P(\mu)$ in terms of the moments, Θ_2, Θ_{P2}, and Θ_{P0}.

(b) Expand $\Theta_P(\mu)$ in terms of Legendre polynomials, keeping only the monopole and the quadupole. Then equate the coefficients of $\mathcal{P}_0$ and $\mathcal{P}_2$.

(c) This leads to two equations for three unknowns. Show that solving for the two polarization moments in terms of the temperature quadrupole gives $\Theta_{P0} = 5\Theta_2/4$ and $\Theta_{P2} = \Theta_2/4$

(d) Use the results of (c) to determine Π in terms of Θ_2.

D-13.

This problem concerns the rotation matrix R given in Eq. (10.91). (a) Act with R on the unit vector $(0,0,1)$ and show that it gets transformed into $\hat{k}$.

(b) Derive R. One way to do this is to first rotate the $x-y$ - z frame about the z-axis by an angle ϕ'. Then, rotate about the y-axis by an angle $-\theta'$. The product of these two rotations is R.

D-14.

In the text we considered polarization patterns from a single planewave perturbation due to gravity waves. There are actually two such orientations. We considered only $h_\times$. In this problem, consider polarization from h_+. In a frame in which $\hat{k}$ is along the z-axis the anisotropies have a $\sin^2\theta\cos(2\phi)$ dependence. (a) Find the dependence of Θ^T on angle in the more general frame in which $\hat{k}$ does not lie along the z-axis.

(b) Determine Q and U from this incoming distribution. (c) Plot the anisotropy pattern near the outgoing $\hat{z}$-direction for the four sets of θ_k, ϕ_k shown in Figure 10.19.

D-15.

Find expressions for the cross-correlation spectra between the temperature anisotropy and polarization anisotropy $C_{TQ}(\vec{l})$ and $C_{TU}(\vec{l})$ in terms of Θ_l and Θ_{Pl}. Assume scalar perturbations only. Express $C_{TE,l}$ in terms of these.

Solution some problems by Dodelson chapter 10

Solution to

2 The total intensity received at the detector is the angular integral of $I_{\rm obs}\,(\theta)$ over θ. The total intensity emitted is the angular integral of $I_{\rm true}\,(\theta_S)$ over θ_S. The magnification μ is the ratio of the two:

$$\mu \equiv \frac{\int d^2\theta I_{\rm obs}(\theta)}{\int d^2\theta_S I_{\rm true}\,(\theta_S)}$$

Change variables in the denominator to θ, leading to a factor of $\det(A)$ where A is defined in Eq. (10.15). Recall now that $I_{\rm true}\,(\theta_S) = I_{\rm obs}\,(\theta)$, so except for the determinant, the numerator and denominator cancel. This leaves

$$\mu = \frac{1}{\det(A)} = \frac{1}{(1-\kappa)^2 - (\gamma_1^2+\gamma_2^2)}.$$

If all the perturbations are small, then the magnification depends only on κ:

$$\mu \simeq 1 + 2\kappa.$$

Solution to

3 (a) Reading off from Eq. (10.14), we see immediately that

$$\phi = 2\int_0^{\chi S} d\chi \frac{\chi_S - \chi}{\chi_S \chi}\Phi(\chi\vec{\theta},\chi)$$

where I have let $\chi \to \chi_S$ in Eq. (10.14) and replaced the dummy variable χ' there with χ. The only subtlety here is the extra factor of χ in the denominator. This comes from changing the derivative with respect to position (the comma in Eq. (10.14)) to an angular derivative.

Solution to

4 Recall that, in the Newtonian limit, the gravitational potential can be written in terms of the mass density:

$$\Phi(\vec{x}) = -G\int \frac{d^3x'}{|\vec{x}-\vec{x}'|}\rho\,(\vec{x}')$$

We will do this integral in cylindrical coordinates, so that $\vec{x}' = \left(\vec{R},\chi'\right)$. Thus,

$$\phi \simeq -2G\frac{\chi_S - \chi_L}{\chi_S\chi_L}\int d^2R\int d\chi'\rho\left(\vec{R},\chi'\right)\int_0^{\chi s}\frac{d\chi}{\sqrt{\left(\vec{R}-\chi_L\vec{\theta}\right)^2+(\chi-\chi')^2}}$$

where I have set $\chi = \chi_L$ in the slowly varying factors out front. The innermost integral can be done analytically: it is equal to

$$2\ln\left|x+\sqrt{\left(\vec{R}-\chi_L\vec{\theta}\right)^2+x^2}\right)\right|_0^\infty$$

where I have set the upper limit to infinity because there is no contribution to the relevant part of the projected potential from large x. In fact, the only part which depends on $\vec{\theta}$ (and hence is relevant when derivatives are taken) comes from the lower limit: $-2\ln\left|\vec{R}-\chi_L\vec{\theta}\right|$. The integral over χ' then becomes the surface density leaving the desired result.

15.0.3 Problems about Quantum Cosmology (???)

Leuven-2023hw7. Inflation in quantum cosmology (????????)

(?????? тут у меня идейного характера проблемы, так что отдельно нужно засесть в эту задачу!!!)

In this long exercise, we consider the semiclassical approximation of the no-boundary wave function (NBWF). We restrict our attention to FLRW metrics with spherical spatial slices and consider a homogeneous scalar field. Thus, the NBWF is a function of the (real) scale factor b and scalar field value χ. In the semiclassical approxmation, it is given by

$$\Psi(b,\chi) \approx \mathrm{e}^{-\bar{I}(b,\chi)}$$

where $I(b,\chi)$ is the on-shell action of a saddle point. (There could potentially be multiple terms here, but we will only consider one.) The no-boundary proposal is based on a Euclidean path-integral but, as we will see, the saddle points will generically be complex. Hence, they are described by two complex functions $a(\tau)$ and $\phi(\tau)$ taking on the real values b and ϕ, respectively, at some point in the complex τ-plane. The "no-boundary condition" that the saddle should describe a compact, regular geometry reduces to the conditions

$$a(\tau) = \tau + \mathcal{O}\left(\tau^2\right), \quad \phi(\tau) = \phi_0 + \mathcal{O}\left(\tau^2\right)$$

around $\tau = 0$. In the exercise, you will derive some consequences and illustrate some properties of the no-boundary proposal that are valid quite generally in slow-roll inflation. For concreteness, we will consider a quadratic potential for the inflation. The (Euclidean) action of this model is

$$I = \frac{3\pi}{4H^2}\int \mathrm{d}\tau \left[-a\dot{a}^2 - a + a^3 + a^3\left(\dot{\phi}^2 + \mu^2\phi^2\right)\right],$$

which is obtained from

$$I = \int\limits_M \mathrm{d}^4x\sqrt{g}\left[-\frac{1}{16\pi G_N}(R - 2\Lambda) + \frac{1}{2}(\partial\varphi)^2 + \frac{1}{2}m^2\varphi^2\right],$$

by considering Euclidean FLRW metrics $\mathrm{d}s^2 = \mathrm{d}\tilde{\tau}^2 + \tilde{a}^2(\tilde{\tau})\mathrm{d}\Omega_3^2$, where $\mathrm{d}\Omega_3^2$ is the usual metric on the unit three-sphere, and homogeneous scalar fields $\varphi = \varphi(\tilde{\tau})$. To arrive at (3) we have also rescaled the quantities such that everything in (3) is dimensionless, for instance $H^2 = \Lambda/\left(3G_N\right)$.

a) Derive the scalar equation of motion

$$\ddot{\phi} + 3\frac{\dot{a}}{a}\dot{\phi} - \mu^2\phi = 0$$

from (3). Here and below, a dot represents a τ-derivative. Instead of the equation of motion for a, we use the Hamiltonian constraint, which together with the scalar field equation implies the second-order equation for a. To derive the Hamiltonian constraint, change variables from τ to λ by $\mathrm{d}\tau = N\,\mathrm{d}\lambda$ where N is such that the range of λ is $\lambda \in [0,1]$. Since the range of τ was not fixed to begin with, N should be treated as dynamical (even though it does not depend on λ). Show that the Hamiltonian constraint can be written as

$$\left(\frac{\dot{a}}{a}\right)^2 - \frac{1}{a^2} + 1 - \dot{\phi}^2 + \mu^2\phi^2 = 0$$

by demanding that the action is stationary with respect to a variation in N. Interpret the terms in this equation by comparing it to the first Friedmann-Lemaitre equation.

b) The simplest solution to these equations is obtained by setting $\phi = 0$, which reduces the problem to the case with only a cosmological constant and no scalar field. Solve the equation for a in this case. Find the points in the complex τ-plane where $a(\tau) = b \in \mathbb{R}_+$.

Consider now the slow-roll scenario. Recall from the lecture that slow-roll is achieved in a quadratic potential when ϕ is sufficiently large. We will find that many of the properties of the $\phi = 0$ solution generalise to this case. Specifically, the solution will be approximately Euclidean along a horizontal segment starting at $\tau = 0$ and approximately Lorentzian along a vertical line where the scalar field is approximately real as well.

c) Solve (6) close to $\tau = 0$ by using the "no-roll" approximation $\phi \approx \phi_0$. Use (5) to derive the second term in the expansion $\phi = \phi_0 + \mathcal{O}\left(\tau^2\right)$.

d) Show that the slow-roll solution of (5) and (6) is

$$a = A\exp\left[-i\mu\phi_0\tau + \frac{\mu^2}{6}\tau^2\right], \quad \phi = \phi_0 + i\frac{\mu}{3}\tau$$

by assuming that $\ddot{\phi}$ is negligible compared to the other terms in (5) and that the scalar potential term $\mu^2\phi^2$ gives the dominant contribution to $\dot{a}/a$. Comment on the behaviour of a around $\tau = 0$.

g) Show that the classicality condition

$$\left(\nabla \bar{I}^{\mathrm{Re}}\right)^2 \ll \left(\nabla \bar{I}^{\mathrm{Im}}\right)^2$$

is satisfied in the large volume limit. Here,

$$(\nabla \bar{I})^2 = f^{\alpha\beta}\partial_\alpha \bar{I}\partial_\beta \bar{I} = -\frac{2H^2}{3\pi b}\left(\frac{\partial \bar{I}}{\partial b}\right)^2 + \frac{2H^2}{3\pi b^3}\left(\frac{\partial \bar{I}}{\partial \chi}\right)^2$$

where $f_{\alpha\beta}$ is the metric on "minisuperspace" [4] deduced from the kinetic term $\frac{1}{2}f_{\alpha\beta}\dot{q}^\alpha\dot{q}^\beta$ in the action and $f^{\alpha\beta}$ is the inverse of $f_{\alpha\beta}$

$$f_{\alpha\beta} = \frac{3\pi}{2H^2}\begin{pmatrix} -a & 0 \\ 0 & a^3 \end{pmatrix}, \quad f_{\alpha\beta} = \frac{2H^2}{3\pi}\begin{pmatrix} -a^{-1} & 0 \\ 0 & a^{-3} \end{pmatrix}.$$

h) The classicality condition implies that the wave function predicts (approximately) classical histories. These are the integral curves of the $\bar{S} = -\bar{I}^{\mathrm{mm}}$, that is, the solutions to

$$p_\alpha^{\mathrm{cl}} \equiv f_{\alpha\beta}\frac{\mathrm{d}q_{\mathrm{cl}}^\beta}{\mathrm{d}t} = \partial_\alpha \bar{S}\left(q_{\mathrm{cl}}\right)$$

Show, using (12), that these reduce to the classical (Lorentzian) slow-roll equations

$$\frac{\dot{a}_{\mathrm{cl}}}{a_{\mathrm{cl}}} = \mu\phi_{\mathrm{cl}}, \quad \dot{\phi}_{\mathrm{cl}} = -\frac{1}{3}\mu.$$

What does this say about the assumption $\chi \sim \phi_0^{\mathrm{Re}}$ in the calculation of $\bar{I}^{\mathrm{Im}}$?

j) In the approximation we are working

$$\Psi \sim \exp\left[-i\frac{\pi}{2}\frac{\mu\chi b^3}{H^2} + \frac{\pi}{2}\frac{1}{(H\mu\chi)^2}\right].$$

Interpret the weighting $|\Psi|^2$ assigned to the different classical histories. Does this wave function seem to predict many or few efolds of inflation?

e) Next, we want to find a point in the complex τ-plane where $(a, \phi) = (b, \chi)$

i) Assume that ϕ_0 is approximately real and show that the solution valid close to the origin is approximately real along the vertical

$$\tau = \frac{\pi}{2\mu\phi_0^{\mathrm{Re}}} + iy, \quad \text{where} \quad \phi_0^{\mathrm{Re}} = \mathrm{Re}\left(\phi_0\right), \quad y \in \mathbb{R}.$$

Verify that the approximate solution is valid at $y = 0$ by checking that the $\mathcal{O}\left(\tau^2\right)$ term in ϕ is small. ii) Now use the slow-roll solution and show that requiring that ϕ is approximately real along the same vertical implies that

$$\phi_0^{\mathrm{Im}} = -\frac{\pi}{6\phi_0^{\mathrm{Rm}}}, \quad \text{where } \phi_0^{\mathrm{Im}} = \mathrm{Im}\,\phi_0,$$

consistent with the assumption that the imaginary part of ϕ_0 is small since we are assuming that ϕ_0^{Re} is large to be in the slow-roll regime. iii) Show that A in the slow-roll solution is given by

$$A \approx \frac{i}{\mu\phi_0^{\mathrm{Re}}}$$

by matching the two solutions at $y = 0$. Then verify that the slow-roll solution is approximately real along the same vertical. [3]

We have now found approximate saddles describing complex slow-roll saddles. The two parameters that are left unfixed, ϕ_0^{Re} and y, determine the arguments of the wave function, χ and b.

f) At last, we compute the on-shell action (and hence Ψ in the semiclassical approximation) using the approximate solutions.

i) First simplify the on-shell action by using (6) to eliminate $\dot{a}$ in (3).

ii) The dominant contribution to the real part comes from the approximately Euclidean region. Use the approximate solution valid there to show that

$$\bar{I}^{\mathrm{Re}} \approx -\frac{\pi}{2\left(H\mu\phi_0^{\mathrm{Re}}\right)^2}$$

iii) The main contribution to the imaginary piece of the action evaluated on the saddle, on the other hand, comes from the approximately Lorentzian region. To simplify the calculation, assume that $\chi \approx \phi_0^{\mathrm{Re}}$. Show that

$$\bar{I}^{\mathrm{Im}} \sim \frac{\pi\mu\chi b^3}{2H^3}$$

Comments about this problem

One might think that initially $\psi_0 = 0$ because there diff. eq. tells us this. (??? I'll add explanation of this, didn't finish thinking about it)

Part VI
Other Topics in Cosmology

(мб потом отдельные части про них сделаю, пока всё остальное тут.)

16 Stochastic backgrounds of cosmological origin

22.1 Characteristic frequency of relic GWs
22.2 GW production by classical fields
22.3 GWs from preheating after inflation
22.4 GWs from first-order phase transitions
22.5 Cosmic strings
22.6 Alternatives to inflation
22.7 Bounds on primordial GW backgrounds

In Chapter 21 we have studied in detail the production of a stochastic GW background due to the amplification of vacuum fluctuations during inflation. Because of its potential importance, and of the many technical steps needed in the relevant computations, we devoted a full chapter to this topic. In this chapter we will examine several other cosmological production mechanisms that have been proposed in the literature, and we will then summarize the present knowledge on stochastic GW backgrounds.

16.1 22.1 Characteristic frequency of relic GWs

We first discuss what is the typical frequency today of a GW signal of cosmological origin. Part of the answer depends on the dynamics of the production mechanism, and therefore is model-dependent, and part is kinematic, depending on the redshift from the production era to the present time. First of all, it is useful to separate the kinematics from the dynamics.

We consider a graviton produced with a frequency f_*, at a production time $t = t_*$, when the temperature had a value T_*, within the RD or MD phases. Its frequency today is redshifted to a value $f_0 = f_* a(t_*)/a(t_0)$. To compute the ratio $a(t_*)/a(t_0)$ we use eq. (17.113), setting $a_r = a_0 = 1$ and $T_r = T_0 \simeq 2.7255(6)$K. This gives

$$f_0 = f_* \frac{a(t_*)}{a(t_0)} \simeq 7.80 \times 10^{-14} f_* \left(\frac{106.75}{g_*^S(T_*)}\right)^{1/3} \left(\frac{1\text{GeV}}{T_*}\right) \tag{22.1}$$

where, as usual, we have normalized the effective number of relativistic species to its high-energy value in the Standard Model; see Section 17.5. We now want to estimate the characteristic value of the frequency f_* of a graviton produced in the early Universe at time t_*, when the temperature was T_*. Here of course the dynamics of the specific production mechanism enters, but still some general considerations are possible. One of the relevant parameters in this estimate is certainly the Hubble parameter at the time of production, $H(t_*) \equiv H_*$. It can then be useful to write the reduced wavelength λ_* of a graviton at the time of production as

$$\lambda_* = \epsilon_* H_*^{-1} \tag{22.2}$$

Since H_*^{-1} is the size of the horizon at time t_*, $\epsilon_* > 1$ corresponds to super-horizon modes at the time of production. Because of causality, the generation of super-horizon modes will be suppressed. This does not mean that the production of modes with $\epsilon_* > 1$ is strictly

forbidden by causality. The spectrum of modes produced by causal mechanisms is continuous with frequency, and does not drop suddenly to zero below a critical frequency. Thus, to some extent, even super-horizon modes are produced. However, at sufficiently low frequencies, such that the corresponding wavelengths are well outside the horizon, causality requires that their spectrum goes to zero, as $f \to 0$, as

$$h_0^2 \Omega_{\rm gw}(f) \propto f^3 \tag{22.3}$$

This follows from the fact, for super-horizon modes, the source term $\tilde{\sigma}_A^{\rm TT}(\mathbf{k})$ in eq. (19.220) should have a flat power spectrum, i.e. $\left\langle \left|\tilde{\sigma}_A^{\rm TT}(\mathbf{k})\right|^2 \right\rangle$ will be independent of $\mathbf{k}$. This corresponds to white noise and reflects the absence of causal correlations. The same will then be true for $\tilde{h}_A(\mathbf{k})$. This means that, for super-horizon modes, the power spectrum $\mathcal{P}_T(k)$ at the time of production satisfies

$$\mathcal{P}_T(k) \propto k \tag{22.4}$$

[see eq. (19.280)] or, equivalently, $S_h(f)$ in eq. (19.284) is independent of the frequency (recall that $k = 2\pi f$). Then, from eq. (19.288) or from eq. (7.202) of Vol. 1, we get eq. (22.3).

Thus, for typical gravitons produced at time t_*, we expect $\epsilon_* = O(1)$ or smaller. More precisely, in the absence of any other length-scale in the problem, we can indeed expect that the peak of the spectrum will be at $\epsilon_* = O(1)$, while if other length-scales smaller than H_*^{-1} enter the problem (or small dimensionless parameters such as a speed of sound $c_s^2 < 1$) , ϵ_* will in general be some orders of magnitude smaller than 1.

During RD, $H_*^2 = (8\pi/3) G \rho_{\rm rad}$. Then, from eq. (17.98),

$$H_*^2 = \frac{\pi^2 g_* T_*^4}{90 m_{\rm Pl}^2} \tag{22.5}$$

and, using $2\pi f_* \equiv H_*/\epsilon_*$, eq. (22.1) can be written as

$$f_0 \simeq 2.65 \times 10^{-8} \frac{1}{\epsilon_*} \left(\frac{T_*}{1{\rm GeV}}\right) \left(\frac{g_*}{106.75}\right)^{1/6} \ {\rm Hz} \tag{22.6}$$

The effect of the dynamics on the value of f_0 has therefore been isolated into the parameter ϵ_*[1]

We will typically be interested in production mechanisms taking place at temperatures $T \gtrsim 100{\rm GeV}$. Then the relation between time and temperature during the RD phase can be obtained using eqs. (17.114) and

Table 22.1 The production time t_* and the production temperature T_* for GWs observed today at frequency f_0, if at the time of production they had a reduced wavelength equal to the horizon scale.

f_0(Hz)	t_*(s)	T_*(GeV)
10^{-4}	1.6×10^{-14}	3.8×10^3
1	1.6×10^{-22}	3.8×10^7
10^2	1.6×10^{-26}	3.8×10^9
10^3	1.6×10^{-28}	3.8×10^{10}

(17.138). Inserting the numerical values, this gives

$$t_* \simeq 0.23 \left(\frac{106.75}{g_*}\right)^{1/2} \left(\frac{1{\rm MeV}}{T_*}\right)^2 \ {\rm s} \tag{22.7}$$

This tells us how far back in time we are exploring the Universe, when we observe a graviton produced at temperature T_*. Using eq. (22.6) we see that, by detecting a stochastic background of relic GWs that today has a typical frequency f_0, we are looking back at the Universe at time

$$t_* \simeq 1.6 \times 10^{-22} \frac{1}{\epsilon_*^2} \left(\frac{1\ \text{Hz}}{f_0}\right)^2 \left(\frac{106.75}{g_*}\right)^{1/6}\ \text{s} \tag{22.8}$$

Table 22.1 gives some representative values for the production time t_* and the temperature of the Universe T_* corresponding to frequencies relevant to space-borne and to ground-based interferometers, setting $\epsilon_* = 1$. One should, however, keep in mind that the estimate $\epsilon_* \sim 1$ can sometimes be incorrect, even as an order of magnitude. We will later illustrate this point with some specific examples. The values in Table 22.1 are more correctly interpreted as a starting point for understanding how the result is affected by the dynamics of the specific production mechanism.

The highest possible value of the frequency that a relic GW frequency could have today can be obtained assuming that at the Planck epoch a graviton is produced with energy of order of the reduced Planck mass $m_{\rm Pl}$, and redshifting it to the present epoch, assuming no inflationary phase and only RD followed by MD. This would give

$$f_0 \simeq 64 \left(\frac{g_*}{106}\right)^{1/6} \text{GHz} \quad (T_* \simeq m_{\rm Pl}) \tag{22.9}$$

The dependence on g_* is rather weak because of the power 1/6 in eq. (22.6). For $g_* = 1000$, f_0 only increases by a factor ~ 1.5 relative to $g_* = 100$. More realistically, we have by now very convincing evidence for the existence of an inflationary phase in the early Universe, so the maximum production temperature for primordial gravitons should rather be determined by the reheating temperature. Indeed, a stochastic background produced by classical mechanisms before inflation would be diluted and completely washed away by the subsequent inflationary phase. As we already mentioned in Chapter 21, the reheating temperature is at most equal to the inflationary scale (if reheating is almost instantaneous and all the energy density in the inflaton field is immediately converted into radiation), and in typical reheating models is several orders of magnitude lower. With the existing bounds on the scale of inflation discussed in Section 21.3.6, the highest possible frequency today of a relic GW background will rather be $O(0.1)$GHz [see eq. (21.361)], and possibly much smaller, depending on the reheating temperature.

16.1.1 22.2 GW production by classical fields

16.1.2 22.2.1 General formalism

We now study the GWs produced by a classical field. The subject is conceptually interesting by itself, and covers a broad range of situations. [2]

We consider a generic inhomogeneous, time-evolving scalar field in an expanding universe. Such a field has a time-varying and spatially dependent energy-momentum tensor and is therefore in general a source for a stochastic background of GWs. The simplest approach for computing the resulting GW production, which indeed was used in early papers on the subject, is to use the formalism reviewed in Section 3.1 of Vol. 1 [and originally developed in Section 10.4 of the textbook by Weinberg (1972)]. In particular, in this formalism the GW amplitude in the far zone and the GW energy spectrum are given, in terms of the energy-momentum tensor of the source, by eqs. (3.14) and (3.16), which we recall here, [3]

$$h_{ij}^{\rm TT}(t,\mathbf{x}) = \frac{4G}{r}\Lambda_{ij,kl}(\hat{\mathbf{n}}) \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \tilde{T}_{kl}(\omega, \omega\hat{\mathbf{n}}) e^{-i\omega(t-r)} \tag{22.10}$$

$$\frac{dE_{\rm gw}}{d\Omega} = \frac{G}{2\pi^2}\Lambda_{ij,kl}(\hat{\mathbf{n}}) \int_{0}^{\infty} d\omega \omega^2 \tilde{T}_{ij}(\omega, \omega\hat{\mathbf{n}}) \tilde{T}^*_{kl}(\omega, \omega\hat{\mathbf{n}}) \tag{22.11}$$

where $\Lambda_{ij,kl}$ is the Lambda tensor that projects onto the TT gauge, defined in eq. (1.36), and $\hat{\mathbf{n}}$ is the propagation direction of the wave. One could then take an ensemble average of $\left\langle \tilde{T}_{ij}(\omega, \omega\hat{\mathbf{n}}) \tilde{T}^*_{kl}(\omega, \omega\hat{\mathbf{n}}) \right\rangle$, to compute the resulting stochastic background. However, in the present cosmological setting such an approach would be inadequate for several reasons. First of all, in this case the source is not localized and therefore there is no wave zone where eq. (22.10) could hold. Second, this expression has been obtained by expanding the metric perturbation around flat space, rather than around the FRW background. The correct approach is to use cosmological perturbation theory, as we have developed in Chapter 19. In particular, the dynamics of the tensor perturbations is given by eq. (19.220), where the source term σ_A is defined by eqs. (18.114), (18.120), (18.123) and (19.215). In Section 19.5 we were mostly interested in the evolution of the GWs, given some initial value $h_{A,\,\rm in}$, so in eq. (19.220) we set the source term to zero (except when we studied the effect of neutrino free-streaming). Here we are considering the production mechanism, so the role of σ_A is crucial.

Lowering the upper index in eq. (18.114), the helicity decomposition of a generic energy-momentum tensor T_{ij} reads

$$T_{ij} = a^2 \left(p\delta_{ij} + \Sigma_{ij} \right) \tag{22.12}$$

where Σ_{ij} is given in eqs. (18.120)-(18.123). The tensor $T_{ij}^{\rm TT} = a^2 \sigma_{ij}^{\rm TT}$ is the TT part of T_{ij}. It follows from the discussion in Section 1.2 that it can be extracted from T_{ij} by taking the Fourier transform and multiplying the momentum mode $\tilde{T}_{ij}(\mathbf{k})$ by the Lambda tensor $\Lambda_{ij,kl}(\hat{\mathbf{k}})$.

It is convenient to introduce the field $\mathrm{h}_{ij} = a h_{ij}$ and, correspondingly, $\mathrm{h}_A = a h_A$, similarly to what we did in Section 21.3.4 [where we introduced φ_A from eq. (21.309) and, as in eq. (21.177), $\chi_A = a\varphi_A$]. Then eq. (19.220) becomes

$$\tilde{\mathrm{h}}_A''(\mathbf{k}) + \left(k^2 - \frac{a''}{a} \right) \tilde{\mathrm{h}}_A(\mathbf{k}) = 16\pi G a^3 \tilde{\sigma}_A^{\rm TT}(\mathbf{k}) \tag{22.13}$$

This equation further simplifies if the typical momenta $\mathbf{k}$ for which the source term is important are well inside the horizon. For such momenta $k^2 \gg a''/a \sim 1/\eta^2$, and we can solve eq. (22.13) using the retarded Green's function of the operator $\partial_\eta^2 + k^2$. This is just the well-known retarded Green's function of the harmonic oscillator,

$$G\left(\eta - \eta'\right) = \frac{\sin\left[k\left(\eta - \eta'\right)\right]}{k} \theta\left(\eta - \eta'\right) \tag{22.14}$$

In particular, if we assume that before an initial conformal time η_i the source was not active, and as initial condition we set $\tilde{\mathrm{h}}_A\left(\eta_i, \mathbf{k}\right) = \tilde{\mathrm{h}}_A'\left(\eta_i, \mathbf{k}\right) = 0$, the solution is

$$\tilde{\mathrm{h}}_A(\eta,\mathbf{k}) = 16\pi G \int_{-\infty}^{\infty} d\eta' G\left(\eta-\eta'\right) a^3\left(\eta'\right) \tilde{\sigma}_A^{\mathrm{TT}}\left(\eta',\mathbf{k}\right)$$
$$= \frac{16\pi G}{k} \int_{\eta_i}^{\eta} d\eta' \sin\left[k\left(\eta-\eta'\right)\right] a^3\left(\eta'\right) \tilde{\sigma}_A^{\mathrm{TT}}\left(\eta',\mathbf{k}\right) \tag{22.15}$$

If the source turns off at some final conformal time η_f, then

$$\tilde{\mathrm{h}}_A\left(\eta_f,\mathbf{k}\right) = \frac{16\pi G}{k} \int_{\eta_i}^{\eta_f} d\eta' \sin\left[k\left(\eta_f-\eta'\right)\right] a^3\left(\eta'\right) \tilde{\sigma}_A^{\mathrm{TT}}\left(\eta',\mathbf{k}\right) \tag{22.16}$$

is the initial value of the subsequent free evolution. During RD and MD, modes that were generated as sub-horizon remain inside the horizon, so their subsequent evolution is determined by eq. (22.13) with the source term set to zero and again $|a''/a| \ll k^2$, i.e. by the free wave equation

$$\tilde{\mathrm{h}}_A'' + k^2 \tilde{\mathrm{h}}_A \simeq 0 \tag{22.17}$$

whose solution is simply

$$\tilde{\mathrm{h}}_A(\eta,\mathbf{k}) = \mathcal{A}_A(\mathbf{k}) \sin\left[k\left(\eta-\eta_f\right)\right] + \mathcal{B}_A(\mathbf{k}) \cos\left[k\left(\eta-\eta_f\right)\right] \quad (\eta \geqslant \eta_f) \tag{22.18}$$

Matching at $\eta = \eta_f$ the values of $\tilde{\mathrm{h}}_A$ and $\tilde{\mathrm{h}}_A'$ obtained from eqs. (22.16) and (22.18) one finds

$$\mathcal{A}_A(\mathbf{k}) = \frac{16\pi G}{k} \int_{\eta_i}^{\eta_f} d\eta' \cos\left[k\left(\eta_f-\eta'\right)\right] a^3\left(\eta'\right) \tilde{\sigma}_A^{\mathrm{TT}}\left(\eta',\mathbf{k}\right) \tag{22.19}$$

$$\mathcal{B}_A(\mathbf{k}) = \frac{16\pi G}{k} \int_{\eta_i}^{\eta_f} d\eta' \sin\left[k\left(\eta_f-\eta'\right)\right] a^3\left(\eta'\right) \tilde{\sigma}_A^{\mathrm{TT}}\left(\eta',\mathbf{k}\right) \tag{22.20}$$

The corresponding GW energy density is given by eq. (1.136). Expressed in terms of h and of conformal time, it reads

$$\rho_{\mathrm{gw}}(\eta) = \frac{1}{16\pi G a^4} \sum_{A=+,\times} \left\langle \left(\mathrm{h}_A' - \mathcal{H}\mathrm{h}_A\right)^2(\eta,\mathbf{x}) \right\rangle \tag{22.21}$$

where $\langle \ldots \rangle$ represents a spatial average over several wavelengths and, as usual, $f' \equiv df/d\eta$. For sub-horizon modes, $\mathrm{h}_A' \sim k\ \mathrm{h}_A \gg \mathcal{H}\mathrm{h}_A$, so the second term in parentheses can be neglected, and, in this limit,

$$\rho_{\mathrm{gw}}(\eta) = \frac{1}{16\pi G a^4} \sum_{A=+,\times} \left\langle \mathrm{h}_A'^2(\eta,\mathbf{x}) \right\rangle \tag{22.22}$$

We now expand $\mathbf{h}_A'(\eta,\mathbf{x})$ in Fourier modes. Then

$$\left\langle \mathbf{h}_A'^2(\eta,\mathbf{x}) \right\rangle = \int \frac{d^3k}{(2\pi)^3} \frac{d^3k'}{(2\pi)^3} \mathbf{h}_A'(\eta,\mathbf{k}) \mathbf{h}_A'^*\left(\eta,\mathbf{k}'\right) \left\langle e^{i(\mathbf{k}-\mathbf{k}')\cdot\mathbf{x}} \right\rangle \tag{22.23}$$

The spatial average over a volume V of size much larger than the reduced wavelengths $1/k$ and $1/k'$ gives

$$\left\langle e^{i(\mathbf{k}-\mathbf{k}')\cdot\mathbf{x}}\right\rangle = \frac{(2\pi)^3}{V}\delta^{(3)}\left(\mathbf{k}-\mathbf{k}'\right) \tag{22.24}$$

so in the end we get

$$\rho_{\rm gw}(\eta) = \frac{1}{16\pi G a^4}\frac{1}{V}\sum_{A=+,\times}\int\frac{d^3k}{(2\pi)^3}\mid \mathrm{h}'_A(\eta,\mathbf{k})\mid^2 \tag{22.25}$$

where $\mathrm{h}_A(\eta,\mathbf{k})$ is given by eq. (22.15) for $\eta\leqslant\eta_f$, and by eq. (22.18) for $\eta\geqslant\eta_f$. Observe that this formalism allows us to follow the time evolution of the energy density in the tensor perturbations, not only during the period in which the source is no longer active and the tensor perturbations evolve freely in a FRW background, but even in the earlier epoch when the source was active and the tensor perturbations were building up. For $\eta\geqslant\eta_f$ eq. (22.25) can be further simplified if we are not interested in the details of the time evolution of the signal on time-scales of the order of $1/k$ or smaller. In this case we can further perform a temporal average of $\rho_{\rm gw}$ over several periods, retaining only the coarser features of the temporal evolution. Then, using eq. (22.18), together with $\left\langle\sin^2\left[k\left(\eta-\eta_f\right)\right]\right\rangle = \left\langle\cos^2\left[k\left(\eta-\eta_f\right)\right]\right\rangle = 1/2$ and $\langle\sin[k(\eta-\eta_f)]\cos\left[k\left(\eta-\eta_f\right)\right]\rangle = 0$, we get[4]

$$\begin{aligned}\rho_{\rm gw}\left(\eta\geqslant\eta_f\right) &= \frac{1}{32\pi G a^4(\eta)V}\sum_{A=+,\times}\int\frac{d^3k}{(2\pi)^3}k^2\left[\left|\mathcal{A}_A(\mathbf{k})\right|^2+\left|\mathcal{B}_A(\mathbf{k})\right|^2\right]\\ &= \frac{4\pi G}{a^4(\eta)V}\sum_{ij}\int\frac{d^3k}{(2\pi)^3}\left[\left|\int_{\eta_i}^{\eta_f}d\eta'\cos\left(k\eta'\right)a\left(\eta'\right)\tilde{T}_{ij}^{\rm TT}\left(\eta',\mathbf{k}\right)\right|^2\right.\\ &\qquad\left.+\left|\int_{\eta_i}^{\eta_f}d\eta'\sin\left(k\eta'\right)a\left(\eta'\right)\tilde{T}_{ij}^{\rm TT}\left(\eta',\mathbf{k}\right)\right|^2\right]\end{aligned}$$

[4] See eq. (26) of Dufaux, Bergman, Felder, Kofman and Uzan (2007). The different factor $(2\pi)^3$ follows from our different conventions for the Fourier transform.

$$= \frac{4\pi G}{a^4(\eta)V}\sum_{ij}\int\frac{d^3k}{(2\pi)^3}\int_{\eta_i}^{\eta_f}d\eta' d\eta'' a\left(\eta'\right)a\left(\eta''\right)\cos\left[k\left(\eta'-\eta''\right)\right]\quad\tilde{T}_{ij}^{\rm TT}\left(\eta',\mathbf{k}\right)\tilde{T}_{ij}^{*,\rm TT}\left(\eta'',\mathbf{k}\right) \tag{22.26}$$

where in the second equality we have expanded $\cos\left[k\left(\eta_f-\eta'\right)\right]$ and $\sin\left[k\left(\eta_f-\eta'\right)\right]$ in terms of sin and cos of $k\eta_f$ and $k\eta'$ and recombined the various terms. We have also made use of

$$\sum_A\left|\tilde{\sigma}_A\right|^2 = \frac{1}{2}\sum_{ij}\left|\tilde{\sigma}_{ij}\right|^2 \tag{22.27}$$

which follows from eqs. (19.215) and (19.218), and we have used $T_{ij}^{\rm TT} = a^2\sigma_{ij}^{\rm TT}$ instead of $\sigma_{ij}^{\rm TT}$. The overall factor $1/a^4$ correctly gives the cosmological redshift of the energy density of the GWs, as it should for sub-horizon modes; compare with the discussion in Section 19.5.1.

These results allow us to compute the energy density of the GWs generated by a given classical source in a FRW background. In the special case of a localized source in flat space, we must therefore be able to recover eq. (22.11). Observe that eq. (22.11) gives the total energy radiated by the source, up to time $+\infty$. To recover it, we therefore set $a(\eta)=1$ in eq. (22.26)

(so η becomes the same as t) and we extend the integration up to $\eta_f = \infty$. Recall that the lower limit of integration was actually $\eta = -\infty$, which we replaced by η_i because the source was not active before η_i; see eq. (22.15). So, the total GW energy density produced by the source in the flat-space limit, as predicted by eq. (22.26), is

$$\rho_{\rm gw} = \frac{2\pi G}{V}\sum_{ij}\int\frac{d^3k}{(2\pi)^3}\int_{-\infty}^{+\infty}dt'dt''\left[e^{ik(t'-t'')}\tilde{T}_{ij}^{\rm TT}\left(t',\mathbf{k}\right)\tilde{T}_{ij}^{*,\rm TT}\left(t'',\mathbf{k}\right)+e^{-ik(t'-t'')}\tilde{T}_{ij}^{\rm TT}\left(t',\mathbf{k}\right)\tilde{T}_{ij}^{*,\rm TT}\left(t'',\mathbf{k}\right)\right]$$
$$= \frac{4\pi G}{V}\sum_{ij}\int\frac{d^3k}{(2\pi)^3}\tilde{T}_{ij}^{\rm TT}(k,\mathbf{k})\tilde{T}_{ij}^{*,\rm TT}(k,\mathbf{k}) \tag{22.28}$$

where, in the last line, $\tilde{T}_{ij}^{\rm TT}(\omega,\mathbf{k})$ (with $\omega = k$) is the Fourier transform of $\tilde{T}_{ij}^{\rm TT}(t,\mathbf{k})$ with respect to the time variable. We next write (with the summation over repeated indices understood)

$$\begin{aligned}\tilde{T}_{ij}^{\rm TT}(k,\mathbf{k})\tilde{T}_{ij}^{*,\rm TT}(k,\mathbf{k}) &= \Lambda_{ij,kl}(\hat{\mathbf{k}})\tilde{T}_{kl}(k,\mathbf{k})\Lambda_{ij,mn}(\hat{\mathbf{k}})\tilde{T}_{mn}^{*}(k,\mathbf{k})\\ &= \Lambda_{kl,mn}(\hat{\mathbf{k}})\tilde{T}_{kl}(k,\mathbf{k})\tilde{T}_{mn}^{*}(k,\mathbf{k})\end{aligned} \tag{22.29}$$

where we have used $\Lambda_{ij,kl}(\hat{\mathbf{k}})\Lambda_{ij,mn}(\hat{\mathbf{k}}) = \Lambda_{kl,mn}(\hat{\mathbf{k}})$; see eq. (1.37). Then the total GW energy $E_{\rm gw} = V\rho_{\rm gw}$ is given by

$$\begin{aligned}E_{\rm gw} &= 4\pi G\Lambda_{ij,kl}\int\frac{d^3k}{(2\pi)^3}\tilde{T}_{ij}(k,\mathbf{k})\tilde{T}_{kl}^{*}(k,\mathbf{k})\\ &= \frac{G}{2\pi^2}\Lambda_{ij,kl}\int_0^\infty k^2dk\int d\Omega\tilde{T}_{ij}(k,\mathbf{k})\tilde{T}_{kl}^{*}(k,\mathbf{k})\end{aligned} \tag{22.30}$$

Therefore, in the flat-space limit, $dE_{\rm gw}/d\Omega$ is indeed given by eq. (22.11).

16.1.3 22.2.2 GW generation by a stochastic scalar field

If the source is given by random fields, a stochastic average over the field configurations is further required. Thus, the energy density becomes

$$\begin{aligned}\rho_{\rm gw}(\eta) =& \frac{4\pi G}{a^4(\eta)V}\int\frac{d^3k}{(2\pi)^3}\int_{\eta_i}^{\eta_f}d\eta'd\eta''a\left(\eta'\right)a\left(\eta''\right)\cos\left[k\left(\eta'-\eta''\right)\right]\\ &\times\sum_{ij}\left\langle\tilde{T}_{ij}^{\rm TT}\left(\eta',\mathbf{k}\right)\tilde{T}_{ij}^{*,\rm TT}\left(\eta'',\mathbf{k}\right)\right\rangle\end{aligned} \tag{22.31}$$

where now $\langle\ldots\rangle$ denotes the ensemble average over the field configurations. We consider for illustration a single scalar field ϕ with action (21.22). The energy-momentum tensor is then given by eq. (21.24), so in particular

$$T_{ij} = \partial_i\phi\partial_j\phi - g_{ij}\left[\frac{1}{2}g^{\rho\sigma}\partial_\rho\phi\partial_\sigma\phi + V(\phi)\right] \tag{22.32}$$

In eq. (22.32), writing $g_{ij} = a^2(\delta_{ij} + h_{ij})$, the term h_{ij} gives a secondorder contribution, in which the GWs produced at first order become themselves sources for further GW production. To first order, we can therefore replace g_{ij} by $a^2\delta_{ij}$. Then, recalling that $\Lambda_{ij,kl}\delta_{kl} = 0$, to first order the term in square brackets in eq. (22.32) does not contribute to the TT part, and we obtain

$$\begin{aligned}\tilde{T}^{\rm TT}_{ij}(\eta,\mathbf{k}) &= \Lambda_{ij,kl}(\hat{\mathbf{k}})\tilde{T}_{kl}(\eta,\mathbf{k}) \\ &= \Lambda_{ij,kl}(\hat{\mathbf{k}})\int d^3x e^{-i\mathbf{k}\cdot\mathbf{x}}\partial_k\phi\partial_l\phi \\ &= \Lambda_{ij,kl}(\hat{\mathbf{k}})\int \frac{d^3p}{(2\pi)^3}p_k(p-k)_l\tilde{\phi}(\eta,\mathbf{p})\tilde{\phi}(\eta,\mathbf{k}-\mathbf{p})\end{aligned} \tag{22.33}$$

Recalling further from Section 1.2 that $\Lambda_{ij,kl}(\hat{\mathbf{k}})k_l = 0$, we get

$$\tilde{T}^{\rm TT}_{ij}(\eta,\mathbf{k}) = \Lambda_{ij,kl}(\hat{\mathbf{k}})\int \frac{d^3p}{(2\pi)^3}p_kp_l\tilde{\phi}(\eta,\mathbf{p})\tilde{\phi}(\eta,\mathbf{k}-\mathbf{p}) \tag{22.34}$$

Then

$$\begin{aligned}\sum_{ij}\left\langle \tilde{T}^{\rm TT}_{ij}(\eta',\mathbf{k})\,\tilde{T}^{*,\rm TT}_{ij}(\eta'',\mathbf{k})\right\rangle &= \Lambda_{kl,mn}(\hat{\mathbf{k}})\int\frac{d^3p}{(2\pi)^3}\frac{d^3p'}{(2\pi)^3} \\ \times p_kp_lp'_mp'_n\left\langle\tilde{\phi}(\eta',\mathbf{p})\,\tilde{\phi}(\eta',\mathbf{k}-\mathbf{p})\,\tilde{\phi}^*(\eta'',\mathbf{p}')\,\tilde{\phi}^*(\eta'',\mathbf{k}-\mathbf{p}')\right\rangle\end{aligned} \tag{22.35}$$

where we have again used $\Lambda_{ij,kl}(\hat{\mathbf{k}})\Lambda_{ij,mn}(\hat{\mathbf{k}}) = \Lambda_{kl,mn}(\hat{\mathbf{k}})$. If the random field ϕ obeys Gaussian statistics, [5] the four-point correlator can be computed in terms of the two-point functions using Wick's theorem,

$$\begin{aligned}&\left\langle\tilde{\phi}(\eta',\mathbf{p})\,\tilde{\phi}\,(\eta',\mathbf{k}-\mathbf{p})\,\tilde{\phi}^*(\eta'',\mathbf{p}')\,\tilde{\phi}^*(\eta'',\mathbf{k}-\mathbf{p}')\right\rangle \\ &\qquad= \left\langle\tilde{\phi}(\eta',\mathbf{p})\,\tilde{\phi}^*(\eta',\mathbf{p}-\mathbf{k})\right\rangle\left\langle\tilde{\phi}(\eta'',-\mathbf{p}')\,\tilde{\phi}^*(\eta'',\mathbf{k}-\mathbf{p}')\right\rangle \\ &\qquad+ \left\langle\tilde{\phi}(\eta',\mathbf{p})\,\tilde{\phi}^*(\eta'',\mathbf{p}')\right\rangle\left\langle\tilde{\phi}(\eta',\mathbf{k}-\mathbf{p})\,\tilde{\phi}^*(\eta'',\mathbf{k}-\mathbf{p}')\right\rangle \\ &\qquad+ \left\langle\tilde{\phi}(\eta',\mathbf{p})\,\tilde{\phi}^*(\eta'',\mathbf{k}-\mathbf{p}')\right\rangle\left\langle\tilde{\phi}(\eta',\mathbf{k}-\mathbf{p})\,\tilde{\phi}^*(\eta'',\mathbf{p}')\right\rangle\end{aligned} \tag{22.36}$$

[5] In the case of preheating that we will discuss in Section 22.3, this is only true in the initial linear phase. At the end of the preheating phase the dynamics becomes highly non-linear, and the fields strongly non-Gaussian.

[6] Observe that in all computations in this section we use the normalization (17.39) of the Fourier transform, rather than the normalization (19.161). Therefore there is no explicit factor $1/V$ in eq. (22.37), in contrast to eq. (19.164), where the normalization (19.161) was used.

[7] Observe that this contraction corresponds to a disconnected diagram, in which the two fields at time η are contracted among themselves, and also the two fields at time η' are contracted among them. So, the disconnected diagram does not contribute, as we know from experience with quantum field theory. Technically, disconnected diagrams can just be reabsorbed into a redefinition of $\tilde{T}^{\rm TT}_{ij}(\eta,\mathbf{k})$, which is equivalent to a renormalization of the corresponding operator in the fieldtheoretical language. where we have used $\tilde{\phi}(\eta,-\mathbf{k}) = \tilde{\phi}^*(\eta,\mathbf{k})$ for real fields. Assuming invariance under spatial translations and rotations, the two-point function has the general form

$$\left\langle \tilde{\phi}\left(\eta', \mathbf{p}\right) \tilde{\phi}^{*}\left(\eta'', \mathbf{p}'\right) \right\rangle = (2\pi)^3 \delta^{(3)}\left(\mathbf{p}-\mathbf{p}'\right) F\left(\eta', \eta''; p\right) \tag{22.37}$$

where the proportionality to $\delta^{(3)}\left(\mathbf{p}-\mathbf{p}'\right)$ follows from invariance under spatial translations, and the dependence of the function $F\left(\eta', \eta''; p\right)$ on $p = |\mathbf{p}|$ follows from invariance under rotations. [6]

Using eq. (22.37) we see that the first contraction on the right-hand side of eq. (22.36) is proportional to $\delta^{(3)}(\mathbf{k})$. After integration over $d^3k = k^2 dk d\Omega$ in eq. (22.31), it therefore gives a vanishing contribution. [7] Using eq. (22.37) to compute the other two terms in eq. (22.36) and recalling that $(2\pi)^3\delta^{(3)}(\mathbf{p}=0) = V$, we get

$$\sum_{ij} \left\langle \tilde{T}_{ij}^{\mathrm{TT}}\left(\eta', \mathbf{k}\right) \tilde{T}_{ij}^{*,\mathrm{TT}}\left(\eta'', \mathbf{k}\right) \right\rangle = V \Lambda_{kl,mn}(\hat{\mathbf{k}}) \tag{22.38}$$
$$\times \int \frac{d^3p}{(2\pi)^3} p_k p_l \left[p_m p_n + (k-p)_m (k-p)_n\right] F\left(\eta', \eta''; p\right) F\left(\eta', \eta''; |\mathbf{k}-\mathbf{p}|\right)$$

The terms containing k_m or k_n give zero when contracted with $\Lambda_{kl,mn}(\hat{\mathbf{k}})$, while, using the explicit expression (1.39), we get

$$\Lambda_{kl,mn}(\hat{\mathbf{k}}) p_k p_l p_m p_n = \frac{1}{2} p^4 \sin^4\theta(\hat{\mathbf{k}}, \hat{\mathbf{p}}) \tag{22.39}$$

where $\theta(\hat{\mathbf{k}}, \hat{\mathbf{p}})$ denotes the angle between $\hat{\mathbf{k}}$ and $\hat{\mathbf{p}}$ [compare with the computation leading to eq. (4.346) in Vol. 1]. Plugging this result into eq. (22.31) we finally obtain

$$\rho_{\mathrm{gw}}(\eta \geqslant \eta_f) = \frac{4\pi G}{a^4(\eta)} \int \frac{d^3k}{(2\pi)^3} \int_{\eta_i}^{\eta_f} d\eta' d\eta'' a\left(\eta'\right) a\left(\eta''\right) \cos\left[k\left(\eta'-\eta''\right)\right]$$
$$\times \int \frac{d^3p}{(2\pi)^3} p^4 \sin^4\theta(\hat{\mathbf{k}}, \hat{\mathbf{p}}) F\left(\eta', \eta''; p\right) F\left(\eta', \eta''; |\mathbf{k}-\mathbf{p}|\right) \cdot (22.4 \tag{22.40}$$

The integral over d^3p in the second line depends on $\mathbf{k}$, through $|\mathbf{k}-\mathbf{p}|$ and $\theta(\hat{\mathbf{k}}, \hat{\mathbf{p}})$. However, since it is a scalar, and there is no other vector with which we can contract k_i, it can depend on $\mathbf{k}$ only through the modulus k, and not on the direction $\hat{\mathbf{k}}$. This means that the integral over d^3k can be written as $d^3k = 4\pi k^2 dk$. As in eq. (7.197), we write

$$\rho_{\mathrm{gw}}(\eta) = \int_{k=0}^{k=\infty} d(\log k) \frac{d\rho_{\mathrm{gw}}}{d\log k}(\eta, k) \tag{22.41}$$

Then, for $\eta \geqslant \eta_f$,

$$\frac{d\rho_{\mathrm{gw}}}{d\log k}(\eta, k) = \frac{2G}{\pi a^4(\eta)} k^3 \int_{\eta_i}^{\eta_f} d\eta' d\eta'' a\left(\eta'\right) a\left(\eta''\right) \cos\left[k\left(\eta'-\eta''\right)\right]$$
$$\times \int \frac{d^3p}{(2\pi)^3} p^4 \sin^4\theta(\hat{\mathbf{k}}, \hat{\mathbf{p}}) F\left(\eta', \eta''; p\right) F\left(\eta', \eta''; |\mathbf{k}-\mathbf{p}|\right)$$

This is the final result of this section, and gives the energy spectrum of the stochastic background of GWs generated by a random Gaussian scalar field, for $\eta \geqslant \eta_f$, i.e. after the source has switched off, in terms of its two-point function $F\left(\eta', \eta''; p\right)$, defined by eq. (22.37).

16.1.4 22.3 GWs from preheating after inflation

If a thermalized hot plasma ever existed before inflation, at the end of inflation its temperature would be redshifted away by a factor $e^{\Delta N}$, where the number of e-folds during inflation, ΔN, is larger than a minimum value $(\Delta N)_{\rm min}$ typically of order $50-60$, as we saw in Section 21.1. In order to generate the hot thermalized relativistic plasma that we identify as the initial state of the hot big-bang theory, the Universe must therefore be reheated. For single-field slow-roll inflation the first successful reheating mechanism that was studied is the perturbative decay of the inflaton field into other matter fields after the end of the slow-roll phase. It was later realized that the energy transfer from the inflaton to normal matter at the end of inflation can be much more efficient, involving non-linear physics and explosive production of particles, which of course is also potentially interesting from the point of view of GW generation. This non-linear mechanism is referred to as "preheating". In particular, two interesting preheating mechanisms have emerged, namely parametric resonance in single-field inflation and tachyonic preheating in hybrid inflation. We discuss them in the following subsections.

16.1.5 22.3.1 Parametric resonance in single-field inflation

We consider a single-field slow-roll inflationary model, of the type discussed in Section 21.1.4, with an inflaton field ϕ and an inflationary potential $V(\phi)$, and we couple it for simplicity to a single scalar matter field χ with a coupling $\chi^2\phi^2$,

$$S=\int d^4x\sqrt{-g}\left[\frac{1}{16\pi G}R-\frac{1}{2}g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi-V(\phi)-\frac{1}{2}g^{\mu\nu}\partial_\mu\chi\partial_\nu\chi-\frac{1}{2}g^2\chi^2\phi^2\right] \tag{22.43}$$

where g is a coupling constant. The background solution is $\phi=\phi(t)$, $\chi=0$ so, including perturbations around it, we write

$$\phi(t,\mathbf{x})=\phi(t)+\delta\phi(t,\mathbf{x}) \tag{22.44}$$
$$\chi(t,\mathbf{x})=\delta\chi(t,\mathbf{x}) \tag{22.45}$$

At the end of inflation the field ϕ performs oscillations around the minimum of $V(\phi)$ with a frequency given by $m_\phi=\sqrt{d^2V/d\phi^2}$, with the second derivative evaluated at the minimum of $V(\phi)$. Therefore the solution of the equation of motion for $\phi(t)$ is approximately

$$\phi(t)=\Phi(t)\sin m_\phi t \tag{22.46}$$

where $\Phi(t)$ is a function that changes slowly on the time-scale m_ϕ^{-1}, and which we will approximate just by a constant. The equation for the perturbations is [compare with eq. (21.175)]

$$\begin{aligned}\delta\ddot{\phi}_{\mathbf{k}}+3H\delta\dot{\phi}_{\mathbf{k}}+\left(\tfrac{k^2}{a^2}+m_\phi^2\right)\delta\phi_{\mathbf{k}}=0\\ \delta\ddot{\chi}_{\mathbf{k}}+3H\delta\dot{\chi}_{\mathbf{k}}+\left(\tfrac{k^2}{a^2}+g^2\phi^2(t)\right)\delta\chi_{\mathbf{k}}=0\end{aligned} \tag{22.48}$$

The equation for $\delta\phi_{\mathbf{k}}$ is the usual equation for the perturbations of a scalar field in FRW, damped by the friction term due to the expansion of the Universe, and furthermore has a mass term with the "correct", non-tachyonic sign. This equation has no unstable mode, as we studied in Section 19.3. In contrast, the equation for $\delta\chi_{\mathbf{k}}$ has a time-dependent frequency

$$\begin{aligned}\omega_k^2(t)&=k^2+g^2a^2(t)\phi^2(t)\\&=k^2+g^2\Phi^2a^2(t)\sin m_\phi t\end{aligned} \tag{22.49}$$

We can rewrite eq. (22.48) in the form

$$\frac{d^2}{dz^2}(\delta\chi_k) + 3\frac{H}{m_\phi}\frac{d}{dz}(\delta\chi_k) + [A(k) - 2q\cos(2z)]\delta\chi_k \tag{22.50}$$

where $z = m_\phi t$,

$$q = \frac{g^2\Phi^2}{4m_\phi^2} \tag{22.51}$$

is called the resonance parameter and

$$A(k) = \frac{k^2}{m_\phi^2 a^2} + 2q \tag{22.52}$$

Equation (22.50), with the friction term proportional to H/m_ϕ neglected (which is a good approximation during the rapid phase of parametric resonance that we will find below), is a Mathieu equation. Depending on the values of $A(k)$ and of q, it can have either oscillatory or exponential solutions, with a band structure corresponding to sets of stable or unstable modes. In general, if q is large, a broad range of values of k can be in resonance, and one is then in the broad-resonance regime. In this situation energy is efficiently pumped from the inflaton field into the resonant modes $\delta\chi_k$, leading to large time-dependent and inhomogeneous field configurations. Once the resonant modes reach an amplitude $\chi^2 \sim \Phi^2$, the perturbative approach in which we expanded around $\chi = 0$ breaks down, and preheating ends. At this point the field χ dissipates its energy via interaction with the other fields of the theory, eventually leading to thermalization.

The scalar field dynamics can be computed numerically, solving the equation of motion of the interacting scalar fields in FRW. The numerical study shows that there is an initial linear phase in which the field χ
grows and its statistics is still Gaussian. In this regime some analytic checks of the numerical results for GW production can be made using the results of Section 22.2.2. This phase evolves into a highly nonlinear phase, where the statistics of the field χ is highly non-Gaussian, characterized by the formation, expansion and collision of bubble-like field inhomogeneities. This is followed by a stage of turbulence and, finally, thermalization. Most of the GW production takes place in the violent bubble-like phase. The resulting GW production can then be computed from eq. (22.13), either dropping the term a''/a and using eq. (22.26), or directly integrating eq. (22.13) numerically. The fact that most of the GWs are produced in the bubble collisions makes the GW production mechanism somewhat similar to that operating in strongly first-order phase transitions, which we will discuss in Section 22.4.

The details of the numerical results depend of course on the specific inflationary model used. Most numerical results have been obtained for the inflationary potential $V(\phi) = (1/4)\lambda\phi^4$, which, as we have seen in Section 21.3.5, is now ruled out, or for $V(\phi) = (1/2)m^2\phi^2$, which is presently very close to being ruled out. The result depends of course also on the coupling g between the inflaton and the field χ or, more generally, on the form assumed for the interaction between ϕ and χ. Thus, the predictions for the GW spectrum are necessarily strongly dependent on the details of the model used.

The typical frequency of the GWs produced can, however, be estimated as in Section 22.1. The characteristic scale H_* in this case is provided by the Hubble parameter at the peak of GW production. In a first approximation, we can identify H_* with the value of the Hubble parameter at the end of the reheating phase and the beginning of RD. In this approximation we can use eq. (22.5) with T_* equal to the reheating temperature. However, the numerical studies typically show that the spectrum peaks at wavelengths one or two orders of magnitude smaller than H_*^{-1}, so the peak frequency is shifted toward correspondingly larger values. We see from

eq. (22.6) (taking ϵ_* of order, say, 0.1) that, to have a signal at $f \sim 200 - 300$ Hz, near the best sensitivity region of ground-based interferometers such as LIGO and VIRGO, one should have $T_* \sim 10^9$GeV. The spectrum is quite peaked around the maximum; on the low-frequency side its tails must decrease as f^3 by causality [see eq. (22.3)], while at frequencies higher than the peak frequency it declines even more rapidly, corresponding to the fact that modes with larger values of k are not excited by parametric resonance. The numerical studies also indicate that, for inflationary models of the type $V(\phi) = (1/2)m^2\phi^2$, the typical peak value of $\Omega_{\rm gw}$ today is roughly independent of the inflationary scale, and of order

$$h_0^2\Omega_{\rm gw} \sim 10^{-11} \tag{22.53}$$

This is considerably higher than the value obtained in inflation from the amplification of vacuum fluctuations which, as we saw in eq. (21.368), with the current bounds on the tensor-to-scalar tensor ratio r cannot exceed a value of order 10^{-16}.

16.1.6 22.3.2 Tachyonic preheating in hybrid inflation

In hybrid inflationary models, discussed in Section 21.1.4, preheating occurs when the inflaton field ϕ decreases below the critical value ϕ_c for which the Higgs-like field Φ acquires a tachyonic mass; see the discussion following eq. (21.84).

Naively, one might think that the process in which a Higgs field Φ evolves from the local maximum $\Phi = 0$ of its Mexican hat potential, toward a spontaneous symmetry-breaking minimum, could be described in terms of the evolution of a spatially homogeneous component of the Higgs field [or, equivalently, in terms of a spatially homogeneous configuration of the field $\sigma \equiv \left(\Phi^\dagger\Phi\right)^{1/2}$, see the definitions after eq. (21.82)], which rolls down from the top of the potential to the symmetry-breaking minimum (which, for hybrid inflation, is at $\phi = 0$ and $\sigma = v$). The field should then starts performing oscillations around this minimum. Initially the oscillations would have an amplitude comparable to the vacuum expectation value itself, and would then be damped by the production of particles coupled to σ, so that σ eventually settles into the minimum of the potential, with amplitude of oscillations much smaller than v. This can take place after a large number of oscillations.

However, numerical investigations have revealed that the actual dynamical evolution leading to the final spontaneous symmetry-breaking state is more complex and violent, and in particular the approximation of homogenous field is inadequate. Indeed, when the field σ acquires a tachyonic mass $-(1/2)m^2\sigma^2$, all momentum modes with $k < m$ become unstable, and start to grow exponentially as

$$\tilde{\sigma}_k(t) \propto e^{t\sqrt{m^2-k^2}} \tag{22.54}$$

When these fluctuations become large they correspond to quantum states with large occupation numbers and can then be described as classical waves. As soon as the oscillations in the various momentum modes become large, the process becomes very complicated and non-linear, with these classical waves scattering among them because of the $\lambda\sigma^4$ interaction in eq. (21.83). The full dynamics can, however, be studied numerically by solving relativistic wave equations on a lattice, and one finds that the field sets into its minimum after only $O(1)$ oscillations. The rapid transfer of energy from the potential $V(0)$ into the amplitude of the inhomogeneous oscillations due to the tachyonic instability has been called tachyonic preheating, and is substantially different from the parametric resonance phenomenon that drives preheating in single-field inflation.

Again, the process of tachyonic preheating can efficiently create GWs. The specific form of the potential $U(\phi)$ in eq. (21.83) mostly affects the dynamics during preheating by setting the

velocity with which ϕ reaches the critical value ϕ_c, so we can just use $\dot{\phi}_c$ as one of the parameters of the model or, equivalently, we can use the dimensionless quantity $V_c = g\dot{\phi}_c/(\lambda v^2)$ [not to be confused with the potential $V(\phi)$ defined in eq. (21.84)]. The parameters of the model are therefore $\{\lambda, g, v, V_c\}$. The
dependence on v can be extracted analytically, since by passing to the dimensionless variables $\phi/v, \sigma/v$ and vx^μ (and neglecting the expansion of the Universe during the short preheating era) the dependence on v drops from the equations of motion derived from eq. (21.83). In particular, one finds that the peak frequency is independent of v while the value of $h_0^2\Omega_{\rm gw}$ at the peak scales as v^2. A detailed analysis of the dependence of the results on the model parameters can be found in Dufaux, Felder, Kofman and Navros (2009). For instance analytic estimates (confirmed within one order of magnitude by the numerical simulations) indicate that, when V_c is not too low, so that preheating is actually initiated by the classical rolling of the inflaton, the peak frequency today, f_0, is given by

$$f_0 \sim 7 \times 10^{10} \lambda^{1/4} V_c^{1/3} \text{ Hz} \tag{22.55}$$

(except if $g^2/\lambda \ll 1$, in which case, after the first tachyonic growth, the typical momenta are significantly shifted toward lower frequencies), while the corresponding peak value of the GW energy density is given by

$$h_0^2\Omega_{\rm gw}(f_0) \sim 10^{-6} V_c^{-2/3} \left(\frac{v}{M_{\rm Pl}}\right)^2 \tag{22.56}$$

As an example, in Fig. 22.1 we show the predictions for $h_0^2\Omega_{\rm gw}(f)$ from tachyonic preheating for $\lambda = 10^{-5}$ and different values of V_c, while in Fig. 22.2 we show the result for fixed $V_c = 10^{-3}$, two different values $\lambda = 10^{-14}$ (left) and 10^{-5} (right), and several different values of λ/g^2. All spectra are shown for $v = 10^{-3} M_{\rm Pl}$. Lowering v leaves the shape of the spectra unchanged but reduces their amplitude proportionally to v^2, as we see from eq. (22.56). Observe from eq. (22.55) that for sufficiently small values of λ the peak of the spectrum can be in the region accessible to ground-based or even space-borne interferometers.

16.2 22.4 GWs from first-order phase transitions

16.2.1 22.4.1 Crossovers and phase transitions

During its cosmological evolution the Universe has undergone a number of changes of regime that, depending on the precise dynamics of the model, can be either phase transitions or smooth crossovers. The most recent one took place at the QCD scale, at a critical temperature T_c whose value is estimated from lattice QCD simulations to be about 150 MeV. Above this temperature quarks and gluons are deconfined and form a quark-gluon plasma, while below they are confined into hadrons. At earlier times and higher temperature, $T_c \sim 100$GeV, there takes place the electroweak phase transition (or, as we will see, crossover). As the Universe cools and T decreases below T_c, the Higgs field acquires a non-vanishing expectation value, breaking $SU(2) \times U(1)$ to $U(1)_{\rm em}$, and

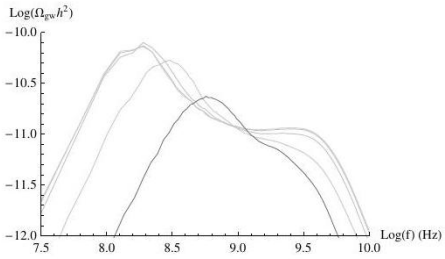

Fig. 22.1 Gravity wave spectra after preheating for $\lambda = 10^{-5}$ and different values of V_c. From Dufaux, Felder, Kofman and Navros (2009). (C)SISSA Medialab Srl. Reproduced by permission of IOP Publishing. All rights reserved.

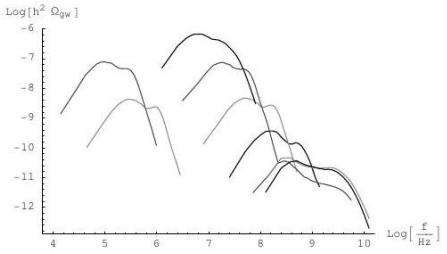

Fig. 22.2 $h_0^2\Omega_{\rm gw}(f)$ for fixed $V_c = 10^{-3}$, two different values $\lambda = 10^{-14}$ (left) and 10^{-5} (right), and several different values of λ/g^2. From Dufaux, Felder, Kofman and Navros (2009). CSISSA Medialab Srl. Reproduced by permission of IOP Publishing. All rights reserved.
the W and Z bosons become massive. Further phase transitions could have occurred earlier, for instance at the grand unification scale.

From the point of view of GW production, the interesting situation is when there is a first-order phase transition. A first-order phase transition is a violent event, and can be a significant source of GWs, as we will see in this section. In contrast, if the transition is second-order (or just a smooth crossover), no significant GW production is expected to take place.

Crossover/phase transition at the electroweak scale

The order of the electroweak phase transition depends on the value of the parameters of the underlying particle physics model, and in particular on the Higgs mass. Unfortunately, in the Standard Model, with the observed value of the Higgs mass $m_H = 125.09 \pm 0.21$ (stat.) $\pm$ 0.11 (syst.) GeV, at the electroweak scale there is no first-order phase transition. Rather, there is just a smooth crossover at a temperature $T = 150.5 \pm 1.5$GeV (a first-order phase transition would have taken place if the Higgs field had been much lighter, $m_H \lesssim 80$GeV) and no GW production. This is unfortunate since, as we will see in more detail in eq. (22.135) (and we already understand from the approximate estimate in Table 22.1 on page 646), the GW signal from a first-order phase transition at the electroweak scale can fall within the LISA frequency band.

However, a strong first-order phase transition at the electroweak scale would also be welcome because it would make possible electroweak baryogenesis. Thus, the search for extensions of the Standard Model which feature a strong first-order phase transition is well motivated. In the minimal supersymmetric Standard Model (MSSM), a strong first-order phase transition requires $m_H < 115$GeV, so again with the actual Higgs mass there is no appreciable GW signal. One can, however, construct other extensions of the Standard Model where the phase transition is first-order. In particular, the addition of an extra real singlet field or of a second Higgs doublet can induce a strong first-order phase transition (in the latter case, if the extra Higgs states are heavier than about 300GeV). Another example of a model that leads to a first-order phase transition is obtained by adding to the Standard Model a dimension-6 operator, which could emerge as an effective low-energy description of some strongly-coupled dynamics at the TeV scale.

Crossover/phase transition at the QCD scale

For the QCD deconfinement transition the situation is somewhat similar. On the one hand, for a first-order phase transition the GW signal could be in the frequency range accessible to pulsar timing arrays [see eq. (22.135)], so it is potentially very interesting. On the other hand,

after many years of studies, lattice QCD simulations with three dynamical quark flavors have conclusively shown that in QCD there is no phase transition but just a crossover.

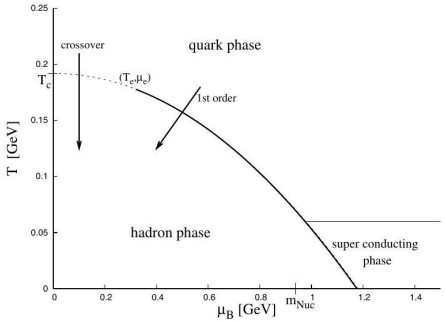

Fig. 22.3 A conjectured form of the phase diagram of QCD in the (μ_B, T) plane. Solid lines indicate a first-order phase transition, while the dashed line indicates a crossover. From Schwarz and Stuke (2009). (c)SISSA Medialab Srl. Reproduced by permission of IOP Publishing. All rights reserved. [Observe that the exact phase diagram, including the existence of the critical endpoint (μ_e, T_e), and the value of the critical temperature, are still under debate. In particular, more recent lattice QCD calculations give a critical temperature $T_c \simeq 155$MeV].

These studies have, however, been performed assuming that the baryonic chemical potential μ_B (i.e. the energy needed to add a baryon to a thermalized state at fixed volume and entropy) is small, $\mu_B \ll T$. The situation for larger values of μ_B is still uncertain. Figure 22.3 shows the conjectured QCD phase diagram in the (μ_B, T) plane, using results from perturbative computations, lattice QCD and nuclear physics. The solid line indicates a first-order phase transition, which terminates at a critical endpoint (μ_e, T_e). The correctness of this picture is still under debate. In the standard cosmological setting, μ_B/T is very small. Indeed, CMB and nucleosynthesis data show that the baryon-to-photon ratio

$$\frac{n_B}{n_\gamma} \sim \frac{\mu_B}{T} \sim 10^{-9} \tag{22.57}$$

This quantity is conserved after baryogenesis and the last first-order phase transition, when the evolution conserves entropy. Thus, in the standard scenario, at the QCD scale $\mu_B/T \sim 10^{-9}$, and in this case the cosmological transition at the QCD scale is a crossover and does not generate GWs.

Non-standard scenarios have been investigated that could lead to a large value of μ_B/T and then, possibly, to a first-order phase transition. A possibility is that, at temperatures above the QCD phase transition, the value of μ_B/T was $O(1)$ thanks to some mechanism that generates a high baryon number. Then the QCD phase transition could be of first order. At the same time, during this first-order phase transition, the QCD vacuum could become trapped in a false vacuum state, generating a short period of inflation that dilutes μ_B/T to the current value. A different attempt at obtaining a large value of μ_B/T is based on the observation that μ_B depends both on the specific baryon asymmetry b (i.e. the baryon asymmetry per entropy) and on the specific lepton asymmetry l. The specific baryon asymmetry is fixed by cosmological observations and is very small, $b = (8.85 \pm 0.24) \times 10^{-11}$. Direct measurement of the specific lepton asymmetry l are more difficult, because the cosmic neutrino background escapes direct detection and is only indirectly constrained. The combined bounds from CMB and nucleosynthesis are only of order $|l| \lesssim 0.02$. The standard cosmological scenario predicts that the lepton asymmetry should be of the same order as the baryon asymmetry. This is due to the fact that after inflation any preexisting baryon or lepton asymmetry has been washed away. They must therefore be re-generated after inflation, by baryon- and lepton-numberviolating processes. In the Standard Model this can happen somewhat above the electroweak scale,

due to sphaleron processes. In this case in each single sphaleron process the baryon-number violation is equal to the lepton-number violation, $\Delta(B-L)=0$. However, there are extensions of the Standard Model, for example with heavy (s)neutrinos, where a large lepton asymmetry can be produced. For $|l| \gg b, \mu_B$ grows linearly with l, reaching values of order 0.2GeV for $|l| \sim 0.02$, so not far from the critical point (μ_e, T_e) in Fig. 22.3. Thus, considering also the theoretical uncertainties in Fig. 22.3, it is not yet completely excluded that in extensions of the Standard Model leading to a large lepton asymmetry the QCD transition could be first-order.

The bottom-line is that, both at the electroweak scale and at the QCD scale, using the Standard Model (and, for the QCD scale, standard scenarios for the baryonic chemical potential) there is no first-order phase transition, so no GW production. We also see from eq. (22.6) that a phase transition at the grand-unification scale would give a signal at frequencies to high to be observed, even at ground-based interferometers. There is, however, at present still room for extensions of the Standard Model, or of standard scenarios, that could lead to a first-order phase transition, either at the electroweak or at the QCD scale. This is an example of the fact that the predictions for cosmological stochastic backgrounds suffer from uncertainties in the particle physics model at high energies, as well as from uncertainties in the cosmological model at early times. On the other hand, this means that the detection of a primordial stochastic background due to a first-order cosmological phase transition would reveal features of high-energy particle physics that would hardly be accessible otherwise, and would therefore be a very remarkable result. In Section 22.4.2 we will therefore study the GW production in a first-order phase transition in the early Universe. We will see that this study is also quite interesting from a conceptual point of view.

16.2.2 22.4.2 First-order phase transitions in cosmology

The dynamics of a phase transition is governed by the finite-temperature effective potential. [8] A typical example of a finite-temperature effective potential $V(\phi, T)$ inducing a first-order phase transition is given by

$$V(\phi, T) = \frac{1}{2}M^2(T)\phi^2 - \frac{1}{3}\delta(T)\phi^3 + \frac{1}{4}\lambda\phi^4 \tag{22.58}$$

where $\phi \geqslant 0$ (for example ϕ is the modulus of a field) and, at least in some range of temperatures near a value T_0,

$$M^2(T) = \gamma\left(T^2 - T_0^2\right) \tag{22.59}$$

$$\delta(T) = AT \tag{22.60}$$

where the parameters γ, A and λ are strictly positive. The potential $V(\phi, T)$ is shown in Fig. 22.4 for different values of T, in the case $A^2 < 4\lambda\gamma$. For $T > T_0$ the field has a minimum at $\phi = 0$, where $V = 0$. If ϕ is the order parameter of a symmetry, then at this minimum the symmetry is unbroken. At $T \gg T_0$ this is the only minimum of the potential. If $A^2 < 4\lambda\gamma$, then, as we lower the temperature, a second extremum of $V(\phi)$ appears, at a temperature T_1 given by

$$T_1^2 = \frac{T_0^2}{1 - A^2/(4\lambda\gamma)} \tag{22.61}$$

This extremum is at $\phi = \phi_1 = AT_1/(2\lambda)$, and $V(\phi_1) > 0$. At $T < T_1$ this extremum splits into a local maximum and a local minimum. Lowering the temperature further, the value of the potential at the local minimum gets lower and lower, until is becomes degenerate with the minimum at $\phi = 0$, at a critical temperature T_c given by

$$T_c^2 = \frac{T_0^2}{1 - 2A^2/(9\lambda\gamma)} \tag{22.62}$$

At $T < T_c$ this minimum becomes the true minimum of the potential. Finally, as the temperature is lowered further to the value T_0, the extremum in $\phi = 0$ becomes a local maximum.

Before entering into a more technical analysis, let us first understand qualitatively, from Fig. 22.4, how a first-order phase transition takes place in an expanding Universe. At large temperatures the effective potential $V(\phi, T)$ has only the minimum at $\phi = 0$, and the field sits at this minimum. As the Universe cools down and its temperature becomes lower than T_c, this minimum becomes metastable, so the Universe is now trapped in a false vacuum. The transition to the true vacuum can take place via either thermal or quantum fluctuations, which nucleate bubbles of true vacuum. At temperature T, the nucleation of a vacuum bubble results in an energy gain equal to $(4\pi/3)r^3\Delta\rho_{\rm vac}\,(T)$, where r is the bubble radius and $\Delta\rho_{\rm vac}(T)$ is the energy density difference between the metastable state and the true vacuum. On the other hand, one loses an energy equal to $4\pi r^2\sigma$, where σ is the surface tension of the bubble [8] For a review of the definition of the finite-temperature effective potential and the relevant computational techniques in thermal field theory see for example Quiros (1999).

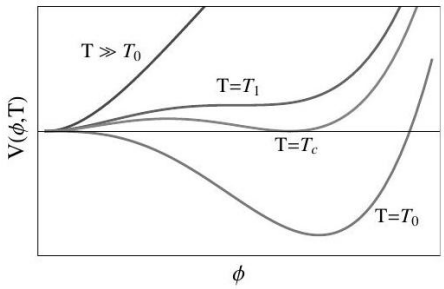

Fig. 22.4 The potential $V(\phi, T)$ for a first-order phase transition, for different values of T. We have set $A^2/(4\lambda\gamma) = 0.5$.

[9] A more precise quantitative estimate will be given in eq. (22.124). (which is calculable given the effective potential, as we will see). For a given value of $T < T_c$, corresponding to a given value of $\Delta\rho_{\rm vac}(T)$, there is therefore a critical radius $r_c(T) = 3\sigma/\Delta\rho_{\rm vac}(T)$ (a more precise computation, using the exact profile of the scalar field, will be given below) such that bubbles nucleated with $r < r_c(T)$ shrink and disappear because of the surface tension, while bubbles with $r > r_c(T)$ survive and expand.

Of course, the probability of nucleating a large bubble is small. In standard equilibrium thermodynamics, if the system is in a metastable state and we wait long enough, it will eventually undergo the transition to the true vacuum state, even if the transition rate is small. In the cosmological setting, however, there is an explicit time-scale due to the expansion of the Universe, and we must compare the transition rate from the false to the true vacuum with the Hubble expansion rate. If, at a given temperature, the nucleation rate $\Gamma(T)$ of supercritical bubbles, i.e. bubbles with $r > r_c(T)$, is much smaller than the Hubble parameter $H(T)$, the Universe will have cooled down significantly further before nucleation of supercritical bubbles has a significant chance of taking place. When T is smaller than T_c but close to it, $\Delta\rho_{\rm vac}\,(T)$ is small, so $r_c(T)$ is large and the nucleation rate of bubbles with $r > r_c(T)$ is small. As the Universe cools down further, $\Delta\rho_{\rm vac}(T)$ increases, $r_c(T)$ decreases, and the nucleation rate $\Gamma(T)$ of supercritical bubbles increases. A firstorder phase transition will take place if, at some temperature T_* in the range $T_0 < T_* < T_c, \Gamma\,(T_*)$ becomes as large as $H\,(T_*)$.[9] If this never happens, then, once the system reaches the temperature T_0, the field ϕ smoothly rolls down for $\phi = 0$, which is now a maximum, toward the true minimum, and we have a second-order phase transition.

Denoting by $\eta(T)$ the vacuum expectation value of the scalar field at the true vacuum at temperature T and observing that the effective potential $V(\phi, T)$ is actually the free energy density of the system, the vacuum energy density associated with the transition is

$$\rho_* = \left[-V[\eta(T), T] + T\frac{d}{dT}V[\eta(T), T]\right]_{T=T_*} \tag{22.63}$$

Since we are interested in transitions taking place during RD, it is convenient to normalize this quantity to the radiation energy density (17.98), defining

$$\alpha = \frac{30\rho_*}{\pi^2 g_*\left(T_*\right) T_*^4} \tag{22.64}$$

Another important parameter is the bubble nucleation rate at the transition temperature, which is modeled as an exponential,

$$\Gamma(t) = \Gamma_* e^{\beta(t-t_*)} \tag{22.65}$$

where t_* is the time at which the transition takes place [defined more quantitatively in eq. (22.123)], and at which the rate has a value Γ_*. We will see later how this exponential form emerges, and how to compute β from the effective potential. Since β has dimensions of inverse time, the relevant dimensionless quantity is actually the ratio β/H_*, where $H_* = H\left(T_*\right)$, which indeed will appear in the computation of GW production.

16.2.3 22.4.3 Thermal tunneling theory

We now discuss more quantitatively how bubbles of true vacuum are nucleated and how their nucleation rate can be computed, first reviewing the bounce computation in quantum mechanics, then studying QFT at zero temperature and finally turning to the relevant case of tunneling in QFT at finite temperature. Apart from the application to GW production in first-order phase transitions, the theory has several applications in QFT, and is of great elegance in itself.

Tunneling and the bounce solution

Let us consider a quantum-mechanical system with one degree of freedom $q(t)$ and Hamiltonian $H = p^2/2 + V(q)$, where

$$V(q) = \frac{1}{2}\omega^2 q^2 + \frac{1}{2}gq^4 \tag{22.66}$$

We have set the particle mass $m = 1$, and g is a coupling constant. For $g > 0$ the potential is bounded from below and the Hamiltonian H is positive definite. The partition function of the system at temperature $T = 1/\beta$ can be computed using the basic result relating the operator formalism of quantum mechanics to the Euclidean path-integral formulation

$$\operatorname{tr} e^{-\beta H/\hbar} = \int\limits_{q(-\beta/2)=q(\beta/2)} [dq] e^{-S_E/\hbar} \tag{22.67}$$

where the trace is over the Hilbert space of the system and $[dq]$ denotes the integration measure in the path integral. [10] Since we will use a semiclassical approximation, which is formally an expansion in $\hbar$, it is convenient for the moment to keep $\hbar$ explicit rather than setting $\hbar = 1$. The path integral in eq. (22.67) is performed over trajectories $q(t)$ with $-\beta/2 \leqslant t \leqslant \beta/2$, and periodic boundary conditions. In eq. (22.67) we have performed the rotation to Euclidean space, and the Euclidean action is

$$S_E = \int_{-\beta/2}^{\beta/2} dt \left[\frac{1}{2}\dot{q}^2 + V(q)\right] \tag{22.68}$$

In the limit $\beta \to \infty$ the left-hand side of eq. (22.67) is dominated by the contribution of the ground state, whose energy we denote by E_0, so $\mathrm{tr}\, e^{-\beta H/\hbar} \simeq e^{-\beta E_0/\hbar}$, while on the right-hand side the only trajectories that contribute are those that satisfy $q(-\beta/2) = q(\beta/2) = 0$, since otherwise the Euclidean action diverges as $\beta \to \infty$. Thus, the groundstate energy can be computed from

$$E_0(g) = -\lim_{\beta\to\infty} \frac{\hbar}{\beta} \log \int_{q(-\beta/2)=q(\beta/2)=0} [dq] e^{-S_E/\hbar} \tag{22.69}$$

As long as $g > 0$, this allows us to compute the energy $E_0(g)$, which will have the form $E_0(g) = (1/2)\hbar\omega[1 + O(g)]$, corresponding to a harmonic [10] See for example Section 9.6 of Maggiore (2005).

[11] For a detailed discussion of how analytic continuation works in this problem, see Chapter 36 of Zinn-Justin (2002).

[12] Observe that for $g < 0$ the Hamiltonian does not have a real spectrum, because it is unbounded from below and the boundary conditions on the wavefunction at spatial infinity are not real.

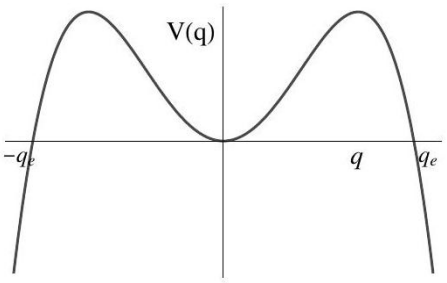

Fig. 22.5 The potential $V(q)$ for $g < 0$. The points $q = \pm q_e$ where $V(q) = 0$ correspond to the escape points of the tunneling process in Minkowski space. oscillator with frequency ω, plus anharmonic corrections parametrized by g. Observe that, in the limit $\beta \to \infty$, rescaling $q \to q/\sqrt{g}$,

$$\frac{1}{\hbar}\int_{-\infty}^{\infty} dt \left[\frac{1}{2}\dot{q}^2 + \frac{1}{2}\omega^2 q^2 + \frac{1}{2}g q^4\right] \to \frac{1}{g\hbar}\int_{-\infty}^{\infty} dt \left[\frac{1}{2}\dot{q}^2 + \frac{1}{2}\omega^2 q^2 + \frac{1}{2}q^4\right] \tag{22.70}$$

so the perturbative expansion in powers of g is the same as the semiclassical expansion in powers of $\hbar$.

We now want to consider the situation $g < 0$. The corresponding potential is shown in Fig. 22.5. Now the potential is unbounded from below, and $E_0(g)$ can be obtained by analytic continuation from the expression valid for $g > 0$, given in eq. (22.69). [11] As is physically clear, and as we will show below, this analytic continuation generates an imaginary part for E_0, so that now the wavefunction $\psi(t)$ of the corresponding eigenstate evolves as

$$\psi(t) \propto e^{-i(\mathrm{Re}E_0)t - |\mathrm{Im}\, E_0|t} \tag{22.71}$$

corresponding to the fact that a state localized near the minimum at $q = 0$ eventually decays by tunneling. [12] Thus, to find E_0 we still have to compute the path-integral on the right-hand

side of eq. (22.69), except that now $g < 0$ so the potential is the one given shown in Fig. 22.5. Observe also that, from the procedure of analytic continuation, we inherit the boundary conditions $q(-\beta/2) = q(\beta/2) = 0$.

We compute this path integral in the semiclassical approximation. Thus, we look for the classical solutions $q_{\rm cl}(t)$ of the equation of motion derived from the action S_E, that satisfy the boundary conditions $q(-\beta/2) = q(\beta/2) = 0$, with $\beta \to \infty$. We then write

$$q(t) = q_{\rm cl}(t) + \hbar^{1/2}\varphi(t) \tag{22.72}$$

where φ are the quantum fluctuations, and we integrate over φ. Then, to quadratic order in φ

$$\begin{aligned} &\int\limits_{q(-\beta/2)=q(\beta/2)=0} [dq] e^{-S_E/\hbar} = \\ &= e^{-S[q_{\rm cl}]/\hbar} \int [d\varphi] e^{-\frac{1}{2}\int\limits_{-\infty}^{\infty} dt_1 dt_2 \varphi(t_1) M(t_1,t_2) \varphi(t_2)} \end{aligned} \tag{22.73}$$

where the operator $M(t_1, t_2)$ is given by

$$\begin{aligned} M(t_1,t_2) &= \left.\frac{\delta^2 S}{\delta q(t_1)\,\delta q(t_2)}\right|_{q=q_{\rm cl}} \\ &= \left[-\frac{d^2}{dt_1^2} + V''[q_{\rm cl}(t_1)]\right] \delta(t_1 - t_2) \end{aligned} \tag{22.74}$$

Let $\varphi_n(t)$ be a complete set of (in general complex) normal modes of the operator M,

$$\int\limits_{-\infty}^{\infty} dt' M(t,t')\,\varphi_n(t') = \lambda_n \varphi_n(t) \tag{22.75}$$

We take these normal modes to be orthogonal with respect to the scalar product

$$\langle f|g\rangle = \int\limits_{-\infty}^{\infty} dt f^*(t) g(t) \tag{22.76}$$

but we find it convenient not to require them to be orthonormal, so

$$\langle \varphi_n|\varphi_m\rangle = \delta_{nm} u_n \tag{22.77}$$

where the u_n give the norms of the modes. We then expand

$$\varphi(t) = \sum_n \xi_n \varphi_n(t) \tag{22.78}$$

where the ξ_n are real coefficients, ranging from $-\infty$ to $+\infty$. The measure of the path integral is defined as

$$[d\varphi] = \mathcal{N} \prod_n \sqrt{\frac{u_n}{2\pi\hbar}} d\xi_n \tag{22.79}$$

where $\mathcal{N}$ is a normalization constant that we will fix later. We then have

$$\int_{-\infty}^{\infty} dt_1 dt_2 \varphi(t_1) M(t_1, t_2) \varphi(t_2) = \sum_n \lambda_n u_n \xi_n^2 \tag{22.80}$$

The integration over the modes with non-zero eigenvalues λ_n is Gaussian and gives a result proportional to

$$e^{-S[q_{c1}]/\hbar} (\det' M)^{1/2} \tag{22.81}$$

where the prime means that we have excluded the eigenvectors with $\lambda_n = 0$.[13]We will discuss later the treatment of the zero modes. If $S[q_{cl}]$ is non-zero, the factor $e^{-S[q_{cl}]/\hbar}$ is non-perturbative in $\hbar$. If the non-zero eigenvalues of M are all positive, or more generally if there are an even number of negative eigenvalues, $\det' M > 0$ and the contribution (22.81) is real, so it contributes to the real part of E_0. However, in this case we have no right to retain it, since this term is exponentially small as $\hbar \to 0^+$. It is then negligible compared with the terms obtained by performing perturbation theory around the trivial solution $q_{cl}(t) = 0$, since these contributions are given by an expansion in powers of the coupling g, which, in view of the comment after eq. (22.70), is the same as an expansion in powers of $\hbar$. However, if there is one or, more generally, an odd number of negative eigenvalues, then $\det' M < 0$ and the contribution (22.81) is imaginary. In this case, it gives the leading correction to $\mathrm{Im}\, E_0$.

The equation of motion obtained from the Euclidean action (22.68) is

$$\ddot{q} = V' \tag{22.82}$$

which is formally the same as that obtained from a Minkowskian action with a potential $-V(q)$, shown in Fig. 22.6. One obvious solution satisfying the boundary conditions $q(-\beta/2) = q(\beta/2) = 0$ is the trivial [13] The integration over a mode with $\lambda_n < 0$ is defined by analytic continuation and again gives a factor proportional to $\lambda_n^{1/2}$, so eq. (22.81) holds for both positive and negative eigenvalues. For negative eigenvalues, however, the proportionality constant differs by a factor 1/2 because of the procedure of analytic continuation; see the detailed discussion in Callan and Coleman (1977), after their eq. (2.22). In the following we will not need the explicit proportionality factors, and we will not keep track of them, limiting ourselves to quoting the final result in eq. (22.98). These factors are accurately computed in Coleman (1977a,b) and Callan and Coleman (1977).

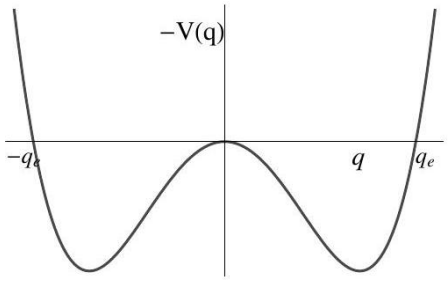

Fig. 22.6 The potential $-V(q)$ for $g < 0$.

one, $q_{cl}(t) = 0$. However, in this case $V''(q_{cl}) = V''(0) \equiv \omega^2$ and the operator M is the one corresponding to the harmonic oscillator, with only positive eigenvalues. So, it does not contribute to the imaginary part. Thus, we have to look for non-trivial solutions. The first integral of eq. (22.82) is

$$\frac{1}{2}\dot{q}_{cl}^2 - V(q_{cl}) = E \tag{22.83}$$

The solutions with $E < 0$ corresponds to oscillations around a minimum of $-V$, say the minimum at $q > 0$, with inversion points q_1 and q_2. From eq. (22.83), the period β of this solution is given by

$$\begin{aligned}\beta &= 2\int_{q_1}^{q_2} dq \frac{1}{\sqrt{2(E+V)}} \\ &= 2\int_{q_1}^{q_2} dq \frac{1}{\sqrt{2E+\omega^2 q^2 + (1/2)gq^4}}\end{aligned} \tag{22.84}$$

In the limit $\beta \to \infty$ the integral on the right-hand side must diverge. For $E < 0$ but close to zero, the inversion point q_1 is at $q_1 \simeq 2|E|/\omega$, and the integrand near the extremum $q = q_1$ is approximately proportional to $1/\sqrt{q^2 - q_1^2}$. For $q_1 \neq 0$, $\sqrt{q^2 - q_1^2} \simeq \sqrt{(q - q_1)\, 2q_1}$ and this singularity is integrable. In contrast, for $q_1 = 0$, we have $1/\sqrt{q^2 - q_1^2} = 1/q$, whose integral diverges at $q = 0$. This means that the solution whose period $\beta \to \infty$ is the one whose inversion point $q_1 \to 0^+$, and therefore with $E \to 0$. Thus, in the limit $\beta \to \infty$, on the solution satisfying the boundary conditions $q(-\infty) = q(\infty) = 0$ the first integral of eq. (22.82) is

$$\frac{1}{2}\dot{q}_{\rm cl}^2 - V\left(q_{\rm cl}\right) = 0 \tag{22.85}$$

In the limit $\beta \to \infty$ we understand from Fig. 22.6 that this solution starts from $q \to 0^+$at $t \to -\infty$, goes to the point $q = q_e$ where it bounces, and then goes back to $q = 0$ as $t \to \infty$. This solution is called the bounce. Actually, in the limit $\beta \to \infty$ the system is invariant under time translations, so if $q_{\rm cl}(t)$ is a solutions of the equations of motion with these boundary conditions, then $q_{\rm cl}\left(t; t_0\right) = q_{\rm cl}\left(t - t_0\right)$ is also a solution, for an arbitrary value of the parameter t_0. Therefore, there is a whole family of classical bounce solutions around which we must expand the path integral, parametrized by t_0, which is called a "collective coordinate". Using eq. (22.85), we see that the action (22.68) evaluated on this solution is positive-definite and, in the limit $\beta \to \infty$, has the value

$$S_{\rm cl} = \int_{-\infty}^{\infty} dt \dot{q}_{\rm cl}^2 \tag{22.86}$$

independent of t_0. We next consider the fluctuations around a bounce solution. It is easy to see that there is a zero mode, i.e. an eigenvector with zero eigenvalue, given by

$$\varphi_0(t) = \dot{q}_{\rm cl}(t) \tag{22.87}$$

Indeed, differentiating eq. (22.82) with respect to time, we get

$$\left[-\frac{d^2}{dt^2} + V''\left[q_{\rm cl}(t)\right]\right]\dot{q}_{\rm cl}(t) = 0 \tag{22.88}$$

which shows that $\dot{q}_{\rm cl}(t)$ is an eigenvector of the operator M, with zero eigenvalue. More generally we can observe that, whenever the classical solution $q_{\rm cl}(t;\gamma)$ depends on a set of collective coordinates γ_i, the functions $\partial q_{\rm cl}/\partial\gamma_i$ are zero modes. This can be shown starting from the classical equation of motion, $(\delta S/\delta q)_{q=q_{\rm cl}} = 0$, and taking its derivative with respect to γ_i,

$$0 = \frac{\partial}{\partial \gamma_i}\left(\frac{\delta S}{\delta q(t)}\right)_{q=q_{\rm cl}} = \int dt' \left(\frac{\delta^2 S}{\delta q(t)\delta q\left(t'\right)}\right)_{q=q_{\rm cl}} \frac{\partial q_{\rm cl}\left(t';\gamma\right)}{\partial \gamma_i} \tag{22.89}$$

The operator $\left[\delta^2 S/\delta q(t)\delta q\left(t'\right)\right]_{q=q_{\rm cl}}$ is just $M\left(t,t'\right)$, and we see that $\partial q_{\rm cl}/\partial\gamma_i$ are zero modes. In our case the collective coordinate is t_0 and $q_{\rm cl}$ is a function of $t-t_0$, so $\partial q_{\rm cl}/\partial t_0 = -\partial q_{\rm cl}/\partial t$, and hence $\dot{q}_{\rm cl}(t)$ is a zero mode.

From the fact that $\dot{q}_{\rm cl}(t)$ is a zero mode it also follows that the operator M in eq. (22.74) has one and only one negative eigenvalue. In fact, M has the form of a Hermitian Hamiltonian in a one-dimensional quantummechanics problem. As we know from quantum mechanics, its spectrum is such that the eigenfunction with the lowest eigenvalue (i.e. the ground state in the Hamiltonian analogy) has no node, the first excited state has one node, etc. Since the zero mode $\dot{q}_{\rm cl}(t)$ has one node, corresponding to the point $q=q_e$ where the solution bounces back, it follows that the zero mode is the first excited state of the operator M, and M has one and only one eigenvector with lower eigenvalue, i.e. with $\lambda<0$. Thus, $\left(\det' M\right)^{1/2} = i\left|\det' M\right|^{1/2}$, and we get a contribution to $\operatorname{Im} E_0$.

We must next understand how to treat the zero mode, i.e. the integration over the variable ξ_0 associated with the mode $\varphi_0(t)=\dot{q}_{\rm cl}(t)$. In the path integral the integration over ξ_0 runs from $-\infty$ to $+\infty$, and nothing else depends on ξ_0, so this is a formally divergent term. However, we must recall that we are working in the limit $\beta\to\infty$, and that there is already a factor of $1/\beta$ on the right-hand side of eq. (22.69), which eventually must cancel. So, while for the other occurrences of β in our computation to lowest order it was legitimate to set directly $\beta=\infty$ [for example in the integration limits in eq. (22.86)], here we have to be more careful. The infinitesimal fluctuation in the direction parametrized by ξ_0 actually corresponds to moving in the space of classical solutions. Indeed, consider an infinitesimal fluctuation $\delta\xi_0\varphi_0$ around the classical solution $q_{\rm cl}\left(t;t_0\right)$. Using the fact that $\varphi_0(t) = (\partial/\partial t) q_{\rm cl}\left(t;t_0\right) = -\left(\partial/\partial t_0\right) q_{\rm cl}\left(t;t_0\right)$, we see that

$$\begin{aligned} q_{\rm cl}\left(t;t_0\right) + \delta\xi_0\varphi_0(t) &= q_{\rm cl}\left(t;t_0\right) - \delta\xi_0 \frac{\partial}{\partial t_0} q_{\rm cl}\left(t;t_0\right) \\ &= q_{\rm cl}\left(t;t_0-\delta\xi_0\right) \end{aligned} \tag{22.90}$$

[14] More precisely, we can transform the integral over $d\xi_0$ into an integral over dt_0 using a simpler version of the Faddeev-Popov trick used in the quantization of gauge theories. First of all observe that, given a classical configuration $q_{\rm cl}\left(t;t_0\right)$, we define the fluctuations around it as

$$\varphi\left(t;t_0\right) \equiv q(t) - q_{\rm cl}\left(t;t_0\right) \tag{22.91}$$

The generic field configuration $q(t)$ knows nothing about t_0, so φ depends on both t and t_0. We start from the identity

$$1 = \int dt_0 \delta\left[f\left(t_0\right)\right] \left|\frac{\partial f}{\partial t_0}\right| \tag{22.92}$$

which is valid for any (differentiable) function $f\left(t_0\right)$, and we chose

$$f\left(t_0\right) = \int dt \varphi\left(t;t_0\right) \dot{q}_{\rm cl}\left(t;t_0\right) \tag{22.93}$$

i.e. the projection of the quantum fluctuations $\varphi(t;t_0)$ onto the zero mode. Using eq. (22.78), $f(t_0) = \xi_0(t_0)\, u_0$ while, using eq. (22.91),

$$\frac{\partial f}{\partial t_0} = \int dt \left[-\dot{q}_{\rm cl}(t;t_0) \frac{\partial}{\partial t_0} q_{\rm cl}(t;t_0) + \varphi(t;t_0) \frac{\partial}{\partial t_0} \dot{q}_{\rm cl}(t;t_0) \right] \tag{22.94}$$

In the first term we use $-\partial q_{\rm cl}/\partial t_0 = +\dot{q}_{\rm cl}$, where the dot is as usual the derivative with respect to t, so the first term is just u_0. Then we get

$$1 = \int dt_0 \delta(\xi_0) \left[1 - \frac{1}{u_0} \varphi(t;t_0)\, \ddot{q}_{\rm cl} \right] \tag{22.95}$$

The second term depends on the quantum field φ. Exponentiating the square bracket in the form $\exp\{-(1/u_0)\,\varphi(t;t_0)\,\ddot{q}_{\rm cl}\}$, this term can be reabsorbed into the action. However, the action appears in the exponent in the form $S_E/\hbar$, while this term has no factor of $\hbar$, and is therefore a loop correction (actually, it can be shown that it only contributes at the two-loop level). To lowest order in the semiclassical expansion we can therefore neglect it, and write eq. (22.95) as

$$1 \simeq \int dt_0 \delta(\xi_0) \tag{22.96}$$

Inserting this into eq. (22.79) eliminates the integral over ξ_0 and replaces it with an integral over the collective coordinate t_0, with a Jacobian equal to 1.
Thus, moving by $\delta\xi_0$ in the direction of the zero mode $\varphi_0(t)$ is equivalent to changing the classical solution around which we are expanding, i.e. it is equivalent to performing a shift of the collective coordinate $t_0 \to t_0 + \delta t_0$, with $\delta t_0 = -\delta\xi_0$. Thus, the integration over ξ_0 is equivalent to the integration over the collective coordinate t_0, and corresponds to summing, in the path integral, over all possible bounce solutions. [14] For finite β, t_0 ranges between $-\beta/2$ and $\beta/2$, so this finally give an overall factor of β, which is very welcome since it matches the factor $1/\beta$ on the right-hand side of eq. (22.69).

The final step of this (long!) computation is to observe that, besides the bounce solutions, we have multi-bounces, corresponding to solutions bouncing back and forth several times between $q = 0$ and $q = q_e$. Their effect is to exponentiate the one-bounce contribution, which compensates for the log in eq. (22.69).

Thus, writing $\mathrm{Im}\, E_0 = \Gamma/2$, the tunneling rate Γ is given by

$$\Gamma = A e^{-S_b} \tag{22.97}$$

where S_b is the value of the Euclidean action, evaluated on the bounce solution, and A is a proportionality constant, which is given by

$$A = \hbar \left(\frac{S_b}{2\pi\hbar} \right)^{1/2} \left| \frac{\det'\left[-\partial_t^2 + V''(\phi_b)\right]}{\det\left[-\partial_t^2 + V''(0)\right]} \right|^{-1/2} \tag{22.98}$$

The factor $(S_b/2\pi\hbar)^{1/2}$ is related to the integration over the zero mode, and comes from the factor $(u_0/2\pi\hbar)^{1/2}$ in eq. (22.79) on observing, from eq. (22.86), that the norm u_0 of the zero mode $\varphi_0 = \dot{q}_{\rm cl}$ is just S_b. The factor $\mathcal{N}$ in eq. (22.79) is fixed by requiring that the path integral computed with the integration measure (22.79) reproduces the standard result for the transition amplitude of the harmonic oscillator, and provides the factor $\det^{1/2}\left[-\partial_t^2 + V''(0)\right]$ in

eq. (22.98). Finally, the factor of two from $\Gamma = 2\,\mathrm{Im}\,E_0$ is compensated by an extra factor 1/2 from the integration over the negative eigenvalue; see Note 13.

The same computation can be performed for a potential $V(q)$ such as that shown in Fig. 22.7. Now the system has a "false vacuum" in $q = 0$ and a true vacuum in $q = q_0$. The equation of motion (22.82) derived from the Euclidean action is again formally the same as that of a particle moving in the potential $-V(q)$, which is shown in Fig. 22.8, and again has a bounce solution, from $q = 0$ to $q = q_e$ and back. Observe, however, that, in this case, what we are computing in this way is not the imaginary part of the energy of a state in the spectrum of the Hamiltonian. The potential shown in Fig. 22.7 is bounded from below, and the corresponding Hamiltonian has a spectrum of purely real eigenvalues. The rate Γ must simply interpreted as the tunneling rate of a state initially localized near the false vacuum.

Tunneling in QFT at zero temperature

We next consider a scalar field theory in flat space, with Minkowskian action

$$S_M = \int d^4x \left[-\frac{1}{2}\eta^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - V(\phi) \right] \tag{22.99}$$

[recall that our signature is $\eta_{\mu\nu} = (-,+,+,+)$], and we consider first QFT at zero temperature. We chose a potential $V(\phi)$ that has a false vacuum in $\phi = 0$, chosing the zero of the potential such that $V(\phi) = 0$, and a true vacuum at $\phi = \phi_0 > 0$, with $V(\phi_0) < 0$, as in Fig. 22.7 (with $q \to \phi, q_0 \to \phi_0$).[15] The rotation to Euclidean signature $(+,+,+,+)$ is obtained by performing the Wick rotation, i.e. introducing Euclidean time τ from $\tau = it$.[16] Then $d^4x = -id\tau d^3x \equiv -i\,(d^4x)_E$. Defining the Euclidean action S_E from $e^{iS_M} = e^{-S_E}$, i.e. $S_E = -iS_M$, we therefore find

$$S_E = \int d^4x_E \left[\frac{1}{2}\partial_\mu\phi\partial_\mu\phi + V(\phi) \right] \tag{22.100}$$

where the sum over repeated lower indices is performed with the Euclidean metric, $\partial_\mu\phi\partial_\mu\phi \equiv (\partial\phi/\partial\tau)^2 + (\partial_i\phi)^2$. We can now repeat the computation performed in the quantum-mechanical case, with minor modifications. Namely, we look for solutions of the equations of motion derived from the Euclidean action, subject to the boundary condition

$$\lim_{\tau\to\pm\infty} \phi(\tau, \mathbf{x}) = 0 \tag{22.101}$$

Furthermore, we must now also impose

$$\lim_{|\mathbf{x}|\to\infty} \phi(\tau, \mathbf{x}) = 0 \tag{22.102}$$

otherwise the action evaluated on the solution would be infinite. Again, the fluctuations around the trivial solution $\phi(\tau, \mathbf{x}) = 0$ have no negative eigenvalue and do not contribute to the imaginary part, so we must rather look for a non-trivial classical solution. In the zero-temperature case that we are considering here, it is reasonable to look for a solution that respects the $O(4)$ symmetry of Euclidean space. Namely, we chose an arbitrary point of four-dimensional Euclidean space, and we use it as the origin for the coordinate system. With respect to this origin, we define a radial coordinate $\rho = (\tau^2 + \mathbf{x}^2)^{1/2}$, and we look for a solution $\phi = \phi(\rho)$. Of course, the origin of the coordinate system can be chosen arbitrarily, which means that now the solution has a set of collective coordinates $\{\tau_0, \mathbf{x}_0\}$ corresponding to the choice of the origin, reflecting the invariance under (Euclidean) time translation as well as spatial translation. As in the quantum-mechanical tunneling computation of the previous subsection, we let τ run over the finite interval $-\beta/2 < \tau < \beta$, letting $\beta \to \infty$ at the end, and similarly we

work in a large but finite spatial volume V. Then, the integration over the collective coordinate in the path integral gives a factor βV. The factor β is canceled by the factor $1/\beta$ in eq. (22.69), as in the quantum-mechanical case. The result [15] More precisely, we take $V(\phi)$ to be the effective potential, which also takes into account the loop corrections. As first shown in a classic paper by Coleman and Weinberg (1973), radiative corrections can change the qualitative shape of the potential, and develop a true minimum at $\phi = \phi_0 > 0$, thus inducing spontaneous symmetry breaking.

[16] The plus sign in the definition $\tau = +it$ is fixed by the condition that the pole structure of the propagator obtained from the Euclidean action is the same as that of the $-i\epsilon$ prescription of the Feynman propagator in Minkowski space.

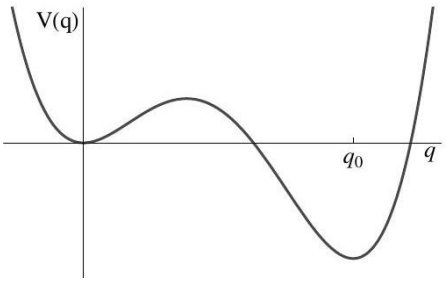

Fig. 22.7 The potential $V(q)$.

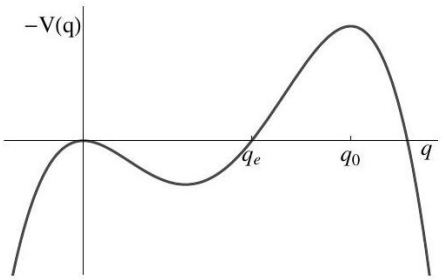

Fig. 22.8 The function $-V(q)$.

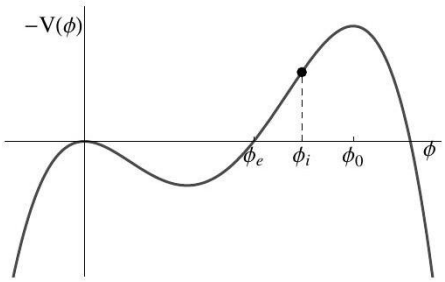

Fig. 22.9 The function $-V(\phi)$, and the initial position ϕ_i.

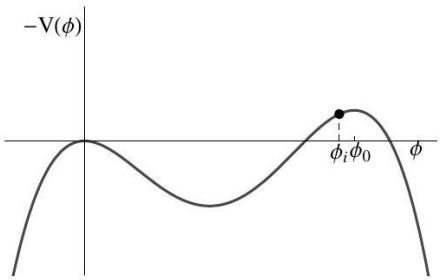

Fig. 22.10 As in Fig. 22.9, with a smaller energy difference between the true and the false vacuua is therefore that in QFT the rate Γ is proportional to the volume V, and the quantity that is finite is the rate per unit volume, Γ/V. This corresponds to the fact that the nucleation of bubbles of true vacuum can take place anywhere in space.

On a function $\phi = \phi(\rho)$, the action (22.100) reads

$$S_E = 2\pi^2 \int_0^\infty d\rho \rho^3 \left[\frac{1}{2} \left(\frac{d\phi}{d\rho} \right)^2 + V(\phi) \right] \tag{22.103}$$

(where $2\pi^2$ is the solid angle in four dimensions), so the equation of motion becomes

$$\frac{d^2\phi}{d\rho^2} + \frac{3}{\rho} \frac{d\phi}{d\rho} = V'(\phi) \tag{22.104}$$

On the $O(4)$-symmetric solution, the two boundary conditions (22.101) are unified into a single boundary condition

$$\lim_{\rho \to \infty} \phi(\rho) = 0 \tag{22.105}$$

Furthermore, requiring that the solution be regular at the origin of the polar coordinate system gives

$$\left. \frac{d\phi}{d\rho} \right|_{\rho=0} = 0 \tag{22.106}$$
